Studies of the Cobalt(III) Complexes of 8-Amino-3,6-diazaoctanate Ion. III.[1] Preparations and Some Properties of Complexes with Chloro, Nitro, or Aqua Ligands

Kiyokatsu WATANABE

Department of Chemistry, Faculty of Science, Ehime University, Matsuyama, Ehime 790

(Received April 27, 1981)

The following new cobalt(III) complexes containing the 8-amino-3,6-diazaoctanate ion (adao)[2] have been prepared: α-[Co(adao)Cl_2], two isomers of *β-mer(N)*-[Co(adao)Cl_2], *β-fac(N)*-[Co(adao)Cl_2], α-[Co(adao)$(NO_2)_2$], two isomers of *β-mer(N)*-[Co(adao)$(NO_2)_2$], α-[Co(adao)$(H_2O)_2$]$(ClO_4)_2$, and *β-mer(N)*-[Co(adao)$(H_2O)_2$]$(ClO_4)_2$. The geometrical structures have been determined on the basis of the electronic spectra, the proton NMR spectra, and the deductions from their derivation processes.

Four geometrical isomers, α, *β-mer(N)*, *β-fac(N)*, and *trans*,[3] are possible in each [Co(adao)X_2] type complex ($X=Cl^-$, NO_2^-, or H_2O), as is shown in Fig. 1-a. When we consider the configuration of the secondary amine nitrogen atom (*s*-N) in adao, further discrimination is possible in the *β-mer(N)*, *β-fac(N)*, and *trans* isomers (Fig. 1-b). Thus, seven racemic geometrical isomers, α-(*SR,RS*), *β-mer(N)*-(*RS,SR*), *β-mer(N)*-(*RR,SS*), *β-fac(N)*-(*RS,SR*), *β-fac(N)*-(*SS,RR*), *trans*-(*RS,SR*), *trans*-(*SS,RR*),[4] are possible when two same unidentate ligands occupy the residual sites. In a previous paper,[1] the present author reported that three geometrical isomers, α, *β-mer(N)*, and *β-fac(N)*, were isolated in each [Co(adao)(O–O)] type complex ($O-O=CO_3^{2-}$, ox, and mal). Also in the [Co(adao)X_2] type, the existence of other isomers than *β-mer(N)* is to be expected. However, only the existence of *β-mer(N)* coordination mode was suggested by Schneider *et al.*[3] Furthermore, their *s*-N configurations were not decided. In order to clarify this problem, the isolation of the isomers was attempted. Thus, the author succeeded in isolating some of α, *β-mer(N)*, and *β-fac(N)* isomers for the dichloro, dinitro, and diaqua complexes.

Experimental

Preparation of Ligand. 8-Amino-3,6-diazaoctanoic acid (Hadao) was prepared by modifying the method of Schneider and Collman.[3]

Preparations of Complexes. *(1) Crude-[Co(adao)$(NO_2)_2$]*: The crude dinitro complex was isolated by modifying the Collman's method.[3]

(2) Crude-[Co(adao)Cl_2]: The crude dichloro complex was prepared by modifying the Collman's method.[3]

(3) α-*[Co(adao)Cl_2]*: The treatment of the crude-[Co(adao)Cl_2] with $HClO_4$ gave *β-mer(N)*-[Co(adao)(Cl)(H_2O)]-ClO_4. The detailed preparative procedure and the structural assignment will be described elsewhere. The resulting *β-mer(N)*-[Co(adao)(Cl)(H_2O)]ClO_4 (7.44 g) was added to 30 cm^3 of water containing Li_2CO_3 (2.22 g). The suspension was heated on a water bath at 80 °C for 4 h. After cooling, the resulting precipitate was removed by filtration. When the filtrate was concentrated on a water bath with an aid of air stream, red crystals began to deposit. After the product was cooled, the crystals were collected on a filter, and then washed with an ethanol–ether (1 : 1) mixture. The filtrate was concentrated again, and then the second precipitate was filtered off. To the remaining filtrate was added 5 cm^3 of 6 M (1 M=1 mol dm^{-3}) HCl. When the mixture was heated at about 65 °C in a water bath for 20 min, blue crystals began to appear. To the resulting product was poured 10 cm^3 of water, and the mixture was then cooled in an ice bath. The deep blue crystals precipitated were collected on a filter, and washed with water, ethanol, and ether, in turn. Yield, ≈0.3 g.

Found: C, 24.38; H, 4.97; N, 14.28%. Calcd for [Co(adao)Cl_2]=$CoC_6H_{14}N_3O_2Cl_2$: C, 24.85; H, 4.87; N, 14.49%.

(4) β-mer(N)-[Co(adao)Cl_2]: *a)*: *β-mer(N)*-[Co(adao)-Cl_2]·$2H_2O$ (violet gray); The crude dichloro complex (30 g) obtained in *(2)* was dissolved in 390 cm^3 of hot 2 M HCl (≈80 °C), and then the product was filtered. The filtrate was cooled in a refrigerator for 3 d. The crystals were collected on a filter, and washed first with ethanol, then with a mixture of ethanol and ether (1 : 1). Yield, ≈5 g.

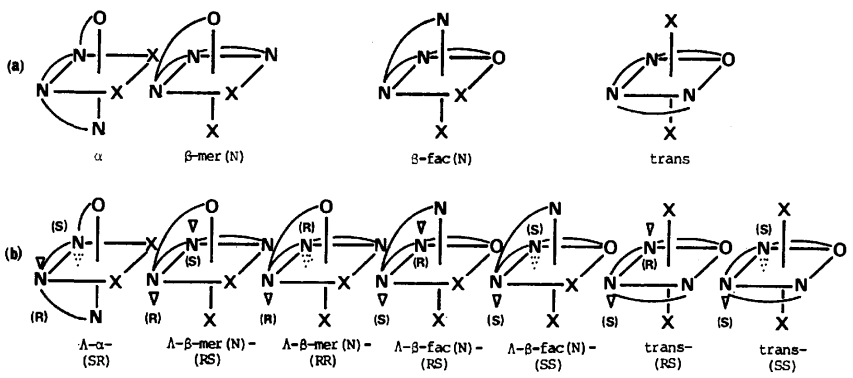

Fig. 1. The possible isomers of [Co(adao)X_2] type complex. (a): Without consideration of *s*-N configurations, (b): under consideration of *s*-N configurations.

Found: C, 22.40; H, 5.43; N, 13.18%. Calcd for [Co(adao)Cl_2]·2H_2O=$CoC_6H_{16}N_3O_4Cl_2$: C, 22.10; H, 5.56; N, 12.89%.

b): *β-mer(N)*-[Co(adao)Cl_2]·HCl·0.5H_2O (silver gray); The filtrate obtained in the previous procedure *(4-a)* was evaporated with an aid of air stream until silver gray crystals appeared. After cooling, the crystals were collected, and then washed with ethanol, a mixture of ethanol and ether (1 : 1), in turn. Yield, ≈15 g.

Found: C, 21.19; H, 4.95; N, 12.49%. Calcd for [Co(adao)Cl_2]·HCl·0.5H_2O=$CoC_6H_{16}N_3O_{2.5}Cl_3$: C, 21.48; H, 4.81; N, 12.52%.

(5) *β-fac(N)-[Co(adao)Cl_2]*: *β-fac(N)*-[Co(adao)(Cl)-(H_2O)]ClO_4·H_2O (0.26 g), of which preparative procedure will be described elsewhere, was suspended in 10 cm³ of water. To the suspension, 2 cm³ of 2 M HCl was added, and the mixture was heated until it dissolved. The resulting solution was concentrated to dryness on a water bath with an aid of air stream. After 5 cm³ of water and 2 cm³ of 2 M HCl were added to the concentrated product, the mixture was concentrated again, and then the product was allowed to stand at room temperature. The product was convered with 2 cm³ of 2 M HCl, and then this mixture was evaporated to a half of its original volume. After the violet blue crystals were collected on a filter, they were washed with ethanol, and ether in this order. Yield, ≈0.1 g.

Found: C, 24.55; H, 4.64; N, 14.46%. Calcd for [Co(adao)Cl_2]=$CoC_6H_{14}N_3O_2Cl_2$: C, 24.85; H, 4.87; N, 14.49%.

(6) *α-[Co(adao)(NO_2)$_2$]*: To a solution of silver perchlorate (3 g) in 10 cm³ of water, α-[Co(adao)Cl_2] (1.45 g) was suspended, and then the suspension was heated at 60 °C for 10 min. During the reaction, silver chloride came out. After the reaction mixture had been cooled in an ice bath, the silver chloride was filtered off. The pink red filtrate was reduced in volume to about 2 cm³ in a rotary evaporator below 40 °C, and then a small amount of 2 M NaBr solution was added until no more white crystals precipitated. After the silver bromide was removed by filtration, the filtrate was diluted to 10 cm³ with water. To the solution, sodium nitrite (0.69 g) was added, and then the mixture was heated at 65 °C for 5 min. Orange crystals appeared. They were collected, and then washed with ethanol, and with ether. Yield, ≈0.6 g.

Recrystallization was carried out by means of fractional extraction with hot water (≈80 °C). The first extract (≈50 cm³) was discarded. The crystals in the second and third extract (150 cm³ respectively) consisted of only α-dinitro isomer. Yield, ≈0.3 g.

Found: C, 22.98; H, 4.60; N, 22.94%. Calcd for [Co(adao)(NO_2)$_2$]=$CoC_6H_{14}N_5O_6$: C, 23.16; H, 4.54; N, 22.51%.

(7) *β-mer(N)-[Co(adao)(NO_2)$_2$]*: Although the *β-mer(N)*-dinitro isomer had been separated by Schneider and Collman,[3] the present author found that the following procedure gave the *β-mer(N)* isomer in a higher purity. Furthermore, it was also found that there are two *β-mer(N)* dinitro isomers, namely one sparingly soluble isomer and another soluble one.

a): The sparingly soluble isomer with an orange yellow color; Sodium nitrite (0.7 g) and *β-mer(N)*-[Co(adao)(Cl)-(H_2O)]ClO_4 (1.86 g) were added in 30 cm³ of water, and the mixture was heated at 80 °C for half an hour with stirring. During this period, a large amount of orange yellow crystals appeared. After cooling, the crystals were collected on a filter, and washed with a mixture of ethanol and ether (1 : 1). The filtrate was reserved for the isolation of soluble isomer.

Recrystallization was carried out by the fractional extraction. The orange yellow crystals (1.2 g) were extracted with four 20 cm³ portions of hot water (≈80 °C), and then 50 cm³ one. The last main extract (≈50 cm³) was cooled in an ice bath, then the orange yellow crystals were deposited. They were washed with ethanol, and with ether. Yield, ≈0.2 g.

Found: C, 23.07; H, 4.61; N, 22.28%. Calcd for [Co(adao)(NO_2)$_2$]=$CoC_6H_{14}N_5O_6$: C, 23.16; H, 4.54; N, 22.51%.

b): The soluble isomer with a yellow color; The reserved filtrate in *(7-a)* was allowed to stand at room temperature for 3 h, whereupon the yellow needles precipitated. When the yield of needles was very small, the filtrate was permitted to stand for 3 d. After filtration, the crystals were washed with an ethanol–ether (1 : 1) mixture. Yield, ≈0.1 g. They were recrystallized from 5 cm³ of hot water.

Found: C, 23.02; H, 4.62; N, 22.54%. Calcd for [Co(adao)(NO_2)$_2$]=$CoC_6H_{14}N_5O_6$: C, 23.16; H, 4.54; N, 22.51%.

(8) *α-[Co(adao)(H_2O)$_2$](ClO_4)$_2$·H_2O*: In 3 cm³ of water, α-[Co(adao)(NO_2)$_2$] (0.15 g) was suspended, and then to the suspension, 3 cm³ of 6 M $HClO_4$ was added dropwise. The mixture was heated at 80 °C about 10 min. The resulting solution with a red orange color was concentrated on a water bath under an air stream. The color of solution changed to a red one. The concentrated solution was cooled, and then filtered. After ethanol (30 cm³) was added to the filtrate, ether (150 cm³) was poured to it. When the mixture was cooled in an ice bath, pink crystals appeared. The crystals were collected on a filter, and washed with ethanol, and then stored over silica gel in a desiccator. Yield, ≈0.05 g.

Found: C, 15.53; H, 4.36; N, 8.96%. Calcd for [Co(adao)(H_2O)$_2$](ClO_4)$_2$·H_2O=$CoC_6H_{20}N_3O_{13}Cl_2$: C, 15.27; H, 4.27; N, 8.90%.

(9) *β-mer(N)-[Co(adao)(H_2O)$_2$](ClO_4)$_2$·H_2O*: *β-mer(N)*-[Co(adao)CO_3] (1.4 g), of which preparative procedure was described in the previous paper,[1] was suspended in 3 cm³ of iced cold water. To the suspension, 2 cm³ of 6 M $HClO_4$ was added slowly drop by drop under cooling in an ice bath. The product was filtered out, and then the filtrate was evaporated below 40 °C with an aid of air stream. When the red crystals began to deposit, the reaction mixture was cooled sufficiently for the complete deposition. They were filtered, and washed with a mixture of ethanol and ether (1 : 2). Yield, ≈0.4 g.

Found: C, 15.24; H, 4.23; N, 8.97%. Calcd for [Co(adao)(H_2O)$_2$](ClO_4)$_2$·H_2O=$CoC_6H_{20}N_3O_{13}Cl_2$: C, 15.27; H, 4.27; N, 8.90%.

Analyses. The carbon, hydrogen, and nitrogen in the isolated complexes were analyzed at the Microanalysis Center of Osaka University, and at the Analysis Center of the Institute for Chemical Reserch, Kyoto University.

Measurements. The absorption spectra in solution were measured with a Shimadzu UV-200 Recording Spectrophotometer using 1 cm or 10 cm silica cells. The diffuse reflectance spectra of solid samples in the range 340—750 nm were measured with a Hitachi EPU-2A Spectrophotometer equipped with a reflectance attachment (Type R-3), and MgO disks for the reference. The IR spectra were recorded with a JASCO IRA-1 Spectrophotometer by a Nujol mull method. The proton NMR spectra were recorded with a Varian XL-100 Spectrometer or a Japan Electron Optics JNM-4H-100 Spectrometer in a deuterium oxide, with *t*-butyl alcohol as the internal reference.

Results and Discussion

Preparative Remarks. The preparation routes for [Co(adao)X_2] are shown schematically in Fig. 2. Schneider and Collman[3] reported that *β-mer(N)*-

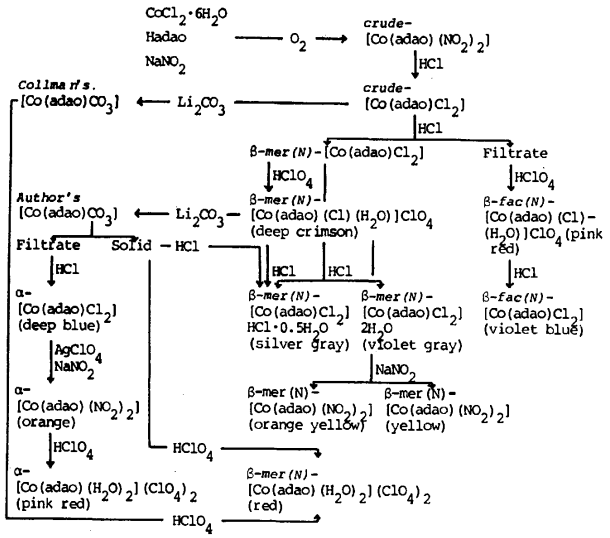

Fig. 2. The preparation scheme of $[Co(adao)X_2]$ (X= Cl^-, NO_2^-, and H_2O).

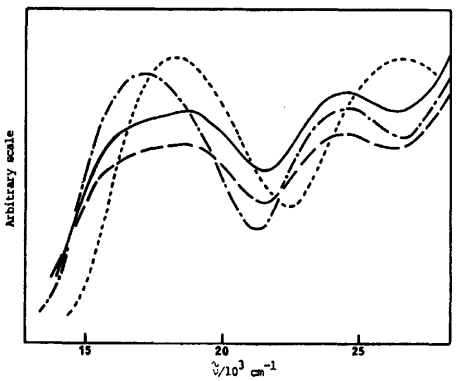

Fig. 3. The reflectance spectra of $[Co(adao)Cl_2]$.

a) in HCl solution.

$[Co(adao)(NO_2)_2]$ could be obtained by air oxidation of the suspension of $CoCl_2 \cdot 6H_2O$, $NaNO_2$, and Hadao. However, the present author found that the *β-mer(N)*-dinitro isomer prepared according to the Collman's method *(1)* was different from the *β-mer(N)*-dinitro isomer which was prepared by the present author's method *(7)*, from the differences of their absorption spectra as well as their solubilities in water. It was also found that the reaction of the author's *β-mer(N)*-dinitro isomer and $HClO_4$ gave *β-mer(N)*-$[Co(adao)(NO_2)(H_2O)]ClO_4$ with a higher yield than that of the Collman's *β-mer(N)*-dinitro isomer and $HClO_4$. These facts indicate that the Collman's *β-mer(N)*-dinitro isomer contains another complex than *β-mer(N)*-$[Co(adao)(NO_2)_2]$. On the other hand, the author's method, in which the reaction of *β-mer(N)*-$[Co(adao)(Cl)(H_2O)]ClO_4$ and $NaNO_2$ was used, gave two kinds of *β-mer(N)*-$[Co(adao)(NO_2)_2]$ in a pure state *(7-a, b)*. α-, and *β-fac(N)*-$[Co(adao)(NO_2)_2]$ have not been isolated so far. For the isolation of these dinitro isomers, each reaction of α-$[Co(adao)(H_2O)_2]^{2+}$ or *β-fac(N)*-$[Co(adao)(Cl)(H_2O)]^+$ with sodium nitrite was attempted. Although the reaction of former complex afforded α-$[Co(adao)(NO_2)_2]$*(6)*, the latter complex gave *β-fac(N)*-$[Co(adao)(Cl)(NO_2)]$ (this will be described elsewhere).

For the α-diaqua isomer, it was recognized that the aquation of α-$[Co(adao)Cl_2]$ with silver perchlorate in acidic solution gave the desired species. However, because of contamination with other salts such as silver chloride, it was difficult to isolate the α-diaqua isomer in a pure state. Hence, the preparation route using the α-dinitro isomer and $HClO_4$ was adopted for the isolation of α-$[Co(adao)(H_2O)_2](ClO_4)_2$ *(8)*.

The Structures of [Co(adao)Cl$_2$] Isomers. As may be seen in Fig. 2, four kinds of isomers of $[Co(adao)Cl_2]$, deep blue, silver gray, violet gray, and violet blue isomers, could be isolated. Among these four dichloro isomers, the silver gray and violet gray isomers are sparingly soluble in HCl, while the yield of violet blue isomer is very poor. Therefore, three reflectance spectra of the deep blue, silver gray, and violet gray isomers are shown in Fig. 3, together with the absorption

spectrum in solution for the violet blue isomer. Their electronic spectral data are summarized in Table 1. From Fig. 3, it is found that the first bands of silver gray and violet gray isomers show more pronounced splitting ($\approx$16100, 18670 cm^{-1}) than that of the deep blue one (17240 cm^{-1}). Furthermore, it is found that the deep blue and violet blue isomers show symmetrical first absorption bands, although the first band of the violet blue isomer is observed at a higher wave number (18150 cm^{-1}) than that of the deep blue one (17480 cm^{-1}). Also in their second absorption bands, the band of violet blue isomer is located at a higher wave number (26230 cm^{-1}) than that of the deep blue one (25190 cm^{-1}).

In IR spectral measurements, all dichloro isomers show a strong band at around 1650 cm^{-1}. These spectral results suggest that their adao's carboxyl groups coordinate to the central cobalt.[5,6] The IR spectral patterns assignable to the N–H stretching in the region of 3400—3100 cm^{-1} are not the same; these differences are proof for that the four dichloro isomers are different. It is further recognized that the violet blue isomer, which places the second absorption band at a higher wave number region, exhibits no peak due to the aqua ligand in any wave number region higher than 3400 cm^{-1}. This observation indicates that the violet blue isomer in the solid state is not an aquachloro complex.

Study of the ligating atoms of $[Co(adao)Cl_2]$ shows that the dichloro complex belongs to the complex of $[CoN_3OCl_2]$ type. In the case of *trans(Cl)*-$[CoCl_2(NH_3)_3(H_2O)]Cl$,[7,8] its first band splits into two components (15870, 19470 cm^{-1}).[9] When this splitting (3600 cm^{-1}) is compared with that of the silver gray $[Co(adao)Cl_2]$ (2570 cm^{-1}), the former is larger than the latter. Therefore, it is found that the silver gray isomer is not the *trans* one.

It was reported that the difference of the first d-d band splitting pattern in the Co(III) complexes mainly depends upon the symmetry of the complex.[10,11] Then, Yamatera proposed the so-called "Yamatera's rule," which predicts the d-d bands splitting pattern in the Co(III) complex.[12] It is possible to calculate the positions of the first band splitting components in the respective isomers of $[Co(adao)Cl_2]$ according to the Yamatera's rule.[12] Their predicted positions are calculated by using the following three shift parameters: $\delta(N) = +330\ cm^{-1}$ (estimated from $[Co(en)_3]^{3+}$),[13] $\delta(O) = -3800\ cm^{-1}$ (estimated from *fac*-$[Co(gly)_3]^{3+}$ and $[Co(en)_3]^{3+}$),[13] and $\delta(Cl) = -10070\ cm^{-1}$ (estimated from *trans(Cl)*-$[CoCl_2(en)_2]^+$).[14] This estimation indicates that the difference between the highest and the lowest wave number components increases in the order of $\alpha \simeq \beta\text{-}fac(N) < \beta\text{-}mer(N) < trans$.

From the comparison of this estimation and the observed absorption bands, it is found that the silver gray and violet gray isomers take the β-*mer*(*N*) coordination mode, and the deep blue and violet blue isomers, the α or β-*fac*(*N*) one. The reflectance spectral resemblance and IR spectral difference suggest that two kinds of β-*mer*(*N*)-dichloro isomers with the different *s*-N configurations were isolated. It is very difficult to decide their *s*-N configurations. However, Buckingham *et al.*[15,16] obtained two diastereoisomers of β_1-$[Co(gly)(trien)]I_2$[17] with the different *s*-N(trien) configurations. It was also found that A-β_1-$(S_N{}^aS_N{}^\delta)$-$[Co(gly)(trien)]I_2$[18] is more stable than A-β_1-$(S_N{}^aR_N{}^\delta)$-$[Co(gly)(trien)]I_2$, on the basis of their isomerization experiments and strain energy calculations. Also in β_2-$[Co(gly)(trien)]Cl_2$,[16,17] it was found that A-β_2-$(S_N{}^aS_N{}^\delta)$ isomer is more stable than the A-β_2-$(S_N{}^aR_N{}^\delta)$ one, and the former's yield is higher than the latter's. When these facts are considered, it is reasonable to assume that the *s*-N(adao) configurations of silver gray isomer with the higher yield are $(R_{N_1}{}^aS_{N_2}{}^\delta,\ S_{N_1}{}^aR_{N_2}{}^\delta)$[19] and those of violet gray with the lower yield are $(R_{N_1}{}^aR_{N_2}{}^\delta,\ S_{N_1}{}^aS_{N_2}{}^\delta)$.

It is difficult to determine the structures of the deep blue and violet blue isomers on the basis of their reflectance spectra alone. In the case of the deep blue isomer, however, the absorption spectrum of the diaqua species, which was derived from the deep blue isomer by the treatment with $AgClO_4$ in acidic solution, resembles to that of α-$[Co(adao)(H_2O)_2](ClO_4)_2$, of which structure will be decided in the later section on the basis of the proton NMR spectrum. Furthermore, the reaction of α-$[Co(adao)(H_2O)_2](ClO_4)_2$ and HCl gave mainly the deep blue isomer. Therefore, the deep blue isomer seems to take the α structure. For the violet blue isomer, decisive data for the determination of its structure were not obtained. However, because the violet blue isomer was obtained from β-*fac*(*N*)-$[Co(adao)(Cl)(H_2O)]ClO_4$ by the treatment with HCl, and the deep blue isomer takes the α structure, the violet blue isomer is assigned to the β-*fac*(*N*) structure, at present.

The Structures of $[Co(adao)(NO_2)_2]$ *Isomers.* As is shown in Fig. 2, three isomers of $[Co(adao)(NO_2)_2]$, orange, orange yellow, and yellow isomers, were isolated. The orange isomer was derived from α-$[Co(adao)Cl_2]$ by the treatment with $NaNO_2$, and the orange yellow and yellow isomers were derived from β-*mer*(*N*)-$[Co(adao)(Cl)(H_2O)]ClO_4$. Differences in solubilities were observed among the three isomers, that is, at about 20 °C, 4230 cm^3 of H_2O was required for the dissolution

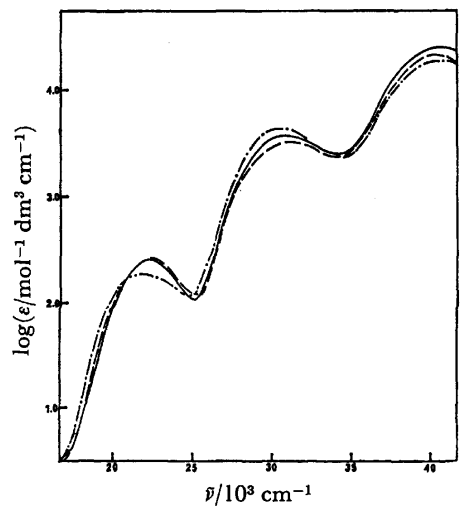

Fig. 4. The absorption spectra of $[Co(adao)(NO_2)_2]$. -·-·-: α-$[Co(adao)(NO_2)_2]$ (orange), ——: β-*mer*(*N*)-$[Co(adao)(NO_2)_2]$ (orange yellow), – – –: β-*mer*(*N*)-$[Co(adao)(NO_2)_2]$ (yellow).

of one gram orange isomer, 2500 cm^3 for the orange yellow, and 794 cm^3 for the yellow.

As is seen in Fig. 4, and Table 1, the first absorption band of orange yellow isomer is almost identical to that of the yellow one. On the other hand, the first band of orange isomer is broader than those of the other two isomers. It has been reported that the so-called nitro specific band of *trans* dinitrocobalt(III) complex is located at a lower wave number region (28570—29850 cm^{-1}) than that of the corresponding *cis* one.[10,14,20-26] Judging from the fact that the maxima of the nitro specific bands of three $[Co(adao)(NO_2)_2]$ are located at similar wave numbers (30520 cm^{-1} for the orange isomer, 30860 cm^{-1} for the orange yellow, and 31000 cm^{-1} for the yellow), the isomers are *cis*.

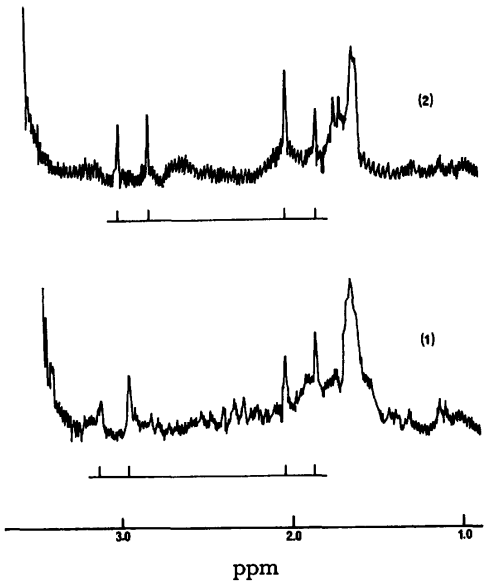

Fig. 5. The proton NMR spectra of $[Co(adao)(NO_2)_2]$. (1): *β-mer(N)*-$[Co(adao)(NO_2)_2]$ (orange yellow), (2): *β-mer(N)*-$[Co(adao)(NO_2)_2]$ (yellow).

Although the proton NMR spectrum of orange isomer could not be measured because of its low solubility in D_2O, the proton NMR spectra of orange yellow and yellow isomers were obtained, as is shown in Fig. 5. The former's NMR spectrum shows one AB quartet in the range of 1.87 to 3.13 ppm, and the latter's one, in the range of 1.85 to 3.01 ppm. As can be inferred from the coordination modes of adao in Fig. 1-a, these four coordination modes may be classified into two groups from the standpoint of the disposition of adao glycinate ring.[27] One group is composed of the isomers with an apical glycinate ring (α and *β-mer(N)*), and another, those with an equatorial ring (*β-fac(N)* and *trans*). Therefore, the proton NMR spectra of the former should be different from those of the latter at the resonances of the glycinate ring protons.

It has been reported that a considerable difference exists between the proton NMR spectra for the isomers of [Co(edda)(AA)](AA=$(NH_3)_2$, en, ox, and mal),[28-31] that is, a AB quartet appears for the apical ring (R-ring)[32] protons and an apparent singlet for the equatorial ring (G-ring)[32] protons. It has also been observed in the proton NMR spectra of edda- and ed3a-Co(III) complexes that the value of $\delta_{AB}(=\delta_A-\delta_B)$[33] for the apical ring protons is in the range of 0.7 to 1.0 ppm, while that for the equatorial ring protons is in the range of 0.0 to 0.4 ppm.[29] The proton NMR spectra of two dinitro isomers (Fig. 5) show the AB quartet pattern, and their values of δ_{AB} are 1.09 ppm for the orange yellow isomer, and 0.96 ppm for the yellow one. Therefore, the orange yellow and yellow isomers take the α or *β-mer(N)* structure. Furthermore, it was found that the reaction of orange isomer and $HClO_4$ gave α-$[Co(adao)(H_2O)_2](ClO_4)_2$, as was described in Fig. 2. From these facts, it is inferred that the orange isomer takes the α structure.

When the same shift parameters as used in the previous case of $[Co(adao)Cl_2]$ and $\delta(NO_2)=+4300$ cm^{-1} (estimated from *mer*-$[Co(NO_2)_3(NH_3)_3]$ and *cis*-$[Co(NO_2)_2(NH_3)_4]^+$),[34,35] are used for the calculation of the first band components of four possible dinitro isomers, the Yamatera' srule suggests that the predicted first band of α isomer is broader than that of *β-mer(N)*. Therefore, it is reasonable to assign the orange yellow and yellow isomers to the *β-mer(N)* structure, and the orange isomer, to the α one.

Consequently, it is certain that two kinds of *β-mer(N)* isomers were isolated also in $[Co(adao)(NO_2)_2]$. Furthermore, the difference of these *β-mer(N)* isomers is checked by the comparison of their IR spectra, which are shown in Fig. 6. For the assignment of their *s*-N configurations, it is inferred on the basis of their yields

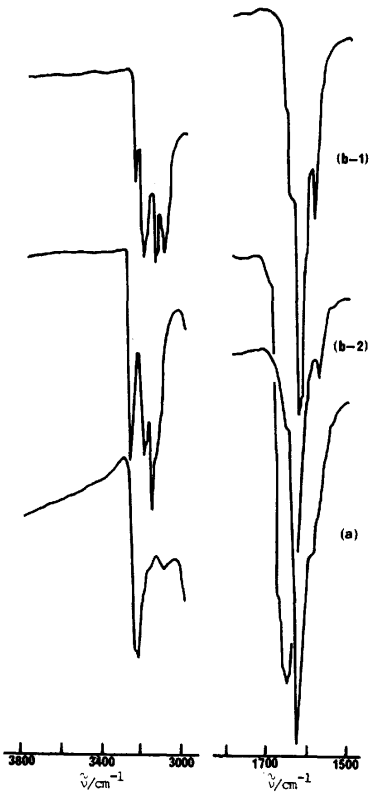

Fig. 6. The infrared spectra of $[Co(adao)(NO_2)_2]$. (a): α-$[Co(adao)(NO_2)_2]$ (orange), (b-1): *β-mer(N)*-$[Co(adao)(NO_2)_2]$ (orange yellow), (b-2): *β-mer(N)*-$[Co(adao)(NO_2)_2]$ (yellow).

that the orange yellow isomers with a higher yield adopts the ($R_{N_1}^{a}S_{N_1}^{b}$, $S_{N_1}^{a}R_{N_1}^{b}$) configuration, and the yellow isomer with a lower yield, the ($R_{N_1}^{a}R_{N_1}^{b}$, $S_{N_1}^{a}S_{N_1}^{b}$) one.

The Structures of [Co(adao)(H_2O)$_2$](ClO_4)$_2$ Isomers. Four possible geometrical isomers of the diaqua complex belonging to a type of [CoN_3O_3] may be classified into two groups, that is, the α and *β-fac(N)* isomers belong to a *fac*-[CoN_3O_3] type, and the *β-mer(N)* and *trans* isomers, to a *mer*-one. It is well known that the first band of the *mer*-type is broader than that of the *fac*-one.[36-39] In Fig. 7, the absorption spectra of the pink red and red isomers are shown, and in Table 1, their numerical data are summarized.

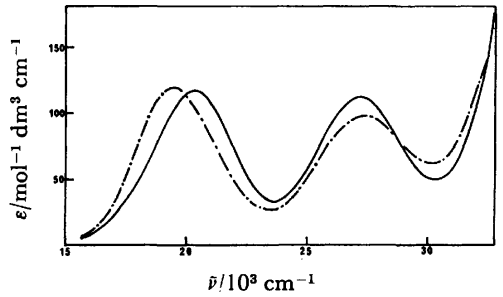

Fig. 7. The absorption spectra of [Co(adao)(H_2O)$_2$]-(ClO_4)$_2$.
-·-·-: α-[Co(adao)(H_2O)$_2$](ClO_4)$_2$ (pink red), ——: *β-mer(N)*-[Co(adao)(H_2O)$_2$](ClO_4)$_2$ (red).

As is seen in Fig. 7, the half width of first absorption band for the pink red isomer is almost identical to that for the red one. On account of this, their structures can not be distinguished by the application of the empirical rule for the first band width in a [CoN_3O_3] complex.[36-39] However, the first absorption maximum of the red isomer is located at a higher wave number than that of the pink red one. On the contrary, the second band maximum of the former is located at a lower wave number than that of the latter.

It has been found that the first band of *mer*-[$Co(NH_3)_3(H_2O)_3$]$^{3+}$ is broader than that of the *fac*-one, and that the apparent first band maximum of the *mer* isomer is located at a higher wave number than that of the *fac* one.[40,41] Furthermore, it has been reported that *mer*-[Co(dien)(H_2O)$_3$]$^{3+}$ places the first band maximum at a higher wave number than that of the corresponding *fac* one, although these isomers have not been obtained as crystalline forms.[42,43] On the basis of the different first band positions, it is found that the red isomer adopts the *β-mer(N)* or the *trans* structure, and the pink red one, the α or the *β-fac(N)* structure.

The proton NMR spectrum shows one AB quartet pattern in the range of 2.16 to 3.20 ppm for the red isomer, and in the range of 2.15 to 3.13 ppm for the pink red one. These observations suggest that the coordination mode of adao in each isolated isomer is either the α or the *β-mer(N)* one. Taking into consideration of their preparative routes (Fig. 2), it can be concluded that the red isomer is the *β-mer(N)* one, and the pink red, the α.

Summary. In the three kinds of [Co(adao)X_2] type complexes (X=Cl^-, NO_2^-, and H_2O), α and *β-mer(N)* isomers were isolated. Consequently, the previously unknown α coordination mode could be established also in [Co(adao)X_2] type complex. As to the *cis(Cl)*-[CoN_3OCl_2] type complex, the *β-fac(N)*-[Co(adao)Cl_2] besides the α- and *β-mer(N)*-[Co(adao)-Cl_2] were also detected. Furthermore, two kinds of *β-mer(N)* isomers could be isolated in the cases of [Co(adao)Cl_2] and [Co(adao)(NO_2)$_2$]. From the comparison of the yields in a pair of *β-mer(N)* isomers respectively, it is inferred that the silver gray dichloro and the orange yellow dinitro complexes, which were isolated with the higher yields, adopt the ($R_{N_1}^{a}S_{N_1}^{b}$, $S_{N_1}^{a}R_{N_1}^{b}$) configurations, while the violet gray dichloro and yellow dinitro complexes, which were isolated with the lower yields, adopt the ($R_{N_1}^{a}R_{N_1}^{b}$, $S_{N_1}^{a}S_{N_1}^{b}$) configurations.

The author is sincerely grateful to Professor Yoichi Shimura of Osaka University for the guidance of this work. He also thanks Professor Kashiro Kuroda of Ehime University for his continuing interest and encouragement during the work.

Fluorometric Determination of Aluminium(III) and Cadmium(II) by Solvent Extraction of the Ternary Complex Composed of Metal Ion, 8-Hydroxy-5-quinolinesulfonic Acid, and Methyltrioctylammonium Ion

Yukihiro KONDOH, Masamitsu KATAOKA, and Tomihito KAMBARA*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received June 3, 1981)

A fluorometric micro determination of aluminium(III) and cadmium(II) using the formation of metal–8-hydroxy-5-quinolinesulfonic acid–capriquat (methyltrioctylammonium) ternary complex is described. These complexes are easily extracted into chloroform phase and the extract emits a strong fluorescence. Spectra of aluminium(III) and cadmium(II) ternary complexes have the excitation maximum at 396 nm and 400 nm, and emission maximum at 501 nm and 524 nm, respectively. Fluorescence intensity of the aluminium(III) and cadmium(II) ternary complexes extracted into chloroform showed the constant and maximum values in the pH range of aqueous phase from 5.3 to 8.5 and 8.1 to 8.5, respectively. The calibration curves for aluminium(III) and cadmium(II) show good proportionality in the concentration range from 0.5 to 5.0 and 1.0 to 50.0 μg, respectively. The relative standard deviation observed with four measurements was found to be 1.8% for 0.5 μg of aluminium(III) and 1.1% for 10.0 μg of cadmium(II). The effect of diverse ions is studied and a 25-fold amount of Cu(II), Ni(II), Fe(II), Fe(III) in weight gave errors, however, the interferences were easily eliminated by the addition of appropriate masking agent. In the determination of cadmium(II), an equal amount of Co(II), Ni(II), Mn(II), Fe(III) and twice amount of Al(III) gave negative errors, however, the interference of Fe(III) and Al(III) were also eliminated as above.

It has been recognized that the 8-hydroxy-5-quinolinesulfonic acid (abbreviated as H_2qs), which is well known as a derivative of oxine, forms several water soluble complexes with many metal ions, which emit strong fluorescence around 520 nm. Cadmium(II)[1] and magnesium(II),[2] were determined fluorometrically in aqueous phase by using H_2qs as the chelating agent. Kina *et al.*[3] reported that the fluorescence intensity of some metal complex is enhanced in the presence of surfactant.

We reported the photometric determination of iron(III),[4] cobalt(II),[5] and zinc(II)[6] employing the ion-pair extraction of metal–H_2qs chelate anion with Zephiramine (benzyldimethyltetradecylammonium chloride) cation. Cadmium(II) was also determined spectrophotometrically with H_2qs after separation as an ion-pair of tetraiodocadmate(II) anion with Capriquat (methyltrioctylammonium chloride, abbreviated as Cq^+-Cl^-) cation. We also reported the fluorometric determination of zinc(II) by using the formation of zinc(II)–H_2qs–Cq ternary complex.[8]

In the present paper, the fluorometric micro determination of aluminium(III) and cadmium(II) was described. The fluorescence intensity of the ternary complex composed of aluminium(III)–, as well as cadmium(II)–H_2qs–Cq in chloroform phase is proportional to the amount of metal ion in the aqueous phase.

Experimental

Reagents. *Standard Solution of Aluminium(III) and Cadmium(II)*: Aluminium(III) and cadmium(II) standard solution (Wako Pure Chemicals Co., for atomic absorption use, 1000 ppm) was applied and diluted with water as required.

1 mM H_2qs Solution:† The solution was prepared by dissolving 0.2252 g of H_2qs (Wako Pure Chemicals Co.) with 1 dm^3 of water.

7 mM Capriquat–Chloroform Solution: The solution was prepared by dissolving Dotite Capriquat (methyltrioctylammonium chloride, Dojindo Laboratories) in chloroform.

Buffer Solutions: Acetate, borate, and acetic acid–ammonia buffer solutions were prepared and adjusted to the appropriate pH values.

Organic solvents used in this study were all of analytical reagent grade. All the solutions were prepared with once deionized and then twice distilled water.

Apparatus. Fluorescence intensity was measured with a Shimadzu Digital Spectrofluorophotometer, Model RF-510, equipped with a Shimadzu recorder, U-125MU. Fused quartz cells, 10 mm × 10 mm × 45 mm, were used throughout the study.

Procedure. *Determination of Aluminium(III)*: To a sample solution containing (0.1—5.0)μg of aluminium(III) are added a 7-ml portion of 1 mM H_2qs solution and a 10-ml portion of the buffer solution (pH 6.5). The mixture is diluted to 50 ml with water and shaken with 10 ml of 6 mM Capriquat–chloroform solution for 3 min and then allowed to stand for 30 min. The organic layer is transferred into a beaker containing anhydrous sodium sulfate to remove the remaining water. Then, the fluorescence intensity of the extract is measured at 396 nm (excitation) and 501 nm (emission).

Determination of Cadmium(II): To a sample solution containing (1.0—50.0) μg of cadmium are added 8 ml of 1 mM H_2qs solution and 10 ml of borate buffer solution (pH 8.3). The mixture is diluted to 50 ml with water and shaken with 10 ml of 7 mM Capriquat–chloroform solution for 3 min and then allowed to stand for 30 min. Organic layer is separated and fluorescence intensity is measured at 400 nm (excitation) and 524 nm (emission).

Results and Discussion

Fluorescence Spectra. The fluorescence spectra of the organic extract obtained by the above procedure are given in Fig. 1. The aluminium(III)–H_2qs–Capriquat ternary complex in chloroform exhibited the excitation maximum at 396 nm and the fluorescence emission maximum at 501 nm, whereas the cadmium(II) complex showed at 400 nm and at 524 nm, respectively.

† 1 M = 1 mol dm^{-3}.

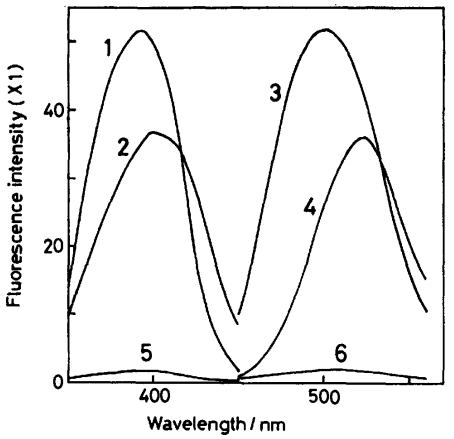

Fig. 1. Excitation and emission spectra.

Emission spectrum of ternary complex: 3: Al(III) (λ_{Ex}=396 nm), 4: Cd(II) (λ_{Ex}=400 nm), 5: excitation spectrum of reagent blank (λ_{Em}=501 nm), 6: emission spectrum of reagent blank (λ_{Ex}=524 nm).

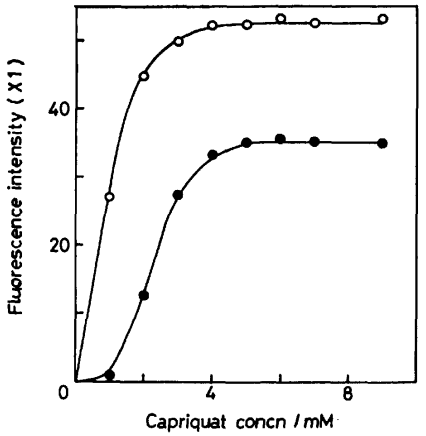

Fig. 2. Effect of Capriquat amount on the fluorescence intensity of chloroform extract.
—○—: Al(III) 5 μg/50 ml; $[H_2qs]_w$=0.2 mM; pH=7.7; λ_{Ex}=396 nm; λ_{Em}=501 nm. —●—: Cd(II) 50 μg/50 ml; $[H_2qs]_w$=0.2 mM; pH=8.3; λ_{Ex}=400 nm; λ_{Em}=524 nm.

An ion-pair of H_2qs–Capriquat was also extracted into chloroform, but showed a very weak fluorescence.

Effect of Capriquat Concentration. Effect of the Capriquat concentration on the fluorescence intensity is shown in Fig. 2. Capriquat–chloroform solutions of the various concentrations were added to the solution containing 5.0 μg of aluminium or 50.0 μg of cadmium with an excess amount of H_2qs at the optimum pH, and after extraction, the fluorescence intensity of the extract was measured. It was found that the fluorescence intensity shows a constant value for more than 4 mM of Capriquat for aluminium and 5 mM for cadmium. Thus, the concentration of Capriquat was adjusted to 6 mM for aluminium and 7 mM for cadmium.

Effect of H_2qs Amount. The effect of H_2qs concentration on the fluorescence intensity is shown in Fig. 3. The fluorescence intensity was found to be almost

a) Al(III) taken: 1.00 μg. b) Cd(II) taken: 10.0 μg. c) With thiourea. d) With ascorbic acid and phen. f) pH 5.3. g) With tiron.

Effect of pH. Effect of the pH of aqueous layer was examined. As shown in Fig. 4, the fluorescence intensity is constant over the pH range from 5.3 to 8.5 for aluminium(III) and from 8.1 to 8.5 for cadmium(II), while the observed blank value is very low. Thus, the pH was kept to 6.5 by 0.2 M acetic acid and 0.2 M ammonia for aluminium and to 8.3 by borate buffer for cadmium.

Organic Solvents. The effect of the various organic solvents on the fluorescence intensity was studied and the results were shown in Table 1. Benzene and xylene gave high blank value. Chloroform, 1,2-dichloroethane, and IBMK (isobutyl methyl ketone) gave low blank value, but the separation speed of IBMK was slow. Chloroform is adopted as the best organic slovent, because it shows the highest fluorescence intensity and the good separation was rapidly attained for both aluminium(III) and cadmium(II) complexes.

Effect of Shaking and Standing Time. A stable and constant fluorescence intensity of the extract was found with a shaking time longer than 1 min for both aluminium(III) and cadmium(II), so the shaking time was kept to 3 min. The optimum standing time was found to be 30 min for the both metal ions.

Calibration Curves. The calibration curves for aluminium(III) and cadmium(II) were obtained by the above procedures. A good proportionality between the fluorescence intensity and the concentration was observed in the concentration range from 0.1 to 2.0 μg for aluminium(III) and from 1.0 to 10.0 μg for cadmium-(II). At higher concentrations the calibration curve deviated slightly from the linearity, but the determination was feasible up to 5.0 μg for aluminium(III) and 30.0 μg for cadmium(II). The relative standard deviation observed with four measurements was found to be 1.8% for 5 μg of aluminium and 1.1% for 10.0 μg of cadmium.

Effect of Diverse Ions. The effect of sixteen cations on the determination of aluminium(III) and cadmium-(II) was studied. The results are summarized in Table 2. In the determination of 1.0 μg of aluminium(III), a 5-fold amount of cobalt(II) and 25-fold amount of copper(II), nickel(II), iron(II), and iron(III) reduced the fluorescence intensity, whereas a 5-fold amount of zinc(II) gave a positive error. However, the interferences were eliminated by the addition of thiourea for copper(II), together with 1,10-phenanthroline for nickel(II) and iron(II), and ascorbic acid with 1,10-phenanthroline for iron(III). The interference of zinc-(II) was eliminated by adjusting the pH to 5.3.

In the determination of 10.0 μg of cadmium(II), an equal amount in weight of cobalt(II), nickel(II), manganese(II), and iron(III) and a twice amount of iron(II) gave the negative errors, whereas an equal amount of zinc(II) and a twice amount of aluminium-(III) gave the positive errors. The interferences were eliminated, however, by the addition of 1,10-phenanthroline for iron(II) and tiron for aluminium(III).

The Vapor-phase Reaction of Aluminium Trichloride with Oxygen in the Presence of Steam and Properties of the Aluminium Oxide Formed

Yuichi Shoji, Ryoko Matsuzaki, and Yuzo Saeki*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received July 3, 1981)

The reaction of gaseous $AlCl_3$ with oxygen containing 2—5 vol% H_2O in the temperature range of 200 to 1000 °C, and the thermal transitions of the Al_2O_3 formed under various conditions were examined. At 200 °C, only the reaction of gaseous $AlCl_3$ with H_2O occurs, regardless of the H_2O content in oxygen. Above about 400 °C, the reactions of gaseous $AlCl_3$ with both H_2O and oxygen occur, and all the $AlCl_3$ reacts at 1000 °C. The reaction with H_2O mainly occurs below about 900 °C, and the reaction with oxygen mainly occurs at 1000 °C. Regardless of the H_2O content in oxygen, the reaction product is amorphous Al_2O_3 below 600 °C, amorphous Al_2O_3 containing poorly crystallized γ-Al_2O_3 at 800 °C, γ-Al_2O_3 containing amorphous Al_2O_3 at 900 °C, and a mixture of γ-Al_2O_3 and δ-Al_2O_3 at 1000 °C. It was also observed that the Al_2O_3 formed below 800 °C included a chloride oxide of aluminium. On heating the amorphous Al_2O_3 formed by the reaction of gaseous $AlCl_3$ with oxygen containing 2—5 vol% H_2O, the amorphous $\xrightarrow{ca.\ 700\ °C}$ χ $\xrightarrow{ca.\ 800\ °C}$ κ $\xrightarrow{ca.\ 1000\ °C}$ α transition occurs; on heating the γ-Al_2O_3 formed, the γ $\xrightarrow{ca.\ 900\ °C}$ δ $\xrightarrow{ca.\ 1000\ °C}$ θ $\xrightarrow{ca.\ 1000\ °C}$ α transition occurs.

To study the chemical process for preparing fine powders of aluminium oxide(Al_2O_3) from aluminium trichloride ($AlCl_3$) by the vapor-phase reaction, the present authors have examined the reactions of $AlCl_3$ with oxygen[1] and with steam[2] in the vapor phase, as well as the properties of the Al_2O_3 formed.

Cuer *et al.*[3] have examined the oxidation of gaseous $AlCl_3$ in a hydrogen-oxygen flame. From the particle size of the Al_2O_3 formed, they estimated that during the oxidation of gaseous $AlCl_3$ with a gaseous mixture of oxygen and steam, the reaction with oxygen was predominant at higher temperatures (>2000 K) and that the reaction with steam mainly occurred at low temperature (1700 K). No report on the vapor-phase reaction of gaseous $AlCl_3$ with oxygen in the presence of steam is presently available.

In this paper, the reaction of gaseous $AlCl_3$ with oxygen containing 2—5 vol% steam in the temperature range of 200 to 1000 °C was examined. The thermal transitions of the Al_2O_3 formed under various conditions were also examined.

Experimental

The $AlCl_3$ used was prepared by the reaction of pure aluminium (Al: 99.99%) with chlorine at 400 °C.[1]

A transparent quartz reaction tube (1000 mm length) with an inner concentric tube was used. Gaseous $AlCl_3$ was formed by heating $AlCl_3$ placed in the inner tube at 150 °C, and was carried by a stream of argon (40 cm^3/min) to the reaction zone (27 mm i.d. and 250 mm length) held at a specified temperature. In the meantime, a stream of oxygen (100 cm^3/min) containing a specified amount of steam was introduced through a separate tube into the reaction zone. The mean flow-rate of the $AlCl_3$ was approximately 3.8 cm^3 Al_2Cl_6 (g)/min. The reaction was allowed to proceed for 2 h.

The total amount of chlorine (Cl_2) and hydrogen chloride (HCl) formed during the reaction was absorbed in a known amount of 0.1 M sodium hydroxide (NaOH) solution,† and was determined by neutralization titration of the excess NaOH. The Cl_2 formed by the reaction was absorbed in a potassium iodide solution and was determined by iodometry. The amount of HCl formed was determined as the difference between the total amount of Cl_2 and HCl and the amount of Cl_2.

The unreacted $AlCl_3$, which was deposited outside the reaction zone together with the reaction product, was separated by heating the mixture in an argon stream at 250 °C. The $AlCl_3$ adsorbed on Al_2O_3 formed was separated by washing the Al_2O_3 with ethanol at the boiling point with stirring.[1]

X-Ray analysis of the solid product was performed with an X-ray powder diffractometer equipped with a proportional counter, using Ni filtered Cu radiation.

Throughout this work, $AlCl_3$ and the reaction products were handled in an argon atmosphere or *in vacuo* to prevent any contamination with moisture in the air.

Results and Discussion

Reaction of Gaseous Aluminium Trichloride with Oxygen

† 1 M=1 mol dm^{-3}.

in the Presence of Steam. Amounts of Cl_2 and HCl formed by the reaction of gaseous $AlCl_3$ with oxygen containing 2 or 5 vol% steam (H_2O) at various temperatures were examined. A reaction temperature above 200 °C was employed, because gaseous $AlCl_3$ was generated by heating $AlCl_3$ at 150 °C. The amounts of chlorine formed as Cl_2 and as HCl at various temperatures are shown in Fig. 1. For comparison, the amounts of Cl_2 formed by the reaction of gaseous $AlCl_3$ with oxygen at various temperatures, which have been reported in the previous paper,[1] are also shown in Fig. 1. The broken line (a) in Fig. 1 shows the calculated value of the amount of chlorine formed as Cl_2 or as HCl, based on the assumption that all the $AlCl_3$ introduced reacts with oxygen or H_2O to form Cl_2 or HCl. The broken lines (b) and (c) show the calculated values of chlorine formed as HCl, based on the assumption that all the H_2O which is contained in a stream of oxygen containing 5 or 2 vol% H_2O reacts with gaseous $AlCl_3$ to form HCl.

These results indicated that, at 200 °C, only the reaction of gaseous $AlCl_3$ with H_2O occurred, regardless of the H_2O content in oxygen. At 400—900 °C, all the H_2O introduced reacted with $AlCl_3$ and the reaction of gaseous $AlCl_3$ with oxygen also occurred. The amount of Cl_2 formed by the reaction with oxygen increased markedly with the increase in the reaction temperature above 800 °C. At 1000 °C, total amounts of chlorine formed as Cl_2 and as HCl agreed with the value shown by the broken line (a), regardless of the H_2O content in oxygen. This fact indicated that the percentage of the reacted $AlCl_3$ reached 100 at 1000 °C. It was also found that a part of the H_2O introduced did not react with gaseous $AlCl_3$ at 1000 °C. This result indicates that, during the vapor-phase reaction of $AlCl_3$ with oxygen in the presence of H_2O, the reaction of gaseous $AlCl_3$ with H_2O mainly occurs below about 900 °C and that the reaction with oxygen mainly occurs at 1000 °C.

The products formed by the reaction of gaseous $AlCl_3$ with oxygen containing 2 and 5 vol% H_2O at temperatures above 400 °C were examined by similar experiments[1,2] through X-ray analysis, thermogravimetry, and differential thermal analysis; these were employed in the examination of the reaction products of gaseous $AlCl_3$ with oxygen and with H_2O.

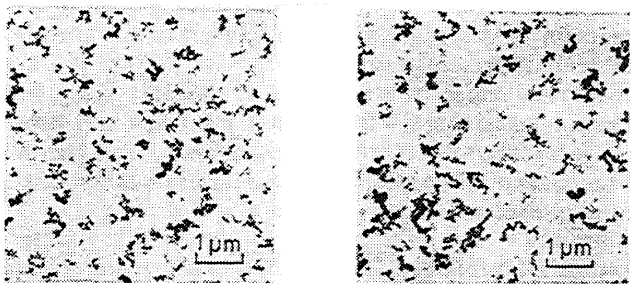
The results for the products formed by the reaction with oxygen containing 5 vol% H_2O show that the reaction product is amorphous Al_2O_3 at 400—600 °C, amorphous Al_2O_3 containing poorly crystallized γ-Al_2O_3 at 800 °C, γ-Al_2O_3 containing amorphous Al_2O_3 at 900 °C, and a mixture of γ-Al_2O_3 and δ-Al_2O_3 at 1000 °C. It was also observed that the Al_2O_3 formed below 800 °C included the chloride oxide of aluminium, which was found to be included in the Al_2O_3 formed by the reaction between gaseous $AlCl_3$ and H_2O below 900 °C.[2] On heating the chloride oxide, it decomposes to γ-Al_2O_3 with the evolution of gaseous $AlCl_3$ in the vicinity of 830 °C.[2] The weight losses due to the decomposition of the chloride oxide contained in the Al_2O_3 formed at 400, 600, and 800 °C were 8, 3, and 2 %, respectively.

The modification of the Al_2O_3 formed by the reaction of gaseous $AlCl_3$ with oxygen containing 2 vol% H_2O at each temperature was found to be the same as that formed by the reaction with oxygen containing 5 vol% H_2O, which was described above. Also, the Al_2O_3 formed below 800 °C included the chloride oxide mentioned above.

The modification of the Al_2O_3 formed by the reaction with oxygen containing 2—5 vol% H_2O at each temperature was found to be the same as that of the Al_2O_3 formed by the reaction with H_2O,[2] except that the Al_2O_3 formed by the reaction with H_2O at 1000 °C was γ-Al_2O_3. The Al_2O_3 formed by the reaction of gaseous $AlCl_3$ with oxygen is amorphous Al_2O_3 at 800 °C, γ-Al_2O_3 containing amorphous Al_2O_3 at 900 °C, and γ-Al_2O_3 at 1000 °C.[1] While, the Al_2O_3 formed by the reaction with oxygen containing 2—5 vol% H_2O is amorphous Al_2O_3 containing poorly crystallized γ-Al_2O_3 at 800 °C, and a mixture of γ-Al_2O_3 and δ-Al_2O_3 at 1000 °C, as described above.

The products formed by the reaction of gaseous $AlCl_3$ with oxygen containing 2—5 vol% H_2O at various temperatures were examined by electron microscopy.

The Al_2O_3 formed by the reaction with oxygen is relatively uniform, ultrafine powders with the particle diameters of the order of 1/100 μm.[1] The range of the particle sizes of the Al_2O_3 formed by the reaction with oxygen containing 5 vol% H_2O was observed to be wide, as was that of the Al_2O_3 formed by the reaction with H_2O.[2] The Al_2O_3 formed by the reaction with oxygen containing 2 vol% H_2O at 800 and 900 °C were relatively uniform, ultrafine powders, as seen from Figs. 2 (a) and (b).



(a) 800 °C (b) 900 °C

Fig. 2. Electron micrographs of the Al_2O_3 formed by the reaction of gaseous $AlCl_3$ with oxygen containing 2 vol% H_2O at 800 and 900 °C.

Thermal Transition of the Aluminium Oxide Formed. The thermal transitions of the Al_2O_3 formed under various conditions were examined. The samples obtained by heating the Al_2O_3 at a specified temperature for 2 h both in an argon atmosphere and in the air were examined by X-ray analysis.

The results for the Al_2O_3 formed by the reaction with oxygen containing 5 vol% H_2O are shown in Table 1.

The experimental results show that on heating the amorphous Al_2O_3 formed at 400 and 600 °C both in an argon atmosphere and in the air, the amorphous $\xrightarrow{ca.700\,°C}$ χ $\xrightarrow{ca.800\,°C}$ κ $\xrightarrow{ca.1000\,°C}$ α transition occurs, re-

Table 1. Thermal transitions of Al_2O_3 formed by the reaction of gaseous $AlCl_3$ with oxygen containing 5 vol% H_2O at various temperatures

Heating temp/°C	Formation temperature of Al_2O_3 and heating atmosphere							
	400 °C		600 °C		800 °C		900 °C	1000 °C
	In argon	In air	In argon	In air	In argon	In air	In argon and air	In argon and air
600	Amorphous		Amorphous		Amorphous		γ	γ, δ
700	χ	χ	χ	χ	χ	χ	γ, χ	γ, δ
800	χ, κ, γ	χ, κ	χ, κ, γ	χ, κ	χ, κ, γ	χ, κ, γ	γ, χ, κ	γ, δ
900	χ, κ, γ	χ, κ	χ, κ, γ	χ, κ	χ, κ, γ, δ	χ, κ, γ, δ	γ, δ, κ	γ, δ
1000	κ, $\delta > \alpha$	κ, α	κ, $\delta > \alpha$	κ, α	κ, $\delta > \theta$, α	κ, δ, θ, α	δ, θ, α	δ, $\theta > \alpha$
1100	α	α	α	α	$\alpha > \theta$, δ	$\alpha > \theta$, δ	$\alpha > \theta$, δ	δ, θ, α
1200	—	—	—	—	α	α	α	α, θ
1300	—	—	—	—	—	—	—	$\alpha > \theta$

Amorphous = amorphous Al_2O_3, $\chi = \chi$-Al_2O_3,[4,5] $\kappa = \kappa$-Al_2O_3,[4,6] $\alpha = \alpha$-Al_2O_3,[7] $\gamma = \gamma$-Al_2O_3,[4,8] $\delta = \delta$-Al_2O_3,[4,9] $\theta = \theta$-Al_2O_3.[10]

gardless of the heating atmosphere. The γ-Al_2O_3 observed in the samples obtained after heating the amorphous Al_2O_3 at 800 and 900 °C in an argon atmosphere is due to the decomposition of the chloride oxide which is included in the amorphous Al_2O_3, and the δ-Al_2O_3 observed at 1000 °C is due to the thermal transition of the γ-Al_2O_3 formed.[2] The samples obtained after heating the amorphous Al_2O_3 in the air give neither diffraction line corresponding to γ-Al_2O_3 nor corresponding to δ-Al_2O_3, because the chloride oxide is oxidized in the air to amorphous Al_2O_3 which transforms in the same manner as the amorphous Al_2O_3 formed from gaseous $AlCl_3$.[2]

The results for the γ-Al_2O_3 containing amorphous Al_2O_3, formed at 900 °C, and for the mixture of γ-Al_2O_3 and δ-Al_2O_3, formed at 1000 °C, indicate that, on heating the γ-Al_2O_3, the $\gamma \xrightarrow{ca.900\,^\circ C} \delta \xrightarrow{ca.1000\,^\circ C} \theta \xrightarrow{ca.1000\,^\circ C} \alpha$ α transition occurs, regardless of the heating atmosphere. The χ-Al_2O_3 and κ-Al_2O_3 observed in the samples obtained after heating the Al_2O_3 formed at 900 °C are due to the thermal transition of amorphous Al_2O_3 which is contained in the γ-Al_2O_3.

On heating the amorphous Al_2O_3 containing poorly crystallized γ-Al_2O_3, formed at 800 °C, both the amorphous$\rightarrow\chi\rightarrow\kappa\rightarrow\alpha$ and $\gamma\rightarrow\delta\rightarrow\theta\rightarrow\alpha$ transitions occur, as is expected from the above results.

The experimental results for the Al_2O_3 formed by the reaction with oxygen containing 2 vol% H_2O at temperatures below 800 °C were similar to those for the Al_2O_3 formed by the reaction with oxygen containing 5 vol% H_2O. The results for the γ-Al_2O_3 containing amorphous Al_2O_3, formed at 900 °C, and for the mixture of γ-Al_2O_3 and δ-Al_2O_3, formed at 1000 °C, are shown in Table 2.

Table 2. Thermal transitions of Al_2O_3 formed by the reaction of gaseous $AlCl_3$ with oxygen containing 2 vol% H_2O at 900 and 1000 °C

Heating temp/°C	Formation temperature of Al_2O_3 and heating atmosphere	
	900 °C In argon and air	1000 °C In argon and air
600	γ	γ, δ
700	γ, χ	γ, δ
800	γ, χ, κ	γ, δ
900	γ, δ, χ, κ	γ, δ
1000	δ, θ, α, κ	$\delta > \theta$, α
1100	δ, θ, α	δ, $\theta > \alpha$
1200	$\alpha > \theta$	α, θ
1300	$\alpha > \theta$	α, θ

From these results, the thermal transitions of amorphous Al_2O_3 and of γ-Al_2O_3, formed by the reaction of gaseous $AlCl_3$ with oxygen containing 2 vol% H_2O, are found to be the same as those of the Al_2O_3 formed by the reaction with oxygen containing 5 vol% H_2O. In more details, the sample obtained after heating at 1300 °C the γ-Al_2O_3 containing amorphous Al_2O_3, formed by the reaction with oxygen containing 2 vol% H_2O at 900 °C, was found to be a mixture of α-Al_2O_3 and θ-Al_2O_3 (Table 2). The sample obtained after heating at 1200 °C the γ-Al_2O_3 containing amorphous Al_2O_3, formed by the reaction with oxygen containing 5 vol% H_2O at 900 °C, gave diffraction lines corresponding to α-Al_2O_3 alone (Table 1). These results can be well understood, considering the thermal transitions of γ-Al_2O_3 containing amorphous Al_2O_3, formed by the reactions of gaseous $AlCl_3$ with oxygen[1] and H_2O[2] at 900 °C.

These experimental results show that on heating the amorphous Al_2O_3 formed by the reaction of gaseous $AlCl_3$ with oxygen containing 2—5 vol% H_2O, the amorphous $\xrightarrow{ca.700\,^\circ C} \chi \xrightarrow{ca.800\,^\circ C} \kappa \xrightarrow{ca.1000\,^\circ C} \alpha$ transition occurs. On heating the γ-Al_2O_3 formed, the $\gamma \xrightarrow{ca.900\,^\circ C} \delta \xrightarrow{ca.1000\,^\circ C} \theta \xrightarrow{ca.1000\,^\circ C} \alpha$ transition occurs.

The thermal transition of the amorphous Al_2O_3 is the same as that of the amorphous Al_2O_3 formed by the reactions with oxygen[1] and with H_2O.[2] The transition temperatures of $\gamma\rightarrow\delta$, $\delta\rightarrow\theta$, and $\theta\rightarrow\alpha$ on heating the γ-Al_2O_3 are approximately 100 °C lower than those of the γ-Al_2O_3 formed by the reaction with oxygen[1] and are the same as those of the γ-Al_2O_3 formed by the reaction with H_2O.[2]

Plasma Treatment of Packing Materials for Gas Chromatography. Diatomaceous Earth Coated with Squalane

Yukio YAMAMOTO,* Seiji OKA, and Koichiro HAYASHI

The Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita, Osaka 565

(Received July 9, 1981)

Commercially obtained column packings for gas chromatography, diatomaceous earth coated with 5% squalane, were treated with argon plasma by using a radiofrequency generator. It has been shown that the plasma treatment improves the chromatographic properties, in particular, reduces the tailing of aromatic hydrocarbon peaks. The effect of the plasma treatment has been attributed to the reduction of the support adsorptivity by the formation of inert coating on the support surface.

A growing interest has been arising in the application of plasma chemistry to surface treatment of solid materials.[1-3] An attempt has been made to apply inert gas plasma to the treatment of packing materials for gas chromatography, and the results of the preliminary experiments suggested that the argon plasma treatment of the packing such as diatomaceous earth coated with Apiezon L or squalane improves its chromatographic properties.[4] The effect has been attributed to the formation of inert coating on the support surface. The surface of diatomite supports is known to be covered with reactive silanol groups which cause tailing of chromatographic peaks, and several methods are used to reduce the activity of the supports.[5] It is expected that the argon plasma treatment of packings is effective for the reduction of the support adsorptivity. In the present study the effect of the plasma treatment of diatomaceous earth coated with 5% squalane was studied in some detail.

Expermental

Column packings, 60/80 mesh Chromosorbs W and P (non-acid washed) coated with 5% squalane, were obtained from Wako Pure Chemical Industry. The reactor used for the plasma treatment is shown in Fig. 1. The packing (about 4 g) was treated on a glass plate (9 cm diameter) in a bell jar with argon plasma at a pressure of 0.20 Torr (27 Pa). The power for the reactor was supplied by a radiofrequency generator operated at 13.56 MHz and an output of 50 W. After the treatment the packing was packed with tamping and vibration into a 1 m × 3 mm i.d. stainless steel tube as well as the untreated packing. Before its use the column was conditioned overnight at 130 °C. The gas chromatography was carried out on a Hitachi gas chromatograph, Model 063, equipped with a flame ionization detector by injecting about 0.1 μl hydrocarbon mixtures. The flame ionization detector was substituted for a thermal conductivity cell detector when the retention time of oxygen was measured for determination of the adjusted retention times. The column was operated at 40 °C with a nitrogen flow of 30 ml/min. ESCA measurement of the support recovered from the packing by Soxhlet extraction was performed on a Du Pont ESCA 650 B electron spectrometer by employing a Mg $K\alpha_{1,2}$ photon source at 1253.6 eV.

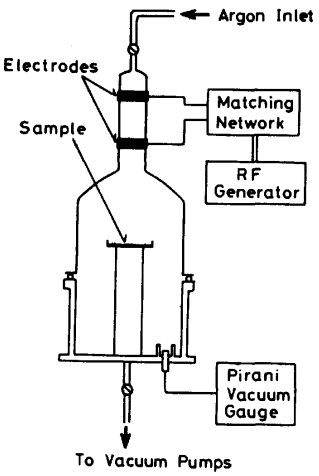

Fig. 1. Reactor used for the plasma treatment.

Results and Discussion

The effect of the argon plasma treatment of 60/80 mesh Chromosorb W (non-acid washed) coated with 5% squalane is shown in Fig. 2 where the chromatograms of a mixture of hexane, benzene, cyclohexane, heptane, toluene, ethylbenzene, and *o*- and *m*-xylenes on the untreated and 30 min treated packings are presented. It can be seen that the retention times of all the compounds and the tailings of the aromatic hydrocarbon peaks are reduced by the plasma treatment. Greater peak separation is also shown for benzene and cyclohexane on the treated packing. The changes in the adjusted retention times of the aliphatic and aromatic hydrocarbons are shown in Figs. 3 and 4, respectively, where the ratio of the adjusted retention time on the treated packing to that on the untreated packing, t'_{RO}/t'_{Rt}, is plotted against treatment time. A comparison of the figures shows that the retention times

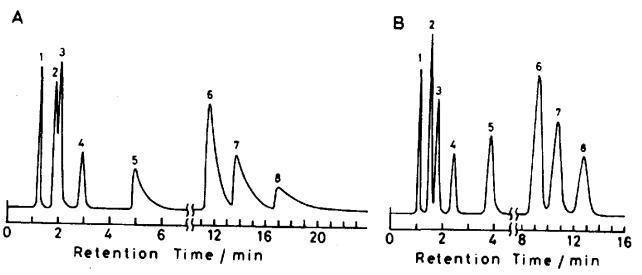

Fig. 2. Gas chromatograms on (A) untreated and (B) 30 min treated packings (Chromosorb W coated with 5% squalane) at 40 °C: the peaks are 1, hexane; 2, benzene; 3, cyclohexane; 4, heptane; 5, toluene; 6, ethylbenzene; 7, *m*-xylene; and 8, *o*-xylene.

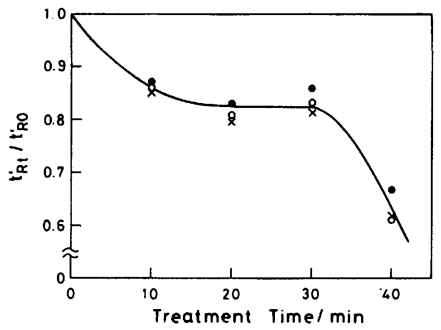

Fig. 3. Change in the adjusted retention times of aliphatic hydrocarbons: (○), hexane; (●), cyclohexane; and (×), heptane.

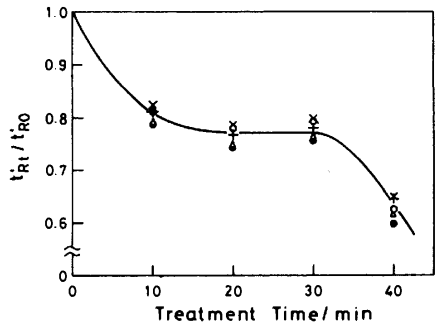

Fig. 4. Change in the adjusted retention times of aromatic hydrocarbons: (○), benzene; (●), toluene; (×), ethylbenzene; (△), *o*-xylene and (+), *m*-xylene.

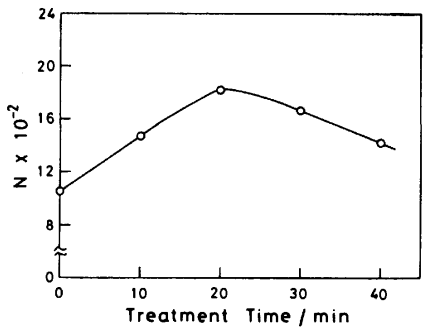

Fig. 5. Change in the number of theoretical plates (N).

of the aromatic hydrocarbons are reduced more than those of the aliphatic hydrocarbons by the plasma treatment. Figure 5 shows the change in the number of theoretical plates (N) by the plasma treatment, which was calculated from the peaks of ethylbenzene and *o*- and *m*-xylenes as $16(t_R/W_b)^2$, where t_R and W_b are the retention time and the peak width at base, respectively. The value attains maximum at around 20 min and then decreases by further treatment. The weight loss of the packing during the plasma treatment was too small to measure accurately, less than 0.4% up to a treatment time of 40 min.

In order to elucidate the modification of the packing by the plasma treatment the stationary liquids were extracted from the untreated and 20 and 40 min treated packings with tetrahydrofuran by using Soxhlet extractors and refluxing for 5 h, and then the recovered supports were dried under vacuum. The weight losses of the untreated and 20 and 40 min treated packings by the extraction were 4.9, 4.0, and 3.4%, respectively. Since the original packing has a liquid phase content of about 4.8% (5% relative to the support), the result means that the stationary liquid is almost completely extracted from the untreated packing but not from the treated packing, and the remaining component increases with increasing treatment time.

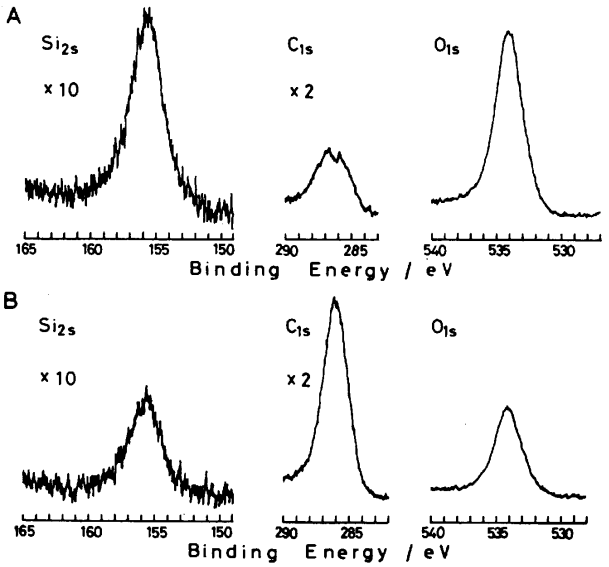

Fig. 6. ESCA Si_{2s}, C_{1s}, and O_{1s} peaks of supports recovered from (A) untreated and (B) 20 min treated packings.

ESCA measurement of the recovered supports was examined to obtain information about their surface compositions. Figure 6 shows the Si_{2S}, C_{1S}, and O_{1S} peaks of the ESCA spectra obtained for the untreated and 20 min treated packings. The C_{1S} peak is much larger for the treated sample than for the untreated sample, and the Si_{2S} and O_{1S} peaks arising from the diatomite support are reduced for the treated sample. The spectra demonstrate that the surface of the support recovered from the treated packing is covered with an organic component. On the other hand, the relative heights of the Si_{2S} and O_{1S} peaks are not affected by the plasma treatment, indicating that the surface composition of the support itself does not change.

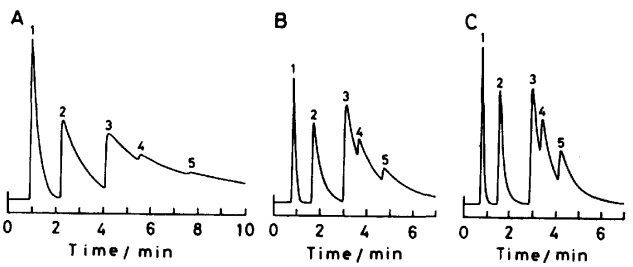

Fig. 7. Gas chromatograms on supports recovered from (A) untreated, (B) 20 min and (C) 40 min treated packings at 40 °C: The peaks are 1, benzene; 2, toluene; 3, ethylbenzene; 4, *m*-xylene; and 5, *o*-xylene.

The supports recovered from the packings were packed into the 1 m stainless steel tubes, and the columns were examined for gas chromatography. Figure 7 shows the gas chromatograms of a mixture of the aromatic hydrocarbons on the recovered supports. The retention times and tailings are reduced with increasing treatment time, suggesting that the adsorptivity of the support is reduced by the plasma treatment.

The untreated and treated packings were washed with carbon tetrachloride, and after filtration the carbon tetrachloride solutions of the stationary liquids were submitted to NMR spectrometry. There was no detectable difference in the spectra between the untreated and treated samples, and the spectra were identical with that of commercially obtained squalane. The result suggests that the soluble component of the stationary liquid of the treated packing remains unchanged.

On the basis of these results it can be considered that the plasma-induced reaction is restricted to the support surface and results in the formation of inert coating which is not extracted with tetrahydrofuran. The effect of the plasma treatment on gas chromatogram was shown to be more pronounced for the aromatic hydrocarbons than for the saturated aliphatic hydrocarbons. This is due to the fact that aromatic hydrocarbons have greater interaction with the surface silanol groups of the support than saturated aliphatic hydrocarbons.

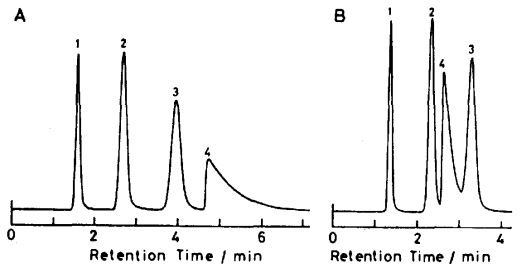

Fig. 8. Gas chromatograms on (A) untreated and (B) 20 min treated packings (Chromosorb P coated with 5% squalane) at 40 °C: the peaks are 1, hexane; 2, cyclohexane; 3, heptane; and 4, benzene.

The argon plasma treatment of the packing with another kind of support, 60/80 mesh Chromosorb P (non-acid washed) coated with 5% squalane, was examined by the same way to investigate the effect on the support adsorptivity. Figure 8 shows the gas chromatograms on the untreated and 20 min treated packings. On the untreated packing with Chromosorb P benzene is eluted later than heptane with a significant tailing, while on the untreated packing with Chromosorb W benzene is eluted faster than cyclohexane with a much smaller tailing (Fig. 2). It is known that Chromosorb P is more adsorptive than Chromosorb W because of the greater number of hydroxyl groups on the surface.[5] Therefore, the difference in the gas chromatograms between the untreated packings with Chromosorbs P and W can be explained by the great interaction of aromatic hydrocarbons compared with saturated aliphatic hydrocarbons. The result also demonstrates that the gas chromatograms are significantly affected with the support adsorptivity. On the other hand, on the treated packing with Chromosorb P benzene is eluted faster than heptane with a reduced tailing, indicating that the plasma treatment is effective for the reduction of the support adsorptivity.

Usually, the lower the column temperature, the greater is the tailing of gas chromatographic peaks. The results of the present study show that the plasma treatment makes it possible to use the packings at lower column temperature. Unfortunately, no information has been obtained about the chemical composition and formation mechanism of the insoluble component produced on the support surface. However, it seems reasonable to assume that the stationary liquid is converted to a highly crosslinked polymer on the support surface by the plasma treatment and the reaction is promoted by the reactive support surface.

This work was supported in part by Shimadzu Co. The authors wish to thank Mr. Hitoshi Yamada for his assistance in measuring the ESCA spectra.

^{197}Au Mössbauer effect measurements of mixed-valence compounds and chelates of Au(III) with ligands of 1,10-phenanthroline, 8-quinolinol, and their derivatives have been carried out. The Mössbauer data of $Cs_2Au_2Cl_6$, $Cs_2AgAuCl_6$, and [Au(phen)Cl_2]Cl show the existence of an interaction between metal atoms through Cl atoms. Although the metal-metal interaction in [Au(Hdmg)$_2$][$AuCl_2$] has been postulated by X-ray study, no such interaction was observed. Two kinds of 8-quinolinol Au(III) complexes which have *cis-trans* isomers are assigned to the compounds of the [Au(oxine)$_2$][$AuCl_4$] and [Au(oxine)Cl_2] types.

Mössbauer spectroscopy has been widely used to study the nature of chemical bonding and the structures of inorganic and organometallic compounds, especially those of iron and tin compounds.

Although the ^{197}Au Mössbauer experiment has some disadvantages, such as the short half-life (18 h) of the source nuclide and the low recoil-free fraction, which require the use of a nuclear reactor and low-temperature measurement, the application of Mössbauer spectroscopy has recently become popular as a useful physicochemical technique because the spectrum is generally unambiguous and sensitive to the nature of chemical bonding and the structures of gold compounds.[1,2]

The present work was carried out in order to elucidate the interaction between the two different gold atoms in different sites in the mixed-valence compounds, such as $Cs_2Au_2Cl_6$, [Au(Hdmg)$_2$][$AuCl_2$], and [Au(phen)Cl_2][$AuCl_4$], and in order to clarify the structure of chelate complexes of Au(III) with 1,10-phenanthroline, 8-quinolinol, and their derivatives as ligands.

Experimental

$CsAuCl_4$,[3] $Cs_2AgAuCl_6$,[3] [Au(Hdmg)$_2$][$AuCl_2$] (Hdmg=dimethylglyoximato(1-)),[4] [Au(phen)Cl_2]Cl (phen=1,10-phenanthroline),[5] [Au(phen)Cl_2]ClO_4,[5] [Au(phen)Cl_2][$AuCl_4$],[5] Au(dmp)Cl_3 (dmp=2,9-dimethyl-1,10-phenanthroline),[6] Au(dmp)Br_3,[6] [Au(oxine)$_2$][$AuCl_4$] (oxine=8-quinolinol),[7] and [Au(oxine)Cl_2][7] were prepared by the methods described in the literature. Thermal decomposition product of $CsAuCl_4$, $Cs_2Au_2Cl_6$(dec) was prepared by a method similar to that of Brauer and Sleater[8] by checking the decomposition process by TGA and DSC. Another sample of $Cs_2Au_2Cl_6$(syn) was prepared directly by heating the stoichiometric mixture of CsCl, Au, and $CsAuCl_4$ in an evacuated quartz tube at 450 °C for one week and then cooling it rapidly in water. The crystal thus obtained was annealed at 250 °C for 3 d.

[Au(5-Cl-oxine)Cl_2] (5-Cl-oxine=5-chloro-8-quinolinol) was prepared by a method similar to that used in the preparation of 8-quinolinol gold complexes.[7] The purity of the samples was checked by elemental analysis and powder X-ray diffractometry (Cu $K\alpha$ radiation).

^{197}Au Mössbauer spectroscopic measurements were carried out with a source and an absorber, both cooled to 18 K by using a constant acceleration-type spectrometer accompanied by a pure-Ge diode detector. The data were stored in a microcomputerized multichannel analyser constructed by Uehara and Maeda.[9] A ^{197}Pt source was made by irradiating a 100-mg disk of metallic Pt enriched to 98% in ^{196}Pt. The velocity scale was calibrated by taking the spectrum of an iron foil against a ^{57}Co(Pt) source, both at room temperature. The spectra were fitted with Lorentzian line shapes by using the least-squares fitting program. The precision of the Mössbauer parameters obtained is within $\pm$0.04 mm/s for single component spectra and $\pm$0.08 mm/s for double component spectra. All the isomer shift data are referred to the Au-metal resonance at 18 K.

Results and Discussion

$CsAuCl_4$, $Cs_2Au_2Cl_6$(syn), $Cs_2Au_2Cl_6$(dec), and $Cs_2AgAuCl_6$. Some typical Mössbauer spectra of $CsAuCl_4$, $Cs_2Au_2Cl_6$(syn), and $Cs_2AgAuCl_6$ are shown in Fig. 1. Table 1 summarizes the Mössbauer parameters, isomer shift (*IS*), quadrupole splitting (*QS*), and half-width (Γ_{exp}) derived from the observed spectra. The isomer shift and quadrupole splitting of $CsAuCl_4$ are similar to those of the compounds containing discrete square-planar-complex ions, $[AuCl_4]^-$.[10,11] This indicates that gold atoms are coordinated essentially in the square-planar form and that the isolated $[AuCl_4]^-$ ion exists in a solid. The complicated spectra of both the

Au(III)	1.56	0.95	2.00
$Cs_2AgAuCl_6$	1.54	—	2.33

$Cs_2Au_2Cl_6$(dec and syn) samples suggest the presence of two or more different sites or oxidation states for the gold atom in these compounds. The crystal structure of $Cs_2Au_2Cl_6$ was determined first by Elliot and Pauling from powder X-ray diffraction data.[12]

According to their results, this compound contains complex ions of linear $[AuCl_2]^-$ and square-planar $[AuCl_4]^-$ units, and they postulated the possibility of interaction between Au(I) and Au(III) sites through Cl atoms. In recent years, however, the structure was redetermined by using single crystal data by Tindermans-v. Eijindhoven and Verschoor.[13] They pointed out that there was no interaction between Au(I) and Au (III) atoms through Cl atoms. In Fig. 1(b), the outer doublet is assigned to the Au(I), and the inner doublet to the Au(III). The slight differences in Mössbauer parameters between the two samples (syn and dec), and between ours and those reported by Faltens and Shirley,[10] may be due to the different preparation process and/or an error in the deconvolution of the spectra. In the work by Faltens and Shirley, $Cs_2Au_2Cl_6$ was prepared from an acid solution of CsCl and AuCl. The values of *IS* for Au(III) in both $Cs_2Au_2Cl_6$ (syn) and $Cs_2Au_2Cl_6$ (dec) are smaller than that of $CsAuCl_4$ and those of some compounds containing a discrete $[AuCl_4]^-$ ion. Unfortunately, Faltens and Shirley did not interpret the correlation of the Mössbauer parameters with the structures of $Cs_2Au_2Cl_6$. If the postulation of Elliot and Pauling were correct, the configuration around the Au(III) atom in the $[AuCl_4]^-$ site should be a distorted octahedron with four Cl atoms of the $[AuCl_4]^-$ ion and two additional Cl atoms from adjacent $[AuCl_2]^-$ ions, as is shown in Fig. 2. In this case, it would be impossible to form six equivalent $5d^26s6p^3$ hybrid bonds involving the promotion of two electrons. The formation of six equivalent bonds using a $5d6s6p^36d$ hybridization also seems to be unlikely from the point of view of energy. However, the formation of an octahedron elongated to the z-axis (normal to the square plane of $[AuCl_4]^-$) with six Cl atoms, may be explained by assuming that two 6p6d hybrid bonds are added to the $5d6s6p^2$ hybrid bonds which hold the four Cl atoms in square-planar form. The additional co-linear 6p6d hybrid bonds should be elongated in the direction of the z-axis because of the repulsion of the filled $5d_z$ gold orbital in the gold atom. This explanation was suggested by Sutton to interpret hexa-coordinated Au(III) ions, such as $[Au(diars)_2I_2]^+$ (diars = *o*-phenylenbis(dimethylarsine)) and $[AuBr_6]^{3-}$.[14,15] The additional electrons of the 6p6d hybrid orbital may be expected to decrease the isomer shift because of the increased shielding effect of p- and d-electrons on s-electrons.

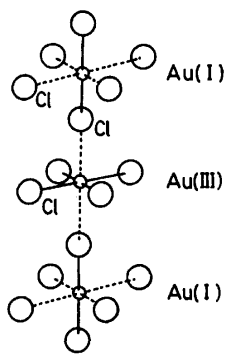

Fig. 2. Stacking arrangement of the $[AuCl_4]^-$ and $[AuCl_2]^-$ units.

The *IS* value of the Au(I) site is considerably smaller than that of the corresponding Au(I) chloride, $(C_6H_5)_4AsAuCl_2$ (*IS*=1.72 mm/s and *QS*=6.13 mm/s).[16] Au-atoms are also surrounded by six Cl atoms and form a contracted octahedron, as is shown in Fig. 2.

The additional four bonds may be formed by using $6p^26d^2$ hybridization; hence, the s-electron density decreases as a result of the increased shielding effect of p- and d-electrons, as in the case of Au(III).

The decreasing tendency of *QS* values for Au(I) and Au(III) sites also supports the hexa-coordinated structure of gold atoms. As is known in the case of covalent square-planar Au(III) compounds where Au (III) uses the $5d_{x^2-y^2}$, 6s, $6p_x$, and $6p_y$ orbitals, the occupation of these orbitals will cause a positive contribution to the electric field gradient (EFG), while a nonbonding $5d_{z^2}$ orbital will produce a negative contribution to the EFG. By assuming that the EFG of the original $[AuCl_4]^-$ site is positive, it may be concluded that the increase in electron densities along the z-axis as a result of 6p6d hybridization produces a negative contribution to the EFG, so that the total EFG becomes smaller. For linear Au(I) compounds, the z-axis is taken along the molecular axis and 6s6p hybrid orbitals of gold are used as σ-bonds. This has been confirmed experimentally for $K[Au(CN)_2]$, in which the EFG value for linear Au(I) compounds is negative.[17] Since four additional Au–Cl bonds, using the $6p^26d^2$ hybrid orbitals, produce a positive contribution to the EFG, the total EFG can be expected to decrease.

The crystal structure of $Cs_2AgAuCl_6$ is known to be the same as that of $Cs_2Au_2Cl_6$. From the discussion presented above of Mössbauer parameters of $Cs_2Au_2Cl_6$, the unresolved quadrupole splitting found on $Cs_2AgAuCl_6$ can be explained as follows: the positive and negative contributions to the EFG are almost equal, so that the effective EFG becomes zero or negligible. This result suggests that there is a strong interaction between Ag(I) and Au(III) sites through Cl atoms. The existence of such a strong interaction between the metal atoms in $Cs_2AgAuCl_6$ has also been pointed out by Yamada and Tsuchida from the dichroism measurement of this

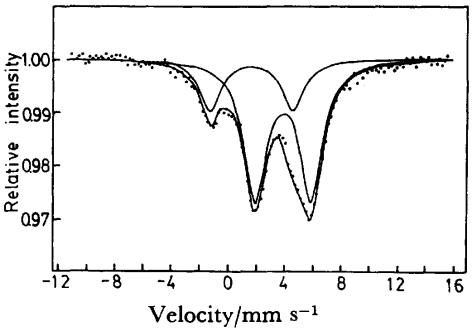

Fig. 3. Mössbauer spectrum of $[Au(Hdmg)_2][AuCl_2]$.

TABLE 2. MÖSSBAUER DATA OF $[Au(Hdmg)_2][AuCl_2]$

Compound	IS / mm s^{-1}	QS / mm s^{-1}	Γ_{exp} / mm s^{-1}
$[Au(Hdmg)_2][AuCl_2]$			
Au(I)	1.58	6.03	1.74
Au(III)	3.88	4.04	2.03

compound.[3] The present data also support their conclusion that the interaction between two metal atoms in $Cs_2AgAuCl_6$ is stronger than that in $Cs_2Au_2Cl_6$.

[Au(Hdmg)$_2$][AuCl$_2$]. The Mössbauer spectrum and the derived parameters of $[Au(Hdmg)_2][AuCl_2]$ are shown in Fig. 3 and in Table 2, respectively. Rundle determined the structure of this compound and postulated the existence of a direct interaction between the Au(I) and Au(III) atoms.[4] However, the fact that the values of *IS* and *QS* for the Au(I) site are similar to those of the isolated $[AuCl_2]^-$ ion in $[(C_6H_5)_4As][AuCl_2]$ indicates no metal-metal interaction between Au(I) and Au(III) atoms.

This result is consistent with the results of dichroism measurement obtained by Yamada and Tsuchida.[18] The values of *IS* and *QS* for Au(III) in the $[Au(Hdmg)_2]^+$ ion are larger than those of the $[AuCl_4]^-$ ion. If the $5d6s6p^2$ hybrid orbitals are used to form a square-planar form, this difference can be explained by the stronger σ-donating power of the Hdmg ligand compared to the Cl ligand, because the increased σ-donation by the ligand to the 6s orbital increases the s-electron density, and hence the isomer shift. At the same time, the EFG will increase as a result of the donation to the $6p_x$ and $6p_y$ orbitals. Therefore, the values of *IS* and *QS* depend mainly on the σ-donating character of the Hdmg ligand, which is estimated to lie between those of the N_3^- and CN^- ligands, this is consistent with the estimation based on the spectrochemical series of ligands.

[Au(phen)Cl$_2$]Cl, [Au(phen)Cl$_2$]ClO$_4$, [Au(phen)Cl$_2$][AuCl$_4$], Au(dmp)Cl$_3$, and Au(dmp)Br$_3$. The Mössbauer spectra of $[Au(phen)Cl_2]X$ (X=Cl, ClO_4, and $AuCl_4$) and $Au(dmp)Cl_3$ are shown in Fig. 4. The Mössbauer parameters of these complexes are summarized in Table 3, together with those of $Au(dmp)Br_3$. The values of *IS* and *QS* for $[Au(phen)Cl_2]Cl$, $[Au(phen)Cl_2][AuCl_4]$ and $Au(dmp)Cl_3$ are in good agreement with those reported by Takeda *et al.*[19] $[Au(phen)Cl_2]Cl$ and $Au(dmp)X_3$ (X=Cl or Br) show

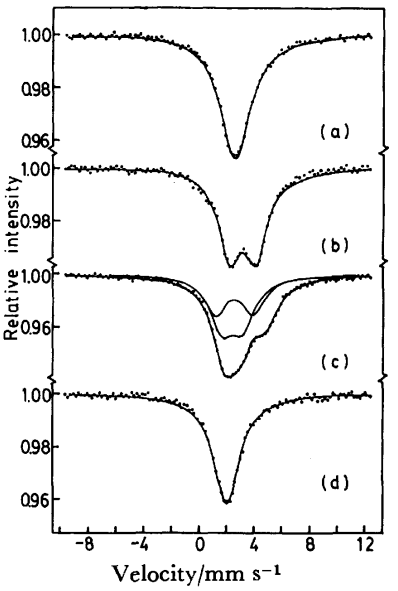

Fig. 4. Mössbauer spectra of (a) $[Au(phen)Cl_2]Cl$, (b) $[Au(phen)Cl_2]ClO_4$, (c) $[Au(phen)Cl_2][AuCl_4]$, and (d) $Au(dmp)Cl_3$.

TABLE 3. MÖSSBAUER DATA OF 1,10-PHENANTHROLINE AND 2,9-DIMETHYL-1,10-PHENANTHROLINE Au(III) COMPLEXES

Compound	IS / mm s^{-1}	QS / mm s^{-1}	Γ_{exp} / mm s^{-1}
$[Au(phen)Cl_2]Cl$	2.39	—	2.66
$[Au(phen)Cl_2]ClO_4$	3.01	1.95	2.06
$[Au(phen)Cl_2][AuCl_4]$			
$[Au(phen)Cl_2]^+$	3.33	2.74	1.97
$[AuCl_4]^-$	2.24	1.53	2.13
$Au(dmp)Cl_3$	1.87	—	2.31
$Au(dmp)Br_3$	2.07	—	2.76

spectra consisting of a single broad line with unresolved quadrupole splitting. This suggests that the structures of these complexes are different from the square-planar structure which is to be expected for a number of Au(III) chelate compounds. The smaller value of *IS* for $[Au(phen)Cl_2]Cl$, compared with those for $[Au(phen)Cl_2]ClO_4$ and $[Au(phen)Cl_2][AuCl_4]$, also supports a gold atom with a coordination number beyond four.

Harris has investigated the structure of the 1,10-phenanthroline complexes of Au(III) halides by

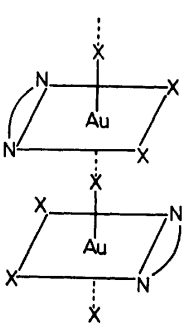

Fig. 5. Coordination of gold in $[Au(phen)X_2]X$.

conductance and spectral measurements in nonaqueous solvents.[5] From the molecular conductivities of the complexes, $[Au(phen)X_2]X$ (X=Cl or Br), he has suggested that those complexes have a polymeric structure, in which there are two elongated gold-halogen bonds normal to the square-planar $[Au(phen)X_2]^-$ ion, as is shown in Fig. 5. Two additional elongated Au–X bonds have been explained by assuming a colinear 6p6d hybrid bond. In accordance with his conclusion, the present Mössbauer results of $[Au(phen)Cl_2]Cl$ can also be explained by the consideration described in the case of $Cs_2AgAuCl_6$.

On the other hand, the quadrupole splitting is clearly observed for $[Au(phen)Cl_2]ClO_4$ and the *IS* is higher than that of $[Au(phen)Cl_2]Cl$, both indicating little or no interaction between the Au atoms in the $[Au(phen)Cl_2]^+$ ion and the counter anion, ClO_4^-. The rather complicated Mössbauer spectrum of $[Au(phen)Cl_2][AuCl_4]$ shown in Fig. 4(c) consists of two overlapped doublets. The outer doublet corresponds to the $[Au(phen)Cl_2]^+$ ion, and the inner doublet, to the $[AuCl_4]^-$ ion. Both the *IS* and *QS* of the $[Au(phen)Cl_2]^+$ ion in $[Au(phen)Cl_2][AuCl_4]$ show the highest values among a series of $[Au(phen)Cl_2]X$ salts. The Mössbauer parameters of the $[AuCl_4]^-$ ion found in $[Au(phen)Cl_2][AuCl_4]$ are similar to those of discrete $[AuCl_4]^-$ ions in other compounds previously reported by several researchers.[10,11] The results indicate that the $[Au(phen)Cl_2]^+$ cation has no effect on its counter anion $[AuCl_4]^-$, although the existence of metal-metal interaction in $[Au(phen)Cl_2][AuCl_4]$ might be expected, as in the case of Magnus's salt, $[Pt(NH_3)_4][PtCl_4]$, and similar complexes. Two complexes with chelating ligand 2,9-dimethyl-1,10-phenanthroline instead of 1,10-phenanthroline, $Au(dmp)Cl_3$ and $Au(dmp)Br_3$, were prepared, and their crystal structures were determined by Robinson and Sinn.[6] According to their results, these complexes have a five-coordinated structure, described as a distorted square-pyramidal structure or as an intermediate one between trigonal- and square-pyramidal. These structure are sterically hindered from forming the expected square-planar coordination as is found in 1,10-phenanthroline complexes. The smaller *IS* value compared with those of $[Au(phen)Cl_2]X$ (X=Cl, ClO_4, or $AuCl_4$) can be explained as follows: the structural data show that these complexes possess an approximately square-pyramidal geometry, with a weaker extra Au–N bond along the z-axis (perpendicular to the plane of the square); therefore, it is impossible to form five equivalent σ-bonds using $5d6s6p^3$ hybridization. Another possible explanation of these structures is to assume the vacant $6p_z$ orbital is used to form an extra Au–N bond, which is elongated to the z-axis due to the repulsion of the filled $5d_z^2$ orbital. The population in the $6p_z$ orbital decreases the s-electron density, and hence the isomer shift. The unresolved quadrupole splitting of these complexes can be interpreted by assuming that the magnitude of the negative contribution to the EFG nearly balances the positive contribution by the extra Au–N bond formation.

[Au(oxine)$_2$][AuCl$_4$], [Au(oxine)Cl$_2$], and [Au(5-Cl-oxine)Cl$_2$]. 8-Quinolinol complexes may be used as typical examples of the diagnosis of the structure and chemical bonding of two kinds of gold chelate complexes described with the same chemical formula. The spectra of these complexes and $[Au(5\text{-Cl-oxine})Cl_2]$ are shown in Fig. 6, while the Mössbauer parameters are summarized in Table 4.

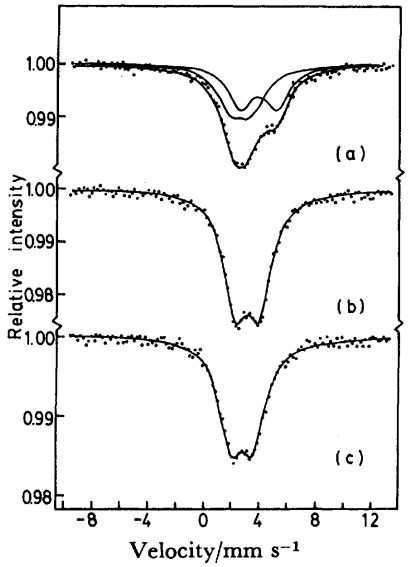

Fig. 6. Mössbauer spectra of (a) $[Au(oxine)_2][AuCl_4]$, (b) $[Au(oxine)Cl_2]$, and (c) $[Au(5\text{-Cl-oxine})Cl_2]$.

Table 4. Mössbauer data of 8-quinolinol and 5-chloro-8-quinolinol complexes

Compound	*IS* / mm s^{-1}	*QS* / mm s^{-1}	Γ_{exp} / mm s^{-1}
$[Au(oxine)_2][AuCl_4]$			
$[Au(oxine)_2]^+$	3.64	2.64	2.12
$[AuCl_4]^-$	2.43	1.49	2.39
$[Au(oxine)Cl_2]$	2.91	1.72	2.12
$[Au(5\text{-Cl-oxine})Cl_2]$	2.72	1.62	2.11

Two kinds of 8-quinolinol complexes, $[Au(oxine)_2][AuCl_4]$ have first been prepared and explained by Inazu[7] by assuming the *cis* and *trans* isomers with respect to the coordination of oxine ligands to the central gold atom, although he did not determine which was *cis*-form or *trans*-form. One is green, and the other is amber in color. The latter complex was assigned to the compound, consisting of either a *cis* or *trans* $[Au(oxine)_2]^+$ cation and an $[AuCl_4]^-$ anion, by Inazu on the basis of paper-ionophoreisis measurements. Concerning the green-colored species, an alternative stereoisomeric cation was suggested, although no experimental information on the green-colored complex was available. We prepared these complexes according to Inazu's method and obtained green and amber-colored samples. The Mössbauer spectrum of the amber-colored complex shows the existence of two kinds of gold atoms. The present result partially confirms Inazu's conclusion, in which gold exists as both cationic and anionic species in the amber-colored compound. On the other hand, our findings for the

green complex are different from the conclusion suggested by Inazu. The spectrum consisting of the doublet indicates the existence of only one kind of gold atom in its chemical state. Therefore, the formula of $[Au(oxine)Cl_2]$ instead of $[Au(oxine)_2][AuCl_4]$ may be appropriate for this compound. The possible structure should be square-planar, denoted as $[Au(oxine)Cl_2]$, in view of the Mössbauer parameters. The values of *IS* for the $[Au(oxine)_2]^+$ ion and for the $[AuCl_4]^-$ ion also support the conclusion concerning the green-colored complex, $[Au(oxine)Cl_2]$. On the other hand, the 5-chloro-8-qunolinol ligand gives no structural isomer, and only a green complex is synthesized. As may be seen from Fig. 6, the Mössbauer spectrum for the $[Au(5\text{-}Cl\text{-}oxine)Cl_2]$ consists of only one doublet, and the Mössbauer parameters are similar to those of the green-colored 8-quinolinol complex, $[Au(oxine)Cl_2]$.

This work has been carried out at the research Reactor Institute, Kyoto University. We are grateful to Assistant Professor Haruhiko Tanaka and Mr. Satoshi Oshima of Hiroshima University for their cooperation in obtaining the TGA and DSC results for $CsAuCl_4$.

(Received July 21, 1981)

The techniques of thermogravimetry (TG) and differential thermal analysis (DTA) were applied to the study of the thermal decomposition of the lanthanoid (Ln) complexes of *N,N,N',N'*-tetramethylurea (TMU), $Ln(TMU)_6X_3$ ($X=ClO_4$, PF_6, or BPh_4). In general, the ease of decomposition increases in the order of $BPh_4<ClO_4<PF_6$; in the latter two cases, the release (and, in the case of ClO_4, partial oxidation) of the coordinated TMU molecules takes place together with the decomposition of the anions, leading finally to the formation of $LnCl_3$ or LnF_3, respectively. The data were also discussed on the basis of the effects of the lanthanoid contraction.

N,N,N',N'-Tetramethylurea (TMU) is an interesting new solvent and coordinating agent. Its donor ability is expected to be quite high, but the four *N*-methyl groups protruding around its coordinating atom (*i.e.*, the C=O oxygen) bring about considerable steric hindrance for its complexation. It is expected, therefore, that stable complexes with it can be formed with large and hard cations, which have strong affinity toward oxygen-containing ligands.[1]

In fact, it has been found that the lanthanoid(III) ions, which just fulfill these conditions, can readily form numerous complexes with TMU; when the coexisting anion is a non-coordinating one (ClO_4^-, PF_6^-, or BPh_4^-), the complexes obtained are usually of the type $Ln(TMU)_6X_3$.[2-4]

We recently tried to apply the techniques of thermogravimetry (TG) and differential thermal analysis (DTA) to these complexes, to study the modes of their thermal decomposition. The obtained results will be briefly summarized and discussed.

Experimental

Preparation of Materials. The complexes studied are listed in Tables 1 and 2. They were prepared according to previously reported methods.[2-4] The complexes of La and Ce were not studied because of the strong hygroscopicity of their perchlorates.

TG-DTA Measurements. The TG and DTA measurements were made with a Shinku Riko TGD-3000 differential thermal microbalance under two conditions, *i.e.*, in static N_2 and in a vacuum (*ca.* 10^{-1} Torr≈13.3 Pa), with the heating rate of 3 °C/min. The sample amount taken in each run was *ca.* 10 mg.

Results and Discussion

Perchlorates. The general appearance of the TG-DTA curves obtained in N_2 is shown in Fig. 1, taking the case of the Nd complex as an example. Essentially similar data are obtained with other perchlorates.

The complex begins to lose a part of its TMU molecules when heated to a certain temperature t_i, and a step AB, which is usually rather dull as shown in Fig. 1, appears on the TG curve. At the end of this step, *n* molecules of TMU are lost from the complex.

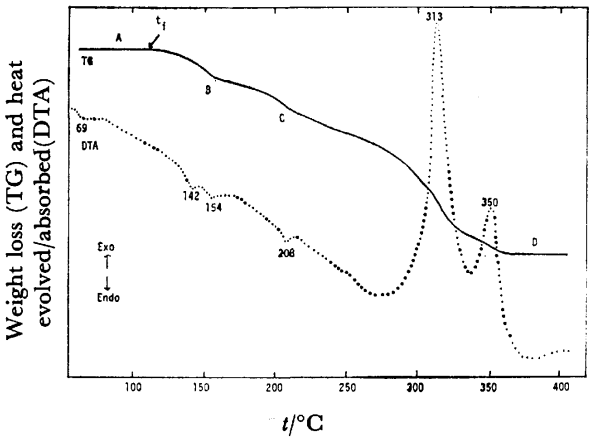

Fig. 1. TG and DTA curves of $Nd(TMU)_6(ClO_4)_3$ in N_2.

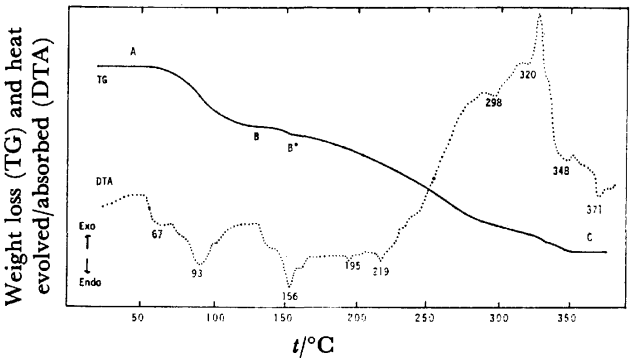

Fig. 2. TG and DTA curves of $Nd(TMU)_6(ClO_4)_3$ in a vacuum.

Then comes another step BC, which is more dull than the step AB and often is observed as a slight inflection of the TG curve, in the course of which some more TMU molecules are lost. Then comes the decomposition of the remaining complex, first gradually but more and more quickly with the rise of temperature, up to a point D, where the weight of the residue becomes nearly constant. The weight loss at D, expressed in percent of the initial weight, will be denoted with Δ.

Table 1 summarizes the values of t_i, *n*, and Δ of all the perchlorates studied, together with the values observed in a vacuum (see later). One can readily

Table 1. Values of t_1, n, and Δ for the complexes $Ln(TMU)_6(ClO_4)_3$

Ln	In N_2			In a vacuum		
	t_1	n[a]	Δ[b]	t_1	n[c]	Δ
Pr	108	1.2	79.1(78 2)	34	2.9	82.5
Nd	110	1.3	77.6(78.0)	48	2.6, 2.9	88.5
Sm	109	1.3	79.2(77.6)	63	2.3, 3.1	88.5
Eu	115	1.2	80.2(77.5)	65	2.8, 3.1	87.2
Gd	124	1.4	76.8(77 2)	57	1.6, 2.3	89.5
Tb	123	1.4	76.6(77.0)	59	1.6	90.2
Dy	124	1.3	75.8(76.8)	67	1.7	90.4
Ho	122	1.3	75.7(76.6)	66	2.1	89.6
Er	134	1.2	77.1(76.5)	73	1.4	89.2
Tm	134	1.3	76.7(76.4)	72	2.7	88.6
Yb	141	1.2	72.3(76.1)	65	2.6, 2.8	91.2
Lu	140	1.3	76.2(76.0)	70	2.7, 2.9	90.9
Y	143	1.2	82.3(82.0)	73	3.1	92.3

a) The values are only approximate owing to the dullness of the step in most cases. b) The values calculated for the complete transformation into $LnCl_3$ are shown in parentheses. c) Two inflection points are often observed at the foot of the step, as the points B and B′ in Fig. 2. The n values corresponding to each of them are given in such cases.

understand that, as to the thermal changes in N_2, there are the following relationships among these values:

1) The value of t_1 rises gradually from Pr to Lu, corresponding to the strengthening of the Ln–TMU bonds caused by the effect of the lanthanoid contraction.

2) The values of n lie in the range of 1—1.5, and do not depend remarkably on the position of Ln in the series. Nearly the same amount of TMU seems to be lost in the next step BC. Taking the dullness of these steps and their possible overlap into account, one can estimate that, in general, about 1.5 molecules of TMU are lost in the step AB, and about 3 in the two consecutive steps AB+BC.

3) The values of Δ correspond, reasonably well, to those expected when the complexes are converted completely into $LnCl_3$ at the end of their decomposition.

4) The steps AB and BC are accompanied by a few weakly endothermic peaks on the DTA curve, but the subsequent decomposition CD is accompanied by a very strong exothermic peak, with a much weaker one which appears at the high temperature end of CD.

All these relationships can now be reasonably well understood by the following picture. On heating the complex, a part of the coordinated TMU molecules are liberated endothermically in two steps which, approximately, can be formulated as follows:

$$Ln(TMU)_6(ClO_4)_3 \longrightarrow Ln(TMU)_{4.5}(ClO_4)_3 + 1.5TMU,$$

$$Ln(TMU)_{4.5}(ClO_4)_3 \longrightarrow Ln(TMU)_3(ClO_4)_3 + 1.5TMU.$$

In the course of these changes,** on the other hand, the ClO_4^- ions will come into closer contact with the Ln^{3+} ions which lost some of their bulky ligands. So they will be polarized and eventually begin to decompose by further heating:[6]

$$ClO_4^- \longrightarrow Cl^- + 4O.$$

The O atoms liberated will oxidize the TMU molecules which are still in the complex. Since the number of O atoms liberated is insufficient to oxidize them completely, there will be partial oxidation or incomplete combustion of the ligands by the anions. This will certainly be a strongly exothermic process. When this combustion is over, $LnCl_3$ is left as the final residue.

The data obtained in a vacuum*** are, in general, similar to those in N_2, but some apparent differences can be discerned.

1) The t_1 values are much lower than those in N_2, showing that the initial release of TMU is notably facilitated by evacuation. Here again there is a general rise of t_1 along the series, but there are some deviations which suggest that they are composed of three parts, Pr–Eu, Gd–Er, and Tm–Lu, corresponding to the variation of n (see below; *cf.* Fig. 3A).

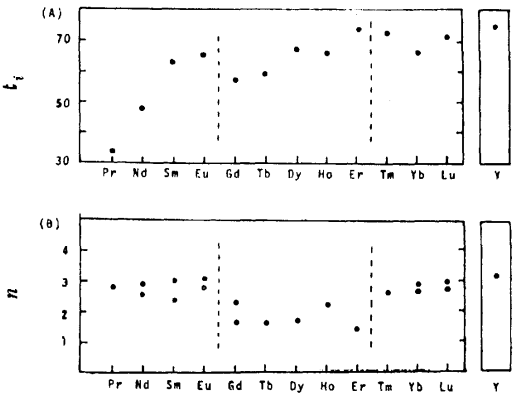

Fig. 3. t_1 and n values of $Ln(TMU)_6(ClO_4)_3$ in a vacuum plotted against the atomic number of Ln.

2) The n values are again *ca.* 1.5 for the middle-weight members of the series, Gd–Er, but are definitely larger and *ca.* 3 for the lighter and heavier members and Y. In these latter cases, the two steps AB and BC observed in N_2 are seemingly united into a single more well-defined step; one can also say that, in a vacuum, all the three TMU molecules which are lost in two steps in N_2 are driven off at once, at temperatures which are much lower than in N_2. In the case of the middle-weight members, however, the complex $Ln(TMU)_{4.5}(ClO_4)_3$ retain certain thermal stability even in a vacuum, and the release of further TMU ligands and the final decomposition occur without any clear step (*cf.* Fig. 3B).

These results can now be explained as follows: The complexes of the lighter members, with larger ionic radii of Ln^{3+}, will contain weaker Ln–TMU bonds, and

** It is highly probable that the complexes thus formed, with 4.5 and 3 molecules of TMU, respectively, are dimeric or polymeric in nature; for example, the one with 4.5 TMU can be formulated as $Ln_2(TMU)_9(ClO_4)_6$, *i.e.*, a dimer with each Ln^{3+} surrounded by three terminal and three bridging TMU ligands.[5]

*** Only TG data will be discussed here, because the DTA curves obtained in a vacuum are complicated in their appearance, and their accuracy cannot be as high as those in N_2 in principle.

it is also possible that their coordination spheres are not perfectly packed with six TMU ligands, so that the $Ln^{3+}\cdots ClO_4^-$ interaction will be stronger than in the complexes with smaller Ln^{3+} ions. These situations will favor the driving out of as many TMU molecules as possible by slight heating. In the case of the heavier members, on the other hand, the coordination spheres will be heavily crowded with TMU ligands, and their mutual repulsion will destabilize the structure, so that the driving out of many TMU molecules by heating is again favored. There is probably a "safety zone" between these two extremes, where the complexes $Ln(TMU)_{4.5}X_3$ can enjoy their thermal stability.

3) The Δ values are all much higher than those in N_2, and the differences between the two sets of values increase from Pr to Lu (*cf.* Table 1). In most cases, rather strangely, the weights of the final residues were even lower than those of the lanthanoid elements themselves in the original samples. Taking the experimental conditions (relatively low temperature, slow heating rate, *etc.*) and the nature of the samples into account, the most probable reason for this anomaly seems to be found in the formation of some volatile Ln-containing product in the course of the decomposition. Such a product will escape from the sample as soon as it is formed in a vacuum, causing the decrease of Δ as observed.**** However, we could not identify this volatile complex, mainly owing to its small quantity (at most 1 mg).

Table 2. Values of t_i and Δ for the complexes $Ln(TMU)_6X_3$, where X is PF_6 or BPh_4

Ln	X	In N_2		In a vacuum	
		t_i	Δ	t_i	Δ[a]
Sm	PF_6	73	80.5	40	82.8(83.8)
Gd	PF_6	64	80.8	43	81.1(83.4)
Dy	PF_6	79	81.2	43	81.7(83.1)
Er	PF_6	85	77.8	53	82.6(82.7)
Nd	BPh_4	176	82.0	119	86.6
Eu	BPh_4	136	82.2	131	—
Y	BPh_4	194	86.5	154	93.5

a) The values for the complete transformation into LnF_3 are shown in parentheses.

Hexafluorophosphates. The complexes $Ln(TMU)_6(PF_6)_3$ shown in Table 2 all show a single step in their TG curves, either in N_2 or in a vacuum (see Fig. 4 for an example), and the Δ values observed roughly correspond to those of LnF_3 formed by the reaction:

$$Ln(TMU)_6(PF_6)_3 \longrightarrow LnF_3 + 3PF_5 + 6TMU.$$

It can be seen that the t_i values for this single step are much lower than in the case of the perchlorates, corresponding to the high heats of formation of LnF_3 and PF_5.[7] Since PF_5 is a fairly stable molecule, only a strong endothermic peak is observed on the DTA curves, corresponding to the total disintegration of the complex.

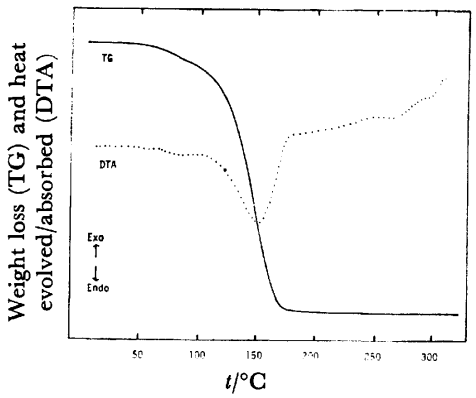

Fig. 4. TG and DTA curves of $Gd(TMU)_6(PF_6)_3$ in a vacuum. Essentially similar curves are obtained, either in N_2 or in a vacuum, with the complexes shown in Table 2. In some case it is seen that a small part of TMU is lost in advance of the main decomposition (*cf.* the small DTA peak (and weak TG shoulder) at *ca.* 85 °C and the large peak at 152 °C in this figure), but its amount is difficult to estimate.

Tetraphenylborates. On the other hand, the complexes $Ln(TMU)_6(BPh_4)_3$, also shown in Table 2, decompose only with much difficulty. Their TG curves are more or less like those of the hexafluorophosphates, composed of a single TG step and DTA peak, but their t_i values are quite high, and their Δ values are incompatible with any simple picture for their decomposition.

Although the nature of the thermal changes involved here is thus not clear as yet, the higher t_i values (or difficulty of decomposition) of these complexes can certainly be related to the inability of BPh_4^- for coordination. We can imagine that the thermal decompositions observed here are, in general, initiated by the S_N2-type attack of the anion (or a part of the anion, such as F^-), by which some TMU ligands are driven out of the coordination sphere. If this idea is essentially true, it is easy to see why the ease of decomposition increases in the following order of anions:

$$BPh_4^- < ClO_4^- < PF_6^-,$$

since BPh_4^- is a practically non-coordinating anion, and PF_6^- is easily split into F^- and PF_5, they will come before and after ClO_4^- in this series, respectively.

Thus we see that TG and DTA techniques can bring about a number of new insights into these complexes, as in the case of the Ln complexes of dimethyl sulfoxide and tetrahydrothiophene 1-oxide studied before.[8] The earlier TG-DTA data of Seminara *et al.*[9-10] on the Ln complexes of various urea derivatives, including $Gd(TMU)_3Cl_3$, may also be of interest in connection with the present study.

**** At first, it was suspected that the complexes $Ln(TMU)_3Cl_3$ may be the volatile complexes, but preliminary studies on them (Ln=Nd and Er) showed that they are not remarkably volatile in a vacuum, and lose their TMU molecules by heating (t_i: 85—90 °C) in a complicated way.

Stereochemistry of Bis[*N*-(2,6-diisopropylphenyl)salicylideneaminato]-cobalt(II) Complexes

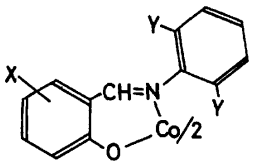
Shoichiro YAMADA* and Kuniko YAMANOUCHI

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received July 28, 1981)

The compounds bis[*N*-(2,6-diisopropylphenyl)salicylideneaminato]cobalt(II) and analogous species with substituents at the 5-position of the salicyl moiety have been synthesized. They prefer the tetra-coordinate tetrahedral geometry in non-donor solvents, while some of them are forced into planar structures in the solid state. In pyridine, exclusively predominant species are five-coordinate complexes with the base bound with the cobalt(II) ion. Monopyridine adducts, which consist of five-coordinate complexes, have been isolated as crystals.

The stereochemistry of the cobalt(II) complexes with bidentate *N*-aryl- and *N*-alkylsalicylideneaminates, abbreviated as Co(X-sal-R)$_2$, has been widely studied.[1,2] In order to investigate the steric and electronic effects of the Schiff bases on the stereochemistry of these cobalt(II) complexes, a series of bis[*N*-(2,6-dialkylphenyl)salicylideneaminato]cobalt(II) complexes were studied previously, the alkyl being methyl and ethyl.[3]



I

In the present work, cobalt(II) complexes of the type Co(X-sal-R)$_2$, for which R is 2,6-diisopropylphenyl, have been examined. It is anticipated that the steric effects arising from the substituents at the 2- and 6-positions may become more explicit in the complexes of this series, since the isopropyl group is more bulky than the methyl and ethyl groups. During this study, we have isolated for the first time the spin-paired planar cobalt(II) complexes with the *N*-arylsalicylideneaminates.

Experimental

Materials. 2,6-Diisopropylaniline was obtained commercially.

Bis[*N*-(2,6-dissopropylphenyl)salicylideneaminato]cobalt(II) and analogous species, which are abbreviated as Co(X-sal-dpp)$_2$, were synthesized in red-orange crystals in the same manner as reported previously.[2,3] They are readily soluble in chloroform, benzene, and acetone, but slightly soluble in ethanol.

Monopyridine adducts were also obtained in orange crystals as described previously.[2,3]

Analytical data of these complexes are given in Table 1.

Measurements. Electronic absorption spectra of the complexes in solution and in Nujol were recorded on a Shimadzu MPS-500 spectrophotometer. Magnetic measurements at room temperature were carried out by the Gouy method using $CoHg(SCN)_4$ as a calibrant.

Results and Discussion

Previous extensive studies of cobalt(II) complexes with bidentate *N*-alkyl- and *N*-arylsalicylideneaminates have disclosed that all these cobalt(II) complexes are tetrahedral,[1,2] with the exception of bis(*N*-methylsalicylideneaminato)cobalt(II), which consists of binuclear molecules with the cobalt(II) ion in five-coordinate environment.[4]

In the complexes (I), the steric constraint due to the bulky substituent (R-2,6-Y_2-C_6H_3) seems to be appreciable. In view of the conformations observed in all known crystal structure analyses, the phenyl group in the complexes is expected to be essentially perpendicular to the salicylideneaminate plane.[1] The cobalt(II) complexes with R=2,6-Me_2-C_6H_3 and 2,6-Et_2-C_6H_3 prefer the tetra-coordinate tetrahedral geometry in the solid state and in non-donor solvents, although the steric constraint is not slight.[3] In the cobalt(II) complexes with R=2,6-(*i*-Pr)$_2$-C_6H_3, which is more bulky than 2,6-$Et_2C_6H_3$, there is remarkable steric constraint not only on the tetrahedral configuration but also on the planar one. However, either of the two configurations is not precluded from the steric condition alone.

The cobalt(II) complexes Co(X-sal-dpp)$_2$ (X=H, 5-Cl, 5-Br, and 5-NO_2) in chloroform show electronic spectra typical of the tetrahedral cobalt(II) complex.[2] Some of the representative spectra are shown in Fig. 1, the main absorption maxima being set out in Table 2.

In the solid state, the configuration of these cobalt(II) complexes depends upon the substituent X at the 5-position of the salicyl moiety. The cobalt(II) complex (X=H) in the solid state is concluded to have a tetrahedral configuration on the basis of the magnetic moment (4.4 BM) and an electronic spectrum with a broad d-d band consisting of double humps at about 8.2

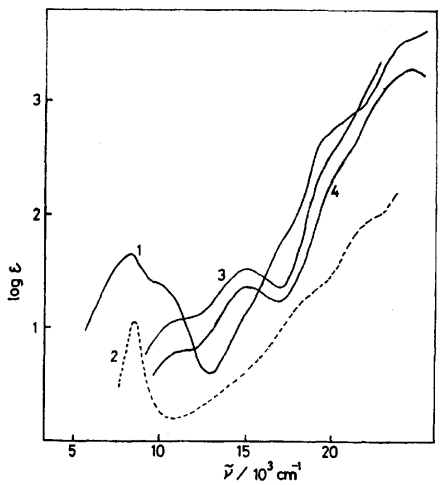

Fig. 1. Electronic absorption spectra of Co(5-Br-sal-dpp)$_2$ (curves 1—3) and Co(5-Br-sal-dpp)$_2$·py (curve 4).
1: In $CHCl_3$, 2: in Nujol (arbitrary absorbance scale), 3: in pyridine; 4: in Nujol (arbitrary absorbance scale).

and 10.7×10^3 cm^{-1}. On the contrary, the two complexes (X=5-Cl and 5-Br) in the solid state are paramagnetic with magnetic moments at room temperature of 2.6 and 2.4 BM, respectively, which lie in the range expected for the spin-paired planar cobalt(II) complex.[5] Their electronic spectra have a comparatively sharp d-d band at about 8.5 and 8.4×10^3 cm^{-1}, respectively, in agreement with the spin-paired planar structure.[6] Thus they provide new examples of spin-paired planar cobalt(II) complexes with bidentate *N*-arylsalicylideneaminates. Since the two complexes are tetrahedral in chloroform, the energy gap between the tetrahedral and the planar configurations seems to be small.

In pyridine, these cobalt(II) complexes Co(X-sal-dpp)$_2$ (X=H, 5-Cl, 5-Br, and 5-NO_2) exist exclusively as five-coordinate species with a pyridine molecule coordinated. Beer's law is found to hold good, so that no assumption of equilibria among various species with different structures is needed. The five-coordinate pyridine adducts have been isolated in crystals from the pyridine solutions, their spectra (Fig. 1 and Table 2) being in agreement with the proposed five-coordinate structure. Six-coordinate bis(pyridine)adducts have neither been detected in the solutions, nor isolated in crystals.

The complex (X=5-NO_2) in the solid state has magnetic moment of 5.1 BM, which is in the range expected for the 6-coordinate cobalt(II) complex. Its electronic spectrum (Table 2) is also typical of the 6-coordinate cobalt(II) complex. A multinuclear structure is most likely, although a definitive conclusion about the precise structure must await further studies.

An X-Ray Diffraction Study on the Structures of Bis- and Tris-(ethylenediamine)nickel(II) Complexes in Solution

Tadao FUJITA and Hitoshi OHTAKI*

Department of Electronic Chemistry, Tokyo Institute of Technology at Nagatsuta, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received August 21, 1981)

The structures of nickel(II) complexes with ethylenediamine(en) in solution have been determined by means of X-ray diffraction. The measurements were performed at 25 °C for aqueous ethylenediamine solutions of nickel nitrate, the mole ratios (en/Ni) in the solutions being 3.964, 3.672, 2.071, and 1.892. In the two solutions of the higher en/Ni mole ratio, the tris(ethylenediamine)nickel(II) complex was predominant, whereas in the other solutions the bis(ethylenediamine)nickel(II) complex was contained as the main species. From the analysis of the X-ray scattering data of the solutions, it was shown that in the bis-complex four nitrogen atoms within ethylenediamine and two oxygen atoms within water molecules were octahedrally coordinated to the central nickel(II) atom, the oxygen atoms being assumed to be axially bonded. The Ni–N bond length within the bis-complex was 2.10 Å, which was almost the same as the length of the Ni–O bonds. The nonbonding Ni···C distance was 2.82(2) Å. In the tris-complex the nickel ion was coordinated with six nitrogen atoms and Ni–N and Ni···C distances were determined to be 2.202(4) Å and 2.88(1) Å, respectively. These parameter values obtained in the experiment were compared with the crystallographic data reported.

The structures of the bis- and tris(ethylenediamine)-zinc(II) and -cadmium(II) complexes have recently been reported.[1,2] In the present study, we have attempted to determine the structures of the bis- and tris(ethylenediamine)nickel(II) complexes in aqueous nitrate solutions in a series of structural studies of chelate complexes of transition metals in solution. The ground state of a nickel(II) octahedral complex is known to have the electronic configuration of $(t_{2g})^6(e_g)^2$ and thus most nickel(II) complexes have the O_h symmetry in the solid state. In a complex of the NiA_4B_2 type (A and B denote ligand atoms) in which B atoms locate along the axis of the octahedron, the symmetry of the complex may be approximated to be D_{4h}. Most of the bis-nickel(II) chelate complexes with bidentate ligands have the symmetry of this type.[3] The distortion of the symmetry of such nickel(II) complexes has been extensively investigated by means of electronic spectra and X-ray diffraction in crystal.[4]

Dorosh and Skryshevskii[5] reported the distorted octahedral structures of $Ni(OH_2)_6^{2+}$ with two different Ni–O bond lengths of 2.0—2.1 and 2.25—2.30 Å by means of X-ray diffraction in solution. However, according to a recent study the $Ni(OH_2)_6^{2+}$ complex has a regularly octahedral structure with the length of Ni–O=2.04 Å.[6]

Many works on the crystal structures of the $Ni(en)_3^{2+}$ complex with various counter anions have been carried out and showed that the $Ni(en)_3^{2+}$ complex has a regularly octahedral structure independent of the counter anions. In the $Ni(en)_3SO_4$ salt, the Ni–N bond length was found to be 2.12 Å.[7] In the structure of $Ni(en)_2(NCS)_2$, on the other hand, the equatorial Ni–N bond distance was 2.10 Å and the Ni–NCS bond length in the axial position was 2.15 Å, the latter being slightly longer than the former. Thus the structure of the $Ni(en)_2(NCS)_2$ complex is distorted octahedral.[8] The structure of the $Ni(en)_2(OH_2)_2^{2+}$ has not been investigated either in the crystalline state or in solution. In this paper, the structural determination of the bis- and tris(ethylenediamine)nickel(II) complexes has been attempted by the X-ray diffraction method in solution.

Experimental

Preparation and Analysis of Sample Solutions. Ethylenediamine was purified by the method previously reported.[1] Nickel(II) nitrate of reagent grade was purchased from Wako Pure Chemical Co., Osaka and was recrystallized twice from water. The sample solutions were prepared by dissolving nickel(II) nitrate into aqueous ethylenediamine solutions.

The concentration of nickel(II) ions in the test solutions was determined by gravimetry using dimethylglyoxime. The concentration of the nitrate ion was calculated from the stoichiometry of the nickel nitrate. The density of the test solutions was measured pycnometrically. The composition of the test solutions is given in Table 1.

Table 1. Composition of solutions A, B, C, and D (mol/dm³)

	A	B	C	D
Ni	1.476	1.356	1.717	1.787
N	13.79	13.46	10.54	10.34

en/Ni	3.672	3.964	2.071	1.892

Method of Measurements and Treatment of X-Ray Scattering Data. The method of measurements and the apparatus used were essentially the same as those in previous papers.[6,9] Mo $K\alpha$ radiation (λ=0.7107 Å) was used for the measurements over the range $1° < \theta < 70°$ (2θ is the scattering angle). The data were recorded twice over the whole angle range. Corrections and analysis of the scattering data were performed in the same ways to those previously reported.[1,2,6,9,10] Coherent and reduced intensities of the test solutions are given in Figs. 1 and 2, respectively. The radial distribution function $D(r)$ was calculated by the following equation:

$$D(r) = 4\pi r^2\rho_0 + \frac{2r}{\pi}\int_0^{s_{max}} s\cdot i(s)\cdot M(s)\cdot\sin(rs)\mathrm{d}s, \quad (1)$$

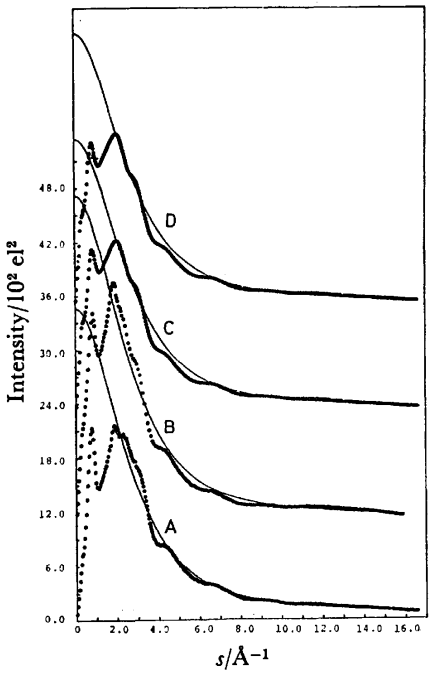

Fig. 1. Coherent scattering intensities of sample solutions A, B, C, and D. Experimentally obtained intensities I^{coh} are shown by circles and calculated values of independent scattering intensities by solid lines.

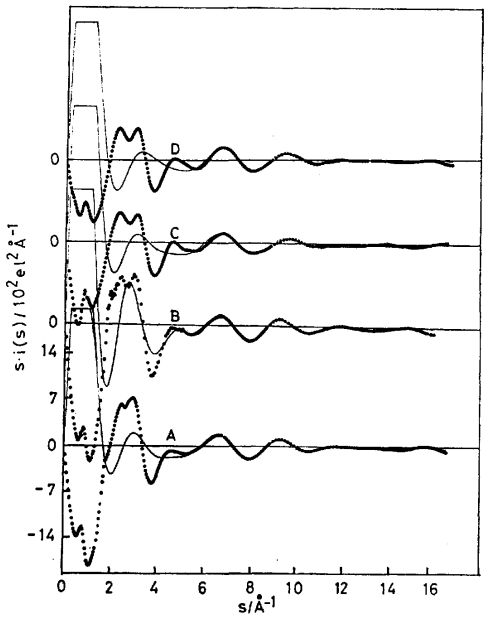

Fig. 2. The reduced intensities multiplied by s for solutions A, B, C, and D. The observed $s \cdot i(s)$ curves are shown by circles and the calculated ones by solid lines.

where ρ_0 is the average scattering density in the stoichiometric volume V of the solution per Ni atom, and s_{max} denotes the maximum s-value attained in the measurements ($s_{max}=16.7$ Å^{-1}). $M(s)$ represents the modification function[10] and the reduced intensities $i(s)$ are given by

$$i(s) = I^{coh}(s) - \sum n_i\{(f_i(s) + \Delta f_i')^2 + (\Delta f_i'')^2\}, \quad (2)$$

where n_i is the number of atom i and $f_i(s)$ denotes the scattering factor of atom i at s. $\Delta f_i'$ and $\Delta f_i''$ represent the real and imaginary parts of the anomalous dispersion, respectively.[11] The radial distribution curves $D(r)$ of the solutions were drawn after the Fourier transform of the reduced intensities which had been smoothed by the method described previously.[6]

The theoretical scattering intensities due to atom pairs of all possible combinations in the system were given as follows:

$$i_{calcd}(s) = \sum_{i}\sum_{i\neq j}\sum_{j} n_{ij}\{(f_i(s) + \Delta f_i')(f_j(s) + \Delta f_j') + (\Delta f_i'')(\Delta f_j'') \cdot \frac{\sin(r_{ij}s)}{(r_{ij}s)} \cdot \exp(-b_{ij}s^2), \quad (3)$$

where r_{ij}, b_{ij}, and n_{ij} denote the distance, the temperature factor, and the frequency factor of the atom pair i-j, respectively.

All calculations were performed with the electronic computers M-160 and M-180 by means of KURVLR program.[12]

Results and Discussion

According to the formation constants so far reported, sample solutions A and B contain the tris(ethylenediamine)nickel(II) complex as the main species and, on the other hand, sample solutions C and D contain the bis(ethylenediamine)nickel(II) complex as the predominant one.[13] Solutions A and B may contain a little amount of the bis-complex. In solutions C and D, small amounts of the mono- and tris-complexes may coexist with the bis-complex.

Solution A. From the diffraction data after corrections for absorption and polarization[9] (Fig. 1A), the $s \cdot i(s)$ curve (Fig. 2A) was obtained and then, the radial distribution function $D(r)$ was drawn by using the Fourier transformation according to Eq. 1 (Fig. 3a). A broad and small peak at about 1.0—1.3 Å in the $D(r)$ curve is composed of peaks due to the O–H bond within water, the N–H, C–H, C–C, and C–N bonds within ethylenediamine molecules and the N–O bond within nitrate ions as we have pointed out in the previous papers[1,2] (Fig. 3b). The second peak appearing at 2.2 Å is attributed to the Ni–N bond within the metal complex, the O···O pairs within nitrate ions and the C···N interactions within ethylenediamine molecules.

The third peak at about 2.9 Å may be mainly ascribed to nonbonding Ni···C and O···O interactions within the metal complex and in bulk water, respectively. The O···O interactions between nitrate ions and water molecules may contribute to some extent to this peak. In the analysis of the radial distribution curve of solution A which contains a small amount of the bis-complex, the amount of the bis-complex coexisting was assumed to be negligible at the first approach. After subtraction of the theoretical peaks of the intramolecular interactions within ethylenediamine molecules and nitrate ions, the chain line (·—·—·) was obtained as the residual curve, from which we obtained the parameter values of intramolecular interactions of the tris-complex. A successive approximation which has been described in the previous papers[1,2] was employed in order to refine the parameter values thus obtained on the assumption of the existence of the only tris-complex, but assumptions taking into account the coexistence of various amounts of the bis-complex in

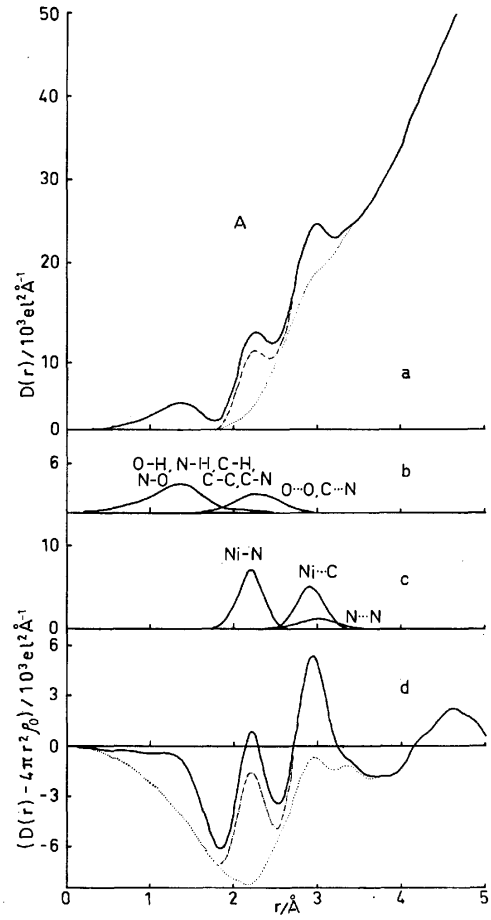

Fig. 3. (a) : $D(r)$ curve for solution A. The chain line (·–·–) shows the residual curve after subtraction of the theoretical peak shapes shown in (b) from the original radial distribution curve represented by the solid line. The dotted line shows the residual curve after subtraction of the theoretical peak shapes shown in (c) from the data represented by the chain line. (b) and (c) : The theoretical peak shapes for atom pairs. (d) : The corresponding $D(r)-4\pi r^2\rho_0$ curve to (a).

solution A did not improve the parameter values of the tris-complex. The lengths of the Ni–N bond and nonbonding Ni···C interaction were found to be 2.20 and 2.90 Å, respectively. The distance of the N···N pair was estimated to be $\sqrt{2}$ times the length of the Ni–N bond. The area under the peak at 2.20 Å corresponded to six Ni–N bonds. The temperature factors of the Ni–N and Ni···C interactions were evaluated to be 0.002—0.003 Å² and 0.005—0.007 Å², respectively. Subtraction of the peaks of all the intramolecular interactions from the original radial distribution curve led to a smooth background having no appreciable peak over the range <4 Å, expect for the peak at about 2.9 Å which was ascribed to the adjacent O···O interactions in the bulk water and hydrated nitrate ions. From the analysis of the radial distribution curve of solution A, the tris(ethylenediamine)nickel(II) complex in the solution was concluded to have an octahedral structure.

Solution B. The atomic composition in solution B was almost the same as that in solution A, and solution B was considered to contain the tris(ethylenediamine)-nickel(II) complex as the main species with a very small amount of the bis-complex. The analytical procedure of solution B was the same as that in the case of solution A. The radial distribution curve of solution B showed that the lengths of the Ni–N bond and nonbonding Ni···C interaction were 2.20 Å and 2.90 Å, respectively, which were consistent with the results obtained in solution A. The parameter values of the tris(ethylenediamine)nickel(II) complex are further refined by the least squares method by using the reduced intensity data in the high angle region of the $s\cdot i(s)$.

Solutions C and D. According to the stability constants previously reported, solutions C and D contain a small amount of the tris- and mono-complexes besides the bis-complex as the main species.[10] In the course of the analysis of the radial distribution curve

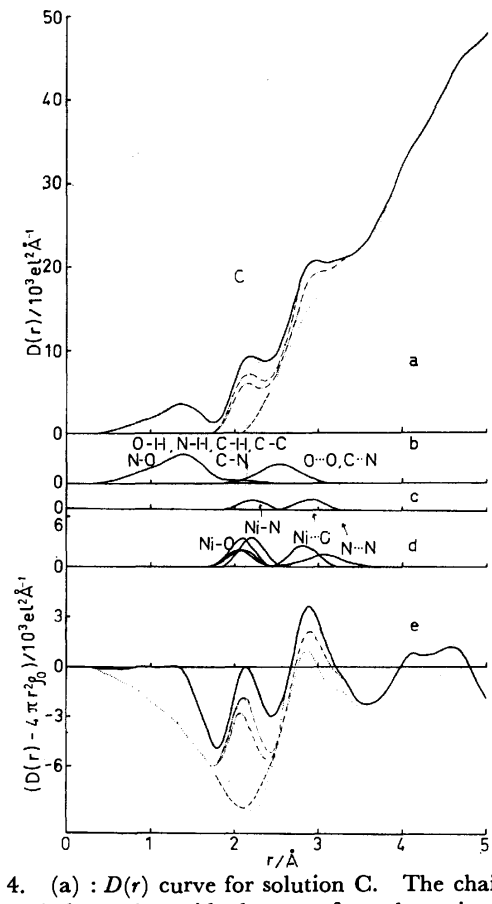

Fig. 4. (a) : $D(r)$ curve for solution C. The chain line (·–·–) shows the residual curve after subtraction of the theoretical peaks in (b). The chain line with double-dots (···–··) is obtained after further subtraction of the theoretical peak shapes due to the tris-complex in (c) from the data represented by the chain line, ·–·–. After subtraction of the theoretical peak shapes due to the biscomplex assuming that both the Ni–N and Ni–O bond distances are 2.10 Å, the dashed line is obtained as the residual curve. Assuming that the Ni–O distance is the same as that $Ni(OH_2)_6^{2+}$ and that the Ni–N distance is slightly larger than 2.10 Å, the dotted line is obtained as the residual curve. (b), (c), and (d) : The theoretical peak shapes for atom pairs. (e) : The corresponding $D(r)-4\pi r^2\rho_0$ curve to (a).

in solution C, the tris-complex was assumed to coexist with the bis-complex, whereas the formation of the mono-complex was neglected.

The analytical procedure of the radial distribution curve of solution C is as follows.

By introducing the parameter values of the tris-complex found from the analysis of solutions A and B, the parameter values of the bis(ethylenediamine)nickel(II) complex was obtained by changing the mole ratio of the bis-/tris-complexes until a smooth background curve was obtained in the residual radial distribution curve. The chain line (·-·-·) in Fig. 4 was obtained after subtraction of the peaks of the intramolecular interactions of ethylenediamine molecules and nitrate ions from the original radial distribution curve, and further subtraction of the theoretical peaks of the tris-complex from the curve led to the chain line with double-dots (·····). The curve (·····) might show the radial distribution curve due to the bis-complex. The area under the peak at 2.10 Å approximately corresponded to six Ni–N pairs. Since the bis-complex has at most four Ni–N bonds within it, the other two pairs must be Ni–O ones, because X-ray scattering due to the Ni–O bond is close to that due to the Ni–N bond as far as the bond lengths of the pairs are practically the same. Thus, we concluded that the bis-complex has four Ni–N bonds and two Ni–O bonds within the complex.

The structure of $Ni(OH_2)_6^{2+}$ in an $Ni(ClO_4)_2$ solution has been determined by X-ray diffraction method and the length of the Ni–O bond has been estimated to be 2.04 Å.[6] Bol, *et al.*[14] reported a slightly longer Ni–O bond length (2.06 Å) in a nickel(II) nitrate solution than that reported by Ohtaki *et al.*[6] However, if we assume that the Ni–O bond length within the $Ni(en)_2(OH_2)_2^{2+}$ was 2.04—2.06 Å, the theoretical radial distribution curve showed descrepancies from the experimental curve, and the radial distribution curve in solution C could be better explained by assuming the Ni–O bond distance within the bis-complex to be about 2.10 Å, which was almost the same length as the Ni–N bond. The results obtained from the studies by means of infrared[15] and electronic[16] spectroscopic analyses suggested that the bis(ethylenediamine)nickel(II) complex has two water molecules at the axial positions. Since the area under the peak at 2.10 Å corresponded to the sum of four Ni–N and two Ni–O bonds, the bis-complex was concluded to be almost regularly octahedral which contained two water molecules at the axial positions, and thus, the residual radial distribution curve of solution C was well analyzed by assuming the bond distances of the Ni–N: 2.10 Å (the frequency factor $n_{Ni-N}=4$), Ni–O : 2.10 Å ($n_{Ni-O}=2$), Ni···C : 2.87 Å ($n_{Ni...C}=4$), and N···N (or N···O)$=\sqrt{2}\times 2.10$ Å ($n_{N...N}+n_{N...O}=12$), and no appreciable peak remained on the double-dotted curve over the range <4 Å except for the broad peak at around 3.0 Å, which was attributed to the O···O interactions in bulk water and the hydrated nitrate ions.

Solution D may contain a small amount of the mono-complex and a lesser amount of the tris-complex according to the literature.[13] However, the concentration of the mono-complex is too small to be determined by the present X-ray diffraction method, and thus, the radial distribution curve of solution D could be analyzed assuming the only bis-complex existed in the solution. The essentially same procedure as that used in the analysis of the radial distribution curve of solutions A and B was employed. The parameter values of the bis-complex obtained from the analysis of the radial distribution curve of solution D were almost consistent with those obtained in solution C. The parameter values obtained by analyzing the radial distribution curves of each solution were refined by the least squares method using the intensities $s\cdot i(s)$ in the high angle region ($4\ Å^{-1}\lesssim s\lesssim 16\ Å^{-1}$).

Least Squares Refinements. The intensity data in the high angle region ($s>4\ Å^{-1}$) of the $s\cdot i(s)$ curves of solutions A, B, and C were used for the least squares refinements[17] of the structural parameters of the bis- and tris-complexes. For avoiding errors introduced by neglecting long range intermolecular interactions in the course of least squares calculations, the lowest s-value was varied from 4.5 $Å^{-1}$ to 7 $Å^{-1}$.

In the A-1 type calculation of the least squares refinement of the intensity data of solution A, the frequency factor (n) of the metal-ligand bond was floated. The frequency factors of the Ni–N and Ni···C interactions of the tris(ethylenediamine)nickel(II) complex were actually six. In the A-2 type calculation, the bond distances and temperature factors were floated, while the frequency factors of the Ni–N and Ni···C interactions were kept constant ($n=6$). The final values of the Ni–N and Ni···C distances were 2.191(3) Å and 2.876(8) Å, respectively (Table 2). The values of the Ni–N and Ni···C distances were practically independent of the type of calculations.

TABLE 2. RESULTS OF THE LEAST SQUARES REFINEMENTS OF SOLUTION A

Interaction	Parameter	A-1[b]	A-2[b]
O···O(NO_3^-)	r/Å	2.25(2)	2.24(2)
C···N (en)	r/Å	2.46(4)	2.48(3)
N···N (en)	r/Å	2.87(6)	2.92(5)
$Ni(en)_3^{2+}$			
Ni–N	r/Å	2.193(4)	2.191(3)
	b/Å^2	0.0022(3)	0.0025(2)
	n	5.99(9)	6[a]
Ni···C	r/Å	2.87(1)	2.876(8)
	b/Å^2	0.005[a]	0.005[a]
	n	6.2(1)	6[a]

a) Fixed. b) Standard deviations are given in parentheses.

By the same procedure of the least squares refinements of the intensity data of solution B, the Ni–N and Ni···C distances were found to be 2.202(4) Å and 2.88(1) Å, respectively.

In the least squares calculations of solution C, an assumption of two water molecules binding to the central nickel(II) ion within the bis(ethylenediamine)-nickel(II) complex was introduced as an initial condition which should be refined in the course of the calcula-

Table 3. Results of the least squares refinements of solution C[a)]

Interaction	Parameter	$5.0<s/Å^{-1}<16.7$	$6.0<s/Å^{-1}<16.7$
Ni–O	r/Å	2.10(1)	2.10(1)

	n	4.1(2)	4.2(2)
N···N	r/Å	3.01(5)	3.06(7)

a) The concentration of the tris-complex is assumed to be 20 mol% on the basis of the stability constants reported in the literature. Standard deviations are given in parentheses.

Table 4. Final values of the intramolecular distances (Å) within the bis- and tris-(ethylenediamine)Ni(II)complexes

	Bis-complex[a)]	Tris-complex[a)]
Ni–N	2.102(7)	2.202(4)
Ni–O	2.10(1)	—
Ni···C	2.82(2)	2.88(1)
Structure	Regular octahedron	

a) The values in parentheses are their standard deviations.

tions. The final results showed that the frequency factors of the Ni–O interaction was about two and those of the Ni–N and Ni···C interactions within the bis-complex were approximately four (Table 3). In the least squares calculations of the intensity data of solution C, various types of calculation were carried out. In one case, the frequency factors of the Ni–N or Ni···C interactions within the bis-complex were held constant at four, other parameter values being refined. In other cases, the frequency factor of the Ni–O bond was fixed at two by assuming the structures of the bis-complex, and other parameters were refined. The s_{min}-value was changed in some cases. All the calculations examined here led to almost the same values of the Ni–N and Ni–O bond lengths. The final results obtained in the calculations were summarized in Table 3, in which the bond lengths, temperature, and frequency factors were floated. The results obtained by the calculations gave almost the same results as listed in Table 3 and the distances of the Ni–N and Ni–O bonds were finally determined to be 2.10 Å. Consequently, the bis(ethylenediamine)nickel(II) complex has almost a regularly octahedral structure with four nitrogen and two oxygen atoms. The parameter values obtained in the analysis of the intensity data of solution D were almost the same as those obtained for solution C. As shown in Fig. 2, the $s\cdot i(s)$ curves calculated from the refined parameters thus obtained well fit the observed $s\cdot i(s)$ curves in the region $5\ Å^{-1}<s<16\ Å^{-1}$. The final parameter values found in this study are summarized in Table 4.

In the X-ray crystal analysis, the Ni–N bond distance within the tris(ethylenediamine)nickel(II) complex has been found to be 2.07—2.17 Å (Table 5). The Ni–N bond distance within the tris-complex in solution found in the present study is 2.20 Å, which is slightly longer than the distances found in crystals. The bis(ethylenediamine)nickel(II) complex in crystals has the Ni–N bond distances of 2.08—2.12 Å, which is almost the same as that in this study (Table 5).

The work has partially been supported by the Grant-in-Aid for Scientific Research No. 343011 from the Ministry of Education, Science and Culture.

A Potentiometric Study on Mixed Ligand Cadmium(II) Complexes with 2-Amino Carboxylic Acids

Haruo MATSUI* and Hitoshi OHTAKI†

Government Industrial Research Institute, Nagoya, Hirate-cho, Kita-ku, Nagoya 462
†*Department of Electronic Chemistry, Tokyo Institute of Technology at Nagatsuta, Nagatsuta-cho, Midori-ku, Yokohama 227*

(Received August 22, 1981)

Formation constants of mixed ligand cadmium(II) complexes, CdLL′, were determined in aqueous solutions containing 3 mol dm^{-3} $LiClO_4$ as a constant ionic medium at 25 °C by potentiometric titration, where the ligands HL and HL′ are 2-amino carboxylic acids such as glycine, α-alanine, 2-aminobutanoic acid, 2-aminopentanoic acid, and 2-aminohexanoic acid. Ten kinds of the mixed ligand cadmium(II) complexes were examined with the combination of five 2-amino carboxylic acids. The formation constant, $\beta_{prs}=[Cd_pL_rL_s'^{(2p-r-s)+}]/([Cd^{2+}]^p\times[L^-]^r[L'^-]^s)$, of the mixed ligand cadmium(II) complexes containing glycine as one of the ligands lie between those of the parent complexes, while the formation constants of the other complexes are larger than those of the parent complexes. No protonated mixed ligand complex has been observed. The small values of β_{111} of the Cd(gly)L complexes are due to the considerably small values of the first stepwise formation constants of the CdL^+ complexes. On the other hand, the stepwise formation constants of the CdL^+ complexes with glycinate ion are larger than the stepwise formation constants with 2-amino carboxylate ions and the second stepwise constant of the bis(glycinato)cadmium(II) complex. Interactions between the ligands through the central cadmium(II) ion are discussed. The b-values ($b=\log\{(K_{110}\cdot K_{101})/(K_{120}\cdot K_{102})\}$, where K_{1rs} denotes the stepwise formation constant of the complex $CdL_rL'_s$) of the mixed ligand cadmium(II) complexes containing glycinate ion as one of the components lie between 0.93 and 0.98, and are larger than those of the other complexes ($b=0.83$—0.90), the fact indicating that the mixed ligand glycinato complexes have larger inter-ligand interactions within the complexes than those within complexes containing other 2-amino carboxylate ions. The inter-ligand interaction may occur through the central cadmium ion within the complex.

Mixed ligand complexes of a number of metal ions with various amino acids have been extensively investigated because of their biological importance, and the role of the metal ions in the mixed ligand complexes in various reactions has been discussed. Among them, copper(II) complexes are the most extensively studied ones, and zinc(II) complexes have also drawn attentions of chemists due to their interesting behavior in catalytic reactions in biological systems. Cadmium(II) ions often show similar properties in chemical reactions to zinc(II) ions because of their similar electron configurations (d^{10} electrons).[1] However, mixed ligand amino acido complexes of cadmium(II) ion have scarecely been examined so far. Toxity of cadmium(II) ion is an important problem to be elucidated in the view-point of medical science, as well as of complex chemistry. Reactions of cadmium(II) ions with amino acids which exist in human plasma[2] and other biological tissues and organs, therefore, are worthwhile studying in connection of complex chemistry of cadmium(II) ions with biochemistry.

The aim of the present work is to determine formation constants of mixed ligand complexes of cadmium(II) ion with a series of 2-amino carboxylic acids, such as glycine, α-alanine, 2-aminobutanoic acid, 2-aminopentanoic acid and 2-aminohexanoic acid, and variations of the formation constants of the mixed ligand complexes are discussed in terms of the effect of substituted alkyl groups at the carbon atom of glycine.

The effect of the size of chelate rings of amino acids in the complexes on formation constants of various mixed ligand complexes has also been examined by using 3- and 4-amino carboxylic acids, but the complexes of cadmium(II) ions with the acids are so weak that the complexes are not practically formed.

Experimental

Reagents. The amino acids were obtained from Wako Pure Chemicals Ind., Osaka, Nakarai Chemicals Co., Kyoto, and Katayama Chemicals Ind., Osaka. Each reagent was purchased from at least two different companies and purity of the reagents was checked by paper chromatography. A reagent having better quality was chosen, and then, it is recrystallized and used after drying crystals for several hours at 90—110 °C in an electric oven. Cadmium perchlorate, lithium perchlorate and lithium hydroxide were prepared by the methods as described in previous papers.[3,4]

Apparatus. Beckman (Nos. 40495 and 40498) glass electrodes were used in combination with an Orion Digital pH Meter 801. The Kawai-type half cell[5] was used, in which an Ag–AgCl electrode was set. The Ag–AgCl electrode was prepared according to Brown.[6]

Measurements. During potentiometric titrations the total concentration of perchlorate ions was kept constant at 3 mol dm^{-3} by using lithium perchlorate. The ratio of the total concentration of ligands (the sum of the concentrations of two amino acids) to that of cadmium(II) ions (C_L^t/C_{Cd}^t) was 5 in all the cases. The total concentration of amino acids in the solution (C_L^t) was changed, but the ratio of the concentrations of each amino acid was kept 1 : 1. The method of emf measurements was essentially the same as that employed in the previous work.[3,4]

All the measurements were carried out under a nitrogen atomosphere at 25.00±0.02 °C in a liquid paraffin bath set in a room thermostated at 25.0±1.5 °C.

Results

Typical results of titration curves of the systems of cadmium(II)–amino acids are shown in Fig. 1, in which the degree of neutralization of the total amino acids in the solutions X ($=-\boldsymbol{H}/C_L^t$; $\boldsymbol{H}$ stands for the analytical

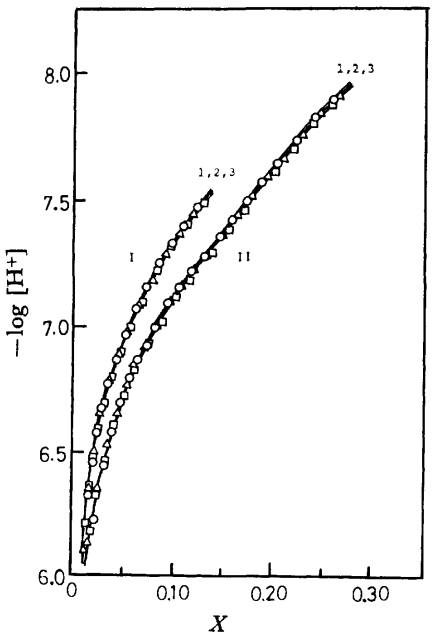

Fig. 1. Typical titration curves of cadmium(II)–amino acid mixed solutions.

Curve II (Cd(II)–glycine–2-aminobutanoic acid): 1 (○), 7.571, 18.80, 18.81; 2 (△), 7.771, 19.38, 19.38; 3 (□), 8.139, 20.39, 20.37.

excess concentration of hydrogen ion) was plotted against $-\log [H^+]$. The least squares method was employed to determine the best value of the formation constant of a mixed ligand complex, CdLL', by taking into account the formation constants of the parent cadmium(II) complexes with each amino acid as the component, which had been determined by separate experiments using solutions containing cadmium(II) ions and one kind of amino acid as a ligand. The formation constants of the mixed ligand complexes $\beta_{pqrs}=[Cd_pH_qL_rL'_s]^{(2p+q-r-s)+}/([Cd^{2+}]^p[H^+]^q[L^-]^r[L'^-]^s)$ are summarized in Table 1, together with the ionization constants of the ligands (pK_1 and pK_2) and the formation constants of mono- and bis-complexes with one kind of amino acid as the ligand ($\log K_{11}$ and $\log K_{12}$). Neither the protonated complexes nor the tris(amino acido)cadmium(II) complexes have been found with reliable accuracies under the present experimental conditions. The values of K_{11} and K_{12} are refined ones which had been determined,[7] the refinement being done for eliminating titration data at higher pH regions where white precipitates sometimes appeared. The formation of hydroxo complexes of cadmium ions[8] has been taken into consideration in the course of the least squares refinement of the formation constants of the mixed ligand complexes. The calculations were carried out by using the SCOGS program[9] with an electronic computer FACOM M-160S.

The solid lines in Fig. 1 were drawn using calculated values of X (X_{calcd}) by the following equation:

$$X_{calcd} = \frac{C_L^t + K_t[H^+]^{-1} - [H^+] - \sum_p \sum_q \sum_r \sum_s q\beta_{pqrs}[Cd^{2+}]^p[H^+]^q[L^-]^r[L'^-]^s}{C_L^t}, \quad (1)$$

where K_t represents the autoprotolysis constant of water in 3 mol dm^{-3} $LiClO_4$ aqueous solution at 25 °C ($10^{-13.87}$ mol^2 dm^{-6} [10]). Under the present conditions, the values of p, q, r, and s for the mixed ligand cadmium(II) complexes are 1, 0, 1, and 1, respectively. The formation of the $CdOH^+$ ($p=1$, $q=-1$, $r=s=0$) and Cd_2OH^{3+} ($p=2$, $q=-1$, $r=s=0$) complexes[8] has been taken into account in the determination of formation constants of the mixed ligand complexes, β_{pqrs}, by using Eq. 1. Since only the 1 : 1 : 1 type mixed ligand complexes without protons ($p=1$, $q=0$, $r=1$, $s=1$) have been found in the present work, the formation constants of the mixed ligand complexes will be simply denoted as β_{1rs} (*e.g.*, β_{111} for a 1 : 1 : 1 mixed complex).

Table 1. Formation constants of cadmium(II) complexes with 2-amino carboxylic acids in 3 mol dm^{-3} $LiClO_4$ at 25 °C

		Glycine	α-Alanine	2-Amino-butanoic acid	2-Amino-pentanoic acid	2-Amino-hexanoic acid
a) Ionization constants of 2-amino carboxylic acids.						
pK_1		2.76	2.81	—	—	—
pK_2		9.68	9.72	9.73	9.75	9.76
b) Formation constants of mono- and bis(2-amino carboxylato)cadmium(II) complexes.						
$\log K_{11}$		4.01	3.69	3.64	3.72	3.74
$\log K_{12}$		3.48	3.24	3.24	3.29	3.29
c) Formation constants of mixed ligand complexes of cadmium(II) ion.[a]						
$\log \beta_{111}$	Glycine	7.49	7.47	7.34	7.41	7.43
	α-Alanine		6.93	7.13	7.15	7.24
	2-Aminobutanoic acid			6.88	7.05	7.20
	2-Aminopentanoic acid				7.01	7.31
	2-Aminohexanoic acid					7.03

a) Values underlined are $\log \beta_{120}$ or $\log \beta_{102}$ ($=\log K_{11}+\log K_{12}$). Standard deviations are ±0.02.

Protonation reactions of mono- and bis(amino acido)-cadmium(II) complexes have not been observed under the present experimental conditions.

It should be noted from the results in Table 1 that the values of pK_1 and pK_2 are increased, whereas the values of log K_{11} and log K_{12} are decreased, by introducing alkyl groups to glycine, where K_{11} and K_{12} represent the stepwise formation constants of the CdL^+ and CdL_2 complexes, respectively.

Discussion

The formation constant of a mixed ligand complex should be larger than the average value of the formation constants of the parent complexes by a statistical factor as long as the bond strength between the central metal ion and the ligands is unaffected by replacing a ligand with another one and the contribution of entropy changes in each reaction to the formation constants are the same.

In the formation of a 1 : 1 : 1 mixed ligand complex CdLL′ from the parent bis-complexes, CdL_2 and CdL'_2, the statistical factor is 4.

The formation reaction of the mixed ligand CdLL′ complex from the parent complexes can be described as follows:

$$CdL_2 + CdL'_2 = 2CdLL'. \quad (2)$$

The formation constants of the mixed ligand complex β_{111} are related to the formation constants of the parent CdL_2 and CdL'_2 complexes, β_{120} and β_{102}, respectively, by the following equation:

$$2 \log \beta_{111} = \log \beta_{120} + \log \beta_{102} + \log F_m. \quad (3)$$

F_m is 4 in the ideal case.

For most mixed ligand complexes examined here, β_{111} is larger than β_{120} and β_{102}. However, as we can see from Table 1c, the formation constants of the mixed ligand complexes containing glycinate ion as one component lie between the values of the two parent complexes, thus, $\beta_{120} > \beta_{111} > \beta_{102}$, although the relationship $\beta_{111}^2 > \beta_{120} \cdot \beta_{102}$ still holds for the complexes.

The second stepwise formation constants K_{12}^m of the mixed ligand complexes in the reaction

$$CdL^+ + L'^- = CdLL' \quad (4)$$

are calculated by using the following equation:

$$\log K_{12}^m = \log \beta_{111} - \log K_{11}. \quad (5)$$

The values of log K_{12}^m are summarized in Table 2. The values of log K_{12}^m of the Cd(gly)L complexes with various 2-amino carboxylate anions L^-

$$CdL^+ + gly^- = Cd(gly)L \quad (6)$$

are in the range of 3.69 to 3.78, which are larger than the log K_{12} value of the bis(glycinato)cadmium(II) complex. On the other hand, the log K_{12}^m values of the reaction

$$Cd(gly)^+ + L^- = Cd(gly)L \quad (7)$$

fall in the range of 3.33 to 3.46, which are comparable to the values of the other complexes given in Table 2. Therefore, we see that the small values of β_{111} of the Cd(gly)L complexes are due to the considerably small values of the first stepwise formation constants of the CdL^+ complexes compared with those of the $Cd(gly)^+$ complex (Table 1b).

The second formation constants of the mixed ligand complexes containing glycinate ion as the second entering ligand are larger than those of other complexes, and even larger than the K_{12} value of the bis(glycinato)-cadmium(II) complex. This fact implies that glycinate ion combines more favorably with a CdL^+ than with the $Cd(gly)^+$ complex. Since direct interactions between glycinate and another ligand within the CdL^+ complex may hardly be expected, interactions between the ligands through the central metal ion should be considered.

Electrons in the highest orbitals of cadmium(II) ion which is a considerably soft acid according to classification by Ahrland, *et al.*[11] and Pearson[12] may partially delocalize over the central metal ion and the ligand atoms within the complex in order to decrease the total energy of the whole complex. Although it is generally accepted that atoms of the first and second rows of the periodic table cannot be acceptors of such electrons, we think that the possibility may not be completely excluded in cases where a central atom has electrons with very large principal quantum numbers, or in other words, it has a very soft character, because energy levels of electrons of the central metal ion and ligand atoms such as oxygen and nitrogen are so different that even small delocalization of electrons of the metal ion by using a higher orbitals of the ligand atoms may decrease, to some extent, the total energy of the system.

Table 2. The second stepwise formation constants (log K_{12}^m) of the CdLL′ complexes in 3 mol dm^{-3} $LiClO_4$ at 25 °C[a]

CdL[b]	L′				
	Glycinate	Alaninate	2-Amino-butanoate	2-Amino-pentanoate	2-Amino-hexanoate
$Cd(gly)^+$	<u>3.48</u>	3.46	3.33	3.40	3.42
$Cd(ala)^+$	3.78	<u>3.24</u>	3.44	3.46	3.55
$Cd(but)^+$	3.70	3.49	<u>3.24</u>	3.41	3.56
$Cd(pen)^+$	3.69	3.43	3.33	<u>3.29</u>	3.59
$Cd(hex)^+$	3.69	3.50	3.46	3.57	<u>3.29</u>

a) Values underlined are log K_{12} of the bis(2-amino carboxylato)cadmium(II) complexes. b) Ala : Alaninate ion, but : 2-aminobutanoate ion, pen : 2-aminopentanoate ion, hex : 2-aminohexanoate ion.

This kind of electron delocalization may easily be prevented by an increase in the charge density at the ligand atoms due, for instance, to inductive effects of substituted groups within the ligand molecules.

An interpretation of the change in the K_{12}^{m} value of the Cd(gly)L complex may thus be given in the following way: the basicity of the functional groups (amino and carboxyl groups) of glycine increases by introduction of an alkyl group to the carbon atom due to its inductive effect, and therefore, the pK_1 and pK_2 values of 2-amino carboxylic acids having alkyl groups become larger than the pK_1 and pK_2 values, respectively, of glycine (see Table 1a). The introduction of the alkyl groups thus results an increase in electron densities at the nitrogen and oxygen atoms within the amino and carboxyl groups, and it may prevent electron donation from the central cadmium(II) ion. Therefore, the affinity of the amino acid anions to cadmium(II) ion decreases, as we can see from the values of K_{110} and K_{120} of the bis(amino acido)cadmium(II) complexes smaller than the corresponding values of the bis(glycinato)cadmium(II) complex (see Table 1b). The increased charge density of the cadmium(II) ion due to the decreased electron donation to the ligand atoms may result a decreased acceptability of electron pairs from the coordinated water molecules. As the result, the $H_2O\cdots CdL^+$ bonds in the solvated CdL^+ complex weaken, and the water molecules can be easily substituted with the second ligand. Since glycinate anion has the largest acceptability (*i.e.*, the smallest electron density at the ligand atoms) among the ligands examined here for the electron donation from the cadmium(II) ion, the substitution of glycinate ion with the water molecules coordinated to the cadmium(II) ion might occur most favorably to form the strongest metal-ligand bond. Thus the K_{12}^{m} value of the reaction

$$CdL(H_2O)_n^+ + gly^- = Cd(gly)L(H_2O)_{n-2} + 2H_2O \quad (8)$$

becomes larger than the K_{12} value of the following reaction:

$$Cd(gly)(H_2O)_n^+ + gly^- = Cd(gly)_2(H_2O)_{n-2} + 2H_2O. \quad (9)$$

The statistical factors $\log F_m$ defined by Eq. 3 for various mixed ligand complexes are summarized in Table 3, but no systematic trend of the values can be found.

Another relationship

$$\log \beta_{111} = \log \beta_{110} + \log \beta_{101} + \log F'_m \quad (10)$$

TABLE 3. VALUES OF $\log F_m$, F'_m, AND b IN EQS. 3, 10, AND 13, RESPECTIVELY

Exptl No.	Complex	$\log F_m$	$\log F'_m$	b
1	Cd(gly)(ala)	0.52	−0.23	0.98
2	Cd(gly)(but)	0.31	−0.31	0.93
3	Cd(gly)(pen)	0.32	−0.32	0.96
4	Cd(gly)(hex)	0.34	−0.32	0.98
5	Cd(ala)(but)	0.45	−0.20	0.85
6	Cd(ala)(pen)	0.36	−0.26	0.88
7	Cd(ala)(hex)	0.52	−0.19	0.90
8	Cd(but)(pen)	0.21	−0.31	0.83
9	Cd(but)(hex)	0.49	−0.18	0.85
10	Cd(pen)(hex)	0.58	−0.15	0.88

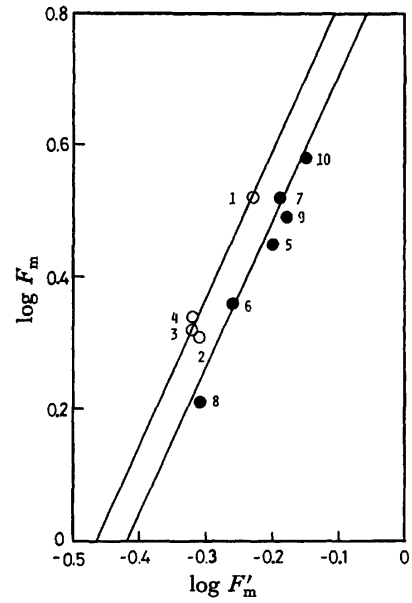

Fig. 2. The relationship between $\log F_m$ and $\log F_m'$. ○: Mixed ligand cadmium(II) complexes containing glycinate ion, ●: other mixed ligand cadmium(II) complexes. The numbers given in the figure correspond to those of the complexes in Table 3.

is obtained for the formation of the CdLL' complex from the parent CdL^+ and CdL'^+ complexes as follows:

$$CdL^+ + CdL'^+ = CdLL' + Cd^{2+}. \quad (11)$$

F'_m is 2 in the ideal case. The values of $\log F'_m$ found are summarized in Table 3. Since the following relationship holds between F_m and F'_m

$$\log F_m = 2 \log F'_m + b, \quad (12)$$

where

$$b = \log\{(K_{110}\cdot K_{101})/(K_{120}\cdot K_{102})\} \quad (13)$$

plots of $\log F_m$ against $\log F'_m$ should give straight lines as we can see in Fig. 2. The experimental points fell on the two straight lines with a slope 2. The open circles show the mixed ligand complexes containing glycinate ion and the closed circles show the complexes not containing glycinate ion. The b-values found from the plots are given in Table 3, which should be zero in the ideal case. The b-values of the mixed ligand glycinato complexes are obviously larger than those of the other complexes, the fact indicating that the inter-ligand interactions within the mixed ligand glycinato complexes are larger than those of other complexes.

The authors thank Prof. O. Yamauchi of Kanazawa University for his helpful discussion.

Binuclear Metal Complexes. XLII.[1] Manganese(IV) Complexes Synthesized by Oxidation of Binuclear Manganese(II) Complexes of 2-(Salicylideneamino)phenols with Tetrachloro-*o*-benzoquinone

Hisashi Ōkawa,* Masaaki Nakamura, and Sigeo Kida
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812
(Received July 24, 1981)

Manganese(IV) complexes $Mn(R\text{-}R'\text{-}sap)_2$, where $H_2(R\text{-}R'\text{-}sap)$ denotes 2-(salicylideneamino)phenols with the substituent R on the salicylaldehyde ring and the R′ on the *o*-aminophenol ring, were prepared by the oxidation of binuclear manganese(II) complexes $Mn_2(R\text{-}R'\text{-}sap)_2$ with tetrachloro-*o*-benzoquinone (TCOQ). The complexes showed magnetic moments corresponding to three unpaired electrons and strong absorptions in the region $15—20\times10^3$ cm^{-1} attributable to CT transitions. Cyclic voltammograms of $Mn(R\text{-}R'\text{-}sap)_2$ showed two redox waves which can be interpreted in terms of a two-step reaction, $Mn(IV)\rightleftharpoons Mn(III)\rightleftharpoons Mn(II)$. Both redox potentials of the first and the second processes depend on the substituents R and R′, and there is a good correlation between the redox potentials and Hammett's σ-values of R and R′ to the phenolic oxygen. $Mn_2(R\text{-}R'\text{-}sap)_2$ reacts with TCOQ to give a binuclear manganese(III) complex $Mn_2(R\text{-}R'\text{-}sap)_2(tcoq)$, which decomposes in the presence of water forming $Mn(R\text{-}R'\text{-}sap)_2$.

Manganese is known to play several important roles in biological processes.[2] Among these, manganese in the photosystem-II has become particularly of interest, where manganese in higher oxidation state functions as a catalyst for oxidizing water to molecular oxygen.[3,4] The recent findings that two or more manganese ions are involved in the active center of the photosystem-II[5-7] stimulated interest in binuclear manganese complexes in higher oxidation states (Mn(III) and Mn(IV)).[8,9] On the other hand, Wang[10] proposed a mechanism of water oxidation promoted by mononuclear manganese(IV). Thus, much attention is being devoted to synthesis, redox behavior and reactivity of new manganese complexes in higher oxidation state. However, both mononuclear manganese(IV) complexes and binuclear manganese(III) and manganese(IV) complexes seem to be very limited.

Previously, we have reported synthesis, magnetism and structure of binuclear manganese(III) complexes of 3-(salicylideneamino)-1-propanols.[11,12] As a part of the continuing study on binuclear manganese complexes in higher oxidation state, we brought binuclear manganese(II) complexes of 2-(salicylideneamino)-phenols to reaction with tetrachloro-*o*-benzoquinone (TCQO), in an attempt to prepare binuclear manganese(III) complexes bridged by two phenolic oxygens in the equatorial plane and tetrachlorocatecholate moiety in the apical position. Deep colored products, however, were free from TCOQ and the metal to ligand (2-(salicylideneamino)phenols) ratio was 1 : 2, suggesting the formation of manganese(IV) complexes. In this study, we have characterized the new complexes in terms of magnetic susceptibilities, electronic spectra and cyclic voltammetry. The mechanism of formation of the manganese(IV) complexes has been discussed.

Experimental

Preparations. Ligands employed in this study are the 1 : 1 condensation products of salicylaldehyde or a substituted salicyladehyde and 2-aminophenol or a substituted 2-aminophenol. The ligands are abbreviated as $H_2(R\text{-}R'\text{-}sap)$, in

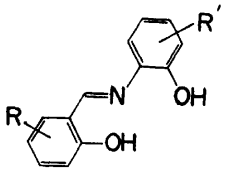

Fig. 1.

which R and R′ are the substituents on salicylaldehyde and 2-aminophenol, respectively (Fig. 1). Following ligands were used in this study: 2-(salicylideneamino)phenol (H_2(sap)), 2-(3-methoxysalicylideneamino)phenol (H_2(3-MeO-sap)), 2-(5-methylsalicylideneamino)phenol (H_2(5-Me-sap)), 2-(5-bromosalicylideneamino)phenol (H_2(5-Br-sap)), 2-(salicylideneamino)-4-chlorophenol (H_2(4′-Cl-sap)), and 2-(salicylideneamino)-5-nitrophenol (H_2(5′-NO_2-sap)). Manganese(II) complexes of $H_2(R\text{-}R'\text{-}sap)$ were prepared by the method described in the literature.[13]

Mn(sap)$_2$·1/2H$_2$O. To a suspension of $Mn_2(sap)_2$ (266 mg) in methanol (20 cm^3) was added tetrachloro-*o*-benzoquinone (TCOQ) (125 mg) under stirring. The mixture was gently refluxed for 3 h and allowed to stand overnight to give black-purple prisms. They were collected, washed with methanol, and dried over P_2O_5 *in vacuo*. The yield was 130 mg.

Found: C, 64.23; H, 3.92; N, 5.72%. Calcd for $C_{26}H_{18}N_2O_4Mn\cdot1/2H_2O$: C, 64.21; H, 3.94; N, 5.76%.

Mn(3-MeO-sap)$_2$·H$_2$O. A mixture of Mn_2 (3-MeO-sap)$_2$ (296 mg) and TCOQ (125 mg) in methanol (20 cm^3) was refluxed for 30 min to give almost black prisms. They were collected, washed with methanol, and dried over P_2O_5 *in vacuo*. The yield was 75 mg.

Found: C, 60.66; H, 4.55; N, 4.91%. Calcd for $C_{28}H_{22}N_2O_6Mn\cdot H_2O$: C, 60.55; H, 4.36; N, 5.04%.

Mn(5-Me-sap)$_2$·1/2H$_2$O. A mixture of Mn_2 (5-Me-sap)$_2$ (280 mg) and TCOQ (125 mg) in methanol (20 cm^3) was refluxed for 2 h to give a deep colored solution. To this solution was added dropwise a 1 : 1 mixture of methanol–water (1 cm^3), and stirring was continued for additional 30 min. Almost black prisms thus obtained were collected, washed with a small amount of methanol, and dried over P_2O_5 *in vacuo*. The yield was 90 mg.

Found: C, 65.11; H, 4.34; N, 5.30%. Calcd for $C_{28}H_{22}N_2O_4Mn\cdot1/2H_2O$: C, 65.40; H, 4.53; N, 5.45%.

Mn(5-Br-Sap)$_2$·H$_2$O. This complex was obtained as deep blackish green prisms (80 mg) by the reaction of Mn$_2$(5-Br-sap)$_2$ (345 mg) with TCOQ (125 mg) in methanol (30 cm^3) for 1 h at room temperature.

Found: C, 47.53; H, 2.53; N, 4.07%. Calcd for $C_{26}H_{16}N_2O_4Br_2Mn\cdot H_2O$: C, 47.81; H, 2.78; N, 4.29%.

Mn(4'-Cl-sap)$_2$·3/2H$_2$O. This complex was prepared as almost black powder (130 mg) by the reaction of Mn$_2$(4'-Cl-sap)$_2$ (620 mg) and TCOQ (250 mg) in methanol (50 cm^3) for 30 min at room temperature.

Found: C, 54.24; H, 3.09; N, 4.65%. Calcd for $C_{26}H_{16}N_2O_4Cl_2\cdot 3/2H_2O$: C, 54.47; H, 3.34; N, 4.89%.

Mn(5'-NO$_2$-sap)$_2$·2H$_2$O. This complex was obtained as deep green crystalline powder (150 mg) by the reaction of Mn$_2$(5'-NO$_2$-sap)$_2$ (620 mg) and TCOQ (250 mg) in methanol (60 cm^3) for 1 h at room temperature.

Found: C, 51.94; H, 3.09; N, 9.65%. Calcd for $C_{26}H_{16}N_4O_8Mn\cdot 2H_2O$: C, 51.93; H, 3.35; N, 9.32%.

Mn$_2$(sap)$_2$(tcoq). A mixture of Mn$_2$(sap)$_2$ (275 mg) and TCOQ (125 mg) in absolute acetonitrile (25 cm^3) was stirred for 3 h at room temperature in an atmosphere of nitrogen. The reaction was protected from the moisture by means of a VAC Inert Atmosphere and Vaccum Deposition equipment Model HE-43-2. Dark green prisms which separated were collected, washed with acetonitrile, and dried *in vacuo.*

Found: C, 49.23; H, 2.47; N, 3.83%. Calcd for $C_{32}H_{18}N_2O_6Cl_4Mn_2$: C, 49.39; H, 2.33; N, 3.60%.

Ti(sap)$_2$. H$_2$(sap)$_2$ (2.13 g) was dissolved in absolute methanol (50 cm^3), and to this solution was added TiCl$_4$ (0.95 g) dropwise under stirring. The mixture was stirred for 3 h at room temperature to give red crystals. They were collected, washed with methanol, and dried *in vacuo.*

Found: C, 66.20; H, 3.90; N, 5.90%. Calcd for $C_{26}H_{18}N_2O_4Ti$: C, 66.40; H, 3.86; N, 5.96%.

Measurements. Elemental analyses were performed at the Service Center of Elemental Analysis, Kyushu University. Electronic spectra were recorded on a Shimadzu multipurpose spectrometer Model MPS-5000 in dichloromethane or methanol. Magnetic susceptibilities were measured by the Faraday method. The apparatus was calibrated by the use of [Ni(en)$_3$]S$_2$O$_3$.[14] Diamagnetic corrections were made with Pascal's constants[15] and magnetic moments were calculated by the equation, $\mu_{eff}=2.828(\chi_A\times T)^{1/2}$. Cyclic voltammograms were recorded with a Yanagimoto voltammetric analyzer Model 1000. Measurements were made on dichloromethane solutions containing 0.1 M tetrabutylammonium perchlorate as the supporting electrolyte, using a three-electrode cell. The working electrode is glassy carbon and the auxiliary electrode is platinum coil. The saturated calomel electrode was used as the reference. All the potentials were corrected by the use of ferrocene as an internal standard (Fc$^+$/Fc: $E_{1/2}$=0.400 V *vs.* NHE[16]).

Results and Discussion

Manganese(II) complexes of H$_2$(R-R'-sap) were already synthesized,[13,17,18] whose metal to ligand ratio (1 : 1) suggests a polynuclear structure. The 1 : 1 copper(II) complexes with H$_2$(R-R'-sap) was demonstrated to be binuclear on the basis of magnetic measurements.[19] The two copper(II) ions are supposed to be bridged by the phenolic oxygen atoms of 2-aminophenol, in analogy with the result of X-ray structural analysis of the copper(II) complex for the Schiff base derived from acetylacetone and 2-aminophenol.[20] Thus, it is naturally assumed that the manganese(II) complexes of H$_2$(R-R'-sap) also possess a binuclear structure bridged by the 2-aminophenol oxygen, hence the complexes being represented as Mn$_2$(R-R'-sap)$_2$. According to Consiglio *et al.*,[13] the magnetic moments of Mn$_2$(R-R'-sap)$_2$ are temperature-dependent. For example, they reported that the moment of Mn$_2$(sap)$_2$ is 5.82 BM at room temperature and 3.89 BM at 140 K. Thus, they presumed an antiferromagnetic spin-exchange interaction operating between a pair of manganese(II) ions. Magnetic properties of Mn$_2$-(R-R'-sap)$_2$ were reexamined in this study in the temperature range 78—300 K. Our measurements revealed that all of the complexes possess a magnetic moment falling in the range 5.8—6.0 BM at room temperature and the moments are almost independent of temperature down to the liquid nitrogen temperature. Magnetic data for Mn$_2$(sap)$_2$ reported by Consiglio *et al.* can not be interpreted by the susceptibility equation for the (s=5/2)–(s=5/2) system on the basis of the Heisenberg model. We believe that Mn$_2$(R-R'-sap)$_2$ has a binuclear skeleton,  , and spin-exchange interaction between the metal ions is very weak.

Table 1. Magnetic moments (μ_{eff}) of Mn(R-R'-sap)$_2$ at room temperature

Complex	μ_{eff}/BM(T/K)
Mn(sap)$_2$·1/2H$_2$O	3.91(297.3)
Mn(3-MeO-sap)$_2$·H$_2$O	3.94(294.8)
Mn(5-Me-sap)$_2$·1/2H$_2$O	3.96(296.4)
Mn(5-Br-sap)$_2$·H$_2$O	4.03(294.9)
Mn(4'-Cl-sap)$_2$·3/2H$_2$O	4.01(298.0)
Mn(5'-NO$_2$-sap)$_2$·2H$_2$O	4.16(298.1)

Oxidation of Mn$_2$(R-R'-sap)$_2$ with TCOQ in the open atmosphere resulted in the formation of deeply colored Mn(R-R'-sap)$_2$. Magnetic moments of Mn-(R-R'-sap)$_2$ except for Mn(5'-NO$_2$-sap)$_2$·2H$_2$O fall in the range 3.91—4.03 BM (Table 1), which is in good agreement with the moments of the characterized manganese(IV) complexes.[21] Magnetic moment of Mn(5'-NO$_2$-sap)$_2$·2H$_2$O (4.16 BM) is slightly higher than the spin-only value. This may be attributed to the contamination of impurities such as manganese-(III) or manganese(II) species. It seems that Mn(sap)$_2$·1/2H$_2$O, Mn(3-MeO-sap)$_2$·H$_2$O and Mn(5-Me-sap)$_2$·1/2H$_2$O are stable in dichloromethane and in the solid state. On the other hand, Mn(5-Br-sap)$_2$·H$_2$O, Mn-(4'-Cl-sap)$_2$·3/2H$_2$O and Mn(5'-NO$_2$-sap)$_2$·2H$_2$O are unstable in dichloromethane and amorphous substance precipitates when the solutions are exposed to air for a few hours. Mn(5'-NO$_2$-sap)$_2$·2H$_2$O is particularly unstable and it gradually decomposes in the open atmosphere even in the solid state.

1,2-Naphthoquinone and 9,10-phenanthroquinone do not oxidize Mn$_2$(R-R'-sap)$_2$. This may be due to the low oxidation potentials of these quinones compared with TCOQ.[22]

Table 2. Band maxima ($\tilde{\nu}/10^3\,cm^{-1}$) and extinction coefficients (log ε) of CT bands of Mn(R-R'-sap)$_2$

Mn(sap)$_2$·1/2H$_2$O	15.38(3.32), 18.42(3.68), 19.42(3.66)
Mn(3-MeO-sap)$_2$·H$_2$O	13.50(3.38), 16.21(3.50), 18.02(3.48)
Mn(5-Me-sap)$_2$·1/2H$_2$O	15.10(3.36), 18.02(3.69), 18.87(3.69)
Mn(5-Br-sap)$_2$·H$_2$O	15.15(3.39), 17.95(3.68), 19.05(3.67)
Mn(4'-Cl-sap)$_2$·3/2H$_2$O	15.00(3.40), 18.18(3.65), 19.23(3.67)
Mn(5'-NO$_2$-sap)$_2$·2H$_2$O	14.70(3.48), 17.70(3.68), 19.42(3.81)

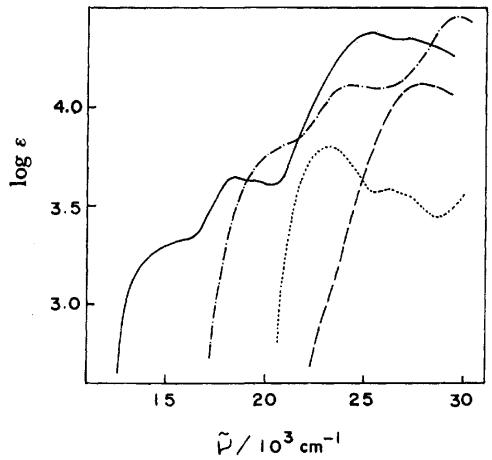

Fig. 2. Electronic spectra of (——) Mn (sap)$_2$·1/2H$_2$O, (– – –) H$_2$(sap), (------) Mn$_2$(sap)$_2$, and (–·–) Ti (sap)$_2$.

Electronic spectra of Mn(R-R'-sap)$_2$ were measured in dichloromethane. All the spectra are similar to each other. The spectrum of Mn(sap)$_2$·1/2H$_2$O is shown in Fig. 2. Figure 2 also includes the spectra of H$_2$(sap), Mn$_2$(sap)$_2$ and Ti(sap)$_2$ for comparison. The intra-ligand transition around $28\times10^3\,cm^{-1}$ of H$_2$(sap) (measured in methanol) shifts to lower frequency and its intensity decreases when it coordinates to a metal. H$_2$(sap) and Mn$_2$(sap)$_2$ do not show any strong absorption in the frequency region less than $20\times10^3\,cm^{-1}$. On the other hand, Mn(sap)$_2$·1/2H$_2$O exhibits strong absorptions at $\approx15\times10^3$ and $\approx19\times10^3\,cm^{-1}$, the latter band being composed of two components. The band maxima and the extinction coefficients of these new bands are given in Table 2. These absorptions are too strong to assign to the ligand field bands. Judging from the fact that Ti(sap)$_2$ shows a strong band around $20\times10^3\,cm^{-1}$, the 15 and $19\times10^3\,cm^{-1}$ bands of Mn(R-R'-sap)$_2$ may be assigned to the charge transfer transitions from phenolic oxygens to manganese(IV) ion. Recently, Matsushita *et al.*[23] synthesized manganese(IV) complexes Mn(R-X-sal)$_2$Cl$_2$ of *N*-alkylsalicylideneamines and assigned the strong absorption near $17\times10^3\,cm^{-1}$ (log ε=3.5) to the charge transfer transition p_π(Cl)→d_π(Mn). This band is similar to those of Mn(R-R'-sap)$_2$ in frequency and intensity, despite no chloride ion being included in Mn(R-R'-sap)$_2$.

Electrochemical properties of Mn(R-R'-sap)$_2$ were studied by means of cyclic voltammetry. All of the complexes displayed two redox waves. Cyclic voltammetric data are given in Table 3. Cyclic voltammogram of Mn(sap)$_2$·1/2H$_2$O is shown in Fig. 3. Electrochemical behaviors of Mn(R-R'-sap)$_2$ can be interpreted

Table 3. Cyclic voltammetric data of Mn(R-R'-sap)$_2$

Complex	E_{pc}	E_{pa}	ΔE_p / mV	$E_{1/2}$
Mn(sap)$_2$·1/2H$_2$O	−0.11	−0.01	100	−0.06
	−0.87	−0.65	220	−0.76
Mn(3-MeO-sap)$_2$·H$_2$O	−0.15	−0.05	100	−0.10
	−0.88	−0.69	190	−0.78
Mn(5-Me-sap)$_2$·1/2H$_2$O	−0.15	−0.04	110	−0.10
	−0.94	−0.64	300	−0.79
Mn(5-Br-sap)$_2$·H$_2$O	−0.01	+0.08	90	+0.04
	−0.73	−0.58	150	−0.66
Mn(4'-Cl-sap)$_2$·3/2H$_2$O	0.00	+0.08	80	+0.04
	−0.76	−0.55	210	−0.66
Mn(5'-NO$_2$-sap)$_2$·2H$_2$O	+0.18	+0.23	50	+0.21
	−0.53	−0.45	80	−0.49

E_{pc} and E_p are calibrated by the use of E_{Fc/Fc^+}[16] and are given in V *vs.* NHE; $E_{1/2}$ is approximated by $E_{1/2}=1/2(E_{pc}+E_{pa})$.

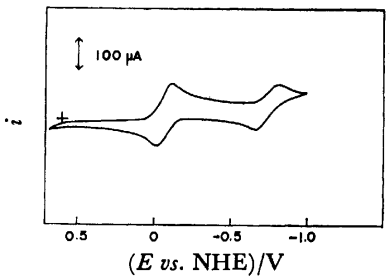

Fig. 3. Cyclic voltammogram of Mn(sap)$_2$·1/2H$_2$O.

by the following processes:

$$\text{Mn(IV)} \overset{E^1_{1/2}}{\rightleftharpoons} \text{Mn(III)} \overset{E^2_{1/2}}{\rightleftharpoons} \text{Mn(II)}.$$

The separation between the cathodic and the anodic peaks of the first process is less than 110 mV, indicating a reversible or quasi-reversible redox of this process. The potentials of the first and the second processes, $E^1_{1/2}$ and $E^2_{1/2}$, markedly depend on the substituents R and R'. Complexes containing an electron-withdrawing group, Mn(5-Br-sap)$_2$·H$_2$O, Mn(4'-Cl-sap)$_2$·3/2H$_2$O and Mn(5'-NO$_2$-sap)$_2$·2H$_2$O, possess higher redox potentials than other complexes. It is evident that an electron-withdrawing group destabilizes the oxidation state of manganese(IV). The substituents R and R' primarily alter the electron density on the phenolic oxygens. Thus, we plotted the potentials $E^1_{1/2}$ and $E^1_{1/2}$ against the Hammett σ values[24] of R and R' to the phenolic oxygen (σ_m for 5'-NO$_2$ and σ_p for 5-Me, 5-Br, and 4'-Cl). As is seen in Fig. 4, a good correlation exists between the redox potentials and the substituents of the ligand. The redox potentials of Mn(3-MeO-sap)$_2$-

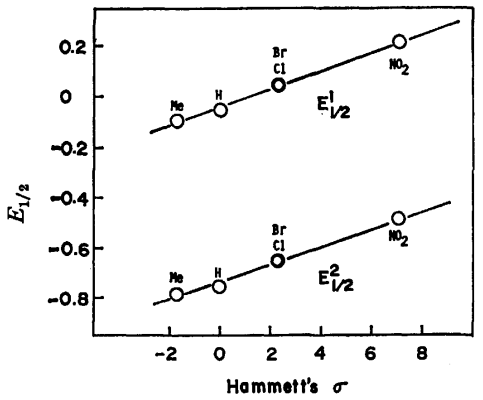

Fig. 4. Correlation between the redox potentials $E_{1/2}$ and $E_{1/2}$ and the Hammett σ values of the substituents R and R′ to the phenolic oxygen for Mn(R-R′-sap)$_2$.

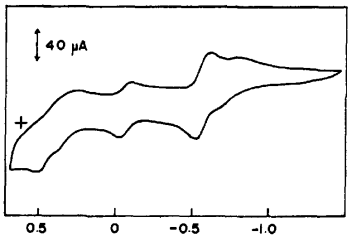
H_2O are comparable to those of Mn(sap)$_2$·1/2H_2O, in spite of the prominent electron releasing ability of methoxy group. This may be interpreted in terms of the "ortho effect."[25]

It is likely that the redox potential of the first process of Mn(5′-NO_2-sap)$_2$·2H_2O (0.21 V. *vs.* NHE) is close to the potential for water oxidation and the instability of this complex must be due to its high redox potential. Similarly, relatively high potentials of Mn(5-Br-sap)$_2$-H_2O and Mn(4′-Cl-sap)$_2$·3/2H_2O ($E^1_{1/2}$=0.04 V) may be responsible for the ready decomposition of these complexes in dichloromethane.

In order to examine the formation mechanism of Mn-(R-R′-sap)$_2$, we brought Mn_2(sap)$_2$ to reaction with TCOQ in acetonitrile under nitrogen atmosphere free from moisture and obtained Mn_2(sap)$_2$(tcoq) as dark green prisms. The magnetic moment of this complex is 4.89 BM at room temperature and 4.80 BM at the



(*E vs.* NHE)/V

Fig. 5. Cyclic voltammogram of Mn_2(sap)$_2$ (tcoq).

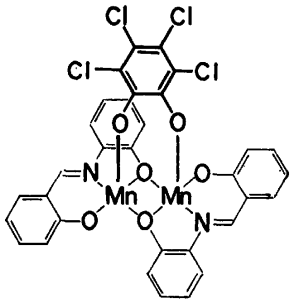


Fig. 6. A possible structure for Mn_2(sap)$_2$(tcoq).

liquid nitrogen temperature. Based on the composition and the magnetic moment, we presume that Mn_2-(sap)$_2$(tcoq) is a binuclear manganese(III) complex. Cyclic voltammogram of this complex revealed a redox wave at −0.58 V, which can be attributed to the Mn(III)⇌Mn(II) process (Fig. 5). In analogy with the molecular structure of a binuclear manganese(III) complex Mn_2(spa)$_2$(CH_3COO)$_2$ of 3-(salicylidene-amino)-1-propanol in which two mangenese(III) ions are bridged by two alcoholic oxygens and two bidentate acetate groups,[12] the most plausible structure for Mn_2(sap)$_2$(tcoq) is given in Fig. 6.

Mn_2(sap)$_2$(tcoq) is very sensitive to water. When water was added dropwise to a methanolic solution of this complex, yellow and blackish purple products were isolated. They were found to be identical with the authentic samples of Mn_2(sap)$_2$ and Mn(sap)$_2$-1/2H_2O, respectively, on the basis of IR spectra. The additional waves at −0.06 and −0.75 V found in cyclic voltammogram of Mn_2(sap)$_2$(tcoq) (Fig. 5) well correspond to the waves of Mn(sap)$_2$·1/2H_2O (Fig. 3 and Table 3). This suggests that Mn_2(sap)$_2$(tcoq) was partly decomposed by the atmospheric moisture to form Mn(sap)$_2$·1/2H_2O. On the basis of these facts, we can represent the reaction between Mn_2(R-R′-sap)$_2$ and TCOQ as follows: Mn_2(R-R′-sap)$_2$+TCOQ⟶ Mn_2 (R-R′-sap)$_2$ (tcoq) $\xrightarrow{H_2O}$ Mn(R-R′-sap)$_2$ Mn_2 (R-R′-sap)$_2$, and others.

Binuclear Metal Complexes. XLIII.[1] Magnetic, Spectroscopic, and Electrochemical Studies on Hetero-metal Binuclear Complexes of *N,N'*-Bis(3-carboxysalicylidene)-1,1-dibenzylethylenediamine

Wakako KANDA, Masaaki NAKAMURA, Hisashi ŌKAWA,* and Sigeo KIDA

Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812

(Received August 24, 1981)

Copper(II)–M(II) and copper(II)–iron(III) hetero-metal binuclear complexes of *N,N'*-bis(3-carboxysalicylidene)-1,1-dibenzylethylenediamine (H_4fsadb), CuM(fsadb)·nH_2O (M=Co, Ni, Cu, Zn, Mg, Ca, Ba) and CuFe(fsadb)Cl·1.5H_2O, have been prepared and characterized. Cryomagnetic measurements (78—300 K) revealed that an antiferromagnetic spin-exchange interaction operates between the metal ions in the cases CuM(fsadb)·nH_2O (M=Co, Ni, Cu) and CuFe(fsadb)Cl·1.5H_2O, exchange integrals being evaluated on the basis of the Heisenberg model. Ligand field bands due to the copper(II) ion bound at the N_2O_2-site of CuM(fsadb)·nH_2O (M=Co, Ni, Cu, Zn, Mg) and CuFe(fsadb)Cl·1.5H_2O are in the range 1.9×10^3—21.4×10^3 cm^{-1}, while in the cases of CuCa(fsadb)·4H_2O and CuBa(fsadb)·3.5H_2O the frequencies of the bands are close to that (17.8×10^3 cm^{-1}) of the mononuclear complex Cu(H_2fsadb)·H_2O. This spectral feature has been explained in terms of the configuration of the second metal ion adjacent to the copper(II) ion: *trans*-octahedral in the cases of small metal ions (Fe(III), Co(II), Ni(II), Cu(II), Zn(II), Mg(II)) and presumably *cis*-octahedral in the cases of large metal ions (Ca(II), Ba(II)). Copper(II/I) redox potentials of the hetero-metal complexes are much low compared with that of Cu(H_2fsadb)·H_2O. This shift has been discussed in terms of the electronic effect of the carboxylate group and the covalency in the bonding between the bridging phenolic oxygen and the second metal ion.

Recently there is a growing interest in chemistry of binuclear metal complexes in connection with metalloenzymes which involve two metal ions at their active sites.[2] Particularly, the recognition that superoxide dismutase[3] and cytochrome oxidase[4] contain two kinds of metal ions has stimulated an interest in hetero-metal binuclear complexes. Electrochemical technique is one of the essential tools for bioinorganic approach to metalloenzymes and several recent papers have been devoted to the analysis of the redox behavior of binuclear copper(II) complexes[5–9] in the hope to clarify the oxido-reductive function of copper proteins. On the other hand, electrochemical investigations on hetero-metal binuclear complexes are very limited,[10] because of the difficulty in preparation and the low stability in solvents.

Previously we reported the synthesis and the magnetic properties of copper(II)–M(II),[11–14] nickel(II)–M(II),[13] and cobalt(II)–M(II)[15,16] complexes of N,N'-bis(3-carboxysalicylidene)alkanediamines, which were demonstrated to be an excellent binucleating ligand possessing coordination selectivity. However, electrochemical properties of these complexes could not be examined because of their low solubility in solvents suitable for electrochemical measurements. In this study, we have prepared copper(II)–M(II) and copper(II)–iron(III) complexes of a new binucleating ligand, *N,N'*-bis(3-carboxysalicylidene)-1,1-dibenzylethylenediamine (abbreviated as H_4fsadb) which possesses hydrophobic benzyl groups in the ethylenediamine moiety (Fig. 1). These complexes, CuM(fsadb)·nH_2O (M=Co, Ni, Cu, Zn, Mg, Ca, Ba) and CuFe(fsadb)Cl·1.5H_2O, are soluble in dichloromethane or *N,N*-dimethylformamide. Thus, we have examined the optical and electrochemical properties of the copper(II) ion bound at the N_2O_2-site varing the second metal ion at the O_4-site. We have also studied magnetic spin-exchange interaction in CuM(fsadb)·nH_2O (M=Co, Ni, Cu) and CuFe(fsadb)Cl·1.5H_2O, comparing the results with those previously reported.[11–16]

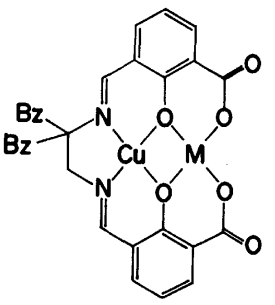

Fig. 1. The structure of hetero-metal binuclear complexes; M=Fe(III)Cl, Co(II), Ni(II), Cu(II), Zn(II), Mg(II), Ca(II), and Ba(II).

Experimental

Syntheses. 3-Formylsalicylic acid was prepared after the method of Duff and Bills.[17]

1,1-Dibenzylethylenediamine. An aqueous solution (20 cm^3) containing ammonium chloride (2.95 g), sodium cyanide (2.5 g) and ammonia water (28%, 7 cm^3) was placed in a round-bottomed flask, and to this was added an ethanolic solution (15 cm^3) of benzyl ketone (10.5 g). The flask was sealed with a rubber stopper and heated at 60 °C on a water bath for 5 hours to give an orange colored solution. The reaction mixture was shaken three times with 70 cm^3 portions of ether. The combined etherial solution was dried over sodium sulfate. Evaporation of the solvent left 2-amino-2-benzyl-3-phenylpropionitrile as pale orange solid. It was washed with a small amount of methanol and recrystallized from methanol to give colorless needles.

Found: C, 81.20; H, 7.02; N, 11.78%. Calcd for $C_{16}H_{16}N_2$: C, 81.32; H, 6.82; N, 11.85%.

This amino nitrile (15 g) was added to a suspension of $LiAlH_4$ (5 g) in absolute ether (250 cm^3). The mixture was stirred for 3 h at room temperature and then refluxed for 40 h on an oil bath. Unreacted $LiAlH_4$ was decomposed by addition of methanol–water (1: 1, 40 cm^3), while the flask was cooled by means of ice–water. The reaction mixture

was shaken with 150 cm³ portions of ether four times and the combined etherial solution was dried over sodium sulfate. On evaporating the solvent, there remained 1,1-dibenzylethylenediamine as a hygroscopic, yellow solid. It was used for the preparation of the complexes without further purification.

Cu(H₂fsadb)·H₂O. 3-Formylsalicylic acid (310 mg) and 1,1-dibenzylethylenediamine (270 mg) were dissolved in absolute methanol (40 cm³). To this solution was added a methanolic solution (20 cm³) of copper(II) acetate monohydrate (220 mg), and the mixture was refluxed for several hours to give purple crystalline solid. It was collected, washed with methanol and recrystallized from a mixture of *N,N*-dimethylformamide and water.

Found: C, 62.77; H, 4.49; N, 4.74; Cu, 12.3%. Calcd for $C_{32}H_{26}N_2O_6Cu \cdot H_2O$: C, 62.38; H, 4.55; N, 4.55; Cu, 12.24%.

CuFe(fsadb)Cl·1.5H₂O. This complex was synthesized as purplish brown prisms by reacting Cu(H₂fsadb)·H₂O (50 mg) and iron(III) chloride (14 mg) in methanol (20 cm³) in the presence of triethylamine.

Found: C, 53.68; H, 3.76; N, 3.80; Cu, 8.8; Fe, 8.2%. Calcd for $C_{32}H_{24}N_2O_6ClCuFe \cdot 1.5H_2O$: C, 53.79; H, 3.81; N, 3.92; Cu, 8.89; Fe, 7.82%.

CuCo(fsadb)·3H₂O. Cu(H₂fsadb)·H₂O (100 mg) was dissolved in a solution of lithium hydroxide monohydrate (16 mg) in methanol (40 cm³). The solution was once filtered to separate insoluble materials. To the red-colored filtrate was added a methanolic solution (10 cm³) of cobalt(II) acetate tetrahydrate (41 mg), and the mixture was heated at *ca.* 60 °C for a while. After the reaction mixture was left stand overnight, reddish orange needles which separated were collected, washed with water and dried under reduced pressure.

Found: C, 54.22; H, 4.12; N, 4.04; Co, 8.5; Cu, 8.8%. Calcd for $C_{32}H_{24}N_2O_6CoCu \cdot 3H_2O$: C, 54.20; H, 4.28; N, 3.95; Co, 8.31; Cu, 8.96%.

CuNi(fsadb)·6H₂O. This complex was obtained as reddish purple needles in the same way as that of CuCo(fsadb)·3H₂O except for using nickel(II) chloride hexahydrate (39.7 mg) instead of cobalt(II) acetate tetrahydrate.

Found: C, 50.28; H, 4.32; N, 3.59; Cu, 8.3; Ni, 8.0%. Calcd for $C_{32}H_{24}N_2O_6CuNi \cdot 6H_2O$: C, 50.38; H, 4.76; N, 3.67; Cu, 8.33; Ni, 7.69%.

CuCu(fsadb)·1.5H₂O. To a red solution of Cu(H₂fsadb)·H₂O (100 mg) and lithium hydroxide monohydrate (16 mg) in methanol (40 cm³) was added a methanolic solution (10 cm³) of copper(II) acetate monohydrate (37 mg). The mixture was heated at *ca.* 60 °C for 3 h to give pale green solid. It was collected and recrystallized from a mixture of *N,N*-dimethylformamide and water.

Found: C, 55.84; H, 4.01; N, 4.26; Cu, 18.6% Calcd for $C_{32}H_{24}N_2O_6Cu_2 \cdot 1.5H_2O$: C, 55.97; H, 3.96; N, 4.08; Cu, 18.51%.

CuZn(fsadb)·3H₂O. This complex was obtained as reddish orange needles in the same way as that of CuCo(fsadb)·3H₂O using zinc(II) chloride (22.8 mg). It was recrystallized from a chloroform–ether mixture.

Found: C, 53.34; H, 4.20; N, 3.86; Cu, 8.9%. Calcd for $C_{32}H_{24}N_2O_6CuZn \cdot 3H_2O$: C, 53.72; H, 4.23; N, 3.92; Cu, 8.88%.

CuMg(fsadb)·4H₂O. This complex was obtained as reddish pink needles in the same way as that of CuCo(fsadb)–3H₂O using magnesium(II) acetate tetrahydrate (36 mg). It was recrystallized from a chloroform–ether mixture.

Found: C, 55.75; H, 4.32; N, 3.93; Cu, 9.1%. Calcd for $C_{32}H_{24}N_2O_6CuMg \cdot 4H_2O$: C, 55.51; H, 4.66; N, 4.05; Cu, 9.18%.

CuCa(fsadb)·4H₂O. This complex was obtained as reddish pink needles by the reaction of Cu(H₂fsadb)·H₂O (100 mg) and calcium(II) chloride dihydrate (24.4 mg) in methanol (50 cm³) in the presence of lithium hydroxide monohydrate (16 mg).

Found: C, 54.34; H, 4.34; N, 4.01; Cu, 8.7%. Calcd for $C_{32}H_{24}N_2O_6CaCu \cdot 4H_2O$: C, 54.27; H, 4.55; N, 3.96; Cu, 8.97%.

CuBa(fsadb)·3.5H₂O. This complex was obtained as greenish purple needles by the reaction of Cu(H₂fsadb)·H₂O (100 mg) and barium(II) chloride dihydrate (41 mg) in the presence of lithium hydroxide monohydrate (16 mg).

Found: C, 48.20; H, 3.81; N, 3.59; Cu, 7.7%. Calcd for $C_{32}H_{24}N_2O_6BaCu \cdot 3.5H_2O$: C, 48.27; H, 3.92; N, 3.65; Cu, 7.98%.

Cu(saldb)·0.5H₂O. A mixture of salicylaldehyde (102 mg), 1,1-dibenzylethylenediamine (100 mg) and copper(II) acetate monohydrate (83 mg) in methanol (50 cm³) was heated under stirring for 3 h. The reaction mixture was allowed to stand overnight to give purple prisms, which were collected and dried *in vacuo*.

Found: C, 68.91; H, 5.60; N, 5.25; Cu, 12.3%. Calcd for $C_{30}H_{26}N_2O_2Cu \cdot 0.5H_2O$: C, 69.41; H, 5.24; N, 5.40; Cu, 12.24%.

Measurements. Elemental analyses of carbon, hydrogen, and nitrogen were carried out at the Service Center of Elemental Analysis, Kyushu University. Analyses of copper, cobalt, iron, and nickel were made with a Shimadzu Atomic Absorption-Flame Spectrometer Model AA-610S. Infrared spectra were measured with a Hitachi Infrared Spectrometer Model 215 on a KBr disk. Electronic Spectra were recorded on a Shimadzu Multipurpose Spectrophotometer Model MPS-5000 in dichloromethane or in *N,N*-dimethylformamide. Magnetic susceptibilities were measured by the Faraday method in the temperature range from liquid nitrogen temperature to room temperature. Diamagnetic correction was made using Pascal's constants.[18] Effective magnetic moments were calculated by the equation, $\mu_{eff}=2.828\times\sqrt{(\chi_M-N\alpha)T}$, where χ_M is the susceptibility per molecule. In the case of CuCu(fsadb)·1.5H₂O, the moment was calculated for one copper atom. Cyclic voltammograms were recorded with a Yanagimoto Voltammetric Analyzer Model P-1000 in dichloromethane or in *N,N*-dimethylformamide containing 0.1 M tetrabutylammonium perchlorate as the supporting electrolyte. A three-electrode cell was used for measurements, in which the working electrode is a glassy carbon, the auxiliary electrode a platinum coil, and the reference electrode a saturated calomel electrode. All the redox potentials were corrected by the use of ferrocene as an internal standard,[19] where the ferrocenium/ferrocene redox potential is assumed to be 0.400 V *vs.* NHE.[20]

Results and Discussion

Hetero-metal binuclear complexes were prepared by reacting the mononuclear copper(II) complex Cu(H₂fsadb)·H₂O with a metal ion. The formation of the hetero-metal complexes can be diagnosed by the presence of a strong band at 1550 cm⁻¹ attributable to the coordinated carboxylate group, while Cu(H₂fsadb)·H₂O exhibits a band at 1710 cm⁻¹ due to the free carboxyl group.

Magnetic susceptibilities of the complexes were measured in the temperature range 78—300 K. Magnetic moments of CuM(fsadb)·nH₂O (M=Co, Ni, Cu)

and CuFe(fsadb)Cl·1.5H_2O are temperature-dependent, indicating that a spin-exchange interaction operates between the metal ions. Magnetic properties of these complexes could be interpreted in terms of the magnetic susceptibility equations (1), (2), (3), and (4) for the (s=1/2)-(s=5/2),[21,22] (s=1/2)-(s=3/2),[13,14] (s=1/2)-(s=1),[10,13,14] and (s=1/2)-(s=1/2)[23] systems, respectively, on the basis of the Heisenberg model:

$$\chi_M = \frac{Ng^2\beta^2}{kT} \times \frac{5\exp(-6J/kT)+14}{5\exp(-6J/kT)+7} + N\alpha, \quad (1)$$

$$\chi_M = \frac{Ng^2\beta^2}{kT} \times \frac{2\exp(-4J/kT)+10}{3\exp(-4J/kT)+5} + N\alpha, \quad (2)$$

$$\chi_M = \frac{Ng^2\beta^2}{kT} \times \frac{\exp(-3J/kT)+2}{\exp(-3J/kT)+10} + N\alpha, \quad (3)$$

and

$$\chi_A = \frac{Ng^2\beta^2}{kT} \times \frac{1}{\exp(-2J/kT)+3} + N\alpha, \quad (4)$$

where χ_M and χ_A represent magnetic susceptibilities per molecule and per atom, respectively, and other symbols have their usual meanings. Best-fits of magnetic susceptibilities to the theoretical curves are shown in Figs. 2 and 3. Magnetic parameters thus determined are given in Table 1. The exchange integrals found for the present complexes are all negative, indicating antiferromagnetic spin-exchange interactions operating between the metal ions. Each integrals obtained is close to the value of corresponding hetero-metal complex of *N,N'*-bis(3-carboxysalicylidene)alkanediamine reported previously.[11-14,22] Magnetic moments of CuM(fsadb)·$n$$H_2O$ (M=Zn, Mg, Ca, Ba) fall in the range 1.83—1.88 BM at room temperature, which indicates the presence of one unpaired electron per molecule.

Conductance measurements revealed that the hetero-metal complexes are nonelectrolytes in *N,N*-dimethylformamide, suggesting the coordination of the second metal ion to the O_4-site.

Electronic spectra of the hetero-metal complexes were measured in dichloromethane. Because of the sparing solubility of CuCu(fsadb)·1.5H_2O in dichloromethane, the spectrum of this complex was measured in *N,N*-dimethylformamide. Some representatives of absorption spectra are shown in Fig. 4. Absorption maxima and

a) Data obtained by the measurements in *N,N*-dimethylformamide.

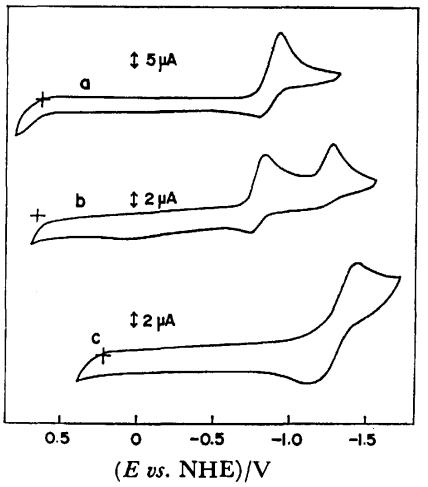

Fig. 5. Cyclic voltammograms of (a) $Cu(H_2fsadb)\cdot H_2O$ (in CH_2Cl_2), (b) $CuCu(fsadb)\cdot 1.5H_2O$ (in DMF), and (c) $CuMg(fsadb)\cdot 3H_2O$ (in CH_2Cl_2).

extinction coefficients of the ligand field bands are given in Table 2. The d-d band of $Cu(H_2fsadb)\cdot H_2O$ was observed at $17.8\times10^3\ cm^{-1}$ in dichloromethane and at $17.0\times10^3\ cm^{-1}$ in *N,N*-dimethylformamide. On the other hand, $CuCu(fsadb)\cdot 1.5H_2O$ shows two bands at 12.6×10^3 and $19.0\times10^3\ cm^{-1}$, which are assigned to the ligand field bands of the copper(II) ions bound at the O_4- and the N_2O_2-sites, respectively.[12] The spectrum of $CuCo(fsadb)\cdot 3H_2O$ is composed of the bands at 7.5×10^3, 16.2×10^3, 18.0×10^3, and $20.2\times10^3\ cm^{-1}$. The $20.2\times10^3\ cm^{-1}$ band is attributed to the $[CuN_2O_2]$ chromophore. The remaining bands can be ascribed to the $[CoO_6]$ chromophore,[14] which consists of four oxygen atoms of the ligand in the equatorial plane and of two water oxygens at apical positions. This is supported by the single-crystal X-ray analysis of $CuCo(fsaen)\cdot 3H_2O$.[24] Electronic spectrum of $CuNi(fsadb)\cdot 6H_2O$ can also be explained by the superposition of the d-d bands of the planar $[CuN_2O_2]$ and the $[NiO_6]$ chromophores. This is also supported by the X-ray analysis for $CuNi(fsaen)\cdot 3H_2O$.[25] In the cases of $CuFe(fsadb)Cl\cdot 1.5H_2O$ and $CuM(fsadb)\cdot nH_2O$ (M= Zn, Mg, Ca, Ba), no absorption was found in the region less than $18.0\times10^3\ cm^{-1}$. This is natural since high-spin iron(III) has no spin-allowed d-d transition and zinc(II), magnesium(II), calcium(II) and barium(II) ions have no ligand field band. It is likely that the second metal at the O_4-site takes a six-coordinate configuration with two water molecules.[26]

The d-d band due to the copper(II) ion in $CuFe(fsadb)Cl\cdot 1.5H_2O$ and $CuM(fsadb)\cdot nH_2O$ (M=Co, Ni, Cu, Zn, Mg) fall in the range 19.0×10^3—$21.4\times10^3\ cm^{-1}$, which is higher than $17.8\times10^3\ cm^{-1}$ of $Cu(H_2fsadb)\cdot H_2O$. Such a blue shift of the d-d band may be attributed to the increased planarity of the $[CuN_2O_2]$

chromophore on forming a binuclear complex with a second metal bridged by the phenolic oxygens.[26,27] On the other hand, the frequencies of the d-d bands of $CuCa(fsadb)\cdot 4H_2O$ and $CuBa(fsadb)\cdot 3.5H_2O$ are close to that of $Cu(H_2fsadb)\cdot H_2O$. It seems that this spectral feature is closely concerned with the configuration around the second metal ion at the O_4-site. Since iron(III), cobalt(II), nickel(II), copper(II), zinc(II) and magnesium(II) are small in size (ionic radii being less than 0.9 Å; Table 2), these metal ions can fit to the O_4-site to form a *trans*-octahedral configuration with water molecules at the apical positions.[24-26] On the other hand, calcium(II) and barium(II) are considerably large (radius being 1.14 and 1.50 Å respectively) so as to be forced to take a distorted structure such as *cis*-β-octahedral configuration when the metal ions bind at the O_4-site. This steric requirement may bring about the distortion of the CuN_2O_2 plane and hence the d-d bands of these complexes shift to a lower frequency compared with other hetero-metal binuclear complexes.

Electrochemical properties of the hetero-metal complexes were investigated by means of cyclic voltammetry in dichloromethane. In the case of $CuCu(fsadb)\cdot 1.5H_2O$ the measurement was carried out in *N,N*-dimethylformamide. Typical examples of cyclic voltammograms are shown in Fig. 5. Cathodic and anodic peaks, peak separations, and redox potentials ($E_{1/2}$) are given in Table 3. Cyclic voltammogram of $Cu(H_2fsadb)\cdot H_2O$ showed a Cu(II/I) redox wave at -0.86 V *vs.* NHE. Cyclic voltammogram of $CuCu(fsadb)\cdot 1.5H_2O$ (in *N,N*-dimethylformamide) was characterized by two redox waves at -0.80 and -1.24 V *vs.* NHE, indicating the difference in coordination environment between the two metal ions. Though the first redox potential is close to that of $Cu(H_2fsadb)\cdot H_2O$, we attributed the -0.80 V wave to the Cu(II/I) redox process of the copper at the O_4-site and the -1.24 V wave to the copper at the N_2O_2-site, on the grounds described below. Cyclic voltammogram of $CuFe(fsadb)Cl\cdot 1.5H_2O$ also reveals two redox waves at -0.27 and -1.29 V *vs.* NHE, which are tentatively assigned to the Fe(III/II) and the Cu(II/I) redox processes respectively. Only one redox wave was observed for other hetero-metal complexes at -1.28—-1.45 V *vs.* NHE. This is unambiguously attributed to the redox of the copper(II) bound at the N_2O_2-site. This adds a strong support for the electrochemical interpretations for $CuCu(fsadb)\cdot 1.5H_2O$ and $CuFe(fsadb)Cl\cdot 1.5H_2O$ described above.

It is noteworthy that the Cu(II/I) redox potentials for the hetero-metal complexes are very lower than that of $Cu(H_2fsadb)\cdot H_2O$. Recently, we have found that the reduction potential of the copper(II) ion of *N,N'*-disalicylidenealkanediaminatocopper(II) practically remains constant even when it forms a hetero-metal binuclear complex with a metal(II) halide, bridged by the phenolic oxygens.[28] Further, Gagne *et al.*[10] pointed out that the Cu(II)–M(II) complexes of a macrocycle (M=Mn, Fe, Co, Ni, Cu, Zn) show the Cu(II/I) redox at similar potentials, irrespective of second metal ions. Thus, the marked difference in the Cu(II/I) redox potential between the mononuclear and the hetero-metal binuclear complexes can not be attributed to the different coordination modes of the phenolic oxygen (simple coordination in the former and bridging in the latter). Since the peripheral substituents of the ligands are known to change the redox potential of the central metal in a striking manner,[29,30] it is likely that carboxyl and carboxylate groups differ in electronic effect on the redox potential of the copper(II) ion at the N_2O_2-site. In fact, *N,N'*-disalicylidene-1,1-dibenzylethylenediaminatocopper(II) $Cu(saldb)\cdot 0.5H_2O$, containing no carboxyl group on the ring, shows the Cu(II/I) redox wave at -1.36 V *vs.* NHE, which is more lower than that of $Cu(H_2fsadb)\cdot 1.5H_2O$ and comparable to those of the hetero-metal complexes. This implies that the electron-withdrawing effect of the carboxyl group diminishes the electron density on the phenolic oxygen and hence destabilizes the copper(II) oxidation state of $Cu(H_2fsadb)\cdot H_2O$ compared with $Cu(saldb)\cdot 0.5H_2O$. On the other hand, the electronic effect of the carboxyl group almost vanishes when it is deprotonated.[30] Thus, the substitution of a metal ion for the carboxyl protons of $Cu(H_2fsadb)\cdot H_2O$ may bring about the negative shift of the Cu(II/I) redox potential.

It is also noticed that the Cu(II/I) redox potential depends somewhat on the second metal ion. In the cases of $CuM(fsadb)\cdot nH_2O$ (M=Co, Ni, Zn, Mg) and $CuFe(fsadb)Cl\cdot 1.5H_2O$, the Cu(II/I) redox potentials fall in the range -1.27——-1.31 V *vs.* NHE, while the potentials of $CuCa(fsadb)\cdot 4H_2O$ and $CuBa(fsadb)\cdot 3.5H_2O$ are -1.42 and -1.45 V *vs.* NHE respectively. We presume that the bonding between the phenolic oxygen and calcium(II) or barium(II) ion is practically ionic. On the other hand, the bonding between the phenolic oxygen and the second metal ion of $CuM(fsadb)\cdot nH_2O$ (M=Co, Ni, Cu, Mg, Zn) and $CuFe(fsadb)Cl\cdot 1.5H_2O$ must contain some covalent character. This might result in the decrease in electron density on the phenolic oxygens and hence the positive shift of the Cu(II/I) redox potential compared with those of $CuCa(fsadb)\cdot 4H_2O$ and $CuBa(fsadb)\cdot 3.5H_2O$.

(Received August 27, 1981)

A platinum(II)complex containing a 2,4-pentanedionate dianion as a trihapto ligand [Pt(acac(2−)-C^1—C^3)-{P(p-ClC_6H_4)$_3$}$_2$] was prepared by the reaction of [Pt(acac)$_2$] with tris(p-chlorophenyl)phosphine and reacted with pyridinium perchlorate to afford [Pt(acac-C^1)(py){P(p-ClC_6H_4)$_3$}$_2$](ClO_4). A similar terminal-carbon-bonded complex of 1,1,1-trifluoro-2,4-pentanedionate monoanion with platinum(II) was also derived from [Pt(tfac(2−)-C,O)($AsPh_3$)$_2$] by the reaction with pyridinium perchlorate. These novel platinum(II) complexes were characterized mainly by IR and NMR spectroscopy.

2,4-Pentanedione and other β-dicarbonyl compounds are very popular ligands,[1] and widely used as a chelating monoanion.[2] Recently coordination chemistry of their dianions has been greatly advanced and at present seven coordination modes illustrated in Fig. 1 are known. This paper reports a platinum(II) complex of type **5** containing a trihapto 2,4-pentanedionate dianion (acac-(2−)-C^1—C^3) as well as the first examples of platinum (II) complexes containing the terminal-carbon-bonded acac and 1,1,1-trifluoro-2,4-pentanedionate (tfac) monoanions.

Experimental

Preparation. The starting chelates bis(2,4-pentanedionato)platinum(II), [Pt(acac)$_2$] and bis(1,1,1-trifluoro-2,4-pentanedionato)platinum(II), [Pt(tfac)$_2$] were prepared by the method reported recently.[12] Tris(p-chlorophenyl)phosphine was purchased and used without further purification. 1,1,1-Trifluoro-2,4-pentanedionato(2-)-C,O-bis(triphenylarsine)platinum(II), [Pt(tfac(2-)-C,O)($AsPh_3$)$_2$] was prepared by the reaction of [Pt(tfac)$_2$] with triphenylarsine.[9] Pyridinium perchlorate was prepared by adding concentrated perchloric acid dropwise to a dichlotomethane solution of pyridine kept in an ice bath and a white precipitate dried *in vacuo* was recrystallized from ethanol. Found: C, 33.29; H, 3.39; N, 7.78%. Calcd for [pyH]ClO_4=$C_5H_6O_4NCl$: C, 33.45; H, 3.37; N, 7.80%. The compound is hygroscopic.

η^3-1-Acetyl-2-oxoallylbis {tris(p-chlorophenyl)phosphine} platinum-(II), [Pt(acac(2-)-C^1—C^3){P(p-ClC_6H_4)$_3$}$_2$] (8): When tris-(p-chlorophenyl)phosphine (1.086 g, 2.97 mmol) was added to a chloroform solution (2 cm^3) of [Pt(acac)$_2$] (584 mg, 1.48 mmol) with stirring under nitrogen, color of the solution changed from yellow to red. After being left to stand for 10 h, the solvent was removed under reduced pressure to leave a red oil, which changed to a yellow solid on prolonged pumping. The product was pulverized and treated with a mixture of dichloromethane (5 cm^3) and hexane (30 cm^3). A pale yellow powder, which remained undissolved, was filtered and dissolved in dichloromethane (10 cm^3). Hexane (30 cm^3) was added to the solution and the mixture was left to stand, depositing a white crystalline solid, which was filtered, washed with small portions of methanol and diethyl ether, and dried *in vacuo*. The yield was 769 mg (49%). Dec temp 190—210 °C. Inclusion of one molecule of water and one fourth molecule of dichloromethane per metal atom was confirmed by ^{1}H NMR spectroscopy. Found: C, 46.68; H, 3.07%. Calcd for $C_{41.25}H_{32.5}O_3P_2Cl_{6.5}Pt$: C, 46.58; H, 3.08%. Recrystallization from pyridine–diethyl ether gave a white crystalline solid which contained one molecule of water and a half molecule of pyridine per metal atom. Found: C, 48.43; H, 3.38; N, 0.53%. Calcd for $C_{43.5}H_{34.5}N_{0.5}O_3P_2Cl_6$: C, 48.29; H, 3.21; N, 0.65%. The former specimen was used for spectral measurements and reaction studies.

2, 4-Pentanedionato-C^1-(pyridine) bis{tris(p-chlorophenyl) phosphine} platinum(II). Perchlorate, [Pt(acac-C^1)(py){P(p-ClC_6H_4)$_3$}$_2$]ClO_4 (9a): An acetone solution (2 cm^3) of pyridinium perchlorate (55 mg, 0.31 mmol) was added to a dichloromethane solution (1 cm^3) of **8** (126 mg, 0.118 mmol) and the mixture was heated to 40 °C with stirring for 5 min. Undissolved portion of the pyridinium salt was filtered and the filtrate was left standing overnight at ambient temperature to make the solvent evaporate spontaneously. White needles left on the wall of vessel were recrystallized from dichloromethane–hexane to afford white needles (96 mg) in a 64%

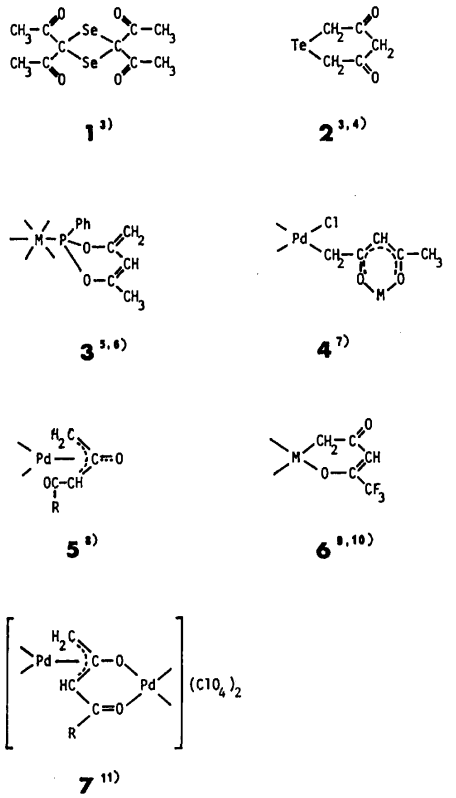

Fig. 1. Bonding modes of β-diketonate dianions in metal complexes.

yield. Dec temp 190—200 °C. Inclusion of three fourths molecule of dichloromethane as the solvent of crystallization was confirmed by ^{1}H NMR spectroscopy. Found: C, 44.31; H, 2.95; N, 1.14%. Calcd for $C_{46.75}H_{37.5}NO_6P_2Cl_{8.5}Pt$: C, 44.29; H, 2.98; N, 1.10%.

Measurements. Infrared spectra were obtained in Nujol mull with a Hitachi 295 infrared spectrophotometer. NMR spectra were recorded on JEOL FX-60Q (for ^{1}H and ^{13}C) and FX-90Q (for ^{31}P and ^{195}Pt) instruments.

Results and Discussion

Trihapto Complex of the 2,4-Pentanedionate Dianion with Platinum(II). The reaction of [Pt(acac)$_2$] with twice molar P(*p*-ClC$_6$H$_4$)$_3$ under a very mild condition gave a platinum(II) complex containing a 2,4-pentanedionate dianion as a ligand, [Pt(C$_5$H$_6$O$_2$){P(*p*-ClC$_6$H$_4$)$_3$}$_2$]·H$_2$O·S (**8**) (S = 1/4CH$_2$Cl$_2$ or 1/2py depending on the solvent of recrystallization, which could not be removed by pumping). The infrared spectra in the 1700—1500 cm^{-1} region are quite similar to those of [Pd(acac(2−)-*C*^{1}—*C*^{3})(NN)] (NN=bpy (**5a**), 4,4′-Me$_2$bpy, and phen)[8] and [Pd(acac(2−)-*C*^{1}—*C*^{3})(PP)] (PP=Ph$_2$PCH$_2$CH$_2$PPh and Ph$_2$PCH=CHPPh$_2$(**5b**)),[11]

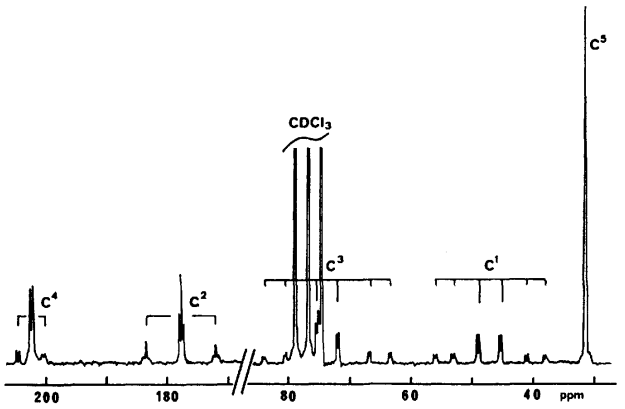

Fig. 2. ^{13}C{^{1}H}NMR spectrum at 15.0 MHz of [Pt(acac(2−)-*C*^{1}—*C*^{3}){P(*p*-ClC$_6$H$_4$)$_3$}$_2$]·H$_2$O·1/4CH$_2$Cl$_2$ (**8**) in CDCl$_3$ with Me$_4$Si as an internal reference. Signals of the phenyl carbons are omitted.

exhibiting a medium ν(C=O) band at 1650 cm^{-1} and a very strong and broad band at 1548 cm^{-1} assignable to the ν(C···O) and/or ν(C···C) vibration.

Figure 2 shows the ^{13}C{^{1}H} NMR spectrum of **8**. Assignment of the three sets of higher-field signals to the methyl, methylene, and methine carbons was made on the basis of the ^{1}H off-resonance data and listed in Table 1. Except the highest-field signal assignable to the methyl carbon, all carbons of the acac(2−) ligand couple to ^{31}P atom(s) and are flanked by the ^{195}Pt satellites. The methylene and methine carbons couple much more strongly to the ^{31}P atom situated at the *trans* position than to the *cis* ^{31}P atom, both appearing as a doublet of doublets. On the other hand, the central carbonyl carbon (C^2) resonates as a triplet, indicating that the coupling constants to both ^{31}P atoms are nearly equal in spite of their environmental nonequivalence (*vide infra*). The other carbonyl carbon (C^4) is remote from the coordination sites and weakly couples only to the *trans* ^{31}P. The fact that the J(Pt–C) values are much larger for C^1, C^2, and C^3 than for C^4 strongly supports the proposed trihapto structure, and the chemical shifts of C^1 and C^3 are well in accord with those recorded for other η-allylic systems.[13] The central carbon of the η-allyl moiety usually resonates at about 100 ppm,[13] but substitution of a proton bonded to a carbon atom with a hydroxyl group is generally known to shift the carbon resonance to 36—51 ppm lower field.[14] Now substitution with oxo anion causes downfield shift by about 80 ppm and the shielding of C^2 (177.8 ppm) nearly coincides with those of **5a** (180.5 ppm)[8] and **5b** (177.0 ppm).[11]

The ^{1}H NMR spectrum of **8** is composed of signals at 1.31 (CH$_3$), 1.97 (H$_2$O), 2.2—4.7 (CH$_2$ and CH), 5.30 (CH$_2$Cl$_2$), and 7.3 (phenyl protons) ppm with the relative intensities 3 : 2 : 3 : 0.5 : *ca.* 30 (Table 1). The signals at 1.97 and 5.30 ppm were assigned to solvents of crystallization since they increased their intensities on addition of water and dichloromethane, respectively. The signals in the 2.2—4.7-ppm region are complex because of coupling of CH$_2$ and CH protons to ^{31}P and ^{195}Pt atoms, and are divided into three groups of which two are flanked by ^{195}Pt satellites: a broad multiplet

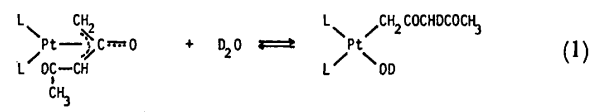
a) Chemical shift (δ) in ppm from internal Me$_4$Si and coupling constant (J) in Hz.

at 2.55 ppm (H^c), a multiplet at 2.91 ppm (H^b, J(Pt–H) =*ca.* 70 Hz), and a broad doublet at 4.22 ppm (H^a, J(Pt–H)=35 Hz). The ^{1}H NMR spectra of **5a** and related complexes are much more simpler due to lack of couplings to P and Pt atoms and were assigned unequivocally.[8] By reference to these data, the doublet at 4.22 ppm is assigned to the methine proton H^a, of which coupling to H^c demonstrates that the dangling acetyl moiety occupies the anti position of the η-allylic skeleton, making the H^a and H^c protons accord with the so-called W rule.[15]

When one drop of D_2O was added to a $CDCl_3$ solution of **8**, the signal at 1.97 ppm diminished at once and the one at 4.22 ppm decreased remarkably on stirring of the mixture overnight. The *ca.* 3 Hz coupling which had been observed for the multiplet at 2.55 ppm also disappeared on D_2O addition. These results indicate that the signal at 4.22 ppm is assigned to an exchangeable unique proton H^a. Partial decoupling of the signal at 2.55 ppm by deuteration of H^a also accords with the proposed structure. The fact that the ^{13}C signal from the methine carbon (C^3) at 73.8 ppm was remarkably diminished by the D_2O treatment also certifies that the methine proton was deuterated. As to the mechanism of methine deuteration, an intermediate containing the terminal-carbon-bonded acac ligand of keto form must be presumed.



(1)

Since the terminal-carbon-bonded acac ligand contained in the stable Pt(II) complex **9a** (*vide infra*) is composed almost of the enol tautomer, the intermediate containing the unidentate keto acac presumed in Eq. 1 may be far less stable, and this situation might be the reason why the deuteration reaction is so slow.

Assignment of the multiplet signals centered at 2.55 and 2.91 ppm to the syn (H^c) and anti (H^b) protons, respectively, was made by reference to data for **5a**. The ^{1}H{^{31}P} NMR data for [Pt($C_5H_6O_2$)(PPh_3)$_2$] reported by Ito and Yamamoto[16] were also very helpful. They obtained the complex from the reaction of [Pt(acac)$_2$] with twice molar PPh_3 in refluxing THF and tentatively presumed a π-oxoallylic coordination.

Figure 3 shows the ^{31}P{^{1}H} NMR spectrum of complex **8** in $CDCl_3$. Main signals appear as an AB quartet at 18.6_3 and 19.2_8 ppm downfield from external H_3PO_4 with ^2J(P–P)=7 Hz. Both signals are flanked by ^{195}Pt satellites, ^1J(Pt–P) being $2.88_4\times10^3$ and $3.18_6\times10^3$ Hz, respectively. The spectrum indicates that the two phosphorus atoms are not equivalent but the difference in their environments is slight, since differences in the chemical shifts and ^1J(Pt–P) values are small. Unequivocal discrimination of phosphorus atoms is not easy, but the signal at 19.2_8 ppm with larger ^1J(Pt–P) value may be assigned to P^2 situated at the site *trans* to C^3, since the dangling acetyl moiety is electron attracting and the acetonyliden group will exert slightly smaller *trans* influence than the unsubstituted methylene end (C^1).

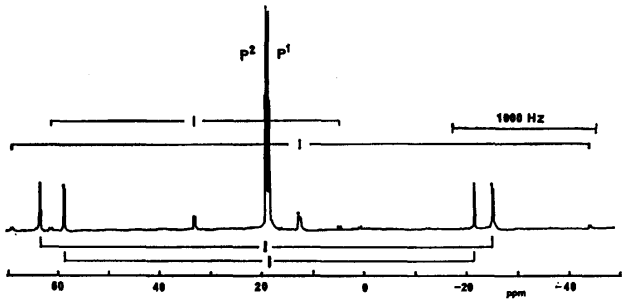


Fig. 3. ^{31}P{^{1}H}NMR spectrum at 36.3 MHz of [Pt(acac(2−)-C^1—C^3){P(p-ClC_6H_4)$_3$}$_2$]·H_2O·1/4CH_2Cl_2 (**8**) in $CDCl_3$ with H_3PO_4 as an external reference.

As is noticed in Fig. 3, the spectrum involves another AB quartet at 12.6_7 and 33.1_4 ppm with ^2J(P–P)=11 Hz, indicating contamination with a minor product which also contains two nonequivalent phosphine ligands. The ^1J(Pt–P) values are $4.06_0\times10^3$ and $2.03_4\times10^3$ Hz, respectively, of which the difference is large, suggesting a large difference in the environments of two phosphorus atoms situated at mutually *cis* positions. The pattern of the minor signals resembles closely to the ^{31}P{^{1}H} spectrum of [Pt(tfac(2−)-C,O)L_2] which contains a C,O-chelated 1,1,1-trifluoro-2,4-pentanedionate dianion with PPh_3 or P(p-ClC_6H_4)$_3$ as L (**6a**).[9] Thus the minor product is presumed to be [Pt(acac(2−)-C,O){P(p-ClC_6H_4)$_3$}$_2$] which is an isomer of **8**. Relative intensities of signals in Fig. 3 suggest that content of the minor product is less than 10% and could not be detected in ^{13}C{^{1}H} and other NMR spectra, whereas [Pd(acac(2−)-C^1—C^3)(NN)] (NN=bpy, 4,4′-Me_2bpy, and phen) contained [Pd(acac(2−)-C,O)-(NN)] in 20—25% proportions which were determined by ^{1}H NMR spectroscopy.[8] Isolation of the minor isomers has not been successful for either of the Pd(II) and Pt(II) complexes and it is not certain whether the isomerization equilibria are attained in solution or both isomers are inert, preserving the products ratio under the conditions of preparation.

The ^{195}Pt{^{1}H} NMR spectrum at 19.2 MHz of **8** in $CDCl_3$ was observed as a doublet of doublets at 3373.5 ppm upfield from external $K_2[PtCl_4]$. The coupling constants ^1J(Pt–P) to the two phosphorus atoms are $2.88_6\times10^3$ and $3.18_9\times10^3$ Hz, showing excellent agreement with the values obtained from the ^{31}P{^{1}H} NMR spectroscopy (*vide supra*).

It is surprising that the reaction of [Pt(acac)$_2$] with P(p-ClC_6H_4)$_3$ to produce **8** proceeds under a very mild condition. Comprehensive studies have been carried out on the reactions of [M(β-dik)$_2$] (M=Pd(II) and Pt(II)) with nitrogen bases[17] and tertiary phosphines.[18] The ^{1}H NMR spectroscopy revealed that the reaction of [Pt(tfac)$_2$] with twice molar PPh_3 in $CDCl_3$ produces [Pt(tfac)(PPh_3)$_2$](tfac) at first, which is then transformed into [Pt(tfac(2−)-C,O)(PPh_3)$_2$]. The tfac anion in the outer sphere seems to abstract a proton from the chelating tfac ligand, whereas the corresponding Pd(II) complex salt [Pd(tfac)(PPh_3)$_2$](tfac) is stable in solution and deprotonated only by added bases such as pyridine and its derivatives.[10] In the present case, changes of ^{1}H and ^{13}C NMR spectra during the reaction of

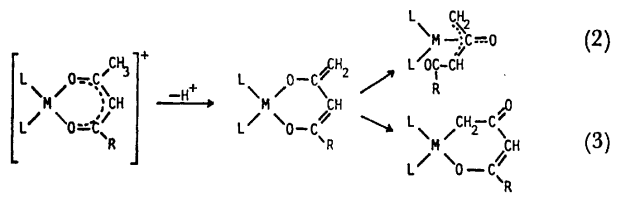
a) Same as footnote a) for Table 1. Q=quartet. b) J(H–H)=5 Hz. c) Indistinguishable because of overlapping. d) Not recorded due to insufficient scans.

$[Pt(acac)_2]$ with twice molar PPh_3 in $CDCl_3$ were complex and could not be analyzed satisfactorily. However intermediate formation of $[Pt(acac)(PPh_3)_2]$-(acac) is evidenced by isolation in high yields of $[Pt(acac)(PPh_3)_2]X$ (X=BPh_4[19] and ClO_4[20]) on addition of NaX.

Deprotonation of the chelating β-diketonate ligand will produce a complex of type **3** primarily. Although such a dienediolate type bonding of acac(2–) was found for $[(\eta\text{-}C_5H_5)(CO)_2Mn\{PPh(C_5H_6O_2)\}]$[5] and $[(CO)_5M\{PPh(C_5H_6O_2)\}]$ (M=Cr and W),[6] analogous complex of transition metals has not been reported. In the present Pd(II) and Pt(II) cases, complexes of type **3** are not stable, but transformed either to the trihapto coordination or to *C,O*-chelation. The tfac(2–) ligand carrying the electron-attracting trifluoromethyl group prefers *C,O*-chelation in both Pd(II)[10] and Pt(II)[9]



(2)

(3)

complexes, while the dianion of ethyl acetoacetate carring the electron-releasing ethoxyl group affords the trihapto Pd(II) complexes exclusively.[8] The acac(2–) ligand exhibits an intermediate behavior, producing the trihapto complexes accompanied by a small amount of *C,O*-chelate.

Terminal-carbon-bonded Complexes of the β-Diketonate Monoanions with Platinum(II). Terminal-carbon-bonded complexes of 2,4-pentanedionate[21] and 1-ethoxy-1,3-butanedionate (etac)[22] monoanions with palladium(II) were derived from the corresponding trihapto complexes $[PdCl(\eta^3\text{-}\beta\text{-dik})]_2$, where β-dik is acac[21] and etac,[23] respectively. Trihapto complexes of β-diketonate monoanions with platinum(II) have not yet been obtained and thus the terminal-carbon-bonded β-dik complexes with platinum(II) are not known either.

Now the reaction of **8** with pyridinium perchlorate in a mixture of dichloromethane and acetone gave $[Pt(acac\text{-}C^1)(py)\{P(p\text{-}ClC_6H_4)_3\}_2]\cdot 3/4CH_2Cl_2$ (**9a**), which is the first example of the terminal-carbon-bonded acac complex with platinum(II). Figure 4 shows ^1H and ^{13}C NMR spectra of **9a** in $CDCl_3$ and results of the signal analysis are listed in Table 2. The

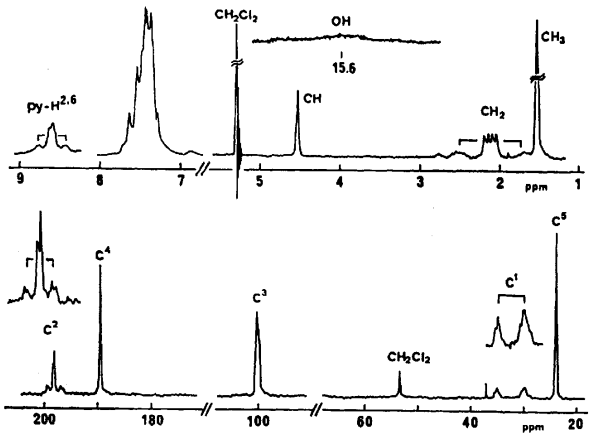


Fig. 4. ^1H and $^{13}C\{^1H\}$ NMR spectra at 100 and 15.0 MHz, respectively, of $[Pt(acac\text{-}C^1)(py)\{P(p\text{-}ClC_6H_4)_3\}_2]ClO_4\cdot 3/4CH_2Cl_2$ (**9a**) in $CDCl_3$ with Me_4Si as an internal reference. In the ^1H NMR spectrum, intensity of the ring protons except py-$H^{2,6}$ is decreased to *ca.* 1/4 and that of OH is increased about four times. In the ^{13}C NMR spectrum, signals of all ring carbons are omitted.

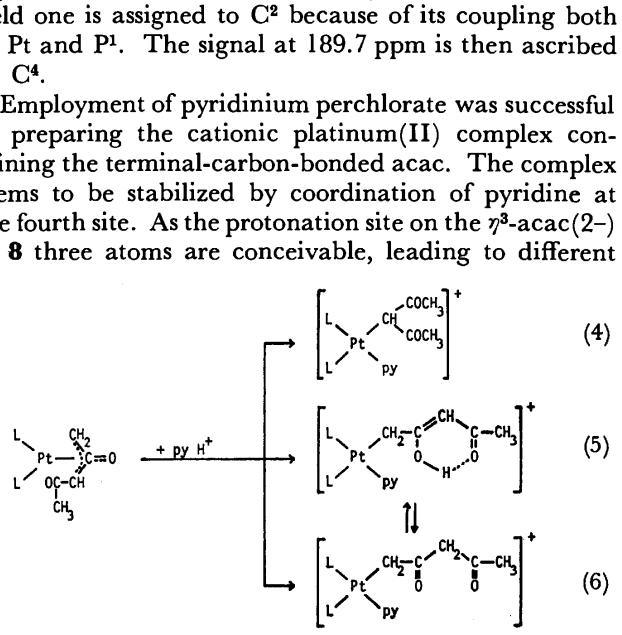
proton signal at 2.11 ppm appearing as a doublet of doublets flanked by ^{195}Pt satellites with a large J(Pt–H) value is assigned to the methylene group bonded to platinum(II). The signal multiplicity indicates unequivocally that **9a** has a *cis* configuration. No other methylene signal is observed, but instead a methine signal and a broad OH signal are observed, indicating that the terminal-carbon-bonded acac ligand is composed mainly of the enol tautomer. The coupling constant of the methine protons to ^{195}Pt is smaller than that in [Pt(acac)$_2$] (^4J(Pt–H) = 10.7 Hz)[24] in accordance with the unidentate state. Coordination of pyridine is demonstrated by the fact that the signal from the ring protons adjacent to nitrogen is flanked by the ^{195}Pt satellites.

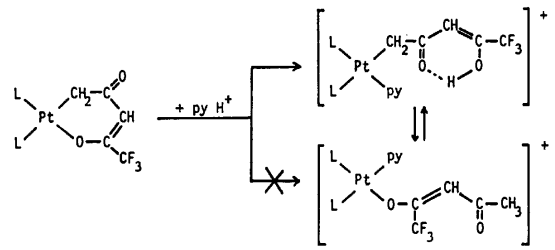
It is worth noting that keto tautomer of **9a** is not detected on the ^{1}H NMR spectrum. The equilibrium quotient Q=[enol]/[keto] for [PdCl(acac-C^1)(bpy)] was reported to be 0.7 in $CDCl_3$ at 25 °C.[21] This value is smaller than 6.7 for free acacH molecules in $CDCl_3$ at 33 °C[25] and the PdCl(bpy)$^+$ moiety was considered to be electron releasing,[21] since an electron-attracting substituent on acacH increases Q, while an electron-releasing substituent exerts the opposite effect. Thus Q is 32 for tfacH and 0.43 for 3-methyl-acacH as neat liquids at 33 °C.[26] Now the Pt(py){P(p-ClC$_6$H$_4$)$_3$}$_2^{2+}$ moiety is functioning as a powerful electron-attracting substituent comparable to the trifluoromethyl group. The remarkable discrepancy in behaviors of this and PdCl(bpy)$^+$ moieties may arise from the difference in charge densities at the central metals, since Pt is coordinated with three neutral ligands of which two are π accepting, whereas Pd is bonded to a chloride anion and 2,2′-bipyridine which is a weaker π-acceptor than phosphines.[27]

The ^{13}C{^{1}H} NMR spectrum of **9a** accords well with the proposed structure. The methylene carbon bonded to the metal appears as a broad doublet in accordance with the *cis* structure, the ^2J(P^1–C) being 70 Hz and ^2J(P^2–C) indiscernibly small. Of the two signals attributable to the carbonyl carbons, the lower field one is assigned to C^2 because of its coupling both to Pt and P^1. The signal at 189.7 ppm is then ascribed to C^4.

Employment of pyridinium perchlorate was successful in preparing the cationic platinum(II) complex containing the terminal-carbon-bonded acac. The complex seems to be stabilized by coordination of pyridine at the fourth site. As the protonation site on the η^3-acac(2−) in **8** three atoms are conceivable, leading to different products (Eqs. 4—6). If a proton adds to the terminal methylene, the central-carbon-bonded complex will be resulted (Eq. 4). On the other hand, addition of a proton to the methine carbon will give rise to a complex of the terminal-carbon-bonded keto tautomer of acac (Eq. 6). Either of these two was not the case, but reaction 5 was predominant, indicating that the proton affinity is highest at the enolate oxygen atom.



When an equimolar amount of pyridinium perchlorate was added to a solution of [Pt(tfac(2−)-C,O)(AsPh$_3$)$_2$]·1/4CH$_2$Cl$_2$[9] in $CDCl_3$, [Pt(tfac-C^1)(py)(AsPh$_3$)$_2$]ClO$_4$ (**9b**) was produced quantitatively as evidenced by ^{1}H and ^{13}C NMR spectra listed in Table 2, although its isolation was not successful. The tautomerization equilibrium of the terminal-carbon-bonded tfac in **9b** is also shifted to enol completely. Protonation did not occur at the terminal carbon, but occurred at the enolate oxygen.



We wish to thank Mr. Junichi Gohda for elemental analyses. S. O. and S. K. are grateful to the Ministry of Education, Science and Culture for Grant-in-Aid for Scientific Research, Nos. 454196 and 243014, respectively.

Dinuclear Palladium(II) Complexes Containing Anilide Anions as Bridging Ligands

Seichi OKEYA,* Hisako YOSHIMATSU, Yukio NAKAMURA,† and Shinichi KAWAGUCHI*,†

(Received August 27, 1981)

The reactions of $[Pd(hfac)_2]$ with aniline and its derivatives (L) in benzene at room temperature afforded $[Pd(hfac)(hfac\text{-}C^3)L]$, $[Pd(hfac)L_2](hfac)$, and $[PdL_4](hfac)_2$ depending on the reactants mole ratio. On the other hand, the reactions of various $[Pd(\beta\text{-dik})_2]$ complexes with L in refluxing benzene (in most cases) gave rise to the anilide-bridged dinuclear complexes $[Pd(\beta\text{-dik})(L-H)]_2$, which in turn reacted with primary amines and pyridine (L′) to produce $[PdL'_2(L-H)]_2(\beta\text{-dik})_2$.

Comprehensive investigations on the reactions of bis(β-diketonato)palladium(II) and -platinum(II), $[M(\beta\text{-dik})_2]$ (**1**), with various nitrogen bases[1] and tertiary phosphines[2] have revealed that the chelating β-diketonate anions are readily converted into other bonding states, affording a series of complexes, $[M(\beta\text{-dik})_2L]$ (**2**), $[M(\beta\text{-dik})(\beta\text{-dik-}O)L]$ (**3**), $[M(\beta\text{-dik})L_2](\beta\text{-dik})$ (**4**), $[ML_4](\beta\text{-dik})_2$ (**5**), $[M(\beta\text{-dik-}O)_2L_2]$ (**6**), $[M(\beta\text{-dik})(\beta\text{-dik-}C^3)L]$ (**7**), and $[M(\beta\text{-dik-}C^3)_2L_2]$ (**8**) depending on the natures of the metal, β-dik, and Lewis base (L). Here, β-dik, β-dik-*O*, and β-dik-C^3 in the coordination sphere represent the chelating, O-unidentate, and central-carbon-bonded states, respectively, β-dik in the outer sphere acting as a counter anion.

Characteristics of β-diketones (β-dikH) in keto-enol tautomerization and acid dissociation as well as the basicities and steric requirements of Lewis bases are the most important factors influencing the preference of bonding modes. Less basic β-dik ligands are readily displaced by L to outer sphere, while the keto-favorable β-dik anions prefer the carbon bonding. Thus, 1,1,1,5,5,5-hexafluoro-2,4-pentanedione (hfacH), which exists solely as enol and is strongly acidic, has not given the carbon-bonded complexes **7** and **8**.[1,2]

This paper reports the reactions of $[Pd(\beta\text{-dik})_2]$ with aniline and its derivatives which afford complexes **7** as well as **4** and **5** at room temperature and the anilide-bridged dinuclear complexes at higher temperatures. Dialkylamide and disilylamide complexes of early transition metals are well-known[3] but those of the d^8 metals are rather scanty, and the amide-bridged dinuclear palladium(II) complexes reported in this paper are the first examples.

Experimental

Preparation of Complexes. The starting bis(β-diketonato)-palladium(II) complexes were prepared by the methods reported recently.[4] Aniline and its derivatives were used as supplied without further purification but some samples which had been stored for a good while were purified by the method analogous to that employed for purification of aniline.[5]

*Bis(aniline)(1,1,1,5,5,5-hexafluoro-2,4-pentanedionato)palladium(II) 1,1,1,5,5,5-Hexafluoro-2,4-pentanedionate–Benzene (2/1), $[Pd(hfac)(C_6H_5NH_2)_2](hfac)\cdot 1/2C_6H_6$ (**4a**)*: On addition of a benzene solution (1 cm³) of aniline (233 mg, 2.50 mmol) to a solution of $[Pd(hfac)_2]$ (**1a**) (325 mg, 0.624 mmol) in benzene (5 cm³), color of the solution changed immediately from orange yellow to red and orange crystallites began to deposit. After being left overnight, the crystals were filtered, washed with petroleum ether (bp<50 °C) and dried *in vacuo*. The product (306 mg) was recrystallized from hot benzene. The final yield of red-orange plates was 237 mg (51%). Hexane was added to the filtrate and the mixture was left to stand for a week. Yellow plates deposited were filtered, washed with a mixture (1:1 by volume) of benzene and hexane, dried *in vacuo* and characterized to be $[Pd(C_6H_5NH_2)_4](hfac)_2$ (**5a**), of which the yield was 124 mg (22%).

*$[Pd(hfac)(2,5\text{-}(CH_3)_2C_6H_3NH_2)_2](hfac)$ (**4b**)*: Hexane (1 cm³) was added to a mixture of **1a** (89 mg, 0.17 mmol) and 2,5-dimethylaniline (41 mg, 0.34 mmol) in benzene (2.5 cm³) and the solvent mixture was allowed to vaporize spontaneously to leave an orange-red crystalline solid, which was washed with petroleum ether and dried *in vacuo*. The yield was 14 mg (11%).

*$[Pd(hfac)(2,6\text{-}(CH_3)_2C_6H_3NH_2)_2](hfac)\cdot H_2O$ (**4c**) and $[Pd(hfac)(3,5\text{-}(CH_3)_2C_6H_3NH_2)_2](hfac)$ (**4d**)*: Orange crystallites of **4c** and orange-red plates of **4d** were obtained in 88 and 92% yields, respectively, by the reactions of **1a** with twice molar amounts of 2,6- and 3,5-dimethylanilines in benzene at room temperature.

*$[Pd(hfac)(2,4,6\text{-}(CH_3)_3C_6H_2NH_2)_2](hfac)\cdot H_2O$ (**4e**)*: A benzene solution (6 cm³) containing **1a** (322 mg. 0.619 mmol) and 2,4,6-trimethylaniline (168 mg, 1.24 mmol) was heated under reflux for 2.5 h and then concentrated to 1 cm³ by evaporation under reduced pressure. After being left overnight at room temperature, big orange crystals were filtered, washed with petroleum ether, and dried *in vacuo*. The yield was 339 mg (68%).

*$[Pd(hfac)(3\text{-}CF_3C_6H_4NH_2)_2](hfac)$ (**4f**)*: Hexane (0.2 cm³) was added to a benzene solution (1 cm³) containing **1a** (40 mg, 0.077 mmol) and 3-(trifluoromethyl)aniline (91 mg, 0.56 mmol) and the mixture was kept in a refrigerator to deposit orange plates (42 mg) in a 65% yield.

*Tetrakis(aniline)palladium(II) 1,1,1,5,5,5-Hexafluoro-2,4-pentanedionate, $[Pd(C_6H_5NH_2)_4](hfac)_2$ (**5a**)*: Pale yellow plates of **5a** were obtained by addition of hexane (1 cm³) to a mixture of **1a** (55 mg, 0.11 mmol) and aniline (77 mg, 0.83 mmol) in benzene (1.5 cm³). The crystals lost lattice solvent to turn opaque on being dried *in vacuo*. The yield was 68 mg (72%).

*$[Pd(2\text{-}CH_3C_6H_4NH_2)_4](hfac)_2$ (**5b**)*: When a solution (0.5 cm³) of 2-methylaniline (27 mg, 0.25 mmol) in diethyl ether was added to a solution (0.5 cm³) of **1a** (35 mg, 0.067 mmol) in the same solvent, color of the solution changed from orange to orange red, depositing yellow crystals, which were filtered, washed with diethyl ether and air-dried. The yield was 55 mg (86%). Recrystallization was performed from dichloromethane–petroleum ether.

*$[Pd(4\text{-}CH_3C_6H_4NH_2)_4](hfac)_2$ (**5c**)*: 4-Methylaniline (98 mg, 0.91 mmol) was added to a suspension of **1a** (97 mg,

0.19 mmol) in benenze (1 cm³) to result in a clear orange solution and deposit soon a pale yellow precipitate, which was filtered, washed with benzene and dried *in vacuo*. The yield was 90 mg (51%). Recrystallization from dichloromethane gave yellow plates.

[Pd(2,4-(CH₃)₂C₆H₃NH₂)₄](hfac)₂ (5d), *[Pd(2,5-(CH₃)₂C₆H₃NH₂)₄](hfac)₂ (5e)*, *and [Pd(3,5-(CH₃)₂C₆H₃NH₂)₄](hfac)₂ (5f)*: A benzene solution (2 cm³) of **1a** (74 mg, 0.14 mmol) and 2,4-dimethylaniline (66 mg, 0.54 mmol) was allowed to stand overnight to produce yellow crystals of **5d**. The yield was 91 mg (64%). When 2,5- or 3,5-dimethylaniline was used as a base, a benzene solution containing **1a** and each of these anilines in the mole ratio of 1 : 4 was left at room temperature until the solvent vaporized spontaneously to leave a yellow crystalline solid of **5e** or yellow plates of **5f** in an 85 or 57% yield, respectively.

2,6-Dimethylaniline(1,1,1,5,5,5-hexafluoro-2,4-pentanedionato)-(1,1,1,5,5,5-hexafluoro-2,4-pentanedionato-C³)palladium(II), *[Pd(hfac)(hfac-C³)(2,6-(CH₃)₂C₆H₃NH₂)] (7a)*: A benzene solution (1 cm³) of 2,6-dimethylaniline (70 mg, 0.58 mmol) was added to a benzene solution (10 cm³) of **1a** (298 mg, 0.573 mmol) and the solvent was allowed to evaporate spontaneously to leave orange-red columns, which were washed with benzene and dried *in vacuo*. The yield was 358 mg (97%). This compound is sparingly soluble in organic solvents.

[Pd(hfac)(hfac-C³)(3,5-(CH₃)₂C₆H₃NH₂)] (7b): When a benzene solution (1 cm³) of 3,5-dimethylaniline (42 mg, 0.35 mmol) was added to a benzene solution (2 cm³) of **1a** (178 mg, 0.342 mmol), color of the solution changed gradually from orange yellow to orange red and orange-red crystals began to deposit. After being left overnight the precipitate was filtered, washed with benzene and dried *in vacuo*. The yield was 92 mg (42%).

[Pd(hfac)(hfac-C³)(2,4,6-(CH₃)₃C₆H₂NH₂)] (7c): When a mixture of **1a** (509 mg, 0.978 mmol) and 2,4,6-trimethylaniline (135 mg, 0.998 mmol) in benzene (12 cm³) was heated under reflux for 2.5 h, color of the solution changed gradually from orange yellow to dark red. The solution was then concentrated to 3 cm³ by evaporation under reduced pressure. Hexane (2 cm³) was added to the concentrate and the solvent mixture was allowed to vaporize spontaneously to leave orange-red columns, which were washed with diethyl ether (5 cm³) and air-dried. The yield was 365 mg. The washings were allowed to vaporize spontaneously, leaving another crop of **7c**, which was filtered and washed with a mixture (1 : 1 by volume) of diethyl ether and petroleum ether. The total yield was 447 mg (70%).

Di-μ-anilidobis(2,4-pentanedionato)dipalladium(II), *[Pd(acac)-(C₆H₅NH)]₂ (9a)*: Aniline (98 mg, 1.05 mmol) was added to a benzene solution (5 cm³) of [Pd(acac)₂] (**1b**) (42 mg, 0.14 mmol) and the mixture was heated under reflux for 7 h. The solvent was then distilled away under reduced pressure to leave a red-brown powder, which was washed with diethyl ether and air-dried. The yield was 16 mg (39%). Very low solubility of **9a** prevented recrystallization.

[Pd(acac)(2-CH₃C₆H₄NH)]₂ (9b): A benzene solution containing **1b** and excess 2-methylaniline was refluxed for 30 min and cooled to room temperature to deposit a red-brown precipitate, which was filtered, washed with petroleum ether, and then recrystallized from hot benzene. The yield was 92%.

[Pd(acac)(2,5-(CH₃)₂C₆H₃NH)]₂ (9c): 2,5-Dimethylaniline (1.58 g, 13.0 mmol) was added to a benzene solution (5 cm³) of **1b** (405 mg, 1.33 mmol) and the mixture was refluxed for 8 h. The solvent was then distilled away under reduced pressure, leaving an orange powder behind, which was washed with petroleum ether and dried *in vacuo*. The same compound was obtained by spontaneous evaporation of the washings. The total yield of **9c** was 295 mg (68%). With an aim of recrystallization, the product was dissolved in hot dichloromethane (10 cm³) and the solution was kept in a refrigerator overnight to deposit red plates (**9c**-α; 62 mg, 13%), which were filtered, washed with diethyl ether, and air-dried. The filtrate was kept further in a refrigerator to precipitate orange needles (**9c**-β; 68 mg, 16%), which was filtered, washed with diethyl ether, and air-dried. Red plates were analysed to contain one half molecule of dichloromethane per palladium as the lattice solvent and orange needles to contain one sixth molecule of dichloromethane. Results of the elemental analysis indicate that these two compounds are isomers (*vide infra*). The α-form is more soluble than the β-form in chloroform and dichloromethane.

[Pd(acac)(2,6-(CH₃)₂C₆H₃NH)]₂ (9d), *[Pd(acac)(2-C₂H₅-C₆H₄NH)]₂ (9e)*, *[Pd(acac)(C₁₀H₇-1-NH)]₂ (9f)*, *and [Pd-(acac)(5-NH₂C₁₀H₆-1-NH)]₂ (9g)*: The reactions of **1b** with 2,6-dimethylaniline, 2-ethylaniline, 1-naphthylamine, and 1,5-naphthalenediamine were carried out in a similar way to the case of **9b** and the orange-red products were recrystallized from hot benzene, the yields being *ca.* 3, 56, 11, and 98%, respectively.

Di-μ-anilidobis(1-phenyl-1,3-butanedionato)dipalladium(II), *[Pd-(bzac)(C₆H₅NH)]₂ (9h)*: On addition of excess aniline (*ca.* 0.2 cm³) to a solution of [Pd(bzac)₂] (101 mg, 0.236 mmol) in dichloromethane (3 cm³), color of the solution changed from orange yellow to red. A small amount of petroleum ether was added to the solution and the solvent mixture was allowed to evaporate spontaneously to leave an orange residue, which was washed with diethyl ether. The yield was 80 mg (94%).

Di-μ-anilidobis(1,1,1-trifluoro-2,4-pentanedionato)dipalladium-(II), *[Pd(tfac)(C₆H₅NH)]₂ (9i)*: Excess aniline was mixed with [Pd(tfac)₂] (**1c**) (351 mg, 0.851 mmol) in dichloromethane (10 cm³) and the solvent was vaporized spontaneously to leave a red crystalline solid on the wall and a red oily substance at the bottom of the vessel. The solid was washed with methanol. The oil was dissolved in dichloromethane. Hexane was added to the solution and the mixture was cooled to deposit a red crystalline solid, which was filtered and washed with methanol. The two specimens gave the same IR spectra. After drying *in vacuo*, the total yield was 175 mg (58%). Recrystallization from *N,N*-dimethylformamide gave brown needles of **9i**. On the other hand, the combined washings were kept in a refrigerator for 6 h to precipitate orange-yellow needles of Shiff base complex, *bis(4-phenylamino-1,1,1-trifluoro-3-penten-2-onato)palladium(II)* *[Pd{N(C₆H₅)C(CH₃)CHCOCF₃}₂] (11)*, which were filtered, washed with methanol, and dried *in vacuo*. The yield of **11** was 10%. Recrystallization was performed from methanol or dichloromethane. Found: C, 47.32; H, 3.35; N, 5.03%. Calcd for $C_{22}H_{18}N_2O_2F_6Pd$: C, 46.95; H, 3.22; N, 4.98%. IR in Nujol: ν(C=O)+ν(C=C)+ν(C=N), 1616 vs, 1586 m, 1524 vs; no ν(NH) band.

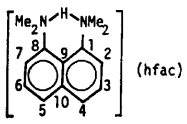
[Pd(tfac)(2-CH₃C₆H₄NH)]₂ (9j), *[Pd(tfac)(4-CH₃C₆H₄-NH)]₂ (9k)*, *and [Pd(tfac)(2,6-(CH₃)₂C₆H₃NH)]₂ (9l)*: The reactions of **1c** with three times molar 2-methylaniline, equimolar 4-methylaniline, and excess 2,6-dimethylaniline in refluxing benzene for several hours followed by spontaneous evaporation of the solvent gave **9j**, **9k**, and **9l** as an orange powder, orange-yellow needles, and orange-red needles in 32, 34, and several percent yields, respectively.

[Pd(hfac)(2-CH₃C₆H₄NH)]₂ (9n): A mixture of **1a** (497 mg, 0.955 mmol) and 2-methylaniline (103 mg, 0.963 mmol) in benzene (10 cm³) was heated under reflux for 7 h and then concentrated to 2 cm³ by evaporation under reduced pressure. Hexane (several cm³) was added to the concentrate and the

mixture was left to stand for three days to deposit dark red needles, which were filtered, washed with hexane and dried *in vacuo*. The yield was 295 mg (74%).

[Pd(hfac)(C$_6$H$_5$NH)]$_2$ (9m) and [Pd(hfac)(4-CH$_3$C$_6$H$_4$NH)]$_2$ (9o): These complexes were obtained in a similar manner as above as dark red crystals in 55 and 25% yields, respectively.

Alternatively, employment of 1,8-bis(dimethylamino)-naphthalene, "proton sponge," greatly enhanced the reaction of **1a** with 4-methylaniline to form **9o**. After addition of "proton sponge" (87 mg, 0.41 mmol) to a chloroform solution (1.5 cm^3) of **1a** (207 mg, 0.398 mmol) and 4-methylaniline (43 mg, 0.40 mmol), the solvent was distilled away under reduced pressure and the residue was washed with a mixture (1 : 1 by volume) of methanol and water, and dried *in vacuo*. The yield of a red-brown powder was 148 mg (88%). The washings were vaporized under reduced pressure and the residue was recrystallized from methanol–water. Pale yellow columns (46 mg) were identified to be the naphthylammonium salt of hfac (**12**) based on the following analytical and spectroscopic data and the yield was 27%. Found: C, 54.15;



12

H, 4.80; N, 6.66%. Calcd for $C_{19}H_{20}N_2O_2F_6$: C, 54.03; H, 4.77; N, 6.63%. Dec temp (sublimation) 105—130 °C. IR in Nujol: ν(C=C)+ν(C=O) 1675 vs, 1550 vs, and 1530 s; ν(C–F) 1250 vs, 1172 vs, 1145 vs, 1123 vs. NMR in $CDCl_3$ (δ, ppm from internal Me_4Si), ^{1}H: 3.29d (12H, N–CH$_3$, J(NH–CH$_3$)=1.$_2$ Hz), 5.68s (1H, hfac-CH), *ca.* 7.8 m (6H, ring-CH), 18.6 br (1H, N–H–N); ^{13}C: 118.4 q (CF$_3$, ^1J(C–F) =292 Hz), 173.5 q (CO, ^2J(C–F)=30 Hz), 84.2 (hfac-CH, ^1J(C–H)=159 Hz), 46.6 (CH$_3$, ^1J(C–H)=140 Hz), 144.8 (C^1, C^8), 120.9 (C^2, C^7, ^1J (C–H)=159 Hz), 129.2 (C^3, C^6, ^1J (C–H)=164 Hz), 126.9 (C^4, C^5, ^1J (C–H)=160 Hz), 118.9 (C^9), 135.5 (C^{10}). (Ring-carbon assignments are tentative.)

[Pd(hfac)(2,5-(CH$_3$)$_2$C$_6$H$_3$NH)]$_2$ (9p) and [Pd(hfac)(2,6-(CH$_3$)$_2$C$_6$H$_3$NH)]$_2$ (9q): The reactions of **1a** with equimolar 2,5-dimethylaniline and 2,6-dimethylaniline were allowed to proceed in refluxing benzene for 1 and 2 h, respectively. After evaporation of the solvent, residues were treated with hexane and methanol, respectively. Dark red needles of **9p** and a dark red powder of **9q** were obtained in 68 and 60% yields, respectively. Compound **9q** was also obtained as orange-red needles in a 9% yield when **7a** was dissolved in methanol and the solution was left to stand at room temperature.

[Pd(hfac)(3,5-(CH$_3$)$_2$C$_6$H$_3$NH)]$_2$ (9r): The reaction of **1a** with equimolar 3,5-dimethylaniline in refluxing toluene for 1.5 h and work up similar to the case of **9n** gave dark red needles in a 57% yield.

[Pd(hfac)(2,4,6-(CH$_3$)$_3$C$_6$H$_2$NH)]$_2$ (9s): Compound **7c** (20 mg, 0.031 mmol) was dissolved in hot methanol (1 cm^3) and the solution was left to stand at ambient temperature to deposit orange-red plates, which were filtered, washed with hexane and dried *in vacuo*. The yield was 5 mg (36%).

[Pd(hfac)(3-CF$_3$C$_6$H$_4$NH)]$_2$ (9t): A benzene solution (5 cm^3) of **1a** (138 mg, 0.265 mmol) and 3-(trifluoromethyl)-aniline (43 mg, 0.27 mmol) was refluxed for 1.5 h and then concentrated to 1 cm^3 by evaporation under reduced pressure. Petroleum ether (several cm^3) was added to the concentrate and the mixture was left to stand for a week at room temperature to deposit a red-orange crystalline solid, which was filtered and washed with petroleum ether. The yield was 90 mg (72%). Recrystallization from dichloromethane–petroleum ether gave a mixture of red plates (α-form) and dark red column (β-form), which was filtered, washed with petroleum ether, and air-dried. Manual separation gave **9t**-α (20 mg) and **9t**-β (34 mg) in 16 and 27% yields, respectively.

[Pd(hfac)(2-NO$_2$C$_6$H$_4$NH)]$_2$ (9u): Hexane (several cm^3) was added to a benzene solution (2.5 cm^3) of **1a** (81 mg, 0.16 mmol) and 2-nitroaniline (22 mg, 0.16 mmol) and the mixture was left to stand for five days to precipitate red needles, which were filtered, washed with petroleum ether, and dried *in vacuo*. The washings were evaporated spontaneously to separate another crop. The total yield was 34 mg (48%).

[Pd(hfac)(4-NO$_2$C$_5$H$_4$NH)]$_2$ (9v): 4-Nitroaniline (39 mg 0.28 mmol) was allowed to react with **1a** (146 mg, 0.281 mmol) in refluxing dichloromethane (2 cm^3) for 3 h. The solvent was then distilled away under reduced pressure and the residue was recrystallized from dichloromethane–petroleum ether to give red plates. Another crop of red crystalline solid was also obtained by cooling the filtrate. The total yield was 85 mg (67%).

Di-μ-anilidotetrakis(propylamine)dipalladium(II) 1,1,1-Trifluoro-2,4-pentanedionate, [Pd(C$_6$H$_5$NH)(n-PrNH$_2$)$_2$]$_2$(tfac)$_2$ (10a): Complex **9i** (61 mg, 0.087 mmol) was dissolved in propylamine (0.5 cm^3) and the excess amine was allowed to evaporate spontaneously to leave a yellow crystalline solid (64 mg) in a 78% yield.

[Pd(C$_6$H$_5$NH)(py)$_2$]$_2$(tfac)$_2$·2H$_2$O (10b): Complex **9i** was dissolved in a minimum amount of pyridine and diethyl ether was added to the solution. On cooling the mixture, yellow columns appeared, which were filtered, washed with diethyl ether, and dried *in vacuo*. The yield was about 50%.

[Pd(4-CH$_3$C$_6$H$_4$NH)(4-CH$_3$C$_6$H$_4$NH$_2$)$_2$]$_2$(tfac)$_2$·1/2 C$_6$H$_6$ (10c): 4-Methylaniline (76 mg, 0.71 mmol) reacted with **1c** (81 mg, 0.20 mmol) in benzene (1.5 cm^3) at room temperature to deposit orange crystals, which were filtered, washed with hexane, and dried *in vacuo*. The yield was 73 mg (62%).

[Pd(2-CH$_3$C$_6$H$_4$NH)(2-CH$_3$C$_6$H$_4$NH$_2$)$_2$]$_2$(hfac)$_2$ (10d): A mixture of complex **9n** (123 mg, 0.146 mmol) and 2-methylaniline (93 mg, 0.87 mmol) in benzene (5 cm^3) was heated under reflux for 4.5 h and concentrated by evaporation under reduced pressure to deposit a yellow-brown crystalline solid, which was filtered, washed with petroleum ether, and dried *in vacuo*. The yield was 108 mg (58%).

[Pd(2-CH$_3$C$_6$H$_4$NH)(3,5-(CH$_3$)$_2$C$_6$H$_3$NH$_2$)$_2$]$_2$(hfac)$_2$ (10e): 3,5-Dimethylaniline (75 mg, 0.62 mmol) was added to a benzene solution (5 cm^3) of **9n** (65 mg, 0.077 mmol) and the mixture was left to stand at room temperature to deposit a yellow-brown precipitate. The solvent was removed under reduced pressure and the residue was recrystallized from dichloromethane–petroleum ether to give orange tiny crystals (46 mg) in a 45% yield.

[Pd(2-CH$_3$C$_6$H$_4$NH)(CH$_3$NH$_2$)$_2$]$_2$(hfac)$_2$ (10f): Complex **9n** was dissolved in methylamine and the excess amine was removed under reduced pressure to leave a yellow powder of **10f** in a quantitative yield.

[Pd(2-CH$_3$C$_6$H$_4$NH)(n-PrNH$_2$)$_2$]$_2$(hfac)$_2$·2H$_2$O (10g): Complex **9n** (54 mg, 0.064 mmol) was dissolved in propylamine (3 cm^3) and the excess amine was vaporized spontaneously. The residue was washed with hexane and dried *in vacuo* to give a yellow powder (31 mg) in a 44% yield. Yellow columns were obtained by recrystallization from dichloromethane–petroleum ether.

[Pd(2-CH$_3$C$_6$H$_4$NH)(py)$_2$]$_2$(hfac)$_2$ (10h): Small amounts

of diethyl ether and hexane were added to a solution of **9n** (23 mg, 0.027 mmol) in pyridine (0.1 cm^3) and the mixture was cooled to deposit a yellow precipitate, which was filtered, washed with diethyl ether, and dried *in vacuo*. Although solubilities in usual solvents are low, recrystallization was possible from dichloromethane–petroleum ether. The yield was very low (less than 10%).

[Pd (3,5-$(CH_3)_2C_6H_3NH$) (3,5$(CH_3)_2C_6H_3NH_2$)$_2$]$_2$ (hfac)$_2$ (10i): 3,5-Dimethylaniline (34 mg, 0.28 mmol) was added to a benzene solution (2 cm^3) of complex **9r** (56 mg, 0.065 mmol) and the mixture was left to stand at room temperature for three days to deposit an orange precipitate, which was filtered, washed with hexane, and dried *in vacuo*. The yield was 42 mg (48%).

Measurements. IR spectra were recorded in Nujol mull on Hitachi EPI-S2 and 295 spectrophotometers. NMR spectra were measured with JEOL-C60 HL (^1H), FX60Q (^1H and ^{13}C), and PS-100 (^{19}F) spectrometers. The molecular weight was determined in dichloromethane at room temperature by vapor pressure osmometry with an instrument manufactured by Knauer in West Berline, West Germany.

Results and Discussion

Table 1 shows the analytical data for most of the newly prepared complexes together with their decomposition temperatures, but data for twelve compounds were omitted for brevity. The reactions of [Pd(hfac)$_2$] (**1a**) with aniline and its derivatives (L) mostly in benzene at room temperature afforded [Pd(hfac)L$_2$](hfac) (**4**) and [PdL$_4$](hfac)$_2$ (**5**) when twice molar and more than

Table 1. Analytical data for newly prepared complexes, [Pd(hfac)L$_2$](hfac) (**4**), [PdL$_4$](hfac)$_2$ (**5**), [Pd(hfac)(hfac-C^3)L] (**7**), [Pd(β-dik)(L−H)]$_2$ (**9**), and [PdL'$_2$(L−H)]$_2$(β-dik)$_2$ (**10**)

a) Benzene solvate (one half molecule per Pd). b) Monohydrate. c) Crystals contain solvent of crystallization which is lost gradually at room temperature. Solvent-free specimens were analyzed which were obtained by pulverizing and through pumping. d) The compound sublimes at this temperature. e) Dichloromethane solvate (1/2 molecule per Pd). f) Dichloromethane solvate (1/6 molecule per Pd). g) Dihydrate.

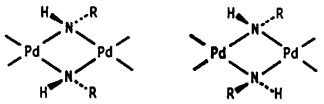
four times molar amounts of L was used, respectively, while the equimolar reaction gave rise to [Pd(hfac)-C^3)L] (**7**). The carbon-bonded complex of hfac has never been produced by the reactions of **1a** with alkylamines, pyridines, and tertiary phosphines.[1,2b] Now the presence of type **7** complexes in the equimolar reaction mixtures of **1a** and various aniline derivatives was confirmed by the NMR assay, although isolation of the products was successful only for **7a**, **7b**, and **7c**. 2,6-Dimethyl- and 2,4,6-trimethylanilines gave type **4** and **7** complexes but do not produce **5** probably because of their large steric demands.

Refluxing of an equimolar mixture of **1a** and an aniline derivative L in benzene gave rise to dinuclear complexes [Pd(hfac)(L−H)]$_2$ (**9**) containing the bridging anilide anions (L−H). Complexes **9** were also derived spontaneously from **7** in methanol solutions. The reactions of other [Pd(β-dik)$_2$] complexes (β-dik= 2,4-pentanedionate (acac), 1-phenyl-1,3-butanedionate (bzac), and 1,1,1-trifluoro-2,4-pentanedionate (tfac) anions) with L did not give **4**, **5**, and **7**, but produced **9** exclusively. Solubilities of anilide complexes **9** in organic solvents are very low and somewhat improved by methy substitutions on thephenyl ring. The molecular weight of **9n** (842) determined in dichloromethane (0.005—0.05 mol dm^{-3}) coincides well with the value (839) calculated for the dinuclear strueture, whereas those for **9c**-β (732) and **9i** (610) observed only for very dilute solutions are far less accurate and do not coincide with but are near the calculated values, 666 and 704, respectively. The analytical results in Table 1 together with these molecular-weight data accord with the dinuclear formulation of **9**, which is also supported by the NMR data reported below.

Deprotonation of amine groups coordinated to d^8 metals is usually effected by a strong base such as potassium amide in liquid ammonia,[6] but the reaction of dichloro(2,2′-bipyridine)platinum(II) with *cis,cis*-1,3,5-triaminocyclohexane (tach) in aqueous solution was found to result in [Pt(bpy)(tach−2H)H$_2$O]Cl$_2$, an octahedral Pt(IV) complex containing the tach dianion as a terdentate ligand.[7] In the present case, the coordinated aniline seems to be deprotonated by the β-diketonate anion situated in the inner or outer sphere (*vide infra*).

Although the hfac complexes **4** and **5** containing alkylamines as L are yellow and colorless, respectively,[1a] the corresponding aniline complexes are generally reddish and complexes **9** are dark red. The dinuclear anilide complexes **9** are thermally stable and the hfac complexes except **9o** can be sublimed in accordance with the general trend that substitution of the methyl groups of acac with CF$_3$ increases volatility of the complex.[8] The anilide-bridged dinuclear structure is very stable in solution, too. Treatment of complexes **9** with pyridine or primary amines (L′) does not effect cleavage of the bridge, but displaces the chelating β-dik ligands to produce [PdL′$_2$(L−H)]$_2$(β-dik)$_2$ (**10**). A platinum(II) complex containing an anilide anion as a unidentate ligand, *trans*-[PtCl(C$_6$H$_5$NH)(PEt$_3$)$_2$] was prepared by the reaction of *trans*-[PtH(Cl)(PEt$_3$)$_2$] with phenyl azide,[9] and was treated with silver hexafluorophosphate in acetone.[10] Abstraction of the chloride ligand did not occur, but oxidative coupling of the anilide was effected to result in a benzidine complex. The ancillary ligands may strongly affect the behavior of the anilide ligand.

Recrystallization of **9c** from dichloromethane gave two kinds of crystals, red plates and orange needles, containing different numbers of solvent molecules per palladium, which are tentatively designated as α and β forms, respectively. The two specimens **9c**-α and **9c**-β exhibit different IR and NMR spectra (*vide infra*) and seem to constitute a pair of isomers. The following two stereoisomers are conceivable for the di-μ-anilide structure, although it is difficult at present to identify which of **9c**-α and **9c**-β has the syn structure. Recrystallization of **9t** from dichloromethane–petroleum ether also gave both red plates and dark red columns. The IR spectra suggest that the former has the same structure as that of **9c**-α and the latter corresponds to the β form.



syn *anti*

When complex **9i** was prepared by the reaction of **1c** with aniline, complex **11** was obtained as a by-product and characterized by elemental analysis and IR spectroscopy. A Schiff base ligand 4-phenylamino-1,1,1-trifluoro-3-penten-2-one was prepared by Röhrscheid *et al.*[11] according to a previous method for 4-phenylamino-3-penten-2-one,[12] and the structure of *mer*-[V{N(C$_6$H$_5$)C(CH$_3$)CHCOCF$_3$}$_3$] was confirmed by ^{1}H and ^{19}F NMR spectroscopy.[11] In the present case, tfacH which was freed from **1c** by its reaction with aniline must have reacted with excess aniline to produce the Schiff base, which in turn seems to have replaced the tfac ligand in **1c** to give rise to **11**.

Infrared Spectra. Figure 1 exemplifies the characteristic IR bands of complexes **4d**, **5f**, **7b**, **9r**, and **10i**, all of which contain the hfac anion and 3,5-dimethylaniline as L and are suitable for comparing the IR spectra of complexes of different types. In general complexes **4** and **5** show two or three broad ν(NH) bands of strong to medium intensity in the 3300—3090 cm^{-1} region, while complexes **7** have sharper bands. Complexes **9** show one or two sharp bands of medium to weak intensity in the 3320—3220 cm^{-1} region, which are assigned to the ν(NH) vibration of the bridging anilide ligand. Each of the isolated α and β isomers of **9c** and **9t** shows a single ν(NH) band, of which the frequency is 20—30 cm^{-1} higher for the α form than for the β form. Then other complexes **9** exhibiting two bands in this region seem to be a mixture of both isomers. In the case of complexes **10** containing primary amines as L′, the ν(NH) band from the bridging anilide is indiscernible because of overlapping with the ν(NH) bands from L′. On the other hand, the pyridine complex **10h** shows a sharp band at 3255 cm^{-1}.

The IR bands in the 1800—1500-cm^{-1} region are useful for diagnosing the bonding mode of β-diketonate

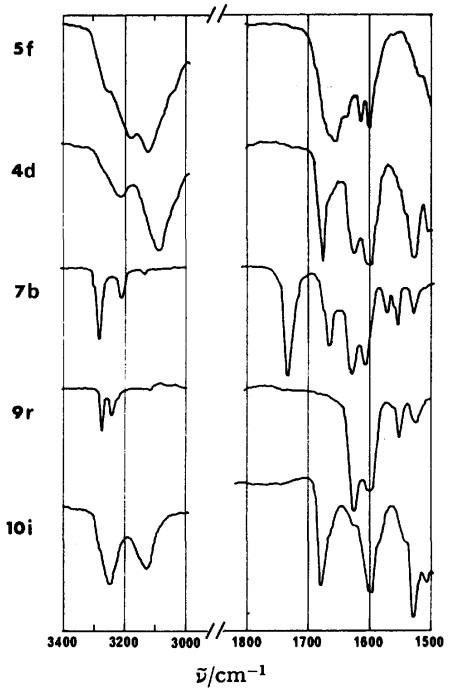


Fig. 1. IR spectra of complexes **5f**, **4d**, **7b**, **9r**, and **10i** in Nujol mull.

anions,[1,2] although aromatic ν(C=C) bands are also observed in this region. The strong absorption of **4d** at 1675 cm^{-1} and a very broad band of **5f** at 1655 cm^{-1} are assigned to the hfac anion in the outer sphere, since these bands are very close to the band exhibited by K(hfac) at 1675 cm^{-1}. Complex **4d** shows additional strong bands caused by the chelating hfac at 1625 and 1526 cm^{-1}. Besides the absorption of chelating hfac at 1628 and 1528 cm^{-1}, complex **7b** exhibits a very strong band at 1733 cm^{-1} which is characteristic of the central-carbon-bonded β-dik ligand.[1,2] The spectrum of **9r** includes the bands caused by the chelating hfac at 1626 and 1526 cm^{-1} but lacks bands in the region higher than 1626 cm^{-1}, certifying absence of hfac either carbon-bonded or situated in the outer sphere. On the other hand, the spectrum of **10i** again demonstrates the existence of hfac in the outer sphere.

NMR Spectra. Solubilities of compounds **4**, **5**, and **7** in organic solvents are generally insufficient to allow NMR measurements and ^{1}H NMR data for only a limited number of compounds were recorded (Table 2). Complexes **4** exhibit two methine signals, of which the lower-field one is assigned to CH of the chelated hfac by reference to the spectrum of [Pt(hfac)-(2-$CH_3C_6H_4NH_2$)$_2$](hfac) showing two methine signals at 5.79 and 6.03 ppm of which the latter is flanked by ^{195}Pt satellites with ^4J(Pt–H)=8 Hz.[1b] Spectra of **5** are generally broad over the whole field, but three kinds of amine-proton signals are observed inclusive of those from the corresponding **4** and free L, indicating attainment of the following equilibria.

$$\underset{\mathbf{5}}{[PdL_4](hfac)_2} \overset{K_1}{\rightleftharpoons} \underset{\mathbf{4}}{[Pd(hfac)L_2](hfac)} + 2L \qquad (1)$$

The same value of about 2×10^{-3} $mol^2\,dm^{-6}$ was obtained as K_1 at 25 °C for **5c**, **5e**, and **5f**.

Complex **7c** is not stable either in $CDCl_3$, but signals assignable to **4e** and **1a** are noticed about 1 min after dissolution and grow gradually with time to attain equilibrium (Eq. 2 with 2,4,6-$(CH_3)_3C_6H_2NH_2$ as L), K_2 being estimated as 0.25 at 25 °C. The corresponding platinum(II) complex does not undergo such a disproportionation reaction. The methine proton of the

$$2\underset{\mathbf{7}}{[Pd(hfac)(hfac\text{-}C^3)L]} \overset{K_2}{\rightleftharpoons} \underset{\mathbf{4}}{[Pd(hfac)L_2](hfac)} + \underset{\mathbf{1a}}{[Pd(hfac)_2]} \qquad (2)$$

carbon-bonded hfac in **7c** resonates at higher field than that of the chelating hfac and the ^{13}C signal of the methine carbon bonded to the metal also appears at much higher field (33.6 ppm) than that of the chelating hfac (92.0 ppm). The chemical shift of the amine protons in **7c** is also smaller by more than 1 ppm as compared with those in compounds **4** and **5**, indicating absence of the hydrogen-bonding anion in the outer sphere.[1]

Table 3 lists the ^{1}H NMR data for complexes **9**. All complexes except **9h** and **9v** exhibit two sets of signals, demonstrating that they contain stereoisomers α and β. Both the acac methyl protons and the anilide proton of **9c**-α resonate at higher field than those of **9c**-β. Thus the higher-field one of the two NH signals from each complex was assigned to the α form by reference to **9c**. Then the hfac methine signals from **9m**—**9u** were distinguished based on the area ratio to accord with that of the NH signals. In each case the hfac methine proton of the α form resonates at higher field than that of the β form, although the chemical shifts

Table 2. ^{1}H NMR data for [Pd(hfac)L_2](hfac) (**4**), [PdL_4](hfac)$_2$ (**5**), and [Pd(hfac)(hfac-C^3)L] (**7**) in $CDCl_3$ at room temperature[a]

a,c) Same as footnotes a) and c) for Table 2. b) Figures in brackets give the J(C–F) values in Hz. d) Indiscernible because of overlapping with other signals or low intensity.

were accidentally same for acac methine protons of **9c-α** and **9c-β**. The abundance ratio of isomers for each complex determined by the ^{1}H NMR measurements parallels the relative intensities of the ν(NH) bands in the IR spectrum.

Very recently a single crystal of [$AlMe_2$(*i*-PrNH)]$_2$ was revealed by X-ray analysis to contain two stereoisomers in the ratio of 2 : 1, of which both have four-membered $(AlN)_2$ rings.[13] The syn to anti ratio of 2 : 1 was preserved in toluene solution and changed only slightly with temperature. In the case of [AlBr(Et)-(*t*-BuNH)]$_2$, five stereoisomers are conceivable, of which two were isolated and shown to isomerize in benzene solution at room temperature to give an equilibrium mixture containing three principal isomers.[14] In the case of the present palladium(II) complexes, the stereoisomers are very inert in solution. Even when heated to 60 °C for several hours, **9c-α** in $CDCl_3$ solution showed no sign of isomerization to **9c-β**. The isomer ratios of other compounds **9** do not change with temperature either. Transformation between the syn and anti forms either by cleavage of the anilide bridge or by dissociation of the anilide proton does not occur easily, and the isomer ratio observed is not an equilibrium value in solution, but was realized under the preparative conditions.

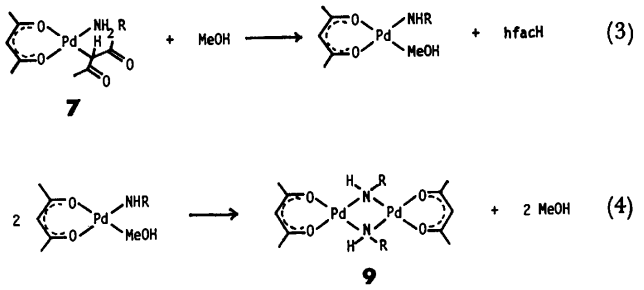
The ^{19}F NMR spectrum of **9n** in dichloromethane at room temperature exhibits two signals at 3.36 and 3.06 ppm downfield from external CF_3COOH. The area ratio (2 : 3) coincides with the isomer ratio determined by ^{1}H NMR spectroscopy. Therefore the two ^{19}F signals are assigned to the α and β forms, respectively.

As is seen in Table 3, the NH proton of the anilide ligand in complexes **9** resonates usually in the field higher than 1.5 ppm, but that of **9u** absorbs in remarkably lower field. This exceptional behavior may stem from the hydrogen bonding of the NH group to the ortho nitro group, the NH group being retained on the same plane as the phenyl ring and suffering its anisotropic effect.

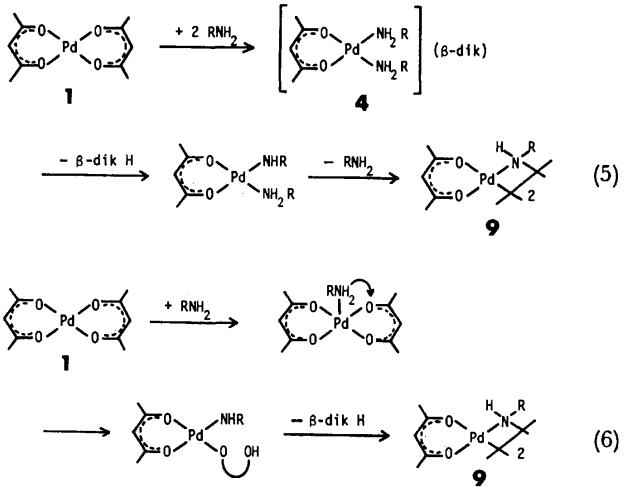
The ^{13}C NMR spectra of complexes **4**, **5**, and **7** are similar to those for corresponding β-dik complexes containing other nitrogen bases as L.[1] Therefore $^{13}C\{^1H\}$ NMR data only for the new type complexes **9** are listed in Table 4. In each case two sets of signals from the phenyl-ring carbons are observed and assigned to α and β forms based on the relative intensities to accord with the isomer ratios determined by ^1H NMR measurements. Shieldings of the β-diketonate carbons in **9** are quite similar to those of the corresponding bis-chelates **1**[4b] and chelating ligands in **4** and **7** containing alkylamines as L.[1a] Signals of the β-dik carbons do not show any difference due to the stereoisomerism, suggesting that the splitting observed for proton signals may be caused by different anisotropic effect exerted through space and not through bonds by the phenyl rings of bridging anilide ligands in the syn and anti isomers. Complexes **10** are not sufficiently soluble in usual solvents to allow NMR measurements.

Relative Stabilities of Complexes. Relative stabilities of the palladium(II) complexes **4**, **5**, and **7** containing ammonia, alkylamines, and pyridines as L were found to depend on basicities of both the nitrogen bases and β-dik anions as well as bulkiness of the former.[1a] Thus complexes **5** are favored by more basic L and less basic β-dik. Anilines are far less basic than alkylamines and pyridines, and can not displace the β-dik ligands in $[Pd(acac)_2]$ (**1b**), $[Pd(bzac)_2]$, and $[Pd(tfac)_2]$ (**1c**), reacting only with $[Pd(hfac)_2]$ (**1a**) to produce complexes **4**, **5**, and **7**. It is noteworthy that reactions between anilines and **1a** afford either **4** or **5** depending on the reactants mole ratio, whereas primary alkylamines and pyridine gave solely **5**[1a] because of higher reactivity of $[Pd(hfac)L_2](hfac)$ toward L than that of **1a** when L are these bases. 2-Nitro- and 4-nitroanilines, which are less basic than aniline, the pK_a values of conjugate acids being -0.26 and 1.11 as compared with 4.60 for aniline,[15] do not give **4** and **5**, but produce anilide complexes **9**. On the other hand, 2-methyl- and 2,4-dimethylanilines are more basic than aniline, giving **4** and **5**. It may be due to their bulkiness that 2,6-dimethyl- and 2,4,6-trimethylanilines produce **4** and **7** but do not give **5**. The central-carbon-bonded complexes **7** were supposed to be preferred by β-diketones which favor the keto form over enol.[1,16] In spite of the fact that hfacH is composed exclusively of the enol tautomer,[17] some substituted anilines give rise to complexes **7**. Besides the basicity at the central carbon atom of β-dik anion (the keto-favoring factor), some balance between basicities of L and β-dik might be important for stabilization of **7**.

Mechanism for Formation of the Anilide-bridged Complexes. Kinetic and equilibrium studies on the reactions of **1b** with alkylamines revealed that complexes of type **7** are produced not directly from **1b** but *via* **4** reversibly, and the equilibrium is favorable to **7** in dichloromethane and to **4** in methanol when diethylamine is used as L.[18] The same situation will be reallized for the present aniline complexes. Complexes **7a**—**7c** were prepared in benzene and changed spontaneously to complexes **9** in methanol. The transformation reaction might be represented by Eqs. 3 and 4.



It is a characteristic feature of anilines to afford anilide complexes **9** irreversibly by the reactions with **1** on heating. The overall reaction might proceed *via* complex **4** (Eq. 5) or alternatively in a direct fashion as depicted in Eq. 6. In previous papers,[1a,19] complexes



4 and **5** containing secondary and primary amines as L, respectively, were reported to catalyze the hydrogen exchange reactions between amines and chloroform. Deprotonation of the coordinated amine molecule by the β-dik anion in the outer sphere was presumed to be a key step and the rate was found to parallel the basicity of the β-dik anion. The present results that the reactions of $[Pd(\beta\text{-dik})_2]$ (β-dik=acac, bzac, and tfac) with aniline and its methyl derivatives as well as reactions of **1a** with nitroanilines do not afford complexes **4** but give rise directly to **9** seem to support reaction scheme 6.

1,8-Bis(dimethylamino)naphthalene, a powerful proton acceptor known as "proton sponge," greatly accelerates the **9**-forming reactions. An equimolar mixture of **1a** and 4-methylaniline in $CDCl_3$ promptly attains an equilibrium shown by Eq. 2, K_2 being estimated as 0.1 from ^1H NMR spectroscopy. On addition of an equimolar amount of "proton sponge" to this mixture, the reaction to form **9o** proceeds almost quantitatively at room temperature and **9o** and the hfac salt **12** were isolated in 88 and 27% yields, respectively. An equimolar mixture of **1a** and 2-nitroaniline in $CDCl_3$ showed no sign of reaction on the NMR spectra after a while at room temperature, but reacted immediately on addition of the equimolar base to result in **9u** and **12** quantitatively (based on the ^1H and ^{13}C NMR spectra), which were isolated in 60 and 48% yields, respectively.

These results demonstrate that the deprotonation of anilines is the most important step in production of **9**. In the absence of added base, basicity of the β-dik anion and acidity of the amine seem to be the most important factors to facilitate formation of the anilide complexes. Much lower acidities of alkylamines as compared with those of anilines may be the reason why alkylamines fail to afford amide complexes.

We wish to thank Mr. Junichi Gohda for elemental analyses and also Professor T. Tanaka and Dr. K. Kawakami of Osaka University for ^{19}F NMR measurements. S. O. and S. K. are grateful to the Ministry of Education, Science and Culture for Grant-in-Aid for Scientific Research, Nos. 454196 and 243014, respectively.

Carbene in Rigid Matrix. XI.[1] Temperature and Matrix Effect on Phenylcarbene Processes in Ether and Amine

Hideo Tomioka,* Shinji Suzuki, and Yasuji Izawa

Department of Industrial Chemistry, Faculty of Engineering, Mie University, Tsu, Mie 514

(Received February 20, 1981)

Product distributions from reactions of phenylcarbene with diethyl or diisopropyl ether or diethylamine were found to be highly dependent on reaction temperature. As temperature decreases, the C–O displacement reaction and N–H insertion are decreased. Concomitantly, primary C–H insertion products markedly increase especially at lower matrix temperatures.

In recent years the importance of the method of generation of a carbene for its chemical behavior has become evident. Among examples which may be cited, the low temperature photolysis of aryldiazomethanes in rigid matrices has been shown[2,3] to be a unique method for looking into the triplet arylcarbene chemistry, especially in systems in which competitive singlet and triplet reactions occur. Photolysis of aryldiazomethane in olefin matrices at −196 °C, for example, results[2] in a dramatic increase in the yield of C–H insertion products at the expense of cyclopropane, which is a dominant product in a liquid phase photolytic run. A similar dramatic yield increase of C–H insertion products is also observable[3] in the photolysis of aryldiazomethanes in alcoholic matrices, whereas O–H insertion is generally a major reaction pathway of arylcarbene generated at ambient temperature. These C–H insertion products are proposed[2,3] to be formed *via* an abstraction-recombination (*a-r*) of the triplet carbene on the basis of ample spectroscopic[4] and chemical[4a] evidence for the presence of the ground-state triplet carbene in the low temperature matrix photolysis of most aryldiazomethanes at −196 °C. The method is thus expected to serve as a useful adjunct in the investigation of the relationship between the multiplicity and reaction pattern of carbene. However, since there is still some ambiguity as to the exact mechanism by which the matrix controls C–H insertion processes within itself, we have investigated temperature effects on carbene reactions with other reactive substrates involving hetero atoms, *i.e.*, ether and amine. Temperature effect studies of reactions of carbene with these substrates are intriguing in the following points in connection with results in alcohols. First, one can expect to get information on the temperature dependence of C–H insertion selectivity in both the liquid and solid phases, since C–H insertion is a major pathway[5] for these substrates; in contrast, C–H insertion scarcely proceeds[2] in reactions with alcohol, especially in the liquid phase. Second, it is quite important to examine the temperature effect on characteristic reactions[5] of the singlet carbene in these solvents, *i.e.*, the successive sequence of two reactions: the electrophilic attack on the lone pair of electrons on the hetero atom (X) to form an ylidic intermediate; and the Stevens rearrangement and/or the Hoffman type β-elimination, leading to C–X insertion and C–X displacement. The N–H insertion process of carbene will especially be informative because, unlike its reaction with alcohols[2] involving, if possible, abstraction of a hydrogen atom from the α-carbon atom, the triplet carbene may be expected to abstract[5b] hydrogen from the N–H bond in view of the bond energy and hence will take part also in the N–H insertion together with the singlet-state carbene. Thus, the present systems are expected to throw additional light not only on the applicability of the technique to looking into the triplet carbene chemistry but also on the mechanism of reactions of arylcarbene with ether or amine.

Reaction of Phenylcarbene with Ethers. A solution of phenyldiazomethane (**1**) in ether (**2**, R=H, CH_3) was irradiated at 0 °C and analysed by GC. This analysis revealed formation of the C–O displacement product (**3**), the C–O insertion product (**4**), and two C–H insertion products (**5** and **6**) (Table 1). The product distributions are found to be sensitive to the structure of ethers. Thus, either **3** or **4**, presumably resulting *via* an oxygen ylide intermediate, is formed in more suppressed yield as the ether changes from ethyl ether to isopropyl ether. This is apparently due to the steric hindrance on the accessibility to the central oxygen. A similar steric hindrance on the ylide formation has been noted with a photolysis[6] of dimethyl diazomalonate in allyl ethers, where the yield of the ylidic product decreases from 31 to 0% as the ether changes from allyl methyl ether to allyl *t*-butyl ether. Since it is quite important here to examine the exact intermediates leading to each insertion product, we have examined effects of precursor, triplet sensitizer, and singlet carbene quencher on product distributions (Table 1). First, photolysis of *cis*- and *trans*-1,2-diphenyloxiranes, a nitrogen-free precursor[7] of phenylcarbene, in ethyl ether gave a comparable result with that observed in similar photolysis of **1**. This eliminates the possible intervention of the diazomethane as an intermediate in the reaction and thus indicates involvement of free carbene. Second, product distributions were not altered by the addition of a large excess of benzophenone as a triplet sensitizer so as to assure absorption of 99% of the incident light by the sensitizer. This is often observed[8] in the arylcarbene system and can be interpreted as indicating that singlet-triplet equilibrium is faster than reactions with ether. Third, the examination of effect of 2-propanol, an efficient quencher for singlet carbene,[2,9] on the product distribution indicated that both the ylidic products and the C–H insertion products were quenched but with different degrees of efficiency. Thus, the ratio of the C–H insertion products to the ylidic products increased as the concentration of alcohol increased. This implies

Table 1. Product distribution in photolysis of **1** in ethers at 0 °C[a]

R_2O	Additive (mmol dm^{-1})	Relative yield/%[b]			
		3	**4**	**5**	**6**

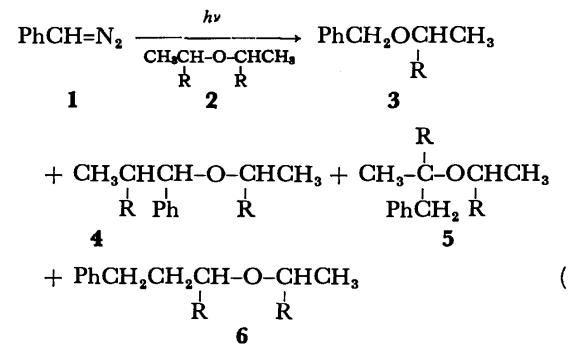
a) Normarized to 100%. Total yields were *ca.* 50—60%. Other minor products detected in each run were toluene, bibenzyl, stilbenes, and aldehyde azine. Control experiments ruled out the interconversion of products during irradiation. b) Liquid phase. d) Solid phase. d) Diphenyloxiranes used as a carbene precursor.

that singlet carbene takes part in the ylidic products but that not only singlet but also triplet carbenes are involved in the C–H insertion reaction.

The effect of temperature on the product distribution was next examined and the results are summerized in Table 2. Two apparent trends of temperature dependence can be seen from an inspection of Table 2. First, as the photolysis temperature was lowered, yields of the displacement product (**3**) and C–O insertion product (**4**) decreased continuously, especially in the reaction with ethyl ether, and they were almost completely suppressed at −196 °C, whereas the C–H insertion product increased. Similar phenomena have been observed[2] in the O–H/C–H insertion ratio in the

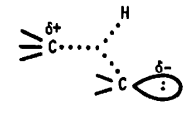


(1)

a, R = H; **b**, R = Me

reaction of phenylcarbene with alcohols as temperature is lowered. This can be interpreted as indicating that triplet reactions gain over singlet reactions since it has been demonstrated[4] that a photolysis of aryldiazomethanes in organic matrices at −196 °C results in an almost exclusive formation of triplet carbenes. Thus the present results indicate that the characteristic reaction of singlet carbene with ethers is also suppressed at lower temperature. This suggests that the process has a higher activation energy than the competitive C–H insertion process. Alternatively, the reason for suppression of **3** and **4** at lower temperature probably lies partly in the ramification of stabilization by solvation. Thus, the transition state for the formation of **3** and **4** might be more polar than that leading to the C–H insertion and hence is more stabilized by solvation. Such solvation becomes less important as temperature decreases and hence yields of **3** and **4** decrease.

One more interesting feature of the present reaction is that C–H insertion selectivity is also highly temperature dependent; the selectivity increases as temperature is lowered as far as the reaction phase is liquid, but it dramatically decreases when the reaction phase changes from liquid to solid. Similar phenomena have been observed[10] in the C–H insertion selectivity of phenylcarbene in hydrocarbons with various types of C–H bonds and can be explained in terms of competitive temperature and matrix effects. Thus, as temperature decreases, the tertiary C–H insertion gains over the primary one because the tertiary C–H insertion is favored by lower activation energy. It has been suggested that both singlet and triplet carbenes take part in the C–H insertion at least in liquid phase, but if the C–H "insertion" takes place *via* the *a-r* reaction of the triplet, apparently tertiary abstraction is favored over primary one in view of bond energy, and if, on the other hand, the concerted insertion of the singlet is assumed, the transition state (**7**) proposed[11] for the insertion predicts that tertiary insertion is favored by an electronic factor. In the matrix photolysis, however, triplet carbene is thought to be a dominant intermediate for the C–H insertion product since recent studies[4b]



7

on decay rates of triplet arylcarbenes in various organic matrices have shown that the predominant decay pathway of the triplet is hydrogen atom tunneling to give C–H "insertion." Intervention of free carbene was again verified by the finding that the photolysis of the diphenyloxirane in rigid matrix gave a comparable trend in the product distribution. The decrease in the C–H insertion selectivity observed in rigid matrix is, however, a completely unexpected behavior for triplet carbenes since triplet carbenes have been shown[12] to be much more selective intermediates in the C–H insertion reaction than the corresponding singlet in gas- as well as liquid-phase experiments. The reason for the marked increase in the primary C–H insertion in a rigid matrix then probably lies partly in that a matrix imposes steric demand on the C–H insertion process. It is not unreasonable to assume that the size and shape provided by the host molecule and its rigidity impose severe steric hindrance on the guest molecule (PhCH:) in the accessibility to tertiary C–H bonds. A similar argument can be applied to explain that a much less dramatic change in the C–H insertion selectivity was observed even at −196 °C in the reaction with ethyl ether matrix which has less sterically-hindered secondary C–H bonds.

Reactions of Phenylcarbene with Diethylamine. Photolysis of **1** in diethylamine resulted in formation of the N–H insertion product (**8**) and two C–H insertion

$$\mathbf{1} \xrightarrow[HNEt_2]{h\nu} \underset{\mathbf{8}}{PhCH_2NEt_2} + \underset{\mathbf{9}}{\overset{PhCH_2}{\overset{|}{CH_3}}CHNH(Et)} + \underset{\mathbf{10}}{\overset{PhCH_2}{\overset{|}{CH_2}}CH_2NH(Et)} \quad (2)$$

products (**9** and **10**). Temperature dependence of the product distribution (**8**—**10**) is summerized in Table 3. From the Table, it is evident that the N–H insertion product decreases steadily concomitant with the increase in the C–H insertion product, as temperature is lowered. Accepting that triplet arylcarbene is generated also in the amine matrix, it is somewhat surprising to note that **8** is not appreciably formed even at −196 °C, because the energy for N–H bond must be less by some 3 kcal mol^{-1} than that for the α-CH bond[5b] in the amine and hence the abstraction of hydrogen by triplet carbene should occur from the N–H bond more easily than from C–H bonds especially at lower temperature,

Table 3. Product distribution as a function of temperature. Photolysis of **1** in diethylamine

T/°C	Relative yield/%[a]		
	8	**9**	**10**
0[b]	62.5	37.5	0
−50[b]	59.9	38.5	1.6
−78[c]	35.1	59.8	5.1
−110[c]	25.5	69.6	4.9
−150[c]	18.1	80.8	1.1
−196[c]	17.0	80.8	1.2

a) See footnote a in Table 2. b) Liquid phase. c) Solid phase.

resulting in the production of **8** *via a-r* mechanism. It is worth noting that, in gas-phase reactions of methyl radical with methylamine, the N–H bond is more than twice as reactive as the C–H bond.[13] Moreover, CIDNP studies of thermal (80 °C) decomposition of diphenyldiazomethane in butylamines have shown[5b] that triplet diphenylcarbene actually abstracts hydrogen from the N–H bond to form the radical pair $\overline{Ph_2CH\cdot \cdot NHR}$, which however separates to each component to give radical dimeric products at this temperature. The kinetics of the reaction have indicated,[5b] on the other hand, that the N–H insertion product is formed *via* an initial attack of the singlet carbene on nitrogen atom of the amine followed by rearrangement of the resulting ylide. The present results support this mechanism. Since the recombination of the radical pair is shown[2] to be favored in rigid media due to the increased viscosity, a decrease in the formation of **8** even in rigid amine matrix suggests that the triplet carbene generated in rigid matrix does not abstract hydrogen from the N–H bond in spite of the energetic advantage. Exact reason for this interesting phenomena is not known at present. It might partly lie in that the interaction of solvent molecules themselves comes to predominate over interactions between guest and amine molecules as temperature is lowered.[14]

Concluding Remarks. The present results have suggested that the low temperature photolysis of aryldiazomethanes in a rigid matrix is a very useful technique to suppress characteristic reactions of singlet carbene and to increase C–H insertions presumably resulting *via a-r* reaction of triplet arylcarbenes. The method has its merits in that (i) it generates the triplet arylcarbene which is usually in a rapid equilibrium with the upper-lying singlet states and hence is not populated generally in liquid phase to the extent which permits the prominent formation of the product derived from it in the sensitized experiment and (ii) it also makes the triplet arylcarbene a synthetically more useful intermediate, while the triplet arylcarbene generated in the liquid phase usually leads to a complex mixture of radical-derived products.

Experimental

The infrared, ^{1}H NMR, and GC-MS spectra were recorded on a JASCO IR-G spectrometer, a JEOL JNM-MH-100 NMR spectrometer, and a Shimadzu GC-MS 1000 spectrometer, respectively. The GC analyses performed on a Yanagimoto instrument, Model G-180, with a flame ionization detector. The following columns were used: A, 4.0 mm × 2.0 m 10% PEG 20 M on 60—80 mesh Diasolid L; B, 4.0 mm × 2.0 m 10% OV-17 on 60—80 mesh Diasolid L.

Materials. Diazomethane **1** was prepared from the corresponding tosylhydrazone immediately before use. All authentic ethers (**3**—**6**) in Eq. 1 were prepared by treatment of the corresponding aromatic alcohols with either ethyl bromide or isopropyl bromide in the presence of silver oxide according to the literature procedure.[5c] Authentic amines (**8**—**10**) were prepared by the reaction of appropriate bromide with excess diethylamine or ethylamine. Their boiling points were 101—103 °C/23 mmHg† (**8**), 103—105 °C/24 mmHg (**9**),

† 1 mmHg≈133.3 Pa.

and 117—119 °C/21 mmHg (**10**), respectively. Preparations of commercially unavailable alcohols were reported elsewhere.[2a,6] Satisfactory spectroscopic and mass spectral data have been obtained on all compounds.

Irradiations and Analyses. All irradiations were conducted using a Halos 300-W high-pressure mercury lamp with a water-cooled quartz jacket. In a typical procedure, 0.005 mmol of the diazomethane was added to 2.0 cm^3 of the appropriate solvent in Pyrex tubes. The sample was then degassed using three freeze-thaw cycles, and the sample tube was sealed in vacuum. The tube was suspended in a transparent Pyrex Dewar flask filled with coolant and irradiated until all diazomethane was destroyed. Photolysis of diphenyloxirane was carried out in quartz tubes in a transparent quartz Dewar. Control experiments ruled out the interconversion of the product during irradiations and also showed that no reaction occurred in the absence of light in the range of temperature studied.

The product identification and relative yields were conveniently determined by standard GC and/or GC-MS techniques.

This work was supported by Grant-in-Aid for Scientific Research No. 454140 from the Ministry of Education, Science and Culture and the Asahi Glass Foundation.

High Pressure Organic Chemistry. V.[1] Diels-Alder Reactions of Furan with Acrylic and Maleic Esters

Hiyoshizo KOTSUKI,* Hitoshi NISHIZAWA,* Masamitsu OCHI, and Kiyoshi MATSUOKA

Department of Chemistry, Faculty of Science, Kochi University, Akebono-cho, Kochi 780

(Received February 5, 1981)

A series of Diels-Alder reactions of furan with acrylic and maleic esters has been investigated under conditions of high pressure. The approximate *endo/exo* ratios of the adducts with acrylic and maleic esters were 6 : 4 and 8 : 2 respectively. The observed isomer distributions are ascribed to the kinetic control.

In a previous paper we reported the successful Diels-Alder reaction of thiophene with maleic anhydride at 15 kbar and 100 °C, which afforded stereoselectively the *exo*-adduct.[2] In the pioneering work of Dauben and Krabbenhoft on the cycloaddition reactions of furan, it has been reported that both *endo* and *exo* isomers are obtained in approximate ratios of 1 : 1 with acrylic esters and only the *endo* isomer with dimethyl maleate.[3]

As a continuation of our investigation in this area, we were particularly interested in the stereochemical outcome of the Diels-Alder reaction at very high pressure.

Generally, steric factors play a significant role in determining the reactivity of dienophiles for high pressure reactions.[3,4] We presumed that in the Diels-Alder reaction of furan with acrylic and maleic esters, the *endo/exo* ratio would change with the variation o alkoxyl in the ester group, since the volume of the transition state for the *endo* addition is expected to be increased by crowding of R function, as shown in the Scheme 1 for the reaction of the acrylic esters. Based on this assumption, we have examined the Diels-Alder reaction of furan with several acrylic and maleic esters at very high pressure.

a) Measured in $CDCl_3$. b) Measured in $CHCl_3$.

isomer distributions of the reactions were analyzed by means of NMR (Table 3).[5]

The observed *endo*/*exo* ratios of the adducts with acrylic and maleic esters were approximately 6 : 4 and 8 : 2 respectively. The *endo*/*exo* ratios were not substantially affected by the change of pressure up to 20 kbar[6] nor by the variation of the alkoxyl in the ester group in the reactions with either acrylic or maleic esters.[7] To examine the possibility of equilibrium between the stereoisomers, the isolated *endo* and *exo* products with methyl acrylate and dimethyl maleate were each kept at 15 kbar for 15 h. However, no isomerization was observed by NMR measurements. These results are in accordance with the restricted retro-Diels-Alder reaction under high pressure conditions.[8] Therefore, the obtained *endo*/*exo* isomer distributions would be the results of kinetic control rather than the type of kinetic and thermodynamic pattern mentioned for the furan-

9		*i*-Bu	0.75
10		C_6H_5	0.41

a) Rate relative to that of reaction 5 ($k=3.77\times10^{-5}$ l mol^{-1} s^{-1}). The values are the average of three or more runs.

maleic anhydride reaction.[9] The high *endo* selectivity of maleic esters is probably due to large secondary orbital interactions.[10]

The steric effects of an alkoxyl group on the reactivity of these dienophiles were explored by a kinetic approach. All the reactions were clearly second-order at 15 kbar. The rate constant (k_2) for the reaction of furan with methyl acrylate was 3.77×10^{-5} l mol^{-1} s^{-1} at 27 °C. The relative rates are shown in Table 4. These show that the reactivity of both acrylic and maleic esters was slightly decreased by increasing the bulkiness of the alkoxyl in the ester group. The most notable decrease is in the reaction with phenyl acrylate (No. 10). The steric factors, such as expected from "rule of six,"[11] might affect the reactivity of these dienophiles. For the usual Diels-Alder reactions, *e.g.*, the reactions of cyclopentadiene with acrylic esters at atmospheric pressure, no such effects due to the variation of an alkoxyl group were observed.[12] Our findings suggest the steric effects must be more serious for high pressure reactions.

Experimental

General Methods. All boiling points and melting points are uncorrected. ^{1}H NMR spectra were obtained on a JEOL-MH-100 spectrometer using solutions in carbon tetrachloride with TMS as the internal standard; the IR spectra were recorded as films on a JASCO IRA-1, unless otherwise stated.

a) Bath temperature. 1 mmHg=133.322 Pa.

All high pressure reactions were performed at a concentration of 3 M† of the reactants in dry dichloromethane. For a description of our high pressure equipment and of the general procedure for high pressure reactions, see Ref. 2.

Since the direct distillation of oily adducts gave a complete decomposition,[3] the elemental analyses were performed after hydrogenation and are expressed as their dihydro derivatives.

Diels-Alder Reaction of Furan with Maleic Esters. The general procedure is as follows. A CH_2Cl_2 solution (1 ml) of furan (3 mmol) and dimethyl maleate (3 mmol) was subjected to 15 kbar hydrostatic pressure for 8 h at 27 °C. After the run, the solution was concentrated to a clear, colorless liquid whose NMR spectrum indicated that the cycloadduct was obtained in a 90% yield and in an *endo*/*exo* ratio of 8 : 2. By chromatographic separation on neutral alumina (elution with hexane–ether), a pure *endo* isomer was obtained as a colorless liquid.[13] An analytical sample was obtained as a colorless liquid after hydrogenation in AcOEt on 10% Pd/C and bulb-to-bulb distillation.[3]

For a large scale preparation of the *exo* isomer, a mixture of 1 g (7 mmol) of dimethyl maleate and 0.48 g (7 mmol) of furan was subjected to 15 kbar pressure at 60 °C for 16 h *without solvent*.[14] The crude product was purified by column chromatography on neutral alumina using hexane–dichloromethane (1 : 1) as the eluent to give the *endo*-adduct **1a** (232 mg; 15.7%). Further elution with dichloromethane gave the *exo*-adduct **2a** (345 mg; 23.4%), which was recrystallized from ether or hexane–dichloromethane.

The spectral data and physical constants are given in Tables 3 and 5.

Diels-Alder Reaction of Furan with Acrylic Esters. The reaction of furan with methyl acrylate was performed as described above. A pure sample of each *endo* and *exo* isomer was obtained after column chromatography on neutral alumina (with hexane–ether, *endo* isomer was obtained from earlier fractions).[13] Analytical samples **6b** and **7b** were obtained as in the case of dimethyl maleate after hydrogenation and distillation.[3] The spectral data and physical constants are given in Tables 3 and 5.

Equilibrium Experiments. A pure sample of each *endo* and *exo*-adduct with methyl acrylate or dimethyl maleate was kept at 15 kbar and 27 °C for 15 h in dichloromethane (*ca.* 1.5 M solution). After the treatments all equilibrium mixtures were checked by NMR.

† 1 M = 1 mol dm^{-3}.

Kinetic Experiments. Kinetic measurements were made using a piston-cylinder type high pressure apparatus[2] in teh same manner as was used for the other high pressure reactions. Each kinetic solution of a diene and a dienophile in dichloromethane was transferred into a Teflon cell (0.8 cm^3) and subjected to pressure. The amount ratio of dienophile and adduct were measured by NMR at appropriate time intervals for 16 h.

Each reaction studied was clearly second-order and gave a mixture of *end-exo* isomeric products. The second-order rate constants were calculated by the usual second-order rate expression.

The authors wish to thank Professor Takashi Tokoroyama, Osaka City University, for valuable discussions and continuous encouragement. They also thanks Mr. Sachio Kitagawa for his experimental assistance.

13) Column or preparative thin layer chromatography on silica gel resulted in a considerable decomposition of the products. Both the *endo* and the *exo* products from maleic or acrylic esters were simply separated by using alumina columns. For the use of silica gel–$AgNO_3$, see Ref. 5a.

14) Considerable amounts of unidentified by-products were also obtained, as well as *ca.* 20% of recovered dimethyl maleate.

NMR and CD Spectral Features of Thiaheterohelicenes. Effect of Intramolecular Overlap of Aromatic Rings

Koh-ichi YAMADA,* Hisao TANAKA, Hiroko NAKAGAWA, Susumu OGASHIWA, and Hiroshi KAWAZURA

Faculty of Pharmaceutical Sciences, Josai University, Sakado, Saitama 350-02

(Received March 30, 1981)

NMR and CD spectral features of a series of thiaheterohelicenes containing alternant thiophene and benzene rings were examined as associated with their helical structures. The terminal ring protons of the thiaheterohelicenes reflected the characteristics of intramolecular overlap of aromatic rings in ^{1}H NMR spectra. With the progression of the helix a sudden chemical shift of the β proton in the end thiophene ring to the higher field occurred, in contrast to carbohelicenes in which the drift of the upfield shift of the corresponding terminal ring proton was gradually suppressed. The CD spectra of thiaheterohelicenes were quite different from those of carbohelicenes. The intensities of the α and β absorption bands weakened with the progressive annelation, whereas the intensity of the p absorption band gradually increased, accompanied by a successive increase in the anisotropy factor of the band. These facts suggest that the structures of thiaheterohelicenes differ from those of carbohelicenes in having a peculiar distortion of the helix.

It has been of interest in helicene chemistry that helicenes are powerful inherently-dissymmetric chromophores of themselves, and that they possess the possibility of interactions between overlapping aromatic rings owing to their helically shaped structures. Chiroptical properties,[1,2] NMR[3] and ESR[4,5] spectral features, and X-ray analyses[6–8] of helicenes have been widely studied, together with molecular orbital calculations.[9,10] However, these investigations have so far been limited to [9] rings, especially in the field of heterohelicenes, presumably because of difficulties in preparations and purifications of the compounds with multi-rings; thus the properties of helicenes higher than [9] rings have remained uncertain. We found high performance liquid chromatography (HPLC) very useful for purifications and optical resolutions of thiaheterohelicenes annelated with alternant thiophene and benzene rings.[11,12] The pure racemic and enantiomeric thiaheterohelicenes obtained by applying this method to the final stages of preparations enabled us to perform the present work.

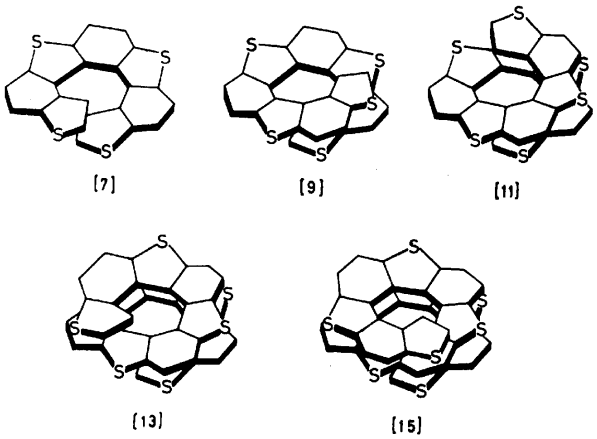
We describe here the characteristics of ^{1}H NMR and circular dichroism (CD) spectra of thiaheterohelicenes ([7] to [15]), compare them with those of carbohelicenes, and discuss the effect of intramolecular overlap of aromatic rings.

Experimental

The preparations[11] and the optical resolutions[12] of thiaheterohelicenes studied have been reported in previous papers. ^{1}H NMR spectra (in $CDCl_3$) were recorded on a JEOL PFT-100 spectrometer operating at 100 MHz in the Fourier transform mode. CD spectra (in $CHCl_3$) were measured on a JASCO J-20A automatic recording spectropolarimeter at 23 °C with concentrations of 8.5×10^{-6}—6.0×10^{-5} mol dm^{-3}; the concentration was 4.25×10^{-4} mol dm^{-3} for the measurement of the α band of [13]thiaheterohelicene.

Results and Discussion

^{1}H NMR Spectral Features. In the previous communication we have assigned the ^{1}H NMR spectra of thiaheterohelicenes studied here, except for that of [15] homolog, where some ambiguity remained because of the partial overlapping of the peaks.[11] Among the protons in this series of compounds the chemical shifts of two protons in the terminal thiophene rings, giving AB or AX type quartet peaks, reflected most characteristically the effect of intramolecular overlap of the aromatic rings. Figure 1 demonstrates the changes in the chemical shifts of the terminal ring protons in the thiaheterohelicene series (A and B protons) against the number of rings, along with the changes in the carbohelicene series (X and Y protons).[13] To clarify the degree of helical turns, the abscissa indicates also the internal angles of the molecules, which were assessed by allocating 45° for a thiophene and 60° for a benzene ring.[2]



The chemical shifts of both A proton in [5]thiaheterohelicene and X proton in [4]carbohelicene likewise appeared in the lower field owing to the mutual van der Waals compressions between the continuous hydrogens.[3,14] When an overlap between the terminal rings occurs (internal angle is more than 360°), large upfield shifts of the protons appeared in both series. Molecular models suggest that A proton is located approximately above the center of the adjacent faced ring and B proton is located in the vicinity outside the helix, whereas X proton lies in the vicinity of the axis of the helix and Y proton lies above the faced ring. These situations are supported by the fact that A and Y

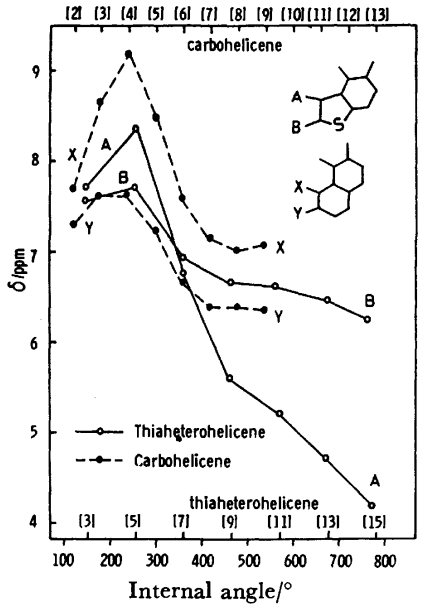


Fig. 1. Influence of the progressive overlap of aromatic rings on the chemical shifts of the terminal ring protons in thiaheterohelicenes and carbohelicenes. The data for carbohelicenes were quoted from the literature.[3]

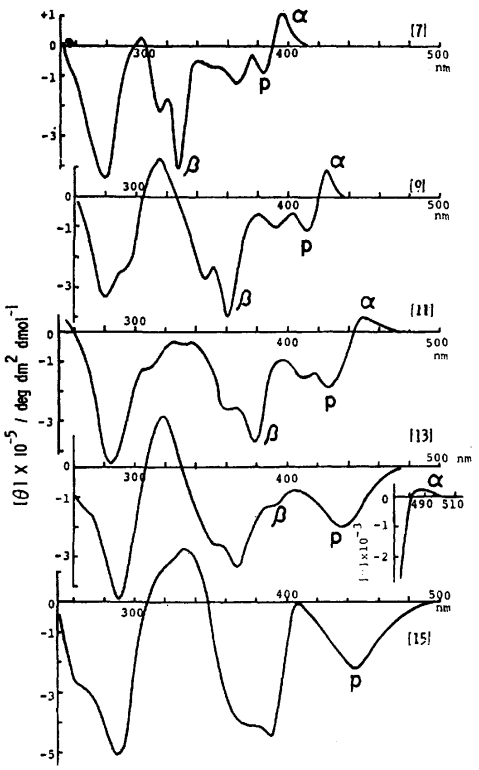

Fig. 2. CD spectra of (*M*)-(−)-thiaheterohelicenes in $CHCl_3$.

protons shifted to higher fields than B and X protons, as a consequence of the stronger diamagnetic shielding by the ring current of the faced rings.

In the carbohelicene series the drifts of upfield shifts of both X and Y protons seem almost to converge with an increase of helical turns, indicating that the diamagnetic shielding effect might become constant at the higher homologs. This is substantiated by X-ray analyses which show that the pitch of the inner helix of carbohelicenes has not varied so much with an increase of number of benzene rings ([7], [10], and [11]-carbohelicene: 3.17, 3.22, and 3.22 Å, respectively).[6] In the thiaheterohelicene series this trend holds approximately for B proton, but not for A proton, the behavior of the latter in the chemical shifts making the thiaheterohelicenes very peculiar. A few reports on the syntheses of carbohelicenes up to [14] rings have been published;[15] nevertheless, to our regret, no NMR data of the carbohelicenes are available for comparing the trends of chemical shifts.

The extents of upfield shifts by the ring current remained in the range of 0.6—1.0 ppm for X and Y and B protons; these values may be compared with those for naphthalene ([2]carbohelicene) and benzo[1,2-*b* : 4,3-*b'*]dithiophene ([3]thiaheterohelicene), which possess no diamagnetic shielding effect. On the other hand, the upfield shift of A proton went up far beyond this range; 2.1 ppm in [9]thiaheterohelicene and 3.5 ppm in [15]. It is rare that an aromatic ring proton shifts as high as about 4 ppm(δ); this is only found for those of metacyclophanes which have a great constraint in a molecule.[16] The trend of A proton shifts may imply that the proton comes closer to the adjacent faced ring with the progression of the helix, since their relative position does not alter, as molecular models suggest. In this case the degree of diamagnetic shielding may be mainly determined by the distance between the proton and the aromatic ring. In order to shorten the distance we can not make the pitches of the thiaheterohelicene helices become smaller with the progressive annelation, because this does not occur in the case of carbohelicenes, as mentioned above.

The significant structural difference between thiaheterohelicenes and carbohelicenes lies in the presence of bulky sulfur atoms. The sulfur atoms in the upper and lower decks of the molecules are relatively close to each other (refer to the Figure). The repulsive forces between the sulfur atoms may keep them as far away from each other as possible and thus bring about distortion of the molecules. This distortion compels the A proton to come closer to the faced ring. With an increase of the number of rings an accumulation of the distortions caused by the repulsions between some pairs of sulfur atoms in a molecule makes the distance smaller and smaller, resulting in the more and more upfield shift of A proton.

CD Spectral Features. In order to study the chiroptical properties of helicenes, precise optical resolutions are needed. We reported the resolutions by HPLC fitted with a silica-gel column containing a chiral charge transfer complexing agent, 2-(2,4,5,7-tetranitro-9-fluorenylideneaminooxy)propionic acid, which functions as a selector.[12] The preparative HPLC was somewhat tedious, but ensured the complete separations between enantiomers. Though CD spectra of some helicene congeners have been described, few changes of the spectra have been discussed from the standpoint of the progression of the helix.

Figure 2 shows the CD spectra of (*M*)-(−)-enantiomers of [7] to [15]thiaheterohelicenes. CD absorption

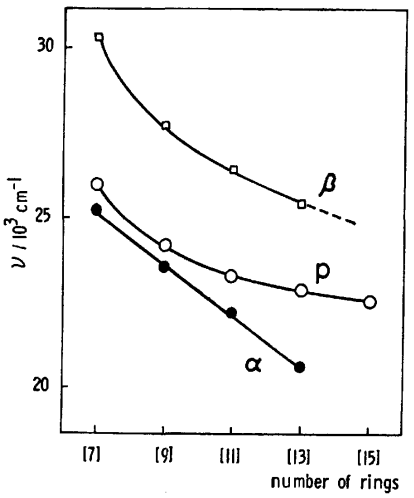

Fig. 3. Changes in transition energies of α, p, and β absorption bands of thiaheterohelicenes.

bands of thiaheterohelicenes are resolved well in comparison with those of carbohelicenes, and there is a clear difference between the spectra.[17] Band assignments to α, p, and β absorptions according to the Clar's nomenclature were tentatively made by the comparison with their UV spectra and by the supposition that the more the extension of the conjugated systems, the longer the wavelength light they absorb. The transition energies of the three longest wavelength absorptions thus assigned are illustrated in Fig. 3 for each thiaheterohelicene. The energies for p and β absorptions appear nearly to converge, but not that for α absorption which is anticipated to have the same tendency in homologs higher than [13]. It is interesting, though the reason is not clear as yet, that the convergency of the energies becomes faster in the order of p>β>α, which is contrary to that of the case in polynuclear aromatic hydrocarbons.[18]

As seen in Fig. 2, each band became successively broader, showing some variation of its intensity with an increase of the number of rings. The broadening of the bands may be ascribable to the increasing overcrowding of the molecules. The intensity of p band was gradually enhanced as the number of rings increases, while those of α and β bands were gradually diminished and finally could not be discerned in the [15] homolog. Wavelength at absorption maxima and molecular ellipticity(θ) of the three bands, together with molecular absorption coefficient(ε) and anisotropy factor(g) of p band, are tabulated in Table 1. Apparent ε values of p band decreased from [7] to [15]thiaheterohelicenes, but the absolute values of [θ], in contrast, increased, leading the absolute values of g to become greater.

As the absorption for p band is due to the transition polarized mainly along the molecular axis,[17] the increment of the intensity may be explicable in terms of the enhanced transition moments caused by an increase of helical turns along the axis. The trend of g factors may reflect the cumulatively increasing distortions with the progression of the helix, as noted in the NMR study. It turns out that the extent of molecular dissymmetry of the present thiaheterohelicene is enhanced as the number of rings increases. On the other hand, as the absorptions for α and β bands are due to the transitions polarized along the perpendicular (C_2 axis) to the molecular axis,[17] the intensities of these bands are not expected to vary significantly with the progressive annelation because molecular diameters along the C_2 axis on a molecular plane are almost the same for each thiaheterohelicene studied. In addition, the increasing overcrowding of the series of molecules may bring about the gradually broadening of the two absorption peaks, resulting in the weak intensity which makes them unobservable in [15]thiaheterohelicene.

In consequence, the configurations of thiaheterohelicenes studied are anticipated to differ considerably from those of carbohelicenes owing to the existence of bulky sulfur atoms. However, we inferred the difference on the basis of the properties only in solutions, and X-ray crystallographic analysis on the compounds may reveal such interesting results.

Selective Dimerization of Aldehydes to Esters Catalyzed by Hydridoruthenium Complexes

Takashi Ito,† Hiroshi Horino,†† Yoshitaka Koshiro, and Akio Yamamoto*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259, Nagatsuta, Midori-ku, Yokohama 227

(Received April 11, 1981)

$RuH_2(PPh_3)_4$ and other hydridoruthenium complexes catalyze selective conversion of aldehydes into esters in high yields. The method is applicable to most aliphatic aldehydes as well as to aromatic aldehydes. The purity of aldehydes is critical for achieving high conversions, since the presence of carboxylic acid completely inhibits the reaction and alcohol and triphenylphosphine reduce the yields of esters. $RuH_2(PPh_3)_4$ is converted into $Ru(CO)_3(PPh_3)_2$ through the reaction indicating the occurrence of decarbonylation of aldehyde. A mechanism involving the acyl-H cleavage of aldehyde is proposed to account for the catalysis and formation of compounds accompanying the reaction. The mechanism is compared with an alternative one which comprises of consecutive insertions of two aldehyde molecules into Ru–H bond followed by β-hydrogen abstraction from an alkoxo intermediate formed. Addition of water changes the reaction course to give carboxylato carbonyl complexes $Ru(OCOR)_2(CO)_m(PPh_3)_2$ ($m=1$ and 2). Cross esterification studies showed the reactivity order of RCHO as R = Et > Me > *n*-Pr > *i*-Pr ≫ Ph.

In contrast to the much utilized aldol reaction of aldehydes another type of aldehyde dimerization converting aldehydes into esters, known as Tishchenko reaction,[1] has been much less explored. The reaction is usually catalyzed by aluminium alkoxides and somewhat detailed studies have been made concerning the structural effects of aldehydes and catalysts.[2-6] Studies have been also made concerning the catalyst systems with boric acid[7] and a system without catalyst.[8] Only a limited study,[9] however, has been made to utilize a transition metal complex for the Tishchenko reaction.

Some transition metal complexes coordinated with tertiary phosphines have been found to decarbonylate aldehydes to hydrocarbons,[10-17] *e.g.*,

$$RCHO + RhCl(PPh_3)_3 \longrightarrow RH + RhCl(CO)(PPh_3)_2 + PPh_3. \quad (1)$$

The reaction is considered to proceed by coordination of the aldehyde to rhodium, followed by oxidative addition of the aldehyde group to give an acyl intermediate which is decarbonylated.[18] Such an assumption seems reasonable in view of the known examples of aldehyde coordination to transition metal complexes[19,20] and of acyl-H bond cleavage.[21-25]

Hydrido-ruthenium complexes, particularly $RuH_2(PPh_3)_4$ (**1**) exhibit quite a variety of stoichiometric as well as catalytic reactions,[26-35] and are considered to possess yet unexploited potentiality to catalyze various reactions. Catalytic hydrogenation of aldehydes to give alcohols with molecular hydrogen[36,37] or with organic hydrogen donors[38,39] using Ru, Rh, or Ir complexes have been reported. From a system containing **1** and propionaldehyde a reportedly "intermediate" complex formulated as $Ru(EtCHO)(PPh_3)_3$ has been isolated[38] but this was later refuted as a mixture of $RuH_2(CO)(PPh_3)_3$ (**2**) and $RuH(OCOEt)(PPh_3)_3$ (**3a**).[29]

We report here the catalytic conversion of aldehydes into carboxylic esters catalyzed by **1** and related ruthenium hydride complexes. Characterization of the ruthenium complexes recovered from the reaction systems is also included with a hope to shed light on the reaction mechanism. A preliminary account of this system was made previously.[40]

Results

Reactions of Butyraldehyde with $RuH_2(PPh_3)_4$ (1). When carefully purified butyraldehyde is brought into contact with a catalytic amount of **1** *in vacuo* at room temperature, a violent, exothermic reaction starts in 2—3 min. The reaction is completed in several minutes to give a dark brown solution, the GLC analysis of which shows conversion of most butyraldehyde into butyl butyrate.

$$2\,Pr^nCHO \xrightarrow{\text{cat.}} Pr^nCOOBu^n \quad \text{cat.} = \mathbf{1} \quad (2)$$

Although the reaction is accompanied by the formation of a stoichiometric amount of 1-butanol, the reaction product is free of either aldol-condensation products or trimeric glycol ester, indicating the high selectivity of the reaction. On working up the system after completion of the reaction, the known tricarbonyl complex, $Ru(CO)_3(PPh_3)_2$[41-43] (**4**) is isolated as a sole characterizable ruthenium complex. A careful purification of aldehyde, especially rigorous exclusion of carboxylic acid and water was found essential for initiating the catalytic reaction.

The results of typical experiments are listed in Table 1. The ester forming reaction took place at −20 to +100 °C, with the highest conversion around 0 °C (compare runs 3, 10, 20, and 21). The system kept at −20 °C afforded a lower yield of ester and a dihydrido carbonyl complex, tentatively assigned to $RuH_2(CO)(PPh_3)_3$(**2**),[44] was isolated from the reaction mixture. The system is essentially inactive at −30 °C and the carboxylato complex, $RuH(OCOPr^n)(PPh_3)_3$(**3b**), was obtained on working up the system kept at −30 °C for 2 h. One

possible reaction for the catalyst deactivation at the low temperature is the conversion of catalyst **1** into the carboxylato complex **3b** prior to the initiation of the esterification reaction. Complex **3b** was found to be inactive for the esterication reaction (*vide infra*).

For pure aldehydes, complex **1** proved to be quite active achieving *ca.* 2000 turnovers at 0 °C with the concentration of as low as 0.05 mol% (run 15). Although the catalyst is deactivated at the completion of the reaction, addition of the new crop of the catalyst to the reaction system containing remaining unreacted aldehyde initiated the catalysis (runs 3—7).

Addition of butyric acid completely inhibits the reaction (run 9) whereas the presence of two equivalents of 1-butanol per catalyst did not completely block the reaction but considerably reduced the conversion of aldehyde to ester (run 8). The reaction can be performed under nitrogen as well as in vacuum (run 11) whereas hydrogen somewhat reduced the conversion (run 12). Solvents such as hexane, toluene and tetrahydrofuran may be used provided they are appropriately purified (runs 16—18) but employment of the more coordinating solvent such as pyridine notably reduced the catalytic activity (run 19).

Complex **1** can be used for conversion of other aldehydes such as acetaldehyde, propionaldehyde,

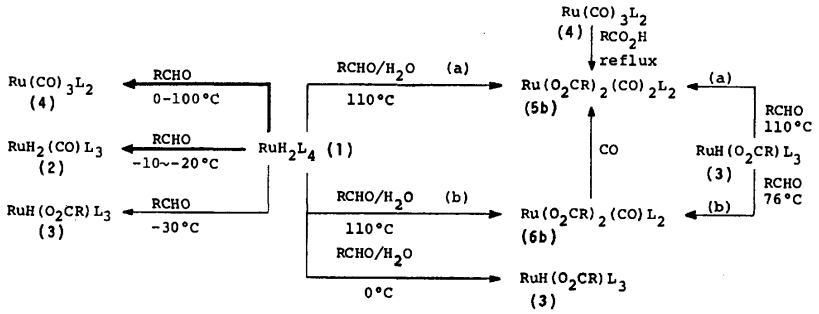
a) Reactions were carried out *in vacuo* for 2 h in a Schlenk type flask unless otherwise stated. b) **2**: $RuH_2(CO)(PPh_3)_3$; **3b**: $RuH(OCOPr^n)(PPh_3)_3$; **4**: $Ru(CO)_3(PPh_3)_2$; **5b**: $Ru(OCOPr^n)_2(CO)_2(PPh_3)$; **6b**: $Ru(OCOPr^n)_2(CO)(PPh_3)_2$. c) Other products(yield in mmol): H_2 (0.04), C_3H_6 (0.018), C_3H_8 (0.059), and CO (trace). d) The yield was not measured. e) Reactions were carried out in a Pyrex glass-autoclave. f) Reactions were carried out in a stainless steel-autoclave. g) Other products: H_2 (0.21), C_3H_6 (0.04), C_3H_8 (0.05), and CO(0.272). h) Amount of $RuH(OCOPr^n)(PPh_3)_3$ **3b**. i) Heated under reflux under N_2 atmosphere for 2 h in a Schlenk type flask.

isobutyraldehyde, valeraldehyde, isovaleraldehyde, hexanal, and benzaldehyde (Table 2). The yields are somewhat low for some aldehydes, but optimization of the reaction conditions may well enhance the yields. Considerable hindrance of the catalysis by addition of triphenylphosphine was noted (run 27). The reaction of acrylaldehyde with **1** either at 0° or at −20 °C afforded a massive brown polymeric material, which is insoluble in most organic solvents.[45]

Cross-esterification Reaction. For examining relative reactivities of aldehydes cross esterifications using about 1 : 1 binary mixtures of aldehydes have been carried out. Cross esterification of the 1 : 1 mixture of acetaldehyde and propionaldehyde, for example, catalyzed by **1** at room temperature afforded ethyl acetate (A), propyl acetate (B), ethyl propionate (C), and propyl propionate (D) in a ratio of 1.00 : 0.53 : 1.95 : 1.35. The result, indicating the higher yield of D than A as well as the higher yield of C than B, suggests that the reactivity of propionaldehyde to the esterification reaction is slightly higher than that of acetaldehyde. Similar comparison of the product distributions, using especially the ratios of A/D as the reactivity index in Table 3 in the mixed esterification reactions of various aldehydes, allows one to estimate their relative reactivities toward esterification reaction as $CH_3CH_2CHO > CH_3CHO > CH_3(CH_2)_2CHO > (CH_3)_2CHCHO \gg PhCHO$. The same order was obtained for the relative proton donor ability of each aldehyde which was estimated from the comparison of values B and C in Table 3. The similar values of the product distribution have been reported for the systems containing acetaldehyde and butyraldehyde, and benzaldehyde and butyraldehyde catalyzed by aluminium alkoxides.[2,3]

Absence of the ester exchange reaction between the product esters under the reaction conditions was confirmed by the additional experiments in which propionaldehyde and butyraldehyde, respectively, were allowed to react with **1** at 85 °C in the presence of ethyl acetate. In both cases, the resulting systems contained only propyl propionate and butyl butyrate, respectively, in addition to the added ethyl acetate and no mixed esters were detected showing the absence of the ester exchange reaction.



(a): Reactions were carried out *in vacuo* in a stainless steel autoclave.
(b): Reactions were carried out *in vacuo* or under N_2 in a Pyrex glass flask.
L=PPh_3, R=*n*-C_3H_7, broad arrows stand for the reactions accompanied with catalytic ester-formation reactions.

Examination of Ruthenium Complexes Recovered from the Reaction Mixture of Aldehyde and $RuH_2(PPh_3)_4$ in the Presence or Absence of Added Water. In order to obtain insight into the mechanism of the present reaction, the ruthenium complexes recovered after completion of the reactions under various conditions were examined. The results are summarized in Table 4 and Scheme 1. As mentioned previously, tricarbonyl complex **4** was isolated from the reaction system carried out at temperatures above 0 °C where high conversions to ester was achieved (run numbers 1 and 39 in Table 4). Hydridocarbonyl complex **2** was also formed when the reaction was carried out at −10 ——20 °C (runs 20 and 21). On the other hand, wherever no esterification reaction proceeded, as in the reaction at −30 °C (run 22) or at 0 °C in the presence of water (run 40), hydridocarboxylato complex **3b** was isolated a as sole ruthenium complex. Heating the reaction mixture at 110 °C in the presence of water resulted in the formation of carboxylato-carbonyl-complexes, $Ru(OCOPr^n)_2(CO)_2(PPh_3)_2$ (**5b**) or $Ru(OCOPr^n)_2(CO)(PPh_3)_2$ (**6b**) depending on the experimental conditions (runs 41—43).

In some reaction systems listed in Table 4, examination of gaseous product revealed the formation of H_2, methane, propane and propene (runs 39 and 41).

Properties of Dicarboxylato-mono- and -dicarbonyl Complexes and Some Related Reactions. Spectroscopic data for the new carboxylato–carbonyl complexes **5b** and **6b** thus obtained are listed in Table 5. Their reactions with an excess of methyl iodide afforded methyl propionate, although their yields were less than stoichiometric amount. Complex **6b** absorbed about one mole of carbon monoxide per mole of **6b** in toluene at room temperature to give complex **5b** quantitatively. Complexes **5b** and **6b** were also obtained by the reaction between hydridocarboxylato complex **3b** and butyraldehyde in the absence of water (runs 44 and 45 in Table 4). The reaction of **4** with Pr^nCHO at 100 °C either with or without added water only resulted in the recovery of the unreacted complex. These results suggest that the ability of the ruthenium complexes to decarbonylate aldehydes decreases with increase in the number of CO ligand attached to ruthenium.

A propionato homolog of **6b**, $Ru(OCOEt)_2(CO)(PPh_3)_2$ (**6a**), was obtained by the reaction of $RuH_2(PPh_3)_4$ **1** with a slightly impure propionaldehyde at 80 °C *in vacuo*.[46] Spectral data of **6a** are included in Table 5. In the ^{1}H-NMR spectrum of **6a**, triplet and multiplet signals at room temperature assignable to the

a) Reactions were carried out *in vacuo* in a Schlenk type glass flask. b) Propionaldehyde (R=C_2H_5) for runs 46—52 and butyraldehyde (R=*n*-C_3H_7) for runs 54—62. c) Propyl propionate for runs 46—52 and butyl butyrate for runs 53—62. d) Starting complex was recovered quantitatively.

ethyl groups of the propionato ligands split into a set of pairs of triplets and quartets at −20 °C indicating the existence of two unequivalent carboxylato groups in **6a**. Similarly to **6b**, complex **6a** released about a half mole of methyl propionate per mole of complex on reaction with excess methyl iodide.

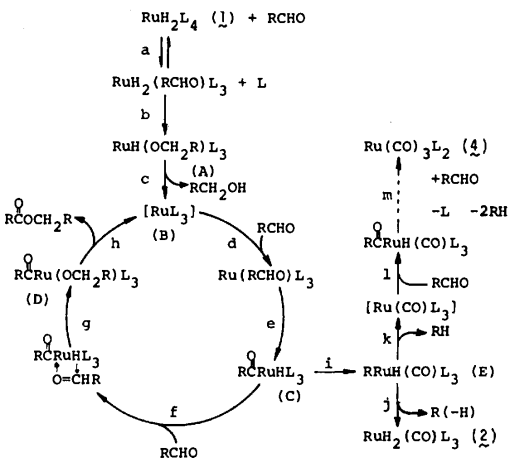
Examination of the Catalytic Activities of Various Transition Metal Complexes for Conversion of Aldehydes into Esters. As shown in Table 6, most hydrido ruthenium complexes possess catalytic ability of esterification reaction among various transition metal complexes examined. That the "ethylene" complex of a composition $Ru(C_2H_4)(PPh_3)_3$ also shows the catalytic activity may be due to the presence of the hydrido species such as $RuH(o\text{-}C_6H_4PPh_2)(PPh_3)_2(C_2H_4)$ or $RuH_2(o\text{-}C_6H_4PPh_2)(CH=CH_2)(PPh_3)_n$ in solution.[28,29] The introduction of a chloride anion to the hydrido complex considerably reduced its efficiency (runs 48 and 49). Dichloro derivative and tricarbonylruthenium(0) complex were inactive, although a stoichiometric amount of 1-propanol was formed in the reaction with the former complex.

Among hydrido and alkyl transition metal complexes other than ruthenium ones examined, only hydrido rhodium complex showed a feeble activity yielding ester in more than a stoichiometric amount (run 55).

Discussion

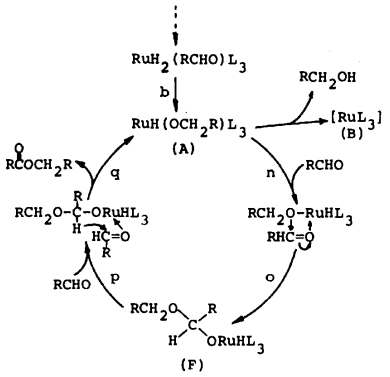
The Mechanism of the Catalytic Reaction. Two alternative routes, shown in Schemes 2 and 3 are conceivable for the present catalytic conversion of aldehyde to ester.

In Scheme 2 aldehyde first coordinates to $RuH_2(PPh_3)_3$, formed by ligand dissociation, to give $RuH_2(RCHO)(PPh_3)_3$ followed by insertion of the carbonyl group of aldehyde into Ru–H bond (path b). The insertion of the organic carbonyl group into the metal to carbon or hydrogen bond, not unusual reaction for the main group elements such as Grignard reagent and alkyllithium, has been postulated in some reactions involving organo transition metal complexes.[47] Reductive elimination of alkoxo and hydrido ligands from intermediate A yielding RCH_2OH and the Ru(0) species, $[RuL_3]$, then follows (path c). The similar processes to paths a—c have been proposed by Imai



L = PPh_3, R = CH_3, CH_3CH_2, $CH_3(CH_2)_2$, etc.

Scheme 2.



L = PPh_3; R = CH_3, CH_3CH_2, etc.

Scheme 3.

et al. for the catalytic hydrogen transfer reaction from organic hydrogen donor molecule to aldehyde by complex **1**.[38]

The second molecule of aldehyde coordinates to [RuL_3] and oxidatively adds to Ru to give hydrido acyl intermediate (path e). The oxidative addition of aldehyde involving a cleavage of aldehydic hydrogen-carbon bond has been postulated in many examples accounting for the decarbonylation from aldehyde with transition metal complexes,[10-17] and the hydridoacyl type complex corresponding to the intermediate C has been isolated in some cases.[21-25]

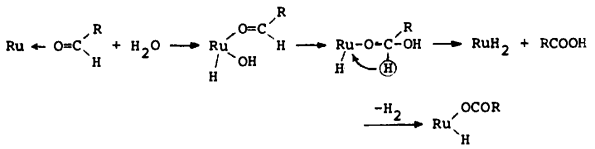
The third aldehyde molecule coordinates to the intermediate C and is inserted into the Ru–H bond to give an acyl-alkoxo type intermediate D, which on reductive elimination releases ester accompanied by regeneration of B. In this catalytic cycle, acyl intermediate C may isomerize *via* a decarbonylation reaction (path i) to alkyl carbonyl intermediate E, which may give hydrido carbonyl complex **2** and alkene by the β-elimination reaction (path j), or tricarbonyl complex **4** on repetition of the reductive elimination of alkane, the oxidative addition of aldehyde, and decarbonylation (paths k, l, and m). Both complexes **2** and **4** are the final products isolated in the ester formation reaction carried out at −20 °C and above 0 °C, respectively.

The mechanism of catalytic ester formation alternative to Scheme 2 is shown in Scheme 3 which is somewhat similar to those proposed for the so called Tishchenko reaction catalyzed by aluminium alkoxide.[5] In this mechanism, hydridoalkoxo intermediate A which is formed in a similar path as in Scheme 2 reacts with the second aldehyde molecule (path n) which is inserted into Ru–O bond to give another alkoxo intermediate F (path o). The following hydrogen transfer from alkoxo ligand to the third aldehyde, presumably by a β-hydrogen elimination mechanism, affords ester regenerating A. The hydrido and alkoxo ligands in A may be eventually removed as alcohol by a reductive elimination process.

It is difficult to decide which mechanism is operative in the catalytic conversion on the basis of limited information presently available. However, formation of the carbonyl complexes **2**, **4**, **5**, and **6** indicates that a decarbonylation reaction of aldehyde involving the acyl-H bond cleavage is taking place during or after the catalytic process. Assumption of the oxidative addition of aldehyde is consistent in Scheme 2, although the occurrence of the oxidative addition of aldehyde to RuL_3 (B) to give the carbonyl complexes *after* the completion of the catalytic process can not be excluded. Furthermore the high activity of hydrido ruthenium complexes is in favor of the mechanism involving aldehyde insertion into Ru–H.

The presence of a small amount of water drastically alters the reaction path (run 40 of Table 4).

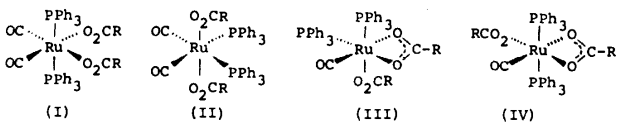
The formation of the hydrido(carboxylato) complex **3** may be caused by interaction of water with **1** by a possible mechanism as shown below. Disproportionation



of aldehydes into alcohols and carboxylic acids in the presence of water was recently found to be catalyzed by ruthenium and rhodium complexes under neutral conditions presumably by a different mechanism.[48] The reaction of **1** with carboxylic acid is known to give **3**.[49]

Recently, catalytic dimerization of terminal epoxides to carboxylic ester by $RuCl_2(PPh_3)_3$ has been reported.[50] Although epoxides can be regarded as one of the isomeric forms of aldehyde, the mechanism of the ester formation of this system differs from that of the present study described above, since the order of reactivity, *i.e.*, aromatic epoxides >aliphatic epoxides, is opposed to that found in our system.

The Configuration of Carboxylato Complexes of Ruthenium-(II). Analogous complexes to di(butyrato)dicarbonylbis(triphenylphosphine)ruthenium **5b** was previously prepared by reaction of $Ru(CO)_3(PPh_3)_2$ with carboxylic acids RCOOH in benzene,[51] or in 2-methoxyethanol,[49,52] by treatment of RuH(OCOR)-$(PPh_3)_3$ with CO,[42] for R=H, CH_3, C_2H_5, p-ClC_6H_4, p-$NO_2C_6H_4$, and CF_3. By analogy to discussion presented for $Ru(OCOCF_3)_2(CO)_2(PPh_3)_2$,[53] complex **5b** probably has the configuration (I). However, the possibility of (II) is not completely ruled out since the $^{31}P\{^1H\}$ NMR chemical shift of **5b** (Table 5) deviates from that observed in this type of complexes where two phosphorus atoms are in mutually *trans* positions (44±0.5 ppm).[53]



(I) (II) (III) (IV)

Dicarboxylato monocarbonyl complexes Ru-$(OCOR)_2(CO)(PPh_3)_2$ **6** have been prepared by treating $RuH_2(CO)(PPh_3)_3$ with carboxylic acid in 2-methoxyethanol (R=p-ClC_6H_4, and p-$NO_2C_6H_4$)[49] or in toluene (R=CF_3).[52] Acetato analogue has been prepared by the action of $NaOCOCH_3$ with trifluoro-

acetato complex,[54] or by the action of CO with $Ru_2O(OCOMe)_4(PPh_3)_2$.[55] According to the configurational assignment made by Dobson and Robinson,[54] complexes **6a** and **6b** may have structure III where unidentate and bidentate carboxylato ligands are exchanging in an NMR time scale above room temperature. The alternative structure IV which has been assigned for the acetato complex prepared by Wilkinson's method[55] can be ruled out for the present product because of the significant resemblance of the spectra of complexes **6a** and **6b** to those reported by Dobson and Robinson.[54] Similarly to the trifluoroacetato complex,[54] complex **6** was converted into dicarbonyl analogue **5** on treatment with carbon monoxide.

Experimental

All reactions and manipulations were carried out under dry, oxygen-free nitrogen or *in vacuo* using Schlenk-type flasks unless otherwise stated. Solvents were dried and purified in the usual manner and stored under an inert atmosphere. Commercial aldehydes were purified by a careful distillation over calcium hydride or molecular sieve 5A through the Widmer type fractionating column of 30 cm length under nitrogen. Aldehydes thus purified was stirred with calcium hydride or, more preferably to avoid the formation of aldol condensates, molecular sieve 5A for about 1 h just before the reaction and distilled at room temperature directly into the flask containing the catalyst complex *in vacuo* (*ca.* 10^{-3} mmHg, 1 mmHg≈133.3 Pa). Dihydridotetrakis(triphenylphosphine)ruthenium(II) **1** was prepared from $RuCl_3 \cdot 3H_2O$ (Nippon Engelhard) by the methods reported by Levison and Robinson[56] and Harris *et al.*[57] The other complexes used in the present study were prepared according to the reported method as follows: $RuH_2(PPh_3)_3$,[56] $RuH_2(CO)(PPh_3)_3$,[58] $RuHCl(PPh_3)_3$,[59] $RuHCl(CO)(PPh_3)_3$,[58] $RuH\{-CH=C(Me)-COOEt\}(PPh_3)_3$,[31] $Ru(C_2H_4)(PPh_3)_3$,[28] $RuCl_2(PPh_3)_3$,[60] $Ru(CO)_3(PPh_3)_2$,[58] $[RuH(PPh_3)_4]^+[PF_6]^-$,[61] $RhH(PPh_3)_4$,[56] $FeH_2N_2(PEtPh_2)_3$,[62] $CoH(N_2)(PPh_3)_3$,[63] $MoH_4(Ph_2PCH_2CH_2PPh_2)_2$,[64] $Mo(C_2H_4)(Ph_2PCH_2CH_2PPh_2)_2$,[65] $Pd(C_2H_5)_2(PMePh_2)_2$,[66] and $Pt(C_2H_5)(C_5H_7O_2)(PPh_3)_2$.[67] Hydridopropionato complex $RuH(OCOPr^n)(PPh_3)_3$ **3b** was prepared according to the method reported for the preparation of the acetato analogue $RuH(OCOMe)(PPh_3)_3$[49] with some modification.

The reaction products in the ester formation reaction was quantitatively analyzed by GLC using internal standard. GLC was performed on Shimadzu GC-3BT, GC-5AP$_3$F, and GC-6APT models using Shimadzu ITG-2A and Chromatopac-ElA integrators. SDC-410 (4m) and -550 (4m), PEG-20M (3 and 4m), TCP (3 m), and DOP (3 m) were employed as columns for the analyses of esters. Gaseous products were analyzed quantitatively by a Toepler pump and characterized by GLC using Molecular sieve 5A (for H_2, N_2, and CH_4 analyses), activated charcoal (for C_2) and Porapak Q (for C_3–C_4) as columns. Infrared spectra were recorded on a Hitachi model 295 spectrometer using KBr disks prepared under inert atmosphere. ^{1}H- and ^{31}P-NMR spectra were measured on JEOL's JNM-PS-100 and FX-100 instruments at 100 MHz for ^{1}H and 40.5 MHz for ^{31}P operated by Mr. Y. Nakamura of our Laboratory. Microanalyses were carried out on a Yanagimoto's CHN autocorder type MT-2 by Mr. T. Saito of our Laboratory.

Catalytic Ester Formation Reaction. Reactions were carried out with various aldehydes under a variety of conditions. However, since the routine procedure does not differ so much with each other, the typical process is described below for the reaction of butyraldehyde at different temperatures. Schlenk type flasks were used for the most of runs, but the use of small autoclave made of Pyrex glass or stainless steel is indispensable for reactions of acetaldehyde in order to avoid the dangerous breakage of the vessel due to the violent exothermic reaction.

The reaction can also be carried out in the atmosphere of nitrogen instead of under vacuum (run 11). This method is more convenient in a practical sense than that using vacuum line technique, but a sufficient care is necessary to control the explosive exothermic reaction.

Although the reactions were usually brought to completion in the initial several minutes, most reactions were carried out for 2 h unless otherwise stated.

a) Reactions of Butyraldehyde at 0 °C: Into the Schlenk flask containing $RuH_2(PPh_3)_4$ **1** (0.149 g, 0.129 mmol), 4.71 cm^3 (52.4 mmol) of butyraldehyde was distilled over molecular sieve 5A *in vacuo* by a trap-to-trap method. In about 2 or 3 min at 0 °C *in vacuo*, the system evolved a lot of heat causing refluxing and the initial yellow suspension was converted into a dark brown turbid solution. The rapid heat evolution is ceased in a few min. After the system was stirred in an ice-bath for 2 h, gases evolved by the reaction were analyzed to reveal the formation of H_2, propane and propene. GLC analysis of the resulting solution indicated the presence of butyl butyrate (26.0 mmol) and a small amount of 1-butanol. The reactions at 20 °C and 100 °C proceeded similarly.

For the purpose of isolating the complex formed by the reaction, the similar reaction as above was carried out in a larger scale. From the dark brown solution obtained as above from 0.630 g of **1** (0.547 mmol) and 69 mmol of Pr^nCHO, volatile matters were evaporated off *in vacuo* to leave brown solid which was washed with Et_2O and hexane to afford a brown powder. The powder was dissolved in 40 ml of toluene. The resulting brown solution was repeatedly filtered to remove traces of decomposed product such as ruthenium metal. On concentration of the filtrate *in vacuo*, a yellow precipitate came out which was filtered, washed with hexane and dried *in vacuo*. The yellow complex thus obtained was charaterized as the known $Ru(CO)_3(PPh_3)_2$ (0.217 g, yield 56%) on the basis of its IR spectrum (ν(CO) 1900 cm^{-1} vs; lit, 1900 cm^{-1} vs[58]).

b) Reactions of Butyraldehyde at −10—−20 °C: The reaction mixture prepared as *a*) from 0.173 g of $RuH_2(PPh_3)_4$ (0.150 mmol) and 61.1 mmol of Pr^nCHO, when kept at −20 °C, evolved heat in 10 min to give a dark grey, turbid solution. After stirring at −20 °C for 2 h, formation of 18.7 mmol of butyl butyrate was observed by GLC analysis together with a small amount of 1-butanol. On working up the system as *a*), about 50 mg of a white micro crystalline powder was obtained which was identified tentatively on the basis of IR spectrum as $RuH_2(CO)(PPh_3)_3$ (ν(Ru–H) 1960 sh, and ν(CO) 1935 cm^{-1} vs; lit, ν(Ru–H), 1960 m, 1898 m, and ν(CO), 1940 cm^{-1} vs[58]).

c) Reactions of Butyraldehyde at −30 °C: Stirring the yellow suspension of $RuH_2(PPh_3)_4$ (0.180 g, 0.156 mmol) in 63.9 mmol of Pr^nCHO prepared similarly to the method described in *a*) at −30 °C resulted in the color change of the system to a greenish yellow, heterogeneous mixture in 2 h without any heat evolution. No ester was detected in the system. Working up the system as *a*) yielded 0.12 g of a yellow microcrystalline powder which was identified as $RuH(OCOPr^n)(PPh_3)_2$ (yield 80%) on the basis of the comparison of the IR data with those reported for RuH-

$(OCOR)(PPh_3)_2$ where R=Me or Et[49] (ν(Ru–H) 1990 w and $\nu(CO_2)$ 1515 m and 1415 cm^{-1}).

Preparation of Dibutyratodicarbonylbis(triphenylphosphine)-ruthenium(II), $Ru(OCOPr^n)_2(CO)_2(PPh_3)_2$ 5b. Dihydrido-complex **1** $RuH_2(PPh_3)_4$ (0.96 g, 0.83 mmol) was put into a stainless steel autoclave flashed with nitrogen, then the autoclave was connected to a vacuum line and evacuated. Butyraldehyde (187 mmol) and 2.87 mmol of water were added successively *in vacuo* by means of a trap-to-trap method to the reaction vessel. The system was heated at 110 °C *in vacuo* by immersing the autoclave in an oil bath. After 2 h, the amounts of gases evolved by the reaction were measured and the resulting pale grey heterogeneous mixture was transferred to the Schlenk flask and worked up as already described. An off-white powder thus obtained was recrystallized from toluene to give pale yellow crystals of $Ru(OCOPr^n)_2(CO)_2(PPh_3)_2$ **5b** (0.22 g, yield 30%). IR and ^1H- and ^{31}P-NMR data are as listed in Table 5. Found: C, 63.9; H, 5.3%. Calcd for $C_{46}H_{44}O_6P_2Ru$: C, 64.6; H, 5.2%. The purified sample was still contaminated with a trace amount of $RuH_2(CO)(PPh_3)_2$ **2** as indicated by its IR spectrum.

Complex **5b** was also obtained by the similar reaction as above from $RuH(OCOPr^n)(PPh_3)_2$ **3b** and butyraldehyde in a stainless steel autoclave at 110 °C. The reaction was accompanied by the formation of a small amount of H_2, CO, Pr^nCOOBu^n, and Bu^nOH.

Preparation of Dibutyratocarbonylbis(triphenylphosphine)ruthenium (II), $Ru(OCOPr^n)_2(CO)(PPh_3)_2$ 6b. The similar reaction as above between 2.95 g of $RuH_2(PPh_3)_4$ **1** (2.22 mmol) and 340 mmol of Pr^nCHO in the presence of 16.1 mmol of water in a glass autoclave yielded a clear, orange solution. On cooling the solution to room temperature, pale yellow crystals deposited, which were filtered, washed with diethyl ether and hexane and dried in vacuo and identified as $Ru(OCOPr^n)_2(CO)(PPh_3)_2$ **6b** (1.21 g, yield 55%) on the basis of IR and ^1H- and ^{31}P-NMR spectra (Table 5). Found: C, 64.4; H, 5.4%; Mw, 806. Calcd for $C_{45}H_{44}O_5P_2Ru$: C, 65.3; H, 5.3%; Mw, 828. The reaction accompanied the formation of the dicarbonyl complex **5b** which was sometimes difficult to remove.

Complex **6b** was also obtained by the reaction of hydridocarboxylato complex **3b** (1.84 g, 1.64 mmol) with butyraldehyde (222 mmol) in a Pyrex glass Schlenk flask heated under reflux under nitrogen for 2 h. On working up, 1.00 g of **6b** was obtained (yield 86%).

Photoreduction of Bisviologen Compounds, Viologen-$(CH_2)_n$-Viologen, by 2-Propanol

Masaoki FURUE* and Shun-ichi NOZAKURA

Department of Macromolecular Science, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received May 13, 1981)

In order to study the polymer effect in the photoreduction of viologen-containing polymers by 2-propanol, bisviologen compounds, V^{2+}-$(CH_2)_n$-V^{2+}, were subjected to photoreduction. The rates of photoreduction occur in the order $n=2>3>4>5>MV^{2+}$. The structure of the photoreduced species was found to be predominantly the doubly reduced species, V^+-$(CH_2)_n$-V^+, in the cases of $n=2$ and 3, and mixtures of the doubly reduced and singly reduced species, V^+-$(CH_2)_n$-V^{2+}, in the cases of $n=4$ and 5. Intramolecular dimeric association of V^+ units was observed for all the compounds except for $n=2$, where the intramolecular association was structurally inhibited. The variation of rate and structure distribution of reduced species was interpreted in terms of the local concentration effect in the photoreduction step.

Methylviologen (MV^{2+}) is known as an efficient electron transfer mediator in the conversion of light energy into chemical energy.[1-5] We are interested in the viologen-containing polymers because we expect the facilitated electron migration along the polymer chain and some possible multi-electron transfer from the reduced polymer. In the previous paper we reported the synthesis of some viologen-containing vinyl polymers and studied the polymer effect in the photoreduction by 2-propanol and in the properties of the reduced polymer.[6] It was found that the two neighboring viologen units on a polymer chain appeared to cooperate in the photoreduction and that this cooperation resulted in the increase of the rate of photoreduction and in the dimeric association of two reduced viologen units. This may be a kind of local concentration effect.

The object of the present paper is to confirm the local concentration effect by the use of model compounds **1** containing two viologen units at various polymethylene intervals. The part of the present work on compound **1b** ($n=3$) has been briefly communicated.[7]

1 (a,b,c,d for $n=2,3,4$, and 5, respctively)
1′,1″-(Polymethylene)bis(1-methyl-4,4′-bipyridinium)perchlorate.

Results and Discussion

Structure of Reduced Species ($n=3$). Figure 1 shows the time profile for the photoreduction of compound **1b** ($n=3$) in an aqueous solution. A monotonous increase of the radical cation species absorbing at 360, 533, and ≈850 nm was observed. The same spectral change was observed by the treatment of **1b** ($n=3$)

2

3

2: Doubly reduced form, **3**: singly reduced form (a,b,c,d for $n=2,3,4$, and 5, respectively).

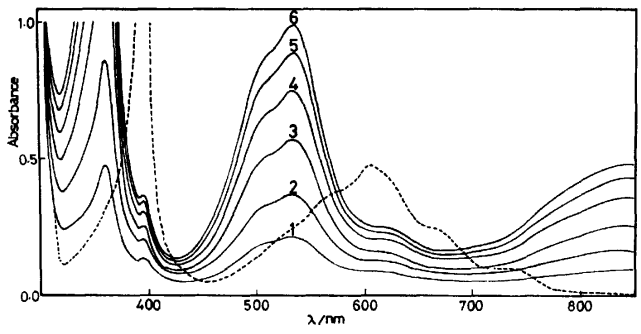

Fig. 1. Absorption spectra of photoreduced species of **1b** ($n=3$) in phosphate buffered aqueous solution (pH 5.9) containing 2-propanol (0.65 mol dm^{-3}). The concentration was [**1b**]$=5.0\times10^{-4}$ mol dm^{-3}. Irradiation time, 1: 0.5, 2: 1.0, 3: 2.0, 4: 3.0, 5: 4.0, 6: 5.0 h. Absorption spectrum of MV^+ was shown by a dotted line.

(6.5×10^{-5} mol dm^{-3}) with an excess of sodium dithionite (1.7×10^{-2} mol dm^{-3}) under anaerobic condition, where both viologen units of **1b** ($n=3$) were reduced to form the doubly reduced form **2**. As shown in Fig. 1, the spectrum obtained on photoreduction was different from that of MV^+ at ambient temperature. MV^+ has been known to exist in an equilibrium with a dimeric associated species $(MV^+)_2$, as in Eq. 1:[8,9]

$$MV^+ + MV^+ \rightleftharpoons (MV^+)_2. \quad (1)$$

The observed spectrum in the photolysis corresponds to that of the associated form, which was stable only at very low temperatures. Thus, the spectral difference between the photoreduced **1b** ($n=3$) and MV^+ in Fig. 1 can be explained by intramolecular association of the V^+ groups in the photoreduced **1b** ($n=3$). Moreover, we prepared the singly reduced form **3** ($n=3$) and confirmed that its spectrum corresponds to that of monomeric MV^+, as shown in Fig. 2. The singly reduced form **3** ($n=3$) was prepared by the electron transfer reaction from hydroxydiphenylmethyl radicals, which were generated *in situ* by the unimolecular thermolysis of benzpinacol at 60 °C in a methanol solution containing **1b** ($n=3$, Cl^- form) under an anaerobic condition. It has been known that the reduction of MV^{2+} by the hydroxydiphenylmethyl radical was very efficient.[10] The time profile for the

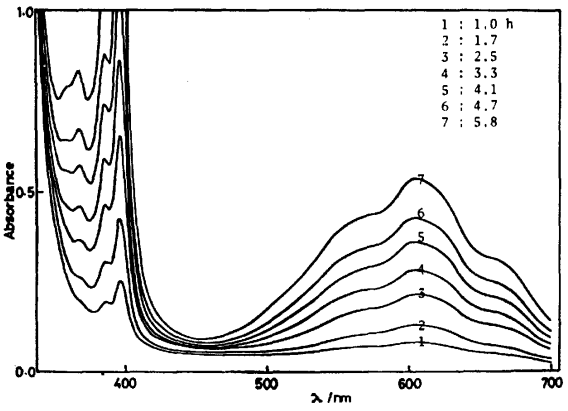

Fig. 2. Reduction of **1b** ($n=3$, Cl^- form) by hydroxyphenylmethyl radical in a methanol solution at 60°C. The concentrations were [**1b**]$=8.0\times10^{-3}$ mol dm^{-3} and [benzpinacol]$=2.0\times10^{-3}$ mol dm^{-3}.

thermal reaction (Fig. 2) showed a monotonous increase of the MV^+-type absorption of **3** ($n=3$). Thus, the photoreduced **1b** ($n=3$) has been shown to be **2** in the intramolecular associated form.

It is interesting to note that this assignment excludes the possibility of molecular complexes between the V^+ unit and the V^{2+} unit, although several examples of aromatic compounds are known to exhibit this kind of association.[11] Furthermore, in spite of the exothermicity of the dimeric association, there was no indication of an intermolecular electron transfer process which would lead to the formation of **2** ($n=3$) by the electron exchange between **3**'s ($n=3$).[12,13]

Structure of Photoreduced Species (n=*2, 4, and 5*).

The absorption spectrum of the partially photoreduced **1a** ($n=2$) shown in Fig. 3A, however, is entirely of the MV^+ type and the completely reduced species obtained with $Na_2S_2O_4$-treatment also showed the same spectrum. It is therefore reasonable to assign the structure **2a** ($n=2$) to the photoreduced **1a** ($n=2$) and to assume that **2a** ($n=2$) does not take an associated structure. Inspection of molecular models shows conformational difficulty in the association.

When **1c** ($n=4$) and **1d** ($n=5$) were completely reduced by $Na_2S_2O_4$, the spectra showed maxima at 536 and 539 nm, respectively, indicating that **2c** ($n=4$) and **2d** ($n=5$) show the intramolecular association like that in **2b** ($n=3$) (Figs. 3C and D). The spectra of the partially photoreduced specimens of **1c** ($n=4$) and **1d** ($n=5$) in Figs. 3 C and D have maxima at 540 and 603 nm in 6 : 4 ratio for $n=4$ and 5 : 5 for $n=5$. These two specimens may be concluded to be mixtures of **2** and **3**.

Rate of Photoreduction by 2-Propanol. Based upon the above interpretation of the absorption spectra, the concentrations of the singly reduced and doubly reduced species are evaluated. The observed absorbance (A) at any given wavelength is given by

$$A = \varepsilon_1 C_1 L + \varepsilon_2 C_2 L, \qquad (2)$$

where ε_1 and ε_2 are the molar extinction coefficients at the wavelength of the singly reduced and doubly reduced species, respectively, C_1 and C_2 are the corresponding concentrations, and L is the light path (1 cm). Table 1 shows λ_{max} and ε_{max} of bisviologen compounds (**1**) and doubly reduced species (**2**) together with the other ε values necessary for the estimation of C_1 and C_2. ε_2 in each case was determined from the absorption spectrum of the doubly reduced species which was produced by the treatment with an excess of $Na_2S_2O_4$. The singly reduced species was assumed to have the same extinction coefficient (ε_1) as that of MV^+. C_1 and C_2 were calculated using equation 2 from absorbance values at two different wavelengths, namely, at 603 nm and 530—540 nm. The latter wavelength is the maximum absorption of the doubly reduced species of **1b** ($n=3$), **1c** ($n=4$), and **1d** ($n=5$). In the case of **1a** ($n=2$), the photoreduced product was found to be only the doubly reduced species, as shown in Fig. 3A. ε_2 in this case is the value of **2a** ($n=2$).

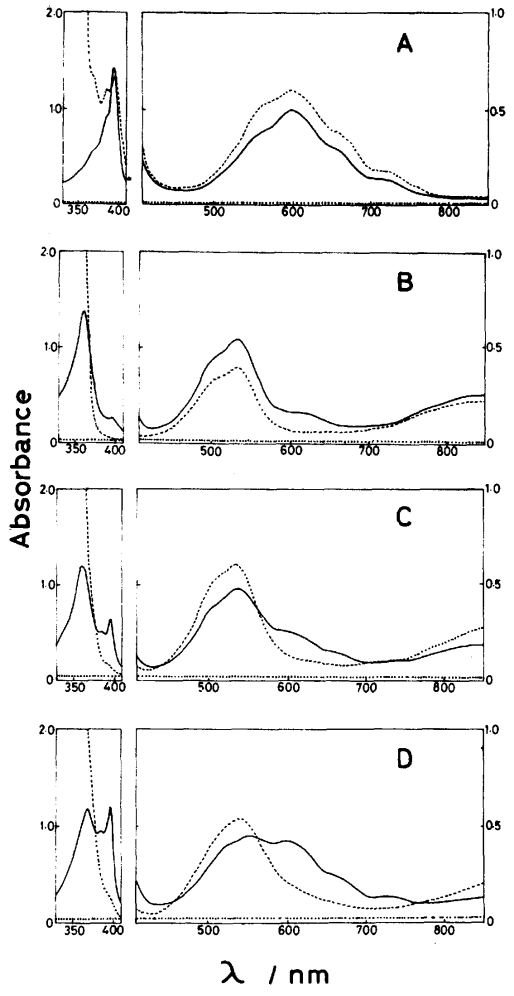

Fig. 3. Absorption spectra of radical cations of **1** partially photoreduced (——) and completely reduced with $Na_2S_2O_4$ (------) and base lines (·····) for the latter.
A: [radical ion]$=4.95\times10^{-5}$ unit mol dm^{-3}, [2a ($n=2$)] $=3.01\times10^{-5}$ mol dm^{-3}.
B: [radical ion]$=5.14\times10^{-5}$ unit mol dm^{-3}, [2b ($n=3$)] $=1.67\times10^{-5}$ mol dm^{-3}.
C: [radical ion]$=4.59\times10^{-5}$ unit mol dm^{-3}, [2c ($n=4$)] $=2.54\times10^{-5}$ mol dm^{-3}.
D: [radical ion]$=5.08\times10^{-5}$ unit mol dm^{-3}, [2d($n=5$)] $=2.43\times10^{-5}$ mol dm^{-3}.

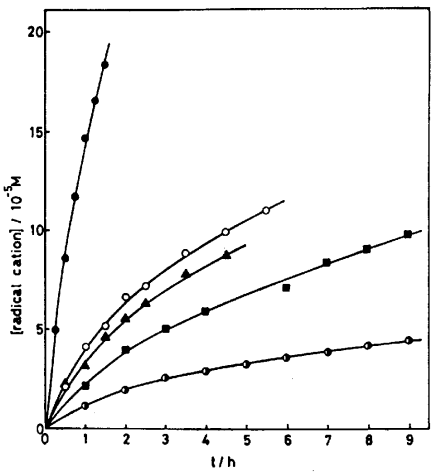

Fig. 4. Photochemical formation of radical cations from bisviologen compounds **1** and MV^{2+} in phosphate buffered aqueous solution (pH 5.9) containing 2-propanol (0.65 mol dm^{-3}). The concentrations were $[\mathbf{1}]=5.0\times10^{-4}$ mol dm^{-3} and $[MV^{2+}]=1.0\times10^{-3}$ mol dm^{-3}.
●: **1a** ($n=2$), ○: **1b** ($n=3$), ▲: **1c** ($n=4$), ■: **1d** ($n=5$), ◑: MV^{2+}.

The total amount of photoreduced species, C_1+2C_2, is plotted *versus* time in Fig. 4. Bisviologen compounds were found to show no special interunit interaction at the ground state, as shown by similar absorption maxima in Table 1. The rate curves of the photoreduction in Fig. 4, however, show marked differences. The initial rate decreased in the order $n=2>3>4>5>MV^{2+}$. This fact may be explained in terms of the local concentration effect by the following argument. The photoreduction of MV^{2+} by 2-propanol is known to proceed by the following mechanism:[10]

$$MV^{2+} \xrightarrow{h\nu} MV^{2+*}, \quad (3)$$

$$MV^{2+*} + (CH_3)_2CHOH \longrightarrow MV^{+} + (CH_3)_2CHO\cdot + H^{+}, \quad (4)$$

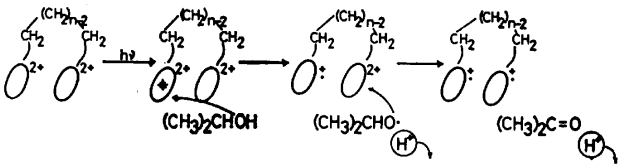
$$MV^{2+} + (CH_3)_2CHO\cdot \longrightarrow MV^{+} + (CH_3)_2C{=}O + H^{+}, \quad (5)$$

$$\text{Net}\quad 2MV^{2+} + (CH_3)_2CHOH \xrightarrow{h\nu} 2MV^{+} + (CH_3)_2C{=}O + 2H^{+}. \quad (6)$$

The excited viologen receives an electron from 2-propanol, leaving the alkoxyl radical. The latter in turn gives up another electron to a ground state MV^{2+}. One photon eventually results in the reduction of two MV^{2+} molecules and the oxidation of one alcohol molecule. The alkoxyl radical $(CH_3)_2CHO\cdot$, in addition to reaction 5, has another possibility of reaction 7, which is a backward electron transfer reaction. The competition between reactions 5 and 7

$$MV^{+} + (CH_3)_2CHO\cdot \longrightarrow MV^{2+} + (CH_3)_2CHO^{-} \quad (7)$$

depends on the relative local concentration of MV^{+} and MV^{2+}. In the case of bisviologen compounds, the alkoxyl radical will find nearby another viologen unit of the bisviologen compound before it diffuses out of the reaction site, and reaction 5 will take place (Scheme 1). Thus the local concentration effect will be exerted favorably on the rate of reaction in bisviologen compound- and viologen polymer-systems, compared with MV^{2+}. It is reasonable that bisviologen compounds with shorter intervening polymethylene chains have higher initial rate because of higher local concentrations of V^{2+} units.



Scheme 1. Mechanism of photoreduction of bisviologen compounds ($n=2$—5) by 2-propanol.

Figure 4 shows that there was a saturation phenomenon and that the saturation appeared at an earlier stage of conversion in the compounds whose initial rate was slower. The saturation phenomenon is also explained in terms of reaction 7. When the concentration of V^{+} unit increases, the contribution of the backward reaction 7 relative to the forward reaction 5 will increase, leading to saturation in the concentration of V^{+} units. Moreover, if the local concentration effect is small, as in the case of **1d** ($n=5$) in comparison to **1a** ($n=2$), the larger contribution of reaction 7 relative to reaction 5 will result in the slower initial rate and at the same time the earlier occurrence of the saturation phenomena. The saturation phenomena in the case of MV^{2+} were explained by Ledwith in terms of the quenching reaction 8 of excited

$$MV^{2+*} + MV^{+} \longrightarrow MV^{2+} + MV^{+} \quad (8)$$

MV^{2+} with MV^{+}.[10,14] This reaction alone, however, does not explain the difference in onset of the saturation phenomena among bisviologen compounds.

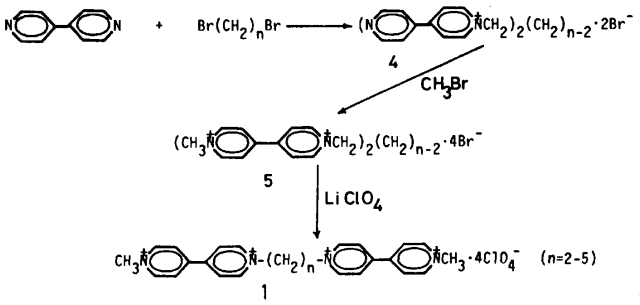
Table 1. Absorption spectral data of methylviologen and bisviologen compounds[a]

Compound	1 (Bisviologen compounds)		2 (Doubly reduced species)			
	λ_{max}/nm	ε_{max}/mol^{-1} cm^{-1}	λ_{max}/nm	ε_{max}/mol^{-1} cm^{-1}	λ/nm	ε/mol^{-1} cm^{-1}
1a ($n=2$)	263	4.40×10^4	595	1.99×10^4	603	1.96×10^4
1b ($n=3$)	260	4.38×10^4	533	2.36×10^4	603	0.18×10^4
1c ($n=4$)	259	3.88×10^4	536	2.39×10^4	603	0.41×10^4
1d ($n=5$)	258	4.52×10^4	539	2.20×10^4	603	0.68×10^4
MV^{2+}	256	1.39×10^4	603	1.20×10^4	533[c]	0.53×10^4

a) Measured at 25 °C. b) Reduced with $Na_2S_2O_4$. c) ε : 0.62×10^4 mol^{-1} cm^{-1} at 539 nm and 0.53×10^4 mol^{-1} cm^{-1} at 536 nm.

Experimental

*Preparation of Bisviologen Compounds, **1a** (n=2), **1b** (n=3), **1c** (n=4), and **1d** (n=5).* 1′,1″-(Polymethylene)bis(1-methyl-4,4′-bipyridnium)perchlorate **1** was prepared according to the following general procedure.



1,1′-(Polymethylene)bis(4-bipyridinium)dibromide **4** was prepared by warming a solution of 4,4′-bipyridine (25 g, 0.16 mol) in *N,N*-dimethylformamide (DMF) (200 ml) with α,ω-dibromoalkane (40 mmol) at 70 °C for 24 h. A light yellow precipitate separated out and was recrystallized from water for $n=2$ and 3 and from an acetone–methanol mixture for $n=4$ and 5. Yields of **4** were 25, 55, 50, and 64% for $n=2$, 3, 4, and 5, respectively.

Treatment of **4** (20 mmol) with an excess of methyl bromide (30 ml) in DMF (270 ml) in a glass autoclave (400 ml) at 90 °C for 24 h afforded **5** in nearly quantitative yields. **5** (4 mmol) was converted to the corresponding perchlorate **1** by the treatment with an aqueous solution (100 ml) of $LiClO_4$ (47 mmol) at room temperature. For $n=5$, 94 mmol of $LiClO_4$ was used under the same conditions. Recrystallization from water gave colorless crystals. Yields of **1** were 75, 61, 73, and 47% for **1a** ($n=2$), **1b** ($n=3$), **1c** ($n=4$), and **1d** ($n=5$), respectively.

1a. Found: C, 37.25: H, 3.49; N, 7.30; Cl, 18.43%. Calcd for $C_{24}H_{26}N_4O_{16}Cl_4$: C, 37.52; H, 3.31; N, 7.29; Cl, 18.46%.

1b. Found: C, 37.70; H, 3.71; N, 7.18; Cl, 18.01%. Calcd for $C_{25}H_{28}N_4O_{16}Cl_4$: C, 38.38, H, 3.61; N, 7.16; Cl, 18.13%.

1c. Found: C, 39.16; H, 3.90; N, 7.07; Cl, 17.91%. Calcd for $C_{26}H_{30}N_4O_{16}Cl_4$: C, 39.21; H, 3.80; N, 7.04; Cl, 17.81%.

1d. Found: C, 39.68; H, 4.11; N, 6.98; Cl, 17.41%. Calcd for $C_{27}H_{32}N_4O_{16}Cl_4$: C, 40.02; H, 3.98; N, 6.91; Cl, 17.50%.

A chloride ion type of **1** ($n=3$) was prepared by the replacement of the bromide ion of **5** with a chloride ion; this involved passing an aqueous solution of **5** through a column of anion exchange resin (Amberlite IRA 400).

Photoreaction. Light from a 300 W high pressure mercury lamp was filtered through aqueous 5% potassium hydrogen phthalate to remove light of shorter wavelength than 300 nm. A quartz cell was charged with a viologen sample in an aqueous solution of 2-propanol (0.65 mol dm^{-3}) at pH 5.9 (phosphate buffer, 1/15 mol dm^{-3}), degassed, sealed, and set in a thermostat equipped with a merry-go-round.

Measurements. Electronic absorption spectra were measured by a Hitachi Model 124 spectrophotometer with a thermostatically controlled cell compartment.

The Photo-induced Radical Rearrangement of 7-Oxocholesteryl Hypoiodite in the Presence of Mercury(II) Oxide and Iodine[1]

Hiroshi SUGINOME*, ** and Fumihiro YONEBAYASHI

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received May 15, 1981)

7-Oxocholesteryl hypoiodite in benzene containing mercury(II) oxide and iodine underwent a photo-induced rearrangement to give 5-iodomethyl-*A*-nor-5ξ-cholestane-3,7-dione and 2-iodo-7-oxo-*A*-nor-2,3-secocholest-5-en-3-yl formate in low yields, together with cholesta-3,5-dien-7-one without any accompanying 3α,5-epoxy-6-iodo-*A*-homo-4-oxacholestanes which are common products in the reactions of cholest-5-en-3-ols. The results thus show that the introduction of an oxo group at the C-7 position results in an appreciable change in the products of the reactions of cholest-5-en-3-ols.

The mercury(II) oxide-iodine reagent has been shown to be an effective reagent for the formation of hypoiodites from alcohols.[2] A variety of hypoiodites of steroidal alcohols thus prepared undergo either heat or light-induced reactions to give products which can be explained as having originated by the homolysis of the hypoiodites.[2,3] The active species generated from mercury(II) oxide and iodine is believed to be iodine oxide, I_2O,[4] which transforms the alcohols into the hypoiodites.

In a series of previous papers, we reported the results of our investigations of the photo- and thermally-induced rearrangements of hypoiodites of cholesterol,[5] the related 5-cholesten-3-ols,[6,7] and *C*-nor-*D*-homosteroid-5-en-3β-ols[8] in the presence of mercury(II) oxide and iodine. Cholesteryl hypoiodite has been found to afford oxabicyclic compounds, 3α-5-epoxy-6β-iodo-*A*-homo-4-oxa-5α-cholestane and its 6α-isomer, accompanied by a moderate yield of 2-iodo-*A*-nor-2,3-secocholest-5-en-3-yl formate.[5] The pathways to these products, which involve the reactions of iodine oxide and intermediary radical species generated by the β-scission of the corresponding oxyl radicals, have been discussed in the previous papers.[5-8]

In this paper, we wish to report the results of the photoinduced reaction of 7-oxocholesteryl hypoiodite in the presence of mercury(II) oxide and iodine, which was undertaken in order to assess the effects of the carbonyl group adjacent to the potential allyl radical portion of the intermediate generated by the β-scission of the 3β-oxyl radical.

7-Oxocholesterol (**1**)[9] in dry benzene containing mercury(II) oxide and iodine in a Pyrex vessel was irradiated with a 100-W high-pressure mercury arc under an argon atmosphere for 8.5 h to afford a mixture of products. The preparative TLC of the mixture gave three crystalline compounds, (**2**) (4%), (**3**) (13%), and (**4**) (5%), in the order of their mobility, together with several unidentified minor products (Scheme 1). Compound **2**, carrying an iodine atom, has a molecular formula of $C_{27}H_{43}O_2I$ as determined by mass spectrometry and the elemental analysis. The chemical ionization mass spectrum gave a series of ions attributable to $M^+ + 1$, $M^+ + 29$ and $M^+ + 41$ indicative of a molecular weight of 526, while the EI mass spectrum gave the molecular ion of *m/e* 526. All the spectral results on **2** can be reconciled with the 5-iodomethyl-*A*-nor-5ξ-cholestane-3,7-dione structure. The infrared spectrum showed two bands in the carbonyl region ascribed to five- and six-membered cyclic ketones. The presence of these carbonyl groups was further confirmed by the ^{13}C NMR spectrum, which showed two signals arising from carbonyl carbons at δ 212.4 and 206.7 ppm. The ^1H NMR spectrum, which was most instructive, showed an AB quartet (τ 6.65 and 6.75 $J=10.7$ Hz) with very small outer peaks ascribable to the iodomethyl group attached to the C-5 and a one-proton doublet at τ 7.07 ($J=13.5$ Hz) ascribed to one of the protons attached to the C-6. It also showed another doublet at τ 7.91 ($J=13.5$) which was superimposed on the other protons. On irradiation at the center of doublet at τ 7.07, the doublet at τ 7.91 collapsed to a singlet while on irradiation at the center of the doublet at τ 7.91, the other doublet collapsed to a singlet. The doublet at τ 7.91 is thus ascribed to one of the protons attached to the C-6. The 10β- and 13β-methyl groups resonated at τ 8.69 and 9.35.

The spectral evidence also enabled us to formulate the structure of compound **3** as 2-iodo-7-oxo-*A*-nor-2,3-secocholest-5-en-3-yl formate. The IR spectrum showed three strong bands at 1738, 1677, and 1178 cm^{-1}. The former two are assigned to bands arising from formate and α,β-unsaturated carbonyl groups. The latter is attributed to the C–O stretching of formate. The UV spectrum showed a strong absorption maximum at 231 nm (ε; 11570) ascribable to an α,β-unsaturated carbonyl group. The NMR spectrum showed two one-proton singlets at τ 1.86 and 3.98 ascribable to the formate proton[10] and the C-6 proton. It also showed an AB quartet with the very small outer peaks (5.11 and 5.30, $J=15.0$ Hz) ascribed to the methylene protons carrying a formyloxy group and a two-proton multiplet at from τ 6.86 to 7.30 ascribed to the C-2 methylene carrying an iodine atom. The 10β- and 13β-methyl groups resonated at τ 8.77 and 9.31.

Finally, product **4** was found to be cholesta-3,5-dien-7-one[9] on the basis of its IR, UV, ^1H NMR, and mass spectra.

The foregoing results show that the introduction of an oxo group at the C-7 of cholest-5-en-3-ol results in an appreciable change in the products in this reaction. Thus, we failed to isolate the 7-oxo derivative of 3α,5-

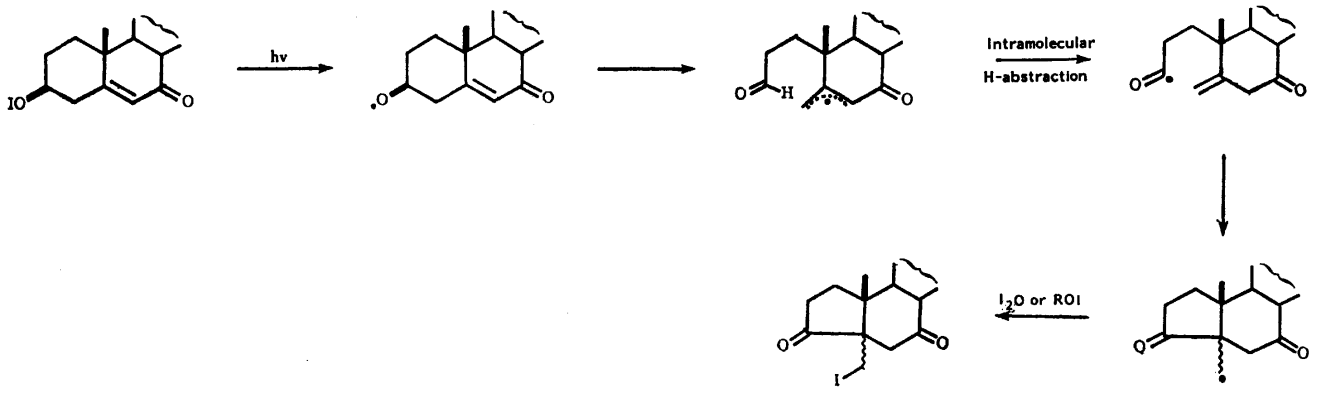

Scheme 2.

epoxy-6-iodo-*A*-homo-4-oxacholestanes, which are 7-oxo-derivatives of the products from cholesterol, from the product mixture in spite of repeated careful experiments. It is almost certain, therefore, that these oxabicyclic compounds are not formed in the present reaction.

The iodo-seco compound **3**, on the other hand, is an example of the type of products which are commonly obtained in the reaction of 5-cholesten-3β-ols.[5-8] A probable pathway by which this class of compound is formed has already been discussed in a previous paper.[5] The OI group appears to be a good leaving group, and dienone **4** may thus be formed by an ionic removal of the element of IOH.

The diketone **2** is a new type of product in this reaction. The mechanism by which this compound is formed is not clear at the present stage. One probable pathway to lead to the diketone **2**, which passes through the allyl radical intermediate and involves an intramolecular hydrogen abstraction *via* a seven-membered transition state by the C-6 center of the allyl radical to form an acyl radical which cyclizes to the five-membered ring,[11] is depicted in Scheme 2. A pathway involving the photo-rearrangement of β,γ-unsaturated ketone,[12] which can be formed from the 3β-oxyl radical, is, however, another possibility.

Experimental

For the instruments used and the general procedures, see Ref. 5. The mass spectrum was recorded by Miss Yuko Chiba in the Faculty of Agriculture with a JEOL JMS-D 300 spectrometer (70 eV).

7-Oxocholesterol. To a solution of 7-oxocholesteryl acetate[13] (2.48 g) in methanol (150 cm^3), there was added potassium hydroxide (10 g) in water (3 cm^3) and chloroform (40 cm^3). The solution was stirred for 2.5 h at room temperature. The solution was neutralized with 2 mol dm^{-3} hydrochloric acid, and a part of the solvent was removed by means of a rotary evaporater. The solution was then extracted with chloroform, and the chloroform solution was washed with water and dried over anhydrous sodium sulfate. The subsequent evaporation of the solvent gave a crude 7-oxocholesterol. Its recrystallization from diethyl ether–hexane gave pure 7-oxocholesterol (**1**); mp 172—174 °C (lit,[9] mp 157 °C). NMR, τ 9.30 (18-H), 8.81 (19-H), and 4.30 (6-H).

Irradiation of 7-Oxocholesteryl Hypoiodite in the Presence of Mercury(II) Oxide and Iodine. 7-Oxocholesterol (1 g) in benzene (145 cm^3) containing mercury(II) oxide (1.62 g) and iodine (1.91 g) in a Pyrex vessel was irradiated with a 100-W high pressure mercury arc under an argon atmosphere. The lamp was placed outside the reaction vessel. The irradiation was discontinued after 8.5 h since the decomposition of 7-oxocholesterol was nearly complete at this point. The solution was filtered, and the filtrate was worked up in a usual manner.[2] The oily product was subjected to column chromatography (Merck Kiesel gel 60, 70—230 mesh, 30 g). Elutions with benzene gave two fractions, A (836 mg) and B (34 mg). Further elutions with benzene containing an increasing amount of chloroform and with chloroform gave Fraction C (310 mg). Further elutions with chloroform containing an increasing amount of diethyl ether, diethyl ether only, and a 1 : 1 mixture of diethyl ether and acetone gave Fraction D (256 mg). Elutions with acetone, a 1 : 1 mixture of acetone and methanol, and methanol gave Fraction E (66 mg). Fraction A was a mixture, and it was subjected to preparative TLC with hexane–diethyl ether (5 : 1) to give four fractions; A^1, (7 mg), A^2 (24 mg), A^3 (171 mg), and A^4 (52 mg). Fraction A^2 was a diketone which was identical with Fraction B. Fraction A^3 was a formate **3**. Fraction A^4 was a diene **4**.

Fraction A^2 and B were combined and recrystallized from acetone to afford compound **2**, mp 188.5—190.0 °C; IR, 1739 (5-membered-ring ketone) and 1714 cm^{-1} (6-membered-ring ketone); for NMR, see text. MS, *m/e* (rel intensity) 526 (M^+, 0.7), 511(M^+-CH_3, 0.9), 399 (M^+-I, 100), 95

(24.4), 69 (19.8), 57 (25.4), 55 (22.5), and 43 (24.3). (Found; C, 61.46; H, 8.30; I, 24.17, Calcd for $C_{27}H_{43}O_2I$; C, 61.59, H, 8.23, I, 24.10%). Fraction A[3] was recrystallized from methanol to give **3**; mp 99—100 °C. (Found: C, 58.78: H, 7.90; I, 23.87. Calcd for $C_{26}H_{41}O_3I$; C, 59.08, H, 7.82; I, 24.01%); IR, 1738 (OCHO), 1738 and 1677 (α,β-unsaturated carbonyl), and 1178 cm^{-1} (OCHO): for NMR, see text; UV_{max} (C_2H_5OH), 231 (ε: 11570). Fraction A[4] was recrystallized from methanol to yield cholesta-3,5-dien-7-one, (4)[9]; mp 108—110 °C. (Lit,[9] mp 112 °C); IR 1653 cm^{-1} ($\alpha,\beta,\gamma,\delta$-unsaturated C=O); UV_{max} (C_2H_5OH) 278 (ε 26320); NMR τ 9.29 (3H, s, 18-H), 8.87 (3H, s, 19-H); 4.39 (1H, broad s, 3-H), 3.88 (1H, s, 6-H), and 3.88 (1H, broad s, superimposed on 6-H signal, 4-H).

We wish to thank Mrs. Tomoko Okayama for the measurements of the ^1H NMR spectrum and the spin-decoupling experiments. We also wish to thank the Finnigan Corporation, Sunnyvale, California, U. S. A., for the chemical-ionization mass spectrum of Compound **2**.

The Cyclic Voltammetry and Cathodic Reduction of Steroidal Homoallylic Nitro Esters. Dimerization *vs.* Cyclopropane Formation[1]

Takeo SATO,* Yoshihisa KOMEICHI, Shoichi KOBAYASHI, and Akira OMURA
Department of Chemistry, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158
(Received May 20, 1981)

The cathodic reduction of homoallylic nitro esters was carried out in DMF–TBAP using platinum electrodes. The reaction was found to be highly dependent on the ester-leaving group: Whereas 6-nitrocholest-5-en-3β-yl acetate (**3a**) gave a 3,3′-dimer **4**, 3β-tosylate **3d** gave a cyclosteroid, 6β-nitro-3α,5-cyclo-5α-cholestane (**7**). 3β-Trifluoroacetate showed intermediate behavior and gave both **4** and **7**. Similarly, 6-nitrocholest-5-ene-3β,19-diol 3-acetate 19-tosylate gave 5β,19-cyclosteroid. The cyclic voltammetry was carried out for these and related compounds. A reversible cyclic voltammogram was recorded for **3a**, but **3d** showed no anodic peak on potential reversal. A possible electron-transfer and the following chemical-reaction mechanism was discussed.

The cathodic reactions of conjugated or homoconjugated systems in aprotic media are potentially useful as a means to induce remote reactions without reducing or protonating the electroactive group which itself is serving as the electron inlet. In this investigation we carried out the cathodic reduction of homoallylic nitro esters, such as **1**, in a steroid series. We found two

$$ROCHCH_2C{=}CNO_2$$

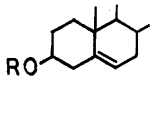
1, R = Ac, Ts *etc.*

types of reactions, namely, dimerization and cyclopropane-ring formation, which were highly dependent on the nature of the ester-leaving groups. The results are discussed in relation to the electrochemical parameters, as determined by cyclic voltammetry.

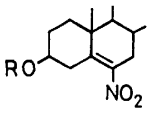
Results

Controlled-potential Electrolyses of Two Nitro Esters, 3a and 3d. 6-Nitrocholest-5-en-3β-yl acetate (**3a**) was obtained by the nitration reaction of cholesteryl acetate (**2a**).[2] The acylation or sulfonylation of 6-nitrocholest-5-en-3β-ol (**3**, R=H) gave benzoate **3b**, trifluoroacetate **3c**, and tosylate **3d**. For comparison, some cholesteryl esters **2a—d** were also prepared.

The cathodic reduction was carried out in a divided cell using platinum electrodes. Anhydrous DMF containing tetrabutylammonium perchlorate (TBAP, 0.1 mol dm^{-3}) was used as the reaction medium; it had been purged with nitrogen before the electrolysis. As reference, a saturated calomel electrode (SCE) was used.



2



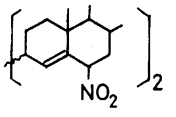
3

a, R = Ac
b, R = PhCO
c, R = CF_3CO
d, R = Ts

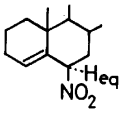
The controlled-potential electrolysis of the acetate **3a** supplied from a potentiostat at −1.44 V gave a precipitate after 1 F mol^{-1} of electricity had been consumed. We thus obtained a high-melting material with a molecular weight of 826 (the Rast method), for which a dimeric structure **4** (MW 829) was assigned based on the spectral evidence to be presented below. The yield of **4** was 45%.

Compound **4** showed an IR absorption at 1550 cm^{-1}, indicating the presence of a nitro group substituted on a saturated carbon. The proton NMR spectrum showed two single-proton resonances due to a vinylic proton (C-4H) at δ 5.90 as a multiplet and a proton attached to a saturated carbon carrying a nitro group (C-6H) at δ 4.67 (multiplet).

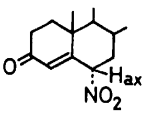
The location of the olefinic linkage and the configuration of the nitro group were determined by spectral comparison with related materials, 6β-nitrocholest-4-ene



4



5



6

(**5**)[3] and 6α-nitrocholest-4-en-3-one (**6**).[4] Compound **5** showed the C-4H proton resonance at δ 5.90. The half-band width of C-5H in **4** (7.5 Hz, H_{eq}) can be compared with that of **6** (16.5 Hz, H_{ax}). The configuration at C-3 could not be determined.[5]

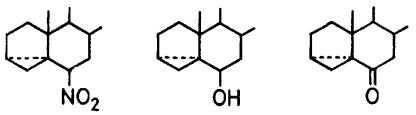
The use of a lead cathode instead of platinum reduced the yield of **4**. When tetrabutylammonium tetrafluoroborate (TBAF) was used as a supporting electrolyte instead of TBAP, the yield of **4** was also reduced. The addition of methanol to the reaction mixture caused intense coloration and greatly reduced the yield of **4**, indicating that a reduction of the nitro group occurred.

When the tosylate **3d** was electrolyzed at −1.45 V as above (1.5 F mol^{-1}), we obtained only a 4% yield of the dimer **4**. Instead, a new compound was formed which showed the IR maxima at 3030, 3070, and 3080 cm^{-1}, indicating the presence of a cyclopropane ring. A nitro group was assumed to be attached to a saturated carbon (1550 cm^{-1}). The proton NMR spectrum showed no vinylic proton resonance, but it did show a one-proton absorption at δ 3.87 with a half-band width of 8.3 Hz, which was attributable to an equatorial proton at C-6. Accordingly, the nitro group exists in an axial configuration. The compound showed the highest-field carbon-13 NMR resonance at δ 12.3. For comparison, compound **8**[6] showed the C-4 carbon resonance at δ 12.1. These results indicate the compound

Table 1. Controlled-current electrolyses of nitro esters **3a**—**3d**[a]

Compound	Concn/mmol dm^{-3}	Potential variation/$-$V[b]	Yield/% 4	7
3a	5.1	1.23—2.00	13.8	—
3a	25.6	1.23—2.00	29	—
3a	50.8	1.23—2.00	54	—
3b	25.4	1.54—2.00	30	—
3c	50.0	1.28—2.00	12	10
3d	39.2	1.10—2.00	2	36

a) The electrolysis was carried out at a constant current of 0.85 mA cm^{-2} in DMF–TBAP (0.1 mol dm^{-3}) using platinum elctrodes. The yields shown were obtained after 1.0—1.2 F mol^{-1} of electricity had been passed through (for **3c** 1.9 F mol^{-1}). b) Reference electrode, SCE.



7 8 9

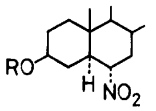
obtained is 6β-nitro-3α,5-cyclo-5α-cholestane (**7**). Chemical evidence for the suggested structure, including the stereochemistry of the cyclopropane ring, comes from the conversion of **7** into the known 3α,5-cyclo-5α-cholestan-6-one (**9**)[7] (see below). The yield of **7** from **3d** was 43%.

Controlled-current Electrolyses of Nitro Esters 3a—d. In order to investigate the effect of C-3 substituents on the course of the cathodic reaction, we further examined the reaction of the benzoate **3b** and the trifluoroacetate **3c**. During the controlled-potential electrolyses of these nitro esters, the current showed a wide variation. In order to avoid current-density variation during the dimerization reaction, we employed controlled-current conditions for the purposes of comparison. The compounds **3a**—**d** were reduced cathodically under the same current density of 0.85 mA cm^{-2} until 1.0—1.2 F mol^{-1} of electricity had been consumed (with **3c** 1.9 F mol^{-1}). The results are summarized in Table 1.

The concentration of the substrate had a marked effect on the yield of the intermolecular reaction product **4**. Table 1 shows several experiments carried out for **3a** using 5 to 50 mmol dm^{-3} solutions which gave yields of **4** ranging from 14 to 54%. For **3c** and **3d**, 40—50 mmol dm^{-3} solutions were used, but for the benzoate **3b** a more dilute solution had to be used because of the limited solubility. The course of the reaction appeared to be primarily determined by the leaving-group ability for the nucleophilic reactions;[8] the compound with a good leaving group such as tosylate gave a high yield of **7**. Both the acetate **3a** and the benzoate **3b** gave only a dimer ever when a dilute solution was used. The trifluoroacetate **3c** showed an intermediate behavior and gave comparable yields of **4** and **7**.

Both the dimer and cyclosteroid are stable under the present electrolytic conditions. No interconversion between **4** and **7** was observed in the control experiments, suggesting that they were formed by independent routes (see Discussion). The rest of the material was a colored matter which could not be characterized.

Cyclic Voltammetry. To obtain further insight into the structural dependence on the one-electron transfer reaction, we carried out cyclic voltammetric measurements in DMF containing 0.1 mol dm^{-3} TBAP using the cell and instruments as has been described before.[1] The measurements were carried out for related compounds, including the starting esters **2a**—**d**, **5**, **7**, and 6α-nitro-5α-cholestan-3β-yl acetate (**11**).[9]



10, R = H
11, R = Ac

The results are summarized in Table 2. When an anodic peak was recorded on a potential reversal, the cathodic potential, $E^0=E_{pc}-(E_{pc}-E_{pa})/2$, was calculated. As a measure of reversibility, the current ratio, i_{pa}/i_{pc}, was also calculated. In cases where no anodic peak was recorded, the potential at which $i=0.85i_{pc}$ was taken as E^0.[10]

As the control, the CV curves of the starting cholesteryl esters **2a**—**d** were determined. None of these materials showed a cathodic peak in the potential range of 0——2 V, indicating that the ester carbonyl or sulfonyl groups were not reducible at the potentials used for the reduction of the nitro esters **3**.

Saturated nitro acetate **11** showed a cathodic potential, E^0, at -1.6 V. The β,γ-unsaturated nitro compound **5** and cyclosteroid **7** showed E_{pc}'s higher than -2.0 V and had no corresponding E_{pa}. Their cathodic potentials were estimated[10] to be -1.9 V and *ca.* -2 V respectively. Whereas compound **11**, with an equatorial nitro group, gave a quasi-reversible wave, compound **5** and **7**, with a nitro group in an axial geometry, showed no anodic wave. Figure 1 records

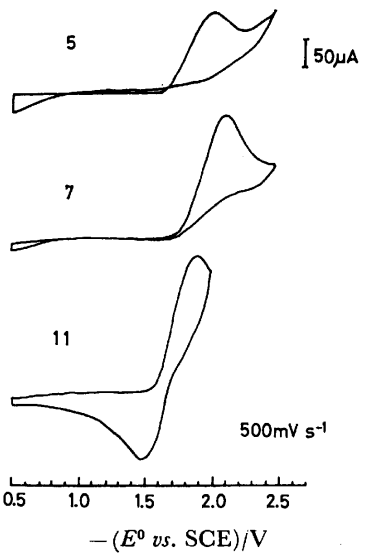


Fig. 1. Cyclic voltammograms for compounds **5**, **7**, and **11** determined in DMF using TBAP as supporting electrolyte.

a) The cyclic voltammetry was carried out in DMF–TBAP (0.1 mol dm^{-3}) using a platinum inlay electrode (Beckman No. 39273) and platinum wire as cathode and the counter electrode respectively. b) Reference electrode, SCE. c) When no anodic peak was recorded on potential reversal, the potential at which $i=0.85\ i_{pc}$[10)] was calculated.

the voltammograms for compounds **5**, **7**, and **11**, determined at the scan rate of 500 mV s^{-1}.

The α,β-unsaturated nitro esters **3a—d** showed E_{pc} values at considerably anodic potentials. Compounds **3a**, **3b**, and **3c** showed a quasi-reversible wave with quite similar E^0's at -1.35——1.37 V. Compound **3d**, on the other hand, showed only a cathodic wave with *ca.* -1.5 V (Table 2). Figure 2 shows the CV curves for **3a** at 50 and 250 mV s^{-1} and for **3b—d** either at 250 or 500 mV s^{-1}.

At the slow scan rate of 50 mV s^{-1}, for example, **3a** showed a fairly good reversible wave with $E^0=-1.35$ V. The peak potential difference, $\Delta E_p=E_{pc}-E_{pa}$, was 240 mV, whereas the current ratio, i_{pa}/i_{pc} was 0.84. When higher scan rates were used, the peak separation increased, and, unexpectedly, the current ratio showed a decrease. These phenomena were supposed to be caused both by a limited electron-transfer rate and a coupled chemical reaction.[10)] Based on the Randles-Cevcik equation[10)] the ratio, $i_p/269\,ACv^{1/2}=D^{1/2}n^{3/2}$, was calculated; it was found to be essentially unchanged on scan-speed variation.

The benzoate **3b** showed an even more prominent reversible wave with respect both to the peak separation and the current ratio (Fig. 2, Table 2). The current ratio for these compounds showed no change at the scan rates employed.

With the tosylate **3d** no anodic wave was recorded, not even when a high speed scan was used. The anion radical formed at this potential was shown to be highly reactive and was lost by the following chemical reaction in the time scale of the CV measurements. When the CV of **3a** and **3d** was determined under the same conditions using a similar concentration of the substrates, the cathodic current of **3d** was larger than that of **3a**, suggesting that the cathodic wave for **3d** might involve a two-electron transfer, whereas those for **3a—c** were quasi-reversible one-electron transfer processes.

Discussion

Whereas the electrochemical reduction of nitro compounds in protic media provides a useful synthetic process,[11)] a similar reaction under aprotic conditions results only in a reversible electron-transfer process involving an anion radical, as is shown by cyclic voltam-

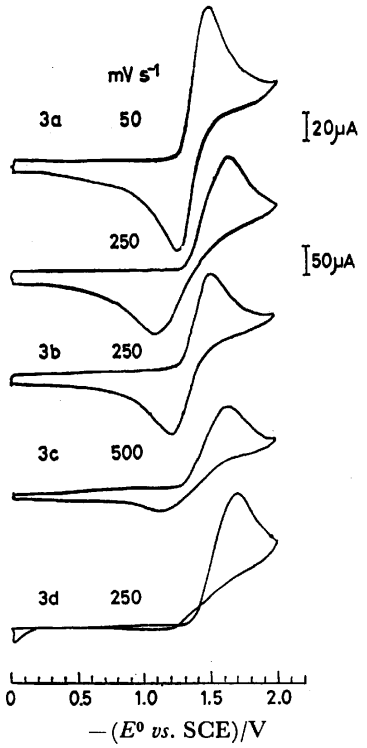

Fig. 2. Cyclic voltammograms for compounds **3a**, **3b**, **3c**, and **3d** determined in DMF using TBAP as supporting electrolyte. Current units (ordinate) for **3b**, **3c**, and **3d** are 20, 10, and 50 μA, respectively for the range shown for **3a**.

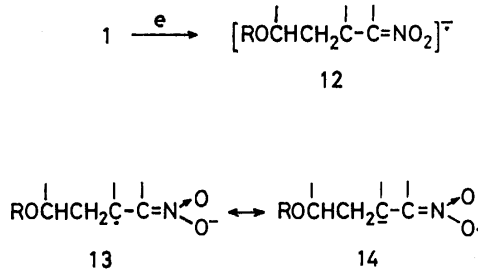
metry and ESR spectroscopy.[12,13] Accordingly, not much is known about the behavior of the anion radical in aprotic solvents. The anion radical of 2-methyl-2-nitropropiononitrile has been reported[14] to be cleaved into an alkyl radical and a nitrate ion.

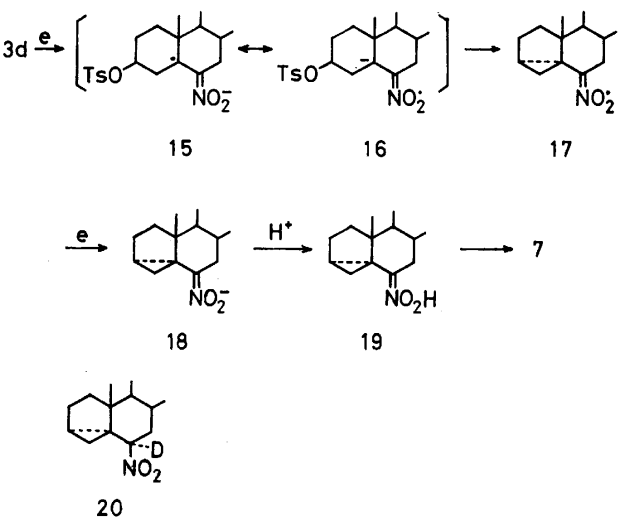
The cathodic reactions of the homoallylic nitro esters **3a—d** were found to give a dimer and/or a cyclosteroid, depending on the nature of the ester group. The situation was found to be well reflected in the CV curves: those compounds that show a reversible wave tend to give the dimerization reaction product, whereas, those which fail to show an anodic wave tend to give the cyclosteroid. The time-dependent CV behavior of **3a** and **3b** suggests that the reaction involves an EC step, in which a reversible electron-transfer process is followed by the chemical reaction with the rate constant k_1. When k_1 is small and the scan rate is low,

$$O \underset{-e}{\overset{e}{\rightleftharpoons}} R \xrightarrow{k_1} P$$

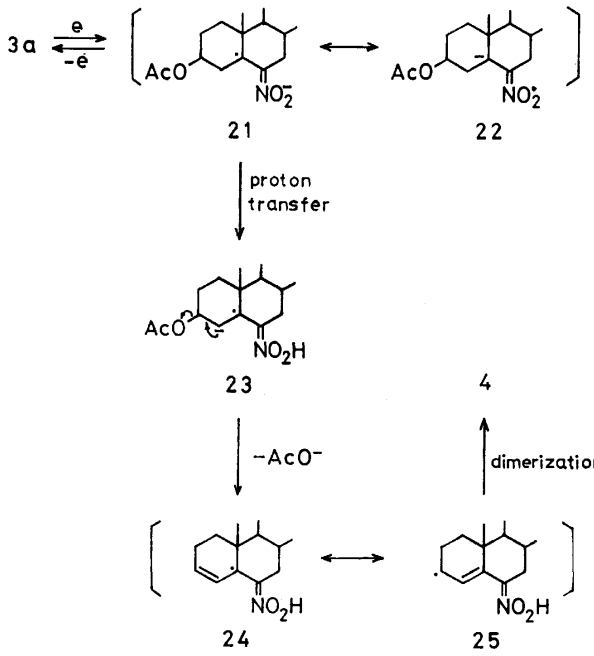
the reversibility is good and the current ratio becomes nearly unity. The CV measurements carried out for related model compounds, such as **2a—d**, **5**, **7**, and **11** revealed that electrophores in these compounds could be reduced only at considerably cathodic potentials. On the other hand, **3a—d** were reduced at less cathodic potentials, indicating that the reduction occurred on an α,β-unsaturated nitro electrophore. As a result of the one-electron reduction, the electrophore is converted to an anion radical **12**, which is a resonance hybrid **13↔14**.



The tosylate **3d** showed no corresponding anodic peak on potential reversal, not even when the scan speed was increased by using a storage-memory technique. This indicates that the anion radical derived from **3d** is short-lived and hence possesses a high reactivity. The anion radicals equivalent to **13** and **14** can be written as **15** and **16**. The high reactivity of **16** can be expected, since a tosylate anion is an extremely good leaving group. An intramolecular nucleophilic displacement reaction gives **17**, which, on further one-electron reduction, forms an aci-anion **18**, the protonation of which gives **7** *via* **19**. The protonation of **18** appeared to occur in the isolation step, since the addition of D_2O, after the reaction was over, gave a deuterated product **20**. The mass-spectral analysis indicated the formation of **20** in up to a 60% yield by quenching the electrolysis reaction with D_2O. Before the addition of water, the reaction mixture remained colored, suggesting the stability of the aci-anion species **18**. No deuterium incorporation was observed in the control experiments in which **7** was treated with D_2O after electrolysis. The preferential formation of the thermodynamically unstable 6β-nitro compound **7** with an axial nitro group suggests that the proton attack occurs from a less hindered α-side for steric reasons.

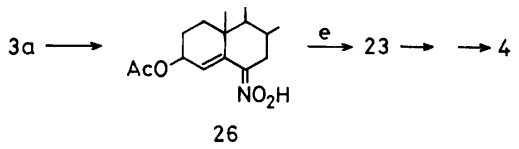


In the case of the acetate **3a** the corresponding anion radical exists as a resonance hybrid **21↔22**. Since an acetate ion is a less efficient leaving group, prototropy precedes to give **23** from **21**. The C-4 proton is sufficiently acidic, and its abstraction by the aci-anion is favored by the proximity effect.[3] The elimination of an acetate ion gives the corresponding allyl radical (**24↔25**).



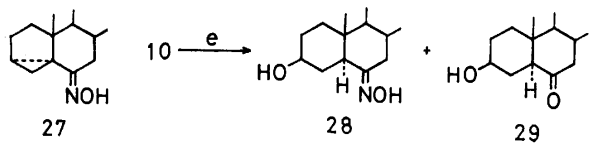
Dimerization is expected to occur on **25** to iveg **4**.

Alternatively, it is also possible to assume the isomerization of **3a** to give **26** prior to the one-electron reduction. The radical anion **23** can be derived from **26** by means of a cathodic reaction.



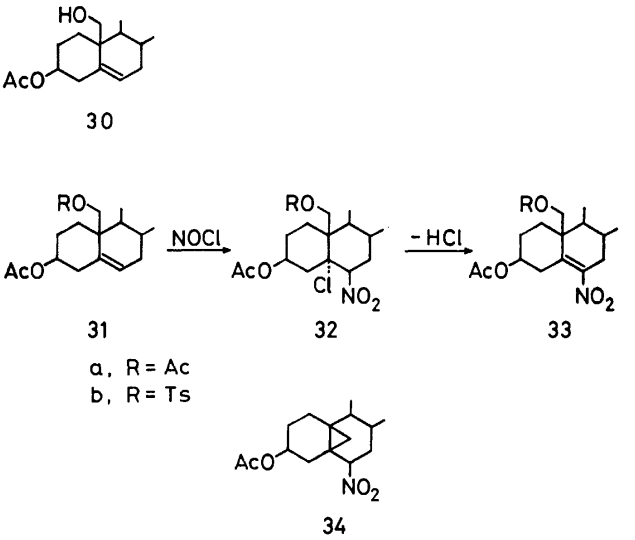
It might be possible that the dimer **4** was formed *via* the cyclosteroid **7** as an intermediate. That this is not likely is shown by the electrolysis reaction of **7**, coupled with the CV data indicating that it was reducible only at a more cathodic potential than that used for the actual electrolysis. Moreover, the controlled potential electrolysis of **7** at −1.90 V gave no trace of **4**, but instead gave the cyclosteroidal ketone **9** in a 16% yield, 72% of the starting material being recovered. Compound **9** was identical with the authentic material[7] and thus served as chemical evidence for the structure of **7**.

The ketone **9** may be formed *via* the oxime **27**. As support of this idea, we have observed that 6β-nitro-5α-cholestan-3β-ol (**10**) gives a hydroxy oxime **28** and a hydroxy ketone **29** upon controlled potential electrolysis in DMF–TBAP containing methanol at −1.70 V.[15]



Related Reactions

The homoallylic nitro ester electrophore can be constructed in the steroidal system in another disposition. We further investigated the CV and controlled-potential electrolyses of 19-acetate **33a** and -tosylate **33b**. These were obtained by the above scheme.



Cholest-5-ene-3β,19-diol 3-acetate (**30**)[16] was converted to 19-acetate **31a** and 19-tosylate **31b**, which were then treated with nitrosyl chloride using the method previously reported from these laboratories[17] to give two nitro chlorides **32a** and **32b**; this was followed by dehydrochlorination with pyridine.

The CV data of **33a** and **33b** are shown in Table 2. Whereas compound **33a** showed a quasi-reversible couple, $E^0 = -1.33$ V, the tosylate **33b** showed a cathodic peak at −1.5——1.7 V, but not any anodic peak, on potential reversal (Fig. 3). In view of the data found for **3a—d**, the CV results suggested that the tosylate **33b** might be highly reactive and might give the corresponding cyclosteroid. In fact, the electrolysis of **33b** carried out at −1.30 V in DMF–TBAP gave a 27% yield of 6β-nitro-5,19-cyclo-5β-cholestan-3β-ol acetate (**34**). The electricity consumed amounted to 1.7 F mol^{-1}. The structure was supported by the IR spectral data, which showed absorptions at 3070 (cyclopropane ring), 1730 (acetoxy), and 1545 cm^{-1} (nitro group on saturated carbon), and also by the NMR spectra, which showed a one-proton multiplet at δ 4.77 with a half-band width of 9 Hz. On the other

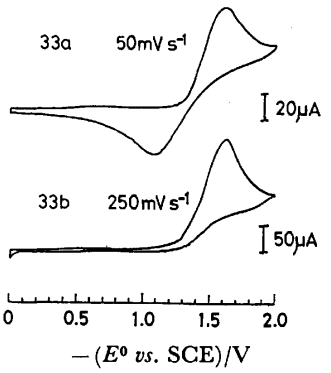


Fig. 3. Cyclic voltammograms for compounds **33a** and **33b** determined in DMF using TBAP as supporting electrolyte.

hand, no isolable compounds were obtained by similar experiments carried out for **33a**.

Experimental

6-Nitrocholest-5-en-3β-yl Acetate (3a). Cholesteryl acetate was nitrated with concd nitric acid and potassium nitrite according to the method of Shoppee *et al.*,[2] to give **3a**: mp 103.5—104.5 °C. The hydrolysis of **3a** with 60% perchloric acid in methanol gave **3** (R=H); mp 129—131 °C.[18]

6-Nitrocholest-5-en-3β-yl Benzoate (3b). A mixture of 14.6 g (27 mmol) of **3** (R=H) and 12 cm³ (54 mmol) of benzoyl chloride, in 10 cm³ of pyridine, was left to stand overnight. A subsequent usual work-up gave benzoate **3b** in an 86% yield; recrystallized from ethyl acetate: mp 191—196 °C; IR (KBr) 1510, 1710 cm⁻¹; NMR ($CDCl_3$) δ 0.72 (3H, s, C-18H), 1.18 (3H, s, C-19H), 6.35 (1H, m, $W_{1/2}$= 16.8 Hz, C-3αH), 7.35—8.15 (5H, m, ArH).

Found: C, 75.90; H, 9.37; N, 2.62%. Calcd for $C_{34}H_{49}NO_4$: C, 76.20; H, 9.22; N, 2.61%.

6-Nitrocholest-5-en-3β-yl Trifluoroacetate (3c). A mixture of 9.2 g (21 mmol) of **3** (R=H) and 11 cm³ (78 mmol) of trifluoroacetic anhydride in 80 cm³ of pyridine was left to stand overnight; recrystallization from methanol then gave 49% of **3c**: mp 110.5—111.5 °C; IR (KBr) 1510, 1780 cm⁻¹; NMR ($CDCl_3$) δ 0.69 (3H, s, C-18H), 1.18 (3H, s, C-19H), 4.87 (1H, m, $W_{1/2}$=17.4 Hz, C-3αH).

Found: C, 65.68; H, 8.14; N, 2.65%. Calcd for $C_{29}H_{44}NO_4F_3$: C, 66.00; H, 8.40; N, 2.65%.

6-Nitrocholest-5-en-3β-yl Tosylate (3d). A mixture of 15 g (31.7 mmol) of **3** (R=H), 7.5 g (39.3 mmol) of tosyl chloride, and 100 cm³ of pyridine was warmed at 50 °C for 1 h. A usual work-up subsequently gave an 88% yield of **3d** after recrystallization from acetone–methanol: mp 168—169 °C (dec); IR (KBr) 1510, 1780 cm⁻¹; NMR ($CDCl_3$) δ 0.67 (3H, s, C-18H), 1.10 (3H, s, C-19H), 2.47 (3H, s, ArMe), 4.35 (1H, m, $W_{1/2}$=16.2 Hz, C-3αH), 7.55 (4H, m, ArH).

Found: C, 69.92; H, 8.95; N, 2.31%. Calcd for $C_{34}H_{51}NO_5S$: C, 69.72; H, 8.79; N, 2.39%.

Electrolyses. Both controlled-potential and controlled-current electrolyses were carried out for **3a**—**d**. As representative examples, the controlled-potential electrolysis of **3a** and **3d** and the controlled-current electrolysis of **3d** will be described. The results of the controlled-current electrolysis are summarized in Table 2.

The cylindrical cell used for the electrolysis was equipped with a side arm for connecting the reference electrode, SCE, using two junction bridges, filled with saturated KCl and DMF–TBAP (0.1 mol dm⁻³) solutions. A ceramic thimble (o. d. 3 cm) was used as a divider and was placed on a spacer to allow stirring using a magnetic bar. A punched platinum electrode with an area of 60 cm² was used as the cathode, while a platinum wire was used as the anode. Before the electrolysis, the reaction mixture was purged with nitrogen for at least 20 min. A Hokuto potentiostat/galvanostat HA-101 apparatus (max. output 30 V, 1 A) was used, together with a Hokuto digital coulometer HF-102.

The Controlled-potential Cathodic Reduction of 3a. 6β,6'β-Dinitro-3,3'-cholesta-4,4'-diene (4): A solution of 600 mg (12.7 mmol) of **3a** in 250 cm³ of purified DMF containing TBAP (0.1 mol dm⁻³) was purged with nitrogen and electrolyzed at the controlled potential of −1.44 V. During the reaction, a solid material was separated out as a precipitate. After 1 F mol⁻¹ of electricity had been consumed, the precipitate was filtered, washed with DMF, water, and dried. Recrystallization from benzene gave colorless needles; mp 234—235 °C. The filtrate was evaporated to dryness, extracted with ether, and washed with water to eliminate TBAP. The residue was dissolved in benzene and passed through a Florisil column to give a second crop (mp 233—235 °C) of **4**; the total yield was 45%: IR (KBr) 1550, 1635 cm⁻¹; NMR ($CDCl_3$) δ 0.72 (3H, s, C-18H), 0.92 (3H, s, C-19H), 4.67 (1H, m, $W_{1/2}$=8.25 Hz, C-6αH), 5.90 (1H, m, $W_{1/2}$=4.2 Hz, C-4H); MW 829 (Rast).

Found: C, 77.81; H, 10.69; N, 3.24%. Calcd for $C_{54}H_{88}N_2O_4$: C, 78.02; H, 10.91; N, 3.37%.

The Controlled-potential/current Cathodic Reduction of 3d. A solution of 1.0 g (1.7 mmol) of **3d** in 100 cm³ of DMF–TBAP was electrolyzed at the controlled potential of −1.45 V. After 1.5 F mol⁻¹ of electricity had been consumed, the product was purified by silica-gel chromatography and eluted with hexane containing an increasing amount of benzene. Compound **7** was thus obtained in a 43% yield (mp 102—102.5 °C), after recrystallization from methanol: IR (KBr) 3080, 3030, 3007, 1550 cm⁻¹; NMR ($CDCl_3$) δ 0.73 (3H, s, C-18H), 0.94 (3H, s, C-19H), 3.87 (1H, m, $W_{1/2}$=8.25 Hz, C-6αH).

Found: C, 77.84; H, 10.77; N, 3.27%. Calcd for $C_{27}H_{45}NO_2$: C, 78.03; H, 10.91; N, 3.37%.

The controlled-current reduction of **3d** was carried out using a solution of 5.8 g (9.8 mmol) of **3d** in 250 cm³ of DMF–TBAP at the current density of 0.85 mA cm⁻². The electrolysis was continued until the potential between the working and reference electrodes reached −2.0 V and 1 F mol⁻¹ of electricity had been consumed. A 36% yield of **7** and a 2% yield of **4** were obtained.

When D_2O (1 cm³) was added after the electrolysis was over, a 6α-deuterio compound **20** was isolated. Compound **20** was characterized by means of its mass spectrum; *m/e* 370. NMR analysis showed that **20** was present in a 60% quantity together with 40% of **7**.

The Controlled-potential Reduction of 7. A solution of 430 mg (1.0 mmol) of **7** in 100 cm³ of DMF–TBAP was electrolyzed at −1.90 V. A usual work-up, followed by silica-gel chromatography and eluting with benzene–hexane (1 : 4), gave 310 mg of colorless needles; mp 101—102 °C; recrystallized from acetone–methanol. It was identical with the **10** prepared by the known route.[11] The yield was 16%.

5-Chloro-6β-nitro-5α-cholestane-3β,19-diol Diacetate (32a). Nitrosyl chloride (4.9 g, 75 mmol) was added to a solution of 3.7 g (7.6 mmol) of cholest-5-ene-3β,19-diol diacetate (**31a**) in 41 cm³ of ether at 0 °C. Then 2.9 g of potassium acetate had been added, the mixture was left to stand for 4 d in a refrigerator. Filtration and then evaporation gave a blue oil, which, after solidification, was recrystallized from acetone–methanol; mp 120.5—121.5 °C. The yield was 58%: IR (KBr) 1745, 1550 cm⁻¹; NMR ($CDCl_3$) δ 0.73 (3H, s, C-18H), 2.04 (6H, s, CH_3COO), 5.35 (1H, m, $W_{1/2}$=28.5 Hz, C-3αH).

Found: C, 65.80; H, 8.97; N, 2.39%. Calcd for $C_{31}H_{50}NO_6Cl$: C, 65.52; H, 8.87; N, 2.46%.

6-Nitrocholest-5-ene-3β,19-diol Diacetate (33a). Compound **32a** was dissolved in pyridine, warmed at 50 °C for 30 min, and then left to stand overnight. The product was recrystallized from acetone–methanol; mp 114.5—115.5 °C (69%): IR (KBr) 1740, 1520 cm⁻¹; NMR ($CDCl_3$) δ 0.73 (3H, s, C-18H), 2.03 (3H, s, CH_3COO), 2.07 (3H, s, CH_3COO), 4.32 (2H, dd, C-19H), 4.60 (1H, m, $W_{1/2}$=21 Hz, C-3αH).

Found: C, 70.15; H, 9.34; N, 2.56%. Calcd for $C_{31}H_{49}NO_6$: C, 70.02; H, 9.29; N, 2.63%.

5-Chloro-6β-nitro-5α-cholestane-3β,19-diol 3-Acetate 19-Tosylate (32b). To a solution of 2.6 g (4.3 mmol) of cholest-5-ene-3β,19-diol 3-acetate 19-tosylate (**31b**) in ether (94 cm³), were added nitrosyl chloride (2.8 g) and potassium acetate (1.7 g) at 0 °C. The product was then recrystallized from

acetone–methanol; mp 131—132 °C (47% yield): IR (KBr) 1735, 1565 cm^{-1}; NMR ($CDCl_3$) δ 0.41 (3H, s, C-18H), 2.04 (3H, s, CH_3COO), 5.32 (1H, m, C-3αH), 7.38—7.80 (4H, m, ArH).

Found: C, 63.55; H, 8.05; N, 1.88%. Calcd for $C_{36}H_{54}O_7NSCl$: C, 63.55; H, 8.00; N, 2.06%.

*6-Nitrocholest-5-ene-3β,19-diol 3-Acetate 19-Tosylate (**33b**).* The dehydrochlorination of **32b** with pyridine gave **33b**, mp 116.5—117.5 °C (85%, recrystallized from acetone–methanol): IR (KBr) 1735, 1520 cm^{-1}; NMR ($CDCl_3$) δ 0.63 (3H, s, C-18H), 1.98 (3H, s, CH_3COO), 2.44 (3H, s, ArMe), 7.35—7.79 (4H, m, ArH), 4.53 (1H, m, $W_{1/2}$=25.5 Hz, C-3αH).

Found: C, 67.43; H, 8.37; N, 2.10%. Calcd for $C_{36}H_{53}O_7NS$: C, 67.15; H, 8.29; N, 2.17%.

*Controlled-potential Reduction of **33b**.* A solution of 590 mg (0.91 mmol) of **33b** in 60 cm^3 of DMF–TBAP was electrolyzed at −1.30 V until 1.7 F mol^{-1} of electricity had been consumed. Chromatography on silica gel eluted with benzene–hexane (1 : 4) gave a 27% yield of 5β,19-cyclo-6β-nitro-5β-cholestan-3β-ol 3-acetate (**34**); mp 88—89 °C (recrystallized from methanol): IR (KBr) 1730, 1545 cm^{-1}; NMR ($CDCl_3$) δ 0.52 and 0.98 (2H, dd, J=6 Hz, cyclopropyl CH_2), 2.05 (3H, s, CH_3COO).

Found: C, 73.48; H, 10.01; N, 2.80%. Calcd for $C_{29}H_{47}O_4N$: C, 73.53; H, 10.00; N, 2.96%.

Cyclic Voltammetry. The measurements were carried out using a generator, Hokuto HB-107A and a potentiostat, Hokuto HA-101. As a cathode, a platinum inlay electrode, Beckman No. 39273, was used. Samples are dissolved in DMF containing 0.1 mol dm^{-3} of TBAP. The results are shown in Table 2 and Figs. 1—3. For high-speed scans, the output was stored in a wave-memory unit, NF Circuit Block WM-812A.

Collins Oxidation of Methyl (+)-13β-Abiet-8-en-18-oate and Absolute Configuration of Suaveolic Acid

Takashi MATSUMOTO,* Sachihiko IMAI,* Shuhei YUKI, Arata KATAYAMA, and Manabu FURUTANI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730

(Received May 29, 1981)

The oxidation of methyl (+)-13β-abiet-8-en-18-oate with Collins reagent yielded nine oxidation products. Their structures were elucidated on the basis of spectroscopic and chemical data to be methyl (−)-14-hydroxy-7-oxoabieta-8,11,13-trien-18-oate (1% yield), methyl (−)-11,14-dioxoabieta-8,12-dien-18-oate (1%), methyl (+)-11-oxo-13β-abiet-8-en-18-oate (18%), methyl (−)-8α,9α-epoxy-7-oxo-13β-abietan-18-oate (2%), methyl (+)-7-oxoabieta-8,11,13-trien-18-oate (2%), methyl (+)-11,14-dihydroxy-7-oxoabieta-8,11,13-trien-18-oate (2%), methyl (+)-7,11-dioxo-13β-abiet-8-en-18-oate (17%), methyl (+)-14-oxo-13β-abiet-8-en-18-oate (**15**) (4%), and methyl (+)-7-oxo-13β-abiet-8-en-18-oate (23%) respectively. It is noteworthy that oxygenation occurs not only at the C-7 and C-11 positions but also at the C-14 position. The oxygenated products obtained in this studies could be useful intermediates for the synthesis of the oxidized diterpenoids of abietane skeleton. To exemplify this, **15** was converted to methyl suaveolate and suaveolol. Hydrolysis of the former yielded suaveolic acid, thus confirming its absolute configuration to be 4R, 5R, 10S, 13S, and 14S.

The allylic oxygenated derivatives of methyl (+)-13β-abiet-8-en-18-oate (**1**)[1] seem to be useful intermediates for the partial syntheses of naturally occurring diterpenes possessing oxygen functions at the C-7, C-11, and/or C-14 positions. For this reason we attempted the oxidation of **1** with Collins reagent, which was superior to other reagents used for allylic oxidation,[2] and obtained the products oxygenated at the C-14 position in addition to those with oxygen functions at the C-7 and C-11 positions. This result is in contrast with the previously reported oxidation of **1** with *t*-butyl chromate.[3] A compound of the former type has been successfully converted to suaveolic acid;[4] this conversion confirms its absolute configuration.

Collins Oxidation of Methyl (+)-13β-Abiet-8-en-18-oate (1). The oxidation of **1** was carried out with Collins reagent[5] in dichloromethane at room temperature for 24 h. The reaction mixture was carefully separated by repeated column chromatography on silica gel to give nine keto ester compounds: A (1%), B (1%), C (18%), D (2%), E (2%), F (2%), G (17%), H (4%), and I (23%), in the order of elution. The structure elucidation of these oxidation products was carried out as follows.

Compounds A and B were obtained as a mixture which could not be separated satisfactorily. Therefore the mixture was acetylated with refluxing acetic anhydride in the presence of sodium acetate and the resulting crude product was successfully separated by column chromatography on silica gel to give an acetylated A and the original ketone B. The more polar acetylated A showed the presence of an acetoxyl group at 1763 cm^{-1} in its IR spectrum and a conjugated carbonyl group at 1673 cm^{-1}. Its ^{1}H NMR spectrum indicated signals due to a pair of ortho-coupling aromatic protons at δ 7.14 and 7.37 (each 1H, d, and J= 8 Hz). Consequently, the structure of the acetylated A was determined to be methyl 14-acetoxy-7-oxoabieta-8,11,13-trien-18-oate (**2**). Hydrolysis of the acetate **2** with sodium hydrogencarbonate in refluxing aqueous methanol gave the original ketone A, methyl 14-hydroxy-7-oxoabieta-8,11,13-trien-18-oate (**3**),[6] whose ^{1}H NMR spectrum showed a reasonable signal at δ 13.08 (1H, s), indicating the presence of a hydroxyl group chelated with a conjugated carbonyl group (IR: 1622 cm^{-1}). The compound B, which was less polar than the acetate **2**, showed the presence of a *p*-quinone moiety [IR: 1640, 1597 cm^{-1}; ^{1}H NMR: δ 6.32 (1H, d, J=1 Hz); UV: λ_{max}^{EtOH} 257 nm (ε 11800), 338 (340), 420 (40)]. On the basis of these spectral data and mass spectrum [*m/e* 344 (M$^+$)] the structure of the compound B was determined to be methyl 11,14-dioxoabieta-8,12-dien-18-oate (**4**).[7]

The compound C (mp 108—110 °C; IR: 1715, 1652 cm^{-1}) was identified as methyl 11-oxo-13β-abiet-8-en-18-oate (**5**) by direct spectral comparison with an

authentic sample.[3,8]

The compound D (mp 122—123 °C, $C_{21}H_{32}O_4$) showed absorption bands at 1718 and 1695 cm^{-1} in its IR spectrum and no UV absorption band in the 220—250 nm region, indicating the presence of an ester group and a non-conjugated carbonyl group. The fourth oxygen atom should be an epoxide one. In its ^1H NMR spectrum a signal at δ 2.81 (1H, dd, J=11.5 and 8 Hz) assignable to a C-5α proton[9] suggested that the structure of the ketone D was methyl 8α,9α-epoxy-7-oxo-13β-abietan-18-oate (**6**). This structure was subsequently confirmed by transformation of **6** to the known methyl 9α-hydroxy-13β-abiet-7-en-18-oate (**7**)[10] by refluxing with hydrazine hydrate in methanol containing a small amount of acetic acid under a stream of nitrogen. For comparison, methyl 8β,9β-epoxy-7-oxo-13β-abietan-18-oate (**8**) was also synthesized by epoxidation of methyl 7β-hydroxy-13β-abiet-8-en-18-oate (**9**)[11] with *m*-chloroperbenzoic acid followed by oxidation of the resulting methyl 8β, 9β-epoxy-7β-hydroxy-13β-abietan-18-oate with Jones reagent. The epoxide **8** was then converted to methyl 9β-hydroxy-13β-abiet-7-en-18-oate (**10**) by a similar treatment with hydrazine hydrate. The ^1H NMR signals corresponding to the methyl groups at the C-4 and C-10 positions in **6**, **7**, **8**, and **10** are shown in Table 1. The chemical shifts of the C-10 methyl groups in the 9β series are more deshielded than those in 9α series; this follows from the stereochemistry of their oxygen functions. The pyridine-induced solvent shift[12] (Δ −0.21 ppm) of the C-10 methyl group in **10** also supported the conclusion that the stereochemistry of the hydroxyl group at the C-9 position was in β-configuration.

Compounds E and F were obtained as a mixture which contained one component possessing a free phenolic hydroxyl group [^1H NMR: δ 6.01 (1H, bs)]. Therefore, the mixture was acetylated with acetic anhydride in pyridine at room temperature and the resulting crude product was purified by column chromatography on silica gel to give the original E and an acetylated F. The acetylated F, mp 158.5—159.5 °C, which was less polar, showed the presence of an acetoxyl group [IR: 1757 cm^{-1}, ^1H NMR: δ 2.32 (3H, s)], an aromatic proton [^1H NMR: δ 6.95 (1H, s)], and a hydroxyl group [^1H NMR: δ 13.54 (1H, s)] chelated with a conjugated carbonyl group (IR: 1630 cm^{-1}). These spectral data suggested that the structure of the acetylated F was methyl 11-acetoxy-14-hydroxy-7-oxoabieta-8,11,13-trien-18-oate (**11**). Hydrolysis of the acetate **11** with sodium hydrogencarbonate in refluxing aqueous methanol gave the original ketone F, methyl 11,14-dihydroxy-7-oxoabieta-8,11,13-trien-18-oate (**12**), mp 233.5—234.5 °C, whose ^1H NMR spectrum showed a signal at δ 3.47 (1H, dm, J=12 Hz) assignable to C-1β proton; this supported the presence of a hydroxyl group at the C-11 position.[13] The compound E isolated from the more polar fraction was identified as methyl 7-oxoabieta-8,11,13-trien-18-oate (**13**) by direct spectral comparison with an authentic sample.[14]

Compound G (mp 87—89.5 °C; IR: 1720, 1670 cm^{-1}) was also identified as methyl 7,11-dioxo-13β-abiet-8-en-18-oate (**14**) by direct spectral comparison with an authentic sample.[3,8]

TABLE 1. CHEMICAL SHIFTS OF C_4- AND C_{10}-METHYL GROUPS OF **6**, **7**, **8**, AND **10** (δ VALUE)

	9α Series			9β Series		
	6		**7**	**8**		**10**
Solvent[a]	A	B	C	A	B	C
C_4–Me	1.18	1.30	1.39	1.15	1.30	1.37
C_{10}–Me	0.94	0.96	1.03	1.15	1.08	1.29

a) A, carbon tetrachloride; B, chloroform-*d*; C, pyridine-d_5.

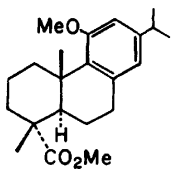
Compound H showed the presence of a conjugated carbonyl group in the IR spectrum (1655 cm^{-1}) and a characteristic isopropyl group in the ^1H NMR spectrum [δ 0.79 and 0.94 (each 3H, d, and J=7 Hz)]. The IR and ^1H NMR spectra of ketone H were identical with those reported for methyl 14-oxo-13β-abiet-8-en-18-oate (**15**).[4]

Compound I (mp 111—112 °C; IR: 1725, 1652 cm^{-1}) was identified as methyl 7-oxo-13β-abiet-8-en-18-oate (**16**) by direct spectral comparison with an authentic sample.[3,8]

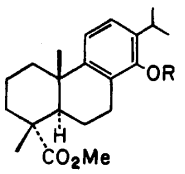
Thus, the structures of nine oxidation products could be elucidated. The present oxidation of **1** with Collins reagent occurred not only at the C-7 and C-11 positions, as was the case with *t*-butyl chromate, but also at the C-14 position; this latter resulted in the formation of **3**, **4**, **12**, and **15**. The latter compounds would be useful intermediate for the synthesis of 14-oxygenated abietane diterpenes as illustrated below.

The compounds, **5** and **14**, were each converted[15] to methyl 11-methoxyabieta-8,11,13-trien-18-oate (**17**).[16] Treatment of **15** with copper(II) bromide and lithium bromide in refluxing acetonitrile afforded methyl 14-hydroxyabieta-8,11,13-trien-18-oate (**18**),[17] which was then methylated with methyl iodide and sodium hydride in *N*,*N*-dimethylformamide to give methyl 14-methoxyabieta-8,11,13-trien-18-oate (**19**).[17] These compounds, **17** and **19**, seem to be useful intermediates for the syntheses of nellionol (**20**),[18] premnolal (**21**),[18,19] and the like.[18]

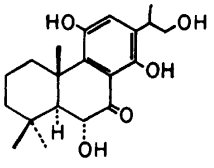
Absolute Configuration of Suaveolic Acid. Suaveolic acid and suaveolol have been isolated from the leaves and stems of *Hyptis suaveolens* (L) Point (Labiatae) by Manchand *et al.*[4] On the basis of chemical and spectro-



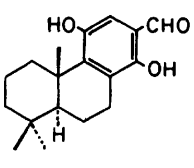
17



18 R=H
19 R=Me



20



21

scopic studies, the structures of suaveolic acid and suaveolol were assigned respectively to be **22** and **23**; their relative stereochemistry were further confirmed by an X-ray structure analysis of methyl suaveolate (**24**).[4] In order to clarify the absolute configurations of these unusual[4] tricyclic diterpenes, metal hydride reductions of the 14-oxo compound **15** were carried out.

The compound **15** was reduced with sodium borohydride in refluxing tetrahydrofuran in the presence of aqueous sodium hydroxide to afford a mixture of alcohols. The mixture was then separated by column chromatography on silica gel to give four alcohols: W (24%), X (38%), Y (7.5%), and Z (15%), in the order of elution. Treatment of **15** with sodium methoxide in refluxing methanol provided an inseparable mixture of **15** and its C-13 epimer (**25**) [^{1}H NMR: δ 0.90 and 0.91 (each 3H, d, and J=6 Hz, $-CH(C\underline{H}_3)_2$)]. The ^{1}H NMR spectrum of the mixture showed these epimers were present approximately in a 2 : 1 ratio. However, when **15** was treated with aqueous sodium hydroxide in refluxing tetrahydrofuran, the starting ketone **15** was recovered. Therefore, it is clear that no epimerization at the C-13 position in **15** occurred under the above reduction conditions.

The oily alcohol W ($[\alpha]_D$+125°) showed the presence of a hydroxyl group (3620, 3460 br cm^{-1}) and an ester group (1720 cm^{-1}) in the IR spectrum. Its ^{1}H NMR spectrum showed signals at δ 0.95 and 0.98 (each 3H, d, and J=6 Hz) due to an isopropyl group and at δ 3.78 (1H, br, $W_{1/2}$=5.5 Hz) due to C-14α proton. These physical and spectral data were not identical with those of methyl suaveolate (**24**). Oxidation of the alcohol W with pyridinium chlorochromate in dichloromethane afforded the ketone **15**. The alcohol W was then acetylated with acetic anhydride in pyridine to give an oily monoacetate (**27**) ($[\alpha]_D$+181°, IR: 1713 cm^{-1}). Thus, the structure of the alcohol W was identified as methyl 14β-hydroxy-13β-abiet-8-en-18-oate (**26**).

The alcohol X (mp 102—103 °C, $[\alpha]_D$+59°; IR: 3600, 3450 br, 1720 cm^{-1}) was further characterized as its acetate (**28**) (mp 134.5—135 °C, $[\alpha]_D$−41°, IR: 1720 cm^{-1}). Oxidation of the alcohol X with pyridinium chlorochromate in dichloromethane afforded the ketone **15**. The physical and spectral data, including optical rotation of the alcohol X and **28**, were identical with those of methyl suaveolate and its acetate.

The oily alcohol Y ($[\alpha]_D$+92°; IR: 3625, 3450 br cm^{-1}) showed the presence of hydroxyl groups [^{1}H NMR: δ 3.15 and 3.44 (each 1H, d, and J=10.5 Hz, $-C\underline{H}_2OH$) and 3.77 (1H, br, $W_{1/2}$=6 Hz, $-C\underline{H}OH$)] and the absence of an ester group. Acetylation of the alcohol Y with acetic anhydride in pyridine afforded the corresponding diacetate (**30**) (mp 93—95 °C, $[\alpha]_D$+201°, IR: 1722 cm^{-1}). The physical and spectral data of the alcohol Y and **30** were different from those of suaveolol and its diacetate. Thus, the structure of the alcohol Y was identified as 13β-abiet-8-ene-14β,18-diol (**29**).

The alcohol Z (mp 180—182 °C, $[\alpha]_D$+84°; IR: 3620, 3290 br cm^{-1}) showed signals at δ 2.97 and 3.46 (each 1H, d, and J=11 Hz) due to a hydroxymethyl group and at δ 3.77 (1H, bd, J=7 Hz) due to C-14β proton in the ^{1}H NMR spectrum. Acetylation of the alcohol Z with acetic anhydride in pyridine yielded an oily diacetate (**31**) ($[\alpha]_D$−41°, IR: 1720 cm^{-1}). The physical and spectral data of the alcohol Z and **31** were identical with those of suaveolol and its diacetate.

Subsequently, the ketone **15** was reduced with lithium aluminium hydride in refluxing ether. Chromatographic purification of the crude product gave **23** (47%) and **29** (23%).

Finally, the synthetic methyl suaveolate **24** was hydrolyzed with potassium *t*-butoxide in dimethyl sulfoxide at room temperature to give suaveolic acid **22**, mp 188—190 °C, $[\alpha]_D$+71°.

From the present study, the absolute configurations of suaveolic acid and suaveolol were conclusively assigned as 4R, 5R, 10S, 13S, and 14S.

Experimental

All melting points are uncorrected. The IR and optical rotations were measured in chloroform, and the ^{1}H NMR spectra in carbon tetrachloride at 90 MHz, with tetramethylsilane as an internal standard, unless otherwise stated. The chemical shifts are presented in terms of δ values; s: singlet, bs: broad singlet, d: doublet, bd: broad doublet, dd: double doublet, dm: doublet of multiplet, t: triplet, bt: broad triplet, m: multiplet. The low-resolution mass spectra were obtained by direct inlet (ion-source temperature 200 °C and ionizing voltage 70 eV). The column chromatography was performed using Merck silica gel (0.063 mm).

Methyl (+)-13β-Abiet-8-en-18-oate (1). A suspension of (+)-13β-abiet-8-en-18-oic acid[1] in acetone was methylated with diazomethane at room temperature for 3 h to give **1**[3] as an oil, $[\alpha]_D$ +79° (*c* 3.82), which without purification was used in the next reaction.

Oxidation of 1 with Collins Reagent. Chromium trioxide

(113.2 g) was added to a mechanically stirred solution of pyridine (188 g) in dichloromethane (2.4 l) over a period of 20 min with cooling in an ice-bath. After the mixture had been stirred at room temperature for 2 h, a solution of **1** (24.0 g) in dichloromethane (200 ml) was added over a period of 30 min. The reaction mixture was further stirred at room temperature for 24 h and then decanted from a tarry residue, which was washed with ether (3.2 l). The combined organic solution was washed successively with aqueous sodium hydrogencarbonate, dilute hydrochloric acid, and brine. The solution was concentrated to *ca.* 2 l of volume, dried over sodium sulfate, and evaporated to give a reddish brown oil (24.0 g). The crude product (48.0 g) obtained from two runs of the oxidation was chromatographed on silica gel (1.5 kg), using benzene as the eluent, to give the recovered **1** (5.66 g: 12%).

Subsequent elution with benzene gave a mixture of two ketones (1.02 g), A (**3**) and B (**4**), whose separation and purification are described later.

Further elution with benzene afforded a ketone C (8.95 g: 18%) which was recrystallized from methanol, mp 108—110 °C, $[\alpha]_D$ +104° (*c* 0.743, EtOH) [lit,[3] mp 108—109 °C, $[\alpha]_D^{25}$ +104° (EtOH)]; IR: 1715, 1652, 1608 cm^{-1}; ^1H MNR ($CDCl_3$): 0.90 (6H, bd, J=5.5 Hz, $-CH(C\underline{H}_3)_2$), 1.18 and 1.21 (each 3H and s, C_4-CH_3 and $C_{10}-CH_3$), 2.87 (1H, dm, J=13 Hz, $C_{1\beta}-H$), 3.65 (3H, s, $-CO_2CH_3$). The IR and ^1H NMR spectra of the ketone C were identical with those of methyl 11-oxo-13β-abiet-8-en-18-oate (**5**).[3,8]

Elution with ether–benzene (1 : 99) gave a fraction (1.36 g) containing a ketone D, which was further purified by column chromatography on solica gel (150 g) to afford the pure ketone D (0.84 g: 2%), methyl 8α,9α-epoxy-7-oxo-13β-abietan-18-oate (**6**). This was recrystallized from methanol to give colorless needles, mp 122—123 °C, $[\alpha]_D$ −64° (*c* 1.70); IR: 1718, 1695 cm^{-1}; ^1H NMR: 0.88 (6H, bd, J=7 Hz, $-CH(C\underline{H}_3)_2$), 0.94 (3H, s, $C_{10}-CH_3$), 1.18 (3H, s, C_4-CH_3), 2.81 (1H, dd, J=11.5 and 8 Hz, $C_{5\alpha}-H$), 3.65 (3H, s, $-CO_2CH_3$). Found: C, 72.33; H, 9.19%. Calcd for $C_{21}H_{32}O_4$: C, 72.38; H, 9.26%.

Elution with ether–benzene (1 : 99) afforded a mixture of two ketones (3.02 g), E (**13**) and F (**12**), whose separation and purification are described later.

Further elution with ether–benzene (1 : 99) gave a ketone G (8.96 g: 17%) which was recrystallized from methanol, mp 87—89.5 °C, $[\alpha]_D$ +78° (*c* 1.10) (lit,[3] mp 88—89.5 °C, $[\alpha]_D^{25}$ +87°); IR: 1720, 1670 vs cm^{-1}; ^1H NMR ($CDCl_3$): 0.94 (6H, bd, J=6 Hz, $-CH(C\underline{H}_3)_2$), 1.28 and 1.32 (each 3H and s, C_4-CH_3 and $C_{10}-CH_3$), 2.84 (1H, dm, J=12 Hz, $C_{1\beta}-H$), 3.67 (3H, s, $-CO_2CH_3$). The IR and ^1H NMR spectra of the ketone G were identical with those of methyl 7,11-dioxo-13β-abiet-8-en-18-oate (**14**).[3,8]

The next fraction (2.40 g) containing ketone H was rechromatographed on silica gel (240 g), using ether–hexane (1 : 4) as the eluent, to give the pure ketone H (1.91 g: 4%) as an oil, $[\alpha]_D$ +99° (*c* 0.985) (lit,[4] $[\alpha]_D^{25}$ +115.2°); IR: 1720, 1655, 1620 cm^{-1}; ^1H NMR ($CDCl_3$): 0.79 and 0.94 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.11 (3H, s, $C_{10}-CH_3$), 1.21 (3H, s, C_4-CH_3), 3.66 (3H, s, $-CO_2CH_3$); UV: λ_{max}^{EtOH} 245.5 nm (ε 12700). Found: C, 75.96; H, 9.60%. Calcd for $C_{21}H_{32}O_3$: C, 75.86; H, 9.70%. The IR and ^1H NMR spectra of the ketone H were identical with those reported for methyl 14-oxo-13β-abiet-8-en-18-oate (**15**).[4]

Elution with ether–benzene (3 : 97) gave a ketone I (11.4 g: 23%) which was recrystallized from methanol; mp 111—112 °C; $[\alpha]_D$ +110° (*c* 5.54); IR: 1725, 1652, 1618 cm^{-1}; ^1H NMR: 0.95 (6H, bd, J=6 Hz, $-CH(C\underline{H}_3)_2$), 1.11 (3H, s, $C_{10}-CH_3$), 1.24 (3H, s, C_4-CH_3), 3.66 (3H, s, $-CO_2CH_3$). Found: C, 75.96; H, 9.89%. Calcd for $C_{21}H_{32}O_3$: C, 75.86; H, 9.70%. The IR and ^1H NMR spectra of the ketone I were identical with those of methyl 7-oxo-13β-abiet-8-en-18-oate (**16**).[3,8]

*Separation and Purification of the Ketones A (**3**) and B (**4**).* A part (125 mg) of the above mixture of ketones A and B was refluxed with acetic anhydride (5.5 mL) in the presence of sodium acetate (270 mg) for 5 h. After removal of the acetic anhydride *in vacuo*, the residue was mixed with brine and extracted with ether. The ether extract was washed successively with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and evaporated to give an oil (136 mg), which was chromatographed on silica gel (20 g). The less polar fraction eluted with ether–hexane (5 : 95) afforded the ketone B (38 mg), $[\alpha]_D$ −77° (*c* 0.575) (lit,[7] $[\alpha]_D$ −68.9°); IR: 1715, 1640, 1597 cm^{-1}; UV: λ_{max}^{EtOH} 257 nm (ε 11800), 338 (340), 420 (40); ^1H NMR ($CDCl_3$): 1.11 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.26 and 1.31 (each 3H and s, C_4-CH_3 and $C_{10}-CH_3$), 3.67 (3H, s, $-CO_2CH_3$), 6.32 (1H, d, J=1 Hz, $C_{12}-H$); MS (*m/e*): 344 (M^+). The IR, ^1H NMR, and low-resolution mass spectral data were identical with those reported for methyl 11,14-dioxoabieta-8,12-dien-18-oate (**4**).[7]

The more polar fraction eluted with ether–hexane (4 : 6) afforded an acetylated ketone A (37 mg), methyl 14-acetoxy-7-oxoabieta-8,11,13-trien-18-oate (**2**), which was recrystallized from hexane, mp 160—161.5 °C, $[\alpha]_D$ +19° (*c* 0.520); IR: 1763, 1725, 1673 cm^{-1}; ^1H NMR: 1.16 and 1.21 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.25 and 1.30 (each 3H and s, C_4-CH_3 and $C_{10}-CH_3$), 2.28 (3H, s, $-OCOCH_3$), 3.62 (3H, s, $-CO_2CH_3$), 7.14 and 7.37 (each 1H, d, and J=8 Hz, $C_{11}-H$ and $C_{12}-H$); MS (*m/e*): 386 (M^+).

The acetoxy ketone (**2**) (20.5 mg) was refluxed with sodium hydrogencarbonate (17.5 mg) in 90% aqueous methanol (2.5 mL) for 1 h. After evaporation of the solvent *in vacuo*, the residue was mixed with brine, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated. The residue was chromatographed on silica gel (5.0 g), using benzene as the eluent, to give the original hydroxy ketone A (14.0 mg) as an oil, $[\alpha]_D$ −18° (*c* 0.560); IR 1725, 1622 cm^{-1}; ^1H NMR ($CDCl_3$): 1.21 and 1.23 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.25 and 1.34 (each 3H and s, C_4-CH_3 and $C_{10}-CH_3$), 3.67 (3H, s, $-CO_2CH_3$), 6.77 and 7.36 (each 1H, d, and J=8 Hz, $C_{11}-H$ and $C_{12}-H$), 13.08 (1H, s, -OH); MS (*m/e*): 344 (M^+). The IR and ^1H NMR spectra of the hydroxy ketone A were identical with those reported for methyl 14-hydroxy-7-oxoabieta-8,11,13-trien-18-oate (**3**).[6]

*Methyl 9α-Hydroxy-13β-abiet-7-en-18-oate (**7**).* A mixture of **6** (45.0 mg), 80% hydrazine hydrate (0.1 ml), and acetic acid (0.03 ml) in methanol (1.57 ml) was refluxed for 30 min under a stream of nitrogen. After the solvent had been removed, the residue was extracted with ether. The ether extract was washed successively with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and evaporated. The residual oil was chromatographed on silica gel (5.0 g), using ether–benzene (5 : 95) as the eluent, to afford **7**[10] (7.9 mg: 18%), $[\alpha]_D$ −120° (*c* 0.395); IR: 3600, 3450 br, 1713 cm^{-1}; ^1H NMR ($CDCl_3$): 0.88 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 0.96 (3H, s, $C_{10}-CH_3$), 1.30 (3H, s, C_4-CH_3), 3.64 (3H, s, $-CO_2CH_3$), 5.41 (1H, bd, J=4 Hz, C_7-H); MS (*m/e*): 334 (M^+).

*Methyl 8β,9β-Epoxy-7-oxo-13β-abietan-18-oate (**8**).* Sodium borohydride reduction[11] of **16** afforded methyl 7β-hydroxy-13β-abiet-8-en-18-oate (**9**), mp 101—102 °C, $[\alpha]_D$ +71° (*c* 2.41, EtOH) [lit,[11] mp 100—101 °C, $[\alpha]_D^{25}$ +66° (EtOH)]; IR: 3600, 3425 br, 1720 cm^{-1}; ^1H NMR ($CDCl_3$): 0.89 (6H, d, J=6.5 Hz, $-CH(C\underline{H}_3)_2$), 1.04 (3H, s, $C_{10}-CH_3$), 1.20 (3H,

s, C_4–CH_3), 3.65 (3H, s, $-CO_2CH_3$), 4.07 (1H, bt, J=8 Hz, $C_{7\alpha}$–H).

A mixture of **9** (334 mg) and 85% *m*-chloroperbenzoic acid (406 mg) in dichloromethane (15 ml) was stirred at room temperature for 5 h and diluted with ether. The organic solution was washed successively with aqueous potassium iodide, aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and brine. After drying over sodium sulfate, the solution was evaporated *in vacuo*. The residual oil was chromatographed on silica gel (30 g), using ether–benzene (5 : 95) as the eluent, to give methyl 8β,9β-epoxy-7β-hydroxy-13β-abietan-18-oate (165 mg); IR: 3575, 3400 br, 1718 cm^{-1}; ^1H NMR ($CDCl_3$): 0.85 (6H, d, J=6.5 Hz, $-CH(C\underline{H}_3)_2$), 1.06 (3H, s, C_{10}–CH_3), 1.16 (3H, s, C_4–CH_3), 3.67 (3H, s, $-CO_2CH_3$), 3.78 (1H, bt, J=8 Hz, $C_{7\alpha}$–H).

A solution of the above epoxy compound (165 mg) in acetone (3.3 ml) was treated with Jones reagent (2.5 M: 0.5 ml) at 0 °C for 5 min. After the usual work-up, the crude product was purified by column chromatography on silica gel (15 g), using ether–benzene (1 : 99) as the eluent, to give **8** (107 mg: 31% from **9**) as an oil, $[\alpha]_D$ +32° (*c* 2.11), IR: 1710 cm^{-1}; ^1H NMR: 0.88 (6H, bd, J=6.5 Hz, $-CH(C\underline{H}_3)_2$), 1.15 (6H, s, C_4–CH_3 and C_{10}–CH_3), 3.65 (3H, s, $-CO_2CH_3$). Found: C, 72.23; H, 9.32%. Calcd for $C_{21}H_{32}O_4$: C, 72.38; H, 9.26%.

*Methyl 9β-Hydroxy-13β-abiet-7-en-18-oate (**10**).* A mixture of **8** (56 mg) and 80% hydrazine hydrate (0.12 ml), and acetic acid (0.04 ml) in methanol (1.86 ml) was treated as described for the preparation of **7**. The crude product was chromatographed on silica gel (5.0 g), using ether–benzene (3 : 97) as the eluent, to give **10** (14 mg: 26%) as an oil, $[\alpha]_D$ −66° (*c* 0.455); IR: 3615, 3410 br, 1715 cm^{-1}; ^1H NMR ($CDCl_3$): 0.88 (6H, d, J=6.5 Hz, $-CH(C\underline{H}_3)_2$), 1.08 (3H, s, C_{10}–CH_3), 1.30 (3H, s, C_4–CH_3), 3.65 (3H, s, $-CO_2CH_3$), 5.38 (1H, bd, J=4 Hz, C_7–H); MS (*m/e*): 334 (M^+).

*Separation and Purification of the Ketones E (**13**) and F (**12**).* The mixture of the ketones (400 mg) E and F was treated with acetic anhydride (2.0 ml) in pyridine (2.0 ml) at room temperature for 2.5 h. After the usual work-up, the crude product was purified by column chromatography on silica gel (40 g), using ether–benzene (1 : 99) as the eluent, to give methyl 11-acetoxy-14-hydroxy-7-oxoabieta-8,11,13-trien-18-oate (**11**) (99 mg) which was recrystallized from methanol, mp 158.5—159.5 °C, $[\alpha]_D$ +93° (*c* 1.13); IR: 1757, 1723, 1630 cm^{-1}; ^1H NMR ($CDCl_3$): 1.23 (6H, d, J=6 Hz, $-CH(C\underline{H}_3)_2$), 1.32 and 1.34 (each 3H and s, C_4–CH_3 and C_{10}–CH_3), 2.32 (3H, s, $-OCOCH_3$), 3.69 (3H, s, $-CO_2CH_3$), 6.95 (1H, s, C_{12}–H), 13.54 (1H, s, –OH). Found: C, 68.50; H, 7.62%. Calcd for $C_{23}H_{30}O_6$: C, 68.63; H, 7.51%. Subsequent elution gave a mixture of **11** and **13** (154 mg) (*ca.* 2 : 3 ratio by ^1H NMR analysis).

Further elution afforded the original ketone E (86 mg), $[\alpha]_D$ +20° (*c* 3.91); IR: 1720, 1672, 1608 cm^{-1}; ^1H NMR: 1.25 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.25 and 1.31 (each 3H and s, C_4–CH_3 and C_{10}–CH_3), 3.62 (3H, s, $-CO_2CH_3$), 7.20 (1H, d, J=8.5 Hz, C_{11}–H), 7.27 (1H, dd, J=8.5 and 2 Hz, C_{12}–H), 7.76 (1H, d, J=2 Hz, C_{14}–H). The IR and ^1H NMR spectra of the ketone E were identical with those of methyl 7-oxoabieta-8,11,13-trien-18-oate (**13**).[14]

A mixture of **11** (90 mg) and sodium hydrogencarbonate (80 mg) in 90% aqueous methanol (12 ml) was refluxed for 1 h and the solvent was removed *in vacuo*. The residue was extracted with ether and the ether extract was washed with brine, dried over sodium sulfate, and evaporated. The residue was recrystallized from methanol to give methyl 11,14-dihydroxy-7-oxoabieta-8,11,13-trien-18-oate (**12**) (52 mg), mp 233.5—234.5 °C, $[\alpha]_D$ +121° (*c* 0.595); IR: 3590, 3330 br, 1720, 1630 cm^{-1}; ^1H NMR (acetone-d_6): 1.16 and 1.17 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.33 and 1.45 (each 3H and s, C_4–CH_3 and C_{10}–CH_3), 3.47 (1H, dm, J=12 Hz, $C_{1\beta}$–H), 3.66 (3H, s, $-CO_2CH_3$), 7.05 (1H, s, C_{12}–H), 7.87 (1H, s, disappeared with D_2O, C_{11}–OH), 13.02 (1H, s, disappeared with D_2O, C_{14}–OH). Found: C, 70.07; H, 8.05%. Calcd for $C_{21}H_{28}O_5$: C, 69.97; H, 7.83%.

*Methyl 14-Hydroxyabieta-8,11,13-trien-18-oate (**18**).* A mixture of **15** (332 mg), copper(II) bromide (402 mg), and lithium bromide (78 mg) in acetonitrile (16.6 ml) was refluxed for 6.5 h and then evaporated *in vacuo*. The residue was dissolved in ether. The ether solution was washed with brine, dried over sodium sulfate, and evaporated. The crude product was chromatographed on silica gel (40 g), using ether–benzene (1 : 99) as the eluent, to give **18**[17] (190 mg: 57%) as an oil, $[\alpha]_D$ +38° (*c* 0.635); IR: 3610, 1718, 1610, 1570 cm^{-1}; ^1H NMR ($CDCl_3$): 1.22 and 1.28 (each 3H and s, C_4–CH_3 and C_{10}–CH_3), 1.23 and 1.26 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.65 (3H, s, $-CO_2CH_3$), 4.69 (1H, bs, –OH), 6.83 and 6.99 (each 1H, d, and J=8.5 Hz, C_{11}–H and C_{12}–H). Found: C, 76.32; H, 9.10%. Calcd for $C_{21}H_{30}O_3$: C, 76.32; H, 9.15%. Further elution with ether–benzene (3 : 97) gave the recovered **15** (123 mg: 37%).

*Methyl 14-Methoxyabieta-8,11,13-trien-18-oate (**19**).* A mixture of **18** (1.18 g) and 55% sodium hydride (0.78 g) in *N,N*-dimethylformamide (39 ml) was stirred at room temperature for 45 min under a stream of nitrogen. After the addition of methyl iodide (0.30 ml), the mixture was stirred at 35—40 °C for 3 h and then some additional methyl iodide (0.30 ml) was added. The mixture was further stirred at the same temperature for 4 h, cooled, poured into a mixture of ice and dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated. The residue was chromatographed on silica gel (100 g), using benzene as the eluent, to give **19**[17] (0.76 g: 67%) which was recrystallized from methanol, mp 102—104 °C, $[\alpha]_D$ +50° (*c* 1.82); IR: 1712 cm^{-1}; ^1H NMR ($CDCl_3$): 1.20 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.21 and 1.27 (each 3H and s, C_4–CH_3 and C_{10}–CH_3), 3.67 and 3.71 (each 3H and s, $-CO_2CH_3$ and $-OCH_3$), 7.04 (2H, s, C_{11}–H and C_{12}–H). Found: C, 76.71; H, 9.46%. Calcd for $C_{22}H_{32}O_3$: C, 76.70; H, 9.36%.

*Isomerization of **15**.* *a)*: A solution of **15** (67 mg) and sodium methoxide (44 mg) in absolute methanol (3.4 ml) was refluxed for 1 h. The solution was poured into dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (10 g), using ether–hexane (1 : 9) as the eluent, to give an inseparable mixture (62 mg) of **15** and its C-13 epimer (**25**) (*ca.* 2 : 1 ratio by ^1H NMR analysis). ^1H NMR ($CDCl_3$) signals assigned to **25**: 0.90 and 0.91 (each 3H, d, and J=6 Hz, $-CH(C\underline{H}_3)_2$), 1.09 (3H, s, C_{10}–CH_3), 1.21 (3H, s, C_4–CH_3), 3.67 (3H, s, $-CO_2CH_3$).

b): A solution of **15** (67 mg) and 5% aqueous sodium hydroxide (0.3 ml) in tetrahydrofuran (3.4 ml) was refluxed for 10 h. The solution was poured into dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo* to give an oil (66 mg), whose IR and ^1H NMR spectra were identical with those of the starting **15**.

*Reduction of **15** with Sodium Borohydride.* A mixture of **15** (670 mg), sodium borohydride (1.52 g), and 5% aqueous sodium hydroxide (3.0 ml) in tetrahydrofuran (34 ml) was refluxed for 10 h. The mixture was poured into dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on

silica gel (65 g), using ether–benzene (3 : 97) as the eluent, to give methyl 14β-hydroxy-13β-abiet-8-en-18-oate (**26**) (159 mg: 24%) as an oil, $[\alpha]_D$ +125° (*c* 2.17); IR: 3620, 3460 br, 1720 cm^{-1}; ^1H NMR ($CDCl_3$): 0.95 and 0.98 (each 3H, d, and J=6 Hz, $-CH(C\underline{H}_3)_2$), 1.01 (3H, s, $C_{10}-CH_3$), 1.20 (3H, s, C_4-CH_3), 3.66 (3H, s, $-CO_2CH_3$), 3.78 (1H, br, $W_{1/2}$=5.5 Hz, $C_{14\alpha}-H$). Found: C, 75.68; H, 10.48%. Calcd for $C_{21}H_{34}O_3$: C, 75.40; H, 10.25%.

Further elution with ether–benzene (3 : 97) gave methyl 14α-hydroxy-13β-abiet-8-en-18-oate (**24**) (256 mg: 38%), which was recrystallized from methanol; mp 102—103 °C (after drying *in vacuo* at 40 °C for 5 h), $[\alpha]_D$ +59° (*c* 0.625) (lit,[4] mp 102—103 °C, $[\alpha]_D^{25}$ +66.7°); IR: 3600, 3450 br, 1720 cm^{-1}; ^1H NMR ($CDCl_3$): 0.83 and 0.96 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.00 (3H, s, $C_{10}-CH_3$), 1.20 (3H, s, C_4-CH_3), 3.65 (3H, s, $-CO_2CH_3$), 3.80 (1H, bd, J=7.5 Hz, $C_{14\beta}-H$). Found: C, 75.35; H, 10.47%. Calcd for $C_{21}H_{34}O_3$: C, 75.40; H, 10.25%. The identity of **24** with natural methyl suaveolate was confirmed by mixed melting point determination and by IR and ^1H NMR spectral comparison.[20]

Elution with ether–benzene (1 : 1) afforded 13β-abiet-8-ene-14β,18-diol (**29**) (46 mg: 7.5%) as an oil; $[\alpha]_D$ +92° (*c* 0.39); IR: 3625, 3450 br cm^{-1}; ^1H NMR ($CDCl_3$): 0.81 (3H, s, C_4-CH_3), 1.03 (3H, s, $C_{10}-CH_3$), 0.95 and 0.98 (each 3H, d, and J=6 Hz, $-CH(C\underline{H}_3)_2$), 3.15 and 3.44 (each 1H, d, and J=10.5 Hz, $-C\underline{H}_2OH$), 3.77 (1H, br, $W_{1/2}$=6 Hz, $C_{14\alpha}-H$). Found: C, 78.40; H, 11.25%. Calcd for $C_{20}H_{34}O_2$: C, 78.38; H, 11.18%.

Subsequent elution with ether–benzene (1 : 1) gave 13β-abiet-8-ene-14α,18-diol (**23**) (95 mg: 15%) which was recrystallized from dichloromethane; mp 180—182 °C; $[\alpha]_D$ +84° (*c* 0.285) (lit,[4] mp 186—187 °C, $[\alpha]_D^{25}$ +81.3°); IR: 3620, 3290 br cm^{-1}; ^1H NMR ($CDCl_3$): 0.76 (3H, s, C_4-CH_3), 0.82 and 0.95 (each 3H, d, and J=6.5 Hz, $-CH(C\underline{H}_3)_2$), 1.00 (3H, s, $C_{10}-CH_3$), 2.97 and 3.46 (each 1H, d, and J=11 Hz, $-C\underline{H}_2OH$), 3.77 (1H, bd, J=7 Hz, $C_{14\beta}-H$). Found: C, 78.15; H, 11.47%. Calcd for $C_{20}H_{34}O_2$: C, 78.38; H, 11.18%. The identity of **23** with natural suaveolol was confirmed by mixed melting point determination and by IR and ^1H NMR spectral comparison.[20]

*Reduction of **15** with Lithium Aluminium Hydride.* A mixture of **15** (166 mg) and lithium aluminium hydride (57 mg) in dry ether (5.0 ml) was refluxed for 4 h with stirring. The mixture was poured into aqueous ammonium chloride solution and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated. The residue was chromatographed on silica gel (20 g), using ether–benzene (3 : 7) as the eluent, to give an oil (35 mg: 23%). The IR and ^1H NMR spectra of the oil were superimposable with those of **29**.

Further elution with ether–benzene (1 : 1) gave a solid (72 mg: 47%). The IR and ^1H NMR spectra of the solid were identical with those of suavelol.

*Oxidation of **24** and **26** with Pyridinium Chlorochromate. a)*: A mixture of **24** (23 mg) and pyridinium chlorochromate (22 mg) in dichloromethane (1.0 ml) was stirred at room temperature for 2 h. The mixture was then decanted from a tarry residue, which was washed with ether. The combined organic solution was washed with brine, dried over sodium sulfate, and evaporated to give an oil (21 mg), whose IR and ^1H NMR spectra were identical with those of **15**.

b): A mixture of **26** (14 mg) and pyridinium chlorochromate (14 mg) in dichloromethane (1.0 ml) was treated as described in *a)* to give an oil (14 mg), which was shown to be identical with **15** by spectral comparison.

*Methyl 14β-Acetoxy-13β-abiet-8-en-18-oate (**27**).* A mixture of **26** (70 mg), acetic anhydride (1.0 ml), and pyridine (1.0 ml) was allowed to stand overnight at room temperature. After the usual work-up, the crude product was chromatographed on silica gel (10 g), using ether–hexane (1 : 9) as the eluent, to give **27** (64 mg) as an oil; $[\alpha]_D$ +181° (*c* 0.575); IR: 1713 cm^{-1}; ^1H NMR ($CDCl_3$): 0.90 (6H, d, J=6 Hz, $-CH(C\underline{H}_3)_2$), 1.02 (3H, s, $C_{10}-CH_3$), 1.19 (3H, s, C_4-CH_3), 2.03 (3H, s, $-OCOCH_3$), 3.64 (3H, s, $-CO_2CH_3$), 5.32 (1H, br, $W_{1/2}$= 5 Hz, $C_{14\alpha}-H$). Found: C, 73.97; H, 9.83%. Calcd for $C_{23}H_{36}O_4$: C, 73.67; H, 9.64%.

*Methyl 14α-Acetoxy-13β-abiet-8-en-18-oate (**28**).* The alcohol **24** (58 mg) was acetylated with acetic anhydride in pyridine, as described for the preparation of **27**. The acetate (**28**) (47 mg) was recrystallized from methanol; mp 134.5—135 °C; $[\alpha]_D$ −41° (*c* 0.245) (lit,[4] mp 132—133 °C, $[\alpha]_D^{25}$ −44.5°); IR: 1720 cm^{-1}; ^1H NMR ($CDCl_3$): 0.82 and 0.92 (each 3H, d, and J=6.5 Hz, $-CH(C\underline{H}_3)_2$), 0.99 (3H, s, $C_{10}-CH_3$), 1.19 (3H, s, C_4-CH_3), 2.06 (3H, s, $-OCOCH_3$), 3.65 (3H, s, $-CO_2CH_3$), 5.37 (1H, bd, J=8 Hz, $C_{14\beta}-H$). Found: C, 73.68; H, 9.79%. Calcd for $C_{23}H_{36}O_4$: C, 73.67; H, 9.64%.

*14β,18-Diacetoxy-13β-abiet-8-ene (**30**).* The diol **29** (68 mg) was acetylated as described for the preparation of **27**. The crude product was chromatographed on silica gel (10 g), using ether–hexane (15 : 85) as the eluent, to give **30** (64 mg), which was recrystallized from methanol; mp 93—95 °C; $[\alpha]_D$ +201° (c 1.695); IR: 1722 cm^{-1}; ^1H NMR ($CDCl_3$): 0.88 (3H, s, C_4-CH_3), 1.04 (3H, s, $C_{10}-CH_3$), 0.92 (6H, d, J=6 Hz, $-CH(C\underline{H}_3)_2$), 2.04 and 2.05 (each 3H and s, 2-$OCOCH_3$), 3.68 and 3.88 (each 1H, d, and J=11 Hz, $-C\underline{H}_2$-OAc), 5.35 (1H, br, $W_{1/2}$=5.5 Hz, $C_{14\alpha}-H$). Found: C, 74.09; H, 10.11%. Calcd for $C_{24}H_{38}O_4$: C, 73.80; H, 9.81%.

*14α,18-Diacetoxy-13β-abiet-8-ene (Suaveolol Diacetate) (**31**).* The diol **23** (71 mg) was acetylated as described for the preparation of **27**. The crude product was chromatographed on silica gel (10 g), using ether–hexane (15 : 85) as the eluent, to give **31** (71 mg) as an oil; $[\alpha]_D$ −41° (*c* 0.590) (lit,[4] $[\alpha]_D^{25}$ −39.1°); IR: 1720 cm^{-1}; ^1H NMR ($CDCl_3$): 0.83 and 0.95 (each 3H, d, and J=6.5 Hz, $-CH(C\underline{H}_3)_2$), 0.89 (3H, s, C_4-CH_3), 1.02 (3H, s, $C_{10}-CH_3$), 2.06 and 2.07 (each 3H and s, 2-$OCOCH_3$), 3.72 and 3.85 (each 1H, d, and J=11 Hz, $-C\underline{H}_2OAc$), 5.39 (1H, bd, J=8.5 Hz, $C_{14\beta}-H$). Found: C, 74.07; H, 10.09%. Calcd for $C_{24}H_{38}O_4$: C, 73.80; H, 9.81%.

*Suaveolic Acid (14α-Hydroxy-13β-abiet-8-en-18-oic Acid) (**22**).* A mixture of **24** (68 mg) and potassium *t*-butoxide (381 mg) in dimethyl sulfoxide (3.4 ml) was stirred at room temperature for 1 h. The mixture was poured into ice–water, acidified with 10% aqueous acetic acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo* to give a pale yellow oil (70 mg). The crude product was chromatographed on silicic acid (Mallinckrodt, CC-4, 10g), using ether–benzene (3 : 7) as the eluent, to give **22** as a solid (34 mg: 55%). It was recrystallized from hexane to give needles, mp 188—190 °C after drying at 80 °C for 2 h, $[\alpha]_D$ +71° (*c* 0.14) (lit,[4] mp 198—201 °C dec, $[\alpha]_D^{25}$ +68.2°); IR (KBr): 3390—2630, 1698 cm^{-1}; ^1H NMR ($CDCl_3$): 0.82 and 0.95 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 0.99 (3H, s, $C_{10}-CH_3$), 1.19 (3H, s, C_4-CH_3), 3.83 (1H, bd, J=7.5 Hz, $C_{14\beta}-H$), 6.02 (2H, br, $-CO_2H$ and $-OH$). The IR and ^1H NMR spectra of **22** were identical with those of natural suaveolic acid.[20]

The authors are grateful to Arakawa Chemical Co. Ltd. for the generous gift of (+)-13β-abiet-8-en-18-oic acid. Thanks are also due to Dr. P. S. Manchand, Hoffmann-La Roche Inc., for kindly supplying the natural samples and their spectral data.

Carbon-Carbon Bond Formation by the Use of Chloroiodomethane as a C_1 Unit. III.[1] A Convenient Synthesis of the Mannich Base from Enol Silyl Ether by a Combination of Chloroiodomethane and *N,N,N',N'*-Tetramethylmethanediamine[2]

Sotaro MIYANO,* Hiroshi HOKARI, and Harukichi HASHIMOTO

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki-Aoba, Sendai 980

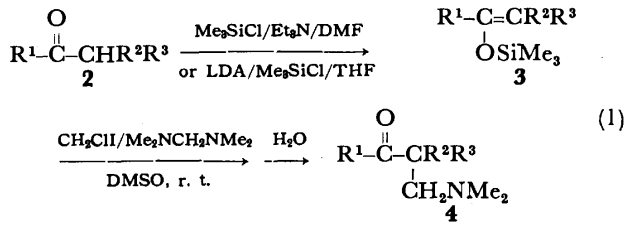
(Received June 15, 1981)

The Mannich dimethylaminomethylation of carbonyl compounds is conveniently carried out *via* enol trimethylsilyl ethers by a combination of chloroiodomethane (CH_2ClI) and *N,N,N',N'*-tetramethylmethanediamine (TMMD) in DMSO as the solvent at ambient temperature. The mechanism of the transformation is discussed on the basis of product analysis and ^1H NMR spectral studies. The reagent system CH_2ClI/TMMD also provides a convenient route to the Eschenmoser's salt ($Me_2\overset{+}{N}=CH_2,\bar{I}$).

One of the most general entrances into the α-methylene carbonyl system[3] is by deamination of α-aminomethyl carbonyl compounds, *i.e.* the Mannich base.[4] In this context, much attention has been centered in the last few years on the Mannich reaction of carbonyl substrates *via* enolates by means of preformed *N,N*-dimethylmethyleneiminium reagents, ($Me_2\overset{+}{N}=CH_2$, $\bar{X}$) (**1**),[5] among which the Eschenmoser's salt (X=I)[6] has conventionally been utilized because of its relative easiness of handling and compatibility with a variety of reaction conditions.[7]

From a practical point of view, however, operationally simple Mannich reaction which does not require separate preparation and handling of these highly reactive iminium salts may be desirable.[8]

We recently communicated briefly that the reagent system chloroiodomethane (CH_2ClI)/*N,N,N',N'*-tetramethylmethanediamine (TMMD) can serve as the *in situ* Mannich dimethylaminomethylation reagent of enol trimethylsilyl ethers under mild conditions (Eq. 1),[9] and herein we wish to report the results we have obtained in the course of this investigation and the relative experimental details.



(1)

Results and Discussion

Synthesis of the Mannich Base. 3-Pentanone enol silyl ether (**3a**) was treated with 1.5 molar amounts of CH_2ClI and TMMD in DMSO; after 3-h stirring at ambient temperature, almost all of the substrate was consumed with the formation of 2-(dimethylaminomethyl)-3-pentanone (**4a**) in a 93% yield. After the usual work-up, a pure sample of the amino ketone was isolated in a 68% yield by distillation; the product was fully characterized by IR and ^1H NMR spectral studies and elemental analysis.

As the transformation seemed to be of synthetic utility because of its mildness, operational simplicity, and reasonable yield of the Mannich base, further investigations with respect to both reagent system and substrate were carried out. Among the several solvents examined, DMSO gave the best result in the reaction of cyclohexanone enol silyl ether (**3c**) with CH_2ClI/TMMD (Table 1). Both DMF and CH_2Cl_2 may also be utilized as the reaction medium, while THF and diethyl ether gave poor results. It is reported that preformed iminium salts **1** (X=Cl, I) did not work in diethyl ether for the aminomethylation of propiophenone enol silyl ether (**3b**), presumably because of the insolubility of the halide salts.[7]

As for the dihalide component, CH_2ClI seemed to be the one of choice under a given reaction conditions (3-h reaction in DMSO), while even CH_2Br_2 gave a good result when the reaction was allowed to continue for 50 h (Table 2). It is interesting that the reactivity of the dihalides was in the order of $CH_2ClI > CH_2I_2 > CH_2Br_2 > CH_2Cl_2$ as judged by the unchanged halide.

Table 1. Effect of solvent on the reaction of cyclohexanone enol silyl ether (**3c**)[a]

a) **3**, 15—20 mmol; **3**/CH_2ClI/TMMD≈1/1.5/1.5 (molar ratio); solvent, DMSO, 20 ml; room temp. b) Isolated yields unless otherwise noted. c) Determined by GLC. d) Determined by ^1H NMR. e) After CH_2ClI and TMMD had been stirred for 3 h, the enol silyl ether was added.

Table 3 lists the results of the Mannich reaction of various carbonyl compounds *via* enol silyl ethers with CH_2ClI/TMMD in DMSO as the solvent. It can be seen that the substrates in the Table can be divided into three categories: The first group enol silyl ethers (**3a** to **3e**) gave the corresponding mono(aminomethylation) products in fair to good yields, though **3e** required a longer reaction period in order to obtain appreciable yield. It should be noted that regioselective aminomethylation of 1-methylcyclohexanone was accomplished *via* enol silyl ether **3d**.

In the case of the second group enol silyl ethers (**3f** to **3i**), the Mannich reaction was accompanied by the formation of considerable amounts of α-methylenation products. GLC analysis showed that the reaction mixture of heptanal enol silyl ether (**3f**) (3-h reaction) contained 2-methyleneheptanal in a 12% yield based on the starting substrate. Distillation caused serious resinification of the reaction mixture, allowing the isolation of the desired Mannich base in a poor yield (18%). The exact mechanism by which the α-methylene carbonyl derivatives were formed remains to be determined, while it seems that the initially formed Mannich base released dimethylamine under

the reaction conditions.[10] Thus, upon treatment of **3f** with CH_2ClI/TMMD in DMSO for 24 h, the amount of the α-methylene aldehyde reached a 42% yield; this may be of some utility for the synthesis of α-methylene aldehydes (Eq. 2).

$$n\text{-}C_5H_{11}\text{-}CH{=}CH\text{-}OSiMe_3 \quad \textbf{3f}$$

$$\xrightarrow[\text{DMSO, r.t., 24h}]{CH_2ClI/Me_2NCH_2NMe_2} \xrightarrow{H_2O} n\text{-}C_5H_{11}\text{-}\underset{\underset{CH_2}{\|}}{C}\text{-}CHO \quad \textbf{5f} \qquad (2)$$

As was stated earlier the Mannich base itself is frequently utilized as the precursor for the α-methylene carbonyl compound, so the concurrent deamination in these transformations may not always be deteriorative to the Mannich aminomethylation.

The third group enol silyl ethers (**3j** and **3k**) which are characterized by bearing terminal methylene function gave bis(aminomethylation) products (**4'**) preferentially (Eq. 3). Even under the reaction conditions

$$\underset{Me_3SiO}{\overset{R}{\diagdown}}C{=}CH_2 \xrightarrow[\text{DMSO, r. t., 3h}]{CH_2ClI/Me_2NCH_2NMe_2} \xrightarrow{H_2O}$$

$$\textbf{3j or 3k} \quad R\text{-}\overset{O}{\overset{\|}{C}}\text{-}CH_2CH_2NMe_2 \quad \textbf{4}$$

$$+\,R\text{-}\overset{O}{\overset{\|}{C}}\text{-}CH(CH_2NMe_2)_2 \quad \textbf{4'} \qquad (3)$$

where 40% of the substrate **3k** was remained unchanged, a 57 : 43 mixture of mono- to diamino ketone was resulted (Table 4). This is a sharp contrast to the report that the preformed Mannich reagent (**1**) did not afford disubstitution products from these type of enol silyl ethers.[7] At present, we have no idea to explain these discrepancies.

*A Convenient Synthesis of the Eschenmoser's Salt (**1**, X=I) from CH_2ClI and TMMD.* In 1971, Böhme *et al.* reported that CH_2Br_2 slowly reacts with TMMD to afford **1** (X=Br)[11] (Eq. 4).

$$Me_2NCH_2NMe_2 + CH_2Br_2 \longrightarrow 2Me_2\overset{+}{N}{=}CH_2,\ Br^- \qquad (4)$$

From the results in Table 2, it seems reasonable to anticipate that CH_2ClI would react more promptly with TMMD than CH_2Br_2 to give similar iminium salt of mixed halides (**1**, X=Cl and I). Thus, upon mixing TMMD with CH_2ClI, a mild exothermic reaction set in with the formation of white precipitate. To our surprise, however, the solid was shown to be the Eschenmoser's salt (**1**, X=I), as was evidenced by elemental analysis (*vide infra*). NMR and GLC study showed the presence of CH_2Cl_2 as a reaction product in the liquid part of the reaction mixture. Then, the overall transformation may be represented as follows:

$$Me_2NCH_2NMe_2 + 2CH_2ClI \longrightarrow 2Me_2\overset{+}{N}{=}CH_2,\ \bar{I} + CH_2Cl_2. \qquad (5)$$

On the basis of the stoichiometry according to Eq. 5, an 82% yield of the iminium iodide was attained after the mixture was allowed to stand for 3 d at ambient temperature in the dark. Under the similar reaction conditions, CH_2Br_2 and CH_2I_2 did not give appreciable amounts of the corresponding precipitate.

The conventional method for the preparation of the Eschenmoser's salt requires time-consuming, two-step procedure which must be carried out under strictly anhydrous conditions.[6] Recently Bryson *et al.* reported a convenient preparation of the iodide *via* cleavage of TMMD with stoichiometric amount of trimethylsilyl iodide.[12] In our Mannich reaction, separate preparation of the iminium reagent is not required for the aminomethylation of groups 1 and 2 enol silyl ethers in Table 3, but if desired, the transformation depicted in Eq. 5 will provide another convenient route to the Eschenmoser's salt.

Mechanistic Aspects of the Mannich Reaction of Enol Silyl Ether with CH_2ClI/TMMD. The time-course of the reaction of CH_2ClI with TMMD in DMSO was followed quantitatively by GLC (Fig. 1). On the basis of the material balance on chlorine and CH_2ClI, the amount of iminium iodide and chloride species are obtainable (see Experimental part). In this regard, NMR study of the reaction in DMSO-d_6 is suggestive

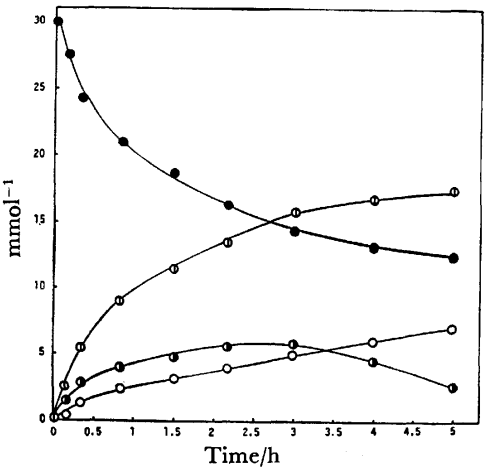

Fig. 1. Reaction of CH_2ClI with TMMD in DMSO. Reaction conditions: CH_2ClI, 30 mmol; TMMD, 30 mmol; DMSO, 20 ml; room temp. ●: CH_2ClI, ⓘ: $Me_2\overset{+}{N}{=}CH_2,\bar{I}$, ◑: $Me_2\overset{+}{N}{=}CH_2,\bar{Cl}$, ○: CH_2Cl_2.

TABLE 4. REACTION OF ACETOPHENONE ENOL SILYL ETHER (**3k**)[a]

3k (mmol)	CH_2ClI (mmol)	TMMD (mmol)	Solvent (ml)	Reacted **3k**(%)	Reacted CH_2ClI (mmol)	**4k**/**4'k** Ratio	Me_2NCH_2- Required (mmol equiv.)
16.1	24.0	27.4	DMSO 20	100	16.3	22/78	28.7

a) Room temp, 3 h.

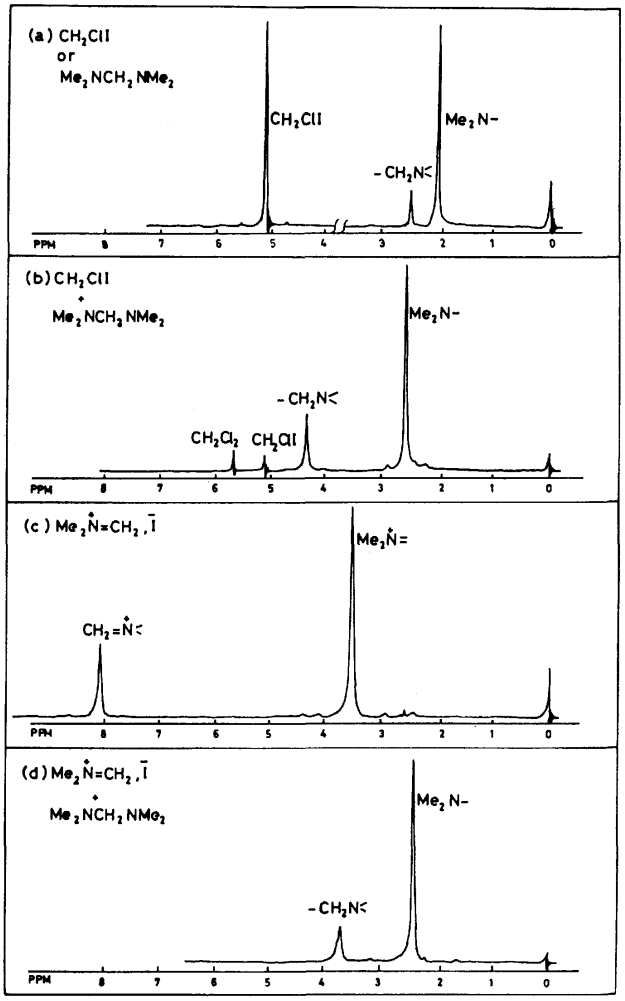

Fig. 2. NMR study of the reaction of CH_2ClI with TMMD in DMSO-d_6.
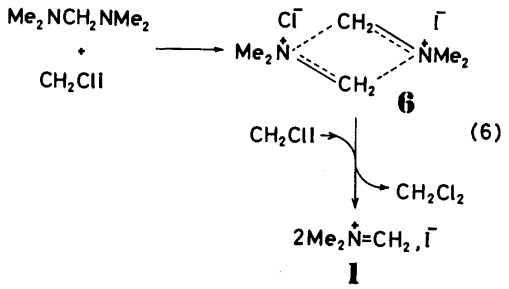
Internal standard, hexamethyldisiloxane; 35 °C.
(a) Spectrum of CH_2ClI and TMMD before mixing.
(b) A mixture of CH_2ClI (3.46 mmol) and TMMD (4.88 mmol) was stirred in DMSO-d_6 for 2 h at 35 °C.
(c) Eschenmoser's salt ($Me_2\overset{+}{N}=CH_2,\bar{I}$). (d) A mixture of $Me_2\overset{+}{N}=CH_2$, $\bar{I}$(0.146 mmol) and TMMD (0.166 mmol).

(Fig. 2). Mixing of the two components (Fig. 2-a) caused gradual decrease of CH_2ClI proton with concomitant downfield shift of the $-CH_2N<$ proton, accompanied by the formation of CH_2Cl_2 (Fig. 2-b). In some cases, depending on the relative amounts of the reagents and the solvent, a white precipitate separated from the reaction mixture. The precipitate, upon dissolution in another portion of DMSO-d_6, showed identical NMR spectrum with that of the authentic sample of the Eschenmoser's salt (Fig. 2-c). On the other hand, a mixture of the Eschenmoser's salt and TMMD showed only two signals of ^1H NMR absorption at 35 °C, which were assigned to CH_3–N and $-CH_2$–N protons, suggesting rapid exchange between iminium species and TMMD (Fig. 2-d).

These observations indicate that the reagent system CH_2ClI/TMMD contains complex iminium species, while most simply, the reaction of CH_2ClI and TMMD is depicted as follows (Eq. 6) (TMMD complexed with **6** or **1** is omitted), where plausibe intermediate species such as **6** can also serve as the Mannich reagent for the enol silyl ether present in the system.



In fact, detailed inspection of the results in Table 4 indicates that up to 2 molar amounts of Me_2NCH_2- moiety could be trapped into acetophenone enol silyl ether from 1 mol of CH_2ClI and TMMD. It is well demonstrated that iminium salt (**1**) readily reacts with not only enol silyl ethers but also various enolates,[5b,13] where highly electrophilic iminium methylene attacks enolate carbon in a regiospecific manner.[7,14]

Experimental

IR spectra were obtained on a Shimadzu IR 430 spectrophotometer. NMR spectra were determined on a Hitachi R-24A instrument using hexamethyldisiloxane as an internal standard in CCl_4 unless otherwise stated. Mass spectra were recorded on a JEOL JMS-D 300 double focusing spectrometer. Analytical GLC was recorded on a Shimadzu GC 3AF with FID detector or Shimadzu 3BT with TCD detector, on a Silicone GE SE-52 on Chromosorb W(AW), Apiezon Grease L on Diasolid M, or Silicone DC 550 on Uniport C column. Preparative GLC was carried out on a Shimadzu GC 6AM using appropriate column mentioned above. Microanalyses were performed at the Microanalysis Center, Chemical Research Institute of Nonaqueous Solutions, Tohoku University.

Materials. CH_2ClI (bp 108 °C) and CH_2I_2 (bp 70 °C/12 mmHg)† were obtained *via* halogen exchange of CH_2Cl_2 with NaI, and stored over a few tin pellets in the dark.[15] CH_2Br_2 was dried over $CaCl_2$, and distilled before use (bp 94—95 °C). Commercial carbonyl compounds were dried over $MgSO_4$ and distilled before use, while 1,2-diphenylethanone (**2h**) (mp 55—56 °C) was used as purchased. TMMD (bp 83—84 °C)[16] and Et_3N (bp 90 °C) were distilled from CaH_2 after having been refluxed for several hours. Solvents were purified as usual. Purified materials were stored under positive nitrogen pressure.

Phenylacetone (2g): The method of Hass *et al.*[17] was slightly modified. A mixture of benzaldehyde (106 g, 1 mol) and nitroethane (≈85 g, ≈1.1 mol) in 50 ml of benzene was refluxed for 15 h with continuous removal of water as benzene azeotrope. Volatiles were removed *in vacuo*, and the residue was recrystallized from ethanol to give 135 g of 1-phenyl-2-nitropropene (83%), mp 64—65 °C (lit,[17] mp 65 °C). A 75 g sample of the phenylacetone, bp 74—74.2 °C/3 mmHg, was prepared from 100 g of the 1-phenyl-2-nitropropene by treatment with 250 g of Fe powder as was described in the literature.[17]

† 1 mmHg≈133.322 Pa.

Enol Silyl Ethers (3): These were prepared from the corresponding carbonyl compounds and trimethylsilyl chloride[18] by means of lithium diisopropylamide in THF (**3d**, bp 33—35 °C/1.5—1.7 mmHg; **3i**, bp 72—76 °C/6—7 mmHg), or by refluxing in Et_3N-DMF (**3a**, bp 65—70 °C/50 mmHg, $E/Z=35/65$; **3b**, bp 54—57 °C/3—4 mmHg; **3c**, bp 65—66 °C/17—18 mmHg; **3e**, bp 68—71 °C/9—10 mmHg; **3f**, bp 60—62 °C/16 mmHg, $E/Z=59/41$; **3g**, bp 87—89 °C/3 mmHg; **3h**, bp 135 °C/1.3 mmHg; **3j**, bp 58—59 °C/45—46 mmHg; **3k**, 97—99 °C/16—17 mmHg).

General Procedure for the Synthesis of the Mannich Base from Enol Silyl Ether (3) with CH_2ClI/TMMD. The reactions were conveniently carried out in a two-necked, 50 ml Schlenk tube under a nitrogen atmosphere. To a water-cooled, stirred solution of the enol silyl ether (**3**) (≈20 mmol) and CH_2ClI (≈30 mmol) was added ≈30 mmol of TMMD. After a slight exothermic reaction subsided, the mixture was stirred at room temperature. Net reaction times are specified in Table 3. At the end of the reaction, 30 ml of 2 M HCl was added, and the mixture was stirred for *ca.* 1 h. Non-basic components, which included unchanged CH_2ClI, starting carbonyl substrate or enol silyl ether, and α-methylenation product, were extracted with portions of cyclohexane. The aqueous phase was made alkaline with 10% NaOH, and extracted with CH_2Cl_2 (4×30 ml). The combined extracts were washed successively with 10% NaOH, brine, and water. After the solution had been dried over $MgSO_4$, CH_2Cl_2 was evaporated *in vacuo*, and the residue was trap-to-trap distilled under reduced pressure; after a small forerun was discarded, middle distillate was collected as the product Mannich base. Results are summarized in Tables 3 and 5.

Upon termination of the reaction of **3h**, addition of aq HCl caused separation of hydrogen halide salt of the Mannich base; the solid was separated by filtration. The Mannich base (**4h**) was liberated by treatment with aq NaOH, and taken into ether.

The cyclohexane extracts were treated as usual, concentrated to an appropriate volume, which was subjected to preparative GLC to recover the α-methylene products (**5**).

5f: NMR: δ ≈0.9 (3H, Me–), 1.1—1.6 (6H, $-(\underline{CH_2})_3-$Me), 2.0—2.5 (2H, $-CH_2-\dot{C}=C\langle$), 5.8 (1H, br) and 6.1 (1H, br) (2H for $H_2C=C\langle$), 9.4 (1H, s, –CHO). (1H, br) (2H for $H_2C=C\langle$), 7.1 (5H, -Ph). MS (70 eV), *m/e* (%): 146 (M^+, 24.4), 131 (16.3), 104 (6.6), 103 (36.7), 77 (3.3).

5h: NMR: δ 5.4 (1H, s) and 5.8 (1H, s) (2H for $H_2C=C\langle$), 6.9—8.0 (10H, 2Ph-). IR (liq. film): 1670, 1440, 1215, 990 cm^{-1}.

5i: NMR: δ ≈0.9 (3H, Me-$(CH_2)_3$-), 1.2 (3H, t, J=6.8 Hz, Me-CH_2O-), 1.1—1.8 (4H, Me-$(CH_2)_2$-), 2.2 (2H, t, J=6.0 Hz, $-CH_2-C=C\langle$), 4.1 (2H, q, J=6.8 Hz, Me-CH_2O-), 5.35 (1H, br) and 5.95 (1H, br) (2H for $H_2C=C\langle$).

Reaction of Acetophenone Enol Silyl Ether (3k): The following example is illustrative. A mixture of **3k** (3.10 g, 16.1 mmol), CH_2ClI (4.24 g, 24.0 mmol), and TMMD (2.80 g, 27.4 mmol) was stirred in 20 ml of DMSO at room temperature for 3 h, and was worked up as above. The cyclohexane extract was analyzed by GLC to determine the amount of CH_2ClI and acetophenone (Table 4). Evaporation of the CH_2Cl_2 layer *in vacuo* left a 3.5 g of syrupy residue which was comprised of the monoamino (**4k**) and diamino ketone (**4'k**) as was evidenced by NMR. The relative amount of the two was estimated to be 22/78 by integration of the Me_2N-resonance (δ 2.12 for **4k** and δ 2.06 for **4'k**). The residue was dissolved in 15 ml of hot pentane, and was kept at −20 °C overnight to give 2.19 g of **4'k** as white crystals (Table 5). Distillation of the filtrate caused serious deamination of the amino ketones, while following distillates were recovered:

Phenyl Vinyl Ketone: Trace, bp 55 °C/0.7 mmHg. NMR: δ 5.7 (1H, dd, J_{cis}=10.2 Hz, J_{gem}=2.4 Hz, for $HC=C\langle$ *trans* to -CO-Ph), 6.25 (1H, dd, J_{trans}=16.8 Hz, for $HC=C\langle$ *cis* to -CO-Ph), 7.0 (1H, dd, $-CH=CH_2$), 7.1—8.0 (5H, -Ph). IR (liq. film): 1670, 1660, 1610, 1450, 1400, 1230, ≈1000—960 cm^{-1}.

4k: Trace, see Table 5.

2-Methylene-3-(dimethylamino)propiophenone: 0.74 g, bp 115—120 °C/3 mmHg. NMR: δ 2.1 (6H, s, Me_2N-), 3.1 (2H, br, $-CH_2N\langle$), 5.5 (1H, br) and 5.75 (1H, br) (2H for $H_2C=C\langle$), 7.1—8.0 (5H, -Ph). IR (liq. film): 2820, 2780, 1660, 1450, 1325, 1280, 1040, ≈1000—970, 860 cm^{-1}.

Formation of the Eschenmoser's Salt from CH_2ClI and TMMD. Under a nitrogen atmosphere, 1.18 g (11.5 mmol) of TMMD was added to a 6.0 g (34 mmol) of CH_2ClI which was chilled in an ice-water bath. The bath was removed after 3 h, and the mixture was allowed to stand at room temperature for 3 d in the dark. Precipitated white crystal was filtered under nitrogen, and was washed with CCl_4, yield, 3.50 g (18.9 mmol calculated as **1** (X=I), 82% based on TMMD). Found: C, 19.60; H, 4.58; N, 7.60; I, 69.0%. Calcd for C_3H_8IN: C, 19.48; H, 4.36; N, 7.57; I, 68.59%. NMR (DMSO-d_6): δ 8.05 (2H, br, $CH_2\overset{+}{N}=$), 3.52 (6H, br, $Me_2\overset{+}{N}=$). On heating, the precipitate colored from white to yellow (≈100 °C) and to dark-brown (≈220 °C), and melted with decomposition at *ca.* 235 °C. By the use of 1 ml of DMSO as the solvent, the yield of the precipitate was improved to 90%. Control of the temperature at the early stage of the reaction and exclusion of moisture seemed essential in order to obtain pure product.

Time-course of the Reaction of CH_2ClI with TMMD. A mixture of CH_2ClI (5.30 g, 30 mmol), TMMD (3.07 g, 30 mmol), and 1.20 g of ethylbenzene (internal standard) in 20 ml of DMSO was stirred at room temperature. Samples (*ca.* 1 ml) were withdrawn at various times through a septum cap by means of a hypodermic syringe, and quenched with aq HCl. After three extractions with cyclohexane, the combined organic phase was analyzed by GLC (Apiezon Grease L column); only CH_2Cl_2 was detected as the reaction product. Material balance on chlorine and CH_2ClI requires following equations:

$$[CH_2ClI \text{ reacted}] = [\overset{+}{Me_2N}=CH_2, \bar{I}],$$

$$[\overset{+}{Me_2N}=CH_2, \bar{Cl}] = [CH_2ClI \text{ reacted}] - 2[CH_2Cl_2],$$

where it is supposed that species which lose halide ion on hydrolysis can be represented as **1** (X=Cl or I).

Proton and Carbon-13 Nuclear Magnetic Resonance Studies of the Effects of Retinal on the Dynamic Structure and Stability of Lipid Bilayer

Yoshio INOUE,* Yoshito HANAFUSA, Masakazu TODA, and Riichiro CHŪJŌ
Department of Polymer Chemistry, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152
(Received June 23, 1981)

The effects of retinal and vitamin A on the dynamic structure and stability of hen egg yolk lecithin bilayers have been studied by means of carbon-13 and proton NMR spectroscopies. ^{13}C spin-lattice relaxation and paramagnetic ion permeability studies on lecithin bilayers indicate a marked decrease in flexibility of the lipid acyl chain and a breakdown of membrane impermeableness to ion by the intercalated *all-trans*- and 11-*cis*-retinal, whereas the effect of incorporated vitamin A on the fluidity of bilayers is small and its impermeableness to ion remains effective even in the presence of higher concentration of vitamin A. The experimental results are discussed in connection with the mechanism of the permeability change in photoreceptive disk membrane.

Rod outer segments are organelles in which the photon is captured by rhodopsin, the visual pigment of the retinal photoreceptor cells for black and white vision in the eye. Rhodopsin is composed of the vitamin A_1 aldehyde isomer 11-*cis*-retinal and the lipoprotein opsin, in which the former is bonded through a Schiff base linkage to the ε-amino group of a lysine residue. Upon exposure to light, rhodopsin bleaches through a series of transformations and finally releases *all-trans*-retinal from opsin into lipid medium in retina.[1] During these events the ionic permeability of the disk membrane is altered and thus the photoreception is translated into an electrical response.[2]

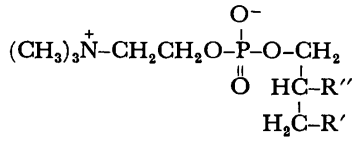
Much is known about bleaching process of rhodopsin,[1] while the mechanism of the translation of photoinformation to the neural system has so far remained almost an event of conjecture. The fact, which seems established, is that the absorption of a single photon by rhodopsin leads to a reduction of the sodium influx[2-4] and consequent hyperpolarization of the disk membrane.[5]

There are considerable interests in the role of membrane lipid in these photochemical events; almost half of the retina rod outer segment fragments is lipid on a weight basis and most of lipid is phospholipid.[6] Phosphatidylethanolamine (PE), phosphatidylcholine (PC), and phosphatidylserine (PS) are the major phospholipids of bovine rod outer segments, making up about 39, 40, and 13%, respectively, of the lipid phosphorus. The major fatty acids in PE and PS are 18 : 0 and 22 : 6, while PC is made up predominantly of 16 : 0 and 22 : 6, and all of the phospholipids contain high levels of polyunsaturated fatty acids.[6,7] Rhodopsin is considered to be an integral membrane protein and at least a part of the protein is embedded within the membrane interior. The interactions between rhodopsin and phospholipid including artificially reconstructed model membranes have been studied by many authors,[8-15] while those between retinal isomers and phospholipid have not been studied well. Retinal has been thought to decompose some biomembranes,[16] especially, *all-trans*- and 11-*cis*-retinal hemolyse rabbit erythrocytes.[17] Retinal isomers may, therefore, affect the arrangement of lipid membrane and *all-trans*-retinal released from rhodopsin plays significant roles in alteration of ionic permeability of plasma membrane.

By the way, the chromophore *all-trans*-retinal released from bleached pigment can be recycled with newly incorporated one *in vivo* to rhodopsin regeneration.[18] Rhodopsin regeneration is believed to occur *via* two discrete reactions: isomerization of *all-trans*-retinal to 11-*cis*-retinal and binding of 11-*cis*-retinal with opsin. *In vivo*, little free retina is found in the photoreceptor cell in contrast to the presence of retinylidene phosphatidylethanolamine.[19-21] Shichi and Somers[18,22,23] have found that phospholipid stimulates the photo-regeneration of rhodopsin from opsin and *all-trans*-retinal. The enhancement of stereoselective isomerization of retinal by an addition of phosphatidylethanolamine has been demonstrated *in vivo* experiment[24] and a series of molecular orbital calculations.[25] It was pointed out[22] that the role of phosphatidylethanolamine in retina are (i) to maintain the integrity of the visual pigment and (ii) to participate in the regenaration of rhodopsin after bleaching, although the latter role is still a matter of speculation.[7,26,27]

In this paper, the interactions between model membrane lipid and retinal and vitamin A were studied by observing the proton and carbon-13 nuclear magnetic resonance spectra. The locations of retinal compounds in the membrane and their effects on the dynamic structure and stability of membrane were investigated by measuring the carbon-13 spin-lattice relaxation time and by monitoring the ionic permeability of the membrane by proton spectra. The determinations of the position of retinals in the lipid bilayers and their effects on the membrane properties are expected to give valuable informations required for the elucidation of the visual process, including the ion permeation and rhodopsin regeneration. As pigments, we will choose *all-trans*- and 11-*cis*-retinal, and vitamin A: the former two are compounds participating in a visual cycle, and the latter one was chosen for the sake of comparison with the formers.

Hen egg yolk phosphatidylcholine (egg yolk lecithin, EYL) bilayer will be used as a model membrane of disk. Use of phosphatidylethanolamine, in spite of one of major phospholipid constituents of rod outer segment's membrane, will be excluded, since it forms Schiff base with retinal. The formation of Schiff base may shade off our purposes. Egg yolk lecithin has several advantages as a lipid membrane system for a model study of disk membrane. Needless to say phosphatidylcholine is one of major constituents of lipid of rod outer segments. The structure of EYL is,



where the predominant esterified residues of fatty acids R′ are palmitic (16 : 0) and stearic (18 : 0), and those of R″ are oleic (18 : 1) and linoleic (18 : 2).[28,29] Long-chain esterified fatty acids with varying degree of unsaturation amounts to 12% are also contained in EYL. EYL thus contains high levels of polyunsaturated fatty acids like a disk phospholipid, and EYL bilayer is in the liquid crystalline states at physiological temperature corresponding to the state of disk membrane. The kinetic study of interconversion from metarhodopsin I to II in a rhodopsin recombinant indicates comparable rate of interconversion in rod outer segments membrane and rhodopsin-EYL bilayers.[30] Thus, EYL could be convinced for a pertinent model for phospholipids of rod outer segments.

Experimental

Vitamin A was purchased from Riken Vitamin Co. Ltd., Tokyo. The crystal of *all-trans*-retinal was prepared by oxidation of vitamin A with manganese dioxide in petroleum ether. The crystal of 11-*cis*-retinal was prepared by successive procedures,[31] *i.e.*, photoisomerization of *all-trans*-retinal in ethanol at 0 °C, fractionation of retinal isomers on an alumina column by eluting with petroleum ether, and seeded recrystallization at −20 °C. Details of preparation of these retinal compounds were described elsewhere.[32]

Egg yolk lecithin was isolated from fresh hen egg yolk according to the procedure of Singleton *et al.*[33] The purity of EYL was checked by thin-layer chromatography. Paramagnetic reagents, $Eu(NO_3)_3 \cdot 6H_2O$, $K_3[Fe(CN)_6]$, and $MnSO_4$ were purchased from Nakarai Chemicals, Ltd., Kyoto. Before use, $Eu(NO_3) \cdot 6H_2O$ were treated by repeated process of dissolving in deuterium oxide and freeze-drying to exchange H_2O with D_2O.

Lecithin dispersions (10% w/v) were prepared by shaking the dry EYL with 0.05 M KCl/D_2O solution (pH 5.6±0.2). The dispersions were then sonicated under cooling by ice/water until translucence (about 20 min) with an Ultrasonic Disruptor Model UR-200P (Tomy Seiko Co. Ltd., Tokyo, frequency 20 kHz, output power 200 W). The resultant vesicle solutions were thoroughly deoxygenated by bubbling argon gas, and were centrifuged (10000 min^{-1} for 1 h) to remove titanium fragment from sonicator's microtip and to remove multilayer liposomes. The vesicle solution was transfered under argon to NMR glass-tubes (5 mm for ^1H and 8 mm for ^{13}C NMR samples) and the NMR spectra were measured immediately after the preparation. Retinal compound-lipid mixed vesicle solution was prepared by first co-dissolving both components in chloroform followed by evaporating the solvent and then treating the resulting dry mixture in a similar manner as described above. KCl was not added to the sample for the proton NMR study of cationic permeability. In this case pH of sample was 7.0. The total concentrations of lipid and retinal-compounds were about 5% (w/v) for proton and 10—20% (w/v) for carbon-13 NMR samples. It has been reported that lecithin concentration over the range of 10—20% (w/v) and changes of pH from 2.5 to 8.0 did not have a significant effect on the carbon-13 relaxation time.[34] Proton and carbon-13 NMR spectra were measured using a JEOL JNM PS-100 spectrometer operating at 100 and 25 MHz, respectively. Proton spectra were measured in a continuous-wave mode. In the ^1H NMR experiment of ionic permeability, $1—2 \times 10^{-2}$ mol dm^{-3} paramagnetic compounds were added to the vesicle dispersion.

In the measurement of carbon-13 spectrum, the spectrometer was equipped with a JEOL JNM PFT-100 Fourier transform system, internal deuterium lock, noise-modulating proton-decoupler, JEOL JEC-6 computer (12K), and JEOL CM-219 IC core (8K) as an auxiliary memory device. A width of frequency domain spectra was 5000 Hz and a data file was 4096 points. The normal spectra were recorded after 1024 or 2048 pulses. The pulse sequence was repeated after a delay time at least five times greater than the largest spin-lattice relaxation time to be measured in order to avoid the effect of saturation. The duration time for 90° pulse was about 2×10^{-5} s. Chemical shifts were measured as down field shifts from external tetramethylsilane (TMS). Carbon-13 spin-lattice relaxation time (T_1) was determined by fast inversion recovery method[35] with a waiting time 5s in order to circumvent the required waiting period. T_1 values for several carbon atoms were checked by the so-called inversion recovery method[36] and were found to be in agreement with the fast inversion recovery determination within experimental error (±10% for well-resolved large peaks and ±15% for less-resolved and small peaks). The sample temperature was kept at 36±1 °C. The preparations of samples and NMR measurements were carried out in the dark. Electron micrographs of sonicated aqueous dispersions of EYL vesicle were observed on a copper sheet mesh soiled by a drop of 2% tungstophosphoric acid with a JEOL JEM-7A type electron microscopy. Ultraviolet spectra were observed on a Beckman-25 spectrometer.

Results

Electron Micrograph. Electron micrographs of sonicated dispersions of EYL indicated the presence of a distribution of vesicle sizes but the most of vesicle have a narrow range of sizes (200—300 Å in diameter). The addition of 20 mol% 11-*cis*-retinal shifted and spread the distribution of vesicle sizes (300—500 Å in diameter). The formations of multilayer or large aggregate with diameter greater than 500 Å were found to be scarce but not negligible. Thus the incorporation of retinal causes the expansion of vesicle size although most of the vesicles remained small. The structural invariableness of retinals and vitamin A before and after the sonication in an EYL dispersion was confirmed by observing ultravilet spectra. Furthermore no major differences were noted between the electron micrographs of sonicated dispersions, even the dispersions with retinals and vitamin A, observed at immediately after and 3—4 d after the preparation.

Carbon-13 Spin-lattice Relaxation Time. The ^{13}C spin-lattice relaxation times for EYL, EYL with 20 mol% incorporated *all-trans*- and 11-*cis*-retinal, and vitamin A are shown in Table 1, where the carbons are listed along the lipid backbone. Since the EYL's esterified fatty acids are heterogeneous, there is some ambiguity in the exact position of the carbon on the fatty acyl chain. Spectral assignments were followed to those made previously.[34] No detectable chemical shifts differences over the experimental error were found between EYL alone and EYL with incorporated

TABLE 1. VALUES OF ^{13}C NT_1[a,b] FOR EGG YOLK LECITHIN(EYL)-RETINALS AND -VITAMIN A BILAYERS IN 5×10^{-2} mol dm^{-3} KCl/D_2O SOLUTIONS AT 36 °C[c]

$-\underline{C}H_3$	9.60	5.64 (0.59)	5.40 (0.56)	7.80 (0.81)

a) Here, T_1 is the spin-lattice relaxation time and N is the number of protons attached to the carbon. The measured T_1 values correspond to the underlined carbons. b) Estimated maximum error in T_1 is $\pm15\%$. c) The values shown in parentheses are the T_1 ratios of EYL-additive mixture to EYL alone. d) The values shown are T_1's. e) Not measured accurately.

retinals and vitamin A. At the concentrations employed here, resonance intensities of the retinal additives were too weak for an accurate determination of their relaxation times. The ^{13}C relaxation times for some carbon resonances of EYL also could not be measured accurately due to their low signal to noise ratios and are not included in Table 1. Since no major differences were noted between normal spectra observed at the beginning and the end of a set of inversion-recovery experiment, and between micrographs observed at immediately after and 3—4 d after the preparation of dispersion, an extent of vesicle fusion during the course of NMR experiment may be small.

The decrease in the rate of motion and in the acyl chain disorder of EYL will result in smaller NT_1 values, although an interpretation of ^{13}C T_1 value is hampered by the fact that the relaxation rate is determined by the anisotropy of molecular motion as well as the rate of motion.[37] Here N is the number of protons bonded to a given carbon atom. For dispersions of EYL alone and EYL with retinals and vitamin A in bilayers, NT_1 values increase from the glycerol carbons toward both the $N^+(CH_3)_3$ group and the terminal methyl carbon of acyl chains, indicating that there are increases in the mobility along the lipid chain in going from the glycerol carbons to the terminal methyl groups. These observations are in agreement with previous ^{13}C relaxation studies of lecithin dispersions.[34,38]

Inspection of ^{13}C T_1 values of EYL listed in Table 1 reveals that the effects of added retinals and vitamin A on T_1 values of EYL are relatively small but almost all T_1 values decrease, namely the motion of EYL molecule is slowed down by additions of retinals and vitamin A. It is noticeable that the reductions of T_1 values of acyl chain carbons are larger in EYL–retinal systems than in EYL–vitamin A system. In the former systems, the carbons of methyl terminal region of acyl chain ($-CH_2CH_2CH_3$) show especially larger T_1 reductions than the other part of EYL molecules, indicating that the retinal molecules locate rather preferentially at the acyl chain region than at the choline polar region of the lipid bilayer. Since retinal is not soluble in water alone, retinal molecule may be solubilized and incorporated into the acyl chain region of lipid bilayer by the hydrophobic interaction between retinal and lipid acyl chain.

On the other hand, the reductions of NT_1 values for EYL–vitamin A system are relatively small and not suggesting any localization of vitamin A molecule at special region in the lipid bilayer. Vitamin A may be allowed to stay near the polar hydrophilic site of lipid bilayer, exposing its hydroxyl group to aqueous medium and extending its hydrophobic part into nonpolar region of lipid bilayer.

For a comparison, ^{13}C T_1 values for EYL alone and EYL with 22 mol% *all-trans*-retinal were also measured in $CDCl_3$ solutions, where lecithin molecules exist as spherical inverted micelles. The results are shown in Table 2. As reported previously,[38] NT_1 values of the chain resonances in $CDCl_3$ are longer than those for the corresponding nuclei in bilayers in D_2O and there is a marked increase in NT_1 values from carbonyl carbon toward the terminal methyls. The NT_1 value of choline methyl resonance is similar to that of $OOC-CH_2-$ methylene carbon resonance in $CDCl_3$ solution, contrasting with the results in D_2O solution where choline methyl NT_1 value is much larger than $OOC-CH_2-$ methylene carbon value. The small NT_1 value for choline methyl groups may result from tight packing of these groups in the inverted micellar structure.[38] In $CDCl_3$ solutions, the inverted micellar structure of EYL is not perturbed by *all-trans*-retinal, since NT_1 values are not changed greatly by an addition of it. Furthermore the resonances corresponding to the retinal carbons are sharper in $CDCl_3$ solution than in D_2O solution. Thus, there isn't any specific interaction between EYL and retinal in $CDCl_3$ solution. These results also confirm that the nature of interaction between EYL and retinals and vitamin A in D_2O solution is essentially hydrophobic.

TABLE 2. VALUES OF ^{13}C T_1[a] FOR EGG YOLK LECITHIN(EYL) IN $CDCl_3$ AT 37 °C

Carbon	EYL		EYL+22 mol% *all-trans*-Retinal		T_1 Ratio[c]
	T_1/s	NT_1/s[b]	T_1/s	NT_1/s[b]	
$-N(\underline{C}H_3)_3$	0.15	0.44	0.14	0.41	0.93

$-\underline{C}H_2-CH_2-CH_3$	2.53	5.06	2.77	5.54	1.09
$-\underline{C}H_2-CH_3$	3.49	6.99	3.51	7.02	1.00
$-\underline{C}H_3$	4.70	14.10	5.05	15.15	1.07

a) Here, T_1 is the spin-lattice relaxation time of the underlined carbon. Estimated maximum error in T_1 is ±10%. b) N is the number of protons attached to the carbon. c) The observed T_1 values of EYL under the coexistence of 22 mol% *all-trans*-retinal relative to those obtained for EYL alone.

^1H NMR Studies on Ionic Permeability of Bilayers. The stability and vesicular nature of the lipid has been further investigated using ^1H NMR. The ionic permeability of lipid bilayers can be correlated with the membrane fluidity as described by ^{13}C spin-lattice relaxation times. In this paper, we studied the effect of the incorporation of retinals and vitamin A on the permeability of EYL vesicles using a paramagnetically induced variation of choline methyl proton resonance. It had previously been shown for ^1H, ^{13}C, and ^{31}P NMR that an addition of paramagnetic ion to lipid bilayer systems results in broadening or shifting of resonances from nuclei near the bilayer surface.[39,40] Paramagnetic ions can hence be used to distinguish the internal and external surface of a phospholipid vesicle by selectively adding the paramagnetic ion to the interior or exterior of the vesicle. Furthermore a variation of resonances induced by paramagnetic ion can be used to study the ionic permeability of lipid bilayers. Here, we used Eu^{3+} and $Fe(CN)_6^{3-}$ ions as the shift reagents and Mn^{2+} ion as the broadening reagent.

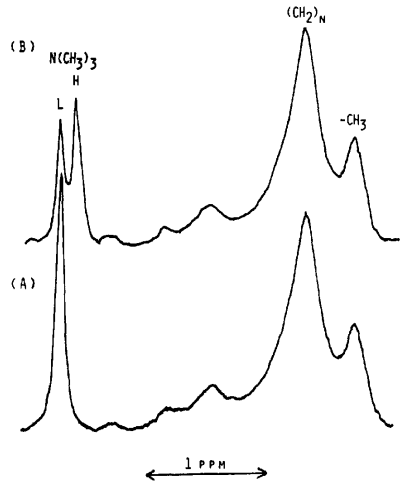

Fig. 1. 100 MHz proton NMR spectra of: (A) sonicated egg yolk lecithin vesicles (5 w/v%) in deuterium oxide solution and (B) sample A plus 10^{-2} mol dm^{-3} Eu^{3+} outside the vesicles. The spectra weretaken at 36 °C.

Figure 1 illustrates the effects of shift reagent $Eu(NO_3)_3$ as typical example. Spectral assignments are taken from those made previously.[40] Spectra A and B were obtained from the same sample without and with $Eu(NO_3)_3$. Upon addition of the $Eu(NO_3)_3$ to sample A, the choline methyl resonance splits into a doublet, while the other resonances are hardly affected. The high-field, shifted(H) and low-field, non-shifted(L) parts of the choline methyl resonance correspond to choline $N(CH_3)_3$ protons on the outside and the inside of the lecithin bilayers, respectively. The intensity ratio L : H of the non-shifted and shifted choline methyl resonance were 1 : 1.4. Assuming that the packing densities of both outside and inside layers of vesicle bilayers are equal and the thickness of the membrane is 37 Å,[40] the diameter of vesicle is estimated from the intensity ratio to be about 480 Å, which is slightly larger than that of prominent particles found by electron micrograph.

If the bilayers are permeable to Eu^{3+} and $Fe(CN)_6^{3-}$ ions, the inward-facing choline methyl groups are exposed to these ions, and the intensity of the shifted signal increases while that of the non-shifted signal correspondingly decreases with progress of ion permeation. When Mn^{2+} is added to the permeable bilayers, the resonance of only inward-facing choline methyl group may be firstly observed, but all finally disappears from ^1H NMR spectrum.

The intensity ratio of the choline methyl doublet shown in Fig. 1B remained practically constant for two days, indicating that Eu^{3+} cation is impermeable through EYL bilayers. Same impermeableness was also observed for Mn^{2+} and $Fe(CN)_6^{3-}$ ions. We have investigated the influences of incorporated retinals and vitamin A in the concentration range 5—33 mol% on the ionic permeability of EYL bilayers. It was found that an addition of vitamin A even at the concentration of 33 mol% does not disturb the impermeableness of bilayers which are effective ion barriers. Furthermore EYL vesicle containing less than 20 mol% *all-trans*- or 11-*cis*-retinal was found to form bilayers stable on the time scale of our experiments and also practically

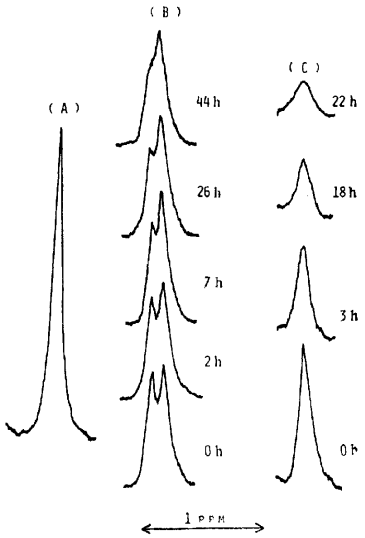

Fig. 2. Time dependence of choline methyl resonance of sonicated egg yolk lecithin vesicles (5 w/v%) with 33 mol% incorporated *all-trans*-retinal in deuterium oxide solution at 36 °C. (A) spectrum before adding the paramagnetic ions; (B) spectra of sample A just after (0 h) and 2, 7, 26, and 44 h after adding the $Eu(NO_3)_3$ (10^{-2} mol dm^{-3}); and (C) spectra of sample A just after (0 h) and 3, 18, and 22 h after adding the $MnSO_4$ (10^{-2} mol dm^{-3}).

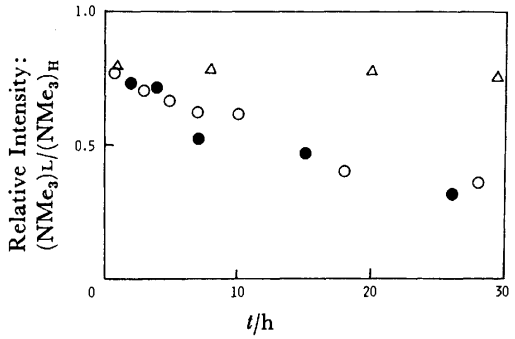

Fig. 3. Time dependence of intensity ratio of low-field(L) to high-field(H) choline methyl resonances for egg yolk lecithin(EYL) with 20 mol% incorporated *all-trans*-retinal plus 10^{-2} mol dm^{-3} Eu^{3+} (△), EYL with 33 mol% incorporated *all-trans*-retinal plus 10^{-2} mol dm^{-3} Eu^{3+} (●), and EYL with 33 mol% incorporated *all-trans*-retinal plus 2×10^{-2} mol dm^{-3} $Fe(CN)_6^{3-}$ (○).

impermeable to Eu^{3+}, $Fe(CN)_6^{3-}$, and Mn^{2+} ions.

On the contrary, less but significant ion permeation was found with the incorporation of over 20 mol% *all-trans*- and 11-*cis*-retinal to the system. Figure 2 shows the change of the choline methyl resonance with time after adding Eu^{3+} and Mn^{2+} ions to EYL dispersion with 33 mol% incorporated *all-trans*-retinal. The rate of penetration of ions across the bilayers is reflected in the rate of the spectral change. Time dependence of the intensity ratio of low-field to high-field choline methyl resonances after the addition of Eu^{3+} and $Fe(CN)_6^{3-}$ for EYL–*all-trans*-retinal systems are shown in Fig. 3. The increased amount of incorporated *all-trans*-retinal results in the increased rate of permeation of ion. Similar plots were also obtained for EYL–11-*cis*-retinal systems.

The ^1H results show that the incorporations of *all-trans*- and 11-*cis*-retinal but not vitamin A disturb the integrity of the lipid bilayers and cause the formation of a channel through which the ion is allowed to permeate.

Discussion

The results of ^1H permeability studies parallel those of ^{13}C relaxation studies. The ^{13}C and ^1H NMR studies have shown a decrease in flexibility of the lipid acyl chain and a breakdown of membrane impermeableness to ion caused by the intercalation of *all-trans*- and 11-*cis*-retinal, whereas the effect of vitamin A on the fluidity of bilayers is small and its impermeableness to ion remains effective even in the presence of higher concentration of vitamin A. From the results reported here, it is clear that retinal and vitamin A are incorporated into EYL bilayers and they expand the bilayers slightly without significant disruption of overall vesicular structure. These incorporated molecules may be situated in the bilayer orienting its polyene chain nearly parallel to the lipid acyl chain. *All-trans*- and 11-*cis*-retinal molecules stay preferentially at the acyl chain region due to the hydrophobic interaction. On a molecular level, incorporations of *all-trans*- and 11-*cis*-retinal, which have inflexible polyene chain and bulky ionone ring, stiffen the flexible chain of lipid molecules surrounding the intercalated retinal molecules and disrupt the packing of the hydrocarbon region of phospholipid bilayers. In other words, the incorporated retinal molecules obstruct the formation of stable association of lipid acyl chains, which is considered to be responsible for the impermeableness of lipid membrane to ion.[41] The significant difference was not observed between the effects of incorporated *all-trans*- and 11-*cis*-retinal on the structure and stability of bilayers.

The position of vitamin A molecule, on the other hand, may be not restricted only at the hydrocarbon region, but it can interject further into the polar hydrophilic region of the EYL bilayers than does retinal, since the former has the hydroxyl group. Vitamin A seems to be alike cholesterol, in respect that the intercalation of the latter does not cause any appreciable change in ^{13}C spin-lattice relaxation time of EYL[42] and further the incorporation of the latter is known to decrease the permeability of phospholipid bilayers to Na^+, K^+, and Cl^-.[43] The cholesterol hydroxyl, which is on the bulky steroid ring, is found at the position of the ester carbonyl of phospholipid.[44] Vitamin A hydroxyl, which attaches to the nonbulky polyene chain, is expected to penetrate as far into the hydrophilic region or parallel, at least, that occupied by the hydroxyl of incorporated cholesterol. In this situation, the effect of incorporated vitamin A molecule on the structural integrity and dynamic nature of lipid bilayers is not expected to be large, because the lipid head group and acyl chain end region near the head have essentially high ordering and low mobility and vitamin A hydroxyl is not effective to disrupt the strong electrostatic interac-

tion between lecithin head groups.

Several studies[16,17] have indicated that vitamin A as well as retinal are effective in lysis of erythrocytes. These results are not necessarily to match well with whole of our results observed here, since the erythrocytes membrane contains not only phospholipid but also lipoproteins and glycolipids. In that case, vitamin A and retinal can affect the arrangement of lipid and/or protein molecules in the membrane. It is not clear whether retinal acts on the same site on the erythrocyte membrane as vitamin A.

The experimental results described above give some suggestions meaningful in physiology; the incorporated retinal resides inside of the lipid bilayer and causes the ionic permeability change of the membrane. Hence the released *all-trans*-retinal from the photobleached pigment is suggested to be able to effect an increase in the ionic permeability of the disk membrane. Namely, it is not unreasonable to assume that *all-trans*-retinal released from photobleached pigment affects the arrangement of lipid and plays significant or at least some role in the alteration of ionic permeability of disk membrane, and in this way it participates the transmission of photosignal to the neural system. Since the chromophore 11-*cis*-retinal in the unbleached visual pigment is fixed to and surrounded by an opsin through Schiff base linkage, its ability to increase in permeability of membrane may be less important in visual process.

It is known that the thermal stability of rhodopsin, the completion of the photolytic cycle, and the regeneration of rhodopsin from opsin and retinal require the presence of a lipid membrane.[44] The experimental fact that hydrophobic retinal molecule can stay stable in the lipid bilayer in aqueous dispersion supports the idea that the isomerization of *all-trans*-retinal to 11-*cis*-form and the regeneration of rhodopsin from opsin and retinal take place in the disk membrane.

The authors thank Dr. T. Komoto of Tokyo Institute of Technology for measuring the electron micrograph. The present work was partially supported by Grant-in-Aid for Special Project Research No. 510309 from the Ministry of Education, Science and Culture.

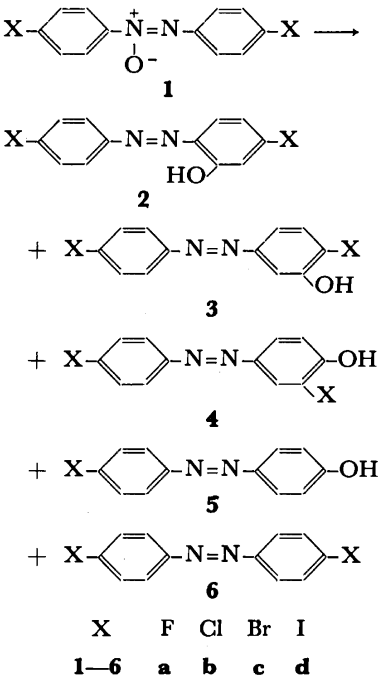
(Received June 27, 1981)

Treatment of 4,4′-dihaloazoxybenzenes with sulfuric acid afforded 4,4′-dihaloazobenzenes (**6**) as the major product and 5-halo-2-(*p*-halophenylazo)phenols, the Wallach rearrangement products as minor products, besides 2-halo-5-(*p*-halophenylazo)phenols, 2-halo-4-(*p*-halophenylazo)phenols, and 4-(*p*-halophenylazo)phenols as abnormal rearrangement products. The reaction of fluoro compound gave the azophenols (**3a** or **5a**) in the best yields. However, the ratio of **3a** to **5a** was found to vary with the concentration of sulfuric acid. Treatment of 4-haloazoxybenzenes with sulfuric acid gave 4-(*p*-halophenylazo)phenols and 4-haloazobenzenes (**13**) as major products together with 2-(*p*-halophenylazo)phenols and 5-halo-2-(phenylazo)phenols as minor products. Yields of reduction products **6** and **13** increased as the halosubstituent became heavier in the following sequence: F→Cl→Br→I.

In 1951, Gore and Hughes[1] reported that a treatment of 4,4′-dichloroazoxybenzene (**1b**) with concentrated sulfuric acid yielded 5-chloro-2-(*p*-chlorophenylazo)-phenol (**2b**) and 4,4′-dichloroazobenzene (**6b**). Recently, Cox and Buncel[2] reported briefly that a reaction of 4,4′-dihaloazoxybenzene (**1**) with concentrated sulfuric acid produced their corresponding 5-halo-2-(*p*-halophenylazo)phenols (**2**) together with a large amount of 4,4′-dihaloazobenzenes (**6**), except in the case of the iodo compound (**1d**).

Our recent study[3] on reactions of 4,4′-dialkylazoxybenzenes with sulfuric acid revealed that the major product was 2-alkyl-5-(*p*-alkylphenylazo)phenols and not 4,4′-dialkyl-2-hydroxyazobenzenes as early workers[1] had reported; formation of 4,4′-dialkylazobenzenes was observed as rather a minor reaction. Thus, it is anticipated that a detailed investigation of the Wallach rearrangement of various *p*-halo-substituted azoxybenzenes may provide vital information useful for understanding the nature of the Wallach hydroxyl migration as well as that of the deoxygenation which often predominates. This paper describes results of our reinvestigation and presents our new interpretation of reactions of **1** and 4-haloazoxybenzenes (**11**) with sulfuric acid.



Results and Discussion

Reaction of **1** with 92% sulfuric acid gave a mixture of azophenols and **6**. **6** was separated from azophenols by column chromatography on alumina. Azophenols were separated from one another by chromatography on a deactivated silica-gel column in most cases. Some unidentified resinous materials also were formed in the reaction. The results are shown in Table 1.

In all cases, the main reaction was the reduction of **1** to give **6**; especially, **1d** gave **6d** predominantly. **1d** was reported[2] to be reduced exclusively to **6d** on treatment with sulfuric acid. However, the rearrangement product **2d** also was found to be formed, though in a small amount.

In general, azoxy group is known[1,4] to be reduced partially to azo group in reaction of azoxybenzenes with

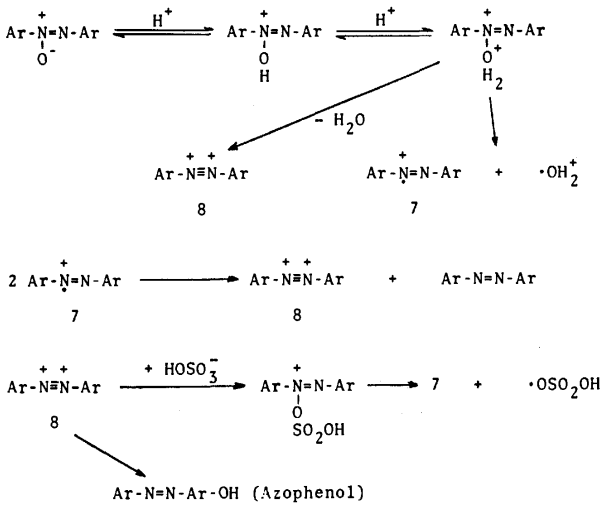


Scheme 1.

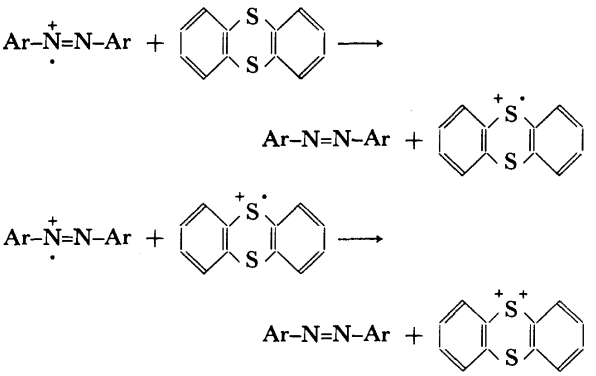
sulfuric acid. In order to understand the nature of the formation of azoarene, the reaction of azoxybenzene with 92% sulfuric acid was carried out with varying amounts of sulfuric acid used. The results are shown in Table 2. The yield of azobenzene depends clearly on the ratio of azoxybenzene to sulfuric acid. The extent of reduction decreases as the concentration of azoxybenzene decreases.

Earlier, we[5] noticed predominat reduction to azobenzene in a reaction of azoxybenzene with acetic anhydride around 190 °C, presuming the reduction to proceed *via* a radical cation species. In the present reaction, the reduction to azobenzene is presumed to proceed *via* radical cation **7** shown in Scheme 1. Diprotonation of the azoxy group followed by heterolysis of the N–O bond gives dicationic intermediate **8**, whereas homolytic fission of the N–O bond affords radical cation **7** similarly to an oxygen exchange[6] of diaryl sulfoxide in concentrated sulfuric acid. Disproportionation of **7** gives both an azo compound and dicationic intermediate **8**. This must be a bimolecular process in view of the observation that the amount of the reduction product, azobenzene, increases as the amount of sulfuric acid used decreases. One-electron reduction of **8** can also afford cation radical **7**.[7] There would be a possibility that **7** is partly reduced to give the azo compound by one-electron transfer. Of course, **8** can also formed by diprotonation and subsequent dehydration of the azoxy group.[2] The resulting $\cdot OH^+$ radical cation may be consumed in the oxidation of phenolic substance formed during the reaction to give a resinous material which would also be formed in the reduction of **7** or **8** with phenolic substance. Actually, the yield of reduced products increases under the conditions in which the yield of resinous material increases.[1]

Table 3. Reaction of 4,4′-dichloroazoxybenzene (**1b**) and thianthrene with sulfuric acid

	Yield/%	
	6b	Thianthrene *S*-oxide
1b	54	
1b+Thianthrene	70	56
Thianthrene		42

The amount of the reduction product from **1b** increased somewhat in the presence of thianthrene, a good electron transfer agent, as shown in Table 3. Since the cation radical is known to be formed when thianthrene is dissolved in concentrated sulfuric acid, eventually affording thianthrene *S*-oxide,[8] both thianthrene and its radical cation would be involved in the electron transfer to afford azoarene.



When an equimolar mixture of **1b** and 4-(phenylazo)-phenol was treated with 92% sulfuric acid, **1b** was reduced to **6b** nearly quantitatively, though with 65% of 4-(phenylazo)phenol recovered. Thus azophenol acts as a reducing agent. The azophenol would be oxidized by radical cations, such as H_2O^+ or **7**, and/or dication **8**, to form resinous material.

The amount of the reduction product, azoarene, seems to be related to the relative stability of the cation radical **7**. Within the same series in the periodic table, heavier atoms are known to stabilize the α-carbon radical to a higher extent.[9]

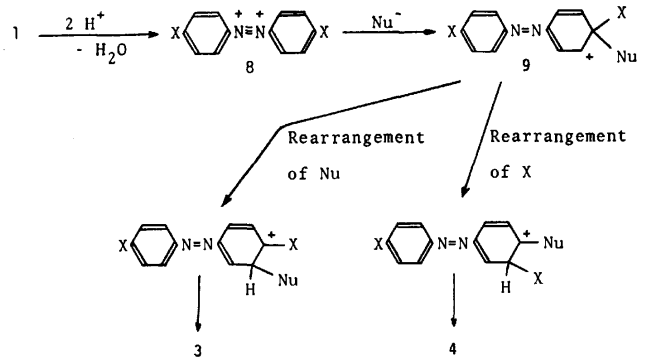
In the cases of **1b** and **1c**, *o*-hydroxy azo compounds, **2b** and **2c**, were obtained in substantial yields, in accordance with earlier reports.[1,3] However, **1c** gave a small amount of **4c** and **5c**, and **1b** yielded **3b**, **4b**, and **5b**. Although **3b** and **4b** were not separated from each other by column chromatography, they were partially separated by fractional crystallization described in the Experimental, while the ratio of **3b** to **4b** was determined by high-speed liquid chromatographic analysis.

The reaction of **1a** is peculiar. The yield of *o*-hydroxy azo compound, **2a**, the normal Wallach rearrangement product, was only 0.6%. Beside the reduction product, azophenol **5a** which is also a rearrangement product, was the second main product, accompanied with a comparable amount of **3a**.

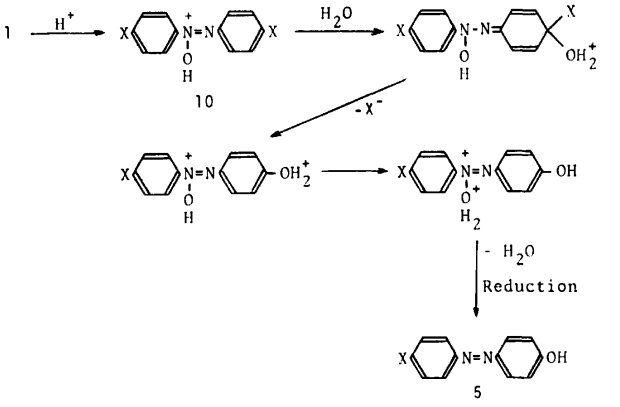
These reaction products, **2**, **4**, **5**, and **6**, were identified by comparison with authentic samples, respectively, while **3b** was acetylated, and the resulting acetate was identified by comparing physical properties with those of the authentic sample obtained independently. Attempts to obtain the authentic sample of **3a** were unsuccessful. The mass spectrum of **3a** showed *m/e* values: 234 (M^+), 139 ($C_6H_4FN_2O$), 123 ($C_6H_4FN_2$), and 111 (C_6H_4F). Chemical shift of the OH proton in $CDCl_3$ was δ 5.60 ppm. A characteristic NMR absorption signal of *o*-hydroxyazobenzene (hydrogen bonded OH, δ about 13 ppm) was not observed.

Further, mp and IR spectrum of this compound are different from those of **4a** obtained by diazo-coupling reaction. Consequently, this compound was ascribed to 2-fluoro-5-(*p*-fluorophenylazo)phenol (**3a**), by analogy with the reaction of **1b**.

Shemyakin *et al.*[10] and we[11] reported independently on the basis of ^{18}O-tracer experiment that the rearrangement leading to *o*-hydroxy azo compound, **2**, is intramolecular. However, the formation of azophenols, **3** and **4**, is considered to be effected by a rearrangement similar to that in the reaction of 4,4'-dialkylazoxybenzenes described previously.[3] Either halide or an other nucleophile, *e.g.*, hydroxysulfonyloxy group or water, is shifted to the adjacent carbon atom in the intermediate (**9**) formed by nucleophilic attack on the dicationic intermediate **8**,[2,3] eventually affording **3** or **4** as shown in Scheme 2. Apparently the shift of chloride is more facile than that of fluoride, while bromide is more readily shifted than hydroxysulfonyloxy or hydroxyl group.



Scheme 2.



Scheme 3.

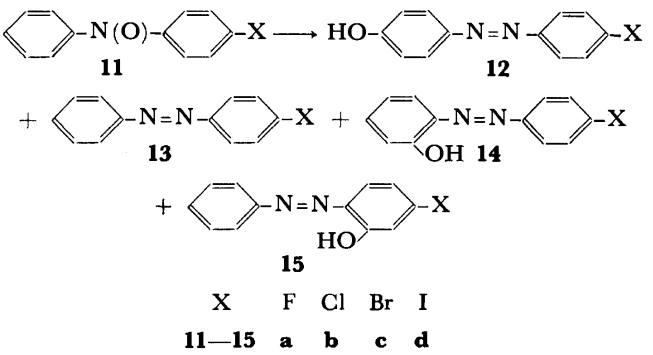
TABLE 4. REACTION OF 4,4'-DIFLUOROAZOXYBENZENE (**1a**) WITH SULFURIC ACID
(**1a**: 0.5 g, sulfuric acid: 25 cm³)

H_2SO_4 Concn %	Temp °C	Time h	Yield/% 2a	3a	5a	6a
92	25	4	0.4	8.8	18	42
92	50	0.5	0.6	7.4	25	40
92	80	1/6	0.9	6.8	27	38
85	80	1	0.6	0.6	58	15
98	25	1	1.2	30	3	43

Compound **5** may be formed by the aromatic nucleophilic substitution on the monoprotonated azoxybenzenes as shown in Scheme 3, *i.e.*, the replacement of halide by nucleophile in the intermediate (**10**). The mechanism of Wallach rearrangement appears to change with chang of concentration of sulfuric acid and structure of azoxy compound. At higher acid concentrations, the dicationic intermediate is generally considered to be formed; in some cases, at lower acid concentrations, a mechanism *via* a quinonoid intermediate formed from monoprotonated azoxybenzenes has been proposed.[2]

In the reaction of **1a**, the distribution of products changed markedly by change of reaction conditions, particularly of the concentration of sulfuric acid. Table 4 shows these results. When a concentrated sulfuric acid was used, **3a** was the main rearrangement product probably because fluoride, which is certainly not a good leaving group, is not a good nucleophile to compete in the migration. On the other hand, **5a** was formed as the major product when a dilute sulfuric acid (85%) was used.[23] The leaving of fluoride is obviously facilitated by the presence of water. In the cases of **1b** and **1c**, however, the acid concentration had little effect on the product distribution. The natures of neither chloride nor bromide ion is much changed by the small change in acid concentration.

4-Haloazoxybenzenes (**11**) were allowed to react with 92% sulfuric acid at 50 °C. The sample **11** was an equimolar mixture of α- and β-isomers. The distribution of products in the reaction of **11** with sulfuric acid are listed in Table 5.



Main products were corresponding 4-(*p*-halophenylazo)phenols (**12**) and 4-haloazobenzenes (**13**), while no

TABLE 5. REACTION OF 4-HALOAZOXYBNZENES (**11**) WITH SULFURIC ACID
(**11**: 0.5 g, 92% H_2SO_4: 25 cm³, temp: 50 °C, time: 30 min)

	X	Yield/% 12	13	14	15
	H	65	20	0.3	
11a	F	54	26	0.5	0.3
11b	Cl	34	46	1.4	0.2
11c	Br	27	55	1.7	0.3
11d	I	5	72	2.0	0.3

11cβ		27	52	2.0	0.1

abnormal rearrangement product, such as 2-halo-4-(phenylazo)phenol or 2-halo-5-(phenylazo)phenol, was obtained. The *p*-halosubstituent did not allow the ipso nucleophilic attack which was observed in the reaction of 4-alkylazoxybenzenes.[12]

Hahn and Jaffe[13] reported that treatment of 4-bromoazoxybenzenes (**11c**) with sulfuric acid gave only 4-(*p*-bromophenylazo)phenol (**12c**). However, under the same reaction conditions the rearrangement product **12c** was a minor product, the major product being the reduction product, *i.e.*, azo compound **13c**. The yield of reduction product **13** was found to increase in the following sequence for substituents: H→F→Cl→Br→I. The same trend was observed in the reactions of 4,4'-dihaloazoxybenzenes. Apparently the *p*-halo substituent facilitates the formation of radical cation intermediate **7** which is stabilized by resonance interaction with the *p*-halo substituent, especially with heavy halo substituents. The radical cation is considered to give eventually the azo compound **13**, as mentioned above.

When both α- and β-isomers of **11c** and their mixture were treated separetely with 92% sulfuric acid, the two isomers and the mixture gave practically the same products (**12c** and **13c**), except the *o*-hydroxy azo compounds (**14c** and **15c**). Interconversion between α- and β-isomers, **11c**α and **11c**β, was not observed by high-speed liquid chromatographic analysis of the unchanged azoxy compound recovered at about 25% conversion of the reaction, thus supporting the mechanism that *p*-hydroxy azo compound **12** is formed *via* the dicationic intermediate, $C_6H_5N^+{\equiv}N^+C_6H_4X(p)$. The ratio of the rates of **11c**α and **11c**β, $k\alpha/k\beta$, was determined as about 0.85 from the α/β ratio of the starting material and that of the azoxy compound recovered at 60% conversion. Duffey and Hendley[14] also reported through UV spectrographic experiments that the value of $k\alpha/k\beta$ was 0.9.

In all cases, *o*-hydroxy azo compounds, **14** and **15**, also were obtained in very low yields. The ortho rearrangement to a benzene ring having a *p*-halo substituent is more difficult than that to the other rings. However, the products obtained by UV irradiation of these samples **11** consisted of nearly equal amounts of **14** and **15**.

Experimental

No melting points were corrected. IR spectra were recorded on a JASCO-IRA-1 spectrophotometer. NMR spectra were obtained with a JEOL MH-100 spectrometer using TMS as the internal standard, and mass spectra with a JEOL-OlSG spectrometer. High-speed liquid chromatographic analyses were carried out with a JASCO-FLC 150 apparatus on a 0.5 m×2.1 mm column packed with JASCODAC SV-02 (the solvent was methanol–water).

4,4'-Dihaloazobenzenes, **6a** and **6d**, were obtained from their corresponding *p*-haloanilines by oxidation with active manganese dioxide.[24] **6b** and **6c** were prepared by air oxidation of their corresponding hydrazo compounds which had been obtained by reduction of *p*-nitrohalobenzenes with zinc powder and sodium hydroxide.[24] 4-Haloazobenzenes, **13**, were prepared by condensation of nitrosobenzene with *p*-haloanilines.[24]

4,4'-Dihaloazoxybenzenes, **1a** and **1d**, and 4-haloazoxybenzenes, **11**, were prepared by oxidation of their corresponding azoarene with hydrogen peroxide.[15] Compounds **1b** and **1c** were obtained by reduction of *p*-halonitrobenzenes with D-glucose.[16] Isomeric *p*-bromoazoxybenzenes, **11c**α and **11c**β, were prepared by the well known method described in the literature.[17,18]

Reaction of 4,4'-Dihaloazoxybenzenes (1) with Sulfuric Acid. A mixture of **1** (0.5 g) and 92% sulfuric acid (25 cm^3) was heated at 50 °C for 30 min. The reaction mixture was poured into cold water and then extracted with benzene. After removal of the solvent, the residue was chromatographed on an alumina column using benzene as the eluent. The eluate gave **6** which was recrystallized from benzene or toluene.

Azophenols remaining at the top of column were extracted with ethanol–water. The extract was chromatographed on a silica gel column using benzene as the solvent.

The first fraction gave **2** which was recrystallized from hexane or benzene.

The second fraction gave **3** and/or **4**. Compound **3a** was recrystallized from hexane, mp 119—121 °C. Found: C, 61.34; H, 3.40; N, 11.83%. Calcd for $C_{12}H_8F_2N_2O$: C, 61.53; H, 3.45; N, 11.96%. IR (KBr): 3480, 1595, 1459, 1280, and 1230 cm^{-1}. In the reaction of **1b**, this fraction gave a mixture of **3b** and **4b**. High-speed liquid chromatographic analysis of the mixture showed that the ratio of **3b** to **4b** was 3 : 2. The mixture was recrystallized from benzene to yield **3b**. The mother liqour was evaporated and the resulting crystalline mass was dissolved in methanol. When the methanol solution was allowed to stand for a long time open in air, two kinds of crystals were formed. The crystals were extracted with boiling hexane for a short time and then the hexane solution was quickly separated by decantation. After removal of the solvent, the residue was recrystallized from hexane–benzene to give **4b**. Compound **3b**: mp 197—198 °C. Found: C, 54.23; H, 2.87; N, 10.52%. Calcd for $C_{12}H_8Cl_2N_2O$: C, 53.96; H, 3.02; N, 10.49%. IR (KBr): 3480, 1580, 1490, and 1410 cm^{-1}. In the case of **1c**, **4c** was obtained.

The third fraction gave **5** which was recrystallized from hexane or toluene.

Compounds **3a** and **3b** were acetylated with acetic anhydride and pyridine. Acetate of **3a**: mp 65—66 °C. Found: C, 60.71; H, 3.38; N, 10.14%. Calcd for $C_{14}H_{10}F_2N_2O_2$: C, 60.87; H, 3.65; N, 10.14%. IR (KBr): 1780 and 1495 cm^{-1}. Acetate of **3b**: mp 116.5—118 °C. The mp and IR spectra of **3b** acetate were identical with those of an authentic sample.

Reaction of 1b and Thianthrene with Sulfuric Acid. A solution of **1b** (0.267 g) and thianthrene (0.216 g) in 98% sulfuric acid (50 cm^3) was stirred at 27 °C for 3 h. The reaction mixture was poured into cold water, and then extracted with benzene. The extract was chromatographed on an alimina column using benzene as the solvent. The eluate geve a mixture of **6b** and thianthrene. **6b** was separated from thianthrene by recrystallization from acetone. The residue on the column was eluted with a mixture of ethanol, benzene, and water, and then the eluate chromatographed on a silica-gel column using benzene as the solvent. The first fraction gave **2b** in 2% yield. Treatment of the second fraction with dilute sodium hydroxide solution gave thianthrene *S*-oxide. Acidification of the mother liquor yielded a mixture of **3b** and **4b** (1%).

Reaction of 4-Haloazoxybenzene (11) with Sulfuric Acid. Compound **11** (0.5 g) was treated with 92% sulfuric acid

(25 cm^3) at 50 °C for 30 min. The reaction mixture was poured into excess cold water and then extracted with benzene. When the extract was chromatographed on an alumina column using benzene as the eluent, 4-haloazobenzene **13** was eluted out. The residue on the column was then eluted with a mixture of ethanol, benzene, and water, to give azophenols. The mixture of azophenols was chromatographed on silica gel. The first fraction was a mixture of **14** and **15** as analyzed by GLPC, while the second fraction was **12**.

In the case of **11c**, when the reaction was stopped in a few min, the unchanged azoxy compound was eluted out together with **13c** by the chromatography on alumina of the reaction mixture, and then the eluent was separated by chromatography on alumina using hexane–benzene as the solvent. The azoxy compound was analyzed by high-speed liquid chromatography.

Preparation of the Authentic Samples. 5-Halo-2-(*p*-halophenylazo)phenols (**2**) were prepared by irradiation of an ethanolic solution of **1**.[25] **2a**: mp 126—126.5 °C. Found: C, 61.40; H, 3.20; N, 11.79%. Calcd for $C_{12}H_8F_2N_2O$: C, 61.53; H, 3,45; N, 11.96%. IR (KBr): 1595 and 1495 cm^{-1}. **2b**: mp 178—180 °C. (lit,[19] 176.5 °C). **2c**: mp 182—184 °C. (lit,[19] 181.5 °C). **2d**: mp 213—215 °C. Found: C, 32.18; H, 1.60; N, 6.22%. Calcd for $C_{12}H_8I_2N_2O$: C, 32.02; H, 1.79; N, 6.23%. IR (KBr): 1590, 1460, and 1395 cm^{-1}.

2-Halo-4-(*p*-halophenylazo)phenols (**4a—4c**) and 4-(*p*-halophenylazo)phenols (**5**) were obtained by diazo-coupling of the corresponding phenols and diazonium salts.[24] **4a**: mp 153—155 °C. Found: C, 61.43; H, 3.23; N, 11.89%. Calcd for $C_{12}H_8F_2N_2O$: C, 61.53; H, 3.45; N, 11.96%. IR (KBr): 3480 and 1495 cm^{-1}. **4b**: mp 141—142 °C. Found: C, 53.77; H, 3.24; N, 10.72%. Calcd for $C_{12}H_8Cl_2N_2O$: C, 53.96; H, 3.02; N, 10.49%. IR (KBr): 3480 and 1480 cm^{-1}. **4c**: mp 158—159.5 °C. Found: C, 40.66; H, 2.26; N, 8.05%. Calcd for $C_{12}H_8Br_2N_2O$: C, 40.48; H, 2.27; N, 7.87%. IR (KBr): 3480, 1485, and 1475 cm^{-1}. **5a**: mp 157—159 °C. Found: C, 66.55; H, 4.17; N, 12.85%. Calcd for $C_{12}H_9FN_2O$: C, 66.66; H, 4.20; N, 12.96%. IR (KBr): 1585 and 1495 cm^{-1}. **5b**: mp 158—160 °C (lit,[20] 154 °C). **5c**: mp 161—163 °C (lit,[21] 162 °C). **5d**: mp 174—176 °C (lit,[22] 172 °C).

3-Acetoxy-4,4'-dichloroazobenzene (3b Acetate): 2-Chloro-5-nitrophenol was acetylated with acetic anhydride and pyridine. Recrystallization from hexane–benzene gave 2-chloro-5-nitrophenyl acetate, mp 78—79 °C. Found: C, 44.82; H, 2.55; N, 6.58%. Calcd for $C_8H_6ClNO_4$: C, 44.56; H, 2.78; N, 6.49%. IR (KBr): 1760, 1525, and 1350 cm^{-1}.

The acetate was reduced by catalytic hydrogenation to yield 3-acetoxy-4-chloroaniline which was recrystallized from hexane–benzene, mp 98—99 °C.

A solution of the amine (0.32 g) and *p*-chloronitrosobenzene (0.24 g) in acetic acid was allowed to stand for 24 h at room temperature. The reaction mixture was poured into cold water. The precipitate was filtered off and purified by chromatography on silica gel, and then recrystallized from hexane (yield 42%), mp 117—118.5 °C. Found: C, 54.25; H, 3.09; N, 9.14%. Calcd for $C_{14}H_{10}Cl_2N_2O_2$: C, 54.39; H, 3.26; N, 9.06%. IR (KBr): 1780 and 1480 cm^{-1}.

Acetate of **3c** was obtained by a similar method, mp 139—141 °C. Found: C, 42.05; H, 2.37; N, 7.27%. Calcd for $C_{14}H_{10}Br_2N_2O_2$: C, 42.24; H, 2.54; N, 7.04%. IR (KBr): 1770 cm^{-1}. The acetate was hydrolyzed by the chromatography on alumina to yield **3c**, mp 212—212.5 °C. Found: C, 40.66; H, 2.32; N, 7.92%. Calcd for $C_{12}H_8Br_2N_2O$: C, 40.48; H, 2.27; N, 7.87%. IR (KBr): 3480 and 1480 cm^{-1}.

Products and Kinetic Substituent Effects in the Reactions of Diaryldiazomethanes with 2,5-Dichloro-*p*-benzoquinone

Takumi OSHIMA and Toshikazu NAGAI*

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received May 28, 1981)

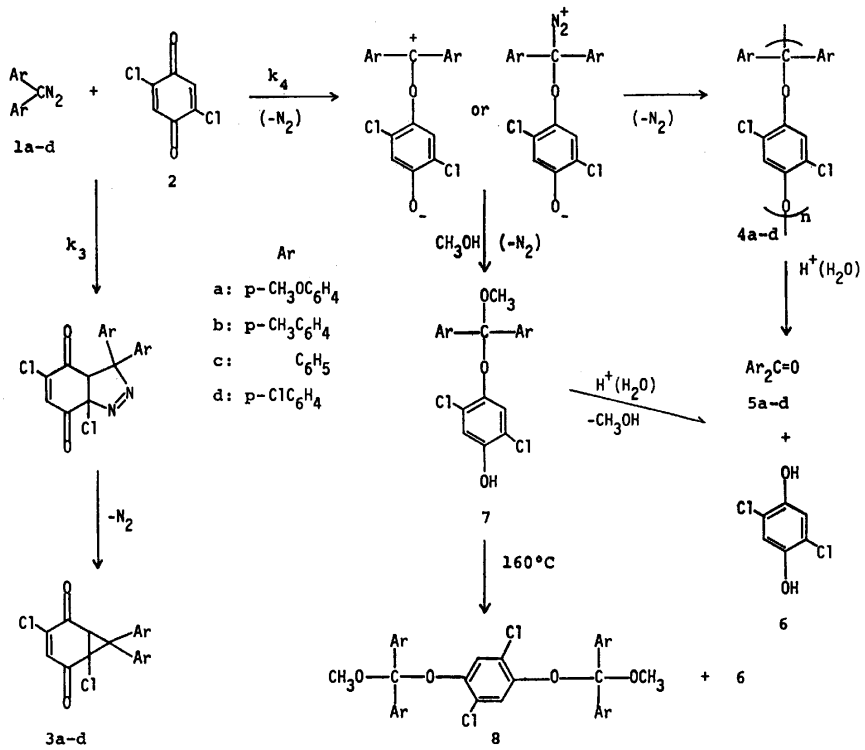
Substituted diphenyldiazomethanes[$(x\text{-}C_6H_4)_2CN_2$; x=*p*-OCH_3, *p*-CH_3, H, *p*-Cl] were found to react with 2,5-dichloro-*p*-benzoquinone at its conjugated C=C and C=O bonds to give bicyclic diones and poly(2,5-dichlorohydroquinone benzhydryl ether)s respectively, obeying the second-order kinetic law. The product ratios of the polyethers to the bicyclic diones increased from 1.1 to 8.1 with the electron-donating ability of the substituents. The individual rate constants were well correlated with the Hammett equation: $\log k_3 = -2.15 - 1.55\,\sigma$ ($r=0.996$) and $\log k_4 = -2.03 - 1.85\,(\sigma^0 + 0.515\Delta\bar{\sigma}_R^+)$ ($r=1.00$) for the bicyclic diones and polyethers processes respectively. The presence of methanol as a trapping agent stopped the polymerization completely and afforded the methanolysis product, though no essential change was found in the formation of the bicyclic dione.

In the reaction of diazomethane or diazoethane with 2,5-dichloro-*p*-benzoquinone (**2**), Eistert *et al.*[1] obtained pyrazoline derivatives formed *via* 2+3 cycloaddition toward the C=C bonds of the quinone. In contrast to **2**, tetrasubstituted quinones, such as chloranil and 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ), are known to react with diazomethane at the C=O bonds, giving oxirane derivatives.[2,3] Recently, we showed that these quinones also react at the C=O bonds with aryl- and diaryldiazomethanes to give stilbenes and spirooxetanes[4] and poly(hydroquinone benzhydryl ether)s[5,6] respectively. Thus, **2** differs from chloranil or DDQ in its reaction pattern toward the diazoalkanes. However, no reactions of **2** with diaryldiazomethanes have hitherto been known. Therefore, we have carried out the reactions of diaryldiazomethanes with **2** in order to obtain further insight into the factors governing the reaction mode and also in order to compare the results with those of chloranil and DDQ reactions.

We found that **2** reacts with diaryldiazomethanes at both the C=C and C=O bonds, yielding bicyclic diones and poly(2,5-dichlorohydroquinone benzhydryl ether)s. Kinetic substituent effects in these two reaction courses were also discussed.

Results and Discussion

Product Analysis. The reactions of disubstituted diaryldiazomethanes (**1a—d**) with an equimolar amount of 2,5-dichloro-*p*-benzoquinone (**2**) were carried out in 1,2-dichloroethane at 30 °C. The **1a** with the *p,p'*-OCH_3 substituents violently decomposed, with an evolution of N_2 and the immediate deposition of white precipitates, while the **1d** with the *p,p'*-Cl substituents needed *ca.* 10 h for the complete disappearance of the diazo color. All these reactions gave considerable amounts of white precipitates. The filtrate was evaporated to dryness, followed by column chromatography



Scheme 1.

on silica gel to give bicyclic diones (**3a**—**d**) (Scheme 1). The ^{1}H NMR spectra showed the vinylic proton at the lower fields (δ, 6.60—6.65) and the cyclopropyl proton at the higher fields (3.58—3.67), in accordance with the bicyclic structure. The precipitate isolated in the reaction of **1a** was gradually hydrolyzed into almost equimolar amounts of *p,p'*-dimethoxybenzophenone (**5a**) and 2,5-dichlorohydroquinone (**6**) during the work-up. However, the precipitates for **1b**—**d** were so stable that the complete hydrolyses needed refluxing for 8—20 h in aqueous methanol containing hydrochloric acid. These hydrolyses gave almost equimolar amounts of benzophenones (**5b**—**d**) and **6**. Next, we examined the effect of methanol as an additive on the reaction features employing **1c**. No essential change was found in the yield of **3c**, but a different product, 2,5-dichloro-4-[(methoxy)diphenylmethoxy]phenol (**7**), was provided instead of the precipitate. The **7** was easily hydrolyzed into **5c** and **6** under the influence of hydrochloric acid, whereas a short-time heating slightly over its melting point (151 °C) smoothly brought about the disproportionation to yield 2,5-dichloro-1,4-bis[(methoxy)-diphenylmethoxy]benzene (**8**) and **6**.

It can be suggested that the bicyclic diones (**3a**—**d**) may be produced *via* 1,3-dipolar cycloaddition, followed by the rapid elimination of N_2 from the resulting pyrazolines, considering that methanol does not participate as an additive. With regard to the structure of white precipitates, poly(2,5-dichlorohydroquinone benzhydryl ether)s (**4a**—**d**) are conceivable from the observations that the IR spectra of the stable precipitates for the **1b**—**d** showed no carbonyl, but strong absorptions assignable to the ethereal bonds, and also that the hydrolyses gave equimolecular amounts of benzophenones and **6**. In analogy with the reactions with chloranil[5] and DDQ,[6] the formation of polyethers prompted us to suggest the operation of the same mechanism in these polymerization reactions (Scheme 1). We had previously proposed the diazonium or carbonium betaine as the intermediate in chloranil and DDQ systems.[5,6] In fact, the presence of methanol as a trapping agent stopped the polymerization completely and afforded the methanolysis product, **7**, instead of the polyether, though the 2+3 cycloaddition process leading to **3c** was little affected.

The results are summarized in Table 1. The product ratios of **4** to **3** increased in the order of **1a**>**1b**>**1c**>**1d**, with the electron-donating ability of the substituents.

Table 2. Observed second-order rate constants, k_{obsd}, and the individual rate constants, k_3 and k_4, for the process giving **3** and **4** in the reactions of **1a**—**d** with **2** in CH_2ClCH_2Cl at 30°C

Compound	$10^3 k_{obsd}$ / l mol^{-1} s^{-1}	$10^3 k_3$[a] / l mol^{-1} s^{-1}	$10^3 k_4$[a] / l mol^{-1} s^{-1}
1a	463	51.0	412
1b	81.9	24.1	57.8
1c	14.9	5.81	9.09
1d	3.24	1.54	1.70

a) The values determined by multiplying k_{obsd} by the relative yields of **3** and **4**.

A comparison of the present results with those observed in the reaction with diazomethane[1] and in the diaryldiazomethanes–chloranil[5] and –DDQ systems[6] is of some interest from the mechanistic point of view. The **2** is known to react at the C=C bonds with two moles of diazomethane to produce the pyrazoline derivative,[1] while the C=O bonds of **2** are unreactive toward diazomethane. On the other hand, the diaryldiazomethanes can react at both the C=O and the C=C bonds of **2**. In contrast to the case of **2**, the 2+3 cycloaddition process is not anticipated in the reactions of diaryldiazomethanes with chloranil[5] and DDQ,[6] where the C=O bonds selectively participate in the reactions. The lack of such bicyclic diones in the chloranil and DDQ reactions is certainly attributable to the larger steric hindrance due to the bulky Cl and/or CN substituents on either side of the C=C bonds, by which the approach of diaryldiazomethanes (even diazomethane and aryldiazomethane) to the double bonds is inhibited.

It is also noticed that the polyethers derived from **2** are more stable against solvolyses than those derived from chloranil or DDQ. In addition, the presence of methanol in the chloranil or DDQ reaction inhibited the formation of polyether, as in the present case, but the initially resulting methanolysis products like **7** further underwent a nucleophilic attack by methanol to be converted into α,α-dimethoxydiphenylmethane and the respective hydroquinones.[5,6] These chemical observations are probably the result of the stronger electron-acceptor ability of chloranil and DDQ moieties than that of **2**;[7] hence, the ethereal C–O linkage for the chloranil or DDQ reaction is much more subject to hydrolysis and methanolysis than those for the **2** reaction.

Kinetic Study. Substituent Effects: The 1,2-dichloroethane solutions of **1a**—**d** used for kinetic purposes were diluted by a factor of about 10 compared to those for the product study. Thus, the decompositions of **1a**—**d** at 30 °C could be followed spectrophotometrically over 60—70% reactions without the disturbance due to the suspension of polyethers (**4a**—**d**). The observed second-order rate constants increased with the electron-donating ability of the *p*-substituents (Table 2). From the results in Tables 1 and 2, one can easily obtain the

Table 1. Product distributions in the equimolar (5.67 mmol) reactions of diaryldiazomethanes (**1a**—**d**) and 2,5-dichloro-*p*-benzoquinone (**2**) in CH_2ClCH_2Cl at 30 °C

Compound	Additive	Reaction time / h	Yield/%[a] **3**	**4**	**7**
1a	—	1	10.5	85.1[c]	—
1b	—	1	28.0	67.3[c]	—
1c	—	2	38.1	59.7[c]	—
1c	CH_3OH[b]	2	37.6	—	58.6
1d	—	6	46.3	51.2[c]	—

a) Yield as mole percentage based on **1**. b) A five-fold molar excess was added with respect to **1c**. c) Based on the benzophenones (**5a**—**d**) obtained by the hydrolyses of **4a**—**d**.

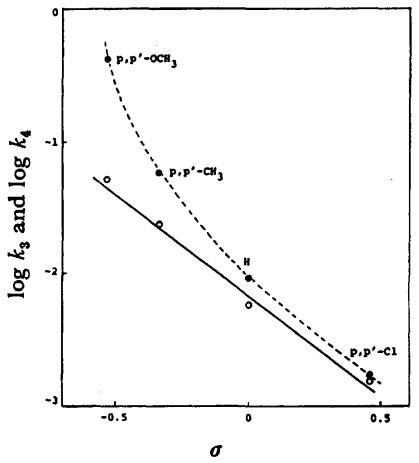


Fig. 1. The plots of log k_3 (○) and log k_4 (●) against the Hammett σ constants.

individual rate constants leading to the formations of **3a—d** and **4a—d** by multiplying the observed rate constants by the relative product ratios. The rate constants, k_3 and k_4, thus determined may also be seen in Table 2.

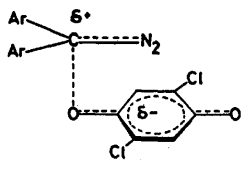
The dependence of the logarithmic rate constants on the Hammett σ constants[8] is shown in Fig. 1. As may easily be noticed, **3a—d** formation gave an excellent linear dependence (Eq. 1), where r, s, and n are the correlation coefficient, the standard deviation, and the data points respectively:

$$\log k_3 = -2.51 - 1.55\sigma \quad (r = 0.996,\ s = 0.0735,\ n = 4). \qquad (1)$$

However, the correlation line for the **4a—d** process displayed an upward deviation, especially in the OCH_3 substituent. The replacement of σ by the Brown σ^+ constants[9] was also unsuccessful, causing a downward deviation. Neither the σ nor σ^+ values apparently fit the correlation of the logarithmic rate constants for the **4a—d** process well. Therefore, we attempted the two-parameter Yukawa-Tsuno equation,[10] $\log k = \rho(\sigma^0 + R\Delta\bar{\sigma}_R^+)$, where σ^0, R, and $\Delta\bar{\sigma}_R^+$ are the normal substituent constants, the resonance reaction constant, and the resonance substituent constant respectively. The result of regression analysis indicates that the use of the two-parameter equation improves the correlation significantly (Eq. 2):

$$\log k_4 = -2.03 - 1.85\,(\sigma^0 + 0.515\,\Delta\bar{\sigma}_R^+) \quad (r = 1.00,\ s = 0.0105,\ n = 4). \qquad (2)$$

A comparison of the ρ values in Eqs. 1 and 2 shows a larger susceptibility of the rate of the **4a—d** process on the substituents than that of the **3a—d** process. Also, the value of R=0.515 confirms that a substantial



I

π-resonance stabilization of a transition state operate in the **4a—d** process. By analogy to the mechanism of the reactions of diaryldiazomethanes with chloranil and DDQ, a similar transition state such as I is likely to account for the electronic demand. On the contrary, the process leading to **3a—d** may be through the 1,3-dipolar addition mechanism, since the rate constants were well correlated with the simple Hammett equation using normal σ values† in accordance with the product analysis, where no essential change was found in the yield of the bicyclic dione, as has been mentioned above.

Experimental

The IR, NMR, and UV spectra were recorded on a Hitachi 215, a Varian EM-360, and a JASCO UVIDEC 505 spectrophotometer respectively.

Materials. The 2,5-dichloro-*p*-benzoquinone (**2**) was prepared according to the procedure described by A. R. Ling[12] and was recrystallized from ethanol; pale yellow prisms, mp 164—166 °C (lit, 161 °C).[12] The diaryldiazomethane were made by the oxidation of the corresponding hydrazones with yellow mercury(II) oxide, as has been described.[5] The physical properties of these diazoalkanes were listed in previous papers.[5,13] The 1,2-dichloroethane was dried over phosphorus pentaoxide and fractionated.

Kinetic Measurements. The values of k were determined spectrophotometrically by monitoring the decrease in the absorption of **1a—d** at the maximum wavelength (524—540 nm) in the visible region. The mean deviations were ±3% (usually two determinations). The temperature was kept at 30 °C (±0.1 °C) by means of a Haake circulator.

Reactions of Diaryldiazomethanes (1a—d) with 2 in CH_2ClCH_2Cl. The reaction of **1c** is described below as a typical example; the reactions of the other diazoalkanes were carried out similarly till the diazo color completely disappeared . To a stirred 1,2-dichloroethane solution (30 ml) of **2** (1.0 g, 5.65 mmol) was added, drop by drop, a 1,2-dichloroethane solution (10 ml) containing **1c** (1.1 g, 5.67 mmol) at 30 °C. A vigorous evolution of N_2 was observed except for the case of **1d**. After the mixture had been stirred for 2 h (1 h for **1a** and 6 h for **1d**), the white precipitate which appeared was filtered, washed with a small portion of 1,2-dichloroethane, and submitted to IR measurement. The precipitate in the case of **1a** was easily hydrolyzed into *p,p'*-dimethoxybenzophenone (**5a**) and **6** on the work-up. On the other hand, the precipitates in the cases of **1b—d** were stable enough to be hydrolyzed only in refluxing aqueous methanol containing hydrochloric acid for 8—20 h; they thus gave the corresponding benzophenones (**5b—d**) and **6**. The column chromatography (silica gel) of the hydrolyzed products gave an almost equimolar amount of **5a—d** (benzene as an eluent) and **6** (benzene–ether). These compounds were identified by a comparison of their IR spectra with those of authentic samples.[5,12] On the other hand, the filtrate parts were dried *in vacuo*, and the residues were chromatographed on silica gel. Elution with benzene gave pure bicyclic diones (**3a—d**). The structures of **3a—d** were identified by means of the IR, the NMR, and the elemental analyses.

† The rate enhancement by the electron-donating substituents can be explained in terms of the increase in the HO-(dipole)-LU (dipolarophile) interaction in the concerted 1,3-dipolar addition by a raising of the HO energy.[11]

1, 4-Dichloro-7, 7-bis(p-methoxyphenyl)bicyclo[4. 1. 0]hept-3-ene-2,5-dione (3a). Pale yellow prisms (petroleum ether–benzene); mp 148—150 °C. IR (KBr): 3055, 1693, 1509, 1243 cm^{-1}. NMR (δ, $CDCl_3$): 3.62 (1H, s, cyclopropyl H), 3.73 (3H, s, OCH_3), 3.77 (3H, s, OCH_3), 6.56 (1H, s, vinyl H), 6.8—7.5 (8H, m, aromatic H). MS: *m/e* 402 (M^+). Found: C, 62.64; H, 4.05%. Calcd for $C_{21}H_{16}Cl_2O_4$: C, 62.54; H, 4.00%.

1,4-Dichloro-7,7-di-p-tolylbicyclo[4.1.0]hept-3-ene-2,5-dione(3b). Pale yellow prisms (ether); mp 151—153 °C. IR (KBr): 3053, 1684, 1588, 1512, 1291. 1063, 995, 820 cm^{-1}. NMR (δ, $CDCl_3$): 2.27 (3H, s, CH_3), 2.30 (3H, s, CH_3), 3.62 (1H, s, cyclopropyl H), 6.60 (1H, s, vinyl H), 7.03 (4H, s, aromatic H), 7.1—7.5 (4H, m, aromatic H). MS: *m/e* 370 (M^+). Found: C, 68.16; H, 4.41%. Calcd for $C_{21}H_{16}Cl_2O_2$: C, 67.94; H, 4.34%.

1,4-Dichloro-7,7-diphenylbicyclo[4.1.0]hept-3-ene-2,5-dione(3c). Pale yellow prisms (petroleum ether–benzene); mp 179—180 °C. IR (KBr): 3052, 1703, 1689, 1597, 1295, 1062, 996, 709 cm^{-1}. NMR (δ, $CDCl_3$): 3.67 (1H, s, cyclopropyl H), 6.61 (1H, s, vinyl H), 7.0—7.6 (10H, m, aromatic H). MS: *m/e* 342 (M^+). Found: C, 66.71; H, 3.59%. Calcd for $C_{19}H_{12}Cl_2O_2$: C, 66.49; H, 3.53%.

1,4-Dichloro-7,7-bis(p-chlorophenyl)bicyclo[4.1.0]hept-3-ene-2,5-dione (3d). Pale yellow prisms (benzene); mp 209—210 °C. IR (KBr): 3051, 1701, 1677, 1584, 1485, 1087, 995, 833 cm^{-1}. NMR (δ, $CDCl_3$): 3.58 (1H, s, cyclopropyl H), 6.63 (1H, s, vinyl H), 7.1—7.3 (8H, m, aromatic H). MS: *m/e* 410 (M^+). Found: C, 55.58; H, 2.48%. Calcd for $C_{19}H_{10}Cl_4O_2$: C, 55.37; H, 2.45%.

Reaction of 1c with 2 in CH_3OH–CH_2ClCH_2Cl. To a stirred 1,2-dichloroethane solution (30 ml) of **2** (1.0 g, 5.65 mmol) was added, drop by drop, a 1,2-dichloroethane solution (10 ml) containing **1c** (1.10 g, 5.67 mmol) and a 5-fold molar excess of methanol (0.9 g) at 30 °C. In contrast to the reactions in the absence of methanol, no precipitate was found. After having been stirred for 2 h, the solvent was evaporated and the trituration of the resinous products with 3×30 ml pentane left **3c** (0.72 g, 37%). The combined pentane solution was concentrated to afford 2,5-dichloro-4-[(methoxy)diphenylmethoxy]phenol (**7**); mp 151 °C (dec) IR (KBr): 3520, 1476, 1203, 1002 cm^{-1}, NMR (δ, $CDCl_3$): 3.30 (3H, s, OCH_3), 5.17 (1H, s, OH), 7.0—7.8 (12H, m, aromatic H), MS: *m/e* 343 ($M^+ - OCH_3$), Found: C, 64.03; H, 4.13%. Calcd for $C_{20}H_{16}Cl_2O_3$: C, 64.02; H, 4.26%. The **7** was easily hydrolyzed into benzophenone and **6** under the influence of aqueous methanol saturated with hydrochloric acid. When heated at 160 °C for 2 min, however, the **7** underwent a disproportionation into 2,5-dichloro-1,4-bis[(methoxy)diphenylmethoxy]benzene (**8**) and **6**. The **8** had a mp of 269—271 °C (from benzene); IR (KBr): 1477, 1211, 1091, 991, 697 cm^{-1}, NMR (δ, $CDCl_3$): 3.20 (6H, s, OCH_3), 7.0—7.7 (22H, m, aromatic H), MS: *m/e* 539 ($M^+ - OCH_3$), Found: C, 71.55; H, 4.97; Cl, 12.60%. Calcd for $C_{34}H_{28}Cl_2O_4$: C, 71.45; H, 4.94; Cl, 12.40%.

Kinetic Solvent Effects in the Decomposition of Diphenyldiazomethane with Chloranil and 2,5-Dichloro-*p*-benzoquinone

Takumi OSHIMA and Toshikazu NAGAI*

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received July 21, 1981)

A kinetic study was made of the reactions of diphenyldiazomethane (DDM) with chloranil and 2,5-dichloro-*p*-benzoquinone (DCQ) at 30 °C in 20 and 22 aprotic solvents respectively (19 solvents are common). The chloranil reaction gave poly(tetrachlorohydroquinone benzhydryl ether) alone, obeying the second-order kinetic law. On the other hand, the DCQ reaction afforded bicyclic dione and poly(2,5-dichlorohydroquinone benzhydryl ether), also obeying the second-order kinetic law. All these rate constants generally increased with the solvent polarity and decreased with the solvent basicity. The kinetic solvent effects can be interpreted in terms of the effects of the polarity and the basicity of the solvents respectively to the transition and to the initial states. Thus, the multiple linear correlations of the logarithmic rate constants with a suitable function of the polarity and the basicity of the solvents are fairly successful. It was found that the basicity is more pronounced in the chloranil reaction than in the DCQ reaction, whereas the reverse can be said for the solvent polarity. These results were compared to those of the reactions of DDM with 2,3-dichloro-5,6-dicyanobenzoquinone and tetracyanoethylene.

In our previous paper,[1] we proposed an empirical basicity parameter, D_π, based on the kinetic solvent effects on the reaction of diphenyldiazomethane (DDM) with tetracyanoethylene (TCNE) as a typical π-acceptor. The D_π was found to be preferable to the conventional solvent basicity parameters, such as Kagiya's $\Delta\nu_D$[2] Kamlet-Taft's β scale,[3] and Gutmann's DN (donor number),[4] to describe the solvent effects in the kinetics of the various reactions involving π-acceptor soft acids. For example, the correlation of log k with D_π for the 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ)–DDM reaction over a wide range of aprotic solvents was highly successful (r=0.977).[1] We have now extended the work to the chloranil– and 2,5-dichloro-*p*-benzoquinone (DCQ)–DDM reactions in order to examine further the application of D_π in the interpretation of the kinetic solvent effects. In this paper, we also discuss the results in comparison with those for the DDM–TCNE and DDM–DDQ systems.

Results and Discussion

The Dependence of the Rate Constants on the Properties of the Aprotic Solvents in the Reactions of Diphenyldiazomethane with Chloranil. The chloranil–DDM reaction is found to afford poly(tetrachlorohydroquinone benzhydryl ether) by way of a diazonium or carbonium betaine intermediate, **1** or **1'** (Scheme 1).[5] The second-order rate constants over a wide range of aprotic solvents are shown in Table 1, together with the D_π[1] and the solvent polarity parameters, the Kirkwood function of the dielectric constants ε, $f(\varepsilon)=(\varepsilon-1)/(2\varepsilon+1)$,[6] and Dimroth and Reichardt's E_T values.[7] An inspection of the results shows that the rates did not correlate well only with the usual solvent basicity or polarity parameter. Dipolar solvents, *e.g.*, nitro compounds and nitriles, tended to increase the rates, while the basic aromatic hydrocarbons and cyclic ethers decrease them. A preliminary correlation of log k with the conventional basicity parameters, such as $\Delta\nu_D$, the β scale, and DN, yielded worse results because of the marked deviation of the aromatic hydrocarbons: log k= $-0.0048\Delta\nu_D-1.97$ (correlation coefficient(r)=0.35, data points (n)=18), log $k=-0.198\beta-2.23$ (r=0.10, n=11), and log $k=-0.028DN-1.76$ (r=0.45, n=11). However, a plot of log k against D_π values showed a better correlation, suggesting the stabilization of the initial state as a result of the basic solvation of the chloranil molecule; log $k=-0.536D_\pi-2.23$ (r=0.826, n=20) (Fig. 1). The six nonpolar aromatic hydrocarbons and derivatives (Solv. Nos. 9, 10, 11, 18, 21, and 23) were well correlated (slope=−0.600, r=0.998), but the dipolar solvents displayed an inverted U-shaped deviation. The apparent acceleration by the dipolar solvents may be attributed to the stabilization of the transition state by the dipole-dipole interaction. The effects of the substituents on the rate supported the polar transition state with a partial positive charge on

a) The product ratios (**2**/**3**) were determined by means of high-performance liquid chromatography; the yield of **3** was taken as the amount of benzophenone after the hydrolysis of **3**. b) Relative logarithmic rate constants of the reaction of diphenyldiazomethane with TCNE in benzene as the reference solvent and in a given solvent; Ref. 1. c) Dimroth and Reichardt's E_T values; Ref. 7. d) Kirkwood function; $f(\varepsilon)=(\varepsilon-1)/(2\varepsilon+1)$; Ref. 6.

the diazo-carbon: $\log k/k_0=-1.67(\sigma^0+0.66\Delta\bar{\sigma}_R^+)+0.009$,[5] at 30 °C in THF. However, the correlation of log k with f(ε) (r=0.69) or E_T (r=0.74) was less satisfactory than that with D_π. This implies that the chloranil reaction is more dependent on the basic property (D_π) of the solvents.

To obtain a more satisfactory regression, let us examine the multiple correlation of log k with D_π values and with E_T or f(ε) as the solvent polarity parameter. The two parameter equations consisting of linear combination of D_π and E_T or f(ε) improved the correlation, as may be seen in Eq. 1 for 19 solvents and in Eq. 2 for 20 solvents:

Chloranil-DDM reaction:

$$\log k = -4.77 - 0.421 D_\pi + 0.0650 E_T \quad (r = 0.977, s = 0.0945, n = 19), \quad (1)$$

$$\log k = -3.16 - 0.450 D_\pi + 2.45 f(\varepsilon) \quad (r = 0.963, s = 0.120, n = 20). \quad (2)$$

The Kirkwood function, f(ε), appears less successful than E_T, as is shown by the values of r in Eqs. 1 and 2. A plot of log k(obsd) *vs.* log k(calcd) according to Eq. 1 is shown in Fig. 2.

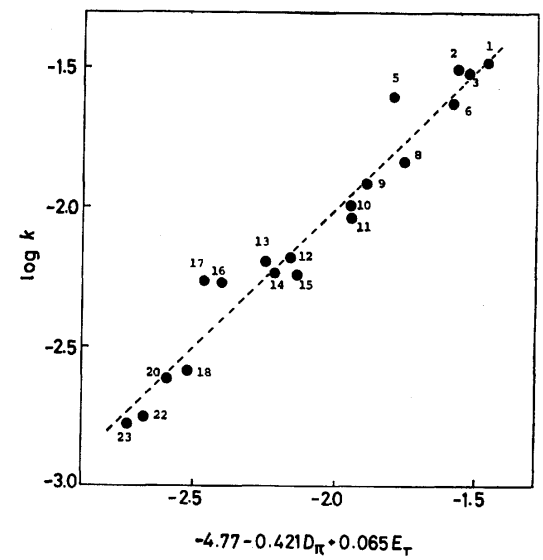

Fig. 2. Plot of log k (obsd) against log k (calcd) according to Eq. 1, for point numbers, see Table 1.

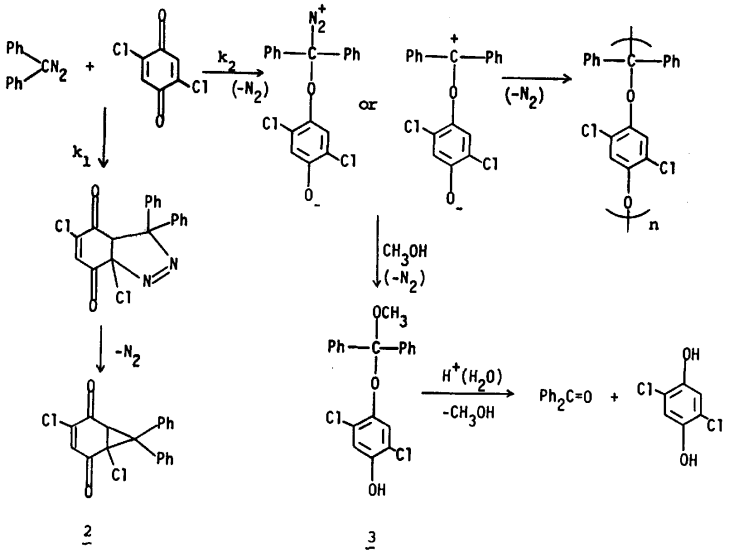
The Dependence of the Rate Constants on the Properties of the Aprotic Solvents in the Reactions of Diphenyldiazomethane with 2,5-Dichloro-p-benzoquinone (DCQ). The DCQ decomposed DDM to give two products, bicyclic dione (**2**) and poly(2,5-dichlorohydroquinone benzhydryl ether) (Scheme 2).[8] The formation of **2** may be explained as arising from the initial product, pyrazoline, followed by the loss of N_2; the polyether may then be thought to be made up by the polymerization of a diazonium or carbonium betaine intermediate, like **1** or **1'**. The participation of the betaine intermediate was evidenced by the isolation of 2,5-dichloro-4-



Scheme 2.

[(methoxy)diphenylmethoxy]phenol (**3**) in the reaction carried out in the presence of a trace amount of CH_3OH;[8] **3** was easily hydrolyzed into benzophenone and 2,5-dichlorohydroquinone. Thus, the yield was taken as the amount of benzophenone. However, no essential change was noticed in the observed rate constant or in the yield of **2** between the reaction in the absence and in the presence of a trace of CH_3OH as an additive, as exemplified by a 1,2-dichloroethane solution.[8] Therefore, we made product and kinetic studies of the solvents containing a 5 molar excess of CH_3OH with respect to DDM, and then the total and the relative yields of **2** and benzophenone after the hydrolysis were conveniently determined by means of high-performance liquid chromatography. The combined yields of **2** and **3** amount to more than 95% in all the solvents used. The observed second-order rate constants (k_{obsd}) were divided into the individual rate constants, k_1 and k_2, for the paths leading, respectively, to **2** and **3**, by combining them with their relative yields. The kinetic data and the relative product yields are also shown in Table 1.

An examination of the results shows that, although the variation in the rate constants with the changing solvent is considerably low, k_1 and k_2 depend on both the basicity and the polarity of the solvents, as in the case of a chloranil reaction; $\log k_1 = -1.35 + 0.584 \log k$ ($r=0.962$, $n=19$) and $\log k_2 = -1.05 + 0.644 \log k$ ($r=0.946$, $n=19$), where k is the rate constant in the chloranil-DDM reaction. For a comparison of k_1 and k_2, a similar but slightly greater dependence of k_2 on the properties of the solvents can be anticipated from the linear correlation: $\log k_2 = 0.392 + 1.08 \log k_1$ ($r=0.973$, $n=22$).

For example, a single-parameter correlation of the logarithmic rate constants with the D_π, E_T, and $f(\varepsilon)$ values is as follows: $\log k_1 = -2.65 - 0.289D_\pi$ ($r=0.769$, $n=22$), $\log k_1 = -4.87 + 0.0582E_T$ ($r=0.797$, $n=20$), $\log k_1 = -3.38 + 2.05\,f(\varepsilon)$ ($r=0.673$, $n=22$), and $\log k_2 = -2.48 - 0.311D_\pi$ ($r=0.743$, $n=22$), $\log k_2 = -5.02 + 0.0664E_T$ ($r=0.807$, $n=20$), $\log k_2 = -3.37 + 2.46\,f(\varepsilon)$ ($r=0.727$, $n=22$). A comparison of the r values of these correlations indicates that both k_1 and k_2 are more affected by the solvent polarity (E_T) than by the basicity (D_π). This trend is the opposite of that found in the chloranil reaction. Attempts to obtain more satisfactory correlations were done using two parameters, D_π and E_T or $f(\varepsilon)$. The results are shown as Eqs. 3 and 4 for $\log k_1$ and as Eqs. 5 and 6 for $\log k_2$:

DCQ–DDM reaction:

$$\log k_1 = -4.45 - 0.205D_\pi + 0.0460E_T \quad (r = 0.962,\ s = 0.0176,\ n = 20), \tag{3}$$

$$\log k_1 = -3.24 - 0.240D_\pi + 1.55f(\varepsilon) \quad (r = 0.912,\ s = 0.110,\ n = 22), \tag{4}$$

$$\log k_2 = -4.57 - 0.218D_\pi + 0.0535E_T \quad (r = 0.953,\ s = 0.090,\ n = 20), \tag{5}$$

$$\log k_2 = -3.22 - 0.249D_\pi + 1.94f(\varepsilon) \quad (r = 0.926,\ s = 0.113,\ n = 22). \tag{6}$$

As the case of the chloranil reaction, both the equations involving D_π and E_T gave better correlations than the corresponding expressions involving D_π and $f(\varepsilon)$. The superiority of the E_T paramater may be ascribed to the intrinsic combined measure of solvent polarity and acidity,[9] by which the specific solvation of the transition state with the negatively charged quinone moiety is effected. Furthermore, a comparison of the coefficients of D_π and E_T in Eqs. 3 and 5 shows that the **3** path receives more influence of the solvent polarity than does the **2** path; the absolute coefficients of D_π increased *ca.* 6%, but the corresponding values of E_T increased *ca.* 16%, in going from Eq. 3 to Eq. 5. The plots of $\log k_1$ (obsd) *vs.* $\log k_1$ (calcd) and $\log k_2$ (obsd) *vs.* $\log k_2$ (calcd), according to, respectively, Eqs. 3 and 5, are shown in Fig. 3. The greater susceptibility of the **3** path to the solvent polarity than the **2** path can be ascribed to the more-charged transition state suggested by the kinetic substituent effects: $\log k_1 = -2.15 - 1.55\sigma$ and $\log k_2 = -2.03 - 1.85$ ($\sigma^0 + 0.515\,\Delta\bar{\sigma}_R^+$).[8]

Comparison of the Kinetic Solvent Effects of the Chloranil–

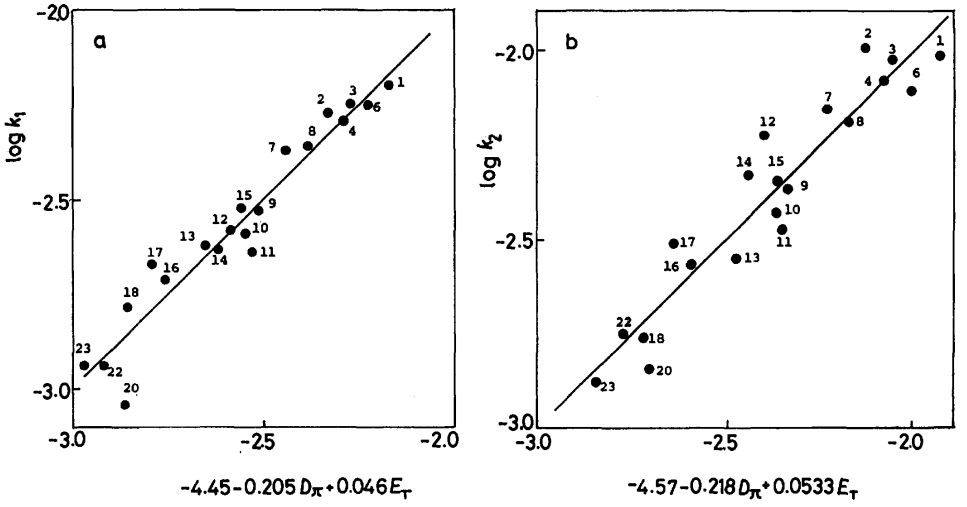


Fig. 3. a) Plot of log k_1 (obsd) *vs.* log k_1 (calcd) according to Eq. 3. b) Plot of log k_2 (obsd) *vs.* log k_2 (calcd) according to Eq. 5, for point numbers, see Table 1.

DDM and DCQ–DDM Reactions with Those of the DDQ–DDM and TCNE–DDM Reactions. We are now in a position to compare the kinetic solvent effects in the decomposition of DDM with various π-acceptor acids, *i.e.*, chloranil, DCQ, DDQ, and TCNE.

In formulating the D_π scale in 34 aprotic solvents,[1] we used the difference between the logarithmic rate constants of the TCNE–DDM reaction in benzene (as a reference solvent) and the solvent at 30 °C, so the log k can be described by this modified form:

TCNE–DDM reaction:

$$\log k = -1.01 - D_\pi, \tag{7}$$

where the intercept is log k for benzene.

This empirical parameter could successfully be applied to the kinetics of the DDQ–DDM reaction in 26 aprotic solvents at 30 °C.[1] The least-square correlation equation is as in Eq. 8:

DDQ–DDM reaction:

$$\log k = 0.623 - 1.10D_\pi \quad (r = 0.977,\ s = 0.161,\ n = 26). \tag{8}$$

A comparison of the intercepts and the slopes in Eqs. 7 and 8 indicates that the DDQ reaction is *ca.* 30 times faster in the benzene solution ($D_\pi = 0$) and depends slightly more on the solvent basicity than the TCNE reaction. On the contrary, the chloranil and DCQ reactions, both having substantially the same orders of rates, gave rates about 50 times lower in benzene and showed a less effective contribution of the D_π compared to the TCNE reaction, as may be seen in the coefficients of D_π in Eqs. 1, 3, and 5. It should also be noted that these equations are characteristic in incorporating the solvent-polarity parameter.

The solvation effects in both initial and transition states must be taken into account in order to understand the influence of the solvent on the rate. In the initial state, the basic solvation of the π-acceptor acids is the chief factor influencing the rate constants, as exemplified by the UV blue shifts and the appearance of the charge-transfer absorption of TCNE[10,11] and chloranil[12] on going to more basic solvents† (Table 2). One can easily notice the parallelism between the absolute coefficients of D_π and the electron affinity of these π-acids in the order of DDQ (1.95 eV)>TCNE (1.80)> chloranil (1.37)>DCQ (1.1).[13] This means that the extent of the basic solvation can be related to the π-acceptor ability of these acids. On the other hand, the transition states may be stabilized by the dipole-dipole interaction in the polar media, since the kinetic substituents effects of all these reactions suggest charged transition states.

Here again, let us summarize the Hammett parameters, ρ, with the correlation fashion: TCNE reaction; −2.67 (with Brown's σ^+)[14], DDQ; −2.33 (Yukawa-Tsuno equation),[15] chloranil; −1.67 (Yukawa-Tsuno equation),[5] and DCQ; −1.85 (for the path giving **3**, Yukawa-Tsuno equation) and −1.55 (for path giving **2**, with normal σ).[8] If the ρ values may be taken as a suitable estimate of the charge appearance of the transition state, the TCNE and DDQ reactions are more likely to be stabilized by the polar solvent than are the chloranil and DCQ reactions. An examination of Eqs. 1—8, however, shows that the DDQ reaction is satisfactorily correlated only with D_π, while the chloranil and DCQ reactions are well expressed by a linear combination of D_π and a polarity parameter, such as E_T and $f(\varepsilon)$. This apparent discrepancy can be easily explained by the relative significance of the stabilizations in the initial and transition states in comparison with that for the model TCNE–DDM reaction. By definition, the D_π parameter inherently reflects the influence of the solvent, not only on the initial state, but also on the transition state of the TCNE–DDM reaction. The free energies of the solvation of the initial state (ΔG_B) are, of course, greater than those of the transition state (ΔG_P), as was demonstrated earlier by the statistically better correlation of the logarithmic rate constants with the conventional basicity param-

† By contrast, the π-π^* absorption of DDM in the ultraviolet region remained essentially unchanged during such a variation of solvents, reflecting the lower solvation of DDM.[1]

Table 2. Solvent effects on the UV absorption spectra of TCNE and chloranil at 25 °C

Solvent	TCNE λ_{max}/nm (log ε)		Chloranil λ_{max}/nm (log ε)

eters, such as $\Delta\nu_D$, β, and DN, than those with E_T and $f(\varepsilon)$.[1] This situation is schematically shown in Fig. 4, together with the other cases of DDQ, chloranil, and DCQ reactions.

In the case of the DDQ reaction, the lack of a polarity parameter and the slightly excess sensitivity to the D_π may, therefore, be ascribed to essentially the same $\Delta G_P/\Delta G_B$ ratios, but to somewhat greater individual values, compared to the TCNE reaction. On the other hand, the incorporation of the polarity parameter in the chloranil and DCQ reactions is the result of the significant decrease in the basic solvation; therefore, the relative role of ΔG_p may be pronounced with respect to ΔG_B.

Recently, Krygowski and Fawcett proposed a similar two-parameter regression with the aid of E_T and DN, where Q is a physicochemical quantity and α and β are the regression coefficients:[9]

$$Q = Q_0 + \alpha E_T + \beta DN.$$

The application of this empirical equation to the present chloranil and DCQ reactions, however, resulted in a much worse correlation because DN is inadequate to describe the softness of aromatic solvents.

Experimental

The bicyclic dione (**2**): benzophenone ratios and the overall yields of **2** and benzophenone were determined by means of JASCO trirotor high-performance liquid chromatography (HPLC), using biphenyl as the internal standard. The HPLC analysis was carried out at room temperature using a 250 mm × 4.6 mm column packed with ODS (octadecylsilane) on silica gel; methanol–water (7 : 3 by volume); flow rate, 1 ml/min. The UV detector was calibrated at 245 nm with standard mixtures of known concentrations of benzophenone, **2**, and biphenyl. The relative retention times were as follows: benzophenone (0.53), **2** (0.68), and biphenyl (1.0).

Materials. The diphenyldiazomethane (DDM) was synthesized as has been described by Smith and Howard[16] and recrystallized from light petroleum; mp 29—30 °C. The chloranil was of commercial origin and was recrystallized twice from benzene; mp 290 °C. The 2,5-dichloro-*p*-benzoquinone (DCQ) was prepared according to the procedure described by Ling[17] and was recrystallized from ethanol; mp 164—166 °C. All the solvents were dried and purified according to the standard procedures.[18]

Kinetic Measurements. The values of k were determined spectrophotometrically as has previously been described[5,8] by the use of Hitachi 323 and JASCO UVIDEC-505 instruments. The absorption cells were thermostated at 30±0.1 °C with a Haake circulator. The mean deviations for k were ±3% (usually two determinations).

Highly Selective Carbon-Carbon Bond Forming Reactions Mediated by Chromium(II) Reagents

Tamejiro HIYAMA,* Yoshitaka OKUDE, Keizo KIMURA, and Hitosi Nozaki

Department of Industrial Chemistry, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

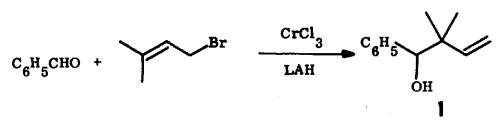
(Received July 14, 1981)

A low valent chromium reagent is generated from chromium(III) chloride and a half mol of lithium aluminum hydride in tetrahydrofuran. The reagent behaves similarly to anhydrous chromium(II) chloride, which is commercially available, and reduces allylic halides to produce unisolable allylchromium species which add efficiently to aldehydes or ketones with high degree of stereo- and chemoselectivity. Particularly, high *threo* selectivity is observed in the reaction of aldehydes and 1-bromo-2-butene and is ascribed to a chair-like six-membered transition state. Simple reduction of allylic and benzylic halides produces biallyls and bibenzyls, while *gem*-dibromocyclopropanes afford the corresponding allenes in excellent yields.

Main group organoelement compounds containing lithium, magnesium, or boron have been basic reagents for carbon-carbon bond formation.[1] These are generally so reactive as to make C–C bonds indiscriminately. In contrast, highly selective reactions are accomplished recently with the aid of transition metal elements such as chromium,[2] samarium,[3] ytterbium,[3] manganese,[4] tin,[5] titanium,[6] and zirconium.[7] This article deals with the Barbier-Grignard type reaction by means of chromium reagents with the emphasis on the chemo- and stereoselectivity.

Preparation of Allylic Chromium Reagent and the Carbonyl Addition. Chromium(II) salts are widely used in organic synthesis as one-electron reducing agents.[8] These are generally prepared and used in aqueous media. Therefore, when organic halides are treated with conventional chromium(II) reagents, the intermediary organochromium species, assumed to be formed at the initial stage of the reaction, are soon attacked by the coexisting water.[9] This has been the largest limitation and the chromium(II) reagents could not be utilized for intermolecular C–C bond forming reactions. We have found that chromium(III) chloride is reduced by lithium aluminum hydride (LAH)[10] in tetrahydrofuran (THF) to form a reagent which behaves quite analogously to chromium(II) chloride. Although the identity has not been established yet, we will call it chromium(II) reagent hereafter. This allows us to work in non-aqueous solutions.

When anhydrous chromium(III) chloride[11] suspended in THF was treated with a half mol of LAH at 0 °C, exothermic reaction took place spontaneously with hydrogen evolution. The initial purple color of the reaction mixture darkened and finally turned dark brown after 10 min. The reagent thus prepared can be stored for more than a month in a refrigerator without appreciable loss of activity. Treatment of a mixture of benzaldehyde and 1-bromo-3-methyl-2-butene with this reagent produced 2,2-dimethyl-1-phenyl-3-buten-1-ol (**1**). The optimum $CrCl_3$/LAH ratio was estimated to be 2 based on the results shown in Table 1. When



1

TABLE 1. REACTION OF BENZALDEHYDE AND 1-BROMO-3-METHYL-2-BUTENE WITH THE CHROMIUM REAGENTS GENERATED FROM VARIOUS RATIO OF CHROMIUM (III) CHLORIDE AND LITHIUM ALUMINUM HYDRIDE[a]

$CrCl_3$:	$LiAlH_4$	Yield of **1**/%
1	1	25[b]
2	1	90
4	1	48[c]
$CrCl_2$[d]		89

a) Benzaldehyde (1 mmol) and 1-bromo-3-methyl-2-butene (2 mmol) were added to the chromium reagent (4 mmol) in THF (20 cm^3) at room temperature and the reaction was stopped after 3 h. b) Benzyl alcohol was produced as a main product. c) Benzaldehyde remained as evidenced by TLC assay. d) Purchased from Research Organic/Inorganic Chemical Corp.

an equimolar amount of LAH was applied, active hydride remained unchanged and reacted with benzaldehyde competitively to produce benzyl alcohol. In the experiment with a ratio of 4, the yield of the adduct decreased to *ca.* 50%. The same transformation could be achieved by means of the commercially available anhydrous chromium(II) chloride. The results of the reaction between allylic halides (or tosylate) and aldehydes or ketones are listed in Table 2. The general features of the chromium(II) mediated Barbier-Grignard reaction are as follows:

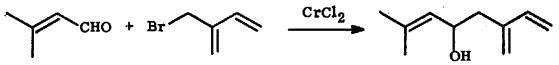
(1) The stoichiometry says that 2 mol of the chromium reagent is required for reduction of each halide.

(2) Although stoichiometric amount of allylic halide was sufficient for aldehyde, the use of excess allylic chromium reagents gives better yields in the reaction with ketones (*vide infra*).

(3) Generally the more substituted γ-carbon of an allyl group is attached to the carbonyl carbon. However, the methylene carbon of 3-bromopropyne preferentially connected with the carbonyl carbon of nonanal to give 1-dodecyn-4-ol (run 20).[12]

(4) *N,N*-Dimethylformamide (DMF) solvent is more effective than THF and, in particular, essential for the reaction with allyl chloride or tosylate.

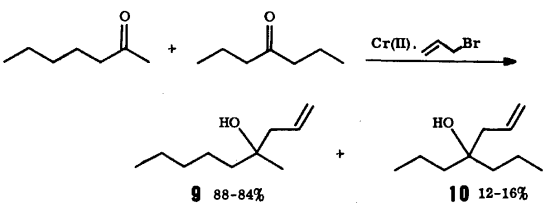
(5) With α,β-unsaturated aldehydes, the reaction proceeds exclusively in 1,2-fashion. Examples are seen in runs 9 and 14 (altemisia alcohol synthesis), and also in the synthesis of Ips dienol (**2**).[13]



Ips dienol **2**

(6) Ketones are in general less reactive than aldehydes and required 2 mol of halides (*i.e.*, 4 mol of chromium reagent). Thus, chemospecific carbonyl addition is effected (run 17). Furthermore, the reagent discriminated 2-heptanone from 4-heptanone with the selectivity of 88 to 84%. α,β-Unsaturated ketones such as benzylideneacetophenone and 1,4-naphthoquinone do not give the corresponding adduct cleanly.

(7) Nitriles and carboxylates are not affected. Thus, selective carbonyl addition was achieved with respect to aldehydes having cyano or alkoxycarbonyl groups (runs 18 and 19).



9 88-84% **10** 12-16%

(8) Allylation of 4-*t*-butylcyclohexanone resulted in the preferential formation of the axial alcohol (runs 5 and 6). Namely, equatorial attack predominates with the selectivity of 88% (for $CrCl_3$–LAH reagent) and

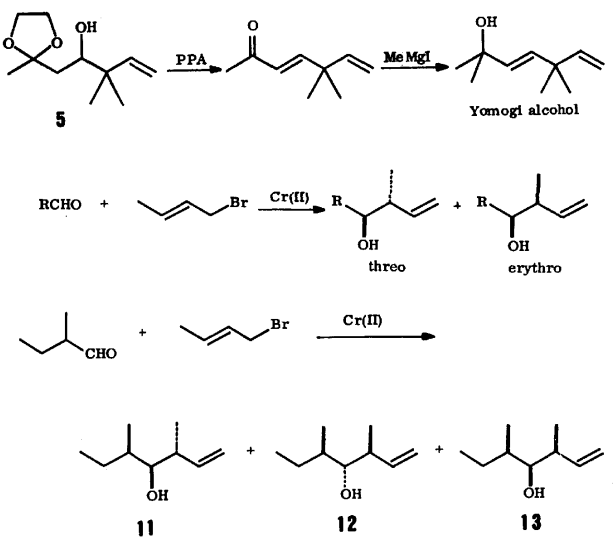
a) Chromium reagent (4 mmol) and 1-bromo-2-butene (2 mmol) were allowed to react with an aldehyde (1 mmol) at room temperature. b) A: $CrCl_3$–1/2$LiAlH_4$ reagent and mmol values are given. B: $CrCl_2$. c) The stereochemistry of the products was determined by comparing the spectral properties and retention times with those of the authentic samples (Ref. 15). d) Determined by ^1H NMR (the absorption of the methine proton H–C–OH): *threo*, δ=4.26 (d, J=6.8 Hz); *erythro*, δ=4.43 (d, J=5.8 Hz). e) *cis*-1-Bromo-2-butene was used. f) At THF refluxing temperature. g) Triphenylphosphine (1.18 g, 4.5 mmol) was added. h) Pyridine (0.86 g, 10.9 mmol, 2 equivalents of chromium) was used. i) Determined by ^{13}C NMR: *threo* (intensity)/*erythro* (intensity) δ=15.83 (94)/15.00(20), 44.32(99)/43.69(20), 115.62(99)/115.03(19).



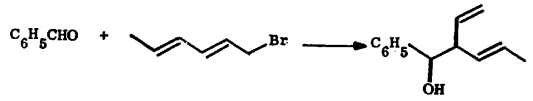
is not affected as evidenced by the reaction of 1-bromo-3-methyl-2-butene with 3,3-ethylenedioxybutanal (runs 15 and 16). The product **5** was subsequently dehydrated and deacetalized with polyphosphoric acid (PPA). Treatment of the resulting enone with methylmagnesium iodide yielded Yomogi alcohol.[15]

threo-*Selective Synthesis of Homoallyl Alcohols.* Benzaldehyde and 1-bromo-2-butene gave only one diastereomer of 2-methyl-1-phenyl-3-buten-1-ol whose stereochemistry was determined later to be *threo* by Heathcock and his coworker.[16] The *threo*-selectivity was found valid for various aldehydes as shown in Table 3 and independent both of the chromium reagents and the stereochemistry of 1-bromo-2-butenes.[17] The selectivity in THF was in general extremely high for relatively unhindered aldehydes (runs 1—11) compared with the reaction of 2-butenylmetals derived from magnesium, zinc, or cadmium.[18] In DMF the *erythro* alcohol (runs 12—14) was produced as much as 25—34%. The

only exception is seen in the reaction of a bulky aldehyde, 2,2-dimethylpropanal, which gave preferentially the *erythro* alcohol irrespective of the solvent (runs 15 and 16). As both *cis*- and *trans*-1-bromo-2-butene gave the *threo* alcohol as the sole product (runs 1, 2, and 3), the stereochemical integrity was lost completely in contrast to the reaction of 2-butenylboron and -silicon derivatives.[17]

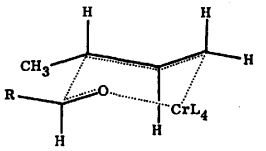
The reaction of 2-methylbutanal with 1-bromo-2-butene under the standard conditions gave three adducts whose stereochemical assignments were based on the ^{13}C NMR spectra of the hydrogenated products. Thus, *threo* selectivity in this case turned out to be 93%, although *α-erythro* induction[16] was 69%.

The C–C bond formation with benzaldehyde and 1-bromo-2,4-hexadiene took place exclusively at the γ-position of the bromide[19] to give **14**. The stereochemistry of the major product was assumed to be the one depicted in analogy to the above results.



14

The *threo* selectivity observed on the relatively unhindered aldehydes is explained reasonably by a chair form transition state I wherein interaction between the methyl and R groups is most reduced.[20] As chromium-



I

(III) ion has an octagonal configuration and consequently accepts six ligands,[21] these ligands will have an effect on the stereoselectivity. The low *threo*-selectivity in DMF may be attributed to the good solvating power of DMF compared with THF and consequently to the increased bulkiness around the chromium metal to disfavor the transition state I. This rationale is applicable to explaining the results of the experiment carried out in the presence of triphenylphosphine (run 10) or pyridine (run 11) which stabilizes the complex of type $RCrCl_2(ligand)_3$.[22]

Reduction of Organic Halides with the Chromium(II) Reagents. In the absence of electrophiles such as aldehydes or ketones allyl halides are dimerized under dehalogenation. For example, 1-bromo-3-methyl-2-butene gave three isomers of the coupling product (see Table 6, runs 1 and 2). Benzylic halides were transformed into the corresponding bibenzyls.[23] However, the assumed intermediate, benzylchromium, did not add across aldehydic carbonyl group. Reductive elimination of vicinal dihalides to olefins proceeded non-stereospecifically as evidenced by the transformation of *trans*-1,2-dibromocyclododecane into a mixture or

Table 4. Reduction of organic halides with the chromium(II) reagents

a) A: $CrCl_3$–1/2$LiAlH_4$ reagent, B: $CrCl_2$. All the reaction was carried out at room temperature unless otherwise specified. b) The mixture of the product was purified by preparative TLC and analyzed. The ratio of these products was determined by GLC (Apiezon L, 5%, KOH 1%, on Chromosorb WAW DMS, 1.5 m, 76 °C) to be 72 : 22 : 6. c) Overnight. d) These products were isolated by distillation (Kugelrohr) and the ratio was found to be 62 : 27 : 11 by the GLC assay. e) Estimated by ^1H NMR. f) Based on the consumed starting material. g) At 90 °C. h) Starting dibromide (30 mg, 5%) was recovered. i) At 60 °C. j) GLC yield. k) At reflux temperature.

cis- and *trans*-cyclododecene. α-Bromocyclododecanone was reduced to the parent ketone quantitatively. Trapping experiment of the intermeidary chromium enolate with methyl iodide or trimethylsilyl chloride failed to give the expected product. Quenching with deuterium oxide resulted in only 38% deuterium incorporation. Therefore, hydrogen abstraction from the solvent has possibly occurred during the reaction.

A salient feature of the chromium(II) reagent is illustrated by the very smooth conversion of *gem*-dibromocyclopropanes to allenes (runs 8—11). The reaction is a key in an effective synthetic route to 1,2-dienes. In this particular transformation, the $CrCl_3$–LAH reagent was essential for clean reaction, as the commercial reagent, anhydrous chromium(II) chloride gave products contaminated with monobromocyclopropanes.

In conclusion, reduction of organic halides with the chromium(II) reagent in anhydrous media gives organochromium intermediates which react with aldehydic carbonyl carbon with high selectivity. This will provide a new tool for selective methodology of C–C bond formation.

Experimental

Distillation was carried out by use of Kugelrohr (Büchi) and boiling points were determined by measuring the bath temperature. All the temperatures are uncorrected. ^1H NMR spectra (tetramethylsilane as an internal standard) were taken in carbon tetrachloride solution on a Varian EM 390 spectrometer or EM 360 spectrometer, chemical shifts being given in ppm units. ^{13}C NMR spectra were recorded on a Varian CMR-20 spectrometer (tetramethylsilane, internal standard). IR spectra were obtained on a Shimadzu IR-27G spectrometer in neat liquid film unless otherwise stated, mass spectra on a Hitachi RMU-6L spectrometer. Chromium(III) chloride hexahydrate was dehydrated by the reported procedure.[11] Anhydrous chromium(II) chloride was purchased from Research Inorganic/Organic Chemical Corp., and all reactions as well as all operations dealing with chromium salts were carried out under an argon or a nitrogen atmosphere. LAH purchased from Metalgesellschaft A.-G., West Germany, was used directly. TLC analyses were carried out with Merck Silica Gel 60 F_{254} plates. Preparative TLC plates (20 cm × 20 cm) were prepared by use of Merck Kiesel-gel PF_{254}. Column chromatography was carried out with silica gel (Wakogel C-100) at atmospheric pressure or under pressure of $4—6 \times 10^5$ N/m^2 (Wakogel C-300). In this text 1 Torr corresponds to 133.322 N/m^2.

Preparation of the Chromium Reagent from Chromium(III) Chloride and Lithium Aluminum Hydride. A Typical Procedure. Lithium aluminum hydride (101 mg, 2.6 mmol) was added portionwise to chromium(III) chloride (0.84 g, 5.3 mmol) suspended in THF (5 cm^3) at 0 °C. Immediate gas evolution occurred with darkening of the initial purple color which finally turned dark brown. After the gas evolution had ceased the reaction mixture was stirred for 5 to 10 min at 0 °C, and the reagent was used for reaction. Replacing THF with DMF was effected by evaporation of THF under reduced pressure, introduction of argon, and addition of DMF.

Reaction of Benzaldehyde with 1-Bromo-3-methyl-2-butene. A Typical Procedure. To the chromium reagent, prepared from chromium(III) chloride (0.37 g, 2.3 mmol) and LAH (44 mg, 1.2 mmol) in THF (5 cm^3), were added benzaldehyde (92 mg, 0.86 mmol) and successively a THF (5 cm^3) solution of 1-bromo-3-methyl-2-butene (173 mg, 1.2 mmol) at room temperature. After 2 h the reaction mixture was treated with water (5 cm^3) and extracted thoroughly with ether. The ethereal solution was washed with brine, dried with sodium sulfate, and concentrated. Distillation of the residue at 105—110 °C (bath temp)/0.12 Torr gave 2,2-dimethyl-1-phenyl-3-buten-1-ol (**1**) (124 mg, 82% yield). In another experiment the yield estimated by GLC was 90%. IR 3425, 3095, 3075, 3035, 1638, 1605, 1490, 1020, 1000, 915, 730, and 702 cm^{-1}; ^1H NMR δ=0.94 (s, 3H), 0.99 (s, 3H), 1.5—1.8 (br s, OH), 4.34 (s, 1H), 4.8—6.2 (m, 3H, vinyl), and 7.26 (s, 5H); MS, *m/e* (rel intensity), 176 (M$^+$, trace), 107 (100), 82 (33), 79 (69), and 70 (64).

The reactions between various aldehydes and allylic bromides are summarized in Table 2. Physical properties of the new compounds follow.

3-Chloro-1-phenyl-3-buten-1-ol (3). Bp 88—93 °C (bath temp)/0.07 Torr; IR 3360, 3050, 3020, 1630, 1605, 1495, 1040, 883, 758, and 700 cm^{-1}; ^1H NMR δ=2.3 (br s, 1H, OH), 2.60 (two d, J=7.5 Hz, 2H), 4.91 (dd, J=7, 5 Hz, 1H), 5.10 (s, 1H), and 7.25 (s, 5H); MS *m/e* (rel intensity), 182 (M$^+$, 0.07), 107 (100), 79 (67), and 77 (33). Found: C, 65.53; H, 6.03%. Calcd for $C_{10}H_{11}ClO$: C, 65.76; H, 6.07%.

Phenyl(1-vinylcyclohexyl)methanol (4). Bp 160—162 °C (bath temp)/0.15 Torr; IR 3450, 3045, 1630, 1605, 1493, 1453, 1040, 1022, 918, 733, and 708 cm^{-1}; ^1H NMR δ=1.1—2.0 (m, 11H), 4.23 (s, 1H), 4.8—5.9 (m, 3H, vinyl), and 7.16 (s, 5H); MS *m/e* (rel intensity), 198 (M$^+-H_2O$, 0.7), 110 (98), 107 (100), 81 (86), and 67 (43). Found: C, 83.33; H, 9.59%. Calcd for $C_{15}H_{20}O$: C, 83.28; H, 9.32%.

6,6-Ethylenedioxy-3,3-dimethyl-1-hepten-4-ol (5). Bp 115—120 °C (bath temp)/4 Torr; IR 3510, 3070, 1634, 1368, 1120, 1094, 1036, and 904 cm^{-1}; ^1H NMR δ=1.00 (s, 6H), 1.28 (s, 3H), 1.57 (d, J=9 Hz, 1H), 1.67 (d, J=2 Hz, 1H), 2.95 (br s, 1H, OH), 3.43 (dd, J=9, 2 Hz, 1H), 3.92 (s, 4H), and 4.7—6.1 (m, 3H, vinyl); MS *m/e* (rel intensity), 185 (M$^+-CH_3$, 1.5), 167 (1.5), 97 (100), and 43 (59). Found: C, 65.94; H, 10.29%. Calcd for $C_{11}H_{20}O_3$: C, 65.97; H, 10.07%.

10-Hydroxy-12-tridecen-5-one (6). Bp 109—112 °C (bath temp)/0.06 Torr; IR 3425, 3080, 1705, 1640, 1128, 1000, and 916 cm^{-1}; ^1H NMR δ=0.8—1.9 (m, 14H), 2.0—2.6 (m, 6H), 3.3—3.8 (m, 1H), and 4.7—6.2 (m, 3H, vinyl); MS, *m/e* (rel intensity), 194 (M$^+-H_2O$, 2), 171 (M$^+-CH_2CH{=}CH_2$, 7), 153 (21), 135 (17), 85 (75), and 57 (100). Found: C, 73.46; H, 11.62%. Calcd for $C_{13}H_{24}O_2$: C, 73.54; H, 11.39%.

Methyl 6-Hydroxy-8-nonenoate (7). Bp 90—95 °C (bath temp)/0.04 Torr; IR 3450, 3080, 1728, 1632, 1435, 1200, 1092, 998, and 914 cm^{-1}; ^1H NMR δ=1.2—1.9 (m, 6H), 2.0—2.5 (m, 5H), 3.4—3.9 (m+s (δ=3.62), 4H), and 4.9—6.2 (m, 3H, vinyl); MS, *m/e* (rel intensity), 155 (1), 145 (M$^+-CH_2$-$CH{=}CH_2$, 12), 113 (100), 85 (24), and 67 (85). Found: C, 64.20; H, 9.91%. Calcd for $C_{10}H_{18}O_3$: C, 64.49; H, 9.74%.

*(4Z)-8-Hydroxy-*cis*-4,10-undecadienenitrile (8).* Bp 115—120 °C (bath temp)/0.06 Torr; IR 3430, 3070, 3005, 2265, 1633, 992, and 913 cm^{-1}; ^1H NMR δ=1.1—1.7 (m, 2H), 2.0—2.5 (m, 9H), 3.57 (quintet, J=6 Hz, 1H), 4.7—6.2 (m, 3H, vinyl); MS, *m/e* (rel intensity), 138 (M$^+-CH_2CH{=}CH_2$, 66), 120 (44), 110 (20), 94 (66), and 67 (100). Found: C, 73.53; H, 9.81; N, 7.88%. Calcd for $C_{11}H_{17}NO$: C, 73.70; H, 9.56; N, 7.81%.

Competitive Reaction of 2-Heptanone and 4-Heptanone. A mixture of 2-heptanone (86 mg, 0.75 mmol) and 4-heptanone (86 mg, 0.75 mmol) dissolved in THF (1.5 cm^3) was added to chromium(II) chloride (0.38 g, 3.1 mmol) suspended in THF (3 cm^3) at 0 °C. Then allyl bromide (186

mg, 1.5 mmol) dissolved in THF (3 ml) was added to the reaction mixture at room temperature in 6 min and the mixture was stirred for 3 h. Work-up and GLC analysis (PEG 20 M, 10%, on Chromosorb W, 1.5 m, 100 °C) revealed that the reaction had proceeded with 54% conversion to give 4-methyl-1-nonen-4-ol (R_t 30.0 min) and 4-propyl-1-hepten-4-ol (R_t 23.7 min) (84 : 16) in 49% yield (91% yield based on the consumed ketones). In a repeated experiment the ratio was 88 : 12.

Conversion of **5** *into Yomogi Alcohol.* A THF (5 cm³) solution of **5** (1.01 g, 5.0 mmol) was added to a THF (5 cm³) solution of PPA (105% H_3PO_4, 1.3 g) under a nitrogen atmosphere and the mixture was stirred for 1 h, then heated to reflux for 3.5 h. Work-up followed by preparative TLC (hexane–ether 3 : 1, R_f 0.74) gave (3*E*)-5,5-dimethyl-*trans*-3,6-heptadien-2-one (0.59 g, 84% yield), bp 123—127 °C (bath temp)/28 Torr. IR 1670, 1616, 1350, 1245, 974, and 908 cm⁻¹; ¹H NMR δ=1.18 (s, 6H), 2.14 (s, 3H), 4.7—6.1 (m (vinyl)+d (δ=5.87, J=16 Hz), totally 4H), and 6.60 (d, J=16 Hz, 1H); MS, *m/e* (rel intensity), 138 (M^+, 4), 123 ($M^+ - CH_3$, 26), 95 (70), 67 (35), and 43 (100). Found: C, 78.06; H, 10.36%. Calcd for $C_9H_{14}O$: C, 78.21; H, 10.21%.

To the ether (2 cm³) solution of the dienone (138 mg, 1.00 mmol) excess methylmagnesium iodide (generated from 5 mmol of each of magnesium and methyl iodide in ether (5 cm³)) and the reaction mixture was stirred at room temperature for 30 min. Work-up and distillation gave Yomogi alcohol (124 mg, 81% yield), bp 80 °C (bath temp)/1 Torr, having spectral properties consistent with the reported one.[15]

*Synthesis of Ips-dienol (***2***).* A THF (3 cm³) solution of 2-bromomethyl-1,3-butadiene (0.20 g, 1.35 mmol) was added to a mixture of chromium(II) chloride (0.26 g, 2.1 mmol) and 3-methyl-2-butenal (44 mg, 0.52 mmol) at room temperature and the whole was stirred for 3.6 h. Work-up followed by distillation at 72 °C (bath temp)/0.03 Torr gave the desired product (34 mg, 45% yield) having the correct spectra.[13]

threo-*2-Methyl-1-phenyl-3-buten-1-ol.* A THF (4 cm³) solution of *trans*-1-bromo-2-butene (0.34 g, 2.5 mmol) was added at room temperature over a period of 20 min to a mixture of benzaldehyde (140 mg, 1.31 mmol) and the chromium reagent A prepared by mixing chromium(III) chloride (0.81 g, 5.1 mmol) and LAH (96 mg, 2.5 mmol) in THF (5 cm³). The reaction mixture was stirred for 3.4 h at room temperature. Work-up and distillation at 110 °C (bath temp)/4 Torr gave the title alcohol (0.21 g, 96% yield) which proved uniform on TLC analysis (hexane–ether 3 : 1, R_f 0.35) and GLC (PEG 20 M, 5%, on Celtite 545, 1.5 m, 141 °C; or Apiezon L 5%, KOH 1%, on Chromosorb, 2 m, 140 °C).

Reaction of 2-Methylbutanal with 1-Bromo-2-butene. A THF (6 cm³) solution of 2-methylbutanal (182 mg, 2.1 mmol) and 1-bromo-2-butene (0.62 g, 4.6 mmol) was added to chromium(II) chloride (1.14 g, 9.3 mmol) suspended in THF (9 cm³) over a period of 10 min at room temperature, and the whole was stirred for 3 h. Work-up and column chromatography gave a mixture (0.27 g, 90% yield) of adducts (**11**, **12**, and **13**) with the ratio of 62 : 31 : 7 as revealed by GLC assay (PEG 20 M, 5%, on Celite 545, 1.5 m, 80 °C).

The mixture of the adduct (130 mg) in ethanol (6 cm³) was stirred under a hydrogen atmosphere in the presence of 10% palladium on charcoal for 31 h. Filtration and short column chromatography gave a stereoisomeric mixture of 3,5-dimethyl-4-heptanol. ¹³C NMR ($CDCl_3$, TMS an internal standard) spectra showed clearly two sets of chemical shifts (δ), (intensity): [11.26 (80), 11.86 (100), 12.44 (82), 15.43 (77), 24.99 (77), 27.19 (85), 36.79 (81), 37.74 (87), and 78.41 (80)] for the dihydro derivative of **11**; [11.65 (70), 16.14 (66), 23.52 (71), 37.29 (74), and 80.60 (35)] for the dihydro derivative of **12**. The minor product, the dihydro derivative of **13**, was characterized by the peaks at δ=13.90 (13), 26.46 (11), and 77.98 (7).[17a,25]

*4-Methyl-1-nonen-4-ol (***9***).* Bp 61—65 °C (bath temp)/13 Torr; ¹H NMR δ=0.9—1.6 (m, 12H), 1.13 (s, 3H, Me), 2.20 (d, J=8.1 Hz, 2H), and 5.0—6.1 (m, 3H, vinyl); IR 3390, 1642, 1155, 999, and 913 cm⁻¹. Found: C, 77.07; H, 13.06%. Calcd for $C_{10}H_{20}O$: C, 76.86; H, 12.90%.

*4-Propyl-1-hepten-4-ol (***10***).* Bp 56—59 °C (bath temp)/13 Torr; ¹H NMR δ=0.8—1.5 (m, 15H), 2.11 (d, J=7.2 Hz, 2H), 4.97 (dd, J=2.3, 15.3 Hz, 1H, CH=CH–H), 5.00 (dd, J=2.3, 9.0 Hz, 1H, CH=CH–H), and 5.5—6.0 (m, 1H, CH=CH_2); IR 3400, 1637, 1152, 989, and 919 cm⁻¹. Found: C, 76.68; H, 13.14%. Calcd for $C_{10}H_{20}O$: C, 76.86; H, 12.90%.

threo-*3-Methyl-1-nonen-4-ol.* Bp 88—91 °C (bath temp)/11 Torr; ¹H NMR δ=0.92 (t, J=7.5 Hz, 3H, terminal methyl), 1.04 (d, J=6.6 Hz, 3H, $CHCH_3$), 1.0—1.6 (m, 8H, methylenes), 1.80 (br s, 1H, OH), 2.0—2.4 (m, 1H, $CHCH_3$), 3.2—3.5 (m, 1H, CHOH), 5.01 (dd, J=2.7, 17.1 Hz, 1H, CH=CH–H), 5.18 (dd, J=2.7, 10.8 Hz, 1H, CH=CH–H), and 5.6—5.9 (m, 1H, CH=CH_2); IR 3380, 1638, 1260, 1081, 1001, and 911 cm⁻¹; MS, *m/e* (rel intensity), 141 ($M^+ - CH_3$, 2), 138 ($M^+ - H_2O$, 2), 101 (9), 83 (29), 56 (41), 55 (38), 44 (46), and 40 (100). Found: C, 76.74; H, 13.18%. Calcd for $C_{10}H_{20}O$: C, 76.86; H, 12.90%.

*1-Phenyl-2-vinyl-3-penten-1-ol (***14***).* ¹H NMR δ=1.37 (d, J=6 Hz, 0.78H), 1.62 (d, J=6 Hz, 2.22H), 1.88 (br s, 1H, OH), 2.8—3.5 (two multiplets, 1H), 4.3—4.6 (m, 1H), 4.9—6.0 (m, 5H, olefinic H), and 7.23 (s, 5H, Ph); IR 3450, 3090, 3040, 2980, 2930, 2890, 2865, 1640, 1608, 1500, 1458, 1038, 1024, 997, 968, 914, 760, 718, and 698 cm⁻¹; MS, *m/e* (rel intensity), 170 ($M^+ - H_2O$, 2), 107 (77), 91 (8), 82 (47), 79 (100), 77 (56), 67 (31), and 51 (25). *Cf.* Ref 24.

A Typical Procedure for the Reduction of 1,1-Dibromocyclopropanes. Synthesis of Phenylpropadiene: To the chromium reagent, prepared from chromium(III) chloride (0.82 g, 5.2 mmol) and LAH (99 mg, 2.6 mmol) in THF (5 cm³) and by replacing the solvent with DMF (5 cm³), a DMF (2 cm³) solution of 1,1-dibromo-2-phenylcyclopropane (0.29 g, 1.04 mmol) was added at room temperature and the mixture was stirred for 4 h. Work-up followed by distillation at 80—85 °C (bath temp)/20 Torr gave phenylpropadiene (75 mg, 62% yield): IR 1940, 850, 760, and 692 cm⁻¹; ¹H NMR δ=5.06 (d, J=7 Hz, 2H), 6.05 (t, J=7 Hz, 1H), and 7.15 (s, 5H).

The Solvomercuration, Bromination, and Related Reactions of 1,5-Dimethyl-6-methylenetricyclo[3.2.1.0^{2,7}]oct-3-en-8-one and Its Related Compounds

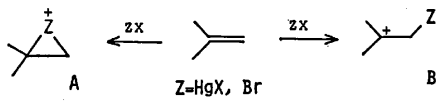
Makoto NITTA,* Akihiko OMATA, and Hiroshi SUGIYAMA

Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160

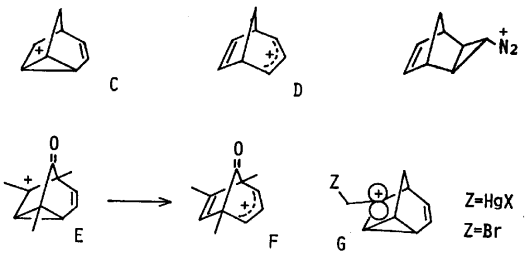
(Received July 20, 1981)

The solvomercuration-demercuration reactions of 1,5-dimethyl-6-methylenetricyclo[3.2.1.0^{2,7}]oct-3-en-8-one (**1**), its corresponding alcohol, and 5,8-dimethyl-9-methylenetricyclo[3.3.1.0^{2,8}]non-3-en-7-one (**2**) were investigated. In all cases, the solvent was stereospecifically incorporated on the exomethylene group, and the original tricyclic skeleton did not undergo rearrangement. Similarly, **1** and **2** underwent a stereospecific bromination on the exomethylene group by means of the reaction with pyridinium tribromide. These results suggest the stabilization of the formal cyclopropylcarbinyl cation intermediates by the adjacent acetoxymercury moiety or the bromine atom. On the other hand, the reaction of NBS–MeOH or NBS–H_2O with **1** afforded an addition product on the exomethylene group, and 1,4-addition originated from the cleavage of the cyclopropane ring, while with **2** the reaction afforded only an addition product on the exomethylene group. The difference in this reaction mode is discussed on the basis of the solvent effect and the ring strain of **1**.

The solvomercuration reaction of olefins has been widely studied and has been the subject of frequent reviews.[1-3] Mercurinium ions of Type (**A**) have been postulated as the intermediates in the electrophilic addition of mercury(II) acetate to olefins.[4-7] However, there is an oposing mechanistic interpretation that oxymercuration occurs to give an unsymmetrical open carbocation of Type (**B**).[8-10] The bromination of olefins seems also to be an atypical systems, for its cationic intermediates are not in all cases cyclic, but can also be opened carbocations.[11] Recently, Tidwell *et al.* concluded, in comparison with the rate of the acid-catalyzed hydration and addition reaction of arenesulfenyl chloride to various olefins, that the bromination of various olefins proceeds *via* bridged ion-like intermediates.[12] The high rate of the bromination of cyclopropylethylene is explained by a mechanism involving an open-ion-like rate-determining transition state. This change in mechanism is due to the great ability of the cyclopropyl group to stabilize an adjacent carbocation by resonance electron donation.



It has been elucidated that the tricyclo[3.2.1.0^{2,7}]-oct-3-en-6-yl cation (**C**) rearranges to bicyclo[3.2.1]-oct-3,6-dienyl cation (**D**) at a rate competing with solvent (MeOH) attack, as is shown by the generation of the latter cation from the *exo*-tricyclo[3.2.1.0^{2,4}]oct-6-en-3-anti diazonium ion.[13] Furthermore, the acid-catalyzed rearrangement of 1,5-dimethyl-6-methylenetricyclo[3.2.1.0^{2,7}]oct-3-en-8-one (**1**) has been investigated, and it has been elucidated that the tricyclic cation (**E**) rearranges to the bicyclic cation (**F**).[14] A consideration of the formal cation (**G**), which has a skeleton similar to those of the (**C**) and (**E**) cations, suggests that the solvomercuration or bromination reaction of compounds possessing a 6-methylenetricyclo[3.2.1.0^{2,7}]-oct-3-en-8-one or its related skeleton would seem to be of interest for several reasons. The formal cation (**G**) has an adjacent mercury moiety or bromine atom,

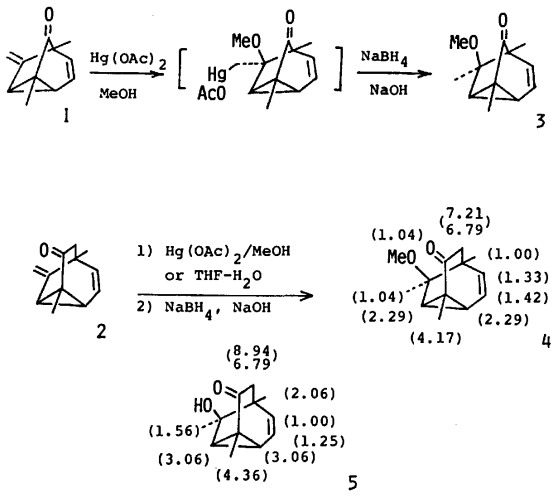


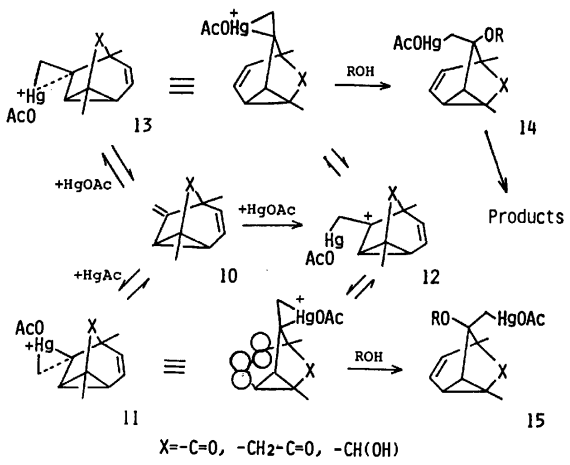
both of which can stabilize the cationic center by making mercurinium ions or bromonium ions similar to Type (**A**), and a cyclopropane ring which also can stabilize the cationic center by resonance electron donation in a bisected conformation.[15] Therefore, if the stabilizing effect of a cyclopropane to the cationic center by electron donation overcomes the formation of mercurinium ions[16] or bromonium ions, the rearrangement of (**G**) to the bicyclo[3.2.1]heptadienyl cation may compete with the solvent attack, as in the case of the behavior of the cation (**C**) or (**E**). From this point of view, the solvomercuration-demercuration, bromination, and related reactions of **1**[17] and 5,8-dimethyl-9-methylenetricyclo[3.3.1.0^{2,8}]non-3-en-7-one (**2**)[18] and their related compounds were investigated. The results will be presented in this paper.

Solvomercuration-demercuration Reaction

A solution of **1** in anhydrous methanol was treated with an equivalent amount of mercury(II) acetate. After the reaction mixture has been stirred for 30 min, it was treated with 3 mol dm^{-3} aqueous sodium hydroxide and then with sodium borohydride in 3 mol dm^{-3} aqueous sodium hydroxide, according to the reported procedure.[19] The usual workup afforded, in a 98% yield, *exo*-6-methoxy-1,5,6-trimethyltricyclo-[3.2.1.0^{2,7}]oct-3-en-8-one (**3**), the structure of which was identified by a comparison of the spectral data.[14] No *endo*-methoxy isomer was detected at all.

In order to examine the ring-size effect on the solvomercuration reaction, the reaction of **2** was carried out in a way similar to the case of **1**, and *exo*-9-methoxy-



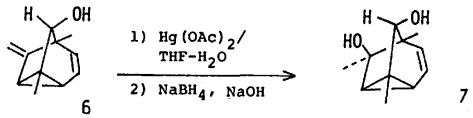


Scheme 1.

5,8,9-trimethyltricyclo[3.3.1.$0^{2,8}$]non-3-en-7-one (**4**) was thus obtained in a 93% yield. Similarly, the reaction of **2** with mercury(II) acetate in tetrahydrofuran (THF)–H_2O and a subsequent demercuration reaction afforded *exo*-9-hydroxy-5,8,9-trimethyltricyclo[3.3.1.$0^{2,8}$]non-3-en-7-one (**5**) in a 94% yield. The spectral data of **4** and **5** were consistent with the proposed structures (see Experimental). The stereochemistry of the methoxyl or the hydroxyl group of **4** or **5** was determined clearly by means of the pseudo-contact NMR spectra obtained by using $Eu(fod)_3$. The relative downfield shifts of δ's are given in parentheses in the structural formulae **4** and **5**.[21] The relatively small shifts of methoxyl and methyl at the 9-position of **4** suggest that the coordination of $Eu(fod)_3$ does not occur on methoxyl oxygen, but on the carbonyl oxygen, and that the methyl group on the 9-position is located anti to the carbonyl group. In the case of **5**, the coordination of $Eu(fod)_3$ seems to occur on the hydroxyl oxygen as well as the carbonyl oxygen. However, the relatively small shifts of the methyl group on the 9-position compared to that of the methyl group on the 8-position suggest that methyl group on the 9-position is *anti* to the carbonyl group.

Compounds **1** and **2** have an electron-withdrawing carbonyl function adjacent to the cyclopropane ring. This carbonyl group may possibly reduce the electron-donating character of the cyclopropane ring to the cationic center. Therefore, the solvomercuration-demercuration reaction of 1,5-dimethyl-6-methylenetricyclo[3.2.1.$0^{2,7}$]oct-3-en-8-*endo*-ol (**6**)[20] was investigated. When **6** was allowed to react with an equivalent amount of mercury(II) acetate in THF–H_2O (4/1) in a manner similar to that in the case of **1** or **2**, 1,5,6-trimethyltricyclo[3.2.1.$0^{2,7}$]oct-3-en-6-*exo*-,8-*endo*-diol (**7**) was obtained in a 95% yield. The spectral data of **7** are in good agreement with those of the known compounds, obtained by the sulfuric acid-catalyzed hydration of **6**.[22]

In all of the presented reactions, the solvent was



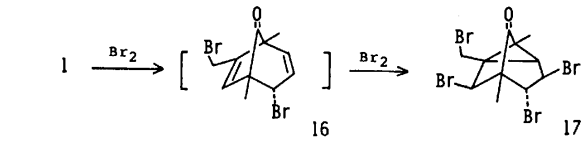
stereospecifically incorporated on the exomethylene group, and the original tricyclic skeleton did not undergo rearrangement. The ring size and the absence of the electron-withdrawing carbonyl group adjacent to the cyclopropane ring did not affect the reaction pathway. These experimental results suggest the formation of mercurinium ions such as **13**, as is shown in Scheme 1. The cationic center of a tricyclic skeleton such as that of **12** is stabilized by the formation of **13**. This fact seems to indicate that the stabilization of the cationic center of the cyclopropylcarbinyl cation by the mercury moiety adjacent to the cationic center is preferable over the resonance-electron donation of the cyclopropane ring in the present case. The initial addition of $^{+}$Hg(OAc)[23] to the exocyclic double bond seems to favor the formation of **11** over the formation of **13** because of the steric hindrance (*vide infra*). In the supposition of a *trans* addition mechanism, however, the *endo*-attack of the solvent molecule on **11** seems to be unfavorable because of the electronic repulsion of the π-electron lobe of the endocyclic double bond with the solvent molecule, as is shown in the structural formula, **11**.[22] Therefore, the mercuration-demercuration (equilibration) step or the possible short-lived intermediate of the opened cation, **12**, should participate in the present reactions, thereby causing the formation of **13**. In the mercurinium cation **13**, some stabilization by the coordination of the endocyclic double bond to the mercury atom would be expected,[24] the *trans* additions of the solvent molecule from the less hindered site then afford the products.[25]

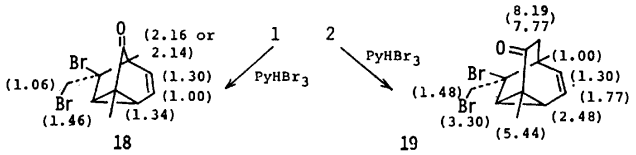
Bromination and Related Reaction

It has been reported that the bromination of **1** with an equivalent amount of bromine in dichloromethane at −78 °C gives an unstable dibromide, **16**, which then affords tricyclic tetrabromide, **17**, by further bromination.[26] In relation to this reaction and the solvomercuration-demercuration reaction described above, the addition reactions of pyridinium tribromide (PyH-Br_3), *N*-bromosuccinimide (NBS)–H_2O, and NBS–MeOH with **1** and **2** were also investigated.

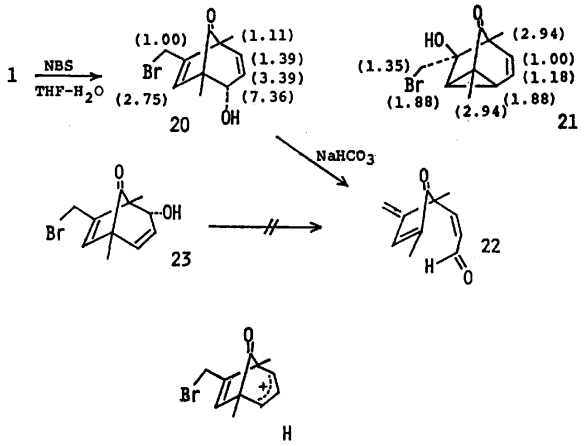
The reaction of **1** with an equivalent amount of $PyHBr_3$ in dichloromethane–carbon tetrachloride (1/1)

at 0 °C for 2 h, and the subsequent column chromatography on alumina afforded a dibromide, **18** (mp 92.9—93.5 °C) in a 77% yield. Similarly, the reaction of $PyHBr_3$ with a one-carbon-ring enlarged ketone, **2**, afforded **19** in a 55% yield. The NMR spectrum of the crude product of the reaction did not exhibit the presence of any other addition product. The dibromide **19** is an unstable oil and turns black even in the refrigerator. Therefore, a correct elemental analysis has not been obtained. However, the mass-spectral data of **18** and **19** clearly indicate that **18** and **19** are dibromides of **1** and **2** respectively. The spectral data of **18** and **19** clearly indicate that these bromides have skeletons similar to those of their starting ketones, **1** and **2** respectively, and that the bromination proceeds on the exomethylene group. The stereochemistry of the bromomethyl group of **18** and **19** was deduced from the pseudo-contact NMR spectra obtained by using $Eu(fod)_3$.[21] These results are completely different from that of **1** and molecular bromine, but are similar to the solvomercuration- demercuration reaction of **1** and **2** described above.





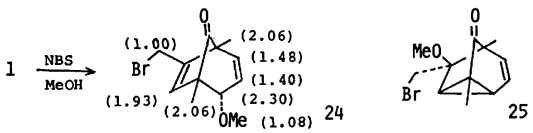
On the other hand, when **1** was allowed to react with NBS in THF–H_2O (4/1) at 25 °C for 30 min, a mixture of two products was obtained. This mixture was separated by TLC on silica gel to afford **20** and **21** in 34% and 17% yields respectively. The partial decomposition of **20** and **21** on the TLC plates causes the low yields of the products. The mass spectral data and the other spectral data indicates that **21** has a tricyclic skeleton and a bromine atom and that a hydroxyl group was incorporated on the exomethylene group. The stereochemistry of the hydroxyl group of **21** was assigned on the basis of the pseudo-contact NMR spectra.[21] Compound **20** is an unstable oil, and so a correct elemental analysis has not been made. However, satisfactory mass-spectral data were obtained. The NMR spectrum of **20** exhibited three protons of vinyl groups at δ 5.72 (dxd, J=10.2, 3.0 Hz), δ 6.26 (dxd, J=10.2, 1.8 Hz), δ 6.14 (s), in addition to two methyl groups at δ 1.25, δ 1.35, an allylic hydrogen at δ 4.07—4.21. The proton of the hydroxyl group has not been assigned distinctly. These NMR data are in accord with the proposed structure of **20**. Another structural possibility for **20** is **23**, however, **23** was discarded on the basis of the following chemical transformation. When **20** was treated with an aqueous sodium hydrogencarbonate solution in THF, **22** was obtained in a 90%



yield. The formation of **22** was considered to be the base induced Grob-type fragmentation of **20**.[7] Therefore, the structure of **20** was determined. The formation of **20** also indicates the absence of a bicyclic intermediate such as (H), from which both of **20** and **23** could be expected to be derived.

The pseudo-contact NMR spectra of **20** were obtained by using $Eu(fod)_3$.[21] The large value (7.36) of the allylic hydrogen indicates that the coordination of $Eu(fod)_3$ occurs on hydroxyl oxygen. The stereochemistry of the hydroxyl group is not elucidates here however, it must be *endo*, judging from the following experimental results.

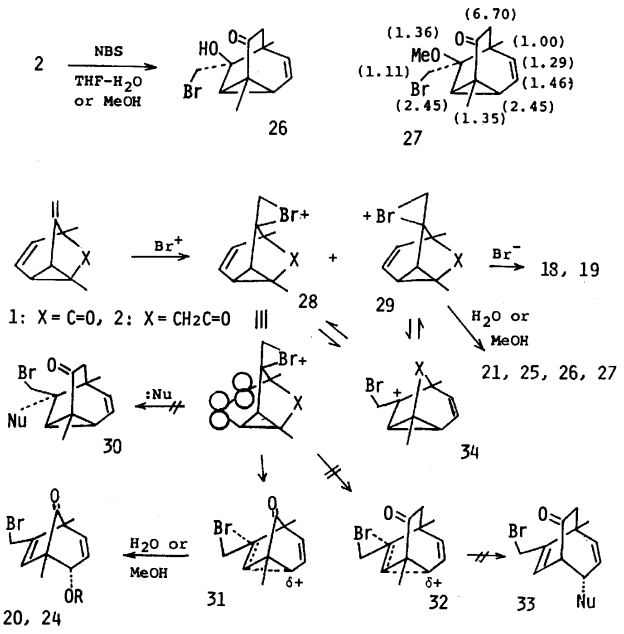
The reaction of **1** with NBS in anhydrous methanol afforded two products, **24** and **25**, in a ratio of 9/5 and in a 90% yield. This mixture was separated by TLC on silica gel. The two compounds, **24** and **25** gradually decomposed and turns black, therefore, satisfactory elemental analyses have not been obtained. However, satisfactory mass-spectral data were obtained. The other spectral data were consistent with the proposed



structures, **24** and **25**. The pseudo-contact NMR spectra of **24** was obtained by using $Eu(fod)_3$.[21] The small value of 1.08 for the methoxyl group suggest that coordination of $Eu(fod)_3$ occurs not on the methoxyl oxygen, but on the carbonyl oxygen. The large value of 2.30 for the allylic hydrogen suggests that the methoxyl group of **24** is located in the *endo* position. Therefore, the stereochemistry of the hydroxyl group of **20** must also be *endo* in this analogy. The orientation of the methoxyl group of **25** has not been determined directly because of the instability of **25**. However, it is probably *exo*, by analogy with the hydroxyl group of **21**.

In these reactions induced by NBS, 1,2-addition on the exomethylene group and 1,4-addition accompanying cyclopropane-ring opening took place with a stereospecific solvent incorporation. The 1,4-addition in the present case is very similar to the case of **1** with molecular bromine.[26]

On the other hand, the reaction of **2** with NBS–H_2O



Scheme 2.

or NBS–MeOH in a similar manner to that in the case of **1** afforded only a 1,2-addition product, **26** (mp 115—117 °C) or **27**, in a 47 or 83% yield respectively, after separation by TLC on silica gel. The structures of **26** and **27** were deduced by a comparison of the spectral data (see Experimental) with those of the related compounds which had been obtained by the solvomercuration-demercuration reaction described in this paper. The stereochemistry of the hydroxyl group or the methoxyl group was assigned on the basis of the pseudo-contact NMR spectra of **27**.[21]

The plausible reaction sequences are summarized in Scheme 2. It has been indicated that the tricyclo-[3.2.1.$0^{2,7}$]oct-3-en-6-yl cation (**C**) rearranges to the bicyclo[3.2.1]octa-3,6-dienyl cation (**D**) at a rate competing with the solvent (MeOH) attack.[13] Furthermore, in the acid-catalyzed reaction of **1**, it was indicated that the cation (**E**) was rearranged to bicyclic cation (**F**).[14] In the case of the reaction of **1**, the cyclopropane-ring opening took place to afford **20**, but not **23**. Therefore, the present experimental results seem to suggest that an initial attack of $^{+}$Br on the *exo*-methylene group affords a bromonium ion, such as **28** or **29**. From the product composition of **20**/**21** or **24**/**25**, the formation of **28** seems more likely than that of **29** because of the steric effect. The *exo*-attack of the nucleophile on **29** (X=–C=O) should afford **18** and **19** or **21**, **25**, **26**, and **27**. On the other hand, the attack of the nucleophile on a bromonium ion such as **28** to afford **30** must be hindered by the π-electron lobe of the endocyclic double bond presented in the structural formula **28**. In the case of **1**, however, a transition state such as **31** may be stabilized in a polar media, such as methanol or THF–H_2O.[28] The nucleophile may then be incorporated in the cyclopropane ring from the *endo* site to afford **20** and **24**. On the other hand, the one-carbon ring-enlarged **32** should be less strained than **31**, therefore, **33** should not be obtained. This fact seems to suggest that an equilibrium between such substances as **28** and **29** may be made possible by bromination-debromination *via* **1** and **2** or by possible short-lived, opened cation, **34**. The difference between the reactions of **1** with molecular bromine and with $PyHBr_3$ is not clear at the present stage.

Consequently, the present results suggest that bromine atoms adjacent to cyclopropylcarbinyl cation centers stabilize these cationic centers, as in the case of the solvomercuration reaction described above, and that the nucleophilic attacks on them are probably affected by the stereoelectronic factor existing in the molecular framework.

Experimental

The IR spectra were recorded with a Shimadzu IR-400 spectrometer. The mass spectra were obtained with a Hitachi RMU-60 mass spectrometer. The NMR spectra were recorded on a JEOL PS-100 high resolution spectrometer. The abbreviations "s, d, dxd, t, m, and br" in the NMR spectra denote "singlet, doublet, doublets of doublet, triplet, multiplet, and broad" respectively. All of the melting points are uncorrected.

Methoxymercuration-demercuration of ***1***. To a well stirred solution of **1** (320 mg, 2 mmol) in 2 cm^3 of anhydrous methanol, was added 689 mg (2 mmol) of mercury(II) acetate. After the reaction mixture had then been stirred for 30 min, 2 cm^3 of 3 mol dm^{-3} sodium hydroxide solution was added, followed by 34 mg (2 mmol) of sodium borohydride in 2 cm^3 of 3 mol dm^{-3} aqueous sodium hydroxide. To this mixture, was added 10 cm^3 of brine and 10 cm^3 of ether. It was then filtered. The filtrate was extracted with ether, and the ether extract was dried over sodium sulfate. After the removal of the solvent *in vacuo*, 376 mg (98%) of **3** was obtained: bp 107 °C/582.8 Pa.

Methoxymercuration-demercuration of ***2***. The reaction was carried out as has been described above using 174 mg (1 mmol) of **2**, 319 mg (1 mmol) of mercury(II) acetate, and 19 mg (0.5 mmol) of sodium borohydride. The product, **4**, was obtained in a 93% yield (191 mg): IR (CCl_4), 3027—2848, 1681, 1119, 1058 cm^{-1}; NMR (CCl_4), δ 0.98 (3H, s), 1.13 (3H, s), 1.19 (3H, s), 1.68 (1H, d, J=20.7 Hz), 1.85 (2H, m), 2.58 (1H, d, J=20.7 Hz), 3.26 (3H, s), 5.43 (1H, dxd, J=9.6, 1.5 Hz), 5.76 (1H, dxd, J=9.6, 4.8 Hz).

Oxime of ***4***. A solution of **4** (35 mg, 0.17 mmol), hydroxylamine hydrochloride (24 mg, 0.3 mmol), and sodium acetate (55 mg, 0.67 mmol) in 1 cm^3 of ethanol was refluxed overnight. The reaction mixture was poured into 5 cm^3 of water and then extracted with ether. The combined organic portion was dried over sodium sulfate, filtered, and evaporated *in vacuo*. The residue was crystallized from ethanol to give 24 mg (72%) of an oxime, **8**: mp 134—135 °C; IR (CCl_4), 3516—3064, 2947, 1688, 1114, 947 cm^{-1}; NMR ($CDCl_3$), δ 1.00 (3H, s), 1.12 (3H, s), 1.30 (3H, s), 1.60—1.82 (1H, m), 1.70 (1H, d, J=6.4 Hz), 2.41 (1H, d, J=18.0 Hz), 2.56 (1H, d, J=18.0 Hz), 3.32 (3H, s), 5.42 (1H, dxd, J=9.2, 1.0 Hz), 5.79 (1H, dxd, J=9.2, 3.2 Hz), 9.36 (1H, br s); MS, *m/e* (rel intensity), 221 (M^+, 12), 115 (100). Found: C, 70.69; H, 8.69; N, 6.25%. Calcd for $C_{13}H_{19}O_2N$: C, 70.56; H, 8.65, N, 6.33%.

Hydroxymercuration-demercuration of ***2***. The reaction was carried out as has been described above using 174 mg (1 mmol) of **2**, 319 mg (1 mmol) of mercury(II) acetate, and 19 mg (0.5 mmol) of sodium borohydride. The product, **5**, was obtained in 94% (194 mg) yield: IR (CCl_4), 3450, 1678, 1098, 1045

cm^{-1}; NMR ($CDCl_3$), δ 1.03 (3H, s), 1.25 (6H, s), 1.72 (1H, d, J=8.0 Hz), 1.75—2.00 (1H, m), 2.02 (1H, d, J=18.7 Hz), 2.60 (1H, d, J=18.7 Hz), 3.10 (1H, br s), 5.47 (1H, dxd, J=9.5, 2.0 Hz), 5.75 (1H, dxd, J=9.5, 6.0 Hz). An oxime of **5** was prepared in a manner similar to that used in the case of **4**. The oxime, **9**, exhibited the following physical data: mp 213—215 °C; MS, *m/e* (rel intensity), 207 (M^+, 26), 101 (100). Found: C, 69.95; H, 8.38; N, 6.81%. Calcd for $C_{12}H_{17}O_2N$: C, 69.54; H, 8.27; N, 6.76%.

Hydroxymercuration-demercuration of ***6***. To a stirred solution of **1** (162 mg, 1 mmol) in 5 cm^3 of THF–H_2O (4/1), was added 345 mg (1 mmol) of mercury(II) acetate. After the reaction mixture had then been stirred for 30 min, 2 cm^3 of 3 mol dm^{-3} aqueous sodium hydroxide was added, followed by 17 mg (0.5 mmol) of sodium borohydride in 1 cm^3 of 3 mol dm^{-3} sodium hydroxide. To this reaction mixture, was subsequently added 10 cm^3 of brine and 10 cm^3 of ether. It was then filtered. The filtrate was extracted with ether, and the extract was dried over sodium sulfate. After the removal of the solvent *in vacuo*, 160 mg (94%) of **7** was obtained.

Reaction of ***1*** *with Pyridinium Tribromide.* To a stirred solution of pyridinium tribromide ($PyHBr_3$) (320 mg, 1 mmol) in carbon tetrachloride (3 cm^3), was added **1** (160 mg, 1 mmol) in dichloromethane (3 cm^3) at 0 °C. After this reaction mixture had then been stirred for 2 h, the precipitated pyridinium bromide was filtered off. The filtrate was concentrated under reduced pressure, and the resulting residue was chromatographed on alumina (10 g), using benzene–hexane (1/1) as the eluent, to give 246 mg (77%) of **18**: mp 92.5—93.5 °C (from CCl_4); IR (CCl_4), 1735 cm^{-1}; NMR (CCl_4), δ 1.25 (3H, s), 1.30 (3H, s), 2.10 (1H, m), 2.52 (1H, d, J=7.0 Hz), 3.57 (1H, d, J=11.0 Hz), 3.73 (1H, d, J=11.0 Hz), 5.27 (1H, dxd, J=8.0, 2.0 Hz), 6.06 (1H, dxd, J=8.0, 5.0 Hz); MS, *m/e* (rel intensity), 322 (M^+, 2), 320 (M^+, 2), 119 (100), 117 (95). Found: C, 41.14; H, 3.58%. Calcd for $C_{11}H_{12}OBr_2$: C, 41.29; H, 3.78%.

Reaction of ***2*** *with Pyridinium Tribromide.* The reaction was carried out as has been described above using 320 mg (1 mmol) of $PyHBr_3$ and 174 mg (1 mmol) of **2**. After the reaction mixture had been stirred for 2.5 h, it was worked up as described above to give 183 mg (55%) of **19**: oil, IR (film), 1690 cm^{-1}; NMR (CCl_4), δ 1.24 (3H, s), 1.27 (3H, s), 1.90—2.10 (1H, m), 2.12 (1H, d, J=18.0 Hz), 2.58 (1H, d, J=8.0 Hz), 2.74 (1H, d, J=18.0 Hz), 5.65 (1H, dxd, J=9.0, 2.0 Hz), 5.93 (1H, dxd, J=9.0, 5.0 Hz); MS, *m/e* (rel intensity), 336 (M^+, 3), 334 (M^+, 8), 332 (M^+, 4), 199 (97), 197 (100). Found: C, 44.35; H, 4.23%. Calcd for $C_{12}H_{14}OBr_2$: C, 43.15; H, 4.22%.

Reaction of ***1*** *with NBS in THF–H_2O.* To a stirred solution of **1** (160 mg, 1 mmol) in 2.5 cm^3 of THF–H_2O (4/1). was added NBS (178 mg, 1 mmol). After the reaction mixture has been stirred for 30 min, it was extracted with ether. The ether extract was dried over sodium sulfate and evaporated under reduced pressure to give 205 mg (80%) of a mixture of **20** and **21** in a ratio of 9/5, as determined by means of the NMR spectrum. This mixture was separated by TLC on silica gel, using benzene–dichloromethane (1/1) as the eluent. The first band from the TLC plates afforded 44 mg (17%) of **21**: mp 120—121 °C (from benzene); IR ($CHCl_3$), 3573, 1739 cm^{-1}; NMR ($CDCl_3$), δ 1.17 (3H, s), 1.34 (3H, s), 2.08—2.25 (2H, m), 2.25—2.60 (1H, br s), 3.61 (1H, d, J=10.8 Hz), 3.81 (1H, d, J=10.8 Hz), 5.50 (1H, dxd, J=7.8, 3.0 Hz), 6.21 (1H, dxd, J=7.8, 4.5 Hz); MS, *m/e* (rel intensity), 258 (M^+, 5), 256 (M^+, 2), 177 (100). Found: C, 51.21; H, 4.97%. Calcd for $C_{11}H_{13}O_2Br$: C, 51.38; H, 5.10%.

The second band from the TLC plates gave 88 mg (34%) of **20**: oil; NMR (CCl_4), δ 1.25 (3H, s), 1.35 (3H, s), 3.02—3.35 (1H, br s), 4.07—4.21 (2H, br s), 5.72 (1H, dxd, J=10.2, 3.0 Hz), 6.14 (1H, s), 6.26 (1H, dxd, J=10.2, 1.8 Hz).

Reaction of ***20*** *with Sodium Hydrogencarbonate.* A solution of **20** (129 mg, 0.5 mmol) in 3 cm^3 of methanol and 3 cm^3 of saturated aqueous sodium hydrogencarbonate was stirred for 5 h. The reaction mixture was then extracted with ether, and the combined ether extract was dried over sodium sulfate. After the removal of the solvent, 158 mg (90%) of **22** was obtained as an oil; IR (film), 1710, 1679 cm^{-1}; NMR (CCl_4), δ 1.47 (3H, s), 1.92 (3H, br s), 5.13 (2H, s), 5.73 (1H, dxd, J=12.0, 8.0 Hz), 6.32 (1H, d, J=12.0 Hz), 7.40 (1H, br s), 9.66 (1H, d, J=8.0 Hz); MS, *m/e* (rel intensity), 176 (M^+, 100). Found: C, 74.58; H, 6.81%. Calcd for $C_{11}H_{12}O_2$: C, 74.97; H, 6.86%.

Reaction of ***1*** *with NBS in Methanol.* To a stirred solution of **1** (160 mg, 1 mmol) in 4 cm^3 of methanol, was added 214 mg (1.2 mmol) of NBS. After this mixture had been stirred for 2 h at the ambient temperature, it was extracted with ether. The ether extract was dried over sodium sulfate, the subsequent evaporation of the ether afforded 244 mg (90%) of a mixture of **24** and **25** in a ratio of 9/5, as determined by the study of the NMR spectrum. This mixture was separated by TLC on silica gel, using benzene–dichloromethane (1/1) as the eluent. The first band from the TLC plates gave **24**: IR (CCl_4), 1765 cm^{-1}, NMR (CCl_4), δ 1.22 (3H, s), 1.29 (3H, s), 3.50 (3H, s), 3.84 (1H, m), 4.22 (2H, br s), 6.17 (1H, s), 5.92 (1H, dxd, J=10.8, 2.7 Hz), 6.37 (1H, dxd, J=10.8, 2.7 Hz); MS, *m/e* (rel intensity), 272 (M^+, 1), 270 (M^+, 1), 191 (100), 159 (99). Found: C, 52.14; H, 5.71%. Calcd for $C_{12}H_{15}O_2Br$: C, 53.16; H, 5.58%.

The second band from the TLC plates contained **25** and decomposed material. This portion could not be purified because of its instability: NMR (CCl_4), δ 1.10 (3H, s), 1.19 (3H, s), 2.03—2.23 (2H, m), 3.45 (1H, d, J=10.5 Hz), 3.68 (1H, d, J=10.5 Hz), 5.54 (1H, dxd, J=8.4, 2.7 Hz), 6.18 (1H, dxd, J=8.4, 4.5 Hz).

Reaction of ***2*** *with NBS in THF–H_2O.* To a solution of **2** (174 mg, 1 mmol) in 2.5 cm^3 of THF–H_2O (4/1), was added NBS (214 mg, 1.2 mmol). After the mixture had been stirred for 1 h, it was extracted with ether. The ether extract was dried over sodium sulfate and evaporated under reduced pressure to give 190 mg, (70%) of a solid, which was then recrystallized from CCl_4 to give colorless crystals of **26**: mp 115—117 °C; IR (CCl_4), 3612—3210, 1693 cm^{-1}; NMR (CCl_4), δ 1.14 (3H, s), 1.31 (3H, s), 1.99 (1H, d, J=18.6 Hz), 1.79—1.99 (1H, m), 2.19 (1H, d, J=7.5 Hz), 2.80 (1H, d, J=18.6 Hz), 2.63—3.12 (1H, br s), 3.60 (1H, d, J=9.9 Hz), 3.83 (1H, d, J=9.9 Hz), 5.69 (1H, dxd, J=9.6, 1.5 Hz), 6.12 (1H, dxd, J=9.6, 6.0 Hz); MS, *m/e* (rel intensity), 272 (M^+, 17), 270 (M^+, 18), 149 (100), 105 (98). Found: C, 53.65; H, 5.61%. Calcd for $C_{12}H_{15}O_2Br$: C, 53.16; H, 5.58%.

Reaction of ***2*** *with NBS–Methanol.* To a stirred solution of **2** (174 mg, 1 mmol) in 4 cm^3 of methanol, was added 214 mg (1.2 mmol) of NBS. After this mixture had been stirred for 1 h at the ambient temperature, it was extracted with ether. The ether extract was dried over sodium sulfate and the subsequent evaporation of the ether afforded 240 mg (83%) of **27**: oil; IR (CCl_4), 1688 cm^{-1}; NMR (CCl_4), δ 1.10 (3H, s), 1.36 (3H, s), 1.92 (1H, d, J=18.6 Hz), 2.67 (1H, d, J=18.6 Hz), 2.42 (1H, d, J=8.4 Hz), 1.91—2.14 (1H, m), 3.60 (1H, d, J=10.5 Hz), 3.72 (3H, s), 3.86 (1H, d, J=10.5 Hz), 5.79 (1H, dxd, J=9.4, 1.5 Hz), 6.25 (1H, dxd, J=9.3, 6.6 Hz); MS, *m/e* (rel intensity), 286 (M^+, 4), 284 (M^+, 4), 205 (100), 177 (99). Found: C, 51.02; H, 5.64%. Calcd for $C_{13}H_{17}O_2Br$: C, 54.75; H, 6.01%.

(Received July 31, 1981)

A computer program ("PROSEQ2") was designed for determining the amino acid sequence of polypeptides from molecular weights and *N*-terminal amino acid residues of two or more sets of peptide mixtures obtained from polypeptides by two or more specific cleavage methods, together with 3-phenyl-2-thiohydantoin derivatives of amino acids released from two or more sets of peptide mixtures by Edman-degradation. Computation of sequences of several polypeptides using this program is described.

Gas chromatography/mass spectrometry is in use for sequencing a peptide mixture obtained from a polypeptide or protein by partial hydrolysis followed by conversion into volatile derivatives. Numerous experimental data thus obtained were handled with computer programs[2,3] capable of deducing the sequence of the original polypeptide or protein.

Recently[4-6] we reported a new method for sequencing a peptide mixture by combination of Edman-degradation and field-desorption mass spectrometry. This method does not involve any extensive chemical processing to convert peptides into volatile derivatives. The principle of this method is to measure mass values of individual "underivatized" peptides in a mixture and their degraded peptide fragments by field-desorption mass spectrometry. *N*-Terminal amino acid residues of individual peptides in a mixture can be determined by calculation of possible mass differences before and after degradation. Amino acid sequences of individual peptides in a mixture can be determined by repeating this operation. If two or more sets of peptide mixtures are to be produced from a polypeptide or protein by two or more specific cleavage methods, the amino acid sequence of the polypeptide or protein can be determined, by use of the computer program "PROSEQ1,"[7] from the molecular weights and *N*-terminal partial amino acid sequences which have been obtained by the above procedure for the peptides present in the resulting peptide mixtures. This method does not necessarily require determination of complete sequences or major portions of sequences for individual peptides.

After attempting sequence determinations on various polypeptides by this new method, we have succeeded in designing a new program which necessarily requires no amino acid sequences of constituent peptides and which can determine the sequence from molecular weights and *N*-terminal amino acid residues of constituent peptides in two or more sets of peptide mixtures and 3-phenyl-2-thiohydantoin derivatives of amino acids (denoted as PTH-amino acids) released in each cycle of Edman-degradation.

In this paper, we describe some applications of the new program (named "PROSEQ2") to determining amino acid sequences for several polypeptides; sequencing of a polypeptide of unknown structure[8] is included.

Methods

The computer program "PROSEQ2" described here is written in FORTRAN, its flow chart being outlined in Fig. 1. The single letter abbreviations for amino acid residues presented by Eck and Dayhoff[9] are adopted as input and output words. The ACOS 700 computer in the Crystallographic Research Center (Institute for Protein Research, Osaka University) was used for calculation.

The analytical data used for the calculation are as follows:

1) The amino acid composition of the sample polypeptide or protein as integer values, as obtained from an amino acid analysis of acid hydrolysate.

2) The *N*- and *C*-terminal amino acid residues of the sample polypeptide or protein, as obtained by well known methods.

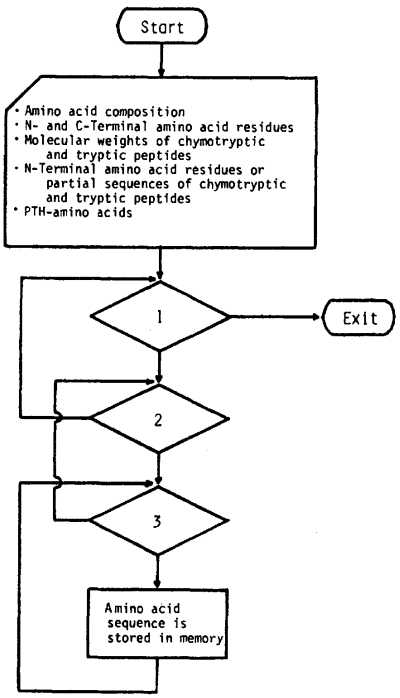

Fig. 1. Flow chart of the computer program "PROSEQ2." The numerals correspond to those given in the explanation of the program in the text.

3) The molecular weights and *N*-terminal amino acid residues of the individual peptides in two or more sets of peptide mixtures prepared from the sample polypeptide or protein by specific cleavage methods, as determined as described in Refs. 4 and 6. Peptide mixtures are degraded by the Edman method[10] with modifications[11] favorable for mass measurements. Mass spectra are obtained with a second-order double focusing mass spectrometer[12] with a mono field-desorption ion source.

4) The kind and compositional ratio, as integer values within some limits between possible maxima and minima, of the PTH–amino acids released from two or more sets of peptide mixtures in each cycle of Edman-degradation and analyzed by high-performance liquid chromatography (HPLC).[13]

In this paper, we use analytical data on peptides obtained from polypeptides by specific cleavage with chymotrypsin and trypsin. Amino acid sequences of polypeptides or proteins are sought by the computer in the following order:

1) Amino acid combinations in chymotryptic peptides are examined in the amino acid composition of the sample polypeptide or protein, and each of the combinations is simultaneously compared with the PTH–amino acids released in each cycle of degradation.

2) Tryptic peptides are aligned in a given order from the *N*-terminus. The tryptic peptide placed at the *N*-terminus has the same *N*-terminal amino acid residue as that of the sample polypeptide or protein. In this case, no amino acid combinations in each tryptic peptide are examined.

3) Chymotryptic peptides are aligned by comparison with the alignment of tryptic peptides from the *N*-terminal position. In this step, the following procedures are carried out simultaneously:

i) Comparison of the molecular weight from the *N*-terminus to the chymotryptic peptide in question with that from the *N*-terminus to the overlapping tryptic peptide.

ii) Collation of the known *N*-terminal amino acid residue of the chymotryptic peptide in question to those of tryptic peptides or the PTH–amino acids released from tryptic peptides.

iii) Collation of the possible amino acid residues in chymotryptic peptides to the PTH–amino acids released from both chymotryptic and tryptic peptides.

iv) Examination of possible similarities of the known *N*-terminal amino acid residues of tryptic peptides with unknown sequences of chymotryptic peptides and also with the PTH–amino acids released from chymotryptic peptides.

In these processes, data on chymotryptic and tryptic peptides are of course interchangeable.

Results and Discussion

In a previous paper,[7] we showed that amino acid sequences of polypeptides or proteins can be deduced from the molecular weights and *N*-terminal partial sequences of their constituent peptides by the computer program "PROSEQ1." By this program, complete sequences or major portions of amino acid sequences of polypeptides or proteins can be determined from sequence

Fig. 3. Computer out-put sequence of glucagon, sought from the molecular weights, the *N*-terminal sequences of two amino acid residues and the kind and ratio of PTH–amino acids released by Edman-degradation of the chymotryptic and tryptic peptides, respectively.

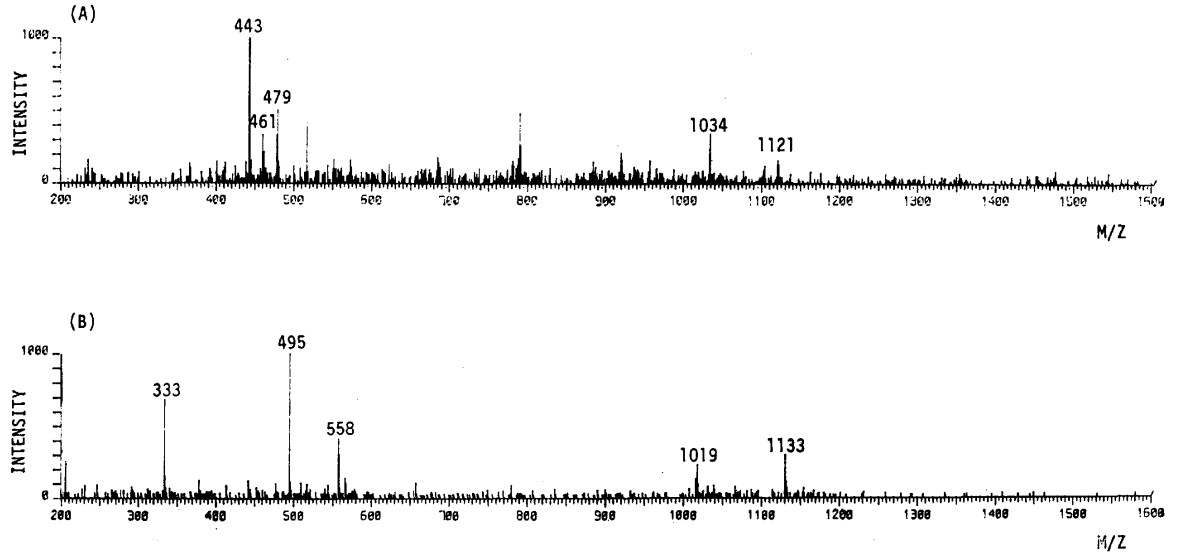

Fig. 4 Field-desorption mass spectra of the chymotryptic (A) and tryptic (B) peptides of human β-endorphin. The spectra were measured with a JMS-DX300 double focusing mass spectrometer equipped with a JMA-2000 mass data analysis system.

information on constituent peptides, but with increasing difficulty with increase in the number of amino acid residues. Therefore, increasing numbers of mass measurements on degraded peptide fragments are necessary to obtain sufficient information on the amino acid sequence of constituent peptides for deducing almost complete amino acid sequences. The present program uses information obtained on PTH–amino acids liberated from peptide mixtures by Edman-degradation in place of that on amino acid sequences of constituent peptides, because using HPLC makes it easy to determine PTH–amino acids liberated from peptide mixtures by successive Edman-degradation.

Figures 2, 3, 5, and 6 show computer output sequences of some polypeptides. The first example (Fig. 2) illustrates the sequence of glucagon, which has been deduced from the molecular weights and *N*-terminal amino acid residues of the chymotryptic and tryptic peptides (Table 1) and the PTH–amino acids released in each cycle of Edman-degradation (Table 2). The output sequences have exchangeable residues (Ser and Asp) at the 8th and 9th positions from the *N*-terminus. This is because PTH–Ser (S) and PTH–Asp (D) were liberated together in the 2nd and 3rd cycles of degradation from the chymotryptic peptides, and the ratio of serine to other amino acids was inaccurate, because

Fig. 6. Computer out-put sequence of the *N*-terminal BrCN fragment of *Streptomyces erythraeus* lysozyme,[14] sought from the molecular weights, the *N*-terminal amino acid residues and the kind and ratio of PTH-amino acids released by Edman-degradation of the chymotryptic and tryptic peptides, respectively.

the recovery of PTH-Ser is generally poor in Edman-degradation. The output sequences suggest that if sequences of two amino acid residues from the *N*-terminus of each peptide are determined as described previously,[4-6] either of the two sequences output is determined. In fact, one sequence was output as illustrated in Fig. 3.

The second example is a sequence determination for human β-endorphin. The mass spectra of the tryptic and chymotryptic peptides are shown in Fig. 4. While the tryptic peptides gave five intense mass peaks of peptides, as expected from the content of basic amino acid residues (4 Lys residues), the chymotryptic peptides gave a number of mass peaks as $[M+H]^+$ and/or $[M+2H]^{2+}$ of expected peptides together with weak mass peaks of peptides, resulting from unspecific cleavage

under the conditions used. The recoveries of the PTH-amino acids liberated from the tryptic and chymotryptic peptides by Edman-degradation are summarized in Table 3. In the method described previously,[4,6] the molecular weights and *N*-terminal amino acid residues of the tryptic and chymotryptic peptides were determined from their mass values and the PTH-amino acids released in the first-cycle of Edman-degradation, as described in Table 1. Figure 5 shows the computer output sequence of human β-endorphin, based on the data described above. The results suggest that the

sequence can be completed by the molecular weights and *N*-terminal amino acid residues of the tryptic and chymotryptic peptides, respectively, and also that the PTH-amino acids released from the second to third cycle of Edman-degradation of the tryptic peptides and from the second to fourth cycle of Edman-degradation of the chymotryptic peptides, although these were rather complicated as shown in Table 3.

Figure 6 shows the amino acid sequence of the *N*-terminal BrCN fragment of *Streptomyces erythraeus* lysozyme,[14] which consists of 55 amino acid residues. The sequence was deduced from the molecular weights, the *N*-terminal amino acid residues of the tryptic and chymotryptic peptides, and the ratios of PTH-amino acids liberated until the 7th step of Edman-degradation. U and W were put in as many data as possible, because

TABLE 4. RECOVERIES (nmol) OF PTH–AMINO ACIDS RELEASED FROM CHYMOTRYPTIC (1.0 mg) AND TRYPTIC (0.7 mg) PEPTIDES OF THE *N*-TERMINAL BrCN FRAGMENT OF *Streptomyces erythraeus* LYSOZYME BY EDMAN-DEGRADATION

the former derivative (PTH–Homoser) was not identified and the latter residue (PTH–Trp) was not recovered in good yield under our experimental conditions.[11] The results suggest that the whole sequence was determined except for 4 amino acid residues from the 8th to 11th position from the *N*-terminus and was completed by 4 further cycles of Edman-degradation of the tryptic peptides, as described elsewhere.[8,11] In the calculation reported in this paper, peptides containing a Lys residue[4,6] were used for sequence calculation, and these are shown by asterisks (*) in Figs. 2—5, although the data were not used in the previous paper.[8] This improvement greatly reduced the number of possible combinations of amino acid residues in the peptides with consequent shortening of calculation time.

Thus, the computation by the program described here is very effective for determining amino acid sequences, because all possible candidates of sequences can be searched from a little, simple information. In the current experimental procedure, the recovery of PTH–amino acids from a peptide mixture becomes rather more complicated with increase in the number of peptides in the mixture, because the recovery of PTH–amino acids from smaller or hydrophobic peptides is generally poorer than that from larger or hydrophilic peptides, *etc.* However, the improvement of Edman-degradation increases the usefulness of the present procedure.

(Received May 25, 1981)

The removal of aluminium cations from Y type zeolite, faujasite, was studied by means of three methods of treatment, *i.e.*, acetic acid–sodium acetate buffer treatment, acetate buffer–Na_2H_2EDTA treatment and H_4EDTA treatment. It was confirmed from the results that the reagent for dealumination of faujasite should have two functions, *i.e.* weakly acidic and chelating ability with aluminium cations. When more than 23 aluminium cations were extracted from 53 aluminium atoms in a unit cell, lattice was seriously destroyed. But the analysis of the adsorption isotherms suggested that more than 66% of α-cages remained even in a nearly amorphous sample obtained after dealumination as far as 75%. The differential heat of immersion of the dealuminated Y type zeolite in water showed that the acid strength of the surface increased slightly by dealumination.

Since Kerr[1-3] showed that the tetracoordinate aluminum atoms of faujasite were readily extracted by ethylenediaminetetraacetic acid (H_4EDTA) treatment or by the ion exchange in deep bed method followed by extraction with a sodium hydroxide solution, dealumination of faujasite has been reported by may investigators.[1-12] Beaumont and Barthomeuf[4-6] showed that aluminium atoms could be removed from faujasite with organic solvent such as acetylacetone. They also examined to treat faujasite with diethylenetriaminepeantaacetic acid and 1,2-cyclohexanediamine-*N,N,N',N'*-tetraacetic acid. Miecznikowski *et al.*[7] showed the dealumination of faujasite by the treatment with aqueous tartaric acid solution. Garwood *et al.*[8] reported the partial dealumination of faujasite by chromium salt solution.

The stability of the crystallographic structure of faujasite through dealumination process was mainly related to the silica/alimina molar ratio of starting zeolite. Kerr[2] indicated that the silica/alumina molar ratio should be more than 5.0. Tsutsumi *et al.*[9] attempted dealumination of faujasite whose silica/alumina molar ratio was 4.8 and noted that about 50% of the aluminium atoms was removed by H_4EDTA treatment successfully without collapse of the crystallographic structure. Kerr *et al.*[10] recently reported the technique to remove more than 80% of tetracoordinate aluminium atoms from Y type zeolite retaining 60—70% of the crystallinity. Sherzer[11] produced highly siliceous faujasite with silica/alumina molar ratio over 100 from the starting material whose silica/alumina molar ratio was 5.2.

These reports put focuses on the high crystalline structure retained through the dealumination processes. But, when the starting materials with the silica/alumina molar ratio smaller than 4.8 are dealuminated, the loss of crystallinity is inevitable. This study concerns the amorphous structure of dealuminated faujasite and its properties which were examined by X-ray diffraction analysis, SEM observation, N_2 adsorption, and the measurement of heat of immersion into water.

Experimental

Y type zeolite ($NaY_{4.73}$) used in this work was obtained from Shokubai Kasei Co. Ltd., whose silica/alumina molar ratio

a) V is the amount of refluxing water poured into the flask at a time.

was 4.73. As the first experiment, $NaY_{4.73}$ (10 g) was mixed only with acetate buffer solution at pH 0.47—4.05 (100 cm^3) in a 300 cm^3 eggplant type flask, and heated at the boiling temperature of the slurry for 20 h. In the second treatment, chelating agent, ten grams of ethylenediamineteraacetic acid disodium salt (Na_2H_2EDTA), was added to the acetate buffer solution to check the role of the chelating agent on the dealumination. The third H_4EDTA treatment was performed with a modified Soxhlet extractor containing 20 g of faujasite and 200 cm^3 of distilled water in the flask of extractor and different amount of H_4EDTA in the extraction room. The conditions of preparing the samples were summarized in Table 1. The amount of refluxing water poured at a time into the flask was controlled by using glass beads between the filter paper thimble and the extraction room to decrease the volume of the extraction room.

The crystallinity of the dealuminated sample was studied by X-ray diffraction analysis. The lattice constant was determined from the interplaner spacing of (533) and (642) with reference to anatase as a standard. The crystallite size was determined from the X-ray line-profile of (533) using silicon as a standard. The appearence of pseudomorphic particles of the sample were observed by MINI SEM of Hitachi-Akashi Co., Ltd. Nitrogen adsorption was measured at −196 °C with Orr Surface-Area Pore-Volume Analyzer 2100D. Heat of immersion was measured in a twin isothermal type calorimeter of Tokyo Rico Co., Ltd. Before measurement, each sample was pretreated at 400 °C under 10^{-5} Torr† for 5 h. The total weight of sample, quartz wool stopper, glass ampule and glass manifold which connected with a vacuum line and a water vapor chamber through glass cocks and joints was measured before and after the pretreatment. Then the different amount of water vapor was injected to the ampule and was adsorbed on the sample. After this adsorption, the amount of water adsorbed was weighed.

Results and Discussion

Dealumination of Faujasite. The properties of the dealuminated Y type zeolite were comparatively studied.

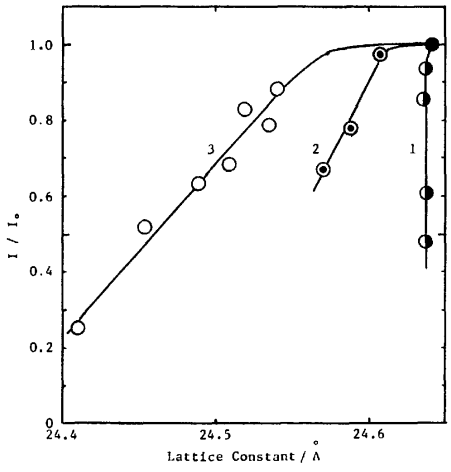

Fig. 1. Correlation between lattice constant and I/I_0.

† 1 Torr≈133.32 Pa.

Figure 1 shows the correlation between unit cell constants and the average intensities of (111), (533), and (642) peaks of the dealuminated samples treated with the different three methods. The lattice of faujasite is known to contract through dealumination,[9,12] but the treatment with acetic acid–sodium acetate solution brought about only the collapse of the crystallographic structure without successful dealumination. When Na_2H_2EDTA was added to the acetate buffer solution, a little amount of aluminium was extracted. Na_2H_2-EDTA, as described by Kerr,[2] could not react with sodium zeolite by itself. By the treatment with H_4-EDTA, about 40% of tetracoordinate aluminium of $NaY_{4.73}$ was removed retaining 80% of the crystallinity. These results coincided with the mechanism of dealumination reaction proposed by Kerr.[2] That is, the first step of dealumination reaction is decationization by weak acid, forming basic aluminium hydroxide which is neutralized by Brönsted acid sites, and the second step is the formation of a chelate, NaAlEDTA. The second step of the reaction was not attained by the treatment with acetate buffer solution. The removal of aluminium cations by the chelating agent seems to ensure the partial migration of silicon atoms into the vacant sites by aluminium removal.[12] But this silicon migration did not cause the destruction of the structure of zeolite in H_4EDTA treatment. The limit of dealumination keeping high crystallinity seems to depend on the silica/alumina molar ratio in the starting material.[2,6] The silica/alumina molar ratio of the sample used by Kerr[2] was 5.25, and 37 among 53 aluminium atoms per unit cell were extracted. Barthomeuf *et al.*[6] succeeded to remove 29 aluminium atoms from a unit cell containing 56 aluminium atoms. In our study, the silica/alumina molar ratio of the starting material was 4.73, and 23 among 57 aluminium atoms were extracted with the retention of high crystallinity. The probability of collapse of lattice due to the removal of aluminium atoms seems to increase steeply with the increasing number of the aluminium atoms per unit cell of the starting material. Dealumination and formation of amorphous part from Y type zeolite progressed without noticeable destruction of the shape and the reduction of the size of pseudomorphic particles (Fig. 2). Figure 3 shows the correlation between the ratio of dealumination and the apparent crystallite size determined from the X-ray line-profile of (533). The diameter of pseudomorphic particles of the starting material were between 1000—8000 Å, and their average crystallite size was about 2200 Å. It means that a pseudomorphic particle consists of one or several crystallites. Probably, almost all of the crystallites could be contracted with the dealuminating solution containing H_4EDTA. The process of the formation of amorphous state by dealumination and destruction of the crystal structure of zeolite is schematically described by a model in Fig. 4-a, and is further simplified to the model illustrated in Fig. 4-b. The calculated crystallite sizes from this model are shown in Fig. 3 with dotted line. In this model, $r/r_0=(I/I_0)$,[3] where r and r_0 are the crystallite sizes and I and I_0 are the X-ray diffraction intensities of the dealuminated and original particles,

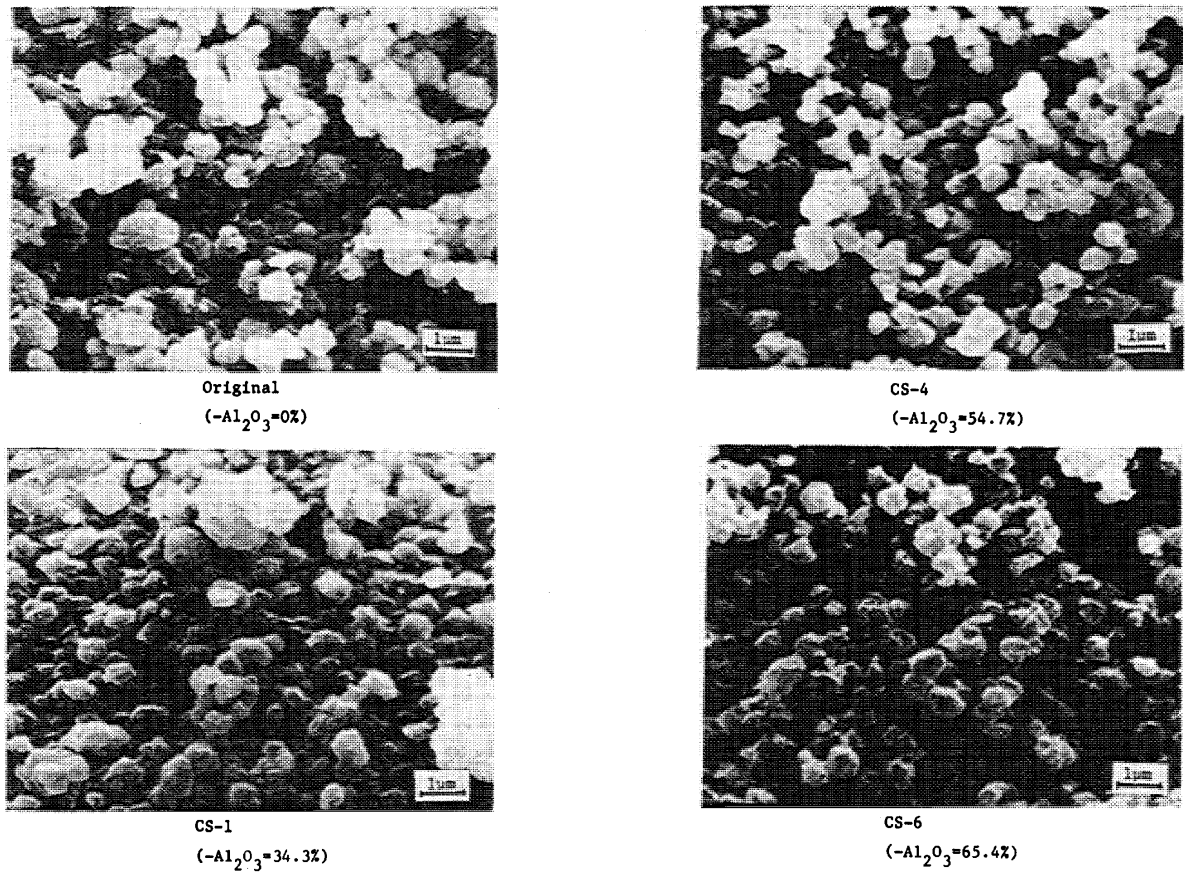

Fig. 2. Electron micrographs of dealuminated Y type zeolite.

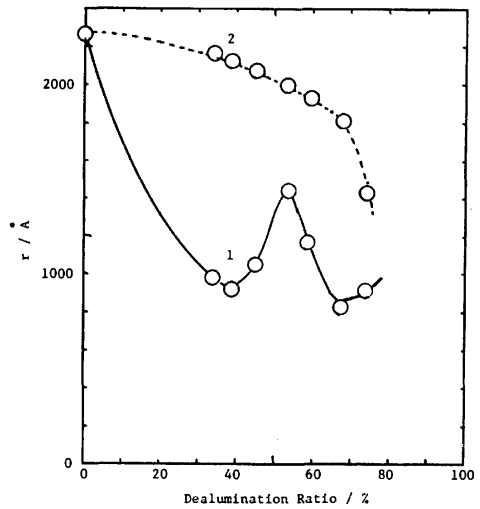

Fig. 3. Changes of apparent crystallite sizes by dealumination.
1: Calculated from line profile of (533), 2: calculated from following equation.
$r/r_0=(I/I_0)^{1/3}$, r,r_0=crystallite sizes of dealuminated and original zeolite, respectively.

respectively. From this calculation, crystallite size of the sample whose dealumination ratio was about 65% should have decreased to 80% of that of the starting material. However, the calculated values did not agree with those observed. Another unexpected phenomenon is the increase of crystallite size after first decrease.

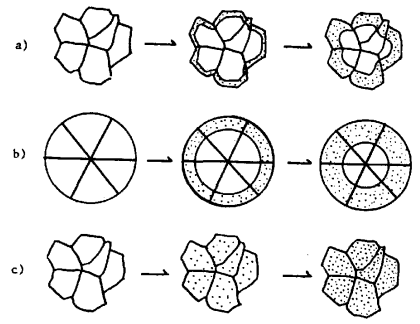

Fig. 4. Models of dealumination and formation of amorphous state.
a): Formation of amorphous state, b): approximation of amorphous state for calculation, c): dealumination.

Since the lattice constant is affected by the silica/alumina molar ratio as described in Fig. 1, the difference of silica/alumina molar ratio in the different crystallites would cause the increase of the half width of X-ray diffraction peak. The first decrease of apparent crystaleite size would be attributed to the heterogeneity of the silica/alumina molar ratio. After the partial dealumination, some part became more siliceous and had extended stability in acid media. Then, the unreacted part of zeolite would be attacked by H_4EDTA. In such a manner, Y type zeolite would be dealuminated nearly homogeneously (Fig. 4-c).

On the assumption that the formation of amorphous state had only negligible effect on the decrease of

a) CS-0 means the starting zeolite.

crystallite size, the heterogeneity of the silica/alumina molar ratio of the sample was calculated from the increase of half width of (533). The correlation between the silica/alumina molar ratio of faujasite crystal and the unit cell constant was previously reported by Tsutsumi *et al.*[9] On the basis of their results, the silica/alumina molar ratio of the crystalline fraction, and that of the solid phase from the results of chemical analysis, are shown in Table 2. This table shows that in the range of 0 to 38.1% of dealumination, the silica/alumina ratios of faujasite and of the solid phase were similar. The silica/alumina ratio of faujasite in the sample of CS-3 was lower than that of CS-2. In the preparation of CS-1-7, the extent of dealumination was controlled by reaction time and reaction rate. For dealumination to higher extent, the reaction rate must be kept slow to prevent the lattice from destruction, and for this purpose, the more amount of refluxing water was used. In the preparation of CS-3, however, the same amount of refluxing water with and more amount of H_4EDTA than those of CS-2 were used, resulting in the similar reaction time. The rapid dealumination seems to lead to the different silica/alumina molar ratios in faujasite fraction and amorphous fraction. As for CS-6 and CS-7, the lattice constant to be referred to has not been reported. The sample dealuminated at more than 50% of tetracoordinate aluminium have slightly different silica/alumina molar ratios in the faujasite crystal fraction and amorphous fraction. Aluminium atoms in the amorphous state would be extracted easily compared to those in faujasite crystal. The dispersion of silica/alumina molar ratio of faujasite was in the range of 0.9 to 1.8, and the difference of silica/alumina molar ratio between crystalline part and solid phase was in the range of 0 to 2.4.

Changes in Pore Size Distribution. The external forms of particles were not destroyed by acidic H_4EDTA treatment, but their crystallinity decreased to 25%. The change of the pore size distribution due to the treatment was studied next by means of nitrogen adsorption at −196 °C. Figures, 5, 6, and 7 show the pore size distribution curves obtained from the analysis of nitrogen adsorption isotherms in Cranston-Inkley method.[13] For samples CS-1 to CS-4, a large peak of the distribution curves were observed in the range of 12 to 50 Å diameter, and the pores with the larger diameter than 100 Å was negligible. CS-2 has the almost similar distribution curve to those of CS-1, 3, and 4. The peak maxima of these curves are in very narrow range of 14 to 18 Å, and the peak shapes are similar to that of the starting material, CS-0. For CS-5 and CS-6, the pore size distributed to 100—150 Å, and the several peaks lie around 12—120 Å. The pore size seems to distribute over a broader range with the progress of dealumination. But in case of CS-7, the peak shape of the distribution curve is similar to those of CS-1 to CS-4, though the pore size distribution extend to about 100 Å. This would be the result of very slow dealumination, because CS-7 was prepared by the treatment using one third of refluxing water poured at a time than the other samples and the dealumination took 26 d.

The micro pore volume was evaluated by deducing the volume of transitional pores with the diameter of 12—300 Å from the total volume of pores observed as the volume of adsorbed nitrogen at relative pressure of 0.931. At this relative pressure, all pores smaller than 300 Å have been filled by capillary condensation. The wall of pores larger than 300 Å and the external

surface were assumed to be negligible. The result are shown in Fig. 8. In these calculations, the specific gravity of nitrogen adsorbed on the solid surface at −196 °C assumed to be that of liquid nitrogen at same temperature. For CS-0, the volume of micro pores is about 0.281 cm³/g. M. M. Dubinin[14] calculated the total void volume of sodium X type zeolite from the known crystal structure to be 0.322 cm³/g. The void volume of faujasite consists of two kinds of cavities, *i.e.* α-cages and β-cages. The ratio of void volume of α-cages to that of β-cages in a unit cell is 6700 Å³/1200 Å³. So, the void volume of α-cages calculated is about 0.271 cm³/g, and this value is slightly lower than the observed micro pore volume of CS-0. Breck *et al.*[15] reported the void volume of α-cages of X type zeolite to be 0.291 cm³/g, which was determined from the adsorption of water. This value is slightly larger than the micro pore volume of CS-0. From these values, it would be considered that the micro pore volume consists mainly of α-cages, or most of α-cages would be evaluated as the micro pores, and the change of micro pore volume would be affected mainly by the decrease of α-cages through dealumination. By dealumination, the volume of α-cages seems to decrease slightly, but even in CS-6 and CS-7, the volume only decreased to 58.1 and 66.2% of the original volume, respectively. The rate of dealumination seems to have an influence on the retention of α-cages. The slow rate of dealumination changes the shapes of α-cages partly, but not the pore size essentially.

Calorimetric Study. To make clear the properties of remaining cationic sites, new structural hydroxyl groups and transitional pores of zeolite after dealumination, immersional heats into water of the dealuminated samples were examined. The results are shown in Fig. 9. The initial immersional heat seems to be related to the acidity at the remaining cationic sites. The

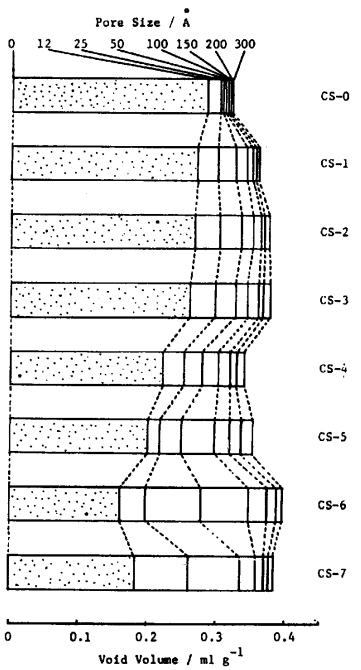

Fig. 8. Void volume of dealuminated Y type zeolite calculated from the amount of N_2 adsorbed using Cranston-Inkley method.

initial heat of immersion on the starting material was in the range of 31.8 to 32.6 kJ/mol, and those on the dealuminated samples were slightly larger, *i.e.* 32.6—33.9 kJ/mol. The amounts of water adsorbed in the range of 31.8 to 33.9 kJ/mol of immersional heat seem to correspond to the amounts of water adsorbed on the cationic sites of the samples, and were 3.7, 3.0, and 1.8 mmol/g for the starting material, CS-1 and CS-5, respectively. The amounts of cationic sites calculated from sodium contents of these samples were 4.0, 3.0, and 1.8 mmol/g, and the amounts of cationic sites

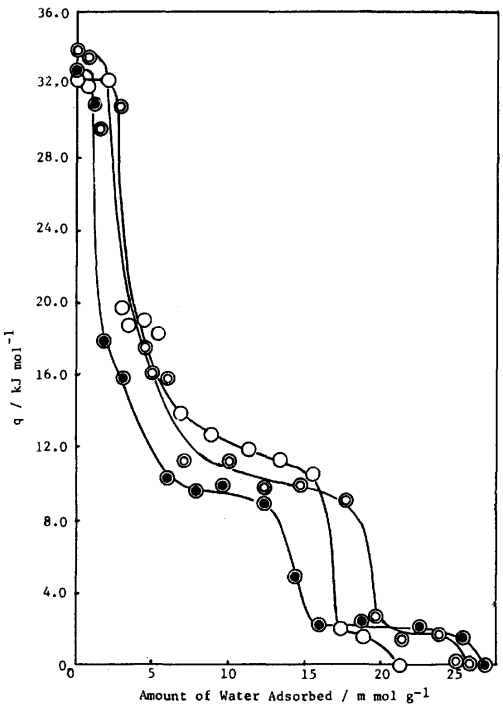

Fig. 9. Differential heat of immersion of dealuminated Y type zeolite.
○: CS-0, ◎: CD-1, ⊙: CS-5.

calculated from aluminium contents were 4.5, 3.2, and 2.2 mmol/g, respectively. After immersion of one water molecule per one sodium ion, the immersional heats of the samples into water decreased sharply to about 11.7 kJ/mol. Each curve of differential heat of immersion has two shoulders at about 10.0—12.5 kJ/mol and at about 1.55—2.51 kJ/mol. The first shoulders seem to be due to the immersion of water molecules in α-cages, partially modified α-cages and β-cages. On the assumption that the volumes of micro pores smaller than 12 Å are nearly equal to the volumes of α-cages and partially modified α-cages of the samples, the amounts of water with different heat of immersion were compared with the pore volumes calculated by Cranston-Inkley method. As for CS-1 and CS-5, it was assumed that the destruction of α-cages accompanied the equivalent collapse of β-cages, and the ratio of the volume of α-cages to that of β-cages in the dealuminated sample was similar to that of the starting material, *i.e.* 6700 Å^3/1200 Å^3, because each silicon or aluminium atom at T site in faujasite belongs to β-cage as well as α-cage. The volume of micro pores smaller than 12 Å in the starting material was 0.281 cm^3/g, and this value corresponds to 0.331 cm^3/g for α-cages and β-cages. The amount of water immersed with the heat larger than 8.37 kJ/mol was about 0.32—0.35 cm^3/g assuming the density of immersed water is the same with that of water at 25 °C. For CS-1, the volume of micro pores smaller than 12 Å was about 0.270 cm^3/g, which leads 0.318 cm^3/g for both cages. The total volume of α-cages, β-cages, and the transitional pores smaller than 25 Å in diameter was about 0.352 cm^3/g which accorded with the amount of water immersed with the heat larger than 8.37 kJ/mol, 0.35—0.39 cm^3/g. For CS-5, the micro pore volume was 0.200 cm^3/g which means 0.235 cm^3/g for both cages. The total volume of pores smaller than 25 Å was 0.254 cm^3/g and the amount of water immersed with the heat larger than 8.37 kJ/mol was about 0.25—0.29 cm^3/g. The electrostatic field of the cationic sites of the starting material seems to affected only the water molecules immersed in both cages, even though in the dealuminated samples the electrostatic field of remaining cationic sites seems to affect the water molecules immersed in the pores smaller than 25 Å. The transitional pores in the starting material would be produced by coagulation of pseudomorphic particles and there would be no cationic site on the wall of transitional pore, but the transitional pores in the dealuminated samples were formed by the partial destruction of α-cages and have some remaining cationic sites and dealuminated sites on the wall. Second shoulder at about 1.55—2.51 kJ/mol seems to correspond to the water molecules immersed in the transitional pores larger than 25 Å. The average immersional heat of water in the large transitional pores seems not to be affected by the dealumination.

(Received November 17, 1980)

Kinetics of oxidation of thiosulfate to tetrathionate by *trans*-dihydroxotetraoxoosmate(VIII) (Os(VIII)) and by hexacyanoferrate(III) in the catalytic presence of Os(VIII) have been studied in aqueous alkaline media. The observed pseudo-first-order rate constants for disappearance of Os(VIII) in the Os(VIII)–$S_2O_3^{2-}$ system (k_{obsd}), and those for disappearance of hexacyanoferrate(III) in the Os(VIII)-catalysed $Fe(CN)_6^{3-}$–$S_2O_3^{2-}$ system (k_{cat}) conform, respectively, to Eqs. A and B:

$$k_{obsd}=k_3K_{Os}K_2[S_2O_3^{2-}](1+K_{Os}[OH^-]+K_{Os}K_2[S_2O_3^{2-}])^{-1}, \quad (A)$$

$$k_{cat}=k_6K_{Os}K_2[Os(VIII)][OH^-][S_2O_3^{2-}](1+K_{Os}K_2[S_2O_3^{2-}])^{-1}, \quad (B)$$

where K_{Os} is the stability constant of *trans*-dihydroxotetraoxoosmate(VIII) in aqueous alkaline media, K_2 and k_3 are the formation and decomposition constant of the intermediate complex **1**, and k_6 refers to the rate constant of electron-transfer from **1** to hexacyanoferrate(III). The values of K_{Os} and K_2, as obtained from spectrophotometric titrations and stopped-flow spectrophotometry, respectively, are 19.5 ± 3 dm^3 mol^{-1} and 5.58 ± 0.13; the computed values from kinetic data of K_{Os}, K_2, and k_3 at 30 °C and $\mu=0.32$ mol dm^{-3}, and that of k_6 at 35 °C and $\mu=0.32$ mol dm^{-3} are 22.5 ± 2 dm^3 mol^{-1}, 6.12 ± 0.5, $(3.32\pm0.3)\times10^{-1}$ dm^3 mol^{-1} s^{-1}, and $(3.31\pm0.3)\times10^{-2}$ dm^6 mol^{-2} s^{-1}, respectively. Possible mechanisms for electron-transfer are discussed in terms of an initial equilibrium interaction between Os(VIII) and $S_2O_3^{2-}$ forming an intermediate complex $[OsO_4(OH)(S_2O_3)^{3-}]$ (**1**) followed by (a) a rate-determining decomposition of **1**, with concomitant electron-transfer, in the Os(VIII)–$S_2O_3^{2-}$ system, and (b) a rate-determining outersphere electron-transfer from **1** to hexacyanoferrate(III) in the Os(VIII)-catalyzed $Fe(CN)_6^{3-}$–$S_2O_3^{2-}$ system.

The oxidation of thiosulfate by various metallic oxidants has been shown to proceed either through the intermediacy of metal-thiosulfato complexes[1-5] formed prior to electron-transfer or without a change in the inner co-ordination sphere of the metal.[6-9] We have observed[7] that the oxidation of thiosulfate is zero-order in hexacyanoferrate(III) over a pH range 6.03—12.3, the main reaction being the spontaneous decomposition of thiosulfate. Similar observations were made by Howlett and Wedzicha[6] who reported that the initial 5% reaction of hexacyanoferrate(III) with thiosulfate in the presence of H_2(edta) and acetate was of zero-order in hexacyanoferrate(III). In the presence of 'Osmium Tetraoxide' and an 8—10% aqueous solution of potassium hydroxide, hexacyanoferrate(III) was found to oxidise thiosulfate to sulfate,[10] but the details of the reaction were not presented. In the present study, we are reporting the *trans*-dihydroxotetraoxoosmate(VIII)-catalyzed hexacyanoferrate(III) oxidation of thiosulfate to tetrathionate. Unlike earlier reports on the Os(VIII)-catalyzed electron-transfer reactions, the present kinetics exhibit a first-order dependence in hexacyanoferrate(III).

An understanding of the extent to which Os(VIII) can function as an electron-transfer agent is crucial to the interpretation of kinetics and mechanism of Os(VIII)-catalyzed electron-transfer reactions. Quite a few organic functions have been directly oxidized by Os(VIII); however, no study appears to have been carried out on the direct oxidation of inorganic compounds by Os(VIII). Keeping this in view, the electron-transfer in the Os(VIII)–$S_2O_3^{2-}$ system has been studied as an extension by stopped-flow spectrophotometry.

Experimental

Materials and Methods. All the chemicals used were of Analar grade, and the solutions were prepared using doubly distilled water exclusively. A requisite amount of Os(VIII) solution from the stock (prepared by dissolving 'OsO_4' of Johnson-Matthey in a weakly aqueous alkaline solution, estimated by iodometry[11] and stored in a cool dark place) was taken (as such for the direct oxidation by Os(VIII) or along with hexacyanoferrate(III) solution in the case of catalyzed reactions), made up, thermostated and mixed with the thiosulfate solution at appropriate pH and ionic strength. The ionic strength (μ) of the medium was adjusted by the addition of a required amount of the supporting electrolyte, sodium sulfate. The pH of the medium (±0.01), maintained by the addition of suitable amounts of standard aqueous buffers or carbonate-free hydroxide, as the case may be, was recorded by a Systronics 335 digital pH meter both before and after the reaction; the hydroxide concentrations were calculated from the mean recorded pH after correcting for the ionic strength effect of the medium. The Os(VIII)-catalyzed hexacyanoferrate(III) oxidation reactions were performed by mixing 1 ml aliquots of reactant solutions in a 1 cm-quartz cell by means of semimicro syringes. The course of the reactions was monitored for the decrease in absorbance of hexacyanoferrate(III), continuously as a function of time, at 420 nm (ε_{420} 9.8×10^2 dm^3 mol^{-1} cm^{-1}), in a Pye Unicam SP 1800 spectrophotometer maintained at a desired temperature (±0.1 °C). An extended absorbance scale was used for experiments in which lower concentration of the oxidant was taken.

The electronic spectrum of an aqueous alkaline solution of *trans*-$OsO_4(OH)_2^{2-}$, abbreviated as Os(VIII), showed characteristic bands at 316 nm (ε_{316} 500 $dm^3\ mol^{-1}\ cm^{-1}$) and 247 nm (ε_{247} 690 $dm^3\ mol^{-1}\ cm^{-1}$); earlier workers[11] did not report this observation. In visible region, the solution absorbed strongly around 390 nm, the absorption decreasing with increasing wavelength but without any characteristic maximum in the 390—750 nm region. Tetrathionate, the oxidation product of thiosulfate, absorbed significantly around 247 nm. The kinetic runs for the Os(VIII)-$S_2O_3^{2-}$ system were, therefore, followed by monitoring the disappearance of $OsO_4(OH)_2^{2-}$ at 316 nm in an Aminco stopped-flow spectrophotometer with quartz windows and a 1 cm-light path coupled to a Beckman D. U. monochromator. The nominal mixing time for this spectrophotometer is 0.2 ms. For every entry, at least five replicate runs were performed.

The pseudo-first-order rate constants were computed by least-squares analysis of the expression: $-\ln[(A_t-A_\infty)/(A_o-A_\infty)]=k_{obsd}t$, where A_t, A_o, and A_∞, respectively, represent the absorbance of the reactant at time 't', the initial absorbance and the absorbance at effective infinite time.

For experiments where $[Substrate]_o$—$[Oxidant]_o$, the second-order rate constants (k') were calculated by the usual method; for these experiments the first-order rate constants were calculated from the expression: First-order-rate constant=k' $[Substrate]_o$.

Computations were done by a D. C. M. Data Products minicomputer Microsystem 1121. The self-decomposition of thiosulfate in air was found to be negligible in the conditions employed.

Stoichiometry. The stoichiometric experiments were performed in the presence of 7.8×10^{-7} mol dm^{-3} of Os(VIII) and in the absence of sodium sulfate. The experiments for the stoichiometric runs were carried out at 35 °C under the conditions of $[S_2O_3^{2-}]_o \geq [Fe(CN)_6^{3-}]_o$; for higher concentrations of hexacyanoferrate(III), under the conditions of $[S_2O_3^{2-}]_o \geq [Fe(CN)_6^{3-}]_o$, the runs were carried out at 35 °C and at pH 11.3 till the reaction, with respect to hexacyanoferrate(III), was complete (Table 1). The unconsumed $[S_2O_3^{2-}]_\infty$ was determined iodimetrically. Tests for tetrathionate were done following an earlier procedure.[12] The observed stoichiometric ratio ($\Delta[Fe(CN)_6^{3-}]/\Delta[S_2O_3^{2-}]$) of 0.98±0.02 is in accord with the overall Eq. 1:

$$2Fe(CN)_6^{3-} + 2S_2O_3^{2-} \longrightarrow 2Fe(CN)_6^{4-} + S_4O_6^{2-}. \quad (1)$$

In the oxidation of thiosulfate in aqueous medium at pH 11.3 and 35 °C, 1 mol of Os(VIII) consumed 1.96± 0.03 mol of thiosulfate (Table 1) conforming to the formation of tetrathionate.

$$OsO_4(OH)_2^{2-} + 2S_2O_3^{2-} + 2H_2O \longrightarrow OsO_2(OH)_4^{2-} + S_4O_6^{2-} + 2OH^-. \quad (2)$$

On allowing the final reaction solution to stand for 24 h at room temperature (≈35 °C), it was observed that about 80% of the originally consumed thiosulfate was being reformed. Back-formation of thiosulfate in reaction mixtures of completed thiosulfate oxidation has been reported earlier and explained[1a] to be due to the hydrolysis of tetrathionate. The reformation is, however, very slow and does not complicate the kinetics studied.

Results and Discussion

Electron-transfer in the Os(VIII)-$S_2O_3^{2-}$ System. In weakly alkaline solutions, OsO_4 appears to exist in the form of $OsO_3(OH)_3^-$ which combines with OH^- to yield the reactive form of Os(VIII), *trans*-$OsO_4(OH)_2^{2-}$. This is in accord with the findings of Sauerbrum and Sandell[13] on the dissociation of osmic acid.

$$OsO_3(OH)_3^- + OH^- \overset{K}{\rightleftharpoons} OsO_4(OH)_2^{2-} + H_2O,\ K/[H_2O] = K_{Os}. \quad (3)$$

(K_{Os}=24±4 $dm^3\ mol^{-1}$ at 25 °C and μ=1.0 mol dm^{-3}, ΔH and ΔS associated with this equilibrium are 24±1 kJ mol^{-1} and −146+6 J $K^{-1}\ mol^{-1}$).[11]

Applying Benesi-Hildebrand equation[14] for the determination of equilibrium constant and ε,

$$[Os(VIII)]_o A^{-1} = (K\varepsilon[OH^-])^{-1} + \varepsilon^{-1} \text{ at } [Os(VIII)]_o < [OH^-], \quad (4)$$

where $[Os(VIII)]_o$ is the total analytical concentration

of Os(VIII) fixed by iodometry, and A and ε respectively refer to the absorbance and molar absorptivity of the complex at 316 nm, the values of K_{Os} and ε_{316} at 30 °C and μ=0.32 mol dm^{-3} have been obtained by a weighted non-linear least-squares programme of the absorbance data at various [Os(VIII)]$_o$ and [OH$^-$] ([Os(VIII)]$_o$ 0.6×10^{-4}—20.4×10^{-4} mol dm^{-3}, [OH$^-$] 1×10^{-3}—40.1×10^{-3} mol dm^{-3}) as 19.5±3 dm^3 mol^{-1} and 500±20 dm^3 mol^{-1} cm^{-1}, respectively; these values should be independent of the concentrations of Os(VIII) and OH$^-$ employed. The K_{Os} value of this work is in good agreement with that obtained earlier.[11]

The Os(VIII)–$S_2O_3^{2-}$ reaction exhibits a first-order dependence on [Os(VIII)] in the range 0.45×10^{-4}—9.06×10^{-4} mol dm^{-3}. At 316 nm, first there is an abrupt increase in the absorbance ($t_{1/2}\approx125$ ms) followed by a subsequent slower step where the absorbance decreases. The first step probably represents a fast formation of an intermediate complex and is followed by a slower decay. The k_{obsd} value (corresponding to the decrease in absorbance) at a constant [$S_2O_3^{2-}$]$_o$ ($=5.0\times10^{-2}$ mol dm^{-3}) registers a marginal increase with the increase in [OH$^-$] from 6.18×10^{-8} mol dm^{-3} to 1.0×10^{-2} mol dm^{-3}, remains almost unchanged till [OH$^-$]$=3.06\times10^{-2}$ mol dm^{-3}, and decreases significantly at much higher [OH$^-$]. The k_{obsd} is found to increase almost linearly with increasing [$S_2O_3^{2-}$] for [$S_2O_3^{2-}$]$_o=1.0\times10^{-4}$—10×10^{-3} mol dm^{-3}; however, beyond [$S_2O_3^{2-}$] of 50×10^{-3} mol dm^{-3}, the k_{obsd} varies only slightly by about 5% for an almost two-fold increase in [$S_2O_3^{2-}$]. The rate expression for the reduction of Os(VIII) should, therefore, include a distinct [$S_2O_3^{2-}$]- dependent term, getting saturated at higher [$S_2O_3^{2-}$].

The k_{obsd} increases with an increase in ionic strength of the medium. It does not appreciably change in the range 25—45 °C. Added acrylonitrile retards the rate, but no polymerisation could be observed.

Rate Law and Mechanism: The preliminary kinetic results suggest that the mechanism of reduction of Os(VIII) by $S_2O_3^{2-}$ involves incorporation of a thiosulfato-ligand into the inner-coordination sphere of Os(VIII) prior to an electron-transfer step.

$$OsO_4(OH)_2^{2-} + S_2O_3^{2-} \overset{K_2}{\rightleftharpoons} [OsO_4(OH)(S_2O_3)^{3-}] + OH^-, \quad (5)$$

$$[OsO_4(OH)(S_2O_3)^{3-}] + H_2O \xrightarrow{k_3} OsO_4(OH)(H_2O)^{2-} + S_2O_3^-, \quad (6)$$

$$OsO_4(OH)(H_2O)^{2-} + S_2O_3^{2-} + H_2O \xrightarrow[\text{fast}]{k_4} OsO_2(OH)_4^{2-} + OH^- + S_2O_3^-, \quad (7)$$

$$2S_2O_3^- \xrightarrow[\text{fast}]{k_5} S_4O_6^{2-}. \quad (8)$$

Since $S_2O_3^{2-}$ is an effective one-electron reducing agent, an Os(VII) species will probably be produced which will further get reduced rapidly to Os(VI) with another $S_2O_3^{2-}$. Os(VII) is known in solution[16] and has been prepared in solid state.[17] Such a one-electron change can take place only with a high activation enthalpy because two very unstable species are formed (Eq. 6) and that the subsequent step, Os(VII)$+e^- \rightarrow$ Os(VI), can proceed without obstacle.

Consequently, the mechanism of the reaction would result in the rate law (Eq. 9), on the basis of Eqs. 3, 5—8, and on applying a steady-state treatment to the intermediate complex [$OsO_4(OH)(S_2O_3)^{3-}$] (**1**)

$$-\frac{d[Os(VIII)]}{dt} = \frac{k_3K_{Os}K_2[Os(VIII)]_T[S_2O_3^{2-}]}{1+K_{Os}[OH^-]+K_{Os}K_2[S_2O_3^{2-}]}, \quad (9)$$

where the total analytical [Os(VIII)]$_T$=[$OsO_3(OH)_3^-$] +[$OsO_4(OH)_2^{2-}$]+[$OsO_4(OH)(S_2O_3)^{3-}$]. If as a first approximation, a reasonable assumption is made that at the low [OH$^-$] employed, K_{Os}[OH$^-$]$\ll$(1+$K_{Os}\times K_2$[$S_2O_3^{2-}$]), Eq. 10 is obtained.

$$-\frac{d[Os(VIII)]}{dt} = \frac{k_3K_{Os}K_2[Os(VIII)]_T[S_2O_3^{2-}]}{1+K_{Os}K_2[S_2O_3^{2-}]}, \quad (10)$$

$$k_{obsd} = k_3K_{Os}K_2[S_2O_3^{2-}](1+K_{Os}K_2[S_2O_3^{2-}])^{-1}, \quad (11)$$

which on rearrangement becomes

$$(k_{obsd})^{-1} = (k_3)^{-1} + (k_3K_{Os}K_2)^{-1}([S_2O_3^{2-}])^{-1}. \quad (12)$$

Eq. 12 predicts that $(k_{obsd})^{-1}$ should be a linear function of $([S_2O_3^{2-}])^{-1}$. From the intercept and slope of this least-squares plot (Fig. 1), using the experimentally determined K_{Os} value, the k_3 and K_2 values have been computed respectively as $(3.32\pm0.3)\times10^{-1}$ dm^3 mol^{-1} s^{-1} and 6.12±0.5 at 30 °C and 0.32 mol dm^{-3} of ionic strength. The computed K_2 is very close to the average value (5.58) of the observed constant pertaining to the first abrupt increase in the absorbance at 316 nm. Also the agreement of the k_{calcd} (Eq. 12) values obtained (employing the estimated values of k_3, K_2, and the experimental value of K_{Os}) with the experimentally determined k_{obsd} is in support of the postulated mechanism.

Eq. 9 can be rearranged to Eq. 13:

$$(k_{obsd})^{-1} = (1+K_2[S_2O_3^{2-}]K_{Os})(k_3K_2[S_2O_3^{2-}]K_{Os})^{-1} + [OH^-](k_3K_2[S_2O_3^{2-}])^{-1}. \quad (13)$$

At [$S_2O_3^{2-}$]$_o=5.0\times10^{-2}$ mol dm^{-3}, employing the value of k_3 computed earlier, K_{Os} has been calculated from the least-squares slope and intercept of the $(k_{obsd})^{-1}$ *vs.* [OH$^-$] plot as 22.5±2 at 30 °C and μ= 0.32 mol dm^{-3}. This value is quite close to that experimentally determined. There is also agreement of the k_{calcd} (Eq. 13) values with the k_{obsd} values (Table 2).

Supporting evidences from kinetics or otherwise,

have been well presented for the formation of intermediate complexes between metal ions and thiosulfate.[1-5] In the Os(VIII)–$S_2O_3^{2-}$ system also, the kinetic evidences and the abrupt increase in absorbance at 316 nm, as soon as Os(VIII) and thiosulfate are mixed, are suggestive of the inner-sphere substitution of a hydroxo-ligand by a thiosulfato-ligand in the *trans*-$OsO_4(OH)_2^{2-}$.

The attack by the sulfur-end rather than by the oxygen-end of thiosulfate is consistent[18,4] with the value of the formation constant of the intermediate complex $[OsO_4(OH)(S_2O_3)^{3-}]$. Spectrophotometric titrations could not be performed because of the rapidity of the change in absorbance of Os(VIII) and also due to the considerable absorption of tetrathionate between 240—290 nm. However, we got indications for the formation of a 1:1 intermediate complex involving Os(VIII) and thiosulfate by the following method. Zero-time absorbance at 316 nm were obtained by extrapolation for different [Os(VIII)]: [$S_2O_3^{2-}$] ratios in isomolar and non-isomolar mixtures. When the increase in the absorbance difference, $+\Delta A$, was plotted against the mole-fraction of Os(VIII), a maximum in ΔA was observed at the mole-fraction of Os(VIII)=0.5.

It is more rational to assume that an electron-transfer from thiosulfate to Os(VIII) has taken place during the substitution. The activated complex could then offer, at the same time, the lowest energy barrier to substitution and also to electron-transfer (Eq. 5), since the orbitals of the central osmium are disturbed (Table 2, foot note for activation parameters pertaining to the first abrupt increase in absorbance at 316 nm); the process starts as a substitution and continues with a one-electron transfer. Since *trans*-dihydroxotetraoxoosmate(VIII) ends up finally as *trans*-dioxotetrahydroxoosmate(VI), an equatorial attack by the outer-sulfur of thiosulfate on osmium is likely,[15b] leading to a fair degree of displacement of the axial hydroxo-ligand.

Os(VIII)-catalyzed $Fe(CN)_6^{3-}$–$S_2O_3^{2-}$ Electron-transfer. Studies on Os(VIII)-catalysed oxidation reactions of various inorganic[11] and organic substrates[19] by hexacyanoferrate(III) are increasingly becoming useful probes in the elucidation of the nature of oscillatory catalysis of Os(VIII). In these studies and in numerous other studies of Os(VIII)-catalyzed oxidations by other oxidants,[20,21] Os(VIII) is involved in an initial equilibrium formation of an intermediate Os(VIII)-substrate complex which breaks down rate-determingly to the products and Os(VI); the Os(VI) formed is oxidised rapidly to Os(VIII) by the main oxidant, resulting in zero-order kinetics with respect to the main oxidant.

In contrast to the earlier observations, the Os(VIII)-catalysed hexacyanoferrate(III) oxidation of thiosulfate is first-order in hexacyanoferrate(III) over the $[Fe(CN)_6^{3-}]_o$ range 0.1×10^{-4}—20.1×10^{-4} mol dm^{-3}. The observation is interesting as it is probably the first report of a main oxidant exhibiting first-order kinetics in the presence of an oscillatory catalyst.

At constant ionic strength and constant $[Na^+]$ ($[Na^+]\gg[K^+]$), the k_{cat} value linearly increases with the increase in [$S_2O_3^{2-}$], [Os(VIII)], or [OH^-] for their respective ranges of concentration: 1.0×10^{-5}—2.46×10^{-3}, 3.9×10^{-7}—97.3×10^{-7}, and 1.0×10^{-5}—50.5×10^{-3} mol dm^{-3} (Fig. 2). Also the good reproducibility of the k_{cat} value obtained by following the first-order disappearance of thiosulfate at 217 nm (in a representative run) with that obtained by monitoring the disappearance of hexacyanoferrate(III), shows that the rate of disappearance of thiosulfate is the same as that of hexacyanoferrate(III). There is a retardation in the rate in the presence of added mannitol, acrylonitrile or hexacyanoferrate(II) in this system (Table 3).

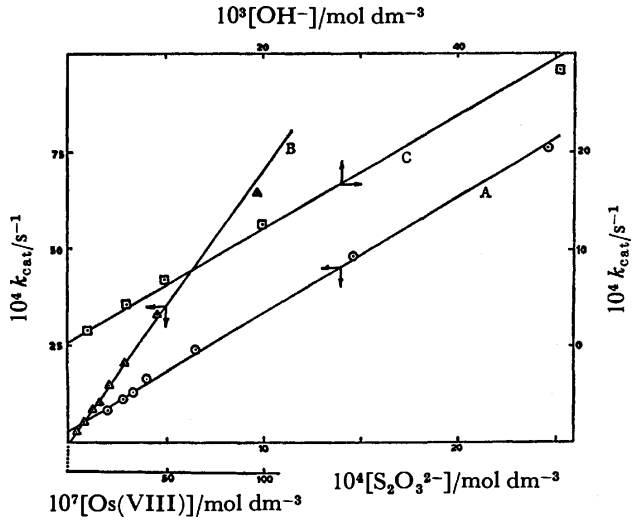

Fig. 2. k_{cat} *vs.* $[S_2O_3^{2-}]$, $[OH^-]$ or [Os(VIII)] (The Os(VIII)-catalyzed $Fe(CN)_6^{3-}$–$S_2O_3^{2-}$ reaction). A: $[OH^-]=1\times10^{-2}$, $[Os(VIII)]=7.8\times10^{-7}$; B: $[S_2O_3^{2-}]=1.2\times10^{-4}$, $[OH^-]=1\times10^{-2}$; C: $[S_2O_3^{2-}]=1.6\times10^{-4}$, $[Os(VIII)]=7.8\times10^{-7}$; $[Fe(CN)_6^{3-}]=1\times10^{-4}$, aqueous medium, 35 °C, $\mu=0.32$ (All concentrations are in mol dm^{-3}).

The k_{cat} value increases linearly with μ. Considerable ion-pairing has been reported in oxidations by alkaline hexacyanoferrate(III), but in the present case as the rate is independent of the $[Fe(CN)_6^{3-}]_o$, any ion-pairing between K^+ or Na^+ and hexacyanoferrate(III) will have no significant effect[22] on the rate. A plot of oxidation rate (k_{cat}) against μ yields a straight line with no zero-rate at zero-electrolyte concentration. This, therefore, appears to be a mere ionic strength effect.[15a] A plot of $\log k_{cat}$ *vs.* $\mu^{1/2}$ is also linear, but no meaningful inference regarding the charge of the reacting ions could be drawn[23a] from the slope of the straight line, as the oxidation process is a multi-step one.

Rate Law and Mechanism: In the absence of Os(VIII), the oxidation of thiosulfate by hexacyanoferrate(III) does not virtually proceed[7] under the conditions employed for the catalysed oxidation, demonstrating that the presence of catalytic amounts of Os(VIII) accelerates the reaction tremendously. The observed kinetic data for the catalyzed system can be presented in terms of a reaction scheme consisting of Eqs. 3, 5, and 14.

$$[OsO_4(OH)(S_2O_3)^{3-}] + Fe(CN)_6^{3-} \xrightarrow[k_6]{OH^-} OsO_4(OH)_2^{2-} + Fe(CN)_6^{4-} + S_2O_3^{-}. \quad (14)$$

Since in the catalysed system, $[S_2O_3^{2-}]\gg[Os(VIII)]\ll[Fe(CN)_6^{3-}]$, the contribution of the catalytic [Os(VIII)] to the direct oxidation of thiosulfate is negligible. Applying steady-state treatment to $[OsO_4(OH)(S_2O_3)^{3-}]$, a rate expression can be derived as in Eq. 15.

$$-\frac{d[Fe(CN)_6^{3-}]}{dt} = \frac{k_6K_{Os}K_2[Os(VIII)][Fe(CN)_6^{3-}][OH^-][S_2O_3^{2-}]}{1+K_{Os}K_2[S_2O_3^{2-}]}, \quad (15)$$

Table 3. Typical average[a] rate constants for Os(VIII)-catalyzed $Fe(CN)_6^{3-}$ oxidation of $S_2O_3^{2-}$

(Aqueous medium, 35 °C, $\mu=0.32$,[b] $[Fe(CN)_6^{3-}]_o=(1.0-1.05)\times10^{-4}$, $[Os(VIII)]=7.8\times10^{-7}$, $[OH^-]=(10.0-10.2)\times10^{-3}$)

or

$$k_{cat}(1+K_{Os}K_2[S_2O_3^{2-}]) = k_6K_{Os}K_2[Os(VIII)][OH^-][S_2O_3^{2-}]. \quad (16)$$

A plot of k_{cat} $(1+K_{Os}K_2[S_2O_3^{2-}])$ *vs.* $[S_2O_3^{2-}]$ should be a straight-line. At constant [Os(VIII)] and $[OH^-]$, employing the experimental value of K_{Os} and the computed value of K_2, the k_6 value for this system at 35 °C and $\mu=0.32$ mol dm^{-3} can be calculated from the least-squares slope of the above straight-line (neglecting the small value of the intercept) as $(3.31\pm0.3)\times10^{-2}$ dm^6 mol^{-2} s^{-1}. The $k_{cat(calcd)}$ values, calculated with the above values of k_6, K_{Os}, and K_2, agree with those obtained experimentally lending credence to the proposed rate expression.

Inasmuch as the redox potentials[24] for the couples $S_2O_3^{2-}/S_4O_6^{2-}$ and $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$, are thermodynamically favourable for electron-transfer from thio-

sulfate to $Fe(CN)_6^{3-}$, it is expected that the oxidation of thiosulfate to tetrathionate should proceed by a direct interaction between thiosulfate and hexacyanoferrate(III). In fact, in numerous oxidation studies of thiosulfate by metallic oxidants like complexes of Cu(II),[1] Co(III),[2] Au(III),[3] Cr(VI),[4] and Fe(III),[5] kinetic and other evidences suggest that intermediate metal-thiosulfato complexes (where the metal has lost one formal oxidation state and thiosulfate has gained one) are formed prior to the rate-determining electron-transfer step. Even though hexacyanoferrate(III) oxidations mostly involve outer-sphere electron change, in an analogous system[25] involving hexacyanoferrate(III) and SO_3^{2-}, intermediate complexes of $Fe(CN)_5(CNSO_3)^{5-}$ and $Fe(CN)_5(CNSO_3)^{4-}$ have been evidenced in aqueous alkaline solution and definitely identified. Lancaster and Murray[25] have suggested that many oxidations by transitional-metal complexes which are weak oxidants may proceed *via* intermediate complexes as described in the case of $Fe(CN)_6^{3-}$–SO_3^{2-} system. Legros[26] has also reported that the hydrolysis of $Fe(CN)_5(S_2O_3)^{5-}$ in aqueous medium is accompanied by a high activation energy and positive activation entropy.

In the present system, however, no indication of any intermediate complex could be obtained from repeated and continuous scanning of the reaction solutions (from 250 nm to 650 nm). Also if the experiment is conducted in the presence of $^{14}CN^-$, there is no labelled cyano-ligand in the $Fe(CN)_6^{4-}$ product ensuring the absence of cyano exchange. Any direct interaction between hexacyanoferrate(III) and thiosulfate to form an intermediate complex necessiates a thiosulfato-ligand of very low Lewis-basicity to substitute or attach itself to, a cyano-ligand in a non-labile low-spin d^5-octahedral complex $Fe(CN)_6^{3-}$, and this is inherently not allowed in all probability. A comparison of the divergent pK of CN^- and SO_3^{2-} with that of $S_2O_3^{2-}$ (respectively 9.1, 9.1, and 1.9)[15c] would show that even if any analogous complexes of $[Fe(CN)_5(CNS_2O_3)^{5-}]$ and $[Fe(CN)_5(CNS_2O_3)^{4-}]$ are thought of, they would not be stable enough in aqueous alkaline medium to be experimentally distinguishable.

However, in view of the expected higher redox potential of the couple Os(VIII)/Os(VI), the d^0-configuration of Os(VIII) and the decreased $10Dq$ value of Os(VIII) in the substitution of an octahedral complex, as compared to that in a substitution-inert $Fe(CN)_6^{3-}$, the substitution of a hydroxo-ligand by a thiosulfato-ligand in *trans*-dihydroxotetraoxoosmate (VIII) is possible. The intermediate complex thus formed, between Os(VIII) and $S_2O_3^{2-}$, undergoes hydrolysis (in the direct oxidation reaction by Os(VIII)) with concomitant electron transfer, or is involved in an outer-sphere electron-transfer in the presence of alkaline hexacyanoferrate(III) in a termolecular rate-determining step.

Evidences for the presence of $S_2O_3^-$, thiosulfate(1—), have been well presented.[5] In the present system radical-trapping agents retard the rate; polymerisation, however, is not detected. This may be because $k(S_2O_3^- + S_2O_3^-) \gg k$ (induced polymerisation) so that the induced change is too insignificant to be practically detectable. Moreover, absence of polymerisation does not necessarily mean absence of radical formation; in acidic medium, in the presence of dissolved oxygen, acrylonitrile does not polymerise even if the process is initiated by γ-radiolysis or by thermal decomposition of peroxodisulfate.

A reprisal of the data in Table 3 shows that there is a near-linear-k_{cat} *vs.* $[S_2O_3^{2-}]$-relationship. To verify the validity of Eq. 16, experiments at higher $[S_2O_3^{2-}]_o$ appear necessary; such an investigation is precluded as the $[S_2O_3^{2-}]$-dependence beyond $[S_2O_3^{2-}]_o = 24.6 \times 10^{-4}$ mol dm^{-3} tends to be somewhat different from that observed in the concentration range employed suggesting that another reaction path[27] probably becomes important at higher $[S_2O_3^{2-}]_o$.

The reactions are accompanied by an imperceptible temperature co-efficient in the range 30—60 °C as there is no appreciable change in the rate. This is probably due to the fact that the reaction has been studied at or very near the isokinetic temperature. We cannot offer at this stage any other reasonable explanation for this than that the large negative activation entropy created in the substitution step is probably counterbalanced by the more positive activation enthalpy in the electron-transfer step so that the net $\Delta G^* \approx 0$, thus causing no appreciable rate constant variation.[23b]

Grateful acknowledgements are due to the UGC, New Delhi for the grant of a National Associateship Scheme, and to the Director, CLRI for providing some of the facilities. We thank Prof. P. S. Radhakrishnamurti for helpful discussions. The CSIR, New Delhi for providing a Junior Research Fellowship to G. Neogi, and Mrs. H. Ranganathan, C. K. Ranganathan and D. Rajendra Prasad of CLRI for some technical assistance are acknowledged.

27) At higher $[S_2O_3^{2-}]_o$, there is probably a further interaction involving the product $S_4O_6^{2-}$, in addition to the involvement of one more $S_2O_3^{2-}$ molecule; this should, we feel, provide the basis for further fruitful study.

Stability Constants of Some Chromium(II) Complexes

Roderick David CANNON*,† and Mohammad Jan GHOLAMI

Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, Ō-Okayama, Meguro-ku, Tokyo 152

(Received November 17, 1980)

Equilibria between the binuclear complex $Cr_2(O_2CMe)_4$ and various chelating ligands have been studied spectrophotometrically in acetate buffer media. Combining the results with previous data on the stability of $Cr_2(O_2CMe)_4$, we obtain formation constants for mononuclear chromium(II) complexes with the following ligands: malonate, $\log \beta_2 = 6.0 \pm 0.2$; *N*-methyliminodiacetate, $\log \beta_2 = 12.3 \pm 0.5$; ethylenediamine-*N*,*N*′-diacetate, $\log K_1 = 9.1 \pm 0.2$; at $T = 25$ °C, $I = 1.0$ M (1 M = 1 mol dm^{-3}) ($NaClO_4$).

In a previous paper[1] we showed that the binuclear chromium(II) complex present in aqueous acetate buffer media has the composition $Cr_2(O_2CMe)_4$, the same as in the solid state, and from a combination of solubility and spectrophotometric measurements, we obtained equilibrium constants for the reactions

$$Cr_2(O_2CMe)_4 \overset{K_{DO}}{\rightleftharpoons} 2\,Cr(O_2CMe)_2, \quad (1)$$

$$Cr_2(O_2CMe)_2 \overset{\beta_{A2}^{-1}}{\rightleftharpoons} Cr^{2+} + 2\,MeCO_2^-. \quad (2)$$

The binuclear complex is red-brown in colour, with $\lambda_{max} = 490$ nm, while mononuclear chromium(II) complexes are generally sky-blue, with λ_{max} in the range 600 to 700 nm. The contrast in colours makes it possible to study competitive monomer-dimer equilibria spectrophotometrically, and we have now used this method to obtain stability constants of the mononuclear chromium(II) complexes of malonate, *N*-methyliminodiacetate, and ethylenediamine-*N*,*N*′-diacetate ions.

Experimental

Preparations. Chromium(II) chloride stock solutions were prepared by zinc-reduction of chromium(III), and stored under nitrogen, as described previously.[1] The solutions contained Zn^{2+} ion equal to half the chromium(II) concentration, but this had little effect on the results, as shown by experiments in which an equal additional concentration of Zn^{2+} ion was added (see, Fig. 4).†† Organic acids were Reagent grade, recrystallized twice from water, and standardized by titration with sodium hydroxide. Sodium acetate and sodium perchlorate solutions were prepared by mixing the AnalaR acids with AnalaR sodium hydroxide solution, from freshly opened ampoules.

Measurements. A Beckman DB spectrophotometer was used, with modified temperature-control system.[1] The titration procedure was as previously described.[1]

† On leave from the School of Chemical Sciences, University of East Anglica, Norwich, NR4 7TJ, England; to which correspondence should be addressed.

†† The effect of zinc is expected to be a reduction in the concentration of free ligand by complex formation, thus decreasing the dissociation of the chromium(II) dimer. Since Cr^{2+} and Zn^{2+} stability constants are generally comparable, the greatest perturbation by Zn^{2+} is expected in the system for which dissociation of dimer to monomer is found to be greatest, *i.e.* the malonate system. If the zinc ions are completely complexed as ZnL_2^{2-}, the depletion of free malonate ion is about 10%, giving a reduction of about 0.1 in $\log f$ (see Eq. 15). This is within the experimental error. For the other ligands the effect is expected to be smaller.

Theory

Defining $[Cr_1]$ and $[Cr_2]$ as total concentrations of mononuclear and binuclear species, we may summarise the dimer-monomer equilibria in the solution in the equation

$$Cr_2 \overset{K_D}{\rightleftharpoons} 2\,Cr_1, \quad (3)$$

where K_D is the dimer dissociation constant averaged over all complexes, defined by

$$K_D = [Cr_1]^2/[Cr_2]. \quad (4)$$

In the absence of any ligands other than acetate ion, only one dimer species is important, hence we may write $[Cr_2] = [Cr_2(O_2CMe)_4]$ and $[Cr_1] = [Cr]_T - 2[Cr_2]$, where $[Cr]_T$ denotes the total chromium(II) concentration, giving

$$K_D = ([Cr]_T - 2[Cr_2(O_2CMe)_4])^2/[Cr_2(O_2CMe)_4]. \quad (5)$$

The concentration of $Cr_2(O_2CMe)_4$ may be calculated from the absorbance at 490 nm, using the known extinction coefficient,[1] and assuming that absorption by monomers is negligible. A plot of $[Cr_2(O_2CMe)_4]$ against $([Cr]_T - 2[Cr_2(O_2CMe)_4])^2$ is then expected to be a straight line of slope K_D^{-1}. When an additional ligand L is present which forms mononuclear complexes CrL_n, we have the additional reactions

$$(1/2)[Cr_2(O_2CMe)_4] + nL \overset{\beta_n'}{\rightleftharpoons} CrL_n + 2\,MeCO_2^-, \quad (6)$$

where $n = 1, 2, .. N$, $\beta_n' = (K_{DO})^{1/2}\beta_{A2}^{-1}\beta_n$, and β_n is the overall formation constant:

$$Cr^{2+} + nL \overset{\beta_n}{\rightleftharpoons} CrL_n. \quad (7)$$

(In Eqs. 6 and 7 some ionic charges are omitted). A calculation of the average dimer dissociation constant by the same method as before then yields the value K_D', where

$$K_D' = ([Cr^{2+}] + [CrO_2CMe^+] + [Cr(O_2CMe)_2] + \sum_1^N [CrL_n])^2/[Cr_2(OOCMe)_4]$$
$$= (\beta_{A2}^{-1}[MeCO_2^-]^{-2} + K_{A2}^{-1}[MeCO_2^-]^{-1} + 1 + \sum_1^N \beta_n[L]^n/\beta_{A2}[MeCO_2^-]^2)^2 K_{DO}, \quad (8)$$

where K_{A2} is the second stepwise formation constant of $Cr(O_2CMe)_2$. Equation 8 may be simplified to

$$(K_D')^{1/2} = (K_D)^{1/2} + (K_{DO})^{1/2} \sum_1^N \beta_n[L]^n/\beta_{A2}[MeCO_2^-]^2, \quad (9)$$

where K_D is the dissociation constant observed at the same acetate concentration in the absence of the ligand L. For the purpose of discussion we shall define the function

$$f = [(K_D')^{1/2} - (K_D)^{1/2}][MeCO_2^-]^2, \quad (10)$$

which in turn is related to [L] by

$$f([L]) = (K_{DO})^{1/2}\beta_{A2}^{-1} \sum_{1}^{N} \beta_n[L]^n. \quad (11)$$

The slope of a plot of log f against log ([L]) is equal to $\bar{n}$, the average value of n for complexes formed at a particular value of [L]. Knowing K_{DO} and β_{A2}, the values of β_n may be obtained.

Results

For each ligand, two sets of measurements were obtained. (1) With fixed total chromium(II), acetate, and acetic acid concentrations, the ligand concentration was varied over the range to be used in the later experiments. With increasing added ligand, the momomer and dimer absorbances increased and decreased respectively, and sharp isosbestic points were observed, *i.e.* at λ=600 nm (malonate system, Fig. 1), 620 nm (*N*-methyliminodiacetate system), 395 and 585 nm, (ethylenediamine-*N*,*N*'-diacetate system). This shows that oxidation to chromium(III) is negligible under the conditions of the experiments. (2) With fixed total acetate, acetic acid, and ligand concentrations, the chromium(II) concentration was varied, the first three all being in large excess over chromium(II). At low concentrations, the monomer absorption was dominant, but with increasing concentration the shape of the spectrum steadily changed to that of the dimer (Fig. 2). These experiments were repeated with different acetic acid, acetate and ligand concentrations. Typical plots of $[Cr_2]$ against $[Cr_1]^2$ are shown in Fig. 3.

Malonate (propanedioate) System. The total malonate concentration $[L]_T$ was varied over the range 0—0.09 M and for each malonate concentration, total chromium(II) was varied over the range 2—8 mM. The acetate and acetic acid concentrations were varied over the ranges 0.3—0.6 and 0.3—0.5 M. pK_a values of malonic acid[2] are such that in acetate buffer the first dissociation is complete, and the second partially complete (Eqs. 12—13, $L^{2-}=CH_2(CO_2)_2^{2-}$):

$$H_2L + MeCO_2^- \longrightarrow HL^- + MeCO_2H, \quad (12)$$

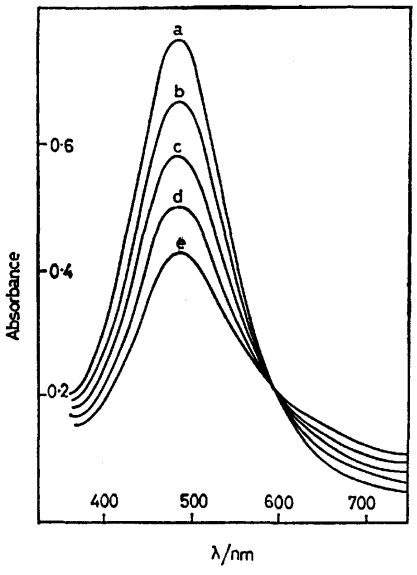

Fig. 1. Spectra of chromium(II) in acetate buffer with various concentrations of added malonic acid (H_2L). $[Cr]_T$=2.75 mM; $[L]_T$=0.0, 2.5, 5.0, 7.4, 9.9 mM (curves a to e respectively); $[MeCO_2H]=[MeCO_2^-]$= 0.2 M; I=1.0 M ($NaClO_4$). Path length 4 cm, T= 25 °C.

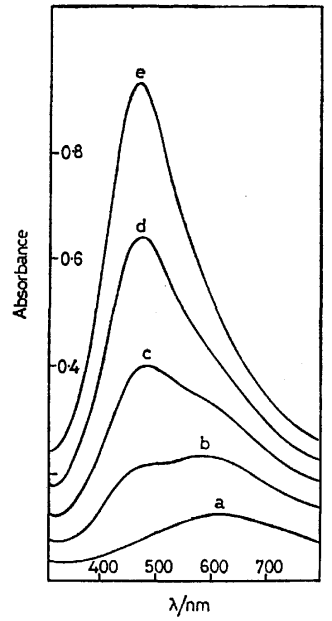

Fig. 2. Spectra of chromium(II) at various concentrations in an acetate-malonate mixture. $[L]_T$=50 mM; $[Cr]_T$=1.9, 3.7, 5.4, 7.0, 8.6 mM (curves a to e respectively); $[MeCO_2H]=[MeCO_2^-]$=0.3 M; I=1.0 M ($NaClO_4$). Path length 4 cm, T=25 °C.

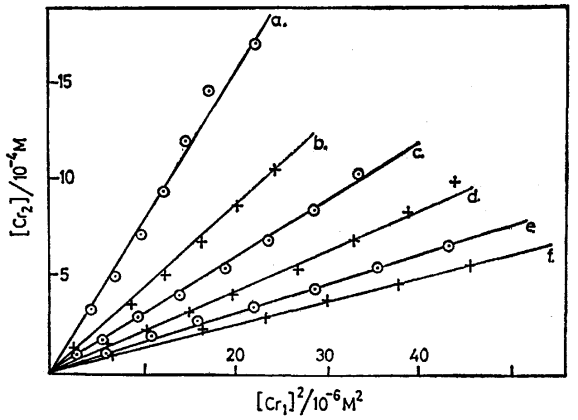

Fig. 3. Variation of chromium(II) dimer concentration with chromium(II) monomer concentration. $[Cr_2]=[Cr_2(O_2CMe)_4]$, $[Cr_1]=[Cr]_T-2[Cr_2]$. H_2L=malonic acid. $[L]_T$=40, 50, 60, 70, 80, 90 mM (curves a to f respectively); $[MeCO_2H]-2[L]_T=[MeCO_2^-]+2[L]_T$=0.3 M; I=1.0 M ($NaClO_4$). T= 25 °C.

$$HL^- + MeCO_2^- \overset{K_{Aa}^{-1}K_{La2}}{\rightleftharpoons} L^{2-} + MeCO_2H. \quad (13)$$

Hence we may write

$$[L^{2-}] = [L]_T/(1+K_{Aa}K_{La2}^{-1}[MeCO_2H]/[MeCO_2^-]), \quad (14)$$

where $[L]_T$ denotes total ligand concentration and K_{Aa} and K_{La2} are acid dissociation constants of $MeCO_2H$ and HL^-. Using $pK_{Aa}=4.58$ (the mean of three literature values at $I=1.0$ M)[2] and $pK_{La2}=5.15$,[3] we have $K_{Aa}K_{La2}^{-1}=3.7$. The plot of $\log f$ against $\log([L^{2-}])$, shown in Fig. 4(a), has the slope 2.0. This is consistent with the equation

$$f([L^{2-}]) = (K_{DO})^{1/2}\beta_{A2}^{-1}\beta_2[L^{2-}]^2, \quad (15)$$

which yields the parameters shown in Table 1.

N-Methyliminodiacetate System. The total ligand concentration was varied over the range $[L]_T=0$ to 0.12 M and total chromium(II) was varied over the range 0.8 to 3.1 mM. Acetate and acetic acid varied from 0.3 to 0.5 M. The acid H_2L has pK_a values 2.2 and 9.3,[4] hance we take $[HL^-]=[L]_T$, where HL^- denotes the ion $MeNH(CH_2CO_2)_2^-$. To show the dependence of f upon $[L^{2-}]$, we have plotted log f against $\log\{[HL^-][MeCO_2^-]/[MeCO_2H]\}$ in Fig. 4(c). The slope of 2.0 is consistent with the formation of CrL_2^{2-} as the predominant species:

$$HL^- + MeCO_2^- \overset{K_{Aa}^{-1}K_{La2}}{\rightleftharpoons} L^{2-} + MeCO_2H, \quad (16)$$

$$Cr^{2+} + 2\,L^{2-} \overset{\beta_2}{\rightleftharpoons} CrL_2^{2-}. \quad (17)$$

Using the equation

$$f([L^{2-}]) = (K_{DO})^{1/2}\beta_{A2}^{-1}\beta_2K_{La2}^2K_{Aa}^{-2} \times [HL^-]^2[MeCO_2^-]^2[MeCO_2H]^{-2}, \quad (18)$$

we obtain the parameters shown in Table 1.

Ethylenediamine-N,N′-diacetate System. With this ligand complexation was less than with the others, and it was necessary to use lower acetate concentrations ($[MeCO_2H]+[MeCO_2^-]=0.4$ M) in order to displace the equilibrium 6 to the right. The total ligand concentration $[L]_T$ was varied over the range 0 to 0.10 M, and total chromium(II) over the range 0.8 to 3.5 mM. The acetic acid-dependence of f was not studied. From the acid dissociation constants, $pK_{La1}=6.7$ and $pK_{La2}=9.9$,[5] we have $[L]_T=[H_2L]$. The plot of $\log f$ against $\log([H_2L])$ has a slope of 1.0 (Fig. 4(b). Hence the equation

$$f([L^{2-}]) = (K_{DO})^{1/2}\beta_{A2}^{-1}K_1K_{La1}K_{La2}K_{Aa}^{-2}[H_2L] \times [MeCO_2^-]^2[MeCO_2H]^{-2}, \quad (19)$$

was used to obtain the parameters shown in Table 1.

Other Ligands. With 5-sulfosalicylate(3-carboxy-4-hydroxybenzenesulfonate) ion, under our conditions ($[L]_T=0.01$ to 0.12 M, $[MeCO_2^-]=0.06$ to 0.3 M, $[MeCO_2H]=0.32$ to 0.62 M), dissociation of the $Cr_2(O_2CMe)_4$ complex was only slightly greater than that observed in the absence of added ligand. Assuming the complex CrL^-, we calculate an upper limit for log K_1 as shown in Table 1. With glycine, no dissociation could be detected. With edta, dissociation of the dimer into monomer was complete.

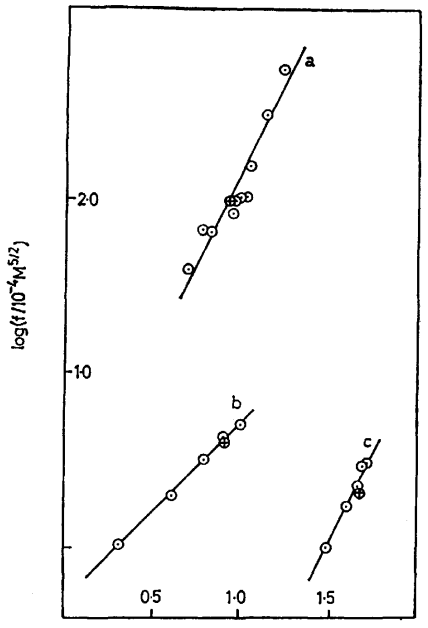

Fig. 4. Plots of log f (see text, Eqs. 10—11) against (a) $\log([L^{2-}]/10^{-3}\,M)$, H_2L=malonic acid; (b) log $([H_2L]/10^{-2}\,M)$, H_2L=ethylenediamine-*N*,*N*′-diacetic acid, $[MeCO_2H]=[MeCO_2^-]$; (c) $\log([HL^-][MeCO_2^-][MeCO_2H]^{-1}/10^{-3}\,M)$, H_2L=*N*-methyliminodiacetic acid. Points ⊙, $[Zn]=(1/2)[Cr]_T$; points ⊕, $[Zn]_T=[Cr]_T$.

Discussion

For the chromium(II)–malonate system, Fukuda

TABLE 1. SUMMARY OF RESULTS

Ligand	Reaction[a]	log Q[b]	log (β_n/M^n)[c]
Malonate	$(1/2)Cr_2A_4+2L^{2-} \rightleftharpoons CrL_2^{2-}+2A^-$	2.23 ± 0.10	$\log\beta_2 = 6.0\pm0.2$
5-Sulfosalicylate	$(1/2)Cr_2A_4+HL^{2-} \rightleftharpoons CrL^-+HA+A^-$	$\leqslant -2.64$	$\log K_1 \leqslant 7.8$
N-Methyliminodiacetate	$(1/2)Cr_2A_4+2HL^- \rightleftharpoons CrL_2^{2-}+2HA$	-0.98 ± 0.03	$\log\beta_2$ 12.3±0.5[d]
Ethylenediamine-*N*,*N*′-diacetate	$(1/2)Cr_2A_4+H_2L \rightleftharpoons CrL+2HA$	-2.30 ± 0.10	$\log K_1 = 9.1\pm0.2$[e]

a) A^-: $MeCO_2^-$, L^{2-} or L^{3-}: the anion specified in column 1. b) Q: equilibrium constant of reaction specified in column 2; units $M^{1/2}$ or $M^{3/2}$. Temperature 25 °C, ionic strength, $I=1.0$ M ($NaClO_4$). Limits of error are root-mean-square deviations of $\log f$ from the lines shown in Fig. 4. c) β_n refers to the reaction $Cr^{2+}+nL \rightleftharpoons CrL_n$, calculated using $\log[(K_{DO}/M)^{1/2}]=-2.17$, $\log(\beta_{A2}/M^{-2})=1.70$ (Ref. 1). Limits of error are rough estimates. d) Calculated using $pK_a=4.6$ for HA (Ref. 2) and $pK_a=9.3$ for HL^- (Ref. 4). e) Calculated using $pK_a=4.6$ for HA (Ref. 2) and $pK_{a2}=6.68$ and 9.85 for H_2L (Ref. 5), neglecting the difference in ionic strength in the latter case.

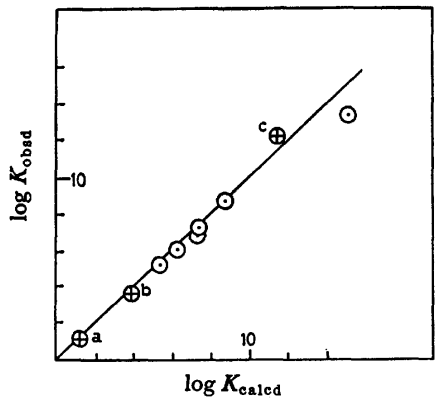

Fig. 5. Comparison of observed stability constants (log K_1) of chromium(II) complexes with those calculated from Eq. 20 of the text. Points ⊙, previous data (Ref. 8). Points ⊕, subsequent data: (a) $MeCO_2^-$ (Ref. 1); (b) malonate (Ref. 6); (c) *N*-methyliminodiacetate (this work). For point (c), log β_2 is plotted, not log K_1. Note that equation 20 yields log K_1= 7.4 (Ref. 8), and log K_2=4.2, using data from the same original sources.

et al.,[6] reported log K_1=3.92, log K_2=3.21. Our value log β_2=6.0 is more consistent with log $K_1 \cong 4$, log K_2=2, bearing in mind the usual difference between first and second stepwise stability constants of chelate complexes.[2] The formation curve reported by Fukuda *et al.*, deviates from the expected S-shape and it seems possible that their value of log K_1 is more reliable than that of log K_2. For the 5-sulfosalicylate system, the limiting value log $K_1 \leqslant 7.8$ is consistent with that of Pecsok and Schaefer (7.1)[7] but not with that of Fukuda *et al.* (9.9).[6]

Cannon[8] previously put forward an empirical expression for stability constants of chromium(II) complexes, based on the Irving-Williams series:

$$\log K_{Cr} = \alpha \log K_{Cu} + \frac{1}{5}(6-\alpha) \log K_{Mn} - \frac{1}{5}(1+4\alpha) \log K_{Zn}. \quad (20)$$

Here K_{Cr}, K_{Cu}, K_{Mn}, and K_{Zn} are stability constants of Cr^{2+}, Cu^{2+}, Mn^{2+}, and Zn^{2+} complexes with the same ligand under the same conditions (they may be step-constants K_n or overall constants β_n), and α=0.55. A comparison of predicted and observed values of log K_{Cr} is shown in Fig. 5, and it can be seen that the new data are in satisfactory agreement with the formula.

The experimental work was carried out at the University of East Anglia. Funds for equipment were provided by the Science Research Council. M. J. G. held an Iranian Government Scholarship for study abroad. R. D. C. held a Foreign Lectureship under the British Council/Mombusho scheme.

(Received April 20, 1981)

Polarographic behavior of 4-morpholine carbodithioate has been studied in various base electrolytes. It gives a well defined, diffusion controlled, reversible with one electron change, anodic wave above pH 9 extending over a fairly wide span of potential, +0.2 V to −0.3 V *vs.* SCE. The relation between diffusion current and concentration is linear upto 2.7 mM (1 M=1 mol dm^{-3}) of the reagent. The reagent has been successfully applied for the amperometric determination of Bi^{3+}, Cu^{2+}, Ni^{2+}, Te^{4+}, and Zn^{2+} individually as well as in mixtures like Cu–Zn and Cu–Ni. Conditions have also been developed for the determination of copper, nickel, and zinc in various alloys. The error does not exceed more than ±0.85% in any case. The method is simple, less time consuming and easily adoptable for the micro determination of these metal ions.

4-Morpholine carbodithioates of many metals were prepared and characterized by Brown[1] and Marcotrigiano and coworkers.[2] Zinc complex has been used as a releasing agent in atomic absorption spectrometry of noble metals.[3] Beyer and Ott utilized this compound in the spectrophotometric determination of some metal ions.[4] Recently potassium salt of this reagent has been used in the gravimetric determination of tellurium, copper, bismuth, zinc, cadmium, and mercury.[5–8] Some of the metal ions have also been characterized by thin layer[9] and paper chromatography[10] using this reagent. Extraction behavior of some divalent metals with this reagent have also been studied.[11] In the present paper, the polarographic study of 4-morpholine carbodithioate in various supporting electrolytes has been undertaken with a view to explore the possibility of utilizing it as an analytical reagent for the amperometric determination of various metal ions.

Experimental

Reagents. Sodium 4-morpholine carbodithioate was prepared by the method reported by Marcotrigiano.[2] Stock solution of sodium 4-morpholine carbodithioate was prepared by dissolving a calculated amount in distilled water and standardized against a standard solution of mercury(II) nitrate using diphenyl carbazone as the indicator. The base electrolytes, potassium nitrate, potassium chloride, sodium perchlorate, ammonium tartrate, tetraethylammonium bromide, and buffers like Britton-Robinson, Michaelisborate and ammonia–ammonium chloride were prepared in distilled water from their G. R. samples. Stock solutions of various metal ions were prepared from their G.R. samples and standardized by known methods.[12]

Equipment. Polarograms in all the cases were recorded at 25±0.5 °C with a manual Toshniwal polarograph. An H-type cell with fine porosite sintered glass disk between the two compartments was used. A saturated calomel electrode used as a reference electrode was connected to one compartment of the polarographic cell through potassium chloride-agar bridge. Dropping mercury electrode had the following characteristics, m=2.08 mg/s, t=3.10 s, and H=50 cm in aqueous solution of the base electrolyte with open circuit. In all instances, the solution was deaerated with nitrogen before recording the polarogram. An ECIL digital pH meter with glass electrode was used.

Results and Discussion

Effect of pH on the Polarogram of 4-Morpholine Carbodithioate. Polarograms for 1.25 mM carbodithioate in 0.1 M ammonium tartrate +0.1 M potassium nitrate were recorded at different pH values in the range of 5.75—11.7 using Britton-Robinson buffer. An anodic wave associated with a small prewave at more negative potentials was obtained at all pH values below 9. At pH above 9.0, the prewave was almost disappeared (Fig. 1). Even though the nature of the wave remained unaffected, the values of $E_{1/2}$ shifted towards more negative potentials with

11.68	−0.375	Pre-wave disappeared Well define single wave obtained

increase in pH (Fig. 1, Table 1).

Polarograms of 1.25 mM of the reagent solution recorded in different buffers such as Britton-Robinson, Michaelisborate, NH_3–NH_4Cl showed that the nature of the wave was not affected by the constituents of buffers.

Effect of Various Supporting Electrolytes and Solvents. Polarograms of 1.25 mM carbodithioate at pH 9.58 in presence of 0.1 M several supporting electrolytes and solvents were recorded. The nature of the wave remained unchanged and the diffusion current constant was found to increase in the following order:

$(C_2H_5)_4NBr > KNO_3 > KCl > NaClO_4$ and

Acetonitrile > Methanol > Ethanol > DMSO > 2-Propanol.

This may be due to the variation in viscosity of the solution,[13] ($I \propto 1/\text{viscosity}$).

Effect of Mercury Pressure. Polarograms for 1.45 mM of the carbodithioate solution at various heights of the mercury column were recorded. The linear dependence of the limiting current on the square root of the height of the mercury column indicates that the rate of oxidation of 4-morpholine carbodithioate is diffusion controlled.

Effect of 4-Morpholine Carboditioate Concentration. Several polarograms with varying concentration of the reagent were recorded in 0.1 M ammonium tartrate +0.1 M potassium nitrate+ammonia buffer of pH 9.6. The anodic wave extends over a fairly wide span of potential (0.2 V to −0.3 V *vs.* SCE). The plot of diffusion current *vs.* concentration gave a straight line upto 2.7 mM of the reagent. The mean value of diffusion current constant determined with the Ilkovic equation, $I = i_d/cm^{2/3}t^{1/6}$ was found to be 1.64, which indicates the method may be applied

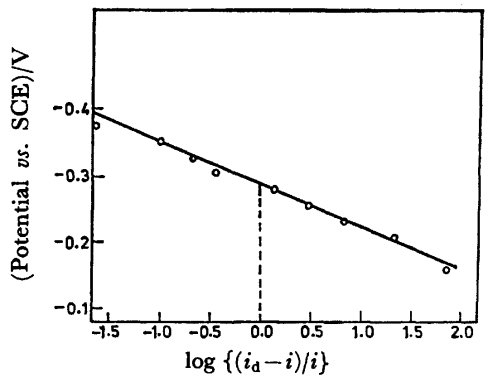

Fig. 2. Plot of $\log\{(i_d-i)/i\}$ *vs.* $E_{d.e.}$ for 2.7 mM sodium 4-morpholine carbodithioate in 0.1 M tartrate buffer (pH 11.7). Rest of the conditions are the same as in Fig. 1.

for the quantitative determination of 4-morpholine carbodithioate.

The electrooxidation of the reagent may not involve the formation of disulfide, RSSR (R=4-morpholine–thiocarbonyl) because the plots of $\log\{(i_d-i)/i\}$ *vs.* E did not yield a straight line with a slope 0.059 V/2, but yield a straight line with a slope of 0.065 V (Fig. 2) for one electron transfer. Also from Lingane equation, 1.5 $n=I$, the value of "n" corresponds to 1 to allow the conclusion that:

$$RSH + Hg \rightleftharpoons RSHg + H^+ + e \quad (1)$$

may represent the electrode reaction. Furthermore, the $E_{1/2}$ values were found to be independent of [RSH] which is characteristics of Eq. 1.

In the amperometric procedures reported for the determination of zinc,[14–15] copper,[16–17] nickel,[18] bismuth,[19] and tellurium,[20–21] the titrations have been carried out at a potential corresponding to the reduction wave of the cation concerned. It may be pointed out that an electroactive organic compound which is capable of forming an insoluble precipitate with these cations may serve as a potential titrant in their estimation. In this connection, the use of 4-morpholine carbodithioate as an analytical reagent for the quantitative estimation of bismuth, copper, nickel, tellurium(IV), and zinc has been investigated. Preliminary observations showed that under regulated conditions of base electrolyte concentration and pH, the reagent reacted with these cations to give characteristic precipitates. These observations paved the way to the estimation of microquantities of these cations by the amperometric titration procedure. The appropriate operative conditions for the quantitative estimation were established by trial experiments and are summarised in Table 2.

The applied potential (−0.2 V for Zn^{2+} and Ni^{2+}, −0.05 V for Bi^{3+}; and Te^{4+}; −0.01 V for Cu^{2+}, *vs.* SCE) was such that the metal ion was not reduced but the reagent was oxidized at the DME. The titration, therefore, involved the measurement of the anodic current of the excess titrant only after complete precipitation. Reverse L shaped curves were obtained by plotting these readings against the volume of the titrant and the end point was located graphically (Fig. 3).

Table 2. Optimum conditions for the amperometric titration of metal ions

Metal	Potential of DME *vs.* SCE V	Supporting electrolytes	pH
Bismuth	−0.05	0.1 M Potassium nitrate 0.1 M Sodium acetate	4.5— 6.5

In a series of experiments an aliquot of the unknown solution of the cation was taken in the cell containing appropriate base electrolyte. The pH of the medium was adjusted to the desired value (Table 2). The solution was thoroughly deaerated by a slow stream of nitrogen gas. Necessary connections were made and the desired potential was applied to the dropping mercury electrode. A 2 ml microburette was used to deliver the titrant in small increment. In each case, the solution was stirred with nitrogen and the precipitate was allowed to stand for 1—2 min before observing the current reading. The mean deflection of the galvanometer was noted in each case. In all these determinations the solution taken in the burette was kept 20 times stronger than the solution in the cell in order to eliminate dilution effect. The end point was located graphically as the point of intersection of two straight lines (Fig. 3). The results are presented in Table 3, indicate that the microquanties of these cations can be estimated accurately.

Interferences. Metal ions such as Mo(VI), W-(VI), Te(VI), V(V), Th(IV), U(VI), Zr(IV), As-(III), Sb(III), Mg(II), Ca(II), Sr(II), Ba(II), In-(III), upto 10 fold excess; Cr(III), Al(III), and Fe-(III) upto 4-fold excess (they are precipitated as their hydroxide before titration) and Se(IV) in equal quantities can be tolerated in all cases. The interference of Pb(II), Tl(I), and Ag(I) was eliminated with sulfate and chloride ions before the titration. The interference of Cd(II), Ni(II), Hg(II), Co(II), and Zn(II) was eliminated in the determination of Te(IV), and Bi(III) by masking them with cyanide ions[22] (5 ml of 5% solution of sodium cyanide). Te-(IV) only interfered in the determination of bismuth.

In the determination of copper, Cd(II), Ni(II), Co(II), and Bi(III) interfered but the interference of Ni(II) and Co(II) can be eliminated by their successive determinations. Only Zn(II), Cd(II), and Bi(III) interfered in the analysis of nickel. Cd(II), Ni(II), Co(II), Bi(III), and Cu(II) interfered in the determination of zinc. The interference of copper can be eliminated by their successive determination. Obviously these methods are sufficiently selective and may be applied for the determination of these metal ions in complex materials. The method is quite simple rapid and easily adoptable.

It is obvious from the above results (Table 2) that some metals react with this reagent in alkaline medium while other do not. It is thus possible to titrate one metal of a mixture at higher pH and then by changing the pH after the end point to continue the titration of the other metal. This was demonstrated with a mixture of copper–zinc and copper–nickel.

Two methods have been used for the amperometric titrations. The first utilizes the decrease in height of the reduction wave of the uncomplexed copper ion during the course of titration. The second is based on the measurement of the anodic diffusion current of the excess titrating agent after the end point (Fig. 4). A combination of these two methods makes possible the determination of mixture of these metal ions.

Simultaneous Determination of Cu–Zn and Cu–Ni. To an aliquot of the synthetic mixture containing copper+zinc or copper+nickel, added 0.1 M potassium nitrate +0.01% gelatin and aqueous ammonia (pH 9.8) for the first and 0.05 M ammonium acetate +0.05 M potassium nitrate+0.01% gelatin for the second mixture. The total volume was made 20 ml in each case. The residual current of the air free solutions was noted at −0.2 V *vs.* SCE. Under these conditions only copper reacts. The titration was carried out with the reagent solution. In each case, the solution was stirred with nitrogen gas before recording the galvanometer reading. After the copper end point the pH was lowered to ≈6.5 for zinc and 7.2 for nickel by adding 1 M acetic acid at the same potential and determined the mixture end point as the intersection between residual and excess reagent lines. A series of experiments with mixture containing copper+zinc or copper+nickel in different ratios were performed. The results are given in Tables 4 and 5 respectively.

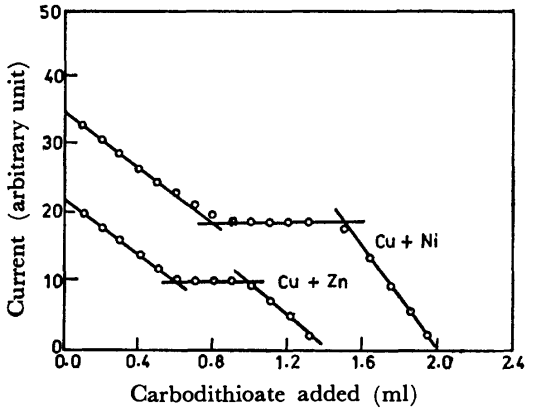

Fig. 4. Typical amperometric titration curves of Cu+Zn and Cu+Ni.
Cu+Zn: Cu(1.0×10^{-3} M): 3.00 ml+Zn(1.0×10^{-3} M): 2.00 ml+0.1 M potassium nitrate +0.01% gelatin+ammonia, pH 9.8 upto copper end point; 0.1 M potassium nitrate +0.01% gelatin+ammonium acetate, pH: 6.4 after copper end point. Applied potential: −0.2 V *vs.* SCE. Carbodithioate: 0.01 M. Cu+Ni: Cu(2.0×10^{-3} M): 4.00 ml+Ni(2.0×10^{-3} M): 3.5 ml+0.05 M ammonium chloride+0.05 M ammonium nitrate, +0.01% gelatin pH 9.5 upto copper, pH 7.2 after copper, end point. Applied potential: −0.2 V *vs.* SCE. Carbodithioate: 2×10^{-2} M.

Analysis of Alloys. 0.1 g of the alloy was taken in a beaker to which were added 10 ml of concentrated hydrochloric acid and a few ml of concentrated nitric acid. This was heated on a hot plate till the mixture dissolved completely and the solution was reduced to about 5 ml. The solution was cooled, added 5 ml of concentrated hydrochloric acid, then diluted and the final volume was made 100 ml exact

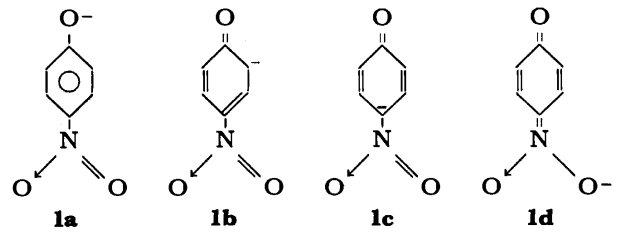
(Received May 6, 1981)

A quantitative analysis of the effects of hydroxylic and aprotic solvents on the electronic absorption spectrum of 4-nitrophenoxide anion is described. By means of linear solvation energy relationships, the contributions of solvent dipolarity, polarizability, and hydrogen bonding are assessed. A significant conclusion is that ion-pairing strongly influences the 4-nitrophenoxide ion in aprotic solvents, but not in hydroxylic solvents. In the latter, specific solvation of both the nitro group and the phenoxide ion center are important.

The last two decades have witnessed a steady effort in the field of study of solvent effects on the UV-visible spectra of polar solutes. An important result of this work has been the development of a number of empirical solvent polarity scales.[1] Recently, the ability of bulk solvents to act as proton donors in hydrogen bonding interactions has also been quantified.[2] Although a number of questions still remain unanswered, we feel that sufficient information is already available to allow the use of these scales in order to gain structural and mechanistic information. Thus the π^* scale of solvent dipolarity/polarizabilities[3] and the α scale of solvent HBD (hydrogen bond donor) acidities[2] have been extensively used[4] to analyze solvent effects on physical properties and chemical reactivity.

Ueji and Kitadani (henceforth abbreviated as U. and K.) have recently described in this journal the influence of solvents on the absorption spectrum of sodium *p*-nitrophenoxide.[5] By adding substantial amounts of 15-crown-5, these authors were able to obtain the spectrum in a wide variety of solvents. The frequencies, $\nu(\mathbf{1})_{max}$, corresponding to the $\pi\rightarrow\pi^*$ electronic transition of 4-nitrophenoxide ion (represented by canonical structures **1a—d**) in a number of solvents are given in Table 1, together with solvent π^* and α values.



1a **1b** **1c** **1d**

Inspection of the $\nu(\mathbf{1})_{max}$ values shows two different effects: one is a bathochromic shift with increasing solvent dipolarity/polarizability; the other is a hypsochromic shift with increasing HBD acidity of the solvent. U. and K. have pointed out and discussed both effects. While we basically agree with their interpretation of the experimental results, we wish to reexamine them from a somewhat more quantitative standpoint. Our aim is to demonstrate that, when solvent dipolarity, polarizability, and hydrogen bonding effects on $\nu(\mathbf{1})_{max}$ are unravelled by means of the solvatochromic comparison method, the same experimental data can be made to yield additional important information regarding the detailed nature of the electronic transition.

Results and Discussion

When hydrogen bonding effects are excluded, as when solute and solvent are both non-hydrogen bond donors, solvent effects on electronic spectra can take either of two forms. For p$\rightarrow\pi^*$ and $\pi\rightarrow\pi^*$ transitions of uncharged indicators with all solvents considered together, and for other types of electronic transitions when families of solvents with similar polarizability characteristics are treated separately (*e. g.*, only non-chlorinated aliphatic solvents, only polychlorinated aliphatics, or only aromatic solvents) the linear solvation energy relationship (LSER) takes the form,

$$\nu(i)_{max} = \nu(i)_0 + s\pi^*, \quad (1)$$

where s is a measure of the response of $\nu(i)_{max}$ to solvent dipolarity. For the other electronic transitions, when all solvents need to be considered together, the appropriate form of the LSER is,

$$\nu(i)_{max} = \nu(i)_0 + s(\pi^* + d\delta), \quad (2)$$

where δ, a 'polarizability correction term'=0.0 for non-chlorinated aliphatic solvents, 0.5 for polychlorinated aliphatics, and 1.0 for aromatic solvents.

Solvent Dipolarity/Polarizability Effects. Considering first the $\nu(\mathbf{1})_{max}$ values in the six non-protic aliphatic solvents of Table 1 according to Eq. 1, the regression equation with π^* is,

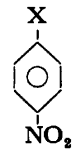
$$\nu(\mathbf{1})_0 = (26.71 - 3.99\pi^*) \times 10^3\ cm^{-1}, \quad (3)$$

r (the correlation coefficient) = 0.980,

sd (the standard deviation) = $0.24 \times 10^3\ cm^{-1}$.

The ν_0 and s values in Eq. 3 provide important mechanistic information. Thus, it is evident from the shift to lower absorption frequencies with increasing π^* that the electronic transition is from a ground state which is relatively more charge-diffuse to an electronic excited state which is relatively more charge-concentrated.

It is profitable to consider Eq. 3 in the context of solvent effects equations for corresponding spectral bands of related indicators as, for example, the [$^+X=C(4)\rightarrow C(1)=NO_2^-$] electronic transitions of the 4-substituted nitrobenzenes, **2—7**, which we reported



2, X=Me_2N- **5**, X=C_2H_5-
3, X=H_2N- **6**, X=F-
4, X=MeO- **7**, X=H-

earlier.[1d] It was then shown that the $\nu(i)_0$ and s values in the solvatochromic equations for **2**—**7** are linear with the substituent σ^+ values, the correlation equations being,

$$\nu(i)_0 = (6.39\sigma^+ + 39.50) \times 10^3 \text{ cm}^{-1}, \quad (4)$$

and

$$s = 1.021\sigma^+ - 1.685. \quad (5)$$

In order to ascertain whether 4-nitrophenoxide conforms with these relationships, we have back-calculated values of σ^+ for the 4-oxy substituent by substituting the $\nu(\mathbf{1})_0$ and s terms from Eq. 3 into Eqs. 4 and 5, and compared the results with independent estimates of the value of this substituent constant. The $\nu(\mathbf{1})_0$ value of 26.71 in Eq. 4 calls for a σ^+ of −2.00, while the s value of −3.99 in Eq. 5 is consistent with $\sigma^+ = -2.25$. For comparison, Hine[6] has reported that σ^+ for the p-O^- substituent is −2.3, with the comment that σ^+ values for electrically charged substituents are relatively less reliable, being dependent to some extent on solvation and ion pairing.

The at least approximate conformance of 4-nitrophenoxide with Eqs. 4 and 5 indicates that, as with **2**—**7**, the direction of charge migration in the electronic excitation is away from the p-substituent and towards the nitro group. Taken with the finding that there is concentration of charge in the electronic excitation, this leads to the conclusion that electron density in the ground state is delocalized into canonical structures like **1a**—**d** (with **1a** probably being the dominant contributor), whereas in the electronic excited state charge is redistributed and concentrated into canonical structures like **1c** and **1d** (with **1d** being the dominant contributor).

If the data in the non-protic aliphatic, polychloroaliphatic, and aromatic solvents of Table 1 are considered together, the appropriate form of the linear solvation energy relationship is given by Eq. 2. The d value is calculated to be −0.26,[7] and the least squares correlation of $\nu(\mathbf{1})_{max}$ with $(\pi^* - 0.26\delta)$ leads to the regression equation,

$$\nu(\mathbf{1})_{max} = \{26.67 - 3.93(\pi^* - 0.26\delta)\} \times 10^3 \text{ cm}^{-1}, \quad (6)$$
$$n = 11,\ r = 0.988,\ sd = 0.17 \times 10^3 \text{ cm}^{-1}.$$

A plot of $\nu(\mathbf{1})_{max}$ against $(\pi^* - 0.26\delta)$ is shown in Fig. 1.

Since we have shown earlier[1d,7] that the d value in Eq. 2 is effectively zero for the $\pi \rightarrow \pi^*$ transitions of indicators **2**—**7**, it is necessary to inquire why d should have a large negative value for the corresponding transition of indicator **1**. This is particularly important because, in all correlations of electronic spectra which we have hitherto carried out, the general conclusion had been that solvatochromic equations reflected either of two patterns of behavior: (a) If ν_{max} was shifted bathochromically with increasing solvent dipolarity/polarizability, as was usually the case for $\pi \rightarrow \pi^*$ transitions of uncharged indicators, d in Eq. 2 was zero. (b) For all spectra shifted hypsochromically with increasing solvent π^* values, as was usually the case for $n \rightarrow \pi^*$ transitions of uncharged indicators and $\pi \rightarrow \pi^*$ transitions of zwitterionic indicators, d was always finite and negative. 4-Nitrophenoxide is the first example we have investigated of an anionic indicator, and it is of interest that it follows still a third pattern of behavior, *i.e.*, a bathochromic shift with increasing solvent π^* values coupled with a large negative value of d in Eq. 2.

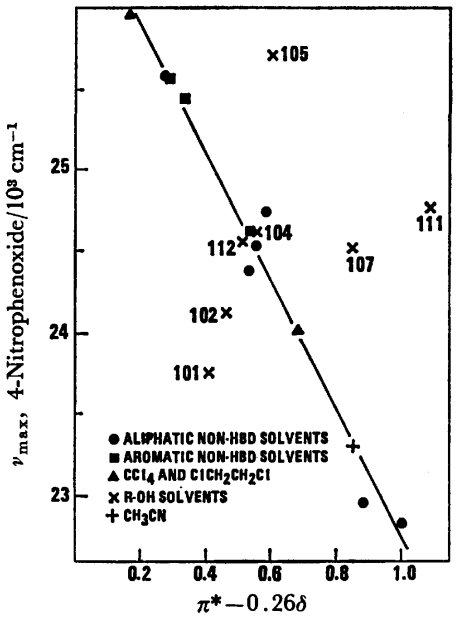


Fig. 1. $\nu(\mathbf{1})_{max}$ plotted against $(\pi^* - 0.26\delta)$.

We had earlier suggested[1d,7] that d is zero when the indicator dipole does not change direction in the electronic excitation (so that solvent molecules which are optimally situated to solvate the indicator ground state are also well oriented to solvate the excited state). Finite negative values of d had been associated with transitions wherein the direction of the indicator dipole changed in the electronic transition and, in conformance with the Franck-Condon principle, solvent molecules which were well situated to solvate the ground state were poorly oriented to solvate the excited state. On this basis the large negative d value for **1** suggests that the dipole changes direction in the electronic excitation and is consistant with canonical structure **1a** being the dominant contributor to the ground state and **1d** the dominant excited state contributor.

Effects of Hydrogen Bonding by Protic Solvents. The correlations become particularly interesting when we consider the HBD (hydrogen bond donor) solvents, $\nu(\mathbf{1})_{max}$ values for which are also plotted in Fig. 1, where it is evident that they do not conform with the correlation with $(\pi^* - 0.26\delta)$. We denote the vertical displacements of the HBD solvent data points from the regression line by $\Delta\Delta\nu(\mathbf{1}-\pi^*)$, and we define this quantity as the additional shift in $\nu(\mathbf{1})_{max}$ caused by hydrogen bonding to **1** by the solvent after the solvent dipolarity/polarizability effects have been accounted for by a correlation with the π^* scale. We

a) Solvent numbering is the same in all papers of this series.

calculate this hydrogen bonding effect by,

$$\Delta\Delta\nu(\mathbf{1}-\pi^*) = \nu(\mathbf{1})_{max}^{obsd} - \nu(\mathbf{1})_{Eq.\,3}^{calcd}. \quad (7)$$

Values of $\Delta\Delta\nu(\mathbf{1}-\pi^*)$ for the protic solvents are also assembled in Table 1.

It is seen in the table and the figure that while the net hydrogen bonding effect is essentially *nil* for the very weak HBD solvent acetonitrile (solvent 50), significant displacements from the regression line are observed for the R–OH solvents. For the intermediate strength hydrogen bond donors, *t*-butyl alcohol (101) and 2-propanol (102), the $\Delta\Delta\nu$ terms are negative (shifted bathochromically relative to Eq. 3); for the stronger HBD solvents, methanol (105), ethylene glycol (107), and water (111), $\Delta\Delta\nu$'s are positive (shifted hypsochromically).

While this hints at a complex solvation mechanism, the relationship between $\Delta\Delta\nu(\mathbf{1}-\pi^*)$ and the solvent α values (α being the parameter which measures solvent HBD acidity)[2] is noticeably simple and precise. A plot of $\Delta\Delta\nu(\mathbf{1}-\pi^*)$ against α for the R–OH solvents is shown in Fig. 2. It is seen that linear regression is excellent; the correlation equation is,

$$\Delta\Delta\nu(\mathbf{1}-\pi^*) = (-7.30 + 8.80\alpha) \times 10^3\ \text{cm}^{-1}, \quad (8)$$
$$n = 7,\ r = 0.989,\ sd = 0.20 \times 10^3\ \text{cm}^{-1}.$$

Equations 3 and 8 can be combined to give the total solvatochromic equation for 4-nitrophenoxide spectra in hydroxylic solvents,

$$\nu(\mathbf{1})_{max} = (19.41 - 3.99\pi^* + 8.80\alpha) \times 10^3\ \text{cm}^{-1}. \quad (9)$$

Alternatively the dependence of $\nu(\mathbf{1})_{max}$ on the solvatochromic parameters may be determined by the method of multiple linear regression analysis. For the seven hydroxylic solvents of Table 1, the multiple parameter least squares fit is given by Eq. 10a.

$$\nu(\mathbf{1})_{max} = (19.88 - 3.13\pi^* + 7.67\alpha) \times 10^3\ \text{cm}^{-1}, \quad (10a)$$
$$r = 0.936,\ sd = 0.22 \times 10^3\ \text{cm}^{-1}.$$

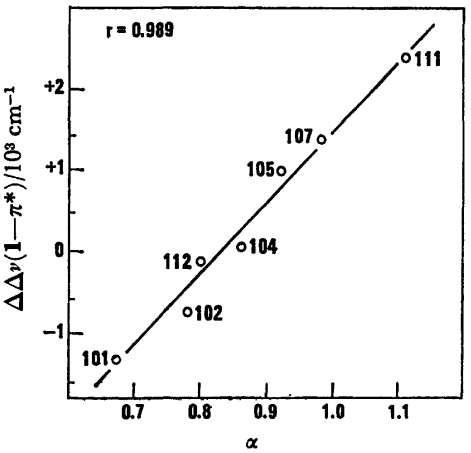

Fig. 2. $\Delta\Delta\nu(\mathbf{1}-\pi^*)$ for hydroxylic solvents plotted against solvent α values.

If, however, the result for ethylene glycol (whose π^* and α values are relatively less certain) is excluded, the correlation equation becomes,

$$\nu(\mathbf{1})_{max} = (19.44 - 3.90\pi^* + 8.66\alpha) \times 10^3\ \text{cm}^{-1}, \quad (10b)$$
$$r = 0.963,\ sd = 0.20 \times 10^3\ \text{cm}^{-1}.$$

The agreement between Eqs. 9 and 10b is surprisingly good if one considers that (a) the *s* values are based on completely different data sets; (b) the π^* values for hydroxylic solvents are somewhat less precise than those for aprotic solvents; and (c) the effects of dipolarity and hydrogen bonding are in different directions and tend to cancel one another, thus narrowing the range of the $\nu(\mathbf{1})_{max}$ values in the hydroxylic solvents compared with the aprotic solvents. The negative sign of the π^* term indicates that increasing solvent dipolarity/polarizability leads to a red shift; the positive sign of the α term indicates that increasing solvent HBD acidity leads to a blue shift. The similar

values of s in Eqs. 3 and 10b imply (perhaps incorrectly or adventitiously, as discussed below) that the dipolarity effects on $\nu(\mathbf{1})_{max}$ are the same in hydroxylic and non-protonic solvents. There are additional considerations, however, which affect the results.

Specific solvation effects are complicated by the expectation of bonding at two sites. For example, hydrogen bonding to the nitro oxygens[8,9] should stabilize canonical structure **1d** and hence the electronic excited state, and thus lead to a bathochromic shift (as has been demonstrated for *N,N*-diethyl-4-nitroaniline).[8] Bonding to the phenoxide oxygen should stabilize structure **1a** and the ground state, and lead to a hypsochromic shift (as mentioned by U. and K.). The phenoxide site being significantly the more basic,[9] the net hypsochromic effect of hydrogen bonding (or other specific solvation)[10] is as expected.

The 7.3×10^3 cm^{-1} difference in the $\nu(\mathbf{1})_0$ values (intercepts) in Eqs. 3 and 10b requires explanation. The $\nu(\mathbf{1})_0$ value represents the regression result in a saturated hydrocarbon environment ($\pi^*=0$, $\alpha=0$ for cyclohexane).

We take the difference in $\nu(\mathbf{1})_0$ as implying that the electronic structures of 4-nitrophenoxide in both ground and electronic excited states are different in aprotic and hydroxylic solvents. From the 7.3 10^3 cm^{-1} higher $\nu(\mathbf{1})_0$ in Eq. 3 relative to Eq. 10b, the difference would appear to derive from significant stabilization of the ground state and/or destabilization of the excited state structure in the aprotic solvents relative to the corresponding 4-nitrophenoxide structures in the hydroxylic solvents. An explanation proposed by U. and K. provides an adequate rationale for such an effect.

These workers have pointed out that in aprotic solvents there is strong ion-pairing between the phenoxide anion and the 15-crown-5-bound sodium cation, whereas in hydroxylic solvents ion-pairing is negligible [indeed, the addition of crown ether produced essentially no effect on $\nu(\mathbf{1})_{max}$ in the hydroxylic solvents]. In the extrapolation of the experimental results of Table 1 back to $\pi^*=0$ and $\alpha=0$, such ion-pairing should significantly stabilize the ground state structure of **1** relative to the excited state in the case of the non-protonic solvents, but not in the hydroxylic solvents. Furthermore, 'tighter' ion-pairing with decreasing solvent dipolarity (as well as the decrease in any specific solvation of the nitro substituent)[10] should increase the magnitude of this effect as the π^* values became smaller in the solvents studied experimentally. It should be recognized, however, that if this rationale is correct, the agreement between Eqs. 9 and 10b may be largely adventitious, or possibly regression equation 10a may be more nearly correct.

Part of the work of J.-L.M.A. was carried out while on leave at Centro Meccanismi di Reazioni Organiche del C.N.R., Istituto di Chimica Organica, Universita di Padova, Italy. Valuable discussions with Professors G. Modena and G. Scorrano, and the financial support from C.N.R. (Rome) are gratefully acknowledged. The work by R.W.T. was supported in part by a grant from the Public Health Service. The work by M.J.K. was done under Naval Surface Weapons Center Foundational Research Task IR-201.

(Received March 30, 1981)

Synopsis. Kinetic studies of the dimerization reaction of fluorescein (doubly charged anion) in aqueous solution were performed by the ultrasonic absorption method. The data obtained could not be interpreted by the rate equation derived with the usual viscosity effect assumed for the diffusion process. Rather, an experimental equation was found, which adequately fits the data. Here, the viscosity contribution is $k_f=k_f^0/\eta_r$, $k_b=k_b^0$, and $K=K^0/\eta_r$.

The aggregation of many dyes have been investigated both spectrophotometrically and kinetically as a simple model system of molecular aggregation. The kinetics of the aggregation of fluorescein, however, has not been investigated because the aggregate is unstable and the rates of the reaction are too rapid to be studied by conventional techniques.

Ultrasonic absorption of fluorescein in aqueous solution was measured in the frequency range 4.5—95 MHz under the condition of pH 12.0, where the dye exists as the doubly charged anion, 25 °C, ionic strength 5 M.† The absorptions could be explained by a single relaxation.

Since fluorescein is known to form a dimer under the present experimental conditions,[1-5] the relaxation absorption is ascribed to the following equilibrium:

$$2\,M^{2-} \underset{k_b}{\overset{k_f}{\rightleftharpoons}} D^{4-}, \qquad (1)$$

where M^{2-} is the monomer and D^{4-} is the dimer. For this reaction, the relaxation frequency f_r is related to the rate constants by the following equation:

$$(2\pi f_r)^2 = k_b^2 + 8k_fk_bC_0, \qquad (2)$$

where C_0 is the total concentration of the dye. This equation predicts that f_r^2 increases monotonously with C_0, which was not satisfied by the experimental data.

The fact that the viscosity of the solution changes greatly with increase of the dye concentration lead us to consider the viscosity effect on the rate constants. Dimerization reaction involves the diffusion process, whose rate constants are theoretically calculated by the Smoluchowski-Debye-Eigen Equations.[6] Combining with the Stokes-Einstein relation, which represents the viscosity dependence of the diffusion coefficients, the diffusion rate constants are shown to have the viscosity dependence $k=k^0/\eta_r$ where η_r is the relative viscosity, and the superscript 0 represents the value at $\eta_r=1$. Following the usual treatment of the kinetics, k_f and k_b have the same viscosity dependence as that of the diffusion rate constants.[7] Accordingly, Eq. 2 becomes

$$(2\pi f_r)^2 = (k_b^{02} + 8k_f^0k_b^0C_0)/\eta_r^2. \qquad (3)$$

If this is correct, the $(2\pi f_r)^2\eta_r^2$ *vs.* C_0 plot should be linear. As shown in Fig. 1, however, the plot deviates greatly from a straight line. Further, this idea also fails to give a satisfactory explanation for the concentration dependence of the absorption amplitude. Thus we must look further for a satisfactory explanation.

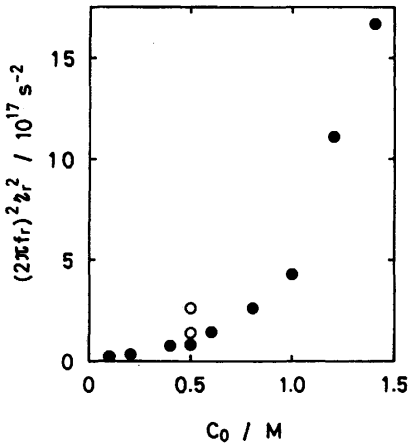

Fig. 1. Plot of $(2\pi f_r)^2\eta_r^2$ *vs.* C_0.
●: Glycerol free, ○: glycerol added.

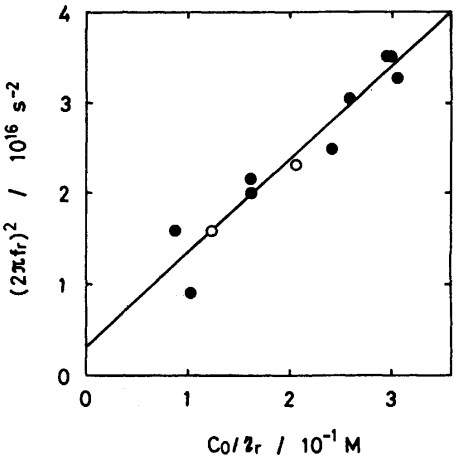

Fig. 2. Plot of $(2\pi f_r)^2$ *vs.* C_0/η_r.
●: Glycerol free, ○: glycerol added.

Petrucci[8] has proposed an empirical formula for the viscosity dependence of the rate constants, *i.e.*, $k_f=k_f^0/\eta_r$ and $k_b=k_b^0$. In this case, Eq. 2 can be rewritten as

$$(2\pi f_r)^2 = k_b^{02} + 8k_f^0k_b^0C_0/\eta_r. \qquad (4)$$

Equation 4 predicts a linear relationship for $(2\pi f_r)^2$ *vs.* C_0/η_r plot, which is well satisfied, as shown in Fig. 2. Further, this type of viscosity dependence of f_r was ascertained by changing the viscosity of the solution with the addition of glycerol, *i.e.*, to the 0.5 M dye solution, 8.3 and 16.6 wt% glycerol were added. The results obtained are also plotted in Fig. 2 with the open circles and the tendency displayed is similar to that for dye alone. From the slope and the intercept of the straight

† In this paper, 1 M=1 mol dm^{-3}.

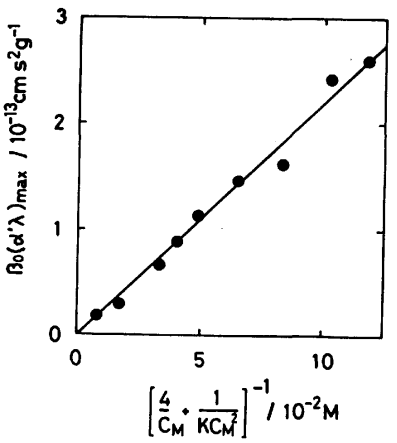

Fig. 3. Plot of $\beta_0(\alpha'\lambda)_{max}$ *vs.* $(4/C_M+1/KC_M^2)^{-1}$ with $C_M=(-1+(1+8KC_0)^{1/2})/4K$.

line, the rate constants were determined to be $k_f^0=2.3\times10^8$ M^{-1} s^{-1} and $k_b^0=5.6\times10^7$ s^{-1}; the equilibrium constant $K^0(=k_f^0/k_b^0)$ was determined to be 4.1 M^{-1}, which is in good agreement with the literature value determined by the spectrophotometric measurements.[1-5] The value of k_f^0 is in the same order of magnitude as that of other dyes,[9,10] which means that the electric charge effect is relatively small in k_f^0, while the value of k_b^0 is the largest of those dyes studied, which is the reason for the small equilibrium constant. The experimental result that the viscosity dependences of k_f and k_b are different from each other, in conflict with the theoretical prediction described before, is interesting.

The result obtained for the rate constants also means that the equilibrium constant changes with the viscosity, *i.e.*, $K=K^0/\eta_r$. This fact was further ascertained by the result of the absorption amplitude. The relaxation absorption $(\alpha'\lambda)_{max}$ of reaction 1 is expressed by

$$(\alpha'\lambda)_{max}=\frac{\pi(\Delta V)^2}{2\beta_0RT}\left(\frac{4}{C_M}+\frac{1}{KC_M^2}\right)^{-1} \quad (5)$$

with

$$C_M=\{-1+(1+8KC_0)^{1/2}\}/4K,$$

where ΔV is the volume change of the reaction and β_0 is the adiabatic compressibility. If we use the viscosity dependent equilibrium constant $K=K^0/\eta_r$, a good linear relationship is obtained, which is well coincident with that predicted by Eq. 5. The value of ΔV was determined from the slope of the straight line in Fig. 3 to be -6.0 cm^3 mol^{-1}.[11]

In conclusion, the viscosity effect on k_f and the fact that the value of k_f is in the same order of magnitude with those of other dyes, show that the association reaction is diffusion controlled. On the other hand, the viscosity independence of k_b implies that the dissociation reaction is limited by some intramolecular process of the dimer.

Infrared Study of the Oxidation of 2-Propanol on TiO_2

Takashi NAKAJIMA, Hisashi MIYATA,* and Yutaka KUBOKAWA*
Department of Applied Chemistry, University of Osaka Prefecture, Mozuumemachi, Sakai, Osaka 591
(Received June 1, 1981)

Synopsis. Oxidation of 2-propanol on TiO_2 was studied by infrared spectroscopy as well as analysis of reaction products. Propene and acetone are formed from isopropoxide species on TiO_2. Only adsorbed acetone is oxidized to carbon dioxide *via* carboxylate species. Propene undergoes no oxidation.

We previously studied surface species formed in oxidation of alcohols on metal oxides such as MgO,[1] NiO,[1] and ZnO[2,3] and concluded that secondary alcohols are dehydrogenated to ketones, which are in turn oxidized to carboxylate species *via* enolate complexes of ketones. However, Walker *et al.*[4] reported that over a UV-irradiated TiO_2 secondary alcohols are oxidized *via* alkenes which have been formed by dehydration. In order to decide to what extent the conclusion obtained with MgO and ZnO is applicable, in the present research similar experiments were extended to the 2-propanol/TiO_2 system for which propene formation is expected to be predominant.

The titanium dioxide used was obtained from Japan Aerosil Co. The details of the apparatus and procedures were as reported previously.[1-3,5] A sample disk was degassed, oxidized at 673 K for several hours, degassed for a short period at the same temperature, and cooled to room temperature. After introduction of 1 cm^3/g of the reactant into an IR cell, an oxygen of 2 kPa was circulated over the TiO_2, the temperature of which was raised in steps. Each of stepwise heat-treatments of the sample was followed by recording infrared spectra at ambient temperature on a JASCO IR-G infrared spectrometer, no reference disk being used.

The infrared spectrum of 2-propanol adsorbed on TiO_2 (1.0 cm^3/g) exhibits a number of bands (Fig. 1a), which does not change significantly on evacuation at 353 K. All the bands except for the one at 3430 cm^{-1} agree with those due to the surface isopropoxide formed on metal oxides,[1,2,6] confirming the formation of the surface isopropoxide species on TiO_2.

The temperature of the disk containing isopropoxide was raised in steps under circulation of oxygen. The bands due to isopropoxide were slightly reduced in intensity at 423 K (Fig. 1b) and disappeared at 523 K (Fig. 1c). The band appearing at 1690 cm^{-1} at 423 K can be attributed to a coordinately adsorbed acetone as will be described later. As regards the new bands appearing at 523 K, the following assignments are possible from comparison of surface carboxylate species on metal oxides.[1-3,7,8] The bands at 1560 and 1360 cm^{-1} are due to the formate species,[7] while those at 1530 and 1440 cm^{-1} are due to the acetate species.[8]

Figure 2 shows the amount of oxygen taken up as well as the amount of reaction products, measured at each step in the stepwise heating in oxygen. At 523 K, formation of water occurs together with uptake of oxygen in an appreciable amount, as expected from the formation of carboxylate species described above.

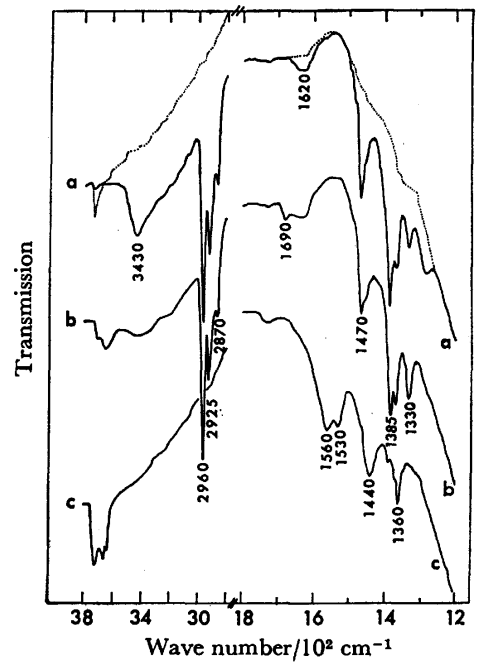

Fig. 1. Interaction of oxygen with 2-propanol adsorbed on TiO_2.
(a): After 1 h adsorption of 2-propanol (1.0 cm^3/g) at 293 K, (b): followed by 1 h at 423 K in oxygen (2.0 kPa), (c): 1 h at 523 K in oxygen.

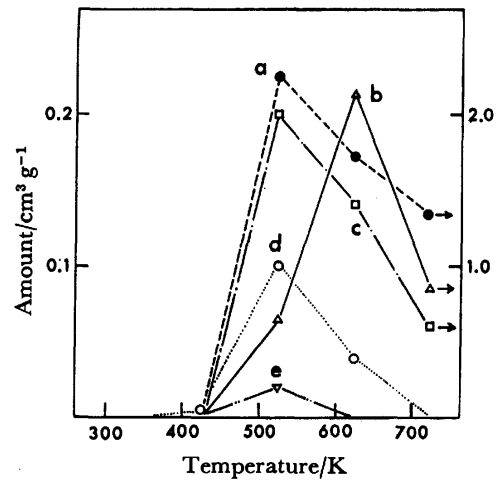

Fig. 2. Reaction of oxygen with 2-propanol adsorbed on TiO_2.
(a): Oxygen uptake or consumed by the reactions, (b): CO_2 formed, (c): H_2O formed, (d): propene formed, (e): acetone formed. Amount of 2-propanol adsorbed at 293 K was 1.1 cm^3/g.

CO_2 is formed above 523 K. In addition, propene and a small amount of acetone are also formed, providing information on intermediates for the oxidation.

In order to obtain information on the pathway of the

oxidation, similar experiments were carried out with propene or acetone adsorbed on TiO_2. When a small amount of propene (500 Pa) was introduced to the TiO_2 at ambient temperature, bands appeared at 2950, 2920, 1635, and 1460 cm^{-1}. Evacuation of the sample at ambient temperature reduced the intensity of the bands, suggesting that propene is weakly adsorbed on TiO_2. On raising the temperature of the sample containing propene in oxygen, few carboxylate bands could be observed. On the other hand, the acetone adsorption was found to be strong. The adsorbed acetone shows bands at 1700, 1620, and 1590 cm^{-1} in the carbonyl stretching region (Fig. 3a). Their corresponding bands were observed at 1690, 1600, and 1570 cm^{-1} with acetone-d_6. The 1700- or 1690-cm^{-1} band of acetone or acetone-d_6 can be assigned to CO-stretching vibrations of coordinately adsorbed species on Lewis acidic sites.[9] The same assignment appears applicable to the bands at 1620 and 1590 cm^{-1}, as proposed by Kiselev and Uvarov.[10] The possibility that these bands arise from mesityl oxide as proposed by Griffiths and Rochester,[9] may be excluded since no mesityl oxide

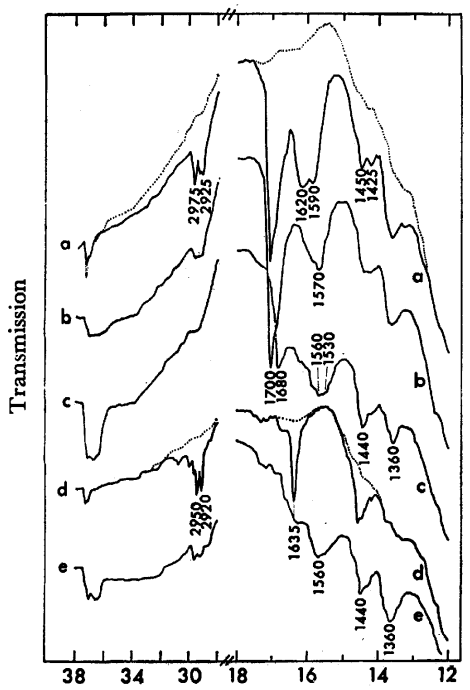

Fig. 3. Interaction of oxygen with acetone or propene on TiO_2.
(a): After 2 h adsorption of acetone (1.0 cm^3/g) at 293 K, (b): followed by 1 h at 353 K in oxygen (1.0 kPa), (c): 1 h at 423 K in oxygen, (d): after introduction of propene (500 Pa) at 293 K, (e): after 1 h reaction at 423 K in a mixture of propene (500 Pa) and oxygen (2.0 kPa). In Figs. 1 and 3, the dotted lines show background spectra.

was detected in the present system. Although at present it is not decided whether or not the band at 1570 cm^{-1} appearing at 353 K is attributable to the enolate species, its formation is supported by the occurrence of hydrogen isotopic exchange between acetone-d_6 and surface OH groups, which proceeds *via* the enolate intermediate.[11] The spectral behavior of adsorbed acetone upon raising the temperature was similar to that of adsorbed 2-propanol in that the carbonyl bands were reduced in intensity, while the carboxylate bands appeared (Fig. 3c).

Contribution of the weakly adsorbed propene to the oxidation was examined by allowing a mixture of propene (500 Pa) and oxygen (2 kPa) to circulate over the TiO_2 at 423 K. The results were compared with those of similar experiments using acetone instead of propene. The amount of carbon dioxide formed in the acetone/oxygen system was found to be more than ten times that in the propene/oxygen system, where carboxylate bands were observed as shown in Fig. 3e.

Figure 2 shows that about 12% of the 2-propanol adsorbed on TiO_2 is converted to propene, in contrast to the negligible formation of propene observed with MgO[1] and ZnO.[2] Such a difference may by expected from acid-base properties of metal oxides. From the results described above, it is concluded that the propene formed on TiO_2 makes no contribution to the formation of oxidation products. It appears that the acetone formed by dehydrogenation is oxidized to carboxylate species, from which CO_2 is formed. About 88% of the 2-propanol adsorbed on TiO_2 was oxidized *via* this reaction pathway. Thus, the same conclusion as that with MgO and ZnO is also applicable to TiO_2.

X-Ray Structure of (1*RS*, 5*RS*, 7*SR*)-1-Acetoxy-7-cyano-5-methylbicyclo-[3.2.0]heptan-2-one, a Photocycloadduct of 2-Acetoxy-3-methyl-2-cyclopenten-1-one and Acrylonitrile

Akio Furusaki,* Katsumi Abe, and Takeshi Matsumoto
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received July 20, 1981)

Synopsis. The main product of the photocycloaddition between 2-acetoxy-3-methyl-2-cyclopenten-1-one and acrylonitrile has been found to be (1*RS*, 5*RS*, 7*SR*)-1-acetoxy-7-cyano-5-methylbicyclo[3.2.0]heptan-2-one by means of X-ray crystal structure analysis.

Previously, we reported the synthesis of a sesquiterpene through a process involving the (2+2) photocycloaddition between a 2-acetoxy-3-methyl-2-cyclopenten-1-one (**1**) derivative and 1,1-diethoxyethylene.[1] In the course of studies on the synthesis of a related sesquiterpene, it became necessary to investigate the photoaddition of **1** with acrylonitrile (**2**). Few studies seem to have been made on the photoaddition of cycloalkenones with this electron-deficient olefin since the classical work of Corey *et al.*[2] They showed that the reaction of 2-cyclohexen-1-one with **2** was extremely slow, compared with similar reactions with electron-rich olefins, and suggested that the main products were 8-epimeric 8-cyano-*cis*-bicyclo[4.2.0]octan-2-ones. In order to establish the structure of the main product (**3**, 15.7% yield at 56% conversion) of the photocycloaddition between **1** and **2**, we have now undertaken an X-ray crystal structure analysis.

Experimental

Photoaddition. A solution of **1**[3] (1 g, 6.5 mmol) and freshly-distilled **2** (10.33 g, 195 mmol) in a mixture of THF (21 ml) and EtOH (70 ml) was irradiated with a Hanovia 75-W high-pressure mercury lamp under ice-cooling and N_2 atmosphere. A Pyrex filter was used. After 5 h, the mercury lamp was shut off, a white polymeric deposit was removed by filtration, and the filtrate was concentrated *in vacuo*. The residual oil (2.5 g) was chromatographed on silica gel (Kanto, 40 g) using EtOAc–benzene (1 : 9) as the eluent. The first fraction contained the cycloadduct, **3** (98 mg, 7.8%): mp 100.0—101.5 °C; IR (Nujol) 2260 (C≡N), 1752 (ester C=O), 1736 cm^{-1} (cyclopentanone); NMR (CCl_4) δ=1.38 (3H, s), 1.90 (2H, m), 2.11 (3H, s), 2.14 (2H, d, J=6.5 Hz), 2.58 (2H, m), 3.11 (1H, t, J=6.5 Hz). Found: C, 63.39; H, 6.39; N, 6.72%. Calcd for $C_{11}H_{13}NO_3$: C, 63.76; H, 6.32; N, 6.76%. The second fraction was an oily mixture (170 mg) of **3** and an unidentified product, **4** (2 : 1 by NMR). The third fraction was an oil composed of **4** and the other product, **5** (1 : 1 by NMR). From the fourth fraction, 443 mg of **1** was recovered.

X-Ray Measurement. A colorless, single crystal with dimensions of about 0.3×0.3×0.4 mm^3 was used. The crystal data are as follows: $C_{11}H_{13}NO_3$, mol wt 207.2, monoclinic, space group $P2_1$, a=13.852(4), b=6.750(3), c=13.096(4) Å, β=116.69(5)°, Z=4, D_c=1.258 g cm^{-3}. The cell dimensions and diffraction intensities were measured on an automated, four-circle diffractometer with LiF-monochromated Cu $K\alpha$ radiation (λ=1.5418 Å). The θ—2θ scan technique was applied at a θ scan rate of 0.5° min^{-1}; the background was measured for 30—60 s at each end of the scan range. Three standard reflections, measured at intervals of every 62 reflections, showed no significant decrease in intensity during the course of data collection. The intensities were corrected for the Lorentz and polarization factors, but not for the absorption or the extinction effect. In the range of 2θ values up to 140°, 2229 unique structure-factor magnitudes above the $\sigma(F)$ level were selected for the structure determination.

Structure Determination

The structure was solved by the Monte Carlo direct method,[4] using the 30 strongest reflections as the starting set. In order to extend the tentative-phase set derived from random numbers, 12 cycles of the tangent procedure were carried out using 447 $|E|$ values above 1.30. The 21st phase set led to the correct solution; an E-map based on 439 phases revealed the locations of all the 30 non-hydrogen atoms. After all the 26 hydrogen atoms had been located in a difference Fourier map, the structure was refined by the block-diagonal least-squares method with anisotropic temperature factors for the non-hydrogen atoms and isotropic ones for the hydrogen atoms. For this refinement, the following weighting scheme was used:

$$w = 1/\{\sigma(F)^2 \exp(AX^2 + BY^2 + CXY + DX + EY)\},$$

where $X=|F_0|$ and $Y=\sin\theta/\lambda$. The A, B, C, D, and E coefficients are constants which were determined from the $(\Delta F)^2$ values; A=0.001199, B=20.61, C=1.079, D=−0.2608, and E=−30.11. The final R value was 0.044. The final atomic parameters are listed in Table 1.†

The calculations were performed on FACOM 230-75 and HITAC M-200H computers at the Hokkaido University Computing Center, using our own programs. The atomic scattering factors were taken from the International Tables.[5]

Results and Discussion

The two crystallographically-independent molecules, A and B, have almost the same geometries, except that their absolute configurations are opposite. The skeleton of the B molecule is drawn in Fig. 1(a); the structure of **3** has thus been established as shown in Fig. 1(b). The position of the cyano group agrees with that predicted by the frontier-orbital theory.[6] The torsion angles for the bicyclic system are given in Fig. 2. The

a) $B_{eq}=8\pi^2(u_1^2+u_2^2+u_3^2)/3$, where u_i is the root-mean-square deviation in the ith principal axis of the thermal ellipsoid.

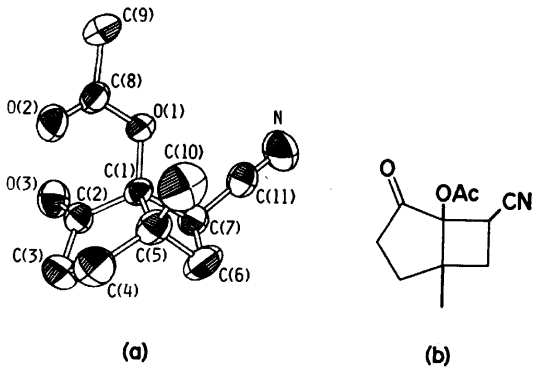

Fig. 1. A perspective view of the **3** molecule, and the corresponding structural formula.

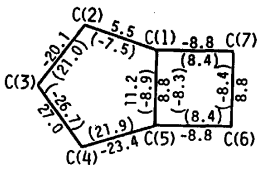

Fig. 2. The torsion angles (ϕ/°) for the bicyclic system. The values for the B molecule are given in parentheses.

cyclopentanone ring takes a half-chair form; the C(4) and C(3) atoms deviate from the C(2)–C(1)–C(5) plane onto the side of the acetyl group and the opposite side, respectively. It should be noted that the acetyl oxygen atom, O(2), approaches closely the ketonic carbon atom, C(2); their distance is 2.661(3) and 2.682(5) Å for the A and B molecules respectively. In this connection, the C(2) atom deviates slightly from the plane through the C(1), C(3), and O(3) atoms onto the side of the O(2) atom; this deviation is 0.018 and 0.011 Å for the A and B molecules respectively. The cyclobutane ring is somewhat puckered; the puckering angle is about 12° for both molecules.

Determination of Thermodynamic Properties of Diaspore from Its Solubility Data in NaOH Solutions

Byong-Tae CHANG

Department of Chemistry, Faculty of Science, Korea University, Kodaira, Tokyo 187

(Received February 27, 1981)

Synopsis. Thermodynamic properties of diaspore in the alkaline pH range were determined from its solubility data in NaOH solutions by a method presented earlier by the author. The ionic solubility product, $K_S^\circ = a_{Al}a_H/a_w^2$, of diaspore was found to depend upon temperature between 280 and 325 °C as follows: $\log K_S^\circ = -1367/T - 8.67$.

In the previous paper,[1] the following general equations were derived in order to determine thermodynamic properties of alumina monohydrate from its solubility data in NaOH solutions, they were applied successfully to a dissolution process of boehmite in NaOH solutions:

$$AlOOH(s) + 2H_2O\,(l) = Al(OH)_4^-(l) + H^+(l), \quad (1)$$

$$K_s^\circ = a_{Al}a_H/a_w^2 = K_s\gamma_1^2/a_w^2, \quad (2)$$

$$\left.\begin{aligned} f(I) &= \log(m_{Al}/m_{OH}) + \log(K_w^\circ/a_w) \\ &= \log K_s^\circ + 2\log(\gamma_2/\gamma_1) \end{aligned}\right\}, \quad (3)$$

where $K_S = m_{Al}m_H$, m_i the molality of species i, $\gamma_1^2 = \gamma_{Al}\gamma_H$, $\gamma_2^2 = \gamma_H\gamma_{OH}$, $K_w^\circ = a_Ha_{OH}/a_w$, and a_w the activity of water in a given sodium aluminate and hydroxide. The authors reported solubility data of diaspore in NaOH solutions and discussed its thermodynamic properties by applying an extended Debye-Hückel equation to the solubility data.[2] An essential question arose because the slopes of the straight lines of $\log K_S$ *vs.* $I^{1/2}/(1+1.5I^{1/2})$ or $I^{1/2}/(1+2.0I^{1/2})$ were only about half of the theoretical Debye-Hückel limiting slopes. The purpose of this paper is to revaluate the solubility data according to Eqs. 1—3.

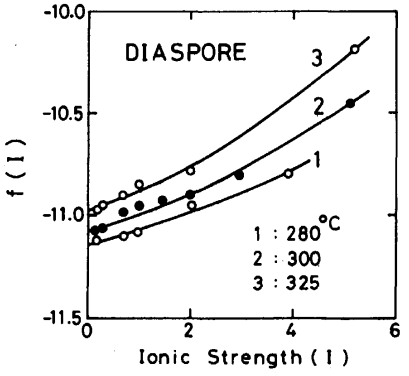

Fig. 1. Relationships between $f(I)$ and ionic strength, I, according to Eq. 3.

Figure 1 gives relationships between $f(I)$ and ionic strength, I, obtained from the solubility data and Eq. 3.[3] Under an assumption of the same ionic size parameters, Eq. 3 can be rewritten as

$$f(I) = \log K_s^\circ + CI + DI^2, \quad (4)$$

where C and D are adjustable parameters. Table 1 gives the values of $\log K_s^\circ$, C, and D determined from the data in Fig. 1 by a method of least squares. Figure 2 shows a temperature dependence of $\log K_s^\circ$ together with that of $\log K_r^\circ$ calculated by following relations:

$$AlOOH(s) + OH^-(l) + H_2O(l) = Al(OH)_4^-(l), \quad (5)$$

$$K_r^\circ = a_{Al}/a_{OH}a_W = K_s^\circ/K_w^\circ. \quad (6)$$

These values are expressed as functions of temperature as follows:

TABLE 1. TEMPERATURE DEPENDENCES OF $\log K_S^\circ$, C, D, AND $\log K_r^\circ$ FOR DIASPORE

No.	Temp/°C	$\log K_S^\circ$	$C\times10^2$	$D\times10^3$	$\log K_r^\circ$
1	280	−11.15	8.56	0.80	−0.13
2	300	−11.06	6.95	8.77	−0.02
3	325	−10.96	6.43	16.46	0.19

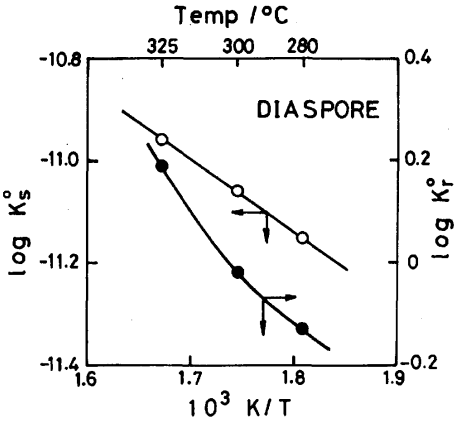

Fig. 2. Temperature dependences of $\log K_s^\circ$ and $\log K_r^\circ$.

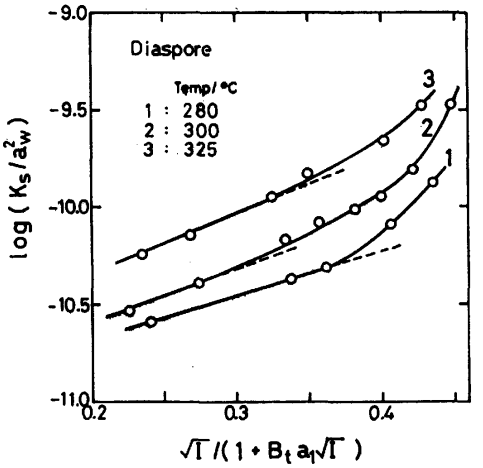

Fig. 3. Plots of $\log(K_s/a_w^2)$ *vs.* $I^{1/2}/(1+B_ta_1I^{1/2})$ at 280, 300, and 325 °C in the case of $a_1 = 4.5$ Å and $a_2 = 5.0$ Å. Values of B_ta_1 are equal to 1.75, 1.79, and 1.87 for curves 1, 2, and 3, respectively.

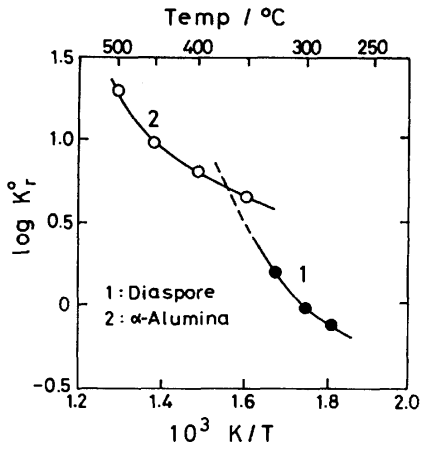

Fig. 4. Temperature dependences of equilibrium constant, K_r°, for diaspore and α-alumina.

$$\log K_s^\circ = -1367/T - 8.67, \quad (7)$$

$$\log K_r^\circ = 2907 - 3.11 \times 10^4/T + 8.27 \times 10^6/T^2, \quad (8)$$

and the heat of Reaction 1 is estimated to be 26.15 kJ.

In the case of different ionic size parameters, the following equations are derived for the dissolution process of alumina monohydrate in NaOH solutions under some assumptions.[1)]

$$\log(K_s/a_w^2) = \log(K_w^\circ/a_w) + \log(m_{Al}/m_{OH}) + 2A_t I^{1/2}/(1 + B_t a_2 I^{1/2}), \quad (9)$$

$$\log(K_s/a_w^2) = \log K_s^\circ + 2A_t I^{1/2}/(1 + B_t a_1 I^{1/2}), + 2c_1 I + 2d_1 I^2, \quad (10)$$

Figure 3 gives plots of log (K_s/a_w^2) *vs.* $I^{1/2}/(1+B_t a_1 I^{1/2})$ at 280, 300, and 325 °C in the case of $a_1=4.5$ Å and $a_2=5.0$ Å. All the curve consist commonly of a straight line in the range of low ionic strength and a positive deviation from it in the range of high ionic strength. Slopes of the straightline are nearly equal to the theoretical Debye-Hückel limiting slopes, $2A_t$. This means that the essential question about the limiting slope described above could be solved by applying more reasonably the extended Debye-Hückel equation. Furthermore, such behaviors of the curves in Fig. 3 are quite consistentwith those of gibbsite[4)] and boehmite.[1)]

Comparison of the temperature dependence of K_s° for diaspore with that of boehmite suggested that the transition temperature between diaspore and boehmite was 170 °C. On the other hand, the transition temperature between diaspore and α-alumina become 368 °C as shown in Fig. 4,[5)] which agrees well with the Al_2O_3-H_2O phase diagram presented by Neuhaus[7)] and Yamaguchi.[8)]

The Thermal Decomposition of Crystalline Antimonic(V) Acid

Mitsuo ABE* and Kazufuyu SUDOH

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, 2-12-1, Ookayama, Meguro-ku, Tokyo 152

(Received December 8, 1980)

Synopsis. The thermal decomposition of crystalline antimonic(V) acid (C-SbA) was studied by means of DTA, DSC, and DTG. The amount of water evolved from the heated C-SbA was determined by the Karl Fischer method. The material heated in the range of 600—1000 °C is Sb_6O_{13}, neither $Sb_3O_6(OH)$ nor $H_2Sb_{12}O_{26}$. The thermal decomposition of C-SbA consists of four dehydration and two reduction steps up to 1000 °C.

The thermal analysis of antimonic(V) acid or hydrous antimony(V) oxide has been studied by various authors.[1-9] The existence of the two forms, valentinite and senarmontite of Sb_2O_3, is unquestionable, and both the Sb_2O_4 dimorphs (α- and β-) have been well characterized by single-crystal X-ray studies. However, much confusion can be found in the literature regarding the higher oxides and their hydrous oxides. Especially, the material heated at 600—800 °C gave an X-ray pattern with a pyrochlore structure (Fd3m) rather than that of Sb_2O_4, which prompted Dihlstöm and Westgren to reassign the Sb_3O_6OH composition.[4] This compound is accepted on the basis of many present texts.

Moreover, the X-ray powder data of material heated at 780 °C is erroneously listed in the ASTM X-ray powder data card file (No. 11-690 in the 1966 edition) as having the composition of Sb_2O_5.[5,7]

Extensive studies of the materials obtained by heating the different antimonic(V) acids (amorphous, glassy, and crystalline) have been carried out by Abe and Ito using X-ray, DTA, TG, IR, and chemical analysis.[5,6] The thermal decomposition of crystalline antimonic(V) acid (C-SbA) up to 1300 °C follows the scheme:

$$(H_3O)_2Sb_2O_5(OH)_2 \xrightarrow{200°C} H_2Sb_2O_5(OH)_2 \xrightarrow{350°C}$$
$$Sb_2O_5 \xrightarrow{550°C} Sb_6O_{13} \xrightarrow{800°C} Sb_2O_4(\alpha\text{- and }\beta\text{-}) \xrightarrow{1200°C}$$
$$Sb_2O_3 \xrightarrow{1250°C} \text{sublimation.}$$

A similar conclusion was recently observed by Stewart *et al.*[7] Kleshchev *et al.* have suggested that the product of the antimonic acid heated at 600—800 °C is $H_2Sb^{III}_5Sb^{V}_7O_{26}$ or $H_2Sb^{III}_{10}Sb^{V}_{16}O_{56}$,[8,9] from structural studies of its pyrochlore phase, and that it is not possible to determine such a hydrogen content by means of gravimetric analysis. Another scheme of the thermal decomposition of crystalline antimonic acid, leading to the stepwise formation of H_3OSbO_3 (148 °C at DTA temp.), Sb_3O_6OH(348 °C), Sb_6O_{13}(620 °C), and Sb_2O_4 (940 °C), has been reported by Novikov *et al.*[10] However, no direct evidence has been obtained for the existence of Sb_3O_6OH or $H_2Sb^{III}_{10}Sb^{V}_{16}O_{56}$.

In the present work, the thermal decomposition of the C-SbA has been reexamined by means of DTA, DTG, and DSC, and the water content has been determined by using the modified Karl Fischer method.[11]

Experimental

The C-SbA was prepared as has been described previously.[5] The C-SbA air dried for over 1 year was humidified on a desiccator over saturated NaCl solution (with a relative humidity of 75% at 20 °C) and was then used in the following experiments.

The inside of the systems of the heating and titration apparatus was free from moisture by passing through dried air at a flow rate of 70 cm^3 min^{-1}. The dried air was obtained by passing through (in the order), silica gel, anhydrated $Mg(ClO_4)_2$, and finally diphosphorus pentoxide. The titration apparatus was set at 20±0.3 °C in order to prevent volumetric error caused by the thermal expansion of the Karl Fischer reagent. The C-SbA of 240 mg was heated in dried air by using a Rigaku Denki Thermoflex 8002 with a thermogravimetric analyser at a heating rate of 10 °C min^{-1} up to the desired temperature, it was then kept for 12 h at that temperature. The water evolved from the heated C-SbA was absorbed into an anhydrous solvent "Mitsubishi ME" (a mixture of methanol and ethylene glycol)supplied by the Mitsubishi Kasei Co.; it was then titrated by using Karl Fischer reagent of SS "Mitsubishi." The strength of the Karl Fischer reagent was standardized with appropriate amounts of deionized water.

For the thermal analysis, about a 40-mg portion of the C-SbA was packed in a platinum crucible. The DTG curve of the C-SbA was determined by differentiating the TG curve obtained with the temperature. The DSC and DTG curves thus obtained were separated into individual peaks by means of non-linear least-squares fit, assuming that each peak of the DSC and DTG curves can be approximated by the following equation:

$$\text{Peak}=A\cdot\exp\{-B\cdot(C-T)^2\}.$$

Where A, B, and C are parameters, and T is the temperature from thermal analysis (°C).

The X-ray diffraction data for the heated C-SbA were determined by using a JEOL X-ray diffractometer, Model JDX-7E, with Ni-filtered Cu $K\alpha$ radiation.

Results and Discussion

The X-ray analysis of the C-SbA heated at 900 °C indicated a mixture of a large amount of α-Sb_2O_4 and a small amount of β-Sb_2O_4, as was observed by Abe.[5] Table 1 showed the weight loss and the evolved water from the C-SbA heated at a different temperature for 12 h. The weight loss of C-SbA was obtained as 20.7% at 600—800 °C and as 22.2% at 900 °C. The evolved water contents, as determined by the modified Karl Fischer method showed an almost constant value of 18.0—18.1%, regardless of the heating temperature in the range of 500—900 °C. The calculated composition of the C-SbA is $Sb_2O_5\cdot3.9H_2O$; this agree well with earlier results.[5]

The observed weight loss of 1.8±0.1%, obtained by heating the material from 750 °C to 900 °C for 30 min,

Table 1. Dependence of the weight loss and the evolved water of the C-SbA at the heating temperature for 12 h

Temp °C	Weight loss %	Water evolution %	Water composition[a] (n)
100	7.5	7.5	
200	13.6	13.6	
300	16.6	16.1	
400	18.3	17.3	
500	20.6	18.0	3.95
600	20.8	18.1	3.97
700	20.7	18.1	3.97
800	20.7	18.0	3.96
900	22.2	18.0	3.96
1000	40.3	18.0	3.96

a) Water composition: $Sb_2O_5 \cdot nH_2O$.

agree well with the theoretical value of 1.70% from Sb_6O_{13} to Sb_2O_4 within the limits of experimental error. If the change from 700 °C to 900 °C corresponds to that of the hydrated material of the antimony oxide, the weight loss should be obtained as 1.8% from $2Sb_3O_6$-OH to Sb_6O_{13}, as 0.97% from $H_2Sb_{12}O_{26}$ to $Sb_{12}O_{25}$, and as 0.45% from $H_2Sb_{26}O_{56}$ to $Sb_{26}O_{55}$. The value of the evolved water from the heated C-SbA is almost constant in the range of 500—900 °C. The evolved water was less than the blank value of 0.1% and/or the same heating conditions of 750—900 °C. Thus, we conclude that the change in the C-SbA heated at 750 to 900 °C is from Sb_6O_{13} to Sb_2O_4. This conclusion agree well with those of Abe[5] and Stewart *et al.*[7]

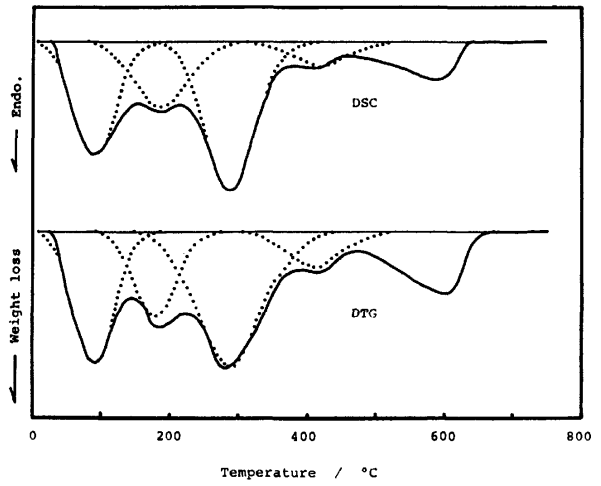

Fig. 1. DSC and DTG curves of C-SbA in H^+ form.
Heating rate: 10 °C min^{-1}, sample size: 100—200 mesh, atmosphere: air.
——: Observed, ····: calculated.

The observed DSC and DTG curves are shown in Fig. 1. The maximum temperatures were observed at about 100, 190, 300, 420, and 600 °C up to 700 °C in five curves. This result is in good agreement with that reported earlier, except for the endothermic peak of 190 °C. Such a small peak as that at 190 °C was detectable because the apparatus of thermal analysis used here is more sensitive than that used earlier. The shape of the last peak at 600 °C was different from the other four peaks and would correspond to the deoxidation of Sb_2O_5. We attempted to separate the first four peaks into four individual peaks by means of a non-linear least-square fit. The sum of the four separated peaks was successfully reproducible on the original DTG curve by means of computer curve-fitting. The weight loss of the C-SbA calculated by means of the total area of the four separated peaks at 90, 180, 290, and 420 °C was 17.9%, almost the same as the water content of the C-SbA in Table 1. Thus, thermal decomposition of the C-SbA in the H^+form follows four dehydration and two deoxidation steps up to 1000 °C:

$$Sb_2O_5 \cdot 4H_2O \xrightarrow{90^\circ C} Sb_2O_5 \cdot 2.9H_2O \xrightarrow{180^\circ C}$$
$$Sb_2O_5 \cdot 2.15H_2O \xrightarrow{290^\circ C} Sb_2O_5 \cdot 0.45H_2O \xrightarrow{420^\circ C}$$
$$Sb_2O_5 \xrightarrow{600^\circ C} Sb_6O_{13} \xrightarrow{940^\circ C} Sb_2O_4.$$

The authors wish to express their thanks to Dr. Takumi Hikida and Dr. Hiroshi Hiratsuka of the Tokyo Institute of Technology for their helpful advices regarding the computer curve fitting.

Circular Dichroism Spectra of *cis,cis*-$[Co(OO)(N)_2(py)_2]^+$-Type Complexes

Shuhei FUJINAMI,* Kenshi TSUJI, Ritsuko MUSA, and Muraji SHIBATA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received April 4, 1981)

Synopsis. Four new complexes, *cis,cis*-$[Co(OO)(NH_2C_2H_5)_2(py)_2]^+$($OO=CO_3^{2-}$, ox^{2-}, or mal^{2-}) and *cis,cis*-$[Co(ox)(NH_3)_2(py)_2]^+$, have been prepared and optically resolved. The CD patterns regularly change in the order of carbonato, oxalato, and malonato complexes, the aspect in the change being opposite to that of related *cis,cis*-$[Co(NO_2)_2(OO)(NH_3)_2]^-$-type complexes.

Many complexes of $[Co(N)_4(O)_2]^+$-type have been prepared and optically resolved. The chirality of those complexes is considered to be derived from helical distributions of chelate rings. Recently, *cis,cis*-$[Co(OO)(NO_2)_2(NH_3)_2]^-$ ($OO=CO_3^{2-}$, ox^{2-}, or mal^{2-})[1] and *cis,cis*-$[Co(CO_3)(NH_3)_2(py)_2]^+$ [2] have been prepared and resolved. These complexes are interesting, because the chirality is derived from the arrangement of three kinds of donor atoms. In this paper, the preparations and optical resolutions of *cis,cis*-$[Co(OO)(NH_2C_2H_5)_2(py)_2]^+$ and *cis,cis*-$[Co(ox)(NH_3)_2(py)_2]^+$ complexes are reported. Furthermore, the influence of the chelated OO ligands upon the CD intensity is investigated.

Experimental

Syntheses and Optical Resolutions. a) cis,cis-*Carbonatobis(ethylamine)bis(pyridine)cobalt(III) Chloride Trihydrate*, cis,cis-*[Co(CO$_3$)(NH$_2$C$_2$H$_5$)$_2$(py)$_2$]Cl·3H$_2$O*: Ethylamine (40 cm^3, 0.4 mol) was added to a solution of $[Co(CO_3)_3]^{3-}$ ($Co(NO_3)_2\cdot 6H_2O$, 0.05 mol scale)[3] and the mixture stirred until the solution became blue in color. After filtration, ethanol (150 cm^3) and acetone (100 cm^3) were successively added to the filtrate in an ice-bath. The crude product precipitated was recrystallized from water. The product was *cis*-$K[Co(CO_3)_2(NH_2C_2H_5)_2]\cdot H_2O$. To a solution of the above product (30 g, 0.13 mol, in 30 cm^3 H_2O) pyridine (25 cm^3, 0.31 mol) was added and the resultant solution acidified to pH 5 with $HClO_4$ (60%). After filtration, the filtrate was stirred at room temperature for a day, whereupon some pink crystals deposited. An aqueous solution of the crystals was charged on a column of Dowex 50W-X8 resin in Na^+ form (100—200 mesh, $\phi 7\times 5$ cm^2). By elution with 0.3 mol/dm^3 NaCl, one red band descended. The eluate was concentrated and kept in a refrigerator. The crude product was recrystallized from warm water; yield *ca.* 7 g. Found: C, 39.31; H, 6.52; N, 12.20%. Calcd for $[Co(CO_3)(NH_2C_2H_5)_2(C_5H_5N)_2]Cl\cdot 3H_2O$: C, 39.42; H, 6.57; N, 12.26%.

To a solution of the chloride (4.0 g, 0.017 mol, in 20 cm^3 H_2O) was added $(-)_{546}Ag[Co(ox)_2(en)]$ (3.7 g, 0.017 mol), and the resulting AgCl was filtered off. On concentrating the filtrate, at first, one diastereoisomeric salt of the $(-)_{589}$-carbonato complex deposited, and then another salt of the $(+)_{589}$-one deposited. Since the optical purity of the former salt could not be raised by recrystallization, the latter salt was recrystallized ten times from warm water. The yield was *ca.* 1.0 g.

b) cis,cis-*Bis(ethylamine)oxalatobis(pyridine)cobalt(III) Perchlorate Monohydrate*, cis,cis-*[Co(ox)(NH$_2$C$_2$H$_5$)$_2$(py)$_2$]ClO$_4$·H$_2$O*: $H_2C_2O_4\cdot 2H_2O$ (8 g, 0.089 mol) was added to a solution of *cis,cis*-$[Co(CO_3)(NH_2C_2H_5)_2(py)_2]Cl\cdot H_2O$ (10 g, 0.043 mol) and the mixture was stirred at 35 °C for 2 d. The solution was neutralized with $KHCO_3$. After filtration, the filtrate was charged on a column containing Dowex 50W-X8 resin in Na^+ form (100—200 mesh, $\phi 4\times 30$ cm^2). By elution with 0.1 mol/dm^3 $NaClO_4$, two red bands were discharged from the column (labeled E1 and E2 in the order of elution), and the desired E2 band was collected in a fraction. After concentration and filtration, the filtrate was kept in a refrigerator. The crude product was recrystallized from water. The yield was 4 g. Found: C, 37.73; H, 5.03; N, 10.85%. Calcd for $[Co(C_2O_4)(NH_2C_2H_5)_2(C_5H_5N)_2]ClO_4\cdot H_2O$: C, 37.47; H, 5.12; N, 10.93%.

This complex was partially resolved by column chromatography on SP-Sephadex C-25 ($\phi 2.5\times 95$ cm^2, Na^+ form) using 0.05 mol/dm^3 $K_2[Sb_2(d\text{-tart})_2]$ as an eluent.

c) cis,cis-*Bis(ethylamine)malonatobis(pyridine)cobalt(III) Perchlorate Dihydrate*, cis,cis-*[Co(mal)(NH$_2$C$_2$H$_5$)$_2$(py)$_2$]ClO$_4$·2H$_2$O*: To a solution of *cis*-$K[Co(CO_3)_2(NH_2C_2H_5)_2]\cdot H_2O$(32 g, 0.1 mol, in 120 cm^3 H_2O) potassium malonate (17 g, 0.09 mol) was added, and the mixture acidified to pH 5 with 60% $HClO_4$ in an ice-bath. After filtration, the filtrate was stirred for 1 h, and then adjusted to pH 1 with 60% $HClO_4$. The solution was filtered and the filtrate was chromatographed on a column of Dowex 50W-X8 resin in H^+ form (100—200 mesh, $\phi 7\times 15$ cm^2) using 0.2 mol/dm^3 NaCl as an eluent. A univalent complex species was collected in a fraction. To the fraction was added $KHCO_3$ to adjust pH to 9 and the solution concentrated to *ca.* 50 cm^3. After filtration, pyridine (15 cm^3, 0.19 mol) was added to the filtrate followed by 60% $HClO_4$ to adjust the pH to 5 in the cold. The solution was filtered once and the filtrate stirred at room temperature for 3 d. The solution was charged on a column of Dowex 50W-X8 resin in Na^+ form (100—200 mesh, $\phi 4\times 30$ cm^2). By elution with 0.1 mol/dm^3 NaCl, three bands were discharged. The first eluted band was collected and concentrated to *ca.* 20 cm^3. After filtration, the filtrate was kept in a refrigerator. The product obtained was recrystallized from warm water; yield *ca.* 0.5 g. Found: C, 37.54; H, 5.52; N, 10.44%. Calcd for $[Co(C_3H_2O_4)(NH_2C_2H_5)_2(C_5H_5N)_2]ClO_4\cdot 2H_2O$: C, 37.47; H, 5.56; N, 10.28%.

This complex was partially resolved on a column chromatograph of Dowex 50W-X8 resin in Na^+ form (100—200 mesh, $\phi 4\times 46$ cm^2) using 0.1 mol/dm^3 $K_2[Sb_2(d\text{-tart})_2]$ as eluent.

d) cis,cis-*Diammineoxalatobis(pyridine)cobalt(III) Perchlorate 2.5-Hydrate*, cis,cis-*[Co(ox)(NH$_3$)$_2$(py)$_2$]ClO$_4$·2.5H$_2$O*: This complex was prepared in the same manner as described in *b)* except for the use of *cis,cis*-$[Co(CO_3)(NH_3)_2(py)_2]Cl\cdot H_2O$[2] (10 g, 0.027 mol) instead of *cis,cis*-$[Co(CO_3)(NH_2C_2H_5)_2(py)_2]Cl\cdot H_2O$. The yield was *ca.* 2 g. Found: C, 29.32; H, 4.34; N, 11.48%. Calcd for $[Co(C_2O_4)(NH_3)_2(C_5H_5N)_2]ClO_4\cdot 2.5H_2O$: C, 29.24; H, 4.34; N, 11.58%.

The perchlorate was converted to chloride by column chromatography. The chloride was optically resolved by adding equimolar $(+)_{543}Na[Co(edta)]\cdot 2H_2O$. The less soluble diastereoisomeric salt containing the $(-)_{589}$-oxalato complex was recrystallized from water.

The optical rotation, absorption and CD spectra were measured in the same manner as described in the previous

Table 1. Absorption and CD spectral data

paper.[2] Prior to the above measurements, the samples had been converted into chlorides by means of an ion-exchange technique. The absorption and CD spectra of the diaqua complex, after the corresponding carbonato complex was acid-hydrolyzed with 10% $HClO_4$, were measured.

Results and Discussion

The absorption and CD spectral data are summerized in Table 1. The three complexes, $(+)_{589}$[Co(CO_3)-($NH_2C_2H_5$)$_2$(py)$_2$]$^+$, $(+)_{589}$[Co(ox)($NH_2C_2H_5$)$_2$(py)$_2$]$^+$, and $(+)_{589}$[Co(mal)($NH_2C_2H_5$)$_2$(py)$_2$]$^+$, exhibit two CD peaks with opposite sign in the first absorption band region. When the value of the extremum at the lower frequency is designated $\Delta\varepsilon_1$, and that at the higher frequency $\Delta\varepsilon_2$, the ratio, $|\Delta\varepsilon_1/\Delta\varepsilon_2|$, decreases in the order of the carbonato, oxalato, and malonato oomplexes, as is seen in Table 1. The two diammine complexes, $(-)_{589}$[Co(CO_3)(NH_3)$_2$(py)$_2$]$^+$ [2] and $(-)_{589}$[Co(ox)-(NH_3)$_2$(py)$_2$]$^+$, also exhibit two CD peaks, the ratio decreasing in the order of the carbonato and oxalato complexes. Such a decrease is not apparent in [Co(OO)-(en)$_2$]$^+$ or *cis*-[Co(OO)(NH_3)$_2$(en)]$^+$ complexes (OO represents CO_3^{2-}, ox^{2-}, or mal^{2-}),[2] which contain tris or bis bidentate ligands and show a single CD peak in the first absorption band region. These phenomena reveal a difference between the chiral complexes due to the arrangements of three kinds of donor atoms and those due to the helical distribution of bidentate ligands. On the other hand, CD spectra of *cis,cis*-[Co(NO_2)$_2$-(OO)(NH_3)$_2$]$^-$ complexes,[1] which also belong to the same type of chiral complex as the present complexes, exhibit two CD peaks in the first absorption band region. However, the ratio increases in the order of the carbonato, oxalato, and malonato complexes; the values are 0.13, 0.57, and 0.97, respectively (in the case of the malonato complex, an extremely small extremum at the lowest frequency side is neglected). Mason[4] has succeeded in explaining the rotatory strength of *all-cis*-[Co(CN)$_2$(NH_3)$_2$(H_2O)$_2$]$^+$ in terms of a dynamic coupling model in which ligand-polarization induced by other ligands is treated. The different behavior between CD spectra of *cis,cis*-[Co(OO)($NH_2C_2H_5$)$_2$(py)$_2$]$^+$ and those of *cis,cis*-[Co(NO_2)$_2$(OO)(NH_3)$_2$]$^-$ may be explained by the dynamic coupling model rather than a static coupling model,[5] since both complexes approximately belong to the same *cis*-[Co(O)$_2$(N)$_4$]-type complexes. It is considered that a factor such as polarizability or formal charge on the ligands is more intimately associated with the rotatory strength of the present complexes than the ligand field strength. This is supported by the observation that the CD spectrum of $(+)_{589}$[Co($NH_2C_2H_5$)$_2$(py)$_2$(H_2O)$_2$]$^{3+}$ derived from $(-)_{589}$[Co(CO_3)($NH_2C_2H_5$)$_2$(py)$_2$]$^+$ by acid-hydrolysis shows an opposite pattern to that of the $(+)_{589}$-carbonato complex. The ligand field strength of carbonato ligand is nearly equal to that of the aqua ligand. However, the polarizability of the former ligand is very different from that of the latter one.

The absolute configuration of $(-)_{589}$[Co(CO_3)(NH_3)$_2$-(py)$_2$]$^+$ has been assigned *S* on the basis of the CD spectral comparison with related complexes.[2] The CD patterns of three $(+)_{589}$[Co(OO)($NH_2C_2H_5$)$_2$(py)$_2$]$^+$ (OO=CO_3^{2-}, ox^{2-}, mal^{2-}) isomers are opposite to that of $(-)_{589}$[Co(CO_3)(NH_3)$_2$(py)$_2$]$^+$, and the CD spectrum of $(-)_{589}$[Co(ox)(NH_3)$_2$(py)$_2$]$^+$ exhibits the same pattern. Consequently, the three ethylamine complexes are assignable to an *R* configuration, and the ammine complex an *S* configuration. The $(+)_{589}$[Co(NH_2C_2-H_5)$_2$(py)$_2$(H_2O)$_2$]$^{3+}$ species derived from the corresponding $(+)_{589}$-carbonato complex is also assigned to *R*, since the acid-hydrolysis should proceed with retention of the configuration.

(Received May 8, 1981)

Synopsis. A new phase of $CaMnO_{2+\delta}$ was synthesized by a wet process, followed by calcining. The structure was determined to be orthorhombic, with these lattice constants: $a=5.96$, $b=14.38$, and $c=5.72$ Å. Phase transformations among $CaMnO_{2+\delta}$ compounds were studied in various atmospheres, such as N_2, CO_2, and air.

Compounds of alkaline-earth oxide with transition metals have various crystal structures depending on whether there is an excess or deficiency of oxygen. The $CaMnO_{2+\delta}$ system was chosen in order to study systematically how the crystal structures of manganese oxides change with varied valences of Mn ions.

Mizutani *et al.*[2,3)] reported that $SrMnO_3$ perovskite was transformed to $Sr_2Mn_2O_5$ brownmillerite-type compound, under N_2 atmospheres at 1500 °C. Since both Sr and Ca are alkaline-earth metals, a new phase with the composition of $Ca_2Mn_2O_5$ was expected to be synthesized.

Experimental

The synthesis of the compounds was carried out as follows. The reagents used were: $CaCO_3$ (alkaline metal analysis grade; Kanto Chemical Co., Inc.), Na_2CO_3 (reagent grade; Kanto Chemical Co., Inc.), and $MnCO_3$ (reagent grade; Wako Pure Chemical Industries Ltd.). A mixture of $CaCO_3$ and $MnCO_3$ in a molar ratio of 1:1 was dissolved into an HCl solution. An excess of an aqueous solution of Na_2CO_3 was added to the above solution to coprecipitate both Ca and Mn ions as carbonates in order to prepare a homogeneous materials; washing with distilled water followed to eliminate the Na ions thoroughly. The mixed precipitate was filtered, dried in air, and then calcined in an atmosphere with a volume ratio of $H_2/Ar=1/3$ at 900 °C for 2 h in a platinum crucible. Finally, the compound was heated again in the same atmosphere and at the same temperature for 17 h. The light green product was identified as a cubic (Ca, Mn)O solid solution by X-ray diffractometry. The composition of the solid solution was determined to be $CaMn_{1.01}O_{2.07}$ with 0.05 wt% of Na and 0.089 wt% of H_2O as minor constituents.

Results and Discussion

It is of much interest that a remarkable difference in the oxidation processes of the compound was observed, depending on the heating conditions. When the compound was oxidized in air at 600—610 °C, only one line with a considerable broadness was found in X-ray powder diffractometry, suggesting an amorphous phase[2)] in the range of $\delta=0.74$—0.91. When the solid solution was kept in air above 610 °C, however, $CaMnO_{3-\chi}$ perovskite[4)] was obtained in the stable range of $\chi=0.00$—0.17 in oxygen vacancies. On the other hand, the (Ca,Mn)O in high-temperature oxidation behaves quite differently from that in low-temperature oxidation.

323	1.35	1.35	13

Orthorhombic, $a=5.961$, $b=14.38$, $c=5.72$ Å.

When the (Ca,Mn)O compound was kept at 1000 °C for 2 h in CO_2 ($P_{O_2}=2\times10^{-4}$ atm) and then rapidly quenched to room temperature, a new phase appeared, with the *d*-values shown in Table 1. The phase is very stable, for it was hardly oxidized at all even when kept at 1000 °C for about 1 h in air. The oxidation process was examined using a high-temperature X-ray diffractometer. When the new phase was heated in air at a constant rate of 10 °C/min, the $CaMnO_3$ perovskite peaks appeared at about 1050 °C; this reaction was completed at 1200 °C. The perovskite was reduced to the new phase when held in N_2 gas ($P_{O_2}=5\times10^{-4}$ atm) at 1000 °C for 20 h; it was examined using a rapidly-quenched sample. The transition between the

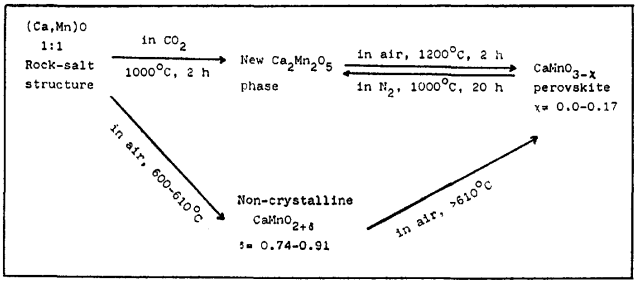

Fig. 1. Reaction diagram for $CaMnO_{2+\delta}$: (Ca, Mn)O solid solution, new $Ca_2Mn_2O_5$ phase and $CaMnO_3$ perovskite.

new phase and $CaMnO_3$ was reversible. These reaction processes are shown in Fig. 1.

Since the X-ray pattern in Table 1 is quite similar to that of orthorhombic $Sr_2Mn_2O_5$ (a brownmillerite-type compound), the new phase was identified as orthorhombic $Ca_2Mn_2O_5$ with the lattice constants of $a=5.96$, $b=14.38$, and $c=5.72$ Å, and with the axis ratios of $b/a=2.42$ and $c/a=0.96$. Using these values, the observed d_{obsd}'s are indexed in Table 1; they are in fair agreement with the calculated d_{calcd}'s except for a few lines. The chemical analysis of the new compound showed the composition of $CaMn_{1.01}O_{2.58}$.

The authors are much indebted to Mr. Hideki Yamamoto of Tokai University, and Dr. Jun-ichi Mohri, Mr. Yuji Sugaya, and Mr. Terumasa Ono of Chiba University for helping with the experiments and for their useful discussions; Mr. Takeshi Nagashima and Mrs. Michiko Kobayashi of NIRIM for their chemical analysis, and Drs. Nobuyasu Mizutani and Masanori Kato of Tokyo Institute of Technology and Mr. Syuzo Tamura and Mr. Eiji Takayama of NIRIM for their helpful suggestions.

Spectrophotometric Determination of Sodium 4-Dodecylbenzenesulfonate with 1-(*N*-Methylpyridinium-4-yl-azo)-4-(4-diethylaminophenylazo)-naphthalene Iodide

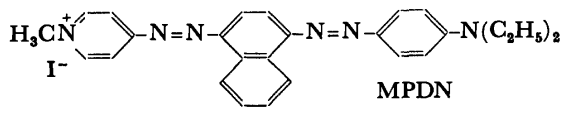
Keiro HIGUCHI, Yasuaki SHIMOISHI, Haruo MIYATA,* and Kyoji TÔEI

Department of Chemistry, Faculty of Science, Okayama University, Tsushima-naka 3-1-1, Okayama 700

(Received August 29, 1981)

Synopsis. A new reagent, 1-(*N*-methylpyridinium-4-yl-azo)-4-(4-diethylaminophenylazo)naphthalene iodide, can react with sodium 4-dodecylbenzenesulfonate to show a color change in an aqueous phase in the presence of iodide ion. The calibration graph is straight line up to 1.2×10^{-5} M (1 M= 1 mol dm^{-3}); $\varepsilon=3.25\times10^{4}$ l mol^{-1} cm^{-1} at 580 nm.

The developmental study on the new reagent is invaluable in the determination of micro amounts of anionic surfactant in an aqueous phase.[1] A new reagent, 1-(*N*-methylpyridinium-4-yl-azo)-4-(4-diethylamino-



MPDN

phenylazo)naphthalene iodide (MPDN), forms an ion pair with the anionic surfactants such as sodium 4-dodecylbenzenesulfonate (DBS) and dodecyl sulfate (SDS) in the presence of iodide ion. Using this phenomenon, DBS or SDS up to 1.2×10^{-5} M has been determined in an aqueous phase without extraction procedure.

Experimental

Materials. A typical synthetic method of MPDN is as follows. A solution of 1.8 g of 4-aminopyridine in 10 ml of 85% phosphoric acid and 5 ml of concentrated nitric acid were mixed at −8 °C; sodium nitrite (1.4 g) and 25 g of ice were then added successively.[2] The solution was poured into 100 ml of ethanol containing 2.9 g of 1-naphthylamine. After the reaction, the solution was neutralized with sodium carbonate, and the precipitate was filtered off and recrystallized from benzene. The crystals of 4-(4-amino-1-naphthylazo)pyridine (ANP) were reddish violet plates. Found; C, 72.52; H, 4.56; N, 22.18%. Calcd for $C_{15}H_{12}N_4$: C, 72.60; H, 4.87; N, 22.57%.

ANP (1 g) was dissolved in 30 ml of glacial acetic acid, and diazotized with 0.28 g of sodium nitrite by adding in small portions. The solution was poured into 100 ml of ethanol containing 0.6 g of *N,N*-diethylaniline. After the reaction, the solution was neutralized with sodium carbonate, and the precipitate was filtered off and recrystallized from ethanol–water solution. The crystals of 1-(4-pyridylazo)-4-(4-diethylaminophenylazo)naphthalene (PDN) were violet needles. Found: C, 73.70; H, 6.03; N, 20.28%. Calcd for $C_{25}H_{24}N_6$: C, 73.50; H, 5.92; N, 20.58%.

PDN (0.3 g) was quarternized by refluxing with 0.2 g of methyl iodide in 30 ml of *N,N*-dimethylformamide at 50 °C for 8 h. The iodide, 1-(*N*-methylpyridinium-4-yl-azo)-4-(4-diethylaminophenylazo)naphthalene iodide (MPDN), obtained was washed with toluene until the washings were no longer colored and then dried under reduced pressure at 50 °C to a constant weight. A 6.6×10^{-4} M solution of MPDN was prepared by dissolving it in ethanol.

Anionic Surfactants. Anionic surfactants used were sodium 4-dodecylbenzenesulfonate (DBS) and dodecyl sulfate (SDS). They were dried at 50 °C under the reduced pressure to a constant weight.

Procedure. Place a suitable aliquot of the standard DBS or SDS solution, containing less than 1.2×10^{-5} M, into a 25-ml calibrated flask. Add 1 ml of 0.25M sodium iodide and 1.5 ml of 6.6×10^{-4} M MPDN solution. Dilute the solution to the mark with distilled water. Measure the absorbance at 580 nm in 1-cm cell against water as a reference.

Results and Discussion

In addition of iodide ion to the reagent solution at pH between 4 and 10, the blue color of the reagent solution changed into a reddish violet color, and the reddish violet color changed to a blue by the addition of the surfactants. The formation of the ion pair occured instantaneously, and the surfactants could be determined directly in an aqueous phase without extraction. Figure 1 shows the absorption spectra of these solutions; the wavelength of maximum absorption occurs at 620 nm for MPDN, at 520 nm for MPDN containing 10^{-2} M iodide ion, and at 575 nm for MPDN containing 10^{-2} M iodide ion and 1.2×10^{-5} M DBS, respectively. The determination was carried at 580 nm.

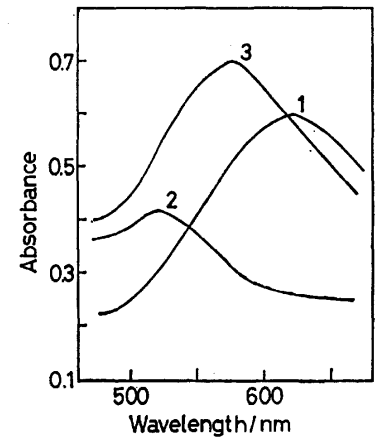


Fig. 1. Absorption spectra.
1: 3.96×10^{-5} M MPDN, 2: 3.96×10^{-5} M MPDN+ 10^{-2} M I^-, 3: 3.96×10^{-5} M MPDN+10^{-2} M I^-+ 1.2×10^{-5} M DBS.

The effect of amounts of sodium iodide on the absorbance at 580 nm was examined. The absorbance difference between the ion pair and the reagent blank was constant within 1 h when iodide ion existed from 5×10^{-3} M to 2×10^{-2} M, and above the concentration,

Table 1. Effect of anions on colouration

Anion	Concentration/M		
	10^{-1}	10^{-2}	10^{-3}
F^-	—	—	—
Cl^-	++*	+	—

CH_3COO^-	—	—	—
SO_4^{2-}	++*	+	—
HPO_4^{2-}	+	—	—

++ Very good, + good, *precipitation.

very fine precipitates appeared on standing. Therefore in the following studies the concentration of iodide ion was kept at 1×10^{-2} M. The effect of other anions on coloration of the reagent solution is shown in Table 1. The most satisfactory results were obtained by use of iodide ion.

The effect of amounts of ethanol was studied. When the amount of ethanol added was 3 ml or more for the total volume of 25-ml, the both absorbances of the reagent blank and the sample solution increased gradually. And a constant absorbance difference was obtained between 1 and 2.5 ml of ethanol to 25 ml of the total solution.

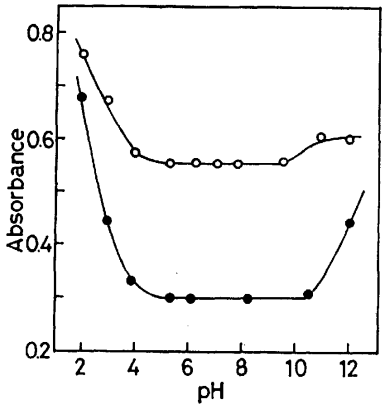

Fig. 2. Effect of pH.
—○—: MPDN-DBS, —●—: MPDN, [MPDN]= 3.96×10^{-5} M, [DBS]=8.0×10^{-6} M, [I^-]=1×10^{-2} M.

Table 2. Tolerance limits for diverse ions

Ion	Tolerance limit/M	Absorbance
None		0.553
Cl^-	10^{-3}	0.558
NO_3^-	10^{-3}	0.550
HCO_3^-	10^{-3}	0.548
SO_4^{2-}	10^{-3}	0.563
HPO_4^{2-}	10^{-3}	0.549
SiO_3^{2-}	10^{-4}	0.553
Na^+	10^{-3}	0.550
K^+	10^{-3}	0.553
NH_4^+	10^{-3}	0.548
Mg^{2+}	10^{-3}	0.558
Ca^{2+}	10^{-3}	0.553
Sodium stearate	10^{-5}	0.556

The effect of pH on the absorbance is shown in Fig. 2. The optimum pH range was between pH 5 and 10. And the pH of the solutions was adjusted with hydrochloric acid or sodium hydroxide solution to avoid the interference from anions intermixed.

The calibration graph obtained by the procedure was linear up to 1.2×10^{-5} M of DBS or SDS. The practical molar absorptivities of DBS and SDS were 3.25×10^4 and 1.45×10^4 l mol^{-1} cm^{-1} at 580 nm, respectively.

The interferences due to various ions were examined, and the results obtained are shown in Table 2. The common cations and anions of 10^{-3} M levels did not interfere with the procedure. Stearate ion above 10^{-5} M caused a positive error, because the precipitate separated out gradually on standing.

Oxidative Addition of Esters of Formic Acid and β-Lactones to Ni(0)-Complexes Involving Cleavage of the C-O Bond

Takakazu YAMAMOTO,* Junichi ISHIZU, and Akio YAMAMOTO

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227

(Received September 12, 1981)

Synopsis. Reactions of esters of formic acid, HCOOR ($R=C_2H_5$, $CH_2C_6H_5$), with Ni(0)-complexes (mixtures of bis(1,5-cyclooctadiene)nickel ($Ni(cod)_2$) and tertiary phosphines (PR'_3)) lead to decarbonylation of HCOOR to afford $(Ni(CO)_n(PR'_3)_{4-n}$ and ROH. Vinyl formate gives a mixture of CH_3CHO, $Ni(CO)_n(PR'_3)_{4-n}$, C_2H_4, and CO_2 on interaction with the Ni(0)-complexes. β-Lactones liberate CO_2 on treatment with the Ni(0)-complexes. Oxidative addition of the reactants to Ni involving cleavage of the C–O bond(s) accounts for the formation of the products.

Oxidative addition of organic compounds to transition metals involving C–O bond cleavage is the subject of recent interest. In the previous papers we reported oxidative addition of aryl carboxylates,[1] vinyl acetate,[1a,2] allyl-O compounds[2] to Ni(0)-complexes. We now report reactions of esters of formic acid, β-lactones, and related compounds with Ni(0)-complexes, where somewhat different types of C–O bond cleavage reactions occur.

Results and Discussion

Table 1 shows products of reactions of formates and β-lactones with mixtures of bis(1,5-cyclooctadiene)-nickel, $Ni(cod)_2$ and tertiary phosphines, PR'_3.

Ethyl and Benzyl Formates. Although the reaction of $HCOOC_2H_5$ with a mixture of $Ni(cod)_2$ and PPh_3 at room temperature causes no C–O bond cleavage of the ester, the reaction at 60 °C causes C–O bond cleavage to afford $Ni(CO)(PPh_3)_3$ and C_2H_5OH. A similar decarbonylation reaction of methyl formate by Mo(0)-complexes to give CH_3OH has been reported.[3]

The following reaction pathway involving the initial cleavage of $HCO-OC_2H_5$ bond best accounts for the reaction products,

$$Ni(cod)_2 + 2L(PPh_3) \underset{}{\overset{-cod}{\rightleftharpoons}} Ni(cod)L_2 \overset{-cod}{\rightleftharpoons} NiL_2$$

$$NiL_2 + HCO-OC_2H_5 \xrightarrow[\text{addition}]{\text{oxidative}} [HCO-NiL_2-OC_2H_5] \quad (1)$$

$$\xrightarrow{\text{decarbonylation}} [H-\overset{\overset{CO}{|}}{Ni}L_2(OC_2H_5)] \quad (2)$$

$$\xrightarrow{-HOC_2H_5} Ni(CO)L_3. \quad (3)$$

We have proposed a similar reaction mechanism involving cleavage of the $RCO-OC_6H_5$ bond of phenyl carboxylates for the reaction of $RCOOC_6H_5$ with Ni(0)-complexes.[1] An alternative mechanism involving initial cleavage of the $H-COOC_2H_5$ bond to give an $H-Ni-COOC_2H_5$ intermediate and ensuing decarbonylation to give $H-Ni-OC_2H_5$ is also conceivable, since the H–C bond in $HCOOC_2H_5$ is considered to have a similar reactivity to that of the C–H bond of –CHO group in aldehydes which are known to oxidatively add to transition metals involving the C–H bond cleavage.[4] This alternative mechanism, however, is less plausible, because alkoxycarbonylnickel(II) complexes, $Ni(X)(COOR)L_n$, are known to liberate CO_2 on their degradation[5] whereas the present reaction releases no CO_2.

When the nucleophilicity of Ni is enhanced by coordination of more basic PEt_3, the oxidative addition of $HCOOC_2H_5$ proceeds under milder conditions (Expt 2). In this case $Ni(CO)_2(PEt_3)_2$[6] is formed

TABLE 1. REACTIONS OF FORMATES AND LACTONES WITH MIXTURES OF $Ni(cod)_2$ AND PHOSPHINE LIGANDS PR_3

Expt	Reactant mol/Ni	PR_3 mol/Ni	Solvent cm^3/cm^3 of reactant	Temp °C	Time h	Product[a] mol%/Ni
1	$HCOOC_2H_5$(38)	PPh_3(2.0)	None	60	40	$Ni(CO)L_3$(60), C_2H_5OH(50), cod-isomers[c]
2	$HCOOC_2H_5$(38)	PEt_3(2.0)	None	25	12	$Ni(CO)_2L_2$[b], C_2H_5OH(50)
3	$HCOOCH_2C_6H_5$(4.0)	PPh_3(3.0)	Eher(4)	65	4	$Ni(CO)L_3$(90), $C_6H_5CH_2OH$(93), C_6H_5CHO(tr), cod-isomers[c]
4	$HCOOCH=CH_2$(1.7)	PPh_3(3.0)	Toluene(4)	26	24	CH_3CHO(15), $Ni(CO)L_3$(51), C_2H_4(2), CO_2(5), 1-butene(tr), butadiene(tr)
5	$HCOOCH=CH_2$(2.0)	PCy_3(2.0)	Toluene(28)	15	28	CH_3CHO(16), $Ni(CO)_3(PCy_3)_2$[b], CO_2(2), C_2H_4(2), 1-butene(4)
6	$\overline{CH_2OCOCH_2}$(120)	PPh_3(2.0)	None	10	12	C_2H_4(45), CO_2[b], polyester, $Ni(CO)_2L_2$[b]
7	$CH_2=\overline{COCOCH_2}$(1.1)	PPh_3(2.1)	Ether(7)	10	9	CO_2(42), polymer
8	$\overline{CH_2CH_2OCOCH_2}$(20)	PPh_3(2.2)	None	65	48	No C–O bond cleavage proceeds

a) L=PR_3. tr=Trace. b) Formation of the compound was confirmed by IR, GLC, and/or NMR, but the amount was not measured. c) Cod isomers: 1,3-cyclooctadiene, 1,4-cyclooctadiene, bicyclooctene-1, and bicyclooctene-2.

instead of the $Ni(CO)L_3$ type complex. The fact that the reaction proceeds more easily by using more basic PEt_3 indicates that the reaction proceeds through nucleophilic attack of the Ni(0) complex at the carbonyl carbon of HCOOR, similarly to the reactions of aryl carboxylates[1] and allyl-O compounds[2] with Ni(0)-complexes.

Employment of $HCOOCH_2C_6H_5$ also leads to a similar type of bond cleavage in the reaction with the mixture of $Ni(cod)_2$ and PPh_3 affording $Ni(CO)(PPh_3)_3$ and $C_6H_5CH_2OH$ (Expt 3).

Vinyl Formate. Vinyl formate undergoes a similar type of bond cleavage to give $Ni(CO)_n(PR'_3)_{4-n}$ and CH_3CHO, a tautomer of vinyl alcohol, in the reaction with the mixture of $Ni(cod)_2$ and PR'_3 ($PR'_3=PPh_3$ and tricyclohexylphosphine (PCy_3)) at room temperature.

$$NiL_2 + HCO\text{-}OCH=CH_2$$
$$\longrightarrow [HCO\text{-}Ni\text{-}OCH=CH_2] \quad (4)$$
$$\longrightarrow [HNi(CO)(OCH=CH_2)] \quad (5)$$
$$\longrightarrow Ni(CO)_nL_{4-n} + CH_2=CHOH \quad (6)$$
$$\downarrow$$
$$CH_3CHO$$

However, in this case the ester undergoes, besides the C–O bond cleavage described above, another type of bond cleavage between HCOO– and $-CH=CH_2$ groups to liberate CO_2 and C_2H_4,

$$NiL_2+HCOO\text{-}CH=CH_2$$
$$\longrightarrow [HCOO\text{-}NiL_2\text{-}CH=CH_2] \quad (7)$$
$$\xrightarrow{-CO_2} [H\text{-}NiL_2\text{-}CH=CH_2] \quad (8)$$
$$\longrightarrow CH_2=CH_2 + NiL_2. \quad (9)$$

This type of bond cleavage has been observed for reactions of Ni(0)-complexes with alkenyl acetates.[2]

β-Lactones. 2-Oxetanone liberates C_2H_4 and CO_2 on interaction with a mixture of $Ni(cod)_2$ and PPh_3, indicating both the O–CH_2 and CO–CH_2 bonds in the lactone are cleaved in the reaction. Oxidative addition of 2-oxetanone involving cleavage of the O–CH_2 or CO–CH_2 bond to form a nickel-containing cyclic compound (*e.g.*, $L_2\overline{Ni\text{-}OCOCH_2CH_2}$) and bond rearrangement in the supposed cyclic intermediate account for the evolution of C_2H_4 and CO_2. A part of 2-oxetanone is converted into polyester, $\{CH_2CH_2COO\}_n$.

A reaction of 4-methylene-2-oxetanone with the $Ni(cod)_2/PPh_3$ mixture also causes cleavage of the C–O bond in the four-membered ring to liberate CO_2, although propadiene which is expected to be formed as the product of the C–O bond cleavage was not obtained. It is known that Ni complexes catalyze polymerization and oligomerization of propadiene,[7] and occurrence of such reactions accounts for the absence of propadiene in the liquid phase. Dihydro-2(3*H*)-furanone having stable 5-membered ring does not undergo the C–O bond cleavage.

Experimental

General Procedures and Materials. Manipulation of complexes and the reactions were carried out under deoxygenated nitrogen or argon or under vacuum. $Ni(cod)_2$ was purchased from Merck Co., Ltd., and recrystallized. Formates and lactones were purified by repeated distillation until their gas chromatogram show no signicant peaks of contaminants. Tertiary phosphine ligands were used as purchased or synthesized by the methods given in the literature.[8] Solvents were dried by usual procedures, distilled, and stored under argon or nitrogen.

Spectral Measurement and Analysis. IR spectra were taken on a Hitachi Model 295 spectrometer using KBr disks under nitrogen. The analysis of gaseous and liquid products was carried out with a Shimadzu GC-3BT or GC-6A gas chromatograph.

Reactions of Formates and Lactones (cf. Table 1). *Expt 1*: Ethyl formate (3 cm^3, 38 mmol) was added to a Schelnk tube containing $Ni(cod)_2$ (0.27 g, 0.98 mmol) and PPh_3 (0.25 g, 2.0 mmol) at −50 °C. The reaction mixture was stirred at 60 °C for 40 h to obtain a brown solution. GLC analysis of the solution showed formation of 0.49 mmol of ethanol. Removing volatile material under vacuum yielded 0.63 g of a light yellow solid whose IR spectrum is almost identical with that of $Ni(CO)(PPh_3)_3$, showing a sharp ν(C=O) band at 1926 cm^{-1}.[9]

Expt 3: Benzyl formate (0.50 cm^3, 4.0 mmol) was added to a Schlenk tube containing $Ni(cod)_2$ (0.25 g, 0.91 mmol), PPh_3 (0.72 g, 2.7 mmol), and diethyl ether (2 cm^3) at room temperature. The mixture was stirred at 65 °C for 4 h to obtain a pale brown homogeneous solution, which was cooled down to −30 °C to yield a yellow solid of $Ni(CO)(PPh_3)_3$ (0.72 g, 90%). GLC analysis of the solution showed formation of 0.84 mmol of benzyl alcohol.

The other reactions listed in Table 1 were carried out analogously. IR spectrum of the viscous polymer obtained in expt. 6 showed absorption bands characteristic of the polyester, $\{CH_2CH_2COO\}_n$ (1750 cm^{-1} (ν(C=O)), 1350 cm^{-1} (ν(C–O)), 1170 cm^{-1}, 1010 cm^{-1}).[10]

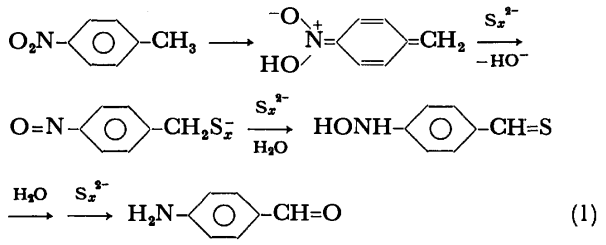
Reaction of Nitrostyrenes and 1-Nitrohexane with Sodium Polysulfides and Sodium Hydroxide[1)]

Yoshiro OGATA,* Yoshiaki NAKAGAWA, and Morio INAISHI
Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464
(Received March 25, 1981)

Synopsis. The reaction of β-nitrostyrene with NaOH in refluxing EtOH–H_2O (1 : 2) gives benzaldehyde, benzyl alcohol, benzoic acid, phenylacetic acid, β-phenylethyl alcohol, and polymeric materials. On the other hand, the reaction of β-nitrostyrene with Na_2S_4–NaOH in the same solvent gave acetophenone besides the same products obtained with NaOH. Acetophenone was likewise detected in the Na_2S–NaOH and Na_2S_2–NaOH reactions. 4-Nitrostyrene was also allowed to react with Na_2S_4–NaOH in EtOH–H_2O (4 : 1) to give a small amount of 4-aminoacetophenone. The formation of acetophenones suggests the occurrence of the Michael addition of polysulfide ion and supports our mechanism proposed previously for the reaction of *p*-nitrotoluene with Na_2S_4. The reaction of 1-nitrohexane with Na_2S_4–NaOH, in which the Michael addition is not conceivable, gives the same products as the reaction with NaOH.

In our previous report[2)] on the mechanism for the reaction of *p*-nitrotoluene with sodium polysulfides, we assumed the addition of polysulfide ion to a quinonoid isomer of *p*-nitrotoluene as the steps to *p*-(hydroxyamino)thiobenzaldehyde and then to *p*-aminobenzaldehyde (Eq. 1).



(1)

The similar type of the Michael addition of thiols to olefins bearing electron-withdrawing groups is well known, *e.g.*, a facile addition of thiolate ion to acrylonitrile and acrylate.[3,4)]

In order to confirm the Michael addition step of polysulfide ion in our proposed mechanism (Eq. 1) and to search for other possible substrates which undergo the simultaneous oxidation-reduction, we examined the reaction of Na_2S_x–NaOH (x=4, 2, and 1) with β-nitrostyrene as well as 4-nitrostyrene. The Michael addition of thiols to β-nitrostyrene is known.[5)] For comparison, 1-nitrohexane, the analogous saturated substrate, was examined on the reaction with Na_2S_4–NaOH.

Results and Discussion

β-Nitrostyrene was refluxed with Na_2S_x–NaOH in EtOH–H_2O (1 : 2) for 3 h. The products were acetophenone, benzaldehyde, benzyl alcohol, benzoic acid, phenylacetic acid, β-phenylethyl alcohol, and polymeric materials. The yields of identified products were listed in Table 1. On the other hand, the reaction of β-nitrostyrene with NaOH in the same solvent gave similar products besides acetophenone (Table 1).

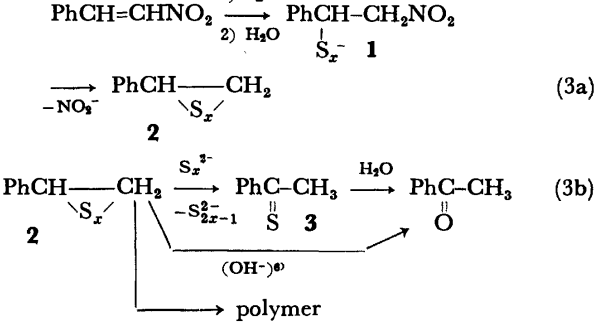
$$PhCH{=}CHNO_2 \xrightarrow{Na_2S_x\text{-}NaOH} PhCOCH_3,\ PhCHO,\ PhCH_2OH,\ PhCO_2H,\ PhCH_2CO_2H,\ PhCH_2CH_2OH \quad (2)$$

Hence, a characteristic product in the presence of sulfide and polysulfide ions is only acetophenone. The reactions of β-nitrostyrene with Na_2S–NaOH and Na_2S_2–NaOH gave a rather low yield of acetophenone with the similar products as shown in Table 1. Hence, for the formation of acetophenone the participation of sulfide or polysulfide ion is conceivable.

The mechanism for the formation of acetophenone may be as follows. The α-carbon of β-nitrostyrene is attacked by polysulfide ion to give a Michael adduct (**1**), and then the polysulfide ion in the adduct (**1**) may attack internally the β-carbon with simultaneous elimination of nitrite ion. The resulting cyclic polysulfide **2** will decompose to thioacetophenone which is hydrolyzed to acetophenone (Eq. 3).



(3a)

(3b)

The step giving **3** from **2** must be the spontaneous intramolecular hydride shift in the case of Na_2S, causing

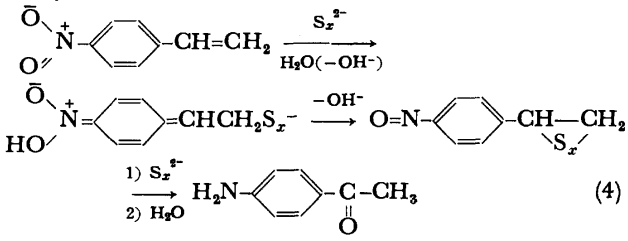
† 1 M=1 mol dm^{-3}.

the lower yield of acetophenone.

Benzaldehyde may be formed *via* the reverse reaction of the synthesis of β-nitrostyrene,[7] and it can give benzyl alcohol and benzoic acid *via* the Cannizzaro reaction. Benzoic acid may be formed by autoxidation of benzaldehyde. Phenylacetaldehyde which is produced *via* analogous reaction of nitroalkanes with NaOH[8] is autoxidized to give phenylacetic acid.

A decrease of the NaOH concentration resulted in the low yield of acetophenone; *e.g.*, the yield of acetophenone was only 0.4% with 0.15 M NaOH in contrast to 5.4% with 0.42 M NaOH.

The reaction of 4-nitrostyrene with Na_2S_4–NaOH gave a considerable amount of polymeric and monomeric 4-aminostyrenes and a small amount of 4-aminoacetophenone which was detected by NMR in comparison with the authentic specimen. The formation of 4-aminoacetophenone suggests the Michael addition of polysulfide ion to the β-position, and the following path *via* a cyclic sulfide.



(4)

The formation of acetophenones supports the hypothetical Michael addition of polysulfide ion to the quinonoid form of *p*-nitrotoluene, which has been proposed as a step to the formation of *p*-aminobenzaldehyde from *p*-nitrotoluene (Eq. 1).[2]

On the other hand, the reaction of 1-nitrohexane (a saturated counterpart of nitrostyrenes) with Na_2S_4–NaOH gave hexanal, hexanal oxime, hexanoic acid, *etc.* All the products detected by the GLC peaks were the same as those of the reaction of 1-nitrohexane with NaOH, in which the yields and reaction rates were lower than those with Na_2S_4–NaOH. This fact shows that no oxidation of internal carbon atoms occurs unless a nitro group is conjugated with a C=C bond.

Experimental

Melting points were measured by a Yanagimoto micro melting point apparatus and were not corrected. NMR spectra were recorded on a Hitachi R-24B spectrometer using Me_4Si as an internal standard. The GLC analysis was performed with a Yanagimoto G 180 gas chromatograph with a flame ionization detector. GC-MS analysis was performed with a JEOL JMS-D300 mass spectrometer.

Materials. β-Nitrostyrene was prepared according to the literature;[7] mp 56—58 °C (lit,[7] 57—58 °C); NMR (CCl_4): δ 7.3—8.0 (dd, 2H, -CH=CH-), 7.4 (s, 5H, ArH). 4-Nitrostyrene was prepared by the method of Strassburg *et al.*;[9] NMR (CCl_4): δ 7.8 (d, 2H, ArH), 7.2 (d, 2H, ArH), 6.5 (m, 1H, α-CH), 5.2 (t, 2H, β-CH_2). 1-Nitrohexane was prepared by the method of Kornblum *et al.*;[10] bp 96—98 °C/22 Torr† (lit,[10] 76 °C/10 Torr); NMR (CCl_4); δ 4.3 (t, 2H, 1-CH_2), 1.8 (m, 2H, 2-CH_2), 1.2 (m, 6H, 3,4,5-CH_2), 0.8 (t, 3H, CH_3).

Reaction of β-Nitrostyrene with Na_2S_x–NaOH. A hot aqueous solution (20 ml) of $Na_2S \cdot 9H_2O$ and NaOH (and S) was poured into a 100 ml round-bottomed flask containing a hot ethanolic solution (10 ml) of β-nitrostyrene (1.00 g, 6.7 mmol) (Table 1). The mixture was heated under reflux for 3 h and then cooled in an ice bath. The resulting solution containing the precipitate of polymeric materials and elemental sulfur was filtered off, and the filtrate was steam-distilled. The distillate was extracted with ether, and the extract was dried (Na_2SO_4), and analyzed by GLC using two sorts of columns (2.5 mm × 1 m, packed with PEG 20M and KG-02) at 100—240 °C. Biphenyl was used as an internal standard. The residual solution after distillation was acidified with HCl and, after removal of elemental sulfur precipitated, it was extracted with ether. The extract was esterified by diazomethane and analyzed by GLC (PEG 20M) using benzophenone as an internal standard. Similar work-up was employed for the reaction with NaOH.

Reaction of 4-Nitrostyrene with Na_2S_4–NaOH. The reaction analogous to that of β-nitrostyrene was carried out with a mixture of 4-nitrostyrene (1.00 g, 6.7 mmol), $Na_2S \cdot 9H_2O$ (0.53 g, 2.2 mmol), S (0.28 g, 8.7×10^{-3} g atom), and NaOH (0.53 g, 13 mmol) in EtOH–H_2O (16 ml–4 ml). After refluxing for 3 h the solution was cooled, and the precipitate was removed by filtration. The filtrate was extracted with ether, and the extract was dried over anhydrous sodium sulfate. Then the extract was analyzed by NMR after distilling ether off. 4-Aminoacetophenone was identified by NMR in comparison with its authentic specimen; NMR ($CDCl_3$): δ 7.8 (d, 2H, ArH), 6.6 (d, 2H, ArH), 4.2 (s, 2H, NH_2), 2.5 (s, 3H, CH_3).

Reaction of 1-Nitrohexane with Na_2S_4–NaOH. According to the procedure analogous to that for β-nitrostyrene, 1-nitrohexane (0.21 g, 1.6 mmol), $Na_2S \cdot 9H_2O$ (0.15 g, 0.62 mmol), S (0.06 g, 2×10^{-3} g atom), and NaOH (0.18 g, 4.5 mmol) were refluxed for 9 h in EtOH–H_2O (5 ml–2 ml). The products were extracted with ether from the alkaline solution and also from the acidified solution. Both extracts were analyzed by GLC (PEG 20M) and GC-MS (2.5 mm × 2 m, packed with Silicone OV-1). The similar work-up was applied to the reaction of 1-nitrohexane (0.24 g, 1.8 mmol) with NaOH (0.20 g, 5.0 mmol).

Synthesis of Unsubstituted Thia Crown Ethers *via* Intramolecular Cyclization

Yohji NAKATSUJI, Yoshitaka WATANABE, and Mitsuo OKAHARA*

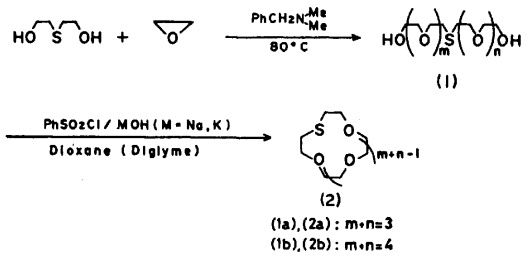
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka 2-1, Suita, Osaka 565

(Received May 2, 1981)

Synopsis. A remarkable temperature dependence of the template effect of alkali metal cations was found in the cyclization of thio analogs of penta- or hexaethylene glycols to thia 15-crown-5 or 18-crown-6. The optimum range of the reaction temperature was found to be 80—100 °C.

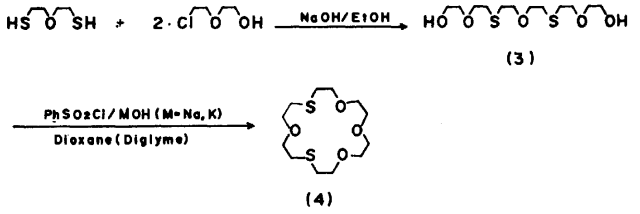
Thia crown ethers are interesting compounds because they can complex with transition metal cations, unlike normal crown ethers.[1-3] The known synthetic methods, however, are mostly restricted to the condensation reactions between two molecules.[4-6] We previously developed a new synthetic method of preparing crown ethers *via* intramolecular cyclization.[7] Template ions are important in obtaining macrocyclic compounds in good yields. The template effect of alkali metal cations in cyclization of oligoethylene glycols to the corresponding crown ethers was found to be dependent on the reaction temperature.[8] We here applied the intramolecular cyclization method to the synthesis of unsubstituted mono and dithia crown ethers and observed a more remarkable temperature effect on the reaction than occurred in the reaction of oligoethylene glycol.

Monothio oligoethylene glycol (**1**), the precursor of monothia crown ether (**2**), was prepared by the addition of ethylene oxide to 2,2′-thiodiethanol at 80 °C using *N*,*N*-dimethylbenzylamine as a catalyst. The three and four mole ethylene oxide adducts were separated from other adducts by distillation under reduced pressure.



A dioxane solution of **1** and an equimolar amount of benzenesulfonyl chloride was added dropwise to a stirred suspension of powdered sodium hydroxide in dioxane at a fixed temperature for 4 h. The mixture was stirred for another hour to give monothia crown ether (**2**). The yield was best at 100 °C for 15-crown-5 (**2a**) and at 80 °C for 18-crown-6 (**2b**) respectively, as shown in Table 1. It is noteworthy that reaction temperatures over 100 °C drastically lowered the yield. These optimum reaction temperatures (80—100 °C) in the synthesis of thia crown ethers are relatively higher than those of normal crown ethers (60—80 °C[8]). In addition, the temperature dependence of the template effect is remarkable in the reaction of **1**, compared with that of the oligoethylene glycols, so the consideration of the reaction temperature is more important in this case. The stability constant (log K') of **2a** toward Na^+ in methanol at 25 °C was determined to be 2.1 by using a cation-selective electrode, while that toward K^+ was too low to measure. Christensen and coworkers[3] reported that the value for **2b** was 2.57 toward Na^+ and 3.61 toward K^+. This trend in the stability constant may explain why K^+ does not display any template effects in the synthesis of **2a** and yet is suitable as the template ion for **2b**.

3,9,15-Trioxa-6,12-dithiaheptadecane-1,17-diol (**3**), which was obtained from the reaction between bis-(2-mercaptoethyl) ether and 2-(2-chloroethoxy)ethanol, was successfully cyclized to 1,7-dithia-18-crown-6 (**4**) according to the procedure mentioned above. The trend of the template effect of sodium and potassium cations in this case was similar to the case of **2b**.



However, the cyclization of 6,9-dioxa-3,12-dithiatetradecane-1,14-diol (**5**) gave very little of the desired crown ether (1,7-dithia-15-crown-5 (**6**)). Instead, a small

Solvent: Dioxane, *diglyme. Yields were determined by GLC.

amount of 1,4-dithia-12-crown-4 (**7**) was isolated by preparative GLC together with the unreacted **5**. The template effect is not effective in this case and **5** may be cyclized to **7** after the removal of ethylene oxide.

Experimental

The ^{1}H NMR spectra were taken at 100 MHz on a JEOL JNM-PS-100 spectrometer using tetramethylsilane as the internal standard. The infrared spectra were obtained on a Hitachi 260-10 spectrometer. The mass spectra were measured with a Hitachi RMU-6E mass spectrometer at an ionization potential of 70 eV.

*Monothia-15-crown-5 (**2a**) (1,4,7,10-tetraoxa-13-thiacyclopentadecane).* A dioxane solution (40 ml) of monothio pentaethylene glycol (**1a**) (3.0 g, 0.012 mol) and benzenesulfonyl chloride (2.12 g, 0.012 mol) was added dropwise to a stirred suspension of sodium hydroxide (1.90 g, 0.048 mol) in dioxane (60 ml) over 4 h at a fixed temperature; then the mixture was stirred for one more hour at that temperature. The insoluble salt was removed by filtration and washed with dichloromethane. The solvent was removed *in vacuo* to give the crude product. The yields were determined by GLC (Shimadzu GC 3BF, FID, 2 m×3 mm packed with 10% Silicone Gum SE-30 on Celite 545, 60—80 mesh, 220 °C) using methyl myristate as the internal standard. Bp 110—114 °C/0.06 Torr† (Kugelrohr apparatus). NMR ($CDCl_3$, δ): 2.66 (t, 4H), 3.55 (s, 12H), and 3.68 ppm (t, 4H). MS (*m/e*): 236 (M^+), 203, 174, 149, 133, 104, 86, 73, 60, and 45. IR (Neat): 2920 (s), 1460 (m), 1355 (m), 1300 (m), 1245 (m), and 1115 cm^{-1} (s). The NMR spectrum of **2a** was coincident with that in the literature.[4]

*Monothia-18-crown-6 (**2b**) (1,4,7,10,13-pentaoxa-16-thiacyclooctadecane).* Monothia-18-crown-6 (**2b**) was prepared according to the procedure mentioned above. The yields were determined by GLC using dihexyl sebacate as the internal standard. The NMR spectrum of **2b** was coincident with that in the literature.[5]

*3,9,15-Trioxa-6,12-dithiaheptadecane-1,17-diol (**3**).* A suspended mixture of bis(2-mercaptoethyl) ether (27.0 g, 0.195 mol) and sodium hydroxide (24.6 g, 0.585 mol) in ethanol (230 ml) was stirred for 1.5 h. Then, 2-(2-chloroethoxy)ethanol (53.44 g, 0.429 mol) was added dropwise to the resultant mixture at 78 °C. The mixture was refluxed for another 1.5 h. The insoluble salt was removed by filtration and washed with ethanol. The solution was neutralized with aq hydrochloric acid and concentrated. The residue was dissolved in a mixed solvent of ethanol and ether and the insoluble salt was removed by filtration again. The solvent was concentrated to give the crude product of **3** (51.3 g, 84%). The crude product was distilled (190—200 °C/0.007 Torr) by using flash distillation apparatus to give **3** in a 48% yield. NMR ($CDCl_3$, δ): 2.75 (t, 8H), 3.00 (s, 2H), and 3.55—3.85 ppm (m, 16H). MS (*m/e*): 314 (M^+), 296, 283, 252, 149, 117, 105, 88, 75, and 45. IR (Neat): 3400 (s), 2920 (s), 1460 (m), 1355 (m), 1200 (m), and 1115 cm^{-1} (s).

*1,7-Dithia-18-crown-6 (**4**) (1,4,7,13-tetraoxa-10,16-dithiacyclooctadecane).* 1,7-Dithia-18-crown-6 was prepared according to the procedure mentioned above. The yields were determined by GLC using ethyl stearate as the internal standard. The NMR spectrum of **4** was coincident with that in the literature.[4]

*6,9-Dioxa-3,12-dithiatetradecane-1,14-diol (**5**).* Purified Yield: 37%. Bp 184—190 °C/0.03 Torr (Kugelrohr apparatus). NMR ($CDCl_3$, δ): 2.75 (t, 8H), 3.30 (s, 2H), and 3.60—3.85 ppm (m, 12H). MS (*m/e*): 252 ($M^+ - H_2O$), 149, 105, 87, 61, and 45. IR (Neat): 3400 (s), 2900 (s), 1640 (m), 1405 (m), 1350 (m), 1100 cm^{-1} (s).

*Cyclization Reaction of **5**.* The cyclization reaction of **5** was carried out according to an analogous procedure. 1,4-Dithia-12-crown-4 (**7**) was detected by GLC, together with unreacted **5**, and isolated by preparative GLC. The analytical data of **7** were as follows: NMR ($CDCl_3$, δ): 2.73 (t, 4H), 2.88 (s, 4H), 3.68 (s, 4H), and 3.78 ppm (t, 4H). MS (*m/e*): 208 (M^+), 149, 120, 104, 86, 73, 61, and 45. IR (Neat): 2870 (s), 1650 (m), 1460 (m), 1350 (m), 1300 (m), and 1130 cm^{-1} (s). The NMR spectrum of this compound was coincident with that in the literature.[4]

† 1 Torr≈133.322 Pa.

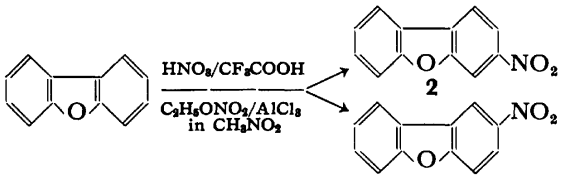
Regioselective Preparation of 2- and 3-Nitrodibenzofurans by the Direct Nitration of Dibenzofuran

Takashi KEUMI,* Hideyo YAMADA, Hisakazu TAKAHASHI, and Hidehiko KITAJIMA
Department of Fiber and Color Chemistry, Faculty of Engineering, Fukui University, Bunkyo, Fukui 910
(Received May 21, 1981)

Synopsis. Nitration of dibenzofuran with nitric acid in trifluoroacetic acid gave 3-nitrodibenzofuran selectively under very mild conditions. In contrary, the Friedel-Crafts type nitration using alkyl nitrates and aluminium chloride in nitromethane gave 2-nitrodibenzofuran as the main product.

Nitrodibenzofurans are important precursors for many kinds of dibenzofuran derivatives. Nitration of dibenzofuran (**1**) with mixed acids gives 3-nitrodibenzofuran (**2**) as a main product.[1-3] Yamashiro had reported that the nitration of **1** with 12 equiv. of fuming nitric acid in acetic acid gave **2** in a yield of 70%.[3] As for a synthesis of 2-nitrodibenzofuran (**3**), circuitous processes have been taken due to a difficulty of the preparation from the direct nitration of **1** by the usual methods.[4-6] Cullinane had obtained **3** in a total yield of 16% from **1** by the dinitration of **1**, followed by partial reduction and deamination.[4] On the other hand, Gilman had prepared **3** in the total yield of 13% *via* a process of 6 steps starting from **1**.[5]

By choosing the appropriate nitration method, we have succeeded in controlling the main product to **2** or **3** in the direct nitration of **1**. We would like to report the regioselective nitration of **1** to give **2** or **3**.



2 **3**

Using trifluoroacetic acid in place of acetic acid in Yamashiro's procedure, the mononitration of **1** was attained in a quantitative yield with 1.2 equiv. of 99% nitric acid under very mild conditions, at 0 °C for 0.5 h. In addition, it was observed that **2** was very predominantly formed in the reaction. The GLC analysis of the crude product showed that a mixture of mononitrodibenzofurans was obtained in a quantitative yield and that the distribution of the 1-, 2-, 3-, and 4-nitroisomers in the mixture was 4 : 6 : 90 : trace. By a recrystallization of the crude product, **2** was isolated in a yield of 80%. In contrast, when the nitration in acetic acid was carried out with 1.2 equiv. of 99% nitric acid at 0 °C for 0.5 h, the yield of mononitrodibenzofurans was only 2% and the distribution of the isomers was 1-, 10 : 2-, 26 : 3-, 62 : 4-, 2.

On the other hand, in the Friedel-Crafts type nitration using alkyl nitrate and Lewis acid, the main product significantly changed from **2** to **3**. It was observed from the GLC analysis that the reaction of **1** with 1-cyano-1-methylethyl nitrate (CMN) in the presence of aluminium chloride in nitromethane gave a mixture of mononitrodibenzofurans in a yield of 92%, in which the distribution of the isomers was 1-, 11 : 2-, 51 : 3-, 36 : 4-, 2. For the preparative method, ethyl nitrate was used in place of CMN. Thus, in the reaction of **1** with 1.2 equiv. of ethyl nitrate and aluminium chloride in nitromethane at 25 °C for 1 h, mononitrodibenzofurans were obtained in a yield of 80%, from which **3** was isolated in a yield of 28% by the column chromatograpy on alumina with benzene. This yield is much higher than the total ones for the derivation from **1** by the indirect methods described in literatures.[4,5]

We can prepare **2** or **3** regioselectively by the direct nitration of **1** with either the nitric acid/trifluoroacetic acid system or with the ethyl nitrate-aluminium chloride/nitromethane system. We believe, therefore, the procedures described here should be much simpler and more convenient for the preparation of **2** and **3** than those reported previously.

Experimental

Materials and Measurements. 1-Nitrodibenzofuran (mp 123 °C, lit,[7] 120—121 °C), 4-nitrodibenzofuran (mp 138 °C, lit,[8] 138—139 °C), and CMN (bp 84 °C/34 mmHg,† lit,[9] 62—65 °C/10 mmHg) were prepared according to the methods described in the literature. Other chemicals were obtained commercially.

The GLC analysis was carried out on a Hitachi GC 163 Model gas chromatograph using a steel column (length 3 m, i.d. 3 mm) packed with 3% Dexil 300 GC on Chromosorb W and a hydrogen flame ionization detector. Isomer distribution of nitrodibenzofurans was calculated from the peak areas obtained using a Takeda TR 2220A Model integrator after calibration against authentic samples.

2-Nitrodibenzofuran (3). To a solution of **1** (5.00 g, 30 mmol) and ethyl nitrate (3.2 g 36 mmol) in nitromethane (30 ml), a solution of aluminium chloride (4.8 g, 36 mmol) in nitromethane (10 ml) was added at 5 °C over 0.1 h and then, the mixture was stirred at 25 °C for 1 h. After an addition of 0.1 mol dm^{-3} hydrochloric acid (30 ml) to the mixture, the solvent and the unreacted **1** were distilled off with steam to yield a crude product of nitrated dibenzofuran; 6.07 g, mp 102—142 °C. The crude product was treated with boiling ethanol (280 ml) and the insoluble by-product, dinitrodibenzofuran was collected; 0.47 g (6.1%), mp 261—269 °C. Evaporation of the filtrate gave a mixture of mononitrodibenzofurans as a light yellow solid, 5.09 g (80%), mp 108—139 °C. After treatment with hot ethanol (first 45 ml, then 35 ml) as above, the resulted ethanol-soluble component (4.12 g, mp 122—134 °C) was chromatographed on alumina with benzene to afford **3**: 1.76 g (28%), mp 152—153 °C (lit,[4] 151 °C), **2**; 1.08 g (17%), mp 162—174 °C, and 1-nitrodibenzofuran; 0.33 g (5%), mp 123 °C (lit,[7] 120—121 °C).

3-Nitrodibenzofuran (2). To a suspension of **1** (4.00 g, 24 mmol) in trifluoroacetic acid (50 ml), a solution of 99% nitric acid (1.82 g, 29 mmol) in trifluoroacetic acid (10 ml) was added dropwise at a rate such as to maintain the temperature

† 1 mmHg≈133.322 Pa.

at 0 °C. The reaction mixture was stirred at 0 °C for 0.5 h and poured into ice–water. The resulted precipitates were filtered and washed thoroughly with alkali and water to give crude nitrodibenzofuran; 5.06 g (100%), mp 168—174 °C. The well refined product was heated with ethanol (50 ml) at 50 °C for 1 h and the insoluble material was recrystallized from acetic acid (29 ml) to give **2** in a almost pure form; 4.07 g (80%), mp 182 °C (lit,[3] 182 °C).

The Direct Synthesis of Methyl 2,4-Di-*O*-benzyl-α-D-xylopyranoside by the Regiospecific Benzylation of Methyl α-D-Xylopyranoside

Naohiko MORISHIMA, Shinkiti KOTO,* Chiharu KUSUHARA, and Shonosuke ZEN

School of Pharmaceutical Sciences, Kitasato University, Shirokane, Minato-ku, Tokyo 108

(Received May 30, 1981)

Synopsis. The regiospecific benzylation of methyl α-D-xylopyranoside with benzyl chloride and sodium hydride produces methyl 2,4-di-*O*-benzyl-α-D-xylopyranoside in a 70% yield, together with the by-products, methyl 2,3- and 3,4-di-*O*-benzyl-α-D-xylopyranosides. The structure of the 2,4-di-*O*-benzyl derivative was confirmed through the alternative synthesis of the 2,3- and 3,4-di-*O*-benzyl derivatives *via* the *O*-isopropylidene and *O*-cyclohexylidene derivatives of methyl α-D-xylopyranoside.

Partially benzylated monosaccharide derivatives are important synthetic intermediates, especially in the synthesis of oligosaccharides.[1] Usually, they are prepared *via* a multi-step sequence of reactions.[2] However, the regiospecific benzylation has often been useful for the ready preparation of the partially benzylated derivative of carbohydrates.[3] This report will present the direct synthesis of methyl 2,4-di-*O*-benzyl-α-D-xylopyranoside (**3**) through the regiospecific benzylation[3] of methyl α-D-xylopyranoside (**1**).

A brief heating of **1** with benzyl chloride containing the stoichiometric amount of sodium hydride, followed by chromatography, furnished crystalline **3** in a 70% yield. Small amounts of two other isomers, 2,3- and 3,4-di-*O*-benzyl derivatives (**2** and **4**), were also isolated through the chromatography. This shows that the reactivity of OH-2 and OH-4 is greater than that of OH-3 under such benzylation reactions.[4] The structure of the main product, **3**, was confirmed through the the alternative synthesis of **2** and **4** from **1**, as will be described below.

The reaction of 2,2-dimethoxypropane with **1** in *N,N*-dimethylformamide containing *p*-toluenesulfonic acid gave the 2,3- and 3,4-*O*-isopropyridene derivatives (**5** and **6**); the former predominated. The structure of the isopropylidene derivatives was confirmed by observing the ^{1}H NMR spectra of their acetates (**7** and **8**). The isopropylidene derivative, **5**, was transformed into **2** *via* allylation, deisopropylidenation, benzylation, and then deallylation, successively. Another isopropylidene compound, **6**, was similarly derived into **4**.

Compounds **2** and **4** were also synthesized *via* the cyclohexylidene derivatives (**9** and **10**) in essentially the same manner as above: 1,1-dimethoxycyclohexane, with *p*-toluenesulfonic acid as the catalyst, in *N,N*-dimethylformamide converted **1** into a mixture of **9** and **10**, which were then derived into **2** and **4** respec-

tively *via* allylation, decyclohexylidenation, benzylation, and deallylation.

Experimental

The melting points were determined on an MP-1 melting-point apparatus (Yanagimoto); they are uncorrected. The optical rotations were measured in a jacketed 1-dm cell at 20 °C, with a DIP-180 automatic polarimeter (Japan Spectroscopic). The ^{1}H NMR spectra were recorded with a Varian EM-390 spectrometer in $CDCl_3$, using Me_4Si as the internal standard. Column chromatography was carried out on silica gel (Kanto Kagaku); each fraction was examined by TLC on silica gel (Merck, 7731).

Methyl 2,4-Di-O-benzyl-α-D-xylopyranoside (3). A mixture of **1** (Pfanstiehl, 2.0 g, 12 mmol), NaH (Wako, ≈50% disp., 1.2 g, 24 mmol), and benzyl chloride (Tokyo Kasei, 40 ml) was stirred for 1.5 h at 100 °C. After acetic acid (0.1 ml) had then been added, the mixture was evaporated at 95 °C to give an oily residue. This was chromatographed (benzene–butanone, gradient, 100 : 1→3 : 1) to afford three fractions (Fraction A, R_f=0.55; B, 0.30; and C, 0.23 and 0.21; benzene–butanone (10 : 1)). Fraction A (0.05 g, 1%) was crystallized from hexane and identified with methyl 2,3,4-tri-*O*-benzyl-α-D-xylopyranoside.[5] Fraction B (2.88 g, 70%) was crystallized from diisopropyl ether to yield **3** (2.10 g). Fraction C (0.32 g) was rechromatographed to afford **2** (0.15 g, 8%) and then **4** (0.04 g, 1%).

Methyl 2,3- and 3,4-O-Isopropylidene-α-D-xylopyranosides (5 and 6). A solution of **1** (656 mg, 4 mmol), 2,2-dimethoxypropane (Tokyo Kasei, 4.9 ml), and *p*-toluenesulfonic acid monohydrate (Wako, 38 mg) in distilled *N,N*-dimethylformamide (Tokyo Kasei, 13 ml) was heated for 2 h at 70 °C.[6] After a few drops of triethylamine had then been added, the mixture was evaporated and chromatographed (diisopropyl ether–ethylacetate (20 : 1)) to afford **5** (380 mg, 39%) and **6** (123 mg, 13%).

A small portion of **5** was acetylated with acetic anhydride and pyridine to afford the 4-*O*-acetyl derivative (**7**); ^{1}H NMR: δ 1.42 and 1.46 (2s, Me_2C), 2.06 (s, Ac), 3.28 (t, $J_{4,5ax}$=10 Hz, $J_{5ax,5eq}$=10.5 Hz, H-5ax), 3.42 (s, MeO), 3.50 (q, $J_{1,2}$=3 Hz, $J_{2,3}$=10 Hz, H-2), 3.89 (q, $J_{4,5eq}$=5.5 Hz, H-5eq), 4.07 (t, $J_{3,4}$=10 Hz, H-3), 4.99 (d, H-1), and 5.01 (sext, H-4). Compound **6** was similarly converted into the 2-*O*-acetyl derivative (**8**); ^{1}H NMR: δ 1.44 (s, Me_2C), 2.12 (s, Ac), 3.36 (s, MeO), 3.47 (sext, $J_{3,4}$=9 Hz, $J_{4,5eq}$=4.5 Hz, $J_{4,5ax}$=9 Hz, H-4), 3.70 (t, $J_{5ax,5eq}$=9 Hz, H-5ax), 3.87 (q, $J_{2,3}$=10.5 Hz, H-3), 3.94 (q, H-5eq), 4.83 (q, $J_{1,2}$=4 Hz, H-2), and 5.02 (d, H-1).

Methyl 2,3- and 3,4-O-Cyclohexylidene-α-D-xylopyranosides (9 and 10). A solution of **1** (500 mg, 3.05 mmol), 1,1-dimethoxycyclohexane (0.8 ml), and *p*-toluenesulfonic acid monohydrate (5.7 mg) in *N,N*-dimethylformamide (4.0 ml) was heated for 15 h at 140 °C.[7] After triethylamine had then been added, the mixture was evaporated and chromatographed (toluene–butanone, gradient, 100 : 1→3 : 1) to elute **10** (94 mg, 13%) and **9** (467 mg, 63%).

Alternative Synthesis of 2. Compound **5** (180 mg, 0.88 mmol) was stirred in allyl bromide (1.8 ml) containing NaH (≈60% disp., 50 mg) for 1.5 h at 65 °C. The mixture was then filtered and evaporated to give the sirupy 4-*O*-allyl derivative (180 mg). This was treated with a mixture of 0.25 M H_2SO_4, acetone, and 1,4-dioxane (1 : 1 : 1) for 0.5 h at 25 °C. After methanol and $Ba(OH)_2 \cdot 8H_2O$ had been added, the mixture was evaporated to dryness. The residue was stirred in benzyl chloride (3.0 ml) containing KOH (0.8 g) for 5 h at 110 °C, followed by chromatography, to give methyl 4-*O*-allyl-2,3-di-*O*-benzyl-α-D-xylopyranoside (**11**) (150 mg, 44%). Compound **9** was also converted into **11** in a similar way.

Compound **11** (42.5 mg, 0.11 mmol) was heated in dimethyl sulfoxide (0.34 ml) containing potassium *t*-butoxide (Aldrich, 119 mg) for 2.5 h at 110 °C under N_2.[8] The mixture was then diluted with benzene and processed as usual. The organic layer was evaporated, and the residue was heated in a mixture of 2.6 M H_2SO_4† (0.09 ml) and 1,4-dioxane (0.9 ml) for 1 h at 85 °C. After neutralization with $Ba(OH)_2 \cdot 8H_2O$, evaporation and chromatography gave **2** (24.6 mg, 65%).

Alternative Synthesis of 4. Compound **6** was similarly converted into methyl 2-*O*-allyl-3,4-di-*O*-benzyl-α-D-xylopyranoside (**12**), which was, in turn, derived into **4**.

Methyl 2,4-Di-O-acetyl-3-O-methyl-α-D-xylopyranoside (13). Compound **3** (50 mg, 0.15 mmol) was heated in *N,N*-dimethylformamide (0.25 ml) containing methyl iodide (70 μl) and BaO (95 mg) for 1.5 h at 90 °C under stirring.[9] Chromatography gave a homogeneous oil (49.2 mg), which was subsequently hydrogenated over Pd in acetic acid at 340 KPa. The hydrogenolyzate, which was not oxidized with aq $NaIO_4$, was acetylated as usual to give **13** (32.6 mg, 83%); ^{1}H NMR: δ 2.06 (s, Ac), 2.12 (s, Ac), 3.37 (s, MeO), and 3.47 (s, MeO); ^{13}C NMR: δ 20.9, 55.3 (Me-1), 58.5 (C-5), 60.4 (Me-3), 71.1 (C-4), 72.7 (C-2), 77.9 (C-3), 97.1 (C-1), 169.8, and 170.1.

Synthesis of N^2-Protected L-2,3-Diaminopropanoic Acids

Noriyoshi NOGUCHI, Tsuyoshi KURODA, Minoru HATANAKA, and Toshiyasu ISHIMARU*

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565

(Received July 11, 1981)

Synopsis. The title compounds have been synthesized from *N*-protected L-aspartic acid *via* Curtius rearrangement.

In the course of synthetic studies of 3-aminonocardicinic acid (the nucleus of nocardicins),[1] we needed N^2-protected L-2,3-diaminopropanoic acid. L-2,3-Diaminopropanoic acid (L-DAPr) is well known as a constituent amino acid of several antibiotics including tuberactinomycins[2] and bleomycins.[3] Although N^2- or N^3-protected L-DAPr and $N^{2,3}$-diprotected L-DAPr have been required for constructing these antibiotics,[4] many of previous methods for the synthesis of these L-DAPr derivatives employ inconvenient procedure.[5,6] We report here a simple synthesis of N^2-protected L-DAPr and $N^{2,3}$-diprotected L-DAPr from *N*-protected L-aspartic acid *via* Curtius rearrangement.

The α-carboxyl groups of *N*-(2,2,2-trichloroethoxycarbonyl)-L-aspartic acid (**1a**) and *N*-benzyloxycarbonyl-L-aspartic acid (**1b**) were protected by the formation of the oxazolidines **2a** and **2b** according to the published method.[7] The oxazolidine **2a** was treated with diphenyl phosphorazidate[8] in benzene to give the acid azide, which was subsequently heated with *p*-methoxybenzyl alcohol in refluxing benzene to produce **3a** in 70% yield. Ring-opening of **3a** with aqueous sodium hydroxide provided the diprotected diamino acid **4a** as an oil, which produced the crystalline dicyclohexylammonium salt. Similarly, the oxazolidine **2b** gave **4b** as crystals. Removal of *p*-methoxybenzyl groups of **4a** and **4b** was carried out with hydrogen chloride in dioxane to give the N^2-protected diamino acids **5a** and **5b** in 73% and 92% yields, respectively. The physical data of the products are shown in Table 1.

Reductive deprotection of **5a** with zinc in formic acid gave L-DAPr, the hydrochloride of which had identical $[\alpha]_D$ value with that reported.[5a] The total synthesis of 3-aminonocardicinic acid using **4** as a starting material will be reported elsewhere.

(9.65 g, 0.03 mol) in anhydrous benzene (150 ml) was treated with diphenyl phosphorazidate (9.1 g, 0.033 mol) and triethylamine (3.36 g, 0.033 mol). After the mixture was stirred for 15 h, *p*-methoxybenzyl alcohol (4.14 g, 0.03 mol) was added and the mixture was refluxed for 3 h. The solution was cooled, washed with saturated aqueous $NaHCO_3$, 5% hydrochloric acid and water, dried ($MgSO_4$), and then concentrated *in vacuo*. The residue was chromatographed on silica gel with benzene–ethyl acetate to give **3a** (9.6 g, 70%) as a pale yellow oil; IR (CH_2Cl_2) 1810 and 1735 cm^{-1}.

*(S)-3-Benzyloxycarbonyl-4-(p-methoxybenzyloxycarbonylaminomethyl)-5-oxazolidinone (**3b**).* This compound was prepared from **2b** by the procedure described for **3a** in 80% yield.

N^3-*(p-Methoxybenzyloxycarbonyl)*-N^2-*(2,2,2-trichloroethoxycarbonyl)*-L-*2,3-diaminopropanoic Acid (**4a**).* To a solution of **3a** (9.1 g, 0.02 mol) in aqueous acetone (80 ml), 1 M aqueous NaOH (20 ml) was added dropwise at 0 °C over 1 h. After being stirred for 2 h at 0—5 °C, the solution was concentrated *in vacuo*. The residue was diluted with water (20 ml), washed with ether, acidified with 20% hydrochloric acid, and then extracted with ethyl acetate. The extracts were washed with brine, dried ($MgSO_4$), and concentrated *in vacuo* to give **4a** (8.71 g, 98%) as a pale yellow oil.

The oily product (464 mg) was treated with dicyclohexylamine (227 mg) in ethanol (10 ml) to yield the dicyclohexylammonium salt (595 mg, 91%); mp 190—191 °C.

N^2-*Benzyloxycarbonyl*-N^3-*(p-methoxybenzyloxycarbonyl)*-L-*2,3-diaminopropanoic Acid (**4b**).* This compound was prepared from **3b** according to the procedure described for **4a** in 95% yield. The product was crystallized by trituration in ether; mp 145—147 °C. This compound also produced the crystalline dicyclohexylammonium salt; mp 178—180 °C.

N^2-*(2,2,2-Trichloroethoxycarbonyl)*-L-*2,3-diaminopropanoic Acid (**5a**).* A solution of **4a** (8.7 g, 0.0195 mol) in dioxane (100 ml) was treated with a 4 M HCl–dioxane solution (100 ml). After being stirred for 3 h, the solution was concentrated *in vacuo* and the remaining solid was dissolved in ethanol. The solution was ajusted to pH 7 with triethylamine and left in a refrigerator overnight. The white precipitates were collected by filtration, washed with chilled ethanol, and dried *in vacuo* to give **5a** (4.0 g, 73%); mp 179—180 °C.

N^2-*Benzyloxycarbonyl*-L-*2,3-diaminopropanoic Acid (**5b**).* This compound was prepared from **4b** by the procedure described for **5a** in 92% yield; mp 213—214 °C (dec) [Lit,[9] mp 240—241 °C (dec)].

L-*2,3-Diaminopropanoic Acid Hydrochloride.* The compound **5a** (280 mg) was dissolved in formic acid (10 ml) and cooled in an ice bath. Activated zinc dust (654 mg) was added with vigorous stirring and stirring was continued for 3 h at 0—5 °C. The mixture was filtered and the filtrate was concentrated *in vacuo*. The residue was diluted with water, treated with H_2S, and then filtered. A few drops of 20% hydrochloric acid was added to the filtrate and the solvent was evaporated *in vacuo*. The residue was crystallized from water–ethanol to give 99 mg (71%); mp 233—235 °C (dec); $[\alpha]_D^{25}$ +19.4° (*c* 1, H_2O). [Lit,[5a] mp 236 °C (dec); $[\alpha]_D^{12}$ +19° (*c* 1, H_2O)].

Preparation of α-Nitro Olefins from α-Halo Ketoximes

Tohru SAKAKIBARA,* Yutaka IKEDA, and Rokuro SUDOH

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received July 23, 1981)

Synopsis. α-Nitro olefins were synthesized from α-haloketones through oximation and subsequent oxidation with trifluoroperacetic acid.

α-Nitro olefins are versatile and unique synthetic intermediates, for examples, for the introduction of nucleophiles and electrophiles at the β- and α-carbon atom, respectively, or for annulation reactions.[1,2] Furthermore the nitro group is convertible into such a function as an amino or a carbonyl group.[1]

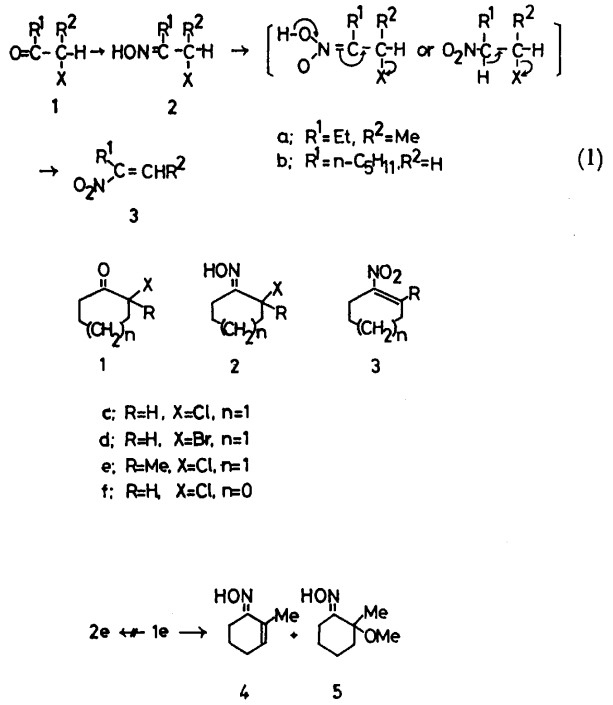
Although the conversion of α-nitro olefins into the α-chloro ketoximes was reported,[3] the reverse reaction is not developed. This reaction seems to be attractive because α-chloro ketoximes are prepared in good yields by the reaction of olefins with nitrosyl chloride in the presence of hydrochloric acid.[4]

In this paper we described the preparation of α-nitro olefins from α-halo ketones according to Eq. 1, in which the nitro group could be introduced regioselectively.

Although the ketoximes were generally prepared by treatment of the ketones with hydroxylamine acetate or hydroxylamine hydrochloride in the presence of such a weak base as sodium acetate, oximation of 2-chlorocyclohexanone by the conventional methods afforded a complex mixture. However, the desired 2-chlorocyclohexanone oxime was obtained in 64% yield together with 2-chloro-1,1-dimethoxycyclohexane (17.5%) by treatment with hydroxylamine hydrochloride in methanol.[5] Similar treatment of several α-halo ketones provided the corresponding α-halo ketoximes in moderate yields (Table 1). Under the same conditions, however, 2-chloro-2-methylcyclohexanone did not afford the expected oxime, but 2-methyl-2-cyclohexenone oxime (**4**) (39% yield) and 2-methoxy-2-methylcyclohexanone oxime (**5**) (23% yield).

The oximes **2** were oxidized with trifluoroperacetic acid in acetonitrile in the presence of disodium hydrogenphosphate and urea,[6] giving the corresponding α-nitro olefin in moderate yield as shown in Table 1.

Similar oxidation of **5** yielded 2-methyl-1-nitrocyclohexene in 40% yield.



Experimental

IR spectra were recorded with a Hitachi 285 Infrared Spectrophotometer. NMR spectra were determined with a Varian EM 360A NMR Spectrometer. GLC analyses were performed with a Varian 940 instrument equipped with an OV 101 column (*N,N*-diethylaniline as internal standard). Column chromatography was carried out on silica gel (C-300, Wakogel).

2-Chlorocyclohexanone Oxime. Typical Procedure: To a solution of 2-chlorocyclohexanone (1.325 g, 10 mmol) in methanol (6 mL) was added hydroxylamine hydrochloride (765 mg, 11 mmol). The mixture was stirred at room temperature for 2 h and then worked up in the usual way to give a syrup. The syrup was chromatographed on silica gel, eluting with benzene–ethyl acetate (25 : 1, v/v) to afford 944 mg (64%) of the oxime and 312 mg of 2-chloro-1,1-dimethoxycyclohexane (17.5%). Without further purification the oxime was used for oxidation.

1-Nitrocyclohexene. Typical Procedure: An acetonitrile solution (90 mL) of 2-chlorocyclohexanone oxime (590 mg, 4 mmol) was added dropwise a stirred solution of oxidant, prepared by mixing successively acetonitrile (10 mL), trifluoroacetic anhydride (2.0 mL), 90% aqueous hydrogen peroxide

Convenient Synthesis of 2,7-Disubstituted 5*H*-1,3,4-Thiadiazolo[3,2-*a*]-pyrimidin-5-ones and Related Compounds

Tadakazu Tsuji* and Keiko Takenaka

Department of Chemistry, Japan Women's University, Mejirodai, Bunkyo-ku, Tokyo 112

(Received July 28, 1981)

Synopsis. 2,7-Disubstituted 5*H*-1,3,4-thiadiazolo[3,-2-*a*]pyrimidin-5-ones were synthesized from the reaction of 3-amino-6-methyl-2-thiouracil with carboxylic acid or from that of thiosemicarbazide with carboxylic acid and β-keto ester in the presence of phosphorus pentaoxide and methanesulfonic acid. The synthesis of related compounds is also described.

Our work on the chemistry of 2,7-disubstituted 5*H*-1,3,4-thiadiazolo[3,2-*a*]pyrimidin-5-ones (**1**)[1] has required a wide and convenient entry to this ring system, which is of their chemical[2,3] and biological[4] interests. Okabe *et al.*[4] have synthesized **1** by the condensation of 5-substituted 2-amino-1,3,4-thiadiazole (**2**) with β-keto ester in the presence of polyphosphoric acid (PPA). However, we failed to obtain the 2-(nitrophenyl or chlorophenyl) derivative of **1** by this method. This paper describes the general and facile methods for the synthesis of **1** and related compounds by the use of 1 : 5 molar ratio of phosphorus pentaoxide (P_2O_5)-methanesulfonic acid (MsOH).[5] The synthetic routes are illustrated in Scheme 1, and the results are summarized in Table 1. PPA was less effective in the present synthesis, since the product yields were generally poor in Method A and B; no desired product was obtained in Method C, D, or E.

The treatment of 3-acylamino-6-methyl-2-thiouracil (**4**) with P_2O_5–MsOH at 70 °C for 10 h, followed by aqueous basic work-up afforded **1** (Method A). Moreover, the reaction of 3-amino-6-methyl-2-thiouracil (**3**) with carboxylic acid (**5**) in the presence of P_2O_5–MsOH gave **1** including the 2-(nitrophenyl and chlorophenyl) derivatives in 37.8—97% yields (Method B).

We then attempted the synthesis of **1** from thiosemicarbazide or its 1-substituted derivatives in the presence of P_2O_5–MsOH. Thus, **1** was obtained from the reaction of acetone thiosemicarbazone (**7**) with β-keto ester (**6**) and **5** (Method C), or from that of 1-acylthiosemicarbazide (**8**) with **6** (Method D), but the yields were unsatisfactory. In connection with these reactions, **2** was prepared by the treatment of thiosemicarbazide with **5** in 40.1—89.9% yields. Based on this result, one pot synthesis of **1** was carried out by

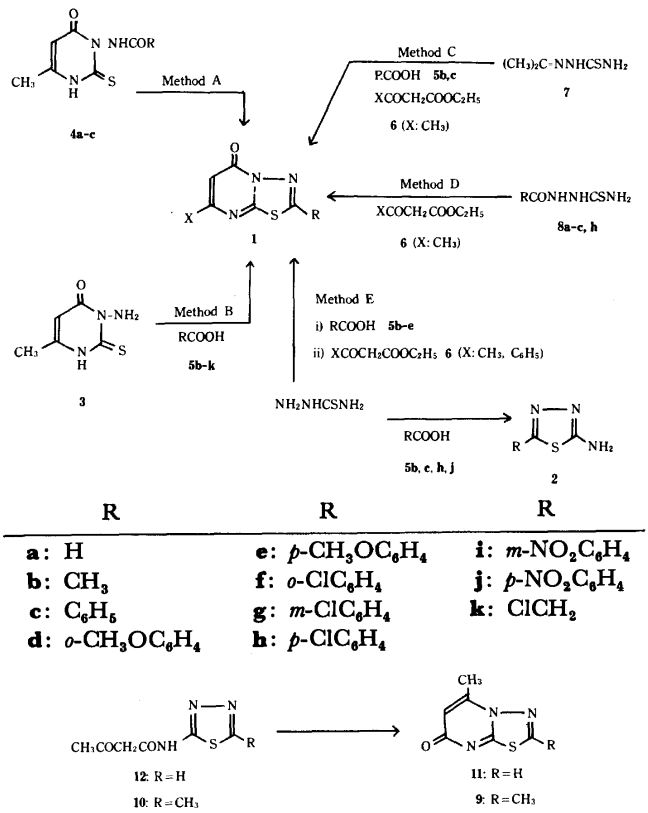
a) From **4**. b) From **3** with **5**. c) From **7** with **5** and ethyl acetoacetate. d) From **8** with ethyl acetoacetate. e) From thiosemicarbazide with **5** and **6** by one-pot reaction. f) Recrystallized from water. g) Recrystallized from methanol. h) Recrystallized from *N*,*N*-dimethylformamide. i) Lit,[4] mp 169—172 °C.



Scheme 1. Synthesis of 2,7-Disubstituted 5*H*-1,3,4-thiadiazolo[3,2-*a*]pyrimidin-5-ones (**1**) and related compounds in the presence of P_2O_5–MsOH.

heating the mixture of thiosemicarbazide and **5** in the presence of P_2O_5–MsOH, followed by the treatment of the above mixture with **6**. The yields were 72.4—76.5% (Method E). This method is inapplicable to the synthesis of **1** which has a 2-(nitrophenyl or chlorophenyl) substituent.

Previously, 2,5-dimethyl-7*H*-1,3,4-thiadiazolo[3,2-*a*]-pyrimidin-7-one (**9**) was prepared by the treatment of 2-acetoacetylamino-5-methyl-1,3,4-thiadiazole (**10**) with PPA in 18% yield.[4] Upon heating **10** with P_2O_5-MsOH, the yield of **9** was raised to 87.4%. Similarly, compound (**11**) was obtained in 61.2% yield.

The P_2O_5–MsOH reagent was at first used for the intramolecular acylation of olefinic acids and the Beckmann rearrangement of ketoxime, since this reagent resembles PPA in reaction rate, product distribution and yield.[5] It is notable that the product yield increased markedly by converting the reagent from PPA to P_2O_5–MsOH in the synthesis of heterocycles.

Experimental

General Procedures for the Preparation of 2,7-Disubstituted 5H-*1,3,4-thiadiazolo*[*3,2-*a]*pyrimidin-5-ones (1). a) From 3 or Its Acyl Derivatives (4)*: Compound **4**[2] (0.01 mol) or a mixture of **3**[1a] (0.01 mol) and **5** (0.01 mol), MsOH (0.05 mol), and P_2O_5 (0.01 mol) was placed in a flask in this order, and heated at 70 °C for 10 h. When nitrobenzoic acids were used for **5**, the reaction was carried out at 100 °C. The reaction mixture was poured into water, and made basic with 10% NaOH to pH 8. The precipitate was extracted with chloroform, and the extract was washed with water. The dried extract was evaporated to dryness in vacuum to obtain **1**.

b) From Acetone Thiosemicarbazone (7): To the mixture of **7** (0.01 mol), ethyl acetoacetate (0.01 mol), and **5** (0.01 mol) was added MsOH (0.05 mol) and P_2O_5 (0.01 mol), and the whole was heated at 100 °C for 10 h. A work-up similar to that in Method A gave **1**.

c) From 1-Acylthiosemicarbazide (8): The mixture of **8** (8 mmol) and ethyl acetoacetate (8 mmol) was heated with P_2O_5 (8 mmol)–MsOH (40 mmol) at 70 °C for 5 h. In the case of **8c** or **8h**, the mixture was heated at 100 °C for 10 h.

d) From Thiosemicarbazide: The mixture of thiosemicarbazide (0.01 mol) and **5** (0.01 mol) was heated at 70 °C for 10 h with P_2O_5 (0.01 mol)–MsOH (0.05 mol). At the end of the reaction time, **6** (0.01 mol) and P_2O_5 (5 mmol) were added to the reaction mixture and the whole was further heated at 70 °C for 10 h. The resulting solution was similarly worked up to give **1**.

Preparation of 5-Substituted 2-Amino-1,3,4-thiadiazole (2). A mixture of thiosemicarbazide (0.01 mol), **5** (0.01 mol), MsOH (0.05 mol), and P_2O_5 (0.01 mol) was heated at 70 °C for 10 h. The reaction mixture was poured into water, and made basic (pH 8) with aqueous ammonia. **2** (R: CH_3,[6,7] C_2H_5,[8] C_6H_5,[6,8] p-$NO_2C_6H_4$,[8] and p-ClC_6H_4[9]) was obtained in 89.9, 64.5, 74.2, 40.4 and 40.1% yields, respectively.

*Preparation of 2,5-Dimethyl-7*H*-1,3,4-thiadiazolo*[*3,2-*a]*pyrimidin-7-one (9).* Upon heating **10** (5 mmol) with P_2O_5 (5 mmol)–MsOH (25 mmol) at 100 °C for 10 h, **9**[4] was obtained in 87.4% yield. In a similar manner, **11**[4] was prepared in 61.2% yield.

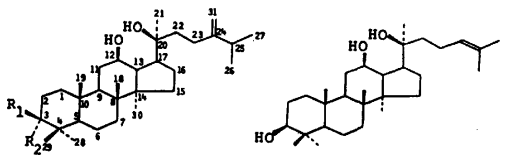
(Received September 17, 1981)

Synopsis. The structure of a new C_{31} dammarane-type triterpenoid, alnuserrutriol, isolated from the male flowers of *Alnus serrulatoides* CALL. (Betulaceae) has been elucidated to be (3*S*,12*R*, 20*S*)-3,12,20-trihydroxy-24-methylene-dammarane by a combination of chemical and spectroscopic methods.

In our previous studies, we have elucidated the structures of novel C_{31} dammarane-type triterpenoids and glycosides, such as alnuserol,[1] alnuseric acid,[2] alnuselide,[2] and alnuserrudiolone[3] isolated from the male flowers of *Alnus serrulatoides* CALL. (Japanese name: Kawara-hannoki) and monoglycosides of alnustic acid[4] isolated from the female flowers of the plant. In a continuation of these studies, a new C_{31} dammarane-type triterpenoid, named alnuserrutriol (I), has now been isolated from the male flowers of the plant. We here wish to describe evidence leading to the establishment of the structure of this new triterpenoid.

Results and Discussion

The male flowers of *Alnus serrulatoides* CALL. grown naturally on a river side were collected just before the flowering and immersed in acetone. An ether-soluble fraction of the acetone extract exhibited 15 spots on a silica-gel TLC plate with hexane–EtOAc (7: 3 v/v) as a solvent; a small spot (A) was observed between those of alnuserrudiolone (II)[3] and a residue at the origin. The ether-soluble fraction was then subjected to chromatography using silica gel to isolate a constituent corresponding to the spot (A), which gave a new triterpenoid, alnuserrutriol (I).



I: R_1=OH, R_2=H
II: R_1, R_2=O

III

The molecular formula $C_{31}H_{54}O_3$ of I was determined by elemental analysis and appearance of a molecular ion peak at *m/z* 474 in the mass spectrum. The IR band at 3350 cm^{-1} and the ^1H NMR signal at δ 3.58 indicated the presence of a hydroxyl group. The existence of a terminal methylene was proved by appearance of the IR bands at 3080, 1635, and 885 cm^{-1} and the ^1H NMR signal at δ 4.78. Comparison of the ^{13}C NMR chemical shifts of I with those of alnuserrudiolone (II)[3] and protopanaxadiol (III)[5] indicated that I possesses a C_{31} dammarane-type skeleton with two secondary hydroxyl groups on C-3 (δ_c 78.9) and C-12 (δ_c 71.1), a tertiary hydroxyl group on C-20 (δ_c 74.1), and a terminal methylene (δ_c 157.0 and 106.5 due to C-24 and C-31, respectively), as shown in Table 1. The configurations of C-3, C-12, and C-20 were suggested to be *S*, *R*, and *S*, respectively, by comparing the ^{13}C NMR chemical shifts with those of (3*S*, 12*R*, 20*S*)-

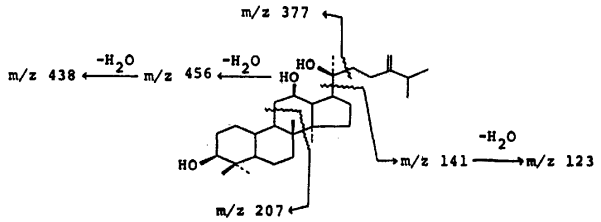

Scheme 1. The MS spectral fragmentation pattern of alnuserrutriol (I).

protopanaxadiol (III)[5] and its related compounds.[5,6] The structure I was thus proposed for alnuserrutriol and possessed all the feature necessary to explain its MS spectrum (Scheme 1). The MS spectral fragmentation pattern was completely supported by the high-resolution MS.

Finally, the proposed structure (I) was confirmed by relating it with a triol which was obtained by the reduction of alnuserrudiolone (II) with $LiAlH_4$. The configuration of C-3 of this triol should be *S*, because it is well known that the $LiAlH_4$ reduction of dammarane-type triterpenoids with the carbonyl group at the 3-position gives exclusively the 3β-hydroxyl derivatives.[7,8] The physical and spectral data of naturally occurring alnuserrutriol (I) were perfectly identical with those of the prepared triol. Thus, the structure of alnuserrutriol (I) has been established to be (3*S*, 12*R*,-20*S*)-3,12,20-trihydroxy-24-methylenedammarane.

Experimental

The ^1H NMR spectra were taken on a varian T-60 spectrometer using TMS as an internal standard. The ^{13}C NMR spectra were obtained on a JEOL JNM FX-60 (15.1 MHz) and a Hitachi R-42 FT NMR (22.6 HMz) spectrometers ($\delta_{TMS}=0$). The EI-MS were obtained on Hitachi RMS-4 and RMU-7L mass spectrometers at 70 eV.

Extraction and Isolation. The male flowers (10.3 kg) of *Alnus serrulatoides* CALL. grown naturally on a river side in the suburbs of Hiroshima city were collected just before the flowering in December. The flowers, after minced mechanically, were immersed in acetone (54 dm^3) at room temp for 2 months. Removal of the solvent from the acetone soln gave a viscous sirup, which was extracted with ether (500 cm^3 × 5) to give a viscous oil (66.0 g). A part (7.0 g) of the viscous oil was subjected to centrifugal chromatography using silica gel (160 g) and a hexane–EtOAc mixture with EtOAc increasing 0 to 100% as a solvent, and then to preparative TLC on a silica-gel plate (Merck; Type 60, GF_{254}, 0.75 mm thick) with hexane–EtOAc (7 : 3 v/v) to give alnuserrutriol (I) (75 mg; R_f 0.05).

Alnuserrutriol (I). Mp 200—202 °C; $[\alpha]_D^{25}$ +89.1° (*c* 0.15, MeOH); IR (Nujol) ν_{max} 3350 (OH), 3080, 1635, and 885 cm^{-1} (C=CH$_2$); ^1H NMR ($CDCl_3$) δ=0.78—1.12 (Me × 8), 3.58 (2H, br, >C<u>H</u>–OH × 2), 4.78 (2H, br, >C=CH$_2$); ^{13}C NMR ($CDCl_3$) (see Table 1); MS *m/z* (rel intensity) 474 (0.5, M$^+$), 456 (11), 438 (23), 377 (12), 341 (37), 207 (43), 189 (26), 141 (69), 123 (71), and 108 (100). High-resolution MS *m/z* 438.3941 ($C_{31}H_{50}O$ (M−2H$_2$O): 438.3859), 377.3010 ($C_{24}H_{41}O_3$: 377.3053), 207.1750 ($C_{14}H_{23}O$: 207.1748), 141.1290 ($C_9H_{17}O$: 141.1279), and 123.1138 (C_9H_{15}: 123.1172).

Found: C, 78.17; H, 11.37%. Calcd for $C_{31}H_{54}O_3$: C, 78.42; H, 11.47%.

Preparation of I from Alnuserrudiolone (II). A soln of alnuserrudiolone (II) (100 mg), which was isolated from *A. serrulatoides*,[3] in dry ether (2 cm^3) was dropped into a suspension of $LiAlH_4$ (10 mg) in dry ether (2 cm^3), followed by stirring for 20 min at 0 °C. The reaction mixture, after acidification, was extracted with ether to give a triol (97 mg): mp 200—203 °C; $[\alpha]_D^{25}$ +87.3° (*c* 0.30, MeOH); IR (Nujol) ν_{max} 3350 (OH), 3080, 1640, and 885 cm^{-1} (>C=CH$_2$); ^1H NMR ($CDCl_3$) δ=3.58 (2H, br, >C<u>H</u>–OH × 2), 4.76 (2H, br, >C=CH$_2$); ^{13}C NMR ($CDCl_3$) δ_c=157.2 (s, C-24), 106.3 (t, C-31), 78.8 (d, C-3), 74.0 (s, C-20), 71.1 (d, C-12), 28.0, 27.1, 21.9, 17.0, 16.0, 15.6, 15.3 (q, Me × 8); MS *m/z* (rel intensity) 474 (0.5, M$^+$), 456 (12), 438 (21), 377 (9), 341 (35), 207 (37), 189 (30), 141 (60), 123 (65), and 108 (100). The physical and spectral data of the triol were identical with those of the naturally occurring alnuserrutriol (I).

The authors thank JEOL Co. Ltd. for obtaining the ^{13}C NMR spectra. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 354189 (1978, to T.A.) from the Ministry of Education, Science and Culture.

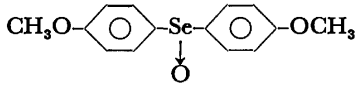
Bis(*p*-methoxyphenyl) Selenoxide as a Mild and Selective Oxidizing Agent

Fumio OGURA,* Hachiro YAMAGUCHI, Tetsuo OTSUBO, and Hiroyuki TANAKA
Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Sendamachi, Naka-ku, Hiroshima 730

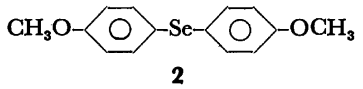
(Received October 2, 1981)

Synopsis. The title compound oxidized thiols to disulfides, sulfides to sulfoxides, hydroquinone or catechol to benzoquinones, and phosphine to phosphine oxide in high yields under very mild conditions. In addition, it functioned as a useful reagent for the syntheses of 1,2,4-thiadiazole derivatives from thioureas or thioamides.

Although the chemistry of organoseleniums is growing rapidly,[1] little attention has been paid to the use of selenoxides as an oxidizing agent for organic syntheses. Selenoxides are usually unfavorable because of their nasty smell, but more reactive due to the greater basicity of the seleninyl oxygen than sulfoxides. For example, dimethyl selenoxide, dibenzyl selenoxide, or diphenyl selenoxide oxidized amines,[2] anilines,[3] catechols,[4] sulfides,[5] phosphines,[6] and thiones[6,7] unlike the sulfur counterparts.



1



2

Bis(*p*-methoxyphenyl) selenoxide **1** is an odorless, tractable material, and accordingly expected to be of practical use as an oxidizing agent. We now report the reactivity of **1** as shown in Table 1. Like the preceding selenoxides, **1** oxidized sulfides to sulfoxides, hydroquinone or catechol to benzoquinones, and phosphine to phosphine oxide in high yields. In addition, **1** effected the oxidation of thiols to disulfides under very mild conditions, in contrast to the fact that sulfoxides did it under forced conditions.[8] The main by-product was bis(*p*-methoxyphenyl) selenide **2**, which could be used to regenerate **1**. On the other hand, **1** did not react with amines, anilines, phenylhydrazines, alcohols, and simple phenol.

The milder oxidizing properties of **1** relative to the preceding selenoxides were demonstrated by the reactions with thiones. For example, dimethyl selenoxide and dibenzyl selenoxide oxidized thiouracil **3** to uracil **4**[6] and thiourea to urea,[7] respectively. On the other hand, **1** effected milder oxidation to convert thiouracil **3** to 2,2′-dithio-di-4(3*H*)-pyrimidone **5**, and thiourea **6** to 3,5-diamino-1,2,4-thiadiazole **7**. As shown in Table

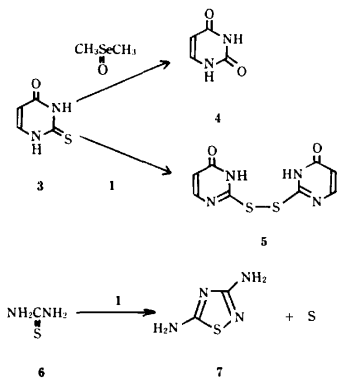
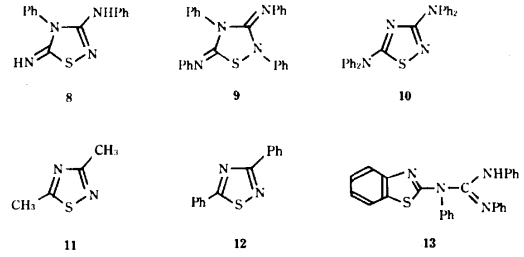
a) Reaction time 1 h at room temperature. b) Gas chromatographic analysis. c) F. Kurzer, *J. Chem. Soc.*, **1955**, 1. d) D. S. Hector, *Ber.*, **22**, 1176 (1889). e) Ref. 11. f) T. Charkrabarti and S. Chandra De, *J. Indian Chem. Soc.*, **5**, 661 (1928). g) A. W. Hofmann, *Ber.*, **2**, 645 (1869).



2, some thiadiazole derivatives were prepared not only from thioureas but from thioamides. Phenylthiourea reacted with **1** in a somewhat different way to give 5-imino-4-phenyl-3-phenylamino-4,5-dihydro-1,2,4-thiadiazole **8** as the exclusive product. *N,N'*-Diphenylthiourea can not lead to thiadiazole structure, but was smoothly oxidized by **1** to afford 2,4-diphenyl-3,5-bis(phenylimino)-1,2,4-thiadiazolidine **9**. Hector reported in 1890 that **9** was synthesized by treatment of the same thiourea with hydrogen peroxide,[9] but later the product was claimed to be a different compound **13**.[10] Very recently Kinoshita *et al.* succeeded the formation of **9** by use of benzoyl peroxide as an oxidizing agent.[11] The yield (84%) of **9** by the present method is much higher than that (13%) by Kinoshita's method.



Experimental

Melting points are uncorrected. Solvents are of reagent grade. All products were confirmed by comparison of the melting points and spectroscopic data with those of the authentic samples or the reported data.

Bis(*p*-methoxyphenyl) selenide **2** was readily prepared from a reaction mixture of anisole, selenium dioxide, and water according to the procedure of Boyd *et al.*,[12] and converted to bis(*p*-methoxyphenyl) selenoxide **1** by oxidation with sodium periodate.[13]

General Method of Oxidation by Bis(p-methoxyphenyl) Selenoxide 1. A typical procedure is described in the reaction of thiobenzamide as below. A mixture of thiobenzamide (0.137 g, 1.0 mmol) and **1** (0.339 g, 1.1 mmol) in 6 ml of ethanol was stirred for one hour at room temperature. After the solvent was evaporated, the residue was taken up in chloroform and the insoluble sulfur was removed by filtration. The preparative gel-permeation liquid chromatography (JAI LC-08) of the filtrate using chloroform as eluent gave first bis(*p*-methoxyphenyl) selenide **2** in almost quantitative yield and then 3,5-diphenyl-1,2,4-thiadiazole **12** in 86% yield, colorless needles from methanol.

For isolation and purification in some of the other reactions, column chromatography was employed as well.

The Conversion of Benzyl Alcohols into Phenylacetic Acid Derivatives by Cobalt Carbonyl Catalyzed Carbonylation

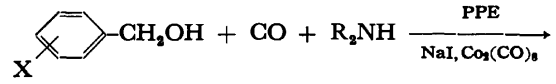
Tsuneo IMAMOTO,* Tetsuo KUSUMOTO, and Masataka YOKOYAMA
Department of Chemistry, Faculty of Science, Chiba University, Yayoi-cho, Chiba 260

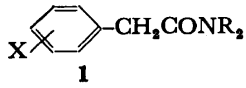
(Received October 12, 1981)

Synopsis. Benzyl alcohols were converted into the corresponding one carbon-homologated amides or esters in one pot by cobalt carbonyl catalyzed carbonylation in the presence of ethyl polyphosphate (PPE) and sodium iodide.

Recently, attention is focused on the catalytic carbonylation under mild conditions and many efficient methods including catalytic systems have been developed.[1-6] For example, phase transfer technique has been successfully employed for the carbonylation of benzyl, aryl, and vinyl halides to the homologous acids.[7-10] However, direct carbonylation of alcohols requires drastic conditions (high temperature and high pressure).[11] We report here a facile method for the conversion of benzyl alcohols into one carbon-homologated amides or esters by cobalt carbonyl catalyzed carbonylation under mild conditions.

In the previous papers,[12-14] we noted the synthetic utility of ethyl polyphosphate (PPE).[15,16] The reagent PPE has strong dehydration power as well as the commonly used polyphosphoric acid (PPA), but it is, different from PPA, essentially aprotic and has good solvent power at room temperature. Taking account of these characteristics of PPE, we have examined the title reaction.

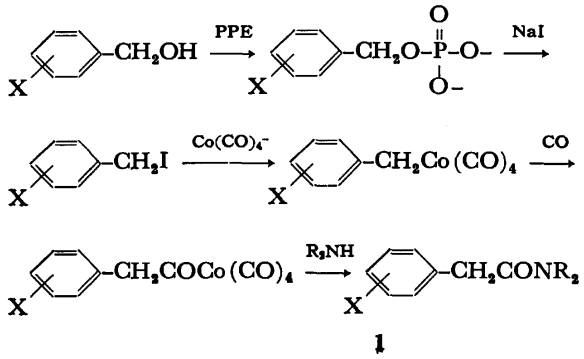




1

Scheme 1.

Our initial work was conducted with the preparation of substituted phenylacetamides (**1**), as is shown in the Scheme 1. This work was undertaken based on the following considerations; a benzyl alcohol is activated by PPE to form a polyphosphoric acid benzyl ester which is subject to nucleophilic attack of iodide ion to generate a benzyl iodide. This intermediate readily undergoes cobalt carbonyl catalyzed carbonylation in the presence of secondary amine to afford an amide (**1**).



1

After various screenings of the reaction conditions, it was found that the reaction proceeded smoothly at room temperature under carbon monoxide atmosphere by the use of large excess of sterically hindered secondary amine. While, the use of less sterically hindered amine such as diethylamine resulted in poor yields. These results are summarized in Table 1.

Next, we tried the conversion of benzyl alcohol into phenylacetic esters (**2**) in one pot, according to the

2

Scheme 2.

Scheme 2. In these cases, better results were obtained by initial stirring of a mixture of benzyl alcohol, sodium iodide, and PPE for 2 h, prior to the addition of a mixture of an alcohol, dicobalt octacarbonyl, and tributylamine. The results are shown in Table 2.

From these data, it may be concluded that our method is superior to those[11] reported hitherto, since the procedure is simple and the products are isolated in moderate yields.

Experimental

Spectra. Proton NMR spectra were measured on a JEOL C-60HL spectrometer. The chemical shifts are given in ppm with TMS as an internal standard. Infrared spectra

were recorded on a Hitachi 215 spectrophotometer. Products were identified by NMR and IR spectra together with elemental analyses.

Materials. Ethyl polyphosphate was prepared according to the method described in the Ref. 15. Benzyl alcohols, secondary amines, and tributylamine were distilled or recrystallized before use. Dicobalt octacarbonyl was purchased from Strem Chemicals, Inc. and was used without purification.

*General Procedure for the Preparation of Phenylacetamides (**1a—h**).* A mixture of a benzyl alcohol (2 mmol), sodium iodide (600 mg, 4 mmol), dicobalt octacarbonyl (34 mg, 0.1 mmol), a secondary amine (20 mmol), and PPE (3 ml) was stirred at room temperature under carbon monoxide atmosphere. After 12 h, water was added and the mixture was extracted with chloroform. The combined extracts were dried over sodium sulfate and evaporated. The residual oil was chromatographed on silica gel using benzene–ethyl acetate (6 : 1) as the eluent. The product was further purified by short-path distillation under reduced pressure (Kugelrohr apparatus; *ca.* 190 °C/0.3 Torr). Pure materials thus obtained crystallized on standing at room temperature except *N,N*-diethylphenylacetamide (**1c**). The NMR, IR, and analytical data of the products are listed in Table 3.

*General Procedure for the Preparation of Phenylacetic Esters (**2**).* A mixture of benzyl alcohol (216 mg, 2 mmol), sodium iodide (400 mg, 4 mmol), and PPE (3 ml) was stirred at room temperature for 2 h. To this mixture was added a mixture of an alcohol (8 mmol), dicobalt octacarbonyl (34 mg, 0.1 mmol), and tributylamine (3.7 g, 20 mmol) under carbon monoxide atmosphere. After stirring for 12 h, water was added and the mixture was extracted with chloroform. The combined extracts were dried over sodium sulfate and evaporated. The residual oil was chromatographed on silica gel using benzene as the eluent. The product was further purified by short-path distillation under reduced pressure. The esters thus obtained were identified by comparison of their IR and NMR spectra with those of authentic samples.

Mechanochemical Reactions at High Pressures. II. Reaction of Methacrylamide

Yasuhiro Okuri and Yoshiaki Ogo*

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, 3-3-138, Sugimoto, Sumiyoshi-ku, Osaka 558

(Received May 9, 1981)

The mechanochemical behavior of methacrylamide was investigated at room temperature and at static pressures of up to 15 kbar. The determinations of the IR spectrum, the ESR signal, the X-ray diffraction pattern, and the molecular weight by GPC apparatus confirmed that the reaction products were amorphous polymethacrylamide. The reaction of methacrylamide under conditions of high pressure combined with simultaneous shear deformation(HP+SSD) is a free radical polymerization. The concentration of radicals of polymethacrylamide and the relation between the conversion and the shearing degree suggest that an acrylamide crystal is less stable than one of methacrylamide. Methacrylamide was not reached 100% conversion even at about 2π rad shearing.

The first paper[1] of this series described the design and the construction of the apparatus and the reaction of acrylamide. Acrylamide was polymerized under conditions of HP+SSD. We concluded that the polymerization of acrylamide proceeded by the free radical mechanism. The present paper is concerned with methacrylamide. The compound was selected because its similarity to acrylamide suggested that it might undergo an analogous behavior under HP+SSD, and thus allow a comparison of the mechanochemical behavior at high pressure.

Experimental

The experimental procedure is similar to that in the previous paper[1] except for the molecular weight determination. The molecular weight of the product was determined by gel permeation chromatography(GPC) using a Sephadex column constructed in our laboratory.

In this experiment, the reactions proceeded at the constant shearing velocity of 2.51 rad/h(2.4 °/min) at room temperature.

Methacrylamide was a commercial sample which was purified by repeated crystallization from benzene solution and finally vacuum dried at room temperature for 24 h. The purity of this material was confirmed by its melting point, determined as 109—110 °C.

The sample which has been sheared at up to 15 kbar (1 kbar=10^8 Pa) static pressure was extracted from a large amount of methanol for separating into soluble and insoluble fractions. The insoluble fraction (as will be described below) was dried *in vacuo* to constant weight at room temperature, and the conversion was determined. The identifications of the product were carried out by means of the measurements of melting point, IR spectrum, X-ray diffraction patterns and molecular weight distribution.

ESR spectra were recorded at 22 °C on a JEOL JES-ME-3X spectrometer equipped with an X-band microwave unit and 100 kHz field modulation. The concentrations of free radicals were determined by integrations of the spectra and by subsequent comparison with those of 1,3,5-triphenylverdazyl as references.

Results and Discussion

Methacrylamide was polymerized under conditions of HP+SSD, as occurred for acrylamide. The following experimental evidence showed this. The product did not show any definite melting point. The IR spectra of the product were very broad peculiar to a polymer rather than a methacrylamide monomer. The major difference is in the C=C vibration region at 1660—1580 cm^{-1}, where a strong absorption of C=C bonds has disappeared in the product. When X-ray diffraction patterns of methacrylamide monomer were compared with those of the product, the product was found to be in the amorphous state. Therefore, we concluded that the product in this reaction was amorphous polymethacrylamide.

The ESR signal gives a quintet system, and no other signals were detected under our experimental conditions. This signal suggests that the propagating polymer radicals at the side of such methyl groups as $-CH_2-\dot{C}(CONH_2)-CH_3$, which resulted from the rupture of C=C bonds, were generated by this type of reaction. Thus, evidently, the reaction of methacrylamide under conditions of HP+SSD is a free radical polymerization similar to that of acrylamide. Table 1 shows the concentrations of free radicals generated in the sample layer, together with those of polyacrylamide at the same conditions. The concentrations of free radicals increase with the shearing degree. Accordingly, the shearing stresses seem to play a major part in the rupture of C=C bonds. There is no difference in the concentration at each pressure for the same

Table 1. Concentrations of free radicals generated in sample layers

P	Shearing degree		Free radical $\times 10^{-18}$/spin g^{-1}

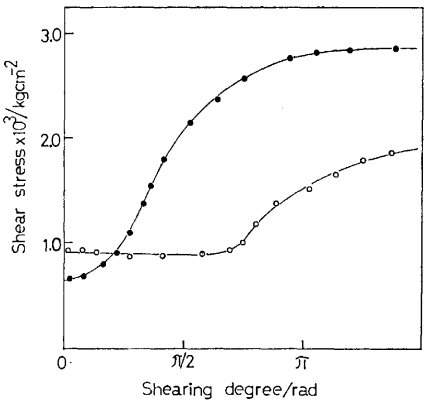

Fig. 2. Shearing curves at 10 kbar.
●: Acrylamide, ○: methacrylamide.

shearing degree (*i.e.* 3.14 rad). The concentration of radicals of polyacrylamide is generally larger than that of polymethacrylamide. It can be seen that the acrylamide crystal is relatively unstable and easily produces radicals due to the mechanical shear force under high pressure. The relation between the conversion and the shearing degree also suggests these conclusions.

Figure 1 shows the dependence of the conversion on the shearing degree at 5, 10, and 15 kbar static pressures, respectively. This relation showed an S-type curve, as do the acrylamide curves. Unlike the relation of acrylamide (refer to Fig. 9 in the previous paper[1]), methacrylamide was not reached 100% conversion even at about 2π rad shearing. Figure 2 shows the relation between the shearing stress and the shearing degree. In Fig. 2, the shearing curve for acrylamide is very similar to its conversion curve. It is therefore concluded that the shearing stress is loaded on the full sample layer and reflects directly on the conversion of polyacrylamide. On the other hand, the value of the shearing stress for methacrylamide is nearly constant up to $\theta=\pi/2$ rad. The shearing force does not affect the whole area of the

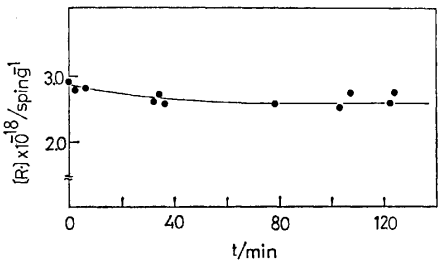

Fig. 3. Time dependence of radical concentrations at room temperature.

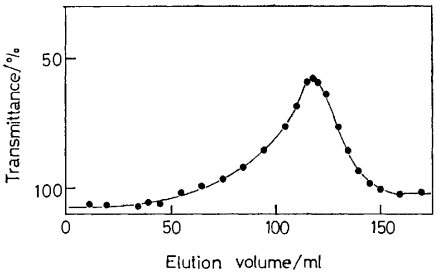

Fig. 4. Molecular weight distribution of the product.

sample, and the only surface destruction which occurs is in the case of methacrylamide. That is presumed from Fig. 3, which shows the time dependence of the polymethacrylamide radical concentrations at room temperature. In this figure, the radical reduction rate was obtained as 13.2%/120 min for polymethacrylamide radicals; this value is larger than that for polyacrylamide radicals, 5.4%/120 min. Polymethacrylamide radicals are thus relatively unstable because most of the radicals are generated in the region of the sample surface.

The relations between the intrinsic viscosity and the molecular weight of polymethacrylamide are unknown. Thus a Sephadex column was prepared in our laboratory to determine the molecular weight and its distribution. The experimental result is shown in Fig. 4. We could determine the average molecular weight of the product from this peak, using a calibration curve for this column. Calibration was undertaken by using polyethylene glycol and dextran as calibrants. The molecular weight determined by this method was about 1000. No variation of the average molecular weight was observed with the change of the reaction conditions. The above value, 1000, was also confirmed by another column (G3000PW, manufactured by Toyo Soda Kogyo Co., Ltd.).

The authors are greatly indebted to Dr. Yozo Miura of Osaka City University for the ESR measurements.

Mechanochemical Reactions at High Pressures. III. Reactions of Acrylamide–Methacrylamide and Acrylamide–Propionamide Solid Solutions

Yasuhiro Okuri and Yoshiaki Ogo*

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, 3-3-138, Sugimoto, Sumiyoshi-ku, Osaka 558

(Received May 9, 1981)

The mechanochemical behavior of acrylamide–methacrylamide (AA–MAA) and acrylamide–propionamide (AA–PA) solid solutions was investigated at room temperature and at static pressures of up to 15 kbar. The AA–MAA solid solution was copolymerized under the experimental conditions. On the other hand, the reaction product of AA–PA solid solution was an amorphous homopolymer of polyacrylamide. That is, the mechanochemical reaction of AA–PA solid solution proceeded only in the acrylamide area by a free radical mechanism. The mechanical behavior of both solid solutions was also discussed.

The previous papers[1,2] were concerned with the design and construction of the apparatus and the reactions of acrylamide and methacrylamide. Both compounds were polymerized by a free radical mechanism under conditions of high pressure combined with simultaneous shear deformation(HP+SSD). The present paper deals with acrylamide–methacrylamide(AA–MAA) and acrylamide–propionamide(AA–PA) solid solutions.

The solid-phase reaction of both solid solutions has not been investigated under high pressures. Only polymerization of acrylamide–propionamide with γ-rays has been reported by several investigators.[3–5]

As a general rule, solid solutions have an unstable crystal structure unlike uni-component materials. Crystal instabilities of both solid solutions are expected to appear in some parameters measured in this type of reaction.

In this paper, the mechanochemical behavior and the pressure effect on acrylamide–methacrylamide solid solution and acrylamide–propionamide solid solution are discussed.

Experimental

The principles of the experimental procedure were similar to the preceding papers.[1,2] Acrylamide, methacrylamide, and propionamide were recrystallized from benzene, respectively.

All the solid solutions were prepared by melting the ingredients in the tubes which were closed to the atmosphere, followed by rapid cooling, so that crystalline films were formed on the walls of the tubes.

The molecular weight of the reaction product from AA–MAA solid solution was estimated by gel-permeation chromatographic analysis, using a Sephadex column made in our laboratory and calibrated by using polyethylene glycol and dextran as the standard substances.

The molecular weight of the reaction product from AA–PA solid solution(polyacrylamide, as will be described below) was determined, by means of the following relation,[6] from the viscosity data obtained from the Ubbelohde viscometer at 30 °C.

$$[\eta]_{30}^{H_2O} = 3.73 \times 10^{-4} M_v^{0.66}$$

ESR spectra were recorded at 22 °C on a JEOL JES-ME-3X spectrometer equipped with an X-band microwave unit and 100 kHz field modulation.

Results and Discussion

Reaction of Acrylamide–Methacrylamide Solid Solution. Figure 1 shows the two component phase diagram obtained by a DSC(Differential Scanning Calorimeter) and melting point measurements with the naked eye. This diagram shows that 87 mol% acrylamide–13 mol % methacrylamide mixture melts congruently at 79—80 °C. This congruent transformation is observed for some binary solid solutions. It is thought that this ratio mixture is an optimum experimental sample.

We concluded from the following experimental evidence that AA–MAA solid solution was copolymerized under conditions of HP+SSD. IR spectra of the product were very broad with peak positions at 3200 and 1650 cm^{-1}. The sharp absorption of C=C bonds at 1650 cm^{-1} in IR spectra of the reactant AA–MAA solid solution disappeared during the reaction. The X-ray diffraction patterns of the product showed an

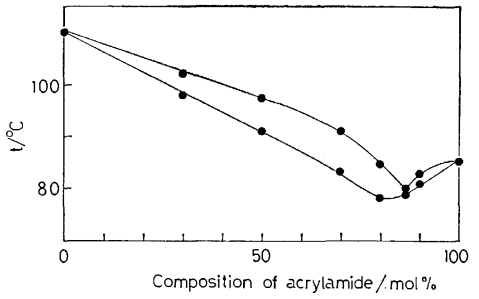

Fig. 1. Binary system phase diagram of acrylamide–methacrylamide.
Upper curve: solidus, lower curve: liquidus.

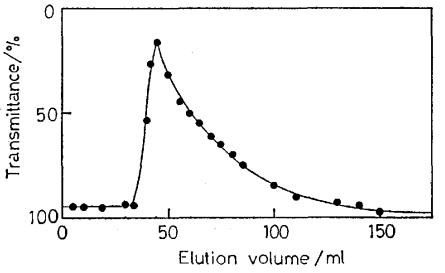

Fig. 2. Molecular weight distribution of the product of AA–MAA solid solution.

amorphous state. The product did not show a definite melting point. In addition, the physical properties of the methanol soluble fraction of the product was the same as the original AA–MAA solid solution. The gel-permeation chromatographic curve showed a single peak as shown in Fig. 2, and its molecular weight was determined as 15000.

Assuming that the ESR data measured immediately after the experiment belong to the growing polymer radical, the molecular weight of the product can be estimated of the order of 10^4 from the following equation if two radicals exist in one polymer chain.

$$(2mNC/n)/m = [R],$$

where m mol of sample, N Avogadro number, C conversion, n the degree of polymerization, and [R] is the radical concentration. The value is similar in magnitude to the chromatographic value.

Table 1. Half widths of X-ray diffraction patterns of various samples

	Acrylamide			
$\frac{2\theta}{^\circ}$	12.0—12.1	19.4	24.1—24.2	28.6—28.7
$\frac{\text{Half width}}{^\circ}$	0.50	0.63	0.62	0.53
	Methacrylamide			
$\frac{2\theta}{^\circ}$	10.8	21.6	23.8	26.4
$\frac{\text{Half width}}{^\circ}$	0.65	0.72	0.75	0.46
	AA–MAA solid solution			
$\frac{2\theta}{^\circ}$	11.8	19.2	23.7	28.2
$\frac{\text{Half width}}{^\circ}$	0.66	0.78	0.75	0.75

Table 1 shows the half widths of the X-ray diffraction patterns of acrylamide,[1] methacrylamide,[2] and AA–MAA solid solution, respectively. The half width of the X-ray diffraction pattern closely relates to the stability of the crystal structure. It seems from Table 1 that the AA–MAA solid solution has a more unstable crystal structure than the others.

The crystal instability or the mechanical weakness of AA–MAA solid solution also appears in Fig. 3, which shows the relation between the conversion and the shearing degree at 5, 10, and 15 kbar (1 kbar= 10^8 Pa) static pressures. The conversion rapidly increased at an earlier shearing stage than those of acrylamide and methacrylamide alone reported in the previous paper.[1,2] The shearing curve at 10 kbar of the congruent solid solution(a) was compared with that of the corresponding (87 mol%AA–13 mol% MAA) mixture(b) as shown in Fig. 4. Although the shearing stress generated in the solid solution was slightly larger than that in the corresponding mixture at an earlier stage of the shearing, the difference gradually increased as the shearing proceeded. The reason for this can be explained by the shear reaction proceeding more actively owing to the instability of the crystal structure of the solid solution. AA–MAA solid solution was not reached 100% conversion even at about 2π rad shearing for the same reason of methacrylamide.[2]

The terminal of this copolymer is an acrylamide radical, because the typical ESR spectrum of the sheared sample is the same as that of acrylamide. No other signals were identified under our experimental conditions. The radical concentrations of the sheared sample at 10 kbar are listed in Table 2 together with the values of the corresponding monomers. Those of AA–MAA solid solution at various shearing degree

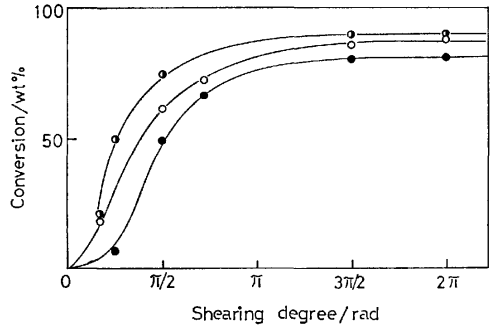

Fig. 3. Relation between conversion and shearing degree at various static pressures for 87AA–13MAA solid solution.
●: 5 kbar, ○: 10 kbar, ◑: 15 kbar.

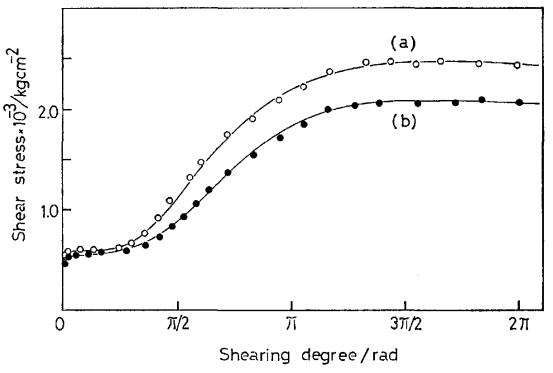

Fig. 4. Shearing curve at 10 kbar for 87AA–13MAA solid solution(a) and 87AA–13MAA mixture(b).

Table 2. Concentrations of free radical generated in sample layer of various samples

P	Shearing degree		Free radical/spin g^{-1}		
kbar	rad	°	Acrylamide[1]	Methacrylamide[2]	AA–MAA solid solution
10	2.27	130	1.29×10^{18}	0.98×10^{18}	9.02×10^{18}
10	3.14	180		1.39×10^{18}	10.7×10^{18}
10	4.71	270	4.25×10^{18}	3.39×10^{18}	12.1×10^{18}

are apparently larger than any other. These facts also suggest the relatively low mechanical stability of the original solid solution.

Reaction of Acrylamide–Propionamide Solid Solution. The crystal structure of propionamide was investigated by Fadner and Morawetz,[3] who described it as monoclinic and the dimensions of the unit cell $a_0=9.74$ Å, $b_0=5.74$ Å, $c_0=9.02$ Å, $\beta=113.5°$. The unit cell of acrylamide is characterized by $a_0=9.69$ Å, $b_0=5.77$ Å, $c_0=8.36$ Å, $\beta=118°$.[7] Therefore acrylamide and propionamide are isomorphous. The mixture of 90 mol% acrylamide–10 mol% propionamide is mainly used as an experimental sample, and 50 mol% acrylamide–50 mol% propionamide and 10 mol% acrylamide–90 mol% propionamide are used for the comparison. Each sample is abbreviated as 90AA–10PA, 50AA–50PA, and 10AA–90PA solid solutions.

A homopolymer was obtained by the reaction of 90AA–10PA solid solution, while the AA–MAA solid solution was copolymerized under the same conditions. The reactive sites of this solid solution are to be polyacrylamide from the following experimental evidence. In the first place, IR spectra of the product were very broad at 1620 cm^{-1}. The sharp absorption of C=C vibration region of 90AA–10PA solid solution has disappeared. Therefore, it is concluded that the C=C bonds of acrylamide were ruptured through this reaction. Secondly, the pattern of the ESR signal of the sheared sample at high pressures was identical with that of polyacrylamide. This fact suggests that the reaction was initiated by the rupture of C=C bonds in acrylamide, in other word, the mechanochemical reaction of this solid solution proceeds only in the acrylamide area by a free radical mechanism, and the propionamide did not participate to the reaction as a reactive monomer.

Figures 5 and 6 show the relations between the conversion and the shearing degree at 5, 10, and 15 kbar static pressures for 90AA–10PA solid solution and for 50AA–50PA solid solution. Figure 6 also shows the range of data because the conversion of this solid solution was fairly low under these experimental conditions. It may be noted that no difference of the conversion with the pressure appear in the latter case. These relations show the S-type curve as well as acrylamide and AA–MAA solid solution. However the values of the conversion of 90AA–10PA and 50AA–50PA solid solutions are respectively smaller and much

●: 5 kbar, ○: 10 kbar, ◐: 15 kbar.

Table 3. Molecular weight of the product polymer of 90AA–10PA

P / kbar	Shearing degree/rad			
	$\pi/2$	π	$3\pi/2$	2π
5	51900	13200	11800	
10	55600	12800	10600	10200
15	26000	12600	8600	

smaller than those of acrylamide[1] and AA–MAA solid solution. These results suggest that propionamide in solid solutions may act as a surprisingly efficient chain transfer agent, that is, a retarder. This assumption is consistent with the experimental results on γ-ray radiation polymerization of AA–PA solid solution reported by Fadner *et al.*[3] It can be seen that propionamide with the active N–H bond reacts with the propagating radicals, and the degradative chain transfer reaction occurs in the reaction system.

Table 3 shows the viscosity-average molecular weight of produced polymer at 5, 10, and 15 kbar at different shearing degrees. The molecular weight of the polymer obtained by HP+SSD was much lower than those of the polymer obtained by the same technique from acrylamide alone.[1] The shorter polymer chain length presents a clear evidence supporting that propionamide may act as a chain transfer agent (a retarder) in solid solutions as just suggested in Figs. 5 and 6. This table also suggests that this polymer degrades, judging from the molecular weight reduction, with the increase in the shearing degree. Consequently, the same conclusion is derived from the above facts as for acrylamide alone.[1]

The Mechanochemical Behaviors of Both Solid Solutions. The shearing stress reflects both on the conversion (polymer production) and on the stability of the crystal structure. In view of many experimental data, at the early stage of the reaction the shearing stress reflects on the stability of the crystal structure, and at the later stage it does on the conversion. The shearing stresses of both solid solutions were nearly equal at the early shearing degree; later the shearing stress of the AA–MAA solid solution was larger than that of the 90AA–10PA solid solution. It can also be concluded from the above experimental result on

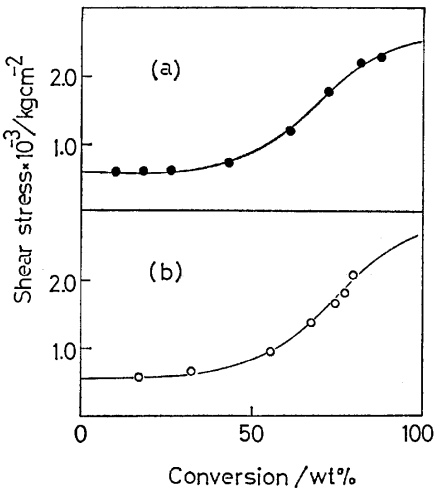

Fig. 7. Relations between shear stress and conversion for AA–MAA(a) and 90AA–10PA(b) solid solutions.

the mechanical behavior that the crystal stability of both solid solutions are similar, and that the conversion of AA–MAA solid solution into copolymer is larger than that of 90AA–10PA solid solution into polymer.

Figure 7 shows the relation between the shearing stress and the conversions of AA–MAA(a) and 90AA–10PA(b) solid solutions.

Some physical properties of two-phase material, k, in which one phase is dispersed randomly in another, can be well-known expressed[8,9] as the corresponding volume fraction, f.

$$k = k_c \frac{1+2f_d\dfrac{1-k_c/k_d}{2k_c/k_d+1}}{1-f_d\dfrac{1-k_c/k_d}{2k_c/k_d+1}} \qquad (1)$$

In this equation the subscripts c and d refer to the continuous phase and to the dispersed phase respectively. This equation is plotted in Fig. 8 for two examples of $k_c/k_d=10$ and $k_d/k_c=10$. As the conversion corresponds to volume fraction of the polymer material in our experiment, measurements should appear between the two curves as a dashed line. The experimental results showed the same relation between the conversion and the shearing stress. It can be concluded, therefore, that the shearing strength of the polymer-monomer composite, τ, may be expressed by the similar equation (2).

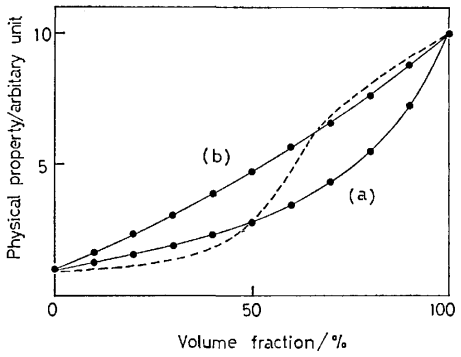

Fig. 8. Plot of Eq. 1.
(a): $k_c/k_d=10$, (b): $k_d/k_c=10$. Dashed line: The curve corresponding to the experimental results. Refer to Fig. 7.

$$\tau = \tau_M \frac{1+2f_d\dfrac{1-\tau_M/\tau_P}{2\tau_M/\tau_P+1}}{1-f_d\dfrac{1-\tau_M/\tau_P}{2\tau_M/\tau_P+1}} \qquad (2)$$

Here the subscripts P and M refer to the polymer and the monomer, respectively, and f_d can be substituted by the conversion into polymer in this case.

The authors wish to thank Dr. Yozo Miura of Osaka City University for the ESR studies.

(Received May 26, 1981)

The hyperfine splitting constants for the 8,8-dicyanoheptafulvene anion radical generated electrolytically at low temperature indicate that the unpaired spin belongs to an a_2 orbital of the group C_{2v}. Its 4,5-benzo derivative gives a stable anion radical by reduction with alkali metals. The odd electron belongs to a b_2 orbital.

8,8-Dicyanoheptafulvene (=2,4,6-cycloheptatrien-1-ylidenepropanedinitrile),[1] which is one of the most stable derivatives of heptafulvene, is not reduced with alkali metals. Electrochemical generation of the anion radical to measure the ESR spectrum at room temperature has also been unsuccessful because of its instability. We have then carried out an electrolytical generation at low temperature. The result will be reported together with results on the anion radical of its 4,5-benzo derivative prepared by reduction with alkali metals.

Results and Discussion

Electrolytic generation of 8,8-dicyanoheptafulvene in degassed butyronitrile was carried out within the cavity of an ESR spectrometer, using a cell modified slightly from Allendoerfer *et al.*[2] and Ohya-Nishiguchi.[3] Tetrabutylammonium perchlorate was used as the supporting electrolyte. The reduction at −100 °C gave the ESR spectrum shown in Fig. 1. A similar spectrum was obtained by an electrolysis in a mixed solvent of acetonitrile and 1,2-dimethoxyethane (DME) (1:9) at −80 °C using tetrapropylammonium perchlorate as the supporting electrolyte. Three splitting constants (Table 1) obtained correspond closely to those of the tropone anion radical (0.858, 0.01, and 0.505 mT).[4]

Similarity of the hyperfine structure to that of the tropone anion radical substantiates that the unpaired spin belongs to an a_2 orbital, in which the spin localizes in the seven-membered ring. Therefore, as has been discussed for the C_{2v} tropone structure,[4] the Hückel MO calculation would show zero spin densities at all atoms in the C=C(CN)$_2$ moiety. The McLachlan spin densities calculated by employing the parameters proposed by Streitwieser are shown in Table 1, demonstrating a good agreement between the experimental and calculated spin densities. Calculations were also carried out by introducing the bond alternation parameter k ($=\beta_s/\beta_d$, the ratio of resonance integral parameters for the C–C and C=C bonds in the seven-membered ring) in order to represent the aromaticity of 8,8-dicyanoheptafulvene. However, the reduction of k-parameter to 0.9 replaced the unpaired spin orbital by the b_2 orbital, with which the observed splitting constants cannot be rationalized. Although such a replacement of the orbitals is avoidable if one adopts other resonance and Coulomb integral parameters for the C=C(CN)$_2$ group, the calculations by the use of some possible parameters show poorer agreements than that seen in Table 1. It is thus concluded that the k-parameter must be close to 1, which means the complete delocalization of π-electrons in the 8,8-dicyanoheptafulvene anion radical, while a considerable bond alternation in the conjugated seven-membered ring has been observed for the neutral species in solid state.[5]

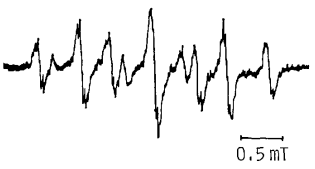

Fig. 1. ESR spectrum of the 8,8-dicyanoheptafulvene anion radical generated by the electrolysis in butyronitrile at −100 °C.

sium metal in tetrahydrofuran (THF). A much complicated structure in the latter spectrum is caused by an appearance of the splittings due to the potassium ion. Analysis of the hyperfine structures afforded the splitting constants summarized in Table 2 together with those for the Na–THF system. The assignments for the constants were tentatively given according to the type of splitting and by comparing them with the calculated spin densities. As seen from Table 2, the agreement between the calculated and experimental spin densities is satisfactory. An introduction of k-parameter to the seven-membered ring does not lead to the replacement of unpaired spin orbital (b_2 species) by another one, in distinction from the case of 8,8-dicyanoheptafulvene. However, the reduction of the k-value to less than 0.8 makes the agreement between the experimental and calculated spin densities worse. Thus, no information of the bond alternation in the seven-membered ring was obtained.

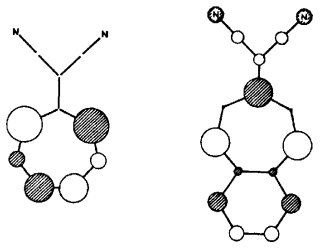

Fig. 3. Illustration of the unpaired-spin distributions for two anion radicals.

The contrast in stability between the above two anion radicals is properly ascribed to the difference in their π-electron systems. The difference can be illustrated with Fig. 3 as an idiomatic expression for the unpaired spin orbitals. In this figure, the radii of the circles are proportional to the absolute value of the LCAO-coefficient in the Hückel MO calculations and blank and shadowed circles refer to relative signs of these coefficients. A noteworthy difference between the unpaired-spin distributions in their dicyanoheptafulvene moieties might be related to the contrast in their stabilities.

Experimental

8,8-Dicyanoheptafulvene, mp 199—200 °C,[1)] and the 4,5-benzo derivative, mp 267 °C,[6)] were prepared by the authentic methods and recrystallized from methanol and a mixture of benzene–cyclohexane, respectively. Solvent butyronitrile (guaranteed reagent) was treated with potassium permanganate and sodium carbonate[7)] and distilled under a nitrogen pressure of 2×10^3 Pa. The middle fraction was degassed and distilled again under a high vacuum to be stored over previously dried molecular sieves 4A in a storage vessel. Other solvents were purified by the procedures reported previously.[8)]

ESR spectra were measured with a Varian E-109E EPR spectrometer. An electrolysis cell for ESR measurements was constructed by modifying slightly from those reported earlier.[2,3)] In this cell, a helical electrode wound with a 0.5 mm diameter silver wire and a straight platinum wire of 0.5 mm diameter are supported in a quartz tube (3.2 mm in inner diameter) connected to a Pyrex tube through a graded seal. The upper Pyrex part, holding two leading wires sealed, has no glass joints and is connected to a branch tube, which can be joined to a vacuum line in order to prepare solutions under vacuum. Spectral simulations were carried out with a JEOL JEC-5 minicomputer.

(Received June 19, 1981)

An electrohydrodynamic dissipative structure appearing in a suspension system of TiO_2 particles in organic solvents is analyzed from a viewpoint of thermodynamics. This analysis gives rather a general explanation for electrohydrodynamic instability caused by unipolar injection and for that caused by bipolar injection. Dimensionless parameters which are the criteria of the hydrodynamic instability are given as $R=\varepsilon V/\eta\mu$ and $R=\varepsilon^2V^2/nq\mu\eta c^2$ respectively for the former and latter cases. The lattice constant of the hexagonal dissipative structure is derived to be proportional to the thickness of the liquid layer.

It has been known that there exist regular structures which appear only by a constant supply of energy. The Bénard's thermal convection[1-4] and a convection caused by the Felici instability[5] are well known examples. In these cases, energy flux is flowing along a potential gradient across a liquid layer whose surfaces contact respectively with two different systems. The energy flux thus generated causes a periodic structure of convection which usually shows a two-dimensional hexagonal lattice and does not have the translational symmetry of the static liquid layer any more. Such lowering of symmetry means that only some components in the wavenumber spectrum of convective disturbance grows. Both the Bénard and Félici instabilities were considered from the above viewpoint by some authors.[3,6,7] In their treatments the terms of higher order of the small disturbances were neglected and thus linearized equations were solved. In this sense it can be judged by their treatments whether a small fluctuation generated in a fluid system can begin to grow or not, but it is impossible to judge if the growing of the fluctuation can bring the system into a steady convective state.

In the previous paper,[8] we reported a photoelectroexcited convective structure appearing in a suspension of TiO_2 particles in an organic solvent. In the system, TiO_2 particles (1 μm in diameter) had a negative surface charge ($q_d=-48$e, e; unit charge) in the dark. When the system was subjected to a d.c. voltage between a pair of transparent electrodes and to light of the intrinsic absorption region of TiO_2, the sign of the electric charge of the particles is inverted on the anode surface and thus positively charged particles ($q_+=3500$e) showed a photoelectromigration toward the cathode. On the cathode the positively charged particles again acquired a negative charge ($q_-=-660$e) and migrated toward the anode.[9] This process was repeated during illumination. Consequently, TiO_2 particles showed an oscillatory motion between the two electrodes under a stationary illumination, and when the applied voltage exceeded a critical value, a convective flow of insulating fluid with a two-dimensional hexagonal symmetry appeared with a lattice constant proportional to the thickness of the suspension layer.[10] The system looks similar to that of Félici in the sense that the convections in the both cases were generated by amovement of charged particles through a liquid layer, though the charged particles in the Félici instability are ions or electrons and ours were photosensitive TiO_2 particles dispersed in the suspension.

The Félici instability was treated by Schneider and Watson[6] for the case of unipolar injection, while in our case[8-10] there are positively charged TiO_2 particles and negatively charged ones in a suspension system. In the case of Schneider and Watson, the problem was treated as a space charge limited conduction of unipolar carriers. In the present case, however, there is no space charge in the static state with no macroscopic convection. Thus the both cases are physically different from each other. In the present paper we consider which of the two stationary states, *i.e.* the convective state and the non-convective state of the present system, is more favorable and discuss the transition between the two states from the irreversible thermodynamic standpoint, instead of discussing the problem in terms of the growth of small convective fluctuations. The size of a convection cell in the stationary state is estimated with the condition for minimum energy dissipation.[11]

Photoelectrophoresis without Convection. TiO_2 particles may be in two charged states under the stationary illumination, *i.e.* the positively charged state ($q_+=3500$e) and the negatively charged state ($q_-=-660$e).[9] Under an electric field, E, the velocity of TiO_2 particles is given by Stokes' law,

$$v_\pm = \frac{q_\pm E}{6\pi\eta R}, \tag{1}$$

where R and η are the radius of a TiO_2 particle and the viscosity of the surrounding liquid, respectively. Then, the mobility of the particles of each electric charge is given as

$$\mu_\pm = \frac{q_\pm}{6\pi\eta R}. \tag{2}$$

We take the Cartesian coordinates where the z-axis is in the direction vertical to the electrodes (see Fig. 1). We express the number density of total TiO_2 particles, that of the particles carrying positive charge and that carrying negative one by $n(z)$, $n_+(z)$ and $n_-(z)$, respectively. Among the above three quan-

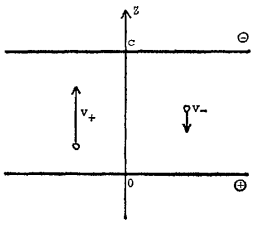

Fig. 1. Co-ordinates of the system for analysis, the anode being at $z=0$ and the cathode at $z=c$.

tities the following relation should hold,

$$n(z) = n_+(z) + n_-(z).$$

By the law of conservation for the particles of each electrical sign under a stationary state, we have

$$\frac{\partial[n_+(z)\cdot v_+(z)]}{\partial z} = \frac{\partial[n_-(z)\cdot v_-(z)]}{\partial z} = 0. \tag{3}$$

The continuity condition at the electrode surfaces ($z=0$ and $z=c$) in a stationary state is given as

$$n_+(0)\cdot v_+(0) + n_-(0)\cdot v_-(0) = n_+(c)\cdot v_+(c) + n_-(c)\cdot v_-(c) = 0. \tag{4}$$

From Eqs. 3 and 4, we have a general condition holding also in the bulk of the liquid layer as

$$n_+(z)\cdot v_+(z) + n_-(z)\cdot v_-(z) = 0. \tag{5}$$

Using Eqs. 1 and 5, we can obtain

$$n_+(z)\cdot q_+(z) + n_-(z)\cdot q_-(z) = 0, \tag{6}$$

that is, there exists no space charge in the bulk of the liquid layer. This suggests that the electric field in the bulk is uniform and can be expressed as V/c, there V is the applied voltage. In consequence, the distribution function of particles, $n_+(z)$ and $n_-(z)$, are also uniform from Eq. 3. Thus the current density in such a stationary state is given as

$$\begin{aligned} i &= n_+\cdot q_+\cdot v_+ + n_-\cdot q_-\cdot v_- \\ &= nq\mu V/c, \end{aligned} \tag{7}$$

where $q\equiv\sqrt{|q_+\cdot q_-|}$ and $v_\pm=\mu_\pm E=\mu_\pm V/c$.

Photoelectrophoresis with Macroscopic Convection Stream Field: As reported before,[8,10] the structure of convection showed a two-dimensional hexagonal lattice. In Fig. 2 intersections of solid lines are the lattice points with the lattice constant, a, and the hexagon given with broken lines is the Wigner-Seitz's unit cell. Vertices, A, B, C, D, E, F of the Wigner-Seitz's unit cell form a dual lattice. If the hexagonal lattice corresponds to the ascending flow, then its dual lattice corresponds to the descending flow of the fluid. The number of lattice points within the dual lattice is twice of that of original hexagonal lattice. Therefore, the ascending flow and the descending flow of the fluid are not symmetrical. This might be the result of the fact that the magnitude of charges carried by a positively charged particle and that by a negatively charged one are not equal. In a unit cell *ABCDEF*, the fluid flows up at the lattice point O, and spreading in the six directions, it falls downward at the boundary of this unit cell, that is, this flow is totally symmetric within this cell.

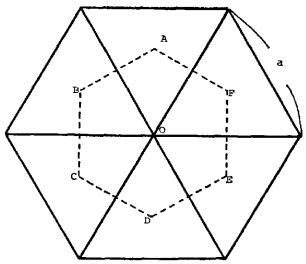

Fig. 2. Two-dimensional hexagonal lattice and the unit cell.
Intersections of real lines are the lattice points. The hexagon shown with dashed line is a Wigner-Seitz's unit cell.

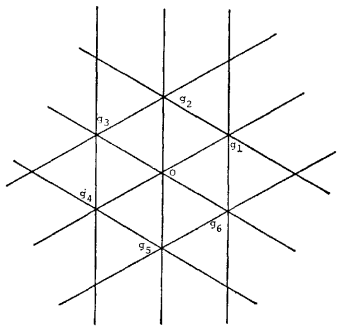

Fig. 3. Reciprocal lattice of convective structure.

We assume that the z-component, $v_z(\boldsymbol{r})$, of the hexagonal stream field, $\boldsymbol{v}(\boldsymbol{r})$, can be expressed as the following form,

$$v_z(x, y, z) = v\cdot f(x, y)\cdot g(z),$$

where v is a constant with the dimension of velocity. Then, $f(x,y)$ must satisfy a periodicity of the two-dimensional hexagonal lattice and $g(z)$ must satisfy a boundary condition at the electrode surfaces. The components of larger wavenumber in $f(x,y)$ will be unfavorable for a stationary state because they will make the larger velocity gradient in the bulk of liquid layer and increase the energy dissipation rate. Thus, taking account of the total symmetry of the flow, we assume that $f(x,y)$ is expressed by Eq. 8, which is constructed with six plane-wave whose wavenumbers are equal to the reciprocal lattice in Fig. 3, $\boldsymbol{g}_i$ ($i=$ 1, 2, 3, 4, 5, 6).

$$f(\boldsymbol{r}_1) = \frac{1}{6}\sum_{i=1}^{6}\exp(i\boldsymbol{g}_i\cdot\boldsymbol{r}_1), \tag{8}$$

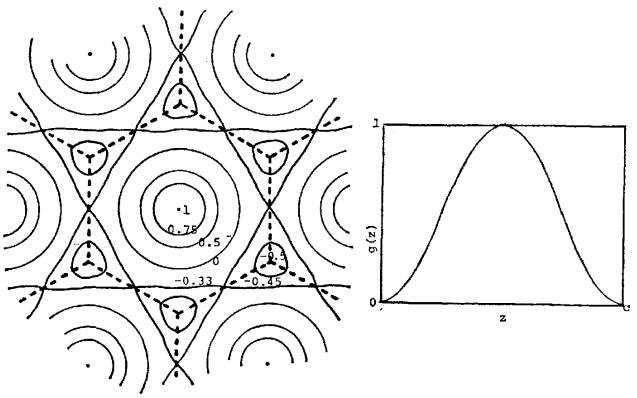
where $\boldsymbol{r}_1\equiv(x,y)$ and the factor, 1/6, is a normalization constant making $f(x,y)$ unity at the lattice points. The length of the shortest reciprocal lattice vectors are $g=4\pi/\sqrt{3}a$. Figure 4a illustrates the profile of the function, $f(x,y)$.

With the continuity condition of incompressible fluid flow,

$$\operatorname{div}\boldsymbol{v} = 0, \tag{9}$$

and the relation

$$\left(\boldsymbol{\nabla}_1^2+\frac{4}{3}a^{*2}\right)f = 0, \tag{10}$$



(a) (b)

Fig. 4. Profiles of functions, $f(x,y)$: (a) and $g(z)$: (b).

where $\nabla_1 \equiv \left(\frac{\partial}{\partial x}, \frac{\partial}{\partial y}\right)$ and $a^* \equiv 2\pi/a$, one can obtain the stream field as

$$v_x(x,y,z) = \frac{3}{4}\frac{1}{a^{*2}} v \frac{\partial f(x,y)}{\partial x}\frac{dg(z)}{dz},$$
$$v_y(x,y,z) = \frac{3}{4}\frac{1}{a^{*2}} v \frac{\partial f(x,y)}{\partial y}\frac{dg(z)}{dz}, \qquad (11)$$

and

$$v_z(x,y,z) = v \cdot f(x,y) \cdot g(z).$$

The function, $g(z)$, must be chosen to satisfy the boundary condition, $v_x = v_y = v_z = 0$, at the electrode surfaces ($z=0$, c), so we assume that $g(z)$ has the form as Eq. 12, which satisfies the above conditions with the smallest wave number.

$$g(z) = \frac{1}{2}(1-\cos(c^* z)) \qquad (c^* \equiv 2\pi/c), \qquad (12)$$

where the factor, 1/2, is a normalization constant making $g(z)$ unity at $z=c/2$. The function $g(z)$ is illustrated in Fig. 4b.

Thus, the Eq. 11, together with Eqs. 8 and 12, give the stream field of two-dimensional hexagonal convective domain with the thickness c and the lattice constant a.

Dissipation Function: We assume that TiO_2 particles move on the stream of fluid, then an energy dissipation by the friction between the particles and the fluid will be neglected compared with that within the fluids. The amount of heat generated in a unit volume and a unit time at any point in the fluid is given by the viscous dissipation function,

$$\Phi(x,y,z) = \frac{1}{2}\eta \sum_{i,j}\left(\frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i}\right)^2. \qquad (13)$$

Substituting Eq. 11 into v_i in Eq. 13, one obtains

$$\Phi(x,y,z) = \eta v^2\left[\left\{4f^2 + \frac{9}{4}\frac{1}{a^{*2}}\left(\left(\frac{\partial^2 f}{\partial x \partial y}\right)^2 - \frac{\partial^2 f}{\partial x^2}\frac{\partial^2 f}{\partial x^2}\right)\right\}\left(\frac{dg}{dz}\right)^2 + \left\{\left(\frac{\partial f}{\partial x}\right)^2 + \left(\frac{\partial f}{\partial y}\right)^2\right\}\left(g + \frac{3}{4}\frac{1}{a^{*2}}\frac{d^2 g}{dz^2}\right)^2\right]. \qquad (14)$$

Substituting Eqs. 8 and 12 into Eq. 14 and integrating it over a unit cell, then dividing the result by the unit cell volume, $(\sqrt{3}/2)a^2 c$, we obtain the mean viscous dissipation function, $\langle\Phi\rangle$,

$$\langle\Phi\rangle = \int_{\text{unit cell}} \Phi(x,y,z) v / \frac{\sqrt{3}}{2} a^2 c$$
$$= \eta\left(\frac{v^2}{c^2}\right)\frac{\pi^2}{16}\left[\frac{a^2}{c^2} + \frac{16}{3}\frac{c^2}{a^2} + 8\right]$$
$$= \eta\frac{v^2}{c^2}\pi^2\left[\frac{1}{3}\gamma^2 + \frac{1}{16}\gamma^{-2} + \frac{1}{2}\right], \qquad (15)$$

where $\gamma = c/a$ is the axial ratio of this stream.

Lattice Constant: The stream field, v_x, v_y, v_z, contains the lattice constant, a, as a parameter, since $f(x,y)$ must satisfy the hexagonal symmetry. Consequently, the parameter, a, also appears in the expression of the mean dissipation function, $\langle\Phi\rangle$. In Fig. 5, the variation of $\langle\Phi\rangle$ corresponding to the virtual variation of the parameter is illustrated. Figure 5 will be interpreted as follows: Under a condition in which the lattice constant is smaller enough than the distance between the two electrodes, *i.e.* the thickness of the suspension layer, c, a large velocity gradient of v_z would occur in the xy-plane, making a large energy dissipation (Fig. 6a). On the other hand, larger enough value of the lattice constant compared with c also increases the dissipation, because the region of fluid transport along the direction perpendicular to the z axis increases and the directions of the flow in the upper and lower parts this region are opposite to each other, so the region where a gradient of v_x and that of v_y along z axis are large becomes wider (Fig. 6c). Consequently a lattice constant of the same order as the thickness of the liquid layer would be most favorable for the smallest dissipation rate of energy (Fig. 6b). We do not have any *a priori* principle to determine the stationary state under a given condition thermodynamically. However, if we assume that the principle of the minimum energy dissipation which

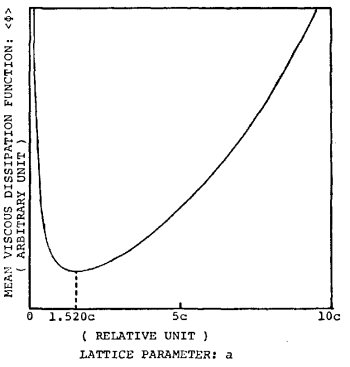


Fig. 5. Variation of $\langle\Phi\rangle$ corresponding to the variation of lattice parameter, a.

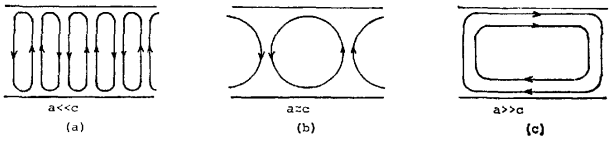

Fig. 6. Illustration of the shapes of cellular convective flows.
(a): Lattice constant, a, is smaller than the electrode spacing, c, (b): a is nearly equal to c, (c): a is larger than c.

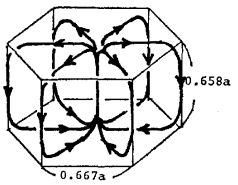

Fig. 7. Most favorable structure of convection.

has been known to be applied close to equilibrium also holds at the stationary state where a dissipative structure has been formed, the most favorable lattice constant can be estimated from Eq. 15 as

$$a = 2 \times 3^{-1/4}c \approx 1.520c. \tag{16}$$

Thus the lattice constant is proportional to the thickness of the liquid layer. The axial ratio of the stream, γ, is given as $\gamma=0.658$ (Fig. 7). The experimental values of γ was 0.86 as reported in the previous paper, which was larger than the theoretical value to some extent. The mean viscous dissipation function at $a=1.520c$ is given as

$$\langle \Phi \rangle = \eta \frac{v^2}{c^2} \frac{\pi^2}{2}\left(1+\frac{1}{\sqrt{3}}\right). \tag{17}$$

Electric Current by Convection: Assuming that TiO_2 particles are moving on the convection stream of the surrounding fluid, their velocity coincides with that of convection of the fluid, $\boldsymbol{v}(\boldsymbol{r})$.

From the continuity equation of the flow in a stationary state, div $\boldsymbol{v}=0$, and that of the TiO_2 particles flow, $\mathrm{div}(n\boldsymbol{v})=0$, we obtain

$$\frac{dn}{dt} = \boldsymbol{v}\cdot\mathrm{grad}\, n = \mathrm{div}(n\boldsymbol{v}) - n\cdot\mathrm{div}\,\boldsymbol{v} = 0. \tag{18}$$

Thus, in a stationary state, there is no change in the particle number density along a stream line. Therefore, there is also no change in the charge density along the stream line. More correctly, since the particles can discharge at the electrodes, there are two regions in a unit cell in each of which v_z is positive or negative, and the charge density along a stream line is kept constant within each region.

The mean number density of TiO_2 particles, n, in the present system was 1.2×10^{11} (cm^{-3}),[9] so if each of them have a positive charge ($q_+=3500e$) and are distributed uniformly in the xy-plane, the charge density on a unit area of a electrode, σ_p, is $3.15\times10^{12}e$ (cm^{-2}). The surface charge induced on an electrode by the application of external voltage, σ_e, is $\varepsilon V/c$, where ε is the dielectric constant of the fluid. In the present case we assume $\varepsilon=3\varepsilon_0$, where ε_0 is the dielectric constant of vaccum. Then, when an external voltage of 100 V is applied between the electrodes, the value of σ_e is $2.25\times10^{10}e$ (cm^{-2}), thus σ_p is about 100 times as large as σ_e. When all the particles have a negative charge ($q_-=-660e$), the absolute value of σ_p is about 20 times as large as σ_e. If the discharge of the TiO_2 particles at the electrodes is a fast process, there exists positive charge in the region of positive v_z, while in the region of negative v_z, there exists negative charge. Thus, spatial separation of the positive charge and the negative charge

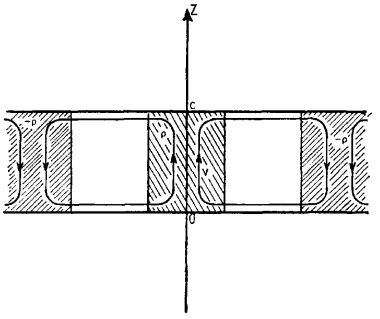

Fig. 8. Model of convective unit cell.

takes place in the periodical convective state, while there is no space charge in the static state without convection. However, the absolute value of the charge density per unit area of the electrode in each region does not exceed σ_e, since, for instance in the region of positive v_z, the increase of the positive charge density reduces the potential gradient near the anode and prevents the discharge of negatively charged particles at the anode, consequently too much increase of the positively charged particles in the region is suppressed. Electric current under this condition is just a space charge limited one. The situation is same in the region of negative v_z.

From the consideration mentioned above, together with Eq. 18, we assume a simple model for such a unit convective cell as shown in Fig. 8. It is assumed that the unit cell can be separated into three regions; the first one is the region in which the positively charged particles are distributed uniformly with the charge density, $+\rho$, and the fluid flows upward. The second region whose cross section area is equal to that of the first one, is that in which the negatively charged particles are distributed uniformely $(-\rho)$ and the fluid falls downward, and the third region between the above two regions is that in which no charge density and no fluid motion exist. The velocity of fluid is v in the first and $-v$ in the second region. From Poisson's equation, we obtain

$$\rho \approx \frac{2\varepsilon V}{c^2}, \tag{19}$$

where V is the applied voltage. The profile of the electric field in the suspension layer along z axis is given as follows:

$$E_1(z) \approx \frac{\rho}{\varepsilon} z \text{ (in the region of positive charge)}, \tag{20}$$

$$E_2(z) \approx \frac{\rho}{\varepsilon}(c-z) \text{ (in the region of negative charge)}. \tag{21}$$

Then we obtain the force by the external field acting on the fluid in the stream tube of a unit cell along a stream line as

$$F \approx \frac{1}{2}S_e\int_0^c \rho E_1(z)dz - \frac{1}{2}S_e\int_0^c (-\rho)E_2(z)dz = 2S_e\varepsilon V^2/c^2, \tag{22a}$$

where S_e is a sum of the cross section area of the first

and the second regions, *i.e.* S_e corresponds to the conducting area in a unit cell. If we assume that S_e is approximately equal to a half of the total cross section area of a unit cell, $S_e=c^2$, we obtain

$$F \approx 2\varepsilon V^2. \tag{22b}$$

Therefore, a work done by the external electric field on the fluid in a unit cell and a unit time is given as

$$W_e = v \cdot F \approx 2v\varepsilon V^2. \tag{23}$$

On the other hand, the energy dissipation within a unit cell and a unit time is written as

$$W_t = 2c^3\langle\Phi\rangle = \pi^2\left(1+\frac{1}{\sqrt{3}}\right)\eta v^2 c, \tag{24}$$

where $2c^3$ is the volume of a unit cell. Since W_e and W_t are equal to each other in the steady state, we obtain the following expression for v by equating Eq. 23 to Eq. 24,

$$v \approx \frac{2}{\pi^2\left(1+\frac{1}{\sqrt{3}}\right)}\frac{\varepsilon V^2}{\eta c} = 0.128\frac{\varepsilon V^2}{\eta c}. \tag{25}$$

One can see in Eq. 25 that v is proportional to the square of the applied voltage. Consequently, the average current density, $\langle i\rangle$, is proportional to V^3:

$$\langle i\rangle \approx \frac{1}{2}\rho v = 0.128\frac{\varepsilon^2 V^3}{\eta c^3}. \tag{26}$$

Transition from the Static State of Fluid to Convective State. When a d.c. voltage is supplied to the TiO_2 particles dispersion system under illumination, migration of the particles transports electric charge between the electrodes in the nonconvective state. The charge transport in this state occurs against the friction between TiO_2 particles and their surrounding insulating fluid, and the current is proportional to the applied voltage as shown in Eq. 7. On the other hand, TiO_2 particles are carried by a flow of fluid in the convective state. In other words, electric charge is transported by a flow of charged fluid between two electrodes. The charge transport in this state occurs against the friction within the fluid. The current in that state is proportional to the cube of the applied voltage as shown in Eq. 26. The two kinds of currents in the both states are illustrated in Fig. 9 as a function of the applied voltage. In the region of lower voltage than V_c, which is the voltage at which two i-V curves in Fig. 9 cross each other, the static state is more favorable than the convective state for electric conduction. On the other hand, in the region of higher voltage than V_c, the state with the convection becomes more favorable. Consequently, a transition between the two states occurs at the critical voltage, V_c. From Eqs. 7 and 26, the critical voltage, V_c is given as

$$V_c \approx 2.8\frac{\sqrt{nq\mu\eta}}{\varepsilon}c. \tag{27}$$

As mentioned in the experimental section of the previous paper,[9,10] $n=1.2\times10^{11}$ cm^{-3}, $q=1520e$, $\mu=1.72\times10^{-5}$ cm^2/V s, $\eta=7.5$ cP, $c=50$—100 μm, $\varepsilon=3\varepsilon_0$. When $c=75$ μm, we estimate $V_c\approx153$ V. The experimental value of the critical voltage[10] was about 200 V which is in good agreement with the theoretical value. A dimensionless parameter indicating the transition between the states is given from Eq. 27 as

$$R_1 = \frac{\varepsilon^2 V^2}{nq\mu\eta c^2}. \tag{28}$$

From the above consideration we may expect that the transition occurs at $R_1\approx8$.

Electrohydrodynamic Instability in the Case of Unipolar Injection. The injection of carriers of one kind and one sign is called as "unipolar injection." In such a case a space charge limited conduction may occur even in the static fluid state if the amount of the injected carriers is large enough (Fig. 10a). Such a case was analyzed by Schneider and Watson[6] and Atten and Moreau,[12] by solving a set of equations which express the turbulance in fluid in the system. However, our method mentioned above is also adequate for such a case and can give a reasonable explanation.

In the space charge limited conductive state without convection, if the charge carriers are of one kind with mobility μ, the current in such a state is given by the Langmuir-Child's law,[13]

$$i = \frac{9}{8}\frac{\varepsilon\mu}{c^3}V^2. \tag{29}$$

Now we consider the current carried by a convective flow in the case of the unipolar injection. We assume tentatively that the carriers are cations. If all the cations which flow up toward the cathode do not discharge as the cathode surface completely, a portion of the cations will remain in the flow toward the anode. When the probability of discharge of cations on the cathode is κ, the charge density in the downward flow is given as $\rho'=(1-\kappa)\rho$, where ρ is the charge

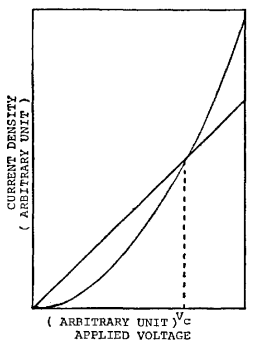

Fig. 9. Current-voltage curves by two state of conduction in bipolar injection.
A transition between two states occurs at the critical voltage, V_c.

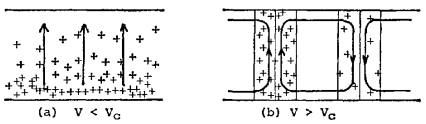

Fig.10. Current-voltage curves by two states of conduction in unipolar injection.
A transition between two states occurs at the critical voltage, V_c.

density in the upward flow, *i.e.* $\rho \approx 2\varepsilon V/c^2$ (see Fig. 10b). And the force acting on the region of upward flow along a stream line in a unit cell, F_1, is given in the same manner as Eq. 22,

$$F_1 \approx \varepsilon V^2.$$

Similarly, the force acting on the region of downward flow along a stream line, F_2, is given as

$$F_2 \approx -(1-\kappa)\varepsilon V^2.$$

Then, the work exerted on a unit cell within a unit time, W_e, is

$$W_e = v(F_1+F_2) \approx \kappa v \varepsilon V^2. \tag{30}$$

Using Eqs. 24 and 30, we obtain the expression for the flow velocity, v, as

$$v \approx \frac{\kappa}{\pi^2\left(1+\frac{1}{\sqrt{3}}\right)}\frac{\varepsilon V^2}{\eta c} = 0.064\kappa\frac{\varepsilon V^2}{\eta c}. \tag{31}$$

Therefore, the average current density, $\langle i \rangle$, is given as

$$\langle i \rangle \approx \frac{1}{4}\kappa\rho v \approx 0.032\kappa^2\frac{\varepsilon^2 V^3}{\eta c^3}. \tag{32}$$

One can see from Eqs. 29 and 32 that the space charge limited current without convection is proportional to the square of the applied voltage but, on the other hand, the current by the convection is proportional to the cube of the voltage. Current densities in the both conduction regimes are illustrated in Fig. 11 which shows that, in the region of the lower voltage, the static state without convection is more favorable for the electric conduction, and in the region of the higher voltage, the convective state is more favorable. The critical voltage, V_c, at which the transition between the two states occurs is given by comparing Eqs. 29 and 32,

$$V_c \approx \frac{27.8}{\kappa^2}\frac{\eta\mu}{\varepsilon}. \tag{33}$$

A dimensionless parameter indicating the transition is given by Eq. 33 as

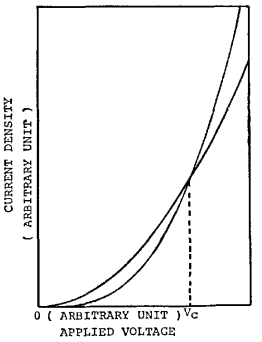

Fig.11. Current voltage curves in the two conduction regimes under unipolar injection.
A transition occurs at the critical voltage, V_c.

$$R_2 = \frac{\varepsilon V}{\eta\mu}. \tag{34}$$

The dimensionless parameter, R_2, coincides with one derived by Schneider and Watson[6] as the criterion of the stability. The transition is expected to occur at $R_2 \approx 27.8/\kappa^2$, while Schneider and Watson calculated the value of R_2 as 99[6] although their boundary condition is somewhat different from the present case.

Electrolytic Reduction of Carbon Dioxide at Mercury Electrode in Aqueous Solution

Yoshio Hori* and Shin Suzuki

Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba 260

(Received June 22, 1981)

Cathodic reduction of carbon dioxide at a mercury pool electrode was investigated in aqueous solutions of $NaHCO_3$, NaH_2PO_4–Na_2HPO_4, NaCl, $NaClO_4$, Na_2SO_4, $LiHCO_3$, and $KHCO_3$ as well as their combinations. The reaction product was confirmed to be $HCOO^-$ by a qualitative spot test. $HCOO^-$ was quantitatively analyzed by a permanganate titration. The partial current densities of $HCOO^-$ formation (i_C) and H_2 evolution (i_H) were calculated. In the present paper, relationships between electrode behavior and solution properties, some of which have been qualitatively described in previous papers, are quantitatively clarified as follows. The electrode potential E_C for constant i_C (0.5 mA/cm^2) remains constant irrespective of pH and anions in the pH region of 2.4 to 7.8, whereas the potential E_H for constant i_H (0.5 mA/cm^2) varies linearly with a slope of 125 mV/pH. The present experimental results verify Eyring *et al.*'s presumption that in a relatively high overvoltage region (region 2) the cathodic reduction of CO_2 at Hg proceeds with the charge transfer to CO_2 as the rate determining step. CO_2 reduction and H_2 evolution are concluded to proceed independently at the Hg electrode. The dependence of E_C on electrolyte concentration is interpreted in terms of the diffuse double layer theory. The effect of cation species on E_C also is discussed.

Carbon dioxide has been suggested to be feasible as an energy storage medium by Russell *et al.*[1] and Williams *et al.*[2] Carbon dioxide is electrolytically reduced to methanol or formic acid, which in turn can be fed to a fuel cell or a decomposer to generate hydrogen. This process is superior to the hydrogen energy system, since the transport and storage of these liquid fuels are more convenient and less expensive than hydrogen. In addition to the advantage of energy storage, this process will contribute to fixation of carbon dioxide and prevent the recent increase of atmospheric concentration of carbon dioxide.

The electrolytic reduction of carbon dioxide in aqueous solution has been reported by many authors.[1–11] The principal difficulty of this process appear to be high overvoltage and low current efficiency. Excellent electrocatalysts are consequently requisite for the development of this process. However, the overvoltage and current efficiency depend upon properties of electrolytic solutions as well as electrodes.

Udupa *et al.*[6] studied cathodic reduction of CO_2 at a rotating amalgamated copper electrode in aqueous solutions. They reported that the current efficiency increased in the presence of sodium hydrogencarbonate in the solution as compared with the reaction in the solution containing sodium sulfate alone. Paik *et al.*[5] and Ryu *et al.*[7] studied pH effect on the reaction at Hg. They reported that the current efficiency tends to decrease with increasing acidity of the solution because of the competition with hydrogen evolution. Ito *et al.*[10] studied the reaction at various metal cathodes in several aqueous solutions. According to Ito *et al.*, the current efficiency at In electrode increased in alkali metal carbonate solutions with the sequence of Rb^+, K^+, Na^+, and Li^+, whereas the current efficiency increased with the sequence of PO_4^{2-}, SO_4^{2-}, and CO_3^{2-} in lithium salt solutions.

In these previous papers, effects of pH and species of electrolytes on the electrode reactions of CO_2 reduction and H_2 evolution were only qualitatively reported. In the present paper, they are quantitatively investigated at a mercury electrode which has a smooth and reproducible surface. The results obtained will contribute to the investigation of the electrocatalysis and reaction mechanism.

Experimental

Apparatus and Procedures. The experiments were carried out in a Pyrex H-type cell immersed in a thermostat maintained at 25 °C. The cathode and anode compartments were separated by a sheet of cation exchange membrane (Selemion) donated by Asahi Glass Co., Ltd. The cathode consisted of a pool of purified mercury (4.9 cm^2) which was electrically connected by a Pt wire lead. The anode was a Pt sheet. The potential of the cathode was measured with respect to an Ag/AgCl electrode at room temperature (20±1 °C), which was connected to the cathode by a Pyrex Luggin tube.

The galvanostatic electrolysis measurements were carried out for 15 to 100 min (depending on the current density), by a potentiogalvanostat (Model 2020) manufactured by Toho Giken Co., Ltd. The electrode potential was measured and recorded by a Yokokawa digital voltmeter (Model 2502) and recorder (Model 3066).

The product resulting from the reduction of CO_2 was qualitatively tested by the chromotropic acid test.[12] The solutions in the cell were quantitatively analysed for their $HCOO^-$ content by the permanganate titration technique. pH of the solution was measured before and after electrolysis; the difference between the two pH values was within 0.2.

Materials and Solutions. Commercial reagent grade mercury was washed with 2 M HNO_3,† distilled and again washed with 2 M HNO_3. The mercury thus purified was used as the cathode.

The electrolytes used were aqueous solutions of $NaHCO_3$, Na_2HPO_4–NaH_2PO_4, NaCl, Na_2SO_4, $NaClO_4$, H_3PO_4, and their combinations. The reagents except $NaClO_4$ and H_3PO_4 were triply recrystallized from reagent grade chemicals. The solutions were prepared from distilled water treated with active charcoal and ion exchange resin. The solutions used are tabulated in Table 1.

Commercial nitrogen and CO_2 were purified by passing them through columns of activated copper and wash bottles

† 1 M=1 mol dm^{-3}.

containing aqueous solution of $KHCO_3$. The gases were then introduced to the electrolytic cell and bubbled through the solution under the atmospheric pressure.

Results

Reaction Products and Current Efficiency. The pH-potential diagram was constructed for the system CO_2–water at 25 °C on the basis of the thermochemical data.[13] (Fig. 1) The substances considered in Fig. 1 are CO_2, HCO_3^-, CO_3^{2-}, HCOOH, and $HCOO^-$, the activities of which are taken to be unity.

The product resulting from the electrolytic reduction of CO_2 was confirmed to be formic acid in all the solutions by the chromotropic acid test, which agrees with the previous reports.[1,3,5,7,8] CO_2 stably exists in aqueous media of pH less than 8 (Fig. 1). The equilibrium potential of CO_2 reduction is more cathodic in the lower pH range than that of the competitive reaction of H_2 evolution. Therefore, the reduction of CO_2 would effectively proceed between 7 and 8 of pH.†† Figure 1 shows also $HCOO^-$ to be formed predominantly instead of HCOOH in the solution of pH above 3.7.

The activity of hydrogencarbonate ion $[HCO_3^-]$ is related to the pH value in equilibrium with CO_2 at 1 atm:†††

$$pH = pK_a + \log[HCO_3^-], \quad (1)$$

$$pK_a = 7.82 \ (25\ °C).$$

The pH of phosphoric buffer solution will alter from the value originally prepared with formation of HCO_3^-, according to Eq. 2, if CO_2 is in contact with the solution:

$$HPO_4^{2-} + CO_2 + H_2O = H_2PO_4^- + HCO_3^-. \quad (2)$$

The pH is determined by the following reactions

$$H_2PO_4^- = HPO_4^{2-} + H^+, \quad (3)$$

$$CO_2 + H_2O = HCO_3^- + H^+. \quad (4)$$

The equilibrium concentrations of respective ions are readily calculated in accordance with Eqs. 3 and 4 and corresponding pK_a values; the equilibrium concentrations thus obtained are given in Table 1.

The results of the permanganate titration are to give the values of the current efficiency and the partial current i_C of $HCOO^-$ formation. The experimental current efficiencies are presented as a function of pH in Fig. 2. The trend in Fig. 2 qualitatively agrees with the thermodynamic considerations.

Partial Current of CO_2 Reduction. The limiting current of CO_2 reduction would be approximately 7—10 mA/cm^2,[15] and the present experiments were made under the condition where the partial current density of CO_2 reduction did not exceed 1.5 mA/cm^2.

The electrode potential of cathode remained constant within 2 to 3 mV in every run during the steady state galvanostatic electrolysis of carbon dioxide. The measured potential did not vary by more than 10 mV on different runs in solutions of identical compositions. Each partial current i_C of $HCOO^-$ formation may include an error of up to 2% due to the inaccuracy of the titration technique. The partial current i_H of H_2 evolution was estimated as the difference between the total electrolytic current i and i_C. i, i_C, and i_H are plotted against the electrode potential E (referred to SHE) for the phosphate buffer solution of pH=5.7 (Fig. 3), the composition of which is shown in Table 1. Figure 3 contains also the data obtained in ternary electrolytes consisting of NaCl, $NaClO_4$, or Na_2SO_4 solution mixed with phosphate buffer (NaH_2PO_4–Na_2HPO_4) (pH=5.5). These data for ternary electrolytes were corrected for pH values and zeta potential as described later.

The results for all the solutions showed that the Tafel relationship holds as exemplified in Fig. 3. The values of transfer coefficient α are 0.26—0.28 for CO_2 reduction and 0.41—0.45 for H_2 evolution in the solutions of pH below 6. Thus, the potentials E_C and E_H can be determined at a constant partial current

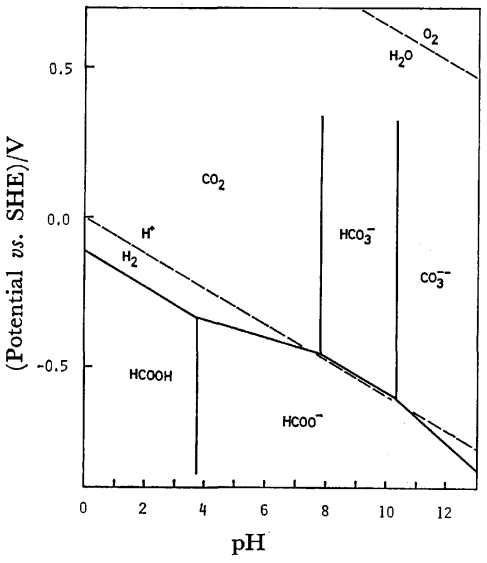

Fig. 1. pH-potential diagram of CO_2 and its related compounds.
pH-potential relations for water are shown in broken lines.

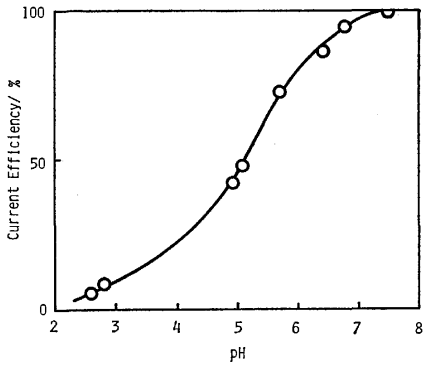

Fig. 2. Current efficiency of CO_2 reduction plotted against pH at constant total current 1 mA cm^{-2}.

†† Iwahara *et al.*[14] recently reported that HCO_3^- was electrolytically reduced on Hg without bubbling CO_2. Their observation contradicts with van Rysselberghe *et al.*'s;[3] the details of this reaction still remain unclarified.

††† 1 atm=1.013×10^5 Pa.

●: E_H observed under N_2 flow.

of pH. Figure 5 presents the relationship between E_H and pH. The current-potential measurements for hydrogen evolution at Hg under a N_2 flow give the electrode potentials at 0.5 mA/cm², which also are

shown in Fig. 5, falling on the line. The slope is approximately 125 mV/pH. Therefore, the hydrogen evolution reaction, taking place simultaneously with CO_2 reduction, appears to proceed in the same way as in a N_2 flow.

Electrolytes and their Concentrations. The current efficiencies of $HCOO^-$ formation were 100% within the experimental error in the solutions containing $NaHCO_3$ and at pH above 6.6. The potentials E_C at a constant cathodic current density 0.5 mA/cm^2 are shown in Fig. 6 for various concentrations of $NaHCO_3$. E_C varies linearly with $NaHCO_3$ concentration, the slope being approximately 60 mV/decade. However, E_C at 0.5 mA/cm^2 is independent of $NaHCO_3$ concentration, where the total equivalent concentrations of electrolytes are kept constant at 1.2 equiv·dm^{-3} by adding NaCl, $NaClO_4$, or Na_2SO_4. pH in aqueous solution increases from 6.6 to 7.8 with increasing $NaHCO_3$ concentration from 0.05 to 1.2 M while the CO_2 pressure is kept 1 atm. E_C consequently depends upon the total concentration of electrolytes but not upon pH values.

Figure 7 shows the variation of E_C at 0.5 mA/cm^2 of CO_2 reduction with respect to the concentration of electrolytes $LiHCO_3$ and $KHCO_3$. The slopes are about 75 mV/decade and 66 mV/decade for $LiHCO_3$ and $KHCO_3$, respectively. They are close to the value for $NaHCO_3$. E_C for a constant concentration of the electrolyte appears to become remarkably nobler with the sequence of Li^+, Na^+, and K^+.

Discussion

Reaction Mechanism and Electrode Potential. Paik *et al.*[5] and Ryu *et al.*[7] studied CO_2 reduction on mercury in neutral aqueous solution. They revealed that the feature of this reaction is the occurrence of two Tafel regions: one at low current densities (region 1) and the other at high current densities (region 2). The present measurements were made in the region 2. They presumed that the following reaction determines the rate of the reaction in region 2:

$$CO_2 + e^- \longrightarrow CO_2^- \text{ (ads)}$$

or

$$CO_2 + H_2O + e^- \longrightarrow HCO_2\cdot\text{(ads)} + OH^-. \quad (5)$$

If one of them is the rate determining step, the electrode potential will be written as follows:

$$E_C = -\frac{RT}{\alpha_C F}\cdot\ln|i| + \zeta + \text{const}, \quad (6)$$

where α_C is the transfer coefficient. This expression suggests that the electrode potential at a constant current will not depend upon pH, if ζ is kept constant. Since E_C obtained experimentally remains constant irrespective of pH (Figs. 4 and 6), the present results confirm Paik *et al.*'s and Ryu *et al.*'s presumptions in the pH region of 2.4 to 7.8.

The point of zero charge (pzc) for the mercury electrode without specific adsorption in aqueous media is about 0.4 to 0.5 V (referred to the normal calomel electrode),[16] and the potential region discussed in this paper is far below pzc. The bulk concentration of Na^+ is much higher than H^+. Na^+ will naturally predominate in the neighborhood of the electrode surface in the present experimental conditions. The surface of the mercury electrode will not significantly be covered with H or H_2, because the discharge of H^+ is considered to be the rate determining step of H_2 evolution. Thus the pH change will not practically affect the ionic distribution near the electrode surface. Accordingly, the CO_2 reduction process will proceed irrespective of pH.

The hydrogen evolution reaction proceeds at mercury in acidic to neutral aqueous media with the discharge of proton as the rate determining process:

$$H^+ + e^- \longrightarrow H. \quad (7)$$

The electrode potential will be expressed as[17]

$$E = -\frac{RT}{\alpha_H F}\cdot\ln|i| + \frac{RT}{\alpha_H F}\cdot\ln[H^+] - \frac{1-\alpha_H}{\alpha_H} + \text{const}$$
$$= -\frac{0.05916}{\alpha_H}\cdot\ln|i| - \frac{0.05916}{\alpha_H}\,\text{pH} - \frac{1-\alpha_H}{\alpha_H} + \text{const (25 °C)}. \quad (8)$$

The values of α_H are between 0.41 and 0.45 as determined from the Tafel plots in the present study. The dependence of E_H on pH with constant current and ζ is thus seen to be *ca.* 137 mV/pH at 25 °C from Eq. 8, which agrees approximately with a value of

125 mV/pH as estimated from the slope in Fig. 5, where CO_2 is simultaneously reduced. The hydrogen evolution process is apparently independent of the competitive CO_2 reduction. Aylmer-Kelly *et al.*[18] studied the intermediate species in the CO_2 cathodic reduction at mercury in aqueous media by means of reflectance spectroscopy. They reported that the coverage of the intermediate CO_2^- on mercury is approximately 0.02. Such a small value of coverage would not affect the hydrogen evolution reaction.

Thus, the two reactions, CO_2 reduction and H_2 evolution, proceed independently at the Hg electrode. The current efficiency of CO_2 reduction varies with pH (Fig. 2) as derived from the pH dependence of H_2 evolution.

Effects of Electrolyte. The zeta potential ζ at the outer Helmholtz plane for mercury and 1-1 electrolyte without specific adsorption varies approximately according to

$$\zeta = \text{const} \pm \frac{RT}{n_1 F} \cdot \ln C, \tag{9}$$

where n_1 and C are the charge number of ion and the bulk concentration of the electrolyte, respectively, and the $\pm$sign holds for $\zeta \gtrless 0$.[16] The above relationship was verified by Delahay for electrode potentials sufficiently positive or negative with respect to the pzc. The pzc for mercury in aqueous media without specific adsorption is about 0.4 to 0.5 V (referred to the normal calomel electrode),[16] and E_C at i_C 0.5 mA/cm^2 is about -1.5 V (referred to SHE) as shown in Fig. 4; Eq. 9 would be applicable to the present experimental situations.

With Eq. 9 inserted into Eq. 6, the electrode potential E_C at constant current is expected to vary with the logarithm of electrolyte concentration with a slope of 0.05916 V/decade at 25 °C. This value is in good agreement with the experimentally observed one as described for $NaHCO_3$ (Fig. 6).

All the electrolysis experiments were not carried out at the same electrolyte concentration; the corrections of ζ were made for different concentrations as mentioned in the previous sections. The correction was made for 1-1 electrolyte according to Eq. 9 with the reference concentration of 0.274 M arbitrarily chosen. The corrections for electrolytes other than 1-1 ones were calculated according to the manner as described in Appendix. Tafel relationship illustrated in Fig. 3 (pH 5.7) contains experimental values for phosphate buffer solutions mixed with NaCl, $NaClO_4$, or Na_2SO_4 after appropriate corrections. The partial current i_H is corrected not only for ζ potential according to Eqs. 9 and 13 but for pH difference, because the electrolyses in phosphate buffer solution mixed with NaCl, $NaClO_4$, or Na_2SO_4 were carried out at pH$\approx$5.5. These data for i_C and i_H fall on the respective lines representing experimental values in phosphate buffer solution without other electrolytes.

Since the electrode potential is far below pzc, anions will hardly affect the structure of the Helmholtz layer of the electrode, if these anions are not specifically adsorbed. The present study confirms this expectation, since any anions employed make no difference in either CO_2 reduction or H_2 evolution (Figs. 3—6).

As pointed out previously, the electrode potential E_C varies to noble values with the sequence Li^+ to Na^+ to K^+. It will qualitatively result from the increasingly specific adsorption of the larger cations, and ζ will become more positive.

The authors would like to thank Mr. Nobuyuki Nakajima for his assistance in part of experiments.

Appendix

The correction of ζ for electrolytes other than 1-1 followed the derivation of Eq. 9 for 1-1 electrolytes given by Delahay.[16] According to the Gouy-Chapman theory of the diffuse double layer, the charge q on the electrode per unit area is deduced as

$$q = \pm\left[\frac{RT\varepsilon}{2\pi} \cdot \Sigma C_i^s \left\{\exp\left(-\frac{n_i F}{RT} \cdot \zeta\right) - 1\right\}\right]^{1/2}, \tag{10}$$

where ε is dielectric constant, and C_i^s and n_i are the bulk concentration of solution and the ionic valence (with sign) of ion i, respectively.

The correction of ζ is exemplified below for an aqueous solution consisting of xM NaH_2PO_4, yM Na_2HPO_4, and zM $NaHCO_3$. The concentrations of each ionic species are tabulated in Table 2. Insertion of these values into Eq. 10 will give

$$\frac{2\pi}{RT} \cdot \frac{q^2}{\varepsilon} = (x+2y+z) \cdot \exp\left(-\frac{F}{RT} \cdot \zeta\right) + (x+z) \cdot \exp\left(\frac{F}{RT} \cdot \zeta\right) + y \cdot \exp\left(\frac{2F}{RT} \cdot \zeta\right) - (2x + 3y + 2z). \tag{11}$$

Then, for $\zeta < -0.1$ V which is applicable to the present case, the terms $\exp\left(\frac{F}{RT} \cdot \zeta\right)$ and $\exp\left(\frac{2F}{RT} \cdot \zeta\right)$ can be dropped. If q is considered to be independent of electrode potential E in the present narrow range of E, the following equation is obtained by differentiation:

$$\frac{F}{RT} \cdot \mathrm{d}\zeta = \frac{\mathrm{d}(x+2y+z)}{x+2y+z} - \frac{\mathrm{d}(2x+3y+2z)}{x+2y+z} \cdot \exp\left(\frac{F}{RT} \cdot \zeta\right). \tag{12}$$

When the variations $\Delta(x+2y+z)$ and $\Delta(2x+3y+2z)$ are small, Eq. 12 is written as

$$\frac{F}{RT} \cdot \Delta\zeta = \frac{\Delta(x+2y+z)}{x+2y+z} - \frac{\Delta(2x+3y+2z)}{x+2y+z} \cdot \exp\left(\frac{F}{RT} \cdot \zeta\right). \tag{13}$$

Table 2. Concentration of each ionic species in an aqueous solution consisting of xM NaH_2PO_4, yM Na_2HPO_4, and zM $NaHCO_3$

Electrolyte	Concentration/M	Na^+	HCO_3^-	$H_2PO_4^-$	HPO_4^{2-}
NaH_2PO_4	x	x		x	
Na_2HPO_4	y	$2y$			y
$NaHCO_3$	z	z	z		
n_i		1	-1	-1	-2
C_i^s		$x+2y+z$	z	x	y

If ions are not specifically adsorbed on the electrode, the value of ζ will be close to the one estimated for NaF solutions.[16] $\Delta\zeta$ is thus calculated as the deviation from the reference solution 0.274 M of 1-1 electrolyte, *i.e.*, $x+2y+z=0.274$ and $2x+3y+2z=0.548$, with ζ -0.11 V. The values of $\Delta\zeta$ are tabulated in the last row of Table 1.

Heterogeneous Photocatalytic Reactions on Semiconductor Materials. III. Effect of pH and Cu^{2+} Ions on the Photo-Fenton Type Reaction

Masamichi Fujihira,* Yoshiharu Satoh, and Tetsuo Osa
Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980

(Received June 29, 1981)

The effect of pH and Cu^{2+} ions on the heterogeneous photocatalytic oxidation of toluenes by H_2O_2 formed from dissolved O_2 in the presence of illuminated TiO_2 powders, *i.e.* "the photo-Fenton type reaction," was investigated. At low and high pH, a total amount of products increased drastically compared with that of the additive free system (pH 7). In the acidic region (aqueous H_2SO_4), side-chain oxidation prevailed over cresol formation and benzaldehyde was formed quite selectively at pH 1. Oxidation of the side chain in preference to hydroxylation of aromatic ring was also observed in the alkaline region (aqueous NaOH). By adding Cu^{2+} ion to the aqueous H_2SO_4 (pH 1 and 2), the yield of benzaldehyde increased further and cresols, benzyl alcohol, and bibenzyl were formed newly in high yields. At high Cu^{2+} concentrations (pH 2), the cresol formation in preference to the side-chain oxidation was attained. The observation was in good agreement with the Fenton reaction reported in which Cu^{2+} and Fe^{3+} ions are added as oxidants for the intermediate products, such as hydroxycyclohexadienyl and benzyl radicals, formed by HO· attack to toluene. Cu^{2+} ion was more preferable to Fe^{3+} ion as the oxidant, since "short circuiting" by Cu^{2+} due to the reversible redox reaction at semiconductor particles was much lower than that by Fe^{3+}. By adding a large amount of Cl^- ions to the Cu^{2+}–H_2SO_4 aqueous system, no oxidation of toluene resulted.

Previously we described the heterogeneous photocatalytic oxidation of aromatic compounds by the illuminated semiconductor powders under the air atmosphere.[1–3] By this new synthetic method, all the products expected from the Fenton reaction[4] were obtained when the reactions were carried out in the aqueous solutions.[1,2] For example, phenol and biphenyl from benzene and benzaldehyde, cresols, and bibenzyl from toluene were obtained. From the distribution of these products[1] and from the effect of the semiconductor materials on the reaction,[2] it was concluded that the reaction proceeded *via* the same mechanism as the Fenton reaction and consequently the reaction was named "the photo-Fenton type reaction."[1,2] The real oxidant in the aqueous TiO_2 systems was considered to be the hydroxyl radical, HO·, which is formed either from the cathodic reaction product, H_2O_2, (Eqs. 1—3 and 5—7) as in

$$h\nu \longrightarrow e^- + h^+ \quad (1)$$

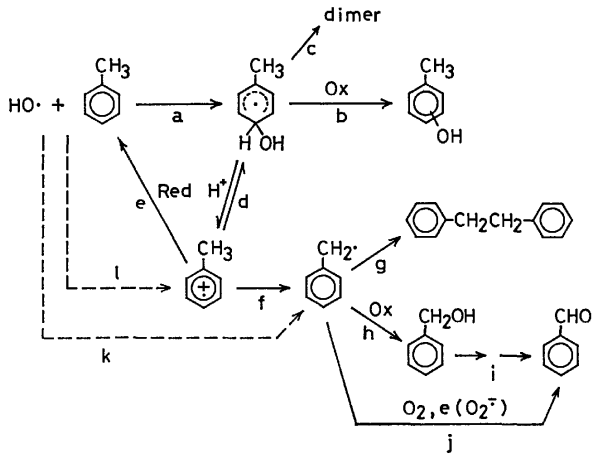
$$2h^+ + H_2O \longrightarrow 1/2O_2 + 2H^+ \quad (2)$$

$$O_2 + 2H^+ + 2e^- \longrightarrow H_2O_2 \quad (3)$$

Fenton's reagent[5] or from the anodic oxidation of OH^- or H_2O (Eqs. 8 and 22).[6–11] The role of hydroxyl radicals was also suggested in the photodecomposition of hydrocarbons in oxygen-containing aqueous solutions at platinized TiO_2.[12]

On the other hand, the reaction proceeded differently, when TiO_2 powders suspended in the aromatic hydrocarbon themselves were irradiated. For example, irradiation of toluene gave benzaldehyde under the air, and gave bibenzyl under nitrogen very selectively.[3] The observation under the air atmosphere corresponded well to the reported results for vapor-phase oxidation of alkyltoluenes by oxygen in contact with UV irradiated TiO_2 in which alkylbenzaldehydes were yielded selectively.[13] The difference in the distribution of the products caused by the absence of water was interpreted by proposing the other mechanism.[3] In this mechanism, oxidation was initiated by the anodic oxidation of toluene by a photogenerated hole to form a toluene cation radical[14] and inexistence of the reactive oxidant, HO· was assumed. The mechanism explained well not only the absence of the hydroxylated products, but also the reason for failure in oxidation of benzene in the absence of water.[3]

If we compare the results observed in the presence and absence of water, we will readily come to the conclusion that a distinctive feature of "the photo-Fenton type reaction" in the presence of water is its ability to hydroxylation of aromatic rings. Consequently in the present work, we investigated the effect of the solution conditions such as pH and Cu^{2+} ions on "the photo-Fenton type reaction," because these solution conditions are well known in the usual Fenton reaction[4] to affect the distribution of the products, especially the ratio of the yield of hydroxylated product to that of side-chain oxidation product (Scheme 1). We will also describe the effect of these factors on the total yield of product.



Scheme 1.

Experimental

As a photocatalyst, 99.99% anatase from Rare Metallic Co. was used as received. Each photocatalyst (1 g), in a mixture of aqueous solution of various pH's (100 cm^3) and toluene (5 cm^3), was irradiated for 2 h by a 500 W high pressure mercury arc lamp in a 100 cm^3 Pyrex glass round bottomed flask with a condenser cooled with running water. The solutions were prepared using doubly distilled water and reagent grade chemicals without further purification. To keep the solution saturated with oxygen in the air and to maintain homogeneous mixing of the suspension, the solution was stirred by a magnetic stirrer. After photolysis, the solution was made acidic by HCl addition, then extracted with ether, and finally concentrated under a reduced pressure. A Shimadzu GC-4CM gas chromatograph was used for the analysis of the products. The injection temperature was 250 °C and the column temperature was programmed from 140 °C to 180 °C at the raising rate of 1 °C min^{-1}. Nitrogen was used as the carrier gas at the flow rate of 30 cm^3 min^{-1}. The column used was 2 m × 3ϕ SUS packed with 10% Lanoline on Chromosorb W. Identification of products was based on comparison of the retention times of samples and standards. Acetophenone was used as the internal standard material for quantitative analysis. The amount of a gaseous product, CO_2, was determined by the method in the literature.[12] Total amount of products and the quantum yield were calculated on the basis of the amount of the starting material transformed. Therefore 1 mol of cresols, benzaldehyde, or benzyl alcohol counted as 1 mol of products while 1 mol of bibenzyl counted as 2 mol of product. The number of incident photons (s^{-1}) was estimated by the use of a calibrated Hamamatsu silicon photocell model S 1337-1010 BQ on the assumption that irradiated light through a Toshiba UV filter UV-D35 mainly consisted of photons of 365 nm.

Results and Discussion

Effect of pH. The effect of pH on the distribution of the products and on the total yield of product is shown in Table 1. In these experiments, pH was controlled by adding H_2SO_4 or NaOH and the solutions were irradiated without UV filter except for run Nos. 2 and 3. On calculation of quantum yields, effective light intensity without UV filter was assumed to be about 1.9 times stronger than that with the filter on the basis of the previous results for neutral systems (pH 7).[2] It seems quite reasonable because the quantum yields calculated on the assumption for the experiments at pH 1 with and without the filter are in good agreement with each other (Nos. 1 and 2). By merely adding H_2SO_4, the total amount of products increased with increase in H_2SO_4 concentrations and at pH 1 it becomes about 5 times more than that of additive free system. Although the amount of CO_2 evolved was not determined for every run of the experiment, about 100 μmol of CO_2 was evolved at pH 7 while only a trace amount of CO_2 was detected at pH 1. The suppression of CO_2 formation may explain partly the high yield at low pH.[15] There has been also prediction that the Haber-Weiss reaction can be a potential HO· radical source in the absence of metal impurities at high and low pH.[16] It is also clear from the data in the acidic region (Nos. 1—4) that the yield of side-chain oxidation products prevailed over the yield of cresols and at pH 1 benzaldehyde was formed quite selectively. The total yields increased also with increase in pH in the alkaline region and preferential oxidation of the side chain becomes clearer with increase in pH. But as the side-chain oxidation products, not only benzaldehyde but also bibenzyl was formed and the latter yield is rather higher than the former yield (Nos. 9 and 10) in contrast with the results at pH 1.

The pH dependence of the heterogeneous photocatalytic oxidation of toluene in the acidic region can be interpreted reasonably with reference to the mechanism of the Fenton reaction as previously.[1,2] In the Fenton reaction, H_2O_2 decomposes into hydroxy radical and hydroxide anion by the reductive cleavage with ferrous ion as follows:[4]

$$H_2O_2 + Fe^{2+} \longrightarrow HO^- + HO\cdot + Fe^{3+} \quad (4)$$

In the present system, where the metal ion catalyst for HO· formation such as Fe^{2+} was not added, we considered the following four reactions are responsible for HO· formation as probable paths.[1,2] HO· formed is very reactive and takes part in the hydroxyla-

tion of aromatic ring and the side-chain oxidation of alkylbenzenes *via* the mechanism as shown in Scheme 1.[17-19] Steps for which there is substantial evidence[18] are indicated by solid arrows, others which are also discussed by dashed arrows. It indicates that most hydroxyl radical attack on aromatics occurs *via* addition, a, to yield hydroxycyclohexadienyl radicals. This is in agreement with conclusions by previous researchers[17-19] and the frequent detection of the hydroxycyclohexadienyl radical by spectroscopic means[20,21] and is strongly supported by the present result described later that phenolic products can be detected in every system in the presence of adequate oxidant, particularly Cu^{2+}, and can be made the major products. This shows that direct side-chain attack, k, cannot be more than a minor reaction path.[22] The rates of hydroxyl radical reactions with aromatics are much faster than would be anticipated for side-chain hydrogen abstraction.[18] In order to account for an apparent high reactivity of aromatic alcohols compared with benzene, Hamilton has proposed either path, l (perhaps concerted with f) or initial formation of a π complex.[23] It is, however, suggested from a correlation of the rate constants with Hammett substituent constant σ[24,25] that sulfate radical anions, $SO_4^{\cdot-}$, form the cation radicals by an electron transfer from the ring to $SO_4^{\cdot-}$ while hydroxyl radicals add to the aromatic ring to form hydroxycyclohexadienyl radicals.

If pH of the solution becomes low, the hydroxycyclohexadienyl radical, will be changed promptly to a radical cation (route d in Scheme 1).[21] The formed cation radical has been known to lose a proton irreversibly to give a benzyl radical (route f) which undergoes dimerization to bibenzyl in the absence of oxidant (route g) or side-chain oxidation to benzyl alcohol (route h) or benzaldehyde (route h and i or route j) in the presence of oxidant. In the systems described above, there is no oxidant added such as Cu^{2+} and Fe^{3+} ions, and therefore only dissolved oxygen acts as the oxidant. Since the yield of benzyl alcohol is much less than that of benzaldehyde (Nos. 1 and 2), benzaldehyde may be formed directly *via* a route j in the presence of dissolved oxygen as in the oxidation in aromatic hydrocarbons.[3] The selective formation of benzaldehyde agrees well with the reaction with Fenton's reagent generated electrochemically in the presence of oxygen.[26] With increase in pH, cresols formation by oxidation of hydroxycyclohexadienyl radical with dissolved oxygen (route b) seems to prevail over the side-chain oxidation described above due to slow down in the water elimination reaction to cation radicals (route d). Above pH 3, another product which may be attributable to a dimer as biphenyl was also detected (route c).

In the alkaline region especially at extremely high pH where only a small amount of cresols was obtained (No. 10), it seems difficult to explain the reaction only by the above described mechanism for the Fenton reaction. For example in such a high pH region, the concentrations of H_2O_2 and $HO\cdot$ are lowered by deprotonation as follows:

$$H_2O_2 \longrightarrow HO_2^- + H^+ \quad (pK_a = 11.62)^{27} \quad (9)$$

$$HO\cdot \longrightarrow O^- + H^+ \quad (pK_a = 11.9^{28,29} \text{ and } 11.8^{30}) \quad (10)$$

Consequently, it is preferable to propose the additional mechanism for the reaction in this pH region. Fortunately, it has been already demonstrated[22,31-34] by pulse radiolysis studies that benzyl radicals can be produced in irradiated aqueous solution by the reaction of O^- with toluene at high pH. Although $HO\cdot$ radicals add to the aromatic ring much more rapidly than they abstract hydrogen from an aliphatic side chain, the situation is reversed when $HO\cdot$ is converted into O^-. At pH>13, the main reaction in irradiated solutions of toluene involves abstraction of H from the methyl group to produce the corresponding benzyl radicals. Consequently, the preferential oxidation of side-chain at high pH (pH>13) in Table 1 can be interpreted by the further reactions of the benzyl radicals formed by this hydrogen abstraction by O^-. In the presence of oxygen, O^- reacts with O_2 very rapidly to form the ozonide ion with the rate constant of $2.6\times10^9\ M^{-1}\ s^{-1}$.[35] However, from careful pulse radiolysis studies, Gall and

$$O^- + O_2 \longrightarrow O_3^- \quad (11)$$

Dorfman[36] concluded that O^- species through thermal dissociation reaction is again the true reactive species in the presence of O_3^-.

$$O_3^- \longrightarrow O_2 + O^- \quad (12)$$

Although the explanation given above is most probable, the alternative mechanism described below was considered at first as a probable mechanism which is similar to the mechanism for the reaction in the absence of water described previously.[3]

$$h\nu \longrightarrow e^- + h^+ \quad (13)$$

$$C_6H_5CH_3 + h^+ \longrightarrow C_6H_5CH_3^{+\cdot} \quad (14)$$

$$C_6H_5CH_3^{+\cdot} \longrightarrow C_6H_5CH_2\cdot + H^+ \quad (15)$$

$$C_6H_5CH_2\cdot \longrightarrow 1/2(C_6H_5CH_2)_2 \quad (16)$$

$$C_6H_5CH_2\cdot + O_2 \longrightarrow C_6H_5CH_2O_2\cdot \quad (17)$$

$$C_6H_5CH_2O_2\cdot + e^- \longrightarrow C_6H_5CHO + OH^- \quad (18)$$

Instead of Eqs. 17 and 18, the alternatives are possible as follows:

$$O_2 + e^- \longrightarrow O_2^{\cdot-} \quad (19)$$

$$C_6H_5CH_2O_2\cdot + O_2^{\cdot-} \longrightarrow C_6H_5CHO + OH^- + O_2 \quad (20)$$

$$C_6H_5CH_2\cdot + O_2^{\cdot-} \longrightarrow C_6H_5CHO + OH^- \quad (21)$$

This seems to be rationalized by the consideration of pH dependent change in energy levels of the band edges of TiO_2[37,38] and the redox potentials of species in solution as shown in Fig. 1. For lack of data, the redox potential of toluene/toluene cation radical measured in acetonitrile[39] is adopted in place of that

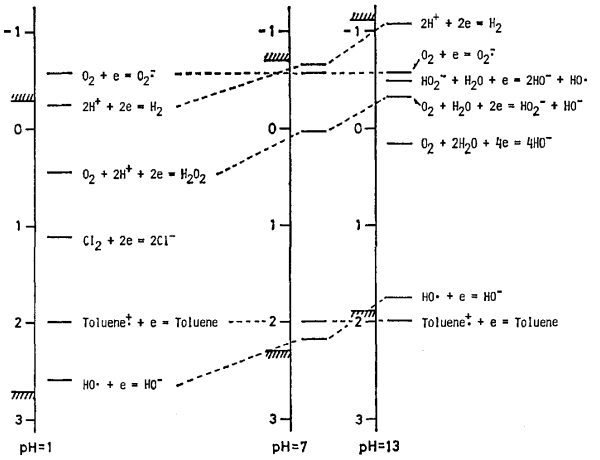

Fig. 1. Changes in position of conduction-band and valence-band edges of TiO_2[37,38] and redox potentials of solution species[39,42,46] in V *vs.* SCE by pH of the aqueous solution.

in water. The potential should be more cathodic than the value shown in Fig. 1 due to the higher solvation energy of cation radical in water than in acetonitrile.[40] Taking this into account, it can be reasonably proposed that toluene is oxidized directly into cation radical even at high pH (Eq. 14) as well as HO^- by positive holes created in the valence band.

$$HO^- + h^+ \longrightarrow HO· \quad (22)$$

Previously the reaction under the air in the absence of water only gave benzaldehyde,[3] but bibenzyl was also formed in the aqueous alkaline solution. The difference may be partly due to the lower solubility of oxygen in water than that in toluene[41] and partly due to the shorter life time of superoxide ion in water[42] than that in hydrocarbon. Furthermore the direct formation of cation radical by positive holes can be considered reasonably as a parallel initiation reaction as well as the reaction initiated *via* addition by HO· at pH<12, since the cation radical formed by $SO_4^{\cdot-}$ gave the similar isomer distributions to those obtained by HO·,[43] but in a strongly alkaline solution, applicability of this parallel mechanism cannot be ascertained since conversion of $SO_4^{\cdot-}$ to HO· should compete with attack on toluene[44] and the HO·–O^- equilibrium becomes significant as described above. If it prevailed, reversible hydration by water to hydroxycyclohexadienyl radicals from the cation radical (route d)[21] would give more phenolic compounds even at high pH. Anyhow, the very low yield of cresols at pH 14 indicates that contribution of the Fenton type reaction by HO· radical is very low, but it is not negligible in contrast with the previous results in the absence of water[3] due to the equilibrium of reaction of Eq. 10.

In addition to the above described pH dependence of CO_2 formation[15] and the yield of Haber-Weiss reaction,[16] the following will partly account for the present observation as to the effect of pH on the total yield of products. In neutral solution, the equilibrium of reaction route d lies to so far to the hydroxycyclohexadienyl radical side and furthermore the rate of reaction route b is limited by the oxidation with dissolved oxygen in the absence of additional oxidants. Consequently if there is another path through which hydroxycyclohexadienyl radicals decay, this accounts for the minimum in the total yield of product in the neutral region. The Hückel theory predicts that the hydrogenated aromatic radical, ArH·, derived from alternant hydrocarbons should have the same half-wave potentials, about −1.1 V *vs.* SCE, since the highest occupied orbital into which a further electron is uptaken is the non-bonding molecular orbital. This fact was ascertained experimentally by Dietz and Peover.[45] Due to its higher electronegativity of HO than H, the reduction potential of hydroxycyclohexadienyl radical can be considered reasonably to be more positive than that of cyclohexadienyl radical of −1.1 V *vs.* SCE. Consequently there is a possibility for hydroxycyclohexadienyl redical to be reduced to yield toluene and HO^- by either electron from conduction band of TiO_2 or superoxide ion. In the alkaline region, the direct formation of benzyl radical by O^- as described above may account for the increase in total yield.

Effect of Cu^{2+} Ions. The effect of Cu^{2+} ion concentrations at pH 1 and pH 2 on "the photo-Fenton type reaction" is summarized in Table 2. On run Nos. 2, 3, and 11—17, pH of the solution was adjusted by adding H_2SO_4, while in run Nos. 18 and 19, HCl was used as acids and in the latter case NaCl was also added. As is evident from the mechanism shown in Scheme 1, the total yield of product will be expected to increase if oxidants are added in the acidic region where the Fenton type reaction mechanism was found to be applicable. This is because the reactions of routes b and h will be accelerated and the backward reaction (route e) will be retarded by the addition of oxidants. As one would expect, the side-chain oxidation products increased by addition of 10 mM Cu^{2+} ions at pH 1 (No. 11). Absence of cresols seems to be reasonable since the reaction between hydroxycyclohexadienyl and cation radicals (route d) lies to the cation radical side at such a very low pH.[4] It is also worthy of note that bibenzyl and benzyl alcohol were formed in additon to benzaldehyde. Cresols formation by further increase in Cu^{2+} ion concentrations (Nos. 12—14) seems to be due to the acceleration of route b which is so high as to be able to compete with the reaction to cation radical (route d). Among the side-chain oxidation products, bibenzyl decreased dramatically with increase in Cu^{2+} ion concentration according to our expectation from Scheme 1. Sudden increase in benzyl alcohol yield by addition of Cu^{2+} ions supports the above interpretation that benzaldehyde was formed directly *via* route j in the presence of only oxygen. The further increase in the formation of benzaldehyde and almost the constant yield of benzyl alcohol with increase in Cu^{2+} ion concentration up to 50 mM indicate that a part of benzaldehyde was formed *via* the intermediate benzyl alcohol in the presence of Cu^{2+} ions (routes h and i). In the presence of high concentration of Cu^{2+} ions (Nos. 13 and 14), cresols formation increased, but the total yield decreased with

Table 2. Effect of Cu^{2+} concentration on yield for photo-Fenton type reaction of toluene[a)]

a) All experiments were done with UV filter and pH of solutions were controlled by adding H_2SO_4 unless otherwise noted. 1 M=1 mol dm^{-3}. b) 10 mM HCl aqueous solution. c) 3.4 M NaCl in 10 mM HCl aqueous solutinn.

increase in Cu^{2+} concentration. This tendency was also observed in the experiments carried out at pH 2 (Nos. 3, 15—17). At this pH, by adding Cu^{2+} oxidation occurred on the ring in preference to the side chain and furthermore the yield of the side-chain oxidation products rather decreased compared with the result in the absence of Cu^{2+}. In spite of addition of Cu^{2+}, benzaldehyde may be formed mainly *via* route j at this pH as only little benzyl alcohol and bibenzyl are formed. At present the reason for this is not clear. Among the experiments done in H_2SO_4 aqueous solutions, 500 mM of Cu^{2+} ions at pH 2 gave the highest ratio of the yield of hydroxylated products to that of side-chain oxidation products.

In addition to acceleration of routes b and h and retardation of route e, it may be possible that addition of Cu^{2+} ions also increases the total yield by the action of Cu^{+} ions, formed by the oxidation reactions in route b and h, as a catalyst for the Fenton type reaction as follows:

$$H_2O_2 + Cu^{+} \longrightarrow HO\cdot + OH^{-} + Cu^{2+} \quad (23)$$

Here Cu^{+} ion is unstable thermodynamically[46)] because Cu^{+} ion easily disproportionates to Cu^{2+} and Cu metal in H_2SO_4. The decrease in the total yield observed in the high Cu^{2+} concentration, which is not so obvious as in Fe^{2+} addition described previously[1,2)] can be attributed to the "short circuiting" reactions as follows:

$$Cu^{2+} + 2e^{-} \longrightarrow Cu \quad (24)$$

$$Cu + 2h^{+} \longrightarrow Cu^{2+} \quad (25)$$

Sluggishness of Reaction 25, may be the main reason for inefficiency of the "short circuiting" reaction of Cu^{2+} ions.[47)]

If chloride ion is added, cuprous ion will be stable thermodynamically by complex formation[46)] as shown in Eqs. 26—28. The redox couple would also expected to be active as a catalyst for HO· formation.[48)] The result at pH 2 by adding HCl is shown in run No. 18. Almost comparable result to that observed with H_2SO_4 solution was obtained in the aqueous HCl solution, but no product was formed when 3.4 M NaCl was added further (No. 19). The latter result may be explained by the "short circuiting" reaction of the following reversible redox reactions:

$$Cu^{2+} + Cl^{-} + e^{-} \longrightarrow CuCl \quad (26)$$

$$CuCl + h^{+} \longrightarrow Cu^{2+} + Cl^{-} \quad (27)$$

where, in high Cl^{-} concentration, cuprous chloride is in equilibrium with its complexes with chloride anion as follows:[49)]

$$nCuCl + mCl^{-} \rightleftharpoons Cu_nCl_{m+n}^{m-} \quad (28)$$

The preferential hole quenching by the undesirable anodic reaction of chloride anions:[50)]

$$2Cl^{-} + 2h^{+} \longrightarrow Cl_2 \quad (29)$$

also seems to be responsible for no oxidation of toluene.

In conclusion, lowering pH and adding Cu^{2+} ions increased the quantum yield of the heterogeneous photocatalytic oxidation of toluene up to 5% as to total products, which is about 20 times more efficient than that observed in the additive free system. The effect of these solution conditions on the distribution of products was very similar to those observed in the usual Fenton reactions in the acidic media containing H_2O_2, Fe^{2+}, and Cu^{2+}. In the alkaline media, O^{-}, deprotonated form of HO·, abstracts H from side-chain of toluene rather than adds to the aromatic ring and consequently the side-chain oxidation products were formed in preference to the phenolic compounds. In other words, the selective formation of benzaldehyde, bibenzyl, or cresols was possible by controlling pH and/or adding Cu^{2+} ions. By these observations we could confirm further the previous conclusion that the real oxidant in the aqueous TiO_2 system is the hydroxyl radical as in Fenton's reagent. Cu^{2+} ion was not so serious as Fe^{2+} for decreasing the yield due to the "short circuiting" by its redox reaction occurring at the same semiconductor particle, unless the solution contained a large amount of Cl^{-} ions.

New Application of PAS for *In Situ* Observation of Semiconductor Electrode Surface

Hideki MASUDA, Akira FUJISHIMA,* and Kenichi HONDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received July 15, 1981)

The photoacoustic spectroscopic technique was used to study *in situ* cathodic decomposition of CdS and ZnO semiconductor electrodes and electrochemical deposition of metal ions (Cd^{2+} and Zn^{2+}) on the semiconductor electrodes.

Photoacoustic spectroscopy (PAS) has recently been emphasized as an useful tool for the study of materials.[1-4] In particular, absorption spectra of highly absorbing materials can easily be obtained by the PAS technique. Additionally, thermal conductivity[5] and information regarding to radiationless processes[6,7] can be obtained from photoacoustic effects. Although PAS has extensively been used to study solids, gases, and liquids,[8] application to *in situ* studies of electrode surface is just beginning. In previous publications,[9,10] we reported that change in a few monolayers on electrode surface during anodic oxidation of a gold electrode could easily be detected *in situ* by the PAS technique.

We report here an application of PAS to *in situ* measurement of semiconductor electrode reactions. Specifically, cathodic reactions of n-type semiconductor electrodes (CdS, ZnO) and electrochemical deposition of metal ions (Cd^{2+}, Zn^{2+}) from solution on electrodes are studied.

These reactions were studied by Kolb *et al.*[11,12] by use of differential reflectance spectroscopy, in which mechanically polished surfaces were examined because the surface had to be flat for this technique.

Experimental

The photoacoustic cell, shown in Fig. 1, was constructed of stainless steel and its outside surface was coated with an epoxy resin for the purpose of insulation from the electrolyte.

An electret condenser microphone (SONY Model ECM-150), a pressure transducer, was mounted on the PAS cell. It was favorable for electrochemical study because a high voltage power source was not required. A Pyrex window was situated at the other side of the cell which was directly across the sample electrode, so that the light which was not absorbed by the sample electrode could pass through the window.

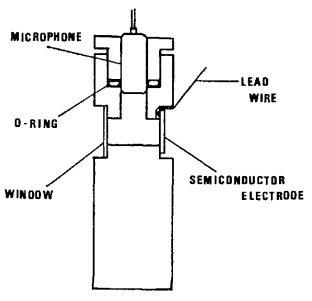

Fig. 1. Photoacoustic cell for semiconductor electrode. The cell width is 20 mm and the height is 60 mm.

Samples measured in this work were a single crystal CdS $(000\bar{1})$ [Teikoku Tsushin (with a donor concentration $N_D = 1.6 \times 10^{16}$ cm^{-3})] and a sintered polycrystalline ZnO which was made with the same procedure as described before.[13] The donor concentration of the polycrystalline ZnO was not known.

Because the amplitude of the photoacoustic signal depends on the thickness of the sample, especially for semiconductors which have lower thermal conductivities than metals, the samples were polished to a thin plate with thickness of less than 0.5 mm.

Ohmic contact was established by evaporating indium on the rear surface of the semiconductor plate, and a lead wire was contacted to the sample with Ag epoxy. Each surface of the samples, CdS and ZnO, was etched with concentrated hydrochloric acid for a few seconds prior to measurement.

The experimental instrumentation was similar to those described previously for the metal electrode-PAS measurement.[9,10] In the present work, a Rhodamin 6G dye laser (Spectra Physics Model 375) which has a wavelength range of approximately 550—660 nm, was used as a high intensity monoenergetic light source in addition to an argon ion laser (Spectra Physics Model 164) and a Xe lamp (Ushio, 1 kW). The light beam from lasers was magnified by a convex lens (f=5 cm) so that the entire surface of the sample electrode except the region of the lead wire contact could be irradiated.

Before a PAS spectrum was taken, the phase angle was adjusted so that the photoacoustic signal due to light absorption at the surface could be optimized. Excitation sources of energy corresponding to the absorption band regions of CdS and ZnO, respectively, were used during the phase adjustment. This procedure was repeated whenever the thickness of samples or modulation frequency was varied.

Results and Discussion

CdS Single Crystal Electrode. Figure 2 shows the photoacoustic signal of the CdS electrode *versus* the wavelength of excitation before and after electrolysis (about 100 mC cm^{-2}) at −2.0 V *vs.* SCE in 1 M KCl (1 M=1 mol dm^{-3}) solution.

In the spectrum of CdS before electrolysis, the photoacoustic signal began to increase when the excitation energy approached the absorption band edge of CdS (2.4 eV or 520 nm). When the energy of radiation is comparable to the band gap energy of the semiconductor electrode, electrons are excited into the conduction band, and when there is no current flow, electrons will recombine with holes in the valence band, and heat will be dissipated.

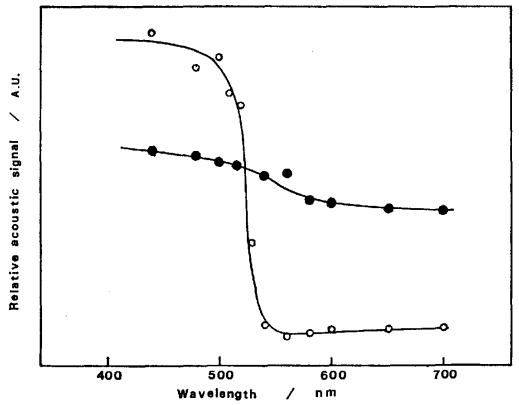

Fig. 2. Photoacoustic spectra of the CdS electrode before (—○—) and after (—●—) electrolysis at −2.0 V *vs.* SCE in 1 M KCl.

When the CdS electrode was electrolyzed at −2.0 V, decomposition of the electrode occurred as follows:

$$CdS + 2e^- \longrightarrow Cd + S^{2-}.$$

The decomposition potential was found to be −1.5 V in the dark. The surface of the CdS was covered with a deposited thin metallic layer of Cd. The photoacoustic signal in the longer wavelength region was due to the intrinsic absorption of the metallic Cd layer. There was a small increase in the photoacoustic signal beginning at an energy corresponding to the absorption band edge of CdS. This extra signal was probably due to the absorption by the CdS underneath the thin metallic Cd layer.

Based on the wavelength response of the photoacoustic signals, we used photons of two different wavelengths, one longer than (610 nm) and the other comparable to (514.5 nm) the absorption band edge of CdS, to prove surface change of the CdS electrode during a reduction and oxidation cycle.

Figure 3 shows the current-potential curve and the relative photoacoustic signal-potential curve of the CdS electrode in 1 M KCl electrolyte solution. The irradiation wavelength was 610 nm. At this wavelength, no photoeffect occurred at the CdS electrode. In the current-potential curve, during the first scan, reduction of oxygen at an onset potential of −0.9 V and hydrogen evolution at an onset potential of −1.4 V were observed, but no cathodic decomposition peak was observed because of the large cathodic current of hydrogen evolution. However, the photoacoustic signal began to increase at −1.5 V. This increase in the photoacoustic signal was due to an increase in the absorption of light at the electrode surface. The increase in the absorption of light reflected the basic change in the absorptivity of the electrode surface and was due to the Cd deposition from lattice at −1.5 V. The photoacoustic signal was not influenced by the oxygen reduction or the hydrogen evolution in the sensitivity region of the present study.

On the anodic scan, a sharp anodic peak appeared at −0.7 V in the current-potential curve, and could be attributed to the dissolution of Cd. At the corresponding potential, the photoacoustic signal decreased and finally returned to its initial value. This behavior suggests that the deposited Cd layer is completely stripped off after an anodic scan.

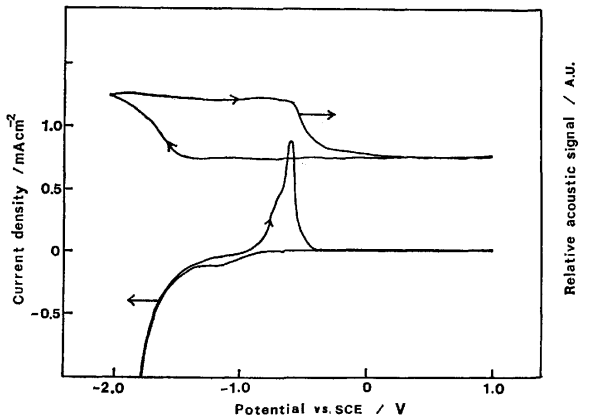

Fig. 3. Photoacoustic signal-potential and current-potential curves of the CdS electrode in 1 M KCl. Potential sweep rate: 40 s/V; λ=610 nm (Rh-6G dye laser irradiation).

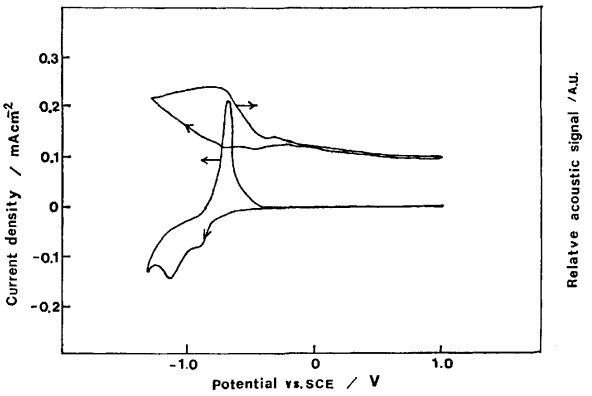

Fig. 4. Photoacoustic signal-potential and current-potential curves of the CdS electrode in the presence of 5×10^{-5} M Cd^{2+} and 1 M KCl.
Potential sweep rate: 40 s/V; λ=610 nm (Rh-6G dye laser irradiation).

Figure 4 shows the current-potential and the photoacoustic signal-potential curves of the CdS electrode in 1 M KCl solution containing 5×10^{-5} M Cd^{2+}. The potential was scanned between 1.0 and −1.4 V, and in this potential range the decomposition of CdS did not take place. A cathodic current at −0.8 V in the current-potential curve was due to the reduction of Cd^{2+} from solution on the CdS surface, thus causing the photoacoustic signal to increase.

Assuming that the deposited layer was uniform, the thickness of the deposited layer was estimated to be about 7 Å from the amount of the charge passed for the electrochemical deposition and the density of Cd (8.7 g cm^{-3}).

We could also detect a change of the CdS electrode surface during the cathodic decompositon by use of the intrinsic absorption wavelength of irradiation (514.5 nm). Figure 5 shows the current-potential and photoacoustic signal-potential curves in 1 M KCl solution using 514.5 nm irradiation. At this wavelength, the anodic photoeffect took place remarkably

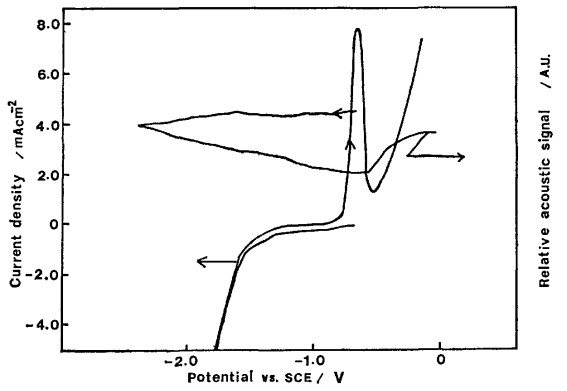

Fig. 5. Photoacoustic signal-potential and current-potential curves of the CdS electrode in 1 M KCl. Potential sweep rate: 50 s/V; λ=514.5 nm (Ar ion laser irradiation).

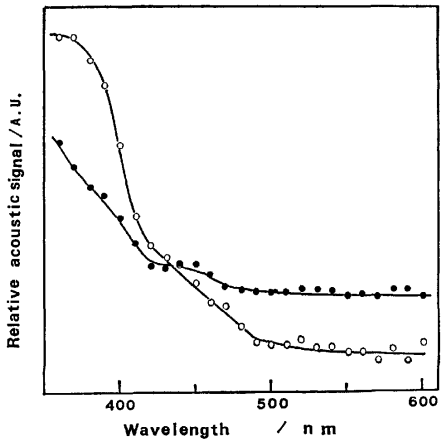

Fig. 6. Photoacoustic spectra of the ZnO electrode before (—O—) and after electrolysis (—●—) at −1.6 V in 1 M KCl.

but the cathodic did negligibly. As was expected, the photoacoustic signal was larger when there was no Cd present on the CdS surface because of the intrinsic absorption of CdS at this wavelength, as shown in Fig. 2. The photoacoustic signal began to decrease at −1.5 V where the CdS decomposition took place. This decrease in signal was due to the Cd deposition. However, the change in the photoacoustic signal was less obvious when the 514.5 nm irradiation was used.

ZnO Polycrystalline Electrode. Photoacoustic spectra of the ZnO electrode before and after electrolysis at −1.6 V (about 100 mC cm^{-2}) in 1 M KCl are shown in Fig. 6. On cathodic polarization, the ZnO electrode decomposed and a deposited Zn layer was formed as follows:

$$ZnO + 2H^+ + 2e^- \longrightarrow Zn + H_2O.$$

After electrolysis the spectra changed, that is, the absorption in the longer wavelength region increased due to deposition of Zn from the ZnO lattice. Because the metallic zinc layer was not uniformly deposited on the surface in the case of polycrystalline ZnO, the absorption of ZnO remained in the spectrum after electrolysis.

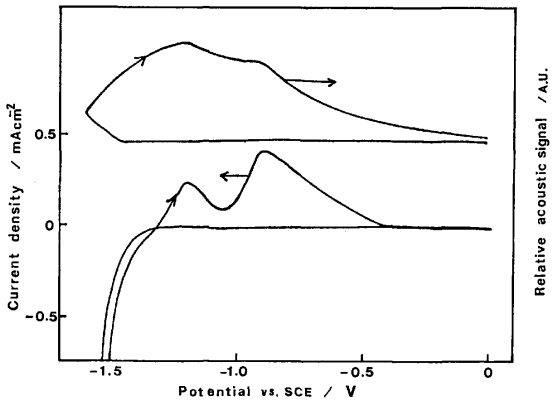

Fig. 7. Photoacoustic signal-potential and current-potential curves of the ZnO electrode in 1 M KCl. Potential sweep rate: 60 s/V; $\lambda \geqq 600$ nm (Xe lamp irradiation with a sharp cut filter).

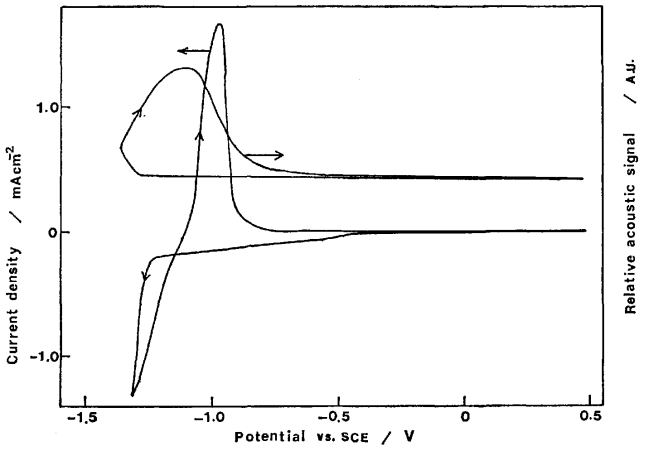

Fig. 8. Photoacoustic signal-potential and current-potential curves of the ZnO electrode in the presence of 10^{-3} M Zn^{2+}, and 1 M KCl.
Potential sweep rate: 30 s/V; $\lambda \geqq 600$ nm (Xe lamp irradiation with a sharp filter).

Figure 7 shows the photoacoustic signal under irradiation at λ>600 nm (Xe lamp irradiation) and current-applied potential curves for ZnO in 1 M KCl electrolyte. The photoacoustic signal began to increase at −1.5 V, which implied decomposition of ZnO. On the anodic scan, two anodic current peaks, both of which seemed to be attributed to dissolution of Zn layer to the solution, were observed in the current-potential curve. The photoacoustic signal decreased stepwise at the corresponding potentials. The photoacoustic signal did not return to the initial value even after the anodic scanning. This behavior implied that the deposited zinc layer could not completely dissolve and remained partially on the polycrystalline ZnO surface.

Figure 8 shows the photoacoustic signal and current-potential curves in 1 M KCl solution containing 10^{-3} M Zn^{2+} ion. A reduction current between −0.5 and −1.25 V was due to the reduction of dissolved oxygen, which did not affect the PAS signal. However, when the large cathodic current flowed from −1.25 V which was attributed to the electrochemical

deposition of Zn^{2+} on the ZnO surface from the solution, the photoacoustic signal began to increase at almost the same potential. On the anodic scan, the anodic current peak was observed at −1.0 V and the photoacoustic signal decreased from −1.1 V. In this case, only one steep peak was observed. Though detailed characters of the two kinds of metallic zinc in the cathodic decomposition (in Fig. 7) are unknown, the results relating to the current-potential and optical measurements of the ZnO in this work are in accord with those by Kolb *et al.*[11,12]

Conclusion

We have demonstrated that photoacoustic spectroscopy is surface sensitive and applicable to *in situ* characterization of the semiconductor electrode surface change during a reduction and oxidation cycle. We could detect deposition of several layers of metal using laser irradiation. This technique is simple and useful for studies of rough or porous surfaces. The problem that the sample has to be thin in our method might be solved by use of other techniques, *e.g.* the piezoelectric photoacoustic detection technique.[14–16] Application of PAS to photoelectrochemical reactions of semiconductor electrodes was described elsewhere.[17]

The authors would like to thank Dr. Boon H. Loo at SRI International for his valuable suggestions.

^{1}H and ^{19}F Nuclear Magnetic Relaxation Studies of Molecular Motion in Solid Fluoroform

Taro EGUCHI,* Michihiko KISHITA, Hideaki CHIHARA,†
and (the late) Gen SODA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received July 29, 1981)

Spin-lattice relaxation times of proton and fluorine nuclei in solid CHF_3 were measured by the pulsed magnetic resonance technique between 7 and 116 K. In ^{1}H resonance, non-exponential recovery of magnetization was clearly observed. T_1 data as well as magnetization recoveries were interpreted in terms of intramolecular magnetic dipole interactions between like spins and also between unlike spins, which are modulated by the isotropic reorientation of a whole molecule. A calculation of the temperature dependence of T_1 was made by using an activation energy of 17 kJ mol^{-1} and a pre-exponential factor of 1.0×10^{-16} s for the motion, yielding results in agreement with the present experimental results.

Fluoroform (CHF_3) has no phase transition below the melting point, $T_m=118$ K, and has a wide range of liquid phase up to the boiling point, $T_b=191$ K.[1] Nuclear magnetic relaxation studies of fluoroform have been concentrated on its liquid state. Spin-rotational interactions have been found to be the main relaxation mechanism in the ^{19}F resonance in the liquid state[2] as well as in the gas state.[3] The cross relaxation between ^{1}H and ^{19}F connected with the Overhauser effect has also been studied in the liquid state where effects of intermolecular magnetic interactions are predominant over those of intramolecular interactions.[4]

In this paper, we will discuss experimental results of temperature dependence of ^{1}H and ^{19}F spin-lattice relaxation times in order to elucidate the molecular motion in the solid state and to examine the cross relaxation effect between the two kinds of nuclei.

Experimental

A sample of fluoroform was purchased in a cylinder from Seitetsu Kagaku (a product of Dupont), the nominal purity being higher than 99%. The method of purification of the sample and the cryostat used in the measurement of T_1 were the same as in the case of silane reported previously.[5]

The relaxation time measurements were carried out between 7 K and just below the melting point at both 10.00 and 25.54 MHz using pulsed NMR techniques. In the ^{19}F resonance, we measured T_1 by the null-method above 80 K since the magnetization recovery showed exponential behavior over more than one decade within the experimental error.

On the other hand, the magnetization recovery for the ^{1}H resonance showed clear non-exponential behavior as shown in Fig. 1. We therefore used the $\pi/2$(comb)-τ-$\pi/2$ pulse sequences as well as the π-τ-$\pi/2$ pulse method; the two methods gave identical results within the experimental error.

Results and Discussion

The ^{19}F spin-lattice relaxation time T_1 above 80 K is shown in Fig. 2 and that below 80 K is shown in Fig. 3. A minimum in T_1 occurs at 105 K with a value of 10.7 ms at 10.0 MHz. Anomalous T_1 behavior is observed below 50 K where T_1 becomes

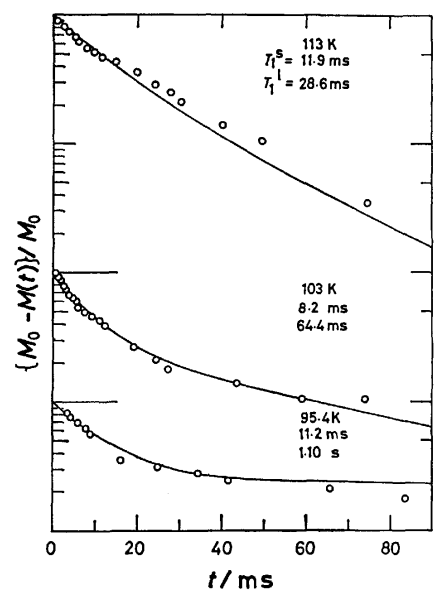

Fig. 1. Reduced magnetization recoveries in ^{1}H resonance.
Solid curves are the results of theoretical fitting.

almost independent of temperature, and on further cooling, the magnetization recovery tends to be more complex with two time constants. The relaxation mechanism in this temperature region is not obvious. The trace of paramagnetic oxygen, which has been detected by a gas chromatographic analysis (less than 0.02%), might be a candidate.[6]

A unique value of ^{1}H spin-lattice relaxation time was not to be determined because of the non-exponential recoveries as shown in Fig. 1. This behavior is due to the cross relaxation effect caused by the dipole coupling between ^{1}H and ^{19}F. In other words, for a quantitative treatment of the ^{1}H resonance data, it is necessary to consider the spin system as one of two unlike spins, ^{1}H (spin S) and ^{19}F (spin I).

In this case, we may describe the equation of motion for the magnetization as follows:[7]

$$\begin{pmatrix} \frac{d\langle I_z\rangle}{dt} \\ \frac{d\langle S_z\rangle}{dt} \end{pmatrix} = -\Gamma \begin{pmatrix} \langle I_z\rangle - I_0 \\ \langle S_z\rangle - S_0 \end{pmatrix}, \quad (1)$$

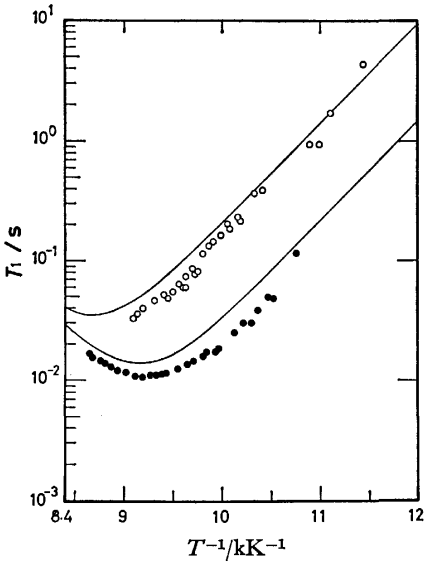

Fig. 2. The temperature dependence of ^{19}F spin-lattice relaxation time above 80 K.
●: At 10.0 MHz, ○: at 25.54 MHz, ——: calculated curves.

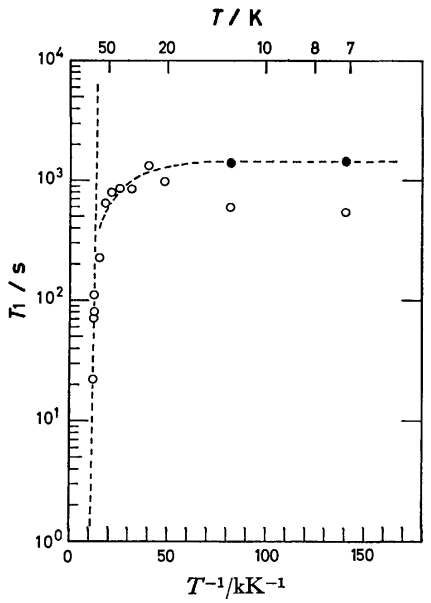

Fig. 3. The temperature dependence of ^{19}F spin-lattice relaxation time below 80 K at 25.54 MHz.

where I_0 and S_0 denote the magnetization at thermal equilibrium, and the relaxation matrix Γ is defined by

$$\Gamma \equiv \begin{pmatrix} \Gamma_{II} & \Gamma_{IS} \\ \Gamma_{SI} & \Gamma_{SS} \end{pmatrix}. \tag{2}$$

For simplicity, with only the intramolecular dipole coupling taken into account, each component of the relaxation matrix may be written as

$$\left.\begin{aligned} &\Gamma_{II} = 2\gamma_{II}^{L} + \gamma_{II}^{U}, \\ &\Gamma_{IS} = \gamma_{IS}^{U}, \\ &\Gamma_{SI} = 3\gamma_{SI}^{U}, \\ \text{and} \\ &\Gamma_{SS} = 3\gamma_{SS}^{U}, \end{aligned}\right\} \tag{3}$$

where the superscripts L and U mean the contribution of a like spin pair and that of an unlike spin pair, respectively. In the case of dipole coupling, theses are given by Abragam as follows:[7]

$$\left.\begin{aligned} \gamma_{II}^{L} &= \frac{9}{8}\gamma_I^4\hbar[J^{(1)}(\omega_I) + J^{(2)}(2\omega_I)] \\ \gamma_{II}^{U} &= \frac{3}{4}\gamma_I^2\gamma_S^2\hbar^2\left[\frac{1}{12}J^{(0)}(\omega_I-\omega_S) + \frac{3}{2}J^{(1)}(\omega_I) + \frac{3}{4}J^{(2)}(\omega_I+\omega_S)\right], \\ \gamma_{IS}^{U} &= \frac{3}{4}\gamma_I^2\gamma_S^2\hbar^2\left[-\frac{1}{12}J^{(0)}(\omega_I-\omega_S) + \frac{3}{4}J^{(2)}(\omega_I+\omega_S)\right], \end{aligned}\right\} \tag{4}$$

and similar equations for γ_{SS}^{U} and γ_{SI}^{U} are obtainable by interchanging the indices I and S, where $J^{(n)}(\omega)$'s are spectral densities.

The observable relaxation rates $\lambda_+ = (T_1^l)^{-1}$ and $\lambda_- = (T_1^s)^{-1}$ are the eigenvalues of the relaxation matrix Γ.

When we use the $\pi/2$(comb)-τ-$\pi/2$ pulse sequences, these eigenvalues determine the magnetization recoveries according to the equations

$$\left.\begin{aligned} &\frac{I_0 - \langle I_z\rangle}{I_0} = a_S\exp(-t/T_1^l) + b_S\exp(-t/T_1^s), \\ \text{and} \\ &\frac{S_0 - \langle S_z\rangle}{S_0} = a_I\exp(-t/T_1^l) + b_I\exp(-t/T_1^s), \end{aligned}\right\} \tag{5}$$

where the coefficients a and b are given by

$$\left.\begin{aligned} &a_S = (\Gamma_{SS}-\lambda_-)/(\lambda_+-\lambda_-) = b_I, \\ \text{and} \\ &b_S = (\Gamma_{SS}-\lambda_+)/(\lambda_+-\lambda_-) = a_I. \end{aligned}\right\} \tag{6}$$

It is worth noting that not only T_1^l and T_1^s but also a and b are temperature-dependent through temperature dependence of correlation time associated with the particular type or types of molecular motion that are responsible for the relaxation. Expressions such as Eqs. 4 and 5 have been used to interprete experimental results on more complicated systems.[8-12] However, the values of a and b were taken as independent of temperature.

In calculating the matrix elements (Eq. 3) for CHF_3, isotropic reorientation of a whole molecule will be assumed to be the dominant relaxation mechanism. The spectral densities are then given by

$$\left.\begin{aligned} &J^{(1)}(\omega) = \frac{4}{15}r_{ij}^{-6}[\tau_c/(1+\omega^2\tau_c^2)], \\ \text{where} \\ &J^{(0)}:J^{(1)}:J^{(2)} = 6:1:4, \end{aligned}\right\} \tag{7}$$

with

$$\tau_c = \tau_0\exp(V/RT), \tag{8}$$

where r_{ij} is the distance between two spins, V is the relevant activation energy, and τ_0 is the pre-exponential factor.

Taking r_{FF}=0.216 and r_{FH}=0.198 nm,[13] we obtain the explicit values of the long and short components, T_1^l and T_1^s, and the coefficients a_S and b_S, which are shown in Fig. 4 as functions of $\omega\tau_c$ in the case of ^{19}F resonance. It is clear that T_1^l has a minimum

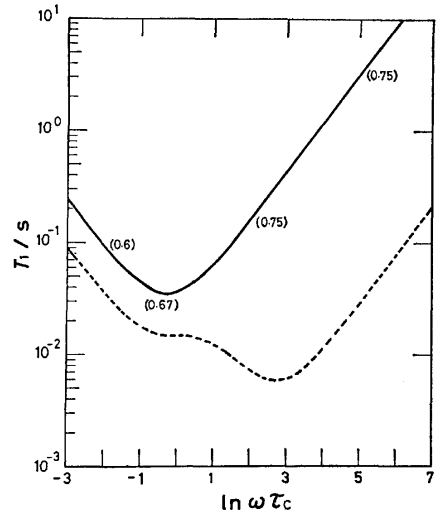

Fig. 4. Theoretical ^{19}F T_1 curves (T_1^l and T_1^s components) *vs.* ln $\omega\tau_c$.
The numbers in the parentheses indicate the coefficient a_S in Eq. 5.

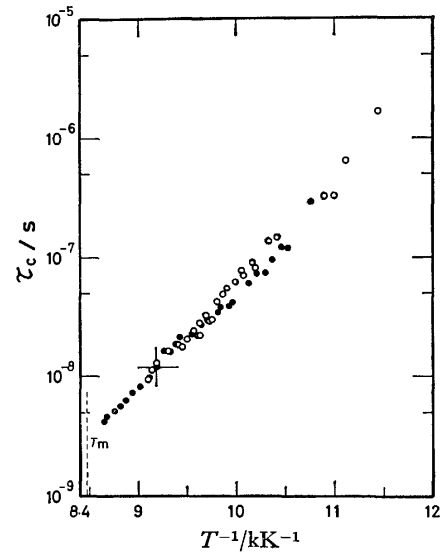

Fig. 5. The temperature dependence of the correlation time associated with isotropic reorientation.
●: From the T_1 data at 10.0 MHz, ○: from the T_1 data at 25.54 MHz.

at $\omega\tau_c=0.75$ ($\ln\omega\tau_c=-0.28$) and a_S assumes a nearly constant value of 0.75 where $\omega\tau_c \gg 0.75$. Judging from the fact that the observed magnetization recovery in ^{19}F resonance can be described by a single exponential function over the time span of experiment, it is reasonable to consider that the observed T_1 is equal to T_1^l. By using the T_1^l curve in Fig. 4 and the observed T_1 values, we can estimate the correlation time τ_c due to isotropic molecular reorientation, the temperature dependence of which is shown in Fig. 5. The straight line in this figure gives us an activation energy $V=17$ kJ mol^{-1} and $\tau_0=1.0\times10^{-16}$ s,[14] as well as the solid curve in Fig. 2.

On the other hand, the magnetization recoveries in ^1H resonance were analyzed by means of Eq. 5 using only one parameter τ_c. A few examples of curve-fitting are drawn in Fig. 1. The two time con-

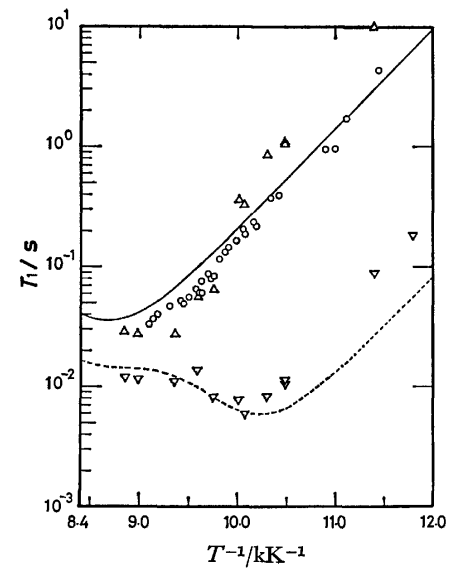

Fig. 6. The temperature dependence of T_1 at 25.54 MHz.
○: ^{19}F resonance, △: T_1^l in ^1H resonance, ▽: T_1^s in ^1H resonance, ——: calculated T_1^l, — —: calculated T_1^s.

stants T_1^l and T_1^s obtained in this manner are plotted against the reciprocal of temperature in Fig. 6, where the T_1^l and T_1^s curves were calculated from the same parameter values as above and are shown by the solid and broken lines, respectively. Here the calculated T_1^s curve has a shoulder around $\omega\tau_c=0.75$ besides a clear minimum at $\omega\tau_c=15$, which arises from the (ω_I—ω_S) terms in Eq. 4.

The calculated minimum value of T_1^l is 13.9 ms at 10.0 MHz and that of T_1^s is 5.8 ms at 25.54 MHz. There are some discrepancies between the calculated and observed T_1 values, which may be caused by the approximation that intermolecular contribution is to be ignored. However, the trend of the temperature dependence of T_1 is described satisfactorily by our simple but more or less rigorous treatment using a single correlation time τ_c.

As is apparent from the foregoing analysis of the experimental results, the data of ^{19}F relaxation can be used to deduce the relaxation behavior of protons in the present case. In other words, when there is a cross-relaxation effect between two nuclear species, one needs to know the relaxation behavior on only one of them which would then permit deductions on the other.

In the absence of structural information on CHF_3 it is difficult to rationalize the magnitude of the activation energy for molecular tumbling (17 kJ mol^{-1}). In the case of the low-temperature phase of CF_4, the activation energy was reported to be 18 kJ mol^{-1}.[15] Because the closest intermolecular approach is probably through F···F contacts, the similarity in the activation energy in these two substances would reflect the similarity in the intermolecular interaction.

The amounts of oxygen in the sample were kindly determined by gas chromatography at Osaka Oxygen Industries, Ltd. This work was supported by a grant

from the Ministry of Education, Science and Culture, to whom the authors express their gratitude.

Elementary Patterns in Protein-Nucleic Acid Interactions. III.† Crystal Structure of Adenine:Phthalic Acid (3:1) Complex Hexahydrate

Akio TAKENAKA* and Yoshio SASADA

Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received August 5, 1981)

Crystal of adenine:phthalic acid (3:1) complex hexahydrate were obtained from an aqueous solution containing equimolar amounts of adenine and *N,N*-phthaloyl-DL-glutamic acid. The space group is $P\bar{1}$ with unit-cell dimensions of $a=14.232(2)$, $b=16.730(2)$, $c=7.336(1)$ Å, $\alpha=78.97(1)$, $\beta=96.14(1)$, and $\gamma=68.99(1)°$. The structure was solved by the direct method and its parameters were refined by a block-diagonal least-squares technique. The two carboxyl groups of the phthalic acid are dissociated and they are hydrogen-bonded to the amino group and the protonated N(1) of the two adeninium monocations. The geometrical characteristics in adeninium monocations are explained with the electronic structures perturbed by the surroundings. A typical feature of the C–H···N hydrogen bond is observed between the adeninium cations. The third adenine molecule is neutral and disordered. A comparison of the dissociation constants of the related compounds suggests that the protonation of adenine occurs when the hydrogen bonds are formed between the carboxyl group of acidic amino acid residue in protein and the unpaired adenine base in nucleic acid.

We have been engaged in the structural studies on elementary patterns in protein-nucleic acid interactions, using crystals in which nucleotide base and amino acid coexist.[1–6] In case of the systems containing cytosine and carboxyl group, for instance, the α-carboxyl group is dissociated and hydrogen-bonded to the amino group and the protonated N(3) atom in cytosine,[1,2] whereas the γ-carboxyl group of glutamic acids interacts with the amino group of base-paired cytosine.[3] In the present paper, we deal with the system containing adenine and carboxyl group.

Experimental

Single crystals of adenine: phthalic acid (3:1) complex hexahydrate were obtained by slow evaporation of an aqueous solution containing equimolar amounts (0.2 mmol) of adenine and *N,N*-phthaloyl-DL-glutamic acid, both of which were purchased from Tokyo Kasei Kogyo Co. An elementary analysis. Found: C, 40.7; H, 4.5; N, 30.5%. Calcd. for $3C_5H_5N_5\cdot C_8H_6O_4\cdot 6H_2O$: C, 40.6; H, 4.9; N, 30.9%. It means that *N,N*-phthaloyl-DL-glutamic acid is hydrolyzed by heating the solution in presence of adenine. A crystal, $0.2\times0.3\times0.6$ mm³ in size, was used for X-ray data collection on a Rigaku four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation ($\lambda=0.71073$ Å). The unit-cell dimensions were calculated with 65 high-angle reflexions. The crystal data are given in Table 1.

Diffraction intensities were measured in the $\omega/2\theta$ scan mode with a scan width of 1.3° (in ω) plus α_1-α_2 divergence and a scan speed of 4° (in 2θ) min^{-1}. Five reference reflexions showed no significant intensity deterioration throughout the data collection. The intensities were corrected for Lorentz and polarization factors but not for absorption effects. Of 7193 independent reflexions in the range $2<2\theta<55°$, 3117 weak reflexions with F_o less than $3\sigma_p(F_o)$ were considered to be unobserved, where $\sigma_p(F_o)$ is evaluated by counting statistics. The standard deviations were estimated by the equation of $\sigma^2(F_o)=\sigma_p^2(F_o)+qF_o^2$, where q (7.77×10^{-5}) was derived from the variations of the monitored reflexions.[7]

TABLE 1. CRYSTAL DATA

Adenine:Phthalic (3:1) complex hexahydrate

$U=1570.7(4)$ Å³	$Z=2$
$D_x=1.437$ g·cm^{-3}	$D_m=1.43_7$ g·cm^{-3}

Structure Determination

The space group was assumed to be $P\bar{1}$ from normalized structure factor statistics. The phases were derived by using the MULTAN programme[8] with 436 E's ($E>1.9$); two reflexions with the largest E's (>5.0) were omitted in the calculation. Molecular skeletons of phthalic acid and three adenines were found on the E map derived from the phase set with the smallest R_{Karle} value.[9] Subsequent electron density calculations gave the positions of the six water molecules and then revealed that one of the three adenines was disordered in the two modes of orientations and that one of the six waters occupied the two sites. Positional and thermal parameters of the non-hydrogen atoms were refined by block-diagonal least-squares techniques, half occupancies being assumed for the disordered atoms. Hydrogen atoms except for the water and disordered adenine molecules were found on a difference map, which were included in later refinements. The quantity minimized was $\Sigma w(|F_o|-|F_c|)^2$ with $w=1/\sigma^2(F_o)$. The final R was 0.085 for the observed 4076 reflexions; the maximum shift of parameters in the last cycle was 0.2σ for C, N, and O atoms and 0.7σ for H atoms.

Atomic scattering factors used were taken from "International Tables for X-Ray Crystallography."[10] Atomic parameters are listed in Table 2.[11]

† Part II of this series is Ref. 6.

TABLE 2. FRACTIONAL COORDINATES AND ISOTROPIC TEMPERATURE FACTORS

The B values accompanied with $\langle\ \rangle$ are the equivalent isotropic temperature factors calculated from anisotropic thermal parameters using the equation $B=8\pi^2(U_1+U_2+U_3)/3$, where U_1, U_2, and U_3 are principal components of the mean square displacement matrix $\boldsymbol{U}$. Values in $\langle\ \rangle$ are anisotropicity defined by $(\sum(B-8\pi^2U_i)^2/3)^{1/2}$. The e.s.d.'s in ( ) refer to last decimal places.

Results and Discussion

Molecular Structure. Both the two carboxyl groups of phthalic acid, I and II, are dissociated and the two adenine molecules, A and B, are monoprotonated at N(1), as confirmed by a difference synthesis. The third adenine, C, is neutral and disordered in the two modes of orientations. Bond distances and angles are shown in Fig. 1.

The two C–O distances in the carboxyl group I differ significantly from each other, while those in the carboxyl group II are almost the same. The longer C(7P)–O(71P) bond suggests that the negative charges are localized mainly on O(71P). The benzene ring of the phthalic acid is planar within 0.002 Å, from which the carboxyl carbon atoms, C(7P) and C(8P), are deviated by −0.050 Å and 0.070 Å, respectively, perhaps owing to repulsions between them. The mean planes of the carboxyl groups make angles of 27.6(2)° for I and 64.6(2)° for II with that of the benzene ring. These values do not seem to be inherent though they resemble those of bivalent phthalic acid salt;[12] the relative orientation of the carboxyl groups varies easily by packing effects of crystal.[13]

It is known that adenine molecule exists in acidic circumstances as mono- or di-cation, whose bond lengths and angles are dependent on protonation.[14,15] The dimensions of the present adeninium cations, A and B, correspond to typical ones of the monocationic species.[14] Figure 2 shows the environments of molecules surrounded by hydrogen bonds. The protonated N(1) and the amino nitrogen N(6) atoms in adeninium B are hydrogen bonded to the carboxylate oxygens, O(71P) and O(72P) of the group I, respectively, while those in A form a similar double-

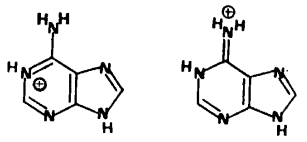
hydrogen bond with the carboxyl group II. Here it is noted that the N(1)···O(71P) hydrogen bond (2.594(5) Å) is significantly shorter than the others, and the negative charges are predominant at O(71P), as mentioned above. In such situation, the adeninium B is perturbed, so that the contribution of canonical formula **1** increases, as compared with the adeninium A in which the canonical formula **2** is predominant. The shorter C(6)–N(6) bond of adeninium A, accompanied by the slightly longer C(6)–N(1) bond



1 **2**

than that of B, is consistent with this anticipation. Table 3 shows the atomic net charges calculated by CNDO approximation[16] for these two adeninium cations. In adeninium A, the positive charges on the amino group increase and those on N(1)–H(1) group decrease, as compared with those in B. These charges, though small, seem to be consistent with the above interpretation.

The adeninium monocations so far analysed show the marked differences in C(6)–N(6) and C(6)–N(1) bond distances, which suggest the change in relative contributions from the two canonical formulae, **1** and **2**. The difference between adenosine hydrochloride[14f] and adenine hydrochloride hemihydrate[14d] can be correlated to the hydrogen bond distances, just as mentioned above. It may be concluded that the adenine cation can be adapted to the various surroundings by changing its electronic structure to some extent.

Crystal Structure. The crystal structure viewed down the c axis is shown in Fig. 3. Hydrogen bond distances and angles are given in Fig. 2 and Table 4.

The adenine C is disordered with a local approximate mirror symmetry; the mirror plane is perpendicular to the adenine plane passing through N(6) and C(4). As seen from Fig. 3, only the C(5) and C(6) atoms give the resolved peaks on the electron density map. The disordered adenine molecules around the inversion centre at 0,0,1/2 may be hydrogen bonded with the scheme shown in Fig. 4. According to this scheme, the water oxygen, O(6W) and O(7W), are also disordered by the hydrogen bonds with the adenine C.

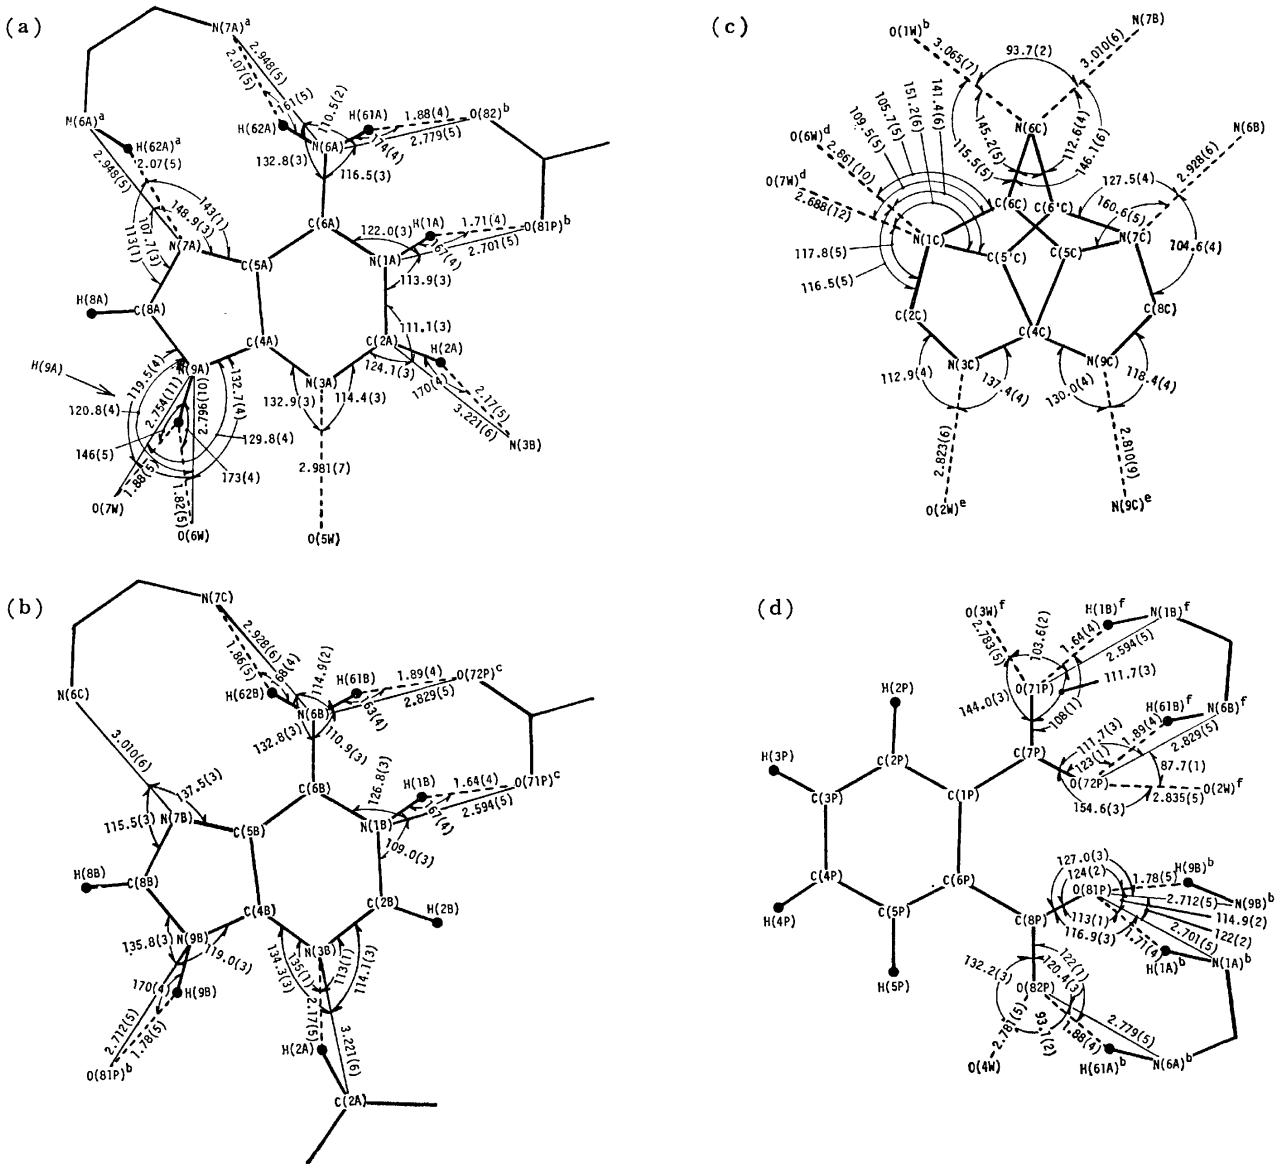

Fig. 2. Hydrogen bond distances (l/Å) and angles (ϕ/°) for (a) adenine A, (b) adenine B, (c) adenine C, and (d) phthalic acid.
The symmetry codes, a—f, are the same as those in Table 4.

The two adeninium A's form a dimer around the inversion centre at 0,0,0 through the N(6)–H···N(7) hydrogen bond. The adeninum B forms a dimer with the adenine C through the N(7B)···H–N(6C) and N(6B)–H···N(7C) [or disordered N(1C)] hydrogen bonds.

Intermolecular stackings are made with different kinds of adenine. The adeninium A and the adenine C at $-x,1-y,-z$ are stacked alternatively along the c axis with the dihedral angle of 2.4(1)° and with the spacings of 3.26 and 3.56 Å. The adeninium B is stacked parallel to that related by the inversions at 0,1/2,0 or 0,1/2,1/2 along the c axis with the spacings of 3.23 and 3.33 Å, respectively. By this way, all kinds of adenines form a layer parallel to the bc plane.

The phthalic acid is linked to the three adeninium cations by the hydrogen bonds between the carboxyl I and the adeninium B [N(6) and the protonated N(1)] and between the carboxyl II and the adeninium A [the same atoms as B] at $-x,1-y,-z$, O(81P) of the latter carboxyl group II being at the same time an acceptor of hydrogen bond from N(9) of adeninium B at $-x,1-y,-z$. The benzene ring of this acid is stacked parallel to that related by the inversion at 1/2,1/2,1/2 with the spacing of 3.45 Å. The water molecules lie between the adenine layers, forming hydrogen bonds with adenine, phthalic acid, and other water molecules.

A short C–H···N contact is observed between the adeninium A and B, as shown in Fig. 2. The C(2)–H(2) bond points to a lone pair lobe of N(3). Since N(3) is significantly negative and the C(2)–H(2) group is positive (Table 3), this contact is favourable to assume the C–H···N hydrogen bond, which has been proposed in hydrogen cyanide,[17] α-1-[(*p*-bromophenyl)-

TABLE 4. HYDROGEN BOND DISTANCES AND ANGLES OF WATER MOLECULES

Some short contacts are also shown. Standard deviations are given in parentheses.

phenylmethylene]-3-oxo-1,2-diazetidinium inner salt,[18] and (5-methyl-2-pyridinecarbaldehyde 2-pyridylhydrazone)tetracarbonylmolybdenum(0).[19]

Hydrogen Bonding between Adenine and Carboxyl Group. As mentioned above, the two dissociated carboxyl groups of phthalic acid interact respectively with the two protonated adenines by the double hydrogen bond, as shown in Fig. 5. This pattern resembles that found in adenine:*m*-bromobenzoic acid (2:4) complex.[20a] In the latter complex, however, the proton-transfer between the two components is ambiguous due to the disordered structure.[20b]†† The dihedral angle between the base and the carboxyl group is 12.9(2)° for adeninium A and 45.6(2)° for adeninium B; the binding geometry is given in Table 5. Such non-planarity occurs because the phthalic acid is bridged between the two adeninium A and B which are stacked in the different columns, ACAC.. and BB.., respectively. The hydrogen bond scheme with the smaller dihedral angle may be more favourable one.

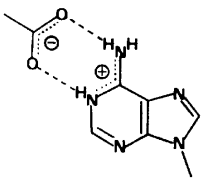

Fig. 5. Interaction pattern between adenine and carboxyl group.

Table 5. Geometrical data to define the interaction between adenine and carboxyl group

The symmetry codes, b and c, are the same as those in Table 4. Hydrogen bond distances and angles are shown in Fig. 2.

†† Lancelot has reported the three types of hydrogen bonds for adenine with butyric acid in chloroform solution from NMR study.[21] Although one of them is similar to the present pattern, the proton transfer is not assumed between the two components.

We have attempted an interpretation in terms of dissociation constant, which was successful for the binding mode in cytosine:glutamic acid system.[2a] Since the pK_a^I value of phthalic acid (2.95) is lower than that of adenine (4.25), the latter molecule is easily protonated by the first dissociation of phthalic acid in solution, but it could scarcely take a proton from the second dissociation because of higher pK_a^{II} (5.41) than that of adenine. In the present crystal, however, even the latter dissociation takes place. It is suggested that when the carboxyl group approaches adenine within a distance sufficient to form hydrogen bonds, their mutual perturbation favours to induce the ionizations.

The pK_a value of acidic side group of proteins is near pK_a of *N*-acetylglutamic acid α-methylamide (4.34),[22] whose value is comparable to that of the second carboxyl group of phthalic acid. On the other hand, adenine bases in nucleic acid would have a pK_a close to that of adenosine-5′-monophosphate (3.74) or its deoxy form (4.4), which is approximate to the adenine's value. Therefore, the pattern of hydrogen bonding, as shown in Fig. 5, would be found in the interaction between the side group of an acidic amino acid residue in protein and an unpaired adenine base in nucleic acid; the proton transfer must occur and their hydrogen bonds would be strengthened by an ionic effect induced.

Figure 3 was drawn by TSD:XTAL[23] for a NOVA 3 computer. The present work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture, and by the Kawakami Foundation, to which the authors' thanks are due.

The Adsorption of Amino Acids from Water on Activated Carbons

Ikuo Abe,* Katsumi Hayashi, and Mutsuo Kitagawa**

Osaka Municipal Technical Research Institute, Ogimachi, Kita-ku, Osaka 530

***Society for Activated Carbon Research, Ogimachi, Kita-ku, Osaka 530*

(Received August 5, 1981)

Freundlich's adsorption constants of 17 amino acids from aqueous solutions onto an activated carbon have been determined and correlated with various physical constants. A good linear relationship is obtained between the adsorption constants and such physical constants as the molecular refraction and the parachor. The adsorption isotherms of amino acids can be predicted from the molecular refraction or the parachor alone.

The ability to predict the adsorbability for a given adsorbent from a knowledge of the physical properties of the adsorbate is an important objective in adsorbent-adsorbate interaction research. In a previous paper,[1] the partition coefficients of 93 organic compounds between an aqueous solution and activated carbon phases at an infinite dilution have been calculated and correlated with various physical constants. Further, the adsorptive mechanism on activated carbon in an aqueous solution has been discussed.[2] Abe *et al.*[3,4] have presented an adsorption equation for predicting the adsorption isotherms of organic compounds from water on activated carbons and showed that, for aliphatic monofunctional compounds, such physical constants as the molecular refraction or the parachor are useful for the prediction. The present paper aims to examine whether or not the method of prediction is applicable to such multifunctional compounds as amino acids.

Experimental

The adsorbent (Pittsburgh Activated Carbon Co., grade CAL activated carbon) and experimental techniques were the same as those described in a previous paper.[2] All of the adsorbates came from commercial sources (stated minimum assay 99%) and were used without further purification. The substances tested were adsorbed from pure solutions, with no special effort being made to control their pH, since ampholytes in solution tend to maintain pH values near their isoelectric points. A comparison of the pH values of many amino acid solutions before and after adsorption revealed relatively little change in the pH.

Results and Discussion

Figure 1 shows the adsorption isotherms of 17 amino acids onto CAL activated carbon at 25 °C. The adsorption isotherms have been approximated by means of the Freundlich equation:

$$\log X = \log k + \frac{1}{n} \log C, \quad (1)$$

where C is the equilibrium concentration(mg/l), X is the amount of adsorption(mg/g), and k and $1/n$ are constants. The results of regression analysis using Eq. 1 are presented in Table 1.

In order to clarify the adsorptive mechanism of amino acids, the correlation between the adsorption constants and various physical constants has been examined. Table 2 shows the results of the regression analysis for Eq. 2:

$$\log k = a\Phi + b, \quad (2)$$

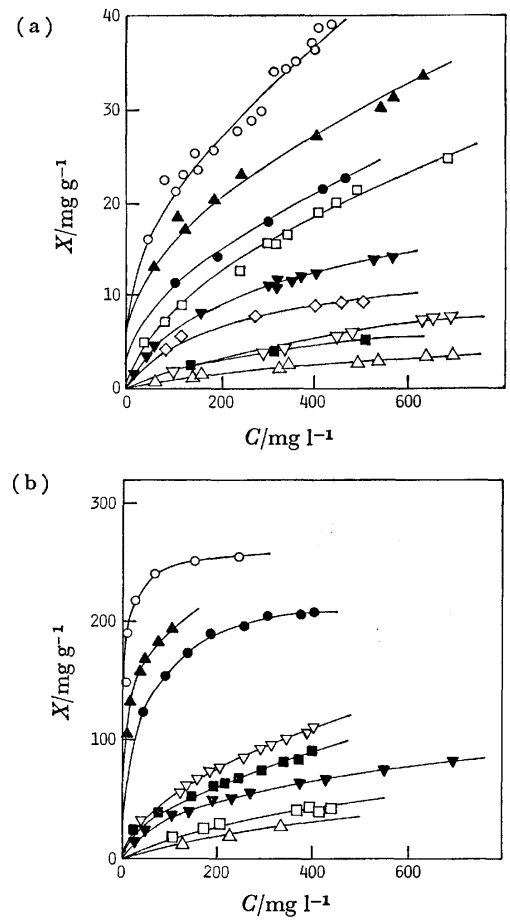

Fig. 1. Adsorption isotherms of 17 amino acids from water onto CAL activated carbon.
(a) ○: L-Glutamic acid, ▲: L-glutamine, ●: L-proline, □: DL-valine, ▼: L-asparagine, ◇: L-threonine, ▽: DL-alanine, ■: L-serine, △: glycine.
(b) ○: L-Tryptophan, ▲: L-tyrosine, ●: L-phenylalanine, ▽: L-methionine, ■: L-histidine, ▼: L-leucine, □: L-isoleucine, △: L-aspartic acid.

where Φ is the physical constant of amino acids and where a and b are constants. In this table, r is the correlation coefficient; s, the standard deviation, and F and t, the values of the statistical test. A high correlation coefficient has been obtained for the molecular-size parameters, such as the molecular refraction, the parachor, or the molecular weight. This result resembles that observed for aliphatic monofunctional compounds.[4] Further, a good linear relationship has been obtained for a very simple value, the carbon-atom number in a molecule. This sug-

gests that the decisive component of the adsorption forces on an activated carbon surface is the hydrophobic interaction. It is well known that compounds with a low solubility are more readily adsorbed than compounds with a high solubility, but the data in Table 2 indicate that solubility is not a dominant factor governing the adsorption of amino acids. Figure 2 shows the relationship between $\log k$ and the molecular refraction.

Table 3 shows the results of regression analysis for Eq. 3:

$$1/n = a\Phi + b. \quad (3)$$

The correlation coefficients for Eq. 3 are lower than those for Eq. 2. Figure 3 shows the relationship between $1/n$ and the molecular refraction.

Table 1. Adsorption parameters of amino acids on CAL activated carbon (25 °C)

Compound No.	Compound	k	$1/n$

the adsorption isotherms of 14 amino acids on Darco G-60, a commercial-grade lignite carbon. Urano et al.[6] measured the adsorption isotherms of 8 amino acids on two activated carbons from coal and petroleum pitch. Table 4 shows the relationship between Freundlich's constants and the molecular refraction. In the original papers, the k values were expressed in mol/g; therefore, the correlation coefficients between log k and the molecular refraction are very low because of the compounds with a high adsorbability, such as tryptophan, phenylalanine, and tyrosine, indicate a maximum adsorption at fairly low concentrations less than 1 mol/l. However, when the k values are expressed in mg/g, the correlation coefficient becomes high. It can be seen from Table 4 that Eqs. 2 and 3 are also applicable to the other activated carbons.

From Eqs. 1 and 2 we obtain the following equation, with a slight change in notation:

$$\log X = \alpha\Phi + \beta + \gamma \log C, \quad (4)$$

where α, β, and γ are constants. The data of 151 plots of 17 amino acids have been given to a NEC PC-8001 computer in order to determine the α, β, and γ values by means of multiple regression analysis. The constants and statistic analysis for several physical constants are given in Table 5. High correlation coefficients have been obtained for the molecular refraction and the parachor. Figure 4 shows a plot of the log X values observed *vs.* the log X values calculated by means of:

$$\log X_{\text{calcd}} = 0.07134\,MR - 1.983 + 0.4401 \log C. \quad (5)$$

We can see from Fig. 4 that the molecular refraction gives a good prediction of the isotherms.

If the α, β, and γ constants for a given activated carbon are determined from the adsorption data of several compounds, the adsorption isotherms of many other amino acids can be predicted from the molecular refraction alone. It should be remembered, however, that the solution pH influences the adsorption of ionized solutes.[7-9] These prediction methods may not be applicable for adsorptions at pH values extremely removed from the isoelectric point.

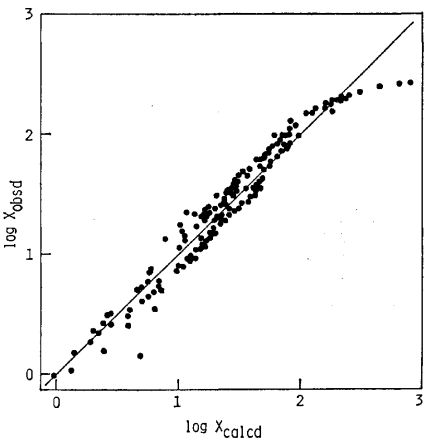

Fig. 4. Relationship between log X observed and log X calculated using Eq. 5.

UV Absorption Studies of the Pyrolysis of Isobutane in Shock Waves

Tohru KOIKE* and Kihei MORINAGA

Department of Chemistry, National Defense Academy, Hashirimizu, Yokosuka 239

(Received March 24, 1981)

The UV absorption measurements at 216 nm were carried out for two shock-heated mixtures, 1.5 and 2.0% i-C_4H_{10} diluted in Ar, in the temperature range of 1300—1800 K, and at an atmospheric pressure of about half. From the initial absorption rise attributed to the CH_3 growth, the rate constant of the initiation reaction, i-C_4H_{10} = CH_3+i-C_3H_7, was evaluated as $k=10^{12.8\pm0.5}\exp[-(60.8\pm4.6)\ \text{kcal}/RT]/\text{s}^{-1}$. A comparison between the k value so derived and the formerly reported values was made. A computer modeling using a 39-reaction mechanism could reproduce the absorption at the early stage of the reaction at temperatures lower than 1550 K, whereas the modeled absorption was smaller than the measured at much high temperatures. The absorption by C_3H_5 (allyl radical) must be taken into account in order to lessen this difference.

Computer modeling has been used often in studying complex reaction mechanisms. We ourselves demonstrated the capability of the method in studies of C_3H_8[1] and n-C_4H_{10}[2] pyrolysis and have proposed reaction mechanisms for them.

In comparison with the n-C_4H_{10} pyrolysis, the i-C_4H_{10} pyrolysis can be interpreted rather simply, as in the case of the C_3H_8 pyrolysis, since it gives only one initiation reaction:

$$i\text{-}C_4H_{10} = CH_3 + i\text{-}C_3H_7. \quad (1)$$

Therefore, if the k_1 value can be determined precisely by means of a time-resolved measurement of the growth or the decay of any species appearing in Reaction (1), only secondary reactions, the k values of most of which are available in the existing literature, need to be examined. Computer modeling shows its usefulness in such a case.

Bradley[3] proposed the basic reaction mechanism of the i-C_4H_{10} pyrolysis from his discernment of alkane pyrolysis at high temperatures. He measured the product distribution of the pyrolysis in the temperature range of 1200—1500 K by means of a single-pulse shock-tube technique and confirmed the validity of the mechanism by computer modeling. At lower temperatures than Bradley's, many studies of the pyrolysis by other experimental techniques have been reported.[4-8] Pratt and Rogers[4] investigated the pyrolysis around 1000 K using a wall-less reactor and proposed a reaction mechanism after surveying almost all of the i-C_4H_{10} pyrolysis studies ever reported. They also compared their own k_1 value with those reported by several other workers.[3,5-8] The k_1 value obtained by Bradley[3] exhibited a distinct fall-off with a smaller activation energy than those reported around 1000 K.

Since Bradley's study is the only one carried out in the high-temperature range, as far as we are aware, and since it gave a k_1 value different from others, another shock-tube study of the pyrolysis, especially devised to check the k_1 value, is required. In this study, we measured the 216 nm absorption in the i-C_4H_{10} pyrolysis behind incident shock waves. From the initial increase in the absorption attributed to the CH_3 growth alone, the k_1 value was evaluated. The k_1 value thus obtained is incorporated into a reaction mechanism of the pyrolysis, and the absorption at 10 μs in lab. time, when C_2H_4 and C_3H_6 are expected to appear much and when these species as well as CH_3 absorb the 216 nm light, is elucidated by computer modeling.

Experimental

The shock tube and the optical system used in this study have been described in detail in a preceding paper.[9] Briefly, the test gases, i-C_4H_{10}/Ar=1.5/98.5 and 2.0/98.0, prepared from 99.8% pure i-C_4H_{10} (Takachiho Co.) and 99.999% pure Ar (Nippon Sanso Co.) at starting pressure of 20.0± 0.5 Torr (1 Torr≈133.322 Pa) were heated up to high temperatures (1300—1800 K) by means of incident shock waves. The reaction profile was observed by means of UV absorption spectroscopy with a D_2-lamp (Hanau, D200F). The light from the lamp was passed through the shock-tube windows and was detected by means of a photomultiplier (Hamamatsu-TV, R208) with a monochromator (Jarrell-Ash, JE25; dispersion=3.3 nm/mm, entrance and exit slit width=1 mm).

Computer modeling was done using the program mentioned previously.[9] The flow model assumed in the modeling was a laminar-boundary-layer growth with a limiting separation. The thermochemical data of each species were taken from several available sources; these sources are shown in the footnote of Table 1.

Results and Discussion

Figure 1 shows a typical oscillogram of the absorption profile at 216 nm obtained in this study. The absorption increases right after the arrival of the shock at the observation window and thereafter maintains a plateau. Since no absorption was observed at the shock front, i-C_4H_{10} does not absorb the 216 nm light. This is in accordance with the former experimental

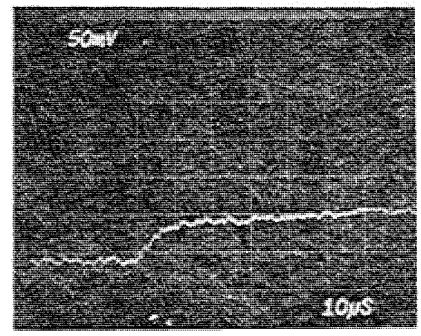

Fig. 1. A representative oscillogram for 1.5% i-C_4H_{10} in Ar mixture, P_1=20 Torr, and T_2=1478 K.

results reported for small alkanes,[10] such as CH_4,[11] C_2H_6,[11,12] C_3H_8,[13] and n-C_4H_{10},[2] having no absorption band in this wavelength region.

The unimolecular decomposition of i-C_3H_7 produced by Reaction (1) also gives CH_3.

$$i\text{-}C_3H_7 = CH_3 + C_2H_4 \qquad (19)$$

The methyl radical so produced reacts mainly with i-C_4H_{10} at early in the reaction as:

$$CH_3 + i\text{-}C_4H_{10} = CH_4 + i\text{-}C_4H_9, \qquad (4)$$

$$CH_3 + i\text{-}C_4H_{10} = CH_4 + t\text{-}C_4H_9. \qquad (5)$$

Methyl recombination is another important step in the CH_3 disappearance:

$$2CH_3 + M = C_2H_6 + M. \qquad (-27)$$

The computer modeling adopted later indicates that the rates of Reactions (4), (5), (19), and (−27) are much smaller than that of Reaction (1) early in the reaction. Thus, the influence of these secondary reactions on the CH_3 profile can be neglected, and the CH_3 growth rate is given by:

$$d[CH_3]/dt = k_1[i\text{-}C_4H_{10}].$$

It has been reported that the absorptivity of i-C_3H_7 at 216 nm is at least 10 times smaller than that of CH_3.[14] Moreover, i-C_3H_7 is very unstable under the present experimental conditions, and the modeled [i-C_3H_7] is about three orders of magnitude smaller than that of CH_3. Thus, the increase in the absorption early in the reaction can be attributed solely to the CH_3 growth. The above equation implies that the evaluation of the initial slope of the absorption provides the k_1 value with an explicit relation of $[CH_3]_t=\log(I_0/I_t)/(a\cdot d)$, where I_0=incident light intensity, I_t=transmitted light intensity at reaction time t (in particle time), a=absorptivity ($cm^2\ mol^{-1}$), and d=optical path length (7.2 cm). The absorptivity of CH_3 was taken from that reported elsewhere.[11,12] Since the absorptivity reported was measured in an effective bandwidth of 1.6 nm, which is almost equal to the present one, it was assumed to be applicable to the present study without any correction.

The k_1 values so evaluated are shown in Fig. 2. The least-squares calculation provides the following Arrhenius expression for k_1 with one standard error (the data points above 1600 K, which deviate from the linear extrapolation of the low-temperature values, were not taken into account in the calculation):

$$k_1 = 10^{12.8\pm0.5} \exp\left[-(60.8\pm4.6)\ \text{kcal}/RT\right]/s^{-1}.$$

Tsang[5] estimated the rate constants of alkane decompositions within the high-pressure limit, k^∞, around 1100 K by means of a single-pulse-shock-tube experiment. Recently, he studied the temperature dependence of the k^∞ value and reached the conclusion that these A factors decrease with an increase in the temperature in the temperature range of 300—1100 K. If such an effect is negligibly small in a narrower temperature range, and if the k_1^∞ value, the k_1 value within the high-pressure limit, is extrapolated to above 1100 K, as is shown in Fig. 2, we can see a distinct deviation of the present k_1 value from the k_1^∞ value with an increase in the temperature, though the present k_1 is almost equal to the k_1^∞ value at temperatures around 1300 K. Besides the k_1^∞ value by Tsang,[5] several k_1^∞ values measured around 1000 K have been reported. One of them is by Golden *et al.*[8] This k_1^∞ value, however, can not be comparable with others, since it is doubtful if the VLPP technique used to obtain it is free from the surface effects, which may lead to a high k_1^∞ value. Another one is by Pratt and Rogers.[4] At 1300 K, their k_1^∞ value extrapolated is about 10 times smaller than the present k_1 value. Even if the decrease of the A_1^∞ factor of the k_1^∞ value is expected as above, we can not explain such a large difference between the two values. Therefore, the k_1^∞ value by Pratt and Rogers[4] seems also to have some error.

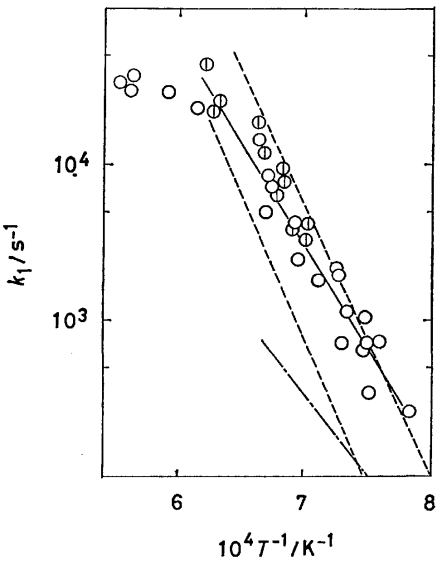

Fig. 2. Arrhenius plots for k_1.
The symbols used are as follows: ○; for 2% i-C_4H_{10} in Ar mixture and ⊕; for 1.5% i-C_4H_{10} in Ar mixture. The solid line shows a least squares fit for the data points below 1600 K. The upper and lower broken lines show the k_1 values in Ref. 5 (Tsang) and in Ref. 4 (Pratt and Rogers), respectively. The chain line shows the k_1 value in Ref. 3 (Bradley).

Although it has been confirmed qualitatively that the present k_1 value above 1300 K is in the fall-off range, it is difficult to find precisely where the present k_1 value is on the fall-off curve, for the present k_1 value was measured at almost equal pressures (P_2=0.45—0.60 atm, 1 atm=101325 Pa) and there is an ambiguity in the k_1^∞ value at high temperatures. Further experiments at different pressures might be necessary to ascertain the exact fall-off behavior of the k_1 value. The k_1 value reported by Bradley,[3] which is considered to be in the fall-off range, will be referred to later.

As the pyrolysis proceeds, many kinds of products appear, and the absorption is an aggregated one by these products. We interpreted the absorption profile with the aid of computer modeling and tried to propose a reaction mechanism of the i-C_4H_{10} pyrolysis. To facilitate the computer modeling, we adopted the absorption at lab. time 10 μs, $A_{10}=\ln(I_0/I_{10})$ for the

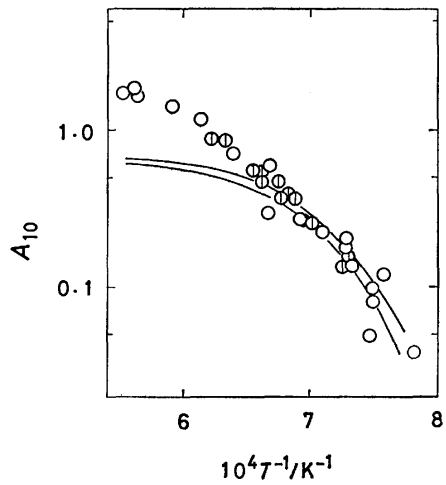

Fig. 3. A comparison between measured and modeled A_{10}.
The symbols are as in Fig. 2. The upper and lower lines show the modeled A_{10} for the 2% and 1.5% mixtures, respectively.

parameter, as in the study of the n-C_4H_{10} pyrolysis reported before. In Fig. 3, the A_{10} values so evaluated are shown *vs.* $10^4/T$. The output of the computer modeling given by the time variation in the concentration of each species is converted to the absorption as: $A=2.303\times a_i[C_i]d$, where $[C_i]$ is the modeled concentration of each species. The A value at the same lab. time is considered to correspond to the above A_{10}. The species which were assumed to absorb the 216 nm light were CH_3,[11,12] C_2H_4,[9] and C_3H_6.[2] The absorptivities of the latter two species, which were measured with the same optical set-up as the present, were mentioned in a previous paper.[9] The absorption by C_2H_2 is expected to be negligible under the present experimental conditions, since a negligible effect of C_2H_2 absorption on the A_{10} value was seen in the modeling of the n-C_4H_{10} pyrolysis previously reported.[2] The absorption by i-C_4H_8 was assumed to be negligible.

Figure 3 shows that a nice agreement between the modeled and measured A_{10} values is established at lower temperatures below 1550 K; at much higher temperatures, however, the modeled A_{10} values are much smaller than the measured ones. The sensitivity test to be discussed later indicates that there might be no way of improving the disagreement only by changing any k values in Table 1. In the modeling of the absorption, there does not seem to be any species which appears in a large amount and which shows a large absorption at higher temperatures.

With an increase in the temperature, the modeled concentration of $C_3H_5(CH_2{=}CH{-}\dot{C}H_2)$ gets much larger than those of other radicals and is comparable to the concentrations of stable products, such as CH_4 and C_2H_4. The strong absorption of C_3H_5 in this wavelength range was observed in the C_3H_6 pyrolysis measured in shock waves[2] and in the 1-C_4H_8 photolysis at room temperature.[16] If we adopt the absorptivity of about 2×10^7 cm^2 mol^{-1} reported in the latter study, the modeled A_{10} values drastically go up to near the measured values. Besides the main route of forming C_3H_5 *via* C_3H_6, the following route *via* i-C_4H_8 may be present in the i-C_4H_{10} pyrolysis:

$$i\text{-}C_4H_8 = CH_3 + (CH_2{=}\dot{C}{-}CH_3).$$

The radicals thus formed is expected to be stabilized to the allyl radical after a few collisions, since it has been reported that,[17] due to the resonance, the heat of formation of the allyl radical is about 20 kcal/mol smaller than that of $(CH_2{=}\dot{C}{-}CH_3)$. Thus, in the modeling of the high-temperature absorption of the i-C_4H_{10} pyrolysis, it is necessary to clarify the route of forming C_3H_5 and to take into account the absorption by the allyl radical.

Table 1 shows the reaction mechanism of the i-C_4H_{10} pyrolysis derived in this study. The reaction mechanism can explain the absorption profile early in the reaction at temperatures lower than 1550 K. Pratt and Rogers' mechanism,[4] which includes explicitly the reactions of C_4H_9 isomers, is the original of the present mechanism. The reactions accompanying the species having more than 5 carbons and the reactions which may have an influence on the overall reaction at a later time were not included. Since the reaction temperature of this experiment is much higher than that of Pratt and Rogers,[4] some of the major products may be expected to decompose further. From this point of view, Reactions (15)—(18), (22)—(26), (28), and (30)—(35) were included as in the study of the reaction mechanism of the n-C_4H_{10} pyrolysis previously reported.[2] Most of the k values of these reactions are identical with those used in the previous study.[2] Among the reactions which were considered to be important under the conditions of Pratt and Rogers' experiment,[4] the k values of unimolecular reactions, (14) and (27), adopted were those determined in an experiment similar to the present one.[13,18]

Since the primary reactions of C_4 species giving the major products have been discussed in detail by Pratt and Rogers,[4] we will give our attention here to the fates of the smaller hydrocarbons produced. The major products in the pyrolysis in the temperature range of 1200—1500 K have been reported to be CH_4, C_2H_6, C_2H_4, C_3H_6, and i-C_4H_8; no appreciable amount of C_3H_8 has been detected.[3] It may be seen from the product distribution reported at that time[3] that $[i\text{-}C_4H_8]$ decreases abruptly with an increase in the temperature and it is less than 5% of the concentration sum of the products at the upper end of the reaction temperature; a similar tendency of the modeled $[i\text{-}C_4H_8]$ above 1500 K will also be seen later. Thus, no consideration will be given here to the fates of i-C_4H_8 and C_3H_8. Among the major products left, CH_4 and C_2H_4 are relatively stable in this temperature range, and their direct decompositions, Reaction (33), $C_2H_4{=}C_2H_2{+}H_2$, and $C_2H_4{=}C_2H_3{+}H$, are considered to be negligible. Only H-atom abstractions, Reactions (34) and (35), are effective in accounting for the disappearance steps of the molecules. Since the reactivities of C_2H_6 and

C_3H_6 are larger than those of the above two species, the disappearance steps, Reactions (23)—(26) and (27)—(32), are taken into account. At much higher temperatures than the present, the reaction mechanisms of the C_2H_6 and C_3H_6 pyrolysis are not so simple, as has been considered above.[19]

The radicals larger than C_2, such as C_4H_9, C_3H_7, and C_2H_5, are decomposed to produce H or CH_3 with molecules in this temperature range. Therefore, the chain terminations are accomplished by the radical reactions of H and CH_3. The chain termination for the H-atom are $H+H=H_2$ and Reaction (−33); the rate of former reaction is very small compared with those of the other reactions in Table 1, and so it is not included in the reaction mechanism. The disproportionations, Reactions (31) and (36), as well as the recombinations, Reactions (−14), (−27), and (−33), are chain terminations for the CH_3 radical. Reaction (30) can go in either direction and can not be explained simply. Thus, co-radical reactions with CH_3 are not so simple as in the case of the H-atom.

The modeled $[C_3H_6]$ and $[i\text{-}C_4H_8]$ at 1500 K are 1.3×10^{-8} and 1.0×10^{-10} mol cm^{-3} respectively at 10 μs lab. time. At much higher temperatures, for example, at 1700 K, the modeled $[i\text{-}C_4H_8]_{10\mu s}$ is less than 10^{-11}. Thus, because of the smallness of $[i\text{-}C_4H_8]$, it is confirmed that both the influence of the absorption by i-C_4H_8 on the total absorption and the route of forming C_3H_5 *via* i-C_4H_8 are negligible in deriving the present reaction mechanism. On the other hand, it is necessary to examine the C_3H_6 pyrolysis in detail. A recent study of the C_3H_6 pyrolysis in shock waves[19] has predicted that such expressions as Reactions (23)—(26) are not satisfactory in explaining the reaction profile at high temperatures. Also the absorptivity of C_3H_5 at high temperatures is uncertain and must be measured precisely. Since the situation for the C_3H_5 chemistry is as above, we have left the modeling of the absorption profile at high temperatures unfinished.

The results of sensitivity tests at 1500 K and 1700 K are shown in Fig. 4. It may be seen that the sensitivity spectra given by the values of the percent deviations of each reaction are completely different between the two temperatures. At 1500 K, the reactions accompanying the CH_3 radical, the initiation (1), the chain propagations (5) and (30), and the chain terminations, (−14), (−27), and (31), have large influences on the A_{10} value. Since the sensitivities of Reactions (1) and (27) are much larger than those of the other reactions, the k values of these two reactions should be examined carefully. As for Reaction (1), several factors which may give uncertaities in determining the k_1 value have already been discussed in detail, and the error boundary for the expression has been given. The error boundary of the k_1 value may be given as above, but the error boundary seems to be much smaller than that, since the A_{10} value can not be reproduced by computer modeling when a k_1 value different by a factor of 2 from the value in Table 1 is adopted. As for the k_{27} value, we selected the value determined in the C_2H_6 pyrolysis study[18] in which conditions similar

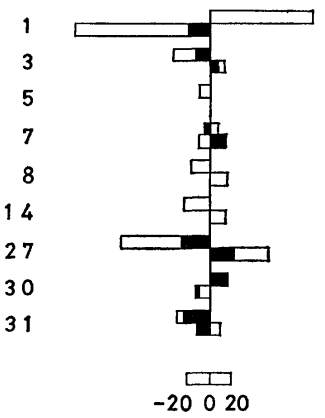

Fig. 4. Sensitivity spectrum for the 2% mixture.
The numbers refer to the reaction number in Table 1. The abscissa is percent deviation defined as: $(A_{10}'/A_{10}-1)\times100$. A_{10} is the standard value modeled using Table 1 mechanism and rate constants. A_{10}' is the perturbed value by multiplying each rate constant by 5, upper bar of each reaction; by 0.2, lower bar. The reactions whose percent deviations are less than 5 are not shown.
The bars used are: □, T_2=1500 K; ■, T_2=1700 K.

to those of the present experiment were adopted, because the k_{27} value is expected to show a pressure dependence. Although we can not find the error boundary of the k_{27} value explicitly,[18] we can elucidate the error boundary to be less by a factor of 2 from the sensitivity spectra shown in the previous report.[18] Likewise, the present A_{10} value can not be reproduced by computer modeling with a changed k_{27} value as above. As for the C_4H_9 decompositions, the value of the percent deviations of Reactions (7) and (8) are given with different signs when each k value is changed with the same factor; *i.e.*, only small variation of the A_{10} value can be seen by changing the k_7 and k_8 values at the same time. On the other hand, very small deviations were observed for Reactions (6), (9), and (39). These results may indicate that it is possible to reproduce the A_{10} value even after making a fall-off correction for each k value of Reactions (6)—(9) and (39) with a similar factor. From the sensitivity spectra at 1700 K, the percent deviations of most reactions can be expected to get smaller with an increase in the temperature, and it is hard to tell which reaction is more sensitive to the A_{10} value. Thus, the A_{10} value at high temperatures can not be reproduced only by changing any of the k values in Table 1.

Since the experimental conditions of the single-pulse shock-tube technique adopted by Bradley[3] is similar to the present (P_5=0.66—0.91 atm), the computer modeling with reaction mechanism shown in Table 1 can be expected to reproduce his experimental results. However, the modeled decay of $[i\text{-}C_4H_{10}]$ is too fast compared with his results. We are led to assume that the gas-cooling effects due to the boundary-layer growth[20] existed in his data also.

Effect of Mixed Surfactant upon Stability and Particle Size of Emulsion

Kimihiko Ogihara,* Minoru Ueno, and Kenjiro Meguro
Department of Applied Chemistry, Faculty of Science, Science University of Tokyo, 1-3 Kagurazaka, Shinjuku-ku, Tokyo 162

(Received June 26, 1981)

An effect of a mixed surfactant of SDS and homogeneous octaethylene glycol dodecyl ether (8ED) upon the stability and particle size of an octane-in-water emulsion was studied. The mixed surfactant solutions were found to exhibit equi-interfacial-tension over a wide concentration region of a mixed 8ED; the SDS concentrations were 6, 8, and 20 mmol dm^{-3}. The emulsion prepared by using mixed surfactant solution in such a concentration region showed a similar mean particle size. When SDS concentration was kept at 8 or 20 mmol dm^{-3}, the emulsions prepared by the mixed surfactant solutions had similar stability, independently of the mixed 8ED concentration. In the presence of 1 mmol dm^{-3} of SDS, the stability of the emulsions increased with the increasing concentration of mixed 8ED. In the case of SDS concentration of 6 mmol dm^{-3}, the emulsion was most stable at 1×10^{-3} mol dm^{-3} of mixed 8ED.

We have so far reported on the surface properties of mixed aqueous solutions containing SDS as an anionic surfactant and a series of polyethylene glycol dodecyl ethers ($C_{12}E_n$: $n=1$—8), having no distribution of poly(oxyethylene) chain lengths, as the nonionic surfactant.[1-3] We have found that an equi-surface-tension exists on the surface tension *vs.* the concentration curve over a wide concentration range of the nonionic surfactant in the presence of 6.3 mmol dm^{-3} of SDS, and also that the mixed micelle exists in the region. The existence of such a plateau region in the surface tension curve will also be expected to appear on the interfacial tension curve for the oil/water system consisting of a similar mixed surfactant solution and octane as the oil. The emulsion prepared by these surfactant solutions and octane will also be anticipated to become more stable over a wide concentration range of a nonionic surfactant.

Additives such as higher alcohols are often utilized as emulsion stabilizers,[4-12] since the emulsion becomes more stable by adding a small amount of a higher alcohol. This effect has so far been explained by formation of some more stable complex between alcohols and emulsifiers[5-7] due to the van der Waals interaction between the hydrocarbons or the ion-dipole interaction between the head groups.[13,14]

In this work, in order to confirm the emulsion stability for the octane-in-water emulsion system in the plateau region of the interfacial tension curve, the interfacial tensions were measured. These tensions are related to the stability of the emulsion produced from the corresponding individual and mixed surfactant solutions; the relation is also justified by the extent of drainage of the emulsion.

Experimental

Materials. The solium dodecyl sulfate (SDS) used here was obtained from Wako Pure Chemical Industries; it was purified by repeated crystallization from either ethanol or a mixture of 2-propanol and water. The purity was confirmed by the absence of any minimum in the surface tension *vs.* concentration curve. The octaethylene glycol dodecyl ether (8ED) supplied by Nikko Chemicals Co. has been confirmed to have a high purity and no distribution of poly(oxyethylene) chain lengths by GLC and TLC. The octane was a GR quality oil which was used without further purification. The water used for all experiments was purified by passing deionized water through a MILLI-Q Reagent-Grade Water System (MILLIPOR Ltd.) until its specific conductivity fell below 0.1 μS cm^{-1}.

Measurements. Interfacial tension was determined at 25 °C by a modified Wilhelmy type surface tensiometer, Shimadzu ST-1. Five ml of surfactant solution and of octane were poured slowly into a weighing bottle, and an octane/surfactant solution interface was formed. Then the bottle was stoppered, and left to stand for 40 min at the measurement temperature. This period was determined from the measurement of the time-dependence of the interfacial tension. After this period the interfacial tension was measured.

Emulsions were prepared as follows: Each mixture consisting of 20 ml of both surfactant solution and octane was emulsified with a Universal Homogenizer (Nihonseiki Kaisha) operated at 6000 min^{-1} for 5 min at room temperature. The emulsion thus prepared was transferred to sedimentation tubes, which had a stop cock, and left standing at 25 °C. The drainage of liquid from the emulsion (degree of separation; *DS*) was determined after 1 h, 2 h, and 24 h. The *DS* value is defined in the present work as follows:

$$DS \text{ value} = \frac{\text{volume of drained phase}}{\text{total volume of emulsion}} \times 100\,(\%)\,.$$

The mean particle size of the emulsions was determined immediately after preparation of each emulsion by a centrifugal particle size analyzer, Shimadzu CP-50.

Results and Discussion

Before discussing the stability of the octane-in-water emulsion system prepared using a surfactant mixture of SDS and 8ED, we must determine whether the properties of the interface of the octane/aqueous solution of each surfactant reflect the stability of the corresponding emulsion. The interfacial tension of 8ED solution against octane is shown in Fig. 1(a). The value decreased from 35 mN m^{-1} to 0.3 mN m^{-1} with the increase of 8ED concentration, and an apparent cmc (critical micelle concentration) was observed at about 1×10^{-3} mol dm^{-3}. Figure 2(a) shows the interfacial tension of SDS solution against octane. The cmc was observed at about 8 mmol dm^{-3}.

Figure 1(b) shows *DS* values of the emulsion which had been prepared with 8ED as an emulsifier. The emulsion began to be stable with increasing concen-

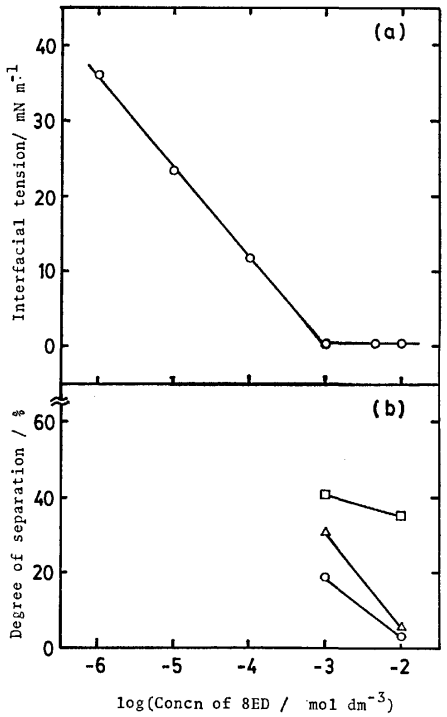

Fig. 1. (a) Interfacial tension of 8ED solution against octane.
(b) Degree of separation of octane emulsion prepared by 8ED, after 1 h (—○—), 2 h (—△—), and 24 h (—□—).

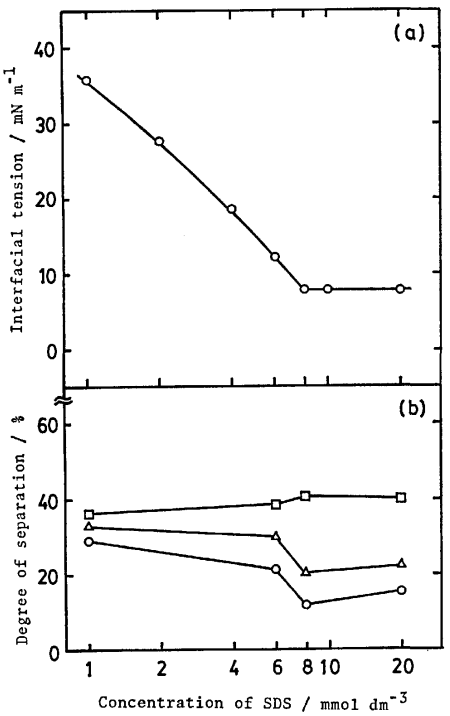

Fig. 2. (a) Interfacial tension of SDS solution against octane. (b) Degree of separation of octane emulsion prepared by SDS, after 1 h (—○—), 2 h (—△—), and 24 h (—□—).

tration above the apparent cmc of 8ED. Figure 2(b) also shows *DS* values of the emulsion prepared with SDS. The *DS* value became smaller as the SDS concentration increased; in the presence of 8 mmol dm^{-3} of SDS the *DS* value was smallest, in the measurement after one hour.

According to our previous data,[1] the surface tension *vs.* concentration curve for the mixed surfactant solution of SDS and homogeneous pentaethylene glycol dodecyl ether (5ED) showed a plateau region (equi-surface-tension region) over a wide concentration range of a mixed 5ED (from 3×10^{-6} to 1×10^{-3} mol dm^{-3}) in the presence of 6.3 mmol dm^{-3} of SDS. The existence of a mixed micelle between SDS and 5ED has been proved by the appearance of this plateau region.[1]

From these findings, such a mixed surfactant will be expected to show an equi-interfacial-tension region even in the interfacial tension curve. The interfacial tension of the mixed surfactant solution of SDS and 8ED against octane is shown in Fig. 3. In the presence of 6, 8, and 20 mmol dm^{-3} of SDS, each interfacial tension curve had an equi-interfacial-tension region.

If the O/W type emulsion of octane is prepared from the mixed surfactant solution which shows the plateau region in the interfacial tension *vs.* concentration curve, a homogeneous emulsion will be formed.

Table 1 indicates the mean particle size of the emulsion prepared from the mixed surfactant solution of SDS and 8ED. In the cases of SDS concentrations of 6, 8, and 20 mmol dm^{-3}, it was found that the mean particle sizes of the emulsions were almost the same for each SDS concentration, independently of the concentration of added 8ED. However, in the

Additive concentration of SDS: 0 (—□—), 1 (—●—), 6 (—○—), 8 (—◑—), and 20 mmol dm^{-3} (—◐—).

Table 1. Mean particle size (μm) of the emulsion

8ED concn / mol dm^{-3}	SDS concn/mmol dm^{-3}			
	1	6	8	20
1×10^{-6}		9.5	8.8	9.9
1×10^{-5}	11.4	9.9	9.5	9.2
1×10^{-4}	10.1	9.5	9.1	9.2
1×10^{-3}	9.7	10.5	9.9	9.5
1×10^{-2}	8.9	10.0	9.2	9.0

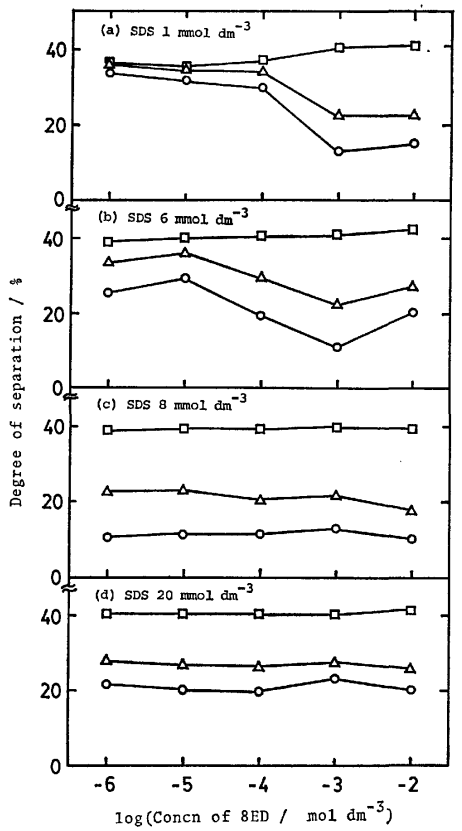

Fig. 4. (a), (b), (c), (d) Degree of separation of octane emulsion prepared by the mixed surfactant of SDS and 8ED, after 1 h (—○—), 2 h (—△—), and 24 h (—□—).

presence of 1 mmol dm^{-3} of SDS, the mean particle size of the emulsion decreased with the increasing concentration of added 8ED.

Figures 4(a), (b), (c), and (d) show the *DS* values of the emulsions prepared by the mixed surfactant solution of SDS and 8ED. At SDS concentration of 1 mmol dm^{-3} (Fig. 4(a)), the *DS* values of the emulsion after one hour began to become smaller at about 1×10^{-3} mol dm^{-3} of added 8ED. On the other hand, in the presence of 6 mmol dm^{-3} of SDS (Fig. 4(b)), in which the mixed surfactant solution gave an equi-interfacial-tension (see Fig. 3.), the *DS* value of the emulsion decreased with the increasing concentration of a mixed 8ED; the emulsion separation was smallest at 1×10^{-3} mol dm^{-3} of 8ED. In the cases of 8 and 20 mmol dm^{-3} (Figs. 4(c) and (d)), the *DS* value of the emulsion was almost constant at the respective SDS concentration, independently of the mixed 8ED concentration. In the presence of 8 mmol dm^{-3} of SDS, the smallest *DS* value in this series of the emulsion was observed after 1 h.

When an oil is emulsified by mixed surfactant solutions which have an equi-interfacial-tension, the emulsion can be expected to have a narrow distribution of emulsion particle sizes, and so the emulsion stability increases; The stability is also explained from the point of view of the properties of the adsorbed film at the oil/water interface. According to our previous data,[15] in the presence of 8 and 20 mmol dm^{-3} of SDS, the properties of the adsorbed layer of the mixed surfactant at octane/water interface are governed primarily by SDS. Thus these emulsions exhibit the same stability independent of the mixed 8ED concentration. However, in the presence of 6 mmol dm^{-3} of SDS, as the properties of the mixed adsorbed layer change from SDS-like properties to 8ED-like ones with increasing concentration of mixed 8ED, the emulsion stability may vary with the concentration of mixed 8ED.

(Received August 10, 1981)

A cubic-tetragonal phase transformation of EuC_2 was observed at 623 K. The phase transition temperatures of metal dicarbides (MC_2) were discussed in terms of the band structure proposed by previous authors. The compound EuC_2 was a ferromagnet with a zero field curie temperature of 20 K, which was close to the value expected from the Curie temperature *vs.* nearest neighbor Eu–Eu distance relation for the Eu chalcogenides. The solid solutions, $La_xEu_{1-x}C_2$, became ferromagnetic at low temperatures over the whole composition range, while the solid solutions, $Gd_xEu_{1-x}C_2$, have continuously changed the kind of magnetic order from ferromagnetic to antiferromagnetic. All the effective moments obtained for $R_xEu_{1-x}C_2$ were in good agreement with the theoretical values of Eu^{2+} and R^{3+} contained. The electrical resistivities of EuC_2 and its solid solutions had a sharp peak near the Curie temperature. When magnetic field was applied, the peak became broader and shifted to higher temperature.

Metal dicarbides (MC_2), which possess a CaC_2-type tetragonal structure at room temperature, are composed of metal ion (M^{n+}), acetylide ion (C_2^{2-}), and ($n-2$) electrons. Since the ($n-2$) electrons occupy a conduction band,[1] tervalent or quadrivalent metals form metallic dicarbides, while bivalent metals form nonmetallic dicarbides. An isostructural europium dicarbide (EuC_2), whose existence has been established by Gebelt and Eick,[2] is expected to contain bivalent europium ions (Eu^{2+}) and has a variety of interesting physical properties such as observed for Eu chalcogenides.[3] However, in contrast with the tervalent rare-earth dicarbides which have been intensively investigated, the carbide EuC_2 has received the least attention to date. In this paper, we report thermal, magnetic, and electrical properties of EuC_2 and its solid solutions, $R_xEu_{1-x}C_2$ (R=La and Gd).

Experimental

Europium carbide was synthesized by following two techniques. (1) Europium metal of 99% purity (Research Chemicals, Div. of Nucor Corp.) together with spectroscopic grade graphite (Nippon Carbon Corp.) was sealed under a vacuum (10^{-2} Pa) in a silica capsule and heated at 1000 °C for 30 h. (2) Europium oxide of 99.99% (Shin-etsu Chem. Corp.) was mixed with graphite powder in an agate mortar and then pressed into pellets at 10 kbar. The pellets were placed in a molybdenum container and heated at 1800 °C under a flow of argon for 5 h. Solid solutions, $La_xEu_{1-x}C_2$ and $Gd_xEu_{1-x}C_2$, were prepared from mixed lanthanoid oxides and graphite by heating them under the same conditions as the above method (2). The mixed oxides as starting materials were obtained as follows; europium and gadolinium (or lanthanum) trioxides (99.99% purity) were weighed and dissolved in 2 mol dm^{-3} HCl and a saturated solution of oxalic acid was added. The precipitate formed was filtered, oven-dried at 110 °C, and ignited at 900 °C. Strontium dicarbide was synthesized by the reaction of $SrCO_3$ (99.9%, Shin-etsu Chem. Corp.) and graphite at 1600 °C under an argon atmosphere. In all cases, 5 at% excess graphite was used to ensure removal of oxides. The samples obtained here were kept immersed in carbon tetrachloride or in evacuated glass capsules. All manipulations were carried out in an argon dry box in order to prevent hydrolysis.

Powder X-ray diffraction data were obtained with a Rigaku-Denki Rota-flex diffractometer by use of Ni-filtered Cu $K\alpha$ radiation and Si as an internal standard. The atomic ratios (La or Gd:Eu) in the solid solutions were determined with a Rigaku-Denki energy dispersion type X-ray fluorescent spectrograph unit, Ultra trace system. For the purpose of chemical analyses, weighed sample was hydrolyzed in 2 mol dm^{-3} HCl. After the solution was filtered to remove the free graphite, metal content in it was determined by the EDTA titration. Total carbon content was determined by elemental analysis with a Yanagimoto CHN-corder. Bound carbon content was obtained by the difference between the total and free carbon contents. These analyses gave the weight percentages of the free carbon in the range of 1—2% and a metal:bound carbon atomic ratio of 1:2 for all the carbides.

Phase transformation was examined by the method reported previously;[4] differential thermal analysis (DTA) in the range 290—1000 K. Magnetic susceptibility data were obtained with a Curie-chénevea magnetic balance (Shimadzu MB-11) equipped with a low temperature apparatus in the temperature range 4.2—300 K. The samples for magnetic measurements were mixed with apiezon grease L (Apiezon Products Ltd.) to protect them from moist air. Electrical resistivities were measured with strip samples cut from the polycrystalline sintered pellets in the range 1.5—300 K. The measurements were performed on a four-probe d.c. potentiometric technique. Thermoelectric power measurement was carried out in the range 120—300 K. A barshaped sample was held in a place between two copper blocks with Ag paste. Thermal gradient was controlled by small heaters wound on the copper blocks so as to be always less than 5 K.

Results and Discussion

X-Ray Data. Both of the europium carbides obtained by the two different methods possess the CaC_2-type body-centered tetragonal structure though they contain a second phase. This second phase, whose existence has been reported by previous authors,[2] could not be removed by annealing techniques. The lattice constants of the b.c.t. phase are in good agreement with the literature values[2] and those obtained for SrC_2 as shown in Table 1. Since Sr^{2+} in SrC_2 has the almost same ionic radius as Eu^{2+},

this result supports the assumption that all the Eu ions in EuC_2 are bivalent.

Rare-earth dicarbides, LaC_2 and EuC_2, form solid solutions ($La_xEu_{1-x}C_2$) with the b.c.t. structure. The sample of $x=0.08$ contains the same unknown phase as observed for EuC_2, while the sample of the composition range from $x=0.39$ to 0.94 are single phase of b.c.t. The lattice constants of $La_xEu_{1-x}C_2$ are summarized in Table 2.

For the solid solutions, $Gd_xEu_{1-x}C_2$, the compounds with compositions of $x=0.13$, 0.73, and 0.92 are formed with the b.c.t phase, while the compounds of $x=$ 0.40 and 0.62 have a face-centered cubic structure. The occurrence of the f.c.c. phase has been observed by previous authors[5] in the binary systems RC_2–$R'C_2$ (R=rare-earth elements). This phenomenon has been explained successfully in terms of a strain energy in the crystal which was produced by a large difference in the ionic radii of metals.[6,7] The lattice parameters of $Gd_xEu_{1-x}C_2$ are tabulated in Table 3.

The disappearance of the unidentified second phase in the mixed carbides may be in connection with the increase of the conduction electron density.

Phase Transformation. It is well known that the CaC_2-type dicarbides have a transformation from the b.c.t. phase at low temperature to the f.c.c. one at high temperature. The nature of the cubic-tetragonal phase transformation has been studied extensively for metal dicarbides (MC_2) except for EuC_2.[4–14] The data of EuC_2 which we obtained are tabulated in Table 1, compared with those obtained for SrC_2. The f.c.c. modification in EuC_2 occurs at 623 K, which is close to the value observed for SrC_2.

The phase transition temperatures (T_t) of MC_2 vary significantly from 423 K for BaC_2[8] to 2058 K for UC_2.[9] Since the transformation in MC_2 occurs through rotation of the C_2^{2-} group from the c-axis, the T_t values are expected to reflect the M–C_2 bond energy and then depend on two parameters; ionic radius of metal and the number of the conduction electrons. We plotted the T_t values of MC_2 against the ionic radii of metals,[15] $r(M^{n+})$, for coordination number six in Fig. 1. The T_t values are divided into three groups with respect to the number of con-

a) Ferromagnetic. b) Antiferromagnetic.

duction electrons and increase linearly with decreasing the ionic radius of metal, that is, with an increase in the lattice energy. The T_t *vs.* $r(M^{n+})$ plot for $M^{2+}C_2^{2-}$ indicates that EuC_2 is a member of the bivalent metal dicarbide group.

It has been proposed by Atoji[1] that excess electrons occupy the conduction band formed with the d-orbitals (d_{zx} and d_{yz}, z≡c-axis) of metal and the antibonding orbitals of C_2^{2-} and that the increase of conduction electron density causes to increase the C–C bond distance in MC_2. Since the C–C bond distances in MC_2 seem to be independent of the ionic radii of M^{n+},[16,17] their average values are listed in Table 4. Assuming that the C–C bond distances increase with increasing the M–C_2 covalent bond energy, we can expect that the increase in the T_t value has a linear relationship with the C–C bond distance. In order to discuss the T_t values under the same ionic radius of metal, the T_t values at $r(M^{n+})=0.89$ Å, which is identical with the ionic radius of U^{4+}, were estimated from the linear T_t *vs.* $r(M^{n+})$ plots in Fig. 1 and summarized in Table 4. The T_t values of MC_2 are plotted linearly against the C–C bond distances in Fig. 2 in support of the above assumption.

Magnetic Properties. Magnetization (σ) *vs.* temperature (T) curves for EuC_2 are shown at various fields in Fig. 3. Inset is the field dependence of magnetization at various temperatures. These magnetic data exhibit that EuC_2 becomes ferromagnetic at low temperature. Curie temperatures (T_c) at various fields (H) were determined by the method described in Ref. 18; extrapolation of σ^2 *vs.* T plot to $\sigma^2=0$. The zero field Curie temperature, $T_c(H\to 0)=20$ K, was obtained from the $T_c(H)$ *vs.* H plot in Fig. 6. Reciprocal magnetic susceptibility (χ_m^{-1}) *vs.* T plot obeys a Curie-Weiss law, giving an effective moment of

8.04 μ_B and a paramagnetic Curie temperature (θ_p) of +14 K. The effective moment is in good agreement with that expected for Eu^{2+}.

The exchange mechanism in EuX (X=O, S, and Se) has been studied by Kasuya.[19] They have proposed that the ferromagnetic interaction is due to the f-f interaction between Eu^{2+} nearest neighbors throughout the 5d-4f exchange interaction. Therefore, the exchange integral between Eu^{2+} nearest neighbours becomes a function of the Eu^{2+}–Eu^{2+} distance. The europium dicarbide has a nearest neighbour Eu^{2+} distance of 4.12 Å, which is very close to that of EuS, 4.21 Å. Since both the values of T_c and θ_p observed for EuC_2 are comparable to those of EuS ($T_c=16$ K, $\theta_p=19$ K), it is reasonable to assume that the exchange mechanism in EuC_2 is the same as that in EuX.

The tervalent rare-earth dicarbides (RC_2), which have one conduction electron per formulae unit, become antiferromagnetic at low temperatures.[20–22] Their magnetic properties have been discussed in terms of the f-f indirect exchange interaction *via* conduction electrons. The replacement of Eu^{2+} with La^{3+} varies two parameters, that is, the concentration of the conduction electron and the magnetic ion, while the replacement of Eu^{2+} with Gd^{3+} varies only the concentration of the conduction electron because the spin configuration of $Gd^{3+}(^8S_{7/2})$ is identical with that of Eu^{2+}. We can expect a continuous change in the exchange mechanism with changing the composition (x) in the solid solutions, $R_xEu_{1-x}C_2$ (R=La and Gd).

The magnetic data of the solid solutions, $R_xEu_{1-x}C_2$ (R=La and Gd), are tabulated in Tables 2 and 3, respectively. All the effective moments obtained from the χ_m^{-1} *vs.* T linear relation are in good agreement with the calculated values on the assumption that all the Eu ions in the compounds are bivalent. The solid solutions, $La_xEu_{1-x}C_2$, become ferromagnetic at low temperatures over the composition range from $x=0.08$ to $x=0.76$. The values of T_c(or θ_p) remain almost constant in the composition range from 0 to 0.47 and decrease rapidly with further dilution. In

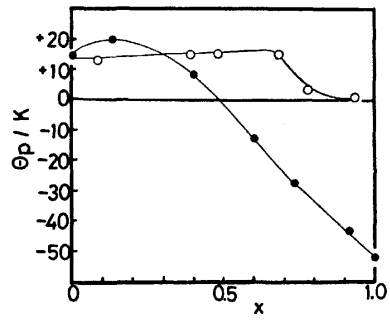

Fig. 4. Paramagnetic Curie temperature (θ_p) as a function of composition (x) for the solid solutions, $La_xEu_{1-x}C_2$ (—○—) and $Gd_xEu_{1-x}C_2$ (—●—).

the solid solutions, $Gd_xEu_{1-x}C_2$, the kind of magnetic order varies from ferromagnetic to antiferromagnetic with increasing the concentration of the Gd^{3+} ion. The composition dependence of θ_p for $R_xEu_{1-x}C_2$ (R=La and Gd) is shown in Fig. 4.

The carbides, $R_xEu_{1-x}C_2$, differ from the Eu chalcogenides such as $R_xEu_{1-x}Se$[23] in the magnetic behavior for small values of x ($x<0.1$). The compounds, $R_xEu_{1-x}Se$, have a drastic increase in θ_p and T_c for very low concentration of dopant (R=La^{3+} or Gd^{3+}) and this behavior was explained theoretically by Kasuya[24,25] in terms of the magnetic impurity model as follows. An excess electron with spin $\vec{s}_i$, which is trapped by a tervalent ion, magnetically polarizes the nearest neighbouring Eu spin, $\vec{S}_n$, by means of a strong exchange interaction between the impurity electron and the 4f electrons (the i-f exchange interaction). The large increase of T_c, ΔT_c, is deduced from the additional i-f exchange interaction, $-2\sum J_{in}\vec{s}_i\cdot\vec{S}_n$, and given by

$$k_B\Delta T_c = 2\sum J_{in}\vec{s}_i\cdot\vec{S}_n. \quad (1)$$

The Eu chalcogenides have a 6s character on the impurity state,[25] while the Eu dicarbides are expected to have a 5d character on the impurity state.[1,26] The almost constant T_c values of the solid solutions, $R_xEu_{1-x}C_2$, for the small values of x seem to be understood in the light of the small special spread of the impurity electron which would suppress the i-f exchange interaction. The magnetic behaviors of $R_xEu_{1-x}C_2$ for higher values of x resemble those of the Eu chalcogenides[23] and would be explained in terms of the change of Ruderman-Kittel function given by[27]

$$F(2k_FR) = [2k_FR\cos(2k_FR) - \sin(2k_FR)](2k_FR)^{-4}, \quad (2)$$

$$k_F = 1/r_0(9\pi z/4)^{1/3}, \quad (3)$$

where R is the distance from the magnetic ion of the reference site, k_F the Fermi wavenumber, r_0 the atomic radius, and z the number of conduction electrons.

Electrical Properties. Electrical resistivities of EuC_2 (ρ) decrease with decreasing temperature down to 160 K, and has a sharp peak at T_p=20 K as shown in Fig. 5. Inset is the ρ *vs.* T curves at various external fields (H). As the H values increase, the peak in ρ decreases, becomes broader, and shifts to higher temperature side. The T_p values exhibit the same

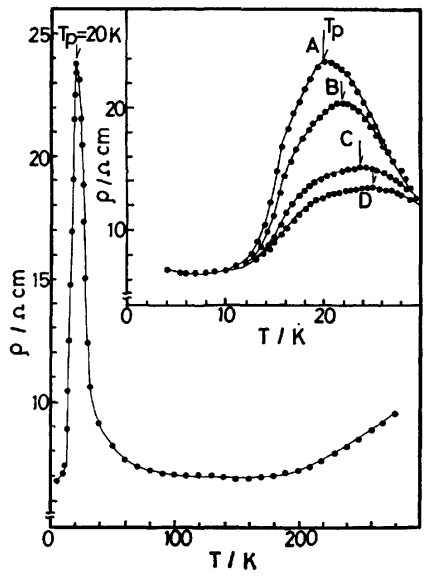

Fig. 5. Electrical resistivity (ρ) *vs.* temperature curve for EuC_2. Inset; the ρ *vs.* T curves at various fields (A: 0 kOe, B: 2.80 kOe, C: 5.60 kOe, D: 6.85 kOe).

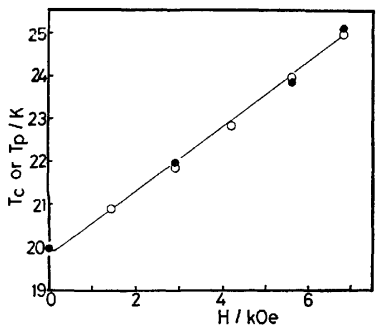

Fig. 6. Magnetic field (H) dependence of the Curie temperature (T_c, —○—) and the temperature at which the resistivity has the peak (T_p, —●—) for EuC_2.

field dependence as the Curie temperatures (Fig. 6). The temperature dependence of the thermoelectric power (S) in EuC_2 is shown in Fig. 7. The sign of the S values is negative over the whole range of temperatures, indicating electron-type conduction. The creation of the excess electron in EuC_2 may be due to the existence of anion (C_2^{2-}) vacancies in small amount.

The rapid increase in ρ near the Curie temperature was observed previously for the Eu chal-

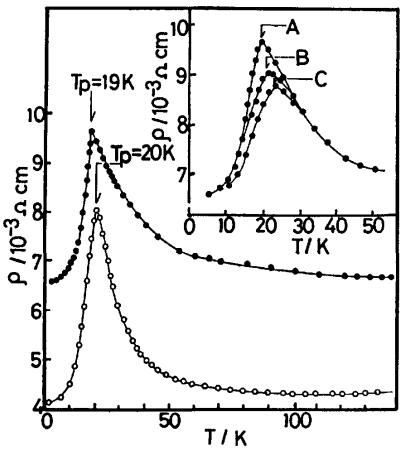

Fig. 8. Electrical resistivity (ρ) *vs.* temperature (T) curves for $La_{0.39}Eu_{0.61}C_2$ (—●—) and $Gd_{0.13}Eu_{0.87}C_2$ (—○—). Inset; the ρ *vs.* T curves at various magnetic fields (A: 0 kOe, B: 3.50 kOe, C: 6.85 kOe) for $La_{0.39}Eu_{0.61}C_2$.

cogenides.[28] Kasuya ascribed this electrical behavior to the exchange interaction between the impurity electron and the 4f electrons.[24,25] The impurity electron aligns the spins of nearest neighbour Eu^{2+} ions throughout the i-f exchange interaction, forming magnetic polarons. Therefore, the mobility of the impurity electron decreases near T_c. Since below T_c all the 4f spins are aligned and the magnetic polarons disappear, the resistivities decrease rapidly. When a magnetic field is applied, an activation energy which is necessary for hopping of the impurity electron is reduced and the peak in ρ decreases.

The electrical resistivity of $La_{0.39}Eu_{0.61}C_2$ or $Gd_{0.13}Eu_{0.87}C_2$, decreases to 1/1000 of that of EuC_2, reflecting the increase of conduction electron density (Fig. 8). A peak in ρ *vs.* T curve is similar to that observed for EuC_2 and would be explained on the basis of the same model as described above.

The Analysis of Lanthanoid-induced ^{13}C Shifts for Naphthylamines. Contact Shifts Induced by Gd-chelates and the Spin-delocalization Mechanism

Masatoshi HIRAYAMA,* Kenji AKUTSU, and Kazuko FUKUZAWA

Department of Chemistry, Faculty of Science, Ibaraki University, Bunkyo 2-1-1, Mito 310

(Received August 27, 1981)

The ^{13}C shifts of 1- and 2-naphthylamines induced by $Gd(fod)_3$ and $Gd(dpm)_3$ were shown to consist predominantly of a contact contribution, based on the fact that these shifts excellently correlate with the hyperfine coupling constants obtained from the graphical analysis of ^{13}C shifts induced by other $Ln(fod)_3$, where Ln is La, Pr, Nd, Sm, Eu, Dy, Ho, Er, or Yb. It was found from the INDO MO calculations of the spin densities of ligand moieties that these Gd-induced shifts parallel the spin-density distribution of the naphthylmethyl radical better than that of the naphthylamine cation radical and that these shifts are best interpreted in terms of the superposition of the β-spin of the naphthylmethyl radical and the α-spin of the naphthyl radical. This may suggest that a direct spin transfer occurs through space from Gd^{3+} to the amine molecule, in addition to the normal through-bond delocalization *via* the N-lone pair.

In order to employ lanthanoid-induced shifts(LIS) for the elucidation of molecular structures, particularly of the sterically detailed geometries of molecules, one must separate a purely dipolar contribution from LIS. It has been well recognized that LIS consists of three contributions: contact(cs), pseudo contact(pcs), and complex formation shifts(cfs).[1] The third term can be easily determined from the shifts induced by a La- or Lu-complex on the plausible assumption that the diamagnetic shift due to the adduct formation with a Ln-complex is equal in magnitude along the lanthanoid series. Among several methods proposed for the separation of a pcs term, there is one which can be carried out by a relatively simple procedure using the experimental shifts induced by a Gd-complex.[2] This is based on the theoretical prediction that Gd^{3+} has an isotropic g-tensor[3] and on the expectation that all the other analogous Ln-complexes cause a ligand cs-pattern identical with that due to the Gd-complex. Indeed, this method has successfully been applied to the ^{13}C shifts of several kinds of organic molecules by Ajisaka *et al.*[2] However, no more such studies have been found, probably because of the severe broadening of resonance lines caused by this ion.

The object of this report is to confirm that Gd-induced shifts are only contact in origin in actual complexes and to investigate a spin-delocalization mechanism for such complexes by means of a "relative method." Some of the results have been reported in a preliminary paper.[4] Naphthylamines were chosen because many kinds of carbons assignable to each position are included, their molecular structures are rigid, which are convenient for pcs calculations, and their chemical equilibria are well known.[5]

Experimental

1- and 2-Naphthylamines were of commercial origin (Nakarai Chemicals, Ltd). $CDCl_3$(Merck Sharp & Dohme Canada, Ltd.) was used as a solvent after having been dried over molecular sieves for 24 h. The lanthanoid shift reagents(LSR) were synthesized by the methods in the literatures[6] and were used after having been dried over P_2O_5 in a vacuum desiccator. The LSR employed in the present study are $Ln(fod)_3$,[7] where Ln is La, Pr, Nd, Sm, Eu, Gd, Dy, Ho, Er, or Yb, and $Ln(dpm)_3$,[7] where Ln is La or Gd.

The ratio of LSR(L) to the substrate (S) (ρ) was varied by the addition of well-defined amounts of LSR to a 1 M solution of 1-naphthylamine in $CDCl_3$(0.8 M in 2-naphthylamine). For each LSR, five or six ^{13}C spectra were recorded with ρ values ranging from 0 to 0.2 (0 to 0.03 for $Gd(fod)_3$ and $Gd(dpm)_3$), using TMS as the internal standard at 24 °C, on a Varian CFT-20 spectrometer. The assignments of ^{13}C lines were made by the methods in the literature.[8]

The INDO MO calculations of spin densities were carried out on HITAC 8800/8700 computers at The Computer Center of the University of Tokyo. The program used was Y4CB04[9] of the library programs collected in this center. The LISA2 program prepared by Shapiro *et al.*[10] was used for the nonlinear least-squares analysis of LIS *vs.* ρ plots.

Results and Discussion

The nonlinear least-squares analyses of ^1H-LIS *vs.* ρ plots ($0<\rho<2.5$, the number of data points is 27), carried out for 1-naphthylamine with $Eu(fod)_3$ in $CDCl_3$, indicated that this system is best interpreted in terms of two-step equilibria:

$$L + S \rightleftharpoons LS \quad K_1, \delta_{LS}, \tag{1}$$

$$LS + S \rightleftharpoons LS_2 \quad K_2, \delta_{LS_2}, \tag{2}$$

with no self-association of $Eu(fod)_3$ in solution, $L + L \rightleftharpoons L_2$, where K's, δ_{LS}, and δ_{LS_2} are the equilibrium constants and intrinsic shifts of the 1:1 and 1:2 adducts respectively. The equilibrium constants determined are $K_1=75$—95 and $K_2=1$—5,[11] implying that the second equilibrium is negligible compared with the first. Then, considering the one-step equilibrium, the observed shift, δ_{obsd}, is given by:

$$\delta_{obsd} = \frac{[LS]}{[S_0]}\delta_{LS}, \tag{3}$$

in the fast-exchange limit, where $[S_0]$ is the total concentration of the substrate. When $\rho \ll 1$ and $K_1 \cdot [S_0] \gg 2(1+\rho)$, one has $[LS]/[S_0] \approx \rho$ and Eq. 3 simplifies to:

$$\delta_{obsd} = \rho \cdot \delta_{LS}.^{12} \tag{4}$$

Actually, a good linear relation has been obtained for these ^1H-LIS *vs.* ρ plots in the range of $\rho \ll 1$.

a) Values in ppm relative to that of the free naphthylamine. Negative signs denote highfield shifts.
b) $\delta_{LS}(Gd(fod)_3)-\delta_{LS}(La(fod)_3)$. c) $\delta_{LS}(Gd(dpm)_3)-\delta_{LS}(La(dpm)_3)$.

Also, in the present ^{13}C experiments, an excellent linear relation between δ_{obsd} and ρ was obtained within the examined range of $\rho(\rho \ll 1)$. Thus, Eq. 4 can be applied to the analyses of the present ^{13}C data. The correlation coefficients(R) in this linear relation with $Gd(fod)_3$ and $Gd(dpm)_3$ were >0.998 for all the carbons except for the C_1 of 1- and the C_2 of 2-naphthylamine, for which the accuracies of measured shifts are poor because of the severe broadening of the resonance lines (>0.9). Thus, in the present system, δ_{LS} can be found from the slope of the δ_{obsd} *vs.* ρ plot. As is generally accepted, the correction of δ_{LS} for a diamagnetic shift can be made by using the $La(fod)_3$- or $La(dpm)_3$-induced δ_{LS} value, the corrected δ_{LS} being denoted as δ'_{LS} in the present paper. The δ'_{LS} values observed for 1- and 2-naphthylamines with $Gd(fod)_3$ and $Gd(dpm)_3$, $\delta'_{LS}(Gd)$, are summarized in Table 1.

In order to examine whether or not $\delta'_{LS}(Gd)$ consists solely of a cs contribution, δ_{LS} values with a series of $Ln(fod)_3$ for 1-naphthylamine were first observed; the δ'_{LS} values were obtained using the $La(fod)_3$-induced δ_{LS} value. For all the carbons with each $Ln(fod)_3$, the R-values in the δ_{obsd} *vs.* ρ plots were >0.999. These were then separated into cs and pcs contributions by the graphical method,[12,13] which has successfully been utilized in recent years: the δ'_{LS} for a given nucleus, i, $\delta'_{LS,i}$ in a lanthanoid adduct can conveniently be expressed as a sum of two terms:

$$\delta'_{LS,i} = A_i \cdot \langle S_z \rangle + G_i \cdot D, \quad (5)$$

where A_i is the hyperfine coupling constant between the nucleus and the unpaired electron, $\langle S_z \rangle$ is the projection of the lanthanoid total electron-spin magnetization in the direction of the external field, G_i is the geometric factor $(3\cos^2\theta-1)r^{-3}$, and D is a constant for a given lanthanoid and temperature. If, for this adduct, the constancy of A_i and G_i can be assumed along the series, the contributions of the two terms can readily be separated. By a rearrangement of Eq. 5, one obtains:

$$\delta'_{LS,i}/\langle S_z \rangle = A_i + G_i \cdot D/\langle S_z \rangle. \quad (6)$$

Using the tabulated values of $\langle S_z \rangle$[14] and of D,[3a] a plot of $\delta'_{LS,i}/\langle S_z \rangle$ against $D/\langle S_z \rangle$ can be constructed; the plot should be linear, with a slope of G_i and an intercept on the ordinate of A_i. However, some scattering of points may be anticipated in view of the fact that the values of D were calculated with an arbitrary set of crystal-field parameters.[3] The present data are plotted in this way in Fig. 1. It may be seen that, apart from some scattering of points, all sets of the data closely obey the linear relationship. The R-values are shown in the footnotes of Fig. 1. The data points from Sm-adducts were excluded, since these deviate considerably from the linear relation because of the great sensitivity of $\delta'_{LS}/\langle S_z \rangle$ to a small experimental error in δ'_{LS} because of the extremely small value of $\langle S_z \rangle$. Thus, it may be said that an effective axial symmetry holds in this system and that G_i and A_i are constant through out the series.

The relative A_i-values determined from Fig. 1 are compared with the relative values of $\delta'_{LS}(Gd)$ in Table 2. These two quantities correspond well with each other ($R=0.985$), considering the A_i-values determined from such plots containing theoretical quantities. Next, the addition of the relative G_i as a pcs pattern to the relative A_i was made tentatively in order to

a) Determined graphically from Fig. 1. b) Calculated geometric factors. The geometric parameters used are shown in Ref. 15. The number in parenthesis is the correlation coefficient between G_1 and GF_{calcd}.

interprete $\delta'_{LS}(Gd)$; this resulted in a further, better correlation (R=0.997), as is shown in Table 2. This effectiveness of G_i on the improvement of R may not be completely reliable, considering the effect of the use of theoretical values of D and $\langle S_z\rangle$ on the accuracies of A_i and G_i. However, as long as a relative method is used for the discussion, the possibility of the inclusion of a small amount of a dipolar contribution can not be completely excluded. On the other hand, the G_i-values have fairly well been explained in terms of the geometric factors, calculated using plausible geometric parameters,[15] as is shown in Table 3.

If the observed ^{13}C shifts are purely contact in origin, their intramolecular ratio should correspond to the spin-density distribution of the carbon 2s-orbitals of the ligand (ρ_{2s}). Therefore, the INDO MO calculations of ρ_{2s} were carried out for the cation radicals of naphthylamines, which can be expected to be a real model for the ligand moiety of lanthanoid adducts. The following standard geometries were used with 120° or tetrahedral bond angles: C–H (aromatic), 1.08 Å; C–C (aromatic), 1.40 Å; C–N, 1.37 Å. Considering the pyramidal structure of nitrogen, the angle between the N–C bond and the NH_2 plane (χ) was taken as 50°.[17] The calculated results imply that the highest occupied MO containing an electron spin is of the π-type, as anticipated. In Table 4, the calculated ρ_{2s} values of cation radicals, ρ_{2s}(Naam$^+$), are compared with the $\delta'_{LS}(Gd)$ values observed with Gd(fod)$_3$. The feature of sign alternation is almost identical in both; however, only a poor agreement

a) Relative values. The numbers in parentheses are the correlation coefficients between $\delta'_{LS}(Gd)$ and ρ_{2s} or δ_{calcd}. b) With $Gd(fod)_3$. The negative signs denote highfield shifts and thus correspond to the negative signs of ρ_{2s}. c) Relative shifts calculated using Eq. 7 from the least-squares fits of the superposition of $\rho_{2s}(Name)$ and $\rho_{2s}(Naph)$ to $\delta'_{LS}(Gd)$.

is obtained.

Horrocks *et al.*[19] and Morishima *et al.*[20] have shown that, for a variety of pyridine-type bases, the $Ni(acac)_2$-induced contact shifts parallel the spin-density distribution in the analogous hydrocarbon radical better than that for the pyridine-like cation radical. Therefore, taking into account this effect for the present system, the spin-density distributions of naphthylmethyl radicals, $\rho_{2s}(Name)$, were calculated. The distance between the ring and the CH_2 group was taken as 1.40 Å. Table 4 implies that, on going from $\rho_{2s}(Naam^+)$ to $\rho_{2s}(Name)$, the agreement with $\delta'_{LS}(Gd)$ becomes considerably better in both 1- and 2-naphthylamines. The difference between these two INDO spin-density distributions may be ascribed mainly to the changes in the σ-π interaction caused by the energy variation in each MO due to the lowering of the nuclear charge of the hetero atom. From this result, one may consider that, in the present system, the interaction between an Ln 4f-orbital and the ligand affects the valence orbital of the ligand fairly much. Thus, the cation radical perturbed in a manner analogous to the effect of lowering the nuclear charge of the hetero atom appears to be a better model for the spin-density distribution of this type of ligand in $Ln(fod)_3$- or $Ln(dpm)_3$-adducts.[21] Comparisons of $\delta'_{LS}(Gd)$ and $\rho_{2s}(Name)$ indicate that a β-spin is delocalized into the ligand π-orbital from Gd^{3+}; this seems to be consistent with the minus sign of $\langle S_z \rangle$ calculated for this ion by Golding *et al.*[14]

Although the feature of sign alternation is completely identical in $\delta'_{LS}(Gd)$ and $\rho_{2s}(Name)$, it is found that an anomalous component of shifts is included in the shifts of carbons bound to the NH_2 group and of its neighbours: considerably large lowfield shifts at C_1 and small highfield shifts at C_2 and C_9 for 1-naphthylamine, and considerably large lowfield shifts at C_2 and small highfield shifts at C_1 and C_3 for 2-naphthylamine. Although an attempt was made to reproduce $\delta'_{LS}(Gd)$ by the superposition of a relative pcs on $\rho_{2s}(Name)$, this was unsuccessful. It is then considered that a second contribution to $\delta'_{LS}(Gd)$ may be required as a cs occurring through another pathway of an electron spin. Taking into account the mixed delocalization, the addition of the spin-density distribution of the lowest vacant MO (ρ_{2s} of the naphthylamine anion radicals) to $\rho_{2s}(Name)$ was tentatively made; however, this was also unsuccessful. From the comparison of $\delta'_{LS}(Gd)$ and $\rho_{2s}(Name)$ in Table 4, one may consider that the distribution of such an anomalous component of shifts is very similar to that expected from a σ-type delocalization of the positive spin placed on C_1 for 1- and on C_2 for 2-naphthylamine into the ring. Naphthyl radicals may thus be expected to have a required spin-density distribution. Then, the relative spin-density distribution of this radical($\rho_{2s}(Naph)$) was added to $\rho_{2s}(Name)$ to obtain the least-squared values in Eq. 7:

$$\delta_{calcd} = X \cdot \rho_{2s}(Name) + Y \cdot \rho_{2s}(Naph), \quad (7)$$

where X and Y are constants. This examination led to a further, better agreement with the $\delta'_{LS}(Gd)$-pattern in both 1- and 2-naphthylamines, as may be

Table 5. Correlation coefficients between δ'_{LS}(Gd) and the relative shifts predicted tentatively

	1-Naphthylamine		2-Naphthylamine	
	fod	dpm	fod	dpm
A_1 only	0.985	0.982	—	—
A_1+G_1	0.997	0.992	—	—
ρ_{2s}(Naam$^+$) only	0.611	0.673	0.583	0.553
ρ_{2s}(Naam$^+$)+ ρ_{2s}(Naph)	0.913	0.898	0.920	0.926
ρ_{2s}(Name) only	0.937	0.970	0.925	0.893
ρ_{2s}(Name)+ ρ_{2s}(Naph)	0.987	0.982	0.990	0.984
ρ_{2s}(Naam$^+$)$+G_1$	0.690	0.711	0.636	0.465
ρ_{2s}(Name)$+G_1$	0.972	0.985	0.940	0.917

seen from Table 4. The correlation coefficients are summarized in Table 5, together with those for the other cases with Gd(fod)$_3$ and Gd(dpm)$_3$. This result may correspond to the delocalization of a significant amount of α-spin into the ligand, in contrast to a β-spin of ρ_{2s}(Name); thus, it may suggest that a through-space transfer of spin occurs from Gd^{3+} to the ligand.

Pattern Formation by Rhythmic Crystallization of Methyl Mesitylcarbamate

Kazutoshi Iwamoto, Shun-ichi Mitomo, Jun-ichi Fukide, Tadashi Shigemoto, and Manabu Senō*

Institute of Industrial Science, The University of Tokyo, Minato-ku, Tokyo 106

(Received August 27, 1981)

Rhythmic crystallization behavior of methyl mesitylcarbamate from chloroform solutions under appropriate conditions was found. Effects of temperature, evaporation rate of solvent, and sample weight per area on this behavior are studied in detail, and the qualitative explanation based on the autocatalytic branching process is proposed.

It has been demonstrated that some chemical systems far from equilibrium occasionally show regular changes of the concentrations of intermediate species in space or time during the reactions.[1] The well-known example is the Belousov-Zhabotinskii reaction,[2,3] where malonic acid is oxidized by bromate in the presence of cerium (or iron, manganese) ions. When the reaction is carried out in a well-stirred homogeneous medium, sustained oscillations in concentrations of intermediate chemicals appear spontaneously. On the other hand, when the same reaction is carried out in a thin layer, pattern of developing spiral bands appears.[4]

As a similar example of the periodic spatial structures,[5] the Liesegang rings are well-known since long ago. When crystalline $AgNO_3$ is placed in a thin layer of swollen gelatin gel containing K_2CrO_4, after several days concentric rings of Ag_2CrO_4 crystals are formed around the original $AgNO_3$ crystal. Recently, Feinn *et al.* proposed a model of coupled autocatalytic coagulation and diffusion for explanation of this ring formation.[6,7]

We found occurrence of the rhythmic crystallization on a glass wall of an eggplant type flask, when methyl mesitylcarbamate was crystallized from its chloroform solution in a rotary evaporator equipped with a water-jet pump. A typical example is shown in Fig. 1.

The similar crystallization phenomena of the other substances in the thin films of concentrated solutions or molten substances were sometimes noticed. Miers reported rhythmic crystallization of potassium dichromate from its aqueous solution.[8] The explanation for rhythmic crystallization given by Miers is as follows: the first precipitation ring is formed by inoculation in a labile, supersaturated solution. The precipitates grows so rapidly that the concentration of the solution in an immediate neighborhood decreases within its solubility limit and then the crystallization ceases: in the meantime the next ring of solution becomes labile by vaporization or cooling and induces the next rapid crystallization. Such an explanation seems to meet one aspect of the rhythmic crystallization but more detailed explanation is needed to make clear total mechanism of the rhythmic crystallization. For instances, it should be clarified what switching mechanism is working to produce such periodic patterns.[9] Moreover, it is important to reveal the autocatalytic process involved, if it exists, because an autocatalytic process is always necessary for the appearance of some peculiar behaviors like chemical oscillations or other periodic phenomena according to the recent knowledge on the dissipative structure formation.[10]

In this paper, we wish to report a result of detailed observation of the rhythmic crystallization behavior of methyl mesitylcarbamate following after evaporation of its chloroform solution and to propose a tentative mechanism of the pattern formation involving the autocatalytic process. These investigations serve to systematic understanding of rhythmic crystallization as a typical example of pattern formation in nature.

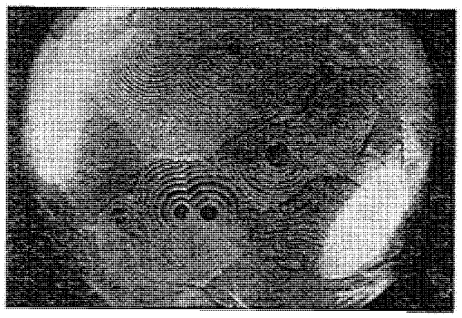

Fig. 1. Typical crystal pattern of methyl mesitylcarbamate from chloroform solution in a 50 cm^3 eggplant type flask.
A rotary evaporator equipped with a water-jet pump was used. Sample weight and bath temperature are about 100 mg and 40 °C, respectively.

Experimental

Materials. Methyl mesitylcarbamate was prepared by the reaction between methanol and mesityl isocyanate, which was produced by thermal rearrangement of mesitonitrile oxide,[11] in xylene at its reflux temperature. Recrystallization of the precipitates from methanol–water solutions yields colorless needle-like crystals. This compound was purified twice by recrystallization. Chloroform was purified with a standard procedure[12] before use.

Procedures. Schematic feature of the apparatus used for observation of crystallization behaviors is shown in Fig. 2. A 0.5 cm^3 portion of a chloroform solution of methyl mesitylcarbamate was put into a watch glass (6 cm in inner diameter and 1 cm in height) settled in a temperature-controlled bath of ethylene glycol. The watch glass was surrounded by a cylindrical polyethylene wall, of which the diameter is fixed to be 7.5 cm and the height is varied from 3 cm to 50 cm in order to control evaporation rate of chloroform. The watch glasses were specially ordered to polish smoothly their inside walls. The temperature of the meas-

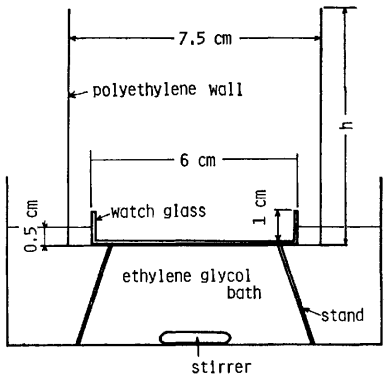

Fig. 2. Schematic feature of measuring apparatus.

uring room was kept constant at about 24±1 °C. Measurements were carried out under the conditions changing the following items: (a) the height of polyethylene wall (the vaporization rate of solvent), (b) the sample weight per area (weight density), and (c) the temperature of bath. All the results were recorded by photographs.

Results

Effect of Wall Height (Vaporization Rate). Each of 0.5 cm^3 chloroform solution containing 60.5 mg (2.14 mg/cm^2) of methyl mesitylcarbamate was put into a watch glass in the temperature-controlled ethylene glycol bath at 39.5 °C, and the rhythmic crystallization behaviors were investigated for various heights of the polyethylene wall. The results are shown in Fig. 3. The evaporation rate of chloroform from the solution decreases with an increase of polyethylene wall height. When the wall height h is 3 cm, the rhythmic crystallization does not appear, and when h is 5 cm, large and small rhythmic patterns appear simultaneously. In the range of h from 6 to 9 cm, we can see clear rhythmic crystallizations and, as h increases higher than 10 cm, the rhythmic patterns become obscure, although the local faint patterns can be observed even at h=50 cm.

Effect of Sample Weight Density. The bath temperature and the wall height are fixed to be 39.5 °C and 7 cm, respectively. Various amounts of methyl mesitylcarbamate were dissolved into 0.5 cm^3 of chloroform and these solutions were put into respective watch glasses. The results are shown in Fig. 4. The rhythmic crystallizations do not appear, when the sample weight density is 0.71 mg/cm^2 or less, but when the weight density is larger than 0.71 mg/cm^2, the rhythmic crystallizations appear in rather wide range of weight density; the clearest pattern is observed at the weight density of 2.14 mg/cm^2.

Effect of Bath Temperature. A 0.5 cm^3 chloroform solution containing 60.5 mg (2.14 mg/cm^2) of methyl mesitylcarbamate was put into a watch glass surrounded by a polyethylene wall of 7 cm in height and the rhythmic crystallization behaviors were investigated at various bath temperatures. The results are shown in Fig. 5. When the bath temperatures are 29.5 and 39.5 °C, the rhythmic crystallizations are clearly observed, but when the bath temperature is 21.0 °C, they disappear completely. When the temperature is 49.5 °C or higher, the rhythmic crystallizations become obscure and only vague periodicity is observed.

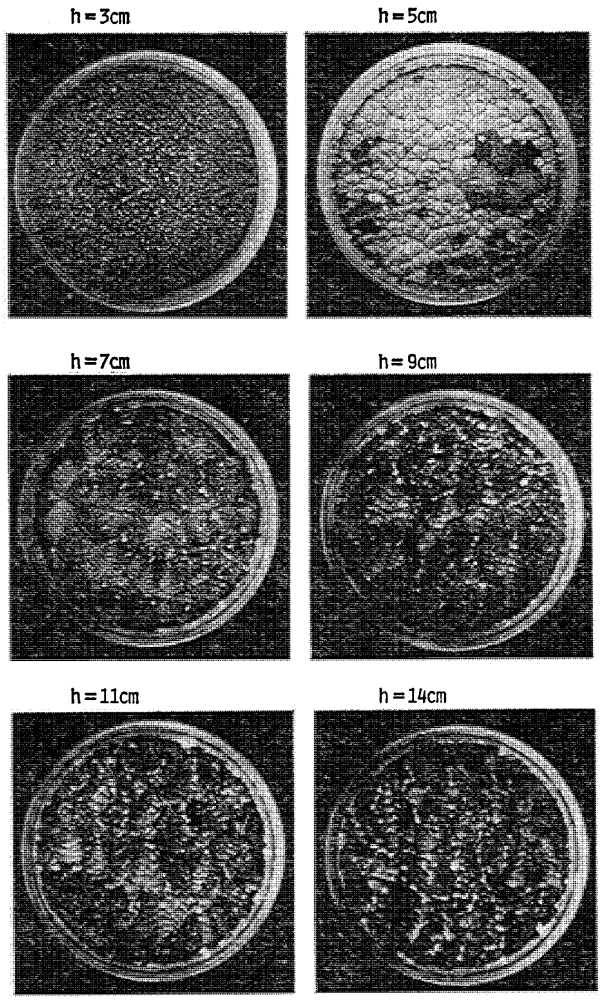

Fig. 3. Effect of polyethylene wall height on the rhythmic crystallization.
Sample weight density and bath temperature are 2.14 mg/cm^2 and 39.5 °C, respectively.

Discussion

The studies of effects of the bath temperature, the sample weight density, and the wall height on the rhythmic pattern formation imply that coupling of the solvent evaporation process with the crystallization process plays an essential role for the phenomena. In order to confirm the steady coupling effect, the following experiment was done: while methyl mesitylcarbamate was rhythmically crystallizing, the atmosphere inside the wall was exchanged by fresh air; by this procedure the evaporation of chloroform increased suddenly. The experimental result is shown in Fig. 6, which shows sudden stop of pattern formation. That is, the increase of evaporation rate of solvent extinguishes the rhythmic crystallization. This result supports our idea.

According to the Mier's explanation,[8] the solvent evaporation leads to formation of a supersaturated solution. As it is labile state, once nucleation occurs

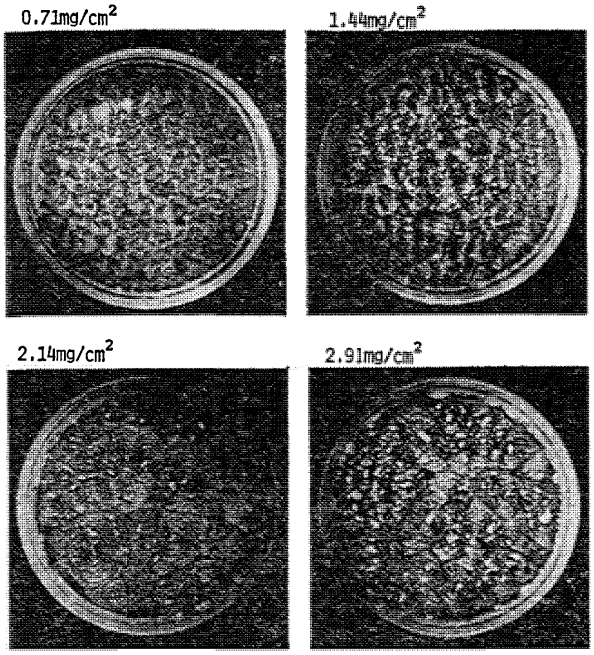

Fig. 4. Effect of sample weight density on the rhythmic crystallization.
Wall height and bath temperature are 7 cm and 39.5 °C, respectively.

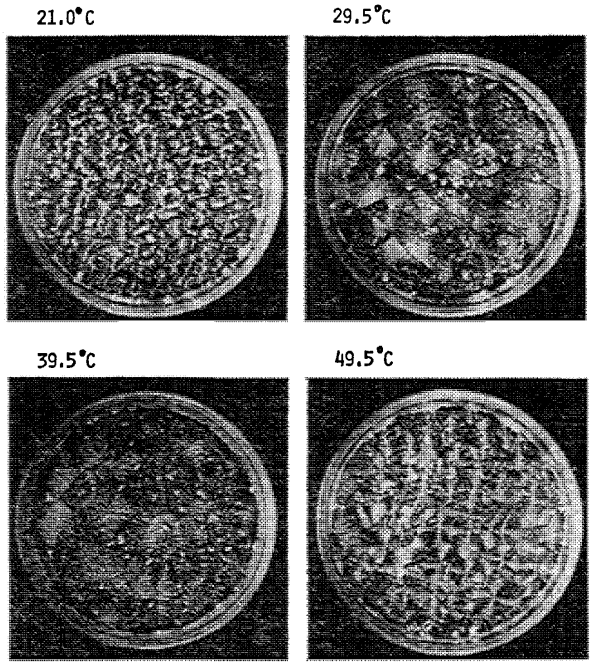

Fig. 5. Effect of temperature on the rhythmic crystallization.
Sample weight density and wall height are 2.14 mg/cm² and 7 cm, respectively.

somewhere, it is followed by a rapid crystal growth. The crystallization process reduces the solute concentration in front of crystals, and slows down until the evaporation process of solvent produces again a new supersaturated state. Repetition of these processes produces the rhythmic crystallization.

Detailed observation of periodic precipitate zones of methyl mesitylcarbamate clarified that two neighboring zones are clearly distinguishable and they are formed alternately. In order to explain completely the precipitate pattern formation, the mechanism of alternating from one zone to another zone should be made clear.

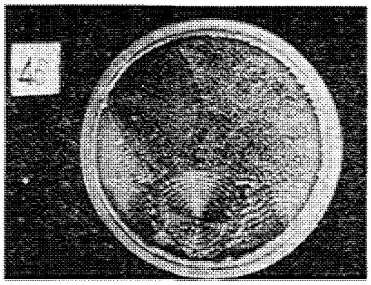

Fig. 6. Effect of sudden change in evaporation rate of chloroform on the rhythmic crystallization.
Sample weight density and wall height are 2.14 mg/cm² and 7 cm, respectively. When the atmosphere inside the wall was exchanged by fresh air, the rhythmic crystallization ceases.

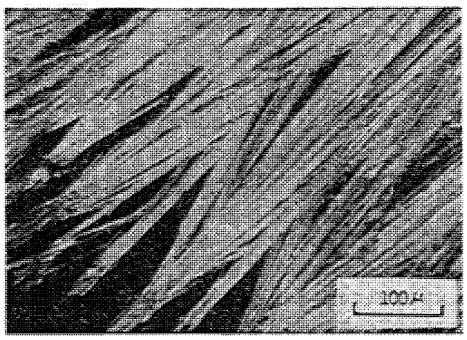

Fig. 7. Feature of crystals near the roots of crystal zone.
Branching and growing of needle-like crystals are clearly observed.

In Fig. 7, the detailed microscopic feature of crystals formed during the rhythmic crystallization is shown. The crossed polaroids were used for the observation with a microscope. The black parts indicate no existence of crystals. The crystals begin to grow from several roots, being followed by repetition of branching to form bundles of needle-like crystals. The branching process is an autocatalytic process, because branching continues to produce new sites for branching. On this account, the number of branches increases nonlinearly as crystallization proceeds. Such an autocatalytic irreversible process may produce a periodic change of crystallization rate, which is recognized as a periodic pattern.

We presume that the number of branches N in every zone is given by

$$\frac{dN}{dx} = f(C, T)N, \tag{1}$$

where $f(C, T)$ represents the number of branches produced per unit length from one branch at the concentration C in the front of crystals and the temperature T, and x is the distance measured from the root of each crystal zone.

The advancing rate of the front at crystal zone

is about a few millimeters per second and it is large compared to the diffusion rate of solute in a liquid phase. Therefore, the front boundary contacts always with a fresh liquid; the concentration of solution at the front of crystals is not practically affected by the crystallization process. This supposition is different from the Mier's view. According to this view, the function $f(C, T)$ is independent of x, and the solution of Eq. 1 is given by

$$N = N_0 e^{fx} \tag{2}$$

at a given temperature, where N_0 is the initial number at $x=0$.

As mentioned already, the crystallization rate is large compared to the diffusion rate and, therefore, we could presume that the total amount w of the substance in a unit volume of crystal zone is constant and expressed by

$$w = \rho N \pi r^2, \tag{3}$$

where N is the number of branches per unit area, r is the radius of each branch, and ρ is the density of crystal. As w is independent of x, the radius r decreases with an increase in N. When N becomes indefinitely large and r becomes indefinitely small, the crystallization rate increases drastically and the solute concentration in the front of the crystal zone reduces remarkably and the diffusion is too slow to compensate this reduction. At this point, the crystallization process ceases. After then, the solution in the vicinity of crystal zone is concentrated by vaporization and the crystallization starts again at some points.

We investigated some specific behaviors of the rhythmic crystallization of methyl mesitylcarbamate and proposed a tentative explanation for it. The explanation is somewhat awkward and a detailed and mathematically elegant treatment is needed. For this purpose, the treatment of Haase *et al.*[9] for the oscillatory zoning in plagioclase feldspar is very suggestive.

We would like to thank Professor D. H. Everett of the University of Bristol for valuable and stimulating discussions.

Protolytic Kinetics of Some Pyridine Derivatives in Non-buffered Aqueous Solution

Isao Ando, Kikujiro Ujimoto, and Hirondo Kurihara*

Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma 11, Nishi-ku, Fukuoka 814-01

(Received August 31, 1981)

The deprotonation rates of the conjugate acids of 2,2′-bipyridine and pyridine, and the protonation rates of 2-aminopyridine and 4-aminopyridine were measured in non-buffered aqueous solution by means of a stopped-flow pH jump method. These pyridine derivatives showed quite slow protolytic behavior, similar to that of 1,10-phenanthroline and cyclopentadienes: the deprotonation rate constants of conjugate acids of 2,2′-bipyridine and pyridine are $(4.8\pm0.7)\times10^{-1}$ and $(6.0\pm2.2)\times10^{-2}$ s^{-1}, respectively. The deprotonation rates of barbituric acid and acetylcyclopentadiene as authentic samples were also measured. Their deprotonation rate constants are in good agreement with the literature values, this demonstrates the validity and the applicability of the stopped-flow pH jump method. This method is superior to the NMR method for the determination of the protontransfer rates of azaaromatic compounds.

It is well known that a proton transfer plays an important role in the reactions in aqueous solution such as complex formation, acid and base catalyses, and enzymatic reaction. In order to clarify the reaction mechanism in aqueous solution, it is necessary to evaluate accurately the contribution of the proton transfer process involved in the reaction. So far the proton transfer reactions of a wide variety of compounds have been kinetically studied by many investigators.[1-13] It was reported that the proton transfer reactions of nitrogen acids and oxygen acids are very fast and their protonation reactions are diffusion-controlled, whereas carbon acids and β-diketones undergo quite slow protolytic reactions.

Previously, we examined the proton transfer reactions of 1,10-phenanthroline, 2-aminopyridine, and 3-aminopyridine by means of a stopped-flow pH jump method, and found that the conjugate acids of these azaaromatic compounds undergo slow deprotonation reactions.[14] So far as we know, these are the first nitrogen acids displaying a slow deprotonation reaction. In order to further investigate the proton transfer reaction of nitrogen acids, in this study the proton transfer rates of 2,2′-bipyridine, pyridine, 2-aminopyridine, and 4-aminopyridine were measured in non-buffered aqueous solution, by means of a stopped-flow pH jump method. The reliability of this method for determining proton transfer rates was also tested by the use of authentic samples with known rate constants.

Experimental

Materials. 2,2′-Bipyridine (bpy), pyridine (py), and 2-aminopyridine (2-ampy) were purchased from Wako Pure Chemical Industries, Ltd., and 4-aminopyridine (4-ampy) and barbituric acid from Nakarai Chemicals, Ltd. Sodium acetylcyclopentadienide (Na-accp) was synthesized from cyclopentadiene according to the method described in the literature[15] and stored under an atmosphere of nitrogen. All other chemicals were of guaranteed grade and used without further purification.

The stock solution of each compound was prepared by dissolving a weighed amount of it in deionized, distilled water. The solution of Na-accp was freshly prepared before each measurement.

pK_a *Measurements.* pK_a values of the conjugate acids of py, 4-ampy, and accp were determined spectrophotometrically by the use of a JASCO Uvidec-2 digital spectrophotometer equipped with a water-jacketed cell holder, as described in the previous paper.[14] The measurements were carried out at 25 °C in the cases of py and 4-ampy and at 30 °C in the case of accp. The ionic strengths of py and 4-ampy solutions were adjusted to 0.20 mol dm^{-3} and that of accp to 0.50 mol dm^{-3} with sodium chloride. The wavelengths employed to determine the concentration ratios of the deprotonated to the protonated species in the sample solutions at various pH values were 256 nm for py, 263 nm for 4-ampy, and 314 nm for accp. The absorbance of accp solution at the time immediately after preparation was used in order to rule out any effects due to decomposition.

Kinetic Measurements. The rates of deprotonation and protonation reactions were measured by the use of a Union RA-1300 stopped-flow spectrophotometer by the following pH jump method. For measuring the deprotonation rate, the pH of a sample solution was adjusted with hydrochloric acid or perchloric acid to values lower than pK_a value of the conjugate acid of the sample. For determining the protonation rate, the pH of the solution was adjusted with sodium hydroxide solution to values higher than the pK_a value. As a perturbing solution, which causes a perturbation of the acid dissociation equilibrium of the sample solution owing to a pH jump up or down by mixing, we used a sodium hydroxide solution or hydrochloric acid at the concentration appropriate for pH jumps smaller than about one pH unit. The ionic strengths of the solutions were adjusted to 0.20 mol dm^{-3} with sodium chloride or sodium perchlorate.

Equal volumes of the sample solution and the perturbing solution were mixed rapidly by a pressure drive device. The changes in absorbances of the mixture were followed at the wavelengths of 300, 256, 302, 263, 257, and 314 nm for bpy, py, 2-ampy, 4-ampy, barbituric acid, and accp, respectively, and were stored in a high speed memory unit and displayed on an X-Y recorder as a function of time. The kinetic measurements using basic solutions were carried out under an atmosphere of purified nitrogen.

Each rate constant for deprotonation and protonation reactions was obtained from fifteen or twenty kinetic runs. The calculation of rate constants was performed by the use of a Hewlett-Packard HP9825A/S desktop computer according to the method reported previously.[14]

The deprotonation rates of barbituric acid and accp were

also measured in non-buffered systems under the same experimental conditions as in the literature.[7,21]

Results and Discussion

Buffers used to keep the pH of a system constant after pH jumping occasionally accelerate the rate of proton transfer in a striking manner. Therefore, the application of the stopped-flow pH jump technique to rate determinations in buffered solutions is rather limited. Recently, we have shown that in non-buffered systems the stopped-flow pH jump method is applicable for the determination of the rate constants for the proton transfer reactions of weak acids.[14] Thus, we utilized the same method for measuring the proton transfer rates of py, bpy, 2-ampy, and 4-ampy in this investigation.

The spectra of the protonated and the deprotonated species of the present azaaromatic compounds were essentially the same as those in the literature.[16-20] Figure 1 shows a typical example of the spectral change of bpy caused by pH jumping, measured by a rapid scanning technique. The comparison between the spectra of the protonated and the deprotonated species revealed that the proton transfer process can be followed spectrophotometrically by the pH jump method.

As in the case of the previous study,[14] the apparent first-order rate constants observed for deprotonation reactions of the present samples, k_{dpo}, were dependent on hydroxide ion concentration, and the apparent second-order rate constants observed for protonation reactions, k_{po}, were dependent on hydrogen ion concentration. This indicates that the proton transfers of the present compounds also proceed in the following reaction scheme:[14]

$$HL^+ \underset{k_p}{\overset{k_{dp}}{\rightleftharpoons}} L + H^+, \quad (1)$$

$$HL^+ + OH^- \underset{k_{H_2O}}{\overset{k_{OH}}{\rightleftharpoons}} L + H_2O, \quad (2)$$

where HL^+ and L are the protonated and the deprotonated species of the sample. The k_{dp} and k_p denote the rate constants for the deprotonation of HL^+ and for the protonation of L, respectively, and k_{OH} and k_{H_2O} those for the protolysis of HL^+ with OH^- and for the hydrolysis of L, respectively.

Since k_{dpo} and k_{po} are defined as

$$-d[HL^+]/dt = k_{dpo}[HL^+] - k_{po}[L][H^+], \quad (3)$$

their values at reaction time zero, $(k_{dpo})_0$ and $(k_{po})_0$, can be expressed as functions of $[H^+]_0$ and $[OH^-]_0$ in the following equation:

$$(k_{dpo})_0 = k_{dp} + k_{OH}[OH^-]_0, \quad (4)$$

$$(k_{po})_0 = k_p + k_{H_2O}([H_2O]/[H^+]_0), \quad (5)$$

where $[H^+]_0$ and $[OH^-]_0$ denote the concentrations of hydrogen and hydroxide ions at reaction time zero in the mixture of the sample and the perturbing solutions. For obtaining k_{dpo}, k_{po}, $[H^+]$ and $[OH^-]$ at any reaction time, the change in pH of the mixed solution caused by the proton transfer of sample was evaluated from the absorbance change of HL^+, presuming that the ionic product of water holds constant at any time of the reaction.

The plot of $(k_{dpo})_0$ against $[OH^-]_0$ and the plot of $(k_{po})_0$ against $[H_2O]/[H^+]_0$ yielded straight lines, as shown in Figs. 2 and 3 for py and 2-ampy, respectively. The values of k_{dp} and k_{OH} (or k_p and k_{H_2O}) were obtained from the intercept and the slope of the linear regression line given in Fig. 2 (or Fig. 3).

a) Values are shown together with the 0.95 confidence intervals. b) The value was taken from Ref. 21. c) The value was taken from L. G. Sillen and A. E. Martell, The Chem. Soc., Spec. Publ., No. 17 (1964). d) The values were taken from Ref. 14.

Table 1 summarizes pK_a and the rate constants for the azaaromatic compounds obtained in this study and in the previous paper,[14] together with those for barbituric acid and accp employed as authentic samples. The k_{dp} values of the authentic samples in non-buffered systems were in good agreement with the reported values, 10 s^{-1} for barbituric acid[1,21] and 2.5×10^{-3} s^{-1} for accp.[7] The k_{OH} value of accp also agreed well with that observed by Okuyama *et al.*[7] in buffered systems (2.0×10^2 $mol^{-1}\,dm^3\,s^{-1}$). This fact adds a strong support to the validity of the present method for the determination of the rate constants of the proton transfer in non-buffered systems. Thus, the present study has again demonstrated that the rates of the deprotonation reactions of the conjugate acids of the azaaromatic compounds are slow and comparable to those of carbon acids.

The rate constants of the deprotonation, k_{dp} and k_{OH}, for the present azaaromatic compounds decrease with increasing basicity, while those of protonation, k_p and k_{H_2O}, increase with the increasing basicity. The correlations of the logarithms of k_{dp} and k_{OH} with pK_a for the azaaromatic compounds are shown in Fig. 4. Figure 4 also includes the correlations for cyclopentadienes (kinetic data obtained by a stopped-flow method),[7] alkylamines[22-24] and methyl-substituted pyridines[25,26] (by NMR method) for comparison. The log k_{dp} *vs.* pK_a plot for the azaaromatic compounds gives a straight line with a slope of −0.93, while the plot for the cyclopentadienes forms a straight line with a slope of −0.33. The log k_{OH} *vs.* pK_a plots of these two groups also give straight lines, but their slopes are different from each other. These facts imply that the azaaromatic compounds and the cyclopentadienes differ in proton transfer mechanism, though the rate constants for both groups are similar. The slow protolytic reaction of carbon acids including cyclopentadienes has been attributable to the following factors:[4] (i) the electronic and the structural reorganizations on going from the acid to its conjugate base, (ii) the small hydrogen-bonding ability with solvent and (iii) the accompanying reorientation of solvation. Okuyama *et al.*[7] proposed that the nuclear reorganization of carbon is the main factor retarding

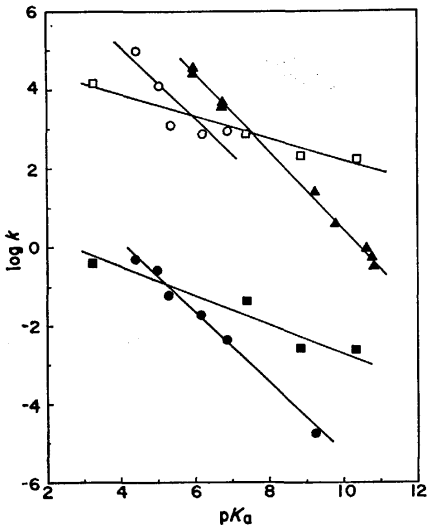

Fig. 4. The correlations between logarithms of the rate constants and pK_a for the azaaromatic compounds in this study (●, ○), the cyclopentadienes (■, □), and the alkylamines and the methyl-substituted pyridines (▲). Solid symbols are the k_{dp} plots and open symbols are the k_{OH} plots.

the proton transfer of cyclopentadienes. On the other hand, we can not explain at present the reason for the slow deprotonation reaction of the azaaromatic compounds.

It is noteworthy that the k_{dp} values determined by the NMR method for the alkylamines and the methyl-substituted pyridines are higher by several orders of magnitude than those for the azaaromatic compounds and the cyclopentadienes. Although the k_{dp} values for the aminopyridines are lower by a factor of 10^7 than those for the methylpyridines, as shown in Fig. 4, it is unlikely that there is such a significant difference in the mechanism of their protolytic reactions. In fact, our preliminary experiment for the deprotonation reaction of 2-methylpyridinium ion showed that the k_{dp} is about 10^{-2} s^{-1}, comparable to the k_{dp} values of the aminopyridines.[27] Accordingly, the fact that the k_{dp} values for the azaaromatic compounds greatly differ from those for the alkylamines

and the methylpyridines may be attributed to the difference in the experimental conditions used for rate-determination. In the present study, the rates were determined in dilute azaaromatic solutions (10^{-5}—10^{-4} mol dm^{-3}) at moderate pH. On the other hand, the rates for the alkylamines and the methylpyridines were determined by means of the NMR method in highly concentrated solutions (more than 0.02 mol dm^{-3}) at higher acidity. It has been reported that in concentrated solution two or more molecules of 1,10-phenanthroline form a stacking compound which can take one proton in acidic solution.[28,29] Though there is no evidence for stacking in the cases of pyridine derivatives, the difference in the concentration of solutes may alter the observed protolytic phenomena. Furthermore, the deprotonation rates determined by NMR method may include the contribution from the proton exchange between R_3N and R_3NH^+ in the crowded state.

Thus, we may conclude that the deprotonation reaction of the conjugate acids of azaaromatic compounds may depend upon the concentration. We believe that the stopped-flow pH jump method is superior to the NMR method for the rate determination, since NMR measurements are usually carried out in highly concentrated solutions in which some intermolecular interactions might affect the rate of the reaction.

The authors are sincerely grateful to Professor S. Kida of Kyushu University for his many useful suggestions and encouragement during this work.

Highly Aggregated State of the Dye with the Detergent in the Premicellar Region as Revealed by Resonance Raman Spectra

Masaaki KATSUMATA, Kazuo KASATANI, Masahiro KAWASAKI, and Hiroyasu SATO*

Chemistry Department of Resources, Faculty of Engineering, Mie University, Tsu 514

(Received September 3, 1981)

Resonance Raman spectra of 3,3′-diethylthiacarbocyanine iodide–sodium dodecyl sulfate (SDS) system are characterized by [SDS]-dependent change of band intensities. The change was much larger than that accompanied with the shift of monomer-dimer equilibrium in the aqueous solution. The spectra for [SDS]≪critical micelle concentration (cmc) resemble that of the dye in the solid state, indicating the highly-aggregated state of the dye caused by the interaction with the detergent.

The dye-detergent systems are currently attracting considerable interest from several viewpoints, *e.g.*, highly enhanced energy transfer between the dyes in these systems making these as good model membrane systems of chloroplasts,[1–6] and the study of photophysical processes of the dye in micelles in relation to the improvement of lasing properties of dyes.[7–8]

The presence of peculiar interaction between the dye and detergent carrying the opposite charge has long been known by the color change of the dye which is dependent on the concentration of the detergent (metachromasy).[9] Some investigations have been made on this phenomenon by absorption and fluorescence spectra,[10–12] and also by conductivity measurements.[12] Recently, the fluorescence decay studies provide very efficient means to clarify the nature of the dye-detergent interaction.[2,13–14] All of these investigations indicate the formation of some dye-detergent aggregate *below* the critical micelle concentration (cmc), *i.e.*, in the *premicellar* region.

In this paper, the resonance Raman spectra of 3,3′-diethylthiacarbocyanine iodide (DTC), a cationic dye, was studied in the presence of sodium dodecyl sulfate (SDS), an anionic detergent, to elucidate the nature of change dependent on the concentration of SDS (abbreviated as [SDS]) in the aggregation state of DTC, especially in the premicellar region. The interaction of DTC with SDS was discussed in comparison with its interaction with polyethylene glycol mono-[*p*-(1,1,3,3-tetramethylbutyl)phenyl] ether (PGME), a nonionic detergent, with hexadecyltrimethylammonium bromide (HTAB), a cationic detergent, and with potassium poly(vinyl sulfate) (PVSK), an anionic polyelectrolyte.

Experimental

Laser-grade DTC ("Dotite" reagent from Dojindo), protein-research grade SDS (Nakarai Chemicals), liquid-scintillation grade PGME (Nakarai), G. R. grade HTAB (Nakarai), and PVSK (Wako) were used as received. Water was distilled twice. Spectrograde methanol was used without further purification.

Raman spectra were recorded using a JASCO CT-80D double monochromator and a Hamamatsu R-649/C-1050 photomultiplier-photon counting unit. The excitation lines at 457.9 nm, 465.8 nm, 472.7 nm, 476.5 nm, and 488.0 nm were obtained from a Spectra-Physics model 164 Ar^+ laser. Since some color change was observed for DTC–SDS solutions after mixing, the solutions were kept in the dark until the color change became undetectable (more than 30 min). A flow-cell composed of a 2.5 mm i.d. glass tube was used in the measurements to avoid the degradation of the dye by the continued irradiation. Solid samples were measured as spinning KBr discs.

Absorption and fluorescence spectra were recorded on a Shimadzu UV-200 recording spectrophotometer and on a Hitachi 650-10S fluorescence spectrophotometer, respectively.

The cmc of SDS was determined conductometrically to be 7.4±0.1 mM (at 25±0.1 °C).†

Results

DTC–SDS Solutions. Some of the Raman spectra of DTC–SDS solutions are shown in Fig. 1, together with that of the aqueous solution. The concentration of the dye is 1.0×10^{-5} M. The excitation wavelength is 488.0 nm. The spectra changed with [SDS]. The spectrum at [SDS]≪cmc[15] has a large difference from that of the aqueous solution. The difference decreased with [SDS], and the spectrum above cmc was again similar to that of aqueous solution. While the positions (in cm^{-1}) of Raman bands did not show appreciable shift, their relative inten-

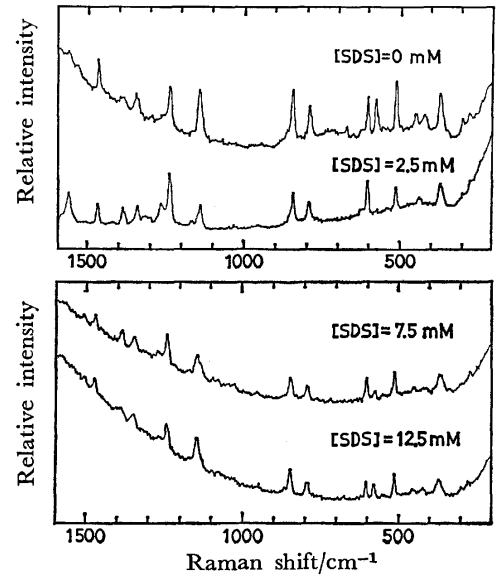

Fig. 1. Raman spectra of aqueous solution of DTC and DTC–SDS, [DTC]=1.0×10^{-5} M, exciting wavelength: 488.0 nm.

† 1 M=1 mol/dm³, 1 mM=1×10^{-3} mol/dm³ in this paper.

sities varied substantially as a function of [SDS], as shown in Fig. 2 for some of the bands. The intensities of each band were corrected for reabsorption in the cell. The intensity of 841 cm^{-1} band was chosen as an internal reference standard.[16] The bands can be classified into three groups by their [SDS]-dependent behavior: (a) the intensity increases for [SDS]$\ll$cmc, (b) the intensity was almost independent of [SDS], and (c) the band disappeared for [SDS]$\ll$cmc. The most peculiar is the band at 569 cm^{-1}, which belonged to the last group.

Aqueous and Methanol Solutions of DTC. The Raman spectra of aqueous solution of DTC were measured in the concentration range 1×10^{-5} M—1×10^{-4} M. The tenfold change in the concentration is accompanied with a large shift in the monomer-dimer equilibrium as shown by the absorption spectra (Fig. 3). The 554 nm and 507 nm peaks can be attributed to monomer and dimer, respectively.[14] However, the intensity change of Raman bands was found to be rather small, as depicted in Fig. 4. The absorption spectra of DTC in methanol show that DTC is present essentially as a monomer, because (1) the shape of the absorption band does not show any appreciable concentration dependence, and (2) it is similar to that of dilute ([DTC]$<2.0\times10^{-5}$ M) aqueous solution, apart from a small red shift. The Raman spectrum of methanol solution of DTC (4.0×10^{-5} M) was quite similar to that of aqueous solution (1.0×10^{-5} M). These results indicate that the shift of monomer-dimer equilibrium in the aqueous solution causes only a small change in the relative intensities of Raman bands.

Solid Spectrum (KBr Disc). The Raman spectrum of DTC in KBr disc is shown in Fig. 5. It is to be noted that relative intensities of the bands in the spectrum of DTC–SDS at [SDS]$\approx$2.5 mM closely resemble those of the solid. The 569 cm^{-1} band disappeared completely in the solid spectrum.

DTC–PGME, –HTAB, and –PVSK. Absorption and Raman spectra of these systems were studied. PGME, a nonionic detergent, has a deaggregation

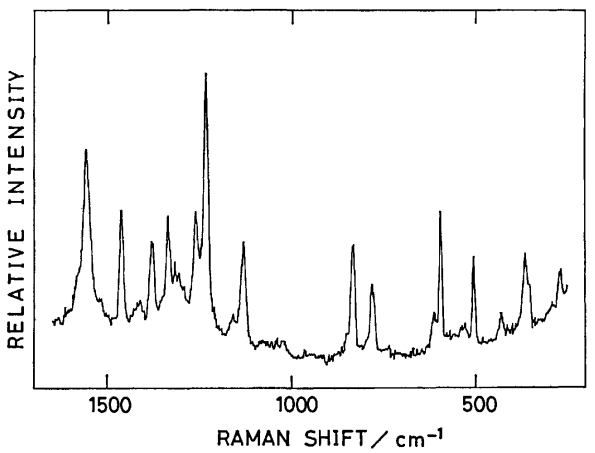

Fig. 5. Raman spectrum of solid DTC (KBr disc), exciting wavelength: 488.0 nm.

effect on DTC as revealed by the decrease of the intensity of dimer band (at 507 nm). However, the corresponding change in the Raman spectra was very little. HTAB, a cationic detergent, did not give any appreciable change in either of absorption and Raman spectra. The positive charge of the HTAB micelle will repel the cationic dye, DTC. PVSK, an anionic polyelectrolyte, (1×10^{-2} g/l—10 g/l)–DTC(1×10^{-4} M) gave the absorption spectra and Raman spectra which are very similar to those of DTC–SDS ([SDS]≈2.5 mM), showing the interaction of $-OSO_3^-$ groups on the polymer chain with DTC.

Effect of Excitation Wavelength. When we measure the resonance Raman spectra of DTC–SDS solutions as a function of [SDS] by exciting at a fixed wavelength, the change in the resonance conditions is inevitable because the absorption spectra changes with [SDS], as shown in Fig. 6. The observed results should be attributed to the joint effect of (1) change in the aggregation state of the dye, and (2) change in the resonance condition. The latter effect can be divided into those due to (2-a) the change in absorption spectra by the shift of monomer-aggregate equilibrium and (2-b) the simple wavelength shift of absorption bands due to environmental effect. The effect (2-a) has the common origin as (1), and what is to be investigated in this study. If the observed results are solely due to (2-b), they are only apparent results, nothing to do with the change in the aggregation state of the dye. In case the observed results are solely due to (2-b), the same results will be obtained by the change in the excitation wavelength. The effect of excitation wavelength on the relative Raman band intensities (the intensity of 841 cm^{-1} being taken as a standard) was studied for aqueous solutions ([DTC]=1.0×10^{-4} M and 1.0×10^{-5} M) and methanol solution ([DTC]=4.0×10^{-5} M). Although the effect of excitation wavelength did exist as shown in Fig. 7 taking [DTC]=1.0×10^{-5} M as an example, there was no direct relationship to the classification of (a), (b), and (c) of [SDS]-dependent intensity change mentioned above. Therefore, the observed [SDS]-dependent change cannot be attributed to the change of resonance condition caused by the shift in the absorption bands (*i.e.* effect 2-b).

Discussion

The dye-detergent interaction was studied with Raman spectra by several authors on several occasions. Verma and Wallach[17] reported the intensities of 1530 cm^{-1} (–C=C– stretching) and 1165 cm^{-1} (=C–C= stretching) of β-carotene were reduced by the addition of SDS. Kim *et al.*[18] found the change of relative intensities of Raman bands at 1420 cm^{-1} and 1155 cm^{-1} of Methyl Orange (MO, an anionic dye) on addition of HTAB below and above cmc. Takenaka and Nakagawa[19] studied the monolayer of MO–HTAB adsorbed at the interface between carbon tetrachloride and aqueous solution. They found a shift of band frequencies of MO in the monolayer from those in bulk aqueous solution toward those of solid MO, indicating that the MO molecules in the monolayer were in an environment similar to a crystal field. Koyama and Matsuo[20] found that 594 cm^{-1} band in the azobenzene–behenic acid system was present in the molten state, but absent in the solid state. They stated that this band can be used as a probe of the aggregation state of the system.

The [SDS]-dependent change of Raman spectra presently studied is not due merely to the change of resonance condition caused by the shift in the absorption bands, and is due to the change of aggrega-

tion state of the dye. For [SDS]≪cmc (*e.g.*, 2.5 mM), the dye is in the aggregation state like in the solid. As the dye is considered to be in a highly aggregated state in the solid, the state of the dye for [SDS]≪ cmc can also be characterized as a highly aggregated state. The comparison with aqueous solution shows that the aggregation state of the dye in SDS solution with [SDS]≪cmc and in solid state is different from that of the dimer in a concentrated aqueous solution. The data in Fig. 2 show that the intensity maxima of bands characteristic to the highly aggregated dye lie around [SDS]=2.5—3.0 mM. When [SDS] approaches cmc, the spectra show the intermediate feature between [SDS]=2.5—3.0 mM and [SDS]>cmc.

The study of absorption and fluorescence spectra, fluorescence intensity and decay behavior as a function of [SDS][14] revealed that there are two regions below cmc. The region [SDS]≪cmc is characterized with a very broad absorption band and the anomolous long-wavelength fluorescence (655 nm). The dye-detergent salt (with nearly 1:1 stoichiometry) as proposed by Mukerjee and Mysels[12] for pinacyanol-SDS seems to be formed. "The highly aggregated dye" must be found in such a dye-detergent aggregate. The resemblance of absorption and Raman spectra to those of DTC–PVSK supports this assumption. For some dye-detergent systems, the dye-detergent aggregate forms a large particle and precipitates from the solution in the low [SDS] region. In the DTC–SDS system presently studied, very minute solid particles seem to be formed in the solution. The formation of such particles can be monitored by the appearance of naturally emitting lines of Ar^+ laser in the observed Raman spectra. These lines are found around [SDS]=1.0 mM. Since the maximum intensities of the bands characteristic to the highly aggregated dye were observed around [SDS]=2.5—3.0 mM, we can safely say that the observed bands are due to dye-detergent aggregate, but not due to solid particles.

For 5.0×10^{-3} M≲[SDS]<cmc, the absorption bands of monomer and dimer dye were observed along with the monomer fluorescence.[14] (Dimers are non-fluorescent.) The energy transfer efficiency between dyes are highly enhanced in this [SDS] region. The presence of dye-rich induced micelles as proposed by Mukerjee and Mysels[12] is plausible in this region. As far as the Raman spectrum is concerned, this region is not characterized by any peculiar feature, but by the intermediate one between [SDS]≪cmc and [SDS]>cmc. In other words, the gradual change of dye-detergent aggregate to micellized monomer dye did not show any peculiarity in the Raman spectra.

For [SDS]>cmc, the absorption spectra draw nearer to the monomer dye. The Raman spectra were similar to those of aqueous and methanol solutions. The deaggregation effect of SDS on the dye did not give any significant change in the Raman spectra.

In summary, resonance Raman spectra proved to be a very useful tool in elucidating the aggregation state of the dye in the dye-detergent systems. The 569 cm^{-1} band works as an useful monitor of the aggregation state of DTC.

The present authors would like to thank Dr. Katsunosuke Machida, Kyoto University, for measurement of solid spectra and for helpful discussions. They are grateful to Miss Yuko Hanyu for her assistance. This study is partly supported by a Grant-in-Aid for Scientific Research No. 447006 from the Ministry of Education, Science and Culture.

(Received September 10, 1981)

The bromine-doped polyacetylenes were studied by X-ray photoelectron spectroscopy. The IR, Raman, and mass spectra were also measured. We find that below the doping content at which the electrical conductivity shows the maximum, bromine content is higher in the surface region than in the bulk. The C ls peak of X-ray photoelectron spectrum is composed of at least two components with the splitting of about 1.7 eV. The relative intensities of two components change with bromine content. The higher-binding-energy component of C ls peak is attributed to positively charged carbon atoms in the metallic domains where dopant is highly concentrated, and the lower-binding-energy component to carbon atoms in the undoped low-conductive domains. The amount of charge transfer in the metallic domain is estimated to be about 0.3|e| per carbon atom. A possible reaction mechanism of bromine with polyacetylene is discussed.

Recently polyacetylene, $(CH)_x$, has attracted great interests because it exhibits metallic conductivity when treated with various dopants.[1–4] Its electrical conductivity at room temperature varies over twelve orders of magnitude by doping with suitable electron acceptors such as halogens and AsF_5. Although the properties of these doped polyacetylenes have been investigated by many groups, more information concerning their structures and electronic states is needed in order to understand the electrical behaviors of these systems. It is important to determine the chemical state of dopant in the polymer and the nature of interaction between dopants and polymer chains. Previously we reported the results of X-ray photoelectron spectroscopic (XPS) studies of the iodine-doped polyacetylene.[5] The bromine-doped polyacetylene shows an electrical behavior similar to that of the iodine-doped polyacetylene when doping content is low. However, much heavier doping is possible in the case of bromine as compared with iodine.[3] Here we report the results of XPS studies on the bromine-doped polyacetylene.

Experimental

A polyacetylene film was prepared by the method described previously.[6] All samples used in the present experiment were obtained from the same batch of polyacetylene. Polymerization was performed at −78 °C to give *cis*-polyacetylene. A *trans*-polyacetylene film was obtained by heating a *cis*-polyacetylene film at 200 °C for 1 h. Film thickness was approximately 0.1 mm.

Bromine treatment was carried out at room temperature by direct contact of a polyacetylene film with Br_2 vapor. The extent of doping was controlled by measuring the electrical conductivity of a reference film contained in the same vessel by means of the standard four-probe method. The bromine content of a doped sample was determined by elemental analysis.

Prior to XPS studies, a sample film was cut off to several parts to measure Raman, IR, and mass spectra.

X-Ray photoelectron spectra were taken with a McPherson ESCA 36 electron spectrometer employing Mg $K\alpha$ (1253.6 eV) radiation. Special care was taken to prevent samples from exposing to the air prior to XPS measurements. After XPS measurements, sample films were used for elemental analysis and for measurements of Raman and IR spectra. The binding energies of observed photoelectron peaks were calibrated by use of Au $4f_{7/2}$ peak (83.8 eV) of a very thin gold film deposited onto the sample surface.

Raman spectra were taken with a Spex 1401 double monochromator equipped with a Spectra Physics 166-01 Kr ion laser, a JEOL JLG-4A Ar ion laser, and an NEC He-Cd laser. The laser lines between 647.1 nm and 325.0 nm were used to obtain Raman spectrum. The IR spectra were measured by ATR method by use of a HITACHI EPI-G3 double beam grating IR spectrometer.

Mass spectra were obtained on a JMS-D300 mass spectrometer (JEOL) using a direct insertion probe. Polyacetylene samples were directly inserted into the ion source and the mass spectra were measured at room temperature.

Results

The electrical conductivity of bromine-doped *trans*-polyacetylene, $(CHBr_n)_x$ is shown in Fig. 1 as a function of the bromine content, n, which was determined by elemental analysis. The general feature of conductivity change is almost same as those previously reported by other authors,[3] except for small differences as regards the bromine content and the conductivity value at the maximum. It should be noted that a bromine-doped polyacetylene film exhibits conductivity as high as $10^{-2}\,\Omega^{-1}\,cm^{-1}$ even at a high doping level of $n=0.63$. The conductivity abruptly decreased when bromine content was further increased. The variation of conductivity with bromine content was found to be almost same in the case of *cis*-polyacetylene, but the conductivity at the maximum point was a little higher as compared with *trans*-polyacetylene.

As shown in Fig. 2, the Br 3d peak in the XPS spectrum of a bromine-doped polyacetylene film decreased its intensity as we repeated XPS measurements on the same sample, indicating that doped bromine was

gradually lost from the film during XPS measurements. We observed a similar phenomenon in the case of iodine-doped polyacetylene.[5] But there is a slight difference between two cases. In the case of bromine-doped polyacetylene, Br 3d peak does not appreciably change its shape accompanying the decrease of its intensity whereas I 3d peak of iodine-doped polyacetylene was found to change its shape.[5]

Figure 3 shows the Br 3d peaks of several films of different bromine content. The spectra shown here are those obtained by the initial measurement on each sample. The binding energy of Br 3d peak did not vary with bromine content. The peak width (FWHM) was about 2.3 eV in the cases of bromine-doped polyacetylene films of $n>0.04$, it being a little larger at lower bromine content. In the cases of bromine-doped *cis*-polyacetylene films, the Br 3d peak width was about 2.6 eV.

In contrast to Br 3d peak, the shape of C ls peak of bromine-doped polyacetylene markedly varies with bromine content as shown in Fig. 4. The observed peak shape suggests that the peak is composed of two components separated by 1.7—2.0 eV, and the intensity of the higher-binding-energy component increases while that of the lower-binding-energy component decreases on increasing bromine content. Figure 5 shows the change of the C ls peak shape of a doped film upon the reduction of bromine content caused by keeping the film in a vacuum. Note that the peak shape varies with bromine content, but the

total intensity remains nearly constant.

We estimated the atomic ratio of bromine to carbon, n_{XPS}, from the ratio of the integrated intensities of Br3d and C1s peaks, with the reference to the relative intensities of the corresponding peaks in the XPS spectrum of tetrabromobenzene. The results are given in Table 1, where the value in the column expressed as "initial" is the Br/C atomic ratio which was determined from the data of the first XPS measurement of the sample concerned, and the value in the column expressed as "final" is the one which was determined from the data of the last measurement of the same sample usually after repetition of XPS measurements for 15—20 h. The XPS atomic ratio n_{XPS} is larger than the atomic ratio n from elemental analysis in the cases of $n \lesssim 0.127$, but they almost agree with each other in the cases of $n > 0.127$. This shows that doped bromine is more concentrated in the surface region than in the bulk at lower bromine content, but is distributed more homogeneously in heavily doped films.

Figure 6 shows the change of n_{XPS} with the time for which the sample has been kept in a vacuum. The

a) Br/C atomic ratio determined by elemental analysis (initial; the value before XPS measurement, final; the value after XPS measurement). b) Br/C atomic ratio determined by XPS measurements at initial and final measurements. c) Relative area ratio of the higher-binding-energy component of C 1s peak to total C 1s peak. d) Splitting of two components of the spectra.

n_{XPS} value rapidly decreases first, but its decrease is leveled off after about 8 h.

Since the C1s peak of a bromine-doped film seems to be composed of two components, we decomposed the observed peak into two component peaks using the C1s peak shape of an undoped polyacetylene film as the standard. The procedures used here are almost the same as those described in our previous paper.[7] Let us denote the carbon atom which is responsible for the higher-binding-energy C1s component, as C_1. We estimated the ratio of C_1 atoms to the total carbon atoms. The C_1/C atomic ratio thus obtained is always close to the Br/C atomic ratio n_{XPS}. Thus we can consider that the atomic ratio of C_1 to Br is always about 1:1.

The Raman spectra of undoped and lightly doped ($n<0.05$) polyacetylene films were previously investigated by several groups.[8-10] It was reported that, according to the observed Raman spectra, doped bromine must be exclusively in the form of Br_3^-. We obtained the same conclusion for lightly doped films. The Raman spectra of heavily doped films were found to be similar to those of lightly doped films showing that doped bromine is primarily in the form of Br_3^- ion, but the possibility of the presence of other bromine species could not be excluded from the observed data. In fact, the band attributable to C–Br stretching vibration was found in the IR spectra of heavily doped films. After XPS measurements, the Raman lines at 158 and 316 cm^{-1}, which are due to the symmetric stretching mode of Br_3^- and its overtone, respectively, appreciably reduced their intensities, indicating the decrease of Br_3^- during the XPS measurements. As we have already mentioned, bromine content decreases when a doped film is kept in a vacuum. It was confirmed by mass spectroscopy that the chemical species which come out from a doped film are mostly HBr in the case of a lightly doped film, and HBr and Br_2 in the case of a heavily doped film. Therefore, we have to consider that the decrease of Br_3^- is accompanied by the formation of C–Br bond. However, it was hard to confirm whether the intensity of C–Br stretching band in IR spectrum increased after XPS measurement or not.

Discussion

According to the conductivity change with bromine content, we can classify the bromine doping of polyacetylene into the following three stages: The stage A ($n\leq0.127$) where conductivity steeply increases with increasing bromine content, the stage B ($0.127<n\leq 0.63$) where conductivity gradually decreases and the stage C ($n>0.63$) where an abrupt decrease of conductivity takes place on further increase of bromine content.

In the case of films of the stage A, the atomic ratio of hydrogen to carbon was found to be 1:1 by elemental analysis. From this fact we can conclude that doped bromine exists primarily as Br_3^- without forming C–Br bond by the substitution of hydrogen of polyacetylene chain with bromine. However, HBr is evolved as a doped film is kept in a vacuum. Possibly this is because Br_3^- can be lost from a film only by performing a reaction with polymer chain to form C–Br bonds with an evolution of HBr.

In the XPS spectrum of a lightly doped film, the C1s peak is asymmetric with a shoulder in the higher-binding-energy side of the main peak. This shoulder is likely to be due to the higher-binding-energy component which clearly appears as a peak in the spectrum of a heavily doped film. One possible interpretation for this higher-binding-energy component could be to attribute it to the carbon atom forming C–Br bond. But this is rather unlikely to be the case since its intensity decreases in parallel to the decrease of bromine content when the film is kept in a vacuum. It should be also noted that the energy separation 1.7 eV from the main peak is too large in comparison with the chemical shift of C1s between C–Br and C–H carbons: the shift is expected to be about 1 eV or less. Thus we consider that the higher-binding-energy C1s component is associated with positively charged carbon atoms which are closely interacting with Br_3^- ions.

Recently Fincher *et al.*[11] proposed, from the investigations of the optical absorption spectra and Raman spectra of doped polyacetylene films, that, in a lightly doped polyacetylene film, the dopant is not uniformly distributed, but forms domains of high dopant concentration, where polyacetylene chain becomes metallic having a uniform C–C bond length, and the remaining regions are in the undoped low-conductive state. This inhomogeneous domain model seems to be consistent with our XPS data. We will attribute the higher-binding-energy C1s component to the carbon atoms in the metallic domain and the other component to the carbon atoms in the low-conductive domain. In the metallic domain, carbon atoms must be positively charged as a result of charge transfer to bromine to form Br_3^-. The positive charge per carbon atom (C_1) of the metallic domain can be estimated from the observed splitting of the two components of C1s peak. Since C1s level is known to be shifted by about 5.6 eV per unit charge,[12] the splitting observed for the doped film of $n=0.127$ corresponds to about $+0.3|e|$. The C_1/Br atomic ratio determined from XPS data provides another independent way to estimate the positive charge per carbon atom since one electron per three bromine atoms should be transferred from polyacetylene chains in the metallic domain, in other words, from C_1 atoms. As shown in Table 2, the values obtained by this way are also about $+0.3|e|$ in agreement with the values from the chemical shift.

It was reported by Salaneck *et al.* that a shoulder appeared on the higher-binding-energy side of C1s peak of polyacetylene upon doping with AsF_5[13] or with iodine.[14] They attributed this shoulder to the plasmon loss associated with charge carriers along polyacetylene chain. However we believe that the shoulder observed in these cases is of the origin similar to the higher-binding-energy C1s component of bromine doped polyacetylene.

Doped bromine must exist mainly in the form of Br_3^- also in the stages B and C, but the substitution

Table 2. Comparison of the charge per C atom estimated from the intensity ratio of higher-binding energy C1s component (C_1) and Br 3d peak and from the splitting of C1s peak of lightly doped polyacetylene

	Estimated from C_1/Br_3 atomic ratio		Estimated from C1s splitting	
	C_1/Br_3^-	Charge per C atom	ΔE/eV	Charge per C atom
trans-$(CHBr_{0.127})_x$	3.2	0.31	1.7	0.30
trans-$(CHBr_{0.042})_x$	4.5	0.22	1.5	0.26
cis-$(CHBr_{0.194})_x$	4.4	0.23	2.0	0.36

or addition reaction of bromine with polyacetylene chain is likely to take place more in these stages. In fact, H/C atomic ratio was found to be 0.95 by elemental analysis in the case of a heavily doped polyacetylene film.

When a film of the stage B is kept in a vacuum, Br3d peak and the higher-binding-energy C1s component decrease their intensities, by evolving HBr from the film. This HBr evolution was markedly enhanced as the film was heated to 150 °C.[15] Probably HBr is formed by the reaction of Br_3^- with polyacetylene chain as in the case of a film of the stage A.

In the stage C, all experimental evidences do suggest that the addition reaction of bromine to C=C double bond significantly takes place in the doping process. The abrupt drop of conductivity in the stage C is likely to be due to the breakdown of π-electron conjugated system of a polyacetylene chain. Thus there must be a considerable amount of carbon atoms having C–Br bond. However even in this case, the higher-binding-energy C1s component which is stronger than the lower-binding-energy one, can not be attributed to the carbon atoms with C–Br bond since its intensity rapidly decreases just by keeping the film in a vacuum at room temperature, by evolving Br_2 and HBr. Seemingly the higher-binding-energy C1s component which appears in the XPS spectra of films of the stage C, is again due to the carbon atoms positively charged by the electron transfer to bromine and in close interaction with Br_3^- ions thus formed, as we have postulated for the stages A and B. Probably the C1s peak due to the carbon atoms with C–Br bond and the one due to the carbon atoms in the undoped regions emerge into the lower-binding-energy C1s component because their energy difference is small, possibly less than 0.5 eV.

Summary and Conclusion

Summarizing all the experimental results obtained in the present study, we postulate the following picture for the bromine doping of polyacetylene. In the first doping stage ($n \leq 0.127$), the doping proceeds inhomogeneously by forming domains in which doped bromine, in the form of Br_3^-, is highly concentrated and polyacetylene chains are in metallic state as the result of charge transfer to bromine by the amount of about 0.3 electron per carbon atom. The conductivity steeply increases on increasing average bromine content because of the increase of the volume fraction of metallic domain.

In the second stage ($0.127 < n \leq 0.63$), the substitution reaction takes place beside the above mentioned doping mechanism, so that the rate of the conductivity-increase with bromine content is leveled down. In the third stage ($n > 0.63$), the addition reaction of bromine to C=C double bond of polyacetylene chain significantly takes place, which results in a marked reduction of the length of π-conjugated system, thus causes an abrupt decrease of conductivity.

The computer used was HITAC-M200H at the Computer Center, the University of Tokyo.

Investigation on the Complex Formation of Some Lanthanoids(III) and Actinoids(III) with Chloride and Bromide

Tetsuo FUKASAWA,† Isamu KAWASUJI,* Toshiaki MITSUGASHIRA, Akiko SATÔ, and Shin SUZUKI

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Katahira 2-chome, Sendai 980

(Received April 17, 1981)

Stability constants (β_1 and β_2) of the chloro and bromo complexes of tervalent Sm, Eu, Gd, Tb, Ac, Am, Cm, Bk, and Cf were determined by a solvent extraction method under the conditions of ionic strength and acidity to be 3.0 and 0.15 M (1 M=1 mol/dm^3), respectively. Stability constants obtained were discussed with respect to the formation mechanism. A much larger contribution from the inner sphere complex formation was observed in chloro complexes than bromo complexes on tripositive actinoids.

Diamond *et al.*[1] reported the difference in the distribution behavior between tripositive actinoids and lanthanoids on the cation exchange resin at high concentrations of HCl. Hulet *et al.*[2] presented the anion exchange method using 10 M LiCl as an eluent to separate tripositive actinoids from lanthanoids, and showed that the distribution ratio(D_v) of actinoids were higher than those of lanthanoids. These phenomena have been explained by the difference in the complex formation between actinoids(III) and lanthanoids(III). Only a few studies have been carried out to determine the stability constants for many actinoids(III) under those conditions.[3] Therefore, the pronounced difference in the complex formation between actinoids(III) and lanthanoids(III) can not be discussed in detail from the available data on stability constants. In this paper, we prepared the adequate tracers of Sm, Ac, Cm, and Bk which are not available in general, determined the stability constants accurately under the same conditions by a solvent extraction method with bis(2-ethylhexyl)hydrogenphosphate, HDEHP, and discussed the phenomena mentioned above.

Experimental

Radioisotopes. ^{152,154}Eu, ^{153}Gd, ^{160}Tb, and ^{252}Cf were obtained from The Radiochemical Centre, Amersham, and ^{241}Am from Oak Ridge National Laboratory. ^{225}Ac was isolated from ^{229}Th which was obtained from ^{233}U.[4] ^{242,243,244}Cm, obtained and purified as reported previously,[5,6] was used in this experiment. ^{145}Sm and the mixture of ^{243}Bk and ^{244}Bk[7] were produced by means of ^{142,143,144}Nd+α and ^{241}Am+α reaction, respectively. For the bombardment, A. V. F. cyclotron at the Cyclotron and Radioisotope Center, Tohoku University, was used. ^{145}Sm was purified by successive extraction with HDEHP. ^{243,244}Bk was separated from irradiated ^{241}Am and fission products by HDEHP extraction of quadrivalent Bk. These tracers were dissolved into 3.0 M $HClO_4$ solutions and stored in Pyrex vessels.

Reagents. The organic extractant HDEHP was purified by the copper-salt precipitation method,[8] and stored as copper salt. LiCl and $LiClO_4$ were prepared from a reagent grade Li_2CO_3. LiBr was obtained in 99.9% purity from MITSUWA Chemical Reagents Co., Ltd. These lithium salts were recrystallized twice before use. All the other chemicals were of the highest grade available.

Apparatus. Gamma-rays of ^{152,154}Eu, ^{153}Gd, ^{160}Tb, ^{241}Am, and ^{243}Cm were counted by means of an auto-well scintillation counter, Packard model 5230. ^{225}Ac, in radioequilibrium with the decay series nuclides, was assayed by the same apparatus. ^{252}Cf was assayed by the prompt fission γ-rays. For the counting, another well type NaI(Tl) ($1.5\phi \times 2''$) counting system was used with a discriminator adjusted to 2.8 MeV with respect to γ-energy. For ^{145}Sm, 61 keV γ-ray was counted by a γ-ray spectrometry system; Tracor Northern TN-11, using an intrinsic Ge(PGT model IGC13) and a Ge(Li) (ORTEC model 8101-1820) detectors. For mixture of ^{243}Bk and ^{244}Bk, the KX-rays of Cm and 218 keV γ-ray were counted by the same γ-ray spectrometry system.

Procedures. Six ml of sample solution was prepared by mixing of appropriate amounts of the stock solution, 3.0 M $LiClO_4$ solution, and 3.0 M LiCl or LiBr solution in a separatory funnel. The sample solution was equilibrated with an equal volume of the HDEHP/octane solution pre-equilibrated by a solution of the same composition as the sample solution. The HDEHP/octane solution was prepared just before the experiment converting the Cu(DEHP)$_2$ to acid form. To determine the relation between distribution ratio and ligand concentration, the acidity was fixed at 0.15 M and the concentration of HDEHP was controlled so that the distribution ratio in the absence of the ligand was to be 1.5—1.8. Extraction equilibrium was reached by shaking for 20 min at about 20 °C. From each phase in equilibrium, a 2 ml portion was taken into a polyethylene test tube and the radioactivity was counted. For the bromide solution, values were corrected for self-absorption of γ-rays by preliminary determined absorption data.

Calculation of the Overall Stability Constants β_1 and β_2. Distribution ratio was calculated by Eq. 1. In the

$$D = \frac{[M]_{org,\ total}}{[M]_{aq,\ total}} \quad (1)$$

presence of complexing anion L^- (L=Cl or Br) in the aqueous phase, complex formation reaction of tripositive cation exists

$$M^{3+} + xL^- \overset{\beta_x}{\rightleftharpoons} ML_x^{3-x},\ (x=1—n), \quad (2)$$

where $\beta_x=[ML_x^{3-x}]/[M^{3+}][L^-]^x$. HDEHP is a cation exchange extractant and the extraction of the complex species can be neglected because of the decrease in the positive charge on the complex species. For example, tervalent lanthanoids and actinoids ions show a distribution ratio a few order of magnitude higher ($>10^3$) than the divalents.[9] Therefore, the distribution ratio can be expressed as follows:

† Present address: Energy Research Laboratory, Hitachi, Ltd., Moriyama-cho, Hitachi 316.

$$D = \frac{[M]_{org,\ total}}{[M^{3+}] + \sum_{x=1}^{n} [ML_x^{3-x}]} = D_0 \frac{1}{1 + \sum_{x=1}^{n} \beta_x [L^-]^x}. \quad (3)$$

And the equation,

$$(D_0/D) - 1 = \beta_1[L^-] + \beta_2[L^-]^2 + \cdots \quad (4)$$

is derived, where D_0 is the distribution ratio in the absence of the ligand. From Eq. 3, the slope of $\log D$ *vs.* $\log [L^-]$ curve is represented as

$$\frac{\partial \log D}{\partial \log [L^-]} = -\sum_{x=1}^{n} x \frac{\beta_x [L^-]^x}{1 + \sum_{x=1}^{n} \beta_x [L^-]^x} = -\sum_{x=1}^{n} x f_x. \quad (5)$$

Where, f_x is a mole fraction of ML_x^{3-x} in the aqueous phase. Equation 4 was used to calculate β_x by the least mean squares fitting of the data points $(D_0/D)-1$ *vs.* $[L^-]$. In order to determine the maximum ligand number, n, a graphic method was applied using the relation of (5).

Results and Discussion

The relation between $\log D$ and $\log [HDEHP]_{org}$ for Bk is shown in Fig. 1. And for Gd, the relation between $\log D$ and $\log [HDEHP]_{org}$ at various ligand concentration is shown in Fig. 2. In these figures, it is shown that D is proportional to the 2.5 power of $[HDEHP]_{org}$ and the relation is not affected by the addition of Cl^- or Br^-. The dependence of $\log D$ on $\log [H^+]_{aq}$ is shown in Fig. 3 for Bk. As shown in Fig. 3, D is inversely proportional to the third power of $[H^+]_{aq}$. The other lanthanoids(III) and actinoids (III) examined in this investigation exhibit the same dependency of D on $[HDEHP]_{org}$ and $[H^+]_{aq}$. HDEHP exists as dimer, $(HA)_2$, in the organic solution. Then the extraction reaction can be written as

$$M^{3+}_{aq} + 2.5(HA)_{2\,org} \rightleftharpoons MA_3(HA)_{2\,org} + 3H^+_{aq}. \quad (6)$$

The relations between $\log D$ and $\log [Cl^-]_{aq}$ or $\log [Br^-]_{aq}$ are shown in Figs. 4 and 5. As shown in these figures, the values of $\partial \log D/\partial \log[L^-]$ at maximum ligand concentration, $[L^-]=2.85$ M, are around -1.5. It is reasonable that f_3, the fraction of the species ML_3, is negligible under the experimental conditions employed in this work. Therefore, we determined the overall stability constants β_1 and β_2 by the least mean squares method based Eq. 4. Some examples of fitting are shown in Figs. 6 and 7. The values of β_1 and β_2 are given in Table 1.

As shown in Table 1, β_1 of the chloro complexes of actinoids(III) are 0.4—0.6 and obviously larger than β_1 of actinoids(III) bromo complexes. And for lanthanoids(III), β_1 of the chloro complexes are also 0.4—0.6 and slightly larger than β_1 of bromo complexes. But for β_2, no significant difference between chloro and bromo complexes was recognized. This means that the second formation constants K_2, calculated as β_2/β_1, of actinoids(III) bromo complexes are obviously larger than those of the others. Moreover, K_2 of the chloro complexes of actinoids(III) and lanthanoids(III) are 0.5—0.7, *i.e.*, almost similar values to $K_1(\beta_1)$. But for Am, Bk, and Cf, K_2 values of the bromo complexes are larger than ≈ 1, as is shown in Table 1.

Tanaka and Yamada[10] proposed that the complex

formation reaction proceeds along with the Eigen mechanism[11] and the apparent formation constant K is expressed as follows:

$$K = K_{os}(1+K_{is}), \tag{7}$$

where K_{os} is an outer sphere formation constant and K_{is} is a transformation constant of an inner sphere complex. Fuoss[12] proposed an equation which has been applied frequently to the calculation of K_{os};

$$K_{os} = \frac{4\pi Na^3}{3000}\exp[\mu/kT], \tag{8}$$

where $4\pi a^3/3$ is exclusive volume of a cation and μ is the electrostatic energy. This equation gives cal-

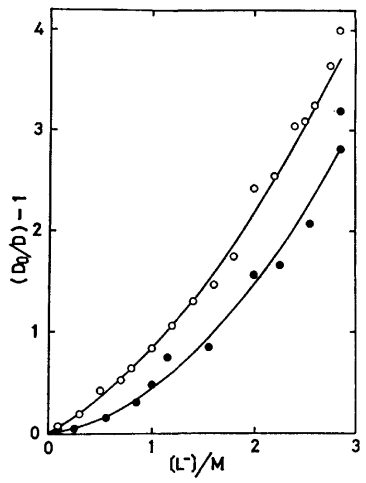

Fig. 6. Dependence of $D_0/D-1$ of Bk on chloride ion(○) and bromide ion(●).

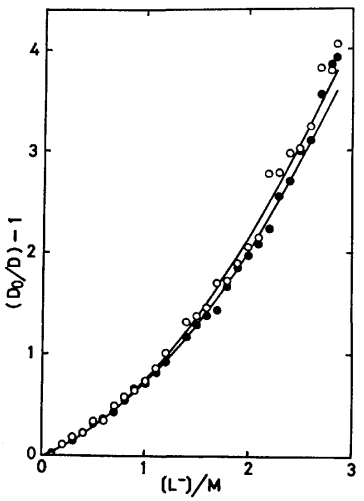

Fig. 7. Dependence of $D_0/D-1$ of Ac on chloride ion(○) and bromide ion(●).

culated formation constants for the bromo complexes of actinoids(III) and lanthanoids(III) of 0.34—0.35 in good agreement with the experimental values of β_1, *i.e.*, K_1. On the other hand for the chloro complexes of actinoids(III), the experimental values of β_1 are obviously higher than the calculated values by Eq. 8, *i.e.*, $K_{os}=0.35-0.36$. According to Eq. 7, this implies that an inner sphere mechanism can not be neglected for the formation of actinoids (III) chloro complexes.

As was mentioned before, in high concentration of LiCl solution actinoids(III) were absorbed by anion exchange resin more strongly than lanthanoids(III), and the distribution ratio(D_v) for actinoids(III) series showed a distinct minimum at Cm, whereas for lanthanoids(III) such trend was not observed.[2] These two facts have been explained by the different complexing ability between two f-series elements and it is widely recognized that actinoids(III) have a much larger ability for complex formation than lanthanoids (III). In order to examine this difference from the data obtained in this work, we calculated the fraction

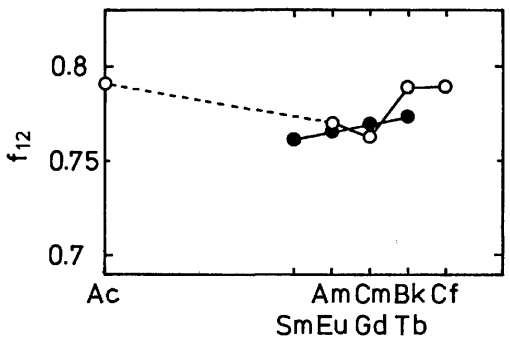

Fig. 8. Variation of f_{12} with atomic number.

of complex species, *i.e.*, $f_{12}=f_1+f_2$, for chloride at $[Cl^-]=2.85$ M, where no anionic complexes are formed. The result is shown in Fig. 8, where f_{12} shows the similar trend as the behavior of D_v for anion exchange and shows a minimum at Cm for actinoids (III), whereas for lanthanoids(III) f_{12} increases continuously with atomic number. However, there is no significant difference in the magnitude of f_{12} between actinoids(III) and lanthanoids(III), thought it has been observed for D_v of anion exchange system. This implies that the large difference in the complex formation between actinoids(III) and lanthanoids(III), which should be observed in the anionic complex formation and gives the experimental basis on the group separation, can not be observed in β_1 and β_2 values experimentally determined in the aqueous system of $\mu=3.0$ and $[Cl^-]\leq 2.85$ M.

The authors wish to thank the members of Cyclotron and Radioisotope Center, Tohoku University, for their handling the cyclotron and monitoring the irradiated sample in the production of Sm and Bk tracers. A part of the expenses for this investigation has been defrayed by a Grant-in-Aid for Scientific Research No. 505002 from the Ministry of Education, Science and Culture.

Reduction of Chromium(VI) by Iron(II) Hydroxide in Alkaline Solution

Toyoaki Aoki* and Makoto Munemori

Environmental Chemistry, College of Engineering, University of Osaka Prefecture, Mozu-umemachi, Sakai 591

(Received May 18, 1981)

Iron(II) hydroxide stoichiometrically reduces CrO_4^{2-} to chromium(III) in alkaline solutions of pH 8 or above. This reduction was finished in less than one minute even at 5 °C. Although chromium(III) dissolves as CrO_2^- above pH 9.5, it did not dissolve in the presence of iron(III) hydroxide which had resulted from the oxidation of iron(II) hydroxide.

This paper reports a fundamental study on the removal of chromium(VI) from wastewaters. In the two-step process[1,2] used at present, chromium(VI) is first reduced to chromium(III) with sulfur dioxide, sodium bisulfite, or iron(II) sulfate below pH 3, and is then precipitated as chromium(III) hydroxide at pH 7.0—8.5 with sodium hydroxide or lime. The first step is always carried out at this low pH because there is a belief that the reduction of chromium(VI) is fast below pH 3 and very slow at pH 4—10.[3]

Recently, we have developed a new process for the chemical treatment of wastewaters which permits simultaneous removal of hazardous metals. In this process, chromium(VI) is reduced by iron(II) at pH 10. A plant for the treatment of laboratory wastewaters was constructed using the new process at the University of Osaka Prefecture and has been in continuous operation since August 1974. Chromium(VI), with a maximum value in influent of 8.2 ppm, is removed to below the detection limit of 0.2 ppm[4] as are the other hazardous metals.

The reduction of chromium(VI) by iron(II) has been studied below pH 7[5,6] and at pH 6.8—7.8,[7] but it has not been studied at pH of 8 or above, at which iron(II) is precipitated as iron(II) hydroxide. In this paper, we report on the heterogeneous reduction of chromium(VI) by iron(II) hydroxide in order to explain the successful treatment of chromium(VI) at the wastewater treatment plant described above.

Experimental

Reagents. All reagents were of analytical-reagent grade. Water was doubly distilled, the second distillation being carried out from alkaline permanganate in an all-Pyrex still. Stock solution of 0.20 mol dm^{-3} chromium(VI) was prepared by dissolving potassium dichromate which had been dried for two hours at 105 °C in redistilled water. Stock solution of 1.00 mol dm^{-3} iron(II) was prepared by dissolving iron(II) sulfate in 0.2 mol dm^{-3} sulfuric acid. When more than 1.0% of the 1.00 mol dm^{-3} iron(II) had been oxidized by oxygen in the air, a stock solution of iron(II) was freshly prepared.

Apparatus. The pHs of the solutions were measured with a Horiba Model F-7DE pH meter. Total iron and total chromium in the solution were determined by atomic absorption spectroscopy using a Nippon Jarrel-Ash Model AA-1W. A Shimadzu Model UV-200 spectrophotometer was used to determine chromium(VI).

Procedure. A solution containing an appropriate amount of 0.2 mol dm^{-3} chromium(VI) solution was adjusted with sodium hydroxide to a pH of 8 or above. Another solution containing an appropriate amount of 1.00 mol dm^{-3} iron(II) solution was similarly adjusted to the same pH. Both solutions were mixed, and stirred at 25 °C. At 0, 2, 5, 10, 20, and 30 min, samples of the resultant mixture were put through glass filters (3G4). Glass filters were used in preference to filter paper, because paper reduced part of the chromium(VI) to chromium(III).

Chromium(VI) in alkaline solution absorbs in the ultraviolet at 370 nm, but chromium(III) does not absorb at this wavelength, so chromium(VI) in the filtrate can be selectively determined in the presence of chromium(III). Total chromium in the filtrate was determined by an atomic absorption method using ammonium perchlorate as a releasing agent to remove interference from other metals and anions.[8]

Futhermore, the reduction of chromium(VI) by iron(II) hydroxide was examined in a nitrogen atmosphere. Commercial nitrogen gas contains traces of oxygen, so this oxygen was removed by passage of the nitrogen gas through an impinger containing an iron(II) hydroxide suspension. With this system, only 1.0% of 500 ppm iron(II) was oxidized after stirring for 30 min at pH 10.

Results and Discussion

Stoichiometry of Reduction Reaction. In order to determine reduction times of chromium(VI) by iron(II) hydroxide at pH 8.0, 10.0, and 11.6, the remaining chromium(VI) in the mixture of a suspension containing iron(II) hydroxide and a solution containing chromium(VI) at the same pH was determined at appropriate time intervals. The sampling and filtering process took two minutes and so the first two minutes of the reaction could not be examined. Within this limitation, Table 1 shows that pHs in this range have no effect on the rate of reduction of chromium(VI) by iron(II) hydroxide in a nitrogen atmosphere. In all of these cases, the reduction of chromium(VI) finished in less than two minutes. In the experimental

Table 1. Effect of pH on reduction of Cr(VI) by iron(II) hydroxide[a]

Time/min	Remaining concentration of Cr(VI)/ppm		
	pH 8.0	pH 10.0	pH 11.6
0	100	100	100
2	24.5	30.2	32.1
5	25.2	30.8	31.8
10	24.1	31.2	31.6
20	24.9	30.4	32.3

a) Initial concentration of iron(II) and chromium(VI) are 224 ppm and 100 ppm, respectively. Experiments were carried out at 25±1 °C in a nitrogen atmosphere.

conditions of Table 1, 30.9 ppm chromium(VI) should have remained in solution if the reduction proceeded at a stoichiometric 3:1 molar ratio of iron(II) to chromium(VI) according to the following equation:

$$3Fe(II) + Cr(VI) \longrightarrow 3Fe(III) + Cr(III). \quad (1)$$

The reduction proceeded stoichiometrically at pH 10.0 and 11.6, but the concentration of chromium(VI) remaining at pH 8.0 was less than the predicted value. It appears that a little of the remaining chromium(VI) was adsorbed at pH 8.0 on iron(III) hydroxide which was the oxidized product of iron(II) hydroxide.[9]

The reduction of chromium(VI) by iron(II) hydroxide was also examined using air instead of nitrogen. In this case, the reduction was also completed in less than two minutes.

To elucidate the stoichiometry of this reduction, the chromium(VI) remaining in the solution after 30 min was determined when various concentrations of iron(II) hydroxide were added to 100 ppm of chromium(VI). Figure 1 shows that the remaining chromium(VI) decreases with increasing iron(II) hydroxide and, in a nitrogen atmosphere, coincides with the curve estimated from the stoichiometry at a 3:1 molar ratio of iron(II) to chromium(VI). On the other hand, experimental data obtained in the presence of air deviated from the stoichiometric curve. In this case, dissolved oxygen competed with the chromium(VI) for the available iron(II) hydroxide.[10] This competition made iron(II) hydroxide unavailable for the reaction with chromium(VI), thereby increasing the concentration of chromium(VI) remaining.

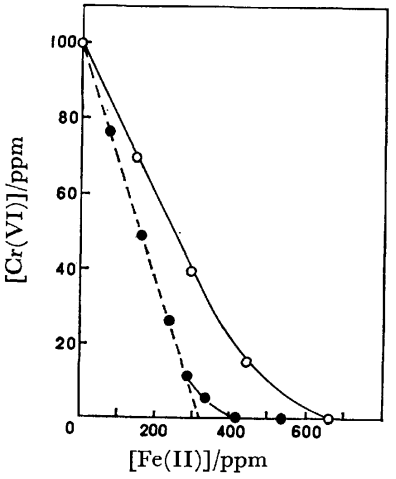

Fig. 1. Relation between remaining concentration of Cr(VI) and concentration of added Fe(II). Experiments were carried out at pH 10.3 (25 °C) in air(○) and in a nitrogen atmosphere(●). Stoichiometric curve is (----).

Chemical Species Taking Part in the Reduction. Chromium(VI) exists in solution as various species as shown in the following equilibria:

$$Cr_2O_7^{2-} + H_2O \rightleftharpoons 2HCrO_4^- \quad pK\ 1.5, \quad (2)$$

$$HCrO_4^- \rightleftharpoons CrO_4^{2-} + H^+ \quad pK\ 6.5. \quad (3)$$

These equilibrium constants were taken from Sillén and Martell.[11]

Chromium(VI) is present as CrO_4^{2-} in alkaline solution of pH 8 or above as in Eq. 3. On the other hand, iron(II) hydrolyzes to produce iron(II) hydroxide above pH 8. From our results and from thermodynamic considerations, it seems that iron(II) hydroxide reduces CrO_4^{2-} by the following reaction:

$$3Fe(OH)_2 + CrO_4^{2-} + 4H_2O \longrightarrow 3Fe(OH)_3 + Cr(OH)_3 + 2OH^-. \quad (4)$$

This reaction indicates that, for every mole of iron(II) hydroxide oxidized, 2/3 mol of hydroxide ion is produced, and in fact, when a suspension of iron(II) hydroxide and a chromium(VI) solution adjusted to same pH were mixed, the pH of the mixture was increased. Therefore, we tried to determine the rate of reduction by following this change of pH. The pH of each mixture became constant immediately after mixing at 5—8 °C. It takes about one minute to mix the solution completely. Thus, the reduction of chromium(VI) by iron(II) hydroxide proceeds in less than one minute in alkaline solutions even at these low temperatures.

Table 2 indicates the increase in pH caused by the reduction at various pHs at 5—8 °C, and the theoretical final pH based on Eq. 4. It is thought that the reduction proceeds stoichiometrically according to Eq. 4 since the theoretical pHs agree very closely with the pHs obtained experimentally.

Removal Mechanism of Chromium(VI). The reaction products are chromium(III) hydroxide and iron (III) hydroxide, according to Eq. 4. However, the precipitate formed from reduction in alkaline solution does not seem to be a simple mixture of these hydroxides.

When a suspension of this precipitate at pH 10 was incubated for 30 min, no chromium(III) was detected in its filtrate, while when a suspension (pH 10) of chromium(III) hydroxide was mixed with a suspension (pH 10) of iron(III) hydroxide, the concentration of dissolved chromium(III) increased with

Table 2. Increase of pH by the reduction of Cr(VI)

a) Volume: 200 cm^3

time, reaching 0.31 ppm at 30 min as shown in Table 3. Chromium(III) hydroxide redissolves in highly alkaline solutions as shown in curve a of Fig. 2. This redissolution is explained by the formation of CrO_2^-. However, the redissolution of chromium(III) was not observed (curve b of Fig. 2) when sodium hydroxide was added to the acidic solution (pH 2) containing chromium(III) and iron(III). This result shows that chromium(III) is coprecipitated with iron(III) hydroxide. From the results above mentioned, when chromium(VI) was reduced by iron(II) hydroxide in alkaline solution, chromium(III) seems to be incorporated in an undissolved form into iron(III) hydroxide. Therefore, the coprecipitation of chromium (III) with iron(III) hydroxide seems to be the incorporation of chromium(III) into iron(III) hydroxide. This can be explained by the similarity of chemical behavior of iron(III) and chromium(III). Both of them have similar polymerization mechanisms[12,13] and hydrolyze even in acidic solutions,[14] and both ions have the same charge and a similar ion radius.

Table 3. Difference between a mixture of $Fe(OH)_3$ and $Cr(OH)_3$[a] and the precipitate from reduction[b]

Time/min	Dissolved Cr(III)/ppm	
	$Fe(OH)_3$+ $Cr(OH)_3$(pH10)	Precipitate(pH10)

Initial concentration of Cr(III) and Fe(III) are 50 ppm and 500 ppm, respectively. a; (○) in the absence of Fe(III), b; (●) in the presence of Fe(III).

Conclusion

Iron(II) hydroxide reduces chromium(VI), CrO_4^{2-}, to chromium(III) in less than one minute at pH 8 or above, at 5—8 °C, and at concentrations from 0.5—2.0 mmol dm^{-3}. The chromium(III), concurrently precipitated without adjusting the pH, seems to be incorporated into iron(III) hydroxide which results from the oxidation of iron(II) hydroxide. Thus, iron(II), as iron(II) hydroxide, quickly reduces chromium(VI) even in this heterogeneous system. Therefore, the conventional two-step process mentioned above is not necessary for chromium(VI) removal from wastewaters, since chromium(VI) can be removed, along with other hazardous metals, by iron(II) at pH 8 or above.

The authors thank Mr. Masao Fujita for assistance with experimental measurements.

Characterization of Prussian Blue Analogs of the Type $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$

Hidenari INOUE,* Takashi KAWAI, Masaki NAGAO, and Saburo YANAGISAWA

Department of Applied Chemistry, Faculty of Science and Technology, Keio University, 3-14-1, Hiyoshi, Kohoku-ku, Yokohama 223

(Received May 22, 1981)

A series of compounds of the type $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$ (M=Mn, Co, Ni, Cu, and Zn) have been studied by means of the X-ray diffraction powder patterns, magnetic measurements, infrared, electronic, and Mössbauer spectra. Three compounds $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$ (M=Mn, Co, and Ni) crystallize in the face-centered cubic system. Copper compound $Cu_3[Fe(CN)_5CO]_2 \cdot 18.5H_2O$ belongs to the tetragonal system, zinc compound $Zn_3[Fe(CN)_5CO]_2 \cdot 13.5H_2O$ being amorphous. The structure of these compounds is described as a three-dimensional framework of two octahedral coordination units FeC_6 in the low spin state and $MN_{10/3}O_{8/3}$ in the high spin state. The back donation in the $Fe(CN)_5CO^{3-}$ moiety is enhanced by the bridge formation through CN^- and CO ligands, *i.e.* upon the formation of $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$ from the corresponding sodium salt.

A number of Prussian blue analogs have been synthesized by the reaction of hexacyanometalate ions $Me(CN)_6^{n-}$ with the first row transition metal ions. Substituted pentacyanoferrate ions such as $Fe(CN)_5X^{n-}$ (X=NO, CO, NH_3, and H_2O) are also known to react with the first row transition metal ions to yield insoluble polynuclear complexes similar to Prussian blue analogs.[1] Most of these transition metal salts of substituted pentacyanoferrates having a general formula $M[Fe(CN)_5X] \cdot xH_2O$ (M=Mn, Fe, Co, Ni, Cu, and Zn) are shown to crystallize in the face-centered cubic system characteristic of Prussian blue analogs.[2]

In spite of considerable interest in $M[Fe(CN)_5X] \cdot xH_2O$, there have been relatively few systematic studies on the transition metal salts of carbonylpentacyanoferrate(II) ions of the type $M_3[Fe(CN)_5]_2 \cdot xH_2O$. Brown and Brown[3] have investigated transition metal salts of the $Fe(CN)_5CO^{3-}$ ion such as $Co_3[Fe(CN)_5CO]_2 \cdot xH_2O$ to demonstrate the bridge structure of carbonyl ligands. On the basis of Keggin's structure model,[4] Ludi *et al.*[5] have proposed a modified crystal structure model for $Mn_3[Co(CN)_6]_2 \cdot xH_2O$, in which the cubic unit cell contains one and a third formula units. In view of the similarity in composition between $Mn_3[Co(CN)_6]_2 \cdot xH_2O$ and $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$, it is of interest to find whether the crystal structure of transition metal salts of carbonylpentacyanoferrate(II) ions can be understood according to this modified structure model by Ludi *et al.* or not.

In the previous paper we showed that a three-dimensional framework is formed by the bridging of cyanide ligands upon the formation of $Fe[Fe(CN)_5X]$ (X=CO, NH_3, and H_2O) from $Na_3[Fe(CN)_5CO] \cdot H_2O$.[6] Furthermore, we discussed the influence of the bridge formation on the electronic structure of the $Fe(CN)_5X^{3-}$ moiety and the dependence of the electronic structure of the central iron(II) ion on the ligand X. The present work was attempted to characterize Prussian blue analogs of the type $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$ (M=Mn, Co, Ni, Cu, and Zn). This type of compounds provides a good model to study a change in the electronic structure of the $Fe(CN)_5CO^{3-}$ moiety with the systematic change in the counter cation M^{2+} from manganese(II) to zinc(II) ion.

Experimental

Sodium carbonylpentacyanoferrate(II) was prepared by the literature method and purified by recrystallization.[7] A series of compounds of the type $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$ (M=Mn, Co, Ni, Cu, and Zn) were precipitated by the addition of an excess of 0.05 mol dm^{-3} MCl_2 to 0.05 mol dm^{-3} $Na_3[Fe(CN)_5CO]$. The precipitate obtained was allowed to stand for 24 h for aging, collected on a glass filter by suction, washed with distilled water, alcohol, and finally ether, then dried over calcium chloride. The compounds prepared were analyzed chelatometrically: Found: Fe, 12.4; Mn, 18.0%. Calcd for $Mn_3[Fe(CN)_5CO]_2 \cdot 17.5H_2O$: Fe, 12.30; Mn, 18.15%. Found: Fe, 12.9; Co, 19.9%. Calcd for $Co_3[Fe(CN)_5CO]_2 \cdot 15.0H_2O$: Fe, 12.77; Co, 20.21%. Found: Fe, 11.9; Ni, 17.5%. Calcd for $Ni_3[Fe(CN)_5CO]_2 \cdot 18.0H_2O$: Fe, 12.30; Ni, 18.97%. Found: Fe, 12.0; Cu, 20.1%. Calcd for $Cu_3[Fe(CN)_5CO]_2 \cdot 18.5H_2O$: Fe, 11.73; Cu, 20.03%. Found: Fe, 13.0; Zn, 22.1%. Calcd for $Zn_3[Fe(CN)_5CO]_2 \cdot 13.5H_2O$: Fe, 12.88; Zn, 22.61%. X-Ray diffraction powder patterns were taken with a Rigaku-Denki X-ray diffractometer at room temperature. The lattice constants were determined using Fe $K\alpha$ radiation (λ=1.937 Å) and sodium chloride as a standard. Infrared spectra were recorded on a Hitachi Perkin-Elmer Model 225 grating infrared spectrophotometer in the range 200 to 4000 cm^{-1} by the Nujol mull and CsI disk methods. The calibration of wave numbers was made using polystyrene film and water vapor absorption. Diffuse reflection spectra were measured with the Hitachi Perkin-Elmer Model 139 spectrophotometer equipped with the standard integrating attachment using alumina as a standard. Magnetic susceptibilities were measured at room temperature by the Gouy method using $Hg[Co(SCN)_4]$ as a calibrant.[8] Diamagnetic corrections were carried out with Pascal's constants.[9] Mössbauer spectra were measured with a constant-acceleration transducer of the Canberra type. A ^{57}Co source in Pd foil with an original intensity of about 10 mCi which was supplied by Radiochemical Centre, Amersham was used at room temperature. The absorbers with a thickness of about 5 mg of natural iron per cm^2 were kept at 77 or 300 K. The Doppler velocity was calibrated with natural iron foil kept at room temperature.

Results and Discussion

Crystal Structure. A series of compounds of the type $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$ (M=Mn, Co, and Ni)

showed the X-ray diffraction powder patterns very similar to those for Prussian blue analogs belonging to the face-centered cubic system. This indicates that compounds other than copper and zinc compounds are isomorphous with Prussian blue analogs: space group O_h^5–F_{m3m}. According to the modified structure model proposed for $Mn_3[Co(CN)_6]_2 \cdot xH_2O$ by Ludi, *et al.*,[5] the unit cell contains 1 1/3 formula units of $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$. As Fig. 1 shows, 4M coordinated by 3 1/3 nitrogen atoms of cyanide ligands, 2 oxygen atoms of water molecules and 2/3 oxygen atom of carbonyl ligands are distributed at the 4a (0,0,0) positions, while 2 2/3 Fe coordinated by five carbon atoms of cyanide ligands and a carbon atom of the carbonyl ligand occupy the 4b(1/2,1/2,1/2) positions in the face-centered cubic unit cell. The 24e (x,0,0) positions are occupied by 16C, 13 1/3 N, and 10 1/3 O atoms. Eight water molecules coordinate to M to fill the empty nitrogen positions. Additional water molecules are distributed around 8c(1/4,1/4,1/4) positions and have a zeolitic nature. These water molecules could be readily removed on heating and are responsible for the different degree of hydration.

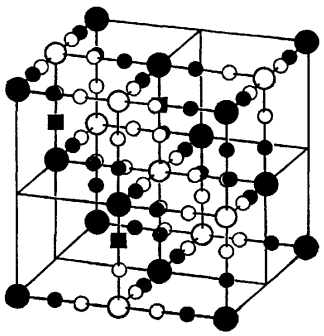

Fig. 1. The structure of $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$.
The number of Fe, C, N, and O does not correspond exactly to the modified structure model and water molecules are not shown for brevity. Symbols: ●, 4M at 4a; ○, 2⅔Fe at 4b; ○, 16C at 24e; ●, 13⅓N at 24e; ■, 2⅔O at 24e.

The crystal structure can be described as a three-dimensional framework of the two octahedral coordination units FeC_6 and $MN_{10/3}O_{8/3}$, where the formula of the latter complex represents an average composition. However, the space group is not O_h^5–F_{m3m} in a strict sense because the symmetry group of the $Fe(CN)_5CO^{3-}$ moiety is not O_h but C_{4v}. In fact, the diffraction powder pattern of the cobalt compound was very diffuse, suggesting that the site symmetry of cobalt ions is lowered due to the C_{4v} symmetry of the $Fe(CN)_5CO^{3-}$ moiety. The preparation of $Fe_3[Fe(CN)_5CO]_2 \cdot xH_2O$ was unsuccessful even in the rigorously purified nitrogen atmosphere since this compound is readily oxidized to give iron(III) carbonylpentacyanoferrate(II) $Fe[Fe(CN)_3CO] \cdot xH_2O$ which is described elsewhere in detail.[6] As reported on $Cu[Fe(CN)_5NO]$,[2] copper compound $Cu_3[Fe(CN)_5CO]_2 \cdot 18.5H_2O$ does not crystallize in the face-centered cubic system but in the tetragonal system. The zinc compound fails to give crystalline precipitate in the present preparative way, *i.e.* it is amorphous. Table 1 lists the lattice constants calculated from the X-ray diffraction powder patterns. The lattice constants obtained fall within the range typical of those commonly found for Prussian blue analogs. Moreover, the lattice constants decrease with the increase of the crystal field stabilization energy of M^{2+} ion in the octahedral weak field, which is quite similar to

the phenomena observed for other Prussian blue analogs.[10]

IR Spectra and Bridge Structure of Cyanide and Carbonyl Ligands. The infrared absorption frequencies observed for $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$ are listed in Table 2 along with those for $Na_3[Fe(CN)_5CO] \cdot H_2O$. In the CN stretching region, very intense absorption bands typical of cyanide complexes were observed in the range 2095 to 2138 cm^{-1}. Since the $Fe(CN)_5CO^{3-}$ moiety belongs to point group C_{4v}, two different species of CN stretching modes $2A_1+E$ are expected to appear in $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$. However, the CN stretching mode was observed as a single intense band with the exception of $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$ (M=Ni and Cu). Taking into account the high site symmetry of the $Fe(CN)_5CO^{3-}$ moiety, the environment of the iron(II) ion is approximated to O_h symmetry even though one of six cyanide ligands is substituted for a carbonyl ligand. On the other hand, four shoulders other than the main strong absorption band were observed for $Na_3[Fe(CN)_5CO] \cdot H_2O$. This splitting of the CN stretching bands must be due to the lowering in the site symmetry of the $Fe(CN)_5CO^{3-}$ moiety. The CN stretching bands of $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$ are observed at higher frequencies than the main strong band (2095 cm^{-1}) of the corresponding sodium carbonylpentacyanoferrate(II). This shift of the CN stretching mode to higher frequencies is considered to be characteristic of the bridge formation of cyanide ligands.[11] Moreover, it is noteworthy that the increasing order in the CN stretching frequencies is very similar to that of the electronegativity of M^{2+} ion or the crystal field stabilization energy in the octahedral weak field.

A strong absorption band assigned to the CO stretching mode appeared at the lower frequencies side of the CN stretching bands. The CO stretching vibration of $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$ was observed as a single broad band whereas the CO stretching modes of $Na_3[Fe(CN)_5CO] \cdot H_2O$ appeared at 1981, 1999, and 2033 cm^{-1} as three strong absorption bands. Of these three bands the absorption bands at 1981 and 1999 cm^{-1} must be caused by hydrogen bonding between the oxygen end of carbonyl ligand and water of crystallization. This is in marked contrast to the fact that the CO stretching band is scarcely affected although the Fe–CO–M bridge is formed in going from $Na_3[Fe(CN)_5CO] \cdot H_2O$ to $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$.

The symmetric and antisymmetric OH stretching modes of water were observed in the range 3340 to 3440 cm^{-1}, while the bending mode appeared in the range 1590 to 1610 cm^{-1}. This observation agrees with that of Prussian blue analogs by Ludi *et al.*;[5] there are two different types of water molecules such as lattice and coordinated water. However, the rocking and wagging vibrations of the coordinated water molecules could not be found probably due to their weakness and/or broadening.

The δ_{Fe-CO} bending and $\nu_{Fe-C(CO)}$ stretching modes appeared in the range 624 to 627 and 535 to 546 cm^{-1}, respectively. It is worth noting that the frequencies of both δ_{Fe-CO} and $\nu_{Fe-C(CO)}$ modes are almost independent of the bridge formation. This is probably because the effect of the bridge formation is compensated by the hydrogen bonding through the oxygen end of the carbonyl ligand. A similar phenomenon was also observed for transition metal salts of substituted pentacyanonitrosylferrates(II).[2] On the other hand, both of the $\nu_{Fe-C(CN)}$ stretching and δ_{Fe-CN} bending modes are simplified in going from $Na_3[Fe(CN)_5CO] \cdot H_2O$ to $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$ because the site symmetry of the $Fe(CN)_5CO^{3-}$ moiety is higher in the latter than the former. The $\nu_{Fe-C(CN)}$ stretching bands observed in the range 462 to 500 cm^{-1} are shifted to higher frequencies upon the formation of $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$ while the δ_{Fe-CN} bending band observed in the range 585 to 588 cm^{-1} is scarcely affected. A shoulder located at the lower frequency side of the $\nu_{Fe-C(CN)}$ stretching band is strong evidence for the bridge structure of cyanide ligand.[12] Indeed, the MN stretching modes were confirmed in nickel and copper compounds. However, no absorption band could be observed in other compounds because the absorption band is very weak in intensity or lies out of the present experimental region.

Electronic Structure and Chemical Environment of M^{2+} Ion. The nature of counter cation, M^{2+} ion, is supposed to affect the electronic structure of the $Fe(CN)_5CO^{3-}$ moiety upon formation of $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$ from $Na_3[Fe(CN)_5CO] \cdot H_2O$. Therefore, it is very important to understand in what ligand field the counter cation is situated or what symmetry the environment of the counter cation has. Magnetic measurements as well as electronic spectra will be a sophisticated mean for this purpose. The effective magnetic moment, μ_{eff}, per M^{2+} ion of $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$ was calculated from the magnetic susceptibilities at room temperature and listed in Table 1. The effective Bohr magnetons calculated agreed with the expectation that Prussian blue analogs of the type $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$ consist of $Fe(CN)_5CO^{3-}$ moieties in the low spin state and M^{2+} ions in the high spin state. As shown in Fig. 2, the absorption bands of electronic spectra in the visible region are very similar in position to those of hexaaqua complexes of M^{2+} ion. This is in good agreement with the magnetochemical conclusion that M^{2+} ion is in the high spin state. Accordingly, the absorption bands are assignable on the basis of the term diagram for M^{2+} ion in the octahedral weak field.[13] Two very weak shoulders occurred in $Mn_3[Fe(CN)_5CO]_2 \cdot 17.5H_2O$ at approximately 17.6 and 23.0×10^3 cm^{-1} which may be assigned to the spin-forbidden transitions, $^6A_{1g} \rightarrow {}^4T_{1g}$ and $^4T_{2g}$ respectively. The absorption band at 16.8×10^3 cm^{-1} for $Co_3[Fe(CN)_5CO]_2 \cdot 15.0H_2O$ is very intense and low in energy as compared with that expected for the corresponding transition $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$ in the octahedral weak field, indicating that the environment of Co^{2+} ions is distorted from O_h symmetry. An absorption maximum and a shoulder which appear in $Ni_3[Fe(CN)_5CO]_2 \cdot 18.0H_2O$ at 16.0 and 25.6×10^3 cm^{-1} are assigned to the spin-allowed transitions $^3A_{2g}(F) \rightarrow {}^3T_{1g}(F)$ and $^3T_{1g}(P)$ respectively. The energies of these two transitions are comparable to those of the corresponding hexaaqua complexes. The absorption band of $Cu_3[Fe(CN)_5$-

$CO]_2 \cdot 18.5H_2O$ assignable to the transition $^2E_{2g} \rightarrow {}^2T_{2g}$ is split into two bands (14.1 and 15.2×10^3 cm^{-1}) due to the lowering of the environment of Cu^{2+} ion from O_h symmetry. This splitting of the d-d transition is responsible for the heterogeneous environment around Cu^{2+} ion rather than the Jahn-Teller effect because the Cu^{2+} ion is surrounded by 10/3 N and 8/3 O statistically. A very broad intense band observed at about 26.0×10^3 cm^{-1} is associated with the so-called intervalence electron transfer band. This type of intense absorption band was also observed for $Fe[Fe(CN)_5CO] \cdot xH_2O$.[14]

Influence of Bridge Formation on the Electronic Structure of $Fe(CN)_5CO^{3-}$ Moiety. The bridge formation of the cyanide and carbonyl ligands is expected to influence the electronic structure of the $Fe(CN)_5CO^{3-}$ moiety. The bonding character between iron(II) and carbon atoms would change upon the systematic change in the counter cation. The Mössbauer and electronic spectra afford useful information about these problems. The Mössbauer spectra of $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$ are shown in Fig. 3 where that of $Na_3[Fe(CN)_5CO] \cdot H_2O$ is also presented for comparison. All the compounds of the type $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$ exhibited a relatively small quadrupole splitting doublet which is comparable to that of sodium carbonylpentacyanoferrate(II). The Mössbauer parameters obtained at 77 and 300 K are summarized in Table 3.

As Fig. 2 shows, the intense absorption bands commonly observed for the electronic spectra of $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$ in the range 29.2 to 29.8×10^3 cm^{-1} are assigned to the lowest spin-allowed transition of the $Fe(CN)_5CO^{3-}$ moiety. This assignment is supported by the fact that a relatively strong band is also observed for $Zn_3[Fe(CN)_5CO]_2 \cdot 13.5H_2O$ and $Na_3[Fe(CN)_5CO] \cdot H_2O$ in the near ultraviolet region in which no d-d transition other than that of the $Fe(CN)_5CO^{3-}$ moiety is expected. Since carbonyl and cyanide ligands are located near each other in the spectrochemical series, the iron(II) ion is considered to be situated to a first approximation in the environment of O_h symmetry. Consequently, the intense band in the near ultraviolet region is assigned to the spin-allowed transition $^1A_{1g} \rightarrow {}^1T_{2g}$. This point of view is consistent with the following facts. The solution spectrum of $Na_3[Fe(CN)_5CO]$ resembles closely that of $K_4[Fe(CN)_6]$.[15] The quadrupole splittings of both

$M_3[Fe(CN)_5CO]_2 \cdot xH_2O$ and $Na_3[Fe(CN)_5CO] \cdot H_2O$ are not only small, but also their isomer shifts are comparable to that of potassium hexacyanoferrate-(II).[16] The carbonyl and cyanide ligands are located near each other in the partial isomer shift and partial quadrupole splitting proposed by Bancroft *et al.*[17]

The temperature-variation in the quadrupole splittings may be associated with the thermal vibration of the crystal lattice. Evidently the quadrupole splittings increase upon formation of $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$ from $Na_3[Fe(CN)_5CO] \cdot H_2O$. This indicates that the charge distribution around the iron nucleus in $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$ is more aspherical than that in $Na_3[Fe(CN)_5CO] \cdot H_2O$ because the quadrupole splitting is due to non-zero electric field gradients at the nucleus which are caused by the aspherical charge distribution of ligand and/or crystal lattice. Unfortunately, such systematic tendency as found for the variation in the lattice constants is not always observed for the increasing order of the quadrupole splittings. Therefore, only a single factor of electronegativity of M(II) ions, size of M(II) ions, d_π-orbitals of M(II) ions to form the back donation, etc. does not play a principal role in the electric field gradient at the iron nucleus, but some combination of these factors must contribute to the quadrupole splittings of $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$.

The isomer shifts of $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$ fall within the range characteristic of low-spin iron(II) complexes.[18] The isomer shifts at 300 K are generally smaller than those at 77 K. This temperature shift in the isomer shifts is ascribed to the second-order Doppler effect. The isomer shifts decrease in going from $Na_3[Fe(CN)_5CO] \cdot H_2O$ to $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$. As is well known, the isomer shift of iron compounds is a measure of the total s-electron density at the iron nucleus and the former decreases with the increase in the latter. Thus the decrease of the isomer shifts accompanied by the formation of $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$ is responsible for the increase of the total s-electron density at the iron nucleus, which is caused by the decreased shielding effect of 3d-electrons. This delocalization of iron 3d-electrons is due to the increased back donation, in other words, due to the increased tendency of the cyanide and carbonyl ligands to withdraw electrons from the central iron atom. On the other hand, the spin-allowed transition $^1A_{1g} \rightarrow {}^1T_{1g}$ in $M_3[Fe(CN)_5CO]_2 \cdot xH_2O$ is slightly shifted to higher frequencies compared to the corresponding transition in $Na_3[Fe(CN)_5CO] \cdot H_2O$. As pointed out in Prussian blue analogs of the type $M[Fe(CN)_5NO] \cdot xH_2O$,[2] this blue shift is also correlated with an increase in the back donation. In conclusion, the coordination of M(II) ions to the nitrogen and oxygen ends of carbonyl ligands leads to the increased back donation from the filled iron d_π-orbitals to the empty ligand antibonding π^*-orbitals.

This work was partly supported by a grant from the Kawakami Foundation to which our thanks are due.

Crystallographic Data for New Phases in the $CaSO_3$–H_2O System

Yasuo Arai,* Tamotsu Yasue, Norifumi Nagata, and Hiroaki Shiino
Department of Industrial Chemistry, Faculty of Science and Engineering, Nihon University, Kanda-Surugadai, Chiyoda-ku, Tokyo 101
(Received May 29, 1981)

Among the three modifications of calcium sulfite hemihydrate, two of them, hexagonal β-$CaSO_3 \cdot 1/2H_2O$ with a rhombohedral lattice and γ-$CaSO_3 \cdot 1/2H_2O$ with a simple triangular hexagonal lattice, were found in the authors' recent work.[1] By heating α- and/or γ-hemihydrate at 330—360 °C in a nitrogen atmosphere, the orthorhombic anhydrate α-$CaSO_3$ was formed, with lattice constants of 6.472, 15.93, and 23.44 Å for *a*, *b*, and *c* respectively, while the body-centered tetragonal anhydrate β-$CaSO_3$, with lattice constants of 15.68 and 19.44 Å for *a* and *c* respectively, was formed by heating the β-hemihydrate. The dehydration of three hemihydrates and the hydration of two anhydrates were discussed. The phase relationships in the $CaSO_3$–H_2O system were summarized as follows:

$$\alpha\text{-}CaSO_3 \cdot 1/2H_2O \underset{\text{Hydration (30 °C)}}{\overset{\text{Dehydration (360 °C)}}{\rightleftharpoons}} \alpha\text{-}CaSO_3 + 1/2H_2O;$$

$$\beta\text{-}CaSO_3 \cdot 1/2H_2O \underset{\text{Hydration (30 °C)}}{\overset{\text{Dehydration (340 °C)}}{\rightleftharpoons}} \beta\text{-}CaSO_3 + 1/2H_2O;$$

$$\gamma\text{-}CaSO_3 \cdot 1/2H_2O \xrightarrow{\text{Dehydration (330 °C)}} \alpha\text{-}CaSO_3 + 1/2H_2O;$$

$$\gamma\text{-}CaSO_3 \cdot 1/2H_2O \xrightarrow{\text{Transformation (in water at 20 °C)}}$$

$$\beta\text{-}CaSO_3 \cdot 1/2H_2O \xrightarrow{\text{Transformation (in water at 20 °C)}} \alpha\text{-}CaSO_3 \cdot 1/2H_2O.$$

Calcium sulfite hemihydrate ($CaSO_3 \cdot 1/2H_2O$) is useful as an architectural material since it has a high thermal stability and a low water solubility in comparison with calcium sulfate dihydrate ($CaSO_4 \cdot 2H_2O$). A large amount of the hemihydrate has been produced by the milky-lime process for the desulfurization of flue gas. The hemihydrate has also attracted some attention as an inorganic filler in a plastic composite. The present authors have undertaken several fundamental and applied experiments[1–5] on the hemihydrate for use as industrial material.

In the $CaSO_3$–H_2O system, five compounds have been reported: $CaSO_3 \cdot 4H_2O$;[6] $CaSO_3 \cdot 2H_2O$;[7–10] $CaSO_3 \cdot H_2O$;[11] $CaSO_3 \cdot 1/2H_2O$;[12–16] and $CaSO_3$.[16–18] However, the phase relationships in the $CaSO_3$–H_2O system have not yet been established. The existence of di- and monohydrates has, though, been disproved. The tetrahydrate is known to exist at low temperatures below 4 °C and to be converted into hemihydrate instantly at room temperature. Although several papers on the X-ray diffraction data of the hemi- and anhydrates in the $CaSO_3$–H_2O system have been published,[12–18] they are not consistent with each other.

In recent years, the present authors have found three modifications of the hemihydrate, formed by passing SO_2 through a suspension of $Ca(OH)_2$.[1] The present work was undertaken in order to elucidate the crystallographic data of anhydrate formed by the thermal dehydration of the hemihydrate and to establish the phase relationships in the $CaSO_3$–H_2O system.

Experimental

Preparation of Samples. The chemical composition of the guaranteed reagent used, $Ca(OH)_2$, was 74.9% CaO and 24.1% H_2O. The purity of the SO_2 used was 99.98%, judging from the results of gas chromatography. The three modifications of calcium sulfite hemihydrate were prepared by passing dried and decarboxylated SO_2 through a suspension of 2% $Ca(OH)_2$. After finishing the reaction at pH 6—8, the precipitate was filtered and rinsed with water, methanol, and acetone.

Table 1. Synthesis of calcium sulfite hemihydrate

Conditions	A	B	C
$Ca(OH)_2$ in milky lime/%[a]	2	2	2
Flow speed of SO_2/cm³ min	10	10	100
Temperature/°C	20	80	95

a) 4.1 g $Ca(OH)_2$/200 cm³ H_2O.

Table 1 shows the synthesis conditions of the hemihydrate. The composition of the products under the conditions A, B, and C was 43.1—43.2% CaO, 49.0—49.2% SO_2, 0.5—0.6% SO_3, and 6.86—7.13% H_2O. These values were sufficiently close to the calculated values for $CaSO_3 \cdot 1/2H_2O$ (43.4% CaO, 49.6% SO_2, 7.00% H_2O). The hemihydrates, A—C, were dehydrated at 330—360 °C in a nitrogen atmosphere and then kept them for 1 h to convert in order to the anhydrates. In order to avoid the oxidation and moisture absorption of the products, they were kept in a vacuum desiccator with silica gel.

Measurements. The samples were analyzed by means of the X-ray diffraction method, thermal analysis (micro TG-DTA), infrared spectroscopy, and the scanning-microscope technique. The X-ray diffraction measurement of the samples was made by the use of a Rigaku Denki 2001 diffractometer using Ni-filtered Cu $K\alpha$ radiation (λ=1.5418 Å), with high-purity silicon (d=3.138 Å) as the internal standard. The X-ray diffraction data were obtained as the average values from 15—20 samples of a hemihydrate or an anhydrate. The chemical analyses were made as has been described previously.[3]

Results and Discussion

Identification of the New Phases of Calcium Sulfite Hemihydrate. In the previous paper,[1] three modifications of hemihydrate were reported in detail. The conventional orthorhombic hemihydrate was prepared under the A synthesis conditions in Table 1, the new phase I, with the known phase as part of a mixture, was formed under the B conditions, and the new phase II, including the former two phases, was formed as a mixture under the C conditions. Unfortunately, these new phases could not be distinguished as a single phase. In the previous paper, the above new phases were called Phase I and Phase II as a matter of convenience. In this paper, these three modifications of hemihydrate are named α-$CaSO_3\cdot 1/2H_2O$ (orthorhombic system), β-$CaSO_3\cdot 1/2H_2O$ as Phase I, and γ-$CaSO_3\cdot 1/2H_2O$ as Phase II.

Table 2 lists the crystallographic data for the three modifications. The orthorhombic hemihydrate reported by Waerstad *et al.*[15] will be called α-$CaSO_3\cdot 1/2H_2O$ hereafter.

New Phases of Anhydrous Calcium Sulfite. The dehydrated products of the hemihydrates obtained under the A, B, and C preparing conditions will here-

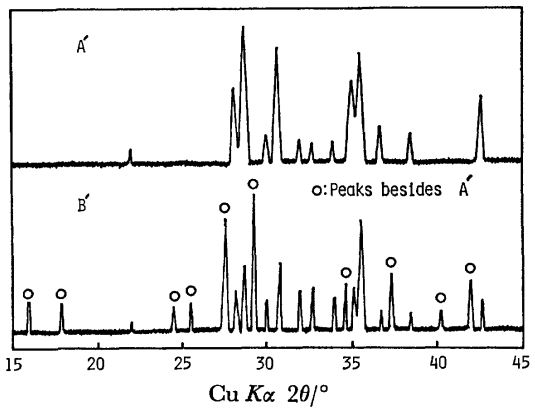

Fig. 1. X-Ray diffraction patterns of anhydrous calcium sulfite.

after be called A′, B′, and C′ respectively. The composition of A′—C′ is shown in Table 3. All of the dehydrated products can be identified as anhydrates. Figure 1 shows the X-ray diffraction patterns for the A′ and B′ anhydrates. The C′ anhydrate gave a pattern identical with that of B′. The X-ray diffraction pattern for A′ agreed generally with that reported by Lutz *et al.*,[18] but it showed many additional diffraction peaks. The X-ray diffraction patterns of B′ and C′ contained peaks identical with those observed on A′, but gave many diffraction peaks which were not observed on A′. Therefore, the existence of two modifications in an anhydrate may be inferred from both the chemical analysis and X-ray diffraction.

Though X-ray diffraction data on anhydrous calcium sulfite have been presented by several investigators,[16–18] their crystallographic information has not yet been published. On the basis of these X-ray diffraction results, obtained with a high accuracy, the crystallographic analysis was carried out by using Hull-Davey's graph[19–20] and a microcomputer. The crystallographic data for two modifications of the anhydrate are shown in Table 4. Thus, it was proved that A′ belonged to an orthorhombic system with a= 6.472 Å, b=15.93 Å, and c=23.44 Å. This phase is named α-$CaSO_3$ in this paper. On the other hand, it was found that B′ and C′ existed as mixtures of α-$CaSO_3$ and another anhydrous phase. In fact, this new phase was found to have a body-centered tetragonal lattice with a=15.68 Å, and c=19.44 Å. This phase is named β-$CaSO_3$. The X-ray diffraction pattern for the mixture of α- and β-anhydrates agreed generally with that reported by Matsuzaki et al.[17]

Phase Relationships in the $CaSO_3$–H_2O System. It was confirmed that three modifications in hemihydrates and two modifications in anhydrates existed. In order to elucidate the mutual relationships of these five phases,

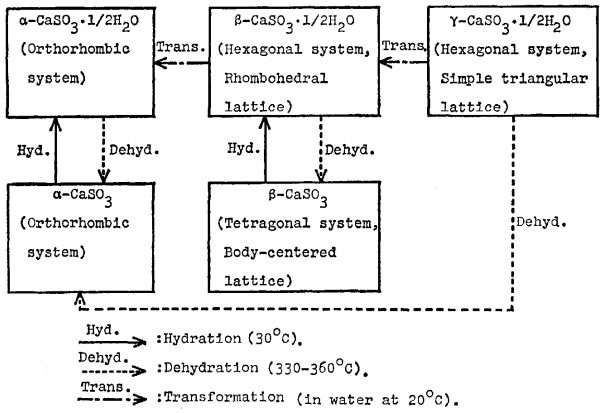

Fig. 2. Phase relationships in the system $CaSO_3$–H_2O.

the phase changes on hydration and dehydration in the $CaSO_3$–H_2O system were traced by means of X-ray diffraction, thermal analysis, and infrared spectroscopy. The phase relationships are summarized in Fig. 2.

The α-$CaSO_3$ anhydrate (orthorhombic system) was formed by the dehydration of both α-$CaSO_3 \cdot 1/2H_2O$ (orthorhombic system) and γ-$CaSO_3 \cdot 1/2H_2O$ (hexagonal system, simple triangular lattice). The β-$CaSO_3$ anhydrate (tetragonal system, body-centered lattice) was formed by the dehydration of β-$CaSO_3 \cdot 1/2H_2O$ (hexagonal system, rhombohedral lattice). When these anhydrates were hydrated in water, α-$CaSO_3$ changed to α-$CaSO_3 \cdot 1/2H_2O$ and β-$CaSO_3$ changed to β-$CaSO_3 \cdot 1/2H_2O$. These results suggest that there were reversible reactions among these phases. In addition, when β- and γ-$CaSO_3 \cdot 1/2H_2O$ were immersed in water, β-$CaSO_3 \cdot 1/2H_2O$ was converted to α-$CaSO_3 \cdot 1/2H_2O$, and γ-$CaSO_3 \cdot 1/2H_2O$ was finally converted to α-$CaSO_3 \cdot 1/2H_2O$ through β-$CaSO_3 \cdot 1/2H_2O$.

The authors wish to thank Mr. Akira Takeshi of Nihon University for his experimental assistance.

Determination of Trace Amounts of Iron, Nickel, and Tin in Zircaloys by X-Ray Fluorescence Spectrometry after Coprecipitation with Hexamethyleneammonium Hexamethylenedithiocarbamate

Yoshikazu YAMAMOTO,* Michiyuki SUGITA, and Kazumasa UEDA

Department of Industrial Chemistry, Faculty of Technology, Kanazawa University, Kodatsuno, Kanazawa 920

(Received June 8, 1981)

A rapid and precise X-ray fluorescence spectrometry is proposed for the determination of the trace amounts of iron, nickel, and tin in zircaloys. A zircaloy sample was dissolved in a mixture of tetrafluoroboric acid and hydrochloric acid, diluted to a definite volume with water. After the addition of 3 cm³ of 1% (*R*,*R*)-tartaric acid solution as an auxiliary chelating agent and 50 μg of cobalt as an internal standard to an aliquot (less than 200 μg of tin) of the solution, the pH was adjusted to 2 with ammonia solution and 3 cm³ of 1% hexamethyleneammonium hexamethylenedithiocarbamate (HMA–HMDC) was added. The resulting HMA–HMDC complexes were collected on a membrane filter and dried. The contents of iron, nickel, and tin in zircaloys were calculated by the calibration curves with the ratios of *Kα* intensities for each element to that for cobalt. The coefficients of variation (5 results for each metal) were 2.16, 0.63, and 1.52% for 10, 10, and 200 μg of iron, nickel, and tin, respectively. The analytical results of iron, nickel, and tin in zircaloy samples by the proposed method agreed with the certified values.

Various methods for the determination of chromium,[1] iron,[2] nickel,[3] and tin[4] in zircaloys, including atomic absorption spectrometry[5] for the former three elements, have been reported. Polarographic methods[6,7] for tin and spectrographic methods[8,9] for chromiun, iron, and nickel, have suffered from the interference of lead and from relatively high coefficients of variation, respectively. In the determination of tin by a volumetric[10] or coulometric method,[11] meticulous attention must be given to the reduction of tin(IV). X-Ray fluorescence analysis using an "oxide"[12] or "extraction" method[12] needs troublesome treatment and one using a "nondestructive" method[13] can be easily influenced by a matrix effect or by segregation.

The present paper will describe the determination of trace amounts of iron, nickel, and tin in zircaloys by coprecipitation-X-ray fluorescence spectrometry with hexamethyleneammonium hexamethylenedithiocarbamate (shortened to HMA–HMDC), which didn't react with the zirconium matrix but formed stable complexes with these trace elements in a lower pH range. Cobalt was also used as an internal standard in order to improve the accuracy.

Experimental

Apparatus. The X-ray fluorescence measurements were performed using a Rigaku-Denki Model KG-X with a Philips tungsten target tube; lithium fluoride ($2d$=4.028 Å) was used as the analyzing crystal. The detection of the fluorescence X-rays was accomplished using a scintillation counter. The HMA–HMDC complexes of chromium, iron, nickel, tin, and cobalt were collected on membrane filters TM-80 (25 mm in diameter, 0.8 μm pore size). The pH measurements of sample solutions were carried out using a Hitachi-Horiba M-5 pH meter with a glass electrode.

Reagents. Chromium(VI) standard solution: A 1000 μg/cm³ solution was prepared by dissolving potassium dichromate (analytical-reagent grade) with hydrochloric acid (1+5) and by diluting with water.

Iron(III) Standard Solution: A 1000 μg/cm³ solution was prepared by dissolving electrolytic iron with a mixture of nitric acid and hydrochloric acid and by diluting with water.

Nickel(II) Standard Solution: A 1000 μg/cm³ solution was prepared by dissolving nickel metal (99.9%) with hydrochloric acid (1+1) and by diluting with water.

Tin(IV) Standard Solution: A 2500 μg/cm³ solution was prepared by dissolving tin metal (99.999%) with hydrochloric acid and by diluting with water.

Zirconium(IV) Standard Solution: A 4000 μg/cm³ solution was prepared by dissolving zirconium dichloride oxide (analytical-reagent grade) with water.

Cobalt(II) Standard Solution: A 1000 μg/cm³ solution was prepared by dissolving cobalt nitrate (analytical-reagent grade) with nitric acid and by diluting with nitric acid (1+100). The solution was standardized by EDTA titrimetry.

The above standard solutions were diluted as required.

Tetrafluoroboric Acid Solution: Tetrafluoroboric acid solution was prepared by dissolving 50 g of boric acid in 100 cm³ of 47% hydrofluoric acid and was retained in a polyethylene bottle.

HMA–HMDC Solution: A 1% ethanol solution was prepared by dissolving HMA–HMDC which had been synthesized and recrystallized by Busev's method.[14]

All the other chemicals used were of analytical-reagent grade; deionized-distilled water was used throughout the work.

Proposed Procedure. A zircaloy standard sample, 0.2 g, was dissolved in a mixture of 1 cm³ of tetrafluoroboric acid and 14 cm³ of hydrochloric acid (1+1) on a sand bath, and diluted to 100 cm³ with water. After an aliquot (less than 200 μg of tin; corresponding to 10 mg of zircaloys) was pipetted into a 100 cm³-beaker, 3 cm³ of 1% (*R*,*R*)-tartaric acid solution as an auxiliary chelating agent and 50 μg of cobalt as an internal standard were added; the total volume of the solution should be around 50 cm³ with water. The pH of the solution was adjusted to 2 with ammonia solution (1+3). Three cm³ of 1% HMA–HMDC ethanol solution was mixed into the solution. The resulting HMA–HMDC complexes for chromium, iron, nickel, tin, and cobalt were allowed to stand for 20 min at room temperature. After the HMA–HMDC complexes were collected on a membrane filter, the precipitate was washed with 10 cm³ of water three times and dried at room temperature. The precipitate on the filter, covered with a Mylar film, was fixed onto an aluminium holder and fitted with a titanium mask to remove the scattered background

intensity. The X-ray intensity for each element was measured three times for 20 s, operating at 40 kV and 20 mA. The counting was performed for the $K\alpha$ lines of each HMA–HMDC complex for chromium, iron, nickel, tin, and cobalt at the 2θ angles of 69.34°, 57.49°, 48.64°, 14.03°, and 52.81°, respectively. The background correction of each element was made by the blank values measured in a similar manner to that described above. The amounts of the four elements were calculated from their calibration curves, which gave the ratios of the average X-ray intensities for chromium, iron, nickel, and tin to that for cobalt.

Results and Discussion

Effect of the pH on the Formation of HMA–HMDC Complexes. The maximum X-ray intensity of each element was examined for the solutions containing 50 μg each of chromiun, iron, nickel, and cobalt, and 250 μg of tin. The pH range was varied from 1 to 5 with the proposed procedure. The results obtained are shown in Fig. 1. The maximum constant X-ray intensities were shown in the pH range of 1 to 5 for nickel and cobalt, and in that of 1.5 to 5 for chromium and tin. For iron, its maximum constant intensity was found in the pH range of 1.5 to 4. In 1 and 2 molar media of hydrochloric acid, chromium and iron showed an abrupt decrease of their X-ray intensities. The pH range of 1.5 to 4 is available for the formation of HMA–HMDC complexes of these elements; we carried out the experiment at pH 2.

Effect of Adding Amounts of (R,R)-Tartaric Acid Solution. Though HMA–HMDC reacts with tin(IV) to form a complex, the X-ray intensity of its complex shows a poor reproducibility of the results obtained. When (*R,R*)-tartaric acid was added to the solution containing tin, reproducible results were obtained. (*R,R*)-Tartaric acid, therefore, seems to be effective for tin as an auxiliary chelating agent in the formation of the tin–HMA–HMDC complex. To the solutions containing 20 μg each of chromium, iron, and nickel, 200 μg of tin, and 50 μg of cobalt, 1% (*R,R*)-tartaric acid solution was added in the range of 1 to 5 cm^3 and the X-ray intensities of the elements were measured using the proposed procedure. As shown in Fig. 2, the five elements recorded constant X-ray intensities with no marked variations due to tin. Three cm^3 of 1% (*R,R*)-tartaric acid solution, therefore, was used.

Effect of Adding Amounts of HMA–HMDC Solution. The X-ray intensities of the five elements were examined by adding from 1 to 6 cm^3 of 1% HMA–HMDC solution and using the proposed procedure. The results obtained are shown in Fig. 3. The addition of less than 2 cm^3 of HMA–HMDC solution

1: I_{Ni}/I_{Co}, 2: I_{Fe}/I_{Co}, 3: I_{Sn}/I_{Co}, 4: I_{Cr}/I_{Co}.

gives extremely low X-ray intensities for each element because a part of the precipitate must pass through membrane filters. The addition of more than 4 cm³ of HMA–HMDC solution makes the filtration of the precipitate more difficult, because of the fine particles of the complexes, and gives lower X-ray intensities of tin. Three cm³ of 1% HMA–HMDC was thus added.

Effect of Aging Time of the Complexes. The aging time required to obtain quantitative complex formation was examined for the same solutions by varying the time over the range from 5 to 60 min. As shown in Fig. 4, the maximum constant ratios of X-ray intensities for chromium, iron, nickel, and tin to that for cobalt were obtained after more than 10 min of aging time. The complexes were thus allowed to stand for 20 min at room temperature.

Calibration Curves. The calibration curves were made for chromium, iron, nickel, and tin as follows. Fifty μg of cobalt as an internal standard and 60 mg of zirconium were added to the solutions containing 5—150 μg of chromium, 5—100 μg each of iron and nickel, and 50—200 μg of tin. By using the proposed procedure, the ratios of X-ray intensities for the elements to be determined to that for cobalt were plotted against the amounts of the elements. The calibration curves were linear in the concentration range of up to 100 μg of iron and nickel, and up to 150 μg of chromium. For tin, a reproducible result could not be obtained in the absence of (*R*,*R*)-tartaric acid, but the calibration curve was linear up to 300 μg in the presence of 3 cm³ of 1% (*R*,*R*)-tartaric acid solution as an auxiliary chelating agent.

The calibration curves of applying zircaloy samples were also made as follows. To the solutions containing 2—15 μg each of chromium and nickel, 5—30 μg of iron and 50—300 μg of tin, also added were 1 cm³ of 5% tetrafluoroboric acid solution, 10 mg of zirconium, 3 cm³ of 1% (*R*,*R*)-tartaric acid solution and 50 μg of cobalt. The procedure mentioned above was then carried out. The calibration curves, which are used for the determination of the amounts less than 300 μg of tin, 15 μg of nickel, and 30 μg of iron in 10 mg aliquots of zircaloy sample, are shown in Fig. 5. For chromium, however, a nonlinear relationship was found with a lowering of sensitivity.

TABLE 1. COMPARISON OF THE PROPOSED METHOD WITH OTHER METHODS

Element	Element added (μg)	Proposed method (μg)	Other method (μg)
Fe	20.0	20.0	20[a]
Ni	20.0	19.8	20[a]
Sn	240.0	243.4	240[b]

a) Determined by atomic absorption spectrometry. b) Determined by extraction spectrophotometry with oxine.

Precision and Detection Limits. The precision of the proposed method was examined for the solution containing 10 μg each of iron and nickel, and 200 μg of tin. The coefficients of variation for iron, nickel, and tin in five determinations were 2.16, 0.63, and 1.52%, respectively.

The detection limits of iron, nickel, and tin were 1.4×10^{-2}, 5.5×10^{-3}, and 3.0×10^{-1} μg, respectively; these amounts correspond to the X-ray intensities that are equal to three times standard deviations of their backgrounds.

Comparison of the Proposed Method with Other Methods. For the solutions containing 20 μg each of iron and nickel or 240 μg of tin, the analytical data obtained by the proposed method were compared with those by atomic absorption spectrometry or spectrophotometry. The results obtained are shown in Table 1. The results by the proposed method agreed with those by other methods.

Effect of Diverse Elements. HMA–HMDC forms complexes with chromium(VI), iron(III), nickel, and tin as well as cobalt, but does not form a complex with zirconium matrix; these complexes can be separated from zirconium by the filtration of them. Negligible interferences of excitation and absorption occurred among the elements studied, because these elements were measured below several hundreds micrograms in total amounts as a thin film.

Simultaneous Determination of the Trace Amounts of Chromium, Iron, Nickel, and Tin in Zircaloys. The analytical results of chromium, iron, nickel, and tin

TABLE 2. ANALYSIS OF ZIRCALOYS

Zircaloys	Element found (%)				Certified values[a] (%)			
	Fe	Ni	Sn	Cr	Fe	Ni	Sn	Cr
Z-9	0.138	0.057	1.45	—	0.148	0.057	1.47	0.097
Z-11	0.200	0.021	1.83	—	0.209	0.021	1.83	0.041
Z-12	0.128	0.095	0.91	—	0.129	0.094	0.92	0.013
Z-13	0.134	0.061	1.48	—	0.136	0.058	1.48	0.098

a) Certified by Japan Atomic Energy Research Institute.

in zircaloy standard samples, JAERI Z-9, Z-11, Z-12, and Z-13, are shown in Table 2, along with their values certified by the Japan Atomic Energy Research Institute. The content of tin is fairly high in zircaloy samples used, compared with the contents of chromium, iron, and nickel, and the intensities of their $K\alpha$ lines are more sensitive than that of tin. Thus 10 mg of sample was sufficient for the determination of their elements, with no addition of standard material. When chromium exists in a trivalent state in the zircaloy samples, the complex formation with HMA–HMDC would not proceed. The oxidations of chromium with hydrogen peroxide, potassium periodate, ammonium persulfate, and potassium permanganate were thus tried, but no effective results were obtained. The analytical results of the other three elements obtained by the proposed method were in agreement with their certified values.

The proposed method is free from the interference by the zircaloy matrix and has advantages in speed (about 2 h), simplicity and precision compared with other chmical methods.

(Received June 9, 1981)

Reaction of hyperoxide with $Fe(phen)_3^{2+}$ in DMSO was studied by polarography, cyclic voltammetry, and spectroscopy. Voltammetric study of oxygen showed that disproportionation of hyperoxide is promoted by $Fe(phen)_3^{2+}$. Controlled potential coulometry exemplified the stoichiometry of the reaction to be 2:1 for hyperoxide to $Fe(phen)_3^{2+}$ in support of the proposed disproportionation mechanism of hyperoxide. Analysis of reaction products proved that $Fe(phen)_3^{2+}$ decomposes on reaction with hyperoxide in DMSO; the reaction products were iron(III) hydroxide and liberated ligands, neither metal hyperoxide nor oxygen bridged metal complexes being detected.

In aprotic media electrochemical reduction of oxygen occurs in two one-electron steps, the first step being well defined as formation of hyperoxide anion.[1-4] Effects of acids,[1-3] metal ions,[4,5] metal complexes,[6] water,[7] and organic materials[8] on oxygen waves have been studied, general characteristics of reactions of hyperoxide being reviewed by several authors.[9-11]

The discovery of metalloenzyme catalyzing hyperoxide dismutation[12,13] has increased interest in reactions of hyperoxide with transition metal complexes, and some low molecular weight metal complexes containing Mn(III), Cu(II), Fe(II), or Co(II) have been found to catalyze disproportionation of hyperoxide.[6,14-17]

Metal complexes of 1,10-phenanthroline are of interest, since they have heterocyclic nitrogen ligands similar to hystidine imidazole sites thought to be present in the enzyme.[13] However, quite few investigations have been performed on reactions of such complexes with hyperoxide.[14] In a preliminary work,[18] the authors presented that 1,10-phenanthroline complexes of Mn(II), Cu(II), or Fe(II) promote the disproportionation of hyperoxide in DMSO. The present paper is concerned with details of reaction of hyperoxide with $Fe(phen_3)^{2+}$ in DMSO.

Experimental

Materials. Dimethyl sulfoxide (DMSO) of Wako GR grade was shaken with dried activated alumina for one day and distilled twice under a nitrogen of reduced pressure. The portion distilled out at 53—54 °C at *ca.* 3 Torr (1 Torr ≈ 133.322 Pa) was collected. Tetraethylammonium perchlorate (TEAP) was prepared as described elsewhere[19] and $Fe(phen)_3(ClO_4)_2 \cdot H_2O$ by literature method.[20] Potassium hyperoxide obtained from Alfa Division and 1,10-phenanthroline from Wako Pure Chemicals were used as received.

Apparatus and Procedure. The cyclic voltammetry and controlled potential electrolysis were performed on a potentiostat constructed according to a circuit configuration similar to the one cited in literature.[21] Modification was made in the current booster so as to supply max. 700 mA. The platinum electrode used for the cyclic voltammetry was soaked in aqua regia for 30 s and heated in a blue flame. The controlled potential electrolysis was carried out with both a platinum plate and a mercury pool cathode. The counter electrode was a spiral platinum electrode. The two compartments of the cell were separated with a fine sintered glass filter. The current through the cell was recorded on a coulometer by integrating the potential drop across a 10 Ω resistor placed in the electrolysis current path. The coulometer was constructed according to a circuit configuration described elsewhere.[22] Modification was made in the input circuit in such a way that it was replaced with an instrumentational amplifier. Correction for blank current was made in the measurement of electrolysis current. Polarograms were recorded on a Shimadzu RP 50 polarograph. Potentials are all referred to SCE as described previously.[19] All electrochemical measurements were thermostated at 25.0±0.2 °C. The UV and visible absorption spectra were measured on a Hitachi Model 100-60 spectrometer.

The solubility of oxygen in DMSO was determined by gas chromatography. Dry oxygen was bubbled through DMSO in a test tube for 30 min at 25.0 °C and the test tube was then sealed with a serum-type rubber stopper. In order to assure that all the oxygen bubbles had got off the solution, gas chromatographic measurements of oxygen were repeated at 30 min intervals until measured values became constant. The concentration of oxygen saturated in DMSO was determined to be 2.36 mmol dm^{-3} at 25.0 °C. The concentration of oxygen in the aerated DMSO was determined to be 0.42 mmol dm^{-3} at 25.0 °C by comparing the first polarographic reduction wave height of oxygen obtained in the aerated DMSO with that obtained in the oxygen-saturated DMSO.

Results and Discussion

Cyclic voltammograms of oxygen and $Fe(phen)_3^{2+}$ are given in Fig. 1. The cathodic and anodic current peaks of oxygen correspond to the well established reversible one-electron redox process:

$$O_2 + e^- \rightleftharpoons O_2^{\cdot-}. \quad (1)$$

The potential separation between the cathodic and anodic current peaks was 0.079 V, a little greater than 0.059 V, the separation for the reversible process, but sufficiently lower than those reported in literature.[1,9] The usual cyclic polarization method for pretreatment of the platinum electrode in DMSO[17] did not improve the potential separation between the cathodic and anodic current peaks lower than 0.11 V, indicating that the method for pretreatment performed in this work is preferred to the usual method and is recommendable as one of the best methods

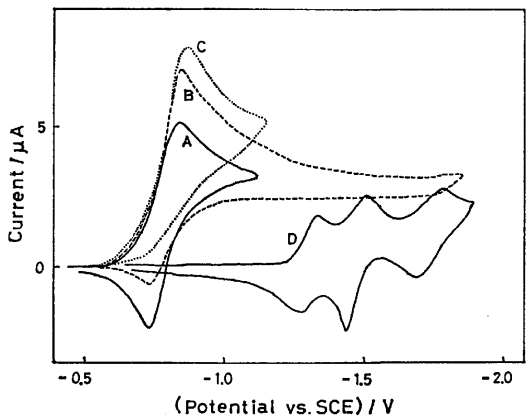

Fig. 1. Cyclic voltammograms of oxygen and Fe(phen)$_3^{2+}$ in DMSO containing 0.1 mol dm^{-3} TEAP. ever adopted.

Polarograms of oxygen and Fe(phen)$_3^{2+}$ are shown in Fig. 2. The logarithmic analysis of the first wave of oxygen gave a slope of 0.068 V. An ac polarographic current peak was observed at the first wave, showing that the first wave corresponds to the reversible one-electron process as given in Eq. 1.

When Fe(phen)$_3^{2+}$ was added to the solution, the cathodic current peak of the cyclic voltammogram of oxygen increased and the anodic current peak decreased in height as shown in Fig. 1. The first wave of polarogram increased in height with the addition of Fe(phen)$_3^{2+}$ as shown in Fig. 2, approaching asymptotically twice its original height as shown in Fig. 3. The half wave potential slightly shifted to less negative and the slope of the logarithmic analysis was 0.066 V after the first wave attained its maximun

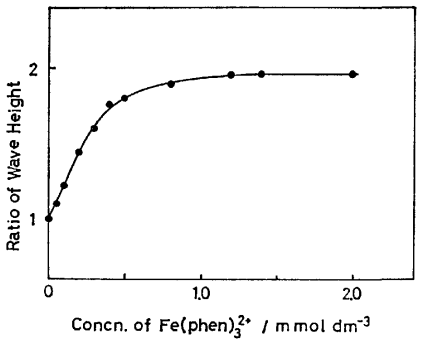

Fig. 3. Effect of Fe(phen)$_3^{2+}$ on the first wave height of the polarogram of O_2 in DMSO containing 0.1 mol dm^{-3} TEAP.
O_2: 0.42 mmol dm^{-3}.

height.

These observations are well explained by the disproportionation mechanism: The regeneration of oxygen is promoted by the reaction of Fe(phen)$_3^{2+}$ on hyperoxide as shown in Eqs. 2—4:

$$Fe(phen)_3^{2+} + O_2^{\cdot-} \longrightarrow Fe(phen)_3^{2+}\cdot O_2^{\cdot-}, \quad (2)$$

$$Fe(phen)_3^{2+}\cdot O_2^{\cdot-} + O_2^{\cdot-} \longrightarrow Fe(phen)_2^{2+}(O_2^{\cdot-})_2 + phen, \quad (3)$$

$$Fe(phen)_2^{2+}(O_2^{\cdot-})_2 \longrightarrow Fe(phen)_2^{2+}O_2^{2-} + O_2. \quad (4)$$

This reaction mechanism is similar to that of the dissociation of Fe(phen)$_3^{2+}$ induced by the attack of nucleophilic anions:[27] The close approach of the metal and hyperoxide due to the formation of an ion pair (Eq. 2) causes the interaction between the π-orbital of hyperoxide and the antibonding d-orbital of the metal with resultant destabilization of the metal ligand bond and subsequent dissociation of the complex, the single bonded ligand in the intermediate being replaced with another hyperoxide (Eq. 3). The liberation of oxygen (Eq. 4) is caused by the formation of stronger Fe–O bonds with the bidentate peroxide ion according to a mechanism similar to that given for the liberation of oxygen in the reaction of hydrogen peroxide with triethylenetetramine-di-hydroxo-iron complex.[28]

The irregular minimum observed in the polarogram B in Fig. 2 appeared at a low concentration of Fe(phen)$_3^{2+}$. This minimum may be due to the adsorption of the reaction product inhibiting part of the electrode process. At higher concentrations of Fe(phen)$_3^{2+}$, the reduction waves of the metal complex and the reaction product are clearly seen to be superimposed on the oxygen wave.

In order to establish the stoichiometry for the reaction, a controlled potential reduction of oxygen was accomplished at −1.0 V *vs.* SCE in a DMSO solution containing 0.2 mmol dm^{-3} Fe(phen)$_3^{2+}$ and 0.1 mol dm^{-3} TEAP under continuous bubbling of dry oxygen. As electrolysis proceeds, the color of the solution changed from red to yellow and simultaneously an yellow substance precipitated on the cathode. The change of the UV and visible absorption spectra of the solution is given in Fig. 4.

The autoxidation of Fe(phen)$_3^{2+}$ within the time frame of the present experiment was completely ruled

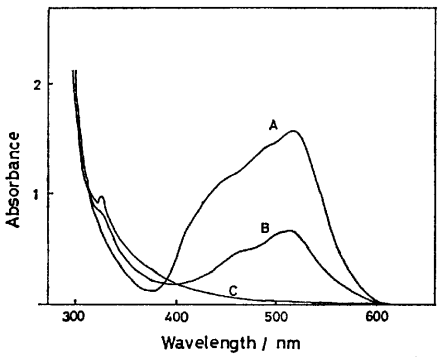

Fig. 4. UV and visible spectra of $Fe(phen)_3^{2+}$ in DMSO containing 0.1 mol dm^{-3} TEAP.
A: 0.20 mmol dm^{-3} $Fe(phen)_3^{2+}$, B: half electrolyzed, C: completely electrolyzed.

out by confirming that the spectrum of a solution with the same composition as that used for the electrolysis showed no substantial change under sunlight as well as in the dark for over 50 h.

By knowing the amount of current used for the electrolysis until the color of the solution turned yellow, 1.93 electrons were found to be required for each $Fe(phen)_3^{2+}$; namely, the stoichiometry of the reaction is 1:2 for $Fe(phen)_3^{2+}:O_2$, in accord with that required for Eqs. 1—4.

The peroxo complex shown in Eq. 4 is not a reaction product with a defined chemical structure but assumed to be a transiently lived reaction intermediate, since no peroxo species could be stable in DMSO.[23] Indeed, the direct mixing of a DMSO solution of KO_2 with one of $Fe(phen)_3^{2+}$ provided a dark violet solution which decayed in a few seconds, yielding an yellow solution and a brown precipitate. Although this transiently lived reaction intermediate has not been identified, it is supposed to be a peroxo complex as shown in Eq. 4. A similar peroxo complex has been found in reaction of Fe^{II}-edta with hyperoxide,[16] where a violet colored reaction intermediate was identified to be a peroxo complex of a formula of Fe^{III}-edta-O_2^{3-}.

Degradation of the peroxo complex may give an oxygen bridged iron complex, since formation of such a complex seems to be favored in aprotic media because it would not require utilization of water or proton donor. Indeed, a stable μ-peroxo-dicobalt(II) complex was obtained in DMSO in reaction of bis(acetylacetonato)Co(II) with hyperoxide.[6] For the autoxidation of iron containing porphyrin, where hyperoxide is considered to play an important role, an oxygen bridged iron dimer was suggested to be formed.[24] In order to check the formation of oxygen bridged iron complex, a μ-oxo complex of iron, $(Fe(phen)_2X)O(ClO_4)_2$, where X is Cl^- or NO_3^-, was prepared by literature method[25] in attempt to use it as a reference.

The cyclic voltammogram of the μ-oxo-diiron(II) complex is shown in Fig. 5. The reversible cathodic and anodic current peaks at -1.3—1.7 V *vs.* SCE are typical for the octahedral 1,10-phenanthroline complex of iron(II) since the lowest vacant molecular

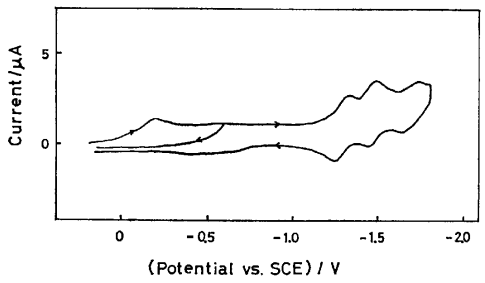

Fig. 5. Cyclic voltammogram of 0.20 mmol dm^{-3} [{$Fe(phen)_2Cl$}O_2]$^{2+}$ in DMSO containing 0.1 mol dm^{-3} TEAP.

orbitals of the complex consist mainly of the π-orbital of the ligand.[26] The yellow colored solutions obtained by the electrolysis and the direct reaction of KO_2 with $Fe(phen)_3^{2+}$ showed no redox current peaks over the potential range shown in Fig. 5. Thus, any oxygen bridged complexes are ruled out as stable reaction products. The presence of hydrogen peroxide also was ruled out since the polarogram of the yellow solution did not give any waves corresponding to hydrogen peroxide.

The qualitative analysis of the yellow solution exemplified chemical properties quite similar to a DMSO solution containing both 1,10-phenanthroline and a saturated amount of iron(III) hydroxide: Addition of Fe^{2+} regenerated the spectrum of $Fe(phen)_3^{2+}$ but addition of 1,10-phenanthroline did not, indicating the presence of liberated 1,10-phenanthroline as well as the absence of free Fe^{2+}: Exposure to mercury gave no color change, showing the absence of free Fe^{3+} since a DMSO solution containing Fe^{3+} and 1,10-phenanthroline generates the spectrum of $Fe(phen)_3^{2+}$ upon reduction with mercury: Addition of hydrogen peroxide evolved oxygen, the spectrum of $Fe(phen)_3^{2+}$ being regenerated.

The yellow substance precipitated on the cathode turned brown when dried. The qualitative analysis of this as well as the brown precipitate obtained by

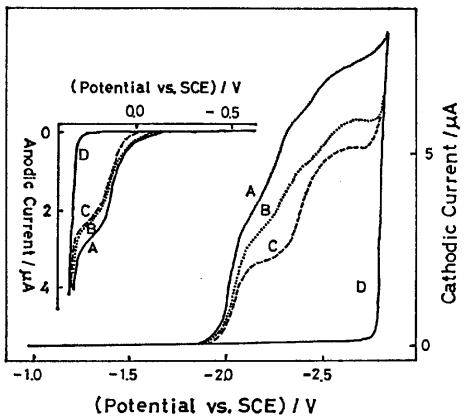

Fig. 6. Polarograms of DMSO solutions containing 0.1 mol dm^{-3} TEAP.
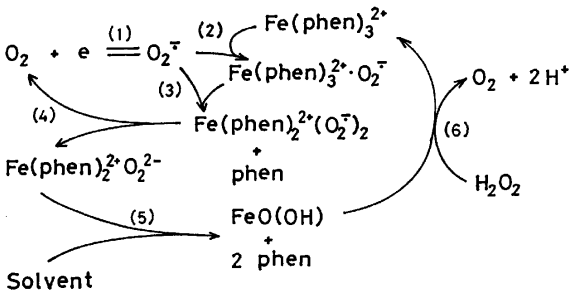
A: Electrolyzed solution of 0.81 mmol dm^{-3} $Fe(phen)_3^{2+}$, B: 1.7 mmol dm^{-3} 1,10-phenanthroline with saturated amount of iron(III) hydroxide, C: 1.9 mmol dm^{-3} 1,10-phenanthroline, D: base current.

direct mixing of KO_2 with $Fe(phen)_3^{2+}$ exhibited chemical properties similar to iron(III) hydroxide: They dissolved in acidic aqueous solution without evolution of gas, ruling out the presence of hyperoxide species in the precipitate; subsequent addition of 1,10-phenanthroline showed no color change, suggesting the absence of free Fe^{2+}; further exposure to mercury generated the spectrum of $Fe(phen)_3^{2+}$ due to the reduction of Fe^{3+}.

The polarographic results shown in Fig. 6 demonstrate that the polarogram of the yellow solution resulting from reaction of 1 mol of $Fe(phen)_3^{2+}$ with O_2^- corresponds quantitatively to that of a solution containing *ca.* 3 mol of 1,10-phenanthroline and a saturated amount of iron(III) hydroxide.

These results indicate that $Fe(phen)_3^{2+}$ decomposes on reaction with hyperoxide. In this sense, $Fe(phen)_3^{2+}$ does not act as a catalyst but acts as a promoter for the disproportionation of hyperoxide, since an alternate reduction and oxidation of Fe^{2+}/Fe^{3+} is not involved in the reaction. The reaction scheme presented in this work is summarized as follows:



The mechanism of the degradation of peroxo complex (Reaction 5) may consist of the combination of the decomposition of peroxide ion in DMSO yielding hydroxide ion[23] and the fission of bis(phen)-iron(II) complex yielding iron(II) hydroxide with release of ligands.[27] The result that the final product was iron(III) hydroxide may be due to the oxidation of iron(II) hydroxide with DMSO, since the former is a strong reducing reagent and the latter an oxidizing one.

Reaction 6 was found to be too slow to expect to restore the catalytic activity of $Fe(phen)_3^{2+}$ during the electrochemical reaction. However, Reaction 6 would be noticeable as a reaction which demonstrates the restoration of the catalytic activity of $Fe(phen)_3^{2+}$ in DMSO.

(Received June 12, 1981)

An ab initio MO calculation of $[Ni(CN)_4]^{2-}$ has been carried out with a double zeta basis set. The nickel-cyanide interactions are discussed and the electronic change occurring on the coordination of CN^- to Ni^{2+} is shown by using the MO contours and the electron-density difference map. The map shows σ donation from the cyanide orbitals and π back-donation from the metal d_{xy} orbital.

The tetracyanonickelate ion, $[Ni(CN)_4]^{2-}$, is one of the simplest square-planner complexes. Its coordinate bonding is of great interest for inorganic chemists because of its fundamental importance for comparison with the bonding in octahedral complexes. Demuynck *et al.*[1-2] have reported an ab initio molecular orbital (MO) calculation of $[Ni(CN)_4]^{2-}$; however, the bonding structure has not been discussed in detail in terms of the orbital mixing and the electron-density difference on coordination. We have reported the electronic structures of the octahedral complexes, $[M(CN)_6]^{3-}$ (M=Cr, Mn, Fe, and Co) and $[Fe(CN)_6]^{4-}$, by means of both the Hartree-Fock and the discrete-variational-Xα molecular orbital calculations.[3-4] In these reports, the metal-cyanide bonding has been discussed for complexes of different metals and of different oxidation states, and the validity of the orbital mixing rule[3,5,6] has been demonstrated for the coordinate bond.

In the present work, an ab initio MO computation of $[Ni(CN)_4]^{2-}$ has been undertaken to clarify (1) the metal-cyanide bonding structure in $[Ni(CN)_4]^{2-}$ and (2) the electronic change occurring on the coordination of CN^- to Ni^{2+}, on the basis of the MO contours and the electron-density maps.

Computation

The calculation was done in the SCF LCAO MO scheme with a basis set of Gaussian functions ([11s, 7p, 5d][7] for the Ni atom and [9s, 5p][8] for the C and N atoms). The 250 Gaussian functions were reduced to 112 contracted functions. The program JAMOL3 used in the present calculation has been written by Kashiwagi *et al.*,[9] who made the integral calculation more tractable by making use of symmetry properties and an integral approximation scheme based on semi-orthogonalized orbitals.[10-11] The threshold value for the degree of overlap was set at 0.001 in the present calculation. The bond lengths were taken as:[1-2]

Ni-C=1.86 Å and C-N=1.15 Å in D_{4h}.

The x and y axes were taken along the coordinate axes. The calculation of the electron density map was carried out by using the program written by Miyoshi *et al.*[12]

Results and Discussion

The calculated orbital energies and the approximate valence-shell MO's are given in Table 1, together with the corresponding energy values given by Demuynck *et al.*[1] The present results for the orbital energies are 0.02—0.05 a.u. lower than the previous ones. However, the order of MO levels is almost the same as that reported by Demuynck *et al.*,[1] except for two reversals of the orders of adjacent levels. The calculated orbital levels are schematically illustrated in Fig. 1, together with those of the free CN^- ion. Table 2 gives the symmetries of orbitals on the D_{4h} point group. Sigma interactions exist in the orbitals of the a_{1g} and b_{1g} types, π interactions in those of the a_{2u}, b_{2g}, and e_g types, and both interactions in the e_u-type orbitals. The CN^- π orbitals of the a_{2g} and b_{2u} types have no interacting metal orbitals. The important orbitals in forming the metal-cyanide bonds are the 3d, 4s, and 4p orbitals of Ni and the 5σ, 1π, and 2π orbitals of CN^-.

Table 1. Symmetries and energies of valence shell MO's

Symmetry	Energy/a.u.		
	Present results	Literature[1]	
$1a_{2g}$	−0.1449	−0.122	1π
$8e_u$	−0.1457	−0.120	1π
$2e_g$	−0.1495	−0.131	1π
$1b_{2u}$	−0.1589	−0.136	1π
$2b_{2g}$	−0.1746	−0.155	1π
$3a_{2u}$	−0.1821	−0.159	1π
$9a_{1g}$	−0.1923	−0.182	d_{z^2}
$5b_{1g}$	−0.2022	−0.182	5σ
$7e_u$	−0.2136	−0.194	5σ
$8a_{1g}$	−0.2494	−0.231	5σ
$1e_g$	−0.2661	−0.266	d_{zx}, d_{yz}
$4b_{1g}$	−0.3011	−0.262	4σ
$6e_u$	−0.3200	−0.277	4σ
$1b_{2g}$	−0.3371	−0.355	d_{xy}
$7a_{1g}$	−0.4215	−0.378	4σ
$3b_{1g}$	−0.9261	−0.875	3σ
$5e_u$	−0.9268	−0.877	3σ
$6a_{1g}$	−0.9313	−0.879	3σ

The Natures of MO's. We will discuss the natures of MO's and the orbital interactions. Demuynck *et al.*[1-2] reported that the $d_{x^2-y^2}$ and 4p orbitals of the metal are important in the Ni–CN σ bond. However, the mechanism of the orbital interaction has not been reported. Figure 2 shows the important MO wavefunctions which contribute to the Ni–CN bonding; *i.e.* $8a_{1g}$, $9a_{1g}$, and $5b_{1g}$ in the σ system,

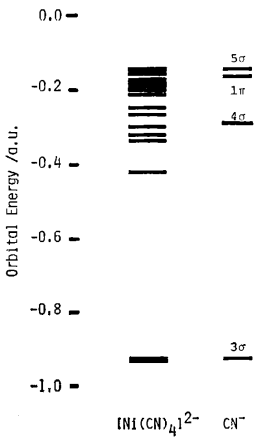

Fig. 1. Schematically illustrated MO energy levels with the levels of free CN^- orbitals.
The MO orderings (from the top to the bottom) are: $1a_{2g}$, $8e_u$, $2e_g$, $1b_{2u}$, $2b_{2g}$, $3a_{2u}$, $9a_{1g}$, $5b_{1g}$, $7e_u$, $8a_{1g}$, $1e_g$, $4b_{1g}$, $6e_u$, $1b_{2g}$, $7a_{1g}$, $3b_{1g}$, $5e_u$, $6a_{1g}$ (See Table 1.).

$1b_{2g}$, $2b_{2g}$, $1e_g$, $2e_g$, and $3a_{2u}$ in the π system, and $7e_u$ and $8e_u$ in the mixed σ and π system. The order of orbital energies in the σ system is $5\sigma<3d\sigma<4s<4p$. In a_{1g} symmetry, two occupied MO's are formed by the combinations of the $5\sigma+3d_{z^2}+4s$ ($8a_{1g}$, Fig. 2a) and $3d_{z^2}-5\sigma-4s$ ($9a_{1g}$, Fig. 2b) types; here the + signs show that the component orbitals have the same sign as that of the main component orbital

Table 2. Symmetry orbitals for D_{4h}

Symmetry	Metal orbital	Cyanide orbital[a]
a_{1g}	s, d_{z^2}	σ
a_{2g}		π
a_{2u}	p_z	π
b_{1g}	$d_{x^2-y^2}$	σ
b_{2g}	d_{xy}	π
b_{2u}		π
e_g	d_{zx}, d_{yz}	π
e_u	p_x, p_y	σ, π

a) Ligand symmetry orbital.

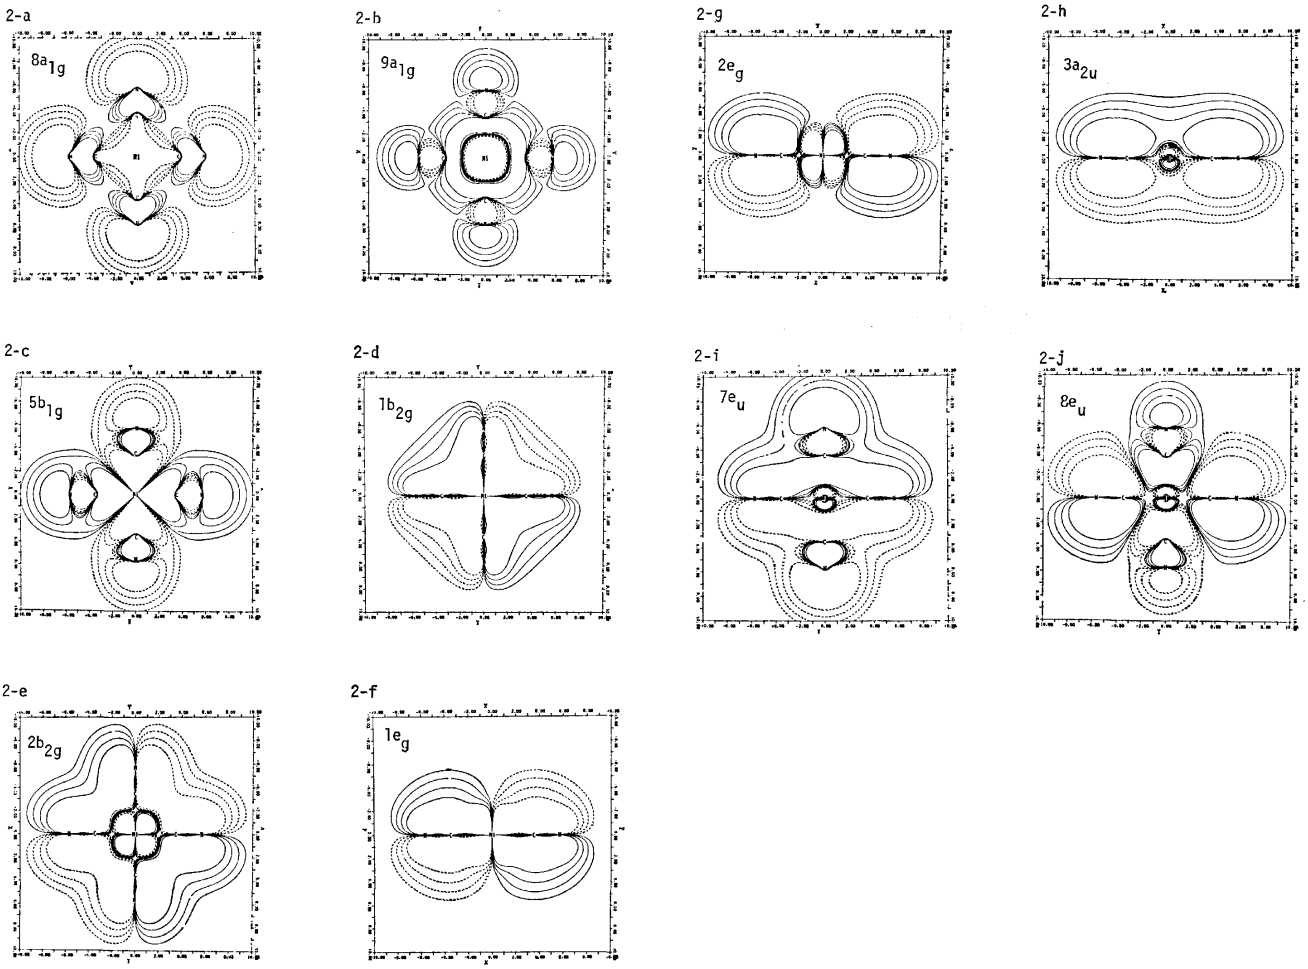

Fig. 2. Selected wavefunction contours for the valence-shell MO's of $[Ni(CN)_4]^{2-}$.
Each set of contours is drawn in a frame of 20 a.u. × 20 a.u. (1 a.u. = 0.529 Å = 52.9 pm). The Ni atom is located at the center of the frame, and four C and four N atoms at the distances of 3.516 a.u. and 5.690 a.u. from the center, respectively, on the xy plane (However, the three figures, f, g, and h, show the wavefunction contours on the xz plane, and two C and two N atoms are located before and behind the Ni atom.). The first solid and dotted contours show ± 0.002, respectively, and neighboring contours differ by a factor of two (For some of the MO's, the signs are reversed.).

(given first) in the region of the Ni–C bonds. If the 4s orbital did not contribute to the two MO's, the linear combinations would be $5\sigma+3d\sigma$ and $3d\sigma-5\sigma$ types; this latter is antibonding and weakens to the Ni–C bonds. This antibonding interaction is relaxed by the mixing of 4s, which thus makes an important contribution to the Ni–CN σ-bond formation. To the b_1 symmetry belongs the occupied $(5\sigma+d_{x^2-y^2})$-type MO ($5b_{1g}$, Fig. 2c), which contributes to the Ni–C bond formation through σ donation.

The order of the energies of π type orbitals is $d\pi<1\pi<4p\pi<2\pi$; $d\pi$ and 1π are originally occupied. The formation of a coordinate bond gives two occupied MO's, $d\pi+1\pi+2\pi$ ($1b_{2g}$, Fig. 2d, and $1e_g$, Fig. 2f) and $1\pi-d\pi-2\pi$ ($2b_{2g}$, Fig. 2e, and $2e_g$, Fig. 2g); the mixing of 2π stabilizes the antibonding $1\pi-d\pi$ MO. In a_{2u}, the $1\pi+4p\pi+2\pi$ combination is formed ($3a_{2u}$, Fig. 2h). The e_u interaction gives the linear combinations $5\sigma+1\pi+4p$ ($7e_u$, Fig. 2i) and $1\pi-5\sigma-4p$ ($8e_u$, Fig. 2j), where the 5σ orbitals of a pair of the CN^- ligands interact with the 1π orbitals of the other pair of the CN^- ligands.

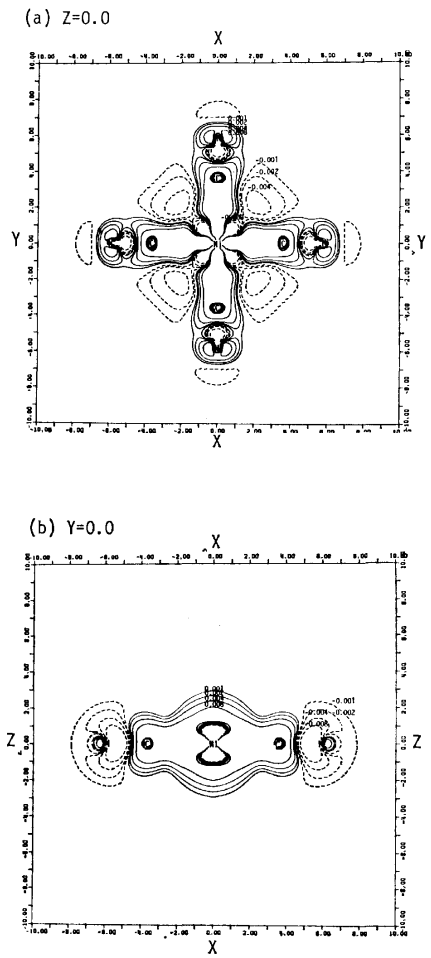

Fig. 3. The electron density difference between $[Ni(CN)_4]^{2-}$ and a cluster of Ni^{2+} (d^8 configuration with unfilled $d_{x^2-y^2}$ orbital) and $(CN^-)_4$: (a) on the xy plane and (b) on the xz plane.
The first solid and dotted contours show ±0.001 e(a.u.)$^{-3}$, respectively, and neighboring contours differ by a factor of two.

As is described above, the interaction of the ligand and the metal occupied orbitals gives rise to two MO's, one with bonding and one with antibonding character; a mixing of the virtual orbitals makes the bonding orbitals more suitable, and the antibonding orbital less unsuitable, to the M–C bonding.

The Electron Density and Population. Figure 3 shows the maps (for the xy and the xz plane) of the electron density difference between $[Ni(CN)_4]^{2-}$ and a system of Ni^{2+} (d^8 configuration with an unfilled $d_{x^2-y^2}$ orbital) and $(CN^-)_4$; the change in the electron density on the formation of the complex is shown in terms of contours. The large positive region between the Ni and C atoms represents a significant σ donation from cyanide to metal. The same feature is also reported by Demuynck *et al.*[2] on the basis of the electron density contours of the localized orbital. The decrease of the electron density in the nickel d_{xy} region results from π back-donation. This π back-donation of d_{xy} increases the nitrogen π_x and π_y populations by the combination of $1\pi-d\pi-2\pi$. This is clearly shown by Fig. 3a. As can be seen from the decrease in the d_{xy} electron density, the extent of π back-donation from d_{xy} is as large as that in $[Fe(CN)_6]^{4-}$ and is larger than that in $[Co(CN)_6]^{3-}$ reported previously.[2,13] There is no indication of the decrease in electron density in the region of d_{zx} (Fig. 3b), suggesting little π back-donation from d_{yz} and d_{zx}. The density increase in the C–Ni–C region and the density decrease in the outer region of CN^- may show the polarization of the coordinated CN^- by the central Ni^{2+} charge and/or the donation of the CN^- electrons to the Ni $3d_{x^2-y^2}$, 4s, and 4p orbitals.

TABLE 3. POPULATION ANALYSIS OF $[Ni(CN)_4]^{2-}$

Orbital	Population (population in free CN^-)			
	Present results		Literature[1]	
Nickel d_{z^2}	1.935		1.96	
$d_{x^2-y^2}$	0.437		0.91	
d_{xy}	1.956		1.95	
d_{yz}	1.956		1.97	
d_{zx}	1.956		1.97	
4s	0.144		0.52	
$4p_x$, $4p_y$	0.235		0.17	
$4p_z$	0.066		0.07	
Atomic charge	+1.533		+0.46	
Carbon 2s	1.660	(1.860)	1.26	(1.62)
$2p\sigma$	1.219	(1.164)	1.14	(1.13)
$2p\pi_y$	0.801	(1.528)	0.84	(0.84)
$2p\pi_z$	0.877		0.91	(0.84)
Atomic charge	−0.549	(−0.546)	−0.14	(−0.43)
Nitrogen 2s	1.647	(1.637)	1.66	(1.69)
$2p\sigma$	1.326	(1.351)	1.53	(1.56)
$2p\pi_y$	1.222	(2.472)	1.18	(1.16)
$2p\pi_z$	1.145		1.10	(1.16)
Atomic charge	−0.335	(−0.454)	−0.47	(−0.57)
Bond overlap population				
Ni-C	0.138			
C-N	1.564	(1.666)		

Although the population analysis is to some extent artificial, especially when based on the double-zeta set,[14] the Mulliken populations are given in Table 3 to allow qualitative considerations. (In the free CN^- ion, for example, the listed Mulliken populations are an overestimate for C and an underestimate for N, probably because the wavefunctions are more diffuse for C than for N. However, a comparison of the Mulliken populations before and after the bond formation will give us at least qualitatively reliable information about the nature of the bond, provided that the populations are calculated with the same basis set.) Table 3 also lists the values reported by Demuynck *et al.*[1] They in general agree with our results, but differ in a couple of respects. The Mulliken populations are known to depend on the basis functions; our $d_{x^2-y^2}$ population may thus be an underestimate, probably because one of the components of the split 2p orbital of carbon was too diffuse. Correspondingly, the calculated charge of the nickel atom is higher and that of the carbon atom is lower than the literature values. A significant donation from the C 2s orbital to the Ni $d_{x^2-y^2}$ and 4s orbitals can be seen in Table 3 and also in Fig. 3. The π back-donation from the Ni d_{xy} orbital to the N $2p\pi$ orbitals, which is not found in Table 3, is clearly shown by Fig. 3a, while the small π back-donation from the Ni d_{zx} (and d_{yz}) orbitals to the CN^- $2p\pi_z$ orbitals and the polarization of the latter are demonstrated both by Fig. 3b and by the present and previous results shown in Table 3. The electron-density difference maps are more useful and probably more reliable than the numerical results of the population analysis in discussing the nature of the bonds.

The work was partly supported by the Joint Studies Program (1979—1980) of the Institute for Molecular Science. The computation has been carried out on a HITAC M-180 computer of the Institute for Molecular Science.

Determination of Circular Dichroism in Multiple Scattering Systems

Yutaka TANIGUCHI* and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received June 12, 1981)

In a thick suspension circular dichroism cannot be directly determined by the Grosjean-Legrand type CD instrument, because Lambert's law does not hold in it. The transfer of light intensity is discussed when polarized light is incident on a plane-parallel scattering medium containing randomly oriented, optically active particles. This problem is analyzed based on a two-beam radiative transfer model. We provide a method to determine the molar CD in a multiple scattering system. The measurements of ellipticity and transmittance with conventional instruments is served for our method by using a plate of opal glass. The molar CD is determined in Nujol mulls of Λ-$[Co(en)_3]Br_3 \cdot H_2O$ and $[Co(NH_3)_6](d\text{-tart})_{1.5} \cdot 5H_2O$. The results are reproducible and reliable.

The measurement of circular dichroism (CD) spectrum is a useful method in the study of molecular structure in solution. The CD spectrum is easily measured by the Grosjean-Legrand method.[1] Because the intensity of incident light decreases in a transparent material exponentially following Lambert's law, the ellipticity of the transmitted light is given by the familiar equations

$$\Theta = (1/4)(k_L - k_R), \tag{1}$$

and

$$\Theta = (1/4)\ln(I_{t,R}/I_{t,L}), \tag{2}$$

where Θ is the ellipticity in radians, k the absorption coefficient, I_t the light intensity transmitted by a sample, and the subscripts L and R denote the left and right circular polarization, respectively. Actually, Θ can be adequately approximated by

$$\Theta = (1/4)(I_{ac}/I_{dc}), \tag{3}$$

where $I_{ac}=I_{t,R}-I_{t,L}$ and $I_{dc}=(I_{t,R}+I_{t,L})/2$. Therefore, Θ is obtained electronically by detecting I_{ac} and I_{dc} as the alternating and direct current signals, respectively, in the photomultiplier of a Grosjean-Legrand type CD instrument.

The CD measurement has recently been extended to suspensions of biological materials.[2,3] The decrease in light intensity transmitted by a dilute suspension also follows Lambert's law. The CD of a suspension, which contains a scattering contribution, is also measured by the conventional Grosjean-Legrand type CD instrument. However, on account of unequal scattering of left and right circularly polarized light by optically active particles, the interpretation of the resulting CD spectra is very complicated. A few investigations based on classical scattering theory were made to analyze the scattering effect on CD spectra,[4] but general approaches to this problem have not been confirmed yet.

In the previous studies suspensions were always assumed to be dilute, where multiple scattering effects were neglected. However, multiple scattering effects are no longer negligible in a somewhat thick suspension. Lambert's law does not hold in it, and hence the Θ measured by the Grosjean-Legrand type CD instrument is not the direct information of CD.

In this paper, we propose a method to determine the molar CD of a thick suspension, a Nujol mull of solid-state complex salt, by the Grosjean-Legrand type CD instrument. The reproducibility of CD data obtained by our method will be shown too.

Principles and Practical Method

Stokes Vector. The light beams suffered multiple scattering have randomly different phases from one another, and hence the scattered beams are incoherent. The polarization state of an incoherent light beam is conveniently expressed by a Stokes vector[5] with four components having the dimensions of light intensity. In this study, the representation based on the left and right circular polarizations[6] will be used instead of the original Stokes vector. It is defined as

$$\boldsymbol{I} = \begin{bmatrix} I_1 \\ I_R \\ I_L \\ I_4 \end{bmatrix} = \begin{bmatrix} \langle E_R E_L^* \rangle \\ \langle E_R E_R^* \rangle \\ \langle E_L E_L^* \rangle \\ \langle E_L E_R^* \rangle \end{bmatrix}, \tag{4}$$

where E is the amplitude of electric field vector, the brackets denote time averages, and the asterisks complex conjugates. In the Grosjean-Legrand type CD instrument, the Stokes vector of the incident beam $\boldsymbol{I}_o$ (total intensity$=I_o$) is

$$\boldsymbol{I}_o = (I_o/2)\begin{bmatrix} \cos(\delta \sin \omega t) \\ 1-\sin(\delta \sin \omega t) \\ 1+\sin(\delta \sin \omega t) \\ \cos(\delta \sin \omega t) \end{bmatrix}, \tag{5}$$

where δ is the maximum phase difference produced in the modulator and ω the modulation frequency.

Equation of Radiative Transfer. The problem of radiative transfer in a scattering medium has been well investigated by Chandrasekhar.[7,8] It is assumed in this paper that a homogeneous scattering medium consisting of randomly oriented particles is bounded by two parallel planes and extends over a region very large compared to its thickness. In such a plane-parallel scattering medium, the radiation field is characterized by the coordinate z on the axis normal to the boundary planes, the polar angle θ with respect to the z-axis, and the azimuthal angle ϕ referred to a suitably chosen x-axis (see Fig. 1). The variation of a light flux travelling through a layer dz in the direction (θ,ϕ) is given by

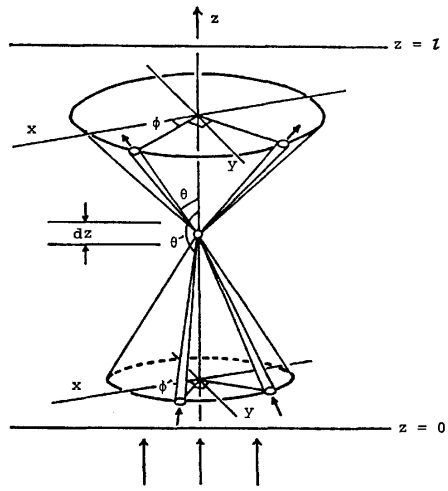

Fig. 1. Coordinate system and the directions of the incident and scattered beams.

$$(\cos\theta/\mathrm{d}z)\mathrm{d}\boldsymbol{I}(z,\theta,\phi) = -(k+s)\boldsymbol{I}(z,\theta,\phi) + (s/4\pi)\int_0^{\pi}\int_0^{2\pi} P(\theta,\phi;\theta',\phi')\boldsymbol{I}(z,\theta',\phi')\sin\theta'\mathrm{d}\theta'\mathrm{d}\phi', \tag{6}$$

where k and s are the absorption and scattering coefficients, respectively, and $P(\theta,\phi;\theta',\phi')$ is the normalized phase matrix defining the angular distribution of the scattered light incident from a direction (θ',ϕ') into the direction (θ,ϕ). The phase matrix is represented by a 4×4 matrix. When scattering particles are optically active, k and s are rewritten by the diagonal matrices, *viz.*,

$$K = \mathrm{diag}(k_1, k_R, k_L, k_4) \text{ and } S = \mathrm{diag}(s_1, s_R, s_L, s_4). \tag{7}$$

For the problem in a plane-parallel scattering medium, the Stokes vector is customarily referred to the directions parallel and perpendicular to the meridian plane,[9] which is defined by the z-axis and the propagation direction of a light beam.

We shall now consider the nature of the radiation scattered from the direction (θ',ϕ') into the direction (θ,ϕ), and that of the radiation from the direction $(\theta',\phi'+\chi)$ into the direction $(\theta,\phi+\chi)$; so the azimuthal angles of both beams are greater for the latter than for the former by an angle χ. The phase matrix depends only on the characteristics of the scattering medium. The phase matrix $P(\theta,\phi+\chi;\theta',\phi'+\chi)$ is identical with the matrix $P(\theta,\phi;\theta',\phi')$ because the scattering medium containing particles with random orientation has, on the whole, an axial symmetry about the z-axis.

When a parallel beam of light is incident into a scattering medium perpendicularly to the boundary plane (parallel to the z-axis), the relation between $\boldsymbol{I}(z,\theta',\phi')$ and $\boldsymbol{I}(z,\theta',\phi'+\chi)$ can be derived as follows. The Stokes vector $\boldsymbol{I}(z,\theta',\phi'+\chi)$ is identical with the new vector which should be yielded in the direction (θ',ϕ') when the reference axes of the original parallel beam are rotated around its propagation axis by the angle χ in the clockwise direction, as viewed in the direction of propagation. The rotation matrix $R(\chi)$ for the Stokes vector $\boldsymbol{I}=(I_1,I_R,I_L,I_4)$ is a diagonal matrix with the elements $(e^{2i\chi}, 1, 1, e^{-2i\chi})$.[6] The components I_R and I_L are invarient for the rotation of the axes. But the other components I_1 and I_4 change with such a rotation. When $\chi=\pi/2$, each of I_1 and I_4 has the value equal in magnitude but opposite in sign to the original value before the rotation.

In the CD measurements, any of the four components of the Stokes vector, (I_1,I_R,I_L,I_4), is not separately detected by our instrument. The CD signals are obtained by measuring the ac and dc components of the total intensity, I_R+I_L, emitted in the forward direction. The total intensities, even in different directions, can be added arithmetically. From the above discussion it is found that the scattering contributions to the total intensity of $\boldsymbol{I}(z,\theta,\phi)$ by the I_1 and I_4 components of $\boldsymbol{I}(z,\theta',\phi')$, and those to the total intensity of $\boldsymbol{I}(z,\theta,\phi+\pi/2)$ by the corresponding components of $\boldsymbol{I}(z,\theta',\phi'+\pi/2)$ are cancelled out each other. The same argument applies to any couple of scatterings having such a directional relation. The azimuthal angles ϕ and ϕ' can be chosen arbitrarily. Therefore, when light beams scattered in the directions with the polar angle θ are all accepted simultaneously, the total intensity is, on the whole, not contributed by the components I_1 and I_4 of the incident beams from the directions with another polar angle θ'. Then the transfer equation of the total intensity is written by a 2-vector with the components I_R and I_L. The matrices P, K, and S are, of course, rewritten by 2×2 matrices.

Two-beam Model. The exact solution of the transfer equation is rarely obtained, because in most cases the phase matrix is seldom known. To a fairly good approximation, a two-beam model, dividing the radiation field into the two streams in the forward and backward directions, has been employed to solve the practical problems of radiative transfer. The scattering particles dealt with in previous papers were always optically inactive. We now extend the two-beam model to an optically active case.

Let $\boldsymbol{I}=(I_R,I_L)^t$ and $\boldsymbol{J}=(J_R,J_L)^t$ represent the streams propagating in the forward and backward directions, respectively (see Fig. 2). The superscript t denotes the transposed matrix. Assuming that the optical activity (circular birefringence and circular dichroism) of a particle is small, we may, as a first approximation, let the elements of the phase matrix be

$$p_{RR} = p_{LL} = 1 \text{ and } p_{RL} = p_{LR} = 0. \tag{8}$$

Within the limits, the transfer equation 6 can be replaced by the two equations of Schuster[10] or Kubelka-

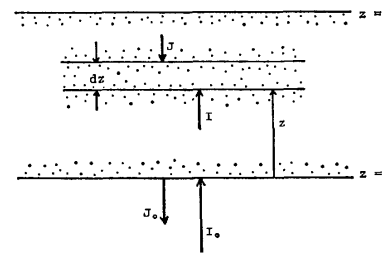

Fig. 2. Directions of the light streams used in the two-beam model.

Munk:[11]

$$dI/dz = -(K+S)I+SJ, \quad (9)$$

$$dJ/dz = (K+S)J-SI, \quad (10)$$

where $K=\mathrm{diag}(k_R,k_L)$ and $S=\mathrm{diag}(s_R,s_L)$. The general solutions of the Eqs. 9 and 10 are

$$I_i = A_i(1-\beta_i)e^{\alpha_i z} + B_i(1+\beta_i)e^{-\alpha_i z};\ i = R, L, \quad (11)$$

$$J_i = A_i(1+\beta_i)e^{\alpha_i z} + B_i(1-\beta_i)e^{-\alpha_i z};\ i = R, L, \quad (12)$$

where A_i and B_i are arbitrary constants to be determined by the boundary conditions, α_i and β_i are constants, given by

$$\alpha_i = [k_i(k_i+2s_i)]^{1/2}, \quad (13)$$

$$\beta_i = [k_i/(k_i+2s_i)]^{1/2}. \quad (14)$$

If

$$I_i = (I_o)_i;\ i = R, L \quad (15)$$

at the illuminated surface ($z=0$), and

$$I_i = (I_t)_i,\ J_i = 0;\ i = R, L \quad (16)$$

at the back surface ($z=l$), we have

$$A_i = -(1-\beta_i)e^{-\alpha_i l}(I_o)_i/[(1+\beta_i)^2e^{\alpha_i l}-(1-\beta_i)^2e^{-\alpha_i l}], \quad (17)$$

$$B_i = (1+\beta_i)e^{\alpha_i l}(I_o)_i/[(1+\beta_i)^2e^{\alpha_i l}-(1-\beta_i)^2e^{-\alpha_i l}]. \quad (18)$$

Therefore, the transmittance of the i component is given by

$$T_I = 4\beta_i(I_o)_i/[(1+\beta_i)^2e^{\alpha_i l}-(1-\beta_i)^2e^{-\alpha_i l}]I_o, \quad (19)$$

when

$$I_o = \Sigma_i(I_o)_i. \quad (20)$$

Determination of Δk. The Eq. 1 between the ellipticity Θ and the circular dichroism $\Delta k=k_L-k_R$ is not valid for a multiple scattering system, because Lambert's law does not hold in it. The Θ measured in such a system only gives the ratio of the ac and dc components of the light intensity transmitted, as indicated in Eq. 3.

The Eq. 3 can be rewritten by the transmittances for the left and right circular polarizations:

$$\Theta = -(1/4)\Delta T/T, \quad (21)$$

where

$$\Delta T = T_L - T_R, \quad (22)$$

and

$$T = (T_R+T_L)/2. \quad (23)$$

From Eqs. 21, 22, and 23 it follows that

$$T_R = T-\Delta T/2 = (1+2\Theta)T, \quad (24)$$

and

$$T_L = T + \Delta T/2 = (1-2\Theta)T. \quad (25)$$

According to Eqs. 13, 14, and 19, k_R and k_L can be calculated from the values of T_R, T_L, s_R, and s_L. The T_R and T_L are evaluated from the Θ and T which are measurable by conventional spectrometers. If the values of s_R and s_L are known, we can determine k_L-k_R, *viz.*, Δk, even in a multiple scattering system.

Estimation of Scattering Coefficients. In the Kubelka-Munk equations, s is the back-scattering coefficient. When scatterers are optically active, the scattering coefficients for left- and right-circularly polarized light are, in general, different from each other. The angular dependence of the difference between scattering of left- and right-circularly polarized light by optically active spheres has been discussed recently.[12,13] It has been indicated that the difference is virtually significant in the forward scattering directions. Therefore, the back-scattering coefficients s_R and s_L may be taken as equal, and hence their values are equal to that for natural light:

$$s_R = s_L = s. \quad (26)$$

In Eq. 19, if k approaches zero, the equation of transmittance becomes the simplified expression

$$\lim_{k\to 0}T = 1/(1+sl). \quad (27)$$

At a wavelength where scattering particles have no absorption, the scattering coefficient s can be calculated by substituting the value of transmittance in Eq. 27.

While the scattering coefficient in an absorption band region cannot be determined directly. The scattering coefficient generally varies with wavelength; it's value normally increases with decreasing wavelength. Kortüm and Oelkrug[14] showed that for the powder samples having no absorption, there exists the empirical relation between s and λ:

$$\log s \propto \log \lambda^{-1}, \quad (28)$$

where λ is wavelength. At any wavelength in an absorption band region, we now estimate the value of the scattering coefficient by extrapolating the linearity between $\log s$ and $\log \lambda^{-1}$ in the wavelength region having no absorption to a desired wavelength (see Fig. 3).

Molar Circular Dichroism. The present paper is concerned with Nujol mulls of complex salts. The Nujol mull is composed of particles of different shapes and sizes. Because the shape and size distributions are different in every mull, neither absorption nor scattering coefficient is identical for every mull, even if it may have the same concentration. Then the values of k and s are not characteristic of a material. Nevertheless, the ratio of Δk to k should be characteristic of a material, even if it is in different mulls. Then we have

$$\Delta k/k = \Delta\varepsilon(\mathrm{cryst})/\varepsilon(\mathrm{cryst}), \quad (29)$$

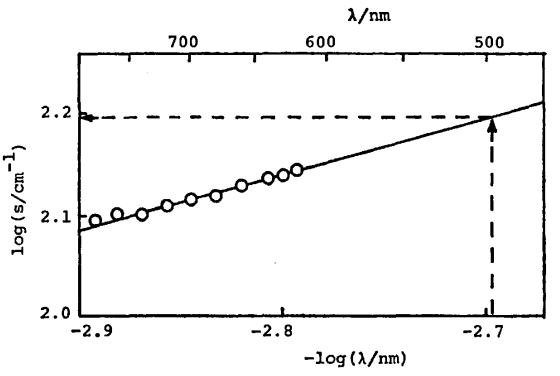

Fig. 3. Extrapolation of the scattering coefficient to a desired wavelength.
This figure is drawn based on the transmittance data in a Nujol mull of Λ-$[Co(en)_3]Br_3\cdot H_2O$.

where $\Delta\varepsilon$(cryst) is the molar circular dichroism and ε(cryst) the molar absorption coefficient in crystalline state.

By using a microspectrophotometer Kondo measured the absorption spectra of nine crystalline hexaamminecobalt(III) complex salts in the d-d transition band region.[15] The spectrum in crystal is not much different from that in aqueous solution, *e.g.*, the molar absorption coefficients of hexaamminecobalt(III) chloride are ε_{max}(cryst)=59.7 and ε_{max}(soln)=57.6 mol^{-1} dm^3 cm^{-1} for the first absorption band. We now assume that the molar absorption coefficient in crystal is equal to that in solution in the d-d transition band region:

$$\varepsilon(\text{cryst}) = \varepsilon(\text{soln}). \tag{30}$$

From Eqs. 29 and 30 the molar CD is given by

$$\Delta\varepsilon(\text{cryst}) = \varepsilon(\text{soln})\Delta k/k. \tag{31}$$

The value of k is, of course, calculated from the values of T and s for natural light.

Experimental

Measurements. In the Kubelka-Munk model the radiation field is divided into two streams in the forward and backward directions. Therefore, the light transmitted in the forward directions ($0 \leqq \theta < \pi/2$) has to be all detected in order to obtain the transmittance based on the Kubelka-Munk model. In a usual measurement parallel light, which passes through the space among suspended particles and hence contains no information from the particles, is more effectively detected by a photomultiplier than scattered light. By setting a plate of opal glass[16] on the unilluminated side of a sample cell, both of the parallel and the scattered light passing through the sample cell are accepted and transformed into diffused light at the plate of opal glass. If the diffused light emerging from the plate of opal glass has the same angular distribution for the incidence of parallel and scattered light, the transmittance is measured by detecting the diffused light on a photomultiplier of a conventional spectrophotometer. The plate of opal glass needs to be much larger than the cross section of light-path in order to prevent missing any of light scattered in the forward directions.

A mull between two parallel plates of quartz may be regarded as a plane-parallel scattering medium. When all of the light scattered into a cone, whose axis is colinear with the z-axis, is accepted simultaneously, the scattering contribution of the Stokes parameters I_1 and I_4 is eliminated from the transfer equation of light intensity. Then the opal glass method is served for the measurement of Θ.

The transmittance was measured with a Shimadzu UV-200 spectrophotometer, and the measurements of Θ were carried out on a JASCO MOE-1 spectropolarimeter at room temperature.

The measurements on Nujol mulls were made by using a quartz cell with demountable window (path length 9.15×10^{-3} cm). The blank values were also obtained by setting the plate of opal glass on the unilluminated side of the blank cell containing the mulling agent Nujol only.

A mull was prepared by adding Nujol (40—50 mg) to a sample complex salt (5—30 mg) in an agate mortar, and good grinding and mixing it.

Materials. The preparation of Λ-$[Co(en)_3]Br_3 \cdot H_2O$ was performed by well-known procedures.[17]

Hexaamminecobalt(III) tartrate was obtained by treating the solution of its chloride salt with an equivalent amount of freshly prepared silver *d*-tartrate. Silver chloride was precipitated and filtered off; the tartrate salt was crystallized from the filtrate. Found: C, 15.00; H, 7.24; N, 17.66%. Calcd for $[Co(NH_3)_6](d\text{-tart})_{1.5}5H_2O$: C, 15.23; H, 7.24; N, 17.76%.

Results and Discussion

In a scattering system, the ellipticity Θ recorded in a usual manner without a plate of opal glass was always smaller than that recorded by the opal glass method. This is because the parallel light, which contributes not to the numerator I_{ac} but to the denominator I_{dc} in Eq. 3, is more effectively detected by the photomultiplier when a plate of opal glass is absent.

When the CD spectrum was measured on mulls in a conventional manner, no reproducibility was found in the intensity and shape of the spectrum. By using a plate of opal glass, the reproducibility of the CD data was obtained. Especially the shape of recorded CD curves was well reproducible on repeated runs. For two complex salts the values of $\Delta\varepsilon$(cryst) at the maximum or the minimum in the first absorption region, which were measured on the samples having various concentrations of the salts, are shown in Table 1. As can be seen from the table, the deviations from the average value of $\Delta\varepsilon$(cryst) are, at most, 5% for Λ-$[Co(en)_3]Br_3 \cdot H_2O$ and 4% for $[Co(NH_3)_6](d\text{-tart})_{1.5} \cdot 5H_2O$. Particles in every mull have different shape and size distributions, so that the values of absorption and scattering coefficients

Table 1. Concentrations and the molar CD in Nujol mulls

Complex	Concentration	$\Delta\varepsilon$(cryst)[a]
Λ-$[Co(en)_3]Br_3 \cdot H_2O$	10.6%	+1.79
	12.3	+1.91
	12.7	+1.86
	14.2	+1.86
	14.6	+1.83
	15.8	+1.84
	15.9	+1.73
	18.3	+1.79
	19.0	+1.81
		av. +1.82
$[Co(NH_3)_6](d\text{-tart})_{1.5} \cdot 5H_2O$	14.6%	−0.61
	24.6	−0.62
	25.0	−0.61
	31.9	−0.65
	33.6	−0.64
	39.2	−0.66
	39.8	−0.65
	40.2	−0.65
		av. −0.64

a) The values are observed at 496 nm for Λ-$[Co(en)_3]Br_3 \cdot H_2O$, and at 478 nm for $[Co(NH_3)_6](d\text{-tart})_{1.5} \cdot 5H_2O$.

are characteristic not of materials but of every mull. Taking this fact into account, the magnitudes of the deviations are not so large; rather good reproducibility can be attained in the CD intensity regardless of the sample concentrations.

The CD spectrum of Λ-$[Co(en)_3]Br_3 \cdot H_2O$ in Nujol, which will be given elsewhere,[18] resembles that in aqueous solution. We have observed $\Delta\varepsilon(\text{cryst}) = +1.83$ at 496 nm, -0.26 at 435 nm, and $+0.24$ at 346 nm in a Nujol mull, and $\Delta\varepsilon(\text{soln}) = +1.89$ at 491 nm, -0.14 at 430 nm and $+0.24$ at 347 nm in an aqueous solution. Since the spectroscopic discrepancy is small, we suppose that the chirality around the central cobalt ion in crystal is not so different from that in solution. Kuroda and Saito have reported the CD data of some cobalt(III) complexes in KBr matrices.[19] For Λ-$[Co(en)_3]Cl_3 \cdot (1/2)NaCl \cdot 3H_2O$ the values of $\Delta\varepsilon = +2.0$ at 505.5 nm, -0.59 at 445.5 nm and $+0.19$ at 352 nm have been obtained. These values are appreciably different from the solid-state CD data obtained for Λ-$[Co(en)_3]Br_3 \cdot H_2O$ in this study. However, this is supposed to be caused by the influence of outer-sphere configuration.[20] Thus the value of $\Delta\varepsilon$(cryst) in our method is regarded as the value of the molar CD in crystal, which seems free from the effects of crystal anisotropies.[21]

On the other hand, the induced CD of $[Co(NH_3)_6]$-$(d\text{-tart})_{1.5} \cdot 5H_2O$ in crystal is more intensive than that in aqueous solution, *i.e.*, the value of $\Delta\varepsilon$(cryst), -0.64, is about 65 times that of $\Delta\varepsilon$(soln), -0.0098, in the first absorption band. It is because the chirality is induced in the achiral complex ion by surrounding tartrate ions more effectively in crystal than in solution.

At present our method is the only approach to determine the molar CD in multiple scattering systems. In the study of solid-state CD, the advantage of our method is that the isotropic solid-state CD, likewise the CD in solution, is obtained by easy experimental procedures, even if a minor error may exist.

Kinetics of Racemization and Dissociation of Tris(1,10-phenanthroline)-iron(II). Hydrophobic Interaction between the Complex Cation and Alkylammonium Cations

Satoshi TACHIYASHIKI* and Hideo YAMATERA†

Laboratory of Chemistry, Kagawa Nutrition College, Sakado, Saitama 350-02

†*Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464*

(Received June 16, 1981)

The rates of racemization and dissociation of $[Fe(phen)_3]^{2+}$ were determined in the presence of series of alkali-metal bromides, symmetrical tetraalkylammonium bromides, and alkyltrimethylammonium bromides. The alkali-metal bromides did not affect the racemization rate, but they decreased the dissociation rate. The retarding effect increased with increasing bromide concentrations and decreased in the order of $Li^+ > Na^+ > K^+ > Rb^+ > Cs^+$. The alkylammonium bromides increased the racemization rate up to three fold and decreased the dissociation rate down to half the rate in pure water; alkylammonium ions with longer alkylchains induced greater changes of the rates. The effect of alkylammonium ions on the reaction rates was analyzed in terms of the formation of 1:1 aggregates of the complex cation with the alkylammonium cation caused by hydrophobic interactions. The equilibrium constant for the aggregate formation was greater for the alkylammonium ions with longer alkyl chains. The reaction rate constants of the hydrophobic aggregates remain almost constant with the increase in the alkyl chain length. The rate behaviors of the hydrophobic aggregates are discussed in terms of the reaction mechanisms of racemization and dissociation of $[Fe(phen)_3]^{2+}$.

Tetraalkylammonium ions can be used as model compounds for investigating hydrophobic interactions.[1] Salting-in of a hydrophobic solute by tetraalkylammonium ions has mainly been attributed to hydrophobic interactions between the cations and nonelectrolytes.[2] Tris(1,10-phenanthroline)metal chelates are also considered to be hydrophobic because of the large hydrophobicity of the ligand. Tris(1,10-phenanthroline)nickel(II) is reported to salt-in tris(acetylacetonato)cobalt(III) to water by hydrophobic interactions.[3] A stacking interaction, caused by hydrophobic interaction and a polarization effect, was proposed for the enhancement of the rates of the mixed complex formation of mono(2,2′-bipyridine)-, mono(1,10-phenanthroline)-, and mono(2,2′:6′,2″-terpyridine)-metal complexes with some aromatic nitrogen donors.[4] Thus, it is interesting to study the nature of the interaction between hydrophobic alkylammonium cations and hydrophobic metal complex cations. The rate of aquation of tris(5-nitro-1,10-phenanthroline)iron(II) was reported to be influenced by the addition of alkylammonium cations.[5] The effects were analyzed in terms of salt effects on both the initial and transition states. Jensen *et al.*[6] reported the effect of octadecyltrimethylammonium chloride on the dissociation rate of $[Fe(phen)_3]^{2+}$ (phen=1,10-phenanthroline).

We previously reported the effects of added inorganic salts on the rates of racemization and dissociation of $[Fe(phen)_3]^{2+}$.[7] The racemization rate increased slightly with the increase in the polarizability of the anion, whereas the dissociation rate remarkably increased with the increase in the pK_a value of the conjugate acid of the anion. The racemization of $[Fe(phen)_3]^{2+}$ is known to occur much faster in organic solvents than in aqueous solution.[8] The ability of the solvent to accelerate the racemization rate was correlated with its solvating power to the ligand[9] or with its electron-donating ability.[10] However, the details of the nature of this acceleration effect of the solvents are not clear. Since organic salts can be regarded as compounds intermediate between inorganic salts and organic solvents, the study of the effects of added organic salts such as alkylammonium bromides and sodium alkanesulfonates on the kinetics of racemization and dissociation is expected to give information concerning the nature of the solvent effects. With this expectation, we decided to study the effect of alkali-metal and alkylammonium cations on the rates of racemization and dissociation of $[Fe(phen)_3]^{2+}$. The comparison of the effects of inorganic and organic cations on the reaction rates will lead us to understand the solvent effects and the mechanisms of the dissociation and the intramolecular twist racemization. The present study will also give information about the interactions between the hydrophobic alkylammonium cations and the hydrophobic complex cation. The effect of organic anions on the reaction rates of $[Fe(phen)_3]^{2+}$ will be reported elsewhere.

Experimental

The symmetrical tetraalkylammonium bromides used were reagents of the best grade obtainable from Wako Pure Chemical Industries, Ltd. Ammonium bromide was recrystallized from water, tetramethylammonium bromide from aqueous methanol(1:1), tetraethyl- from ethanol, tetrapropyl- from methanol, tetrabutyl- and tetrapentyl- from acetone. They were dried by heating at 110 °C for 18 h. Alkyltrimethylammonium bromides were guaranteed-grade reagents of Tokyo Kasei Kogyo Co., Ltd. Hexyl-, octyl-, decyl-, dodecyl-trimethylammonium bromides were recrystallized from acetone, while tetradecyl- and hexadecyl-trimethylammonium bromides were recrystallized from 10:1 and 2:1 acetone–ethanol, respectively. They were dried by heating at 90 °C for 24 h. Tetraphenylphosphonium chloride of Dojindo Laboratories, and lithium, sodium, potassium, rubidium, and caesium bromides of Merck(Suprapur) were used without further purification. The concentrations of the solutions of tetraethylammonium bromide, hexyltrimethylammonium bromide, and lithium bromide were determined by argentometry. Those of other salts were deter-

mined by weighing well-dried reagents. The purities of tetrapentylammonium bromide, and octyl-, decyl-, dodecyl-, and tetradecyl-trimethylammonium bromides were more than 99%, as determined by argentometry. Kinetic data were obtained at 32.0 °C using the perchlorate of the complex. The bromide of the metal complex was preferred to the perchlorate for the systems containing dodecyl- and tetradecyl-trimethylammonium ions, since the addition of perchlorate would precipitate alkylammonium perchlorate. In measuring the dissociation rate for the systems containing tetrapentylammonium bromide and alkyltrimethylammonium bromides, hydrochloric acid was added to the solution up to two percent of the alkylammonium bromide concentration; otherwise iron hydroxide might be precipitated in the course of the reaction due to the presence of a trace amount of the alkylamines contained in alkylammonium bromides. Other chemicals and procedures were the same as those described in a previous paper.[7]

Results and Discussion

Alkali-metal Cations. Table 1 and Fig. 1 show the observed first order rate constants of racemization and dissociation of $[Fe(phen)_3]^{2+}$ in the presence of a series of alkali-metal bromides. The racemization rate was not appreciably influenced by the addition of the alkali-metal bromides. The dissociation rate decreased with the increase in the alkali-metal bromide concentration. The order of the cation efficiency in decreasing the rates was $Li^+ > Na^+ > K^+ > Rb^+ > Cs^+$, which is consistent with the previously reported order of $Li^+ > K^+$.[11] As the order is the same as that for the effect of decreasing the activity of water,[12] the effect of cations on the dissociation rates can be at least partly explained in terms of the changes in the activity of water; this change should affect the dissociation rate if the dissociation proceeded through a 7-coordinate transition state with an H_2O ligand.[7]

Alkylammonium Cations. The racemization rate increased and the dissociation rate decreased with the increase in the concentration of tetraalkyl- and alkyltrimethyl-ammonium bromides, as shown in Figs. 2—5. These also show that the extent of the rate change with the alkylammonium ion concentrations becomes greater with increasing length of the alkyl chain for both racemization and dissociation. However, both the racemization and dissociation rates are almost constant above certain concentrations of tetraphenylphosphonium cation and alkyltrimethylammonium cations, as shown in Figs. 2, 3, and 5. The critical concentrations above which the rates were almost constant shifted toward lower concentrations with the increase

in the length of the alkyl chain. As is shown in Table 2, the critical concentration is close to the critical micelle concentration (cmc) for each electrolyte. Thus, these phenomena can reasonably be correlated with the micelle formation of the cations above cmc. As the concentration of the monomeric cations remains unchanged above cmc, the kinetic results suggest that the interaction of the complex ion with the monomeric cations is responsible for the observed features of the rate changes. A previously reported phenomenon,[6] that the added octadecyltrimethylammonium chloride had no effect on the rate of dissociation of $[Fe(phen)_3]^{2+}$, can be reasonably accounted for by the very low concentration of the monomeric alkylammonium ion, as indicated by the extremely low cmc value. The slight increase of the rates observed for octyl- and decyl-trimethylammonium ions above cmc would be caused by some interactions of the complex with micelles.

As the alkali-metal cations have no effects on the racemization rate, the acceleration of the racemization rate by the monomeric alkylammonium ions can be attributed to the hydrophobic interactions between the complex and the alkylammonium ions. The kinetic results can reasonably be accounted for by assuming the formation of 1:1 hydrophobic aggregates between the alkylammonium ions and complex cations. The following mechanism was considered:

$$[Fe(phen)_3]^{2+} + Br^- \overset{K_1}{\rightleftharpoons} [Fe(phen)_3]^{2+}\cdot Br^-, \quad (1)$$

$$[Fe(phen)_3]^{2+} + R_4N^+ \overset{K_2}{\rightleftharpoons} [Fe(phen)_3]^{2+}\cdot R_4N^+, \quad (2)$$

$$[Fe(phen)_3]^{2+}\cdot Br^- + R_4N^+ \overset{K_3}{\rightleftharpoons} [Fe(phen)_3]^{2+}\cdot Br^-\cdot R_4N^+, \quad (3)$$

$$K_1 = \frac{[Fe(phen)_3{}^{2+}\cdot Br^-]}{[Fe(phen)_3{}^{2+}][Br^-]}\cdot\frac{f_1}{f_2 f_1}, \quad (4)$$

$$K_2 = \frac{[Fe(phen)_3{}^{2+}\cdot R_4N^+]}{[Fe(phen)_3{}^{2+}][R_4N^+]}\cdot\frac{f_3}{f_2 f_1}, \quad (5)$$

$$K_3 = \frac{[Fe(phen)_3{}^{2+}\cdot Br^-\cdot R_4N^+]}{[Fe(phen)_3{}^{2+}\cdot Br^-][R_4N^+]}\cdot\frac{f_2}{f_1 f_1}, \quad (6)$$

$$[Fe(phen)_3]^{2+} \xrightarrow{k_0}, \quad (7)$$

$$[Fe(phen)_3]^{2+}\cdot Br^- \xrightarrow{k_1}, \quad (8)$$

$$[Fe(phen)_3]^{2+}\cdot R_4N^+ \xrightarrow{k_2}, \quad (9)$$

$$[Fe(phen)_3]^{2+}\cdot Br^-\cdot R_4N^+ \xrightarrow{k_3}, \quad (10)$$

where f_z means the activity coefficient of an ion with a charge of $\pm z$, and can be expressed by the Debye-Hückel equation, as discussed previously.[7] The closest distance of approach, a, was assumed to be 8, 9, and 9—11 $\times 10^{-8}$ cm for $z=\pm1$, ±2, and ±3, respectively. The rate constants k_0, k_1, k_2, and k_3 mean the first order rate constants (Eqs. 7—10) for either racemization (r) or dissociation (d) of each chemical species. Additional subscripts, r and d, may be used to specify the type of reaction. The observed

TABLE 2. THE CRITICAL CONCENTRATIONS (C/mol dm^{-3}) ABOVE WHICH THE RATES SHOW CONSTANT VALUES

a) J. N. Phillips, *Trans. Faraday Soc.*, **51**, 561 (1955).

rate constant is expressed as:

$$k^{obsd} = \frac{k_0 + k_1K_1[Br^-]f_2 + k_2K_2[R_4N^+]f_1f_2/f_3 + k_3K_1K_3[Br^-][R_4N^+]f_1^2}{1 + K_1[Br^-]f_2 + K_2[R_4N^+]f_1f_2/f_3 + K_1K_3[Br^-][R_4N^+]f_1^2}, \quad (11)$$

where $[Br^-]$ and $[R_4N^+]$ can be taken to be equal to the total alkylammonium ion concentration (C_t) at a very low concentration of the complex. At very low alkylammonium ion concentrations, Eq. 11 is transformed to:

$$k^{obsd} = k_0 + (k_1-k_0)K_1[Br^-]f_2 + (k_2-k_0)K_2[R_4N^+]f_1f_2/f_3$$
$$= k_0 + \{(k_1-k_0)K_1 + (k_2-k_0)K_2\}C_t.$$

The gradient (m) of k^{obsd} *vs.* C_t is then;

$$m = (k_1-k_0)K_1 + (k_2-k_0)K_2. \quad (12)$$

For systems containing symmetrical tetraalkylammonium ions, tetraphenylphosphonium ion, hexyl-, octyl-, and decyl-trimethylammonium ions, the kinetic data were analyzed on the basis of Eq. 11. Among the parameter values in Eq. 11, $k_{0r}=k_{1r}=(1.94\pm0.09)\times10^{-3}$ s^{-1}, $k_{0d}=(2.54\pm0.03)\times10^{-4}$ s^{-1}, $k_{1d}=(2.1\pm0.2)\times10^{-4}$ s^{-1}, and $K_1=3$ mol^{-1} dm^3 were previously obtained.[7] Since the simultaneous determination of the values of k_2, K_2, k_3, and K_3 was impossible because of experimental errors in the kinetic data, they were determined in the following way. The formation constant of $[Fe(phen)_3]^{2+}\cdot R_4N^+$ would be small compared with that of $[Fe(phen)_3]^{2+}\cdot Br^-\cdot R_4N^+$. Therefore, we analyzed the kinetic data, considering only the formation of $[Fe(phen)_3]^{2+}\cdot Br^-$ and $[Fe(phen)_3]^{2+}\cdot Br^-\cdot R_4N^+$, to obtain approximate k_3 and K_3 values. Using the approximate k_3 and K_3 values and taking the formation of $[Fe(phen)_3]^{2+}\cdot R_4N^+$ into account, the kinetic data were reanalyzed to obtain approximate k_2 and K_2 values. Then using the values of k_2, K_2, k_3, and K_3 thus obtained as the initial values, the least-squares fitting[13] of the kinetic data to Eq. 11 were carried out to give more reliable values for k_2, K_2, k_3, and K_3. The results of the analysis are listed in Table 3.

For the systems containing dodecyl- and tetradecyltrimethylammonium ions, their small cmc values restricted the measurement of the rates within a narrow range of the ammonium ion concentrations; therefore, Eq. 11 was not applicable in the analysis of the kinetic data. Thus, Eq. 12 was used to analyze the kinetic data for these systems, as well as for the systems containing octyl- and decyl-trimethylammonium ions. As the values of k_0, k_1, and K_1 have been previously obtained, Eq. 12, together with the experimental determination of the value of m, gives us the relation between k_2 and K_2. Then, K_2 can be obtained on the assumption that k_{2d} values for the complex in the hydrophobic aggregates with octyl-, decyl-, dodecyl-, and tetradecyl-trimethylammonium cations are negligibly small, an assumption which seems reasonable if we compare the k_{2d} values for the homologs (see Table 3). Then, the K_2 value thus obtained and the m_r value experimentally determined will be substituted in Eq. 12 to give the value of k_{2r}. The K_2 and k_{2r} values obtained in this manner are listed in Table 3 within parentheses.

The K_2 and K_3 values increased with the increase in the number of carbon atoms of the alkyl chains, as shown in Table 3 and Fig. 6. This implies that the formation of the aggregates is caused by the hydrophobic interaction between the complex and alkylammonium cations, which is presumed to be larger for a longer alkyl chain. The aggregate formation constant (K_2) for the complex and tetraphenylphosphonium ions falls on the line of the K_2 values for tetraalkylammonium ions as shown in Fig. 6; this shows the similarity of the interaction of the complex ion with phenyl groups to that with alkyl groups. Figure 6 also shows that the dependence of the log K_2 value on the total carbon number of the ammonium ion is twice as large for alkyltrimethylammonium ions as for tetraalkylammonium ions. That is, the energies of hydrophobic interaction with complex cations were 0.8 kJ/mol and 0.4 kJ/mol per methylene group for alkyltrimethylammonium cations and tetraalkylammonium cations, respectively.

a) The values were obtained from the analysis based on Eq. 11, except for a few cases where the results from the analysis based on Eq. 12 are given in parentheses.

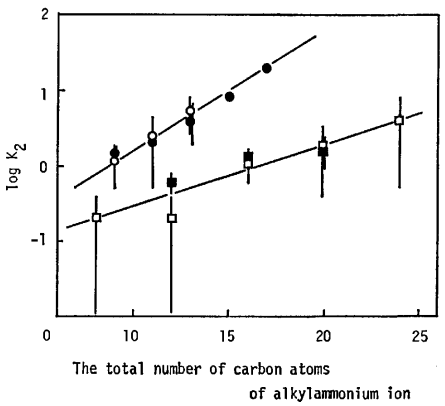

Fig. 6. Plot of $\log K_2$ against the total number of carbon atoms of the alkylammonium ion.
The open marks are the results of the analysis based on Eq. 11 and the closed marks are those based on Eq. 12. ○,●: Alkyltrimethylammonium ion. □,■: Symmetrical tetraalkylammonium ion.

The k_2 and k_3 values both for racemization and for dissociation did not significantly depend on the alkyl chain length, as shown in Table 3. The k_2 values for the racemization rate of the complex were about three times as large as k_0, and for the dissociation rate, the k_2 values were much smaller than k_0 (Table 3). As the alkylammonium ions have no electron-donating ability, the increase in the racemization rates due to the formation of the hydrophobic aggregates may come from a kind of solvating effect of the alkyl groups of the ammonium ions and/or from the modification of the iceberg structure[14] surrounding the complex ion. The exceptionally slow racemization in water, compared with the rates in other solvents, may result from the cage effect of the iceberg structure. The slow dissociation rate of the complex in the aggregate would result from the decrease in the water concentration around the complex cation by the formation of the aggregates and/or from the decrease in the activity of water due to modification of the iceberg structure.

The Raman Spectra of Cobalt(III) Complexes. III. Differentiation between *cis* and *trans* Isomers of Tetraamminecobalt(III) Complexes

Kan KANAMORI* and Kiyoyasu KAWAI

Department of Chemistry, Faculty of Science, Toyama University Gofuku, Toyama 930

(Received June 19, 1981)

The Raman and the infrared spectra of tetraamminecobalt(III) complexes have been measured to find the vibrational criteria for differentiating between the *cis* and *trans* configurations. Conspicuous differences between the isomers were found in the ν(Co–NH_3) region. Thus, generally the *trans* isomers have two bands at ca. 480 and *ca.* 450 cm^{-1} in the Raman spectra and one band at *ca.* 510 cm^{-1} in the infrared spectra, and the mutual exclusion rule virtually holds. On the other hand, the *cis* isomers have more than three bands in the region of both the Raman and the infrared spectra.

In our previous paper,[1] we identified the Raman criterion for differentiating the geometrical isomers of bis(ethylenediamine)cobalt(III) complexes. Many infrared criteria[2–6] have been also used for these complexes. However little vibrational work has been done to study the stereochemistry of tetraamminecobalt(III) complexes. Faust and Quagliano[7] first applied infrared measurements in the NaCl region to *cis*- and *trans*-tetraamminedinitrocobalt(III) ions and found that the spectrum of the *cis* isomer reveals a slightly more complicated feature than that of the *trans* isomer in the NO_2 stretching region. Conspicuous differences between the geometrical isomers have been found in the skeletal vibration region (200—600 cm^{-1}) in both the infrared[8] and the Raman[9] spectra.

The present study was undertaken to find definite vibrational criteria for differentiating the geometrical isomers of tetraamminecobalt(III) complexes. For this purpose, the Raman and the infrared spectra of a large number of tetraamminecobalt(III) complexes were examined in the ν(Co–NH_3) region (350—550 cm^{-1}). The established criteria were then applied to $[Co(NCS)_2(NH_3)_4]^+$, $[CoCl(NCS)(NH_3)_4]^+$ and $[CoX(NO_2)(NH_3)_4]$-type complexes prepared in the present work (X=Cl^-, H_2O, CN^-).

Experimental

Preparation. *$[Co(NCS)_2(NH_3)_4]Cl$*: One of the isomers has been obtained by Werner.[10] We prepared the isomeric pair by the following method. A solution containing 24 g of cobalt(II) chloride hexahydrate and 76 g of ammonium thiocyanate in 200 cm^3 of 10% aqueous ammonia was oxidized by bubbling air for 6 h at 40 °C, whereupon a red powder separated. The red powder was filtered and washed with a large amount of ethanol. The yield of the crude product was about 13 g. One gram of the crude product was dissolved in 1000 cm^3 of water and the solution was passed through Sephadex cation-exchange resin (SP, C-25; 30 mm×600 mm). By elution with a 0.05 M LiCl solution, two bands, pinkish red one and brick red one, descended in that order. Each eluate was concentrated to a small volume below 40 °C and mixed with ethanol. Each compound thus obtained was recrystallized from water by adding a saturated solution of lithium chloride. Yield 0.3 g for the pinkish red isomer. 0.2 g for the brick red isomer. The infrared spectrum of the brick red isomer is identical with that of the complex obtained by Werner's method.[3] Absorp. max. $10^{-3}\,\sigma/cm^{-1}$ ($\log \varepsilon/mol^{-1}\,dm^3\,cm^{-1}$): 19.5(2.24), 31.75(3.38) for the pinkish red isomer; 20.3 (2.54), 32.3 (3.58) for the brick red isomer. Found: C, 8.66; H, 4.60; N, 30.27% for the former isomer. C, 8.60; H, 4.43; N, 29.72% for the latter isomer. Calcd for $[CoC_2H_{12}N_6S_2]Cl$: C, 8.62; H, 4.34; N, 30.16%.

$[CoCl(NCS)(NH_3)_4]Cl$: The *trans* isomer was obtained according to the method of Poon.[11] The *cis* isomer was obtained by the following method. A solution of 6 g of *trans*-$[CoCl_2(NH_3)_4]SCN$ in 80 cm^3 of water was stirred at 50 °C for half an hour. The resulting reddish violet solution was cooled to room temperature and 80 cm^3 of concd HCl was added. Then a reddish violet precipitate was deposited. The precipitate was added to 400 cm^3 of 6 mol dm^{-3} HCl and the mixture was warmed on a water bath for a few minutes and then filtered. The filtrate was cooled to room temperature and ethanol was added to it. The complex thus precipitated was filtered, washed with methanol and dried in air. The complex was recrystallized from cold water by adding concd HCl. Yield 4 g. Found: C, 4.51; H, 4.96; N, 26.70%. Calcd for $[CoCClH_{12}N_5S]Cl\cdot 0.5H_2O$: C, 4.53; H, 4.76; N, 26.43%.

$[CoCl(NO_2)(NH_3)_4]Cl$: The *trans* isomer was obtained by the method of Werner.[12] Meyer and Rampoldt[13] have shown the scheme for the preparation of the *cis* isomer through a reaction of tetraamminecarbonatocobalt(III) salt with nitrosyl chloride but the detailed procedure has not been described. So, the *cis* isomer was obtained by the following method. A solution of 2.8 g of sodium nitrite in 30 cm^3 of water was added to a solution of 10.8 g of *cis*-$[CoCl(NH_3)_4(H_2O)]Cl_2$ in 400 cm^3 of water and the mixture was stirred at 40 °C for 10 min. The resulting brown solution was evaporated to a small volume below 40 °C under reduced pressure, and a large amount of ethanol was added to it. The precipitate thus obtained was added to 400 cm^3 of 6 mol dm^{-3} HCl and the mixture was stirred for half an hour and then filtered. To the filtrate, 400 cm^3 of methanol was added and the solution was cooled in a refrigerator for 12 h. The desired complex was deposited as brownish red needle-like crystals. Yield 5 g. Found: H, 5.00; N, 28.64%. Calcd for $[CoClH_{12}N_5O_2]Cl$: H, 4.96; N, 28.71%.

$[Co(NO_2)(NH_3)_4(H_2O)](NO_3)_2$: The *trans* isomer was obtained by the method of Jörgensen.[14] The *cis* isomer has been prepared from $[Co(SO_4)(NH_3)_4(H_2O)]NO_2$ by King and Mistry[15] and from $[Co(ONO)(NH_3)_4(H_2O)](NO_3)_2$ by Yalman and Kuwana.[16] However, the isomer was obtained more easily from *cis*-$[CoCl(NO_2)(NH_3)_4]Cl$ by the following method. A solution of 3.4 g of silver nitrate in 20 cm^3 of water was added to a solution of 2.6 g of *cis*-$[CoCl(NO_2)(NH_3)_4]Cl$ in 20 cm^3 of water and the mixture was stirred at 50 °C. The silver chloride deposited was filtered off and 20 cm^3 of concd HNO_3 and then methanol was added to the filtrate. The crude orange powder was recrystallized from hot water by adding concd HNO_3. Yield 1.5 g. Found: H, 4.51; N, 30.99%. Calcd for $[CoH_{14}N_5$-

$O_3](NO_3)_2$: H, 4.48; N, 31.12%.

[Co(CN)(NO$_2$)(NH$_3$)$_4$]Cl: The *trans* isomer was obtained from $[CoCl(CN)(NH_3)_4]Cl$.[17] To a suspension of 1.2 g of $[CoCl(CN)(NH_3)_4]Cl$ in 30 cm^3 of water, 0.35 g of solid sodium nitrite was added and the mixture was stirred at 50 °C for 2 h, then a brownish yellow solution was obtained. Ethanol was added to the solution and the yellow crystals deposited were filtered and recrystallized from hot water by adding ethanol. Yield 0.7 g. Found: C, 4.79; H, 5.59; N, 32.70%. Calcd for $[CoCH_{12}N_6O_2]Cl\cdot H_2O$: C, 4.76; H, 5.59; N, 33.28%.

The *cis* isomer was obtained from *cis*-$[CoCl(NO_2)(NH_3)_4]$-Cl. A solution of 1.7 g of silver nitrate in 30 cm^3 of dimethylsulfoxide (DMSO) was added to a solution of 2.6 g of *cis*-$[CoCl(NO_2)(NH_3)_4]Cl$ in 150 cm^3 of DMSO and the silver chloride deposited was filtered off. Then, 2 g of silver cyanide was added to the filtrate. The suspension was stirred at 60 °C for 5 h; the color of the liquid phase was changed from brownish red to orange yellow. To the suspension, 500 cm^3 of water was added and the insoluble product was filtered off. The filtrate was poured onto Sephadex ion-exchange resin (SP, C-25; 30 mm×700 mm). By elution with a 0.05 M LiCl solution, three bands colored brownish yellow descended. The desired complex was obtained from the second eluate. This eluate was concentrated to a small volume. A brownish yellow precipitate was obtained by the addition of ethanol and recrystallized from warm water. Yield 0.5 g. It was found from absorption measurements that the first eluate contains *trans*-$[Co(CN)(NO_2)(NH_3)_4]^+$ and the third one contains *cis*-$[Co(NO_2)_2(NH_3)_4]^+$. Found: C, 5.00; H, 5.36; N, 33.94%. Calcd for $[CoCH_{12}N_6O_2]Cl\cdot 0.5H_2O$: C, 4.93; H, 5.35; N, 34.51%.

Other Complexes: *trans*-$Na[Co(SO_3)_2(NH_3)_4]$ was prepared by the method of Akamatsu *et al.*[18] All the other complexes are well known and were prepared by standard means.

Measurements. The Raman spectra were recorded on a JASCO R-800 Laser Raman spectrometer with a data processor, using a He–Ne (632.8 nm) or an Ar^+ ion (514.5 nm) laser as an excitation source. The infrared spectra were recorded on a JASCO A-3 spectrometer. The observed frequencies were calibrated by the 533.8 cm^{-1} band of indene for the Raman spectra and the 618.0 cm^{-1} band of polystylene film for the infrared one. The observed frequencies are accurate within ±2 cm^{-1}.

Results and Discussion

If it is assumed that a *trans* isomer of $[Coa_2(NH_3)_4]$-type complexes (a represents a unidentate ligand) possesses a D_{4h} symmetry, the cobalt-ammonia stretching vibrations transform as $(A_{1g}+B_{1g}+E_u)$, the g modes being Raman allowed and the u mode infrared allowed. Therefore mutual exclusion will be expected. Supposing a C_{4v} symmetry for *trans*-$[Coab(NH_3)_4]$-type complexes (a and b represent an unidentate ligand), the cobalt-ammonia stretching vibrations transform as (A_1+B_1+E), all of which are formally Raman active, and A_1+E modes are formally infrared active. However, the A_1 and the E modes are closely correlated with the A_{1g} and the E_u modes of D_{4h} symmetry, respectively. So we expect that the E mode will be hardly detectable in the Raman spectra of $[Coab(NH_3)_4]$-type complexes. In the same way, the infrared intensity of the A_1 mode will be very weak. Thus, the mutual exclusion will virtually hold for this type of complex. If the *cis* isomers of $[Coa_2(NH_3)_4]$-type and $[Coab(NH_3)_4]$-type complexes have a C_{2v} and a C_s symmetry, respectively, the cobalt-ammonia stretching vibrations transform as $(2A_1+B_1+B_2)$ and $(3A'+A'')$, respectively, and all of the modes are active in both the Raman and the infrared spectra.

Figures 1 and 2 show the Raman and the infrared spectra of 350—550 cm^{-1} region, where the cobalt-ammonia stretching vibrations, ν(Co–NH_3), are expected. As shown in Fig. 1, the Raman spectra of the *trans* isomers have a similar spectral feature. Thus, each spectrum shows a very strong band at *ca.* 480 cm^{-1} and a medium or a weak one at *ca.* 450 cm^{-1}, except for that of the dinitro complex in which the two bands are situated at about 10 cm^{-1} higher. The bands at *ca.* 480 and *ca.* 450 cm^{-1} are assigned to the A_{1g} (or A_1) mode and the B_{1g} (or B_1) mode of ν(Co–NH_3), respectively, by polarization measurements. The resemblance in the Raman frequencies of ν(Co–NH_3) among the trans isomers may be interpreted in terms of mechanical couplings among normal modes. The A_{1g} species of D_{4h} symmetry contain ν(Co–NH_3) and ν(Co–a), but the displacement vector of these vibrations are perpendicular to each other. So mechanical coupling between these vibrations will be virtually absent. The B_{1g} species contains only one mode, ν(Co–NH_3). Therefore, the Raman active ν(Co–NH_3) modes of *trans*-tetraamminecobalt(III) complexes are expected to be mechanically free from the other modes. The very weak bands at *ca.* 510 cm^{-1}

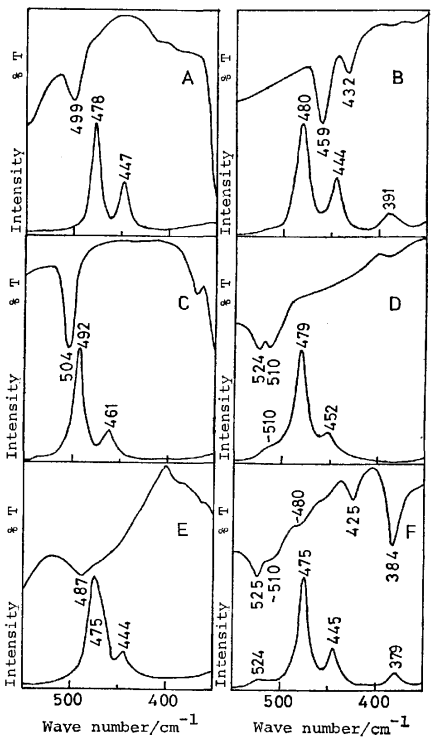

Fig. 1. Raman and infrared spectra of *trans*-$[Coab(NH_3)_4]X$- or *trans*-$M[Coab(NH_3)_4]$-type complexes.
A: a=b=Cl^-; X=Cl^-, B: a=b=CN^-; X=Cl^-, C: a=b=NO_2^-; X=Cl^-, D: a=b=SO_3^{2-}; M=Na^+, E: a=b=Br^-; X=ClO_4^-, F: a=CN^-; b=SO_3^{2-}.

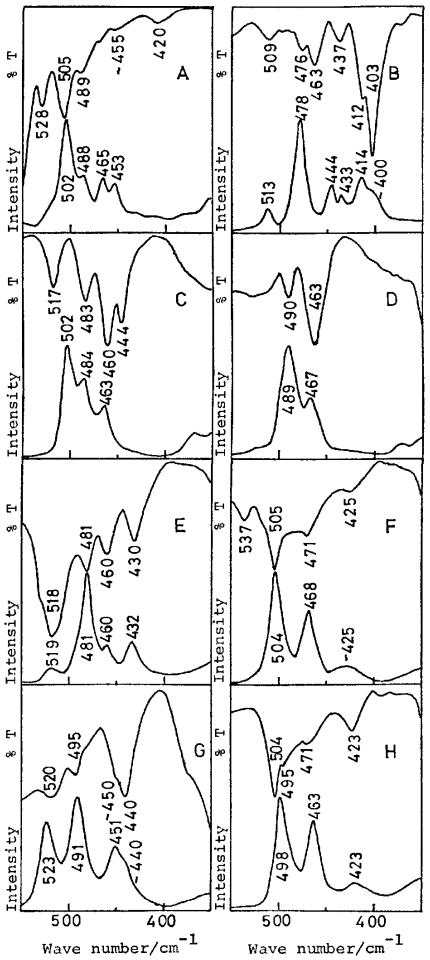

Fig. 2. Raman and infrared spectra of *cis*-[Coab$(NH_3)_4$]X- or *cis*-M[Coab$(NH_3)_4$]-type complexes.
A: a=b=Cl^-; X=Cl^-, B: a=b=CN^-; X=Cl^-, C: a=b=NO_2^-; X=Cl^-, D: a=b=NO_2^-; X=NO_3^-, E: a=b=SO_3^{2-}; M=NH_4^+, F: a=b=F^-; X=Cl^-, G: a=b=H_2O; X=$(NO_3^-)_3$, H: a=Cl^-; b=H_2O; X=$(Cl^-)_2$.

(Fig. 1-D) and at 524 cm^{-1} (Fig. 1-F) are assigned to the degenerate bending of the coordinated sulfito group, $\delta_d(SO_3)$. The bands at 391 cm^{-1} (Fig. 1-B) and at 379 cm^{-1} (Fig. 1-F) are assigned to the ν(Co–CN) by measurements of the deuterated compounds.

The infrared spectra of *trans*-tetraamminecobalt(III) complexes show one band due to the E_u (or E) mode of ν(Co–NH_3) in the region of 490—510 cm^{-1}, except for that of the dicyano complex, in which the ν(Co–NH_3) is observed at 459 cm^{-1} (see Fig. 1). The bands at 524 cm^{-1} (Fig. 1-D) and at 525 cm^{-1} (Fig. 1-F) are assigned to the $\delta_d(SO_3)$ and the bands at 432 cm^{-1} (Fig. 1-B) and at 425 and 384 cm^{-1} (Fig. 1-F) to the ν(Co–CN) or δ(Co–CN). The mutual exclusion with respect to the ν(Co–NH_3) virtually holds in all of the spectra in Fig. 1.

On the other hand, both the Raman and the infrared spectra of the *cis* isomers generally show at least three bands in the region of 400—550 cm^{-1} and many coincidences are found in the frequency between the Raman and the infrared bands (see Fig. 2). Although the Raman spectrum of *cis*-[Co$(NO_2)_2$-$(NH_3)_4$]NO_3 (Fig. 2-D) show two bands similar to that of the *trans* isomer, the Raman bands have counterparts in the infrared spectrum incontrast to that of the *trans* isomer.

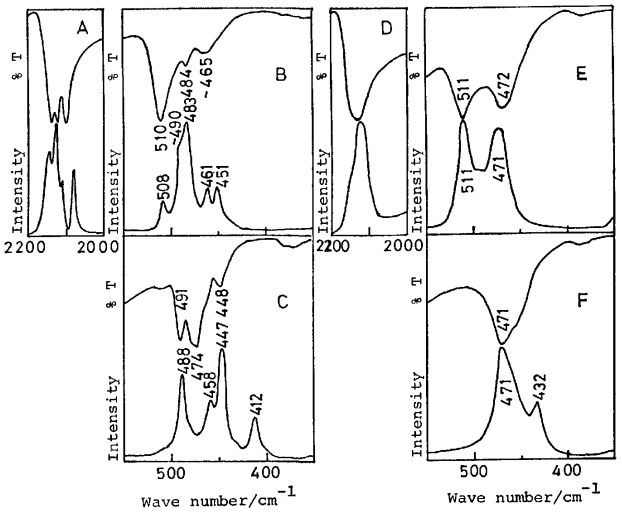

Fig. 3. Raman and infrared spectra of [Co$(NCS)_2$-$(NH_3)_4$]Cl.
A and B: Pinkish red isomer, C: *N*-deuterated pinkish red isomer, D and E: brick red isomer, F: *N*-deuterated brick red isomer.

In conclusion, two criteria will be established for differentiating the geometrical isomers of tetraamminecobalt(III) complexes. The first is based on the number of bands due to ν(Co–NH_3) and their frequencies; *trans* isomer of tetraamminecobalt(III) complexes shows two Raman bands (generally at *ca.* 480 cm^{-1} and at *ca.* 450 cm^{-1}) and one infrared band (generally at 490—510 cm^{-1}), while the *cis* isomer generally shows more than three bands in both the infrared and the Raman spectra. Another is based on mutual exclusion; this mutual exclusion virtually holds in the *trans* isomers and not in the *cis* isomers. It is clear that only a combination of both these two criteria would provide reliable structural diagnosis.

It is obviously of interest to apply these vibrational criteria to tetraamminecobalt(III) complexes of unknown or doubtful configurations. Werner[10] has obtained one of the isomers of [Co$(NCS)_2(NH_3)_4$]$^+$ and the infrared spectrum of this complex has been studied for the C–N and the C–S stretching region by Chamberlain and Bailar.[3] They have regarded this complex as the *trans* isomer. We obtained the other isomer in this work. The Raman and the infrared spectra of the isomeric pair in the region of 350—550 cm^{-1} are shown in Fig. 3, together with the ν(CN) region. The pinkish red isomer (see Experimental section) has three or four bands in the ν(CN) region, while the brick red one shows only one broad band. The splitting of ν(CN) was frequently identified with a *cis* configuration for the related complexes. Also in the region of 400—550 cm^{-1}, the spectra of the pinkish red isomer (Fig. 3-B) are apparently more complicated than those of the brick red one (Fig. 3-E), though more than two bands seem

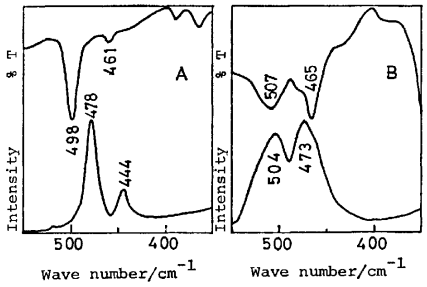

Fig. 4. Raman and infrared spectra of [CoCl(NCS)-$(NH_3)_4$]Cl.
A: The isomer obtained by Poon's method,[11] B: the isomer obtained in this work.

to be overlapped in the spectra of the latter isomer. In these complexes, the bands due to δ(NCS) will appear in the same region as the ν(Co–NH_3). In order to eliminate the bands due to δ(NCS), the spectra of the *N*-deuterated complexes have been measured (Figs. 3-C,F). By the comparison of the spectra of normal complexes with those of the deuterated ones, the bands at *ca.* 490 cm^{-1} and *ca.* 460 cm^{-1} of the pinkish red isomer and a part of the band at *ca.* 470 cm^{-1} of the brick red isomer can be assigned to the δ(NCS). Then the bands at 510 cm^{-1} (very weak in the Raman but very strong in the infrared spectrum), at 483 cm^{-1} (very strong in the Raman but very weak in the infrared spectrum) and at 451 cm^{-1} (which does not appear in the infrared spectrum) are assigned to the ν(Co–NH_3) for the pinkish red isomer. This spectral feature is a characteristic of a *trans* configuration, except for the appearance of the very weak bands. The Raman and the infrared spectra of the brick red isomer show apparently two bands. However, the facts that the intensity of the Raman band at 511 cm^{-1} is very strong and the Raman spectrum has no band at about 450 cm^{-1} suggest that the isomer has not a *trans* configuration but a *cis* configuration. In the *trans* isomer, the appearance of the band at 510 cm^{-1} (E_u mode) in the Raman spectrum and the band at 483 cm^{-1} (A_{1g} mode) in the infrared spectrum, and the complicated feature in the ν(CN) region may be due to the symmetry lowering in the solid state. This assignment of the geometrical configurations is compatible with that on the basis of the relative positions of the absorption maxima in the first d-d absorption band or the "specific band" of thiocyanato groups, and also with the elution order of the column chromatography.

The Raman and the infrared spectra of the isomeric pair of [CoCl(NCS)$(NH_3)_4$]Cl are shown in Fig. 4. On the basis of the observed band positions in the Raman and the infrared spectra and the comparison between the two spectra, the isomer which was obtained by Poon's method[11] is assigned to the *trans* structure and the isomer obtained in this work to the *cis* structure.

The Raman and the infrared spectra of [CoX-$(NO_2)(NH_3)_4$]-type (X=NCS^-, Cl^-, H_2O, CN^-) complexes are shown in Fig. 5. The Raman spectra (Figs. 5-A,C,E, and G) of the complexes, whose geometrical configurations are assumed to be *trans*, show

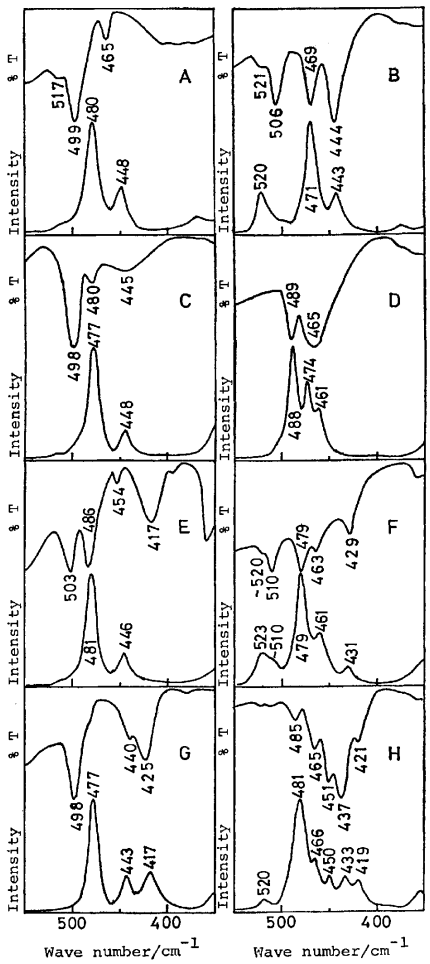

Fig. 5. Raman and infrared spectra of [Coa(NO_2)-$(NH_3)_4$]X-type complexes.
A (*trans*) and B (*cis*): a=NCS^-; X=Cl^-, C(*trans*) and D(*cis*): a=Cl^-; X=Cl^-, E(*trans*) and F(*cis*): a=H_2O; X=$(NO_3^-)_2$, G(*trans*) and H(*cis*): a=CN^-; X=Cl^-.

the characteristic feature of a *trans* configuration. The band at 417 cm^{-1}, which was observed for *trans*-[Co(CN)$(NO_2)(NH_3)_4$]Cl is assigned to the ν(Co–CN). The Raman spectra of the others (Figs. 5-B,D,F, and H) have more than three bands due to ν(Co–NH_3) and most of the bands have counterparts in the infrared spectra, so *cis* configurations are confirmed for these complexes. It is seen from Fig. 5 that the assignments of the geometrical configurations by the infrared spectra alone are not conclusive for these complexes.

The authors wish to express their sincere thanks to Professor Yoichi Shimura, Osaka university, and to Dr. Isao Kanesaka of our university for valuable discussions. Their thanks are also due to Miss Junko Nomura for carrying out a part of the experiments.

Solubility Diagrams of Cobalt(III) Complexes Containing Amino Acid. II.[1] Spontaneous Resolution of Bis(ethylenediamine)glycinatocobalt(III) Salts

Satoshi KAKI,* Kazuaki YAMANARI, and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received June 30, 1981)

The binary and ternary solubility phase diagrams of the racemic and optically active complexes $[Co(gly)(en)_2]X_2$ were determined in water ($X_2=SO_4$, S_2O_3, $(NO_3)_2$, $(SCN)_2$, $(CH_3CO_2)_2$, $(ClO_4)_2$, $(CH_3CO_2)ClO_4$, and $[Sb_2(d\text{-tart})_2]$). Spontaneous resolution was found for the double salt of $[Co(gly)(en)_2](CH_3CO_2)ClO_4$ at 5—50 °C and for $[Co(gly)(en)_2]SO_4$ at 39—50 °C; the latter of these has been shown to crystallize as both a racemic compound (below 39 °C) and a conglomerate (above 39 °C).

The solubility diagrams of tetraammine(leucinato)-cobalt(III) sulfate have revealed that the sulfate has a large solubility ratio of DL-complex/L-complex and crystallizes as both a racemic compound (below 30 °C) and a conglomerate (above 30 °C).[1] It is of interest to clarify whether this is characteristic of the counter ion SO_4^{2-} or not. The present paper deals with the binary and ternary solubility diagrams of a variety of salts of the glycinato complex $[Co(gly)(en)_2]X_2$, where X_2 stands for SO_4, S_2O_3, $(CH_3CO_2)_2$, $(ClO_4)_2$, $(CH_3CO_2)ClO_4$, $(NO_3)_2$, $(SCN)_2$, and $[Sb_2(d\text{-tart})_2]$ (tart=tartrate(4—) ion, $C_4H_2O_6^{4-}$).

Experimental

Materials. rac-$[Co(gly)(en)_2]X_2$: Iodide salt obtained by the method of Meisenheimer[2] was converted into acetate salt through an anion exchanger column of Dowex 1-X8 ($CH_3CO_2^-$ form). Found: C, 28.95; H, 7.45; N, 16.79%. Calcd for $[Co(gly)(en)_2](CH_3CO_2)_2\cdot 2.5H_2O=C_{10}H_{31}N_5O_{8.5}Co$: C, 28.85; H, 7.51; N, 16.82%. Sulfate and thiosulfate salts were prepared from an aqueous solution of the acetate salt by adding a calculated amount of $(NH_4)_2SO_4$ or $Na_2S_2O_3$. Found for sulfate salt: C, 17.46; H, 6.44; N, 16.99%. Calcd for $[Co(gly)(en)_2]SO_4\cdot 3.5H_2O=C_6H_{27}N_5O_{9.5}SCo$: C, 17.48; H, 6.60; N, 16.99%. Found for thiosulfate salt: C, 19.52; H, 5.61; N, 18.87%. Calcd for $[Co(gly)(en)_2]S_2O_3\cdot 0.5H_2O=C_6H_{21}N_5O_{5.5}S_2Co$: C, 19.25; H, 5.61; N, 18.71%. For the preparation of perchlorate, nitrate, and thiocyanate salts, a slight excess of $Ba(ClO_4)_2$, $Sr(NO_3)_2$, or $Ba(SCN)_2$ was added to the solution of sulfate salt. The desired crystals were obtained by evaporating the filtrate. Found for perchlorate salt: C, 14.79; H, 4.97; N, 14.31%. Calcd for $[Co(gly)(en)_2](ClO_4)_2\cdot 2H_2O=C_6H_{24}N_5O_{12}Cl_2Co$: C, 14.76; H, 4.96; N, 14.35%. Found for nitrate salt: C, 18.16; H, 5.57; N, 24.98%. Calcd for $[Co(gly)(en)_2](NO_3)_2\cdot H_2O=C_6H_{22}N_7O_9Co$: C, 18.23; H, 5.61; N, 24.81%. Found for thiocyanate salt: C, 25.99; H, 5.46; N, 26.58%. Calcd for $[Co(gly)(en)_2](SCN)_2=C_8H_{20}N_7O_2S_2Co$: C, 26.02; H, 5.46; N, 26.55%. Acetate perchlorate double salt was obtained by mixing equimolar amounts of the perchlorate salt and the acetate salt. Found: C, 23.47; H, 5.67; N, 16.95%. Calcd for $[Co(gly)(en)_2](CH_3CO_2)ClO_4=C_8H_{23}N_5O_8ClCo$: C, 23.34; H, 5.63; N, 17.01%.

Optical Resolution of $[Co(gly)(en)_2]^{2+}$: The resolving agent $Na_2[Sb_2(d\text{-tart})_2]\cdot 5H_2O$ (9.7×10^{-2} mol) was added to the dilute solution of the acetate salt (16.2×10^{-2} mol) in 800 cm^3 of water. The less soluble Λ-diastereomer which deposited was removed by filtration and recrystallized from warm water. Further addition of $Na_2[Sb_2(d\text{-tart})_2]\cdot 5H_2O$ (9.7×10^{-2} mol) to the filtrate gave Λ-diastereomer. Each diastereomer was purified by the fractional crystallization until the CD values became constant. Found for Λ-diastereomer: C, 19.46; H, 3.77; N, 8.11%. Calcd for Λ-$[Co(gly)(en)_2][Sb_2(d\text{-tart})_2]\cdot 4H_2O=C_{14}H_{32}N_5O_{18}Sb_2Co$: C, 19.53; H, 3.75; N, 8.14%. Found for Λ-diastereomer: C, 19.57; H, 3.76; N, 8.20%. Calcd for Λ-$[Co(gly)(en)_2][Sb_2(d\text{-tart})_2]\cdot 4H_2O=C_{14}H_{32}N_5O_{18}Sb_2Co$: C, 19.53; H, 3.75, N, 8.14%. The Λ-diastereomer was added to an aqueous solution containing ion exchange resin Dowex 1-X8($CH_3CO_2^-$ form) and stirred for 2 h at 50 °C. The resin was removed by filtration and the filtrate was evaporated to give the acetate salt. Found: C, 27.84; H, 7.41; N, 16.59%. Calcd for Λ-$[Co(gly)(en)_2](CH_3CO_2)_2\cdot 3H_2O=C_{10}H_{32}N_5O_9Co$: C, 28.24; H, 7.58; N, 16.47%. The other Δ- or Λ-salts were prepared by the same method as was used the corresponding racemic salts. Found for sulfate salt: C, 19.61; H, 6.03; N, 19.11%. Calcd for Λ-$[Co(gly)(en)_2]SO_4\cdot H_2O=C_6H_{22}N_5O_7SCo$: C, 19.62; H, 6.04; N, 19.07%. Found for thiosulfate salt: C, 19.59; H, 5.49; N, 19.19%. Calcd for Λ-$[Co(gly)(en)_2]S_2O_3=C_6H_{20}N_5O_5S_2Co$: C, 19.73; H, 5.52; N, 19.17%. Found for perchlorate salt: C, 15.47; H, 4.84; N, 14.99%. Calcd for Λ-$[Co(gly)(en)_2](ClO_4)_2\cdot H_2O=C_6H_{22}N_5O_{11}Cl_2Co$: C, 15.33; H, 4.72; N, 14.90%. Found for nitrate salt: C, 18.77; H, 5.37; N, 25.75%. Calcd for Λ-$[Co(gly)(en)_2](NO_3)_2\cdot 0.5H_2O=C_6H_{21}N_7O_{8.5}Co$: C, 18.66; H, 5.48; N, 25.39%. Found for thiocyanate salt: C, 26.14; H, 5.45; N, 26.72%. Calcd for Λ-$[Co(gly)(en)_2](SCN)_2=C_8H_{20}N_7O_2S_2Co$: C, 26.02; H, 5.46; N, 26.55%. Found for acetate perchlorate double salt: C, 23.10; H, 5.68; N, 16.92%. Calcd for Λ-$[Co(gly)(en)_2](CH_3CO_2)ClO_4=C_8H_{23}N_5O_8ClCo$: C, 23.34; H, 5.63; N, 17.01%.

Measurements. The solubility of complexes in water was determined in the same way as previously reported.[3] The absorption and CD values which were used for the calculations of concentrations of complexes in solutions are summarized in Table 1. The solid phases were identified from the elemental analysis and the absorption and CD spectra. Optical densities were measured with a JASCO UVIDEC-1 spectrophotometer and CD with a JASCO MOE-1 spectropolarimeter.

Results and Discussion

The binary solubility data are given in Table 2 and Figs. 1 and 3, and the ternary data in Table 3 as well as Figs. 2, 4, and 5. In the triangular isotherms the top part (H_2O corner) is enlarged for the sake of convenience and the tie lines are omitted.

The Sulfate and Thiosulfate Salts. The solubility curves of *rac*-$[Co(gly)(en)_2]SO_4$ and Λ-$[Co(gly)(en)_2]SO_4$ are shown in Fig. 1. The curve of racemate intersects the curve of the active one at *ca.* 21 °C, the solubility of racemic salt being less than that of the active one below this temperature. The solubili-

a) The ε and $\Delta\varepsilon$ values are given in the units of mol^{-1} dm^3 cm^{-1}.

ity curve of racemate shows an inflection at *ca.* 39 °C where the solid phase changes from 3.5-hydrate (below 39 °C) to monohydrate (above 39 °C), whereas the curve of the optically active complex shows no inflection. The slope of the racemic curve above 39 °C is similar to that of the optically active salt. The solubility ratio of racemate/*Λ*-complex is 0.46 at 5 °C, 1.34 at 25 °C, and 2.68 at 40 °C.

Generally spontaneous resolution is expected in the case in which the solubility of racemic salt is more than $2^{1/2}(=1.41)$ times that of the corresponding optically active salt, for a 1:1 electrolyte.[4] Thus, the sulfate salt would be spontaneously resolvable above 39 °C, above which both racemate and *Λ*-complex crystallize as monohydrate salt. To confirm the expectation, the solubility isotherms of the ternary system, H_2O–*Λ*-$[Co(gly)(en)_2]SO_4$–*Λ*-$[Co(gly)(en)_2]SO_4$, were measured at three temperatures: 10, 30, and 45 °C (Fig. 2). The isotherm at 10 or 30 °C shows two invariant points, between which the formation of racemic compound *Λ*-$[Co(gly)(en)_2]\cdot$*Λ*-$[Co(gly)(en)_2](SO_4)_2\cdot 7H_2O$=*rac*-$[Co(gly)(en)_2]SO_4\cdot 3.5H_2O$ is observed. However, this racemic compound disappears in the isotherm at 45 °C, and the two enan-

a) Metastable phase.

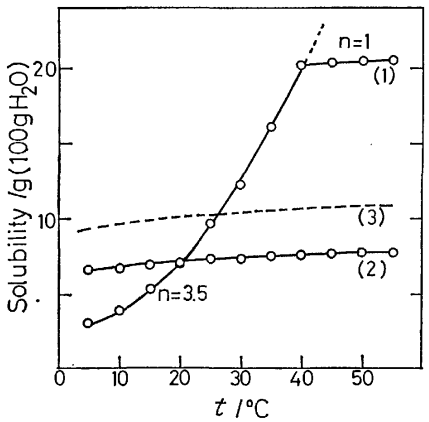

Fig. 1. Solubility curves of *rac*-$[Co(gly)(en)_2]SO_4\cdot nH_2O$(1), Δ-$[Co(gly)(en)_2]SO_4\cdot H_2O$(2), and calculated curve(3): (2)$\times 2^{1/2}$.

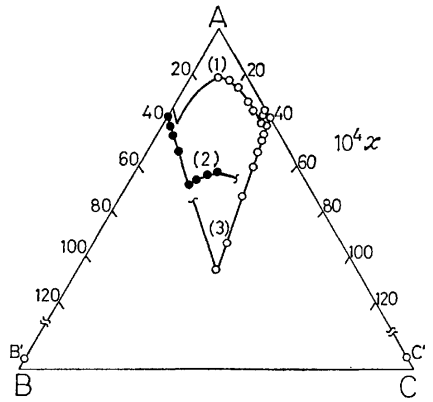

Fig. 2. Solubility isotherms of H_2O(A)–Δ-$[Co(gly)(en)_2]SO_4$(B)–Δ-$[Co(gly)(en)_2]SO_4$(C) at 10 °C(1), 30 °C(2), and 45 °C(3).
The points at 30 °C(●) are plotted at a left side for convenience. The solid phase B′ or C′ is monohydrate of B or C, respectively.

tiomers form a conglomerate.[3] The intersection of the solubility curves at about 21 °C in Fig. 1 has no special meaning with respect to spontaneous resolution. The racemic sulfate $[Co(gly)(en)_2]SO_4$ crystallizes as both a racemic compound (below 39 °C) and a conglomerate (above 39 °C). A similar case has been found for $[Co(leu)(NH_3)_4]SO_4$[1] but the examples such as $K_3[Co(ox)_3]\cdot H_2O$ and $[Rh(rac\text{-cptn})_3](ClO_4)_3\cdot 12H_2O$ reported by Jaeger[5] do not seem to be exact enough in some details (cptn=*trans*-1,2-cyclopentanediamine).

The solubility of racemic thiosulfate salt is larger than that of the corresponding active salt in the range 12—55 °C. The curve has an inflection at *ca.* 35 °C where the solid phase changes from 0.5-hydrate (below 35 °C) to anhydrate (above 35 °C), whereas the solid phase of the optically active salt is anhydrate at 12—55 °C. The curve of racemic salt is lower than $2^{1/2}$ times that of the active salt. The ternary isotherm

at 45 °C confirms the existence of the racemic compound Δ-[Co(gly)(en)$_2$]·Δ-[Co(gly)(en)$_2$](S$_2$O$_3$)$_2$=*rac*-[Co(gly)(en)$_2$]S$_2$O$_3$ (Table 3). It is interesting that the solubility of thiosulfate salt is much lower than that of sulfate salt, whether it is in racemate or active form.

The Acetate Perchlorate Double Salt. The solubility of the optically active perchlorate salt is larger than that of the racemic salt; two enantiomers form a racemic compound. The solubility of the acetate salt is determined at only 5 °C because of its extremely high solubility (Table 2). This salt also crystallizes as a racemic compound.

As described in the Experimental section, the double salt [Co(gly)(en)$_2$](CH$_3$CO$_2$)ClO$_4$ can be prepared from the constituent salt. Figure 3 shows the solubility curves of *rac*- and Δ-[Co(gly)(en)$_2$](CH$_3$CO$_2$)-ClO$_4$. The double salt is not decomposed into the constituent salts in water at 5—50 °C. The solubility of the racemic salt is larger than $2^{1/3}$ times that of the optically active one and both the solid phases are anhydrous at 5—50 °C.[4] Therefore, spontaneous resolution is expected for this double salt at 5—50 °C, though each constituent salt forms a racemic compound. The ternary isotherm at 20 °C is the only invariant point and confirms the formation of a conglomerate (Fig. 4). This case is the first one of spontaneous resolution found for a complex double salt.

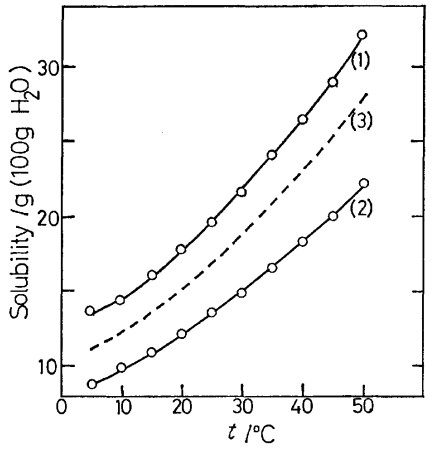

Fig. 3. Solubility curves of *rac*-[Co(gly)(en)$_2$]-(CH$_3$CO$_2$)ClO$_4$(1), Δ-[Co(gly)(en)$_2$](CH$_3$CO$_2$)ClO$_4$ (2), and calculated curve(3): (2)×$2^{1/3}$.

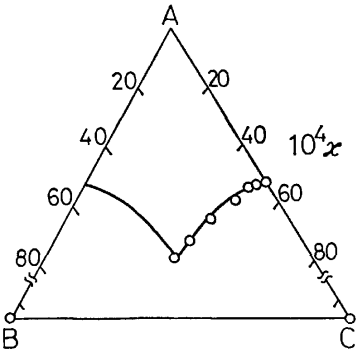

Fig. 4. Solubility isotherm of H$_2$O(A)–Δ-[Co(gly)-(en)$_2$](CH$_3$CO$_2$)ClO$_4$(B)–Δ-[Co(gly)(en)$_2$](CH$_3$CO$_2$)-ClO$_4$(C) at 20 °C.

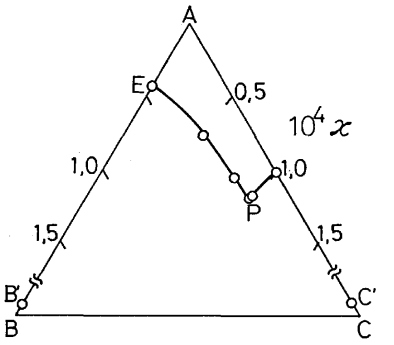

Fig. 5. Solubility isotherm of H$_2$O(A)–Δ-[Co(gly)-(en)$_2$][Sb$_2$(*d*-tart)$_2$](B)–Δ-[Co(gly)(en)$_2$][Sb$_2$(*d*-tart)$_2$] (C).
The solid phase B′ or C′ is 4-hydrate of B or C, respectively.

The Nitrate and Thiocyanate Salts. In the system of nitrate salt, a metastable monohydrate phase is observed for the racemate. This phase is so stable that the solubility could be determined in the range 5—50 °C. The metastable solid phase in contact with the solution was stirred mechanically one day to undergo conversion into the stable solid phase. The solubility of the stable racemate is lower than that of the active one, whereas the solubility of the metastable racemate is larger than $2^{1/3}$ times that of the active complex. However, the ternary isotherm at 45 °C (Table 3) revealed the existence of the racemic compound Δ-[Co(gly)(en)$_2$]·Δ-[Co(gly)(en)$_2$](NO$_3$)$_4$·2H$_2$O=*rac*-[Co(gly)(en)$_2$](NO$_3$)$_2$·H$_2$O.

The solubility of optically active thiocyanate salt is larger than that of the racemate. This salt also forms a racemic compound Δ-[Co(gly)(en)$_2$]·Δ-[Co-(gly)(en)$_2$](SCN)$_4$=*rac*-[Co(gly)(en)$_2$](SCN)$_2$.

The Optical Resolution of [Co(gly)(en)$_2$]$^{2+}$ Complex. This complex have been optically resolved by *d*-BCS[2,6] and Ag$_2$[Sb$_2$(*d*-tart)$_2$][7] as a resolving agent (*d*-BCS=(+)$_{589}$-(1*R*,3*S*,4*S*,7*R*)-3-bromocamphor-9-sulfonate). However, we found that the combination of the acetate salt and the resolving agent Na$_2$[Sb$_2$(*d*-tart)$_2$]·5H$_2$O is more convenient. Figure 5 shows the ternary isotherm of H$_2$O–Δ-[Co(gly)(en)$_2$][Sb$_2$(*d*-tart)$_2$]–Δ-[Co-(gly)(en)$_2$][Sb$_2$(*d*-tart)$_2$] at 25 °C; its only invariant point is P, at the right hand side. When an aqueous solution of an equimolar amount of the two diastereomers is concentrated at this temperature, the less soluble diastereomer Δ-[Co(gly)(en)$_2$][Sb$_2$(*d*-tart)$_2$]·4H$_2$O will crystallize out first and then the solution composition will change along the solubility curve EP. Finally, the solid phase will be composed of the two diastereomers at P. No pseudo racemic compound appears in this system.

Solubility Isotherms of Systems Containing Optically Active Tris(ethylenediamine)cobalt(III) Ion. III.[1] Quaternary System, (Λ-$[Co(en)_3]^{3+}$, Δ-$[Co(en)_3]^{3+}$, H^+)-(R,R)-$C_4H_4O_6^{2-}$-H_2O, at 25 °C

Akira Fuyuhiro,* Kazuaki Yamanari, and Yoichi Shimura
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received July 6, 1981)

A part of quaternary solubility isotherm, (Λ-$[Co(en)_3]^{3+}$, Λ-$[Co(en)_3]^{3+}$, H^+)-(R,R)-$C_4H_4O_6^{2-}$-H_2O, $C_{H^+} \leqq C_{(R,R)\text{-}C_4H_4O_6^{2-}}$, was determined at 25 °C. It was found that three double salts Λ- and Λ-$[Co(en)_3](d\text{-}C_4H_5O_6)\cdot(d\text{-}C_4H_4O_6)\cdot nH_2O$ and Λ-$[Co(en)_3]_{0.48}\cdot\Delta$-$[Co(en)_3]_{0.52}(d\text{-}C_4H_4O_6)_{1.5}\cdot 5H_2O$ exist, three invariant points appearing. The yield for optical resolution of $[Co(en)_3]^{3+}$ found to be constant regardless of $[H^+]$. The existence of complete ternary system containing double salts, Λ-$[Co(en)_3](d\text{-}C_4H_5O_6)(d\text{-}C_4H_4O_6)$-$\Delta$-$[Co(en)_3](d\text{-}C_4H_5O_6)$-$(d\text{-}C_4H_4O_6)$-$H_2O$, was found and the solubilities of Λ- and Λ-$[Co(en)_3](d\text{-}C_4H_5O_6)(d\text{-}C_4H_4O_6)$ were measured at 5—65 °C.

The diastereomer of double salt Λ-$[Co(en)_3]X(d\text{-}H_2tart)$ (X^-=Br^- and I^-; $d\text{-}H_2tart^{2-}$=(R,R)-$C_4H_4O_6^{2-}$) can be used for the optical resolution of $[Co(en)_3]^{3+}$ ion. The particular role of the optically inactive component X^- has been revealed by the solubility phase diagrams of reciprocal salt-pairs, (Λ-$[Co(en)_3]^{3+}$, Δ-$[Co(en)_3]^{3+}$)-(X^-, $d\text{-}H_2tart^{2-}$)-H_2O.[1,2] A similar compound Λ-$H[Co(en)_3](d\text{-}H_2tart)_2\cdot 3H_2O$ was recently reported by Tada *et al.*[3] This diastereomer can be considered to be Λ-$[Co(en)_3](d\text{-}H_3tart)(d\text{-}H_2tart)\cdot 3H_2O$ corresponding to the case of X^-=$d\text{-}H_3tart^-$ in the above formula and have, so to speak, two optically active resolving agents. The system containing this diastereomer will be completely described by a quaternary system (Λ-$[Co(en)_3]^{3+}$, Δ-$[Co(en)_3]^{3+}$, H^+)-$d\text{-}H_2tart^{2-}$-H_2O. When the concentration of H^+ is lower than that of $d\text{-}H_2tart^{2-}$, a part of the system, however, can be formally regarded as the following reciprocal salt-pairs (Λ-$[Co(en)_3]^{3+}$, Δ-$[Co(en)_3]^{3+}$)-($d\text{-}H_3tart^-$, $d\text{-}H_2tart^{2-}$)-H_2O.

In this paper, we report the solubility isotherm of quaternary system (Λ-$[Co(en)_3]^{3+}$, Δ-$[Co(en)_3]^{3+}$, H^+)-$d\text{-}H_2tart^{2-}$-H_2O. This system was covered incompletely by the present experiment because the body of the solubility phase diagram does not form a closed space owing to the lack of solid phases Λ- and Δ-$[Co(en)_3](d\text{-}H_3tart)_3\cdot nH_2O$, and Λ-$[Co(en)_3]_p\cdot\Delta$-$[Co(en)_3]_q(d\text{-}H_3tart)_{3(p+q)}\cdot n'H_2O$. As regards optical resolution, the isotherms of X^-=$d\text{-}H_3tart^-$, however, can be effectively compared with those of X^-=Br^- and I^-.

Experimental

Materials. *$[Co(en)_3](d\text{-}H_2tart)_{1.5}\cdot nH_2O$*: The Λ- and Δ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}\cdot nH_2O$ and the Λ-$[Co(en)_3]_{0.48}\cdot\Delta$-$[Co(en)_3]_{0.52}(d\text{-}H_2tart)_{1.5}\cdot 5H_2O$ diastereomers were the same as reported.[2]

d-*H_4tart*: A guaranteed reagent of Nakarai Chemicals Ltd. was employed.

$[Co(en)_3](d\text{-}H_3tart)(d\text{-}H_2tart)\cdot nH_2O$: The Λ- (or Δ-)$[Co(en)_3](d\text{-}H_3tart)(d\text{-}H_2tart)\cdot nH_2O$ diastereomer was prepared by mixing solutions of Λ- (or Δ-)$[Co(en)_3](d\text{-}H_2tart)_{1.5}\cdot nH_2O$ and $d\text{-}H_4tart$ in a 2:1 mole ratio. Found: C, 28.55; H, 6.62; N, 14.30%. Calcd for Λ-$[Co(en)_3](d\text{-}H_3tart)(d\text{-}H_2tart)\cdot 3H_2O$: C, 28.48; H, 6.66; N, 14.23%. Found: C, 24.84; H, 7.08; N, 12.49%. Calcd for Λ-$[Co(en)_3](d\text{-}H_3tart)(d\text{-}H_2tart)\cdot 7.5H_2O$: C, 25.04; H, 7.20; N, 12.52%.

Measurements. The solubility in water was determined in molality and the calibration of CD was also carried out according to the previous method.[2] The concentration of H^+ was determined by titration with a 0.01 mol dm^{-3} NaOH solution. The solid phases were identified by elemental analysis, absorption and CD spectra. Optical densities were measured with a Hitachi 330 spectrophotometer and CD with a JASCO MOE-1 spectropolarimeter. The absorption maximum value, ε(466 nm)=88.4, was used in this study.

Results and Discussion

Ternary System *Λ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$-$\Lambda$-$[Co(en)_3](d\text{-}H_3tart)_3$-$H_2O$.* The ternary system, Λ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$-$d\text{-}H_4tart$-$H_2O$, was partially determined at 25 °C (Fig. 1 and Table 1). The axis (1) expresses the molality of Λ-$[Co(en)_3](d\text{-}H_3tart)_3$, though the salt does not exist as solid. When the concentration of H^+ is lower than that of $d\text{-}H_2tart^{2-}$, the present system can be represented formally as the ternary one, Λ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$(4)-$\Lambda$-$[Co(en)_3](d\text{-}H_3tart)_3$(1)-$H_2O$, and then can be compared with

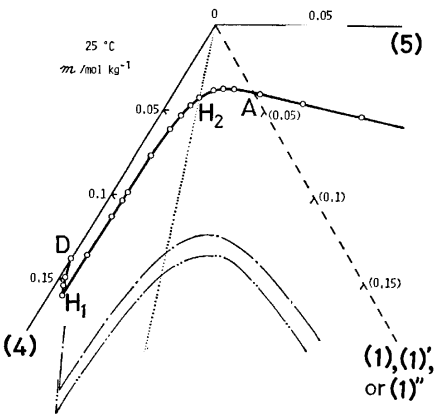

Fig. 1. Solubility isotherm (partial) of the ternary system, Λ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$(4)-$(d\text{-}H_4tart)_{1.5}$(5)-$H_2O$, at 25 °C.
Solubility is presented in molality m of anhydrous salt.
—·—: The ternary system, Λ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$(4)-$\Lambda$-$[Co(en)_3]Br_3$(1)'-$H_2O$, —··—: the ternary system, Λ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}$(4)-$\Lambda$-$[Co(en)_3]I_3$(1)"-$H_2O$.

Table 1. Equilibrium of (Λ-$[Co(en)_3]^{3+}$, Δ-$[Co(en)_3]^{3+}$, H^+)-d-H_2tart^{2-}-H_2O system at 25 °C ($[H^+] \leqq [d\text{-}H_2tart^{2-}]$)

In liquid phases, solubility is presented in molality m of the component ions. Abbreviations are as follows: Λ-$[Co(en)_3]^{3+} = \Lambda^{3+}$, Δ-$[Co(en)_3]^{3+} = \Delta^{3+}$, Λ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}\cdot nH_2O (n \gtrsim 7) = \Lambda(tart)_{1.5}$, Δ-$[Co(en)_3](d\text{-}H_2tart)_{1.5}\cdot nH_2O (n \simeq 8) = \Delta(tart)_{1.5}$, Λ-$[Co(en)_3]_{0.48}\cdot\Delta$-$[Co(en)_3]_{0.52}(d\text{-}H_2tart)_{1.5}\cdot 5H_2O = (\Lambda,\Delta)(tart)_{1.5}$, Λ-$[Co(en)_3](d\text{-}H_3tart)(d\text{-}H_2tart)\cdot 3H_2O = \Lambda(Htart)(tart)$, Δ-$[Co(en)_3](d\text{-}H_3tart)(d\text{-}H_2tart)\cdot 8H_2O = \Delta(Htart)(tart)$.

a) Reported data for C, D, G_1, G_2, D→G_1, and G_1→G_2[2] are not shown. Values in parentheses are estimated errors and calculated from twice the standard deviations of measurements repeated 5—8 times.

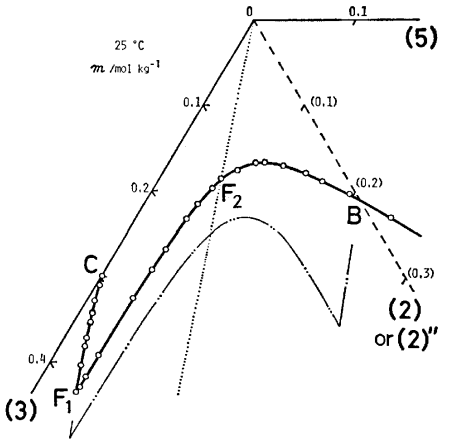

Fig. 2. Solubility isotherm (partial) of the ternary system, Λ-[Co(en)$_3$](d-H$_2$tart)$_{1.5}$(3)–(d-H$_4$tart)$_{1.5}$(5)–H$_2$O, at 25 °C.
Solubility is presented in molality m of anhydrous salt. —·—: the ternary system, Λ-[Co(en)$_3$](d-H$_2$tart)$_{1.5}$ (3)–Λ-[Co(en)$_3$]I$_3$(2)″–H$_2$O.

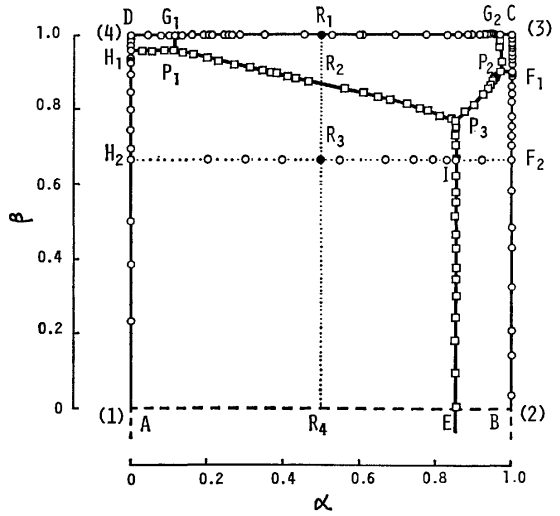

Fig. 3. The clinographic projection of solubility isotherm of the system, (Λ-[Co(en)$_3$]$^{3+}$, Λ-[Co(en)$_3$]$^{3+}$)–(d-H$_3$tart$^-$, d-H$_2$tart^{2-})–H$_2$O, at 25 °C.
α: Mole fraction of Λ-[Co(en)$_3$]$^{3+}$ to all the cations, β: mole fraction of (d-H$_2$tart)$_{1.5}^{3-}$ to {(d-H$_3$tart)$_3^{3-}$+(d-H$_2$tart)$_{1.5}^{3-}$}, (1): Λ-[Co(en)$_3$](d-H$_3$tart)$_3$, (2): Λ-[Co(en)$_3$](d-H$_3$tart)$_3$, (3): Λ-[Co(en)$_3$](d-H$_2$tart)$_{1.5}$, (4): Λ-[Co(en)$_3$](d-H$_2$tart)$_{1.5}$, □: solubility of four-components, ○: solubilities of two- or three-components. Each area has the following solids: $DH_1P_1G_1$: Λ-[Co(en)$_3$](d-H$_2$tart)$_{1.5}$·nH$_2$O, $H_1H_2AR_4EIP_3R_2P_1$: Λ-[Co(en)$_3$](d-H$_3$tart)(d-H$_2$trat)·3H$_2$O, $F_1P_2P_3IEBF_2$: Λ-[Co(en)$_3$](d-H$_3$tart)(d-H$_2$tart)·8H$_2$O, $CG_2P_2F_1$: Λ-[Co(en)$_3$](d-H$_2$tart)$_{1.5}$·nH$_2$O, $G_1P_1R_2P_3P_2G_2R_1$: Λ-[Co(en)$_3$]$_{0.48}$·Λ-[Co(en)$_3$]$_{0.52}$(d-H$_2$tart)$_{1.5}$·5H$_2$O.

the previous systems,[1,2] Λ-[Co(en)$_3$](d-H$_2$tart)$_{1.5}$(4)–Λ-[Co(en$_3$)]X$_3$–H$_2$O, X$^-$=Br$^-$(1)′ and I$^-$(1)″.

Point H$_2$ expresses the binary solubility of double salt Λ-[Co(en)$_3$](d-H$_3$tart)(d-H$_2$tart)·3H$_2$O. The region of the salt occupies a very wide region (H$_1$↔H$_2$↔A↔) and the salt exists in the area where the liquid phase contains little d-H$_2$tart^{2-} (the right area of A). The binary solubility for X$^-$=d-H$_3$tart$^-$ of Λ-[Co(en)$_3$]X(d-H$_2$tart) (m=0.0426 mol kg^{-1}) is much smaller than that for X$^-$=Br$^-$ and I$^-$ (m=0.135 and 0.148 mol kg^{-1}, respectively) at 25 °C. The isotherms of the latter two salts in the ternary systems locate in much lower region than that of the former salt. These facts relate to the appearance of a new ternary system, Λ-[Co(en)$_3$](d-H$_3$tart)(d-H$_2$tart)–Λ-[Co(en)$_3$](d-H$_3$tart)(d-H$_2$tart)–H$_2$O, which is useful for optical resolution.

Ternary System Δ-[*Co(en)*$_3$](d-*H*$_2$*tart*)$_{1.5}$–Δ-[*Co(en)*$_3$](d-*H*$_3$*tart*)$_3$–*H*$_2$*O*. The Λ-ternary system is shown in Fig. 2 and Table 1. Point F$_2$ shows the binary solubility of the new double salt Λ-[Co(en)$_3$](d-H$_3$tart)(d-H$_2$tart), whose region spreads widely as in the case of Λ-system. The corresponding double salt for X$^-$=I$^-$ of Λ-[Co(en)$_3$]X(d-H$_2$tart) has a lower isotherm[1] than that for X$^-$=d-H$_3$tart$^-$, whereas this region for X$^-$=Br$^-$ cannot be measured because of a gelatinous precipitate.[2]

The Solubility Isotherm of Reciprocal Salt-pairs, (Λ-[*Co(en)*$_3$]$^{3+}$, Δ-[*Co(en)*$_3$]$^{3+}$)–(d-*H*$_3$*tart*$^-$, d-*H*$_2$*tart*$^{2-}$)–*H*$_2$*O*. Figure 3 shows the clinographic projection of the system of the reciprocal salt-pairs. The left and right sides correspond to Figs. 1 and 2, respectively, and the upper side is the same ternary system as in the previous systems. However, the lower side shows a imaginary ternary system because neither Λ- nor Λ-[Co(en)$_3$](d-H$_3$tart)$_3$ exists as a solid compound. The boundary curve P$_1$R$_2$P$_3$, where two solids Λ-[Co(en)$_3$](d-H$_3$tart)(d-H$_2$tart)·3H$_2$O and Λ-[Co(en)$_3$]$_{0.48}$·Λ-[Co(en)$_3$]$_{0.52}$(d-H$_2$tart)$_{1.5}$·5H$_2$O coexist, lies at the upper region than the corresponding curves of the Br$^-$ and I$^-$ systems. This fact is advantageous for the optical resolution because the less soluble diastereomer enlarges its region. The double salts Λ- and Λ-[Co(en)$_3$](d-H$_3$tart)(d-H$_2$tart) have a long boundary P$_3$↔I↔E↔. When we utilize the Λ-[Co(en)$_3$](d-H$_3$tart)(d-H$_2$tart) diastereomer for the optical resolution, the point corresponding to maximum yield lies on P$_3$IE. Since the curve is almost parallel to

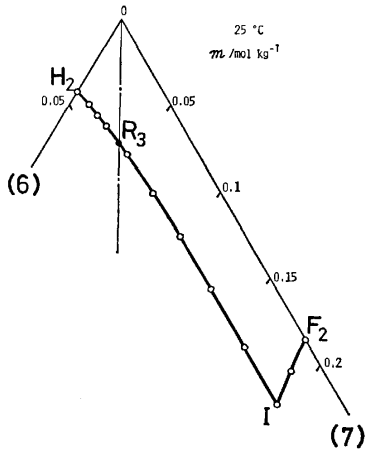

Fig. 4. Solubility isotherm of the ternary system, *Λ*-[Co(en)$_3$](*d*-H$_3$tart)(*d*-H$_2$tart)(6) – *Λ*-[Co(en)$_3$](*d*-H$_3$tart)(*d*-H$_2$tart)(7)–H$_2$O, at 25 °C.
Solubility is presented in molality *m* of anhydrous salt.

the ordinate, the yield is constant at 25 °C (83% for *Λ*-[Co(en)$_3$]$^{3+}$ and 42% for *rac*-[Co(en)$_3$]$^{3+}$) in spite of the large variation of [*d*-H$_3$tart$^-$]/[*d*-H$_2$tart^{2-}] in solution.

Ternary System Λ-[*Co(en)*$_3$](d-*H*$_3$*tart*)(d-*H*$_2$*tart*)–Δ-[*Co(en)*$_3$](d-*H*$_3$*tart*)(d-*H*$_2$*tart*)–*H*$_2$*O*. The ternary system, *Λ*-[Co(en)$_3$]X(*d*-H$_2$tart)–*Λ*-[Co(en)$_3$]X(*d*-H$_2$tart)–H$_2$O, is formed in the present case of X$^-$= *d*-H$_3$tart$^-$ (Fig. 4), though the participation of *Λ*-[Co(en)$_3$]$_{0.48}$·*Λ*-[Co(en)$_3$]$_{0.52}$(*d*-H$_2$tart)$_{1.5}$·5H$_2$O prevents from occurring such kind of ternary system for X$^-$=Br$^-$ or I$^-$. This system corresponds to $\beta=2/3$ in Fig. 3. Though the solubility of *Λ*-[Co(en)$_3$](*d*-H$_3$tart)(*d*-H$_2$tart) slightly decreased with the increase of *Λ*-[Co(en)$_3$](*d*-H$_3$tart)(*d*-H$_2$tart), it is interesting that the *Λ*-double salt shows the reverse relationship.

The solubilities of the double salts are listed in Table 2. The solubility ratio *Λ*/*Λ* becomes maximum (*ca.* 12.2) at the transition temperature (about 47 °C) from 8-hydrate to monohydrate of *Λ*-[Co(en)$_3$](*d*-H$_3$tart)(*d*-H$_2$tart). The ratio is 4.37 at 25 °C, and therefore the yield of optical resolution will be improved by experimenting at 47 °C.

Formation of Mixed-ligand Complexes of Cobalt(II) with Bromide and Substituted Pyridines in 1,2-Dibromoethane

Kiyoshi SAWADA,* Kazue MIURA, and Toshio SUZUKI

Laboratory of Analytical Chemistry, Faculty of Science, Niigata University, Niigata 950-21

(Received July 20, 1981)

The equilibria of a series of complexes of the $CoBr_2(R\text{-}py)_2$ type (where R-py=2-methyl-(2Me-py), 3-methyl-(3Me-py), 4-methyl-(4Me-py), 4-acetyl-(4Ac-py), and 4-cyanopyridine (4CN-py), and pyridine(py)) with TBA·Br (tetrabutylammonium bromide) in 1,2-dibromoethane have been investigated spectrophotometrically. In the presence of an excess of R-py, the dibromocomplex gives rise to the following configurational equilibrium:

$$\underset{\text{(tetrahedral)}}{CoBr_2(R\text{-}py)_2} + 2R\text{-}py \overset{K_c}{\rightleftharpoons} \underset{\text{(octahedral)}}{CoBr_2(R\text{-}py)_4}$$

with log K_C=0.67, 0.11, and 0.53±0.03 for the 4Me-py, 3Me-py, and py complexes respectively. The substitution equilibria of the tetrahedral complexes are written as:

$$CoBr_2(R\text{-}py)_2 + TBA\cdot Br \overset{K_3}{\rightleftharpoons} (TBA)CoBr_3(R\text{-}py) + R\text{-}py,$$

$$(TBA)CoBr_3(R\text{-}py) + TBA\cdot Br \overset{K_4}{\rightleftharpoons} (TBA)_2CoBr_4 + R\text{-}py.$$

The successive formation constants, log K_3, were determined as 2.23, 2.44, and 2.89±0.03 for the 4Me-py, 3Me-py, and py complexes respectively. The constants log K_4 for the 4Me-py, 3Me-py, 2Me-py, py, 4Ac-py and 4CN-py complexes are −1.07, −0.94, 0.09, −0.74, −0.09, and 0.47±0.01 respectively. The values of log K_3 and log K_4 show a linear correlation with the basicity of R-py, pK_b, except for the 2Me-py complex.

In nonaqueous solvents containing an excess of pyridine bases, R-py, the dihalogenocomplex of cobalt(II) is in a configurational equilibrium between tetrahedral $[CoX_2(R\text{-}py)_2]$ and octahedral $[CoX_2(R\text{-}py)_4]$ structures (where X=halogenide ion). Libuś and his co-workers[1,2] have studied the configurational equilibria for a series of complexes of cobalt(II) and other first-row transition metals by means of solubility and spectrophotometric measurements. The thermodynamic data of the equilibria with a series of substituted pyridines have been reported by Nelson *et al.*,[3-5] and the kinetic parameters have been measured by means of nitrogen-14 NMR[6] and T-jump method.[7,8] The addition of the halogenide ion to the dihalogenocomplex solution results in the formation of the tetrahedral trihalogeno $[CoX_3(R\text{-}py)^-]$ and tetrahalogeno $[CoX_4^{2-}]$ complexes.[9] Besides the visible spectra, UV,[10] near-IR,[9,11,12] and far-IR[13-15] spectra of the di- and trihalogenocomplexes in solution and in crystals have been measured.

Nelson *et al.*[5] have interpreted the solution behavior and spectra of the $CoX_2(R\text{-}py)_2$ complexes in terms of Co–N π bonding, which depends mainly on X^- and, to a lesser extent, on R-py and its pK_b. Wayland and Drago[16,17] have explained the effect of the Co–X bond strength on the Co–N bond in terms of the molecular orbital theory, whereas Graddon and Watton[18] and La Mar[19] have attributed the effects to the ligand-ligand repulsion.

The effect of the basicity of pyridine bases on the metal-nitrogen bond strength has been systematically investigated for the zinc complexes, $ZnX_2(R\text{-}py)_2$, by means of the heat of complex formation,[20,21] the far-IR spectra,[20,22-24] and the crystal structure:[24] and the role of the π bonding has been discussed. Almost no such systematic study has been attempted for the cobalt(II) complexes, however.

In a previous paper[9] we have investigated the equilibria of $CoCl_2(R\text{-}py)_2$ with tetrabutylammonium chloride (TBA·Cl) in 1,2-dichloroethane, and reported the linear correlation between the cobalt(II)-pyridine bond strength and pK_b of R-py. In the present paper, the equilibria of $CoBr_2(R\text{-}py)_2$ with TBA·Br in 1,2-dibromoethane are investigated spectrophotometrically, and the results are compared with those for the chlorocomplexes.

Experimental

Reagents. 1,2-Dibromoethane dehydrated by means of the molecular sieve was distilled. Tetrabutylammonium bromide (TBA·Br) was dried at 140 °C, and its purity was determined by argentometry. The substituted pyridines, R-py, and dibromobis(substituted pyridine)cobalt(II) were prepared by a method similar to that described in a previous paper.[9]

Measurements. The $CoBr_2(R\text{-}py)_2$ solution was prepared by dissolving $CoBr_2(R\text{-}py)_2$ crystals in 1,2-dibromoethane containing 10^{-3} mol dm^{-3} of R-py. This solution was titrated with a TBA·Br solution in a stoppered quartz cell (volume: 50 cm^3, light path: 10 mm), and the change in the visible spectra of the solution was measured by a Shimadzu double-beam spectrophotometer UV-200 at 25.0± 0.2 °C.

Results

Configurational Equilibria of Dibromocomplexes. The visible spectra of $CoBr_2(R\text{-}py)_2$ are shown in Fig. 1 (A). By the addition of 10^{-3} mol dm^{-3} of R-py, the formation of a lower pyridine complex such as $CoBr_2(R\text{-}py)$ is surpressed. The fact that the spectra have no peaks of such higher bromocomplexes as the tribromocomplex indicates that they are the spectra of the pure dibromocomplex. The solubilities of the 4Ac-py and 4CN-py complexes are too low for the spectra to be measured.

Upon the addition of a large excess of R-py, the absorbance decreases monotonously, while the ratios of the peak heights do not change. This spectral

change can be interpreted in terms of the formation of an octahedral complex,[1-5,9] which has quite a small molar extinction coefficient compared with that of the tetrahedral complex; *i.e.*, the molar extinction coefficient of the tetrahedral complex of cobalt(II) is about 10^3, as is shown in Fig. 1, whereas that of the octahedral complex is less than 10 in the region of 600—700 nm.[2,25] We thus obtain the following equilibrium:

$$CoBr_2(R\text{-}py)_2 + 2R\text{-}py \overset{K_c}{\rightleftharpoons} CoBr_2(R\text{-}py)_4. \quad (1)$$

As the concentration of R-py, $C_{R\text{-}py}$, is much larger than that of the complex, C_{Co}, and as the absorption of the octahedral complex is negligible, the apparent molar extinction coefficient, $\bar{\varepsilon}$, is written as:

$$\bar{\varepsilon} = \frac{\varepsilon_2}{1+K_cC_{R\text{-}py}{}^2}. \quad (2)$$

We thus obtain Eq. 3 immediately:

$$\log\left(\frac{\varepsilon_2}{\bar{\varepsilon}}-1\right) = \log K_c + 2\log C_{R\text{-}py}. \quad (3)$$

Plot of the log $(\varepsilon_2/\bar{\varepsilon}\text{-}1)$ values of the peaks of the dibromocomplex as a function of log $C_{R\text{-}py}$ gives rise to a straight line with a slope of 2. The equilibrium constants of configurational change, K_c, obtained from the intercept are listed in Table 1.

Formation of Tribromocomplexes. The change in the spectra of the $CoBr_2py_2$ solution (containing 0.05 mol dm^{-3} pyridine) upon the addition of TBA·Br is shown in Fig. 2. These spectra show an isosbestic point at 658 nm. In Fig. 3 the apparent molar extinction coefficient of the pyridine complex at 596 nm is plotted as a function of the mole ratio, $C_{TBA\cdot Br}/C_{Co}$, where $C_{TBA\cdot Br}$ refers to the total concentration of TBA·Br added. These results indicate a reaction of one molecule of bromide with a cobalt(II) complex, *i.e.*, the formation of a tribromocomplex:

$$CoBr_2py_2 + TBA\cdot Br \overset{K_3}{\rightleftharpoons} (TBA)CoBr_3py + py. \quad (4)$$

As will be shown in the next section, the successive formation constant of the tetrabromocomplex, K_4, is much smaller than that of the tribromocomplex, K_3; the formation of the tetrabromocomplex in this region of $C_{TBA\cdot Br}/C_{Co}$ is negligible. Thus, the total concentration of cobalt(II) is given by:

$$C_{Co} = [CoBr_2py_4] + [CoBr_2py_2] + [(TBA)CoBr_3py], \quad (5)$$

where [ ] denotes the equilibrium concentration. As the molar extinction coefficient of the octahedral com-

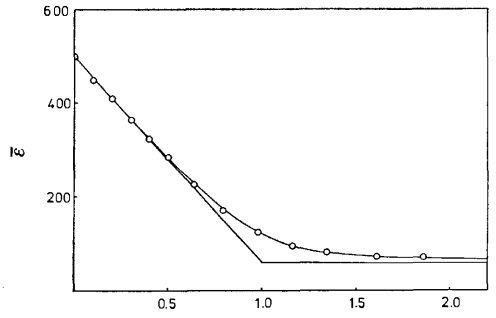

Fig. 3. Plot of apparent molar extinction coefficient at 596 nm as a function of mole ratio, $C_{TBA\cdot Br}/C_{Co}$. $C_{Co}=1.01\times10^{-3}$ mol dm^{-3}. $C_{py}=1.60\times10^{-2}$ mol dm^{-3}. Solid line is the plot of $\bar{\varepsilon}$ calculated by using the values of ε_3, ε_2, and K_3 shown in Fig. 1 and Table 1.

plex is negligibly small at this wavelength, we obtain:

$$\bar{\varepsilon} = \{\varepsilon_2[CoBr_2py_2] + \varepsilon_3[(TBA)CoBr_3py]\}C_{Co}^{-1}, \quad (6)$$

where the molar extinction coefficient of (TBA)-$CoBr_3py$, ε_3, was evaluated by the extrapolation of the plot of $\bar{\varepsilon}$ to $C_{TBA\cdot Br}/C_{Co}=1$. The formation constant of the tribromocomplex:

$$K_3 = \frac{[(TBA)CoBr_3py][py]}{[CoBr_2py_2][TBA\cdot Br]}$$

is calculated by using Eqs. 5 and 6. The spectrum of the tribromocomplex obtained from the ε_3 values at various wavelengths, as evaluated by the extrapolation of the plot of $\bar{\varepsilon}$ to $C_{TBA\cdot Br}/C_{Co}=1$, is shown in Fig. 1. (B).

The value of the apparent molar extinction coefficient calculated by using the ε_2, ε_3, and K_3 values thus obtained is shown in Fig. 3 by a solid line; it is in good agreement with the experimental results. The K_3 of the pyridine complex is listed in Table 1, along with those of the 4Me-py and 3Me-py complexes obtained in the same manner as the pyridine complex.

Formation of Tetrabromocomplexes. 10^{-4} mol of $CoBr_2$ were dissolved in 100 cm^3 of 2×10^{-3}—10^{-1} mol dm^{-3} TBA·Br 1,2-dibromoethane solutions ($C_{R\text{-}py}=0$). The spectra of the solutions (Fig. 1 (C)) show the characteristics of the tetrabromocomplex.[25] The spectra have no peaks of other complexes and do not change upon a change in the concentration of TBA·Br. Concequently, the spectrum of Fig. 1 (C) is that of pure $(TBA)_2CoBr_4$.

The addition of a large excess of bromide to the $CoBr_2(R\text{-}py)_2$ solution causes further spectral change, as is shown in Fig. 4. These spectra show an isosbestic point at 694 nm, and the spectrum at the highest $C_{TBA\cdot Br}$ value shows the characteristics of the tetrabromocomplex. Thus, the reaction in this region of $C_{TBA\cdot Br}$ may be written as:

$$(TBA)CoBr_3(R\text{-}py) + TBA\cdot Br \overset{K_4}{\rightleftharpoons} (TBA)_2CoBr_4 + R\text{-}py. \quad (7)$$

The total concentration of cobalt(II) and the apparent molar extinction coefficient are written as follows:

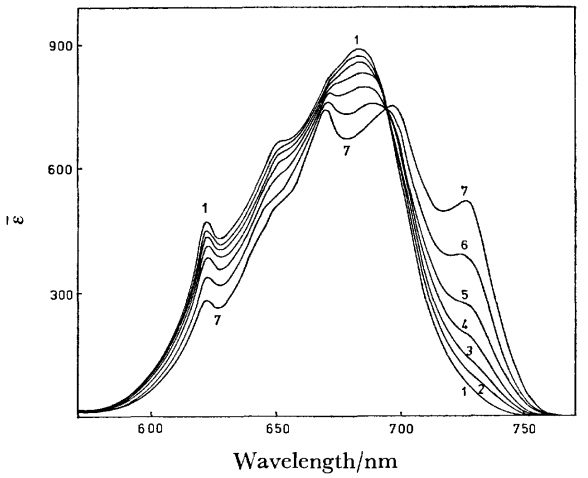

Fig. 4. Absorption spectra of pyridine complex at high TBA·Br concentrations.
$C_{TBA\cdot Br}$: 1, 2.53; 2, 4.51; 3, 6.59; 4, 9.86; 5, 15.5; 6, 25.5; 7, 41.1×10^{-3} mol dm^{-3}. $C_{Co}=1.33\times10^{-3}$ mol dm^{-3}. $C_{py}=0.996\times10^{-2}$ mol dm^{-3}.

$$C_{Co} = [(TBA)CoBr_3(R\text{-}py) + [(TBA)_2CoBr_4], \quad (8)$$

$$\bar{\varepsilon} = \{\varepsilon_3[(TBA)CoBr_3(R\text{-}py)] + \varepsilon_4[(TBA)_2CoBr_4]\}C_{Co}^{-1}, \quad (9)$$

where ε_4 refers to the molar extinction coefficient of $(TBA)_2CoBr_4$. From Eqs. 8 and 9, we obtain the following equation:

$$\frac{[(TBA)_2CoBr_4]}{[(TBA)CoBr_3(R\text{-}py)]} = \frac{\bar{\varepsilon}-\varepsilon_3}{\varepsilon_4-\bar{\varepsilon}}. \quad (10)$$

By using the equilibrium constant of Eq. 7, K_4, and Eq. 10, we obtain:

$$\log\frac{\bar{\varepsilon}-\varepsilon_3}{\varepsilon_4-\bar{\varepsilon}} = \log K_4 + \log\frac{[TBA\cdot Br]}{[R\text{-}py]}. \quad (11)$$

The plot of the left-hand side of Eq. 11 as a function of log [TBA·Br]/[R-py] falls on a straight line with a slope of unity. This indicates the validity of the assumption of the equilibria (7).

In the cases of the 4Ac-py and 4CN-py complexes, the solution of the tribromocomplex, $(TBA)CoBr_3(R\text{-}py)$, was prepared by saturating the 10^{-2} mol dm^{-3} TBA·Br solution with the $CoBr_2(R\text{-}py)_2$ complex. The mole ratio of the TBA·Br and $CoBr_2(R\text{-}py)_2$ of the saturated solution was determined as $C_{TBA\cdot Br}/C_{Co}=1$. Thus, the formation of only the tribromocomplex was ascertained. The spectra of the tribromocomplexes are shown in Fig. 1 (B).

Discussion

As can be seen from Fig. 5, there is no systematic correlation between the K_c and pK_b of R-py. Generally, the configurational change from tetrahedral to octahedral structures is enthalpy-driven, and the enthalpy is largely compensated by the entropy term.[3-5,26] Thus, the effect of the entropy change on the configurational equilibrium is so appreciable that the difference in the basicity of the pyridines may be overwhelmed by the change in the entropy. The K_c of

the 3Me-py complex is considerably smaller than those of the py and 4Me-py complexes. This may indicate steric hindrance in the octahedral complex caused by the substitution at the 3-position of the pyridine.[16-19]

As is revealed in Fig. 5, the plot of log K_3 and log K_4 *vs.* pK_b of R-py shows a linear correlation; *i.e.*, the Co–R-py bond strength decreases upon a decrease in the basicity of R-py. The fact that the constants, K_3 and K_4, of the 3Me-py complexes show normal values indicates that the steric effect of 3Me-py is not important in the tetrahedral complexes. La Mar[19] has suggested the presence of steric hindrance of 3Me-py in the tetrahedral complexes, whereas Wayland and Drago[17] have denied this argument on the basis of the rasults of the molecular model and the contact shift of proton NMR. Our results support the latter conclusion. The K_4 value of the 2Me-py complex is much larger than those of the complexes of the other pyridines having comparable pK_b value. Thus, the steric effect of 2Me-py is significant even in the tetrahedral configuration.

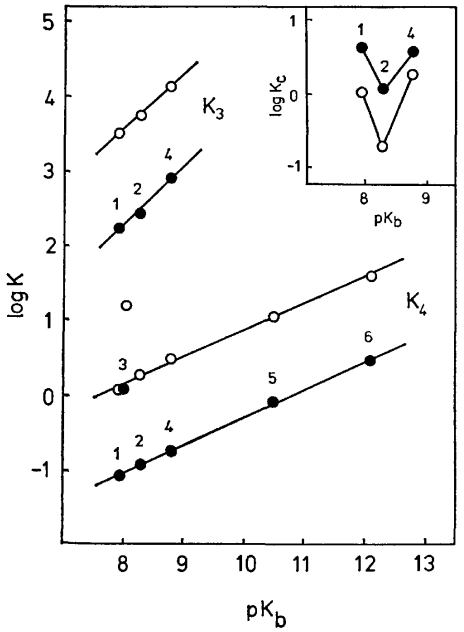

Fig. 5. Plot of log K_c, log K_3, and log K_4 as a function of pK_b of R-py.
R-py: 1, 4Me-py; 2, 3Me-py; 3, 2Me-py; 4, py; 5, 4Ac-py; 6, 4CN-py. Filled circle: bromocomplexes, open circle: chlorocomplexes (Ref. 9).

The ratio of the successive formation constants, K_3/K_4, is much larger than the statistical one, $(K_3/K_4)_{stat}=8/3$. As has been shown in the previous paper,[9] this fact can be interpreted in terms of the steric hindrance increasing in the order of: $CoX_2(R\text{-}py)_2<CoX_3(R\text{-}py)^-<CoX_4^{2-}$.

The formation constants, K_3 and K_4, of the bromocomplexes are smaller than those of the corresponding chlorocomplexes: this trend agrees with the results of other systems.[25] The difference in log K_4 between the chloro- and bromocomplexes (Δ log $K_4=1.16$) is almost the same as that of log K_3 (Δ log $K_3=1.24$). This may indicate that the steric effect of the bromocomplex is of the same magnitude of that of the chlorocomplex. This is consistent with the fact that the magnitude of the steric effects of the octahedral 3Me-py chlorocomplex and the tetrahedral 2Me-py chlorocomplex is almost the same as those of the bromocomplexes respectively.

The effect of the basicity of substituted pyridine on the metal-pyridine bond strength has also been discussed. Wong and Brewer[22] have suggested that, when the substituent on pyridine is more electron-attractive than hydrogen, the metal-nitrogen σ bond is weakened by the decrease in electron density on the nitrogen atom of pyridine, but that the π bond is strengthened by the back-donation of the π electron from metal to nitrogen. Thus, the decrease in metal-pyridine bond strength upon the decrease in σ bonding is partially compensated by the increase in π bonding. Steffen and Palenik[24] have concluded that the linear correlation of the Zn–N bond length in $ZnCl_2(R\text{-}py)_2$ with the pK_b of R-py suggests a minimum contribution of π bonding. As can be seen from Fig. 5 a linear correlation of the Co–N bond strength with pK_b is observed even for the cobalt(II) complex. This can be interpreted in terms of the linear correlation between the π bond and the σ bond, or a minimum contribution of the π bond to the Co–N bond. Wayland and Drago[16] have suggested that the contribution of the π bond is not so significant

Table 2. Frequency of the gravity center and oscillator strength of the absorption band of the tetrahedral halogeno complexes of cobalt(II) in 1,2-dihaloethane, acetic acid, and acetone[a]

for the ligand with no low-lying empty π orbital such as pyridine.

Much as with the chlorocomplexes, the dibromocomplexes and the tribromocomplexes have virtually the same visible spectra irrespective of the change in the pyridine bases, although those of the 2Me-py complexes are slightly shifted to a higher wavelength (Figs. 1 (A) and (B)). The frequency of the gravity center, ν_c, and the oscillator strength, f, of the absorption band are listed in Table 2, along with the data on chlorocomplexes in 1,2-dichloroethane,[9] bromo- and chlorocomplexes in acetic acid,[25] and chlorocomplexes in acetone.[28]

The plot of ν_c *vs.* the number of the halogenide ion coordinated to cobalt(II) gives rise to a good linear relationship. The ν_c of cobalt(II) coordinated by four pyridine molecules tetrahedrally, $Co(py)_4^{2+}$, is estimated as $\nu_c=17.64\times10^3\,cm^{-1}$. This may indicate that the rule of average environment can be applied to both the ligand-field strength and the electron-repulsion parameter. The trend of change in f with the number of the halogenide ion in the complex depends on the neutral ligand. This may indicate that the structures of the dihalogeno- and trihalogenocomplexes are seriously affected by the structure of the solvent or neutral ligand. On the other hand, as can be seen from Fig. 1, the effect of the basicity of the neutral ligand on the spectra is very small.

We are grateful to the Ministry of Education, Science and Culture for its financial support through Grant No. 374188.

Optically Active Vanadium(IV) and (V) Complexes Containing (*S*)-*N*-[1-(2-Pyridyl)ethyl]iminodiacetate Ion

Kenichi Okazaki and Kazuo Saito*

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received July 22, 1981)

New optically active vanadium(IV) and (V) and mixed valence(IV,V) complexes containing a quadridentate ligand (*S*)-*N*-[1-(2-pyridyl)ethyl]iminodiacetate (*S*-peida^{2-}) have been prepared: *i.e.* uninuclear distorted octahedral [$V^{IV}O$(*S*-peida)(H_2O)] and Li[$V^{V}(O)_2$(*S*-peida)], a mixed valence binuclear Na[$V_2^{IV,V}O_3$(*S*-peida)$_2$], and an oxo-peroxo complex Na[$V^{V}O(O_2^{(2-)})$(*S*-peida)]. The tertiary amino nitrogen of *S*-peida^{2-} occupies the trans position to the oxo ligand in the first three complexes, but *trans* to the peroxo ligand in the last complex. Three absorption bands of [$V^{IV}O$(*S*-peida)(H_2O)] in the region from 10000 to 30000 cm^{-1} have been assigned to the d-d transitions, $d_{xy}\rightarrow(d_{xz},d_{yz})$, $d_{xy}\rightarrow d_{z^2-y^2}$, and $d_{xy}\rightarrow d_{z^2}$, in the order of increasing frequency. The mixed valence complex gives an intervalence transfer band and two d-d bands in the region from 9000 to 25000 cm^{-1}. It gives a negative and a positive CD peak corresponding to the intervalence transition. The $V^{V}(O)_2$ and the $V^{V}O(O_2)$ complex give a characteristic absorption shoulder at 25000 and a peak at 23500 cm^{-1} with corresponding weak negative CD peaks, respectively. They are assigned to charge transfer bands from oxo and peroxo to V^{V}, respectively. The sign of CD peaks seems to be governed mostly by asymmetric arrangement of the ligating atoms and asymmetric deviation of ligating atoms from regular octahedron.

Oxo complexes of early transition metal ions are attracting increasing interest of coordination chemists. Asymmetric structure of some binuclear optically active $Mo^{V}(d^1)$ complexes was studied in solution and in solid by circular dichroism (CD) spectroscopy and X-ray diffraction.[1] However, much less is known for V^{IV} complexes with the same d^1 configuration. Jones and Larsen[2] first studied CD spectra of optically active oxovanadium(VI) complexes containing (*R*)-lactate, (*S*,*S*)-tartrate, and (*R*)-1,2-diiminopropanebis(acetylacetonate) ions with aims of assigning the absorption peaks. However, they succeeded in the isolation only of the complex with the third ligand. Optical activity was also studied with the complexes containing quadridentate Schiff bases derived from optically active diamines and salicylaldehyde derivatives.[3] Their absorption spectra involve not only d-d transitions (12000—20000 cm^{-1}) but also π-π^* transitions within the azomethine (*ca.* 28000) and the phenyl (*ca.* 36000) chromophore. The relationship between the sign of exciton CD bands of the azomethine chromophore and the configuration of the basal plane was mainly discussed. However, the CD spectra in the d-d region have not been much discussed.

Nishizawa and Saito synthesized new octahedral oxovanadium(IV) complexes with the quadridentate ligands *N*-(2-pyridylmethyl)iminodiacetate (pmida^{2-}) and nitrilotriacetate (nta^{3-}) in crystalline state. X-Ray crystallography of [$V^{IV}O$(pmida)(H_2O)][4] disclosed that only one of the geometrical isomers was exclusively formed with the tertiary amino nitrogen at the apical position. They also prepared a deep blue mixed valence binuclear complex bridged with oxide [$V_2^{IV,V}O_3$(nta)$_2$]$^{3-}$. X-Ray crystallography and ESR spectroscopy in the aqueous solution showed that the two vanadium atoms are equivalent to each other both in crystals and in aqueous solution.[5]

In order to clarify the electronic state and the relationship between the structure and the CD spectrum of the octahedral complexes with $V^{IV}O^{2+}$ and $V^{V}(O)_2^{+}$ core and of the mixed valence complex, we intended to introduce optical activity to those complexes by use of a similar quadridentate ligand (*S*)-*N*-[1-(2-pyridyl)ethyl]iminodiacetate ion (*S*-peida^{2-}).[6] Optically active complexes [$V^{IV}O$(*S*-peida)(H_2O)], [$V_2^{IV,V}O_3$(*S*-peida)$_2$]$^{-}$, [$V^{V}(O)_2$(*S*-peida)]$^{-}$, and [$V^{V}O(O_2^{(2-)})$(*S*-peida)]$^{-}$ have been prepared in crystalline state and their steric and electronic structures discussed.

Experimental

Preparation of Ligand. Sodium (*S*)-*N*-[1-(2-pyridyl)ethyl]iminodiacetate[6] was prepared in aqueous solution by treating (*S*)-1-(2-pyridyl)ethylamine[7] with sodium chloroacetate, and used without separating the crystals for preparing the complexes in aqueous phase.

Preparation of Complexes. [$V^{IV}O$(S-*peida*)(H_2O)]·2H_2O: [$V^{IV}O$(acac)$_2$][8] (Hacac, acetylacetone) (3.2 g, 0.012 mol) was stirred in an aqueous solution of the ligand (prepared from 0.02 mol of (*S*)-1-(2-pyridyl)ethylamine). The pH was maintained at 3 until [VO(acac)$_2$] dissolved completely. The dark blue solution was concentrated under a reduced pressure to about 5 cm^3 and poured onto a column (4 cm×22 cm) of Dowex 50W-X8 (Na^+ form, 100—200 mesh). Elution with dilute $HClO_4$ (pH 4) gave three adsorption bands. The first eluate was dark green and seemed to contain negatively charged complexes. The third band was not eluted and may consist of aqua VO^{2+} complex. The purplish blue eluate (500 cm^3, pH *ca.* 4) of the second band was concentrated to give blue granules of the dihydrate. Yield: 4.0 g (93%). Found: C, 37.27; H, 5.27; N, 8.02%. Calcd for $C_{11}H_{18}N_2O_8V$: C, 36.98; H, 5.08; N, 7.84%.

Na[$V_2^{IV,V}O_3$(S-*peida*)$_2$]·*NaClO*$_4$·H_2O: This complex was prepared by oxidizing [VO(*S*-peida)(H_2O)] with half a mole of nitrite. The [VO(*S*-peida)(H_2O)]·2H_2O (0.21 g, 0.59 mmol) was stirred in methanol (50 cm^3) containing $NaNO_2$ (0.021 g, 0.30 mmol) for 2 h at room temperature. Solid $NaClO_4$ (*ca.* 1 g) was added to the dark blue solution to precipitate dark blue granules, which were filtered off. Addition of diethyl ether to the filtrate gave further crops. Yield: 0.22 g (93%). Found: C, 33.44; H, 3.23; N, 7.00%. Calcd for $C_{22}H_{26}N_4O_{16}ClNa_2V_2$: C, 33.63; H, 3.33; N, 7.13%.

Li[$V^{V}(O)_2$(S-*peida*)]·2CH_3OH·5H_2O: The V^{IV} complex was oxidized with an excess of nitrite. The suspension of

$[V^{IV}O(S\text{-peida})(H_2O)]$ (1 g, 2.8 mmol) in methanol (20 cm^3) containing $LiNO_2$ (0.5 g, 9.4 mmol) was stirred for 3 h at room temperature until the solution turned yellow. The solution was mixed with diethyl ether (25 cm^3) and left in a refrigerator overnight to give yellow crystals. Yield: 1.0 g (89%). Found: C, 39.09; H, 5.14; N, 6.95%. Calcd for $C_{13}H_{21}N_2O_{8.5}LiV$: C, 39.11; H, 5.30; N, 7.02%.

Na[$V^VO(O_2)$(S-peida)]: $[V^{IV}O(S\text{-peida})(H_2O)]$ (0.5 g, 1.4 mmol) was dissolved in 100 cm^3 of water and treated with an excess of hydrogen peroxide (30%, 5 cm^3) at room temperature to give orange solution immediately, which was made pH 6 with aqueous NaOH solution, concentrated to about 10 cm^3, mixed with ethanol (*ca.* 15 cm^3), and left in a refrigerator to give fine orange needles. Yield: 0.3 g (60%). Found: C, 36.85; H, 3.42; N, 7.52%. Calcd for $C_{11}H_{12}N_2O_7NaV$: C, 36.89; H, 3.38; N, 7.82%.

Measurement. The pK_a value of $[VO(S\text{-peida})(H_2O)]$ (Eq. 1) was obtained by titrating the aqueous solution of the complex (30 cm^3, 0.005 mol dm^{-3}) with *ca.* 0.1 mol dm^{-3} NaOH solution at I=0.1 mol dm^{-3} ($NaClO_4$) and 25±0.3 °C in a current of nitrogen. The complex $[V_2^{IV,V}O_3(S\text{-peida})_2]^-$ is in equilibrium with the V^{IV} and V^V complexes in an aqueous solution.[5] The equilibrium constant (see Eq. 2) was determined spectrophotometrically[9] at 740 nm by use of the complex solutions of 2.5—10 mmol dm^{-3} at I=0.1 mol dm^{-3} ($NaClO_4$), pH 4.5, and at 6.3±0.8, 15.0±0.4, and 25.0±0.1 °C.

The absorption and CD spectra were recorded in aqueous solutions and KBr disks with a Hitachi 323 Spectrophotometer, and JASCO Model J-40 A (200—700 nm), J-20 A (700—1000 nm), and J-200 (1000—2000 nm) CD Spectropolarimeters. A Varian A 60 D NMR Spectrometer was used for recording ^{1}H-NMR spectra of the two vanadium(V) complexes in D_2O.

Results and Discussion

Structure. X-Ray crystallography disclosed the structure of $[V^{IV}O(S\text{-peida})(H_2O)]$, $[V_2^{IV,V}O_3(S\text{-peida})_2]^-$, and $[V^V(O)_2(S\text{-peida})]^-$ (Fig. 1); the details are reported elsewhere.[10] The tertiary amine is at the trans position to the oxo ligand in all these complexes, and the methyl group on the asymmetric carbon has an equatorial orientation in the puckered five membered chelate ring.

The $[V^{IV}O(S\text{-peida})(H_2O)]$ and the mixed valence complex have similar CD patterns both in solution and in solid (see CD spectra). ^{1}H-NMR spectrum of the $V^V(O)_2$ complex supports the existence of only one isomer in solution. Its structure estimated by ^{1}H-NMR spectroscopy (*vide infra*) is not in conflict with the X-ray analysis. Hence all these three complexes seem to have the same geometrical isomerism in solution as in crystals.

The ^{1}H-NMR spectrum of the $[V^V(O)_2(S\text{-peida})]^-$ ion in D_2O (Table 1 and Fig. 2) exhibits one doublet, three quartets, and three multiplets from the high field. The doublet and one of the quartets with average chemical shifts 1.73 and 5.23 ppm, respectively, and with a common coupling constant 7 Hz, are assigned to the protons of the methyl group and that on the asymmetric carbon, respectively. The AB patterns centered at 3.46 and 4.18 ppm must arise from methylene protons of the acetates of which the ligating oxygens are at trans and cis to the pyridine nitrogen,

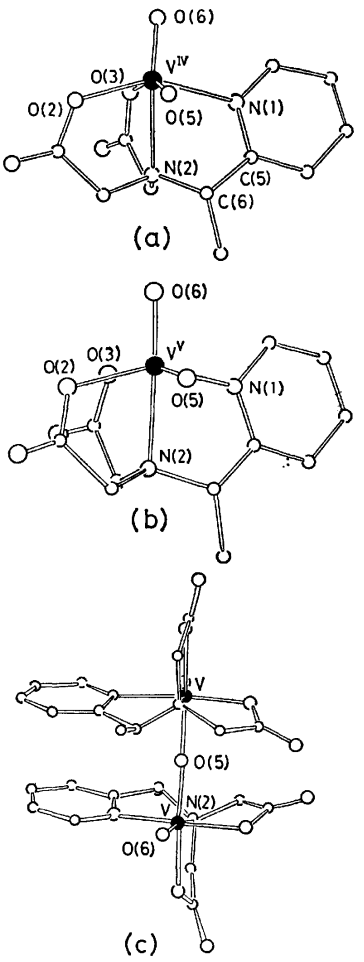

Fig. 1. Structures of the complexes determined by X-ray crystallography.
(a); $[V^{IV}O(S\text{-peida})(H_2O)]$. O(5) is oxygen atom of H_2O. The torsion angle between N(1)–N(2) and C(5)–C(6) is 17.0° (δ). (b); $[V^V(O)_2(S\text{-peida})]^-$. (c); $[V_2^{IV,V}O_3(S\text{-peida})_2]^-$.

respectively. The reasons are follows. The two protons of the cis acetate are subject to a more marked influence of the methyl group on the asymmetric carbon, and have therefore lower chemical shifts than those of the trans acetate; the difference between the anisotropic effects upon the two protons of the cis acetate can also cause a rather large difference of the chemical shifts between them ($\delta_A-\delta_B$ in Table 1). A free pyridine gives three multiplets over 7 ppm which correspond to the 3- and 5-, 4-, and 2- and 6-protons from the high field. Therefore, the multiplets over 7.5 ppm are assigned to the 3- and 5-, 4-, and 6-protons on the pyridine ring from the high field.

The structure of $[V^VO(O)_2(S\text{-peida})]^-$ has not been determined by the X-ray method. Its NMR spectrum shows a similar pattern to $[V^V(O)_2(S\text{-peida})]^-$ in D_2O except that the signal of the 6-proton on pyridine shifts to lower field by *ca.* 0.8 ppm. The similarity suggests that there are two different acetate chelates. The O_2^{2-} ligand may be at the trans site to the tertiary amine, because the signal of the 6-proton has the largest shift and therefore should be nearest to the trans site of the tertiary amine. The

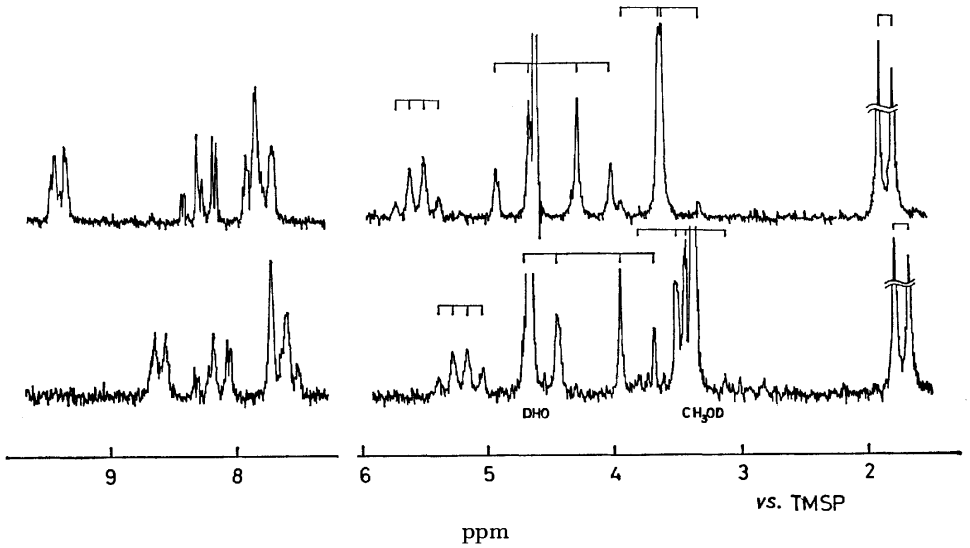

Fig. 2. ^{1}H-NMR spectra of $[V^{V}O(O)_2(S\text{-peida})]^-$ (upper) and $[V^{V}(O)_2(S\text{-peida})]^-$ (lower) in D_2O at *ca.* 30 °C.

Table 1. ^{1}H-NMR Chemical shifts and coupling constants of $[V^{V}(O)_2(S\text{-peida})]^-$ and $[V^{V}O(O_2)(S\text{-peida})]^-$

A. The methylene protons of the two acetate groups.

Complex	$\{(\delta_A+\delta_B)/2\}$	$\delta_A-\delta_B$	J_{AB}/Hz
$V(O)_2^+$	3.46	0.21	18.0
	4.18	0.71	16.0
$VO(O_2)^+$	3.63	0.18	17.5
	4.48	0.59	16.0

B. The methyl and methylidyne protons.

Complex	Proton	δ	J/Hz
$V(O)_2^+$	$-CH_3$	1.73	7.0
	$\geq CH$	5.23	
$VO(O_2)^+$	$-CH_3$	1.86	7.0
	$\geq CH$	5.57	

C. The pyridyl protons.

Complex	Proton	δ
$V(O)_2^+$	3-, 5-	7.6
	4-	8.1
	6-	8.6
$VO(O_2)^+$	3-, 5-	7.8
	4-	8.3
	6-	9.4

NMR spectrum, however, cannot clarify the bonding mode of the peroxo ligand and the geometrical relationship between this ligand and the others. Nevertheless, X-ray structure of the oxo-peroxo complexes[11-13] of early transition metal ions suggests that the present peroxo complex is the isomer in which the peroxide ion is of side-on type and the V=O and the O–O (O_2^{2-}) bonds are across each other (Fig. 3).

Equilibrium. The pK_a of the $V^{IV}O$ complex to give the hydroxo complex is 6.5 at 25 °C and I=1.0 mol dm^{-3} in aqueous solution.

$$[V^{IV}O(S\text{-peida})(H_2O)] \rightleftharpoons [V^{IV}O(OH)(S\text{-peida})]^- + H^+ \quad (1)$$

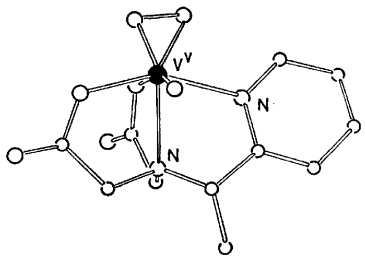

Fig. 3. Estimated structure of $[V^{V}O(O)_2(S\text{-peida})]^-$.

The mixed valence complex of $[V_2^{IV,V}O_3(S\text{-peida})_2]^-$ is in equilibrium with $[V^{IV}O(S\text{-peida})(H_2O)]$ and $[V^{V}(O)_2(S\text{-peida})]^-$ in water as shown in Eq. 2.

$$[V^{IV}O(S\text{-peida})(H_2O)] + [V^{V}(O)_2(S\text{-peida})]^- \rightleftharpoons [V_2^{IV,V}O_3(S\text{-peida})_2]^-(+H_2O) \quad (2)$$

The equilibrium constant, K, is 44±1 mol^{-1} dm^3 at 15 °C, I=0.1 mol dm^{-3} and pH 4.5. The $\Delta H°$ and $\Delta S°$ are −6±3 kJ mol^{-1} and 11±8 J mol^{-1} K^{-1}, respectively, in the temperature region from 5 to 25 °C. The small negative $\Delta H°$ and the small positive $\Delta S°$ suggest that the mixed valence complex is slightly more stable than the mixture of the $V^{IV}O$ and $V^{V}(O)_2$ complexes. Since the number of particles does not change on the reaction, the positive $\Delta S°$ suggests that the formation of mixed valence complex brings about less hydration of the system. The charge distribution in the more bulky $[V_2^{IV,V}O_3(S\text{-peida})_2]^-$ ion should be less concentrated than in the $V^{IV}O$ and $V^{V}(O)_2$ complexes.

Absorption Spectra. *V^{IV} Complex*: Oxo-vanadium(IV) complexes generally give three absorption bands with low intensity (ε=10—200), in the region from 10000 to 30000 cm^{-1} at room temperature. The two lower frequency bands sometimes overlap each other, and the highest frequency band in 21000—30000 cm^{-1} region is not always observed because of the overlap with a band of higher intensity at a higher frequency. Ballhausen and Gray[14] first assigned the three d-d absorption bands of some oxo-

vanadium(IV) complexes to $d_{xy}\rightarrow(d_{xz},d_{yz})$, $d_{xy}\rightarrow d_{x^2-y^2}$, and $d_{xy}\rightarrow d_{z^2}$ transitions in the order of increasing frequency (z axis on the V=O bond, C_{4v} symmetry) with the aid of a molecular orbital energy level scheme. However, Selbin and co-workers[15] found a fine structure with three peaks in the first absorption band (at *ca.* 13000 cm^{-1}) of $[VO(acac)_2]$ (C_{2v} symmetry) at 77 K and assigned the three peaks to those from d_{xy} to d_{xz}, d_{yz}, and $d_{x^2-y^2}$, respectively. They assigned the second band at *ca.* 18000 cm^{-1} to $d_{xy}\rightarrow d_{z^2}$ transitions. Jones and Larsen studied the CD spectra of (*R*)-lactato-, (*S,S*)-tartrato-, and (*R*)-1,2-diiminopropanebis(acetylacetonato)oxovanadium(IV) complexes and discussed the usefulness of CD spectrum for assigning the d-d transitions. However, only the third Schiff base complex was isolated and others were known only in solution. They also failed to observe the important peaks in the low frequency region.

The spectral pattern of the $[V^{IV}O(S\text{-peida})(H_2O)]$ complex gives four peaks at 13200 (ε=27.4), 17700 (16.4), 28200 (357), and 38800 cm^{-1} (4970) and a shoulder at *ca.* 34000 cm^{-1} (642) in aqueous solution of pH *ca.* 4 (Fig. 4). The first three bands are assigned to d-d transitions in the $V^{IV}O$ complex of pseudo C_{4v} symmetry, $d_{xy}\rightarrow(d_{xz},d_{yz})$, $d_{xy}\rightarrow d_{x^2-y^2}$, and $d_{xy}\rightarrow d_{z^2}$. The band in the 13200 cm^{-1} region gives two CD peaks, whilst those at 17700 and 28200 cm^{-1} do one each. Hence the first peak should involve the transition to the degenerated levels, $d_{xy}\rightarrow(d_{xz},d_{yz})$. The other two bands at 17700 and 28200 cm^{-1} are assigned to the $d_{xy}\rightarrow d_{x^2-y^2}$ and $d_{xy}\rightarrow d_{z^2}$, respectively. The band at 28200 cm^{-1} has a larger intensity (ε=357) than the first two bands do. The absorption bands of oxovanadium(IV) complexes of other amino carboxylates without pyridine ring give small ε values (*ca.* 20) at similar wave numbers.[16] Hence the large peak may involve some charge transfer transition related to the pyridine ring. The shoulder at 34000 cm^{-1} gives a CD shoulder (Fig. 4). However, $V^{IV}O$ complexes with amino carboxylates without pyridine ring do not give this absorption shoulder.[16] Hence the transition should be of charge transfer nature involving the pyridine ring. Not only the $V^{IV}O$ complex but also $[V^{V}(O)_2(S\text{-peida})]^-$ and $[V^{V}O(O_2)(S\text{-peida})]^-$ give strong bands near 38800 cm^{-1} (Fig. 4). They are assinged to π-π^* transitions within the pyridine ring, since the π-π^* transitions of pyridine itself exist around 39000 cm^{-1}.

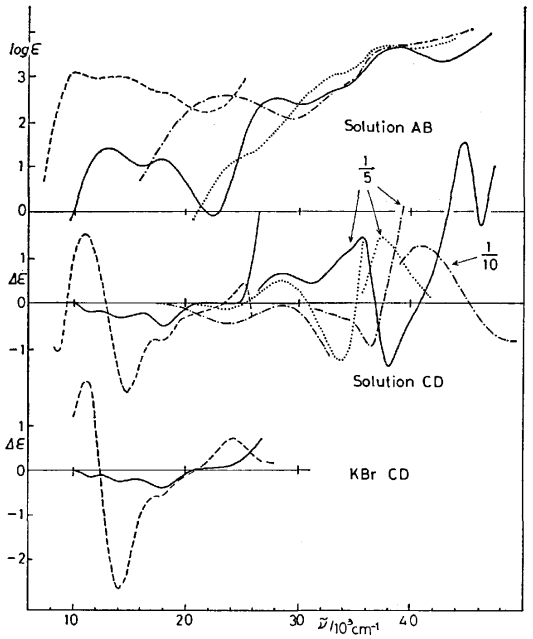

Fig. 4. Absorption and CD spectra of $[V^{IV}O(S\text{-peida})(H_2O)]$ (——), $[V_2^{IV,V}O_3(S\text{-peida})_2]^-$ (— —), $[V^{V}(O)_2(S\text{-peida})]^-$ (……), and $[V^{V}O(O)_2(S\text{-peida})]^-$ (—·—). Upper, absorption in solution; middle, CD in solution; lower, CD spectra in KBr disks.

Mixed Valence Complex: The absorption spectrum was estimated by use of the equilibrium constant, 44 mol^{-1} dm^3. The ε values are calculated per unit molarity of $V_2O_3^{3+}$. To increase the concentration of mixed valence complex in the equilibrium state, a concentrated solution (0.013 mol dm^{-3}) was used in a 0.1 cm cell. Because of the strong absorption in the ultraviolet region under this condition, the discussion is limited in the visible and near infrared region. Three bands are seen in the measurable region: *i.e.* 10200 (ε=1200), 13600 (940), and 17700 cm^{-1} (shoulder, 470), and each overlaps the neighboring band. The frequencies of the second and third bands are similar to those of the first and second bands of $[V^{IV}O(S\text{-peida})(H_2O)]$ and assigned to the d-d transitions, $d_{xy}\rightarrow(d_{xz},d_{yz})$ and $d_{xy}\rightarrow d_{x^2-y^2}$, respectively. The first band should be due to the intervalence transition. The high intensity of the second and third bands may result from partial mixing of the metal d orbitals with the p orbitals of the bridging O atom.

$V^{V}(O)_2$ Complex: The spectrum of $[V^{V}(O)_2(S\text{-peida})]^-$ has two strong bands at *ca.* 33300 (shoulder, ε=1070) and 37700 cm^{-1} (peak, 4640) in aqueous solution of pH 4.5. The former may be the charge transfer band from the pyridine ring to V^{V} and the latter is assigned to the π-π^* transition within the pyridine moiety by the same reason as for the V^{IV} complex. A weak shoulder is seen at *ca.* 25000 cm^{-1} (ε=17.8). The spectrum of $[V^{V}(O)_2(OH_2)_4]^+$ solution prepared by dissolving NH_4VO_3 in *ca.* 4.5 mol dm^{-3} $HClO_4$ has a weak shoulder at 24000 cm^{-1} (ε=7.15).[17] $Na_3[V^{V}(O)_2(edta)]$[18] also gives an absorption shoulder at 25000 cm^{-1} (ε=25.8). Since V^{V} has no d electron, the origin of these shoulders must be a transition involving the oxo or the aqua ligands, most probably a spin-forbidden (singlet to triplet) charge transfer band from oxo to V^{V}. The reasons are as follows: (i) Its low intensity denies the participation of spin allowed charge transfer. (ii) The oxo ligand has π-bonding p orbitals with higher energy than the σ-bonding orbital of oxo and aqua ligands.[14] Hence the charge transfer from the π orbital to the d orbital may possess the lowest energy among the charge transfers from ligand to V^{V}.

$V^{V}O(O)_2$ Complex: The $[V^{V}O(O)_2(S\text{-peida})]^-$ gives two peaks and a shoulder in aqueous solution at 23500 (ε=372), 33300 (shoulder, 500), and 38500 cm^{-1} (3720). Lever and Gray[19] discussed the origin of

electronic spectra of side-on peroxo complexes of some early transition metals and assigned their lowest energy bands to the transition from the highest occupied π antibonding orbital of O_2^{2-} to the metal d orbital. We tend to assign the band at 23500 cm^{-1} to the charge transfer from O_2^{2-} to V^V and those at 33300 and 38500 cm^{-1} to the charge transfer from the pyridine ring to V^V and the π-π^* transition within the pyridine ring, respectively. The possible spin forbidden transition from the oxo ligand to V^V around 25000 cm^{-1} may be hidden by the strong band at 23500 cm^{-1}.

Pattern of CD Spectra. V^{IV} Complex: The CD spectra of $[V^{IV}O(S\text{-peida})(H_2O)]$ and $[V_2^{IV,V}O_3(S\text{-peida})_2]^-$ in KBr disks (Fig. 4) have similar pattern in the region from 10000 to 25000 cm^{-1} to those in aqueous solution. The $V^{IV}O$ complex gives four peaks in the d-d region. The two at 11900 ($\Delta\varepsilon=-0.23$) and 14300 cm^{-1} (-0.33) must correspond to the absorption band at 13200 cm^{-1} [$d_{xy}\rightarrow(d_{xz},d_{yz})$]. This complex has a lower symmetry than C_{4v} and the degenerate levels of d_{xz} and d_{yz} split to give two CD peaks. The peaks at 18100 (-0.53) and 28200 cm^{-1} ($+3.4$) are naturally assigned to the $d_{xy}\rightarrow d_{x^2-y^2}$ (17700 cm^{-1}) and the $d_{xy}\rightarrow d_{z^2}$ band (28200 cm^{-1}), respectively. A positive and a negative peak are seen from lower wave number around 38000 cm^{-1}, corresponding to the π-π^* transition. A large positive peak is also seen at 44800 cm^{-1} (Table 2).

Mixed Valence Complex: The discussion is limited in the infrared and visible region (*vide supra*). This complex gives two CD peaks at 8620 ($\Delta\varepsilon=-1.1$) and 11100 cm^{-1} ($+1.6$) in the intervalence transfer region. The intensities are much larger than those of $V^{IV}O$ complex. It has two peaks at 14700 (-2.0) and 17500 cm^{-1} (-0.84) in the d-d region (13000—20000 cm^{-1}). The patterns in these regions are more or less similar to those of the $V^{IV}O$ complex.

$V^V(O)_2$ and $V^VO(O)_2$ Complexes: The two V^V complexes naturally fail to give CD in the lower wave number region than 19000 cm^{-1}. The $V^V(O)_2$ complex has two negative peaks and one positive peak in the region from 20000 to 34000 cm^{-1} (Table 2). They must correspond to the absorption shoulders at the respective wave numbers. Its large positive peak at 37500 cm^{-1} should correspond to the π-π^* transition of the pyridine moiety. The peroxo complex gives one broad negative peak and one negative shoulder in the 20000 to 34000 cm^{-1} region, corresponding to the broad absorption band at 23500 and a shoulder at 33300 cm^{-1}, respectively. In the π-π^* transition region there are two peaks at 36400 ($\Delta\varepsilon=-4.7$) and 41000 cm^{-1} ($+12.8$).

Source of CD Spectra. It is generally understood that the magnitude of contribution of various sources of asymmetry to the CD of a coordination compound with regular polyhedral structure decreases in the sequence; asymmetric configuration of chelate rings designated by Δ or Λ>asymmetric arrangement of ligating atoms≥vicinal effect including asymmetry on ligating atoms, asymmetry on remote atoms and asymmetric conformation of chelates. The importance of asymmetric deviation of ligating atoms from regular polyhedra has been lately discussed and the magnitude of contribution is sometimes comparable to that of asymmetric configuration of chelate rings.[1,20]

Since both the V^{IV} and the mixed valence complex give similar CD patterns in aqueous solution and in KBr disk, the asymmetric field influencing the CD spectra should not be very different in solution and in the solid state, at least for the transitions in the d-d and intervalence charge transfer region. Hence the relation between structure and CD can be discussed on the basis of X-ray crystal structure.

Table 2. Absorption and CD spectra

	Absorption[a]	CD in solution[b]	CD in KBr[b]
$[V^{IV}O(S\text{-peida})(H_2O)]$	13.2 (27.4)	11.9 (-0.23, -2.4) 14.3 (-0.33, -12)	11.6 (-0.17, -6.2) 14.2 (-0.27, -9.9)

a) $\nu/10^3$ cm^{-1} (ε/dm^3 mol^{-1} cm^{-1}). b) $\nu/10^3$ cm^{-1} ($\Delta\varepsilon$/dm^3 mol^{-1} cm^{-1}, $\Delta\varepsilon$ at peak/ε at absorption peak or shoulder ($\times10^3$)). c) $\Delta\varepsilon/\varepsilon$ at 44800 cm^{-1}.

The present *S*-peida complexes have no chilarity coming from the configuration of chelate rings, but the non-equivalent ligating atoms have asymmetric arrangement as shown in Fig. 5. The present V^{IV} complex has configuration (a) of Fig. 5.

There is no established way for expressing the asymmetric deviation, although proposals have been made by some authors.[1,20] The vanadium atom is slightly over the mean basal plane consisting of N(1), O(2), O(3), and O(5) in Fig. 1 (a) by 0.4 Å and the location of ligating atoms deviates largely from a regular octahedron. When one considers an imaginary basal plane which passes the V atom and is perpendicular to the V=O bond, the asymmetric deviation can be expressed by the torsion angles of the basal edges connecting the ligating atoms in cis positions toward the edges of the imaginary plane. These angles are listed in Table 3.

The vicinal effect, the asymmetric arrangement of ligating atoms, and the asymmetric deviation of ligating atoms from regular octahedron can be responsible for the CD. The vicinal effect can come from the asymmetric carbon and the δ-conformation of the five-membered chelate ring containing the asymmetric carbon. Such a vicinal contribution cannot be denied

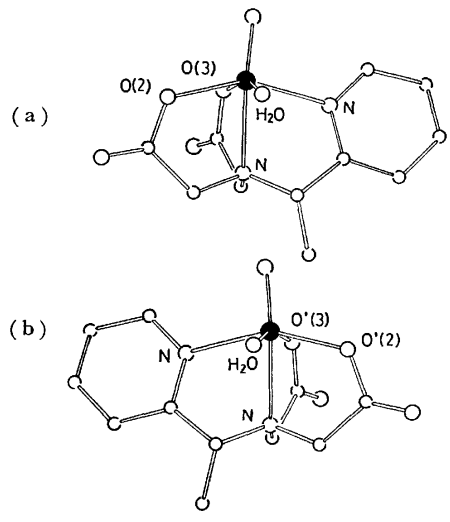

Fig. 5. Optical isomers of $[V^{IV}O(S\text{-peida})(H_2O)]$ due to asymmetric arrangement of ligating atoms.

a) See Ref. 10.

but does not seem predominating because of the following reasons: (i) The 5-membered chelate ring involving asymmetric carbon gives an envelope-like conformation with δ-chilarity and the torsion angle between N(1)–N(2) and C(5)–C(6) (Fig. 1 a) is rather small as compared with other puckered rings of various metal complexes in which significant vicinal contribution is seen in the d-d transition region (*e.g.* (*R*)- or (*S*)-1,2-propanediamine rings in Co^{III} complexes). (ii) The V^{IV} complex of (*S*)-alanine-*N*,*N*-diacetate has a similar skeletal structure to $[V^{IV}O(S\text{-peida})(H_2O)]$, and has a common asymmetrically distorted δ-conformation of the 5-membered chelate ring containing *S*-carbon atom. However, its CD strength is nearly one tenth of that of $[V^{IV}O(S\text{-peida})(H_2O)]$ in the d-d transition region, and the sign is reversed.[16] Hence we tend to consider that the vicinal contribution is not significant. The contribution of asymmetric arrangement and asymmetric deviation can be separated with difficulty, because the ligating atoms are connected by chelate rings. The main origin of CD strength may come from the asymmetric arrangement of the ligating atoms and asymmetric deviation from regular octahedron.

The CD strength of the mixed valence complex is much larger than that of the V^{IV} complex, particularly in the intervalence charge transfer region. This must be related to the large absorption intensity of the former. In the region from 15000 to 23000 cm^{-1}, both patterns are more or less similar, suggesting the function of a common origin. If very small angles less than 1° are ignored (Table 3), both the V^{IV} and the mixed valence complexes are reckoned to have qualitatively similar distorsion. This fact provides support to the above mentioned discussion in the d-d transition region.

The peaks and shoulders of the $V^{IV}O$, $V^{V}(O)_2$, and $V^{V}O(O_2)$ complexes over 30000 cm^{-1} give corresponding CD peaks or shoulders. All the absorption peaks and shoulders are considered to be related to the transitions from the pyridine ring (*i.e.* π-π^* transition or N(pyridine)-V^{IV} charge transfer). However, there does not seem to be simple relationship between the CD sign and the structure of the complexes including the asymmetric distorsion (Table 3). The asymmetry linked to such transitions may be related to the distortion of the N(py)-site from the regular octahedron, or to the orientation of the pyridine ring, both depending on the delicate skeletal structure of the complex. It is difficult to discuss the CD pattern in the UV region more precisely at the present stage.

The authors are grateful to Professor M. Hatano and Dr. T. Murakami of Tohoku University for the use of JASCO Model J-20 A and J-200 CD Spectropolarimeters for the measurement of the spectra in longer wavelength region than 700 nm.

The Phases Formed by the Dehydration of Disodium Zirconium(IV) Bis(orthophosphate) Trihydrate and Their Ion-exchange Behavior

Yasushi INOUE* and Yoshimune YAMADA

Department of Nuclear Engineering, Faculty of Engineering, Tohoku University, Aramaki-aza-Aoba, Sendai 980

(Received August 6, 1981)

The phase transformation of $Na_2Zr(PO_4)_2 \cdot 3H_2O$ which had been obtained from zirconium(IV) bis(hydrogenphosphate) monohydrate(α-zirconium phosphate), prepared by the direct precipitation method, was studied by means of gravimetry, X-ray analysis, and acid-base titration. When the material was heated for 2 d, it was transformed to a monohydrate at 80 °C and then successively to three anhydrous phases, depending on the temperature. The monohydrate was also formed by letting the trihydrate stand over P_2O_5 at room temperature for longer than two weeks. The processes were confirmed to be irreversible by an examination of the rehydration behavior, from which the conditions of the storage of five modifications of disodium zirconium(IV) bis(orthophosphate) were established. It is of special interest that the second anhydrous phase reverted to the first one when it was allowed to stand at room temperature in air or in a desiccator. The rate of the reversion decreased with the temperature of heat-treatment and with a decrease in the relative humidity of the surroundings. The difference between the present results and Clearfield's[1,2] was clarified and attributed mainly to the difference in the crystallinity of the starting α-zirconium phosphate.

During our study of the isotopic exchange rate of Na^+ ions between crystalline disodium zirconium(IV) bis(orthophosphate) trihydrate ($Zr(Na_2PO)_2 \cdot 3H_2O$) and aqueous solutions, it was difficult to obtain reproducible results. This irreproducibility is due to the difference in the crystal structure of the exchanger, which depends subtly on the conditions adopted in the preparation and in the storage of the material. The phases existing under various circumstances should, therefore, be clarified in order to obtain accurate rate data and to give a correct interpretation of the results.

There has been no literature referring to the subject except the studies of Clearfield *et al.*,[1,2] who first elucidated the structure and the dehydration behavior of $Na_2Zr(PO_4)_2 \cdot 3H_2O$, which had been prepared by replacing the H^+ ions in $Zr(HPO_4)_2 \cdot H_2O$ (zirconium(IV) bis(hydrogenphosphate) monohydrate, α-ZP) by Na^+ ions. They made it clear that one monohydrate and three anhydrous phases were irreversibly formed by thermal treatment. Their results will be helpful, but not directly applicable to our purpose, since the exchanger in sodium form prepared from α-ZP synthesized by the method recommended by the present authors will behave differently from that by Clearfield; in fact H^+/Na^+ titration and differential thermal analysis (DTA) studies have clearly shown the difference in crystallinity between these materials.[3]

The present report describes the studies made of the dehydration behavior of sodium-substituted α-ZP and the reversibility of the process by means of gravimetry, X-ray analysis, and pH titration; these studies were enabled us to find the most suitable conditions for the preparation and storage of various phases and to determine the phase changes brought about by immersing them in aqueous solutions.

Experimental

α-Zirconium phosphate was prepared by a procedure recommended previously.[3] Five and a half grams of $ZrOCl_2 \cdot 8H_2O$ were dissolved in distilled water in a polyethylene beaker. The desired amounts of hydrofluoric acid and of phosphoric acid were then vigorously stirred in successively to make the concentrations 0.715 mol dm^{-3} and 9 mol dm^{-3} respectively and to make total volume 130 cm^3. The solution was then kept at 60 °C in a thermostatted water bath for about 100 h. A white, flaky product was separated by filtration, washed with distilled water until the pH of the filtrate became 5, and stored over P_2O_5 for two weeks. The α-ZP thus prepared was then equilibrated with a mixture of 0.1 mol dm^{-3} NaCl and NaOH solutions at pH 12. After filtration, the exchanger was washed with distilled water until the effluent became free of chloride ions; it was then dried in a desiccator over a saturated NaCl solution (relative humidity, 75%) for two weeks. The material thus prepared was confirmed to be $Na_2Zr(PO_4)_2 \cdot 3H_2O$ (hereafter this material will be refereed to as Phase I).

The monohydrate and three anhydrous phases were obtained by the methods established in the present study, as will be described later; the monohydrate phase (Phase II) was obtained by drying Phase I over P_2O_5 for longer than three weeks, while the anhydrous phases (Phases III, IV, and V) were formed by heating Phase I at the desired temperatures (250 °C for Phase III, 700 °C for Phase IV and 820 °C for Phase V) for 2 d. These phases were then stored over P_2O_5.

The other experimental procedures were the same as had been described previously,[3] except for the analysis of sodium ions in the exchanger, which was carried out with a Jarrell-Ash atomic-absorption spectrophotometer, Model AA-782.

Results and Discussion

The material obtained by replacing H^+ by Na^+ in α-ZP in the aqueous solution with a pH of 12 was identified by means of chemical, X-ray, and thermal analyses. The composition was: Found: ZrO_2, 32.63; P_2O_5, 37.23; Na_2O, 16.20; H_2O, 14.57%, which corresponded to the formula of $Na_2Zr(PO_4)_2 \cdot 3H_2O$ (Phase I) and which was in good agreement with the data published by other authors.[2,4,5] The X-ray pattern indicated that this phase had an interlayer distance of 0.983 nm, which agreed well with the Phase D reported by Clearfield *et al.*[1,2] The thermogravi-

metric-analysis (TGA) and DTA curves of Phase I are shown in Fig. 1. The TGA curve reveals that this phase lost water in two steps; that is, it lost two molecules of water up to 100 °C, and then the last molecule of water before 250 °C. In the DTA curve, one large and one small endothermic peak appeared at 110 °C and 150 °C; they apparently corresponded to the release of two molecules of water and one molecule of water respectively, while no exothermic peak appeared.

The static method was then applied to the dehydration studies; Phase I was heated at various temperatures for two days, except as otherwise specified, followed by cooling to room temperature. When Phase I was heated to a constant weight at 80 °C, it lost two molecules of water to form a monohydrate, Phase II, which had an interlayer distance of 0.843 nm. This phase could alternatively be obtained in a pure form by letting Phase I stand over P_2O_5 for longer than two weeks. This can be verified from Fig. 2, which shows the dehydration behavior of Phase I in the P_2O_5 desiccator, and from the agreement of the X-ray pattern of the product with that of the monohydrate mentioned above. This phase will correspond to the Phase E which was prepared by Clearfield *et al.*[2] by heating Phase D at a temperature between 50—100 °C. However they reported that Phase E could not be obtained in pure form by dehydrating Phase D in a desiccator containing P_2O_5.

Over the range of 80—150 °C, an anhydrous phase, Phase III, with an interlayer distance of 0.839 nm, appeared in addition to Phase II. When the mixture was heated above 150 °C, Phase II disappeared, being completely transformed to Phase III, which began transforming to the second anhydrous phase, Phase IV, on further heating (above 300 °C). At 500 °C, Phase III was transformed completely to Phase IV, which had an interlayer distance of 0.763 nm. However, when Phase III was heated for longer than 10 d, it was transformed completely to Phase IV at a far lower temperature (170 °C). Only Phase IV was formed over the range of 500—800 °C. When it was heat-treated at a temperature above 800 °C, the third anhydrous phase, Phase V, which had an X-ray pattern appreciably different from those of the other phases mentioned above, was formed. This phase could not be formed by heating Phase I below 800 °C, no matter how long the heating period was. Figure 3 schematically illustrates the thermal transformation of Phase I.

It must be noted that an interesting phenomenon was observed concerning Phase IV. When being allowed to stand after cooling, Phase IV were transformed to Phase III. To make clear the factors affecting this behavior, the rate of transformation during storage was measured on samples subjected to heat-treatment under different conditions, as is shown in Figs. 4 and 5. The ordinate of these figures shows R, which is defined as $(I_{III}/I_{III+IV}) \times 100$, where I represents the intensity of the diffraction line from the (002) plane which gives the strongest peak in

d: Interlayer distance/nm.

the designated phase. R is considered to be roughly equal to the abundance ratio of Phase III, since the density of the zirconium atom on the plane responsible for the reflection will not be appreciably changed by this phase transformation.

Figure 4 indicates that the rate of transformation was slower with the samples heat-treated at higher temperatures, but was independent of the length of heating. The relative humidity of the atmosphere strongly affected the rate of the transformation, as is shown in Fig. 5. A decrease in the humidity suppressed the transformation. From these facts, we can conclude that Phase IV can be stored in a desiccator over P_2O_5 without suffering from phase transition for at least two weeks. Phases III and IV respectively will correspond to Phases F and G reported by Clearfield *et al.*, but Phase G is more stable than Phase IV; Phase G, obtained by heating Phase F at a temperature higher than 200 °C, did not revert to Phase F at all.[2)]

In order to examine the reversibility of the dehydration process, the X-ray patterns and the weight recoveries were measured on samples obtained by heat-treatment when they were humidified to a constant weight in a desiccator containing a saturated NaCl solution. Their X-ray patterns were also measured after they had been immersed in 0.1 mol dm^{-3} NaCl, 0.1 mol dm^{-3} NaOH, and H_2O for periods ranging from one day to two weeks. The results are summarized in the 4th through the 8th columns of Table 1. Phase II was gradually rehydrated and partially reverted to Phase I, the degree increasing with the lapse of time. Phase III, though it showed recovered water of 1.48 mole per unit of formula weight during humidifying, did not change its crystal form even when it was immersed in the aqueous solution. As to Phase IV, it completely reverted to Phase III in spite of the fact that it absorbed as much water as the same amount of Phase III. When Phase V was allowed to stand in the aqueous solutions for 10 d, it was transformed to a new phase, the crystal structure of which has not yet been identified.

The titration curves of these phases were constructed in order to ascertain the effect of heat-treatment on their ion-exchange properties, as is shown in Fig. 6. For the convenience of comparison, the abscissas of the figure are represented by percentages converted to hydrogen form. In addition, the samples were separated from the solutions at different stages of exchange, and their X-ray powder patterns were taken while they were wet. The curves for Phases I through IV were similar to each other; they all exhibited two plateaus, each of them corresponding to the replacement of each mole of the Na^+ ion with the H^+ ion. However, a comparison of the X-ray patterns of these four phases at various stages of ex-

TABLE 1. PREPARATION AND STORAGE OF THE VARIOUS PHASES OF DISODIUM ZIRCONIUM BIS(ORTHOPHOSPHATE)

change indicated that the replacement of Na^+ ions with H^+ ions proceeded through different paths, as is shown in Fig. 7. At the initial point of titration with acid, the exchangers transformed their crystal structures into low-temperature forms according to the observation mentioned above. In the range of 0—50% H^+ ion-uptake, however, the progressive exchange led to the formation of a monosodium phase of composition, $Zr(HPO_4)(NaPO_4) \cdot 5H_2O$, which was present exclusively at the half-exchange point of the titration, irrespective of the starting materials. Beyond this point, the exchangers in dihydrogen form, which resulted from the replacement of the second Na^+ ions with H^+ ions, consisted of a mixture of $Zr(HPO_4)_2 \cdot H_2O$ and $Zr(HPO_4)_2 \cdot 8H_2O$. The relative amount of the highly hydrated phase ($Zr(HPO_4)_2 \cdot 8H_2O$) differed with the difference in the phase of the starting materials; that is, at the end point of titration, the hydrogen form obtained from Phase II contained 64% $Zr(HPO_4)_2 \cdot 8H_2O$, while the hydrogen form obtained from samples heat-treated at 250 °C (Phase III) and 700 °C (Phase IV) contained 72% and more than 95% of the octahydrate respectively. In contrast, the samples without heat-treatment yielded no highly hydrated phase; *i.e.*, they returned to the original α-ZP. This highly hydrated phase could be converted to $Zr(HPO_4)_2 \cdot H_2O$ by drying over P_2O_5, as had been reported by Clearfield *et al.*[1] The hysteresis (dependence of the curves on the direction of titration) observed in the titration curves of the Phases from II through IV is ascribable to the appearance of $Zr(HPO_4)_2 \cdot 8H_2O$ when these phases are converted to the dihydrogen form. In this connection, it is worthwhile to cite the study of Alberti *et al.*,[6-8] who have described the dependence of the titration curves on the method of synthesizing α-ZP. They made it clear that the degree of crystallinity affected the reversibility of ion exchange and the resolution between two ion-exchange steps in the curves; the reversibility and the resolution became better with an improvement in the degree of crystallinity. Based on this view, it is considered, from the above findings, that the α-ZP prepared by the method recommended by the present authors possesses a very high degree of crystallinity, while a rise in the temperature of the thermal treatment of the sodium-substituted phase reduces the degree of crystallinity of the exchanger.

On the other hand, the Na^+/H^+ titration curve for Phase V exhibited a three-stage ion-exchange, unlike the titrations for the other phases described above. The complete substitution of Na^+ ions for H^+ ions led to the formation of the dihydrogen phase, which has an interlayer distance of 1.047 nm. When this phase was dried in a P_2O_5 desiccator, it was converted to a phase having an interlayer distance of 0.763 nm and the formula of $Zr(HPO_4)_2 \cdot 0.68H_2O$. Furthermore, this phase showed DTA and TGA curves different from those of α-ZP in that the former showed a two-step dehydration up to 150 °C, while the latter showed a one-step dehydration, as is shown in Fig. 1. Therefore, this phase is considered to have a crystal structure different from α-ZP and to be similar to the ι-phase reported by Clearfield *et al.*[9] Figure 8 indicates that the H^+/Na^+ titration curve of this phase was different from that of ι-ZP; the former had three plateaus at pH 2.3, 4.5, and

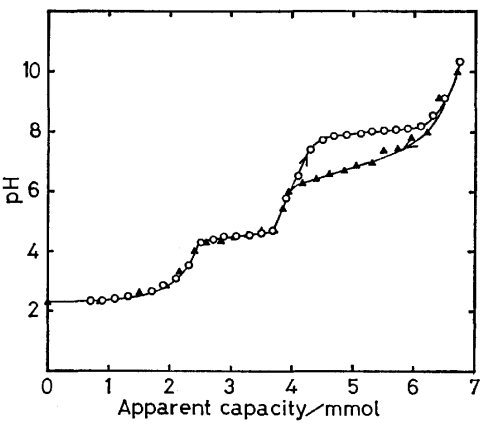

Fig. 8. Titration curves of ZP in H^+ form regenerated from Phase V.
○: Forward titration, 0.1 mol dm^{-3} (NaCl+NaOH),
▲: backward titration, 0.1 mol dm^{-3} (HCl+NaCl).

8.0, whereas the latter exhibited no plateau. Furthermore, the titration curve of $Zr(HPO_4)_2 \cdot 0.68H_2O$ showed hysteresis in the high-pH region. This irreversibility is due to the difference in phases participating in the titration.

There are many other disagreements between the present results and Clearfield's in addition to those explicitly described in this report. They are considered to be attributable mainly to the difference in the crystallinity of the starting α-ZP, as was pointed out in the preceeding paper,[3] although the difference in the details of the experimental conditions may be partly responsible.

In conclusion, the 3rd and the last columns of Table 1 summarize the recommended method for the preparation of, and the conditions for the storage of, five modifications of disodium substituted zirconium phosphate.

A Ruthenium(IV)-Ruthenium(III) Dimer, Product of the Reaction of Aqua(ethylenediaminetetraacetato)ruthenium(III) with Chlorate Ions

Masato IKEDA,† Kunio SHIMIZU,* and Gen P. SATÔ

Department of Chemistry, Faculty of Science and Technology, Sophia University, 7-1, Kioi-cho, Chiyoda-ku, Tokyo 102

(Received August 7, 1981)

An oxo-bridged, mixed-valence complex of ruthenium(IV,III), $[(edta)Ru^{IV}ORu^{III}(edta)]^{3-}$, has been obtained from the oxidation of $[Ru^{III}(edta)(H_2O)]^-$ by chlorate ions. The formulation of the complex as a μ-oxo dimer of ruthenium(IV,III) is based on the results of a variety of experiments, including elemental analyses, magnetism, by spectrophotometry, and by electrochemical studies. These studies in acetate buffer solution show that the dimeric ion can be reduced at mercury electrode to $[(edta)Ru^{III}ORu^{III}(edta)]^{4-}$ and then is monomerized to the original $[Ru(edta)(H_2O)]^-$ in a fast reaction.

In the course of the studies of the chemical and electrochemical redox reactions of ruthenium(II)- and (III)-EDTA, it was found that the $[Ru(edta)(H_2O)]^-$ in an acetate buffer solution gave an intense green color on the addition of oxidizing agent such as sodium chlorate or hydrogen peroxide. Examination revealed that the coloration was due to the formation of a mixed-valence μ-oxo ruthenium(IV,III) dimeric complex.

Green or bluish green solutions of ruthenium complexes have become of much interest in recent years. Meyer *et al.*[1,2] have isolated several blue-green complexes of ruthenium, and identified them as μ-oxo dimers of ruthenium(III,III) or (IV,III). As early as 1966, Ezerskaya *et al.*[3,4] obtained a green complex from the reaction between Ru(III)-EDTA and hydrogen peroxide; this seems to be the same as the complex we obtained. They claimed that the complex might be μ-oxo and μ-peroxo double bridged dimer, however, no supporting evidence was presented.

Recently Uehiro *et al.*[5,6] also obtained the green complex from oxidation of Ru(III)-EDTA by Mn(III)-EDTA or platinum electrode, or from irradiation of light.

This paper reports the isolation of mixed-valence ruthenium(IV,III) dimer and the identification and electrochemical properties of the complex.

Experimental

Reagents. Aqua(hydrogenethylenediaminetetraacetato)-ruthenium(III) 4-water, $[Ru(Hedta)(H_2O)]\cdot 4H_2O$, was prepared according to the procedure described previously,[7] and characterized by elemental analysis, alkalimetric titration,[8] and UV-visible, and IR spectra.

Sodium chlorate was recrystallized from water and then dried under a vacuum. The assay was made by alkalimetric titration of the cation-exchanged solution of one-gram samples.

Deionized water distilled in an all-glass apparatus was used throughout the experiment. Nitrogen gas for deoxygenation was purified by passing it through an acid vanadium(II) sulfate solution and then water. The other chemicals were of guaranteed reagent grade and used without further purification.

Apparatus. UV-visible and IR spectra were measured with a Hitachi 624 Digital Spectrophotometer and a Hitachi EPI-G2 IR spectrophotometer.

Polarographic measurement, controlled potential coulometry, and cyclic voltammetry were carried out as described earlier.[9] The flow rate of the dropping mercury electrode (DME) was 1.77 mg s^{-1} under a mercury head of 50 cm. The drop time of the DME was mechanically controlled and the instantaneous currents at 3.50 s after the dislodgement were sampled by means of a dislodger-cutoff device.[10] All the potentials cited here are referred to the saturated calomel electrode (SCE). A Radiometer pH meter 25E was used for pH determination. All the electrochemical measurement was carried out at (25±0.1) °C under a nitrogen atmosphere.

Magnetic properties were measured by the Gouy method. The apparatus was calibrated with $Hg[Co(NCS)_4]$. The observed magnetic susceptibility was corrected for diamagnetism by means of Pascal's constants. The magneton number, magnetic moment $\boldsymbol{m}$ divided by Bohr magneton $\boldsymbol{m}_B$, was calculated by using the following expression:††

$$\boldsymbol{m}/\boldsymbol{m}_B = 798(T/\mathrm{K})^{1/2}(\chi V_m/\mathrm{m^3\ mol^{-1}})^{1/2},$$

where T is the thermodynamic temperature, χ is the corrected magnetic susceptibility, and V_m is the molar volume.

Isolation and Analysis of the Binuclear Complex. One-tenth gram of $[Ru(Hedta)(H_2O)]\cdot 4H_2O$ was dissolved in 50 cm^3 of sodium acetate–acetic acid solution (0.2 mol dm^{-3} each). A 20 cm^3 portion of 0.01 mol dm^{-3} $NaClO_3$ was added dropwise to the mixture. The color of the solution turned from pale yellow to deep green. The green solution was allowed to stand overnight in the dark. After the solution was concentrated to about one-fifth the initial volume by evaporation under a reduced pressure at 30 °C, its pH was adjusted to *ca.* 1 with hydrochloric acid. Ethanol was added to the resulting solution on cooling until fine, green crystals precipitated, which were collected by filtration. The crystals were washed several times with small volumes of ethanol, and then dried *in vacuo* at room temperature (yield 40 mg).

The ruthenium content of the green complex was determined spectrophotometrically according to the ruthenate method.[11] The amount of cation in the product was determined by the cation-exchange method. The elemental analysis of C, H, and N was carried out by means of a Yanagimoto MY2 CHN Corder.

†† This expression is based on SI. What is often called inappropriately "molar susceptibility" corresponds to $\chi V_m/4\pi$.

Results and Discussion

D. c. Polarography and Stoichiometry of the Reaction between Aqua-edta-Ru(III) and ClO_3^-. A typical polarogram of the aqua-edta-Ru(III) complex, which shall be abbreviated as Ru(III)L,[†††] is shown in Fig. 1a. The step corresponds to the diffusion-controlled, Nernstian reduction of Ru(III)L to Ru(II)L.[12] When a small amount of sodium chlorate was added to the solution, the pale yellow solution turned green. At the same time, a new step (step A in Fig. 1b) began to appear at a more positive potential, while the original step remained essentially unchanged (step B in Fig. 1b). The limiting current of step A was diffusion-controlled unless a large excess (more than ten times) of chlorate ions was present, and the log-plot analysis indicated that step B was Nernstian (the reciprocal slope was −58 mV). The height of step A gradually increased with respect to time and finally reached a constant value after a few hours. The final step height depended on the amount of the chlorate ions added.

Amperometric and spectrophotometric titrations were carried out: acetate buffer solutions containing known amounts of Ru(III)L and sodium chlorate at various ratios were prepared and left to stand overnight. The polarograms and the UV-visible spectra were then recorded. As shown by the examples in Fig. 2, there was a clear end-point at $n(ClO_3^-)/n(\text{Ru(III)-L}) = 0.083$ or 1/12, where n is the amount of the specified substance. Beyond the end-point, the height of step A of the polarogram remained constant till a large excess of chlorate ions was added; the ratio of the heights of step A and step B was very close to 1:2.

These results are readily explained by assuming that a chlorate ion undergoes a six-electron reduction as in the case of the reaction with vanadium(II) ions,[13] oxidizing six Ru(III)L entities to the Ru(IV) state, and each Ru(IV) species combines with another Ru-

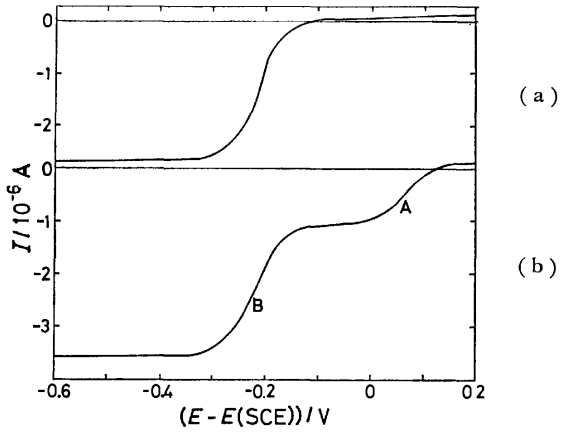

Fig. 1. D. c. polarograms of 1.0 mol m^{-3} [Ru(edta)-(H_2O)]$^-$ in 0.2 mol dm^{-3} sodium acetate-acetic acid buffer (pH=4.7) at 25 °C before (a) and after the addition of 0.1 mol m^{-3} $NaClO_3$ (b).

††† In the pH region under study, this complex actually exists mainly as [Ru(edta)(H_2O)]$^-$ (pK_a=2.65).[7]

(III)L to form a green mixed-valence dimeric species:

$$12\text{Ru(III)L} + ClO_3^- \longrightarrow 6\text{Ru(IV)-Ru(III)} + Cl^- + \cdots . \quad (1)$$

Here Ru(IV)–Ru(III) represents the green dimeric species; its chemical formula will be discussed later.

If the one-electron, Nernstian step A is the reduction of Ru(IV)–Ru(III), its immediate product should be an Ru(III)–Ru(III) dimer. But the fact that the half-wave potential of step B is the same as that of Ru(III)L indicates that the Ru(III)–Ru(III) dimer is unstable, so that it dissociates rapidly to give two Ru(III)L entities. In fact, a reversible reoxidation peak was observed on the cyclic voltammogram only at a high scan rate. The first-order rate constant of the dissociation reaction was about 1 s^{-1} at pH=4.7 at 25 °C; the details of the kinetics will be reported separately.

The Ru(III)L species thus produced would be reoxidized to Ru(IV)–Ru(III) in the presence of chlorate ions. However, this reaction is too slow to produce an appreciable polarographic catalytic current unless a large excess of chlorate ions is present. Controlled potential coulometry revealed that this reaction did occur. It also corroborated the above stoichiometry.

Coulometry. A green solution containing a known small excess of chlorate ions was electrolyzed with a mercury pool electrode at a potential of the first plateau (−0.1 V) and the polarograms were recorded intermittently by suspending the electrolysis and letting the solution stand for a while. The polarogram remained almost unchanged until a certain quantity of electricity, Q_1, was consumed. The magnitude of the diffusion current of step A, $I_{d,A}$, began to diminish in proportion to the advancement of elec-

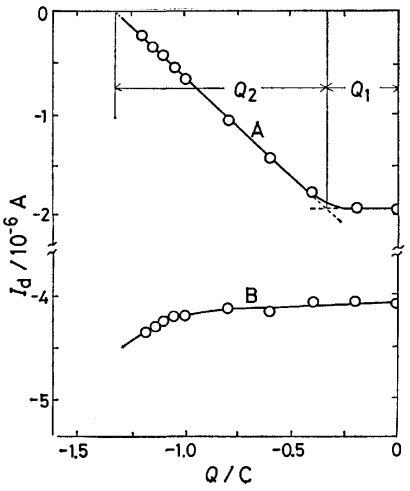

Fig. 3. Coulometric curves of 1.0 mol m^{-3} [Ru(Hedta)(H_2O)]·4H_2O+0.110 mol m^{-3} $NaClO_3$ in 0.2 mol dm^{-3} sodium acetate-acetic acid buffer at 25 °C. Reduction potential=−0.1 V. A, diffusion current at −0.1 V. B, diffusion current at −0.4 V. The current and quantity of electricity for reduction are considered to be negative.

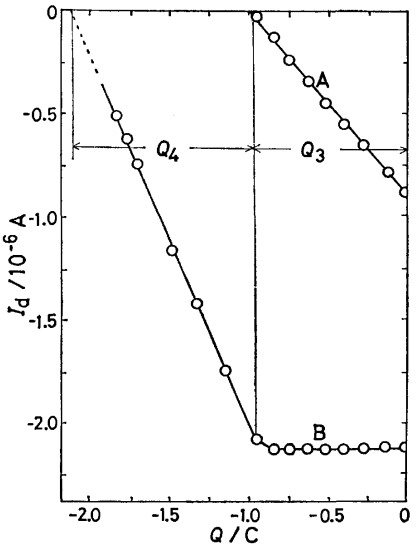

Fig. 4. Coulometric curves of 1.0 mol m^{-3} [Ru(Hedta)(H_2O)]·4H_2O+0.104 mol m^{-3} $NaClO_3$ in 0.2 mol dm^{-3} sodium acetate-acetic acid buffer at 25 °C. Reduction potential=−0.4 V. A, diffusion current at −0.1 V. B, diffusion current at −0.4 V. The current and quantity of electricity for reduction are considered to be negative.

trolysis, whereas the diffusion current of step B, $I_{d,B}$ (total step height less $I_{d,A}$), remained fairly constant (Fig. 3). Another quantity of electricity, Q_2, was consumed before the completion of the electrolysis; the polarogram and UV-visible spectrum of the solution were then the same as those of Ru(III)L. During the first stage of the electrolysis, Ru(III)L produced by the reduction of the mixed valence dimer was reoxidized by the chlorate ions, so that Q_1 was equal to the quantity of electricity that was required for the six-electron reduction of the excess chlorate ions. The roundness of $I_{d,A}$-Q curve reflects the slowness of the reoxidation process. When no more chlorate ions were present, the process was simply the reduction of the mixed-valence dimer, as was indicated by the fact that Q_2 was equal to the quantity of electricity corresponding to the one-electron reduction of half the amount of Ru(III)L originally contained in the solution.

The electrolysis at a potential of the second plateau (−0.4 V) showed that Ru(IV)–Ru(III) reacted with Ru(II)L. In this case, $|I_{d,A}|$ decreased linearly from the beginning until a quantity of electricity, Q_3, was consumed, when step A disappeared (Fig. 4). During this stage, $I_{d,B}$ remained constant and no oxidation step was observed. On further electrolysis, $|I_{d,B}|$ began to decrease and the oxidation step of Ru(II)L began to grow, both in proportion to the advancement of electrolysis. For the completion of the electrolysis another quantity of electricity, Q_4, was consumed. The quantity of electricity Q_3 was equal to that required for the six-electron reduction of all the chlorate ions added to the solution and Q_4 to that required for the one-electron reduction of Ru(III)L which was originally contained in the solution. At this potential the mixed-valence dimer undergoes a three-electron reduction to Ru(II)L, which reacts both with the excess chlorate ions and with the dimer to regenerate Ru(III)L during the first stage:

$$\text{Ru(IV)-Ru(III)} + 3e^- \longrightarrow 2\text{Ru(II)L}, \quad (2)$$

$$6\text{Ru(II)L} + ClO_3^- \longrightarrow 6\text{Ru(III)L} + Cl^-, \quad (3)$$

$$\text{Ru(II)L} + \text{Ru(IV)-Ru(III)} \longrightarrow 3\text{Ru(III)L}. \quad (4)$$

When no more Ru(IV)–Ru(III) and chlorate ions are present, the reduction is simply that of Ru(III)L to Ru(II)L (the second stage).

The coulometric data are summarized in Table 1; the last two columns are the results for the isolated dimer, which will be discussed later. These data reconfirm the above-mentioned stoichiometry of the reaction between Ru(III)L and ClO_3^-.

Characterization of the Green Complex. The isolated green complex is readily soluble in water. The titration curve of the solution with a standard sodium hydroxide solution showed a single pH jump corresponding to the dissociation of carboxylic protons; there was no second pH jump characteristic of the dissociation of the proton of aqua ligand, as observed in the case of Ru(III)L.[12] The amount of the dissociable protons was 1.0 mol per 1 mol of ruthenium. The solution of the complex was passed through a column of an H-form cation-exchange resin, and the eluate was titrated with a standard alkali solution. The results indicated that 1.5 mol of hydrogen ions per 1 mol of ruthenium was present in the eluate, *i.e.* the complex contained 0.5 mol of cations (sodium ions) per 1 mol of ruthenium. These results, together with those of the elemental analysis, are in fair agreement with the values calculated for Na[(Hedta)-RuORu(Hedta)]·10H_2O (molar mass 999.7 g mol^{-1}).

Found: Ru, 20.24; C, 23.94; H, 3.87; N, 5.72; Na, 2.31; rest, 43.98%. Calcd for Ru, 20.22; C, 24.03; H, 4.64; N, 5.60; Na, 2.30; O, 43.21%. The above results show that the overall reaction between Ru(III)L and chlorate ion can be written as follows:

$$12[\text{Ru(edta)}(H_2O)]^- + ClO_3^- \longrightarrow 6[(\text{edta})\text{RuORu(edta)}]^{3-} + Cl^- + 6H^+ + 9H_2O. \quad (5)$$

The IR spectrum (KBr disk) was almost the same as that of Ru(III)L. The absorption bands of coordinated carboxyl groups (1630 cm^{-1}) and of protonated carboxyl groups (1725 cm^{-1}) was observed. According to Hewkin and Griffith,[14] Wing and Callahan,[15] and Filippo *et al.*,[16] for a linear Ru–O–Ru species, a weak, infrared-active asymmetric stretching band should appear in the range of 800 cm^{-1}—900 cm^{-1} (for a non-linear Ru–O–Ru system, at a lower frequency). Attempts to identify this band failed because many small bands covered this region.

The UV-visible spectrum of the green complex was the same as that of the Ru(III)L–ClO_3^- reaction mixture and showed two absorption bands (Table 2). According to Meyer *et al.*[1] an intense, low energy band at about 650 nm is characteristic of the oxo-bridged Ru(III) dimers and this band is considerably blue-shifted for the one-electron oxidized species, *i.e.* the corresponding Ru(IV)–O–Ru(III) dimers.†††† It is most likely that the intense band at 392 nm indicates the presence of the Ru(IV)–O–Ru(III) system in the green complex.

The polarogram of the isolated green complex was the same as that presented in Fig. 1b, except that the height of the second step was a little larger than twice the first step height and varied from sample to sample. The isolated green complex is not very stable and decomposes in the presence of the air and/or light.

The coulometric curves of the reduction at −0.5 V were similar to those in Fig. 4. But in this case the quantity of electricity consumed during the first stage, Q'_3, should be equal to that required for the one-electron reduction of the dimer to Ru(III)L, since no excess chlorate ions were present and reaction(3) was not involved. The quantity of electricity consumed during the second stage, Q'_4, should be that required for the reduction of Ru(III)L to Ru(II)L. Consequently the ratio Q'_3/Q'_4 must be 1/2, as was the case (Table 1).

The molar mass calculated from the coulometric data was 996 g mol^{-1}, while that calculated from the pH titration data was 996.4 g mol^{-1}. These were in good agreement with the calculated value (999.7 g mol^{-1}) for the monosodium decahydrate. However, the thermogravimetric data and coulometric data on other samples, which are not cited in Table 1, indicated that the number of the waters of crystallization might be variable (probably from 8 to 10) according to the condition of crystallization and storage.

The green complex was paramagnetic, and the value of χV_m, corrected for diamagnetism, was 2.34×10^{-8} m^3 mol^{-1} at 23 °C. The magneton number, $m/\underline{m}_B$, was 2.10. This value will be compatible with the existence of one unpaired electron. Dunitz and Orgel[17] have reported that $[Cl_5RuORuCl_5]^{4-}$, a linearly oxo-bridged Ru(IV) dimer, was diamagnetic. In their extensive study of Ru(III)–O–Ru(III) systems Meyer *et al.*[1] explained the magnetic data in terms of the delocalization through the bridging oxide ion and pointed out that the relative stability of [(bpy)$_2$ClRuORuCl(bpy)$_2$]$^{3+}$ is reasonable because the electron lost comes from a π^* level. In the present case too, the observed magneton number can be attributed to the presence of one unpaired electron in the lowest π^* MO delocalized over both ruthenium centers.

Ezerskaya and Solovykin[3,4] reported that a dimer was formed by the oxidation of K[RuCl(Hedta)] with hydrogen peroxide or oxygen. The spectral and polarographic data[4] suggest that their complex was the

†††† "Ru(IV)–O–Ru(III)" is only a formal representaion; the two ruthenium centers are equivalent.[1]

same as or very similar to the present green complex. These authors described the compound as a μ-oxo and μ-peroxo double bridged dimer. But their arguments do not seem to be very convincing. Although no direct evidence is available for the oxo single bridge in the present case, μ-peroxo structure is less plausible than μ-oxo structure in explaining the stoichiometry, electrochemical behavior, and the results of pH titration.

Yoshino *et al.*[5] reported a green substance obtained by oxidizing Ru(III)L either anodically at a platinum electrode, chemically with several oxidizing agents, or photochemically in the presence of oxygen. The substance was later characterized by Uehiro[6] to be the acid form of the present complex: H[(Hedta)RuORu-(Hedta)]·6.5H_2O. His spectral and magnetic data are essentially the same as ours.

Oxidation of Ru(III)L at a Platinum Electrode and with Hydrogen Peroxide. The cyclic voltammogram of Ru(III)L in the acetate buffer with a platinum wire electrode over a range of −0.4 V to +0.5 V showed coupled oxidation and reduction peaks corresponding to Ru(III)L+e^-=Ru(II)L. When the anodic sweep was extended, a shoulder rose on the anodic current at +0.7 V and a new reduction peak at +0.25 V appeared; this reduction peak was attributable to the reduction of the Ru(IV)–O–Ru(III) dimer, since the same peak was observed on the cyclic voltammogram of the green solution prepared by the oxidation of Ru(III)L with chlorate ions. These results confirm the observation of Yoshino *et al.* that the green dimer could be obtained by anodic oxidation of Ru(III)L with platinum electrode. The reduction potential of the dimer at platinum electrode was much more positive than the half-wave potential of the polarographic step A, probably owing to faster decomposition of the Ru(III)–Ru(III) dimer on the platinum surface than on mercury.

The oxidation of Ru(III)L with hydrogen peroxide was reexamined. The UV-visible spectrum and the polarogram of the oxidized solution was the same as those of the solution obtained by the oxidation with chlorate ions. The stoichiometry, however, was complicated. If hydrogen peroxide acted as a two-electron oxidizing agent, $n(H_2O_2)/n(\mathrm{Ru(III)L})$ should be 0.25, whereas the experimental ratio determined from the end-points of the amperometric and spectrophotometric titrations was 0.3. Very likely, partial decomposition of hydrogen peroxide took place owing to the catalytic action of the dimer.[3] No further study was made on this reaction.

Preliminary Study on the Kinetics of the Oxidation of Ru(III)L with Chlorate Ions. The kinetics was examined by measuring the increase of the absorbance at 630 nm and by measuring the growth of the polarographic diffusion current of step A in a weakly acid solution.

If the rate of increase of the concentration of the dimer is proportional to the concentrations of both Ru(III)L and chlorate ions, *i.e.*,

$$dx/dt = k(a-2x)(b-x/6),$$

then

$$[6/(12b-a)] \ln [a(b-x/6)/b(a-2x)] = kt, \quad (6)$$

where x is the concentration of the dimer at time t, and a and b are the initial concentrations of Ru(III)L and chlorate ions, respectively. The value of x was determined either spectrophotometrically or polarographically. In both cases, the experimental plots of the left-hand side of Eq. 6 against time were quite linear up to about 80% of the completion of the reaction. The values of k thus obtained were fairly constant. The average value of the second-order rate constant was 5.3_2 mol^{-1} dm^3 s^{-1} at 25 °C in 0.2 mol dm^{-3} acetate buffer of pH 4.7.

It is rather surprising that this complicated reaction followed a simple second-order rate equation. Uehiro[6] in his study of the oxidation of Ru(III)L with $[Mn(edta)(H_2O)]^-$ observed that the rate equation was compatible with a mechanism that involved the dimerization of Ru(III)L followed by the electron transfer. Since the range of the initial concentration of Ru(III)L was quite limited (1 to 2 mol m^{-3}) in the present study, the above result is not conclusive.

The authors thank Dr. F. S. Howell of the Department of Chemistry of Sophia University for correcting the manuscript. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 547045 from the Ministry of Education, Science and Culture.

Cation Exchange Separation of Metal Ions Using HF–H_3BO_3 Media

Takeo Adachi

Analytical Chemistry Laboratory, Japan Atomic Energy Research Institute, Tokai, Ibaraki 319-11

(Received August 14, 1981)

Using hydrofluoric–boric acid media, a new cation exchange method for the mutual separation of metals which form stable fluoride complexes has been developed. The addition of boric acid to a hydrofluoric acid solution reduces the free fluoride ion concentration to about one hundredth because of the formation of fluoroboric acid. This reduction of the free fluoride ion concentration makes it easy to control the formation of metal fluoride complexes, favoring their separation. As the fluoroboric acid has a buffer action relating to the fluoride ion concentration, the distribution coefficients of metal ions are not affected by the increase in the concentrations of metal ions, even at a low concentration of fluoride ions in the solution. By the use of hydrofluoric–boric acid media, such metals as zirconium, titanium, aluminium, and uranium can be separated from each other. The distribution coefficients of eighteen metals were investigated both in hydrofluoric acid and hydrofluoric–boric acid solutions.

Although the ion exchange method in hydrofluoric acid solutions has been widely used for the separation of metals, most of the works have used anion exchange resin in mixed media of hydrofluoric and hydrochloric[1–4] or nitric[5,6] acids. In the absence of hydrochloric or nitric acid, separation can be done to only two groups,[7–9] that is, metals which form stable fluoride complexes and others. The presence of Cl^- or NO_3^- is believed to be effective in differentiating the adsorbabilities of metal fluoride complexes to the anion exchange resin.[6,10] In more than 0.1 M (1 M=1 mol dm^{-3}) of hydrofluoric acid, metals which form stable fluoride complexes, namely hard acid-metals,[11] form highly fluorinated complexes, such as ZrF_6^{2-}, TiF_6^{2-}, and AlF_6^{3-}, and the difference in the adsorbabilities of these complexes either on cation or anion exchange resin is not large enough to separate them from one another.

If the concentration of hydrofluoric acid can be controlled to a certain value far less than 0.1 M, at which such lower fluorinated complexes as ZrF_5^-, TiF_3^+, and AlF^{2+} are formed, the mutual separation of metals based on the difference in the charges of the fluoride complexes may be expected. However, it is not easy to control hydrofluoric acid to a constant concentration of less than 0.1 M in practical operations including the dissolution of the sample in hydrofluoric acid.

By adding boric acid, which is widely used as a masking agent for fluoride ions, the present author has now succeeded in controlling the fluoride ion concentration without reducing the total hydrofluoric acid concentration (C_{HF}). Boric and fluoroboric acids themselves do not form stable complexes with metal ions in acidic solutions, and fluoroboric acid can easily be removed from the solution by evaporation. Hydrofluoric–boric acid media have the practical advantage that the concentration of the free fluoride ion is almost unchanged with the amount of metal ions which consume fluoride ions.

In the present work, cation exchange adsorption data for metal ions in hydrofluoric–boric acid media are investigated in comparison with the data in hydrofluoric acid, and a new mutual-separation method for hard acid-metals is developed using hydrofluoric–boric acid media.

Experimental

Chemicals and Apparatus. Standard solutions of metal ions (0.01 M) were prepared by dissolving the materials described below in 13 M HF with and without the addition of a small amount of nitric acid or hydrochloric acid: V(IV) from $VOSO_4 \cdot 3H_2O$, V(V) from NH_4VO_3, W(VI) from $Na_2WO_4 \cdot 2H_2O$, Mo(VI) from $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$, Nb(V) from Nb_2O_5, and others from metals. After dissolution, the concentration of the residual hydrofluoric acid in each solution was adjusted to about 0.2 M.

A Shimadzu UV-210 spectrophotometer and a Nippon Jarrell-Ash AA-855 atomic absorption spectrophotometer were used for the determination of the metals.

Ion Exchange Resin. A sulfonated, polystyrene-type, strongly acidic cation exchange resin, Diaion SK #1, a product of Mitsubishi Chemical Ind., Ltd. (8% DVB, 75 to 150 μm, H^+-form), was used. After the resin had been washed in a column with sufficient volume of 4 M hydrochloric acid and with distilled water until the effluent was free from chloride, it was dried to a constant weight at 105 °C and stored in a vacuum desiccator.

Determination of Distribution Coefficient. A sample solution containing 2×10^{-4} M of a metal ion and a definite concentration of hydrofluoric acid or hydrofluoric–boric acid was prepared. Fifty ml of the solution was added onto 0.500 g of the dried resin in a 150-ml polyethylene bottle, and the bottle was shaken gently for 24 h at room temperature (the equilibrium was attained within 4 h). After the filtration of the resin, the metal ion concentration in the solution was determined by means of a suitable method (*cf.* Table 1).

The distribution coefficient, K_d, was determined by means of the following equation:

$$K_d = (\text{Amount of metal ion in resin/Amount of metal ion in solution}) \times (\text{ml of solution/g of resin}) \quad (\text{ml/g}).$$

Column Operation. About 4 g of dry-form resin which had been swelled well with distilled water was packed in a polyethylene column (10 mm $\phi \times 120$ mm), and the column was conditioned with about 50 ml of an eluent (with a definite concentration of hydrofluoric acid or hydrofluoric–boric acid the same as in the test solution). After the addition of 10 ml of a test solution containing from 1 to 5 mg of a metal ion, the same eluent was passed through the column. The effluent was collected with a fraction collector, and the concentration of the metal ion in each fraction was determined by the method shown in Table 1.

Results

Distribution Coefficients. The distribution coefficients of 18 elements for cation exchange resin (Diaion SK #1) in hydrofluoric acid and hydrofluoric–0.65 M boric acid media are shown in Tables 2 and 3, along with the stability constants of metal fluoride complexes ($\log K_1$). The metals are arranged in the order of the K_d values in 0.1 M hydrofluoric acid. The K_d values of zirconium, titanium, aluminium, and uranium were investigated more precisely, as is shown in Fig. 1. In both media, the K_d values of metals increased with a decrease in the hydrofluoric acid concentration. The effect of the boric acid concentration on the K_d values is not so great as that of the hydrofluoric acid concentration. For example, when the boric acid concentration was changed from 0.65 M to 0.4 M in 0.2 M HF media, the K_d values of Ti(IV) and Al(III) were decreased to 42 and 420 from 77 and 580 respectively.

Ringbom[12] described how the ion exchange separation of two metals by the column filtration method

can be achieved when the K_d value of one ion is larger than from 10^2 to $10^{2.5}$ and that of the other is less than from $10^{0.5}$ to 10^1.

According to Ringbom's criterion, the following can be expected for the column-elution behavior of metal ions from the K_d values in Tables 2 and 3: (1) In 2 M hydrofluoric acid, Cd(II), Co(II), Mn(II), Ni(II), and Cu(II) are retained in the column. In addition to these metals, V(IV) and Fe(III) are retained in 0.5 M and 0.1 M HF respectively. The adsorptions of Cr(III), V(V), and U(VI) are not quantitative, not even in 0.1 M. Other metals are not retained in the range from 0.1 to 2 M. (2) In hydrofluoric–boric acid media, the number of elements retained in the column increases. In 2, 0.5, or 0.1 M HF containing 0.65 M H_3BO_3, Cr(III) and Fe(III), U(VI) and Al(III), or Ti(IV) and V(V) are retained respectively, in addition to the metals which are retained in the respective concentration of the hydrofluoric acid medium. Hard acid-metals, such as Zr(IV), Hf(IV), Mo(VI), W(VI), Sn(VI), Nb(V), and Ta(V), are not retained at all in either medium. From the K_d values shown in Tables 2 and 3, the possibility of the mutual separation of Zr(IV), Ti(IV), and Al(III) can be presumed in hydrofluoric–boric acid media

Elution Behavior. In order to ascertain the practical conditions for the separation of metals, the elution behavior of Zr(IV), Ti(IV), Al(III), U(VI), and Fe(III) was investigated in hydrofluoric acid and hydrofluoric–boric acid media using a column filled with 4 g of dry-form resin (10 mmϕ × 120 mm). The elution curves are shown in an integrated form in Fig. 2. The inflection points of the elution curves give the volume of the elution maxima (V_{max}, in ml). The K_d values were calculated from the elution maxima

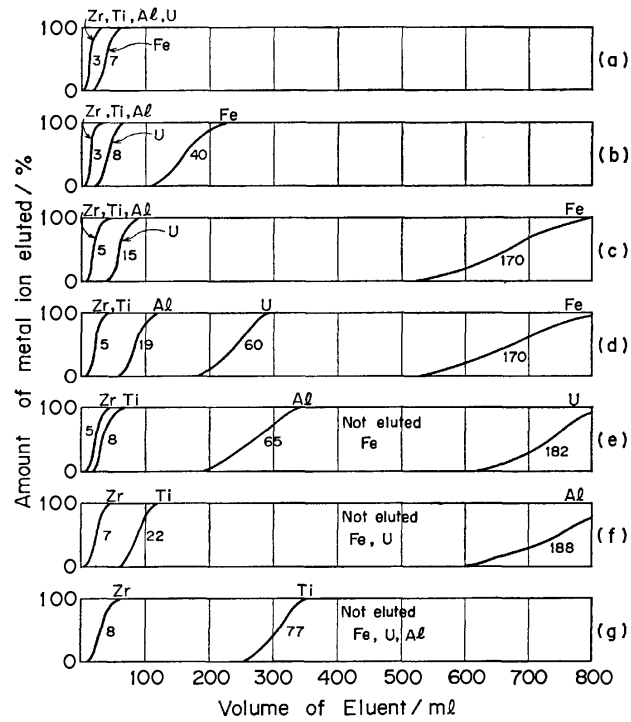

Fig. 2. Column elution behavior of metal ions in HF and HF–H_3BO_3 media.
Diaion SK #1: 4 g, flow rate: 1.2 ml/min. Figures in each column are K_d values obtained. (a): 0.5 M HF, (b): 0.2 M HF, (c): 0.1 M HF, (d): 2 M HF–0.65 M H_3BO_3, (e): 1 M HF–0.65 M H_3BO_3, (f): 0.5 M HF–0.65 M H_3BO_3, (g): 0.2 M HF–0.65 M H_3BO_3.

using the following relation:[13]

$$V_{max} = K_d \times w,$$

where w is the weight of dry resin (g). The calculated K_d values shown in Fig. 2 are in good agreement with the K_d values obtained by the batch method shown in Tables 2 and 3. This fact indicates that the elution was carried out while keeping the ion exchange equilibrium at the flow rate used (1.0 to 1.5 ml/min).

In both hydrofluoric acid and hydrofluoric–boric acid media, metal ions are retained more strongly in the column with a decrease in the concentration of hydrofluoric acid. In hydrofluoric–boric acid media, the metals investigated were retained more tightly than in hydrofluoric acid. For example, as may be seen in Fig. 2 (a), Zr(IV), Ti(IV), Al(III), U(VI), and Fe(III) were eluted when 60 ml of 0.5 M HF was passed through the column, while in 0.5 M HF–0.65 M H_3BO_3 (Fig. 2 (f)) Fe(III) and U(VI) were not eluted even when more than 800 ml of the eluent was passed, and Al(III) was retained in the column until 600 ml.

On the basis of the results shown in Fig. 2, a separation scheme for Zr(IV), Ti(IV), Al(III), U(VI), and Fe(III) was designed. These metals were eluted successively by the following solutions: Zr(IV) by 0.2 M HF–0.65 M H_3BO_3, Ti(IV) by 0.5 M HF–0.65 M H_3BO_3, Al(III) by 2.0 M HF–0.65 M H_3BO_3, U(VI)

by 0.1 M HF, and Fe(III) by 0.5 M HF.

Effect of Amounts of Metal Ions on K_d. In the hydrofluoric–boric acid media, the concentration of free fluoride ions is extremely low, as will be discussed in the Discussion section, because the fluoride ions are consumed by the complex formation with boric acid. Therefore, it is considered that the K_d values might be affected by the amount of metal ions as a result of the deficiency of fluoride ions in addition to the loading.

The effect of the amount of metal ions on K_d in the batch method is presented in Table 4. In this experiment, 4 g of the dry resin was used in order to keep the loading less than 0.1, the metal ion solutions were made free from fluoride ions, and the concentration of hydrofluoric acid was chosen so that the K_d values of the metals were between 10 and 100 in solutions containing 1 mg of metal ions.

It is evident that, in hydrofluoric–boric acid solutions, the K_d values are almost unchanged upon variations in the amount of metal ions. On the contrary, in dilute hydrofluoric acid, the K_d values of Zr(IV), Ti(IV), and Al(III) became larger with the increase in the amount of metal ions because of the consumption of free fluoride ions by the metals.

The effect of the amount of zirconium on the column-elution behavior is shown in Fig. 3 as an example. With an increase in the amount of Zr(IV), the elution of Zr(IV) was retarded extensively in 10^{-3} M HF and moderately in 10^{-2} M HF (Figs. 3 (a) and (b)). In 0.1 M HF–0.65 M H_3BO_3, however, the elution of Zr(IV) was hardly affected by an increase in the amount of Zr(IV) up to 250 mg (Fig. 3 (c)). Less than 100 mg of Zr(IV) did not affect the elution of Ti(IV) (Fig. 3 (d)). Although the elution of Ti(IV) is expected to be retarded when

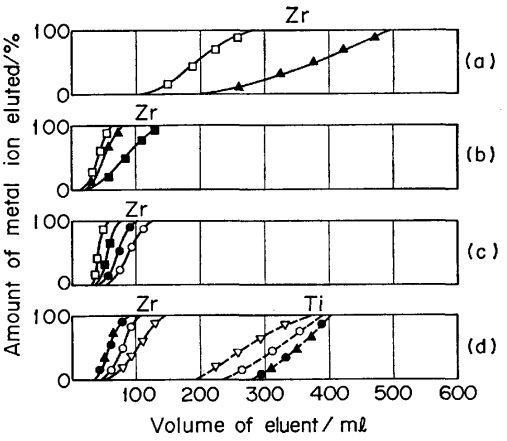

Fig. 3. Effect of amount of Zr(IV) on elution behaviors of Zr(IV) and Ti(IV).
Diaion SK #1: 4 g, flow rate: 1.2 ml/min. (a): 10^{-3} M HF, (b): 10^{-2} M HF, (c): 0.1 M HF–0.65 M H_3BO_3, (d): 0.2 M HF–0.65 M H_3BO_3. Ti: 2 mg, Zr; □: 0.5 mg, ▲: 5 mg, ■: 25 mg, ●: 100 mg, ○: 250 mg, ▽: 500 mg.

the concentration of the fluoride ion is reduced because of the complex formation with a large amount of Zr(IV), the elution of Ti(IV) was slightly accelerated with more than 250 mg of Zr(IV).

Discussion

The experimental results may be summarized as follows:

(1) The K_d values of metals which form stable fluoride complexes are larger in hydrofluoric–boric acid media than in hydrofluoric acid.

(2) The K_d values are scarcely affected by the amount of metal ions in hydrofluoric–boric acid media, whereas they are considerably affected in dilute hydrofluoric acid solutions.

(3) Mutual separations of hard acid-metals using cation exchange resin are possible when hydrofluoric–boric acid solutions are employed as the eluent.

Factors Which Control Cation Exchange Equilibria of Metal Ions in Media Containing Fluoride Ions. The K_d values of metals for the cation exchange resin in a solution involving complexing agent can be expressed by the equation presented by Helfferich.[14] The equation can be rewritten as Eq. 1, considering the adsorption of a metal, M^{n+}, to H^+-form cation exchange resin in a solution containing the fluoride ion as a complexing agent:

$$K_d = \sum_{j=0}^{N} [x_j K^{MF_j}_{(n-j)H}([H^+]_r/[H^+])^{n-j}], \quad (1)$$

$$x_j = [MF_j^{(n-j)+}]/[M^{n+}](1+[F^-]\beta_1+\cdots+[F^-]^N\beta_N)$$

$$= [F^-]^j\beta_j/\sum_{k=0}^{N}([F^-]^k\beta_k), \quad (2)$$

where j is the number of fluoride ions complexed, N is the maximum coordination number of F^- for M^{n+}, β_j is the cumulative stability constant, and r shows the concentration in the resin phase. The $K^{MF_j}_{(n-j)H}$ term is an exchange constant or a selectivity

coefficient which indicates the adsorbability of $MF_j^{(n-j)+}$ to H^+-form resin. As is evident from Eq. 1, the K_d value depends on the fraction, x_j, of a species, $MF_j^{(n-j)+}$, in relating to the total metal species, the selectivity coefficient, $K^{MF_j}_{(n-j)H}$, and the concentration ratio of hydrogen ions in the resin and the solution phase.

Assuming that the ion exchange equilibrium is mainly controlled by one kind of cation species, $MF_j^{(n-j)+}$ $(n-j \geq 1)$, Eq. 1 can be simplified to Eq. 1′:

$$K_d = x_j K^{MF_j}_{(n-j)H}([H^+]_r/[H^+])^{n-j}. \quad (1)'$$

When the amount of metal ion exchanged is negligibly small compared with the capacity of the resin, $[H^+]_r$ is considered to be constant, and, of course, $K^{MF_j}_{(n-j)H}$ is constant. The relation among K_d, x_j, and $[H^+]$ can then be expressed as Eq. 3:

$$\log K_d = \log x_j - (n-j)\log[H^+] + \text{constant}. \quad (3)$$

The charge of the adsorbed species can be obtained from Eq. 3 by changing the hydrogen ion concentration at a constant fluoride ion concentration and, therefore, at a constant x_j.

Ion Exchange Equilibria of Metals in HF. In Fig. 4, the K_d values of various metals in hydrofluoric acid solutions containing 10^{-4} M of free fluoride ions are illustrated as a function of $[H^+]$. From the log K_d—log $[H^+]$ plots of zirconium, titanium, aluminium, uranium, and iron, the linear relations are obtained with slopes of −1.1, −1.7, −1.9, −1.6, and −2.3 respectively. It is considered from these slopes that species of ZrF_3^+, TiF_2^{2+}, AlF^{2+}, UO_2^{2+}, and FeF^{2+} are mainly adsorbed to the resin in the media mentioned above.

In Fig. 5, the K_d values of zirconium and titanium in hydrofluoric acid solutions of pH 1 are illustrated as a function of the concentration of free-fluoride ions, which is calculated using Eq. 4:

$$[F^-] = [HF]/K_{HF}[H^+] = [HF]/10^3 \times 10^{-1} = 10^{-2}\ C_{HF}, \quad (4)$$

where K_{HF} is the stability constant of hydrofluoric acid. The log K_d linearly increases with the decrease

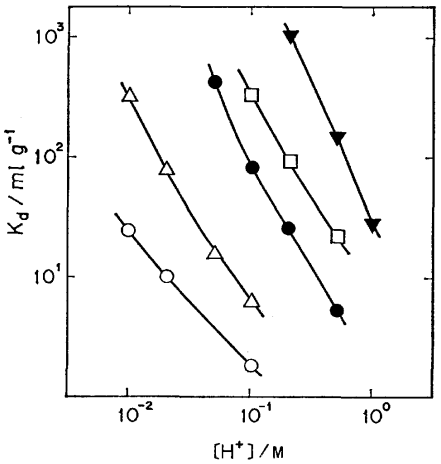

Fig. 4. Relation between K_d and $[H^+]$ in HF at 10^{-4} M $[F^-]$.

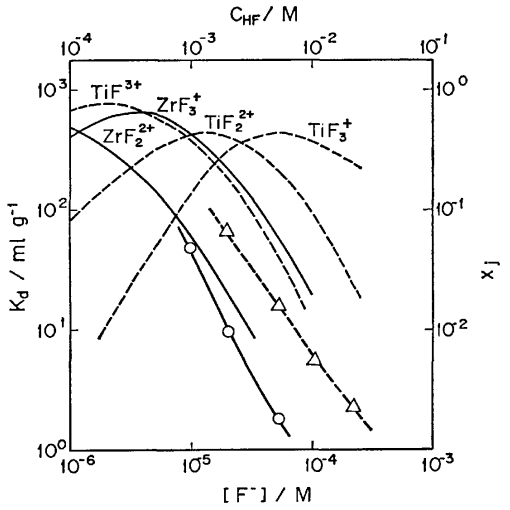

Fig. 5. Relations between changes in K_d in HF at pH 1 and fraction x_j with $[F^-]$.
○: Zr, △: Ti.

in log $[F^-]$. The K_d values of zirconium and titanium increase from 1 to 100 when $[F^-]$ changes from $10^{-4.0}$ to $10^{-5.2}$ M and from $10^{-3.5}$ to $10^{-4.8}$ M respectively. Figure 5 also presents the relations between x_j and $[F^-]$ for zirconium and titanium, calculated using Eq. 2 and the stability constants given in the tables by Sillen and Martell.[15] From these relations, it follows that ZrF_3^+ and TiF_2^{2+} are the main fractions when $[F^-]$ is about $10^{-5.2}$ or $10^{-4.8}$ M respectively. Therefore, it may be considered that ZrF_3^+ and TiF_2^{2+} are the main species which control the adsorption behavior. This estimation agrees with the results obtained from Fig. 4.

Ion Exchange Equilibria of Metals in HF–H_3BO_3 Media. In HF–H_3BO_3 media, $[F^-]$ and $[H^+]$ are calculated according to the chemical equilibria given by the following equations:[15,16]

$$H_3BO_3 + F^- = BF(OH)_3^- \quad (\log \beta_1 = -0.36), \quad (5)$$

$$H_3BO_3 + 2F^- + H^+ = BF_2(OH)_2^- + H_2O \quad (\log \beta_2 = 7.06), \quad (6)$$

$$H_3BO_3 + 3F^- + 2H^+ = BF_3OH^- + 2H_2O \quad (\log \beta_3 = 13.69), \quad (7)$$

$$H_3BO_3 + 4F^- + 3H^+ = BF_4^- + 3H_2O \quad (\log \beta_4 = 19.0), \quad (8)$$

$$H^+ + F^- = HF \quad (\log K_{HF} = 3.0), \quad (9)$$

$$HF + F^- = HF_2^- \quad (\log K_{HF_2^-} = 0.6). \quad (10)$$

The concentrations of hydrogen and fluoride ions in solutions which contain 0, 0.2, 0.4, and 0.65 M H_3BO_3 and various concentrations of hydrofluoric acid (C_{HF}) are summarized in Fig. 6. In the presence of boric acid, $[F^-]$ is extremely low compared with the value in hydrofluoric acid in the absence of boric acid. The reason why K_d in HF–H_3BO_3 media is similar to that in dilute hydrofluoric acid, even at a high concentration of hydrofluoric acid, can be explained by the complex formation of F^- with H_3BO_3 (Eqs. 5 to 8).

For example, the K_d value of titanium in 0.33 M

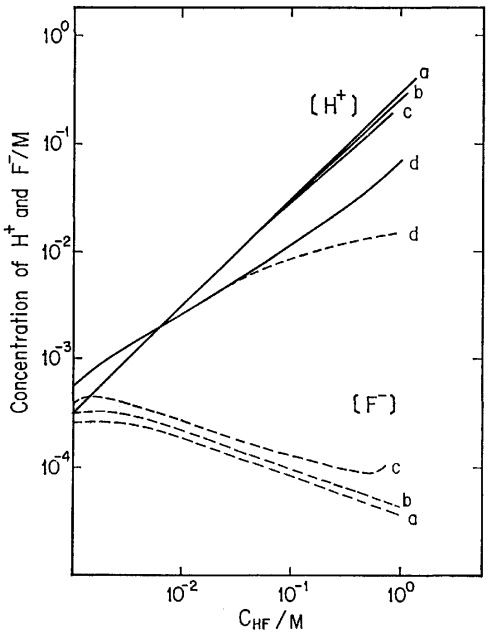

Fig. 6. Calculated concentration of H^+ and F^- in HF-H_3BO_3 media.
[H_3BO_3]; a: 0.65 M, b: 0.4 M, c: 0.2 M, d: 0 M.

HF-0.65 M H_3BO_3 (pH=1) is nearly equal to that in 3.2×10^{-3} M HF, the pH of which is adjusted to 1 (see Figs. 1 and 5). The concentration of the free-fluoride ion in 0.33 M HF-0.65 M H_3BO_3 is considered to be 5.2×10^{-5} M from Fig. 6, while the [F^-] in 3.2×10^{-3} M HF is 3.2×10^{-5} M from Eq. 4.

As is shown in Fig. 6, [F^-] decreases slightly and [H^+] increases proportionally with the increase in C_{HF} in HF-H_3BO_3 media. From Fig. 5 and Eq. 3, the K_d value should increase with the decrease in [F^-] and should decrease with the increase in [H^+]. It can be seen from Fig. 1 that the K_d values of metals in HF-H_3BO_3 media decrease with the increase in C_{HF}. This indicates that K_d in HF-H_3BO_3 media is not governed by the change in [F^-], but by the change in [H^+].

Using the [H^+] value presented in Fig. 6, the K_d values in HF-H_3BO_3 media given in Fig. 1 were replotted against [H^+] instead of C_{HF}: the relations are shown in Fig. 7. The plots of log K_d—log [H^+] are almost straight lines, the slopes of which are similar to those of the lines in Fig. 4. This fact indicates that the adsorbed species in HF-H_3BO_3 media, in which [F^-] is reduced to about 10^{-4} M, are the same as those in a hydrofluoric acid solution, in which [F^-] is about 10^{-4} M.

Fluoride-ion Buffer Action of HF-H_3BO_3. In HF-H_3BO_3 media, BF_4^- and BF_3OH^- are the main species, as is to be expected from the values shown in Eqs. 7 and 8. If a fluoride ion is consumed by a metal ion, fluoride may be supplied from BF_4^- and BF_3OH^- and the concentration of free fluoride ions in the media may thus be kept constant.

This buffer action is effective when the concentration of metal ions is less than one-fifth of the concentration of hydrofluoric acid. For example, the K_d of zirconium in 0.02 M HF-0.65 M H_3BO_3 is not

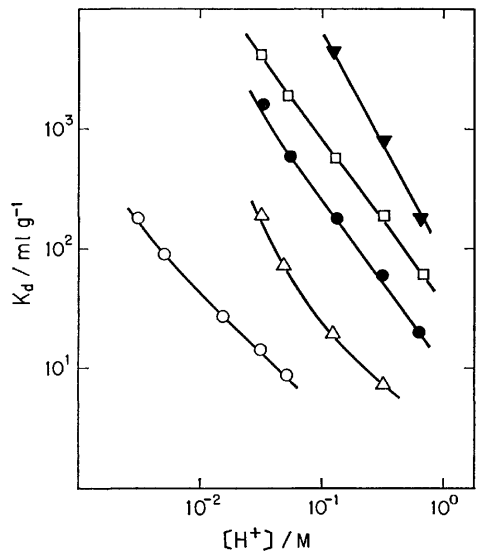

Fig. 7. Relation between K_d and concentration of H^+ in HF-H_3BO_3 media.
[H_3BO_3]: 0.65 M, ○: Zr, △: Ti, ●: Al, □: U, ▼: Fe.

changed up to 4×10^{-3} M of zirconium (20 mg/50 ml), as is shown in Table 4. The F^- buffer action in HF-H_3BO_3 media is remarkable in the column-elution behavior, not only when the amount of an element is changed, but also when the amounts of other co-existing elements are changed, as is shown in Fig. 3.

The F^- buffer action can be expected even in a hydrofluoric acid solution if the concentration is higher than 0.1 M, but the action is not appreciable in the solution with a concentration of less than 0.1 M used in the present work.

Merits of the Use of HF-H_3BO_3 Media in the Cation Exchange Separation of Metals. Using HF-H_3BO_3 media, a successive cation exchange separation of zirconium, titanium, aluminium, and uranium, which has been found difficult in other media, is possible, as is shown in Fig. 2.

From the point of view of practical analysis, the proposed method has the following advantages:

(1) In the analysis of hard acid-metals, anion exchange methods in HF-HCl or -HNO_3 media have been used for separating them from each other. In these methods, metals that form more stable fluoride complexes, M_{ms}, are retained in the column, while metals that form less stable fluoride complexes, M_{ls}, are eluted from the column. Therefore, in the separation of such M_{ls} as aluminium or titanium in a matrix of such M_{ms} as zirconium, an extremely large amount of the resin and an eluent containing hydrofluoric acid are required.[17] In the proposed method using the cation exchange resin, the separation mentioned above can be attained using relatively small amounts of resin and eluent, because M_{ls} are retained in the column and M_{ms} are eluted from the column. The successive elution of impurities retained in the column after eluting matrix elements is also possible. The F^- buffer action of HF-H_3BO_3 media and the reduction of the fluoride-ion concentration with H_3BO_3 are effectively used in the proposed method.

(2) Generally, metals and alloys containing hard acid-metals as the main components are dissolved with the aid of hydrofluoric acid. It is not easy to control the concentration of hydrofluoric acid in the resulting solution to a constant concentration of less than 0.1 M. In HF–H_3BO_3 media, however, it is not so hard to adjust the hydrofluoric acid concentration to the desired value, because separation is carried out at more than 0.1 M HF.

In this connection, the fluoroboric acids in the effluent can easily be evaporated prior to the subsequent determination.

The author wishes to thank Professor Taitiro Fujinaga, Drs. Tooru Kuwamoto, Kakuzo Tada, Hiroshi Hashitani, Sorin Kihara, Osamu Tochiyama and Mr. Hideyo Yoshida for their helpful discussions and useful suggestions.

Photoreaction of Tris(ethylenediamine)cobalt(III) Ion with Bis(2-hydroxyethyl)dithiocarbamate Ion

Michio NAKASHIMA and Sigeo KIDA*

Department of Chemistry, Faculty of Science, Kyushu University
33, Hakozaki, Higashi-ku, Fukuoka 812

(Received August 20, 1981)

Complete ligand replacement of tris(ethylenediamine)cobalt(III) ($[Co(en)_3]^{3+}$) by bis(2-hydroxyethyl)-dithiocarbamate ion(htc^-) forming $[Co(htc)_3]$ is induced by visible light in aqueous solution. The quantum yield of the reaction depends on the wavelength of the light and on the concentrations of the complex and the ligand. The distinct feature of this photo-induced substitution is that the quantum yield is higher than unity for the solution containing 0.02 mol dm^{-3} $[Co(en)_3]^{3+}$ and 0.13 mol dm^{-3} htc^-. The unusually high quantum yield is explained on the basis of a primary photoredox process followed by a chain reaction involving cobalt(II) species as chain carriers. Cobalt(III) complexes of an N_6 donor set such as $[Co(NH_3)_6]^{3+}$, $[Co(NH_3)_4(pn)]^{3+}$, $[Co(chxn)_3]^{3+}$, and $[Co(dien)_3]^{3+}$ also undergo similar photo-reaction, where pn, chxn, and dien denote 1,2-propanediamine, 1,2-cyclohexanediamine, and diethylenetriamine, respectively.

It is well known that irradiation on cobalt(III) complexes with light in the d-d band region causes ligand substitutions with quantum yields much lower than those of chromium(III) complexes.[1-4] Among cobalt(III) complexes, $[Co(en)_3]^{3+}$ is known to be quite inert for the irradiation of visible light. Recently, however, Matsubara and Kida found that $[Co(en)_3]^{3+}$ reacts with diethyldithiocarbamate ion(dtc^-) in aqueous solution forming solid $[Co(dtc)_3]$ upon irradiation at 550 nm (or even at longer wavelengths).[5] Although they were unsuccessful in determining quantum yield due to the precipitation of the product, they inferred the extremely high quantum yield for this photoreaction. Such a facile replacement of the ligand by the irradiation of light in the d-d band region is unusual for the photochemistry of cobalt(III) complexes. Therefore, the present study was aimed to elucidate the mechanism of this photoreaction by quantitative measurements.

In this study bis(2-hydroxyethyl)dithiocarbamate ion (htc^-) was used instead of diethyldithiocarbamate ion. The use of htc^- enabled quantitative measurements of the reaction, because the product, $[Co(htc)_3]$, is fairly soluble in water. The overall reaction is simply expressed as

$$[Co(en)_3]^{3+} + 3htc^- \xrightarrow{h\nu} [Co(htc)_3] + 3en. \quad (1)$$

Experimental

Materials. $[Co(en)_3]Cl_3 \cdot 3H_2O$,[6] $[Co(NH_3)_6]Cl_3$,[7] $[Co(NH_3)_4(pn)]Cl_3$,[8] $[Co(chxn)_3]Cl_3 \cdot 2H_2O$,[6] $[Co(dien)_2]Cl_3 \cdot 3H_2O$,[9] $[Co(trien)(en)]Br_3$,[10] and $[Cr(en)_3]Cl_3 \cdot 3.5H_2O$[11] were prepared and purified according to the procedures described in the literature. The ligands are abbreviated as: en=ethylenediamine, pn=1,2-propanediamine, chxn=1,2-cycrohexanediamine, dien=diethylenetriamine, trien=triethylenetetraamine. Standard compounds for actinometry, $K[Cr(NH_3)_2(NCS)_4] \cdot H_2O$ and $K_3[Fe(ox)_3] \cdot 3H_2O$ (ox=oxalate ion), were prepared by the procedures described in the literature.[12,13] The crystals were recrystallized in the dark at least three times.

$K(C_2H_4OH)_2NCS_2$: An ethanol solution (100 cm^3) of carbon disulfide (20 g) was slowly added with stirring to a mixture of potassium hydroxide (20 g) and diethanolamine (40 g) in ethanol (300 cm^3). After stirring for 3 h, pale yellow crystals deposited were filtered by suction and dried in air stream. The crude crystals were dissolved in water (70 cm^3), and 300 cm^3 of ethanol was added to this solution. When the solution was cooled in an ice box, colorless crystals were separated out in 4 h. The crystals were recrystallized three times. Since this compound is apt to undergo gradual decomposition at room temperature, it was newly prepared every month and stored in a refrigerator. Found: C, 27.29; H, 4.63; N, 6.53%. Calcd for $C_5H_{10}NO_2S_2K$: C, 27.38; H, 4.60; N, 6.39%.

$[Co(htc)_3]$: An aqueous solution of $[Co(en)_3]Cl_3 \cdot 3H_2O$ (0.6 g in 20 cm^3) was mixed with an aqueous solution of K(htc) (0.5 g in 30 cm^3), and the solution was exposed to room light for three hours. Dark green crystal precipitated was recrystallized from DMF–water (1:1). Found: C, 30.32; H, 5.04; N, 6.84%. Calcd for $C_{15}H_{30}N_3O_6S_6Co$: C, 30.04; H, 5.15; N, 7.01%.

The elementary analyses were carried out at the Kyushu University Elementary Analysis Center.

Apparatus. A tungsten lamp (300 W) was used as a light source. The light beam which passed through a UV filter was monochromatized by an interference filter of transmission maximum at 451 nm (T_{max}=43%, bandwidth at $1/2\,T_{max}$=11 nm). A cell jacket was mounted in a black box which has a window of interference filter. The cell jacket was thermostated at 20±0.1 °C by circulating water with a Taiyo Thermo Unit C-550. Spectroscopic quartz (10 mm) cells were used as reaction vessels. The cells were placed in the jacket at least 30 min before the irradiation so that the solution could reach the temperature of the cell jacket. The wavelength dependence of the photoreaction was studied by irradiating monochromatic lights at 585, 571, 535, 511, 486, and 460 nm with a JASCO Spectroirradiator Model CRM-FA. The irradiator equipped with a 3 kW Xe-lamp gives monochromatic light beams of bandwidth less than 15 nm.

Electronic absorption spectra were measured with a Shimadzu Multipurpose Spectrophotometer Model MPS-5000.

Actinometry. The intensity of 451 nm monochromatic light was measured by the method of Wegner and Adamson (Reineckate actinometry) and by the method of Hatchard and Parker(ferrioxalate actinometry).[12-14] The ratio of the light intensities determined by the different methods was 1.03±0.05, showing the reliability of the measurements. At the actual runs of experiments the intensity of 451 nm light was measured before and after the photoreaction of interest by the ferrioxalate actinometry. For the study of

wavelength dependence of the photoreaction, intensity of the monochromatic lights of 585, 571, 535, 511, 486, and 460 nm were determined by the Reineckate actinometry.

Photoreaction. One milliliter of an aqueous solution of $[Co(en)_3]^{3+}$ and 2 cm^3 of an aqueous solution of htc^- were mixed in a quartz cell under dim light. In order to make the error due to the absorption of $[Co(htc)_3]$ formed as small as possible the irradiation time was adjusted for each 451 nm irradiation so that the internal filtration of the light by the absorption of $[Co(htc)_3]$ formed is less than 5% of the total absorption at the end of the irradiation.

Calculation of Quantum Yield. The amount of $[Co(en)_3]^{3+}$ reacted was determined by measuring the concentration of $[Co(htc)_3]$ formed, because no mixed complexes such as $[Co(htc)(en)_2]^{2+}$ and $[Co(htc)_2(en)]^+$ were detected from the observation of the spectra. The concentration of $[Co(htc)_3]$ formed was determined from the difference of absorbance at 630 nm between the solutions before and after irradiation. Thus, the quantum yield at 451 nm was calculated by the equation,

$$\phi = \frac{C_m}{I(1-\tau)t}, \qquad (2)$$

where, C_m is the concentration of $[Co(htc)_3]$(mol dm^{-3}), and I, τ, and t denote the intensity of light(einstein dm^{-3} s^{-1})-(einstein represents 1 mol of light quanta), transmittance of the initial solution, and irradiation time, respectively. In the cases of irradiation in the range 460—585 nm, quantum yield was calculated by using the equation derived by King *et al.*, in which the internal filtration effect was taken into consideration.[15,16]

Results and Discussion

Absorption spectra of $[Co(en)_3]Cl_3$ and K(htc) are shown in Fig. 1, where quantum yield for the solution containing 0.02 mol dm^{-3} $[Co(en)_3]^{3+}$ and 0.13 mol dm^{-3} htc^- are also plotted in the range 460—585 nm. It is to be noted that very high quantum yields were obtained even at the lower-energy side of the d-d band of $[Co(en)_3]^{3+}$. From this fact it appears that the spin-triplet or -quintet states concern with this photoreaction, although no definite conclusion can be drawn at present.

Cobalt(III) complexes of an N_6-donor set such as $[Co(NH_3)_6]^{3+}$, $[Co(NH_3)_4(pn)]^{3+}$, $[Co(chxn)_3]^{3+}$, and $[Co(dien)_2]^{3+}$ also undergo similar reactions with htc^- upon irradiation of light in the d-d band region forming $[Co(htc)_3]$. The quantum yields were determined for 451 nm irradiation, and are summarized in Table 1. The table shows that the quantum yields determined are unusually high for cobalt(III) complexes. It is to be noted that the quantum yield for $[Cr(en)_3]^{3+}$ is much less than those of the cobalt(III) complexes (see Table 1). This is the reverse relation to the general rule for the photosubstitution of chromium(III) and cobalt(III) complexes.[1-4]

In Fig. 2, quantum yields are plotted against the initial concentration of htc^-, the initial concentration of $[Co(en)_3]^{3+}$ being kept at 0.02 mol dm^{-3}. The quantum yield increases with increasing concentration of htc^-, reaching a plateau at higher concentration of htc^-. In Fig. 3, quantum yields are plotted against the initial concentration of $[Co(en)_3]^{3+}$, the initial concentration of htc^- being kept at 0.13 mol dm^{-3}. As seen in the figure, the quantum yield increases almost linearly with the concentration of $[Co(en)_3]^{3+}$ in this range of concentration. These facts may be interpreted on the assumption that the photoreaction

occurs on the ion-pair $[Co(en)_3]^{3+}\cdot$htc$^-$, *i.e.*, the increase of the concentrations of $[Co(en)_3]^{3+}$ and htc$^-$ increases the ratio of concentrations, $[Co(en)_3]^{3+}\cdot$htc$^-$/$[Co(en)_3]^{3+}$.

The formation of ion-pairs is evidenced by the fact that the absorbance of the solution containing $[Co(en)_3]^{3+}$ (0.02 mol dm^{-3}) and htc$^-$ (0.13 mol dm^{-3}) is higher than the sum of the absorbances of the solution of $[Co(en)_3]^{3+}$ (0.02 mol dm^{-3}) and the solution of htc$^-$ (0.13 mol dm^{-3}) in the region <500 nm as shown in Fig. 1. If the above assumption is correct, the quantum yield should be reduced by the addition of the other anions which compete with htc$^-$ in forming ion-pairs with $[Co(en)_3]^{3+}$. In order to elucidate the effect of anions on the quantum yield, the photoreactions were run in the presence of various anions. The results are illustrated in Fig. 4 and summarized in Table 2, together with the formation constants of the ion-pairs. As seen in Table 2, the presence of the anions considerably reduced the quantum yield, and the effect becomes stronger in the order, $NCS^-<I^-<Br^-<Cl^-<C_2O_4^{2-}$, which is the same order as that of the ion-pair formation constants. This fact is in good harmony with the above assumption that the photoreaction initiates at the ion-pair $[Co(en)_3]^{3+}\cdot$htc$^-$.

Since the quantum yields higher than unity can be

a) Potassium salts. b) K is the formation constant of the ion-pair with $[Co(en)_3]^{3+}$.

rationalized only in terms of a chain reaction induced by the photoreaction, we have assumed that the chain-carriers are produced in the reaction as shown below.

$$[Co(en)_3]^{3+}\cdot htc^- \xrightarrow{h\nu} [Co(en)_3{}^*]^{3+}\cdot htc^- \longrightarrow [Co(en)_3]^{2+} + htc\cdot \quad (3)$$

On this assumption, the reaction rate must be affected by the presence of an oxidizing agent, *e.g.*, O_2. In fact, the formation of $[Co(htc)_3]$ was considerably decreased in the reaction under O_2 stream as compared with the case under N_2 stream, (1/30 at the optimum condition so far examined). In the product of a long time irradiation pale yellow solid was detected. It was revealed to be solid sulfur, because it melted at 118 °C and showed no peaks in the IR spectrum.[20] Thus, it is likely that the radical htc· which had been formed in the reaction 3 was removed from the reaction system forming –S–S– bonds finally yielding S_8. Since $[Co(en)_3]^{2+}$ is labile, it readily undergoes the ligand substitution reaction in the solution containing excess of htc$^-$.

$$[Co(en)_3]^{2+} + 3htc^- \longrightarrow [Co(htc)_3]^- + 3en \quad (4)$$

This reaction may be followed by the reaction,

$$[Co(en)_3]^{3+} + [Co(htc)_3]^- \longrightarrow [Co(en)_3]^{2+} + [Co(htc)_3]. \quad (5)$$

Thus, the net reaction of 4 and 5 is

$$[Co(en)_3]^{3+} + 3htc^- \longrightarrow [Co(htc)_3] + 3en, \quad (6)$$

where $[Co(en)_3]^{2+}$ acted as a chain-carrier of the reaction 4 and 5.

In order to examine the validity of the above assumption we have added a small amount of aqueous cobalt(II) chloride to a solution containing $[Co(en)_3]^{3+}$ (0.02 mol dm^{-3}) and htc$^-$ (0.13 mol dm^{-3}) in the dark. The reaction proceeded readily in the dark forming $[Co(htc)_3]^{3+}$. In order to describe the effect of $[Co(H_2O)_6]^{2+}$ on the reaction 6, we defined a parameter ρ= the final amount of $[Co(htc)_3]$/the amount of $[Co(H_2O)_6]^{2+}$ added. In Table 1 quantum yield(ϕ) and ρ for various cobalt(III) complexes of the $[CoN_6]^{3+}$ type are summarized. As seen in the table, ρ is generally larger than unity, except for $[Co(dien)_2]^{3+}$ and $[Co(trien)(en)]^{3+}$, clearly indicating that the chain reaction took place. Table 1 also shows that the increasing order of the quantum yield is exactly in accord with that of ρ. Thus, it is clear that the unusually high quantum yield and the complete replacement of ligands is due to the chain reaction initiated

at the photoredox process 3 and the labile cobalt(II) species $[Co(en)_3]^{2+}$ which undergoes complete ligand replacement in the presence of excess htc^- (reaction 4).

On the basis of the above discussion, we propose the total reaction mechanism as follows:

$$[Co(en)_3]^{3+} + htc^- \longrightarrow [Co(en)_3]^{3+}\cdot htc^- \quad \text{ion-pair formation}$$

$$[Co(en_3]^{3+}\cdot htc^- \xrightarrow{h\nu} [Co(en)_3{}^*]^{3+}\cdot htc^- \longrightarrow [Co(en)_3]^{2+} + htc\cdot \quad \text{photoredox reaction}$$

$$[Co(en)_3]^{2+} + 3htc^- \longrightarrow [Co(htc)_3]^- + 3en$$
$$[Co(htc)_3]^- + [Co(en)_3]^{3+} \longrightarrow [Co(htc)_3] + [Co(en)_3]^{2+} \quad \text{chain reaction}$$

$$[Co(htc)_3]^- \xrightarrow{O_2} [Co(htc)_3]$$
$$[Co(en)_3]^{2+} \xrightarrow{O_2} [Co(en)_3]^{3+}$$
$$htc\cdot \longrightarrow \text{----} \longrightarrow S_8 \quad \text{chain-stopping reactions}$$

The authors wish to acknowledge Prof. M. T. Beck of Kossuth Lajos University, Hungary and Prof. A. W. Adamson of University of Southern California for the discussions and valuable suggestions during their visits to our laboratory.

Temperature-jump Studies of the Complex Formation of Nickel(II) L-Glutamate in Aqueous Solutions

Kiyoshi TAMURA,* Shoji HARADA,† Yoshinori FUNAKI,† and Tatsuya YASUNAGA†

Department of Chemistry, National Defense Academy, Hashirimizu, Yokosuka 239

†*Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730*

(Received August 27, 1981)

Temperature-jump relaxation studies have been carried out on aqueous nickel(II)–L-glutamic acid solutions. The observed relaxation phenomenon is ascribed to the successive complex formation reactions:

$$Ni^{2+} + L^{2-} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} NiL,$$

$$NiL + L^{2-} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} NiL_2^{2-},$$

$$NiL_2^{2-} + L^{2-} \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} NiL_3^{4-},$$

where L^{2-} denotes a glutamate ion. The rate constants are: 2.0×10^4, 1.1×10^4, and 9.2×10^3 M^{-1} s^{-1} (1 M = 1 mol dm^{-3}) for k_1, k_2, and k_3, and 0.048, 0.69, and 27 s^{-1} for k_{-1}, k_{-2}, and k_{-3}, respectively, at 25 °C and I=0.1. The rate-determining step of the complex formation reactions, which follows the initial formation of ion-pairs, is the dissociation of a water molecule from the inner hydration sphere of the nickel; the glutamate ion acts as a bidentate ligand forming a five-membered chelate ring in the complexes.

Recent developments of relaxation kinetics[1,2] have enabled us to study the rapid reactions involved in the metal-ligand interactions. Complex formation reactions of labile metal ions with various ligands have been widely studied,[3,4] and most of them can be interpreted well by a mechanism involving the rate-determining release of the solvent molecule from the inner coordination sphere of the metal ion.[1,3–5] Particular interest has been directed to the metal complexes with amino acid ligands[6–10] not only from the view point of the coordination chemistry but also of their biological importance as model systems of metal-protein interactions. The metal-amino acid complexes are characterized by the formation of five- or six-membered chelate rings, together with especially large complexation constants compared with those of the other non-chelate-forming agents. The above situation inevitably causes a condition where one must study a reaction system containing two or three kinds of complexes and, therefore, be faced with the relaxation treatment of coupled chemical equilibria.

In the present work, we studied nickel(II)–L-glutamic acid interactions by means of a temperature-jump relaxation technique. Glutamic acid is of interest as a potentially terdentate ligand and because it forms mixed ligand complexes with the other chelating agents. However, in spite of the familiar nature and the biological importance of the acid, few kinetic studies[11] have been done on metal-complexes of this ligand. Any information obtained will be helpful in elucidating the metal-glutamic acid interactions.

Experimental

All chemicals used were of a reagent grade. Each solution studied was prepared by mixing aqueous stock solutions of $Ni(NO_3)_2$ and a colorimetric pH indicator, adding sodium hydrogen L-glutamate, and finally diluting. Indicators employed were Phenol Red for pH 7.5—8.5 and Phenolphthalein for pH 9.3—9.8. The ionic strength, I, of the solutions was kept to 0.1 by the addition of KNO_3. The pH of the solution was adjusted with NaOH and/or HNO_3.

The temperature-jump apparatus and the experimental procedure have been described previously.[12,13] All the relaxation experiments were carried out at 25±1 °C.

Results and Treatment of Data

The experimental conditions and the kinetic data observed are summarized in Table 1. All the solutions studied showed a single relaxation phenomenon. The reciprocal relaxation time, τ_{obsd}^{-1}, quoted in Table 1 represents an average of at least four relaxation measurements. The maximum errors are about ±10%. As shown in Table 1, the experiments were carried out in two different pH regions, *i.e.*, around pH 8.0 and 9.8, and the relaxation effect was observed by following the absorbance at the wavelengths 558 (Phenol Red) and 553 nm (Phenolphthalein), respectively. A representative relaxation effect is shown in Fig. 1. Blank solutions of the nickel-indicator and ligand-indicator systems showed no relaxation effect in the same time range. The above fact indicates that the observed relaxation effect is really associated with nickel-ligand interactions.

Under the experimental conditions studied, the formation of nickel(II) glutamate complexes may proceed most generally by the following reaction mechanism:

$$Ni^{2+} + L^{2-} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} NiL \qquad K_1, \qquad (1)$$

$$NiL + L^{2-} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} NiL_2^{2-} \qquad K_2, \qquad (2)$$

$$NiL_2^{2-} + L^{2-} \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} NiL_3^{4-} \qquad K_3, \qquad (3)$$

with the rapid protolytic reactions

$$H_2L \rightleftharpoons H^+ + HL^- \qquad K_{a2}, \qquad (4)$$

$$HL^- \rightleftharpoons H^+ + L^{2-} \qquad K_{a3}, \qquad (5)$$

where the symbols L^{2-} and In^- denote glutamate ion and anionic form of indicator, respectively, and where

TABLE 2. EQUILIBRIUM CONSTANTS FOR THE NICKEL-GLUTAMIC ACID SYSTEM AT 25 °C AND $I=0.1$

Formation constants of nickel(II) glutamate complexes	$K_1=4.17\times10^5$ [a] $K_2=1.59\times10^4$ [a] $K_3=(3.37\pm0.43)\times10^2$ [b]
Dissociation constants of glutamic acid	$pK_{a2}=4.18$[a] $pK_{a3}=9.64$[a]
Nickel(II) hydrolysis constant	$pK_{OH}=10.07$[c]
Ionic product of water	$pK_w=13.79$[d]
Indicator constants	$pK_{In}=7.74$[e] (Phenol Red) $pK_{In}=9.63$[f] (Phenolphthalein)

a) Ref. 14. b) This work. c) Calculated from the value at $I=0$ (Ref. 15) by using the Davies equation for the activity coefficients of the ions (Ref. 16). d) Calculated from the value at $I=0$ (Ref. 17) by using the Davies equation for the activity coefficients of the ions. e) Ref. 18. f) Ref. 19.

K_1, K_2, K_3, K_{a2}, K_{a3}, K_{OH}, K_w, and K_{In} are the equilibrium constants for the corresponding reactions. Since the protolytic reactions (4)—(8) reach equilibrium much faster than the metal complex reactions under consideration here, they can be assumed to be in equilibrium at all times.

All the pertinent equilibrium constants used in this study are given in Table 2. In the earlier equilibrium studies of nickel-glutamate systems,[14,20-22] few investigators[21] reported the presence of the tris-complex NiL_3^{4-}. Therefore, in the preliminary study, we tried to explain the kinetic data in Table 1 by some mechanisms without Eq. 3; *i.e.*, by the complexation reaction (1) or (2), or by coupling the two, or by adopting the disproportionation reaction $Ni^{2+}+NiL_2^{2-}\rightleftharpoons 2\,NiL$. None of them were found to be successful.

By including the three successive complexation equilibria and adopting the usual relaxation treatment, the relaxation times of the system are found to be the solutions of the secular equation:

$$\begin{vmatrix} a_{11}-1/\tau & a_{12} & a_{13} \\ a_{21} & a_{22}-1/\tau & a_{23} \\ a_{31} & a_{32} & a_{33}-1/\tau \end{vmatrix} = 0. \qquad (9)$$

By employing the equilibrium relations $K_n=k_n/k_{-n}$ ($n=1, 2, 3$), the determinant elements a_{ij} are given by

$$\left.\begin{aligned} a_{11} &= k_1\left\{\left(\frac{1-\beta_1}{1+\alpha}\right)[Ni]+(1-\gamma)[L]+\frac{1}{K_1}\right\}, \\ a_{12} &= k_1\left\{\left(\frac{1-\beta_2}{1+\alpha}\right)[Ni]-\frac{1}{K_1}\right\}, \\ a_{13} &= k_1\left(\frac{1-\beta_2}{1+\alpha}\right)[Ni], \\ a_{21} &= k_2\left\{\left(\frac{1-\beta_2}{1+\alpha}\right)[NiL]-[L]\right\}, \\ a_{22} &= k_2\left\{\frac{[NiL]}{1+\alpha}+[L]+\frac{1}{K_2}\right\}, \\ a_{23} &= k_2\left\{\frac{[NiL]}{1+\alpha}-\frac{1}{K_2}\right\}, \end{aligned}\right\} \qquad (10)$$

$$a_{31} = k_3\left(\frac{1-\beta_2}{1+\alpha}\right)[NiL_2],$$
$$a_{32} = k_3\left\{\frac{[NiL_2]}{1+\alpha} - [L]\right\},$$
$$a_{33} = k_3\left\{\frac{[NiL_2]}{1+\alpha} + [L] + \frac{1}{K_3}\right\},$$

with

$$\alpha = \{([HL]+[H_2L]) - ([HL]+2[H_2L])^2/G\}/[L],$$
$$\beta_1 = \gamma\{2([HL]+2[H_2L]) - \gamma([L]+[HL]+[H_2L])\}/G,$$
$$\beta_2 = \gamma([HL]+2[H_2L])/G,$$
$$\gamma = K_{OH}/(K_{OH}+[H]),$$
$$G = [HL] + 4[H_2L] + [H] + [OH] + \gamma[Ni] + [H][In]/(K_{In}+[H]),$$

where the square brackets indicate the molar concentration at equilibrium, and where the charges of the ions are omitted for the sake of simplicity.

Solving Eq. 9, we obtain three relaxation times τ_1, τ_2, and τ_3 ($\tau_1<\tau_2<\tau_3$) as functions of the determinant elements (see Appendix). Since we measured only one relaxation time in each solution studied, we must assign it to one of the three relaxation times predicted by the mechanism. Therefore, we tested the above reaction mechanism for the three cases, in each of which all the experimental data in Table 1 are exclusively associated with only one relaxation time, *i.e.*, (i) τ_1, (ii) τ_2, or (iii) τ_3. The simulation analyses were carried out on computer by iterating the four adjustable parameters K_3, k_1, k_2, and k_3 and by comparing the computed τ^{-1} with the values experimentally observed. The adjustable parameters were optimized by minimizing the root-mean-square percentage deviation between the computed and the observed values of τ^{-1}.

The above simulation analyses revealed that only case (i) gives results consistent with the experiment; case (ii) and (iii) cannot be fitted to the experimental results. As shown in Table 1, the calculated τ_1^{-1} values (denoted by τ_{calcd}^{-1}) agree fairly well with the observed values (r.m.s. % deviation=7.2). The K_3 value determined is shown in Table 2. Considering the differences in ionic strengths, the value garees well with that reported by Gergely and Farkas in their equilibrium studies:[21] K_3=437 at 25 °C and I=0.2. The rate constants determined are shown in Table 3. The contribution of each successive complexation reaction to the relaxation process can be realized from the uncertainty interval of the pertinent rate constant k_n in Table 3.

In the above data treatment, reaction pathways *via* protonated ligands HL^- and H_2L are omitted.

Table 3. Kinetic results for the formation of nickel(II) glutamate complexes at 25 °C and I=0.1

n	k_n/M^{-1} s^{-1}	k_{-n}/s^{-1}
1	$(2.0\pm0.3)\times10^4$	$(4.8\pm0.7)\times10^{-2}$
2	$(1.1\pm0.2)\times10^4$	$(6.9\pm1.4)\times10^{-1}$
3	$(9.2\pm0.5)\times10^3$	$(2.7\pm0.4)\times10$

Reactants of these types lead to additional terms in k_n and k_{-n}. These terms are proportional to either hydrogen-ion concentration or the square of it. Nevertheless, the same set of rate constants gave uniformly good agreement between τ_{obsd} and τ_{calcd} in the pH range 7.5—9.8, without including additional hydrogen-ion dependent terms. We may therefore conclude that, within the experimental error, the major contribution to the relaxation time involves only terms arising from reactions (1)—(3). An additional experiment for the solution containing 0.01 M nickel and 0.01 M glutamic acid, using Methyl Red indicator, at pH 5, where the concentration of glutamate ion L^{2-} is of the order of 10^{-7} M, did not show any relaxation effect.

Discussion

As shown in Table 3, the rate constants k_n are all of the same order of magnitude and show a slightly decreasing tendency of $k_1>k_2>k_3$, which may reflect the electrostatic interactions between the reaction partners. The above result indicates that the successive complex formation reactions (1)—(3) proceed *via* a similar process. The three glutamate ions in the tris-complex NiL_3^{4-} are very likely to be all bidentate, forming five-membered chelate rings, with the γ-carboxylato groups remaining uninvolved in complexation. Therefore, the kinetic result suggests that the glutamate ions in the mono- and bis-complexes NiL and NiL_2^{2-} act as bidentate ligands similar to those in the tris-complex. On the contrary, if the mono- and/or bis-complex contained terdentate ligand, the formation of NiL_2^{2-} or NiL_3^{4-} must involve the cleavage of at least one nickel-ligand bond, and therefore the rate constant k_2 or k_3 would be very different from k_1. This is inconsistent with the present result. The above structural assignment for nickel glutamate complexes is also supported by some equilibrium studies.[21,22]

The k_n values in Table 3 are close to the corresponding rate constants for nickel complexes with univalent α-amino acid ligands such as glycinate,[6] α-alanate,[8] and α-aminobutyrate:[9] $(1.0—2.0)\times10^4$, $(1.5—6.0)\times10^4$, and $(3.0—4.2)\times10^4$ M^{-1} s^{-1} for k_1, k_2, and k_3, respectively, at 20—25 °C and I=0.1—0.15. On the other hand, the k_1 value in Table 3 is significantly smaller than those with bivalent anionic ligands such as oxalate,[23] malonate,[24] and cysteine:[25] $(7.0—15)\times10^4$ M^{-1} s^{-1} at 20—25 °C and I=0.1. According to the widely accepted mechanism of metal-complex formation,[3-5] the rate constants k_n are described in terms of the first-order rate constant k_o for the dissociation of water from the inner hydration sphere of the metal and the association constant K_o of the ion-pair as: $k_n=K_ok_o$. The similarity of the k_n values in Table 3 to those for the univalent anionic ligands indicates that glutamate ion behaves virtually as an univalent anionic ligand for the ion-pair formation. This aspect seems to be reasonable since the negative charge of γ-carboxylato of the ligand resides on a site remote from the chelate-forming groups and the metal ion sees an effective charge

less than −2 owing to the electrostatic shielding of the large ligand.[7] Through the formal estimation of K_o (for 2-1, 1-1, and 0-1 valent ion-pairs) by using Fuoss equation[26] and by setting the minimum approach distance between the reaction partners at 5 Å, the rate constants k_o of ligand substitution were calculated to be 1.0×10^4, 1.4×10^4, and 2.9×10^4 s^{-1} from k_1, k_2, and k_3, respectively, in Table 3. All these values are consistent with the first-order rate constant of the water exchange of nickel ion as determined by an NMR technique:[27] 3×10^4 s^{-1} at 25 °C. The tendency of the increasing water release rate with the higher complexes agrees well with those found in the other nickel-amino acid complexes,[6-9] indicating a significant effect of glutamate ions on the enhancement of the rate of water replacement.

The conclusion is that glutamate ion acts as a bidentate ligand in the nickel complexes and that the formation of the complexes is rate-determined by the release of a coordinated water molecule from the metal rather than by the formation of a chelate-ring closure.

Appendix

Expanding Eq. 9, we obtain the cubic equation

$$\tau^{-3} \quad a\tau^{-2} + b\tau^{-1} - c = 0, \tag{A1}$$

where

$$\begin{aligned} a &= a_{11} + a_{22} + a_{33}, \\ b &= (a_{11}a_{22} - a_{12}a_{21}) + (a_{22}a_{33} - a_{23}a_{32}) \\ &\quad + (a_{33}a_{11} - a_{31}a_{13}), \\ c &= a_{11}(a_{22}a_{33} - a_{23}a_{32}) + a_{12}(a_{23}a_{31} - a_{21}a_{33}) \\ &\quad + a_{13}(a_{32}a_{21} - a_{31}a_{22}). \end{aligned}$$

The secular equation 9 has only real positive eigenvalues of τ^{-1}.[1,5] Thus, by solving Eq. Al, the three relaxation times are given by[28]

$$\begin{aligned} 1/\tau_1 &= a/3 + 2\sqrt{p}\cdot\cos(\theta/3), \\ 1/\tau_2 &= a/3 - 2\sqrt{p}\cdot\cos\{(\theta+\pi)/3\}, \\ 1/\tau_3 &= a/3 - 2\sqrt{p}\cdot\cos\{(\theta-\pi)/3\}, \end{aligned} \tag{A2}$$

with

$$\begin{aligned} \theta &= \cos^{-1}(q/2p^{3/2}) \qquad (0\leqq\theta\leqq\pi), \\ p &= (a^2 - 3b)/9 \qquad (p>0), \\ q &= (2/27)a^3 - ab/3 + c. \end{aligned}$$

As can be realized easily from Eq. A2, we have the inequality relations $\tau_1^{-1} > \tau_2^{-1} > \tau_3^{-1}$ and $\tau_1^{-1} > a/3 > \tau_3^{-1}$.

The Structure of Nickel(II) Bromide in Highly Concentrated Aqueous Solution by X-Ray Diffraction Analysis

Hisanobu WAKITA,* Mitsuyoshi ICHIHASHI, Takeharu MIBUCHI,** and Isao MASUDA

Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma, Nishi-ku, Fukuoka 814-01

(Received August 31, 1981)

An X-ray diffraction analysis of the aqueous nickel(II) bromide solutions with the concentrations of 2.004, 4.064, and 4.845 mol dm^{-3} demonstrated the presence of the complex $[NiBr(H_2O)_5]^+$. This inner-sphere type complex has interatomic distances of 2.52—2.58 Å for Ni–Br and of 2.04—2.05 Å for Ni–OH_2. With an increase in the concentration the average number of the Ni–Br contacts per one Ni^{2+} ion increased; it was found to be 0.18, 0.47, and 0.68 in the 2.004, 4.064, and 4.845 mol dm^{-3} solutions, respectively.

The X-ray diffraction investigation by Mizuno[1] showed that in crystalline $NiCl_2 \cdot 6H_2O$ the nickel ion has a unitary coordination geometry formulated as *trans*-$[NiCl_2(H_2O)_4]$. Caminiti *et al.*[2] investigated the structure of the aqueous $NiCl_2$ solution by X-ray scattering measurements and showed that the nickel ion existed in the form of the hexaaqua complex $[Ni(H_2O)_6]^{2+}$ even if the concentration was as high as 4 mol dm^{-3}. The neutron diffraction measurement on the aqueous 4.41 mol kg^{-1} $NiCl_2$ solution carried out by Soper *et al.*[3] did not indicate any Ni–Cl interaction, though it confirmed the Ni–OH_2 and Cl–OH_2 interactions. The EXAFS spectra for the aqueous solutions of $NiCl_2$ (0.5 and 4 mol dm^{-3}) and of $NiBr_2$ (0.4 and 4 mol dm^{-3}), obtained by Lagarde *et al.*[4] indicated no contact between Ni^{2+} and halide ions. Sandstrom[5] also demonstrated the EXAFS spectra of the aqueous $NiCl_2$ solutions of 2.78 and 3.74 mol dm^{-3} indicated the presence of only the hexaaqua complex ion with the Ni–OH_2 distance of 2.07 Å.

On the other hand, the ^{17}O-NMR relaxation rate measurements by Hertz *et al.*,[6,7] supported the presence of the Ni–halogen bond in the first coordination sphere in the aqueous $NiCl_2$ and $NiBr_2$ solutions. Libuś *et al.*[8,9] determined the molal-scale stability constant, β_1, of the halogenonickel(II) complex to be 0.10 for X=Cl^- and 0.05 for X=Br^-, in the aqueous 2 mol kg^{-1} NiX_2 solutions; however, they proposed that the Ni–Br interaction occurred with an outer-sphere coordination.

In this paper, in order to determine whether the nickel ion could form a halogeno complex of the inner-sphere type, an X-ray diffraction investigation has been carried out with highly concentrated aqueous $NiBr_2$ solutions.

Experimental and Data Treatment

Sample Solutions. Sample solutions were prepared by dissolving $NiBr_2$, which was obtained by recrystallizing commercially available reagent grade nickel(II) bromide twice from water. The nickel and bromide ion concentrations in the solutions were determined by EDTA titration and the Volhard method, respectively. The density of the solutions was determined pycnometrically. The amount of water in the solutions was calculated from the nickel and bromide ion concentrations and the density. The composition of the sample solutions is shown in Table 1 along with the X-ray linear absorption coefficient of the solutions which were used for the absorption correction of X-ray intensity data.

Table 1. Composition and parameter values of sample solutions

	Solution		
	A	B	C
Ni (mol dm^{-3})	4.845	4.064	2.004
Br (mol dm^{-3})	9.690	8.129	4.008
O (mol dm^{-3})	46.48	47.95	53.02
H (mol dm^{-3})	92.96	95.90	106.0
v/Å^3	342.7	408.6	828.6
ρ/g cm^{-3}	1.896	1.752	1.393
μ/cm^{-1}	76.05	63.97	32.20

v, Stoichiometric volume per one atom of nickel; ρ, density; μ, linear absorption coefficient.

X-Ray Diffraction Measurements. The X-ray diffraction intensity data were recorded on a diffractometer by applying the Bragg-Brentano geometry.[10] A cylindrical quartz-cell with 42 mm in diameter and 21 mm in depth filled with a sample solution was placed in the cell holder. Then the holder was covered with a holder cover which was made of Pyrex-glass and had a double layer Mylar window. The holder was set in a furnace thermostatted by means of circulating water. A Johansson type LiF monochrometer was placed between a receiving slit and a scintillation counter; a pulse height analyzer was used for further effective monochromatization. A Philips Mo X-ray tube (λ=0.7107 Å) was employed. The diffraction intensities were recorded at about 300 points in the angle range 60—0.5°, which corresponds to the s value range 15.3—0.15 Å^{-1}, where $s=4\pi\sin\theta/\lambda$. The time required for accumulating 40000 counts was recorded at every 0.5° to θ=36°, 0.25° to θ=18°, and 0.1° to θ=0.5°. Two sets of divergent and scattering slit combinations, 1°:1° and 1/6°:1/2° were employed. The recording was repeated twice for each sample solution.

Treatment of Diffraction Intensity Data. The diffraction intensities recorded by using each set of the slit combinations were corrected for the background scattering recorded for the cell without solution by using the same slit combination. And the intensities for 1°:1° slit combination were normalized to the intensities measured with the 1/6°:1/2° slit combination by using the data in the overlapping angle regions. Moreover, the intensity data were corrected for the polarization and absorption due to the sample solution. The

scaling to the absolute intensities was made by the conventional high angle region method comparing the data in the high angle region ($\theta>45°$) with the sum of the coherent scattering, and by the method proposed by Norman[11] and Krogh-Moe.[12]

The atomic scattering factors for Ni, Br, and O atoms were cited from Cromer and Waber's paper,[13] and for H atom from the International Tables;[14] the incoherent scattering factors for Ni, Br, and O atoms were obtained from Balyuzi[15] and for H atom from Compton and Allison.[16] The incoherent scattering factors were corrected for the Breit-Dirac effect.[17] The values of the anomalous dispersion for these atoms were taken from Cromer's paper.[18] The reduced intensities $i(s)$ due to the combinations of each pair of atoms were evaluated from the scaled intensities $I(s)$ in Eq. 1. In Eq. 1, s represents $4\pi\sin\theta/\lambda$

$$i(s) = I(s) - \sum_i n_i \cdot \{f_i(s)^2 + del(s) \cdot I_i^{inco}(s)\} \quad (1)$$

(λ=0.7107 Å), n_i the number of atoms i, $f_i(s)$ the atomic scattering factor corrected for the anomalous dispersion; $f_i(s)^2=(f_i^\circ(s)+\Delta f_i'(s))^2+(\Delta f_i'')^2$ where $\Delta f_i'$ and $\Delta f_i''$ is the real and imaginary parts of the anomalous dispersion, respectively; $del(s)$ is the fraction of the incoherent radiation $I_i^{inco}(s)$ reaching the counter,[19] and was determined by measuring the resolving power of the monochrometer with the use of a calcite single crystal.[20]

The radial distribution function $D(r)$ was calculated by Eq. 2:

$$D(r) = 4\pi r^2\rho_0 + \frac{2r}{\pi}\int_0^{s_{max}} s \cdot i(s) \cdot M(s) \cdot \sin(r \cdot s) ds, \quad (2)$$

where ρ_0, given in electron units, is the average scattering density of a sample solution, s_{max} (=15.3 Å) the maximum s value during the measurements; the modification function $M(s)$ given by Eq. 2′ was used in this study.

$$M(s) = \{\sum_i n_i \cdot f_i(0)^2 / \sum_i n_i \cdot f_i(s)^2\} \cdot \exp(-0.01 s^2) \quad (2')$$

In the calculated radial distribution curve a small spurious peak appears in the region less than 1 Å where no interatomic interactions besides the O–H interactions in water molecules could be expected to appear. Then the correction for this spurious peak was made with the Fourier inversion method by considering the contribution of the O–H interactions in water molecules.[21] The intensities due to the interatomic interactions were calculated by Eq. 3:

$$i(s)_{calcd} = \sum_i^{i\neq j}\sum_j n_{ij} \cdot f_i(s) \cdot f_j(s) \frac{\sin(r_{ij} \cdot s)}{r_{ij} \cdot s} \exp(-b_{ij} \cdot s^2), \quad (3)$$

where $f_i(s)$ and $f_j(s)$ denote the scattering factors of atom i and j, respectively, and r_{ij} the average distance between atom i and j, b_{ij} the temperature factor ($=\langle\Delta r_{ij}^2\rangle/2$; $\langle\Delta r_{ij}^2\rangle$ is the mean square amplitude of the molecular vibration), and n_{ij} the frequency factor that were refined to minimize the following function U by a least squares method.

$$U = \sum_{s_{min}}^{s_{max}} s^2 \cdot [i(s)_{obsd} - i(s)_{calcd}]^2 \quad (4)$$

In Eq. 4, s_{max} and s_{min} are the upper and lower limits in the selected s regions. Calculations were carried out on a TOSBAC ACOS-600 computer at our University and on a FACOM M-200 computer at Kyushu University; the KURVLR[19] and NLPLSQ[22] programs were used.

Results and Discussion

Both $D(r)$ and $D(r)-4\pi r^2\rho_0$ curves, shown in Figs. 1 and 2, exhibit four distinct peaks at 1.0, 2.1, 2.6, and 3.4 Å. As for the solution C, which is more diluted than the other solutions A and B, the peak at 2.6 Å is rather obscure, though the other three peaks are apparent. The distance of the first peak at 1.0 Å is consistent with that of the O–H bond in water molecules.[23] The second peak at 2.1 Å can be ascribed to the Ni–O interaction in the aqua complexes; a similar peak of the $D(r)$ curves has been reported to appear in the aqueous solutions of 2.491 mol dm^{-3} $Ni(ClO_4)_2$ at 2.04 Å,[22] of 4 mol dm^{-3} $NiCl_2$ at 2.06 Å,[2] and of 1 mol dm^{-3} $Ni(NO_3)_2$ at 2.06 Å.[24]

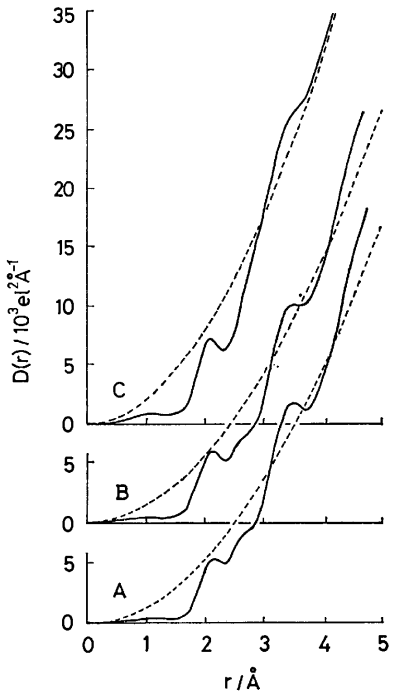

Fig. 1. Radial distribution curves $D(r)$ for the solutions A, B, and C; dashed line shows $4\pi r^2\rho_0$ curve.

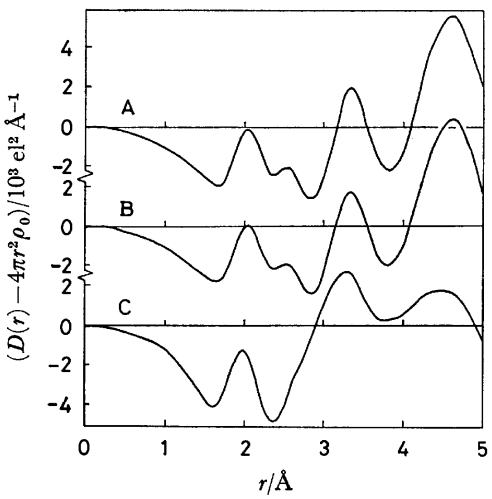

Fig. 2. $D(r)-4\pi r^2\rho_0$ curves for the solutions A, B, and C.

The peak at 2.6 Å may be attributed to the Ni–Br interaction, because the appearance of this peak is reflected by the concentration of $NiBr_2$ and the distance 2.6 Å is very close to the sum of the crystal radii of Ni^{2+} and Br^-, *i.e.* 2.65 Å {=0.83 Å (Ni^{2+})+1.82 Å (Br^-)}.[25] The solution equilibrium investigations indicated the formation of a monobromo complex. However, the formation constants β_1 were very small, ranging from 0.05 to 0.95.[26] By taking the datum β_1=0.05 reported by Libuś *et al.* for the aqueous 2 mol kg^{-1} $NiBr_2$ solution, the monobromo complex presented in our solution C is evaluated to be 16% of the total Ni^{2+} content.

The peak at 3.4 Å can be attributed to the Br–OH_2 interaction, because no comparable peak in this region on the radial distribution curve is observed for the aqueous 2.491 mol dm^{-3} $Ni(ClO_4)_2$ solution, while a clear peak due to the Br–OH_2 interaction is observed at 3.4 Å for the aqueous 2.5 mol kg^{-1} LiBr solution.[27]

On the basis of the above considerations, refinements of the numerical data on the interatomic distances, and frequency and temperature factors of these interactions have been made by the method of Eq. 4. The final data thus obtained are listed in Table 2. And Fig. 3 shows that the $s\cdot i(s)$ curves calculated from these final data are in good agreement with the observed $s\cdot i(s)$ curves in the region above $s>4$. Moreover, subtracting the calculated curve from the radial distribution curve gives a smooth curve indicating a good reliability of the final data, as seen in Figs. 4, 5, and 6.

Table 2. Refined parameters obtained from the reduced intensity curve

Interaction	Parameter	Solution A	Solution B	Solution C
Ni-O	*r*	2.04	2.05	2.04
	b	0.003	0.004	0.004
	n	5.40	5.46	5.73
Ni-Br	*r*	2.52	2.53	2.58
	b	0.007	0.008	0.008
	n	0.68	0.47	0.18

r, Bond distance, Å; *b*, temperature factor, $Å^2$; *n*, frequency factor.

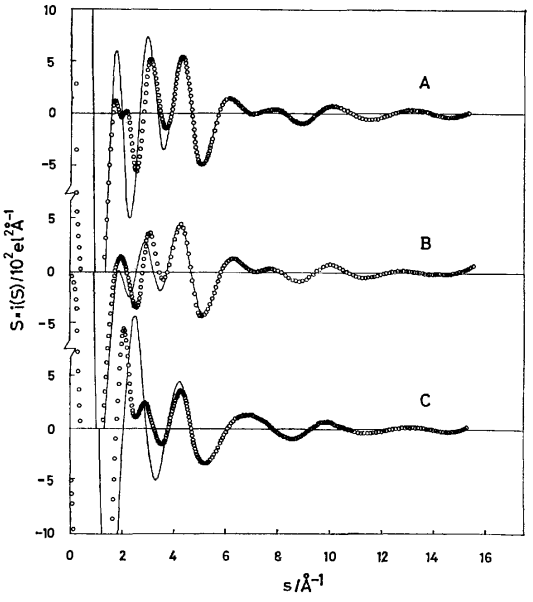

Fig. 3. The reduced intensities $i(s)$ multiplied by s for the solutions A, B, and C.
Observed $s\cdot i(s)$ curve, circles; calculated curve, solid line.

The bond distance of Ni–Br given in Table 2 indicates that the bromo complex is in the inner-sphere type of coordination. Moreover, as seen in the frequency factor, the molar ratio of the bromo complex *vs.* hexaaqua complex increases with an increase in the total $NiBr_2$ concentration. This tendency agrees with the prediction from the stability constant determined by Libuś and Kowalewska.[9] However, they interpreted their formation constant β_1=0.05 for the 2 mol kg^{-1} solution by proposing a monobromo complex with the outer-sphere type of coordination. In fact, on varying the concentration from 0.86 to 4.27 mol kg^{-1}, the ligand field absorption spectra of $NiBr_2$ aqueous solutions changed very little.[28]

For $NiCl_2$ in an aqueous 4 mol dm^{-3} solution, the X-ray investigation was made by Caminiti *et al.*[2] Though they concluded that no chloro complex was formed, a small shoulder is seen around 2.6 Å in their correlation function; this is ascribable to the Ni–Cl

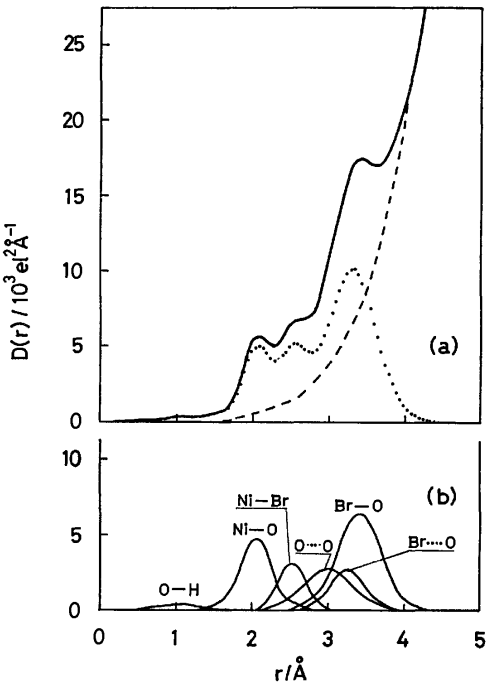

Fig. 4. (a) Radial distribution curve for the solution A. (b) Calculated peak shapes: the O–H interaction is in H_2O; the Ni–O and Ni–Br interactions, and the O···O and Br···O contacts are in $[NiBr(H_2O)_5]^+$; the O···O contact is in hydrogen bonded H_2O molecules; and the Br–O interaction is in $[Br(H_2O)_6]^-$. The O···O peak is composed of two interactions, *i.e.*, the O···O contact in $[NiBr(H_2O)_5]^+$, and the O···O contact in hydrogen bonded H_2O molecules.

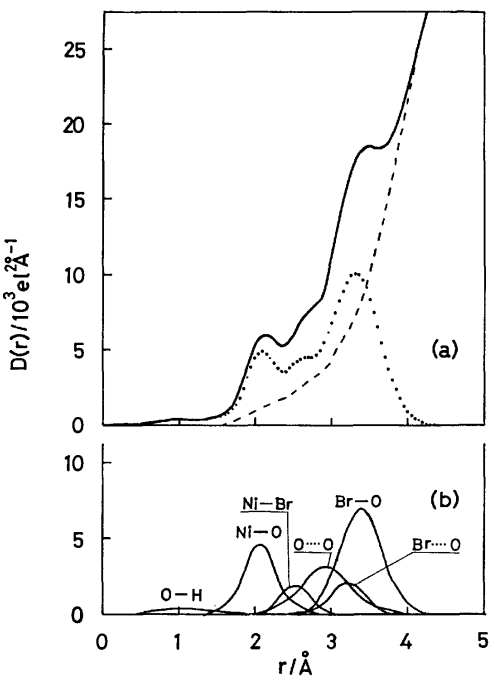

Fig. 5. (a) Radial distribution curve for the solution B. (b) Calculated peak shapes: the O–H interaction is in H_2O; the Ni–O and Ni–Br interactions, and the O···O and Br···O contacts are in $[NiBr(H_2O)_5]^+$; the O···O contact is in hydrogen bonded H_2O molecules; and the Br–O interaction is in $[Br(H_2O)_6]^-$. The O···O peak is composed of two interactions, *i.e.*, the O···O contact in $[NiBr(H_2O)_5]^+$, and the O···O contact in hydrogen bonded H_2O molecules.

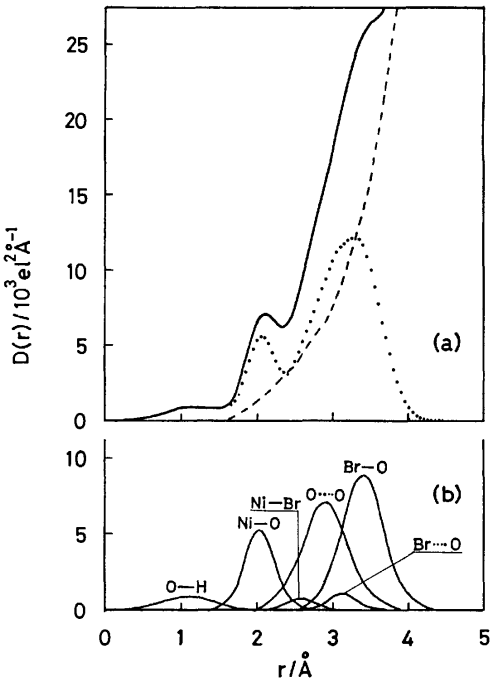

Fig. 6. (a) Radial distribution curve for the solution C. (b) Calculated peak shapes: the O–H interaction is in H_2O; the Ni–O and Ni–Br interactions, and the O···O and Br···O contacts are in $[NiBr(H_2O)_5]^+$; the O···O contact is in hydrogen bonded H_2O molecules; and the Br–O interaction is in $[Br(H_2O)_6]^-$. The O···O peak is composed of two interactions, *i.e.*, the O···O contact in $[NiBr(H_2O)_5]^+$, and the O···O contact in hydrogen bonded H_2O molecules.

interaction. Therefore, in our work the larger X-ray scattering factor of the bromine resulted in the appearance of a pronounced peak of the Ni–Br interaction in the radial distribution curve.

Table 2 shows that the refined data of the bond distance of Ni–Br, 2.52 Å, is smaller than the sum of their ionic radii, 2.65 Å as mentioned above, and is rather approximated by the sum of their covalent bond radii, 2.50 Å {=1.39 Å (Ni^{2+})+1.11 Å (Br^-)}.[29] The bond distance 2.05±0.01 Å of Ni–OH_2 in the bromoaqua complex falls in the same range with those 2.04—2.06 Å of the hexaqua complexes in the aqueous $Ni(ClO_4)_2$[22] and $NiCl_2$[2] solutions. And the temperature factors of the Ni–OH_2 bond in both bromoaqua and hexaaqua complexes are also similar.[22] The Ni–OH_2 distance of the aqua complexes in the solutions seems to be slightly shorter than that of the crystalline $NiCl_2 \cdot 6H_2O$ (2.10 Å).

(Received September 7, 1981)

μ-Oxo-bis[(hydroxo)(octaethylporphyrinato)ruthenium(IV)] was prepared by the oxidation of (carbonyl)-(octaethylporphyrinato)ruthenium(II) with *t*-butyl hydroperoxide in good yield. Facile replacement of the hydroxyl group with various anions afforded μ-oxo dimer complexes formulated as $[\{Ru^{IV}(oep)X\}_2O]$ (X= Cl, Br, and $OCOCH_3$). The same type of osmium complexes, $[\{Os^{IV}(oep)(OCH_3)\}_2O]$, $\{[Os^{IV}(oep)(OCH_3)\}$-$O\{Os^{IV}(oep)(OH)\}]$, and $[\{Os^{IV}(oep)(OH)\}_2O]$ were obtained from the air oxidation product of (carbonyl)-(methanol)(octaethylporphyrinato)osmium(II) in the presence of 2,3-dimethylindole. These complexes are diamagnetic. The ^1H NMR data are in conformity with the linear oxo-bridged dimer structure which was proved by X-ray crystallography with $[\{Ru^{IV}(oep)(OH)\}_2O]$. The redox potentials were measured by the cyclic voltammetry. These complexes showed three distinct quasi-reversible redox couples assignable to $metal^{II}$/$metal^{III}$, $metal^{III}$/$metal^{IV}$, and porphyrin ligand oxidation, respectively. Significantly lower redox values and anomalous spectral features indicate a strong pπ-dπ interaction between the bridging oxygen atom and the two quadrivalent metal ions.

Higher-valent metalloporphyrins such as quadrivalent iron porphyrins have attracted the attention of chemists in relation to the structure of catalases, horseradish peroxidases, and cytochrome c peroxidases in the redox process.[1] During the course of catalytic cycle of peroxidases, the reaction of the ferric enzyme with hydrogen peroxide and successive reduction with an electron generates the oxidized enzyme which was shown to involve an iron(IV) porphyrin moiety.[2,3] Ruthenium and osmium which have the same number of outer shell (d+s) electrons are considered to form metalloporphyrins analogues to those of iron porphyrins. Complexes of bivalent ruthenium[4] and osmium[5] have been investigated as plausible models for hemoproteins and heme enzymes. For the quadrivalent complex, only one complex of osmium, $[Os^{IV}(oep)(OCH_3)_2]$ has been reported by Buchler *et al.*,[6] and synthesis of ruthenium(IV) porphyrins has never been reported before to our knowledge. Through an investigation of the oxidation of indole derivatives with molecular oxygen catalyzed by various metalloporphyrins, we found that bivalent ruthenium and osmium porphyrins as catalysts were oxidized to quadrivalent complexes.[7,8] Our crystallographic study of the quadrivalent ruthenium complex showed a linear oxo-bridged dimer structure represented as $[\{Ru^{IV}(oep)(OH)\}_2O]$.[9] Moreover spectral data of quadrivalent osmium complexes indicate that they have the same structure. Here we wish to report the first synthesis and physicochemical properties of ruthenium(IV) and osmium(IV) porphyrins.

Experimental

Synthesis of Complexes. *μ-Oxo-bis[(hydroxo)(octaethylporphyrinato)ruthenium(IV)]*, $[\{Ru^{IV}(oep)(OH)\}_2O]$ ***(1)***: To a benzene solution (100 cm^3) of $[Ru^{II}(oep)CO]$ (100 mg)[10] was added 1 cm^3 of 70% aqueous *t*-butyl hydroperoxide. The reaction mixture was stirred at room temperature until the color of the solution turned from orange red to dark brown. After removal of the solvent under reduced pressure, the residual solid was chromatographed on an alumina gel with dichloromethane as an eluent. The purple green fraction was collected and evaporated to dryness. Crystallization of the resulting solid from benzene–petroleum ether afforded slightly hygroscopic dark red crystals (90 mg) in 87% yield. Found: C, 64.59; H, 6.90; N, 8.20%. Calcd for $C_{72}H_{90}N_8O_3Ru_2 \cdot H_2O$: C, 64.68; H, 6.93; N, 8.38%.

μ-Oxo-bis[(chloro)(octaethylporphyrinato)ruthenium(IV)], $[\{Ru^{IV}(oep)Cl\}_2O]$ ***(2)***: The dichloromethane solution (100 cm^3) of **1** was treated with 10% aqueous HCl. The mixture was stirred for 5 h. The solution was dried over anhydrous Na_2SO_4 and condensed to dryness by evaporation. Crystallization of the residual solid from dichloromethane–methanol gave purple crystals (86 mg) in 80% yield. Found: C, 63.51; H, 6.51; N, 8.26%. Calcd for $C_{72}H_{88}N_8Cl_2ORu_2$: C, 63.78; H, 6.54; N, 8.27%.

μ-Oxo-bis[(bromo)(octaethylporphyrinato)ruthenium(IV)], $[\{Ru^{IV}(oep)Br\}_2O]$ ***(3)***: The procedure similar to that descrived for the preparation of **2** by using aqueous HBr instead of HCl gave dark purple crystals of **3**i n 85% yield. Found: C, 59.79; H, 6.26; N, 7.71%. Calcd for $C_{72}H_{88}N_8Br_2ORu_2$: C, 59.85; H, 6.14; N, 7.76%.

μ-Oxo-bis[(aceta)(tooctaethylporphyrinato)ruthenium(IV)], $[\{Ru^{IV}(oep)(OCOCH_3)\}_2O]$ ***(4)***: The mixture of **1** (100 mg) in dichloromethane (100 cm^3) and 10% acetic acid (1 cm^3) was stirred until the color of the solution changed from purple green to green. The dichloromethane solution was washed with water and dried over anhydrous Na_2SO_4. The solution was condensed under reduced pressure to a small volume. Crystallization of the residue from dichloromethane–methanol containing trace amount of acetic acid gave purple red crystals (95 mg) in 90% yield. Found: C, 65.15; H, 7.03; N, 7.70%. Calcd for $C_{76}H_{94}N_8O_5Ru_2$: C, 65.05; H, 6.75; N, 7.99%.

μ-Oxo-bis[(methoxo)(octaethylporphyrinato)osmium(IV)], $[\{Os^{IV}(oep)(OCH_3)\}_2O]$ ***(5)***, μ-Oxo-*[(hydroxo)(octaethylporphyrinato)*-

osmium (IV)] [*(methoxo) (octaethylporphyrinatoosmium (IV)*], [{Os^{IV}(oep)(OH)}O{Os^{IV}(oep)(OCH_3)}], ***(6)***, *and* *μ-Oxo-bis[(hydroxo)(octaethylporphyrinato)osmium(IV)]*, [{Os^{IV}(oep)-(OH)}$_2$O] ***(7)***: To a dichloromethane solution (100 cm^3) of (carbonyl)(methanol)(octaethylporphyrinato) osmium(II) (100 mg)[5,6,11] was added 2,3-dimethylindole (100 mg). The mixture was stirred for about 24 h in air until the color of the solution turned from orange red to brown. After removal of solvent, the residue dissolved in benzene was adsorbed on the silica gel column and first eluted with benzene–acetone (9:1 vol/vol). The dark purple effluent was collected. After removal of solvent the residual solid was recrystallized from benzene to give **5** (30 mg) as dark purple crystals. Found: C, 58.12; H, 6.16; N, 7.46%. Calcd for $C_{74}H_{94}N_8O_3Os_2$: C, 58.32; H, 6.22; N, 7.46%. The dark brown second band was eluted with benzene–acetone (8:2 vol/vol). After removal of solvent the crude crystals obtained were recrystallized from benzene–acetone (1:1 vol/vol) to give 6 (30 mg) as dark purple crystals. Found: C, 58.23; H, 6.16; N, 7.30%. Calcd for $C_{73}H_{92}N_8O_3Os_2$: C, 58.06; H, 6.14; N, 7.42%. Finally the dark brown third band was eluted with benzene–acetone (7:3 vol/vol). After removal of solvent the residual solid was recrystallized from acetone to give **7** (25 mg) as dark purple crystals. Found: C, 56.15; H, 5.91; N, 7.31%. Calcd for $C_{72}H_{90}N_8O_3Os_2\cdot H_2O$: C, 56.45; H, 6.19; N, 7.31%.

Protonated forms of μ-oxo osmium(IV) complexes, *i.e.*, μ-hydroxo complexes were obtained according to the following procedure. To a dichloromethane solution (10 cm^3) of **5** (50 mg) was added 10% aqueous acid HX (1 cm^3, X=Cl and CF_3CO_2). After removal of solvents, the residual solid was recrystallized from benzene to afford purple red crystals.

[{Os^{IV}(oep)Cl}$_2$OH]Cl ***(8)***: Found: C, 55.24; H, 5.81; N, 7.10%. Calcd for $C_{72}H_{89}N_8OCl_3Os_2$: C, 55.49; H, 5.72; N, 7.14%.

[{Os^{IV}(oep)($OCOCF_3$)}$_2$OH]($OCOCF_3$) ***(9)***: Found: C, 51.89; H, 5.09; N, 6.39%. Calcd for $C_{78}H_{88}N_8O_7F_9Os_2$: C, 52.02; H, 4.93; N, 6.22%.

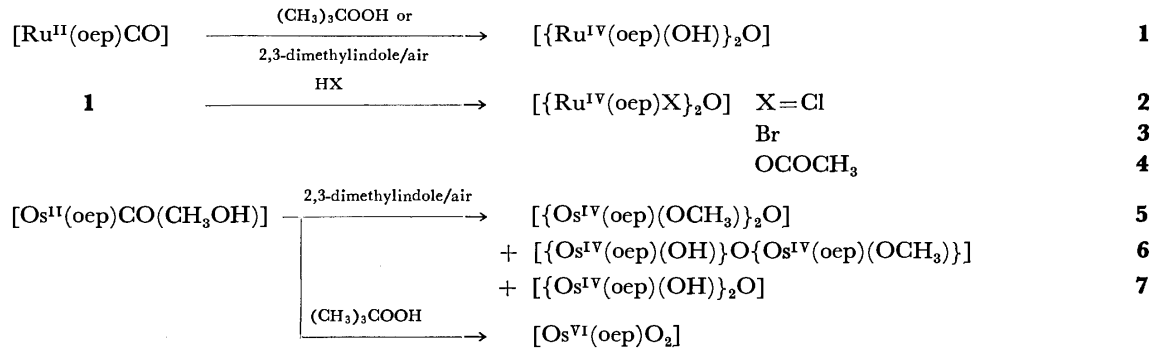
Molecular Weight Measurements. Molecular weights were measured at 31.5 °C in chloroform on a Knour vapor pressure osmometer.

Spectral Measurements. ^{1}H NMR spectra were obtained on a Varian HA-100D and JEOL HM-100 spectrometers. Infrared spectra were measured on Hitachi G-3 and JASCO DS-701G spectrophotometers. Absorption spectra were obtained on a Hitachi model 200-10 spectrophotometer.

Cyclic Voltammetry. Dichloromethane used as a solvent was dried and distilled before use. As a supporting electrolyte, tetrabutylammoium perchlorate (TBAP) was used after being subjected twice to crystallization from benzene. Cyclic voltammograms were obtained on a HA-104 potentiostat (Hokuto Denko) in combination with a HB-107A function generator. A three electrode system was used, consisting of platinum working and counter electrodes and a commercial saturated calomel electrode (SCE). The half-wave potentials were measured as that potential lying midway between the oxidation and reduction peaks for a given couple. Potentials are reported with respect to the saturated calomel electrode.

Results and Discussion

Synthesis. Oxidation of (carbonyl)(octaethylporphyrinato)ruthenium(II) by *t*-butyl hydroperoxide gave the hydroxo derivative **1** of the μ-oxo binuclear ruthenium(IV) porphyrin in a high yield, its axial hydroxyl group being readily replaced with various anions by the treatment with the respective acids. The action of the same oxidant upon (carbonyl)(methanol)(octaethylporphyrinato)osmium(II) gave sexivalent dioxo derivative, [Os^{VI}(oep)O_2] as reported by Buchler *et al.*[6] On the other hand, air oxidation of (carbonyl)-(methanol)(octaethylporphyrinato)osmium(II) in the presence of 2,3-dimethylindole gave three quadrivalent complexes **5**, **6**, and **7**,[8] which could be separated by the chromatography on a silica gel. Thus a sort of peroxide derivative generated *in situ*[7] from 2,3-dimethylindole/air system oxidizes the bivalent complex only to the quadrivalent complex. The bivalent ruthenium complex was also oxidized to the quadrivalent one by this system in good yield.



Molecular weight measurements indicate that all of the complexes of Ru(IV) and Os(IV) thus obtained contain two metalloporphyrin moieties.

Molecular weights and infrared, ^{1}H NMR, and absorption spectra are summarized in Table 1.

^{1}H NMR Spectra. All of the binuclear Ru(IV) and Os(IV) complexes obtained in this study are diamagnetic both in solid and solution states,[12] molar susceptibility of **1** in polycrystalline state being $\chi_M = -8.63\times10^{-6}$ cgs emu at 30 °C. ^{1}H NMR spectra of these complexes showed usual diamagnetic spectra.[13] As listed in Table 1, the characteristic features that are common to all of the complexes are the chemical shifts of the meso protons and the coupling pattern of the α-methylene protons of the pheripheral ethyl groups.

The signals for the meso protons of the binuclear ruthenium and osmium complexes appear at higher magnetic field by about 0.5—1.0 ppm than those in monomeric ruthenium(II) and osmium(II) porphy-

Table 1. Molecular weights, IR, absorption maxima and ^{1}H NMR chemical shifts of ruthenium(IV) and osmium(IV) μ-oxo bridged dimers

rins,[10,11] The X-ray crystallography[9] for **1** showed that it is a μ-oxo binulear porphyrinato complex of ruthenium(IV) and that the interplaner distance between the mean planes of the porphyrinato cores is 3.17 Å. The up-field shifts of the meso proton signals are, therefore, explained in terms of the mutual ring current effect in the dimeric complex. It is thus most likely suggested that ruthenium(IV) and osmium(IV) complexes **1**—**7** all have the linear μ-oxo bridged dimer structure.[9] The meso proton signals of mixed ligand complex **6** appear reasonably at 9.02 and 8.98 ppm as two singlets.

Another characteristic ^{1}H NMR feature of the present complexes that suggests the μ-oxo dimer structure is the coupling pattern of the peripheral α-methylene protons. As shown in Fig. 1, all of these complexes showed the ABX_3 coupling pattern which could be analyzed with the aid of the decoupling method. Diastereotopism of the α-methylene protons of ethyl group is due to the different magnetic circumstances above and below the porphyrinato plane. The complicated pattern of the α-methylene signals has been reported for some metalloporphyrins.[14,15] Splitting of the proton signal of α-methylene group in octaethylporphyrin is attributed to out-of-plane central ion or asymmetric axial ligation. The ruthenium atom

in **1** was found to be displaced only 0.03 Å off the plane defined by the four porphyrinato nitrogen atoms.[9] The eight ethyl groups are oriented outside so as to avoid steric constraint between the peripheral ethyl groups of the two porphyrinato cores. Therefore, the hindered rotation of the ethyl group causes the nonequivalence of the α-methylene in the different magnetic atmosphere due to asymmetric ligation.

The proton of the axial ligands OH and $OCOCH_3$ for the ruthenium complexes **1** and **4** resonated at −4.20 and −3.70 ppm respectively as sharp singlets. Methoxyl protons for osmium complexes **5** and **6** appeared at −3.70 and −3.54 ppm, respectively, also as sharp singlets. These anomalous high-field shifts of the proton signal of the axial ligand can be described by a large shielding effect of the ring current in the near proximity of the metal ion. It is noteworthy that the axial hydroxyl protons for the osmium complexes **6** and **7** resonated at about −3.5 ppm as much broader signals compared with those of ruthenium complexes. Such broadening of the signals indicates a more dissociable nature of the proton of the axial hydroxyl group, and suggests lower electron density on the axial oxygen atom in the osmium complex. On the other hand, electronic and ^1H NMR spectra of these binuclear osmium(IV) complexes in the presence of acids show that their bridging oxygen atoms have certain tendency to be protonated while those of similar ruthenium(IV) complexes do not. This suggests higher electron density on the bridging oxygen of the osmium complexes. These problems will be described more fully under a separate section.

IR, VIS, and UV Absorption Spectra. Infrared spectra of **1**, **6**, and **7** showed sharp bands at 3606 (in CCl_4), 3602 (KBr), and 3598 (KBr) cm^{-1}, respectively, assignable to the stretching vibration (ν_{O-H}) of the axial hydroxyl group.[16] Two absorption peaks at 1659 and 1225 cm^{-1} for **4** are due to $\nu_{C=O}$ and ν_{C-O} of the axial acetoxyl group.[16] Three absorption bands at 2785, 1010, and 525 cm^{-1} for **5** and those at similar positions for **6** are due to the axial methoxide ligands.[6]

Data of VIS and UV absorption spectra are given in Table 1. The Soret bands of the binuclear Ru(IV) and Os(IV) complexes are observed at 373—387 and 351—355 nm, respectively, which are considerably in the shorter wave length region than those of the respective bivalent metalloporphyrins,[10] in conformity with the usual empirical rule.

The general features of the absorption spectra of these binuclear complexes at the longer wave length region are considerably different from those of usual porphyrin complexes as shown in Figs. 1 and 2. Since the absorption spectrum of monomeric quadrivalent complex, $[Os^{IV}(oep)(OCH_3)_2]$ has only normal α and β bands at 530 and 497 nm in this region,[6] the band appearing at 550—800 nm of the present osmium(IV) complexes are considered to be the characteristics of the oxo-bridged dimer structure. The same is probably true with the binuclear Ru(IV) complexes, although no mononuclear Ru(IV) porphyrins have been reported to date.

A number of chemically well defined dimeric and oligomeric halogen complexes of ruthenium[17] and osmium[18] are known having a μ-oxo bridging link between halogeno-metal moieties. These complexes exhibit anomalous light absorption mainly in the longer wave length region, which is probably of the similar nature to those of the present complexes. This, as well as other anomalous physical and chemical properties of these series of μ-oxo halogeno complexes have been successfully interpreted using an MO scheme.[17a] Such scheme presupposes a strong electronic coupling between the halogeno-metal moieties and even leads to a sort of a new chemical system. The present complexes seem to be in a more or less similar situation. The above-mentioned absorption peaks appearing at 550—800 nm that characterize such anomalous features of the spectra of these binuclear complexes are sensitive to the kind of the axial ligand. They probably have main contribution from the charge

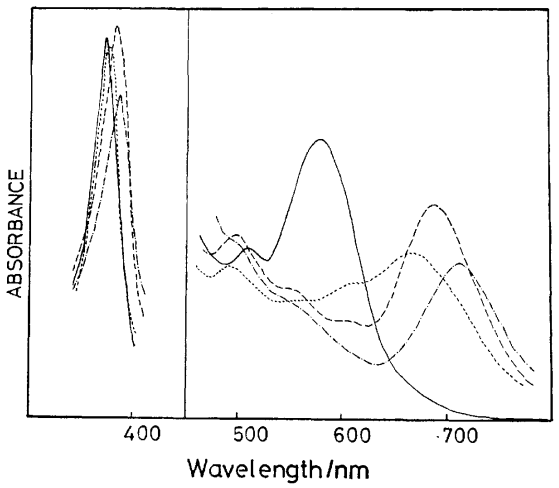

Fig. 1. Absorption spectra of the μ-oxo bridged ruthenium(IV) dimers in CH_2Cl_2.

transfer of the type $a_{1u},a_{2u}(p\pi)\rightarrow e_g(d_{xz},d_{yz})$. The excitation energy of the transition was in the order OH> $OCOCH_3$>Cl>Br of the axial ligand of the ruthenium complexes, and $(OH)_2>(OH)(OCH_3)>(OCH_3)_2$ of those of osmium complexes. This trend seems to reflect the extent of an interaction between $p\pi$ orbitals of the axial ligand and $d\pi$ orbitals of the metal ions.

Behavior of μ-Oxo Binuclear Complexes toward Acids. As has been described previously, action of acids upon complex **1** replaces the axial hydroxyl group with the respective acid groups to give **2**, **3**, and **4**, leaving μ-oxo group unchanged. Such a change could be followed by observing the change of the absorption spectrum of **1** upon addition, *e.g.*, of aqueous HCl; no more spectral change was observed in the presence of excess amount of acids. Complexes **2**, **3**, and **4** readily regenerate **1**, *e.g.*, by simple column chromatography of them on alumina, due to reverse reaction with trace amount of water on the gel.

The behaviors of the μ-oxo bridged osmium complexes toward acids are considerably different. Treatment of these complexes with acids seems to protonate the bridged oxygen first as evidenced by electronic and ^{1}H NMR spectra. Thus, the absorption spectra of the osmium complexes vary largely with the addition of acids finally to give the same spectra *independent of* the kind of acids. The ^{1}H NMR spectrum of the osmium complex **5** in the presence of 1% CF_3CO_2D is illustrated in Fig. 3. By the addition of trifluoroacetic acid, the meso protons are slightly shifted toward lower magnetic field and the geminal coupling constant of the ABX_3 pattern for α-methylene protons becomes a little smaller. It is noteworthy that the axial methoxide protons are shifted toward higher magnetic field without decrease in the intensity or broadening of the signal. These results indicate that the protonation occurs not on the axial oxygen atom but on the bridged oxygen atom, because if the protonation occured on the oxygen of the axial methoxide, the positive charge on the oxygen would be increased and the methoxyl protons should rather be shifted toward lower magnetic field. However an attempt to isolate the protonated species, $[\{Os^{IV}(oep)(OCH_3)\}_2OH]^+X^-$ only gave the complexes $[\{Os^{IV}(oep)X\}_2OH]^+X^-$ (X=Cl, and CF_3CO_2), respectively, in which methoxyl group were replaced by the chloro and trifluoroacetato groups. Treatment of **8** and **9** with aqueous alkali not only deprives it of the proton from the hydroxyl bridge but also causes hydrolysis resulting

X=Cl **8**

CF_3CO_2 **9**

in the replacement of the axial acid groups by the hydroxyl group. This has so far prevented the authors from obtaining oxo-bridged osmium(IV) complexes having acidic axial ligands comparable to ruthenium complexes **2**, **3**, and **4**.

As shown in Fig. 4, the Soret band for the μ-oxo osmium complexes was shifted to 359 nm and became sharp by the protonation. The charge transfer bands also were largely affected, and absorption at around 700 nm disappeared. The same spectral changes were observed in the presence of other acids such as HCl, HBr, and $HClO_4$. The absorption spectra of complexes **8** and **9** also show similar spectra. This kind of spectrum is, therefore, considered to be characteristic of the species protonated at the bridging oxygen atom represented as $[\{Os^{IV}(oep)(OCH_3)\}_2OH]^+$. The lack of the absorption near 700 nm may be due to the decrease of the interaction between two metalloporphyrins through bridged oxygen caused by the protonation to the oxygen atom. Moreover the same characteristic absorption spectrum could be also observed in the presence of silver perchlorate instead of protons. This means that the silver ion can also react with the bridged oxygen as a Lewis acid, although the adduct of silver perchlorate could not be isolated as analytically pure crystals.

In order to understand the different behavior toward acids between ruthenium(IV) and osmium(IV) complexes in spite of having similar molecular structures, it seems helpful to consider the following canonical structures. The behavior toward acids and ^{1}H NMR data for osmium(IV) complexes indicate considerable contribution of structure (C). Canonical structure (C) points to an easy dissociation of axial hydroxyl protons

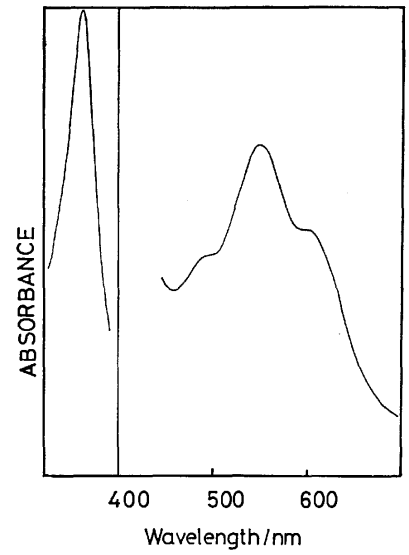

Fig. 4. Absorption spectra of $[\{Os^{IV}(oep)(OCH_3)\}_2O]$ in CH_2Cl_2 containing 1% CF_3CO_2H.

$$HO^- \underset{(A)}{[M{=}\overset{2+}{O}{=}M]} OH^- \leftrightarrow \underset{(B)}{HO\text{-}M\text{-}O\text{-}M\text{-}OH}$$
$$\leftrightarrow H^+ \underset{(C)}{[O{=}M\text{-}\overset{2-}{O}\text{-}M{=}O]} H^+$$

and high affinity of proton toward the bridged oxygen. On the other hand, experimental results for ruthenium(IV) complexes suggest that the more important contribution here is rather structure (A) predicting the easy replacement of axial hydroxyl group and low affinity of proton toward bridged oxygen atom. For a more detailed and quantitative discussion, a theoretical treatment involving the molecular orbital calculations seems to be indispensable.

Electrochemistry. The redox behavior of Ru(IV) and Os(IV) metalloporphyrins seems to form one of the most interesting facets of their chemistry especially from the biological point of view. Unless very accurate data are required, necessary information can be obtained simply from cyclic voltammetry. All of these complexes show three distinct quasi-reversible redox couples (Eo1, Eo2, and Eo3) as shown in Fig. 5, and half-wave potentials estimated therefrom are listed in Table 2. The number of electron concerned in each couple was determined to be about 2 by the controlled coulometry,[19] which means that two metal atoms or porphyrin ligands in a molecule are oxidized and reduced at the same time. In connection with the existing data especially of osmium porphyrins, these three redox couples of both ruthenium and osmium complexes seem to be assignable to metal^{II}/metal^{III}, metal^{III}/metal^{IV}, and to porphyrin ring oxidation, respectively.[20,21] The assignment of Eo3 to the porphyrin ring oxidation is also confirmed by the fact that the redox couple is almost insensitive to the difference of both metal and axial ligand.[20] It is noteworthy that although the redox couple Ru^{II}/Ru^{III} has been confirmed electrochemically for [Ru^{II}(porphyrin)(pyridine)$_2$],[21] the redox couple Ru^{III}/Ru^{IV} has never been observed before, probably because the latter is more positive than that of porphyrin ring oxidation. Appearance of the Ru^{III}/Ru^{IV} in the present complex at a potential lower than that of the ring oxidation, thus, proves the marked stabilization of Ru^{IV} caused by the formation of the linear Ru–O–Ru system in conformity with the successful isolation of Ru(IV) complexes only in the form of oxo-bridged dimers. Here, strong electron-donating ability of the μ-oxo (O^{2-}) ligand probably plays an important role. The Ru^{III}/Ru^{IV} couple of complex **1** having axial hydroxyl groups is somewhat more negative than those of halogeno derivatives **2** and **3**. This means that the electron donation from the axial ligand, which also contributes to the lowering of the Ru^{III}/Ru^{IV} couple is larger in the former.

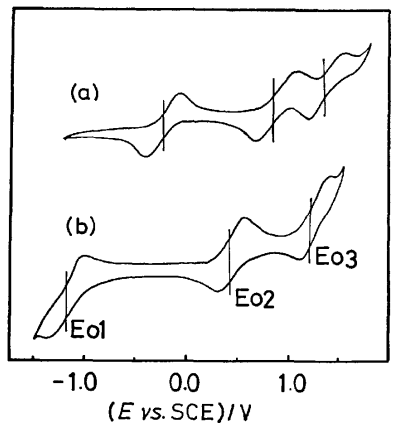

Fig. 5. Cyclic voltammograms of (a) [{Ru^{IV}(oep)Cl}$_2$O], and (b) [{Os^{IV}(oep)(OCH$_3$)}$_2$O] in CH_2Cl_2–TBAP.

Table 2. The half-wave potentials of ruthenium(IV) and osmium(IV) μ-oxo bridged dimer complexes (V *vs.* SCE)

Compound	Eo1	Eo2	Eo3
[{Ru^{IV}(oep)(OH)}$_2$O]	−0.82	+0.68	+1.18
[{Ru^{IV}(oep)Cl}$_2$O]	−0.24	+0.85	+1.32
[{Ru^{IV}(oep)Br}$_2$O]	−0.22	+0.84	+1.30
[{Os^{IV}(oep)(OCH$_3$)}$_2$O]	−1.18	+0.41	+1.20
[{Os^{IV}(oep)(OH)}O-{Os^{IV}(oep)(OCH$_3$)}]	−1.13	+0.40	+1.22
[{Os^{IV}(oep)(OH)}$_2$O]	−1.12	+0.37	+1.23

Formation of the μ-oxo bridges, of course, lowers the redox values of Os^{III}/Os^{IV} and Os^{II}/Os^{III} also. Their redox values for [Os^{II}(oep)(1-methylimidazole)$_2$] were recently reported to be 0.61 and −0.63 V, which are considerably more positive than the values of around 0.4 and −1.1 V for the present osmium dimer complexes. The influence of the protonation to the bridging oxygen on the redox values was also investigated. Figure 6 shows that in the presence of 1% CF_3CO_2H only the redox couple Eo2 was specifically shifted toward positive region by about 0.5 volt. Unfortunately the redox couple Eo1 was completely concealed by the large back ground current due to the presence of trifluoroacetic acid. These results indicate that the protonation on the bridged oxygen considerably decreases the electron donation from the bridged oxygen to the central metals. The redox values for Eo1 and Eo2 of osmium complexes are almost insensitive to the axial ligands, so that the interaction between the metals and the axial ligands acting as electron donors is considered to occur to about the same

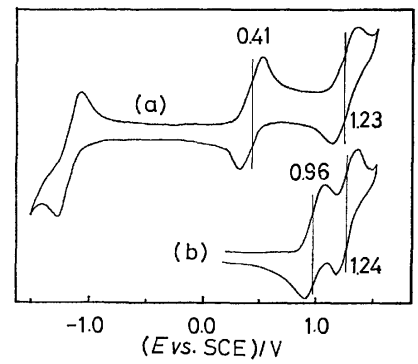

Fig. 6. Cyclic voltammograms of [{Os^{IV}(oep)(OCH$_3$)}$_2$O] in (a) CH_2Cl_2 and (b) CH_2Cl_2 containing of 1% CF_3CO_2H.

extent.

Tervalent iron porphyrins form μ-oxo bridged dimer complexes represented as $[\{Fe^{III}(porphyrin)\}_2O]$.[22] Phillippi and Goff reported[23] that electrochemical oxidation of $[\{Fe^{III}(tetraphenylporphyrin)\}_2O]$ gave both one-electron oxidized ($[Fe^{III}-O-Fe^{IV}]^+$) and two-electron oxidized ($[Fe^{IV}-O-Fe^{IV}]^{2+}$) species at 0.79 and 1.03 V, respectively. This behavior of the iron complex is different from that of ruthenium and osmium complexes, because in ruthenium and osmium binuclear complexes two metal atoms are oxidized at the same time as discussed above. The different redox behavior of the iron complex might be explained in terms of weaker interaction between two metalloporphyrin moieties through bridged oxygen. In fact, X-ray crystallography revealed that the Fe–O–Fe group is not completely linear.[22] Moreover there is still a major question concerning oxidation of the iron complexes, that is, whether electron abstraction occurs formally from the metal (ferryl iron) or from ligand (porphyrin radical).[3c,24]

Chemistry of Chiral Vitamin B_6 Analogs. IV. Syntheses of Chiral Pyridoxal and Pyridoxamine Analogs Having a Branched "Ansa Chain" between 2′- and 5′-Positions

Makoto Ando,* Yoji Tachibana, and Hiroyoshi Kuzuhara
The Institute of Physical and Chemical Research, Wako, Saitama 351
(Received June 13, 1981)

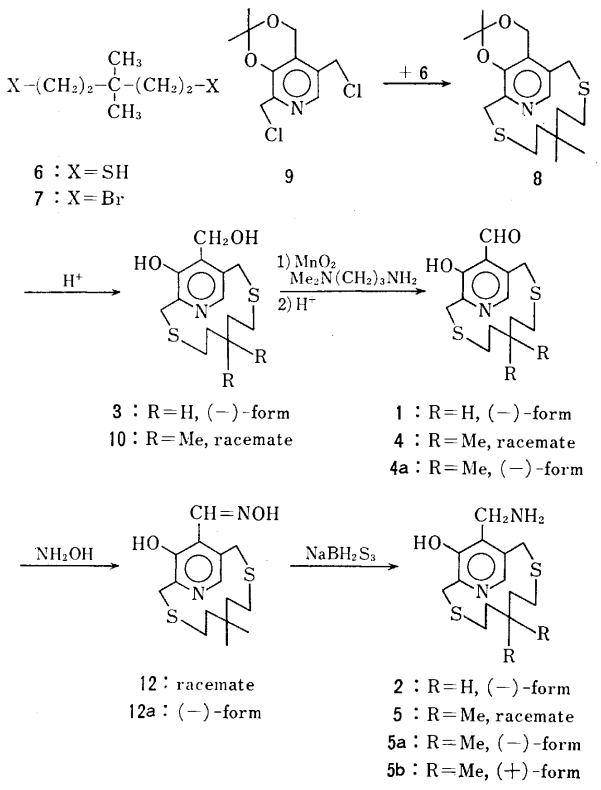
Racemic 15-formyl-14-hydroxy-5,5-dimethyl-2,8-dithia[9](2,5)pyridinophane (**4**), an analog of pyridoxal having a branched "ansa chain" between 2′- and 5′-positions, was synthesized from 2,5-bis(chloromethyl)-3-hydroxy-*O*,*O*′-isopropylidene-4-pyridinemethanol. Optical resolution of **4** was achieved *via* the formation of Schiff base with 3-amino-3-deoxy-1,2:5,6-di-*O*-isopropylidene-D-glucofranose, giving the levorotary enantiomer of **4** (**4a**). Racemic 15-aminomethyl-14-hydroxy-5,5-dimethyl-2,8-dithia[9](2,5)pyridinophane (**5**), the same type of pyridoxamine analog as **4**, and its levorotary enantiomer were synthesized from the corresponding **4** and **4a**. Both levorotary and dextrorotary enantiomers of **5** were also obtained by the optical resolution of the racemate *via* the formation of chiral dibenzoyltartaric acid salts of **5**.

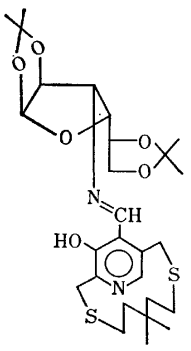
In the course of our study on mimics of vitamin B_6-dependent enzymes, we have prepared a new type of chiral analogs of pyridoxal (**1**),[1] pyridoxamine (**2**),[2] and pyridoxine (**3**)[3] which have a straight "ansa chain" between 2′- and 5′-positions. In the presence of a suitable metal ion, **1**[1] and **2**[2] have proved very active in the enzyme-mimics reactions such as racemization or transamination of amino acids. Although such reactions proceed *via* the formation of Schiff base[4] stereospecifically and/or stereoselectively owing to the chirality of the B_6 analogs used, the degree of such steric effects is rather limited in comparison to the corresponding enzymic reactions. This will be because the "ansa chain" to which the B_6 analogs owe their planer chirality is too small and separated too far from the reaction center in the transition state. This prompted us to replace the straight "ansa chain" by a more bulky one. We prepared new B_6 analogs having a branched "ansa chain".

This paper deals with 15-formyl-14-hydroxy-5,5-dimethyl-2,8-dithia[9](2,5)pyridinophane (**4**) and 15-aminomethyl-14-hydroxy-5,5-dimethyl-2,8-dithia[9]-(2,5)pyridinophane (**5**), a new type of pyridoxal and pyridoxamine analogs, and their optical resolution. The levorotary enantiomer of **5** (**5a**) was also obtained by derivation from the corresponding enantiomer of **4** (**4a**).

3,3-Dimethyl-1,5-pentanedithiol (**6**) was prepared by the reaction of 1,5-dibromo-3,3-dimethylpentane (**7**)[5] with thiourea and subsequent alkaline hydrolysis. The ansa compound (**8**) was obtained by slow addition of a benzene solution of an equimolar mixture of **6** and 2,5-bis(chloromethyl)-3-hydroxy-*O*,*O*′-isopropylidene-4-pyridinemethanol (**9**)[1] to a dilute solution of sodium ethoxide in ethanol at 0 °C. Removal of the isopropylidene group in **8** by acidic hydrolysis afforded an analog of pyridoxine (**10**), which was oxidized with manganese(IV) oxide in the presence of *N*,*N*-dimethyl-1,3-propanediamine in pyridine–benzene.[6] The resulting Schiff base was hydrolyzed with acid to give racemic 15-formyl-14-hydroxy-5,5-dimethyl-2,8-dithia[9](2,5)pyridinophane (**4**). The optical resolution of **4** was performed by forming the Schiff base (**11**) by treatment with 3-amino-3-deoxy-1,2:5,6-di-*O*-isopropylidene-D-glucofranose.[1] Levorotary enantiomer of **4** (**4a**) was obtained by recrystallization of one of the less soluble diastereomers of the Schiff base (**11a**) from benzene and subsequent acidic hydrolysis of **11a**. Compounds **4** and **4a** were treated with hydroxylamine in ethanol to give the corresponding (±)-oxime (**12**) and (−)-oxime (**12a**), respectively. Reduction of **12** and **12a** to the corresponding pyridoxamine analogs, **5** and **5a**, were performed with sodium (dihydrotrithio)borate in tetrahydrofuran, following the earlier synthesis of **2**.[2]

We also succeeded in the optical resolution of **5**; that is, when **5** was treated with (−)-(*R*,*R*)-dibenzoyltartaric acid in ethanol, the crude (−)-dibenzoyltartaric acid salt of **5** (neutral equimolar salt) (**13a**) contaminated with its diastereomeric salt was prepared. Owing to the poor solubility of the salt in the usual solvents, fractional crystallization of **13a** proved very difficult. Therefore, such crude **13a** was treated with aqueous sodium hydrogencarbonate to give crude **5a**





11 : mixture of diastereomer

13b

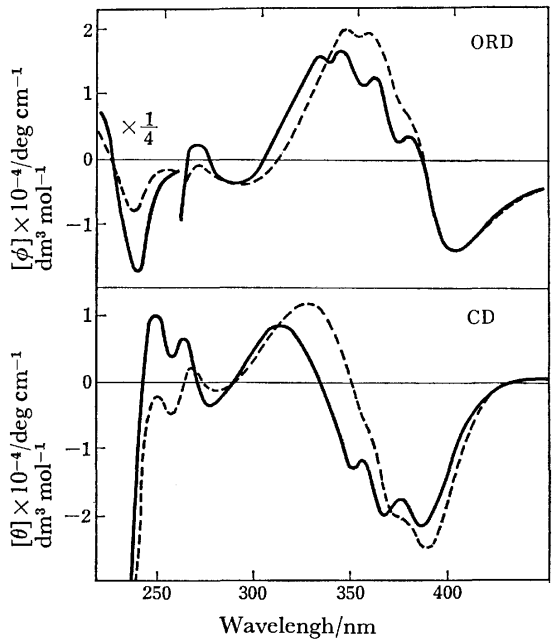

Fig. 1. ORD and CD spectra of **4a** and **1** (1.76×10^{-4} M solution in MeCN at 21 °C.).
4a: ——, **1**: ----.

including a little (+)-enantiomer (**5b**). This was repeatedly treated as described above and gave **5a**. Using (+)-(*S*,*S*)-dibenzoyltartaric acid in the same way resulted in (+)-enantiomer (**5b**). The physical properties, including optical rotation, of **5a** obtained by the resolution of **5** completely agreed with those of **5a** prepared from **12a**.

In order to determine the absolute configuration of **4a**, its ORD and CD spectra were measured. They were very similar to those of **1** (Fig. 1), indicating that **4a** has the same configuration as **1** has. Because **1** had been shown to have *S*-configuration on the basis of the results of X-ray analysis of (−)-pyridoxine analog (**3**) derived from **1**,[3] the absolute configuration of **4a** was determined to be *S*. Therefore, **5a** and **12a** derived from **4a** also had *S*-configuration and the enantiomer **5b** had *R*-configuration.

Studies on the function of these new B_6 analogs with definite configuration are under way. These indicate that in some systems they are very superior to the former analogs, **1** and **2**. The results will be reported in the near furture.

Experimental

All melting and boiling points are uncorrected. Optical rotations were measured with a Perkin-Elmer 241MC polarimater. UV, IR, and ^{1}H NMR spectra were recorded on a Hitachi 124 Spectrophotometer, a Shimadzu IR-27G infrared spectrophotometer, and a JEOL PS-100 spectrometer, respectively. ORD and CD spectra were obtained using a JASCO J20A automatic recording spectropolarimeter. Column chromatography was performed on a Merck silica gel 60 (No. 7734).

*3,3-Dimethyl-1,5-pentanedithiol (**6**).* A stirred mixture of 1,5-dibromo-3,3-dimethylpentane (**7**)[5] (64.8 g), thiourea (61.0 g), and water (45 ml) was refluxed for 20 h. A solution of potassium hydroxide (100 g) in water (200 ml) was added all at once to the resulting solution at room temperature, refluxed for 6 h with stirring, diluted with water, and extracted with ether. The aqueous layer was acidified with hydrochloric acid and extracted with ether. The ethereal extract was dried ($MgSO_4$), concentrated, and distilled, giving 35.8 g (82%) of **6**: bp 100—101 °C/7 mmHg (1 mmHg≈133 Pa); n_D^{23} 1.5141; IR (film) 2550 cm^{-1} (SH). Found: C, 50.84; H, 9.73; S, 39.07%. Calcd for $C_7H_{16}S_2$: C, 51.17; H, 9.81; S, 39.02%.

*14-Hydroxy-15-hydroxymethyl-O,O′-isopropylidene-5,5-dimethyl-2,8-dithia[9](2,5)pyridinophane (**8**).* A solution of **6** (4.6 g) and 2,5-bis(chloromethyl)-3-hydroxy-*O*,*O*′-isopropylidene-4-pyridinemethanol (**9**)[1] (6.9 g) in benzene (500 ml) was added to a stirred solution of sodium ethoxide (prepared from sodium (1.7 g) in ethanol (2.5 l)) over a period of 6 h in an ice bath and kept overnight at 0 °C. The solvents were removed and the residue was extracted with chloroform–water. The organic layer was washed with water, dried ($MgSO_4$), concentrated, and chromatographed. Elution with dichloromethane gave 7.5 g (81%) of **8**: mp 139—140 °C; UV_{max} (MeCN) 297 (ε 6.3×10^3) and 211 nm (ε 15.0×10^3); ^{1}H NMR ($CDCl_3$) δ=7.94; (1H, s), 5.26 (1H, d, J=16 Hz), 4.77 (1H, d, J=16 Hz), 4.15 (1H, d, J=12 Hz), 3.73 (1H, d, J=12 Hz), 3.61 (1H, d, J=13 Hz), 3.50 (1H, d, J=13 Hz), 1.63 (3H, s), 1.59 (3H, s), and 0.70 (6H, s). Found: C, 61.23; H, 7.67; N, 3.92; S, 18.11%. Calcd for $C_{18}H_{27}NO_2S_2$: C, 61.15; H, 7.70; N, 3.96; S, 18.14%.

*14-Hydroxy-15-hydroxymethyl-5,5-dimethyl-2,8-dithia[9](2,5)-pyridinophane (**10**).* A stirred mixture of **8** (7.3 g) in 1 M (1 M=1 mol/dm^3) hydrochloric acid (240 ml) was heated at 80—85 °C for 1 h. Soon **8** was dissolved and the hydrochloride of **10** was deposited. The mixture was made basic with solid sodium hydrogencarbonate and stirred for 1 h at room temperature. Separation of the precipitates gave 5.2 g of **10**. Additional **10** (1.2 g; total 99%) was recovered by concentrating the filtrate to dryness, extracting the residue with pyridine, and removing the pyridine; mp> 280 °C. Found: C, 57.49; H, 7.36; N, 4.30; S, 20.44%. Calcd for $C_{15}H_{23}NO_2S_2$: C, 57.47; H, 7.40; N, 4.47; S,

20.45%.

Hydrochloride: Mp 208—209 °C dec Found: C, 51.50; H, 6.90; Cl, 10.11; N, 3.97; S, 18.38%. Calcd for $C_{15}H_{24}ClNO_2S_2$: C, 51.49; H, 6.91; Cl, 10.13; N, 4.00; S, 18.32%.

(±)-15-Formyl-14-hydroxy-5,5-dimethyl-2,8-dithia[9](2,5)-pyridinophane (4). A stirred mixture of *N,N*-dimethyl-1,3-propanediamine (7.2 ml), manganese(IV) oxide (27.0 g), and a solution of **10** (5.2 g) in pyridine (100 ml) and benzene (70 ml) was refluxed for 4 h while the generated water was azeotropically separated.[6] The insoluble material was filtered off with celite and the filtrate was evaporated to dryness. Dioxane (100 ml) and 1.2 M hydrochloric acid (65 ml) were added to the residue and stirred for 1 h at room temperature. Dilution of the solution with water (*ca.* 1 l) and adjustment of pH to *ca.* 3 with aqueous sodium hydroxide gave precipitates. These were passed through a silica-gel column with dichloromethane, giving 3.6 g (70%) of **4**: mp 147—148 °C; IR (KBr) 1660 cm^{-1} (C=O). Found: C, 57.82; H, 6.73; N, 4.41; S, 20.54%. Calcd for $C_{15}H_{21}NO_2S_2$: C, 57.85; H, 6.80; N, 4.50; S, 20.59%.

(−)-Schiff Base of 4 with 3-Amino-3-deoxy-1,2:5,6-di-O-isopropylidene-D-glucofranose (11a). A solution of **4** (6.24 g) and 3-amino-3-deoxy-1,2:5,6-di-*O*-isopropylidene-D-glucofranose[1] (5.74 g) in benzene (500 ml) was refluxed for 2 h while the generated water was azeotropically separated. Evaporating the solution to *ca.* 100 ml afforded crude **11a**, which was recrystallized twice from benzene, giving 4.17 g (75% based on half of **4**) of **11a**: mp>280 °C; UV_{max} ($CHCl_3$) 353 nm (ε 4.9×10^3); IR (KBr) 1660 cm^{-1} (C=N); $[\alpha]_D^{25}$ −337° (*c* 0.392, $CHCl_3$). Found: C, 58.90; H, 7.30; N, 4.98; S, 11.37%. Calcd for $C_{27}H_{40}N_2O_6S_2$: C, 58.67; H, 7.29; N, 5.07; S, 11.60%.

(−)-15-Formyl-14-hydroxy-5,5-dimethyl-2,8-dithia[9](2,5)-pyridinophane (4a). To a solution of **11a** (3.98 g) in dioxane (400 ml) was immediately added 1 M hydrochloric acid (60 ml). The mixture was stirred for 1 h at room temperature. Treating the solution as described in the preparation of **4** gave 1.80 g (80%) of **4a**: mp 93 °C; $[\alpha]_D^{24}$ −422° (*c* 0.264, $CHCl_3$); UV_{max} (MeCN) 360 (ε 4.0×10^3), 248 (ε 8.2×10^3), and 225 nm (ε 10.8×10^3); IR (KBr) 1660 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=10.53 (1H, s), 8.06 (1H, s), 4.35 (1H, d, J=12 Hz), 4.28 (1H, d, J=14 Hz), 3.77 (1H, d, J=14 Hz), 3.66 (1H, d, J=12 Hz), and 0.70 (6H, s). Found: C, 57.92; H, 6.78; N, 4.42; S, 20.57%. Calcd for $C_{15}H_{21}NO_2S_2$: C, 57.85; H, 6.80; N, 4.50; S, 20.59%.

(−)-14-Hydroxy-15-hydroxyiminomethyl-5,5-dimethyl-2,8-dithia[9](2,5)pyridinophane (12a). To a solution of **4a** (1.22 g) in ethanol (60 ml) was immediately added solid hydroxylamine hydrochloride (0.38 g) and sodium acetate trihydrate (1.0 g). The mixture was stirred overnight at room temperature, concentrated to dryness, and extracted with chloroform–water. After being washed with aqueous sodium hydrogencarbonate and with water, the organic layer was dried ($MgSO_4$), concentrated, and chromatographed. Elution with chloroform afforded 1.01 g (79%) of **12a**: mp 218—219 °C; $[\alpha]_D^{23}$ −363° (*c* 0.204, $CHCl_3$); UV_{max} (MeCN) 330 (ε 4.6×10^3), 260 (ε 9.9×10^3), and 215 nm (ε 18.9×10^3); IR (KBr) 3400 (OH) and 1660 cm^{-1} (CH=N); ^1H NMR (CD_3SOCD_3) δ=12.28 (1H, s), 10.99 (1H, s), 8.73 (1H, s), 8.06 (1H, s), 4.28 (1H, d, J=12 Hz), 4.22 (1H, d, J=12 Hz), 3.77 (1H, d, J=13 Hz), 3.58 (1H, d, J=12 Hz), and 0.65 (6H, s). Found: C, 55.02; H, 6.80; N, 8.51; S, 19.54%. Calcd for $C_{15}H_{22}N_2O_2S_2$: C, 55.19; H, 6.79; N, 8.58; S, 19.64%.

(±)-14-Hydroxy-15-hydroxyiminomethyl-5,5-dimethyl-2,8-dithia[9](2,5)pyridinophane (12). Racemic isomer (**4**) was treated as described in the treatment of **4a**, yielding **12** in 93% yield: mp 205—206 °C. Found: C, 55.05; H, 6.79; N, 8.40; S, 19.58%. Calcd for $C_{15}H_{22}N_2O_2S_2$: C, 55.19; H, 6.79; N, 8.58; S, 19.64%.

(−)-15-Aminomethyl-14-hydroxy-5,5-dimethyl-2,8-dithia[9]-(2,5)pyridinophane (5a). Dry THF (15 ml) was added all at once to a stirred mixture of sulfur (675 mg) and sodium tetrahydroborate (264 mg) under nitrogen atmosphere and stirred for 1 h at room temperature. A solution of **12a** (1.13 g) in dry THF (30 ml) was added to the mixture over a period of 20 min at room temperature with stirring and refluxed for 6 h. After removal of the solvent, the residue was dissolved in hot chloroform–methanol and extracted with dilute hydrochloric acid. The aqueous layer was treated with charcoal, made basic with solid sodium hydrogencarbonate, and extracted with chloroform. The organic layer was dried ($MgSO_4$), concentrated, and chromatographed. Elution with chloroform–methanol (9:1 v/v) gave 617 mg (57%) of **5a**: mp 174—175 °C dec; $[\alpha]_D^{25}$ −262° (*c* 0.409, $CHCl_3$); ORD: λ_{max} 314 ($[\alpha]$ $-1.32°\times10^4$), 285 ($[\alpha]$ $+1.58°\times10^4$), 247 ($[\alpha]$ $-5.0°\times10^2$), and 220 nm ($[\alpha]$ $+4.8°\times10^4$) (*c* 6.4×10^{-5} M, MeCN, 21 °C); CD: λ_{max} 300 ($\Delta\varepsilon$ −22.3), 260 ($\Delta\varepsilon$ +1.65), and 239 nm ($\Delta\varepsilon$ −19.3) (*c* 6.4×10^{-5} M, MeCN, 21 °C); UV_{max} (MeCN) 299 (ε 5.7×10^3) and 214 nm (ε 14×10^3); IR (KBr) 3350, 3200, and 3150 cm^{-1} (NH_2, OH); ^1H NMR (CD_3SOCD_3) δ=7.79 (1H, s), 5.99 (2H, s), 4.18 (2H, s), 4.15 (1H, d, J=11 Hz), 3.78 (1H, d, J=13 Hz), 3.70 (1H, d, J=13 Hz), 3.45 (1H, d, J=11 Hz), and 0.64 (6H, s). Found: C, 57.45; H, 7.79; N, 8.79; S, 20.57%. Calcd for $C_{15}H_{24}N_2OS_2$: C, 57.65; H, 7.74; N, 8.96; S, 20.52%.

(±)-15-Aminomethyl-14-hydroxy-5,5-dimethyl-2,8-dithia[9]-(2,5)pyridinophane (5). The racemate (**12**) was treated as described in the preparation of **5a**, affording **5** in 59% yield: mp 154—155 °C dec. Found: C, 57.37; H, 7.74; N, 8.80; S, 20.43%. Calcd for $C_{15}H_{24}N_2OS_2$: C, 57.65; H, 7.74; N, 8.96; S, 20.52%.

Optical Resolution of 5. (−)-Enantiomer of 5 (5a): A solution of (−)-(*R,R*)-dibenzoyltartaric acid (1.59 g) in ethanol (15 ml) was added to a hot solution of **5** (1.31 g) in ethanol (100 ml), concentrated to *ca.* 30 ml, and cooled in an ice bath. The precipitates were collected and stirred with a mixture of chloroform and saturated sodium hydrogencarbonate solution at room temperature for 1 h. The organic layer was washed with water, dried ($MgSO_4$), and concentrated to dryness, giving crude **5a**. Two more treatments of the crude **5a** with (−)-dibenzoyltartaric acid and sodium hydrogencarbonate, successively yielded 295 mg (45% based on half of **5**) of **5a**: mp 174—175 °C dec; $[\alpha]_D^{21}$ −262° (*c* 0.327, $CHCl_3$).

(−)-Dibenzoyltartarate of 5a (13a): Mp >280 °C; $[\alpha]_D^{23}$ −186° (*c* 0.273, DMF). Found: C, 59.18; H, 5.70; N, 4.14; S, 9.52%. Calcd for $C_{33}H_{38}N_2O_9S_2$: C, 59.09; H, 5.71; N, 4.18; S, 9.56%.

(+)-Enantiomer of 5 (5b): By the use of (+)-(*S,S*)-dibenzoyltartaric acid instead of (−)-optical isomer, **5b** was obtained in 43% yield (based on half of **5**): mp 174—175 °C dec; $[\alpha]_D^{21}$ +262° (*c* 0.330, $CHCl_3$). Found: C, 57.37; H, 7.74; N, 8.78; S, 20.46%. Calcd for $C_{15}H_{24}N_2O_2S_2$: C, 57.65; H, 7.74; N, 8.96; S, 20.52%.

(+)-Dibenzoyltartarate of 5b (13b): Mp >280 °C; $[\alpha]_D^{21}$ +187° (*c* 0.330, DMF). Found: C, 59.19; H, 5.65; N, 4.10; S, 9.55%. Calcd for $C_{33}H_{38}N_2O_9S_2$: C, 59.09; H, 5.71; N, 4.18; S, 9.56%.

The authors wish to express their thanks to Dr. Haruo Homma and his assistants for elementary

analyses and to Dr. Jun Uzawa and Mrs. Tamiko Chijimatsu for measurements of ^{1}H NMR spectra.

A Kinetic Study on Reduction of 9,9′-Bifluorenylidene by Sodium Isopropoxide

Shoji KAJIGAESHI,* Shizuo FUJISAKI, Yasuhiko NAKASHIGE, and Sadaaki MURAKAMI

Department of Industrial Chemistry, Faculty of Engineering Yamaguchi University, Tokiwadai, Ube 755

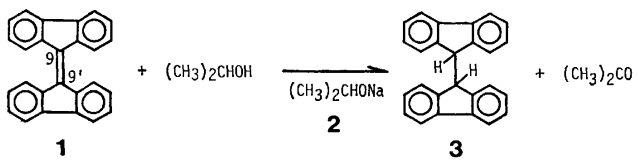
(Received February 7, 1981)

The kinetics and mechanism of reduction of 9,9′-bifluorenylidene (**1**) by sodium isopropoxide (**2**) in isopropyl alcohol to yield 9,9′-bifluorenyl (**3**) were investigated spectrophotometrically. The kinetic data suggest that the reduction proceeds autocatalytically, the reduction product **3** acting as the catalyst. It was found that

$$\mathbf{1} \xrightarrow[\mathbf{2}]{k_1} \mathbf{3} \qquad (1) \qquad\qquad \mathbf{1} + \mathbf{3} \xrightarrow[\mathbf{2}]{k_2} \mathbf{3} + \mathbf{3} \qquad (2)$$

Reactions 1 and 2 are of the first order with respect to **1**, but that the former is of the third order with respect to **2**, whereas the latter is of the first. The fourth- and third-order rate constants, k_1 and k_2, for Reactions 1 and 2 were determined to be 3.0×10^{-5} dm^9 mol^{-3} s^{-1} and 1.1×10^{3} dm^6 mol^{-2} s^{-1}, respectively, at 130 °C. Probable mechanisms for Reactions 1 and 2 have been offered on the basis of the reaction order for each molecular species involved.

Obviously, the symmetry of the fulvalene system demands that the central double bond has no dipole moment; however, it would also be expected that it has unusual properties.[1] Indeed, the bond index of that linkage is very low for a double bond and, taking 9,9′-bifluorenylidene (**1**) as an example, the linkage has an unusually high polarizability, which results in various interesting results: *e.g.*, a large molecular refraction[2] and an unusually low reduction potential.[3–5] Among the unusual reactions of fulvalenes, the reduction of the central double bond by sodium alkoxides may be a typical example, since the C=C double bond is, in general, not reducible by such weak reductants.[6] In the previous work[7] it was found that **1** is readily reduced by sodium ethoxide and gives 9,9′-bifluorenyl (**3**). In order to elucidate this mechanism, a kinetic study on reduction of **1** by sodium isopropoxide (**2**) in isopropyl alcohol (Scheme 1) has been made. Sodium isoproxide was chosen as an alkoxide because its oxidation product was acetone, which did not lead to any side reaction, and, in addition, the sequence of the reduction rate of **1** by alkoxide was methoxide<ethoxide<isopropoxide.[8]



Scheme 1.

Experimental

Reduction of **1** *by Sodium Isopropoxide.* Metallic sodium (0.23 g, 1.0×10^{-2} g-atom) was treated with 5 ml of isopropyl alcohol; the resulting solution was transferred into a glass tube. Then 0.17 g (5.2×10^{-4} mol) of **1** was added. The glass tube was sealed and heated at 130 °C in an oil bath until the orange-red color of the solution disappeared completely. After cooling, the content was poured into water and extracted with benzene–ether (1:1). The solvent was evaporated. Recrystallization of the residue from benzene gave **3**, 0.16 g (93%); mp 245 °C. This compound was identified by direct comparison with an authentic sample. On the other hand, when the chemical components in the distillate from the reduction mixture were analyzed by gas chromatography, acetone was found.

Stock Solutions of **1** *and* **3**. Compounds **1** and **3** were dissolved separately in isopropyl alcohol to a concentration of 2×10^{-3} mol dm^{-3}. These solutions were stored in a dark room and were stable for at least a month. Each solution was diluted with isopropyl alcohol as required for experiments.

Kineitc Measurements. Red compound **1** has an absorption spectrum in the visible region, with its maxium absorbance at 458 nm and with the molar absorptivity of 2.13×10^{4} dm^3 mol^{-1} cm^{-1}, probably attributable to a π-π^* electronic transition, while **3** shows no visible absorption spectrum. The decrease in the absorbance due to the reduction of **1** was a function of the time when measured spectrophotometrically. A required amount of isopropyl alcohol solution of **2** and 2.5 ml of 2×10^{-4} mol dm^{-3} solution of **1** were taken in a 25 ml volumetric flask and diluted with isopropyl alcohol up to the mark. A 5 ml of the aliquot was transferred into a glass tube, 11 mm in external diameter and about 100 mm high, which was used as both a reaction vessel and a spectrophotometric cell.[9] The tube was sealed and then immersed in an oil bath thermostated at 130 °C within an accuracy of 0.2 °C. The oil bath was covered with aluminium foil to prevent any effect of light on the reaction. The absorbance at 458 nm was measured at a given interval (at least 10 min) with a Shimadzu SP-20 spectrophotometer, after taking out the glass tube and wiping off the oil which had stuck on its outside surface. Another glass tube of the same size and quality containing isopropyl alcohol was used as the reference during the spectrophotometry.

Results

The reduction rate of **1** by **2** was measured at 130 °C for various concentrations of **2** (6×10^{-3} to 1.4×10^{-1} mol dm^{-3}) under a constant concentration of **1** (2×10^{-5} mol dm^{-3}). The dimensionless quantity X as a function of the time t was plotted in Fig. 1, where $X=[\mathbf{1}]/[\mathbf{1}]_0$: $[\mathbf{1}]_0$ and $[\mathbf{1}]$ denote the concentrations of **1** at the initial time and at the time of measure-

ment. The reduction for all the cases did not proceed appreciably at the initial stage and only began to proceed after some inductive period; the more the reduction proceeded, the greater the rate became, as seen in Fig. 1. Such behavior of X *vs.* t is frequently observed in the autocatalytic reactions such are as found in the acid-catalyzed hydrolyses of various esters and in various biochemical processes.[10,11]

A kinetic model of conversion from A to B which proceeds by an autocatalytic reaction in addition to the direct conversion would be:

$$\mathrm{A} \xrightarrow{k_1} \mathrm{B}, \tag{1a}$$

$$\mathrm{A} + \mathrm{B} \xrightarrow{k_2} \mathrm{B} + \mathrm{B}. \tag{1b}$$

If the concentrations of the molecular species A at the start and at the measurement time are denoted by A_0 and $A(t)$ and if Reactions 1a and 1b are both of the first order with respect to each substrate, the dimensionless quantity, $X_A(t)=A(t)/A_0$. and the rate, $-\mathrm{d}X_A(t)/\mathrm{d}t$, can be formalized as[10,11]

$$X_A(t) = \frac{k_1+k_2A_0}{k_1e^{(k_1+k_2A_0)t}+k_2A_0}, \tag{2}$$

$$-\frac{\mathrm{d}}{\mathrm{d}t}X_A(t) = \frac{k_1(k_1+k_2A_0)^2e^{(k_1+k_2A_0)t}}{[k_1e^{(k_1+k_2A_0)t}+k_2A_0]^2}. \tag{3}$$

In the above equations, k_1 and k_2 are the first- and second-order rate constants for Reactions 1a and 1b, respectively. The rate reaches its maximum at a particular time, t^*, which satisfies the equation, $\mathrm{d}^2X_A(t)/\mathrm{d}t^2=0$ *i.e.*,

$$k_1e^{(k_1+k_2A_0)t^*} = k_2A_0, \tag{4}$$

when $k_2A_0 \gg k_1$, Approximations 5 to 7 will be derived from the combination of Eqs. 2 to 4.

$$X_A(t^*) \simeq \frac{1}{2}, \tag{5}$$

$$-\frac{\mathrm{d}}{\mathrm{d}t}X_A(t^*) \simeq \frac{1}{4}k_2A_0, \tag{6}$$

$$k_1e^{k_2A_0t^*} \simeq k_2A_0. \tag{7}$$

Approximations 5 to 7 indicate that (i) the dimensionless quantity becomes equal to 1/2 when the conversion rate reaches its maximum, (ii) the k_2A_0 value is four times the slope of the tangential line at $t=t^*$ for the curve of $X_A(t)$ *vs.* t, and (iii) the k_1 value is obtainable with the use of Approximation 7 provided that the values of both t^* and k_2A_0 are known. All the curves of X *vs.* t measured for the reduction of **1** by **2** under the present conditions suggested that $k_2A_0 \gg k_1$, because the reduction rates were at their maximum when $X=1/2$, as seen in Fig. 1.

The apparent first- and second-order rate constants, k_1^{ap} and k_2^{ap}, for each concentration of **2** added were determined from the slope of the tangential line and from the time when $X=1/2$, with the use of Approximations 6 and 7, as indicated by a dashed line and an arrow for Curve 5 in Fig. 1: $k_1^{ap}=2.4\times10^{-10}$ s^{-1} and $k_2^{ap}=2.2\times10$ $dm^3\ mol^{-1}\ s^{-1}$ were obtained for $[\mathbf{2}]=2.0\times10^{-2}$ mol dm^{-3} from Curve 5. The $k_2^{ap}A_0$ values determined were 3.8×10^4 to 2.1×10^7 times larger than the k_1^{ap} values over the concentration range of 1.4×10^{-1} to 6×10^{-3} mol dm^{-3} for **2**.

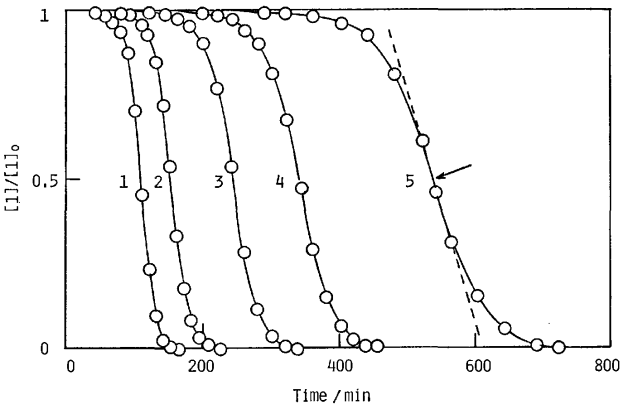


Fig. 1. Reduction of 9,9′-bifluorenylidene (**1**) by sodium isopropoxide (**2**) at 130 °C.
$[\mathbf{1}]_0$: 2.0×10^{-5} mol dm^{-3}. [**2**]: 1—8.0×10^{-2}, 2—6.0×10^{-2}, 3—4.0×10^{-2}, 4—3.0×10^{-2}, and 5—2.0×10^{-2} mol dm^{-3}.

As seen on the curves in Fig. 1, the inductive period in reduction becomes shorter with increase in the concentration of **2** added; in addition, the tangential line at the maximum rate becomes steeper, indicating that both k_1^{ap} and k_2^{ap} are dependent on the concentration of **2**. If Reactions 1a and 1b for the reduction of **1** are of the n- and m-th order with respect to **2**, the apparent first- and second-order rate constants, k_1^{ap} and k_2^{ap}, will be expressed by

$$k_1^{ap} = k_1[\mathbf{2}]^n \quad \text{and} \quad k_2^{ap} = k_2[\mathbf{2}]^m. \tag{8}$$

This is because **2** acts as the catalyst in this reaction and its concentration remains constant during the reaction. Plots of both $\ln k_1^{ap}$ and $\ln k_2^{ap}$ *vs.* $\ln$ [**2**] will give a straight line with each slope of n and m. Each linear plot with a slope of $n=3$ and $m=1$ in Figs. 2 and 3 suggests that Reaction 1a is of the third order and Reaction 1b is of the first order with respect to **2**. The values $k_1=3.0\times10^{-5}$ $dm^9\ mol^{-3}\ s^{-1}$ and $k_2=1.1\times10^3$ $dm^6\ mol^{-2}\ s^{-1}$ are obtained by extrapolating each linear part to $\ln$ [**2**]$=0$.

Summarizing the foregoing discussion, we can say

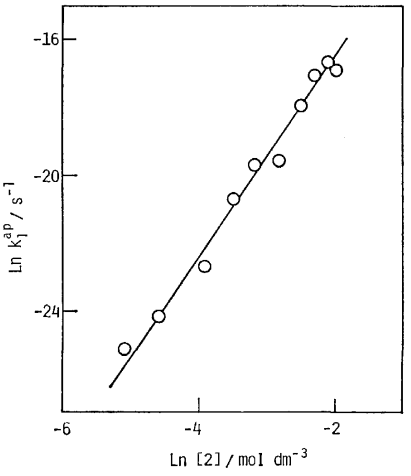

Fig. 2. Dependence of the apparent first-order rate constant, k_1^{ap}, on the concentration of sodium isopropoxide (**2**).

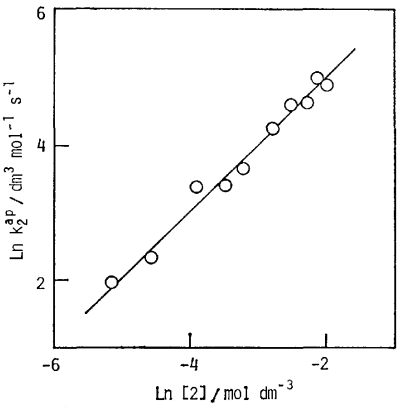

Fig. 3. Dependence of the apparent second-order rate constant, k_2^{ap}, on the concentration of sodium isopropoxide (**2**).

that the reduction of **1** by **2** in isopropyl alcohol to yield **3** proceeds by the following parallel reaction paths:

$$\mathbf{1} \xrightarrow[\mathbf{2}]{k_1} \mathbf{3}, \tag{9a}$$

$$\mathbf{1} + \mathbf{3} \xrightarrow[\mathbf{2}]{k_2} \mathbf{3} + \mathbf{3}, \tag{9b}$$

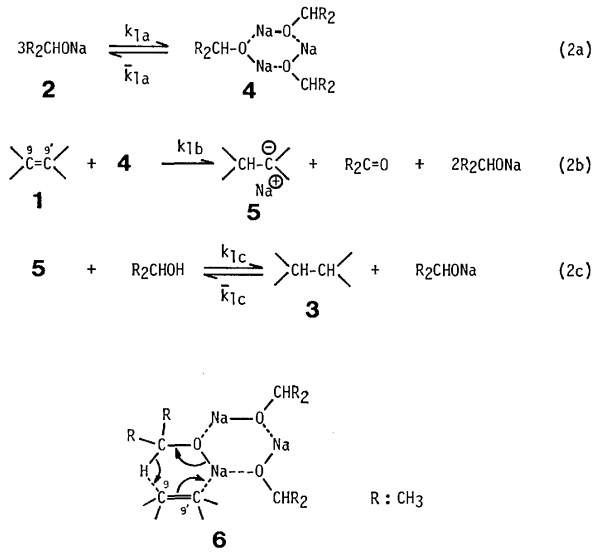
and its reduction rate is expressed by

$$-\frac{d}{dt}[\mathbf{1}] = k_1[\mathbf{2}]^3[\mathbf{1}] + k_2[\mathbf{2}][\mathbf{1}][\mathbf{3}]. \tag{10}$$

Discussion

It is of interest to note that the reaction rate for Reaction 9a is of the third order with respect to **2**. High-order reactions regarding alkoxide are frequently observed in various reductions by alkoxide, *e.g.*, the second order in reduction of nitrobenzene by sodium methoxide,[12] the first and second orders in benzophenone reduction by aluminium isopropoxide,[13] and the third and forth orders in acetophenone reduction by aluminium isopropoxide.[14] Such a high-order process regarding alkoxide is explaned by the association of alkoxide,[15] and the transition-state complex is formed between the oxidant and the associated alkoxide.[16] According to this interpretation, we offer Scheme 2 as a mechanism of Reaction 9a. The pre-equilibrium 2a between the monomer and trimer of **2** is supposed to exist. The trimer (**4**) reacts with **1** and the hydride ion from **4** is transferred to the C(9) or C(9') atom of **1** to give an intermediate carbanion (**5**) (Step 2b), which will react readily with isopropyl alcohol to yield the final product **3** (Step 2c). Step 2b with a rate constant k_{1b} may be rate-determining: a transition-state complex with a six membered ring,[17,18] as indicated in Formula **6**. Step 2c is in an equilibrium, as will be discussed later, which may shift strongly to the righthand side.

The reduction products of **1** by **2** in isopropyl alcohol were 9,9'-bifluorenyl **3** and acetone. Accordingly, one of these compounds is considered to act as the catalyst in this reaction. The reaction rate was measured in the presence of **3** or acetone. It was found that the reaction was remarkably accelerated in the presence of the former, but no effect was found for the latter. Figure 4 shows plots of X *vs.* t for the various initial concentrations of **3** when 2×10^{-5} mol dm^{-3} of **1** and 2×10^{-2} mol dm^{-3} of **2** were added. On the other hand, the dimensionless quantity $X_A(t)$ for the kinetic model (1) is expressed by Eq. 11, when the intial concentration of B (B_0) is not zero (see Appendix).



Scheme 2.

$$X_A(t) = \frac{k_1+k_2A_0+k_2B_0}{(k_1+k_2B_0)e^{(k_1+k_2A_0+k_2B_0)t}+k_2A_0} \tag{11}$$

In the case of the reduction of **1** by **2**, k_1 and k_2 in the above equation will be replaced by $k_1[\mathbf{2}]^3$ and $k_2[\mathbf{2}]$, because Reactions 9a and 9b are found to be of the third and first orders with respect to **2**, which acts as the catalyst and keeps its concentration constant during the reaction. The X values for this reaction were calculated for the various initial concentrations of **3** on the basis of Eq. 11, with the use of the k_1 and k_2 values determined above. The experimental plots in Fig. 4 can be explained reasonably by the calculated values; this confirms that the reduction product **3** acts as the catalyst.

A catalytic reaction such as indicated by Scheme 3 is offered as a probable mechanism. Product **3** reacts with **2** to give an intermediate carbanion **5** (Step 3a), which is the reverse reaction of Step 2c. An electron transfer may take place from the carbanion **5** to the compound **1** to give 9-(9-fluorenyl)fluoren-9-yl radical (**8**) and its anion radical (**7**). The protonation of the anion radical **7** to give **8** may be in a rapid equilibrium (Step 3c). One molecule of the radical **8** may attack isopropyl alcohol and an α-hydrogen atom of the alcohol may be transferred to yield a final product **3** and an alcohol radical (**9**) (Step 3d). Another molecule of the radical **8** may react with the alcohol radical **9** produced in Step 3d to yield another molecule of the product **3** and acetone (Step 3e). Step 3b with an rate constant k_{2b} may be rate-determining, because (i) Equilibria 3a and 3c may be established very rapidly and (ii) each radical involved in the process may be very

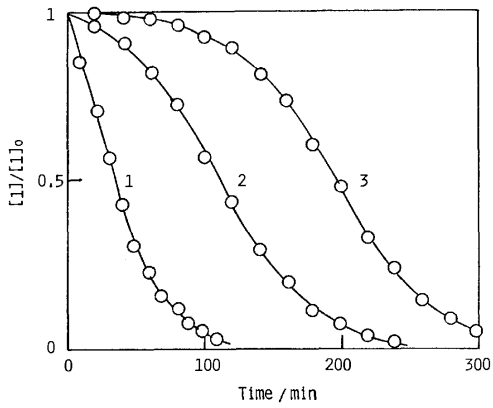


Fig. 4. Reduction of 9,9′-bifluorenylidene (**1**) by sodium isopropoxide (**2**) in the presence of added 9,9′-bifluorenyl (**3**) at 130 °C.
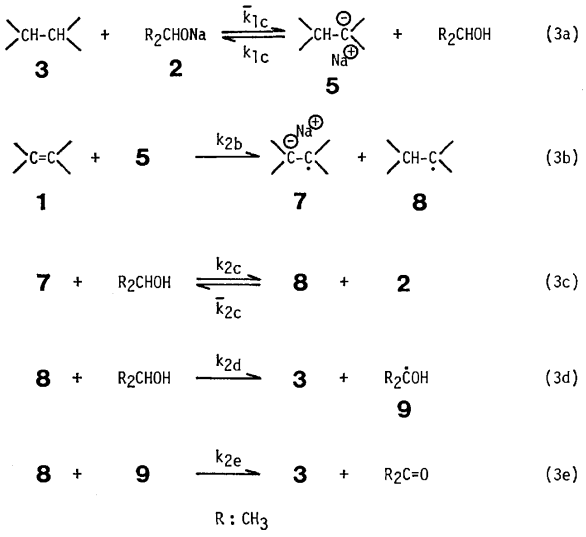
$[\mathbf{1}]_0$: 2.0×10^{-5} mol dm^{-3}. $[\mathbf{2}]$: 2.0×10^{-2} mol dm^{-3}.
$[\mathbf{3}]_0$: 1—1.0×10^{-5}, 2—1.0×10^{-6}, and 3—1.0×10^{-7} mol dm^{-3}.



Scheme 3.

reactive.

If the autocatalytic reaction actually proceeds through the foregoing steps, some amount of the pinacol might be formed. This may be explained by that the dimerization of the alcohol radical **9** does not occur in alkaline media.[19,20] The existence of the radicals **7** to **9**, and also the kinetics of various 9,9′-bifluoreylidene derivatives, are now under investigation; we must await these results before giving a valid conclusion for the autocatalytic reaction.

Usually the C=C double bond is not reducible by sodium alkoxide. Regarding Compound **1**, two fluorene moieties are not on a plane, and the central C(9)=C(9′) double bond is twisted sterically.[21,22] Furthermore, despite the symmetry of the molecule, **1** has a considerably larger molar-polarization than expected.[2] This high distortion polarization is also reflected in the particular chemical reactivity of its central double bond; it is capable of adding an organometallic compound[23,24] and amines,[25] of reacting with lithium aluminium hydride,[26] and of undergoing the Michael condensation[27,28]—all reactions typical of high polar substances. Hydrogenation of this double bond by sodium isopropoxide **2** can be interpreted along the same line. However, the direct reduction of **1** by **2**, *i.e.*, Reaction 9a, proceeds very slowly even at 130 °C, as seen in the inductive period in Fig. 1. The most important factor in its reactivity with **2** is that the process involves the autocatalytic reaction 9b; the autocatalytic reaction proceeded 3.8×10^4 to 2.1×10^7 times rapidly as the direct reaction when 2×10^{-5} mol dm^{-3} of **1** and 1.4×10^{-1} to 6×10^{-3} mol dm^{-3} of **2** were reacted.

Appendix

If each process in the kinetic model (1) is of the first order with respect to each molecular species involved, the rate of change in the concentration of A with the time is given by

$$-\frac{d}{dt}A(t) = k_1A(t) + k_2A(t)B(t). \tag{A1}$$

The initial conditions for the above equation are:

$$A(0) = A_0 \quad \text{and} \quad B(0) = B_0. \tag{A2}$$

The total concentration of A and B at any time must satisfy the equation:

$$A(t) + B(t) = A_0 + B_0. \tag{A3}$$

Under the condition A3, Eq. A1 is rewritten as

$$\frac{d}{dt}A(t) + (k_1+k_2A_0+k_2B_0)A(t) - k_2A^2(t) = 0. \tag{A4}$$

The differential equation A4 has the general solution A5:

$$A(t) = \frac{k_1+k_2A_0+k_2B_0}{Ce^{(k_1+k_2A_0+k_2B_0)t}+k_2}, \tag{A5}$$

where

$$C = \frac{K_1+K_2B_0}{A_0}. \tag{A6}$$

From Eqs. A5 and A6, $X_A(t)$ $[=A(t)/A_0]$ is derived as Eq. 9.

Hydrolysis of Carbohydrates in the Presence of a Reversed Micelle. III. Hydrolysis of Dextrin in Benzene

Kenichiro ARAI* and Yoshitaka OGIWARA
Faculty of Engineering, Gunma University, Kiryu, Gunma 376
(Received May 1, 1981)

The secondary solubilization of dextrin in a dodecylbenzenesulfonic acid (DBSH) reversed micelle in benzene containing a small amount of water was examined; a perfectly clear solution was obtained. The solution showed a CMC of DBSH, estimated by the method of Methylene Blue methachromasis, just like that of sucrose-containing similar reversed-micelle system. The hydrolysis of the dextrin in the system was investigated; the maximum rate enhancement of 285-fold was obtained on the basis of the reaction in DBSH aqueous solution. The CMC and the reaction rate showed changes similar to those in the case of sucrose-containing similar reversed-micelle system with changing the amount of water solubilized, but they showed different changes with changing the concentration of the substrate. These different changes were supposed to result from the differences in the molecular weights of the substrates. These results suggested that the rate enhancement mechanism due to solvent effect and micelle effect which was proposed for the hydrolysis of sucrose in the presence of a DBSH reversed micelle operates in the hydrolysis of the high molecular weight substrate such as dextrin.

Recently, the effective use of carbohydrates as renewable resources has again been recognized to be important. Many modifications of carbohydrates-containing raw and waste materials to, for example, a raw material for preparation of ethanol and livestock feed have been the subject of numerous investigations. In these cases, an effective and economical and if possible, selective depolymerization of the polysaccharides such as cellulose and starch in the raw material is essential.[1]

In previous papers, the hydrolysis of sucrose in the presence of dodecylbenzenesulfonic acid (DBSH) reversed micelles in a dioxane–water mixed solvent[2] and in benzene[3] was investigated. Rate enhancements up to 400-fold were observed on the basis of the reaction in an aqueous solution in the presence of hydrochloric acid. The greater part of the rate enhancement resulted from the formation of the reversed micelle.[3]

In the present paper, we report the hydrolysis of dextrin as a model of polysaccharides, which was carried out to investigate the effect of high molecular weight of the substrate on the reaction in the presence of the reversed micelle.

Experimental

Materials. Commercially available dextrin was purified by pouring a 20% aqueous solution into 5-fold volume of methanol to cause it to precipitate. The number-average molecular weight of the purified dextrin, estimated by the method of end group determination, was 66. Commercially available sodium dodecylbenzenesulfonate was passed through a cation exchange resin column to obtain a free acidic surfactant. Deionized and distilled water was used.

UV Spectrum and Maximum Amount of Solubilized Water. The UV spectra and the maximum amounts of solubilized water in benzene were obtained with the methods previously reported.[2,3]

Measurement of Reaction Rate. DBSH was dissolved in benzene and a dextrin aqueous solution was added with vigorous stirring to get a clear solution. The resulting reaction mixture was maintained at 60 °C in a thermostat, and aliquots were taken out at intervals to determine the amount of reducing sugar according to the method of Somogyi.[4] The logarithm of the ratio of [the amount of reducing sugar at reaction time infinity (r_∞)] to [the difference in the amount of reducing sugar at a reaction time t (r_t) and at infinity (r_∞)] was plotted against the reaction time. A pseudo-first-order rate constant was estimated from the slope of the straight line obtained.

Results and Discussion

In the present experiment, the first problem was whether polysaccharides such as dextrin could be solubilized in benzene in the presence of DBSH or not; polysaccharides could hardly be supposed to be solubilized easily because of their high molecular weights, at least in the same manner as occurs for low molecular weight analogs. In a preliminary experiment, however, addition of dextrin aqueous solution drop by drop to benzene with vigorous stirring was found to give a perfectly clear solution.

Then, we measured the maximum amount of solubilized water containing dextrin. Figure 1 shows the plots of the maximum amount of solubilized water containing dextrin at several concentrations in DBSH

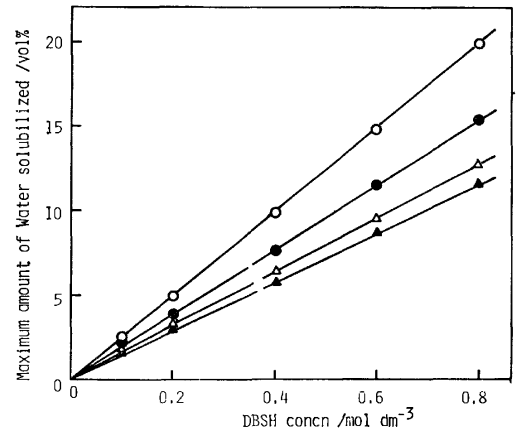

Fig. 1. Plots of maximum amount of solubilized water containing dextrin at several concentrations in DBSH benzene solution against concentration of DBSH, at room temperature.
Concentration of dextrin, %: ○, 0; ●, 2.49; △, 5.79; ▲, 17.7.

benzene solution against concentration of DBSH. The maximum amount of solubilized water was found to increase proportionally with an increasing concentration of DBSH. Figure 2 shows changes in the maximum amount of solubilized water with changing concentration of dextrin in the water. The maximum amounts of solubilized water are found to decrease with an increasing concentration of dextrin, especially in the lower range of the concentration.

The critical micelle concentration (CMC) was estimated with the method of methachromasis of Methylene Blue solubilized in the micelle; we measured the red shift of a peak in the UV spectrum of the added Methylene Blue with changing concentration of DBSH.[2] Figure 3 shows a typical change in the wavelength corresponding to the left-hand side peak in an absorption spectrum of Methylene Blue (shown in the figure), with changing concentration of DBSH. The inflection point of the sigmoidal curve obtained was presumed to be the CMC of DBSH, just as the case of a sucrose-containing reversed-micelle system. Figure 4 shows the plot of the CMC against the amount of water solubilized in the DBSH benzene solution. The CMC is found to increase proportionally with the increasing amount of solubilized water. This result does not conflict with the relationship between the maximum amount of solubilized water and the concentration of DBSH, and agrees with the change in the CMC obtained in the case of a sucrose-containing reversed-micelle system.[2] Figure 5 shows plots of the CMC against concentration of dextrin in water solubilized and the CMC's are found to increase slightly with increasing concentration of dextrin. This tendency is contrary to that observed in the case of the sucrose-containing reversed-micelle system,[3] and is supposed to result from the high molecular weight of dextrin; the higher molecular weight of the substrate is inferred to need more DBSH molecules to form the reversed micelle.

The hydrolysis of dextrin in water solubilized in DBSH benzene solution was investigated. In this case, the concentration of dextrin was expressed as moles of anhydroglucose repeating unit in the total volume, not in water alone. Figure 6 shows typical first-order plots of the amount of reducing sugar in

the reaction mixture; a fairly good straight line is obtained for each plot. A pseudo-first-order rate constant, k_1, was estimated from the slope of the straight line. Figure 7 shows plots of k_1 against concentration of DBSH. The values of k_1 are found to increase proportionally with an increasing concentration of DBSH in the range of the concentration higher than 0.30 mol dm^{-3}. No break point, such as was found in the similar plot in the case of a sucrose-containing reversed-micelle system at CMC of DBSH, was found of the plots in this range, although the CMC of DBSH in this case is in a range of 0.45 to 0.60 mol dm^{-3}. The difference may be related to the solubilizing states of the substrates; the high molecular weight of the substrate may make the solubilizing state of the substrate less stable. The details are now under investigation. The maximum apparent second-order

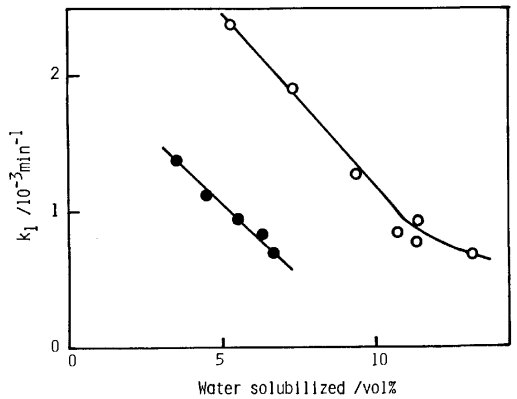

Fig. 8. Plots of k_1 against the amount of solubilized water.
Concentration of dextrin, 13.5×10^{-3} mol dm^{-3}. Concentration of DBSH, mol dm^{-3}: ○, 0.80; ●, 0.40.

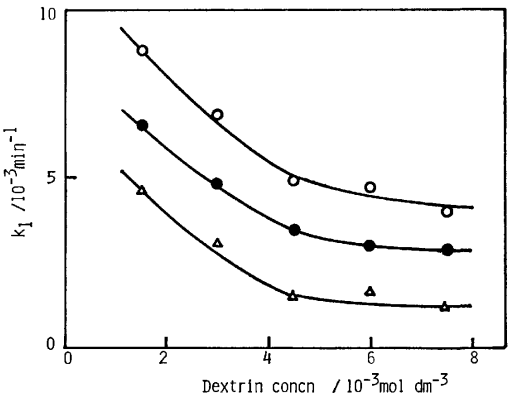

Fig. 9. Plots of k_1 against concentration of dextrin. Solubilized water, 4.77 vol%. Concentration of DBSH, mol dm^{-3}: ○, 0.50; ●, 0.40; △, 0.30.

rate constant estimated from the slope of the straight line in Fig. 7, not considering the amount of solubilized water, is 2.8×10^{-2} dm^3 mol^{-1} min^{-1}, which is about 285-times larger than that of dextrin hydrolysis in aqueous solution in the presence of DBSH normal micelle, under similar conditions.

Figure 8 shows plots of k_1 against the amount of solubilized water. The k_1 is found to decrease considerably with increasing amounts of solubilized water. Figure 9 shows plots of k_1 against concentration of dextrin. The k_1 is found to decrease with an increasing concentration of dextrin, especially in the lower range of concentration. This change in k_1 is contrary in tendency to that observed in a sucrose hydrolysis in the same reversed-micelle system. The difference may result from the difference in molecular weights of the substrates; the higher molecular weight of the substrate is inferred to lead to the less stable reversed micelle.

Conclusion

Even an addition of water containing a higher molecular weight substrate such as dextrin to the DBSH benzene reversed-micelle system gave a perfectly clear solution. The CMC of DBSH estimated

with the method of Methylene Blue methachromasis was observed in the solution, just like in the system containing the low molecular weight analogs. Furthermore in the hydrolysis reaction of the dextrin in this system, large rate enhancement, up to 285-fold, on the basis of the reaction in an aqueous DBSH solution, were observed. Some behaviors different from those in the case of sucrose in the same reversed-micelle system were found in the dependences of CMC and hydrolysis rate on the concentration of substrate and in that of k_1 on the concentration of DBSH. These different behaviors may be due mainly to the high molecular weight of dextrin; the high molecular weight of the substrate influences the stability of the reversed micelle, and consequently the association of the substrate and DBSH molecules and the activity of hydrogen ions. These results suggest that the rate enhancement mechanism due to the solvent effect and micelle effect which was observed in the hydrolysis of sucrose in the same reversed-micelle system operates also on the hydrolysis of the high molecular weight substrate such as dextrin, although the state of association of the substrate with water and DBSH is not apparent at the present time.

Photooxygenation Reaction and Chemiluminescence of (Arylmethylenehydrazono)triphenylphosphoranes. Possible Generation of Phospha-1,2-dioxetanes[1]

Nobutaka Suzuki,* Kaniti Sano, Satoshi Wakatsuki, and Yasuji Izawa
Department of Industrial Chemistry, Faculty of Engineering, Mie University, Tsu, Mie 514
(Received May 28, 1981)

Photosensitized oxygenation of (benzylidenehydrazono)-, (diphenylmethylenehydrazono)-, (9-fluorenylidenehydrazono)-, (9-xanthenylidenehydrazono)-, and (10-methyl-9,10-dihydroacridin-9-ylidenehydrazono)triphenylphosphoranes at −78 °C gave the corresponding carbonyl compounds and triphenylphosphine oxide and also gave light emission upon warming-up to room temperature.

In the course of the studies on the 1,2-dioxetanes having a hetero atom in the ring and their chemiluminescence,[1,2] we found that photosensitized oxygenation of (arylmethylenehydrazono)triphenylphosphoranes (**1a—b**) gave the corresponding carbonyl compounds (**5a—b**) and triphenylphosphine oxide (**6**) with chemiluminescent light emission (CL) upon warming-up to room temperature.[1] The reactions above can be extended to the more complex (arylmethylenehydrazono)triphenylphosphoranes (**1c—e**). This phenomenon seems to result from the generation and the decomposition of 1,2,3-dioxaphosphetanes as the intermediates (**4**), which apparently resembles to the 1,2,3-dioxathietanes found on the oxygenation of thioketones.[2] The former reactions were the first examples of chemiluminescent 1,2-dioxetanes containing one hetero atom in the ring. In the present paper, we wish to describe the oxygenation reactions of **1** in details (Fig. 1).

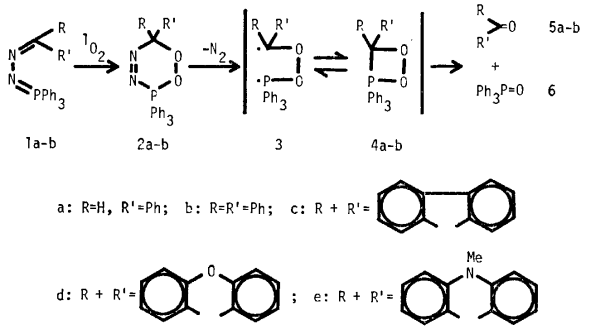

Fig. 1.

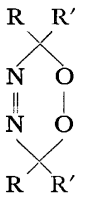
Results and Discussion

A solution of **1** (10^{-3}—10^{-2} mol/l) in CH_2Cl_2 with Methylene Blue (10^{-4}—10^{-3} mol/l) was irradiated at −78 °C with a tungsten-halogen lamp through a yellow optical filter (<510 nm cut off) with bubbling O_2. The irradiated solution gave pale-blue light emission upon warming-up to room temperature. The quantum yields of CL (ϕ_{CL}) were *ca.* 10^{-6}—10^{-7} einstein/mol relative to the luminol CL in aqueous solutions.[3] The half life time ($\tau_{1/2}$) of CL were 8.2 s (*ca.* 0 °C) for **1b** and 5.1 s for **1c** at 10^{-4} mol/l for **1**. The CL's were so weak and the $\tau_{1/2}$ were so short that the emission spectra could not be measured, and hence, the emitters were not characterized and the ϕ_{CL} were estimated approximately, provided that the emitter would be the produced ketones or the fluorescer added into the solutions. Lechtken had reported a sensitized photooxidation of acetone azine and the CL of the photooxygenation product, which was assigned to be 3,3,6,6-tetramethyl-3,6-dihydro-1,2,4,5-dioxadiazine (**7**: R=R'=Me) from the NMR spectra of the irradiated solution.[4] Talwar described similar photooxygenation of a several azines which could react through **7** (R=Ph, R'=H; R=Ph, R'=Me; R=R'=Ph).[5]

Recently, Landis and Madoux claimed on Lechtken's report that the supposed peroxide was not a cyclic peroxide **7** but a linear peroxide polymer which was formed by a free-radical oxidation initiated by $^1O_2$.[6]



7

A cold photooxygenated solution in CD_2Cl_2 of **1b** was analyzed by ^{13}C-FT NMR at −78 °C: signals centered at δ 103.25 ppm (d, J_{C-P}=197.9 Hz) were assigned as the quart. C in the 6-membered peroxide (**2b**), which disappeared thoroughly upon warming up to room temperature in 5 min. In turn, signals of benzophenone (**5b**) and triphenylphosphine oxide (**6**) took place.

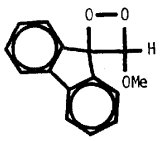
The spent solutions gave only two spots on TLC; the ketones (**5**) and triphenylphosphine oxide (**6**) almost quantitatively (GLC). These data suggest that the 6-membered peroxide (**2**) could be formed as an intermediate with the reaction of $^1O_2$ to **1** and the successive extrusion of N_2 from **2** resulted in the 4-membered peroxide (**4**) which gave the light emission.

Energy liberated on the decomposition of the supposed dioxaphosphetane (**4**) was calculated as *ca.* 66.1 kcal/mol[7] which is not large enough for exciting some of the ketones (**5**) or **6** to the S_1 states (82.3 kcal/mol for **5a**; 68.9 for **5b**; 56.0 for **5c**; 68.8 for **5d**; 65.5 for **5e**; 65.3 kcal/mol for **6**). Therefore, additional energy (maybe the activation energy) is needed for excitation of **5a—b** and **5c** to the singlet state.

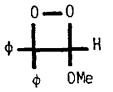
Methylene Blue, irradiation, and O_2 were essential for the present photooxygenation. On addition of

KO_2, **1** did not give **5** and/or **6**. Addition of $^1O_2$-quenchers[6] (β-carotene and 1,4-diazabicyclo[2.2.2]-octane (DABCO)) quenched the reaction. A radical scavenger (2,4,6-tri-*t*-butylphenol)[6] did not affect the reaction. These data suggest that the present photooxygenation reactions are non-radical ones initiated by $^1O_2$ and seems to support the Lechtken's mechanism rather than the Landis' one.

Apparently, the "dioxaphosphetane" derivatives, **4**, were the first chemiluminescent dioxetanes having one additional hetero atom instead of the carbon atom.[8]



8



9

Nearly all the dioxetanes studied so far give carbonyl products with lowest excited states of n,π^* configuration.[9] It is conceivable that a dioxetane giving excited carbonyls in which the excitation energy was more delocalized (in a π,π^* state) may be less stable and give relatively more singlet products (greater ϕ_{CL}). A switch from a stepwise mechanism of decomposition (*via* a short-lived diradical-like intermediate as is now generally accepted) to a concerted cleavage may then take place.[9]

Wilson *et al.*[10] compared dioxetanes (**8** and **9**), which produce fluorenone [**5c**: S_1 (π,π^*)] and benzophenone [**5b**: S_1 (n,π^*)] and found significant difference between them: *i.e.*, **8** has much smaller E_a (activation energy) and log A than **9** has. Moreover, **8** gives the singlet excited product, while **9** the triplet one. They suggested that the difference in the electronic configuration of the two ketones (π,π^* instead of n,π^*) allows a change of mechanism of dioxetane cleavage (from a two-step radical mechanism to perhaps a concerted cleavage).[10]

The present results on **1b** and **1c**, however, did not satisfy the expectation of the effect of the electronic configurations of the products on the chemiluminescence efficiency. This might be explained by the fact that **2** may give the radical intermediate (**3**) first, which decomposes directly to the products (**5** and **6**) or indirectly through the dioxaphosphetane (**4**). The direction of the decomposition is in a reverse order to the decomposition of the ordinary 1,2-dioxetanes.

Experimental

Instrumentation. All mp were uncorrected. Following spectrophotometers were used for spectral measurements: IR: JASCO IR-G and A-100; UV: Shimadzu UV-200; NMR JEOL JNM-MH-100 (100 MHz) and FX-100 (99 MHz for ^1H and 25.05 MHz for ^{13}C); MS: JEOL JMS-D-100; Fluorescence: Hitachi MPF-2A. The spectral data are presented as follows: IR in cm^{-1}; UV: in nm (ε given in parentheses); NMR: δ in ppm from int. TMS and J in Hz (accuracy ± 0.5 Hz); MS in m/z; fluorescence: λ_{max} in nm. GLC were carried out by Yanagimoto Yanaco G-80FP and G-180F.

Materials. Ketones (**5a—e**) and $Ph_3P{=}O$ (**6**) were purchased. (Arylmethylenehydrazono)triphenylphosphoranes (**1a—c**) were prepared according to the literatures. **1a**: Yellow-green granules, mp 141—142 °C (lit,[11] 141—142 °C); λ_{max} (KBr) 1435, 1100, 840 cm^{-1}; δ ($CDCl_3$) 7.42 (20H, m), 8.36 (1H, d); m/z 380 (M^+); UV: λ_{max} (CH_2Cl_2) 328 nm (ε 23000); FL: λ_{max} (CH_2Cl_2) 483 nm. **1b**: pale-yellow crystalline powder ($CHCl_3$), mp 167—174 °C (lit,[11] mp 173°); m/z 456 (M^+); UV: λ_{max} (CH_2Cl_2) 231 (ε 20400), 323 nm (9900). **1c**: yellow granules (EtOH), mp 208.5—210 °C (lit,[12] mp 209—210 °C); m/z 454 (M^+); UV: λ_{max} (CH_2Cl_2) 247 (ε 27400), 257 (14200), 294 (6900), 387 nm (10700).

*(9-Xanthenylidenehydrazono)triphenylphosphorane (**1d**)*: A solution of triphenylphosphine (3 g: 1.2×10^{-2} mol) in abs. benzene (50 ml) was cooled in an ice–salt bath under argon streams. Into the solution was added bromine (1 ml: *ca.* 1.0×10^{-2} mol) and then triethylamine (2 g: 2.0×10^{-2} mol). After the resulted solution was stood for a while at room temperature, 9-xanthenone hydrazone[13] (2.1 g: 1.0×10^{-2} mol) in abs. benzene (50 ml) was added and the mixture was stirred overnight at room temperature. After removing triethylamine·HBr with suction and evaporation of benzene gave a redish-brown oil, which resulted in crude crystals of **1d** after crystallization from $CHCl_3$, ether, and pet. ether at 0 °C. Orange-yellow granules, 0.9 g (19.1%). Main parts of the crystals were recrystallized from $CHCl_3$ and pet. ether, purified with Nylon-column chromatography (Woelm Silicagel: *ca.* 30 cm, ϕ 1.9 cm; CH_2Cl_2), and then recrystallized from EtOAc.

Yellow granules, mp 196—199 °C, Found: C, 78.88; H, 4.66%. Calcd for $C_{31}H_{23}N_2PO$: C, 79.14; H, 4.93%. m/z 470 (M^+); ν_{max} (KBr) 1450, 1030, 900 cm^{-1}; δ ($CDCl_3$) 7.26 (m), 10.20 (d); UV: λ_{max} (CH_2Cl_2) 394 (ε 14000), 296 nm (ε 6400).

*(10-Methyl-9,10-dihydroacridin-9-ylidenehydrazono)triphenylphosphorane (**1e**)*: A solution of 9-(*N'*-formylhydrazono)-10-methyl-9,10-dihydroacridine[14] (0.7 g: 2.8×10^{-3} mol) in 15% $HClO_4$ (12 ml) was heated at 100 °C for 2 min and then cooled to room temperature. The resulted perchlorate was collected and recrystallized from EtOH containing a few drop of $HClO_4$ to give dark-tan needles, mp>300 °C. Yield 0.51 g (56.7%). ν_{max} (KBr) 1590, 1465, 760 cm^{-1}; δ (DMSO-d_6) 7.82 (d), 7.40 (m), 3.94 (s). This was used immediately for the following preparation.

To a solution of the perchlorate (565 mg: 1.75×10^{-3} mol) and KOH (1.2 g: 2.1×10^{-2} mol) in EtOH (100 ml) was added HgO (red: 0.4 g: 1.85×10^{-3} mol) and the mixture was stirred overnight at room temperature under argon streams. To the filtrate of the mixture was added a solution of Ph_3P (0.46 g: 1.76×10^{-3} mol) saturated in ether under argon streams and the resulted mixture was stirred overnight at room temperature. After evaporation, the mixture was chromatographed on silica gel (Woelm: 30 cm, ϕ 1.9 cm; CH_2Cl_2). Reddish-brown needles, mp $\approx$189 °C: Yield, 75.4 mg (19.5%). Found; C, 79.66; H, 5.30%. Calcd for $C_{32}H_{26}N_3P$: C, 79.485; H, 5.420%. m/z 277 ($M^+ - 206$); ν_{max} (KBr) 1595, 1360, 1180, 740 cm^{-1}; δ ($CDCl_3$) 8.62 (d), 7.56 (m), 3.80 (s); UV: λ_{max} (CH_2Cl_2) 400 (ε 16000), 382 (12000), 306 (4700), 293 nm (7400).

*Sensitized Photooxygenation of **1a—e**.* A solution of **1** (10^{-3}—10^{-2} mol/l) in CH_2Cl_2 (dried over CaH_2: 5 ml) containing Methylene Blue (10^{-4}—10^{-3} mol/l) was irradiated in a Pyrex cell (ϕ 10 mm) or a quartz cell (ϕ 10 mm) at −78 °C with bubbling O_2 with a 300 W tungsten-halogen lamp (Kondo/Sylvania Projector lamp; ELH 120 V/300 W at 100 V) through a yellow optical filter (Toshiba

a) Q: Quenched. b) N: Not effected.

O-52: <510 nm cut off) for 60 min.

Chemiluminescence with/without Fluorescer. The irradiated solutions as above were warmed up to room temperature with/without fluoresceres (9,10-dibromo- and 9,10-diphenylanthracene, or rubrene: 10 mmol/l) in the cell chamber of MPF-2A and the light emitted was recorded. The quantum yields are shown in Table 1.

*^{13}C-NMR of the Irradiated Solution of **1b** in CD_2Cl_2.* CD_2Cl_2 Solution irradiated as above in a Pyrex NMR tube was analysed by ^{13}C-FTNMR at −78 °C. δ (TMS) 103.25 (d, J=197.9) at −78 °C, disappeared when warmed-up to room temperature for 5 min.

Product Analyses. The spent solutions of the irradiated samples were analysed by GLC and TLC: only two spots on TLC were appeared and identified as the ketones and Ph_3PO, which were estimated by GLC as shown in Table 1.

Effect of Inhibitors on CL. Inhibitors were added into the solutions and the effect on the photochemical reactions and the CL was estimated (Table 2).

We thank Drs. T. Kondo and H. Nakamura and Professor T. Goto, Nagoya University, for their taking MS and FT NMR and the Ministry of Education, Science, and Culture of Japan for the financial support (Grant-in-Aid).

Preparation and Conformational Properties of Several 1,8-Diarylnaphthalenes

Eiichi Ibuki,* Shigeru Ozasa, Yasuhiro Fujioka, and Hiroshi Mizutani†

Department of Organic Chemistry, Kyoto College of Pharmacy, Misasagi-nakauchi-cho, Yamashina-ku, Kyoto 607

(Received June 5, 1981)

Six new 1,8-diarylnaphthalenes, each having closely held parallel aromatic rings, were synthesized by a Kharash-type Grignard cross-coupling of arylmagnesium iodide and 1,8-diiodonaphthalene in the presence of *N,N'*-bis(1-methyl-3-oxobutylidene)ethylenediaminatonickel(II) as a catalyst. Among them, 1,8-di(1-naphthyl)naphthalene was obtained as *cis* and *trans* rotamers, caused by the restricted rotation at the 1,8-position. Interconversion between the rotamers on heating above their melting points was confirmed by differential scanning calorimetry. The proton magnetic resonance spectral studies of the 1,8-diarylnaphthalenes indicated the presence of a face-to-face arrangement of aromatic rings in the peri-position. Two new 8,8'-diaryl-1,1'-binaphthyls, each having two sets of closely held parallel aromatic rings, were isolated as minor coupling products. *Trans-trans* conformations were proposed for them on the basis of their thermal behavior. Several nickel(II) complexes were found to be effective catalysts for preparative Grignard cross-coupling reaction involving closely crowded geometry.

A number of compounds having closely held parallel aromatic rings, *e.g.* paracyclophanes,[1] janusene,[2] 1,8-diarylnaphthalenes,[3] diarylanthracenes,[4] have been synthesized and studied extensively in view of their specific geometry and their inherent strain due to steric overcrowding. Most of their unusual properties have been ascribed to the existence of such molecules in conformations in which the two benzene rings lie parallel to one another. Recently, Clough and Roberts[5] have found that 1,8-di(*o*-tolyl)naphthalene could be resolved into *cis* and *trans* isomer pair due to a restricted rotation around the tolyl-naphthyl bonds. The two isomers were found to be stable in the crystalline state, but interconversible in solution having a half-life of about one day at room temperature.

The present study was undertaken to synthesize stable rotational isomer pairs of a series of closely related 1,8-diarylnaphthalenes having adjacent parallel π-systems, and to elucidate their structure-physical property correlations. Thus six new 1,8-diarylnaphthalenes (**1**—**6**), having biphenylyl, naphthyl, or terphenylyl groups in the peri-position, were synthesized. Their infrared (IR), ultraviolet (UV), and proton magnetic resonance (^{1}H-NMR) spectra were measured, and the relationship is discussed between the structures and physical properties of the diarylnaphthalenes, especially the characteristics due to the presence of adjacent face-to-face arrangement of two benzene rings. In addition, the characterization and interconversion of the stable *cis* and *trans* rotational isomers of 1,8-di(1-naphthyl)naphthalene (**4**) are also described.

For the synthesis of 1,8-diarylnaphthalenes, the Kharash-type Grignard cross-coupling reaction of the Grignard reagent derived from an appropriate aryl iodide and 1,8-diiodonaphthalene in the presence of nickel(II) complex as a catalyst was employed. Though the similar cross-coupling reaction has already been used for the synthesis of 1,8-di(*o*-tolyl)naphthalene,[5] we introduced the diarylnaphthalenes under modified reaction conditions.

Preliminary experiments using phenylmagnesium iodide and each of two nickel(II) complexes, bis(acetylacetonato)nickel(II) [Ni(acac)$_2$] and *N,N'*-bis(1-methyl-3-oxobutylidene)ethylenediaminatonickel(II) [Ni(acaen)],[6,7] to provide 1,8-diphenylnaphthalene (**7**) indicated that the relative activities of the two complexes were essentially the same (the yields of **7** are 67 and 66%, respectively). Furthermore, alternate preliminary experiments using 1-naphthylmagnesium iodide and each of the following nickel(II) complexes to provide 1,8-di(1-naphthyl)naphthalene showed that all the complexes except potassium tris(L-prolinato)niccolate(II) trihydrate [K[Ni(L-pro)$_3$]·

† Present address: Osaka Kosei-nenkin Hospital, Fukushima, Fukushima-ku, Osaka 553.

$3H_2O$][8] effectively catalyzed the coupling reaction involving considerably crowded geometry: $Ni(acac)_2$, Ni(acaen), bis(4-imino-2-pentanonato)nickel(II) [$Ni(acNH)_2$],[8] bis(η-cyclopentadienyl)nickel(II) [$Ni(C_5H_5)_2$],[8] bis(salicylaldehydato)nickel(II) dihydrate [$Ni(sal)_2 \cdot 2H_2O$],[8] bis(trifluoroacetylacetonato)nickel(II) [$Ni(tfa)_2$],[8] and $K[Ni(L\text{-}pro)_3] \cdot 3H_2O$ (Table 1). On the basis of the foregoing results, Ni(acaen) was used as a catalyst in the preparative experiments.

Among the iodo compounds used, iodobiphenyls[9] (2- (**26**), 3- (**27**), and 4-iodobiphenyl (**28**)) and 2'-iodo-*p*-terphenyl (**31**)[10] were prepared by the methods previously reported. 2'-Iodo-*m*-terphenyl (**33**) was derived by the Ullmann coupling of 1,3-dibromo-2-nitrobenzene and iodobenzene,[11] followed by reduction and then conversion into the iodo compound by the usual method. Although, 1-iodo- (**29**) and 1,8-diiodonaphthalene (**8**)[4] were prepared from corresponding amino compounds, 2-iodonaphthalene (**30**) and iodobenzene (**32**) were commercially available.

The coupling reaction was proceeded by adding a solution of diiodo compound (**8**) and nickel(II) complex (0.1—0.3 mol%) in benzene as a single batch to a refluxing solution of each arylmagnesium iodide (4 fold to 8 fold excess) in an ether–benzene mixture. The reaction products were subjected to column chromatography on alumina. The 1,8-diarylnaphthalenes (**1**—**7**)[12] and by-products thus obtained are given in Table 2.

Table 1. Catalytic activity of various nickel complexes for the cross-coupling of $1\text{-}C_{10}H_7MgI$ with $C_{10}H_6I_2$(1,8-) (**8**)[a]

Catalyst	Conversion of **8**	Products (Yield/%)[b]		
	%	**4**	**17**	**29**

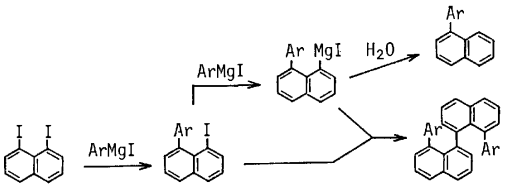
The hitherto-unknown 1,8-diarylnaphthalenes (**1a**, **1b**, **2**, **3**, **4a**, **4b**, **5**, and **6**) thus prepared and 8,8'-diaryl-1,1'-binaphthyl (**16** and **17**) thus isolated as minor products, gave satisfactory analytical results and spectral data (IR, UV, and MS) consistent with the indicated structures. In the coupling reaction, rather low yields of diarylnaphthalenes (**1**—**5**) (27—42%) as compared with that of **7** (58%) may due to enhanced overcrowded conformations of the formers. Furthermore, a very low yield of **6** (11%) and unsuccessful result in the attempted coupling of **8** and Grignard reagent derived from **33**, may also be attributable to the steric crowd during the course of the reactions. The table also shows the formation of 1-arylnaphthalenes (**9**—**14**)[13] and 8,8'-diaryl-1,1'-binaphthyls (**16**—**18**) as common and uncommon by-products, respectively. These by-products formations may reasonably be ascribed to have proceeded *via* the process of Grignard exchange[14] between the Grignard reagent and the iodo compound as follows. In most of the coupling reactions, homo-coupling products (**20**—**25**) of the Grignard reagents were also isolated.



Among the diarylnaphthalenes, **1** was obtained in two forms, **1a** (plates, mp 144.8—145.7 °C) and **1b** (needles, mp 150.3—151.3 °C), from cyclohexane. Repeated crystallizations of **1a** from ethanol yielded **1b**. Both **1a** and **1b** gave slightly different IR spectra, but practically identical ^{1}H-NMR, UV, and mass spectra. The DSC curve for melting of **1a** showed an endothermic peak at 144 °C. After two weeks' annealing period, however, the second run of the melt showed two peaks at 144 °C and 149 °C. While, the DSC curve of **1b** showed a peak originally at 150 °C, after two weeks the second run of the melt showed a new small peak at 144 °C together with the original one at 149 °C. The thermoanalytical analyses suggest the formation of an equilibrium mixture of **1a** and **1b** at or above 150 °C. Though lacking a conclusive proof, it seems very likely that **1a** and **1b** are a rotational isomer pair.

On the other hand, **4** was obtained as more soluble needles **4a** (mp 155.4—156.8 °C) and less soluble plates **4b** (mp 173.3—174.2 °C) in a benzene–ethanol mixture. Both **4a** and **4b** revealed similar UV, slightly different IR, and different ^{1}H-NMR spectra which were found to be compatible with *cis* and *trans* conformations, respectively. The DSC curve of **4a** showed endothermic peaks at 158 °C and 173 °C, having approximately the intensities of 2:1. After cooling, the second run of the melt also showed two peaks at practically the same temperatures but having reverse intensities of 1:5. Further run of the melt did not exhibit any appreciable change compared with

that of the second. However, **4b** displayed at first only one peak at 174 °C. The second run of the melt showed practically the same DSC curve as that of the second run of **4a**, having two peaks at 157 °C and 173 °C with approximate intensities of 1:5. In addition, ^{1}H-NMR spectra ($CDCl_3$) of both melts of each second run of **4a** and **4b** are superimposable, and are compatible to that of a mixture of **4a** and **4b**. On the basis of the foregoing results, it was clarified that **4a** (*cis*) and **4b** (*trans*) were interconversible by heating, and that either of **4a** (*cis*) and **4b** (*trans*) formed same equilibrium mixture of a ratio of approximately 1:4 at or above 176 °C.[15] Both rotamers **4a** and **4b** are quite stable in a solution ($CDCl_3$) at room temperature over two weeks. The stability seems to be remarkable as compared with the half-life of only about one day in solution with respect to interconversion between *cis* and *trans* of 1,8-di(*o*-tolyl)naphthalene at room temperature.[5] Though the *cis* rotamer **4a** would be achiral, the *trans* rotamer **4b** would be a racemic mixture. Identification of the antipodes by resolution was not attempted.

Another crowded diarylnaphthalene, **6** was obtained as colorless needles mp 225.6—227.6 °C, presumably having a *trans* conformation on the basis of its heat stable character.[16] Analogously, both heat stable 8,8′-diaryl-1,1′-binaphthyls, **16** and **17**, may possibly be considered to have *trans-trans* conformations.[16] Although, each of these compounds, **6**, **16**, **17**, and **18**, would be a racemic mixture, their resolutions were not attempted. Each of the other diarylnaphthalenes (**2**, **3**, and **5**) proved to be single substances suggesting a sufficiently low energy barrier to rotation of two aryl rings around the bonds at the peri-position.[4]

The IR spectra of the 1,8-diarylnaphthalenes and related compounds were measured by the KBr-disk method and their characteristic bands in the 680—915 cm^{-1} region were tentatively assigned. These bands are consistent with the kinds of aryl groups and naphthalene ring(s) comprising each of the compounds. All of the compounds show very similar spectra to those of polyphenyls.[9-11] In addition, the characteristic C–C out-of-plane bending vibration bands of substituted naphthalene were observed commonly in the 800—850 cm^{-1} region. However, no significant spectral differences between 1-aryl- and corresponding 1,8-diarylnaphthalenes (presumably due, if any, to the face-to-face arrangement of two benzene or naphthalene rings in the peri-position) were noticed.

18

The slightly different spectra of **4a** and **4b** in the regions 770—780 cm^{-1} and 820—840 cm^{-1}, assignable to C–H out-of-plane bending on the 1-naphthyl ring and to C–C out-of-plane bending of the naphthalene ring, may be ascribed to their *cis* and *trans* conformation, respectively.

The UV spectra of the 1,8-diarylnaphthalenes and related compounds were measured in cyclohexane solution.

The absorption curves of **4** and **17** were related closely to that of **12**, which corresponds to structural unit of **4** and **17**. Thus, a blue shift and an increase in intensity of the band at 223 nm of **12** with an increase of 1-naphthyl unit were observed.

The spectra of the *cis* rotamer **4a** and the *trans* rotamer **4b** were found to be practically identical. This suggests the lack of significant transannular π-electronic interaction between parallel peri-naphthyl rings of **4a** and **4b**, presumably due to the remote distance of the parallel rings beyond the limit of interaction.[17] Both spectra of 8,8′-diaryl-1,1′-binaphthyls, **18** and **16**, showed similarly a significant red shift (near 316 nm) as compared with that of simpler analog **12**. However, it is difficult to ascertain whether the shifts are due to an increase of aromatic rings[18] or to the transannular π-electronic interaction of parallel aromatic rings. Among the spectra of 1,8-di(biphenylyl)-naphthalenes, that of **3** revealed an increase in intensity of the E-band and a red shift of the longest wavelength absorption band as compared with that of **11**. The spectral differences of **1** with **9**, and of **2** with **10** are essentially similar to that of **7** with **14**.

The foregoing UV spectral results indicated that no significant influence originated from the face-to-face arrangement of the aromatic rings in the peri-positions.

The ^{1}H-NMR spectra of the diarylnaphthalenes and related compounds were measured at 80 MHz in $CDCl_3$ solution.

In the spectrum of the simplest 1,8-diarylnaphthalene **7**, a sharp singlet of phenyl protons appears at higher field by approximately 0.5 ppm compared with that of the monoaryl analog **14**, owing to the anisotropic effect of the faced benzene rings. This high field shift may be comparable to those observed for the faced aromatic protons of [2.2]paracyclophane (δ 6.37)[19] and of janusene (δ 6.60)[2a] as compared with those of *p*-xylene (δ 7.05)[20] and of *o*-xylene (δ 7.10),[2a] respectively. In the spectra of **1**, **2**, and **5**, the aromatic proton signals were also observed at rather high field region as compared with those of corresponding monoaryl analogs **9**, **10**, and **13**, sug-

gesting the presence of a face-to-face arrangement of benzene or 2-naphthyl rings in the peri-position. In the case of **3**, a sharp singlet, which can be assigned to the protons of both phenyl rings, is observed at lower field than that of **7** but similar to that of **14**, indicating that the faced phenyl rings are situated further apart from each other than in **7**.

In the spectrum of isomer **4b**, the chemical shift of naphthyl-C_4 protons (δ 7.03) is nearly comparable to that of the phenyl protons of **7**, whereas the signals of naphthyl-C_2,C_3 protons are shifted appreciably toward higher field presumably owing to the ring current effects caused by the partially parallel naphthyl rings. Analogous but more prominent upfield shifts over 1 ppm have been observed in the spectrum of *anti*-[2.2](1,4)anthracenophane, in which C_2, C_3-protons were located nearly above the opposed anthracene ring.[21] Spectrum of isomer **4a**, however, shows quite different signal pattern of naphthyl-C_2,C_3,C_4-protons (δ 7.00—6.65), but similar signals for other protons in the spectrum of **4b**. Although an assignment of the former pattern is difficult, lack of the characteristic signals of **4b** in the high filed region (δ 6.50—6.14) reflects undoubtedly the absence of protons located nearly above the opposite naphthalene ring.

Thus the foregoing spectral aspects on **4a** and **4b** are obviously compatible with the proposed conformations as *cis* and *trans* rotamers, respectively.

Experimental

Instruments. Low melting points were determined with a Mettler FP-51 or FP-52 apparatus; for those above 300 °C, a Shimadzu DSC-30M differential scanning calorimeter was employed. The calorimeter was also used for thermoanalytical purpose. The UV spectra were measured on a Shimadzu MPS-50L spectrophotometer, IR spectra on a Leitz III-G spectrophotometer, and ^{1}H-NMR spectra on a Varian CFT-20 spectrometer at 80 MHz, using TMS as an internal standard. The molecular weights were determined with a Hitachi RMU-6E mass spectrometer. Quantitative GLPC was performed on a Shimadzu GC-5APTF gas chromatograph using a 1 m×3 mm ϕ glass column 3% Silicone OV-17 on Chromosorb W AW-DMCS.

Materials. 2- (**26**), 3- (**27**), and 4-Iodobiphenyl (**28**),[9] 2′-iodo-*p*-terphenyl (**31**),[10] *N*,*N*′-bis(1-methyl-3-oxobutylidene)ethylenediaminatonickel(II), bis(4-imino-2-pentanonato)nickel(II), bis(salicylaldehydato)nickel(II) dihydrate, bis(trifluoroacetonato)nickel(II), and potassium tris(L-prolinato)niccolate(II) trihydrate[7] were prepared as reported previously. 2′-Iodo-*m*-terphenyl (**33**) was prepared by the Ullmann cross-coupling of 1,3-dibromo-2-nitrobenzene[11] and iodobenzene, followed by reduction and iodo-substitution of the corresponding diazonium compound. Colorless prisms, mp 114.4 °C (Found: C, 60.99; H, 3.87%. Calcd for $C_{18}H_{13}I$: C, 60.69; H, 3.68%). 1-Iodonaphthalene (**29**) was prepared from 1-aminonaphthalene by the usual method. A colorless oil, bp 117—121 °C/2.66×10^2 Pa. 1,8-Diiodonaphthalene (**8**) was prepared by the method used by House *et al.*[4] Tan prisms, mp 110 °C (lit,[4] mp 108.5—110 °C) (Found: C, 31.88; H, 1.63%). 2-Iodonaphthalene (**30**), iodobenzene (**32**), bis(acetylacetonato)nickel(II), and bis(η-cyclopentadienyl)nickel(II) were commercially available.

General Procedure of Grignard Cross-coupling. Magnesium turnings were placed in a four-necked round-bottomed flask equipped with a reflux condenser. To the flask was added *ca.* 20% of an ethereal solution of aryl iodide (c: 0.8—1.0 mol dm^{-3}) under nitrogen atmosphere, and the mixture was stirred and (if necessary) heated to initiate the reaction. The remaining aryl iodide solution was added dropwise just rapidly enough to maintain a gentle reflux (*ca.* 45 min). After additional 0.5 h heating, the resulting solution was diluted with half its volume of benzene. To the refluxing Grignard reagent was added all at once a hot benzene solution of **8** (c: 0.3 mol dm^{-3}) and a catalyst Ni(acaen) (0.13 mol%, based on Grignard reagent), and the reflux then continued to complete the reaction. After cooling, the mixture was hydrolyzed with concentrated ammonium chloride solution. The resulting mixture was extracted with benzene. The organic layer was separated, washed with water, and then dried. The crude mixture, remaining after removal of the solvent, was subjected to chromatography on alumina with a mixture of cyclohexane and benzene as eluent to separate into each product.

Preparation of 1,8-Diphenylnaphthalene (7). The Grignard reagent prepared from the aryl iodide **32** (4.90 g, 24 mmol) was treated with **8** (2.28 g, 6 mmol) in the presence of Ni(acaen) (8.4 mg, 0.03 mmol) and the mixture was refluxed for additional 10 min, as described in the general procedure. The benzene extract of the product was chromatographed on alumina with a cyclohexane–benzene (9:1, v/v) mixture (C–B(9:1)) to separate into the following compounds.

7: Colorless needles from cyclohexane; mp 151.0 °C lit,[3a] mp 149.5—150.5 °C); yield, 0.98 g (58.0%). IR: 698 vs, 706 m (γ_{C-C}, B); 750 s, 758 s, 765 m (γ_{C-H}, M); 775 vs (γ_{C-H}, d); 829 s, 843 m (γ_{C-C}, N); 880 w.[22] UV: $\lambda_{max}(\varepsilon)$ 198 (42400), 215 (39900), 237 (57700), 302 nm (12000) (lit,[3a] $\lambda_{max}(\varepsilon)$ (95% ethanol) 235.5 (54500), 300 nm (11500)). ^{1}H-NMR δ: 6.89 (10H, s, C_6H_5); ν_2 7.36, ν_3 7.49, ν_4 7.90 (6H, $J_{2,3}$=7.0 Hz, $J_{3,4}$=8.5 Hz, $J_{2,4}$=1.4 Hz, $C_{10}H_6$). (Found: C, 94.38; H, 5.92%; mol wt, 280 (M^+)).

1-Phenylnaphthalene (**14**): A colorless oil (lit,[23] bp 147—154 °C/133—160 Pa); 0.18 g (14.8%). IR: 702 s (γ_{C-C}, B); 735 w; 758 s (γ_{C-H}, M); 775 s (γ_{C-H}, α); 800 s (γ_{C-H}, α; γ_{C-C}, N); 840 w (γ_{C-C}, N); 866 w, 909 w. UV: $\lambda_{max}(\varepsilon)$ 227 (65200), 288 nm (10900). ^{1}H-NMR δ: 7.42 (5H, s, C_6H_5), 7.30—8.00 (7H, m, other protons).

8,8′-Diphenyl-1,1′-binaphthyl (**18**): Colorless prisms from cyclohexane; mp 208.9—210.7 °C (lit,[4] mp 210.5—212.0 °C); 0.15 g. IR: 696 vs, 709 m (γ_{C-C}, B); 750 m, 763 s (γ_{C-H}, M); 770 vs (γ_{C-H}, d); 821 s, 831 m (γ_{C-C}, N). UV: $\lambda_{max}(\varepsilon)$ 195 (55200), 220 (52600), 240 (sh) (34800), 318 nm (12700) (lit,[4] $\lambda_{max}(\varepsilon)$ (95% ethanol), 221 (58000), 248 (sh) (29000), 285 (11000), 315 nm (12000)). ^{1}H-NMR δ: 6.05—6.65 (10H, m, C_6H_5), 6.90—7.63 (12H, m, $C_{10}H_6$). (Found: C, 94.82; H, 5.71%; mol wt, 406 (M^+)).

Perylene: Yellow plates from benzene; mp 274.7—275.7 °C (lit,[24] mp 274—275 °C); 0.01 g.

Preparation of 1,8-Di(2-biphenylyl)naphthalene (1). The Grignard reagent prepared from the aryl iodide **26** (48.8 g, 160 mmol) was treated with **8** (7.6 g, 20 mmol) in the presence of Ni(acaen) (0.14 g, 0.5 mmol), and the mixture was refluxed for additional 2 h. The benzene extract of the product, after removal by distillation under reduced pressure of a large part of the biphenyl and naphthalene, was subjected to chromatography on alumina with a C–B (9:1) mixture and separated into the following compounds.

1a: Obtained by concentration and cooling of the mother liquor of **1b**; colorless plates from cyclohexane; mp 144.8—

145.7 °C; 0.31 g (3.4%). IR: 697 sh s, 701 s (γ_{C-C}, B); 720 m, 738 vs, 747 m, 758 s (γ_{C-H}, M, *o*); 772 s (γ_{C-H}, d); 829 s, 847 w (γ_{C-C}, N). Repeated crystallizations of **1a** from cyclohexane or ethanol gave **1b**.

1b: Colorless needles from cyclohexane; mp 150.3—151.3 °C; 2.12 g (23.3%). IR: 701 s, 706 sh s (γ_{C-C}, B); 720 m, 740 vs, 752 s (γ_{C-H}, M, *o*); 775 s (γ_{C-H}, d); 831 s, 846 w (γ_{C-C}, N). UV: $\lambda_{max}(\varepsilon)$ 204 (72500), 218 (sh) (65100), 244 (sh) (42800), 294 nm (10100). ^{1}H-NMR δ: 7.60—7.65 (2H, q, C_4–, C_5–H of $C_{10}H_6$), 6.75—7.30 (22H, m, other protons). Found: C, 94.70; H, 5.32%; mol wt, 432 (M^+). Calcd for $C_{34}H_{24}$: C, 94.40; H, 5.60%; mol wt, 432.

1-(2-Biphenylyl)naphthalene (**9**): Colorless fine needles from ethanol; mp 113.2—114.4 °C; 1.32 g (22.4%). IR: 699 s (γ_{C-C}, B); 738 m, 745 s, 751 s (γ_{C-H}, M, *o*, α); 770 s (γ_{C-H}, *o*, α); 780 vs, 795 m (γ_{C-H}, α); 803 s (γ_{C-H}, α; γ_{C-C}, N); 866 w, 882 w. UV: $\lambda_{max}(\varepsilon)$ 205 (59300), 225 (60200), 290 nm (9600). ^{1}H-NMR δ: 7.00 (5H, s, C_6H_5), 7.18—7.90 (11H, m, *o*-C_6H_4 and $C_{10}H_7$). Found: C, 94.35; H, 5.83%. Calcd for $C_{22}H_{16}$: C, 94.24; H, 5.76%.

trans, trans-8,8′-Di(2-biphenylyl)-1,1′-binaphthyl (**16**): Colorless plates from hexane; mp 270.8—272.1 °C; 0.46 g. IR: 705 s (γ_{C-C}, B); 737 s, 743 vs, 755 s (γ_{C-H}, M, *o*); 762 sh m, 772 vs (γ_{C-H}, d); 820 m, 830 m, 849 w (γ_{C-C}, N); 866 w. UV: $\lambda_{max}(\varepsilon)$ 203 (81400), 224 (77200), 254 (sh) (33300), 316 nm (10400). ^{1}H-NMR δ: 6.25—7.65 (30H, m, all protons). Found: C, 94.30; H, 5.17%; mol wt, 558 (M^+). Calcd for $C_{44}H_{30}$: C, 94.58; H, 5.42%; mol wt, 558.

1,1′:2′,1″:2″,1‴-Quaterphenyl (**20**): Colorless cubes from ethanol; mp 118.7 °C (lit,[9] mp 118—119 °C); 1.86 g.

Preparation of 1,8-Di(3-biphenylyl)naphthalene (2). The Grignard reagent prepared from the aryl iodide **27** (16.8 g, 60 mmol) was treated with **8** (3.8 g, 10 mmol) in the presence of Ni(acaen) (20 mg, 0.07 mmol), and the mixture was refluxed for additional 2.5 h. The benzene extract, after removal by distillation of a large part of the biphenyl and naphthalene, was chromatographed on alumina with C–B(9:1), C–B(4:1), and finally with C–B(1:1).

2: Colorless needles from benzene–ethanol; mp 148.4—150.3 °C; 1.79 g (41.4%). IR: 697 s, 706 s (γ_{C-C}, B); 754 s, 756 s (γ_{C-H}, M); 778 s (γ_{C-H}, *m*, d); 799 m (γ_{C-H}, *m*, d; γ_{C-C}, N); 833 s, 849 w (γ_{C-C}, N); 892 m (γ_{C-H}, *m*). UV: $\lambda_{max}(\varepsilon)$ 204 (70900), 231 (67100), 302 nm (15100). ^{1}H-NMR δ: 7.85—8.01 (2H, q, C_4–, C_5–H of $C_{10}H_6$), 6.90—7.63 (32H, m, other protons). Found: C, 94.11; H, 5.33%; mol wt, 432 (M^+). Calcd for $C_{34}H_{24}$: C, 94.40; H, 5.60%; mol wt, 432.

1-(3-Biphenylyl)naphthalene (**10**): A colorless oil; 1.02 g (36.7%). IR: 690 m, 698 s, 707 s (γ_{C-C}, B); 754 s (γ_{C-H}, M, α); 778 s, 792 s (γ_{C-H}, *m*, α); 799 s (γ_{C-H}, *m*, α; γ_{C-C}, N); 848 w (γ_{C-C}, N); 865 w; 897 m (γ_{C-H}, *m*). UV: $\lambda_{max}(\varepsilon)$ 205 (49600), 225 (59200), 292 nm (sh) (11400). ^{1}H-NMR δ: 7.30—8.08 (16H, m, all protons). Found: C, 94.02; H, 5.78%. Calcd for $C_{22}H_{16}$: C, 94.24; H, 5.76%.

1,1′:3′,1″:3″,1‴-Quaterphenyl (**21**): Colorless leaves from ethanol; mp 87.1 °C (lit,[9] mp 86—87 °C); 1.46 g.

Preparation of 1,8-Di(4-biphenylyl)naphthalene (3). The aryl iodide **28** (16.8 g, 60 mmol), **8** (3.8 g, 10 mmol), and Ni(acaen) (56 mg, 0.2 mmol) were worked up as described in the general procedure, and the mixture was refluxed for additional 3 h. The benzene extract was concentrated to separate a solid (1,1′:4′,1″:4″,1‴-quaterphenyl, **22**, colorless leaves). After filtration of the solid, the mother liquor was distilled to remove a large part of the biphenyl and naphthalene. The resulting residue was chromatographed on alumina with C–B(3:1), C–B(2:1), and finally with C–B(1:2).

3: Colorless needles from benzene–ethanol; mp 202.4—203.8 °C; 1.83 g (42.4%). IR: 699 s, 704 m (γ_{C-C}, B); 733 s, 762 s, 766 s (γ_{C-H}, M); 781 s (γ_{C-H}, d); 829 s, 842 s (γ_{C-H}, *p*; γ_{C-C}, N); 885 w. UV: $\lambda_{max}(\varepsilon)$ 200 (73300), 214 (sh) (59200), 241 (43700), 254 (35000), 304 nm (23300). ^{1}H-NMR δ: 7.11 (8H, d, J=1.5 Hz, *p*-C_6H_4), 7.27 (10H, s, C_6H_5), 7.35—7.73 (4H, m, C_2–, C_3–, C_6–, C_7–H of $C_{10}H_6$), 7.90—8.10 (2H, q, C_4–, C_5–H of $C_{10}H_6$). Found: C, 94.34; H, 5.89%; mol wt, 432 (M^+). Calcd for $C_{34}H_{24}$: C, 94.40; H, 5.60%; mol wt, 432.

1-(4-Biphenylyl)naphthalene (**11**): Colorless needles from benzene–ethanol; mp 149.3—150.7 °C (lit,[25] mp 147—148 °C); 0.59 g (19.2%). IR: 697 s (γ_{C-C}, B); 729 m; 739 w, 751 m, 765 vs (γ_{C-H}, M, α); 781 vs, 792 m (γ_{C-C}, α); 800 s (γ_{C-H}, α; γ_{C-C}, N); 837 m, 848 w (γ_{C-H}, *p*; γ_{C-H}, N); 873 w. UV: $\lambda_{max}(\varepsilon)$ 209 (42200), 228 (45400), 262 (16400), 294 nm (19000). ^{1}H-NMR δ: 7.30—8.10 (16H, m, all protons). (Found: C, 94.41; H, 5.62%).

Preparation of 1,8-Di(1-naphthyl)naphthalene (4). The aryl iodide **29** (20.3 g, 80 mmol), **8** (3.8 g, 10 mmol), and Ni(acaen) (70 mg, 0.25 mmol) were worked up as described for the preparation of **3**. The benzene extract, after removal by distillation under reduced pressure of a large part of the naphthalene, was chromatographed on alumina with C–B(9:1), C–B(4:1), and finally with C–B(1:1). Crystallization of the eluate with C–B(9:1) from benzene–ethanol afforded **4b**. After filtration of **4b**, the mother liquor was concentrated to afford **4a**.

cis-1,8-Di(1-naphthyl)naphthalene (**4a**): Colorless needles from benzene–ethanol; mp 155.4—156.8 °C; 0.46 g (12.2%). IR: 713 w, 724 w, 770 vs, 772 vs, 781 sh s (γ_{C-H}, α); 792 s, 796 s (γ_{C-H}, α, d); 824 w, 837 m (γ_{C-C}, N); 860 w. UV: $\lambda_{max}(\varepsilon)$ 216 (115400), 294 nm (16700). ^{1}H-NMR δ: 6.65—7.00 (6H, m, C_2–, C_3–, C_4–H of $C_{10}H_7$), 7.10—7.64 (12H, m, C_2–, C_3–, C_6–, C_7–H of $C_{10}H_6$; C_5–, C_6–, C_7–, C_8–H of $C_{10}H_7$), 7.94—8.13 (2H, q, C_4–, C_5–H of $C_{10}H_6$). Found: C, 94.90; H, 5.58%; mol wt, 380 (M^+). Calcd for $C_{30}H_{20}$: C, 94.70; H, 5.30%; mol wt, 380.

trans-1,8-Di(1-naphthyl)naphthalene (**4b**): Colorless plates from benzene–ethanol; mp 173.3—174.2 °C; 0.93 g (24.4%). IR: 714 w, 729 w; 773 vs (γ_{C-H}, α); 792 s, 797 s (γ_{C-H}, α, d); 823 m, 837 w (γ_{C-C}, N); 861 w. UV: $\lambda_{max}(\varepsilon)$ 216 (119700), 294 nm (15900). ^{1}H-NMR δ: ν_2 6.27, ν_3 6.43, ν_4 7.03 (6H, $J_{2,3}$=7.0 Hz, $J_{3,4}$=8.5 Hz, $J_{2,4}$=1.4 Hz, $C_{10}H_7$), 7.10—7.64 (12H, m, C_2–, C_3–, C_6–, C_7–H of $C_{10}H_6$; C_5–, C_6–, C_7–, C_8–H of $C_{10}H_7$), 7.94—8.13 (2H, q, C_4–, C_5–H of $C_{10}H_6$). Found: C, 94.76; H, 5.55%; mol wt, 380 (M^+). Calcd for $C_{30}H_{20}$: C, 94.70; H, 5.30%; mol wt, 380.

1,1′-Binaphthyl (**12**): Colorless plates from benzene–ethanol; mp 158.8 °C (lit,[26] mp 147.5 °C); 2.35 g. IR: 740 m, 743 w, 770 vs, 779 vs, 783 vs (γ_{C-H}, α); 805 vs (γ_{C-H}, α; γ_{C-C}, N); 869 w. UV: $\lambda_{max}(\varepsilon)$ 223 (75200), 284 (13400), 295 nm (13300) (lit,[27] $\lambda_{max}(\varepsilon)$ (95% ethanol) 221 (95500), 283 (13200), 294 nm (12900)). ^{1}H-NMR δ: 7.17—8.05 (14H, m, all protons). (Found: C, 94.16; H, 5.73%).

trans,trans-8,8′-Di(1-naphthyl)-1,1′-binaphthyl (**17**): Colorless plates from benzene; mp 287.5—288.0 °C; 0.41 g. IR: 730 m; 770 vs (γ_{C-H}, α); 791 s, 796 m, 802 m (γ_{C-H}, α, d); 826 m, 834 m (γ_{C-C}, N); 865 w. UV: $\lambda_{max}(\varepsilon)$ 212 (146400), 278 (16000), 306 nm (15100). ^{1}H-NMR δ: 6.48—7.69 (26H, m, all protons). Found: C, 95.08; H, 5.30%; mol wt, 506 (M^+). Calcd for $C_{40}H_{26}$: C, 94.82; H, 5.18%; mol wt, 506.

Preparation of 1,8-Di(2-naphthyl)naphthalene (5). The aryl iodide **30** (15.24 g, 60 mmol), **8** (3.8 g, 10 mmol), and

Ni(acaen) (56 mg, 0.2 mmol) were worked up as described for the preparation of **2**. The benzene extract, after removal by distillation under reduced pressure of a large part of the naphthalene, was subjected to crystallization from C–B(9:1). After filtration of a solid (**23**), the solvent of the filtrate was distilled off. The residue was chromatographed on alumina progressively with C–B(9:1), C–B(5:1), C–B(2:1), and finally with C–B(1:1) to give following compounds.

5: Colorless needles from benzene–ethanol; mp 142.4—144.7 °C; 1.16 g (30.5%). IR: 714 w; 738 s, 754 w (γ_{C-H}, β); 766 m, 775 s (γ_{C-H}, β, d); 804 m (γ_{C-H}, d); 814 s, 833 m, 854 m (γ_{C-H}, β; γ_{C-C}, N); 893 m (γ_{C-H}, β). UV: $\lambda_{max}(\varepsilon)$ 220 (sh) (98300), 227 (101200), 282 nm (19500). ^{1}H-NMR δ: 7.90—8.07 (2H, q, C_4–, C_5–H of $C_{10}H_6$), 6.90—7.88 (18H, m, other protons). Found: C, 94.96; H, 5.26%; mol wt, 380 (M^+). Calcd for $C_{30}H_{20}$: C, 94.70; H, 5.30%; mol wt, 380.

1,2′-Binaphthyl (**13**): Colorless needles from ethanol; mp 77.4 °C (lit,[26] mp 78 °C); 0.88 g (34.6%). IR: 737 m, 746 s, 777 s (γ_{C-H}, α, β); 794 m (γ_{C-H}, α); 801 s (γ_{C-H}, α; γ_{C-H}, N); 826 m, 833 m (γ_{C-H}, β; γ_{C-C}, N); 860 m, 866 w; 895 w (γ_{C-H}, β). UV: $\lambda_{max}(\varepsilon)$ 220 (72300), 227 (70300), 283 nm (17000) (lit,[28] $\lambda_{max}(\varepsilon)$ 219 (63100), 226 (61000), 272 (sh) (13500), 282 nm (15900)). ^{1}H-NMR δ: 7.32—7.70 (7H, m, 2-$C_{10}H_7$), 7.72—8.07 (7H, m, 1-$C_{10}H_7$). (Found: C, 94.72; H, 5.59%).

2,2′-Binaphthyl (**23**): Colorless plates from C–B(9:1); mp 186.6 °C (lit,[26] mp 187.0 °C); 0.74 g. IR: 738 s, 749 m (γ_{C-H}, β); 812 vs (γ_{C-C}, β; γ_{C-C}, N); 854 vs (γ_{C-C}, N); 883 s (γ_{C-H}, β). UV: $\lambda_{max}(\varepsilon)$ 205 (sh) (33300), 213 (44100), 248 (sh) (66700), 255 (97500), 272 (sh) (25700), 306 nm (18100) (lit,[27] $\lambda_{max}(\varepsilon)$ 212 (39800), 248 (sh) (63100), 254 (97700), 271 (sh) (27500), 280 (sh) (17000), 305 nm (19500)). ^{1}H-NMR δ: 7.22—8.22 (14H, m, all protons). (Found: C, 94.76; H, 5.57%).

Reaction of **8** *and Magnesium Compound of* **33**. Magnesium turnings (0.83 g, 34 mmol) were placed in a flask as described in the general procedure. To the flask was added a solution of **33** (12.1 g, 34 mmol) in a ether–benzene mixture (80 ml; 3:1, v/v) all at once, and the reaction mixture was refluxed for 5 h. The hot Grignard reagent thus prepared was treated with **8** (3.04 g, 8 mmol) in the presence of Ni(acaen) (22 mg, 0.08 mmol) and the mixture was refluxed for additional 3 h. The benzene extract of the product, after removal of the solvent, was subjected to crystallization from benzene to give 2,2′,6,6′-tetraphenylbiphenyl (**25**). After filtration of **25**, followed by removal of solvent from the filtrate, the residue was chromatographed on alumina with C–B(3:1).

1-Iodo-8-(*m*-terphenyl-2′-yl)naphthalene (**15**): Pale yellow needles from benzene–ethanol; mp 186.5—187.5 °C; 2.04 g. IR: 701 s (γ_{C-C}, B); 739 w; 753 s, 758 s (γ_{C-H}, M); 763 s, 767 s (γ_{C-H}, d); 804 m (γ_{C-H}, *as*); 818 w, 825 w (γ_{C-C}, N); 862 w. Found: C, 69.92; H, 4.20%; mol wt, 482 (M^+). Calcd for $C_{28}H_{19}I$: C, 69.70; H, 3.97%; mol wt, 482.

8-Iodo-8′-(*m*-terphenyl-2′-yl)-1,1′-binaphthyl (**19**): Colorless needles from benzene-ethanol; mp 263.6—266.2 °C; 0.05 g. IR: 699 s (γ_{C-C}, B); 747 m, 758 s (γ_{C-H}, M); 764 s (γ_{C-H}, d); 773 m (γ_{C-H}, d, *as*); 803 w (γ_{C-H}, *as*); 817 m, 827 w, 837 w (γ_{C-C}, N). Found: mol wt, 608 (M^+). Calcd for $C_{38}H_{25}I$: mol wt, 608.

25: Colorless cubes from benzene; mp 390 °C (lit,[29] mp 396 °C); 0.13 g.

*Preparation of 1,8-Di(*p*-terphenyl-2′-yl)naphthalene (***6***).* The Grignard reagent prepared from the aryl iodide **31** (4.98 g, 14 mmol) was treated with **8** (1.24 g, 3.25 mmol) in the presence of Ni(acaen) (9.1 mg, 0.033 mmol) as described for the preceding reaction. The benzene extract of the product, was crystallized to give *p*-terphenyl and 2,2′,5,5′-tetraphenylbiphenyl (**24**). After filtration of the solid, followed by removal of solvent from the filtrate, the residue was chromatographed on alumina with C–B(3:1).

trans-1,8-Di(*p*-terphenyl-2′-yl)naphthalene (**6**): Colorless needles from benzene–ethanol; mp 225.6—227.6 °C; 0.21 g (11.1%). IR: 700 s, 704 s (γ_{C-C}, B); 727 w, 740 m, 744 m, 757 s (γ_{C-H}, M); 779 s (γ_{C-H}, d); 826 w (γ_{C-C}, N); 835 m (γ_{C-C}, N; γ_{C-H}, *as*); 894 m (γ_{C-H}, *as*). UV: $\lambda_{max}(\varepsilon)$ 212 (84400), 225 (sh) (66400), 282 nm (50700). ^{1}H-NMR δ: 7.68—7.82 (2H, q, C_4–, C_5–H of $C_{10}H_6$), 6.63—7.55 (30H, m, other protons). Found: C, 94.74; H, 5.81%; mol wt, 584 (M^+). Calcd for $C_{48}H_{32}$: C, 94.48; H, 5.52%; mol wt, 584.

24: Colorless needles from ethanol; mp 194—195 °C (lit,[10] mp 194—195 °C); 0.11 g.

The authors are indebted to Nippon Shinyaku Co., Ltd. for the measurements of the IR spectra. Thanks are due to Dr. Keiji Hashimoto and Mr. Yasuhiro Fujiwara of this college for their help in MS and ^{1}H-NMR spectral measurements.

12) Previous attempted Ullmann coupling reactions of **8** and aryl iodide (**26**, **27**, **28**, or **32**) in the presence of copper powder to prepare 1,8-diarylnaphthalenes were unsuccessful.

13) These by-products were identified by mixed-melting-point determination (except **10**), elemental analyses, and comparison of the IR and UV spectra with those of samples prepared alternatively by the analogous Ni(acaen)-catalyzed Kharash-type Grignard cross-coupling of an appropriate Grignard reagent and 1-iodonaphthalene.

14) Clough *et al.* reported that the unfavorable formation of 1-phenylnaphthalene in the attempted coupling of ex-

cess of phenylmagnesium iodide and 1,8-diiodonaphthalene might have proceeded by the Grignard exchange between the both reactants (Ref. 3b).

15) The first scanning of the DSC determination of the melt, which consisted of the equilibrium mixture of **4a** and **4b**, was stopped at 169 °C (just before the second peak). After cooling, the next run of the melt showed only one peak at 174 °C, indicating that the melt used in the present scanning consisted of pure **4b**. The result was compatible with the ^{1}H-NMR spectrum of the melt used. The above experiment provides a novel procedure for obtaining the more stable rotamer in a pure state from an equilibrium mixture of the two rotamers. *Cf.* E. Ibuki, S. Ozasa, Y. Fujioka, and H. Mizutani, *Chem. Pharm. Bull.*, **29**, 2103 (1981).

16) Thermoanalytical data of **6**, **16**, and **17**, measured before and after heat treatment up to *ca.* 50 °C above their melting points, were practically identical, suggesting each of the compounds has the most stable conformation towards heating.

Nickel(0) Catalyzed [2+2] Cross-addition of Bicyclo[2.2.1]heptene Derivatives with Electron-deficient Olefins[1)]

Hidemasa TAKAYA, Masashi YAMAKAWA,† and Ryoji NOYORI*,†

Chemical Materials Center, Institute for Molecular Science, Myodaiji, Okazaki 444

†*Department of Chemistry, Nagoya University, Chikusa-ku, Nagoya 464*

(Received June 10, 1981)

In the presence of bis(acrylonitrile)nickel(0) or bis(1,5-cyclooctadiene)nickel(0), *exo*-tricyclo[3.2.1.$0^{2,4}$]oct-6-ene cycloadds to acrylonitrile and methyl acrylate to give *anti*- and *syn*-3-cyano-*exo*,*exo*-tetracyclo[4.3.1.$0^{2,5}$.$0^{7,9}$]-decane or the corresponding methoxycarbonyl derivatives. The cycloaddition with dimethyl maleate proceeds with retention of configuration. Benzonorbornadiene also enters into the 2+2 reaction, while *endo*-tricyclo-[3.2.1.$0^{2,4}$]oct-6-ene, bicyclo[2.2.1]heptene, and 5-methylenebicyclo[2.2.1]heptene are unreactive. Origins of the observed selectivities in the catalyzed reaction are discussed.

Under the influence of Ni(0) catalysts, bicyclo-[2.2.1]heptadiene (**1**), a homoconjugated diene[2)] having large strain energy (25.6 kcal/mol[3)]), undergoes a variety of cycloadditions. The diene dimerizes readily to give various regio- and stereoisomers.[4)] Reactions with acetylene and its derivatives afford different types of cycloadducts depending on the nature of the substituents.[4)] Electron-deficient olefins such as methyl acrylate, acrylonitrile, crotononitrile, and dimethyl maleate also react smoothly to yield the formal homo-Diels-Alder adducts of type **2**,[4,5)] while certain strained olefins such as methylenecyclopropane give the endo [2+2] cycloadducts of type **3** as the major product.[6,7)] The endo stereochemistry is considered as originating from the mixed ligand complex, depicted as **4**, in which the diene **1** coordinates to the Ni(0) atom as an endo bidentate ligand. This paper describes a Ni(0) catalyzed reaction of several bicyclo[2.2.1]heptene derivatives that are structurally related to the diene **1**. The principal aim was to determine how, and to what extent, the structural modification of one of the double bonds would affect the reaction course and reactivity with respect to those of the parent diene **1**.
