The high-temperature behavior of alkali-metal nitrates, especially sodium nitrate, accompanying thermal decomposition is of interest in the manufacture of multicomponent glass fibers for optical wave guides, the vitrification of radioactive wastes from nuclear reactors, the surface treatment of metals and alloys, *etc.* In the previous papers,[1,2] it has been revealed that several wt% of sodium nitrite is formed as an intermediate during the decomposition of sodium nitrate, irrespective of the coexistence of silica. The investigation of the thermal decomposition of sodium nitrite should give some useful information on the high-temperature behavior of the nitrates.

With respect to the thermal decomposition of sodium nitrite, only a few studies have been made. Reactions 1 and 2 have been investigated by Freeman[3] and Bond *et al.*[4] respectively:

$$NaNO_2 + 1/2\ O_2 \rightleftarrows NaNO_3 \quad (1)$$

$$NaNO_2 = 1/2\ Na_2O + \text{Gaseous Products (in Ar)} \quad (2)$$

Freeman[3] has calculated the changes in the free energy of Reaction 1 to be −14.8, −7.4, and −2.8 kJ mol^{-1} at 600, 650, and 700 °C respectively, and the apparent activation energy to be 86.6 kJ mol^{-1} for the forward reaction and 187 kJ mol^{-1} for the backward reaction. The apparent activation energy of 179 kJ mol^{-1} has been obtained for Reaction 2 by analyzing the thermograms with the Avrami-Erofe'ef equation.[4] There is, however, not enough data with respect to the gaseous and solid reaction products in the paper by Bond *et al.*[4]

According to the acid-base theory by Lux and Flood, both sodium nitrate and nitrite behave as bases, namely oxide-ion donors, during the decomposition process. Therefore, in the binary system containing an acidic oxide, the reaction process to form oxide species, such as O^{2-}, O_2^{2-}, and O_2^-, is supposed to be predominant. This may be a clue to the clarification of the reaction mechanism. In the present study, the reaction of sodium nitrite with silica has been mainly investigated by a simultaneous measurement of thermogravimetry (TG), differential thermal analysis (DTA), differential thermogravimetry (DTG), and gas chromatography (GC), and the analysis of the solid reaction products. The decomposition mechanism of sodium nitrite is also discussed.

Experimental

Materials. Reagent-grade sodium nitrite (Wako Pure Chemical Industries, Ltd.) was ground under 100 mesh in an agate mortar and dried in an oven at 100 °C. Commercially available α-quartz was ground by means of a ball mill, washed with nitric acid and distilled water, and dried in the oven. The sodium nitrite and silica were mixed by dry-blending for each run. The compositions of the sample mixtures will be represented by the atomic ratio of silicon to sodium (Si/Na=Y_{Si}).

Apparatus and Procedure. For the TG-DTA measurement, a high-temperature thermobalance (Rigaku Denki Co., Ltd.) was used. DTG was carried out with a differentiator (Rikadenki Kogyo Co., Ltd.) in order to differentiate thermograms. A GC-2C-type gas chromatograph (Simadzu Seisakusyo, Ltd.) was used for quantitative gas analysis, in which silica gel and molecular sieve 5A were used as column-packing reagents after treatment by the method described by Sakaida *et al.*[5]

A weighed sample mixture (6.9—66.9 mg) containing 0.1 or 0.2 mmol of sodium nitrite in a platinum vessel was placed on a sample holder in the thermobalance; the ambient gas (Ar or O_2) was then introduced and adjusted to the desired flow rate (50 $cm^3\ min^{-1}$). Then the sample was heated at the rate of 5.0 or 20 °C min^{-1} after holding it at 250 °C for an hour to remove a trace amount of adsorbed water. The gas formed from the sample was introduced into the gas chromatograph every two minutes by using Ar as the carrier gas.

On the other hand, the solid reaction products were identified by means of X-ray diffractometry with Cu $K\alpha$ radiation, followed by chemical analysis. The heat-treated samples were kept in a desiccator with magnesium perchlorate as a desiccant. For the quantitative analysis, 100 mg portions of the reaction products were dissolved in water and then filtered with a membrane filter. Unreacted silica was determined by gravimetry. The amounts of sodium and silicon in the filtrate were determined by means of flame spectrophotometry and atomic absorption spectrometry respectively. The sodium nitrate and nitrite were determined by means of ion-exchange chromatography (with Dionex model 10).

The details of the experimental procedures and various factors which seem to affect the reaction have been discussed in the previous papers.[1,2]

Results and Discussion

Reaction Products. Figures 1 and 2 show the gaseous and solid reaction products respectively. The gases formed up to 720 °C were O_2 and NO on the thermal decomposition of sodium nitrite, irrespective of the presence of silica. A trace amount of N_2 was generated above 680 °C. The final solid reaction product was sodium metasilicate and/or disodium disilicate. It is evident from Figs. 1 and 2 that sodium nitrite decomposes above 400 °C generating only NO, and above 500 °C generating NO and O_2 to form sodium nitrate, sodium metasilicate, and disodium disilicate. It is also evident from Fig. 1 that the sample weight scarcely affects the reaction.

Figure 3 show the distribution of the sodium ion among the solid reaction products. In Fig. 3 (A) and (B), analytical values can be obtained below 600 °C, for sodium nitrite reacts with the platinum vessel above 600 °C, in the absence of silica.[6] In an argon atmosphere, sodium nitrite decomposed above 450 °C to form almost equimolar sodium nitrate and sodium oxide by generating NO [Fig. 3 (A)]. In an oxygen atmosphere, sodium nitrite reacted with O_2 above 400 °C to form nitrate, while above 500 °C it decomposed to form oxide [Fig. 3 (B)]. Under a high partial pressure of atmospheric oxygen, such highly oxidized compounds as peroxide might be formed. The reactions are expressed by the following equations:

$$3\,NaNO_2 = NaNO_3 + Na_2O + 2\,NO(\text{in Ar}) \quad (3)$$

$$2\,NaNO_2 + O_2 = 2\,NaNO_3(\text{in } O_2) \quad (4)$$

The reaction of sodium nitrite with silica in an argon

atmosphere can be roughly classified into two stages. In the early stage (<600 °C), especially below 530 °C, the main anion species in the melt is nitrite. In Fig. 3 (C), the mol percent of sodium compounds other than nitrate and nitrite is about 20% at 530 °C. However, it was found by chemical analysis that silicates are scarcely formed below 530 °C. This indicates that some oxide species, probably including peroxide,[7] can exist stably in an argon atmosphere. The reaction below 530 °C is expressed by Eq. 5:

$$2\,NaNO_2 = Na_2O_2 + 2\,NO \qquad (5)$$

Sodium nitrate and silicates were formed in the temperature range from 530 to 600 °C. In the later stage (>600 °C), the reaction is almost identical with that of sodium nitrate with silica, as the main anion species in the melt is nitrate. In the present paper, the early stage of the reaction is mainly discussed.

Isothermal Reaction of Sodium Nitrite with Silica. Figure 4 shows thermograms obtained when samples containing 0.1 mmol of sodium nitrite were heated at various temperatures in an argon atmosphere. Thermograms have a trend to approach gradually the dashed line below 550 °C at 1.0 and 2.0 in Y_{Si}, or below 500 °C at 5.0 in Y_{Si}. After a reaction time of 3 h, α indicates a value from 0.789 to 1.000 in all cases. This suggests that the reaction of sodium nitrite with silica consists of two stages: the rapid formation of sodium peroxide, and the sluggish reaction of peroxide with silica. These two reaction stages correspond to the early and later stages described above. The apparent activation energy (ΔE) and the frequency factor ($\ln k^\circ$) for the rapid reaction were obtained by extrapolating DTG curves to 0 in the fraction of weight loss (α) and by plotting the $(d\alpha/dt)_{\alpha=0}$ values versus the reciprocal temperatures. The plot is shown in Fig. 5. The values of ΔE and $\ln k^\circ$ are listed in Table 1. The fact that the apparent activation energies at both 2.0 and 5.0 in Y_{Si} are almost the same, irrespective of the composition, strongly indicates that the early-stage reaction is characteristic of the decomposition of sodium nitrite to form peroxide in the melt. In the later stage, the thermograms for the sample with 1.0 in Y_{Si} were analyzed by the Avrami-Erofe'ef equation as was described in a previous paper.[2] The Arrhenius plot showed a good linearity, and the value of 181 kJ mol^{-1} was obtained for the apparent activation enrgy. This value is quite close to that obtained for the final stage of the reaction of sodium nitrate with silica, 179 kJ mol^{-1}, and to that obtained by Bond *et al.*[4]

Table 1. Activation energy and frequency factor for the NO-formation reaction obtained from Fig. 5

Composition Y_{Si}	Apparent activation energy, ΔE/kJ mol^{-1}	Frequency factor, $\ln(k^\circ/\text{min}^{-1})$
1.0	81.2	8.8
2.0	98.3	12.3
5.0	97.1	12.9

Reaction of Sodium Nitrite with Silica at a Constant Heating Rate. It is difficult to obtain data to discuss the elementary reactions in the early stage isothermally, because the nitrite considerably decomposes before reaching the desired temperatures. Therefore, the

reaction of sodium nitrite with silica was investigated at a constant heating rate.

Zambonin *et al.*[8–10] reported that oxide species such as O_2^-, O_2^{2-}, O^-, and O^{2-} act as bases in the nirate melt. For the early reaction stage of sodium nitrite with silica, the following assumptions are appropriate judging from the results of various analyses of reaction products, *etc*:

(i) The formation and the dissociation of O_2 are neglected.

(ii) The formed nitrate does not decompose.

(iii) Approximately spherical ions with an identical charge, for example O_2^- and O_2^{2-}, do not react with each other.

(iv) The gas formed (NO) is carried away from the system by the carrier gas.

If these assumptions are valid, the following equations may be considered for the reaction mechanism:

$$NO_2^- \xrightarrow{k_1} NO + O^- \quad (6)$$

$$NO_2^- + O^- \xrightarrow{k_2} NO + O_2^{2-} \quad (7)$$

$$O_2^{2-} \underset{k_4}{\overset{k_3}{\rightleftharpoons}} O^{2-} + O \quad (8)$$

$$O_2^{2-} \xrightarrow{k_5} O^- + O^- \quad (9)$$

$$O_2^- \underset{k_7}{\overset{k_6}{\rightleftharpoons}} O^- + O \quad (10)$$

$$NO_2^- + O \xrightarrow{k_8} NO_3^- \quad (11)$$

$$NO_2^- + O \xrightarrow{k_9} NO + O_2^- \quad (12)$$

For the thermal decomposition of sodium nitrite, the concentration of O, O^-, O_2^-, and O_2^{2-} is supposed to be very low.[8–10] If the stationary state is assumed to the formation of these species, Eq, 13 is obtained:

$$-\frac{d[NO_2^-]}{dt} = 3k_8[O][NO_2^-] \quad (13)$$

As [O] is considered to be almost constant in a relatively narrow temperature range, Eq. 13 can be rearranged, thus:

$$-\ln[NO_2^-] = 3k_8[O]t \quad (14)$$

The concentration of nitrite, the reaction time (t), and the kinetic constant (k_8) are expressed by Eqs. 15 to 17:

$$[NO_2^-] = \frac{3(1-1.9\alpha)}{3-1.9\alpha} \quad (15)$$

$$t = \frac{T-T_0}{v} \quad (16)$$

$$k_8 = k_8^\circ \exp\left(-\frac{\Delta E_8}{RT}\right) \quad (17)$$

where the constant value of 1.9 in Eq. 17 is the ratio of the final weight loss of Reaction 18 to that of Reaction 3 per mol of sodium nitrite:

$$4\,NaNO_2 = 2\,Na_2O + 4\,NO + O_2 \quad (18)$$

T, T_0, and v are the sample temperature, the temperature when the reaction starts, and the heating rate respectively. By substituting Eqs. 15, 16, and 17 into Eq. 14, Eq. 19 can be obtained:

$$y = \ln\left[-\ln\frac{3(1-1.9\alpha)}{3-1.9\alpha}\right] - \ln\frac{3(T-T_0)}{v} = \ln k_8^\circ[O] - \frac{\Delta E_8}{RT} \quad (19)$$

For the reaction of sodium nitrite with silica, Reaction 5 consists of the elementary reactions of (6) and (7). Assuming the stationary state with respect to the formation rate of O^-, Eqs. 20 and 21 are obtained:

$$-\frac{d[NO_2^-]}{dt} = 2k_1[NO_2^-] \quad (20)$$

$$y = \ln\left[-\ln\frac{2(1-1.27\alpha)}{2-1.27\alpha}\right] - \ln\frac{2(T-T_0)}{v} = \ln k_1^\circ - \frac{\Delta E_1}{RT} \quad (21)$$

where the constant value of 1.27 in Eq. 21 is the ratio of the final weight loss of Reaction 18 to that of Reaction 5 per mol of sodium nitrite.

Thermograms obtained for the samples heated at a constant rate of 5 °C min^{-1} are analyzed by means of Eq. 19 for the decomposition of sodium nitrite and by means of Eq. 21 for the reaction of sodium nitrite with silica. The heating rate from 1.25 to 10.0 °C min^{-1} scarcely affected the y *versus* T^{-1} plot.

Figures 6 and 7 show the thermograms and the DTG curves for the samples containing 0.1 mmol of sodium nitrite. The DTG curve with 1.0 in Y_{Si} has three peaks (550, 600, and 640 °C). The two peaks at lower temperatures belong to the early stage of the reaction.

Figures 8 and 9 show the y *versus* T^{-1} plots for the thermal decomposition of sodium nitrite and for the reaction of sodium nitrite with silica respectively. In Figs. 8 and 9, the y *versus* T^{-1} plots consist of two straight lines, irrespective of the coexistence of silica, and the early stage of the reaction is further divided into two reaction processes; Process I at lower temperatures and Process II at higher temperatures.

In Process I, the value of ΔE_8 for the thermal decomposition of sodium nitrite was 111 kJ mol^{-1}. The value of ΔE_1 in Process I for the reaction of sodium nitrite with silica were almost constant; their average value was 69

a: $Y_{Si}=0$, b: $Y_{Si}=1.0$, c: $Y_{Si}=2.0$, d: $Y_{Si}=5.0$, e: $Y_{Si}=7.5$, f: $Y_{Si}=10.0$.

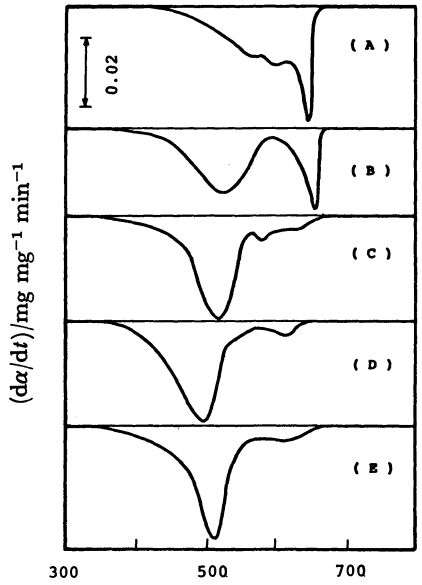

Fig. 7. DTG curves in sodium nitrite–silica system at constant heating rate in argon atmosphere.
(A): $Y_{Si}=1.0$, (B): $Y_{Si}=2.0$, (C): $Y_{Si}=5.0$, (D): $Y_{Si}=7.5$, (E): $Y_{Si}=10.0$.

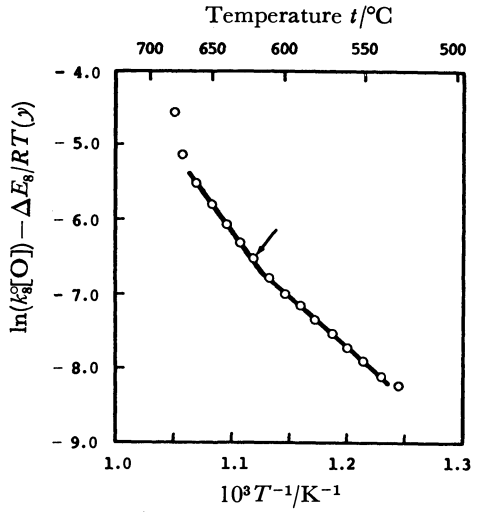

Fig. 8. $[\ln(k_8^\circ[O])-\Delta E_8/RT)]$ *vs.* T^{-1} plot for the thermal decomposition of sodium nitrite in argon atmosphere.
$T_0=278$ °C, $v=5.0$ °C min^{-1}. The arrow indicates the point where oxygen was detected by gas chromatography.

kJ mol^{-1} (S. D.: 8 kJ mol^{-1}), which was considerably smaller than the value of 111 kJ mol^{-1} for ΔE_8. It is clear from this result that silica acts an acid and lowers the activation energy of the formation of peroxide by stabilizing the peroxide at the solid-liquid interface on the melt and silica.

In Process II, the value of 187 kJ mol^{-1} was obtained for the activation energy of the thermal decomposition of sodium nitrite. For the system of sodium nitrite and silica, the activation energies in Process II are listed in Table 2. These values depend upon the composition and tend to increase with an increase in Y_{Si} below 5.0. Above 5.0 in Y_{Si}, however, they are almost constant, and the average value is 211 kJ mol^{-1} (S. D.: 10 kJ mol^{-1}). This large value of activation energy compared to that for Process I may be caused by the formation of disilicate on the solid-liquid interface because of the existence of a considerable quantity of silica compared to that of the melt above 5.0 in Y_{Si}.

In Process II, the reactions accompanying a trace amount of O_2 generation might be caused by the increase in the amount of atomic oxygen in the melt. These

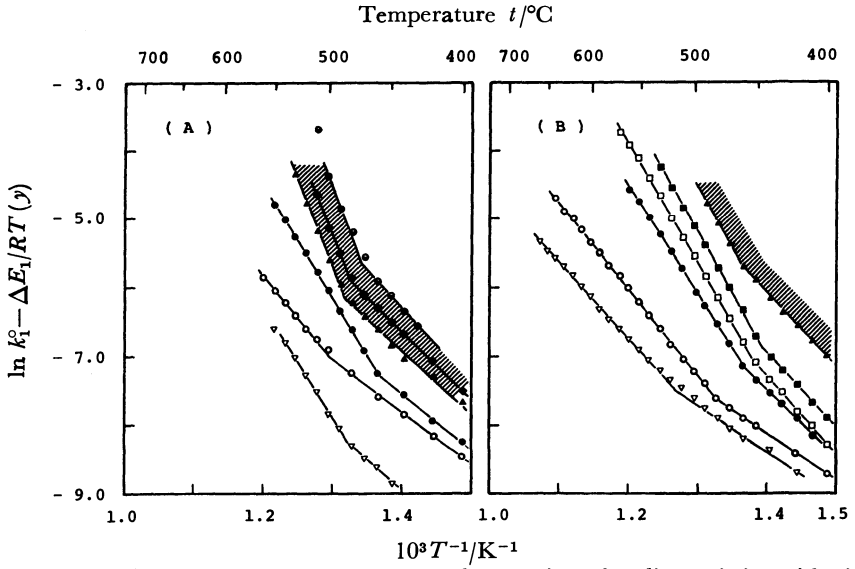

Fig. 9. $[\ln k_1^\circ-\Delta E_1/RT]$ *vs.* T^{-1} plots for the reaction of sodium nitrite with silica in argon atmosphere.
$T_0=278$ °C, $v=5.0$ °C min^{-1}. (A): 0.1 mmol $NaNO_2$, (B): 0.2 mmol $NaNO_2$, ▽: $Y_{Si}=0.5$, ○: $Y_{Si}=1.0$, ●: $Y_{Si}=2.0$, □: $Y_{Si}=3.0$, ■: $Y_{Si}=4.0$, ▲: $Y_{Si}=5.0$, ◒: $Y_{Si}=7.5$, ◆: $Y_{Si}=10.0$.
Above 5.0 in Y_{Si} (Shadows), the effect of silica addition on the reaction is not evident.

Table 2. Activation energy for process II obtained by the use of the y *vs.* T^{-1} plot

Composition Y_{Si}	Apparent activation energy/kJ mol^{-1}	
	0.1 mmol $NaNO_2$	0.2 mmol $NaNO_2$
0.25	97.7	—
0.50	127	89.4
1.00	94.2	103
2.00	137	131
3.00	—	148
4.00	—	159
5.00	209	213
7.50	203	—
10.00	217	—

reactions are expressed by Eqs. 22 and 23:

$$O + O_2^{2-} \longrightarrow O_2 + O^{2-} \quad (22)$$

$$O + O \longrightarrow O_2 \quad (23)$$

Atomic oxygen would be supplied by the following reactions:

$$NO_3^- \longrightarrow NO_2^- + O \quad (24)$$

$$2\,SiO_2 + O_2^{2-} \longrightarrow Si_2O_5^{2-} + O \quad (25)$$

$$Si_2O_5^{2-} + O_2^{2-} \longrightarrow 2\,SiO_3^{2-} + O \quad (26)$$

$$O_2^{2-} \longrightarrow O^{2-} + O \quad (8)$$

$$O_2^- \longrightarrow O^- + O \quad (9)$$

Below 1.0 in Y_{Si}, the activation energy in Process II is quite close to that for the decomposition of sodium nitrite in Process I, and the rate-determining step of these processes seems to be Reaction 11. This is supported by the facts that the amount of oxygen generated in these processes is quite small and that both processes are nitrate-formation reactions. The apparent activation energy obtained by analyzing the thermograms at 1.0 in Y_{Si} with Eq. 19 agrees with the activation energy for the decomposition of sodium nitrite in Process I better than the average value of the activation energies for the system of sodium nitrite and silica below 1.0 in Y_{Si}, 102 kJ mol^{-1}.

The authors wish to thank the Kato Kagaku Shinkokai foundation for its helpfull support. They also wish to thank Mr. Akinori Ohba for carrying out a part of the experiments. This work was partly supported by a Grant-in-Aid for Scientific Research No. 56550544 from the Ministry of Education, Science and Culture.

Mineralogical Characterization of the Reference Material of "Pond Sediment"

Yasuo IWATA, Hiroki HARAGUCHI,* Jon C. VAN LOON,† and Keiichiro FUWA
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
†*Department of Geology and Chemistry, The Institute for Environmental Studies, University of Toronto, Toronto, Ontario, Canada*

(Received January 13, 1982)

The identification of rock-forming and clay minerals contained in the reference material of "Pond Sediment" (Reference Material NIES No. 2 from the National Institute for Environmental Studies, Japan) has been made with X-ray diffraction method. It was found that the sediment contained α-quartz and feldspars as the principal components along with small quantity of pyroxenes, amphiboles, and some clay minerals. The sediment sample was treated chemically for extraction, and also separated with density and with grain sizes. Elemental compositions of such extracted or separated fractions of the sediment were determined by inductively coupled argon plasma emission and atomic absorption spectrometry. The identified minerals and the elemental distributions in the separated fractions helped to characterize the pond sediment.

In recent years, much attention has been paid to environmental and biological reference materials because of the importance of pollution control. Recently NBS issued a standard reference material of "River Sediment."[1] We have also prepared independently a reference material of "Pond Sediment,"[2] which was collected from the Sanshiro-ike (Pond at the University of Tokyo), and issued as Reference Material No. 2 from the National Institute for Environmental Studies, Japan. The Sanshiro-ike pond sediment consists basically of volcanic ash called Kanto loam, atmospheric dust, and organic matters originating from plants, animals, and microorganisms. There have been no significant flows of freshwater, and industrial or sewage waste into the pond. Therefore, the composition of the sediment sample should mainly reflect air pollution from a big city environment (*i.e.*, imports of pollutants arisen from traffic and industrial discharges into the air). Goldberg reported that the history of the environmental pollution in Tokyo was recorded in the Palace Moat Sediment.[3]

The procedure for preparing reference materials, homogeneity test, and its elemental composition have been reported in the previous communication.[2] In order to understand the significance of the "Pond Sediment," it may be further desirable to investigate the elemental distributions in a variety of partial extractions of the sedimant. Hence, in this study, extraction tests and mineralogical characterization of the "Pond Sediment" have been performed, and the origins and the chemical forms of elements are described.

Experimental

Chemicals. All the chemicals used were of analytical reagent grade. Standard solutions were prepared by dissolving pure metals, metallic oxides and their salts in acidic or deionized distilled water. Final acidity of each working standard solution was adjusted at 1 M (1 M=1 mol dm^{-3}) with nitric acid and/or hydrochloric acid. In addition, standard rock sample JB-1 (basalt) from the Geological Survey of Japan[4] was also analysed to examine the accuracy and precision of the analytical method for elemental compositions.

Instruments. X-Ray diffraction measurements were performed using an X-ray diffractometer, Model JEOL-GOS. The diffraction patterns were measured in the range of the diffraction angle (2θ) from 4° to 70°. An inductively coupled plasma (ICP) emission spectrophotometer (Model Jarrell-Ash Plasma AtomComp Mark II), and an atomic absorption spectrophotometer (Model Shimadzu AA-640-13) was used for the determination of the elemental distributions in separated fractions. Total carbon and nitrogen were determined using a C. H. N. Coder (Model Yanagimoto MT-2).

Separation of the Sediment for Mineral Identification. The "Pond Sediment" was separated into 4 groups, *i.e.*, organic matters and carbonates, iron oxides, primary and secondary minerals, and heavy and light minerals. The separation procedure which is a modified method of those reported in the literature,[5,6] is summarized as follows:

(1) Organic Matter and Carbonates: Ten ml of 30% H_2O_2 was added to 5 g of the sediment sample, and the mixture was heated until the vigorous reaction was over. After cooling, 50 ml of 0.2 M HCl was added with stirring for 1 h at room temperature. Then, the suspension was filtered by means of suction with a No. 5C filter paper (Toyo Co., Ltd.). The filtrate was diluted to 100 ml with water (F-1).

(2) Iron Oxides: The air-dried residue of (1) was suspended in 50 ml of 0.3 M sodium citrate solution, and 5 g of sodium dithionite was added into suspension. The suspension was heated at 80 °C with occasional agitation for about 30 min, and then filtered by means of suction with a No. 5C filter paper. The filtrate was diluted to 100 ml (F-2).

(3) Primary and Secondary Minerals: The residue of (2) was transferred into water. Then, the secondary minerals (diameters less than 20 μm) was separated from the primary minerals (diameters larger than 20 μm) by the elutriation as follows: After stirring the suspension vigorously, the mixture was allowed to stand for 4 min and 48 s. Then the supernatant down to 10 cm depth was removed with a siphon. This siphoning was repeated several times. In this procedure, the particles of diameter larger than 20 μm remain in the lower part of the solution, which was difined as the primary minerals. Most of these particles may be classified as fine sand, and consist mainly of the primary minerals. The siphoned materials, which is the mixture of silt and clay, consists mainly of secondary minerals.

(4) Heavy and Light Minerals: The air-dried primary minerals of (3) was treated with heavy organic liquids such as dibromomethane (d=2.5), tribromomethane (d=2.9), and diiodomethane (d=3.3) for further separation. Each fraction of heavy organic liquids was separated by centrifugation, and each separated sample was washed well with acetone, and then

dried under an IR lamp.

In addition to the above treatments, magnetic minerals were separated independently using a magnet, although they were found in very small quantities. In order to determine the elemental distributions, the sample was boiled with 12 M HCl.[6] The residue in 12 M HCl solution was dried at 500 °C to examine on the primary minerals.

Elemental Analysis of Separated Fractions. Each separated fraction was treated for elemental analysis according to the following procedure, which was modified from the one reported by Yoshida.[7] The sample was digested with a mixture of 10 ml concd HNO_3 and 10 ml concd $HClO_4$ for 30 min on a hot plate at 200 °C. After cooling, 20 ml of HF was added and the mixture was kept standing at room temperature for 30 min. Then it was evaporated until fuming, and 5 ml HNO_3 and 5 ml $HClO_4$ were again added, and the mixture was heated. After dissolution the mixture was heated to incipient dryness. The residue was dissolved with 10 ml of 6 M HCl and then diluted to 100 ml with water.

Results and Discussion

The amount of each separated fraction in weight % is shown in Table 1. Organic matter, oxides, and minerals were approximately 20, 15, and 60%, respectively. Fine sand (>20 μm), silt (2—20 μm), and clay (<2 μm), separated by the siphoning procedure, were found to be 20, 30, and 10%, respectively.

Mineral Composition. Minerals identified by the X-ray diffraction are summarized in Tables 2 and 3. For identification the ASTM (American Society for Testing Materials) cards were used.

Table 2 shows good agreement between the densities of separated primary minerals and their reported values.[8] These results are substantiated by the data of the elemental analyses mentioned later. It can then be stated that this "Pond Sediment" contains quartz and feldspars as the principal components, together with a small quantity of pyroxenes, amphiboles, micas, and iron ores.

Besides these rock-forming minerals, the sediment contains montmorillonite, halloysite, vermiculite, and many other clay minerals, as shown in Table 3. Since the separation of clay minerals was difficult and their X-ray peaks were not sharp, the identification of secondary minerals was not so easy. However, a few clay minerals could be identified, and these are summarized in Table 3. In addition to the above clay minerals, the sediment contains likely gibbsite and hematite, because much Al and Fe were found in the extractable fractions of the "Pond Sediment." However, X-ray peaks of these minerals were not identified because of the interferences of other large peaks. Further separation of the secondary minerals were tried based on sinking velocity using mixtures of bromoform and acetone as heavy liquids. Separation of secondary minerals could not, however, be made because of co-adsorption of fine particles.

It is known that allophane is present in high concentration in the Tachikawa loam in the upper stratum of the Kanto loam.[8] Although the "Pond Sediment" may contain such a non-crystalline clay mineral, allophane could not be identified by X-ray diffraction.

Table 1. Amount of each fraction separated with various treatments

Elemental Compositions of Fractions Separated with Density. The elemental compositions concerned with major constituents in primary minerals are shown in Fig. 1 for each fraction separated with heavy liquids. The separated fractions are represented as H-1 (d>3.3), H-2 (3.3>d>2.9), H-3 (2.9>d>2.5), and H-4 (d<2.5).

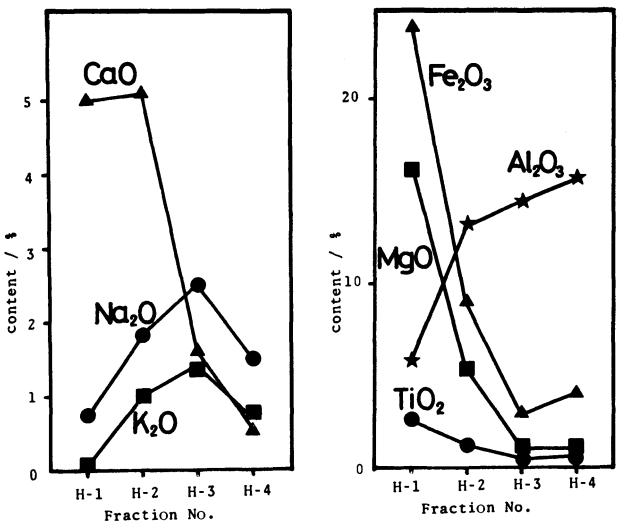

Fig. 1. Elemental compositions of primary minerals in the "Pond Sediment" separated with heavy liquids.
Fraction No. H-1: $d>3.3$, H-2: $3.3>d>2.9$, H-3: $2.9>d>2.5$, H-4: $d>2.5$.

Fraction H-1 contains Ca, Mg, and Fe as the principal constituents. This result may be related to the fact that pyroxenes have Ca, Mg, and Fe end-members of the solid solution $[(Ca, Mg, Fe)_2Si_2O_6]$.[10] As can be seen in Fig. 1, the contents of Fe, Mg and Ca are high, while that of Al is less. These elemental compositions also suggest that fraction H-1 contains much hypersthene $[(Mg, Fe)SiO_3]$ and a little augite $[Ca(Mg, Fe, Al)(Si, Al)O_6]$.[10] In addition Fe and Ti are richer in fraction H-1 than in other fractions. This may indicate that magnetite $[Fe_3O_4]$ and ilmenite $[FeTiO_3]$ are contained in fraction H-1,[11] although they could not be identified clearly. Consequently, the large contents of Fe, Ca, Mg, and Ti in fraction H-1 may be interpreted by the existence of minerals such as pyroxenes, hypersthene, and augite as well as magnetite and ilmenite.

Fraction H-2 ($3.3>d>2.9$) contains much Al, Ca, Mg, and Fe (see Fig. 1). Since the densities of amphiboles are in the range from 2.9 to 3.3, it is likely that fraction H-2 mainly contains amphiboles. In many cases, hornblende $[Ca_2Na_{0-1}(Mg, Fe, Al)_5[(Al, Si)_4O_{11}]_2]$[10] can be identified by X-ray diffraction. The elemental composition of fraction H-2 supports the presence of hornblende, and it likely consists of hornblende as the principal component, as well as of small quantities of other amphiboles.

As can be seen in Fig. 1 the contents of Na and K were largest in fraction H-3 ($2.9>d>2.5$), although Na, K, and Ca were contained at almost equal levels in this fraction. Fraction H-3 appears to contain much feldspar in a mixture of solid solutions which consist of three end-members such as $NaAlSi_3O_8$, $KAlSi_3O_8$, and $CaAlSi_2O_8$.[10]

There were more clay minerals in fraction H-4 ($d<2.5$), although the elemental composition was almost similar to fraction H-3. Fraction H-4 contains clay minerals, quartz, and feldspars which are not separated by the siphoning treatment and/or by heavy liquid separation because of co-adsorption and fineness of the materials.

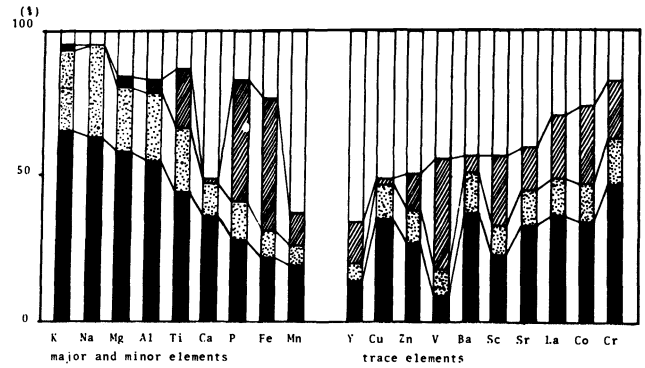

Fig. 2. Distributions of major, minor, and trace elements in the fractions separated with various treatments.
□: "H_2O_2" treatment, ▨: "$Na_2S_2O_4$" treatment, ▩: secondary minerals, ■: primary minerals.

Distribution of Major, Minor, and Trace Elements in the Fractions. The distribution of major, minor and trace elements in each separated fraction was determined, and the calculated percentage of each element is illustrated in Fig. 2. The separated fractions of "H_2O_2" and "$Na_2S_2O_4$" in Fig. 2 correspond to solutions F-1 and F-2, respectively, as described previously in the separation procedure. The "primary" and "secondary" in Fig. 2 indicate primary and secondary minerals, respectively, which were separated and digested with HNO_3, $HClO_4$, and HF, as described previously. From these results, it is evident that Fe, P, and Ti are mostly leached with the dithionite-citrate treatment. This suggests that these elements may be present mainly in the chemical form of easily reducible oxides. It is known that hydrous iron oxides have great scavenging efficiency, and so many trace elements may be caught by the concretion or coatings around the second particles.

The fraction treated with hydrogen peroxide and hydrochloric acid contains much Mn and Ca. Calcium may be in the form of carbonate minerals such as dolomite or in the form of exchangeable cations. Manganese is considered to be in two modes: the one is related to the organic matter which is decomposed by hydrogen peroxide, and the other is hydrous manganese oxides which are decomposed by the mixture of hydrogen peroxide and hydrochloric acid. Na, K, Mg, and Al exist mostly in primary and secondary minerals, and more than half of them appear in the fractions containing the rock-forming minerals.

Most of trace elements were leached in the fraction treated with hydrogen peroxide–hydrochloric acid. Therefore, they may be present as species adsorbed on the minerals or as the constituents in the organic matter.

Variation of Major and Minor Components in Minerals. Figure 3 shows the variations of elemental compositions in primary minerals with and without various chemical treatments. The amount of Fe and Al decrease after each treatment step, suggesting that various oxides and organic matter exist as coatings around mineral particles which were separated only by the siphoning method. Therefore, the primary fractions after the hydrogen peroxide–hydrochloric acid and dithionite–citrate treat-

Element	Content/%
C	5.5
N	0.27
P	0.12

Ignition loss was 15.5%.

ments contain only rock-forming minerals.

The variation of major and minor components in secondary minerals are also shown in Fig. 4. Without the dithionite–citrate treatment the content (%) of most elements slightly decreased. This decrease may be caused by the loss of the principal elements of rock-forming minerals. In the last bar which corresponds to the dithionite–citrate treatment Fe decreases significantly, and the percentages of other elements increase slightly. Most of the removed Fe is considered to be iron oxides and some clay minerals (*e.g.*, goethite) which are easily degradable.

The elemental composition of secondary minerals treated with dithionite–citrate is almost identical to that of primary minerals with the same treatment, which their X-ray diffraction patterns showed some differences.

Evaluation of Non-metallic Elements. The analytical results of carbon and nitrogen are summarized in Table 4 along with the content of phosphorus. The results show that the "Pond Sediment" contains much carbon. Most of carbon exists as organic matter, and the remainder appears to be carbonate minerals such as dolomite [$(Ca, Mg)CO_3$] and calcite [$CaCO_3$].[10] The content of Ca in the hydrogen peroxide–hydrochloric acid soluble fraction is large, suggesting the presence of calcite in the "Pond Sediment." Carbonate minerals, however, were not positively identified probably because all the carbonate minerals were degraded by the chemical treatments using acids.

Half of phosphorus content occurs in the mineral fractions, but the phosphorus-rich minerals like apatite were not identified by the X-ray diffraction method, and the petrographic microscopic method is required for positive identification.

The content of nitrogen in the "Pond Sediment" (2700 $\mu g\ g^{-1}$) is close to the average value of the general soils, which contain nitrogen in the range of 200—5000 $\mu g\ g^{-1}$.[11]

Conclusion

It has been found that the principal components of the pond sediment are quartz and feldspars. Other identified minerals present at lower levels were pyroxenes, amphiboles, and clays. Olivines were not found in the sample. These results indicate that this sediment has not undergone extensive weathering because of the existence of many rock-forming minerals along with quartz. The results obtained by the extraction with citrate–dithionite suggest a scavenging action of trace metals by iron oxides.

Besides the identification of minerals the fractionation including chemical extraction has been found to be useful for environmental and geochemical characterization of sediments, because some elements are partitioned into specific fractions separated with appropriate chemicals.

The authors thank Dr. T. Yamanaka in the Department of Mineralogy, Faculty of Science, The University of Tokyo, for his assistance and discussion in mineral identifications. They also thank Dr. K. Okamoto in the National Institute for Environmental Studies for providing the sediment samples and carrying out the determination of carbon and nitrogen by a C. H. N. Corder. One of the authors (J.C.V.L.) expresses his sincere thanks to the Japan Society for Promotion of Science for supporting the fellowship to stay in the University of Tokyo as the visiting professor (1981).

Mössbauer and ESR Studies of Potassium Borophosphate Glasses

Tetsuaki NISHIDA,* Yoshiaki MIYAMOTO, and Yoshimasa TAKASHIMA
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812
(Received January 20, 1982)

A linear decrease in isomer shifts of Fe^{3+} and Fe^{2+} was observed with an increase in alkali content of borophosphate glasses. The decrease is attributed to a change in the role of iron from a network modifier to a network former, or a decrease in the interatomic distance between iron and oxygen atoms. A linear decrease in quadrupole splitting and linewidth was also observed with increasing alkali content, and the decrease is attributed to the increased symmetry around iron nucleus. A linear decrease in relative absorption area of Fe^{2+} in Mössbauer spectra was also observed with increasing alkali content of the glasses. This result is attributed to an increased oxidation atmosphere brought about by alkali oxide into BPO_4 units. Gamma-ray irradiation (1×10^8 R) experiments resulted in no change in these Mössbauer parameters, indicating that the glasses are less sensitive to γ-rays than borate or phosphate glasses. ESR absorption intensity of PO_4^{2-} observed in γ-ray irradiated, iron-free borophosphate glasses increased linearly with an increase in the alkali content in the lower alkali region, and the increase is attributed to a linear increase in the fraction of non-bridging oxygen in PO_4 tetrahedra constituting BPO_4 (and PO_4) units.

Mössbauer studies of borate glasses[1-6] suggested formation of non-bridging oxygen (NBO) to start at an alkali content of 20 mol%. The fraction of NBO constituting BO_4 or FeO_4 tetrahedra was obtained from the Mössbauer absorption area of Fe^{2+} produced by γ-ray irradiation of borate glasses[5] containing a small amount of iron, and also from the absorption area of a hyperfine structure in partially relaxed spectra observed at low temperature.[6] These two results are well consistent with each other, within the experimental error, and the fraction of NBO proved to increase linearly with increasing alkali content of the borate glasses in the alkali region$\geqslant$20 mol%. Gamma-ray irradiation experiments of borate glasses containing 7 mol% of Fe_2O_3 resulted in an increase in s-electron density at the iron nucleus,[3] and this was confirmed from the reduction of Fe^{3+} to Fe^{2+} in γ-ray irradiated borate glasses[3,5] containing a small amount of Fe_2O_3. Mössbauer and ESR studies of potassium phosphate glasses[7,8] were also performed to investigate the formation of NBO in these glasses, and a continuous increase in relative absorption area of Fe^{2+} in the Mössbauer spectra was attributed to an increase in the fraction of NBO. This was also confirmed from a linear increase in ESR absorption intensity of PO_4^{2-} radicals in γ-ray irradiated, iron-free phosphate glasses.[7] The γ-ray irradiation experiments also resulted in a decrease in the Mössbauer absorption area of Fe^{2+} ions.[8] As for borophosphate glasses, it is well known that the glasses are essentially composed of BPO_4 units[9] in which individual boron and phosphorus atoms are tetrahedrally bonded with oxygen atoms to form BO_4 and PO_4 tetrahedra.

The present study was carried out to investigate the formation of NBO and γ-ray irradiation effects in borophosphate glasses.

Experimental

All the glass samples denoted by a formula $x\mathrm{K_2O}\cdot(100-x)(\mathrm{B_2O_3},\mathrm{P_2O_5})\cdot7\mathrm{Fe_2O_3}$ were prepared by fusing the individual mixture of weighed quantitities of K_2CO_3, H_3BO_3, $NH_4H_2PO_4$, and Fe_2O_3 of guaranteed reagent grade at 1200 °C for 3 h in an electric muffle furnace. Prior to this fusion, the mixture in a platinum crucible was calcined at 800 °C for 30 min. The value of x was changed from 10 to 50, and the molar ratio of P_2O_5 to B_2O_3 was so chosen as to be 1.0 and 2.0. Transparent and dark brown glasses were prepared by quenching the platinum crucible with cold water in a beaker. All the glass sample prepared in this way were confirmed to be amorphous by X-ray diffractometry, and they were preserved in a desiccator filled with dry nitrogen gas to protect them from the atmospheric moisture.

These glasses were exposed to γ-rays of 1×10^6 R and 1×10^8 R with a dose rate of 1×10^6 R/h at the ambient temperature in the ^{60}Co-γ ray irradiation facilities of Kyushu University and Japan Atomic Energy Research Institute. During the irradiation each glass sample was kept in a polyethylene bag filled with dry nitrogen gas, and the bag was placed in a glass tube filled with nitrogen gas and silica gel.

Mössbauer measurements were performed by the constant acceleration method at room temperature, with a source of cobalt-57 diffused into a palladium foil. A pure iron foil enriched with iron-57 was used to calibrate the velocity of spectrometer and for the reference of isomer shift. All the Mössbauer spectra were fitted to Lorenzian lineshapes by computer calculations. ESR measurements (X-band) of γ-ray irradiated borophosphate glasses were performed at room temperature in the National Universities' Laboratory for the Common Use of the JAERI Facilities, and also in Kyushu University. The magnetic field was calibrated by using JEOL standard material of MgO : Mn^{2+}.

Results and Discussion

Each of the Mössbauer spectra for potassium borophosphate glasses consists of two quadrupole doublets due to Fe^{3+} and Fe^{2+} ions. Isomer shifts for both the iron species are shown in Fig. 1 as a function of the alkali content of the borophosphate glasses having a P_2O_5/B_2O_3 ratio of 1.0. It is seen from Fig. 1 that both the Fe^{3+} and Fe^{2+} ions are primarily surrounded by six oxygen atoms just like in phosphate glasses.[7,8,10-12] Iron will therefore be present at the interstitial site of the three dimensional network structure of BPO_4 units constituted by BO_4 and PO_4 tetrahedra, facing to two or three NBOs. A linear decrease in isomer shift (Fig. 1) is attributed to an increase in covalency of both iron species, probably because the coordination number of some parts of iron changes from 6 to 4 with the

increase in the alkali content of the glasses.[10-12] This change in the coordination number means the formation of FeO_4 tetrahedra in which iron plays a role of network former, instead of a network modifier at the interstitial site. Another possible reason for the increase in the covalency is a decrease in the interatomic distance between iron and oxygen, produced by the introduction

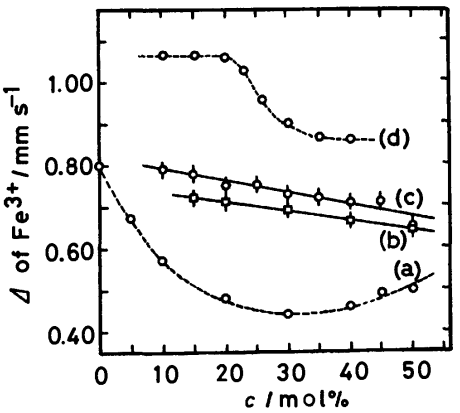

Fig. 4. Quadrupole splitting of Fe^{3+} in glasses.

of alkali oxide into BPO_4 units.

Quadrupole splitting values for both the iron species are plotted against the alkali content of the borophosphate glasses ($P_2O_5/B_2O_3=1.0$) in Fig. 2, where the values decrease linearly with increasing alkali content. The decrease in quadrupole splitting of Fe^{3+} (high spin) means the increase in the symmetry around the iron nucleus because each d-orbital of Fe^{3+} ion is occupied by one electron and therefore the effect of valence electrons on the electric field gradient can be negligible. Quadrupole splitting for Fe^{2+} ion also decreased in the alkali region $\geqslant$25 mol%, and the decrease is attributed to the increase in the symmetry around the iron nucleus. An increase in the quadrupole splitting of Fe^{2+} ion in the lower alkali region is difficult to explain, but the alkali content at which quadrupole splitting shows a distinct maximum, *i.e.*, 25 mol%, is well consistent with that in the composition dependence of ESR intensity of PO_4^{2-} to be discussed later.

Linewidth (FWHM) values for Fe^{3+} and Fe^{2+} ions also show a linear decrease when the alkali content of the glasses increases (Fig. 3). The broad linewidth for iron in glasses is attributed to the non-uniformity of the steric configuration around the individual iron nucleus.[12-14] The decrease in linewidth therefore suggests that the steric configuration around iron nucleus becomes more uniform as the fraction of alkali oxide increases in these borophosphate glasses. It is seen from the Mössbauer results Figs. (1—3) for the γ-ray irradiated borophosphate glasses that iron atoms in these glasses are not affected by γ-ray irradiation up to 1×10^8 R. This is inconsistent with the results of borate[3] or phosphate[8] glasses where a decrease in isomer shift of Fe^{3+} or a linear decrease in the absorption area of Fe^{2+} ions was observed by γ-ray irradiation. These results lead to a conclusion that the borophosphate glasses are less sensitive to γ-rays than the parent borate or phosphate glasses.

Mössbauer studies of potassium borophosphate glasses with a P_2O_5/B_2O_3 ratio of 2.0 were also performed. These results are summarized in Table 1. Isomer shifts and linewidths are well consistent with the corresponding values of the borophosphate glasses with a P_2O_5/B_2O_3

ratio of 1.0. Quadrupole splitting values of Fe^{3+} ions in these borophosphate glasses are also shown in Fig. 4, where the previous results on borate and phosphate glasses are shown for comparison. It is obvious from Fig. 4 that the quadrupole splitting values for the borophosphate glasses are intermediate between those for the borate and phosphate glasses, and that the values increase when the concentration of B_2O_3 increases. These results suggest that the symmetry around iron nucleus decreases with the introduction of B_2O_3 into phosphate glasses of which network comprises only PO_4 units, probably because the network structure becomes more complicated as a result of the formation of BPO_4 units in which equal numbers of BO_4 and PO_4 tetrahedra are arranged alternately. The network structure is considered to be more complicated for the borophosphate glasses with an P_2O_5/B_2O_3 ratio higher than 1.0 because the network is composed of both PO_4 and BPO_4 units.

Absorption areas of Fe^{2+} ions in these glasses are shown in Fig. 5, in which a linear decrease in the absorption area is observed with increasing alkali content for the borophosphate glasses having a P_2O_5/B_2O_3 ratio of 1.0. This is quite different from the

results for phosphate glasses, in which formation of NBO was speculated.[7,8] The decrease in the absorption area is attributed to an increased oxidation atmosphere brought about by the introduction of alkali oxide into BPO_4 units in which all the boron and phosphorus atoms are singly bonded with oxygen atoms to form BO_4 and PO_4 tetrahedra.[9] It is seen from the results for the borophosphate glasses with a P_2O_5/B_2O_3 ratio of 2.0 (Fig. 5; curve 5b is intermediate between 5a and 5c) that some parts of iron are in the environment similar to that of phosphate glasses. This is explained by the presence of PO_4 units as well as BPO_4 units because one half of phosphorus atoms can be assumed to be present as PO_4 units having P=O double bonds when the P_2O_5/B_2O_3 ratio is 2.0.

The ESR spectrum of γ-ray (1×10^8 R) irradiated, iron-free borophosphate glasses consists of an almost isotropic doublet. The g value and hyperfine coupling constant of ^{31}P were found to be 2.01 and 41-32 G (1 G=10^{-4} T), respectively. The doublet has been attributed to PO_4^{2-} radical[7,15-20] produced by X-ray or γ-ray irradiation. As is shown in our previous paper,[7] the absorption intensity of PO_4^{2-} can be correlated with the fraction of NBO in PO_4 units because the energy level for the electrons on NBO is known to be higher than that on bridging oxygen[21] and therefore more electrons will be scattered by γ-ray irradiation in the former. The ESR results are summarized in Tables 2 and 3, from which a decrease in coupling constant of PO_4^{2-} doublet is seen when the alkali content of borophosphate glasses exceeds 25 or 30 mol%. This is identical with the decrease in the absorption intensity of the PO_4^{2-}

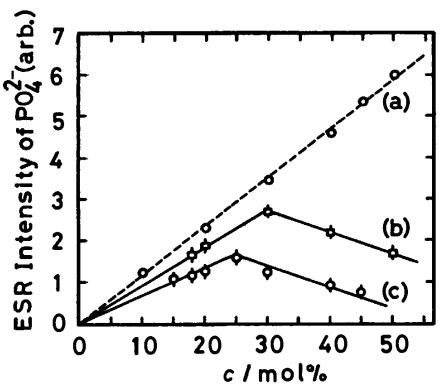

Fig. 6. ESR absorption intensity of PO_4^{2-} in glasses.

radical, *i.e.*, the intensity shows a distinct maximum at 25 or 30 mol% when the P_2O_5/B_2O_3 ratio is 1.0 or 2.0, respectively. This is shown in Fig. 6, where the result of phosphate glasses[7] which are free from iron is also shown for comparison. Figure 6 demonstrates that the concentration of PO_4^{2-} radical in borophosphate glasses increases with increasing alkali content in the lower ($x \leq 25$ or 30 mol%) alkali region. This is the same as the result of phosphate glasses (Fig. 6a). The increase in the absorption intensity of the PO_4^{2-} radical is therefore attributed to a linear increase in the fraction of NBO in PO_4 tetrahedra constituting BPO_4 units for the borophosphate glasses with a P_2O_5/B_2O_3 ratio of 1.0, of which composition is expressed as $xK_2O\cdot(100-x)BPO_4\cdot 7Fe_2O_3$. It is very noteworthy that the absorption intensity shows a maximum at an alkali content of 25 mol%, which is not observed in the study of phosphate glasses. The decrease in the absorption intensity in the alkali region higher than 25 mol% will be attributed to the formation of NBO in BO_4 tetrahedra which are the other component of BPO_4 units, although the formation could not be confirmed in the present study. It is therefore considered that the formation reaction of NBO in borophosphate glasses is competitive between PO_4 and BO_4 tetrahedra, and that the formation in PO_4 tetrahedra is predominant in the alkali region lower than 25 mol%, *i.e.*, in such an alkali region that the K_2O/BPO_4 ratio is less than one third. This is also the case for the borophosphate glasses with a P_2O_5/B_2O_3 ratio of 2.0 of which composition is expressed as $xK_2O\cdot 2/3(100-x)BPO_4\cdot 1/3(100-x)P_2O_5\cdot 7Fe_2O_3$. That is to say, formation of NBO at PO_4 tetrahedra in BPO_4 units is predominant until 18 mol% ($K_2O/BPO_4=1/3$) and then the formation in PO_4 units of which environment is essentially the same as that of phosphate glasses will be predominant in the alkali region of 18—30 mol%. It is then considered in borophosphate glasses that the fraction of NBO bonded with phosphorus atoms is increased with increasing fraction of P_2O_5.

The authors are grateful to Dr. Toshiyuki Isobe of Kyushu University for his kind help in the ESR measurements of the glass samples. They are also grateful to Dr. Hisao Yamamoto and Mr. Kiyoshi Matsumoto of Kyushu University for the kind help in the γ-ray irradiation experiments.

X-Ray Diffraction Studies on the Structures of Hydrated Oxonium Ion, and the Chlorocobalt(II) and Tetrachlorocobaltate(II) Complexes in Aqueous Solutions

Hyo-Gwang Lee, Yukiei Matsumoto, Toshio Yamaguchi, and Hitoshi Ohtaki*

Department of Electronic Chemistry, Tokyo Institute of Technology at Nagatsuta, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received March 1, 1982)

The structure of hydrated oxonium ion has been determined in a concentrated hydrochloric acid solution by the X-ray diffraction method. The oxonium ion H_3O^+ combines with four water molecules to form a trigonal pyramid structure in which three water molecules have an H_3O^+–H_2O distance of 2.44 Å, while the water molecule at the apex of the pyramid is separated by 2.90 Å from the central oxygen atom of the oxonium ion. The structure of the $CoCl^+$ determined in a relatively dilute lithium chloride solution (the Cl/Co mole ratio is 3.38) shows that the cobalt(II) ion is coordinated with five water molecules, the Co–OH_2 distance being 2.14 Å. The Co–Cl distance within the complex is 2.35 Å. The $CoCl_4^{2-}$ complex has a regular tetrahedral structure both in a concentrated lithium chloride (Cl/Co=22.1) and a hydrochloric acid (Cl/Co=21.1) solutions with the Co–Cl bond length of 2.29 Å.

Proton is present as H_3O^+ in water. The H_3O^+ ion is further hydrated with some water molecules through hydrogen bonds to form hydrated oxonium ion $H_3O(H_2O)_n^+$. The hydration number of oxonium ion has been determined by various methods, but the results are not well consistent with each other. For instance, the hydration number n is estimated to be 3—4 from X-ray and neutron diffraction measurements,[1-3] but the number is zero (*i.e.* H_3O^+) or one according to compressibility studies.[4] Most thermodynamic investigations give the hydration number of 3, *i.e.*, $H_9O_4^+$.[5,6]

Oxonium ion H_3O^+ can probably combine with four water molecules through hydrogen bonds. In crystal, however, an oxonium ion has three hydrogen bonds to combine with other oxonium ions or anions.[7-9] A theoretical calculation by a molecular orbital method[10] suggests that an oxonium ion has an almost planar structure in which each hydrogen atom binds to a water molecule through the hydrogen bond, the bond energy being about 190 kJ mol^{-1}. One water molecule situates above the oxonium ion, but the interaction between the oxonium ion and the water molecule is so weak that the bond energy is about 0 kJ mol^{-1}.[10]

The structure of oxonium ion so far estimated by diffraction methods[1-3] was regular tetrahedral, which was not in a satisfactory agreement with the structure expected from the crystallographic analysis[7-9] and the quantum mechanical calculation.[10] Moreover, the hydration number of an oxonium ion determined by the diffraction methods does not coincide with the numbers obtained by other methods. One of the aim of the present study is to establish the structure of hydrated oxonium ion in solution.

Cobalt(II) chloride complexes are formed in an alkali chloride or in a hydrochloric acid solution. It is a well known fact that cobalt(II) chloride solutions show dichromism with temperature and concentrations of chloride ions originating from a change of the octahedral structure to the tetrahedral one with varying numbers of chloride ions and water molecules coordinated.

A number of equilibrium studies have been carried out for cobalt(II) chloride complexes in aqueous solutions with various techniques. According to stability constants determined by Bjerrum *et al.*[11,12] and Smithson and Williams,[13] the mono- and tetrachloro complexes are present as dominant species in solutions of relatively low and high concentrations, respectively, of chloride ions, while the dichloro and trichloro complexes have a narrow concentration range of the existence.

X-Ray diffraction measurements of aqueous and alcoholic solutions of cobalt(II) chloride have been made by Wertz *et al.*,[14] and they have determined the structures of the $Co(OH_2)_6^{2+}$ and $CoCl_4^{2-}$ complexes in the solutions. The structure of hexahydrated cobalt(II) ion has also been determined by Ohtaki *et al.*[15] who obtained the Co–OH_2 bond length of 2.08 Å.

In the present investigation the structures of hydrated oxonium ion, and the $CoCl^+$ and $CoCl_4^{2-}$ complexes have been determined in aqueous solutions of lithium chloride and hydrochloric acid by the X-ray diffraction method.

Experimental

Preparation and Analysis of Sample Solutions. Cobalt(II) chloride and lithium chloride (Wako Pure Chemical Co., reagent grade) were recrystallized twice from water. Three sample solutions (A, B, and C) were prepared for the X-ray diffraction measurements. Solutions A and B contained lithium chloride and solution C was a concentrated hydrochloric acid solution, in all the solutions cobalt chloride was dissolved. The former two solutions were prepared by mixing a cobalt(II) chloride solution with a lithium chloride solution. Suitable Cl/Co mole ratios of the solutions for the present study were estimated from the stability constants given by Bjerrum *et al.*[11,12] In solution A the $CoCl^+$ complex existed as the main species, besides the hydrated cobalt(II) ion. On the other hand, the $CoCl_4^{2-}$ complex was formed in solutions B and C. A small amounts of hydrochloric acid was added to solutions A and B in order to prevent the hydrolysis of Co(II) ion.

The concentration of cobalt(II) ions was determined both by EDTA titration using a Cu–PAN indicator and electrogravimetry. The results obtained by the two methods agreed each other within the error of $\pm 0.2\%$. The concentration of chloride ions was determined gravimetrically as AgCl. Con-

centrations of hydrogen ions in the lithium chloride–cobalt chloride systems were determined coulometrically. The concentration of lithium ions was estimated from the material balance of ions in the solutions. The density of the solutions was measured with a pycnometer. The composition of the solutions is given in Table 1.

X-Ray Scattering Measurements. X-Ray scattering measurements were carried out with a JEOL θ-θ diffractometer in a room thermostated at (25±1) °C. Mo $K\alpha$ radiation (λ= 0.7107 Å) was used as an X-ray source. The scattering intensities were measured at discrete points of θ values from 1° to 70°, where 2θ is the scattering angle. Times required to accumulate 80000 counts were measured at each angle. Details of the measurements and treatments of X-ray scattering data were described in previous papers.[15–17]

All calculations were carried out by using programs KURVLR[18] and NLPLSQ.[15]

Results and Discussion

When several complexes coexist in a solution, it is usually necessary to know the formation constants of the complexes for analyzing X-ray scattering data. Since the formation constants determined in high ionic media are available in the literature for cobalt(II) chloride complexes,[11,12] the distribution of the complexes can be estimated for the sample solutions used in the present study.

Solution A contained two kinds of complexes, about 60 mol% of $CoCl^+$ and 40 mol% of Co^{2+}. In solutions B and C, the only $CoCl_4^{2-}$ complex should be formed, since the solutions contained a large excess of chloride ions. In solution C, H_3O^+ ions are present in contrast to hydrated lithium ions which are contained in solution B. The observed $s \cdot i(s)$ and $D(r)$ curves are shown in Figs. 1 and 2, respectively.

Solution A. The solution A is magenta. In the $D(r)$ (Fig. 2A) and $D(r)-4\pi r^2\rho_0$ (Fig. 3) curves we see four peaks around 1.0, 2.2, 3.3, and 4.5 Å. The small and broad peak at 1.0 Å is due to the O–H bond distance in water molecules. The second peak is attributed to the interactions between the central Co(II) and ligand atoms of its first neighbor. The Li–O distance of hydrated Li^+ ions also partly contributes to this peak. The third peak can be attributed to the Cl–O contact of hydrated Cl^- ions. The fourth peak contains contributions from several kinds of atom pairs; for instance, O–O interactions due to the tetrahedral network of bulk water and interactions between the Co(II) atom and solvent molecules in the second coordination shell. In order to estimate the structural parameters of the

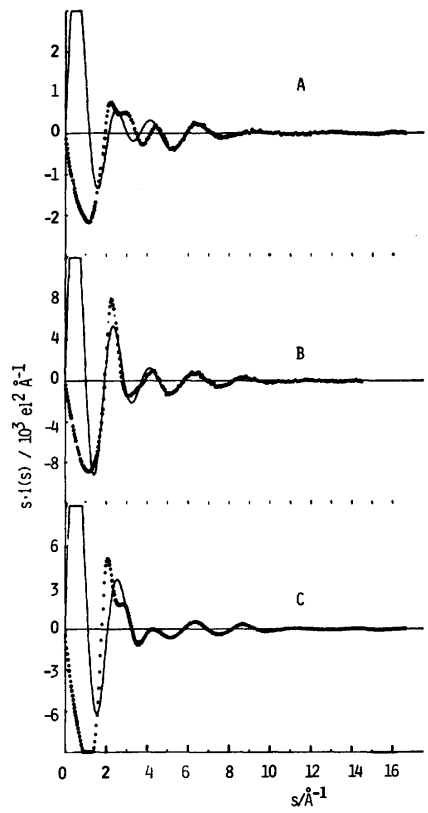

Fig. 1. The reduced intensities multiplied by s for solutions A, B, and C. The observed $s \cdot i(s)$ curves are shown by circles and the calculated ones by solid lines.

$CoCl^+$ complex, the appropriate interactions within hydrated cobalt, lithium and chloride ions should be subtracted from the observed radial distribution curve. The structural parameters used for the subtraction were quoted from the result reported for aqueous solutions of cobalt(II) perchlorate by Ohtaki *et al.*,[15] ($Co(OH_2)_6^{2+}$, Co–OH_2: 2.08 Å) and lithium chloride by Licheri *et al.*,[20] ($Li(OH_2)_4^+$, Li–OH_2: 2.10 Å; $Cl(H_2O)_6^-$, Cl–H_2O: 3.20 Å). The residual curve (chain line) in Fig. 3 shows two peaks which locate around 2.2 Å and 3.0 Å. The peak around 2.2 Å should be due to the Co–Cl and Co–O bonds within the $CoCl^+$ complex. The structure of the $CoCl^+$ complex was thus determined from the residual curve by a trial-and-error method. From the analysis, we found that the Co(II) ion within $CoCl^+$ complex combines with one chloride ion and five water molecules at the distance of 2.35 Å and 2.14 Å, respectively. Subtraction of peaks due to the Co–Cl, Co–O, O–O, and Cl–O interactions within the $CoCl(OH_2)_5^+$ complex from the residual curve led to a smooth background curve (broken line) having no appreciable peak over the range $r<4$ Å, except for the peak at about 2.9 Å which was ascribed to the O–O bonds within the bulk water. The parameter values thus estimated from the analysis of the radial distribution curve were finally refined by the least-squares method for the $s \cdot i(s)$ curve over the range $s>5$ Å^{-1}. The low-angle scattering data, which were dominated by contributions from long-range intermolecular interactions, were not included in the refinements. The results are summerized in Table 2. In the A-1 calculation, all

parameters given in the table were floated, the values being first guessed from the analysis of the radial distribution curve of solution A. On the other hand, the frequency factors of the atom-pairs in the table were fixed at the given values in the A-2 treatment. No significant difference was found in the bond lengths in the both calculations. The Co–OH_2 bond within the $CoCl(OH_2)_5^+$ complex is longer by 0.06 Å than that within the $Co(OH_2)_6^{2+}$ complex. This result suggests

that a stronger electron-donation from the Cl^- ion compared with that from a water molecule weakens the Co–OH_2 bond within the former complex. The Li–O distance was not definitely determinable by the least-squares method, because of the low concentration and low scattering power of lithium ion.

Solution B. The solution B is blue and the $D(r)$ and $D(r)-4\pi r^2\rho_0$ curves in Figs. 2B and 4 show three peaks and a shoulder at about 1.0, 2.3, 3.2, and 3.7 Å, respectively, in the range of $r<4$ Å. The peaks at 1.0 and 3.2 Å are ascribed to the O–H and Cl–O interactions, respectively, as previously observed in the case of solution A. The second peak centered around 2.3 Å may correspond to the interatomic distance between Co(II) and Cl^- ions, which has been found in the $CoCl_4^{2-}$ complex in alcoholic solutions.[14] A part of the peak is also due to the Li–O distance within hydrated lithium ions.

In the analysis of the radial distribution curve, the

The broken line gives the curve after subtraction of the peak shape calculated from model c of the hydrated oxonium and the hydrated chloride ions.

essentially same procedure as that used for solution A was employed. After subtraction of theoretical peaks due to the interatomic interactions within $Li(OH_2)_4^+$ and $Cl(H_2O)_6^-$, the chain line was obtained as the residual curve as seen in Fig. 4, from which we estimated the parameter values of interatomic interactions within the $CoCl_4^{2-}$ complex. The Co–Cl and Cl–Cl distances within the $CoCl_4^{2-}$ complex were estimated to be 2.30 Å and 3.75 Å, respectively. The ratio of the distances of Co–Cl to Cl–Cl is close to the value expected from a tetrahedral structure. The results of least-squares refinements are given in Table 3. In the course of the least-squares refinement of the structural parameters of the atom-pairs given in the table, all parameter values were allowed to change to search the best-fit result in the B-1 calculation, while the frequency factors of the Co–Cl and Cl–Cl atom-pairs were fixed at 4.0 and 6.0, respectively, in the B-2 calculation. The essentially same results were obtained in the both treatments. No evidence has been found for the existence of the hexacoordinated tetrachlorocobaltate(II) ion, $CoCl_4(OH_2)_2^{2-}$, in the present system and, therefore, no information has been obtained for the equilibrium between the hexa- and tetracoordinated $CoCl_4^{2-}$ ions.

In the $CoCl^+$ and $CoCl_4^{2-}$ complexes the Co-Cl bond distance of the former is slightly longer than that of the latter. According to Shannon,[21] the crystal radius of Co^{2+} ion having the coordination number 6 is 0.79 Å, but the radius of the Co^{2+} ion becomes 0.72 Å when the coordination number of the Co^{2+} ion decreases to 4. The change in the Co–Cl distance with changing number of chloride ion within $CoCl_n^{(2-n)+}$ complexes observed in the present investigation is consistent with Shannon's estimation for the ionic radius of cobalt(II) ion.

Solution C. The Cl/Co mole ratios of solutions B and C are almost the same. Therefore, we can reasonably assume that the $CoCl_4^{2-}$ complex in solution C has the same structure with that in solution B, and then, calculated the theoretical $s\cdot i(s)$ curve for the interactions due to Co–Cl and Cl–Cl pairs within the $CoCl_4^{2-}$ complex and the Cl–O contact within hydrated Cl^- ions. However, a comparison between the theoretical and experimental $s\cdot i(s)$ curve gave no satisfactory agreement. This might arise from the structure of hydrated oxonium ions which was not taken into consideration in the calculation in spite of a very high concentration of hydrochloric acid in the solution. Therefore, at the next step of the analysis of the $D(r)$ curve, the structure of $H_3O(H_2O)_n^+$ was taken into account. At first, peak shapes due to the Co–Cl and Cl–Cl interactions within $CoCl_4^{2-}$ were subtracted from the radial distribution curve, as seen in Fig. 5. The residual curve (chain line) shows a peak centered at 2.45 Å. The peak has not been observed in the $D(r)$ curve of the lithium chloride systems. Triolo and Narten[2] observed that the peak characteristic of the O–O hydrogen bond in hydrochloric acid solutions shifts toward a shorter distance with increasing HCl concentration from 2.85 Å in $HCl{-}95.7H_2O$ to 2.52 Å in $HCl{-}3.99H_2O$. The peak found at about 2.45 Å should be ascribed to the O–O bond within hydrated oxonium ion.

In order to determine the structure of the hydrated oxonium ion, a least-squares method was applied to the following three models.

(a) $H_3O^+(OH_2)_4$ (regular tetrahedron)
(b) $H_3O^+(OH_2)_3$ (planar triangle)
(c) $H_3O^+(OH_2)_3\cdots(H_2O)$ (trigonal pyramid)

for searching the optimum distance for the H_3O^+–H_2O interactions.

Defining an R-factor as a measure of propriety of models

$$R=\frac{\Sigma\{s\cdot i(s)_{\mathrm{calcd}}-s\cdot i(s)_{\mathrm{obsd}}\}^2}{\Sigma\{s\cdot i(s)_{\mathrm{obsd}}\}^2},$$

we calculated the R-values for the three models over the ranges $5\ \text{Å}^{-1}<s<16\ \text{Å}^{-1}$ and found the R-factor to be 0.110, 0.100, and 0.065 at the best values of the H_3O^+–H_2O bond distances for models a, b, and c, respectively. The results are summarized in Table 4. The $s\cdot i(s)$ curves of model c gave the best fit result

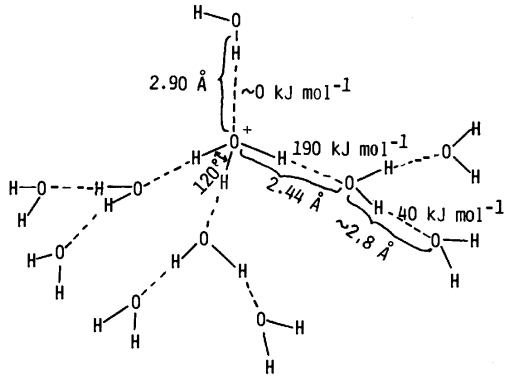

Fig. 6. The structure of the hydrated oxonium ion.

to the experimental data. The structure of model c well explains the picture of hydrated oxonium ion proposed by Grahn[10] from a molecular orbital calculation. The calculations of the total energy of the hydrated H_3O^+ ion by Grahn as a function of the H–O–H bond angle led to the minimum value when the bond angle to be 120°, *i.e.*, a planar configuration for the $H_3O^+(H_2O)_3$ moiety. The H–O–H bond angle of the hydrated H_3O^+ ion has been estimated to be 115—119° from NMR measurements for crystalline hydrates of strong acids.[22,23] From these results the structure of the $H_3O^+(OH_2)_3$ unit of the hydrated oxonium ion is anticipated to be an almost planar triangle, and one water molecule combines with the central oxygen atom of the $H_3O^+(H_2O)_3$ moiety of the hydrated oxonium ion through a weak interaction. The structure of the hydrated oxonium ion is depicted in Fig. 6, together with the bond energies calculated by Grahn.[10]

The picture shown in Fig. 6 well explains structural models of oxonium ion so far proposed by various authors by using different methods. Thus, a method which can detect water molecules most strongly combined with a proton (H^+) (*e.g.*, the compressibility method) reveals the structure of the H_3O^+ ion. When we use a method by which water molecules having relatively strong interactions compared with those between water molecules in the bulk, we might determine the hydration number of the oxonium ion to be 3. Most thermodynamic methods may be included in this category. On the other hand, diffraction methods detect water molecules at the nearest neighbor of the central oxonium ion independent of the strength of the interactions, and therefore, the methods give the hydration number four for each oxonium ion, if the oxonium ion has the structure shown in Fig. 6. The result obtained by the neutron diffraction method[3] perhaps gave an average value of the two different H_3O^+–H_2O distances, which were observed in the present investigation. The water molecule at the apex of the pyramidal structure of the hydrated oxonium ion, which interacts very weakly with the central oxygen atom of the oxonium ion, may be removed by crystallization.

Thus, the structure of oxonium ion determined in the present study gives a satisfactory interpretation for different models previously proposed by various methods, and moreover, it agrees well with the result of the theoretical calculation.[10]

The hydration number of 5.0 was obtained for a chloride ion in the hydrochloric acid system (solution C). The value is significantly smaller than that found in the lithium chloride systems, *i.e.*, n=6 (solutions A and B). The decrease in the hydration number of the chloride ion in the concentrated hydrochloric acid solution may be explained by assuming the formation of a contact ion pair between H_3O^+ and Cl^- ions. In the concentrated hydrochloric acid solution the distance between an oxonium ion and a chloride ion may simply be estimated to be about 3.1 Å, and there is practically no free water molecule in the solution. Therefore, some oxonium ions may exist in the first solvation shell of chloride ions, and the ion-dipole repulsion between the oxonium ion and water molecules in the nearest neighbor of the chloride ion becomes so large that some water molecules may be expelled from the solvation shell of the chloride ion. If a part of the total chloride ions pairing with oxonium ions has a much lower coordination number ($n \ll 6$) compared with the free chloride ion (n=6), the average coordination number of the total chloride ions in the concentrated hydrochloric acid solution may become small even if the concentration of the $H_3O^+ \cdot Cl^-$ pair is relatively low.

The present study has been partially supported by the Grant-in-Aid for Special Project Research No. 510806 from the Ministry of Education, Science and Culture.

(Received May 17, 1982)

Optically active (1*R*,2*S*)-1-aminomethyl-2-methylcyclohexylamine (*R*,*S*-2m-amcha) was synthesized and two Pt(II) and two types of Co(III) complexes containing this ligand were prepared. ^{1}H-NMR and ^{13}C-NMR spectra of the Pt(II) complexes and CD spectrum of *trans*-$[CoCl_2(R,S\text{-2m-amcha})_2]^+$ indicated that the chelate ring takes predominantly the λ conformation with the equatorial C_1–C_2 bond of the cyclohexane ring. The absolute configuration of the ligand has been assigned on the basis of the conformation of the complexes. All possible isomers of the tris Co(III) complex, *fac*-$\Delta(lel_3)$, *mer*-$\Delta(lel_3)$, *mer*-$\Lambda(ob_3)$, and *fac*-$\Lambda(ob_3)$, were isolated and characterized.

It is widely known that a chelated 1,2-diamine having mono- or disubstitution at the carbon atom of the chelate ring, such as 1,2-propanediamine or racemic 2,3-butanediamine, preferentially adopts the conformation with the substituent disposed equatorially.[2-4] However, there have been few reports on complex formation with 1,2-diamines which have two different substituents at the same carbon atom. (1*R*,2*S*)- or (1*S*,2*R*)-1-Aminomethyl-2-methylcyclohexylamine (abbreviated as 2m-amcha) is regarded as a *C*,*C*-unsymmetrically disubstituted 1,2-ethanediamine. These compounds are considered to take a fixed chair conformation with the methyl group equatorial. By virture of this group, the 2m-amcha chelate ring prefers a conformation in which C_1–C_2 bond of the cyclohexane ring lies in the equatorial position with regard to the chelate ring. In this paper we describe the preparation of (1*R*,2*S*)-1-aminomethyl-2-methylcyclohexylamine (*R*,*S*-2m-amcha), the four isomers of $[Co(R,S\text{-2m-amcha})_3]^{3+}$, *trans*-$[CoCl_2(R,S\text{-2m-amcha})_2]^+$, as well as $[Pt(NH_3)_2(R,S\text{-2m-amcha})]^{2+}$ and $[Pt(bpy)(R,S\text{-2m-amcha})]^{2+}$ (bpy=2,2′-bipyridine). Characterization of the ligand and the complexes was made by means of CD and NMR spectral analysis.

Experimental

Preparation and Resolution of the Ligand. 1-Amino-2-methylcyclohexanecarbonitrile was obtained by a slight modification of the method of Steiger.[5] To a mixture containing NaCN (50 g) and NH_4Cl (59 g) in water (240 cm^3) was added aqueous ammonia (70 cm^3, 25—28%). The resulting solution was stirred at 10—20 °C, and to this was added 2-methylcyclohexanone (112 g) in methanol (160 cm^3) dropwise. After the addition ,the mixture was stirred vigorously at 50—55 °C for 5 h. The reaction mixture was cooled, diluted with water (200 cm^3), and then extracted with ether. The ether extract was evaporated to a smalll volume. The concentrate was diluted with ethanol (100 cm^3) and cooled. Then 4 mol/dm^3 HCl (300 cm^3) was added to this ice chilled solution with stirring. The resulting amino nitrile hydrochloride was filtered by suction and washed with a small amount of cold 4 mol/dm^3 HCl.

To a cold aqueous suspension of the amino nitrile hydrochloride so obtained, was added 7 mol/dm^3 NaOH solution (200 cm^3). The oil which separated was extracted with ether. After removal of the ether, the amino nitrile was dried over K_2CO_3. The amino nitrile was reduced with $LiAlH_4$ by the usual manner.[6] In a typical reduction, 36.2 g of amino nitrile yielded 30.7 g of crude *trans*-diamine which contained small amounts of unreduced amino nitrile and *cis*-diamine.

The reaction product was purified as follows. To a solution of the crude diamine (25 g in 30 cm^3 of ethanol), a solution of (2*R*, 3*R*)-tartaric acid (52 g in 40 cm^3 of H_2O) was added. The solution was kept standing at about 60 °C for 5 min and then cooled. The product which deposited was collected by filtration and washed with ethanol. It was recrystallized from ethanol to give 33 g of colorless powder. Found: C, 41.02; H, 7.32; N, 6.04%. Calcd for $C_{16}H_{30}O_{12}\cdot 3/2\ H_2O$: C, 40.94; H, 7.09; N, 5.97%. Free racemic *trans*-2m-amcha was obtained from the diamine-hydrogentartrate as described in the literature.[7] To a solution of this salt (30 g in 70 cm^3 H_2O) was added a solution of KCl (12 g in 30 cm^3 H_2O). After heating for a while and succesive ice-cooling, the precipitated potassium hydrogentartrate was filtered off. To the filtrate, KOH (60 g) was added . The oil thus separated was extracted with ether. Racemic *trans*-diamine (9 g) was obtained by evaporationg the extract.

To a solution of (2*R*, 3*R*)-di-*O*-benzoyltartaric acid monohydrate (30.4 g in 200 cm^3 of 2-propanol), a solution of racemic 2m-diamine (11.2 g in 60 cm^3 H_2O) was added. The mixed solution was boiled for a few minutes, then cooled to afford 31.9 g of crystals (mp: 156—163 °C). Twice recrystallization of this salt from water gave 12.0 g of the less soluble (2*R*, 3*R*)-di-*O*-benzoyltartarate, mp: 156 °C, $[\alpha]_D=-74.0°$ (1.0 g in 100 cm^3 of methanol). Found: C, 51.87; H, 7.38; N, 4.72%. Calcd for $C_{26}H_{32}N_2O_8\cdot 6H_2O$: C, 51.31; H, 7.38; N, 4.60%. Treatment of this salt (12 g) with 70 cm^3 of 3 mol/dm^3 HCl gave the dihydrochloride of *R*,*S*-2m-amcha (4.5 g) whose absolute configuration was assigned by the CD spectrum of *trans*-$[CoCl_2(R,S\text{-2m-amcha})_2]^+$ as described later. Found: C, 41.57; H, 9.91; H, 11.62%. Calcd for $C_8H_{18}N_2\cdot 2HCl\cdot H_2O$: C, 41.21, H, 9.51; H, 12.01%. $[\alpha]_D=-6.2°$ (2.7 g in 100 cm^3 of H_2O). The optically active free diamine was obtained from this dihydrochloride by adding a stoichiometric quantity of sodium methoxide. It was used for the preparation of the complexes without further purification.

Preparation of Complexes. *[Pt(NH$_3$)$_2$(R,S-2m-amcha)]Cl$_2$ and [Pt(bpy)(R,S-2m-amcha)]Cl$_2$*: $[Pt(NH_3)_2(R,S\text{-2m-amcha})]Cl_2$ was synthesized by a method similar to that described in the literature.[8] $[Pt(bpy)(R,S\text{-2m-amcha})]Cl_2$ was prepared from $[PtCl_2(bpy)]$ and the ligand, according to the literature method.[9]

trans-*[CoCl$_2$(R,S-2m-amcha)$_2$]Cl*: This complex was prepared by the usual method. To a methanol solution of

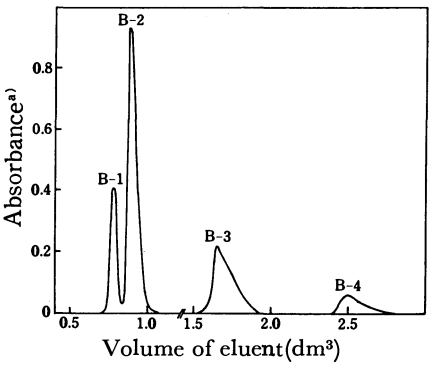

Fig. 1. Elution curve of the isomers of $[Co(R,S\text{-2m-amcha})_3]^{3+}$.
Eluent: 0.20 mol/dm³ Na_2SO_4, a) at 20.8×10^3 cm^{-1}.

$CoCl_2 \cdot 6H_2O$ was added a methanol solution of twice the amount of *R,S*-2m-amcha. The mixture was air-oxidized for 4—5 h and then evaporated. An excess amount of concentrated hydrochloric acid was added to the resulting brown residue. The green powder which formed was collected and washed thoroughly with acetone. The crude complex thus obtained was recrystallized from methanol.

Four Isomers of $[Co(R,S\text{-2m-amcha})_3]Cl_3$: Four isomers of the tris-complex were prepared by the published method[10] with slight modification. To a dimethyl sulfoxide solution (6 cm³) of *trans*-$[CoCl_2py_4]Cl_2 \cdot 6H_2O$(2 mmol) was added *R,S*-2m-amcha (8.4 mmol) dropwise. The resulting solution was stirred for 30 min, diluted with water to 2 dm³ and the pH adjusted to about 3 with hydrochloric acid. The product was adsorbed on SP-Sephadex C-25. A small portion of the adsorbed product was charged on the top of an SP-Sephadex C-25 column (2.7 cm × 65 cm) and the product was eluted with a 0.2 mol/dm³ Na_2SO_4 solution. The four bands which descended were called B-1, B-2, B-3, and B-4 (Fig. 1). Each fraction was adsorbed again on SP-Sephadex and the complex was eluted with 1 mol/dm³ hydrochloric acid solution. The eluent was concentrated on a water bath and then evaporated in a vacuum desiccator over NaOH and P_2O_5. The four complexes named B-1, B-2, B-3, and B-4 were obtained as orange powders. The B-1, B-3, and B-4 complexes were recrystallized from dilute hydrochloric acid. Recrystallization of B-2 in the chloride form was unsuccessfull. It was used without further purification. The analytical data for the complexes are given in Table 1.

Measurements: ^{1}H-NMR spectra were recorded on a JEOL JNM-MH-100 spectrometer with D_2O as a solvent and DSS as an internal reference. ^{13}C-NMR spectra were recorded on a JEOL-FX-100 spectrometer with D_2O as a solvent and TMS as an external reference. CD spectra were measured with a JASCO-J-40 spectropolarimeter, and the absorption spectra with a Shimadzu UV-210-A spectrophotometer. Optical rotations at 589 nm were measured with a JASCO-DIP-4 polarimeter.

Results and Discussion

Conformation of the Ligand. The 2m-amcha ligand has two geometrical isomers, *cis* and *trans*. Chart 1 shows the conformational pairs of the two isomers. Munday[11] reported that 1-amino-2-methylcyclohexanecarboxylic acid obtained by hydrolysis of amino nitrile by Strecker synthesis has an axial carboxyl group. However, Cremlyn[12,13] claimed that the carboxyl group of the same compound is in the equatorial position. As mentioned in the literature,[11] 1-amino-2-methylcyclohexanecarbonitrile resists hydrolysis by an ordinary method. We also obtained a similar experimental result; that hydrolysis of this compound had to be carried out in a sealed vessel at high temperature. This seems to indicate that the cyano group lies in an equatorial position close to the equatorial 2-methyl group. The 2m-amcha obtained *via* Strecker synthesis is considered to have a configuration similar to that of the corresponding amino carboxylic acid. Accordingly, the *trans*-configuration shown in Chart 1, **2a** is a dopted for this diamine.

The 100 MHz ^{1}H-NMR spectrum of amcha·2HCl is shown in Fig. 2. Two multiplet peaks around 1.4 and 1.7 ppm are attributable to the axial and equatorial methylene protons in the cyclohexane ring, respectively, although they were overlapped by one another. The signal around 2.1 ppm was assigned to the methin proton bonded axially to C_2 carbon of the cyclohexane ring, because an equatorial methin proton signal is expected to appear at a lower field. The two doublets (3.36 and 3.61 ppm) regarded as an AB pattern were assigned to the methylene protons of the aminomethyl

group. This spectral pattern suggests that *trans*-2m-amcha has the rigid structure shown in Chart 1, **2a**.

Resolution of the racemic *trans*-diamine was accomplished by recrystallization of its less soluble (2*R*,3*R*)-di-*O*-benzoyltartrate. The absolute configuration of (−)-*trans*-2m-amcha was assigned to (1*R*,2*S*) as described below.

Conformation of the Chelate Ring of the Pt(II) Complexes. In $[Pt(NH_3)_2(R,S\text{-2m-amcha})]^{2+}$ and $[Pt(bpy)(R,S\text{-2m-amcha})]^{2+}$, the equatorial proton of the aminomethyl group showed the $^{3}J_{Pt-H}$ values of 56 and 62 Hz, respectively, while the C_2 carbon of the cyclohexane ring exhibited $^{3}J_{Pt-C}$ 31.7 and 34.2 Hz, respectively (Table 2). These values were somewhat smaller than those of $[Pt(NH_3)_2(pn\text{-}d_1)]^{2+}$ [14] and $[Pt(bpy)(pn)]^{2+}$ [9] (pn-d_1= 1,2-propane-2-*d*-diamine). They were fairly small compared to those of $[Pt(NH_3)_2(R,R\text{-bn})]^{2+}$ [15] and $[Pt(bpy)(chxn)]^{2+}$ [9] having a strongly prefered conformation (*R,R*-bn=*R,R*-2,3-butanediamine, chxn=*trans*-1,2-cyclohexanediamine). We observed that the $^{3}J_{Pt-C}$ value for $[Pt(NH_3)_2(amcha)]^{2+}$ whose chelate ring is considered to interconvert between two conformations was 22.6 Hz (amcha=1-aminomethylcyclohexylamine).[16] This value is also relatively lower than that of $[Pt(bpy)(ms\text{-bn})]^{2+}$ with two conformational forms by rapid ring inversion (*ms*-bn=*meso*-2,3-butanediamine).[9] Erickson *et al.* estimated the relative contribution for the λ conformer of $[Pt(bpy)(pn)]^{2+}$ to be 72%.[9] On the other hand, Yano *et al.* reported that the $^{3}J_{Pt-C}$ values of unsymmetrical diamine complexes are smaller than those of symmetrical ones.[14] As shown in Chart 2 (b), the methyl group of 2m-amcha locates above the chelate ring, if the complex adopts a conformation with axial C_1–C_2 bond. The conformational preference of

sh: Shoulder.

2m-amcha complex is considered to be strong owing to the steric hindrance by this methyl group. Therefore, the smaller $^3J_{Pt-C}$ values for the present complexes are probably due to the unsymmetrical conformation, as claimed by Yano *et al.*,[14] rather than relative population for the $\lambda \rightleftarrows \delta$ equilibrium.

Absolute Configuration of the Ligand. It has been recognized that the conformation of a chelate ring can be assigned on the basis of the signs of the Cotton effect of *trans*-[$CoCl_2$(1,2-diamine)$_2$]$^+$ complexes in the first absorption region.[17,18] To decide the configuration (1*R*,2*S*) or (1*S*,2*R*) of (−)-*trans*-2m-amcha, we prepared *trans*-[$CoCl_2$((−)-2m-amcha)$_2$]$^+$ and examined its electronic and CD spectra. The absorption spectrum of this complex was quite similar to those of *trans*-[$CoCl_2$(*R*-pn)$_2$]$^+$[17,18] and *trans*-[$CoCl_2$(*R*-chxn)$_2$]$^+$[18,19] (Fig. 3 and Table 3). The CD sign of the (−)-2m-amcha complex was positive in the I_a (16200 cm^{-1}) and negative in the I_b (21600 cm^{-1}) regions similar to those of the *R*-pn and *R*-chxn complexes with a λ conformation. In addition, the CD spectral pattern of the (−)-2m-amcha complex in the charge-transfer region resembled those of the corresponding *R*-pn and *R*-chxn complexes, although the intensity of the CD peak was weaker for the present complex. These results indicate that the (−)-2m-amcha complex has a λ conformation. Chart 2 illustrates the λ conformation of (1*R*,2*S*)-2m-amcha and (1*S*,2*R*)-2m-amcha chelate rings. Assuming the (1*S*,2*R*)-configuration of the ligand, the considerably larger steric hindrance between the hydrogen attached

to the nitrogen of the aminomethyl group and the hydrogen of the methyl group would be explained. Therefore the absolute configuration of the (—)-2m-amcha has been deduced to be (1*R*,2*S*).

The Isomers of [*Co*(R,S-*2m-amcha*)$_3$]$^{3+}$. Four isomers named B-1, B-2, B-3, and B-4 were isolated by an SP-Sephadex C-25 chromatography (Fig. 1). The relative ratio, B-1 : B-2 : B-3 : B-4 was approximately 1 : 6 : 1.5 : 0.3. Figure 4 shows their ^{13}C-NMR spectra. Eight and seven signals were observed for the B-1 and B-4 complex, respectively. Therefore, both complexes were assigned to *fac*-isomers (C_3 symmetry). The B-2 and B-3 complexes were assigned to *mer*-isomers (C_1 symmetry) because nonequivalences for each carbon chemical shift were observed. The same assignments were also obtained from ^{1}H-NMR spectra. The B-1 and B-4 isomers showed one doublet in the methyl region, whereas complicated signals appeared for the B-2 and B-3 isomers. The resonances for methin carbons in the *lel* ring of [Co(*R*-pn)$_3$]$^{3+}$ [20] and [Co(en)$_x$-(*R*,*R*-bn)$_y$]$^{3+}$ [21] were shown to be downfield compared with those in the *ob* ring. Almost all of the signals in ^{13}C-NMR spectrum for the B-1 complex were observed in a region downfield to those of the corresponding B-4 complex. Similar downfiled shifts were also observed in the spectrum of the B-2 isomer compared with the B-3 isomer. This spectral behavior, together with relative formation ratio, suggests that the B-1, B-2, B-3, and B-4 are *fac*-(*lel*$_3$), *mer*-(*lel*$_3$), *mer*-(*ob*$_3$), and *fac*-(*ob*$_3$), respectively.

The electronic and CD spectra of these isomers are shown in Figs. 5 and 6. The numerical data are listed

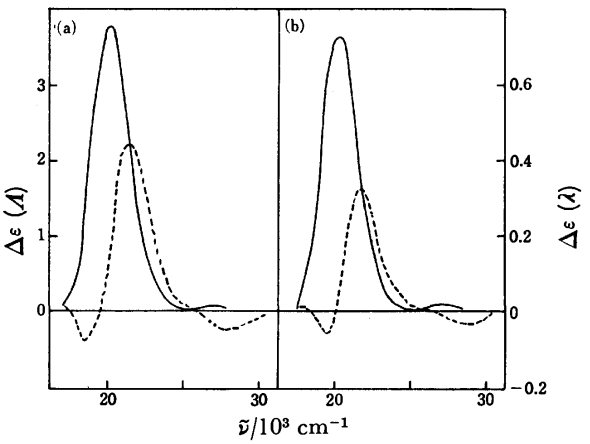

Fig. 7. Configurational effect of CD ($\Delta\varepsilon(\Lambda)$) (—) and vicinal effect of CD ($\Delta\varepsilon(\lambda)$) (---) of [Co(*R*,*S*-2m-amcha)$_3$]$^{3+}$.
(a) —: Calculated $\Delta\varepsilon(\Lambda)=1/2\{mer\text{-}\Lambda(ob_3)-mer\text{-}\Lambda(lel_3)\}$, ---: calculated $\Delta\varepsilon(\lambda)=1/6\{mer\text{-}\Lambda(ob_3)+mer\text{-}\Lambda(lel_3\}$. (b) —: Calculated $\Delta\varepsilon(\Lambda)=1/2\{fac\text{-}\Lambda(ob_3)-fac\text{-}\Lambda(lel_3)\}$, : --- calculated $\Delta\varepsilon(\lambda)=1/6\{fac\text{-}\Lambda(ob_3)+fac\text{-}\Lambda(lel_3)\}$.

in Table 3. The electronic spectral patterns of the four complexes closely resembled each other. In the CD spectra, the B-1 and B-2 isomers showed a negative band in the first absorption region and the B-3 and B-4 isomers a strong positive band in the same region. Accordingly, the former B-1 and B-2 isomers can be assigned to Λ configuration and the latter two isomers to Λ configuration, respectively. These assignments

were also supported by the CD signs and the relative intensities of the ultraviolet band, refering to the published reports.[4,22] It is known that the CD spectra of the *fac* and *mer* isomers of tris complexes having the same configuration are almost identical.[23-25] It was clearly observed that the CD spectrum of B-1(*fac*) isomer closely resembled that of B-2(*mer*) isomer. Therefore, these isomers have the same configuration. Similarly, B-3(*mer*) and B-4(*fac*) isomers have also the same configuration because they showed a similar CD patterns. In conclusion, we have assigned B-1, B-2, B-3, and B-4 isomers to *fac*-$\Delta(lel_3)$, *mer*-$\Delta(lel_3)$, *mer*-$\Lambda(ob_3)$, and *fac*-$\Lambda(ob_3)$, respectively.

Figure 7 shows the configurational and the vicinal CD curves derived from each pair ((B-2 and B-3) and (B-1 and B-4)). The calculated vicinal and configurational CD curves derived from the *fac* isomers were essentially equal to those from the *mer* isomers, respectively. This results suggest that the above assignments for the isomers were reasonable.

The authors would like to thank Misses Setsuko Kato, Shizuko Iwauchi, and Toshiko Naito of the Analytical Center of the Nagoya City University for their measurements of the NMR spectra and elemental analyses.

The Preparation of Poly(dicarbon monofluoride) *via* the Graphite Intercalation Compound

Nobuatsu WATANABE,* Tsuyoshi NAKAJIMA, Masayuki KAWAGUCHI, and Akira IZUMI
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received May 26, 1982)

Poly(dicarbon monofluoride), $(C_2F)_n$ is prepared with a higher reaction rate *via* the graphite interca lation compound formed through a reaction with F_2 and AlF_3 than from exfoliated graphite itself. The former process also has the advantage of including the formation of exfoliated graphite by the decomposition of an intercalation compound and its fluorination. The graphite fluoride thus prepared contained $(C_2F)_n$ by 60—78%. The reaction time required for completing the reaction did not give a linear relationship, but a minimum point around 267×10^2 Pa against the fluorine pressure and there was almost no increase above 667×10^2 Pa of fluorine. However, the F/C ratios of graphite fluoride had, inversely, a maximum point against the fluorine pressure, indicating that the $(C_2F)_n$ content in graphite fluoride was approximately proportional to the reaction time.

There are two kinds of graphite fluorides, poly(carbon monofluoride), $(CF)_n$ and poly(dicarbon monofluoride), $(C_2F)_n$.[1] The former is now commercially available and is used as a cathode material of lithium batteries and as a solid lubricant. $(C_2F)_n$ also has great possibilities as a new active mass for lithium batteries because it shows a higher discharge potential than $(CF)_n$,[2] however, compared with $(CF)_n$, it takes a significantly longer time to prepare $(C_2F)_n$ due to the low formation temperature, 350—400 °C. In order to facilitate the reaction rate of carbon with fluorine, exfoliated graphite[3] has been employed as a starting material; the results indicate that $(C_2F)_n$ in prepared at lower temperatures, 335—374 °C, with a higher reaction rate than in the case of flaky natural graphite.[4] It has been found that metal fluorides, such as AlF_3 and MgF_2, with a high sublimation or boiling point are intercalated into graphite layers with fluorine and that $(C_2F)_n$ is formed through the decomposition and subsequent fluorination of the graphite intercalation compound.[5,6] In this paper, the preparation of $(C_2F)_n$ *via* the graphite intercalation compound is reported.

Experimental

The starting materials are Madagascar natural graphite (149—279 μm, purity 99.4%), petroleum coke heat-treated at 2700 °C, commercial aluminum fluoride (purity 98%), and high-purity fluorine gas (purity 99.7%) supplied by the Daikin Kogyo Company, Ltd. The fluorination reaction was carried out using an automatic thermobalance.[7] Aluminum fluoride (50 mg) and graphite (50 mg) were placed in a nickel vessel hung by a nickel spring. After fluorine gas had been introduced into the nickel reaction vessel, the reaction system was kept at room temperature for 1 or 2 h; the temperature was then increased to 357—393 °C at a rate of 16 °C/min, followed by a reaction at that temperature until no weight increase was observed. The graphite fluoride thus prepared was analyzed by means of X-ray diffractometry and elemental analysis. The reaction was stopped prior to the complete fluorination of graphite, and the reaction rate was compared with that in the fluorination of exfoliated graphite by analysing the intermediate products.

Results and Discussion

Formation Process of Graphite Fluoride via *Graphite Intercalation Compound.* A typical thermogravimetric curve is shown in Fig. 1. Almost no weight charge was detected in the AlF_3–F_2 system at temperatures between room temperature and 400 °C; however, in the ternary system of natural graphite, AlF_3, and F_2, a weight increase due to the formation of a graphite intercalation compound was observed. The increase in temperature to 350—400 °C caused the decomposition of the intercalation compound, with an accompanying weight decrease, when natural graphite was expanded along the c-axis by release of the intercalant. A large weight increase was observed due to the subsequent fluorination of exfoliated graphite at temperatures between 350 and 400 °C:

$$\text{Graphite} + AlF_3 + F_2 \xrightarrow[\text{Room temperature}]{} C_xF(AlF_3)_y$$

$$\xrightarrow[350\text{—}400\ ^\circ C]{F_2} \text{Formation of exfoliated graphite} \xrightarrow[350\text{—}400\ ^\circ C]{F_2}$$

$$\text{Graphite fluoride} + AlF_3$$

a) Prepared from exfoliated graphite.

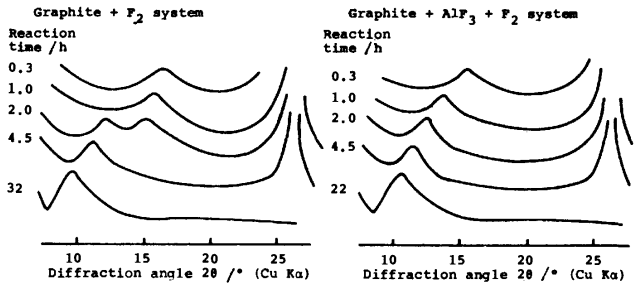

Fig. 2. Variation of (001) diffraction patterns of graphite fluoride prepared at 357 °C as a function of reaction time.

Comparison of Reaction Rates between Exfoliated Graphite and Graphite with AlF_3 Systems. In order to compare the reaction rate of exfoliated graphite with that of flaky natural graphite with an AlF_3 system, the fluorination was stopped at the initial stages of the reaction and the intermediate products were analysed. The reaction times for graphite with an AlF_3 system were those when the reaction system was above 335 °C, while for the reaction of exfoliated graphite, fluorine gas was introduced into the thermobalance maintained at a reaction temperature and the elapsed time after fluorine introduction was adopted as the reaction time. The results of elemental analyses of the products are shown in Table 1. The products obtained from graphite with an AlF_3 system contained more fluorine than those from exfoliated graphite, though the complete combustion of the products was difficult in analysis by the conventional oxygen-flask method.[8)] Figure 2 shows the X-ray diffraction patterns of these products. The small peaks between 10° and 15° in 2θ (by Cu $K\alpha$) are due to graphite fluoride, while the strong ones around 26° are due to the unreacted graphite. Since much unreacted graphite remains at the initial stage of the reaction, the intensity of the X-ray diffraction peaks for graphite fluoride was much weaker than those of unreacted graphite, though they gradually increased with the progress in the fluorination reaction. With an increase in the reaction time, the diffraction peak shifted from a higher angle due to $(CF)_n$ to a lower one due to $(C_2F)_n$ for both exfoliated graphite and graphite with AlF_3 systems, which means that $(CF)_n$ is first formed around the surface with disordered structure, followed by the formation of $(C_2F)_n$. The movement of the diffraction peak to a lower angle is faster in graphite with an AlF_3 system than for exfoliated graphite. Table 2 gives the analytical data of the products as a function of the reaction time at room temperature and also the reaction temperatures after the temperature-increase to 350—400 °C. The time required for completing the reaction was 22 h for graphite with an AlF_3 system, while it was 32 h for exfoliated graphite at 357 °C. The fluorination of graphite proceeds faster *via* the graphite intercalation compound than that of exfoliated graphite. Another advantage is that the former process includes the formation of exfoliated graphite and its fluorination.

The amount of F_2 and AlF_3 intercalated into graphite depends on the reaction time at room temperature. When the reaction time is short, only a small amount of F_2 and AlF_3 is intercalated into graphite. As a result, graphite is not fully expanded in the temperature-increase process and it takes a longer time to finish the fluorination of graphite. However, the product contains larger amount of $(C_2F)_n$ because of the lower expansion of graphite. The reaction time decreased with an increase in the reaction temperature between 357—393 °C. Compared with graphite fluoride prepared from exfoliated graphite at 357 °C, the interlayer spacing, d_{001}, of that prepared from graphite with an AlF_3 system decreased by 0.05—0.08 nm, while the half-width and the F/C ratio increased by 0.6—1° and 0.07—0.14 respectively, which means that the latter graphite fluoride contains a smaller amount of $(C_2F)_n$ than the former. These results are attributed to the larger expansion of the graphite formed by the decomposition of the intercalation compound than that of the exfoliated graphite used for comparison; this attribution was confirmed by the analytical data (Table 2) of the expanded products.

Effect of Fluorine Pressure on the Reaction Rate. The time required for completing the reaction did not give a linear relationship, but a minimum point around 267×10^2 Pa against the fluorine pressure. The reaction times were almost the same above 667×10^2 Pa of fluorine, whereas under 133×10^2 Pa it was about twice that under 267×10^2 Pa (Fig. 3). On the contrary, the F/C ratio of the products had a maximum value under 267×10^2 Pa of fluorine (Fig. 4). As was reported in a previous paper,[3)] the $(C_2F)_n$ contained in graphite fluoride can be related to the F/C ratio by representing the amounts of $(C_2F)_n$ and $(CF)_n$ as x and $1-x$ respectively: $F/C=1-1/2\times x$. The values calculated by the above equation are as follows: $(C_2F)_n$, 76—78% (F_2: 800×10^2—1013×10^2 Pa); $(C_2F)_n$, 70% (F_2: 133×10^2,

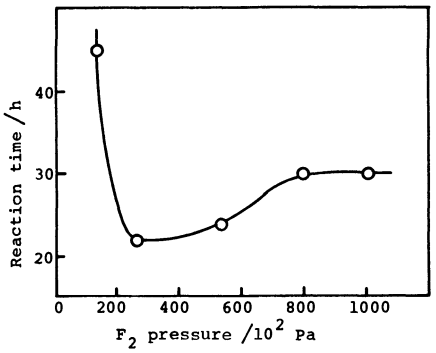

Fig. 3. Variation of reaction time of graphite fluoride as a function of F_2 pressure. Reaction temperature: 357 °C.

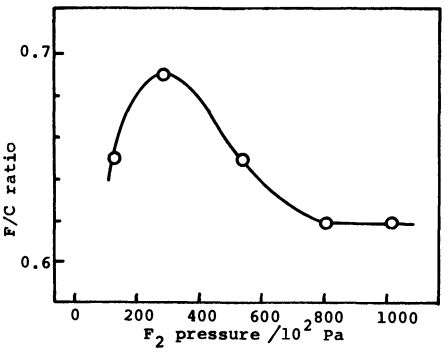

Fig. 4. Variation of F/C ratio of graphite fluuoride as a function of F_2 pressure. Reaction temperature: 357 °C.

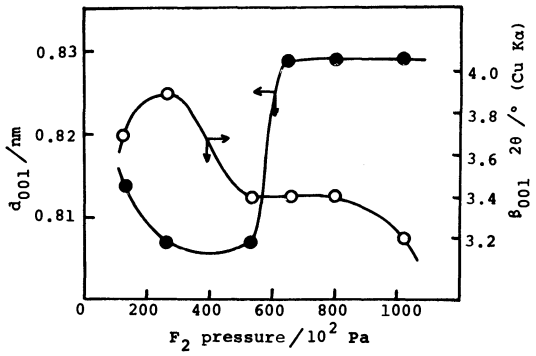

Fig. 5. Variation of d_{001} and β_{001} of graphite fluoride as a function of F_2 pressure. Reaction temperature: 357 °C.

533×10^2 Pa); $(C_2F)_n$, 62% (F_2: 267×10^2 Pa). With a decrease in the content of $(C_2F)_n$ in graphite fluoride, the interlayer spacing d_{001}, decreases, while the half-width, β_{001}, increases much as in graphite fluoride with a low crystallinity. These results show that the highest reaction rate observed under 267×10^2 Pa of fluorine is attributable to the rapid decomposition of the intercalation compound, accompanied by the large expansion of graphite. The fluorine uptake by graphite was almost the same at room temperature even under fluorine pressures of higher than 267×10^2 Pa; however, in the same range of fluorine pressure, a smaller expansion of graphite was observed, probably because the release of fluorine by the decomposition of the intercalation compound was restrained by the higher atmospheric pressure in the temperature-increase process. As a result, the reaction rate of graphite with fluorine is slower under fluorine pressure above 267×10^2 Pa. On the other hand, under a fluorine pressure of 133×10^2 Pa, the amount of fluorine absorbed by graphite at room temperature was much smaller than in other cases and the graphite was not largely expanded on the temperature-increase, which would lead to a slow reaction rate under a low fluorine pressure.

Table 3. Preparation of $(C_2F)_n$ from petroleum coke (PC)

Reaction system	Reaction temp/°C	Reaction time/h	F/C ratio	d_{001}/nm	β_{001}/°
PC–AlF_3	385	7	0.71	0.76	4.4
PC–MgF_2	383	9	0.73	0.81	4.4
PC	380	33	0.71	0.87	4.3
PC	380	13	0.67	0.86	4.3

F_2 pressure: 1013×10^2 Pa.

Preparation of $(C_2F)_n$ from Petroleum Coke (PC). Table 3 shows the data for graphite fluoride prepared from petroleum coke. As in the case of natural graphite, the reaction time decreased in the presence of AlF_3. The addition of MgF_2 also gave a similar result. The F/C ratios and half-widths of the (001) diffraction lines were slightly larger than those for graphite fluorides prepared by the direct fluorination of petroleum coke whereas the interlayer spacings, d_{001}, had an opposite relation.

As is shown in Fig. 4, graphite fluoride prepared under a fluorine pressure of 267×10^2 Pa contains the maximum amount of $(CF)_n$ in the case of natural graphite. A comparison of this graphite fluoride with that prepared from petroleum coke in the presence of AlF_3 or MgF_2 reveals that $(C_2F)_n$ is preferentially formed from natural graphite with larger crystallites. The $(C_2F)_n$ content is estimated to be 54—58% for PC with an AlF_3 or MgF_2 system and 59—66% for a PC system.

The Synthesis and Decomposition of Calcium Bis(hydrogenphosphoramidate)

Makoto WATANABE,* Toshihiko INAGAKI, and Shoji SATO

Department of Industrial Chemistry, Chubu Institute of Technology, Matsumoto-cho, Kasugai, Aichi 487

(Received June 16, 1982)

Calcium bis(hydrogenphosphoramidate)–water (2/3) was made by adding an aqueous calcium chloride solution to an aqueous potassium hydrogenphosphoramidate solution. The product decomposed slowly to diammonium calcium diphosphate monohydrate in air at room temperature. When the product was heated above 600 °C, the decomposition product was β-type calcium metaphosphate. According to the result of the isothermal decomposition of the product at 150 °C in air, no formation of P–NH–P linkages by the elimination of NH_3 from P–NH_2 linkages was observed, and it was concluded that the phosphoramidate thermally decomposed to form only polyphosphates in air.

Phosphoramidates have P–N covalent bonds and have potential of new chemical fertilizers containing phosphorus and nitrogen. Several papers concerning synthesis, decomposition, or hydrolysis of ammonium and alkali-metal salts of phosphoramidic or phosphorodiamidic acid have been published, but other salts of these phosphoramidic and phosphorodiamidic acids have not been studied. This paper describes the synthesis and decomposition of calcium bis(hydrogenphosphoramidate).

Experimental

Materials and Procedure. Ethanol was purified by distillation. Other chemicals used were of reagent grade and used without further purification. Potassium hydrogenphosphoramidate was prepared by the method described in a previous paper,[1] and 0.08 mol of the phosphoramidate was dissolved in 85 cm^{-3} of water. Calcium chloride was dissolved in 40 cm^3 of water by 0.04 mol. The calcium chloride solution was added slowly to the phosphoramidate solution below 5 °C to prevent the hydrolysis of the latter. The resulting mixture was stirred for several minutes. The pH of the solution was 6.5—6.3 during the treatment. A white precipitate was formed and was filtered off, washed with cooled water, ethanol, and then acetone. The product was dried under 5330 Pa at 25 °C for 2 d.

Elemental Analysis. Phosphorus in the product was determined by the gravimetric technique. About 0.2 g of the product was dissolved in 20 cm^3 of 6-mol nitric acid and the solution was heated on a water bath for 1 h. A few drops of concentrated hydrochloric acid was added to the solution and the solution was heated for several hours on a water bath. The orthophosphate in the solution was determined as $Mg_2P_2O_7$ by the gravimetric method.[2] Nitrogen and calcium in the product were determined by the Kjeldahl method and the EDTA (disodium dihydrogen ethylenediaminetetraacetate dihydrate) back-titration method with a calcein indicator respectively.

Paper Chromatography. One-dimensional paper chromatography was used for the separation of the phosphate species in a sample by using acidic (for the separation of chain phosphates) and basic (for the separation of ring phosphates) solvents.[3] About 0.1 g of a sample was dissolved in 10 cm^3 of a 2% EDTA aqueous solution. The pH value of the solution was adjusted to about 7 with a 0.5-mol dm^{-3} aqueous sodium hydroxide solution. About 8 mm^3 of the solution was spotted on Toyo No. 51A filter paper (2 by 50 cm). The development was run at 5 °C for 2 d.

Colorimetric Measurement of Phosphates. Every individual spot on the chromatogram was cut at the demarcation line and placed in a 100-cm^3 beaker containing 10 cm^3 of a 0.1-mol dm^{-3} ammonia solution. After 1 h, the solution was transferred to a 25-cm^3 volumetric flask, together with 10 cm^3 of wash water, and a 1-cm^3 portion of Lucena-Conde and Prat's reagent[4] was added to the flask. The flask was heated in a boiling-water bath for 1 h, subsequently cooled by placing it in a both of cold water, and diluted to the mark with water. The absorbance of the blue solution was measured with a Shimadzu Spectronic 88 spectrophotometer at 830 nm. The phosphate content (P%) was calculated from the absorbance data.

X-Ray Diffractometry. An X-ray diffraction diagram of a testing material was taken with nickel-filtered Cu *Kα* radiation by using a Toshiba X-ray diffractometer, ADG-102.

IR Measurement. IR spectra of samples were measured with a JASCO IR spectrophotometer, model A-3, using a KBr disk method.

DTA and TG. A sample was heated at the heating rate of 5 °C min^{-1} in air by using a Cho Balance $TRDA_1$-H-type apparatus.

^{31}P NMR. About 50 mg of a sample was put in 1.2 cm^3 of a 6% EDTA deuterated-water solution and stirred for several minutes. The ^{31}P NMR spectrum of the solution was recorded on a JEOL JNM-FX-60-FT-NMR instrument.

Determination of Bound Water. The amount of bound water in a sample was determined by the Karl Fisher method with an MK-AII apparatus made by Kyoto Denshi.

Decomposition in Air. The decomposition of the product at room temperature and 150 °C in air was studied by paper chromatography, X-ray diffractometry, IR spectrophotometry, and ^{31}P NMR as described above.

Results and Discussion

Composition of the Product. The yield of the product thus obtained was about 10 g. Found: P, 23.1; N, 10.4; Ca, 16.5; H_2O, 11.0%. Calcd for $Ca(HPO_3NH_2)_2 \cdot 1.5H_2O$: P, 23.9; N, 10.8; Ca, 15.5; H_2O, 10.4%. So the product is calcium bis(hydrogenphosphoramidate)–water (2/3). The product was only slightly soluble in water but soluble in an aqueous solution of EDTA.

Decomposition at Room Temperature. The stability of the product was checked at room temperature in air. The distribution of phosphate species in the decomposition product at several reaction times are listed in Table 1. The phosphoramidate decomposed to form polyphosphates. The main decomposition product was diphosphate. The IR spectra of the decomposition products

Reaction time/d	Phosphate/P(%)			
	Amide and Ortho	Di	Tri	Higher
0	100	—	—	—
15	85	15	—	—
55	66	26	5	3
176	18	70	10	2
220	14	75	9	2

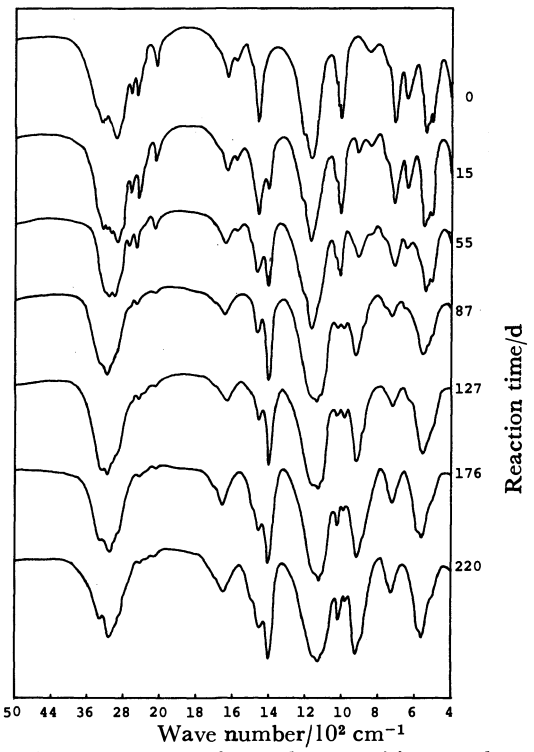

Fig. 1. IR spectra of the decomposition products of $Ca(HPO_3NH_2)_2 \cdot 1.5H_2O$ at room temperature.

are shown in Fig. 1. The assignment of the absorptions is listed in Table 2. The absorption due to a P–O–P linkage appeared and the intensity of the absorption increased with the elapse of the reaction time. The peaks of a $(PO_3)^{2-}$ group were strong even at 220 d. So the degree of polymerization of phosphates seemed to be very low. This means that most of the phosphates contained in the decomposition products are di- and triphosphates. This conclusion agrees well with that shown in Table 1. The absorption due to an ammonium ion appeared and grew with the passage of time, while the height of the absorptions associated with P–O–H and P–N–H linkages decreased with an increase in the reaction time. As Table 3 shows, the total nitrogen content in the decomposition product decreased and that of nitrogen as an ammonium ion increased with tiem. This means that an amido group is converted to an ammonium ion and the ammonia escapes gradually into the air. The discussion explains well the change in the IR spectra. Phosphoramidate having an OH-group is considered to be connected with zwitterion formation as follows:[7]

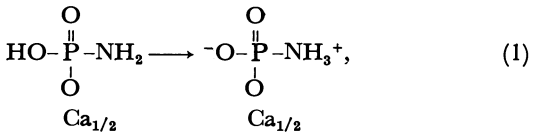
Table 2. Assignment of thf spectra of thf products

Position of absorption maxima $\tilde{\nu}/cm^{-1}$	Assignment[a]
3450	νO–H of bound water
3300—2950	ν(P)–N–H and N–H of NH_4^+
2630—2100	ν(P)–O–H
1635	δ(P)–N–H and/or δH–O–H of bound water
1580	δ(P)–N–H
1460	δ(P)–O–H
1400	δNH_4^+
1280	$\nu_{as}(PO_2)^-$
1150	$\nu_{as}(PO_3)^{2-}$
1100	$\nu_s(PO_2)^-$
1020—980	νP–O–(H) and/or $\nu_s(PO_3)^{2-}$
910	ν_{as}P–O–P
840[b]	(P–N–H or P–O–H)
780—730	νP–O–P
720—640	νP–N–(H)
580—560	$\delta(PO_2)^-$ and/or $\delta(PO_3)^{2-}$
530—500	δP–O–(H)

a) The assignment was made on the basis of Refs. 5 and 6. b) The absorption could not be assigned, but seemed to be associated with a P–N–H or a P–O–H linkage since the absorption decreased with the passage of reaction time and finally disappeared.

Table 3. Content of nitrogen in the decomposition products of $Ca(HPO_3NH_2)_2 \cdot 1.5H_2O$ at room temperature in air

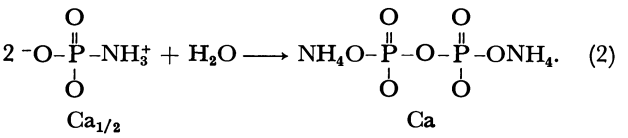
Reaction time/d	Total N(%)	N(%) as NH_4^+
0	10.4	0
15	10.2	1.2
55	9.9	3.0
176	8.3	7.5
220	8.2	7.6



$$HO\text{-}P(=O)(O)\text{-}NH_2 \longrightarrow {}^{-}O\text{-}P(=O)(O)\text{-}NH_3^{+}, \quad (1)$$

$Ca_{1/2}$ $Ca_{1/2}$

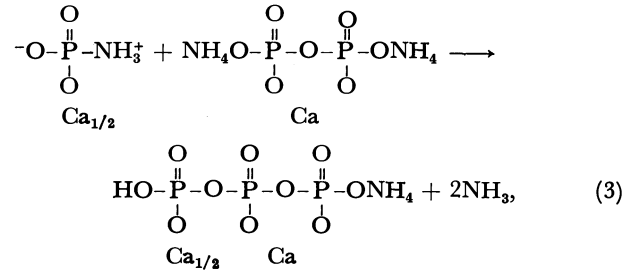
The zwitterion seems to be unstable and to decompose to diphosphate with water,



$$2\ {}^{-}O\text{-}P(=O)(O)\text{-}NH_3^{+} + H_2O \longrightarrow NH_4O\text{-}P(=O)(O)\text{-}O\text{-}P(=O)(O)\text{-}ONH_4. \quad (2)$$

$Ca_{1/2}$ Ca

The formation of polyphosphates higher than diphosphate can be represented as follows:



$$^{-}O\text{-}P(=O)(O)\text{-}NH_3^{+} + NH_4O\text{-}P(=O)(O)\text{-}O\text{-}P(=O)(O)\text{-}ONH_4 \longrightarrow$$

$Ca_{1/2}$ Ca

$$HO\text{-}P(=O)(O)\text{-}O\text{-}P(=O)(O)\text{-}O\text{-}P(=O)(O)\text{-}ONH_4 + 2NH_3, \quad (3)$$

$Ca_{1/2}$ Ca

TABLE 4. WEIGHT LOSS OF THE PRODUCT AND NITROGEN AND WATER CONTENT OF THE THERMAL DECOMPOSITION PRODUCTS

Sample	Total N(%)	Water(%)	Wt. loss/%
Product	10.4	11.0	0
No. 1	7.5	1.2	10.8
No. 2	0.8	—	23.0
No. 3	0.3	—	23.4
No. 4	—	—	23.7

and so on. The X-ray diffraction patterns of the decomposition products are shown in Fig. 2. The intensity of the diffraction peaks decreased with the passage of reaction time and the decomposition product gave very weak peaks at 86 d. Then new peaks appeared and the intensity of the peaks increased with the elapse of time. These new peaks were assigned to diammonium calcium diphosphate monohydrate, $(NH_4)_2CaP_2O_7 \cdot H_2O$ (ASTM card, No. 22-38). The result

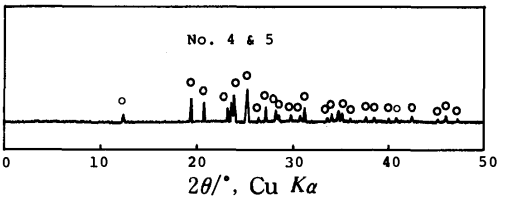

Fig. 5. X-Ray diffraction diagrams of the thermal decomposition products of $Ca(HPO_3NH_2)_2 \cdot 1.5H_2O$.
○: Peaks due to β-$Ca(PO_3)_2$ (ASTM card, No. 17-500).

agrees with that of Table 1. According to the above results, one can write a decomposition process for calcium bis(hydrogenphosphoramidate)–water (2/3) to diammonium calcium diphosphate monohydrate as follows:

$$Ca(HPO_3NH_2)_2 \cdot 1.5H_2O + 0.5H_2O \longrightarrow (NH_4)_2CaP_2O_7 \cdot H_2O. \quad (4)$$

DTA and TG. To study the thermal decomposition of the product, DTA and TG measurements of the product were made with the result shown in Fig. 3. The product decomposes at room temperature, as described above. So the product was used for the analysis immediately after synthesis to prevent the contamination by the decomposition products. The samples as numbered on Fig. 3 were removed from a furnace, cooled in a silica-gel desiccator, and subjected to further analysis. The results are presented in Table 4, and Figs. 4 and 5. As Table 4 shows, the endothermic reaction accompanying weight loss below 170 °C seemed mainly to be due to loss of bound water; the elimination of ammonia from the product was also observed in this

reaction. The sample No. 1 was amorphous and exhibited an IR absorption due to an ammonium ion and a P–O–P linkage. Polyphosphates seemed to be formed in the sample No. 1, but the strong absorption of the antisymmetric stretching of a $(PO_3)^{2-}$ group was also observed at about 1150 cm^{-1} and the absorptions of a $(PO_2)^-$ group (ν_{as}; about 1280 cm^{-1}, ν_s; about 1100 cm^{-1}) were not observed. Accordingly, the main decomposition product at this point may be diphosphate and the paper-chromatographic data concerning the distribution of phosphates in the decomposition product supported the conclusion. There appeared a broad endothermic peak and a corresponding weight loss between 170 and 430 °C. According to Table 4, the elimination of ammonia caused the weight loss. A broad exothermic peak accompanying a slight amount of weight loss was observed between 470 and 570 °C. IR spectra of Nos. 2 and 3 were very similar to each other and they involved a very small amount of nitrogen. The strong absorptions due to a $(PO_2)^-$ group and a P–O–P linkage appeared, while no obvious absorption of a $(PO_3)^{2-}$ group was observed for these samples. So the decomposition products could be highly polymerized phosphates. The samples of Nos. 2 and 3 were X-ray diffractometrically amorphous. A large exothermic peak was observed between 580 and 660 °C. The sample No. 4 gave X-ray diffraction peaks and these were all assigned to those of β-calcium metaphosphate (ASTM card, No. 17-500). Each IR peak of No. 3 split into a few peaks in the spectra of Nos. 4 and 5. According to Table 4, small difference of chemical composition was observed between the samples of Nos. 3 and 4. Therefore, the exothermic reaction may be due to the crystallization of amorphous calcium metaphosphate to the β-form. A small endothermic peak at around 820 °C may be caused by the melting of a small part of the sample because the sample after the thermal reaction was sintered. The melting of the β-form of calcium metaphosphate gave the last endothermic peak at around 950 °C. According to the above results, the following equation can be written for the overall-thermal decomposition reaction of calcium bis(hydrogenphosphoramidate)–water (2/3):

$$Ca(HPO_3NH_2)_2 \cdot 1.5H_2O \xrightarrow{(heat)} Ca(PO_3)_2 + 2NH_3 + 1.5H_2O. \quad (5)$$

The final weight loss of the product was also very close to the calculated value for the above condensation reaction.

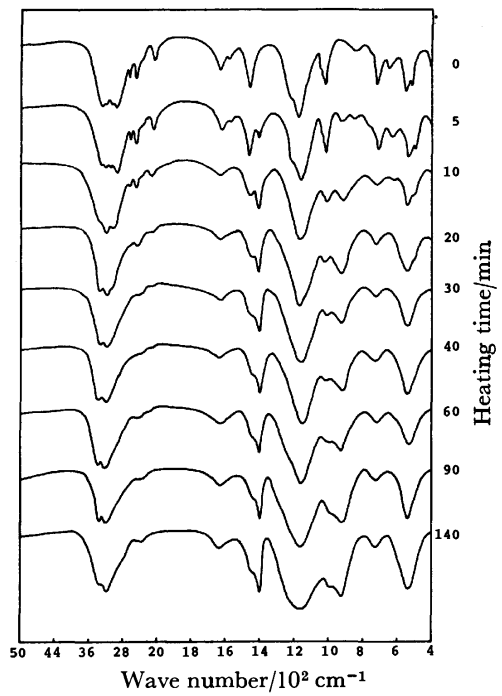

Fig. 6. IR spectra of the thermal decomposition products of $Ca(HPO_3NH_2)_2 \cdot 1.5H_2O$ at 150 °C.

Table 5. Weight loss of the product and nitrogen and water content of the thermal decomposition products at 150 °C in air

0	100	—	—	—
5	80.1	12.8	4.4	2.7
10	56.6	29.5	9.3	4.6
20	34.3	41.9	15.4	8.3
30	27.1	41.4	17.8	13.7
60	19.9	44.6	23.0	12.5
140	18.3	42.4	24.7	14.6

Decomposition at 150 °C. To gain further detailed data about the thermal decomposition of the product, an isothermal decomposition at 150 °C was run. As Table 5 shows, an amido group was converted rapidly to an ammonium ion and elimination of the ammonia from the product also took place rapidly. Bound water in the product could not be removed completely at this temperature. The IR spectra of the decomposition products are shown in Fig. 6. The peaks of P–N–H and P–O–H linkages disappeared gradually, and those due to an ammonium ion and a P–O–P linkage appeared with the elapse of reaction time. The absorptions due to a $(PO_2)^-$ group were equivocal, so the amount of phosphates having a P–O–P linkage longer than triphosphate seemed to be small in the decomposition product. As Table 6 shows, the determination of the phosphates contained in the decomposition products supported this conclusion. The main decomposition product was diphosphate. The decomposition products associated with a heating time longer than 20 min were X-ray diffractometrically amorphous. According to the above results, it is not apparent if the formation of a

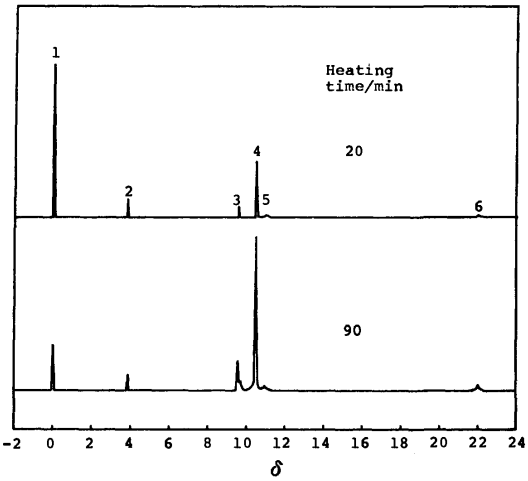

Fig. 7. ^{31}P NMR spectra of the decomposition products at 150°C.
1: Orthophosphate, 2: phosphoramidate, 3 and 4: diphosphate, 5: end PO_4 group of triphosphate, 6: middle PO_4 group of triphosphate.

P–NH–P linkage is proceeded by the elimination of ammonia between P–NH_2 linkages as follows:

$$-\overset{|}{\underset{|}{P}}-NH_2 + NH_2-\overset{|}{\underset{|}{P}}- \longrightarrow -\overset{|}{\underset{|}{P}}-NH-\overset{|}{\underset{|}{P}}- + NH_3 \quad (6)$$

The ^{31}P NMR spectra of the decomposition products at 20 and 90 min are shown in Fig. 7. No peak of any phosphorus compounds having a P–NH–P linkage was observed in the spectra. It was concluded that calcium bis(hydrogenphosphoramidate)–water (2/3) did not decompose thermally to form imidophosphates. The same decomposition processes as Reactions 1, 2, and 3 may be responsible for the thermal decomposition of the product.

Preparation and Chelation Properties of Polystyrene-Divinylbenzene Copolymer Resins Containing Pyridylamines, Salicylamine, and 2-Thenylamine

Toshiro YOKOYAMA, Atsushi KIKUCHI, Tetsuo KIMURA, and Toshishige M. SUZUKI*
Government Industrial Research Institute, Tohoku, Nigatake, Haranomachi, Sendai 983

(Received February 8, 1982)

Bidentate and tridentate ligands, 2-pyridylmethylamine, *N*-[2-(2-pyridyl)ethyl]ethylenediamine, salicylamine, and 2-thenylamine are incorporated into polystyrene–2%-divinylbenzene copolymer beads. These chelating resins are evaluated for their chelation capacity toward transition metal ions (Co^{2+}, Ni^{2+}, Cu^{2+}, and Zn^{2+}) at various pH. The chelating resins containing pyridine derivatives show a high capacity and selectivity. The selectivity of the resins for the metal ions is in the order, $Cu^{2+} \gg Ni^{2+} > Co^{2+} \geq Zn^{2+}$ which is in accord with the order of the formation constants of the introduced ligands. Separation of a metal ion mixture (Cu^{2+}, Ni^{2+}, Zn^{2+}) into its components is undertaken by a column containing the chelating resin derived from *N*-[2-(2-pyridyl)ethyl]ethylenediamine. The present resins can also be used for the elimination of trace amount of harmful heavy metal ions such as Hg^{2+} and CrO_4^{2-}.

Much attention has been drawn to the chelating polymers having the function to recover metal ions from mine tailings[1] and to eliminate trace amount of harmful metal ions from industrial effluents.[2] A large number of chelating polymers have been developed,[3] and some of them are commercially available.[4] Polystyrene–divinylbenzene copolymer is an extensively used matrix for chelating polymers because it is readily available and sufficiently durable. For the chelating polymers used in an aqueous solution, it is essential to introduce a hydrophilic character into the hydrophobic polymer matrix. Multidentate polyamines are such ligands and many polyamine-type chelating polymers based on polystyrene–divinylbenzene copolymer have been synthesized.[5] However, the introduction of multidentate polyamine tends to be accompanied by intra- and inter-strand bridging reactions which create an ambigous structure around the ligand moiety and steric restrictions for the chelate formation.[5a]

In the present work, bidentate and tridentate amines containing an aromatic side arm (Fig. 1) are introduced into insoluble polymer beads by reaction with chloromethylated polystyrene–2%-divinylbenzene copolymer. The ligands must preferentially be linked to the polymer by *N*-alkylation of the primary amine and not from the aromatic ring side. Thus, the undesirable bridging reactions can be greatly diminished. We also took into consideration Pearson's "hard and soft acid and base" concept[6] for the design of the ligands.

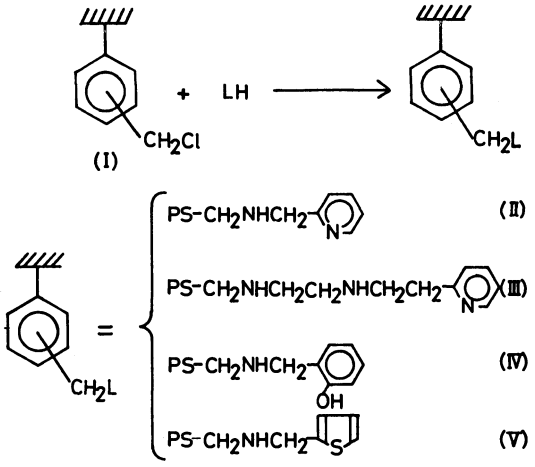

Fig. 1. Proposed structures of polymer chelating resins.

This paper deals with the preparation of the chelating resins, the examination of their capacity and selectivity toward some transition metal ions. Applications for the separation of mixed metal ions into their components and the elimination of harmful metal ions (Hg^{2+}, CrO_4^{2-}) using these resins are also investigated.

Experimental

General Procedures. All the melting and boiling points are uncorrected. The pH from 3.0 to 7.0 was adjusted with acetate buffer and below pH 3.0 with hydrochloric acid. Infrared spectra were recorded with a Hitachi 285 grating infrared spectrophotometer. ^1H NMR spectra were measured with a JEOL FX-100 spectrometer in chloroform-*d* with TMS as the internal standard. Metal ion concentration was determined with a Shimadzu atomic absorption/flame photometer Model AA-610S. Hg^{2+} was analyzed as follows: Solution containing Hg^{2+} was extracted with dithizone–chloroform solution and the solvent was evaporated on a porcelain boat. The dried sample was heated and the evaporized Hg was analyzed with an atomic absorption photometer.

Ligands. 2-Pyridylmethylamine was supplied from Aldrich Chemical Co. and purified by distillation before use. *N*-[2-(2-Pyridyl)ethyl]ethylenediamine, and salicylamine were prepared according to the method described in the literature.[7,8] 2-Thenylamine was prepared by a method similar to that for 2-pyridylmethylamine[9] using thiophene-2-aldehyde instead of pyridine-2-aldehyde. This method gave a better yield than the published one.[10] All the ligands were purified by distillation or recrystallization and identified by ^1H NMR.

Chloromethylated Polystyrene. Polystyrene-2%-divinylbenzene copolymer beads (200—400 mesh, Kanto Chemical Co.) were chloromethylated with chloromethyl methyl ether and tin(IV) chloride according to a published method.[11] The chloromethylated resin was thoroughly extracted with dioxane and dried *in vacuo* at 50 °C.

Preparation of Polymer Chelating Resins. The present ligands were incorporated into polystyrene beads using the following procedure.

TABLE 1. ANALYTICAL DATA AND CAPACITY OF LIGANDS INCORPORATED IN POLYSTYRENE

Resin	Analytical data (%)		Ligand capacity	Conversion
	Cl	N	mequiv. g^{-1} a)	% b)
I	20.82	—	5.86	86.0
II	1.29	8.03	2.87	69.4
III	3.07	9.51	2.26	67.7
IV	8.44	3.20	2.29	58.7
V	0.70	4.07	2.91	71.8

a) Calculated from the actual chlorine content (I), and nitrogen content (II, III, IV, and V).[1b] Ligand capacity (mequiv. g^{-1}) $= \frac{\%\,N}{14\,n} \times 10$, where % N = % nitrogen in product, and n = number of nitrogen atoms in the ligand. b) Based on the ratio of the actual ligand content to the theoretical value calculated from the total displacement of chlorine by the ligand.[1b] % Conversion $= \frac{\%\,N}{14\,n} \times \frac{(L-35.5)\%Cl/100+35.5}{\%Cl/100}$, where % Cl = % chlorine in the original chloromethylated polystyrene, L = ligand molecular weight minus 1.

A mixture of chlorolmethylated polystyrene beads (17.3 g, 0.1 mol) and ligand (0.4 mol) in dioxane (250 cm^3) was refluxed for 48 h with stirring. The resin was filtered off, washed first with water, and then with dioxane and transfered into a Soxhlet extractor. After extraction with dioxane for 48 h, the resin was collected, washed thoroughly with diethyl ether and dried *in vacuo* at 50 °C. The dried resins thus obtained were pale yellow or slightly brown. The analytical results (Cl, N) are summerized in Table 1.

Determination of Capacity for Metal Ion Uptake. Complexation capacities of the resins were determined as a function of pH by treating with buffered solution of Co^{2+}, Ni^{2+}, Cu^{2+}, and Zn^{2+}. Experiments were typically undertaken as follows.

One gram of dry resin was added to 100 cm^3 of buffered metal ion solution (0.2 mol/dm^3). After 20 h stirring at room temperature, the resin was loaded on a glass column (ϕ 1.0 cm × 20 cm) and washed with water. The chelated ion was stripped from the resin by elution with 2 M hydrochloric acid.† The eluate was collected in a volumetric flask and finally diluted to the mark with water. The amount of matal ion in the eluate was determined with and atomic absorption spectrometer. In most cases the resins can be regenerated by treating successively with 0.2 M hydrochloric acid, 0.2 M ammonia, and water. No significant change in capacity was detected after several times recycling the resins except for the treatment with Co^{2+}.

Chromatographic Separation of Metal Ion Mixture. One milliliter of metal salt mixture ($NiCl_2 \cdot 6H_2O$, $CuCl_2 \cdot 2H_2O$, $ZnCl_2 \cdot 2H_2O$; 1 g of each salt was dissolved in 100 cm^3 of water) was poured onto a column (ϕ1.0 cm × 13 cm) containing resin III in Table 1 (5.0 g, dry weight) which was treated with 0.1 M acetate buffer (pH 5.5) in advance. The adsorbed band was eluted at a rate of 0.27 cm^3 min^{-1} with the desired eluent: 0.1 M acetate buffer (pH 5.2) for Zn^{2+}; 0.1 M acetic acid for Ni^{2+}; and 0.5 M hydrochloric acid for Cu^{2+}. The eluate was fractionated into 4 cm^3 portions and the amount of metal ion was determined.

Elimination of Harmful Metal Ions. *Hg^{2+}*: One hundred millgram of dry resin was stirred with a buffered solution (50 cm^3) containing Hg^{2+} (1×10^{-3} g dm^{-3}) at various pH. The resin was removed by filtration after an appropriate time, and the residual Hg^{2+} in the filtrate was analyzed. The time-course of the Hg^{2+} uptake was followed by occasional extraction of samples from the mother liquor without removing the resin. The effect of ionic strength on the elimination of Hg^{2+} was examined using sodium chloride as a co-existing salt.

Cr(VI) (CrO_4^{2-}): The procedure of the elimination experiment was essentially the same as that for Hg^{2+} except that the initial concentration of Cr(VI) was 2.0×10^{-2} g dm^{-3}.

† 1 M = 1 mol dm^{-3}.

Results and Discussion

Preparation of Polymer Chelating Resins. Polystyrene–divinylbenzene copolymer is a convenient substrate for studies of polymer-support ligands because it is readily available and chemically durable. It has been pointed out that the increase in the degree of cross-linking brings about an increase in steric hindrances due to the bulky benzene nuclei, but the reduction of the cross-linking diminishes the mechanical strength of the polymer particles.[2b,5b] The polystyrene–2%-divinylbenzene beads which were used in the present study are low in divinylbenzene content, but have mechanical strength sufficient for the usual experiments. Four-fold excess of ligand to the chloromethylated polystyrene was used throughout this work, since the reaction conversion did not improve on addition of a further amount of ligand. A part of the ligand is quenched as the acid acceptor. The capacity of the incorporated ligand and the reaction conversion derived from the analytical data are summerized in Table 1. The reaction conversion was in the range of 60 to 70% with respect to the available chloromethyl groups. Although the structure of the chloromethylated polystyrene remains ambigous,[12] the ligand must be linked to the polymer matrix by the reaction of the chloromethyl group with the nucleophilic amine. The chlorine contents of the resins II and V are relatively lower than those expected from the reaction conversions. This must be due to the intra- and inter-strand bridging reactions with further alkylation of the hetero atoms. A rough estimation based on the elemental analysis of the resins II and V revealed that 65—70% of the introduced ligands have the structure depicted in Fig. 1. The undesirable side reactions are not significant for the resins III and IV and more than 80% of the ligands incorporated take up a non-bridged structure.

Complexation Capacity of Chelating Resins with Co^{2+}, Ni^{2+}, Cu^{2+}, and Zn^{2+}. The capacity of the polymer chelating resins were evaluated for the uptake of Co^{2+}, Ni^{2+}, Cu^{2+}, and Zn^{2+} as a function of pH. The maximum

TABLE 2. MAXIMUM CHELATION CAPACITY OF POLYMER RESINS FOR TRANSITION METAL IONS

Resin	Co^{2+}	Ni^{2+}	Cu^{2+}	Zn^{2+} (mequiv. g^{-1})
II	0.64	0.98	2.02	1.19
III	0.29	0.77	1.61	0.98
IV	0.01	0.00	0.17	0.08
V	0.03	0.00	0.05	0.10

capacity of the present resins are given in Table 2. The resins containing pyridine derivatives (II, III) reveal high capacities comparable to those of commercial resins[13] for the uptake of the ions. However, resins IV and V which contain relatively "softer" ligating atoms than nitrogen show little or no affinity towards these metal ions. Such a result is in accord with the fact that metal chelates of salicylamine with Cu^{2+}, Ni^{2+}, and Zn^{2+} were not formed in methanol.[14] All the chelating resins revealed a reproducible capacity on repeated adsorption and desorption cycling for most of the metal ions except for III with Co^{2+}. When Co^{2+} was adsorbed on resin III, a considerable amount of the metal ion was strongly retained on the resin, so that it could not be stripped off even by treatment with conc. hydrochloric acid. This is presumably because Co^{2+} is partially oxidized on the resin giving an inert Co^{3+} complex.

The chelating capacity *vs.* pH curves for the resins II and III are given in Figs. 2 and 3, respectively. Copper(II) was most strongly retained on these resins giving a characteristic blue color and the chelation capacity is larger than for other ions. Nickel(II) ion was retained at lower pH region than Co^{2+} and Zn^{2+}. Considerable overlapping of curves is seen for the Co^{2+} and Zn^{2+} indicating that the difference in affinity of the two ions is very small. The pH dependence curves clearly imply that the order of affinity for the resins II and III is $Cu^{2+} \gg Ni^{2+} > Co^{2+} \geq Zn^{2+}$, which is in good accordance with the order of formation constants of introduced ligands, *i.e.*, 2-pyridylmethylamine[15] and *N*-[2-(2-pyridyl)ethyl]ethylenediamine.[7] This observation prompted us to separate a metal ion mixture into its components by column chromatography. A solution containing Cu^{2+}, Ni^{2+}, and Zn^{2+} was adsorbed on a column loaded with resin III and the adsorbed band was eluted with a solution of decreasing pH. Figure 4 shows the elution curve in which the three metal ion components are well separated. This order is in agreement with the results of Storch and Manecke.[16]

Elimination of Harmful Metal Ions. *Hg^{2+}*: Elimination of trace amount of Hg^{2+} was examined under batch process using these chelating resins. Figure 5 shows the plot of residual Hg^{2+} against the pH of the solution. All the resins examined are found to be effective for the removal of nearly 99% of the initial Hg^{2+} at their optimum conditions. Resins II and III can adsorb the ion over a relatively wide pH range, while resins IV and V are effective below pH 3.0 and 2.0, respectively. It is noted that the latter two resins remove Hg^{2+} nearly quantitatively in spite of their low affinity towards the first transition metal ions. This selectivity may be understood by considering that Hg^{2+} is a "soft" acid which prefers to associate with "soft" ligand atoms.[6] Hence the resins IV and V can be used for the selective elimination of Hg^{2+} in the presence of "hard" metal ions. The time-course of Hg^{2+} uptake by the resins IV and V was followed by extraction of samples from the mother solution at appropriate

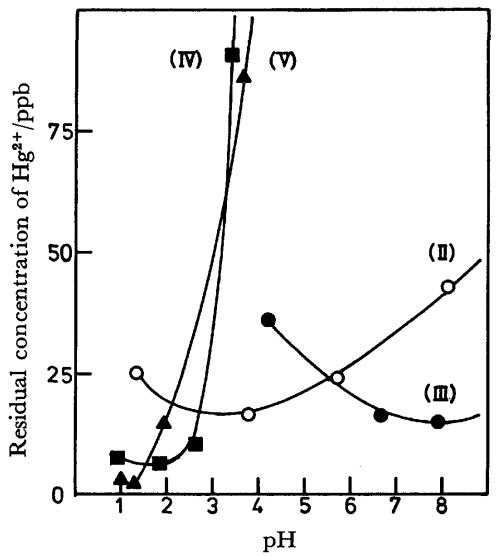

Fig. 5. Elimination of Hg^{2+} by resin II, III, IV, and V.
Conditions: amount of resin; 100 mg in 50 cm^3, concentration of Hg^{2+}; 1×10^{-3} g dm^{-3}, treating time; 15 h.

intervals. In both cases, the rapid decrease in Hg^{2+} concentration was observed and the equilibrium was attained after *ca.* 1 h. The effect of sodium chloride on the removal of Hg^{2+} was also examined for these resins. The activities of both resins do not change significantly in the presence of 0.1 M NaCl and only slightly decreases when the concentration reached 1 M. Thus these resins would be promising materials for the removal of Hg^{2+} in an effluent from soda/chlorine industry in which high concentrations of NaCl are encountered.

CrO_4^{2-}: The removal of CrO_4^{2-} was examined under batch-wise process. Resins II, III, and IV can remove CrO_4^{2-} nearly quantitatively at pH ranging 3 to 6, while the resin V reveals little affinity towards this ion. Thus it seems that "hard" ligating atoms are preferable to "soft" ones towards CrO_4^{2-}. The rate of adsorption of CrO_4^{2-} was examined at the optimum pH of each resin. Resins II and III which contain pyridine derivatives adsorbed 99% of CrO_4^{2-} in less than 10 min and the equilibrium was attained within 30 min, whereas resin IV required *ca.* 3 h for equilibriation. In all cases, CrO_4^{2-} was captured very strongly on the resin and hence quantitative recovery of the ion from the resin was difficult. Resin-CrO_4^{2-} complexes turned dark brown on standing in an aqueous solution for several hours due to oxidation of the ligand moiety. Thus the reduction in activity of the resins is inevitable on repeated cycling. Decrease in activity of the resins was also observed when sodium sulfate (>0.1 M) co-existed in the solution. This may suggest that the resins act as anion exchanger in some extent rather than a chelating agent. The details of the structure of the resin-CrO_4^{2-} complexes are under investigation.

The authors wish to thank Dr. Yoichi Sasaki of Tohoku University for his helpful suggestions and discussions.

†*College of Agriculture, University of Osaka Prefecture, Mozu-umemachi, Sakai 591*
(Received March 8, 1982)

The autoxidation of 2,3-dihydroxy-2-propenal (triose reductone) was investigated between pH 2.83 and 13.91 in the presence of disodium dihydrogen ethylenediaminetetraacetate (EDTA 2NA). The reaction obeyed the first-order rate law with respect to the triose reductone and the zeroth-order rate law with respect to oxygen when the oxygen concentration was higher than 0.246 mM (1 mM = 10^{-3} mol dm^{-3}) at 30 °C. The pH dependence of the reaction rates showed that the reaction rates are governed by the acid-base equilibrium of triose reductone. The rate constants for neutral and singly- and doubly-charged anions of triose reductone at 30 °C were $(3.6\pm0.1)\times10^{-6}$, $(7\pm1)\times10^{-5}$, and $(1.8\pm0.1)\times10^{-2}$ s^{-1} respectively. The hydrogen peroxide produced as a result of the triose reductone oxidation was also found to oxidize triose reductone.

The 2,3-dihydroxy-2-propenal produced from dextrose by alkaline hydrolysis is called triose reductone because of its strong reducing ability. The stoichiometry of the oxidation of triose reductone with hydrogen peroxide,[1] periodic acid,[2] sodium periodate,[3] iodine,[4] iron(III) chloride,[4] 2,6-dichlorophenolindophenol (DCIP),[4] and selenium oxide[5] has been studied by only a few workers. The first kinetic study of the oxidation was attempted by Arndt *et al.*,[4] but they did not determine the rate constants. Recently, Obata *et al.*[6] studied the reduction of DCIP with triose reductone in the pH range between 2 and 11; they obtained the second-order rate constants. The enzymatic autoxidation of the reductone using oxidase and peroxidase was studied in detail.[7] Although the nonenzymatic autoxidation of triose reductone was well known,[8,9] no one has studied it kinetically. Since triose reductone is an endiol compound whose redox behavior quite resembles that of the physiologically important L-ascorbic acid, we were interested in studying the autoxidation of the reductone.

Experimental

The triose reductone was prepared and purified by the method of Euler and Martius.[10] The formic acid,[11] glyoxylic acid,[12] glycolic acid,[12] glyoxal,[13] and hydrogen peroxide[14] were determined colorimetrically according to the procedures described in the literature.

Kinetic Method. The triose reductone was dissolved in a given volume of a solution, containing 4 mM each of acetic acid, phosphoric acid, and boric acid, and 1 mM of EDTA. The concentrations of the dissolved oxygen were controlled by saturating with argon, air, or oxygen gas so as to be 0.246, and 1.23 mM respectively, based on the known oxygen solubility at a given temperature. An aliquot of an aqueous solution of sodium hydroxide was added to 3 cm^3 of the triose reductone solution in a capped quartz cell, with precaution taken to avoid any change in the oxygen concentration. The oxidation time courses were followed spectrophotometrically with a Hitachi 323 Recording Spectrophotometer by measuring the decreasing absorption at 267 or 293 nm. The temperature was controlled at 30±0.1 °C. The pseudo first-order rate contant, k_{obsd}, was determined from the slope of the linear plots of log OD against time in the usual manner. The pH values of the reaction solutions were measured with a digital pH meter (Toyo Model PT-3D) before and after the reaction; we thus confirmed no appreciable pH change during the reaction. The hydrogen peroxide solution was added to the solution of triose reductone before the injection of the sodium hydroxide solution.

Results and Discussion

Dissociation Constants of Triose Reductone. Though the pK_a value for the first dissociation of triose reductone has been reported to be 5.00,[10] 4.93,[15] or 5.12,[16] the value for the second dissociation has not been available in the literature. The UV absorption spectra of triose reductone at pH 3.80, 8.00, and 13.5 under an argon atmosphere are shown in Fig. 1. An acidic solution (pH 1.5—4.1) of triose reductone showed an absorption maximum at 268 nm (ε=16300), neutral and slightly basic solutions (pH 6.8—10.0), at 293 nm (ε=24600), and a strongly basic solution (pH>13.5), at 323 nm

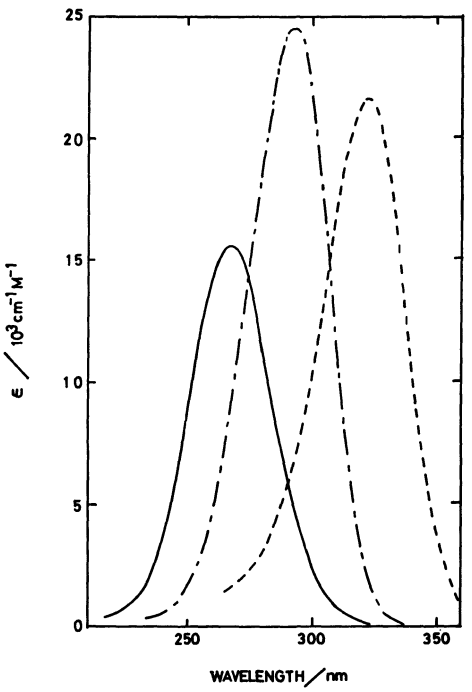

Fig. 1. Absorption spectra of triose reductone.
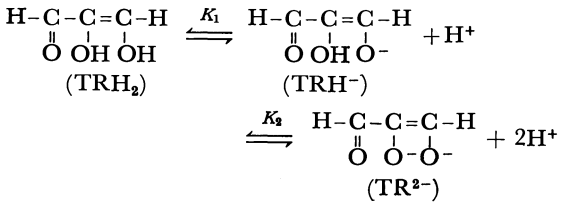
——: pH 3.80, —·—: pH 8.00, ------: pH 13.5.

(ε=23300). Triose reductone has two dissociable hydrogen atoms according to the following acid-base equilibria:



the three absorption spectra corresponding to the neutral molecule (TRH_2), the monoanion (TRH^-), and the dianion (TR^{2-}). The values of pK_{a1} and pK_{a2} can be calculated by means of Eqs. 1 and 2. The concentrations of TRH_2 and TRH^- in Eq. 1 were

$$pK_{a1} = pH + \log \frac{[TRH_2]}{[TRH^-]} \quad (1)$$

$$pK_{a2} = pH + \log \frac{[TRH^-]}{[TR^{2-}]} \quad (2)$$

computed from the spectra at pH 5—6, and those of TRH^- and TR^{2-} in Eq. 2, from the spectra at pH 12—13. The values of pK_{a1} and pK_{a2} obtained were 5.03 and 13.0 respectively at 30 °C.

Stoichiometry of the Oxidation. In the case of the autoxidation of a concentrated triose reductone solution without buffer capacity and EDTA, hydrogen peroxide was detected in the course of the reaction. However, the hydrogen peroxide disappeared after the triose reductone had been completely consumed. Table 1 shows the yields of the oxidation products from triose reductone. It has been reported that the oxidation of triose reductone with an excess of hydrogen peroxide gave carbon dioxide and formic acid.[1] In a similar way, periodic acid gave formic acid and glyoxylic acid,[2] and selenium oxide gave 2,2-dihydroxypropanedial (dehydroreductone hydrate).[5] Sodium periodate gave formic acid and glyoxylic acid in the first step, and then glyoxylic acid was oxidized to formic acid and carbon dioxide.[3] Formic acid and glyoxylic acid were detected in the present work; further, the total concentration of the two acids was found to amount to twice the triose reductone consumed (Table 1). It may be reasonable to consider that the oxidation of triose reductone with oxygen proceeds *via* a step-by-step oxidation as has been described above. The oxidation also proceeds in a similar way with the hydrogen peroxide produced by the reduction of oxygen.

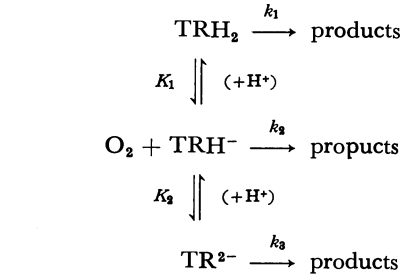
Table 1. Autoxidation of aqueous solution of triose reductone

Product	Yield/%[a]
Hydrogen peroxide	0 (12)[b]
Glyoxylic acid	30
Glycolic acid	0
Formic acid	167
Glyoxal	0

a) The yield presented is based on the assumption that 1 mol of triose reductone yields 1 mol of each of the products. b) The yield in parentheses is a value observed in the course of the reaction.

Effect of pH on Rate of Autoxidation. The UV spectra of a triose reductone solution saturated with oxygen or air were identical with those shown in Fig. 1 below pH 10. However, above pH 10 it was not clear whether or not these spectra were identical due to the fast degradation of the reductone.

The first-order rate constants (k_{obsd}/s^{-1}) were obtained from the slopes of the linear $\log[TR]_t$ *vs.* time plots, where t denotes the total analytical concentration. The pH-rate profile for the autoxidation of triose reductone at 30 °C is sigmoid (Fig. 2). For the effect of the oxygen concentration on the rate, no difference in k_{obsd} was observed in the oxygen concentration range between 0.246 and 1.23 mM. Since no oxidant other than oxygen was involved in the reaction system, the reaction rates should depend on the oxygen concentration. However, the rates were practically constant and independent of the oxygen concentration when it was over 0.246 mM. The pH-rate profile clearly reflects the involvement of various triose reductone species. We may envisage the reaction scheme shown in Scheme 1.



TRH_2 = H–C(=O)–C(OH)=C(OH)–H, $K_1 = 9.3\times10^{-6}$, and $K_2 = 1.0\times10^{-13}$.

Scheme 1.

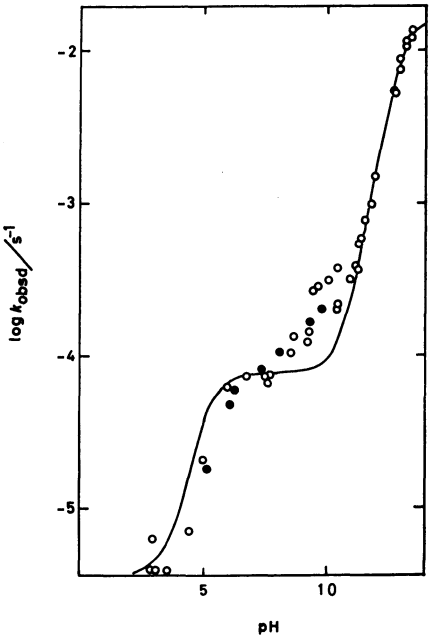


Fig. 2. Relation between log k_{obsd} and pH for the autoxidation of triose reductone at 30 °C.
○: Oxygen saturated, ●: air saturated. The solid line reflects log k_{calcd} according to Eq. 10.

Thus, at a constant acidity, the simplest rate expression is given by Eq. 3:

$$\text{rate} = k[\text{TR}]_t. \quad (3)$$

At various pH values:

$$[\text{TR}]_t = [\text{TRH}_2] + [\text{TRH}^-] + [\text{TR}^{2-}] \quad (4)$$

$$[\text{TRH}_2] = \frac{[\text{H}^+]^2}{[\text{H}^+]^2 + [\text{H}^+]K_1 + K_1K_2}[\text{TR}]_t$$

$$[\text{TRH}^-] = \frac{[\text{H}^+]K_1}{[\text{H}^+]^2 + [\text{H}^+]K_1 + K_1K_2}[\text{TR}]_t, \text{ and}$$

$$[\text{TR}^{2-}] = \frac{K_1K_2}{[\text{H}^+]^2 + [\text{H}^+]K_1 + K_1K_2}[\text{TR}]_t. \quad (5)$$

Hence, the rate equation becomes:

$$-\frac{\text{d}[\text{TR}]_t}{\text{d}t} = \frac{k_1[\text{H}^+]^2 + k_2[\text{H}^+]K_1 + k_3K_1K_2}{[\text{H}^+]^2 + [\text{H}^+]K_1 + K_1K_2}[\text{TR}]_t. \quad (6)$$

Hence, from Eq. 3 we obtain:

$$k = \frac{k_1[\text{H}^+]^2 + k_2[\text{H}^+]K_1 + k_3K_1K_2}{[\text{H}^+]^2 + [\text{H}^+]K_1 + K_1K_2}. \quad (7)$$

In the pH range of 2.8—7.7, Eq. 7 can be simplified to Eq. 8, since there is triose reductone in TRH_2 and TRH^-:

$$k = \frac{k_1[\text{H}^+]^2 + k_2[\text{H}^+]K_1}{[\text{H}^+]^2 + [\text{H}^+]K_1 + K_1K_2}. \quad (8)$$

By substituting the observed values for k and $[\text{H}^+]$ in Eq. 8, k_1 and k_2 were obtained as $(3.6\pm0.1)\times10^{-6}$ and $(7\pm1)\times10^{-5}\,\text{s}^{-1}$ respectively. Similarly, Eq. 7 can be simplified to Eq. 9 in the pH range of 10.4—13.4:

$$k = \frac{k_2[\text{H}^+]K_1 + k_3K_1K_2}{[\text{H}^+]^2 + [\text{H}^+]K_1 + K_1K_2}. \quad (9)$$

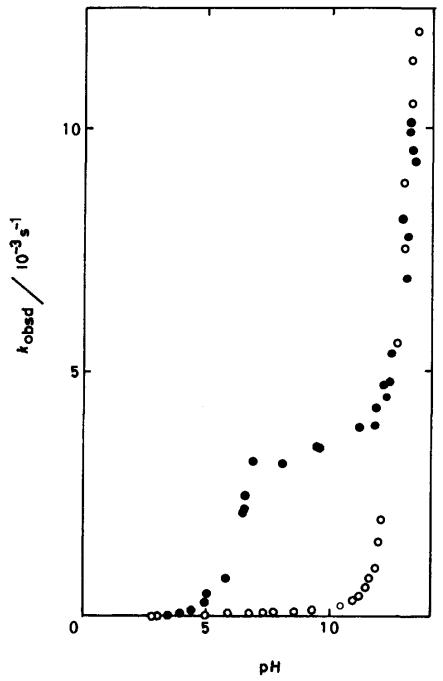

Fig. 3. Relation between k_{obsd} and pH for the autoxidation of triose reductone in the presence and absence of EDTA at 30 °C.
○: In the presence of EDTA, ●: in the absence of EDTA.

The k_3 value thus obtained was $(1.8\pm0.1)\times10^{-2}\,\text{s}^{-1}$, while k_2 was not constant. This fact suggests that the monoanion of triose reductone might be consumed by side reactions at these pHs. Considering the detection of hydrogen peroxide in the course of the autoxidation, the side reaction must be the oxidation of triose reductone with the hydrogen peroxide produced (see below). The solid line in Fig. 2 represents the theoretical plot of log k, calculated using Eq. 7, against the pH. The calculated values of k agree well with the observed k values below pH 8 and above pH 11.

The autoxidation rate constants of L-ascorbic acid at 20 °C have been reported as $8.3\times10^{-7}\,\text{s}^{-1}$ for the monoanion and $8.3\times10^{-2}\,\text{s}^{-1}$ for the dianion; furthter

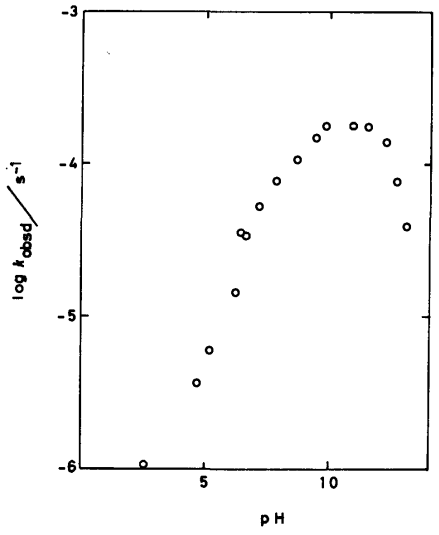

Fig. 4. Relation between log k_{obsd} and pH for the oxidation of triose reductone with hydrogen peroxide in the absence of oxygen at 30 °C.

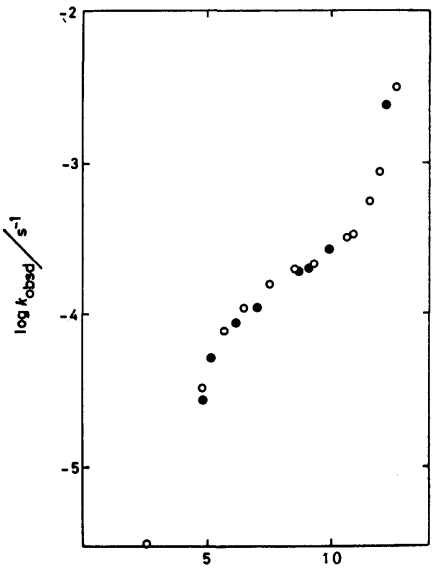

Fig. 5. Relation between log k and pH for the oxidation of triose reductone with hydrogen peroxide in the presence of oxygen at 30 °C.
○: Observed, ●: calculated.

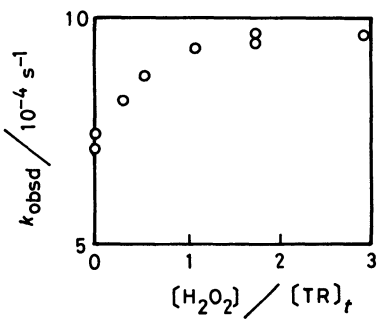

Fig. 6. Relation between k_{obsd} and ratio of hydrogen peroxide to triose reductone in the presence of oxygen at pH 6.6±0.2 and 30 °C.

the reaction rates of the monoanion are independent of the oxygen concentration.[17] Although the reaction rates of triose reductone with DCIP are slower than those of L-ascorbic acid with DCIP throughout the pH range,[6] the autoxidation rate constants are faster than those of L-ascorbic acid in the acidic and neutral pH ranges, but slower in the alkaline range.

Effect of EDTA. The autoxidation of a triose reductone solution without EDTA also obeyed the first-order rate law. Figure 3 shows the pH-rate profile of the autoxidation of triose reductone with and without EDTA. Although the effect of EDTA on rate constants was not appreciable below pH 4 or above pH 12.5, the rate constants for the autoxidation without EDTA were fifty times larger than those with EDTA at pH 7—10. The study of the inhibition of a copper catalyst on the autoxidation of L-ascorbic acid with EDTA[18] suggests that a trace amount of a metal cation may also have a catalytic effect on the autoxidation of triose reductone.

Reaction of Triose Reductone with Hydrogen Peroxide. A triose reductone solution prepared in a manner similar to the solution for the oxygen autoxidation was deoxygenated with argon. This solution was treated with a 2—3-times excess of hydrogen peroxide at 30 °C. The reaction obeyed the first-order rate law with respect to triose reductone. A plot of log k_{obsd} *vs.* pH (Fig. 4) resulted in a bell-shaped curve with a rate maximum at pH 11. On the other hand, when the solution was saturated with air instead of argon, a plot of log k_{obsd} *vs.* pH resulted in a broadly sigmoid curve (Fig. 5) resembling that in Fig. 2. For the effect of the hydrogen peroxide concentration on the rates for the system saturated with air at pH 6.48—6.80, $k_{obsd}-7.4\times10^{-4}$ was proportional to the hydrogen peroxide concentration until the latter reached the mole of triose reductone. However, k_{obsd} was constant, independently of the hydrogen peroxide concentration, when the concentration was larger than that of triose reductone (Fig. 6).

If the oxidation rate constant also depends on the dissociation of both triose reductone and hydrogen peroxide, the relationship of log k_{obsd} and pH (3—13) should be a sigmoid curve and not a bell-shaped curve. Therefore, some reactions to consume hydrogen peroxide in a higher pH range other than reduction with triose reductone might occur in the reaction system. Although the oxidation of triose reductone with hydrogen peroxide has not been explained kinetically, the reaction-rate constants for the oxidation of triose reductone with hydrogen peroxide in the presence of an oxygen molecule agreed with the sum of the reaction-rate constants for the oxygen molecule and those for hydrogen peroxide in the absence of oxygen at the same pH (Fig. 5).

Photooxidation of Some Aromatic Sulfonic Acids with Alkaline Hypochlorite[1)]

Makoto KIMURA and Yoshiro OGATA*

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received April 3, 1982)

Photochemical oxidation of aromatic sulfonic acids such as *p*-cumenesulfonic, 2-mesitylenesulfonic, 1- and 2-naphthalenesulfonic acids with aqueous sodium hypochlorite has been studied. Addition of a large excess of alkali enhances the decomposition of sulfonic acids remarkably. *p*-Cumenesulfonic and 2-mesitylenesulfonic acids are oxidized faster than 1- and 2-naphthalenesulfonic acids. The photooxidation of sulfonic acids with an equimolar amount of hypochlorite gives intermediary oxidation products involving desulfonation to parent hydrocarbons, aromatic hydroxylation, side-chain oxidation, and ring cleavage; *e.g.*, *p*-cumenesulfonic acid gives cumene, 2- and 4-isopropylphenol and 2-phenyl-2-propanol; 1- and 2-naphthalenesulfonic acids give phthalic anhydride. Light-absorbing aromatic sulfonic acids sensitize the decomposition of hypochlorite ion leading to hydroxyl radical, which reacts mainly with ground state sulfonic acid to give radical intermediates. The photooxidation may also involve direct C–S bond fission of sulfonic acids.

Alkyl-substituted aromatic sulfonic acids which are important for surfactants and dyestuffs are often present in waste water causing environmental pollution, being difficultly decomposed by the biochemical method involving microbes. UV-irradiation decomposes aromatic sulfonic acids to their parent hydrocarbons as exemplified by benzenesulfonic acid,[2)] 1-napthalenesulfonic acid, *etc.*[3)] Suitable oxidizing agents are further needed to decompose sulfonic acids into harmless substances such as carbon dioxide and water.

Sodium hypochlorite which oxidizes various organic compounds in the dark[4)] exhibits much higher oxidation power under UV-irradiation because of the formation of atomic oxygen.[5)] Thus, alkylbenzenesulfonic acids,[6)] some ethers[7)] and carboxylic acids[8)] are effectively oxidized by irradiation in the presence of a large excess of hypochlorite to carbon dioxide and water, *etc.*

We wish to report here the photochemical hypochlorite oxidation of other aromatic sulfonic acids such as *p*-cumene-, 2-mesitylene-, 1- and 2-naphthalenesulfonic acids to clarify their intermediary oxidation products and mechanism. Effects of alkali added on sulfonic acid decomposition and relative reactivity of the above sulfonic acids are also examined to elucidate the oxidation pathways.

Results and Discussion

Photodecomposition of Sodium Hypochlorite and Aromatic Sulfonic Acids. Aqueous *p*-cumene-, 2-mesitylene-, 1- and 2-naphthalenesulfonic acids were stable toward alkaline sodium hypochlorite (NaClO) in the dark at room temperature for several days. Short time irradiation of the sulfonic acids and NaClO with UV-light (λ>290 nm) brought about rapid decomposition of NaClO (iodometry) and partial decomposition of sulfonic acids (HPLC analysis). Though the extent of decomposition of sulfonic acid increased with increasing amount of NaClO added, the time for >90% decomposition of NaClO was unaffected (40—60 min) in spite of 1—20 fold change in relative amount of NaClO added. When NaClO equimolar to sulfonic acid was used, the decomposition time of NaClO was apparently independent of the kind of sulfonic acid (the decompostion extent of each sulfonic acid was *ca.* 5%). The above results indicate that the decomposition of NaClO is sensitized by excited sulfonic acids. The excitation energy of aromatic sulfonic acids (>400 kJ/mol), which is much higher than the bond-breaking energy of ClO^- (*ca.* 200 kJ/mol), would cause the effective sensitized decomposition of ClO^- irrespective of the kind of sulfonic acids.

The decomposition of sulfonic acid was found to be increased by addition of a large amount of alkali. Table 1 exemplifies the effect of alkali on the decomposition of *p*-cumenesulfonic acid. Likewise, other sulfonic acids were much more effectively decomposed by the addition of a mixture of NaOH and NaClO than by independent addition of NaOH or NaClO alone.

In order to compare the relative reactivities of sulfonic acids, a mixture of sulfonic acid, an equimolar amount of NaClO and 10-fold mol of NaOH was irradiated for 30 min by an external irradiation to measure the decomposition extents of NaClO and sulfonic acid (Table 2). The consumption of NaClO relates to the total reactivity of sulfonic acid including subsequent reactions between initial products and NaClO, while the consumption of sulfonic acid expresses the disappearance of sulfonic acid itself. The difference in two consumptions may be a measure of the subsequent reactions. Based on the consumption of NaClO, the relative reactivity of sulfonic acid is in the order of *p*-cumene- > 2-mesitylene- > 1-naphthalene- $\gtrsim$ 2-naphthalenesulfonic acid (though the former three sulfonic acids shows a similar initial reactivity on the basis of the consumption of sulfonic acid). Hence, aromatic sulfonic acids possesing side-chain alkyl substituents are relatively more susceptible to the photooxidation leading to carbon dioxide.

Intermediary Products. As observed previously with alkylbenzenesulfonic acids,[8)] the present sulfonic acids can be oxidized to carbon dioxide and water by a large excess of NaClO under irradiation. The necessary amount of NaClO for the complete oxidation was several times as much as the theoretical (25 fold mol). Use of an equimolar amount of NaClO in the photooxidation results in the formation of various intermediates. The photolysis products from a mixture of aqueous sulfonic acid, equimolar NaClO and 10 fold mol of NaOH were analyzed by GLC and GC-MS

TABLE 1. EFFECT OF ALKALI ON THE PHOTO-DECOMPOSITION OF AQUEOUS SODIUM *p*-CUMENESULFONATE[a)]

Additive (rel mol)	Decomposition (%)
None	7.5
NaClO (1)	6.8
NaClO (1) + NaOH (10)	38.0
NaOH (10)	6.4

a) Initial concentration of the sulfonate was 33.3 mM. Internal irradiation (λ>290 nm) was carried out for 45 min at room temperature.

TABLE 2. RELATIVE REACTIVITY IN THE PHOTOOXIDATION OF SODIUM ARENESULFONATE WITH AQUEOUS ALKALINE NaClO[a)]

Sulfonic acid	Consumption (%)	
	NaClO	$ArSO_3^-$
p-Cumene-	74	23
2-Mesitylene-	58	20
1-Naphthalene-	50	23
2-Naphthalene-	49	14

a) Initial concentration of each sulfonic acid was 33.3 mM. The mol ratio of $ArSO_3^-$: NaClO: NaOH was 1 : 1 : 10. External irradiation was conducted for 30 min at room temperature.

techniques, being identified by comparison with the corresponding authentic samples (Table 3).

Alkyl-substituted sulfonic acids such as *p*-cumene- and 2-mesitylenesulfonic acids gave their parent hydrocarbons (*i.e.*, cumene and mesitylene, respectively) in accord with our previous report on *p*-toluene- and *p*-ethylbenzenesulfonic acids.[6)] Though naphthalene was obtained in the simple photolysis of aqueous sodium 1-naphthalenesulfonate alone,[3)] no naphthalene was detectable in the photooxidation of 1- and 2-naphthalenesulfonic acids. Also no benzene was formed in the photooxidation of benzenesulfonic acid with NaClO, while it was formed in 16% yield in the photolysis of benzenesulfonic acid alone. Hence, alkyl substituents in sulfonic acids are hydrogen sources for the conversion of aromatic radicals to aromatic hydrocarbons.

Since the NaClO decomposition is sensitized by aromatic sulfonic acid as noted above, the present photooxidation seems to proceed *via* excited hypochlorite ion ClO^-* (Eq. 1) with less probability of the direct reaction between excited sulfonate ion $ArSO_3^-$* and ground-state hypochlorite ClO^-. Excited hypochlorite ion is known to give oxygen atoms such as O· and O$^{\tau}$,[5)] which react with water to give hydroxyl radical HO· (Eq. 2).[9)]

$$ArSO \xrightarrow{h\nu} ArSO_3^-* \xrightarrow{ClO^-} ArSO_3^- + ClO^-* \quad (1)$$

$$ClO^-* \xrightarrow[-Cl^-(\text{or } Cl\cdot)]{} O\cdot(\text{or } O^{\tau}) \xrightarrow{H_2O} HO\cdot \quad (2)$$

Some products in Table 3 can be explained in terms of an attack of HO·. Phenols such as 4-isopropylphenol and 2,4,6-trimethylphenol were obtained, indicative of aromatic hydroxylation by HO·. Though neither 1- nor 2-naphthol was detectable, 2-naphthalenesulfonic acid gave 1-chloro-2-naphthol which is readily formed even in the dark from 2-naphthol and NaClO. These phenols may be formed by the coupling of HO· with aryl radical precidently cleaved from aromatic sulfonic acid by UV-light (Eq. 3).

$$R\text{-}Ar\text{-}SO_3^- \xrightarrow[-SO_3^{\tau}]{h\nu} R\text{-}Ar\cdot \xrightarrow{HO\cdot} R\text{-}Ar\text{-}OH \quad (3)$$

As to 2-isopropylphenol which was formed in *ca.* 5 time amounts of the 4-isomer, initial hydroxylation of *p*-cumenesulfonic acid followed by Ar–SO_3^- cleavage might occur.

Products oxidized at alkyl side-chain are 2-phenyl-2-propanol from *p*-cumenesulfonic acid, and 3,5-dimethylbenzyl alcohol and 3,5-dimethylbenzoic acid from 2-mesitylenesulfonic acid. Their product ratios in Table 3 suggest that alkylbenzenesulfonic acid undergoes predominantly side-chain oxidation rather than aromatic hydroxylation, in accord with the cases of *p*-toluene- and *p*-ethylbenzenesulfonic acids.[6)] This may be reflected to the reactivities of *p*-cumene- and 2-mesitylenesulfonic acids toward NaClO, which are higher than those of 1- and 2-naphthalenesulfonic acids. The pathway for the side-chain oxidation is explained assuming radical isomerization of aromatic type to benzylic one (Eq. 4), leading successively to alcohol, aldehyde and carboxylic acid (Eq. 5).

TABLE 3. PRODUCTS AND MASS SPECTRA DATA IN THE PHOTOOXIDATION OF SOME AQUEOUS SODIUM ARENESULFONATES WITH ALKALINE NaClO[a)]

Sulfonic acid	Products (rel mol)	*m/e* (rel intensity)[b)]
p-Cumene-	Cumene (1.0)	120(57, P), 105(100)
	2-Isopropylphenol (1.6)	136(67, P), 121(100)
	4-Isopropylphenol (0.3)	136(62, P), 121(100)
	2-Phenyl-2-propanol (6.8)	118(100, P-18), 94(62)
2-Mesitylene-	Mesitylene (1.0)	120(100, P), 105(48)
	2,4,6-Trimethylphenol (2.1)	136(100, P), 121(54)
	3,5-Dimethylbenzyl alcohol (0.9)	136(100, P), 134(26), 121(50)
	3,5-Dimethylbenzoic acid (0.6)	150(100, P), 105(39), 91(31)
1-Naphthalene-	Phthalic anhydride	148(20, P), 104 (100)
2-Naphthalene-	Phthalic anhydride (1.0)	148(20, P), 104(100)
	1-Chloro-2-naphthol (0.1)	180(33, P+2), 178(100, P)

a) Aqueous solutions (300 ml) of sodium sulfonate (10 mmol), NaClO (10 mmol), and NaOH (0.1 mol) were irradiated at room temperature for 45—60 min. b) GC-MS spectra were measured at 20 eV.

$$Me_3C_6H_2\cdot \longrightarrow \cdot CH_2Me_2C_6H_3 \xrightarrow{HO\cdot} Me_2C_6H_3CH_2OH \quad (4)$$

$$Me_2C_6H_3CH_2OH \xrightarrow{[O]} Me_2C_6H_3CHO \xrightarrow{[O]} Me_2C_6H_3CO_2H \quad (5)$$

Formation of phthalic anhydride from both 1- and 2-naphthalenesulfonic acids may involve aromatic hydroxylation by HO·, ring clevage and oxidation to carboxylic acid.

Experimental

Materials. An aqueous NaClO solution was prepared by introducing chlorine gas to 4.0 M (1 M = 1 mol dm^{-3}) NaOH until the iodometry showed 1.85 M NaClO.

Arenesulfonic acids were used as their sodium salts. *p*-Cumenesulfonic acid[10] and 2-mesitylenesulfonic acid[11] were obtained from sulfonation of cumene and mesitylene, respectively. Sodium 1- and 2-naphthalenesulfonates were of commercial reagnts. Since these salts were often contaminated with NaCl, Na_2SO_4 and water, the salts were purified as follows. Crude sodium sulfonate was converted to its anilinium salt with aniline and hydrochloric acid as precipitate from aqueous solution. After repetition of crystallization from water, the resulting pure anilinium sulfonate was again converted to precipitate of sodium salt with an equivalent amount of sodium methoxide in methanol–ether. UV absorption maxima (molar extinction coefficient) of pure sodium sulfonate: *p*-cumesulfonate, 222 nm (1.22×10^4), 260 (400); 2-mesitylenesulfonate 222 (9.3×10^3), 271 (890), 280 (920); 1-naphthalenesulfonate, 222 (5.2×10^4), 283 (5.3×10^3), 317 (600); 2-naphthalenesulfonate, 227 (1.0×10^5), 274 (5.0×10^3), 320(700).

Authetic 2-phenyl-2-propanol was prepared by the Grignard reaction of methylmagnesium iodide with acetophenone.[12] Authentic 3,5-dimethylbenzoic acid was prepared by the oxidation of mesitylene with dilute HNO_3;[13] mp 165—166 °C (lit,[13] 165.5—166.5 °C). 3,5-Dimethylbenzyl alcohol was prepared by $LiAlH_4$ reduction of 3,5-dimethylbenzoic acid;[14] bp 102—103 °C/2 mm (lit,[14] 115—117.5 °C/10 mm). 1-Chloro-2-naphthol was prepared by the NaClO chlorination of sodium 2-naphtholate (80%); mp 70—71 °C (aq EtOH) (lit,[15] 71 °C). The other authentic samples were of commercial guaranteed grade.

Instruments. HPLC analyses for sulfonic acid determination[16] were carried out on a JEOL-Twincle model equipped with an ODS column using H_2O (0.01 M NaCl)/MeOH = 8/1 as the eluent. GC-MS spectra were recorded on a JMS-RD 300 model with the ionization potential set at 20 eV. GLC analyses were carried ont on a Yanaco G-180 using Silicone DC 550 or PEG 20M column.

Irradiation experiments were generally carried out in a 300 ml vessel equippped with a Halos 100 W high-pressure mercury lamp. Controlled irradiation (Table 2) was conducted on a merry-go-round apparatus equipped with a Halos 300 w high-pressure mercury lamp.

Photodecomposition of Sulfonic Acid with NaClO. An aqueous solution (300 ml) of sulfonic acid (10 mmol) and an appropriate amount of NaClO was irradiated internally at ambient temperature. The change in concentration of NaClO was followed by iodometry. When consumption of NaClO reached over 90%, sulfonic acid left was determined by HPLC. Runs in Table 1 were similarly carried out by the addition of 0.10 mol of NaOH.

In the experiments for the relative reactivity of sulfonic acids (Table 2), mixtures of each 10 ml of 0.10 M aqueous sulfonic acid, 0.1 M NaOH and 0.101 M NaClO were irradiated externally for 30 min.

Products in the Photooxidation of Sulfonic Acids with NaClO. An aqueous solution (300 ml) of a sulfonic acid (10 mmol), NaClO (10 mmol), and NaOH (0.1 mol) was irradiated internally until NaClO was consumed over 90% (45—60 min). The resulting solution was acidified with dil. HCl and extracted with ether (100 ml × 2). The ethereal layer was dried over anhydrous sodium sulfate, concentrated by distillation and analyzed by GLC aod GC-MS. Products in Table 3 were identified on the basis of accordance with the authentic samples in their GLC retention times and mass fragment patterns. All products were in low yields. In the case of 2-mesitylenesulfonic acid, formation of 2- and 4-chloro-3,5-dimethylbenzoic acids was indicated by GC-MS (rel mol *ca.* 1.0). Attempts to separate two isomers failed.

We wish to thank Professor T. Tsuda of Nagoya Institute of Technology for his kind advice on the HPLC analysis of sulfonic acids.

Regioselective Carboxylation of 9-Xanthenones with Manganese(III) Acetate

Hiroshi NISHINO* and Kazu KUROSAWA
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860
(Received April 8, 1982)

Seven 9-xanthenones were oxidized with manganese(III) acetate to give carboxy-, dicarboxy-, (acetoxymethyl)-(carboxy)-, (carboxy)(hydroxymethyl)-, and acetoxymethyl-9-xanthenones, and to yield small amounts of (carboxymethyl)(carboxy)-, carboxymethyl-, (acetoxymethyl)(carboxymethyl)-, bis(acetoxymethyl)-, and diacetoxymethyl-9-xanthenones. The carboxyl group was preferentially introduced into the peri positions and the acetoxymethyl groups were located at positions ortho to the methoxyl or methyl group. The regioselectivity and mechanism of the carboxylation reaction is discussed briefly.

We have previously reported that the oxidation of 2-hydroxybenzophenones with manganese(III) acetate gave the corresponding 9-xanthenones and trace amounts of acetoxymethylated 9-xanthenones as by-products.[1] The acetoxymethylated products were considered to be formed by further oxidation of 9-xanthenones. This prompted us to study the reaction of 9-xanthenones with manganese(III) acetate.

The reaction of several aromatic compounds with manganese(III) acetate was first investigated by S. A. Zonis.[2] This oxidation reaction mainly yielded acetoxylated compounds and ketones, and was kinetically studied by Dewar *et al.*[3] However, on oxidation under vigorous reaction conditions acetoxymethylation occurred.[4,5] This reaction specifically takes place in the manganese(III) acetate oxidation and to some extent in lead(IV) acetate oxidation.[6] Heiba and his coworkers oxidized toluene with manganese(III) acetate and obtained acetoxymethyl derivatives.[4] They studied the reaction mechanism kinetically and concluded that a carboxymethyl radical, $\cdot CH_2COOH$, formed directly from manganese(III) acetate, is involved in this reaction. We carried out the oxidation of 9-xanthenones, and obtained carboxy and acetoxymethyl derivatives. In this paper we will discuss the regioselectivity and the mechanisms of these carboxylation reactions of substituted 9-xanthenones.

Results and Discussion

The compounds studied were 9-xanthenone (**1a**), 3-methoxy-9-xanthenone (**1b**), 3,6-dimethoxy-9-xanthenone (**1c**), 2,3,6-trimethoxy-9-xanthenone (**1d**), 3-methoxy-4-methyl-9-xanthenone (**1e**), 3-methoxy-5-methyl-9-xanthenone (**1f**), and 1-methoxy-3-methyl-9-xanthenone (**1g**).

9-Xanthenones were oxidized with manganese(III) acetate dihydrate in boiling acetic acid containing acetic anhydride and the products were separated by TLC. The results are shown in Table 1 and Fig. 1.

When 9-xanthenone (**1a**) was oxidized with manganese(III) acetate, it was found that a significant amount

a) The yields are based on the amount of the substrate consumed. b) The yields of the acidic products are calculated as their methyl esters. c) Potassium acetate (60 mmol) was added to the reaction mixture. d) This oxidation was carried out under an atmosphere of nitrogen.

of acidic compounds were present in the product mixture, from which five compounds (**2a**, **4a**, **9a**, **14a**, and **19a**) were isolated (Entry 1). The IR spectrum of **2a** indicated absorptions at 1720 and 2500—3200 cm^{-1} due to carboxyl group. Its NMR spectrum showed a broad singlet at $\delta=13.0$ for a carboxylic acid and a multiplet at $\delta=7.4$—8.3 for seven aromatic protons, one of which is deshielded. Therefore, the structure of **2a** was determined to be 1-carboxy-9-xanthenone the melting point of which was close to the literature value.[10] **4a** was identified as 1,8-dicarboxy-9-xanthenone by methylation. The NMR spectrum of the methyl ester of **9a** indicated the presence of a hydroxymethyl group, $-CH_2OH$, $\delta=3.5$ (1H, broad s) and 4.99 (2H, s), and an AB quartet due to two aromatic protons $\delta=7.19$ (1H, d, $J=7.8$ Hz, $H_{(2)}$) and 7.80 (1H, d, $J=7.8$ Hz, $H_{(3)}$). In its IR spectrum two carbonyl and a hydroxyl absorptions appeared at 1645, 1745, and 3300—3500 cm^{-1}, respectively. When the corresponding methyl ester was treated with acetic anhydride in pyridine–acetic acid, the NMR spectrum of the product (**7a**) showed an acetoxymethyl group at $\delta=2.16$ (3H, s) and $\delta=5.46$ (2H, s). Accordingly, these spectral data supported the 1-carboxy-4-hydroxymethyl-9-xanthenone (**9a**) structure. Other acidic products were also formed in this oxidation reaction, but they could not be purified by TLC. **14a** was identified as 4-acetoxymethyl-9-xanthenone by comparison of its NMR spectrum with those of other 4-acetoxymethylated derivatives. The NMR spectrum of **19a** indicated the presence of a diacetoxymethyl group, $-CH(OAc)_2$, $\delta=2.16$ (6H, s) and 8.86 (1H, s), and the disappearance of one of the deshielded aromatic protons in **1a**. The IR spectrum showed carbonyl absorptions at 1686, 1755, and 1768 cm^{-1}. These spectroscopic properties are consistent with the 1-diacetoxymethyl-9-xanthenone (**19a**) structure.

The reaction of 3-methoxy-9-xanthenone (**1b**) with manganese(III) acetate gave 1-carboxy-6-methoxy- (**2b**), 1-carboxy-4-hydroxymethyl-3-methoxy- (**9b**), 1-carboxy-5-hydroxymethyl-6-methoxy- (**10b**), 4-acetoxymethyl-3-methoxy- (**14b**), and 2-acetoxymethyl-3-methoxy-9-xanthenone (**15b**) (Entry 2). The structures were confirmed by examining their IR, mass, and NMR spectra, and by elemental analyses. The NMR spectrum of **14b** showed the methylene proton of the acetoxymethyl group at $\delta=5.47$, while the methylene proton of **15b** appeared at $\delta=5.18$.

3,6-Dimethoxy-9-xanthenone (**1c**) gave 1-carboxy-3,6-dimethoxy- (**2c**), 1-carboxy-4-hydroxymethyl-3,6-dimethoxy- (**9c**), 4-carboxymethyl-3,6-dimethoxy- (**11c**), 4-acetoxymethyl-3,6-dimethoxy- (**14c**), 2-acetoxymethyl-3,6-dimethoxy- (**15c**), 4,5-bis(acetoxymethyl)-3,6-dimethoxy- (**17c**), and 2,5-bis(acetoxymethyl)-3,6-dimethoxy-9-xanthenone (**18c**) (Entry 4). The structure of the methyl ester of **11c** was elucidated from the spectroscopic evidence showing the presence of a methoxycarbonylmethyl group $\delta=3.72$ (3H, s) and 3.90 (2H, s), an AB quartet due to two aromatic protons $\delta=7.02$ (1H, d, $J=10.2$ Hz, $H_{(2)}$) and 8.29 (1H, d, $J=10.2$ Hz, $H_{(1)}$), and *m/e* 328.0939 (M^+). **18c** was not separated from **17c** because both have the same R_f values on TLC. However, the NMR spectrum of the mixture could be explained by assuming that it consists of two compounds, **17c** and **18c**. Elemental analysis also agreed with the calculated values for the molecular formula of $C_{21}H_{20}O_8$ that is the same for both compounds.

2,3,6-Trimethoxy-9-xanthenone (**1d**) yielded **2d**, **3d**, **9d**, **11d**, **14d**, and **15d** (Entry 6).

3-Methoxy-4-methyl-9-xanthenone (**1e**) gave five acidic and one neutral product. The acidic products were found to be **2e**, **3e**, **4e**, **5e**, and **9b** which is identical with the product obtained from the reaction of **1b**. The neutral product was found to be **14b**, identical with the sample obtained from the oxidation of **1b** (Entry 7).

3-Methoxy-5-methyl-9-xanthenone (**1f**) yielded two carboxylated products, the structures of which were determined as **2f** and **6f**, being characterized as their methyl esters, and two acetoxymethyl-3-methoxy-5-methyl-9-xanthenones (**14f** and **15f**) substituted at the positions ortho to the methoxyl group (Entry 8).

Oxidation of 1-methoxy-3-methyl-9-xanthenone (**1g**) gave four acidic products (**2g**, **6g**, **11g**, and **13g**) and three neutral products (**14g**, **16g**, and **17g**) (Entry 9).

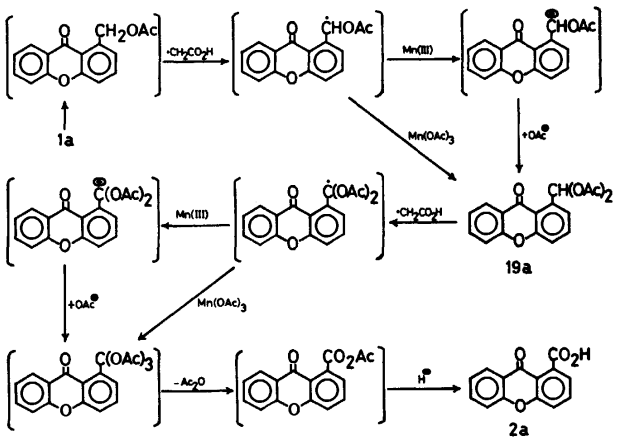
Carboxy derivatives were obtained in 3—30% yields and acetoxymethylated products in 2—25% yields. However, when **1g** was oxidized with eight equivalents of manganese(III) acetate, the yield of **14g** increased to 38% based on the **1g** consumed, while the other products were obtained only in small amounts.

It is known that the addition of potassium acetate to manganese(III) acetate oxidation increases the yield of the $-CH_2OAc$ product.[4] We studied the effect of added potassium acetate on the oxidation of **1b** (Entry 3). Contrary to our expectation the yields of the acetoxymethyl products did not increase, but two new carboxymethyl derivatives (**11b** and **12b**)were produced.

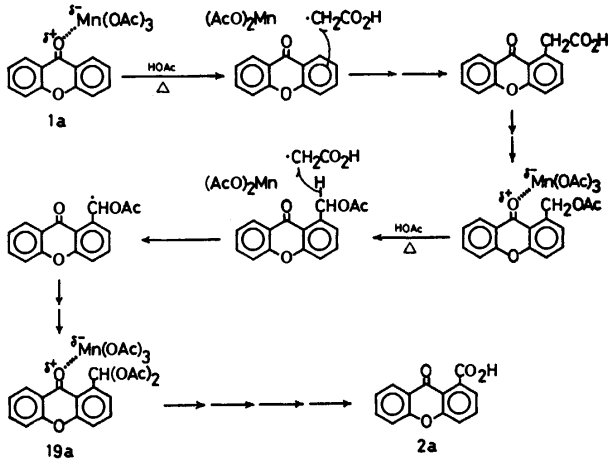
The reaction mechanism of acetoxymethylation of aromatic compounds has been established by the work of Heiba and his co-workers.[4] The carboxymethyl radical, $\cdot CH_2COOH$, which is somewhat electrophilic, attacks the positions of highest electron density. The CH_2COOH group is then converted, by oxidative decarboxylation, into the CH_2OAc group and hence these acetoxymethyl groups are situated at positions ortho to methoxyl or methyl groups. The reaction mechanism of the carboxylation, however, was not straightforward.

It is well known that the introduction of a carboxymethyl groups is the first step in the manganese(III) acetate oxidation of aromatic substrate of a higher ionization potential.[4] However, the introduction of a carboxyl group has been mentioned only by Dewar *et al.*[3] We wondered why carboxyl groups were introduced preferentially at the peri position. In the case of 9-xanthenones it is thought that the electron density of the peri position is lower because of the electron attraction by the carbonyl group, accordingly the rate of the attack at this position by the carboxymethyl radical should be slower. When a $\cdot CH_2COOH$ radical attacked at the position ortho to the methoxyl group, the oxidation reaction stopped at the stage of the $-CH_2OAc$ product. But when the $\cdot CH_2COOH$ radical attacked the peri position the oxidation did not stop at this stage, and further oxidation occurred to give a carboxyl product *via* a $-CH(OAc)_2$ compound.

To explain the fact mentioned above, we suggest that manganese(III) acetate forms a complex with the carbonyl function of 9-xanthenone and the complex subsequently decomposes to form a $\cdot CH_2COOH$ radical near the peri position. Then this position is attacked by the $\cdot CH_2COOH$ radical to form the $-CH_2COOH$ product, which is further oxidized to an acetoxymethyl compound. Another manganese(III) acetate complexes with the carbonyl group of 1-acetoxymethyl-9-xanthenones, and the second complex is decomposed again in acetic acid to yield another $\cdot CH_2COOH$ radical near the acetoxymethyl group. Consequently, the $-CH_2OAc$ compound is attacked by this radical and is then oxidized to give 1-diacetoxymethyl-9-xanthenone, which forms a third complex with manganese(III) acetate and is finally converted into the corresponding carboxy derivative *via* a similar oxidation sequence (Scheme 2). Aerial oxidation was not involved in the carboxylation, because the yields of carboxy derivatives scarcely changed as shown in



Scheme 1. Reaction mechanism of carboxylation of 9-xanthenone (**1a**) by manganese(III) acetate.



Scheme 2. Complexation between 9-xanthenone (**1a**) and manganese(III) acetate.

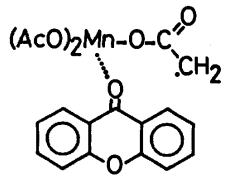


Fig. 2

the oxidation of **1c** under an atmosphere of nitrogen (Entry 5). It is also possible that the $\cdot CH_2COO-$ radical is formed on the manganese(III) acetate which is coordinated with 9-xanthenone as shown in Fig. 2, and then attacks the peri position intramolecularly.

The idea that a substrate will be oxidized *via* a complex with manganese(III) acetate has not been proposed previously. We can explain the regioselectivity of the carboxylation of the 9-xanthenone system only by assuming the complexation.

In order to investigate the carboxylation for other aromatic compounds, we carried out the oxidation of anthraquinone and benzophenone under the same reaction conditions. However, these compounds gave carboxymethyl, acetoxymethyl, and diacetoxymethy derivatives, and an aldehyde, but carboxylated products

were not detected.

It is known that **2a** is synthesized from 3-chlorophthalic acid and phenol in three steps and that it needs a long reaction time (yield: 25%).[14] On the other hand the reaction of **1a** with manganese(III) acetate gave **2a** (yield: 30%) in one step for a short reaction time. Therefore, it may be a convenient synthetic method for **2a** in some cases. The other carboxylated 9-xanthenones are new compounds and their synthetic methods are not known.

A small amount of 4- or 5-hydroxymethyl-9-xanthenones was also obtained. It seems that the corresponding acetoxymethyl-9-xanthenones were hydrolyzed to give the hydroxymethyl derivatives during the work-up.

Experimental

Measurements. ^{1}H-NMR spectra were recorded on a Hitachi Perkin-Elmer R-24 spectrometer with TMS as an internal standard. IR spectra were taken on a JASCO IRA-1 grating spectrometer. Mass spectra were measured on a Hitachi M-80 high resolution, and a JEOL JMS-01 SG-2 mass spectrometer, and a JMS-01 SG-2 instrument with direct inlet at 75 eV. HPLC analyses were performed on an Altex model 330/110A/153 isocratic liquid chromatograph equipped with a HY- ODS-5U column. Melting points were determined with a Yanagimoto micromelting point apparatus and were not corrected.

*Preparation of 9-Xanthenones (**1a—g**).* 9-Xanthenone (**1a**) was commercially available. The general proedure for the preparation of 9-xanthenones (**1b**, **c**, **f**, and **g**) was as follows.[8] A mixture of a benzoic acid (0.15 mol), a resorcinol (0.23 mol), fused zinc chloride (80 g), and phosphoryl chloride (100 ml) was heated for 3 h at 65 °C. The reaction mixture was poured into ice water (1.2 l) containing concd HCl (100 ml). The red gum which formed was decanted and triturated with an aqueous sodium hydrogencarbonate solution (800 ml). A benzophenone was formed and collected by filtration. The benzophenone (0.04 mol) and water (100 ml) were heated for 2.5 h at 210 °C in an autoclave, and the corresponding 9-xanthenone which was obtained was then methylated. **1e** was prepared from 2,4-dihydroxy-2′-methoxy-3-methylbenzophenone, which was heated with potassium hydroxide in ethanol followed by methylation.[9] **1d** was synthesized by the oxidation of 2-hydroxy-3′,4,4′-trimethoxybenzophenone with manganese(III) acetate.[11]

*Oxidation of 9-Xanthenones (**1a—g**).* The typical procedure for the oxidation of 9-xanthenones was as follows. To a mixture of the substrate (1 mmol) and acetic acid (25 ml) containing acetic anhydride (4 ml), the excess amount of manganese (III) acetate dihydrate[3] as shown in Table 1 was added. The mixture was then heated under reflux until the brown color of Mn(III) ion disappeared. After the removal of solvent *in vacuo*, the residue was triturated with 1 M (1 M=1 mol dm^{-3}) sulfuric acid (25 ml) and extracted with chloroform. The chloroform solution was washed with an aqueous sodium hydrogencarbonate solution (100 ml) and concentrated. The aqueous solution was acidified with concd hydrochloric acid and subsequently extracted with ethyl acetate. The ethyl acetate was removed and the acidic products were methylated with diazomethane in methanol. The neutral and esterified products, respectively, were separated on TLC (Wakogel B-10) with chloroform as the developing solvent, and recrystallized. The yields are summarized in Table 1.

*Oxidation Products of **1a**.* 1-*Carboxy-9-xanthenone* (**2a**): Mp 226—228 °C (EtOH) (lit,[10] mp 229—230 °C); IR (KBr) 1680 and 1720 (C=O), and 2500—3200 cm^{-1} (OH); NMR ($(CD_3)_2SO$) δ=7.39−8.26(7H, m, aromatic), and 13.0(1H, br. s, COOH).

*The Methyl Ester of **2a***: Mp 117 °C (MeOH); IR ($CHCl_3$) 1680 (C=O) and 1752 cm^{-1} ($COOCH_3$); NMR ($CDCl_3$) δ=4.03 (3H, s, $COOCH_3$), and 7.04—8.16 (7H, m, aromatic). Found: C, 71.00; H, 4.12%. Calcd for $C_{15}H_{10}O_4$: C, 70.86; H, 3.96%.

*Dimethyl Ester of 1,8-Dicarboxy-9-xanthenone (**4a**)*: Mp 183—184 °C (MeOH); IR ($CHCl_3$) 1685 (C=O) and 1750 cm^{-1} ($COOCH_3$); NMR ($CDCl_3$) δ=3.99 (6H, s, 2×$COOCH_3$), and 7.27—7.92 (6H, m, aromatic). Found: C, 65.12; H, 3.97%. Calcd for $C_{17}H_{12}O_6$: C, 65.38; H, 3.87%.

*Methyl Ester of 1-Carboxy-4-hydroxymethyl-9-xanthenone (**9a**)*: Mp 185—186 °C (MeOH); IR(KBr) 1645 (C=O), and 1745 ($COOCH_3$), and 3300—3500 cm^{-1} (OH); NMR ($CDCl_3$) δ=3.5 (1H, br. s, OH), 4.05 (3H, s, $COOCH_3$), 4.99 (2H, s, $-CH_2-$), 7.04—8.35 (4H, m, aromatic), 7.19 (1H, d, J=7.8 Hz, $H_{(2)}$), and 7.80 (1H, d, J=7.8 Hz, $H_{(3)}$). Found: *m/e* 284.0685 (M^+). Calcd for $C_{16}H_{12}O_5$: M, 284.0685.

*Acetylation of the Methyl Ester of **9a***: The methyl ester of **9a** was treated with acetic anhydride in pyridine–acetic acid at room temperatrure overnight to afford the methyl ester of 4-acetoxymethyl-1-carboxy-9-xanthenone (**7a**); mp 84—85 °C (EtOH); IR ($CHCl_3$) 1675 and 1745 cm^{-1} (C=O); NMR ($CDCl_3$) δ=2.16 (3H, s, OAc), 4.02 (3H, s, $COOCH_3$), 5.46 (2H, s, $-CH_2-$), 7.2—8.3 (4H, m, aromatic), 7.28 (1H, d, J=7.8 Hz, $H_{(2)}$), and 7.76 (1H, d, J=7, 8 Hz, $H_{(3)}$).

*4-Acetoxymethyl-9-xanthenone (**14a**)*: Mp 118—119 °C (EtOH); IR ($CHCl_3$) 1673 (C=O) and 1745 cm^{-1} (OAc); NMR ($CDCl_3$) δ=2.14 (3H, s, OAc), 5.50 (2H, s, $-CH_2-$), and 7.25—8.39 (7H, m, aromatic). Found: *m/e* 268.0736 (M^+). Calcd for $C_{16}H_{12}O_4$: M, 268.0736.

*1-Diacetoxymethyl-9-xanthenone (**19a**)*: Mp 181—182 °C (EtOH); IR (KBr) 1686 (C=O), 1755 and 1768 cm^{-1} (OAc); NMR($CDCl_3$) δ=2.18(6H, s, 2×OAc), 7.24—8.43 (7H, m, aromatic), and 8.86 (1H, s, >CH−). Found: C, 66.25; H, 4.54%. Calcd for $C_{18}H_{14}O_6$: C, 66.25; H, 4.32%.

*Oxidation Products of **1b**. Methyl Ester of 1-Carboxy-6-methoxy-9-xanthenone (**2b**)*: Mp 132—133 °C (MeOH); IR ($CHCl_3$) 1673 (C=O) and 1746 cm^{-1} ($COOCH_3$); NMR ($CDCl_3$) δ=3.82 (3H, s, OCH_3), 4.03 (3H, s, $COOCH_3$), and 6.6—8.2 (6H, m, aromatic). Found: C, 67.48; H, 4.34%. Calcd for $C_{16}H_{12}O_5$: C, 67.60; H, 4.26%.

*Methyl Ester of 1-Carboxy-4-hydroxymethyl-3-methoxy-9-xanthenone (**9b**)*: Mp 212—213 °C (MeOH); IR ($CHCl_3$) 1675 (C=O), 1750 ($COOCH_3$), and 3300—3600 cm^{-1} (OH); NMR ($CDCl_3$) δ=2.5 (1H, br. s, OH), 4.00 (3H, s, OCH_3), 4.05 (3H, s, $COOCH_3$), 5.08 (2H, s, $-CH_2-$), 6.97 (1H, s, $H_{(2)}$), and 7.2—8.3 (4H, m, aromatic); MS *m/e* 314 (M^+).

*Acetylation Product (Methyl Ester of **7b**) of the Methyl Ester of **9b***: Mp 174—175 °C (MeOH); IR ($CHCl_3$) 1670 and 1745 cm^{-1} (C=O); NMR ($CDCl_3$) δ=2.06 (3H, s, OAc), 3.97 (3H, s, OCH_3), 4.03 (3H, s, $COOCH_3$), 5.46 (2H, s, $-CH_2-$), 6.95 (1H, s, $H_{(2)}$), and 7.2—8.3 (4H, m, aromatic). Found: *m/e* 356.0895 (M^+). Calcd for $C_{19}H_{16}O_7$: M, 356.0896.

*Methyl Ester of 1-Carboxy-5-hydroxymethyl-6-methoxy-9-xanthenone (**10b**)*: Mp 198—199 °C (MeOH); IR ($CHCl_3$) 1675 (C=O), 1748 ($COOCH_3$), and 3300—3600 cm^{-1} (OH); NMR ($CDCl_3$) δ=2.4 (1H, br. s, OH), 3.98 (3H, s, OCH_3), 4.03 (3H, s, $COOCH_3$), 4.99 (2H, s, $-CH_2-$), 6.93 (1H, d, J=9.0 Hz, $H_{(7)}$), 7.15—7.65 (3H, m, aromatic), and 8.18 (1H, d, J=9.0 Hz, $H_{(8)}$); MS *m/e* 314 (M^+).

Acetylation Product (Methyl Ester of ***6b****) of the Methyl Ester of* ***10b***: Mp 199—200 °C (MeOH); IR ($CHCl_3$) 1675 and 1745 cm^{-1} (C=O); NMR ($CDCl_3$) δ=2.06 (3H, s, OAc), 3.96 (3H, s, OCH_3), 4.02 (3H, s, $COOCH_3$), 5.47 (2H, s, $-CH_2-$), 7.02 (1H, d, J=9.0 Hz, $H_{(7)}$), 7.23—7.87 (3H, m, aromatic), and 8.26 (1H, d, J=9.0 Hz, $H_{(8)}$). Found: *m/e* 356.0887 (M^+). Calcd for $C_{19}H_{16}O_7$: M. 356.0896.

4-Acetoxymethyl-3-methoxy-9-xanthenone (***14b***): Mp 185—186 °C (EtOH); IR ($CHCl_3$) 1670 (C=O) and 1748 cm^{-1} (OAc); NMR ($CDCl_3$) δ=2.07 (3H, s, OAc), 3.97 (3H, s, OCH_3), 5.47 (2H, s, $-CH_2-$), 6.99 (1H, d, J=9.0 Hz, $H_{(2)}$), 7.20—8.35 (4H, m, aromatic), and 8.30 (1H, d, J=9.0 Hz, $H_{(1)}$). Found: C, 68.14; H, 4.90%. Calcd for $C_{17}H_{14}O_5$: C, 68.45; H, 4.73%.

2-Acetoxymethyl-3-methoxy-9-xanthenone (***15b***): Mp 186—187 °C (EtOH); IR ($CHCl_3$) 1675 (C=O) and 1755 cm^{-1} (OAc); NMR ($CDCl_3$) δ=2.16 (3H, s, OAc), 3.95 (3H, s, OCH_3), 5.18 (2H, s, $-CH_2-$), 6.86 (1H, s, $H_{(4)}$), 7.24—8.36 (4H, m, aromatic), and 8.23 (1H, s, $H_{(1)}$). Found: C, 68.43; H, 4.77%. Calcd for $C_{17}H_{14}O_5$: C, 68.45; H, 4.73%.

Oxidation Products of ***1c***. *Methyl Ester of 1-Carboxy-3,6-dimethoxy-9-xanthenone* (***2c***): Mp 181 °C (MeOH); IR ($CHCl_3$) 1660 (C=O) and 1745 cm^{-1} ($COOCH_3$); NMR ($CDCl_3$) δ=3.89 (6H, s, 2×OCH_3), 4.02 (3H, s, $COOCH_3$), 6.80 (1H, dd, J=10.2 and 2.4 Hz, $H_{(7)}$), 6.84 (2H, br. s, $H_{(2)}$ and $H_{(4)}$), 6.97 (1H, d, J=2.4 Hz, $H_{(5)}$), and 8.12 (1H, d, J=10.2 Hz, $H_{(8)}$). Found: C, 65.06; H, 4.77%. Calcd for $C_{17}H_{14}O_6$: C, 64.96; H, 4.49%.

Methyl Ester of 1-Carboxy-3,6-dimethoxy-4-hydroxymethyl-9-xanthenone (***9c***): IR ($CHCl_3$) 1665 (C=O), 1750 ($COOCH_3$), and 3300—3600 cm^{-1} (OH); NMR ($CDCl_3$) δ=2.5 (1H, br. s, OH), 3.82 (3H, s, OCH_3), 3.91 (3H, s, OCH_3), 3.97 (3H, s, $COOCH_3$), 4.90 (2H, s, $-CH_2-$), 6.74 (1H, s, $H_{(2)}$), and 6.7—8.1 (3H, m, aromatic).

Acetylation Product (Methyl Ester of ***7c****) of the Methyl Ester of* ***9c***: Mp 178—180 °C (MeOH); IR ($CHCl_3$) 1670 and 1745 cm^{-1} (C=O); NMR ($CDCl_3$) δ=2.06 (3H, s, OAc), 3.90 (3H, s, OCH_3), 3.96 (3H, s, OCH_3), 4.01 (3H, s, $COOCH_3$), 5.43 (2H, s, $-CH_2-$), 6.85 (1H, s, $H_{(2)}$), and 6.8—8.2 (3H, m, aromatic). Found: *m/e* 386.0984 (M^+). Calcd for $C_{20}H_{18}O_8$: M, 386.1002.

Methyl Ester of 4-Cardoxymethyl-3,6-dimethoxy-9-xanthenone (***11c***): Mp 196—197 °C (MeOH); IR ($CHCl_3$) 1660 (C=O), and 1750 cm^{-1} ($COOCH_3$); NMR ($CDCl_3$) δ=3.72 (3H, s, $COOCH_3$), 3.90 (2H, s, $-CH_2-$), 3.95 (6H, s, 2×OCH_3), 6.92 (1H, dd, J=8.7 and 2.4 Hz, $H_{(7)}$), 7.02 (1H, d, J=10.2 Hz, $H_{(2)}$), 7.07 (1H, d, J=2.4 Hz, $H_{(5)}$), 8.25 (1H, d, J=8.7 Hz, $H_{(8)}$), and 8.29 (1H, d, J=10.2 Hz, $H_{(1)}$). Found: C, 65.78; H, 5.01%; *m/e* 328.0939 (M^+). Calcd for $C_{18}H_{16}O_6$: C, 65.85; H, 4.91%; M, 328.0947.

4-Acetoxymethyl-3,6-dimethoxy-9-xanthenone (***14c***): Mp 203 °C (EtOH); IR ($CHCl_3$) 1660 (C=O) and 1745 cm^{-1} (OAc); NMR ($CDCl_3$) δ=2.09 (3H, s, OAc), 3.90 (3H, s, OCH_3), 3.96 (3H, s, OCH_3), 5.44 (2H, s, $-CH_2-$), 6.90 (1H, dd, J=8.4 and 2.4 Hz, $H_{(7)}$), 6.96 (1H, d, J=9.0 Hz, $H_{(2)}$), 6.97 (1H, d, J=2.4 Hz, $H_{(5)}$), 8.14 (1H, d, J=8.4 Hz, $H_{(8)}$), and 8.30 (1H, d, J=9.0 Hz, $H_{(1)}$). Found: C, 65.88; H, 4.94%. Calcd for $C_{18}H_{16}O_6$: C, 65.85; H, 4.91%.

2-Acetoxymethyl-3,6-dimethoxy-9-xanthenone (***15c***): Mp 188 °C (EtOH); IR ($CHCl_3$) 1670 (C=O) and 1755 cm^{-1} (OAc); NMR ($CDCl_3$) δ=2.16 (3H, s, OAc), 3.90 (3H, s, OCH_3), 3.93 (3H, s, OCH_3), 5.14 (2H, s, $-CH_2-$), 6.79 (1H, s, $H_{(4)}$), 6.87 (1H, dd, J=9.0 and 2.4 Hz, $H_{(7)}$), 6.96 (1H, d, J=2.4 Hz, $H_{(5)}$), 8.20 (1H, d, J=9.0 Hz, $H_{(8)}$), and 8.21 (1H, s, $H_{(1)}$). Found: C, 65.54; H, 4.98%. Calcd for $C_{18}H_{16}O_6$: C, 65.85; H, 4.91%.

4,5-Bis(acetoxymethyl)-3,6-dimethoxy-9-xanthenone (***17c***) *and 2,5-Bis(acetoxymethyl)-3,6-dimethoxy-9-xanthenone* (***18c***): The mixture of **17c** and **18c** could not be completely separated. However, the NMR spectrum and HPLC study, and the result of elemental analysis supported the structures. Mp 234—235 °C (EtOH); IR ($CHCl_3$) 1665 (C=O) and 1750 cm^{-1} (OAc). NMR spectrum of **17c**; ($CDCl_3$) δ=2.07 (6H, s, 2×OAc), 3.98 (6H, s, 2×OCH_3), 5.47 (4H, s, 2×$-CH_2-$) 6.99 (2H, d, J=9.0 Hz, $H_{(2)}$ and $H_{(7)}$), and 8.27 (2H, d, J=9.0 Hz, $H_{(1)}$ and $H_{(8)}$). NMR spectrum of **18c**; ($CDCl_3$) δ=2.08 (3H, s, OAc), 2.14 (3H, s, OAc), 3.98 (6H, s, 2×OCH_3), 5.19 (2H, s, $-CH_2-$), 5.47 (2H, s, $-CH_2-$), 6.85 (1H, s, $H_{(4)}$), 6.99 (1H, d, J=9.0 Hz, $H_{(7)}$), 8.19 (1H, br. s, $H_{(1)}$) and 8.29 (1H, d, J=9.0 Hz, $H_{(8)}$). Found: C, 62.70; H, 5.15%. Calcd for $C_{21}H_{20}O_8$: C, 62.99; H, 5.04%.

Oxidation Products of ***1d***. *Methyl Ester of 1-Carboxy-2,3,6-trimethoxy-9-xanthenone* (***2d***): Mp 197—198 °C (MeOH); IR ($CHCl_3$) 1665 (C=O) and 1755 cm^{-1} ($COOCH_3$); NMR ($CDCl_3$) δ=3.87 (3H, s, OCH_3), 3.89 (3H, s, OCH_3), 3.98 (3H, s, OCH_3), 4.04 (3H, s, $COOCH_3$), 6.79 (1H, d, J=2.4 Hz, $H_{(5)}$), 6.86 (1H, dd, J=9.0 and 2.4 Hz, $H_{(7)}$), 6.86 (1H, s, $H_{(4)}$), and 8.14 (1H, d. J=9.0 Hz, $H_{(8)}$). Found: *m/e* 344.0892 (M^+). Calcd for $C_{18}H_{16}O_7$: M, 344.0896.

Methyl Ester of 1-Carboxy-3,6,7-trimethoxy-9-xanthenone (***3d***): **12d** could not be completely separated from **11d**, but the NMR spectrum, high resolution mass spectrum, and HPLC study supported the structure. Mp 171—172 °C (MeOH); IR ($CHCl_3$) 1660 (C=O) and 1745 cm^{-1} ($COOCH_3$); NMR ($CDCl_3$) δ=3.84 (3H, s, OCH_3), 3.90 (3H, s, OCH_3), 3.94 (3H, s, OCH_3), 4.02 (3H, s, $COOCH_3$), 6.77 (1H, s, $H_{(5)}$), 6.80 (2H, br. s, $H_{(2)}$ and $H_{(4)}$), and 7.50 (1H, s, $H_{(8)}$). Found: *m/e* 344.0884 (M^+). Calcd for $C_{18}H_{16}O_7$: 344.0896.

Methyl Ester of 1-Carboxy-4-hydroxymethyl-3,6,7-trimethoxy-9-xanthenone (***9d***): IR ($CHCl_3$) 1650 (C=O), 1745 ($COOCH_3$), and 3300—3600 cm^{-1} (OH); NMR ($CDCl_3$) δ=2.5 (1H, br. s, OH), 3.93 (3H, s, OCH_3), 3.97 (3H, s, OCH_3), 3.98 (3H, s, OCH_3), 4.03 (3H, s, $COOCH_3$), 4.89 (2H, s, $-CH_3-$), 6.82 (1H, s, $H_{(5)}$), 6.85 (1H, s, $H_{(2)}$), and 7.51 (1H, s, $H_{(8)}$); MS *m/e* 374 (M^+).

Acetylation Product (Methyl Ester of ***7d****) of the Methyl Ester of* ***9d***: Mp 262—263 °C (MeOH); IR ($CHCl_3$) 1660 and 1745 cm^{-1} (C=O); NMR ($CDCl_3$) δ=2.07 (3H, s, OAc), 3.92 (3H, s, OCH_3), 3.96 (3H, s, OCH_3), 3.99 (3H, s, OCH_3), 4.02 (3H, s, $COOCH_3$), 5.42 (2H, s, $-CH_2-$), 6.90 (2H, s, $H_{(2)}$ and $H_{(5)}$), and 7.54 (1H, s, $H_{(8)}$). Found: *m/e* 416.1115 (M^+). Calcd for $C_{21}H_{20}O_9$: M, 416.1107.

Methyl Ester of 4-Carboxymethyl-2,3,6-trimethoxy-9-xanthenone (***11d***): Mp 198—200 °C (MeOH); IR ($CHCl_3$) 1660 (C=O) and 1755 cm^{-1} ($COOCH_3$); NMR ($CDCl_3$) δ=3.69 (3H, s, $COOCH_3$), 3.92 (2H, s, $-CH_2-$), 3,93 (3H, s, OCH_3), 3.97 (3H, s, OCH_3), 3.99 (3H, s, OCH_3), 6.87 (1H, d, J=2.4 Hz, $H_{(5)}$), 6.87 (1H, dd, J=9.0 and 2.4 Hz, $H_{(7)}$), 7.61 (1H, s, $H_{(1)}$), and 8.23 (1H, d, J=9.0 Hz, $H_{(8)}$). Found: *m/e* 358.1059 (M^+). Calcd for $C_{19}H_{18}O_7$: M, 358.1053.

5-Acetoxymethyl-2,3,6-trimethoxy-9-xanthenone (***14d***): Mp 233 °C (EtOH); IR ($CHCl_3$) 1655 (C=O) and 1745 cm^{-1} (OAc); NMR ($CDCl_3$) δ=2.08 (3H, s, OAc), 3.95 (6H, s, 2×OCH_3), 3.97 (3H, s, OCH_3), 5.40 (2H, s, $-CH_2-$), 6.85 (1H, s, $H_{(4)}$), 6.97 (1H, d, J=9.0 Hz, $H_{(7)}$), 7.54 (1H, s, $H_{(1)}$), and 8.26 (1H, d, J=9.0 Hz, $H_{(8)}$). Found: C, 63.54; H, 5.28%. Calcd for $C_{19}H_{18}O_7$:C, 63.68; H, 5.06%.

2-Acetoxymethyl-3,6,7-trimethoxy-9-xanthenone (***15d***): Mp 208—209 °C (EtOH); IR ($CHCl_3$) 1660 (C=O) and 1750 cm^{-1} (OAc); NMR ($CDCl_3$) δ=2.12 (3H, s, OAc), 3.91 (3H, s, OCH_3), 3.94 (6H, s, 2×OCH_3), 5.12 (2H, s, $-CH_2-$), 6.74 (1H, s, $H_{(5)}$), 6.79 (1H, s, $H_{(4)}$), 7.53 (1H, s, $H_{(1)}$), and 8.16 (1H, s, $H_{(8)}$). Found: *m/e* 358.1043 (M^+). Calcd for $C_{19}H_{18}O_7$: M, 358.1053.

Oxidation Products of ***1e***. *Methyl Ester of 1-Carboxy-6-methoxy-5-methyl-9-xanthenone* (***2e***): Mp 184—185 °C (MeOH); IR ($CHCl_3$) 1665 (C=O) and 1748 cm^{-1} ($COOCH_3$); NMR ($CDCl_3$) δ=2.31 (3H, s, CH_3), 3.92 (3H, s, OCH_3), 4.03 (3H, s, $COOCH_3$), 6.89 (1H, d, J=9.0 Hz, $H_{(7)}$), 7.15—7.82 (3H, m, aromatic), and 8.11 (1H, d, J=9.0 $H_{(8)}$). Found: C, 68.20; H, 4.92%. Calcd for $C_{17}H_{14}O_5$: C, 68.45; H, 4.73%.

1-Carboxy-3-methoxy-4-methyl-9-xanthenone (***3e***): Mp 250 °C (EtOH); IR (KBr) 1610 and 1720 (C=O), and 2800—3100 cm^{-1} (OH); NMR ($(CD_3)_2SO$) δ=2.32 (3H, s, CH_3), 4.00 (3H, s, OCH_3), 7.17 (1H, s, $H_{(2)}$), 7.34—8.23 (4H, m, aromatic), and 13.0 (1H, br. s, COOH): MS *m/e* 284 (M^+). Found: C, 67.48; H, 4.40%. Calcd for $C_{16}H_{12}O_5$: C, 67.60; H, 4.26%.

Methyl Ester of ***3e***: Mp 211—212 °C (MeOH); IR ($CHCl_3$) 1670 (C=O) and 1748 cm^{-1} ($COOCH_3$); NMR ($CDCl_3$) δ=2.33 (3H, s, CH_3), 3.93 (3H, s, OCH_3), 4.02 (3H, s, $COOCH_3$), 6.86 (1H, s, $H_{(2)}$), and 7.15—8.29 (4H, m, aromatic). Found: C, 68.21; H, 4.77%. Calcd for $C_{17}H_{14}O_5$: C, 68.45; H, 4.73%.

Dimethyl Ester of 1,8-Dicarboxy-3-methoxy-4-methyl-9-xanthenone (***4e***): Mp 200—201 °C (MeOH); IR ($CHCl_3$) 1680 (C=O) and 1750 cm^{-1} ($COOCH_3$); NMR ($CDCl_3$) δ=2.34 (3H, s, CH_3), 3.94 (3H, s, OCH_3), 3.96 (6H, s, 2×$COOCH_3$), 6.91 (1H, s, $H_{(2)}$), and 7.18—7.68 (3H, m, aromatic). Found: C, 64.01, H, 4.70%. Calcd for $C_{19}H_{16}O_7$: C, 64.04; H, 4.53%.

Dimethyl Ester of 5-Carboxymethyl-1-carboxy-3-methoxy-4-methyl-9-xanthenone (***5e***): Mp 179—180 °C (MeOH); IR ($CHCl_3$) 1675 (C=O) and 1750 cm^{-1} ($COOCH_3$); NMR ($CDCl_3$) δ=2.37 (3H, s, CH_3), 3.68 (3H, s, $COOCH_3$), 3.93 (5H, s, $-CH_2-$ and OCH_3), 4.01 (3H, s, $COOCH_3$), 6.88 (1H, s, $H_{(2)}$), and 7.00—8.24 (3H, m, aromatic). Found: *m/e* 370.1051 (M^+). Calcd for $C_{20}H_{18}O_7$: M, 370.1053.

Oxidation Products of ***1f***. *Methyl Ester of 1-Carboxy-6-methoxy-4-methyl-9-xanthenone* (***2f***): Mp 193—194 °C (MeOH); IR ($CHCl_3$) 1670 (C=O) and 1755 cm^{-1} ($COOCH_3$); NMR ($CDCl_3$) δ=2.45 (3H, s, CH_3), 3.81 (3H, s, OCH_3), 3.99 (3H, s, $COOCH_3$), 6.78 (1H, d, J=2.4 Hz, $H_{(5)}$), 6.83 (1H, dd, J=9.0 and 2.4 Hz, $H_{(7)}$), 7.11 (1H, s, J=7.8 Hz, $H_{(2)}$), 7.24 (1H, d, J=7.8 Hz, H $_{(3)}$),and 8.05 (1H, d, J=9.0 Hz, $H_{(8)}$). Found: C, 68.50; H, 4.82%. Calcd for $C_{17}H_{14}O_5$: C, 68.45; H, 4.73%.

Methyl Ester of 5-Acetoxymethyl-1-carboxy-6-methoxy-4-methyl-9-xanthenone (***6f***): Mp 152—153 °C (MeOH); IR ($CHCl_3$) 1675 (C=O) and 1747 cm^{-1} ($COOCH_3$ and OAc); NMR ($CDCl_3$) δ=2.06 (3H, s, OAc), 2.54 (3H, s, CH_3), 3.96 (3H, s, OCH_3), 3.99 (3H, s, $COOCH_3$), 5.44 (2H, s, $-CH_2-$), 6.98 (1H, d, J=9.0 Hz, $H_{(7)}$), 7.16 (1H, d, J=7.8 Hz, $H_{(2)}$), 7.48 (1H, d, J=7.8 Hz, $H_{(3)}$), and 8.22 (1H, d, J=9.0 Hz, $H_{(8)}$), Found: *m/e* 370.1043 (M^+). Calcd for $C_{20}H_{18}O_7$: M, 370.1053.

4-Acetoxymethyl-3-methoxy-5-methyl-9-xanthenone (***14f***): Mp 212 °C (EtOH); IR ($CHCl_3$) 1665 (C=O) and 1750 cm^{-1} (OAc); NMR ($CDCl_3$) δ=2.08 (3H, s, OAc), 2.49 (3H, s, CH_3), 3.99 (3H, s, OCH_3), 5.48 (2H, s, $-CH_2-$), 6.96 (1H, d, J=9.0 Hz, $H_{(2)}$), 6.84—8.20 (3H, m, aromatic), and 8.31 (1H, d, J=9.0 Hz, $H_{(1)}$). Found: C, 68.98; H, 5.24%. Calcd for $C_{18}H_{16}O_5$: C, 69.22; H, 5.16%.

2-Acetoxymethyl-3-methoxy-5-methyl-9-xanthenone (***15f***): Mp 187—188 °C (EtOH); IR ($CHCl_3$) 1670 (C=O) and 1755 cm^{-1} (OAc); NMR ($CDCl_3$), δ=2.16 (3H, s, OAc), 2.57 (3H, s, CH_3), 3.98 (3H, s, OCH_3), 5.24 (2H, s, $-CH_2-$), 6.96 (1H, s, $H_{(4)}$), 6.97—8.27 (3H, m, aromatic), and 8.28 (1H, s, $H_{(1)}$). Found: *m/e* 312.0993 (M^+). Calcd for $C_{18}H_{16}O_5$: M, 312.0998.

Oxidation Products of ***1g***. *Methyl Ester of 8-Carboxy-1-methoxy-3-methyl-9-xanthenone* (***2g***): Mp 186—187 °C (Benzene); IR ($CHCl_3$) 1670 (C=O) and 1750 cm^{-1} ($COOCH_3$); NMR ($CDCl_3$) δ=2.39 (3H, s, CH_3), 3.96 (3H, s, OCH_3), 4.04 (3H, s, $COOCH_3$), 6.57 (1H, d, J=2.4 Hz, $H_{(2)}$), 6.79 (1H, d, J=2.4 Hz, $H_{(4)}$), and 7.14—7.80 (3H, m, aromatic). Found: C, 68.37; H, 4.91%. Calcd for $C_{17}H_{14}O_5$: C, 68.45, H, 4.73%.

Methyl Ester of 4-Acetoxymethyl-8-carboxy-1-methoxy-3-methyl-9-xanthenone (***6g***): Mp 197—198 °C (MeOH); IR ($CHCl_3$) 1675 (C=O) and 1750 cm^{-1} ($COOCH_3$ and OAc); NMR ($CDCl_3$) δ= 2.06 (3H, s, OAc), 2.44 (3H, s. CH_3), 3.97 (3H, s, OCH_3), 4.03 (3H, s, $COOCH_3$), 5.41 (2H, s, $-CH_2-$), 6.64 (1H, br. s, $H_{(2)}$), and 7.19—7.83 (3H, m, aromatic), Found: C, 64.60; H, 4.95%. Calcd for $C_{20}H_{18}O_7$: C, 64.86; H, 4.90%.

Methyl Ester of 5-Carboxymethyl-1-methoxy-3-methyl-9-xanthenone (***11g***): Mp 158—159 °C (EtOH); IR ($CHCl_3$) 1670 (C=O) and 1755 cm^{-1} ($COOCH_3$); NMR ($CDCl_3$) δ=2.41 (3H, s. CH_3), 3.68 (3H, s, $COOCH_3$), 3.90 (2H, s, $-CH_2-$), 3.97 (3H, s, OCH_3), 6.58 (1H, d, J=2.4 Hz, $H_{(2)}$), 6.83 (1H, d, J=2.4 Hz, $H_{(4)}$), and 7.08—8.29 (3H, m, aromatic). Found: *m/e* 312.0994 (M^+). Calcd for $C_{18}H_{16}O_5$: M, 312.0998.

Methyl Ester of 4-Acetoxymethyl-5-carboxymethyl-1-methoxy-3-methyl-9-xanthenone (***13g***): Mp 184—185 °C (EtOH); IR ($CHCl_3$) 1670 (C=O) and 1755 cm^{-1} ($COOCH_3$ and OAc); NMR ($CDCl_3$) δ=2.08 (3H, s, OAc), 2.51 (3H, s, CH_3), 3.70 (3H, s, $COOCH_3$), 3.95 (2H, s, $-CH_2-$), 4.00 (3H, s, OCH_3), 5.38 (2H, s, $-CH_2-$), 6.67 (1H, br. s, $H_{(2)}$), and 7.15—8.32 (3H, m, aromatic). Found: *m/e* 384.1196 (M^+). Calcd for $C_{21}H_{20}O_7$: M, 384.1209.

4-Acetoxymethyl-1-methoxy-3-methyl-9-xanthenone (***14g***): Mp 149 °C (EtOH); IR ($CHCl_3$) 1660 (C=O) and 1745 cm^{-1} (OAc); NMR ($CDCl_3$) δ=2.07 (3H, s, OAc), 2.43 (3H, s, CH_3), 3.99 (3H, s, OCH_3), 5.41 (2H, s, $-CH_2-$), 6.59 (1H, s, $H_{(2)}$), and 7.2—8.3 (4H, m, aromatic). Found: C, 69,29; H, 5.28%. Calcd for $C_{18}H_{16}O_5$: C, 69.22; H, 5.16%.

3-Acetoxymethyl-1-methoxy-9-xanthenone (***16g***): Mp 174—175 °C (EtOH); IR ($CHCl)_3$ 1670 (C=O) and 1760 cm^{-1} (OAc); NMR ($CDCl_3$) δ=2.17 (3H, s, OAc), 3.99 (3H, s, OCH_3), 5.11 (2H, s, $-CH_2-$), 6.70 (1H, d, J=1.8 Hz, $H_{(2)}$), 6.98 (1H, d, J=1.8 Hz, $H_{(4)}$), and 7.20—8.35 (4H, m, aromatic), Found: *m/e* 298.0807 (M^+). Calcd for $C_{17}H_{14}O_5$: M, 298.0841.

4,5-Bis(acetoxymethyl)-1-methoxy-3-methyl-9-xanthenone (***17g***): Mp 174—175 °C (EtOH); IR ($CHCl_3$) 1675 (C=O) and 1755 cm^{-1} (OAc); NMR ($CDCl_3$) δ=2.06 (3H, s, OAc), 2,13 (3H, s, OAc), 2.54 (3H, s, CH_3), 4.00 (3H, s, OCH_3), 5.43 (4H, s, 2×$-CH_2-$), 6.69 (1H, s, $H_{(2)}$), and 7.19—8.34 (3H, m, aromatic). Found: *m/e* 384.1221 (M^+). Calcd for $C_{21}H_{20}O_7$: M, 384.1209.

Oxidation of ***1b*** *with Manganese(III) Acetate in the Presence of Potassium Acetate.* Potassium acetate (60 mmol) was dissolved in hot acetic acid (25 ml) containing acetic anhydride (4 ml). **1b** (1 mmol) and manganese(III) acetate dihydrate (12 mmol)were added to this mixture, which was heated under reflux until the brown color of Mn(III) ions disappeared. The resulting liquid was treated in a manner similar to that described above, giving **2b**, **9b**, **10b**, 4-carboxymethyl-3-methoxy-9-xanthenone (**11b**), 2-carboxymethyl-3-methoxy-9-xanthenone (**12b**), **14b**, and **15b**.

Methyl Ester of ***11b***: Mp 181 °C (MeOH); IR ($CHCl_3$) 1675 (C=O) and 1749 cm^{-1} ($COOCH_3$); NMR ($CDCl_3$) δ=3.81 (3H, s, $COOCH_3$), 3.95 (2H, s, $-CH_2-$), 3.95 (3H, s, OCH_3), 6.96 (1H, d, J=9.0 Hz, $H_{(2)}$), 6.81—8.35 (4H, m, aromatic), and 8.29 (1H, d, J=9.0 Hz, $H_{(1)}$). Found: *m/e* 298.0863 (M^+). Calcd for $C_{17}H_{14}O_5$: M, 298.0841.

Methyl Ester of ***12b***: Mp 217—218 °C (MeOH); IR ($CHCl_3$) 1670 (C=O) and 1752 cm^{-1} ($COOCH_3$); NMR ($CDCl_3$)

δ=3.71 (3H, s, $COOCH_3$), 3.71 (2H, s, $-CH_2-$), 3.93 (3H, s, OCH_3), 6.90 (1H, s, $H_{(4)}$), 7.22—8.38 (4H, m, aromatic), and 8.12 (1H, s, $H_{(1)}$). Found: *m/e* 298.0824 (M^+). Calcd for $C_{17}H_{14}O_5$: M, 298.0841.

Oxidation of ***1c*** *with Manganese(III) Acetate under an Atmosphere of Nitrogen.* **1c** (1 mmol) was oxidized with manganese(III) acetate dihydrate (12 mmol) under an atmosphere of nitrogen to give **2c** (mp 181 °C), **7c** (mp 178—180 °C), 1-carboxy-4,5-bis(acetoxymethyl)-3,6-dimethoxy-9-xanthenone (**8c**), **9c**, **11c** (mp 196—197 °C), **14c** (mp 203 °C), **15c** (mp 188 °C), **17c** and **18c** (mp 234—235 °C).

Methyl Ester of ***8c***: Mp 233—234 °C (MeOH); IR ($CHCl_3$) 1675 (C=O) and 1748 cm^{-1} ($COOCH_3$ and OAc); NMR ($CDCl_3$) δ=2.06 (6H, s, 2×OAc), 3.97 (6H, s, 2×OCH_3), 4.01 (3H, s, $COOCH_3$), 5.41 (4H, s, 2×$-CH_2-$), 6.87 (1H, s, $H_{(2)}$), 6.93 (1H, d, J=8.4 Hz, $H_{(7)}$), and 8.24 (1H, d, J=8.4 Hz, $H_{(8)}$). Found: *m/e* 458.1232 (M^+). Calcd for $C_{23}H_{22}O_{10}$: M, 458.1213.

Oxidation of Anthraquinone. Anthraquinone (2 mmol), manganese(III) acetate dihydrate (20 mmol), acetic acid (50 ml), and acetic anhydride (8 ml) were heated under reflux for 40 min under an atmosphere of nitrogen. The reaction mixture was treated in the manner described before to give 2-diacetoxymethylanthraquinone (2%): Mp 144—146 °C (EtOH); IR ($CHCl_3$) 1700 and 1775 cm^{-1} (C=O); NMR ($CDCl_3$) δ=2.15 (6H, s, 2×OAc), 7.27 (1H, s, >CH–), and 7.2—8.4 (7H, m, aromatic); MS *m/e* (rel intensity), 296 (14) ($M^+-CH_2=C=O$), 278 (26) (M^+-AcOH), 254 (24), 237 (100) ($R-\overset{+}{C}HOH$), 236 (74) ($R-CHO^+$), 235 (91) ($R-C=O^+$), and 208 (19) ($M^+-C_5H_6O_4$), 2-formylanthraquinone (3%): Mp 287—290 °C (EtOH); IR ($CHCl_3$) 1700 and 1725 cm^{-1} (C=O); NMR ($CDCl_3$) δ=7.2—8.5 (6H, m, aromatic), 8.77 (1H, br. s, $H_{(1)}$), and 10.16 (1H, s, CHO); Found: *m/e* 236.0493 (M^+), Calcd for $C_{15}H_8O_3$: M, 236.0474, and 1-carboxymethylanthraquinone (5%) characterized as its methyl ester: Mp 179—181 °C (MeOH); IR ($CHCl_3$) 1690 and 1745 cm^{-1} (C=O); NMR ($CDCl_3$) δ=3.74 (3H, s, $COOCH_3$), 4.22 (2H, s, $-CH_2-$), and 7.56—8.44 (7H, m, aromatic); Found: *m/e* 280.0738 (M^+), Calcd for $C_{17}H_{12}O_4$: M, 280.0736.

Oxidation of Benzophenone. Benzopenone (1 mmol) and manganese(III) acetate dihydrate (10 mmol) were heated under reflux for 39 min in acetic acid (25 ml) containing acetic anhydride (4 ml) to yield diacetoxymethylbenzophenone (The position of the substituent group could not be determined.) (4%): IR ($CHCl_3$) 1675 and 1770 cm^{-1} (C=O); NMR ($CDCl_3$) δ=2.14 (6H, s, 2×OAc), 7.61 (1H, s, >CH–), and 7.2—7.9 (9H, m, aromatic); Found: *m/e* 312.1014 (M^+), Calcd for $C_{18}H_{16}O_5$: M, 312.0998. Although some acetoxymethyl and carboxymethyl products were also formed, they could not be purified on TLC.

The authors wish to thank Professor Hitoshi Takeshita, of Kyushu University, Mr. Shuichi Ueda of the Taiho Pharmaceutical Co. Ltd., Tokushima, and Dr. Shinzaburo Hishida, of the Hitachi Co. Ltd., Katsuda, for their measurement of the mass spectra.

The authors also wish to thank Dr. John F. W. McOmie of Bristol University, England, for his helpful discussion and for reading the manuscript.

Synthesis of Octachlorobicyclo[3.3.0]octa-1,4,6-triene and Lewis Acid Catalyzed Isomerization of Hexachlorobicyclo[3.3.0]octa-3,5,8-trien-2-one*

Kousuke KUSUDA

Research Institute for Atomic Energy, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received April 23, 1982)

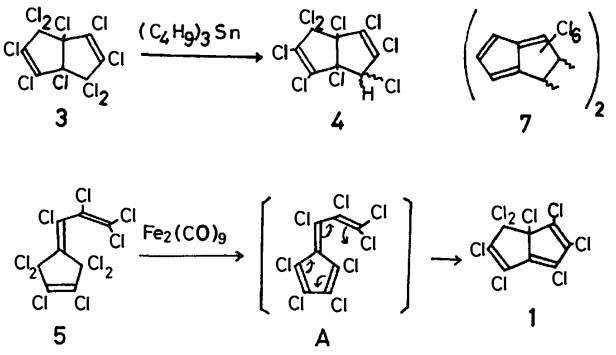
Treatment of decachloro(4-allylidenecyclopentene) with enneacarbonyldiiron(0) gave octachlorobicyclo-[3.3.0]octa-1,3,7-triene (δ-C_8Cl_8) in 40% yield. Dechlorination of decachlorobicyclo[3.3.0]octa-2,6-diene with powdered selenium, sulfur, phosphorus, or titanium in the presence of anhydrous aluminium chloride without any adde d solvent at 90—100 °C afforded octachlorobicyclo[3.3.0]octa-1,4,6-triene (**2**) (ε-C_8Cl_8) in good yield. Hexa-chlorobicyclo[3.3.0]octa-3,5,8-trien-2-one obtained from **2** was chlorinated by a concentrated solution of antimony-(V) chloride in refluxing dichloromethane to give octachlorobicyclo[3.3.0]octa-3,6(or 7)-dien-2-one, but in a dilute solution (less than 0.1 g of antimony(V) chloride/cm^3 of dichloromethane) hexachlorobicyclo[3.3.0]octa-4,6,8-trien-2-one (**14**) was obtained. Mechanism of the isomerization is discussed in terms of antiaromaticity of cyclo-pentadienyl cation. Reaction of **14** with methanol afforded pentachloro-4-methoxybicyclo[3.3.0]octa-3,5,7-trien-2-one. Ethanol or 2-propanol reacted with **14** similarly giving pentachloro-4-ethoxybicyclo[3.3.0]octa-3,5,7-trien-2 -one or pentachloro-4-isopropoxybicyclo[3.3.0]octa-3,5,7-trien-2-one, respectively.

In a series of continuing studies on the chemistry of cyclic conjugated chlorocarbons,[1] the author reported on reactions of δ-C_8Cl_8 (**1**) and ε-C_8Cl_8 (**2**) with antimony(V) chloride or anhydrous aluminium chloride to give dicationic complexes.[2] In the report, octachloro-bicyclo[3.3.0]octa-1,3,7-triene and octachlorobicyclo-[3.3.0]octa-1,4,6-triene were assigned to the structure of **1** and **2**, respectively, which were confirmed later by X-ray crystallographic analyses.[3]

The objective of the present work was to extend the investigation on these chlorocarbons toward develop-ment of a new synthetic method for **2** and elucidation of Lewis acid-catalyzed isomerization of a per-chlorinated ketone obtained from **2**. Since the reported syntheses of **1** and **2**[4] seemed to be unsuitable for a large-scale preparation, it has been desired to develop a convenient synthetic method for **1** or **2**.

Treatment of decachlorobicyclo[3.3.0]octa-2,6-diene (**3**)[5] with tributylstannane[6] at around 50 °C gave a mixture, from which a small amount of 1,2,3,4,4,5,6,7,8-nonachlorobicyclo[3.3.0]octa-2,6-diene (**4**), C_8HCl_9, mp 134 °C, was separated by column chromatography on silica gel eluted by petroleum ether. Dehydrochlorina-tion of **4** with methanolic sodium hydroxide at room temperature gave yellow crystals of **1**. Dechlorination of decachloro(4-allylidenecyclopentene) (**5**)[7] with ennea-carbonyldiiron(0) at room temperature afforded **1** in 37% yield. A reasonable pathway for the formation of **1** could involve transformation of **5** to reactive octa-chlorovinylfulvene (**A**) followed by cyclization, as is similar to the mechanism postulated for the formation of dihydropentalene derivatives.[8] Attempted isolations of intermediate **A** and its iron carbonyl complex[9] were unsuccessful.

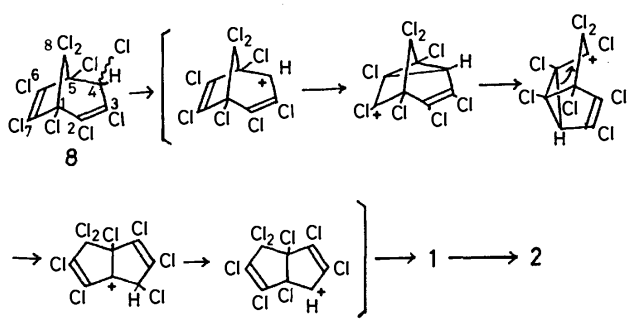
As the foregoing preparations of **1** were unsatisfactory for a large-scale preparation, synthesis of **2** was inves-tigated. When a mixture of **3** and anhydrous aluminium chloride was heated at 220—240 °C for 2.5 h, the reaction mixture changed into a reddish brown mass and sublimed white crystals, from which octachloro-



cyclopentene and hexachlorobenzene were separated by making use of solubility in methanol. Treatment of the dark solid on the bottom of flask with a mixture of water and carbon tetrachloride afforded **2** and hexachlorobicyclo[3.3.0]octa-3,5,8-trien-2-one (**6**), C_8Cl_6O, mp 82 °C, in yields of 35 and 28%, respectively. Structural assignment of **6** rested on its IR, UV, and ^{13}C NMR spectra. Dechlorinations of **3** with powdered copper in petroleum benzine, tin(II) chloride in aq acetone, or aluminium amalgam in diethyl ether[10] gave a dimer of hexachloropentalene (**7**).[4a] It seemed difficult to obtain an octachlorodihydropentalene from **3** by regulating conditions of the usual dechlorination. However, it was expected that Lewis acid metal halide in the reaction mixture should react with an octachloro-dihydropentalene produced by dechlorination of **3**, thus preventing further dechlorination, since known per-chlorinated dihydropentalenes, **1** and **2**, easily react with Lewis acid metal halide affording stable complexes. Most of the popular dehalogenating reagents[11] are inadequate because they react with anhyd aluminium chloride and/or because they are usually used in some solvent which is reactive to anhyd aluminium chloride. With these restrictions taken into account, powdered selenium was chosen for the dechlorination. A mixture of **3**, selenium, and two equivalents of anhyd aluminium chloride was heated at 90 °C for 1 h and then quenched with 2 M (1 M=1 mol dm^{-3}) hydrochloric acid. The crude product was purified by the conventional isolation procedure including chromatography on silica gel to

* Dedicated to Emeritus Professor Takeo Sakan on his 70th Anniversary.

give **2** in 98% yield. Under similar conditions, sulfur, red phosphorus, or titanium gave **2** in yield of 91, 52, or 64%, respectively, but powdered aluminium, tin, silicon, and zinc were ineffective for the dechlorination. A mixture of selenium or sulfur and antimony(V) chloride did not react with **3** at 100 °C. When a mixture of **3** and sulfur was heated at 180 °C, **7** was the only product identified. These findings indicate that anhyd aluminium chloride activates selenium and sulfur in the dechlorination of **3**. Dechlorinations of hexachlorocyclopropane,[12] octachloro(4-methylenecyclopentene),[13] and octachloro(1,2-dimethylenecyclobutane)[14] with selenium–anhyd aluminium chloride were unsuccessful. Treatment of 1,2,3,4,5,6,7,8,8-nonachlorobicyclo[3.3.0]octa-2,6-diene (**8**)[15] with two equivalents of anhyd aluminium chloride at 150 °C gave a black solid, which gave **2** in 69% yield upon quenching with concd hydrochloric acid. The reaction probably proceeds similarly to the rearrangement of homonorbornadienyl cation:[16]



^{35}Cl nuclear quadrupole resonance (NQR) spectra of **2** (Table 1) furnish useful information on the chemical structure. There are six resonance lines indicating the presence of six kinds of chlorine atoms, hence the planarity of the molecule. Each signal in MHz at 78 K shifts downward at higher temperatures. Four lines between 37.056 and 37.372 MHz are in the proper region for vinylic chlorines, whereas two lines at 38.898 and 39.053 MHz suggest two equivalent chlorine atoms on a carbon.[17]

Treatment of **2** with formic acid or sulfuric acid afforded **6** in 65—72% yield.[4d] In order to hydrolyze a dichloromethylene group of **2**, excess fuming nitric acid was added to powdered **2** at room temperature, causing an exothermic reaction immediately. From the reaction mixture **6** and tetrachloro-2,5-cyclopentadiene-1,2-dicarboxylic acid (**9**), $C_7H_2Cl_4O_4$, mp 208 °C, were isolated. The structure of **9** was speculated on the basis of the elemental analysis and IR and UV spectra. Refluxing a mixture of **6** and powdered potassium carbonate in abs methanol afforded pentachloro-4-methoxybicyclo[3.3.0]octa-3,5,8-trien-2-one (**10**), $C_9H_3Cl_5O_2$, mp 96 °C. The transformation is similar to that of **2** with secondary amines.[4d]

Table 1. NQR signals of **2** (MHz)[a]

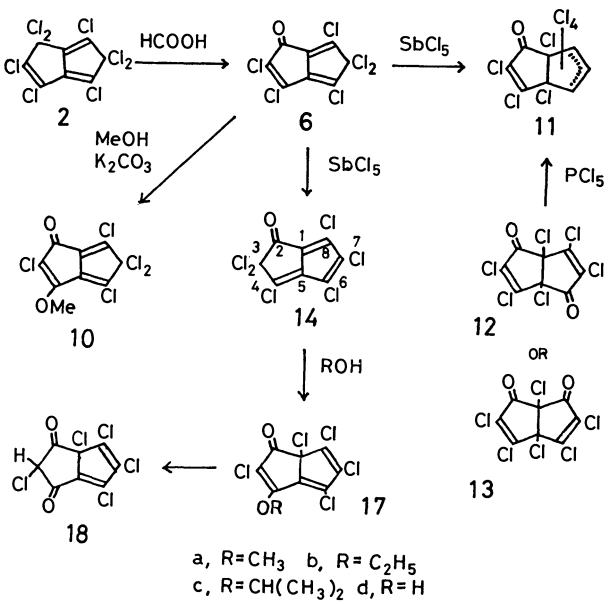
Temp/K	78	200	296
	39.053	38.722	38.392
	38.898	38.577	38.245
	37.372	37.089	36.826
	37.348	37.074	36.785
	37.268	36.976	36.637
	37.056	36.809	36.493

a) Accuracy: ±0.003 MHz.

When a mixture of **6** and excess antimony(V) chloride in dichloromethane was refluxed for 5 h, a deep red color developed during the reaction, but a colorless oily material, octachlorobicyclo[3.3.0]octa-3,6(or 7)-dien-2-one (**11**), C_8Cl_8O, was the product, which was obtained also by chlorination of hexachlorobicyclo[3.3.0]octa-3,7-diene-2,6-dione (**12**) or hexachlorobicyclo[3.3.0]-octa-3,6-diene-2,8-dione (**13**)[5] with phosphorous(V) chloride. The complete structure of **11** remains to be determined. However, diluted antimony(V) chloride (less than 0.1 g/cm^3 of dichloromethane) does not chlorinate **6** but catalyzes a rearrangement, affording quantitatively deep red crystals of hexachlorobicyclo-[3.3.0]octa-4,6,8-trien-2-one (**14**), C_8Cl_6O, mp 70 °C. Treatment of **6** with anhyd aluminium chloride under similar conditions yielded a mixture of **6** and **14** in approximately 1 : 1 ratio (*vide infra*). Reaction of **14** with concd antimony(V) chloride in the same solvent furnished **11**.[18]

The ^{13}C NMR spectrum of **14** shows a peak due to a chlorinated sp^3 carbon at 85.1 ppm and no alkenic carbon peak characteristic of α,β-unsaturated ketone.[19] It can be assumed that the UV spectrum of **14** (Fig. 1) consists of two groups of higher intensities, one between 220 and 300 nm and the other between 300 and 350 nm, and one broad peak of lower intensity. The maxima in the region 300—450 nm are similar to that of hexachlorofulvene (**15**)[20] and quite different from that of cyclopentadienone derivative.[21] These spectral data were all compatible with the assigned structure, which was further confirmed by the following chemical reaction indicating absence of cyclopentadienone moiety. Neither maleic anhydride nor furan reacted with **14** in refluxing benzene. Chlorination of **14** with liquid chlorine in a sealed tube at room temperature afforded white crystals of decachlorobicyclo[3.3.0]oct-6(or 7)-en-2-one (**16**), $C_8Cl_{10}O$, mp 130 °C, which was stable to treatment with anhyd aluminium chloride in boiling dichloromethane. The structure of **16** was assigned on the basis of elemental analysis and IR and UV spectra. Ethereal diazomethane apparently reacted with **14** with evolution of nitrogen gas and with its red color fading, but isolation of a pure product was unsuccessful.

When methanol was added to **14**, a moderate exothermic reaction furnished yellow crystals of pentachloro-4-methoxybicyclo[3.3.0]octa-3,5,7-trien-2-one (**17a**), $C_9H_3Cl_5O_2$, mp 152 °C. Similarly, ethoxy derivative (**17b**), $C_{10}H_5Cl_5O_2$, mp 186 °C, or 2-propoxy derivative (**17c**), $C_{11}H_7Cl_5O_2$, mp 149 °C, was obtained by the reaction with ethanol or 2-propanol, respectively, but 2-methyl-2-propanol did not react with **14** under similar conditions. Methanolic solution of **14a** yielded 1,3,6,7,8-pentachlorobicyclo[3.3.0]octa-5,7-diene-2,4-dione(**18**)[4d] on standing at room temperature for 2 d. Comparison of the UV spectra of **1** and **17a—d** makes it clear that these chlorocarbons have a similar double bond



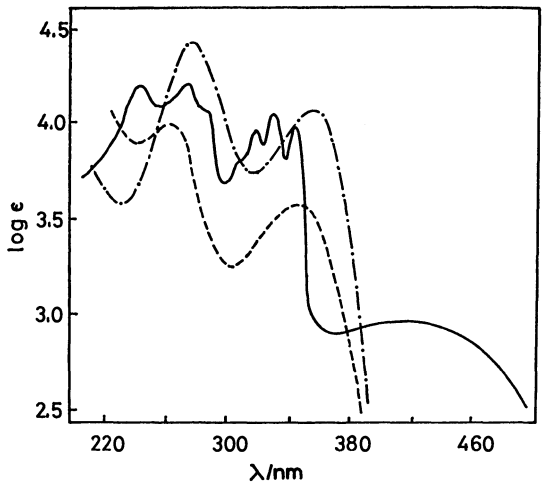


Fig. 1. Ultraviolet and visible absorption spectra of **1**, **14** and **17a**.
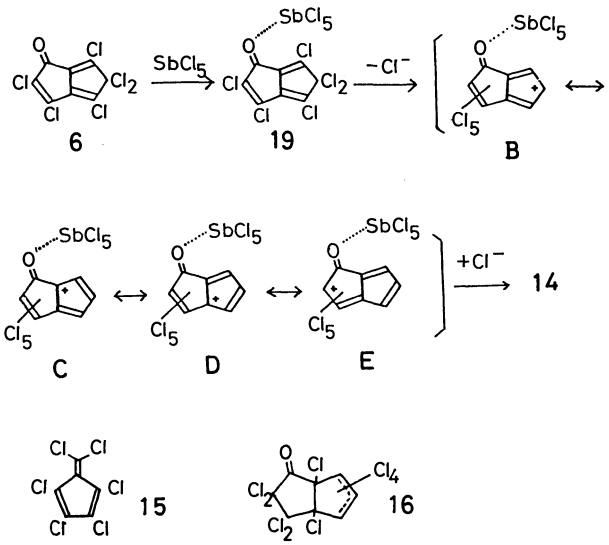
------: **1** (in dichloromethane), ——: **14** (in hexane), -·-·-: **17a** (in hexane).

system (Fig. 1 and Experimental section). ^{13}C NMR and IR spectra as well as these findings support the proposed structures **17a—d**.

In view of the generalization that nucleophilic substitution on a polychlorinated double bond proceeds through the addition-elimination mechanism,[22] the formation of **17a—c** seemed to be abnormal. Although a mechanism composed of catalyzed isomerization of the double bonds of **14** followed by substitution of an alkoxyl group can be written, isomerization of the double bonds is probably not the initial step since **14** cannot be isomerized by hydrochloric acid or acetic acid. On the other hand, it has been known that nucleophiles will initially attack on C(6) of **15**, then allowing the addition-elimination reaction to occur.[23] It is considered that the reactions of alcohols with **14** take place on C(4) similarly with **15**, then allowing the isomerization of the double bonds and 1,7-rearrangement of a chlorine atom to proceed.

Addition of excess antimony(V) chloride to a concd solution of **6** in dichloromethane immediately precipitated a yellow complex (**19**), IR spectrum of which is quite similar to that of **6** in the region 1500—500 cm^{-1}. On the other hand, a large difference was found in the carbonyl and C=C double bond regions, indicating that the complex was formed by coordination of antimony(V) chloride to the carbonyl group. Quenching **19** with 6 M hydrochloric acid afforded **6** quantitatively. The isomerization of **6** to **14** presumably takes place through cationic species (B—E) produced by the attack of antimony(V) chloride on **19**. Monocationic B—D are considered unstable because of the contribution of antiaromatic cyclopentadienylium cation,[24] whereas E is free from such destabilization and contains stable polychlorinated fulvene moiety and hence contribution of E seems to be predominant.[25] Recombination of chloride anion with E completes the rearrangement.



Experimental

General. The melting points were determined on a Yanagimoto micro melting point apparatus and were uncorrected. Elemental analyses of carbon and hydrogen were performed by Mr. J. Goda of Osaka City University. Chlorine analyses, when required, were carried out according to the combustion method by use of a modified flask.[26] IR spectra were recorded on a Perkin-Elemer Model 337 spectrophotometer as mulls in Nujol between KBr disks unless otherwise mentioned. Significant absorptions are reported. UV spectra werer ecorded on a Hitachi Model 200-10 spectrophotometer in solution. Nuclear quadrupole resonance spectra were recorded on a Decca Radar NQR spectrometer and summarized in Table 1. Both ^{1}H and ^{13}C NMR spectra were recorded on a JEOL FX-60 F-T NMR spectrometer. Mass spectra were recorded on a JEOL JMS-01SG-2 double focus mass spectrometer at 80 eV ionizing potential. Petroleum ether and petroleum benzine used are hydrocarbon mixtures boiling in the ranges 48—66 and 68—69 °C, respectively.

1,2,3,4,4,5,6,7,8-Nonachlorobicyclo[3.3.0]octa-2,6-diene (4). A mixture of 4.5 g (10 mmol) of **3** and 5.8 g (20 mmol) of tributylstannane in 30 cm^3 of benzene was heated at around

50 °C under a nitrogen atmosphere with stirring for 33 h. After removal of the solvent under reduced pressure, the reaction mixture was chromatographed on silica gel (3 cm × 60 cm) with petroleum ether as eluent. The crude product obtained from a slightly yellow band was washed with ethanol and crystallized from ethanol to give 48 mg of **4**: mp 133—134 °C; IR 1630, 1610, 1235, 1205, 1175, 1030, 1022, 832, and 755 cm^{-1}; ^1H NMR (CCl_4) δ=5.07. Found: C, 23.29; H, 0.45; Cl, 76.58%. Calcd for C_8HCl_7: C, 23.09; H, 0.24; Cl, 76.67%.

*Octachlorobicyclo[3.3.0]octa-1,3,7-triene (**1**) (δ-C_8Cl_8).* *a) From **4***: To an ethereal solution (1 cm^3) of **4** (35 mg, 0.048 mmol) was added 5 drops of 20% methanolic potassium hydroxide solution and the mixture was stirred for 30 min at room temperature, whereupon the solution turned light yellow. Water was added and the organic materials were extracted with diethyl ether. The combined ethereal solution was washed with water and dried over sodium sulfate. The solvent was evaporated under vacuum to give 30 mg of yellow crystals of **1**. Identification was made by comparison of the IR and UV spectra with those of authentic sample synthesized by the reported method: IR 1615, 1545, 1535, 1267, 1215, 1130, and 765 cm^{-1}; UV λ_{max}^{hexane} 260 (3.99) and 352 (3.67).

*b) From **5***: A mixture of 1.73 g (3.84 mmol) of **5** and 1.40 g (3.84 mmol) of enneacarbonyldiiron(0) in 15 cm^3 of petroleum benzine was stirred for 3 h at 35 °C and was kept at room temperature overnight. The reaction mixture was filtered and the solvent was evaporated to dryness to give 0.546 g (37%) of crude **1**. Column chromatography on silica gel eluted by petroleum benzine gave a pure sample.

*A Dimer of Hexachloropentalene (**7**).* Powdered sulfur (0.50 g) was mixed with 1.32 g (2.93 mmol) of **3** and the mixture was heated at 150—180 °C for 1.5 h. The organic products were extracted with carbon tetrachloride by use of a Soxhlet extractor. The crystals obtained by evaporation of the solvent were sublimed at 135 °C/3 mmHg (1 mmHg= 133.3 Pa) to remove a volatile yellow solid. The residue was 244 mg (27%) of bright deep red crystals of the dimer of hexachloropentalene: mp 315 °C; IR 1638, 1604, 1500, 1232, and 1155 cm^{-1}; UV $\lambda_{max}^{dichloromethane}$ 250 (3.57), 290 sh (3.86), 300 (3.96), 390—460 (2.64). Found: C, 31.15; H, 0.14; Cl, 68.34%. Calcd for $C_{16}Cl_{12}$: C, 31.12; Cl, 68.88%. Identification was made by comparison of mp and IR and UV spectra with those of the authentic sample.

*Octachlorobicyclo[3.3.0]octa-1,4,6-triene (**2**). (ε-C_8Cl_8) a)*: A mixture of 5.00 g (11.1 mmol) of **3**, 1.05 g (13.29 mg atom) of selenium, and 2.96 g (22.17 mmol) of powdered anhyd aluminium chloride was heated in an oil bath at around 90 °C with stirring for 1 h. The reaction mixture melted and turned dark brown. After being cooled to room temperature, the reaction mixture was quenched with a mixture of 2 M hydrochloric acid and chloroform under ice cooling. A small amount of insoluble materials was removed by filtration and the chloroform solution was separated. The water layer was extracted twice with a small amount of chloroform. The combined solution was dried over sodium sulfate. The crude product obtained by evaporation of the solvent was chromatographed on silica gel (12 mm × 7 cm) with petroleum benzine as eluent. Evaporation of the solvent gave 4.14 g (98.2%) of pure **2**: mp 111—112 °C; IR 1685, 1640, 1530, and 800 cm^{-1}; UV λ_{max}^{hexane} 262 (4.01) and 325 (3.38); MS *m/e* (%) 376 (3.1), 341 (33.8), 306 (100), 271 (30.8), 236 (24.6), 201 (13.8), and 153 (29.2).

Dechlorinations of **3** by use of sulfur, red phosphorus and titanium are summarized in Table 2.

e): A mixture of powdered anhyd aluminium chloride (0.60 g, 4.5 mmol) and 0.82 g (2.2 mmol) of **8** was heated at 150 °C for 1.25 h. A dark brown reaction mixture was solidified on standing at room temperature. The reaction mixture was quenched by a mixture of ice and concd hydrochloric acid. Extraction with carbon tetrachloride, drying over sodium sulfate, and evaporation of the solvent gave 0.56 g (69%) of **2**.

Table 2. Dechlorinations of **3**

Dechlorinating reagent(g)	**3**(g)	$AlCl_3$ (g)	Temp/°C	Time/h	Yield of **2**/g(%)
b) S: 0.33	4.60	6.90	80—85	3	3.25(91)
c) Red P: 0.10	1.80	1.21	100	2	0.79(52)
d) Ti: 0.12	1.80	1.21	98—100	2	0.98(64)

f): A mixture of 5.0 g (11.1 mmol) of **3** and 5.0 g (37.5 mmol) of powdered anhyd aluminium chloride in a 50 cm^3 flask was heated at 220—240 °C in an oil bath for 2.5 h. White powders sublimed were collected and treated with water. The mixture was separated by making use of solubility in methanol. The white crystal (20 mg) insoluble in methanol was hexachlorobenzene and the crystal (700 mg) obtained by evaporation of the methanol was octachlorocyclopentene. The reddish-brown reaction mixture on the bottom of the flask was decomposed with a mixture of water and carbon tetrachloride and the organic layer was separated. Evaporation of the solvent gave 3.98 g of mixture. Column chromatography on silica gel (2.2 cm × 13 cm) eluted with petroleum benzine gave 1.48 g (35%) of **2** and 1.02 g (28%) of **6** successively. Both the oily material (0.14 g) from the third and the yellow crystals (0.26 g) from the fourth fraction were not identified.

*Hexachlorobicyclo[3.3.0]octa-3,5,8-trien-2-one (**6**) and Tetrachloro-2,5-cyclopentadiene-1,2-dicarboxylic Acid (**9**).* Fuming nitric acid (d=1.535) was added to 15.0 g (39.5 mmol) of powdered **2**, whereupon a moderate exothermic reaction took place. After having been stirred for 15 min at room temperature, the reaction mixture was diluted with water and the organic materials were extracted with chloroform. Concentration of the organic solution and addition of petroleum benzine afforded 3.46 g of **6**. Recrystallization from petroleum benzine gave an analytical sample of **6**, mp 80—82 °C. Identification was made by comparison of mp and IR spectrum with reported data:[4d] IR (hexane) 1730, 1665, 1630, and 1505 cm^{-1}; UV λ_{max}^{hexane} 260 (4.32) and 270 (4.34); ^{13}C NMR ($CHCl_3$) δ=171.2, 146.1, 142.4, 134.0, 128.9, 127.6, 125.6, and 89.8. Evaporation of the mother solution afforded 11.1 g of an oily product, which was chromatographed on silica gel (18 mm × 14 cm) with petroleum benzine as eluent. The first light yellow band and the second light brown band gave 4.27 g of **6** and the third brown band gave 2.01 g of an oily mixture of **6** and nitro compounds. The upper black part of column was separated and extracted with ethyl acetate. Evaporation of the solvent gave 1.46 g of crude **9**, which was crystallized from a mixed solvent of chloroform and ethyl acetate (4 : 1) to give an analytical sample: mp 204—208 °C; IR 1710 and 1575 cm^{-1}; UV λ_{max}^{hexane} 328 (3.30). Found: C, 28.88; H, 0.69; Cl, 48.69%. Calcd for $C_6H_2Cl_4O_4$: C, 28.80; H, 0.68; Cl, 48.58%.

*Pentachloro-4-methoxybicyclo[3.3.0]octa-3,5,8-trien-2-one (**10**).* A mixture of 1.00 g (3.08 mmol) of **6**, half of 0.426 g (3.08 mmol) of potassium carbonate, and 10 cm^3 of abs methanol was stirred at room temperature for 30 min, then the rest of the potassium carbonate was added and heated to reflux for 1 h. The reaction mixture was diluted with water and the organic materials were extracted with chloroform. Drying over sodium sulfate and evaporation of the solvent afforded 0.84 g of crystals. Recrystallization from petroleum ether gave an

analytical sample of **10**: mp 92—96 °C; IR 1700, 1660, 1630, 1550, 1350, and 800 cm^{-1}. Found: C, 33.49; H, 0.93%. Calcd for $C_9H_3Cl_5O_2$: C, 33.53; H, 0.99%.

*Hexachlorobicyclo[3.3.0]octa-4,6,8-trien-2-one (**14**).* To a suspension of 1.5 g (4.6 mmol) of **6** in 5 cm^3 of dichloromethane was added a solution of 4.10 g (13.7 mmol) of antimony(V) chloride in 40 cm^3 of dichloromethane and the solution was heated to reflux for 3 h. Chloroform (20 cm^3) was added to the deep red reaction mixture and the antimony(V) chloride was decomposed with concd hydrochloric acid. The organic phase was separated and washed twice with water. The solution was dried over sodium sulfate and the solvent was evaporated to dryness. Chromatography of silica gel with petroleum ether gave **14** quantitatively: mp 68—70 °C; IR 1750, 1615, 1560, 1455, 830, and 765 cm^{-1}; UV λ_{max}^{hexane} 245 (4.17), 274 (4.21), 285 sh (4.11), 318 (3.94), 331 (4.06), 346 (3.97), and 410—420 (2.97); ^{13}C NMR ($CHCl_3$) δ=171.6, 144.2, 142.5, 136.8, 130.8, 120.7, 119.8, and 85.1. Found: C, 29.86; H, 0.15%. Calcd for C_8Cl_6O: C, 29.58%.

*Reaction of **6** with Anhydrous Aluminium Chloride.* To 0.92 g (2.83 mmol) of **6** dissolved in 15 cm^3 of dried dichloromethane was added 1.0 g (7.5 mmol) of anhyd aluminium chloride and the mixture was heated under reflux for 7 h and quenched by hydrochloric acid. The organic solution was separated and dried over sodium sulfate and the solvent was evaporated under reduced pressure to give 0.91 g of brown solid, whose IR spectrum showed it was an approximately 1 : 1 mixture of **6** and **14**.

*Decachlorobicyclo[3.3.0]oct-6(or 7)-en-2-one (**16**).* *a) Chlorination of **14** in Liquid Chlorine*: A mixture of 0.377 g (1.16 mmol) of **14** dissolved in 10 cm^3 of carbon tetrachloride and about 10 cm^3 of liquid chlorine was sealed in a thick wall glass tube and kept under sunlight for one week. The tube was chilled in a Dry Ice-acetone bath and opened. Excess chlorine was removed by evaporation and the residue was chromatographed on silica gel (13 mm × 10 cm) with petroleum ether as eluent. The product was eluted as a light brown band. Evaporation of the solvent and recrystallization from a mixture of methanol and ethanol afforded white crystals of **16**: mp 126—130 °C; IR 1795, 1760, 1620, and 1585 cm^{-1}; UV λ_{max}^{hexane} 230 (3.98). Foun d: C, 20.85; H, 0.10; Cl, 75.97%. Calcd for $C_8Cl_{10}O$: C, 20.59; Cl, 75.98%.

b) Chlorination with Phosphorus(V) Chloride: Phosphorus(V) chloride (0.55 g) was mixed with 0.566 g (1.74 mmol) of **14** in a sealed tube and the mixture was heated at 170—200 °C for 4 h. The crude product was purified by column chromatography on silica gel eluted with petroleum benzine. Yield: 0.208 g (26.0%).

*Pentachloro-4-methoxybicyclo[3.3.0]octa-3,5,7-trien-2-one (**17a**).* Abs methanol (5 cm^3) was mixed with with 1.821 g (5.61 mmol) of **14** at room temperature and stirred for 5 min to precipitate yellow crystals. Then, 2 cm^3 of petroleum ether was added and the crystals were separated by filtration. Recrystallization three times from petroleum ether gave 0.365 g of an analytical sample of **17a**: mp 152 °C; IR 1740, 1730, 1595, 1550, and 1290 cm^{-1}; UV λ_{max}^{hexane} 220 (3.70), 277 (4.44), and 355 (4.13); ^{13}C NMR ($CHCl_3$) δ=174.4, 165.4, 140.7, 125.3, 124.6, 117.1 (d),[27] 81.6, and 65.1. Found: C, 33.67; H, 0.92; Cl, 55.60%. Calcd for $C_9H_3Cl_5O_2$: C, 33.74; H, 0.94; Cl, 55.34%.

*Pentachloro-4-ethoxybicyclo[3.3.0]octa-3,5,7-trien-2-one (**17b**).* Into a mixture of ethanol (4.7 cm^3) and chloroform (9.3 cm^3) was dissolved 1.624 g of **14** and the solution was stirred for 5 h at room temperature to precipitate yellow crystals. The solvent was evaporated under reduced pressure to give yellow crystal sludge. The crystals were separated by filtration and washed with a small amount of acetic acid. Crystallization from 7 cm^3 of chloroform afforded 0.67 g of **17b**: mp 186 °C; IR 1740, 1730, 1600, and 1550 cm^{-1}; UV λ_{max}^{hexane} 220 (3.65), 276 (4.50), and 357 (4.19); ^{13}C NMR ($CHCl_3$) δ=174.4, 165.0, 140.6, 125.0, 116.0, 117.1, 82.1, 74.9, and 14.7.[28] Found: C, 35.77; H, 1.50; Cl, 53.25%. Calcd for $C_{10}H_5Cl_5O_2$: C, 35.92; H, 1.50; Cl, 53.01%.

*Pentachloro-4-isopropoxybicyclo[3.3.0]octa-3,5,7-trien-2-one(**17b**).* A mixture of 2-propanol (10 cm^3), chloroform (5 cm^3) and 0.913 g of **14** was stirred for 1 h and kept at room temperature overnight. The yellow crystals obtained by evaporation of the solvent under reduced pressure were separated by filtration and crystallized from carbon tetrachloride: mp 149 °C dec; IR 1740, 1730, 1590, and 1540 cm^{-1}; UV λ_{max}^{hexane} 220 (3.68), 277 (4.27), and 355 (4.16); ^{13}C NMR ($CHCl_3$) δ=174.5, 164.5, 140.1, 124.9, 124.4, 116.6, 115.9, 83.0, and 22.0. Found: C, 37.51; H, 1.97; Cl, 50.88%. Calcd for $C_{11}H_7Cl_5O_2$: C, 37.92; H, 2.02; Cl, 50.88%.

*Pentachloro-4-hydroxybicyclo[3.3.0]octa-3,5,7-trien-2-one (**17d**).* Methanol (10 cm^3) was added to 1.038 g of **14** and refluxed gently for 10 min. The solution turned strongly acidic and dark greenish brown. Evaporation of the solvent left greenish yellow crystals, which were crystallized from a mixture of benzene (5 cm^3) and petroleum ether (3 cm^3) to give 0.837 g of yellow crystals of **17d**: mp 178 °C decomp; IR 3600, 3375, 1715, 1645, 1265, and 1130 cm^{-1}; UV λ_{max}^{hexane} 220 (3.62), 276 (4.56), and 357 (4.23). Found: C, 30.69; H, 0.67%. Calcd for $C_8HCl_5O_2 \cdot 1/2\ H_2O$: C, 30.43; H, 0.64%.[29]

*Chlorination of **6** with Antimony(V) Chloride. Formation of **11**:* A mixture of 5.5 g (16.9 mmol) of **6**, 6.13 g (20.5 mmol) of antimony(V) chloride, and 40 cm^3 of dry dichloromethane was refluxed for 4 h. After quenching the red reaction mixture with 50 cm^3 of concd hydrochloric acid, organic products were extracted with carbon tetrachloride. The organic solution was washed with water and dried over sodium sulfate. Evaporation of the solvent left 3.30 g of crude product. Distillation at 180—190 °C/2 mmHg gave a pure sample which showed single peak on gas chromatography (Nikki Model G-77) column: 20% SE-30 on Celite 545, mesh 60—80, and 2 m, He flow: 16.4 cm^3/min; column temperature: 250 °C: IR 1757, 1616, and 1590 cm^{-1}; UV λ_{max}^{hexane} 248 (3.90). Found: C, 24.80; H, 0.06%. Calcd for C_8Cl_8O: C, 24.28%.

*Chlorination of **12** with Phosphorus(V) Chloride.* In a thick wall glass tube, 1.126 g (3.3 mmol) of **12** and 0.894 g (4.3 mmol) of phosphorus(V) chloride was sealed and heated at 140—150 °C in an oil bath for 8 h, and allowed to cool to room temperature. The reaction mixture was treated with water and the products were taken up in carbon tetrachloride. The crude product was chromatographed on silica gel with petroleum benzine as eluent. A fraction eluted as a light yellow band was collected and evaporation of the solvent afforded 479 mg of **11**. Found: C, 24.38; H, 0.16; Cl, 71.83%. Calcd for C_8Cl_8O: C, 24.28; Cl, 71.68%.

*Chlorination of **13** with Phosphorus(V) Chloride.* Phosphorus(V) chloride (896 mg) was allowed to react with 467 mg of **13** under the same conditions as mentioned for the preceding reaction and 560 mg of **11** was obtained by the conventional isolation procedure.

*3,6,7,7,8-Pentachlorobicyclo[3.3.0]octa-5,8-diene-2,4-dione (**18**).* A methanolic solution of 1.325 g of **17a** was kept at room temperature for 2 d. Evaporation of the solvent afforded a brown oily product, which crystallized on trituration with petroleum ether. The product was chromatographed on silica gel (13 mm × 11 cm) with chloroform as eluent. The first yellowish brown band yield, after being stripped of the solvent, 0.3 g of **18**. Recrystallization from petroleum ether gave an analytical sample, mp 118—119 °C. Identification

was made by comparison of the IR spectrum with that of authentic sample prepared from **1** by the reported method.[4d]

*A Complex of **6** with Antimony(V) Chloride. Formation of **19**:* To a saturated solution of 0.488 g of **6** in dry dichloromethane (2.0 cm^3) were added 4 drops of antimony(V) chloride to precipitate an orange-brown crystalline material immediately, which was washed with a small amount of dichloromethane: IR (suspension in dichloromethane) 1690, 1640, 1500, 1305, 1245, 1195, 1100, 1033, 860, 805, 765, 745, and 580 cm^{-1}.

*Quantitative Analysis of **19**.* To a solution of **6** (0.40 g) in 1 cm^3 of carbon tetrachloride in a dry centrifuge tube (20 mm×9 cm) sealed with a rubber cup was added 0.75 g of antimony(V) chloride in 1 cm^3 carbon tetrachloride. Precipitated yellow crystals were washed with two portions of carbon tetrachloride (2 cm^3) and the residual solvent was evaporated under reduced pressure on phophorus pentaoxide to give 0.595 g of **19**. The complex was decomposed with 40 cm^3 of 6 M hydrochloric acid to give yellow crystals, which were separated by filtration and washed with a small amount of distilled water. Yield: 0.298 g (96.2%) of **6**. To the aq mother solution was added 0.90 g sodium sulfite and the solution was kept at room temperature for 17 h and then refluxed gently for 1.5 h to remove excess sulfite ion (potassium periodate–starch test paper). The filtrate (50.479 g) was divided into three portions and 20 cm^3 of distilled water was added to each portion, which was titrated with 0.02 M potassium permanganate solution. The average volume of permanganate solution corresponding to the whole filtrate was 19.52±0.29 cm^3 (1.1% in excess of the value calcd for $C_8Cl_6O \cdot SbCl_5$).

The author wishes to express his thanks to Professor Toshio Miwa of Osaka City University for useful discussion. He would like also to thank Dr. Takashi Tokuyama of Osaka City University and Dr. Shoji Imakoto of Suntory Co., Ltd. for measuring the mass spectra, and Dr. Koichi Mano of our institute for measuring the NQR spectra.

(Received April 30, 1982)

The thermal oligomerization of methacrylaldehyde oxime leads to 2,4,7-trimethylperhydroisoxazolo[2,3-*a*]-pyridine-2,7-dicarbaldehyde dioxime (**1**). The β-form of **1** was separated, and its crystal structure was determined by X-ray analysis. It is monoclinic with space group $P2_1/c$, $a=13.274(11)$, $b=8.652(7)$, $c=11.618(14)$ Å, $\beta=96.73(8)°$, and $Z=4$. The molecules are linked by two N···O hydrogen bonds, with the N(13)···O(14) and N(8)···O(18) distance of 2.824(5) and 2.897(5) Å respectively.

In the course of a study of the thermal polymerization of α,β-unsaturated aldehyde and ketone oximes, which have a vinylic double-bond conjugated with a hydroxyiminomethyl group, it has been found that methacrylaldehyde oxime (MAOM) and 3-methyl-3-buten-2-one oxime preferentially give a bicyclic trimer and a dimer respectively.[1,2] The bicyclic trimer from MAOM, 2,4,7-trimethylperhydroisoxazolo[2,3-*a*]pyridine-2,7-dicarbaldehyde dioxime (**1**), is isomeric. In our previous paper,[3] the crystal structure of the α-form of **1** was determined by means of X-ray diffraction; the chemical structure of the β-form was assumed on the basis of the spectrometrical data because of the very low yield and the failure to crystallize.

The present paper will describe the separation of the β-form and its X-ray structure analysis.

Experimental

Oligomerization of MAOM. Methacrylaldehyde was prepared by the Mannich reaction of propionaldehyde and formaldehyde,[4] and then oximated with hydroxylamine hydrochloride according to the procedure of Mowry.[5] The oligomerization of MAOM was carried out at 80 °C for 100 h in an ampoule. After the unreacted MAOM had been removed under reduced pressure, the residue was poured into a large amount of ether to precipitate the α-form of **1**. The precipitates were filtered off, and then the ether solution was concentrated and subjected to a large amount of hexane so that a yellow powder containing seven or more compounds was precipitated. The β-form was separated from the yellow powder by preparative TLC on silica gel in chloroform-ethyl acetate (7: 1) and recrystallized form its methanol solution. Colorless columnar crystals with the melting point of 192 °C (decomp). IR: 3325 (ν_{OH}), 1640 ($\nu_{C=N}$), 1380 (δ_{CH3}), and 930 cm^{-1} (ν_{NO}). MS *m/e* (relative intensity): 225 (M^+, 15), 240 (100), and 211 (38). ^{1}H-NMR (DMSO-d_6): $\delta=$ 10.67 (1H, s, OH), 10.55 (1H, s, OH), 7.31 (1H, s, CH=N), 7.21 1H, s, CH=N), 3.00 (1H, broad m, H(9), $J_{9.4}=4$ Hz), 2.25 (1H, t, H(3), $J_{3.3}=11$, $J_{3.9}=11$ Hz), 2.08 (1H, broad m, H(4)), 1.89 (1H, q, H(3), $J_{3.9}=7$ Hz), 1,75 (2H, broad d, H(6)), 1.39 (2H, broad m, H(5)), 1.29 (3H, s. CH_3), 1.20 (3H, s, CH_3), and 0.94 (3H, d, CH_3, $J_{10.4}=7$ Hz).

X-Ray Measurements. A crystal $0.4\times0.4\times0.1$ mm^3 in size was used for the X-ray measurements. The unit-cell dimensions were determined precisely by the least-squares fit of 2θ values of 16 reflections measured on a Syntex R-3 automated four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation. The crystal data are as follows;** $C_{12}H_{21}N_3O_3$, M. W.=255.32, monoclinic, space group $P2_1/c$, $a=13.274(11)$, $b=8.652(7)$, $c=11.618(14)$ Å, $\beta=96.73(8)°$, $U=1325$ Å^3, $Z=4$, $D_x=1.28$ g cm^{-3}, μ(Mo $K\alpha$)=1.0 cm^{-1}.

The reflections within the range of $2\theta<45°$ were collected by the use of an ω-scan mode. The intensities of three reference reflections were measured periodically; they showed no significant fluctuation during the data collection. A total of 1743 independent reflections were collected, among which 1214 reflections with $I\geqq1.96\sigma(I)$ were used for structure refinement. The intensities were corrected for Lorentz and polarization effects, but not for absorption.

Structure Determination and Refinement. The structure was solved by the direct method using the MULTAN program.[6] The atomic parameters were refined by the block-diagonal least-suqares method. The function minimized was $\Sigma w(|F_o|-|F_c|)^2$, where w was fixed as unity for non-zero reflections. The final value of R was 0.063. All the calculations were carried out on a NOVA 3 computer connected to the diffractometer, using the Syntex XTL programs. The atomic scattering factors were taken from the "International Tables for X-Ray Crystallography."[7]

Other Measurements. The ^{1}H-NMR spectra were recorded on a JEOL JNM-FX200 spectrometer (200 MHz), and the ^{13}C-NMR spectra, on a Hitachi R-42 spectrometer (22.6 MHz). The mass spectra were taken on a Shimadzu LKB-9000 mass spectrometer.

Results and Discussion

The atomic parameters, bond distances, and bond angles are listed in Tables 1—3 respectively.[8] Figure 1 shows a perspective drawing of the β-form of **1** and numbering scheme of the atoms. The six-membered ring has a chair form, while the five-membered ring, which is in a half-chair form, is fused to the six-membered ring through two equatorial-type bonds. The two rings are approximately coplanar to each other. The methyl group at the C(4) carbon is axial, while the methyl and hydroxyiminomethyl groups at the C(7) carbon are axial and equatorial respectively. In addition, the

† Part XVI: T. Ota, S. Masuda, H. Tanaka, and M. Kido, *Bull. Chem. Soc. Jpn.*, **55**, 171 (1982).

** There is a printing error in one of our published papers, *Bull. Chem. Soc. Jpn.*, **53**, 3240 (1980). The correct space group of the α-form of **1** is $P2_1/c$.

methyl and hydroxyiminomethyl groups at the C(2) carbon are on the same side of the average coplane of the rings, and on the opposite side, respectively, with the methyl group at the C(7) carbon.

In the previous paper,[3] the chemical structure of the β-form has been spectrometrically assumed. However. the results of X-ray analysis show that the crystal structure of the β-form differs from the estimated one and is the same as that of the α-form, except that the methyl groups at the C(4) and C(7) carbons are axial. This finding is also supported by the ^{1}H-NMR spectra. The C(4) proton resonates at 2.08 ppm with the coupling constant $J_{4,9}$=4 Hz; *i.e.*, the H(4) hydrogen is equatorial, and the C(4) carbon is thus axial. On the basis of these results, a schematic drawing of **1** is shown in Fig. 2.

The mass spectra of both α- and β-forms have a molecular ion peak at m/e 255, and they give similar fragmentation patterns except for the base ion peaks,

TABLE 3. BOND ANGLES, WITH ESTIMATED STANDARD DEVIATIONS IN PARENTHESES

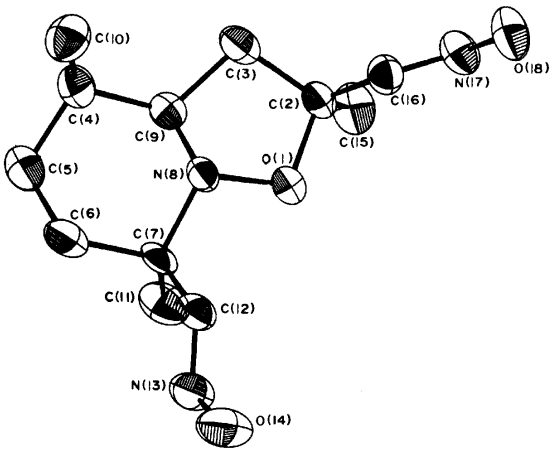

Fig. 1. A perspective drawing of the β-form molecule and the numbering scheme. Thermal ellipsoids of non-hydrogen atoms were drawn by ORTEP.[10]

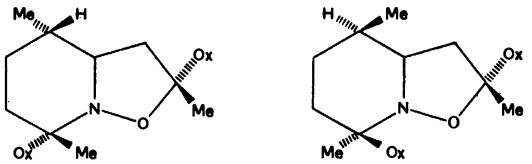

Fig. 2. Schematic drawing of isomeric **1**.

which appear at *m/e* 211 (the lost of the hydroxyiminomethyl radical) for the former and at *m/e* 240 (the lost of the methyl radical) for the latter. These observations show that the axial substituent at the C(7) carbon is more liable to be eliminated than the equatorial one because of steric hindrance.

There are characteristic bond angles which are common to the α- and β-forms. The axial conformation of the substituents at the C(4) and C(7) atoms always gives larger substituent-related interbond angles than do the equatorial ones; *i.e.*, the C(5)–C(4)–C(10), C(9)–C(4)–C(10), C(5)–C(4)–H(4), C(9)–C(4)–H(4), N(8)–C(7)–C(11), C(6)–C(7)–C(11), N(8)–C(9)–C(12), and C(6)–C(7)–C(12) angles are larger in the axial position of C(10), C(11), C(12), and H(4) atoms than those in the equatorial ones.

Figure 3 shows the crystal structure of the β-form viewed along the b axis. There are two intermolecular hydrogen bonds; the N(13)···H(14)–O(14) ($1-x$, $-y$, $-z$) and N(8)···H(18)–O(18) ($2-x$, $0.5+y$, $0.5-z$), with angles of 158(4) and 156(4)° respectively. The bond distances of N(13)···O(14), N(13)···H(14), O(14)–H(14), N(8)···O(18), N(8)···H(18), and O(18)–H(18) are 2.824(5), 1.91(5), 0.96(5), 2.897(5), 2.08(4), and 0.87(4) Å respectively.

The ^{13}C-NMR peak assignments are shown in Table 4, together with those of the α-form. These peak position were assigned by using the off-resonance technique and on the basis of the molecular structure determined by X-ray analysis. The signals assignable to the C(10) and C(11) carbons in the β-form and the C(12) carbon in the α-form are shifted to higher magnetic fields due

Table 4. Assignment of ^{13}C-NMR peaks of **1**

Carbon	Multiplicity	Peak position/ppm from TMS	
		α-Form	β-Form
-C(10)H_3	q	27.42	12.59
-C(11)H_3	q	18.79	10.86
-C(15)H_3	q	24.42	24.38
>C(3)H_2	t	30.16	30.78
>C(5)H_2	t	35.28	27.15
>C(6)H_2	t	44.41	41.75
>C(4)H	d	36.44	30.47
>C(9)H	d	65.99	59.13
>C(2)–O	s	77.62	77.16
>C(7)–N	s	60.75	61.41
-C(12)H=N	d	150.40	156.54
-C(16)H=N	d	154.44	154.41

s: Singlet, d: doublet, t: triplet, q: quartet.

to the axial position of the methyl and hydroxyiminomethyl groups. Since the carbon at the 4-position in a piperidine ring is known to resonate in a higher field than that at the 3-position,[11] the peak assignment of three methylene carbons seems to be reasonable.

Furanosesquiterpenoids: Total Synthesis of Pallescensins 2, F, and G

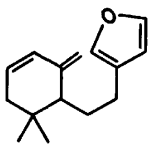
Takashi MATSUMOTO* and Shuji USUI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730

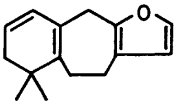
(Received June 7, 1982)

Oxidation of the synthetic pallescensin 1 with *m*-chloroperbenzoic acid, followed by treatment of the resulting epoxide with lithium diethylamide, afforded 3-[2-(2-furyl)ethyl]-4,4-dimethyl-2-methylenecyclohexanol (**6**). The alcohol **6** was dehydrated with refluxing hexamethylphosphoric triamide to give pallescensin 2. Oxidation of **6** with pyridinium chlorochromate, followed by intramolecular cyclization with 85% phosphoric acid, afforded 5,5a,6,7,8,9,9a,10-octahydro-6,6-dimethyl-4*H*-benzo[5,6]cyclohepta[1,2-*b*]furan-9-one. This was converted into the corresponding α,β-unsaturated ketone (**10**) *via* an α-phenylseleno ketone. Reduction of **10** with lithium aluminium hydride, followed by dehydration with hexamethylphosphoric triamide at 200—210 °C, afforded pallescensin G, which was further isomerized to pallescensin F.

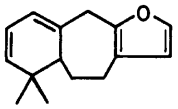
Pallescensins 2, F, and G, have recently been isolated from the marine sponge *Disidea pallescens* by Cimino *et al.*[1] On the basis of spectroscopic studies, they deduced the structures of pallescensins 2, F, and G, to be **1**, **2**, and **3**, respectively. To confirm the validity of these unique structures, we have attempted the total syntheses of **1**, **2**, and **3**, starting from pallescensin 1 (**4**)[2] which was prepared from α-cyclocitral in our laboratory.



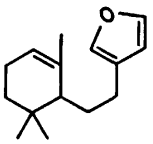
1



2



3



4

Oxidation of **4** with *m*-chloroperbenzoic acid in dichloromethane at 0—5 °C afforded the corresponding epoxide (**5**) which, without purification, was treated with lithium diethylamide[3] in refluxing tetrahydrofuran to give 3-[2-(2-furyl)ethyl]-4,4-dimethyl-2-methylenecyclohexanol (**6**) in 49% yield from **4**. The structure of **6** was supported by its ^{1}H NMR spectrum, which showed broad singlet signals at δ 2.66 (1H) due to a hydroxyl group and at δ 4.71 (1H) and 5.22 (1H) due to an *exo*-methylene group. Dehydration of **6** with refluxing hexamethylphosphoric triamide[4] under a stream of nitrogen afforded the desired 3-[2-(6,6-dimethyl-2-methylene-3-cyclohexenyl)ethyl]furan (**1**) in 89% yield. The ^{1}H NMR spectrum of the synthetic **1** was identical with that of natural pallescensin 2.

Our next effort was directed toward the syntheses of **2** and **3**. Oxidation of **6** with pyridinium chlorochromate in dichloromethane at room temperature afforded the corresponding α,β-unsaturated ketone (**7**) in 80% yield. The IR spectrum of **7** showed a conjugated carbonyl absorption band at 1690 cm^{-1} and its ^{1}H NMR spectrum showed two doublet signals at δ 4.91 (1H, J=2 Hz) and 5.69 (1H, J=2 Hz) due to an *exo*-methylene group. These spectral data suggested the structure of **7** to be 3-[2-(2-furyl)ethyl]-4,4-dimethyl-2-methylenecyclohexanone. Intramolecular cyclization of **7** with 85% phosphoric acid in tetrahydrofuran at room temperature afforded a single tricyclic ketone[5] (**8**) in 79% yield. The ^{1}H NMR spectrum of **8** showed a *gem*-dimethyl group at δ 1.01 (3H, s) and 1.03 (3H, s) and a furan moiety at δ 5.92 (1H, d, J=2 Hz) and 6.97 (1H, d, J=2 Hz). The presence of a non-conjugated carbonyl group (IR: 1705 cm^{-1}) and the chemical shifts of two furan protons suggested the structure of **8** to be 5,5a,6,7,8,9,9a,10-octahydro-6,6-dimethyl-4*H*-benzo-[5,6]cyclohepta[1,2-*b*]furan-9-one. In the present study, the stereochemistry of the ring juncture in **8** has remained unsettled. Treatment of **8** with benzeneselenenyl bromide[6] in tetrahydrofuran at −70 °C in the presence of lithium diisopropylamide under a stream of nitrogen afforded the corresponding α-phenylseleno ketone (**9**) in 80% yield. The ketone **9** in tetrahydrofuran was then treated with 30% hydrogen peroxide at room temperature to give an α,β-unsaturated ketone (IR: 1670 cm^{-1}), 5,5a,6,9,9a,10-hexahydro-6,6-dimethyl-4*H*-benzo[5,6]cyclohepta[1,2-*b*]furan-9-one (**10**), in 69% yield. The ^{1}H NMR spectrum of **10** showed two doublet signals at δ 5.79 (1H, J=10 Hz) and 6.50 (1H, J=10 Hz) due to two olefinic protons, supporting the presence of a disubstituted olefinic moiety. Reduction of **10** with lithium aluminium hydride in ether at 0—5 °C, followed by heating of the resulting alcohol (**11**) with hexamethylphosphoric triamide at 200—210 °C under a stream of nitrogen, afforded the desired 5,5a,6,10-tetrahydro-6,6-dimethyl-4*H*-benzo[5,6]cyclohepta[1,2-*b*]-furan (**3**) in 51% yield from **10**. The structure of **3** was supported by its ^{1}H NMR spectrum, which showed signals at δ 0.99 (3H) and 1.06 (3H) due to a *gem*-dimethyl group, at δ 5.4 (1H) and 5.73 (2H) due to three olefinic protons, and at δ 6.12 (1H) and 7.18 (1H) due to two furan protons. Isomerization of **3** with refluxing hexamethylphosphoric triamide under a stream of nitrogen afforded an isomer (**2**) in 75% yield. The ^{1}H NMR spectrum of **2** showed a *gem*-dimethyl group at δ 1.03 (6H), four methylene groups at δ 2.03 (2H), 2.47 (4H), and 3.37 (2H), two olefinic protons at δ 5.52 (1H) and 5.74 (1H), and two furan protons at δ 5.97 (1H) and 7.02 (1H). These spectral data,

especially the presence of signals due to four methylene groups and two olefinic protons, suggested the structure of **2** to be the desired 5,6,7,10-tetrahydro-6,6-dimethyl-4*H*-benzo[5,6]cyclohepta[1,2-*b*]furan. The ^{1}H NMR spectra of the synthetic **2** and **3** were also in good agreement with those[1] of natural pallescensins F and G.

Experimental

The melting point is uncorrected. The IR spectra were measured in chloroform and the ^{1}H NMR spectra in carbon tetrachloride at 90 MHz, with tetramethylsilane as an internal standard, unless otherwise stated. The chemical shifts are presented in terms of δ values; s: singlet, bs: broad singlet, d: doublet, bd: broad doublet, dd: double doublet, t: triplet, dt: double triplet, m: multiplet, dm: doublet of multiplet. Column chromatography was performed using Merck silica gel (0.063—0.200 mm).

3-[2-(2,6,6-Trimethyl-2-cyclohexenyl)ethyl]furan (Pallescensin 1) (**4**). Pallescensin 1 was prepared from (±)-α-cyclocitral by the known procedure.[2]

3-[2-(2-Furyl)ethyl]-4,4-dimethyl-2-methylenecyclohexanol (**6**). A solution of **4** (412 mg) and 85% *m*-chloroperbenzoic acid (420 mg) in dichloromethane (6.0 ml) was stirred at 0—5 °C for 1 h and then diluted with ether. The solution was washed successively with 10% aqueous potassium iodide, aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and brine. The dried solution was evaporated *in vacuo* to give a crude epoxide (**5**); ^{1}H NMR (60 MHz): 0.83 (3H, s) and 0.90 (3H, s) (–C(CH$_3$)$_2$), 1.30 (3H, s, –OCCH$_3$), 6.23 (1H, bs), 7.18 (1H, bs), and 7.26 (1H, t, J=2 Hz) (furan protons).

A solution of the crude **5** in dry tetrahydrofuran (2.0 ml) was added to a solution of lithium diethylamide which was prepared from butyl lithium in hexane [1.6 M (1 M=1 mol dm^{-3}): 6.0 ml] and diethylamine (1.0 ml) in dry tetrahydrofuran (4.0 ml) at room temperature for 30 min. The mixture was refluxed for 3 h, cooled, and diluted with ether. The solution was washed successively with aqueous ammonium chloride and brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was purified by column chromatography on silica gel (Merck, 0.063 mm: 40 g), usingether–benzene (1: 9) as the eluent, to give **6** (215 mg: 49% from **4**); IR: 3610, 3450 br cm^{-1}; ^{1}H NMR (60 MHz): 0.73 (3H, s) and 0.96 (3H, s) (–C(CH$_3$)$_2$), 2.66 (1H, bs, –OH), 3.88 (1H, m, $W_{1/2}$=16 Hz, –CHOH), 4.71 (1H, bs) and 5.22 (1H, bs) (–C=CH$_2$), 6.18 (1H, bs), 7.12 (1H, bs), and 7.27(1H, t, J=2 Hz) (furan protons). Found: C, 76.75; H, 9.73%. Calcd for $C_{15}H_{22}O_2$: C, 76.88; H, 9.46%.

3-[2-(6,6-Dimethyl-2-methylene-3-cyclohexenyl)ethyl]furan (Pallescensin 2) (**1**). A solution of **6** (200 mg) in hexamethylphosphoric triamide (2.0 ml) was refluxed for 1.5 h under a stream of nitrogen. The solution was cooled, poured into dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was purified by column chromatography on silica gel (20 g), using hexane as the eluent, to give **1** (164 mg: 89%); ^{1}H NMR: 0.84 (3H, s) and 0.97 (3H, s) (–C(CH$_3$)$_2$), 4.71 (1H, bs) and 4.87 (1H, bs) (–C=CH$_2$), 5.57 (1H, dm, J=10 Hz, –CH=CH–C=), 5.99 (1H, bd, J=10 Hz, –CH=CH–C=), 6.14 (1H, bs), 7.10 (1H, bs), and 7.23 (1H, t, J=2 Hz) (furan protons). Found: C, 83.00; H, 9.35%. Calcd for $C_{15}H_{20}O$: C, 83.28; H, 9.32%. The ^{1}H NMR spectrum of the synthetic **1** was identical with that of natural pallescensin 2.

3-[2-(2-Furyl)ethyl]-4,4-dimethyl-2-methylenecyclohexanone (**7**). A mixture of **6** (165 mg) and pyridinium chlorochromate (230 mg) in dichloromethane (4.0 ml) was stirred at room temperature for 3 h, poured into aqueous sodium carbonate, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was chromatographed on silica gel (15 g), using ether–benzene (2: 98) as the eluent, to give **7** (132 mg: 80%); IR: 1690 cm^{-1}; ^{1}H NMR: 1.01 (3H, s) and 1.08 (3H, s) (–C(CH$_3$)$_2$), 4.91 (1H, d, J=2 Hz) and 5.69 (1H, d, J=2 Hz) (–C=CH$_2$), 6.17 (1H, bs), 7.12 (1H, bs), and 7.26 (1H, t, J=2 Hz) (furan protons). Found: C, 77.27; H, 8.79%. Calcd for $C_{15}H_{20}O_2$: C, 77.55; H, 8.68%.

5,5a,6,7,8,9,9a,10-Octahydro-6,6-dimethyl-4H-benzo-[5,6]cyclohepta[1,2-b]furan-9-one (**8**). A solution of **7** (368 mg) in tetrahydrofuran (2.0 ml) was added to a mixture of 85% phosphoric acid (16 ml) and tetrahydrofuran (30 ml). The mixture was stirred at room temperature for 10 h, diluted with ice-water, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporared *in vacuo*. The crude product was purified by column chromatography on silica gel (40 g), using ether–benzene (2 : 98) as the eluent, to give **8** (292 mg: 79%); IR: 1705 cm^{-1}; ^{1}H NMR: 1.01 (3H, s) and 1.03 (3H, s) (–C(CH$_3$)$_2$), 5.92 (1H, d, J=2 Hz) and 6.97 (1H, d, J=2 Hz) (furan protons). Found: C, 77.48; H, 8.78%. Calcd for $C_{15}H_{20}O_2$: C, 77.55; H, 8.68%.

5,5a,6,7,8,9,9a,10-Octahydro-6,6-dimethyl-8-phenylseleno-4H-benzo[5,6]cyclohepta[1,2-b]furan-9-one (**9**). A solution of **8** (67 mg) in dry tetrahydrofuran (1.0 ml) was added at −70 °C to a solution of lithium diisopropylamide [prepared from butyl lithium in hexane (1.6 M: 0.450 ml) and diisopropylamine (0.100 ml) in dry tetrahydrofuran (2.0 ml) at −70 °C] under a stream of nitrogen. The solution was stirred at the same temperature for 10 min and then a solution of benzeneselenenyl bromide (170 mg) in dry tetrahydrofuran (1.0 ml) was added. The mixture was stirred at −70 °C for 10 min more, poured into ice–dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was purified by column chromatography on silica gel (10 g), using benzene as the eluent, to give **9** (89 mg: 80%). This was recrystallized from methanol; mp 115- 117 °C; IR: 1700 cm^{-1}; ^{1}H NMR: 0.99 (6H, s, –C(CH$_3$)$_2$), 4.18 (1H, dd, J=8 and 12 Hz, C_6H_5SeCH–), 5.98 (1H, d, J=2 Hz) and 7.01 (1H,d, J=2 Hz) (furan protons), 7.0—7.6 (5H, m, C_6H_5Se–). Found:

C, 65.27; H, 6.40%. Calcd for $C_{21}H_{24}O_2Se$: C, 65.11; H, 6.24%.

*5,5a,6,9,9a,10-Hexahydro-6,6-dimethyl-4*H*-benzo[5,6]cyclohepta-[1,2-*b*]furan-9-one (**10**).* A solution of **9** (165 mg) and 30% hydrogen peroxide (0.09 ml) in tetrahydrofuran (4.0 ml) was stirred at room temperature for 1.5 h and then diluted with aqueous sodium hydrogencarbonate. The mixture was extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was chromatographed on silica gel (5 g), using ether–benzene (1:99) as the eluent, to give **10** (68 mg: 69%); IR: 1670 cm^{-1}; ^1H NMR: 1.09 (3H, s) and 1.19 (3H, s) ($-\dot{C}(CH_3)_2$), 5.79 (1H, d, $J=10$ Hz) and 6.50 (1H, d, $J=10$ Hz) ($-CH=CHCO-$), 5.98 (1H, d, $J=2$ Hz) and 7.03 (1H, d, $J=2$ Hz) (furan protons); MS (*m/e*): 230 (M^+).

*5,5a,6,10-Tetrahydro-6,6-dimethyl-4*H*-benzo[5,6]cyclohepta[1,2-*b*]furan (Pallescencin G) (**3**).* A mixture of **10** (68 mg) and lithium aluminium hydride (15 mg) in dry ether (2.0 ml) was stirred at 0—5 °C for 30 min. The mixture was poured into ice–dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo* to give a crude alcohol (**11**); IR: 3590, 3430br cm^{-1}; ^1H NMR: 0.93 (3H, s) and 0.98 (3H, s, $-\dot{C}(CH_3)_2$), 2.40 (1H, bs, –OH), 3.72 (1H, bd, $J=10$ Hz, $-\dot{C}\underline{H}OH$) 5.28 (1H, d, $J=10$ Hz) and 5.42 (1H, d, $J=10$ Hz) ($-CH=CH-$), 5.99 (1H, d, $J=2$ Hz) and 7.03 (1H, d, $J=2$ Hz) (furan protons).

The crude alcohol **11** was heated with hexamethylphosphoric triamide (2.0 ml) at 200—210 °C for 1 h under a stream of nitrogen. The mixture was cooled, poured into ice–dilute hydrochloric acid, and extracted with ether. The ether extract was washed successively with dilute hydrochloric acid and brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was purified by column chromatography on silica gel (10 g), using hexane–benzene (1 : 1) as the eluent, to give **3** (32 mg: 51% from **10**); ^1H NMR ($CDCl_3$): 0.99 (3H, s) and 1.06 (3H, s) ($-\dot{C}(CH_3)_2$), 3.41 (1H, d, $J=17$ Hz) and 3.67 (1H, d, $J=17$ Hz) ($=\dot{C}CH_2\dot{C}=$), 5.4 (1H, m) and 5.73 (2H, m) (olefinic protons), 6.12 (1H, d, $J=2$ Hz) and 7.18 (1H, d, $J=2$ Hz) (furan protons); MS (*m/e*): 214 (M^+). The ^1H NMR spectrum of the synthetic **3** was in good agreement with that of natural pallescensin G.

*5,6,7,10-Tetrahydro-6,6-dimethyl-4*H*-benzo[5,6]cyclohepta[1,2-*b*]furan (Pallescensin F) (**2**).* A solution of **3** (22.0 mg) in hexamethylphosphoric triamide (2.0 ml) was refluxed for 1 h under a stream of nitrogen. After the same work-up as described for the preparation of **3**, the crude product was chromatographed on silica gel (5 g), using hexane–benzene (1 : 1) as the eluent, to give **2** (16.4 mg: 75%); ^1H NMR: 1.03 (6H, s, $-\dot{C}(CH_3)_2$), 2.03 (2H, dd, $J=4$ and 2 Hz, $=CHC\underline{H}_2\dot{C}-$), 2.47 (4H, s, $-CH_2CH_2-$), 3.37 (2H, bs, $=\dot{C}CH_2\dot{C}=$), 5.52 (1H, dt, $J=10$ and 4 Hz) and 5.74 (1H, dt, $J=10$ and 2 Hz) ($-CH=CH\dot{C}=$), 5.97 (1H, d $J=2$ Hz) and 7.02 (1H, d, $J=2$ Hz) (furan protons); MS (*m/e*): 214 (M^+). The ^1H NMR spectrum of the synthetic **2** was in good agreement with that of natural pallescensin F.

The authors are grateful to Dr. G. Cimino for kindly supplying the spectral data of natural pallescensins.

5) When the cyclization was carried out with 85% phosphoric acid in dichloromethane at room temperature, a mixture of **8** and its other isomer (**8a**) (*ca.* 3 : 7) was obtained in 33% yield. The ^1H NMR spectrum of **8a** showed a *gem*-dimethyl group at δ 1.04 (3H, s) and 1.25 (3H, s) and a furan moiety at δ 5.96 (1H, d, $J=2$ Hz) and 7.04 (1H, d, $J=2$ Hz).

Synthetic Studies on the Validamycins. I. Synthesis of β-D-Glucopyranosylvalidamine: 1L-2-O-(β-D-Glucopyranosyl)-(1,3,4/2,6)-4-amino-6-hydroxymethyl-1,2,3-cyclohexanetriol[1]

Seiichiro OGAWA, Yasuhito SHIBATA, Noritaka CHIDA, and Tetsuo SUAMI*

(Received June 10, 1982)

β-D-Glucopyranosylvalidamine, the structure of which had first been assigned to a degradation product of validamycin A, was synthesized by condensation of a protected validamine with 2,3,4,6-tetra-O-acetyl-α-D-glucopyranosyl bromide, followed by removal of protecting groups. The synthesized β-D-glucopyranoside was not identical with an authentic sample derived from the antibiotic.

Validamycin A is a main component of the validamycin complex which is used to control sheath blight of rice plants and produced by *Streptomyces hygroscopicus* var. *limoneus*. It was isolated by Iwasa *et al.*[2] in 1970 and the structure was first assigned by Horii and Kameda[3] in 1972 on the basis of degradative studies. The unique structural feature of the validamycins prompted us to study the synthesis and structure-activity relationship of this class of antibiotics.

Scheme 1.

The hydrogenolitic cleavage of validamycin A yields β-D-glucopyranosylvalidamine (**1**), validatol, and deoxyvalidatol.[4] Compound **1** was hydrolyzed to afford validamine (**2**) and D-glucose, and its structure was formulated as shown in Scheme 1 based on results of the periodate oxidation of its *N*-acetyl derivative.[4] The present paper, as part of studies directed toward total synthesis of validamycin A and related substances, describes the synthesis of the original structure of **1**, 1L-2-O-(β-D-glucopyranosyl)-(1,3,4/2,6)-4-amino-6-hydroxymethyl-1,2,3-cyclohexanetriol, by condensation of a properly protected DL-validamine with 2,3,4,6-tetra-O-acetyl-α-D-glucopyranosyl bromide. In addition, two diastereomeric β-D-glucopyranosides thus obtained were hydrolyzed to generate enantiomeric validamines, which constituted an optical resolution of racemic validamine.

Acid hydrolysis of DL-penta-*N*,*O*-acetyl-(1,3,4/2,6)-4-amino-6-hydroxymethyl-1,2,3-cyclohexanetriol (peracetyl-DL-validamine) (**3**)[5] with 4 M hydrochloric acid (1 M=1 mol dm^{-3}) at reflux temperature gave the amine hydrochloride (**4**) as an amorphous solid in quantitative yield. Treatment of **4** with benzyloxycarbonyl chloride in an alkaline solution gave a crystalline *N*-benzyloxycarbonyl derivative (**5**), which was further characterized as the tetra-O-acetyl derivative (**6**). Compound **5** was then converted into the *N*,*O*-carbonyl derivative (**7**) in 75% yield by treatment with 10% aqueous sodium hydroxide, whose IR spectrum revealed an absorption at 1730 cm^{-1}, indicative of the cyclic carbamate function. The structure of **7** was confirmed by the ^{1}H NMR spectrum of the corresponding tri-O-acetyl derivative (**8**). Thus, the signals for H-1, H-2, and H-3 protons appeared as a triplet (J=9 Hz), a doublet of doublets (J=6.5 and 9 Hz), and a doublet of doublets (J=6.2 and 6.5 Hz) at δ 4.99, 5.26, and 4.60, respectively, being consistent with the chair conformation slightly distorted by the introduction of the cyclic carbamate portion. Isopropylidenation of **7** with 2,2-dimethoxypropane in *N*,*N*-dimethylformamide (DMF) in the presence of *p*-toluenesulfonic acid gave the 1,7-O-isopropylidene derivative (**9**) in 97% yield. The assigned structure was supported by the ^{1}H NMR spectra of the corresponding O-acetyl (**10**), di-*N*,*O*-

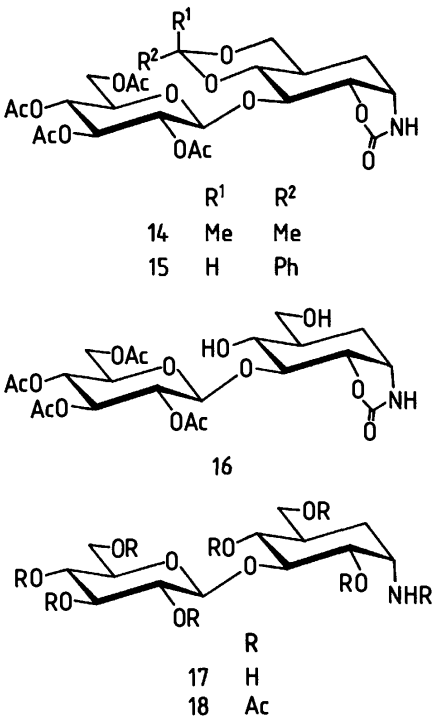

Scheme 3. Synthesis of β-D-glucopyranosylvalidamine. The formulas depict one of the respective diastereomers.

acetyl (**11**), and di-*N*,*O*-methyl derivatives (**12**). For further confirmation, **9** was transformed into DL-1,7-di-*O*-acetyl-3,4-*N*,*O*-carbonyl-2,4-di-*N*,*O*-methyl-(1,3,4/2,6)-4-amino-6-hydroxymethyl-1,2,3-cyclohexanetriol (**13**), whose ^{1}H NMR spectrum was fully consistent with the assigned structure. Thus, there appeared two coupled doublets of doublets (J=6 and 8 Hz) attributable to H-2 and H-3 at δ 3.36 and 4.50, respectively. Therefore, **9** was shown to possess a free hydroxyl group at C-2, being a suitable intermediate for the synthesis of **1**.

Condensation of **9** with 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide was carried out in a mixture of benzene and dioxane (2 : 1, v/v) in the presence of mercury(II) cyanide and anhydrous calcium sulfate at 65 °C for 6 d. Formation of two components was observed and they were clearly separated by chromatography on silica gel with 2-butanone–toluene (1 : 1, v/v) as an eluent, giving the protected β-D-glucopyranosides [**14**(+)], $[\alpha]_D$+77.8°, and [**14**(−)], $[\alpha]_D$−30.4°, as a syrup in 47 and 50% yields, respectively. They were shown to have four acetoxyl, one carbonyl, and one isopropylidene groups by the IR and ^{1}H NMR spectra, and their analytical data supported the assigned structures. The β-configurations were proposed both by the optical rotations and by the reaction conditions employed for the condensation reaction. Treatment of **14**(+) and **14**(−) with 80% aqueous acetic acid at ambient temperature afforded the corresponding dihydroxy compounds [**16**(+)] and [**16**(−)] in 44 and 76% yields, respectively. The presence of two hydroxyl groups at C-1 and C-7 was evidenced by the exclusive transformation into the 1,7-*O*-benzylidene derivatives [**15**(+) and **15**(−)] in 74 and 66% yields, respectively, by treatment with 1,1-dimethoxy-1-phenylmethane in DMF in the presence of acid catalyst. The ^{1}H NMR spectra of **15**(+) and **15**(−) exhibited one-proton sharp singlets at δ 5.56 and 5.55, respectively, due to the benzylic protons. Removal of the protecting groups of **16**(+) and **16**(−) was effected by treatment with refluxing 10% aqueous barium hydroxide. The free bases [**17**(+) and **17**(−)] thus obtained as a homogeneous syrup were further characterized as the corresponding octa-*N*,*O*-acetyl derivatives [**18**(+) and **18**(−)]. Acid hydrolysis of **17**(+) with 6 M hydrochloric acid gave D-glucose and validamine hydrochloride, which were detected by TLC on cellulose. They were acetylated in the usual way to give, after chromatography, penta-*O*-acetyl-α-D-glucopyranose and penta-*N*,*O*-acetyl-(+)-validamine [**3**(+)], $[\alpha]_D$ +60.2°, mp 146—148 °C. The latter compound was identified with an authentic sample, $[\alpha]_D$ +61.6°, mp 147—149 °C, prepared from (+)-validamine hydrochloride,[6,7] by the mixed melting point method and by comparison of their IR (in chloroform) and ^{1}H NMR spectra, and behavior on TLC. The enantiomer **3**(−), $[\alpha]_D$ −59.8°, mp 147—149 °C, similarly obtained from **17**(−), was shown to be identical with an authentic sample except for the optical rotations being opposite in sign. Therefore, the optical resolution of racemic validamine was accomplished by the above experiments.

Attempts were then made to compare **18**(+) with an authentic sample[6] derived from validamycin A, and they were found to be completely different from each other, on the basis of ^{1}H and ^{13}C NMR spectra, and chromatographic behavior. Consequently, we concluded that the original structure of β-D-glucopyranosylvalidamine must be reinvestigated and revised. We will report an unequivocal synthesis of β-D-glucopyranoside identical with an authentic sample in all respects in the succeeding paper.

Experimental

Unless otherwise noted, melting points were determined on a Mitamura Riken micro hot stage and uncorrected. The ^{1}H NMR spectra were taken on a Varian EM-360 (60 MHz) in chloroform-*d* ($CDCl_3$) or dimethyl-d_6 sulfoxide (DMSO-d_6) with reference to tetramethylsilane as an internal standard and the peak positions are given in terms of δ-values. Values given for coupling constants are of first-order. The IR spectra were measured on a Hitachi 225 spectrometer in potassium bromide pellets or in chloroform. Optical rotations were measured on a Japan Spectroscopic DIP-4 polarimeter in a 10 mm cell. TLC was performed on a precoated silica gel 60 F-254 plate or cellulose F-254 plate (Merck, Darmstadt). The silica gel used for column chromatography was Wakogel C-300.

DL-*(1,3,4/2,6)-4-Amino-6-hydroxymethyl-1,2,3-cyclohexanetriol Hydrochloride (DL-Validamine Hydrochloride) (**4**).* A solution of DL-tetra-*O*-acetyl-(1,3,4/2,6)-4-acetamido-6-hydroxymethyl-1,2,3-cyclohexanetriol (**3**)[5] (3.8 g) in 4 M hydrochloric acid (240 ml) was refluxed for 2 h. The reaction mixture was concentrated to give a pale yellow syrup, which was dissolved in water and decolorized with active carbon. Evaporation of the solvent gave **4** (2.1 g, 100%) as a chromatographically homogeneous glass, which showed a single spot at R_f 0.41 on TLC [cellulose, 1-butanol–ethanol–water–17% aqueous ammonia (4 : 5 : 2 : 4)].

Found: C, 39.07; H, 7.74; N, 6.39; Cl, 16.33%, Calcd for $C_7H_{15}NO_4 \cdot HCl$: C, 39.35; H, 7.55; N, 6.56; Cl, 16.59%.

DL-*(1,3,4/2,6)-4-Benzyloxycarbonylamino-6-hydroxymethyl-1,2,3-cyclohexanetriol (5).* To a stirred solution of **4** (2.1 g) in a mixture of acetone–water (2 : 1) (220 ml) containing 1 M aqueous sodium hydroxide (30 ml) was added dropwise 30% benzyloxycarbonyl chloride in toluene (11 ml) at ambient temperature. The reaction mixture was agitated for 17 h at ambient temperature, and then neutralized with 1 M hydrochloric acid and concentrated. The residue was extracted with acetone and the extracts were concentrated to give a white solid, which was crystallized from ethyl acetate to give **5** (1.51 g, 52.3%) as prisms: mp 148—150 °C; IR (KBr disk) 1710 cm^{-1} (C=O).

Found: C, 57.69; H, 6.72; N, 4.35%. Calcd for $C_{15}H_{21}NO_6$: C, 57.86; H, 6.80; N, 4.50%.

DL-*Tetra*-O-*acetyl-(1,3,4/2,6)-4-benzyloxycarbonylamino-6-hydroxymethyl-1,2,3-cyclohexanetriol (6).* Compound **5** (0.1 g) was treated with acetic anhydride (1 ml) in pyridine (2 ml) at ambient temperature overnight. The reaction mixture was poured into ice–water and the resulting gum was collected by decantation. The product was dried over phosphorus pentaoxide under vacuum to give **6** (0.1 g, 69%) as a homogeneous syrup: ^1H NMR ($CDCl_3$) δ=1.91 (3H, s), 1.99 (3H, s), 2.00 (3H, s), and 2.05 (3H, s) (OAc), 4.32 (1H, m, H-4), 5.06 (2H, s, $C\underline{H}_2Ph$), and 7.29 (5H, broad s, phenyl).

Found: C, 57.58; H, 6.12; N, 2.82%. Calcd for $C_{23}H_{29}NO_{10}$: C, 57.61; H, 6.10; N, 2.92%.

DL-*3,4*-N,O-*Carbonyl-(1,3,4/2,6)-4-amino-6-hydroxymethyl-1,2,3-cyclohexanetriol (7).* To a solution of **5** (0.8 g) in acetone–water (3 : 1) (30 ml) was added 1 M aqueous sodium hydroxide, the pH of the solution being adjusted to 11. After having been stood at ambient temperature for 4 h, the reaction mixture was neutralized with 1 M hydrochloric acid, concentrated, and dried by coevaporation with ethanol. The residue was extracted with hot 1,4-dioxane (5 ml × 3) and, after being cooled, the extracts gave **7** (0.39 g, 75%) as prisms: mp 164—165 °C; IR (KBr disk) 3500—3200 (OH) and 1730 cm^{-1} (cyclic carbamate).

Found: C, 47.29; H, 6.52; N, 6.71%. Calcd for $C_8H_{13}NO_5$: C, 47.29; H, 6.45; N, 6.89%.

Compound **7** (1.2 g) was directly obtained in 77% yield from **3** (2.9 g) without isolation of the intermediates.

DL-*Tri*-O-*acetyl-3,4*-N,O-*carbonyl-(1,3,4/2,6)-4-amino-6-hydroxymethyl-1,2,3-cyclohexanetriol (8).* Compound **7** (0.1 g) was acetylated in the conventional manner and the product was crystallized from ethanol to give **8** (0.14 g, 85%) as needles: mp 133—134 °C; ^1H NMR ($CDCl_3$) δ=2.04 (6H, s) and 2.06 (3H, s) (OAc), 3.90 (2H, q) and 4.22 (2H, q) ($J_{6,7}$=3 Hz, $J_{6,7'}$=5 Hz, J_{7gem}=11.5 Hz, H-7 and H-7'), 4.60 (1H, dd, $J_{2,3}$=6.2 Hz, $J_{3,4}$=6.5 Hz, H-3), 4.99 (1H, t, $J_{1,2}$=$J_{1,6}$=9 Hz, H-1), 5.26 (1H, dd, H-2), and 6.40 (1H, s, NH).

Found: C, 50.80; H, 5.67; N, 4.11%. Calcd for $C_{14}H_{19}NO_8$: C, 51.06; H, 5.82; N, 4.25%.

DL-*3,4*-N,O-*Carbonyl-1,7*-O-*isopropylidene-(1,3,4/2,6)-4-amino-6-hydroxymethyl-1,2,3-cyclohexanetriol (9).* To a solution of **7** (1.2 g) in dry *N,N*-dimethylformamide (8 ml) was added 2,2-dimethoxypropane (3.5 ml) and *p*-toluenesulfonic acid (20 mg), and the mixture was heated at 80 °C for 2 h. The mixture was treated with Amberlite IRA 400 (OH^-) (2.5 ml) and then concentrated to give a crystalline product. Recrystallization from ethanol gave **9** (1.1 g, 79%) as crystals: mp 243—244 °C (decomp); IR (KBr disk) 3400—3300 (OH and NH) and 1740 cm^{-1} (cyclic carbamate); ^1H NMR (DMSO-d_6) δ=1.27 (3H, s) and 1.37 (3H, s) (isopropylidene), 4.16 (1H, t, $J_{2,3}$=$J_{3,4}$=6.5 Hz, H-3), 5.28 (1H, d, $J_{2,OH}$=5 Hz, OH), and 7.29 (1H, broad s, NH).

Found: C, 54.05; H, 6.89; N, 5.89%. Calcd for $C_{11}H_{17}NO_5$: C, 54.31; H, 7.04; N, 5.76%.

DL-*2*-O-*Acetyl-3,4*-N,O-*carbonyl-1,7*-O-*isopropylidene-(1,3,4/2,6)-4-acetamido-6-hydroxymethyl-1,2,3-cyclohexanetriol (11).* Compound **9** (0.1 g) was treated with acetic anhydride (2 ml) in pyridine (3 ml) at 50 °C for 3 d. The reaction mixture was poured into saturated aqueous sodium hydrogencarbonate and the precipitates were collected by decantation. The product was dissolved in ethyl acetate, and the solution was washed with water and dried. Evaporation of the solvent gave a syrup (0.12 g), which was crystallized from ethanol to give **11** (30 mg, 22%) as needles: mp 142—144 °C; ^1H NMR ($CDCl_3$) δ=1.34 (3H, s) and 1.41 (3H, s) (isopropylidene), 2.10 (3H, s, OAc), 2.51 (3H, s, NAc), 3.58 (1H, t, $J_{1,2}$=$J_{1,6}$=10 Hz, H-1), 4.52 (2H, d, H-3 and H-4), and 5.03 (1H, m, H-2).

Found: C, 54.77; H, 6.40; N, 4.10%. Calcd for $C_{15}H_{21}NO_7$: C, 55.04; H, 6.47; N, 4.28%.

DL-*2*-O-*Acetyl-3,4*-N,O-*carbonyl-1,7*-O-*isopropylidene-(1,3,4/2,6)-4-amino-6-hydroxymethyl-1,2,3-cyclohexanetriol (10).* Compound **9** (61 mg) was treated with acetic anhydride (1 ml) in pyridine (2 ml) at ambient temperature for 25 h. TLC indicated the formation of one major component (R_f 0.28) and one minor component (R_f 0.77) [silica gel, 2-butanone–toluene (1 : 1)]. The reaction mixture was concentrated and the crude product, without further purification, was subjected to measurement of ^1H NMR spectrum. The product was shown to be contaminated with **11**: ^1H NMR ($CDCl_3$) δ=1.34 (3H, s) and 1.41 (3H, s) (isopropylidene), 2.06 (3H, OAc), 3.50 (1H, t, $J_{1,2}$=$J_{1,6}$=10 Hz, H-1), 4.48 (1H, t, $J_{2,3}$=$J_{3,4}$=7 Hz, H-3), 5.14 (1H, dd, H-2), and 6.37 (1H, s, NH).

DL-*1,7-Di*-O-*acetyl-3,4*-N,O-*carbonyl-2,4-di*-N,O-*methyl-(1,3,4/2,6)-4-amino-6-hydroxymethyl-1,2,3-cyclohexanetriol (13).* To a solution of **9** (0.22 g) in dry *N,N*-dimethylformamide (10 ml) was added silver oxide (1 g) and methyl iodide (1 ml), and the mixture was vigorously stirred at ambient temperature in the dark for 14 h. An insoluble material was removed by filtration and washed thoroughly with ethyl acetate. The filtrate and washings were combined and concentrated. The residue was dissolved in ethyl acetate and filtered through a short column of alumina. The filtrate was concentrated to give DL-3,4-*N,O*-carbonyl-1,7-*O*-isopropylidene-2,4-di-*N,O*-methyl-(1,3,4/2,6)-4-amino-6-hydroxymethyl-1,2,3-cyclohexanetriol (**12**) as a homogeneous syrup: ^1H NMR δ=1.40 (3H, s) and 1.47 (3H, s) (isopropylidene), 2.75 (3H, s, NCH_3), 3.55 (3H, s, OCH_3), and 4.37 (1H, t, $J_{2,3}$=$J_{3,4}$=7 Hz, H-3).

Crude **12** was treated with 80% aqueous acetic acid (10 ml) at 65 °C for 3 h. The reaction mixture was concentrated and dried by coevaporation with toluene. The product was acetylated in the conventional manner to give a syrup, which was crystallized from ethanol to give **13** (90 mg, 31% yield based on **7** used) as needles: mp 108—110 °C; ^1H NMR ($CDCl_3$) δ=2.02 (3H, s) and 2.05 (3H, s) (OAc), 2.78 (3H, s, NCH_3), 3.36 (1H, dd, $J_{1,2}$=8 Hz, $J_{2,3}$=6 Hz, H-2), 3.48 (3H, s, OCH_3), 4.50 (1H, dd, $J_{3,4}$=8 Hz, H-3), and 4.85 (1H, t, $J_{1,6}$=8 Hz, H-1).

Found: C, 53.00; H, 6.65; N, 4.34%. Calcd for $C_{14}H_{21}NO_7$: C, 53.33; H, 6.71; N, 4.44%.

Koenigs-Knorr Reaction of **9** *and 2,3,4,6-Tetra*-O-*acetyl-α-*D-*glucopyranosyl Bromide.* A mixture of **9** (1.0 g), 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide (6 g, 3.6 molar equiv.), and benzene–1,4-dioxane (2 : 1) (120 ml) was heated at 65 °C in the presence of mercury(II) cyanide (7 g) and anhydrous calcium sulfate (Drierite) (7.2 g) for 140 h. During the course of reaction, additional bromide (3 g) was added at an interval of 50 h. TLC indicated the disappearance of **9** and the formation of two new components in an approximately equal proportion, together with several side

products. An insoluble material was removed by filtration through a bed of caoline and washed thoroughly with chloroform (50 ml×4). The filtrate and washings were combined and concentrated. The residue was dissolved in ethyl acetate (200 ml) and the solution was washed successively with saturated aqueous sodium hydrogencarbonate and water, dried over anhydrous sodium sulfate, and then concentrated to give a pale yellow syrup (11 g). The product was chromatographed on a silica-gel column (100 g, 35 mm×300 mm) packed with 2-butanone–toluene (3 : 8). The first fractions obtained by elution with the same solvent (1 l) were discarded. Succeeding elution with methanol (500 ml) gave a homogeneous mixture of two β-D-glucopyranosides, which was again chromatographed on a silica-gel column (150 g, 30 mm×500 mm) with 2-butanone–toluene (1 : 1) as an eluent. The first fraction [R_f 0.38, silica gel, 2-butanone–toluene (2 : 1)] gave 1L-3,4-*N,O*-carbonyl-2-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)-1,7-*O*-isopropylidene-(1,3,4/2,6)-4-amino-6-hydroxymethyl-1,2,3-cyclohexanetriol[**14**(+), 1.09 g, 47%] as a homogeneous glass: $[\alpha]_D^{20}$ +77.8° (*c* 1.02, chloroform); ^{1}H NMR ($CDCl_3$) δ=1.33 (3H, s) and 1.44 (3H, s) (isopropylidene), 1.99 (6H, s), 2.00 (3H, s), and 2.09 (3H, s) (OAc), 6.22 (1H, s, NH).

Found: C, 52.56; H, 6.20; N, 2.46%. Calcd for $C_{25}H_{35}NO_{14}$: C, 52.35; H, 6.15; N, 2.44%.

The second fraction (R_f 0.31) gave the diastereomer [**14**(−), 1.16 g, 50%] as a homogeneous glass: $[\alpha]_D^{20}$ −30.4° (*c* 1.02, chloroform); ^{1}H NMR ($CDCl_3$) δ=1.42 (6H, broad s, isopropylidene), 2.01 (9H, s) and 2.08 (3H, s) (OAc), and 6.18 (1H, broad s, NH).

Found: C, 52.48; H, 6.32; N, 2.49%. Calcd for $C_{25}H_{35}NO_{14}$: C, 52.35; H, 6.15; N, 2.44%.

1L-*3,4*-N,O-*Carbonyl-2*-O-*(2,3,4,6-tetra*-O-*acetyl-β-D-glucopyranosyl)-(1,3,4/2,6)-4-amino-6-hydroxymethyl-1,2,3-cyclohexanetriol* [***16***(+)]. A solution of **14**(+) (0.45 g) in 80% aqueous acetic acid (10 ml) was allowed to stand at ambient temperature for 18 h. The reaction mixture was concentrated to give a crystalline residue (0.36 g), which was recrystallized from ethanol to give **16**(+) (0.18 g, 44%): mp 180—182 °C; $[\alpha]_D^{20}$ +73.4° (*c* 1.01, chloroform); ^{1}H NMR ($CDCl_3$) δ=1.99 (3H, s), 2.02 (3H, s), 2.07 (3H, s), and 2.12 (3H, s) (OAc), and 6.31 (1H, s, NH).

Found: C, 49.29; H, 5.80; N, 2.49%. Calcd for $C_{22}H_{31}NO_{14}$: C, 49.53; H, 5.86; N, 2.63%.

1D-*3,4*-N,O-*Carbonyl-2*-O-*(2,3,4,6-tetra*-O-*acetyl-β-D-glucopyranosyl-(1,3,4/2,6)-4-amino-6-hydroxymethyl-1,2,3-cyclohexanetriol* [***16***(−)]. Compound **14**(−) (0.39 g) was treated with 80% aqueous acetic acid (10 ml) as in the preparation of **14**(+). The product (0.35 g) was recrystallized from ethanol to give **16**(−) (0.27 g, 76%) as needles: mp 216—219 °C; $[\alpha]_D^{20}$ −62.8° (*c* 0.85, methanol); ^{1}H NMR (DMSO-d_6) δ=1.98 (3H, s), 2.00 (3H, s), 2.03 (3H, s), and 2.12 (3H, s) (OAc), and 7.47 (1H, s, NH).

Found: C, 49.75; H, 5.83; N, 2.45%. Calcd for $C_{22}H_{31}NO_{14}$: C, 49.53; H, 5.86; N, 2.63%.

Compounds **16**(+) and **16**(−) showed single spots at R_f 0.43 and 0.38, respectively, on TLC [silica gel, chloroform–methanol (5 : 1)], and were clearly differentiated from each other.

1L-*1,7*-O-*Benzylidene-3,4*-N,O-*carbonyl-2*-O-*(2,3,4,6-tetra*-O-*acetyl-β-D-glucopyranosyl)-(1,3,4/2,6)-4-amino-6-hydroxymethyl-1,2,3-cyclohexanetriol* [***15***(+)]. To a solution of **16**(+) (63 mg) in dry *N,N*-dimethylformamide (3 ml) were added 1,1-dimethoxy-1-phenylmethane (0.06 ml) and a catalytic amount of *p*-toluenesulfonic acid, and the mixture was heated at 60 °C for 1.5 h. TLC indicated the formation of a single product [R_f 0.40, silica gel, 2-butanone–toluene (2 : 1)]. The reaction mixture was neutralized with Amberlite IRA-400 (OH^-) (1.2 ml), and then concentrated to give a colorless glass, which was crystallized from ethanol to give **15**(+) (54 mg, 74%) as needles: mp 240—243 °C; $[\alpha]_D^{20}$ +56° (*c* 0.80, chloroform); ^{1}H NMR ($CDCl_3$) δ=1.97 (9H, s) and 2.14 (3H, s) (OAc), 5.56 (1H, s, benzylic), 5.91 (1H, s, NH), and 7.39 (5H, broad s, phenyl).

Found: C, 56.08; H, 5.67; N, 2.25%. Calcd for $C_{29}H_{35}NO_{14}$: C, 56.04; H, 5.68; N, 2.25%.

1D-*1,7*-O-*Benzylidene-3,4*-N,O-*carbonyl-2*-O-*(2,3,4,6-tetra*-O-*acetyl-β-D-glucopyranosyl)-(1,3,4/2,6)-4-amino-6-hydroxymethyl-1,2,3-cyclohexanetriol* [***15***(−)]. Compound **16**(−) (70 mg was treated with 1,1-dimethoxy-1-phenylmethane (0.1 ml) and *p*-toluenesulfonic acid in DMF (3 ml) as in the preparation of **15**(+). The crude product was recrystallized from ethanol to give **15**(−) (54 mg, 66%) as prisms: mp 192—194 °C; $[\alpha]_D^{20}$ −74° (*c* 0.60, chloroform); ^{1}H NMR ($CDCl_3$) δ=1.52 (3H, s), 1.98 (3H, s), 2.02 (3H, s), and 2.09 (3H, s) (OAc), 5.55 (1H, s, benzylic), and 6.16 (1H, s, NH).

Found: C, 56.01; H, 5.59; N, 2.26%. Calcd for $C_{29}H_{35}NO_{14}$: C, 56.04; H, 5.68; N, 2.25%.

Compounds **15**(+) and **15**(−) showed single spots at R_f 0.40 and 0.36, respectively, on TLC [silica gel, 2-butanone–toluene (2 : 1)] and were clearly differentiated from each other.

1L-*2*-O-*β-D-Glucopyranosyl-(1,3,4/2,6)-4-amino-6-hydroxymethyl-1,2,3-cyclohexanetriol* [***17***(+)] *and Its Peracetate* [***18***(+)]. A mixture of **16**(+) (0.142 g), barium hydroxide (0.5 g), and 1,4-dioxane–water (1 : 1) (50 ml) was heated under reflux for 24 h. The reaction mixture was neutralized by addition of solid carbon dioxide and the precipitates were removed by filtration The filtrate was concentrated to give **17** (+) as a syrup, which was shown to be homogeneous on TLC [R_f 0.18, cellulose, 1-butanol–pyridine–water–acetic acid (6 : 4 : 3 : 1)]. The syrup was treated with acetic anhydride (4 ml) in pyridine (4 ml) at ambient temperature for 18 h. The reaction mixture was concentrated and the residue was dissolved in chloroform and the solution was passed through a short column of alumina. The eluate was concentrated to give **18**(+) (0.11 g, 59%) as a homogeneous syrup: $[\alpha]_D^{20}$ −9.5° (*c* 0.89, chloroform): ^{1}H NMR ($CDCl_3$) δ=1.92, 1.96, 2.00, 2.03, and 2.05 (24H, NAc and OAc), and 5.77 (1H, d, $J_{4,NH}$=7.5 Hz, NH); IR (KBr disk) 3400 (NH), 1755 (ester), 1660, and 1535 cm^{-1} (amide).

Found: C, 51.79; H, 6.33; N, 1.93%. Calcd for $C_{29}H_{41}NO_{17}$: C, 51.56; H, 6.12; N, 2.07%.

1D-*2*-O-*β-D-Glucopyranosyl-(1,3,4/2,6)-4-amino-6-hydroxymethyl-1,2,3-cyclohexanetriol* [***17***(−)] *and Its Peracetate* [***18***(−)]. Compound **16**(−) (0.264 g) was hydrolyzed with aqueous barium hydroxide as in the preparation of **17**(+). The free base **17**(−) showed a single spot on TLC [R_f 0.18, cellulose, 1-butanol–pyridine–water–acetic acid (6 : 4 : 3 : 1)]. It was acetylated in the conventional way to give **18**(−) (0.31 g, 92%) as a homogenous syrup: $[\alpha]_D^{20}$ −41.7° (*c* 1.07, chloroform); ^{1}H NMR ($CDCl_3$) δ=1.93, 1.99, 2.04, and 2.09 (total 24H, s, NAc and OAc), and 6.02 (1H, d, $J_{4,NH}$=7 Hz, NH); IR (KBr disk) 3400 (NH), 1755 (ester), 1660, and 1535 cm^{-1} (amide).

Found: C, 51.60; N, 6.21; N, 2.10%. Calcd for $C_{29}H_{41}NO_{17}$: C, 51.56; H, 6.12; N, 2.07%.

Attempts were made to identify **17**(+) and **18**(+) with authentic samples derived from validamycin A. The IR and ^{1}H NMR spectra of **17**(+) and **18**(+) were both shown to be different from those of authentic samples. Compound **17**(+) revealed a single spot at R_f 0.18, while the corresponding authentic sample showed a single spot at R_f 0.12 on TLC [cellulose, 1-butanol–pyridine–water–acetic acid (6 : 4 : 3 : 1)]. Compound **18**(+) revealed a single spot at R_f 0.32 and the authentic sample at R_f 0.51 [silica gel, chloroform–methanol

(10: 1)].

Acid Hydrolysis of **17**(+) *and* **17**(−). *Preparation of Enantiomeric Validamines.* A mixture of **17**(+) (0.13 g) and 4 M hydrochloric acid (6 ml) was heated under reflux for 1 h. The reaction mixture was concentrated and the residue was dried by coevaporation successively with water, ethanol, and toluene. A partly crystalline product was acetylated in the conventional way and the product was chromatographed on a silica-gel column (20 g) with 2-butanone–toluene (1 : 4). The fractions first eluted gave penta-*O*-acetyl-D-glucopyranose (68 mg) as a pale yellow syrup, homogeneous on TLC [R_f 0.52, 2-butanone–toluene (1 : 2)], identical with an authentic sample. The second fractions gave tetra-*O*-acetyl-1L-(1,3,4/2,6)-4-acetamido-6-hydroxymethyl-1,2,3-cyclohexanetriol [(+)-validamine] (73 mg, 40%) as a syrup: $[\alpha]_D^{20}$ +42.6° (*c* 1.08, chloroform). The syrupy product gradually crystallized from ethanol to give prisms or plates: mp 197—202 °C. On the other hand, crystallization from ether gave needles: mp 146—148 °C; $[\alpha]_D^{20}$ +60.2° (*c* 0.60, chloroform). These two crystals were shown to be dimorphic crystals by spectroscopic methods. The compound (needles) was identified with an authentic sample by comparison of IR (in chloroform) and ^{1}H NMR (in $CDCl_3$) spectra and TLC behavior.

Found: C, 52.92; H, 6.41; N, 3.70%. Calcd for $C_{17}H_{25}NO_9$: C, 52.71; H, 6.51; N, 3.62%.

A reference compound was prepared by the conventional acetylation of validamine hydrochloride kindly provided by Dr. Satoshi Horii. The peracetate slowly crystallized from a small amount of chloroform to give needles, which were again recrystallized from ether: mp 147—149 °C; $[\alpha]_D^{20}$ +61.6° (*c* 0.71, chloroform). Found: C, 52.46; H, 6.39; N, 3.57%.

A crude **17**(−) (0.15 g) was treated with 4 M hydrochloric acid as described above. TLC indicated the formation of D-glucose (R_f 0.45) and (−)-validamine hydrochloride (R_f 0.25) [cellulose, 1-butanol–pyridine–water–acetic acid (6: 4: 3: 1)]. The mixture was acetylated in the conventional way and the products were fractionated on a silica-gel column to give penta-*O*-acetyl-D-glucopyranose (57 mg) as a syrup and tetra-*O*-acetyl-1D-(1,3,4/2,6)-4-acetamido-6-hydroxymethyl-1,2,3-cyclohexanetriol [(−)-validamine] (0.13 g, 76%) as a syrup: $[\alpha]_D^{20}$ −54.1° (*c* 0.98, chloroform). This compound crystallized from ethanol to give plates, mp 197—199.5 °C, and from ether to give needles: mp 147—149 °C; $[\alpha]_D^{20}$ −59.8° (*c* 1.3, chloroform). Its IR (in chloroform) and ^{1}H NMR (in $CDCl_3$) spectra were superimposable on those of an authentic sample.

Found: C, 52.95; H, 6.41; N, 3.66%. Calcd for $C_{17}H_{25}NO_9$: C, 52.71; H, 6.51; N, 3.62%.

The present work was partially supported by a Grand-in-Aid for Scientific Research No. 355376 from the Ministry of Education, Science and Culture. The authors wish to express their thanks to Mr. Saburo Nakada for elemental analyses.

(Received June 10, 1982)

The title β-D-glucopyranoside was synthesized *via* an unequivocal route and found to be identical with β-D-glucopyranosylvalidamine derived from antibiotic validamycin A. The position at which the validamine moiety is substituted with D-glucopyranose in validamycin A is revised to C-1 on the basis of the present synthesis.

In the preceding paper,[2)] we described an unequivocal synthesis of the original structure of β-D-glucopyranosyl-validamine (**1**) and found that it was not identical with an authentic sample derived from validamycin A. These results suggested that, contrary to the previous assignment by Horii and Kameda,[3)] D-glucopyranose should be attached to the C-1 or C-3 hydroxyl group rather than to the C-2 hydroxyl group of 1L-(1,3,4/2,6)-4-amino-6-hydroxymethyl-1,2,3-cyclohexanetriol [(+)-validamine] (**2**). Therefore, in order to elucidate the position of the β-glucosidic linkage, attempts were initially made to prepare the 1-*O*-β-D-glucopyranoside (**3**) *via* an unambiguous route. In the present paper, we wish to describe the detail of the successful synthesis of **3**, identical with an authentic sample, and to discuss on the revised structure of validamycin A along with ^{13}C NMR spectral data.

Scheme 1.

DL-7-*O*-Benzoyl-2,3-*O*-isopropylidene-(1,3,4/2,6)-4-azido-6-hydroxymethyl-1,2,3-cyclohexanetriol (**8b**) was chosen as a protected precursor of the aglycone moiety for a condensation with 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide, and was prepared by starting from readily available DL-tri-*O*-acetyl-(1,3/2,4,6)-4-bromo-6-bromomethyl-1,2,3-cyclohexanetriol (**4**)[4)] in the following sequence.

Treatment of **4** with refluxing aqueous ethanol containing 5% hydrobromic acid gave the trihydroxy compound (**5**) in 95% yield. Isopropylidenation of **5** with 2,2-dimethoxypropane in *N,N*-dimethylformamide (DMF) in the presence of *p*-toluenesulfonic acid at 60 °C for 2 h yielded a crystalline mixture of the 1,2-*O*- (**6a**) and 2,3-*O*-isopropylidene derivatives (**6b**) in 86% yield. Without separation, the mixture was directly treated with 2 molar equiv. of sodium benzoate in 90% aqueous DMF at 70 °C for 6 h to give through a preferential displacement of the 7-bromine atom a mixture of the benzoates (**7a** and **7b**). They were clearly separated, by chromatography on silica gel and later

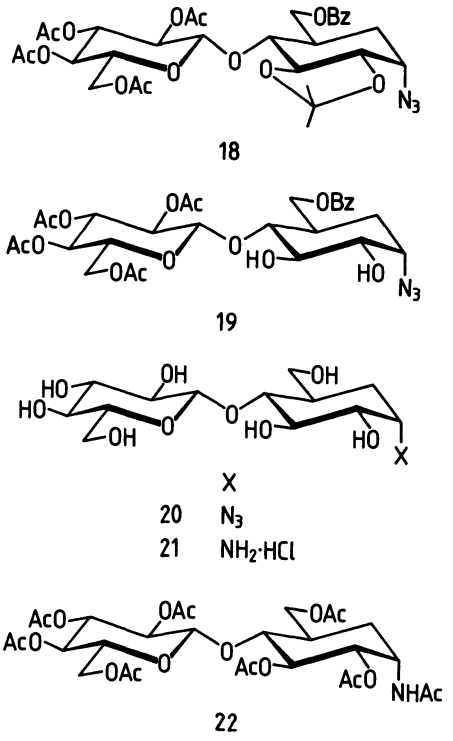
Scheme 2. Synthesis of protected precursors of DL-validamine. All compounds are racemic. The formulas depict one of the respective enantiomers.

by fractional crystallization, to **7a** and **7b** in 8 and 35% yields, respectively. As one of side products, the olefin (**11**) was isolated in pure form, which was further characterized as the acetate (**12**). Compound **11** was also obtained from **7a** in 12% yield by treatment with 1,8-diazabicyclo[5.4.0]undec-7-ene in toluene, together with the epoxide (**13**, 33%). Azidolysis of **7a** with sodium azide in dimethyl sulfoxide (DMSO) at 110 °C for 20 h afforded the azide (**8a**) and **11** in 64 and 4% yields, respectively. On the other hand, a similar treatment of **7b** with an azide ion gave the azide (**8b**) selectively in 73% yield. No formation of any olefinic compound was observed in this case. The structures of **8a** and **8b** were confirmed by converting them into the corresponding *O*-acetyl (**9a** and **9b**), and *O*-methyl derivatives (**10a** and **10b**). Thus, in the ^{1}H NMR spectra, **9a** and **9b** showed a one-proton doublet of doublets (δ=5.05, J=4 and 10.5 Hz) and a one-proton triplet (δ=5.19, J=9 Hz) attributable to a proton attached to the carbon atom bearing the acetoxyl group, respectively, which indicated the location of the acetoxyl groups at C-3 in **9a** and at C-1 in **9b**. For further confirmation, both **8a** and **8b** were converted into penta-*N*,*O*-acetyl-DL-validamine (**17**) by the following sequence: *O*-deisopropylidenation, *O*-deacylation, catalytic reduction, and acetylation. Therefore, **8b** was expected to be a suitable intermediate for the synthesis of the desired β-D-glucopyranoside (**3**). In addition, in order to furnish several reference compounds for assignment of the ^{13}C NMR spectral data of the validamine derivatives, **10a** and **10b** were transformed into the peracetates of 4-*O*-methyl (**16**) and 2-*O*-methyl-validamine (**14**),[5] respectively.

Condensation of **8b** with 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide was conducted in dry benzene in the presence of mercury(II) cyanide and anhydrous calcium sulfate at 70 °C for 50 h. Under these conditions, only β-D-glucopyranosides were expected to be obtainable. The mixture of products was roughly separated by chromatography on silica gel with 1 : 10 2-butanone–toluene as an eluent to give a syrupy mixture of condesation products [**18**(+) and **18**(−)], showing a single spot in several solvent systems. Without further separation, it was *O*-deisopropylidenated by treatment with Amberlite IR-120B (H^+) in ethanol at ambient temperature overnight. The dihydroxy compounds thus obtained could be fractionated by a silica-gel column with 2: 5 2-butanone–toluene to afford **19**(+), $[\alpha]_D$ +27°, and **19**(−), $[\alpha]_D$ −16°, in 18 and 13% yields, respectively, based on **8b** used. Isopropylidenation of **19**(+) and **19**(−) in the usual way could regenerate crystalline **18**(+) and **18**(−) in pure forms, respectively. Judging from the optical rotations, **19**(+)



Scheme 3. Synthesis of 4-*O*-(β-D-glucopyranosyl)validamine. The formulas depict one of the respective diastereomers.

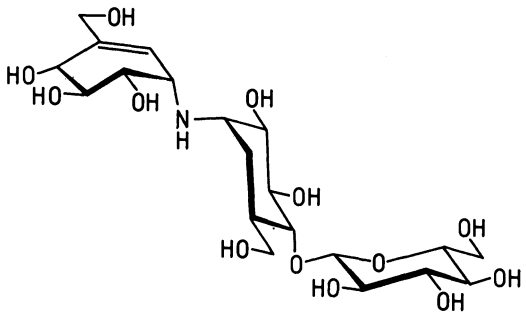
was tentatively assigned as the β-D-glucopyranoside that contained the precursor of (+)-validamine as the aglycone moiety. *O*-Deacylation of **19**(+) with methanolic sodium methoxide in methanol gave the hydroxy azide [**20**(+)], which was successively hydrogenated with 5% palladium on carbon in ethanol containing an excess of hydrochloric acid to give the amine hydrochloride [**21**(+)], $[\alpha]_D$ +22° (H_2O), as a homogeneous syrup in 94% overall yield. This compound was shown to be identical with an authentic sample of β-D-glucopyranosylvalidamine hydrochloride by comparison of chromatographic behavior (TLC on cellulose and silica gel) in several solvent systems. It was further characterized by conversion into the octa-*N*,*O*-acetyl derivative [**22**(+)], $[\alpha]_D$ +16° (lit,[3] $[\alpha]_D$ +17.6°), whose IR (in chloroform) and ^{1}H NMR spectra were superimposable on those of an authentic sample.[6]

On the other hand, the diastereomeric amine hydrochloride **21**(−) obtained similarly from **19**(−) *via* the hydroxy azide [**20**(−)] showed spectral properties similar to those of **21**(+); however, they were clearly differentiated from each other by TLC. Its octa-*N*,*O*-acetyl derivative [**22**(−)] has $[\alpha]_D$ −49°.

Table 1. ^{13}C NMR chemical shifts of peracetates of validamine derivatives in $CDCl_3$

Compound	C-1	C-2	C-3	C-4	C-5	C-6	C-7	OMe
3-*O*-Me (**14**)	71.33	72.83	79.24	45.37	27.90	34.65	63.13	57.21
1-*O*-Me (**16**)	80.24	73.15	71.60	46.32	28.42	36.13	63.64	60.16
17	←———	71.41, 71.63	———→	46.78	28.43	35.21	63.16	
22(+)	—	—	—	45.99	27.92	37.17	62.93	
2-*O*-β-D-Glc[2]	—	—	—	46.15	28.16	35.02	63.51	

A part of the ^{13}C NMR spectral data of validamine derivatives were shown in Table 1. Assignment of the resonances was carried out by comparing the spectrum of the peracetyl derivative with those of the *O*-methyl derivatives. Substitution of the acetoxyl group by methoxyl group causes a downfield shift of the signals for α-carbon atom (8—9 ppm) and β-carbon atom (1—1.5 ppm).[7] The signal for C-6 of octa-*O*-acetyl-2-*O*-β-D-glucopyranosylvalidamine[2] appears at 35.02 ppm, indicative of the location of the acetoxyl group at C-1, whereas the C-6 of **22**(+) resonates downfield at 37.02 ppm, suggesting that D-glucopyranose attaches to the C-1 hydroxyl group by way of β-glucosidic linkage. These assumptions may be compatible with the result of the present synthesis.



Scheme 4. The revised structure of validamycin A.

On the basis of the synthetic studies and the ^{13}C NMR spectral data, the structure of β-D-glucopyranosylvalidamine should be revised to 1L-1-*O*-(β-D-glucopyranosyl)-(1,3,4/2,6)-4-amino-6-hydroxymethyl-1,2,3-cyclohexanetriol. Accordingly, the structure of validamycin A was convincingly formulated as shown in Scheme 4.

Experimental

General Methods. The same method was used as described in the preceding paper.[2] ^{13}C NMR spectra were determined on a Varian FT-80 spectrometer at 20 MHz. The resonance signals are expressed in ppm downfield from the signal of tetramethylsilane.

DL-*(1,3/2,4,6)-4-Bromo-6-bromomethyl-1,2,3-cyclohexanetriol (**5**).* A mixture of DL-1,2,3-tri-*O*-acetyl-(1,3/2,4,6)-4-bromo-6-bromomethyl-1,2,3-cyclohexanetriol (**4**)[4] (4 g) in ethanol (160 ml) containing 48% hydrobromic acid (20 ml) was refluxed for 4 h. The reaction mixture was concentrated, and the crystallized residue was triturated with water and filtered to give a practically pure **5** (2.7 g, 95%). Recrystallization from ethanol and water gave an analytically pure sample (2 g, 71%) as prisms: mp 153.5—154 °C.

Found: C, 27.76; H, 3.92; Br, 52.48%. Calcd for $C_7H_{12}Br_2O_3$: C, 27.66; H, 3.98; Br, 52.57%.

DL-*1,2*-O- *(**6a**) and* DL-*2,3*-O-*Isopropylidene-(1,3/2,4,6)-4-bromo-6-bromomethyl-1,2,3-cyclohexanetriol (**6b**).* A mixture of **5** (2 g), *N,N*-dimethylformamide (DMF) (20 ml), and 2,2-dimethoxypropane (9 ml) was heated in the presence of *p*-toluenesulfonic acid (5 mg) at 70 °C for 2 h. After being cooled to room temperature, the reaction mixture was treated with Amberlite IRA-400 (OH^-) (1.5 ml) and then concentrated. Recrystallization of the residue gave **6a** and **6b** (2 g, 88%) as a homogeneous crystalline mixture: mp 122—125 °C; they showed similar mobilities on TLC in several solvent systems; ^1H NMR ($CDCl_3$) δ=1.42 (6H, s) and 1.48 (6H, s) (isopropylidene).

Found: C, 34.77; H, 4.60; Br, 46.69%. Calcd for $C_{10}H_{16}Br_2O_3$: C, 34.91; H, 4.69; Br, 46.45%.

DL-*1,2*-O- *(**7a**) and* DL-*2,3*-O-*Isopropylidene-(1,3/2,4,6)-6-benzoyloxymethyl-4-bromo-1,2,3-cyclohexanetriol (**7b**).* A crystalline mixture of **6a** and **6b** (2 g) was treated with sodium benzoate (1.7 g) in 90% aqueous DMF (40 ml) at 70—80 °C for 6 h. TLC showed the formation of two main components (R_f 0.38 and 0.32, developed twice in 1 : 8 2-butanone–toluene), together with several minor ones. The reaction mixture was then cooled to room temperature and diluted with ethyl acetate (50 ml), and an insoluble material was removed by filtration. The filtrate was concentrated, the residue was dissolved in chloroform, and the solution was passed through a short column of alumina. Evaporation of the solvent gave a syrupy residue, a small portion of which was fractionated on a silica-gel column with 1 : 8 2-butanone–toluene as an eluent to give pure crystals of **7a** and **7b**. The remaining syrup was dissolved in a small amount of ethanol and crystallization was induced by seeding in turn crystals of **7a** and **7b**. Compound **7b** was first obtained as needles (0.78 g, 35%): mp 130—132 °C; ^1H NMR ($CDCl_3$) δ=1.48 (6H, s, isopropylidene), 4.34 (1H, dd, J_{gem}=11 Hz, $J_{6,7}$=2 Hz, H-7), 4.68 (1H, dd, $J_{6,7'}$=4 Hz, H-7′), and 7.33—8.15 (5H, m, phenyl). The second crop of crystals was **7a** (0.29 g, 13%) obtained as prisms: mp 125—127 °C; ^1H NMR ($CDCl_3$) δ= 1.44 (6H, s, isopropylidene), 4.21 (1H, dd, J_{gem}=11 Hz, $J_{6,7}$= 6 Hz, H-7), 4.58 (1H, dd, $J_{6,7'}$=4 Hz, H-7′), and 7.35—8.15 (5H, m, phenyl).

Found for **7a**: C, 52.78; H, 5.60; Br, 20.88%, and for **7b**: C, 53.12; H, 5.44; Br, 20.59%. Calcd for $C_{17}H_{21}BrO_5$: C, 53.00; H, 5.49; Br, 20.74%.

The mother liquor from **7a** and **7b** was concentrated and the residue was chromatographed on a silica-gel column with 1 : 10 2-butanone–toluene as an eluent. DL-2,3-*O*-Isopropylidene-(1,3/2,4)-4-benzoyloxymethyl-5-cyclohexene-1,2,3-triol (**11**) was purely obtained out of four minor products and recrystallized from ethanol to give prisms (20 mg): mp 105—107 °C; ^1H NMR ($CDCl_3$, 90 MHz) δ=1.43 (6H, s, isopropylidene), 2.43 (1H, broad d, OH), 2.58—3.01 (1H, m, H-4), 3.51 (1H dd) and 3.60 (1H, dd) (J=10 and 11 Hz, H-2 and H-3), 4.27 (1H, dd, J_{gem}=11 Hz, $J_{4,7}$=6 Hz, H-7), 4.53 (1H, dd, $J_{4,7'}$=5 Hz, H-7′), 5.67 (2H, s, H-5 and H-6), and 7.28—8.08 (5H, m, phenyl).

Found: C, 66.82; H, 6.53%. Calcd for $C_{17}H_{20}O_5$: C, 67.09; H, 6.62%.

Compound **11** (41 mg) was treated with acetic anhydride (1 ml) and pyridine (1 ml) at room temperature overnight. Concentration of the reaction mixture gave a crude product, which was crystallized from ethanol to give the acetate (**12**, 20 mg, 43%) as thin needles: mp 99.5—102.5 °C; ^1H NMR ($CDCl_3$, 90 MHz) δ=1.47 (6H, s, isopropylidene), 2.13 (3H, s, OAc), 2.77—3.06 (1H, m, H-4), 3.64 (1H, t, $J_{2,3}$=$J_{3,4}$=9 Hz, H-3), 3.82 (1H, t, $J_{1,2}$=9 Hz, H-2), 4.33 (1H, dd, J_{gem}=11 Hz, $J_{4,7}$=6 Hz, H-7), 4.59 (1H, dd, $J_{4,7'}$=5 Hz, H-7′), 5.56 (1H, broad d, H-1), 5.73, (2H, broad d, H-5 and H-6), and 7.33—8.23 (5H, m, phenyl).

Found: C, 66.08; H, 6.53%. Calcd for $C_{19}H_{22}O_6$: C, 65.88; H, 6.40%.

DL-*1,2*-O-*Isopropylidene-(1,3,4/2,6)-4-azido-6-benzoyloxymethyl-1,2,3-cyclohexanetriol (**8a**) and **11**.* A mixture of **7a** (1.5 g), sodium azide (1 g), and dry dimethyl sulfoxide (30 ml) and heated at 110 °C for 20 h. TLC indicated the formation of two components (R_f 0.40 and 0.33, 1 : 5 2-butanone–toluene). Ethyl acetate (45 ml) was added to the reaction mixture and an insoluble material was removed by filtration. The filtrate

was successively washed with aqueous sodium chloride and water, and passed through a short column of alumina. The eluate was concentrated and the residue was chromatographed on a silica-gel column (75 g) with 1 : 10 2-butanone–toluene. The first fraction was concentrated to give crystals which were recrystallized from ethanol to give **8a** (0.89 g, 64%) as prisms: mp 118.5—121 °C; IR 3460 (OH), 2150 (N_3), and 1715 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=1.45 (6H, s, isopropylidene), 2.92 (1H, broad s, OH), 3.24 (1H, dd, $J_{1,2}$=10 Hz, $J_{1,6}$=8 Hz, H-1), 3.75 (1H, t, $J_{2,3}$=10 Hz, H-2), 4.26—4.70 (2H, m, H-7 and H-7′), and 7.33—8.16 (5H, m, phenyl).

Found: C, 58.54; H, 6.10; N, 11.85%. Calcd for $C_{17}H_{21}N_3O_5$: C, 58.78; H, 6.09; N, 12.10%.

Compound **8a** (35 mg) was acetylated as described for the preparation of **12**. The crude product was recrystallized from ethanol to give the acetate (**9a**, 25 mg, 64%) as prisms: mp 150—153 °C; ^1H NMR ($CDCl_3$) δ=1.43 (3H, s) and 1.47 (3H, s) (isopropylidene), 2.19 (3H, s, OAc), 3.34 (1H, dd, $J_{1,2}$=8.5 Hz, $J_{1,6}$=10.5 Hz, H-1), 3.95 (1H, dd, $J_{2,3}$=10.5 Hz, H-2), 5.05 (1H, dd, $J_{3,4}$=4 Hz, H-3), and 7.35—8.16 (5H, m, phenyl).

Found: C, 58.34; H, 6.02; N, 10.67%. Calcd for $C_{19}H_{23}N_3O_6$: C, 58.60; H, 5.95; N, 10.79%.

The second fraction gave a syrup which crystallized from ethanol to give **11** (52 mg, 4.4%) as prisms, mp 103—105 °C, identical with the compound derived from **6a**.

Reaction of ***7a*** *with 1,8-Diazabicyclo[5.4.0]undec-7-ene (DBU).* A mixture of **7a** (0.2 g), DBU (0.39 ml), and toluene (6 ml) was stirred at 120 °C for 7 h. TLC showed the formation of two major components (R_f 0.58 and 0.21) together with a trace of **7a** (R_f 0.35, 1 : 5 2-butanone–toluene). The reaction mixture was concentrated and the products were fractionated on a silica-gel column (8 g) with 1 : 5 2-butanone–toluene as an eluent. The first fraction gave crystals, which were recrystallized from ethanol to give 1,2-anhydro-3,4-*O*-isopropylidene-(1,2,4/3,5)-5-benzoyloxymethyl-1,2,3,4-cyclohexanetetrol (**13**, 26 mg, 33%) as prisms: mp 87—89.5 °C; IR 1715 (C=O) and 1610 cm^{-1} (phenyl); ^1H NMR ($CDCl_3$) δ=1.45 (6H, s, isopropylidene), 4.26 (1H, dd, J_{gem}=11 Hz, $J_{5,7}$=5 Hz, H-7), 4.53 (1H, dd, $J_{5,7'}$=4 Hz, H-7′), and 7.40—8.18 (5H, m, phenyl).

Found: C, 66.81; H, 6.56%. Calcd for $C_{17}H_{20}O_5$: C, 67.09; H, 6.62%.

The second fraction gave **11** (19 mg, 12%) mp 103—105 °C, identical with the compound obtained from **6a**.

DL-*2,3-O-Isopropylidene-(1,3,4/2,6)-4-azido-6-benzoyloxymethyl-1,2,3-cyclohexanetriol (**8a**).* A mixture of **7b** (1.1 g), sodium azide (0.75 g), and dimethyl sulfoxide (10 ml) was stirred at 120 °C for 18 h. The reaction mixture was processed as described for the preparation of **8a**. The syrupy product was crystallized from ethanol to give **8b** (0.72 g, 73%) as needles: mp 105—108 °C; IR 3480 (OH), 2170 (N_3), 1730 (C=O), and 1610 cm^{-1} (phenyl); ^1H NMR ($CDCl_3$) δ=1.45 (3H, s) and 1.50 (3H, s) (isopropylidene), 3.31 (1H, m, OH), 3.52 (1H, dd, $J_{2,3}$=9 Hz, $J_{3,4}$=3 Hz, H-3), 3.67 (1H, dd, $J_{1,2}$=9 Hz, $J_{1,6}$=8 Hz, H-1), 4.03 (1H, t, H-2), 4.30 (1H, dd, J_{gem}=11 Hz, $J_{6,7}$=2 Hz, H-7), 4.77 (1H, dd, $J_{6,7'}$=4 Hz-H-7′), and 7.35—8.15 (5H, m, phenyl).

Found: C, 58.63; H, 6.11; N, 11.88%. Calcd for $C_{17}H_{21}N_3O_5$: C, 58.78; H, 6.09; N, 12.10%.

Compound **8b** (50 mg) was acetylated in the usual way and the product was recrystallized from ethanol to give the acetate (**9b**, 30 mg, 54%) as needles: mp 116—119 °C; ^1H NMR ($CDCl_3$) δ=1.49 (6H, s, isopropylidene), 2.13 (3H, s, OAc), 3.63 (1H, dd, $J_{2,3}$=9 Hz, $J_{3,4}$=3 Hz, H-3), 4.09 (1H, t, $J_{1,2}$=9 Hz, H-2), 5.19 (1H, t, $J_{1,6}$=9 Hz, H-1), and 7.35—8.20 (5H, m, phenyl).

Found: C, 58.72; H, 5.98; N, 10.84%. Calcd for $C_{19}H_{23}N_3O_6$: C, 58.60; H, 5.95; N, 10.79%.

DL-*1,2-O-Isopropylidene-3-O-methyl-(1,3,4/2,6)-4-azido-6-benzoyloxymethyl-1,2,3-cyclohexanetriol (**10a**).* A mixture of **8a** (0.3 g), methyl iodide (0.54 ml), and silver oxide (0.4 g) in dry DMF (3 ml) was stirred at room temperature for 20 h in the dark. Acetone (10 ml) was added to the reaction mixture and an insoluble material was removed by filtration. The filtrate was concentrated and the residue was coevaporated with 1-butanol several times. The product was dissolved in ethyl acetate and the solution was passed through a short column of alumina. The eluate was concentrated and the residue was crystallized from ethanol to give **10a** (0.13 g, 40%) as prisms: mp 82—85 °C; IR 2150 (N_3), 1720 (C=O), and 1610 cm^{-1} (phenyl); ^1H NMR ($CDCl_3$) δ=1.42 (6H, s, isopropylidene), 3.20 (1H, dd, $J_{1,2}$=9 Hz, $J_{1,6}$=10 Hz, H-1), 3.49 (1H, dd, $J_{2,3}$=10 Hz, $J_{3,4}$=3 Hz, H-3), 3.52 (3H, s, methoxyl), 3.84 (1H, dd, H-2), 4.18 (1H, q, $J_{4,5\,ax}$=$J_{4,5\,eq}$=3 Hz, H-4), 4.22 (1H, dd, J_{gem}=11.5 Hz, $J_{6,7}$=5.5 Hz, H-7), 4.50 (1H, dd, $J_{6,7'}$=4.5 Hz, H-7′), and 7.34—8.13 (5H, m, phenyl).

Found: C, 59.54; H, 6.33; N, 11.85%. Calcd for $C_{18}H_{23}N_3O_5$: C, 59.80; H, 6.42; N, 11.63%.

DL-*2,3-O-Isopropylidene-1-O-methyl-(1,3,4/2,6)-4-azido-6-benzoyloxymethyl-1,2,3-cyclohexanetriol (**10b**).* A mixture of **8b** (1 g), methyl iodide (1.8 ml), and silver oxide (1.3 g) in dry DMF (10 ml) was stirred at room temperature for 20 h in the dark. At this stage, TLC showed the presence of **9b**. Then an additional amount of methyl iodide (0.9 ml) was added to the mixture and the stirring was continued for 23 h. The reaction mixture was processed as described for the preparation of **10a**. The crude product was recrystallized from ethanol to give **10b** (0.33 g, 32%) as needles: mp 105—107 °C; IR 2140 (N_3), 1730 (C=O), and 1610 cm^{-1} (phenyl); ^1H NMR ($CDCl_3$) δ 1.48 (3H, s) and 1.51 (3H, s) (isopropylidene), 3.32 (1H, t, $J_{1,2}$=$J_{1,6}$=9 Hz, H-1), 3.52 (1H, dd, $J_{2,3}$=9 Hz, $J_{3,4}$=3 Hz, H-3), 3.55 (3H, s, methoxyl), 4.03 (1H, t, H-2), 4.21 (1H,q, $J_{4.5ax}$=$J_{4,5eq}$=3 Hz, H-4), 4.47 (2H, d, J=3 Hz, H-7 and H-7′), and 7.35—8.13 (5H, m, phenyl).

Found: C, 59.82; H, 6.36; N, 11.39%. Calcd for $C_{18}H_{23}N_3O_5$: C, 59.80; H, 6.42; N, 11.63%.

DL-*1,2,7-Tri-O-acetyl-3-O-methyl-(1,3,4/2,6)-4-acetamido-6-hydroxymethyl-1,2,3-cyclohexanetriol (**14**).* Compound **10a** (0.1 g) was treated with Amberlite IR-120 (H^+) (1.5 ml) in ethanol (8 ml) at room temperature for 3 h. TLC indicated the formation of a single product (R_f 0.15, 1:2 2-butanone–toluene, **10a**: R_f 0.77). The resin was removed and the solution was concentrated to give a syrup which was treated with 0.3 M methanolic sodium methoxide(3 ml)(1 M=1 mol dm^{-3}) at room temperature for 0.5 h. TLC showed the presence of a single product (R_f 0.46, 5 : 1 chloroform–methanol, the starting compound: R_f 0.78). The reaction mixture was neutralized with Amberlite IR-120 (H^+) (1.5 ml) and then concentrated to give crystals (62 mg). A solution of it in methanol containing 1 M hydrochloric acid (3 ml) was hydrogenated in the presence of 5% palladium on carbon (15 mg) at room temperature for 16 h. The product showed a single spot (R_f 0.27) on TLC (4 : 1 : 1 1-propanol–acetic acid–water). The catalyst was removed by filtration and the filtrate was concentrated to give a crystalline 2-*O*-methyl-DL-validamine hydrochloride (46 mg, 78%). An aqueous solution of the hydrochloride was treated with Amberlite IRA-400 (OH^-) (1.5 ml) and then concentrated to a syrup, which was treated with acetic anhydride and pyridine in the usual way to give the total acetate. Recrystallization from ethanol gave **14** (22 mg, 22%) as prisms: mp 205.5—208 °C; IR 3350, 1645, and 1545 (amide), 1750 cm^{-1} (ester); ^1H NMR ($CDCl_3$, 90 MHz) δ=2.00 (3H, s), 2.03 (6H, s), and 2.04 (3H, s) (NAc and OAc), 3.34 (3H, s, methoxyl), 3.35 (1H, dd, $J_{2,3}$=9 Hz,

$J_{3,4}$=5 Hz, H-7), 3.86 (1H, dd, J_{gem}=11 Hz, $J_{6,7}$=4 Hz, H-7), 4.14 (1H, dd, $J_{6,7'}$=5 Hz, H-7'), 4.42 (1H, m, H-4), 4.88 (1H, t, $J_{1,2}=J_{1,6}$=9 Hz, H-1), 5.10 (1H, t, $J_{2,3}$=9 Hz, H-2), and 5.87 (1H, broad d, J=6 Hz, NH).

Found: C, 53.21; H, 6.87; N, 3.72%. Calcd for $C_{16}H_{25}NO_8$: C, 53.47; H, 7.01; N, 3.90%.

DL-*2,3,7-Tri*-O-*acetyl-1*-O-*methyl-(1,3,4/2,6)-4-azido-6-hydroxymethyl-1,2,3-cyclohexanetriol* (**15**). Compound **10b** (0.1 g) was treated with Amberlite IR-120 (H^+) (1 ml) in ethanol, and the product was successively treated with 0.3 M methanolic sodium methoxide to give a crystalline hydroxy azide (56 mg, 93%). This compounds was acetylated in the usual way and the acetate was recrystallized from ethanol to give **15** (47 mg, 50%) as needles: mp 71—73 °C; IR 2130 (N_3) and 1740 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=2.08 (9H, s, OAc), 3.15 (1H, dd, $J_{1,2}$=9 Hz, $J_{1,6}$=10.5 Hz, H-1), 3.38 (3H, s, methoxyl), 4.05 (1H, q, $J_{3,4}=J=_{4.5ax}=J_{4.5eq}$=3 Hz, H-4), 4.13 (2H, d, J=4 Hz, H-7 and H-7'), 4.86 (1H, dd, $J_{2,3}$=10 Hz, H-3), and 5.38 (1H, dd, H-2).

Found: C, 49.08; H, 6.13; N, 12.32%. Calcd for $C_{14}H_{21}N_3O_7$: C, 48.95; H, 6.17; N, 12.24%.

DL-*2,3,7-Tri*-O-*acetyl-1*-O-*methyl-(1,3,4/2,6)-4-acetamido-6-hydroxymethyl-1,2,3-cyclohexanetriol* (**16**). Compound **15** (75 mg) was hydrogenated and then acetylated as described for the preparation of **14**. The crude product was purified on a silica-gel column (5 g) with 1 : 1 2-butanone–toluene as an eluent to give **16** (60 mg, 76%) as a homogeneous solid: IR 3290, 1655, and 1550 (amide), and 1750 cm^{-1} (ester); ^1H NMR ($CDCl_3$, 90 MHz) δ=2.00 (3H, s), 2.02 (3H, s), and 2.08 (6H, s) (NAc and OAc), 3.11 (1H, t, $J_{1,2}=J_{1,6}$=9 Hz, H-1), 3.41 (3H, s, methoxyl), 4.15 (2H, d, J=4 Hz, H-7 and H-7'), 4.48 (1H, m, H-4), 4.86 (1H, dd, $J_{2,3}$=10 Hz, $J_{3,4}$= 5 Hz, H-3), 5.18 (1H, dd, $J_{1,2}$=9 Hz, H-2), and 6.03 (1H, broad d, J=8 Hz, NH).

Found: C, 53.18; H, 6.85; N, 3.76%. Calcd for $C_{16}H_{25}NO_8$; C, 53.47; H, 7.01; N, 3.90%.

L-[*19*(+)] *and* D-*1*-O-*(2,3,4,6-Tetra*-O-*acetyl-β-D-glucopyranosyl-1,3,4/2,6-4-azido-6-benzoyloxymethyl1,-2,3-cyclohexanetriol* [*19*(−)]. A mixture of **8b** (1.1 g), mercury(II) cyanide (7 g), anhydrous calcium sulfate (Drierite) (7 g), and dry benzene (300 ml) was refluxed at 90 °C with stirring, and 140 ml of benzene was removed by distillation. Then freshly prepared 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide (5.2 g) was added to the mixture and it was stirred vigorously at 65—70 °C for 50 h. After being cooled to room temperature, the reaction mixture was treated with triethylamine (3 ml) and an insoluble material was removed by filtration through a caoline bed and washed thoroughly with chloroform. The filtrate and washings were combined and concentrated to give a brown syrup, which was dissolved in ethyl acetate (180 ml), washed successively with aqueous sodium hydrogencarbonate (3×200 ml) and water (2×200 ml), and dried. Evaporation of the solvent gave a syrup (9.3 g) which was chromatographed on a silica-gel column (130 g) with 1 : 10 2-butanone–toluene as an eluent. Fractions having R_f 0.24 in the same solvent system (irrigated twice) were concentrated to give a pale yellow syrup (1.3 g), whose ^1H NMR spectrum showed the presence of one isopropylidene, four acetoxyl, and one benzoyloxyl groups, and a contamination of traces of unidentified side-products. A 1.3 g-portion of the syrup was dissolved in ethanol (10 ml) and treated with Amberlite IR-120B (H^+) (20 ml) at room temperature for 21 h. The resin was filtered off and the filtrate was concentrated to a syrup (1.3 g), which was chromatographed on a silica-gel column (60 g) with 2 : 5 2-butanone–toluene as an eluent. The main fraction (R_f 0.41, 1 : 1 2-butanone–toluene) gave crystals 0.363 g (18%), which were recrystallized from ethanol to give **19**(+) (0.262 g, 13%) as needles: mp 182—183.5 °C; $[\alpha]_D^{24}$ +27° (*c* 1.0, chloroform); IR 3540 (OH), 2150 (N_3), 1750 (C=O), and 1610 cm^{-1} (phenyl); ^1H NMR ($CDCl_3$) δ=2.00 (3H, s), 2.04 (3H, s), 2.07 (3H, s), and 2.16 (3H, s) (OAc), and 7.35—8.13 (5H, m, phenyl).

The second fractions (R_f 0.34) were concentrated to give an amorphous solid (0.262 g, 13%), which was recrystallized from ethanol and ether to give **19**(−) (0.162 g, 8%) as needles: mp 158—161 °C; $[\alpha]_D^{23}$ −16° (*c* 1.5, chloroform); IR 3500 (OH), 2150 (N_3), 1750 (C=O), and 1610 cm^{-1} (phenyl); ^1H NMR ($CDCl_3$) δ=1.99 (3H, s), 2.0 2(3H, s), 2.10 (3H, s), and 2.17 (3H, s) (OAc), and 7.36—8.13 (5H, m, phenyl).

Found for **19**(+): C, 52.84; H, 5.47; N, 6.32%, and for **19**(−): C, 52.50; H, 5.51; N, 6.45%. Calcd for $C_{28}H_{35}NO_{14}$: C, 52.72; H, 5.54; N, 6.59%.

Preparation of the Isopropylidene Derivative ***18***(+) *of* ***19***(+). A mixture of **19**(+) (50 mg), 2,2-dimethoxypropane (0.1 ml), DMF (2 ml), and *p*-toluenesulfonic acid (2 mg) was heated at 65—70 °C for 11 h. During this reaction time, 0.2 ml portions of 2,2-dimethoxypropane were added to the reaction mixture at intervals of 3 h. TLC showed one major spot (R_f 0.44) and one minor spot (R_f 0.09) due to **19**(+) in 1 : 3 2-butanone–toluene. The mixture was treated with Amberlite IRA-400 (OH^-) (1 ml) and then concentrated to a syrup ,which was chromatographed on a silica gel (2 g) with 1 : 3 2-butanone–toluene as an eluent. The main fraction gave a syrup, which crystallized from ethanol to give **18**(+) (20 mg, 38%) as plates: mp 166—170 °C $[\alpha]_D^{23}$ +21° (*c* 0.5, chloroform); ^1H NMR ($CDCl_3$) δ=1.48 (6H, broad s, isopropylidene), 1.92 (3H, s), 1.99 (3H, s), 2.02 (3H, s), and 2.06 (3H, s) (OAc), and 7.34—8.12 (5H, m, phenyl).

Found: C, 55.00; H, 5.90; N, 6.07%. Calcd for $C_{31}H_{39}N_3O_{14}$: C, 54.94; H, 5.80; N, 6.20%.

Preparation of the Isopropylidene Derivative ***18***(−) *of* ***19***(−). Compound **19**(−) (50 mg) was *O*-isopropylidenated as described for the preparation of **18**(+) to give **18**(−) (49 mg, 92%) as a homogeneous solid, which crystallized from ethanol to give needles (29 mg, 56%): mp 174—174.5 °C; $[\alpha]_D^{23}$ −26° (*c* 0.58, chloroform): ^1H NMR ($CDCl_3$) δ=1.48 (6H, broad s, isopropylidene), 1.99 (6H, s), 2.01 (3H, s), and 2.08 (3H, s) (OAc), and 7.32—8.12 (5H, m, phenyl).

Found: C, 55.16; H, 5.91; N, 6.10%. Calcd for $C_{31}H_{39}N_3O_{14}$: C, 54.94; H, 5.80; N, 6.20%.

Both **18**(+) and **18**(−) had similar mobilities on TLC (R_f 0.44, 1 : 3 2-butanone–toluene).

L-*1*-O-*(β-D-Glucopyranosyl)-(1,3,4/2,6)-4-amino-6-hydroxymethyl-1,2,3-cyclohexanetriol Hydrochloride* [*21*(+)]. To a solution of **19**(+) (100 mg) in methanol (5 ml) was added 1 M methanolic sodium methoxide (8 ml) and the mixture was kept at room temperature for 24 h. The reaction mixture was treated with Amberlite IR-120B (H^+) (12 ml) and then concentrated to give the hydroxy azide **20**(+) (61 mg) as a homogeneous syrup (R_f 0.61, 4 : 1 : 1 1-propanol–acetic acid–water). This compound was directly hydrogenated in a mixture of methanol (4 ml) and water (4 ml) containing 0.5 M hydrochloric acid (0.38 ml) in the presence of 5% palladium on carbon (10 mg) at room temperature overnight. The catalyst was removed by filtration and the filtrate was concentrated to give **21**(+) [56 mg, 94% yield based on **19**(+)] as a syrup, $[\alpha]_D^{23}$ +22° (*c* 1.9, water). This compound was identical with an authentic sample derived from validamycin A, as found from comparison of the mobilities on TLC: silica gel, R_f 0.24 in 4 : 1 : 1 1-propanol–acetic acid–water and R_f 0.35 in 4 : 5 : 2 : 4 1-butanol–ethanol–acetic acid–water; cellulose, R_f 0.15 in 6 : 4 : 3 : 1 1-butanol–pyridine–water–acetic acid (ref. validamine hydrochloride, R_f 0.17).

D-O-*(β-D-Glucopyranosyl)-(1,3,4/2,6)-4-amino-6-hydroxy-*

methyl-1,2,3-cyclohexanetriol Hydrochloride [**21**(−)]. Compound **19**(−) (100 mg) was *O*-deacylated with methanolic sodium methoxide as described for the preparation of **20**(+). The hydroxy azide **20**(−) (64 mg) thus obtained was hydrogenated similarly to give **21**(−) [53 mg, 88% yield based on **19**(−)] as a syrup, which was clearly differentiated from **21**(+) on TLC, showing mobilities slightly higher than those of **21**(+) in all the solvent systems examined; silica gel, R_f 0.28 in 4 : 1 : 1 1-propanol–acetic acid–water and R_f 0.40 in 4 : 5 : 2 : 4 1-butanol–ethanol–acetic acid–water; cellulose, R_f 1.18 in 6 : 4 : 3 : 1 1-butanol–pyridine–water–acetic acid when **21**(+) was used as an reference (R_f 1.0).

1L-1,2,3,6-Tetra-O-acetyl-1-O-(2,3,4,6-tetra-O-acetyl-β-D-glucopyranosyl)-(1,3,4/2,6)-4-acetamido-6-hydroxymethyl-1,2,3-cyclohexanetriol [**22**(+)]. Compound **21**(+) (50 mg) was dissolved in water (5 ml) and treated with Amberlite IRA-400 (OH^-) (1.5 ml) at room temperature for 30 min. The resin was removed by filtration and the filtrate was dried by azeotropic distillation with ethanol and toluene. The residual free base was treated with acetic anhydride (2 ml) and pyridine (2 ml) at 50 °C for 20 h. The reaction mixture was concentrated and the residue was chromatographed on a silica-gel column (4 g) with 1 : 1 2-butanone–toluene as an eluent. The fraction having R_f 0.43 in 20 : 1 chloroform–methanol was concentrated to give **22**(+) (50 mg, 57%) as an amorphous solid: $[\alpha]_D^{23}$ +16° (*c* 0.75, chloroform) [lit,[3] $[\alpha]_D^{23}$+17.6° (chloroform)]; IR ($CHCl_3$) 3440 (NH), 1770—1740 (C=O), 1680, and 1520 cm^{-1} (amide); ^1H NMR ($CDCl_3$) δ=1.98 (3H, s), 2.00 (6H, s), 2.02 (9H, s), 2.07 (3H, s), and 2.10 (3H, s) (NAc and OAc), and 6.30 (1H, d, J=7 Hz, NH). The spectrum was superimposable on that of an authentic sample.[6]

Found: C, 51.30; H, 6.19; N, 2.20%. Calcd for $C_{29}H_{41}NO_{17}$: C, 51.56; H, 6.12; N, 2.07%.

Compound **22**(+) showed a double melting point. Thus, the amorphous solid melted at 114—118 °C (lit,[3] 117—119 °C) and the melt, on continuous heating on a hot stage, crystallized at 150—160 °C to give needles, which melted sharply at 187—189 °C. The same melting and crystallization behavior was observed for an authentic sample (mp 112—119 and 183—185 °C).

1D-1,2,3,6-Tetra-O-acetyl-1-O-(2,3,4,6-tetra-O-acetyl-β-D-glucopyranosyl)-(1,3,4/2,6)-4-acetamido-6-hydroxymethyl-1,2,3-cyclohexanetriol [**22**(−)]. Amine hydrochloride **21**(−) (53 mg) was acetylated as described for the preparation of **22** (+) to give **22**(−) (41 mg,44%) as a homogeneous syrup (R_f 0.51, 20 : 1 chloroform–methanol): $[\alpha]_D^{24}$ −49° (*c* 0.75, chloroform); IR ($CHCl_3$) 3440 (NH), 1740—1765 (C=O), 1680, and 1505 cm^{-1} (amide); ^1H NMR ($CDCl_3$) δ=1.99 (3H, s), 2.01 (6H, s), 2.02 (6H, s), 2.11 (3H, s), and 2.17 (6H, s) (NAc and OAc), and 6.06 (1H, broad d, J=7 Hz, NH).

Found: C, 51.48; H, 6.15; N, 1.93%. Calcd for $C_{29}H_{41}NO_{17}$: C, 51.56; H, 6.12; N, 2.07%.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 355376 from the Ministry of Education, Science and Culture. The authors wish to express their sincere thanks to Mr. Saburo Nakada for his elemental analyses.

Synthetic Studies on the Validamycins. III. Bromination of DL-Tri-*O*-acetyl-(1,3/2)-4-methylene-5-cyclohexene-1,2,3-triol. Preparation of Several Branched-chain Unsaturated Cyclitols Related to Valienamine[1)]

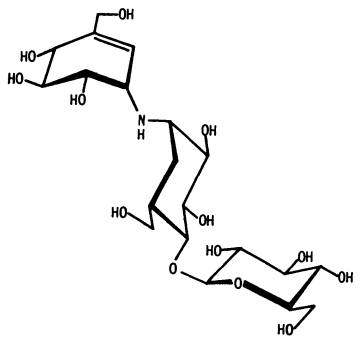
(Received June 10, 1982)

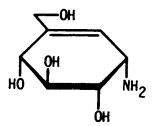
Bromination of DL-tri-*O*-acetyl-(1,3/2)-4-methylene-5-cyclohexene-1,2,3-triol with bromine in an appropriate solvent yielded mainly two 1,4-addition products, from which several branched-chain unsaturated cyclitols, related to biologically interesting valienamine, were selectively prepared. Reaction courses are discussed for the bromination of the diene and the debromination of the bromo(bromomethyl)cyclohexenetriol triacetates obtained under various conditions.

Validamycin A (**1**)[2)] is the major and most active component of the antibiotic validamycins, produced by *Streptomyces hygroscopicus* var. *limoneus* and widely used in order to control sheath blight in rice plants. Microbial degradation of validamycin A with a cell suspension of *Pseudomonas denitrificans* gave, besides validamine,[3)] a branched-chain unsaturated aminocyclitol, valienamine (**2**), which is a common building block of validamycins and the structure of which was assigned to 1D-(1,3,6/2)-6-amino-4-hydroxymethyl-4-cyclohexene-1,2,3-triol on the basis of ^{1}H NMR spectroscopy.[4)]

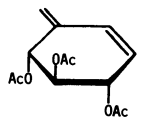
In recent years, some biologically active branched-chain unsaturated cyclitols such as glyoxalase I inhibitor[5)] and rancinamycins I—IV[5)] have been discovered. Very recently, the valienamine moiety linked to D-glucose or 6-deoxy-D-glucose *via* an imino linkage has been found as an essential unit in a homologous series of pseudo-oligosaccharides such as acarboses,[7)] trestatins,[8)] and adiposins,[9)] all of which show a marked inhibitory effect against α-glucosidases in mammals.[10)] Furthermore, valienamine itself has been found to show both the α-glucosidase inhibition and the antibiotic activity against *Bacillus* species.[11)]



Validamycin A (1)



Valienamine (2)



3

In connection with our synthetic studies on the validamycins,[12)] we now report the synthesis of several branched-chain unsaturated cyclitols related to valienamine. The synthetic route involved the preferential 1,4-addition of bromine to the conjugated diene, DL-tri-*O*-acetyl-(1,3/2)-4-methylene-5-cyclohexene-1,2,3-triol (**3**),[13)] assembling all the carbon atoms present in valienamine, and the stereocontrolled syntheses of the branched-chain unsaturated cyclitols by utilization of the different reactivities of the allylic primary and secondary bromine atoms and the neighboring group participation of acetoxyl groups in the replacement process. This synthetic approach may be extended to the synthesis of other analogs of this kind as well. Some intermediates obtained in this study are also important precursors of amino analogs including valienamine.

By consideration of the transition state analogous theory,[14)] the synthetic branched-chain unsaturated cyclitols are expected to display some glucosidase inhibitory activity similarly to valienamine.

Results and Discussion

*Bromination of Conjugated Diene **3** with Bromine. Synthesis of Bromo(bromomethyl)cyclohexenetriol Triacetates **5** and **6**:* Since electrophilic addition to conjugated diene often gives 1,4-addition product in much larger amount than 1,2-addition product, we have undertaken the bromination of readily available **3** with bromine in order to construct the carbon skelton of valienamine.

Treatment of **3** with a molar equiv. of bromine produced preferentially the 1,4-addition products **5** and **6**. In the ^{1}H NMR spectrum, the signal due to the olefinic proton (H-5) of **5** appeared as a doublet (J=5.5 Hz) at δ 6.19, indicating that the C-6 bromine atom is situated at a pseudoaxial position in a favored half-chair conformation,[15)] whereas that of **6** appeared as a broad singlet at δ 6.13, supporting that **6** is the C-6 epimer of **5**. Therefore, the structures of **5** and **6** were assigned to DL-(1,3,6/2)- and DL-(1,3/2,6)-6-bromo-4-bromomethyl-4-cyclohexene-1,2,3-triol triacetates, respectively.

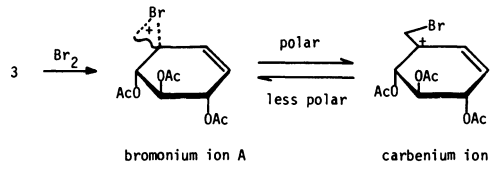
Of interest here is the fact that the product-distribution was affected by the polarity of the solvent used and by reaction temperature. Table 1 gives a summary of the results of the bromination of **3**. When the reaction was carried out in carbon tetrachloride, **6** was produced predominantly over **5** at −15 °C, whereas at room temperature the reverse was the case. On the other hand, the reaction in acetic acid at room temperature resulted in preferential formation of **6**. Both **5** and **6** were found to be interconvertible in the presence of a trace of bromine, but the interconversion took place so slowly that it would be negligible during the following work-up.

The above results can be interpreted by assuming the

Table 1. Bromination of 3 with an equimolar amount of bromine

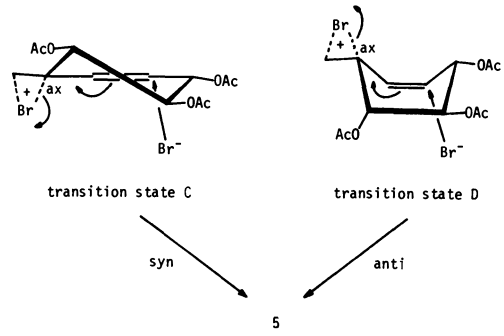
Solvent	Temp/°C	Isolated yield/%[a] 5	6	Total yield/%	Product ratio[b] 5/6
	−15	18	40	79	1.6
CCl_4	−4	33	29	90	0.7
	r.t.	48	17	89	0.4
AcOH	r.t.	10	43	72	3.4
50%aq AcOH[c]	r.t.	7	18	49[d]	2.1

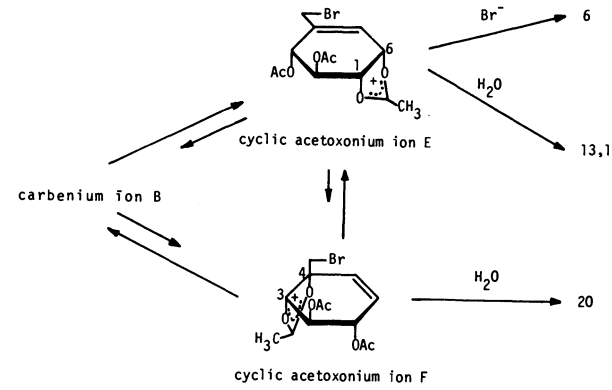
a) After silica-gel column chromatography. b) Determined by ^{1}H NMR analysis of the mixture. c) The resulting product was successively acetylated with acetic anhydride containing a trace of sulfuric acid. d) In addition to **5** and **6**, bromo tetraacetate **7** was obtained in 22% yield.



reaction course, which involves the equilibrium between bromonium ion **A** and carbenium ion **B**.[16] The observed solvent dependence of the bromination may be the result of differential solvation requirement of the bromonium ion **A** and carbenium ion **B** in their equilibrium, leading to more bromonium ion character in nonpolar solvent. Therefore, in carbon tetrachloride at room temperature the equilibrium lies to the bromonium ion **A**. The 1,4-addition product is known to be formed by opening of a bromonium ion by an S_N2' attack by at bromide ion.[17] Although a most theoretical analysis of S_N2' reactions has indicated a preference for syn attack by nucleophile, Toromanoff[18] has recently reported that, if the leaving group departs from an axial position in a half-chair conformation, S_N2' reaction is of syn stereochemistry, and that, if the leaving group is of an axial orientation in a boat form, anti stereochemistry is important. Thus, if bromine approaches from below, the reaction will proceed *via* the transition state **C** (half-chair), resulting in S_N2' attack by a bromide ion in syn stereochemistry, whereas if bromine approaches from above, the reaction will proceed *via* the transition state **D** (boat), resulting in S_N2' attack in anti stereochemistry. Both pathways give **5**.

On the other hand, in acetic acid carbenium ion **B** can be stabilized by allylic rearrangement with an assistance of the C-1 acetoxyl group, producing the 1,6-cyclic acetoxonium ion **E**, which is then opened by attack by a bromide ion from the back side at C-6 to give **6**. Carbenium ion **B** may also be stabilized by an assistance of the C-3 acetoxyl group, resulting in the formation of the 3,4-cyclic acetoxonium ion **F**, but this participation must be unfavorable because of the steric hindrance at C-4. Bromo triacetates **13**, **14**, and **20** were obtained as side-products in trace amounts. Compounds **13** and **14** could result from the opening of the cyclic acetoxonium **E** by attack by a trace of water present, and **20** from a similar opening of **F**. Furthermore, when the reaction was run in 50% aqueous acetic acid, bromotetraacetate **7** was obtained in 22% yield, after acetylation with acetic anhydride containing a trace of sulfuric acid. These findings substantiated the proposed mechanism for the bromination in acetic acid.[19]





Compound **6** could be readily available by crystallization of the bromination products in acetic acid–acetic anhydride[20] from ethanol. From the mother liquor, an inseparable mixture of **7** and **8** was obtained by fractionation by a silica-gel column. These were considered to be formed, respectively, by subsequent acetylation of **13** and **14** under the reaction conditions and by the opening of the acetoxonium ion **E** by an acetate ion from the back side at C-6.

When an excess bromine was used for the bromination in carbon tetrachloride at 0—5 °C, tetrabromides, presumably consisting of two isomers **4a** and **4b**, were obtained as crystals in 91% yield. Recrystallization from ethanol gave one of the isomers **4a** in a pure form in 59% yield. Monitoring of the reaction by TLC indicated the reaction to proceed *via* **5** and **6**, but the structures of the tetrabromides could not definitively be determined by analysis of the ^{1}H NMR spectral data. Hydrogenolysis of **4a** in ethyl acetate with Raney nickel T-4[21] in the presence of Amberlite IR-45 (OH^-) gave a mixture of tri-*O*-acetyl-DL-deoxyvalidatol and its 4-epimer, identical with authentic samples.[13]

Debromination of **5** and **6** was attempted with tributyltin(IV) hydride or with lithium aluminium hydride but, instead of desired debrominated product, **3** was regenerated in a good yield. Compounds **5** and **6** were expected to be potential intermediates for the present synthetic study.

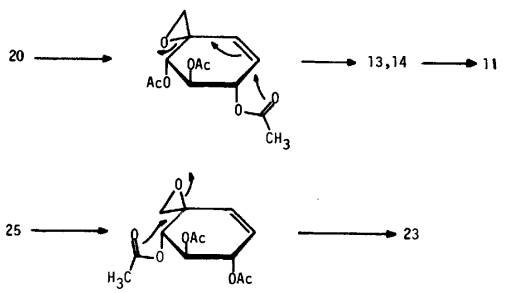
bromination of **3** using *N*-bromoacetamide (NBA) or *N*-bromosuccinimide (NBS) resulted in the preferential formation of 1,2-addition products in contrast to the bromination of **3** with a molar equiv. of bromine.

Treatment of **3** with a molar equiv. of NBA in aqueous acetone buffered with sodium acetate at room temperature for 5 d, followed by acetylation, gave a mixture of products from which 1,2-addition products **20** (9%), **23** (21%), and **26** (trace), and 1,4-addition product **11** (10%) were isolated by a silica-gel column chromatography. On the other hand, when **3** was treated with 1.5 molar equiv. of NBS in aqueous dimethyl sulfoxide for 5 h below 10 °C, 1,2-addition products **20** (36%) and **25** (12%), and 1,4-addition products **13** and **14** (5%) were obtained after chromatography.

The structures of **11**, **13**, **14**, and **20** were confirmed by comparison of their ^{1}H NMR spectra with those of authentic samples prepared later *via* unambiguous routes. In the ^{1}H NMR spectrum of **23**, the signals due to the olefinic protons (H-5 and H-6) appeared as a two-proton singlet at δ 5.37. The facts that acetoxymethyl protons of **23** appeared as AB-quartet (J=12 Hz) at δ 3.84 and 4.02 and that no signal changed upon deuteration except the disappearance of the signal at δ 2.57 due to the hydroxyl proton, indicated that **23** has a tertiary hydroxyl group. Further acetylation of **23** with acetic anhydride and pyridine for 7 d yielded pentaacetate **24** quantitatively. In the ^{1}H NMR spectrum of **24** the H-3 signal appeared as a doublet of doublets (J=9 Hz, 10.5 Hz) at δ 5.19, whereas in that of **23** it appeared in the vicinity of δ 5.33—5.62, partly overlapping with the H-4 signal. This observation suggested that the C-1 hydroxyl group of **23** would occupy a 1,3-diaxial position with respect to H-3, and hence the orientation of the acetoxymethyl group of **23** was assumed to be pseudoequatorial in a favored half-chair conformation. The structure of **25** was tentatively assigned by the elemental analysis and by comparing its ^{1}H NMR spectrum with that of **20**. The spectrum of **25** exhibited two olefinic protons as two doublets (J=10 Hz) at δ 6.00 and 6.09. The ^{1}H NMR spectrum of **26** resembled that of **25** in the region for the ring protons (H-2, H-3, and H-4), except that signals for the bromomethyl protons appearing as a AB-quartet (J=11 Hz) shifted down-field by *ca.* 0.13 ppm, supporting the assigned structure of **26**.

The reaction products suggested that the hydrobromination of **3** using NBA in aqueous conditions would not differ fundamentally from the aforementioned bromination of **3** with bromine in acetic acid. Therefore, the reaction is thought to proceed *via* the carbenium ion **B**. Since solvents such as dimethyl sulfoxide[22] and water are known to serve as nucleophiles, the carbenium ion **B** might be attacked by solvents to give the 1,2-addition products preferentially.

Compounds **11** and **23** were probably derived from the corresponding intermediate spiro-epoxides formed by the dehydrobromination of **20** and **25**, respectively, during subsequent acetylation. Compound **11** seemed to be yielded by the replacement of the remaining allylic bromine atom in **13** and **14** with an acetate ion present followed by acetylation. When the mixture of **13**, **14**, **20**, and **25**, obtained by the hydrobromination of **3** with NBS in aqueous dimethyl sulfoxide, was acetylated, the formation of **7**, **11**, **20**, **23**, and **26** was observed by TLC, supporting partly the above assumption.



Reaction of Dibromocyclohexenes **5** *and* **6**: *Synthesis of Branched-chain Unsaturated Cyclitols.* With **5** and **6** in hand in which two kinds of allylic bromine atoms are present at C-6, we initiated a stereocontrolled synthesis of branched-chain unsaturated cyclitols by taking advantage of different reactivities of the bromine atoms.

With Sodium Acetate: Preferential replacement of the primary allylic bromine atoms in both **5** and **6** by an acetate ion was effected by the reaction with a molar equiv. of sodium acetate in *N*,*N*-dimethylformamide (DMF) at room temperature for 24 h, and a *ca.* 3.5 : 1 mixture of the bromo tetraacetates **9** and **10** was obtained in both cases, from which **9** was easily isolated in 47—49% yield by crystallization from ethanol. The structure of **9** was confirmed by the ^{1}H NMR spectrum

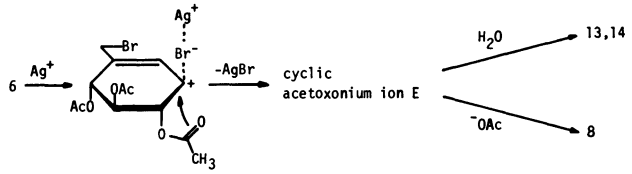
which revealed a down-field shift of the signal due to the C-7 methylene group, resulting from the replacement of the bromine atom by an acetoxyl group, and an olefinic proton (H-5) present as a broad doublet (J=*ca.* 5 Hz) at δ 6.07. A comparison of the ^{1}H NMR spectrum of the mixture of **9** and **10** with that of **9** showed that **10** is the C-6 epimer of **9**. The H-5 signal of **10** appeared as a singlet at δ 5.99.

Interestingly, the product-distribution was almost independent of starting from either **5** or **6**. The C-6 bromine atom seems to be readily exchangeable upon an S_N2 attack of a bromide ion generated in course of the reaction.

When both **5** and **6** reacted with an excess of sodium acetate in DMF at room temperature for 2 d, a 2—3 : 1 mixture of pentaacetates **11** and **12** was obtained.

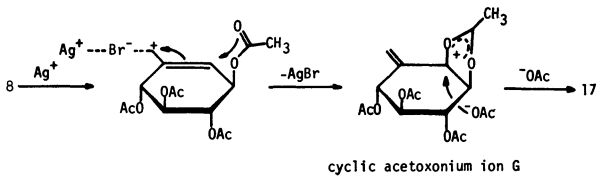
With Silver Acetate: In the presence of silver ion, alkyl halides, even primary, react *via* and S_N1-like mechanism, and the participation of neighboring acetoxyl group in replacement reactions has been extensively studied by Winstein and Buckles.[23]

According to their results, some branched-chain unsaturated cyclitols were expected to be selectively prepared by the following reaction sequences. Treatment of **6** with a molar equiv. of silver acetate in 90% aqueous acetic acid at room temperature for 2 h gave a 3 : 1 mixture of **13** and **14** as crystals in 73% yield, together with a 3 : 1 mixture of tetraacetates **15** and **16** in 13% yield. The latter was readily obtainable from **6** in 56% yield by using 4 molar equiv. of silver acetate in a similar condition at 90 °C for 1 h. On the other hand, treatment of **6** with 1 or 4 molar equiv. of silver acetate in acetic acid–acetic anhydride[20] at 80 °C gave **8** (63%) or **12** (73%). The *exo*-olefin **17**[24] was produced concomitantly by the reaction when 4 molar equiv. of silver acetate was used. Compound **12** was also obtained selectively by the reaction of **8** with sodium acetate at room temperature for 24 h.



In both conditions, acetoxonium ion **E** is considered to be formed as an intermediate by the participation of the neighboring C-1 acetoxyl group either simultaneously with or very short after the removal of the C-6 bromine atom by a silver ion. The cyclic intermediate is then opened by attack of water in the case of the former condition to give a mixture of **13** and **14**, which is further converted into a mixture of **15** and **16**, whereas under the latter condition it is opened by a back-side attack of an acetate ion at C-6 to give **8**, which is then converted into **12**. Compound **17** seemed to be formed from **8** *via* the intermediate **G**. Isolations of **13** and **14** and of **15** and **16** were unsuccessful because of their similar chromatographic mobilities on silica gel.

The structures of **13** and **14** were tentatively assigned by the elemental analysis and ^{1}H NMR spectral data.



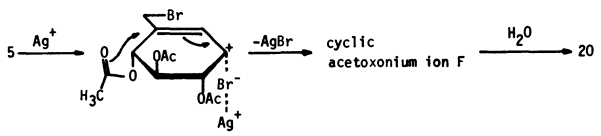
The fact that the signal due to the H-2 proton appeared as a doublet of doublets (J=5 Hz, 11 Hz) at δ 3.91 for **13** and as a doublet of doublets (J=3 Hz, 10 Hz) at δ 4.93 for **14**, indicated that the hydroxyl group of **13** was located at C-2, whereas that of **14** is at C-1. Similarly, the H-2 signals of **15** and **16** appeared as a doublet of doublets (J=4 Hz, 11 Hz) at δ 3.87 and a doublet of doublets (J=5 Hz, 11 Hz) at δ 4.91, respectively, being consistent with the assigned structures.

Acetylation of a mixture of **13** and **14** gave the bromotetraacetate **7**, which was convertible into the pentaacetate **11** by the reaction with sodium acetate in aqueous DMF. Compound **11** was also obtainable either by acetylation of a mixture of **15** and **16** or by treatment of a mixture of **13** and **14** with sodium acetate followed by acetylation.

The structures of **11** and **12** were assigned by the ^{1}H NMR spectra in which the olefinic protons (H-6) of **11** and **12** appeared as a doublet of doublets (J=2 Hz, 6 Hz) at δ 5.94 and a broad singlet at δ 5.82 partly overlapping with the H-4 signal, respectively.

O-Deacetylation of **11** and **12** with methanolic sodium methoxide gave crystalline pentols **18** and **19**, respectively.

When **5** reacted with 1.1 molar equiv. of silver acetate in 90% aqueous acetic acid at room temperature for 24 h, **20** was obtained in 52% yield. Since in the case of **5** the C-1 acetoxyl group and C-6 bromine atom are cis to each other, any neighboring group participation of the C-6 acetoxyl group is unfavorable. Therefore, the reaction is presumed to involve successively an allylic rearrangement (S_N1') with an assistance of the C-3 acetoxyl group, the formation of the 3,4-cyclic acetoxonium ion **F**, and its cleavage by water.



The structure of **20** was assigned on the basis of the appearance of the two-proton singlet at δ 5.83 attributable to two olefinic protons.

An attempt failed to remove the remaining bromine atom in **20** by further treatment with excess silver acetate at 90 °C, presumably because of the low reactivity of C-7 bromine atom under the S_N1-like conditions. On the other hand, reaction of **20** with sodium methoxide in methanol gave a crystalline methyl ether **21**, which was converted into the tetraacetate **22** by acetylation with acetic anhydride in pyridine at room temperature for 9 d. The reaction is considered to proceed *via* a spiro-epoxide, which is subsequently opened by a methoxide ion. The ^{1}H NMR spectrum of **22** showed

the presence of four acetoxyl groups and two olefinic protons (H-5 and H-6); for H-5, a doublet of doublets (J=2 Hz, 10 Hz) at δ 5.76 and for H-6, a doublet of doublets (J=1 Hz, 10 Hz) at δ 6.33.

Reaction of Bromo Tetraacetate ***9*** *with Alcohol.* Nucleophilic substitution of **9** with an alcohol such as methanol, ethanol, or 2-propanol in the presence of silver perchlorate proceeded predominantly with inversion at C-6 leading to the corresponding alkyl ether derivative **28**, **30**, or **32**, respectively (Table 2). This result can be derived as a consequence of either S_N2 attack by alcohol at C-6 or heterolysis of C-6 bromine atom leading to an allyl cation that is stabilized by neighboring group participation of C-1 acetoxyl group, followed by opening of the 1,6-cyclic acetoxonium ion by back-side attack of alcohol. In each case **15**, **16**, and **23** as a mixture were separated in 15% yield as side-products. This fact indicated that both 1,6- and 3,4-cyclic intermediate acetoxonium ions are formed during the course of reaction.

TABLE 2. REACTION OF **9** WITH ALCOHOL CATALYZED BY SILVER ION

Alcohol	Time/min	Yield/%[a]	Product ratio[b]
Methanol	60	25	Only **28**
Ethanol	70	21	**29**/**30**=1/4
2-Propanol	50	17	**31**/**32**=1/4

a) After silica-gel column chromatography. b) Determined by ^{1}H NMR analysis of the mixture.

When **9** was treated with methanolic sodium methoxide at room temperature or with ethanol containing a trace of hydrogen bromide, a 1 : 1 mixture of **27** and **28** in 71% yield or a 1 : 1 mixture of **29** and **30** in 64% yield was obtained, respectively, after acetylation with acetic anhydride and pyridine.

Though each pair of C-1 epimers, **27** and **28**, **29** and **30**, and **31** and **32**, could not be separated because of their similar chromatographic mobilties, **28** was selectively formed by the reaction of **9** with methanol in the presence of silver perchlorate. Their structures were easily assigned by the ^{1}H NMR spectral data, which showed olefinic protons at δ 6.02 (broad d, J=6 Hz), 5.99 (broad d, J=6 Hz), and 5.90 (broad d, J=5 Hz) for **27**, **29**, and **30** and δ 5.82 (broad s), 5.82 (broad s), and 5.75 (broad s) for **28**, **30**, and **32**.

Experimental

General. Melting points were determined on a Büchi 510 capillary melting point apparatus and uncorrected. Unless otherwise noted, ^{1}H NMR spectra were taken on a Varian EM-390 (90 MHz) in chloroform-*d* ($CDCl_3$) with reference to tetramethylsilane as an internal standard. The peak positions were given in terms of δ-values and values given for coupling constants were of first-order. TLC was performed on a precoated silica gel 60 F-254 plaques (Merck, Darmstadt; 0.25 mm thickness), and the spots were visualized by heating above 150 °C after spraying concd sulfuric acid. The silica gel used for the column chromatography was Wakogel C-300 (Wako Pure Chemical Industries, Ltd.). Solutions were dried over anhydrous sodium sulfate and evaporated under reduced pressure at 40—50 °C. Acetylation was conventionally carried out with acetic anhydride in anhydrous pyridine at room temperature overnight and the reaction mixture was evaporated to remove the excess of reagents. Crude syrupy products (acetates) were usually purified preliminarily by rapid passage through a short column of active alumina with chloroform. Catalytic hydrogenations were carried out in a Parr shaker type apparatus at initial hydrogen pressure of 3.2 kg/cm^2.

Bromination of Conjugated Diene ***3*** *with Bromine. With Excess Bromine: Tetrabromides* **4a**,**b**. To a stirred solution of **3** (0.5 g) in carbon tetrachloride (8 ml) was added dropwise bromine (0.35 ml, *ca.* 3.5 molar equiv.) at 0—5 °C, and the mixture was stirred at the same temperature overnight. After removal of the solvent, the residual solid was crystallized from ethanol to give a mixture of **4a**, **b** (1g, 91%) as crystals, (Found: C, 26.32; H, 2.73; Br, 54.65%). Recrystallization from ethanol gave **4a** (0.65 g, 59%), one of the isomers, in a pure forms: mp 147—148 °C; ^{1}H NMR δ=1.96 (3H, s), 2.04 (3H, s), and 2.07 (3H, s) (OAc), 3.58 and 4.02 (AB-quartet, J=11.7 Hz, CH_2Br), 4.68—5.03 (2H, m, H-5 and H-6), and 5.36—5.59 (3H, m, H-1, H-2, and H-3).

Found: C, 26.47; H, 2.85; Br, 54.52%. Calcd for $C_{13}H_{16}Br_4O_6$: C, 26.56; H, 2.74; Br, 54.37%.

From the mother liquor, a mixture of **4a**,**b** was obtained. The other isomer **4b** could not be isolated because of their similar chromatographic mobilities on silica gel. The ^{1}H NMR spectrum of the mixture showed the signal for the bromomethyl protons of **4b** at δ 3.95 and 4.34 as an AB-quartet (J=7.5 Hz).

With an Equimolar Amount of Bromine: Synthesis of DL-*(1,3,6/2)-(5) and* DL-*(1,3/2,6)-6-Bromo-4-bromomethyl-4-cyclohexene-1,2,3-triol Triacetate (****6****):* The results are summarized in Table 1.

General Procedure. a) In Carbon Tetrachloride: To a stirred solution of **3** (0.3 g) in carbon tetrachloride (15 ml) was added dropwise over a period of 15 min 5% bromine solution in the same solvent (1.5 ml, a molar equiv.) at various temperatures, and stirring was continued at the same temperature for 30 min. The mixture was then diluted with carbon tetrachloride (15 ml), washed thoroughly with aqueous sodium hydrogencarbonate solution and water, dried, and evaporated to give a syrup, which was shown by TLC (1: 5 2-butanone-toluene) to contain two major components (R_f 0.65 and 0.62). Chromatography of the products on a silica-gel column (30 g) with 1 : 20 2-butanone-toluene as an eluent gave **5** (R_f 0.65) as a syrup and **6** (R_f 0.62) as crystals (mp 109—110 °C): ^{1}H NMR (60 MHz)[25] for **5**, δ=2.04 (3H, s), 2.09 (3H, s), and 2.11 (3H, s) (OAc), 3.75 and 3.97 (AB-quartet, J=11 Hz, $C\underline{H}_2Br$), 4.75—5.06 (2H, m, H-1 and H-6), 5.62 (1H, dd, J=7 and 10 Hz, H-2), 6.00 (1H, d, J=7 Hz, H-3), and 6.19 (1H, broad d, J=5.5 Hz, H-5), and for **6**, δ=2.04 (3H, s) and 2.11 (6H, s) (OAc), 3.81 and 4.09 (AB-quartet, J=11 Hz, $C\underline{H}_2Br$), 4.67 (1H, m, H-6), 5.10 (1H, dd, J=7 and 10 Hz, H-1), 5.55 (1H, dd, J=8 and 10 Hz, H-2),) 5.85—6.08 (1H, m, H-3), and 6.13 (1H, broad s, H-5).

Found: for **5**, C, 36.64; H, 3.83; Br, 37.47%, and for **6**, C, 36.29; H, 3.75; Br, 37.42%. Calcd for $C_{13}H_{16}Br_2O_6$: C, 36.48; H, 3.77; Br, 37.33%.

When the reactions were carried out at −4 °C and at

−15 °C, trace amounts of **13**, **14**, and **20** were produced as side-products. *b) In Acetic Acids*: The reaction was carried out in the same way as in *a*), except that the reaction mixture was diluted with ethyl acetate (30 ml). Similar to the reaction in carbon tetrachloride at low temperature, **13**, **14**, and **20** were obtained in trace amounts as side-products.

c) In 50% Aqueous Acetic Acid. After the reaction had been carried out in a similar way as described above, the reaction mixture was evaporated below 30 °C, without dilution or washing of the mixture, because TLC analysis (1: 5 2-butanone-toluene) revealed the presence of a large amount of slower-moving components in addition to a small amount of the desired products **5** and **6**. The yellow syrupy residue was treated with acetic anhydride (2 ml) in the presence of a trace of concd sulfuric acid at room temperature overnight and then neutralized with saturated aqueous sodium hydrogencarbonate solution. The mixture was diluted with ethyl acetate (30 ml), and the organic layer was washed with water and dried. Evaporation of the solvent left a syrup which was chromatographed similarly on a silica-gel column. After **5** and **6** had been eluted, tetraacetate **7** was obtained in 22% yield: mp 109—111 °C. The ^{1}H NMR spectrum of **7** is described later. In all cases, tetrabromides **4a**,**b** were detected by TLC analysis.

Interconversion of 5 and 6: When **6** was treated with carbon tetrachloride containing a trace of bromine at room temperature overnight, formation of an equilibrium mixture of **5** and **6** was detected by TLC analysis. Without bromine no interconversion occurs.

Practical Synthesis of 6: To a stirred solution of **3** (1 g) in 3 : 1 acetic acid–acetic anhydride (40 ml)[20] was added dropwise over a period of 50 min 5% bromine solution in the same solvent (3.86 ml, a molar equiv.), and stirring was continued for 50 min. The reaction mixture was processed according to the general procedure and the product was directly crystallized from ethanol (8 ml) to give **6** (0.71 g, 45%): mp 108.5—109.5 °C.

From the mother liquor, an inseparable mixture (0.23 g, 15%) of **7** and **8** was obtained by chromatography on silica gel. The ^{1}H NMR spectrum showed it to be a *ca.* 1 : 1 mixture of **7** and **8**.

Reduction of Tetrabromide 4a with Raney Nickel. A solution of **4a** (0.25 g) in ethyl acetate (10 ml) was hydrogenolyzed with Raney nickel T-4[21] (5 ml) and Amberlite IR-45 (OH^-) (7 ml) at room temperature overnight. After removal of the catalyst and resin by filtration, the filtrate was evaporated to a syrup, which was purified by passage through a short column of alumina with chloroform to give an inseparable syrupy mixture (114 mg, 99%) of tri-*O*-acetyl-DL-deoxyvalidatol and its 4-epimer[13] (*ca.* 1 : 1).

Reduction of 5 and 6. With Tributyltin(IV) Hydride: A solution of **5** (0.17 g) in dry toluene (10 ml) was treated with tributyltin(IV) hydride (0.22 ml) at room temperature overnight under a nitrogen atmosphere. Evaporation of the mixture left an oil, which was purified by passage through a silica-gel column with 1 : 10 2-butanone-toluene to give **3** (87 mg, 80%) as needles: mp 66.5—68 °C.

Similar treatment of **5** with tributyltin(IV) hydride gave **3** in 89% yield: mp 66—67 °C.

With Lithium Aluminium Hydride: A suspension of **5** (0.26 g) and lithium aluminium hydride (0.14 g) in tetrahydrofuran (10 ml) was refluxed gently for 7 h. The mixture was then diluted with water carefully, and the precipitates were removed by filtration. Evaporation of the filtrate left a syrup, which was acetylated in the ususl way. The mixture was evaporated and the residue was purified by an alumina column and crystallized from ethanol to give **3** (0.11 g, 63%) as needles: mp 67—68.5 °C.

Similar treatment of **6** with lithium aluminium hydride gave **3** in 60% yield: mp 67—68 °C.

Hydrobromination of Conjugated Diene 3. With N-Bromoacetamide (NBA): To a stirred solution of NBA (0.25 g, a molar equiv.) and sodium acetate (0.23 g) in water (10 ml) was added dropwise over a period of 10 min a solution of **3** (0.5 g) in acetone (20 ml), and stirring was continued at room temperature for 5 d. The aqueous mixture was then extracted with ether (40 ml + 30 ml × 2) and the organic layer was dried and evaporated. The residue was acetylated in the usual way, during which time the mixture became orange. Evaporation of the mixture left a yellow syrup, which was chromatographed on a silica-gel column 1 : 8 2-butanone-toluene as an eluent. The first and second fractions gave **11** (0.10 g, 10%) and **20** (61 mg, 9%), respectively. They were identical with the samples of which preparations *via* unequivocal routes are to be described later.

The third fraction gave DL-2,3,4,7-tetra-*O*-acetyl-(1,2,-4/3)-1-*C*-hydroxymethyl-5-cyclohexene-1,2,3,4-tetrol (**23**) (0.14 g, 21%) as a homogeneous syrup: ^{1}H NMR δ=2.00 (3H, s), 2.04 (6H, s), and 2.08 (3H, s) (OAc), 2.57 (1H, s, OH, caused to disappear on deuteration), 3.84 and 4.02 (AB-quartet, J=12 Hz, C$\underline{H}_2$OAc), 5.13 (1H, broad d, J=*ca.* 10 Hz, H-2), 5.33—5.62 (2H, relatively sharp m, H-3 and H-4), and 5.37 (2H, s, H-5 and H-6).

Found: C, 52.43; H, 5.85%. Calcd for $C_{15}H_{20}O_9$: C, 52.32; H, 5.85%.

Acetylation of **23** in the usual way for 7 d gave DL-penta-*O*-acetyl-(1,2,4/3)-1-*C*-hydroxymethyl-5-cyclohexene-1,2,3,4-tetrol (**24**) as a syrup quantitatively: ^{1}H NMR δ=2.00 (3H, s), 2.02 (3H, s), 2.05 (3H, s), and 2.07 (6H, s) (OAc), 4.15 and 4.51 (AB-quartet, J=11 Hz, C$\underline{H}_2$OAc), 5.19 (1H, dd, J=9 and 10.5 Hz, H-3), 5.29—5.64 (2H, m, H-2 and H-4), 5.73 (1H, dd, J=2 and 10 Hz, H-5), and 6.33 (1H, dd, J=1 and 10 Hz, H-6).

Found: C, 53,12; H, 5.72%. Calcd for $C_{17}H_{22}O_{10}$: C, 52.85; H, 5.74%.

A trace amount of the other product was isolated from the faster moving component. The structure was tentatively assigned as DL-tetra-*O*-acetyl-(1,3/2,4)-1-*C*-bromomethyl-5-cyclohexene-1,2,3,4-tetrol (**26**): ^{1}H NMR (60 MHz)[25] δ=2.04 (6H, s), 2.06 (3H, s), and 2.10 (3H, s) (OAc), 3.58 and 3.82 (AB-quartet, J=11 Hz, C$\underline{H}_2$Br), 5.20—5.84 (3H, m, H-1, H-2, and H-3), and 6.00 (1H, d, J=10 Hz) and 6.09 (1H, d, J=10 Hz) (olefinic proton).

Found: C, 43.98; H, 4.52; Br, 19.98%. Calcd for $C_{15}H_{19}BrO_8$: C, 44.24; H, 4.70; Br, 19.62%.

With N-Bromosuccinimide (NBS): To a stirred mixture of **3** (0.5 g), dimethyl sulfoxide (10 ml), and water (0.1 ml) was added NBS (0.5 g, 1.5 molar equiv.) as one portion, and then stirring was continued for 5 h below 10 °C. The reaction mixture was then quenched by addition of water (40 ml) and extracted with ether (20 ml × 4). The extracts were dried and evaporated to give a yellow syrup, which was chromatographed on a silica-gel column (50 g) with 1 : 4 2-butanone-toluene. The first fraction gave a syrup (78 mg, 12%), of which structure was tentatively assigned as DL-2,3,4-tri-*O*-acetyl-(1,3/2,4)-1-*C*-bromomethyl-5-cyclohexene-1,2,3,4-tetrol (**25**): ^{1}H NMR (60 MHz)[24] δ=2.04 (6H,s) and 2.11 (3H, s) (OAc), 3.30—3.72 (1H, broad m, O$\underline{H}$, caused to disappear on deuteration), 3.46 and 3.68 (AB-quartet, J=11 Hz, C$\underline{H}_2$Br), 5.10—5.55 (3H, m, H-2, H-3, and H-4), and 5.60 (1H, dd, J=1 and 11 Hz) and 5.87 (1H, dd, J=0.8 and 11 Hz) (olefinic proton).

Found: C, 42.84; H, 4.59; Br, 21.73%. Calcd for

$C_{13}H_{17}BrO_7$: C, 42.76; H, 4.69; Br, 21.88%.

The second fraction gave **20** (0.25 g, 36%) as a syrup.

The third fraction gave an inseparable mixture (33 mg, 5%) of **13** and **14**, whose ^1H NMR spectrum indicated it to be a 3 : 1 mixture of **13** and **14**. The spectrum was superimposable on that of an authentic sample prepared later *via* an unequivocal route.

When the reaction products, without fractionation, were acetylated in the usual way, formation of **7**, **11**, **20**, **23**, and **26** was detected by TLC analysis.

DL-*Tetra*-O-*acetyl*-(*1,2,4/3*)-*5-bromomethyl-5-cyclohexene-1,2,3,-4-tetrol* (**7**). A mixture of **6** (0.11 g), silver acetate (41 mg, a molar equiv.), and 90% aqueous acetic acid (10 ml) was vigorously stirred with protection from light at room temperature for 2 h. The precipitates were then removed by filtration and the filtrate was evaporated to give a syrup, which was chromatographed on a silica-gel column (3 g) with 1 : 3 2-butanone–toluene. Crystallization from ethanol gave an inseparable crystalline mixture (66 mg, 73%) of DL-1,3,4-(**13**) and DL-2,3,4-tri-*O*-acetyl-(1,2,4/3)-5-cyclohexene 1,2,3,4-tetrol (**14**): mp 110.5—111 °C; the ^1H NMR spectrum showed it to be a 3 : 1 mixture of **13** and **14**; ^1H NMR for **13**, δ=2.12 (6H, s) and 2.14 (3H, s) (OAc), 2.42—2.72 (1H, broad s, O<u>H</u>), 3.78 and 3.99 (AB-quartet, J=11 Hz, C<u>H</u>$_2$Br), 3.91 (1H, dd, J=5 and 11 Hz, H-2), 5.32 (1H, dd, J=7.5 and 11 Hz, H-3), 5.35—5.49 (1H,m, H-1), 5.82 (1H, broad d, J=8 Hz, H-4), and 6.15 (1H, J=5 Hz, H-6), and for **14**, δ=4.93 (1H, dd, J=3 and 10 Hz, H-2), and 5.42 (1H, dd, J=7 and 10 Hz, H-3).

Found: C, 42.48; H, 4.69; Br, 21.54%. Calcd for $C_{13}H_{17}BrO_7$: C, 42.76; H, 4.69; Br, 21.88%.

From the mother liquor a mixture of **15** and **16** was separated in 13% yield by chromatography.

The mixture of **13** and **14** (50 mg) was acetylated with acetic anhydride (5 ml) in the presence of a trace of concd sulfuric acid at room temperature overnight and then neutralized with saturated aqueous sodium hydrogencarbonate solution. The mixture was diluted with ethyl acetate, and the organic layer was washed with water and dried. Evaporation of the solvent gave crystals, which were recrystallized from ethanol to give **7** (55 mg, 98%): mp 134—135 °C; ^1H NMR (60 MHz)[25] δ=2.02 (3H, s), 2.04 (3H, s), and 2.08 (6H, s) (OAc), 3.80 and 4.01 (AB-quartet, J=11 Hz, C<u>H</u>$_2$Br), 5.11 (1H, dd, J=3.5 and 10 Hz, H-2), 5.32—5.68 (2H, m, H-1 and H-3), 5.83 (1H, broad d, J=*ca.* 6.5 Hz, H-4), and 6.02 (1H, broad d, J=*ca.* 6 Hz, H-6).

Found: C, 44.04; H, 4.73; Br, 19.86%. Calcd for $C_{15}H_{19}BrO_8$: C, 44.24; H, 4.70; Br, 19.62%.

DL-*Tetra*-O-*acetyl*-(*1,3/2,4*)-*5-bromomethyl-5-cyclohexene-1,2,-3,4-tetrol* (**8**). A mixture of **6** (0.42 g), silver acetate (0.17 g, a molar equiv.), and acetic acid–acetic anhydride (20 ml)[20] was heated to 80 °C with protection from light for 40 min. After cooling, the precipitates were removed by filtration and the filtrate was evaporated to give a syrup, which was purified by a short column of silica gel to give crystals. Recrystallization from ethanol gave **8** (0.25 g, 63%) as columns: mp 133.5—134 °C; ^1H NMR δ=2.01 (6H, s), 2.06 (3H, s), and 2.08 (3H, s) (OAc), 3.79 and 3.99 (AB-quartet, J=11 Hz, C<u>H</u>$_2$Br), 5.25—5.68 (3H, m, H-1, H-2, and H-3), and 5.77—6.01 (2H, m, H-4 and H-6).

Found: C, 44.14; H, 4.65; Br, 19.87%. Calcd for $C_{15}H_{19}BrO_8$: C, 44.24; H, 4.70; Br, 19.62%.

DL-*Penta*-O-*acetyl*-(*1,2,4/3*)-*5-hydroxymethyl-5-cyclohexene-1,2,-3,4-tetrol* (**11**). *a*): A mixture of **6** (0.14 g), silver acetate (0.21 g, 4 molar equiv.), and 90% aqueous acetic acid (10 ml) was heated to 90 °C with protection from light for 1 h. The precipitates were removed by filtration and the filtrate was evaporated to give a syrup, which was chromatographed on a silica-gel column (5 g) with 1 : 3 2-butanone–toluene to give an inseparable mixture (61 mg, 56%) of DL-1,3,4,7- (**15**) and DL-2,3,4,7-tetra-*O*-acetyl-(1,2,4/3)-5-hydroxymethyl-5-cyclohexene-1,2,3,4-tetrol (**16**). The ^1H NMR spectrum indicated it to be a 3 : 1 mixture of **15** and **16**: ^1H NMR for **15**, δ=2.02 (3H, s), 2.04 (3H, s), 2.09 (3H, s), and 2.10 (3H, s) (OAc), 3.71—4.00 (1H, m, H-2, caused to change to dd with J=4 and 11 Hz at δ 3.87 on deuteration), 4.31 and 4.68 (AB-quartet, J=13 Hz, C<u>H</u>$_2$OAc), 5.29 (1H, dd, J=8 and 11 Hz, H-3), 5.38 (1H, dd, J=4 and 6 Hz, H-1), and 5.65 (1H, broad d, J=8 Hz, H-4), 6.02 (1H, broad d, J=6 Hz, H-6), and for **16**, δ=4.91 (1H, dd, J=5 and 11 Hz, H-2).

Found: C, 52.56; H, 5.95%. Calcd for $C_{15}H_{20}O_9$: C, 52.32; H, 5.85%.

A trace of mixture of **13** and **14** was separated from the fast migrating component.

The mixture of **15** and **16** (76 mg) was acetylated in the usual way to give **11** (81 mg, 95%) as a homogeneous syrup: ^1H NMR (60 MHz)[25] δ=2.00 (3H, s), 2.03 (3H, s), 2.04 (6H, s), and 2.09 (3H, s) (OAc), 4.32 and 4.70 (AB-quartet, J=13 Hz, C<u>H</u>$_2$OAc), 5.10 (1H, ddd, J=2, 4, and 10 Hz, H-2), 5.47 (1H, dd, J=7 and 10 Hz, H-3), 5.57 (1H, dd, J=4 and 6 Hz, H-1), 5.66 (1H, broad d, J=7 Hz, H-4), and 5.94 (1H, dd, J=2 and 6 Hz, H-6).

Found: C, 52.63; H, 5.69%. Calcd for $C_{17}H_{22}O_{10}$: C, 52.85; H, 5.74%.

b): The mixture of **13** and **14** (0.1 g) was treated with sodium acetate (24 mg, 1.1 molar equiv.) in 10% aqueous DMF (10 ml) at room temperature for 7 h. Evaporation of the mixture left a residue, which was purified by an alumina column to give a homogeneous syrup. The syrup was acetylated and the product was chromatographed on a silica-gel column (2 g) with 1 : 5 2-butanone–toluene to give **11** (0.9 g, 86%) as a homogeneous syrup.

c): A mixture of **7** (50 mg), sodium acetate (20 mg, 2 molar equiv.), and DMF (1 ml) was stirred at room temperature for 2 d. The mixture was then evaporated and the residue was purified by an alumina column to give **11** (33 mg, 70%) as a homogeneous syrup.

DL-*Penta*-O-*acetyl*-(*1,3/2,4*)-*5-hydroxymethyl-5-cyclohexene-1,2,3,-4-tetrol* (**12**). *a*) A mixture of **6** (1 g), silver acetate (1.56 g, 4 molar equiv.), and acetic acid–acetic anhydride (60 ml)[20] was treated similarly as described in the preparation of **8** for 3 h. The crystalline product was recrystallized from ethanol to give DL-penta-*O*-acetyl-(1,3,5/2,4)-6-methylene-1,2,3,4,5-cyclohexanepentol (**17**) (0.1 g, 12%): mp 188.5—189 °C (lit,[24] 189—190 °C); ^1H NMR δ=1.93 (9H, s) and 2.03 (6H, s) (OAc) and 4.72—5.67 (7H, m, H-1, H-2, H-3, H-4, H-5, and exocyclic methylene).

Found: C, 52.63; H, 5.62%. Calcd for $C_{17}H_{22}O_{10}$: C, 52.85; H, 5.74%.

Evaporation of the mother liquor and crystallization from ethanol gave **12** (0.59 g, 73%): mp 81.5—82.5 °C; ^1H NMR δ=2.03 (3H, s), 2.04 (3H, s), 2.05 (3H, s), 2.06 (3H, s), and 2.08 (3H, s) (OAc), 4.41 and 4.76 (AB-quartet, J=14 Hz, C<u>H</u>$_2$Br), 5.16—5.72 (3H, m, H-1, H-2, and H-3), and 5.82 (2H, broad s, H-4 and H-6).

Found: C, 53.05; H, 5.76%. Calcd for $C_{17}H_{22}O_{10}$: C, 52.85; H, 5.74%.

b): A mixture of **8** (0.26 g), sodium acetate (79 mg, 1.5 molar equiv.), and DMF (5 ml) was stirred at room temperature for 24 h. The mixture was then evaporated and the residue was purified by an alumina column to give crystals. Recrystallization from ethanol gave **12** (0.26 g, 91%): mp 81—82 °C.

DL-(*1,2,4/3*)-*5-Hydroxymehthtyl-5-cyclohexene-1,2,3,4-tetrol*

*(**18**).* A solution of **11** (0.1 g) in methanol (10 ml) was treated with 1 M† methanolic sodium methoxide (0.2 ml) and allowed to stand at 0—5 °C overnight. The mixture was then neutralized with Amberlite IR-120 (H^+) and evaporated to give a syrup, which was crystallized from ethanol to give **18** (40 mg, 87%): mp 139.5—141 °C; ^{1}H NMR (90 MHz, D_2O)[26] δ=3.46—3.86 (2H, m, H-2 and H-3), 4.00—4.42 (4H, m, H-1, H-4, and C$\underline{H}_2$OH), and 5.88 (1H, dd, J=1.5 and 5 Hz).

Found: C, 47.65; H, 6.77%. Calcd for $C_7H_{12}O_5$: C, 47.72; H, 6.87%.

DL-*(1,3/2,4)-5-Hydroxymethyl-5-cyclohexene-1,2,3,4-tetrol (**19**).* Compound **12** (0.1 g) was treated with 1 M methanolic sodium methoxide in the same way as in the preparation of **18**. The crude product was recrystallized from aqueous ethanol to give **19** (45 mg, 98%): mp 150.5—151.5 °C; ^{1}H NMR (90 MHz, D_2O)[25] δ=3.26—3.70 (2H, m, H-2 and H-3), 4.05—4.36 (4H, m, H-1, H-4, and C$\underline{H}_2$OH), and 5.62 (1H, d, J=1.5 Hz).

Found: C, 47.66; H, 6.72%. Calcd for $C_7H_{12}O_5$: C, 47.72; H, 6.87%.

*Reaction of **5** and **6** with Sodium Acetate. With an Equimolar Amount of Sodium Acetate: Synthesis of* DL-*Tetra-O-acetyl-(1,3,6/2)-4-hydroxymethyl-6-bromo-4-cyclohexene-1,2,3-triol (**9**):* A mixture of **5** (0.2 g), sodium acetate (37 mg, a molar equiv.), and DMF (10 ml) was stirred at room temperature for 24 h. The mixture was then diluted with ethyl acetate (20 ml), and the organic layer was washed with water and dried. Evaporation of the solvent left a syrup, which was crystallized from ethanol to give **9** (86 mg, 47%) as needles: mp 66—67.5 °C; ^{1}H NMR δ=2.02 (6H, s), 2.05 (6H, s), and 2.11 (3H, s) (OAc), 4.32 and 4.66 (AB-quartet, J=14 Hz, C$\underline{H}_2$OAc), 4.82 (1H, dd, J=4.5 and 10 Hz, H-1), 4.82—5.00 (1H, m, H-6), 5.58 (1H, dd, J=9 and 10 Hz, H-2), 5.81 (1H, d, J=9 Hz, H-3), and 6.07 (1H, broad d, J=*ca.* 5 Hz, H-5).

Found: C, 44.18; H, 4.69; Br, 19.73%. Calcd for $C_{15}H_{19}BrO_8$: C, 44.24; H, 4.70; Br, 19.62%.

From the mother liquor an inseparable 1.5 : 1 mixture (63 mg, 35%) of **9** and its C-6 epimer **10** was obtained. (Found: C, 43.97; H, 4.60; Br, 19.31%.) The ^{1}H NMR spectrum of **10** could be read in that of the mixture by elimination of the spectrum of **9**: ^{1}H NMR δ=4.32 and 4.66 (AB-quartet, J=14 Hz, C$\underline{H}_2$OAc), 5.11 (1H, dd, J=7.5 and 10 Hz, H-1), 5.46 (1H, dd, J=8 and 10 Hz, H-2), 5.79 (1H, broad d, J=8 Hz, H-3), and 5.99 (1H, broad s, H-5).

When **6** was used instead of **5**, **9** was similarly obtained in 49% yield.

With Excess Sodium Acetate: A mixture of **5** (90 mg), sodium acetate (0.7 g, 4 molar equiv.), and DMF (10 ml) was stirred at room temperature for 2 d. The mixture was worked up in a similar manner as above and the crude product was chromatographed on a silica-gel column (3 g) with 1 : 5 2-butanone–toluene to give an inseparable syrupy mixture (0.5 g, 60%) of **11** and **12**. Found: C, 52.60; H, 5.53%. From a comparison of the ^{1}H NMR spectrum with those of the authentic samples of **11** and **12**, it was found to be a 1 : 2—3 mixture of **11** and **12**.

When **6** was used instead of **5**, a similar result was obtained; a 1 : 2—3 mixture of **11** and **12** in 57% yield.

DL-*2,3,4-Tri-O-acetyl-(1,2,4/3)-1-C-bromomethyl-5-cyclohexene-1,2,3,4-tetrol (**20**).* A mixture of **5** (0.63 g), silver acetate (0.27 g, 1.1 molar equiv.), and 90% aqueous acetic acid (20 ml) was stirred with protection from light at room temperature for 24 h. The precipitates were then removed by filtration and the filtrate was evaporated to give a syrup, which was chromatographed on a silica-gel column (15 g) with 1 : 3 2-butanone–toluene to give **20** (0.28 g, 52%) as a homogeneous syrup: ^{1}H NMR (60 MHz)[25] δ=2.03 (3H, s), 2.06 (3H, s), and 2.13 (3H, s) (OAc), 2.78 (1H, s, O$\underline{H}$), 3.39 (2H, s, C$\underline{H}_2$Br), 5.21—5.66 (3H, m, H-2, H-3, and H-4), and 5.83 (2H, broad s, H-5 and H-6).

Found: C, 42.51; H, 4.72; Br, 21.60%. Calcd for $C_{13}H_{17}BrO_7$: C, 42.76; H, 4.69; Br, 21.88%.

When **20** was treated with an excess of silver acetate at 90 °C for a prolonged period, no further substitution reaction occurred.

DL-*Tetra-O-acetyl-(1,2,4/3)-1-C-methoxymethyl-5-cyclohexene-1,2,3,4-tetrol (**22**).* To a solution of **20** (0.11 g) in methanol (5 ml) was added 1 M methanolic sodium methoxide (1.3 ml, 4 molar equiv.), and the mixture was allowed to stand at room temperature overnight. After the mixture was neutralized by treatment with Amberlite IR 120 (H^+), it was evaporated and the residue was acetylated in the usual way. The product was chromatographed on a silica-gel column (5 g) with 1 : 3 2-butanone–toluene. The first fraction gave, after recrystallization from ethanol, **22** (7 mg, 6%): mp 130—130.5 °C; ^{1}H NMR (60 MHz)[25] δ=2.02 (3H, s), 2.04 (3H, s), and 2.09 (6H, s) (OAc), 3.29 (3H, s, OC$\underline{H}_3$), 3.39 and 3.83 (AB-quartet, J=5 Hz, C$\underline{H}_2$OCH$_3$), 5.17—5.61 (3H, m, H-2, H-3, and H-4), 5.76 (1H, dd, J=2 and 10 Hz, H-5), and 6.33 (1H, dd, J=1 and 10 Hz, H-6).

Found: C, 53.42; H, 6.08%. Calcd for $C_{16}H_{22}O_9$: C, 53.63; H, 6.19%.

The second fraction gave DL-2,3,4-tri-*O*-acetyl-(1,2,4/3)-1-*C*-methoxymethyl-5-cyclohexene-1,2,3,4-tetrol (**21**) (70 mg, 71%) as a homogeneous syrup: ^{1}H NMR (60 MHz)[25] δ=2.00 (3H, s), 2.03 (3H, s), and 2.06 (3H, s) (OAc), 3.02 (1H, s, O$\underline{H}$), 3.30 (5H, s, OC$\underline{H}_3$ and C$\underline{H}_2$OCH$_3$), 5.03—5.69 (3H, m, H-2, H-3, and H-4), and 5.81 (2H, s, H-5 and H-6).

Found: C, 53.29; H, 6.36%. Calcd for $C_{14}H_{20}O_8$: C, 53.16; H, 6.47%.

Further acetylation of **21** for 9 d gave **22** quantitatively.

*Reaction of **9** with Alcohols in the Presence of Silver Ion.* The results are summarized in Table 2.

General Procedure: To a vigorously stirred solution of **9** (0.3 g), alcohol (5 ml), and Drierite (0.5 g) in dry ether (8 ml) was added silver perchlorate (0.2 g) with ice-cooling under a nitrogen atmosphere, and stirring was continued with protection from light for an appropriate time. After the precipitates had been removed by filtration, the filtrate was washed with saturated aqueous sodium hydrogencarbonate solution and water, and then dried. Evaporation of the solvent left a yellow syrup, which was chromatographed on a silica-gel column (6 g) with 1 : 10 2-butanone–toluene to give the corresponding alkyl ether.

After the alkyl ether had been eluted from the column, a mixture of **15**, **16**, and **23** was separated in 13—15% yield. The ratio of (**15**, **16**) and **23** was estimated to be *ca.* 1 : 1.3 from the ^{1}H NMR spectrum.

With Methanol: DL-2,3,4,7-Tetra-*O*-acetyl-1-*O*-methyl-(1,3/2,4)-5-hydroxymethyl-5-cyclohexene-1,2,3,4-tetrol (**28**) only was formed as a syrup: ^{1}H NMR δ=1.96 (3H, s), 1.98 (3H, s), 2.01 (3H, s), and 2.02 (3H, s) (OAc), 3.34 (3H, s C$\underline{H}_3$), 3.92—4.14 (1H, m, H-1), 4.28 and 4.60 (AB-quartet, J=13 Hz, C$\underline{H}_2$OAc), 5.03—5.35 (2H, m, H-2 and H-3), 5.57—5.76 (1H, m, H-4), and 5.82 (1H, broad s, H-6).

Found: C, 53.48; H, 6.20%. Calcd for $C_{16}H_{22}O_9$: C, 53.63; H, 6.19%.

With Ethanol: A 1 : 4 mixture of DL-2,3,4,7-tetra-*O*-acetyl-1-*O*-ethyl-(1,2,4/3)-5-hydroxymethyl-5-cyclohexene-1,2,3,4-tetrol (**29**) and its C-1 epimer (**30**) was formed as a syrup: ^{1}H NMR for **29**, δ=1.17 (3H, t, J=7.5 Hz, C$\underline{H}_3$CH$_2$), 5.48 (1H,

† 1 M=1 mol dm^{-3}.

t, J=8 Hz, H-3), 5.99 (1H, broad d, J=6 Hz, H-6), and for **30**, δ=1.16 (3H, t, J=7.5 Hz, $C\underline{H}_3CH_2$), 1.97 (3H, s), 2.01 (3H, s), and 2.04 (6H, s) (OAc), 3.57 (2H, q, J=7.5 Hz, $CH_3C\underline{H}_2$), 4.01—4.20 (1H, m, H-1), 4.31 and 4.65 (AB-quartet, J=14 Hz, $C\underline{H}_2OAc$), 5.13—5.33 (2H, m, H-2 and H-3), 5.65—5.78 (1H, m, H-4), and 5.82 (1H, broad s, H-6).

Found: C, 54.90; H, 6.41%. Calcd for $C_{17}H_{24}O_9$: C, 54.83; H, 6.50%.

With 2-Propanol: A 1 : 4 mixture of DL-2,3,4,7-tetra-*O*-acetyl-1-*O*-isopropyl-(1,2,4/3)-5-hydroxymethyl-5-cyclohexene-1,2,3,4-tetrol (**31**) and its C-1 epimer (**32**) was obtained as a syrup: ^{1}H NMR for **31**, δ=5.90 (1H, broad d, J=5 Hz, H-6), and for **32**, δ=1.10 (3H, d, J=6 Hz) and 1.15 (3H, d, J=6 Hz) (CMe_2), 1.97 (3H, s), 1.99 (3H, s), and 2.01 (6H, s) (OAc), 3.65 (1H, heptet, J=6 Hz, $\underline{H}CMe_2$), 3.95—4.15 (1H, m, H-1), 4.25 (1H, d) and 4.59 (1H, broad d) (AB-quartet, J=12 Hz, $C\underline{H}_2OAc$), 5.00—5.31 (2H, m, H-2 and H-3), 5.59—5.72 (1H, m, H-4), and 5.75 (1H, broad s, H-6).

Found: C, 56.25; H, 6.73%. Calcd for $C_{18}H_{25}O_9$: C, 56.10; H, 6.54%.

*Treatment of **9** with Methanolic 1 M Sodium Methoxide.* To a solution of **9** (0.2 g) in methanol (5 ml) was added 1 M sodium methoxide (two drops with a syringe) with vigorous stirring at 0 °C, and the mixture was allowed to stand at room temperature for 3 d. At this time the pH of the mixture was 1. After neutralization with IRA 400 (OH^-), the filtrate was evaporated to give a colorless syrup (79 mg), which showed a negative Beilstein test. The syrup was acetylated and the product was purified by an alumina column, giving a 1 : 1 syrupy mixture (125 mg, 71%) of **27** and **28**. Found: C, 53.43; H, 6.21%. The ^{1}H NMR spectrum of **27** could be read partly in that of the mixture by elimination of the spectrum of **28**: ^{1}H NMR δ=3.39 (3H, s, $OC\underline{H}_3$), 5.45 (1H, t, J=9 Hz, H-3), and 6.02 (1H, broad d, J=6 Hz, H-6).

*Treatment of **9** with Ethanol Containing a Trace of Hydrogen Bromide.* To a stirred solution of **9** (0.27 g) in ethanol (5 ml) was added 30% hydrogen bromide in acetic acid (0.06 ml) at 0 °C, and the mixture was allowed to stand at the same temperature for 5 d. After neutralization with IRA 400 (OH^-), the filtrate was evaporated to give a colorless syrup (83 mg), which had a negative Beilstein test. The syrup was acetylated and the product was purified by an alumina column, giving a 1 : 1 syrupy mixture (155 mg, 64%) of **29** and **30**.

Found: C, 54.93; H, 6.31%. Calcd for $C_{17}H_{24}O_9$: C, 54.83; H, 6.50%.

The authors express their sincere thanks to Mr. Saburo Nakada for his elementally analyses, and to Mr. Masaji Omata and Mr. Yoshikazu Iwasawa for assistance in preparative experiments. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 56550617 from the Ministry of Education, Science and Culture.

19) For the reaction in carbon tetrachloride at low temperature, it is thought that the preferential production of **6** may be due to the slightly increasing polarity of the medium by condensation of water vapor; that is to say, the reaction would follow a similar reaction mechanism with the reaction in acetic acid. This speculation was supported by the production of **13**, **14**, and **20** as side-products. Several attempts to make anhydrous conditions were unsuccessful.

20) For the sake of removal of the trace of water present, acetic acid–acetic anhydride was refluxed for 3 h before use.

Electrophilic Additions of Rigid Methylenecyclohexane. A Correlation of the Stereochemical Course of the Methoxymercuration-demercuration and the 1,3-Dipolar Cycloaddition[1]

Makoto NITTA,* Akihiko OMATA, Setsuko HIRAYAMA, and Yuji YAJIMA
Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160
(Received June 10, 1982)

The stereochemical course of the methoxymercuration-demercurations and the 1,3-dipolar cycloadditions of mesitonitrile oxide on the exocyclic double bonds of 2,4-dimethyl-7-methylenetetracyclo[3.3.0.0.^{2,8}0^{4,6}]octan-3-one (**4a**), its corresponding *exo*-3-ol (**4b**), *endo*-3-ol (**4c**), and 2,3,4-trimethyl-7-methylenetetracyclo[3.3.0.0.^{2,8}0^{4,6}]octan-3-*exo*-ol (**4d**) were investigated. In the methoxymercurations of **4a** and **4b**, the methoxyl group was incorporated in the *exo* and *endo* positions, with *endo* preferred over *exo*. On the other hand, **4c** and **4d** underwent the stereospecific incorporation of the methoxyl group in the *endo* position. In the 1,3-dipolar cycloadditions, **4a** or **4b** afforded *exo*- and *endo*-adducts, with the *exo*-adduct preferred. These results seem to imply similar stereochemical course of the formation of the mercurinium-ion intermediates and the 1,3-dipolar cycloadditions. The results are discussed on the basis of the steric hindrance of the molecular framework and the substituents which are located at the C-3 position.

Recently, stereoselectivities of electrophilic additions of molecules containing proximal π-bonds have been explored.[2-5] Previously, we have also shown that the solvomercuration-demercuration and its related reactions on the exocyclic double bond of 1,5-dimethyl-6-methylenetricyclo[3.2.1.0^{2,7}]oct-3-en-8-one and its related compounds, such as **1**, exhibit a remarkable stereoselectivity to give **2**.[6] This stereoselectivity is explained by the steric hindrance and/or electronic factor[7] of the mercurinium-ion formation and the stereoelectronic control of the subsequent incorporation of the nucleophile. The initial addition of +Hg(OAc) to **1** was supposed to give the mercurinium ions, M-*exo* and M-*endo*, which may exist in equilibrium with each other. The *trans* addition of the nucleophile to M-*exo* is hindered by the repelling interaction of the nucleophile with the π-electron lobe of the endocyclic double bond. Therefore, the nucleophile is incorporated into M-*endo* to give **2**. A similar stereoselectivity is also obtained in the 1,3-dipolar cycloaddition of mesitonitrile oxide (2,4,6-trimethylbenzonitrile oxide) with **1** to lead **3**.[8]

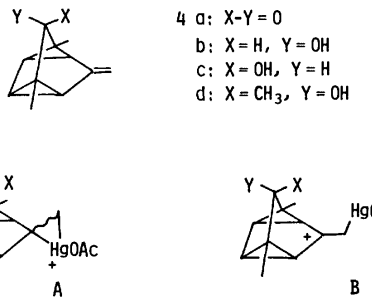
M-endo M-exo

Regarding the mechanistic aspect of the solvomercuration-demercuration of olefins, it has been of further interest to explore the various controlling factor of the stereoselectivities.[9] In this connection, methoxymercuration and 1,3-dipolar cycloadditions, using mesitonitrile oxide, with 2,4-dimethyl-7-methylenetetracyclo[3.3.0.0.^{2,8}0^{4,6}]octan-3-one (**4a**), its corresponding *exo*-3-ol (**4b**), *endo*-3-ol (**4c**), and 2,3,4-trimethyl-7-methylenetetracyclo[3.3.0.0.^{2,8}0^{4,6}]octan-3-*exo*-ol (**4d**) were investigated. The compounds, **4a—d**, contain a boat methylenecyclohexane ring and various degrees of steric hindrance at C-3. Furthermore, **4a—d** also contain a bishomofulvene moiety. Therefore, the methoxymercuration-demercuration sequences should proceed *via* a mercurinium ion intermediate (**A**), because of the bishomoantiaromatic nature of the opened cation (**B**).[10] Consequently, it might be possible to assess how the steric hindrance affects the stereochemical courses of the methoxymercuration and 1,3-dipolar cycloadditions. We wish to discuss here the stereochemical correlation between the solvomercuration reactions and the concerted 1,3-dipolar cycloadditions of mesitonitrile oxide.

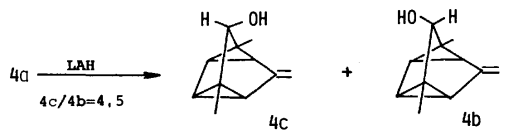


A B

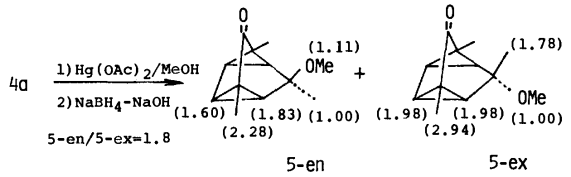
Results and Discussion

Methoxymercuration-demercuration Reactions. The preparation of **4a** and **4b** was previously reported.[11] The preparation of **4d** was also achieved by the photoirradiation of 1,5,8-trimethyl-6-methylenetricyclo[3.2.1.0^{2,7}]oct-3-en-8-*endo*-ol[12] (see Experimental section). The *endo* alcohol derivative **4c** was prepared by the reduction of **4a** with lithium aluminium hydride (LAH), along with *exo* alcohol **4b**. The ratio of **4c**/**4b** (4.5) would indicate the stereochemical preference of the *exo*-attack of the hydride ion.

A solution of **4a** in anhydrous methanol was allowed to react with 1.2 molar equivalent of mercury(II) acetate. The reaction proceeded very slowly, and, after a total reaction time of 6 h, *in situ* reduction[13] by sodium

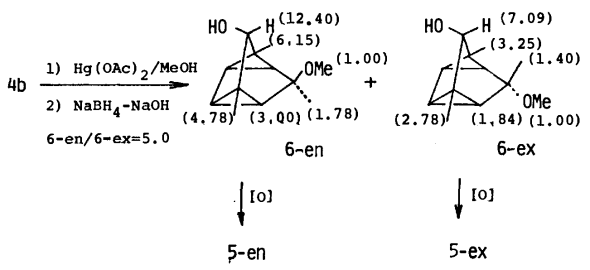


borohydride gave a 58% overall yield of two products, along with a recovery of **4a** in a 26% yield. The methoxyl group was incorporated preferentially at the more hindered site (see the ratio of **4c**/**4b** in the reduction of **4a** with LAH), giving the *endo* and *exo* isomer, **5**-en and **5**-ex, in a ratio of 1.8/1.0. The structural assignment to **5**-en and **5**-ex follows convincingly from their spectral properties. The carbonyl absorption band at 1710 cm^{-1} of **4a** was shifted to 1721 cm^{-1} and 1713 cm^{-1} for **5**-en and **5**-ex respectively. The NMR spectra of **5**-en and



5-ex exhibited five signals, suggesting the symmetric structures (see Experimental section). These facts clearly indicate that the methoxymercuration-demercuration occurred on the exocyclic double bond. The protons of the methoxyl group and the methyl group at C-7 of **5**-en appear as singlets at δ 3.16 and δ 1.46 respectively. For **5**-ex, these signals appear at δ 3.34 and δ 1.23. These characteristics suggest that the methoxyl group of **5**-en and the methyl group of **5**-ex are much shielded by the σ-bond in the molecular framework. Therefore, the orientations of the methoxyl group of **5**-en and **5**-ex were determined as depicted. Furthermore, supportive evidence for the stereochemistries of the methoxyl group was also obtained from the pseudo-contact NMR spectra obtained by using Eu(fod)$_3$.[14] The relative downfield shifts of δ's are given in parentheses in the structural formulae **5**-en and **5**-ex. The relatively small shifts of the methoxyl groups of **5**-en and **5**-ex suggest that the coordination of Eu(fod)$_3$ does not occur on methoxyl oxygen, but on the carbonyl oxygen. The small shift (1.00) of the methyl group of **5**-en as compared to that (1.78) of **5**-ex suggests that the methyl group of **5**-ex is located syn to the carbonyl group. Consequently, the stereochemistry of **5**-en and **5**-ex was clarified.

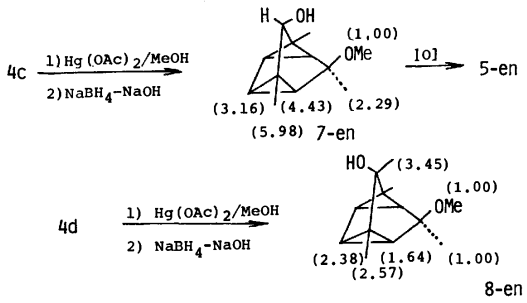
The reaction of **4b** with mercury(II) acetate and subsequent reduction afforded two products, **6**-en and **6**-ex, in a ratio of 5.0/1.0 and in a 73% yield, along



with the starting material, **4b**, in a 25% yield. The structures of **6**-en and **6**-ex were deduced from the spectral data (see Experimental section). The pseudo-contact NMR spectra obtained by using Eu(fod)$_3$,[14] however, could not reveal the stereochemistry of the methoxyl group.

On the oxidation of **6**-en or **6**-ex with pyridinium chlorochromate,[15] **5**-en or **5**-ex was obtained in a fairly good yield. Therefore, the stereochemistry of **6**-en and **6**-ex was confirmed. In this case, the methoxyl group is also incorporated preferentially at the more hindered site.

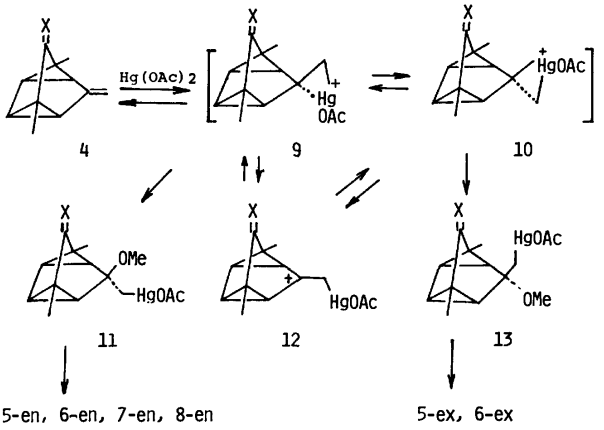
On the other hand, the reaction of **4c** or **4d** with 1.2 molar equivalents of mercury(II) acetate and the subsequent reduction afforded a single product, **7**-en or **8**-en, in a 70% or in a 60% yield respectively, along with the starting material, **4c** (21%) or **4d** (20%). The structures of **7**-en and **8**-en were deduced from the spectral data (see Experimental section). The large coupling constant (J=12.0 Hz) between the protons at C-3 and the hydroxyl proton for **7**-en indicates the intramolecular hydrogen bonding of the hydroxyl hydrogen with methoxyl oxygen. Furthermore, on oxidation with pyridinium chlorochromate, **7**-en was



converted to **5**-en in a fairly good yield. Consequently, the stereochemistry of the methoxyl group was assessed. In this case, the methoxyl group was also introduced at the more hindered site. The stereochemistry of the methoxyl group in **8**-en is not clear from its pseudo-contact NMR spectra obtained by using Eu(fod)$_3$,[14] however, the orientation can tentatively be assigned as *endo* on the basis of the similarities of the preferential *endo* orientation in the reactions of **4a**—**c**.

In all of the presented reactions, methanol was incorporated preferentially from the much-hindered site on the exocyclic double bond (see the ratio of **4c**/**4b** in the reduction of **4a** with LAH), and the original tetracyclic skeleton did not undergo rearrangement. These results seems to suggest the formation of such mercurinium ions as **9** and **10**, as is shown in the scheme.[16-19] Such cationic species[20-22] as **12** should be energetically unfavorable because of an antiaromatic nature of the bishomocyclopentadienyl cation,[10] which would be expected to undergo rearrangement.[23] Recently it has been shown that 3-methyltetracyclo[3.3.0.0.^{2,8}0^{4,6}]-octan-3-yl cation rearranges to another compound at −95 °C.[24] Previously, we have shown that the stabilization of the cationic center of the cyclopropylmethyl cation by the mercury moiety adjacent to the cationic center is preferable over the resonance-electron donation

of the cyclopropane ring.[6] Therefore the cationic center would be stabilized by making such mercurinium ions as **9** and **10**. In the initial addition of $+Hg(OAc)$[25] to the exocyclic double bond, the formation of **9** seems to be faster than the formation of **10** because of the steric hindrance of the molecular framework and the substituent at C-3. Furthermore, **9** should also be thermodynamically more stable than **10**, because of the

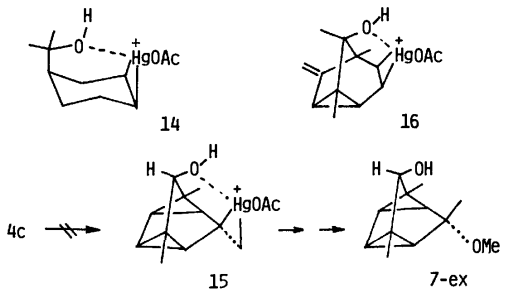


nonbonded interaction of the substituent with the mercury moiety. If the rapid equilibrium between **9** and **10** *via* the possible short-lived intermediate **12** or *via* the mercuration-demercuration sequence is thought to participate in the present reaction, the equilibrium between **9** and **10** should be shifted to **9** as well. Consequently, the *trans* addition of methanol, affording **11** or **13**, and the subsequent reaction should give **5**-en, **6**-en, **7**-en, and **8**-en or **5**-ex and **6**-ex.

The *endo-exo* ratio in the case of **4a** is 1.8, while that in the case of **4b** is 5.0. These values probably reflect the large steric hindrance of the hydrogen at C-3 with the mercury moiety, as compared to that of the carbonyl group in **4a**. Furthermore, in the case of **4c** and **4d**, the hydroxyl group and the methyl group are larger than hydrogen, so such mercurinium ion as **10** should be absent, and only **7**-en or **8**-en could be obtained *via* **9**.

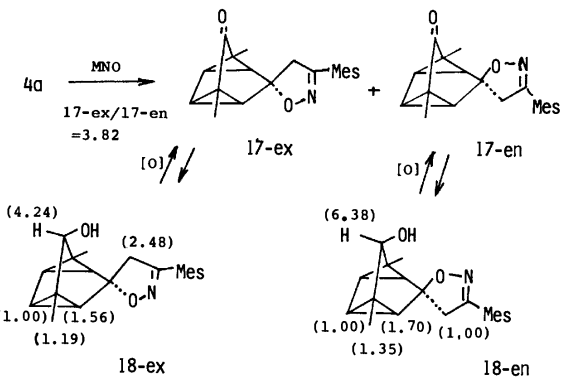
The stereocontrol by a neighboring hydroxyl group in oxymercuration has been demonstrated to proceed *via* an intermediate such as **14**, which includes a favorable interaction of the hydroxyl group with the mercury moiety.[26] In the reaction of **4c**, however, no expected product, such as **7**-ex *via* **15**, could be obtained. In **14**, the hydroxyl group, which is located close to the bisected plane including the mercurinium ion, should coordinate to the mercury moiety in such a way as to make a tetrahedral arrangement. In **15**, however, the hydroxyl group is located on the plane including the postulated mercurinium ion. Therefore, it can be suggested that the interaction of hydroxyl oxygen with the mercurinium ion is not possible in a planar arrangement such as **15**. Also indicated is a favorable interaction of the mercury moiety with the hydroxyl oxygen, which is located on the bisected plane of a postulated mercurinium ion such as **16**.[8]

1,3-Dipolar Cycloaddition of Mesitonitrile Oxide. As has been described above, the solvomercuration of



4a—d seemed to be much affected by the steric hindrance of various substituents at C-3 in the step of mercurinium-ion formation. A study dealing with the steric hindrance is of interest in order to gain insight into the correlation between the mercurinium-ion formation and the 1,3-dipolar cycloaddition, in which two bonds are formed in a concerted manner. For this reason, the steric effect of substituents located at C-3 was investigated. Less is known about the influence of the steric hindrance in concerted 1,3-dipolar cycloadditions. However, it has been shown that the relative rates of the cycloaddition of aromatic nitrile oxide with substituted ethylenes are influenced by the steric factor.[27]

The cycloaddition of **4a** with mesitonitrile oxide (MNO) in dichloromethane gave **17**-ex and **17**-en in 42 and 11% yields respectively. The structural assignment of **17**-ex and **17**-en follows convincingly from their physical properties and the chemical transformations. The carbonyl absorption bands at 1711 cm^{-1} for **17**-ex and, at 1706 cm^{-1} for **17**-en suggest the existence of the tetracyclic skeleton. The mass spectral data, as well as the analytical data, suggest that **17**-ex and **17**-en are one-to-one adducts of **4a** and MNO. The NMR

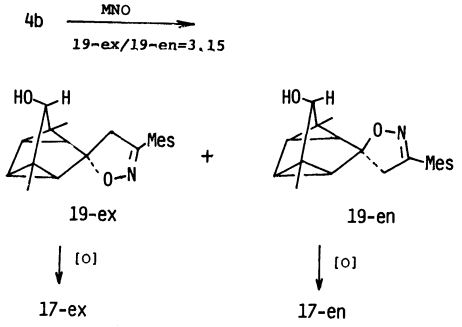


spectra suggested the symmetric structures (see Experimental section), and the addition occurred on the exocyclic double bond of **4a**. The chemical shifts of the protons of the isoxazoline moiety of **17**-ex (δ 3.09) and of **17**-en (δ 3.27) are suggestive of the regiochemistry of the C=N–O moiety, as is depicted.[28] On the reduction of **17**-ex or **17**-en with sodium borohydride, **18**-ex and **18**-en were obtained in good yields. On the oxidation of **18**-ex and **18**-en with pyridinium chlorochromate, **17**-ex and **17**-en were regenerated. The skeletons of **17**-ex and **17**-en are not changed in these chemical

transformations.

The stereochemical arrangements of the C=N–O moiety in **18**-ex and **18**-en were obtained from pseudo-contact NMR spectra obtained by using $Eu(fod)_3$.[14] The relative downfield shifts of δ's of hydrogens for the isoxazoline moiety are 2.48 for **18**-ex and 1.00 for **18**-en. Therefore, it is clarified that the coordination of $Eu(fod)_3$ occurs on the hydroxyl oxygens and that the C=N–O moieties are exo for **18**-ex and endo for **18**-ex. Consequently, the stereochemical arrangements of **17**-ex and **17**-en are assessed.

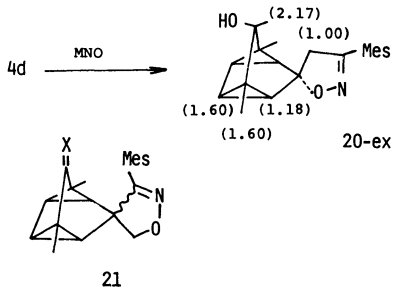
Similarly, **4b** and MNO gave two adducts, **19**-ex and **19**-en, in 63 and 20% yields respectively. On oxidation with pyridinium chlorochromate, **19**-ex and **19**-en were converted to **17**-ex and **17**-en respectively.



This chemical transformation and the results of a comparison of the spectral data with those of **17**-ex, **17**-en, **18**-ex, and **18**-en revealed the structures of **19**-ex and **19**-en convincingly.

On the other hand, **4d** and MNO gave a single adduct, **20**-ex, in an 80% yield, along with 10% of the starting material, **4d**. The structure was deduced from the spectral data. The stereochemical arrangement of the C=N–O moiety is not clarified from the pseudo-contact NMR spectra, however, it should be *exo* because of the large steric effect of the methyl group on C-3.

The regiochemistry of the present cycloadditions seems to suggest the electrophilic nature of MNO, since the unsubstituted terminus of dicyclopropylethylene (large



HOMO coefficient) was bound to the carbon terminus of MNO (larger LUMO coefficient).[29] The regiochemistry observed here is also favorable for a steric reason: the van der Waals non-bonded interaction energies should be very large in such material as **21** as compared to the above products. Recently, theoretical as well as experimental studies of the 1,3-dipolar cycloadditions of nitrile oxide with methyleneadamantane have been shown to exhibit a regiochemistry similar to that of the present reactions.[28]

In the case of the reaction of **4a**, **17**-ex/**17**-en is 3.82, while in that of **4b**, **19**-ex/**19**-en is 3.5. The reaction of **4d**, which has the methyl group at C-3 position, gave only **20**-ex. Previously, the degree of polarization of the exocyclic double bonds of **4a** and **4b** has been ascertained from the ^{13}C-NMR values, in which the electron-withdrawing carbonyl group seems to reduce the polarization through two cyclopropane rings.[30] Therefore, the possible π-orbital distortion of the exocyclic double bond may also conceivably affect the exo, endo-selectivity.[31] However, the increase in the *exo*-adduct **20**-ex upon the introduction of the bulky group on C-3, like the decrease in the *endo* products observed for mercuration reactions of **4a**—**d**, can be classified as a steric effect. The value of **5**-en/**5**-ex (1.8), which could correspond to the ratio of the mercurinium-ion formation of **9**/**10** for the ketone **4a**, is smaller than that of **17**-ex/**17**-en (3.82). The much suppressed **17**-en formation, as compared to that of **17**-ex, may be attributable to the coulombic repulsion of mesitonitrile oxide with the π-electron of the carbonyl function at C-3. Since similar trends for the *exo-endo* ratios of the postulated mercurinium ion formation and the 1,3-dipolar cycloaddition are obtained here, the steric effect seems to affect the reaction pathways in a similar manner. The stereochemical courses of the mercuration reactions of various kinds of compounds may be clarified in comparison with the reaction such as 1,3-dipolar cycloadditions, which involve a two-bond-forming process in the reaction sequences.

Experimental

The IR spectra were recorded on a Shimadzu IR-400 spectrometer. The mass spectral studies were conducted using a Hitachi RMU-60 spectrometer. All NMR spectra were recorded on a JEOL PS-100 high resolution spectrometer, using tetramethylsilane as the internal standard. The shift data were obtained by adding small increments of $Eu(fod)_3$ to the sample and by the n noting the extent to which each peak was shifted. The relative shift-slopes were obtained by dividing each slope by the slope of the least-shifted signal. VPC separations were performed on a Varian model-920 chromatograph, using a column packed with 5% FFAP on Chromosorb W at 110 °C. The analyses were performed by the Science and Engineering Research Laboratory, Waseda University.

Methoxymercuration-demercuration of ***4a***. A solution of **4a** (400 mg, 2.5 mmol) and mercury(II) acetate (960 mg, 3.0 mmol) in 8 cm^3 of anhydrous methanol was stirred for 6 h at room temperature. To this reaction mixture, was added 2.6 cm^3 of 3 mol dm^{-3} aqueous sodium hydroxide. After stirring for 15 min, 10 cm^3 of brine was added to the reaction mixture and mercury precipitated was filtered through Celite. The filtrate was extracted with ether, and the ether extract was dried over sodium sulfate. The removal of the ether *in vacuo* gave an oily material, which was separated by TLC on silica gel, using dichloromethane as the eluent, to give 99 mg (25%) of **4a** and a mixture of **5**-en and **5**-ex in a ratio of 177 mg (37%)/99 mg (21%). This mixture was separated by VPC to give pure **5**-en and **5**-ex. For **5**-en: IR (CCl_4), 2974, 2930, 1721, 1138, 873 cm^{-1}; NMR (CCl_4), δ 1.05 (6H, s), 1.46 (3H, s), 1.53 (2H, d, J=6.0 Hz), 2.10 (2H, d, J=6.0 Hz), 3.16 (3H,

s); MS, *m/e* (rel intensity), 192 (M^+, 63), 161 (100). Found: C, 74.78; H, 8.17%. Calcd for $C_{12}H_{16}O_2$: C, 74.97; H, 8.39% For **5**-ex: IR (CCl_4), 2983, 2939, 1713, 1068, 869 cm^{-1}; NMR ($CDCl_3$), δ 1.05 (6H, s), 1.23 (3H, s), 1.52 (2H, d, J=6.0 Hz), 2.24 (2H, d, J=6.0 Hz), 3.34 (3H, s); MS, *m/e* (rel intensity), 192 (M^+, 63), 161 (100). Found: C, 74.99; H, 8.70%. Calcd for $C_{12}H_{16}O_2$: C, 74.97; H, 8.39%.

Methoxymercuration-demercuration of ***4b***. A solution of **4b** (452 mg, 2.79 mmol) and mercury(II) acetate (1.069 g, 3.35 mmol) in 10 cm^3 of anhydrous methanol was stirred at room temperature for 8 h, followed by the addition of 5 cm^3 of 3 mol dm^{-3} aqueous sodium hydroxide and then sodium borohydride (127 mg, 3.35 mmol) in 5 cm^3 of aqueous sodium hydroxide. A workup similar to that described above gave 502 mg of an oil, which was revealed by VPC analysis and NMR spectroscopy to contain **4b** (112 mg, 25%), **6**-en (328 mg, 61%), and **6**-ex (63 mg, 12%). For **6**-en: IR (CCl_4), 3515—3294 (broad band), 2939, 1136, 1059, 1024 cm^{-1}; NMR (CCl_4), δ 1.11 (6H, s), 1.28 (3H, s), 1.28 (2H, d, J=5.7 Hz, overlapping with methyl signal), 1.59 (2H, d, J=5.7 Hz), 2.75 (1H, s), 3.15 (3H, s), 3.93 (1H, s). For **6**-ex: IR (CCl_4), 3561—3393 (broad band), 2939, 1076, 1061, 1023 cm^{-1}; NMR (CCl_4), δ 1.11 (6H, s), 1.18 (3H, s), 1.18 (2H, d, J=5.7 Hz, overlapping with methyl signal), 1.71 (2H, d, J=5.7 Hz), 1.8—2.0 (1H, broad s), 3.26 (3H, s), 3.56 (1H, s).

Oxidation of ***6****-en*. A suspension of pyridinium chlorochromate (141 mg, 0.65 mmol), anhydrous sodium acetate (11 mg, 0.14 mmol), and **6**-en (70 mg, 0.36 mmol) in 5 cm^3 of dichloromethane was stirred for 6 h under a nitrogen atmosphere. The reaction mixture was then chromatographed on Florisil, using dichloromethane as the eluent, to give a quantitative yield of **5**-en, which was identical with the authentic specimen.

Oxidation of ***6****-ex*. A suspension of pyridinium chlorochromate (50 mg, 0.22 mmol), anhydrous sodium acetate (4 mg, 0.04 mmol), and **6**-ex (24 mg, 0.12 mmol) in 2 cm^3 of dichloromethane was stirred for 6 h under a nitrogen atmosphere. The reaction mixture was then chromatographed on Florisil, using dichloromethane as the eluent, to give 18 mg (76%) of **5**-ex, which was identical with the authentic specimen.

Methoxymercuration-demercuration of ***4c***. A solution of **4c** (300 mg, 1.85 mmol) and mercury(II) acetate (709 mg, 2.23 mmol) in 5 cm^3 of anhydrous methanol was stirred for 11 h at room temperature, followed by the addition of 2 cm^3 of 3 mol dm^{-3} aqueous sodium hydroxide and sodium borohydride (85 mg, 2.23 mmol) in 2 cm^3 of 3 mol dm^{-3} aqueous sodium hydroxide. A workup similar to that described above gave 312 mg of an oil, which was revealed by VPC and NMR spectroscopy to contain **4c** (63 mg, 21%) and **7**-en (251 mg, 70%). This mixture was separated by VPC to afford pure **4c** and **7**-en. For **7**-en: IR (CCl_4), 3422, 2956, 1461, 1128, 1045 cm^{-1}; NMR (CCl_4), δ 1.06 (6H, s), 1.12 (2H, d, J=6.0 Hz), 1.38(3H, s), 1.46 (2H, d, J=6.0 Hz), 3.02 (3H, d, J=12.0 Hz) ,3.28 (3H, s), 3.83 (1H, d, J=12.0 Hz).

Oxidation of ***7****-en*. A mixture of pyridinium chlorochromate (141 mg, 0.65 mmol), anhydrous sodium acetate (11 mg, 0.14 mmol), and **7**-en (69 mg, 0.36 mmol) in 5 cm^3 of dichloromethane was stirred for 5 h at room temperature under a nitrogen atmosphere. The reaction mixture was then chromatographed on Florisil, using dichloromethane as the eluent, to give 53 mg (78%) of **5**-en, which was identified with the authentic specimen.

Methoxymercuration-demercuration of ***4d***. A solution of **4d** (500 mg, 2.84 mmol) and mercury(II) acetate (1.008 g, 3.42 mmol) in 10 cm^3 of anhydrous methanol was stirred for 11 h at 40 °C, followed by the addition of 5 cm^3 of 3 mol dm^{-3} aqueous sodium hydroxide and sodium borohydride (130 mg, 3.42 mmol) in 5 cm^3 of 3 mol dm^{-3} aqueous sodium hydroxide. A workup similar to that described above gave 424 mg of an oil, which was revealed to contain **4d** (102 mg, 20%) and **8**-en (321 mg, 64%). This oil was separated by VPC to afford pure **8**-en: IR (CCl_4), 3586, 3451, 2965, 2939, 1383, 1130, 1065, 919 cm^{-1}; NMR (CCl_4), δ 1.00 (6H, s), 1.24 (3H, s), 1.29 (3H, s), 1.08 (2H, d, J=6.0 Hz), 1.43 (2H, d, J=6.0 Hz). Found: C, 74.86; H, 9.29%. Calcd for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68%.

Reduction of ***4a*** *with Lithium Aluminium Hydride (LAH)*. A solution of **4a** (875 mg, 5.47 mmol) and LAH (208 mg, 5.47 mmol) in 10 cm^3 of anhydrous tetrahydrofuran was refluxed for 5 h. The usual workup afforded 735 mg (83%) of a mixture of **4b** (133 mg, 15%) and **4c** (602 mg, 68%). This mixture was separated by VPC to afford pure **4b** and **4c**. For **4c**: NMR (CCl_4), δ 1.10 (6H, s), 1.58 (2H, d, J=6.0 Hz), 1.82 (2H, d, J=6.0 Hz), 3.97 (1H, broad s), 4.83 (2H, s); MS, *m/e* (rel intensity), 162 (M^+, 23), 58 (100).

Irradiation of 1,5,8-Trimethyl-6-methylenetricyclo[3.2.1.0^{2,7}*]oct-3-en-8-*endo*-ol*. A solution of the tricyclic alcohol (1.0 g, 5.68 mmol) in 200 cm^3 of anhydrous acetonitrile was irradiated using RPR-254 nm lamps for 48 h under a nitrogen atmosphere. After the removal of the solvent, the residue was chromatographed on alumina (30 g), using benzene as the eluent, to give **4d**, which was then recrystallized from hexane to give 582 mg (58%) of pure **4b**: IR (CCl_4), 3595, 3437, 2974, 1653, 1443, 1379, 1342, 1131, 925, 862 cm^{-1}; NMR (CCl_4), δ 1.02 (3H, s), 1.05 (6H. s), 1.45 (2H, d, J=6.0 Hz), 1.77 (2H, d, J=6.0 Hz), 4.76 (2H, s). Found: C, 81.57; H, 9.17%. Calcd for $C_{12}H_{16}O_2$: C, 81.77; H, 9.15%.

Cycloaddition of ***4a*** *with Mesitonitrile Oxide (2,2,6-Trimethylbenzonitrile Oxide)*. A solution of **4a** (160 mg, 1 mmol) and mesitonitrile oxide (161 mg, 1 mmol) in 4 cm^3 of dichloromethane was refluxed for 4 d. After solvent removal *in vacuo*, the resulting residue was separated by TLC on silica gel, using dichloromethane as the eluent. The first band from the TLC plates gave 12 mg (8%) of **4a**. The second band from the TLC plates gave 134 mg (42%) of colorless crystals of **17**-ex: mp 164—165 °C (from ethanol); IR (KBr) 1711, 1609, 1333, cm^{-1}; NMR ($CDCl_3$), δ 1.12 (6H, s), 1.97 (2H, d, J=6.0 Hz) 2.20 (9H, s), 2.48 (2H, d, J=6.0 Hz), 3.09 (2H, s), 6.80 (2H broad s); MS, *m/e* (rel intensity), 321 (M^+, 61), 159 (100). Found: C, 78.62; H, 7.14; N, 4.28%. Calcd for $C_{21}H_{23}O_2N$: C, 78.47; H, 7.21; N, 4.36%. The third band from the TLC plates gave 34 mg (11%) of **17**-en: mp 288—289 °C (from ethanol); IR (KBr), 1706, 1610, 1332 cm^{-1}; NMR ($CDCl_3$), δ 1.15 (6H, s), 1.75 (2H, d, J=6.0 Hz), 2.23 (9H, s), 2.26 (2H, d, J=6.0 Hz), 3.27 (2H, s), 6.83 (2H, s); MS, *m/e* (rel intensity), 321 (M^+, 27), 159 (100). Found: C, 78.41; H, 7.21; N, 4.18%. Calcd for $C_{21}H_{23}O_2N$: C, 78.47; H, 7.21; N, 4.36%.

Reduction of ***17****-ex*. A solution of **17**-ex (70 mg, 0.22 mmol) and sodium borohydride (9 mg, 0.22 mmol) in 11 cm^3 of benzene–ethanol (10/1) was stirred overnight. This reaction mixture was concentrated and extracted with dichloromethane, and then the extract was dried over sodium sulfate. After solvent removal *in vacuo*, the residue was recrystallized from ethanol to give 56 mg (80%) of **18**-ex: mp 230—231 °C; IR (KBr), 3309, 1601, 1333, 1067 cm^{-1}; NMR ($CDCl_3$), δ 1.13 (6H, s), 1.63 (2H, d, J=6.0 Hz), 1.82 (2H, d, J=6.0 Hz), 2.27 (9H, s), 3.37 (2H, s), 4.17 (1H, d, J=3.7 Hz), 6.85 (2H, s).

Oxidation of ***18****-ex*. To a suspension of pyridinium chlorochromate (20 mg, 0.093 mmol) and anhydrous sodium acetate (2 mg), was added **18**-ex (17 mg, 0.052 mmol) in 0.5 cm^3 of dichloromethane under a nitrogen atmosphere. This mixture was stirred for 3 h. Reaction mixture was then chromatographed on Florisil, using dichloromethane as the eluent, to give 14 mg (84%) of **17**-ex.

Reduction of ***17****-en.* The reduction was carried out as has been described above using 48 mg (0.3 mmol) of **17**-en and 6 mg (0.15 mmol) of sodium borohydride. The product was recrystallized from ethanol to give 39 mg (80%) of **18**-en: mp 193—194 °C; IR (KBr), 3468, 1609, 1321, 1043 cm^{-1}; NMR ($CDCl_3$), δ 1.17 (6H, s), 1.35 (2H, d, J=6.0 Hz), 1.68 (2H, d, J=6.0 Hz), 2.26 (9H, s), 3.02 (1H, d, J=11.6 Hz), 3.17 (2H, s), 4.15 (1H, d, J=11.6 Hz), 6.90 (2H, s).

Oxidation of ***18****-en.* The reaction was carried out using **18**-en (30 mg, 0.09 mmol), pyridinium chlorochromate (30 mg, 0.14 mmol), and anhydrous sodium acetate (3 mg). A workup similar to that described above afforded **17**-en (26 mg, 82%).

Cycloaddition of ***4b*** *with Mesitonitrile Oxide.* A solution of **4b** (324 mg, 2 mmol) and mesitonitrile oxide (322 mg, 2 mmol) in 6 cm^3 of dichloromethane was refluxed for 56 h. The reaction was monitored by TLC (silica gel, dichloromethane). After solvent removal *in vacuo*, the resulting residue was separated by TLC on silica gel, using dichloromethane as the eluent. The first band from the TLC plates afforded 404 mg (63%) of **19**-ex: mp 158—159 °C (from ethanol); IR (KBr), 3307, 1609, 1062 cm^{-1}; NMR ($CDCl_3$), δ 1.13 (6H, s), 1.65 (2H, d, J=6.0 Hz), 1.95 (2H, d, J=6.0 Hz), 2.21 (9H, s), 3.00 (2H, s), 3.50 (1H, d, J=8.0 Hz), 6.86 (2H, s). Found: C, 77.80; H, 7.82; N, 4.24%. Calcd for $C_{21}H_{25}O_2N$: C, 77.98; H, 7.79; N, 4.33%. The second band from the TLC plates gave 127 mg (20%) of **19**-en: mp 205—206 °C (from ethanol); IR (KBr), 3386, 1604, 1331 cm^{-1}; NMR ($CDCl_3$), δ 1.23 (6H, s), 1.38 (2H, d, J=6.0 Hz), 1.84 (2H, d, J=6.0 Hz), 2.27 (9H, s), 3.15 (2H, s), 4.26 (1H, d, J=7.8 Hz), 6.09 (2H, s). Found: C, 77.82; H, 7.78; N, 4.66%. Calcd for $C_{21}H_{25}O_2N$: C, 77.98; H, 7.79; N, 4.38%.

Oxidation of ***19****-ex.* The reaction was carried out using **19**-ex (100 mg, 0.31 mmol), pyridinium chlorochromate (100 mg, 0.31 mmol), and anhydrous sodium acetate (20 mg, 0.24 mmol). A workup similar to that described above afforded 83 mg (83%) of **17**-ex, which was characterized by the spectral data.

Oxidation of ***19****-en.* The oxidation was carried out as has been described above, using 50 mg (0.15 mmol) of **19**-en, pyridinium chlorochromate (60 mg, 0.08 mmol), and anhydrous sodium acetate (6 mg, 0.08 mmol). Exactly the same workup as has been described above afforded 28 mg (57%) of **17**-en, which was identified by a mixed-melting-point determination and by a comparison of the spectral data.

Cycloaddition of ***4d*** *with Mesitonitrile Oxide.* A solution of **4d** (176 mg, 1 mmol) and mesitonitrile oxide (161 mg, 1 mmol) in 3 cm^3 of benzene was refluxed for 7 h. After solvent removal *in vacuo*, the resulting residue was separated by TLC on silica gel, using dichloromethane as the eluent. The first band from the TLC plates contained 17 mg (10%) of **4d**. The second band from the TLC plates afforded 279 mg (82%) of the adduct, **20**-ex: mp 163—164 °C; IR ($CHCl_3$), 3340—3210, 1611 cm^{-1}; NMR ($CDCl_3$), δ 1.11 (6H, s), 1.16 (3H, s), 1.62 (2H, d, J=6.0 Hz), 1.86 (2H, d, J=6.0 Hz), 2.24 (6H, s), 2.25 (3H, s), 3.15 (2H, s), 6.84 (2H, s); MS, *m/e* (rel intensity), 337 (M^+, 21), 294 (100). Found: C, 78.07; H, 7.83; N, 3.95%. Calcd for $C_{22}H_{27}O_2N$: C, 78.30; H, 8.07; N, 4.15%.

Studies on 2-Aziridinecarboxylic Acid. IX.[1] Convenient Synthesis of Optically Active *S*-Alkylcysteine, *threo*-*S*-Alkyl-β-methylcysteine, and Lanthionine Derivatives *via* the Ring-opening Reaction of Aziridine by Several Thiols

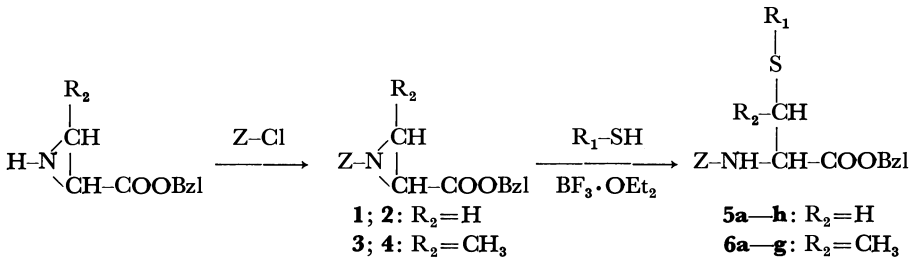
Kiichiro NAKAJIMA,* Hitomi ODA, and Kenji OKAWA
Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Nishinomiya 662

(Received June 11, 1982)

A convenient synthesis of optically active *S*-alkylcysteine, *threo*-*S*-alkyl-β-methylcysteine, and lanthionine derivatives has been investigated. Benzyl 1-benzyloxycarbonyl-(2*S*)-2-aziridinecarboxylate and benzyl (2*S*,3*S*)-1-benzyloxycarbonyl-3-methyl-2-aziridinecarboxylate, and their enantiomers were treated with several thiols, and the corresponding *S*-alkylcysteine, *threo*-*S*-alkyl-β-methylcysteine, and lanthionine derivatives were prepared *via* the ring-opening reaction of aziridine in the presence of a catalytic amount of boron trifluoride etherate in good yields.

Our previous paper[2] reported on the reaction of 1-aminoacyl-2-aziridinecarboxylic acid peptide, namely Z-Gly-L-Azy-Gly-OBzl, with thiophenol, and preparation of the corresponding *S*-phenylcysteine-containing peptide *via* the ring-opening reaction of the aziridine. Bernstein and Ben-Ishai[3] also reported that the 1-substituted 2-aziridinecarboxylate was transformed into the corresponding DL-*S*-methylcysteine derivative *via* a similar ring-opening reaction of the aziridine.

This study reports the synthesis of several optically active *S*-alkylcysteines, *threo*-*S*-alkyl-β-methylcysteines, and lanthionines *via* the ring-opening reaction of (2*S*)-Z-Azy-OBzl (**1**), (2*S*,3*S*)-Z-3-MeAzy-OBzl (**2**), and their enantiomers (**3**, **4**); these were prepared from the corresponding optically active serine and threonine as described in our previous papers.[4] The reactions were carried out with the appropriate thiols. The reaction procedure is shown in Scheme 1.



Scheme 1.

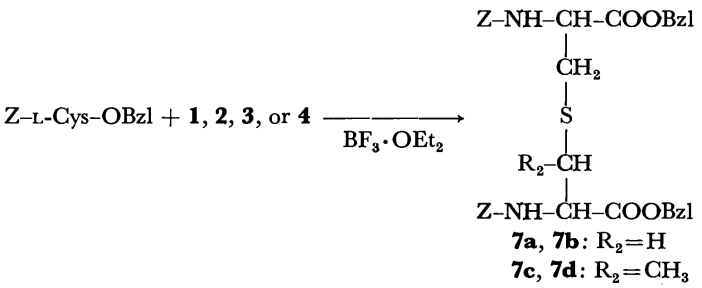
a) The result of (2*S*)-Z-Azy-OBzl(**1**) and (2*S*, 3*S*)-Z-3-MeAzy-OBzl(**3**) with R_1SH. b) The result of (2*R*)-Z-Azy-OBzl(**2**) with $C_6H_5CH_2SH$.

We carried out the reaction of **1**, **2**, or **3** (1 mmol) with a large excess of thiol in a solution of dichloromethane (3 ml) containing a catalytic amount of boron trifluoride etherate at room temperature. The Azy derivatives were very stable in the thiol solution and the ring-opening reaction did not occur at all, but when boron trifluoride etherate was added, the expected ring-opening reaction easily occurred.



Scheme 2.

Table 2. Properties and yields of lanthionine derivatives (**7a—d**)

Product[a]		Yield/%	Mp θ_m/°C	$[\alpha]_D^{23}$/°(MeOH)
Z-L-Ala-OBzl S Z-L-Ala-OBzl	(**7a**)	37	94.5—95.0	−31.5(*c* 1.1)
Z-L-Ala-OBzl S Z-D-Ala-OBzl	(**7b**)	21	86—87	—
Z-L-Ala-OBzl S Z-L-Aba-OBzl	(**7c**)[b]	22	Syrup	−11.6(*c* 1.0)
Z-L-Ala-OBzl S Z-D-Aba-OBzl	(**7d**)[b]	12	104.5—107	−32.0(*c* 1.1)

a) The reaction was carried out in a CH_2Cl_2 solution at 20 °C for 5 d, and Z-L-Cys-OBzl used was 1 equimolar against the Azy derivatives (**1**, **2**, **3**, and **4**). b) Aba: *threo*-2-aminobutylic acid residue.

The reaction results summarized in Table 1 show that this ring-opening reaction of aziridine is very convenient for synthesizing the optically active *S*-substituted cysteine (**5**) and β-methylcysteine (**6**) derivatives. In paticular, the optically active *threo*-β-methylcysteine derivatives (**6**) retained the original configuration of the starting threonine *via* two stereospecific procedures. That is, the aziridine ring-formation and the ring-opening procedures. Thus, the *allo*-threonine derivative is not needed as the starting material to prepare *S*-alkyl-*threo*-β-methylcysteine derivatives (**6**).

We also synthesized lanthionine derivatives from the reaction of **1**, **2**, **3**, and **4** (1 mmol) with benzyl *N*-benzyloxycarbonyl-L-cysteinate (1 mmol) as a thiol component under the same reaction conditions, except for the thiol amount, as shown in Scheme 2. Although the reaction results summarized in Table 2 show that the synthetic yield of each lanthionine derivative was not very good, this procedure is useful for synthesizing optically active lanthionines.

Experimental

Melting points are uncorrected. Optical rotations were determined at the D line on a Perkin-Elmer 141 polarimeter. NMR spectra were obtained with a Hitachi R-20 B high-resolution NMR spectrometer using TMS as the internal reference. The homogeneity of the products was checked by thin-layer chromatography on silica-gel plates.

*Benzyl (2S)-1-Benzyloxycarbonyl-2-aziridinecarboxylate (**1**).* To a solution of (2*S*)-H-Azy-OBzl[4] (2.4 g, 13.4 mmol) and Et_3N (1.52 ml, 10.8 mmol) in $CHCl_3$ was added Z-Cl[1] (1.72 ml, 10.8 mmol) at 0 °C with stirring. After being stirred overnight, the solution was washed with 10% citric acid, 1 M $NaHCO_3$, and water, then dried over Na_2SO_4 and concentrated *in vacuo*. The residue was purified by silica gel column chromatography ($CHCl_3$) and the pure product was isolated as a syrup, 3.2 g (95% from Z-Cl), $[\alpha]_D^{23}$ −19.0° (*c* 1.0, MeOH). NMR ($CDCl_3$) δ: 2.37 (1H q, *J*=1.5, 5.0 Hz), 2.54 (1H q, *J*=1.5, 3.0 Hz), 3.08 (1H q, *J*=3.0, 5.0 Hz), 5.05, 5.07 (4H 2s), 7.26 (10H s).

Found: C, 69.15; H, 5.53; N, 4.42%. Calcd for $C_{18}H_{17}O_4N$: C, 69.44; H, 5.50; N, 4.50%.

*Benzyl (2R)-1-Benzyloxycarbonyl-2-aziridinecarboxylate (**2**).* This compound was prepared by the same procedure from (2*R*)-H-Azy-OBzl[4] and Z-Cl. Compound **2** was obtained as a syrup, $[\alpha]_D^{23}$ +20.0° (*c* 0.9, MeOH). NMR ($CDCl_3$) spectra of **2** was identified with that of **1**.

Found: C, 69.52; H, 5.60; N, 4.39%. Calcd for $C_{18}H_{17}O_4N$: C, 69.44; H, 5.50; N, 4.50%.

*Benzyl (2S, 3S)-1-Benzyloxycarbonyl-3-methyl-2-aziridinecarboxylate (**3**).* To a solution of (2*S*, 3*S*)-H-3-MeAzy-OBzl[4] (4.57 g, 24 mmol) and Et_3N (3.36 ml, 24 mmol) in THF (30 ml) was added Z-Cl (3.84 ml, 24 mmol) at 0 °C with stirring. After being stirred for 4 h, the solution was concentrated *in vacuo*. The residue was dissolved in ethyl acetate and washed with 10% citric acid, 1 M $NaHCO_3$, and water, then dried over Na_2SO_4 and concentrated *in vacuo*. The residue was purified by silica gel column chromatography ($CHCl_3$). Compound **3** was obtained as a syrup, 7.62 g (98%), $[\alpha]_D^{23}$ −66.2° (*c* 1.0, MeOH). NMR ($CDCl_3$) δ: 1.26 (3H d, *J*=6.0 Hz), 2.75 (1H m), 3.18 (1H d, *J*=6.5 Hz), 5.06, 5.12 (4H 2s), 7.27 (10H s).

Found: C, 69.95; H, 5.92; N, 4.28%. Calcd for $C_{19}H_{19}O_4N$: C, 70.14; H, 5.89; N, 4.31%.

*Benzyl (2R, 3R)-1-Benzyloxycarbonyl-3-methyl-2-aziridinecarboxylate (**4**).* This compound was prepared by the same procedure from (2*R*, 3*R*)-H-3-MeAzy-OBzl[4] and Z-Cl. Compound **4** was obtained as a syrup, $[\alpha]_D^{23}$ +66.4° (*c* 1.2, MeOH). NMR ($CDCl_3$) spectra of **4** was identified with that of **3**.

Found: C, 70.26; H, 5.95; N, 4.21%. Calcd for $C_{19}H_{19}O_4N$: C, 70.14; H, 5.89; N, 4.31%.

*N-Benzyloxycarbonyl-S-methyl-L-cysteine Benzyl Ester (**5a**).* *General Procedure for The Reaction of Azy with Thiol*: To a solution of **1** (200 mg, 0.64 mmol) in $CHCl_3$ (3 ml) was added a solution of MeSH (1 g, excess) in $CHCl_3$ (15 ml) and BF_3·OEt_2 (3 drops). After being left for 2 d at room temperature, the solution was concentrated *in vacuo*. The residue was dis-

solved in ethyl acetate, washed with 1 M $NaHCO_3$, dried over Na_2SO_4, and concentrated *in vacuo*. The crude product was purified by silica-gel column chromatography ($CHCl_3$–hexane, 2 : 1 v/v). Compound **5a** was obtained as a syrup, 199 mg (86%), $[\alpha]_D^{23}$ −20.7° (*c* 1.2, MeOH). NMR ($CDCl_3$) δ: 1.96 (3H s), 2.86 (2H d, J=5.9 Hz), 4.59 (1H m), 5.08, 5.12 (4H 2s), 5.80 (1H bd), 7.28 (10H s).

Found: C, 63.41; H, 5.96; N, 3.99; S, 8.86%. Calcd for. $C_{19}H_{21}O_4NS$: C, 63.49; H, 5.89; N, 3.90; S, 8.92%.

N-Benzyloxycarbonyl-S-benzyl-L-cysteine Benzyl Ester (5g). To a solution of **1** (200 mg, 0.64 mmol) in $CHCl_3$ (3 ml) was added α-toluenethiol (3 ml, excess) and $BF_3 \cdot OEt_2$ (3 drops) at room temperature. After being left for 3 d, the solvent was removed *in vacuo*. The residue was dissolved in ethyl acetate, washed with 1 M $NaHCO_3$, dried over Na_2SO_4, and concentrated *in vacuo*. The crude product was purified by silica gel column chromatography ($CHCl_3$). Compound **5g** was obtained as crystals from $CHCl_3$–hexane, 196 mg (72%), mp 68—70 °C, $[\alpha]_D^{23}$ −45.3° (*c* 1.1, MeOH). [Standard sample prepared from L-Cys(Bzl): mp 68—70 °C, $[\alpha]_D^{23}$ −45.1° (*c* 1.0, MeOH)].

Found: C, 68.76; H, 5.82; N, 3.16; S, 7.42%. Calcd for $C_{25}H_{25}O_4NS$: C, 68.94; H, 5.79; N, 3.22; S, 7.36%.

N,N′-Dibenzyloxycarbonyl-L-lanthionine Dibenzyl Ester (7a). To a solution of **1** (427 mg, 1.37 mmol) in CH_2Cl_2 (5 ml) was added Z-L-Cys-OBzl (473 mg, 1.37 mmol) and $BF_3 \cdot OEt_2$ (3 drops) at room temperature. After 5 d, the solvent was removed *in vacuo*. The residue was dissolved in ethyl acetate and was worked up as described above. The crude product was purified by silica-gel column chromatography (hexane–ethyl acetate, 3 : 1 v/v). Compound **7a** was obtained as crystals from ethyl acetate–hexane, 335.5 mg (37.3%), mp 94.5—96.0 °C, $[\alpha]_D^{23}$ −31.5° (*c* 1.1, MeOH).

Found: C, 65.46; H, 5.48; N, 4.24; S, 4.99%. Calcd for $C_{36}H_{36}O_8N_2S$: C, 65.84; H, 5.53; N, 4.27; S, 4.88%.

N,N′-Dibenzyloxycarbonyl-meso-lanthionine Dibenzyl Ester (7b). To a solution of **2** (311 mg, 1 mmol) in CH_2Cl_2 (5 ml) was added Z-L-Cys-OBzl (345 mg, 1 mmol) and $BF_3 \cdot OEt_2$ (3 drops) at room temperature. After 5 d, the reaction mixture was worked up as described above. Compound **7b** was obtained as crystals from ethyl acetate–ether–hexane, 149 mg (21%), mp 86—87 °C.

Found: C, 65.33, H, 5.34; N, 4.29; S, 4.90%. Calcd for $C_{36}H_{36}O_8N_2S$: C, 65.84; H, 5.53; H, 4.27; S, 4.88%.

N,N′-Dibenzyloxycarbonyl-threo-β-methyl-L-lanthionine Dibenzyl Ester (7c). To a solution of **3** (325 mg, 1 mmol) in CH_2Cl_2 (5 ml) was added Z-L-Cys-OBzl (345 mg, 1 mmol) and $BF_3 \cdot OEt_2$ (3 drops) at room temperature. After 5 d, the reaction mixture was worked up as described above. Compound **7c** was obtained as a syrup, 145 mg (22%), $[\alpha]_D^{23}$ −11.6° (*c* 1.0, MeOH).

Found: C, 66.32; H, 5.86; N, 4.06; S, 4.74%. Calcd for $C_{37}H_{38}O_8N_2S$: C, 66.25; H, 5.71; N, 4.18; S, 4.78%.

N,N′-Dibenzyloxycarbonyl-threo-β-methyl-meso-lanthionine Dibenzyl Ester (7d). To a solution of **4** (325 mg, 1 mmol) in CH_2Cl_2 (5 ml) was added Z-L-Cys-OBzl (345 mg, 1 mmol) and $BF_3 \cdot OEt_2$ (3 drops) at room temperature. After 5 d, the reaction mixture was worked up as described above. Compound **7c** was obtained as crystals from ethyl acetate–ether–hexane, 81.4 mg (12%), mp 104.5—107.0 °C, $[\alpha]_D^{23}$ −32.0° (*c* 1.1, MeOH).

Found: C, 66.24; H, 5.81; N, 4.04; S, 4.71%. Calcd for $C_{37}H_{38}O_8N_2S$: C, 66.25; H, 5.71; N, 4.18; S, 4.78%.

(Received June 16, 1982)

A linear peptide, *N-t*-butoxycarbonyl-*S*-acetamidomethyl-L-cysteinyl-D-leucyl-L-histidyl-*S*-acetamidomethyl-L-cysteinyl-D-leucyl-L-histidine methyl ester (**1**) was synthesized by the solid phase method. Subsequent cyclization by the azide method offered a cyclic peptide, *cyclo*-*S*-acetamidomethyl-L-cysteinyl-D-leucyl-L-histidyl-*S*-acetamidomethyl-L-cysteinyl-D-leucyl-L-histidyl (**2**). The circular dichroism (CD) and ^1H NMR were observed for these peptides **1** and **2**, in the absence and presence of metal cations, Zn(II), Ca(II), Mg(II). Spectral results for Zn(II) complexes indicated striking contrasts to those of Ca(II) and Mg(II) complexes. Thus, in H_2O, the addition of Zn(II) caused CD spectral changes for both peptides, while Ca(II) and Mg(II) did not cause changes in any CD spectral region. In methanol, the additions of Zn(II) and Ca(II) caused CD changes, while the addition of Mg(II) did not cause any CD changes. The changes caused by adding Zn(II) were quite different from those by Ca(II), suggesting that Zn(II) is coordinated with the peptides in a mode different from that of Ca(II). ^1H NMR data also suggested the different coordination mode between these two metal complexes in methanol.

A number of studies have been undertaken about the complexation between metal cations and cyclic or linear oligopeptides in order to simulate the natural ionophores such as valinomycin[1] or the natural metalloproteins such as blue copper proteins.[2-4] In the former cases, the peptides studied are cyclic and the most cations used belong to alkali or alkaline earth metals, which are coordinated with the carbonyl oxygens of the main-chain peptide bonds.[5-8] In the latter cases, however, the peptides thus far investigated are primarily linear and metal cations belong to transition metals such as Cu(II), Ni(II), Pd(II), *etc.*, which are coordinated with imidazole, thiol, *etc.*, or deprotonated peptide-bond nitrogen anions.[9-11] There are in nature certain enzymes which contain Zn(II) at their active sites, such as carboxypeptidase A.[12] Since the properties of Zn(II) are intermediate between those of the diamagnetic metal ions and those of the paramagnetic transition metal ions, it seems to be interesting to investigate the interaction between Zn(II) and peptides. However, relatively few studies about Zn(II)–peptide complexes have been carried out. In the present study, therefore, the linear and the cyclic peptides having imidazolyl and acetamido groups at the side chains were synthesized, and circular dichroism (CD) spectra and ^1H NMR spectra of these peptides were measured in the presence or absence of Zn(II). Zn(II) is expected to be coordinated with the imidazolyl and the acetamido groups of the side chains in these complexes. Interactions with divalent diamagnetic metal ions, Ca(II) and Mg(II), were also investigated as well for comparison.

Experimental

Materials. The linear peptide, *N-t*-butoxycarbonyl-*S*-acetamidomethyl-L-cysteinyl-D-leucyl-L-histidyl-*S*-acetamidomethyl-L-cysteinyl-D-leucyl-L-histidine methyl ester (**1**) (Boc-L-Cys(*S*-Acm)-D-Leu-L-His-L-Cys(*S*-Acm)-D-Leu-L-His-OCH_3), and the cyclic peptide, *cyclo*-*S*-acetamidomethyl-L-cysteinyl-D-leucyl-L-histidyl-*S*-acetamidomethyl-L-cysteinyl-D-leucyl-L-histidyl (**2**) (*cyclo*(-L-Cys(*S*-Acm)-D-Leu-L-His-L-Cys(*S*-Acm)-D-Leu-L-His-)), used in this study were synthesized by the solid phase method and subsequent cyclization as follows. *N-t*-Butoxycarbonyl-*S*-acetamidomethyl-L-cysteinyl-D-leucyl-N^{Im}-tosyl-L-histidyl-*S*-acetamidomethyl-L-cysteinyl-D-leucyl-N^{Im}-tosyl-L-histidine-resin was synthesized from *N-t*-butoxycarbonyl-N^{Im}-tosyl-L-histidine-resin (0.27 mmol His/g-resin) on 1 mmol scale by the solid phase procedure in a Beckman model 990B Peptide Synthesizer according to the schedule shown in Table 1. The tosyl group was removed by suspending the obtained resin (*ca.* 4 g) in a solution of 1-hydroxybenzotriazole (1 g) in DMF (30 ml) at room temperature for 8 h.[13] The peptide was then removed from the resin by treatment with 1 M (1 M = 1 mol dm^{-3}) triethylamine in methanol (300 ml) at room temperature for 20 h.[14] The peptide was purified by preparative thin-layer chromatography (preparative TLC) on silica gel in *n*-BuOH–AcOH–H_2O (10 : 1 : 3 in vol.) and by gel filtration on Sephadex LH-20 in methanol. The purified peptide (**1**) showed a single spot (Pauly test, positive; ninhydrin test, negative) at R_f 0.29 on TLC in *n*-BuOH–AcOH–H_2O (10 : 1 : 3 in vol.). ^1H NMR

TABLE 1. SCHEDULE FOR THE SOLID PHASE SYNTHESIS

Step	Operation and reagent	Mixing time / min
1	$CHCl_3$, 45 ml (3 times)	1.5
2	25% trifluoroacetic acid/$CHCl_3$, 45 ml (once)	1.5
3	25% trifluoroacetic acid/$CHCl_3$, 45 ml (once)	30
4	$CHCl_3$, 45 ml (6 times)	1.5
5	10% triethylamine/$CHCl_3$, 45 ml (3 times)	1.5
6	$CHCl_3$, 45 ml (3 times)	1.5
7	CH_2Cl_2, 45 ml (3 times)	1.5
8	Boc-amino acid (3 equivalents) in CH_2Cl_2,[a] 22 ml, and 0.25 M DCC in CH_2Cl_2, 10 ml (once)	120
9	CH_2Cl_2, 45 ml (3 times)	1.5
10	$CHCl_3$, 45 ml (3 times)	1.5

a) The solvent of Boc-L-Cys(*S*-Acm)-OH was the mixture of CH_2Cl_2 (20 ml) and DMF (2 ml).

(D_2O, DMSO-d_6) and field desorption mass spectrometry (FDMS) spectral data were in good agreement with those of the expected structure. Amino acid analysis: Leu : His= 1.00 : 0.93, Cys was not determined correctly. Found: C, 51.20; H, 7.23; N, 16.22; S, 6.13%. Calcd for $C_{42}H_{68}N_{12}O_{11}S_2 \cdot 1/2C_2H_4O_2$: C, 51.09; H, 6.93; N, 16.63; S, 6.34%. The cyclization procedure was as follows. Boc-L-Cys(*S*-Acm)-D-Leu-L-His-L-Cys(*S*-Acm)-D-Leu-L-His-$NHNH_2$ was prepared from **1** (100 mg) by treatment with hydrazine hydrate (0.7 ml) in methanol (2 ml) for 12 h, followed by the removal of *t*-butoxycarbonyl (Boc) group with trifluoroacetic acid (1 ml) in the presence of dimethyl sulfide (0.2 ml) for 10 min. To a solution of H-L-Cys(*S*-Acm)-D-Leu-L-His-L-Cys(*S*-Acm)-D-Leu-L-His-$NHNH_2 \cdot 4CF_3COOH$ (*ca.* 100 mg) in DMF (1 ml) were added 6 M HCl in dioxane (0.07 ml) and isopentyl nitrite (0.02 ml) at −50 °C, and the mixture was stirred in an ice–salt bath until hydrazine test became negative (*ca.* 10 min).[15] The reaction mixture was then added drop by drop into cold pyridine (*ca.* 500 ml) in an ice–salt bath with vigorous stirring.[16] After stirring for an additional 30 min, it was allowed to stand at 4 °C for 48 h and then at room temperature for 12 h. After the solvent was evaporated under reduced pressure at 30—40 °C, the residue was purified by preparative TLC on silica gel in *n*-BuOH–AcOH–H_2O (10 : 1 : 3 in vol.) and by gel filtration on Sephadex LH-20 in methanol. The purified cyclic peptide (**2**) showed a single spot (Pauly test, positive; ninhydrin test, negative) at R_f 0.40 on TLC in *n*-BuOH–AcOH–H_2O (4 : 1 : 2 in vol.). ^1H NMR (D_2O, DMSO-d_6) and FDMS (*m/e*; 848) spectral data agreed well with those of the expected structure. Found: C, 47.68; H, 6.41; N, 17.50; S, 7.50%. Calcd for $C_{36}H_{56}N_{12}O_8S_2 \cdot 1/2\ C_2H_4O_2 \cdot 3H_2O$: C, 47.64; H, 6.87; N, 18.03; S, 6.87%.

Methods. CD spectra were measured on a JASCO J-20 or J-500 spectropolarimeter using 0.1 or 1 mm cells at room temperature. In the case of aqueous solutions, 0.1 M NaCl was contained. Proton NMR spectra were recorded on a Bruker CXP-300 FT NMR spectrometer operating in the pulsed Fourier transform mode at 300.07 MHz in a spinning 5 mm tube at room temperature. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) (0.00 ppm) was used as an internal reference in D_2O solution. In the case of methanol-d_4 solution, the solvent (4.78 ppm from DSS) was used as a reference.

Results

Figure 1 shows CD spectra of the linear peptide at

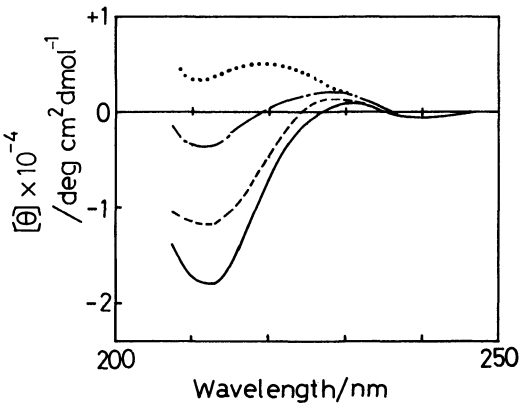

Fig. 1. CD spectra of Boc-(L-Cys(*S*-Acm)-D-Leu-L-His)$_2$-CCH_3 in H_2O: peptide concentration, 2.8×10^{-4} M; pH, 3.57 (——), 5.52 (------), 6.40 (—·—), 7.55 (……).

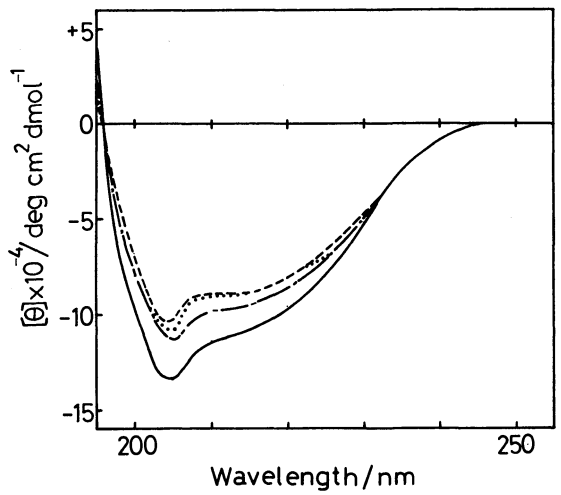

Fig. 2. CD spectra of *cyclo*-(L-Cys(*S*-Acm-D-Leu-L-His)$_2$ in H_2O: peptide concentration, 4.0×10^{-4} M; pH, 3.06 (——), 6.25 (—·—), 8.59 (----); in the presence of $ZnCl_2$ (4.0×10^{-3} M) at pH 6.25 (……).

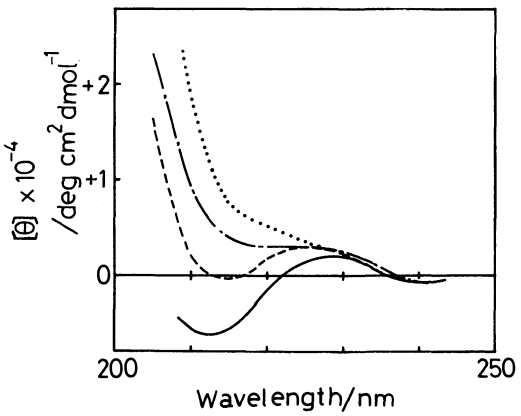

Fig. 3. CD spectra of Boc-L-(Cys(*S*-Acm)-D-Leu-L-His)$_2$-OCH_3 in H_2O: peptide concentration, 2.8×10^{-4} M; pH 6.25; $ZnCl_2$ concentration, 0 M (——), 2.8×10^{-4} M; (------), 5.6×10^{-4} M (—·—), 1.1×10^{-3} M (……).

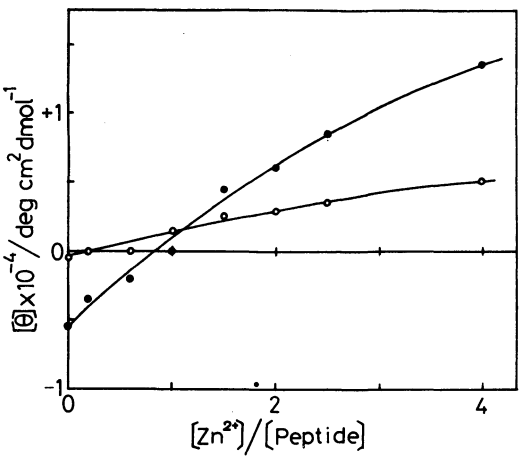

Fig. 4. Relation between molar ellipticity [θ] (deg cm^2 dmol^{-1}) and $[Zn^{2+}]$/[peptide] in H_2O: concentration of Boc-(L-Cys(*S*-Acm)-D-Leu-L-His)$_2$-OCH_3, 2.8×10^{-4} M; at 212 nm (—●—) and 220 nm (—○—).

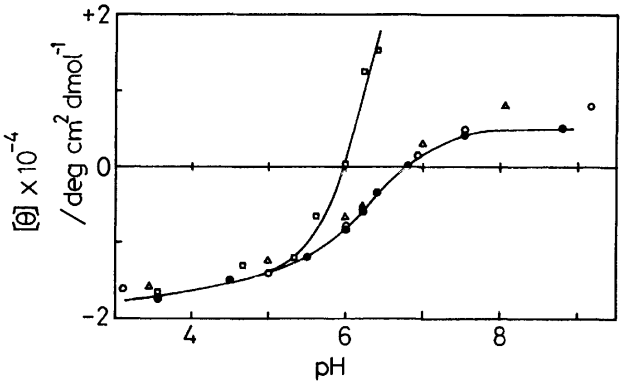

Fig. 5. Titration curves of molar ellipticity [θ] (deg cm^2 dmol^{-1}) at 212 nm of Boc-(L-Cys(*S*-Acm)-D-Leu-L-His)$_2$-OCH_3 in H_2O: peptide concentration, 2.8 $\times 10^{-4}$ M; metal salt free (-●-), 5.6×10^{-3} M $MgCl_2$ (-○-), 5.6×10^{-3} M $CaCl_2$ (-△-), 1.1×10^{-3} M $ZnCl_2$ (-□-).

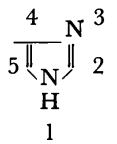
Table 2. Chemical shift (ppm) of imidazolyl C-2 and C-5 protons of linear or cyclic peptides in D_2O at pD 6.22[a]

[Zn^{2+}]/[Peptide]	Linear peptide		Cyclic peptide	
	C-2	C-5	C-2	C-5
0	8.22	7.11	8.28	7.20
	8.15			
3	8.08	7.14	—	—
		6.98		
10	8.05	7.11	8.22	7.17
		6.95		

a) Peptide concentration, 1.0×10^{-3} M; sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) was used as an internal reference (0.00 ppm); C-2 and C-5 are numbered as in the following figure:



neutral and acidic pH regions. Remarkable CD changes dependent upon the pH values are noted. Thus, the CD peak around 218 nm observed at pH 7.55 is decreased when the pH value is decreased. Instead, a CD trough at 212 nm is to be seen at acidic pH regions.

In contrast to the pH-dependent CD spectra of the linear peptide, the CD trough observed from 205 nm to 230 nm of the cyclic peptide is much less pH-dependent as can be seen in Fig. 2. The CD magnitude of the cyclic peptide at pH 8.59 is increased by 20—30% when the pH is decreased to pH 3.06.

Effects of metal salts added to the peptide solutions were investigated at pH 6.25. Typical CD spectrum in the presence of Zn(II) is shown in Fig. 2 (dotted line) for the cyclic peptide. As can be seen, no remarkable CD spectral change is observed by adding Zn(II) to the cyclic peptide solution. Figure 3 shows the effects of Zn(II) on the CD spectra of the linear peptide. CD spectra of the linear peptide are markedly changed by adding Zn(II). The CD magnitudes of the linear peptide are correlated with the Zn(II) concentrations as is shown in Fig. 4 where the molar ellipticity [θ] at ordinate is the values at 212 and 220 nm. Additions of Ca(II) and Mg(II) to the linear peptide solution did not cause any marked change in the CD spectra. In Fig. 5 are shown the pH-titration curves of [θ] at 212 nm of the linear peptide in the presence or absence of the metal salts ($ZnCl_2$, $CaCl_2$, $MgCl_2$). In this case, $ZnCl_2$ brings about a characteristic titration curve in contrast with that of free form, while $CaCl_2$ and $MgCl_2$ essentially do not cause change in the titration curve.

Table 2 summarizes ^{1}H NMR signals of imidazole C-2 and C-5 protons of the linear and the cyclic peptides in D_2O at pD 6.22 (not corrected for isotope effects). The C-2 and C-5 signals of the both peptides as a whole move to high field by adding Zn(II). However, the C-5 signal at 7.11 ppm of the linear peptide splits to two signals at 7.11 and 6.95 ppm when the Zn(II) concentration is large excess against that of the linear

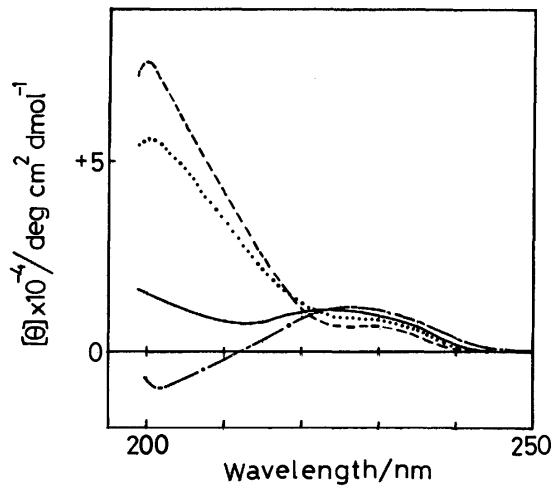


Fig. 6. CD spectra of Boc-(L-Cys(*S*-Acm)-D-Leu-L-His)$_2$-OCH_3 in MeOH: peptide concentration, 2.8×10^{-3} M ;metal salt free or 5.6×10^{-2} M $MgCl_2$ (——), 2.0×10^{-3} M $ZnCl_2$ (----), 2.8×10^{-2} M $ZnCl_2$ (……), 5.6×10^{-2} M $CaCl_2$ (—•—).

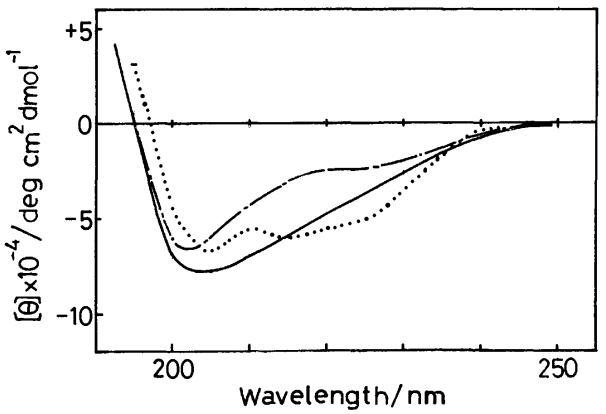

Fig. 7. CD spectra of *cyclo*-(L-Cys(*S*-Acm)-D-Leu-L-His)$_2$ in MeOH: peptide concentration, 4.0×10^{-4} M; metal salt free or 8.0×10^{-3} M $MgCl_2$ (——), 8.0×10^{-3} M $CaCl_2$ (……), 8.0×10^{-3} M $ZnCl_2$ (—•—).

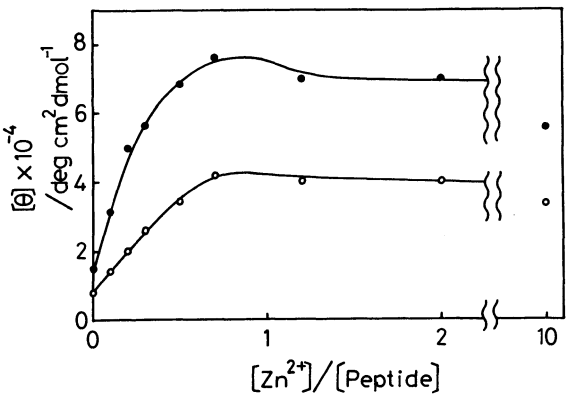

Fig. 8. Relation between molar ellipticity [θ] (deg cm^2 dmol^{-1}) and [Zn^{2+}]/[peptide] in MeOH: concentration of Boc-(L-Cys(*S*-Acm)-D-Leu-L-His)$_2$-OCH_3, 2.8×10^{-3} M; at 200 nm (—●—) and 210 nm (—○—).

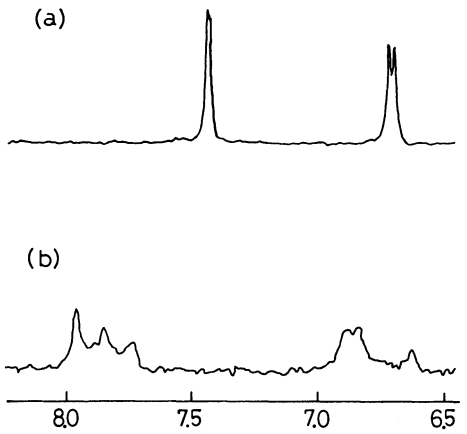

Fig. 9. ^{1}H NMR spectra of Boc-(L-Cys(*S*-Acm)-D-Leu-L-His)$_2$-OCH_3 in methanol-d_4: peptide concentration, 2.0×10^{-3} M; (a) in the absence of $ZnCl_2$, (b) in the presence of 2.0×10^{-3} M $ZnCl_2$.

peptide. In addition, the C-2 signals at 8.22 and 8.15 ppm of the linear peptide coalesce into a signal at 8.05 ppm by the Zn(II) addition.

In less polar solvent, such as methanol, Ca(II) or Mg(II) seems to coordinate with the linear and the cyclic peptides. Figures 6 and 7 show effects of metal cations on the CD spectra of those peptides in methanol. For the linear peptide, Ca(II) as well as Zn(II) brought about the spectral changes, while Mg(II) did not. However, the changes caused by Ca(II) are different from those by Zn(II), possibly because of the differences of the coordination structures between these two metal complexes. For the cyclic peptide, no remarkable CD spectral changes are noted by adding Mg(II), Ca(II) or Zn(II) (Fig. 7). The molar ellipticities [θ] at 200 and 210 nm are plotted against Zn(II)-linear peptide concentration ratios as shown in Fig. 8. One can see that [θ] increases rapidly until [Zn^{2+}]/[peptide] is *ca.* 0.7 and then decreases gradually.

Proton NMR spectra were measured in methanol-d_4, too. As Fig. 9 shows, Zn(II) causes the splitting and the broadening of the imidazolyl resonances of the linear peptide. For the cyclic peptide, the imidazolyl resonances are shifted to lower magnetic field without any significant signal broadenings (Table 3). Effects of Mg(II) and Ca(II) on the peptide NMR signals in methanol-d_4 are summarized in Table 3 for comparison.

TABLE 3. CHEMICAL SHIFT (ppm) OF LINEAR OR CYCLIC PEPTIDES IN METHANOL-d_4 IN THE PRESENCE OR ABSENCE OF METAL SALT[a]

Linear peptide[b]

Metal salt	His C-2	His C-5	OCH_3	Acm-CH_3	Boc-CH_3
Free	7.46	6.74	3.57	1.85	1.29
	7.45	6.71		1.83	
$MgCl_2$ 20 mM	7.52	6.75	3.57	1.85	1.29
	7.49			1.83	
$CaCl_2$ 20 mM	7.54	6.78	3.58	1.86	1.30
	7.51	6.76		1.85	
$ZnCl_2$ 2 mM[c]	7.96	6.89	3.64	1.84	1.30
	7.85	6.85	3.59		
	7.74	6.64			

Cyclic peptide[d]

Metal salt	His C-2	His C-5	Acm-CH_2		Leu[e] α-CH	Acm-CH_3
Free	7.45	6.72	4.31	4.11	3.92	1.84
			4.26	4.06		
$MgCl_2$ 24 mM	7.54	6.77	4.32	4.11	3.92	1.85
			4.28	4.07		
$CaCl_2$ 24 mM	7.57	6.81	4.30	4.17	3.99	1.87
			4.26	4.12		
$ZnCl_2$ 2.4 mM	7.79	7.42	4.35	4.27	4.08	1.85
			4.30	4.22		

a) Methanol-d_4 was used as a reference (4.78 ppm). b) Concentration, 2.0×10^{-3} M. c) Histidyl C-2 and C-5 proton resonances were broadened and split, so the chemical shift values described here are those of the representative resonances. d) Concentration, 2.4×10^{-3} M. e) Triplet resonances apparently.

Discussion

The CD spectra of both the cyclic and the linear peptides in aqueous solution shown in Figs. 1 and 2 can tell us conformational and/or electronic differences between the two types of peptides we studied. It is generally known that β-turn conformation can be seen in certain cyclic hexapeptides.[17,18] Therefore, there is a possibility that the cyclic peptide studied here may take a β-turn. However, the absorptions due to the low-energy band of the split amide π-π^* and the amide n-π^* transitions of the main chain seem to overlap with those due to the imidazolyl π-π^* and the Acm-amide π-π^* or n-π^* transitions of the side chains, and thus the detailed conformational analysis is difficult in the present study. It is shown that the CD spectra of the linear peptide vary remarkably with pH while those of the cyclic one change a little. This indicates that the conformation of the cyclic peptide is fairly rigid, while that of the linear peptide is flexible. For the linear peptide, the spectra at lower pH value might be ascribed to relatively extended conformations caused by electro-

static repulsion force between the charged imidazolyl groups, while those at high pH value might be attributed to less perturbated conformations. From Figs. 3—5, it is concluded that in aqueous solution Zn(II) is much more liable to be coordinated with the linear peptide compared with Ca(II) or Mg(II). On the other hand, the CD spectrum of the cyclic peptide is affected very little by $ZnCl_2$ as shown in Fig. 2, which also suggests the rigid conformation of the cyclic peptide. Since Zn(II) is a medium soft acid, it seems likely that Zn(II) is bound to histidyl imidazoles.

The binding of Zn(II) to histidyl imidazole is supported by the results of ^1H NMR spectra in deuterium oxide (D_2O) at pD 6.22 in that the imidazolyl C-2 and C-5 proton resonances in both the cyclic and the linear peptides were split or shifted on addition of Zn(II) as Table 2 shows. These resonances are shifted to higher magnetic field in general. The splitting in the linear peptide must be due to the environmental difference between the two imidazoles in the molecule.

The CD spectral changes of the linear peptide observed by adding Zn(II) in methanol are correlated with the Zn(II)/peptide concentration ratios as shown in Fig. 8. The first increasing stage of the titration trace observed at 200 or 210 nm is considered to be due to the formation of 1 : 2 ($[Zn^{2+}]$/[peptide]) complex and the next decreasing stage due to that of 1 : 1 or other complexes.

The NMR spectra changes of the linear peptide by adding Zn(II) (Fig. 9) will suggest that there are various populations of conformational isomers interconverting at or near the coalescence state on the NMR time scale. In contrast to this, the corresponding resonances of the cyclic peptide are shifted to lower magnetic field without significant broadening. This will suggest that the population of a certain isomer is predominant or that the interconversion between isomers is sufficiently rapid on the NMR time scale. In view of the conformational rigidity of the cyclic peptide, the former interpretation seems to be more reasonable. For both of the peptides, the magnitude of the induced shifts is as a whole in the order: Zn(II)> Ca(II)>Mg(II), except for the Acm-CH_3. From the Acm-CH_3 chemical shift, an appreciable effect of Ca(II) ion addition is noted. From these results, it seems likely that Ca(II) is bound to the Acm–amide carbonyl, but Zn(II) does not interact with the Acm–CONH group. These NMR findings suggest the structural differences between Zn(II) and Ca(II) peptide complexes, which have been implied by the CD findings.

In concluding remarks, CD and NMR findings offered convincing evidences that the cyclization of the peptide we studied makes the peptide conformation rigid, and the coordination ability of the peptide to metal cations markedly changes. It seems very likely, in addition, that the cyclization of the peptide reduces the differences in the coordination abilities among metal cations to the peptide. As has been shown in the present study, it seems to be very helpful to use the techniques of both CD and NMR, since CD offers the information about the overall structure of a molecule, while NMR offers that about the local structure of a molecule. Although ^1H NMR of the peptides was investigated in the present study, the NMR of the metal cations, such as ^{67}Zn(II),[19,20] ^{43}Ca(II),[19] or ^{25}Mg(II),[21] would be also very useful for the present study.

Lewis Acid Mediated Synthesis of 2-Alkenenitriles Using *C,N*-Bis(trimethylsilyl)ketenimine and Carbonyl Compounds

Isamu MATSUDA,* Hisashi OKADA, and Yusuke IZUMI
Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464
(Received June 23, 1982)

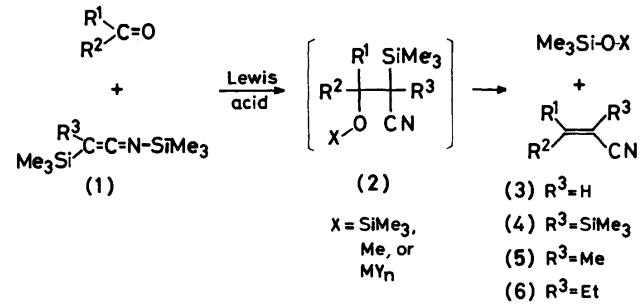
2-Substituted 2-alkenenitriles are obtained in the condensation reaction of carbonyl compounds with *C,N*-bis(trimethylsilyl)ketenimine in the presence of Lewis acid. The combination of tris(trimethylsilyl)ketenimine and aldehydes results in the high *E*-selective formation of 2-trimethylsilyl-2-alkenenitriles. Among some Lewis acids, magnesium bromide gives the best *E*-selectivity in the formation of 2-trimethylsilyl-2-undecenenitrile. Stereospecific protodesilylation of 2-trimethylsilyl-2-alkenenitriles in an aqueous methanol solution of potassium fluoride accomplishes a new route to (*Z*)-2-alkenenitriles from aldehydes.

2-Alkenenitriles have been prepared by the carbonyl olefination with various cyanated reagents under the basic conditions.[1–15] Of these reactions, the silicon methods suffers from the lack of the stereoselectivity in spite of the higher reactivity.[13,14] Introduction of bulky substituents on the silicon atom and exchange of counter cation, lithium to magnesium, are reported in order to circumvent the deficiency.[15] On the other hand, we reported a stereoselective synthesis of methyl 2-alkenoate in the reaction of *C,O*-bis(trimethylsilyl)ketene acetal with aldehydes under the acidic conditions.[16] The bulky trimethylsilyl group on the carbon atom plays an important role to control the stereochemical course in that reaction.

Although it is widely accepted that trimethylsilyl enol ethers behave as an effective C nucleophile in the presence of Lewis acid,[17] there are very few examples[18] of *N*-trimethylsilylketenimine derivatives as an equivalent of α-cyano carbanions. Therefore, it is interesting to reveal a C nucleophilic character of *N*-trimethylsilylketenimine derivatives and to explore the stereoselective route to **3** by use of the trimethylsilyl group as a key stereocontrolling factor. A recent report[18] prompts us to publish our results of the carbonyl olefination using *C,N*-bis(trimethylsilyl)ketenimine (**1**) and Lewis acid, in which 2-substituted 2-alkenenitriles (**4**, **5**, and **6**) are produced in one-pot reactions and 2-alkenenitriles (**3**) are formed *Z*-selectively by the subsequent protodesilylation of **4**.

Results and Discussion

Tris(trimethylsilyl)ketenimine (**1a**) reacted with an equivalent of aldehydes, acetals, and 2-octanone in the presence of an equivalent of $BF_3 \cdot Et_2O$ to give 2-trimethylsilyl-2-alkenenitriles (**4**) in good yields as shown in Table 1. The discrimination of both geometrical isomers in **4** was based on the chemical shift of the vinyl proton in the ^1H NMR spectra[19] and the ratio of the both isomers was determined by HPLC analyses. The reaction is susceptible to the steric environment around the electrophilic carbon, because **1a** is relatively hindered as a nucleophile. Acetal showed lower *E*-selectivity than the corresponding aldehydes (entries 5 and 6 in Table 1) and 2-octanone gave poor result in the yield and the stereoselectivity (entry 7 in Table 1). On the contrary, bis(trimethylsilyl)acetonitrile anion (**7**) derived from bis(trimethylsilyl)acetonitrile could not react with benzaldehyde to give **4c**. Therefore, **1a** is important as a synthon of **7**.



Scheme. 1

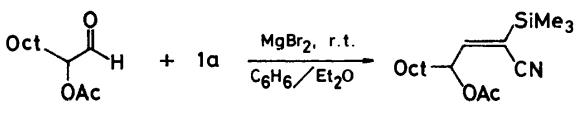
The present condensation proceeds through an intermediate such as aldol type adduct **2**, which is transformed to product **4** by the subsequent β-elimination of Me_3SiOX. The formation of both isomers (*E*)- and (*Z*)-**4** should be attributed to staggered conformers **8A** and **8B** because the *anti* elimination of β-hydroxy trimethylsilyl derivatives is well established[16,20] and the interconversion between *E* and *Z* isomers is not observed under the reaction conditions. Conformer **8A** would

Table 2. The effect of lewis acid in the condensation of **1a** with nonanal

Lewis acid	Solvent	Condition	**4a** Yield/%[a]	**4a** E/Z[b]
$BF_3 \cdot Et_2O$	CH_2Cl_2	−78 °C, 0.5 h ⟶ r.t. 3 h	79	96/4
$ZnCl_2$	C_6H_6/Et_2O = 5/8	r.t. 14 h	73	98/2
$MgBr_2$	C_6H_6/Et_2O = 5/12	r.t. 2 h ⟶ reflux 2.5 h	83	99/1
$TiCl_4$	CH_2Cl_2	−78 °C, 1 h ⟶ r.t. 2 h	47	99/1
$SnCl_4$	CH_2Cl_2	−78 °C, 2 h ⟶ r.t. 24 h	0	—
$MgCl_2$	C_6H_6/Et_2O = 5/12	r.t. 24 h	0	—

a) Isolated yields. b) Determined by HPLC (UV 233 nm, porous silica, hexane/*i*-PrOH=150/1).

be rather stabilized than **8B** because of the presence of two bulky trimethylsilyl groups on the same carbon atom. Therefore, the observed stereoselectivity can be attributed to the predominant presence of **8A** or much faster β-elimination in **8A** than in **8B**. Regardless of the manner (*syn* or *anti*) of Me_3SiOX elimination, respective conformer **8A** and **8B** corresponds specifically to (*E*)-**4** and (*Z*)-**4**. The thermodynamically controlled process would result in the greater stereochemical selectivity. Thus, several kinds of Lewis acid were compared in order to improve the stereoselectivity in the condensation of **1a** with nonanal. The results are summarized in Table 2. Excellent *E*-selectivity (*E*/*Z*= 99/1) was attained by the assist of magnesium bromide. The fruitful result obtained by magnesium bromide makes possible the application of this type condensation to more unstable aldehydes. For example, a reaction of 2-acetoxydecanal with **1a** gives **9** in 60% yield by the assist of magnesium bromide (Eq. 1). The structure of **9** might be convertible to furan and 2-buten-4-olide derivatives.



(9)

Protodesilylation of (*E*)-**4** in an aqueous methanol solution of potassium fluoride gave (*Z*)-**3** selectively. Interconversion of (*Z*)-**3** to (*E*)-**3** was not detected at all in the reaction conditions. The stereospecificity of the reaction is well explained by Koenig and Webers' mechanism.[21] Although a similar protodesilylation of vinylsilane was carried out by hydroiodic acid,[22] iodine and water,[22] or dry hydrogen chloride,[23] potassium fluoride is suitable for stereospecific protodesilylation of **4**. Since it is difficult to form (*Z*)-**3** selectively by Peterson type olefination of aldehydes with trimethylsilylacetonitrile anion,[14,15] the present two-steps method composed of **1a** and aldehydes provides a facile *Z*-selective route to 2-alkenenitriles (**3**).

A similar C-nucleophilicity of **1b** (R^3=Me) and **1c** (R^3=Et) was observed in the condensation with aldehydes. The reaction proceeded smoothly to give trisubstituted olefins **5** or **6** as a mixture of two geometrical isomers at room temperature in the presence of magnesium bromide. Even enolizable aldehydes such as nonanal and cyclohexanecarbaldehyde gave good results under the present conditions. Since *C,N*-bis(trimethylsilyl)ketenimines are easily prepared from α-unsubstituted nitriles,[24] this method could exploit a new general route to 2-substituted alkenenitriles. Experimental simplicity and mildness of conditions make the present method highly advantageous for the direct synthesis of 2-alkenenitriles **5** and **6** from aldehydes. In contrast, the reported methods include the reactions under strong basic conditions.[1-15] Although the stereochemistry could not be controlled in the formation of **5** and **6**, this problem might be solved by the kinetic control in the formation of the posturated intermediate **2**.

Experimental

All reactions were carried out under an atmosphere of argon. The IR spectra in carbon tetrachloride were recorded on a JASCO IR-403G. A JEOL C-60HL instrument was used to record the ^1H NMR spectra in carbon tetrachloride using tetramethylsilane as the internal standard. HPLC analyses were done on a JASCO TWINKLE equipped with a Model VL-611 injector and UVIDEC-100-II spectrophotometer. GLC analyses were performed on a Shimadzu GC-4BPT with TCD and a 2 m×3 mm i.d. column of 10% PEG-2M on Uniport B. Preparative TLC was carried out on precoated silica gel F-254 plates. Ketenimines, **1a**,[25] **1b**,[24] and **1c**[24] were prepared according to the literature. Magnesium bromide was prepared from 1,2-dibromoethane and magnesium in ether.

Condensation of ***1a*** *with Carbonyl Compounds in the Presence of* $BF_3 \cdot Et_2O$. *2-Trimethylsilyl-2-undecenenitrile (****4a****)*: A solution of **1a** (1.92 g, 7.47 mmol) in 15 ml of CH_2Cl_2 was added to a solution of nonanal (0.59 g, 4.16 mmol) and $BF_3 \cdot Et_2O$ (0.87 g, 6.20 mmol) in 20 ml of dry CH_2Cl_2 at −78 °C. The mixture was stirred for 30 min at −78 °C, gradually warmed to 20 °C, and stirred at the same temperature for 3 h. After quenching the mixture with saturated aqueous Na_2CO_3 (10 ml), the phases were separated and the aqueous layer was extracted with ethyl acetate (20 ml×4). The combined organic portions were washed with saturated brine (20 ml× 2), dried over anhydrous $MgSO_4$, and concentrated under reduced pressure. The residual oil was purified by column chromatography on silica gel using a mixed solvent (hexane/ethyl acetate=7/1) as an eluent and Kugelrohr distillation (65—70 °C/0.2 mmHg) [1 mmHg=133.322 Pa] to give 0.79 g (79%) of **4a** (*E*/*Z*=96/4) as a colorless liquid. Found: C, 70.58; H, 11.66; N, 5.95%. Calcd for $C_{14}H_{27}NSi$: C, 70.80; H, 11.46; N, 5.90%. Both isomers of **4a** were isolated, respectively, by a preparative TLC with hexane/etyl acetate (15/1).

(*Z*)-**4e**: IR 2200 ($\nu_{C\equiv N}$), 1595 ($\nu_{C=C}$), and 1252 cm^{-1} ($\delta_{S\ Si-C}$). ^{1}H NMR δ 0.28 (s, 9H, Si-C$\underline{H}_3$), 0.91 (t, J=4.5 Hz, 3H, $CH_2C\underline{H}_3$), 1.1—1.6 (broad m, 8H), 2.13 (s, 3H, C=C-C$\underline{H}_3$), and 2.24 (broad t, J=7 Hz, 2H, C=C-C$\underline{H}_2$).

*Condensation of **1a** with Nonanal in the Presence of Various Lewis Acids.* Analogous reactions of **1a** with nonanal were carried out on a 3 mmol scale in the presence of $ZnCl_2$, $MgBr_2$, $TiCl_4$, $SnCl_4$, and $MgCl_2$, respectively. Reaction conditions, yields of **4a**, and ratios of *E* and *Z* isomers are summarized in Table 2.

*Protodesilylation of **4** with Potassium Fluoride. 2-Undecenenitrile (**3a**)*: To a solution of (*E*)-**4a** (0.263 g, 1.11 mmol) in methanol (8 ml) was added potassium fluoride (0.460 g, 7.92 mmol) and water (0.7 ml). The clear homogenized solution was stirred for 12 h at room temperature and concentrated under reduced pressure. The residue contained water was diluted with ethyl acetate (70 ml). The solution was washed with water (20 ml×2), dried ($MgSO_4$), and concentrated under reduced pressure. The residual oil was purified by Kugelrohr distillation to give **3a** as a colorless liquid (bp 70 °C/0.2 mmHg,[26] 0.178 g, 97%, E/Z=0/100). Found: C, 79.86; H, 11.71; N, 8.31%. Calcd for $C_{11}H_{19}N$: C, 79.94; H, 11.59; N, 8.48%. IR 2240 ($\nu_{C\equiv N}$) and 1622 cm^{-1} ($\nu_{C=C}$). ^{1}H NMR δ 0.89 (t, J=4.5 Hz, 3H, $CH_2C\underline{H}_3$), 1.1—1.6 (broad m, 12H), 2.42 (d of t, J=7.5 and 7.5 Hz, 2H, C=C-C$\underline{H}_2$), 5.21 (t of d, J=1.5 and 10.8 Hz, 1H, C=C$\langle^{\underline{H}}_{CN}$), and 6.36 (t of d, J=7.5 and 10.8 Hz, 1H, $NC\rangle C=C\langle^{\underline{H}}$).

A crude product obtained by a condensation reaction of **1a** (0.969 g, 3.76 mmol), nonanal (0.452 g, 3.18 mmol), and $MgBr_2$ (0.759 g, 4.12 mmol) in a mixed solvent of benzene (15 ml) and diethyl ether (5 ml) was treated with potassium fluoride (1.865 g, 32.1 mmol) in methanol (20 ml) and water (1.5 ml). After an analogous treatment to (*E*)-**4a**, pure **3a** (0.457 g, 87% based on nonanal, E/Z=1/99) was obtained.

*Cinnamonitrile (**3c**)*: An analogous protodesilylation of (*E*)-**4c** (0.260 g, 1.29 mmol) gave **3c**[14] (0.159 g, 95%, E/Z= 0/100).

*3-Cyclohexylpropenenitrile(**3d**)*: An analogous protodesilylation of (*E*)-**4d** (0.138 g, 0.665 mmol) gave **3d** as a colorless liquid (bp 110 °C/7 mmHg, 0.086 g, 96%, E/Z=0/100). Found: C, 79.82; H, 9.51; N, 10.42%. Calcd for $C_9H_{13}N$: C, 79.95; H, 9.69; N, 10.36%. IR 2230 ($\nu_{C\equiv N}$) and 1622 cm^{-1} ($\nu_{C=C}$). ^{1}H NMR δ 0.9—2.0 (m, 10H), 2.4—2.8 (broad m, 1H, C=C-C$\underline{H}$), 5.12 (d, J=11.3 Hz, 1H, C=C$\langle^{\underline{H}}_{CN}$), and 6.18 (d of d, J=9.5 and 11.3 Hz, 1H, $NC\rangle C=C\langle^{\underline{H}}$).

*Condensation of **1a** with 2-Acetoxydecanal in the Presence of $MgBr_2$.* To a solution of $MgBr_2$ prepared from Mg (0.035 g, 1.44 mgatm) and 1,2-dibromoethane (0.336 g, 1.79 mmol) in benzene (3.5 ml) and diethyl ether (3.5 ml) were added 2-acetoxydecanal (0.200 g, 0.93 mmol) and **1a** (0.467 g, 1.81 mmol) successively at room temperature. The mixture was stirred for 3 h at room temperature, refluxed for 1 h, and poured into ethyl acetate (80 ml). The solution was washed with water (20 ml×2), dried ($MgSO_4$), and concentrated under reduced pressure. The residual oil was treated analogously to the case of **4a** to give pure (*E*)-**9** as a colorless liquid (bp 100 °C/0.9 mmHg, 0.172 g, 60%). Found: C, 65.93; H, 10.35; N, 4.52%. Calcd for $C_{17}H_{31}NO_2Si$: C, 65.97; H, 10.10; N, 4.53%. IR 2200 ($\nu_{C\equiv N}$), 1750 ($\nu_{C=O}$), and 1254 cm^{-1} ($\delta_{S\ Si-C}$). ^{1}H NMR δ 0.26 (s, 9H, Si-C$\underline{H}_3$), 0.90 (t, J=5.1 Hz, 3H, $CH_2C\underline{H}_3$), 1.1—1.8 (m, 17H), 2.07 (s, 3H, C(=O)-C$\underline{H}_3$), 5.46 (q, J=6.6 Hz, 1H, O-C$\underline{H}$), and 6.31 (d, J=6.6 Hz, 1H, C=C$\underline{H}$).

*Condensation of **1b** with Aldehydes in the Presence of $MgBr_2$. 2-Methyl-2-undecenenitrile (**5a**)*:[27] Nonanal (0.159 g, 1.12 mmol) and **1b** (0.549 g, 2.76 mmol) were added successively

into a solution of $MgBr_2$ (0.315 g, 1.70 mmol) in benzene (4 ml) and diethyl ether (9 ml) at room temperature. The mixture was stirred for 4h at the same temperature and poured into ethyl acetate (70 ml). The solution was washed with water (20 ml×2), dried ($MgSO_4$), and concentrated under reduced pressure. The residual oil was dissolved in methanol (7 ml). Acidic ammonium fluoride (0.223 g, 5.87 mmol) was added into the solution. The homogeneous solution obtained by the addition of water (0.8 ml) was stirred for 10 min at room temperature and concentrated under reduced pressure. The residue was poured into ethyl acetate (80 ml). The solution was washed with water (15 ml×2), dried ($MgSO_4$), and concentrated under reduced pressure. The residual oil was purified by column chromatography through short pad of silica gel (eluent; hexane/ethyl acetate, 5/1) and Kugelrohr distillation to give **5a** as a colorless liquid (bp 85 °C/2 mmHg, 0.196 g, 98%, E/Z=69/31).

(*E*)-**5a**: IR 2210 ($\nu_{C\equiv N}$) and 1640 cm^{-1} ($\nu_{C=C}$). ^1H NMR δ 0.88 (t, J=5.1 Hz, 3H, $CH_2C\underline{H}_3$), 1.0—1.5 (m, 12H), 1.83 (d, J=1.8 Hz, 3H, C=C–C$\underline{H}_3$), 1.9—2.4 (m, 2H, C=C–C$\underline{H}_2$), and 6.15 (q of t, J=1.8 and 7.5 Hz, 1H, C=C$\underline{H}$).

(*Z*)-**5a**: IR 2210 ($\nu_{C\equiv N}$) and 1640 cm^{-1} ($\nu_{C=C}$). ^1H NMR δ 0.88 (t, J=5.1 Hz, 3H, $CH_2C\underline{H}_3$), 1.0—1.5 (m, 12H), 1.91 (d, J=1.8 Hz, 3H, C=C–C$\underline{H}_3$), 2.0—2.6 (m, 2H, C=C–C$\underline{H}_2$), and 5.93 (q of t, J=1.8 and 7.8 Hz, 1H, C=C$\underline{H}$).

*2-Methyl-3-phenylpropenenitrile (**5c**)*:[6,28,29] An analogous treatment of **1b** (0.861 g, 4.33 mmol) with benzaldehyde (0.136 g, 1.28 mmol) gave **5c** as a colorless liquid (0.150 g, 82%, E/Z =38/62).

*3-Cyclohexyl-2-methylpropenenitrile (**5d**)*:[27] An analogous treatment of **1b** (0.517 g, 2.60 mmol) with cyclohexanecarbaldehyde (0.165 g, 1.47 mmol) gave **5d** as a colorless liquid (bp 135 °C/22 mmHg, 0.187 g, 86%, E/Z=55/45).

(*E*)-**5d**: IR 2210 ($\nu_{C\equiv N}$) and 1640 cm^{-1} ($\nu_{C=C}$). ^1H NMR δ 0.8—1.9 (m, 10H), 1.86 (d, J=1.8 Hz, 3H, C=C–C$\underline{H}_3$), 2.1—2.8 (m, 1H, C=C–C$\underline{H}$), and 6.02 (q of d, J=1.8 and 11.2 Hz, 1H, C=C$\underline{H}$).

(*Z*)-**5d**: IR 2210 ($\nu_{C\equiv N}$) and 1640 cm^{-1} ($\nu_{C=C}$). ^1H NMR δ 0.8—1.9 (m, 10H), 1.90 (d, J=1.8 Hz, 3H, C=C–C$\underline{H}_3$), 2.1—2.8 (m, 1H, C=C–C$\underline{H}$), and 5.83 (q of d, J=1.8 and 9.9 Hz, 1H, C=C$\underline{H}$).

*Condensation of **1c** with Aldehydes in the Presence of $MgBr_2$. 2-Ethyl-2-undecenenitrile(**6a**)*: A reaction of **1c** (0.736 g, 3.45 mmol) with nonanal (0.429 g, 3.01 mmol) in the presence of $MgBr_2$ (0.642 g, 3.39 mmol) gave **6a** as a colorless liquid analogously to the case of **5a** (bp 90 °C/0.75 mmHg, 0.358 g, 62%, E/Z=43/57). Found: C, 80.54; H, 12.13; N, 7.05%. Calcd for $C_{13}H_{23}N$: C, 80.76; H, 11.99; N, 7.24%. IR 2215 ($\nu_{C\equiv N}$) and 1630 cm^{-1} ($\nu_{C=C}$). ^1H NMR δ 0.91 (t, J=6.0 Hz, 3H, $CH_2C\underline{H}_3$), 1.16 (t, J=7.5 Hz, 3H, $CH_2C\underline{H}_3$), 1.0—1.5 (broad m, 12H), 2.23 (q, J=7.5 Hz, 4H, 2×C$\underline{H}_2$$CH_3$), 6.06 (t, J=7.5 Hz, $\underline{H}\rangle C=C\langle_{CN}$), and 6.21 (t, J=7.5 Hz, $\underline{H}\rangle C=C\langle_{CN}$).

*2-Ethyl-3-phenylpropenenitrile (**6c**)*: An analogous treatment of **1c** (0.361 g, 1.69 mmol) with benzaldehyde (0.162 g, 1.53 mmol) gave **6c** as a pale yellow liquid (bp 90 °C/0.2 mmHg, 0.156 g, 65%, E/Z=65/35). Found: C, 83.86; H, 7.14; N, 8.69%. Calcd for $C_{11}H_{11}N$: C, 84.04; H, 7.05; N, 8.91%. IR 2220 ($\nu_{C\equiv N}$) and 1620 cm^{-1} ($\nu_{C=C}$). ^1H NMR δ 1.26 (t, J=7.8 Hz, 3H, $CH_2C\underline{H}_3$), 2.41 (q, J=7.8 Hz, 2H, $C\underline{H}_2CH_3$), 6.79 (s, $\underline{H}\rangle C=C\langle_{CN}$), 7.02 ($\underline{H}\rangle C=C\langle_{CN}$), and 7.2—7.6 (m, $C_6\underline{H}_5$).

*3-Cyclohexyl-2-ethylpropenenitrile (**6d**)*: An analogous treatment of **1c** (0.739 g, 3.46 mmol) with cyclohexanecarbaldehyde (0.326 g, 2.91 mmol) gave **6d** as a colorless liquid (bp 85 °C/0.2 mmHg, 0.276 g, 58%, E/Z=32/68). Found: C, 80.67; H, 10.62; N, 8.64%. Calcd for $C_{11}H_{17}N$: C, 80.92; H, 10.50; N, 8.58%. IR 2210 ($\nu_{C\equiv N}$) and 1630 cm^{-1} ($\nu_{C=C}$). ^1H NMR δ 1.15 (t, J=7.2 Hz, 3H, $CH_2C\underline{H}_3$), 1.0—1.9 (m, 10H), 2.0—2.7 (m, 3H, C=C–C$\underline{H}_2$ and C=C–C$\underline{H}$), 5.84 (t of d, J=1.2 and 9.3 Hz, $\underline{H}\rangle C=C\langle_{CN}$) and 6.01 (t of d, J=0.9 and 9.0 Hz, $\underline{H}\rangle C=C\langle_{CN}$).

The authors thank Mr. Yoshimi Fukutani for an experimental assistance, Shinetsu Chemical Co. for the supply of chlorotrimethylsilane, and Sumitomo Electric Industries Co. for the supply of fluoropore.

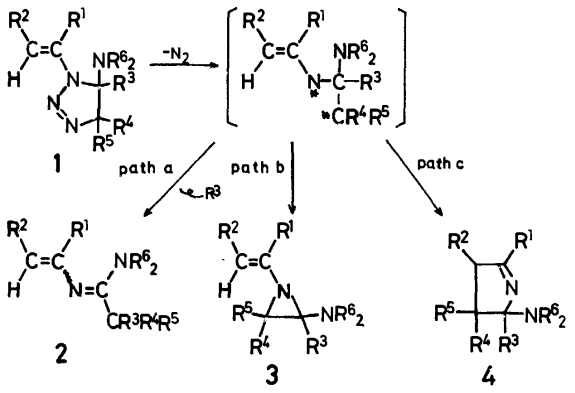
Photochemical Nitrogen Extrusion of 5-Amino-1-vinyl-4,5-dihydro-1*H*-1,2,3-triazoles. Formation of Unusual Pyrroles[1)]

Masato M. Ito, Yujiro Nomura,* Yoshito Takeuchi, and Shuji Tomoda
Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153
(Received June 23, 1982)

Photolysis of 4-alkyl-5-amino-1-vinyl-4,5-dihydro-1*H*-1,2,3-triazoles gave not 3-alkylpyrroles, but unexpected 2-alkylpyrroles in 80—83% yields. 1-Vinylaziridines were assumed as a possible intermediate of this unusual pyrrole formation. In the photolysis of 7a-morpholino-1-styryl-3a,4,5,6,7,7a-hexahydro-1*H*-1,2,3-benzotriazole, however, nitrogen extrusion did not occur, but *trans-cis* isomerization took place.

Three reaction paths are expected in decomposition of 1-vinyl-4,5-dihydro-1*H*-1,2,3-triazoles (**1**) after elimination of nitrogen as shown in Scheme 1: The first is a 1,2-alkyl (or hydrogen) shift to N^2-vinylamidines (**2**) (path a), the second is a direct ring closure to form 1-vinylaziridines (**3**) (path b), and the third is formation of a C–C bond between C-4 of the dihydrotriazole and β-position of the vinyl group to give 1-pyrrolines (**4**) (path c). The N^2-vinylamidines have a 2-aza-1,3-butadiene skeleton, of which no general synthetic method has yet been developed, although its reactivity as a heterodiene has recently attracted attentions,[2-5)] and 1-vinylaziridines are only sparsely reported class of compounds.[6,7)]



Scheme 1. Expected paths for N_2 extrusion reactions of 1-vinyldihydrotriazoles (**1**).

Recently we reported that thermolysis[4)] or acid decomposition[8)] of **1** gave the corresponding N^2-vinylamidines (**2**) *via* path a, in accord with the general trends of 5-aminotriazolines.[9)] In order to elucidate the different reactivity of **1** in different conditions as well as the possibility of controlling reaction paths, we have examined the photo decomposition of the dihydrotriazoles (**1**).

Results and Discussion

Formation of Unusual Pyrroles. The dihydrotriazoles (**1**) were irradiated in methanol at 0 °C with a 100 W high-pressure mercury lamp through a Pyrex filter. The results were shown in Table 1. In 45—140 min **1** was completely consumed, and chromatographic separation of the products gave the 1*H*-pyrroles (**5**) or 2*H*-pyrroles (**6**) in 19—83% yields (Runs 5—8). The pyrroles (**5** or **6**) were not detected among the initial products just after irradiation. This suggests that the pyrroles were formed by deamination during the chromatographic separation from certain initial products, possibly 1-pyrrolines (**7**).

Irradiation of **1a** was carried out in various solvents, but no significant difference was observed either in time required for complete consumption of **1a** or in yields of the pyrrole (**5a**) (Runs 1—5).

Table 1. Photolysis of 5-amino-1-vinyl-4,5-dihydro-1*H*-1,2,3-triazoles (**1**)

Run	Reactant	R^1	R^2	R^3	R^4	R^5	NR^6_2	Solvent	Irradiation time / min	Product (Yield/%)

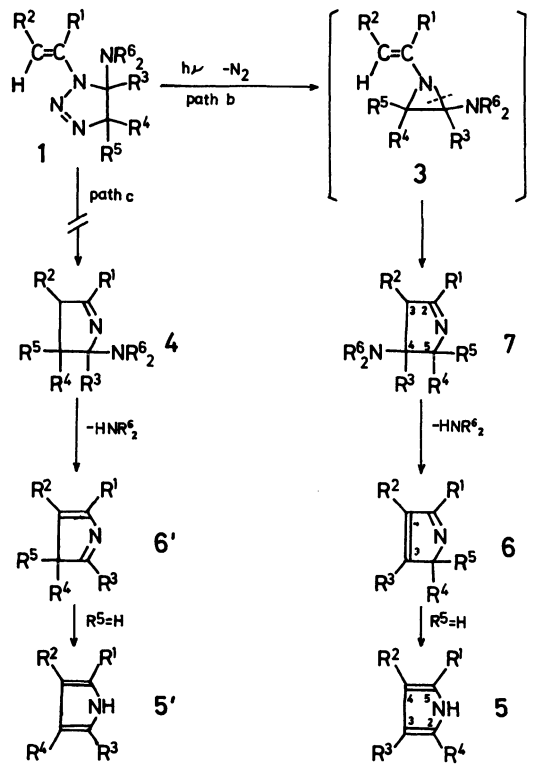


Scheme 2. A tentative route for the photolysis of 1-vinyldihydrotriazoles (**1**).

Table 2. ^{13}C NMR data of pyrroles (**5**) and 1-pyrrolines (**7**) (δ in $CDCl_3$)

	C-2[a]	C-3[a]	C-4[a]	C-5[a]
5a	128.0 s	(106.2 d	108.0 d)[b]	130.7 s
5b	128.4 s	118.8 s	105.2 d	130.1 s
5c	136.1 s	(106.5 d	106.6 d)[b]	131.0 s
5d	117.6 d	123.3 s	123.3 s	117.6 d
7a	170.1 s	40.2 t	69.5 d	72.2 d
7b	171.5 s	38.5 t	65.6 s	72.8 d
7e	167.8 s	40.7 t	73.1 d	73.5 s

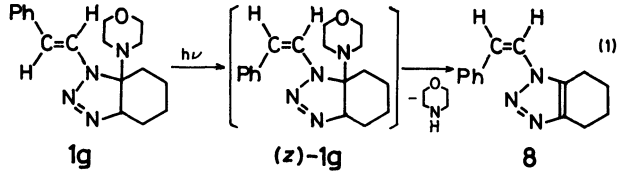
a) Numbers referred to Scheme 2. b) Or may be reversed.

The 2*H*-pyrroles (**6e**, **f**) formed from **1** (**e**, **f**) (Runs 9, 10) were the same as those formed by thermolysis of **1** (**e**, **f**).[4] Structure of 1*H*-pyrroles (**5**) was determined by spectral and analytical results. In the case of **5a**, for instance, existence of an N–H bonds was indicated by the absorption at 3290 cm^{-1} in its IR spectrum. In ^1H NMR, the singlet at δ 2.28 (3H) and the signals at δ 7.3—7.8 (5H) indicated the existence of methyl and phenyl groups, and it was unequivocally demonstrated by ^{13}C NMR that the product was a 2,5-disubstituted pyrrole (Table 2). The signals at δ 106.2 and 108.0 (both are doublet in off-resonance decoupling) are assigned to the methine carbons of the pyrrole ring by two reasons: a) The signal of 3- or 4-methine carbon of pyrrole appears at δ 108,[10] and b) alkyl and aryl substituents on a pyrrole ring have little influence upon chemical shift of its ring carbons which are not connected with these substituents.[11] Thus, it was demonstrated that the product was 2-methyl-5-phenylpyrrole (**5a**). ^{13}C NMR data pertinent to structural confirmation of other pyrroles (**5b—d**) were also listed in Table 2.

In the case of **1e**, 5,5-dimethyl-2-phenyl-4-(1-pyrrolidinyl)-1-pyrroline (**7e**) was isolated among the irradiation products. Mixtures of the 1-pyrrolines (**7a**, **b**) and the corresponding pyrroles (**5a**, **b**) could be afforded from the irradiation products of **1a**, **b**.

^{13}C NMR data corresponding to the pyrrolines (**7a**, **b**, **e**) were collected in Table 2. Both of two signals corresponding to C-4 and C-5 of the 1-pyrroline ring appeared at about δ 70, thus supporting the structure of 1-pyrrolines (**7**) in which C-4 and C-5 are connected with a pyrrolidine and a pyrroline nitrogen atoms, respectively. The 1-pyrrolines (**7**) were gradually deaminated into the corresponding 1*H*-pyrroles (**5**) or the 2*H*-pyrrole (**6e**) by repeated chromatographic separation or simply on standing at ambient temperature.

These results, together with the fact that no pyrroles were detected among the initial irradiation products, indicate that it was 1-pyrrolines (**7**) that were directly formed by photolysis of **1**.



trans-cis *Isomerization by Irradiation of 7a-Morpholino-1-styryl-3a,4,5,6,7,7a-hexahydro-1*H*-1,2,3-benzotriazole (**1g**).* Irradiation of 7a-morpholino-1-[(*E*)-styryl]-3a,4,5,6,7,7a-hexahydro-1*H*-1,2,3-benzotriazole (**1g**) took relatively long time (4.5 h) until **1g** was completely consumed, compared with other dihydrotriazoles (**1a**—**f**). Chromatographic separation of the products gave, accompanied by considerable amount of polymeric substances, 1-[(*Z*)-styryl]-4,5,6,7-tetrahydro-1*H*-1,2,3-benzotriazole (**8**) in 13% yield.

It is likely to consider that irradiation caused C=C bon isomerization into 1-(*Z*)-styryldihydrotriazole ((*Z*)-**1g**) and subsequent chromatographic separation resulted in deamination to give **8**. Although *trans-cis* photoisomerization of C=C bond is quite usual,[12] this is the only case, so far as examined, in which C=C bond isomerization of 1-vinyldihydrotriazole derivatives (**1**) actually occurred (and pyrrole ring (**5**) was not formed).

Mechanistic Consideration. It is unusual that photolysis of **1** gave 1-pyrrolines (**7**), 1*H*-pyrroles (**5**) or 2*H*-pyrroles (**6**) and that no pyrrolines (**4**), 1*H*-pyrroles (**5'**) or 3*H*-pyrroles (**6'**), which were expected from a direct 1,5-ring closure after loss of nitrogen from **1** (path c), were isolated from the irradiation products. The path including the 1-vinylaziridines (**3**) as an intermediate was tentatively assumed to rationalize most simply the formation of 1-pyrrolines (**7**) by photolysis of **1**: After removal of nitrogen, the 1-vinylaziridines (**3**) would be formed *via* path b. Then, selective ring cleavage of **3** at one of the C–N bonds under the reaction conditions followed by ring closure would give **7** as

depicted in Scheme 2. The amino group on the aziridine ring would play a crucial role for the selective C–N bond cleavage.

Photolysis of 4,5-dihydro-1*H*-1,2,3-triazoles is known to give aziridines.[13] Scheiner claims that this reaction proceeds *via* a singlet biradical intermediate.[14] Absence of solvent effect on consumption of **1** (Table 1, Runs 1—5) may indicate a similar radical path in the first stage of the present reaction.

De Poortere and De Schryver reported the formation of 2-dialkylamino-1-phenylaziridines by photolysis of 5-dialkylamino-1-phenyl-4,5-dihydro-1*H*-1,2,3-triazoles.[15] Some 1-vinylaziridines have been prepared from vinyl azides by thermal reactions.[7] Comparing the present results with the stability of 2-amino- and 1-vinylaziridines, if the present reaction really proceeds *via* the 1-vinylaziridines (**3**), the aziridines (**3**) must be unexpectedly unstable.

Both C–C and C–N bond fissions were reported for photolysis of aziridine derivatives, but C–C fission predominantly occurs.[16] The present reaction may add an example of photochemical selective C–N bond fission of an aziridine ring.

Experimental

General. Melting points were determined on a Mitamura Riken hot-stage melting point apparatus and were uncorrected. Infrared spectra were determined on JASCO DS-403G and A-202 grating infrared spectrophotometers. Nuclear magnetic resonance spectra were determined on JEOL MH-100, FX-90Q, Varian EM-390, and FT-80A spectrometers (splitting patterns in ^{13}C NMR data were obtained by off-resonance decoupling). Mass spectra were determined on a Hitachi RMU-6MG mass spectrometer.

4,5-Dihydro-1*H*-1,2,3-triazoles (**1**) were prepared according to the previously reported method.[17] Solvents were distilled under anhydrous conditions before use.

Photolysis of 5-Amino-1-vinyl-4,5-dihydro-1H-1,2,3-triazoles (1). General Procedure: The solution (150 ml) of **1** (3—3.7 mmol) in an appropriate solvent was irradiated with a high pressure mercury lamp (100 W) through a Pyrex filter at 0 °C under nitrogen atmosphere until **1** was completely consumed, as detected by high pressure liquid chromatography (through a Waters 7.8 mm × 30 mm μ-Bondapak C_{18} column eluting with methanol–water (7 : 3)). The solvent was removed *in vacuo* and the residue was separated with column chromatography.

When the neutral alumina (Akt. II) column eluting with hexane–ethyl acetate (2 : 1) was used, 5,5-dimethyl-4-(1-pyrrolidinyl)-1-pyrroline (**7e**) was isolated from the product from **1e**. Separation of the products from **1a**, **b** in a similar manner also gave the pyrrolines (**7a**, **b**), which were accompanied by the pyrroles (**5a**. **b**).

Photolysis of 1-(1-Phenylvinyl)-7a-(1-pyrrolidinyl)-3a,4,5,6,7,7a-hexahydro-1H-1,2,3-benzotriazole (1b): Photolysis of **1b** (1.30 g, 4.39 mmol) in methanol (150 ml) at 0 °C followed by chromatographic purification with neutral alumina (Woelm, Akt. II) eluting with diethyl ether gave 1.10 g of 80 : 20 mixture of 2-phenyl-3a-(1-pyrrolidinyl)-3a,4,5,6,7,7a-hexahydro-3*H*-indole (**7b**) and 2-phenyl-4,5,6,7-tetrahydroindole (**5b**). Elution of the mixture through a neutral alumina (Akt. I) column eluting with dichloromethane gave 480 mg (73% yield) of **5b** as colorless crystals.

2-Phenyl-4,5,6,7-tetrahydroindole (5b): Analytically pure sample was obtained by recrystallization from methanol: mp 105—106.5 °C; MS *m/e* 197 (M^+); IR (KBr) 3405 cm^{-1} (N–H); ^{1}H NMR ($CDCl_3$) δ 1.6—1.9 (4H, m), 2.3—2.7 (4H, m), 6.21 (1H, d, J=3 Hz), 7.0—7.4 (5H, m), and 7.75 (1H, br, NH); ^{13}C NMR ($CDCl_3$) δ 22.8 (2C, t), 23.4 (t), 23.7 (t), 105.2 (d), 118.8 (s), 123.3 (*m*-2C, d), 125.4 (*p*-C, d), 128.4 (s), 128.7 (*o*-2C, d), 130.1 (s), and 133.2 (*ipso*-C, s).

Found: C, 85.08; H, 7.83; N, 7.12%. Calcd for $C_{14}H_{15}N$: C, 85.24; H, 7.66; N, 7.10%.

2-Phenyl-3a-(1-pyrrolidinyl)-3a,4,5,6,7,7a-hexahydro-3H-indole (7b): MS *m/e* 268 (M^+); IR (neat) 1600 cm^{-1} (C=N); ^{1}H NMR ($CDCl_3$) δ 1.1—2.1 (12H, m), 2.4—2.8 (4H, m), 2.64 (1H, dd, J=17 and 1 Hz), 2.95 (1H, dd, J=17 and 1 Hz), 4.15 (1H, m), 7.3—7.7 (3H, m), and 7.8—8.1 (2H, m); ^{13}C NMR ($CDCl_3$) δ 20.8 (2C, t), 23.6 (2C, t), 28.4 (t), 31.6 (t), 38.5 (t), 47.1 (2C, t), 65.6 (s), 72.8 (d), 127.3 (*m*-2C, d), 128.3 (*o*-2C, d), 130.2 (*p*-C, d), 135.0 (*ipso*-C, s), and 171.5 (s, C=N).

2-Methyl-5-phenylpyrrole (5a): Sublimed at 80—90 °C/13 Pa; mp 92.5—94 °C; MS *m/e* 157 (M^+); IR (KBr) 3290 cm^{-1} (NH); ^{1}H NMR ($CDCl_3$) δ 2.28 (3H, s), 5.95 (1H, m), 6.41 (1H, m), 7.3—7.8 (5H, m), and 8.4 (1H, br, NH); ^{13}C NMR ($CDCl_3$) δ 13.2 (q), 106.2 (d), 108.0 (d), 123.4 (*m*-2C, d), 125.6 (*p*-C, d), 128.0 (s), 128.8 (*o*-2C, d), 130.7 (s), and 133.0 (*ipso*-C, s).

Found: C, 84.33; H, 7.05; N, 9.19%. Calcd for $C_{11}H_{11}N$: C, 84.04; H, 7.05; N, 8.91%.

5-Methyl-2-phenyl-4-(1-pyrrolidinyl)-1-pyrroline (7a): Obtained by elution of the photolysis product from **1a** (220 mg, 0.86 mmol) through neutral alumina (Woelm Akt. II) with hexane–ethyl acetate (2 : 1) as a 65 : 35 mixture (150 mg) with **5a**. ^{13}C NMR ($CDCl_3$) δ 21.4 (q), 23.3 (2C, t), 40.2 (t), 52.0 (2C, t), 69.5 (d), 72.2 (d), 127.5 (*m*-2C, d), 128.4 (*o*-2C, d), 130.4 (*p*-C, d), 134.5 (*ipso*-C, s), and 170.1 (s, C=N).

5,5-Dimethyl-2-phenyl-4-(1-pyrrolidinyl)-1-pyrroline (7e): MS *m/e* 242 (M^+); IR (KBr) 1615 cm^{-1} (C=N); ^{1}H NMR ($CDCl_3$) δ 1.22 (3H, s), 1.49 (3H, s), 1.8 (4H, m), 2.6 (5H, m), 3.0 (2H, d, J=8 Hz), 7.4 (3H, m), and 7.8 (2H, m); ^{13}C NMR ($CDCl_3$) δ 21.3 (q), 23.3 (2C, t), 29.4 (q), 40.7 (t), 54.2 (2C, t), 73.1 (s), 73.6 (d), 127.3 (*m*-2C, d), 128.2 (*o*-2C, d), 130.1 (*p*-C, d), 134.8 (*ipso*-C, s), 167.8 (s, C=N).

2-Ethyl-5-phenylpyrrole (5c): Sublimed at 45 °C/130 Pa; mp 47—48.5 °C; MS *m/e* 171 (M^+); IR (KBr) 3390 cm^{-1} (N–H); ^{1}H NMR ($CDCl_3$) δ 1.17 (3H, t, J=7.5 Hz), 2.42 (2H, q, J=7.5 Hz), 5.95 (1H, m), 6.40 (1H, m), 7.1—7.6 (5H, m), 7.9—8.3 (1H, br, NH); ^{13}C NMR ($CDCl_3$) δ 14.1 (q), 21.4 (t), 106.5 (d), 106.6 (d), 123.8 (*m*-2C, d), 126.0 (*p*-C, d), 129.2 (*o*-2C, d), 131.0 (s), 133.4 (*ipso*-C, s), 136.1 (s).

Found: C, 84.46; H, 7.78; N, 8.04%. Calcd for $C_{12}H_{13}N$: C, 84.17; H, 7.65; N, 8.18%.

3,4-Diphenylpyrrole (5d): Distilled with the Kugelrohr apparatus at 115 °C/13 Pa; mp 94.5—95.5 °C (lit, 99 °C[18]); MS *m/e* 219 (M^+); IR (KBr) 3420 cm^{-1} (N–H); ^{1}H NMR ($CDCl_3$) δ 6.79 (2H, d, J=3 Hz), 7.2—7.4 (10H, m), 8.18 (1H, br, NH); ^{13}C NMR ($CDCl_3$) δ 117.6 (2C, d), 123.3 (2C, s), 125.7 (*p*-2C, d), 128.2 (*m*-4C, d), 128.5 (*o*-4C, d), and 136.0 (*ipso*-2C, s).

Found: C, 87.81; H, 5.75; N, 6.35%. Calcd for $C_{16}H_{13}N$: C, 87.64; H, 5.98; N, 6.39%.

Photolysis of 7a-Morpholino-1-[(E)-styryl]-3a,4,5,6,7,7a-hexahydro-1H-1,2,3-benzotriazole (1g): Methanol (150 ml) solution of **1g** (824 mg, 2.64 mmol) was irradiated with a high pressure mercury lamp (100 W) through a Pyrex filter at 0 °C for 4.5 h, until **1g** was completely consumed. The methanol was removed *in vacuo* and the residue was separated with alumina column chromatography to give 1-[(*Z*)-styryl]-4,5,6,7-tetrahydro-1*H*-1,2,3-benzotriazole (**8**) in 13% yield (73 mg). Recrystallized from methanol: mp 91.5—92.5 °C; MS *m/e*

225 (M^+); IR (KBr) 1650 (C=C) and 940 cm^{-1} ($^{H}\!>\!C=C\!<^{H}$); ^1H NMR ($CDCl_3$) δ 1.5—1.8 (4H, m), 2.0—2.2 (2H, m), 2.6—2.8 (2H, m), 6.63 (1H, d, J=9.5 Hz), 6.85 (1H, d, J=9.5 Hz), 6.8—7.0 (2H, m), and 7.1—7.3 (3H, m); ^{13}C NMR ($CDCl_3$) δ 20.3 (t), 21.8 (t), 22.3 (t), 22.5 (t), 121.5 (d, PhCH=) 128.6 (d, *o* and *m*), 128.8 (d), 129.6 (d), 132.7 (s), 133.1 (s), 143.4 (s).

Found: C, 74.17; H, 6.60; N, 18.36%. Calcd for $C_{14}H_{15}N_3$; C, 74.64; H, 6.71; N, 18.65%.

(Received July 3, 1982)

Polyoxaferrocenophanes were synthesized by a one-pot reaction of 1,1′-diacetoxyferrocene with dichloride. Crystalline 1 : 1 complexes of **3a** with LiSCN, NaSCN, and KSCN were isolated. The ^{1}H-NMR and Mössbauer spectra of these complexes suggest the possibility of a certain interaction between the iron atom of the ferrocene nuclei and complexed cation. The new type of ferrocenophane **3a** extracts a thallium ion most effectively, the extractability of several metal ions being in this order; $Tl^+ > Rb^+ > K^+ > Cs^+ > Na^+$.

Although a number of crown ethers and benzo crown ethers have already been reported,[1] polyoxa[*n*]ferrocenophane and its homologs are rare.[2] Polyoxa[*n*]-ferrocenophane (**3**) is a crown ether-like compound including ferrocene subunit as a ring member; in it, the iron atom may act as a coordinatable heteroatom. Therefore, it is of interest to know what kind of interaction can be expected between the iron atom and the complexed cation. With regard to this expectation, several groups of workers[2] have synthesized this type of compounds. Biernat *et al.*[3] have recently reported the preparation of **3** and concluded, on the basis of their electronic spectral data, that there is no interaction between **3b** and the rubidium cation in methanol. On the other hand, we ourselves previously observed a certain interaction between the iron atom of oxathia-ferrocenophane and the complexed silver ion.[4] We now wish to report on a facile modified Williamson synthesis and some chemicophysical properties of **3** and alkali metal complexes of **3a** and **3b**.

Synthesis of 3a—e. The hydrolysis of **1** was carried out under a nitrogen atmosphere by the usual method. A mixture of the potassium salt of 1,1′-dihydroxyferrocene with the dihalide (**2**) in 60% ethanol was refluxed for 5 h. In every case, cyclization proceeded smoothly to afford the desired product, **3**, in a 25—60% yield. Many other products were also observed, but not confirmed because of their tiny amounts. The yields and physical properties of **3** are summarized in Table 1. The results suggest that the yields of **3** remarkably are dependent on the size of the rings, decreasing in this order: $n=4>3>2>1>0$. It is considered that the potassium cation acts as a template in the cyclization, as has been mentioned by Green.[5] It is noteworthy that this new method for preparing **3** directly starting from **1** avoids the isolation of very unstable 1,1′-dihydroxyferrocene[6] and that the yield of **3** is much higher than that in the Biernat method.[3] The structures of these compounds have been assigned on the basis of the following evidence. The IR spectrum of **3** indicates ether-linkage absorption near 1125 cm^{-1} and ferrocene-ring CH absorption near 1440 cm^{-1}, but no absorption attributable to hydroxyl or carbonyl groups. The UV spectra of **3** (λ_{max} (MeOH) 438 nm) suggest the presence of ferrocene nucleus. The mass spectra show the corresponding molecular ion. The electronic, ^{1}H-NMR, and ^{13}C-NMR spectral data are listed in Table 2. However, our ^{1}H-NMR spectra of **3a—d** are completely different from the data in the literature.[3] For example, Biernat *et al.*[3] reported that the ^{1}H-NMR spectrum of **3a** in $CDCl_3$ showed the ferrocene-ring protons at δ 3.35—3.45 as two doublets (J=6.25 Hz), together with methylene protons at δ 3.50—3.60 as multiplet. In the ^{1}H-NMR spectrum of **3a** (Table 2), the signals at δ 4.14 and 3.86 as triplets (J=2.0 Hz) are attributable to α- and β-protons of cyclopentadienyl rings,[7] while the two singlets at δ 3.70 and 3.78 and the two triplets at δ 3.86 and 4.05 (J=4.6 Hz) are attributable to the methylene protons of macrocycle. Furthermore, the ^{13}C-NMR, electronic and mass spectra and microanalysis data also support the idea that the structures of **3a—c** assigned by us are

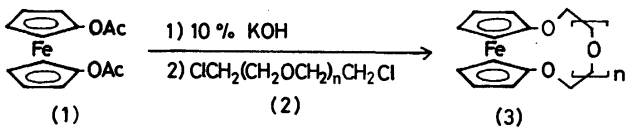
3c	4.17 (4H, t, J=2.0 Hz, H_α), 3.85 (4H, t, J=2.0 Hz, H_β), 3.76 and 3.85 (4H, t, J=5.2 Hz, OCH_2CH_2)	127.2 (C_b), 56.5 (C_α), 61.8 (C_β), 71.8 and 70.2 (methylene)	438 (119)
3d	4.22 (4H, t, J=2.0 Hz, H_α), 3.81 (4H, t, J=2.0 Hz, H_β), 3.85—3.94 and 4.06—4.15 (8H, A_2B_2 pattern, OCH_2CH_2)	126.1 (C_b), 56.0 (C_α), 61.5 (C_β), 70.6 and 70.1 (methylene)	438 (132)
3e	4.38 (4H, t, J=2.0Hz, H_α), 3.89 (4H, t, J=2.0 Hz, H_β), 4.32 (4H, s, OCH_2CH_2)	122.5(C_b), 58.9(C_α), 63.6(C_β), 71.8 (methylene)	428 (120)

a) C_b indicates bridge-head carbon. b) Measured at 40 °C.



2a, 3a : n = 4
2b, 3b : n = 3
2c, 3c : n = 2
2d, 3d : n = 1
2e, 3e : n = 0

correct, although the ^{1}H-NMR spectral data of **3a—d** and the melting points of **3a** and **3c** are different from the results in the literature.

It is noteworthy in Table 2 that **3e** showed a singlet assignable to bridge methylene protons appearing at δ 4.32, in addition to two triplet absorptions of the α- and β-cyclopentadienyl ring protons at δ 4.38 and 3.89 respectively. The downfield shift of about 0.25 ppm of the methylene protons in **3e**, compared with that of the corresponding methylene protons in **3a—d**, may be explained by using the deshielding effect of the ferrocene nucleus proposed by Mulay and Fox,[8] although other possibilities can not be ruled out. The ^{1}H-NMR spectral comparison of **3e** with **3a—d** revealed that the chemical shifts of the β-ring protons of **3a—d** (δ 3.81—3.86) are almost equal to that of **3e** (δ 3.89), whereas in the case of **3e** the α-ring protons appeared considerably downfield (δ 4.38) relative to that of **3a—d** (δ 4.14—4.22) (Table 2). Similar abnormalities are observed in the ^{13}C-NMR and electronic spectra. The ^{13}C-NMR spectra showed that the bridge head carbon of **3e** shifted upfield by about 4.5 ppm compared with that of strain-free **3a—d**, while the α- and β-carbon shifted downfield compared with the corresponding carbon atoms of **3a—d**. The Dreiding ferrocene stereo-model suggests that the ferrocene nucleus can be readily spanned by a four-atom bridge without any distortion of its preferred geometry. Therefore, in the present case, although details are not known at present, the above results may be interpreted in terms of the steric compression[9] or, more probably, in terms of anisotropy effects[10] associated with the OCH_2 bonds. The absorption band of **3e** showed a hypsochromic shift of about 10 nm, although in the case of the ring tilting alkyl bridged [2]- and [3]ferrocenophanes,[9] bridged with two and three methylene groups respectively, the absorption band near 440 nm characteristic of the ferrocene nucleus shifted to 466 nm. The hypsochromic shift may be due to the tilt-deformation of two cyclopentadienyl rings by the bridging, but its real reason is not known at present.

The Additive Effect of Alkali Metal Thiocyanate on the Electronic Spectra of Compounds 3 in Methanol. As is shown in Table 3, all the polyoxaferrocenophanes showed the characteristic peak near 440 nm associated with the d-d transition. On the addition of potassium or sodium thiocyanates to **3a** and **3b** in methanol, a small shift in the absorption peak at 438 nm and a change in the intensity of the absorption band occurred on complexing with cations. Furthermore, the absorption band of the complex of **3c** with KCN and NaCN did not shift, although the absorbance is slightly increased. A similar relationship was observed in the absorption band of **3a—c** when lithium thiocyanate was added. This suggests that the lithium complexes are unstable, probably because lithium ion is too strongly solvated by the solvent. From the above results, it can be concluded that compounds **3a** and **3b** were complexed with sodium and potassium thiocyanate

Table 3. Electronic absorption spectra data and their metal complexes in methanol (λ/nm (ε))[a]

Compound	Additive Salt			
	None	LiSCN	NaSCN	KSCN
3a	438(127)	438(139)	435(129)	434(121)

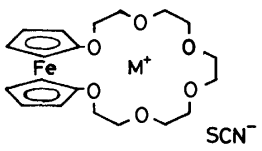
Solvent: water and dichloromethane (1 : 1). Concentration of polyether: 7×10^{-4} M (1 M=1 mol dm^{-3}). Concentration of picric acid: 7×10^{-5} M. Concentration of metal nitrates: 0.1 M.

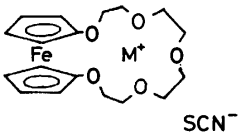
in methanol, although the changes in the absorption band at 438 nm were very complicated.

Extractability. The complexing ability of polyoxaferrocenophanes with alkali, alkaline earth, and transition-metal cations was measured by Pedersen's extraction method.[15] The data are summarized in Table 4, along with that of benzo crown ethers. Unlike from the data obtained by the TLC method,[3] the polyoxaferrocenophanes **3** showed little or no extractability toward alkali and alkaline earth metal cations, the extractability, if any, was much smaller than that of benzo crown ether. This seems reasonable considering that the incorporation of the iron atom of the ferrocene nucleus (a soft atom) or, more likely, the ferrocene nucleus itself into the macrocyclic polyether ring has an influence on the complexing ability with alkali and alkaline earth metal cation (a hard atom). The extractability of these cations is dependent on the size of the crown ether-ring part in polyoxaferrocenophanes. Thus, hexaoxa[16]ferrocenophane (**3a**) and pentaoxa[13]ferrocenophane (**3b**) extract 23 and 4% of the potassium ion respectively, but the ferrocenophanes, with a smaller polyether ring part, showed no extractability toward the potassium ion. Significantly, the selectivity of **3a** and **3b** toward the thallium ion should be noted. Thus, the extractability of **3a** and **3b** toward the thallium ion is remarkably higher than that toward other alkali and alkaline earth metal ions, while benzo crown ether showed a similar extractability toward any of the cations described above. The extractability of several metal ions was in this order: $Tl^+>Rb^+>K^+>Cs^+>Na^+$. No extraction of the silver ion by the polyoxaferrocenophanes was observed because of the oxidative decomposition of the ferrocenophanes.

Isolation of the Complex of Polyoxaferrocenophanes with Alkali Thiocyanates. The uptake of alkali metal cations with **3a** or **3b** containing six or five oxygen atoms was attempted. To an acetonitrile solution of equimolar amounts of **3a** or **3b** and alkali thiocyanate, we added hexane until a yellow or red precipitate appeared. After the precipitate has been completed in a refigerator, the complexes were obtained. These complexes (**4a—c**, **5a**, and **5b**) showed higher melting point than metal-free ligand and were confirmed by microanalysis to be 1 : 1 complexes. Their ^{1}H-NMR spectra gave much information about the character of the complexes **5a** and **5b**. The proton signals of the complexes **5a** and **5b** showed some downfield shift



4a : M = Li
4b : M = Na
4c : M = K



5a : M = Li
5b : M = Na

compared with those of the free ligands **3a** and **3b**. Ferrocene ring protons of the complexes remained in the A_2B_2 pattern, suggesting that the alkali metal cation is strongly incorporated into the center of the cavity of the macrocyclic polyether, because the coordination to one of the sides of the ligand leads to the ABCD pattern of the ring protons. The shifts of the ferrocene ring protons ($\Delta\delta=0.22(H_\alpha)$ and $0.05(H_\beta)$ in **5b**) were larger than those of the methylene protons of the oxyethylene chain ($\Delta\delta=0.03$ in **5b**). The Mössbauer spectra of **3b**, **5a**, and **5b** were measured at room temperature.[12] It was found in this study that both of the complexes (**5a** and **5b**) give larger values (2.55 mm s^{-1}) of quadrupole splitting (qs) than that (2.50 mm s^{-1}) of metal-free ferrocenophane **3b**, although the chemical isomer shifts have the same value as that (0.44 mm s^{-1}) of **3b**. It has been reported that the electron-attracting substituents[13] decrease the qs of ferrocene and that some ferrocene derivatives with electron-donating substituents[14] give larger values of qs than that of ferrocene. Therefore, if the alkali metal cation exerts an electron-attracting effect through the $Na^+\cdots O\cdots C_b$ on the cyclopentadienyl ring, compounds **4a** and **4b** can be expected to give smaller values of qs than that of metal-free ferrocenophane (**3b**). However, as has been described above, the complexes which incorporated sodium and lithium cations into the macrocyclic ether of ferrocenophane gave larger values of qs than that of **3b**. The results obtained suggest that the larger values of qs estimated for these complexes may be ascribed to some interaction between the alkali metal cation incorporated and the iron atom of ferrocene nucleus, although the possibility of the effect of the counter anion ($^-$SCN) on the e_{2g} (or a_{1g}) d-orbital of the ferrocene nucleus can not be ruled out.[16]

Experimental

The melting point are uncorrected. The IR spectra were

measured on a JASCO IRA-2 Diffraction Grating Infrared Spectrometer. The mass spectra were taken by using a JEOL-JMS-OlSG-2 Spectrometer. The ^{1}H-NMR spectra were measured on Varian XL-200 and a Hitachi R24B Spectrometer, TMS being chosen as the internal standard. The ^{13}C-NMR spectra were obtained on a Hitachi R-900 Spectrometer. The electronic spectra were measured on a Hitachi Model 200-10 spectrometer.

Material. The silica gel used for thin-layer chromatography was Wakogel B-5F. 1,2-Dichloroethane (**2e**), bis(2-chloroethyl) ether (**2d**), and 1,8-dichloro-3,6-dioxaoctane (**2c**) were commercially available and were used without further purification. 1,11-Dichloro-3,6,9-trioxaundecane (**2b**) and 1,14-dichloro-3,6,9,12-tetraoxatetradecane (**2a**) were prepared according to the procedures described in the literature.[17] The solvent were purified by distillation. Lithium thiocyanate, sodium thiocyanate, and potassium thiocyanate of Tokyo Kasei Kogyo (first grade) were used without further purification.

*Preparation of 1,1′-Diacetoxyferrocene (**1**).* **1** was prepared by the reaction of 1,1′-dibromoferrocene with copper(I) acetate according to the following modified procedure: 1,1′-Dibromoferrocene (4.5 g, 0.013 mol) and copper(I) acetate (15 g, 0.075 mol) in 50% aqueous ethanol (500 ml) were refluxed for 40 min at the reflux temperature under nitrogen. After the mixture had been cooled to room temperature, the solid was filtered off and the filtrate was added to water (600 ml). The aqueous solution was extracted with ether, washed with water, and dried over anhydrous $MgSO_4$. The residue obtained on the evaporation of the solvent was solidified to give a dark orange solid. Recrystallization from benzene–hexane gave a pure sample (2.2 g, 56% yield) as yellow needles; mp 46—48 °C (lit,[6] 55—56 °C).

*Preparation of Polyoxa[n]ferrocenophanes. General Procedure: 1,4,7,10,13,16-Hexaoxa[16]ferrocenophane (**3a**).* **1** (0.670 g, 2.20 mmol) was added to a 10% aqueous potassium hydroxide solution (10 ml) under nitrogen, and the mixture was stirred under reflux. After 30 min, a solution of 1,14-dichloro-3,6,9,12-tetraoxatetradecane (**2a**) (0.920 g, 3.30 mmol) in 60% ethanol (50 ml) was added all at once, the mixture was then stirred for 5 h at reflux temperature. After the solution had been cooled to room temperature, 100 ml of water was added to the reaction mixture. The aqueous solution was extracted with three 25 ml portions of ether. The ether extracts were combined, washed with water, and concentrated *in vacuo*. The residual oil was chromatographed by silica gel TLC (using benzene–ethyl acetate 5 : 1 as the eluent). The main band was eluted with acetone at room temperature, followed by filtration. The evaporation of the solvent gave yellow oil which solidified on standing, The pure product was obtained as yellow needles by recrystallization from hexane.

General Procedure for the Preparation of the Alkali Metal Thiocyanate Complex. Alkali metal thiocyanate (0.14 mmol) and **3a—b** were dissolved in anhydrous acetonitrile. To the mixture, hexane was added until precipitation occurred. The reaction mixture was then cooled in a refrigerator. After the precipitation was complete, the crystalline product was filtered off and washed with small amounts of acetonitrile and hexane. An almost quantitative yield of these complexes was obtained.

*Lithium Thiocyanate Complex of **3a** (**4a**).* The complex, (yellow needles), exhibited the following physical and spectral properties; mp 123—128 °C. Found: C, 52.19; H, 5.89; N, 2.68%. Calcd for $C_{21}H_{28}O_6NSLiFe$: C, 51.96; H, 5.77; N, 2.89%. ^{1}H-NMR (60 MHz, in $CDCl_3$): δ 4.19 (4H, t, J=2.0 Hz, H_α), 3.93 (4H, t, J=2.0 Hz, H_β), 3.77 (4H, s, OCH_2CH_2O), 3.75 (8H, s, OCH_2CH_2O), 4.00—3.78 (8H, m, OCH_2CH_2O).

*Sodium Thiocyanate Complex of **3a** (**4a**).* Mp 135—137 °C. Found: C, 50.50; H, 5.87; N, 2.53%. Calcd for $C_{21}H_{28}O_6NSNaFe$: C, 50.30; H, 5.59; N, 2.79%. ^{1}H-NMR ($CDCl_3$): δ 4.14 (4H, t, J=2.0 Hz, H_α), 3.87 (4H, t, J=2.0 Hz, H_α), 3.69 (4H, s, OCH_2CH_2O), 3.78 (4H, s, OCH_2CH_2O), and 4.02—3.80 (8H, m, OCH_2CH_2O).

*Potassium Thiocyanate Complex of **3a** (**4c**).* Mp 164—167 °C. Found: C, 49.05; H, 5.72; N, 2.88%. Calcd for $C_{21}H_{28}O_6SNKFe$: C, 48.74; H, 5.42; N, 2.71%. ^{1}H-NMR ($CDCl_3$): δ 4.16 (4H, t, J=2.0 Hz, H_α), 3.91 (4H, t, J=2.0 Hz, H_β), 3.76 (8H, s, OCH_2CH_2O), 3.75 (4H, s, OCH_2CH_2O), and 4.00—3.78 (8H, m, OCH_2CH_2O).

*Lithium Thiocyanate Complex of **3b** (**5a**).* Mp 147—149 °C. Found: C, 51.53; H, 5.74; N, 3.12%. Calcd for $C_{19}H_{24}O_5SNLiFe$: C, 51.70; H, 5.44; N, 3.17%. ^{1}H-NMR ($CDCl_3$): δ 4.32 (4H, t, J=2.0 Hz, H_α), 3.98 (4H, t, J=2.0 Hz, H_β), 3.79 (8H, s, OCH_2CH_2O), and 4.12—3.80 (8H, m, OCH_2CH_2O).

*Sodium Thiocyanate Complex of **3b** (**5b**).* Mp 165.5—167 °C. Found: C, 50.19; H, 5.78; N, 3.01. Calcd for $C_{19}H_{24}O_5SNNaFe$: C, 49.89; H, 5.44; N, 3.17%. ^{1}H-NMR ($CDCl_3$): δ 4.37 (4H, t, J=2.0 Hz, H_α), 3.91 (4H, t, J=2.0 Hz, H_β), 3.74 (8H, s, OCH_2CH_2O), and 4.02—3.80 (8H, m, OCH_2CH_2O).

The Method of Solvent Extraction. Extractability of polyoxaferrocenophanes with the alkali metal cation was examined by the extraction method described by Pedersen.[15] Equal volumes (5 ml) of dichloromethane containing 7×10^{-4} M of polyoxaferrocenophane and an aqueous solution containing 1×10^{-1} M MNO_3 (M; alkali metal cation) and 7×10^{-5} M picric acid were agitated thoroughly at 25 °C. The solution was then equilibrated at 25 °C, the aliquot of the upper aqueous solution was withdrawn, and the electronic spectrum was recorded. A similar extraction was performed with pure dichloromethane. The extractability was determined by reading the difference between the two absorbances of picrate in the aqueous solution. The extractability was calculated by means of the following equation:

$$\text{Extractability} = \frac{A_0 - A}{A_0} \times 100.$$

A_0 is the absorbance in the absence of MNO_3 and A is the absorbance in the presence of MNO_3.

The authors wish to thank Professor Masuo Takeda, Department of Chemistry, Toho University, for the measurement of the Mössbauer spectra.

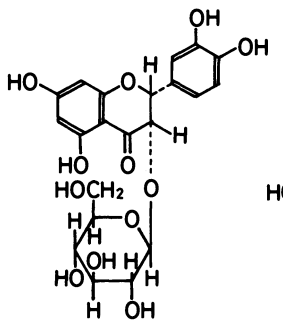
Chemical Studies on the Mistletoe. V.[1] The Structure of Taxillusin, a New Flavonoid Glycoside Isolated from *Taxillus kaempferi*[2]

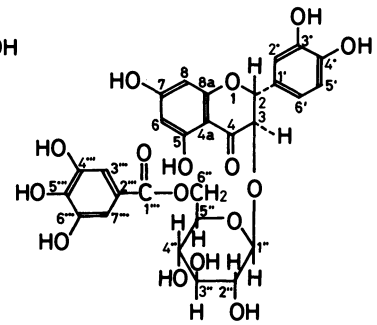
Atsushi SAKURAI* and Yasuaki OKUMURA
Department of Chemistry, Faculty of Science, Shizuoka University, Ohya, Shizuoka 422
(Received July 7, 1982)

A new flavonoid glycoside, taxillusin was isolated from *Taxillus kaempferi* (DC.) Danser and (2*R*,3*R*)-taxifolin 3-β-D-glucopyranoside 6″-gallate was assigned to this substance from studies on the hydrolysis products and from analyses of the ^{1}H-NMR and carbon-13 NMR spectra.

Japanese mistletoe, *Taxillus kaempferi* (DC.) Danser (Matsugumi in Japanese) is a perennial shrub of *Viscaceae*. In our previous paper[1] we reported the isolation and structure of isoglucodistylin (**1**), a flavonoid constituent of this plant, which was assigned to be (2*R*,3*S*)-taxifolin 3-β-D-glucopyranoside. During the course of the isolation of **1** by Sephadex LH-20 column chromatography, we isolated another new flavonoid glycoside and named it taxillusin (**2**). We now wish, to report the isolation and the results which lead to the structure of taxillusin (**2**).



1



2

Compound **2** is hygroscopic faintly yellowish crystals, mp 198—203 °C and optically active, $[\alpha]_D$ +5.2°. Elemental analyses show that **2** has a composition of $C_{28}H_{26}O_{16}$. The UV spectrum of **2** in ethanol shows the absorption maximum at 292 nm, and this absorption maximum and its pattern were similar to those reported for a number of flavonoids of taxifolin type.[3] The IR spectrum of **2** shows absorption bands characteristic of flavonoid glycosides and indicative of the existence of a conjugated ester group at 1690 and 1250 cm^{-1} besides them.

Acetylation of **2** with acetic anhydride and pyridine gave a decaacetate of **2** as colorless fine crystals, mp 125—129 °C.

Acid hydrolysis of **2** with 5% sulfuric acid in 50% aqueous ethanol[4] gave taxifolin (**3**), gallic acid (**4**), and D-glucose as the components. Since the optical rotation value of **3** ($[\alpha]_D$ +12°) is identical with that of (+)-taxifolin,[5,6] the absolute configuration of **3** is 2*R* and 3*R*.[7] Methylation of **2** with dimethyl sulfate and potassium carbonate in acetone followed by acid hydrolysis in the same manner as described above and then air oxidation[3c] gave 3′,4′,5,7-tetra-*O*-methylquercetin (**5**),[3c,8] which was identified with the authentic sample prepared by methylation and acid hydrolysis of rutin in the same manner. This result indicates that either D-glucose or gallic acid might be linked at the 3-position of **3**.

Treatment of **2** with hydrogen chloride in methanol gave **3**, methyl gallate (**6**), methyl α-D-glucopyranoside (**7**), and a substance **8**. The IR spectrum of **8** shows absorption bands indicative of the existence of a conjugated ester group at 1700 and 1240 cm^{-1}. Since **8** gives **6** and **7** by further treatment with hydrogen chloride in methanol, D-glucose and gallic acid should be linked by an ester bond. The ^{1}H-NMR spectrum of a trimethylsilyl derivative of **8** in $CDCl_3$ shows a sharp singlet ascribed to the methoxyl group at δ 3.37 ppm, a doublet corresponding to the 1-proton of glucose at δ 4.62 ppm (J=3 Hz, axial/equatorial coupling indicative of α-D-glucoside), and a sharp singlet attributed to the 3′- and 7′-protons of galloyl group at δ 7.23 ppm. This result indicates **8** to be a gallate of methyl α-D-

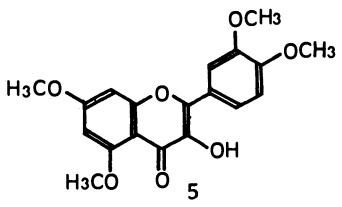
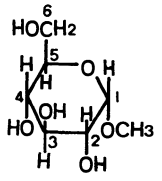
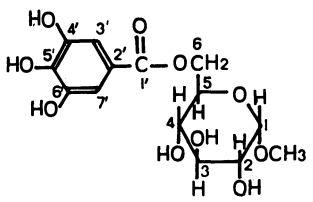
6 : R = CH_3



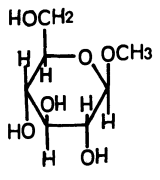
5



7



8



9

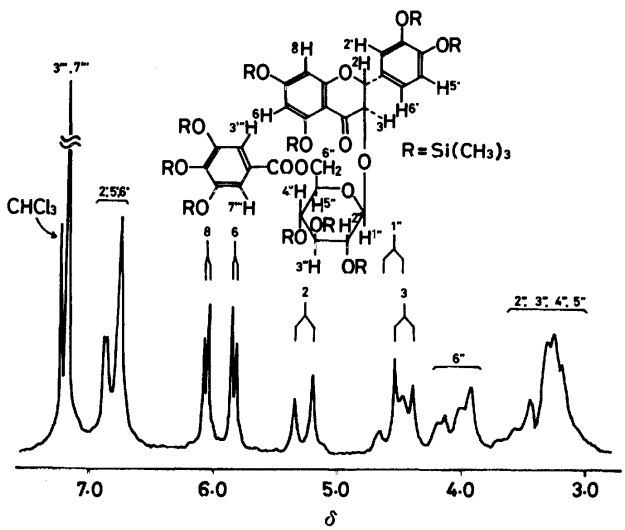


Fig. 1. The ^{1}H-NMR spectrum of trimethylsilyl derivative of taxillusin (**2**) in $CDCl_3$.

glucoside.

The position of linkage between the D-glucose and gallic acid in **8** was confirmed by comparison of the carbon-13 NMR spectra of **6**, **7**, **8**, and their trimethylsilyl derivatives as shown in Table 1. The 6-carbon of the glucose in **8** appears at a field lower by 2.7 ppm and the 5-carbon of the glucose in **8** appears at a field higher by 2.0 ppm than those of **7**. The 5- and 6-carbons of the glucose in a trimethylsilyl derivative of **8** also appear at fields higher by 2.4 ppm and lower by 1.6 ppm respectively than those of a trimethylsilyl derivative of **7**. These results indicate that the gallic acid in **8** should be linked by an ester bond at the 6-position of **7**.

Beisdes the signals characteristic of **3** as shown in Fig. 1, the ^{1}H-NMR spectrum of a trimethylsilyl derivative of **2** in $CDCl_3$ shows a sharp singlet of 3‴- and 7‴-protons of galloyl group at δ 7.20 ppm, signals of the protons in 2′-, 3′-, 4′-, and 5′-positions of glucose between δ 3.0 and 3.8 ppm, a broad doublet of 1″-proton of glucose at δ 5.24 ppm (J= *ca.* 11 Hz, axial/axial coupling indicative of β-D-glucoside), and a two proton AB-type multiplet of 6″-protons of glucose at δ 4.04 ppm (down-field shift by galloyl group). This result indicates that **2** might be (2*R*,3*R*)-taxifolin 3-β-D-glucopyranoside 6″-gallate.

The structure of **2** is supported also by the carbon-13 NMR spectra of **1**, **2**, **3**, **6**, and methyl β-D-glucopyranoside (**9**) in DMSO-d_6 as shown in Table 1. The 1-carbon of the glucose in **2** appears at a field higher by 2.7 ppm than that of **9** and the 4-carbonyl carbon in **2** also appears at a field higher by 5.6 ppm than that of **3**. This fact is the consequence of steric compression between the C-1 of glucose and the C-4 of taxifolin. The 3- and 4-carbons of the taxifolin in **1** appear at fields higher by 1.1 ppm and lower by 0.7 ppm respectively

Table 1. Carbon-13 NMR chemical shifts[a] of **1**, **2**, **3**, **6**, **7**, **8**, **9**, and trimethylsilyl derivatives of **7** and **8**

a) In parts per million down-field from tetramethylsilane. b) TMS: trimethylsilyl derivative. c) Asterisks indicate that assignments are not unambiguous.

than those of **2**. This fact is the consequence of the difference in the configuration at the 3-position of taxifolin between **1** and **2**. The 5- and 6-carbons of the glucose in **2** appear at fields higher by 2.5 ppm and lower by 2.3 ppm respectively than those of **9** and also appear at fields higher by 2.5 ppm and lower by 2.2 ppm respectively than those of **1**, which indicates that gallic acid is linked by an ester bond at the 6-position of D-glucose.

These ^{1}H-NMR and carbon-13 NMR spectroscopic data and all experimental results described above support the structure of taxillusin (**2**) to be (2*R*,3*R*)-taxifolin 3-β-D-glucopyranoside 6″-gallate.

Experimental

All melting points are uncorrected. The proton and carbon nuclear magnetic resonance spectra were measured with a JEOL JNM-PFT-60 NMR spectrometer, and the latter spectra were obtained on sampling interval of 2.0 s. Chemical shifts were obtained by δ value (ppm) from tetramethylsilane as internal standard at 15.04 MHz for carbon and 59.8 MHz for proton. The UV spectra were measured with a Hitachi EPS-3 recording spectrophotometer. The optical rotations were measured with a Union PM-101 polarimeter.

Extraction and Isolation of Taxillusin (2). The fresh leaves and twigs of the mistletoe (2 kg)[9] were extracted with ethanol (6 l) in the usual way, and the extract was condensed to a syrup under reduced pressure. The syrup was triturated with water (2 l) and chloroform (2 l), and the undissolved material which accumulated between both layers was collected and washed with water. After being dried in a desiccator over calcium chloride, the faintly yellowish powder (11.5 g) was dissolved in ethanol (50 ml), and the solution was subjected to chromatography on a column of Sephadex LH-20 (7×40 cm) eluting with ethanol.[10] The last effluent was rechromatographed with a column of Sephadex LH-20 (3.5×120 cm) in the same manner as described above. After removal of the solvent, recrystallization from aqueous ethanol gave taxillusin (**2**) as hygroscopic faintly yellowish crystals: mp 198—203 °C (decomp); yield, 9.2 g (0.46% from wet plant); $[\alpha]_D^{25}$ +5.2° (*c* 1.0, EtOH); UV (EtOH): λ_{max} 292 nm (ε 23300); IR (KBr disk): ν_{max} 3400—3200, 1690, 1653, 1620, 1610, 1550, 1531, 1516, and 1250 cm^{-1}. Found: C, 51.31; H, 4.78%. Calcd for $C_{28}H_{26}O_{16}\cdot 2H_2O$: C, 51.38; H, 4.62%.

Acetylation of 2. Acetylation of **2** with acetic anhydride and pyridine in the usual way gave a decaacetate of **2** as colorless fine crystals: mp 125—129 °C; UV (EtOH): λ_{max} 241 (ε 31900, inflexion), 263 (ε 17900), and 312 nm (ε 6490). Found: C, 55.16; H, 4.42%. Calcd for $C_{48}H_{46}O_{26}$: C, 55.49; H, 4.46%.

Acid Catalyzed Hydrolysis of 2. **2** (100 mg) was dissolved in 50% aqueous ethanol (20 ml) containing concd sulfuric acid (1 ml) and the mixture was refluxed for 3 h. After removal of ethanol by evaporation under reduced pressure, the solution was extracted with ethyl acetate. The extract was subjected to chromatography on a column of Sephadex LH-20 (2×75 cm) eluting with ethanol and gave **3** (mp 240—242 °C; yield, 32 mg; $[\alpha]_D^{25}$ +12° (*c* 0.75, EtOH)) and **6** (mp 233—237 °C (decomp); yield, 12 mg).

Hydrolyzate free from **3** and **6** was neutralized with barium carbonate and was concentrated under reduced pressure, which was subjected to thin layer chromatography for detection of the sugar component. The sugar was proved to be identical with D-glucose.

Methylation of 2. According to Fukui, Nakadome, and Ariyoshi's method,[3c] **2** was methylated with dimethyl sulfate and potassium carbonate in acetone followed by acid hydrolysis and then by air oxidation. The product was identical with authentic 3′,4′,5,7,-tetra-*O*-methylquercetin (**5**) which was prepared by methylation and acid hydrolysis of rutin in the same manner. **5**: mp 194—196 °C[3c]; UV(EtOH): λ_{max} 253 and 362 nm;[8] ^{1}H-NMR ($CDCl_3$): δ 3.92 (3H, s, CH_3O), 3.98 (9H, s, CH_3O), 6.37 (1H, d, J=2 Hz, H-6), 6.54 (1H, d, J=2 Hz, H-8), 6.99 (1H, d, J=9 Hz, H-5′), 7.38 (1H, broad s, 3-OH), 7.78 (1H, dd, J=2 and 9 Hz, H-6′), and 7.81 ppm (1H, d, J=2 Hz, H-2′).

Methanolysis of 2. **2** (620 mg) was dissolved in dry methanol (15 ml), and 30% methanolic hydrogen chloride (5 ml) was added to this solution. After having been allowed to stand for 12 h at room temperature, the reaction mixture was evaporated to dryness under reduced pressure. The residue was subjected to chromatography on a column of Sephadex LH-20 (3×120 cm) eluting with methanol in the same manner as described above and gave **3** (yield, 105 mg), **6** (mp 198—200 °C; yield, 55 mg), **7** (mp 169—170 °C; yield, 60 mg; $[\alpha]_D^{20}$ +159° (*c* 0.5, H_2O)), and **8** (colorless powder from methanol and ether; mp 120—124 °C; yield, 110 mg; $[\alpha]_D^{22}$ +37° (*c* 0.2, EtOH); IR (KBr disk): ν_{max} 3350, 1700, 1614, 1535, 1240, 1150, 1045, 878, 770, and 745 cm^{-1}; Found: C, 48.83; H, 5.23%. Calcd for $C_{14}H_{18}O_{10}$: C, 48.56; H, 5.24%).

Further treatment of **8** with methanolic hydrogen chloride in the same manner as described above gave **6** and **7**.

Acetylation of **8** with acetic anhydride and pyridine in the usual way gave a hexaacetate of **8** as colorless crystals: mp 77—79 °C. Found: C, 51.97; H, 5.01%. Calcd for $C_{26}H_{30}O_{16}$: C, 52.18; H, 5.05%.

Trimethylsilylation. Flavonoid or sugar (50 mg) was treated with anhydrous pyridine (5 ml), trimethylchlorosilane (0.5 ml), and hexamethyldisilazane (1 ml). The mixture was allowed to stand overnight at room temperature. After being evaporated to dryness under reduced pressure, the residue was dissolved in chloroform, and the undissolved materials which separated were filtered off and washed with chloroform. The filtrate and washings were evaporated to dryness under reduced pressure. No further attempt was made to purify the trimethylsilyl derivative before measurement of the NMR spectra.

N-Methyl-*N*-(phenylsulfonyl)benzohydrazonoyl Chloride as a Potential Intermediate for Nitrogen-heterocycles. Preparation of 1-Methyl-3-phenyl-1*H*-1,2,4-triazoles and -pyrazoles

Suketaka Ito,* Yumo Tanaka, Akikazu Kakehi, Toshihiko Fukuyama,† Nobuo Osawa,†† and Noboru Sayo†††

(Received July 7, 1982)

3,5-Disubstituted 1-methyl-1*H*-1,2,4-triazoles and -pyrazoles were obtained in good to moderate yields by the reaction of *N*-methyl-*N*-(phenylsulfonyl)benzohydrazonoyl chloride with nitriles and with acetylenes in the presence of aluminum chloride. The triazoles were also formed by the reaction of acid chlorides with *N*-methyl-*N*-(phenylsulfonyl)benzamidrazone which was generated from the hydrazonoyl chloride and ammonia.

N-Phenylbenzohydrazonoyl chloride (**1**) gives 1-phenyl-1*H*-1,2,4-triazoles by the reaction with nitriles *via* a nitrilium ion (generated from **1** and aluminum chloride)[1] as well as *via* diphenylnitrilimine generated from **1** and triethylamine.[2] *N,N*-Disubstituted hydrazonoyl halides such as *N*-methyl-*N*-phenylbenzohydrazonoyl chloride[3] cannot afford 1,2,4-triazoles as a matter of course. As has been shown in the reaction of *N*-(phenylsulfonyl)benzohydrazonoyl chloride (**2**) with *N,N'*-disubstituted benzamidines and *N*-substituted benzimidates,[4] however, such an arylsulfonyl group attached to the amino nitrogen of hydrazonoyl chlorides as that of **2** can be eliminated as an arenesulfonyl cation. Thus, the title hydrazonoyl chloride carrying an *N*-phenylsulfonyl group can be expected as a potential source for 1-methyl-1*H*-1,2,4-triazoles and -pyrazoles. The present paper deals with the Lewis acid-catalyzed reaction of *N*-methyl-*N*-(phenylsulfonyl)benzohydrazonoyl chloride (**3**) with nitriles and with acetylenes and, in addition, the reaction of *N*-methyl-*N*-(phenylsulfonyl)benzamidrazone (**4**) derived from **3**.

Results and Discussion

The Lewis Acid-catalyzed Reactions of N-*Methy*-N-*(phenylsulfonyl)benzohydrazonoyl Chloride (3) with Nitriles and Acetylenes. Preparation of 3*: Hydrazonoyl chloride **3** was obtained in an almost quantitative yield by the *N*-methylation of *N*-(phenylsulfonyl)benzohydrazonoyl chloride (**2**) with diazomethane. The thionyl chloride treatment of 1-benzoyl-2-methyl-2-phenylsulfonylhydrazine (**5**) obtained from 1-benzoyl-2-phenylsulfonylhydrazine (**6**) by the *N*-alkylation with methyl iodide was also available for preparing **3** (Scheme 1). Except for the trouble and hazard in the preparation of diazomethane, the former method may be convenient. Hydrazonoyl chloride **3** is a stable crystalline compound, but was observed to undergo hydrolysis more appreciably than **2** when allowed to stand in contact with the atmosphere for a long time.

Reactions of 3: A mixture of **3** and small excess amounts of benzonitrile and aluminum chloride was heated at 115—125 °C (oil bath) in a solvent for 30 min. Work-up gave 1-methyl-3,5-diphenyl-1*H*-1,2,4-triazole (**7a**) in a 77% (maximum) yield: in the case of low reaction temperature, unaltered **3** was recovered (Table 1). When the reaction was carried out in the presence of titanium(IV) chloride or boron trifluoride etherate as a catalyst, **7a** was obtained in a diminished yield (at 115—125 °C in *o*-dichlorobenzene). The results are summarized in Table 2 along with those obtained in the reaction with acetonitriles. The reaction of the *N*-unalkylated hydrazonoyl chloride, **2**, with benzonitrile as a control experiment gave 3,5-diphenyl-1*H*(or 4*H*)-1,2,4-triazole (49%), which should be generated by the hydrolysis of 1-phenylsulfonyl-3,5-diphenyl-1*H*-1,2,4-triazole. Under the same reaction conditions, phenylacetylene and diphenylacetylene gave 1-methyl-3,5-diphenyl (**8a**) and 1-methyl-3,4,5-triphenyl-1*H*-pyrazole

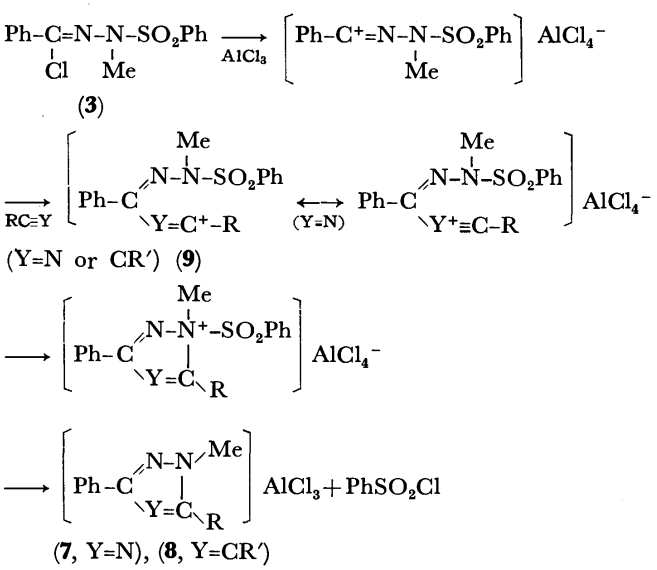
(**8b**) in moderate yields, respectively (Table 2).

The triazoles and pyrazoles obtained were identified by their analytical and spectral data, and the confirmation of the known compounds was made also by direct comparison with authentic specimens. To the present reactions, the following nitrilium ion mechanism[1] may be applicable most reasonably (Scheme 2).



Scheme 2.

The lower yields in the pyrazole formation should be ascribed to the relative instability of the secondarily formed nitrilium ion(**9**,Y=CR′) and/or the weak nucleophilicity of acetylenes. In contrast to the reaction of **1**,[1] no dihydrotetrazine formation from two molecules of **3** could be observed, which may be due to the potential crowdedness of the intermediate ammonium ion required for the dihydrotetrazine formation.

Attempted Reactions with Olefins. Attempts to prepare pyrazolines by the aluminum chloride-catalyzed reaction of **3** with olefins such as cyclohexene, acenaphtylene, and norbornene were unsuccessful. However, small amounts (3%) of (3a*RS*,7a*SR*)-3-phenyl-1-phenylsulfonyl-4,7-methano-3a,4,5,6,7,7a-hexahydro-1*H*-indazole was obtained by the reaction of **2** with norbornene in the presence of aluminum chloride at room temperature.[5]

In this case, the reaction may proceed alternatively *via* the 1,3-dipolar cycloaddition of *N*-(phenylsulfonyl)-benzonitrilimine.[6]

Preparation of Triazoles (7) via N-Methyl-N-(phenylsulfonyl)benzamidrazone (4) (an Indirect Method for Preparing 7 from 3). Amidrazone **4** may fall under one of the simplest classes of derivatives from **3** and its –N–C(Ph)=N–N– part of molecule should be available for constructing a 1,2,4-triazole ring. Compound **4** was obtained in a good yield by the treatment of **3** in DMF with gaseous ammonia.[7]

When amidrazone **4** was allowed to react with benzoyl chloride under reflux in THF, *N*-methyl-*N*-phenylsulfonyl-*N*″-benzoylamidrazone was obtained along with the hydrochloride of **4**. However, fusion of **4** with an aroyl or acyl chlorides at an elevated temperature (145—155 °C) gave 3,5-disubstituted 1-methyl-1*H*-1,2,4-triazoles (**7**) in good yields. The results are summarized in Table 3. A similar treatment with acetic anhydride resulted in no formation of **7c**.

The reaction of hydrazonoyl chloride **3** with benz-

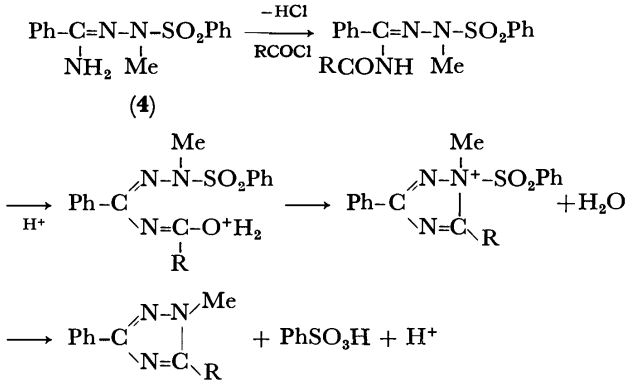

Scheme 3.

amide and with acetamide under the conditions of fusion afforded triazoles **7a** and **7c** in poor yields (18 and 10%, respectively) together with hydrazide **5**. The inferiority in yields should be due to the weak nucleophilicity of amides and also to the hydrolysis of **3** by water generated *in situ*.

The reaction of amidrazone **4** with acid chlorides can be formulated as follows (Scheme 3).

The formation of five-membered heteroaromatics *via* condensation or related reactions is well known to proceed smoothly in general. This specific tendency may be ascribed to the probable aromatic or quasi-aromatic character of the activated complex in reactions. Such situation has been partly discussed elsewhere,[8] and can be postulated in the present reactions including the Lewis acid-catalyzed reaction described above. The attempted pyrazoline-forming reaction is lacking in this type of stabilization.

Evaluation as a Preparative Method. Because of the inferiority in yields, the present Lewis acid-catalyzed reaction may be almost useless for obtaining pyrazoles. For preparing 1-alkyl-1*H*-1,2,4-triazoles, the following four procedures are available as general methods:[9,10,11] the condensation of diacylamines with alkylhydrazines (Einhorn-Brunner reaction), the condensation of amides with 2-alkylhydrazides (Pellizzari reaction), the reaction of *N*-alkylamidrazones with acid derivatives,[12] and the *N*-alkylation of *N*-unsubstituted 1,2,4-triazoles.[13] The former three methods require alkylhydrazines which are expensive or hardly available. In the fourth method, the *N*-alkylation proceeds usually at a specific position when the *C*-substituents are unlike each other. However, this specificity should be reduced in the case that the starting *N*-unsubstituted triazoles bear similar C_3- and C_5-substituents. On the other hand, the present method using *N*-methyl-*N*-sulfonylhydrazonoyl chloride or *N*-methyl-*N*-sulfonylamidrazone does not have such disadvantages as described above, and may be applicable to the preparation of *N*-higher alkyl homologs, since their precursor 1-benzoyl-2-alkyl-2-phenylsulfonylhydrazines can be easily obtained by the alkylation of **6**. Thus, in view of the good to comparable yields of products, the present method is useful for preparing 1-alkyl-1*H*-1,2,4-triazoles.

Experimental

Melting poins were determined with a Yanagimoto MP-S3 micromelting point apparatus, and are uncorrected. Molecular weights were determined with a Hitachi-Perkin-Elmer molecular weight apparatus Model 115. The microanalysis was performed on a Perkin-Elmer 240 elemental analyzer. The IR and NMR spectra were recorded with a Hitachi 260-10 and a Varian EM-360A spectrometer, respectively.

Preparation of N-*Methyl*-N-*(phenylsulfonyl)benzohydrazonoyl Chloride (3). Method A*: To a solution of *N*-(phenylsulfonyl)benzohydrazonoyl chloride[14] (**2**, 2.95 g, 10 mmol) in THF (30 ml), slightly excess amounts of an ethereal solution of diazomethane was added by portions. The reaction came to an end almost immediately with the evolution of nitrogen. The removal of solvent gave almost pure **3** (3.12 g), which was recrystallized from benzene or methanol. Mp 112—113 °C; IR (KBr, cm^{-1}): 1589 (C=N), 1355, 1164 (SO_2); NMR ($CDCl_3$, δ): 3.05 ppm (3H s, N-CH_3), 7.23—8.15 ppm (10H m, 2Ph). Found: MW, 305; C, 54.44; H, 4.25; N, 9.12%. Calcd for $C_{14}H_{13}N_2O_2SCl$: MW, 309; C, 54.46; H, 4.24; N, 9.07%.

Method B: To a solution of 1-benzoyl-2-phenylsulfonylhydrazine (**6**, 5.52 g, 20 mmol) in DMF (50 ml), a 0.58 g-portion (net 24 mmol) of sodium hydride dispersion (70% in liquid paraffin) was added under external cooling. After the ceasing of gas evolution (a few minutes), methyl iodide (3.12 g, 22 mmol) was added to the mixture. After stirring for 1 h at room temperature, the DMF solution was poured into water to separate 1-benzoyl-2-methyl-2-phenylsufonylhydrazine (**5**, 5.50 g), which was purified by crystallization from methanol. Mp 186—187 °C; IR (KBr, cm^{-1}): 3217 (NH), 1667 (C=O), 1352, 1154 (SO_2). Found: MW, 294; C, 57.76; H, 4.83; N, 9.57%. Calcd for $C_{14}H_{14}N_2O_3S$: MW, 290; C, 57.92; H, 4.86; N, 9.65%. A mixture of **5** (4.35 g, 15 mmol) and 30 ml of thionyl chloride was refluxed for 3 h. Removal of excess thionyl chloride *in vacuo* and washing the resulting yellowish residue with small amounts of methanol gave cryatalline **3** (4.40 g), which was recrystallized from methanol or benzene. Mp 112—113 °C.

Reaction of 3 with Nitriles in the Presence of a Lewis Acid. Typical Procedure: A mixture of benzonitrile (0.57 g, 5.5 mmol), freshly sublimed aluminum chloride (0.47 g, 5.5 mmol), **3** (1.55 g, 5.0 mmol), and *o*-dichlorobenzene (5 ml) was heated at 115—125 °C for 30 min in an oil bath. After being cooled. the reaction mixture was basified with a dilute aqueous sodium hydroxide solution and extracted with chloroform. The chloroform layer was washed with dilute hydrochloric acid and then water. After removal of the solvent, the chloroform extract was chromatographed on a silica-gel column (2.0 cm-d, 20 cm-h; eluents: hexane, benzene, and benzene–diethyl ether) to give **7a** (0.91 g, 77%), which was purified by recrystallization from benzene. The results are listed in Table 1 and 2.

*1-Methyl-3-phenyl-5-benzyl-1*H*-1,2,4-triazole (7b)*: Mp 70—71 °C (ethanol); IR (KBr, cm^{-1}): 1600, 1069, 1024 (1,2,4-triazole ring vibrations);[15] NMR ($CDCl_3$, δ): 3.73 ppm (3H s, N-CH_3), 4.23 ppm (2H s, -CH_2-), 7.10—7.60 ppm (8H m, *m,m'*- and *p*-protons of 3-Ph and Ph-CH_2-), 7.97—8.26 ppm (2H m, *o,o'*-protons of 3-Ph). Found: C, 77.00; H, 6.09; N, 17.06%. Calcd for $C_{16}H_{15}N_3$: C, 77.08; H, 6.06; N, 16.85%.

Aluminum Chloride-catalyzed Reaction of 2 with Benzonitrile (A Control Experiment). The reaction and the work-up in a similar way gave 3,5-diphenyl-1*H*(or 4*H*)-1,2,4-triazole. Yield: 49%; mp 191—192 °C (lit,[16] mp 189—190 °C). Found: C, 75.72; H, 5.34; N, 18.93%.

Reaction of 3 with Acetylenes. The reaction was carried out in a manner similar to above except the use of diphenylacetylene or phenylacetylene in the place of nitriles. The results are summarized in Table 2.

Preparation of N-*Methyl*-N-*(phenylsulfonyl)benzamidrazone (4).* Into a solution of **3** (15.5 g, 50 mmol) in DMF (60 ml) which was externally heated at approximately 80 °C in an oil bath, anhydrous ammonia was bubbled. After the completion of precipitation of ammonium chloride (about 30 min), the reaction mixture was cooled and then poured into water to separate *N*-methyl-*N*-(phenylsulfonyl)benzamidrazone (**4**, 13.0 g, 45 mmol), which was purified by crystallization from ethanol. Mp 156—158 °C; IR (KBr, cm^{-1}): 3479, 3373 (NH), 1625 (C=N), 1326, 1155 (SO_2); NMR ($CDCl_3$, δ): 2.83 ppm (3H s, N-CH_3), 5.75 ppm (2H brs, N-H), 7.23—8.12 ppm (10H m, 2Ph). Found: C, 58.07; H, 5.20; N, 14.50%. Calcd for $C_{14}H_{15}N_3O_2S$: C, 58.11; H, 5.23; N, 14.52%.

Reaction of 4 with Benzoyl Chloride in THF under Reflux. A solution of **4** (0.87 g, 3 mmol) and benzoyl chloride (0.42 g,

3 mmol) in THF (20 ml) was refluxed for 7 h. From the reaction mixture, *N*-methyl-*N*-(phenylsulfonyl)benzamidrazone hydrochloride was separated as precipitates. Yield: 0.56 g (1.7 mmol, 57%); mp 186—188 °C; IR (KBr, cm^{-1}): 3370—2600 (broad peaks, $[H_2N\cdots C\cdots N-]^+H$), 1673 (C=N), 1355, 1162 (SO_2). Found: C, 51.36; H, 4.85; N, 12.96%. Calcd for $C_{14}H_{16}N_3O_2SCl$: C, 51.61; H, 4.95; N, 12.90%. After the removal of solvent from the THF layer, the residue was crystallized from ethanol to give *N*-methyl-*N*-phenylsulfonyl-*N''*-benzoylbenzamidrazone (0.37 g, 0.94 mmol, 31%). Mp 179—181 °C; IR (KBr, cm^{-1}): 3330 (NH), 1697 (C=O), 1605 (C=N), 1340, 1162 (SO_2); NMR ($CDCl_3$, δ): 2.94 ppm (3H s, N–CH_3), 7.29—8.30 ppm (10H m, 2Ph), 9.93 ppm (1H brs, N–H). Found: C, 63.91; H, 4.90; N, 10.72%. Calcd for $C_{21}H_{19}N_3O_3S$: C, 64.11, H, 4.87; N, 10.68%.

Reaction of ***4*** *with Acid Chlorides under the Conditions of Fusion. General Procedure*: A mixture of **4** (3 mmol) and an acid chloride (3 mmol) was heated at 145—155 °C in an oil bath for 3.5 h (under the reflux of the acid chloride). After being cooled, the reaction mixture was extracted with chloroform and a portion of dilute sodium hydroxide solution. The chloroform extract was concentrated and chromatographed on a silica-gel column (2.0 cm-d, 15 cm-h) to give the corresponding triazole, which was crystallized from benzene, hexane, or ethanol. The results are summarized in Table 3.

*1-Methyl-5-ethyl-3-phenyl-1*H*-1,2,4-triazole (****7d****)*: Yield: 70 %; mp 51—52 °C (*picrate*: mp 166—167 °C); IR(KBr, cm^{-1}): 1603, 1066, 1024 (1,2,4-triazole ring vibrations);[15] NMR ($CDCl_3$, δ): 1.39 ppm (3H t, J=7.6 Hz, $C\underline{H}_3CH_2$–), 2.84 ppm (2H q, J=7.6 Hz, $CH_3C\underline{H}_2$–), 3.87 ppm (3H s, N–CH_3), 7.23 7.59 ppm (3H m, *m,m'*- and *p*-protons of Ph), 7.94—8.23 ppm (2H m, *o,o'*-protons of Ph). Found: C, 70.64; H, 7.07; N, 22.18%. Calcd for $C_{11}H_{13}N_3$: C, 70.56; H, 7.00; N, 22.44%. (*Picrate*: Found: C, 49.00; H, 3.87; N, 20.33%. Calcd for $C_{17}H_{16}N_6O_7$: C, 49.04; H, 3.87; N, 20.19%).

Hydrolysis of Some Chromogenic Substrates and Adenosine Triphoshate Catalyzed by Phosphodiesterase-phosphomonoesterase from *Fusarium moniliforme*

Hiroshi Yoshida,* Masayuki Kawai, Chiseko Okimura, Nobuyuki Hirama, and Osamu Konno
Department of Chemistry, Faculty of Science, Tohoku University, Aobayama, Sendai 980
(Received July 16, 1982)

For comparison with known phosphodiesterases, the mode of action of phosphodiesterase-phosphomonoesterase from *Fusarium moniliforme* toward some key substrates was examined. The enzyme catalyzed the hydrolysis of either thymidine 3′-(4-nitrophenylphosphate) or thymidine 5′-(4-nitrophenylphosphate). The former substrate was hydrolyzed processively into thymidine, inorganic phosphate and 4-nitrophenol, whereas the latter was split into 4-nitrophenol and thymidine 5′-phosphate. The kinetic constants determined on the basis of 4-nitrophenol liberation were: $K_m = 4.6$ mmol dm^{-3} and $k_{cat} = 115$ s^{-1} for thymidine 3′-(4-nitrophenylphosphate); $K_m = 0.46$ mmol dm^{-3} and $k_{cat} = 19.7$ s^{-1} for thymidine 5′-(4-nitrophenylphosphate) at pH 5.3 and 37 °C. 4-Nitrophenyl phenylphosphonate was a good substrate for the enzyme showing kinetic constants $K_m = 1.4$ mmol dm^{-3} and $k_{cat} = 360$ s^{-1} at pH 5.3 and 37 °C. However, its chiral thio analogue, *O*-(4-nitrophenyl) phenylphosphonothioate, was hydrolyzed by the enzyme only very slowly in a stereo-nonspecific manner. The three phosphoryl groups in adenosine triphosphate was removed by the enzyme sequentially from the terminal position. These findings have made the uniqueness of *Fusarium* phosphodiesterase-phosphomonoesterase clearer.

Snake venom phosphodiesterase and spleen phosphodiesterase are representatives of many phosphodiesterases so far known. Although the classification of these two enzymes is based on the mode of hydrolysis of polynucleotides, they can easily be distinguished by the use of artificial chromogenic substrates; thymidine 3′-(4-nitrophenylphosphate) (TpONph) and thymidine 5′-(4-nitrophenylphosphate) (NphOpT). Snake venom phosphodiesterase is active only with the latter, whereas spleen phosphodiesterase is active only with the former.[1]

Kelly *et al.*[2] introduced a new chromogenic substrate, 4-nitrophenyl phenylphosphonate (PhPONph) for distinguishing these two phosphodiesterases. They showed that PhPONph is hydrolyzed only by phosphodiesterases of snake venom type (5′-nucleotide phosphodiesterases according to their terminology). Dudman and Benkovic[3] showed that the thio analogue of PhPONph, *O*-(4-nitrophenyl) phenylphosphonothioate (PhP(S)-ONph), is hydrolyzed by phosphodiesterases of the same type. PhP(S)ONph has a chiral phosphorus center. Snake venom phosphodiesterase hydrolyzes specifically the S_p diastereomer.[4]

Phosphodiesterase-phosphomonoesterase (PDMase) of the phytopathogenic fungus, *Fusarium moniliforme*, is a unique phosphohydrolase active with either phosphoric diesters or phosphoric monoesters. Yoshida *et al.*[5] pointed out that PDMase resembles snake venom phosphodiesterase, because a diribonucleoside monophosphate is first split by PDMase into a nucleoside and a 5′-nucleotide. Thus it is of interest to compare PDMase with snake venom phosphodiesterase more precisely using the above chromogenic substrates. This paper describes the action of PDMase on these substrates along with adenosine triphosphate (ATP).

Experimental

Materials. TpONph and NphOpT were purchased from Sigma and Calbiochem, respectively. Snake venom phosphodiesterase of *Crotalus adamanteus* was the product of Sigma (Type II), the activity of which was assayed at 37 °C with 1 mmol dm^{-3} bis(4-nitrophenyl) phosphate as a substrate in 50 mmol dm^{-3} Tris–HCl buffer (pH 8. 8) containing 1 mmol dm^{-3} $MgCl_2$. One unit (U) of activity was defined as that amount which liberates 1 μmol of 4-nitr ophenol per min under the above conditions. PDMase was purified from dried powder of the culture filtrate of *F. moniliforme* (commercial name, Toyocelase A, Toyo Brewery Co.) as described previously.[6] An isozyme mixture was used, because no difference in enzymic properties had so far been found among the isozymes.[7] PDMase was determined on the basis of activity toward 4-nitrophenyl phosphate. The assay was performed as described previously.[8] One unit (U) of activity which hydrolyzes 1 μmol of the substrate per min at pH 5.3 and 37 °C was assumed to correspond to 86 pmol of PDMase.[7]

Determination of Kinetic Constants. The kinetic constants of PDMase for TpONph, NphOpT, and PhPONph were determined by the measurements of the initial velocity of 4-nitrophenol liberation at various substrate concentrations. The reaction mixture contained, in a total volume of 2.0 cm^3, various amount of a substrate, sodium acetate buffer, pH 5.3 (100 μmol) and an appropriate amount of PDMase. The mixture was incubated at 37 °C for 10 min, then 0.5 mol dm^{-3}, Na_2CO_3 (1.0 cm^3) was added to stop the reaction. The liberated 4-nitrophenol was determined by measurement of the absorbance at 400 nm of the resulting solution using molar absorbance 18500. At least five different amounts of the substrate were used to cover a substrate concentration range involving K_m for the substrate. A computer-aided determination of K_m and k_{cat} was carried out basically according to the method of Wilkinson.[9]

High Performance Liquid Chromatography (HPLC). A high-speed liquid chromatograph HLC-803A (Toyo Soda) equipped with a variable wavelength UV monitor was used. The column was IEX-540 DEAE (4×150 mm) from the same company. The conditions for elution and detection varied depending on the experiment and will be described each time. The flow rate was fixed at 1.0 cm^3 min^{-1}.

Chemical Syntheses. *4-Nitrophenyl Phenylphosphonate*: The method described by Kelly *et al.*[2] was modified as follows. The solutions of phenylphosphonic dichloride and 4-nitrophenol in dry pyridine, each 16 cm^3 containing 41 mmol of either reagent, were added dropwise at approximately equal rates into 10 cm^3 of dry pyridine under stirring over 2 h. The temperature of the reaction mixture was maintained at 22—

30 °C by cooling in an ice bath. After the complete addition of the reagents, the mixture was stirred overnight at room temperature, then poured onto ice (100 g). After the ice thawed, the solution was adjusted to pH 1 with concd HCl (about 30 cm^3) and extracted three times with chloroform (each 70 cm^3). The combined chloroform layer was washed three times with 1 mol dm^{-3} HCl and twice with half-saturated aqueous NaCl. The chloroform solution was dehydrated with anhydrous Na_2SO_4, filtered and evaporated *in vacuo*. The residue was dissolved in acetone (15 cm^3). Concd aqueous ammonia was added to the solution until pH 7, then the solution was cooled in an ice bath for 1 h. The resulting precipitate of the ammonium salt of PhPONph was collected by centrifugation, washed extensively with cold acetone until no 4-nitrophenol was detected in the supernatant, and dried *in vacuo*. Yield 54%. Found: C, 48.79; H, 4.36; N, 9.27%. Calcd for $C_{12}H_{13}O_5N_2P$: C, 48.68; H, 4.43; N, 9.46%. UV_{max} (H_2O) 292 nm (ε 9800). ^1H NMR (D_2O) δ=8.67 (2H, d, J=9.0 Hz), 8.06—8.54 (5H, m), and 7.73 (2H, d, J=9.0 Hz).

O-(4-Nitrophenyl) Phenylphosphonothioate. Although Dudman and Benkovic[3] obtained the title compound by partial hydrolysis of the corresponding diester, we developed a new method for direct synthesis of the monoester. To phenylphosphonothioic dichloride (24 mmol) in 15 cm^3 of dry pyridine, 4-nitrophenol (24 mmol) in 12 cm^3 of dry pyridine was added dropwise under stirring over 2 h. The temperature of the reaction mixture was maintained at 2—10 °C by cooling in an ice bath. After the complete addition, the mixture was stirred overnight at room temperature, then poured onto ice (65 g). The product was extracted with chloroform (total 60 cm^3) as described in the synthesis of PhPONph. The extract was evaporated up and water (20 cm^3) was added to the residue. The mixture solidified on cooling. The resulting mass of the diester was triturated after addition of ethanol (20 cm^3) and filtered off. The filtrate was evaporated up and the residue was redissolved in water (20 cm^3). After a small amount of insoluble material was filtered off, 1 mol dm^{-3} cyclohexylammonium chloride (25 cm^3) was added to the solution. The precipitate formed on cooling was filtered, dried *in vacuo*, and recrystalized from hot acetonitrile. Yield 41%. Found: C, 54.52; H, 6.16; N, 7.40%. Calcd for $C_{18}H_{23}O_4N_2PS$: C, 54.81; H, 5.88; N, 7.10%. UV and ^1H NMR data agreed with those reported by Dudman and Benkovic.[3] The preparation, however, turned out to contain about 2% of PhPONph as described later.

Isolation of R_p Diastereomer of PhP(S)ONph. One of the diastereomers of chiral PhP(S)ONph was obtained by treatment of the synthetic racemate with snake venom phosphodiesterase. The reaction mixture contained, in a total volume of 12.1 cm^3, PhP(S)ONph (100 μmol), Tris-HCl buffer, pH 8.8 (500 μmol), $MgCl_2$ (10 μmol) and snake venom phosphodiesterase (0.28 U). The mixture was incubated at 37 °C for 25 h, then adjusted to pH 1 with concd HCl and extracted twice with chloroform (each 6 cm^3). The extract was charged on a column (2.2 cm × 14 cm) of silica gel preequilibrated with chloroform. After 4-nitrophenol was washed away with ethyl acetate (150 cm^3), the diastereomeric PhP(S)ONph was eluted with 1 : 1 mixture (50 cm^3) of ethyl acetate and methanol. The eluate was evaporated to dryness, taken up in water (2.0 cm^3), and adjusted to pH 7 with a dilute NaOH solution. The diastereomer thus obtained was not hydrolyzed by snake venom phosphodiesterase and showed CD ($[\theta]_{290\ nm}$ +630° $cm^2\ dmol^{-1}$).

Results

Hydrolysis of TpONph and NphOpT. PDMase hydrolyzed both TpONph and NphOpT, but in different ways. TpONph was degraded into thymidine, inorganic phosphate and 4-nitrophenol (Fig. 1A). A small amount of thymidine 3′-phosphate was detected, whereas 4-nitrophenyl phosphate was not. These results demonstrate that the two ester bonds in TpONph are hydrolyzed processively at the active site of PDMase. Presumably, 4-nitrophenol is the first leaving group, because thymidine 3′-phosphate, though little, was detected during the hydrolysis. On the contrary, NphOpT was cleaved first into 4-nitrophenol and

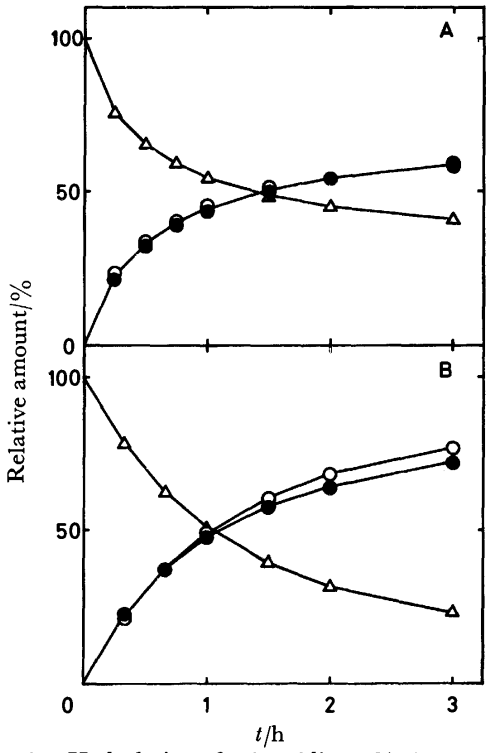

Fig. 1. Hydrolysis of thymidine 3′-(4-nitrophenylphosphate) (A) and thymidine 5′-(4-nitrophenylphosphate) (B) by PDMase.
The reaction mixture contained, in a total volume of 0.12 cm^3, TpONph (340 nmol) or NphOpT (220 nmol), sodium acetate buffer, pH 5.3 (15 μmol) and PDMase (116 mU). Incubation was at 37 °C. At the indicated times, portions (0.01 cm^3) of the mixture were withdrawn and analyzed by HPLC. The eluents were 0.25 and 0.125 mol dm^{-3} KH_2PO_4 for experiments A and B, respectively. Each compound was detected by absorbance at 290 nm and determined on the basis of peak height. Other conditions of HPLC were described in Experimental. The amount of each conpound is expressed in per cent to the sum of 4-nitrophenol and the remaining substrate. The retention times of the compounds were: (A) thymidine (●) 5.3 min, 4-nitrophenol (○) 11.2 min, TpONph (△) 13.1 min; (B) thymidine 5′-phosphate (●) 9.8 min, 4-nitrophenol (○) 11.3 min, NphOpT (△) 14.4 min. Besides the compounds described above, a small and nearly constant amount (less than 1%) of thymidine 3′-phosphate (retention time, 7.7 min) was detected in experiment A. A small and increasing amount (1.8% at 3 h) of thymidine (retention time, 5.3 min) was observed also in experiment B.

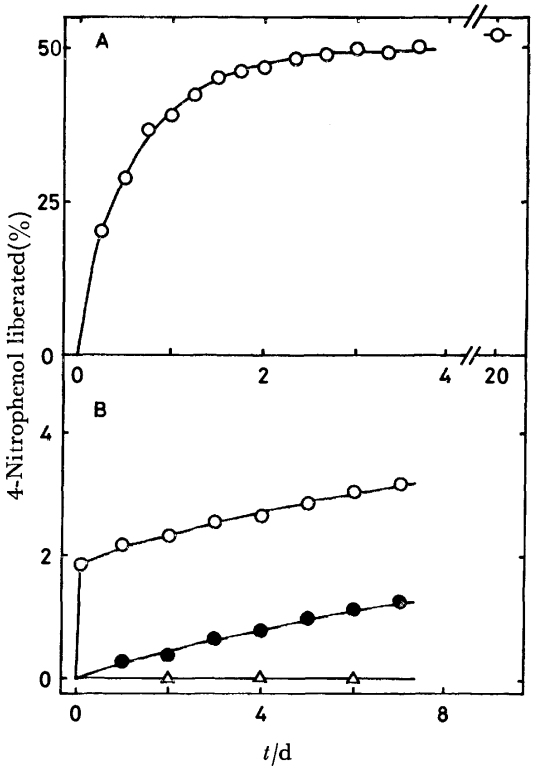

Fig. 2. Hydrolysis of *O*-(4-nitrophenyl) phenylphosphonothioate by snake venom phosphodiesterase (A) and PDMase (B). (A) The reaction mixture contained, in a total volume of 2.0 cm^3, PhP(S)ONph, racemate (2 μmol), Tris-HCl buffer, pH 8.8 (100 μmol), $MgCl_2$ (2 μmol) and snake venom phosphodiesterase (28 mU). Incubation was at 37 °C. At the indicated times, portions (0.05 cm^3) of the mixture were withdrawn and analyzed for 4-nitrophenol. (B) The reaction mixture contained, in a total volume of 1.0 cm^3, PhP(S)ONph, racemate (○) or R_p diastereomer (●) (3.5 μmol), sodium acetate buffer, pH 5.3 (50 μmol) and PDMase (3.9 U). Incubation was at 37 °C. At 1 h intervals, portions (0.1 cm^3) of the mixture were withdrawn and assayed for 4-nitrophenol. A control experiment (△) with the racemate was run in the absence of the enzyme under otherwise the same conditions.

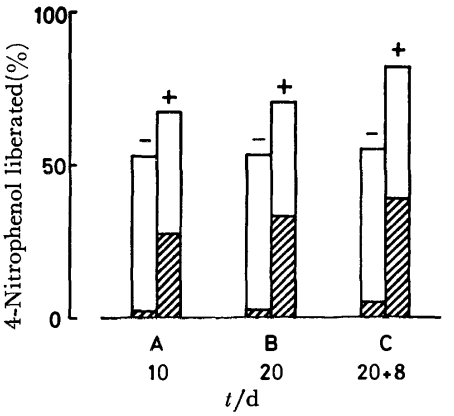

Fig. 3 Examination of the stereochemical course of hydrolysis of *O*-(4-nitrophenyl) phenylphosphonothioate by PDMase using snake venom phosphodiesterase. PhP(S)ONph, racemate (2.2 μmol) was incubated with sodium acetate buffer, pH 5.3 (50 μmol), NaN_3 as an antiseptic (1 mg) and PDMase (19 U) in a total volume of 1.0 cm^3 at 37 °C (first incubation). After 10 d (A) or 20 d (B) of the incubation, a portion (0.05 cm^3) of the mixture was withdrawn and assayed for 4-nitrophenol. Another portion (0.2 cm^3) of the mixture was taken and incubated with Tris-HCl buffer, pH 8.8 (40 μmol), $MgCl_2$ (0.4 μmol) and snake venom phosphodiesterase (12 mU) in a total volume of 0.4 cm^3 at 37°C (second incubation). After 3 h, a portion (0.1 cm^3) of the mixture was analyzed for 4-nitrophenol. The first incubation was renewed after 20 d: 0.2 cm^3 of the reaction mixture was mixed with 0.2 cm^3 of PDMase (7.5 U) solution in 10 mmol dm^{-3} sodium acetate buffer (pH 5.3), incubated at 37 °C for 8 more days (C), and analyzed as described above. The plus and minus signs on the histograms show the presence and absence, respectively, of PDMase during the first incubation. Hatched and blank areas in the histograms represent the percentage of 4-nitrophenol liberated by the first and second incubations, respectively.

thymidine 5′-phosphate, which was dephosphorylated very slowly (Fig. 1B). The kinetic constants for these substrates were determined to be: $K_m=(4.6\pm0.2)$ mmol dm^{-3} and $k_{cat}=(115\pm3)s^{-1}$ for TpONph; $K_m=(0.46\pm0.01)$ mmol dm^{-3} and $k_{cat}=(19.7\pm0.1)s^{-1}$ for NphOpT at pH 5.3 and 37 °C.

Hydrolysis of PhPONph and PhP(S)ONph. PhPONph was a good substrate for PDMase. The kinetic constants were $K_m=(1.4\pm0.3)$mmol dm^{-3} and $k_{cat}=(360\pm40)s^{-1}$ at pH 5.3 and 37 °C. The chiral thio analogue PhP(S)ONph synthesized by us was hydrolyzed by snake venom phosphodiesterase to an extent of 52.1% (Fig. 2A), confirming the observation of Dudman and Benkovic.[3] When this preparation was subjected to PDMase action, a portion (1.8%) was hydrolyzed rapidly but the rest was cleaved only very slowly (Fig. 2B). The R_p diastereomer was hydrolyzed by PDMase at almost the same rate as the racemate. The initial burst of 4-nitrophenol observed with the racemate but not with the R_p diastereomer may be due to contaminating PhPONph, which had resulted from desulfurylation of PhP(S)ONph probably during the isolation procedure in the synthesis.

The rate of 4-nitrophenol liberation from PhP(S)-ONph shown in Fig. 2B (25 pmol min^{-1} U^{-1}) corresponds to only 2×10^{-3}% of the rate which would be observed with PhPONph as the substrate under the same conditions. The low rate of hydrolysis is not due to an extremely high K_m, because the reduction of substrate concentration by a factor of 1/2 did not affect the rate appreciably (data not shown).

Although PhP(S)ONph (racemate) was hydrolyzed very slowly by PDMase, a considerable portion of the substrate could be hydrolyzed by a prolonged incubation with a large amount of the enzyme. When the remaining substrate was treated with snake venom phosphodiesterase, half its amount was always susceptible to the enzyme action (Fig. 3). These results indicate that neither diastereomer was concentrated in the remaining substrate. Therefore, PDMase hydrolyzed both dia-

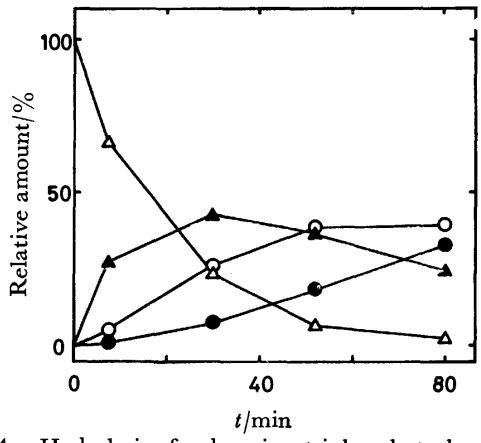

Fig. 4. Hydrolysis of adenosine triphosphate by PDMase. The reaction mixture contained, in a total volume of 0.21 cm^3, ATP (1.1 μmol), sodium acetate buffer, pH 5.3 (10 μmol) and PDMase (350 mU). Incubation was at 37°C. At the indicated times, portions (4 mm^3) of the mixture were withdrawn and analyzed by HPLC. The eluent was 0.5 mol dm^{-3} KH_2PO_4. Each compound was detected by absorbance at 260 nm and determined on the basis of peak area. Other conditions of HPLC were described in Experimental. The retention times of the compounds were: adenosine (●) 5.5 min, AMP (○) 8.9 min, ADP (▲) 13.9 min and ATP (△) 21.6 min.

stereomers at the same rate.

Hydrolysis of ATP. Figure 4 shows that ATP yielded adenosine diphosphate (ADP), adenosine monophosphate (AMP) and adenosine successively on incubation with PDMase. This indicates that the three phosphoryl groups in ATP is removed by PDMase in a sequential way from the terminal position.

Discussion

4-Nitrophenyl esters of thymidine 3′-phosphate and 5′-phosphate are currently used as key substrates for distinguishing phosphodiesterases between snake venom type and spleen type. Snake venom phosphodiesterase is active with NphOpT, whereas spleen phosphodiesterase is active with TpONph. The present study has shown that *Fusarium* PDMase acts on either of these substrates. Recently, Matsuzaki and Hashimoto[10] also reported that the acid phosphodiesterase of cultured tobacco cells was capable of hydrolyzing both NphOpT and TpONph. The dual activity may therefore be a feature common to acid phosphodiesterases of fungal or plant origin.

PDMase hydrolyzed the two chromogenic substrates in different ways. Processive hydrolysis occurred with TpONph as a substrate, whereas hydrolysis of NphOpT proceeded in a stepwise manner. The processive hydrolysis of a phosphodiester is the most prominent feature of PDMase. For example, bis(4-nitrophenyl) phosphate has been shown to be hydrolyzed into two moles of 4-nitrophenol and one mole of inorganic phosphate without appreciable release of the intermediary phosphomonoester, 4-nitrophenyl phosphate.[8] The same phenomenon was observed with TpONph. Presumably, stepwise hydrolysis of NphOpT resulted from the resistance of thymidine 5′-phosphate to PDMase action. The kinetic constants for these substrates were also different by an order of magnitude. Although the reason for such a big difference is not clear at present, it is worth noting that the k_{cat}/K_m value, a measure for goodness of a substrate, is of the same magnitude for these two substrates.

Kelly *et al.*[2] showed that phenylphosphonate esters are hydrolyzed by phosphodiesterase of snake venom type (5′-nucleotide phosphodiesterase according to their terminology), but not by spleen phosphodiesterase. Thus they proposed that phosphonate esters could serve as key substrates for distinguishing between the two types of phosphodiesterases. We have shown that PhPONph is a good substrate of PDMase. In fact, this compound has the highest k_{cat} (360 s^{-1}) among the substrates so far examined.

Dudman and Benkovic[3] demonstrated that the chiral thio analogue of PhPONph, PhP(S)ONph, is hydrolyzed by snake venom phosphodiesterase in a stereospecific manner. They claimed that the thio analogue is hydrolyzed by the same pattern of enzymes which catalyze hydrolysis of PhPONph. Further studies on the stereochemical course of snake venom phosphodiesterase strongly suggest that the S_p diastereomer of PhP(S)ONph is hydrolyzed specifically by the enzyme.[4,11,12] We have shown that the thio analogue is a poor substrate of PDMase, although the parent phosphonate ester is readily hydrolyzed by the enzyme. The rate of hydrolysis of PhP(S)ONph by PDMase was only 2×10^{-3}% of that of PhPONph. Both diastereomers of PhP(S)ONph seems to be hydrolyzed by the enzyme at almost equal rates. These results are in sharp contrast to the observation made with snake venom phosphodiesterase.

As for the mode of hydrolysis of ATP, PDMase also differs from snake venom phosphodiesterase. PDMase removes the three phosphoryl groups in ATP sequentially from the terminal position, whereas snake venom phosphodiesterase splits ATP into AMP and inorganic pyrophosphate.[4]

Precise comparison is now feasible between *Fusarium* PDMase and snake venom phosphodiesterase on the basis of our present and previous studies. PDMase, though unique in its wide substrate specificity, has certain resemblances to snake venom phosphodiesterase. (1) It yields 5′-nucleotide on acting diribonucleoside monophosphate.[5] (2) It hydrolyzes PhPONph. However, PDMase clearly differs from snake venom phosphodiesterase, to say nothing of pH optima and metal ion requirements, in the following points. (1) It hydrolyzes TpONph in addition to NphOpT. (2) It hydrolyzes chiral PhP(S)ONph only very slowly in a stereo-nonspecific manner. (3) It removes the three phosphoryl groups in ATP sequentially from the terminal position.

As a conclusion, the present study has made the uniqueness of *Fusarium* PDMase clearer. It does not seem to fit any entry of the current phosphohydrolase classification. We propose that a new entry be necessary for this unique enzyme, most appropriately among

EC 3.1.4 phosphoric diester hydrolases.

We thank Professor Nobuo Tamiya for valuable discussions, Dr. Yasuo Kikuchi for advice in the chemical syntheses, Dr. Masafumi Yasunami for NMR measurements, and Mr. Kunio Matsumoto of Toyo Brewery Co. for the generous gift of the enzyme source "Toyocelase A." This work was supported in part by a Grant-in-Aid for Scientific Research No. 56580094 from the Ministry of Education, Science and Culture.

Highly Stereoselective Isomerization of Monosubstituted 1-Alkenes to (*E*)-2-Alkenes by Catalysis of $(C_5Me_5)_2TiCl_2/NaC_{10}H_8$

Munetaka AKITA, Hajime YASUDA, Kinya NAGASUNA, and Akira NAKAMURA*
Department of Macromolecular Science, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received July 19, 1982)

The catalyst systems which consist of $MCl_2(C_5R_5)_2$(M=Ti, Zr; R=H, CH_3)/$NaC_{10}H_8$, *i*-C_3H_7MgBr, *n*-C_4H_9Li or $LiAlH_4$ in 1 : 2 ratio were highly effective for the stereoselective isomerization of monosubstituted 1-alkenes to (*E*)-2-alkenes. Unconjugated dienes were converted to (*E*)- or (*E,E*)-dienes. The catalysis of (C_5Me_5)-$TiCl_2/NaC_{10}H_8$ was extremely high and resulted in the complete isomerization of 1-alkenes in >99% stereoselectivity within a short period. The use of the bulky C_5Me_5 ligand is essential to find out the excellent stereoselectivity. Systems, $(C_5H_5)_2TiCl_2/NaC_{10}H_8$ and $(C_5H_5)_2TiCl_2$/*i*-C_3H_7MgBr showed less selectivity and the catalysis of the corresponding zirconium systems was very poor irrespective of the reducing agents and substrates.

Transition metal catalyzed isomerization of terminal olefins into internal olefins has been extensively studied with metal hydrides,[1] metal carbonyls[2] and others.[3] In general, these catalysts require relatively high temperatures (>50 °C) and result in a mixture of 1-alkenes, (*E*)- and (*Z*)-2-alkenes reflecting the thermodynamic equilibrium. The *Z*/*E* ratio varies in a wide range from 0.1 to 3.5. The reactions in some cases involve the carbon skeletal change[4] and the multiple double bond movement.[2a] Exceptional is [Ir(cyclooctadiene)$(PMePh_2)_2$]PF_6 which catalyzes isomerization of allyl ethers to (*E*)-1-propenyl ethers in extreme stereoselectivity at room temperature.[5a] Enantioselective isomerization of allylamines with a Rh(I) complex has also been reported recently.[5b]

We wish to report here the excellent catalysis of low valent titanocene species, "$(C_5Me_5)_2Ti$" and "$(C_5H_5)_2$-Ti", for highly stereoselective isomerization of 1-alkenes to (*E*)-2-alkenes under the mild conditions. Though titanocene species are generally accepted as efficient catalysts for hydrogenation[6] and hydrometalation of olefins,[7] the catalysis for isomerization of olefins has not yet been extensively studied except some works using $(C_5H_5)_2Ti$ species.[8] We found now that these species, especially $(C_5Me_5)_2Ti$, have a good catalysis toward the isomerization of 1-alkenes, allylamines and unconjugated dienes which lead to (*E*)-2-internal alkenes or (*E,E*)-dienes. The use of permethylcyclopentadienyl ligand was crucial to observe the high stereoselectivity.

Results and Discussion

*Catalytic Isomerization of 1-Hexene to (*E*)-2-Hexene.* The catalysts used in this work were generated by reduction of $(C_5Me_5)_2TiCl_2$ (**1**), $(C_5H_5)_2TiCl_2$ (**2**), or $(C_5H_5)_2ZrCl_2$ (**3**) with two equivalents of sodium naphthalene ($NaC_{10}H_8$), *i*-C_3H_7MgBr, butyllithium, or $LiAlH_4$. Photolysis of $(C_5Me_5)_2Ti(p\text{-tolyl})_2$ (**4**), $(C_2H_5)_2Ti(p\text{-tolyl})_2$ (**5**), and $(C_5H_5)_2Zr(p\text{-tolyl})_2$ (**6**) were also examined since ultraviolet ray irradiation to these complexes is known to generate low valent metallocene species.[9]

Catalyst systems	Catalyst systems
Ia $(C_5Me_5)_2TiCl_2/NaC_{10}H_8$	IIa $(C_5H_5)_2TiCl_2/NaC_{10}H_8$

IIId $(C_5H_5)_2ZrCl_2/LiAlH_4$	

The result of isomerization of 1-hexene at 20 °C was listed in Table 1 as a typical example. The distribution of the products was determined by gas chromatographic analysis with authentic samples and the structure of the respective isomers was determined from the chemical shift values of the ^{13}C-NMR spectra. The rate of isomerization was expressed as turnover max (mol/mol min) since these catalyst systems in many cases have an

TABLE 1. DISTRIBUTION OF THE PRODUCTS OBTAINED BY ISOMERIZATION OF 1-HEXENE WITH CATALYST SYSTEMS Ia—e, IIa—e, AND IIIa—e AND THEIR RATE OF ISOMERIZATION[a]

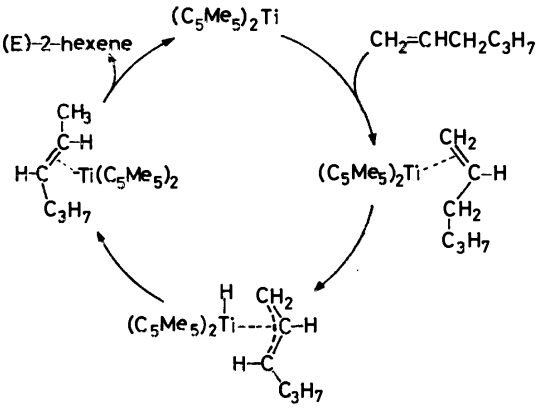
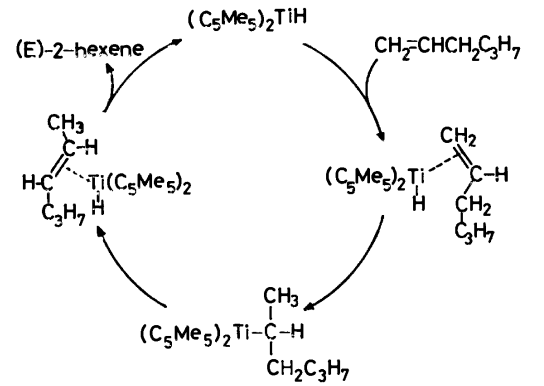
a) Molar ratio of $(C_5R_5)_2MCl_2$(R: H, CH_3; M: Ti, Zr)/reducing agent/1-hexene was 1.0/2.0/200. Reaction was carried out at 20 °C for 1 h when Ia—e or IIa—e was used while the reaction with IIIa—e was done for 10 h. The ratio of 1-hexene to a solvent was 1.2/1.0 (v/v). b) Hydroalumination occurred. c) The reproducibility was invariably poor.



Scheme 1.



Scheme 2.

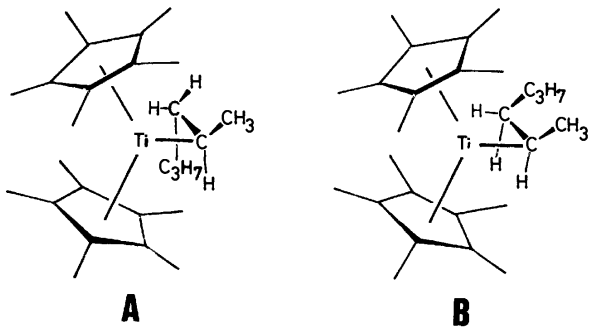
induction period (2—30 min).

1-Hexene was converted to (*E*)-2-hexene quantitatively when 1 mol-% of the catalyst system Ia—d which consists of **1** and $NaC_{10}H_8$(a), *i*-C_3H_7MgBr(b), *n*-C_4H_9Li(c) or $LiAlH_4$(d) in 1 : 2 ratio was added at 20 °C under atmospheric pressure. Catalysis of Ia was especially high in comparison to others and >98% of the substrate was converted to (*E*)-2-hexene within 5 min after the addition of the catalyst. The reaction of $(C_5Me_5)_2TiCl_2$ with $NaC_{10}H_8$ is reported to give "$(C_5Me_5)_2Ti$" which equilibrates with $(C_5Me_5)[(C_5(CH_3)_4(CH_2)]TiH$.[10] Therefore, it seems most likely that the isomerization proceeds following the cycle given in Scheme 1. The coordination of 1-hexene to $(C_5Me_5)_2$-Ti occurs in the initial step and "(η^3-allyl)TiH" species is produced by the successive β-hydride elimination. Liberation of 2-hexene results in the regeneration of $(C_5Me_5)_2Ti$. A similar $^3\eta$-allyltitanium hydride has been postulated as an intermediate in olefin hydrogenation[8a] and, actually, η^3-allylhafnium hydride was recently isolated.[11]

A similar catalytic cycle (1,3-hydrogen shift mechanism) has already been proposed for the isomerization of olefins catalyzed by a Pd(II) complex (though the selectivity was rather poor).[2a] The coordination of liberated (*E*)-2-hexene to the metal is hindered by the steric effect of permethylcyclopentadienyl ligand. The selective formation of (*E*)-2-hexene may be ascribed to the preferential formation of *syn*-η^3-allylic titanium hydride species. The X-ray structure of $(C_5H_5)_2Ti$(*syn*-η^3-butenyl) supports this assumption.[12]

In contrast to Ia, the turnover max for Ib, Ic and Id was remarkably small. Since the system IIb is known to afford $(C_5H_5)_2TiR$ which readily decomposes at ambient temperature to $(C_5H_5)_2TiH$ by β-hydride elimination,[13] the isomerization with Ib—c is best interpreted by the conventional addition-elimination mechanism as shown in Scheme 2.[1c] Actually, these systems have an induction period (5—30 min) before the largest turnover appears while the catalyst system Ia can initiate the isomerization immediately. Raising the reaction temperature to 60 °C (1—3 min) in the initial stage resulted in the shortening of the induction period which was observed for Ib—d.

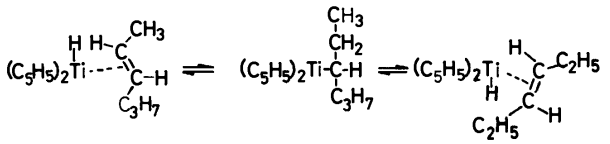
Stereocontrol of the product will come from the predominant elimination of *threo*-hydrogen at the β-carbon. Two intermediates (A) and (B) are conceivable for the adduct, $(C_5Me_5)_2TiH$/1-hexene. However, the placement of (A) will favor over (B) from the steric reasons. If the intermediate assumes the geometry (B), steric repulsion among the C_5Me_5 ring, C_3H_7 and CH_3 group will prevent access of β-hydrogen to metal while the placement of (A) can diminish the steric repulsion. Hence, β-hydride abstraction from (A) was estimated to occur preferentially.



The catalysis of "$(C_5H_5)_2Ti$" or "$(C_5H_5)_2TiH$" was examined to evaluate the importance of the methyl groups of C_5Me_5 in stereoregulation. The catalysis of $(C_5H_5)_2TiCl_2/NaC_{10}H_8$ (IIa) was characterized by the low stereoselectivity (83%) and the diminished activity (turnover max). Isomerization to 3-hexene was not observed. The well-known spontaneous dimerization of $(C_5H_5)_2Ti$ to catalytically inactive $Ti_2H_2(\eta^5\text{-}C_5H_5)_2(\eta^{10}\text{-}C_{10}H_8)$ may be invoked for the lower activity.[14] When $(C_5H_5)_2Ti$ species were immobilized on a polystyrene matrix to inhibit the dimerization, a significant increase in activity was observed as reported by Bergbreiter *et al.*, though the stereoselectivity remained unchanged (72—85%).[8a]

Catalysts IIb—d showed a moderate activity. However, the stereoselection was insufficient and, further, these systems caused the isomerization to 3-hexene. The formation of 3-hexene implies that the isomerization takes place following the addition-elimination mechanism shown below.

Photolysis of $(C_5H_5)_2Ti(p\text{-tolyl})_2$ is also utilized for generation of a catalyst[9] but both activity and stereocontrol are insufficient. In addition, the reproducibility was poor with respect to the rate of isomerization. All



of the above results indicate that coordination of bulky ligand such as C_5Me_5 to metal is crucial to realize this highly stereoselective isomerization. The thermal-stability of Ia gave us an additional advantage in handling the catalyst; no decrease in activity was observed when Ia was kept at 20 °C for 6 h.

We have also examined the catalysis of the corresponding zirconium systems IIa—e and found very poor results irrespective of the reducing agents and substrates. The observed catalysis may be caused by a minute quantities of certain Zr(III) or Zr(II) species formed in the reaction system. Zr(IV) species are generally less readily reduced to Zr(II) or Zr(III) species in comparison to the Ti(IV) species.[15] The poor activity of IIIa—d will be ascribed to such natures existing in zirconium complexes. Photolysis of **6** did not give catalytically active species because **6** is highly resistant to ultraviolet rays under the normal conditions.

Though titanacyclopentane has been proposed as an intermediate in the dimerization of 1-alkenes,[16] any dimerization of alkenes was not observed in the present work.

Characteristics and the Limitation of Titanocene Species as Catalysts. Isomerization of a wide range of terminal olefins was examined with Ia to find broad applications. The results are given in Table 2. C_4–C_8 1-alkenes were readily converted to (*E*)-2-alkenes within a short time even in the absence of a solvent. Thus, the present system provides a very convenient method for preparation of (*E*)-2-alkenes. Treatment of the products with aq HCl followed by one flash distillation or even one filtration is sufficient to obtain the pure sample. In the similar manner, (*E*)-1-phenyl-1-propene and (*E*)-*N*,*N*-diethyl-1-propenylamine were prepared in good yield from 3-phenyl-1-propene and *N*,*N*-diethyl-2-propenylamine, respectively.

Table 2. Isomerization of mono- and disubstituted alkenes with catalyst system Ia at 20 °C[a]

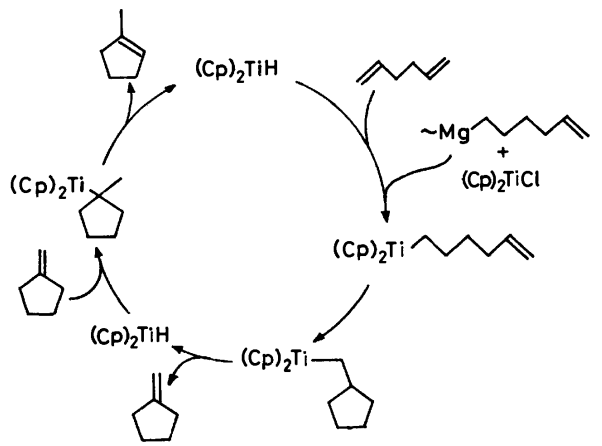
Substrate	Product	*E*/*Z* ratio %	Conversion %
1-Butene	2-Butene	99/1	100
1-Pentene	2-Pentene	100/0	99
1-Octene	2-Octene	100/0	99
3-Phenyl-1-propene	1-Phenyl-2-propene	99/1	100
N,*N*-Diethyl-2-propenylamine	*N*,*N*-Diethyl-1-propenylamine	99/1	98
2-Methyl-1-pentene	Recovered	—	0
3-Methyl-1-pentene	Recovered	—	0
4-Methyl-1-pentene	4-Methyl-2-pentene	99/1	25
Allyl phenyl ether	Recovered	—	0
Allyl acetate	Recovered	—	0

a) Reaction conditions: reaction time, 1 h; ratio of Ia/alkenes, 1/100 (mol/mol); solvent was not used.

In contrast to the results obtained with terminal olefins, internal olefins such as (*E*)- or (*Z*)-isomers of 2-butene, 2-pentene and 3-hexene were completely inert toward the catalyst Ia at 20—50 °C. No isomerization from (*Z*)- to (*E*)- or (*E*)- to (*Z*)-isomer occurred under these reaction conditions. It should be noted, however, that conversion of (*E*)-2-hexene to (*Z*)-2-hexene was observed when the mixture of (*E*)-2-hexene and Ia (100 : 1 molar ratio) was heated to 120 °C for 48 h in a sealed tube. The ratio of (*E*)-, (*Z*)-2-hexene and (*E*)-3-hexene was 94 : 5 : 1. The mechanism may involve (η^3-allyl)TiH species followed by elimination.

Isomerization of 1-alkenes with an alkyl substituent varying in size was examined using Ia as catalyst. Thus, 2-methyl- and 3-methyl-1-pentene were not isomerized but 4-methyl-1-pentene could be converted to (*E*)-4-methyl-2-pentene in low yield (25% at 20 °C for 12 h). The catalyst IIa has higher catalysis for these olefins; *i.e.*, 3- and 4-methyl-1-pentene were converted quantitatively (>98%) to 3-methyl-2-pentene and 4-methyl-2-pentene, respectively, when the reaction was carried out for 12 h at 20 °C. Catalyst Ia was also inert to 1,3-hexadiene, 5-trimethylsilyl-1,3-pentadiene and 1,5-cyclooctadiene. Addition of a stoichiometric amount (3 mol equivalents to Ia) of alkyl allyl ether, allyl alcohol or allyl acetate resulted in the complete deactivation of the catalyst. This will be due to the cleavage of alkyl allyl ether, allyl ester or vinyl ether which was formed by double bond migration. Further studies are required to clarify the stoichiometric reaction.

Catalytic Isomerization of Unconjugated Dienes. The result of isomerization of unconjugated dienes was given in Table 3. The catalyst Ia showed a sufficiently high selectivity for 1,5-hexadiene and 1,7-octadiene, whereas IIa and IIb showed a rather poor selectivity and induced an undesired skeletal isomerization leading to 1-methylcyclopentene. The pathway for formation of 1-methylcyclopentene is interpreted by the catalytic cycle given in Scheme 3. Since $(C_5H_5)_2TiCl_2$ is known to catalyze the hydromagnesiation of olefins,[7b] the formation of 5-hexenylmagnesium compound is most probable in the initial stage. The resulting magnesium compound is readily converted into 5-hexenyltitanium



Scheme 3.

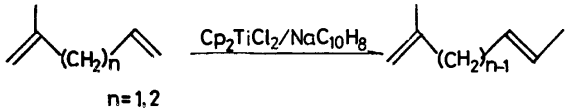
derivative by the metal exchange reaction. Ring closure gives (cyclopentylmethyl)titanium species which releases methylenecyclopentane by the β-elimination. The isomerization of methylenecyclopentane to 1-methylcyclopentene will follow the addition-elimination mechanism similar to that reported by Lehmkuhl.[17)]

Stereocontrolled Regioselective Isomerization of Substituted Dienes. The substrate selectivity observed in the above-mentioned olefin isomerization prompted us to try the regioselective (chemoselective) isomerization of substituted dienes. As shown in Table 4, vinyl groups were shifted to internal (*E*)-type olefins while vinylidene moiety was unaffected. Thus, regio- and stereoselective isomerization of a series of methylpentadienes was established with the catalyst Ia. 4-Vinylcyclohexene was isomerized with the catalyst IIa but not with Ia. A mixture of 4-ethylidenecyclohexene (69%) and 3-ethylidenecyclohexene (31%) were obtained in 91% yield by catalysis of IIa (1 mol%) at 20 °C for 12 h. Recently, quantitative isomerization of



vinylcycloalkanes to ethylidenecycloalkanes was accomplished under rather vigorous conditions (180 °C) with the catalyst IId.[8b)] In these reaction conditions, the catalyst IId was also capable of converting 2,5-dimethyl-1,5-hexadiene or bicyclo[4.3.0]-3,7-nonadiene to conjugated 1,3-dienes.[8b-c)]

The extremely good selectivity and chemoselectivity observed in this work utilizing $(C_5Me_5)_2Ti$ species will be valuable for organic syntheses since the isomerization took place under the mild conditions in a short period.

Experimental

All operations were conducted by Schlenk techniques under an argon atmosphere. ^1H- and ^{13}C-NMR spectra were recorded at 100 and 25.05 MHz on a Varian XL-100 and a JEOL FX-90Q spectrometer, respectively. The infrared pectra were recorded on a Hitachi EPI-2 spectrometer. The structure of the products was determined from the chemical shift values of ^{13}C-NMR spectra referring to the reported data.[18)] The product distribution was determined with a Hitachi Model 163 gas chromatograph. $(C_5Me_5)_2TiCl_2$,[10)] $(C_5H_5)_2TiCl_2$,[19)] and $(C_5H_5)_2ZrCl_2$[19)] were prepared according to the method previously reported. Tetrahydrofuran, diethyl ether and benzene were dried over sodium-potassium alloy and were distilled. All olefins and dienes (Aldrich Chem.) were dried over calcium hydride and purified by distillation.

Isomerization of 1-Hexene with Ia. To a stirred suspension of $(C_5Me_5)_2TiCl_2$ (39.0 mg, 0.10 mmol) in 0.8 ml THF was added a solution of $NaC_{10}H_8$ (30 mg, 0.2 mmol) in THF (1 ml) at room temperature. The color of the solution changed into dark yellow green. After stirring for 10 min, mixture was evaporated to dryness and was extracted with pentane (10 ml) at 20 °C. After the removal of the salt with a centrifuge, flash distillation of the pentane extract was performed *in vacuo* to give the species Ia as a green solid (32 mg). To the resulting catalyst species was added 1-hexene (1.25 ml, 10 mmol) at −70 °C and the mixture was immediately warmed to 20 °C to induce the isomerization. A small portion of the reaction mixture was taken out and hydrolyzed to monitor the reaction with a gas chromatograph. After stirring the mixture for 30 min at 20 °C, 6 mol dm^{-3} aq HCl was added and organic layer was distilled to give (*E*)-2-hexene (1.1 ml, 9 mmol). The removal of the salts or solvent was not neccessarily required because the presence of these materials did not affect on catalysis.

Preparation of Ib—d and IIa—d. To a mixture of $(C_5Me_5)_2TiCl_2$ (19 mg, 0.05 mmol) and ether (0.5 ml) was added $i\text{-}C_3H_7MgBr\cdot(OEt_2)_2$ (26 mg, 0.1 mmol) in ether (1.5 ml). The mixture was stirred at 20 °C for 10 mix the and precipitates was separated by centrifugation using a specially designed two-necked tube fitted with septum caps. The ether solution was evaporated to dryness to give Ib as a green solid and 1-hexene was added to the solid at 20 °C to induce the isomerization. In essentially the same way for Ia, diethyl ether solution (1.5 ml) of butyllithium (6 mg, 0.1 mmol) or $LiAlH_4$ (4 mg, 0.05 mmol) was allowed to react with $(C_5Me_5)_2TiCl_2$ (0.1 mmol) for 10 min and 60 min, respectively, to generate the catalyst Ic

and Id. The ether soluble green solid was used as catalysts. The systems IIa—d were prepared in the similar manner.

Photolysis of $(C_5Me_5)_2Ti$(p-tolyl)$_2$ and $(C_5H_5)_2Ti$(p-tolyl)$_2$. $(C_5Me_5)_2Ti(p\text{-tolyl})_2$ **4** and $(C_5H_5)_2Ti(p\text{-toyl})_2$ **5** were prepared according to the reported procedures.[9] After the addition of **4** or **5** (1 mmol) to 1-hexene (100 mmol) in benzene (10 ml), ultraviolet ray irradiation was carried out with stirring for 2 h using a high pressure (250 W) mercury lamp.

Characterization of the Products. ^{13}C-NMR assignment of a series of (*E*)- or (*Z*)-olefins and dienes including the products obtained in this paper is already established by Haan *et al.*[18] Therefore, the structure was determined with reference to the reported data. The distribution of the products was analyzed using authentic samples (Aldrich Chem.) with a gas chromatograph fitted with a capillary column, HB-2000 or CW (45 m, Gaschro Kogyo, Co.). When the product was contaminated with isomers, characterization was done after the separation into the respective isomers by a preparative gas chromatograph fitted with a Benton-34 or SiDC-560 column. The geometry of *N,N*-diethyl-1-propenylamine was determined by the ^{1}H-NMR spectrum referring with the data reported by Sauer.[20] The IR and ^{1}H-NMR spectra of 1-methylcyclopentene agreed with the data reported by Becker.[21]

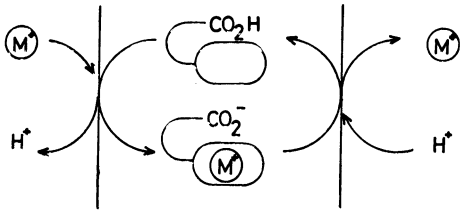
Proton-driven Ion Transport and Metal-assisted Amino Acid Transport with an Anion-capped Azacrown Ether[1)]

Seiji SHINKAI,* Hidefumi KINDA, Yoshikazu ARARAGI, and Osamu MANABE*
Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852
(Received August 9, 1982)

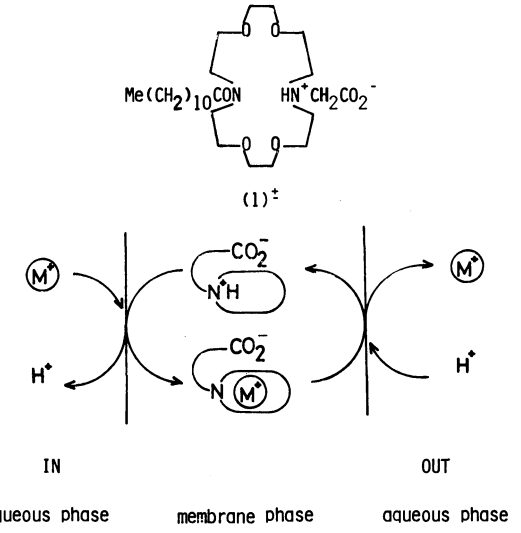
We have found that 1,10-diaza-4,7,13,16-tetraoxa-18-crown-6 with a carboxylate cap and a hydrophobic dodecanoyl group (**1**) acts as a new class of ion carrier for membrane transport. The rate of K^+ transport across a chloroform liquid membrane was significantly affected by pH of the OUT aqueous phase: The rate decreased with increasing or decreasing pH, providing a maximum at around pH 5. The main species of **1** in the neutral pH region should be zwitterionic $\mathbf{1}^{\pm}$, so that one may rationalize the pH-rate profile in terms of (i) "enforced ion release" due to protonation of the ring nitrogen and (ii) high lipophilic nature of zwitterionic $\mathbf{1}^{\pm}$. The efficiency of **1** was further demonstrated by active K^+ transport from the basic IN aqueous phase to the neutral OUT aqueous phase. Also, **1** was capable of carrying amino acids in the presence of alkaline earth metal cations. These results suggest that, being different from conventional anion-capped crown ethers, the aza crown ethers carrying the *N*-substituted carboxylate cap exhibit a new class of ionophore functions.

Cations are known to be transported through biological membranes with the aid of antibiotics.[2,3)] In particular, polyether antibiotics such as nigericin and monension feature "enforced ion-release" and coupled counter-transport of cations and protons due to interconversion between cyclic and acyclic forms.[2-5)] Although coupled counter-transport can be mimicked in an artificial system using anion-capped crown ethers,[6-8)] acyclic polyethers,[9-13)] and metal complexes,[14-16)] few of them permit as ready an enforced ion release as do the polyether antibiotics.[17,18)] As show in Scheme 1, for example, the conventional anion-capped crown ethers mediate the ion-transport, the basic functions of these carriers being related only to the ion-binding ability due to charge neutralization by an intramolecular anionic cap.



Scheme 1.

Recently, several new ionophores have been synthesized from 1,10-diaza-4,7,13,16-tetraoxa-18-crown-6 which is commercially available.[19-24)] In order to attain the "facile enforced ion-release" like natural ionophores, we sythesized an ionophore **1** for which the following novel behaviors are expected (Scheme 2): (i) Ion-release is enforced by protonation of the ring nitrogen, (ii) the main species in the neutral pH region, $\mathbf{1}^{\pm}$, should be highly lipophilic owing to its zwitterionic structure, and (iii) the counter-current of protons should be mediated by the ring nitrogen but not by the carboxylato group and should occur from the neutral OUT aqueous phase. With these expectations in view, we carried out the proton-driven ion-transport and the metal-assisted amino acid transport through a liquid membrane.



Scheme 2.

Experimental

Materials. 1-Dodecanoyl-10-carboxymethyl-1,10-diaza-4,7,13,16-tetraoxa-18-crown-6 (**1**) was prepared by mono-*N*-alkylation of 1,10-diaza-4,7,13,16-tetraoxa-18-crown-6 with chloroacetic acid, followed by acylation of the remaining amine with dodecanoyl chloride. The aqueous solution (20 ml) containing 1.19 g (12.5 mmol) of chloroacetic acid was adjusted to pH 9.0 with sodium carbonate. After the addition of 3.00 g (11.4 mmol) of 1,10-diaza-4,7,13,16-tetraoxa-18-crown-6, the reaction mixture was heated at 90—100 °C with stirring. The progress of the reaction was followed by the potentiometric titration of the aliquot withdrawn from the solution with silver nitrate. The titration showed that the stoichiometric amount of Cl^- was produced after 8 h. The reaction mixture was diluted to 100 ml with water and adjusted to pH 11 with sodium carbonate. The aqueous solution was extracted with chloroform to remove the unreacted diaza crown ether. The aqueous layer was concentrated *in vacuo*, the residue being taken with absolute ethanol. Thus, 3.47 g of the oily product (monocarboxymethylated diaza crown ether) was obtained. The HPLC analysis showed that the product contained a

small amount of bis(carboxymethylated) diaza crown ether, but we used the oil without further purification. 3.47 g of the oil was dissolved 34 ml of *N,N*-dimethylformamide (DMF) containing 4 ml of triethylamine. While stirring the DMF solution at room temperature, 2.50 g (11.4 mmol) of dodecanoyl chloride in 10 ml of DMF was added dropwise. After the addition, the reaction mixture was heated at 60 °C for 1 h. The solution was diluted with 50 ml of water, extracted with chloroform, and the chloroform solvent was evaporated to dryness. The oily residue was dissolved in water adjusted to pH 6.5 and extracted with chloroform. The chloroform solution was concentrated *in vacuo*. Finally, the product (**1**) was isolated by the TLC separation (silica gel, chloroform: ethanol=4 : 1 in volume); oil, yield 16.7%. NMR ($CDCl_3$): CH_3, 0.88 ppm (3H); $(CH_2)_9$, 1.28 ppm (18H); NCO-CH_2, 2.30 ppm (2H); C-N-CH_2 (ring proton), 2.76 ppm (4H); N-CH_2-CO, 3.12 ppm (2H); OCH_2, 3.64 ppm (16H); CO-N-CH_2, 3.80 ppm (4H). IR (KBr disk) of the sodium salt; $\nu_{C=O}$ 1630 and 1600 cm^{-1}, ν_{C-O-C} 1100 cm^{-1}. Found: C, 59.42; H, 10.04; N, 4.95%. Calcd for $C_{26}H_{49}N_2O_7Na$: C, 59.21; H, 9.77; N, 5.31%.

Method of Ion-transport. The ion-transport was carried out using a U-tube apparatus immersed in a thermostated water bath (30 °C). The transport system consists of 50 ml of a liquid membrane phase (chloroform) and 25 ml of IN and OUT aqueous phases in a U-tube with 2.5 cm diameter. The membrane phase was stirred slowly at a constant speed (180 rpm). The concentrations of alkali and alkaline earth metal cations were determined by an atomic absorption spectrophotometer (Shimadzu AA-640), while those of amino acids were determined by the treatment with fluorescamine.[25] Usually, the sampling was continued for 12 h at intervals of 1 h. After an induction period (about 1 h) a linear increase in metal (or amino acid) was observed, from which we determined the transport rates across a chloroform membrane barrier.

Results and Discussion

Transport of Alkali and Alkaline Earth Metal Cations. Potentiometric titration of **1** (30 °C) gave two pK_a values: $pK_{a1}=3.45$ and $pK_{a2}=6.99$. The fraction of zwitterionic $\mathbf{1}^{\pm}$ thus becomes maximum at pH 5.22 $(=(pK_{a1}+pK_{a2})/2)$. As a preliminary step to ion-transport, we estimated the partition of **1** between chloroform and aqueous solution by its absorbance at 270—300 nm which is on the lower slope of the absorption band of **1**. The partitions of **1** to the chloroform layer after agitation with equal volumes of following aqueous solutions were: 90% with 0.01 M HCl,† 96% with pH 5.23 (0.05 M Tris–AcOH), 73% with 0.01 M Et_4NOH, and 99% with 0.01 M KOH. The result indicates that the solubility of **1** in chloroform is in the order, $\mathbf{1}^-$–K^+ complex$>\mathbf{1}^{\pm}>\mathbf{1}^+>\mathbf{1}^-$.

The transport of alkali and alkaline earth metal cations across a chloroform membrane was studied using a U-tube apparatus immersed in a thermostated water-bath (30 °C). The typical experimental results are summarized in Table 1. In passive transport of K^+ (Runs No. 1—5), the rate of K^+ transport gave a maximum when the OUT aqueous phase was maintained in the neutral pH region. When the OUT aqueous phase was strongly basic or acidic, the rates of K^+ transport were significantly suppressed. The plot of K^+ transport rate *vs.* pH of the OUT aqueous phase is well correlated with the pH-dependence of the fraction of zwitterionic $\mathbf{1}^{\pm}$ (Fig. 1). These results establish that the best K^+ transport system consists of the coupled counter-transport of K^+ and protons by interconversion between the $\mathbf{1}^-$–K^+ complex (IN→OUT) and $\mathbf{1}^{\pm}$ (OUT→IN) (see Scheme 2).

a) Buffer: tartarate (50 mM) and Tris. b) Buffer: Tris (50 mM) and HCl. c) Buffer: AcOH (50 mM) and Tris. d) Picric acid (3.8 mM) was added. e) Picric acid (4.3 mM) was added.

Being different from the conventional ion transport with anioncapped carriers (Scheme 1), the transport with (**1**) features that (i) the ion release is enforced by protonation of the ring nitrogen and (ii) proton flux in the counter-current is carried by the ring nitrogen but not by the carboxylate cap. The fact that the rate of the ion-transport is dependent upon the pH of the OUT aqueous phase supports the involvement of the ion-release step in the rate-limiting step. Conceivably, the ion-release is a slow, rate-limiting step when the OUT aqueous phase is basic, whereas the ion-release is facilitated by the "enforced" ion-release due to protonation of the ring nitrogen when the OUT aqueous phase is neutral. A similar enforced ion-release may be expected for the acidic OUT aqueous phase. However, $\mathbf{1}^+$, the main species in acidic pH region, is less soluble in the membrane phase, so that overall transport efficiency is inferior to that of $\mathbf{1}^\pm$.

The proton-driven active transport of K^+ demonstrates the high transport efficiency of $\mathbf{1}^\pm$ more clearly. As recorded in Table 1 (Runs No. 7, 8), the net active transport from the basic IN aqueous phase to the neutral OUT aqueous phase took place (0.97 μmol h^{-1}), whereas that to the acidic OUT aqueous phase was not observed at all. The result implies that only $\mathbf{1}^\pm$ is capable of serving as a recycle ion carrier and carring K^+ against its concentration gradient. As described in introduction, the $\mathbf{1}^-$–K^+ complex is converted to $\mathbf{1}^\pm$ when it contacts with the neutral OUT aqueous phase. Since $\mathbf{1}^\pm$ is highly lipophilic, the species is easily carried back to the side in contact with the IN aqueous plase (see Scheme 2). In case the OUT aqueous phase is strongly acidic, $\mathbf{1}^+$ is the main species after the ion-release. In order to stay in the membrane phase, $\mathbf{1}^+$ must extract some anion, X^-(probably Cl^-) from the OUT aqueous phase. Although we did not estimate the extraction of anion from the acidic aqueous phase, the result in Run No. 7 suggests that the counter-current of $\mathbf{1}^+X^-$ is not sufficient enough to mediate the active transport.

In passive transport, Na^+ was carried less effectively than K^+. This is attributed to the higher affinity of the diaza crown ring toward K^+ in preference to Na^+. Similarly, Ca^{2+} was carried less effectively than Ba^{2+}. Interestingly, Ca^{2+} was transported to the acidic OUT aqueous phase more efficiently than to the neutral OUT aqueous phase. This implies that the enforced Ca^{2+} release occurs only from $\mathbf{1}^+$ and the protonation of the ring nitrogen is not enough to eject the bound Ca^{2+} ion. The trend is quite different from that of K^+ transport. The difference probably stems from the high affinity of Ca^{2+} with the carboxylato group.[2,6]

Amino Acid Transport with ***1****–Metal Complexes.* The transport of amino acids across biological membranes is assumed nowadays to be coupled with Na^+ transport.[26] The transport of amino acids has been investigated by several groups,[27–31] but they mostly employed protected amino acids instead of biologically relevant "free" amino acids. An efficient transport system of free amino acids was reported by Behr and Lehn,[27] who demonstrated that a cationic surfactant is useful for the transport from the basic IN aqueous phase to the acidic OUT aqueous phase, while an anionic surfactant is useful for the transport from the acidic IN aqueous phase to the basic OUT aqueous phase.

It occurred to us that zwitterionic $\mathbf{1}^\pm$ may carry zwitterionic amino acids from the neutral IN aqueous phase to the basic OUT aqueous phase, while alkali metal cations may be carried back from the OUT to the IN aqueous phase. If it occurs, the system has characteristic, like the biological system, of the amino acid transport coupled with the counter-current of alkali metal cations. We thus measured the rate of the transport of phenylalanine from the neutral IN aqueous phase to the basic OUT aqueous phase containing KOH.[32] However, phenylalanine was not transported in an appreciable velocity. This implicates the difficulty

TABLE 2. TRANSPORT OF AMINO ACIDS WITH CARRIER **1**[a]

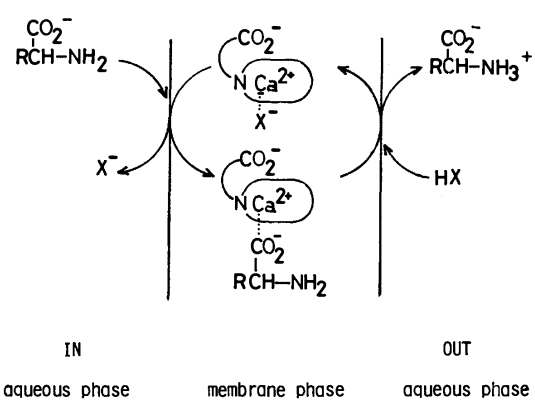
to extract zwitterionic amino acids to the membrane phase.

Here, a new idea arises that the $\mathbf{1}^-$–Ca^{2+} complex may be capable of extracting free amino acids from the basic IN aqueous phase and carrying them to the slightly basic OUT aqueous phase, because Ca^{2+} is scarcely ejected to the basic OUT aqueous phase (Table 1) and the extremely low solubility of zwitterionic amino acids in the membrane phase is rather favorable in the ion-release process. We thus constructed an amino acid transport system with the OUT aqueous phase adjusted mainly to pH 8.0, expecting the $\mathbf{1}^-$–Ca^{2+} complex to extract an anionic amino acid from the basic IN aqueous phase as a counteranion and to release it to the slightly basic OUT aqueous phase as a zwitterionic amino acid (Scheme 3). The pH of the OUT aqueous phase was adjusted with boric acid and LiOH. LiOH was selected because of its low affinity for **1**. The results are summerized in Table 2.



Scheme 3.

Experimental Runs No. 13—16 show the effect of pH in the OUT aqueous phase on the rate of phenylalanine transport. The maximum rate was observed for the strongly basic OUT aqueous phase where Ca^{2+} is not released at all (Run No. 16). Usually, the Li^+ concentration in the IN aqueous phase increased linearly with time. In Run No. 16, however, the counter-current of Li^+ was very fast in the initial stage but became undetected after 5 h. This implies that all the carrier molecules are occupied by Ca^{2+} after 5 h. When the OUT aqueous phase was adjusted to pH 8.0, the rate of phenylalanine transport was somewaht slower than that observed for the basic OUT aqueous phase and Ca^{2+} was released in a speed comparable with phenylalanine. These results show that the release of phenylalanine is not necessarily facilitated in its zwitterionic structure. We added $LiClO_4$ to the OUT aqueous in order to estimate the influence of the X^- concentration. Run No. 15 shows, however, that the effect is almost negligible. In case K^+ was used instead of Li^+ (compare Run No. 19 with Run No. 16), the rate of phenylalanine transport was reduced by 14 fold. Since K^+ is efficiently bound to $\mathbf{1}^-$ in the counter-current path, the rate suppression is attributed to the exchange between K^+ and Ca^{2+} at the interface between the membrane and the IN aqueous phase.

Runs No. 17 and 18 demonstrate that the phenylalanine transport is mediated by Ba^{2+} but not by K^+. In other words, only the $\mathbf{1}^-$–alkaline earth metal complexes are capable of extracting phenylalanine. The comparison of Runs No. 10 and 20 with Run No. 14 reveals that the transport rate is associated with the hydrophobicity of amino acids: The rate of leucine transport is smaller by one order of magnitude than that of phenylalanine transport, and the rate of alanine

transport is undetected in the present experimental precision.

Concluding Remark. The present paper has demonstrated a new class of ion transport involving the rate acceleration due to the enforced ion release and an amino acid transport system with the $\mathbf{1}^-$–metal complexes. The former system well mimicks the basic functions of the natural antibiotics, while the latter system seems still incomplete to call a biomimetic amino acid transport system. We believe, however, that the crown–metal complexes would have greater possibilities as amino acid carriers than simple phase transfer catalysts. Further study is now continued in this laboratory.

NAD(P)$^+$-NAD(P)H Model. 39. Asymmetric Reduction by 1,4-Dihydronicotinamide Derivative Bound to Protein

Atsuyoshi Ohno,* Satoshi Ushida, and Shinzaburo Oka
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received August 18, 1982)

1,4-Dihydronicotinamide derivatives covalently bound to NH_2 or SH group of proteins such as reduced keratin (RK), egg white albumin (EWA), and bovine serum albumin (BSA) have been synthesized and subjected to the reductions of α,α,α-trifluoroacetophenone derivatives. Chiral alcohol is obtained in the reaction with 1,4-dihydronicotinamide modified by the SH group of BSA.

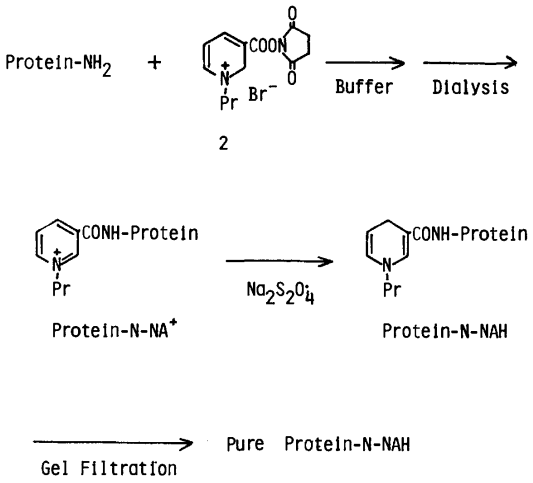
Since our first report on an asymmetric reduction by a model compound of NAD(P)H,[1] many 1,4-dihydronicotinamide derivatives that have chiralities in the molecules have been synthesized.[2,3] Among asymmetric reductions with these model compounds some can compete, in terms of stereospecificity, with enzymic reactions.[3] However, the enzymic reaction is still much more superior to the model reactions in versatility and in reaction rate. Moreover, the stereospecificity in enzymic reactions that require NAD(P)H as a cofactor does not stem from the chirality in NAD(P)H, but from the chiral environment constructed by the enzymes. In fact, NAD(P)H-dependent dehydrogenases are classified into two categories depending on which of hydrogens on the 4-position of 1,4-dihydronicotinamide they utilize during the reduction.[4] The apoenzyme thus plays an important role for the formation of reaction field.

It is interesting to study how far the field effect, exerted by enzymes can be mimicked by organic chemistry, that is, by model compounds. At the same time, it is worthy for organic chemists to study the scope of asymmetric reaction by the use of abundant natural products.

Previously, we reported the syntheses and reactions of 1,4-dihydronicotinamide derivatives covalently bound to protein.[5] In the present work we attempted asymmetric reductions by the use of models covalently linked to proteins. Baba and his coworkers already reported the production of chiral alcohol in the reduction of α,α,α-trifluoroacetophenone (**1**) by 1-propyl-1,4-dihydronicotinamide (PNAH) in aqueous solution of bovine serum albumin (BSA).[6] Kaiser and his coworkers synthesized flavopapain[7] where the active site of the hydrolytic enzyme was utilized for the reaction site of flavin and the modified enzyme was found to exert a dehydrogenase-like property.[8]

Results

Modification of NH_2 Group in Proteins. The NH_2 groups in certain proteins were modified by 1,4-dihydronicotinamide. *N*-Hydroxysuccinimide ester of *N*-propylnicotinic acid (**2**) was employed for the modification as shown in Scheme 1. Thus obtained protein has an absorption maximum at 360 nm which is virtually identical with those of other 1,4-dihydronicotinamide derivatives.[4] This 1,4-dihydronicotinamide derivative of protein can reduce several substrates such as Malachite Green, chloranil, and *N*-methylacridinium iodide in buffered aqueous solution.



Scheme 1.

Table 1. Reductions of α,α,α-trifluoroacetophenone derivatives by BSA-N-NAH

pH[a]	Substrate	[BSA] / mmol dm^{-3}	Molar ratio A[b]	Molar ratio B[c]	Yield/%[d]
8.0	**3**	0.34	3.0	11	19
8.0	**3**	0.31	1.9	23	26
6.5	**3**	0.69	0.82	15	27

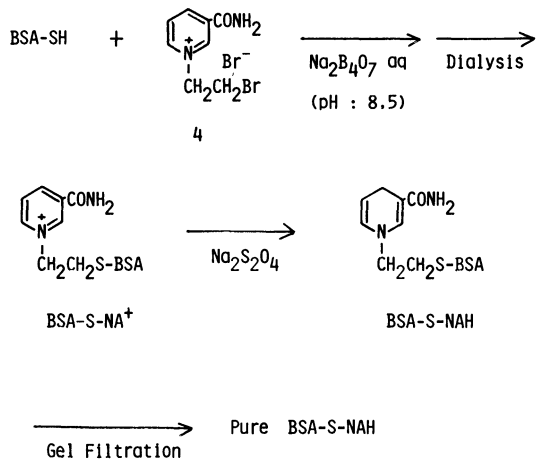
6.0	**1**	0.41	0.66	3	6

a) For modification reaction. b) [dihydropyridine]/[BSA] determined from the absorbance at 360 nm (ε=5900). c) [Substrate]/[BSA]. d) Based on 1,4-dihydropyridine moiety.

The NH_2 groups of *S*-carboxymethylated reduced keratin from human hair (CMRK), *S*-(2-ammonioethyl)ated reduced keratin from wool (AERK), and egg white albumin (EWA) were similarly modified with 1,4-dihydronicotinamide and the proteins were subjected to the reductions of **1** and *m*-trifluoromethyl-α,α,α-trifluoroacetophenone (**3**). The reduction was carried out in an aqueous solution of 0.05 mol dm^{-3} $Na_2B_4O_7$ containing about 2×10^{-4} mol dm^{-3} of 1,4-dihydronicotinamide moiety and $(4—8)\times10^{-3}$ mol dm^{-3} of the substrate. The produced alcohol was converted into the ester of (*R*)-(+)-α-methoxy-α-trifluoromethylphenylacetic acid ((*R*)-(+)-MTPA)[9] and the ratio of two diastereoisomers was determined on GLC. Unfortunate-



Scheme 2.

ly, thus obtained alcohols were racemic in all cases.

Modification of NH_2 Group in BSA. BSA, a carrier protein, is known to act as a chiral environment for certain reactions.[10] On this basis we synthesized 1,4-dihydronicotinamide derivative covalently bound to the NH_2 groups in BSA (BSA-N-NAH). As shown in Table 1, modification was carried out under different pH's to change the number of dihydronicotinamide moiety in a molecule of BSA ([dihydronicotinamide]/[BSA]). The alcohols obtained from the reductions of **1** and **3** were, however, again racemic.

Modification of SH Group in BSA. It has been accepted that BSA contains one SH group in one of three hydrophobic domains.[11] We attempted to modify the SH group with 1,4-dihydronicotinamide by using 1-(2-bromoethyl)-3-carbamoylpyridinium bromide (**4**) according to Scheme 2[12] and obtained BSA-S-NAH with a UV-absorption maximum at 355 nm. That only the SH group was modified and that no other residues of BSA such as $-NH_2$ and $-OH$ were influenced under the reaction conditions employed were confirmed by the following three results: 1) The concentration of modified 1,4-dihydropyridine moiety was comparable to that of original SH group in BSA. 2) When a same procedure was applied to BSA whose SH group had been protected by a carboxymethyl group, no product with an absorption maximum at 355 nm was obtained. 3) L-Cystein reacts with **4** under similar conditions to afford the corresponding sulfide, 1-[2-[(2-amino-2-carboxyethyl)thio]ethyl]-3-carbamoylpyridinium salt. After gel filtration BSA-S-NAH was subjected to the reductions of **1** and **3** at pH 9.4. As shown in Table 2, it was found that thus modified BSA induces chirality in the reduction products and that stereoselectivity increases as the molar ratio of the substrate to BSA decreases.

Table 2. Reaction of α,α,α-Trifluoroacetophenone derivatives with BSA-S-NAH[a]

Substrate	[BSA] mmol dm^{-3}	Molar ratio A[b]	Molar ratio B[c]	e.e./%	Config.
1	0.69	0.52	13	5	*R*
3	0.67	0.48	13	5	*R*
1	1.0	0.32	3.1	10	*R*
1	1.1	0.29	3.0	11	*R*
3	1.1	0.32	2.9	17	*R*
3	1.0	0.32	3.1	15	*R*

a) Reaction was run in 0.05 mol dm^{-3} $Na_2B_4O_7$ (pH: 9.4) at room temperature. The yield of alcohol was about 5% based on 1,4-dihydropyridine moiety. b) [Dihydropyridine]/[BSA] determined from the absorbance at 355 nm (ε=5500). c) [Substrate]/[BSA].

Discussion

The basic idea underlying the present study is to use chiral environment around 1,4-dihydronicotinamide moiety for biomimetic reductions by means of chemical modification on protein, as enzymes do.

When simple proteins, such as RK and EWA, are subjected to modification no chiral products were obtained. In the case of BSA, which is presumed to have much higher degree of functionality than the others, modification of its SH group by 1,4-dihydronicotinamide affords chiral products but modification of its NH_2 group does not. It has been established that BSA contains one SH group in one of three hydrophobic domains. Therefore, by SH modification it must be possible to set a 1,4-dihydronicotinamide moiety into a single chiral circumstance. On the other hand, since BSA and other proteins that we used contain various kinds of NH_2 groups, it seems difficult to carry out the modification selectively. Even if each of modified 1,4-dihydronicotinamide moiety sits itself in a chiral field, the chiralities may be neutralized totally because of a variety of types in modifications. Since NH_2 groups in different environment have different basicities, it is expected that the modification of NH_2 groups under different pH might result in selectively modified protein. However, the attempt was not successful as seen in Table 1.

Alternatively, it is also possible that chiral fields supplied by the protein locate far from the 1,4-dihydronicotinamide moiety, because most of free NH_2 groups stick out of the main domain of the protein.

The present result with BSA-S-NAH is the first example of biomimetic reduction where the chirality in the protein-1,4-dihydronicotinamide complex is transferred, as is observed in enzymic reactions, into a substrate during the reaction in water. Results shown in Table 2 reveal that the reaction between BSA-S-NAH and free substrate does not exert stereoselectivity. On the other hand, the reaction of a substrate trapped on BSA and free reductant ($NaBH_4$ or PNAH) exerts stereoselectivity of about 40% e.e.[6,10] Thus, it seems likely that protein-protein interaction between BSA which binds a substrate and BSA which binds 1,4-dihydronicotinamide is important in the present reaction to determine the stereoselectivity.

There is another possibility; for a bimolecular reaction in micellar system, it is assumed that when one reagent is incorporated into one micelle and the other reagent into another micelle, no reaction takes place because each reagent has no chance to collide each other.[13] Similarly, a substrate incorporated into BSA

might not be able to find a chance to react with 1,4-dihydronicotinamide which is bound to BSA. If this is the case, the substrate which is trapped into a 1,4-dihydronicotinamide-containing crevice of BSA is the only substrate that can undergo the asymmetric reaction. The situation is quite similar to that of ternary complex in an enzymic reaction.

In any case, there is no doubt that the reduction proceeds in a chiral field offerred by such a protein as that which is quite different from dehydrogenases. Although the present result is not satisfactory, it promises further success by appropriate use of crevice in a protein. It should be noted, however, that in the asymmetric reduction with a chiral 1,4-dihydronicotinamide derivative, the interaction between reduced and oxidized forms of the model compound is important in order to exert high stereospecificity.[14,3] If similar situation operates in the present system, high stereoselectivity cannot be expected with BSA-S-NAH because extraordinarily bulky substituent prevents the model compound from the formation of aggregates and more sophisticated design will be necessary for the model compound.

Experimental

Melting and boiling points were not corrected.

Instruments. UV, NMR, and mass spectra were obtained on Union Giken SM-401, JEOL JNMFX-100, and Hewlett Packard 5992B GC/MS spectrometers, respectively. A Yanaco G-1800F was used for GLC analyses. Preparative-scale GLC separations were carried out by using Varian Aerograph Model 920.

Materials. BSA was Fraction V grade from Armour. α,α,α-Trifluoroacetophenone (**1**) (bp 423 K) was prepared according to the literature procedure.[15] *m*-Trifluoromethyl-α,α,α-trifluoroacetophenone (**3**) was prepared from *m*-trifluoromethylphenylmagnesium bromide and trifluoroacetic acid.[16] (*R*)-(+)-α-methoxy-α-trifluoromethylphenylacetic acid was purchased from Aldrich Chem. Co. and was converted into the corresponding chloride (MTPACl) by the use of thionyl chloride.[9]

S-Carboxymethylated Reduced Keratin from Human Hair (CMRK). Human hair (5.0 g) was reductively solubilized by sodium mercaptoacetate (5.0 g) in aqueous sodium sulfide (200 cm^3, pH: 12.0). After being kept for 5 d at room temperature under nitrogen atmosphere, 3.15 g of sodium borohydride was added and the solution was allowed to stand for a day. Carboxymethylation of free SH groups was effected by the addition of iodoacetic acid (8.2 g) at pH 8.5. Thus obtained CMRK was subjected to the modification after dialysis against 2 dm^3 of borate buffer for several times.

Reduced Keratin from Wool Whose SH Group Was Protected with (2-Bromoethyl)trimethylammonium Bromide (AERK).[17] Wool (1.7 g) was reductively solubilized using 2-mercaptoethanol (1.2 g) in 100 cm^3 of 8 mol dm^{-3} urea–0.01 mol dm^{-3} Tris in the presence of 0.001 mol dm^{-3} EDTA. The solution was stirred for 3—5 h at room temperature under nitrogen atmosphere. To the solution 3 g of (2-bromoethyl)trimethylammonium bromide was added. After being kept for a day the solution was dialyzed against 2 dm^3 of borate buffer for several times. Thus obtained solution of AERK was subjected to further modification.

N-Hydroxysuccinimide Ester of N-*Propylnicotinic Acid (2).* Dicyclohexylcarbodiimide (10.3 g) was added to a suspension of nicotinic acid (6.15 g) and *N*-hydroxysuccinimide (5.75 g) in 150 cm^3 of dioxane. The precipitate was separated by filtration. The dioxane was removed from the filtrate under reduced pressure to give *N*-hydroxysuccinimide ester of nicotinic acid quantitatively. Thus obtained ester (10 g) was dissolved in propyl bromide. The mixture was refluxed for a day. The precipitate was separated, washed with anhydrous acetone, and kept *in vacuo* to constant weight (9.4 g, 60% yield).

1-(2-Bromoethyl)-3-carbamoylpyridinium Bromide (4). A mixture of nicotinamide (0.60 g) and 1,2-dibromoethane (7 cm^3) was stirred at 313—323 K for 5 d. The solid was collected and extracted with hot methanol. After the removal of the solvent, the crude product was washed with acetone. Twice recrystalization from methanol gave 0.40 g of **4** (mp 465—467 K).

Found: C, 31.13; H, 3.28; N, 8.95%. Calcd for $Br_2C_8H_{10}N_2O$: C, 31.00; H, 3.25; N, 9.04%.

^1H NMR (D_2O, δ from TSP): 4.09 (2H, t, J=6 Hz), 5.22 (2H, t, J=6 Hz), 8.27 (1H, m), 8.80—9.10 (2H, m), 9.28 (1H, bs).

Modification of NH_2 Group in CMRK, AERK, and EWA. To a buffered solution of a protein (20 cm^3) about 100 mg of **2** was added. After the dialysis against 2 dm^3 of 0.05 mol dm^{-3} $Na_2B_4O_7$ for a day modified pyridinium ion was reduced with sodium dithionite (*ca.* 20 mg). Excess dithionite was removed by gel filtration on a column of Bio-gel P-6.

Modification of NH_2 Group in BSA. The same procedure as described above was employed for a 0.05 mol dm^{-3} $Na_2B_4O_7$ solution of BSA (0.5 mmol dm^{-3}). The amount of **2** and pH of the buffered solution were changed in compliance of the cases.

Modification of SH Group in BSA. To a solution of BSA (1.5 mmol dm^{-3}) in 0.05 mol dm^{-3} $Na_2B_4O_7$ (50 cm^3, pH: 8.5), 50 mg of **4** was added. The BSA contained 0.45—0.55 free SH groups in a molecule. The solution was kept at room temperature under nitrogen atmosphere for about 3 d until no SH group could be detected by DTNB-method. After the dialysis against 2 dm^3 of 0.05 mol dm^{-3} $Na_2B_4O_7$ for several times, 50 mg of sodium dithionite was added to the solution of BSA-S-NA$^+$. Excess dithionite was removed by gel filtration on a column of Bio-gel P-6 to afford pure BSA-S-NAH.

UV-Absorption of Modified Protein. Thus obtained modified protein exerts an absorption maximum at around 360 nm due to 1,4-dihydronicotinamide moiety. The amount of 1,4-dihydronicotinamide moiety in the protein was determined by titration with *N*-methylacridinium iodide on monitoring the absorption at around 360 nm.

Reactions of α,α,α-Trifluoroacetophenone Derivatives. To a solution of modified protein **1** or **3** was added. The solution was stirred for 1—2 weeks until UV-absorption at around 360 nm disappeared. The mixture of the products and starting material was extracted with ether.

Determination of Enantiomer Excess. The ether solution of extracted reaction mixture was concentrated to 0.1 cm^3 under atmospheric pressure and the enantiomeric alcohols were separated by preparative GLC on a PEG column and collected as a solution of carbon tetrachloride (0.1—0.2 cm^3). The alcohol was subjected to esterification by (*S*)-(+)-MTPACl[9] and the mixture of diastereomeric esters was submitted to the GLC analysis. Since the esterification is diastereotopic reaction, it should be confirmed that all the starting alcohol is esterified. Otherwise, GLC analysis does not give correct result.

Diastereomeric esters of **5** and **6** (**7** and **8**, respectively) were separated on GLC (10% DEGS, 1 m). The peaks were identified by comparison with those of authentic **7** and **8**. The

structures of **7** and **8** were also identified by GC/MS analyses. The value of enantiomer excess was determined from the ratio of peak areas for the diastereomeric esters. The ratio for racemic **7** and **8** were 50 : 50, respectively.

Facile Synthesis of Cyclic Dipeptides and Detection of Racemization

Toshihisa UEDA,* Morinobu SAITO,† Tetsuo KATO, and Nobuo IZUMIYA
Laboratory of Biochemistry, Faculty of Science, Kyushu University 33, Higashi-ku, Fukuoka 812
(Received September 10, 1982)

Several cyclic dipeptides were synthesized by refluxing methanolic solution of dipeptide methyl esters in high yield and purity. Cyclic dipeptides prepared by the Fischer method, the Nitecki method, and the present methanol-reflux method were compared with respect to yield and optical purity. The methanol-reflux method usually gave good results. High-performance liquid chromatography was effectively applied to detect racemization.

Various natural cyclic dipeptides (2,5-piperazinedione derivatives) are known by their diverse biological activities such as antibiotic,[1] bitter taste,[2] plant growth retardation,[3,4] and inhibition of hormone secretion.[5] With regard to synthetic cyclic dipeptides, Izumiya *et al.* observed highly asymmetric induction on hydrogenation of cyclic dehydrodipeptides.[6] Shiba *et al.* studied structure-activity relationships of bitter cyclic dipeptides.[7] Kopple *et al.* utilized cyclic dipeptides as a model for studying peptide conformation.[8,9]

Cyclic dipeptides have been prepared by the Fischer method: Aminolysis of dipeptide ester in methanolic ammonia.[10] This method is simple to apply and usually gives high yield. Nitecki *et al.*, however, pointed out appreciable racemization derived from this procedure and proposed another method:[11] Deprotection of Boc-dipeptide methyl ester by formic acid and subsequent reflux of the deprotected ester formate with a mixture of *s*-butyl alcohol and toluene.[12] This Nitecki method was reported to be less prone to racemization. Lee *et al.*[13] reported that a side reaction occurred at the side chain of a serine residue in the course of the Nitecki method. Thus, both synthetic methods seemed to envisage undesired side reactions.

It is well-known that dipeptide esters spontaneously cyclize to form cyclic dipeptides upon hydrogenolysis of a benzyloxycarbonyl protecting group. As a modification of this reaction, reflux of methanolic solution of dipeptide esters has been tried in the present study to facilitate cyclization, and experimental conditions have been examined to improve yield and optical purity of products.

For detection of diastereomers of cyclic dipeptides, Nitecki *et al.*[11] and Westley *et al.*[14] used NMR, TLC, and gas liquid partition chromatography. These methods are easy to operate but precision and sensitivity are insufficient to detect a small amount of racemates. Lee *et al.*[13] and Kanmera *et al.*[15] reported detection of racemization by the Manning-Shimohigashi method.[6,16,17] This method using an amino acid analyzer can be applied with high precision, but the procedure is so complicated that an unexpected error might be possible. Recently, high-performance liquid chromatography has come into use in peptide chemistry.[18,19] This technique is expected to give a simple and convenient method for racemization test.

We report here convenient synthesis of cyclic dipeptides by refluxing methanolic solution of dipeptide methyl esters. Rapid and highly sensitive detection of racemization by HPLC[12] is also described.

TABLE 1. YIELDS AND PHYSICAL CONSTANTS OF CYCLIC DIPEPTIDES

Compound	Yield %	Mp θ_m/°C, decomp	$[\alpha]_D^{20}$ a)/°	Formula	Found(%) (Calcd(%)) C	H	N
cyclo(-L-Val-L-Val-)	64	272—273	−62.0 (*c* 0.5, AcOH)	$C_{10}H_{18}O_2N_2$	60.37 (60.58	9.31 9.15	14.13 14.13)
cyclo(-L-Val-D-Val-)	45	>300		$C_{10}H_{18}O_2N_2$	60.43 (60.58	9.24 9.15	14.14 14.13)
cyclo(-L-Ala-L-Ala-)	80	276—280	−22.8 (*c* 0.5, AcOH)	$C_6H_{10}O_2N_2$	50.78 (50.70	7.17 7.09	19.49 19.71)
cyclo(-L-Ala-D-Ala-)	88	256—259		$C_6H_{10}O_2N_2$	50.84 (50.70	7.14 7.09	19.51 19.71)
cyclo(-L-Ser-L-Ser-)	77	231—233	−54.0 (*c* 0.1, DMF)	$C_6H_{10}O_4N_2$	41.32 (41.38	5.93 5.79	15.97 16.08)
cyclo(-L-Ser-D-Ser-)	74	261—264		$C_6H_{10}O_4N_2$	41.33 (41.38	5.88 5.79	15.99 16.08)
cyclo(-L-Pro-L-Pro-)	64	141—142	−148 (*c* 1, AcOH)	$C_{10}H_{14}O_2N_2$	61.54 (61.84	7.35 7.27	14.20 14.42)
cyclo(-L-Pro-D-Pro-)	83	176—177		$C_{10}H_{14}O_2N_2$	61.53 (61.84	7.34 7.27	14.24 14.42)

a) $[\alpha]_D$ of all *cyclo*(-L-AA-D-AA-) should be 0°, therefore measurement was not carried out.

† Present address: Teikoku Hormone Mfg. Co., Takatsu-ku, Kawasaki 213.

Table 2. Separation conditions by HPLC[a)]

Compound	Filler; LiChrosorb	Eluent (ratio)	Column (cm)	Pressure kg cm^{-2}	Retention time/min LL	Retention time/min DL	Absorption intensity ratio (LL/DL)
cyclo(-L-Leu-(L and D)-Leu-)	PR-18	H_2O–CH_3CN (8 : 2)	0.26×15	300	7.5	5.4	1.06
cyclo(-L-Val-(L and D)-Val-)	RP-18	H_2O–CH_3CN (9 : 1)	0.26×15	300	4.0	2.3	0.98
cyclo(-L-Ala-(L and D)-Ala-)	RP-8	H_2O	0.4 ×25	150	10.3	7.8	1.05
cyclo(-L-Ser-(L and D)-Ser-)	RP-18	KH_2PO_4–Na_2HPO_4[b)]	0.26×50	450	31.7	27.4	1.03

a) Other conditions are as follows: Hitachi 635A liquid chromatograph; flow rate, 1 ml/min; wavelength, 210 nm; temperature, 20 °C. b) 3 M (1 M=1 mol dm^{-3}) at pH 6.6.

Results and Discussion

Separation Conditions of Diastereomers by HPLC. Table 1 shows cyclic dipeptides prepared in this study as model peptides. *cyclo*(-L-Leu-L-Leu-), *cyclo*(-L-Leu-D-Leu-), *cyclo*(-L-Phe-L-Phe-), and *cyclo*(-L-Phe-D-Phe-) were also prepared according to the literature.[11)] Separation conditions by HPLC were examined. Satisfactory separation was obtained by reversed-phase chromatography with LiChrosorb RP-8 and RP-18 as filler, experimental conditions being shown in Table 2. Diastereomers of *cyclo*(-L-Ser-(L and D)-Ser-) were separated by phosphate buffer better than by water. Generally, LiChrosorb RP-18 shows longer retention time than LiChrosorb RP-8 does. On the other hand, unsatisfactory results were obtained for adsorption chromatography with Hitachi gel #3040 and reversed-phase chromatography with gels of large particle size. *cyclo*(-L-Pro-(L and D)-Pro-) could not be satisfactorily separated.

Experimental Conditions for the MeOH-reflux Method. Reaction conditions for the MeOH-reflux method were studied by the use of *cyclo*(-L-Leu-(L and D)-Leu-) as a model. Degree of racemization is given by racemization (%)=[LD%/(LL%+LD%)]×100. A rough estimate of reaction was given in terms of the reaction time elapsed until a TLC spot of the starting ester had disappeared.

Effect of Methyl and Ethyl Ester Groups. Cyclization of H-L-Leu-L-Leu-OMe and H-L-Leu-L-Leu-OEt in MeOH was compared in order to study the effect of methyl and ethyl groups on reaction rate, racemization, and yield of *cyclo*(-L-Leu-L-Leu-). The reaction time, racemization, and yield were 80 h, 1.2%, and 76% for methyl, and 160 h, 1.9%, and 65% for ethyl ester, respectively. Therefore, methyl ester was used hereafter.

Table 3. Effect of reflux solvent on cyclization of H-L-LEU-L-LEU-OME

Solvent	Bp θ_b/°C	Reaction rate h	Racemization (%)	Yield to produce cyclic dipeptide %
MeOH	64	80	1.2	76
EtOH	79	70	0.8	66
s-BuOH	100	48	>26	15
Toluene	110	50	1.9	75

Effect of Reflux Solvent. Table 3 shows the effect of reflux solvent. The reaction rate and racemization increased with the raise of the boiling point of a solvent. Severe racemization was detected in the case of *s*-BuOH and a side reaction was suggested by TLC. Racemization was negligible for MeOH and EtOH, and MeOH gave higher yield. Based on these results, reflux of methanolic solution of dipeptide methyl ester is recommended for facile synthesis of cyclic dipeptides.

Effect of Salt on Racemization. Boc-L-Leu-L-Leu-OMe was deprotected with HCOOH, subsequently neutralized with NEt_3, and the methanolic solution of the mixture was refluxed. The same procedure was repeated without salt, and the degree of racemization was compared. When 1.2, 1.0, and 0 equivalent of $HCOOH \cdot NEt_3$ were present, 2.3, 1.8, and 1.2% racemizations were observed respectively. Clearly, excess of acid and base should be avoided.

Effect of Side Chain of Amino Acid Residues on Cyclization Rate. The effect of the size of a side chain in H-dipeptide-OMe on reaction rate was studied. When H-Gly-L-Ala-OMe, H-L-Ala-L-Ala-OMe, and H-L-Leu-L-Ala-OMe were used as starting compounds, the reaction times to give a cyclic dipeptide were 10, 20, and 24 h, respectively. For H-Gly-L-Leu-OMe and H-L-Leu-L-Leu-OMe, 24 and 80 h, respectively. As expected, cyclization rate decreased with the increase of the size of a side chain.

Effect of Diastereomers in a Dipeptide Ester. Cyclization of H-L-Leu-L-Leu-OMe and H-L-Leu-D-Leu-OMe was compared to examine diastereomeric difference. Reaction time, racemization, and yield of cyclization were 80 h, 1.2%, and 76% for H-L-Leu-L-Leu-OMe, and 70 h, 1.1%, and 67% for H-L-Leu-D-Leu-OMe. The effect of diastereomeric difference is only slight if any.

Comparison of Synthetic Methods. Cyclic dipeptides shown in Table 4 were prepaed by the three methods, and racemization of these peptides except for *cyclo*(-L-Phe-L-Phe-) was detected by HPLC. Racemization of *cyclo*(-L-Phe-L-Phe-) was detected by the Manning-Shimohigashi method.[16)] The Fischer method occasionally gave low yield possibly because of the formation of dipeptide amide. The Fischer method caused appreciable racemization for *cyclo*(-L-Ser-L-Ser-), al-

TABLE 4. COMPARISON OF THE THREE METHODS

Compound obtained	Fischer method		Nitecki method		MeOH-reflux method	
	Yield %	Racemization (%)	Yield %	Racemization (%)	Yield %	Racemization (%)
cyclo(-L-Leu-L-Leu-)	70	1.5	71	5.5	76	1.2
cyclo(-L-Val-L-Val-)	20	0.9	58	0.4	64	0.6
cyclo(-L-Ala-L-Ala-)	72	0.4	85	0.3	81	0.3
cyclo(-L-Ser-L-Ser-)	53	2.7	40	1.5	63	1.4
cyclo(-L-Phe-L-Phe-)	86	0.6	89	0.6	93	0.1

though detected racemization was much lower than reported by Nitecki *et al.* (5—40%).[11] It should be noted that H-dipeptide-OMe was treated with methanolic ammonia in the shortest reaction time in this study, whereas reported reaction time was 1 d to 5 d.[11]

The Nitecki method caused comparatively less racemization. In the case of *cyclo*(-L-Leu-L-Leu-), however, 5.5% racemization was observed. We can not explain this result at present. A side reaction was observed also in the case of *cyclo*(-L-Ser-L-Ser-) producing a mixture of three components. Each component separated by silica gel chromatography was found to be HCO-L-Ser-L-Ser-OMe (**1**), a formylated derivative (**2**) of **1**, and desired *cyclo*(-L-Ser-L-Ser-). This side reaction was observed only in the case of dipeptides containing serine.

Nitecki *et al.* presumed that racemization took place only on cyclization step.[11] However, Fig. 1 shows that racemization proceeds mainly after cyclization. Cyclic dipeptide is found to be susceptible to racemization in the presence of excess base. Possible reason of racemization is keto-enol tautomerism resulted from deprotonation from α-carbon.

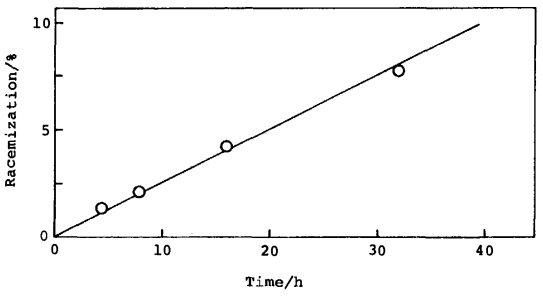

Fig. 1. Time-course of racemization of *cyclo*(-L-Leu-L-Leu-) in methanolic ammonia.

Although the MeOH-reflux method is recommendable compared to the Fischer method and the Nitecki method, it should be noted that Suzuki *et al.*[20] have recently proposed a similar method, AcOH-catalyzed aminolysis of dipeptide esters, *s*-BuOH being used as a solvent. Additionally, Takahashi *et al.* described synthesis of cyclic dipeptides using *N*-carboxy amino acid and amino acid esters.[21]

Experimental

The melting points are uncorrected. TLC was carried out on silica gel G (Merck) with the following solvent systems: R_f^1, $CHCl_3$-MeOH (5 : 1); R_f^2, $CHCl_3$-MeOH-AcOH (50 : 10 : 2). The ratio in parentheses after a solvent system is indicated by volume. HPLC was carried out with a Hitachi 635A liquid chromatograph equipped with multi-wavelength UV monitor 635-0900. Solvents for HPLC were filtered and degassed before use. A Hitachi amino acid analyzer KLA-5 was used for the determination of amino acids and diastereomeric dipeptides under the following conditions: column, 0.6×55 cm; jacket temperature, 55 °C; flow rate, 30 ml/h. ^1H NMR spectra were obtained on a JEOL FX-90Q spectrometer with tetramethylsilane as an internal standard.

Z-Dipeptide Esters. *Z-L-Val-L-Val-OMe*: Preparation of this compound is described as an example of the preparation of Z-dipeptide esters. To a chilled solution of Z-L-Val-OH (1.51 g, 6 mmol), H-L-Val-OMe·HCl (1.01 g, 6 mmol) and NEt_3 (0.84 ml, 6 mmol) in CH_2Cl_2 (18 ml), was added DCC (1.30 g, 6.3 mmol) at 0 °C. The reaction mixture was stirred at 0 °C for 4 h and allowed to stand at room temperature overnight. After removal of *N,N'*-dicyclohexylurea, the filtrate was evaporated *in vacuo* and the residue was dissolved in EtOAc. The solution was washed successively with 2% HCl, 4% $NaHCO_3$, and water, dried (Na_2SO_4), and evaporated. The residue was recrystallized from EtOAc–ether–petroleum ether; yield, 1.68 g (77%); mp 145—147 °C; $[\alpha]_D^{20}$ −28.0° (*c* 1, MeOH); R_f^1 0.88.

Found: C, 62.78; H, 8.00; N, 7.60%. Calcd for $C_{19}H_{28}O_5N_2$: C, 62.62; H, 7.74; N, 7.69%.

Several Z-Dipeptide Esters: Other compounds were prepared in a similar manner. New compounds prepared were as follows: Z-L-Leu-D-Leu-OMe, Z-L-Leu-D-Leu-OEt, Z-L-Ala-D-Ala-OEt, Z-L-Ser-D-Ser-OEt, Z-L-Pro-D-Pro-OMe, and Z-L-Phe-D-Phe-OMe.

Boc-Dipeptide Esters. *Boc-L-Ala-L-Ala-OMe*: Coupling of Boc-L-Ala-OH (0.95 g, 5 mmol) and H-L-Ala-OMe·HCl (0.70 g, 5 mmol) by DCC (1.03 g, 5 mmol) was carried out as described above. The product was recrystallized from EtOAc–ether–petroleum ether; yield, 1.03 g (75%); mp 108—109 °C; $[\alpha]_D^{20}$ −57.8° (*c* 1, MeOH); R_f^2 0.79.

Found: C, 52.55; H, 8.18; N, 10.25%. Calcd for $C_{12}H_{22}O_5N_2$: C, 52.54; H, 8.08; N, 10.21%.

Several Boc-Dipeptide Esters: Known Boc-dipeptide esters such as Boc-L-Leu-L-Leu-OMe were prepared similarly. New compound prepared was Boc-L-Val-D-Val-OMe.

Authentic Cyclic Dipeptides. cyclo(-L-Val-L-Val-): Z-L-Val-L-Val-OMe (182 mg, 0.5 mmol) was dissolved in MeOH (5 ml) and hydrogenolyzed in the presence of Pd black. After the catalyst was filtered off, the filtrate was evaporated *in vacuo* and the residue was dissolved in MeOH (10 ml). The solution was refluxed for 110 h and evaporated *in vacuo*. The residue was recrystallized from MeOH–ether; yield, 63 mg (64%); physical constants being shown in Table 1.

Several Cyclic Dipeptides: Other compounds were prepared by the same procedure. Yields and physical constants are shown in Table 1.

Separation of Cyclic Dipeptide Diastereomers by HPLC.

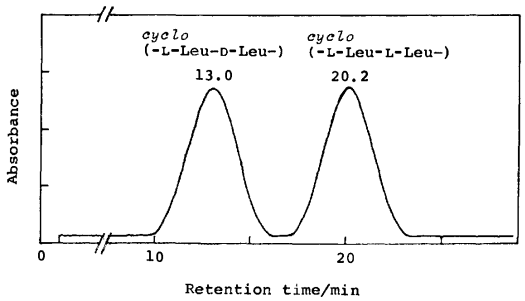

Fig. 2. Separation of cyclic dipeptide diastereomers by adsorption HPLC. Column, Hitachi gel #3040, 0.26×50 cm; eluent, hexane–EtOH (9:1); flow rate, 1 ml/min; wavelength, 210 nm.

a) Reversed-phase HPLC: Hitachi Gel #3050 (particle size, 20—25 μm), #3053 (10 μm), LiChrosorb RP-8 (5 μm), and LiChrosorb RP-18 (5 μm) were used as filler, and aqueous mixtures such as water–MeOH, water–MeOH–*i*-PrOH, water–CH_3CN, and water–CH_3CN–*i*-PrOH were tested as solvent systems. Optimal conditions are shown in Table 2. In the case of *cyclo*(-L-Ser-L,D-Ser-), phosphate buffer was used, which was tested over the wide range of concentrations at pH 6.6. The filler was filled by slurry method.

b) Adsorption HPLC: Solvent systems were tested by TLC using various two or three component systems with MeOH, EtOH, *i*-PrOH, hexane, and CH_3CN. The solvent system, hexane–EtOH, gave good results for the separation of *cyclo*(-L-Leu-L-Leu-) as shown in Fig. 2. However, the separation of other cyclic dipeptides were unsuccessful.

c) Determination of Racemization: Separation conditions for four cyclic dipeptides were shown in Table 2. Ten μl of a sample solution, concentration of which was about 1 mg/ml, was applied to HPLC and analyzed. All values of racemization were corrected with the ratio of absorption intensity.

Effects of Factors on Formation of Cyclic Dipeptide by the MeOH-reflux Method. a) Effect of Ester Groups: Z-L-Leu-L-Leu-OMe or Z-L-Leu-L-Leu-OEt (0.5 mmol each) dissolved in MeOH (5 ml) was treated with H_2/Pd and the solution was refluxed as described in the section of Authentic Cyclic Dipeptides.

b) Effect of Salt on Racemization: After deprotection of Boc-L-Leu-L-Leu-OMe with HCOOH, the solution was evaporated and dried *in vacuo* overnight. After neutralization with NEt_3, the residue was dissolved in MeOH and the solution was refluxed for 72 h. After the solution was evaporated, the residue was dissolved in MeOH and applied to HPLC in order to detect racemization.

c) Effect of Reflux Solvent: H-L-Leu-L-Leu-OMe (0.5 mmol), which was prepared by hydrogenolysis of Z-L-Leu-L-Leu-OMe, was dissolved in 5 ml each of MeOH, EtOH, *s*-BuOH, or toluene, and each solution was refluxed. Effect of each solvent on racemization and yield were compared, the results being shown in Table 3.

Determination of Racemization during the Formation of Cyclic Dipeptides. a) Fischer Method: Z-L-Leu-L-Leu-OMe (0.5 mmol) was dissolved in MeOH (5 ml) and hydrogenolyzed. The filtrate was evaporated, the residue was dissolved in methanolic ammonia (5 ml) and allowed to stand for 12 h, and the solution was evaporated. The residue was dissolved in MeOH (20 ml), a portion of which was applied to HPLC. The rest of the solution was evaporated and the residue was recrystallized from MeOH–ether; yield, 79 mg (70%). Other cyclic dipeptides were prepared by the same procedure, and the yield and racemization are shown in Table 4.

b) Nitecki Method: Boc-L-Leu-L-Leu-OMe (0.5 mmol) was dissolved in HCOOH (2.5 ml) and the solution was allowed to stand for 24 h at room temperature. After evaporation of the solution, the residue was dried *in vacuo* overnight and dissolved in a mixture of *s*-BuOH (5 ml) and toluene (3 ml). After the solution was refluxed for 6 h and evaporated, the residue was dissolved in MeOH (20 ml). A portion of the methanolic solution was evaporated and the residue was recrystallized from MeOH–ether; yield, 71%. Other cyclic dipeptides were prepared by the same procedure, and yields and racemization are shown in Table 4.

c) MeOH-reflux Method: Cyclic dipeptides were prepared by the same procedure as described in the section of Authentic Cyclic Dipeptides. Yields and racemization are shown in Table 4.

Side Reaction in the Nitecki Method. Boc-L-Ser-L-Ser-OMe (168 mg, 0.5 mmol) was dissolved in HCOOH (3 ml) and the solution was allowed to stand for 6 h. After evaporation of the solution, the residue was dried, and dissolved in a mixture of *s*-BuOH (5 ml) and toluene (3 ml). The solution was refluxed for 5 h, evaporated, and the residue (65 mg) was obtained as a mixture of three components, which were separated to component HCO-Ser-Ser-OMe (**1**), a *O*-formylated derivative (**2**) of **1**, and *cyclo*(-L-Ser-L-Ser-) by silica gel chromatography under the following conditions: column size, 1.1×50 cm; eluent, $CHCl_3$–MeOH (9 : 1); fraction volume, 0.7 ml, flow rate, 7 ml/h. Separated compounds were recrystallized from MeOH–ether and afforded **1** and **2**. Yield of **1**, 17 mg (13%); mp 153 °C; ^{1}H NMR (DMSO-d_6) δ=8.02 (s, CHO). Yield of **2**, 7 mg, (5%); mp 138—142 °C; ^{1}H NMR (DMSO-d_6) δ=8.02 (s, CHO), 8.20 (s, CHO). Yield of *cyclo*(-L-Ser-L-Ser-), 38 mg (40%); mp 231—233 °C (dec). The structures of **1** and **2** were assessed by the results of ^{1}H NMR as HCO-Ser-Ser-OMe and its *O*-formylated derivative. However, the formylated hydroxyl group was not identified.

In the case of H-L-Ser-L-Ser-OEt also, ethyl esters **1′** (mp 153—155 °C) and **2′** (mp 116—118 °C) corresponding to **1** and **2** were obtained by the same procedure. *N*-formyl and *N*,*O*-diformyl nature of **1′** and **2′** were ascertained by elemental analyses and ^{1}H NMR.

Degree of Racemization in the Fischer Method. *cyclo*(-L-Leu-L-Leu-) (10 mg) was dissolved in methanolic ammonia (2 ml), and the solution was allowed to stand at room temperature. After 4, 8, 16, and 32 h, an aliquot of the solution was taken and evaporated. The residue was dissolved in MeOH (5 ml), and the solution was applied to HPLC, the results being shown in Fig. 1.

We thank Dr. H. Aoyagi and Dr. M. Waki, Kyushu University, for their helpful discussions during this work.

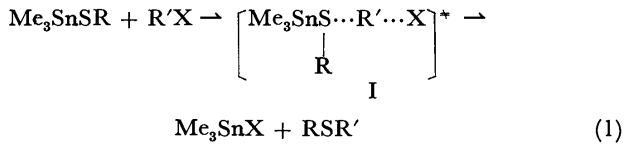
The Mechanism of the Reaction of (Aryloxy)trimethylstannane with Methanesulfonyl Chloride. Solvent and Substituent Effects on the Rate of the Reaction

Seizi KOZUKA,* Shigeru YAMAGUCHI, and Waichiro TAGAKI
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto 3-chome, Sumiyoshi-ku, Osaka 558
(Received September 10, 1982)

A kinetic study has been conducted on the reactions of (aryloxy)trimethylstannanes with methanesulfonyl chloride giving chlorotrimethylstannane and aryl methanesulfonates. The reaction was found to obey a second order kinetic equation. The solvent effect on the rate of the reaction appeared obscure although a small rate enhancement was observed in a polar solvent. Substituent effect of the aryloxyl group was found to be dependent on the solvent used while a clear isokinetic relationship was observed. A charge separated four-center transition state has been suggested for the reaction.

The mechanism of the bimolecular IVb–VIb bond cleavage reactions may be classified into three different types. The first one is a nucleophilic attack of the VIb atom (I). The reaction of (arylthio)trimethylstannane

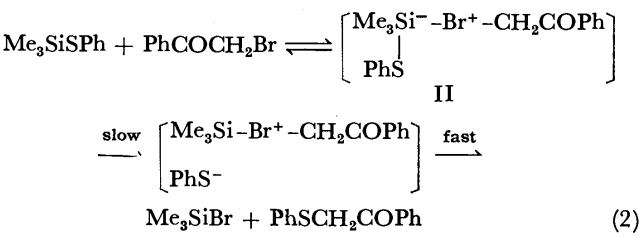


$$Me_3SnSR + R'X \rightarrow [Me_3SnS\cdots R'\cdots X]^{*} \rightarrow \underset{\text{I}}{\begin{bmatrix} Me_3SnS\cdots R'\cdots X \\ | \\ R \end{bmatrix}^{*}} \rightarrow Me_3SnX + RSR' \quad (1)$$

R = alkyl, aryl; R′ = alkyl; X = halogen.

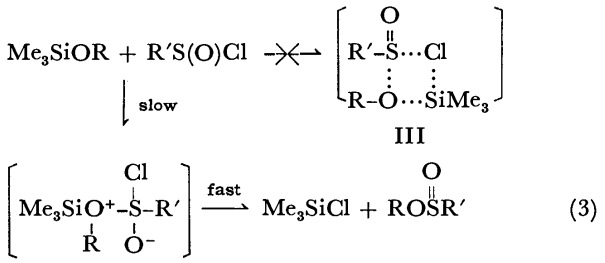
with haloalkanes has been considered to be the nucleophilic reaction based on the kinetic results (Eq. 1). Namely, the reaction obeyed a second order kinetic equation with apparently negative substituent effect of the arylthio moiety ($\rho = -1.4$). Other evidence observed in support of the mechanism were: the solvent effect on the rate of the reaction ($k_{PhCN}/k_{C_6H_6} = ca.$ 100), relative reactivity of the haloalkanes which appeared in comparable to that of common S_N2 reactions, and inversion of configuration of the alkyl group of the haloalkane.[1] The reactions of (aryloxy)trimethylstannane with benzyl bromide[2] and (arylthio)trimethylstannane with benzoyl chloride[3] have also been suggested to proceed in similar manners.

The second is the reaction involving five-coordinated intermediate (II) as has been suggested for the reaction of (arylthio)trimethylsilane with phenacyl bromide based on the kinetic results. A large positive ρ value due to the arylthio moiety (+2.2) was observed with a large negative entropy of activation (-156 J K^{-1} mol^{-1}). As a result, five-coordinated silicon intermediate was suggested to be involved prior to the rate-determining heterolysis of the Si–S bond (Eq. 2).[4] Five-coordinated silicon intermediates have also been suggested for acyloxyl exchange reaction of acyloxysilane with carboxylic acid[5] and the reaction of arylthiosilane with carboxylic acid.[6]



$$Me_3SiSPh + PhCOCH_2Br \rightleftharpoons \underset{\text{II}}{\begin{bmatrix} Me_3Si^{-}\text{-}Br^{+}\text{-}CH_2COPh \\ | \\ PhS \end{bmatrix}} \xrightarrow{\text{slow}} \begin{bmatrix} Me_3Si\text{-}Br^{+}\text{-}CH_2COPh \\ PhS^{-} \end{bmatrix} \xrightarrow{\text{fast}} Me_3SiBr + PhSCH_2COPh \quad (2)$$

The third possibility is a four-centered mechanism. The reaction of alkoxytrimethylsilanes with benzenesulfinyl chloride had once been suggested to involve nonionic four-centered transition state (III) based on the kinetic resuls that the rate of the reaction was little influenced by the solvent polarity but sensitive to the steric effect of the alkoxyl group.[7] This was the only one bimolecular IVb–VIb bond cleavage reaction involving this mechanism supported by kinetic evidences. The mechanism, however, was suspected and a nucleophilic attack of the oxygen atom (IV) has been suggested since the rate of the reaction was clearly accelerated in a more polar solvent and a negative ρ value (-1.44) was observed by the reaction of arylthiosilanes (Eq. 3).[8] Thus, the four-center mechanism



$$Me_3SiOR + R'S(O)Cl \rightleftarrows \underset{\text{III}}{\begin{bmatrix} O \\ \| \\ R'\text{-}S\cdots Cl \\ \vdots \quad \vdots \\ R\text{-}O\cdots SiMe_3 \end{bmatrix}} \quad \text{(slow)}$$

$$\begin{bmatrix} Cl \\ | \\ Me_3SiO^{+}\text{-}S\text{-}R' \\ | \quad | \\ R \quad O^{-} \end{bmatrix}_{\text{IV}} \xrightarrow{\text{fast}} Me_3SiCl + ROSR' \quad (3)$$

R = Me, Et, R′ = Ph; R = Aryl, R′ = Me.

had once been ruled out for the bimolecular IVb–VIb bond cleavage reaction. Our recent preliminary results of the reaction of (aryloxy)trimethylstannane with methanesulfonyl chloride, however, could only be rationalized by the four-center mechanism.[9] A detailed account of this reaction will be described.

Results and Discussion

Product Analysis. Trimethylphenoxystannane was refluxed with an equimolar amount of methanesulfonyl chloride in carbon tetrachloride. The reaction was found to give chlorotrimethylstannane and phenyl methanesulfonate in nearly quantitative yield (Eq. 4).

$$Me_3SnOPh + MeSO_2Cl \xrightarrow[CCl_4]{\text{reflux 5 h}} Me_3SnCl + MeSO_2OPh \quad (4)$$

No other product was found in the reaction solution by NMR analysis. Phenyl methanesulfonate was isolated and characterized.

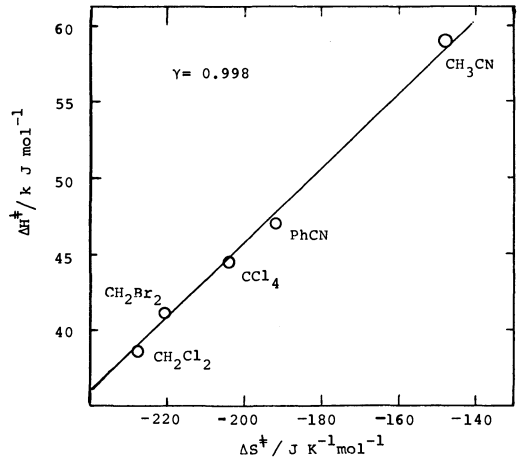

Fig. 1. Plot of $\Delta H^{\ddagger}$ *vs.* $\Delta S^{\ddagger}$ in various solvents.

Kinetics and Mechanism. The rate of the reaction of trimethylphenoxystannane (0.242 mol dm^{-3}) with methanesulfonyl chloride (0.175 mol dm^{-3}) was measured by following the decrease and rise of the ^{1}H NMR methyl signal of the starting chloride ($MeSO_2Cl$, δ 3.58 ppm) and of the sulfonate (δ 3.03 ppm). A good second order kinetic plot (γ=0.998) was obtained for more than 80% completion with tolerable reproducibility (±8%). The rates of the reactions at various temperatures were measured in five different solvents including carbon tetrachloride as a nonpolar solvent and acetonitrile as the most polar one. The results are summerized in Table 1.

The solvent effect shown in Table 1 is quite smaller than that observed for the nucleophilic reaction of arylthiostannane with haloalkane[1] and abnormal. No dependency of the rates on the solvent polarities was observed although it was slightly accelerated in polar solvents except for that in carbon tetrachloride. The result may suggest different mechanism for the reaction in carbon tetrachloride from that in polar solvents.

Table 2. Rate constants for the reactions of $Me_3SnOC_6H_4X$-*p* (0.242 mol dm^{-3}) with $MeSO_2Cl$ (0.175 mol dm^{-3})

Solvent	Temp/°C	Substituent X	k_2/dm^3 mol^{-1} s^{-1}
CCl_4	130	OCH_3	$5.37\pm0.51\times10^{-4}$

CH_3CN	100	NO_2	$5.68\pm0.52\times10^{-3}$

The hypothesis, however, conflicts with the isokinetic relationship. Plots of the activation parameters observed in all the solvents examined, gave a clear straight line as shown in Fig. 1, which strongly rules out the possibility of the different mechanism in polar and nonpolar solvents.

Substituent effects of the aryloxyl groups were examined in these solvents in order to obtain more evidence about the reaction mechanism. The reactions were carried out at 130 °C except for the reactions in acetonitrile which were conducted at 100 °C since some reactions in this solvent were too fast to be measured at the higher temperatures. The results are given in Table 2 and Hammett plots are shown in Figs. 2—5.

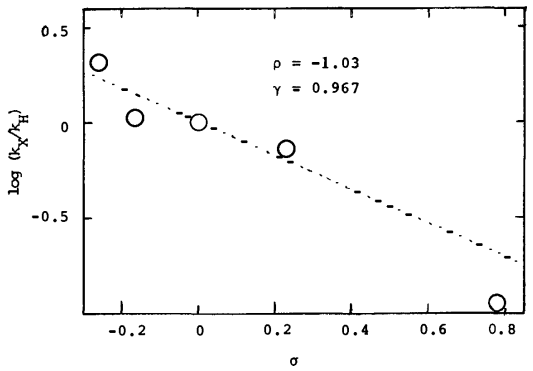

Fig. 2. Hammett plot of the rates in CCl_4 at 130 °C.

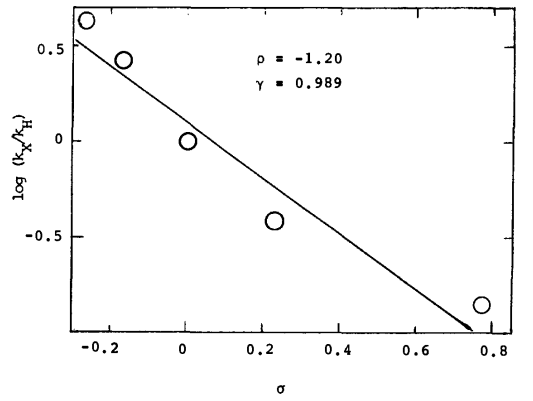

Fig. 3. Hammett plot of the rates in CH_2Cl_2 at 130 °C.

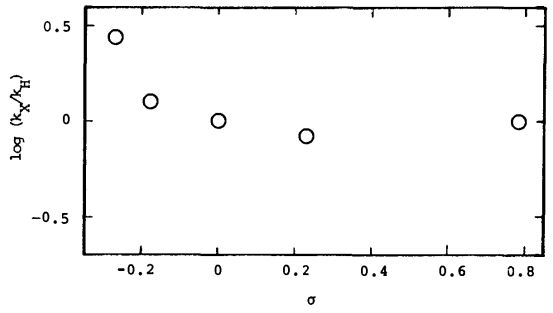

Fig. 4. Hammett plot of the rates in C_6H_5CN at 130 °C.

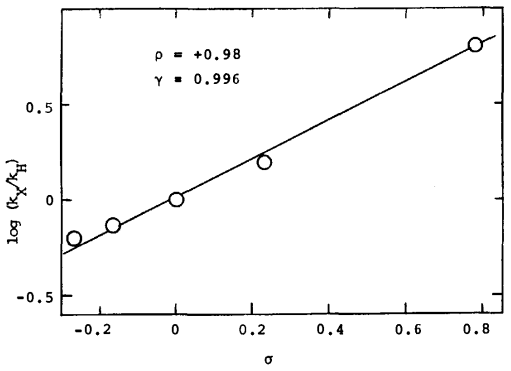

Fig. 5. Hammett plot of the rates in CH_3CN at 100 °C.

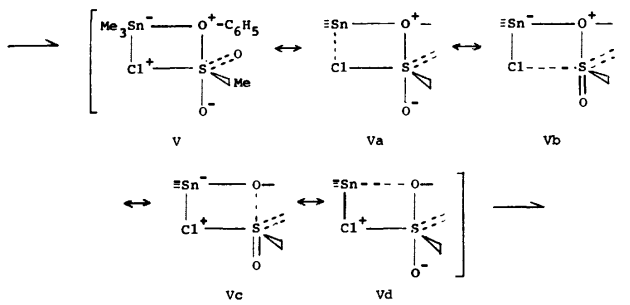
As shown in Figs. 2—5, the substituent effects are markedly dependent on the solvent used. Negative ρ values were observed for the reactions in carbon tetrachloride and dichloromethane though the magnitudes are somewhat smaller than most of that of the IVb-VIb bond cleavage reactions involving nucleophilic attacks of the VIb atom.[1-3] On the contrary, almost no substituent effect and a small positive ρ value were observed in benzonitrile and in acetonitrile, respectively.

The negative ρ values observed in carbon tetrachloride and in dichloromethane may postulate an ionic process for the reaction *i.e.*, a nucleophilic attack of the oxygen atom on the sulfonyl sulfur. The mechanism, however, is inconsistent with the substituent effects observed in benzonitrile and in acetonitrile and also conflicts with the small and obscure solvent effect. If such ionic process was operative even in the nonpolar solvent, it should be facilitated more in the polar solvents. The ρ values observed in the polar solvents have to appear clearly negative and more enhanced solvent effect would be expected as were observed for the analogous reactions.[1,3,8] The ρ values presently observed in the polar solvents together with the solvent effect are inconsistent with these considerations. Furthermore, the positive ρ value observed in acetonitrile could not be explained by postulation of a five-coordination process in the solvent. Different mechanisms in individual solvents are hardly acceptable for the reaction in view of the isokinetic relationship as discussed above.

Large negative entropy of activations were observed for the present reaction in all the solvents as shown in Table 1. These paramters would be an evidence in support of a four-centered mechanism although they could not be a definite evidence. Namely, large negative entropy of activation values were observed for the nucleophilic[1,8] and five-coordination[4] reactions involving cleavages of IVb-VIb bonds, regardless of their mechanisms. Most of the values presently observed, however, are substantially more negative than those observed previously. Consequently, the activation parameters could be considered to be an evidence suggesting a four-center process for the reaction and this is the only remaining possible mechanism.

It is difficult, however, to rationalize the solvent and the substituent effects by a fully concerted nonionic four-center transition state like III. An alternative four-center transition state is a charge separated one, similar to the associative mechanism which has been suggested for the unimolecular rearrangement of β-keto silanes.[10] In the rearrangement of β-keto silanes, little[11] or noticeable solvent effect was observed[10] although a wide variety of solvents has not yet been examined for the rearrangement. Moreover, small substituent effects were also observed for the rearrangements.[11,12] These observations quite resemble to those of the present study although the effect of the solvent on the substituent effect has not been reported yet for the rearrangement. As an analogy, a charge separated associative four-center transition state (V) would be the most suitable process for the present reaction.

Some modifications of the transition state, as shown in Va—d, may profit to account for the present observa-



V Va Vb

Vc Vd

tions. In the nonpolar solvents, the transition state is characterized by the O–S bond forming. The nucleophilic character of the oxygen atom, as depicted in Va as an extreme, would account for the negative substituent effect. Another way to rationalize the negative ρ value in nonpolar solvent is considering the Cl–S bond cleavage at the transition state (Vb). On the other hand, the positive substituent effect observed in acetonitrile may due to the Sn–Cl bond formation (Vc) or to the Sn–O bond fission (Vd) at the transition state. The reaction in benzonitrile may involve nearly ideal four-center transition state, V. All these transition states involve charge separations despite of the small deviations in their characters dependent on the solvents used. Thus, the small but noticeable solvent effect would be expected as was observed except for that in carbon tetrachloride. The small rate enhancement in carbon tetrachloride than in dibromo- and dichloro-methanes is difficult to explain, however, a similar slight rate enhancement in carbon tetrachloride was also observed for the reaction of ketenimine with thioketone.[13] The solvent may be too poor to solvate and to stabilize the reactants and may allow them to cohere and facilitate the bimolecular reactions in some extents.

Experimental

Materials. Preparations of (aryloxy)trimethylstannanes were carried out according to the literature.[2] Solvents for the kinetic runs were dried and distilled before use.

Product Analysis. Trimethylphenoxystannane (0.92 g) was refluxed for 5 h with methanesulfonyl chloride (0.40 g) in carbon tetrachloride (20 ml). The reaction solution was subjected to NMR analysis before work up. Only chlorotrimethylstannane and phenyl methanesulfonate were detected in the solution. The mixture was washed with water and extracted with chloroform. Phenyl methanesulfonate was isolated from the extract by evaporation of the solvent followed by recrystallization from hexane–chloroform (0.55 g, 91%) and identified by comparing with an authentic sample.

Kinetics. A typical procedure is described. (Aryloxy)-trimethylstannane (0.242 mol dm^{-3}) and methanesulfonyl chloride (0.175 mol dm^{-3}) were dissolved in a solvent using 5 ml volumetric flask. The sotution was devided into 10 portions and sealed in glass tubes of *ca.* 0.7 ml volume. The tubes were heated in a constant temperature bath (130 °C) and samples were taken out at time intervals. Each solutions were subjected to ^{1}H NMR analysis with 7—8 repeated recording of methyl signals of methanesulfonyl chloride (δ 3.58 ppm) and of the sulfonate (δ 3.03 ppm). The second order rate constant, k_2 was obtained by least square calculation of the averaged peak intensities of the methyl signals at time t.

Crystal Structure and Related Properties of Phenothiazine Cation Radical-Hexachloroantimonate. Monoclinic(I) Form

Tokiko Uchida,* Masanori Ito, and Kozo Kozawa
Department of Industrial Chemistry, Faculty of Science and Technology, Science University of Tokyo, Noda, Chiba 278

(Received March 15, 1982)

Three forms of crystals were obtained from mixed solutions of phenothiazine and $SbCl_5$; the crystal structure of the monoclinic(I) modification was determined using 2827 reflections at room temperature. Crystal data: $(C_{12}H_9NS)^{+\cdot}SbCl_6^-$, $F.W.=533.7$, monoclinic, $a=16.253(3)$, $b=14.334(1)$, $c=15.786(3)$ Å, $\beta=104.07(1)°$, space group C2/c, $D_m=2.00$, $D_x=1.99$ g cm^{-3}, $Z=8$, $\mu=25.73$ cm^{-1} (Mo $K\alpha$). The structure was solved by the heavy-atom method and refined by block-diagonal least-squares method to $R=0.072$. The crystal consists of phenothiazine cation radicals($PT^{+\cdot}$) and hexachloroantimonate anions($SbCl_6^-$), and every ion exists as a monomer in the crystal. Each $SbCl_6^-$ forms a distorted octahedron. The two C–S distances of $PT^{+\cdot}$ are 1.705 and 1.711 Å, and the C–S–C angle is 103.9°. The dihedral angle between the two outer phenyl rings of $PT^{+\cdot}$ is 176.5°. From the ESR measurements of a single crystal, three principal g-values were determined: $g_1=2.003$, $g_2=2.007$ and $g_3=2.008$. The direction of g_1 is normal to the molecular plane of $PT^{+\cdot}$. These facts suggest some π-delocalization in the central ring of $PT^{+\cdot}$. Absorption spectra polarized parallel to the molecular plane of $PT^{+\cdot}$ are very similar to the polycrystalline reflection spectra of $PT^{+\cdot}$ salts obtained by other authors, and there are no intense bands in the spectra polarized perpendicular to $PT^{+\cdot}$ molecular plane over the wave number range 10 to 27×10^3 cm^{-1}.

Phenothiazine (PT) is a very characteristic electron donor possessing several stepwise oxidation states[1–3] and a variety of folding angles of the molecular plane.[4] On the other hand, antimony chlorides have been known as electron acceptors or Lewis acids strong enough to provide cation radicals of some aromatic molecules easily.[5] Many works have been published about the solid state behavior of electron donor-acceptor complexes[5–8] or graphite intercalation compounds[9] including antimony chlorides. However, few of them discussed their results on the basis of the strictly determined crystal structures, since the samples were usually obtained in very fine polycrystals. Magnetic and optical properties of polycrystalline "PT–$SbCl_5$" were described by Sato *et al.* more than ten years ago.[7,8] Recently, we have been able to distinguish at least three kinds of crystals in the precipitates of a mixture of PT and $SbCl_5$. They are different from each other in both color and crystal system.

In this paper, we wish to report the crystal structure, paramagnetic resonance and electronic absorption spectra for a brown monoclinic single crystal of phenothiazine cation radical-hexachloroantimonate.

Experimental

Preparation of Single Crystals. Both PT and $SbCl_5$ dissolved in 1,2-dichloroethane (concentration of about 3.5×10^{-3} mol dm^{-3}) were mixed in approximately 1 : 1 mol ratio in a dry box at room temperature. By slow evaporation of solvent in a dry atmosphere, three types of crystals were distinguishable in the precipitates: monoclinic(I), monoclinic(II), and triclinic modifications. The monoclinic(I) crystals are brown rectangular platelets with (010) plane developed and [20$\bar{1}$] direction elongated. The monoclinic(II) and triclinic crystals were hexagonal prisms and black parallelepiped columns, respectively.[10] The crystals were fairly stable in the air for a month, if they were completely dried up in a nitrogen atmosphere.

This report concerns the monoclinic(I) modification that consists of the ionic salt of phenothiazine cation radical($PT^{+\cdot}$) and hexachloroantimonate anion($SbCl_6^-$).[11] Triclinic crystals, which will be reported elsewhere, are (3,7-dichlorophenothiazine)$^{+\cdot}$ $SbCl_6^-$, but the components of monoclinic(II) crystals still remain unknown.

X-Ray Data Collection. After determining preliminary cell constants and space group from Weissenberg photographs, a crystal of $0.3\times0.2\times0.08$ mm^3 was mounted on a Hilger & Watts diffractometer with Mo $K\alpha$ radiation at room temperature. From the 12 setting angles, θ's of which were greater than 10.7°, the lattice constants were calculated by a least-squares method. Intensity data were collected by the θ-2θ scan technique at every 0.01° of θ step up to $2\theta\leq55°$. The scan width of θ was 0.8° for all the reflections. Counting time was 1 s per step for peak measurements, and each background was measured for 10 s at the beginning and the end of the scan range. Three standard reflections were monitored every 50 measurements to check both crystal and apparatus. No systematic changes in intensities of the standard reflections were observed throughout the data collection. Lorentz and polarization effects were corrected, but no absorption correction was made. Of the 4345 independent reflections measured, 2827 with $F_o\geq3\sigma(F)$ were used in the subsequent analysis. Density was observed by the flotation method. Crystal data are shown in Table 1. The systematic absences indicated the space group to be either Cc or C2/c, but the further study showed it to be C2/c.

Electronic Absorption Spectra. The solution spectra and

Table 1. Crystal data

polycrystalline reflection spectra were recorded on a Hitachi spectrophotometer, Model 323, at room temperature. Solution spectra were measured with 1,2-dichloroethane as solvent. Polarized absorption spectra with single crystals were observed with Olympus MSP-A-IV microspectrophotometer over the wave number range 10 to 27×10^3 cm^{-1} at room temperature.

Electron Spin Resonance. Measurements of electron spin resonance(ESR) were carried out with a JES-FE3X spectrometer operating at 9.4 GHz microwave and 100 KHz magnetic field modulation. The polycrystalline sample was measured both at room temperature and at 77 K. Angular dependence of resonance field about a single crystal was observed at room temperature. New orthogonal coordinates. a′, b′, and c′, were defined to rotate a specimen: a′ was parallel to the developing [20$\bar{1}$] axis, b′ agreed with the crystal b axis, and the c′ was perpendicular to the a′b′ plane. The resonance field was recorded at every 15° rotation around the a′, b′, and c′ axes. The *g*-values were calculated from spectra in which the resonance fields of both specimen and Mn^{2+}/MgO (a_{Mn}= 8.69 mT) were recorded simultaneously. The spin concentrations were not measured.

Solution and Refinement of the Structure

The structure was solved by the heavy-atom method. From the Patterson synthesis, two Sb atoms were found to occupy two different special equivalent positions (b and e of Wyckoff positions), one on the center of symmetry and the other on the two-fold rotation axis. A Fourier map, computed using the phases from two Sb atoms, revealed the positions of all the non-hydrogen atoms. After five cycles of the isotropic block-diagonal least-squares refinements, the discrepancy index *R* converged at 0.112. Then, five additional cycles of the anisotropic refinement gave the *R* to be 0.075. At this stage of the refinements, the difference Fourier map clearly revealed all the hydrogen atoms. The final cycle was calculated including hydrogen atom parameters with a fixed isotropic thermal parameters, *B*= 4.0 Å^2, and converged to *R*=0.072. The quantity minimized was $\sum w(|F_o|-k|F_c|)^2$, where the weighting scheme $w=(F_{max}/F_o)^2$ for $F_o>F_{max}$, and $w=1$ for $F_o\leq F_{max}$. F_{max}=32.5 after scaling F_o to F_c.[12] In the final cycle, the parameter shifts almost converged to zero except for those of hydrogen atoms which were less than the corresponding standard deviations. A final difference Fourier map showed no extra peaks. The neutral atomic scattering factors and anomalous dispersion factors of Sb were taken from the "International Tables for X-Ray Crystallography."[13] All the computations were carried out at the Computer Centre of the University of Tokyo with the UNICS program system.[14]

Results and Discussion

Crystal Structure. The atomic positional parameters with their estimated standard deviations are

Table 2. The final positional parameters ($\times10^4$; for H, $\times10^3$) and equivalent isotropic thermal parameters

Estimated standard deviations are given in parentheses. The equivalent isotropic thermal paramers for non-hydrogen atoms are calculated using the expression: $B_{eq}=\frac{4}{3}\Sigma_i\Sigma_j a_i a_j \beta_{ij}$, where the a_i's are the unit cell edges in direct space. The isotropic thermal parameter of hydrogen atoms is fixed, *B*=4 0 Å^2.

presented in Table 2. The atomic numbering is given in Fig. 1.

There are two crystallographically different halves of ($SbCl_6^-$)'s and a $PT^{+\cdot}$ in an asymmetrical unit. Each $SbCl_6^-$ anion forms a slightly distorted octahedron. The bond lengths and angles, given in Table 3, are consistent with those found in other $SbCl_6^-$.[15] Of the six independent Sb–Cl distances, Sb(1)–Cl(3) and Sb(2)–Cl(5) are slightly longer than the other four.

In Table 4, the bond distances and angles of $PT^{+\cdot}$ are presented. The C–S bond distances are significantly shorter than those of neutral PT (1.762 Å for orthorhombic form[16] and 1.770 Å for monoclinic form[17]). The sum of the covalent radii is 1.81 Å for C–S single bond, and is 1.61 Å for C–S double bond.[18] The observed C–S bond length of 1.71(2) Å is just an average of these values. It suggests the π-delocalization is spread over the whole molecule of $PT^{+\cdot}$ including the central ring. Similar C–S distances, around 1.71 Å, were found in many compounds,[19] in which the shortening of the C–S bonds and the planarity of the systems characterized a π-delocalization including S atoms.

Much attention has been paid to the planarity of $PT^{+\cdot}$, namely, the dihedral angle between the external two benzene rings of PT molecule (these two planes are denoted as Bz1 and Bz2 in this paper. See Table 5). For substituted phenothiazines, this angle ranges from 134.4° to 173.6°, depending on the kinds and the positions of the substituents at the external benzene rings.[4] Andreetti *et al.* discussed the dihedral angle (so-called butterfly angle) of PT derivatives related to the degree of delocalization in the central ring, which was estimated from the shortening of the C–S bond lengths.[4] Table 5 lists the dihedral angles and related value of PT moieties in complex compounds[20–24] as well as the two modifications of PT itself.[16,17] The top two compounds in Table 5 are $PT^{+\cdot}$ ion radical salts and the next four compounds are charge-transfer (CT) complexes of weak π-π type. Every dihedral angle between Bz1 and Bz2 of PT moiety is close to 180° except for PT–DNB,[24] and the flattened PT moiety

Table 5. Comparison of some parameters of PT species

Compound	Dihedral angle θ/° [a]				Bond distance l/Å		Bond angle ϕ/°		Ref.
	Bz1-Bz2	P1-P2	Bz1-P1	Bz2-P2	C–S (average)	CN (average)	C–S–C	C–N–C

a) Least squares planes are defined as follows. A maximum deviation of constituent atom of each plane is presented in parenthesis. Bz1: C(1), C(2), C(3), C(4), C(5), and C(6) (0.009 Å); Bz2: C(7), C(8), C(9) C(10), C(11), and C(12) (0.01 Å); P1: S, N, C(1) and C(6) (0.009 Å); P2: S, N, C(7) and C(12) (0.001 Å). b) Folding angle of two halves being approximated planar. c) Fundamental structure in disordered crystal. d) Dihedral angle between two planar halves folded along the N–S axis. Nomenclature: tfd=(z)-1,2-bis(trifluoromethyl)-1,2-ethylenedithiolate, PMDA=1,2:4,5-benzenetetracarboxylic dianhydride(pyromellitic dianhydride), TCNQ=7,7,8,8-tetracyanoquinodimethan, TNB=1,3,5-trinitrobenzene, DNBA=3,5-dinitrobenzoic acid.

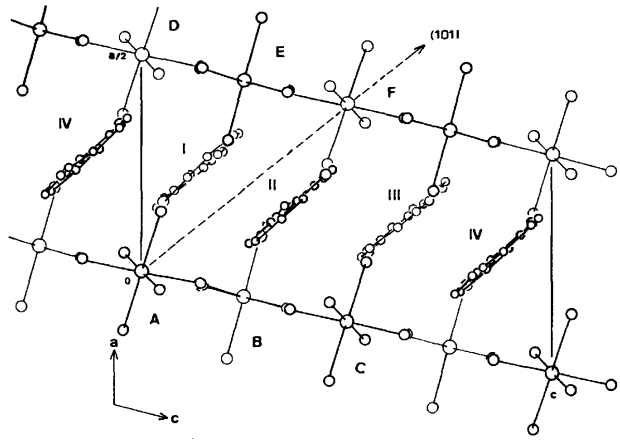

Fig. 2. The packing arrangements in the crystal lattice projected along the b axis. The numbering from I to IV correspond to $PT^{+\cdot}$'s, and those from A to F correspond to $(SbCl_6^-)$'s. The same notations are employed in Figs. 3 and 4. The broken line indicates the direction of [101] together with the intersection of (010) and $(10\bar{1})$ planes.

Symmetry code

$PT^{+\cdot}$: I x, y, z
II $1/2-x, 1/2+y, 1/2-z$
III $x, -y, 1/2+z$
IV $1/2-x, 1/2-y, 1-z$
IV' $1/2-x, 1/2-y, -z$

$Sb(1)Cl_6^-$:
B x, y, z; $-x, y, 1/2-z$
E $1/2-x, 1/2+y, 1/2+z$; $1/2+x, 1/2+y, z$

$Sb(2)Cl_6^-$:
A x, y, z; $-x, 1/2-y, -z$
C $x, -y, 1/2+z$; $-x, y, 1/2-z$
D $1/2+x, 1/2+y, z$; $1/2-x, 1/2-y, -z$
F $1/2+x, 1/2-y, 1/2+z$; $1/2-x, -1/2+y, 1/2-z$

does not always accompany the shortened C–S bond, namely the delocalization of the central ring.

Anthonj *et al.*[21] cited some disorder of PT in the PT–PMDA CT complex: approximately one in fifty molecules has the positions of the S and N atoms reversed. Their basis for disorder was an asymmetrical peak around the N atom, which they interpreted as a twin peak of the H(N) and the disordered S atoms. In the case of the present crystal, however, all the S, N, and H(N) atom peaks were symmetric within the errors. So, the positional disorder was not considered for the $PT^{+\cdot}$ moiety in $PT^{+\cdot}SbCl_6^-$.

Figures 2 and 3 give the packing arrangement in the crystal projected along the b axis and onto the $(10\bar{1})$ plane, respectively. Figure 2 shows that all the Sb atoms exist on (200) planes, and that the $PT^{+\cdot}$ cation radicals put their molecular planes almost parallel to $(10\bar{1})$. However, the four $PT^{+\cdot}$ cation radicals, numbered from I to IV in Fig. 2, do not have any overlap, as illustrated in Fig. 3. In other words, a strong CT interaction is not expected between the $PT^{+\cdot}$ cation radicals in this crystal.

Figure 4 illustrates the relation between the nearest neighbor species viewed down the [101] direction, which is horizontal in Fig. 3. In the figure, the shortest distances between neighboring species are also exhibited.

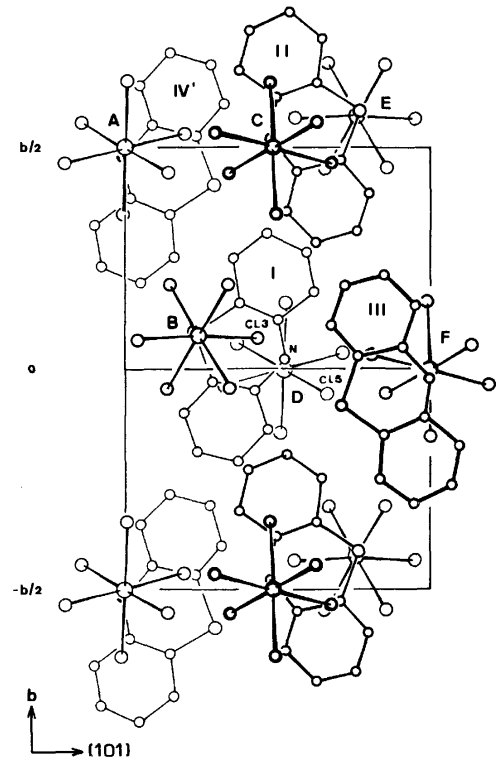

Fig. 3. The packing arrangements in the crystal lattice projected onto the $(10\bar{1})$ plane.

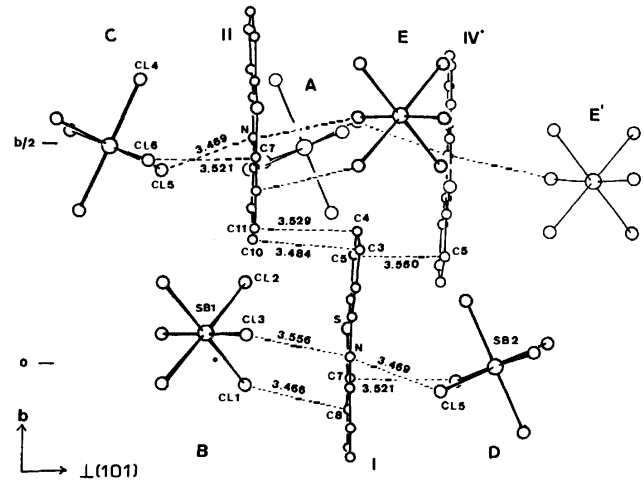

Fig. 4. Perspective relation between the cations and the anions viewed down the [101] direction. Intermolecular atomic distances (Å), less than 3.6 Å, are shown.

It is interesting that the slightly elongated two Sb–Cl bonds, namely Sb(1)–Cl(3) and Sb(2)–Cl(5), are pointed at the N atom of $PT^{+\cdot}$ from both sides of the cation, though the N···Cl intermolecular distances do not suggest considerable shortened contacts of them. Nevertheless the structure implies an appropriate charge deviation in each ion.

Polarized Absorption Spectra. Figure 5(a) shows polarized absorption spectra for the cases parallel to and perpendicular to [101] on the (010) face of a single

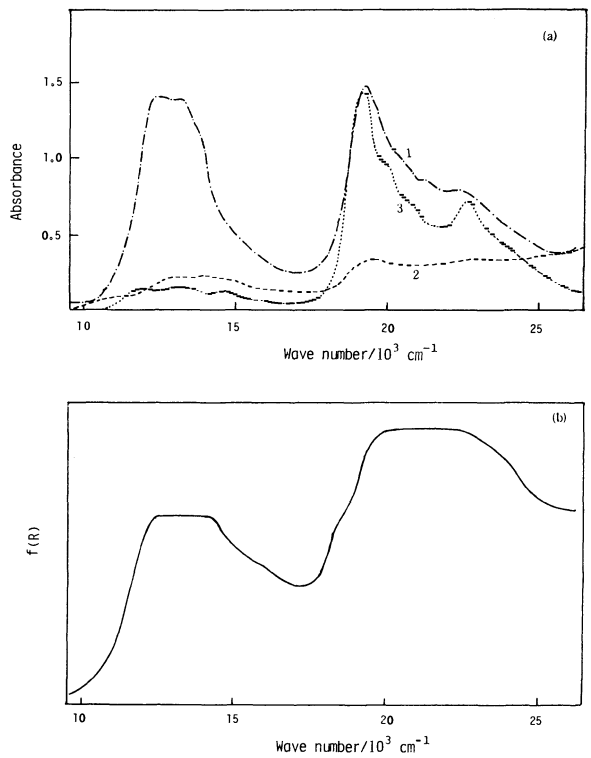

Fig. 5. (a) Polarized absorption spectrum of a single crystal, 1 (—·—·—): //[101], 2(------): ⊥[101], and 3 (·····): solution spectrum in 1,2-dichloroethane. (b) Polycrystalline reflection spectrum.

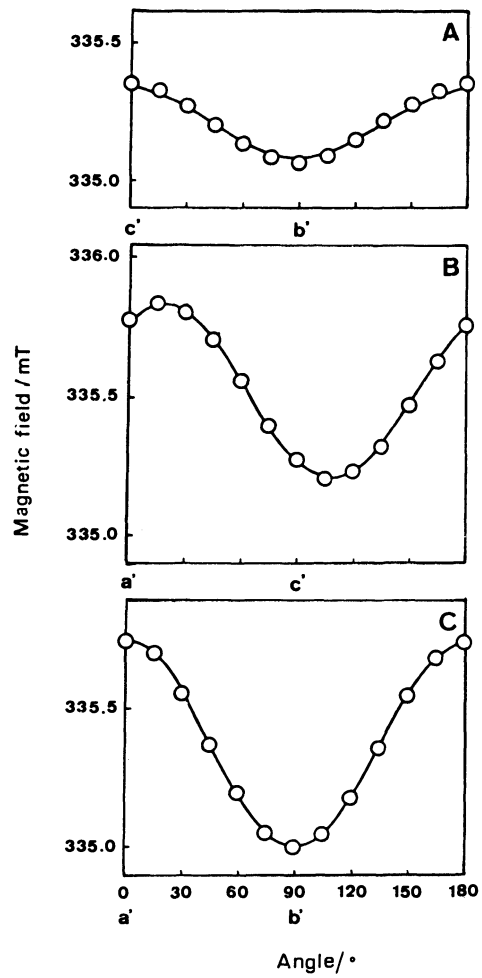

Fig. 6. Angular dependence of the resonance field for rotation about the A: a′ axis, B: b′(=b) axis, and C: c′ axis, where the orthogonal axes a′, b′, and c′ are defined in the text. Circles are experimental, and solid lines are calculated ones.

crystal of $PT^{+\cdot}SbCl_6^-$, as well as its solution spectrum. As mentioned in the previous section and shown in Fig. 3, [101] direction is very close to the short axis in the $PT^{+\cdot}$ molecular plane. The polycrystalline reflection spectrum of monoclinic(I) crystals is shown in Fig. 5(b). They lack the absorption band at 10×10^3 cm^{-1} (1000 nm) that was found in "$PT^+(SbCl_5)^-$" polycrystalline spectra and assigned as the CT band between $PT^{+\cdot}$ radicals by Sato *et al.*[8] Since the monoclinic(I) crystal is a simple salt, as mentioned in the previous section, it is reasonable that the CT band between cation radicals does not appear in the absorption spectra. However, crystals of other forms still have the possibility of being "$PT^+(SbCl_5)^-$" described by Sato *et al.*[8]

Curve 1 in Fig. 5(a), //[101] spectrum, is essentially similar to the polycrystalline reflection spectra of monoclinic(I) (Fig. 5(b)), $PT^{+\cdot}Br^-$,[3,25] $PT^{+\cdot}HSO_4^-\cdot H_2O$ and $PT^{+\cdot}$ picrate;[3] it consists of two intense bands around $(12—14)\times10^3$ cm^{-1} and $(19—23)\times10^3$ cm^{-1}. The latter band well agrees with the solution spectrum (Curve 3), in which the absorption maxima at 19.2 and 22.6×10^3 cm^{-1} are characteristic to $PT^{+\cdot}$.[2,3] On the other hand, the former band at $(12—14)\times10^3$ cm^{-1} is intense only in the solid state. If this band is attributed to cation-anion interaction, it should be weaker in the [101] direction than the other direction according to the structural consideration. Since Curve 2 has no intense band, the lower frequency band at $(12—14)\times10^3$ cm^{-1} is possibly assigned to the $PT^{+\cdot}$ intramolecular electronic transition, the intensity of which is enhansed in the solid state. As a result, in the range of wave numbers measured, there exist only local excitation bands of $PT^{+\cdot}$ cation radical.

Electron Spin Resonance. The ESR spectra of polycrystalline samples at room temperature showed anisotropy of *g*-factor without hyperfine structure. At 77 K, neither the line-splitting nor any large change of line-shape occurred.

The single crystal spectra consisted of a line corresponding to a unique arrangement of $PT^{+\cdot}$ radicals in the crystal lattice. Namely, all the eight $PT^{+\cdot}$ radicals in a unit cell are geometrically parallel and magnetically equivalent to each other. The line width, ΔH_{msl}, was slightly changed from 0.09 to 0.17 mT with the orientation of the crystal to the magnetic field. The observed angular dependencies of the spectra, as shown in A and C of Fig. 6, are symmetrical around the b axis, which is also the crystallographically unique axis. The calculated direction cosines of the magnetic field with respect to the a′, b′, and c′ axes are presented in Table 6, together with the three principal *g*-values. The g_1 value is close to that of free electron, and is directed normal to the molecular plane of the $PT^{+\cdot}$ within the experimental error($\pm3°$). The direction of g_2 is in accord

Table 6. Principal g values and their direction consines with respect to the a′, b′, and c′ axes

	g	Direction cosine		
		a'	b'	c'
g_1	2.003(1)	±0.96(2)	0.00(5)	∓0.29(5)
g_2	2.008(1)	0.00(5)	±1.00	0.00(5)
g_3	2.007(1)	±0.29(5)	0.00(5)	±0.96(2)

with the crystal b axis, and the g_3 approximately coincides with the [101] direction (see Fig. 3). Both g_2 and g_3 are in the molecular plane of $PT^{+\cdot}$. The anisotropic difference between the principal values of g_1 and g_2 is not so large as in the case of the unpaired electron localized at S atom.

Many authors have observed the hyperfine structures of $PT^{+\cdot}$ in solution.[26-29] Malrieu and Pullman calculated the spin density distribution in the ring system of $PT^{+\cdot}$ with a simple MO method, and estimated the same order of the spin density for both N and S atoms (0.244 and 0.217, respectively), provided the radical was assumed to be planar.[27] Chiu *et al.* obtained values similar to those of Malrieu and Pullman by the observation of hyperfine splitting from H, N, and ^{33}S atoms of $PT^{+\cdot}$ in solution.[28] Their experimentally estimated spin density distributions are 0.234 and 0.218 for N and S atoms, respectively. Since the orbital states occupied by unpaired electron of $PT^{+\cdot}$ in solid state should not be much different from that in solution, it is reasonable to conclude for the present crystal that the unpaired electron of $PT^{+\cdot}$ is delocalized in the ring system including hetero-atoms.

The authors express their hearty thanks to Professor Hiroshi Takahashi and Mr. Minoru Suzuki of Tokyo University for the ESR measurements. The authors are also indebted to Professor Haruo Kuroda and Dr. Kyuya Yakushi of Tokyo University for the use of the microspectrophotometer.

10) We confirmed the crystal systems of the three modifications with the Weissenberg photographs. We also observed microscopically three different types of crystals: brown platelets, black columns, and green hexagonal platelets. The former two crystals completely agreed with those determined by X-ray photographs as the monoclinic(I) and triclinic modifications in both color and appearance. The latter green platelet, however, has still not been identified as the monoclinic(II) crystal.
11) It is not clear what kind of reaction occurred in the mixture solution, since $SbCl_5$ is a very active reagent not only for phenothiazine but also for solvent molecules or traces of water.

The Formation of Electronically Excited Fragments by the Electron Impact of Furan and Related Five-membered Heterocycles

Ikuo TOKUE,* Masami IKARASHI, Sadachika TAKIZAWA, and Yoshio ITO
Department of Chemistry, Faculty of Science, Niigata University, Ikarashi, Niigata 950-21
(Received June 19, 1982)

In the wavelength region of 200—600 nm, photoemissions from electronically excited H, CH, C_2, and CS (only from thiophene and tetrahydrothiophene) were observed when furan, tetrahydrofuran, thiophene, and tetrahydrothiophene were excited by electron impact (0—70 eV). Hydrogen atoms ($n=4$) and CH($A^2\Delta$) radicals were produced from these five-membered heterocycles *via* single collision excitations, while CS($A^1\Pi$) radicals from thiophene and tetrahydrothiophene were partly formed in secondary processes. The appearance potentials for the hydrogen Balmer β and the CH($A^2\Delta$-$X^2\Pi$) bands from these five-membered heterocycles are determined, and the dissociation processes forming H($n=4$) and CH(A) are discussed.

The excited electronic states of furan, tetrahydrofuran, thiophene, and tetrahydrothiophene have been investigated by means of their ultraviolet absorption spectra for more than sixty years. Recently, the excited electronic states of these heterocycles have also been studied by means of ultraviolet photoelectron spectroscopy.[1,2] Several decay processes from the electronically excited states of these five-membered heterocycles have been investigated by means of photolysis,[3] flash photolysis,[4] and electron-impact mass spectroscopy.[5-7] However, we have only a little information about electronically excited fragments from five-membered heterocycles and their fragmentation mechanisms. There seem to be only a few papers[8,9] on this subject.

In a previous paper, we have reported on the emission spectra of the fragment species from pyrrole and pyrrolidine.[10] The appearance potentials for the hydrogen Balmer β (H_β), CH($A^2\Delta$-$X^2\Pi$), and NH($A^3\Pi$-$X^3\Sigma$) bands from pyrrole and pyrrolidine are 18—23 eV about twice as large as the first ionization potentials of the parent heterocycles. In these cases, it appears that an ionic fragment is a by-product of the formation of neutral fragments.[10]

This paper will present the emission spectra of the fragments produced by the electron-impact dissociation of furan, tetrahydrofuran, thiophene, and tetrahydrothiophene. Further, the appearance potentials for the H_β and CH(A-X) emissions from these heterocycles are determined and possible dissociation processes forming H($n=4$) and CH(A) are discussed.

Experimental

The apparatus consists of a collision chamber, a photon-detection system, and a control system. The collision chamber and the photon-detection system have been described in detail previously.[9] The sample pressures in the collision chamber during the emission measurements, as measured by means of an ionization gauge, were 5—40 mPa. An HTV R585 photomultiplier and an HTV C1230 photon-counter were used with the spectral resolution of 0.6 nm (FWHM). Electron-beam currents of 10 μA near the threshold and 40—50 μA at higher energies were used for the measurement of the excitation function.

A schematic electronic block diagram of the automatic control system used for the measurement of the excitation function is shown in Fig. 1. An AD converter (ICL 7109) is interfaced to a microcomputer (MZ-80K). After a preset

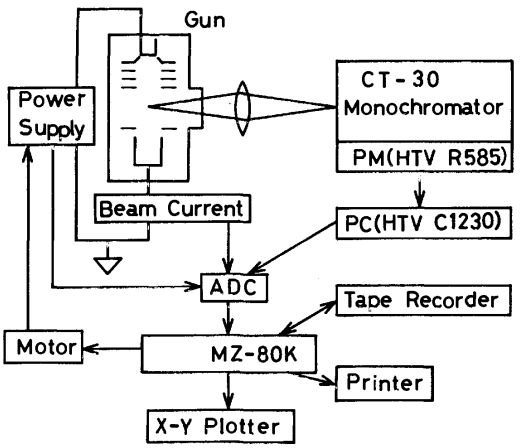

Fig. 1. The schematic electronic block diagram for the automatic control system.

counting time, the current electron-accelerating potential, the electron-beam current, and the photo-electron current are measured. These measurements are repeated several times at the same electron-accelerating potential. At the end of a counting cycle, the microcomputer sends a signal to a motor to advance the voltage regulator to the next voltage, thus setting a new counting cycle. After the experiment, the three values are recorded with a cassette tape recorder. These data, as well as the calculated excitation function, can be printed with a dot printer, while this excitation function can be plotted with as MIPLOT WX4671.

The energy scale for the impinging electron was calibrated on the basis of both the peak of the excitation function for the (0, 0) band of the N_2($C^3\Pi$-$B^3\Pi$) emission reported by Finn *et al.*[11] and the appearance potential for the (0,0) band of the N_2^+($B^2\Sigma$-$X^2\Sigma$) emission reported by Borst and Zipf.[12] Nitrogen was mixed with the sample vapor, and their excitation functions were measured alternately.

The furan, thiophene, and tetrahydrothiophene (Nakarai guaranteed grade), and tetrahydrofuran (Wako guaranteed grade) were dried over sodium for several days. All the samples were subjected to several freeze-pump-thaw cycles just before use.

Results

Emission Spectra and Emission Intensities of Excited Fragment. Figure 2 shows the emission spectra produced by the electron impact of furan and tetrahydrofuran at an electron energy of 70 eV. Many

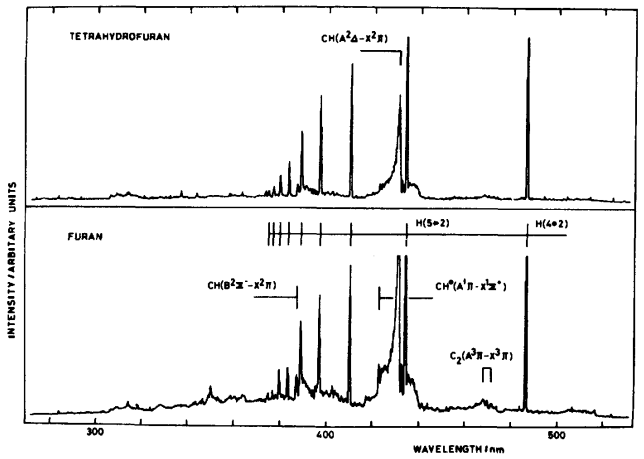

Fig. 2. Emission spectra by electron impact (70 eV, 0.5 mA) of tetrahydrofuran at 26 mPa and furan at 27 mPa.

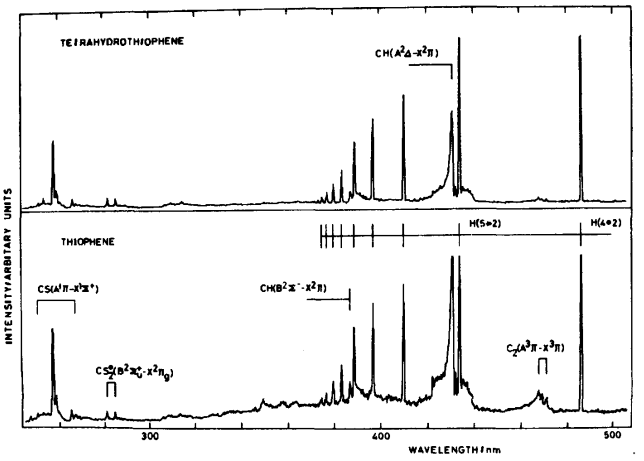

Fig. 3. Emission spectra by electron impact (70 eV, 0.5 mA) of tetrahydrothiophene at 27 mPa and thiophene at 27 mPa.

sharp bands were assigned to the hydrogen Balmer series (n=4—10→2), the CH($A^2\Delta$-$X^2\Pi$) band around 431 nm, the CH($B^2\Sigma$-$X^2\Pi$) band around 388 nm, the CH^+($A^1\Pi$-$X^1\Sigma$) band around 423 nm, and the C_2($A^3\Pi$-$X^3\Pi$) band around 470 nm. Further, weak emissions from CO and CO^+ were observed in the region of 240—470 nm. Figure 3 shows the emission spectra obtained from thiophene and tetrahydrothiophene. Besides the emission spectra for the hydrogen Balmer series and the CH(A-X) and CH(B-X) bands, the CS($A^1\Pi$-$X^1\Sigma$) band around 258 nm and the CS_2^+($B^2\Sigma$-$X^2\Pi$) band around 282 nm were observed.

The photoemission intensities of the H_β and CH(A-X) bands from furan, tetrahydrofuran, thiophene, and tetrahydrothiophene were proportional to the electron-beam current up to 0.5 mA and to the sample pressure up to 35 mPa in the collision chamber.

The emissions of the CS(A-X) band from thiophene and tetrahydrothiophene were weak. The intensities of the CS(A-X) band measured at a sample pressure of 30 mPa were found to deviate significantly from the proportional increase with the electron-beam current. If we assume that the emission intensity of the CS(A-X)

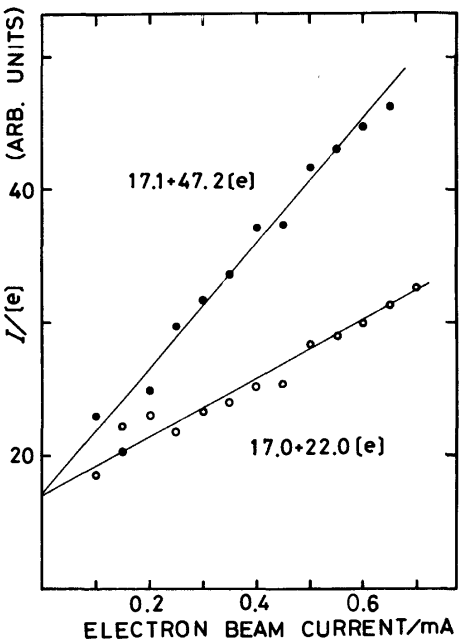

Fig. 4. Dependence of the photoemission intensity divided by the electron-beam current, $[I]/[e]$, on the electronbeam current. CS(A-X) emissionf rom thiophene (○), and from tetrahydrothiophene (●).

band, $[I]$, includes the quadratic term on the electron-beam current, $[e]$, the emission intensity divided by the electron-beam current, $[I]/[e]$, can be represented by the following formula,[13] where A and B are adjustable constants:

$$[I]/[e] = A + B[e]. \quad (1)$$

Figure 4 shows the plot of $[I]/[e]$ as a function of $[e]$ for the CS(A-X) bands from thiophene and tetrahydro-

thiophene. The reasonable fit to a straight line in each plot indicates that the emission intensities of the CS(A-X) band fairly well include the quadratic term on the electron-beam current. On the other hand, the emission intensities of the CS(A-X) band from thiophene and tetrahydrothiophene were found to be proportional to the sample pressure up to 35 mPa. This is probably because the number density of target molecules in the column of the electron beam is about two orders of magnitude lower than the electron density.

Appearance Potentials for the H_β and CH(A-X) Bands. Figure 5 shows the excitation functions for the H_β and CH(A-X) emissions from thiophene from their thresholds to 35 eV. The appearance potentials thus obtained for H(n=4) are listed in the third column of Table 1, while those for CH(A) are listed in the third column of Table 2.

Discussion

Photoemissions from Electronically Excited Fragments. The intensities of the hydrogen Balmer line and the CH(A-X) band from furan, tetrahydrofuran, thiophene, and tetrahydrothiophene were proportional to the electron-beam current and the sample pressure in the collision chamber. The excitation functions for the H_β and CH(A-X) band from these heterocycles were measured at sample pressures of 5—11 mPa; the appearance potentials were found to be independent of the sample pressure. Therefore, the H atoms and CH radicals from these heterocycles seem to be formed by fragmentation *via* a single-collision excitation. The two-step collision with another electron seems to be negligible.

On the other hand, the photoemission intensities of the CS(A-X) band from thiophene and tetrahydrothiophene fairly well include the quadratic term on the electron-beam current. Unknown secondary processes seem to participate in the formation of CS(A) to an appreciable extent; that is, the formation of CS(A) by way of a two-step excitation *via* an unidentified intermediate species is comparable to that by single-collision excitation at a beam current of more than 0.2 mA. The formation rates of CS(A) *via* single-collision excitations from thiophene and tetrahydrothiophene are of the same order of magnitude, for the A values for thiophene and tetrahydrothiophene, which were measured under similar experimental conditions, are nearly equal (see Fig. 4). The relative contributions of the two-electron excitation process to the single-electron excitation process, B/A, for thiophene and tetrahydrothiophene are estimated to be 1.3 and 2.8 respectively from the slope of $[I]/[e]$ and its extrapolation with beam-current to zero. That is, secondary processes in the formation of CS(A) from tetrahydrothiophene are twice

a) Estimated from the heat of formation. b) Estimated from the appearance potential of the by-product ion.[5]

as abundant as those from thiophene.

Ogawa *et al.*[13,19] have reported several similar results and have classified the excited species the emission intensities of which show non-linear relationships with the electron-beam current into the following two groups: (a) Fragments which have at least two heavy atoms and which are produced through the scission of two skeletal bonds, and (b) fragments with a new chemical bond. The CS(A) from thiophene and tetrahydrothiophene can be classified in Group (a). This result is consistent with the fact that the CS_2^+(B-X) band from thiophene and tetrahydrothiophene appears upon electron impact. The formation of the CS_2^+ ion can be classified in Group (b).

Formation of H(n=4). The onsets for the H_β emissions from furan, tetrahydrofuran, thiophene, and tetrahydrothiophene are found at 20.5±0.8, 18.7±0.8, 18.9±0.8, and 19.7±0.8 eV respectively. The dissociation processes which are expected to play an important role in the formation of H(n=4) and CH(A) near their thresholds are shown in the first column of Tables 1 and 2. The threshold energies of the dissociation processes listed in the second column of Table 1 are calculated by using the excitation energy of H(n=4), 12.75 eV,[20] and the bond dissociation energy of the C–H bond, 4.86 eV from benzene[14] or 4.31 eV from saturated hydrocarbons.[15] The excess energy of 1.3—2.9 eV for the difference between the observed and estimated thresholds in these processes is probably dissipated as the kinetic energy of the leaving hydrogen atom. These dissociation processes for the formation of excited H atoms following neither the cleavage of skeletal bonds nor new bond formation are similar to those with benzene,[9,21] pyridine and pyrazine[69] and pyrrolidine.[10]

Derrick *et al.*[22,23] have reported the structure of the Rydberg series in the photoelectron spectra of furan and thiophene and the associated ionization potentials. They have assigned the vertical ionization potentials of 17.5, 19.0, and 19.5 eV in furan to the $7a_1$, $6a_1$, and $4b_2$ orbitals respectively. This energy region is close to the onset of H(n=4). The approximate descriptions of the bonding orbitals have shown[22] that the r-type orbital, $7a_1$, is C–H bonding; the s-type orbital, $6a_1$, is C–C bonding, and the s-type orbital, $4b_2$, is strongly C–H bonding. On the basis of the character of the molecular orbitals and the comparison between the onset of H(n=4) and the ionization potentials, H(n=4) from furan seems to be produced *via* the Rydberg state, converging to the $4b_2$ ionization potential. The vertical ionization potentials of 16.16, 17.6, and 18.3 eV in thiophene have been assigned to the $7a_1$, $4b_2$ and $6a_1$ orbitals respectively by Derrick *et al.*[23] According to the approximate descriptions of the bonding orbitals,[23] the r-type orbital, $7a_1$, is characterized as C–H bonding, and the s-type orbitals, $4b_2$ and $6a_1$, as strongly C–H bonding. In similar considerations of the characters of the molecular orbitals and the ionization potentials, it is concluded that H(n=4) from thiophene is produced *via* the Rydberg state, converging to the $4b_2$ or the $6a_1$ ionization potential.

Formation of CH(A). The onsets for the CH(A-X) band from furan, tetrahydrofuran, thiophene, and tetrahydrothiophene are found at 19.6±0.8, 18.8±1.0, 18.7±1.0, and 20.1±1.1 eV respectively. The dissociation processes leading to the formation of CH(A) from these heterocycles are still uncertain because the available data of the heat of formation of ionic products are insufficient. Nevertheless, if one assumes that the threshold energy consists of the electron-excitation energy of CH(A) and the heat of formation, the main dissociation processes leading to the formation of CH(A) seem to include an ionic by-product. The appearance potentials observed for CH(A) are much higher than the first ionization potentials for furan, 9.06 eV;[24] for tetrahydrofuran, 9.57 eV;[25] for thiophene, 8.87 eV,[26] and for tetrahydrothiophene, 8.57 eV.[6] Accordingly, it is possible that an ionic fragment is a by-product in the formation of CH(A). The threshold energies of the dissociation processes leading to the formation of CH(A) from tetrahydrofuran and tetrahydrothiophene, listed in the second column of Table 2, are calculated from the excitation energy of CH(A) and the heat of formation. The threshold energies for these processes from furan and thiophene are calculated from the excitation energy of CH(A) and the appearance potential for a by-product ion reported by Hissel.[5] The heat of formation and the appearance potentials used for the calculation of the thresholds are summarized in Table 2. The by-product ions in the dissociation processes forming CH(A) (see Table 2) are abundant in mass-spectroscopy measurements.[5,6]

Another possibility for the formation of CH(A) is that by-products are formed in their electronically excited states. It is not possible to derive the processes which may be involved, because the relevant dissociation energies and the electronic energies are not known.

The onsets for the CH(A-X) band resulting from the formation of only neutral fragments are estimated to be 10—16 eV.[9,20] On the basis of the electron-impact energy-loss spectra of furan and thiophene[27] and the photoelectron spectra of furan[22] and thiophene,[23] we may expect the excitation cross-sections for the collision of electrons with furan and thiophene in these energy regions to be relatively large; these excitations seem to be spin-forbidden transitions, mainly in the 11—13 eV region. However, no onset for the CH(A-X) band from any five-membered heterocycles were observed in the 10—16 eV region; competing processes, such as ionization or radiationless decay, may be abundant.

Chemiluminescence from Reactions of $N_2^*(A^3\Sigma_u^+)$ with Solid Organic Compounds at 77 K

Kenichi Mitsumori and Kenzo Hiraoka*
Faculty of Engineering, Yamanashi University, Takeda-4, Kofu 400
(Received July 5, 1982)

The luminescence from reactions of $N_2(A^3\Sigma_u^+)$ with solid benzene, toluene, hexane, cyclohexane and those doped with biacetyl at 77 K has been investigated. For benzene, a broad band appeared in the range of 350—550 nm whose radiative lifetime was determined to be 2.5 s. This band was largely eliminated by addition of a small amount of biacetyl, indicating the participation of an intermediate excited state in solid benzene, *i.e.* triplet excitons. The emitter of the broad band was tentatively assigned to reaction products, possibly benzene isomers. For toluene, a strong appearance of benzyl radical emission was observed. With an addition of biacetyl, the elimination of benzyl emission and a strong growth of biacetyl phosphorescence were observed as for the benzene/biacetyl system. With an increase of biacetyl concentration, a remarkable red shift were observed for biacetyl phosphorescence, while no shift was observed for benzyl emission, indicating the difference of the solvent effect for these electronic transitions. No luminescence was observed for solid hexane and cyclohexane.

The major difficulty in elucidating the reaction mechanisms of reactions of active nitrogen with organic compounds was mainly due to the existence of several active species in active nitrogen which were produced by electrical discharge. The major active species in active nitrogen are long-lived $N(^4S)$ and $N_2(A^3\Sigma_u^+)$.[1] The rate constants for the reactions of $N(^4S)$ with organic compounds have been measured,[2,3] but the reported data are not in good agreement with each other, possibly owing to the contamination of $N(^4S)$ with $N_2(A)$. In order to elucidate the reaction mechanisms of active nitrogen unequivocally, it is indispensable to isolate the active species and study its reactions with organic compounds.

So far only a few investigations have been performed which dealt with $N_2(A)$.[4-6] Dessaux[4,5] reported a simple method for producing "pure" $N_2(A)$ by passing active nitrogen (discharged N_2) through a liquid nitrogen cooled trap. By this method, $N_2(A)$ in the absence of N atoms can be made available owing to the favorable recombination of nitrogen atoms on the cold surface of the trap. Devolder[6] observed the disappearance of ESR signals of nitrogen atoms after passing the active nitrogen through the cold trap at 77 K. Dessaux[4] observed the phosphorescence from the reaction of $N_2(A)$ with solid benzene and he concluded that the emitter of the phosphorescence is the charge transfer complex of $N_2(A)$ and C_6H_6, *i.e.* $N_2(A)^{\pm}\cdots C_6H_6^{\mp}$. We think that Dessaux's conclusion is less likely because the phosphorescence spectrum is very similar to those observed for solid benzene induced by electron impact.[7,8] In this work, the emission spectra from the reactions of $N_2(A)$ with various solid oragnic compounds were measured in order to obtain information on the reaction of $N_2(A)$ with organic compounds at 77 K.

Experimental

The nitrogen gas (0.5 Torr†, Nippon Sanso ultra pure, 99.99999%) was passed through a trap at 77 K and led to a microwave cavity. The active nitrogen generated was passed through a second trap at 77 K and then flowed to the cold finger at 77 K on which organic compounds were deposited. The vacuum system was made of greese-free Pyrex glass. In the presence of nitrogen atoms, a characteristic yellow afterglow (first positive band, $B^3\Pi_g\rightarrow A^3\Sigma_u^+$) was observed which is due to the reaction $2N+M=N_2^*+M$. The yellow afterglow disappeared completely on passing the active nitrogen through the trap at 77 K. The flow speed of N_2 was 4 m/s.

For luminescence measurements, a quartz window was placed on the port of the vacuum system opposite the side face of the cold finger. An Optech GM-N-250 monochromator with a Hamamatsu TV-R585 photomultiplier was positioned in front of the window. A synchronous motor was used to scan the grating and the output from the monochromator was detected by a Hamamatsu TV-C1230 photon counter, and displayed on an x-y recorder. The resolution of the monochromator was 7 nm.

All samples except benzene were Tokyo-Kasei extra pure. Benzene for fluorometry was purchased from Merck. Samples were vacuum degassed prior to inletting by multiple freeze-pump-thaw cycles.

Results and Discussion

Benzene. In Fig. 1(a) is shown the emission spectrum from a reaction of $N_2(A)$ with solid benzene at 77 K. A broad band with a maximum at 400 nm (hereafter, cited as band A) was observed. The decay of the luminescence was recorded by setting the monochromator at the maximum wavelength, following the manual shutting off of the excitation power over a period of time. The lifetime of the luminescence was determined to be 2.5 s, in good agreement with the value obtained by Dessaux.[4] Dessaux suggested that the emitter of the long-lived phosphorescence is the charge transfer complex of $N_2(A)$ with C_6H_6, *i.e.* $N_2(A)^{\pm}\cdots C_6H_6^{\mp}$. If the charge transfer complex $N_2(A)^{\pm}\cdots C_6H_6^{\mp}$ was really formed on the surface of solid benzene, the quenching of this state by the energy transfer to the impurity molecules should be inefficient because of the localization of the charge transfer complex in the benzene matrix. In order to investigate the energy transfer processes in solid benzene, the luminescence spectra of solid benzene doped with biacetyl were measured as a function of the concentration of biacetyl. As shown in Fig. 1, by doping biacetyl in solid benzene,

† 1 Torr = 133.322 Pa.

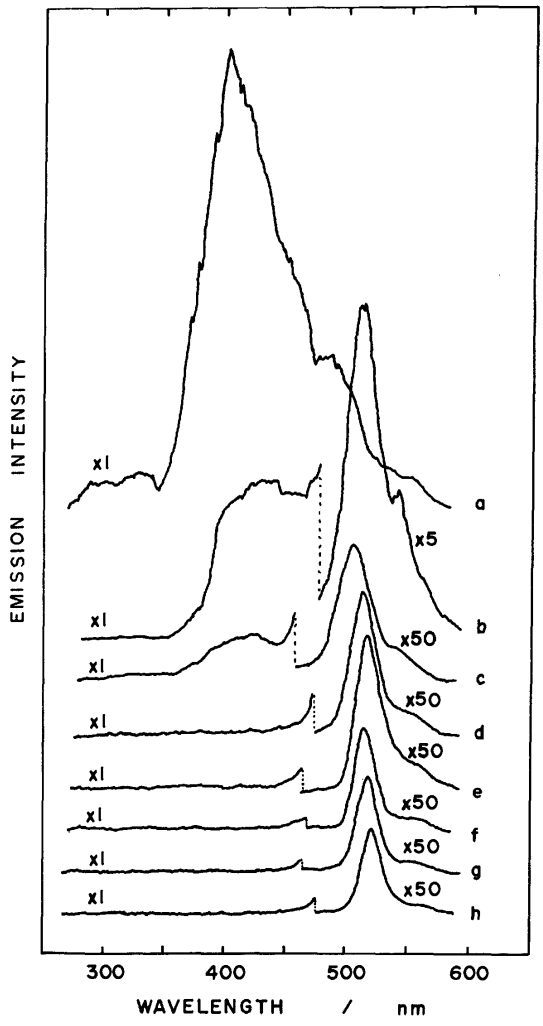

Fig. 1. The luminescence spectra from the reaction of $N_2(A^3\Sigma_u^+)$ with solid benzene doped with biacetyl at 77 K. The mol% of biacetyl in biacetyl-benzene solid solution are: (a) 0, (b) 0.1, (c) 1.0, (d) 5.1, (e) 10.2, (f) 20.4, (g) 50.6, (h) 100.

a remarkable suppression of the band A and an appearance of a characteristic phosphorescence of biacetyl are observed. This result indicates the importance of energy migration in the benzene matrix after the triplet electronic energy transfer from $N_2(A)$ to the benzene molecule. Apparently, the emission of the band A is induced by the long-range energy transfer of triplet excitation in solid benzene. The possibility that the emitter of the band A is the charge transfer complex is, therefore, unlikely. The experimental results described above led us to conclude that the luminescence from the reaction of $N_2(A)$ with solid benzene is due to the emission of some reaction products produced in the benzene matrix.

It is worthwhile noting that the emission spectrum shown in Fig. 1(a) is very similar to that observed for solid benzene induced by electron impact.[9,10] When an ultrathin film of benzene deposited under vacuum at 77 K was bombarded by low-energy electrons ($<\approx$10 eV), only a benzene fluorescence ($^1B_{2u}\rightarrow{}^1A_{1g}$) was observed.[9] With the increase of the incident electron energy ($\geq\approx$20 eV), new bands with maxima at 295 and 400 nm appeared. These bands could still be observed when the incident electron energy was decreased below 10 eV. This result strongly suggests that the emitters of these bands are the radiation products formed in the solid benzene film.

Phillips and Schug[10] also observed the broad band appearing at 400 nm under the stimulation of solid benzene by 1 MeV electrons. They assigned this band to the triplet and triplet excimer emission. We think that their assignment is dubious because the observation of emission from the triplet state in pure organic crystals has been unsuccessful due to the triplet excitation migration and the rapid triplet-triplet annihilation. The large exchange resonance interaction is no doubt a general phenomenon for π-electron system and it corresponds to a transition time for excitation transfer between nearest neighbors of less than 10^{-12} s.[11]

As described previously, the luminescence of benzene induced by electron impact consists of 295 and 400 nm bands as well as the benzene monomer fluorescence at 270 nm. In Fig. 1, a weak band at 290 nm is observed as well as the strong band A at 400 nm. The emitters of these bands seem to be the same for both of these experiments. Quite a few studies have been made of the vacuum-ultraviolet photochemistry of benzene.[12] Benzene irradiated by ultraviolet radiation in the gas and liquid phase is known to undergo isomerization to yield benzene isomers, *i.e.*, mainly benzvalene and fulvene.[13] Although no luminescence of these benzene isomers has been reported, we would like to propose that the 290 nm band and the 400 nm band are fluorescence and phosphorescence of a benzene isomer produced in the benzene matrix. The weak fluorescence of the benzene isomer at 290 nm would be induced by the energy transfer from the singlet excitons which are formed by the homofusion of triplet excitons in the benzene matrix. The formation of benzene isomers from triplet states' benzene has not been reported before,†† but the temperature-dependent radiationless transitions from T_1 are attributed to transitions to an isomeric singlet state.[14] The identification of the benzene isomer could not be done at the present stage. The emitter of the 325 nm band in Fig. 1 could not be specified either. A more detailed investigation is apparently needed in these respects.

With decreasing concentration of biacetyl from 100 to 10 mol%, the phosphorescence intensity of biacetyl shows a gradual increase. This suggests that the efficiency of the energy transfer from $N_2(A)$ to biacetyl is smaller than that from triplet benzene to biacetyl. This seems reasonable because the energy difference between triplet states of $N_2(A)$ and biacetyl is appreciably larger than that between benzene and biacetyl and the energy transfer efficiency for the former pair is considered to be smaller than that for the latter pair (Dexter's theory[15]).

With increase of the concentration of biacetyl, the phosphorescence spectrum of biacetyl shows a red shift as shown in Fig. 1. This indicates that the degree

†† Energetically, $N_2(A^3\Sigma_u^+)$ could excite benzene molecules up to T_3.

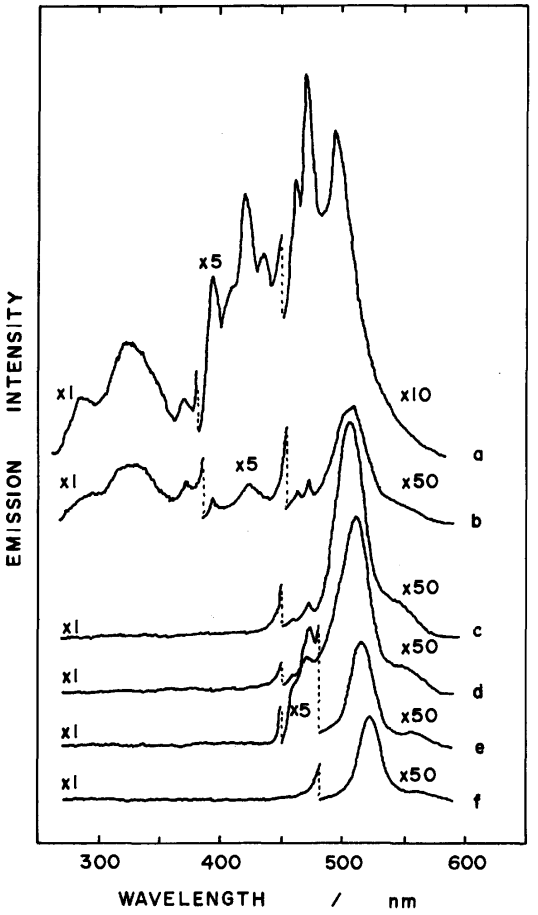

Fig. 2. The luminescence spectra from the reaction of $N_2(A^3\Sigma_u^+)$ with solid toluene doped with biacetyl at 77 K. The mol% of biacetyl in biacetyl-toluene solution are: (a) 0, (b) 0.1, (c) 5.9, (d) 23.0, (e) 54.4, (f) 100.

of solvation of triplet biacetyl by benzene molecules is different from that by biacetyl molecules. Because the polarizability of benzene (10.3 Å^3) is larger than that of biacetyl (9.2 Å^3), the larger solvation energy of biacetyl would be due to its intramolecularly dipolar property. The observation of the red shift of biacetyl phosphorescence indicates that a considerable degree of solvation of the triplet state of biacetyl (*i.e.* rotation of solvent molecules) takes place in rigid solid at 77 K during the lifetime of this state ($\approx 2.25 \times 10^{-3}$ s[16]).

After the measurements of luminescence, the benzene sample was analysed by gas chromatography. No gaseous or liquid products were deteced. The formation of solid products was not observed either on the wall of the cold finger after the evaporation of the benzene sample.

Toluene. The luminescence spectrum from reactions of $N_2(A)$ with solid toluene at 77 K is shown in Fig. 2(a). The three longest-wavelength lines beginning at about 460 nm are easily identified as the fluorescence of the benzyl radical.[17] By doping with 0.1 mol% of biacetyl, a strong emission of biacetyl phosphorescence appeared, clearly indicating the migration of triplet energy in solid toluene. The benzyl emission showed a rather gradual suppression when the biacetyl concentration was increased. In contrast to the case of benzene/biacetyl system the benzyl emission was still observed with a biacetyl concentration of 54 mol%. Because the emission of the benzyl radical by a single collision of $N_2(A)$ with toluene is endoergic, the persistence of benzyl emission must be due to the high concentration of benzyl radicals formed in the toluene matrix.

In addition to the benzyl emission, sharp emission lines are observed in the range of 380—440 nm (Fig. 2(a)). Phillips and Schug[10] also observed similar emission lines from solid toluene induced by 1 MeV electrons. They proposed the benzyl ion to be the most probable candidate for this emission. Although the ionization energy of benzyl radical (7.27 eV[18]) is about 1 eV higher than the available energy of $N_2(A)$ (6.17 and 6.30 eV for $v'=0$ and $v'=1$, respectively), the ionization of benzyl radicals in the solid toluene by $N_2(A)$ could be energetically possible because the polarization energies of ions in solid organic compounds are generally higher than 1 eV.[19-21] For $N_2(A)$, the favored Franck-Condon factors tend to reduce the available energy from 6.17 eV to $\approx$4.7 eV, and this might explain the relatively weak emission of these lines compared to the results obtained by Phillips and Schug.[10] Almost a complete elimination of these emission lines is observed with the addition of 5 mol% of biacetyl, indicating that the concentration of the emitter of these bands is much lower than that of benzyl radical.

Two short-wavelength lines appearing weakly at 290 and 325 nm are observed. These bands could be assigned to monomer and excimer fluorescences of these compounds. The excited singlet states can be formed by a homofusion of triplet excitons (triplet-triplet annihilation) in the solid matrix. The assignment of the band at 325 nm as an excimer emission may not be conclusive because solid thin films of benzene and toluene bombarded by electrons gave only the monomer fluorescence and the excimer emission was not observed.[9,22] These results indicate that solid benzene and toluene deposited at 77 K were crystalline. Thus the band at 325 nm may not be due to the excimer but to some other reaction products.

As in the benzene/biacetyl system, phosphorescence spectra of biacetyl show a red shift with an increase of the concentration of biacetyl as shown in Fig. 2. On the contrary, the emission spectra of the benzyl radical appearing at 465 and 475 nm do not show any noticeable shift with an increase of biacetyl concentration. This indicates that the ground and excited benzyl radical are almost equally solvated by solvent toluene or biacetyl. This seems reasonable because the distributions of a nonbonding electron for the ground and excited states of benzyl radical are highly delocalized owing to the π-electron character of the nonbonding electron.

Alkanes. No chemiluminescence was observed for the reactions of $N_2(A)$ with solid hexane or cyclohexane at 77 K. With an addition of 0.1 mol% of biacetyl in solid hexane or cyclohexane, only a very weak phosphorescence of biacetyl was observed. Its intensity was about 0.1% of the phosphorescence of solid benzene doped with the same amount of biacetyl. The weakness of the phosphorescence suggests that the

phosphorescence was induced by the direct energy transfer from $N_2(A)$ to biacetyl. Apparently an efficient triplet energy migration does not occur in solid alkanes. The absence of the energy migration suggests either that the energy transfer from $N_2(A)$ to alkanes does not occur or that the triplet energy transfered to alkanes does not migrate in the solid matrix. From the results obtained by the ultraviolet absorption spectroscopy and the low-energy electron impact spectroscopy,[23] it is known that a characteristic feature of alkanes is the absence of observable excitation below about 7 eV. This lower limit of energy for the excitation is about 1 eV higher than the available energy of $N_2(A)$ and the energy transfer from $N_2(A)$ to alkanes is endoergic. Actually neither gaseous nor solid products were detected by GC or FT-IR after the reaction of $N_2(A)$ with solid alkanes at 77 K for more than 10 h.

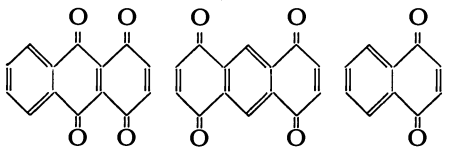
†Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received June 28, 1982)

Assignment of the electronic absorption spectrum of 1,4 : 5,8-anthracenediquinone (1,4 : 5,8-ADQ) has been carried out with the aid of magnetic circular dichroism and LCAO MO SCF CI calculations including all valence electrons. The lowest energy absorption region of 1,4 : 5,8-ADQ has been revealed to be composed of the n-π^* transition or transitions. The higher energy absorption region has been concluded to consist of four π-π^* transitions, which are regarded as L_b, L_a, B_a, and B_b in the Platt's notation for anthracene. The above assignment of 1,4 : 5,8-ADQ has been experimentally confirmed with its linear dichroism spectra in stretched polyethylene sheets and its circular dichroism spectra in the β-cyclodextrin solution. The relationship between the absorption spectra of 1,4 : 5,8-ADQ and 1,4-naphthoquinone has been discussed from the experimental and theoretical points of view.

In spite of the extensive studies on the electronic structures, spectra and reactivities of quinones, those on the chemical and physical properties of diquinones have been little known. They are a potential subject of synthetic and theoretical research.

Anthracenediquinone (ADQ) is considered to be a representative of this interesting quinonoid system. Two isomers of para-ADQ illustrated below are **1** for 1,4 : 9,10-ADQ and **2** for 1,4 : 5,8-ADQ. The electronic



1 **2** **3**

absorption spectrum of **1** in solution has been interpreted in terms of the n-π^* transition and four π-π^* transitions.[1] The π-π^* electronic absorption occurring in **1** has been theoretically confirmed on the basis of an LCAO MO SCF CI calculation.[2] The synthesis of **2** was reported along with its spectroscopic data,[3] where **2** in *N*,*N*-dimethylformamide is described to exhibit absorption at 353 nm. The diquinone **2** was also obtained by selenium dioxide oxidation of a photochemical addition product of 2-cyclohexene-1,4-dione with acetylene.[4] A theoretical calculation based on the simple HMO method was given to elucidate the redox potential of **2**.[5]

In this paper, the electronic absorption, magnetic circular dichroism (MCD) spectra[6,7] in solution, and linear dichroism (LD) spectra[8] in stretched polyethylene sheets of **2** are reported in addition to its circular dichroism (CD) spectrum in the β-cyclodextrin (β-CDx) solution, where the observed CD is known as induced circular dichroism (ICD).[9-11] The experimental spectra of **2** are compared with those of 1,4-naphthoquinone, **3**, and discussed in conjunction with LCAO MO SCF CI calculations including all valence electrons (CNDO/S), so as to give a spectroscopic assignment of the characteristic electronic absorption of **2**.

Experimental and Theoretical

The diquinone **2** and **3** were purified by sublimation under reduced pressure after several recrystallizations from dioxane and petroleum ether. Inclusion complexes of quinones with commercially available β-CDx were prepared in the aqueous solutions. The electronic absorption spectra were recorded on a JASCO UVIDEC 510 recording spectrophotometer. The MCD spectra were measured with a JASCO J500C recording circular-dichrometer equipped with a 1.14T electromagnet. All measurements were carried out at room temperature using spectrograde solvents without further purification.

The experimental oscillator strengths, f, and Faraday parameters, B, were evaluated from the observed spectra after resolving the spectrum into its components according to the curve-fitting procedure assuming a Gaussian function, where B was expressed in units of (Debye)^2 μ_B/cm^{-1}.**

Polyethylene sheets including quinones were prepared by the usual method[8] and stretched five times. Absorption of the set stretched sheets was recorded both for the electric vectors parallel and perpendicular to the stretching direction. The LD spectra in the wavenumber region higher than 25000 cm^{-1} were obtained from the observed dichroic spectra according to the procedure proposed by Thulstrup *et al.*,[8] neglecting out-of-plane polarized absorption.

The electronic transition energies, oscillator strengths and Faraday B terms of **2** and **3** were calculated within the framework of the CNDO/S method,[12,13] including CI among singly excited configurations below 10 eV. The values of the bonding parameters for the carbon and the hydrogen atoms were adjusted so that the ionization potentials and the transition energies of benzene and hydrogen molecules are well reproduced.[14] The values of bonding parameter for the oxygen atom and the empirical σ-π separation parameter, κ, were determined so as to reproduce the n-π^* and the first π-π^* transition energies of *p*-benzoquinone. The quinone ring in **2** was assumed to be identical with that in **3**, while the central six-membered ring was assumed to be a regular hexagon with bond lengths of 1.40 Å. The geometry of **3** was taken from the X-ray diffraction data.[15]

For a molecule possessing non-degenerate states, the theoretical MCD for the transition, a←0, is usually discussed in terms of the Faraday B term. All the atomic integrals in the calcula-

** B-terms in SI units of 10^{-60} C^2 m^2 T^{-1} can be obtained by multiplying by 5.19.

tion of the B terms were evaluated using the Slater AOs, with which the orthogonalized CNDO basis set was expanded by the inverse Löwdin transformation.[16]

Results and Discussion

The electronic absorption spectrum of **2** in dichloromethane is reproduced in Fig. 1. It is characterized by three absorption regions; the first (20000—25000 cm^{-1}) the second (25000—35000 cm^{-1}), and the third (35000—42000 cm^{-1}).

The MCD spectrum of **2** in Fig. 1 reveals a distinct negative extreme at 22200 cm^{-1} in contrast to a discernible shoulder in its electronic absorption spectrum. The first region in the absorption and MCD spectra is considered to arise from an electronic transition or transitions which is or are n-π^* in nature. The n-π^* assignment is partially supported by the solvent effect on the lowest energy absorption and MCD bands. As is clear from Fig. 2, the blue-shift takes place on changing solvents from nonpolar to polar.

The phosphorescence spectrum of **2** was measured in an ether-isopentane-ethanol (EPA) mixture (volume ratio, 5 : 5 : 2) at 77 K, and it is reproduced in Fig. 3. The spectrum exhibits the vibrational structure with spacing of *ca.* 1600 cm^{-1}, which is considered to be due to the carbonyl stretching progression. From the 0-0 band position, which was assumed to be the most intense peak of the spectrum, the lowest triplet level of **2** is estimated to be at 2.45 eV. Provided that the 0-0 band position is at 21350 cm^{-1}, which was assumed to be the lowest wavenumber extreme of the MCD spectrum of **2** in benzene, the energy difference between the lowest singlet and the lowest triplet states is estimated to be 1590 cm^{-1}. The small energy difference and the carbonyl stretching progression suggest that the lowest

phosphorescence state is n-π^* in origin, and in turn that the lowest singlet state is also n-π^* in nature.

In the present work, a symmetry allowed $B_{3u}\leftarrow A_g$ transition is assigned to the observed lowest energy absorption and MCD bands. This seems to require a further confirmation, however.

The MCD spectrum exhibits a positive extreme at 27800 cm^{-1} and a negative extreme at 30300 cm^{-1} in the second absorption region, suggesting that two electronic origins are included in the corresponding spectral region. Both bands are roughly equal in magnitude, but opposite in sign. In the third region, the MCD spectrum manifests two electronic transitions which have never been resolved in the absorption spectrum due to overlapping.

The CD spectrum of the inclusion complex of **2** with β-CDx is shown in Fig. 1. No ICD for the first absorption region has been observed, due to the low solubility of **2** in water. The inclusion complex exhibits only two positive CD extrema, corresponding to the second and third absorption regions. If the long axis of the guest molecule is parallel to the seven-fold symmetry axis of β-CDx (an axial inclusion), the transition polarized along the z-axis gives positive CD and the transition polarized along the y-axis gives negative CD.[9-11] Therefore, the observed positive extreme in the CD spectrum originates from the transition polarized along the z-axis. In general, the positive CD band in inclusion complexes tends to appear larger than the negative one.[17] The negative CD component expected to come from the transition polarized along the y-axis seems to be compensated by the larger positive CD component.

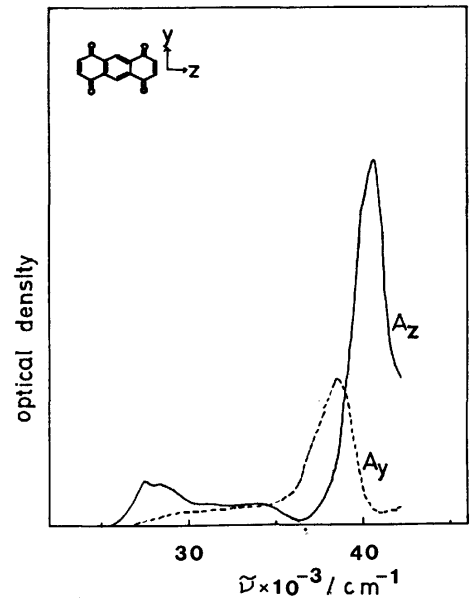

Fig. 4. The linear dichroism spectra of 1,4:5,8-anthracenediquinone in stretched polyethylene sheets at room temperature (redution factors $d^0_{\parallel}=1.02$, $d^0_{\perp}=0.77$). The solid and broken lines stand for the absortion components polarized along the z- and y-axis respectively.

The LD spectra of **2** in the y-direction, A_y, and z-direction, A_z, are illustrated in Fig. 4, which were obtained from the experimental dichroic spectra using the reduction factors of $d^0_{\perp}=0.77$ and $d^0_{\parallel}=1.02$ respectively. The reduction factors, $d^0_{\perp}$ and $d^0_{\parallel}$, were estimated on the assumption that the z- and y-polarized absorption bands have their maxima at 40800 and 35700 cm^{-1} respectively.

According to the present calculation, the lowest two π-π^* transitions take place at 30200 and 32900 cm^{-1} with their directions of polarization along the z- and y-axis respectively. Theoretical B values associated with these transitions are negative for the lower energy transition and positive for the higher, in agreement with the experiment. Therefore, the positive and negative bands are considered to be assigned to the predicted B_{2u} and B_{1u} states respectively. The assignment is further supported by the LD spectra which show the two components polarized along the z-axis in the lower energy region and along the y-axis in the higher. Thus, in the second region there are two π-π^* transitions, where the lower energy transition is polarized along the z-axis and the higher energy one along the y-axis.

The negative and positive MCD bands in the third absorption region are assigned to the $B_{1u}\leftarrow A_g$ and $B_{2u}\leftarrow A_g$ transitions predicted at 40000 and 40200 cm^{-1} respectively. The calculated B values for the both transitions are too large to reproduce experimental values, however. This arises from the small energy difference between two states predicted in the present calculation. The assignment is supported by the LD spectra (Fig. 4) which exhibit the y-component at the lower energy region and the z-component at the higher.

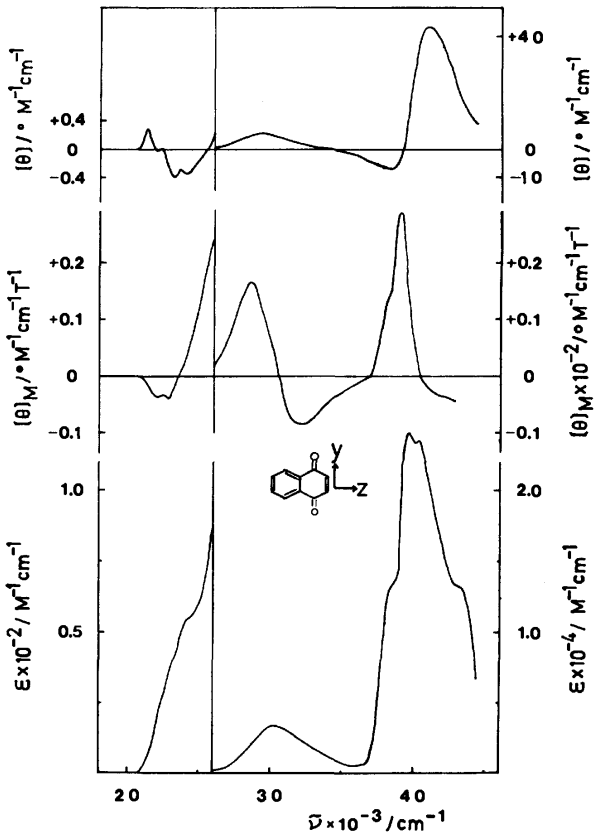

Fig. 5. The magnetic circular dichroism (center) and electronic absorption (bottom) spectra of 1,4-naphthoquinone in dichloromethane and the circular dichroism (top) spectrum of β-cyclodextrin complex with 1,4-naphthoquinone in water at room temperature.

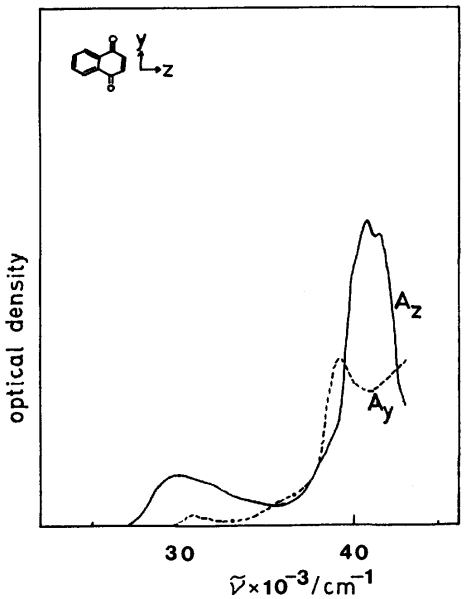

Fig. 6. The linear dichroism spectra of 1,4-naphthoquinone in stretched polyethylene sheets at room temperature (redution factors $d_{\parallel}^{0}=1.07$, $d_{\perp}^{0}=0.69$). The solid and broken lines stand for the absorption components polarized along z- and y-axis respectively.

Taking the theoretical and experimental results into consideration, the third absorption region is concluded to consist of two π-π^* transitions: One is polarized along the y-axis and the other along the z-axis.

The electronic absorption spectrum of **3** in Fig. 5 is divided into three characteristic spectral regions. The first region of the absorption and MCD spectra is considered to come from the n-π^* transitions, which are predicted to take place at the lowest energy region (see Table 2). The ICD spectrum in this region exhibits two extrema at 21280 and 23260 cm^{-1}, which are considered to be either electronic or vibrational in origin.

The positive and negative MCD bands in the second region are considered to be assigned to the theoretically predicted A_1 and B_2 states respectively. The assignment is supported by the LD spectra in Fig. 6, where the lower energy transition is polarized along the z-axis and the higher energy one along the y-axis.

The LD and ICD spectra show that the third absorption region consists of two π-π^* transitions, where the lower energy transition is polarized along the y-axis and the higher energy one along the z-axis. On the contrary, the present CNDO/S calculation predicts the $A_1\leftarrow A_1$ (41100 cm^{-1}) and $B_2\leftarrow A_1$ (41900 cm^{-1}) transitions with the transition moments directed along the z- and y-axis respectively. The theoretical result is in disagreement with the experimental result. The latter, however, is consistent with that of Kuboyama and his coworkers.[18]

The spectral profile of **2** and **3** in the wavenumber region higher than 26000 cm^{-1} seems to be related to the skeletal π-π^* transitions in the annelated aromatics. The singly excited configurations contributing dominantly to the lowest $B_{2u}\leftarrow A_g$ and $B_{1u}\leftarrow A_g$ transitions in the second region of **2** are respectively due to the

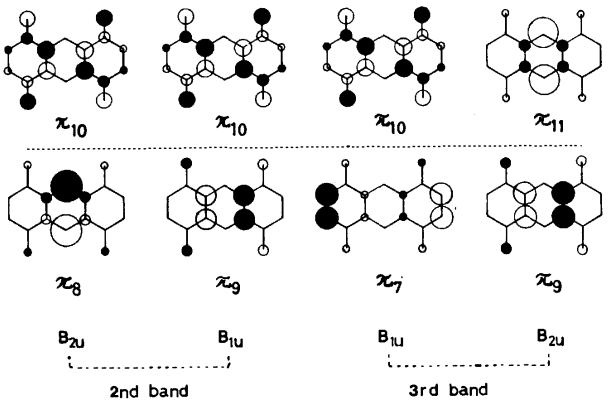

Fig. 7. The bonding π-MOs (bottom) and anti-bonding π-MOs (top) associated with the π-π^* electronic transitions in 1,4: 5,8-anthracenediquinone.

$\pi_8 \rightarrow \pi_{10}$ and $\pi_9 \rightarrow \pi_{10}$, and illustrated in Fig. 7. The two configurations are correlated to the L_b and L_a bands in anthracene. Further, the B_{1u} and B_{2u} states included in the third absorption region of **2** are B_b and B_a respectively, in nature.

Concluding Remarks

The assignment of the electronic absorption spectra of **2** has been carried out. The first absorption region is considered to arise from the n-π^* electronic transition or transitions. The absorption region higher than 25000 cm^{-1} is concluded to consist of four π-π^* transitions.

The present CNDO/S calculation seems to reproduce the absorption and MCD spectra of **2** and **3** fairly well. As has been seen above, however, the agreement between the theoretical and experimental is considered to be less satisfactory in the higher energy region than in the lower energy region.

The authors wish to thank Professor Kokubun of Tohoku University for his kindness in putting a phosphorescence spectrophotometer at their disposal.

Pure Spectra of Actinomycin D Bound to DNA at Various Ionic Strengths Extracted by the Principal-component-analysis Method[1)]

Takumi MATSUDA, Saburo KASHIRAMOTO, and Kiwamu YAMAOKA*
Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received July 6, 1982)

The interaction between actinomycin D (AMD) and native and heat-denatured DNA was studied spectrophotometrically at 25 °C. By applying the principal-component-analysis (PCA) method to the series of observed spectra, the number of light-absorbing components was determined. Two spectroscopically different species of bound AMD, *i.e.*, AMD–DNA complexes, were formed when an aqueous AMD solution was titrated with either the native or the denatured DNA solution over a wide range of the nucleotide residue-to-AMD mixing ratios (P/D) between 0 and 30. The pure spectra of AMD bound to DNA were extracted in the P/D range 0—4 by the extended PCA method with an appropriate binding scheme. These bound-AMD spectra were affected by the DNA conformation but not by the addition of NaCl (1—500 mmol dm^{-3}). The fractions of bound AMD were calculated as a function of P/D.

Actinomycin D (AMD)[2-4)] is an antibiotic that inhibits DNA-dependent RNA synthesis by binding to DNA;[5,6)] the interactions between AMD and DNA and other related compounds have been studied by many physicochemical methods.[5-22)] For example, two classes of AMD–DNA complexes with different binding constants have been reported;[5-7)] the first class is the "strongly" binding complex and the second is the "weakly" binding complex. Although the strongly binding complex has been studied extensively, few attempts have been made to clarify the weakly binding complex. In particular, the absorption spectrum of the AMD–DNA complex, free from the spectrum of unbound AMD, has not been unmasked because of the strong overlap between the two spectra in the visible wavelength region.

The pure spectrum of the AMD–DNA complex or the *bound*-AMD spectrum is important in interpreting the optical behavior and the binding mode of AMD in the AMD–DNA complex. In this paper, therefore, the interaction between AMD and DNA was studied spectrophotometrically, and the results were analyzed with a new technique—the principal-component-analysis (PCA) method.[1,23-27)] This method is useful, because no additional measurement such as equilibrium dialysis is required. By applying the PCA method to a series of observed spectra of AMD–DNA solutions, the number and the pure spectra of light-absorbing components in the system can be determined. The binding curve of AMD can also be evaluated by using an appropriate equilibrium equation.

Experimental

Materials. Actinomycin D was a gift of Merck Sharp and Dohme, Inc. (USA) and used without further purification. The aqueous solution of AMD was filtered through a sintered glass filter and stored in the refrigerator under dark. The concentration of AMD was determined to be 1.81×10^{-5} M (1 M = 1 mol dm^{-3}) with the molar absorption coefficient ε_{441} of 24800 cm^{-1} M^{-1}.[7)] Calf thymus DNA was purchased from Worthington Biochemical Corp.[1)] The concentration of the stock native DNA (nDNA) solution was 9.35×10^{-4} M, which was determined by using the absorption coefficient ε_{260} of 6400 cm^{-1} M^{-1}.[8)] Heat-denatured DNA (dDNA) in 1 mM NaCl was prepared as before.[1,8)] The hyperchromicity of the DNA solution was *ca.* 34% in 1 mM NaCl. Spectrophotometric titration was carried out at 25 °C in a 1 or 2 cm long cuvette cell by the successive addition of the stock DNA solution in the same manner as before.[1)]

Analysis. The absorption spectra of the AMD–DNA solution were analyzed by the PCA procedure, for which the following equilibrium equation was used (Eq. 2 of Ref. 1):

$$K_a = \frac{[DP^*]}{[D][P]}\left(\frac{[P]}{[D]_0}\right)^{1-\alpha}, \quad (1)$$

where K_a is the apparent equilibrium (binding) constant, the brackets denote the equilibrium concentration, DP* is the bound AMD or the AMD–DNA residue complex, D is the free AMD, P is the unoccupied DNA residue (in the nucleotide unit), and $[D]_0$ is the initial AMD concentration. The adjustable parameter α has been introduced to reproduce the sigmoidal change of optical titration curves for various dye-polymer combinations.[1,24,26,27)] When $\alpha=1$, Eq. 1 reduces to the commonly postulated equilibrium scheme, $K'=[DP^*]/[D]\cdot[P]$. When $\alpha>1$, Eq. 1 represents a sigmoidal change in the titration curve.

Results and Discussion

Observed Spectra of AMD–DNA Systems and Number of Light-absorbing Components. Figure 1 shows representative absorption spectra of AMD solutions obtained from the successive titration with (a) nDNA and (b) dDNA in the presence of 1 mM NaCl. The molar absorption coefficients, ε, of the spectra of AMD–DNA solutions are almost the same at 461 nm for nDNA and at 457 nm for dDNA (the isosbestic points) in the low P/D range. The spectral change near 380 nm at higher P/D values, together with the gradual deviation from the isosbestic points, indicates that more than two independent, light-absorbing components are present in each system. (The absorbance of the DNA component is negligibly small above 370 nm.) The exact number of these components may be determined by comparing the relative magnitudes of the eigenvalues, which are obtained from a family of the observed AMD–DNA spectra by the PCA method.[1,23-27)]

The eigenvalues calculated for the AMD–nDNA system at 1 mM NaCl are shown in Fig. 2(a). According to the previously set criteria,[1,23-27)] the significant number of light-absorbing components is determined

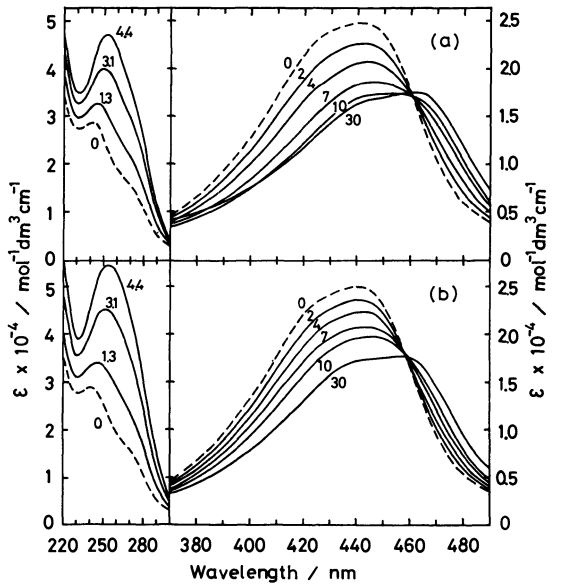

Fig. 1. Representative solution spectra of AMD observed in the presence of nDNA (a) and dDNA (b) at 1 mM NaCl. The dashed curves ($P/D=0$) are the spectra of AMD in the absence of DNA. The numerals denote values of P/D. The apparent molar absorption coefficient, ε, is expressed with the concentration of AMD in aqueous solution which is 1.81×10^{-5} M throughout this work.

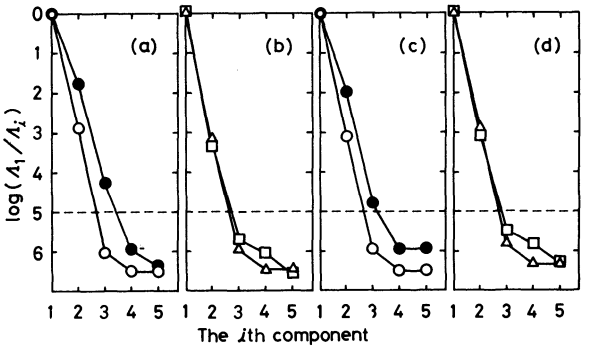

Fig. 2. Variations in eigenvalue Λ_i ($i=1$, 5) with the ith light-absorbing component for the AMD–nDNA solutions (a) and (b) and for the AMD–dDNA solutions (c) and (d). The concentrations of NaCl in those solutions are 1 mM (○), 100 mM (△), and 500 mM (□). The ordinate is expressed in terms of the ratios of the eigenvalue of the first component, which is the largest, to that of the ith component. The dashed lines indicate the criteria set for the significant component. Open symbols are used for the observed spectra which are limited to the low P/D range between 0 and 4, and the closed circle is used for the observed spectra whose P/D values range between 0 and 30.

to be three in a wide P/D range of 0—30. One of these species must be the free AMD and, hence, two differently bound AMD species may exist in agreement with previous reports that calf thymus DNA possesses two classes of binding sites for AMD (strong and weak binding sites).[6,7] The number of absorbing components reduces to two, if the P/D region is limited between 0

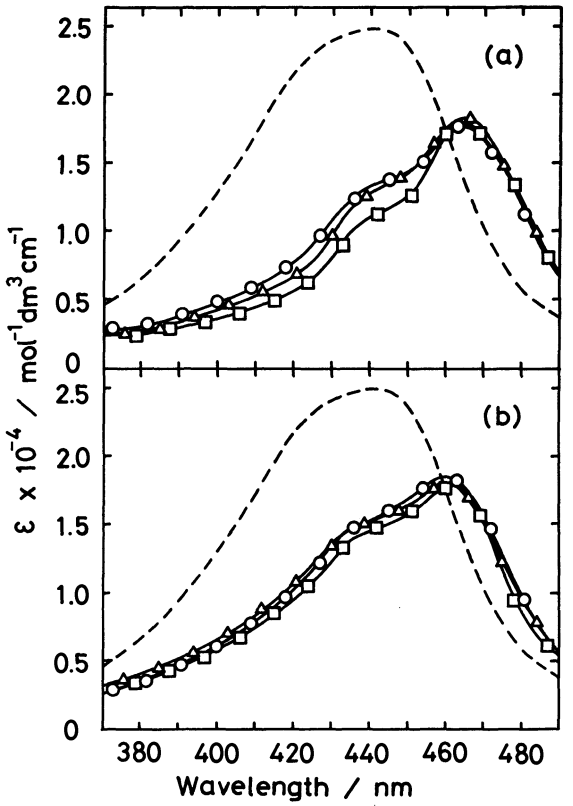

Fig. 3. The pure spectra of AMD bound to nDNA (a) and to dDNA (b). Concentrations of NaCl are 1 mM (○), 100 mM (△), and 500 mM (□). The spectrum of free AMD is shown by the dashed curve for comparison.

and 4; therefore, it may be concluded that the strongly bound AMD almost disappears in the low P/D region and that the dominant species are the weakly bound AMD and the free AMD. The eigenvalues for the AMD–nDNA system at higher ionic strengths (100 and 500 mM NaCl) are shown in Fig. 2(b). The result is the same as in the case of 1 mM NaCl; namely, free AMD and weakly bound AMD are present in the low P/D region.

The eigenvalues for the AMD–dDNA system are shown in Figs. 2(c)—(d). The results are similar to those of the AMD–nDNA system; three light-absorbing components, free AMD and two differently bound AMD, in the wide P/D range 0—30 and two components in the low P/D range 0—4. It is clearly shown that the number of light-absorbing components can be estimated in a straightforward manner by the PCA method without relying on the delicate isosbestic points.

Pure Spectra of AMD Bound to nDNA and dDNA at Various Ionic Strengths. Figure 3(a) shows the pure absorption spectra of AMD, which is weakly bound to nDNA, at three different concentrations of added NaCl. Each bound-AMD spectrum could be extracted by the extended PCA method from a family of observed (five to eight) spectra in the low P/D region 0—4. The binding constant K_a and the parameter a were also determined and are listed in Table 1. Three pure bound-AMD spectra of AMD–nDNA complexes in Fig. 3(a) are nearly identical regardless of the NaCl concen-

Table 1. The apparent binding constants, K_a and K', and the parameter α evaluated by the PCA method

[NaCl] mM	AMD–nDNA			AMD–dDNA		
	α	$K_a\times10^{-3}$	$K'\times10^{-3}$	α	$K_a\times10^{-3}$	$K'\times10^{-3}$
1	1.2	6.0	7.7	1.0	5.3	5.3
100	1.0	4.4	4.4	1.2	6.3	8.2
500	1.1	2.7	3.0	1.1	5.7	6.3

The dimension of K_a is in $(\text{mol/dm}^3)^{-1}$. $K'=K_a([P]/[D]_0)^{\alpha-1}$ and was calculated at $P/D=4$.

trations. This result is surprising in that a five hundred-fold change in ionic strength does not affect the bound-AMD spectrum and, hence, the binding mode. The three bound-AMD spectra all show the absorption maximum at 465 nm and a distinct shoulder at 440—430 nm, being bathochromic and hypochromic relative to the free-AMD spectrum. In addition, the spectral profile is similar to that of the free AMD observed in less polar organic solvents such as benzene and ethanol.[2]

Figure 3(b) shows the pure absorption spectra of AMD, which is weakly bound to dDNA, in the low P/D region at different concentrations of NaCl. Values of K_a and α are given in Table 1. Three bound-AMD spectra at different NaCl concentrations are again almost identical with each other, indicating that nearly the same AMD–dDNA complexes are formed as in the case of the AMD–nDNA system. The bound-AMD spectra of the AMD–dDNA system show both bathochromism and hypochromism relative to the free-AMD spectrum, but the spectral characteristics are less prominent than those of the AMD–nDNA system. Since a bound-AMD molecule would occupy several nucleotide base pairs,[7,9] the difference could be attributed to the presence or absence of the stable double-helical conformation over several base pairs, where the AMD molecule is bound, and also to the extent of the exposure of the AMD-bound site to the environmental water.

The usefulness of the PCA method is clear; a well-defined bound-AMD spectrum (Fig. 3) could be extracted from the broad, nearly featureless experimental spectra of AMD–DNA solutions (Fig. 1). The bound-AMD spectra in Fig. 3 are in excellent accord with the ORD[2] or circular dichroism (CD)[2,12] data previously reported for the AMD–nDNA complex. The CD spectra show three negative bands at 465 nm, 440 nm, and 385 nm in the visible region. The locations of the first two CD bands correspond exactly to the peak and the pronounced shoulder of the bound-AMD absorption spectrum [Fig. 3(a)]. Since the latter reveals a slight hump in the 400—370-nm region, a third, weak-intensity band probably exists there. This absorption band may be related to a large negative CD band at 385 nm. Auer *et al.*[12] have assigned the 465-nm CD band to the quinoid and the 385-nm band to the benzenoid portion of the phenoxazone ring of AMD. We may assign the 440-nm shoulder to a vibrational component of the 465-nm electronic transition on the basis of the spectral profile of the bound-AMD spectrum.

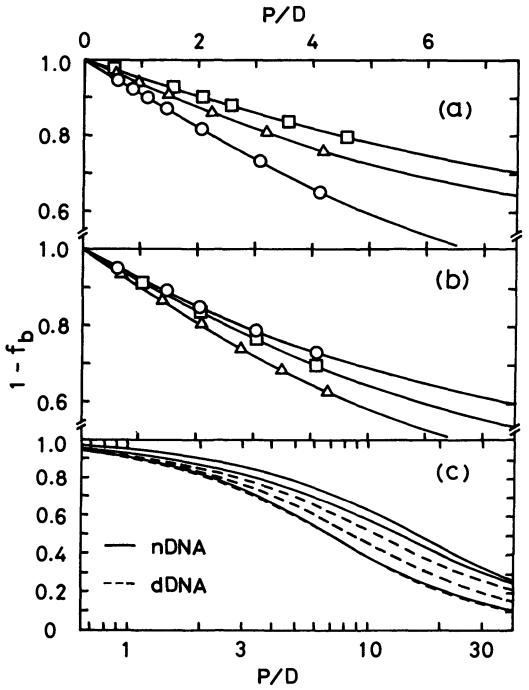

Fig. 4. Fractions of AMD, f_b, bound to nDNA (a) and to dDNA (b) as a function of P/D. Concentrations of NaCl are 1 mM (○), 100 mM (△), and 500 mM (□). Binding curves (solid lines) are expressed in terms of the fraction of the free AMD, $(1-f_b)$. In (c) shown are the curves which are calculated with values of K_a and α over a wider P/D range.

Binding Curves of AMD toward Native and Denatured DNA. Figure 4 shows plots of the mole fraction of free AMD, $(1-f_b)$, against P/D (solid lines).[1] Values of $(1-f_b)$ were calculated with values of K_a and α given in Table 1, and also directly from the **C** matrix by the PCA procedure (symbols).[24-27] Less than 50% of AMD are probably bound to DNA at P/D values 6—15, but more than 90% of AMD may become bound at P/D values >50 for dDNA and >200 for nDNA [Fig. 4(c)], provided that the binding scheme can be described by Eq. 1 throughout the P/D range 0—200. The values of K_a show a trend to decrease with increasing salt concentrations for AMD–nDNA, while they are nearly constant for AMD–dDNA. The small effects of added sodium chloride on K_a and on the bound-AMD spectra (Fig. 3) suggest that the binding mode of AMD toward the DNA site is nonelectrostatic. In the low P/D range, the apparent binding constants, K_a, are in the order of 10^3 for both AMD–nDNA and –dDNA systems (Table 1). In the high P/D range, the values of K_a for the strong binding mode have been reported to be in the order of 10^6 for AMD–DNA.[7,9,10] Thus, it is now clear that the weak binding between AMD and DNA is less by an order of three.

In a number of dye-synthetic polyelectrolyte systems, optical titration curves change sigmoidally in the very low P/D region.[1,24-27] This sigmoidal change has been reproduced well with the adjustable parameter α, if its value is larger than unity.[24,26,27] In the AMD–DNA systems, the fraction of free AMD decreases almost linearly with respect to P/D, as reflected by the values

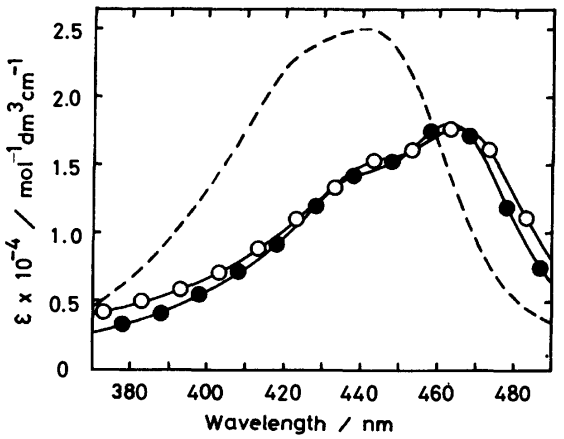

Fig. 5. Mixed-bound spectra of AMD at $P/D=31$ in the presence of 1 mM NaCl. AMD–nDNA (○) and AMD–dDNA (●). The spectrum of free AMD is shown by the dashed curve.

of α which are close to unity (Table 1). It is worth notice that the values of α are also close to unity in other dye–DNA complexes such as crystal violet, trypaflavine, and ethidium bromide.[1,24] This fact supports the use of the commonly postulated binding scheme, *i.e.*, $K'=[DP^*]/[D]\cdot[P]$ $[=K_a([P]/[D]_o)^{\alpha-1}]$, for the binding equilibrium between DNA and small ligands.

Mixed Bound-AMD Spectra in AMD–DNA Systems. At P/D about 30, where both strongly and weakly bound AMD species may coexist (*cf.* Fig. 2), the absorption spectrum of bound AMD results from the mixture of these two bound AMD species. Such a spectrum has been termed the mixed bound-spectrum, expressed with ε_{mix} at a given wavelength,[25] which can be obtained if the equilibrium scheme (Eq. 1) holds for AMD–DNA systems at $P/D \fallingdotseq 30$:

$$\varepsilon_{mix} = \varepsilon_f + (\varepsilon_{obsd}-\varepsilon_f)/f_b, \qquad (2)$$

where ε_f and ε_{obsd} are the molar absorption coefficients of AMD in the free-AMD solution and the AMD–DNA mixture, respectively, and f_b is the mole fraction of bound AMD at a given P/D (*cf.* Fig. 4). Figure 5 shows the mixed bound-AMD spectra for AMD–nDNA and –dDNA complexes at a P/D of 31. These mixed bound-AMD spectra possess the absorption peak and the prominent shoulder almost at the same wavelengths as those of the pure bound-AMD spectra in Fig. 3. Hence, the pure spectrum of the strongly bound AMD in a high P/D range may not differ too markedly from that of the weakly bound AMD in the low P/D range.

Bound-AMD Spectra in the UV Region. Since both AMD and DNA have absorption bands in the ultraviolet region,[2] the AMD–DNA solution also shows a resultant spectrum (Fig. 1). The pure ultraviolet absorption spectrum of weakly bound AMD species, ε_b, can be calculated as

$$\varepsilon_b = \varepsilon_f + (\varepsilon_c-\varepsilon_f)/f_b. \qquad (3)$$

The sum total of the molar absorption coefficients of free and bound AMD, ε_c, is given as

$$\varepsilon_c = (A_{obsd}-A_{DNA})/[D]_o l, \qquad (4)$$

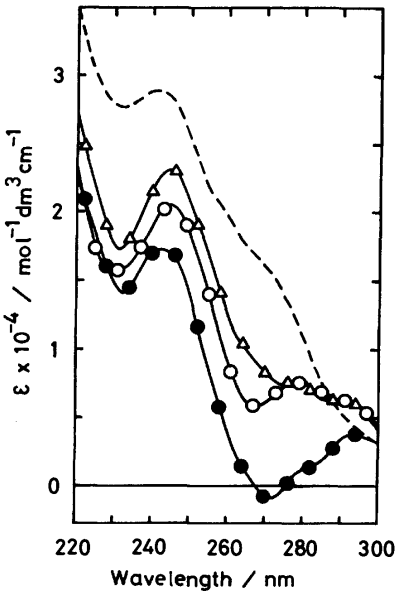

Fig. 6. Pure UV spectra of AMD bound to DNA at 1 mM NaCl calculated from the observed spectra of AMD ($P/D=0$) and of AMD–DNA solutions ($P/D=4.4$), which are shown in Fig. 1. AMD–nDNA (○) and AMD–dDNA (●), both of which were calculated with Eqs. 3 and 4. AMD–dDNA (△) is calculated with Eqs. 3 and 5. The spectrum of free AMD is shown by a dashed curve for comparison.

where l is the optical path length, A_{obsd} is the observed absorbance of the AMD–DNA solution, and A_{DNA} is the absorbance of the DNA component in this solution. For the A_{DNA} of AMD–nDNA solution, the absorbance of nDNA in an AMD-free solution may be assumed (the concentrations of DNA should be the same in the two solutions), considering that the possible conformational change of nDNA by binding of AMD would be small, if any. The procedure, which was utilized for nDNA, was likewise adopted for dDNA of the AMD–dDNA system.

Figure 6 shows the bound-AMD spectra in the ultraviolet region which were calculated on the above assumption. The pure spectrum of AMD bound to nDNA (open circles) seems reasonable, but the pure spectrum of AMD bound to dDNA (closed circles) is unrealistic, because a part of the spectrum has a negative absorbance near 270 nm. This may indicate that the conformation of dDNA in the AMD–dDNA complex (hence, the absorbance of dDNA in Eq. 4) differs from the disordered, single-stranded coil without AMD. Recovery of some kind of partially ordered structure in the AMD–dDNA complex is possible as reported before.[7] If the binding of AMD to dDNA induces an ordered structure, Eq. 4 may be modified as

$$\varepsilon_c = \frac{1}{[D]_o l}\{A_{obsd}-[f_{ord}\cdot A_{ord}+(1-f_{ord})A_{dDNA}]\}, \qquad (5)$$

where f_{ord} and A_{ord} are the fraction and the absorbance of the ordered portion of the dDNA in the AMD–dDNA complex, and A_{dDNA} is the absorbance of dDNA in the absence of AMD.

The pure spectrum of AMD bound to dDNA can be calculated from Eqs. 3 and 5 with appropriate values for f_{ord} and A_{ord}. The ordered structure of dDNA in the AMD-dDNA complex may be approximated as the same as, or close to, the double-helical structure of nDNA. The molar absorption coefficient of the ordered portion of dDNA, ε_{ord}, is then equal to that of nDNA, ε_{nDNA}. The fraction of the ordered structure, f_{ord}, may range between 0 and 1, a unique value being difficult to assign. On the assumption that four nucleotide bases per bound AMD molecule are needed to induce the ordered structure in the AMD–dDNA complex, the following relation may be written as $f_{ord}=4f_b(P/D)^{-1}$; then, $f_{ord}=0.26$ at $P/D=4.4$ ($f_b=0.29$, read from the binding curve in Fig. 4). With these A_{ord} and f_{ord}, the absorbance of the bound AMD in the AMD–dDNA complex was calculated. It now becomes reasonably positive in the 290—260-nm region, as shown in Fig. 6 (open triangles). Although these pure UV spectra of AMD bound to nDNA and dDNA were calculated for the purpose of illustration and can never be claimed unique, they appear to be different from the free-AMD spectrum and hypochromic relative to it.

Conclusion

By using the PCA method, the number of bound AMD species in each of the AMD–nDNA and –dDNA complexes was determined to be one in a low P/D range (0—4) and two in a wide P/D range (0—30). The pure visible absorption spectra of bound AMD were extracted, for the first time, in the weak-binding region. They show a distinct absorption peak at 465 nm (bound to nDNA) and at 460 nm (bound to dDNA) together with a pronounced shoulder near 440 nm. These spectral features are in excellent accord with the measured CD spectra. The variation of the fraction of bound AMD with P/D was calculated from the apparent binding constant K_a which was determined by the extended PCA method. The effect of added sodium chloride on K_a is modest; hence, the binding of AMD to DNA is probably nonelectrostatic. The pure ultraviolet spectrum of AMD bound to dDNA indicates the partial recovery of "nativeness" to the AMD–dDNA conformation. The PCA method is a very useful technique to extract the pure spectra of light-absorbing components from a series of experimentally measured absorption spectra.

Concentration Dependence of the Conversion between the Intermolecular β-Structure and the Disordered State of Poly(*S*-carboxymethyl-L-cysteine) in Aqueous Solutions

Hiroshi MAEDA,* Kaoru SAITO, and Shoichi IKEDA
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received August 21, 1982)

The effects of polymer concentration on the reversible conversion between the intermolecular β-structure and the disordered state of poly(*S*-carboxymethyl-L-cysteine) were examined by means of circular dichroism at constant pHs in 20 mM $NaClO_4$ solutions. The data were tentatively analyzed based on an assumed all-or-none model. A value of −1.1 kJ (−250 cal) per mole of residues was obtained for the standard free energy of association. It was suggested that the obtained results depended significantly on the molecular weight distribution of the used samples.

An important aspect of the β-structure of polypeptides in solution is the problem of whether it is formed by intermolecular association or by chain folding of a single polymer molecule. It is likely that these two types coexist in proportion to their relative stabilities and that other mixed types are also present. Accordingly, assignment of either of the two types can be done only under favorable conditions. Recently, we have shown that fractionated low molecular weight samples of poly(*S*-carboxymethyl-L-cysteine) form the β-structure only by association.[1,2] Further, the conditions for a reversible β-disorder conversion were explored.[2] The stability of the β-structure relative to the disordered state can be thus estimated based on the free energy of association using low molecular weight samples which form the β-structure entirely by association.

In the present study, the concentration dependence of the β-disorder conversion was examined on the same sample as used in the previous study[2] by circular dichroism (CD) in 20 mM $NaClO_4$ solutions at constant pHs: the condition prerequisite to a quantitative analysis.[2] The stability of the intermolecular β-structure was estimated from the concentration dependence based on an assumed type of association.

Another sample of similar molecular weight but significantly different extent of polydispersity was also used to examine the effects of polydispersity on the β-disorder conversion.

Experimental

Two samples (sample code SMA and SMA-2) were prepared from polydisperse low molecular weight samples (A/I=8, 12, and 16) of poly(*S*-carboxymethyl-L-cysteine) by ion-exchange chromatography. The fractionation procedure will be given elsewhere.[3] A sample SMA, used in a previous study,[2] was obtained as a pooled fraction originating from samples A/I=8 and 12, eluted at an ionic strength range 0.59—0.67 M. Another sample SMA-2 was obtained as a fraction originating from sample A/I=16, eluted at an ionic strength range 0.61—0.71 M.

Circular dichroism (CD) was recorded on a Jasco circular dichrograph J-40 A at 25±1 °C using cells of path lengths, 10, 5, 2, 1, 0.5 and 0.2 mm. Measurements of pH were carried out with a Hitachi-Horiba pH meter Model F-7 SS. Light scattering was measured on a Chromatix low angle light-scattering photometer KMX-6 using a 6—7° annulus which collected the scattered light about 4—5° from the cell. The whole assembly was as follows. A Hamilton syringe (5 ml) containing a 3—4 ml solution was connected to a filter holder (Millipore XX30-012-00) by a teflon tubing (ϕ=2 mm). The filter holder equipped with a membrane filter (0.1 μm pore size) (VC WP 01300) was mounted onto the scattering cell. The weight average molecular weight $\overline{M}_w$ was calculated according to the formula

$$\frac{Kc_p}{\Delta R_o} = \overline{M}_w^{-1} + B_2 c_p, \quad (1)$$

here ΔR_o represents the reduced scattering intensity at zero scattering angle (solvent contribution is subtracted), which was approximated by the value at scattering angle of 4—5°. K denotes the optical constant including the refractive index increment $(\partial n/\partial c_p)$. The refractive index increment at a constant salt concentration of 0.2 M NaCl was determined as 0.191 (ml/g) (unpublished results). The concentration c_p was expressed in g/ml referred to sodium salt of the polymer.

Ion-exchange chromatography was carried out on a DEAE-Sephacel (Pharmacia, particle size 40—150 μm) column (ϕ=1.6 cm, l=90 cm) at 25±0.5 °C. Gel permeation chromatography was carried out on a Sephadex G-75 column (ϕ=1.5 cm, l=85 cm) at 25±2 °C. In both chromatographic runs, the effluent was monitored by ultraviolet absorption at 220—235 nm (depending on the applied amount) on a Shimadzu UV-200 S spectrophotometer using a flow cell of 1 cm light path.

Polymer concentration is expressed in residue molarity C_p(N) and 20 mM (1 M=1 mol dm^{-3}) $NaClO_4$ solutions were used as a solvent throughout, unless otherwise stated. Solutions were mostly prepared from the solutions of neutral pH by the addition of HCl. Sometimes, solutions were prepared by dilution. In this case pH changed on dilution and the pH was readjusted to the same value as that before dilution.

Results

Molecular Weight Distributions of Samples. The results of the light scattering measurements on two samples SMA and SMA-2 in their fully charged state in 0.2 M NaCl solutions are given in Fig. 1. Molecular weights and the degrees of polymerization (DP) (in parentheses) were calculated as $(3.1\pm0.2)\times10^3$ (17 ± 1) and $(3.7\pm0.2)\times10^3$ (20 ± 1) for sample SMA and SMA-2, respectively. These values will be increased slightly if the effect of dialysis on the value of the refractive index increment is taken into consideration. Ion-exchange chromatography on DEAE-cellulose and

gel permeation chromatography on Sephadex G-75 were carried out on these two samples to examine the difference in their molecular weights more closely, although these measurements provide rather qualitative information. In Fig. 2(A), the elution patterns on a DEAE-cellulose column at an ionic strength of 0.56 M (0.55 M NaCl+phosphate buffer pH 7.4) are shown for the two samples. The peak position of sample SMA-2 is slightly shifted toward higher molecular weights as compared with that of sample SMA. A shoulder near V_e=250 ml is significant in the case of sample SMA-2.

As shown in Fig. 2(A), the main components constituting these two samples have nearly identical molecular weights but a considerable fraction of longer chains is

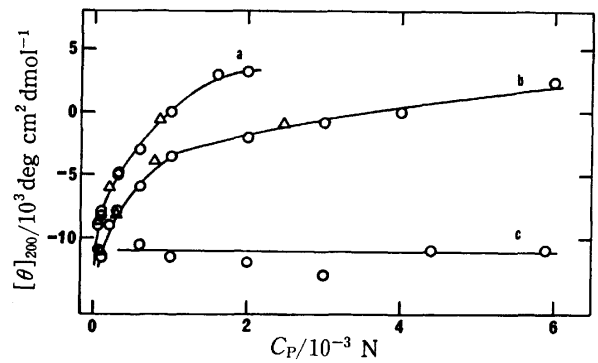

Fig.4. Concentration dependence of the residue ellipticity at 200 nm $[\theta]_{200}$ at constant pH. Sample SMA. pH: (a) 3.30±0.05 (●) and 3.45±0.05 (open symbols) in 20 mM $NaClO_4$, (b) 3.60 in 20 mM $NaClO_4$, and (c) 4.00±0.08 in 10 mM acetate buffer. Triangles refer to the solutions prepared by dilution from the solution of the highest concentration at a given pH.

contained in sample SMA-2. In Fig. 2(B) the elution patterns of the two samples in 0.2 M NaCl solutions on a Sephadex G-75 column are given. The peak positions are V_e=95.4 ml and 94.3 ml for samples SMA and SMA-2, respectively. The distribution shifts only slightly toward higher molecular weights for sample SMA-2 compared to sample SMA. All these three independent measurements, light scattering, ion-exchange chromatography, and gel permeation chromatofraphy, gave consistent results.

Concentration Dependent Conversion at Constant pHs.

In Fig. 3, selected CD spectra of sample SMA at a constant pH of 3.45 in 20 mM $NaClO_4$ solutions are shown for different concentrations. An isodichroic point near 218 nm exists at all concentrations examined at pH 3.45 as well as at pH 3.30 and 3.60 (not shown). The presence of an isodichroic point suggests that charges of each polymeric species are kept constant irrespective of the polymer concentration. This result contrasts with that obtained in the previous study where dilution at a constant degree of neutralization caused enhanced ionization at extremely low concentrations.[2] Further, the p.esence of an isodichroic point shows that the stacking of the pleated sheets does not occur appreciably.[4]

In Fig. 4, the residue ellipticities at 200 nm, $[\theta]_{200}$, are shown at three different pHs, 3.30, 3.45, and 3.60, as functions of the polymer concentration. The variation of pH was within 0.05 in every case. In Fig. 4 the data obtained in 10 mM acetate buffer (pH=4.00±0.08) are also shown. Reversible conversion is shown both at pH 3.45 and 3.60, as expected from the results of the previous study.[2] Further, in 20 mM $NaClO_4$ solutions it was shown that electrostatic interaction among polyion species was negligible due to shielding effect.[2] Accordingly, the concentration dependent conversion shown in Fig. 4 deserves quantitative analyses to estimate the free energy of association, which in turn can be related to the stability of the intermolecular β-structure.

As seen in Fig. 4, the β-structure is favored at lower pHs if compared at a constant concentration. At the

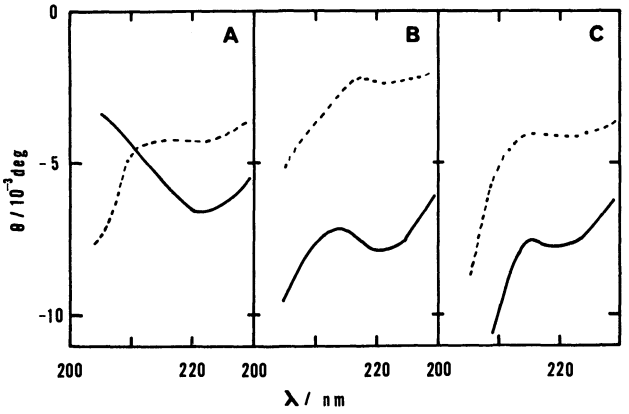

Fig. 6. CD spectra of the solutions at low pHs in 20 mM $NaClO_4$ before and after filtration by membrane filter. Sample: SMA. Solid curves: solutions before filtration Dotted curves: solutions after filtration. Ordinate gives the ellipticity. (A) Initial concentration 5.0×10^{-4} N, pH 3.45, cell length 5 mm. (B) Initial concentration 1.5×10^{-4} N, pH 3.45, cell length 1 cm. (C) Initial concentration 1.5×10^{-4} N, pH 3.60. cell length 1 cm.

same time, solubility decreases from about 6×10^{-3} N at pH 3.60 to about 2×10^{-3} N at pH 3.45 and 3—5×10^{-4} N at pH 3.30. It is to be noted that in Fig. 4 the data obtained at pH 3.30 and at 3.45 are identical within experimental error. This coincidence indicates that the effects of electrostatic interactions on the conversion can be approximately neglected at these pHs, although solubility still depends on the value of pH. On the other hand, it is necessary to separate the electrostatic contribution from the data at pH 3.60 in order to obtain the nonelectric interactions responsible for the β-formation.

The concentration dependent conversion at pH 3.60 was examined for two samples of slightly different molecular weights, SMA and SMA-2. A large difference was found between these two samples as is shown in Fig. 5. As shown in Fig. 2(A), sample SMA-2 contains longer chains much more than sample SMA. These components can form the intermolecular β-structure not only with themselves but also with shorter chains. In other words, the association occurs among chains of different lengths and long chain components act as nuclei for short chain components. This result suggests that the conversion is sensitive to the molecular weight distribution of used samples. From these results, we have to conclude that the extent of the polydispersity of sample SMA-2 is too broad to allow an evaluation of the type of assocation as well as an exact free energy change. It is also uncertain whether the molecular weight distribution of sample SMA is narrow enough for these evaluations.

The light scattering measurements were also carried out on the solutions of sample SMA at low pHs, 3.60 and 3.45, in order to evaluate the aggregation numbers However, a considerable decrease of the polymer concentration was found after solutions were passed through the measuring assembly.

In Fig. 6(A) results obtained for the solution (pH= 3.45, $C_p=5.0\times10^{-4}$ N) are shown. After filtration, the CD spectra (a dashed curve) show a disordered state. while the CD spectra of the solution before filtration show the presence of the β-structure. This kind of change was thought due to the presence of large aggreates which were filtered off. Such an interpretation has been widely accepted since the report of Li and Spector on poly(L-lysine).[5] However, in the present samples, we can prepare non-charged polymer in disordered state and hence we can examine the effects of charge density independently of the aggregation. Such examination cannot be carried out for long chain polymers. At the polymer concentration of 1.5×10^{-4} N most of the polymers are in disordered state at pH 3.45, as easily confirmed from Fig. 4. The decrease of concentration was even pronounced for this solution (pH= 3.45, $C_p=1.5\times10^{-4}$ N) as shown in Fig. 6(B). It is now clear that the decrease of polymer concentration in the present case is a direct consequence of low charge densities rather than due to the presence of large aggregates. From the data of Figs. 6(A) and (B), we calculated the final concentrations as 3.6×10^{-4} N and 4.4×10^{-5} N, respectively. Accordingly, the extent of the concentration decrease became relatively small as the initial concentration increased. In Fig. 6(c), the results on the solution (pH=3.60, $C_p=1.5\times10^{-4}$ N) are shown. The final concentration was 8.1×10^{-5} N. When the results in Figs. 6(B) and (C) are compared, the concentration decrease becomes considerably small as pH increases from 3.45 to 3.60. At neutral pH, the light scattering measurements can be performed without trouble as revealed in Fig. 1.

A Simple Analysis of the Concentration Dependence of the CD Data. A simple analysis of the CD data given in Fig. 4 is considered in the present section. These data give the first example for the conversion between the intermolecular β-structure and the disordered state in aqueous solutions.

We consider mainly the data of sample SMA at pH 3.30 and 3.45, which can be approximated to the conversion of noncharged polymers. For the growth of the pleated sheets consisted of noncharged polypeptides, it is a reasonable assumption that the association takes place with a single association constant K

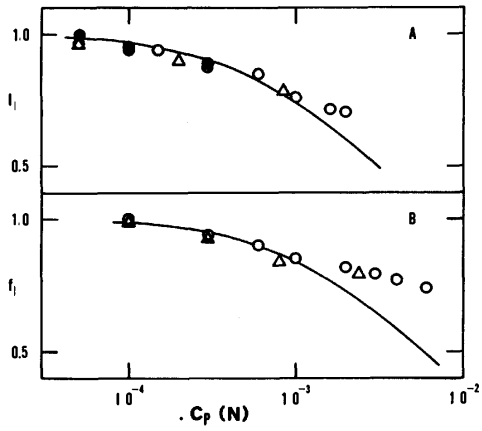

Fig. 7. Fraction of unassociated polymer f_1 as functions of polypeptide concentration C_p at constant pHs in $NaClO_4$ solutions. Sampe: SMA. pH: (A) 3.30(●) and 3.45 (open symbols) and (B) 3.60. Triangles have the same meaning as in Fig. 4. Solid curves are drawn according to Eq. 3 for $K=1.82\times10^2$ N^{-1} (A) and 1.00×10^2 N^{-1} (B).

for any successive addition except dimerization.

$$A_{i-1} + A \overset{K}{=} A_i \qquad (i \geqq 3)$$
$$2A \overset{K^2}{=} A_2 \qquad (i = 2) \qquad (2)$$

The dimerization constant is here approximated as K^2, neglecting the additional contribution for dimerization Then, the fraction f_1 of unassociated polymer is given as follows.[6]

$$KC_p = KC_pf_1 + (KC_p)^2f_1^2(2-KC_pf_1)(1-KC_pf_1)^{-2} \qquad (3)$$

Accordingly, if f_1 is observed as a function of C_p, then we can find a value of K from the concentration C_p^* which satisfies a relation $KC_p^*=1$. At $C_p=C_p^*$, $f_1=(3-5^{1/2})/2$.

With the assumption that all aggregates are in register, we can put $f_1=f_c$, where f_c denotes the fraction of residues in the disordered state. This all-or-none model represents one of the simplest pictures of the pleated sheet proposed by Pauling and Corey.[7] The fraction f_c can be calculated as follows from the CD data.

$$f_1 = f_c = \frac{3.8\times10^4 - [\theta]_{200}}{4.9\times10^4} \qquad (4)$$

Here 3.8×10^4 stands for the residue ellipticity of the β-structure at 200 nm. This value was chosen when available data on the β-structure of the pesent polypeptide were taken into consideration.[1,2,4,8] The residue ellipticity for the disordered state at 200 nm for this pH range (3.30—3.45) was chosen as -1.1×10^4, as shown in Figs. 4 and 5. Accordingly, the figure 4.9×10^4 represents the difference in the residue ellipticity at 200 nm between the β-structure and the disordered state.

In Fig. 7(A), f_1 is plotted against log C_p for the data at pH 3.45, (open symbols) and pH 3.30 (closed symbols). The solid line is drawn assuming that K is 1.82×10^2 N^{-1}. The fit is rather satisfactory. If we take the degree of polymerizationas 20, then K is 3.6×10^3 M^{-1}. The corresponding standard free energy change per polymer ΔG° and that per residue ΔG°(res) are:

$$\Delta G^\circ = -RT\ln K = -20.5 \text{ kJ/mol}$$
$$(-4.9\times10^3 \text{ cal/mol})$$
$$\Delta G^\circ(\text{res}) = \Delta G^\circ/20 = -1.05 \text{ kJ/mol}$$
$$(-2.5\times10^2 \text{ cal/mol}).$$

It is to be noted that the value of ΔG° depends on the concentration unit employed.

In Fig. 7(B) the data at pH 3.60 are analyzed similarly. Deviation from the assumed model is pronounced. This is reasonable, since electrostatic energy of the aggregate cannot be expected to increase linearly with its aggregation number. In other words, the "isodesmic" model is a poor approximation for the aggregation of charged particles.

In the previous study,[2] the converion was examined at a constant degree of neutralization α' rather than at a constant pH. When these data were analysed in the same way, they gave a good fit as shown in Fig. 8. At present, it is not certain whether the good fit is only incidental or not. For the assumed degree of polymerization of 20, the obtained values of $K(10^3$ $M^{-1})$ were 3.8, 3.2, and 2.2 for $\alpha'=0$, 0.15 and 0.25, respectively.

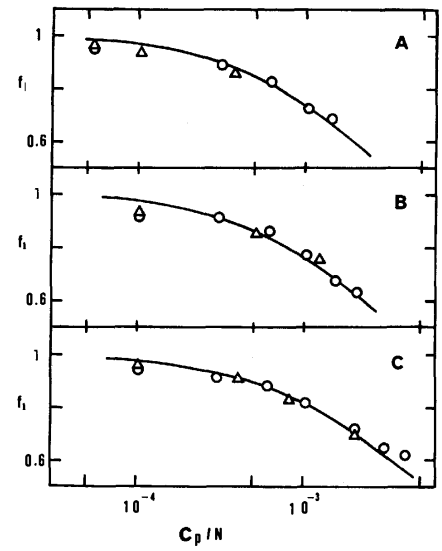

Fig. 8. Fraction of unassociated polymer f_1 as functions of polypeptide concentration C_p at constant degrees of neutralization in 20 mM $NaClO_4$ solutions. Sample SMA. Degrees of neutralization: (A) 0, (B) 0.15, and (C) 0.25. Triangles have the same meaning as in Fig. 4. Solid curves are drawn according to Eq. 3 for $K=1.92\times10^2$ N^{-1} (A), 1.67×10^2 N^{-1} (B), and 1.11×10^2 N^{-1} (C).

Discussion

The non-electrostatic free energy difference between the β-structure and random coils has been estimated from potentiometric titrations of ionizable polypeptides.[9-11] Reported values (per mole of residue) are: −1.25 kJ (−300 cal) for poly(L-tyrosine),[9] −590 J (−140 cal) for poly(L-lysine),[10] and −3.09 kJ (−740 cal) and −4.10 kJ (−980 cal) for poly(*S*-carboxymeth-

yl-L-cysteine) and poly(*S*-carboxyethyl-L-cysteine).[11] In most cases, however, the free energy change evaluated from the potentiometric titrations includes the contributions from various processes; chain folding and aggregation occur often simultaneously and stacking of the pleated sheets occurs as the amount of the β-structure increases. Accordingly, the free energy change cannot be identified with the standard free energy change of any single process, unless the conversion is confirmed to occur as the chain folding process in the absence of aggregation or as the intermolecular association without chain folding process. Plausible but indirect arguments for the absence of aggregation have been provided only for the case of poly(L-tyrosine)[9,12] and poly(*S*-carboxymethyl-L-cysteine).[1]

The stability of the β-structure can be best evaluated if the equilibrium constant for a unimolecular transconformation is obtained in the absence of aggregation. However, this has not been done until now.

In the present study, a value of about -1.1 kJ (-350 cal) was obtained as the standard free energy of association. With this value alone, it is difficult to separate the contribution of a propagation step (or equivalently the formation of a number of hydrogen bonds between peptide groups) from that of an association step. However, when the standard free energies of association are obtained with other samples of different chain lengths, the contributions from the two steps can be separated.

In the case of the intermolecular β-structure, the type of association has to be determined in order to define proper equilibrium constants. It is necessary, therefore to measure average aggregation number in addition to the weight fraction of the residues in the β-structure. Nevertheless, the study of the intermolecular β-structure seems promising for the evaluation of the stability of the β-structure, in contrast to the difficulties to avoid aggregation in the study of the intramolecular β-structure.

Magnetic-superexchange Interactions of Uranium(IV) Chloride-addition Complexes with Amides. I

Chie Miyake,* Yukio Hinatsu, and Shosuke Imoto
Department of Nuclear Engineering, Faculty of Engineering, Osaka University, Suita, Osaka 565
(Received December 7, 1981)

Studies of magnetic susceptibility, χ, from 300 to 2 K on seventeen UCl_4–amide complexes showed that six complexes had maxima in χ between 155 and 82 K. This unusual magnetic behavior occurred only with *N*-methyl or ethyl-substituted amide complexes. Infrared and chemical evidence indicates that these six complexes probably have dimeric structure, in which two U(IV) ions are bridged by the amide ligands. Assuming a dimer structure and a two-spin Heisenberg model with $-2J_{ex}$ of about 90 cm^{-1} for the dimer, the magnetic susceptibilities for the six complexes were calculated in good agreement with the experimental results in the temperature region of the maxima in χ.

Magnetic-exchange interactions at low temperatures in polynuclear complexes of transition metals, especially of dimeric copper(II) complexes, have been extensively studied for thirty years.[1] Similar magnetic behavior of complexes of actinoid ions has been reported previously. Tetrakis(diethylamido)uranium(IV)[2] and tris[bis-(*N*,*N*′-dimethylethylenediamido)]uranium(IV)[3] have dimer and trimer structures respectively, as determined by X-ray-diffraction analysis. In these complexes, magnetic-exchange interactions might be expected to occur, but their magnetic susceptibility increases down to the temperature of liquid helium without showing any magnetic susceptibility maxima. Recently, the superexchange phenomena have been first observed by us on uranium(IV) chloride-addition complexes with amides.[4]

This paper will report on the temperature-dependent magnetic susceptibilities of uranium(IV) chloride-addition complexes with seventeen amide molecules, among which six complexes showed a maximum in their magnetic susceptibility-*versus*-temperature curves that indicates intradimer superexchange interaction. Some results of the infrared-absorption measurements are reported.

Experimental

Table 1 lists the full names of the complexes studied, the abbreviated formula, and the substituents on the carbon and nitrogen atoms of each amide.

Materials. Reagent-grade amides were used as purchased without any further purification. The anhydrous uranium tetrachloride was synthesized by the solid-vapor-phase reaction of uranium dioxide and carbon tetrachloride at 500 °C.[5] The cesium hexachlorouranate was obtained as a crystalline powder by dissolving cesium chloride in a hydrochloric acid solution of uranium tetrachloride and by then slowly evaporating the water.[6]

Preparation of Complexes. *UCl_4·2.5DEA*: A five-fold excess of diethylacetamide was added to a hot acetone solution of Cs_2UCl_6, thus precipitating cesium chloride. After filtering the precipitates, the oily product was obtained by adding isopentane to the filtrate. The oil was dissolved in hot acetone and then precipitated again with isopentane. After several repetitions of this procedure, a green solid was obtained: it was

dried over P_2O_5.

UCl_4·3DPA: Oily solids were obtained from an acetone solution of anhydrous uranium tetrachloride by adding, successively, a dichloromethane solution of the ligand and then petroleum ether. The precipitates were dried under a vacuum.

UCl_4·3MFA and UCl_4·4BAN: Oily solids were obtained from acetone solutions of anhydrous uranium tetrachloride by adding an acetone solution of the ligand. Then the precipitates were dried under a vacuum.

UCl_4·4BAM: Oily solids were precipitated from an acetone solution of anhydrous uranium tetrachloride by adding, successively, a small excess of benzamide in the acetone solution and then petroleum ether. The product was dried under a vacuum and stored in a vessel with P_2O_5.

UCl_4·4AAN: An excess of an acetone solution of acetanilide was added to the acetone solution of uranium tetrachloride, and the product was precipitated by adding isopentane. The precipitates were dried under a vacuum.

UCl_4·4MF: Precipitates were obtained from an ethyl acetate solution of anhydrous uranium tetrachloride by adding an ethyl acetate solution of the ligand. After washing with ethyl acetate, the precipitates were dried in a vacuum.

UCl_4·6AcA: An acetone solution of the ligand and then isopentane was added to an acetone solution of anhydrous uranium tetrachloride to precipitate the product. The precipitates were dried in a vacuum.

UCl_4·2.5DMA,[7] UCl_4·2.5DMF,[8] UCl_4·3DMBA,[9] UCl_4·3MAA,[9] UCl_4·4DPF,[9] UCl_4·4MA,[10] UCl_4·4EA,[11] UCl_4·6AA,[7] and UI_2Cl_2·5DMA[12] were synthesized according to the methods previously reported.

Chemical Analysis. The uranium content was determined gravimetrically by the ammonium method,[13] while the chlorine content was determined by potentiometric titration with a standard $AgNO_3$ solution. The carbon, hydrogen, and nitrogen contents were determined with the Yanagimoto CHN coder, MT-2. The results of elemental analyses are listed in Table 2.

Magnetic Measurement. The magnetic susceptibilities were measured with a torsion balance from room temperature down to 2 K, using powdered $Co[Hg(SCN)_4]$ as a standard[14] and with $\chi_g = 16.44 \times 10^{-6}$ emu g^{-1} (emu $g^{-1} \times 4\pi 10^{-3} \rightarrow m^3$ kg^{-1}) at 20 °C. The temperature was measured with a Au-Co/Cu thermocouple for the range from room termperature to 20 K and with a carbon resistor below 32 K. To test for ferromagnetic impurities in the samples, the dependence of the magnetic susceptibility on the magnetic field was measured at 400, 1470, 3320, 5400, and 7200 Oersted at room temperature, 77 and 4.2 K.

Table 3 lists the values of the diamagnetic-susceptibility correction used in calculating the paramagnetic susceptibility of complexes from the experimentally measured values.[15]

Infrared Absorption. The infrared-absorption spectra were recorded on HITACHI-225 Spectrophotometer using a prism disk of KRS-5 (TlBr-TlI), either as neat compounds or as Nujol mulls. The spectra were also measured in 0.1% CCl_4 solution, if required.

Results and Discussion

Figure 1 shows the magnetic susceptibility *versus*

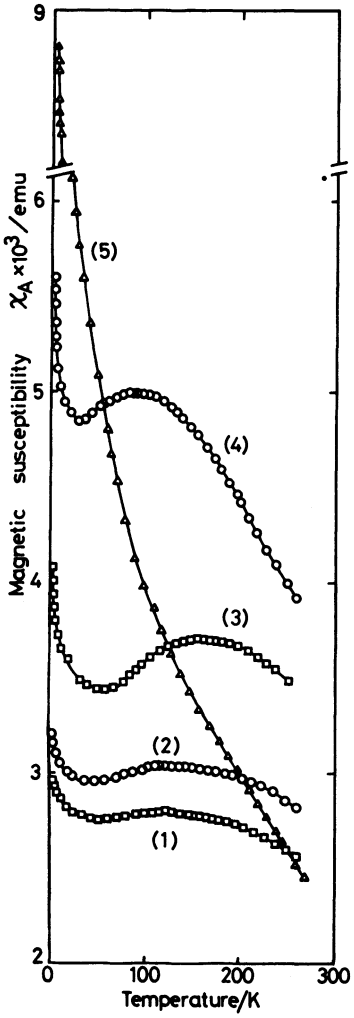

Fig. 1. Temperature dependence of magnetic susceptibility per gram atom.
(1): $UCl_4 \cdot 2.5DMA$, (2): $UCl_4 \cdot 2.5DEA$, (3): $UCl_4 \cdot 4MA$, (4): $UCl_4 \cdot 4EA$, (5): $UCl_4 \cdot 3DPA$. (emu $mol^{-1} \times 4\pi \times 10^{-6} \rightarrow m^3\ mol^{-1}$).

temperature curves for $UCl_4 \cdot 2.5DMA$, $UCl_4 \cdot 2.5DEA$, $UCl_4 \cdot 4MA$, $UCl_4 \cdot 4EA$, and $UCl_4 \cdot 3DPA$. Figure 2 also shows the magnetic susceptibility *versus* temperature curves for $UCl_4 \cdot 6AcA$, $UCl_4 \cdot 6AA$, and $UI_2Cl_2 \cdot 5DMA$. Figure 3 presents the magnetic susceptibility *versus* temperature curves for $UCl_4 \cdot 3DMBA$, $UCl_4 \cdot 3MAA$, $UCl_4 \cdot 4BAN$, $UCl_4 \cdot 4BAM$, and $UCl_4 \cdot 4AAN$. As may be seen from Fig. 1, broad but clearly distinguishable maxima appear at 121.8, 112.0, 155.1, and 81.8 K for $UCl_4 \cdot 2.5DMA$, $UCl_4 \cdot 2.5DEA$, $UCl_4 \cdot 4MA$, and $UCl_4 \cdot 4EA$ respectively, while for $UCl_4 \cdot 3DMBA$ and $UCl_4 \cdot 3MAA$ of Fig. 3, the maxima appear at 134.2 and 142.0 K respectively. For the other eleven complexes, the magnetic susceptibilities monotonically ncrease down to the temperature of liquid helium (see also Fig. 6). The magnetic-susceptibility maxima shown in Figs. 1 and 3 have not previously been observed for uranium(IV) complexes and can not be explained by the usual concept of paramagnetic susceptibility. As has previously been reported,[4] magnetic-exchange interaction is believed to occur between uranium ions in these complexes. The additional maximum at a temperature lower than the 134.2 K of the curve of $UCl_4 \cdot 3DMBA$ in Fig. 3 might be due to the existence of another kind of magnetic-exchange interaction between uranium ions. According to Bagnall *et al.*, the series of *N,N*-dimethylacetamide addition complexes of uranium(IV) are probably dimers, judging from their behavior in preparation and the measurements of their electric conductivities.[7,12,16] Bagnall proposed that $UCl_4 \cdot 2.5DMA$ is a dimer with one ligand bridge and two chlorine ion bridges,[12] while Gans proposed that it had three ligand bridges.[17] Uranium(IV) chloride-*N,N*-dimethyl-*α,α*-diphenylacetamide (1/2.5) shows temperature-independent paramagnetism; this result can be explained by considering a dimeric structure with one ligand bridge and two chlorine-ion bridges per dimer.[9] Although the crystal structure of UCl_4-addition complexes of amides has not yet been determined by X-ray diffraction, $UCl_4 \cdot 2.5DMA$ and $UCl_4 \cdot 2.5DEA$ should have polynuclear structures, probably a dimer structure, judging from their molecular formula. On the other hand, $UCl_4 \cdot 3Me_2SO$ is known

by X-ray diffraction to have an ionic-pair structure, $[UCl_2(Me_2SO)_6]^{2+}[UCl_6]^{2-}$.[18] We have recently observed its magnetic susceptibility to increase monotonically down to 4.2 K and explained its magnetic susceptibility as a sum of those of the individual ions on the basis of the crystalline-field theory.[19]

Assuming that the complexes with maxima have dimer structures, and that magnetic-superexchange interaction operates between the central uranium ions, we can propose an explanation for the anomalous magnetic behavior. According to the Heisenberg model, the exchange-interaction Hamiltonian for a two-spin system is expressed by Eq. 1;

$$H = -2J_{ex}\vec{S}_1\cdot\vec{S}_2, \quad (1)$$

where J_{ex} is the exchange integral for the intradimer interaction between uranium ions with spin angular momenta, $\vec{S}_1$ and $\vec{S}_2$. When the uranium(IV) ion has

a non-degenerate ground state, $S_1=S_2=1$. From the well-known van Vleck equation[20] and Eq. 1, the magnetic susceptibility per gram of the atom is given as:

$$\chi_A = \frac{Ng^2\mu_B{}^2}{kT}\frac{5+\exp(-4J_{ex}/kT)}{5+3\exp(-4J_{ex}/kT)+\exp(-6J_{ex}/kT)}+N\alpha. \quad (2)$$

The value of J_{ex} can be obtained by the relation to the temperature of maximum susceptibility. $N\alpha$ is estimated by extrapolating the magnetic-susceptibility curve to the higher-temperature region (Table 4). Putting values of J_{ex} and $N\alpha$ and $g=2$ in Eq. 2, the magnetic susceptibilities per gram of the atom were calculated: they are shown in Figs. 4 and 5. The calculated curves of Fig. 5 include the effect of the molecular field; they will be discussed in a paper (Part II) to be published later. The discrepancy in the lower-temperature region might be partly due to paramagnetic impurities, such as a monomer, and partly due to the neglect of the orbital contribution. For the temperature region where the data fit the Curie-Weiss law, the Weiss constant and the effective Bohr magneton number are listed in Table 5.

As is shown in Table 6(a), the complexes with the maxima in their magnetic susceptibility versus temperature curves have at least one methyl or ethyl substituent on the amide nitrogen. (See the complexes combined by arrows.) Figure 6 shows the dependence of the magnetic susceptibility on the temperature for four complexes having no substituent on the carbon of amide. None of the four complexes exhibits a maximum similar to those shown in Figs. 1 and 3. Substitution on the carbon of amide is apparently necessary for the complexes to exhibit a maximum in the magnetic susceptibility *versus* temperature curve. (Note the relation in Table 6(b) and recall the experimental susceptibility.) The facts that the kind of substituent on the amide ligand is responsible for the magnetic-exchange interaction and that the value of J_{ex} of the amide complexes has some significance in the comparison of the strength of exchange interaction among the complexes suggest that the amide ligand is involved

in the magnetic-exchange interaction pathway between uranium(IV) ions.

The coordination of the amide molecule was further examined on the basis of the infrared spectra. The amide with the skeleton of RCONHR′ has the characteristic vibration of a peptide, constituted of six amide bands, *i.e.*, amide-band frequencies I—VI. Table 7 shows the results of the measurements of three amide bands, I, II, and III, of free amides and complexes. Amide I absorption is assigned 80% to the C=O stretching vibration; Amide II, 60% to the bending vibration in the plane of N–H and 40% to the C–N stretching vibration, and Amide III, 40% to the C–N stretching vibration and 30% to the bending vibration in the plane of N–H.[21] If the nitrogen of the amide molecule coordinates directly to the uranium ion, the absorptions of Amides II and III are expected to shift toward a lower frequency. In UCl_4·4MA and UCl_4·4EA (with the magnetic susceptibility maxima), and UCl_4·4MF (without the maximum), the directions of the shifts are opposite one another. This indicates a difference in the coordination of amides, suggesting the possibility of coordination through nitrogen in the former case. The N–H absorption for the ligand is known to shift to about 200 cm^{-1} lower than that in the free ligand due to the strong hydrogen bonding. In all three complexes, this absorption shifts to a lower frequency (Table 8). Furthermore, in UCl_4·4MA and UCl_4·4EA, the absorption shifts to a lower frequency, even compared with the N–H stretching frequency in the hydrogen-bonding state, but in UCl_4·4MF the shift is to a higher frequency. Accordingly, in the former two complexes the N–H bonding becomes weaker with complex formation than the strength of N–H bonding, which contributes to the hydrogen bonding. These data also support the possibility of nitrogen coordination. On the other hand, the frequencies of Amide I all shift to lower frequencies, indicating that oxygen

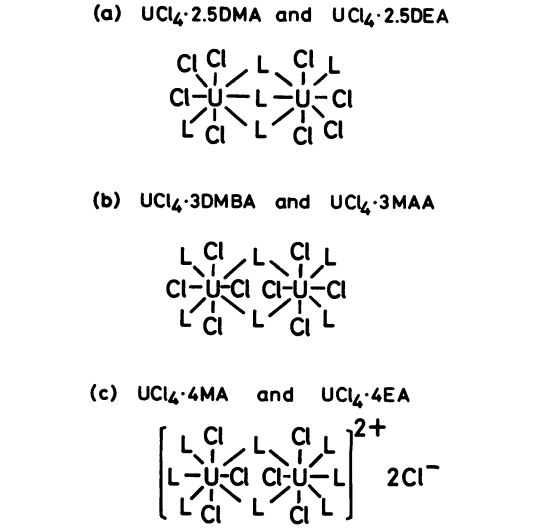

Fig. 7. Structural formulas suggested for dimers which are considered to be octa-coordinated, according to the references 7, 12, 17) for (a) and 9, 12) for (c). Amide molecules are represented as L.

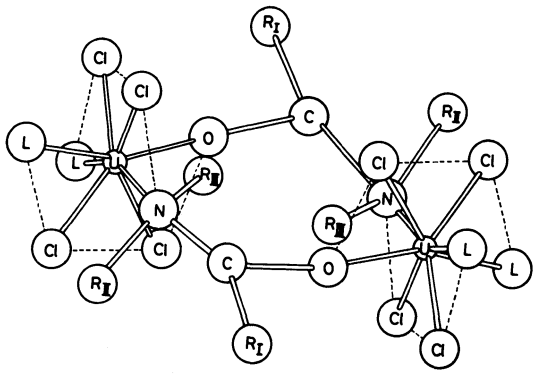

Fig. 8. A coordination diagram for UCl_4·3L type complexes by both oxygen and nitrogen atoms. Amide molecules which do not bridge are represented as L. Broken line shows dodecahedral coordination.

coordinates to the uranium ion. In $Co(DMA)_4(ClO_4)_2$, both oxygen and nitrogen of *N*,*N*-dimethylacetamide are reported to coordinate to the central metal ion.[22] Taking the results of magnetic behavior and infrared absorption into account, both oxygen and nitrogen are considered to coordinate to the uranium ion in UCl_4·4MA and UCl_4·4EA.

It is noteworthy that, in two pairs of a methyl derivative and an ethyl derivative of a given amide, UCl_4·2.5DMA and UCl_4·2.5DEA, and UCl_4·4MA and UCl_4·

4EA, the temperatures of the χ_{max} of the methyl derivatives are higher than those of the corresponding ethyl derivatives. This is consistent with the facts that an amide ligand contributes to the pathway between uranium ions and that the effect of the methyl substituent is predominant over the ethyl substituent in electron-releasing property. Concerning the origin of bridging, these facts indicate that, as the electron dinsity on the nitrogen atom is enhanced by the methyl (ethyl) group, in the case of a large metal ion such as uranium, both oxygen and nitrogen can coordinate to the metal ion; this amide molecule then acts as a bridging molecule. The values of the magnetic susceptibility of methyl derivatives are thus smaller than those of the corresponding ethyl derivatives. Furthermore, the value of the magnetic susceptibility of $UCl_4 \cdot 3MAA$ is smaller than that of $UCl_4 \cdot 3DMBA$, and the temperature of χ_{max} is higher in the former than in the latter. This fact can be explained by the existence of an antiferromagnetic interaction in the dimer.

In conclusion, the complexes which have the maximum of magnetic susceptibility *versus* temperatur curve are considered to be dimers (see Fig. 7), and the pathway for the magnetic-superexchange interaction is considered to be a polyatomic bridging of the amide molecule, probably by coordinating in the manner of U–N–C–O–U, as is shown in Fig. 8.

Magnetic-superexchange Interactions of Uranium(IV) Chloride-addition Complexes with Amides. II. Complexes with Lactams

Chie MIYAKE,* Yukio HINATSU, and Shosuke IMOTO
Department of Nuclear Engineering, Faculty of Engineering, Osaka University, Suita, Osaka 565
(Received December 14, 1981)

The magnetic susceptibilities of five cyclic amide (lactam)-addition complexes of uranium(IV) chloride were measured between room temperature and 2 K. Magnetic-exchange interaction was found only for *N*-methyl-substituted amide complexes, and a dimer structure was assumed for them on the basis of their chemical properties. Treating interdimer interaction with a molecular-field approximation, the magnetic susceptibilities were calculated to be in good agreement with the experimental results in the temperature region of the maxima in χ_A. The transmission of antiparallel spin coupling *via* the π orbitals of the bridging amide ligands is proposed to explain the strong intradimer superexchange interaction for the uranium(IV) chloride–amide complexes with the magnetic-susceptibility maximum.

In the preceding paper,[1] a series of amide-addition complexes of uranium(IV) chloride, $UCl_4 \cdot nL$ (L= $R_1CONR_2R_3$), were prepared, and their magnetic susceptibilities measured. Among the complexes studied, six showed a magnetic-exchange interaction and their magnetic-exchange parameters were calculated, assuming a dimer structure from their chemical properties. The effects of substituents on the bridging amide ligands were discussed.

To elucidate further the effects of the substituents, five uranium(IV) chloride-addition complexes were prepared with lactam (cyclic amide) ligands. Magnetic-exchange interactions were found only for complexes with a methyl group substituted with hydrogen on the amide nitrogen. This paper will report on the magnetic-susceptibility results, and a mechanism for the transmission of spin-exchange coupling in the complexes with *N*-methyl substituents is proposed.

Experimental

Reagents. Reagent-grade 5-, 6-, and 7-membered lactams and *N*-methyl-substituted 5- and 7-membered lactams were purchased from the Nakarai Chemical Industry Co., Ltd., and were used without further purification. Uranium(IV) chloride was prepared by passing carbon tetrachloride vapor over uranium dioxide at 500 °C in a vacuum.[2]

Preparations. Uranium(IV) chloride-*γ*-butyrolactam (1/4), $UCl_4 \cdot 4BuL$, and uranium(IV) chloride-*N*-methyl-*γ*-butyrolactam (1/2.5), $UCl_4 \cdot 2.5MBuL$: An oily product was obtained from an acetone solution of anhydrous uranium(IV) chloride by adding, successively, an excess acetone solution of the ligand and isopentane. After washing with ethyl acetate, the precipitates were rapidly dried in a vacuum and then kept over P_2O_5 for about a week.

Uranium(IV) chloride–*δ*-valerolactam (1/4), $UCl_4 \cdot 4Val$,[3] uranium(IV) chloride–*ε*-caprolactam (1/4), $UCl_4 \cdot 4CaL$,[4] and uranium(IV) chloride–*N*-methyl-*ε*-caprolactam (1/2.5), $UCl_4 \cdot 2.5MCaL$,[4] were synthesized according to the methods previously reported.

Analytical. The uranium content was determined gravimetrically as U_3O_8.[5] The chlorine content was determined by potentiometric titration with a standard $AgNO_3$ solution. The carbon, hydrogen, and nitrogen contents were determined with a Yanagimoto CHN coder MT-2. The analytical results are shown in Table 1.

Magnetic Measurements. The magnetic susceptibilities were measured by the Faraday method from 2 to 300 K on powder samples sealed in quartz tubes. The apparatus was calibrated with $Co[Hg(SCN)_4]$ as a standard.[6] The temperature was measured with a Au-Co/Cu thermocouple for temperature above 20 K and with a carbon resistor below 32 K. The dependence of the magnetic susceptibility on the mangetic-field strength was measured at field strengths of 400, 1470, 3320, 5400, and 7200×10^{-4} T at room temperature, the temperature of liquid nitrogen, and the temperature of liquid helium. No dependence of the susceptibilities on the magnetic field was found. The experimental values for magnetic susceptibilities were corrected for the diamagnetism of the sample using the values reported by Dawson,[7] Pascal's constants, and their constitutive correction.[8] The values of the diamagnetic corrections are listed in Table 2.

Rusults and Discussion

Unsubstituted lactams form $UCl_4 \cdot 4L$ complexes (L= BuL, VaL, and CaL), and the U(IV) ion probably has a coordination number of eight, the most common coordination number for U(IV) complexes. *N*-methyl-substituted lactams coordinate to form $UCl_4 \cdot 2.5L$ complexes (L=MBuL and MCaL), in which the lactam ligands probably bridge between U(IV) ions.

Figure 1 shows the magnetic susceptibility *vs.* temperatue curves for the five lactam complexes. $UCl_4 \cdot$

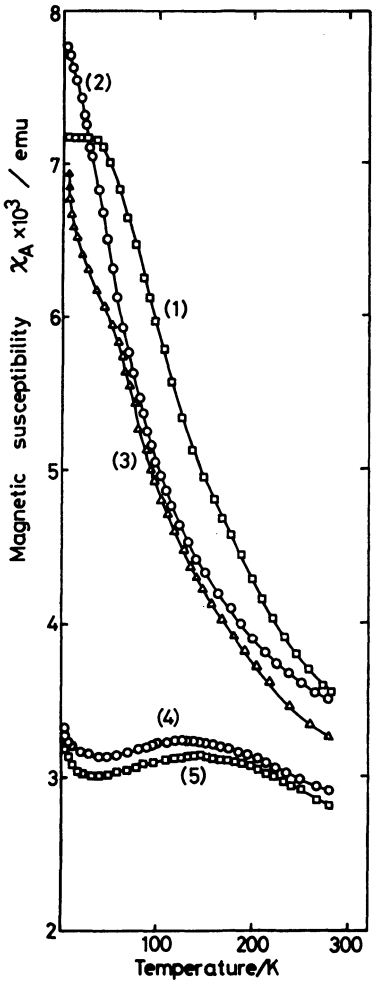

Fig. 1. Temperature dependence of magnetic susceptibility per gram atom. (1), UCl_4·4CaL; (2), UCl_4·4BuL; (3), UCl_4·4VaL; (4), UCl_4·2.5MBuL; (5), UCl_4·2.5MCaL.

2.5MBuL and UCl_4·2.5MCaL differ from the other three complexes having broad susceptibility maxima at 127 and 146 K respectively. Unsubstituted lactam complexes show different magnetic behavior at lower temperature, but show increasing susceptibilities with a decrease in the temperature from room temperature down to the temperature of liquid helium. Their paramagnetism can be explained by a model based on the crystalline field on the U(IV) ion.

Table 3 lists the Weiss contants and the effective Bohr magnetons in the temperature region where the data fit the Curie-Weiss law. The magnetic susceptibilities of UCl_4·2.5MBuL and UCl_4·2.5MCaL show maxima, indicating an antiferromagnetic-exchange interaction.

UCl_4·2.5MCaL	230 —r.t.	−387	2.47

a) Curie-Weiss law as $\chi_A = \frac{C}{T-\theta}$.

A dimeric structure for these complexes was assumed from their composition and the dimeric structures of complexes with similar compositions. UCl_4·2.5DMA has been considered to have a dimeric structure from its composition and from the measurement of its electric conductivity.[9–12] For the three bridges between two uranium ions, these are considered to be one ligand bridge and two chlorine ion bridges by Bagnall *et al.*,[12] while three ligand bridges are proposed by Gans.[13] Uranium(IV) chloride–*N*,*N*-dimethyl-*α*,*α*-diphenylacetamide (1/2.5) shows the temperature-independent paramagnetism characteristic of hexacoordinate U(IV) compounds; a dimeric structure with one ligand, dimethyl-diphenyl-acetamide, and two chlorine ions bridging two U(IV) ions has been proposed to account for the magnetic susceptibility.[4] Some transition-metal chloride complexes with lactam are considered to have dimer structures.[14,15] A dimer model is, therefore, assumed for complexes that have a magnetic-exchange interaction.

For the intradimer magnetic-exchange interaction, it is appropriate to use the isotropic spin Hamiltonian:

$$H_{ex} = -2J_{ex}\vec{S_1}\cdot\vec{S_2}, \quad (1)$$

where J_{ex} is the exchange integral for the interaction between uranium ions with spin operators $\vec{S_1}$ and $\vec{S_2}$. As each uranium(IV) ion has two unpaired spins, the spin angular momentum $S_1=S_2=1$. By substituting the energy levels obtained from the spin Hamiltonian (1) into the well-known van Vleck equation,[16] the magnetic susceptibility per gram of the atom is given as:

$$\chi_A = \frac{Ng^2\mu_B^2}{kT}\frac{5+\exp(-4J_{ex}/kT)}{5+3\exp(-4J_{ex}/kT)+\exp(-6J_{ex}/kT)} + N\alpha. \quad (2)$$

The value of $N\alpha$ is estimated by extrapolating the magnetic-susceptibility curve to the higher-temperature region. Then, the value of J_{ex} can be obtained from the temperature of maximum susceptibility. Susceptibilities calculated using these values, and assuming $g=2$ as in Part I, did not agree with the experimental results. Therefore, the effect of interdimer interaction was considered further.

For the complex that has a low symmetry field and $S>1/2$, zero-field splitting must be considered. Ginsberg *et al.* considered the effects of single-ion zero-field splitting on the magnetic susceptibility of nickel dimers.[17] They dealt with interdimer interactions by means of a molecular-field approximation. The Hamiltonian for this interaction is taken as $-2Z'J'_{ex}$

$\vec{S}_z\langle\vec{S}_z\rangle$. Here, $\vec{S}_z$ is the operator for the Z compounent of the dimer total spin, J'_{ex} is the effective interdimer exchange integral, and Z' is the coordination number of the dimer lattice. Therefore, the magnetic susceptibility per gram of the atom is:

$$\chi_A = \frac{Ng^2\mu_B^2}{3k}\left\{\frac{F_1}{T-4Z'J'_{ex}F_1} + \frac{2F'}{1-4Z'J'_{ex}F'}\right\} + N\alpha, \quad (3)$$

where

$$F' = F_2/D + 3C_2^2F_3/(3J_{ex}-\delta) + 3C_1^2F_4/(3J_{ex}+\delta),$$
$$F_1 = \{1 + \exp(4J_{ex}/kT) + 4\exp(4J_{ex}/kT)\exp(D/kT)\}/F_5,$$
$$F_2 = \{2\exp(4J_{ex}/kT)\exp(D/kT) + \exp(D/kT) - 1 - 2\exp(4J_{ex})/kT)\}/F_5,$$
$$F_3 = \{\exp(4J_{ex}/kT) - \exp(J_{ex}/kT)\exp(\delta/kT)\}/F_5,$$
$$F_4 = \{\exp(4J_{ex}/kT) - \exp(J_{ex}/kT)\exp(-\delta/kT)\}/F_5,$$
$$F_5 = 2 + \exp(D/kT) + \exp(J_{ex}/kT)\exp(-\delta/kT) + \exp(J_{ex}/kT)\exp(\delta/kT) + 2\exp(4J_{ex}/kT) + 2\exp(4J_{ex}/kT)\exp(D/kT),$$
$$\delta = [(3J_{ex} + D)^2 - 8J_{ex}D]^{1/2},$$
$$C_1 = 2(2)^{1/2}D/[(9J_{ex}-D+3\delta)^2+8D^2]^{1/2},$$
$$C_2 = (9J_{ex}-D+3\delta)/[(9J_{ex}-D+3\delta)^2+8D^2]^{1/2}.$$

The single-ion zero-field splitting parameter, D, was assigned an initial value of 10 cm^{-1}. The magnetic susceptibilities calculated by Eq. 3 using the parameters listed in Table 4 are shown in Fig. 2. Table 4 also lists the exchange parameters for UCl_4·2.5DMA and UCl_4·2.5DEA. In the temperature region of χ_{max}, the calculated values agreed well with the experimental magnetic susceptibilities. The discrepancy at lower temperatures is partly due to paramagnetic impurities, such as monomers. The calculation of the magnetic susceptibilities was not further refined, since the aim of this work was not a precise fit of the calculations with the experimental results, but the determination of the relation of the magnitude of the exchange parameter with the substituents on the ligand in the amide-addition complexes of UCl_4. It is noteworthy that UCl_4·2.5MBuL, whose χ_{max} temperature is lower than that of UCl_4·2.5MCaL; has a larger χ_{max} than the latter. This fact suggests that intradimer-exchange interaction is antiferromagnetic.

When a hydrogen bonded to a ligand-nitrogen atom is replaced by a methyl group, the number of lactam ligands coordinated with UCl_4 changes from 4 to 2.5 and the magnetic properties suggest intradimer-exchange interaction. Both complexes with half an integer-lactam molecule must be bridged dimers. The methyl group donates electron density to the nitrogen atom of the lactam ligand, so both the nitrogen and the oxygen atoms can bond to the U(IV) ion and the lactam ligand provides a path for the intradimer magnetic-super-exchange interaction.

Table 4. MAGNETIC-EXCHANGE INTERACTION PARAMETERS AND TIP[a] SUSCEPTIBILITIES FOR COMPLEXES

UCl_4·3DPA	(Ph, Ph)		

a) These complexes have been studied in Part I.

Table 5 lists complexes where magnetic-exchange interactions were found in the right-side column, and the remainder of the amide complexes on the left. Table 5 shows the correlation between *N*-methyl (ethyl) substitution and a magnetic-exchange interaction. The carbonyl oxygen of the amide ligand is the principal donor site, and the nonbonding electron pair on the nitrogen delocalizes into a π-molecular orbital involving oxygen, carbon, and nitrogen atoms. When a methyl group is substituted for a hydrogen on the nitrogen atom, the electron density on the nitrogen increases because of the electron-donating property of the methyl group.

For a large metal ion such as uranium, both oxygen and nitrogen coordinate and the amide ligand acts as a bridging group. As the electron-donating power of a methyl group is greater than that of an ethyl group, the temperature of the χ_{max} values of complexes with *N*-methyl-substituted amides is expected to be higher than that of complexes with *N*-ethyl-substituted amides. The experimental results coincide with this expectation. (Compare $UCl_4 \cdot 4MA$ and $UCl_4 \cdot 4EA$ and/or $UCl_4 \cdot 2.5DMA$ and $UCl_4 \cdot 2.5DEA$ in Part I.) It has been reported, on the basis of the vibrational and NMR spectra, that simultaneous coordination through both carbonyl oxygen and amide nitrogen may be present in $[Co(DMA)_6](ClO_4)_2$.[18]

The exchange interaction originates from an overlap of the wave functions of the unpaired electrons. Here, the superexchange interaction through the amide molecule between uranium ions must be considered.

The coordination number for the U(IV) ion is usually eight or six, but if the complex is hexacoordinate, it will have a constant paramagnetic susceptibility from room temperature corresponding to temperature-independent paramagnetism. When the complex has the coordination number of eight, it will show temperature-dependent paramagnetism. This magnetic behavior of uranium(IV) complexes can be explained on the basis of the crystalline-field theory. Thus, the present complexes are probably octacoordinated. Octacoordinated U(IV) complexes have either a dodecahedral or square antiprismatic field around the U(IV) ion, with the dodecahedral field occurring more often. Assuming a cubic coordination on the U(IV) ion, a probable structure for the $UCl_4 \cdot 3L$ complexes is shown in Fig. 3. In a field of cubic symmetry, seven 5f orbitals are split into a singlet, a_{2u}, and two triplets, t_{1u} and t_{2u}. The t_{1u} orbital is the lowest in energy. Each of the a_{2u}, t_{1u}, and t_{2u} orbitals has charge-density maximum in a certain direction. The t_{1u} orbital has a charge-density maximum in the direction toward the center of the cube-face, and this charge-density maximum is the largest among the three kinds of orbitals[19] (see Fig. 4). The t_{1u} orbital does not participate in the π-overlap with the coordinated oxygen or nitrogen atoms of the ligand, for this orbital is directed toward the center of the cube-face. However, the t_{1u} orbital is favored for the π-overlap with p_z, and this tendency is enhanced when the cubic coordination of the ligands actually becomes dodecahedral by up and down displacements of the corner oxygen and nitrogen atoms, as is shown in Fig. 3. The antiferromagnetic coupling of unpaired electrons of the U(IV) ions can be explained by the bridging of the amide ligands. The high temperature of χ_{max} suggests that the exchange interaction occurs *via* the π orbitals shown in Fig. 3, since the polarized spins in a π-system can couple at a distance with little attenuation[17] and can lead to strong superexchange interaction. A similar transmission of antiparallel spin coupling was found, for example, in the royal-blue modification of anhydrous copper(II) formate.[20] A proton-magnetic-resonance experiment now planned can provide evidence regarding the proposed π-system.[21]

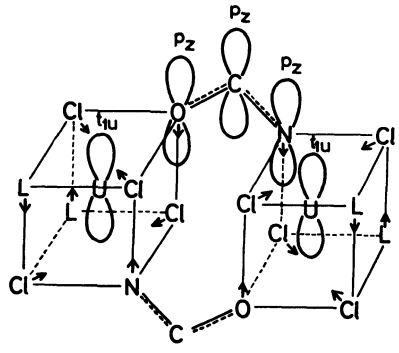

Fig. 3. Presumed structure for $UCl_4 \cdot 3L$ type complex in idealized form. For bridging amide molecules, only O=C–N is drawn, otherwise amide molecules are represented as L. If all ligands move to the directions shown by arrows, coordination polyhedron turns from cube to dodecahedron.

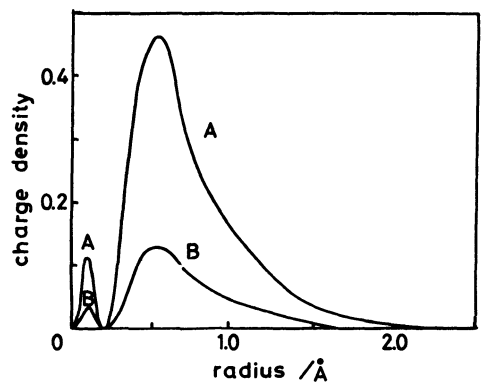

Fig. 4. Charge density distribution of 5f orbitals.

Distribution and Chemical Behavior of 21 Elements in River Water in the Yakushima Island

Yoshiyuki TANIZAKI* and Sumiko NAGATSUKA
Tokyo Metropolitan Isotope Research Center, Fukazawa, Setagaya-ku, Tokyo 158
(Received May 28, 1982)

The concentrations of 21 elements dissolved in the river water collected from around the Yakushima Island were determined by a neutron activation analysis (NAA). From the analytical results, the distribution and chemical behavior of each element in the water were discussed. The chemical composition of the river water was nearly uniform all around the island, and the concentration of each element determined in this work was extremely close to the geochemical background value of river water, since our experimental area had scarcely any pollution. Among the 21 elements chlorine, sodium, and magnesium were mainly supplied into the river water from the ocean, while the others were chiefly driven from the rocks and their efflorescences in the drainage basin. The enrichment factors for the granitic earth crust (F_E-value) were very close to 1 for calcium, strontium, and zinc, while those of selenium, arsenic, tungsten, and antimony were much higher than 1. For the elements such as aluminium, iron, manganese, *etc.*, on the other hand, the F_E-values were very low. These differences in the F_E-values among the elements correspond to differences in their solubilities in the water.

The determination of multi-element concentrations in natural waters is of great importance to substantiate numerous theories on the geochemical migration of the chemical species on the earth surface. However, few articles have dealt with trace element concentrations in river water until recent years,[1-3] for the reason that the analytical methods for the determination of trace elements in the concentration less than part per billion (ppb) were generally quite complicated. More recent developments in instrumental neutron activation analysis (INAA) have facilitated the determination of multi-elements including trace elements. Using INAA, those concentrations in river water have been determined by many workers.[4-11] But no one has mentioned those in a natural freshwater which is perfectly free from pollutions by anthropogeneous sources, even though the analysis of such unpolluted water is very useful to evaluate the geochemical background value of natural water. In a previous paper,[12] it has been reported that the trace element concentrations in the river water collected from the Mikura Island were very close to a geochemical background value, since its basin was virtually unpolluted.

The Yakushima Island, one of the Nansei Islands, lies about 60 km south of Sata Point, the southernmost part of Kyushu, as shown in Fig. 1. It is supposed that the basin in the Island has scarcely any pollution as in the case of Mikura Island, for the reason that our experimental area is thinly populated and is far apart from any big town or industrial area. Furthermore, the streams in the Island flow with a rapid current throughout the year because of its steep topography and abundant rainfall.

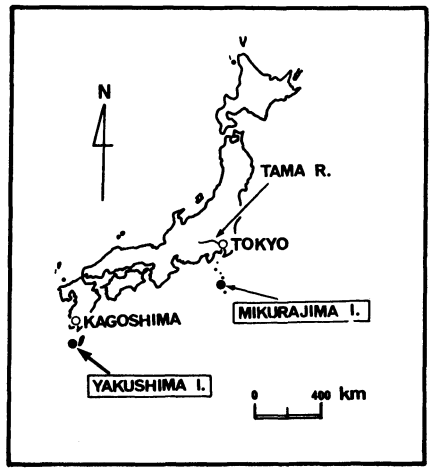

Fig. 1. Locality of the Yakushima Island.

In order to evaluate geochemical background values of river water, the concentrations of 21 elements in the water samples collected from 9 sites in the Island were determined using NAA.

Meanwhile, several workers[13-17] have reported on the chemical species of various elements dissolved in natural water and their solubilities. However, there is also no paper dealing with those of trace elements in unpolluted river water.

In this paper, therefore, the solubilities of trace elements in the river water are discussed; the relation between the enrichment factors for the granitic earth crust of those elements and their ionic potentials is emphasized.

Experimental

Water Sample. The Yakushima Island is composed of three geologic units, the Micocene Yakushima Granite, the Paleogene part of the Shimanto Group and the Quaternary deposits.[18,19] The Miocene Yakushima Granite is distributed most widely in the Island, especially in its basin, as can be seen in Fig. 2.

The river water samples were collected in December 1979 at nine sites in the basin of the Island. All the sampling sites are shown in Fig. 2.

The water samples were filtered within a few hours after the sampling, using a Type HA millipore filter with diameter 142 mm and pore size 0.45 μm. After the filtration, the samples were transferred to a 5-liter polyethylene bottle which was throughly washed with 10% nitric acid, followed by redistilled water, to remove trace element contaminations, and then acidified immediately with 30 ml of nitric acid (Super Special Grade) in order to avoid any adsorption of trace elements on the wall of the bottle.

For the analysis of chlorine, on the other hand, another 1

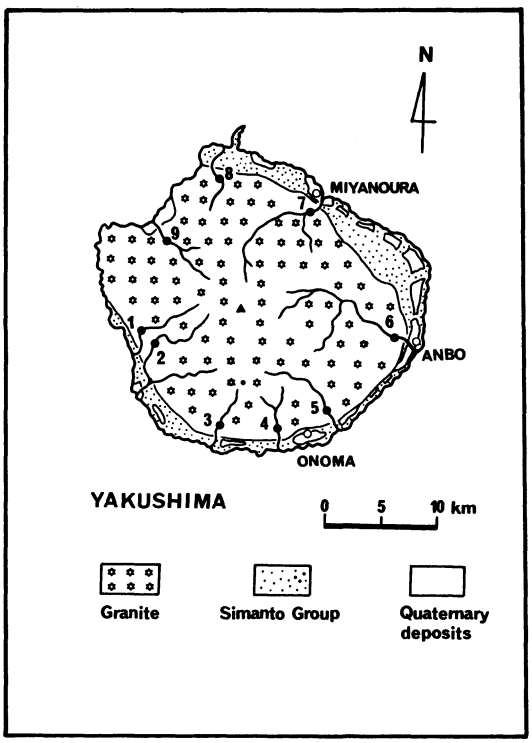

Fig. 2. Geological map of the Yakushima Island showing the sampling sites.

liter of the water sample was taken in another polyethylene bottle without the filtration and acidification.

Preparation of Irradiation Samples. For the NAA in this report, two kinds of irradiation samples, that is an evaporated residue sample and an iron(III) hydroxide coprecipitated one, were prepared from each water sample, according to the process reported in our previous papers.[5,8,20]

Four liters of the water sample were concentrated to 100 ml using a rotary evaporator. The concentrated water sample was then divided into two 50 ml portions.

One was dried on a Pyrex glass dish under an infrared lamp until the weight was constant. The residue was weighed and transferred into a polyethylene bag for neutron irradiation, and then heat-sealed.

The other was diluted with 100 ml of redistilled water, and then boiled for 30 min on a hot-plate after adding 0.5 ml of iron (III) chloride solution (Fe^{3+}: 10 mg/ml) and adjusting to pH 6 with aqueous ammonia. The iron (III) hydroxide precipitate was gathered on a piece of No. 5A filter paper with 5.5 cm in diameter and then rinsed with redistilled water ten times or more. After drying, the precipitate was transferred into another polyethylene bag together with the filter paper, and heat-sealed.

Irradiation and Gamma-counting. The sample and reference standard were encapsulated in a polyethylene capsule for all irradiations. The irradiation was performed by the TRIGA-Mark II Reactor of Rikkyo University, with a thermal neutron flux of 1.5×10^{12} n/cm^2 s. The gamma-spectrometer consists of a Ge(Li) coaxial detector of about 30 cm^3, with 2% efficiency and 2.8 keV resolution, and a 2048 and 4096 channel pulse height analyzer.

The evaporated residue sample was first irradiated for 1 minute to determine the elements induced the short-life nuclides such as Al(^{28}Al), Ca(^{49}Ca), Mg(^{27}Mg), Mn(^{56}Mn), Na(^{24}Na), and V(^{52}V), and these radioactivities were measured for 100 s by the spectrometer. One month later, the same sample was irradiated once more for 12 h to determine the elements induced the long-life nuclides such as Co(^{60}Co), Cr(^{51}Cr), Cs(^{134}Cs), Fe(^{59}Fe), Rb(^{86}Rb), Sb(^{124}Sb), Sc(^{46}Sc), Se(^{75}Se), Sr(^{85}Sr), and Zn(^{65}Zn). The measurement of these long-life activities were carried out for 50000 s after a cooling time of 2—4 weeks to reduce the short or medium-life nuclides.

The iron (III) hydroxide coprecipitate sample, on the other hand, was also irradiated for 12 h to determine the elements induced the medium-life nuclides such as As(^{76}As), La(^{140}La), Sm(^{153}Sm), and W(^{187}W), and after the cooling time of 1 d, these activities were measured for 1000 s.

Analysis of Chlorine. The concentration of chlorine in the river water samples was measured by means of Mohr's method.

Results and Discussion

The concentrations of 20 elements could be determined from the two irradiation samples by NAA. The recovery of several elements, such as arsenic, tungsten, *etc.* in water attendant upon the procedure of iron(III) hydroxide coprecipitation has been reported in the previous papers.[5,20,21]

In Tables 1—3, the concentrations of 21 elements determined in the river water collected from the Yakushima Island are listed, together with the statistical errors based on the gamma-counting.

These tables show that extraordinarily high concen-

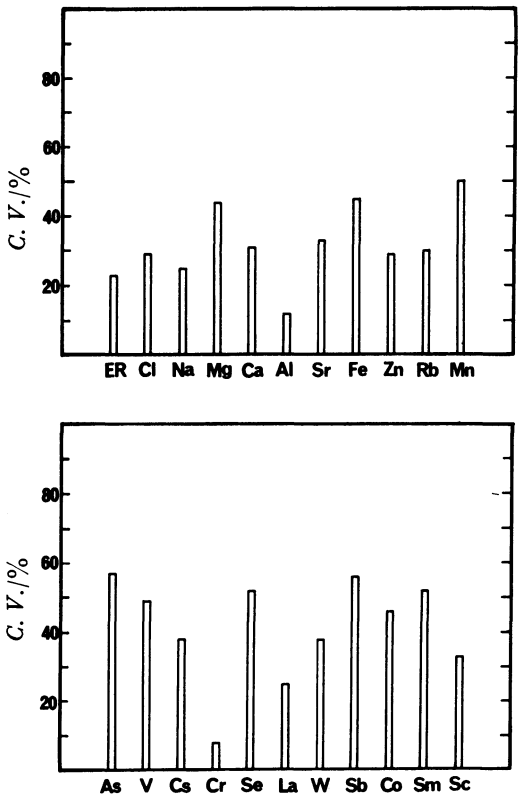

Fig. 3. The coefficients of variation of ER and 21 elements among the 9 sampling sites.

trations were given for heavy metal elements such as iron, manganese, arsenic, and cobalt at sampling site No. 9 (Nagata River), and high concentration of tungsten was found at the No. 3 (Yukawa River) and No. 6 (Anbo River). Utilizing the analytical results, but without these extraordinary values, the coefficients of variation (*C.V.*) were evaluated for 21 elements among all the sampling sites, by the next equation; the results are illustrated in Fig. 3.

$$\sigma = \sqrt{\sum(x_i - \bar{x})^2/n} \qquad (1)$$
$$C.V.(\%) = \sigma/\bar{x}$$

From Fig. 3, it was clarified that the coefficients of variation were less than 50% for almost all elements; those for the elements Cl, Na, Ca, Al, Sr, Zn, Rb, Cr, La, and Sc were less than 30%. These values are generally lower than those in the Tama River[5)] and the Mikura Island.[12)] Consequently, it can be said that the concentrations of almost all elements in the river water are nearly uniform all over the Island.

The basin in the Island had scarcely any pollution, as mentioned above, so that the values in the concentrations of various elements presented in Tables 1—3 are extremely close to the geochemical background value of the Yakushima's river water.

It is of interest to compare the concentrations of the elements in the Island water with those in river water collected from other districts, such as the drainage basin of the Tama River[5)] and the Mikura Island,[12)] so

a) The values are given in milligrams of each element per gram of the amount of evaporated residue (ER).

as to characterize the water quality of the Island. One has to keep in mind, however, that it is unsuitable to compare immediately each element concentration expressed in ppm, ppb and ppt because of their different sampling periods, geological features, *etc.* For this purpose, a relative concentration (C_r-value), using the average values, is evaluated by the next equation; this equation is given in the milligrams quantity of each element per the gram amount of evaporated residue (ER):

$$C_r = \frac{C_i}{C_{ER}} \times 1000, \tag{2}$$

where, C_i and C_{ER} mean the average concentrations of an element i and of the evaporated residue. The C_r-values for various elements in the three different districts are shown in Table 4. From Table 4, the following conclusions are drawn: No large difference in the C_r-values for most elements can be found between the two Islands, although there are some exceptions: the Yakushima Island water is more enriched in rubidium and caesium, and is deficient in vanadium in comparison with those in the Mikura Island water. The disagreement in the C_r-values for these three elements seems to be arise from the differences of their geological features, which is considered in the following way.

The Yakushima Island is mainly composed of the Miocene Yakushima Granite, as previous mentioned, while the Mikura Island is made up by the volcaniclastic rocks of Basalt and Andesite.[22] The concentration ratios of the former to the latter for rubidium, caesium and vanadium are 4.5, 9.2, and 0.11 respectively, provided the analytical values for two geochemical reference rock samples, JG-1 granodiorite and JB-1 basalt,[23] are utilized for the two different kind of rocks distributed in the two Islands. These values are close to the same ratios in the river water, 3.2, 8.2, and 0.089 respectively. Consequently, it could be said that the difference of the geological features has a large influence on the concentrations of these elements in the river water.

In the comparison with the amounts in the Tama River water, on the other hand, the Yakushima Island water is more enriched in chlorine, sodium, rubidium and caesium by 2—10 times. The high C_r-values for chlorine and sodium in the Island water can be explained by the assumption that both elements are easily supplied from the ocean; this will be discussed later. The highr C_r-values for rubidium and caesium in the Island water indicate that these elements tend to be derived from the Miocene Yakushima Granite, which is distributed extensively in the Island, as stated above.

Except these four elements, however, the C_r-values for most elements in the Island water are lower than those of the Tama River water by a factor of 2—10. This tendency is evident for the heavy metal elements such as iron, zinc, arsenic, vanadium, selenium, antimony, and cobalt.

It is well known that the difference of origin of the elements in rain water may be indicated by an enrichment factor for the earth's crust or the ocean, F_E or F_O.[24] The method is applicable not only to rain water, but also to the unpolluted river water.

$$F_E = \frac{C_{Ca}(\text{earth})}{C_{Ca}(\text{sample})} \times \frac{C_i(\text{sample})}{C_i(\text{earth})} \tag{3}$$

$$F_O = \frac{C_{Cl}(\text{ocean})}{C_{Cl}(\text{sample})} \times \frac{C_i(\text{sample})}{C_i(\text{ocean})} \tag{4}$$

Here, C_{Ca}, C_{Cl}, and C_i mean the concentrations of calcium, chlorine and some element i in the earth's crust, the ocean and the water sample, respectively. Calcium is chosen as the reference element for the F_E-values instead of the usually employed sodium, since at the Island sodium is mainly supplied from the ocean. Meanwhile, chlorine is used as the reference element for the F_O-values, because its main source is known to be the ocean.

In Eq. 3, the analytical values of various elements for JG-1[23] were employed in the place of those for the earth's crust, because the trace element concentrations of the Yakushima Granite have not been determined. For tungsten, however, the analytical value for international geochemical reference rock sample USGS G-1[25] was utilized, since the value for JG-1 has not been reported.

In Table 5, the enrichment factors (F_E- and F_O-value) are listed for 21 elements. From Table 5, it is recognized that the F_O-values are close to 1 for chlorine, sodium, and magnesium, and those for almost all of the elements except for above three elements are very high. This fact indicates that the origin of chlorine, sodium, and magnesium in the river water could be presumed to be the ocean, but for all of the elements other than chlorine, sodium, and magnesium their main sources should be

Table 5. Average enrichment factors F_E and F_O for various elements

assumed to be elsewhere. The river water in the Island is virtually free from the anthropogeneous sources. Furthermore, the influence by naturally occurring organic substances such as humic acids appeared to be negligibly small in our experimental area because of th rocky river bed and abundant flow. Therefore, most of the elements other than the above three elements in the river water are derived from the rocks and their efflorescences in the drainage basin.

The F_E-values are close to 1 for calcium, strontium, and zinc; those for chlorine, selenium, arsenic, tungsten, sodium, antimony, and magnesium are much higher than 1. For aluminium, iron, manganese, *etc.* the F_E-values vanishingly low, as can be seen in Table 5. Chlorine, sodium, and magnesium, showed high F_E-values; these originated from the ocean, as stated above.

It is known that in natural water the elements such as calcium, strontium, zinc, *etc.* are present as divalent cations, and the elements such as aluminium, iron, chromium, *etc.* tend to exist as trivalent species. On the other hand, the great portion (70—100%) of arsenic and antimony are present as pentavalent species such as AsO_4^{3-} and SbO_4^{3-}.[26,27] For selenium and tungsten, it is assumed, according to the example of Garrels and Christ,[13] that those elements exist as hexavalent species, although the chemical species of those elements dissolved in natural water are probably either SeO_3^{2-} and WO_3^{2-} or SeO_4^{2-} and WO_4^{2-}.[28,29]

The relation between the F_E-values for various elements and their chemical valencies is demonstrated by Fig. 4, which is a plot of the logarithm of the F_E-value *versus* an ionic potential that is given in the ratio of chemical valency of the element to its radius.[30] In Fig. 4, it can be considered that the ordinate is one kind of measure of solubility, while the abscissa means the tendency of the cation to bond with anions.

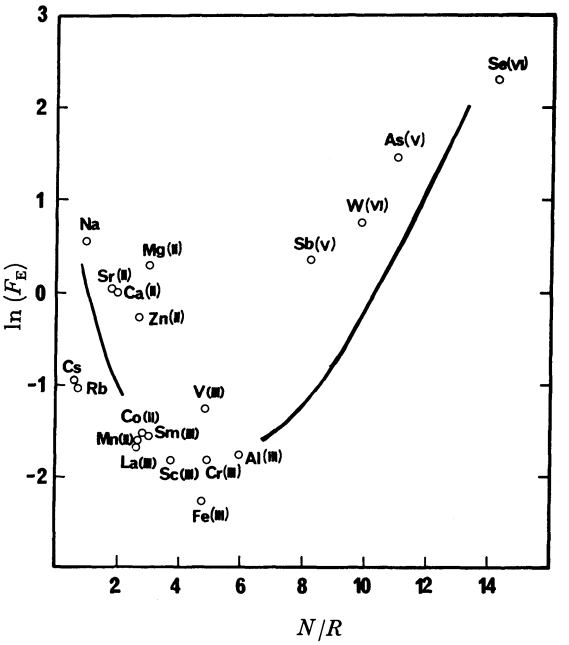

Fig. 4. Plot showing the relation between the logarithm of the enrichment factor (F_E-values) and the ionic potentials of cationic species. A parenthesized Roman numerals show chemical valency (N) of the elements easily formed under the natural conditions. Ionic radii (R) are employed from Shannon and Prewitte.[30]

The diagram shows the following general trends. The scattering pattern of each element in the diagram agrees with those reported by Garrels and Christ,[13] who have studied the behavior of various chemical species in sea water. The relatively high solubilities are found for the elements that form the divalent cations under the range of natural conditions, such as calcium, strontium, and zinc, while the elements that tend to form the trivalent ions such as aluminium, iron, chromium, scandium, *etc.* show very low solubilities. Such trivalent ions not only tend to interact with various anions to form soluble complexes, but also tend to form insoluble hydroxides or oxides in ordinary natural waters. It is well known that the transition elements such as iron, manganese, zinc, vanadium, chromium, cobalt, scandium, *etc.* are being held in the dissolved phase by complexation or chelation with dissolved organic substances in river water.[17,31,32] In our experimental area, however, it is supposed that these organic substances in the river water exist only in very small amounts, as stated above. Thus, the total solubilities for the elements which formed trivalent cations or for the transition elements are still held low in the Yakushima's water.

Zinc shows an exceptionally high solubility among the transition elements; it is extremely hard for zinc to be oxidized to trivalent cation, and easily dissolves in water as a divalent species such as $(Zn(H_2O)_6)^{2+}$.[33] The solubility of vanadium is slightly higher than those of the other transition elements, because a portion of vanadium exists as soluble pentavalent species such as $V_{10}O_{28}^{6-}$,[13] as in the case of arsenic and antimony.

On the other hand, for those elements that form small

penta and hexavalent species, such as selenium, arsenic, tungsten, and antimony, the solubilities have very high values, presumably because they react with oxygen to form metal-oxygen anions because of their high ionic potentials, as shown in Fig. 4.

Conclusion

Using NAA method, it was possible to obtain some knowledge about the distribution and chemical behavior of various elements in the river water in th Yakushima Island.

The analyzed values for the various element concentrations offered in this paper were close to the geochemical background value of river water, because our experimental area was free from any pollution by anthropogeneous sources. Thus, their values will serve satisfactorily as reference data for the concentrations of the elements dissolved in most river water.

The relation between the F_E-values and ionic potentials showed that the solubilities were relatively high for the elements that form the divalent cations in ordinary natural water, while those for the elements that tend to form trivalent ions were very low. For the elements that easily form the small high valent species, the solubilities were given in very high values. The term solubility indicates not only the tendency of each element to be supplied into the river water from the rocks, but the difficulty of being remove from the river water as deposits.

The geological structure of the Island is rather simple, and the Island forms a kind of closed system, since it is an isolated island. Furthermore, the flow of the water in each river is abundant throughout the year. Therefore, it was supposed that a kind of equilibrium was set up between the rocks and water in the basin as for the behavior of various chemical species, such as the dissolution, precipitation, adsorption, *etc.* These reasons made it easy to study the chemical behavior of the elements in the water.

For a general understanding, however, it would be necessary to evaluate the element concentrations much more than determined in this work, and to substantiate exactly the chemical species for various elements, and also to complete studies conducted on natural freshwaters collected from various different districts.

Phase Behavior of 2-Butoxyethanols/Water/Oil Systems

Hironobu KUNIEDA
Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Tokiwadai 156, Hodogaya-ku, Yokohama 240
(Received June 11, 1982)

Synopsis. Phase diagrams of 2-isobutoxyethanol (D)/water (W)/decane (O) system were studied at 2.0, 8.2, 15.0, 19.0, and 19.8 °C. The addition of O lowers the critical solution temperature of the D–W system from 26.2 to 2.0 °C, at which temperature the critical solution curve ends with the lower critical end point (Kc). On the other hand, the addition of W raises the critical solution temperature of the O–D system to 19.8 °C at which the critical solution curve ends with another critical end point (Lc). A three-phase region consisting of O, D, and W phases appears in a temperature range between the two critical end temperatures.

Recently, similarity of phase behavior has been reported among some amphiphilic compound systems, such as an ionic surfactant/brine/(cosurfactant)/oil,[1,2] short-chain alcohol/brine/oil,[3] and nonionic surfactant/water/oil systems.[4] In these systems, an amphiphile changes from water-soluble (hydrophilic) to oil-soluble (lipophilic) with the increase in salt content or changing in temperature. In the transition range of phase behavior, there is a three-phase region in which an amphiphile phase coexists with a water phase and an oil phase in equilibrium.

In this paper, phase behavior of 2-isobutoxyethanol/water/oil system has been investigated around the temperatures of the three-phase region in order to compare with long-chain surfactant systems.

Experimental

Materials. Extra-pure-grade 2-isobutoxyethanol, 2-butoxyethanol, diethylene glycol hexyl ether, and hydrocarbons were obtained from Tokyo Kasei Kogyo Co. and were used with out further purifications.

Procedures for the determination of phase boundaries are described elsewhere.[5]

Results and Discussion

Phase Diagram of 2-Isobutoxyethanol/Water/Decane System. If temperature is taken as an axis perpendicular to a composition plane at constant pressure, the three-dimensional shape of a ternary system is a triangular prism and a horizontal section is the isobaric, isothermal section of the system, *i.e.*, the phase diagram of a three-component system. The phase diagrams of 2-isobutoxyethanol/water/decane system were determined at 2.0, 8.2, 15.0, 19.0, and 19.8 °C, and are shown in Figs. 1(a)—(e). The compositions are given in weight fractions. W, D, and O denote the water, 2-isobutoxyethanol, and oil phases, respectively.

The lower critical solution temperature of the binary

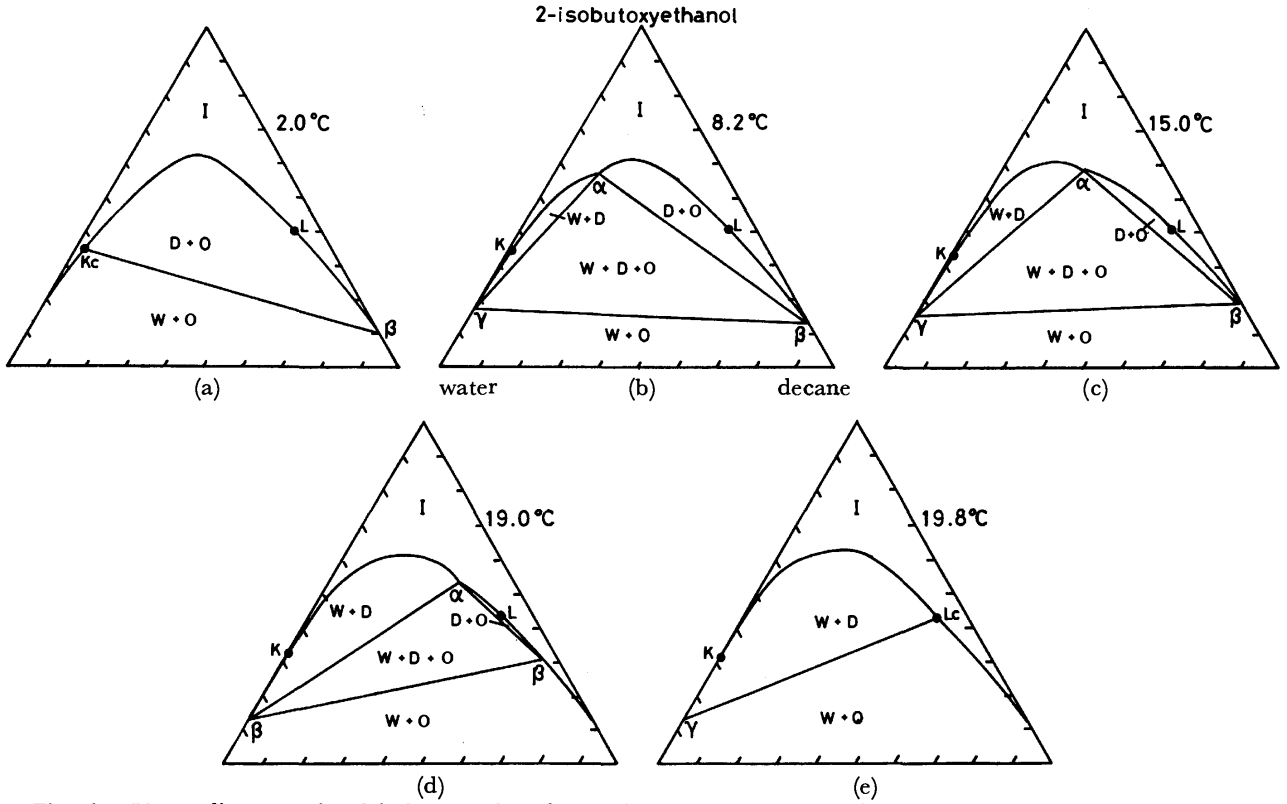

Fig. 1. Phase diagrams for 2-isobutoxyethanol/water/decane system at various temperatures.
O: an oil phase, W: a water phase, D: a 2-isobutoxyethanol phase, α, β, and γ: invariant points, K and L: plait points, Kc: the lower critical end point of W-D, Lc: the upper critical end point of O-D, I: one-phase region.

system of D–W is 26.2 °C, below which there are complete miscibilities in the binary systems of D–W and O–D. But, a large miscibility gap exists in the ternary system due to the poor mutual solubility of O and W. Plait points of the D–W and O–D phases in the three-component system are indicated by K and L. The locus of K in the triangular prism, *i.e.*, in the space of temperature and compositions, ends with the lower critical end point, Kc (water, 62.8 wt%; 2-isobutoxyethanol, 34.8 wt%; decane, 2.4 wt%) at 2.0 °C. On the other hand, the locus of L in the triangular prism ends at the upper critical end point Lc (water, 8 wt%; 2-isobutoxyethanol, 43 wt%; decane, 49 wt%) at 19.8 °C as is shown in Fig. 1(e). At the temperatures between the two critical end temperatures, a three-phase region consisting of O, D, and W phases appears due to the superposition of three-miscibility gaps; O+D, D+W, and O+W regions. The compositions of three coexisting liquid phases are invariant at constant temperature and pressure, and these points are indicated by α, β, and γ in Fig. 1. At the lower critical end temperature (LCET), W and D phases become identical on the line Kc-β, as is shown in Fig. 1(a). On the other hand, O and D phases merge on the line Lc-γ at the upper critical end temperature (UCET), as is shown in Fig. 1(e). The plait point K reaches the D–W axis at 26.2 °C, above which there is no plait point in the phase diagram.

The vertical section of the phase diagrams in Fig. 1 is shown in Fig. 2. The water/oil ratio is unity and the concentration of 2-isobutoxyethanol is plotted horizontally. Similar vertical sections of 2-butoxyethanol water/decane, diethylene glycol hexyl ether/water/decane and triethylene glycol octyl ether/water/decane[4] systems are also shown in Fig. 2. A three-phase region moves toward a water-oilaxis (left-hand axis) with the increase in the molecular size of an amphiphile. On the other hand, the temperature range of the three-phase region is little affected by the molecular size of an amphiphile, because the hydrophile-lipophile property

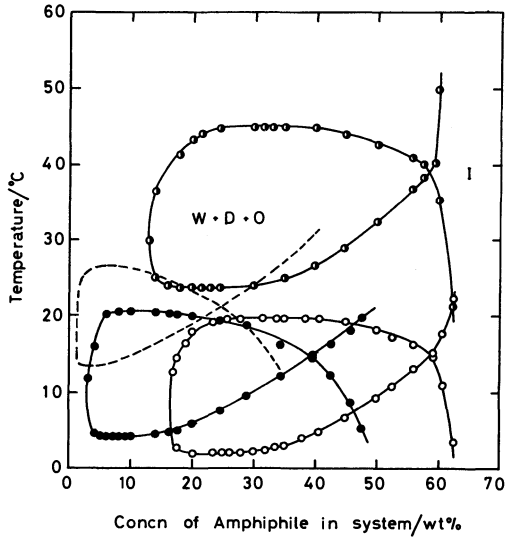

Fig. 2. The effect of the concentrations of an amphiphilic conpound on the equi-weight mixture of water and decane.
-○-: 2-Isobutoxyethanol system, -◑-: 2-butoxyethanol system. -●-: diethylene glycol hexyl ether system, ------: triethylene glycol octyl ether system.

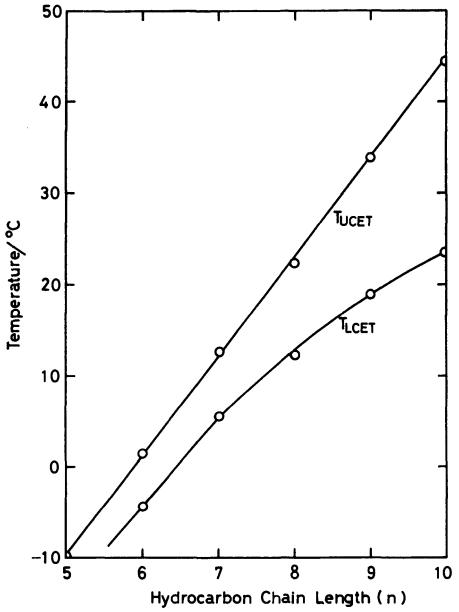

Fig. 3. The effect of hydrocarbon chain length of oil (C_nH_{2n+2}) on the critical end temperatures in the 2-butoxyethanol/water/oil systems.

of a nonionic amphiphile is related to the ratio of the hydrophilic and lipophilic portions.[6]

The Effect of Oil Size on the Difference in LCET and UCET. If three components are fixed, LCET and UCET are invariant at constant pressure. The lower and upper limits of a three-phase region in Fig. 2 correspond to LCET and UCET respectively. LCETs and UCETs in various 2-butoxyethanol/water/oil systems are shown in Fig. 3. With an decrease in the hydrocarbon chain-length of oil, the difference in LCET and UCET becomes smaller. If the two critical end temperatures coincide strictly, a tricritical phenomenon may be observed.[7] The degree of freedom (f) at a pth order critical point ($p=3$ at a tricritical point) is determined by the following equation;[8]

$$f = c - 2p + 3,$$

where c is the number of components. In a three-component system, $f=0$ holds at a tricritical pont, which is an invariant point in the space of temperature, pressure and compositions. Therefore, in order to observe a tricritical phenomenon, the pressure in a ternary system has to be changed.

The author thanks Prof. K. Shinoda for his stimulating discussions.

(Received June 11, 1982)

Synopsis. The absorbances of the azo-hydrazone tautomer of sodium 4-(*p*-sulfonatophenylazo)-1-naphthol-2-sulfonate dissolved in an aqueous solution of polyethylene glycol octyl dodecyl ether (8ED) were measured in the presence of various concentrations of sodium dodecyl sulfate (SDS). The existence of a mixed micellar region of SDS and 8ED in the bulk solution was confirmed by this azo-hydrazone tautomer method.

The present authors have previously reported the properties of mixed micelles between an anionic surfactant and a series of homogeneous polyethylene glycol dodecyl ethers (*n*ED) with no Poisson distribution and their dependence on the oxyethylenechain length.[1-4] The existence of a mixed micellar region in the bulk solution has been suggested from the finding that a long plateau appears on the surface-tension curve of nonionic surfactants in the presence of sodium dodecyl sulfate (SDS) at a constant concentration. Further, the authors have determined the cmc of mixed solutions of SDS and 7ED by the charge-transfer-solubilization method.

Recently, the cmc of nonionic surfactants has been determined spectroscopically by using the keto-enol tautomer of benzoylacetone or benzoylacetoanilide.[5,6] This method might also be used to elucidate the properties of mixed micelles. In this work, the properties of mixed micelles of SDS and polyethylene glycol octyl ether (8ED) were investigated by using an azo-hydrazone tautomer of sodium 4-(*p*-sulfonatophenylazo)-1-naphthol-2-sulfonate (PNDS) as one of the tautomers.

PNDS was prepared in the following way: Sulfanilic acid ($NH_2C_6H_4SO_3H$) was diazotized and coupled with potassium 1-naphthol-2-sulfonate ($HOC_{10}H_6SO_3K$). The PNDS thus obtained was purified by chromatography on Wakogel C-200, using a mixture of 1-butanol, acetic acid, and water as the eluent. The PNDS was dried at 100 °C under a vacuum. A homogeneous nonionic surfactant, polyethylene glycol octyl dodecyl ether (8ED) was supplied by the Nikko Chemicals Co., Ltd. This 8ED was highly pure, as was confirmed by gas-liquid chromatography, thin-layer chromatography, and cloud-point and surface-tension measurements. SDS as an anionic surfactant was synthesized by a modification of the method of Dreger *et al.*,[7] and subsequently purified by repeated recrystallizations from ethanol. The purity of SDS was confirmed by the absence of any minimum in the surface-tension diagram. The water used in all the experiments was purified by passing it through the MILL-Q Reagent-Grade Water System (Millipore, Ltd.) until its specific conductivity fell below $10^{-7}\ \Omega^{-1}$/cm. 2.5×10^{-5} mol dm^{-3} of PNDS in an aqueous solution was prepared, and then the surfactant solutions with various concentrations were prepared by dissolving a certain quantity of each surfactant into the PNDS aqueous solution in order to keep the concentration of PNDS constant. After the temperature of the samples had attained 25 °C, the absorption spectra of the samples were measured in a 1.0-cm quartz cell by means of a spectrophotometer (Model Hitachi ESP-3T).

It is well known that PNDS exists mostly in the hydrazone form in water and is tautomerised to the azo form in polar organic solvents.[8] To confirm this behavior, the absorption spectra of PNDS dissolved in water–ethanol mixtures were measured. It was seen that the spectrum of PNDS in water had an absorption band at 490 nm, where PNDS exists in the hydrazone form, while on the other hand, the spectrum in ethanol provides an absorption band at 410 nm which is attributed to the azo form. The absorbance of the hydrazone form decreased with an increase in the content of ethanol in the mixtures. Furthermore, an isobestic point was clearly observed at 435 nm. The above results support the idea that the azo-hydrazone tautomerism of PNDS exists in water–ethanol mixtures.

It is important to check whether or not an aggregation of PNDS exists in an aqueous solution, because dyes usually form aggregates, such as dimers, trimers, and higher oligomers.[9] When the absorbance of PNDS was plotted against the concentration of PNDS, the absorbances of PNDS in an aqueous solution and in ethanol both strictly obeyed Beer's law. This means that an aggregation, if any, of PNDS would occur to only a negligible extent in these solutions.

As the next step, the azo-hydrazone tautomerism of PNDS was examined in aqueous surfactant solutions.

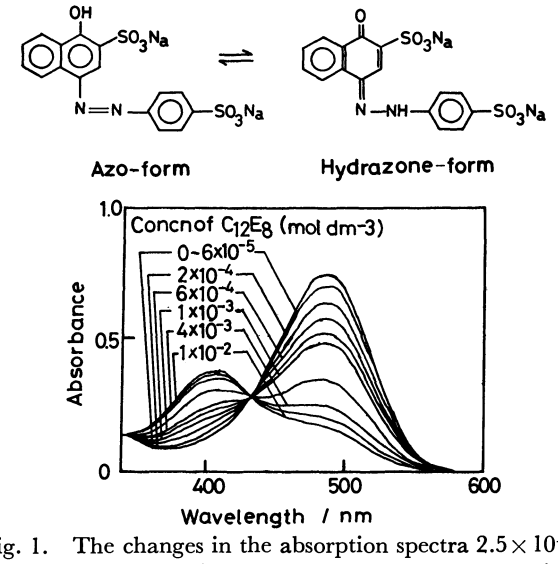

Fig. 1. The changes in the absorption spectra 2.5×10^{-5} mol dm^{-3} of PNDS as a function of the concentration of 8ED solution and the structure of PNDS.

The spectra of PNDS dissolved in surfactant solutions are expected to be different from those in water alone due to the interaction of the PNDS-surfactant. The changes in the absorption spectra of 2.5×10^{-5} mol dm^{-3} of PNDS as a function of the concentration of the 8ED solution and the structure of PNDS are shown in Fig. 1. The absorbance of the hydrazone form was constant until 7.0×10^{-5} mol dm^{-3}; thereafter, it decreased gradually with an increase in the concentration of 8ED. On the other hand, the absorbance of the azo form did not change until 6.5×10^{-5} mol dm^{-3} and then increased with an increase in the concentration of 8ED. Much as in the water–ethanol system, a sharp isobetic point was observed at 435 nm. Thus, the tautomerism from the hydrazone form to the azo form also proceeded in aqueous surfactant solutions. Further, it was found that the absorbances of the hydrazone form and of the azo form began to change near the cmc of 8ED.[10] This fact suggests that the tautomerism from the hydrazone form to azo form is related to a micellar phenomenon, since the absorbances of neither form changes below the cmc.

On the contrary, in the PNDS–SDS system, the absorbance of the hydrazone form decreased negligibly with an increase in the concentration of SDS from 0 to 20 mmol dm^{-3}, while the azo form in the spectrum did not appear at all in this concentration range. Since the cmc of SDS is 8 mmol dm^{-3}, the above result suggests that PNDS molecules are not solubilized into SDS micelles because, presumably, of an electric repulsion between PNDS anion molecules and SDS micelles. Thus, the properties of the mixed surfactant solutions of 8ED and SDS can be estimated by the utilization of the phenomenon that the azo-hydrazone tautomerism is not observed in an aqueous SDS solution, but only in an aqueous 8ED solution.

Figure 2 depicts the absorbances of PNDS *vs.* the concentration of 8ED in the presence of various concentrations of SDS. The concentration of 8ED at which the absorbance of the hydrazone form begins to decline is shifted to a higher concentration of 8ED with an increase in the concentration of SDS present in the mixtures. Similar behavior was observed in the change of the absorbance of the azo form in the mixtures of 8ED and SDS. This result can be interpreted as follows. The PNDS-anion molecules solubilized in 8ED micelles are expelled by the penetration of SDS into 8ED micelles due to electric repulsion; as a result, the mixed micelles of 8ED and SDS are formed. The present authors have previously reported[1,4] that the surface-tension curves of 8ED in the presence of SDS have a long plateau over a wide range of concentrations of 8ED and exhibit two break-points at lower and higher concentrations of 8ED. Further, they have pointed out[1,4] that the first break-points on the surface tension curves correspond to the cmc of mixed micelles of SDS and 8ED, while the second break-points indicate the existence of mixed micelles with excess 8ED. In general, the cmc of mixed micelles is well known to be lowered more than that of each single surfactant.[11–13] Although the present PNDS method does not provide the cmc values of mixed micelles of SDS and 8ED, it seems that the concentration

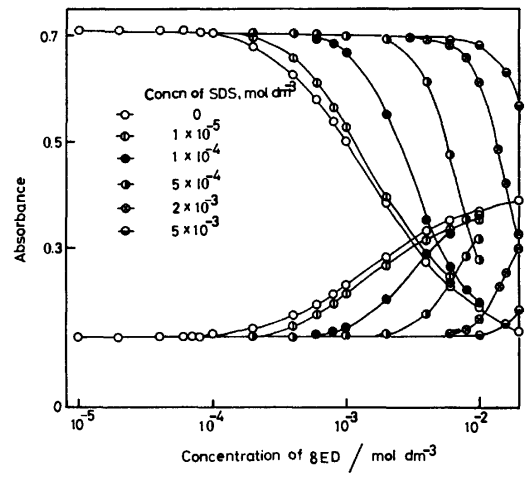

Fig. 2. The absorbances of PNDS *vs.* the concentration of 8ED in the presence of various concentrations of SDS.

region between the cmc of 8ED alone and the concentration of 8ED corresponding to that point at which the absorbance of the hydrazone form or the azo form begins to change is related, at least, to the presence of a mixed micelle of SDS and 8ED. The length of this region is extended with an increase in the concentration of SDS present in the mixtures. With further increase in the concentration of 8ED in the mixtures, the absorbance of the azo form or the hydrazone form begins to change. Since the concentration of 8ED corresponding to that at point which the absorbance of the azo form or the hydrazone form begins to change is correlated with the second break-point on the surface tension, PNDS might be solubilized into mixed micelles with excess 8ED in this concentration range.

Accordingly, the PNDS tautomer is a useful probe for elucidating the properties of mixed micelles of an anionic surfactant and a nonionic surfactant.

The Relation between the Proton-induced Quenching Rate Constants and the Charge Densities of Aromatic Compounds[1)]

Haruo SHIZUKA* and Kinzo TSUTSUMI[2)]
Department of Chemistry, Gunma University, Kiryu, Gunma 376
(Received September 24, 1982)

Synopsis. A plot of log k_q' (the proton-induced quenching rate constants) *vs.* the charge densities P_Σ^* (or superdelocalizabilities S_Σ^*) in the excited state gave a straight line. The linear relation strongly supports the proton-induced quenching mechanism involving electrophilic protonation at the proper carbon atoms in the aromatic ring.[3)]

In previous papers,[4)] it has been shown that proton-induced fluorescence quenching competitive with proton transfer reactions is present (that is, the simple acid-base equilibrium cannot be accomplished in the excited state of aromatic amines) and the dynamic analyses containing the proton-induced quenching are, therefore, needed in order to obtain the correct pK_a^* values. The dynamic analyses by means of nanosecond (or picosecond) time-resolved spectroscopy with fluorimetry are applied to 1-pyrenylamine,[5)] phenanthrylamines,[6)] 1-anthrylamine,[7)] and naphthols.[8)] The Stuttgart group[9)] has supported our method to determine the pK_a^* values of naphthylamines. Similar experiments for excited naphthols have been reported by Harris and Selinger.[10)] The quenching mechanism induced by protons in polar media has been studied recently by this laboratory, and it is found that the fluorescence of aromatic compounds having an intramolecular CT structure is quenched effectively by protons and the proton-induced quenching is caused by electrophilic protonation at one of the carbon atoms of the aromatic ring leading to proton exchange (or isotope exchange).[3)] Hoytink[12)] and Waluk *et al.*[13)] have assumed a linear relationship between the logarithm of the protonation rate constant and π-electron density. It has been shown that the assumption fairly holds.[6)]

In the present paper, a plot of log k_p' (the proton-induced quenching rate constants) *vs.* the π-charge densities[14)] (or superdelocalizabilities)[15)] at the proper carbon atoms in the excited state of aromatic compounds was examined with the aid of a SCF-MO-CI method. The MO calculations of aromatic compounds were carried out by a semiempirical SCF-MO-CI method, which was described elsewhere.[11)] The calculations were performed by an electronic computer, HITAC 8800/8700, located at the Computer Center of the University of Tokyo. The rate constants k_q' for the proton-induced quenching are listed in Table 1.

Initially, the reaction parameter of the maximum charge density P_{max}^* (or superdelocalizability S_{max}^*) at the proper carbon atom of the aromatic compounds for the electrophilic protonation in the excited singlet state was used. A linear relation between log k_q' and P_{max}^* was derived: log $k_q'=22.73\,P_{max}^*-16.24$ (the correlation

a) The proton-induced quenching rate constants for the excited neutral species at 300 K. b) The two reactive positions were selected for determinatoin of the P_Σ^*(or S_Σ^*) value. For details see the text. c) The reactive state of all aromatic compounds in polar media is the lowest excited singlet state (^1L_a). The reactive positions are shown in parentheses.

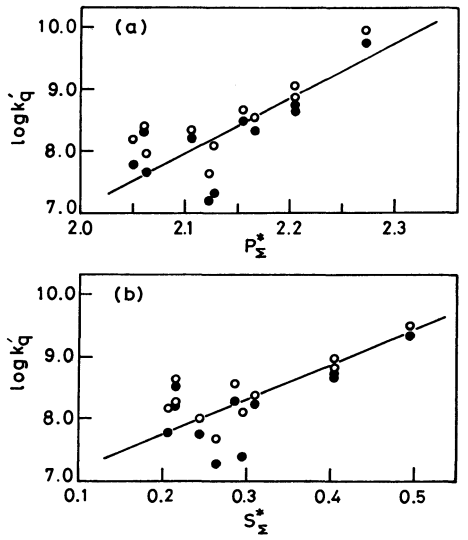

Fig. 1. Plots of (a) log k'_q *vs.* P^*_Σ and (b) log k'_q *vs.* S^*_Σ. ○: The H_2SO_4/H_2O system, ●: the D_2SO_4/D_2O system. The reactive positions were selected for determination of the P^*_Σ (or S^*_Σ) value. For details see the text.

coefficient $r=0.713$). However, lack of linear relation between log k'_q and S^*_{max} ($r=0.403$) was obtained. It is experimentally shown that the excited 1-methoxynaphthalene, for example, is attacked by protons mainly at the position 5 and slightly at the position 8.[3] Therefore, two reactive positions having larger P^* (or S^*) values in the lowest excited singlet state were selected from the carbon atoms as listed in Table 1. Figure 1 shows the plots of (a) log k'_q *vs.* P^*_Σ and (b) log k'_q *vs.* S^*_Σ, where P^*_Σ and S^*_Σ denote the summation values of charge densities and superdelocalizabilities at the two carbon atoms in the excited state, respectively. From Fig. 1, the following relations are obtained by the least squares method:

$$\log k'_q = 8.84\,P^*_\Sigma - 10.59 \qquad (r = 0.792), \qquad (1)$$

and

$$\log k'_q = 5.54\,S^*_\Sigma + 6.68 \qquad (r = 0.737). \qquad (2)$$

A plot of log k'_q *vs.* P^*_Σ (or S^*_Σ) where the reactive positions were expanded to three carbon atoms was also examined, and a straight line similar to that in Fig. 1 was obtained: $\log k'_q = 8.01\,P^*_\Sigma - 17.20$ ($r=0.785$); $\log k'_q = 5.13\,S^*_\Sigma + 8.12$ ($r=0.729$). From these results, the two reactive positions of the aromatic ring in the excited state may be adequate for determination of the P^*_Σ (or S^*_Σ) value. The linear relation in Fig. 1 strongly supports the mechanism that the proton-induced quenching is caused by electrophilic attack at one of carbon atoms of aromatic compounds.[3] Thus, one can approximately estimate the k'_q values for the proton-induced quenching of other aromatic compounds using Eq. 1 or 2.

Preparation of Trifluoronitrosomethane

Teruo UMEMOTO* and Hideo TSUTSUMI
Sagami Chemical Research Center, Nishi-Ohnuma 4-4-1, Sagamihara, Kanagawa 229
(Received February 26, 1982)

Synopsis. Trifluoronitrosomethane was prepared in a good yield by pyrolysis of nitrosyl trifluoroacetate in a flow of nitrogen monoxide at 190 °C using refluxed perfluorotributylamine as a diluent.

Trifluoronitrosomethane (**1**)[1] is an industrially important material for the preparation of nitroso rubber.[2] There have been many investigations on the preparation of **1**.[2-4] Pyrolysis of nitrosyl trifluoroacetate (**2**)[5] in refluxed perfluorotributylamine has been adopted as a preparative method in spite of the low yield of **1**.[2,4] In the kinetic studies on the gas-phase thermal decomposition of **2**, Haszeldine *et al.* examined the effects of additives such as propene, **1**, and nitrogen monoxide under reduced pressure (about 10 mmHg = 1.33×10^3 Pa) and showed that the presence of nitrogen monoxide enhanced the formation of **1** while the presence of propene or **1** inhibited it.[6] The pyrolysis of **2** under reduced pressure was undesirable for the mass production of **1** because a large reactor was necessary for pyrolysis and was difficult to operate.

During our investigation of the pyrolysis of **2**, we found that **1** was obtained in a good yield when **2** was pyrolyzed in a flow of nitrogen monoxide at 190 °C using refluxed

$$\underset{\mathbf{2}}{CF_3COONO} \xrightarrow[\text{in a flow of NO}]{\Delta} \underset{\mathbf{1}}{CF_3NO} + CO_2$$

perfluorotributylamine as a diluent. Nitrogen monoxide could easily be removed from the gaseous products by introduction of oxygen into a stream of the gaseous products followed by washing with aqueous alkaline solution and **1** condensed in liquid nitrogen-isopentane traps as blue liquid (Fig. 1).

The influence of the flow rate of nitrogen monoxide on the yield of **1** was examined at a constant rate of addition of **2** (Table 1). The results show that the yield of **1** increases with an increase of the flow rate of nitrogen monoxide and reaches a maximum (77%) at the flow rate of 0.59 mmol/min. The decrease of the yield at the flow rates of more than 0.59 mmol/min is probably attributed to a shortage of the reaction time for **2** at such fast flow rates of nitrogen monoxide.

Table 1. Pyrolysis of **2** in the flow of nitrogen monoxide

Run	Addition rate of **2** mmol/min	Flow rate of NO mmol/min	Yield of **1**/%
1	1.1	0.09	44
2	1.1	0.18	56
3	1.1	0.45	75
4	1.1	0.59	77
5	1.1	0.89	52
6	1.1	1.79	44

The pyrolysis of **2** in the flow of nitrogen monoxide depressed the formation of by-products condensed in Dry Ice–acetone traps, while that without nitrogen monoxide yielded a large amount of by-products containing trifluoronitromethane and *O*-nitroso-*N*,*N*-bis(trifluoromethyl)hydroxylamine as components.[2,4]

Our procedure provides an efficient process for the preparation of **1** because of good yields as well as a flow system desirable for mass production.

Experimental

Nitrosyl Trifluoroacetate (2).[3d] *Caution*: Nitrosyl trifluoroacetate decomposes explosively at temperatures higher than about 100 °C.[3c]

Method A: Trifluoroacetic anhydride (155 ml, 1.1 mol) was added dropwise to dinitrogen trioxide (84 g, 1.1 mol) at −30 °C for 5 min. After stirring at −30 °C for 30 min and then at −5 °C for 3 h, the reaction mixture was distilled under reduced pressure to give **2** (230 g, 74%): bp 42—43 °C/82 mmHg (lit,[3c] 47 °C/94 mmHg).

Method B: Nitrosyl chloride (100 g, 1.54 mol) was condensed into a flask containing finely powdered silver trifluoroacetate (188 g, 0.85 mol) at −70 °C. Then the mixture was allowed to stand for 2 h at −20 °C and gradually warmed to room temperature. The excess of nitrosyl chloride was

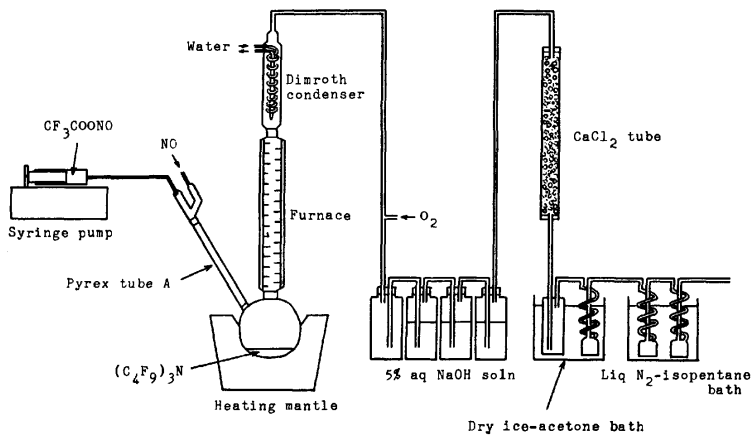

Fig. 1. Apparatus for pyrolysis of **2** in the flow of nitrogen monoxide.

removed and the residue distilled under reduced pressure to give **2** (87.7 g, 72%): bp 48 °C/92 mmHg.

*Trifluoronitrosomethane (**1**).* *Caution*: The pyrolysis must be carried out using a barricade in a hood for protection from a possible explosion hazard. The apparatus is shown in Fig. 1. The furnace is made of a Pyrex tube (2.5 cm × 50 cm, Vigreux tube) wrapped in an electrothermal heating tape controlled by a thermostat. The furnace was maintained at 190 °C. Trifluoroacetate **2** was added at a constant rate to a 500 ml-flask containing refluxed perfluorotributylamine (40 ml, bp 174 °C) through a Teflon tube by means of a syringe pump. A long Pyrex tube A (1.2 cm × 23 cm) is necessary to prevent an explosion of **2**. After the atmosphere in the furnace was replaced with nitrogen monoxide, the pyrolyses using 12.65 g of **2** were done under the conditions shown in Table 1. The results are summarized in Table 1. Oxygen was introduced to the apparatus at the same flow rate as that of nitrogen monoxide. The yields given in Table 1 are those of the product purified by distilling the blue liquid condensed in liquid nitrogen–isopentane traps. The properties of the product were in agreement with those of an authentic sample.

The Spectrophotometric Determination of Phosphate and Arsenate by Selective Extraction with Mixed Solvents

Junichi SHIDA,* Satoru KAKIZAKI, Yasuomi HOZUMI, Akiko ITOH, and (the late) Tsutomu MATSUO
Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Jonan-4, Yonezawa, Yamagata 992
(Received July 15, 1982)

Synopsis. A spectrophotometric method for the simultaneous determination of phosphate and arsenate by selective solvent extraction was examined. First, molybdophosphate was extracted with 1-butanol–chloroform in the presence of molybdoarsenate, and then the molybdoarsenate in the aqueous phase was extracted with MIBK, followed by reduction directly in the organic phase to Molybdenum Blue.

Most methods for the determination of phosphate and arsenate are spectrophotometric methods, based on the formation of the yellow molybdophosphate and molybdoarsenate, followed by the reduction of these complexes to Molybdenum Blue. Arsenate interferes seriously with the determination of phosphate, since their chemical properties are similar.[1-3]

Previous studies of the separation of phosphate, silicate, arsenate, and germanate have shown that phosphate can be separated from mixtures of the four elements as the molybdophosphate by mixed-solvent extraction with (1+3) 1-butanol–chloroform[4] or (2+3) isobutyl alcohol–chloroform.[5]

Paul[6-9] has reported methods for the simultaneous determination of phosphorus, arsenic, silicon, and germanium as heteropoly-blue complexes. However, while simple, these methods lack precision, sensitivity, and rapidity. The present authors have now examined the separation of phosphate and arsenate by selective extraction with various mixed solvents. This paper will report a rapid, sensitive, and accurate method combining solvent extractions and spectrophotometry for the determination of phosphate and arsenate.

Experimental

Apparatus and Reagents. A Hitachi, model 139, spectrophotometer with 10-mm silica cells was used. An Iwaki, model S-L type KM, shaker was used to shake the separatory funnel. All the chemicals were of analytical-reagent grades and were stored in polyethylene bottles to prevent contamination by silica. The water was deionized after distillation.

Standard Phosphate Solution, 200 μg ml^{-1}: Dissolve 0.2198 g of potassium dihydrogenphosphate in water and dilute to 250 ml. This solution is then diluted as required to 2 μg P(V) ml^{-1} with water.

Standard Arsenate Solution, 200 μg As(V) ml^{-1}: Dissolve 0.2082 g of disodium hydrogenarsenate in water and dilute to 250 ml. This solution is then diluted as required to 10 μg As(V) ml^{-1} with water.

Ammonium Molybdate Solution, 0.1 M†: Dissolve 1.77 g of hexaammonium heptamolybdate tetrahydrate, $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ in water and dilute to 1 l.

Procedure. *a) Determination of Phosphate*: Transfer a 20-ml portion of the sample solution (previously neutralized) containing less than 20 μg P(V) and 50 μg As(V) into a 100-ml separatory funnel. Add 4 ml of 0.1 M molybdate solution, 5 ml of 0.5 M potassium chloride, and 3 ml of 2.5 M hydrochloric acid. Dilute with water to 25 ml, mix well, and allow to stand for 10 min. Then, add 10 ml of (7 : 13, v/v)1-butanol–chloroform and shake the funnel vigorously for 5 min with a mechanical shaker. After the phase separation, drain the organic phase into a 20-ml stoppered test tube containing *ca.* 2 g of anhydrous sodium sulfate. Transfer the organic solvent into a 10-ml silica cell, measure the absorbance at 310 nm against a reagent blank. Then, add 10 ml of (3 : 7, v/v) 1-butanol–chloroform to the originasl eparatory funnel, and repeat the extraction and measurement of the absorbance until the molybdophosphate is removed. Refer the total absorbance reading to a calibration curve obtained using a standard phosphate solution.

b) Determination of Arsenate:[10] Add 10 ml of isobutyl methyl ketone (MIBK) to an aqueous solution containing the molybdoarsenate by means of the procedure *a*) described above. Shake the funnel vigorously for 1 min and allow to stand for about 5 min to separate the phases. Discard the aqueous phase and wash the MIBK extract with 10 ml of (1+20)hydrochloric acid. Repeat the washing with 10 ml of (1+20)hydrochloric acid once more to remove the excess of molybdate. Transfer the MIBK extract into a 25-ml volumetric flask, add 4 ml of ethanol and 1 ml of 0.4 M tin(II) chloride, and dilute to the mark with ethanol. Mix well and allow to stand for 20 min. Measure the absorbance at 740 nm against a reagent blank.

Results and Discussion

Effect of the Hydrochloric-acid Concentration. The optimum acidity of the aqueous phase for he formation of the molybdophosphate was found to be 0.15—0.50 M

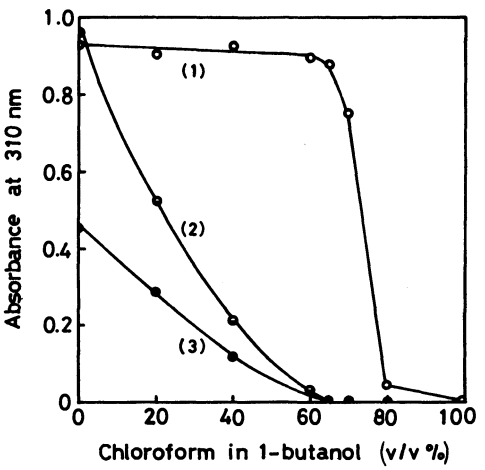

Fig. 1. Effect of the concentration of chlororm in 1-butanol on the extraction.
(1) P(V): 10 μg, (2) As (V): 40 μg, (3) As(V): 20 μg. [HCl]: 0.3 M, [Mo]: 1.6×10^{-2} M, reference: reagent blank.

† 1 M=1 mol dm^{-3}.

hydrochloric acid. Molybdoarsenate was extracted into MIBK in the same range as molybdophosphate. The concentration of 0.3 M hydrochloric acid in the initial solution was, therefore, chosen as the optimum.

Effect of the Concentration of Chloroform in 1-Butanol on the Extraction of Molybdophosphate and Molybdoarsenate. As is shown in Fig. 1, the optimum range was 60—65 v/v % chloroform in 1-butanol to separate the molybdophosphate from the molybdoarsenate. Therefore, 65 v/v% chloroform in 1-butanol, that is, (7 : 13, v/v) 1-butanol–chloroform, was used in the subsequent work. In order to remove the molybdophosphate completely, it was necessary to extract it twice or three times with 1-butanol–chloroform. When the molybdophosphate was extracted with 10 ml of 65 v/v% chloroform in 1-butanol, it was found that the concentration of chloroform in the organic phase turned to 70 v/v%. Then, for the second or third extraction, 70 v/v% chloroform in 1-butanol, that is, (3 : 7, v/v) 1-butanol–chloroform, was used.

The Choice of Extractant. Several mixed organic solvents (1-butanol–cyclohexane, MIBK–chloroform, MIBK-cyclohexane,[1] *etc.*) were examined as extractants. The considerations for the choice of the organic solvents to extract the molybdophosphate are as follows: (1) The solvent should have a greater specific gravity of the organic solvents than that of water, such a greater specific gravity being advantageous for the continuous extraction of molybdoarsenate; (2) the absorbance of reagent blank is low, and (3) it should be possible to separate the phases rapidly after shaking. The mixture of 1-butanol and chloroform was most suitable.

Calibration Curves. The calibration curves for the phosphate and arsenate obtained by the proposed procedure were linear in the ranges of 0—10 μg P(V) and 0—100 μg As(V), and the molar absorptivities, as calculated from the slope of the curve, were 3.0×10^4 $l\cdot mol^{-1}\cdot cm^{-1}$ (at 310 nm) and 1.6×10^4 $l\cdot mol^{-1}\cdot cm^{-1}$ (at 740 nm) respectively.

Recovery of Phosphate and Arsenate. The recovery of phosphate and arsenate in mixtures of the other was examined by the procedure previously described. The results are shown in Table 1. The values were means of the six determinations, and the coefficient of variation was 3—5%. A good recovery and reproducibility were obtained. At higher As(V) concentrations, however, As(V) caused positive error in the determination of P(V).

Table 1. Recovery of phosphorus(V) and arsenic(V)

Amount of elements added μg		Found μg		Recovery %	
P(V)	As(V)	P(V)	As(V)	P(V)	As(V)
4.0	100.0	4.4	98.0	110	98
4.0	50.0	4.2	50.0	105	100
6.0	40.0	6.0	40.8	100	102
20.0	50.0	19.6	51.0	98	102
6.0	15.0	6.0	15.3	100	102
15.0	12.0	14.7	12.0	98	100
20.0	10.0	19.6	10.2	98	102
20.0	6.0	20.0	5.9	100	98

Effect of Diverse Ions. The effect of silicate and germanate ions, which form heteropoly acids, was investigated on the absorbance produced from 6.0 μg P(V) by the proposed procedure. Less than a 2500-fold Si(IV) and a 120-fold Ge(IV) weight excess did not interfere.

Optical Determination of Carboxylate Ions Utilizing Flocculation of Colloidal $Al(OH)_3$

Masayuki MUTO* and Yuko YAMAHACHI
Department of Chemistry, Faculty of Education, Wakayama University, Masago, Wakayama 640
(Received July 19, 1982)

Synopsis. Flocculation of colloidal $Al(OH)_3$ occurs by adding a suitable amount of Congo Red, and the supernatant liquid become scolorless. When some carboxylate ions are present in this colloidal mixture, the quantity of $Al(OH)_3$ decreases because of the formation of complexes, and then excess Congo Red gives a red color to the supernatant liquid. The indirect determination of some kinds of carboxylate ions was carried out by applying the measurement of optical absorption to the supernatant fraction.

An empirical method of measurement of the degree of fatigue was developed by Takeya and Kawada,[1] as described below. A mixture of alkaline Congo Red solution, aluminium potassium sulfate solution, and a body fluid (a serum or urine) was allowed to stand. After centrifugation of the colloidal liquid, the supernatant fraction was determined spectrophotometrically. According to their report, the supernatant fraction became colorless when water was used in place of body fluid. The reason that the supernatant became deep or light in color was, they reported, that the body fluid worked as a protective colloid toward colloidal $Al(OH)_3$.

We considered that the body fluid did not act as a protective colloid, but that carboxylate ions contained in the body fluid functioned as masking agents of Al^{3+}. That is, in the absence of body fluid, $Al(OH)_3$ is flocculated by a suitable amount of pigment anion and the supernatant fraction becomes colorless. However, in the presence of the body fluid, $Al(OH)_3$ decreases, Al^{3+} is masked by carboxylate ions contained in body fluid, and then excess Congo Red which takes no part in flocculation gives a red color to the supernatant fraction.

On the assumption described above, it became possible to determine indirectly carboxylate ion in solution in the suitable concentration range by the measurement of optical absorption of the supernatant fraction of the colloidal mixture.

Experimental

Reagent and Procedure. Takeya and Kawada's method[1] was modified. Aqueous solutions of carboxylate ions, citrate (0.1—1.2 mg/ml), oxalate (0.2—3.2 mg/ml) and lactate (2—32 mg/ml) were used as test solutions; all of these were used as sodium salts.

An aqueous mixture of 1 ml of test solution (including incremental amounts of carboxylate ions), 2 ml of 1.63 mM of aluminium potassium salfate solution, 2 ml of 0.35 mM of Congo Red solution and 2 ml of 4.5 mM of sodium hydroxide solution was allowed to stand for 2 h at 20 °C. In this mixture the Al^{3+}/OH^- is 1/2.76. After centrifugation, the supernatant fraction was measured spectrophotometrically at 490 nm.

Results and Discussion

As shown in Figs. 1—4, the curves of optical absorbance *vs.* content of carboxylate ions are somewhat similar to pH titration curves. In the lower concentration range of test solution, the curves are flat. In that flat part, Congo Red anion is strongly adsorbed. In the higher concentration range of test solution, the curves also appear flat. In the latter, carboxylate ion acts as a masking agent for a large amount of Al^{3+}, and it becomes hard for flocculation of $Al(OH)_3$ to occur.

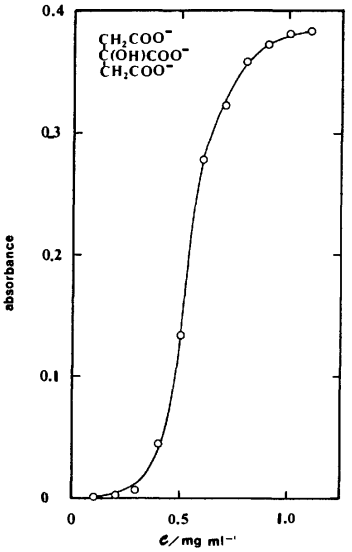

Fig. 1. Absorbance *vs.* content of citrate.

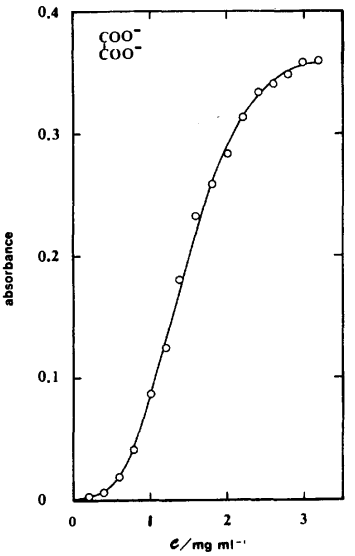

Fig. 2. Absorbance *vs.* content of oxalate.

As shown in Figs. 1—3, the more the number of COO^- and of other anionic groups in a carboxylate ion increases, the larger the masking effect towards Al^{3+} becomes; that is, carboxylate ions can act as chelating agents to Al^{3+}. Mono-dentate ligands, such as acetate and hippurate, are not suitable for this experiment,

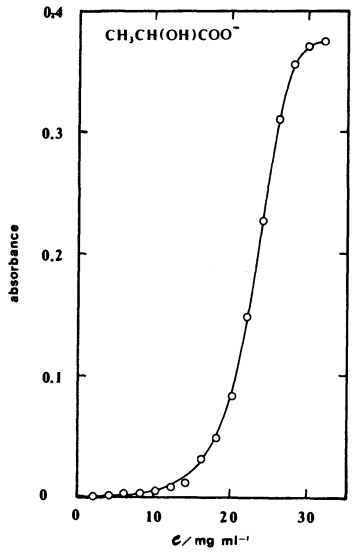

Fig. 3. Absorbance *vs.* content of lactate.

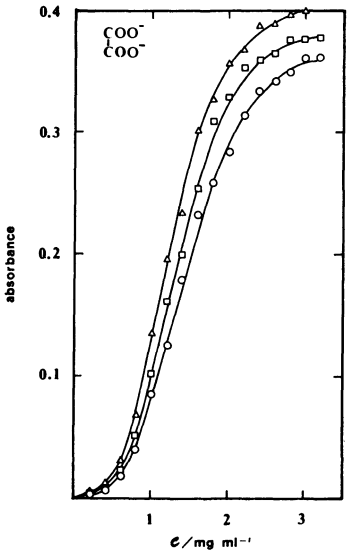

Fig. 4. The effect of temperature on absorbance. —△—: 10 °C, —○—: 20 °C, —□—: 30 °C.

because their masking abilities are very low.

The effect of temperature when oxalate is used as a sample is shown in Fig. 4. The slopes of the curves at lower (10 °C) and higher (30 °C) temperature become greater than that at the appropriate temperature (20 °C); this slope increase is not observed in the range 17—23 °C. At low temperature the formation of colloidal $Al(OH)_3$ is slow, while at high temperature its formation is fast, but the adsorption of pigment anion on the colloidal $Al(OH)_3$ occurs with difficulty. These tendencies are also observed for other carboxylate ions.

Palladium-catalyzed Reaction of Isoprene with Water in Presence of Carbon Dioxide and Base

Yoshio INOUE,* Michio SATO, Masaki SATAKE, and Harukichi HASHIMOTO
Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki-Aoba, Sendai 980
(Received May 21, 1982)

Synopsis. Palladium(0)-catalyzed reaction of isoprene with water was enhanced by the presence of carbon dioxide and a base to give dimethyloctadienols. The same catalyst was found to dehydrate the dimethyloctadienols to afford the corresponding dimethyloctatrienes. The effect of acidity of water on the isoprene-water reaction was also studied.

Terpene alcohols such as geraniol and linalool are considered as made up of head-to-tail dimers of isoprene with the addition of a molecule of water. They occur in oil of rose and other flower essences and are important perfume ingredients.

It is known that the palladium-catalyzed reaction of butadiene with water to give octadienols is accelerated by the presence of carbon dioxide (CO_2).[1] The role of CO_2 is not clear. The possibility of the direct effect has been suggested. To synthesize terpene alcohols in one step from the corresponding reaction of isoprene with water is an interesting subject to be challenged. Usually the reactivity of isoprene is lower than that of butadiene and the reaction has been little studied.[2] Keim *et al.* investigated the reaction by palladium- or platinum-based system and found that the distribution of the isomeric terpenols were subtly influenced by catalyst metal, ligand, reaction temperature, and reaction time.[2a] Concerning the study on the catalytic fixation of CO_2 in 1,3-dienes,[3] we examined the isoprene-water reaction and found that the addition of a base such as $KHCO_3$ accelerated the reaction. The effect of acidity of water on the reaction was also studied.

Results and Discussion

Different from butadiene-water reaction, $Pd(PPh_3)_4$-catalyzed reaction of isoprene with water was very slow even in the presence of CO_2, and the main product was an isoprene dimer, 2,7-dimethyl-1,3,7-octatriene (**1**). But when a base such as $KHCO_3$ was added to the system, a considerable increase in the proportion of dimethyloctadienols was attained. Results are summarized in Table 1. The main alcohols formed were 2,7-dimethyl-1,7-octadien-3-ol (**2**) and 2,7-dimethyl-2,7-octadien-1-ol (**3**), tail-to-tail dimers of isoprene with addition of a molecule of water. The yield of head-to-tail type products, *i.e.*, 2,6-dimethyl-1,7-octadien-3-ol and 3,7-dimethyl-1,7-octadien-3-ol, was small (1—2%) by this catalyst system. It is reported that the addition of *p*-benzoquinone increased **3** in the yield by $Pd(PPh_3)_4$ catalyst.[2a] The reaction occurred from the reaction

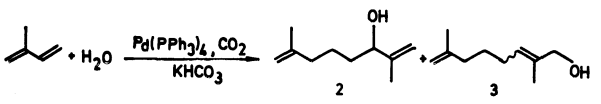

Table 1. Reaction of isoprene with water[a]

Base (mmol)	Isoprene conversion %	Isoprene dimer[b] (%)	C_{10}-Alcohol (%)	Yield/%[c] 2	3

K_2CO_3(27)	79	71	29	12	6
Me_4NOH(5)	59	59	41	16	9

a) Isoprene, 45 mmol; $Pd(PPh_3)_4$, 0.2—0.3 mmol; water, 200—300 mmol; dioxane, 20 ml; CO_2, 40 atm(initial); 110—120 °C; 20 h. b) The main dimer was **1**. c) The yield is based on the isoprene charged (by gas chromatography). d) Without CO_2(under N_2 1 atm). e) Reaction temperature was 90 °C.

temperature 80 °C and the conversion of isoprene increased as the temperature was raised. Bases such as trimethylamine, tetramethylammonium hydroxide, and K_2CO_3 can be used as the co-catalyst. Interestingly $KHCO_3$ was effective by itself as co-catalyst without CO_2, whereas trimethylamine and K_2CO_3 were not effective. $Pd(diphos)_2$[diphos=$Ph_2PCH_2CH_2PPh_2$] scarecely showed the catalytic activity. Dioxane and diethylene glycol dimethyl ether were the best solvent tested. Tetrahydrofuran, 1,2-dimethoxyethane, and *t*-butyl alcohol, which were used for the butadiene-water reaction, were not so effective for the isoprene-water reaction. The same catalyst system accelerated also the butadiene-water reaction. For instance butadiene (180 mmol) and $KHCO_3$ (1 mmol) in 5 ml water gave 1,7-octadien-3-ol (13 mmol), 2,7-octadien-1-ol (49 mmol), and 1,3,7-octatriene (3 mmol) for 4 h reacton at 80 °C in dioxane by $Pd(PPh_3)_4$ (0.18 mmol) and CO_2 (40 atm), while 1,7-octadien-3-ol (7 mmol), 2,7-octadien-1-ol (44 mmol), and 1,3,7-octatriene (4 mmol) were produced under CO_2 pressure without $KHCO_3$.

Interestingly the base-added system catalyzed the dehydration of dimethyloctadienols to give the corresponding dimethyloctatrienes. For example dimethyloctadienols which were composed of **2** (2.8 mmol), **3** (0.7 mmol), and the other octadienols (0.6 mmol) afforded **1** (1.2 mmol) and the other dimers (1.2 mmol) on treatment with $Pd(PPh_3)_4$ (0.2 mmol), trimethylamine (19 mmol), and CO_2 (40 mmol) in dioxane (20 ml) and water (2.6 ml) at 120 °C for 20 h. Control experiments showed that both CO_2 and a base were necessary to the dehydration. This can partly explain the relatively low yield of dimethyloctadienols.

Co-existence of CO_2 and a base is a sort of buffer. The change of acidity of water may accelerate the reac-

Table 2. Effect of the acidity of water[a)]

a) Isoprene, 45 mmol; $Pd(PPh_3)_4$, 0.2 mmol; buffer solution, 5 ml; dioxane, 20 ml; 110—120 °C; 20 h. b) The main alcohols were **2** and **3**. c) KH_2PO_4–Na_2HPO_4. d) KH_2PO_4–NaOH.

tion. So the effect of water acidity on the reaction was examined using several buffer solutions of various pH. Results are shown in Table 2. The reaction did not occur under pH 6 and almost no effect of ionic strength (μ) was observed between μ 0.11 and μ 2.7 at pH 6.8. A slight increase in the proportion of dimethyloctadienols was observed compared to the base-free system, and the proportion was almost constant (about 25%) between pH 6.8 and 12.3. When CO_2 was introduced to 40 atm at pH 6.8, it was improved to 43%. CO_2 in water exists mainly as the form of HCO_3^- in the pH range 7 to 10.[4)] Taking the novel effect of $KHCO_3$ on the isoprene-water reaction, the anion HCO_3^- is possibly playing an important part.[1)]

Experimental

The diene-water reaction was done in a 100 ml stainless-steel autoclave. Typically, isoprene (2.9 g, 43 mmol), $Pd(PPh_3)_4$ (0.36 g, 0.3 mmol), trimethylamine 30% solution (5.4 g), and dioxane (20 ml) were charged in it under an inert atmosphere. Then CO_2 was introduced up to 40 atm and the autoclave was heated at 112 °C for 20 h. After the reaction the organic layer was quantitatively analyzed by gas chromatography (FFAP, 2 m, 150 °C, helium as a carrier gas), showing the formation of 3,7-dimethyl-1,7-octadien-3-ol (0.2 mmol), 2,6-dimethyl-1,7-octadien-3-ol (0.4 mmol), **2** (2.4 mmol), and **3** (0.8 mmol) in addition to isoprene dimers (8.0 mmol). Separation of the octadienols formed from the reaction mixture was done by column chromatography (silica gel/benzene, then methanol). Individual alcohol was isolated by preparative gas chromatography (FFAP, 2 m, 185 °C, hydrogen as a carrier gas).

(Received May 26, 1982)

Synopsis. The reaction of 2-chloro-3,5-dinitropyridine (CDNP) with carboxylic acids and alcohols was examined, and it was found that CDNP was a useful condensing agent. Various esters were prepared in good yields.

It has been reported[1,2] that polynitrohalobenzenes are useful condensing agents for the ester synthesis. In continuation of our studies on the development of new condensing agents, we tried to use 2-chloro-3-nitropyridine, 2-chloro-5-nitropyridine, and 2-chloro-3,5-dinitropyridine (CDNP) and found that CDNP was a useful condensing agent for the preparation of esters.

In the first place, we searched for effective bases for the condensation of benzoic acid and 1-propanol using CDNP.

Pyridine and 4-dimethylaminopyridine (DMAP)[3] proved to give good results (94 and 93% yields, respectively).

Other bases such as triethylamine or 1,8-diazabicyclo-[5.4.0]undec-7-ene did not give good yields (56 and 17% yields, respectively).

In the next experiment, the reaction of benzoic acid with 1-propanol using CDNP was carried out in the presence of Lewis acid with the consideration that the coordination of Lewis acid to CDNP would form reactive species. Lewis acids such as $BF_3 \cdot OEt_2$, $TiCl_4$, $AgBF_4$, and AgCN, which are often used as efficient catalysts, gave only small amounts of the ester.

A significant solvent effect was observed in the condensation of 2,4,6-trimethylbenzoic acid and 1-propanol using CDNP in the presence of DMAP, the ester being obtained in 81% yield in acetonitrile, and 62% yield in dichloromethane as solvents.

Examples of esterification are shown in Table 1.

Benzoic acid was smoothly esterified in pyridine by the procedure in the experimental part. The esterification of sterically hindered 2,4,6-trimethylbenzoic acid with alcohols in pyridine was slow at room temperature. Consequently, the reactions were run by refluxing to give the desired esters in good yields (entries 6, 8, 9, and 11). It has been reported[2] that the esterification of 2,3,6-trimethylbenzoic acid with secondary or tertiary alcohols using 2-chloro-1,3,5-trinitrobenzene is difficult. In contrast, it was found that 2,4,6-trimethylbenzoic acid was esterified with tertiary alcohols such as 2-methyl-2-propanol or 3-ethyl-3-pentanol using CDNP (entries 13 and 15).

The esterification in acetonitrile using a limited amount of DMAP (2 mol equiv. per 1 mol of CDNP) did not give good results (entries 10, 12, 14, and 16) except for entry 7.

When 4-nitro- or 3,5-dinitrobenzoic acid was esterified, yields of the esters were satisfactory (entries 17—26).

On the other hand, when CDNP, benzoic acid, and pyridine were mixed in a 1 : 1 : 2 molar ratio under the absence of alcohol, benzoic anhydride was formed in 79% yield.

Although clear conclusions regarding the esterification reaction mechanism await further study, the main esterification reaction seems to proceed through the acid anhydrides presumably formed from the dinitropyridyl esters by the attack of carboxylate anions remaining in the mixture. However, the direct attack of alcohols on dinitropyridyl esters are considered to participate to varied extents.

TABLE 1. ESTERIFICATION OF CARBOXYLIC ACIDS

	Acid (1 mmol)	Alcohol (1.2 mmol)	Reaction conditions[a] base; temp/°C	Yield of ester/%
1	$C_6H_5CO_2H$	1-Propanol	Pyridine; r.t.	94[b]

a) All reactions were carried out for 30 min. b) Isolated yield of once distilled product. c) Isolated yield of purified product by filtration through a short column of silica gel employing chloroform as an eluant. d) Spectral data (NMR, IR) were consistent with the indicated structure. e) Yield of crude ester. All these crude crystalline esters gave the previously determined mp without further purification.

Experimental

All reagents employed were dried by appropriate methods Commercial 2-chloro-3,5-dinitropyridine (CDNP) was used without further purification.

Ester of Carboxylic Acids. The preparations of *t*-butyl 2,4,6-trimethylbenzoate and *t*-butyl 4-nitrobenzoate are described here as typical examples. To a mixture of 2,4,6-trimethylbenzoic acid (1 mmol, 164 mg) and 2-methyl-2-propanol (1.2 mmol, 114 μl) in pyridine (1 ml) under nitrogen atmosphere was added CDNP (1 mmol, 204 mg) with stirring at 115 °C. After stirring for 30 min, an 8% aqueous sodium hydrogencarbonate solution (20 ml), water (10 ml), and petroleum benzine (40 ml) were added to the reaction mixture, and the whole mixture was well stirred. The mixture was transferred into a separatory funnel and the petroleum benzine layer was separated. The aqueous phase was again extracted with petroleum benzine (20 ml). The combined petroleum benzine extracts were washed with water (10 ml) several times until the yellow color of the solution was removed. The

petroleum benzine layer was then washed twice with 2% hydrochloric acid (20 ml) and twice with water (10 ml), and dried over anhydrous sodium sulfate. The organic layer was concentrated, and the residue was purified by filtration through a short column of silica gel employing chloroform as an eluant. The desired ester (200 mg, 91%) was the only compound observed on solvent removal.

NMR ($CDCl_3$) $\delta = 1.58$ (s, 9H), 2.26 (s, 3H), 2.30 (s, 6H), 6.81 (s, 2H).

t-Butyl 4-nitrobenzoate is a solid, which was obtained directly after the reaction mixture was treated with an aqueous sodium hydrogencarbonate solution and washed with water.

The ester (152 mg, 68%) melted at 115—116 °C, pure enough before recrystallization. (lit,[4] mp 115.5 °C)

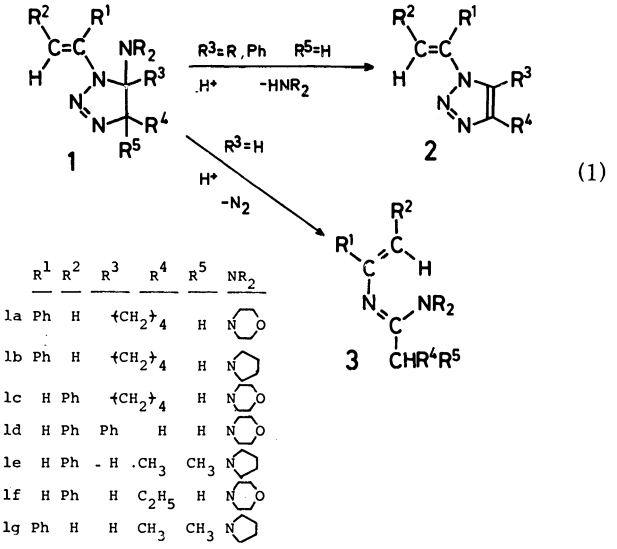
Acid Decomposition of 5-Amino-1-vinyl-4,5-dihydro-1*H*-1,2,3-triazoles. A Novel Formation of 1-Amino-2-azabutadienes

Masato M. Ito, Yujiro Nomura,* Yoshito Takeuchi, and Shuji Tomoda
Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153
(Received June 9, 1982)

Synopsis. Acid decomposition of 4-alkyl-5-dialkylamino-1-vinyl-4,5-dihydro-1*H*-1,2,3-triazoles gave N^1,N^1-dialkyl-N^2-vinylalkanamidines, which have 2-aza-1,3-butadiene skeleton, in fair yields.

We have previously reported the deamination of 5-amino-1-vinyl-4,5-dihydro-1*H*-1,2,3-triazoles (**1a**—**d**, R^3 =alkyl or aryl) to give the corresponding triazoles (**2a**—**d**).[1] Dihydrotriazoles (**1e**—**g**, R^3=H), however, were not deaminated under similar conditions.



(1)

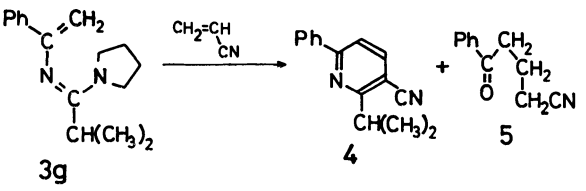
	R^1	R^2	R^3	R^4	R^5	NR_2
1a	Ph	H	$-(CH_2)_4-$		H	N⟨O
1b	Ph	H	$-(CH_2)_4-$		H	N⟨
1c	H	Ph	$-(CH_2)_4-$		H	N⟨O
1d	H	Ph	Ph		H	N⟨O
1e	H	Ph	H	CH_3	CH_3	N⟨
1f	H	Ph	H	C_2H_5	H	N⟨O
1g	Ph	H	H	CH_3	CH_3	N⟨

In the course of our study on nitrogen-extrusion reactions of the dihydrotriazoles (**1**), we noticed that acid decomposition of **1** (R^3=H) might give the corresponding N^2-vinylamidines (**3**) having a 2-aza-1,3 butadiene skeleton, so that the acid decomposition of **1e**—**g** was re-examined.

When the dihydrotriazoles (**1e, f**) were treated with 2 molar amounts of *p*-toluenesulfonic acid at 0 °C, **1** were decomposed with evolution of nitrogen to afford N^2-styrylamidines (**3e, f**) as slightly yellow oil in 46—64% yields.

Determination of the structure of **3e** and **3f** was based on the following spectral data. Mass spectra showed the existence of their molecular ion peak at *m/e* 242 and 258, respectively. In infrared spectra, no absorption corresponding to an N–H bond was observed, and absorption at about 1620 and 1600 cm^{-1} suggested the presence of C=C and C=N bonds. In ^1H and ^{13}C NMR, presence of a newly formed propyl or isopropyl group and an amidine carbon, in addition to a styryl and a 1-pyrrolidinyl or a morpholino group, was demonstrated by their characteristic signals (see Experimental).

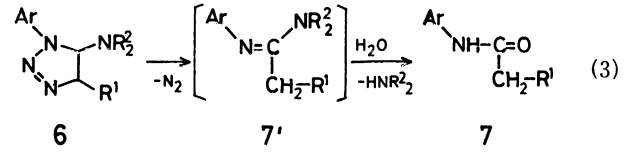
Treatment of the dihydrotriazole (**1g**) with *p*-toluenesulfonic acid was also shown to give the corresponding



(2)

N^2-vinylamidine (**3g**) according to the NMR spectra of the crude product,[2] but attempted isolation of **3g** failed due to its sensitivity to moisture. After the acid in the reaction mixture was removed by neutralization with anhydrous potassium carbonate, the crude product was treated with excess acrylonitrile. Chromatographic separation of the product gave 2-isopropyl-6-phenylnicotinonitrile (**4**) and 5-oxo-5-phenylpentanenitrile (**5**) in 13 and 11% yields, respectively.

Both **4** and **5** were formed by reaction of **3g** with acrylonitrile. It is known that the nicotinonitrile derivative (**4**) is formed by [4+2] cycloaddition reaction of **3g**, formed by thermolysis of **1g** with acrylonitrile, followed by deamination and air oxidation.[2] The oxo nitrile (**5**) would be formed by Michael addition of the enamine moiety of **3g** to acrylonitrile followed by hydrolysis. Thus the formation of **3g** by acid decomposition of **1g** was certified.



(3)

Fusco and coworkers reported that acid decomposition of 4-alkyl-1-aryl-5-dialkylamino-4,5-dihydro-1*H*-1,2,3-triazoles (**6**) gave *N*-arylamides (**7**).[3] They suggested the corresponding amidine (**7'**), which was not actually detected, as an intermediate (Eq. 3).

The present reaction demonstrated the formation of amidines by acid decomposition of 5-dialkylamino-4,5-dihydro-1*H*-1,2,3-triazoles, as well as gave a new route to 1-amino-2-aza-1,3-butadiene derivatives.

Experimental

General. Infrared spectra were determined on JASCO DS-403G and A-202 grating infrared spectrophotometers. Nuclear magnetic resonance spectra were determined on JEOL FX-90Q and Varian EM-390 spectrometers (splitting patterns in ^{13}C NMR data were obtained by off-resonance decoupling). Mass spectra were determined on a Hitachi RMU-6MG mass spectrometer.

4,5-Dihydro-1*H*-1,2,3-triazoles (**1**) were prepared from vinyl azides and enamines according to the previously reported method.[1] Solvents were distilled under anhydrous conditions before use.

2-Methyl-1-(1-pyrrolidinyl)-N-styryl-1-propanimine (3e). To a solution of 4,4-dimethyl-5-(1-pyrrolidinyl)-1-styryl-4,5-dihydro-1*H*-1,2,3-triazole (**1e**, 1.18 g, 4.4 mmol) in dry tetrahydrofuran (THF, 30 ml) was added a THF (30 ml) solution of anhydrous *p*-toluenesulfonic acid (1.57 g, 8.8 mmol) dropwise with stirring at 0 °C. Stirring was continued for further 30 min, until **1e** was completely consumed. Triethylamine (2 ml) was added and the solvent was removed *in vacuo*. After the residue was washed with diethyl ether (3×50 ml), it was alkalized with 5% aqueous solution (50 ml) of sodium hydrogencarbonate and was extracted with three portions (50 ml each) of diethyl ether. The ether layer was washed with saturated aqueous solution (50 ml) of sodium chloride and was dried over anhydrous magnesium sulfate. Removal of the ether *in vacuo* gave **3e** (243 mg, 46% yield) as slightly yellow oil: MS *m/e* 242 (M^+); IR (neat) 1620 and 1600 (C=C and C=N), and 940 cm^{-1} ($_H\rangle C{=}C\langle^H$); ^1H NMR ($CDCl_3$) δ 1.32 (6H, d, J=7 Hz), 1.83 (4H, m), 3.09 (1H, septet, J=7 Hz), 3.46 (4H, m), 6.14 (1H, d, J=13.5 Hz), 6.9—7.4 (5H, m), and 7.76 (1H, d, J=13.5 Hz); ^{13}C NMR ($CDCl_3$) δ 19.5 (q), 25.3 (t), 30.7 (d), 47.9 (t), 117.2 (d, PhCH=), 124.8 (d, *p*), 125.0 (d, *m*), 128.3 (d, *o*), 136.4 (d, =CHN), 139.3 (s, *ipso*), and 163.9 (s, C=N).

Found: *m/e* 242.1805. Calcd for $C_{16}H_{22}N_2$: M, 242.1783.

The amidine (**3e**) could not be induced to crystallize, and chromatographic separation caused decomposition; thus further purification was unsuccessful.

1-Morpholino-N-styryl-1-butanimine (3f). To a solution of 4-ethyl-5-morpholino-1-styryl-4,5-dihydro-1*H*-1,2,3-triazole (**1f**, 1.20 g, 4.20 mmol) in dry THF (40 ml) was added a THF (40 ml) solution of anhydrous *p*-toluenesulfonic acid (1.50 g, 8.40 mmol) dropwise with stirring at 0 °C. Stirring was continued for further 30 min, until **1f** was completely consumed. Then the solution was poured into 0.1 M hydrochloric acid (100 ml), and the solution was washed with diethyl ether (2×80 ml). After alkalization of the aqueous layer with excess sodium carbonate followed by extraction with diethyl ether (3×80 ml), the ether layer was washed with saturated aqueous solution (100 ml) of sodium chloride and was dried over anhydrous magnesium sulfate. Removal of the ether *in vacuo* gave **3f** (696 mg, 64% yield) as slightly yellow oil: MS *m/e* 258 (M^+); IR (neat) 1625 and 1600 (C=C and C=N), and 940 cm^{-1} ($_H\rangle C{=}C\langle^H$); ^1H NMR ($CDCl_3$) δ 0.96 (3H, t, J=7 Hz), 1.47 (2H, sextet, J=7 Hz), 2.21 (2H, t, J=7 Hz), 3.3—3.7 (8H, m), 6.30 (1H, d, J=13.5 Hz), 6.9—7.3 (5H, m), and 7.48 (1H, d, J=13.5 Hz); ^{13}C NMR ($CDCl_3$) δ 13.9 (q), 20.3 (t), 27.5 (t), 45.3 (t), 66.7 (t), 120.2 (d, PhCH=) 125.3 (d, *m*), 125.4 (d, *p*), 128.4 (d, *o*), 135.6 (d, =CHN), 138.6 (s, *ipso*), and 161.7 (s, C=N).

Found: *m/e* 258.1753. Calcd for $C_{16}H_{22}N_2O$: M, 258.1733.

The amidine (**3f**) could not be induced to crystallize, and attempted distillation *in vacuo* or chromatographic separation caused decomposition; thus further purification was unsuccesful.

Decomposition of 4,4-Dimethyl-1-(1-phenylvinyl)-5-(1-pyrrolidinyl)-4,5-dihydro-1H-1,2,3-triazole (1g). To a solution of **1g** (0.50 g, 1.9 mmol) in dry THF (30 ml) was added a THF (30 ml) solution of anhydrous *p*-toluenesulfonic acid (0.71 g, 4.0 mmol) dropwise with stirring at 0 °C. Stirring was continued for further 30 min until **1g** was completely consumed. Then anhydrous potassium carbonate (2.0 g) was added to the solution and stirring was continued overnight. After solid materials had been filtered off and the solvent had been removed *in vacuo*, acrylonitrile (3 ml) was added to the residue and the mixture was stirred for 2 d at room temperature. Excess acrylonitrile was removed and the silica gel preparative thin layer chromatography of the residue gave previously reported 2-isopropyl-6-phenylnicotinonitrile (**4**,[2] 54 mg, 13% yield) and 5-oxo-5-phenylpentanenitrile (**5**, 34 mg, 11% yield).

2-Isopropyl-6-phenylnicotinonitrile (4): Colorless crystals; mp 73.5—75.0 °C, lit, 75.5—76.5 °C.[2] Mixed melting point test with the authentic sample; mp 74.5—76.0 °C.

5-Oxo-5-phenylpentanenitrile (5): Colorless oil; MS *m/e* 173 (M^+); IR (neat) 2220 (C≡N) and 1685 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ 2.09 (2H, quintet, J=6.5 Hz), 2.56 (2H, t, J=6.5 Hz), 3.17 (2H, t, J=6.5 Hz), 7.4—7.7 (3H, m), and 7.9—8.1 (2H, m); ^{13}C NMR ($CDCl_3$) δ 16.6 (t), 19.9 (t), 36.4 (t), 119.3 (s, C≡N), 128.0 (d), 128.7 (d), 133.4 (d), 136.6 (s), and 198.2 (s, C=O).

The Wallach Rearrangement of Some 4,4′-Disubstituted Azoxybenzenes

Ichiro SHIMAO* and Shigeru OAE†

Department of Industrial Chemistry, Faculty of Engineering, Toyama University, Takaoka, Toyama 933

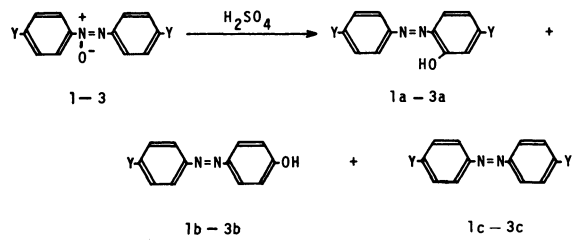
†*Department of Chemistry, The University of Tsukuba, Sakura-mura, Niihari, Ibaraki 305*

(Received June 14, 1982)

Synopsis. The treatment of azoxybenzenes bearing electron-withdrawing substituents at 4,4′-positions with sulfuric acid gave the corresponding 2-hydroxyazobenzenes, together with 4′-substituted 4-hydroxyazobenzenes. The treatment of 4,4′-dimethoxyazoxybenzene with *p*-toluenesulfonic acid and acetic anhydride afforded 4,4′-dimethoxy-3-acetoxyazobenzene and 4,4′-dimethoxy-2-tosyloxyazobenzene as the main rearrangement products.

In the Wallach rearrangement of 4,4′-dialkylazoxybenzenes with sulfuric acid, the main product was not the *o*-hydroxyazo compound, but an abnormal product formed by the ipso nucleophilic attack on the ring carbon atom bearing the alkyl group.[1] Another abnormal rearrangement was also observed in the reaction of 4,4′-dihaloazoxybenzenes with sulfuric acid; in this reaction, however, the major products were the reduction products, *i.e.*, 4,4′-dihaloazobenzenes.[2] The pattern of the reaction of azoxybenzenes with strong acids seems to be markedly affected by the *p*-substituents.

We have now found another example of the ipso substitution reaction of 4,4′-disubstituted azoxybenzenes. That is, when 4,4′-dinitroazoxybenzene (**1**), 4,4′-diacetylazoxybenzene (**2**), and azoxybenzene-4,4′-dicarboxylic acid (**3**) were treated with sulfuric acid, not only the normal rearrangement products (**1a**—**3a**), but also the ipso rearrangement products (**1b**—**3b**), were obtained. The results are shown in Table 1.



Compound **1** was found to rearrange in a normal fashion, giving preferentially 5-nitro-2-(*p*-nitrophenylazo)phenol (**1a**). This is a typical example of the Wallach rearrangement with sulfuric acid to give the ortho-rearranged azophenol.

The reaction of **2** gave 4-(*p*-acetylphenylazo)phenol (**2b**) as the main rearrangement product. When the aqueous solution was carefully concentrated in the work-up process, the characteristic odor of acetic acid was perceived. In the reaction of **3**, the evolution of carbon dioxide was observed when the reaction mixture was heated. These ipso substitution may be explained on the basis of the mechanistic scheme involving the initial formation of the dicationic inetermediate, $Ar\text{–}\overset{+}{N}\equiv\overset{+}{N}\text{–}Ar$, proposed previously.[1,2]

Table 1. Reactions of 4,4′-disubstituted azoxybenzenes with sulfuric acid

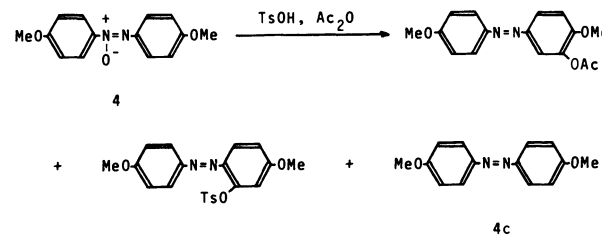
Azoxybenzene Y	Temp °C	Time h	Yield/% a	b	c	Recovered material/%
1 NO_2	100	3	54	11	4	27
2 $COCH_3$	70	5	2.5	46		31
3 COOH	100	1/3	29	49	9	

Although an acetyl group of **2** was readily removed, the reaction of *p*-acetylazoxybenzene (a mixture of *o*- and *p*-isomers) with sulfuric acid afforded **2b** (yield, 93%), without removing acetyl group. In this case, the nucleophilic attack of the hydrogen-sulfate ion on the dicationic intermediate occurs preferentially at the para position of the unsubstituted phenyl ring. This is different from the reaction of 4-*t*-butylazoxybenzene, in which 4-(phenylazo)phenol was formed as the main product.[3]

Several azoxybenzenes were treated with concentrated sulfuric acid at 100 °C for 20 min, and the yields of the recovered azoxy compounds (determination by gas-chromatographic analysis) were the following: **1**, 92%; **2**, 42%; 3,3′-dinitroazoxybenzene, 33%; **3**, 0%. The reaction is obviously retarded by the electron withdrawing substituent, in keeping with the kinetic results reported by Duffey and Hendley.[4]

Contrary to Cox and Buncel's description,[5] 4,4′-dimethoxyazoxybenzene (**4**) was found to react readily with 80% sulfuric acid. A black tarry substance was mainly formed, and only a small amount of 4,4′-dimethoxyazobenzene (**4c**) (yield, 2%) was isolated. However, no rearrangement product was obtained. Similary, 4-methoxyazoxybenzene did not give hydroxymethoxyazobenzene, but 4-methoxyazobenzene (34%) and 4-hydroxyazobenzene (0.5%) were obtained.

Meanwhile, the reaction of **4** with a mixture of *p*-toluene-sulfonic acid (TsOH) and acetic anhydride gave 4,4′-dimethoxy-3-acetoxyazobenzene (42%), 4,4′-dimethoxy-2-tosyloxyazobenzene (3.5%), and **4c** (32%) as the main products.



Under the same conditions, azoxybenzene gave 2- and 4-(tosyloxy)azobenzene as the main rearrangement products, while 4,4′-diacetoxyazoxybenzene gave *p*-acetoxyphenyl tosylate and hydroquinone diacetate.[6] The methoxyl group is a poor leaving group, and it can

stabilize the dicationic intermediate, $Ar-\overset{+}{N}\equiv\overset{+}{N}-Ar$. Hence, the rearrangement is believed to proceed very readily, without cleaving the azo linkage.

Thus, when 4-methoxyazoxybenzene was treated with TsOH and acetic anhydride, 4-methoxy-3-acetoxyazobenzene (38%), 4-methoxy-4′-tosyloxyazobenzene (5.6%), and 4-methoxyazobenzene (42%) were obtained as the main products.

Experimental

The reaction products were identified by a comparison of their properties with those of independently prepared samples.

The azoxy compounds, except **3**, were treated with sulfuric acid according to a procedure similar to those reported previously.[2] **1a**, mp 246—247 °C (from $CHCl_3$). Found: C, 49.85; H, 2.62; N, 19.29%. Calcd for $C_{12}H_8N_4O_5$: C, 50.00; H, 2.80; N, 19.44%. **2a**, mp 206—207 °C (from hexane–benzene). Found: C, 67.85; H, 5.08; N, 9.79%. Calcd for $C_{16}H_{14}N_2O_3$: C, 68.08; H, 5.00; N, 9.92%.

Reaction of 3 with Sulfuric Acid. A solution of **3** (0.5 g) in concentrated sulfuric acid (50 ml) heated at 100 °C for 20 min. The solution was poured into a large amount of cold water. The precipitates were filtered and then extracted with acetone. The extract gave **3b** (0.18 g); mp 270 °C (decomp). The acetone-insoluble material was added to a solution of H_2SO_4 (1 ml) in MeOH (30 ml). The suspension was refluxed for 24 h with stirring and then poured into cold water. The methyl ester was collected by filtration and then treated further with acetic anhydride and pyridine, as usual, to afford the acetate. The resulting esters were chromatographed on silica gel (benzene). The first fraction gave methyl 4-(*p*-methoxyphenylazo)benzoate (0.035 g); mp 170—171 °C (from MeOH). Found: C, 66.83; H, 5.31; N, 10.48%. Calcd for $C_{15}H_{14}N_2O_3$: C, 66.65; H, 5.23; N, 10.37%. The second fraction gave dimethyl azobenzene-4,4′-dicarboxylate (0.05 g); mp 242—243 °C. The third fraction gave dimethyl 2-acetoxyazobenzene-4,4′-dicarboxylate (0.18 g); mp 151—153 °C (from MeOH). Found: C, 60.77; H, 4.25; N, 8.08%. Calcd for $C_{18}H_{16}N_2O_6$: C, 60.66; H, 4.50; N, 7.87%.

Reaction of 4 with TsOH and Ac_2O. A solution of **4** (0.5 g) and $TsOH \cdot H_2O$ (5.0 g) (dehydrated by heating under reduced pressure) in Ac_2O (12.5 ml) was heated at 100 °C for 1 h. The reaction mixture was poured into a cold $NaHCO_3$ solution and then extracted with benzene. The extract was chromatographed on a silica-gel column (benzene). The first fraction gave **4c** (0.15 g); mp 168—169 °C. The second fraction gave 4,4′-dimethoxy-2-tosyloxyazobenzene (0.029 g); mp 100—101 °C. Found: C, 61.09; H, 4.87; N, 7.01%. Calcd for $C_{21}H_{20}N_2O_5S$: C, 61.15; H, 4.89; N, 6.79%. The tosylate was heated with a 30% NaOH solution at 100 °C for 3 h to give 4,4′-dimethoxy-2-hydroxyazobenzene (**4a**) (0.014 g); mp 137—138 °C. The third fraction was recrystallized from hexane–benzene to give 3-acetoxy-4,4′-dimethoxyazobenzene (0.20 g); mp 188—189 °C. The mother liquor was treated with 3% NaOH to give **4a** (0.008 g) and 3-hydroxy-4,4′-dimethoxyazobenzene; mp 177—178 °C (0.038 g). This azophenol was refluxed with dimethyl sulfate in acetone in the presence of K_2CO_3 for 6 h to yield 3,4,4′-trimethoxyazobenzene; mp 128—130 °C. Found: C, 66.36; H, 5.97; N, 10.29%. Calcd for $C_{15}H_{16}N_2O_3$: C, 66.16; H, 5.92; N, 10.28%.

Reaction of 4-Methoxyazoxybenzene with TsOH and Ac_2O. This reaction was carried out according to a procedure similar to those described above. Products: 4-methoxy-4′-tosyloxyazobenzene; mp 131.5—133 °C (from MeOH), 3-acetoxy-4-methoxyazobenzene; mp 112—113 °C (from hexane), 3-hydroxy-4-methoxyazobenzene; mp 95—97 °C (from hexane).

The Reaction of *O*-Silylated Enolates of Carboxylic Esters and of Lactones with Aminomethyl Ethers Catalyzed by $ZnCl_2$

Tatsuo OIDA,* Shigeo TANIMOTO,* Hideyuki IKEHIRA, and Masaya OKANO
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received June 22, 1982)

Synopsis. It was found that the reaction of *O*-silylated enolates of carboxylic esters and of lactones with aminomethyl ethers proceeds smoothly under a catalytic action of zinc chloride to afford the corresponding α-aminomethylated carboxylic esters or lactones, except only one case using *O*-silylated enolate of δ-valerolactone, in which the resultant α-aminomethyl-δ-valerolactone is somewhat unstable and undergoes decomposition, leading to the production of α-methylene-δ-valerolactone.

It is well known that Mannich salts and related compounds bearing a structural resemblance are excellent precursors of α-methylene carbonyl compounds.[1] In 1980 Miyano and his co-workers[1] were successful in preparing the Mannich salts of carbonyl compounds *via* *O*-silylated enolates of ketones and aldehydes by a combination of chloroiodomethane and *N,N,N',N'*-tetramethyldiaminomethane. More recently, Hosomi and his co-workers[2] were successful in preparing the salts by the reaction of *O*-silylated enolates of ketones with aminomethyl ethers catalyzed by the use of iodotrimethylsilane or trimethylsilyl trifluoromethanesulfonate. Though these mthods are found superior in many instances to the earlier procedures, such as those using preformed moisture-sensitive iminium salts[3] with enol silyl ethers, they involve the utilization of relatively expensive and not easily available reagents. With these considerations in mind, we have studied the reaction of *O*-silylated enolates of saturated carboxylic esters (**1**) with aminomethyl ethers (**2**) in the presence of easily available zinc chloride. The reaction proceeds smoothly at room temperature in acetonitrile to afford the corresponding α-aminomethyl carboxylic esters (**3**) in moderate yields; these esters are not readily, if at all, obtainable by other procedures (Table 1).

The reaction may involve the initial loss of the alkoxyl group of **2** to give the aminomethyl cation and its subsequent (or simultaneous) attack on **1**, accompanied by the release of the trimethylsilyl group.

When this procedure was extended to *O*-silylated enolates of δ-valerolactone, γ-butyrolactone, and methyl 3-butenoate (**4**, **5**, and **6**), somewhat different results were observed (Table 2).

It was recognized that, in the reaction of **4** with **2**, the initially formed α-aminomethyl-δ-valerolactones are

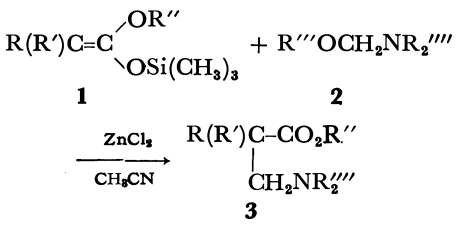
a) The structures of the aminomethyl ethers (**2a**, **2b**, and **2c**) are shown in Table 1. b) The ^{1}H-NMR spectra of these products (60 MHz, δ, in $CDCl_3$) are as follows: **7**: 1.7—2.2(m, 2H), 2.5—2.8 (m, 2H), 4.36 (t, 2H), 5.4—5.7 (m, 1H), 6.2—6.5 (m, 1H). **8a**: 0.97 (t, 3H), 1.01 (t, 3H), 2.2—3.1 (m_2 9H), 4.1—4.5 (m, 2H). **8b**: 2.09 (s, 6H), 2.0—2.5 (m, 5H), 4.0—4.4 (m, 2H). **8c**: 2.0—3.0 (m, 2H), 3.5—3.8 (m, 4H), 4.0—4.5 (m, 9H). **9a**: 1.01 (t, 6H), 2.2—2.7 (m, 8H), 3.68 (s, 3H), 5.83 (d, 1H), 6.96 (dt, 1H). **9b**: 2.20 (s, 6H), 2.1—2.5 (m, 4H), 3.64 (s, 3H), 5.82 (d, 1H), 6.6—7.1 (m, 1H). **9c**: 2.3—2.6 (m, 8H), 3.5—3.8 (m, 4H), 3.68 (s, 3H), 5.84 (d, 1H), 6.7—7.2 (m, 1H). c) Yield of isolated product based on **4**, **5**, or **6**. d) Presumably, **9a**, **9b**, and **9c** are *trans*-isomers. e) Yield in the reaction using the CH_2Cl_2 solvent.



a: R=H, R′=R″=C_2H_5 **b**: R=R′=R″=CH_3
c: R=C_2H_5, R′=R″=CH_3 **d**: R(R′)=$-(CH_2)_5-$, R″=CH_3
e: R(R′)=$-(CH_2)_4-$, R″=CH_3

rather unstable under the present reaction conditions; therefore, they partially undergo decomposition, leading to the production of α-methylene-δ-valerolactone (**7**). The remaining α-aminomethyl-δ-valerolactones, unchanged during the reaction, were converted into **7** in the work-up procedure involving repeated distillation, which causes the thermal decomposition of the aminomethylated compounds (see Experimental section). In contrast, in the cases of **5**, α-aminomethyl-γ-butyrolactone (**8a**, **8b**, and **8c**) were isolated, suggesting that the aminomethylated compounds are stable under the given reaction conditions, as well as during distillation under reduced pressure. The reaction of **6** with **2** proceeded smoothly to afford the products **9a**, **9b**, and **9c** resulting from the attack on the γ-position of **6**.

The general availability of *O*-silylated enolates[6] from carboxylic esters and from lactones, and of aminomethyl ethers from secondary amines, formaldehyde, and primary alcohols, along with the simple work-up procedures required for these reactions, indicates that this procedure may provide a useful method for the preparation of α-aminomethylated carboxylic esters or lactones.

Experimental

Into a solution of zinc chloride (1.36 g, 10 mmol) in dry acetonitrile (20 ml), we added with stirring a mixture of an *O*-silylated enolate (10 mmol) and an aminomethyl ether (10 mmol). The stirring was continued at room temperature for about 24 h under nitrogen. The resultant reaction mixture was poured into dilute aq $NaHCO_3$ and extracted with ether. The ethereal solution was extracted with 5% aq HCl, and the resultant aq layer was basified with 5% NaOH. The basified aq phase was extracted with ether, then dried over $MgSO_4$ and evaporated *in vacuo* to give a residue. The distillation of this residue yielded the product. In the reaction using **4** as the starting substrate, the following work-up procedure was adopted: the resultant reaction mixture was poured into dilute aq Na_2CO_3 and extracted with ether. The ethereal solution was dried over $MgSO_4$ and evaporated *in vacuo* to give a residue, which was repeatedly distilled under reduced pressure.

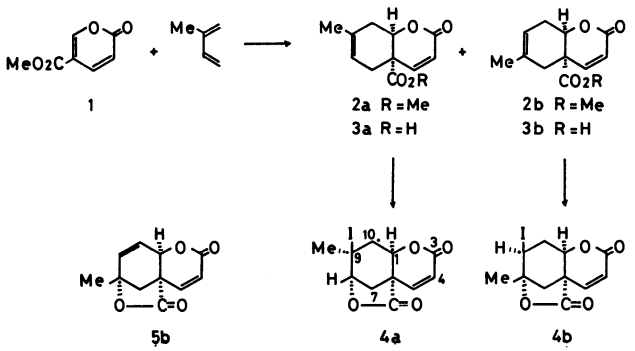
Synopsis. The preparation of 9- and 8-methyl-9-iodo-3-oxo-2-oxabicyclo[4.4.0]dec-4-ene-6,8-carbolactone and 8-methyl-3-oxo-2-oxabicyclo[4.4.0]deca-4,9-diene-6,8-carbolactone from the adducts (**2a** and **2b**) of methyl coumalate with isoprene confirmed the structures of the regioisomers, **2a** and **2b**.

With respect to our studies[1] on construction of the *cis* A, B ring junction of trichothecane-type sesquiterpenes, the cycloaddition of methyl coumalate (**1**) with isoprene was investigated for the preparation of a potential intermediate for these sesquiterpenoid syntheses.

Although the Diels-Alder reaction of **1** with isoprene was previously reported to produce a mixture of regioisomers (**2a** and **2b**),[2] no purification of the adducts has been made and the position of methyl substitution seems not to be confirmed. We have found that separation of the adducts by column chromatography on silica gel is unsuccessful, and the ^{1}H NMR spectra of the mixture showed homogeneous signals. Therefore, we tried to carry out the functionalization of **2a** and **2b** in order to confirm their structures.

The cycloaddition of **1** with isoprene at 110—120 °C in an autoclave afforded a mixture of bicyclic adducts (**2a** and **2b**) along with some other products. Hydrolysis of the regioisomeric mixture (the isomeric ratio was appoximately 10 : 1 as indicated by ^{13}C NMR integrals) with aqueous sodium hydroxide solution afforded the corresponding acids (**3a** and **3b**). Without separation and purification, a mixture of **3a** and **3b** was allowed to undergo iodolactonization. Column chromatography of the resultant iodolactones gave **4a** and **4b** in 10 : 1 ratio (63% yield from **2**). Their ^{1}H NMR spectra showed differences, such as the methylene proton signals, and each showed a characteristic pair of one proton quartets at δ 4.11, 4.59 (**4a**), and 4.36, 4.67 (**4b**), due to the methylidyne protons of C-1, C-8, and/or C-9. However, the assignments were ambiguous. The absence of a distinguishing feature between **4a** and **4b** prompted us to examine dehydrohalogenation of **4** as follows. Treatment of **4b** with 1,8-diazabicyclo-[5.4.0]undec-7-ene (DBU) in THF gave the desired **5b** in 91% yield. The structure of **5b** was confirmed by elemental analysis and spectral data. On the other hand, **4a** resisted an analogous elimination reaction, suggesting that the proton in an *anti* orientation with respect to the iodine is difficult to abstract by DBU due to the steric shielding by the C-9 methyl group.



This result established that the structure of the major product of the Diels-Alder reaction corresponds to **2a**, which would be expected to provide a synthetic intermediate for the preparation of trichothecanes.

Experimental

All the melting points are uncorrected. IR spectra were recorded in $CHCl_3$ on a Hitachi 260-50 spectrophotometer. ^{1}H NMR spectra and ^{13}C NMR spectra were measured in $CDCl_3$ with a JEOL JNM MH-100 spectrometer (100 MHz) and a JEOL JNM-FX 60 Fourier Transform spectrometer (60 MHz) operating at 15.1 MHz, respectively. Chemical shifts are expressed in terms of δ values (ppm) relative to TMS as an internal standard. Mass spectra were recorded on a JEOL JMS-D 300S mass spectrometer with a direct inlet system operating at 70 eV. Column chromatography was performed with Merck silica gel (0.063 mm).

9- and 8-Methyl-6-methoxycarbonyl-2-oxabicyclo[4.4.0]*deca*-4,8-*dien-3-one (2a and 2b).* A mixture of 2.0 g (13 mmol) of methyl coumalate and 6 ml (60 mmol) of isoprene in 20 ml of benzene was heated at 110—120 °C for 18 h in an autoclave under N_2. After removal of the solvent and excess of the diene, the residue (3.0 g) was chromatographed on a silica gel with hexane–ethyl acetate (4 : 1) to afford a mixture of **2a** and **2b** as a colorless viscous oil, 0.93 g (32%). IR: 1740, 1720, 1640 cm^{-1}; ^{1}H NMR: 1.68 (3H, s, $-CH=\underline{C}CH_3$), 1.96—2.86 (4H, m, 2 $-CH_2-$), 3.76 (3H, s, $-CO_2CH_3$), 5.00 (1H, dd, J= 3, 5 Hz, C_1–H), 5.44 (1H, m, C_8– and/or C_9–H), 6.05 and 6.93 (each 1H, d, and J=11 Hz, C_4– and C_5–H); ^{13}C NMR: 22.9 (C_9–CH_3), 31.2, 29.1 (weak) and 33.7, 34.7 (weak) (C_7 and/or C_{10}), 45.8 (C_6), 52.9 ($CO_2\underline{C}H_3$), 76.1 and 75.1 (weak) (C_1), 117.8 and 117.4 (weak) (C_8), 120.9 (C_4), 131.2 (C_9), 149.9 (C_5), 163.4 (C_3), 171.8 ($\underline{C}O_2CH_3$); MS: *m/e* 222 (M^+). The other fractions gave the known product, tricyclo[3.2.1.0]octene derivative[2a] (1.0 g) and unidentified materials (0.4 g).

9- and 8-Methyl-9-iodo-3-oxo-2-oxabicyclo[*4.4.0*]*dec-4-ene-6,8-carbolactone (4a and 4b).* A mixture of 2.3 g (10.3 mmol) of **2** in 300 ml of 5% aqueous sodium hydroxide solution was stirred for 12 h at room temperature. The solution was acidified with 5% hydrochloric acid under ice-cooling and the mixture was extracted with $CHCl_3$. The extract was washed with brine and dried over Na_2SO_4. Removal of the solvent gave 2.0 g of crude acids (**3a** and **3b**). Without further purification, a mixture of the acids in 77 ml of 0.5 M aqueous sodium hydrogencarbonate solution was added to a solution of 6.35 g (25.0 mmol) of iodine and 12.8 g (76.6 mmol) of

potassium iodide in 38 ml of water. The mixture was allowed to stand in a dark room for 48 h with occasional shaking. The reaction mixture was extracted with CH_2Cl_2. The extract was washed with 5% aqueous sodium thiosulfate and brine, and dried over Na_2SO_4. The solvent was evaporated *in vacuo* to give 2.7 g of pale yellow solid, which was repeatedly chromatographed on a silica gel using CH_2Cl_2 as the eluent to afford 2.0 g of **4a** and 0.2 g of **4b**. **4a**: Mp 184.5—187.5 °C (recrystallized from CH_2Cl_2); IR: 1760, 1740 cm^{-1}; ^1H NMR: 1.66 (3H, s, C_9–CH_3), 2.40—2.70 (4H, m, 2 –CH_2–), 4.11 (1H, t, J=9 Hz, C_8–H), 4.59 (1H, dd, J=7, 10 Hz, C_1–H), 6.13 and 7.26 (each 1H, d, and J=11 Hz, C_4– and C_5–H); ^{13}C NMR: 22.5 (C_9–CH_3), 26.4 (C_9), 33.9 and 35.5 (C_7 and/or C_{10}), 43.4 (C_6), 74.5 (C_1), 84.3 (C_8), 122.3 (C_4), 143.6 (C_5), 161.9 (C_3), 169.6 (–CO_2– of C_6); MS: *m/e* 334 (M^+); Found: C, 39.60; H, 3.26%. Calcd for $C_{11}H_{10}O_4I$: C, 39.66; H, 3.03%. **4b**: Mp (decomp) 184—186 °C (recrystallized from CH_2Cl_2); IR: 1785, 1740 cm^{-1}; ^1H NMR: 1.79 (3H, s, C_8–CH_3), 2.0—3.2 (4H, m, 2 –CH_2–), 4.36 (1H, dd, J=2, 4 Hz, C_9–H), 4.67 (1H, dd, J=2, 3 Hz, C_1–H), 6.21 and 7.26 (each 1H, d, and J=11 Hz, C_4– and C_5–H); ^{13}C NMR: 20.7 (C_8–CH_3), 25.5 (C_9), 36.1 and 37.9 (C_7 and/or C_{10}), 49.4 (C_6), 73.6 (C_1), 86.7 (C_8), 123.5 (C_4), 144.4 (C_5), 161.0 (C_3), 169.2 (–CO_2– of C_6); MS: *m/e* 334 (M^+); Found: C, 39.64; H, 3.29%. Calcd for $C_{11}H_{10}O_4I$: C, 39.66; H, 3.03%.

Dehydrohalogenation of ***4a*** *and* ***4b***. To a solution of 100 mg (0.3 mmol) of **4b** in 10 ml of dry THF was added 0.13 ml (0.9 mmol) of DBU with stirring at 10 °C under N_2. After being stirred for 1 h at room temperature and for 30 min at 40—45 °C, the mixture was acidified with aqueous 5% hydrochloric acid under ice-cooling and taken up in benzene. The extract was washed with brine, dried over Na_2SO_4, and concentrated. The residue was chromatographed (benzene–ethyl acetate, 92 : 8) to give 56 mg (91%) of **5b** as a colorless solid. Mp 140—141 °C (recrystallized from benzene–hexane); IR: 1780, 1755, 1740, 1605 (weak) cm^{-1}; ^1H NMR: 1.67 (3H, s, C_8–CH_3), 2.28 and 2.52 (each 1H, d, and J=13 Hz, –CH_2–), 4.98 (1H, d, J=4 Hz, C_1–H), 6.03 (1H, dd, J=4, 10 Hz, C_{10}–H), 6.27, 6.39, and 7.02 (each 1H, d, and J=10 Hz, C_4–, C_9–, and C_5–H); ^{13}C NMR ($(CD_3)_2CO$): 22.9 (C_8–CH_3), 42.1 (C_7), 49.3 (C_6), 72.9 (C_1), 82.0 (C_8), 123.3 (C_4), 128.0 (C_{10}), 139.6 (C_9), 146.0 (C_5), 162.5 (C_3), 175.7 (–CO_2– of C_6); MS: *m/e* 206 (M^+); Found: C, 63.98; H, 4.92%. Calcd for $C_{11}H_{10}O_4$: C, 64.07; H, 4.89%; whereas an analogous reaction of **4a** with DBU led to recovery of the starting material, and to decomposition of **4a** under vigorous conditions.

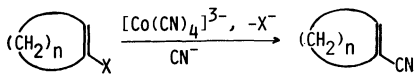
Cyanation of 1-Halocycloalkenes Catalyzed by Tetracyanocobaltate(I). Convenient Synthesis of 1-Cyanocycloalkenes

Takuzo FUNABIKI,* Hirohito KISHI, Yoshihiro SATO, and Satohiro YOSHIDA
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606
(Received July 30, 1982)

Synopsis. 1-Cyanocycloalkenes (1-cyanocyclopentene, -hexene, -heptene, and -octene) were readily synthesized by catalytic cyanation of the corresponding 1-halocycloalkenes with tetracyanocobaltate(I). Reactivities of methyl-substituted 1-chlorocyclohexenes were lower than that of 1-chlorocyclohexene, and 1-chloro-2-methylcyclohexene scarecely reacted. Hydrogenation and isomerization of 1-cyanocycloalkenes were observed only with 1-cyanocycloheptene and 1-cyano-6-methylcyclohexene, respectively.

Previously we have reported the convenient synthetic method of α,β-unsaturated nitriles by cyanation of vinyl halides with tetracyanocobaltate(I), which is formed in an aqueous alkaline solution of pentacyanocobaltate(II) under hydrogen atmosphere.[1] To extend the utility of this method, we have studied the reactivity of 1-halocycloalkenes. Alicyclic α,β-unsaturated nitriles serve as versatile intermediates in organic syntheses, and the methods of preparation of these nitriles may be applicable to the synthetic chemistry of natural products. The most conventional synthetic method of 1-cyanocycloalkenes is the addition of hydrogen cyanide to cycloalkanones to form cyanohydrins, which are dehydrated to nitriles.[2] This method was recently modified to a one-pot reaction by using trimethylsilyl cyanide.[3] Some other reactions have been reported mostly for synthesis of 1-cyanocyclohexene, but examples of synthesis of 1-cyanocyclopentene,[2a,b,e]-heptene,[2b,c,d] and -octene,[2c,3] are very few. The present reaction (Eq. 1) is applicable to 1-halocycloalkenes of various ring sizes, and high yields of 1-cyanocycloalkenes can be obtained under mild conditions from cycloalkenes or cycloalkanones as starting materials.



(1)

Results and Discussion

The reactions were performed in the same way as reported previously.[1] As shown in Table 1, 1-bromocycloalkenes were quantitatively converted into 1-cyanocycloalkenes. The reaction of 1-bromocyclopentene was fairly slower than other three bromides. The reaction proceeded catalytically, but the dropwise addition of the KCN solution at the controlled rate[1] was necessary for cyanation of a large excess of bromides as shown by the reaction of 1-bromocyclooctene. Interestingly, only 1-cyanocycloheptene was significantly hydrogenated. In the cyanation of alkenyl halides, the hydrogenation of acrylonitriles was observed with MeCH=CMeCN, but not with MeCH=CHCN, Me_2C=CHCN, and Me_2C=CMeCN.[1] The relation between the structure of acrylonitriles and facility for hydrogenation has not been clarified.

In order to find the effect of an alkyl substituent on the reactivity, we have studied the reactions of methyl-substituted 1-chlorocyclohexene. Results are shown in Table 2. 1-Chlorocyclohexene was cyanated at the similar rate to 1-bromocyclohexene, supporting that the reaction proceeds stepwise *via* a σ-vinyl cobalt complex and the C–X bond breaking is faster than the C–CN bond formation (Eqs. 2—4).[1] However, methyl-substituted 1-chlorocyclohexenes were less reactive than 1-chlorocyclohexene, regardless of the position of the methyl group, and, unexpectedly, 1-chloro-2-methylcyclohexene was hardly cyanated. In the case of alkenyl halides, the methyl substituent increased the reactivity of the halides, and the rapid reaction was observed with Me_2C=CHX and Me_2C=CMeX. The retardation effect of the methyl group observed with methyl-substituted 1-chlorocyclohexenes is not due to stabilization of the σ-complex (retarding the reaction (4)), but rather retardation or inhibition of the formation of the σ-complex. The result indicates that the rate of cyanation of alkyl-substituted 1-halocycloalkenes

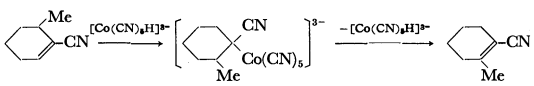
is affected not only by the reaction (4), but also (3).

We have proposed that the C–X bond cleavage and the C–Co bond formation proceeds by an oxidative addition process *via* an electron-transfer interaction.[1] The electron-transfer may take place by the interaction of Co(I) with the π^* orbital of the C–C bond. Since the electronic effect of the methyl substituent may be similar both in alkenyl and cycloalkenyl halides, the retardation by the methyl group must be due to the steric effect of the methyl and methylene hydrogens of the rigid cycloalkene ring, hindering the approach of $[Co(CN)_4]^{3-}$ to the C=C bond.

We have observed the isomerization of 1-cyano-6-methylcyclohexene to 1-cyano-2-methylcyclohexene. This is one of the very few examples of the double bond migration catalyzed by $[Co(CN)_5H]^{3-}$.[4] 1-Cyano-6-methylcyclohexene was selectively formed in the initial stage, but the cyanation became very slow when the isomerization became the predominant reaction. The isomerization proceeds irreversively probably *via* a σ-complex (Eq. 5), which was suggested by broad ^{1}H NMR peaks (δ=1.1—2.2) of the reaction solution prepared in D_2O. The isomerization can be used to synthesize 1-cyano-2-methylcyclohexene which can not be formed from 1-chloro-2-methylcyclohexene.



(5)

Experimental

1-Bromocycloalkenes were synthesized by dehydrobromination of α,β-dibromocycloalkanes[5] with KOH (1-bromocyclopentene),[6] $NaNH_2$-*t*-BuOH (1-bromocyclohexene),[7] and morpholine (1-bromocycloheptene and -octene).[8] 1-Chlorocyclohexenes were synthesized by chlorination of corresponding cyclohexanones with CCl_4/PPh_3,[9] and mixtures (1-chloro-2- and -6-methylcyclohexenes from 2-methylcyclohexanone, and 1-chloro-3- and -5-methylcyclohexenes from 3-methylcyclohexanone) were separated by a preparative GLC. Nitriles obtained here are known compounds (1-cyano-3- and -5-methylcyclohexenes have been reported as a mixture)[10] and gave satisfactory elemental analyses, and identified by IR (JASCO IRA-2, observed as neat films) and ^{1}H and ^{13}C NMR spectroscopy (JEOL FX-100, observed in $CDCl_3$).

Cyanation of 1-Halocycloalkenes. The reaction was performed in the same fassion as described previously.[1] A typical procedure was as follows: $CoCl_2$ (1.00 mmol, 0.130 g), KCN (4.95 mmol, 0.322 g) and KOH (2.0 mmol, 0.12 g) were placed in a 20 cm^3 two-necked flask equipped with a cold-finger. H_2O (5 cm^3) was added under hydrogen atmosphere at 45 °C, and the solution was stirred magnetically for 30 min. *1-Bromocyclopentene* (0.21 cm^3, 2.0 mmol) was added with a microsyringe through a serum cap. It took 8 h to cyanate the added bromide, and the reaction mixture was extracted with dichloromethane. Dichloromethane was evaporated, and the residue was distilled *in vacuo* with a Kügelrohr apparatus to give 1-cyanocyclopentene (0.13 g, 1.4 mmol) bp 95 °C/28 mmHg† (oven temperature); IR 2220 cm^{-1} (CN); ^{1}H NMR δ=1.99 (q, 2H), 2.54 (m, 4H), 6.66 (m, 1H); ^{13}C NMR δ=22.8 (t), 33.7 and 34.2 (t), 115.3 (s), 116.7 (s, CN), 128.9 (d). *1-Bromo* and *-chlorohexene* (2 mmol) yielded 1-cyanocyclohexene (0.18 g, 1.7 mmol) and 0.15 g, 1.4 mmol), respectively, bp 120 °C/28 mmHg; IR 2204 cm^{-1} (CN); ^{1}H NMR δ=1.65 (m, 4H), 2.20 (m, 4H), 6.62 (q,1H); ^{13}C NMR δ=20.7 (t), 21.4 (t), 25.7 (t), 112.3 (s), 119.7 (s, CN), 145.2 (d). *1-Bromo-cycloheptene* (2 mmol) yielded a mixture of 1-cyanocycloheptene and cyanocycloheptane (0.21 g): 1-Cyanocycloheptene bp 60 °C/2 mmHg; IR 2204 cm^{-1}; ^{1}H NMR δ=1.62 (s, br, 6H), 2.34 (m, 4H), 6.78 (t, 1H);^{13}C NMR δ=25.3, 26.2, 29.6, 31.3, and 31.6 (t), 117.6 (s), 120.9 (s, CN), 150.3 (d): *Cyanocycloheptane* bp 60 °C/2 mmHg; IR 2220 cm^{-1}; ^{1}H NMR δ=1.60 (m, 8H), 1.87 (m, 4H), 2.87 (tt, 1H); ^{13}C NMR δ=25.4 and 31.6 (t), 27.6 (t), 30.1 (s), 123.3 (s, CN). *1-Bromocyclooctene* (2 mmol) yielded 1-cyanocyclooctene and cyclooctane (95 : 5, 0.24 g); 1-cyanocyclooctene bp 75 °C/0.5 mmHg; IR 2210 cm^{-1}; ^{1}H NMR δ=1.53 (s, br, 8H), 2.31 (m, 4H), 6.60 (t, 1H); ^{13}C NMR δ=25.5, 26.0, 27.1, 27.8, 28.3, and 28.8 (t), 115.1 (s), 120.3 (s, CN), 148.1 (d). *1-Chloro-2-methylcyclohexene* scarecely reacted, but *1-chloro-3-*, *-4-*, and *-5-methylcyclohexenes* (2 mmol) yielded selectively corresponding 1-cyano(methyl)-cyclohexenes bp 125 °C/28 mmHg; 1-cyano-3-methylcyclohexene (0.18 g, 1.5 mmol) Found: C, 79.01; H, 9.20; N, 79.60%; Calcd for $C_8H_{11}N$: C, 79.29; H, 9.15; N, 11.56%; IR 2210 cm^{-1}; ^{1}H NMR δ=1.05 (d, 3H), 1.75 (m, 4H), 2.20 (m, 3H), 6.46 (tt, 1H); ^{13}C NMR δ=21.2, 25.8, and 34.5 (t), 27.6 (t), 28.8 (d), 111.9 (s), 119.7 (s, CN), 144.7 (d); 1-cyano-4-methylcyclohexene (0.17 g, 1.4 mmol) IR 2210 cm^{-1}; ^{1}H NMR δ=0.98 (d, 3H), 1.32 (m, 1H), 1.72 (m, 3H), 2.23 (m, 3H), 6.59 (m, 1H); ^{13}C NMR δ=21.3 (t), 26.6 (t), 27.0 (d), 29.5 (t), 33.9 (q), 112.0 (s), 119.6 (s,CN), 144.7 (d); 1-cyano-5-methylcyclohexene (0.18 g, 1.5 mmol) Found: C, 79.05; H, 9.30; N, 11.68%; Calcd for $C_8H_{11}N$: C, 79.29; H, 9.15; N, 11.56%; IR 2210 cm^{-1}; ^{1}H NMR δ=1.00 (d, 3H), 1.73 (m, 4H), 2.23 (m, 3H), 6.67 (m, 1H); ^{13}C NMR δ=20.3 (t and q), 26.6 (t), 29.3 (t), 30.8 (d), 111.7 (s), 119.7 (s,CN), 150.5 (d). *1-Chloro-6-methylcyclohexene* (2 mmol) yielded a mixture of 1-cyano-6- and -2-methylcyclohexenes (61: 39 after the 24 h reaction, 0.18 g, 1.5 mmol) bp 125 °C/28 mmHg; 1-cyano-6-methylcyclohexene IR 2205 cm^{-1}; ^{1}H NMR δ=1.19 (d, 3H), 1.69 (m, 4H), 2.15 (m, 3H), 6.60 (m, 1H); ^{13}C NMR δ=19.3 (t), 19.8 (q), 25.8 and 29.9 (t), 30.7 (d), 118.3 (s), 119.1 (s, CN), 145.0 (d); 1-cyano-2-methylcyclohexene IR 2202 cm^{-1}; ^{1}H NMR δ=1.63(m, 4H), 1.99 (s, 3H), 2.14 (m, 4H); ^{13}C NMR δ=21.5 (t), 21.6 (t), 23.0 (t), 27.1 (q), 31.3 (t), 106.2(s), 119.3 (s, CN), 153.4 (s).

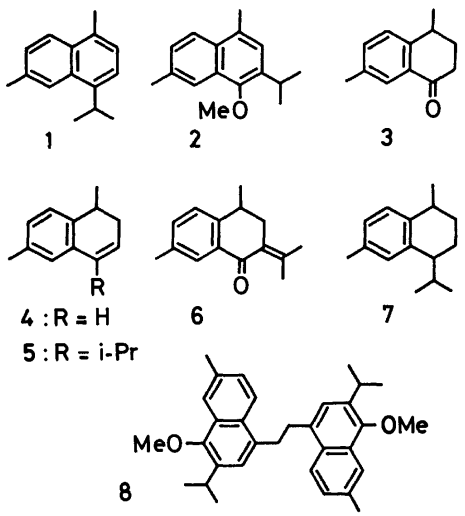
Studies of Aromatic Sesquiterpenes. IV.[1] The Synthesis of γ-Calacorene, Calamenene, and 4-Methoxyisocadalene

Kazuo ADACHI* and Masahito MORI
Osaka Institute of Technology, Omiya, Asahi-ku, Osaka 535
(Received August 28, 1982)

Synopsis. The Grignard reaction of 3,4-dihydro-4,7-dimethyl-1(2*H*)-naphthalenone with isopropylmagnesium bromide gave a 3 : 1 mixture of normal reaction product and α-isopropylidene ketone, from which, the title sesquiterpenes and 1,2-bis(3-isopropyl-4-methoxy-6-methyl-1-naphthyl)ethane were synthesized.

Some sesquiterpenes are dehydrogenated by heating with sulfur, selenium or palladium catalysts giving a parent hydrocarbon of the sesquiterpenes such as cadalene (**1**), which have been recently isolated[2] along with 4-methoxyisocadalene[3] (**2**) or other sesquiterpenes from *Heterotheca* species (Compositae). In the various path ways for synthesis of **1**, 3,4-dihydro-4,7-dimethyl-1(2*H*)-naphthalenone (**3**) have been employed as a key intermediate.[4] However, the isopropylated products of **3** by the Grignard reaction have not been investigated.

In this paper, it is described that the Grignard reaction products of **3** were dehydrated with formic acid giving a mixture of 1,2-dihydro-1,6-dimethylnaphthalene (**4**), γ-calacorene (**5**), and 3,4-dihydro-2-isopropylidene-4,7-dimethyl-1(2*H*)-naphthalenone (**6**). Calamenene (**7**) and 4-methoxyisocadalene (**2**) were synthesized from **5** and **6**, respectively.



The ketone **3** was allowed to react with isopropylmagnesium bromide, and the dehydration of the reaction products gave a mixture of four components (**4**, **5**, and **6** including **3**). The formation of two hydrocarbons **4** and **5** indicates that the corresponding alcohols were respectively prepared by reductive reaction and normal addition of the Grignard reagent on **3**. Furthermore, any other isomers of the *endo*-olefin **5** were not observed. Therefore, an intermediate in the synthesis of cadalene (**1**) from **3** is γ-calacorene (**5**), which has been isolated from the wood of *Juniperus rigida*[5] and the Japanese hop (*Humulus lupulus* L.).[6] The structure of 3,4-dihydro-2-isopropylidene-4,7-dimethyl-1(2*H*)-naphthalenone (**6**) was confirmed by the comparison of its spectral data with those of 3,4-dihydro-2-isopropylidene-1(2*H*)-naphthalenone and the 4-methyl derivative.[7]

The catalytic hydrogenation of **5** afforded calamenene (**7**) in a mixture of diastereomers which consisted of *cis* (80%) and *trans* (20%) isomers on the basis of the ^{1}H-NMR (60 MHz), *i.e.*, the proton signals of two methyl groups in the isopropyl group indicated four pairs of doublets (d, at δ=0.74, 1.01, and 0.69, 0.98).[8] In the literature,[9] it has been reported that the reduction of α-calacorene afforded calamenene which consisted of about 40% of *cis*- and 60% of *trans*-isomers.

The unsaturated ketone **6** on isomerization with Pd–C catalysts and subsequent methylation with dimethyl sulfate afforded 4-methoxyisocadalene (**2**). The prism crystals (mp 165.5—166.0 °C) were obtained as a by-product of **2**, and its IR spectrum showed similar pattern with that of **2**. 1,2-Bis(3-isopropyl-4-methoxy-6-methyl-1-naphthyl)ethane (**8**) was proposed as the structure of this by-product on the basis of its NMR spectrum and the elementaly analysis. During the isomerization of **6**, a part of the reactant was dehydrogenatively dimerized to give **8**.

Experimental

The Grignard Reaction of Isopropylmagnesium Bromide on 3,4-Dihydro-4,7-dimethyl-1-(2H)-naphthalenone (3). The ketone **3** was synthesized from toluene in the same way as the synthesis of 3,4-dihydro-8-isopropyl-4,5-dimethyl-1(2*H*)-naphthalenone from *p*-cymene.[10]

A solution of **3** (10.0 g) in ether (25 ml) was added to the Grignard reagent prepared from Mg (4.2 g) and isopropyl bromide (23.0 g) in ether (150 ml). The reaction mixture was stirred for several hours in an ice bath, allowed to stand for over night, and then refluxed for 8 h. Acetone was added to destroy an excess reagent, and the reaction mixture was decomposed by adding a crushed ice and NH_4Cl. After removal of the solvent from the ethereal solution, the residue (14 g) was dehydrated by stirring with formic acid (70 ml) at 50 °C for 3 h. The reaction mixture was diluted with water and extracted with benzene. Removal of the solvent from the benzene extract and distillation of the residue gave 8.5 g of an oil, bp 94—146 °C/3 mmHg (1 mmHg=133.322 Pa), which was a mixture consisted of **4** (14.3%), **5** (54.8%), **3** (13.4%), and **6** (17.5%) (GC analysis). The oily mixture was separated into two fractions by successive elution with CCl_4 and ether through a silica-gel column. The hydrocarbon mixture eluted with CCl_4 was repeatedly distilled to separate **4** and **5**. The unsaturated ketone **6** in the ethereal eluates was freed from **3** over a silica-gel column chromatography.

1,2-Dihydro-1,6-dimethylnaphthalene (4): Oil, bp 96—97 °C/9 mmHg; IR: 1605, 1490, 1445, 880, 810, 695, and 670 cm^{-1}; NMR (CCl_4): δ=1.18 (3H, d, J=7 Hz, CH_3), about 2.2 (2H, m, CH_2), 2.23 (3H, s, CH_3), 2.78 (1H, m, J=7 Hz, >CH-),

5.81 (1H, dt, J=9 and 4 Hz), 6.32 (1H, dt, J=9 and 2 Hz), 6.73 and 6.88 (3H, each br, s).

γ-Calacorene (1,2-Dihydro-4-isopropyl-1,6-dimethylnaphthalene) (5): Oil, bp 125—126 °C/9 mmHg; IR: 1605, 1485, 1455, 1445, 1380, 1360, 880, 815, and 805 cm^{-1}; NMR (CCl_4): δ= 1.14 (9H, d, J=7 Hz, three CH_3), 2.17 (2H, m, CH_2), 2.30 (3H, s, CH_3), 2.82 (2H, m, J=7 Hz, two >CH–), 5.70 (1H, t, J=5 Hz, =CH–), 6.93 and 7.05 (3H, each br. s).

3,4-Dihydro-2-isopropylidene-4,7-dimethyl-1(2H)-naphthalenone (6): Oil, bp 127—128 °C/3 mmHg; IR: 1665, 1605, 1495, 1450, 1365, 1290, 1175, 820, and 785 cm^{-1}; NMR (CCl_4): δ= 1.24 (3H, d, J=7 Hz, CH_3), 1.90 (3H, br. s, vinyl-CH_3), 2.18 (3H, br. s, vinyl-CH_3), 2.35 (3H, s, CH_3), 2.73 (2H, br, CH_2), 3.00 (1H, m, >CH–), 7.02 (1H, d, J=8 Hz), 7.18 (1H, dd, J=8 and 2 Hz) and 7.82 (1H, br. s). Found: C, 84.01; H, 8.45%. Calcd for $C_{15}H_{18}O$: C, 84.07; H, 8.47%.

Calamenene (7). A solution of **5** (2.0 g) in ethanol (50 ml) was shaken with Pd–C (10%, 0.5 g) under a hydrogen atmosphere for 8 h. The catalysts were then removed by filtration, and the filtrate was evaporated to give an oil, which was distilled to afford **7** (1.9 g), bp 127—130 °C/10 mmHg, n_D^{20} 1.5262, d_4^{20} 0.9305; IR: 1615, 1495, 1455, 1380, 1370, 1360, and 815 cm^{-1}; NMR (CCl_4): δ=0.69 and 0.74 (3H, each d, J=7 Hz, CH_3), 0.98 and 1.01 (3H, each d, J=7 Hz, CH_3), 1.21 (3H, d, J=7 Hz, CH_3), 1.67 (4H, m), 2.23 (3H, s, CH_3), about 2.58 (3H, m, three >CH–) and 6.87 (3H, m). The resulting calamenene (**7**) showed a single peak on GC (a 2 m×3 mm Apiezon Grease L 30% on Cellite 545 column, He), but its NMR spectrum showed the presence of two isomers, *cis*-**7**: *trans*-**7**=4 : 1.

4-Methoxyisocadalene (2) and Its Dimerized Product (8). A mixture of the unsaturated ketone **6** (1.0 g) and Pd–C (10%, 0.5 g) in xylene (10 ml) was refluxed for 12 h. The catalysts were removed by filtration and the filtrate was evaporated. The residual oil was refluxed with K_2CO_3 (2.0 g) and dimethyl sulfate (1.6 g) in acetone (20 ml) for 8 h. After removal of the solvent, ammonia water (2 ml) was added and stirred to destroy an excess dimethyl sulfate at 50 °C for 30 min. The reaction mixture was diluted with water and then extracted with benzene. The benzene extract was washed with water, dried and evaporated to give an oil which was chromatographed over an alumina column. The hexane eluate wa evaporated to give an oil (0.9 g), from which, the precipitated crystals (0.3 g) of **8** were removed by filtration and the filtrate was purified by distillation to afford **2** (0.4 g), bp 128—130 °C/ 10 mmHg, n_D^{20} 1.5587. The IR and NMR spectra of **2** were superimposable with those of the authentic specimen.[1] *Picrate*: Orange brown needles, mp 90.5—91.5 °C (lit,[1] mp 90.5—91.5 °C).

1,2-Bis(3-isopropyl-4-methoxy-6-methyl-1-naphthyl)ethane (8): Prisms from petroleum ether, mp 165.5—166.0 °C; IR (KBr): 1620, 1600, 1565, 1510, 1455, 1440, 1405, 1350, 1225, 1195, 1090, 1060, 985, 880, and 815 cm^{-1}; NMR (CCl_4): δ=1.14 (12H, d, J=7 Hz, two $\langle^{CH_3}_{CH_3}$), 2.52 (6H, s, two CH_3), 3.35 (4H, s, two CH_2), 3.45 (2H, m, J=7 Hz, two >CH–), 3.80 (6H, s, two OCH_3), 6.85 (2H, s), 7.16 (2H, dd, J=9 and 2 Hz), 7.78 (2H, br. s) and 7.79 (2H, d, J=9 Hz). Found: C, 84.50; H, 8.42%. Calcd for $C_{32}H_{38}O_2$: C, 84.54; H, 8.43%.

Optical Resolution of Aspartic Acid by Using Copper Complexes of Optically Active Amino Acids

Kaoru HARADA* and Noriko FUJII
Department of Chemistry, The University of Tsukuba, Sakura-Mura, Niihari, Ibaraki 305
(Received August 30, 1982)

Synopsis. DL-Aspartic acid was resolved with high optical purity in the presence of an optically active amino acid copper complex. The mechanism of the optical resolution was explained by the competitive inhibition of crystallization.

We have reported a new method for the optical resolution of DL-aspartic acid by crystallization from a solution of DL-aspartic acid with a copper complex of optically active alanine, glutamic acid, and proline.[1,2] When the mixture was kept at a room temperature, the optically active aspartic acid copper complex crystallized spontaneously. The resolved aspartic acid had high optical purity and a configuration opposite to the optically active amino acid used in this resolution. This phenomenon had been explained as a stereoselective ligand exchange reaction.[1] However, the last communication confirmed that the proposed stereoselective ligand exchange did not represent the mechanism of these reactions, and that the phenomenon might be explained by the competitive inhibition of crystallization.[3]

L-Amino acid–Cu + DL-Asp → D-Asp–Cu ↓ crystallized
+ L-Asp + L-Amino acid ↓ in solution

This paper reports an optical resolution of DL-aspartic acid using a copper complex of the optically active amino acids other than those stated above. We also confirmed that the mechanism of the optical resolution of DL-aspartic acid was explained by competitive inhibition of crystallization.

Experimental

The optically active amino acids used in this experiment were D- or L-enantiomers of alanine, serine, threonine, valine, histidine, leucine, isoleucine, phenylalanine, methionine, glutamine, aspargine, lysine, and arginine. A solution (10 ml) of an optically active amino acid (2.5 mmol) was mixed with cupric carbonate ($CuCO_3 \cdot Cu(OH)_2 \cdot H_2O$, about 1.25 mmol) and was heated, and the solution was filtrated to remove the excess of cupric carbonate. DL-Aspartic acid (2.5 mmol) was dissolved in 10 ml of hot water and this was added to the solution of the amino acid copper complex and filtered. The solution was kept still at room temperature for 1 d. The crystallized optically active aspartic acid copper complex was collected by filtration. *N*-(trifluoroacetyl)aspartic acid isopropyl ester was prepared in the usual way. The enantiomeric ratios of the resolved aspartic acid were determined by gas chromatography (Hitachi 163 Gas Chromatograph) by using Chirasil-Val capillary glass column (Applied Science, U. S. A.).

Results and Discussion

The results of the resolution of racemic aspartic acid in the presence of copper ion and optically active amino acids (Ala, Ser, Thr, Val, and His) are summarized in Table 1. Racemic aspartic acid was successfully resolved in high optical purity. When L-amino acid was used, D-aspartic acid copper complex crystallized spontaneously. Whereas, L-aspartic acid copper complex precipitated by using D-amino acids as shown in Table 1. By using the other optically active amino acids (Leu, Ile, Phe, Met, $GluNH_2$, $AspNH_2$, Lys, and Arg), the resolution of DL-aspartic acid was not successful under the conditions described in the experimental section.

Table 2 shows the effect of D- or L-aspartic acid addition to the DL-aspartic acid resolution in the presence of a L-serine copper complex. The amount of D- or L-aspartic acid added to the solution was 1/10—1/2 in molar ratio of DL-aspartic acid. When D-aspartic acid was added to the aqueous mixtures of a L-serine copper complex and DL-aspartic acid, the time required for the crystallization was shorter than the case without addition of any other amino acid (control). And the amount of the crystallized copper complex and the

c) Recovery $= \frac{\text{isolated L-(or D-Asp)}}{\text{total L-(or D-Asp)}} \times 100.$

optical purity of aspartic acid both increased. The amount of the crystals increased 1.5 times compared with the control when the amount of L-aspartic acid was 1/2 molar ratio of DL-aspartic acid. However, by the addition of L-aspartic acid, the optical purity of the resolved aspartic acid decreased gradually. When the amount of L-aspartic acid reached 1/2 molar ratio of DL-aspartic acid, the optical purity of aspartic acid decreased to 75% and the amount of crystallized D-aspartic acid copper complex reduced to 40% of the control. Therefore, the results indicate that the newly added L-aspartic acid inhibits the crystallization of a D-aspartic acid copper complex.

We have reported that the racemic aspartic acid copper complex was resolved by seeding with a L- or D-aspartic acid copper complex.[4)] The effect of the seeding to this selective crystallization was studied and the results are summarized in Table 3. L- or D-Aspartic acid copper complex was added to the aqueous mixtures of a D-serine copper complex and DL-aspartic acid. Without seeding, L-aspartic acid copper complex crystallization took place in 10 h. When L-aspartic acid copper complex was added to the mixture as seed, the time required for the crystallization was shortened remarkably (2.5 h), and the amount of the crystallized complex increased. On the contrary, when D-aspartic acid copper complex was added to the mixtures, a small amount of optically active D-aspartic acid copper complex crystallized. After removal of D-aspartic acid copper complex, L-aspartic acid copper complex with high optical purity crystallized spontaneously in 24 h. The resolution of DL-aspartic acid by using L-serine copper complex was similar to that described above. Thus it was found that the seeding procedure crystallized optically active aspartic acid copper complex effectively when the configuration of the seeds have the same configuration as the first crop (Table 3 2nd and 6th columns), which was obtained without seeds. However, when the configuration of the seeds has the opposite configuration to the first crop, the seeds initiate the crystallization of small amount of optically active aspartic acid copper complex which has the same configuration as the seed. After removal of the crystallized complex from the solution, the optically active aspartic acid copper complex, which is favored to precipitate, was crystallized spontaneously.

These experiments indicate that the configuration of optically active amino acids determines the configuration of the crystallized optically active aspartic acid copper complex, and the configuration of the aspartic acid is opposite to the optically active amino acid used in the resolution. The mechanism of the optical resolution could be explained by the stereoselective inhibition of crystallization. When the DL-aspartic acid was resolved in the presence of D-serine copper complex, the solution was composed of L- and D-aspartic acid, D-serine and copper ions. The crystallization of L-aspartic acid copper complex is faster than that of D-aspartic acid copper complex in the presence of D-serine. The crystallization of D-aspartic acid copper complex was inhibited by the presence of D-serine copper complex in the solution. Because these two D-amino acid copper complexes have the same configuration and have stronger interaction between these two. Therefore the rate of the crystal growth is affected by the presence of the other optically active amino acid. The addition of L- or D-aspartic acid, and the seeding of L- or D-aspartic acid copper complex in the reaction mixture could also affect the rate of crystallization of optically active aspartic acid copper complex. All these results could support the competitive inhibition mechanism of crystallization proposed in this kind of the optical resolution of aspartic acid. This type of optical resolution could be applicable to other racemic compounds.

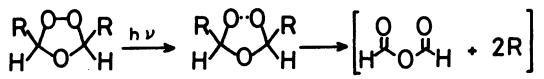
Photolysis of Ozonides in the Gas Phase

Shiro HATAKEYAMA* and Hajime AKIMOTO
Division of Atmospheric Environment, National Institute for Environmental Studies, P.O. Tsukuba-gakuen, Ibaraki 305
(Received September 9, 1982)

Synopsis. Photolysis of four kinds of simple ozonides (ethene, propene, 2-butene, and isobutene ozonides) in the gas phase were carried out. The contribution of the double-β-scission mechanism was 4—13%. The main reaction path is proposed to be intramolecular hydrogen abstraction followed by radical forming unimolecular decomposition.

Ozonides are oxidants possibly present in photochemical smog since they are known to be formed in the gas-phase ozoneolefin reactions.[1,2] While photolytic decomposition is thought to be one of the degradation paths of ozonides in the atmosphere, photolysis of ozonide in gas phase has never been reported yet. Photolysis of ozonides in the liquid phase was suggested to proceed *via* a double-β-scission after the cleavage of oxygen-oxygen bond as follows.[3]



$$\longrightarrow \text{R-R} + \text{RH} + \text{HCOOH} + \text{CO} \quad (1)$$

Formic anhydride, however, has never been detected. In the present study, gas-phase photolysis of ozonides in near UV region was studied and the reaction mechanism is discussed.

Experimental

Ethene, propene, 2-butene, and isobutene ozonides (hereafter referred to as EO, PO, BO, and IO, respectively) were prepared by the reaction of ozone with ethene, propene, *cis*-2-butene, and isobutene, respectively, in isobutane at −78 °C. They were treated with K_2CO_3[4] and further purified with trap-to-trap distillation. UV spectrum of EO was obtained by use of Cary 17D spectrometer.

The photochemical reactor was an 11 L cylindrical quartz vessel (120 mm i.d., 1000 mm long) equipped with multi-reflection mirrors for long-path (40 m) Fourier transform infrared spectroscopy (LP-FTIR). Six Sun lamps (Toshiba FL 20 SE, $260 \leq \lambda \leq 400$ nm, $\lambda_{max}=310$ nm) surrounded the reactor coaxially. Ozonides (15—20 mTorr) (1 Torr = 133.32 Pa) were photolyzed in 1 atm of N_2 at 30±2 °C. Photolysis of BO without any buffer gas was also carried out. The irradiation time was 30 min, 1 h, 2 h, and 2 h for EO, PO, BO, and IO respectively. The concentrations of reactants and products were monitored by means of the LP-FTIR. The spectra were obtained with every 128 scans (scanning time was about 5 min) at a resolution of 1 cm^{-1}.

Results and Discussion

Products and their yields in the photolyses of ozonides are shown in Table 1. Formic anhydride which had been postulated as an intermediate in the liquid phase photolysis was detected for the first time as a product by means of gas-phase IR spectroscopy.

EO has a UV absorption (Fig. 1) due to peroxidic

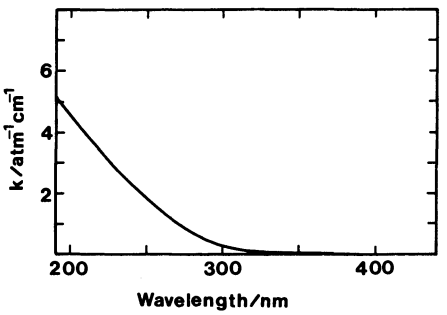

Fig. 1. Gas-phase UV spectrum of ethene ozonide.

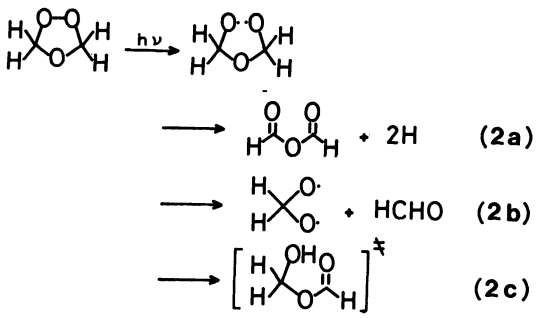
O–O bond suggesting that the primary process of the photolysis of ozonides proceeds *via* the O–O bond rupture in an analogous way to peroxides.[5] Initial splitting of the O–O bond would be followed by unimolecular fragmentation or intramolecular hydrogen abstraction of the intermediate biradical, *e.g.*,



Energy diagram of this reaction sequence in the case

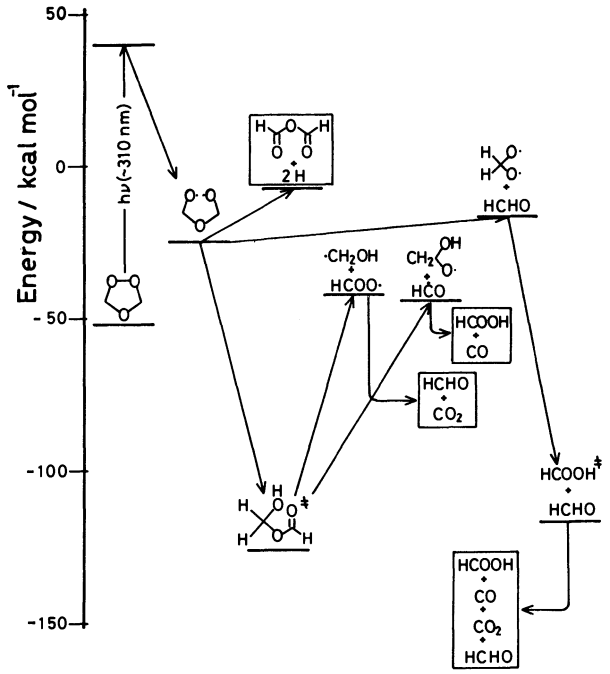


Fig. 2. Energy diagram of the photolysis of ethene ozonide.

of EO is schematically shown in Fig. 2. Heats of formation of the compounds shown in Fig. 2 are estimated by the method of Benson[6] except for OCH_2OCH_2O which is assumed to be $\approx$27 kcal mol^{-1} above ozonide on the basis of activation energy of thermal decomposition reported by Hull *et al.*[4] Reaction 2a is the double-β-scission process, which was suggested[3] to be the main reaction path in the liquid-phase photolysis of ozonides. The detection of formic anhydride in the photolysis of EO, PO, and BO established the participation of the double-β-scission also in the gas-phase photolysis of ozonides. Besides formic anhydride, acetic formic anhydride ($CH_3COOCHO$) was observed in the photolysis of PO, BO, and IO, and acetic anhydride ($CH_3COOCOCH_3$) was produced in the photolysis of BO. These facts indicate that not only alkyl groups but hydrogen atoms can also be released by the double-β-scission. This can account for the production of glutaric anhydride in the photolysis of cyclopentene ozonide in the liquid phase.[3]

Since further fragmentation of acid anhydride cannot occur on energetic basis (see Fig. 2), the contribution of the double-β-scission in the photolysis of ozonides under 1 atm of N_2 can be estimated based on the yields of the anhydrides to be 5.8, 9.8, 18.3, and 12.3% for EO, PO, BO, and IO, respectively. Thus, the contribution of double-β-scission increases as the number of CH_3 substituent group in the ozonides increases. Detection of CH_2CO and CH_3OH in the photolysis of PO and BO, and that of CH_3COOCH_3 in the photolysis of IO suggest the occurrence of the reaction of the type of Eq. 2b. This reaction involves C–O bond cleavage after O–O bond rupture and results in the production of aldehydes or ketones and methylenedioxy-type biradicals. Methylenedioxy biradical ($\cdot OCH_2O\cdot$) is known as an intermediate formed in the course of unimolecular reaction of the Criegee intermediate which is produced in ozone-olefin reactions.[7–9]

Observation of CH_2CO, CH_3OH, and CH_3COOCH_3 in this study may be explained by the contribution of this mechanism. However, the C–O bond cleavage cannot be the main reaction path since the fact that the sum of the yields of CO, CO_2, and HCOOH is much higher than that of HCHO in the photolysis of EO cannot be explained by this mechanism.

Another candidate for the reaction path is the reaction 2c followed by unimolecular decompositions. Such intramolecular hydrogen abstraction has been supposed to be the main route of the pyrolysis of ozonides both in the liquid phase[10] and in the gas phase.[4] Intramolecular hydrogen abstraction in alkoxyl radicals has also been noted by Carter and co-workers.[11]

If such intramolecular hydrogen abstraction occurs to give $HCOOCH_2OH$ as an intermediate in the photolysis of EO, the overall excess energy for the reaction 2c at the wavelength of 310 nm amounts to 166 kcal mol^{-1} as shown in Fig. 2. Therefore, following types of radical-forming unimolecular decomposition rather than the aldehyde-acid pair forming reaction would predominate in the gas-phase.

$$HCOOCH_2OH \rightarrow HOCH_2O + HCO \rightarrow HCOOH + H + HCO(H + CO) \quad (3a)$$

$$\rightarrow H_2COH + HCOO \rightarrow HCHO + CO_2 + 2H \quad (3b)$$

High yield of HCOOH, CO, and CO_2 as well as HCHO can be accounted for by this mechanism. Observation of CH_3COOH in the photolysis of PO, BO, and IO would also be explained by this mechanism.

(Received April 28, 1982)

The crystal structures of (1,5-cyclooctadiene)di-μ-methoxo-dirhodium(I) and tetrakis(η^3-allyl)di-μ-hydroxo-dirhodium(III) were determined by the X-ray method. The former belongs to the triclinic space group $P\bar{1}$ with cell dimensions, $a=7.347(4)$, $b=6.471(3)$, $c=9.554(6)$ Å, $\alpha=87.06(4)$, $\beta=82.50(5)$ and $\gamma=77.98(4)°$. The space group of the latter is also $P\bar{1}$ but two crystallographically independent molecules exist in a cell with dimensions, $a=11.704(7)$, $b=9.793(6)$, $c=7.948(5)$ Å, $\alpha=113.49(5)$, $\beta=54.59(5)$, and $\gamma=110.99(5)°$. Both structures were determined by the heavy atom method and refined by the block-diagonal least-squares method. The final R values were 0.054 for the former and 0.075 for the latter. The coordination of the rhodium atom in the former compound is square planar, the cyclooctadiene ligand being regarded as a bidentate donor. The latter coordination is, in a formal sense, octahedral.

Some of the present authors recently reported the preparation of novel dioxygen complexes of palladium[1] and rhodium[2] which coordinated to both dioxygen and organic substrates, particularly olefins, by means of the anion exchange reaction of corresponding halogen-bridges complexes with potassium superoxide, and concurrently revealed the basic nature of the coordinated dioxygen. μ-Peroxo complexes of palladium and rhodium reacted with active methylene compounds of which pK_a values were less than 20 to result in the abstraction of the proton by the coordinated dioxygen. For example, treatment of μ-peroxo complexes with acetylacetone (pK_a 9), methyl acetoacetate (pK_a 11), dimethyl malonate (pK_a 13), and cyclopentadiene (pK_a 15) gave the acetylacetonato, methyl acetoacetate, dimethyl malonate and cyclopentadienyl complexes, respectively. With alcohols, amines and thiols, the μ-peroxo complexes also reacted to yield the corresponding μ-alkoxo, μ-amido, and μ-alkylthio complexes accompanied by the liberation of hydrogen peroxide. The alkoxo or hydroxo complexes having olefinic ligands have been studied with interest in recent years in connection with the alkoxy metallation reaction of the Wacker reaction.

This paper deals with two crystal structures of (1,5-cyclooctadiene)di-μ-methoxo-dirhodium(I), [{Rh(OMe)(1,5-cod)}$_2$], which was obtained by the reaction of [{RhO(1,5-cod)}$_2$] with methanol, and of tetrakis(η^3-allyl)di-μ-hydroxo-dirhodium(III), [{Rh(OH)(η^3-C_3H_5)$_2$}$_2$], which was prepared by the treatment of [{RhCl(η^3-C_3H_5)$_2$}$_2$] with potassium superoxide.[2]

Experimental

General. All reactions were run under positive pressure of dry nitrogen. Infrared spectra were recorded on a Shimadzu IR-27G or Hitachi Model 260-50 spectrometer. Proton magnetic resonance spectra were recorded on a Hitachi R-24B instrument. Chemical shifts are reported as δ values in parts per million relative to internal tetramethylsilane. Melting points were obtained on a Yanagimoto micro melting point apparatus. In experiments requiring dry solvents, benzene and ether were distilled from sodium benzophenon ketyl. Dichloromethane was distilled from diphosphorus pentaoxide. Methanol was distilled from magnesium turnings prior to use. Potassium superoxide, KO_2, (Ventron) was commercially available and used without further purification. Starting rhodium complexes, [{RhCl(1,5-cod)}$_2$] and [{RhCl(η^3-C_3H_5)$_2$}$_2$], were prepared by a standard procedure.

Preparation of [{*Rh(OMe)(1,5-cod)*}$_2$]. To a suspension of finely powdered potassium superoxide (3.48 g, 49 mmol) in 15 cm^3 of CH_2Cl_2 was added the solution of [{RhCl(1,5-cod)}$_2$] (2.10 g, 4.28 mmol) in 30 cm^3 of CH_2Cl_2 under an atmosphere of dry nitrogen at ambient temperature. The mixture was stirred for 4 h. Then the excess KO_2 together with the precipitated KCl were filtered off under nitrogen pressure. Concentration of the filtrate, followed by the addition of 30 cm^3 of pentane, gave [{RhO(1,5-cod)}$_2$] (1.30 g, 67%) as a yellowish brown microprisms. The [{RhO(1,5-cod)}$_2$] was then dissolved in 20 cm^3 of dry benzene. The addition of 1.0 cm^3 of freshly distilled methanol at room temperature instantaneously gave a yellow solution. Evaporation of the solvent followed by recrystallization from a mixed solvent of CH_2Cl_2 and CH_3OH (1:1 vol. ratio) gave [{Rh(OMe)(1,5-cod)}$_2$] as yellow prisms in a 50% yield (1.04 g) based on [{RhCl(1,5-cod)}$_2$]. IR and H-NMR spectral data and melting point agreed with those of the authentic sample. Elemental analysis was also consistent with the formula, $C_{18}H_{30}O_2Rh_2$. Calcd: C, 44.65; H, 6.24%. Found: C, 44.50; H, 6.45%.

Preparation of [{*Rh(OH)(η^3-C_3H_5)*$_2$}$_2$]. To a suspension of finely powdered KO_2 (718 mg, 10.1 mmol) in 10 cm^3 of CH_2Cl_2 was added the solution of [{RhCl(η^3-C_3H_5)$_2$}$_2$] (200 mg, 0.454 mmol) in 10 cm^3 of CH_2Cl_2 under nitrogen pressure at the ambient temperature. The resulting mixture turned to an orange solution, which was then stirred for 2 h. The excess KO_2 and the precipitated KCl were filtered off under nitrogen pressure and the filtrate was evaporated to dryness. The residue was dissolved in benzene and again filtered. The filtrate was concentrated to *ca.* 4 cm^3 and was allowed to cool to yield [{Rh(OH)(η^3-C_3H_5)$_2$}$_2$] as yellow prisms in a 70% (128 mg) yield; mp 129 °C (decomp). IR (KBr) OH 3580, 3549 cm^{-1}; ^{1}H-NMR ($CDCl_3$) 1.10 (br.d, 4H), 2.18 (br.d, 4H), 3.02 (br.d, 4H), 4.38 (m, 4H), 4.67 (br.s, 4H), −2.40 (br.s, 2H, OH). Found: C, 35.31; H, 5.40%. Calcd for $C_{12}H_{22}O_2Rh_2$: C, 35.66, H, 5.49%.

X-Ray Data Collection. The X-ray diffraction data were obtained with graphite monochromatized Mo $K\alpha$ ra-

diation on a Rigaku four-circle diffractometer equipped with a rotating anode X-ray generator operated at 50 kV 120 mA. An ω-2θ continuous scanning technique was used for measuring integrated intensities. Background countings were made at each side of the scan. Other experimental details are listed in Table 1 together with the crystal data. Lorentz and polarization corrections were applied but no absorption correction was made.

Structure Determination and Refinement

Both structures were solved by the heavy atom method and refined by the block-diagonal least-squares procedure. Hydrogen atoms were located on difference Fourier maps with the help of geometrical consideration. Anisotropic thermal parameters were assigned to all the nonhydrogen atoms. Hydrogen positional parameters, as well as their isotropic thermal parameters which were made equal to B_{eq} of their carrier atoms, were not refined. The function minimized was $\Sigma\omega(\Delta F)^2$, with $\omega=a$ for $F_o=0$ and $\omega=[\sigma^2(F)+b|F_o|+c|F_o|^2]^{-1}$ for $F_o\neq0$, where $\sigma(F)$ is the estimated standard deviation based on counting statistics. The final R and parameters a, b, and c are 0.054, 0.68, −0.25, and 0.01 for [{Rh(OMe)(1,5-cod)}$_2$] and 0.075, 0.13, −0.06, and 0.01 for [{Rh(OH)(η^3-C_3H_5)$_2$}$_2$]. The atomic scattering factors were taken from the International Tables for X-Ray Crystallography.[3] The positional parameters are listed in Tables 2 and 3.[4]

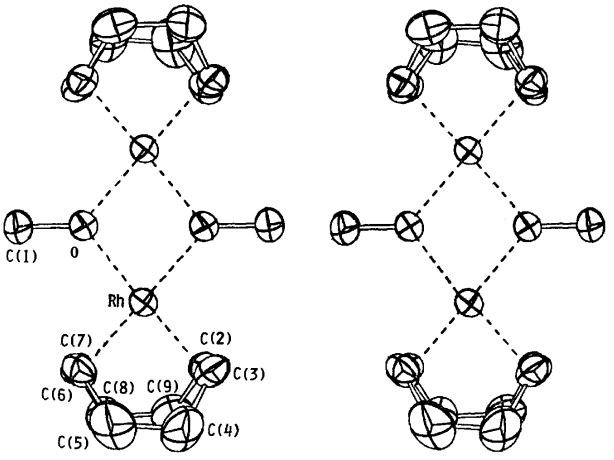

Fig. 1. A stereo drawing of [{Rh(OMe)(1,5-cod)}$_2$]. Thermal ellipsoids are scaled to include 50% probability level.

drawing of the molecule with the numbering of atoms is shown in Fig. 1. The coordination of the Rh atom is essentially square planar, the cyclooctadiene ligand being regarded as a bidentate donor. The geometry of the coordination plane of the Rh atom is given in Table 4. The molecule has an approximate D_{2h} (mmm) symmetry.

The bond lengths and angles are given in Table 5. The two Rh–O lengths, 2.051(5) and 2.063(5) Å, are similar to the values found in previous work, *e.g.* 2.054(5) and 2.066(5) Å for [Rh(acac)(1,5-cod)],[5] or 2.06 and 2.05 Å for [Rh(acac)$(CO)_2$].[6] The C–O length of 1.40(1) Å is shorter than the usual C–O single bond length, 1.43 Å. It indicates that this bond assumes a slight double bond character as a result of the coordination.

The cyclooctadiene ring acquires a tub form of approximate symmetry C_{2v} (2mm), the Rh–Rh vector being the twofold axis. The lengths of the two C=C double bonds participating in the coordination are 1.40(1) and 1.41(1) Å, which are in good agreement with the bond lengths of other complexes in the same situation: 1.41(1) Å for [Rh(acac)(1,5-cod)],[5] 1.44(7) Å for [{RhCl(1,5-cod)}$_2$],[7] or 1.40(1) Å for [Ni(1,5-cod)(duroq)] (duroq=duroquinone).[8] These are significantly longer than the corresponding lengths for the free molecule of 1,5-cyclooctadiene, 1.341 Å,[9] due to π-electron coordination. The two C(4)–C(5) and C(8)–C(9) single bonds have relatively shorter lengths 1.45(2) and 1.47(2) Å, which may be attributed to the larger thermal vibration of these atoms. The distance between the midpoint of the C(2)–C(3) bond and that of the C(6)–C(7) bond is 2.74 Å, which is similar to 2.74 Å for [Rh(acac)(1,5-cod)][5] but shorter than 2.91 Å for [Ni(1,5-cod)(duroq)].[8]

Table 4. The best plane and deviations (d/Å) of atoms from the plane in [{Rh(OMe)(1,5-cod)}$_2$][a]

and perpendicular to the 2 axis. The bond lengths and angles are shown in Table 6 and Figs. 4 and 5.

The coordination of the Rh atom is, in a formal sense, octahedral, if either the two O atoms and the C(1), C(3), C(4), and C(6) atoms or the two O atoms and four midpoints of the C(1)–C(2), C(2)–C(3), C(4)–C(5), and C(5)–C(6) bonds are considered as the ligands. Two atoms C(1) and C(4) of two allyl groups lie roughly on the plane of the Rh and O atoms, and

Table 7. The best plane and deviations (d/Å) of atoms from the planes in $[\{Rh(OH)(\eta^3\text{-}C_3H_5)_2\}_2]$[a]

Rh(A) plane			
$0.2283X-0.5635Y+0.7939Z=0$			
Rh(A)	0.00(2)	C(2A)	1.41(3)
O(A)	−0.19(3)	C(3A)	2.09(3)
C(1A)	0.21(3)	C(5A)	−1.37(3)
C(4A)	−0.19(3)	C(6A)	−2.11(3)
RH(B) plane			
$0.6574X-0.3875Y+0.6463Z-3.8469=0$			
Rh(B)	0.00(1)	C(2B)	−1.43(2)
O(B)	0.18(1)	C(3B)	−2.10(2)
C(1B)	−0.26(2)	C(5B)	1.41(2)
C(4B)	0.26(2)	C(6B)	2.11(2)

a) The planes are defined by Rh, O, C(1), and C(4), and their centrosymmetric equivalents.

the best plane consisting of the Rh, O, C(1), and C(4) atoms and their centrosymmetric equivalents are given in Table 7 together with the deviations of atoms from that plane. The other two terminal atoms C(3) and C(6) of the allyl groups locate far from the plane on both sides. The bond angle C(3)–Rh–C(6) is 172.8(4)° and 174.0(4)° for the A and B molecules, respectively. The planes of four independent allyl groups, C(1A)–C(2A)–C(3A), C(4A)–C(5A)–C(6A), C(1B)–C(2B)–C(3B), and C(4B)–C(5B)–C(6B), make angles of 57.8(6)°, 59.5(6)°, 57.4(6)°, and 56.5(6)° with the above mentioned plane. These structural characteristics are similar to those found for $[\{RhCl(\eta^3\text{-}C_3H_5)_2\}_2]$[10] and $[\{RhBr(\eta^3\text{-}C_3H_5)_2\}_2]$,[11] in which halogen atoms take the place of the OH group of this molecule.

The mean length of the Rh–C(1) and Rh–C(4) bonds, 2.11 Å, is significantly shorter than that of Rh–C(3) and Rh–C(6), 2.22 Å; while that of Rh–C(2) and Rh–C(5) is 2.12 Å. This trend is seen also in $[\{RhCl(\eta^3\text{-}C_3H_5)_2\}_2]$[10] and $[\{RhBr(\eta^3\text{-}C_3H_5)_2\}_2]$.[11] On the other hand the mean length of C(1)–C(2) and C(4)–C(5) bonds, 1.40 Å, and that of C(2)–C(3) and C(5)–C(6), 1.40 Å, show no significant asymmetry in the C–C bonds.

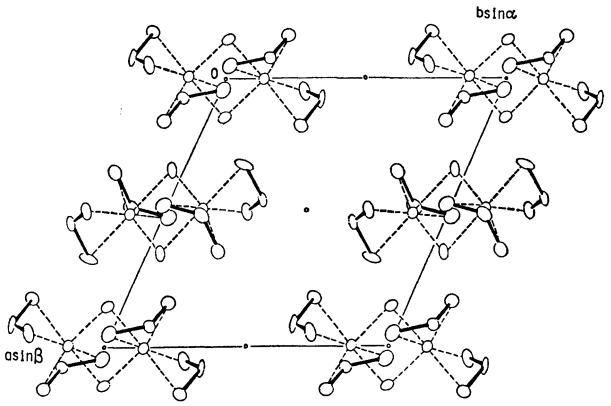

Fig. 6. Molecular packing of $[\{Rh(OH)(\eta^3\text{-}C_3H_5)_2\}_2]$.

The crystal structure is shown in Fig. 6. The molecule A locates at (0,0,0) and B locates at (0.5,0,0). Two Rh–Rh vectors of A and B are roughly parallel with each other, and a slight rotation of A around its Rh–Rh vector gives the orientation of B.

The Reactions of the Singlet NH Radicals with C_4 Olefins in the Liquid Phase

Jun-ichi HAMADA, Shigeru TSUNASHIMA,* and Shin SATO†

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received May 1, 1982)

The reactions of NH radicals with C_4 olefins, *trans*- and *cis*-2-butenes, 1-butene, and isobutene, were investigated by the photolysis of hydrogen azide in the liquid olefin at 0 °C and at the temperature of Dry Ice–methanol. Except for nitrogen and ammonia, amines and aziridines were found to be formed in good yield. 2-Butene-1-amine and *trans*-2,3-dimethylaziridine from *trans*-2-butene, 2-butene-1-amine and *cis*-2,3-dimethylaziridine from *cis*-2-butene, 3-butene-1- and 2-amines and 2-ethylaziridine from 1-butene, and 2-methyl-2-propene-1-amine and 2,2-dimethylaziridine from isobutene. These product formations were successfully explained by the insertion into the C–H bond and the addition to the double bond of olefin by the singlet NH radicals. In the case of 2-butene, no isomerized aziridine formation was observed. This result suggested that the triplet NH radicals rarely add to the double bond of olefin.

The reactions of NH radicals with lower olefins, ethylene and propene, have been reported.[1,2] The formations of aziridine and amine were explained by the addition and the insertion reactions of the singlet NH radicals, NH($a^1\Delta$), which were formed by the photolysis of hydrogen azide. The mechanism and the nature of the intermediate of these reactions have not yet been established. Amines are likely formed in an insertive attack of the NH singlet on the C–H bond of olefins as with paraffin.[3-7] For the aziridine formation, the following possibilities should be considered: (a) a concerted addition of the singlet NH radicals to the double bond of olefin, (b) an addition of the singlet NH radicals to the C atom of the double bond to form a singlet biradical, which is followed by the ring closure, and (c) a triplet biradical formation by the addition of the NH triplet, NH($X^3\Sigma^-$), followed by the spin inversion and ring closure. Aziridine formed by (a) process should retain the conformation of reactant; that is, cis isomer formation from cis olefin and trans isomer formation from trans olefin. Cis and trans isomer formations are expected from (b) and (c) processes, although the cis and trans ratio may depend on the nature of the biradicals and the experimental conditions.

The insertion and the addition reactions of O and CH_2, which are isoelectronic species of NH, have been extensively investigated.[8,9] In the reactions of methylene with 2-butene, it is well known that the singlet species add to the double bond of an olefin while they retain the stereospecificity, and the triplet species add without retaining stereospecificity.[10,11] Although O(^{1}D) adds to 2-butene while retaining the conformation of reactant,[12] O(^{3}P) gives *cis* and *trans* epoxide simultaneously. The cis and trans isomer ratio depended on the reaction temperature and/or the phase.[13,14]

In the previous paper,[1] the aziridine formation by the NH triplet was ignored in order to explain the concentration dependence of the ammonia formation. This explanation was based on the assumption that ammonia is formed by a hydrogen-atom abstraction from hydrogen azide. If ammonia is formed by the reactions of the NH singlet with olefin, the reaction of the NH triplet with olefin has to be included in the mechanism. If this is the case, both *cis*- and *trans*-aziridine formations may be expected in the reactions with *cis*- or *trans*-2-butene.

To continue such studies, we examined the photolyses of hydrogen azide in liquid *cis*- and *trans*-2-butenes, 1-butene, and isobutene at 0 °C and at the temperature of Dry Ice–methanol.

Experimental

The experimental methods and the apparatus used were essentially the same as those described in the previous paper.[1] Hydrogen azide was prepared and purified by the method already described.[1] Pure grade *trans*- and *cis*-2-butenes, 1-butene, and isobutene (Takachiho Shoji Co.) were used after having been distilled at a low temperature under vacuum. The mixture of hydrogen azide and olefin was prepared in a quartz tube (8 mm o.d.) or Pyrex tube (8 mm o.d.). The hydrogen azide solution was irradiated with a medium pressure mercury lamp (Wako Denki Co.) at 0 °C or at the temperature of Dry Ice–methanol. In the case of the quartz tube, a filter (Toshiba UV 27) was used to eliminate the light of wavelengths shorter than 250 nm.

After the irradiation, non-condensable products at −196 °C were analyzed with a combination of a Toepler pump, a gas buret, and a CuO furnace at 300 °C. The solvent hydrocarbon was evacuated at a temperature lower than −80 °C. Less volatile products, including unreacted hydrogen azide, were passed through a trap packed with NaOH coated glass wool, in order to decompose the quarternary ammonium salts which eventually formed.[4] The products thus obtained were analyzed with GLC, using a column packed with Amipack 124 (Gasukuro Kogyo Co., 3 m in length at 60 °C). Since authentic samples for the all products were not available, the sensitivity of an unavailable product i (S_i) was estimated from its retention time (Rt_i) using the relation: $S_i = a\,Rt_i + b$. The constants a and b were estimated using available amines and aziridines. Since the relation holds well for the amines and aziridines examined, the sensitivities, thus estimated, may be correct within an error of 30%.

The identification of the products was mainly done by the comparisons of their relative retention times and their mass spectra. The GC-mass spectrometer (Nichiden Varian, TE 600) was used. An NMR spectrometer (Varian, EM 390) was also used, using D_2O as a solvent.

Results

The photolyses of hydrogen azide in the liquid *cis*- and *trans*-2-butenes, 1-butene, and isobutene were examined at 0 °C or at the temperature of Dry Ice–methanol. In every case examined, nitrogen and ammonia were found to be formed, much as in the cases of ethylene and propene.[1] Neither methane nor hydrogen was detected. The less volatile products were subjected to the analysis by GLC after having been treated with NaOH. The results obtained are summarized as follows:

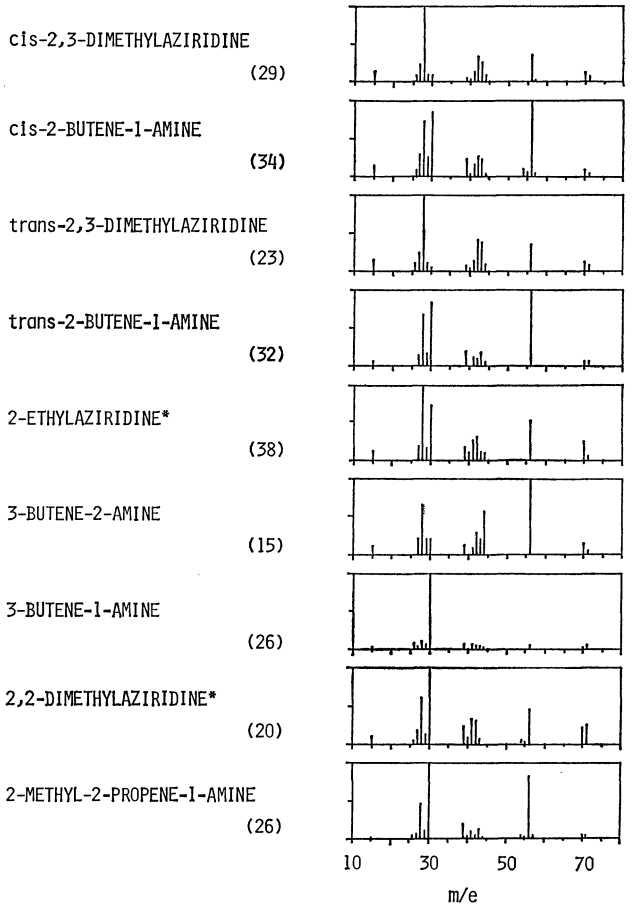

Fig. 1. The mass spectra of the products obtained in the photolyses of hydrogen azide in the liquid *cis*- and *trans*-2-butenes, 1-butene, and isobutene.
The values in the parentheses show the retention times (see Text). The mass spectrum of the compound with an asterisk could be compared with that reported.[18]. The abscissa shows the mass number.

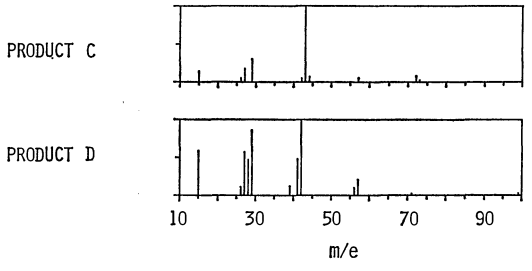

Fig. 2. The mass spectra of the products eluted at 22 min (product C) and 43 min (product D).
For the detail, see Text. The abscissa shows the mass number.

cis-*2-Butene.* In the case of *cis*-2-butene, 6 peaks were separated by GLC using a column of Amipack 124. Their retention times were 5, 15, 22, 29, 34, and 43 min. The main two peaks, which eluted at 29 and 34 min, were identified to be 2,3-dimethylaziridine and 2-butene-1-amine from the mass spectra shown in Fig. 1. The configuration of the aziridine was assigned to be cis isomer on the basis of its NMR spectrum, NMR(D_2O) δ 1.0 (3H, d, CH_3) and 2.1 (1H, m, CH), by the comparison with the reported values for *cis*- and *trans*-2,3-dimethylaziridine.[15] The mass spectra of the minor products eluted at 22 and 43 min are shown in Fig. 2. The 43 min product was tentatively assigned to be *s*-butyl azide. The product of 22 min could not be identified. The mass spectrum is apparently different from that of the product of 23 min obtained in the reaction of *trans*-2-butene. The product of 5 min was identified to be ethanamine by the comparison with the mass spectrum obtained using an authentic sample. The product eluted at 15 min gave the same mass spectrum as was obtained in the case of 1-butene (see later).

The yields of these products relative to that of nitrogen are shown in Table 1. The relative yields of the products were almost constant for the changes in the concentration of hydrogen azide and the irradiation time, except for ethanamine and *s*-butyl azide. The relative yield of ethanamine increased with an increase in the irradiation time. This trend suggested that this product was formed by the secondary reactions.

trans-*2-Butene.* In the case of *trans*-2-butene, 5 peaks were observed on the gas chromatogram. Their retention times were 5, 15, 23, 32, and 43 min. The main products eluted at 23 and 32 min were identified to be 2,3-dimethylaziridine and 2-butene-1-amine from their mass spectra shown in Fig. 1. The *cis-trans* configuration of the aziridine, NMR(D_2O) δ 1.0 (3H, d, CH_3) and 1.7 (1H, m, CH), was assigned to be in trans form by comparison with the reported values.[15] 2-Butene-1-amine formed from *trans*-2-butene, NMR-(D_2O) δ 1.7 (3H, d, CH_3), 3.3 (2H, d, CH_2), and 5.6 (m), eluted at 32 min, while the amine formed from *cis*-2-butene, NMR(D_2O) δ 1.6 (3H, d, CH_3), 3.2 (2H, d, CH_2), and 5.6 (m), eluted at 34 min. It is hard to assign the *cis-trans* configuration from the mass and NMR spectra. Since only one isomer could be obtained, the former was tentatively assigned to be in trans form and the latter to be in cis form. The products eluted at 5, 15, and 43 min were the same as those obtained in the case of *cis*-2-butene. The large peak of *trans*-2,3-dimethylaziridine probably masked the small peak eluted at 22 min obtained in the case of *cis*-2-butene; therefore, the amount of *trans*-2,3-dimethylaziridine was corrected by assuming that the relative yield of the product at 22 min is the same as that obtained in the case of *cis*-2-butene. No *cis*-2,3-dimethylaziridine formation was observed. Table 2 shows the relative yields of products obtained at the various concentrations of hydrogen azide, irradia-

a) A Pyrex cell was used. The abbreviations of the products are *t*DMA=*trans*-2,3-dimethylaziridine and *t*2B1A=*trans*-2-butene-1-amine. A, B, and D are the same as shown in Table 1. Reaction temperature was 0 °C except indicated. The values in the parentheses show the retention times of the products. b) IT=Irradiation time. c) Reactions at the temperature of Dry Ice-methanol.

tion times, and the reaction temperatures. Much as in the case of *cis*-2-butene, the relative yields of the products were almost constant, except for ethanamine and *s*-butyl azide.

1-Butene. In the case of 1-butene, 6 peaks were separated on the gas chromatogram at 5, 15, 22, 26, 38, and 60 min. The main products eluted at 15, 26, and 38 min were identified to be 3-butene-2- and 1-amines and 2-ethylaziridine. The mass spectra of these products are shown in Fig. 1. The amount of the product eluted at 60 min was negligibly small and the identification could not be done. The products eluted at 5, 15, and 22 min were the same as those obtained in the cases of *cis*- and *trans*-2-butenes. The yield of ethanamine, however, was negligibly small. The relative yields of the products are shown in Table 3. Similar to the cases of *cis*- and *trans*-2-butenes, the relative yields were almost constant for the changes in the experimental conditions.

Isobutene. In the case of isobutene, four products were separated at 20, 26, 33, and 41 min. The products eluted at 20 and 26 min were identified to be 2,2-dimethylaziridine and 2-methyl-2-propene-1-amine from their mass spectra, shown in Fig. 1, and their NMR spectra. The products eluted at 33 and 41 min were negligibly small and were not identified. The yields of the products relative to nitrogen are shown in Table 4. In contrast to the cases of 2- and 1-butenes, the relative yields of 2,2-dimethylaziridine decreased with the increases in the irradiation time and the concentration of hydrogen azide. The difference in the reaction cell, quartz or Pyrex, did

not make a difference in this trend, although the effective wavelengths of the light in the former are slightly shorter than those in the latter. These results suggested that the aziridine formed was decomposed by the secondary process. The relative yields of 2,2-dimethylaziridine at the zero irradiation time was estimated to be about 0.45 by the extrapolation.

Discussion

Main Products. In the photolyses of hydrogen azide in the liquid C_4 olefins, the main products observed were nitrogen, ammonia, amines, and aziridines. The formation of these products is expected from the reaction mechanism proposed in the previous paper.[1] The reaction mechanism proposed is shown as follows:

$$HN_3 + h\nu \longrightarrow {}^1NH + N_2 \quad (1)$$

$${}^1NH + Ol \longrightarrow \text{aziridine} \quad (2)$$

$$\longrightarrow \text{amine} \quad (3)$$

$$\longrightarrow {}^3NH + Ol \quad (4)$$

$${}^3NH + HN_3 \longrightarrow NH_2 + N_3 \quad (5)$$

$$NH_2 + HN_3 \longrightarrow NH_3 + N_3 \quad (6)$$

$$N_3 + Ol \longrightarrow OlN + N_2, \quad (7)$$

where ^1NH and ^3NH represent the NH radicals in the excited singlet state, $NH(a^1\Delta)$, and in the ground triplet state, $NH(X^3\Sigma^-)$, respectively. Ol stands for olefin.

Reaction 2 is the addition reaction of the NH singlet to the double bond of olefin: *cis*- or *trans*-2,3-dimethylaziridine from *cis*- or *trans*-2-butene, 2-ethylaziridine from 1-butene, and 2,2-dimethylaziridine from isobutene. The addition occurs by a concerted manner ((a) process); in fact, only *cis*-aziridine was formed from *cis*-2-butene and only *trans*-aziridine from *trans*-2-butene.

Reaction 3 is the insertion reaction of the NH singlet into the C–H bond of olefin: *cis*- or *trans*-2-butene-1-amine from *cis*- or *trans*-2-butene, 3-butene-1- and 2-amines from 1-butene, and 2-methyl-2-propene-1-amine from isobutene. These products were all observed to be formed in good yield.

Role of Triplet NH Radicals. The triplet NH radical formed by a deactivation, Reaction 4, is assumed to abstract a hydrogen atom from hydrogen azide, Reaction 5. The triplet NH radicals possess enough energy to abstract an allylic hydrogen atom from olefin:

$${}^3NH + Ol \longrightarrow NH_2 + R. \quad (8)$$

Reaction 8, however, may be unimportant at the low temperature since the activation energy of Reaction 8 is expected to be high. If Reaction 8 is important and the resultant allyl radical abstracts a hydrogen atom from hydrogen azide,

$$R + HN_3 \longrightarrow Ol + N_3, \quad (9)$$

Reaction 8 followed by Reaction 9 is indistinguishable from Reaction 5.[1]

In the cases of the triplet methylene and oxygen, the addition to the double bond of the olefin has been considered to be important.[8,9] The triplet NH radicals might add to the double bond of the olefin in this way:

$${}^3NH + Ol \longrightarrow \text{triplet biradical.} \quad (10)$$

If Reaction 10 competed with Reaction 5, the yield of ammonia would increase with an increase in the

concentration of hydrogen azide. The yield observed, however, was almost constant for the changes in the concentration. If Reaction 10 competed with Reaction 8, the observed concentration dependence could be explained. In this case, we should expect the difference in the yield of ammonia between ethylene and propene or butenes, since the number of allylic C–H bonds included is different. The yield of ammonia also should increase with the reaction temperature. The yield of ammonia, however, was almost constant for the changes in the reactant and also in the reaction temperature. This inconsistency could be eliminated by assuming that ammonia is formed by a reaction in which the NH singlet abstracts two hydrogen atoms from an olefin:

$$^1NH + Ol \longrightarrow NH_3 + \text{products.} \quad (11)$$

As was discussed in the previous paper, Reaction 11 is unlikely.[1]

If Reaction 10 be included in the mechanism, the triplet biradicals will form aziridine by a ring closure, as observed in the cases of methylene or oxygen:[8,9]

$$\text{triplet biradical} \longrightarrow \text{aziridine.} \quad (12)$$

The aziridine formed by Reaction 12 should contain two geometrical isomers in the case of 2-butene: *cis*- and *trans*-2,3-dimethylaziridine. The results obtained, however, were different from this expectation. Thus we may conclude that the triplet NH radicals rarely add to the double bond of olefin under the present experimental conditions. This conclusion is different from that obtained in the cases of the triplet CH_2 and O. The low reactivity of the NH triplet has recently been suggested by the *ab initio* calculation. Fueno calculated the activation energy of the reaction of the NH triplet with ethylene to be 57 kJ mol^{-1}.[16] For the reactions of the triplet O atoms with ethylene, the activation energy has been estimated to be about 6 kJ mol^{-1}.[17]

Material Balance. From the above reaction mechanism, Reactions 1—7, the following relation can be expected to hold between the relative yields of products:

$$(\text{aziridine} + \text{amine} + 3NH_3)/N_2 = 1.0. \quad (13)$$

Using the values shown in Tables 1—4, the left-hand-side of Eq. 13 was estimated to be 1.2, 1.2, 1.3, and 1.4 respectively for *cis*- and *trans*-2-butenes, 1-butene, and isobutene. In the above estimations, the yields of minor products were neglected. Although the detailed mechanism for the minor product formations cannot be specified at present, these products may probably result from OlN, the product of Reaction 7. In the cases of ethylene and propene, the similar product ratios were found to be 0.7 and 0.96 respectively[1] The small values were tentatively explained by neglecting the ethenamine formation. Ethenamine is a possible insertion product of the NH singlet into the vinylic C–H bond, but this compound is known to be unstable. In the cases of butenes, the sum of the relative yields, the left-hand-side of Eq. 13, were all larger than unity. This may be attributed to the large experimental errors, especially due to the indirect method of estimating the sensitivities of GLC and an incomplete reaction mechanism in which the formation of the minor products is neglected.

Relative Rate of the Insertion and the Addition. Using the values shown in Tables 1—4, the rate of the insertion into the allylic C–H bond can be estimated relative to that of the addition as follows: 0.7_1 (*cis*-2-butene), 0.6_7 (*trans*-2-butene), 0.5_2 (1-butene), and 0.5_7 (isobutene). The relative rate obtained with propene was 0.35.[1] Except for the case of 1-butene, the relative rate per bond was almost equal and about 0.1. In other words, the rate of the insertion into an allylic C–H bond is about 1/10 that of the addition to the double bond of olefin. The large insertion rate obtained with 1-butene may be explained by the fact that the allylic C–H bond of 1-butene is weaker than others.

The authors are much obliged to Professor Takeshi Nakai of this Institute for the NMR analyses.

Brønsted Relation for Hydrogen→Deuterium Exchange Reactions of Imidazole-bearing Molecules with Amino Groups

Toshiya ENDO,† Ichio SHIMADA,†† Fuyuhiko INAGAKI,††† and Tatsuo MIYAZAWA*

Department of Biophysics and Biochemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received June 16, 1982)

The base-catalyzed hydrogen→deuterium exchange rates of the imidazole C-2 protons were measured for the imidazole-bearing molecules with amino groups ($N^2H_2 \cdot Im$) in ^2H_2O at various pH. From the pH dependences of the pseudo-first-order rate constants, the second-order rate constants were obtained for the $N^2H_3^+ \cdot Im^2H^+$ species and for the equilibrium mixtures of the $N^2H_2 \cdot Im^2H^+$ and $N^2H_3^+ \cdot Im$ species. For both the $N^2H_3^+ \cdot Im^2H^+$ and $N^2H_2 \cdot Im^2H^+$ species, the second-order rate constants and microscopic dissociation constants of the imidazolium rings were found to satisfy the Brønsted relation, with concomitant estimation of the abundance ratio of the $N^2H_2 \cdot Im^2H^+$ and $N^2H_3^+ \cdot Im$ species. This abundance ratio was compared with that estimated from the pH dependence of proton chemical shifts.

The C-2 proton of imidazole ring is known to exchange with the hydrogen isotopes (deuterium or tritium) under mild condition by a base-catalyzed scheme.[1–3] For the hydrogen→tritium exchange reactions of imidazole-bearing molecules without amino groups, Minamino *et al.* have found that the second-order rate constants k_b and pK_a's of imidazole rings satisfy the Brønsted relation:

$$\log k_b = \alpha pK_a + \beta, \quad (1)$$

where α and β are the constants for this type of relation.[4]

For the determination of pK_a values the nuclear magnetic resonance (NMR) spectroscopy is useful. The second-order rate constants (k_b) for hydrogen→deuterium exchange reactions may also be measured by NMR, without radioisotope manipulations. Here it may be noted that (1) the rate constant k_b for hydrogen→deuterium exchange reaction may be different from that for hydrogen→tritium exchange reaction; (2) the pK_a value of imidazole ring in ^2H_2O solution is different from that in H_2O solution; (3) the correct k_b values may not be obtained by a simple relation (see Eq. 2) if the imidazole ring is in proximity to other positively-charged ionizable groups with pK_a values close to that of the imidazole ring.

In the present study a novel method for the Brønsted plots (log k_b *versus* pK_a) for hydrogen→deuterium exchange reactions of imidazole-bearing molecules with amino groups has been worked out. These Brønsted plots together with those for imidazole-bearing molecules with no amino groups give a single straight line, and the validity of the Brønsted relation has been confirmed.

Experimental

The imidazole-bearing molecules used in the present study are *trans*-urocanic acid, *N*-acetylhistidine methylamide, *N*-acetylhistidine, and imidazole-4-acetic acid with no amino groups, and histidine methylamide, histidylglycine, histidinol, histidine and histamine with amino groups. 270-MHz proton NMR spectra were recorded on a Bruker WH-270 spectrometer. pH values (direct pH-meter readings)[5] were measured by a Radiometer PHM-26 pH meter. pK_a values were obtained by the nonlinear least square analyses of the pH dependences of proton chemical shifts. The hydrogen→deuterium exchange reaction was carried out in ^2H_2O solution (0.2 M NaCl, 1 M=1 mol dm^{-3}) at 37 °C directly in the 5-mm glass NMR tubes. The intensity decay of the C-2 proton resonance was measured relative to the intensity of C-4 proton resonance, and the observed pseudo-first-order rate constant k_{obsd} were obtained from its semi-log plots.

Results and Discussion

Brønsted Plots for Imidazole-bearing Molecules with No Amino Groups. For the imidazole-bearing molecules with no amino groups, it was sufficient to do hydrogen→deuterium exchange experiments at a given pH (9—11). The second-order rate constant k_b was obtained from k_{obsd} by using the following equation:

$$k_{obsd} = \{k_\phi K_a/[^2H^+]\}/\{1+K_a/[^2H^+]\} \quad (2)$$

$$k_\phi = k_b K_w/K_a, \quad (3)$$

where K_a is the dissociation constant of the imidazolium ring and K_w is the ion product of H_2O ($10^{-13.6}$ at 37 °C). The results are shown in Table 1 and their Brønsted plots in Fig. 1. As clearly seen in Fig. 1, log k_b and pK_a values are correlated by a single straight line and thus satisfy the Brønsted relation ($\alpha=-0.76$ and $\beta=6.7$ in Eq. 1).[6]

Brønsted Plots for Imidazole-bearing Molecules with Amino Groups. For the imidazole-bearing molecules with amino groups (denoted as $N^2H_2 \cdot Im$), the time course of exchange reaction was followed at eight pH's in the range 3—12. For example, the pH dependence of k_{obsd} for histidine is shown in Fig. 2. Exchange reaction does not occur at the acidic pH indicating that acid (or ^2H_2O)-catalyzed exchange mechanism can be neglected. This pH dependence curve exhibits two inflections at pH's each corresponding to the pK_a's of the imidazolium ring and the amino group, as previously reported.[7,8]

For this case k_{obsd} is written as,

$$k_{obsd} = \frac{k_{\phi 1}K_{a1}/[^2H^+] + k_{\phi 2}K_{a1}K_{a2}/[^2H^+]^2}{1+K_{a1}/[^2H^+]+K_{a1}K_{a2}/[^2H^+]^2} \quad (4)$$

$$k_{\phi 1} = k_{b1}K_w/K_{a1} \quad (5)$$

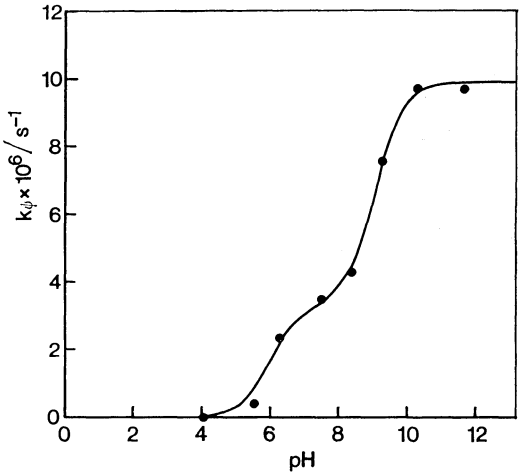

Fig. 2. pH dependence of the observed rate constant k_{obsd} for hydrogen→deuterium exchange reaction of histidine.

$$k_{\phi 2} = \rho k_{b2} K_w / K_{a2} \quad (6)$$

$$\rho/(1-\rho) = [N^2H_2 \cdot Im^2H^+]/[N^2H_3^+ \cdot Im], \quad (7)$$

where K_{a1} and K_{a2} are the first and second dissociation constants respectively, of $N^2H_3^+ \cdot Im^2H^+$, k_{b1} and k_{b2} are the second-order rate constants for the reaction of O^2H^- ion with $N^2H_3^+ \cdot Im^2H^+$ and $N^2H_2 \cdot Im^2H^+$ species respectively. Here it should be noted that the C_α–C_β rotamer populations of histidine compounds are not significantly perturbed by the ionization of the imidazole ring [J. Kobayashi, T. Higashijima, S. Sekido, and T. Miyazawa, personal communication]. By the use of Eqs. 4—7, the values of $k_{\phi 1}$ and $k_{\phi 2}$ were obtained by applying the nonlinear least-square method to the pH-dependence curves of k_{obsd}. These $k_{\phi 1}$ and $k_{\phi 2}$ were then used for calculating k_{b1} and ρk_{b2} (in $s^{-1}M^{-1}$) as shown in Table 2.

D	Histidine	6.06	2.08	9.16	−0.56
E	Histamine	6.18	2.07	9.92	−1.27

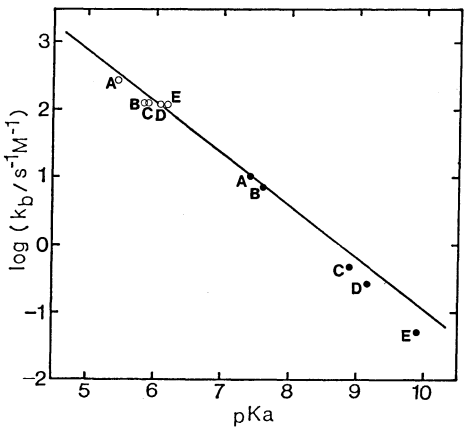

Fig. 3. Brønsted plots for hydrogen→deuterium exchange reactions of imidazole-amino-bearing molecules; ○ for k_{b1} *versus* K_{a1}; ● for ρk_{b2} *versus* K_{a2}.
For the notations A—E, see Table 2.

For this case the Brønsted plots of $\log k_{b1}$ and pK_{a1} (open circles in Fig. 3) show the tendency of slight deviations downward from the Brønsted line. The Brønsted plots of $\log \rho k_{b2}$ and pK_{a2} (closed circles in Fig. 3) lie also downward from the line.

Correction of Brønsted Plots Taking Account of Microscopic Equilibrium. The deviation from the Brønsted relation of the plots for imidazole-bearing molecules with amino groups (Fig. 3) indicates the necessity of taking into account the microscopic equilibrium. That is, the second-order rate constant k_{b1} for the $N^2H_3^+ \cdot Im^2H^+$ species should be correlated with the dissociation constant $K_1=(1-\rho)K_{a1}$ for the microscopic equilibrium $N^2H_3^+ \cdot Im^2H \rightleftarrows N^2H_3^+ \cdot Im + {}^2H^+$. The difference between pK_1 and pK_{a1} is equal to $\log [1/(1-\rho)]$. On the other hand, the second-order rate constant k_{b2} for the $N^2H_2 \cdot Im^2H^+$ species is to be correlated with the dissociation constant $K_2=K_{a2}/\rho$ for the microscopic equilibrium $N^2H_2 \cdot Im^2H^+ \rightleftarrows N^2H_2 \cdot Im + {}^2H^+$. The differences between $\log \rho k_{b2}$ and $\log k_{b2}$ and between pK_2 and pK_{a2} are both equal to $\log (1/\rho)$. In

Table 3. Dissociation constants (K_1 and K_2 in M), second-order rate constants (k_{b1} and k_{b2} in $s^{-1}M^{-1}$), and equilibrium constant (ρ) and its standard deviation (σ) for imidazole-amino-bearing molecules

Molecule		pK_1	$\log k_{b1}$	pK_2	$\log k_{b2}$	ρ (σ)
A	Histidine methylamide	5.71	2.44	7.07	1.37	0.45 (0.08)

D	Histidine	6.11	2.08	8.16	0.44	0.10 (0.02)
E	Histamine	6.19	2.07	8.22	0.43	0.02 (0.01)

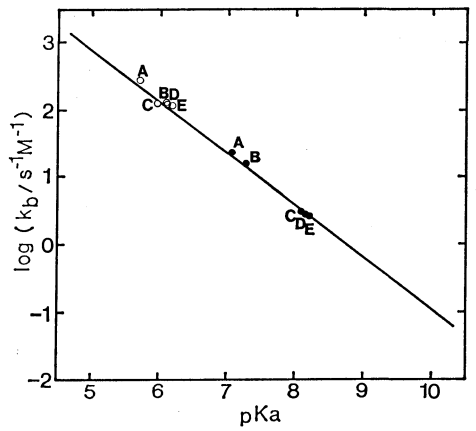

Fig. 4. Brønsted plots for hydrogen→deuterium exchange reactions of imidazole-amino-bearing molecules; ○ for k_{b1} *versus* K_1; ● for k_{b2} *versus* K_2. For the notations A—E, see Table 3.

fact, after adjusting the ratio ρ in the range 0—1, the Brønsted plots for k_{1b} (open circles in Fig. 4) and for k_{b2} (closed circles in Fig. 4) simultaneously lie close to the straight line, on the assumption that the imidazole-bearing molecules with amino groups follow the same Brønsted relation as obtained for the imidazole-bearing molecules with no amino groups. Thus, the values of ρ, pK_1, pK_2, and $\log k_{b2}$ were determined, as shown in Table 3, for the imidazole-bearing molecules with amino groups. The standard deviation for a pair of corrected Brønsted plots (pK_1, $\log k_{b1}$) and (pK_2, $\log k_{b2}$) is now smaller than that for a pair of uncorrected Brønsted plots (pK_{a1}, $\log k_{b1}$) and (pK_{a2}, $\log \rho k_{b2}$); the standard deviation is reduced from 0.12 to 0.091 for histidine methylamide, 0.28 to 0.08 for histidinol, 0.30 to 0.06 for histidine, and 0.44 to 0.08 for histamine.

It may be remarked that the second-order rate constant k_{b1} for the $N^2H_3^+ \cdot Im^2H^+$ species are 10—60 times as large as those (k_{b2}) for the $N^2H_2 \cdot Im^2H^+$ species, indicating that the reactivity of the imidazolium ring with O^2H^- ion is enhanced by the presence of the $N^2H_3^+$ groups in the proximity. Thus, as long as the base-catalyzed scheme is valid, the Brønsted relation applies to the second-order rate constants k_{b1} and k_{b2} with the concomitant estimation of the fractional population ρ of $[N^2H_2 \cdot Im^2H^+]$.

Comparison of ρ Estimated from the Brønsted-plot Correction with That from the pH Dependence of Proton Chemical Shifts. In the base catalyzed hydrogen→deuterium exchange reaction, O^2H^- ions react only with the species whose imidazole rings are protonated *i.e.* $N^2H_3^+ \cdot Im^2H^+$ and $N^2H_2 \cdot Im^2H^+$. This is the reason why we can estimate the microscopic equilibrium constant ρ (the fractional population of $[N^2H_2 \cdot Im^2H^+]$). ρ may be also determined from the pH dependences of proton chemical shifts if some reasonable assumptions are made.[9] One possible assumption is that the increase in the chemical shift upon protonation is equal to that of *N*-acetylhistidine methylamide[10] whether or not the neighboring amino group is protonated. This assumption allows us to calculate the chemical shifts for $N^2H_2 \cdot Im^2H^+$ (δ_{0+}) and $N^2H_3^+ \cdot Im$ (δ_{+0}) from the first and third limiting chemical shifts for $N^2H_2 \cdot Im$ (δ_{00}) and $N^2H^+_3 \cdot Im^2H^+$ (δ_{++}). Then ρ may be determined by using the relation $\rho = (\delta_+ - \delta_{+0})/(\delta_{0+} - \delta_{+0})$, where δ_+ is the second limiting shift obtained from the least-square fitting of the pH titration curve with the simple sum of two Henderson-Hasselbalch functions. Thus values of ρ were calculated for the five imidazole-bearing molecules with amino groups from the pH dependences of their C-2 and C-4 proton chemical shifts, and are listed in Table 4.

Table 4. Equilibrium constant (ρ) calculated from the pH dependences of C-2 and C-4 proton chemical shifts for imidazole-amino-bearing molecules

Molecule		ρ (C-2 proton)	ρ (C-4 proton)
A	Histidine methylamide	0.17	0.14
B	Histidylglycine	0.26	0.15
C	Histidinol	0.02	0.02
D	Histidine	0.03	0.06
E	Histamine	0.03	0.07

Now the values of ρ obtained by the two independent methods, the Brønsted-plot correction procedure (Table 3) and the analyses of the pH dependence of proton chemical shifts (Table 4), may be compared. Although ρ's in Table 4 are smaller than those in Table 3, the trend in ρ's among the five compounds is common to Table 3 and Table 4; histidine methylamide and histidinol have larger ρ's than the other three compounds. The differences in ρ's between Table 3 and Table 4 are probably due to that (1) the assumption used for calculating ρ in Table 4 is too simple because ρ's for C-2 proton chemical shifts differ from those for C-4 proton chemical shifts; (2) the accuracy of ρ in Table 3 is not sufficient for the critical discussion at present.

In conclusion, if an ionizable group with a pK_a

of 6—12 is in proximity to the imidazole ring, the pH dependence of the pseudo-first-order rate constant should be followed and be analyzed on the basis of microscopic equilibrium. Then the reactivity of the imidazole-ring C-2 proton may be compared on the Brønsted plots with those of imidazole-bearing molecules without such ionizable groups. Thus the validity of the Brønsted relation for the imidazole-bearing molecules even with amino groups was confirmed in the present study. This Brønsted relation will hopefully provide a basis for studying the perturbation on the reactivity of histidine residues in proteins.

Infrared and Visible Absorption Spectra of Doped $(CH)_x$, $(CD)_x$, and Copolymers $[(C_2H_2)_{1-y}(C_2D_2)_y]_x$

Hitoshi Fujimoto, Masashi Tanaka,*,† and Jiro Tanaka

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

†*Department of Chemistry, College of General Education, Nagoya University, Chikusa-ku, Nagoya 464*

(Received June 17, 1982)

Infrared and visible absorption spectra of $(CH)_x$, $(CD)_x$, and the copolymers $[(C_2H_2)_{1-y}(C_2D_2)_y]_x$ doped with Br_2 or I_2 were measured for various values of y between 0 and 1. By the doping, the $\pi\rightarrow\pi^*$ band located in the 19000 cm^{-1} region disappeared while several new bands were observed at 800—900-, 1000—1400-, and 5000-cm^{-1} regions. The absorption band shapes and the locations of the 5000- and 19000-cm^{-1} bands did not depend appreciably upon the value of y. The charged soliton induced vibrational bands were found at 870- and 1370-cm^{-1} in $(CH)_x$ and 1230-, 1100-, and 780-cm^{-1} in $(CD)_x$. In addition, another new bands were found around 570—660 cm^{-1} region by decreasing the temperature of the doped film to 160 K. These new bands were not shifted by the isotopic substitution. A plausible mechanism for the appearance of this band is suggested as an oscillation of trapped charged soliton around the negatively charged dopant. For the heavily doped $(CH)_x$ film, the gapless transition was observed and the optical conductivity was estimated by the Drude formula and was compared with the value obtained by a direct conductivity measurement.

Polyacetylene, $(CH)_x$, is one of the simplest linear conjugated polymers with a single chain structure and is a large band gap semiconductor. That is, pure $(CH)_x$ has the configuration of alternating single and double bonds and the $\pi\rightarrow\pi^*$ transition at about 19000 cm^{-1} indicates that the band gap exists due to the bond alternation in the polymer. However, Shirakawa, Heeger, and MacDiarmid and coworkers[1,2] found that this polymer undergoes dramatic increase in electrical conductivity upon exposure to vapors of chlorine, bromine, iodine, and arsenic pentafluoride. Furthermore, doping changes the color of thin films from reddish cupric to transparent blue. Such color change occurs by a new absorption band which may be due to charged soliton or free carrier and the suppression of the $\pi\rightarrow\pi^*$ interband transition. Many optical[3–7] and theoretical[8–10] studies have been presented hitherto to study the above-mentioned spectral changes, but the studies on the charged soliton state are not yet established. For instance, the new bands specific to the doped $(CH)_x$ are observed around 1370-, 1280-, and 870-cm^{-1}.[11–14] Doped $(CD)_x$ films also show additional bands which are located at 1230-, 1100-, and 780-cm^{-1}. These additional bands were assigned to the charged soliton-induced infrared absorption bands.[15–17] On the other hand Raman studies on $(CH)_x$ and $(CD)_x$ indicated that the bond alternation still remained or even enhanced after doping,[18] and ^{13}C NMR measurement did not show presence of Knight shift.[19]

In the present paper, we report the optical absorption spectra of Br_2 or I_2 doped $(CH)_x$, $(CD)_x$, and copolymers $[(C_2H_2)_{1-y}(C_2D_2)_y]_x$ and discuss the change of spectra with varying the y of deuterium composition. The temperature effect upon the 500—800 cm^{-1} band of these films was studied, and new bands were found just as were found in our earlier paper on the AsF_5 or Br_2 doped $(CH)_x$.[7]

Experimental

The copolymer films, $[(C_2H_2)_{1-y}(C_2D_2)_y]_x$, were prepared from the mixture of acetylene and acetylene-d_2 gases by Shirakawa's method.[20] Acetylene was purified before use by being passed successively through a concentrated sulfuric acid solution and Dry Ice-acetone traps. Acetylene-d_2 was prepared by adding heavy water to calcium carbide under vacuum. The isotopic contents were determined by partial pressure of C_2H_2 and C_2D_2.

The thin film was polymerized on the teflon frame with a 4×8 mm^2 hole and mounted in the Dewar vessel. Doping was accomplished by exposure of the film mounted in the Dewar vessel to bromine or iodine vapor. The extent of doping was controlled by measuring the four-probe d.c. conductivity of another thick film. After doping, the film was pumped out for at least 30 min and the infrared absorption of the film was measured with a Hitachi IR 260-50 (350—4000 cm^{-1}). Low temperature measurements were made by putting a liquid nitrogen into the Dewar vessel (see Fig. 1). For the visible absorption measurement, the thin film was polymerized on the inner surface of the 1 cm quartz cell and the absorption spectra of the films were measured with a Carl-Zeiss spectrophotometer (4000—45000 cm^{-1}) after doping.

The best fit of the calculated absorption spectrum to the observed spectrum of Br_2 doped $(CH)_x$ film was made on a FACOM M-200 computer of Nagoya University by using the SALS program.

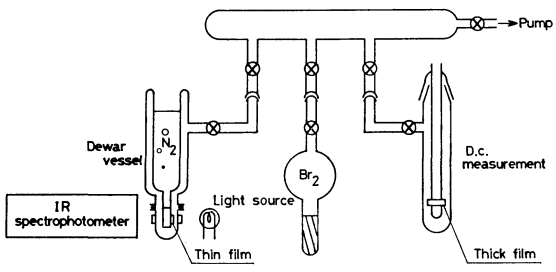

Fig. 1. Apparatus of the system of doping and IR absorption measurement.

Results and Discussion

Absorption Spectra of Thin $(CH)_x$ Films Doped with Br_2. Pure $(CH)_x$ film has a strong $\pi\rightarrow\pi^*$ band in the 19000 cm^{-1} region besides the C–H out-of-plane (740 cm^{-1} in *cis*-$(CH)_x$ and 1015 cm^{-1} in *trans*-$(CH)_x$) and the C–C–C deformation (446 cm^{-1} in *cis*-$(CH)_x$). Figures 2 and 3 show the change of spectra by doping:

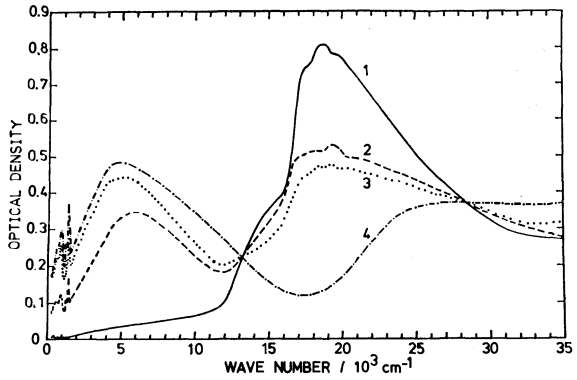

Fig. 2. Absorption spectra of the thin $(CH)_x$ films doped with Br_2.
1: Pure, 2: $\sigma \simeq 6\,\Omega^{-1}\,cm^{-1}$, 3: $\sigma \simeq 30\,\Omega^{-1}\,cm^{-1}$, 4: $\sigma \simeq 40\,\Omega^{-1}\,cm^{-1}$.

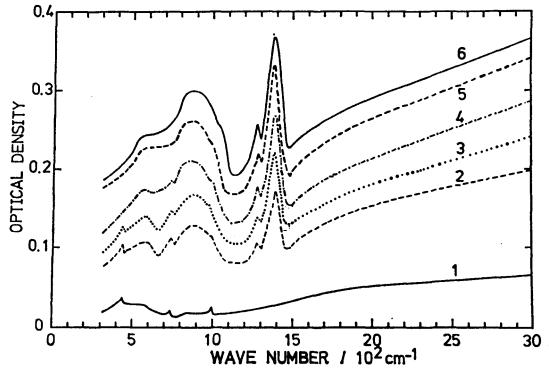

Fig. 3. IR absorption spectra of the thin $(CH)_x$ films doped with Br_2.
1: pure, 2: $\sigma \simeq 1\,\Omega^{-1}\,cm^{-1}$, 3: $\sigma \simeq 6\,\Omega^{-1}\,cm^{-1}$, 4: $\sigma \simeq 15\,\Omega^{-1}\,cm^{-1}$, 5: $\sigma \simeq 30\,\Omega^{-1}\,cm^{-1}$, 6: $\sigma \simeq 40\,\Omega^{-1}\,cm^{-1}$.

a new broad absorption band is observed over the wide region from 300- to 25000-cm^{-1}, while the $\pi \rightarrow \pi^*$ band at 19000 cm^{-1} is diminished and the absorption band of the Br_3^- ion appears in the 23000—35000 cm^{-1} region. Several new vibrational peaks are found at 1370-, 1280-, and 870-cm^{-1}, two of which were assigned by Mele and Rice[15] as the charged soliton-induced vibrations of C–C, C=C, and C–H bonds. Furthermore, the 1015 cm^{-1} band, which is the C–H out-of-plane band of *trans*-$(CH)_x$, is intensified although the 740- and 446-cm^{-1} bands assigned to the vibrational bands of *cis*-$(CH)_x$ are disappeared. This fact means that the doping induces the *cis-trans* isomerization of the $(CH)_x$ films.

Analysis of the Free Carrier Like Absorption Band of Heavily Br_2 Doped $(CH)_x$ Film. The observed optical density of thin films includes the contribution of the multiple reflection from the sample surface. Then, the absorption coefficient is determined from the observed transmittance as follows,[21]

$$T = \frac{(1-R)^2 e^{-\alpha d}}{1-R^2 e^{-2\alpha d}}, \tag{1}$$

where T is the observed transmittance, α the absorption coefficient, d the sample thickness, and R the surface reflectivity. Accordingly, the absorption coefficient is given by the following equation,

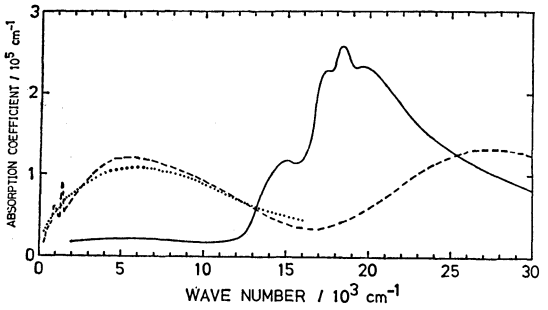

Fig. 4. Absorption spectra of pure and Br_2 doped $(CH)_x$.
——: Pure, ----: observed spectra of doped $(CH)_x$, ……: calculated spectra of doped $(CH)_x$.

$$\alpha = \frac{1}{d} \ln \left\{ \frac{(1-R)^2}{2T} + \left[\frac{(1-R)^4}{4T^2} + R^2 \right]^{1/2} \right\}. \tag{2}$$

As the surface reflectivity R corresponds to the measured reflectivity of the thick $(CH)_x$ film, the absorption spectra of pure and Br_2 doped thin $(CH)_x$ films are estimated as is shown in Fig. 4. Here, the thickness, d, of the film is determined by equating the maximum absorption coefficient of the 19000 cm^{-1} band to 2.58×10^5 cm^{-1}.[5] This value was determined by K-K transformations of the reflection spectra of pure thick films.

The absorption coefficient of the film, $\alpha(\omega)$, is expressed by using the complex dielectric constant, $\varepsilon(\omega)$, as follows,[5]

$$\alpha(\omega) = \frac{\sqrt{2}\,\omega}{c} \{(\varepsilon_1^2 + \varepsilon_2^2)^{1/2} - \varepsilon_1\}^{1/2}, \tag{3}$$

and,

$$\varepsilon(\omega) = \varepsilon_1(\omega) + i\varepsilon_2(\omega). \tag{4}$$

In the heavily doped $(CH)_x$ film, the 19000 cm^{-1} band corresponding to the interband transition disappears in the visible region and the broad band appears in the IR region having maximum at about 5500 cm^{-1}. The edge of the broad absorption band is not clearly found because of the overlapping with vibrational and soliton-induced bands. However, it seems to be decreasing less than 300 cm^{-1} with increasing doping, therefore the band gap seems to be closing at the final stage of doping.

Accordingly, if we suppose that the free carrier is formed by the heavy doping, then the complex dielectric constant will be given by a Drude type equation as,

$$\varepsilon(\omega) = \varepsilon_{core} - \frac{\omega_p^2}{\omega^2 + i\gamma\omega} \tag{5}$$

$$\varepsilon_1(\omega) = \varepsilon_{core} - \frac{\omega_p^2}{\omega^2 + \gamma^2}, \tag{6}$$

and,

$$\varepsilon_2(\omega) = \frac{\gamma}{\omega} \frac{\omega_p^2}{\omega^2 + \gamma^2}, \tag{7}$$

where ω_p is the plasma frequency and γ the band width.

For the heavily Br_2 doped $(CH)_x$ film, the parameters of Eqs. 6 and 7 are determined by the optimum fit of Eq. 3 to the experimental data of Eq. 2. The

best fit is obtained with $\hbar\omega_p=18200\,cm^{-1}$, $\gamma=8270\,cm^{-1}$, and $\varepsilon_{core}=2.77$. The calculated absorption spectrum based on these values is plotted for comparison with the experimental curve in Fig. 4. If we assume that the effective mass of the free carrier is equal to the electron mass, then the number of density, N, of the free carrier contributing to the metallic conduction is given as follows,

$$N=\frac{\omega_p^2 m_e}{4\pi e^2}. \tag{8}$$

Accordingly, the density of free carrier in the heavily doped $(CH)_x$ film is estimated as $3.0\times10^{21}\,cm^{-3}$. The total number of π-electron per unit volume was considered as $1.8\times10^{22}\,cm^{-3}$ from the specific gravity 0.4 g/cm^3 of $(CH)_x$ film.[3] Therefore, one-sixth of all π-electrons are considered to be susceptible to the optical exitation of gapless transition.

By using the values of ω_p and γ, the conductivity of the doped film shown in Fig. 4 is estimated as being $67\,\Omega^{-1}\,cm^{-1}$. The measured value was $40\,\Omega^{-1}\,cm^{-1}$; the agreement is reasonably good. The content of the dopant determined by chemical analysis was correlated with the conductivity, and the present heavily doped film includes 4% of tribromide ion (Br_3^-) per carbon atom. Therefore, one positive carbon atom or charged soliton may exist for twenty-five neutral atoms on an average. Since the probability density of the charged soliton spreads around the positive center, it is remarked that the π-electrons around the charged soliton may be responsible for the gapless transition.

Under the condition that the bond alternation exists in the chain, several mechanisms may be possible for the appearance of the gapless transition. One of them is based on the excitation of electrons around the positively charged soliton. Mele and Rice[8] have calculated the band structure of midgap state showing that the semiconductor to metal transition may occur by the heavy doping.

Absorption Spectra of Thin $(CD)_x$ Films Doped with Br_2. The spectra of the thin *cis*-$(CD)_x$ film are shown in Fig. 5, and the overall spectral change with Br_2 doping is illustrated in the order of increasing dopant concentration. The spectra observed in the near IR to visible region are similar to those of pure and Br_2 doped $(CH)_x$. That is, the strong peak around 19000 cm^{-1}, which is the $\pi\rightarrow\pi^*$ transition of the *cis* form, disappears and intense band grows up at 6000 cm^{-1} as a peak and its maximum moves to 4600 cm^{-1} at the final stage of doping. The position of the peak maxima shifts slightly to red by 200 cm^{-1} in $(CD)_x$ as compared to $(CH)_x$.

In Fig. 6 the spectral change in the IR region is shown with expanded scale. The tail of the 4600 cm^{-1} absorption band falls down gradually and it is overlapped with vibrational bands in the lower energy region. For the heavily doped film the low frequency part is enhanced and it appears to show a onset of the gapless transition. The new bands are observed at 1100- and 770-cm^{-1} regions with Br_2 doping. These bands are correlated with the 1370- and 870-cm^{-1} bands in $(CH)_x$, and the positions and the intensities of these bands are in excellent agreement with the calculation of Mele[16] and Etemad *et al.*[17] as shown in Fig. 6. This result is in conformity with Etemad's result, but our spectra show a shoulder at 1230 cm^{-1} which was predicted at 1270 cm^{-1} and was not clearly indicated in the earlier study.[17]

Temperature Dependence of Br_2 and I_2 Doped Thin Films. The changes of IR bands with temperature are measured in 160—300 K with Br_2 doped $(CD)_x$ and $(CH)_x$

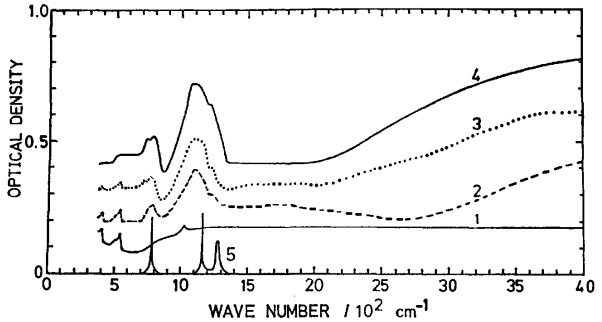

Fig. 6. IR absorption spectra of the thin $(CD)_x$ films doped with Br_2.
1: Pure, 2: $\sigma\simeq0.1\,\Omega^{-1}\,cm^{-1}$, 3: $\sigma\simeq1.3\,\Omega^{-1}\,cm^{-1}$, 4: $\simeq4\,\Omega^{-1}\,cm^{-1}$, 5: calculated by Mele and Rice.[16]

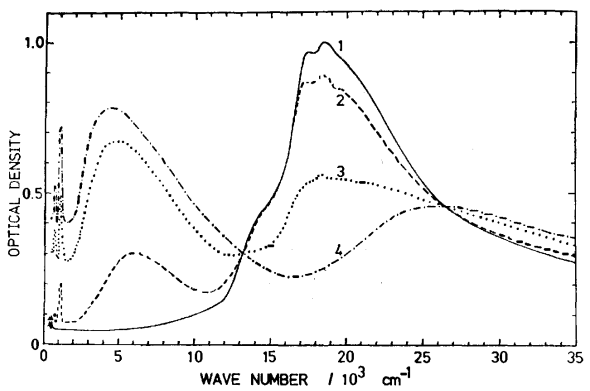

Fig. 5. Absorption spectra of the thin $(CD)_x$ films doped with Br_2.

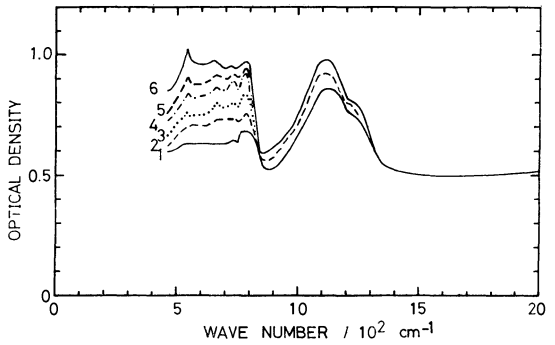

Fig. 9. Temperature dependence of the IR absorption spectra of the heavily Br_2 doped thin $(CD)_x$ film. 1: 300 K, 2: 280 K, 3: 260 K, 4: 240 K, 5: 220 K, 6: 160 K.

and I_2 doped $(CH)_x$. The spectral changes are illustrated in Figs. 7, 8, and 9. A common feature of spectral change is an appearance of new bands around 600 cm^{-1} region. It is remarkable that similar strong bands are observed with these films in spite of differences in isotopic species or chemical dopants. It should be remarked that the AsF_5 doped film showed the same spectral change in this region.[7]

In Fig. 7, the lower frequency bands around 400—1000 cm^{-1} are shown to be enhanced by cooling, and new peaks appear at 570- and 660-cm^{-1}. The 1370 cm^{-1} band and the broad absorption above 2000 cm^{-1} are not enhanced appreciably for this temperature range. In Fig. 8, the spectral change of the I_2 doped $(CH)_x$ film is illustrated, and the same peaks are found at 570- and 660-cm^{-1}. The Br_2 doped $(CD)_x$ film showed remarkably parallel spectral change by lowering the temperature; the broad bands around 500—800 cm^{-1} are enhanced and new peaks are found at 540- and 660-cm^{-1}. The deuterium substitution influences the new band as being found at slightly lower frequency. Moreover the skeletal vibration around 800 cm^{-1} is overlapped with new bands.

As regard to the origin of the new band, the predictions given by Mele and Rice[15] and Su, Schrieffer, and Heeger[22] on the soliton pinning mode should be mentioned. Mele and Rice[15] inferred that the far-infrared absorption may be found around 300—500 cm^{-1} by the pinning of the charged soliton, but they did not mention on the temperature effect on the soliton motion. Su, Schrieffer, and Heeger[22] have shown the pinning modes to appear at 560- and 720-cm^{-1}, and the lower one is due to the bound state of the charged soliton with the dopant and the higher one is a length or shape oscillation. The observed band positions are in excellent agreement with their calculations, but the assignment of the mode is difficult. The absence of isotopic effect indicates that the transition is essentially an electronic or the charged soliton's origin. The independence of the band position on the dopant species also support the soliton mechanism, because an impurity trapped bound state in the semiconductor is sensitive to acceptor species.[23]

The observed intensities of new bands are exceeding as compared to usual vibrational band. We have estimated the transition moment of the pinning mode of the charged soliton by a harmonic oscillator model with parameters given by Su, Schrieffer, and Heeger,[22] and the value was reasonable with their soliton mass of 6 m_e.

The absence of pinning mode at room temperature may be understood by the rapid motion of the charged soliton, because the energy of the pinning mode is dependent on the distance between the positively charged soliton and the dopant anion, and it might be smeared out at high temperature by the rapid motion. With decreasing the temperature, the charged soliton might be trapped at the proximity of anion, and the oscillatory motion will start around the anion.

IR Absorption Spectra of Thin Copolymers $[(C_2H_2)_{1-y}$-$(C_2D_2)_y]_x$ *Doped with* Br_2. In Fig. 10, the room temperature and low temperature absorption spectra of copolymers are shown for the following compositions: y=0, 0.2, 0.5, 0.8, and 1.0. The 870 cm^{-1} band in the Br_2 doped $(CH)_x$ (y=0) shifts to lower frequencies with increasing y. A more careful examination

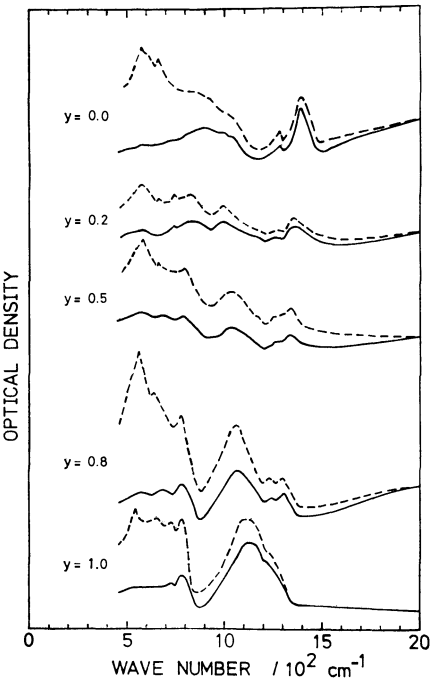

Fig.10. IR absorption spectra of copolymers $[(C_2H_2)_{1-y}$-$(C_2D_2)_y]_x$ doped with Br_2.
——: 300 K, ·····: 160 K.

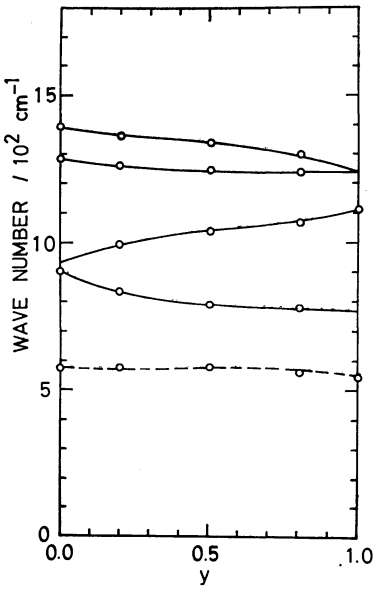

Fig.11. Mode frequencies *versus* composition, y, of Br_2 doped copolymers $[(C_2H_2)_{1-y}(C_2D_2)_y]_x$.
——: 300 K, ·····: 160 K.

reveals that this band shifts by about 100 cm^{-1} from 870 cm^{-1} at $y=0$ to 770 cm^{-1} at $y=1.0$ (Fig. 11). However, the frequency shifts of the 1370 cm^{-1} band in the Br_2 doped $(CH)_x$ ($y=0$) and the 1100 cm^{-1} band in the Br_2 doped $(CD)_x$ ($y=1.0$) show quite different behavior. That is, the 1370 cm^{-1} band in $(CH)_x$ and the 1100 cm^{-1} band in $(CD)_x$ shift to lower frequencies with increasing the isotopic substitution. As a result, the 1370 cm^{-1} band in $(CH)_x$ is not correlated directly with the 1100 cm^{-1} band in $(CD)_x$ at any composition y, as is shown in Fig. 11. This fact shows that these complicated spectral patterns should be analysed on the basis of the coupling of the C–H and C–D and C–C vibrations with π-electron transition of low energies occured with the charged soliton.

The authors would like to thank Mr. Toshiaki Noda and Mr. Gunzo Takamatsu for preparing the Dewar vessel for spectral measurement and the apparatus for the IR absorption measurement.

Radical Formation through Curing Reaction of Epoxy Resins with 2,4,6-Trinitrophenol or 2,4,6-Trinitroresorcinol

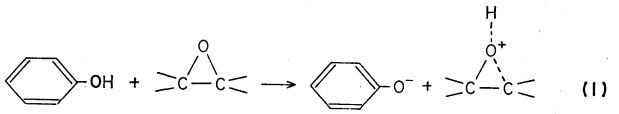
Kazuro KAWAMURA

Department of Chemistry, National Defense Academy, 1-10-20, Hashirimizu, Yokosuka 239

(Received July 7, 1982)

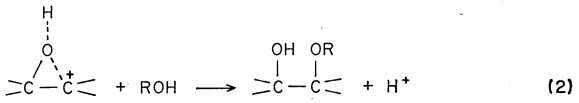
Radicals formed spontaneously during the cure reaction of epoxy resins with 2,4,6-trinitrophenol (TNP) or 2,4,6-trinitroresorcinol (TNR) have been investigated using electron spin resonance (ESR) technique. The ESR spectrum of the radicals stabilized in the epoxy resins cured with TNP was a triplet and the other spectrum of the radicals in the epoxy resins cured with TNR was a triplet with high anisotropy. The triplet splittings and *g*-values were attributed to radicals of the type >N–Ȯ. The asymmetric line shapes of the triplet splittings caused by the ^{14}N coupling constant are induced by the slow motion of the radicals in the polymer. The presence of radicals of this type suggests the transfer of an oxygen of a nitro group of TNP or TNR during the cure reaction.

It has been known that phenols react with epoxy resins at elevated temperatures. The exact mechanism of the reaction has not been made sufficiently clear, but the reaction is likely to proceed through the formation of an intermediate oxonium ion:



(1)

The resultant phenoxide ion may then react with the epoxy group. The carbonium ion from the oxonium complex may react with a hydroxyl group.[1,2]



(2)

If polynitrophenols are used as the ring-opening agent of epoxy resins instead of phenols, reaction (1) may proceed easily because of the strong electron-attracting nature of nitro groups. In fact, the curing occurs by mixing TNP or TNR with the epoxy resins at room temperature.[3]

Recently it has been shown by ESR that radicals are generated during the cure reaction of the epoxy resins with TNP or TNR, and that they are stabilized in the cured resins. The process of radical formation through the cure reaction cannot be explained only from the ionic mechanism shown in the reactions (1) and (2). In the present study, we shall try to obtain some information about the radicals from ESR studies.

Experimental

Nitrophenols of extra pure commercial grade were purified by recrystallization. They were *o*-nitrophenol: mp 44—45 °C, *m*-nitrophenol: mp 96.5—97 °C, *p*-nitrophenol: mp 114—115 °C, 2,4-dinitrophenol: mp 113.0—113.5 °C, 2,6-dinitrophenol: mp 63—64 °C, and 2,4,6-trinitrophenol (TNP): mp 121.5—122.5 °C. 2,4,6-Trinitroresorcinol (TNR) was prepared by sulfonation and nitration of resorcinol: mp 174—175 °C. 2,2-Diphenyl-1-picrylhydrazyl (DPPH) of extra pure commercial grade was purified by recrystallization twice from benzene, and it was dried under reduced pressure at 80 °C: mp 139—140 °C.[4,5]

The epoxy resin was Shell Chemical Company Epikote 828 (diglycidyl ether of bisphenol A, mol wt. approx. 380).[2] 1,2-Epoxypropane was dried with calcium hydride and purified by distillation: bp 35 °C. 1-Chloro-2,3-epoxypropane (a commercial guaranteed reagent grade) was used without further purification.

ESR measurements were carried out with a JEOL X-band spectrometer, model JES-PE-1X, using 100 KHz magnetic field modulation. The *g*-value was measured by comparison with Mn^{2+} in MgO placed in the cavity close to the sample position. The *g*-value of Mn^{2+} was determined beforehand by comparison with the value of DPPH (g= 2.0036). The radical concentration of the sample was evaluated by the comparison of the double-integrated absorption intensity of the first-derivative spectrum with that of DPPH. Sample temperatures were controlled by a standard JES-VT-3A variable-temperature controller. The ESR measurements were made in air and in a vacuum. When the ESR was measured in a vacuum, the cured sample was ground and put into a standard sample-tube. The tube was sealed after evacuation by a vacuum-line system (10^{-4} Torr).

Results and Discussion

When 10—15 weight per cent of TNP or TNR was mixed with Epikote 828, the cure reaction proceeded at room temperature. ESR absorption was observed in these cure systems, as shown in Fig. 1. The Epikote 828–TNP system showed an asymmetrical triplet spectrum with an approximate 1:1:1 intensity distribution and centered at a position corresponding to g=2.007 (Fig. 1 (a)). The Epikote 828–TNR system also showed an asymmetrical triplet with g=2.006 (Fig. 1 (b)). These triplet spectra imply that the radicals formed have the odd electrons coupled strongly to the ^{14}N nuclei, and are most reasonably to be attributed to radicals of the type >N–Ȯ. The change of the line shape and the *g*-value with temperature was examined for the cured sample having a TNP content of 15 per cent. The sample was cooled from room temperature to −170 °C and then heated to 70 °C progressively in a vacuum. The ESR spectra at 70 °C and at −170 °C are shown in Figs. 2 (a) and (b). The component of the triplet at −170 °C was broadened and showed a line width of 18 G† and g=2.007 at the central position, while the spectrum at 70 °C was almost the same as that at room temperature and showed a line width of 8 G and g= 2.007. The difference in the line width is caused by the change of the motion of the radical molecules

† 1 G = 10^{-4} T.

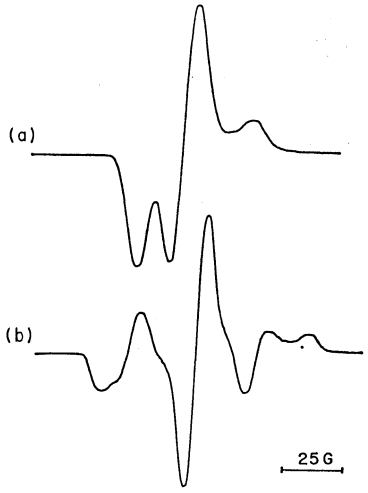


Fig. 1. ESR spectra of the radicals formed in the Epikoto 828–TNP system (a) and the Epikote 828–TNR system (b) at room temperature.

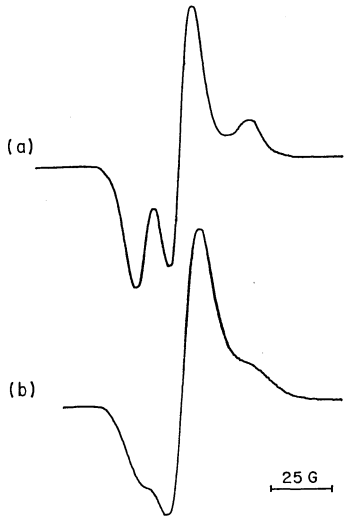

Fig. 2. Temperature dependence of ESR spectra of the radicals formed in the Epikote 828–TNP system. (a): 70 °C, (b): −170 °C.

in the cured resin. The same temperature dependence was seen on the Epikote 828–TNR system. The spectra shown in Figs. 1 and 2 agreed with the absorption pattern of nitroxide radicals when undergoing slow molecular motion, as has been investigated by the spin label technique.[6–10] According to this technique, the outer side lines of the spectrum in Fig. 1 (b) show that the radicals are arranged in parallel, and the inner side ones show that the radicals are arranged parpendicularly to the magnetic field. The splitting shows that the rotational motion of the radicals in the epoxy resin–TNR system is more limited than that of the radicals in the epoxy resin–TNP system. Neither spectra in Fig. 1 are resolved completely. A slow rotational motion of the radicals in the cured resin causes the poorly resolved and asymmetrical line shapes.

When TNP or TNR was mixed with other epoxy resins such as Epikote 812 (triglycidyl ether of glycerol) or Epikote 871 (diglycidyl ester of dimeric linoleic acid),[2] the cure reaction also proceeded at room temperature. In these cured resins the ESR spectra shown in Figs. 1 (a) and (b) were observed. However on adding TNP or TNR to monoepoxy compounds such as 1,2-epoxypropane or 1-chloro-2,3-epoxypropane, no ESR absorption occured. From these results, it is suggested that the radical formation and/or the accumulation result from a ring opening reaction of the epoxy resins which necessarily changes the resins to a high viscous state.

If mono- or dinitrophenol was mixed with Epikote 828 instead of TNP or TNR, the cure reaction scarcely proceeded at room temperature and these mixtures did not give the radicals. The mixtures were therefore heated in order to accelerate the cure reaction. The temperature was raised by 10 °C and left for 5 min. This process was repeated up to 300 °C. No ESR absorption was observed below 200 °C but a singlet spectrum due to carbonization appeared above 200 °C in each case. The result shows that not one or two but three nitro groups bonded to the benzene ring facilitate the radical formation.

The triplet spectra observed in the cure reactions of Epikote 828–TNP and Epikote 828–TNR systems may possibly be seen also in the nitrophenols alone. The ESR measurements of these nitrophenols were made under the same heating conditions as for the Epikote 828–nitrophenol mixtures. Mono- and dinitrophenols did not give the ESR absorption before carbonization, while TNP and TNR produced the radicals at 180—190 °C. Their ESR spectra are shown in Figs. 3 (a) and (b). These well resolved triplet spectra are observed both in a vacuum and in air. The spectra with an 1:1:1 intensity centered at a position corresponding to $g=2.006$ in Fig. 3 and an isotropic coupling constant of 28—30 G have been attributed to the radical $>N-\dot{O}$. This identification can be explained by the following facts: TNP decomposes slightly at 180 °C, and the g-value of the spectra almost agrees with the value of free spin. The intensity and the coupling constant of the spectra are the same as those of the radical $>N-\dot{O}$.[11,12] Therefore, it is appropriate to conclude that the radicals formed in

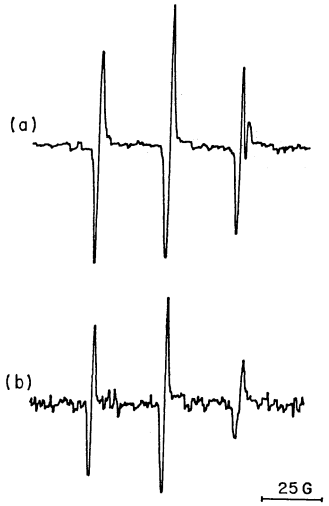

Fig. 3. ESR spectra of the radicals formed in TNP (a) and TNR (b) heated at 190 °C.

the epoxy resin cured with TNP or TNR coincide with those which appear by heating of TNP and TNR, although the radicals in the rigid state give the spectra in Fig. 1 and in the reverse case moving freely the radicals give the spectra in Fig. 3.

The changes in the absorption intensities (peak-to-peak height) of the center lines of the ESR spectra of the Epikote 828–TNP and Epikote 828–TNR systems as a function of time are shown in Figs. 4 and 5, respectively. The ESR absorption intensity of each system in Figs. 4 and 5 showed a maximum at 70 °C and the intensity changed little with time. The intensity curves above 70 °C in Fig. 4 clearly indicate a successive reaction A→B(radical)→C. On the other hand, the two steps-augmentation of the absorption intensity of the spectrum in Fig. 5 may imply that two hydroxyl groups of TNR take part in the ring-opening reaction of the epoxy groups.

More detailed investigations of the radicals formed in the Epikote 828–TNP system have been performed.

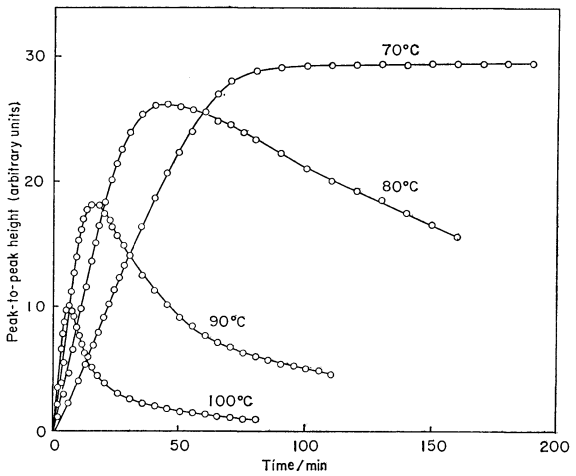

Fig. 4. Change in the intensities of ESR spectra of the radicals observed during the cure reaction of the Epikote 828–TNP system (Epikote 828/TNP=85/15) as a function of time.

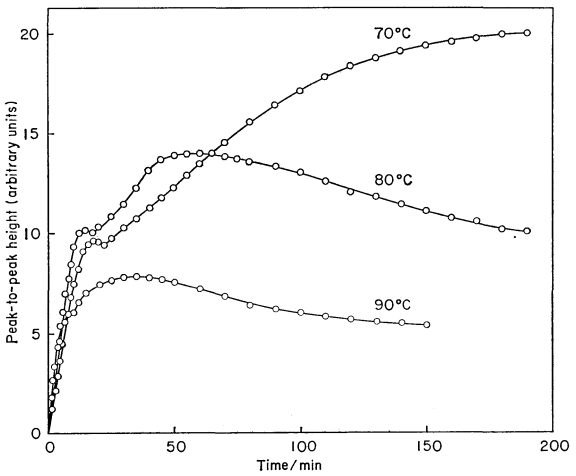

Fig. 5. Change in the intensities of ESR spectra of the radicals observed during the cure reaction of the Epikote 828–TNR system (Epikote 828/TNR=90/10) as a function of time.

Figure 6 shows the change of the absorption intensity of the center line of the triplet against the mixing ratio of TNP to the resin at 70 °C for 1 h. The ESR absorption appeared when the resin contains one per cent of TNP. When about 20 per cent of TNP was present, the ESR absorption showed a maximum. The absorption intensity of the cured resin which contained 15 per cent of TNP is equivalent to a radical concentration of 2×10^{17} spins/g.

The degree of cross-linking of Epikote 828 cured with TNP depends on the curing temperature, and is determined by the insolubility in acetone. The amount of the acetone-insoluble part of the cured resin which is mixed with 15 per cent of TNP is plotted against various temperatures as shown in Fig. 7. The absorption intensity of the ESR spectra of each cured resin is observed and plotted also in Fig. 7. As can be seen from the figure the change of these absorption intensities corresponds nicely to the amount of the acetone-insoluble part. That is, the more extensive the cross-linking is, the more the radicals are stabilized. At the temperature about 110 °C, the amount of acetone-insoluble part changes remarkably.

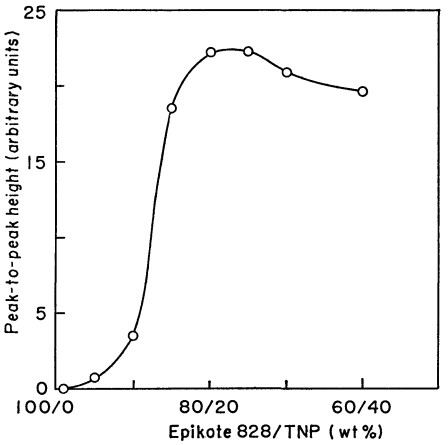

Fig. 6. Change in the intensities of ESR spectra of the radicals observed in the Epikote 828–TNP system by the treatment of 70 °C for 1 h at various ratios of mixing.

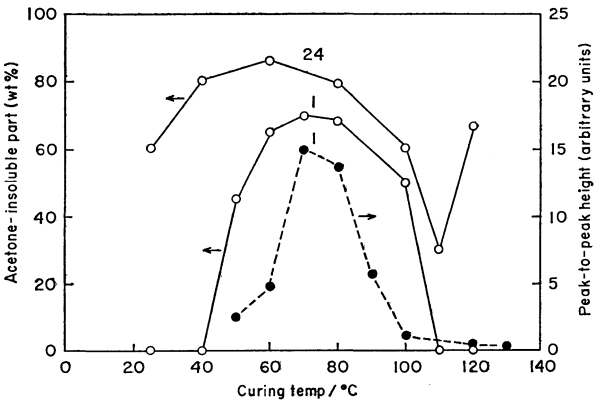

Fig. 7. Dependence of the acetone-insoluble parts and the ESR absorption intensities of Epikote 828 cured with 15 wt% of TNP at various temperatures. Numerals indicate cure time in hours.

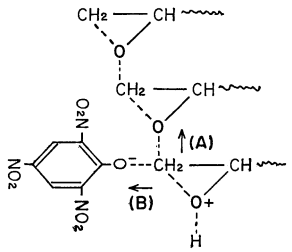
This change of the acetone-insoluble part is caused by a ring-opening mechanism of Epikote 828 with TNP, and is explained by the following ring-opening reaction:



Scheme 1.

Scheme 1 implies that the ring-opening reaction has the character of a competitive reaction. When the reaction proceeds in the direction (A), more than to the direction (B), the cross-linked structure is formed directly. In the reverse case a linear product is formed at the first step, which is soluble in acetone. However many epoxy groups remain in this linear product and react with each other at elevated temperatures.[13] Finally the cross-linking occurs. It is considered that the reaction in the direction (A) proceeds at low temperature and the reaction in the direction (B) proceeds at high temperature. The latter mechanism can be supported by the fact that 2,4,6-trinitrophenyl propyl ether with hydroxyls was produced by the reaction of 1,2-epoxypropane with TNP.[14] However radical formation cannot be explained by this ionic mechanism in Scheme 1 which is almost the same as those of reactions (1) and (2). The radical formation during the cure reaction of the epoxy resins with TNP or TNR suggests that intermediate ions or radicals which appear in the high viscous reaction system promote transfer of the oxygen of a nitro group to an other position.

As the overall reaction under consideration is so complicated, the mechanism is not fully understood at present, but the ESR experiments show that the radical formation reaction must be taken into accout in interpreting the cure reaction discussed above.

Volumetric Study on the 1,3-Dipolar Cycloaddition Reaction of Diazodiphenylmethane with Several Olefins

Yosuke Yoshimura, Jiro Osugi, and Masaru Nakahara*

Department of Chemistry, Faculty of Science, Kyoto University, Oiwake-cho, Kitashirakawa, Sakyo-ku, Kyoto 606

(Received July 19, 1982)

A high pressure kinetic study was made of the 1,3-dipolar cycloaddition reaction of Ph_2CN_2 with dimethyl maleate (DMM), dimethyl fumarate (DMF), methyl acrylate (MA), maleonitrile (MN), fumaronitrile (FN), and acrylonitrile (AN) in toluene at 25 °C. The activation volumes (ΔV^*) at 1 bar obtained for DMM, DMF, MA, MN, FN, and AN are -23.4 ± 0.5, -22.3 ± 0.2, -19.8 ± 0.4, -21.5 ± 0.6, -21.0 ± 1.1, and -23.9 ± 0.5 cm^3 mol^{-1}, respectively. The reaction volume (ΔV) for the reaction between Ph_2CN_2 and DMM was determined dilatometrically by taking advantage of supersaturation of the cycloadduct in solution; $\Delta V=-24.5\pm0.5$ cm^3 mol^{-1} and $\Delta V^*/\Delta V=0.955$. The present volumetric information coupled with a kinetic analysis shows that Firestone's biradical mechanism is not the case; the concerted mechanism is supported. The experimental result is compared with that of a recent *ab initio* molecular orbital calculation with respect to the activation and reaction volumes.

One of the most fundamental thermodynamic quantities is the partial molal volume which is a function of the geometry and polarity of a molecule in solution. When this static viewpoint is taken to consider the transition state of a reaction in solution within the framework of the transition state theory,[1] the activation volume (ΔV^*), which reflects changes in the geometry and charge distribution of reacting molecules during the activation process, can be used as a criterion for distinguishing between some conceivable reaction mechanisms. Such an example is shown in a recent report on competitive 1,2- and 1,4-cycloadditions between tetracyanoethylene and *p*-methoxystyrene.[2]

In the present work, the approach mentioned above has been applied to another kind of cycloaddition, the 1,3-dipolar cycloaddition, for which two quite different mechanisms are proposed: Huisgen[3] has given a concerted mechanism on the basis of such experimental results as the stereospecificity, the reactivity sequence of dipolarophiles, the small solvent effect, and the large negative activation entropy which is similar in magnitude to that for the usual 1,4-cycloaddition (Diels-Alder) reaction, while Firestone[4] states that most of the experimental results are consistent with a two-step mechanism involving biradical intermediates. Recent molecular orbital calculations for the 1,3-dipolar cycloaddition between HCNO and HCCH also have led to different results on the mechanism depending on approximations used; the *ab initio* method[5] indicates a relatively symmetric transition state without an intermediate but the MINDO/3 method[6] a highly unsymmetric transition state with a zwitterionic intermediate.

Since the geometry of the cyclic transition state in the concerted mechanism differs significantly from that of the chainlike intermediate in the two-step mechanism, the volume profile is expected to play a decisively important role in the determination of mechanism of the 1,3-dipolar cycloaddition. As a typical 1,3-dipolar cycloaddition, the reaction of diazodiphenylmethane (Ph_2CN_2) with a series of olefins substituted by CN or $COOCH_3$ groups is chosen in the present study; the effect of temperature and solvent on the reaction rate is already clarified in a previous paper.[7]

Experimental

Ph_2CN_2 and dipolarophiles, such as dimethyl maleate (DMM), dimethyl fumarate (DMF), methyl acrylate (MA), maleonitrile (MN), fumaronitrile (FN), and acrylonitrile (AN), were prepared and purified in the same way as in the previous work.[7] Toluene was purified by the standard method.

The reaction rate at high pressure was determined by the batch method; it was required to prevent the compression heat from masking the pressure effect, so that the half-life period of the reaction was adjusted to 2—3 h by varying reactant concentrations. A dilute (10^{-3} to 10^{-1} mol dm^{-3}) reaction solution filled in a flexible Teflon capsule was put in a pressure bomb convenient for the quick recovery.[8] The recovered solution was analyzed in the same way as in the previous work.[7] The pressure was measured to ±2 kg cm^{-2} (1 kg cm^{-2}=0.9807 bar) by a Bourdon gauge (Heise) calibrated against a free piston gauge (Nagano P-3). The temperature was kept at 25.0 ± 0.05 °C.

For the dilatometric determination of the reaction volume, a pycnometer of the Lipkin-Davison type with a capacity of 4.7 cm^3 was employed, by which the relative volume change was measured to $\pm5\times10^{-5}$. The temperature was controlled to ±0.01 °C.

Results

The rates of the reactions studied obeyed the second-order rate law,

$$-\mathrm{d}[Ph_2CN_2]/\mathrm{d}t = k[Ph_2CN_2][\text{dipolarophile}], \quad (1)$$

where [ ], t, and k denote the concentration, the time, and the rate constant, respectively. The rate constants were determined from the second-order plots, *i.e.*, log $[Ph_2CN_2]/[\text{dipolarophile}]$ *vs.* t at each pressure; they are summarized in the middle columns of Table 1. According to the transition state theory, the pressure (P) effect on the rate constant allows us to determine the activation volume by

$$\left(\frac{\partial \ln k}{\partial P}\right)_T = -\frac{\Delta V^*}{RT} + \kappa, \quad (2)$$

where R, T, and κ are the gas constant, the temperature, and the isothermal compressibility of toluene,[9] respectively. A plot of the logarithmic values of k

TABLE 1. RATE CONSTANTS ($10^4\,k$/mol^{-1} dm^3 s^{-1}) AND ACTIVATION VOLUMES (ΔV^*/cm^3 mol^{-1}) FOR THE 1,3-DIPOLAR CYCLOADDITION OF Ph_2CN_2 IN TOLUENE AT 25 °C

Dipolarophile[a]	P/kg cm^{-2} 1	500	1000	1500	ΔV^*

a) X=$COOCH_3$.

in Table 1 against pressure gives a straight line in each system. Applying Eq. 2 to such a linear relation, we can obtain the activation volume. The ΔV^* values thus obtained are listed in the last column of Table 1.

The values of ΔV^* in Table 1 are in the range of −20 to −24 cm^3 mol^{-1}, which are comparable with a value of −20 cm^3 mol^{-1} for another kind of 1,3-dipolar cycloaddition between a nitrile oxide and HCN in diisopropyl ether at 40 °C[10] but considerably larger than a value of −32 cm^3 mol^{-1} for the same kind of 1,3-dipolar cycloaddition between Ph_2CN_2 and a bicyclic olefin in toluene at 24.5 °C.[11] The small difference in ΔV^* between DMM and DMF might be ascribed to the steric hindrance by the bulky groups of $COOCH_3$, as already noticed in reactions of other kinds.[12,13] A similar trend is found previously for the activation entropy (ΔS^*).[7] The meaning of the obtained activation volumes will be discussed later in relation to the reaction mechanism.

The reaction volume (ΔV) has to be measured in some manner in order to establish the volume profile. However, since the 1,3-dipolar cycloaddition reactions of the dipolarophiles other than DMM are accompanied by a rapid consecutive reaction,[7] only the Ph_2CN_2–DMM system can be studied here. There is another problem: the cycloadduct (4,5-bis(methoxycarbonyl)-3,3-diphenyl-4,5-dihydro-3H-pyrazole) between Ph_2CN_2 and DMM has so low a solubility in toluene that we cannot determine its partial molal volume by the usual density measurement. Very fortunately, however, it turned out that when we employed the dilatometric method the solution could be highly supersaturated with respect to the product. If we assume that the volume change accompanying the 1,3-dipolar cycloaddition is independent of the concentration in the dilute solution, the following equation holds under the condition of $[Ph_2CN_2]=[DMM]$:

$$\frac{1}{A-x}-\frac{1}{A}=kt, \tag{3}$$

$$x=(m_t/m_\infty)A, \tag{4}$$

where A is the initial concentration of Ph_2CN_2, m_t, and m_∞ ($=\Delta V$) are the volume changes at t and $t=\infty$, respectively, and x is the amount of the consumed Ph_2CN_2. From Eqs. 3 and 4, we get

$$m_t=\frac{m_\infty}{1+1/kAt}. \tag{5}$$

Figure 1 shows the plot of m_t against $1/(1+1/kAt)$, and the linearity before the precipitation point indicates adequacy of the assumption utilized for deriving

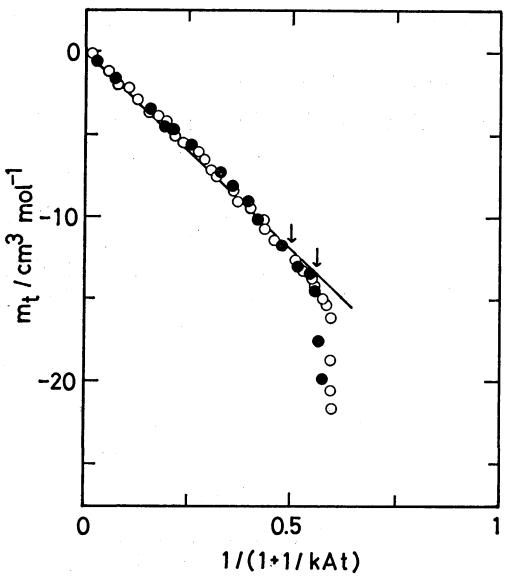

Fig. 1. Plot of Eq. 5.
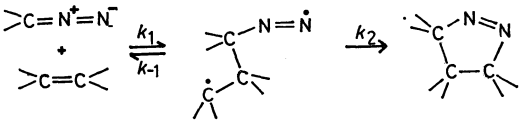
●: A=0.168 mol dm^{-3}, ○: A=0.191 mol dm^{-3}. The arrows indicate the precipitation point at about 6 h; the left-hand one for A=0.168 mol dm^{-3}.

Eqs. 3 and 4. Applying the least-squares method to the linear portion of the plot, we obtained -24.5 ± 0.5 cm^3 mol^{-1} as ΔV for the 1,3-dipolar cycloaddition between Ph_2CN_2 and DMM. Probably, we can take this value as a representative one because ΔV^* does not differ so much from one dipolarophile to another as seen in Table 1.

Discussion

Biradical vs. *Concerted Mechanisms.* It is important to transform Firestone's idea on the reaction mechanism into a kinetic expression, before it is tested by the present volumetric investigation. His reaction scheme is given by



(6)

From the above scheme and the qualitative energy profile illustrated by him,[4] we get the following expression for the observed rate constant (k):

$$k = \frac{k_1 k_2}{k_{-1} + k_2} \tag{7}$$

$$= Kk_2, \tag{8}$$

where

$$K = k_1/k_{-1}, \tag{9}$$

$$k_1 \ll k_2 \ll k_{-1}. \tag{10}$$

From Eqs. 2 and 8, we have

$$\Delta V^* = \Delta V(K) + \Delta V^*(k_2), \tag{11}$$

where $\Delta V(K)$ and $\Delta V^*(k_2)$ are the reaction and the activation volumes correspoding to K and k_2, respectively. The cyclization step (k_2) of an extended biradical intermediate[14] would be diffusion controlled, the rate constant of which is inversely proportional to the bulk shear viscosity (η) of the solvent in the simplest approximation.[15] This approximation leads to

$$\Delta V^*(k_2) = RT(\partial \ln \eta/\partial P)_T, \tag{12}$$

which is 14.5 cm^3 mol^{-1} for toluene-d_8 at 25 °C; *cf.* 10.3 and 7.3 cm^3 mol^{-1} as activation volumes for the molecular and internal rotations, respectively.[16] By using $\Delta V^* = -23.4$ cm^3 mol^{-1} and $\Delta V^*(k_2) = 14.5$ cm^3 mol^{-1} in Eq. 11, we obtain -37.9 cm^3 mol^{-1} as a value of $\Delta V(K)$ for the Ph_2CN_2–DMM system, which is "smaller" than the reaction volume. This contradicts the stepwise bond formation in Firestone's mechanism; it is impossible that the bond formation due to the biradical cyclization is accompanied by as large a "positive" volume change as 13.4 cm^3 mol^{-1} ($=\Delta V - \Delta V(K)$). The value of -37.9 cm^3 mol^{-1} is also too small for the single-bond formation because no dramatic solvation can be expected for such a nonpolar intermediate; in fact, there is little solvent effect on this reaction.[7] Thus, Firestone's two-step mechanism is not supported by the present volumetric investigation.

The difference in the partial molal volume between the transition state and the cycloadduct is only 1.1 cm^3 mol^{-1} in the Ph_2CN_2–DMM system; $\Delta V^*/\Delta V = 0.955$. This indicates that the transition state resembles the product in regard to the geometry and suggests that the two bonds between the 1,3-dipole and dipolarophile develop to a large extent in the transition state. Such a resemblance is exhibited also by the usual 1,4-cycloaddition[17] which is considered to proceed *via* the concerted mechanism; *e.g.*, in the reaction between cyclopentadiene and DMF in 1-chlorobutane at 30 °C, $\Delta V^* = -32.7$ cm^3 mol^{-1} and $\Delta V = -36.7$ cm^3 mol^{-1} with $\Delta V^*/\Delta V = 0.891$.[18] The volumetric analogy between the two typical cycloadditions and the above-mentioned failure of Firestone's mechanism lead us to accept the concerted mechanism for the 1,3-dipolar cycloaddition.

Volume Profile. Figure 2 illustrates the volume profile of the 1,3-dipolar cycloaddition reaction between Ph_2CN_2 and DMM. The main features of the profile would not vary with the dipolarophile because of the similar values of ΔV^* in Table 1. It is interesting to compare the volume profile established experimentally for the 1,3-dipolar cycloaddition in solution with the theoretical one for the 1,3-dipolar cycloaddition between HCNO and HCCH in the gas phase.[5] When the van der Waals radii[19] of the relevant atoms are combined with the geometry determined by the *ab initio* method (double ζ basis set SCF), van der Waals volumes (V_W) of HCNO, HCCH, the transition state, and the product (isoxazole) are computed as 24.1, 23.1, 43.2, and 39.0 cm^3 mol^{-1}, respectively.[20] From these values we get changes in V_W accompanying the activation and reaction; $\Delta V_W^* = -4.0$ cm^3 mol^{-1} and $\Delta V_W = -8.2$ cm^3 mol^{-1} with $\Delta V_W^*/\Delta V_W = 0.49$. The theoretically predicted volumes for the transition state and the product are smaller than the volume of the reactants as a whole, but it seems that the predicted transition state is expanded relative to the product more than the one observed. If we bear it in mind that the packing fraction $\phi = V_W/V$ for most neutral

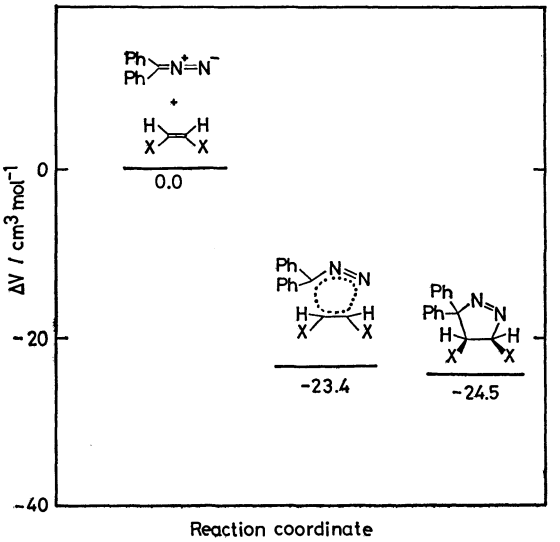


Fig. 2. The volume profile of the 1,3-dipolar cycloaddition between Ph_2CN_2 and DMM in toluene at 25 °C at 1 bar.
X=$COOCH_3$.

molecules are in the range of 0.5 to 0.6, a quantitative agreement between theory and experiment can be obtained; for example, one may take 0.5 and 0.6, respectively, for the reactants and the transition state to get $\Delta V^* = -22.4$ cm^3 mol^{-1}.[22] It is important to clarify how the activation and reaction volumes in the condensed phase are related to the theoretically calculated van der Waals volumes from the point of view of liquid theory in a further study.

Conclusion

The activation volumes for the 1,3-dipolar cycloaddition reactions of Ph_2CN_2 with olefins in toluene at 25 °C at 1 bar are in the range of -20 to -24 cm^3 mol^{-1}, and they are about 10 cm^3 mol^{-1} less negative than those for the usual 1,4-cycloaddition reactions. The partial molal volume of the transition state is close to that of the cycloadduct rather than to the sum of the partial molal volumes of the reactants. These observations are in favor of the concerted mechanism proposed by Huisgen without the volumetric information as obtained here. On the other hand, the product-oriented idea on the mechanism by Firestone that the 1,3-dipolar cycloaddition reaction proceeds *via* an extended-biradical intermediate does not succeed in explaining the pressure dependence of the rate constant. Although the *ab initio* molecular orbital calculation for the chemical reaction has so far been compared with the kinetic experiment with respect to energy, its comparison with respect to volume would serve as a tool for interpreting the experimentally obtained volumes of activation and reaction at the molecular level.

19) A. I. Kitaigorodsky, "Molecular Crystals and Molecules," Academic Press, New York (1973), Chap. 1; van der Waals radii for C, N, O, and H atoms are 180, 158, 153, and 117 pm, respectively.

20) Since overlapping of the van der Waals spheres of the atoms makes the calculation rather complicated, the spheres are divided into a large number of specimens with a dimension of about 5 pm in order to compute V_W by the numerical integration with an error of 0.1%. The molar volume (V) of isoxazole is 64.06 cm^3 mol^{-1} from its density,[21] and the ratio of V_W/V is 0.609 which is comparable with the corresponding quantities for many other nonpolar molecules.[19]

21) "Handbook of Chemistry and Physics," ed by R. C. Weast, CRC Press, Cleveland (1974), p. C-351.

22) It would be reasonable to take a larger packing fraction for the larger molecule in view of an analytical solution[23] of the Percus-Yevick equation for hard-sphere liquids,

$$\left(\frac{\partial \phi}{\partial V_W}\right)_{P,T} = \frac{P}{Nk_BT}\,\frac{(1-\phi)^3}{1+5\phi+9\phi^2-3\phi^3} > 0,$$

where P, N, k_B, and T are the pressure, the molecular number, the Boltzmann constant, and the temperature, respectively. Actually, such a trend is found when we calculate the ϕ values for normal alkane liquids using their molar volumes[24] and V_W obtained by the method employed here.

Pressure and Temperature Effects on Octahedral-Tetrahedral Equilibria in Pyridine Solutions of Some Cobalt(II) Halides

Kazuo KOJIMA,* Minoru SAIDA, Masami DONOUE, and Jiro MATSUDA

Department of Chemistry, Faculty of Science and Engineering, Ritsumeikan University, Kita-ku, Kyoto 603

(Received August 23, 1982)

The visible absorption spectra of CoX_2 (X=Cl, Br) in pyridine solutions have been measured in the ranges 1 bar—3 kbar at room temperature, and ≈4—≈70 °C at 1 atm. The equilibrium, $[CoX_2(py)_2]$(tetrahedral)+ $2py \rightleftharpoons [CoX_2(py)_4]$(octahedral), is found to be followed over these pressure and temperature ranges. High pressure favors the octahedral species, with the volume changes, −41 cm³/mol for the chloride and ≈−30 cm³/mol for the bromide at 1 atm. The pressure dependence of the volume change is less for the bromide than for the chloride. High temperature, however, favors the tetrahedral species, with the heats of reaction, 57.3 and 60.7 kJ/mol for the chloride and the bromide, respectively. Some discussions on both the effects are also presented.

Although the effects of pressure on the ionic equilibria between tetrahedral and octahedral species of cobalt(II) in solutions have been studied quantitatively using spectrophotometric method,[1-4] there exist large discrepancies between their ΔV values, the volume changes accompanying the shift of the equilibria to the octahedral species side with increasing pressure. For example, for $CoCl_2$ in an ethanol solution, Kitamura[1] obtained ΔV to be −154 cm³/mol but Roariguez and Offen[2] −45 cm³/mol under atmospheric pressure at 25 °C, and for $CoBr_2$ in an acetone solution, Ishihara *et al.*[3] estimated ΔV to be −36 cm³/mol but later Ishihara[4] obtained −109 cm³/mol as a more accurate value. These discrepancies appear to arise from the following reason: More than two kinds of complexes exist in each solution, so that the separation of the spectra seems to be difficult.

In some pyridine solutions, the very simple equilibrium is known to exist only as follows:[5-7]

$$\underset{\text{(tetrahedral)}}{[CoX_2(py)_2]} + 2py \rightleftharpoons \underset{\text{(octahedral)}}{[CoX_2(py)_4]}, \quad (1)$$

where X=Cl, Br, or I. On the basis of the method of continuous variations, Katzin and Gebert[5] have shown that the main coordinated species is $[CoCl_2(py)_4]$, but some $[CoCl_2(py)_2]$ is also present in the pyridine solutions of $CoCl_2$. Katzin[6] measured the temperature variation of the absorbance of these solutions in the range 32—66 °C; the validity of Eq. 1 has been confirmed over this temperature range. By means of optical spectroscopy and electrical conductivity, King *et al.*[7] have established that the only equilibrium of Eq. 1 occurs in the solutions of compounds of the type $[CoX_2(py)_2]$ where X is Cl, Br, or I.

As a part of the study on the pressure and temperature effects on tetrahedral-octahedral configuration equilibria and on the structures of some complexes in solutions of cobalt(II) halides, the authors describe the pressure and temperature variations of the absorption spectra of $CoCl_2$ and $CoBr_2$ in pyridine solutions. The spectrophotometric method should be useful for these investigations because the visible spectra of both the species are separate and well-defined.

Experimental

The commercial chemical pure reagent (C. P. grade) $CoCl_2$ was dried under reduced pressure at about 105 °C for 12 h. $CoBr_2 \cdot 6H_2O$ (C. P. grade) was also dried to constant weight. After dried with anhydrous $CaSO_4$, the commercial guaranteed reagent grade pyridine was distilled.

A clamp-type optical cell[8] was used to measure the absorption spectra under high pressures. Silicone O-rings and aluminum gaskets were fitted at the connection parts of the cell to prevent corrosion by the pyridine solutions as well as pressure leaks. The spectra were determined on a Hitachi 340 spectrophotometer at room temperature.

For the measurements with temperature change, however, a Shimadzu model MPS-50L spectrophotometer was used. The maintenance of a constant temperature for an optical cell was effected by circulating water from a thermostat by means of a pump. The temperature was measured with a calibrated chromel-alumel thermocouple inserted in the sample solutions, being kept constant within 1.0 °C. A silicone-rubber lid was fitted to the sample cell to keep constant concentration of the solutions.

Results and Discussion

Pressure Effect. Figure 1 shows the absorption spectra of $CoCl_2$ in pyridine at high pressures. The spectrum at one atmosphere has three peaks at 500, 524, and 608 nm and three shoulders at about 571, 637, and 664 nm in agreement with the results of Katzin.[6] It can be seen that the two higher-energy peaks belong to a strong absorption band (O), the 608-nm peak and the shoulders do to another weak band (T); the O-band is assigned to the $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$ transition of Co^{II} in the octahedral species $[CoCl_2(py)_4]$, and the T-band to the $^4A_2(F) \rightarrow {}^4T_1(P)$ transition of that in the tetrahedral one $[CoCl_2(py)_2]$.[3,5-7]

Although an isosbestic point appears at about 539 nm but is not well-defined, the equilibrium of Eq. 1 is found to be followed over this pressure range. The equilibrium shifts to the $[CoCl_2(py)_4]$ species side with increasing pressure, because the intensity of the O-band increases and that of the T-band decreases with increasing pressure. The O-band position scarcely changes but the 608-nm peak and the 637-nm shoulder shift slightly towards higher frequencies with pressure, which is probably due to a larger degree of distortion or compression in the species $[CoCl_2(py)_2]$ than in the other species $[CoCl_2(py)_4]$.

Figure 2 shows the absorption spectra of $CoBr_2$ in pyridine at high pressures. The spectrum at one atmosphere shows two peaks at 522 and 539 nm, and a shoulder at about 492 nm, which belong to an O'-

band. A peak at 643 nm, and shoulders at about 593, 629, and 711 nm are part of a T′-band. An isosbestic point is observed at about 564 nm. Since the spectra, as a whole, show similar pressure dependence to those of the chloride (Figs. 1 and 2), the equilibrium of Eq. 1 occurs also in the case of the bromide and shifts to the $[CoBr_2(py)_4]$ species side with increasing pressure. The 522-nm peak and the 492-nm shoulder increase in intensity more rapidly than the 539-nm peak, and consequently the O′-band changes its shape and shifts slightly to higher frequencies with increasing pressure, which the O-band scarcely shows (Fig. 1). $[CoBr_2(py)_4]$ may therefore be more distorted or compressed than $[CoCl_2(py)_4]$ probably for steric reasons.

Although for the compounds of the type $[CoX_2(py)_2]$, both the bonds of Co–X and Co–py were observed to be stronger in the chloride than in the bromide by spectroscopic[9–11] and calorimetric[12] methods, it is difficult to observe these differences in Figs. 1 and 2.

Now, we will estimate the volume change accompanying the shift of the equilibrium of Eq. 1 to the octahedral species side. In general, for an equilibrium existing in a diluted solution, the volume change (ΔV) is given by[13]

$$\Delta V = -RT\left(\frac{\partial \ln K}{\partial P}\right)_T + \Delta\nu\cdot\kappa\cdot RT, \qquad (2)$$

where K is the equilibrium constant expressed in terms of the molar concentration of each species, R is the gas constant, $\Delta\nu$ is the change in the number of the species due to the reaction, and κ is the isothermal compressibility of solvent.

Assuming that activity coefficient of each species equals to unity, the equilibrium constant for Eq. 1 is given by

$$K = \frac{c_{[CoX_2(py)_4]}}{c_{[CoX_2(py)_2]}\times c_{py}^2}. \qquad (3)$$

From Eqs. 2 and 3, we can obtain the volume change accompanying the shift of equilibrium of Eq. 1 to the octahedral species side, ΔV, as follows:

$$\Delta V = -RT\frac{d}{dP}\ln\left(\frac{c_{[CoX_2(py)_4]}}{c_{[CoX_2(py)_2]}}\right). \qquad (4)$$

Although we can not estimate the value, $\ln(c_{[CoX_2(py)_4]}/c_{[CoX_2(py)_2]})$, at a given pressure, we can obtain the pressure dependence of this value using the integrated intensities of the octahedral and the tetrahedral band, assuming that the absorbance observed under high pressures follows the Beer-Lambert law (it did at atmospheric pressure), and that the molar absorption coefficient (ε) and the optical path length do not change in this pressure range.

Figure 3 shows the plots of the logarithm of the ratio of both the integrated intensities for the chloride and the absorbances of the peaks for the bromide *vs.*

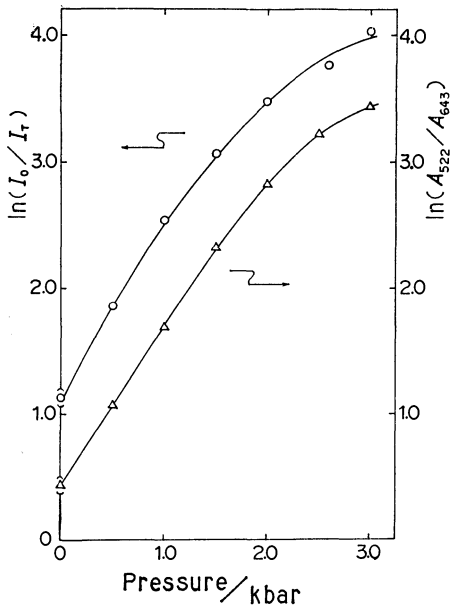

Fig. 3. Logarithm of the integrated-intensity ratio of the O-band to the T-band (I_O/I_T) for $CoCl_2$ and the ratio of the absorbance at 522 nm to that at 643 nm (A_{522}/A_{643}) for $CoBr_2$ *vs.* pressure.
○,△: Experimental, ——: calculated fitting curves.

Table 1. ΔV for $CoCl_2$ and $CoBr_2$ in pyridine solution

P / kbar	$-\Delta V$ / cm³ mol⁻¹	
	$CoCl_2$	$CoBr_2$
0.001	41	29
0.5	35	31
1.0	29	31
1.5	24	28
2.0	18	23
2.5	13	16
3.0	7	6

pressure. For the bromide, instead of the integrated intensities, the absorbances of the peaks at 522- and 643-nm are used, because of the rather changes of the O′-band shape with pressure as described above. These plots are fitted to the following equations by the least-squares method:

$$\ln\frac{I_O}{I_T} = 1.10 + 1.64P - 0.227P^2, \text{ for the chloride,}$$

$$\ln\frac{A_{522}}{A_{643}} = 0.446 + 1.17P + 0.143P^2 - 0.0665P^3, \text{ for the bromide.} \quad (5)$$

From Eqs. 4 and 5, the ΔV values are estimated and listed in Table 1. For the bromide, the absolute values of ΔV evaluated using the integrated intensities of the O′- and the T′-band are ≈5% larger than those in Table 1.

We can regard the ΔV value as the difference in the intrinsic volume between $[CoX_2(py)_4]$ and $[CoX_2(py)_2]$ solvated with two pyridine molecules. These intrinsic volumes, however, cannot be estimated at this

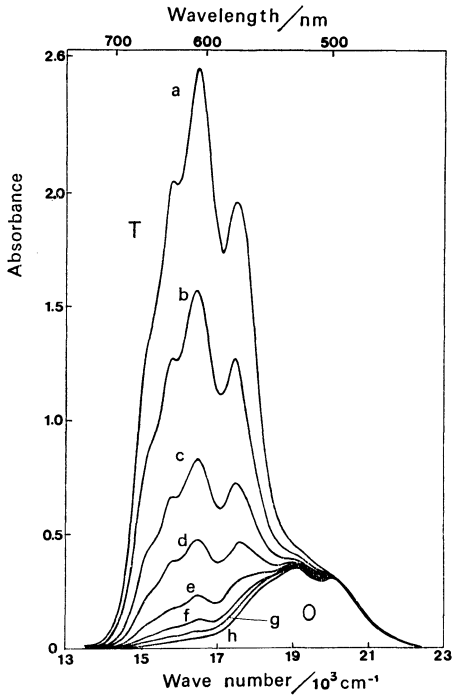

Fig. 4. Absorption spectra of $CoCl_2$ in pyridine at various temperatures (1 atm), uncorrected for thermal expansion of solution.
Concn: 2.043×10^{-2} mol dm^{-3} (25 °C), optical path length: 0.98 cm. a: 67.6 °C, b: 57.7 °C, c: 47.2 °C, d: 38.4 °C, e: 27.4 °C, f: 19.1 °C, g: 11.4 °C, h: 4.0 °C.

stage without the knowledge of the details of the structure of both complexes. The absolute value of ΔV at atmospheric pressure is smaller for the bromide (≈30 cm³/mol) than for the chloride (41 cm³/mol). This may be explained as follows; since the ionic radius of Br^- is larger than that of Cl^-, the volume difference between $[CoX_2(py)_4]$ and $[CoX_2(py)_2]$ is probably smaller for the bromide than for the chloride. Comparison with the chloride, the ΔV for the bromide changes almost linearly with pressure up to ≈1.5 kbar (Fig. 3 and Table 1).

Temperature Effect. Figure 4 shows the absorption spectra of $CoCl_2$ in pyridine at various temperatures. The intensity of the T-band increases steeply with increasing temperature; in particular, the 571- and 637-nm shoulders become well-resolved peaks. The O-band spectra, however, is insensitive against temperature change and covered by the T-band at high temperatures. This may be caused by the fact that $\varepsilon_{[CoCl_2(py)_2]}$ is much greater than $\varepsilon_{[CoCl_2(py)_4]}$.[14]

For $CoBr_2$, the corresponding spectra are shown in Fig. 5. The changes of these spectra quite resemble those of the chloride, except that in this case the 593-nm shoulder becomes a well-resolved peak.

Although no isosbestic point is found in each figure, for both the systems the equilibrium of Eq. 1 presumably occurs and shifts to the tetrahedral-species side with increasing temperature. The equilibrium constant K' is given by

$$K' = \frac{c_{[CoX_2(py)_2]}\times c_{py}^2}{c_{[CoX_2(py)_4]}}. \quad (6)$$

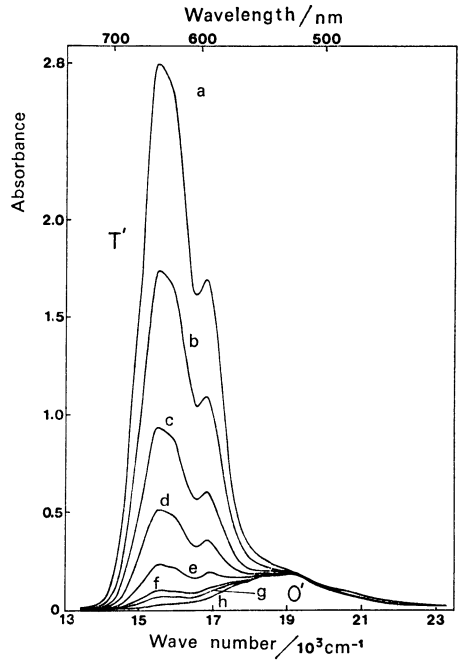

Fig. 5. Absorption spectra of $CoBr_2$ in pyridine at various temperatures (1 atm), uncorrected for thermal expansion of solution.
Concn: 1.022×10^{-2} mol dm^{-3} (25 °C), optical path length: 0.98 cm. a: 71.1 °C, b: 60.3 °C, c: 49.7 °C, d: 39.4 °C, e: 30.2 °C, f: 21.1 °C, g: 10.7 °C, h: 4.8 °C.

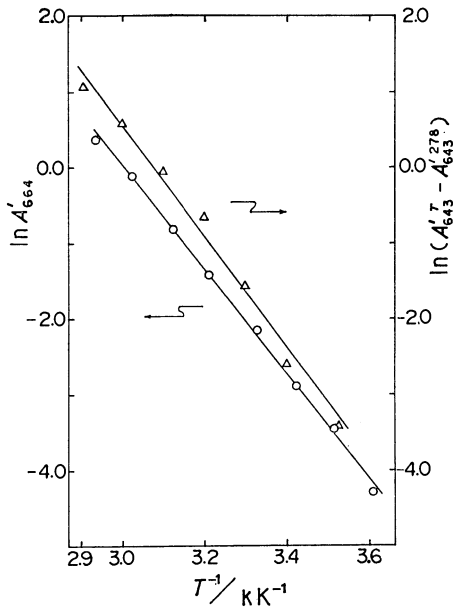

Fig. 6. Logarithm of the corrected absorbance for $CoCl_2$ (○) and for $CoBr_2$ (△) *vs.* reciprocal of absolute temperature.
A'^{278}_{643}, for example, denotes the absorbance at 643 nm and at 278 K corrected by approximate thermal expansion coefficient of pyridine. Solid lines are least-square fits to the data.

Because the concentrations of pyridine and $[CoX_2(py)_4]$ scarcely change, they can be assumed to be constant.[14] Therefore the change of K' can be followed by the intensity changes of the T'-band.

In Fig. 6, the logarithm of the corrected absorbance (A') of the 664-nm shoulder for the chloride and the 643-nm peak for the bromide is plotted against the reciprocal of absolute temperature. In order to correct the concentration, we used the approximate thermal expansion coefficient of pyridine (0.001[16]) over the temperature ranges. In order to express the intensity of the T-band, A' of the 664-nm shoulder is chosen, because there is little contribution of the intensity of the O-band at this wavelength. For the T'-band of the bromide, however, A' of the 643-nm peak subtracted out A'^{278}_{643} due to the O'-band is used. Linearities of the plots are obtained for both the halides. From each slope, the heat of reaction ΔH is estimated to be 57.3 for the chloride and 60.7 kJ/mol for the bromide. Since the similar ΔH values are obtained using the other peaks and shoulders for both cases, the equilibrium of Eq. 1 certainly occurs in each temperature range, and shifts to the $[CoX_2(py)_2]$ species side as temperature increases.

The ΔH value for the chloride is compatible with 56.1 kJ/mol obtained by Katzin.[6] Using the K' of 0.16 at 20 °C[15] and the ΔH of 57.3 kJ/mol, we can estimate ΔG to be $\approx$4.6 kJ/mol and $\Delta S\approx$0.18 kJ/(K mol), these values being comparable with the previous results.[6,7]

ΔH is a measure of the Co–py bond strength in $[CoX_2(py)_4]$. Clark and Williams[9] studied the far-infrared spectra of $[CoX_2(py)_4]$ complexes (X=Cl, Br, or I) by means of mull and assigned the strong band at about 215 cm^{-1} to the asymmetric Co–py vibration, because of the little dependence of its frequency on the type of halogen ion. King *et al.*[7] obtained ΔH for $[CoX_2(py)_4]$ (X=Cl, Br, or I) in chloroform solutions by calorimetric measurements. They were in the order of increase $Cl^-<Br^-<I^-$ and 63.6, 65.3, 69.5 kJ/mol, respectively. Though we lack ΔH for the iodide,** the order in halogen ion shown by King *et al.* is consistent with our result. The result seems to support their following explanation of this halogen ion order: Because I^- is most polarisable, charge is readily transferred to the metal along the σ-bond. This induces two opposite effects; one is to lower the effective electron affinity of Co^{II} towards pyridines, the Co–py bond strength being in the sequence $Cl^->Br^->I^-$, and the other is to enhance the release of non-bonding d-electrons of Co^{II} to antibonding pyridine π-orbitals (dative π-bonding); when the latter is superior to the former, the Co–py bond strengthens in the order $Cl^-<Br^-<I^-$.

The authors would like to thank Professor Keizo Suzuki and Professor Yoshihiro Taniguchi for their cooperation in making the clamp-type optical cell and for their valuable comments.

Phase Equilibria in the La_2O_3–V_2O_3–V_2O_5 System at 1200 °C

Kenzo KITAYAMA,* Daizo ZOSHIMA,† and Takashi KATSURA

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received February 5, 1982)

The phase equilibria in the La_2O_3–V_2O_3–V_2O_5 system were established at 1200 °C by changing oxygen partial pressures from −0.68 (air) to −13.00 in terms of $\log P_{O_2}$. In this system, $0.81La_2O_3 \cdot 0.19V_2O_5(La_{1.62}V_{0.38}O_{3.38})$, $3La_2O_3 \cdot V_2O_5(La_3VO_7)$, $0.71La_2O_3 \cdot 0.29V_2O_5(La_{1.42}V_{0.58}O_{3.58})$, $LaVO_4$, $LaVO_3$, V_nO_{2n-1} (n=2—7), and VO_2 were stable. $LaVO_3$, $LaVO_4$, $La_{1.62}V_{0.38}O_{3.38}$, La_3VO_7, and $La_{1.42}V_{0.58}O_{3.58}$ have nonstoichiometric compositions. On the basis of the phase equilibria, the Gibbs energies of the reactions:

$$31/50\ La_2O_3 + 19/50\ LaVO_3 + 19/100\ O_2 = La_{1.62}V_{0.38}O_{3.38}$$
$$50/31\ La_{1.62}V_{0.38}O_{3.38} + 12/31\ LaVO_3 + 6/31\ O_2 = La_3VO_7$$
$$21/50\ La_3VO_7 + 4/25\ LaVO_3 + 2/25\ O_2 = La_{1.42}V_{0.58}O_{3.58}$$
$$LaVO_3 + 1/2\ O_2 = LaVO_4$$

were determined to be −64.0, −55.8, −21.6, and −131.5 kJ respectively.

The phase equilibria in the Ln_2O_3–V_2O_3–V_2O_5 system (Ln=Sm, Lu, Er, and Gd) at 1200 °C have been established previously.[1-4] In these systems, the existence of V_nO_{2n-1} (n=2—7), VO_2, $LnVO_3$, and $LnVO_4$ were confirmed. In addition to the above vanadium oxides and lanthanoid vanadium oxides, in the Sm_2O_3–V_2O_3–V_2O_5 system, $Sm_{10}V_2O_{20}$ ($5Sm_2O_3 \cdot V_2O_5$); in the Lu_2O_3–V_2O_3–V_2O_5 system, $Lu_7V_3O_{16}$, $Lu_2V_2O_7$, and LuV_4O_8; in the Er_2O_3–V_2O_3–V_2O_5 system, $Er_8V_2O_{17}$ ($4Er_2O_3 \cdot V_2O_5$), and in the Gd_2O_3–V_2O_3–V_2O_5 system, $Gd_{1.62}V_{0.38}O_{3.38}$ ($0.81Gd_2O_3 \cdot 0.19V_2O_5$) were stable as ternary compounds. These diagrams, therefore, have shown different patterns as a result of the different coexisting compounds.

In the present study, we chose La_2O_3 as Ln_2O_3 because lanthanum has the largest ionic radius in the lanthanoid series.

In the La_2O_3–V_2O_3 system, the existence of $LaVO_3$ is well known,[5-8] but the system has not yet been completely studied. The crystallographic properties of $LaVO_3$ has been investigated by many researchers.[5-8] They say that $LaVO_3$, as well as $CeVO_3$, has a tetragonal crystal system, unlike the other orthorhombic $LnVO_3$ substances, although there has been report[8,9] that $CeVO_3$ has a cubic system.

Brusset *et al.*[10] studied the La_2O_3–V_2O_5 system in the temperature range from 600° to 1500 °C; they found that $4La_2O_3 \cdot V_2O_5$ was stable between La_2O_3 and $LaVO_4$ in the temperature range. However, their quench products of the composition usually contained three phases: $4La_2O_3 \cdot V_2O_5 + LaVO_4 + La_2O_3$, because of a sluggish reaction. They did not present any crystallographic data for $4La_2O_3 \cdot V_2O_5$, except a simple powder diffraction pattern (Fig. 2 in Ref. 10).

Much information pertinent to the crystal structure of $LaVO_4$ can be found in the recent literature.[11-14] Almost all lanthanoid vanadium(V) oxides crystallize in the zircon structure with a crystal symmetry of $I4_1/amd$.[15] The only exception is that of the $LaVO_4$ which has been known to have a monoclinic monazite structure with a crystal symmetry of $P2_1/n$.[16]

The objectives of the present study are: (1) to make a detailed phase diagram of the La_2O_3–V_2O_3–V_2O_5 system at 1200 °C in order to ascertain the stable ternary compounds under the present experimental conditions, (2) to calculate the standard Gibbs energy of the reactions found in the phase diagram, and (3) to ascertain whether or not there exists a linear relationship between the standard Gibbs energies of reactions and the ionic radius of the lanthanoid, as found in the Ln–Fe–O system.[17]

Experimental

Analytical-grade quantities of La_2O_3 (99.9%) and V_2O_5, obtained by heating the guaranteed grade of NH_4VO_3 at 500 °C in air for about 24 h, have been employed as the starting materials. The desired ratios of La_2O_3/V_2O_5 were obtained by mixing the appropriate quantities thoroughly in an agate mortar under ethyl alcohol. The mixtures thus obtained were treated by the procedures described in a previous report.[1] The apparatus and procedures for controlling the oxygen partial pressures, P_{O_2} (atm), and keeping a constant temperature, the method of thermogravimetry, the criterion for the establishment of an equilibrium, the method of lattice-constant determination, the method of the actual oxygen-partial-pressure measurement, and the method of chemical analysis are the same as those discussed in previous reports.[1,18-22]

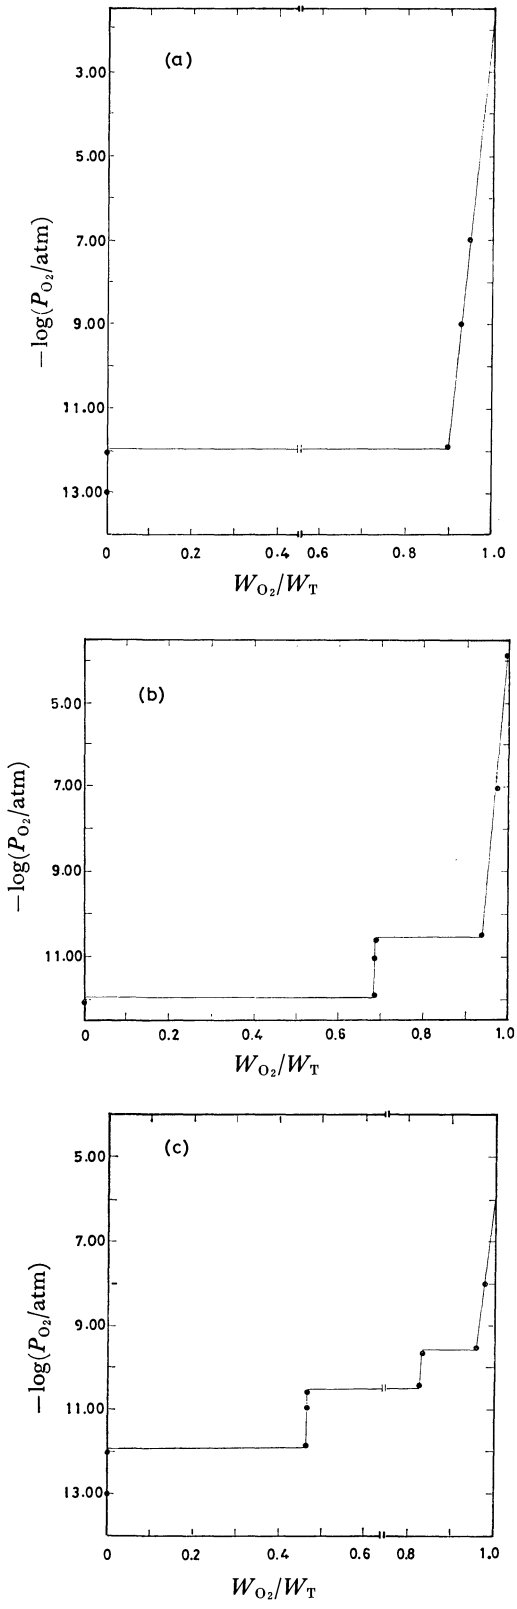
The oxygen partial pressure of $10^{-13.00}$ was chosen as the reference oxygen partial pressure; that is, the weight of a sample in the atmosphere of $10^{-13.00}$ oxygen partial pressure was chosen as the reference weight throughout the present study.

Results and Discussion

Phase Equilibria. Eleven samples with La_2O_3/V_2O_5 mole ratios of 17/3, 31/9, 3/1, 29/11, 7/3, 13/7, 3/2, 1, 9/11, 7/13, and 1/4 were prepared to be used in the thermogravimetric experiment. In Fig. 1, the relationships between the oxygen partial pressure and the composition, W_{O_2}/W_T, are shown, where W_{O_2} is the weight gain of the samples from the reference weight at $\log P_{O_2} = -13.00$, while W_T is the total weight gain that the sample would get if the V_2O_3 in the sample had changed to V_2O_5. Thermogravimetric results of the six samples, 17/3, 31/9, 29/11, 7/3, 13/7, and 1/4, are shown as representative in Fig. 1.

As is shown in Fig. 1a to Fig. 1e, abrupt weight

† Present address: Eisai Co., Ltd., 6-10 Koishikawa-4 Chome, Bunkyo-ku, Tokyo 112.



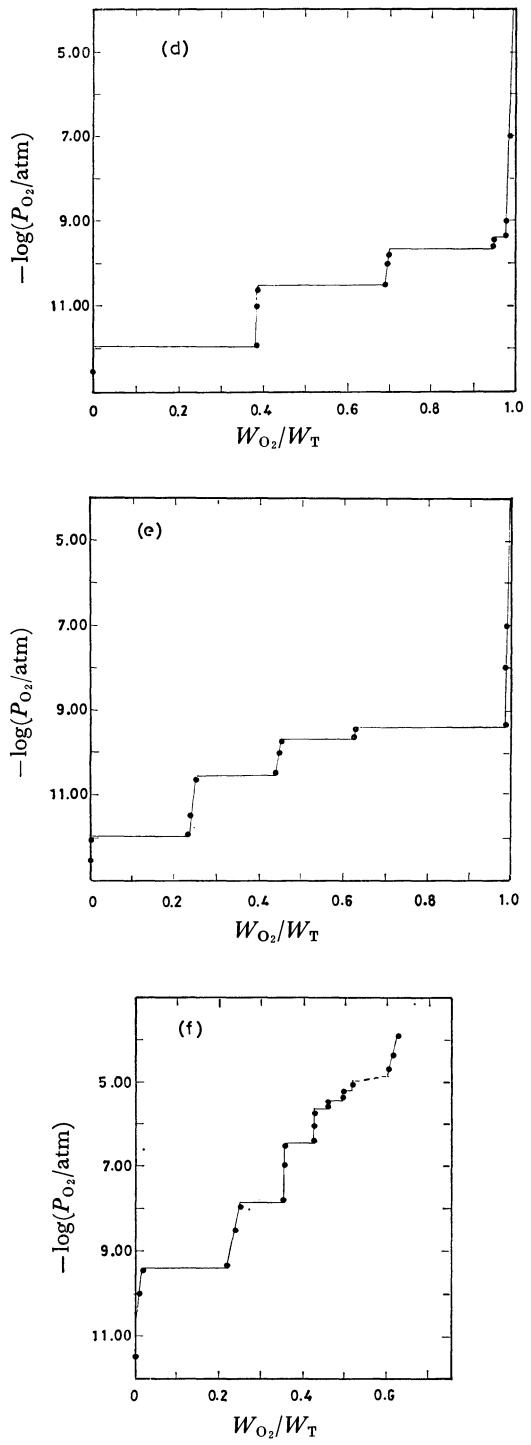


Fig. 1. The relationship between $-\log P_{O_2}$ and the weight gain (W_{O_2}/W_T) of the samples.
(a): $La_2O_3/V_2O_5=17/13$, (b): $La_2O_3/V_2O_5=31/9$, (c): La_2O_3 $V_2O_5=29/11$, (d): $La_2O_3/V_2O_5=7$ 3, (e): $La_2O_3/V_2O_5=13/7$, (f): $La_2O_3/V_2O_5=1/4$.

changes occured at 4 oxygen partial pressures, −11.95, −10.51, −9.68, and −9.35, in terms of $\log P_{O_2}$, in the samples in which the mole ratio is larger than unity. These values correspond to the equilibrium oxygen partial pressures of reactions that were found in the system and which are shown in Table 6. The last figure, $\log P_{O_2}=-9.35$, is lower than the value, -9.16 ± 0.05, previously presented by Nakamura *et al.*[6] for the same reaction at 1200 °C.

As is shown in Figs. 1d and 1e, the oxygen-partial-pressure range in which two phases, $LaVO_3$ and C, coexist is very narrow, about 0.3 in $\log P_{O_2}$, compared with the area of the other two phases. As is shown in Fig. 1f, samples with mole ratios lower than unity

Table 1. Identification of Phases

Starting materials (mol%)		$-\log(P_{O_2}/atm)$	Time h	Phases[a]

a) A: $0.81La_2O_3\cdot0.19V_2O_5(La_{1.62}V_{0.38}O_{3.38})$, B: $3La_2O_3\cdot V_2O_5(La_3VO_7)$, C: $0.71La_2O_3\cdot0.29V_2O_5(La_{1.42}V_{0.58}O_{3.58})$.

show the similar pattern to those in the other systems[1,3,4] except for the oxygen partial pressure, log $P_{O_2}=-9.35$.

Table 1 shows the results of the identification of phases; in the first column is the composition of the starting materials; in the second, the experimental conditions of the oxygen partial pressure in terms of log P_{O_2}; in the third, the experimental duration, and in the last, the phases that are found in the quenched samples by means of an X-ray diffractometer using Cu $K\alpha$ radiation. The letters in the Phase are the abbreviations of the compounds which are shown in the lower part of the table. The abbreviations are the same as those in Tables 3 and 4 and in Fig. 2.

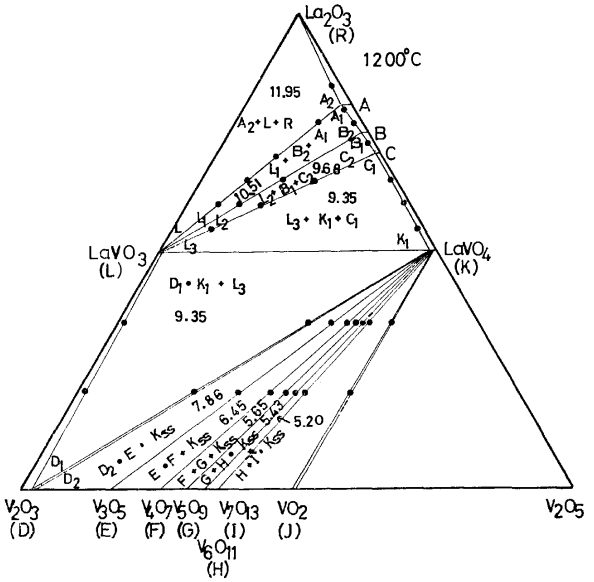

Fig. 2. Phase equilibria in the La_2O_3–V_2O_3–V_2O_5 system at 1200 °C.
Numerical values in the three solid phases regions are the oxygen partial pressures in $-\log P_{O_2}$ in equilibrium.
Abbreviations are the same as those in Tables 1, 2, and 3.

La_2O_3 is stable under the present experimental conditions, as has already been reported by Kimizuka and Katsura.[22]

Based upon the above experimental results, a phase diagram of the system at 1200 °C was drawn; it is shown in Fig. 2. The following phases are stable under the present experimental conditions, except for six compounds in the V_2O_3–V_2O_5 system, $LaVO_4$, and $LaVO_3$: La_2O_3(R), $La_{1.62}V_{0.38}O_{3.38}$(A), La_3VO_7 (B), and $La_{1.42}V_{0.58}O_{3.58}$(C). Compound A may correspond to the composition, $4La_2O_3\cdot V_2O_5$ that Brusset *et al.*[10] have reported, while Compound C may correspond to $7La_2O_3\cdot3V_2O_5$. Under the present experimental conditions, though these compounds have no round mole ratios such as are written above. The straight lines drawn by plotting the experimental points usually concentrate at the compositions presented above, even considering the experimental errors.

There are two possibilities to account for the deviations from the round mole ratios; one is the nonstoichiometry of the compounds toward the La_2O_3 side, and the other is systematic experimental errors in

Table 2. The relationships between the compositions and the oxygen partial pressures of solid solutions: $N_O/N_X=a\log P_{O_2}+b$

X	a	b
A	7.50×10^{-3}	0.0415
B	5.33×10^{-3}	0.0306
C	4.44×10^{-3}	0.0275
$LaVO_3$	0.0178	0.181
$LaVO_4$	6.64×10^{-3}	0.0325

TABLE 3. COMPOSITIONS, STABILITY RANGES IN OXYGEN PARTIAL PRESSURES, SYMBOLS, AND ACTIVITIES IN SOLID SOLUTIONS

Component	Composition	Symbol	$-\log(P_{O_2}/\text{atm})$	$\log a_i$
$La_{1.62}V_{0.38}O_{3.38}$	$La_{1.62}V_{0.38}O_{3.38}$	A	0.68[a]—5.53[b]	0.0772

$La_{1.42}V_{0.58}O_{3.58}$	$La_{1.42}V_{0.58}O_{3.58}$	C	0.68[a]—6.19[b]	0.0135
	$La_{1.42}V_{0.58}O_{3.57}$	C_1	9.35	2.43×10^{-3}
	$La_{1.42}V_{0.58}O_{3.57}$	C_2	9.68	0
$LaVO_4$	$LaVO_{4.00}$	K	0.68[a]—4.89[b]	0.033
	$LaVO_{3.97}$	K_1	9.35	0
$LaVO_3$	$LaVO_{3.00}$	L	13.50[c]—10.57[b]	0
	$LaVO_{3.00}$	L_1	10.51	0.0136
	$LaVO_{3.01}$	L_2	9.68	0.0131
	$LaVO_{3.01}$	L_3	9.35	0.0111

a) The stability limit value in $\log P_{O_2}$ may be higher than -0.68 (air). b) These values are obtained by extrapolation using the experimental data. c) The stability-limit value in $\log P_{O_2}$ may be lower than this value.

the thermogravimetry. However, the following facts seem to eliminate both possibilities. For example, if the composition of Compound C were 7/3 in the La_2O_3/V_2O_5 mole ratio, no such sudden weight change would occur at $\log P_{O_2}=-9.35$ as shown in Fig. 1d; rather, it would show the same pattern as that of Fig. 1c. Also, we found compounds with round mole ratios, such as $3La_2O_3\cdot V_2O_5$(B), $4Er_2O_3\cdot V_2O_5$,[4] and $4Ho_2O_3\cdot V_2O_5$, in the Ho_2O_3–V_2O_3–V_2O_5 system in spite of using the same experimental techniques. On the other hand, $0.81Gd_2O_3\cdot0.19V_2O_5$ was found in the Gd_2O_3–V_2O_3–V_2O_5 system,[4] as has been described above.

Two new compounds, B and C, were found in the La_2O_3–V_2O_5 system. Kiparisov *et al.*[23] reported the existence of $3Er_2O_3\cdot V_2O_5$ at 1300 °C. However, the X-ray powder diffraction pattern of $3Er_2O_3\cdot V_2O_5$ is not similar to that of Compound B. No compound with a Ln_2O_3/V_2O_5 mole ratio of 7/3 or near it has yet been found in the another system.

Ternary compounds, A, B, C, $LaVO_3$, and $LaVO_4$ have nonstoichiometric compositions. The nonstoichiometry of the $LnVO_3$-type compound seems to be very rare, because the other compounds, $SmVO_3$, $LuVO_3$, $ErVO_3$, and $GdVO_3$, are stoichiometric under the same experimental conditions. It is still not clear whether or not $LaVO_3$ is the only special compound with a nonstoichiometric composition at 1200 °C. Nakamura *et al.*[6] pointed out the stoichiometry of $LaVO_3$ at 1000 °C in the oxygen pressure range from $10^{-12.8}$ to $10^{-21.1}$ bar, but they did not write anything about the composition of $LaVO_3$ at 1200 °C.

There are many two- and three-phase areas in Fig. 2. For example, the area that has the equilibrium oxygen partial pressure, -11.95 in $\log P_{O_2}$, has three phases; R, L, and A_2, that is the most reduced end-member of the solid solution A, and the area that has the compositions surrounded by the three points A_2, A, and La_2O_3, have two phases, $A_{ss}+La_2O_3$, in the oxygen partial pressure range from -11.95 to -0.68 in $\log P_{O_2}$. Here, A_{ss} means the solid solution of Compound A; its composition changes from A_2

to A depending upon the oxygen partial pressure.

As is shown in Fig. 2, the pattern of the present phase diagrm is new and different from the patterns of the other systems[1-4] established previously, because of the difference in the coexisting ternary compounds. That is, there are three compounds, A, B, and C, between La_2O_3 and $LaVO_4$ in this system. However, systems which contain Sm_2O_3,[1] Er_2O_3,[3] and Gd_2O_3[4] have one compound, although the compositions of the compounds are different from one another. On the other hand, three compounds were found in the Lu_2O_3-V_2O_3-V_2O_5 system,[2] though they did not appear between Lu_2O_3 and $LuVO_4$. We have not yet been able to find any rule for the appearance of compounds in the series or reasons why all these systems show different patterns.

The relationship between the composition, N_O/N_X, and the oxygen partial pressure of the solid solution, X, were determined using the thermogravimetric results. Here, N_O/N_X is the mole fraction ratio of oxygen to the component X, indicating the deviation from the component composition. Using the method of the least squares with a linear equation, $N_O/N_X = a \log P_{O_2} + b$, the a and b values for each solid solution were determined to be as shown in Table 2.

In Table 3, the compositions of the compounds, the stability ranges of the compounds in terms of log P_{O_2}, the symbols of the compounds, and the activities of the components in the solid solutions are tabulated. The activity of the components in the solid solutions is calculated with Gibbs-Duhem equations using the N_O/N_X *vs.* log P_{O_2} relations presented above. A detailed method of the calculation has been discussed in the paper of Kimizuka and Katsura.[21]

The assignment of indices for new compounds did not succeed. The data of relative intensities and spacings obtained by means of an X-ray diffractometer with powder samples are shown in Table 4. Because of the sluggish reactions, the samples used in this measurement were made in air by about 146 h heating at 1200 °C with four intermediate grindings in an agate mortar.

The lattice constants of the compounds A, $LaVO_3$ and $LaVO_4$, are tabulated in Table 5. The lattice constants of Sample A were successfully determined with the aid of the assignment of the indices of $4Tm_2O_3 \cdot V_2O_5$.[24]

Differences in the unit-cell dimensions are found in the two $LaVO_3$ samples quenched under different conditions of the oxygen partial pressure. Our values of the samples, made in the atmosphere of −9.45 in log P_{O_2}, are in good agreement with all those of authors previously cited except for one.[7]

As for the cell dimensions of $LaVO_4$, no differences are found in the two quenched samples. Three previous data are shown in Table 5, together with ours.

Calculation of the Standard Gibbs Energies of Reactions. On the basis of the present phase diagram, the standard Gibbs energies of reactions appearing in the system can be calculated by means of this equation; $\Delta G^\circ = -RT \ln K$, where R is the gas constant; T, the absolute temperature, and K, the equilibrium constant of each reaction. The equations of reactions, the equilibrium oxygen partial pressures for each reaction, and the ΔG° values obtained are shown in Table 6. The activities of each component in the solid solutions which are necessary for the calculation are listed in Table 3. The ΔG° value, −128.9 kJ, presented by

Table 6. Gibbs free energies of reactions

	Reaction	$-\log(P_{O_2}/\text{atm})$	$-\Delta G^\circ$ / kJ
(1)	$31/50\ La_2O_3 + 19/50\ LaVO_3 + 19/100\ O_2 = La_{1.62}V_{0.38}O_{3.38}$	11.95	64.0
(2)	$50/31\ La_{1.62}V_{0.38}O_{3.38} + 12/31\ LaVO_3 + 6/31\ O_2 = La_3VO_7$	10.51	55.8
(3)	$21/50\ La_3VO_7 + 4/25\ LaVO_3 + 2/25\ O_2 = La_{1.42}V_{0.58}O_{3.58}$	9.68	21.6
(4)	$LaVO_3 + 1/2\ O_2 = LaVO_4$	9.35	131.5

Nakamura *et al.*[6] for reaction (4) is in fairly good agreement with ours, −131.5 kJ.

The $LnVO_3+1/2\ O_2=LnVO_4$ reaction is common in all the systems, and the ΔG° values for the reactions related to La, Sm,[1] Gd,[4] Er,[3] and Lu[2] were obtained as −131.5, −127.2, −127.7, −121.0, and −116.3 kJ respectively. Judging from the values obtained, the values seem to increase gradually as the atomic numbers increase from La to Lu, although the values for Sm and Gd are almost the same.

Phase Equilibria in the Nd_2O_3–V_2O_3–V_2O_5 System at 1200 °C

Kenzo KITAYAMA,* Chikaaki MIZOKUCHI,† and Takashi KATSURA

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received July 8, 1982)

Phase equilibria in the Nd_2O_3–V_2O_3–V_2O_5 system were established at 1200 °C by changing the oxygen partial pressures from −0.68 (air) to −12.50 in terms of log P_{O_2}. In this system, V_nO_{2n-1} (n=2—7), VO_2, Nd_2O_3, $NdVO_3$, $NdVO_4$, $0.81Nd_2O_3 \cdot 0.19V_2O_5$ ($Nd_{1.62}V_{0.38}O_{3.38}$, A), and $3Nd_2O_3 \cdot V_2O_5$ (Nd_3VO_7, B) were stable under the present experimental conditions. Compounds with Nd_2O_3/V_2O_5 mole ratios of 6/1 and 2/1 were not found under the present experimental conditions. Compounds A, Nd_3VO_7, $NdVO_3$, and $NdVO_4$ have nonstoichiometric compositions. The pattern of the phase diagram is different from those of other Ln_2O_3–V_2O_3–V_2O_5 systems that have previously been established by us. On the basis of the phase diagram, the Gibbs energies of the reactions:

(1) $31/50\ Nd_2O_3 + 19/50\ NdVO_3 + 19/100\ O_2 = Nd_{1.62}V_{0.38}O_{3.38}$

(2) $50/31\ Nd_{1.62}V_{0.38}O_{3.38} + 12/31\ NdVO_3 + 6/31\ O_2 = Nd_3VO_7$

(3) $NdVO_3 + 1/2\ O_2 = NdVO_4$

were determined to be −61.4, −47.4, and −128.9 kJ respectively. In the Nd_2O_3–V_2O_3 system, only $NdVO_3$ is stable under the present experimental conditions.

Phase equilibria in the Ln_2O_3–V_2O_3–V_2O_5 systems (Ln=Sm, Lu, Er, Gd, and La) at 1200 °C have been established.[1-5] In these systems, vanadium oxides V_nO_{2n-1} (n=2—7) and lanthanoid vanadium oxides, $LnVO_3$ and $LnVO_4$, were found to be stable in all systems. In addition to the above vanadium oxides and lanthanoid vanadium oxides, in Sm_2O_3–V_2O_3–V_2O_5 system, $Sm_{10}V_2O_{20}$ ($5Sm_2O_3 \cdot V_2O_5$); in the Lu_2O_3–V_2O_3–V_2O_5 system, $Lu_7V_3O_{16}$, $Lu_2V_2O_7$, and LuV_4O_8; in the Er_2O_3–V_2O_3–V_2O_5 system, $Er_8V_2O_{17}$ ($4Er_2O_3 \cdot V_2O_5$); in the Gd_2O_3–V_2O_3–V_2O_5 system, $Gd_{1.62}V_{0.38}O_{3.38}$ ($0.81Gd_2O_3 \cdot 0.19V_2O_5$), and in the La_2O_3–V_2O_3–V_2O_5 system, $La_{1.62}V_{0.38}O_{3.38}$($0.81La_2O_3 \cdot 0.19V_2O_5$), La_3VO_7 ($3La_2O_3 \cdot V_2O_5$), and $La_{1.42}V_{0.58}O_{3.58}$ ($0.71La_2O_3 \cdot 0.29V_2O_5$) have now been found to be stable under the same experimental conditions as the ternary compounds.

These phase diagrams, therefore, have shown different patterns as a result of the difference in coexisting compounds.

In the present study, Nd_2O_3 was chosen as the Ln_2O_3 because Nd_2O_3–$NdVO_4$ system has compounds with Nd_2O_3/V_2O_5 mole ratios of 6/1, 4/1, and 2/1; thus, we could expect a new type of phase diagram under the same experimental conditions.

Brusset *et al.*[6] studied the Nd_2O_3–V_2O_5 system in the temperature range from 600 to 1500 °C in air; they found two compounds, $4Nd_2O_3 \cdot V_2O_5$ and $6Nd_2O_3 \cdot V_2O_5$, besides $NdVO_4$, which is well known. Remizov *et al.*[7] also studied the same system from 645 to 1560 °C and found another two compounds, $2Nd_2O_3 \cdot V_2O_5$ and $Nd_2O_3 \cdot 2V_2O_5$. X-ray powder patterns in a simple form were shown for each compounds by both groups. The lattice constants for $NdVO_4$ have been determined by many researchers.[8-10]

In the Nd_2O_3–V_2O_3 system, only $NdVO_3$ was found; its crystallographic properties have been investigated by many researchers,[11-12] but the system has not been completely studied yet because of the instability of V_2O_3 in air.

The objectives of the present study are; (1) to make a detailed phase diagram of the Nd_2O_3–V_2O_3–V_2O_5 system at 1200 °C in order to establish the stable compounds under the present experimental conditions, (2) to calculate Gibbs energies of the reactions found in the established phase diagram, and (3) to ascertain whether or not there exists a linear relationship between the Gibbs energies of reactions and the ionic radius of the lanthanoid, as was found in the Ln–Fe–O system.[18]

Experimental

Analytical grades of Nd_2O_3 (99.9%) and V_2O_5, made by heating guaranteed-grade NH_4VO_3 at 500 °C in air for about 24 h, have been used as the starting materials. Desired Nd_2O_3/V_2O_5 ratios of the samples were obtained by mixing the appropriate quantities thoroughly in an agate mortar under ethyl alcohol. The mixtures thus obtained were treated by the procedures described in a previous report.[1] The apparatus and procedures for controlling the oxygen partial pressures and keeping a constant temperature, the method of thermogravimetry, the criterion for an equilibrium establishment, the method of actual oxygen-partial-pressure measurement, and the method of chemical analysis are the same as those reported in previous papers.[1,13-17]

The oxygen partial pressure of $10^{-12.50}$ was chosen as the reference oxygen partial pressure; that is, the weight of a sample in the atmosphere of $10^{-12.50}$ oxygen partial pressure was chosen as the reference weight throughout the present study.

Results and Discussion

Phase Equilibria. Nd_2O_3 is stable under the present experimental conditions.[18] Nine samples with Nd_2O_3/V_2O_5 mole ratios of 86/14, 80/20, 78/22, 70/30, 65/35, 60/40, 1, 25/75, and 10/90 were prepared to be used in the thermogravimetric experiment. The thermogravimetric results of the five samples with the mole ratios of 86/14, 80/20, 65/35, 1, and 10/90 are shown in Fig. 1 as representative. In Fig. 1 the ordinate is the oxygen partial pressure in log P_{O_2}, while the abscissa is the composition of the samples represented by W_{O_2}/W_T, where W_{O_2} is the weight gain of

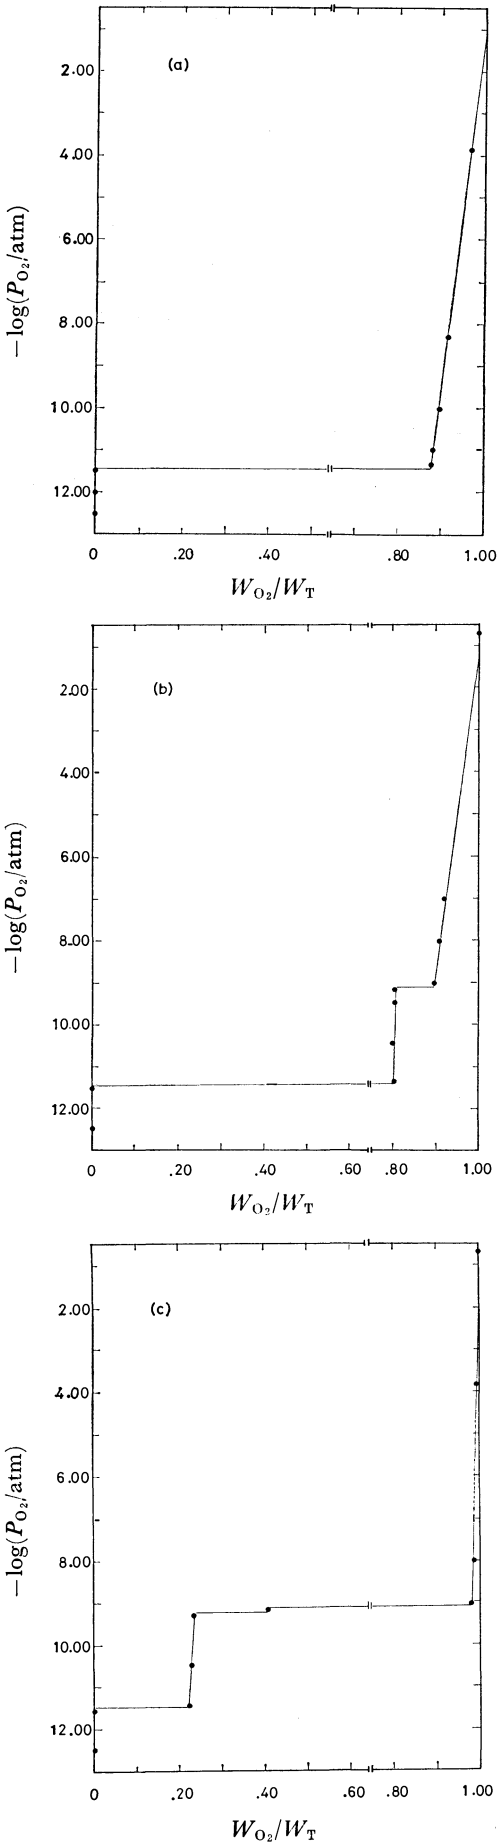

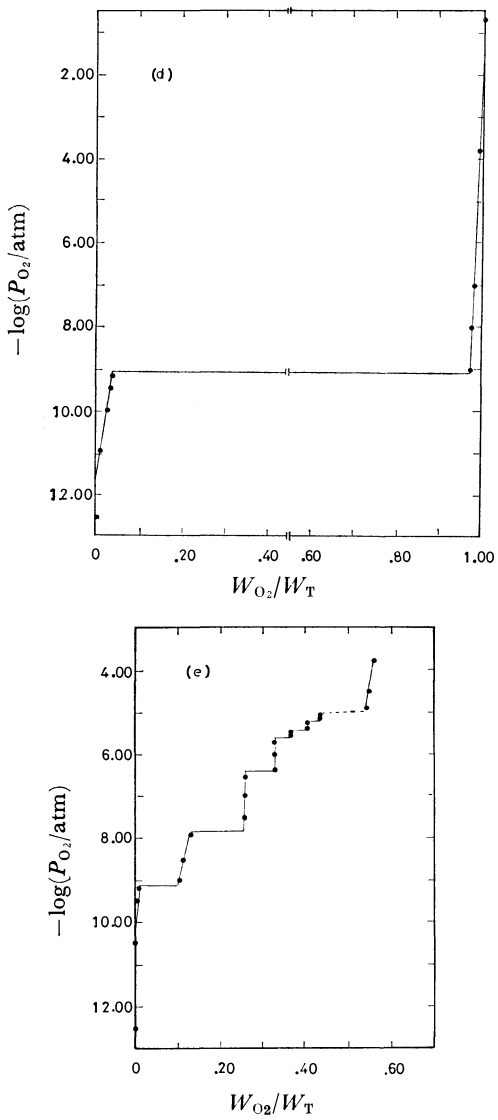

Fig. 1. The relationship between the oxygen partial pressure in $-\log P_{O_2}$ and the weight change of the samples in W_{O_2}/W_T, where W_{O_2} is the weight gain of the samples from the reference weight at $-\log P_{O_2}=12.50$ and W_T is the total weight gain that the samples would get if V_2O_3 in the samples had changed to V_2O_5.
(a): $Nd_2O_3/V_2O_5=86/14$, (b): $Nd_2O_3/V_2O_5=80/20$, (c): $Nd_2O_3/V_2O_5=65/35$, (d): $Nd_2O_3/V_2O_5=1$, (e): $Nd_2O_3/V_2O_5=10/90$.

the samples from the reference weight at $\log P_{O_2}=-12.50$, and where W_T is the total weight gain that the samples would get if V_2O_3 in the samples had been changed to V_2O_5.

As is shown in Figs. 1a to 1d, sudden weight changes occurred at 3 oxygen partial pressures, -11.45, -9.23, and -9.10, in $\log P_{O_2}$ in samples with Nd_2O_3/V_2O_5 mole ratios equal to unity and larger than unity. These figures correspond to the equilibrium oxygen partial pressures of reactions in the system shown in Table 5.

As is shown in Fig. 1c, the range of oxygen partial pressure in which $NdVO_3$ and Nd_3VO_7 coexist is very

a) A: $Nd_{1.62}V_{0.38}O_{3.38}$, B: Nd_3VO_7.

narrow. This range is, indeed, too small for us to find Nd_3VO_7 in the early period of the thermogravimetric experiment. Throughout the experiment aimed at the identification of phases in the quenched samples, Compound Nd_3VO_7 was found as an unexpected phase.

As is shown in Fig. 1e, samples with mole ratios lower than unity showed patterns similar to those of the other systems[1,3–5] except for the oxygen partial pressure of $\log P_{O_2}=-9.10$, which correspond to the equilibrium oxygen partial pressure of the $NdVO_3+1/2\ O_2=NdVO_4$ reaction.

In Table 1, the results of the identification of phases are shown. In the first column is the composition of the starting materials in mol%; in the second, the experimental conditions of the oxygen partial pressure in terms of $\log P_{O_2}$; in the third, the experimental duration in hours, and in the last, phases that are found in the quenched samples by means of an X-ray powder diffractometer using Cu $K\alpha$ radiation. The

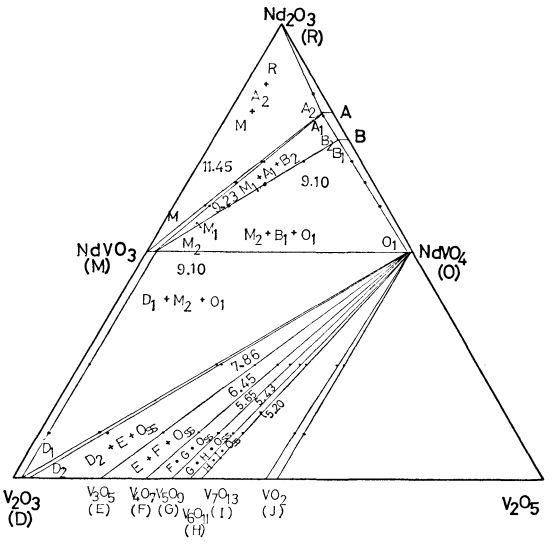

Fig. 2. Phase equilibria in the Nd_2O_3–V_2O_3–V_2O_5 system at 1200 °C. Numerical values in the three solid phases regions are the oxygen partial pressures in $-\log P_{O_2}$ in equilibrium. Abbreviations are the same as those in Tables 1 and 3. ss means the solid solution.

letters in the phases are abbreviations of the compounds shown in the lower part of the table. The abbreviations are the same as those of the other tables and figures in the present report.

Based upon the above experimental results, a phase diagram of the system at 1200 °C is shown in Fig. 2. The following phases are stable under the present experimental conditions, except for compounds in the V_2O_3–V_2O_5 system, $NdVO_3$, $NdVO_4$, and Nd_2O_3. The phases are: $Nd_{1.62}V_{0.38}O_{3.38}$ ($0.81Nd_2O_3\cdot 0.19V_2O_5$, A) and Nd_3VO_7 ($3Nd_2O_3\cdot V_2O_5$, B). Compounds with Nd_2O_3/V_2O_5 mole ratios of 6/1 and 2/1 were not found under the present experimental conditions. Compound A might have the composition, $4Nd_2O_3\cdot V_2O_5$, that Brusset *et al.*[6] and Remizov *et al.*[7] reported. However, under the present experimental conditions it has no round number of the mole ratio. The straight line drawn in Fig. 2 by plotting the experimental points is used to concentrate to the composition described above, even considering the experimental errors.

There are two possible explanations of why the deviation from the round number of the mole ratio occurred; one is the nonstoichiometry of the compound

	$NdVO_{3.035}$	M_1	9.23	−0.0203
	$NdVO_{3.037}$	M_2	9.10	−0.0221

a) These values were obtained by extrapolations using the experimental values.

toward the Nd_2O_3 side, and the other is experimental errors in the thermogravimetry. However, as shown in Fig. 1b, in which the results for $Nd_2O_3/V_2O_5=4/1$ are shown, a sudden change in the weight occurred at the oxygen partial pressure, −9.23 in $\log P_{O_2}$. Besides, this result has a good reproducibility. If the composition of Compound A was 4/1 in the Nd_2O_3/V_2O_5 mole ratio, such a weight change would not occur and there were be the same pattern as in Fig. 1a. Some might point out a systematic shift in the experimental points. To answer this, it is enough to show the existence of $3Nd_2O_3\cdot V_2O_5$. As has been described above, a compound with the same composition of A was found in the systems of both Gd and La.

A compound with a Ln_2O_3/V_2O_5 mole ratio of 3/1 was also found in the systems of La_2O_3,[5] Eu_2O_3,[19] and Sm_2O_3.[7]

Ternary compounds, A, Nd_3VO_7, $NdVO_3$, and $NdVO_4$ have nonstoichiometric compositions. The nonstoichiometry of the $LnVO_3$-type compound seems to be very rare. In this series, only $LaVO_3$[5] had a nonstoichiometric composition like $NdVO_3$. Judging from these two instances, the ionic radius seems to be effective. As is well known, La and Nd have ionic radii rather larger than the others in the lanthanoid series, although the crystal structure of $LaVO_3$ is different from that of $NdVO_3$. On the other hand, $SmVO_3$ is stoichiometric.[1]

There are many two-and three-phase areas in Fig. 2. For example, the area that has the equilibrium oxygen partial pressure of −9.10 in $\log P_{O_2}$ has three phases, B_1, M_2, and O_1; here, B_1 has the composition of the B solid solution at $\log P_{O_2}=-9.10$ and M_2 is the most oxidized end member of the solid solution M, while, on the other hand, O_1 is the most reduced end member of the solid solution O. The square area that is surrounded by points, B, B_1, O_1, and O, is a two-phase area, $B_{ss}+O_{ss}$, where ss indicates the solid solution.

As is shown in Fig. 2, the pattern of the present phase diagram is of a new type and is different from those of the previously reported systems because of the difference in the coexisting ternary compounds.

The relationship between the composition, N_O/N_X, and the oxygen partial pressure of the solid solution, X, were determined using the thermogravimetric results. Here, N_O/N_X is the mole fraction ratio of oxygen to a component X at a certain oxygen partial pressure; it indicates the deviation from the component composition. Using the method of the least squares with a linear equation, $N_O/N_X=a\log P_{O_2}+b$, the constants, a and b, for each solid solution were determined; they are shown in Table 2.

In Table 3, the compositions of the compounds at various oxygen partial pressures, the stability ranges of the compounds in terms of $\log P_{O_2}$, the symbols of the compounds, and the activities of the components in the solid solutions were calculated with Gibbs-Duhem equation using the N_O/N_X *vs.* $\log P_{O_2}$ relations described above. The method of the calculation has been discussed in detail in the paper of Kimizuka and Katsura.[16]

The attempted assignment of Miller indices for new compound was not successful. However, the values of the relative intensities and spacings that were obtained by means of an X-ray diffractometer with powder samples are shown in Table 4, together with $3Eu_2O_3\cdot V_2O_5$[19] and $3La_2O_3\cdot V_2O_5$.[5] The weak peaks

Table 6. Gibbs free energies of reactions

	Reaction	$-\log(P_{O_2}/\text{atm})$	$\frac{-\Delta G^\circ}{\text{kJ}}$
(1)	$\frac{31}{50}Nd_2O_3 + \frac{19}{50}NdVO_3 + \frac{19}{100}O_2 = Nd_{1.62}V_{0.38}O_{3.38}$	11.45±0.07	61.4
(2)	$\frac{50}{31}Nd_{1.62}V_{0.38}O_{3.38} + \frac{12}{31}NdVO_3 + \frac{6}{31}O_2 = Nd_3VO_7$	9.23±0.03	47.4
(3)	$NdVO_3 + \frac{1}{2}O_2 = NdVO_4$	9.10±0.03	128.9

of Nd_3VO_7 and La_3VO_7 were omitted from the table. The pattern of Nd_3VO_7 is very similar to that of La_3VO_7, though its d-values are a little smaller than those of La_3VO_7, while the pattern of Eu_3VO_7 is different from those of Nd_3VO_7 and La_3VO_7.

The lattice constants of the A, $NdVO_3$ and $NdVO_4$ compounds are tabulated in Table 5. The lattice constants of Compound A were successfully determined with the aid of the assignment of indices of $4Tm_2O_3 \cdot V_2O_5$.[20] It is apparent from the table that the values of the lattice constants of $NdVO_4$ depend upon the oxygen partial pressures, and that those quoted in the table are intermediate in nature. The values of $NdVO_3$ are smaller than those of McCarthy *et al.*[11]

Calculation of Gibbs Energies of Reactions. On the basis of the present phase diagram, the Gibbs energies all of the reactions appearing in the system except those in the V_2O_3–V_2O_5 system can be calculated by means of this equation; $\Delta G^\circ = -RT \ln K$, where R is the gas constant; T, the absolute temperature, and K, the equilibrium constant of each reaction. The equation of the reactions, the equilibrium oxygen partial pressures for each reaction, and the ΔG° values calculated are shown in Table 6. The activities of each component in the solid solutions which are necessary for calculation are listed in Table 3.

Association of β-Diketones with Trioctylphosphine Oxide in Solvent Extraction Systems

Tatsuya SEKINE,* Takashi SAITOU, and Hiroto IGA
Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received April 6, 1982)

Distribution of six β-diketones between hexane, benzene, carbon tetrachloride, or chloroform and 0.1 mol dm^{-3} aqueous perchlorate solutions has been measured in the presence of trioctylphosphine oxide (TOPO). The distribution ratio was, in many cases, enhanced by TOPO; this was explained in terms of association of the β-diketones and TOPO. The association constants were greater when the β-diketone was stronger as an acid and also in the following order of the diluent: $CHCl_3 < CCl_4 < C_6H_6 < C_6H_{14}$. It was concluded that, even though the effect was not very large, still correction for the decrease in the concentrations of both the β-diketone and TOPO is necessary for an accurate estimation of the equilibrium involved in solvent extraction of metal ions containing these two reagents, as in the synergistic solvent extraction of metal ions.

Synergistic solvent extraction of metal ions with mixtures of one chelating extractant and one solvating-type ligand has been found in several systems. The reason for the enhancement of the chelate extraction by additions of such a neutral ligand has been explained in terms of adduct formation of the metal chelate in the organic phase. The formation constants of such adducts can be calculated statistically from the enhancement of the extraction as a function of the ligand concentration. However, an association of the extractants in the organic phase is also possible and, in such a case, they should be taken into the account in order to analyse the extraction data.

In the present paper, the distribution of six β-diketones has been measured in several solvent extration systems as a function of trioctylphosphine oxide (TOPO) concentration in the organic phase. Four inert organic solvents were used as diluents of the reagents. The association equilibria of β-diketones and TOPO in the systems were determined from the distribution data. The effects of the chemical properties of the β-diketones and the diluents on the equilibria are discussed.

Experimental

The β-diketones studied are listed in Table 1 with their abbreviated nomenclatures. The β-diketones and TOPO were supplied by Dojindo & Co., Kumamoto. The organic diluents, sodium perchlorate, and perchloric acid were of analytical grade. Chloroform was washed three times with water before use.

Experiments were carried out in a thermostated room at 298 K. Stock β-diketone solutions were prepared by dissolving weighed amounts of each reagent into each diluent. The concentration of the β-diketone in the stock solutions of TFA and HFA was further checked by titration with a standard sodium hydroxide solution. A TOPO stock solution was also prepared in the same manner, and it was washed several times with water. Mixed solutions containing a β-diketone and TOPO at various concentrations were prepared from these stock solutions.

A portion of an organic solvent containing a β-diketone and TOPO and the same volume of an aqueous solution containing 0.010 mol dm^{-3} perchloric acid and 0.090 mol dm^{-3} sodium perchlorate were placed in a stoppered glass tube, agitated by a mechanical shaker, and centrifuged off. The aqueous phase of the experiments with BZA, BFA, or TTA was transferred into another tube and agitated with a portion of the same diluent containing no TOPO. The amount of the β-diketone thus extracted into the organic phase was determined from the optical absorption at 323(BFA in C_6H_{14}), 330(BFA in C_6H_6), 325(BFA in CCl_4), 305(BZA in C_6H_{14}), 310(BZA in C_6H_6), 307(BZA in CCl_4), 315(TTA in C_6H_{14}), 324(TTA in C_6H_6), and 319(TTA in CCl_4) nm, respectively. In the experiments with AA, TFA, and HFA, the amount in the aqueous phase was obtained by direct measurements of its UV absorption at 273, 280, and 305 nm, respectively, because their recovery in the organic phase was not quantitative by only a single extraction. The distribution ratio was calculated from the β-diketone concentration in the aqueous phase at equilibrium and from that in the initial organic phase.

Statistical

The β-diketones hereafter are represented by HA, and TOPO by L. The chemical species in the organic phase are denoted by a subscript "org", and those in the aqueous phase are given without any subscript.

The β-diketones (which are weak acids) in the aqueous phase may be both in the HA and A^- form, while those in the organic phase may be in the undissociated form HA as well as in the associated form with TOPO, HAL_n. Since n was found to be one or two in the present study and no species containing more than one HA was found, the distribution ratio of HA can generally be written as:

$$D = ([HA]_{org} + [HAL]_{org} + [HAL_2]_{org})/([HA] + [A^-]). \quad (1)$$

The dissociation constant and the two-phase distribution constant of the acid can be written as:

$$K_a = [H^+][A^-][HA]^{-1} \quad (2)$$

$$K_d = [HA]_{org}[HA]^{-1}, \quad (3)$$

and the distribution constant of the neutral ligand is:

$$K_d(L) = [L]_{org}[L]^{-1}. \quad (3')$$

The association equilibria of HA and L may be represented by:

$$\left.\begin{aligned} &HA_{(org)} + L_{(org)} \rightleftharpoons HAL_{(org)} \\ &\beta_{1(org)} = [HAL]_{org}[HA]_{org}^{-1}[L]_{org}^{-1} \end{aligned}\right\} \quad (4)$$

$$\left.\begin{aligned} &HA_{(org)} + 2L_{(org)} \rightleftharpoons HAL_{2(org)} \\ &\beta_{2(org)} = [HAL_2]_{org}[HA]_{org}^{-1}[L]_{org}^{-2} \end{aligned}\right\}. \quad (5)$$

In the absence and presence of L, the distribution ratio may be written as:

$$D_0 = [HA]_{org}/([HA]+[A^-]) = K_d/(1+K_a[H^+]^{-1}) \quad (6)$$

$$D = K_d(1+\beta_{1(org)}[L]_{org}+\beta_{2(org)}[L]_{org}^2)/(1+K_a[H^+]^{-1}). \quad (7)$$

When D in Eq. 7 is obtained at a certain $[H^+]$, D_0 at the same $[H^+]$ can be calculated by using the values of K_a and K_d; then the following equation can be written:

$$D/D_0 = 1 + \beta_{1(org)}[L]_{org} + \beta_{2(org)}[L]_{org}^2. \quad (8)$$

Both perchloric acid and sodium perchlorate are extractable with TOPO, but the extraction of the latter is negligible under the conditions of the present study, as can be calculated from the equilibrium constant:

$$K_{ex}(NaClO_4) = [NaL_3^+ClO_4^-]_{org}[Na^+]^{-1}[ClO_4]^{-1}[L]_{org}^{-3}. \quad (9)$$

When the solvent is hexane and when the total concentration of the salt is 1 mol dm^{-3}, this value of K_{ex} ($NaClO_4$) is $10^{1.01}$ and thus $[NaL_3^+ClO_4^-]_{org}$ should be less than 1×10^{-4} mol dm^{-3} when both $[Na^+]$ and $[ClO_4^-]$ are 0.1 mol dm^{-3} and $[L]_{org}$ is lower than 0.1 mol dm^{-3}.[1] When the salt concentration is 0.1 mol dm^{-3}, as in the present study, this value of the organic concentration of sodium perchlorate solvated with TOPO should be even lower.

The extraction equilibrium of perchloric acid is:[2]

$$\left.\begin{aligned} &H^+ + ClO_4^- + 2L_{(org)} \rightleftharpoons HClO_4L_{2(org)} \\ &K_{ex}(HClO_4) = [HClO_4L_2]_{org}[H^+]^{-1}[ClO_4^-]^{-1}[L]_{org}^{-2} \end{aligned}\right\}. \quad (10)$$

Since the volumes of both phases were always the same and the concentration of TOPO in the aqueous phase was very small, as is seen from the values of K_d(L) in Table 1, the following equations can be written:

$$\begin{aligned} &[L]_{org,init} \\ &= [L]_{org} + [HAL]_{org} + 2[HAL_2]_{org} + 2[HClO_4L_2]_{org} \\ &= [L]_{org}(1+\beta_{1(org)}[HA]_{org}) + 2[L]_{org}^2(\beta_{2(org)}[HA]_{org} \\ &\quad + K_{ex}(HClO_4)[H^+][ClO_4^-]) \end{aligned} \quad (11)$$

$$\begin{aligned} &[HA]_{org,init} \\ &= [HA]_{org} + [HAL]_{org} + [HAL_2]_{org} + [HA] + [A^-]. \end{aligned} \quad (12)$$

From the total concentration of the β-diketone in the equilibrated aqueous phase, the following equation can be obtained:

$$[HA]_{org} = K_d([HA]+[A^-])(1+K_a[H^+]^{-1})^{-1}. \quad (13)$$

Among the terms in Eqs. 10 to 12, the value of [HA] can be determined experimentally, $[HA]_{org}$ can be calculated as above, the constant $K_{ex}(HClO_4)$ can be determined by separate experiments in the absence of HA, while $[H^+]$ and $[ClO_4^-]$ may be determined experimentally. Then $\beta_{1(org)}$ and $\beta_{2(org)}$ can be determined with a succesive approximation approach by using a least squares computer program. The calculated value of $[L]_{org}$ at equilibrium can also be obtained when the best-fit values of these constants are computed in this way. The change in the distribution ratio of HA may be given by D/D_0 (*cf.* Eqs. 6 to 8) and the experimental data may be presented in a figure on the basis of Eq. 8.

When the diluent was hexane or carbon tetrachloride and the TOPO concentration was high, the extraction of perchloric acid was somewhat different from that expected from Eq. 10. This deviation could be explained by assuming extractions of trisolvate of the acid, more precise calculation should be possible by introducing these results into Eq. 11. However, since values of the constants in Eqs. 4 and 5 obtained after this correction were not very much different from those obtained by making no correction, all the calculations were made as follows. The data in these diluents were treated on the basis of the following equation:

$$\begin{aligned} &[L]_{org,init} - 2[HClO_4]_{org,obsd} \\ &\quad = [L]_{org} + [HAL]_{org} + 2[HAL_2]_{org}, \end{aligned} \quad (14)$$

where $[HClO_4]_{org,obsd}$ is the concentration of the extracted acid experimentally obtained by titration of the two phases in the absence of HA. Thus the error of the association constants in hexane and cabon tetrachloride could be a little larger than those in the other diluents.

The enhancement of the extraction of a β-diketone by an addition of TOPO can also be considered as an extraction of the β-diketone with TOPO. These extraction equilibria can be written as:

$$\left.\begin{aligned} &HA + L_{(org)} \rightleftharpoons HAL_{(org)} \\ &K_{ex1} = [HAL]_{org}[HA]^{-1}[L]_{org}^{-1} \end{aligned}\right\} \quad (15)$$

$$\left.\begin{aligned} &HA + 2L_{(org)} \rightleftharpoons HAL_{2(org)} \\ &K_{ex2} = [HAL_2]_{org}[HA]^{-1}[L]_{org}^{-2} \end{aligned}\right\}. \quad (16)$$

By introducing Eq. 3, Eqs. 15 and 16 can be rewritten as:

$$K_{ex1} = \beta_{1(org)} \times K_d \quad (17)$$

$$K_{ex2} = \beta_{2(org)} \times K_d. \quad (18)$$

Results and Discussion

The extractions of perchloric acid in 0.1 mol dm^{-3} (Na,H)ClO_4 ionic media with TOPO in the diluents were determined in the manner previously reported.[2] The extraction constants of the acid calculated from the present data are listed in Table 1.

The distribution data of each β-diketone in the four liquid-liquid systems were obtained as a function of $[HA]_{org,init}$, $[L]_{org,init}$, and $[H^+]$.

Figure 1 gives the increase in the distribution ratio as a function of the free TOPO concentration, computed in the way described in the preceding section. The solid curves are the calculated values obtained by introducing the association constants into Eq. 8. Each of the curves has two asymptotes. One of them has a slop zero and the other has a slop +1 or +2. This corresponds to the highest complex in the system, HAL or HAL_2. Since the calculated curves fit well with the experimental data, the constants in

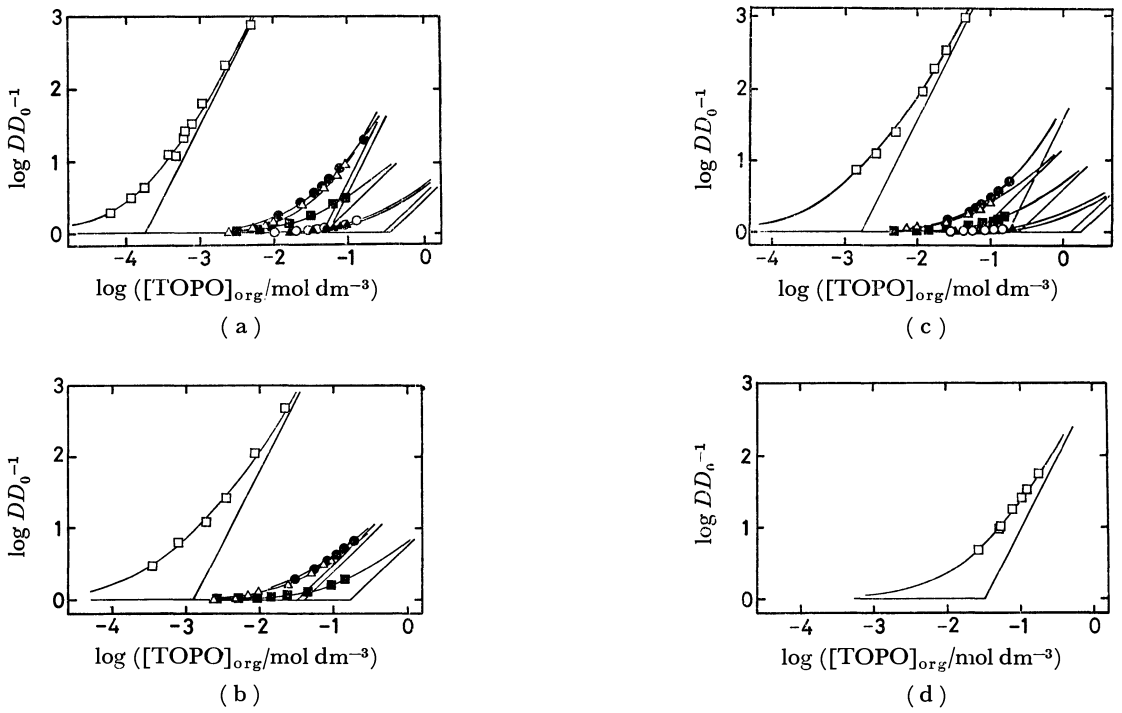

Fig. 1. Enhancement of distribution ratio as a function of calculated TOPO concentrations at equilibrium. The diluents are (a) C_6H_{14}, (b) C_6H_6, (c) CCl_4, and (d) $CHCl_3$. The β-diketones are AA(▲), BZA(○), TFA(●), BFA(■), TTA(△), and HFA(□). The curves are calculated by introducing the constants in Table 2 into Eq. 8. The straight lines are the asymptotes for the curves. Initial concentrations of the β-diketones (mol dm^{-3}) are as follows (The nomenclatures see Table 1).
(a): 1.0×10^{-4}(AA), 2.0×10^{-3}(BZA), 2.0×10^{-3} (TFA), 1.7×10^{-2} (BFA), 2.5×10^{-4}(TTA), and 2.0×10^{-2} (HFA), (b): 2.0×10^{-3}(TFA), 5.0×10^{-3}(TFA), 1.5×10^{-3}(TTA), and 2.0×10^{-2}(HFA), (c): 5.0×10^{-3}(AA), 2.0×10^{-2}(BZA), 2.0×10^{-3}(TFA), 5.0×10^{-3}(BFA), 7.5×10^{-4}(TTA), and 2.0×10^{-2}(HFA), (d): 2.0×10^{-2} (HFA).

Table 1 are reasonable.

The values of the equilibrium constants in Tables 1 and 2 may be summarized as follows.

(i) The distribution constants of TOPO are greater in the following order of the diluent: hexane<benzene<carbon tetrachloride<chloroform, while those of the β-diketones are greater in the order of hexane< carbon tetrachloride<benzene<chloroform.

(ii) The association constants between a certain β-diketone and TOPO are affected by diluent; it is greater in the order of chloroform<carbon tetrachloride<benzene<hexane, although the association constants of acetylacetone and benzoylacetone in benzene could not be determined in the range of the experimental error. This means that the tendency of the association is, in general, greater when the solvent-solute interactions are weaker. The order of $\beta_{n(org)}$ in the diluent, carbon tetrachloride<benzene, should indicate that the difference in the solvent-solute interactions of the β-diketones has a greater effect on

TOPO	$\log K_{ex}(HClO_4)$[a]	2.97	2.74	1.51	0.54[c]

a) For the extraction of perchloric acid with TOPO, the following constants were also obtained: $K_{ex}(HClO_4)_1 = [HClO_4(TOPO)]_{org}[H^+]^{-1}[ClO_4^-]^{-1}[TOPO]_{org}^{-1}$, $K_{ex}(HClO_4)_3 = [HClO_4(TOPO)_3]_{org}[H^+]^{-1}[ClO_4^-]^{-1}\times[TOPO]_{org}^{-3}$, $\log K_{ex}(HClO_4)_1 = 0.54(CHCl_3)$, $\log K_{ex}(HClO_4)_3 = 4.32(C_6H_{14})$, $2.60(CCl_4)$. b) Erroneous. c) Aq phase 1.0 mol dm^{-3} $NaClO_4$. Taken from Ref. 2.

the magnitude of the constant than the difference in those of TOPO.

(iii) When the solvent is chloroform, the association is observed only between HFA and TOPO. With the other β-diketones, a slight decrease in the distribution ratio with an increase in the TOPO concentration is observed.

(iv) Among the β-diketones in a certain given diluent, the association constant is larger when the K_a is higher (stronger as an acid).

The synergistic effect in metal extractions with β-diketones by TOPO or TBP is very well known, but such associations between the β-diketone and TBP or TOPO have not often been discussed quantitatively. The antagonistic effect caused by association of an acidic extractant and a neutral ligand was pointed out by Wang *et al.*[3,4] and also by Healy *et al.*[5,6] However, these reports gave only qualitative discussions. This problem has also been considered by several authors.[7–11] Recently, Khopkar and Mathur have discussed this problem on the basis of their experiments about solvent extraction of metal ions with TTA and TOPO[12] or TBP.[13] They described how the extraction curves in such synergistic systems can be well explained by assuming associations of the β-diketone and the neutral ligand. They determined the association constants between TTA and TBP or TOPO in those extraction systems and gave values $10^{0.57}$ and $10^{1.14}$ for the $\beta_{1(org)}$ of TTA with TBP and TOPO in xylene.

The observations in the present study can be explained by assuming that the β-diketone is extracted with the neutral ligand. As is seen from Eqs. 17 and 18, the extraction constant is the multiplication of K_d and $\beta_{n(org)}$. When pK_a values are similar, $\beta_{n(org)}$ may not be much different. Thus among a group of β-diketones of similar pK_a values, the magnitude of K_{ex1} and K_{ex2} should be dependent on the K_d values, which are higher when the molar volume is larger.

The extraction equilibria of metal ion M^{m+} in such synergistic systems can be written as:

$$M^{m+} + mA^- \rightleftharpoons MA_{m(org)};$$

$$K_{ex,m} = [MA_m]_{org}[M^{m+}]^{-1}[A^-]^{-m} \quad (19)$$

$$MA_{m(org)} + nL_{(org)} \rightleftharpoons MA_mL_{n(org)};$$

$$\beta_{m,n(org)} = [MA_mL_n]_{org}[MA_m]_{org}^{-1}[L]_{org}^{-n}, \quad (20)$$

and the enhancement of the metal extraction can be written as:

$$D/D_0 = 1 + \Sigma \beta_{m,n(org)}[L]_{org}^n, \quad (21)$$

where $D_0 = K_{ex,m}[A^-]^m$. When both $[A^-]$ and $[L]_{org}$ are lowerd by association, the value D/D_0 should be underestimated if no correction for the decreases in the concentrations would be made, and should cause an underestimation of the $\beta_{m,n(org)}$ values which were calculated by Eq. 21. At the same time, if no correction for the decrease in $[L]_{org}$ by associations with HA would be made, it should also cause an underestimation of $\beta_{m,n(org)}$. Thus although it seems to be necessary to recalculate the previously reported values of the adduct formation of metal chelate from such a standpoint, marked differences between the previous values and recalculated values should be found only in HFA–TOPO systems because the $\beta_{n(org)}$ are large enough to affect the results only in the HFA–TOPO systems. The differences will be slight in other systems.

The authors are grateful to Dr. J. N. Mathur for his valuable discussions about the association between 2-thenoyltrifluoroacetone and trioctylphosphine oxide.

Sodium Isotopic Exchange Rate between Disodium Zirconium(IV) Bis(orthophosphate) Trihydrate and Aqueous Solutions

Yasushi INOUE* and Yoshimune YAMADA

Department of Nuclear Engineering, Faculty of Engineering, Tohoku Universitv, Aramaki-aza-Aoba, Sendai 980

(Received June 25, 1982)

The sodium isotopic exchange rate between the large crystals of disodium zirconium(IV) bis(orthophosphate) trihydrate and aqueous solutions was determined radiochemically. The exchange proceeded quickly up to 5% of the total, followed by a slow process. The first step was attributed to the instantaneous attainment of the equilibrium between the imperfect surface layers of the crystals and the solution, and the second step was found to be controlled by the diffusion of sodium ions along the direction perpendicular to the layers consisting of zirconium atoms. The diffusion constant, D, was calculated with the equation obtained by Fick's diffusion law under the conditions of slab geometry and infinite solution volume. From the dependence of D on temperature, the activation energy for the diffusion was evaluated to be 101 kJ mol^{-1}.

Although the investigation of ion-exchange kinetics is very important for understanding the ion-exchange mechanism of crystalline zirconium(IV) bis(hydrogenphosphate) monohydrate (ZP), there has been only a little information up to date.[1–8] The measurement of the isotopic exchange rate of cations between the corresponding salt forms of ZP and aqueous solutions is especially interesting because it would provide the fundamental data which are useful for elucidating ion-exchange kinetics.

One of the outstanding studies made on this subject is that of Costantino *et al.*[8] They determined the isotopic exchange rate of sodium and potassium ions between the corresponding salt forms of powdered ZP, $M_2Zr(PO_4)_2\cdot 3H_2O$ (M=Na and K), and aqueous solutions and analyzed the data by the particle-diffusion mechanism. They assumed that the particles of the exchanger were spherically symmetrical, and succeeded in describing the rate law by one diffusion constant. In principle, however, the rate depends on the direction of diffusion because the crystal is not isomorphous, since it has a layered structure. Their assumption, therefore, is an approximation suitable for microcrystalline powders.

When large crystals having crystals shaped like thin platelets are used, the assumption made by Costantino *et al.* will be no longer valid. Hence, if macrocrystals, which have uniform in size are used and the rate is measured as a function of particle size, we can get a deeper insight into the isotopic exchange rate. This induced us to establish the conditions for preparing ZP with a large and uniform crystal size[9] and to obtain the information of phase stability of its disodium forms,[10] as reported previously. This information enables us to carry out the rate study more elaborately than before.

This paper deals with the results of the radiochemical experiments undertaken to measure the isotopic exchange rate of sodium ions between large crystals of $Na_2Zr(PO_4)_2\cdot 3H_2O$ and concentrated solutions of sodium salts.

Experimental

Preparation of $Na_2Zr(PO_4)_2\cdot 3H_2O$ Spiked with ^{22}Na. The crystals of $Na_2Zr(PO_4)_2\cdot 3H_2O$ prepared by the method recommended previously[9] were classified into four particle sizes: 48—70, 70—100, 100—145, and 145—250 mesh, by using Japan Industrial Standard sieves. The size of each fraction was then made more uniform by the sedimentation method with the equipment of Aly and Latimer.[11] The fraction of each uniform size was collected, dried in a desiccator over a saturated NaCl solution, and the particle size was measured with an optical microscope. The average size of each fraction is given in Table 1. $Na_2Zr(PO_4)_2\cdot 3H_2O$ thus obtained was then labeled with ^{22}Na by equilibrating 1 g of the sample with 10 cm^3 of 0.1 mol dm^{-3} NaOH solution containing ^{22}Na for two weeks at 40 °C. After being washed with distilled water, it was dried again to a constant weight over saturated NaCl solution. The product was verified to be homogeneously labeled at about 40 μCi/g (1 Ci=3.7×10^{10} Bq) and was used for the determination of the isotopic exchange rate.

Apparatus. The apparatus used for the measurements of the isotopic exchange rate is shown in Fig. 1. The sample is placed in a stainless steel cage fitted with a 400 mesh stainless steel screen on the openings at the side wall and the bottom. The cage was designed by modifying the device developed by Kressman and Kitchner;[12] the upper base of

Table 1. Particle size of the samples

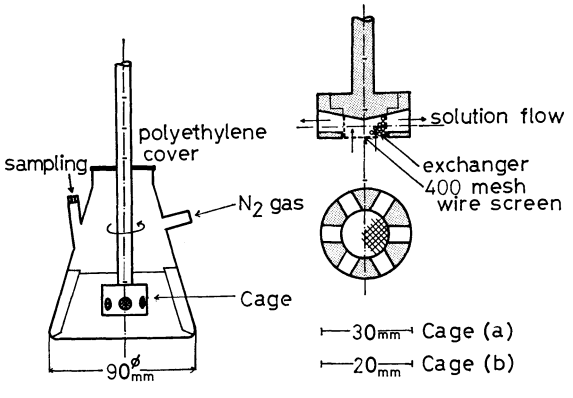

Fig. 1. Apparatus for the measurement of the isotopic exchange rate.

the inner surface was tapered and grooved so that no air might stay in the cage. This ensures the intimate contact of the exchanger with the solution. The cage is connected to the shaft of a stirrer and dipped into the solution in a conical beaker. The lower part of its wall is indented at three places to prevent the surface of the solution from becoming paraboloid when the solution is vigorously agitated by the stirrer. As it is rotated in the solution, the cage draws liquid from the bottom screen and discharges it through the side screen into the bulk of the solution; thus a very rapid stream of the solution passes through the sample placed inside the cage. The frequency of revolution was measured with a Yokogawa Model 2607 Photo Tachometer.

Measurements of the Isotopic Exchange Rate. All the experiments were performed in nitrogen atmosphere. A portion of 400 mg of the sample was placed in the cage and immersed into 200 cm^3 of the test solutions while the cage was rotated. The solution had been adjusted in advance to a constant temperature within ± 0.1 °C (below 50 °C), or within ± 0.2 °C (above 50 °C). Aliquots of the solution (about 0.2 cm^3) were taken out at appropriate time intervals in order to measure the radioactivity. A well-type NaI-(Tl)scintillation counter (Fuji Denki Model NHS-2) was used for the measurement of radioactivity. The time of contact of the solution with the exchanger was taken as the time elapsed between the immersion of the cage and the withdrawal of an aliquot of the solution.

The fractional attainment of equilibrium, $F=C_t/C_\infty$, was calculated from these results; here C_t is the total radioactivity of the solution at time t and C_∞ at $t=\infty$. C_∞ was calculated by the equation, $C_\infty=CM/(M+m)$, where C is the initial total radioactivity of the exchanger, and m and M are the total amounts of Na^+ ions in the exchanger and in the solution, respectively.

Results and Discussion

In order to determine the efficiency of agitation, the effect of the stirring rate and the size of the cage on the half-exchange time was examined for solutions of pH 11 having different $NaNO_3$ concentrations. In solutions as dilute as 0.01 mol dm^{-3} $NaNO_3$, the time required for half-exchange became shorter as the revolution rate increased, and became constant at 1000 min^{-1}. In more concentrated solutions, it was almost independent of the rate of revolution. This observation was irrespective of the diameter of the base screen of the cages used (17 and 12 mm): that is, the constant exchange rate is not due to the limiting hydrodynamic efficiency of the stirring. Furthermore, it was confirmed that no crystals were broken down during the agitation. From these results a revolution rate of 1400 min^{-1} was adopted throughout the subsequent experiments.

To make clear the rate controlling steps of the isotopic exchange, a plot of F against the square root of contact time t, was made for different experimental conditions. Figure 2 shows the comparison of the isotopic exchange rates in solutions of different sodium salts, indicating that no difference was observed in the rates for different anions in the solution. Figure 3 shows the influence of the sodium-ion concentration on the rate. When the concentration was higher than 0.5 mol dm^{-3}, the rate was independent of the sodium-ion concentration, and a linear relation between F and $\sqrt{t}$ held in the F range smaller than about 0.4, except for the initial portion of these plots. When the sodium-ion concentration was 0.01 mol dm^{-3}, however, the rate was much faster than that obtained for the solutions of higher concentrations than 0.5 mol dm^{-3}; in addition, linearity between F and $\sqrt{t}$ did not hold.

The observations that the exchange rate is not affected by the revolution rate of the cage, by the kind of anions, or by the sodium-ion concentration, mean that the rate is controlled by the process within the particles. Moreover, the linearity of F *vs.* $\sqrt{t}$ in the F range smaller than 0.4 indicates that the particle diffusion is rate-controlling, and that the infinite solution-volume approximation is closely obeyed in this range, although the method of the rate measurement is for the limited solution-volume condition. The deviation from the linearity means that the assumption of the infinite solution-volume condition is no longer

effective.

The effect of particle size on the rate was then studied. This is shown in Fig. 4, which indicates that the rate was not affected by the particle size of the samples employed. This observation can be explained as follows. The structure of $Na_2Zr(PO_4)_2 \cdot 3H_2O$ is a layered one similar to ZP: each layer consists of zirconium atoms lying very nearly in a plane and bridged by phosphate groups situated above and below the plane. Adjacent layers are arranged in such a way as to create zeolite-like cavities; these layers are interconnected by openings.[13] The diameters of the openings are 0.263 and 0.24 nm along the directions parallel and perpendicular to the layers, respectively. Since the sodium ion is small in size (0.19 nm), it can diffuse along both directions. Here, let us define the diffusion constants along the direction parallel and perpendicular to the layers respectively as D' and D, where D' is considered to be greater than D because of the difference in the diameters of the passages of ions. When D' is supposed to be very much greater than D, the isotopic exchange rate is determined by the diffusion along the direction parallel to the layers; accordingly, it must depend on the particle size of the samples. The experimental data, however, does not support this assumption. By assuming that D' is nearly equal to D, the diffusion along the direction parallel to the layers can be ignored, since the diffusion distance is much longer along this direction than along the direction perpendicular to the layers. As a result, the rate will be determined only by D. The independence of the rate on the particle size can reasonably be explained by this assumption since the thicknesses of the crystals are equal irrespective of the particle size.

The fractional attainment of equilibrium, therefore, can be obtained by solving the equation for diffusion in slabs immersed in a well-stirred solution under the infinite-solution volume condition:

$$F = 1 - \sum_{n=0}^{\infty} \frac{8}{(2n+1)^2\pi^2} \exp[-\beta(n+1/2)^2\pi^2 t] \quad (1)$$

where, $\beta = D\,l^{-1}$ and l is the half-length of the crystal in the direction perpendicular to the layers.[14,15]

When βt is smaller than 0.1, that is, when F is less than about 0.4, Eq. 1 can be approximated by a simpler form:

$$F = \frac{2}{\pi^{1/2}} \sqrt{\beta t} \quad (2)$$

which holds to a fairly good approximation.

The fractional attainment of equilibrium against square root of time was then studied as a function of temperature, as is shown in Fig. 5. The figure indicates that the slope of the linear relation between F and $\sqrt{t}$ increases with temperature. The straight lines, however, do not pass through the origin and always intersect the F axis at 0.05. This observation can be understood by considering that the defects of the crystal structure exist on the surface of the crystals and that the equilibrium between the surface region of the crystals and the solution is attained rapidly and then the diffusion into the bulk of the crystals proceeds. D was then calculated by taking consideration of the facts that 95% of total sodium ions in the crystals took part in the particle diffusion and that the effective length for diffusion was 95% of the actual crystal size.

When $\log D$ was plotted against $1/T$, good linearity was obtained, as is shown in Fig. 6. From the Arrhenius equation, $D = D_0 \exp(-E_a/RT)$, the activation energy E_a and the constant D_0 were determined. The value of E_a was 101 kJ mol^{-1} and $D_0 = 19$ m^2 s^{-1}. The present value of E_a is considerably higher than that given by Costantino *et al.*, 73 kJ mol^{-1}.[8] One explanation of this discrepancy is as follows. The activation energy of diffusion along the direction perpendicular to the layers is expected to be higher than that along the direction parallel to the layers, because the effective diameter of passage is smaller along the former than along the latter direction. The present value is related to the diffusion along the direction of the highest activation energy while Costantino's value resulted from some average of two diffusion con-

stants.

The experiments so far were performed with the dried exchanger which had been stored in a desiccator containing saturated NaCl solution. The same results were also obtained when the experiments were carried out by using the exchanger which had been equilibrated with distilled water. This fact offers a striking contrast between the trihydrate and high-temperature phases. The results for the latter phases will be reported later.

An Electron Transfer Chain Mechanism for Photoinduced Oxidative Addition of Alkyl Iodide to a Dimeric Rhodium(I) Complex under Low Energy Irradiation (553 nm)

Shunichi Fukuzumi, Nobuaki Nishizawa, and Toshio Tanaka*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received July 23, 1982)

A dimeric Rh^{I} complex, $[Rh_2(dicp)_4]^{2+}$ (dicp=1,3-diisocyanopropane) was found to undergo a photoinduced oxidative addition with butyl iodide and isopropyl iodide in MeCN by 553 nm irradiation in high quantum yields, Φ=25.2 and 22.6, respectively. Electron acceptors (*p*-dinitrobenzene, *p*-benzoquinone, and chloranil) and radical scavengers (oxygen and isopentyl nitrite) act as inhibitors for the photoinduced oxidative addition, providing unambiguous evidence for a chain character of this reaction. The fluorescence quenching of $[Rh_2(dicp)_4]^{2+}$ by the electron acceptors as well as butyl iodide has also been examined. Based on the kinetics of the photochemical reactions in the absence or the presence of electron acceptors and radical scavengers, an electron transfer chain mechanism has been proposed. The formation of butyl radicals in the photoinitiation step was confirmed by the trap with oxygen to yield equimolar amounts of 1-butanol and butyraldehyde. The nature of the excited state of $[Rh_2(dicp)_4]^{2+*}$ ($^1A_{2u}$ or $^3A_{2u}$) involved in the photoinitiation step has also been discussed.

Oxidative additions of transition metal complexes with low-lying metal to ligand charge transfer (MLCT) excited states have recently merited a special attention as offering a possibility for photochemical energy storage.[1] There has, however, been reported only a few photochemical study on the oxidative additions of simple substrates such as alkyl halides and protic acids to transition metal complexes.[2] On the other hand, the thermal oxidative addition of organic halides to transition metal complexes have intensively been studied.[3] Although there is no simple generalization about the mechanisms of oxidative additions, some addition reactions of organic halides to transition metal complexes have been suggested to proceed *via* a radical chain process where the initiation step involves transfer of one electron rather than two electrons.[4] If such a radical chain process is initiated by light, the oxidative addition may be prompted photochemically with high quantum yields.

We have previously reported that a dimeric Rh^{I} complex, $[Rh_2(dicp)_4]^{2+}$ (dicp=1,3-diisocyanopropane), is an excellent one electron donor in the reactions with inorganic oxidants such as $[Fe(N\text{–}N)_3]^{3+}$ (N–N=2,2′-bipyridine and 1,10-phenanthroline).[5] The donor ability of $[Rh_2(dicp)_4]^{2+}$ would be further enhanced in the MLCT excited states, $[Rh_2(dicp)_4]^{2+*}$ ($^1A_{2u}$ or $^3A_{2u}$) formed by the irradiation of the lowest energy band which appears at 553 nm in MeCN.[6,7]

In this paper, we wish to report a photoinduced oxidative addition of butyl iodide (*n*-BuI) and isopropyl iodide (*i*-PrI) toward $[Rh_2(dicp)_4]^{2+*}$ by low energy irradiation (553 nm) under nitrogen atmosphere with exceptionally high quantum yields, Φ=25.2 and 22.6, respectively. The reaction mechanism is discussed based on the kinetics of the photochemical reactions in the absence or the presence of electron acceptors (*p*-dinitrobenzene, *p*-benzoquinone, and chloranil) as well as radical scavengers (oxygen and isopentyl nitrite). Electron transfer quenching of the fluorescence of $[Rh_2(dicp)_4]^{2+*}$ by the electron acceptors has also been examined to obtain the rate constants for the electron transfer reactions between $[Rh_2(dicp)_4]^{2+*}$ and the electron acceptors. A preliminary report of the present study has appeared.[8]

Experimental

Materials. Preparation of $[Rh_2(dicp)_4](BPh_4)_2$ (dicp=1,3-diisocyanopropane) was described previously.[5,8] Commercially available *n*-BuI and *i*-PrI were purified by distillation. Electron acceptors (chloranil, *p*-benzoquinone, *p*-dinitrobenzene, *m*-dinitrobenzene, methyl *p*-nitrobenzoate, *m*-nitrobenzaldehyde, *p*-chloronitrobenzene, nitrobenzene, diethyl fumarate, and benzophenone) and a radical scavenger (isopentyl nitrite) also obtained commercially were purified by the standard methods.[9] Acetonitrile used as a solvent was purified by distillation over P_2O_5 three times before use.

Photoinduced Addition of n-*BuI to* $[Rh_2(dicp)_4]^{2+}$ *under Nitrogen Atmosphere.* Butyl iodide (7.9 mmol) was dissolved in a MeCN solution (45 cm^3) of $[Rh_2(dicp)_4](BPh_4)_2$ (31 μmol) under nitrogen atmosphere in the dark. When the solution was irradiated by the visible light (an Ushio Model Ul-501C Xenon lamp) through a Toshiba glass filter O-55 transmitting the light $\lambda>550$ nm, the intensive violet color of the solution faded in a few minutes to turn yellow. The resulting solution was concentrated to one third volume under reduced pressure, followed by the slow addition of diethyl ether. A precipitate appeared was collected by filtration and recrystallized from MeCN to give brown crystals of $[Rh_2(dicp)_4(n\text{-Bu})(I)](BPh_4)_2$ in a 80% yield. Found C, 59.27; H, 4.95; N, 7.93%.[10] Calcd for $C_{72}H_{73}N_8B_2IRh_2$: C, 61.56; H, 5.24; N, 7.98%. ν(C≡N): 2200 and 2220 cm^{-1} (KBr pellet).

Photochemical Reaction of $[Rh_2(dicp)_4]^{2+}$ *with* n-*BuI under Oxygen Atmosphere.* Upon 1 min irradiation by the visible light ($\lambda>550$ nm) under oxygen atmosphere, a violet MeCN solution (*ca.* 1 cm^3) containing $[Rh_2(dicp)_4]^{2+}$ (0.83 μmol) and *n*-BuI (0.175 mmol) turned into deep green with concomitant disappearance of the absorption band of $[Rh_2(dicp)_4]^{2+}$ at 553 nm. The resulting solution contained equimolar amounts of 1-butanol and butyraldehyde (26% yield) as determined by GLC. The other products were obtained as a mixture of $[Rh_2(dicp)_4(n\text{-Bu})(I)]^{2+}$ (67%) and $[Rh_4dicp)_8(I)_2]^{4+}$ (16%), the composition of which was determined from their absorbances at λ_{max}; 407 nm ($\varepsilon=5.09\times10^5$ mol^{-1} dm^2) and 631 nm ($\varepsilon=8.71\times10^5$ mol^{-1} dm^2),[11] respectively.

Quantum Yield Determination. The visible light from an Ushio Model Ul-501C Xenon lamp was monochromatized with a Nikon G-250 monochromator. The incident light intensity at 553 nm was determined as 7.08×10^{-9} einsteins

min^{-1} by the use of a standard actinometer (potassium hexacyanoferrate(II))[12] under the same conditions as the photochemical experiments. Quantum yields Φ for the photoinduced oxidative addition of *n*-BuI and *i*-PrI to $[Rh_2(dicp)_4]^{2+}$ were then calculated by the equation $\Phi = R/In$, where R is the photochemical reaction rate determined from the disappearance of the 553 nm band due to $[Rh_2(dicp)_4]^{2+}$ and In is the light intensity absorbed by the reactants. In the absence of electron acceptors and radical scavengers, the quantum yields exhibited some decreasing dependence on the percent conversion and the initial values were taken by extrapolating the plots of Φ *vs.* time.

Fluorescence Quenching by Electron Acceptors. Fluorescence measurements were carried out using a Hitachi 650-10S fluorescence spectrophotometer. Relative fluorescence intensities of $[Rh_2(dicp)_4]^{2+*}$ at 656 nm were measured for MeCN solutions containing $[Rh_2(dicp)_4]^{2+}$ (2.7×10^{-4}—8.0×10^{-4} mol dm^{-3}) and a quencher at various concentrations. The absorption band due to $[Rh_2(dicp)_4]^{2+}$ ($\lambda_{max}=553$ nm) was not changed by the addition of quenchers with high concentrations ($>1\times10^{-1}$ mol dm^{-3}) except for chloranil and *p*-benzoquinone. In these cases, the presence of quenchers in high concentrations caused the slight red shift (≈10 nm) of the $[Rh_2(dicp)_4]^{2+}$ band, and thus the lower concentrations ($\ll1\times10^{-1}$ mol dm^{-3}) were used for the experiments of the fluorescence quenching in order to avoid the possible formation of the complexes with the ground state of $[Rh_2(dicp)_4]^{2+}$. Under such experimental conditions, the excitation wavelength agrees with the absorption maximum of $[Rh_2(dicp)_4]^{2+}$ where the quenchers used in this study have neither absorption nor emission. There was no change in the shape but intensity of the fluorescence spectrum of $[Rh_2(dicp)_4]^{2+*}$ by the addition of quenchers. The minimum slit width (1 mm) of the excitation light was chosen for the fluorescence quenching with *n*-BuI in order to avoid the facile photochemical reaction. The Stern-Volmer relationship (Eq. 1) between I_f^0/I_f and [Q] was obtained for each quencher,

$$I_f^0/I_f = 1 + K_q[Q], \quad (1)$$

where I_f^0 and I_f are relative fluorescence intensities in the absence and presence of a quencher, respectively, K_q is the quenching constant, and Q stands for the quencher. The quenching rate constant k_q was obtained by the relation $k_q = K_q\tau^{-1}$, where τ is the emission lifetime of $[Rh_2(dicp)_4]^{2+*}$ ($\tau=1.3$ ns[7]).

Results and Discussion

Photoinduced Oxidative Addition of n-*BuI to* $[Rh_2(dicp)_4]^{2+}$. Figure 1 shows the electronic absorption spectra of a MeCN solution containing $[Rh_2(dicp)_4]^{2+}$ (3.24×10^{-4} mol dm^{-3}) and *n*-BuI (1.75×10^{-1} mol dm^{-3}) before and after irradiation by the visible light through a filter transmitting the light $\lambda>550$ nm under nitrogen atmosphere. Since neither the shape nor intensity of the lowest energy band at 553 nm assigned to $^1A_{1g}\rightarrow{}^1A_{2u}$ transition of $[Rh_2(dicp)_4]^{2+}$ [6,7] has been changed by the addition of *n*-BuI which has no absorption band in the visible region, there seems to be no ground state complex formed between $[Rh_2(dicp)_4]^{2+}$ and *n*-BuI. The intense violet color ($\lambda_{max}=553$ nm) of the solution, however, faded upon irradiation for 1 min. The resulting yellow solution contains the oxidative adduct, $[Rh_2(dicp)_4](n\text{-Bu})(I)]^{2+}$ ($\lambda_{max}=407$ nm), as a main product and a small amount of $[Rh_4(dicp)_8(I)_2]^{4+}$ ($\lambda_{max}=631$ nm, 4.6×10^{-6} mol dm^{-3})[11] as well as octane (4.9×10^{-6} mol dm^{-3}) detected by GLC. No butane has been detected. Thus, the photochemical reaction of $[Rh_2(dicp)_4]^{2+}$ with *n*-BuI under nitrogen atmosphere involves a main path and a side path, as expressed by Eqs. 2 and 3, respectively. The thermal reaction of

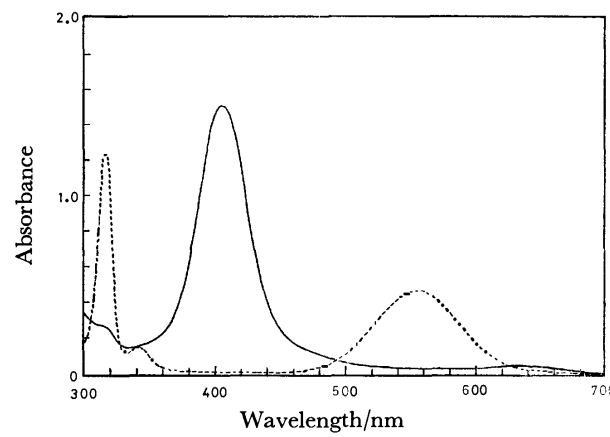

Fig. 1. Electronic absorption spectra of $[Rh_2(dicp)_4]^{2+}$ (3.23×10^{-4} mol dm^{-3}) in MeCN containing *n*-BuI (1.75×10^{-1} mol dm^{-3}) before irradiation (----) and after 1 min irradiation by the 553 nm light (——) under nitrogen atmosphere; 1 mm quartz cell.

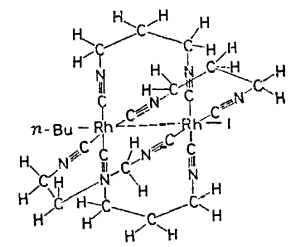
$$[Rh_2(dicp)_4]^{2+} + n\text{-BuI} \xrightarrow[>550\,nm]{h\nu} [Rh_2(dicp)_4(n\text{-Bu})(I)]^{2+} \quad (2)$$

$$2[Rh_2(dicp)_4]^{2+} + 2n\text{-BuI} \xrightarrow[>550\,nm]{h\nu} [Rh_4(dicp)_8(I)_2]^{4+} + \text{Bu-Bu} \quad (3)$$

$[Rh_2(dicp)_4]^{2+}$ with *n*-BuI has been negligible in the extent under the conditions where the photochemical experiment was carried out since the rate of the thermal reaction was at least 10^3 times slower than that of the photochemical reaction.

The oxidative adduct in Eq. 2 was isolated as brown crystals of the tetraphenylborate salt, $[Rh_2(dicp)_4(n\text{-Bu})(I)](BPh_4)_2$. The infrared spectrum of the adduct in a KBr pellet showed two $\nu(C\equiv N)$ bands at 2200 and 2220 cm^{-1}, both of which are higher than the single $\nu(C\equiv N)$ frequency of $[Rh_2(dicp)_4](BPh_4)_2$ (2172 cm^{-1}) and lower than that of $[Rh_2(dicp)_4(I)_2]^{2+}$ (2227 cm^{-1}).[6] This is consistent with the structural formulation as *trans*-$[Rh_2(dicp)_4(n\text{-Bu})(I)](BPh_4)_2$ (**1**). The $[Rh_2(dicp)_4(n\text{-Bu})(I)]^{2+}$ cation in MeCN exhibits an intense absorption band at 407 nm ($\varepsilon=5.09\times10^5$ mol^{-1}



1

dm^2, Fig. 1), which is assigned to $\sigma \rightarrow \sigma^*$ transition in the Rh^{II}–Rh^{II} single bonded species as in the case of the MeI adduct, $[Rh_2(dicp)_4(Me)(I)]^{2+}$.[6]

The $[Rh_2(dicp)_4]^{2+}$ cation reacted with *i*-PrI as well under irradiation at 553 nm, yielding $[Rh_2(dicp)_4(i\text{-}Pr)(I)]^{2+}$ ($\lambda_{max}=414$ nm, $\varepsilon=6.16\times10^5$ mol^{-1} dm^2). The photochemical reaction of $[Rh_2(dicp)_4]^{2+}$ with MeI, however, could not be examined since the thermal oxidative addition of MeI to $[Rh_2(dicp)_4]^{2+}$ occurred appreciably upon mixing the reactants in the dark.[6]

Quantum Yields for the Photochemical Reaction of $[Rh_2(dicp)_4]^{2+}$ *with* n-*BuI.* Quantum yield Φ for the photochemical reaction of $[Rh_2(dicp)_4]^{2+}$ with *n*-BuI on irradiation with the 553 nm light under various conditions are listed in Table 1, which indicates that the Φ value for the reaction under nitrogen atmosphere increases with increasing the *n*-BuI concentration, and an exceptionally high quantum yield ($\Phi=25.2$) is achieved with the concentration of 1.75×10^{-1} mol dm^{-3}. The reaction with 1.0×10^{-1} mol dm^{-3} *i*-PrI also gives a similar high quantum yield (footnote b) in Table 1. Such high quantum yields strongly suggest that the photoinduced oxidative addition of $[Rh_2(dicp)_4]^{2+}$ with *n*-BuI as well as *i*-PrI is a chain process.

In order to elucidate the chain process, the effect of electron acceptors such as *p*-dinitrobenzene, *p*-benzoquinone, and chloranil on the quantum yields was examined. The quantum yields are drastically decreased (*e.g.*, from 25.2 to 0.87) by the addition of *p*-dinitrobenzene which is known as a powerful one electron acceptor.[13] Similarly, the decrease in the quantum yield is observed in the presence of *p*-benzoquinone and chloranil (Table 1). Oxygen, which is a typical radical scavenger, also reduces the quantum yield (Table 1). The addition of isopentyl nitrite which also is a radical scavenger[14] results in the reduction of the quantum yield although less effective than oxygen. Thus, the electron acceptors and radical scavengers act as inhibitors for the photoinduced oxidative addition of *n*-BuI to $[Rh_2(dicp)_4]^{2+}$, providing unambiguous evidence for the chain character of this process where strong one electron donors and radical species must be involved. The photoinitiation step of the chain process is discussed in the following section.

Fluorescence Quenching by Electron Transfer. The excitation of the lowest energy band (553 nm) of $[Rh_2(dicp)_4]^{2+}$ results in fluorescence ($\lambda_{max}=656$ nm, $h\nu_f=1.89$ eV, $\tau=1.3$ ns).[7] The fluorescence was efficiently quenched by the electron acceptors in Table 1 without change in the shape of the fluorescence spectrum.

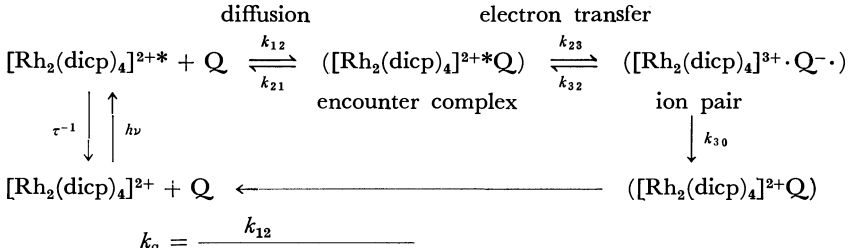
a) Taken from Ref. 15. b) The reduction is irreversible.



$$k_q = \frac{k_{12}}{1+\frac{k_{21}}{k_{23}}\left(1+\frac{k_{32}}{k_{30}}\right)} \quad (4)$$

Scheme 1.

Quenching rate constants of the $[Rh_2(dicp)_4]^{2+*}$ emission by various electron acceptors determined by the Stern-Volmer plots (see Experimental Section) are given in Table 2 together with the reduction potentials of the electron acceptors.

By analogy with the reaction scheme for fluorescence quenching by electron transfer in polar solvents reported previously,[16] the reaction of $[Rh_2(dicp)_4]^{2+*}$ with Q (quencher) may be shown in Scheme 1, according to which the quenching rate constant k_q is given by Eq. 4.[16] The free energy change of the actual electron transfer process, ΔG_{23}, (encounter complex→ion pair in Scheme 1) may be evaluated by Eq.5,[16]

$$\Delta G_{23} = E^0_{ox} - E^0_{red} + w_p - E_{0,0}, \quad (5)$$

where E^0_{ox} and E^0_{red} are the oxidation potential of $[Rh_2(dicp)_4]^{2+}$ and the reduction potential of electron acceptors, respectively, w_p is the work required to bring the product ions $[Rh_2(dicp)_4]^{3+}\cdot$ and $Q^{-}\cdot$ together to form the ion pair (Scheme 1),[17,18] and $E_{0,0}$ is the zero-zero transition energy between the ground state $[Rh_2(dicp)_4]^{2+}$ and the excited state $[Rh_2(dicp)_4]^{2+*}$. The $E_{0,0}$ value is obtained as 2.07 eV from the absorption spectrum (λ_{max}=553 nm, $h\nu$=2.24 eV) and the fluorescence spectrum (λ_{max}=656 nm, $h\nu_f$=1.89 eV) by the equation $E_{0,0}=(h\nu+h\nu_f)/2$.[16] Thus, the oxidation potential of the excited state $[Rh_2(dicp)_4]^{2+*}$ is decreased by 2.07 V relative to that of the ground state. Unfortunately, the oxidation potential of $[Rh_2(dicp)_4]^{2+}$ is unknown because the electrochemical oxidation is irreversible.[5] However, the peak potential E^p_{ox} of the cyclic voltammogram of $[Rh_2(dicp)_4]^{2+}$ (E^p_{ox}=0.92 V *vs.* SCE at the sweep rate of 0.1 V s^{-1})[5,19] gives the upper limit of the E^0_{ox} value. By using the w_p and $E_{0,0}$ values (−0.06 V[18] and 2.07 V, respectively), the upper limit of ΔG_{23} is then given as $\Delta G_{23} < -1.21 - E^0_{red}$. Thus, the quenching process by the electron acceptors except for diethyl fumarate and benzophenone in Table 2 (k_{23}) is exothermic and the reverse process (k_{32}) is thereby endothermic. Then, the relation $k_{30} \gg k_{32}$ may be valid since the free energy change of the back electron transfer to the ground state (k_{30}) is exceedingly negative. Under such a condition, Eq. 4 is reduced to Eq. 6. The

$$k_q = \frac{k_{12}k_{23}}{k_{23}+k_{21}} \quad (6)$$

quenching rate constants by the electron acceptors in Table 2 are thus close to the limiting value in Eq. 6, which is the diffusion rate constant, $k_{12}=2\times10^{10}$ mol^{-1} dm^3 s^{-1}.[16] The fluorescence of $[Rh_2(dicp)_4]^{2+*}$ is quenched also by *n*-BuI although the quenching rate constant k_q (2.6×10^8 mol^{-1} dm^3 s^{-1}) is smaller than those with the other electron acceptors in Table 2. Thus, the excited state $[Rh_2(dicp)_4]^{2+*}$ acts as an excellent electron donor toward various electron acceptors.

One electron transfer to *n*-BuI is known to result in the facile dissociation of the *n*-Bu–I bond, yielding butyl radicals.[20,21] The electron transfer quenching process shown in Eq. 7 is thus followed by the subsequent fast reaction expressed by Eq. 8, producing

$$([Rh_2(dicp)_4]^{2+*}n\text{-BuI}) \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} ([Rh_2(dicp)_4]^{3+}\cdot n\text{-BuI}^{-}\cdot) \quad (7)$$

$$([Rh_2(dicp)_4]^{3+}\cdot n\text{-BuI}^{-}\cdot \xrightarrow{\text{fast}} [Rh_2(dicp)_4(I)]^{2+}\cdot + n\text{-Bu}\cdot \quad (8)$$

butyl radicals, in competition with the back electron transfer to the ground state (k_{30} in Scheme 1). The presence of $[Rh_2(dicp)_4(I)]^{2+}\cdot$ and *n*-Bu· is supported from the formation of the coupling products, $[Rh_4(dicp)_8(I)_2]^{4+}$ and octane (Eq. 3), respectively, as described above.

Formation of Butyl Radicals in the Initiation Step. The formation of butyl radicals in the photoinitiation step (Eq. 8) is confirmed also by the effect of oxygen, which is a typical radical scavenger, on the photochemical reaction. The GLC analysis of the products in the photochemical reaction of $[Rh_2(dicp)_4]^{2+}$ (8.30×10^{-4} mol dm^{-3}) with *n*-BuI (1.75×10^{-1} mol dm^{-3}) by the irradiation ($\lambda>550$ nm) under oxygen atmosphere showed the formation of equimolar amounts of 1-butanol and butyraldehyde (26% based on the initial Rh concentration). A coupling product $[Rh_4(dicp)_8(I)_2]^{4+}$ also was obtained in a 33% yield, being close to those of 1-butanol and butyraldehyde. Thus, the stoichiometry of the photochemical reaction under oxygen may be given by Eq. 9. In the presence of oxygen, the butyl radicals should be trapped by oxygen molecules to yield butylperoxyl radicals (Eq. 10), which is known to undergo a bimolecular self-reaction, producing equimolar amounts of 1-butanol and butyraldehyde as well as oxygen (Eq. 11).[22] Thus, the formation of equimolar amounts of 1-butanol and butyraldehyde (Eq. 9) provides unambiguous evidence for

$$2[Rh_2(picp)_4]^{2+} + 2C_4H_9I + O_2 \xrightarrow[>550\,nm]{h\nu} [Rh_4(dicp)_8(I)_2]^{4+} + C_4H_9OH + C_3H_7CHO \quad (9)$$

$$C_4H_9\cdot + O_2 \longrightarrow C_4H_9O_2\cdot \quad (10)$$

$$2C_4H_9O_2\cdot \longrightarrow C_4H_9OH + C_3H_7CHO + O_2 \quad (11)$$

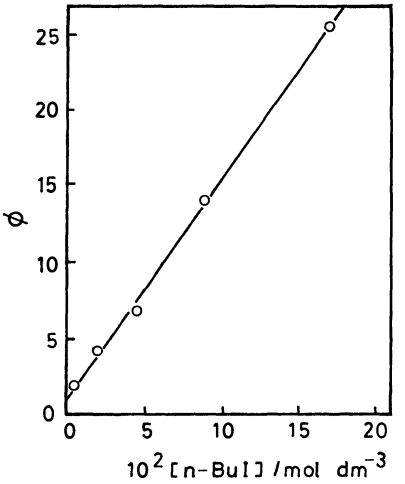


Fig. 2. Quantum yields for the photoinduced oxidative addition of *n*-BuI to $[Rh_2(dicp)_4]^{2+}$ (7.59×10^{-4} mol dm^{-3}) in MeCN at 298 K, as a function of the *n*-BuI concentration.

the formation of the butyl radicals in the photoinitiation step (Eq. 8). Oxygen molecules thus suppress the chain process to yield the oxidative adduct, where the butyl radical may act as a chain carrier, resulting in the reduction of the quantum yields (Table 1).

Kinetics and Mechanism of the Photoinduced Oxidative Addition. At a constant light intensity (7.08×10^{-9} einsteins min^{-1}) the quantum yield for the disappearance of $[Rh_2(dicp)_4]^{2+}$ in the photochemical reaction with *n*-BuI shows a linear dependence on the *n*-BuI concentration with the intercept of unity as shown in Fig. 2, from which Eq. 12 is derived,

$$\Phi = 1 + a[n\text{-BuI}], \tag{12}$$

where a is equal to 1.37×10^{2} mol^{-1} dm^3. A reaction scheme to account for the kinetic result (Eq. 12) is proposed as follows,

Initiation:

$$[Rh_2(dicp)_4]^{2+} + n\text{-BuI} \xrightarrow[h\nu]{\alpha In} [Rh_2(dicp)_4(I)]^{2+}\cdot + n\text{-Bu}\cdot \tag{13}$$

Propagation:

$$n\text{-Bu}\cdot + [Rh_2(dicp)_4]^{2+} \xrightarrow{k_1} [Rh_2(dicp)_4(n\text{-Bu})]^{2+}\cdot \tag{14}$$

$$[Rh_2(dicp)_4(n\text{-Bu})]^{2+}\cdot + n\text{-BuI} \xrightarrow{k_2} [Rh_2(dicp)_4(n\text{-Bu})(I)]^{2+} + n\text{-Bu}\cdot \tag{15}$$

Termination:

$$2[Rh_2(dicp)_4(n\text{-Bu})]^{2+}\cdot \xrightarrow{k_3} Bu\text{-}Bu + 2[Rh_2(dicp)_4]^{2+} \tag{16}$$

$$2[Rh_2(dicp)_4(I)]^{2+}\cdot \xrightarrow{k_4} [Rh_4(dicp)_8(I)_2]^{4+}, \tag{17}$$

Scheme 2.

where *In* is the light intensity absorbed by $[Rh_2(dicp)_4]^{2+}$ and α is the quantum yield for the photoinitiation step. The initiation step (Eq. 13) consists of the electron transfer quenching of $[Rh_2(dicp)_4]^{2+*}$ with *n*-BuI (Eq. 7) and the subsequent fast reaction to yield butyl radicals (Eq. 8). One of the propagation reactions (Eq. 15) also may consist of essentially the same reaction sequence as Eqs. 7 and 8, *i.e.*, an electron transfer from $[Rh_2(dicp)_4(n\text{-Bu})]^{2+}\cdot$ to *n*-BuI, followed by the facile fission of *n*-Bu–I bond to reproduce butyl radicals since the donor ability of $[Rh_2(dicp)_4(n\text{-Bu})]^{2+}\cdot$ is enhanced by the electron donating *n*-Bu group. The termination reactions (Eqs. 16 and 17) account for the coupling products in Eq. 3. The coupling of butyl radicals as a termination reaction is excluded since the rate-limiting step in the propagation process may be the reaction of $[Rh_2(dicp)_4(n\text{-Bu})]^{2+}\cdot$ with *n*-BuI (Eq. 15).[23]

Applying the steady-state approximation to the radical species involved in Scheme 2, the rate of the disappearance of $[Rh_2(dicp)_4]^{2+}$, $-d[Rh_2^{2+}]/dt$, is expressed as Eq. 18, from which the quantum yield Φ is given by Eq. 19. This equation is consistent with the kinetic result (Eq. 12) with respect to the dependence of the quantum yield on the *n*-BuI concentration. The comparison of Eq. 19 with Eq. 12 indicates that the quantum yield α for the photoinitiation step is *unity* and neither the back electron transfer to the ground state (k_{30} in Scheme 1) nor geminate recombination of the radical pair (Eq. 20) occurs in the photoinitiation step.

$$-\frac{d[Rh_2^{2+}]}{dt} = \alpha In + k_2\left(\frac{\alpha In}{2k_3}\right)^{1/2}[n\text{-BuI}] \tag{18}$$

$$\Phi = \alpha + k_2\left(\frac{\alpha}{2k_3 In}\right)^{1/2}[n\text{-BuI}] \tag{19}$$

$$([Rh_2(dicp)_4(I)]^{2+}\cdot n\text{-Bu}\cdot) \not\longrightarrow [Rh_2(dicp)_4(n\text{-Bu})(I)]^{2+} \tag{20}$$

The fluorescence quantum yield of $[Rh_2(dicp)_4]^{2+*}$ ($^1A_{2u}$) is 0.056[7] and therefore the remaining 94% of the excited species falls in the excited triplet state $^3A_{2u}$ by intersystem crossing. Then, the fluorescence quenching by *n*-BuI which is only 0.1% for the smallest concentration of *n*-BuI in Table 1 (2.92×10^{-3} mol dm^{-3})[24] cannot account for the high efficiency of the photoinitiation, $\alpha=1$. The much longer lifetime of the $^3A_{2u}$ state (8.5 μs)[7] than the $^1A_{2u}$ sate (1.3 ns) may, however, make it possible that the $^3A_{2u}$ sate is efficiently quenched by *n*-BuI with $\alpha=1$. The contribution of the lower excited states such as vibrationally excited state to the electron transfer reaction may be negligible since the donor ability of such states is much less than that of the $^3A_{2u}$ state. Thus, the excited state $[Rh_2(dicp)_4]^{2+*}$ involved in the photoinitiation step (Eq. 7) may be the triplet state ($^3A_{2u}$) rather than the singlet state ($^1A_{2u}$). The absence of the singlet geminate recombination of the radical pair (Eq. 20) also supports the electron transfer from the $^3A_{2u}$ state to *n*-BuI since the resultant triplet radical pair may diffusively separate without the singlet geminate recombination, yielding the free radicals (Eq. 8) which initiate the chain process (Eqs. 14 and 15).

It should be noted that a similar electron transfer chain mechanism has been proposed for some organic systems, *e.g.*, a substitution reaction of *p*-nitrobenzyl chloride with the sodium salt of 2-nitropropane which proceeds *via* a multi-stage chain sequence involving radical anions and free radicals as intermediates.[13,25] Recently, Chanon and Tobe in their excellent review[26] have formulated such chain reactions in the organic systems as the "DAISET" (Double Activation Induced by Single Electron Transfer) mechanism. The first activation results from the transfer of an electron to a molecular species (*e.g.*, Eq. 7); the second activation results from the build-up of a reaction chain capable of reproducing the species formed in the first step (*e.g.*, Eqs. 14 and 15). They have attempted to expand the "DAISET" mechanism in organic systems to some inorganic reactions in which the "DAISET" behavior is much less common, and have discussed a possibility of the existence of the "DAISET" mechanism in some reactions of d^8 square-planar complexes (*e.g.*, Rh^I). The present study thus provides an unique and unambiguous example of the "DAISET" mechanism in the inorganic counterpart.

Epilaurallene, a New Nonterpenoid C_{15}-Bromoallene from the Red Alga *Laurencia nipponica* Yamada[1)]

Minoru Suzuki, Kuniko Koizumi, Hajime Kikuchi, Teruaki Suzuki, and Etsuro Kurosawa*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received July 1, 1982)

A new halogenated nonterpenoid C_{15}-compound, epilaurallene, has been isolated as a major constituent from the title alga along with several known compounds, and its structure was determined by the spectral and chemical methods. Epilaurallene is an epimer at C-4 of laurallene and was shown to possess *S*-configuration at C-4.

Within the Japanese species of genus *Laurencia* (Rhodomelaceae), *L. okamurai* Yamada (Mitsude-sozo) collected at various locations have contained laurinterol and debromolaurinterol as the characteristic major metabolites of this species.[2,3)] On the other hand, *L. nipponica* Yamada (Ura-sozo) have produced diverse terpenic and nonterpenic C_{15}-metabolites which seem to be mainly dependent upon the growth locality.[4)] As part of further studies on the constituents of *L. nipponica*, we examined a specimen collected at Tsukotan, near Oshoro Bay, Hokkaido, and isolated a new nonterpenoid C_{15}-bromoallene, designated as epilaurallene, as a major component. In this paper we describe the isolation and structural elucidation of this compound in full details.

Neutral methanol extracts obtained by the usual methods were submitted to repeated column and thin-layer chromatography to yield epilaurallene (**1**) together with known compounds, 10-bromo-α-chamigrene,[5)] laurene,[6)] (*E*)-γ-bisabolene 8,9-oxide,[7)] cycloeudesmol,[8)] (3*E*)-isolaureatin (T-laureatin),[9)] isolaureatin,[10)] and laureatin.[10)]

Epilaurallene (**1**), $C_{15}H_{20}O_2Br_2$ (*m/e* 313 and 311; M^+-Br), $[\alpha]_D^{25}$ +175° (*c* 1.00), mp 51—52 °C, showed the very similar IR ($CHCl_3$), ^1H NMR (200 MHz), and mass spectra to those of laurallene (**2**), which has previously been isolated from *L. nipponica* collected at Oshoro Bay and whose structure has been determined as **2** excluding the stereochemistry of C-4 and bromoallene moiety.[11)] However, the IR spectra of **1** and **2** in Nujol mulls were clearly distinguishable as shown in Fig. 1. Mixed mp of **1** and **2** revealed no depression, and instead higher mp (56—58 °C) than that of each compound. Furthermore, in the ^{13}C NMR spectra of **1** (Table 1) and **2**,[12)] fourteen of the fifteen carbon atoms showed the same chemical shifts while the remaining one carbon, which was assigned to C-4 by proton selective decoupling experiment, revealed the different chemical shift by 0.029 ppm. Above-mentioned data suggest that epilaurallene (**1**) would be an epimer at C-4 of laurallene (**2**). The structure of **1** was established by the following chemical reactions.

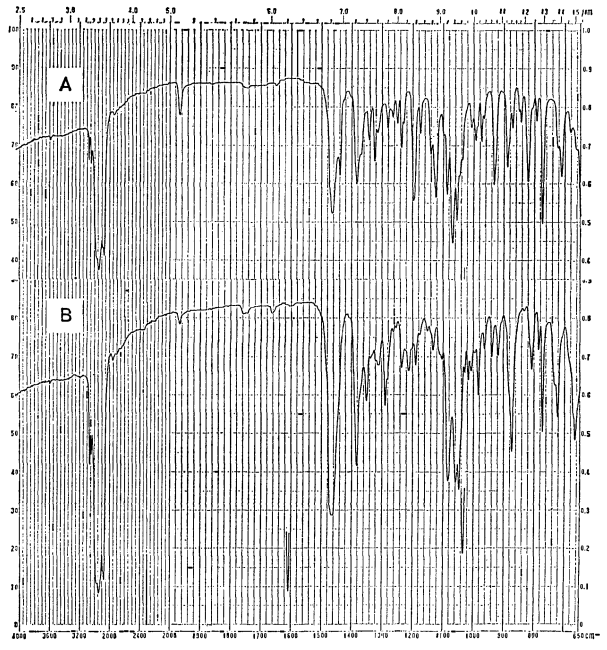

Fig. 1. IR (Nujol) spectra of (A) epilaurallene and (B) laurallene.

Hydrogenation of **1** with PtO_2 in ethanol gave two products, one of which was found to be identical with **3** previously derived from laurallene (**2**).[11)] Another hydrogenated product **4**, $C_{15}H_{27}O_2Br$ (*m/e* 277 and 275; $M^+-C_3H_7$), showed almost identical spectra (IR and ^1H NMR) with those of **5** also derived from **2**.[11)] Treatment of **4** with zinc in acetic acid and methanol

afforded an unsaturated alcohol **6**, $C_{15}H_{28}O_2$ (*m/e* 240; M^+); ν_{max} 3400 and 970 cm^{-1}, δ 3.76 (1H, ddd, J=7, 7, and 3 Hz), 4.1—4.3 (2H, m), and 5.3—5.5 (2H, m), whose spectral data revealed the close resemblance to those of the reduction product **7** of **5**.[11] Compound **6**, when treated with carbon tetrabromide and triphenylphosphine in dry ether, gave a bromide **8**, $C_{15}H_{27}OBr$ (*m/e* 304 and 302; M^+); δ 3.7—4.1 (3H, m) and 5.2—5.5 (2H, m), whose IR spectrum indicated no hydroxyl absorption. Compound **8** was further subjected to Zn–AcOH–MeOH reduction followed by hydrogenation (PtO_2 in ethyl acetate) to yield 4-pentadecanol (**9a**), $C_{15}H_{32}O$ (*m/e* 210; M^+-H_2O), $[\alpha]_{589}^{25}$ +0.87° and $[\alpha]_{365}^{25}$ +3.55°, mp 43 °C; ν_{max} 3350 cm^{-1}, δ *ca.* 3.5 (1H, m). Acetylation of **9a** with acetic anhydride in pyridine gave the corresponding acetate **9b**, $C_{17}H_{34}O_2$ (*m/e* 227; $M^+-C_3H_7$), $[\alpha]_{589}^{25}$ +1.32° and $[\alpha]_{365}^{25}$ +4.25°; ν_{max} 1740 and 1240 cm^{-1}.

On the other hand, compound **3**, on treatment with Raney-Ni in ethanol and successive bromination with carbon tetrabromide and triphenylphosphine in ether, gave a bromide **10**, $C_{15}H_{29}OBr$ (*m/e* 306 and 304; M^+); ν_{max} 1132 and 1080 cm^{-1}, δ 3.3—3.9 (2H, m) and 4.14 (1H, ddd, J=10, 6, and 4 Hz). Moreover, treatment of **10** with zinc in acetic acid and methanol followed by hydrogenation (PtO_2 in ethyl acetate) afforded 4-pentadecanol (**11a**), $C_{15}H_{32}O$, mp 43—44 °C, $[\alpha]_{589}^{25}$ −0.74° and $[\alpha]_{365}^{25}$ −2.17°, which was further converted into the corresponding acetate **11b**, $C_{17}H_{34}O_2$, $[\alpha]_{589}^{25}$ −1.53° and $[\alpha]_{365}^{25}$ −5.60°. The IR, ^1H NMR, and mass spectra of **11a** and **11b** were identical with those of **9a** and **9b**, respectively. Mixed mp of **9a** and **11a** exhibited distinct depression (mp 38 °C).[13]

Since the (*R*)-configuration at C-12 in **3** is kept during the transformation procedure from **3** into **11a**, the configuration at C-4 in **11a** is *S*. Furthermore, 4-pentadecanol (**9a**) derived from **4** was apparently indicated to be an enantiomer of (*S*)-4-pentadecanol (**11a**) by comparison of the optical rotations of **9a**, **9b**, **11a**, and **11b** in different wavelength. Consequently, the stereochemistry at C-4 of epilaurallene (**1**) must be *S*-configuration, and hence the configuration at C-4 of laurallene (**2**) must be *R*.

In view of the strong positive rotations of **1** and **2**, which are due to their bromoallene moieties, the absolute configuration of the allene moiety in **1** and **2** would be assigned as *S* by application of Lowe's rule.[14] Thus, the structure of epilaurallene should be represented by formula **1**.

The finding of epilaurallene (**1**) in *L. nipponica* collected at Tsukotan, near Oshoro Bay, prompted us to reinvestigate the metabolites of Oshoro's specimens which have previously contained laurallene (**2**) as the main component. Surprisingly, fresh algae (coll. at several locations in Oshoro Bay, in April and May, 1982) displayed the existence of epilaurallene (**1**) as a major metabolite and absence of laurallene (**2**). These results appear to suggest that the major secondary metabolite(s) of *L. nipponica* sometimes changes or interconverts in a few years (or every year (?)).[15]

Experimental

All the melting points were uncorrected. The IR spectra were measured on a JASCO A-102 spectrometer. The ^1H NMR spectra were recorded on a JEOL FX-100 spectrophotometer, unless otherwise stated, TMS being used as an internal reference in $CDCl_3$. The ^{13}C NMR spectra were obtained with a JEOL FX-200 spectrophotometer in $CDCl_3$. The optical rotations were measured on a JASCO DIP-181 polarimeter in $CHCl_3$. Aluminium oxide (Merck, activity II-III) and silica gel (Merck, Kieselgel 60, 70—230 mesh) were used for column chromatography. Silica gel (Merck, Kieselgel GF_{254} (Type 60)) was used for preparative thin-layer chromatography. All known compounds were identified by comparison of the spectral data with those of the authentic specimens.

Isolation. *Laurencia nipponica* was collected in April, May, and June 1981, at Tsukotan, near Oshoro Bay,

Hokkaido. The neutral methanol extracts (*ca.* 1% of the half-dried alga) obtained by the conventional methods were fractionated by column chromatography over alumina. The fraction eluted with hexane was chromatographed on silica-gel column to yield 10-bromo-α-chamigrene[5] (1% of the extracts) and laurene[6] (0.5%). The fraction eluted with benzene was repeatedly subjected to a combination of silica gel column and thin-layer chromatography to give a mixture of fatty acid esters (10%; main component, methyl palmitate), (3*E*)-isolaureatin[9] (1%), isolaureatin[10] (1%), laureatin[10] (3%), and (*E*)-γ-bisabolene 8,9-oxide[7] (2%). The fraction eluted with ether was further chromatographed on silica-gel column to yield epilaurallene (**1**) (25%), cycloeudesmol[8] (1%), and an unidentified alcohol (0.5%).

*Epilaurallene (**1**)*: Mp 51—52 °C (from hexane or MeOH); $[\alpha]_D^{25}$ +175° (*c* 1.00); IR (Nujol), ν_{max} 3060, 3025, 1959, 1190, 1120, 1085, 1065, 1053, 928, 818, 765, and 706 cm^{-1}; ^1H NMR (200 MHz), δ 1.09 (3H, t, *J*=7 Hz), 1.7—2.8 (8H, m), 4.0—4.2 (3H, m), 4.24 (1H, m), 4.85 (1H, m), 5.46 (1H, dd, *J*=5 and 5 Hz), 5.7—6.0 (2H, m), and 6.07 (1H, dd, *J*=5 and 2 Hz); MS, *m/e* (rel intensity) 313, 311 (2; M^+-Br), 275, 273 (58; $M^+-C_3H_2Br$), 193 (14; $M^+-C_3H_2Br-HBr$), 149 (9), 123 (15), 121 (15), 109 (31), 107 (75), 81 (30), 79 (100), 77 (38), 67 (69), 65 (29), 55 (56), and 41 (62).

Found: C, 45.94; H, 5.14; Br, 40.75%. Calcd for $C_{15}H_{20}O_2Br_2$: C, 45.88; H, 5.06; Br, 40.55%.

*Hydrogenation of **1**.* The hydrogenation of **1** (40 mg) was performed in EtOH over PtO_2-catalyst. After removal of the catalyst and the solvent, the residual oil was chromatographed on silica-gel column to give **3** (10 mg) and **4** (15 mg). The polar product **3**; colorless oil; $[\alpha]_D^{27}$ +11.1° (*c* 0.718); IR (film), ν_{max} 3450, 1285, 1213, 1128, 1107, 1090, 1053, 958, and 797 cm^{-1}; ^1H NMR, δ 0.89 (3H, br t, *J*=6 Hz), 1.06 (3H, t, *J*=7 Hz), and 3.5—4.1 (4H, m); MS, *m/e* 240 (1; M^+-HBr), 223, 221 (1), 199 (2), 141 (12), 123 (95), 83 (35), 81 (100), 67 (53), 55 (91), 44 (30), and 42 (50): These spectral data were consistent with those of one of the hydrogenation product **3** of laurallene (**2**).[11] The less polar product **4**; colorless oil; $[\alpha]_D^{27}$ +17.0° (*c* 1.17); IR (film), ν_{max} 1277, 1088, 1066, 920, and 795 cm^{-1}; ^1H NMR, δ 0.92 (3H, br t, *J*=6 Hz), 1.08 (3H, t, *J*=7 Hz), 3.6—4.2 (4H, m), and 4.35 (1H, m); MS, *m/e* 277, 275 (10; $M^+-C_3H_7$), 197 (68), 95 (35), 81 (53), 69 (43), 67 (21), 55 (92), 44 (31), and 42 (100).

*Conversion of **4** into **6**.* To a soln of **4** (96 mg) in MeOH (6 ml) containing 350 μl of acetic acid was added activated Zn-dust (350 mg), and the mixture was refluxed for 4 h. After cooling and filtering off Zn-dust, the mixture was extracted with ether. The ether soln was washed successively with water, 5% aqueous $NaHCO_3$, and water. After drying over Na_2SO_4, the solvent was removed to leave residual oil, which was purified by column chromatography on silica gel to afford **6** (72 mg); colorless oil; $[\alpha]_D^{25}$ +4.5° (*c* 1.57); IR, ν_{max} 3400, 1070, 1020, and 970 cm^{-1}; ^1H NMR, δ 0.93 (3H, br t, *J*=6 Hz), 0.96 (3H, t, *J*=7 Hz), 1.8—2.3 (4H, m), 3.76 (1H, ddd, *J*=7, 7, and 3 Hz), 4.1—4.3 (2H, m), and 5.3—5.5 (2H, m); MS, *m/e* 240 (3; M^+), 197 (4), 141 (4), 123 (13), 100 (12), 95 (14), 82 (86), 81 (39), 57 (100), 55 (53), and 42 (22).

*Conversion of **6** into **8**.* A soln of **6** (72 mg) in dry ether (8 ml) was refluxed with triphenylphosphine (160 mg) and carbon tetrabromide (200 mg) for 4 h in N_2 atmosphere and then cooled. The subsequent removal of the solvent gave a residual substance, which was purified by repeated column chromatography on alumina or silica gel to yield **8** (45 mg); colorless oil; $[\alpha]_D^{25}$ −8.6° (*c* 1.09); IR (film), ν_{max} 1091, 1028, and 977 cm^{-1}; ^1H NMR, δ 0.93 (3H, br t, *J*=6 Hz), 0.96 (3H, t, *J*=7 Hz), 1.8—2.2 (4H, m), 3.7—4.1 (3H, m), and 5.2—5.5 (2H, m); MS, *m/e* 304, 302 (1; M^+), 261, 259 (1), 223 (17), 135 (18), 95 (56), 81 (53), 69 (71), 67 (56), 55 (95), and 42 (100).

*4-Pentadecanol (**9a**) from **8**.* To a soln of **8** (45 mg) in MeOH (4 ml) containing 250 μl of acetic acid was added activated Zn-dust (300 mg), and the mixture was refluxed for 3 h. After being cooled and then filtered off, the mixture was extracted with ether. The ether soln was worked up as usual to give an oily residue, which was chromatographed on silica-gel column to yield an unsaturated alcohol (23 mg); colorless oil, IR (film), ν_{max} 3350, 1260, 1020, and 967 cm^{-1}; ^1H NMR, δ 0.93 (3H, br t, *J*=6 Hz), 0.96 (3H, t, *J*=7 Hz), *ca.* 3.5 (1H, m), and 5.2—5.6 (4H, m); MS, *m/e* 224 (0.2; M^+), 206 (1), 110 (33), 96 (26), 82 (34), 81 (34), 68 (48), 67 (50), and 55 (100). The hydrogenation of the unsaturated alcohol was carried out in ethyl acetate over PtO_2-catalyst. After removal of the catalyst and the solvent, the product was purified by column chromatography on silica gel to give **9a** (18 mg); colorless crystals; mp 43 °C; $[\alpha]_D^{25}$ +0.87° (*c* 1.87), $[\alpha]_{577}^{25}$ +1.04°, $[\alpha]_{546}^{25}$ +1.25°, $[\alpha]_{435}^{25}$ +2.30°, and $[\alpha]_{365}^{25}$ +3.55°; IR (Nujol), ν_{max} 3350 cm^{-1}; ^1H NMR, δ 0.8—1.0 (6H) and *ca.* 3.5 (1H, m); MS, *m/e* 210 (2; M^+-H_2O), 185 (19; $M^+-C_3H_7$), 97 (34), 73 (100; $M^+-C_{11}H_{23}$), and 55 (91).

*Acetylation of **9a**.* Acetylation of **9a** (15 mg) was carried out with acetic anhydride in pyridine in the usual manner. The acetylated product was purified by column chromatography on silica gel to give **9b** (13 mg); colorless oil; $[\alpha]_D^{25}$ +1.32° (*c* 1.06) and $[\alpha]_{365}^{25}$ +4.25°; IR (film), ν_{max} 1740, 1240, and 1020 cm^{-1}; ^1H NMR, δ 0.8—1.0 (6H), 2.04 (3H, s), and 4.88 (1H, dddd, *J*=6, 6, 6, and 6 Hz); MS, *m/e* 227 (1; $M^+-C_3H_7$), 210 (2; M^+-CH_3COOH), 115 (7; $M^+-C_{11}H_{23}$), 97 (5), 83 (4), 69 (4), 55 (6), and 43 (100).

*Conversion of **3** into **10**.* To a soln of **3** (110 mg) in EtOH (15 ml) was added freshly prepared W-7 Raney nickel (from 1.5 g of Al-Ni alloy) and then 2 M KOH (1 ml), and the mixture was refluxed for 2 h. After removal of the catalyst, water was added and the most of the solvent was evaporated under reduced pressure. The residue was extracted with ether, and the ether soln was washed with water, dried over Na_2SO_4, and evaporated to leave the debromo alcohol (78 mg); IR (film), ν_{max} 3420, 1125, 1075, 1046, 1012, and 948 cm^{-1}; ^1H NMR, δ 0.8—1.0 (6H) and 3.4—3.8 (3H, m); MS, *m/e* 242 (3; M^+), 82 (100), 57 (59), and 55 (56). Bromination of the above debromo alcohol (150 mg) was performed with triphenylphosphine (300 mg) and carbon tetrabromide (400 mg) in dry ether (10 ml) under the similar reaction conditions in the case of **6** to give **10** (105 mg); colorless oil; $[\alpha]_D^{27}$ −5.8° (*c* 0.24); IR (film), ν_{max} 1180, 1132, and 1080 cm^{-1}; ^1H NMR, δ 0.9—1.0 (6H), 3.3—3.9 (2H, m), and 4.14 (1H, ddd, *J*=10, 6, and 4 Hz); MS, *m/e* 306, 304 (1; M^+), 263, 261 (1), 125 (27), 82 (80), 69 (94), 55 (100), and 42 (8).

*(S)-4-Pentadecanol (**11a**) from **10**.* To a soln of **10** (105 mg) in MeOH (6 ml) containing 350 μl of acetic acid was added activated Zn-dust (200 mg), and the mixture was refluxed for 2 h. After the usual work-up, the resulting unsaturated alcohol was hydrogenated, without further purification, with PtO_2 in ethyl acetate and then purified by column chromatography on silica gel to give **11a** (48 mg); colorless crystals; mp 43—44 °C; $[\alpha]_D^{25}$ −0.74° (*c* 3.33), $[\alpha]_{577}^{25}$ −0.78°, $[\alpha]_{546}^{25}$ −0.92°, $[\alpha]_{435}^{25}$ −1.75°, and $[\alpha]_{365}^{25}$ −2.17°; The spectral properties were identical with those of **9a**.

*Acetylation of **11a**.* Acetylation of **11a** (18 mg) was carried out with acetic anhydride in pyridine by the usual method to give **11b** (15 mg); colorless oil; $[\alpha]_D^{25}$ −1.53° (*c* 1.57) and $[\alpha]_{365}^{25}$ −5.60°; The spectral properties were identical with those of **9b**.

Electrocatalytic Reduction Using Raney Nickel

Toshiro CHIBA,* Mitsuhiro OKIMOTO, Hiroshi NAGAI, and Yoshiyuki TAKATA†

Department of Applied Chemistry, Kitami Institute of Technology, Koen-cho 165, Kitami 090

†*Faculty of Engineering, Hokkaido University, Sapporo 060*

(Received July 3, 1982)

The Raney nickel catalyst was employed as a catalytic electrode in the electrohydrogenation of various unsaturated compounds, including ketones, aromatic aldehydes, Schiff's bases, oximes, nitriles, aromatic nitro compounds, olefins, and acetylenes. The hydrogen generated electrochemically was adsorbed and activated at the surface of the catalyst; it effectively hydrogenated these compounds, affording products which are very similar to those obtained in a normal catalytic hydrogenation with Raney nickel.

Although the Raney nickel (Ra/Ni) catalyst has been widely used as a catalyst in catalytic hydrogenation in the laboratory and on an industrial scale,[1] its application as a catalyst for electrochemical hydrogenation seems to have attracted very little attention.[2,3] Because of a large surface area and a high hydrogen-adsorption activity, Ra/Ni was expected to be applicable as a catalytic electrode. If the electrolytically generated hydrogen is directly used as a reducing agent at the surface of the catalyst, in the hydrogenation with Ra/Ni, it may be possible to avoid the use of an autoclave and comperessed hydrogen gas. Thus, we have attempted electrohydrogenation using a cathode made of nickel plate covered with Ra/Ni powder, and examined its reduction ability.

Results and Discussion

Preparative electrolyses were carried out in the cell depicted in Fig. 2. Almost all of the substrates were electrolyzed in methanol containing sodium methoxide under a constant current and at room temperature. The amount of the catalyst used was 2 g per 0.1 mol of the substrate.

At first, in preliminary experiments using benzophenone, the following facts were confirmed: a) when the Ra/Ni catalyst is omitted and the nickel plate alone is used as the cathode, the reduction of benzophenone to benzhydrol is extremely slow (the current efficiency is less than 10%); instead hydrogen is evolved; b) when the surface of the nickel plate is covered with the catalyst, the reduction proceeds essentially quantitatively, and c) if no current is passed through and hydrogen gas is bubbled through the catholyte in the presence of the catalyst, only about a 20% yield of benzhydrol is formed by the reaction over a period of 10 h. Apparently, Ra/Ni exerted an excellent electrode-catalytic effect.

Table 1 shows the results of the electrohydrogenation of various compounds.

All the ketones employed were effectively reduced predominantly to give the corresponding secondary alcohols. In these cases, hardly no glycols were detectable.[3] Analogous results were obtained with aromatic aldehydes;[4] however, aliphatic aldehydes could not be used since they formed aldol adducts in this medium.

Carbon-nitrogen unsaturated compounds, such as Schiff's bases,[5] nitriles,[6] and oximes,[7] were reduced equally well to the respective amines. The nonaqueous system of methanolic sodium methoxide appeared to be particularly favorable for the reduction of these compounds, which tend to involve C–N bond cleavage in an aqueous solution.[8] Either nitriles or oximes were electrolyzed in the presence of excess amounts of ammonia in order to suppress the formation of undesirable secondary amines.[9]

Under the same conditions, nitrobenzenes afforded anilines as the main products, along with a small amount of hydrodimers,[3,10] whereas aliphatic nitro compounds were not reducible. Probably, this was due to the formation of the anion of the aci-form in the basic solution, which prevented the reduction.[8]

According to this method, not only carbon-carbon conjugated double bonds with a carbonyl group, *etc.*,[11] but also isolated double bonds which are very resistant to conventional electrolytic reduction[12] could readily be hydrogenated. The selective reduction of acetylenes to olefins was not successful, however, since it always was attended by a subsequent reduction to alkanes.

Next, in order to examine the cathodic behavior of Ra/Ni, current-potential relationships were measured in a 0.1 mol dm^{-3} sodium methoxide–methanol solution.

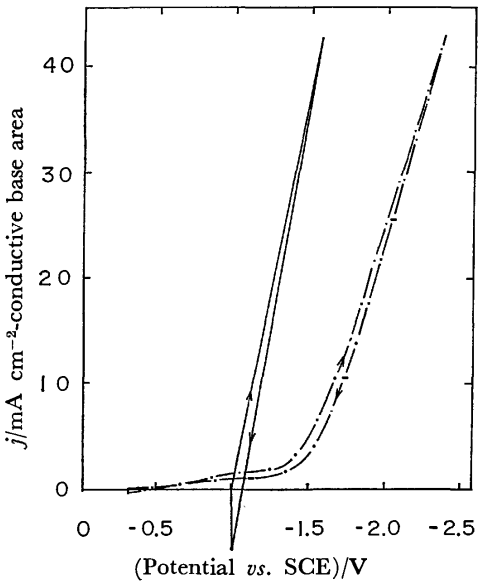

Fig. 1. Current-potential curves for 0.1 M NaOMe–MeOH. ——: at Ra/Ni cathode, ——: at Ni-plate cathode. Sweep rate of 0.1 V/s was used.

a) Anolyte: starting material (0.10 mol) in 150 ml of MeOH containing 0.15 mol of NaOMe. Raney nickel catalyst: 2 g. Constant current: 0.75 A. Temperature: *ca.* 15 °C. b) The products obtained were identified by a comparison of their phisical and IR-spectral data with those of authentic samples or with the literature data. c) Value in brackets refers to yield estimated by GLC. d) Boiling points and melting points are uncorrected. (1 mmHg≈133.322 Pa). e) 180 ml of methanol was used. f) Electrolyzed in 150 ml of a 1.67 mol dm^{-3} NaOH aq solution. g) Continuously extracted with diethyl ether for 12 h. h) The crude products were treated with a saturated sodium hydrogensulfite solution before distillation. i) Isolated as HCl-salt. j) 0.05 mol was used. k) After the removal of the methanol, the residue was diluted with 30 ml of water, refluxed for 10 h, and then continuously extracted with diethyl ether for 12 h. l) An excess amount of ammonia was added to the catholyte. m) Analytical samples were obtained by preparative GLC and were identified with authentic samples by NMR and mass spectroscopy. n) Unreacted acetylene was recovered in a yield of 44%.

As is shown in Fig. 1, the sodium methoxide–methanol electrolyte system was discharged at the potential of −1.0 V *vs.* SCE at a nickel-plate cathode covered with Ra/Ni, in contrast to the potential of −1.5 V at a nickel-plate cathode. Interestingly, in spite of an appreciable increase in the electrolytic current (10 A/dm^2-coductive base area), no evolution of hydrogen was observed, presumably because of a strong adsorption of hydrogen to the Ra/Ni electrode. In this system, the substrates employed, such as ketones and nitriles, showed no reduction waves below the potential of −1.0 V. Consequently, it was reasonable to assume that the reduction takes place by adsorbed hydrogen atoms which are electrolytically generated and activated under the catalytic influence. rather than by direct electron-transfer between the substrate and the electrode.

In conclusion, the Ra/Ni electrode brought about the hydrogenation of various compounds, and the course of the reaction resembled that taken by a normal catalytic hydrogenation with Ra/Ni and elemental hydrogen. It seemed to be especially attractive in that the reduction using Ra/Ni, which usually requires an increased temperature and pressure except for the use of Ra/Ni W-6, is possible at room temperature and atmospheric pressure,[14] while the hydrogenation of aromatic nuclei[15] or the hydrogenolysis of carbonyl groups of acid amides or esters was impossible. Application to compounds with two different functional groups is currently being undertaken, including the

use of other Raney catalysts, *e.g.*, Ra/Co, Ra/Cu, and Ra/Fe.

Experimental

Apparatus. The preparative electrolyses were carried out in the two-compartment cell depicted in Fig. 2. On the bottom of the cathode compartment (200 ml), a conductive base of nickel plate ($\phi=5.0$ cm) is placed. As the anode compartment, a ceramic cup (2 mm wall thickness, 17 cm high, and 1.8 cm in diameter) is used; it is provided with a platinum coil anode and an inlet and outlet for the circulation of the anolyte. The cell is externally cooled with water.

Preparation of Raney Nickel Catalyst. In a 300-ml round-bottom flask, 4.0 g of Raney nickel alloy powder (Ni content, *ca.* 50%) is suspended in 40 ml of distilled water. Then, 6.5 g of sodium hydroxide pellets are added all at once. An exothermic reaction occurs with a vigorous evolution of hydrogen. After the evolution of hydrogen slows, the suspension is digested at 60 °C on a steam bath for 30 min with occasional shaking and then allowed to attain room temperature. The alkaline solution is decanted, and the nickel is washed three times with 50-ml portions of distilled water, followed by three washings with 25-ml portions of methanol. The Raney nickel catalyst obtained in this manner weighs about 2 g, and its activity is comparable to that of W-2.[16]

General Procedure. The cathode compartment is charged with 0.10 mol of a substrate dissolved in 150 ml of methanol containing 0.15 mol of sodium methoxide (unsaturated carboxylic acids, keto acids, and salicylaldehyde are electrolyzed in 150 ml of 1.67 mol dm^{-3} aqueous sodium hydroxide). Then, about 2 g of freshly prepared Raney nickel catalyst is added to the catholyte and allowed to settle on the nickel plate. The anolyte of the same concentration of methanolic sodium methoxide is circulated by pumping, and the current is turned on. During the electrolysis, the catholyte is occasionally stirred with a glass rod.

All electrolyses were conducted under a constant current of 0.75 A until almost all of the substrate has been consumed (1.1—1.8 of the theoretical current is passed through). After the reduction, the catholyte is filtered from the catalyst and treated as follows.

Work-up Procedure. A): The resulting catholyte is diluted to 2 volumes with methanol, and carbon dioxide is bubbled into the solution. The precipitated sodium carbonate is filtered off and washed with methanol (20 ml × 2). The filtrate and washings are combined and distilled.

B): After the removal of the solvent, the residue is acidified with 18% hydrochloric acid. The separated oily layer is extracted with diethyl ether (30 ml × 4), dried with magnesium sulfate, and distilled or recrystallized.

C): The reaction mixture is concentrated to 1/2 volume, acidified with 18% hydrochloric acid, and evaporated to dryness. The remaining solid is dissolved in water, washed thoroughly with diethyl ether, and made strongly alkaline with sodium hydroxide. The separated oily layer is extracted with diethyl ether (30 ml × 4), dried with sodium hydroxide, and distilled over a few pellets of sodium hydroxide.

D): The catholyte is poured into 2 volumes of water. The separated oily layer is extracted with hexane (30 ml × 4), washed with water, dried with anhydrous potassium carbonate, and distilled.

Convenient Preparation of Dimethyl (Trifluoromethyl)malonate and Related Compounds

Nobuo Ishikawa* and Tsutomu Yokozawa

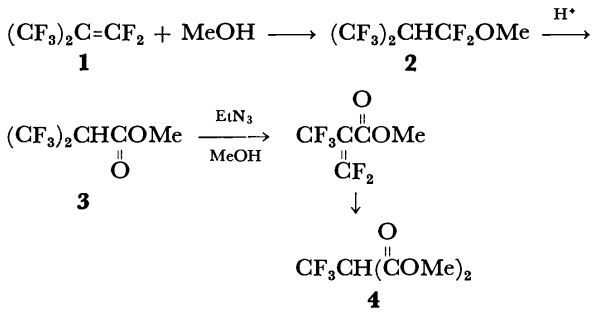
Department of Chemical Technology, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received July 12, 1982)

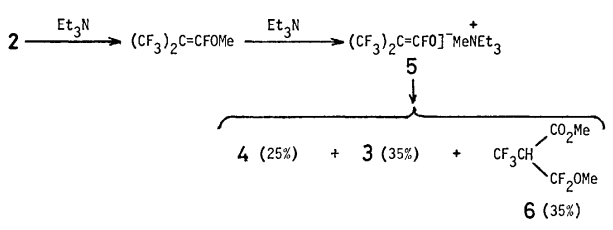
The preparative method for dimethyl (trifluoromethyl)malonate (**4**) from the adduct of perfluoro-2-methylpropene with methanol was improved, and several reactions of this base-sensitive substance were investigated. Alkylation of **4** was achieved by using CsF as a condensing agent, and the Michael addition on vinyl ketones proceeded in triethylamine–pyridine medium.

Organic molecules bearing a trifluoromethyl group have recently been drawing attention because of their possible biological activities.[1,2] One of the attractive methods for the preparation of this kind of compounds is to prepare some versatile intermediates carrying a trifluoromethyl group and to utilize them as building blocks. As one of these building blocks, (trifluoromethyl)malonic ester seemed to be useful because it would afford various trifluoromethylated aliphatic or heterocyclic compounds by the usual synthetic methods.

Dimethyl (trifluoromethyl)malonate (**4**) has already been prepared by Knunyants' group[3,4] from *F*-2-methylpropene (**1**), an extremely toxic perfluoroalkene gas. By their method, the adduct (**2**) of **1** with methanol, a stable liquid, was hydrolyzed with concd sulfuric acid, and the resulting ester (**3**) was subjected to alcoholysis in the presence of triethylamine to give **4**.



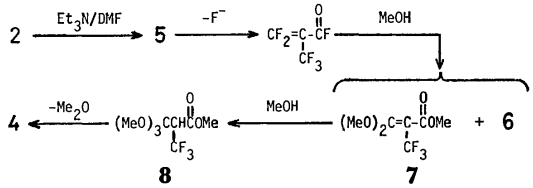
Another report form his group[5] also revealed the formation of **4** together with **3** and **6** from an enolate anion (**5**) generated by the reaction of **2** with triethylamine.



Although the reported yield of **4** is poor, the latter process, a one-step reaction from the adduct **2**, was more attractive to us and we were able to find the optimum conditions to produce **4** in sufficient yields. Some reactions of **4** including alkylations and Michael additions were examined. Although the results were not those which we had expected, we observed several interesting behaviors of **4** in its reaction mode.

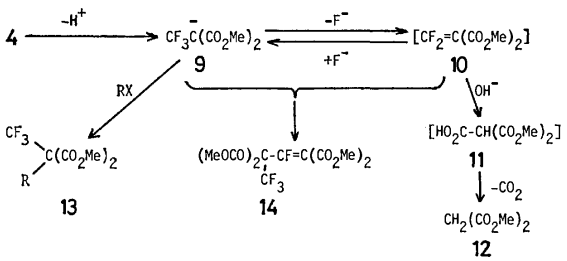
Results and Discussion

Improved Preparation of 4. The adduct **2** was found to be readily converted to the enolate **5** in *N,N*-dimethylformamide by treating it with 2 mol of triethylamine, and **5** thus formed was subjected to methanolysis at room temperature. The major product was a ketene acetal **7**, formed together with a small amount of **6**. By treating the mixture with concd sulfuric acid **4** was obtained in a yield of 68% based on **2**.



Alkylation of 4. Regarding the reactivities of (trifluoromethyl)malonic esters, it is known[4] that they are susceptible to the attack of an alkali, forming a terminal difluoromethylene compound (**10**) which is degraded to the nonfluorinated dimethyl malonate (**12**) *via* a carboxylic acid (**11**). This behavior makes the reaction of **4**, such as alkylation under alkaline conditions, impossible.

To avoid this degradation, cesium fluoride was used as a neutral proton-removing agent. The subsequent alkylation with an alkyl halide gave 2-alkyl-2-(trifluoromethyl)malonic ester (**13**) together with an addition product (**14**) of **9** and **10** as a by-product.



When potassium fluoride instead of cesium fluoride was used in this reaction, the formation of **14** was accelerated considerably. Particularly, in the reaction with benzyl or allyl bromide, the formation of alkylated product **13** was not observed (Table 1). This should be due to the stronger ionizing ability of CsF compared with that of KF. Thus, when CsF was used, the higher concentration of fluoride ions in the reaction

Table 1. Formation of **13** and **14**

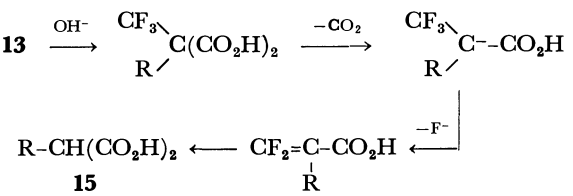
a) Based on ^{19}F NMR signal intensities.

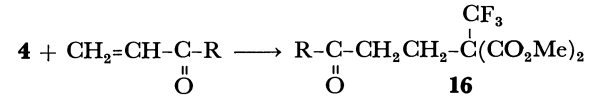
mixture would increase the amount of carbanion **9** rather than **10** in an equilibrium between them, resulting in the increase of the formation of alkylated product **13**. On the other hand, the lower concentration of fluoride ions in the case of KF, would rather favor the formation of the defluorinated intermediate **10** and the subsequent reaction with **9** forming **14** would occur instantly. In the absence of alkyl halides, we could obtain **14** in a good yield by the reaction of **4** with sodium hydride, a much stronger base containing no fluoride ion. A similar compound, tetraethyl ester, had been reported by Knunyants' group.[6]

The alkylation of **4** to give **13** was actually carried out by adding **4** gradually into a mixture of alkyl halide and CsF so that the formation of **14** would be significantly suppressed (Table 2).

Attempted decarboxylation of **13** by heating it with an alkali gave nonfluorinated alkylmalonic acid (**15**), presumably according to the following scheme.



*Michael Addition of **4** to Vinyl Ketones.* As another kind of reactions utilizing the "activated hydrogen" of **4**, its addition to vinyl ketones was carried out. This Michael-type reaction using triethylamine and pyridine as a base and a solvent proceeded smoothly affording 3-oxoalkyl(trifluoromethyl)malonates (**16**) as shown in Table 3.



These derivatives of (trifluoromethyl)malonic esters are expected as useful intermediates for various organic compounds carrying a trifluoromethyl group. Studies for this purpose are now underway.

Experimental[7]

*Dimethyl (Trifluoromethyl)malonate, **4**.* Triethylamine (101.2 g, 1.0 mol) was added dropwise into a mixture of 1,1,3,3,3-pentafluoro-2-(trifluoromethyl)propyl methyl ether (**2**, the adduct of *F*-2-methylpropene with methanol) (116 g, 0.5 mol) and dried *N*,*N*-dimethylformamide (100 ml), keeping the temperature at 10—20 °C. After the addition, methanol (100 ml) was added dropwise into the mixture over a period of 40 min, during which the temperature was kept below 10 °C by cooling with an ice-bath. After being stirred for 70 min at that temperature, the reaction mixture was poured into water and the resultant oily layer was separated. The aqueous layer was subjected to ether extraction and the ethereal extract was combined with the oil and was dried over $MgSO_4$. After removal of the ether, conc. sulfuric acid (10 ml) was added to the residue and the mixture was stirred overnight at room temperature. After the mixture was poured on ice, the resulting oily material was separated, combined with the ethereal extract from the water layer, dried over $MgSO_4$ and subjected to distillation. (Trifluoromethyl)malonate (67.5 g), bp 65—66 °C/10 mmHg† (lit,[3] 72.5—73 °C/9 mmHg), was obtained in a yield of 68%. ^{19}F NMR: δ −11.1 (d, J_{H-F} 8.0 Hz). ^1H NMR: δ 4.11 (q, $CHCF_3$, J_{H-F} 8.0 Hz), 3.83 (s, CH_3). IR: 1755 (C=O) cm^{-1}.

*Dimethyl Methyl(trifluoromethyl)malonate (**13**, R=Me).* A mixture of dried CsF (9.11 g, 60 mmol), diglyme (41 ml), dimethyl (trifluoromethyl)malonate (4 g, 20 mmol), and methyl iodide (3.12 g, 22 mmol) was stirred overnight at room temperature. The reaction mixture was poured into

water and the resultant oily layer and the ether-extract from aqueous layer were combined and washed with water to remove diglyme. After drying over $MgSO_4$, the ether was evaporated and the residue was subjected to distillation, giving dimethyl methyl(trifluoromethyl)malonate (2.56 g, 60%), bp 63—65 °C/10 mmHg. ^{19}F NMR: δ −7.5 (s, $C\underline{F}_3$). ^1H NMR: δ 3.81 (s, 6H, $CO_2C\underline{H}_3$), 1.66 (s, $C\underline{H}_3$).

*Dimethyl Benzyl(trifluoromethyl)malonate (**13**, R=CH_2Ph).* Into a mixture of dried and powdered CsF (9.11 g, 60 mmol), benzyl bromide (8.55 g, 50 mmol), and diglyme (16 ml), a solution of dimethyl (trifluoromethyl)malonate (4.0 g) in diglyme (20 ml) was added at 70—75 °C over a period of 70 min. After being stirred for 50 min at that temperature, the reaction mixture was poured into water and worked up as usual. Benzyl(trifluoromethyl)malonate, **13** (R=CH_2Ph) (2.6 g, 45%) was distilled out at 91—94 °C/0.3 mmHg.

*Tetramethyl 2,4,4,4-Tetrafluoro-1-butene-1,1,3,3-tetracarboxylate (**14**).* Into a mixture of sodium hydride (0.36 g, 15 mmol) and *N,N*-dimethylformamide (5 ml), a solution of **4** (2.00 g, 10 mmol) in *N,N*-dimethylformamide (5 ml) was added dropwise with cooling the vessel in an ice-bath. After being stirred for 2 h at room temperature, the reaction mixture was poured into dilute aqueous HCl, and worked up as usual. Distillation under vacuum gave **13** (1.27 g, 70%), bp 122—124 °C/0.3 mmHg. Found: C, 40.74, H, 3.53%. Calcd for $C_8H_{12}O_8F_4$: C, 40.01; H, 3.36%. ^{19}F NMR: δ −15.1 (d, $C\underline{F}_3$), +10.7 (q, =C$\underline{F}$–). ^1H NMR: δ 3.77 (s, $C\underline{H}_3$), 3.87 (s, $C\underline{H}_3$), 3.90 (s, ($COC\underline{H}_3$)). IR: 1665 (C=C), 1750 (C=O) cm^{-1}.

Degradation of Dimethyl Methyl(trifluoromethyl)malonate. Into a methanolic solution of sodium methoxide prepared from sodium (0.46 g, 20 mmol) and dried methanol (10 ml), a solution of **4** (0.87 g) in methanol (4 ml) was added. After 3.5 h of stirring at room temperature, the reaction mixture was poured into dil aqueous HCl and worked up as usual. Removal of the ether gave pure dimethyl methylmalonate (0.39 g, 67%) which was identified by comparing its IR, ^1H NMR, and GLC data with those of an authentic sample.

*Dimethyl 1,1,1-Trifluoro-5-oxo-2,2-hexanedicarboxylate (**16**, R=Me).* A mixture of **4** (4.0 g, 20 mmol), methyl vinyl ketone (1.54 g, 22 mmol), triethylamine (0.30 g, 3 mmol), and pyridine (20 ml) was heated for 4 h at 70 °C. The reaction mixture was poured into water and worked up as usual. The adduct (3.97 g), bp 88—89 °C/0.2 mmHg, was obtained and identified in a similar way.

Oxidative Dehydrogenation of Bis(salicylideneaminato)copper(II) Complex in Pyridine and Formation of 2-Cyanophenolato Complex

Takayuki MATSUSHITA* and Toshiyuki SHONO

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565

(Received February 8, 1982)

The copper(II) complex of salicylideneamine (salamH) reacts with molecular oxygen in pyridine to give the 2-cyanophenolato complex, $[Cu(2\text{-}CNphO)_2(py)_2]$, in good yield, where 2-CNphOH and py denote 2-cyanophenol and pyridine, respectively. This complex was characterized by the infrared and electronic spectra and by its magnetic susceptibilities, and was compared with the authentic complex, $[Cu(2\text{-}CNphO)_2(py)_2]$. The mechanism for the oxidation of the coordinated imino groups is discussed.

It is well known that copper(II) salts catalyze significantly the oxidation of organic substances by molecular oxygen.[1] Brackman *et al.*[2] have reported that the ammoxidation of alcohols and aldehydes catalyzed by copper(II) salts gives the corresponding nitriles in good yields, and have proposed that the imino function (RCH=NH) which formed by condensation of aldehyde with ammonia was oxidized to nitrile via an intermediate of an imino radical (RCH=N·), involving a Cu(II)/Cu(I) redox system. Misono *et al.*[3] have investigated the kinetics of the formation of benzonitrile from benzaldehyde and ammonia catalyzed by some copper compounds, and have proposed that benzilideneamine is an important intermediate. They have reported that 2-cyanophenol was formed by thermal decomposition of bis(salicylideneaminato)copper(II), $[Cu(salam)_2]$.[4]

The oxidative dehydrogenation of amino and alkylamino groups coordinated to metal ions has been reported.[5] Diamond *et al.*[6] have found that pentaammine(benzylamine)ruthenium(II) ion reacts with molecular oxygen to give pentaammine(benzonitrile)-ruthenium ion. Keene *et al.*[7] have reported that the complexes, $[Ru(bpy)_2(NH_2CH_2R)_2]^{+2}$($NH_2CH_2R$= allylamine, benzylamine, and butylamine) were oxidized chemically and electrochemically to give the corresponding bis(nitrile) complexes, $[Ru(bpy)_2(NCR)_2]^{+2}$ and proposed that the reactions proceed by initial oxidation of Ru(II) to Ru(III), followed by a series of stepwise dehydrogenation reactions which occur via the imine intermediate. Recently, the oxidative dehydrogenation of the coordinated secondary amine moieties to the copper atom has been reported for Cu(II)–4,4′-(ethane-1,2-diyldiimino)bis(pent-3-en-2-one) complex[8] and bi-Cu(I)–macrocyclic complex.[9]

In this paper we wish to report that $[Cu(salam)_2]$ reacts with molecular oxygen to give quantitatively the 2-cyanophenolato complex. This reaction should afford good information on the mechanism of the ammoxidation catalyzed by copper compounds.

Experimental

Preparation of Copper(II) Complexes with Salicylideneamine and Its Analogs. All the complexes with the Schiff bases used in this work were obtained by the method described in the literature. They are abbreviated as follows: Bis(salicylideneaminato)copper(II): $[Cu(salam)_2]$[10a]; bis(substituted salicylideneaminato)copper(II): $[Cu(X\text{-}salam)_2]$[10b], where X can be 5-Me, 3-Me, 3-MeO, 4-Cl, 5-Br, 5,6-Benzo, and 5-NO_2; bis[1-(*o*-hydroxyphenyl)ethylideneaminato)copper(II): $[Cu(hpam)_2]$[10c]; bis(*N*-methylsalicylideneaminato)-copper(II): $[Cu(N\text{-}Mesalam)_2]$[10c].

Isolation of Oxidized Products. Oxidized Product of [Cu(salam)$_2$]: A pyridine solution (300 cm^3) of $[Cu(salam)_2]$ (1.0 g) was kept at 70 °C, with dried air bubbled through it. The green solution turned brown gradually. The reaction was followed by monitering the visible absorption spectra of small portions of the solution at regular intervals. The spectral changes were no longer observed after *ca.* 7 h; the resulting solution was evaporated under reduced pressure. The brown solids were collected on a glass filter, washed with hexane, and dried *in vacuo*. The yield was quantitative. The product is soluble in pyridine (py), *N*,*N*-dimethylformamide (DMF), and dimethyl sulfoxide (DMSO), slightly soluble in dichloromethane, methanol, and benzene, but insoluble in water. This was reprecipitated from a mixture of pyridine and ether.

The oxidized product of $[Cu(salam)_2]$ could be obtained from the reaction between its pyridine solution and an aqueous solution of hydrogen peroxide (30%) at room temperature. This was identified to be the same product as the above. The reaction of $[Cu(salam)_2]$ with molecular oxygen in dioxane was found to give the pale brown product. This is soluble in pyridine, but insoluble in noncoordinating solvents; its formula is [Cu(2-CNphO)(OH)].

All the reaction conditions are summarized in Table 1, together with the empirical formulas of the products. The

analytical data for these products are given in Table 2, along with their magnetic moments determined at room temperature and the frequencies due to ν(CN).

Isolation of 2-Cyanophenol from the Oxidized Product of [Cu(salam)$_2$]. The oxidized product (0.1 g) of [Cu(salam)$_2$] was dissolved in pyridine (10 cm^3). A solution (100 cm^3) of 1 M (1 M=1 mol dm^{-3}) hydrochloric acid was added to it. Hydrogen sulfide gas was passed through the solution for 10 min, followed by passing nitrogen gas for 20 min. The black precipitates were filtered and washed with ether. The filtrate was extracted with ether (50 cm^3). The ethereal washings and extract were combined and dried over anhydrous sodium sulfate, and then evaporated under reduced pressure to yield tan-yellow solids. They were recrystallized from hexane to give white crystals. The yield was 0.04 g. This was identified to be 2-cyanophenol from the elemental analysis, infrared spectrum, and melting point (96.5 °C).

Preparation of 2-Cyanophenolato Complexes. Bis(2-cyanophenolato)bis(pyridine)copper(II), [Cu(2-CNphO)$_2$(py)$_2$]: This complex was obtained by a modification of the method described in the literature.[11] To an aqueous solution (20 cm^3) containing $CuSO_4 \cdot 5H_2O$ (0.75 g, 3 mmol) and pyridine (0.48 g, 6 mmol), an aqueous solution (15 cm^3) of 2-cyanophenol (0.72 g, 6 mmol) and sodium hydroxide (0.24 g, 6 mmol) was added dropwise with stirring. The olive green solids which precipitated were collected on a glass filter, and washed with water, and with small volumes of ethanol and ether, and then dried *in vacuo*. They were recrystallized from dichloromethane to give greenish brown crystals.

2,2′-Bipyridinebis(2-cyanophenolato)copper(II), [Cu(2-CNphO)$_2$(bpy)]. This complex was obtained in a similar way to that used for the above complex, using 2,2′-bipyridine in place of pyridine.

The analytical data for the 2-cyanophenolato complexes are given in Table 2, together with their magnetic moments determined at room temperature and the frequencies due to ν(CN).

Materials. All reagents were of reagent grade. The solvents were purified in the usual manner.

Measurements. The UV, VIS, and NIR spectra were recorded on a Hitachi 340 recording spectrophotometer. The diffused reflectance spectra were obtained by using the above instrument along with a Hitachi R-10 A integrating sphere unit and a NIR integrating sphere unit. The infrared spectra and magnetic susceptibilities were obtained by the method described elsewhere.[12]

Results and Discussion

We have found that a pyridine solution of [Cu(salam)$_2$] changed the color from green to greenish brown on being allowed to stand for a few days at room temperature under air. We are interested in the cause of such a color change.

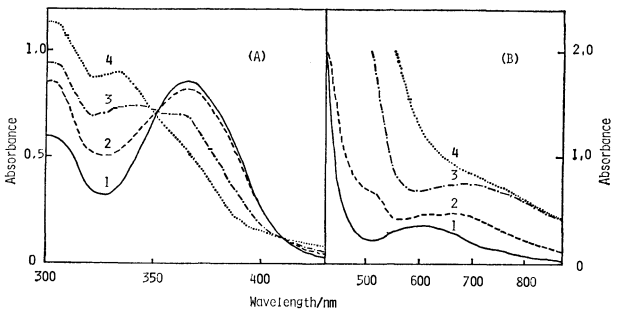

Fig. 1. Absorption spectral changes of pyridine solutions of [Cu(salam)$_2$] at 70 °C under air.
(A); [Complex]=8×10^{-5} M, 1): reaction time=0, 2): 265, 3): 325, 4): 385 min. (B); [Complex]=8×10^{-3} M, 1): reaction time=0, 2): 26, 3): 80, 4): 385 min. Cell length: 1 cm.

Absorption Spectral Changes. Figure 1 shows the absorption spectral changes of a pyridine solution of [Cu(salam)$_2$] at 70 °C under air. The absorption bands at 366 and 598 nm observed for the original spectrum can be assigned to charge-transfer and ligand field transitions, respectively. The absorption spectrum changes remarkably with time, showing the isosbestic points at 351 and 408 nm; the absorption band at 366 nm decreased in intensity and a new absorption band appeared at 333 nm (in Fig. 1-A), and the absorption band at 598 nm was shifted to lower energies with increasing the intensity around 500 nm (in Fig. 1-B). These spectral changes indicate that a marked change occurred in the coordinated ligand and the environment around the central copper atom.

Characterization of the Reaction Product. The analytical data for the reaction product of [Cu(salam)$_2$] in pyridine are in agreement with an empirical formula of [Cu(2-CNphO)$_2$(py)$_2$]. The magnetic moment is 2.05 BM. The electronic spectrum measured in pyridine shows an intense absorption band around 23000 cm^{-1} and a broad absorption band around 14000 cm^{-1} (Fig. 2). These bands can be assigned to a charge-transfer transition between the phenolic oxygen atom and copper atom and the ligand field transitions from higher energies.[13] Figure 3 shows the infrared spectra of [Cu(salam)$_2$] and its reaction product. In the latter compound, the absorption bands at 3280 and 1625 cm^{-1} are due to ν(N–H) and ν(C=N), re-

spectively, which were observed for $[Cu(salam)_2]$, disappeared and new absorption bands were observed at 2220 and 2205 cm^{-1} and at 1221, 1072, and 691 cm^{-1}. The bands at 2220 and 2205 cm^{-1} can be assigned to the stretching vibrations of nitrile group from their frequencies. The latter three bands can be assigned to the characteristic bands of the coordinated pyridine. These results indicate that the imino groups coordinated to the copper atom were oxidized to the nitrile groups by the oxidative dehydrogenation.

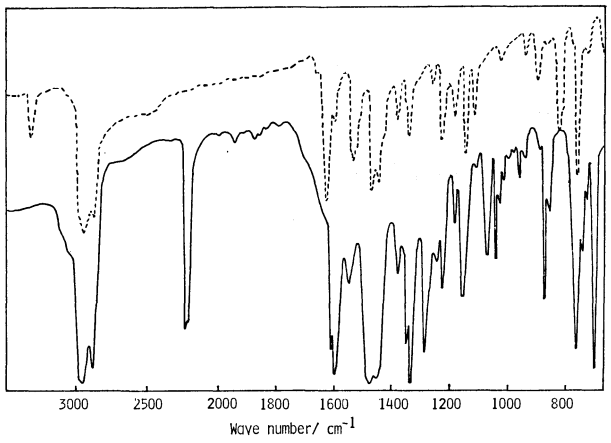

Fig. 3. Infrared spectra in Nujol mulls.
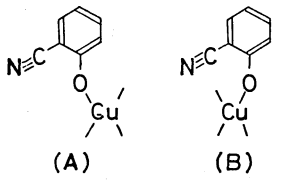
---: $[Cu(salam)_2]$, ——: oxidized product of $[Cu(salam)_2]$ in pyridine.

The authentic complex which was prepared by the reaction of $CuSO_4$, 2-cyanophenol, and pyridine has the same composition, formulated as $[Cu(2\text{-}CNphO)_2(py)_2]$, and shows the same infrared spectrum as that for the oxidized product (Table 2). In the electronic spectra, the absorption maxima for the oxidized product are in agreement with those for the authentic complex (Table 3). However, the intensities around 19000 cm^{-1} are slightly higher in the oxidized product than those in the authentic complex. This may be caused by the difference in orientation of the coordinated 2-cyanophenolato ligands between these complexes as shown below. A molecular model for them



suggests that a free rotation of the 2-CNphO at the Cu–O bond is restricted by the coordinated pyridine molecules. Therefore, on the basis of steric repulsion, the form (A) is a possible configuration for the authentic complex. On the contrary, the form (B) may be maintained in the oxidized product, because the original $[Cu(salam)_2]$ has a *trans*-planar configuration. In this form, a planar configuration around the central copper atom may distort to a tetrahedral configuration by steric requirement. This is one reason why high intensities are observed in the oxidized product.

The magnetic moment of the authentic complex is a slightly lower value (1.91 BM) than that of the oxidized product. This may be caused by a slight difference between configurations of the authentic and the oxidized complexes, as mentioned above.

It should be noted that the doublet bands due to ν(CN) are observed for the 2-cyanophenolato complexes and both peaks are of equal intensity. Moreover, the C–O stretching vibrations of the coordinated 2-cyanophenol are observed around 1320 cm^{-1} as doublet bands. These results suggest that 2-cyanophenolato ligands coordinate to the copper atom in two different fashions. It has been reported that nitrile groups can coordinate to metal ions through either nitrogen atom or π-bond of nitrile.[14] In the former

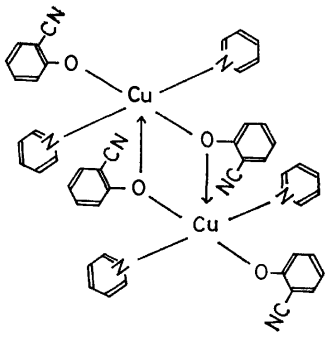

Fig. 4. Proposed structure for $[Cu(2\text{-}CNphO)_2(py)_2]$.

case, the ν(CN) frequencies shifted to higher energies than that of the free ligand, whereas in the latter case, they shifted to lower energies. In the present copper complexes, the ν(CN) frequencies are within a range of 2237 cm^{-1} for 2-CNphOH to 2205 cm^{-1} for 2-CNphONa (Table 2). This indicates that coordination of nitrile groups is not involved in these copper complexes. Therefore, we propose a binuclear structure for $[Cu(2\text{-}CNphO)_2(py)_2]$ as shown in Fig. 4 in which the copper atoms are bridged by the phenolic oxygen atoms. This structure could be easily broken up in pyridine solution. The infrared spectra taken on pyridine solutions of the oxidized and authentic complexes showed only one band due to ν(CN) at 2212 cm^{-1}. Such a binuclear structure has been revealed by X-ray analysis of [Cu(salen)], where salen denotes dianion of *N,N'*-disalicylideneethylenediamine, and its magnetic data (1.84 to 2.0 BM) are not inconsistent with the present results.[15] The facts that the original complex, $[Cu(salam)_2]$, has a *trans*-configuration[16] and that the two bands due to ν(CN) are of equal intensity suggest that a *trans*-form is probable for the oxidized complex, although either a *trans*- or *cis*-configuration is possible for $[Cu(2\text{-}CNphO)_2(py)_2]$. On the other hand, the complex, $[Cu(2\text{-}CNphO)_2(bpy)]$, may have a *cis*-configuration and the infrared spectrum shows two absorption bands due to ν(CN). Thus, this complex also may have a binuclear structure in the solid state.

Mechanism for Oxidative Dehydrogenation. In order to clarify the mechanism for the oxidative dehydrogenation of $[Cu(salam)_2]$ the following effects on the oxidation were investigated.

Solvent Effects: The $[Cu(salam)_2]$ complex was allowed to react with molecular oxygen in various solvents such as pyridine, dioxane, ethanol, and benzene under these conditions: The concentration of the complex was 8×10^{-5} M, at 70 °C, and under air. Absorption spectral changes were observed in the former three solvents, but no spectral change was observed in benzene. The time required for the oxidation increased in the order of: pyridine (4.5 h)<dioxane (5 h)<ethanol (20 h). The oxidized product could be obtained from the dioxane solution of $[Cu(salam)_2]$ and was identified to be [Cu(2-CNphO)(OH)], as mentioned in Experimental.

Effects of Added Bases: The oxidative dehydrogenation of $[Cu(salam)_2]$ in dioxane has been found to be accelerated by the addition of organic aromatic

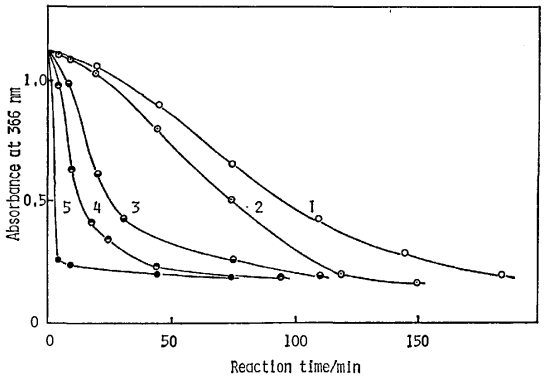

Fig. 5. Effects of added bases to dioxane solutions of $[Cu(salam)_2]$ on oxidation at 70 °C under air. Added bases; 1): none, 2): pyridine (10^{-3} M), 3): 2,2'-bipyridine (10^{-3} M), 4): bpy (10^{-2} M), 5): 1,10-phenanthroline (10^{-3} M). [Complex]=10^{-4} M, Cell length: 1 cm.

bases such as 1,10-phenanthroline (phen), 2,2'-bipyridine (bpy), and pyridine as shown in Fig. 5. The apparent reaction rates increased in the order of phen>bpy>py, and increased with an increase in concentration of the added base.

Concentration of Complex: The reaction of $[Cu(salam)_2]$ in pyridine was made by varying the concentration from 8×10^{-5} M to 1.6×10^{-3} M. All the reactions showed some induction periods. Thus, the maximal rate constants (k_{obsd}) were calculated graphically from the constant slopes after the induction periods obtained in the plots of $\ln(a-x)$ *vs.* reaction time, where a and x are the concentrations at time equal to t_0 and t, respectively, with assumption of the following equation:

$$[Cu(salam)_2] + O_2 \xrightarrow[py]{k_{obsd}} [Cu(2\text{-}CNphO)_2(py)_2] + 2H_2O. \quad (1)$$

A plot of $\log(k_{obsd})$ *vs.* $\log a$ shows a linear relation with a slope nearly equal to unity, as shown in Fig. 6. This indicates that the oxidative dehydrogenation of $[Cu(salam)_2]$ depends on the first order of the complex concentration. The induction periods are found to be decreased with an increase in the complex concentration.

Effects of Substituents on Aromatic Ring: Figure 7 shows the plots of the decreases in the complex concentration against reaction time. The complex concentration was calculated according to the following equation:

$$x = a(A_0-A_t)/(A_0-A_\infty), \quad (2)$$

where A_0, A_t, and A_∞ represent the absorbances at time equal to t_0, t, and at the final state, respectively. Clearly, the induction periods and the maximal rate constants are affected by the substituents on the aromatic ring; the electron-donating groups accelerate the reaction, whereas the electron-withdrawing groups retard it. The maximal rate constants increased in the order of 5-Me>3-Me>H>3-MeO>5-Br>4-Cl>5,6-Benzo>5-NO_2, as listed in Table 4. It should be noted that $[Cu(5\text{-}NO_2salam)_2]$ did not show any spectral changes under the same conditions.

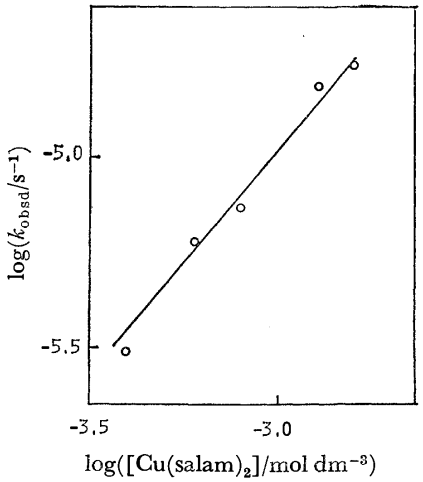

Fig. 6. A plot of log(k_{obsd}) *vs.* log[Cu(salam)$_2$].

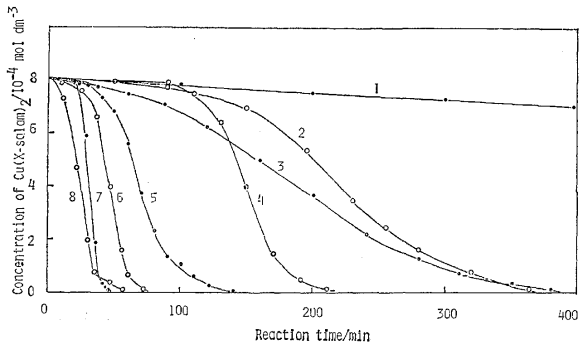

Fig. 7. Effects of substituents of [Cu(X-salam)$_2$] on oxidation in pyridine at 70 °C under air. [Complex]=8×10^{-4} M, 1): X=5-NO_2, 2): 4-Cl, 3): 5,6-Benzo, 4): 5-Br, 5): 3-MeO, 6): H, 7): 5-Me, 8): 3-Me.

TABLE 4. EFFECTS OF THE SUBSTITUENTS OF AROMATIC RING ON THE MAXIMAL RATE CONSTANTS AND THE INDUCTION PERIODS FOR THE OXIDATIVE DEHYDROGENATION OF [Cu(X-salam)$_2$] IN PYRIDINE AT 70 °C UNDER AIR

Substituent X	Maximal rate constant k_{obsd} / 10^{-4} s^{-1}	Induction period Time / min
5-Me	27.8	25
3-Me	15.2	8
H	13.5	40
3-MeO	8.8	50
5-Br	8.7	110
4-Cl	2.8	180
5,6-Benzo	2.1	95
5-NO_2	—	—

Concentration of complexes was 8×10^{-4} M.

Effects of Substituents on Nitrogen and Carbon Atoms of Imino Groups: Several copper(II) complexes, [Cu(hpam)$_2$], [Cu(*N*-Mesalam)$_2$], [Cu(salen)], and [Cu(*N*-OHsalam)$_2$], were made to react in pyridine at 70 °C under air, where *N*-OHsalamH denotes salicylaldehyde oxime. Among them, the carbon atom-substituted complex, [Cu(hpam)$_2$], gave the oxidized product, [Cu(2-CNphO)$_2$(py)$_2$], while the other nitrogen atom-substituted complexes did not show any oxidation under the above conditions. These results indicate that the oxidative dehydrogenation of [Cu(salam)$_2$] may be initiated by a splitting of the N–H bond of the coordinated imino groups.

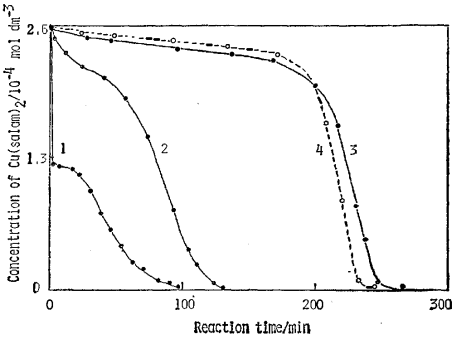

Fig. 8. Effects of added hydrogen peroxide on oxidation of [Cu(salam)$_2$] in pyridine at 70 °C under air. [Complex]=2.6×10^{-4} M, 1): [H_2O_2]=2.6×10^{-4} M, 2): 2.6×10^{-5} M, 3): 2.6×10^{-6} M, 4): no addition.

Effects of Addition of Hydrogen Peroxide: Figure 8 shows the plots for the oxidation of [Cu(salam)$_2$] *vs.* reaction time when various concentrations of hydrogen peroxide were added to the pyridine solutions of the complex at 70 °C under air. With the addition of an equimolar amount of hydrogen peroxide to the complex, a nearly half-mole of the complex was oxidized within 5 min, and the oxidation was completed within 100 min after showing a short induction period (curve 1). With the addition of one-tenth amount of hydrogen peroxide, the initial induction period disappeared, but the reaction rate retarded with time, and a fast oxidation again occurred after 50 min (curve 2). On the other hand, with the addition of one-hundredth of hydrogen peroxide, the reaction pattern (curve 3) was similar to the case of no addition (curve 4).

The available results suggest that the oxidative dehydrogenation of the coordinated imino groups in pyridine may occur according to the following scheme:

$$Cu(II)(R\text{-}CH{=}NH)_2 \rightleftharpoons Cu(I)(R\text{-}CH{=}\dot{N}H^+)(R\text{-}CH{=}NH) \quad (3)$$

$$Cu(I)(R\text{-}CH{=}\dot{N}H^+)(R\text{-}CH{=}NH) + O_2 \longrightarrow Cu(II)(R\text{-}CH{=}\dot{N})(R\text{-}CH{=}NH) + HO_2\cdot \quad (4)$$

$$Cu(II)(R\text{-}CH{=}\dot{N})(R\text{-}CH{=}NH) + HO_2\cdot \longrightarrow Cu(II)(R\text{-}CN)(R\text{-}CH{=}NH) + H_2O_2 \quad (5)$$

$$Cu(II)(R\text{-}CN)(R\text{-}CH{=}NH) + H_2O_2 \xrightarrow{py} Cu(II)(R\text{-}CN)_2(py)_2 + 2H_2O. \quad (6)$$

The initiation reaction is considered to be a thermal one-electron transfer from the imino nitrogen atom to the copper atom, as shown in Eq. 3. The induction periods observed in the oxidation investigated here may be due to the back reaction in Eq. 3, which is the oxidation of copper(I) to copper(II) by the imino radical. In the presence of molecular oxygen, the reactions shown in Eqs. 4 and 5 may occur in competetion with the above back reaction.

The effects of the added aromatic bases (Fig. 5) can be related to Eq. 3. That is, these bases can function as an acceptor of proton (H^+) liberated and as a promoter of electron transfer from the imino group to the copper atom by coordination. Thus the increasing order of the apparent reaction rates (phen> bpy>py) is not correlated to the order of the pK_a values (py>phen>bpy).

The substituent effects that the electron-donating groups on the aromatic ring accelerated the reaction rates and shortened the induction periods can be explained by taking account of Eqs. 3 and 4; the electron-donating groups may facilitate the electron transfers from the imino group to the copper atom (Eq. 3) and from the copper atom to molecular oxygen (Eq. 4). Such a behavior has been found in the autoxidation of the substituted phenylhydroxylamines.[17] And also the autoxidation of phenylhydroxylamine has been found to be accelerated by copper(II) ion.[18]

As described above, the oxidative dehydrogenation investigated here proceeded rapidly after showing induction periods. This indicates that the radical chain autoxidation may be involved in this system. The chain reaction may propagate by the direct attack of molecular oxygen to the imino radical and by the catalytic decomposition of hydrogen peroxide with the copper complex. A tentative scheme for the radical chain autoxidation is proposed, as follows:

$$Cu(II)(R\text{-}CH{=}\dot{N})(R\text{-}CH{=}NH) + O_2 \longrightarrow Cu(II)(R\text{-}CN)(R\text{-}CH{=}NH) + HO_2\cdot \quad (7)$$

$$Cu(II)(R\text{-}CN)(R\text{-}CH{=}NH) + HO_2\cdot \longrightarrow Cu(II)(R\text{-}CN)(R\text{-}CH{=}\dot{N}) + H_2O_2 \quad (8)$$

$$Cu(II)(R\text{-}CN)(R\text{-}CH{=}\dot{N}) + O_2 \longrightarrow Cu(II)(R\text{-}CN)_2 + HO_2\cdot \quad (9)$$

Decomposition of hydrogen peroxide

$$Cu(II)(R\text{-}CH{=}NH)_2 + H_2O_2 \longrightarrow Cu(I)(R\text{-}CH{=}NH)_2 + HO_2\cdot + H^+ \quad (10)$$

$$Cu(I)(R\text{-}CH{=}NH)_2 + H_2O_2 \longrightarrow Cu(II)(R\text{-}CH{=}NH)_2 + HO\cdot + HO^- \quad (11)$$

$$Cu(I)(R\text{-}CH{=}\dot{N}H^+)(R\text{-}CH{=}NH) + H_2O_2 \longrightarrow Cu(II)(R\text{-}CH{=}\dot{N})(R\text{-}CH{=}NH) + HO\cdot + H_2O \quad (12)$$

followed by abstraction of hydrogen atom with $HO_2\cdot$ and $HO\cdot$. The above reaction scheme is supported by the results that the reactions of $[Cu(salam)_2]$ with O_2^- [19] and H_2O_2 in pyridine occurred readily at room temperature.

In the catalytic decomposition of hydrogen peroxide, Sigel *et al.*[20] have found that coordinately saturated copper(II) complexes (four-coordinate complexes) are essentially inactive. And Kochi has pointed out that in the reaction of hydrogen peroxide catalyzed by iron ion the reaction represented in Eq. 13 is more facile than that represented in Eq. 14, because hydrogen peroxide is a strong oxidizing agent but only a mild reducing agent.[21]

$$Fe^{II} + H_2O_2 \longrightarrow Fe^{III} + HO\cdot + HO^- \quad (13)$$

$$Fe^{III} + H_2O_2 \longrightarrow Fe^{II} + HO_2\cdot + H^+ \quad (14)$$

Therefore, in the present oxidation, the reaction represented in Eq. 12 is considered to be more important than those represented in Eqs. 10 and 11.

As shown in Fig. 8, the initial induction period was made to disappear by the addition of an equimolar amount of hydrogen peroxide to the complex, but a short induction period was observed again after producing about a half oxidation of the complex. Furthermore, the catalytic amount of hydrogen peroxide ($[H_2O_2]$:[complex]=1:100) had no effect on the reaction. These results indicate that the radical chain sequence induced by decomposition of hydrogen peroxide may be not so long. These facts suggest that the rate-determining step in the present oxidative dehydrogenation of $[Cu(salam)_2]$ is the splitting of the N–H bond of the coordinated imino group, along with the reduction of copper(II) to copper(I), as shown in Eq. 3.

We have also found that $[Ni(salam)_2]$ and $[Co^{II}(salam)_2]$ were oxidized by molecular oxygen in pyridine to give their 2-cyanophenolato complexes. In the nickel complex, the severe conditions were required to obtain the fully oxidized product: for 120 h at 115 °C under O_2 1 atm. This suggests that the oxidative dehydrogenation of $[Ni(salam)_2]$ may be initiated by the electron transfer from the coordinated imino group to molecular oxygen without change in the oxidation state of the nickel ion. On the other hand, the oxidized product of $[Co^{II}(salam)_2]$ was obtained in the conditions similar to the case of $[Cu(salam)_2]$. In the cobalt complex, the initial reaction is considered to be the oxidation of Co(II) to Co(III) by molecular oxygen, followed by the stepwise dehydrogenation of the coordinated imino groups through a redox couple of Co(II)/Co(III) as in the copper case. Details on the oxidation of these Ni(II) and Co(II) complexes will be reported in the near future.

The Ion-exchange Properties toward Hexaamminecobalt(III) and the Characterization of the Complex Cation Form of α-Zirconium Phosphate[1)]

Yoshitsugu HASEGAWA,* Seiichi KIZAKI, and Hiroshi AMEKURA

Department of Industrial Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Nakamachi, Koganei, Tokyo 184

(Received February 16, 1982)

The ion-exchange properties of α-zirconium phosphate have been investigated for the H^+–$[Co(NH_3)_6]^{3+}$ system. The ion-exchange process was examined by means of the variation in the pH values of the supernatant. α-Zirconium phosphate loaded with hexaamminecobalt(III) was also characterized by chemical analysis, X-ray diffractometry, infrared spectroscopy, and thermal analysis. In spite of the steric hindrance in the crystal structure of α-zirconium phosphate, the ion exchange proceeded gradually. About 30% of the hydrogen ions in α-zirconium phosphate were replaced by hexaamminecobalt(III). The interlayer distance of the exchanger expanded from 0.76 to 1.12 nm.

The ion-exchange properties of α-zirconium phosphate, $Zr(HPO_4)_2 \cdot H_2O$ (α-ZP), have been studied extensively, and its crystal structure has been determined.[2)] The structure is a layered one, and zeolitic-type cavities are present between layers. The cavities are connected by openings, the largest diameter being 0.264 nm.[3)] Hence, the ions of the ionic radius smaller than 0.133 nm can be easily taken up by α-ZP. However, larger cations, such as ammonium and tetra-alkyl-ammonium ions, and cobaltocene also exchange with the proton in α-ZP.[4,5)] These facts indicate that the ion exchange on α-ZP is not necessarily restricted by the size of the exchanging cation.

It has been known that α-ZP has not only catalytic activities, but also the possibility of use as a catalyst support. For example, Nozaki *et al.* have applied α-ZP to a catalyst for the dehydration of 2-propanol,[6)] and Hattori *et al.* studied the catalytic property and the acidity of α-ZP.[7)] Alberti pointed out that α-ZP loaded with a transition metal ion was promising as a catalyst.[8)] The copper form of α-ZP, $ZrCu(PO_4)_2$ was found to be active for the oxydation of carbon monoxide.[9)]

The ion-exchange reaction has been employed to prepare a highly dispersed metal-supported catalyst, especially when the metal is a member of the platinum group.[10)] Since many metal ions are not present in neutral pH solutions, a complex cation must be used for the ion exchange. The use of the metal-ammine complex is suitable, since the ammonia molecule is small and can easily be removed by heating.

In this work, the hexaamminecobalt(III)-hydrogen ion exchange was studied, and the α-ZP loaded with the hexaamminecobalt(III) ion (ZP-Co) was characterized by chemical analysis, X-ray powder diffraction, infrared spectroscopy, and thermal analysis.

Experimental

Preparation of α-ZP and Hexaamminecobalt(III) Trichloride. By the previously reported method α-ZP was prepared.[11)] When the zirconium dichloride oxide octahydrate used as a starting material included free hydrochloric acid, the salt was washed with acetone 2—3 times. The cobalt complex was prepared according to the literature.[12)] Identification was made by means of the X-ray diffraction pattern.[13)]

Ion Exchange. The ion-exchange experiments were carried out in batches. A weighed amount of α-ZP was placed in contact with the solution of hexaamminecobalt(III) in a thermostat bath. The concentration of the solution and the reaction temperature were varied. After the mixture has been shaken continuously or left to stand with a reflux condenser for a given period of time, the solid was centrifuged from the solution. The pH value of the supernatant was measured on a pH meter. Then, the solid was again added to a new solution of the complex. The process was repeated until the pH value of the supernatant became almost equal to that of the complex solution.

Analytical Procedure. The structural change in the exchanger during the ion exchange was measured by means of X-ray diffractometry. The patterns were recorded with a Rigaku Denki Geigerflex diffractometer, using Ni-filtered Cu $K\alpha$ radiation ($\lambda = 0.1542$ nm). The infrared (IR) spectra were measured on a JASCO DS-403G grating infrared spectrophotometer. The thermogravimetric (TGA) curve was obtained with a Shimadzu thermal analyser DT-30 at a heating rate of 10 °C/min in static air. The differential scanning calorimetric (DSC) data were obtained with a Rigaku differential scanning calorimeter under a helium stream to prevent the oxidation of the ammonia gas evolved at the surface of a platinum crucible.[14)]

The chemical analysis of the exchanger was carried out as follows. A weighed sample was decomposed with sodium peroxide. The precipitate was separated from the solution by filtration and then dissolved in hydrochloric acid. Zirconium was separated as cupferrate from cobalt and determined gravimetrically.[15)] Cobalt was titrated with a standardized EDTA solution, using xylenol orange as an indicator. Phosphorus was determined as magnesium pyrophosphate.[16)] Hydrogen and nitrogen were determined by elemental analysis.

Results and Discussion

Ion Exchange. To determine the optimum conditions of the ion exchange, the concentration of the complex cation and the reaction temperature were varied. The concentration range was from 0.025 to 0.2 mol dm^{-3}. The concentration of 0.025 mol dm^{-3} was equal to twice the ion-exchange capacity of the α-ZP used when the weighed amount of α-ZP was 500 mg and the volume of the solution was 100 cm^3. The concentration of 0.2 mol dm^{-3} was nearly equal to that of the saturated solution at 20 °C. Equilibrations were carried out at 25, 50, 75, and 90 °C.

In the first ion-exchange reaction at a given temperature, the equilibrium pH values of the supernatant solution were independent of the concentration of the complex cation. However, the pH values decreased at elevated temperatures. The hexaamminecobalt(III) ion is inert to the substitution of the ligand at room temperature, that is, the complex cation will persist for days. The hydrolysis of the complex cation took place at high temperatures. If the solution of the complex cation was heated at 75 or 90 °C, cobalt hydroxide was precipitated after 1.5 h or 15 min respectively. These facts indicate that, in the α-ZP–hexaamminecobalt(III) solution system, the ion exchange competes with hydrolysis at high temperatures. The change in pH values was steep at the end of ion exchange at 90 °C, and it was difficult to prevent the complex cation from hydrolyzing. The optimum experimental conditions were: concentration, 0.025 mol dm^{-3}, temperature, 75 °C, and reaction time, 1 h.

It is known that α-ZP and its salt forms have a layered structure, and that the interlayer distance depends on the size of the exchanging cation.[17] The structural change in the exchanger phase is usually examined by means of X-ray diffractometry. In an X-ray powder diffractogram, the peak due to the interlayer distance appears in the lowest angle region. Two peaks were observed at $2\theta=11.7°$ and 7.9° ($d=$ 0.76 and 1.12 nm) during the ion exchange, as is shown in Fig. 1. The former originated from the interlayer distance of α-ZP. The intensity of the X-ray reflection of the latter increased, while that of the former decreased, with an increase in the uptake of the complex cation. The precise interplanar spacings (d values) of ZP–Co are shown in Table 1.

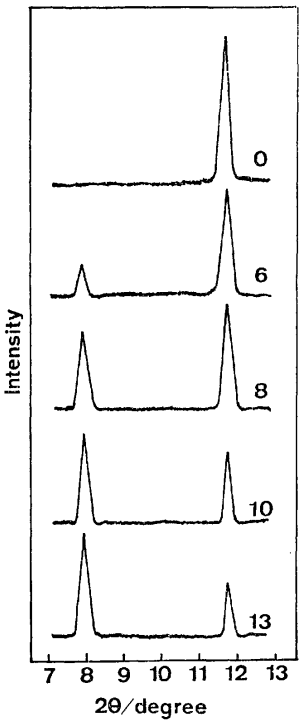

Fig. 1. Schematic diagrams of X-ray powder diffraction at the lowest angle region. Numbers in the figure represent the number of ion-exchange run.

Table 1. Interplanar spacings (d-values) of ZP-Co

d/nm	I/I_0
1.116	100
0.763	49
0.564	23
0.379	8
0.369	8
0.358	21
0.331	6
0.307	55
0.265	10
0.252	4
0.241	7
0.188	12

If the ammonia in the complex cation is abstracted directly by α-ZP or converted to the ammonium ion, thus contributing to the ion exchange, the ammonium form of α-ZP will be present. Since the interlayer distance of the ammonium form is 0.94 nm, the peak must be observed at $2\theta=9.4°$. This peak did not appear in powder diffractograms, however.

At the final stage of the ion exchange, the phase of α-ZP was still present (Table 1), indicating that not all the protons in α-ZP were replaced by $[Co(NH_3)_6]^{3+}$.

The IR spectra of ZP–Co and the ammonium form of α-ZP are shown in Fig. 2. The IR spectrum of α-ZP has been studied previously, and several bands have been assigned.[18] The absorption bands which appear in α-ZP are denoted by the symbol α in the figure. The ammonia in hexaamminecobalt(III) ion gave absorptions in the regions of 3000—3400, 1550—1650, 1300—1400, and 800—950 cm^{-1}.[19] It is clear that the spectrum of ZP–Co is composed of those of α-ZP and the hexaamminecobalt(III) ion, except for the region of 800—950 cm^{-1}, where the rocking vibrations are expected. According to Fujita *et al.*, the rocking mode is sensitive to the kinds of outer ions present and the hydrogen bonding, and the absorption band is shifted to higher frequencies by these effects.[20]

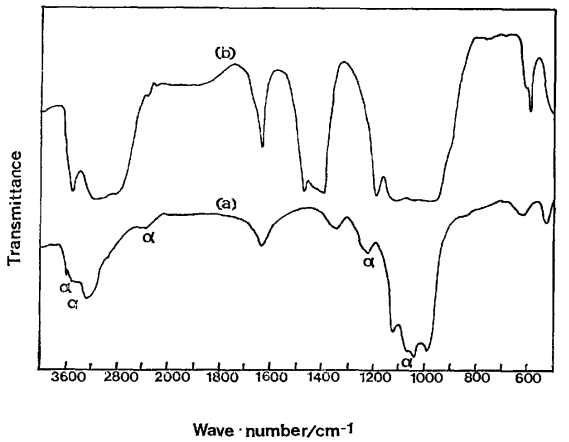

Fig. 2. IR spectra of (a) ZP-Co and (b) the ammonium form of α-ZP.

As is shown in Curve b, the ammonium ion of α-ZP gave strong and characteristic bands in the region of 1400—1500 cm^{-1}, but these bands were absent in Curve a. These facts indicate that the cobalt(III) ion was present as an ammine complex in the exchanger and that the ammonia molecules formed a hydrogen bond with the phosphate group; consequently, the rocking mode shifted to higher frequencies and overlapped with the absorption bands of phosphate.

In order to ascertain the ratio of cobalt to ammonia in ZP–Co, the composition was determined. Found: Zr, 23.8 (1.00); PO_4, 49.4 (1.99); Co, 4.53 (0.292); N, 6.40 (1.74); H, 2.68 (10.2); ignition loss, 22.6% (—). The values in parentheses are the molar ratio of each element to zirconium. It should be noted that the molar ratio of cobalt to ammonia is 1:5.96.

Figure 3 shows that ZP–Co was decomposed when heated in four steps. For each decomposition peak the presence of ammonia was examined by means of evolved gas analysis. Ammonia was detected at the third step. In static air, this decomposition was exothermic because of the oxidation of the evolved ammonia. The presence of zirconium pyrophosphate was confirmed by heating ZP-Co to about 900 °C (Fig. 4). This indicates that the unexchanged monohydrogen orthophosphate group (–HPO_4) was present in ZP–Co, was converted to pyrophosphate, and lost water at high temperatures.

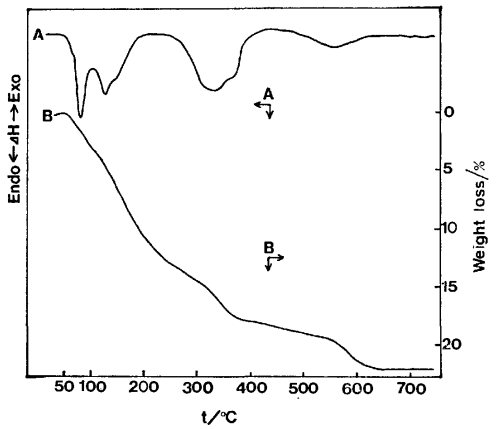

Fig. 3. DSC(A) and TGA(B) curves of ZP-Co.

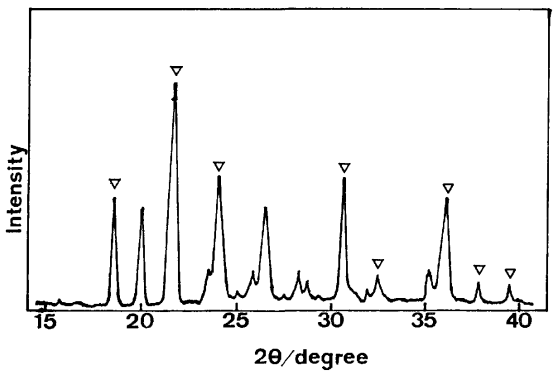

Fig. 4. Schematic diagram of X-ray powder diffraction pattern of the sample obtained by heating ZP-Co to about 900 °C. The symbol ▽ denotes the peak originating from ZrP_2O_7.

Assuming that the formula for ZP–Co is $Zr[Co(NH_3)_6]_m(H)_{2-3m}(PO_4)_2 \cdot nH_2O$ (m=0—2/3) and that the reduction of Co(III) does not occur, ZP–Co decomposes according to these reactions:

$$Zr[Co(NH_3)_6]_m(H)_{2-3m}(PO_4)_2 \cdot nH_2O \longrightarrow ZrCo_m(H)_{2-3m}(PO_4)_2(s) + 6mNH_3(g) + nH_2O(g)$$

$$ZrCo_m(H)_{2-3m}(PO_4)_2 \longrightarrow (1-3m/2)ZrP_2O_7(s) + 3m/2ZrCo_{2/3}(PO_4)_2{}^*(s) + (2-3m)/2H_2O(g)$$

(The compound marked with an asterisk could not be identified by means of its X-ray diffraction pattern.) The weight loss by heating is calculated by means of the following equations:

$$100\times(17.03\times6m+18.01\times n)/M_w = w_1(\%) \quad (1)$$

$$100\times[17.03\times6m+((2-3m)/2+n)\times18.01]/M_w = w_2(\%), \quad (2)$$

where M_w is the molecular weight of ZP-Co, and where w_1 and w_2 are the percentages of weight loss during heating to 420 and 900 °C respectively.

When the cobalt(III) ion in ZP–Co is reduced in the thermal decomposition, as in the case of $[Co(NH_3)_6]X_3$ (X=Cl, Br, I),[21] ZP–Co decomposes through these reactions:

$$Zr[Co(NH_3)_6]_m(H)_{2-3m}(PO_4)\cdot nH_2O \longrightarrow ZrCo_m(H)_{2-2m}(PO_4)_2(s) + 17m/3\,NH_3(g) + m/6N_2(g) + nH_2O(g)$$

$$ZrCo_mH_{2-2m}(PO_4)_2 \longrightarrow (1-m)ZrP_2O_7(s) + mZrCo(PO_4)_2{}^*(s) + (1-m)H_2O(g)$$

Thus, Eqs. 1 and 2 become:

$$100\times(17.03\times6m+18.01\times n-1.01\times m)/M_w = 100W/M_w = w_1\ (\%) \quad (3)$$

$$100\times[W+(1-m)\times18.01]/M_w = w_2\ (\%). \quad (4)$$

The experimental values agreed approximately with those calculated according to Eqs. 3 and 4 (Table 2). These facts indicate that the reduction of the cobalt(III) ocurred during heating.

TABLE 2. WEIGHT LOSS OF ZP-Co BY HEATING (%)

	Experimental	Calculated	
		Eqs. 1 and 2	Eqs. 3 and 4
420 °C	18.0	17.8	18.2
900 °C	22.6	20.5	21.7

In conclusion, the hexaamminecobalt(III)-hydrogen ion exchange partially proceeded in spite of the steric hindrance in the crystal structure of α-ZP. Cobalt(III) was present as a hexaammine complex cation in the exchanger.

The authors wish to express their thanks to Mr. Yukihiro Takekawa for the IR measurements and to Prof. Isao Tomita, Tokyo University of Fisheries, for the measurement of the TGA data.

Lanthanoid Nitrate Complexes with Some Polyethylene Glycols and Glymes

Yoshiyuki HIRASHIMA,* Koji KANETSUKI, Ikuo YONEZU,
Kiyohito KAMAKURA, and Jiro SHIOKAWA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-oka, Suita, Osaka 565
(Received August 7, 1982)

Lanthanoid nitrates($Ln(NO_3)_3$) formed solid complexes with several polyethylene glycols and glymes. The compositions of the complexes were 1:1 (Ln:ligand) for triethylene glycol(EO3), tetraethylene glycol(EO4), pentaethylene glycol(EO5), and tetraglyme, 1:2 (Ln:ligand) for diethylene glycol, 2:1 for heptaethylene glycol, and 4:3 for pentaglyme and hexaglyme. Solid complexes were deposited also for hexaethylene glycol, but their compositions were not definitely determined. The solid complexes obtained here were all deliquescent. The deposition of the complexes was generally interfered with by water in the solution, and was not observed for some heavier lanthanoids when a small amount of water was present in the solution. The solubilities of the solid complexes with EO4 and EO5 increased with an increase in the atomic number of the lanthanoid, a fact suggesting a unique selectivity of the glycols. The infrared absorption bands of polyethylene glycols or glymes in the 1000—1150 cm^{-1} region became sharper upon the complexing of the glycols or glymes with lanthanoids; this sharpening can be explained by the change in the conformations in the ligand molecules.

Macrocyclic polyethers, so-called crown ethers, have been reported to form complexes with several cations.[1-4] The lanthanoid complexes of crown ethers have been reported, too.[5-8] King and Heckley suggested the possibility of the separation of lanthanoids by using crown ethers.[6] On the other hand, Yanagida *et al.* have reported the complexation of alkali and alkaline earth metals with noncyclic polyethers, polyethylene glycols and glymes.[9-11] Vögtle *et al.* have investigated the complexes of several noncyclic poly(oxyethylene) derivatives, which they call noncyclic crown ethers.[12-15] The lanthanoid complexes of polyethylene glycols have been reported by the present authors;[16] X-ray structure analyses indicate that polyethylene glycol molecules in the complexes assume ring-like structures similar to those of crown ethers,[17-19] suggesting that polyethylene glycols may have unique selectivities. The separation of lanthanoids with tetraethylene glycol by means of a fractional precipitation has been attempted on the basis of the fact that the yield of the lanthanoid complexes decreases as the atomic number of the lanthanoid increases.[20] Thus, polyethylene glycols may be promising reagents for the separation of lanthanoids. In the present work, lanthanoid complexes with several polyethylene glycols and glymes were isolated, and their properties were investigated.

Experimental

Materials. The lanthanoid nitrates were prepared by dissolving the corresponding oxides(>99.9% purity, Shin-Etsu Chemical Industry Co., Ltd.) into an excess of nitric acid. The solutions were concentrated on sand baths and then allowed to stand until the salts were deposited. The salts were dried at about 70 °C *in vacuo* for 6 h. The numbers of the hydrating water were 5—7.

The polyethylene glycols($HO(CH_2CH_2O)_nH$, EO*n*) and polyethylene glycol dimethyl ethers($CH_3O(CH_2CH_2O)_nCH_3$, glymes) used in this investigation were as follows: diethylene glycol (EO2, Wako Pure Chemicals Industries, Ltd.); triethylene glycol (EO3, Wako Pure Chemicals Industries, Ltd.); tetraethylene glycol(EO4, Tokyo Kasei Kogyo Co., Ltd.), and tetraethylene glycol dimethyl ether(tetraglyme, MeEO4Me, Tokyo Kasei Kogyo Co., Ltd.). They were all used after distillation. The penta-, hexa-, and heptaethylene glycols(EO5, EO6, and EO7) were offered by the Okahara Lab. (Department of Appled Chemistry of this Faculty). The pentaglyme and hexaglyme(MeEO5Me and MeEO6Me) were prepared by the method reported by Yanagida *et al.*[9]

Isolation of Solid Complexes of Lanthanoid Nitrates with Polyethylene Glycols and Glymes. A typical procedure for the preparation of solid complexes was as follows. About 1 mmol of a hydrous lanthanoid nitrate($Ln(NO_3)_3 \cdot nH_2O$, n= 5—7) in 10 cm^3 of ethyl acetate was mixed with about 1 mmol of a polyethylene glycol or a glyme in 10 cm^3 of ethyl acetate, after which the resulting solution was allowed to stand for a day. The solid complex deposited from the solution was filtered off, washed several times with 2 cm^3 of ethyl acetate, and then dried at about 60 °C *in vacuo* for 8 h. Each solution was dehydrated before mixing for the systems in which no solid complex was deposited, or in which the yield of the complex was low, by means of the method described above. The dehydration was carried out by refluxing each solution through a molecular-sieve layer. The composition of the solid complex deposited was not affected by dehydration. For the preparation of lanthanoid complexes with EO5, a solution of the lanthanoid nitrate was added to the EO5 solution under the conditions where there was always an excess of EO5.

Measurements of Infrared Spectra and Conductance. The infrared spectra were recorded on a Hitachi 260-10 spectrometer. The conductances of the solutions of the complexes were measured at 25.0±0.1 °C with a Yokogawa-Hewlett Packard Universal Bridge.

Measurements of Solubility. A flask containing 30 cm^3 of ethyl acetate and an appropriate amount of a solid complex was shaken in a water bath thermostatted at 25.0± 0.1 °C for 24 h or longer. The solid complex remaining undissolved was filtered off, and the concentration of the lanthanoid in the filtrate was determined by means of EDTA titration, with Xylenol Orange as an indicator.

X-Ray Powder Diffraction Analysis. The X-ray powder diffraction analysis was performed with a Rigaku Rotaflex diffractometer with a scintilation detector and Cu $K\alpha$ radiation (λ=1.5418 Å).

Results and Discussion

Isolation of Solid Complexes. The solid complexes of lanthanoid nitrates and yttrium nitrate with several

polyethylene glycols and glymes were isolated in this investigation. The well-defined complexes are listed in Tables 1—8, along with their analytical data. The solid complexes were deposited also for EO6, though they are not given in the tables because their compositions were not determined definitely. The solid complexes obtained here were all deliquescent. The deposition of the solid complexes was interfered with by water in the solution, and generally the solid complexes were not deposited for the heavier lanthanoids when the dehydration procedure was not carried out.

The Complexes with Diethylene Glycol(EO2): The solid complexes of $Ln(NO_3)_3 \cdot (EO2)_2$ (Ln; Pr, Nd, Sm, and Eu) were obtained as is shown in Table 1. Solid complexes were deposited also for the other lanthanoids and yttrium, but their compositions were not definitely determined. The ratios of metal/EO2 in such complexes ranged from 1/2 to 1/3.

The Complexes with Triethylene Glycol(EO3): Table 2 shows that EO3 formed 1:1 complexes with all the lanthanoids investigated and with yttrium. All the complexes were formulated as $Ln(NO_3)_3 \cdot EO3$, as is shown in Table 2, when the solid complexes were dried *in vacuo* at 80 °C. When the complexes were dried at room temperature (about 20 °C), however, the complex of lanthanum nitrate contained water and ethyl acetate, though the complexes of the other lanthanoid nitrates contained neither water nor ethyl acetate. The X-ray analysis of the complex of neodymium nitrate[19] has also indicated the absence of solvating water or a solvent. The deposition of the solid complexes seems to require the presence of a small amount of water in the solution. No solid complexes were obtained when the solutions were thoroughly dehydrated, and the deposition of the complexes was observed when a small amount of water was present. However, the presence of a large amount of water inhibited the deposition, as in the other EOn

complexes. These results suggest that water plays a part in the deposition of the complexes, but no further investigation was carried out.

The Complexes with Tetraethylene Glycol(EO4): Tetraethylene glycol(EO4) always formed a solid complex with the composition of $Ln(NO_3)_3 \cdot EO4$, irrespective of the mixing ratio or the mixing method of the solutions of the lanthanoid nitrate and EO4 (Table 3). The EO4 complexes were the least deliquescent of the complexes isolated in this investigation. These phenomena may be attributed to the fact that the chain length of EO4 is suitable for the 1:1 complex without any pronounced strain.[18]

The Complexes with Pentaethylene Glycol(EO5): Table 4 shows that the composition of well-defined complexes of EO5 are $Ln(NO_3)_3 \cdot EO5$. The 1:1 complex was deposited when there was an excess of EO5, while the ratio of Ln/EO5 in the complexes deposited was often larger than 1, ranging from 1.0 to 1.5 when the EO5 solution was added to the lanthanoid solution or when the mixing ratio of Ln/EO5 was larger than 1. However, only lanthanum nitrate always formed the 1:1 complex, regardless of the mixing conditions. This fact may be related to the fact that the ionic radius of lanthanum is the largest in the lanthanoids. The solid complexes were all hygroscopic; those of the heavier lanthanoids were more hygroscopic than those of the lighter lanthanoids, that of lutetium nitrate especially being so hygroscopic that the determination of the contents of C, H, and N was unsuccessful in the present method.

a) The contents of C, H, and N could not be determined because of great hygroscopy.

The Complexes with Heptaethylene Glycol(EO7): The 2:1 complexes were deposited for lanthanum and cerium. Table 5 shows the analytical data. For the other lanthanoids, the composition of the complex was not definitely determined or no solid complex was deposited. A heptaethylene glycol is considered to be bonded to two lanthanoid atoms because its chain length is too long to wrap around only one lanthanoid atom. The structures of the complexes prepared here are supposed to be similar to that of the 2:1 complex of merculy(II) chloride with hexaethylene glycol dimethyl ether reported by Iwamoto.[21]

The Complexes with Glymes: The 1:1 (Ln:glyme) complexes were deposited for tetraglyme (MeEO4Me), just as for EO3, EO4, and EO5, while the 4:3 complexes were deposited for pentaglyme (MeEO5Me) and hexaglyme (MeEO6Me). Tables 6, 7, and 8 show the complexes isolated in this investigation, together with the analytical data. The solid complexes of pentaglyme were deposited also for the lanthanoids which are not listed in Table 7, but their compositions were not defined well. Although there is a possibility that the 4:3 complexes prepared here were mixtures of the complexes with simple compositions, such as the 1:1 and 2:1 complexes, the 4:3 complex was always deposited for the system of praseodymium nitrate with pentaglyme, even when the mixing ratio of the nitrate to the glyme was varied from 1/4 to 4/1. Correspondingly, the possibility of the deposition of the mixture may well be neglected. The 4:3 complexes

of the lanthanoid nitrates have been reported also for crown compounds,[22] and the structure of the 4:3 complex of neodymium nitrate with 18-crown-6 ether has previously been reported;[23] *i.e.*, two different complex ions, the 1:1 complex cation $[Nd(NO_3)_2 \cdot 18\text{-crown-6}]^+$ and the complex anion containing no crown ether $[Nd(NO_3)_6]^{3-}$, are included in it.

Infrared Spectra of the Complexes. The infrared spectra of the solid complexes were similar to each other. In particular, there is little difference in the spectra among the complexes of individual lanthanoids with a given ligand (polyethylene glycol or glyme). The spectra of neodymium nitrate complexes with EO3, EO4, and EO5 are shown in Fig. 1 as typical examples, together with those of pure EO4, neodymium nitrate, and hexachlorobutadiene. Remarkable differences were observed between the complexes and the pure ligands in the 1000—1150 cm^{-1} region. The bands of the pure ligand (EO4 in Fig. 1) were broad in this region, while the bands became sharper in the case of the complexes. This change can be explained as follows: the ligand molecule can assume various conformations in a pure ligand; consequently, many bands appear in the spectra, overlapping each other, and resulting in broad bands, while the ligand molecule assumes a definite conformation in the complex. Accordingly, only the absorption bands corresponding to the conformation are observed, and the bands become sharp as a whole. A detailed discussion of similar phenomena in the merculy(II) chloride complexes has been reported by Iwamoto.[24] The absorption bands assigned to the coordinated nitrates were observed at about 1500 cm^{-1} and at about 1300 cm^{-1} for the complexes. There was no absorption band assigned to free nitrates at about 1380 cm^{-1} in the spectra of any of the complexes. According to the X-ray analyses of the neodymium nitrate complexes[17-19] three nitrates are all coordinated to a neodymium atom in the EO3 and EO4 complexes, while one nitrate is not coordinated in the EO5 complex. The results of the X-ray analyses are in agreement with the infrared spectra for the EO3 and EO4 complexes, but appear to be in conflict with that for the EO5 complex. According to the X-ray analyis, the uncoordinated nitrate in the EO5 complex assumes a C_{2v} symmetry rather than the D_{3h} one characteristic of a free nitrate. This fact explains the absence of the absorption band at about 1380 cm^{-1} in spite of the presence of the uncoordinated nitrate in the EO5 complexes.

Powder X-Ray Diffraction. The structures of neodymium nitrate complexes with EO3, EO4, and EO5 have been determined by the X-ray analyses of the single crystals.[17-19] The powder X-ray diffractions were measured for the complexes of the other lanthanoids as well as those of neodymium. Figure 2 shows some typical diffraction patterns. The diffraction patterns for the complexes of most of the lanthanoids with EO3, EO4, and EO5 were similar to those of the complexes of neodymium with the cor-

responding ligands. The complexes are expected to have structures similar to those of the neodymium complexes. The complexes of lanthanum and cerium with EO3 and EO5, and the complexes of terbium and the heavier lanthanoids with EO4 yielded patterns different from those of the corresponding neodymium complexes. These results suggest that the structures of the complexes are dissimilar to those of the neodymium complexes. The structures of the complexes are now being studied in detail by the present authors.

Electric Conductivities of the Solutions. Figure 3 shows the molar conductivities of the acetone solutions of the lanthanoid nitrate complexes of EO3, EO4, and EO5, together with those of the parent nitrates. All the values were lower than 45 S cm² mol⁻¹, suggesting that the complexes and the nitrates were essentially nonelectrolytes or dissociated as the 1:1 electrolytes.[25] The molar conductivities increased in the following order for a given lanthanoid: EO3 complex<parent nitrate<EO4 complex<EO5 complex. The mobility of the cation can reasonably be considered to decrease by complexing with any one of the glycols because of the increase in the size of the species. Therefore, the order of the conductivities described above is attributed to the difference in the degree of ionic dissociation among the complexes. According to the X-ray structure analyses of the complexes of neodymium nitrate, all the nitrates in the EO3 complex are bidentate, while one of the nitrates in the EO4 complex is unidentate and is uncoordinated in the EO5 complex, though the other two are bidentate. The degree of the dissociation is, therefore, expected to increase in this order: EO3 complex< EO4 complex<EO5 complex, since the ease of the dissociation of nitrates increases in this order: bidentate<unidentate<noncoordinated.

Solubilities of the Complexes. In the preparation of the solid complexes, the complexes of lighter lanthanoids appeared to be deposited more easily than those of heavier lanthanoids. This phenomenum is probably related to the difference in the solubilities between the complexes. Figures 4 and 5 show the solubilities of the EO4 complexes and the EO5 complexes respectively in ethyl acetate. The solubility generally increased with the increase in the atomic number of the lanthanoid both for the EO4 complexes and for the EO5 complexes, though some exceptions were observed (the heavier lanthanoids for the EO4 complexes and the lighter lanthanoids for the EO5 complexes). The observed solubilities shown in the figures are actually apparent ones, being affected not only by the solubilities of the undissociated complexes, but also by the stabilities of the complexes, for the complexes are probably, in part, dissociated in the solutions. The trend of the solubility shown in the figures implies an increase in the solubility of the undissociated complex and/or a decrease in the stability constant of the complex with an increase in the atomic number of the lanthanoid. The stability constants of the complexes with EO4 and EO5 may be expected to decrease with the increase in the atomic number of the lanthanoid; this tendency is contrary to those of the lanthanoid complexes with most other ligands, just as the stability constant of the lanthanoid complex with 18-crown-6 ether, which is similar in

molar structure to the complexes with EO4 and EO5, has been reported to decrease with the increase in the atomic number of the lanthanoid.[26] The anomalous behavior observed for terbium–erbium in the EO4 complexes and for lanthanum–praseodymium in the EO5 complexes is probably related to the difference in the crystal structures between those complexes and the other ones, as has been described above. The solubilities were increased by the presence of water in the solution for all the complexes. This result is in accordance with the fact that the deposition of the solid complexes was interfered with by water. The difference in the solubility among the complexes of individual lanthanoids with EO4 or EO5 suggests a new method for the mutual separation of lanthanoids by means of fractional precipitation.[20]

Binuclear Metal Complexes. LI.[1] Synthesis and Characterization of the Tetrachloro-*o*-benzoquinone Adducts of Binuclear Iron(II) Complexes with 2-(Salicylideneamino)phenol and Its Substituted Homologs

Wakako KANDA, Masaaki NAKAMURA, Hisashi ŌKAWA,* and Sigeo KIDA
Department of Chemistry, Faculty of Science, Kyushu University 33 Hakozaki, Higashiku, Fukuoka 812
(Received August 9, 1982)

Binuclear iron(III) complexes Fe_2(R-R′-sap)$_2$(tcoq) have been prepared by the oxidation of binuclear iron(II) complexes Fe_2(R-R′-sap)$_2$ with tetrachloro-*o*-benzoquinone (TCOQ), where H_2(R-R′-sap) represents 2-(salicylideneamino)phenols with the substituent R on the salicylaldehyde ring and the R′ on the *o*-aminophenol ring. Magnetic measurements indicated the operation of an intramolecular antiferromagnetic spin-exchange interaction between the iron(III) ions, the exchange integrals being evaluated at -6——10 cm^{-1}. In both polarograms and cyclic voltammograms of these complexes, two redox processes attributable to Fe(III)–Fe(III) ⇌Fe(III)–Fe(II)⇌Fe(II)–Fe(II) were observed.

Previously we showed that binuclear manganese(II) complexes Mn_2(R-R′-sap)$_2$ of 2-(salicylideneamino)phenols (H_2(R-R′-sap); R and R′ being the substituents on the salicylaldehyde and the *o*-aminophenol rings, respectively) react with tetrachloro-*o*-benzoquinone (TCOQ) in an atmosphere of nitrogen to form binuclear manganese(III) complexes Mn_2(R-R′-sap)$_2$(tcoq), where two metal ions are bridged by the two phenolic oxygens of the Schiff bases in the equatorial plane and by the tetrachlorocatecholate group at the apical position (Fig. 1).[2] These complexes are very sensitive to moisture, hence decompose into Mn(R-R′-sap)$_2$ and Mn_2(R-R′-sap)$_2$ in an open atmosphere.[2]

As an extension of the above investigation, in this study we have prepared the binuclear iron(III) complexes Fe_2(R-R′-sap)$_2$(tcoq) and examined their properties in terms of Mössbauer spectroscopy, polarography, cyclic voltammetry and cryomagnetic measurements, in comparison with Mn_2(R-R′-sap)$_2$(tcoq) and binuclear iron(III) complexes related to the present complexes.

Experimental

Preparations. 2-(Salicylideneamino)phenol and its homologs were obtained by the reaction of salicylaldehyde or a substituted salicylaldehyde with 2-aminophenol or a substituted 2-aminophenol in the 1:1 mole ratio. In this study, the following ligands were used (*cf.* Fig. 1); 2-(salicylideneamino)phenol (H_2(sap)), 2-(5-methylsalicylideneamino)phenol (H_2(5-Me-sap)), 2-(salicylideneamino)-4-methylphenol (H_2(4′-Me-sap)), and 2-(salicylideneamino)-4-chlorophenol (H_2(4′-Cl-sap)).

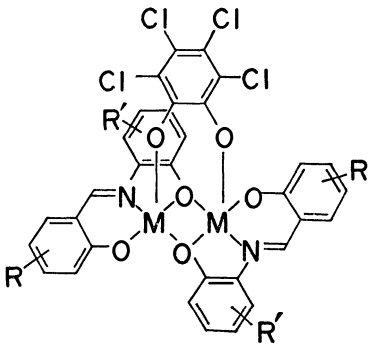

Fig. 1. Chemical structure of M_2(R-R′-sap)$_2$(tcoq) (M=Mn(III) and Fe(III)).

Binuclear iron(II) and iron(III) complexes, Fe_2(R-R′-sap)$_2$ and Fe_2(R-R′-sap)$_2X_2$ (X=Cl, Br), were prepared by the methods described in the literatures.[3,4]

Fe_2(R-R′-sap)$_2$(tcoq). Syntheses of the complexes were carried out in an atmosphere of nitrogen using a VAC Inert Atmosphere & Vacuum Deposition Equipment Model HE-43-2. The synthetic method for the complexes is exemplified by Fe_2(sap)$_2$(tcoq). A mixture of Fe_2(sap)$_2$ (0.50 g) and TCOQ (0.23 g) in absolute acetonitrile (20 cm^3) was refluxed for 5 h and then stirred overnight at room temperature. Black crystalline powder separated was collected, washed with a small amount of acetonitrile and dried *in vacuo*.

Elemental analyses of the complexes are given in Table 1.

Measurements. Elemental analyses of carbon, hydrogen, and nitrogen were carried out at the Service Center of Elemental Analysis Kyushu University. Analyses of iron were made with a Shimadzu Atomic Absorption-Flame Spectrometer Model AA-610S. Infrared spectra were measured with a Hitachi Infrared Spectrometer Model 215 on KBr disks. Mössbauer spectra were measured by the constant acceleration method at room temperature, using a cobalt 57 source (5 mCi) diffused into palladium foil. The velocity of the spectrometer was calibrated by the use of a pure iron foil enriched with iron-57, which was also used as a reference for the isomer shift values. All the Mössbauer parameters were obtained by computer calculations. Magnetic susceptibilities were measured by the Faraday method in the temperature range from liquid nitrogen temperature to room temperature. The apparatus was calibrated by the use of HgCo(NCS)$_4$.[5] Diamagnetic correction was made using Pascal's constants.[6] Effective magnetic moments were calculated by the equation, $\mu_{eff}=2.828(\chi_A \times T)^{1/2}$, where χ_A is the susceptibility per one iron atom corrected for diamagnetism. Electronic spectra were recorded on a Shimadzu UV-VISIBLE Recording Spectrometer Model UV-240 and Shimadzu Multipurpose Spectrophotometer Model MPS-5000 in dichloromethane. Polarograms and cyclic voltammograms were recorded with a Yanagimoto Voltammetric Analyzer Model P-1000 in dichloromethane containing 0.1 mol dm^{-3} tetrabutylammonium perchlorate as the supporting electrolyte. A three-electrode cell was used for measurements. The working electrode is a dropping mercury electrode for polarography and a glassy carbon for cyclic voltammetry. The auxiliary electrode and the reference electrode

Table 1. Elemental analyses of Fe_2(R-R′-sap)$_2$(tcoq)

	Found (%)				Calcd (%)			
	C	H	N	Fe	C	H	N	Fe
Fe(sap)$_2$(tcoq)·H_2O	47.87	2.51	3.82	13.7	48.16	2.53	3.51	14.0
Fe_2(5-Me-sap)$_2$(tcoq)·$2H_2O$	48.60	2.73	3.28	13.0	48.38	3.10	3.32	13.2
Fe_2(4′-Me-sap)$_2$(tcoq)·H_2O	49.75	2.94	3.52	13.3	49.44	2.92	3.39	13.5
Fe_2(4′-Cl-sap)$_2$(tcoq)·CH_3CN	45.80	2.23	4.50	12.3	45.89	2.15	4.72	12.6

were a platinum coil and a saturated calomel electrode, respectively. All the potentials were corrected by the use of ferrocene as an internal standard (Fc^+/Fc: $E_{1/2}=0.40$ V *vs.* NHE).[7]

Results and Discussion

Reaction of reddish brown Fe_2(R-R′-sap)$_2$ and TCOQ under nitrogen atmosphere yielded dark brown crystals. Elemental analyses suggested that these complexes contain (R-R′-sap)$^{2-}$, iron, and TCOQ in the ratio of 2:2:1. These complexes seem to be very stable in the open atmosphere, in contrast to the high sensitivity of Mn_2(R-R′-sap)$_2$(tcoq) to moisture. Infrared spectrum of Fe_2(sap)$_2$(tcoq) resembles that of Mn_2(sap)$_2$(tcoq), suggesting the similarity in the structure between them. The reactions of Fe_2(R-R′-sap)$_2$ with 9,10-phenanthrenequinone or 1,2-naphthoquinone instead of TCOQ gave no pure adducts.

In order to clarify the oxidation state and the spin state of the iron in Fe_2(R-R′-sap)$_2$(tcoq), the Mössbauer spectrum of Fe_2(sap)$_2$(tcoq) was measured at room temperature and is shown in Fig. 2. The quadrupole splitting (ΔE_q) and the isomer shift (δ) of this complex were determined to be 1.05 and 0.44 mm s^{-1}, respectively. It is known that the isomer shifts for most high-spin five-coordinate iron(III) complexes fall in the range 0.35—0.48 mm s^{-1}.[8,9] Thus, it is reasonable to assume that the iron in Fe_2(R-R′-sap)$_2$(tcoq) is in a high-spin state and of five-coordination. This suggests that the complexes possess the binuclear structure with the bridging tetrachlorocatecholate group at the apical position (Fig. 1).

The line-area ratio of the quadrupole doublet is estimated at 1:1, but the line-widths of the doublet are not identical; the positive side band (0.512 mm s^{-1}) is a little larger than that of the other band (0.425 mm s^{-1}). Similar asymmetry in quadrupole doublet has been found for [Fe(salen)Cl]$_2$ (salen^{2-}=*N*,*N*′-disalicylideneethylenediamine dianion) at 78 K, while its quadrupole doublet becomes nearly symmetric at 4.2 K.[4] According to Bergen *et al.* such asymmetry of Mössbauer doublet is attributable to the spin-spin relaxation.[10,11] Asymmetric quadrupole doublet was also observed for [Fe(salpa)Cl]$_2$ (salpa^{2-}=2-salicylideneamino-1-propanol dianion) and other binuclear iron(III) complexes.[9,12-14] In these complexes, spin-spin relaxation was regarded as the main reason for the asymmetric quadrupole splitting. Thus, it is likely that the asymmetric quadrupole doublet observed for Fe_2(sap)$_2$(tcoq) is also due to the spin-spin relaxation, although Mössbauer spectra at low temperatures are not measured.

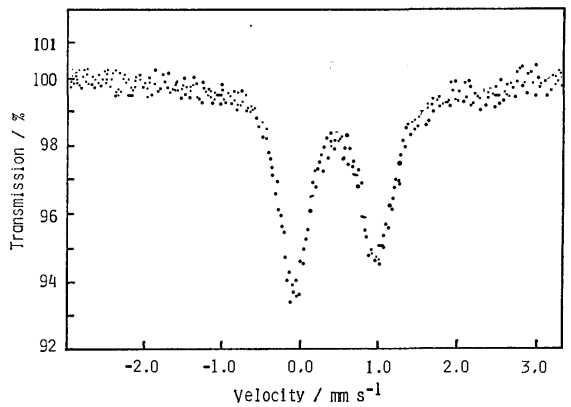

Fig. 2. Mössbauer spectrum of Fe_2(sap)$_2$(tcoq).

Magnetic susceptibilities of Fe_2(R-R′-sap)$_2$(tcoq) were measured in the temperature range 80—300 K. All of the complexes showed subnormal magnetic moments falling in the range 4.73—5.30 BM at room temperature (Table 2). Temperature-dependences of the magnetic moments suggested an operation of antiferromagnetic spin-exchange interaction between the metal ions. Based on the Heisenberg model ($\mathscr{H}=-2\Sigma J_{ij}S_iS_j$) and assuming no orbital contribution, the magnetic susceptibility equation for the Fe(III)-(S=5/2)-Fe(III)(S=5/2) system is given by

$$\chi_A=\frac{Ng^2\beta^2}{kT}\times\frac{55+30X^{10}+14X^{18}+5X^{24}+X^{28}}{11+9X^{10}+7X^{18}+5X^{24}+3X^{28}+X^{30}}+N\alpha$$
$$(X=\exp(-J/kT),$$

where χ_A represents magnetic susceptibility per iron atom and other symbols have their conventional meanings. Magnetic susceptibilities of the present complexes could be well interpreted in terms of this equation. A typical example of best-fits of magnetic susceptibilities to the theoretical curve is shown in Fig. 3. Magnetic parameters ($-J$ and g) thus determined are given in Table 2 (temperature-independent paramagnetism $N\alpha$ being assumed at zero). The exchange integrals range from -6 cm^{-1} to -10 cm^{-1}.

These integrals are close to the values of other di-μ-alkoxo or di-μ-phenoxo bridged binuclear iron(III) complexes so far reported.[4,15,16] It is particularly noticeable that the exchange integrals of the present complexes are essentially the same as those of $Fe_2(sap)_2X_2$ (X=Cl, Br).[4] This fact implies that the antiferromagnetic spin-exchange interaction in Fe_2(R-R′-sap)$_2$(tcoq) occurs *via* the phenolic oxygen bridge but not the tetrachlorocatecholate bridge.

Electronic spectra of the complexes Fe_2(R-R′-sap)$_2$-

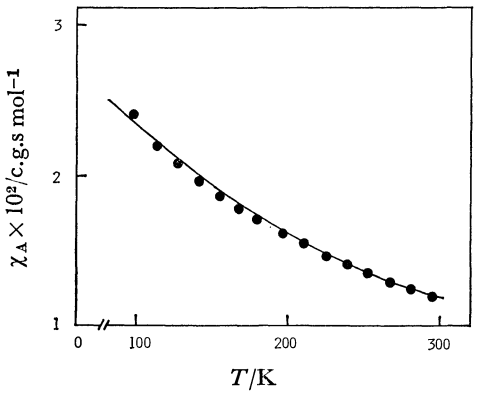

Fig. 3. Temperature variation of magnetic susceptibility for $Fe_2(sap)_2(tcoq)$. Solid curve is drawn based on the theoretical susceptibility equation using the parameters $g=1.98$, $-J=6.0$ cm^{-1} and $N\alpha=0$.

TABLE 2. EFFECTIVE MAGNETIC MOMENTS AT ROOM TEMPERATURE AND MAGNETIC PARAMETERS, J AND g, OF $Fe_2(R\text{-}R'\text{-}sap)_2(tcoq)$

	μ_{eff}/BM (T/K)	J/cm^{-1}	g
$Fe_2(sap)_2(tcoq)$	5.30(295.2)	−6	1.98
$Fe_2(5\text{-Me-sap})_2(tcoq)$	4.75(296.6)	−10	2.00
$Fe_2(4'\text{-Me-sap})_2(tcoq)$	5.00(296.1)	−8	2.00
$Fe_2(4'\text{-Cl-sap})_2(tcoq)$	5.30(297.8)	−6	1.98

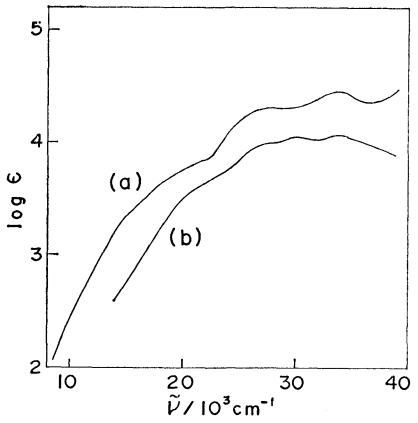

Fig. 4. Electronic spectra of (a)$Fe_2(sap)_2(tcoq)$ and (b) $Fe_2(sap)_2Cl_2$ in dichloromethane.

(tcoq) in dichloromethane are practically the same as each other, and were characterized by a strong absorption around 15×10^3 cm^{-1}, which is absent in the spectrum of $Fe_2(sap)_2Cl_2$. The spectrum of $Fe_2(sap)_2$-(tcoq) is shown in Fig. 4. The spectrum of $Fe_2(sap)_2$-Cl_2 is also shown for comparison. It is likely that the band at 15×10^3 cm^{-1} is due to the charge transfer band between iron(III) and tetrachlorocatecholate oxygen.

Electrochemical properties of the present complexes were investigated by means of polarography and cyclic voltammetry The complexes are stable in dichloromethane, judging from the fact that the electronic spectra obey Beer's law. Thus, electrochemical measurements were carried out in dichloromethane. All the complexes showed two quasi-reversible redox waves.

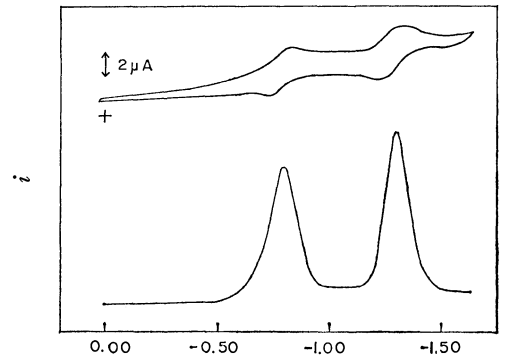

Fig. 5. Cyclic voltammogram (above) and differential pulse polarogram (below) of $Fe_2(5\text{-Me-sap})_2(tcoq)$.

TABLE 3. REDOX POTENTIALS $E_{1/2}$ (V vs. NHE) OF $Fe_2(R\text{-}R'\text{-sap})_2(tcoq)$

	DPP		CV	
	1st	2nd	1st	2nd
$Fe_2(sap)_2(tcoq)$	−0.77	−1.27	−0.91	−1.28
$Fe_2(5\text{-Me-sap})_2(tcoq)$	−0.86	−1.36	−0.83	−1.32
$Fe_2(4'\text{-Me-sap})_2(tcoq)$	−0.84	−1.34	−0.85	−1.35
$Fe_2(4'\text{-Cl-sap})_2(tcoq)$	−0.90	−1.26	−0.91	−1.30

DPP: Differential pulse polarogram, CV: cyclic voltammogram.

Differential pulse polarogram and cyclic voltammogram of $Fe_2(5\text{-Me-sap})_2(tcoq)$ are shown in Fig. 5. Half-wave potentials ($E_{1/2}$), which were determined from differential pulse polarogram and from the arithmetic mean of the cathodic and anodic peaks (E_{pc} and E_{pa}) of cyclic voltammogram, are given in Table 3.

Since binuclear zinc(II) complexes $Zn_2(R\text{-}R'\text{-sap})_2$ do not show any redox process in the range 0——1.8 V, the redox processess observed for $Fe_2(R\text{-}R'\text{-sap})_2$-(tcoq) can be attributed to those at the metal center. The first reduction occured at the potential −0.77——0.90 V and the second reduction at −1.26——1.36 V. The log (i/i_d-i) *vs.* E plots revealed that each process involves one-electron transfer. Based on these facts, we may tentatively attribute the first process to Fe(III)–Fe(III)⇌Fe(III)–Fe(II) and the second process to Fe(III)–Fe(II)⇌Fe(II)–Fe(II). It is to be noted that the redox potentials of $Fe_2(R\text{-}R'\text{-sap})_2(tcoq)$ are practically independent of the substituents R and R′ on the ligand, while the redox potentials of Mn(R-R′-sap)$_2$[2] and Zr(R-R′-sap)$_2$[17] are reported to be markedly dependent on the substituents.

In order to compare the electrochemical property of $Fe_2(R\text{-}R'\text{-sap})_2(tcoq)$ with that of $Fe_2(R\text{-}R'\text{-sap})_2X_2$, cyclic voltammograms of $Fe_2(sap)_2Cl_2$ and $Fe_2(sap)_2$-Br_2 were measured. The cyclic voltammograms, however, involved some complicated waves which could be hardly analyzed. It seems that $Fe_2(sap)_2X_2$ is partly dissociated or decomposed in solution.

Contrary to the step-wise redox behavior of $Fe_2(R\text{-}R'\text{-sap})_2(tcoq)$, $Mn_2(sap)_2(tcoq)$ showed only one redox couple attributable to the process Mn(III)–Mn(III)⇌

Mn(II)–Mn(II).[2] The present complexes Fe_2(R-R′-sap)$_2$(tcoq) are insensitive to moisture, while the manganese(III) complexes Mn_2(R-R′-sap)$_2$(tcoq) are very sensitive to moisture. It seems that the difference in sensitivity to moisture between Fe_2(R-R′-sap)$_2$(tcoq) and Mn_2(R-R′-sap)$_2$(tcoq) is due to their different electrochemical properties.

The authors are grateful to Associate Professor Yonezo Maeda and Dr. Tetsuaki Nishida of Kyushu University for the measurements and useful discussion of Mössbauer spectra.

(Received August 11, 1982)

Measurements were made of field desorption mass spectra of normal and deuterated styrene oligomers synthesized in various alkylbenzenes. Several series of molecular ion peaks are observed in both the spectra. From a comparison between them we have identified oligomers' end groups and derived formation mechanisms for individual molecular species. It has been clarified that molecular species independent of solvents are produced through chain transfer of propagating radicals to styrene dimers. Analysis for the polymerization mechanism of styrene as well as characterization of polymer molecules has been successfully performed by field desorption mass spectrometry.

Field desorption mass spectrometry (FD-MS) has been recognized as a very powerful tool for determination of molecular weights and structural characterization of nonvolatile compounds.[1] Recently, FD-MS has been applied also to examining various synthetic oligomers or polymers which consist of homologous mixtures, and its potentials for characterizing polymers have been demostrated.[2-4] However, until now the applicability of FD-MS to polymer chemistry has been restricted to determination of molecular weight distributions and molecular species.

Bevington[5] proposed from results in kinetic studies that radicals generated through reaction of Diels-Alder adducts with styrene monomers should react as an initiator in the thermally initiated polymerization of styrene. Similar results were obtained in a study[6] with considerations of isotope effect in the case of deuterated styrene.

In our previous works using the FD-MS,[7,8] we discussed on the telomerization of styrene oligomers to a chain transfer agent of 1,1,3,3,5,5-hexamethylhexanethiol and identified molecular species generated by the chain transfer in the thermal polymerization. In this investigation, we have been able to analyze successfully the mechanism of the thermally-initiated polymerization of styrene on the basis of FD-MS spectra of normal and deuterated styrene oligomers.

Experimental

Sample Preparation. Normal styrene monomer, toluene, ethylbenzene, propylbenzene, and isopropylbenzene were all commercial chemicals and used after distillation. Deuterated styrene monomer was obtained from Merck Sharp & Dohme Co., Ltd. and used without purification.

The oligomerization of normal or deuterated styrene was carried out by heating a sealed glass tube containing normal or deuterated styrene in solvent (molar ratio 1/100) at 200 °C for 2 h.

Apparatus. Mass spectrometry was performed on a JEOL-JMS D-300 double focusing mass spectrometer with a combined field desorption/field ionization/electron impact ion source, connected to a JMA 2000S mass data analysis system. The FD emitter used was a 10 μm tungsten wire with carbon needles. The oligomer sample was dissolved in chloroform (about 1 mg/0.5 ml) and loaded on the emitter by the normal dipping technique. The calibration of magnetic field current was done with perfluorokerosene or perfluoropoly(propylene oxide) as the reference *via* the EI mode. The accelerating voltage was either 3 or 2 kV. The instrumental resolution, $M/\Delta M$, was *ca.* 1000 (10% valley). The emitter current was increased linearly in the range 0—25 mA at the rate of 2 mA/min. The cathode potential was 5.5 kV. All FD-MS spectra were recorded as a sum of stored spectra.

Results and Discussion

Figures 1 and 2 show FD-MS spectra in the m/z region 250—800 for normal and deuterated styrene oligomers synthesized in ethylbenzene, respectively. It is seen from Fig. 1 that four series of molecular ion-peak patterns are distinguished by each mass number "104", which is the repetitive unit interval of a normal styrene. These series of peaks are at $92+104n$ (m/z 300—404—508—612), $208+104n$ (m/z 312—416—520—624), $106+104n$ (m/z 314—418—522—626), and $222+104n$ (m/z 326—430—534—638), where n is an integer corresponding to the degree of polymerization. Then, they are generally formulated as "$K+104n$," where K is a constant and is equivalent to the sum of both the mass numbers of the head and tail end groups. In the case of deuterated styrene, five series are also expressed in the same way as normal styrene oligomers except for the repetitive unit interval "107" being applicable to deuterated styrene; the five series are at $94+107n$ (m/z 308—415—522—629), $106+107n$ (m/z 320—427—534—641), $210+107n$ (m/z 317—424—531—638), $214+107n$ (m/z 321—428—535—642), and $226+107n$ (m/z 333—440—547—654). They are generally formulated as "$K+107n$."

Figures 3 and 4 show FD-MS spectra in the m/z region 400—500 for normal and deuterated styrene oligomers synthesized in toluene, ethylbenzene, propylbenzene, and isopropylbenzene. Each oligomer peak in Figs. 3 and 4 is also classified in the above-mentioned way. These results are summarized in Tables 1 and 2 for normal and deuterated styrenes, respec-

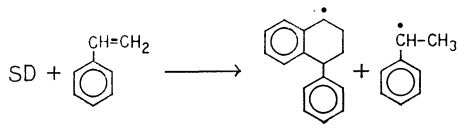
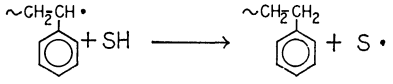
In a subsequent step, SD reacts with a third styrene monomer in a molecule-induced homolysis to produce two kinds of radicals according to

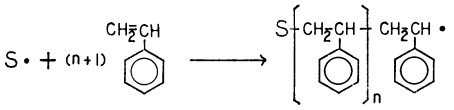


(2)

These two radicals then initiate polymerization, and under our experimental conditions employing circumstances with much more solvent, it is expected that the propagation radicals stimulate the chain transfer to solvent molecules (SH) and furthermore that solvent radicals with hydrogen atom abstracted should play a major role as a reinitiator according to

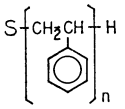


(3)



(4)

On the basis of the dependency of reactivity on the kind of solvents, the mass numbers of normal styrene oligomers with K's 92, 106, and 120 in Table 1 are assigned to the molecular species

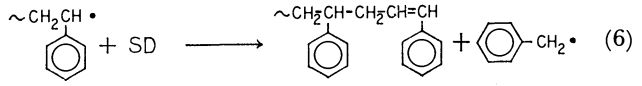


(5)

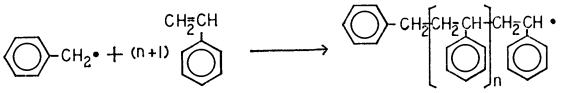
It is shown in Table 2 that such series as have the same K's are observed in deuterated styrene oligomers as well. On the contrary, existence of such molecular species as are independent of the kind of solvents is indicated which have K's 92 and 208 for normal styrene oligomers and 94 and 214 for deuterated ones in Tables 1 and 2, respectively.

Though with no detailed discussion on the mechanism of the chain transfer, Pryor and Coco[10] pointed out from a computer simulation that the propagation mechanism for the thermal polymerization of styrene should be related to the chain transfer of SD and that at 60 °C the chain transfer constant, Cm*, for SD was 10^2—10^3 times higher than that for any aromatic hydrocarbon solvents used here. In our present investigation, the chain transfer to the solvent could occur with a rather high probability because of the low concentration of styrene monomer (below 1 mol%).

In order to explain the appearance of molecular species given in Tables 1 and 2, it is assumed that the chain transfer of propagating radicals to SD should follow the reaction sequences

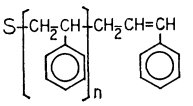


(6)

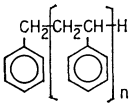


(7)

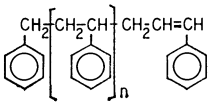
Thus, if the propagating radicals encounter SD, the SD makes a cleavage into benzyl and 3-phenyl-2-propenyl radicals, and then the 3-phenyl-2-propenyl radicals are combined with the propagating radicals, while the benzyl radicals only contribute to the reinitiation process. According to this assumption and considering the chain transfer to solvents, it may be expected that there should exist two head groups and two tail groups, and therefore that the four molecular species represented by Formula 5 and the following formulas should be observed in FD-MS spectra.



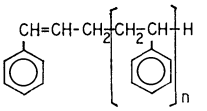
(8)



(9)



(10)



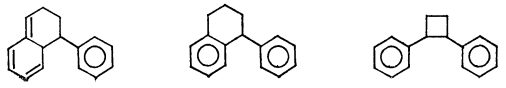
(11)

Indeed, our experimental results may support the proposed mechanism. Furthermore, it is clarified that the abstraction reaction of a benzyl group through the chain transfer to SD dose not occur, as evidenced by the fact that no such molecular species as shown by Formula 11 appears in any FD-MS spectra.

In Figs. 3 and 4, besides the peaks attributed to the chemical structures for Formulas 5 and 8—10, molecular ion peaks independent of the kind of solvents, whose K's correspond to 182, 210, and 238, are observed. They are thought as being produced by the recombination termination between the propagating radicals, since there are generally two termination processes, that is, recombination and disproportionation, and moreover it was reported that the probability of the recombination termination for styrene is nearly 100%.[11] Other intense peaks in Figs. 1 and 2 are observed at 312 and 321 for normal and deuterated styrene oligomers, respectively. These peaks are assigned to the molecular species formed in the trimerization of monomers. These results are in agreement with the fact that the radical pair produced in the reaction between SD and styrene monomers should generate the cage reaction to form trimeric products concertedly against the chain initiation.[12]

In conclusion, it was proved from a detailed analysis of molecular ion peaks observed in FD-MS spectra that some kinds of reactions were generated in the styrene polymerization. They are radical telomerization to solvents and SD and recombination termination and cage reaction between initiating or propagating radicals. Thus, it has been found that the

* SD may be considered as such intermediates:



FD-MS is effective for the investigation on the polymerization mechanism. However, it is not sufficient to discuss the quantitative analysis owing to the bad reproducibility of peak intensities. In near future, if high sensitive measurement in the high mass region becomes available, the whole polymerization mechanism might get clarified and confirmed more accurately.

Aromatic Nucleophilic Substitution. XVI.[1] Stopped-flow Kinetics of Formation and Decomposition of 1,3- and 1,1-Disubstituted Anionic σ Complexes in Reactions of 1-Dimethylamino-2,4-dinitronaphthalene with Potassium Alkoxides in Dimethyl Sulfoxide–Alcohol

Shizen Sekiguchi,* Noboru Tone, Toshio Takei, and Noboru Tomoto†

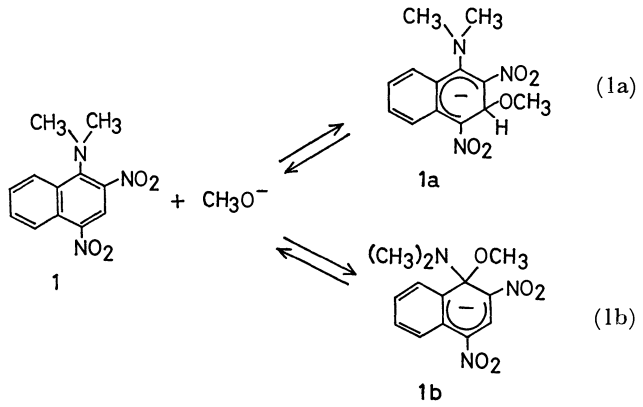
(Received June 10, 1982)

Reactions of 1-dimethylamino-2,4-dinitronaphthalene with potassium methoxide or ethoxide were carried out in DMSO–CH_3OH or DMSO–C_2H_5OH (90:10 v/v), respectively, where the 1,3-disubstituted anionic σ complexes were first rapidly formed, undergoing isomerizations to the 1,1-disubstituted anionic σ complexes. Rates and activation parameters were determined by kinetic studies using stopped-flow and conventional spectrophotometers. The rate constant (25 °C) for the formation of 1,3-disubstituted one in DMSO–CH_3OH is about half that in DMSO–C_2H_5OH, whereas the rate constant (25 °C) for its decomposition is more than twice that in DMSO–C_2H_5OH. The apparent pseudo-first-order rate constant for the formation of 1,1-disubstituted anionic σ complex in DMSO–CH_3OH depends upon the methoxide ion concentration, whereas that in DMSO–C_2H_5OH is almost independent of the ethoxide ion concentration. The mechanism is discussed on the basis of activation parameters.

In our previous work[1] we reported detailed kinetics of reactions of 1-dialkylamino-2,4-dinitronaphthalenes with potassium methoxide in DMSO–CH_3OH, where 1,3-disubstituted anionic σ complexes are first formed, undergoing isomerizations to 1,1-disbustituted ones according to



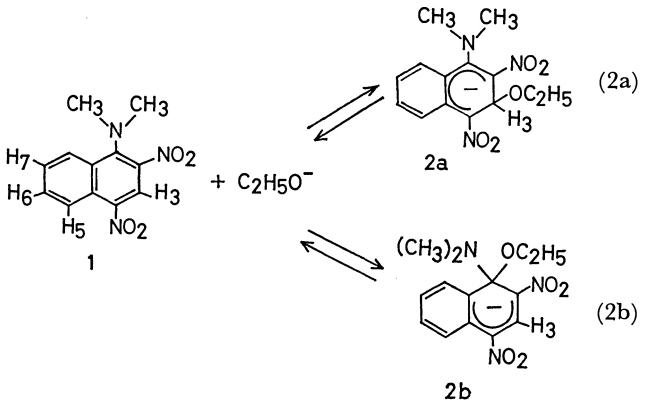
Thus we found that the kind of the 1-dialkylamino groups and the DMSO content in the mixed solvent will affect the rate of formation and decomposition of 1,3- (**1a**) and 1,1-disubstituted anionic σ complexes (**1b**).

Therefore, replacement of potassium methoxide by potassium ethoxide would be expected to affect the rates of formation and decomposition of both complexes.

This paper reports a comparison of the results obtained in the case of potassium ethoxide with those in the case of potassium methoxide in order to elucidate further the reaction mechanism.

Results

Absorption Spectra. Upon addition of excess ethanolic C_2H_5OK to 1-dimethylamino-2,4-dinitronaphthalene (**1**) in DMSO–C_2H_5OH (90:10 v/v), the solution was colored red instantly (Fig. 1): Curve b, for the formation of a complex (**2a**, corresponding to **1a**), was first obtained, which was then gradually changed into Curve d due to the formation of a complex (**2b**, corresponding to **1b**). The time-dependent spectral change is clearly interpreted on the basis of the reaction paths defined by



On the other hand, NMR spectrometry, which is generally recognized useful for elucidating structures of anionic σ complexes,[2,3] also showed that the process (Eq. 2) is valid: Just after addition of ethanolic C_2H_5OK (1.19×10^{-4} mol) to a DMSO solution (0.4 ml) of **1** (1.15×10^{-4} mol) at room temperature, the solution turned red at once, suggesting the formation of a complex. Just after addition, H_3 sharp singlet ($\delta=8.70$) of **1** shifted upfield ($\delta=6.27$, H_3 of **2a**). Fast sweep time (500 Hz/50 s) and fast procedures are indispensable for detecting spectral changes. One minute and a half after addition, a new singlet, due to H_3 of **2b**, appeared at $\delta=9.26$ at the expense of the singlet at $\delta=6.27$ which appeared faintly.

It is thus expected that the discrete kinetics of formation and decomposition of **2a** and **2b** is possible.

Kinetic Runs. Let us rewrite Eq. 2 in a form convenient for quantitative discussion as follows:

$$\mathbf{1} + C_2H_5O^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathbf{2a}, \quad (3a)$$

$$\mathbf{2a} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \mathbf{2b}, \quad (3b)$$

$$K_1 = \frac{k_1}{k_{-1}}, \quad K_2 = \frac{k_2}{k_{-2}}.$$

According to the results of UV-VIS and NMR spectra, the reaction will occur in two distinct stages: The chemical transformations responsible for the first (Spectrum a→b) and second spectral changes (Spectrum b→c→d), to be termed Stage I and Stage II, respectively. The Stage I reaction (**1**⇄**2a**) is much faster than the Stage II reaction (**1**⇄**2b**). Accordingly, in treating the Stage I kinetics, the Stage II reaction can be neglected; the Stage I reaction goes to completion in a few tenths of a second (Table 1), making negligible the possible kinetic effect from the Stage II reaction.

Stage I. The pseudo-first-order rate constant, k_ψ, for the attainment of an equilibrium (K_1) is the sum of forward and reverse components.[4] For the Stage I reaction the kinetic expression (Eq. 4)

$$k_\psi = k_1([C_2H_5O^-]+[\mathbf{1}]) + k_{-1} \quad (4)$$

$$k_\psi = k_1[C_2H_5O^-] + k_{-1} \quad (5)$$

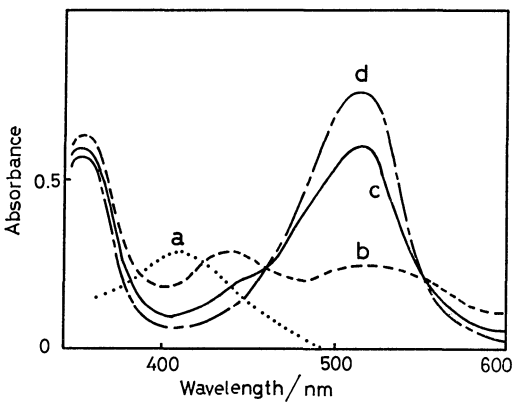


Fig. 1. Spectral change relevant to the reaction of 1-dimethylamino-2,4-dinitronaphthalene (**1**) with C_2H_5OK in DMSO–C_2H_5OH (90:10 v/v) at room temperature.
a: **1** (3.5×10^{-5} M) (1 M=1 mol dm^{-3}), b: just after addition of C_2H_5OK (4.42×10^{-3} M), c: 15 min after addition, d: 90 min after addition.

should hold. Under the actual condition $[C_2H_5O^-]\gg[\mathbf{1}]$, Eq. 4 is simplified to Eq. 5.[5]

As a result, k_1 and k_{-1} are estimated from the slope and intercept in the linear dependence of k_ψ on $[C_2H_5O^-]$ (not shown). Table 1 shows the dependence of k_ψ on the ethoxide ion concentration, including the estimated rate and equilibrium constants. Table 2

shows the dependence of k_1, k_{-1}, and K_1 on reaction temperature.

The kinetic and activation parameters obtained from the Arrhenius plot (not shown) are summarized in Table 3.

Stage II. As shown in Fig. 1, the first spectral change (**1**⇄**2a**) can be followed by stopped-flow spectrophotometry, whereas the second one (**2a**⇄**1**⇄**2b**) can be measured by usual spectrophotometry. As a result, the Stage I reaction is very fast compared with the Stage II one, because the time scale of measurement by stopped-flow spectrophotometry is extremely short compared with that by usual spectrophotometry. Therefore, the Stage I reaction can be treated as a fast mobile equilibrium, with shift almost entirely to the right, in treatments of the Stage II kinetics.

As to the rate of the Stage II reaction, the kinetic expression derivable from Eq. 3 should take account of the possibility that the substrate may be split between **1** and **2a**. Putting $[\mathbf{1}]_{st}=[\mathbf{1}]+[\mathbf{2a}]$ and with K_1 standing for the equilibrium constant for the Stage I reaction, one obtains

$$k_{obsd} = k_{-2} + \frac{k_2[C_2H_5O^-]}{1+K_1[C_2H_5O^-]}, \quad (6)$$

where k_{obsd} is the pseudo-first-order rate constant for the Stage II reaction, and k_2 and k_{-2} the rate constants for the forward and reverse reactions.

From Eq. 6, the dependence of k_{obsd} on $[C_2H_5O^-]$ would afford a curvilinear relationship, in which the curve would not pass through the origin. If the k_{-2} value can be obtained by extrapolation from the relationship between k_{obsd} and $[C_2H_5O^-]$, one may derive the following equation by substituting the value into Eq. 6 and rearranging:

$$\frac{1}{k_{obsd}-k_{-2}} = \frac{1}{k_2[C_2H_5O^-]} + \frac{K_1}{k_2}. \quad (7)$$

Thus, k_2 and K_1 can be obtained from the slope and intercept in the plot of $1/(k_{obsd}-k_{-2})$ against $1/[C_2H_5O^-]$. In the inversion plot the k_{-2} value was determined so that the best linear relationship might be established. Therefore, there might be some ambiguity in the k_{-2} values.

Table 4 shows the dependence of k_{obsd} on the alkoxide concentration, including the estimated rate and equilibrium constants. The relationships (Eqs. 6 and 7) hold for the reaction of **1** with CH_3O^- [1] (Figs. 2 and 3). It is clear, however, that the k_{obsd} values hardly depend upon $[C_2H_5O^-]$.

Discussion

Activation Parameters of Stage I. The difference between the k_1 values depends upon the ΔS_1^* rather than the ΔH_1^* values, although the ΔH_1^* and ΔS_1^* values compensate each other (Table 3). This relationship reasonably arises from the difference between the structures of the transition states leading to **1a** and **2a**. The transition state leading to **2a** would resemble the intermediate **2a** less closely than does the one leading to **1a**; the $C_2H_5O\cdots C_1$ (naphthalene)

Table 4. Rate constant for the formation and decomoosition of 1,1-disubstituted anionic σ complex formed from 1-dimethylamino-2,4-dinitronapthalene (**2**) and potassium ethoxide in DMSO-C_2H_5OH (90:10 v/v) at 25 °C[a]

a) $[\mathbf{2}]_0=3.96\times10^{-5}$ M; $\mu=0.05$ M ($KClO_4$). Measured at λ_{max} 519 nm. For the results of the reaction of **1** with CH_3OK, see Table 4 in Ref. 1. b) The $(k_2/K_1)+k_{-2}$ value is the average of k_{obsd}'s.

bond would be less closer to the covalent bond (C_2H_5O–C_1) in **2a**. This situation would likely originate from the higher nucleophilicity of $C_2H_5O^-$. As a result, the free energy ΔG_1^* ($=\Delta H_1^* - T\Delta S_1^*$) for the forward reaction (Eq. 2a) is less than the free energy ΔG_1^* for the forward reaction (Eq. 1a) due to more delocalization of the negative charge donated by $C_2H_5O^-$.

Stage II. As described previously, the rate expression for Stage II is as shown in Eq. 6. Equation 6 is consistent with the results for the reaction of **1** with CH_3O^- (Fig. 2). The k_{-2} value can be determined by extrapolation of $1/[CH_3O^-]\rightarrow 0$. The inversion plot using the k_{-2} value (Eq. 7) shows a good linearity (Fig. 2).

For the reaction of **1** with $C_2H_5O^-$, however, the k_{obsd} values hardly depend upon $[C_2H_5O^-]$ at the ethoxide ion concentrations studied (Fig. 3). The results could rationally be interpreted as follows: The K_1 value for the reaction of **1** with $C_2H_5O^-$ was determined to be 4380 M^{-1} (1 M=1 mol dm^{-3}). Accord-

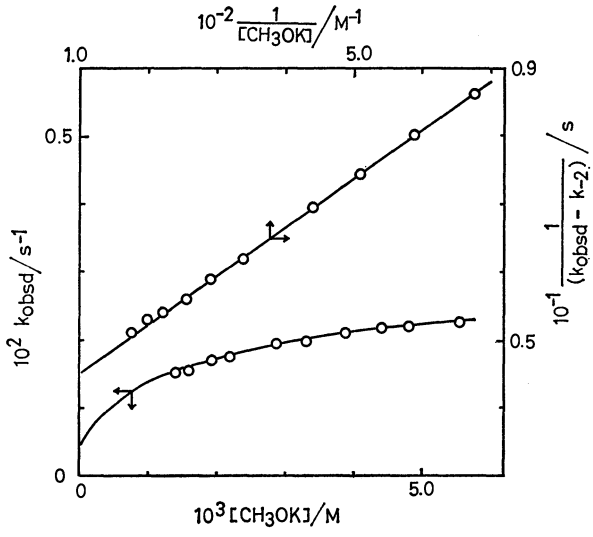

Fig. 2. Relationships between k_{obsd} and $[CH_3OK]$ and between $1/(k_{obsd}-k_{-2})$ and $1/[CH_3OK]$ in naphthalene (**1**) with CH_3OK in DMSO-CH_3OH (90:10 v/v) at 25 °C [cited from Ref. 1]: $[\mathbf{1}]_0$ 3.20×10^{-5} M; μ 0.05 M ($KClO_4$).

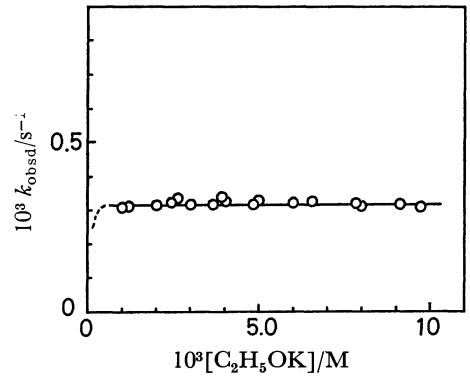

Fig. 3. Relationship between k_{obsd} and $[C_2H_5OK]$ in the reaction of 1-dimethylamino-2,4-dinitronaphthalene (**1**) with C_2H_5OK in DMSO-C_2H_5OH (90:10 v/v) at 25 °C.

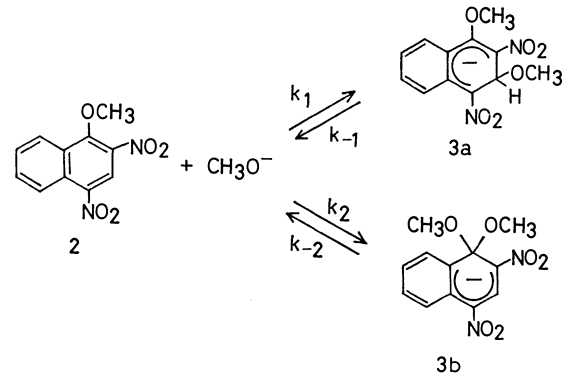
ing to this value, $K_1[C_2H_5O^-]$ varies from *ca.* 4 to *ca.* 43 (Table 4). In Eq. 6, then, $1+K_1[C_2H_5O^-]$ is nearly equal to $K_1[C_2H_5O^-]$ except for the $[C_2H_5O^-]$ range 1.00 to 1.30×10^{-3} M. As a result, k_{obsd} is equal to $k_{-2}+(K_2/K_1)$ (Fig. 3). Accordingly, in the case of **1** with $C_2H_5O^-$, too, the reaction will proceed as shown in Eq. 3.

It is of interest to compare our results with those of Millot and Terrier,[7] who carried out a kinetic study of the reaction of **2** with potassium methoxide in DMSO-CH_3OH (90:10 v/v) at 20 °C and proposed the sequences



The values they specified are as follows: k_1 7800 M^{-1} s^{-1}; k_{-1} 8.5 s^{-1}; K_1 916 M^{-1}; k_2 2100 M^{-1} s^{-1}; k_{-2} too small to be decided.

With the Stage I reactions (Eqs. 1a, 2a, and 8a), the k_1 and k_{-1} values for the reaction of **2** with CH_3O^- are the largest, but the K_1 values are similar in both cases (Eqs. 1a and 8a), whereas the K_1 value for the reaction of **1** with $C_2H_5O^-$ (Eq. 2a) is much larger than those in the other cases (Eqs. 1a and 8a). Further, the k_1(**3a**)/k_1(**1a**) and k_{-1}(**3a**)/$k^{-}{}_1$(**1a**) ratios are *ca.* 12, whereas the k_1(**3a**)/k_1(**2a**) and k_{-1}(**3a**)/k_{-1}(**2a**) ratios are *ca.* 6.6 and *ca.* 28, respectively. That is to say, in the former cases (Eqs. 1a and 8a) the k_1 and k_{-1} ratios are quite the same, whereas in the latter (Eq. 2a) the k_1 ratio is about one seventh the k_{-1} ratio. The difference arises from the fact that the free energy (ΔG_1^*) for the reaction of **1** with $C_2H_5O^-$ is the least among the three cases (Eqs. 1a, 2a, and 8a) and, then, the complex **2a** is the most stable as described above.

In conclusion, it is confirmed that the reactions of 1-dialkylamino-2,4-dinitronaphthalenes with alkoxides will proceed according to Eq. 1 and that the larger the nucleophilicity of alkoxides is, the stabler are the anionic σ complexes.[7]

Experimental

NMR spectra were recorded on a Varian A-60D spectrometer and UV-VIS absorption spectra on a Hitachi Model 200-10 spectrophotometer.

Materials. Compound **1** was prepared according to the method described previously.[7] A small amount of calcium hydride was added to commercial dimethyl sulfoxide, which was then distilled under reduced pressure prior to use. Commercial potassium perchlorate of special grade was used without further purification,

Rate Measurement. As regards the kinetics of formation and decomposition of 1,3-disubstituted anionic σ complex, the transmittance of the complex was measured in order to estimate the apparent pseudo-first-order rate constants (k_{ψ}) with a thermostated Union RA-1300 Stopped-Flow Analyser (Union Giken). The kinetic measurements for the formation and decomposition of 1,1-disubstituted ones (k_{obsd}) were made with a thermostated Hitachi Model 200-10 Spectrophotometer.

This research was supported in part by a Grant-in-Aid for Scientific Research No. 455330 from the Ministry of Education, Science and Culture.

Mechanism of the Photochemical and Thermal Wolff Rearrangement of 2-Diazo-1,3-dicarbonyl Compounds

Hideo Tomioka,* Norihiro Hayashi, Tsuneo Asano, and Yasuji Izawa
Department of Industrial Chemistry, Faculty of Engineering, Mie University, Tsu, Mie 514

(Received July 12, 1982)

Thermolysis and photolysis of 2-diazo-1,3-dicarbonyl compounds were investigated as a function of methanol concentration. As the methanol concentration decreased, methyl group migration increased concomitant with the suppression of O–H insertion into methanol, whereas aryl group migration was essentially unaltered with the methanol concentration. The results are interpreted as indicating that aryl migration occurs directly from the excited state of diazo compounds, but that methyl migration takes place in the singlet carbene in competition with O–H insertion.

The Wolff rearrangement of α-diazo carbonyl compounds has received continuous interests,[1] since the reaction has not only found wide use as the crucial step in the Arndt-Eistert synthesis, but also attracted much interests industrially as a photoresist process.[2] Although the Wolff rearrangement has been the subject of numerous mechanistic investigations,[1] a satisfactory rationalization of this reaction has been achieved only recently. Since Kaplan and Meloy[3] have shown that diazo ketones exist as an equilibrium mixture of *s-cis* and *s-trans* forms as a result of hindered internal rotation about central C–C bond, the crucial question related to the mechanism of the Wolff rearrangement seems to be whether the reactive intermediate is a free keto carbene or the diazo ketone itself. We have recently suggested[4] that the Wolff rearrangement to form ketene takes place directly from the diazo ketone in some cases, whereas singlet keto carbene undergoes either characteristic carbenic reactions, *e.g.*, insertion, or gives rise to ketene. The mechanisms have been shown[4] to account for the relative efficiency of other competing reactions of more complicated polyfunctional diazo compounds. The relative migratory aptitude established[5] with 2-diazo-1,3-dicarbonyl compounds should be re-examined in this respect since it has been generally assumed that only free keto carbene is involved in the migration. The relative migratory aptitudes of individual groups have been reported[1,5] to be sensitive to the method in which the reaction is conducted. Thus, the following series is generally valid for the thermal reaction:

$$H > Ph > Me > R_2N > RO.$$

In the photochemical variant, Ph and Me change places:

$$H > Me > Ph > R_2N > RO.$$

To date, no reasonable scheme to explain the difference has appeared. Thus, we have examined the thermolysis and photolysis of 2-diazo-1,3-dicarbonyl compounds in more detail in order to get deeper insight into the nature of migration.

Results and Discussion

A solution of 2-diazo-1-phenyl-1,3-butanedione (**1a**) in methanol-dioxane was decomposed in Pyrex tubes either photochemically or thermally as detailed in the Experimental section. GC analysis of the product mixture revealed the presence of two rearranged products (**2** and **3**) arising from the migration of both Ph and Me groups, O–H insertion (**4**) and double hydrogen-abstraction products (**5**) of carbene (Eq. 1). The

b: Ar=*p*-Br-C_6H_4, R=Me, **d**: Ar=Ph, R=OEt

product identifications and distributions were determined by GC and/or NMR using authentic samples. As summarized in Table 1, the product distributions were sensitive to the concentration of methanol. Thus,

a) Reactions were performed on a 10 mM solution of **1** in dioxane in sealed Pyrex tubes. b) Determined by GC. c) Irradiations were carried out at 10 °C with 300 W high-pressure Hg lamp. d) Ten-fold excess of 1,3-pentadiene was added as a triplet quencher. e) Five-fold excess of 4-methylbenzophenone was added. f) Thermolyses were carried out at 80±1 °C. g) One-fifth of benzoyl peroxide was added. h) Trace.

in both photolytic and thermal runs, as the methanol concentration decreased, Me group migration product **3** increased concomitant with the suppression of the O–H insertion product **4**, whereas phenyl group migration product **2** was essentially unaltered with the methanol concentration. Similar trends were also observed for other 2-diazo-1,3-diketones (**1b, c**) as summarized in Table 2. Although the high incidence of Me as opposed to Ar migration was generally observed for the photochemical Wolff rearrangement regardless of the methanol concentration, Ar and Me change places for the thermal run as the methanol concentration decreased. Consequently, at high methanol concentration where the Wolff rearrangement has been generally carried out, the apparent relative migratory aptitudes of Me and Ar groups are not same in the thermal and photochemical Wolff rearrangements, but the trends become similar at the lower concentration regardless of the way in which the reaction is conducted.

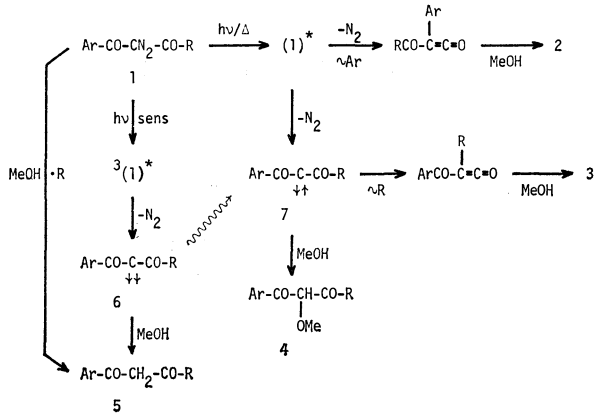
a)—d) They are defined in Table 1. e) Five-fold excess of 4-methylbenzophenone was added. f) Trace.

It is very important to examine the origin of the effect of the methanol concentration on the relative migratory aptitude. The above data indicate that Me migration **3** and O–H insertion products **4** arise from a common intermediate (A), while Ar migration product **2** is derived from a different intermediate (B). In order to obtain information on the multiplicity of the intermediates, the effects of triplet sensitizer and quencher were studied. When the photolysis of **1a** was carried out in the presence of 4-methylbenzophenone, formation of **2** was greatly reduced whereas **3** as well as **4** were still formed in moderate yields. One may propose that the intermediate A may be the triplet carbene, since it is generally accepted[6] that photosensitized decomposition of a diazo compound circumvents the formation of the singlet carbene and generates exclusively the triplet carbene *via* energy transfer and loss of N_2 from the resulting triplet precursor diazo compound. The substantial formation of **3** and **4** in the direct irradiation, then, suggests that the triplet carbene would be formed either *via* a rapid intersystem crossing from the initially generated singlet carbene or *via* dissociation from the triplet diazo compound **1**, probably formed by the intersystem crossing from the singlet excited state. If this were the case, one would expect that the addition of 1,3-pentadiene, an efficient quencher for both triplet carbene and triplet excited states,[1] should cause considerable suppression of the formation of **3** and **4**. No change in the product ratio was, however, observed even in the presence of a high concentration of this quencher. This clearly eliminates the triplet carbene as a possible intermediate A for **3** and **4**. It is generally accepted,[1,7] on the other hand, that the key intermediate leading to the O–H insertion product (*e.g.*, **4**) is singlet carbene, and hydroxylic reagents have been shown[8] to be efficient quenchers for singlet carbene. Thus, the structure for the intermediate A that best fits into these data is that of a singlet carbene.

What is then the intermediate B? It is quite important to note here that there has been accumulating evidence[3,4,9,10] on the mechanism of the Wolff rearrangement which shows that there is a pathway which does not include the singlet carbene but favors the migration accompanied by loss of N_2 directly from the excited diazo compound. It is tempting to suggest the excited (either photochemically or thermally)

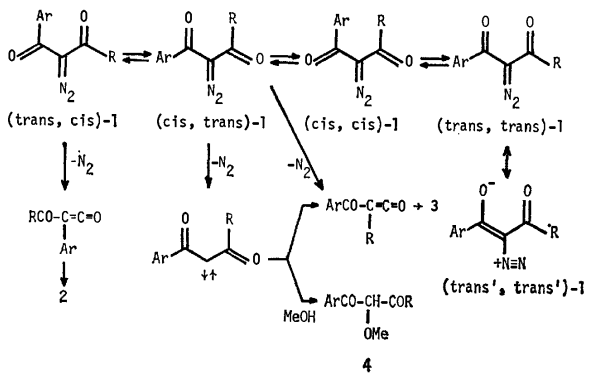


Scheme 1.

1 as the most likely intermediate B for **2**. Suppression of **2** by the photosensitization which circumvents the formation of the excited singlet **1** also supports the above assignment.

On the basis of the above assignments, a reasonable mechanism which explains the data is given in Scheme 1. Thus, **1** is excited either thermally or photochemically to its excited state which can give rise to the Ph migration product directly or dissociate to give N_2 and singlet carbene (**7**). The singlet carbene **7** subsequently undergoes either Me migration or O–H insertion into alcohol. Appreciable formation of **3** and **4** from the singlet carbene **7** even in the sensitized decomposition can be interpreted as indicating that intersystem crossing of the triplet carbene to the singlet is possible, as has frequently been observed in other analogous carbene systems, *e.g.*, $:CHCOCH_3$,[9] $:CHCONEt_2$,[4] and :CHCN.[9] No prominent formation of the characteristic triplet product in the sensitized photolysis is interpreted as indicating that intersystem crossing of the triplet carbene to the singlet is significant and its rate is substantially greater than its overall rate. It has been generally accepted[1] that one of the characteristic product from the triplet carbene is the double hydrogen-abstraction product **5**. Thermolysis of **1** in the presence of benzoyl peroxide (BPO) resulted in almost exclusive formation of **5**. This indicates that **5** is formed mainly *via* radical-induced[11] decomposition of **1** itself, but not from the triplet carbene **6** in this case.

There remains the question of the factors which control the two competitive processes from the excited diazo compounds. One explanation must include Kaplan and Meloy's suggestion[3] that diazo ketones exist as an equibrium mixture of *s-cis* and *s-trans* forms as a result of hindered internal rotation about the central C–C bond. In the investigation of photochemical processes of several α-diazo monocarbonyl compounds, we have suggested[4] that the Wolff rearrangement to form ketene takes place directly from the singlet excited state of the *s-cis* conformer, whereas that of the *s-trans* conformer dissociates N_2 to generate singlet keto carbene which either undergoes characteristic carbenic reactions, *e.g.*, O–H insertion, or gives rise to ketene.



Scheme 2.

Thus, the ratio of the Wolff rearrangement to the competing carbenic processes is shown to be roughly proportional to the ground state population of *s-cis* and *s-trans* conformers. If one assumes here a coplanar molecule for **1** as a result of resonance contribution, one would expect four possible rotamers for **1** (Scheme 2). The influence of steric and electrostatic effects exerted between the Ar, R, C=O, and $C=N_2$ groups causes variations in the relative energy of four conformers and, therefore, in their populations.[12] Electrostatically, conformers (*trans, cis*), (*cis, trans*), and (*cis, cis*) are favorable as a result of electrostatic attraction, whereas (*trans, trans*) is less stable due to the repulsion between two C=O groups, as is predicted from the canonical form (*trans', trans'*). Sterically, on the other hand, (*trans, trans*) would suffer from steric repulsion in the Ar–N_2–R groups, all in a cis relationship, and in (*cis, cis*), the nonbonding repulsion between Ar and R would be severe. Thus, one would expect that conformers (*trans, cis*) and (*cis, trans*) would be more stable than (*trans, trans*) and (*cis, cis*). The conformer (*trans, cis*) presents a favorable situation for Ar migration to occur in its excited state, since migrating and leaving groups in this conformer are situated in positions with respect to each other which permit the migration. In the (*cis, trans*) conformer, on the other hand, Me migration accompanied by loss of N_2 would be expected to occur in its excited state. Experimental results suggest, however, that main pathway from this conformer is dissociation of N_2 to generate singlet carbene in which Me migration occurs in competition with the O–H insertion. The reason for this difference lies partly in the difference in inherent migratory ability between Me and Ph groups. A concerted process with Ph migration and loss of N_2 would be favored[13] by donation of more labile π-electron to the diazo carbon and by the stabilization of a transition state (or short-lived intermediate) through bridging delocalization. Since such stabilization is not attained in Me migration, dissociation of N_2 occurs before Me group shifts to the diazo carbon.

The dependence of the product ratio, **2**/(**3**+**4**), on the method of reaction reflects, at least in part, the influence of the temperature on the relative population of each conformer. It has been reported,[14] for example, that photolysis of diazo ketone $RCOC(CH_2R')N_2$ yields the α,β-unsaturated ketone as the major product at room temperature; however, at higher temperature, the ketene rearrangement product is obtained. The results are similarly explained by assuming that the higher energy conformations are more populated as the temperature is raised. The product distributions in Tables 1 and 2 indicate that (*cis, trans*) conformers are preferred for **1a**—**c**. Apparent decrease in this conformer for **1d** can be attributable to a finite activation energy to migration of the alkoxyl group which is known[1] to be an inefficient migrating group. This group did not migrate at all either in the excited diazo compound or in the singlet carbene even in the absence of an efficient trap for the singlet carbene, *i.e.*, methanol. It is also important to note that the singlet carbene generated thermally undergoes Me migration more readily than that generated photolytically as opposed to the O–H insertion. This is explained in terms of the activation energy difference

between two processes. Alternatively, a part of Me migration would occur directly in the excited state in thermal run.

From the data, we propose a reasonable reaction scheme to explain why Me and Ph migrations take place in the trend of relative migratory aptitude as the method of reaction is changed. We wish to point out that the ground state population of rotational isomers and nature of migration (carbenic or diazo) are definitely related to the apparent relative migratory aptitude in 2-diazo-1,3-dicarbonyl compounds. These factors have not been taken into account in the literature.

Experimental

Instrumentation. UV spectra were recorded on a Hitachi 220-S spectrophotometer. IR spectra were measured on a JASCO IR-G recording spectrometer, and ^{1}H NMR spectra were determined with a JEOL JNM-MH-100 NMR spectrometer in $CDCl_3$ with Me_4Si as an internal reference. GC analyses were performed on a Yanagimoto Model G-180 instrument with flame ionization detector using 80 cm×4.0 mm column packed with (A) 5% PEG 20 M and (B) 5% Silicone SE-GE on 60—80 mesh Diasolid L.

Materials. 2-Diazo-1,3-dicarbonyl compounds **1a—d** were conveniently prepared[13] by diazo-group transfer from *p*-toluenesulfonyl azide to the appropriate dicarbonyl compounds and purified through a short silica-gel column. Authentic samples for product identification were prepared according to the literature procedures. Thus, Ar migration products **2a—c** were prepared by the condensation[15] of ethyl acetate with the corresponding benzyl cyanides, followed by methanolysis[16] of the resulting cyanide. Phenylmalonate **2d** was obtained by stepwise esterification of phenylmalonic acid.[17] Me migration products **3a—c** were synthesized[18] by the reaction of methyl propionate with the corresponding methyl benzoates. OEt migration product **3d** was obtained in the photolysis of methyl diazobenzoylacetate in ethanol. O–H insertion products **4a—c** were obtained in the reaction[19] of acetic anhydride with the corresponding α-methoxyacetophenone in the presence of $BF_3 \cdot OEt_2$. **4d** was isolated in the irradiation of **1d** in methanol.

Photolysis and Thermolysis of 1. All irradiations were carried out with a Halos 300 W high-pressure mercury lamp with a water-cooled jacket. In a typical procedure, 0.05 mmol of **1** was added to 5.0 cm^3 of a mixture of methanol and dioxane in Pyrex tubes. The sample was then degassed, sealed, and irradiated until all of the diazo compound was destroyed. Thermolysis was done in a sealed Pyrex tube in an oil bath thermostated at 80±1 °C. Control experiments ruled out the interconversion of the products during the reaction. Product identification and yields were determined mainly by GC. The product ratio was also determined by NMR. CF_3CO_2H was used as solvent for NMR to prevent the enolization of products. The product ratios determined by both methods were generally in good agreement.

Conversions of Carbonyl Compounds *via* Their Polymeric Sulfonylhydrazones into Alkenes, Alkanes, and Nitriles

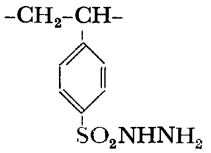
Hiroyoshi KAMOGAWA,* Asami KANZAWA, Masahiro KADOYA, Takeshi NAITO, and Masato NANASAWA

Department of Applied Chemistry, Yamanashi University, Takeda 4, Kofu, Yamanashi 400

(Received July 13, 1982)

Resins consisting of cross-linked poly(styrene-divinylbenzene) matrices functionalized with hydrazinosulfonyl groups react with aldehydes and ketones to form the sulfonylhydrazone derivatives. The extent of the reaction is sensitive to the type of resin and the bulk of the carbonyl compound. When heated strongly under alkaline conditions, the sulfonylhydrazones release the corresponding alkenes; upon the $NaBH_4$ or $LiAlH_4$ treatment, they also release the corresponding alkanes; and, upon refluxing in methanol with potassium cyanide, they release nitriles containing one additional carbon atom.

The preparation of poly(*p*-vinylphenylsulfonylhydrazine) (**1**) and its use as a diazene source have been previously reported.[1,2]

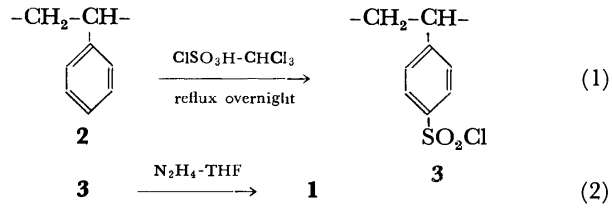


1

Our present interest was in exploring the potential of **1** as a possible polymer reagent for converting aldehydes and ketones into alkenes, alkanes, and nitriles *via* their hydrazones with **1**.

Results and Discussion

The polymers employed as starting reagents for this investigation were commercially available, macroreticular and gel-type styrene (St)–divinylbenzene (DVB) copolymers (**2**) (Table 1).



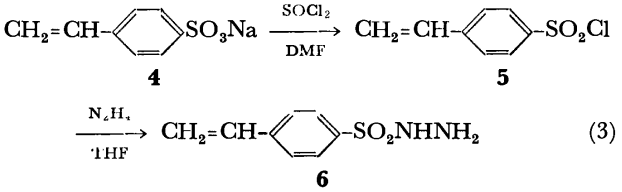
(1)

(2)

Each material (**2**) is readily converted, by refluxing it overnight in a solution of chlorosulfuric acid in chloroform, to the intermediate copoly(St- and DVBsulfonyl chloride) (**3**; 93—100% yield) (Eq. 1), and thence by the action of hydrazine–THF solutions to **1** (77—91% yield) (Eq. 2).

As can be seen in Table 1, macroreticular resins **2** (Nos. 1 and 2) provided higher conversions to **3** and thence to **1** than did gel-type resin **2** (No. 3).

Alternatively, the polymer **1** was prepared by the polymerization of the *p*-vinylphenylsulfonylhydrazine (**6**) synthesized starting with sodium *p*-styrenesulfonate (**4**) *via* sulfonyl chloride (**5**) (Eq. 3).



(3)

An attempt to synthesize **6** by the alkaline dehydrobromination of the *p*-(2-bromoethyl)phenylsulfonylhydrazine synthesized starting with (2-bromoethyl)benzene as in polymer (Eqs. 1 and 2) failed, presumably because of the high alkali-susceptibility of the prod-

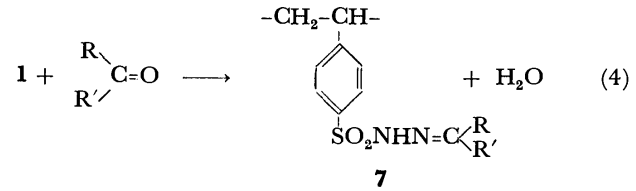
uct, **6**.

The reaction of the polymer **1** with aldehydes and ketones in refluxing ethanol to produce the corresponding hydrazones **7** (Eq. 4) provided varied results (Table 2).

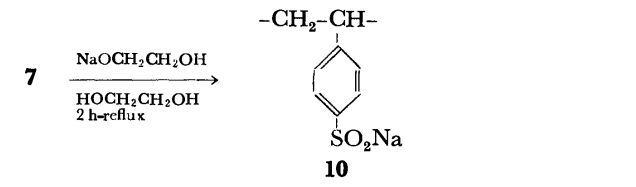


(4)

7

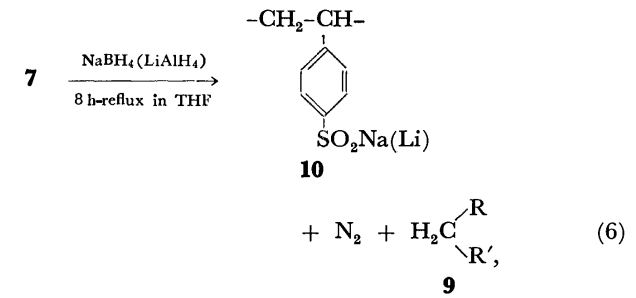
These results suggest that some of the hydrazinosulfonyl groups are in an environment too crowded to accommodate the hydrocarbon residues of bulky carbonyl compounds, even in the macroreticular form. Thus, cyclododecanone and camphor, typical bulky ketones, provided reactions of a low extent (Nos. 7, 8, and 9). The polymer **1**-3 with a gel structure also provided poor results (Nos. 3 and 13), presumably because of a lack of a swelling property for ethanol.

The polymeric arylsulfonylhydrazones (**8**) thus prepared were decomposed in the following two ways (Eqs. 5 and 6).



(5)

10 **8**



(6)

10 **9**

where R″ denotes the substituent attached to the α-carbon atom of the original carbonyl compound.

It is known that tosylhydrazones react with a solution of sodium in ethylene glycol to give diazo compounds, which subsequently decompose with the elimination of nitrogen to form alkenes.[3] This reaction was applied to the polymer **7** with the intention of converting carbonyl compounds to the corresponding alkenes (Eq. 5). Thus, a polymeric sulfonylhydrazone was dispersed in ethylene glycol containing a large excess of sodium, and the mixture was stirred under reflux for 2 h. The alkene (**8**) thus generated was extracted with either carbon tetrachloride or ether. The results are given in Table 3. The apparent low value obtained for the hydrazone with cyclohexanone (**7**-1) seems to be caused partly by the loss of the low-boiling product, cyclohexene, by evaporation during the reaction and the subsequent isolation process,

Table 3. Decomposition of copoly(*p*-vinyl- and divinylphenylsulfonylhydrazone) (**7**)

Sulfonylhydrazone[a] (**7**)	Alkene (**8**) by Eq. 5 (mol%)	Alkane (**9**) by Eq. 6 (mol%)/**7**

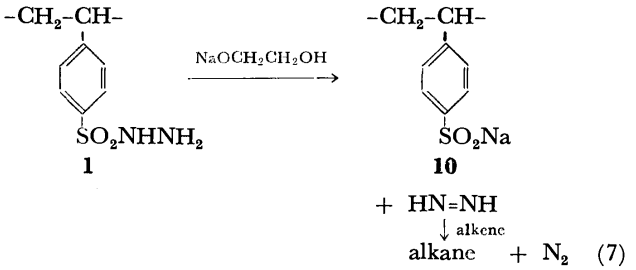
a) No. in Table 2. b) With gel-type resin. c) With benzylacetone for the polymer **1**-2.

since cyclohexanone tosylhydrazone gave cyclohexene almost quantitatively under similar reaction conditions.[3] Another cause of decrease in the yield of alkene is the formation of alkane, presumably due to the production of diazene from the remaining hydrazinosulfonyl group (**1**) in **7** and the subsequent hydrogenation of the alkene,[1] as is indicated in Eq. 7:



(7)

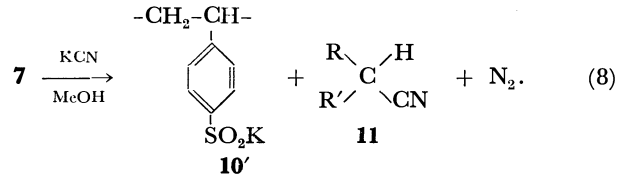
1 **10**

The production of alkanes could be recognized by means of the mass and ^{1}H-NMR spectra in all instances. Since the IR spectra of the resins which had been subjected to the procedure of Eq. 5 indicated no absorptions at 1320 and 1160 cm^{-1} attributable to hydrazones or hydrazines, but indicated every evidence of sodium poly(styrenesulfinate) (**10**), including a strong absorption at 960 cm^{-1},[4] the decomposition of **7** appears to take place completely under the present experimental conditions. The results of elemental analyses indicating the absence of nitrogen also support this conclusion.

Another way of decomposition, that indicated in Eq. 6, is also known for tosylhydrazones,[5] which are reduced with sodium borohydride or lithium aluminium hydride to liberate alkanes under relatively mild conditions, thereby constituting a general way of converting carbonyl compounds to alkanes. Thus, a polymeric sulfonylhydrazone **7** was dispersed in THF, and the mixture was refluxed for 8 h in the presence of a large excess of $NaBH_4$ ($LiAlH_4$ for **7**-11 and **7**-15).

The experimental conditions adopted here were the standard ones for low-molecular weight analogs.[5] Table 3 also indicates the results thus obtained. The relatively low yields of alkanes and the generally small differences between macroreticular and gel-type resins may indicate that the rate of reaction is governed by the permeation and diffusion of reductant $NaBH_4$ or $LiAlH_4$ into resin beads. Judging together with the fact that the IR spectra for macroreticular resins after the decomposition still indicate the absorptions attributable to the remaining hydrazones, it is likely that the reaction takes place mainly at the inner surfaces of resin beads, thereby indicating a poor permeability of the reductant under the present experimental conditions, although satisfactory yields were obtained for low-molecular weight analogs under these conditions.

The third trial carried out on the polymeric sulfonylhydrazine reagents (**1**) was the conversion of aldehydes and ketones *via* their hydrazones (**7**) into nitriles containing one additional carbon atom, as is indicated below:



(8)

The reaction is also known for arylsulfonylhydrazones,[6] and mild reaction conditions have been established. Thus, polymeric sulfonylhydrazone **7** was dispersed in methanol, and the mixture was refluxed with stirring in the presence of a large excess of potassium cyanide to liberate nitrile (**11**). A refluxing lasting approximately 72 h, twice as long as that for low-molecular weight analogs in homogeneous methanolic solutions,[6] was necessary to effect the complete decomposition of macroreticular **7**, as judged from the IR spectra. Table 4 summarizes the obtained results.

In spite of the complete decomposition of **7**, the yields of nitrile isolated are generally lower than those for the corresponding tosylhydrazones, even with macroreticular resins. Particularly in the case of **7**-11, a nucleophilic attack of the solvent methanol of the sp^2-carbon atom of the hydrazone resulted in the production of methyl diphenylmethyl ether, with the absence of the expected product. In other sulfonylhydrazones with macroreticular resins, however, the expected nitriles were isolated to appreciable extents, leaving potassium poly(styrenesulfinate) (**10′**). The macroreticular potassium poly(styrenesulfinate) thus produced was oxidized with aqueous bromine to afford poly(styrenesulfonic acid), which was then treated with chlorosulfuric acid to afford poly(styrenesulfonyl chloride) (**3**) almost quantitatively. This resin, **3**, could be reused as effectively as the fresh resins from **2**.

Table 4. Conversion of aldehydes and ketones into nitriles

Sulfonylhydrazone[a] (**7**)	Nitrile (**11**) by Eq. 8 (mol%)/**7**

a) No. in Table 2.

The production of poly(styrenesulfinates) (**10** and **10′**) is common to all the reactions (Eqs. 5, 6, and 8) investigated here. Good reusability and the easy separation of **10** or **10′** from the low-molecular weight decomposition products constitute the advantages of this type of polymer reagent, although the rates and extents of the reactions of Eqs. 5, 6, and 8 are generally inferior to those of the corresponding low-molecular weight analogs.

Experimental

The infrared (IR), ^{1}H-NMR, and mass spectra were recorded on a Hitachi 215 spectrophotometer, a JNM-PMX 60 spectrometer, and a Hitachi RMU-6M spectrometer respectively. The elemental analyses were done with a Perkin-Elmer 240 instrument.

Copoly(styrene- and divinylbenzenesulfonyl chloride) (3). A copoly(styrene-divinylbenzene) (**2**; 2.6 g, 25 mmol) was stirred in chloroform (100 ml) and then chlorosulfuric acid (20 ml, 250 mmol) was added dropwise. The mixture was subsequently stirred overnight under reflux, with the exclusion of moisture. The mixture was then filtered, and the resin was stirred for 30 min successively in chloroform (100 ml) and acetonitrile (100 ml), followed by thorough washing with water and vacuum drying to a constant weight. The results thus obtained are given in Table 1. The IR spectra of the products (**3**) indicated absorptions at 1170 and 1370 cm^{-1} characteristic of the sulfonyl chloride.

Copoly(p-vinyl- and divinylphenylsulfonylhydrazine) (1). The polymer **3** (4.05 g, 20 mmol) was stirred in THF (150 ml) externally cooled in an ice bath, after which hydrazine hydrate (5.7 ml, 80 mmol) was added dropwise. The reaction mixture was then stirred for further 30 min. The resin was filtered off, stirred in iced 1 mol dm^{-3} hydrochloric acid (150 ml) for 30 min, filtered, washed with water, further stirred in iced 1 mol dm^{-3} sodium hydrogencarbonate (150 ml), filtered, washed again with water, stirred in cold water for 30 min, filtered, and finally dried. The results thus obtained are also given in Table 1. The IR spectra of the products (**1**) indicated absorptions at 1150 and 1310 cm^{-1} characteristic of the sulfonylhydrazine, with the absence of that at 1370 cm^{-1} (sulfonyl chloride).

p-Styrenesulfonyl Chloride (5). A mixture of thionyl chloride (50 ml), 4-*t*-butylcatechol (0.3 g), and anhydrous *N,N*-dimethylfomamide (DMF; 60 ml) was stirred in an ice bath. Sodium *p*-styrenesulfonate (**4**; Tokyo Kasei; 20 g, 86 mmol) was added in small portions, and the mixture was stirred for 3 h to afford a homogeneous solution; it was then left to stand for 24 h in a refrigerator. The reaction mixture was then poured into ice water (300 ml) and extracted twice with benzene (each 200 ml). The extract was washed twice with water (each 200 ml), dried over anhydrous sodium sulfate, and concentrated on a rotary evaporator below 40 °C. Upon drying *in vacuo*, a pale yellow liquid was obtained in a 95% yield. Found: C, 47.01; H, 3.88%. Calcd for $C_8H_7O_2SCl$: C, 47.41, H, 3.48%. IR ($CHCl_3$) 1580

(aryl), 1360 (S=O), 980, 910 (vinyl) cm^{-1}. NMR ($CDCl_3$) δ=5.7 (d, 1H, $C\underline{H}_2$=CH-), 6.1 (d, 1H, $C\underline{H}_2$=CH-), 6.9 (q, 1H, CH_2=C$\underline{H}$-), 7.6—8.3 (q, 4H, ArH). Mass (*m/e*) 202 (M^+).

p-*Vinylphenylsulfonylhydrazine* (**6**). Hydrazine hydrate (3 ml, 50 mmol) was dropped with stirring into a solution of **5** (4 g, 20 mmol) in THF (20 ml), cooled in an ice bath. The turbid mixture was stirred for further 15 min and then poured into 200 ml of water with vigorous stirring. Stirring was continued for a while to separate a crude product, which was purified by dissolution in a small amount of THF and subsequent precipitation into hexane to afford fine colorless needles (mp 90—92 °C) in a 75% yield. Found: C, 48.46; H, 5.20; N, 14.11%. Calcd for $C_8H_{10}N_2SO_2$: C, 48.47; H, 5.08; N, 14.13%. IR (KBr) 3250 (NH_2, NH), 1600 (Ar), 1310, 1150 (SO_2), 1620, 1000, 930 (vinyl) cm^{-1}. NMR (DMSO-d_6+$CDCl_3$) δ=3.9 (b, 2H, NH_2), 5.6 (d, 1H, $C\underline{H}_2$=CH-), 6.1 (d, 1H, $C\underline{H}_2$=CH-), 7.0 (q, 1H, CH_2=C$\underline{H}$-), 7.9 (q, 4H, ArH), 7.5—9.0 (b, 1H, NH). Mass (*m/e*) 198 (M^+, 13), 42 (100).

Polymer **1** *Obtained by the Polymerization of* **6**. A solution of **4** (0.89 g) and α,α'-azobisisobutyronitrile (40 mg) in DMF (10 ml) was put into a glass ampoule, which was then evacuated, filled with nitrogen, and sealed in a conventional manner. Polymerization was carried out at 50 °C for 48 h. The contents of the ampoule were precipitated into methanol to isolate a white powder in an 80% conversion. The polymer was soluble in DMF and dimethyl sulfoxide and afforded a value of the intrinsic viscosity [η] of 0.22 dl/g in DMF at 30 °C. The IR (KBr) spectrum of the polymer was essentially identical with that of **1** with absorptions at 1310 and 1150 cm^{-1} characteristic of the sulfonylhydrazine.

*Formation of Copoly(*p*-vinyl- and divinylphenylsulfonylhydrazones)* (**7**). In a typical example corresponding with No. 2 in Table 2, a solution of cyclohexanone (2.72 ml, 26.3 mmol) in ethanol (70 ml) was added to a vacuum-dried polymer, **1**-2 (3.47 g, 17.5 mmol). The mixture was heated under reflux for 0.5 h, with the exclusion of the moisture. The resin was then filtered off, stirred in methanol (100 ml) for 30 min, filtered, washed thoroughly with methanol, and dried *in vacuo* to a constant weight.

The same reaction conditions were applied to other carbonyl compounds, unless otherwise noted.

The IR spectra of all the polymers thus obtained indicated absorptions at 1620 (C=N), 1600 (Ar), 1320, and 1150 (SO_2) cm^{-1}.

Decomposition of **7** *by Alkali (Eq. 5).* Hydrazone **7** (1 g) was stirred in ethylene glycol (10 ml). Sodium (0.30 g) was added, and the mixture was heated under reflux for 2 h with stirring. The mixture was diluted with water (50 ml) and extracted with carbon tetrachloride or ether. The organic layer was washed with water, dried over anhydrous sodium sulfate, and concentrated on a rotary evaporator below 40 °C. The presence of alkene in the residue was confirmed by a study of the IR [1600—1640 cm^{-1} (C=C)] and mass spectra, and its content was determined from ^{1}H-NMR [δ=5—6 (CH=CH)].

The results thus obtained are given in Table 3. The IR spectra of the resins after alkaline decomposition indicated absorptions at 1600 (Ar), 1010, and 960 cm^{-1}, with the absence of those at 1320 and 1150 cm^{-1}. Elemental analyses indicated the absence of nitrogen.

Decomposition of **7** *with Reduction (Eq. 6).* Hydrazone **7** (10 mmol) was stirred in THF (70 ml), $NaBH_4$ (3.0 g, 80 mmol) was added, and the mixture was heated under reflux for 8 h with stirring. The mixture was then poured into iced dilute hydrochloric acid and extracted with ether. The organic layer was washed with water, dried over anhydrous sodium sulfate, and concentrated on a rotary evaporator. The presence of alkane in the residue was confirmed by a study of the IR and mass spectra, and its content was determined from ^{1}H-NMR. Table 3 also gives the results thus obtained, where $LiAlH_4$ was used in place of $NaBH_4$ for the hydrazone **7** from aromatic carbonyl compounds (**7**-11 and **7**-15).

Decomposition of **7** *with Production of Nitriles (Eq. 8).* Hydrazone **7** (5 mmol) was stirred in methanol (70 ml), potassium cyanide (0.98 g, 15 mmol) was added, and the mixture was heated, under gentle reflux, for 72 h. After water (70 ml) had then been added, the product was extracted with dichloromethane (140 ml) and the extract was washed with saturated aqueous sodium hydrogencarbonate (100 ml) and water (50 ml). The dried (Na_2SO_4) organic layer was concentrated on a rotary evaporator. The presence of nitrile in the residue was cofirmed by a study of the IR 2200—2250 cm^{-1} (CN) and mass spectra, and its content was determined from ^{1}H-NMR. The IR spectra of the resins after decomposition indicated absorptions at 1600, 1010, and 960 cm^{-1}, with the absence of those at 1150 and 1320 cm^{-1}.

Recycling of Used Resins. The macroreticular potassium poly(styrenesulfinate) (**10'**; 5 mmol) left after the decomposition of the polymers **7**-2 according to Eq. 8 was stirred in an aqueous solution of bromine (2.4 g in 100 ml) at room temperature for 1 h. The potassium poly(styrenesulfonate) thus produced was filtered, washed thoroughly with water, and dried. The polymer was then stirred in chlorosulfuric acid (20 g) at 80 °C for 8 h. The mixture was filtered with a glass filter, and the resin was washed successively with two 100 ml-portions of dichloromethane and THF, and dried to regenerate poly(styrenesulfonyl chloride) (**3**) almost quantitatively. The resin **3** thus obtained was then subjected to the same reaction procedures as those used for fresh resin **3** to afford hydrazine **1** and thence cyclohexanone hydrazone **7**. The yield of cyclohexanecarbonitrile generated by the decomposition following Eq. 8 was 22%, based on **7**.

The resin **10**, obtained after decomposition by Eq. 5, was subjected to the same regeneration procedures as above, and the resin **3** thus regenerated was converted again to hydrazone **7**-5, which was subsequently decomposed following Eq. 5 to afford 1,3-diphenyl-1-propene in a 75% yield.

Acknowledgement is made to Mitsubishi Chemical Industries, Ltd., for providing the resins used.

Studies of Bitter Peptides from Casein Hydrolyzate. I. Synthesis of Bitter Peptide BPIa Corresponding to Arg-Gly-Pro-Pro-Phe-Ile-Val from Casein Hydrolyzate by Alkaline Proteinase of *Bacillus subtilis*[1)]

Hiroshi Fukui, Hidenori Kanehisa, Norio Ishibashi, Ichizo Miyake, and Hideo Okai*

Department of Fermentation Technology, Faculty of Engineering, Hiroshima University, Shitami, Saijo-cho, Higashihiroshima 724

(Received July 19, 1982)

A bitter heptapeptide BPIa was synthesized and compared with the natural peptide, isolated by Minamiura *et al.* from casein hydrolyzate, by means of thin layer chromatography, paper electrophoresis, and carboxymethylcellulose column chromatography. All results for the two peptides matched very closely each other. The synthetic BPIa has an extremely bitter taste with its threshold value 0.05 mM. It is one of the most bitter compounds such as phenylthiourea and quinine.

In recent years, many people have investigated chemical properties of various bitter peptides. Some bitter peptides have been isolated from natural foodstuffs such as cheese, natto, sake, and cocoa.[2–5)] In addition, some workers have reported that hydrolysis of proteins with proteolytic enzymes is usually accompanied by formation of bitter taste.[6–9)] Minamiura *et al.*[8,9)] isolated bitter peptides from casein hydrolyzate by alkaline proteinase of *Bacillus subtilis*, and determined their amino acid sequences as shown in Fig. 1.

BPIa Arg-Gly-Pro-Pro-Phe-Ile-Val

BPIb Leu-Val-Pro-Arg-Tyr-Phe-Gly-----

BPIc Val-Tyr-Pro-Phe-Pro-Pro-Gly-Ile-Asn-His

BPII cyclo-(Trp-Leu-Trp-Leu)

Fig. 1. Amino acid sequence of bitter peptides from casein hydrolyzate by Minamiura *et al.*[8,9)]

Although they reported that these peptides possessed a strong bitter taste, they did not report any other characteristics of these peptides. In connection with studies of the relationship between chemical structure and bitter taste, Shiba and Nunami[10)] synthesized some cyclic oligopeptides, including Minamiura's BPII (cyclo-tryptophylleucyltryptophylleucyl). The results indicated that the structure of Minamiura's BPII was actually cyclo-tryptophylleucyl. They also reported that the threshold value of the synthetic cyclo-tryptophylleucyl was 0.063 mM (1 M=1 mol dm^{-3}). The value of the peptide anhydride is the same as that of phenylthiourea and quinine. They are one of the most bitter compounds known.

As for the linear decapeptide BPIc, one of the authors synthesized and compared it with natural BPIc. Details will be described in another investigation.[11)] The present paper deals with synthesis of BPIa, measurement of its threshold value of bitter taste, and comparison between natural and synthetic BPIa.

The synthetic route for BPIa is shown in Fig. 2. *N*-(*t*-Butoxycarbonyl)isoleucine was coupled with valine benzyl ester by means of the mixed anhydride method to form *N*-(*t*-butoxycarbonyl)isoleucylvaline benzyl ester (**1**). Removal of the *t*-butoxycarbonyl group from **1** with hydrogen chloride in dioxane afforded the corresponding dipeptide ester hydrochloride (**2**). Compound **2** was coupled with *N*-(*t*-butoxycarbonyl)phenylalanine by the mixed anhydride method to yield acyltripeptide ester (**3**). Removal of the *t*-butoxycarbonyl group from **3** with hydrogen chloride in dioxane afforded the corresponding tripeptide ester hydrochloride (**4**). *N*-(*t*-Butoxycarbonyl)proline and proline benzyl ester were condensed to yield *N*-(*t*-butoxycarbonyl)prolylproline benzyl ester (**5**) by the dicyclohexylcarbodiimide method. Hydrogenation of **5** easily gave the corresponding acid (**6**). Compounds **6** and **4** were condensed by the same method as was used in the preparation of **1**, and the resulting acylpentapeptide ester (**7**) was converted to the corresponding pentapeptide ester hydrochloride (**8**) by action of hydrogen chloride in dioxane. Saponification of N^{a}-benzyloxycarbonyl-N^{G}-nitroarginylglycine benzyl ester (**9**), derived from N^{a}-benzyloxycarbonyl-N^{G}-nitroarginine and glycine benzyl ester by the mixed anhydride method, gave the corresponding acid (**10**). Compounds **10** and **8** thus obtained were condensed by the dicyclohexylcarbodiimide method to yield the fully protected BPIa (**11**). Catalytic hydrogenation of **11** in methanol–acetic acid (1:1, v/v) gave a heptapeptide BPIa. The synthetic BPIa and its intermediates were subjected to measurement for melting point and specific rotation. Their purity was confirmed by thin layer chromatography on two and/or three solvent systems and by elemental analyses. The homogeneity of the final product was also confirmed by amino acid analysis, paper electrophoresis, and carboxymethylcellulose column chromatography.

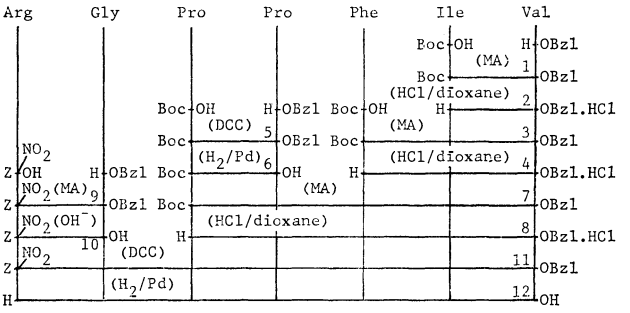

Fig. 2. Synthesis of BPIa.

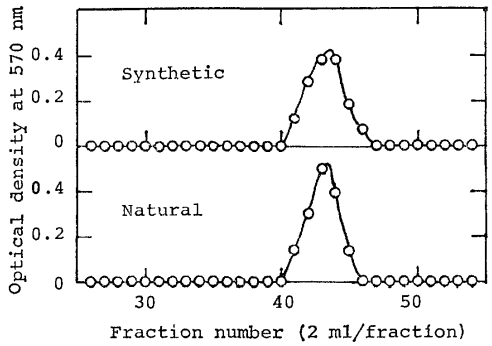

Fig. 3. Carboxymethylcellulose column chromatography of synthetic and natural BPIa.
Solvent: 0.2 M pyridinium acetate, pH 5.0.

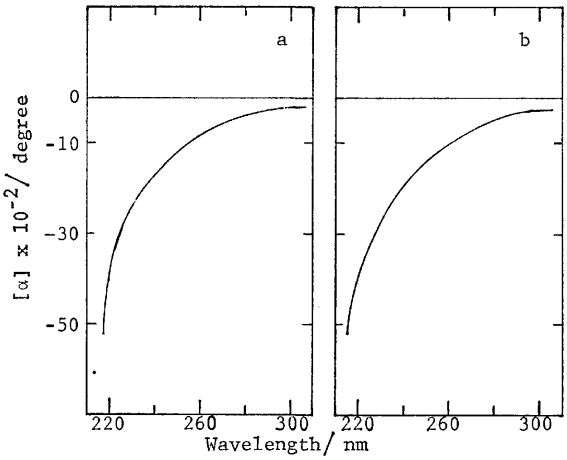

Fig. 4. ORD curves of synthetic BPIa.
Solvent: a; water, b; ethanol.

The synthetic BPIa was then compared with natural BPIa[12] isolated by Minamiura *et al.* Both compounds gave a single spot and identical R_f value on thin layer chromatography. The mobility of synthetic BPIa was indistinguishable from that of natural BPIa on paper electrophoresis. Both compounds also gave the same pattern on carboxymethylcellulose column chromatography as shown in Fig. 3. The ORD curves of synthetic BPIa measured in both aqueous and ethanol solutions are presented in Fig. 4. In both media BPIa exhibited similar curves.

The bitterness of synthesized BPIa was organoleptically determined *via* panel evaluation by four people; the threshold value of BPIa was found 0.05 mM. It is one of the most bitter compounds that are known now.

Dumas *et al.*[13] determined the whole primary structure of bovine β-casein which contains a partial sequence of -Arg^{202}-Gly-Pro-Phe-Pro-Ile-Ile-Val^{209} in the C-terminal portion. Although Minamiura's BPIa cannot be found in the structure of Dumas' formula, it is similar to the C-terminal of that formula. Hashimoto *et al.*[14] synthesized a heptapeptide, H-Gly-Pro-Phe-Pro-Ile-Ile-Val-OH, corresponding to the C-terminal portion (203—209) and compared it with the natural peptide isolated from tryptic hydrolyzate of casein. He reported that the two peptides matched closely each other and supported Dumas' formula. In the same laboratory, Aoyagi and Izumiya[15] suggested, from a result that H-Arg-Gly-Pro-Phe-Pro-Ile-OH (202—207) of Dumas' formula possessed a bitter taste, that Minamiura's BPIa is to be changed so as to correspond to the C-terminal of that formula. However, we submit that Minamiura's findings are indentical with our own as shown herein. Therefore, we suggest that the sequence should be converted at this stage of investigation for the correct C-terminal sequence of β-casein.

Experimental

All the melting points are uncorrected. The thin layer chromatography was carried out on Merck silica gel G. The developing solvents used were 1) 1-butanol-acetic acid-pyridine-water (4:1:1:2, v/v), 2) 1-butanol-acetic acid-water (4:2:1, v/v), and 3) chloroform-methanol (5:1, v/v). Spots of materials possessing free amino group on a thin layer plate were detected by spraying ninhydrin, and those with blocked amino group, by spraying 25% hydrogen bromide in acetic acid and then ninhydrin. Optical rotations were measured on a JASCO automatic polarimeter, DIP-SL type. Amino acid analysis was performed with a Hitachi amino acid analyzer, KLA-5 type. Prior to analysis, compounds were dried over phosphorus pentaoxide at 66 °C and 2 mmHg (1 mmHg=133.332 Pa) for 2 h.

Synthesis of BPIa. N-*(t-Butoxycarbonyl)isoleucylvaline Benzyl Ester (1)*: Boc-Ile-OH·DCHA (9.08 g, 22 mmol) was dissolved in ethyl acetate (150 ml), and 1 M sulfuric acid (50 ml) was added to the mixture with stirring. The organic layer was washed with water and dried over anhydrous sodium sulfate. The solution was concentrated to dryness *in vacuo*, and the oily residue was dissolved in tetrahydrofuran (40 ml) and *N*-methylmorpholine (2.2 ml, 20 mmol). Ethyl chloroformate (2.0 ml, 20 mmol) was added to the mixture at −5 °C. After 10 min, a solution of H-Val-OBzl·TsOH (7.59 g, 20 mmol) and *N*-methylmorpholine (2.2 ml, 20 mmol) in chloroform (40 ml) was added to the mixture. The reaction mixture was stored in an ice bath for 1 h, and then at room temperature overnight. The mixture was evaporated *in vacuo*, and the oily residue was dissolved in ethyl acetate. The solution was washed successively with water, 4% citric acid, 4% sodium hydrogencarbonate, and water, and then dried over anhydrous sodium sulfate. The filtrate was evaporated *in vacuo*. The oily residue was crystallized with petroleum ether; yield 5.67 g (67%); mp 93—94 °C (lit,[14] 89—91 °C); $[\alpha]_D^{20}$ −50.0° (*c* 1, methanol) (Lit,[14] −48° (*c* 1.9, ethanol)); R_f^1 0.98, R_f^2 0.98, and R_f^3 0.93.

Found: C, 65.56; H, 8.61; N, 6.61%. Calcd for $C_{23}H_{36}O_5N_2$: C, 65.69; H, 8.63; N, 6.66%.

Isoleucylvaline Benzyl Ester Hydrochloride (2): To a solution of **1** (4.21 g, 20 mmol) in dioxane (10 ml) 4 M hydrogen chloride in dioxane (40 ml) was added. The solution was allowed to stand at room temperature. After 1 h, the solution was evaporated *in vacuo*. The residual oil was solidified with ether: yield 3.36 g (95%); mp 154—155 °C; $[\alpha]_D^{20}$ −11.0° (*c* 1, methanol); R_f^1 0.80, R_f^2 0.90, and R_f^3 0.47.

Found: C, 60.30; H, 8.18; N, 7.72%. Calcd for $C_{18}H_{29}O_3N_2Cl$: C, 60.57; H, 8.19; N, 7.85%.

N-*(t-Butoxycarbonyl)phenylalanylisoleucylvaline Benzyl Ester (3)*: This was prepared from Boc-Phe-OH·DCHA (4.91 g, 11 mmol) and **2** (3.57 g, 10 mmol) in the same way as described above. The product was solidified from ether–petroleum

ether: yield 5.16 g (91%); mp 148 °C; $[\alpha]_D^{20}$ −48.5° (*c* 1, methanol); R_f^1 0.99, R_f^2 0.99, and R_f^3 0.85.

Found: C, 67.93; H, 8.10; N, 7.48%. Calcd for $C_{32}H_{45}O_6N_3$: C, 67.70; H, 7.99; N, 7.40%.

*Phenylalanylisoleucylvaline Benzyl Ester Hydrochloride (**4**)*: This was prepared from **3** (5.68 g, 10 mmol) by the same procedure as described for the preparation of **2**: yield 4.96 g (98%); mp 231 °C; $[\alpha]_D^{20}$ −37.0° (*c* 1, methanol); R_f^1 0.92, R_f^2 0.94, and R_f^3 0.78.

Found: C, 64.28; H, 7.70; N, 8.17%. Calcd for $C_{27}H_{38}O_4N_3Cl$: C, 64.33; H, 7.60; N, 8.34%.

N-*(t-Butoxycarbonyl)prolylproline Benzyl Ester (**5**)*: To a suspension of Boc–Pro–OH (4.30 g, 20 mmol), H–Pro–OBzl·HCl (5.32 g, 22 mmol) and *N*-methylmorpholine (2.42 ml, 22 mmol) in acetonitrile (60 ml), dicyclohexylcarbodiimide (4.50 g, 22 mmol) was added at 0 °C with stirring. The reaction mixture was stirred at 0 °C for 3 h and then at room temperature overnight. *N,N'*-Dicyclohexylurea was filtered off and the filtrate was evaporated *in vacuo*. The oily residue was dissolved in ethyl acetate and the solution was washed successively with water, 4% citric acid, 4% sodium hydrogencarbonate, and water. The solution was dried over anhydrous sodium sulfate and evaporated *in vacuo*. The residual oil weighed 8.0 g (100%). Deber *et al.*[16] also obtained this compound as an oily form: R_f^1 0.96 and R_f^3 0.79.

N-*(t-Butoxycarbonyl)prolylproline (**6**)*: Compound **5** (8.0 g, 20 mmol, oily form) was dissolved in methanol (50 ml) and hydrogenated in the presence of palladium black at room temperature for 48 h. The catalyst was removed by filtration and the filtrate was evaporated *in vacuo*. The residue was crystallized from ether–petroleum ether. It was recrystallized from hot ethyl acetate: yield 4.60 g (74%); mp 177—180 °C (lit,[17] 187—187.5 °C); $[\alpha]_D^{20}$ −121.5° (*c* 1, methanol); R_f^1 0.70, R_f^2 0.93, and R_f^3 0.48.

Found: C, 57.41; H, 7.67; N, 8.84%. Calcd for $C_{15}H_{24}O_5N_2$: C, 57.67; H, 7.74; N, 8.79%.

N-*(t-Butoxycarbonyl)prolylprolylphenylalanylisoleucylvaline Benzyl Ester (**7**)*: Compounds **6** (1.56 g, 5 mmol) and **4** (2.52 g, 5 mmol) were coupled by the same method as described for the preparation of **1**: yield 3.49 g (92%); mp 109—110 °C; $[\alpha]_D^{20}$ −101.0° (*c* 1, methanol); R_f^1 0.96, R_f^2 0.99, and R_f^3 0.67.

Found: C, 66.46; H, 7.83; N, 8.97%. Calcd for $C_{42}H_{59}O_8N_5$: C, 66.22; H, 7.81; N, 9.19%.

*Prolylprolylphenylalanylisoleucylvaline Benzyl Ester Hydrochloride (**8**)*: Compound **7** (3.80 g, 5 mmol) was treated in the same way as described for the case of **2**: yield 3.40 g (97%); mp 191 °C; $[\alpha]_D^{20}$ −99.0° (*c* 1, methanol); R_f^1 0.81, R_f^2 0.50, and R_f^3 0.45.

Found: C, 63.82; H, 7.45; N, 10.25%. Calcd for $C_{37}H_{52}O_6N_5Cl$: C, 63.64; H, 7.51; N, 10.03%.

N^{α}-*Benzyloxycarbonyl-*N^{G}*-nitroarginylglycine Benzyl Ester (**9**)*: To a solution of Z–Arg(NO_2)–OH (7.06 g, 20 mmol) and *N*-methylmorpholine (2.2 ml, 20 mmol) in tetrahydrofuran (20 ml), ethyl chloroformate (2.0 ml, 20 mmol) was added at −5 °C. After 10 min, a solution of H–Gly–OBzl·TsOH (6.74 g, 20 mmol) and *N*-methylmorpholine (2.2 ml, 20 mmol) in *N,N*-dimethylformamide (20 ml) was added to the mixture. The reaction mixture was stored in an ice bath for 1 h, and then at room temperature overnight. The mixture was evaporated *in vacuo*. The precipitate which was formed upon addition of water to the residue was collected, washed with 0.5 M hydrochloric acid, 4% sodium hydrogencarbonate, and water, and dried. It was dissolved in *N,N*-dimethylformamide (10 ml) and solidified with ethyl acetate–ether: yield 8.70 g (87%); mp 150—151 °C (lit,[18] 145—147 °C); $[\alpha]_D^{20}$ −3.5° (*c* 1, *N,N*-dimethylformamide) (lit,[18] −14.7° (*c* 1, methanol)); R_f^1 0.95, R_f^2 0.99, and R_f^3 0.66.

Found: C, 55.31; H, 5.69; N, 16.79%. Calcd for $C_{23}H_{28}O_7N_6$: C, 55.19; H, 5.64; N, 16.79%.

N^{α}-*Benzyloxycarbonyl-*N^{G}*-nitroarginylglycine (**10**)*: To a suspension of **9** (5.00 g, 10 mmol) in methanol (20 ml), 1 M sodium hydroxide (12 ml, 12 mmol) was added. The mixture was allowed to stand at room temperature. After 3 h, the mixture was evaporated *in vacuo* and 2 M hydrochloric and (7 ml) was added to it. The precipitate thus obtained was collected and washed with water. It was recrystallized from hot ethanol: yield 3.72 g (91%); mp 110—112 °C (Lit,[19] 112 °C); $[\alpha]_D^{20}$ −10.0° (*c* 1, methanol) (lit,[20] −10° (methanol)); R_f^1 0.81, R_f^2 0.85, and R_f^3 0.07.

Found: C, 46.69; H, 5.58; N, 20.66%. Calcd for $C_{16}H_{22}O_7N_6$: C, 46.82; H, 5.40; N, 20.48%.

N^{α} *- Benzyloxycarbonyl -* N^{G} *- nitroarginylglycylprolylprolylphenylalanylisoleucylvaline Benzyl Ester (**11**)*: To a solution of **10** (0.82 g, 2 mmol) in *N,N*-dimethylformamide (10 ml), dicyclohexylcarbodiimide (0.45 g, 2 mmol) was added at 0 °C. After 20 min, a solution of **8** (1.39 g, 2 mmol) and *N*-methylmorpholine (0.22 ml, 2 mmol) in chloroform (10 ml) was added to it. The reaction mixture was stirred at 0 °C for 3 h and then at room temperature overnight. *N,N*-Dicyclohexylurea was removed by filtration, and the filtrate was diluted with ethyl acetate. The solution was washed successively with 0.5 M hydrochloric acid, 4% sodium hydrogencarbonate, and water, dried over anhydrous sodium sulfate, and evaporated *in vacuo*. The residue was solidified with ether. The product was dissolved in methanol (2 ml) and solidified with ethyl acetate–ether: yield 1.45 g (69%); mp 120 °C; $[\alpha]_D^{20}$ −44.0° (*c* 1, *N,N*-dimethylformamide); R_f^1 0.86 and R_f^3 0.64.

Found: C, 60.46; H, 6.71; N, 14.62%. Calcd for $C_{53}H_{71}O_{12}N_{11}$: C, 60.38; H, 6.79; N, 14.62%.

*Arginylglycylprolylprolylphenylalanylisoleucylvaline Diacetate (**12**)*: A solution of **11** (1.05 g, 1 mmol) in methanol—acetic acid (1:1, 10 ml) was hydrogenated in the presence of palladium black at room temperature for 48 h. The catalyst was removed by filtration and the filtrate was evaporated *in vacuo*. The residue was crystallized by the aid of acetone. It was recrystallized from methanol–ether: yield 0.76 g (97%); $[\alpha]_D^{20}$ −92.5° (*c* 1, water); R_f^1 0.59. The spot was detected by Sakaguchi reagent as well as ninhydrin. Amino acid analysis:[21] Arg 1.06; Gly 1.07; Pro 1.83; Phe 1.11; Ile 1.00; Val 1.05.

Found: C, 55.60; H, 7.71; N, 15.34%. Calcd for $C_{38}H_{60}O_8N_{10}2CH_3COOH$: C, 55.74; H, 7.57; N, 15.48%.

Comparison of Synthetic and Natural BPIa. Thin Layer Chromatography: Both compounds gave a single spot with the R_f^1 value 0.59.

Paper Electrophoresis: This was carried out under the following conditions: paper, Toyo Roshi No. 51 A chromatography paper; solvent, pyridine–acetic acid–water (10:0.4:90, v/v) (pH 6.4); voltage gradient, 15 V/cm; charge period, 2 h. The mobility of synthetic BPIa was 7.8 cm and indistinguishable from that of natural BPIa.

Carboxymethylcellulose Column Chromatography: A portion (*ca.* 1 mg) of synthetic or natural BPIa was dissolved in 0.3 ml of 0.2 M pyridinium acetate (pH 5.0). The solution was applied to a column (1.0 cm × 60 cm) of carboxymethylcellulose. Elution was carried out with the same solvent and 2 ml fractions were collected at a flow rate of 8 ml h^{-1}. The peptide content was determined by the method described by Yemm and Cocking.[22] The results shown in Fig. 3 indicate that the pattern of chromatogram of synthetic BPIa

is indistinguishable from that of natural one.

ORD Measurement: This was performed with a JASCO spectropolarimeter Model ORD/UV-5 over a range 215—300 nm. A cell of path length 0.1 cm was used and runs were made at ambient temperature. Patterns in both aqueous and ethanol solutions are shown in Fig. 4.

Sensory Test: The bitterness of the synthetic BPIa was organoleptically determined *via* panel evaluation by four people. A series of solutions of decreasing concentration was prepared in which each solution was half as strong as its proceeding one. Before testing the sample, the mouth was thoroughly rinsed with deionized water. The sample size was usually 2—3 ml. The sample solution was held in the mouth for *ca.* 10 s and then spit out, and the threshold value of the sample was determined. The threshold value of synthetic BPIa was 0.05 mM, the same as that of phenylthiourea and quinine.

The authors wish to express their thanks to Dr. Noshi Minamiura of Osaka City University for his kind offer of the natural sample of BPIa. Thanks are also due to Associate Professor Tetsuo Kato of Kyushu University for the ORD measurements, and Dr. Shinji Okumura of Ajinomoto Co. Inc., for supplying some amino acids.

Coenzyme Models. 33. Evidence for Retro-acyloin Condensation as Catalyzed by Thiazolium Ion and Cationic Micelle. Oxidative Trapping of the "Active Aldehyde" Intermediates by Flavin

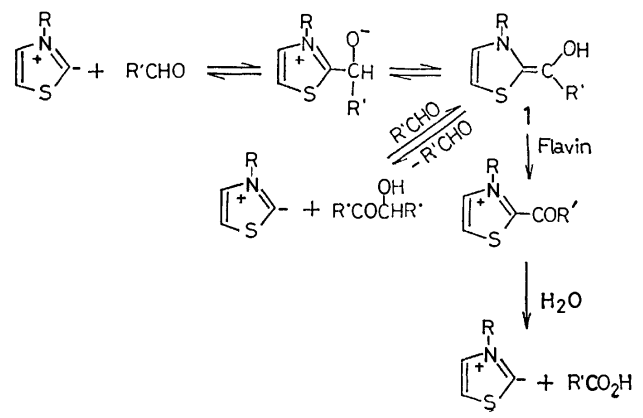
Seiji SHINKAI,* Youichiro HARA, and Osamu MANABE

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852

(Received July 28, 1982)

N-Hexadecylthiazolium bromide(HxdT) in the CTAB micelle, which is known as an excellent catalytic system for acyloin condensation of aldehydes, catalyzes the reverse reaction (*i.e.*, retro-acyloin condensation) to give aldehydes from α-ketols *via* the active aldehyde intermediates. The existence of the novel, HxdT-mediated process was proposed on the basis of an experimental discovery that flavin (3-methyltetra-*O*-acetylriboflavin: MeFl), which is capable of oxidatively trapping the active aldehyde intermediates, is reduced by α-ketols such as acetoin and 3-hydroxy-3-methyl-2-butanone in the micellized HxdT solution. It was further substantiated by detection of acetaldehyde in the final reaction mixture. Based on the disappearance rate of the absorbance of MeFl, we spectrophotometrically estimated the rate constants for the retro-acyloin condensation. Similarly, biacetyl, the monohydrated species of which is analogous to α-ketol, afforded acetaldehyde and acetic acid in the micellized HxdT solution, the rate constant being greater by factors of 10^2—10^3 than those for α-ketols. The relevance of the retro-acyloin condensation to biological systems (*e.g.*, the mechanism of transketolase catalysis) is discussed.

Recently, it has been established that some flavin-dependent enzymes employ carbanion intermediates during the course of the oxidation of bound substrates.[1-3] In previous publications of this series,[4-7] we have demonstrated that the application of the biochemical concept "flavin oxidation of carbanion" to organic chemistry is very useful in exploring a new class of oxidation reactions. For example, flavin is rapidly reduced according to zero-order kinetics in cyanide-catalyzed benzoin condensation,[4] thiazolium-catalyzed acyloin condensation,[5,7] and thiol-catalyzed rearrangement of glyoxals,[6] which all proceed *via* the carbanionic intermediates. The role of flavin oxidation in thiazolium-catalyzed reactions is also discussed by Yano *et al.*[8] The product analyses of these systems showed that the reactions are readily diverted to the oxidation reactions in the presence of flavin as an oxidative trapping agent. Similarly, the "active aldehydes" afforded from aldehydes and the conjugate bases of thiazolium ions are oxidized by nitrobenzene,[9] acridine and its analogues,[10] disulfides,[11] and nitrosobenzene.[12] In Scheme 1, we illustrated a typical example for flavin trapping in thiazolium-mediated acyloin condensation, in which the key intermediate **1** is rapidly oxidized by flavin to yield the corresponding carboxylic acid.[5]

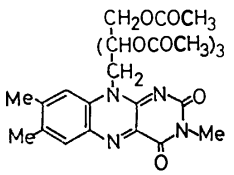


Scheme 1.

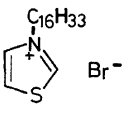
It is a well-known fact that the conjugate bases of thiazolium ions (vitamin B_1 analogues) catalyze acyloin condensation as cyanide ion catalyzes benzoin condensation.[13] To the best of our knowledge, however, there is no clear evidence as to whether the conjugate bases catalyze the reverse reaction (retro-acyloin condensation) to afford aldehydes from α-ketols. It occurred to us that if the retro-acyloin condensation is catalyzed by thiazolium ions, the transient intermediates **1** would be rapidly trapped by flavin. In the enzymatic system, the mechanism of transketolase which requires thiamine pyrophosphate(TPP) as a co-factor and catalyzes the cleavage of xylulose 5-phosphate or D-fructose 6-phosphate in its early stage is analogous to that of the retro-acyloin condensation.[14-16] Christen and Gasser[17] have reported that the 1,2-dihydroxyethyl–TPP intermediates (analogues of **1**) formed from these substrates in the active site of the enzyme can be oxidatively trapped by hexacyanoferrate(III). Based on flavin-trapping of **1** from α-ketols, we here report evidence that *N*-hexadecylthiazolium bromide(HxdT) bound to the CTAB(hexadecyltrimethylammonium bromide) micelle catalyzes not only the acyloin condensation[13,18] but also the retro-acyloin condensation.

Results and Discussion

Flavin Oxidation of α-Ketols and Analogues in Micellized HxdT Solution. We have used 3-methyltetra-*O*-acetylriboflavin(MeFl) and HxdT in the cationic CTAB solution. The kinetic measurements of the flavin oxidation were carried out at 30 °C under anaerobic conditions(N_2). The reaction was followed spectrophoto-



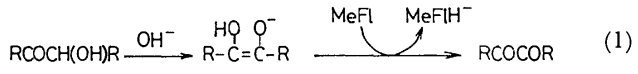
MeFl



HxdT

metrically by monitoring the disappearance of the absorption band of MeFl at 448 nm (ε 12200). Since the active aldehydes rapidly reduce MeFl,[5,8] the production of **1** from the substrates, if it occurs, can be immediately detected as a decrease in the absorption band.

In an anaerobic aqueous solution containing HxdT (1 mM) and CTAB (10 mM), MeFl was reduced by acetoin, benzoin, 3-hydroxy-3-methyl-2-butanone (HMB), 3-hydroxy-3-phenyl-2-butanone(HPB), and biacetyl, but the reaction with benzil and 4,4′-dichlorobenzil was not detected. As reported in the thiazolium-mediated flavin oxidation of aldehydes,[5] the zero-order decrease of the 448 nm band was observed for the initial stage of the reaction and lasted up to, for example, 40% reaction for acetoin (0.1 M). We noticed, however, that acetoin and benzoin in the CTAB micelle solution reduce MeFl even in the absence of HxdT. The reductant in this system is a 1,2-enediolate which is formed by base-catalyzed deprotonation of these "carbon acids" (Eq. 1).[19-21] Thus, the rates



(1)

observed in the micellized HxdT solution (v_{obsd}) are expressed as the sum of the base-catalyzed term (v_{base}) and the HxdT-catalyzed term (v_{HxdT}) (Eq. 2),

$$v_{obsd} = v_{base} + v_{HxdT}, \quad (2)$$

where v_{base} is the rate of the flavin reduction in the CTAB micelle solution and v_{obsd} is that in the presence of both HxdT and the CTAB micelle.

We found that the base-catalyzed deprotonation of benzoin is so fast in the CTAB micelle that the accurate determination of v_{HxdT} from Eq. 2 is rather difficult. The facile deprotonation of benzoin is due to the acidity of benzoin as carbon acid. On the other hand, the v_{base} of acetoin was relatively slow, the v_{obsd} being greater by a factor of 6.1 than the v_{base}. From Eq. 2, we thus determined the v_{HxdT} which is responsible for the HxdT-mediated retro-acyloin condensation. More unequivocal evidence was obtained from the reaction with HMB and HPB since the base-catalyzed deprotonation is not the case in these substrates. In fact, MeFl was not reduced at all by HMB and HPB in the CTAB micelle. On the other hand, the reduction of MeFl occurred on the addition of HxdT to the micelle solution. We thus determined the v_{HxdT} ($=v_{obsd}$) directly. Biacetyl, the monohydrated species of which is an analogue of α-ketol, also reduced MeFl in the micellized HxdT solution, the rate being much faster than that of α-ketols.

For the specification of the reaction order, the HxdT-catalyzed rates (v_{HxdT}) were determined as a function of the concentration of HxdT (0.2—2 mM) or substrates (for the concentration ranges see Table 1). It was found that the rates are first-order with respect to HxdT and substrates under these experimental conditions. The HxdT-catalyzed rates were thus given by Eq. 3. The $k_{2,app}$ values are summarized in Table 1.

$$v_{HxdT} = k_{2,app}[S]^{1.0}[HxdT]^{1.0}[MeFl]^{0} \quad (3)$$

The examination of this table reveals that (i) in aqueous solution, the thiazolium-mediated reduction of MeFl occurs only in the presence of the cationic micelle, (ii) the $k_{2,app}$ for $CH_3COC(OH)(CH_3)X$ series increases with increasing electron-withdrawing nature of X (*i.e.*, $CH_3<H<C_6H_5$), (iii) the reaction with biacetyl is much faster than that with analogous α-ketols, the rate constant being greater by factors of 10^2—10^3, and (iv) benzil and 4,4′-dichlorobenzil are totally unreactive. The effect of the substituents (ii) will be discussed later. The remarkable reactivity difference between biacetyl and benzil analogues is ascribed to the steric effect. For example, we have found that the micellized thiazolium ions is capable of catalyzing the decarboxylation of pyruvic acid but not that of 4-chlorobenzoylformic acid.[5] Both results suggest that the carbonyl group next to a phenyl ring is sterically deactivated in the thiazolium-mediated reactions.

As a summary of the foregoing results, one can safely conclude that the "active aldehydes" are produced from α-ketols and biacetyl in the micellized HxdT solution. In other words, it implies that the retro-acyloin condensation is mediated by micellized thiazolium ions. Subsequently, we carried out the product analyses of these reaction systems.

Product Analyses of the HxdT-mediated Retro-acyloin Condensation Systems. If HxdT-mediated retro-acyloin condensation takes place, 1 mol of acetoin afford

Table 1. Apparent second-order rate constants ($10^3 k_{2,app}$ M^{-1} s^{-1}) for the oxidation of α-ketols and analogues[a]

Substrate(S)	[S] / mM	CTAB / mM	pH	$10^3 k_{2,app}$ / M^{-1} s^{-1}
$CH_3COCH(OH)CH_3$	30—200	10	7.8	0.149
$CH_3COC(OH)(CH_3)_2$	30—200	10	7.8	0.0116
$CH_3COC(OH)(CH_3)_2$[b]	30—200	0	7.8	No reaction
$CH_3COC(OH)(CH_3)C_6H_5$	10— 50	10	7.8	2.05
$CH_3COCOCH_3$	0.5—3.0	10	7.8	21.8

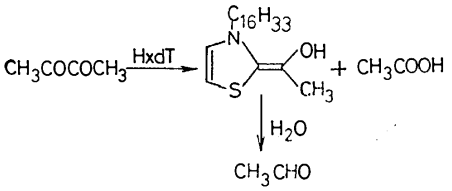
$C_6H_5COCOC_6H_5$	0.2—2.0	10	8.0	No reaction
$4\text{-}ClC_6H_4COCOC_6H_4Cl(4-)$	0.2—2.0	10	8.0	No reaction

a) 30 °C, [HxdT] = 1.00 mM, [MeFl] = 5.00×10^{-5} M. pH was adjusted with 0.01 M phosphate. b) *N*-Benzylthiazolium bromide(1.00 mM) was used instead of HxdT.

2 mol of acetaldehyde, and 1 mol of 3-hydroxy-3-methyl-2-butanone affords 1 mol of acetaldehyde and 1 mol of acetone. The reactions were carried out at 30 °C in anaerobic (N_2) ampuls. After 1 d, we treated the final reaction solution with 2,4-dinitrophenylhydrazinc[22] and analyzed the products as their hydrazone derivatives by using high-pressure liquid chromatography(HPLC). On the other hand, acetic acid was analyzed by GLC before the treatment with 2,4-dinitrophenylhydrazine. The results are summarized in Table 2. The examination of Table 2 reveals that the expected products are detected in the micellized HxdT solution, whereas no such product is afforded in the absence of HxdT. The yields of these products are relatively low, however. The low yields would be ascribed to the consumption of acetaldehyde (or acetone) by aldol-type condensation. In fact, we confirmed in a separate study that the concentration of acetaldehyde decreases with time in the CTAB micelle solution. These data support that HxdT in the CTAB micelle is capable of catalyzing the retro-acyloin condensation. It is now obvious, therefore, that the reduction of MeFl observed in the kinetic measurements is attributable to the reaction of MeFl with the active aldehydes (**1**) afforded from these substrates (see Scheme 1).

Table 3 shows that in the micellized HxdT solution biacetyl is converted to acetaldehyde and acetic acid. This reaction, the socalled biacetyl mutase reaction, has been found by Mizuhara and Oono.[23] The quantitative scission of 1 mol biacetyl gives 1 mol of acetic acid and 1 mol of acetaldehyde (Eq. 4). As shown in Table 3, however, the yield of acetic acid is much higher than that of acetaldehyde. The relatively low yield of acetaldehyde is again attributed to the consumption by aldol-type condensation. The yield of acetic acid calculated on the basis of HxdT was 190%. This



(4)

implies that HxdT acts as a recycle catalyst. It is presumed that this reaction also proceeds *via* the active aldehyde intermediate.[23] In fact, biacetyl in the micellized HxdT solution reduces MeFl (*vide supra*), indicating the formation of the active aldehyde from biacetyl and HxdT. We added flavin to the reaction system, and carried out the product analysis. Entry 3 in Table 3 shows that in the presence of FMN(flavin mononucleotide) the yield of acetaldehyde is lowered, while that of acetic acid is significantly enhanced. It seems likely, therefore, that the added FMN diverts (at least partially) the reaction route from the biacetyl mutase to the oxidation. The incompleteness of the trapping efficiency is related to the following experimental difficulties. When the reaction is carried out under aerobic conditions where FMN serves as recycle oxidation catalyst, hydrogen peroxide formed through the reoxidation process of reduced FMN also oxidizes biacetyl to acetic acid (see entry 4 in Table 3). This makes the reaction system very complex. In order to preclude the oxidation by hydrogen peroxide, one has to carry out the reaction under anaerobic conditions and enhance the flavin concentration. However, MeFl is not so soluble in the reaction medium while water-soluble FMN caused the precipitation of CTAB at its high concentration. Thus, the flavin trapping in the present system could be demonstrated only qualitatively.

TABLE 2. PRODUCT ANALYSES OF HxdT-MEDIATED RETRO-ACYLOIN CONDENSATION OF ACETOIN AND HMB[a]

Entry	Substrate	HxdT (mM)	Product(%)[b]	
			CH_3CHO	$(CH_3)_2CO$
1	$CH_3COCH(OH)CH_3$	5	9.8	Trace (<1)
2	$CH_3COC(OH)(CH_3)_2$	5	7.8	14
3	$CH_3COC(OH)(CH_3)_2$	0	Trace (<0.1)	Trace (<1)

a) 30 °C, pH 7.4 with 0.01 M phosphate, 1 d, anaerobic (N_2), [substrate] = 100 mM, [CTAB] = 30 mM. b) Acetaldehyde and acetone were recovered as their 2,4-dinitrophenylhydrazone derivatives and the yields were determined by HPLC. The yields were calculated on the basis of HxdT.

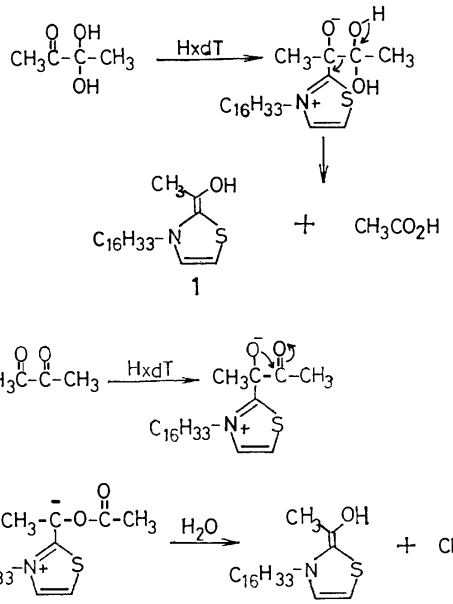
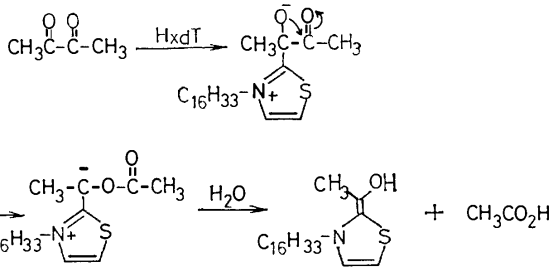
a) 30 °C, pH 7.4 with 0.01 M phosphate, 1 d, anaerobic (N_2), [biacetyl] = 100 mM. b) Acetaldehyde was recovered as its 2,4-dinitrophenylhydrazone derivative and analyzed by HPLC. Acetic acid was analyzed by GLC. The yields were calculated on the basis of HxdT. c) [FMN] = 10.0 mM. d) [$CH_3COCOCH_3$] = 30.0 mM, [H_2O_2] = 30 mM.

Comments on the Mechanism of Thiazolium-mediated Biacetyl Scission. Here, we wish to consider the mechanism of the HxdT-mediated biacetyl scission. Mizuhara and Oono,[23] who found for the first time that thiamine would catalyze the biacetyl mutase reaction, proposed that the mutase reaction begins with the reaction of thiamine and biacetyl enolate to give ketene and **1**. However, the mechanism involving the ketene production is now considered to be most improbable.[24] Here, two possible mechanisms come to mind: one is the reaction analogous to retro-acyloin condensation which occurs from the monohydrated form of biacetyl directly affording acetic acid and **1** (Eq. 5), and the other is the mechanism similar to that proposed for cyanide-ion catalyzed C–C bound scission of α,β-diketones (*e.g.*, benzil)[25,26] (Eq. 6). It



(5)

1



(6)

is not easy to distinguish between these two mechanisms by conventional kinetic methods. Based on the flavin trapping of **1**, we could determine the rate constant for biacetyl scission as well as those of α-ketol scission. Since biacetyl is extensively hydrated in aqueous solution,[27] one may regard diacetyl as a substrate with X=OH in $CH_3COC(OH)(CH_3)X$ series. We noticed that the plot of Taft's σ_I[28] *vs.* $\log k_{2,app}$ of $CH_3COC(OH)(CH_3)X$ holds a good linear relationship (r=0.97) (Fig. 1). Here, one has to take it into account that $k_{2,app}$ in the micellar system is affected not only by the reactivity of the substrate but also by the partition of the substrate between the micelle and the bulk water phase. We carried out the same reaction in a homogeneous solution (methanol) in the presence of strong base (DBU: 1,8-diazabicyclo[5.4.0]-undec-7-ene). As shown in Fig. 1, the plot for X=CH_3, H, and phenyl again held a good straight line (r=0.99). The finding suggests that in the present case the partition would not provide a significant influence upon the rate constant. Thus, the involvement of the plot for X=OH in a single straight line implies that the mechanism of biacetyl scission would be similar to that of the retro-acyloin condensation.

Conclusion. The present study establishes that

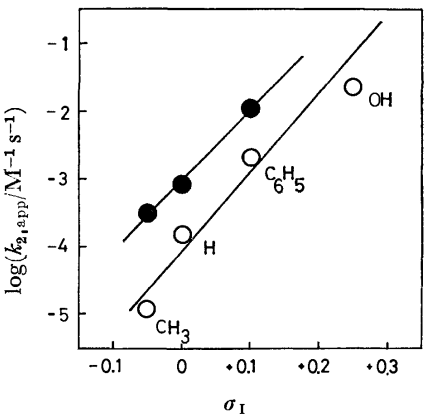


Fig. 1. Plot of σ_I for $CH_3COC(OH)(CH_3)X$ *vs.* log $k_{2,app}$. ○, Rate constants for the micellar system cited from Table 1. ●, Rate constants for the reaction in methanol, where [MeFl]=3.30×10^{-5} M, [*N*-benzylthiazolium bromide]=1.10×10^{-3} M, [DBU]=5.30×10^{-3} M. The $k_{2,app}$ is defined as v_{obsd}/[thiazolium ion][substrate]. In methanol, $k_{2,app}=3.08\times10^{-4}$ $M^{-1}s^{-1}$ for X=CH_3, 8.09×10^{-4} $M^{-1}s^{-1}$ for X=H, and 1.10×10^{-2} $M^{-1}s^{-1}$ for X=C_6H_5.

the micellized thiazolium ion is capable of catalyzing not only the acyloin condensation but also the retro-acyloin condensation. Obviously, the thiazolium-mediated acyloin condensation is reversible. The finding suggests an important insight into the mechanism of the early stage of the transketolase catalysis. We are now devoting our research effort toward the application of this concept to transketone reaction in the model system.

Experimental

Materials. Preparations of the following compounds were described previously: MeFl,[29] HxdT,[5] *N*-benzylthiazolium bromide,[5] and 4,4′-dichlorobenzil.[5] Acetoin, 3-hydroxy-3-methyl-2-butanone, and biacetyl were purchased from Tokyo Kasei Co. Ltd. and were distilled before use. 3-Hydroxy-3-phenyl-2-butanone was prepared from biacetyl and benzene in the presence of $AlCl_3$ according to the method of Wegmann and Dahn.[30]

Kinetic Measurements. The kinetic measurements of the micellar system were carried out at 30 °C under anaerobic (N_2) conditions in 3 vol% of aqueous ethanol. The details of the method were described previously[4,5]. Similarly, the kinetic measurements in methanol were carried out at 30 °C under anaerobic (N_2) conditions. The details of the reaction conditions are recorded in a caption to Fig. 1.

Product Analyses. The reactions for the product analyses were carried out at 30 °C in anaerobic (N_2) sealed ampuls. The detailed conditions were recorded in Table 2. Acetic acid was analyzed by GLC (Shimadzu GC-Mimi I: column, Silicone GE SE-30). To analyze acetaldehyde and acetone, the solution was treated with an excess of 2,4-dinitrophenylhydrazine,[22] and both the precipitate and the filtrate were subjected to HPLC analysis (Shimadzu LC-3: column, Merck Lichrosorb RP-18). The hydrazone derivatives of acetaldehyde and acetone were mainly present in the filtrate. Their yields were determined by comparing the integrated intensity of the peaks with that of the authentic samples.

The authors thank Miss. Y. Kusano and Miss K. Ueda for helpful technical assistance.

(Received August 9, 1982)

New π-donors containing a pyrene or a tetrahydropyrene ring were synthesized by means of a unique transannular reaction of the corresponding [2.2]metacylcophane derivatives. The CT complexes of these donors with a series of TCNQ derivatives different in electron affinity were prepared, and their electrical conductivities on single crystals were measured. The highest conductivity (0.36 Ω^{-1} cm^{-1}) was that of the tetrahydropyrene derivative–TCNQ complex. It was reconfirmed that the partial charge-transfer from a donor to an acceptor is very important for high conductivity.

A wide variety of charge-transfer (CT) complexes with a metal-like conductivity have recently been prepared. Many such highly conductive CT complexes or salts are composed of chalcogen atom-containing π-donors like TTF. Several heterocyclic donors containing one or two nitrogen atoms in condensed-ring systems also give highly conductive CT complexes, *e.g.*, *N*-methylphenazinium–TCNQ[2)] and quinolinium–TCNQ[3)] complexes.

On the other hand, a fairly high conductivity (2 Ω^{-1} cm^{-1} with a compressed sample) has been reported for the TCNQ complex of a diamino derivative of a carbocyclic hydrocarbon, 1,6-diaminopyrene.[4)] The conductivity of a single crystal can usually be expected to be increased by 10^2 times the conductivity on the corresponding pressed pellet. This excellent conductivity prompted us to prepare the complex of 2,7-bis(dimethylamino)pyrene **1**, which has a higher symmetry (D_{2h}) than 1,6-diaminopyrene (C_{2h}). Bis(dimethylamino)tetrahydropyrene **2**, a precursor in the present synthetic course for **1**, is also interesting in connection with the study[5)] of the relationship between the conductivity and the crystal structure of a series of benzidine–TCNQ complexes.

Results and Discussion

Synthesis. Because of the high electron density at the 1-position in the highest occupied molecular orbital (HOMO), pyrene is much more subjected to electrophilic substitution at this position than the others. Therefore, it is difficult to prepare 2,7-disubstituted pyrene by the electrophilic substitution reaction of pyrene itself. Furthermore, the solubility of pyrene derivatives is generally low in usual organic solvents. These facts forced us to choose a synthetic route which leads to the substituted pyrene chromophore in the final step.

According to the literature,[6)] 5,13-bis(bromomethyl)-[2.2]metacyclophane **4** was prepared *via* four steps starting from mesitylene. The Sommelet reaction of **4** was carried out in the usual manner to give **5** in a 72% yield. The oxidation of **5** with potassium permanganate gave **6** quantitatively. The Curtius reaction of **6** *via* acid chloride, acid azide, and isocyanate yielded a diamino compound **7** in a 64% yield. The diamine **7** was converted to **8** with dimethyl sulfate in an 86% yield.

The ready transformation of substituted [2.2]metacyclophane to the tetrahydropyrene framework has been reported by Allinger *et al.*[7)] and by Sato *et al.*[8)] Since then, this unique reaction has been utilized by several groups in the synthesis of substituted tetrahydropyrenes and pyrenes.[9)] We also have been employed this elegant reaction as a key step in the synthesis of **1**—**3**. Thus, the transannular dehydrogenative ring contraction of **7** and **8** with DDQ gave **3** (93% yield) and **2** (96% yield) respectively. The tetrahydro compound **2** was further dehydrogenated with Pd–C in boiling decalin to yield **1** in a 49% yield. The complexation of **1**—**3** was carried out with π-acceptors, such as TCNQ derivatives and chloranil. Single crystals of these CT complexes were obtained by the diffusional method or by recrystallization. The details will be described in the experimental part. The donor-to-acceptor ratio was determined by elemental analysis to be 1:1 for all the complexes.

Cyclic Voltammetry. Cyclic voltammetry was carried out in acetonitrile containing 0.1 M** of tetraethylammonium perchlorate as a supporting electrolyte and with an SCE reference electrode. The voltammograms of **1**—**3** are shown in Fig. 1. In each curve in the figure, two oxidation waves are observed. Both waves of **2** and **3** and the first wave of **1** are reversible,

** 1 M = 1 mol dm^{-3}.

whereas the second one of **1** is irreversible. The half-wave potentials ($E_{1/2}$) of these compounds are summarized in Table 1, together with those of the reference compounds, **9**—**11**. Of the three new donors, **2** shows the lowest value, one which is close to that of the powerful donor **11**. It should be pointed out that the value of **2** is lower by 0.20 V than that of **10**. This observation is particularly surprising in view of the fact that **2** and **10** have the same chromophore, 4,4'-diaminobiphenyl. A similar extent of difference (0.12 V) was also observed between the potentials of **3** and **9**. These data clearly indicate that the planar structure of a biphenyl chromophore forced by two ethylene chains plays an important role in lowering the oxidation potential. Furthermore, the value of **2** remains lower than that of **1**, which has a more condensed aromatic ring than the biphenyl. This might be interpreted as follows. The electron density at the 2- and 7-positions of pyrene at the HOMO level is zero. Hence, the ionization potential of the pyrene is subject to only a small influence of the substituents attached to these positions. The SCF-CI calculation by Nogami[10] showed that the ionization potentials of 1,6-, 1,8-, and 2,7-diaminopyrenes are 6.63, 6.64, and 7.39 eV respectively, supporting the interpretation stated above.

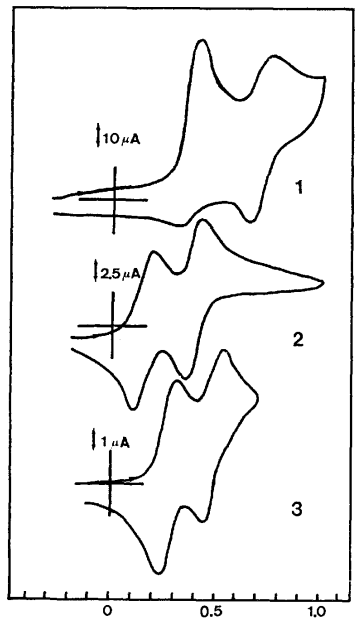

Fig. 1. Cyclic voltammograms of compounds, **1**, **2**, and **3**, in CH_3CN using Et_4NClO_4 as a supporting electrolyte.

Table 1. Half-wave potentials $E_{1/2}$ of **1**—**3** **9**—**11**

	($E^1_{1/2}$ *vs.* SCE)/V	($E^2_{1/2}$ *vs.* SCE)/V
1	0.37	0.71
2	0.14	0.38

3—**13**	5.52×10^{-10}	0.53
10—**12a**	6.49×10^{-6}	0.32
9—**12a**[a]	6.99×10^{-12}	0.54[5]

a) Compressed pellet. b) The activation energy could not be determined because the very weak current was hard to detect.

The values are summarized in the same table, showing the distribution of ρ values between unity and 0.20. A linearity is obtained when the ρ values of the complexes **1**—**12** are plotted against the half-wave potentials, $E^1_{1/2}$, of the acceptors in Table 2. This reveals a close relationship between these two values.

Electrical Conductivity. All the complexes show typical semiconducting behavior in the temperature range measured. Table 4 summarizes the electrical conductivities (σ) of these complexes on a single crystal at room temperature and the activation energies (E_a) based on the temperature dependence of the resistivities. The data on **9**–TCNQ given by Takahashi *et al.*[5] are included for purposes of comparison. In contrast to the high conductivity of 1,6-diaminopyrene-TCNQ on a compressed sample, the value of **1**–TCNQ is lower, even on a single crystal. This may be due to the relatively high $E^1_{1/2}$ value of **1**, as may be seen in Table 1. On the other hand, **2** with low $E^1_{1/2}$ value forms better conducting CT complexes than does **1**. It is noteworthy that, of the fourteen CT complexes in the table, **2**–TCNQ showed the highest conductivity, larger by 10^5 times than that of **10**–TCNQ, despite bearing the same diaminobiphenyl chromophore in **2** and **10**. A difference of similar extent (10^5) was also observed between **3**–TCNQ and **9**–TCNQ. Possibly these results are mainly due to the difference in the oxidation potential between **2** and **10** or between **3** and **9**, as may be seen in Table 1, and partly due to the different packing in a crystal, based on the different extent of planarity between biphenyl and tetrahydropyrene chromophores, although the molecular structures of these complexes are not yet known.

In Fig. 2 the conductivities of a series of complexes of **2** are plotted against the $E^1_{1/2}$ values of the acceptors. A noticeable point is that the conductivity of **2**–TCNQ is the highest. Not only the weaker acceptors, but also stronger acceptors than TCNQ itself diminish the conductivities of the complexes with **2**. In other words, the introduction of substituents to the TCNQ ring results in a decrease in the conductivities of the complexes, apart from the kind of the substituent. This fact clearly indicates that the incomplete electron transfer[14] from a donor to an acceptor has a significant effect on the high conductivity of the charge-transfer complexes.

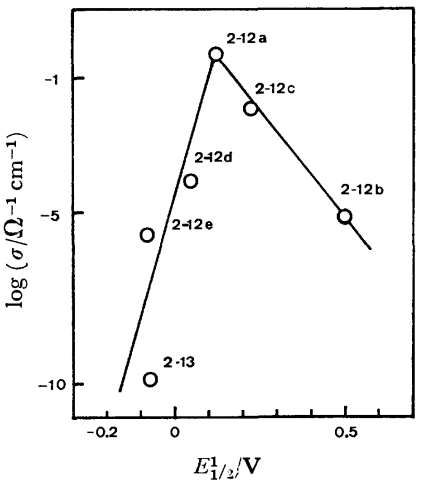

Fig. 2. Plots of conductivities of complexes, **2**—**12** and **2**—**13**, *vs.* $E^1_{1/2}$ of acceptors.

Experimental

All the melting points are uncorrected. The IR, NMR, MS, and electronic spectra were recorded with a Hitachi EPI-G2 and a Hitachi 345, a JEOL JNM-FX-100 (100 MHz for ^{1}H), a Hitachi RMU-7, and a Hitachi EP3-3T spectrometer respectively.

The cyclic voltammetry was carried out at room temperature under argon using the combination of a generator, Hokuto HB-107A, and a potentiostat, Hokuto HA-104. A glassy carbon electrode (Yanagimoto P-13) was used as the anode, and platinum wire was used as the counter electrode.

The electrical resistances for the pressed pellet and for the single crystal were measured with the two probe methods in the region from room temperature down to the temperature where an electrometer (Keithley 616) reached the lower limit of the detectable current (10^{-14} A). The electrical constants were obtained using silver paint (Du Pont 4817). The sizes of the single crystals were measured with a profile projector, Nikon V-24B.

[2.2]Metacyclophane-5,13-dicarbaldehyde (5). To a solution of 5,13-bis(bromomethyl)[2.2]metacyclophane **4**[6] (6.17 g, 15.6 mmol) in chloroform (60 ml) was added hexamethylenetetramine (5.10 g, 35.9 mmol), then the mixture was refluxed for 4 h. After cooling, a precipitate (ammonium salt) was collected and dried. A solution of this salt in 50% acetic acid (80 ml) was refluxed for 15 h. The crystals thus yielded were collected, washed with water, and dried. The subsequent recrystallization of the product from acetone gave **5** (2.98 g, 72% yield).

5: Colorless needles; mp 235—236.5 °C. ^{1}H NMR ($CDCl_3$) δ=3.23, 3.30 (d, J=8 Hz, 8H, CH_2), 4.52 (t, J=2 Hz, 2H, inner ArH), 7.65 (d, J=2 Hz, 4H, outer ArH), 10.04 (s, 2H, CHO). IR (Nujol mull) 2800, 2720, 1690 cm^{-1}.

81.79; H, 6.10%.

[2.2]Metacyclophane-5,13-dicarboxylic Acid (6). An aqueous solution (125 ml) of potassium permanganate (4.0 g, 25.3 mmol) was stirred with a solution of dialdehyde **5** (2.5 g, 9.46 mmol) at 60—70 °C for a period of 2 h. After the addition was over, the mixture was stirred for a further hour. To the solution was added 10% aqueous sodium hydroxide (80 ml), and the insoluble material was filtered off. The filtrate was acidified with dil hydrochloric acid. The precipitate was collected, washed with water, and dried to give 2.6 g (93%) of **6**.

6: Mp >350 °C. IR (Nujol mull) 1690 cm^{-1}. MS *m/e* 296 (M^+).

5,13-Diamino[2.2]metacyclophane (7). A mixture of dicarboxylic acid **6** (2.6 g, 8.8 mmol) and thionyl chloride (60 ml) was refluxed for 4 h, and the excess thionyl chloride was distilled off. The acid chloride thus obtained was dissolved in THF (80 ml). To the stirred, ice-cooled solution was added an aqueous solution (19 ml) of sodium azide (1.35 g, 20.8 mmol). After additional stirring at room temperature for 1 h, water was added to the solution. The precipitate was collected by filtration, washed with water, and dried. The acid azide is fairly stable and can be handled safely at room temperature. A solution of the azide in benzene (60 ml) was refluxed for 4 h. After cooling, 18 ml of conc hydrochloric acid was added, and the mixture was refluxed for 1 h under nitrogen. The benzene was then removed, and the insoluble material was filtered off. The filtrate was neutralized with aqueous sodium hydroxide. The crystals thus deposited were collected by filtration and washed with water to give 1.33 g (64%) of **7**.

7: Colorless prisms from benzene-hexane; mp 232—233 °C with dec. ^{1}H NMR ($CDCl_3$) δ=2.08, 2.91 (d, J=8 Hz, 8H, CH_2), 4.06 (t, J=1.5 Hz, 2H, inner ArH), 6.40 (d, J=1.5 Hz, 4H, outer ArH). IR (Nujol mull) 3400, 3290, 3190 cm^{-1}.

Found: C, 80.36; H, 7.49; N, 11.87%. Calcd for $C_{16}H_{18}N_2$: C, 80.63; H, 7.61; N, 11.75%.

5,13-Bis(dimethylamino)[2.2]metacyclophane (8). To a mixture of **7** (1.70 g, 7.1 mmol) and sodium hydrogencarbonate (4.47 g, 53.2 mmol) in 70 ml of water-THF (3:4) was added dimethyl sulfate (6.08 g, 48.3 mmol) at 0 °C under nitrogen. Stirring was continued at room temperature for 2 h and then at 65—70 °C for 20 min. After cooling, 2-aminoethanol (7 ml) was added, and the mixture was heated at 120 °C (bath temperature) for 9 h with stirring. The THF was then distilled off, and the residue was extracted with dichloromethane. The extracts were washed with a saturated aqueous solution of sodium chloride and dried over $MgSO_4$. After the removal of the solvent, the crude product was passed through a short column of alumina with chloroform–benzene (1:1). Recrystallization from methanol gave 1.79 g (86%) of pure **8**.

8: Mp 208—209 °C. ^{1}H NMR ($CDCl_3$) δ=2.14, 2.97 (d, J=7.8 Hz, 8H, CH_2), 2.96 (s, 12H, Me), 4.04 (t, J=1.2 Hz, 2H, inner ArH), 6.48 (d, J=1.2 Hz, 4H, outer ArH). IR (Nujol mull) 1595 cm^{-1}.

Found: C, 82.26; H, 8.47; 9.29%. Calcd for $C_{20}H_{26}N_2$: C, 82.15; H, 8.27; N, 9.58%.

2,7-Diaminotetrahydropyrene (3). To a stirred solution of **7** (200 mg, 0.84 mmol) in benzene (50 ml) was added a solution of dichlorodicyano-*p*-benzoquinone (DDQ) (190 mg) in benzene (40 ml). After additional stirring for 1 h at room temperature and the removal of the benzene, an

aqueous solution of 10% sodium hydroxide was added and the mixture was extracted with dichloromethane. The extracts were washed with a saturated sodium chloride solution and dried. The subsequent removal of the solvent gave 190 mg (95%) of **3**.

3: Colorless microcrystals by sublimation; mp 242—243 °C with decomp. ^{1}H NMR ($CDCl_3$) δ=2.75 (s, 8H, CH_2), 6.40 (s, 4H, ArH). IR (Nujol mull) 3440, 3390, 3180, 1630, 1610 cm^{-1}.

Found: C, 81.32; H, 6.82; N, 11.85%. Calcd for $C_{16}H_{16}N_2$: C, 81.11; H, 6.66; N, 11.90%.

2,7-Bis(dimethylamino)tetrahydropyrene (2). a): The methylation of **3** with dimethyl sulfate was done in a manner similar to that used in the synthesis of **8**. The crude product was passed through a short column of alumina. Further purification by sublimation gave 224 mg (96%) of **2**.

2: Colorless prisms; mp 142—143 °C. ^{1}H NMR ($CDCl_3$) δ=2.84 (s, 8H, CH_2), 2.96 (s, 12H, CH_3), 6.49 (s, 4H, ArH). UV (MeOH) 220 (ε 3.86×10^4), 321 (3.53×10^4), 333 nm (2.96×10^4).

Found: C, 82.32; H, 8.36; N, 9.69%. Calcd for $C_{20}H_{24}N_2$: C, 82.15; H, 8.27; N, 9.58%.

b): The transannular reaction of **8** with DDQ was carried out in a manner similar to that described for **3**. The crude product was purified by column chromatography with silica gel and dichloromethane-benzene (1:1) and then by recrystallization from methanol (93% yield).

2,7-Bis(dimethylamino)pyrene (1). A mixture of **2** (630 mg, 2.15 mmol), Pd-C (1.378 g), and decalin (50 ml) was refluxed under nitrogen for 1 h. After the filtration of the Pd-C, 2 mol dm^{-3} hydrochloric acid was added to the filtrate. The aqueous layer separated was made basic with 10% sodium hydroxide, extracted with dichloromethane, and the organic layer was dried. After the removal of the solvent, the residue was chromatographed on silica gel containing 10% of water with benzene. Recrystallization from benzene gave 304 mg (49%) of **1**.

1: Yellowish orange columns; mp 222—223 °C with dec. ^{1}H NMR ($CDCl_3$) δ=3.19 (s, 12H, CH_3), 7.55 (s, 4H, ArH), 7.88 (s, 4H, ArH). UV (MeOH) 289 (ε 1.31×10^5), 314 (1.51×10^4), 328 (1.20×10^4), 344 (2.49×10^4), 443 nm (3.29×10^3). IR (Nujol mull) 1605 cm^{-1}.

Found: C, 83.26; H, 7.18; N, 9.56%. Calcd for $C_{20}H_{20}N_2$: C, 83.30; H, 6.99; N, 9.71%.

Preparation of Single Crystals of CT Complexes. a) Difusional Method: In one side of an H-type glass tube was placed **2** (29 mg, 0.1 mmol), and in the other side, TCNQ (20 mg, 0.1 mmol). The apparatus was then gradually filled with acetonitrile under nitrogen and allowed to stand in the dark for 20 d. The black column crystals produced at the middle part of the apparatus were collected, washed with acetonitrile, and dried (46 mg, 95%).

b) Recrystallization: Two solutions of **2** (10 mg, 0.07 mmol) and $TCNQ(Me)_2$ (15 mg, 0.07 mmol) in an equal amount (10 ml) of acetonitrile were mixed at room temperature. The precipitate was collected and recrystallized from THF to give 28 mg (82%) of **2**-$TCNQ(Me)_2$ as dark violet needles.

Single crystals of the other complexes were prepared according to method *a*) or *b*). The data of the elemental analyses, melting points, colors, shapes, and crystal sizes of the complexes are summarized in Table 5.

The present work was supported by a Grant-in-Aid for Scientific Research (No. 543009) from the Ministry of Education, Science and Culture, for which the authors are grateful.

(Received August 13, 1982)

Effects of the β-methyl group at C-10 and some oxygen functions (=O, OH, OAc) at C-11, C-17, and C-20 on the rates of hydrogenation of 3-oxo-4-ene steroids have been studied with palladium catalyst in pyridine or THF/HBr as solvent. In contrast to the hydrogenation in pyridine, the rate in THF/HBr was greatly depressed by the presence of 10β-methyl group. The reactivity of the steroids was enhanced by the oxygen functions, in particular, by 11, 17-dioxo group. The effects of the substituents are discussed from a mechanistic consideration based on the obtained results.

The stereochemistry of catalytic hydrogenation of cyclic α,β-unsaturated ketones to saturated ketones has been of wide interest from the viewpoint of stereoselective synthesis as well as from the mechanistic interpretation of the results.[2] Although a considerable body of studies has been described in literature, in particular, in the fields of 3-oxo-4-ene steroids and bicyclo[4.4.0]dec-1-en-3-one ($\Delta^{1(8a)}$-2-octalone), the mechanistic interpretations proposed do not appear to be sufficient to explain the stereochemical outcomes under various reaction conditions. This may be due to a rather complex nature of the reaction. The polar character of the unsaturated system is susceptible to a variety of factors which can influence the stereochemistry of hydrogenation, including the problem of 1,2- and 1,4-addition of hydrogen. Of these factors the most important is the effects of bases and acids.

As well known, 3-oxo-4-ene steroids are stereoselectively hydrogenated to 3-oxo-5β steroids in basic media.[3] The stereoselectivity, however, is not always satisfactory in these compounds with oxo and hydroxy functions at C-11, C-17, and C-20. The use of 4-methoxypyridine as a solvent has been found most effective for these compounds.[1] On the other hand, the addition of hydrobromic acid to acetic acid or, better, to tetrahydrofuran greatly increases the yields of 3-oxo-5β compounds from 19-nor-3-oxo-4-ene steroids.[1] The results on 19-nor steroids in acidic media are in line with those reported in the hydrogenation of 2-octalone where high yields of *cis*-2-decalone are obtained under acidic conditions.[4] In basic media, however, the results are not always consistent with those on 2-octalone in which the stereoselectivity is usually low under basic conditions.[2] Since 19-nor-3-oxo-4-ene steroids are very similar to 2-octalone in their A/B ring structures, a comparable study on 19-nor and 10β-methyl steroids allows an estimation of the effect of the angular methyl group more directly. Since the kinetic aspect of the hydrogenation of these steroids is little known, we have investigated the rates of hydrogenation of various steroids with or without 10β-methyl group in basic and acidic media in order to know the effect of the angular methyl group as well as the effect of some oxygen functions at C-11, C-17, and C-20.

Results

Hydrogenation in Basic Medium. Seven 3-oxo-4-enes (**1a—g**) and three 19-nor-3-oxo-4-enes (**2c—e**) (see Table 1) have been hydrogenated in pyridine as a solvent at 25 °C and atmospheric pressure with palladium black as a catalyst. The hydrogenation was zero order in the concentration of the steroids and the zero-order kinetics held until the most portion of the steroids had been hydrogenated. The steroids have also been hydrogenated competitively in a 1:1 mixture of an appropriate pair of the compounds. The relative reactivity of a compound to cholest-4-en-3-one (**1a**), (R/R_{1a}), was obtained by employing the relationship of Eq. 1,

$$\log (C^\circ/C) = (R/R_{1a}) \log (C^\circ_{1a}/C_{1a}), \quad (1)$$

where C° and C represent the concentrations of the compound at the initiation and a given time, respectively, and the subscript 1a refers to cholest-4-en-3-one. Most of the values were obtained in competitive hydrogenation of a compound with **1a**, but in some cases, because of difficulty in analysis, the ratios were determined indirectly by competitive hydrogenation with another compound which was in turn hydrogenated competitively with **1a**. From the values obtained in individual and competitive hydrogenations, the ratios of adsorption coefficients, b/b_{1a}, were calculated from the relationship: $R/R_{1a}=(k/k_{1a})(b/b_{1a})$, where k/k_{1a} denotes the ratio of the rate of hydrogenation of a steroid to that of **1a** in individual hydrogenations. The results are summarized in Table 1. It is seen from the results that the rate of hydrogenation is generally enhanced by the oxygen functions at C-11, C-17, and C-20 which tend to lower the selectivity to 5β except the 17β-acetoxy group in **1c**. This trend is most prominently seen in the case of **1g** with 11,17-dioxo group where the rate of hydrogenation is 4 times as great as that of **1a** and the selectivity to 5β is as low as 32%. Since the relative reactivity of **1g** to **1a**, R_{1g}/R_{1a}, is 10, it results that the value for b_{1g}/b_{1a} is 2.5. Thus the compound **1g** is more strongly adsorbed to the catalyst than **1a**. With the compounds having the other oxygen functions, any tendency of strong adsorption over **1a** was not indicated. The reactivities of 19-nor steroids in individual hydrogenations are not much different from those of the corresponding 10β-methyl analogs, but the relative reac-

a) The compound was hydrogenated in 1.8 ml of THF containing 0.2 μl of concd HBr (48%). For the other conditions see the footnote a) in Table 1. b) For the compound structure, see Table 1. c) The figures in parentheses indicate the values for 19-nor steroids relative to the corresponding 10β-methyl analogs. d) Obtained from $R_{2e}/R_{1f}(31.5)$ and $R_{1f}/R_{1a}(2.1)$.

tivities in competitive hydrogenations are somewhat greater in the cases of **2d** and **2e**, indicating slightly stronger adsorption of these 19-nor steroids. The selectivity to 5β is always lower with 19-nor steroids than with the corresponding 10β-methyl analogs, although differences are not so great.

Hydrogenation in Acidic Medium. The results of the hydrogenation in tetrahydrofuran and hydrobromic acid are summarized in Table 2. The hydrogenation was zero order in concentration of steroids. Similar to the hydrogenation in pyridine, the oxygen functions enhance the reactivity of the steroids and lower the selectivity to 5β. As observed in pyridine, 11,17-dioxo steroid **1g** showed the greatest reactivity and afforded the lowest yield of 5β-product. High reactivities of **1g** and **1e** are more pronounced in competitive hydrogenation than in individual hydrogenation and this suggests that under acidic condition 11- and 17-oxo groups may contribute to adsorption to the catalyst probably at the α-face. In contrast to the hydrogenation in pyridine, the rates of hydrogenation of 19-nor steroids are all far greater than those of the corresponding 10β-methyl analogs. The selectivity to 5β is also much higher for the 19-nor steroids where the yields of 5β-products were almost quantitative.

Discussion

The Effect of 10β-Methyl Group. The course of catalytic hydrogenation of α,β-unsaturated ketones over palladium catalysts has been discussed in several papers with respect to product stereochemistry.[2,4-7] It appears likely that in basic or acidic conditions hydrogen adds *via* 1,4, rather than 1,2, to the unsaturated system. In the case of 3-oxo-4-ene steroids, the formation of 5β-compounds increases in both basic and acidic media, while with 2-octalone high stereoselectivity to the *cis* isomer was obtained only in acidic medium.[2]

As seen from the results in Table 1, the reactivities of 19-nor-steroids **2c**, **2d**, and **2e** are almost the same with or only slightly larger than those of the corresponding 10β-methyl analogs. The stereoselectivity to 5β always decreases with the 19-nor steroids, although the degree of the decrease is not great (98.5→95% with **2c**; 93→85% with **2d**; 92.5→89% with **2e**). In view of the rather small effects of 10β-methyl group on the rate and the product stereochemistry, it would be reasonable to assume that the transition state which may control the product is in an sp^3-like conformation at C-5. In this conformation, the formation of 5α isomer would be more favorable for 19-nor steroids than for 10β-methyl steroids, because in the transition state leading to 5α isomers the interaction between an axial 2β-hydrogen and 10β-methyl group lacks in 19-nor steroids (see Fig. 1). On the other hand, at the transition state leading to 5β isomers (Fig. 2), the energy difference between both series of the steroids would be rather small, because 10β-methyl group takes an equatorial conformation with respect to the ring A. Rather small differences in reactivities between 19-nor and 10β-methyl steroids would thus be plausible if we consider that the major products are 5β isomers for both series of the steroids. Accordingly, the increase in the formation of 5α isomers with 19-nor steroids is considered to be due to an increase in the rate of formation of 5α isomers.

In contrast to the results in pyridine, 19-nor steroids are hydrogenated much more rapidly in tetrahydrofuran/hydrobromic acid than the corresponding 10β-methyl steroids (Table 2). This result strongly suggests that in the presence of acid the product controlling transition state is in an sp^2-like conformation at C-5 and the attack of hydrogen from the β-face to C-5 is strongly hindered by 10β-methyl group. Almost exclusive formation of 5β isomers from 19-nor steroids in the presence of acid is thus considered to be a result of a great increase in the rate of β-addition of hydrogen. It is further noted that some favorable β-face adsorption in 19-nor steroids may also contribute to the increase of 5β-products.

The Effects of Functional Groups. It is well known that the stereochemistry of hydrogenation of 3-oxo-4-ene steroids is considerably influenced by the substituents which are located far from the reaction site.[8] The nature of the substituent effect, however, has not clearly been understood yet. Some models for explaining it have been discussed, *e.g.*, by Kirk and Hartshorn.[6] Henbest and coworkers have pointed out some similarities in the substituent effects between catalytic hydrogenation and alkaline epoxidation of 3-oxo-4-ene steroids.[9,10]

The results on the kinetic study (Tables 1 and 2) indicate that the compounds having the oxygen functions which may decrease the 5β/5α ratio of product are generally more reactive than those not carrying such functions (compare **1d**, **1e**, **1f**, and **1g** with **1a** and **1b**). The only exception to this is the case of **1c** in pyridine where the rate of hydrogenation is greater than that of **1a** or **1b** and the selectivity to 5β is very high. The compound **1g** with 11,17-dioxo group is noteworthy in that in both basic and acidic media it is definitely more reactive and affords considerably lower yields of 5β-product, than the other compounds investigated. In general, the effects of the oxygen functions are very similar in basic and acidic conditions, as shown in Fig. 3. Since the high stereoselectivity to 5β is obtained in both basic and acidic conditions which can assist polarized adsorption

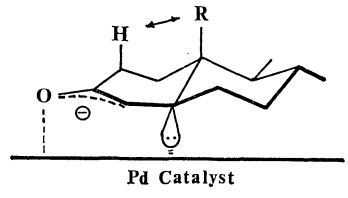

Fig. 1. The transition state leading to 5α-product in an sp^3-like conformation at C-5 (R=Me or H).

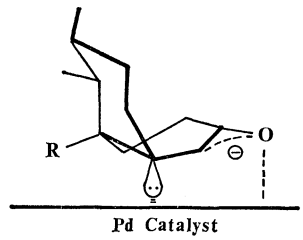

Fig. 2. The transition state leading to 5β-product in an sp^3-like conformation at C-5 (R=Me or H).

of the substrate onto the catalyst, it would be reasonable to consider that the electron-attractive oxygen functions may act in opposition to the π-electron polarization toward 3-oxo group, as suggested by Kirk and Hartshorn for the formation of a 4β,5β-bonded surface complex. Further, it is supposed that the interaction of the substrate with pyridine or hydrogen bromide would be stronger in a polarized state and under such circumstances the rate of hydrogenation would be depressed.[11] Hence the hydrogenation in a less polarized state would result in an increased rate as well as a decreased 5β/5α ratio of the product, as it is supposed to be the case with **1g**. This explanation is further supported by the fact that with **1g** the 5β/5α ratio of the product obtained in tetrahydrofuran was not much different from those observed in pyridine or in tetrahydrofuran and hydrobromic acid, while with other compounds the 5β/5α ratios distinctly increased in pyridine and tetrahydrofuran/hydrobromic acid, compared to those in tetrahydrofuran (see Fig. 4).

Experimental

General. All hydrogenations were carried out at 25 °C and atmospheric pressure in a small glass apparatus driven vibrationally. The compound to be hydrogenated (0.0569 mmol) was added in a solution after the catalyst (3 mg) had been shaken with hydrogen in the reaction medium for 20 min. The combined volume of the solution was 1.8 ml. In competitive hydrogenation an equimolar mixture of 0.0285 mmol of each compound was hydrogenated. Hydrogen bromide was added as a THF solution after the catalyst had been shaken with hydrogen for 20 min, and the mixture was further shaken with hydrogen for 30 min prior to the addition of the compound. The reaction mixture was taken into a microsyringe through a silicone rubber plug in the course of hydrogenation and analyzed by GLC using OV-17 as a stationary phase.

Solvent. Pyridine was treated with Raney nickel, dried over potassium hydroxide, and then distilled. THF was purified using $LiAlH_4$ as described previously.[1]

Catalyst. The palladium black used as the catalyst was prepared by reduction of palladium hydroxide in water.[12]

The authors are grateful to Teikoku Hormone Manufacturing Co. for the gift of androst-4-en-3-one and to the Mitsubishi Chemical Industries Co. for the supply of androst-4-ene-3,17-dione and 19-norandrost-4-ene-3,17-dione. This work was partially supported by a Grant-in-Aid for Scientific Research (C)(No. 57540279) from the Ministry of Education, Science and Culture.

The Hydroxylation of β-Terpineol and Its Acetate with the Cultured Cells of *Nicotiana tabacum*

Takayuki SUGA,* Ym Sook LEE, and Toshifumi HIRATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730

(Received August 16, 1982)

The biotransformation of *c*-4-*p*-menth-8(9)-en-*r*-1-ol (β-terpineol) and its acetate with the cultured suspension cells of *Nicotiana tabacum* were tested. It was found that the cultured cells have the ability to hydroxylate not only the allylic positions of the C-C double bond of these substrates, but also their terminal carbon-carbon double bond. The hydroxylation at the 4-position of their allylic positions was stereospecific, affording a *trans*-1,4-diol.

The biochemical capability of plant cells to metabolize foreign substrates and/or convert them into more useful substances is of considerable interest. In such a status, we recently investigated the transformation of monoterpenoid alcohols and ketones with the cultured cells of *Nicotiana tabacum* "Bright Yellow," and found that the tobacco cells have the ability not only to reduce stereoselectively the carbon–carbon double bond adjacent to the carbonyl group of carvone as well as the carbonyl group,[1] but also to hydroxylate regioselectively the allylic position of the carbon-carbon double bond of linalool.[2] Also, the cultured cells were found to have the ability to hydrolyze the acetoxyl group of linalyl acetate, dihydrolinalyl acetate, and α-terpinyl acetate, but the cells scarcely show such an ability to γ-terpinyl acetate.[3] To generalize how the transformation patterns depend on the type of the functional group of the substrates and the structure around the functional group, we now have investigated the biotransformation of *c*-4-*p*-menth-8(9)-en-*r*-1-ol (β-terpineol) (**1**) and its acetate (**2**). The result was in part outlined in the preliminary communication.[4] This paper will give a full detail of the result.

Results and Discussion

Callus tissues induced from the stem of *N. tabacum* "Bright Yellow" were used in this work. The callus tissues were cultured in Murashige and Skoog's medium[5] with continuous shaking for 3—4 weeks and then the monoterpenoids were administered to the cultures. The cultures were then incubated at 25 °C for 7—10 d with shaking in the dark.

c-4-*p*-Menth-8(9)-en-*r*-1-ol (**1**) was transformed into three products, *c*-4-*p*-menth-8(9)-ene-*r*-1,10-diol (**3**), 4-*p*-menth-8(9)-ene-*r*-1,*t*-4-diol (**4**), and *c*-4-*p*-menthane-*r*-1,8,9-triol (**5**), which were characterized as follows. The major product (**3**) was indicated to be a 10-hydroxylated derivative of **1** on the basis of the fragment ion peaks at *m/z* 155.1042 (M^+-CH_3, $C_9H_{15}O_2$), 152.1185 (M^+-H_2O, $C_{10}H_6O$), and 134.1096 ($M^+-2\times H_2O$, $C_{10}H_{14}$) in the high resolution mass spectrum, the hydroxyl stretching bands at 3635 (primary) and 3618 cm^{-1} (tertiary) in the IR spectrum, and the ^1H NMR signal at δ 4.12 due to a hydroxymethyl group instead of the 10-methyl signal of **1**. Identity of the product **3** with *c*-4-*p*-menth-8(9)-ene-*r*-1,10-diol was established by comparisons of its spectral data with those of an authentic sample, which was prepared by oxidation of *r*-1-acetoxy-*c*-4-*p*-menth-8(9)-ene (**2**) with SeO_2 followed by hydrolysis of the oxidation product. On the other hand, the product **4** was established to be 4-*p*-menth-8(9)-ene-*r*-1,*t*-4-diol on the basis of comparisons of its spectral data with those of the literature[6-8] and those of an authentic sample. Identity of the product **5** with *c*-4-*p*-menthane-*r*-1,8,9-triol was established by comparisons of its TLC, IR and mass spectra with those of the authentic sample prepared by oxidation of **2** with OsO_4 followed by reduction with $LiAlH_4$.

The biotransformation of *r*-1-acetoxy-*c*-4-*p*-menth-8(9)-ene (**2**) with the cells yielded three products, **6**, **7**, and **8**. The ^1H NMR spectrum of **6** revealed a new signal at δ 3.47 due to a hydroxymethyl group with the disappearance of the signal of the terminal ethylenic linkage of **2**. Its mass spectrum exhibited the ion peaks at *m/z* 199 (M^+-CH_2OH), 139 ($M^+-CH_2OH-AcOH$), and 121 ($M^+-CH_2OH-AcOH-H_2O$). These data indicated the product **6** to be *r*-1-acetoxy-*c*-4-*p*-menthane-8,9-diol. Identity of the product with the diol was established by direct comparisons of its IR, ^1H NMR, and mass spectra with those of the authentic sample prepared by oxidation of **2** with OsO_4.[9] The formation of the diol (**6**) indicates the occurrence of hydroxylation of the terminal ethylenic linkage of **2**. On the other hand, the products **7** and **8** were identified as *r*-1-acetoxy-*c*-4-*p*-menth-8(9)-en-10-ol and *r*-1-acetoxy-4-*p*-menth-8(9)-en-*t*-4-ol, respectively, by direct comparisons of their physical and spectral data with those of the

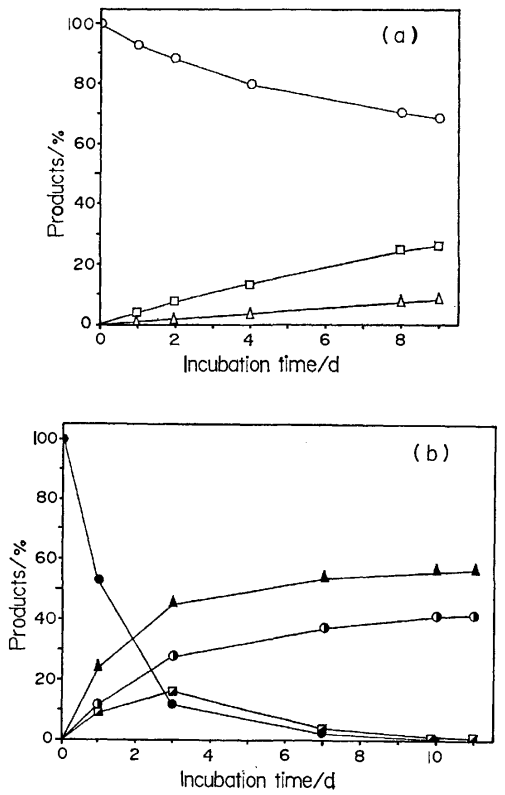

Fig. 1. The time-courses in the biotransformation of **1** (a) and **2** (b) by the cultured cells of *N. tabacum*. ○: **1**, ●: **2**, □: **3**, △: **4**, ▲: **6**, ◪: **7**, and ◑: **8**.

authentic samples, which had been prepared following to the reported procedure.[6,7] The yields of the transformation products are given in Table 1. The time-courses in the biotransformation of β-terpineol (**1**) and its acetate (**2**) with the cultured suspension cells were followed, and it was found that the transformation of **2** is more rapid than that of **1**. The products **3**, **4**, **6**, and **8** gradually increased in their amounts with the lapse of the incubation time, but, after the amounts of the product **7** became maximum at the 3-d incubation, it gradually decreased; this is probably due to the further conversion of **7** to another product. In spite of careful and repeated TLC and GLC analyses, no *cis*-1,4-glycols (**9** and **10**) were found in the reaction mixtures obtained at each regular interval in the time-course experiment. This fact indicates that the hydroxylation with the tobacco suspension cells is more stereoselective than that with SeO_2, which is known to convert **2** into *r*-1-acetoxy-4-*p*-menth-8(9)-en-*t*-4-ol (**8**) and its *cis*-isomer (**10**) in the ratio of 6:5.[6]

Thus, it has been clarified that β-terpineol (**1**) and its acetate (**2**) are hydroxylated not only at the allylic positions of the ethylenic linkage but also at the ethylenic linkage itself by the tobacco cultured suspension cells. However, in contrast to the predominant hydroxylation at the ethylenic linkage in the case of β-terpinyl acetate (**2**), only a small amount of β-terpineol (**1**) is hydroxylated at the ethylenic linkage. The hydroxylation of the 4-position of **1** and **2** is stereospecific and arises from the direction *trans* to the 1-hydroxyl or 1-acetoxyl group. Our recent studies on the biotransformation of carvone[1] showed that its carbon-carbon double bond adjacent to the carbonyl group was reduced, but its terminal carbon-carbon double bond remained unchanged. However, the terminal ethylenic linkage of β-terpinyl acetate (**2**) was hydroxylated to an appreciable extent. It is fascinating to note that the biotransformation pattern of the foreign substrates depends on the functional group of the substrate administered and the structure around the functional group.

Experimental

Analytical (0.25 mm thick) and preparative TLC (0.75 mm thick) were carried out on a silica-gel plate (Merck, Type 60, GF_{254}). GLC analyses were performed on an instrument equipped with an FID and a glass column (3 mm×2 m) packed with 15% DEGS, 2% OV-17, or 2% OV-101 on Chromosorb W (AW-DMCS; 80—100 mesh) by programming the column temperature at 100—200 °C with a rate of 3 °C/min for DEGS and at 90—250 °C, 2 °C/min for OV-17 and OV-101. The areas of the peaks on the gas-liquid chromatogram were calculated by use of a Shimadzu C-R1A Chromatopac recording data processor for chromatography. GC-MS were recorded on a mass spectrometer which was installed with a gas chromatograph equipped with an OV-101 capillary column (0.28 mm×50 m) at 80—210 °C with a rate of 3 °C/min using an EI ion source at 20 eV. ^1H NMR spectra were taken at 60 or 90 MHz for $CDCl_3$ solutions with TMS as an internal reference. FT-IR spectra were obtained on a JIR-40X FT-IR spectrophotometer.

Preparation of the Materials Used for Substrates. Following the method described in the literature,[10,11] *r*-1-acetoxy-*c*-4-*p*-menth-8(9)-ene (**2**) was prepared by pyrolysis of terpin diacetate (**11**) (n_D^{25} 1.4510, d_4^{25} 1.0217), which was derived from terpin hydrate[12] by acetylation, followed by purifications by column chromatography on 10% $AgNO_3$-silica gel with a hexane-EtOAc mixture with increasing EtOAc from 0 to 5% and then by distillation under a reduced pressure: bp 71 °C/3.5 mmHg, 1 mmHg≈133.322 Pa; n_D^{25} 1.4569; d_4^{25} 0.9414 (lit,[10] bp 81—82 °C/4 mmHg; n_D^{25} 1.4562; d_4^{25}

0.9411); >99.8% pure on GLC; IR (neat) 1737 (OAc), 3084, 1644, and 892 cm^{-1} (>C=CH_2); ^1H NMR ($CDCl_3$) δ=1.47 (3H, s, 7-CH_3), 1.69 (3H, bs, 10-CH_3), 1.99 (3H, s, OAc), and 4.69 (2H, bs, >C=CH_2). Found: C, 73.29; H, 10.24%. Calcd for $C_{12}H_{20}O_2$: C, 73.43; H, 10.27%.

c-4-*p*-Menth-8(9)-en-*r*-1-ol (**1**) was prepared from **2** by hydrolysis with 2.5% ethanolic KOH soln, followed by purification by preparative TLC on silica gel with hexane–EtOAc (7:3, v/v): mp 30.5—30.8 °C (lit,[7] 28—30 °C); >99.9% pure on GLC; IR (neat) 3400 (OH), 3095, 1648, and 890 cm^{-1} (>C=CH_2); ^1H NMR ($CDCl_3$) δ=1.23 (3H, s, 7-CH_3), 1.72 (3H, bs, 10-CH_3), and 4.70 (2H, bs, >C=CH_2). Found: C, 77.74; H, 11.73%. Calcd for $C_{10}H_{18}O$: C, 77.86; H, 11.76%.

Feeding of the Monoterpenoids to the Tobacco Suspension Cells. The callus tissues used in this study were induced from the stem of *Nicotiana tabacum* "Bright Yellow" and have been maintained for about 8 years. Just prior to use for this work, the callus tissue was transplanted to freshly prepared Murashige and Skoog's medium[5] (100 ml per 300 ml-conical flask) containing 2 ppm 2,4-dichlorophenoxyacetic acid and 3% sucrose, and it was grown with continuous shaking for 3—4 weeks at 25 °C in the dark. After the substrate (10 mg per one flask; total 250—400 mg) had been added to the suspension cultures (about 50—70 g cells per one flask), the cultures was incubated at 25 °C for 7—10 d on a rotary shaker (70 min^{-1}) in the dark.

Isolation and Identification of the Products. The suspension cells were filtered off and triturated with MeOH. Removal of the solvent from the methanol solution gave an extract, which was again extracted with $CHCl_3$. On the other hand, the culture medium separated from the mass of the cells was extracted with $CHCl_3$. The two $CHCl_3$ extracts were put together, since they exhibited the same behavior on TLC and GLC. Transformation products **3**, **4**, and **6**—**8** were isolated from the combined $CHCl_3$ extract by preparative TLC on silica gel with hexane–EtOAc (1:2 or 7:3, v/v), and identified by direct comparisons of their physical constants, TLC, GLC, and spectral data with those of synthetic specimens prepared as described below.

In the case of β-terpineol (**1**), the aqueous layers separated from the $CHCl_3$ solution were put together, and the combined aqueous solution (850 ml) was exactly neutralized and concentrated into 50 ml by lyophilization. The concentrated aqueous solution was extracted continuously with EtOAc for 17 h by use of a liquid-liquid extractor. Triol **5** was isolated from the EtOAc extract by preparative TLC (0.5 mm thick) on silica gel with EtOAc–MeOH (97:3, v/v), and identified by direct comparisons of its TLC, IR and mass spectra with those of a synthetic sample. To confirm the complete extraction of the triol **5** from the aqueous solution, the residue (6.20 g) obtained from the residual aqueous solution by lyophilization was extracted with MeOH (50 ml×2), and then the sirup (3.75 g) obtained from the MeOH solution on evaporation was subjected to the analytical TLC. However, no spot of the triol (**5**) was observed.

The yields of the products were as shown in Table 1, and the physical constants and spectral data of the products were as follows.

c-*4*-p-*Menth-8(9)-ene*-r-*1,10-diol (3)*: Mp 75.0—76.2 °C (from hexane); IR (KBr) 3327 (OH) and 3100, 1652, and 901 cm^{-1} (>C=CH_2); IR (1.8×10^{-3} M, CCl_4) 3635 (primary OH), 3618 (tertiary OH); ^1H NMR ($CDCl_3$) δ=1.24 (3H, s, 7-CH_3), 4.12 (2H, bs, -CH_2OH), 4.92 and 5.01 (2H, each d, >C=CH_2); MS (70 eV), *m/z* (rel intensity) 155 (6), 152 (33), 137 (12), 134 (20), 119 (17), 109 (34), 94 (33), 84 (34), 71 (66), 55 (30), and 43 (100); High-resolution MS *m/z* 155.1042 (M^+-CH_3, $C_9H_{15}O_2$), 152.1185 (M^+-H_2O, $C_{10}H_6O$), and 134.1096 ($M^+-2\times H_2O$, $C_{10}H_{14}$).

The structure of **7** was further confirmed by its conversion to *c*-4-*p*-menth-8(9)-ene-*r*-1,10-diol (**3**) (mp 74.0—76.0 °C) on reduction with $LiAlH_4$ in dry ether. The diol (**3**) was identified by direct comparisons of the IR and ^1H NMR spectra with those of an authentic specimen.

r-*1-Acetoxy-4*-p-*menth-8(9)-en*-t-*4-ol (8)*: Mp 88.5—89.5 °C (from hexane) (lit,[6] 88—89 °C); IR (KBr) 3480 (OH), 1708 (OAc), 3100, 1642, and 905 cm^{-1} (>C=CH_2); ^1H NMR ($CDCl_3$) δ=1.49 (3H, s, 7-CH_3), 1.78 (3H, m, 10-CH_3), 1.99 (3H, s, OAc), 4.79 and 5.02 (2H, m, >C=CH_2); MS (70 eV), *m/z* (rel intensity) 171 (2), 152 (50), 137 (19), 124 (30), 123 (55), 119 (7), 111 (23), 109 (28), 97 (40), 84 (45), 69 (59), and 43 (100). The structure of **8** was further confirmed by its conversion to 4-*p*-menth-8(9)-ene-*r*-1,*t*-4-diol (**4**) (mp 135—139 °C; lit,[8] 140—141 °C) on reduction with $LiAlH_4$ in dry ether. Identification of **4** was performed by direct comparisons of its spectra (IR and ^1H NMR) with those of an authentic sample.

Time-courses in the Biotransformation of 1 and 2. The substrate (10 mg) was administered to each of five flasks containing 100 ml of the precultured suspension. The cultured mixtures were worked up at a regular time interval in the same manner as described above. The oily product (5—10 mg) obtained from the $CHCl_3$ extract was dissolved in 0.4 ml of ethyl acetate to subject to GLC. Components of the product were identified by co-TLC and co-GLC with authentic samples and then by GC-MS measurements. The yields of the products were determined on the basis of the peak areas on GLC, and expressed as relative percent to the whole products extracted, as shown in Fig. 1.

Preparation of the Authentic Samples. *Preparation of* ***7***, ***8***, *and* ***10***: Following the method described in the literature,[7] *r*-1-acetoxy-*c*-4-*p*-menth-8(9)-ene (**2**) (2.46 g) was oxidized with SeO_2 (0.75 g) dissolved in a mixture of *t*-BuOH (6.0 g) and benzene (8 ml) at 40—50 °C for 9 h under a nitrogen atmosphere. The reaction mixture was subjected to preparative TLC with hexane–EtOAc (7:3, v/v) to give *r*-1-acetoxy-*c*-4-*p*-menth-8(9)-en-10-ol (**7**) (0.11 g; n_D^{25} 1.4769), *r*-1-acetoxy-4-*p*-menth-8(9)-en-*t*-4-ol (**8**) (0.31 g; mp 88.5—89.5 °C), and *r*-1-acetoxy-4-*p*-menth-8(9)-en-*c*-4-ol (**10**) (0.25 g; n_D^{25} 1.4778).

Preparation of ***3*** *and* ***4***: *c*-4-*p*-Menth-8(9)-ene-*r*-1,10-diol (**3**) (22 mg; mp 75.0—76.0 °C) and 4-*p*-menth-8(9)-ene-*r*-1,*t*-4-diol (**4**) (31 mg; mp 139—140 °C) were obtained from **7** (30 mg) and **8** (45 mg) by reduction with $LiAlH_4$ in dry ether for 3 h at 0 °C, respectively.

Preparation of **6**: Following the procedure described in the literature,[9] β-terpinyl acetate (**2**) (0.196 g) was oxidized with osmium tetraoxide (0.275 g) in a mixture of ethyl ether (20 ml) and pyridine (0.4 ml) at room temp for 2 d to give brownish precipitates. The precipitates were filtered off and hydrolyzed with a sodium hydroxide solution (1%) in the presence of mannitol. *r*-1-Acetoxy-*c*-4-*p*-menthane-8,9-diol (**6**) (0.190 g, n_D^{25} 1.4736) was isolated from the reaction mixture by preparative TLC with hexane–EtOAc (3:7, v/v).

Preparation of ***5***: *c*-4-*p*-Menthane-*r*-1,8,9-triol (**5**) (48 mg) was obtained from **6** (68 mg) by reduction with $LiAlH_4$ in dry ether for 8 h at 0 °C: mp 118.0—118.5 °C (from EtOAc) (lit,[13] 118—118.5 °C); FT-IR (neat) 3355 (OH), 1453, 1380, 1168, 1048 (C–O), 900 cm^{-1}; ^1H NMR ($CDCl_3$) $\delta=1.10$ (3H, s, 10-CH_3), 1.16 (3H, s, 7-CH_3), and 3.36 (2H, d, $J=3.7$ Hz, -$C\underline{H}_2OH$); ^{13}C NMR ($CDCl_3$) $\delta_c=$ 74.9(s), 69.1(s), 68.3(t), 44.1(d), 38.8(t, 2×C), 31.4(q), 22.8(t), 21.8(t), and 20.7(q); MS (70 eV), *m/z* (rel intensity) 157 (1), 155 (1.5), 152 (1), 149 (2), 139 (39), 121 (3), 109 (3), 95 (19), 81 (17), 75 (9), 71 (19), 55 (10), and 43 (100).

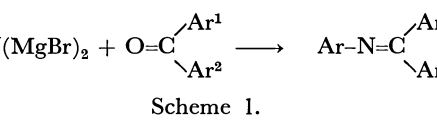
Aryliminodimagnesium Reagents. V. The Reaction with Bifunctional Nitroarenes

Masao Ōkubo,* Hiroyuki Aratani, Takayuki Gondō, and Kōji Koga
Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjō-machi, Saga 840

(Received September 1, 1982)

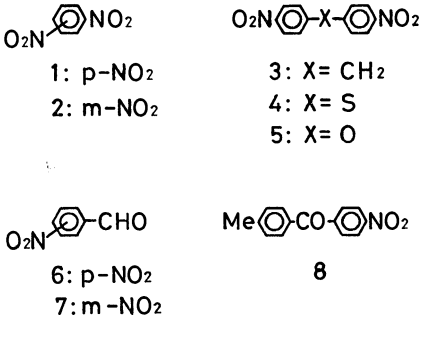
The reactions of *p*-methylphenyliminodimagnesium reagent (*p*-$MeC_6H_4N(MgBr)_2$) with *p*- and *m*-dinitrobenzenes, bis(*p*-nitrophenyl)methane, bis(*p*-nitrophenyl) sulfide and ether, *p*- and *m*-nitrobenzaldehydes as well as 4-nitro-4′-methylbenzophenone were investigated. *p*-Dinitrobenzene, which is the strongest electron-acceptor among the substrates used, gave *ca.* 30% combined yield of bis(azoxy) and azoxy azo products. The oxidative coupling product, 4,4′-dimethylazobenzene, was isolated in 20—30% yields. About 60% combined yield of the bis(azoxy) and azoxy azo products was obtained in the same reaction with *m*-dinitrobenzene, which is less electron-accepting than the *p*-isomer. In the reaction of bis(*p*-nitrophenyl)methane, bis(*p*-nitrophenyl) sulfide and ether with five molar amounts of the reagent, *ca.* 70% combined yields of bis(azoxy), azoxy azo, and bis(azo) products were obtained. On the treatment of the nitrobenzaldehydes and the nitrobenzophenone, in contrast, the reaction took place exclusively on the nitro group. The results are discussed in terms of the electron-accepting ability of substrates.

The aryliminodimagnesium reagents ($ArN(MgBr)_2$, aryl-IDMg) condense with diaryl ketones to give the anils (Scheme 1),[1,2] and also with nitroarenes to give azoxy- and azoarenes (Scheme 2).[3,4] On the basis of the previous results,[1–4] the IDMg reaction with an aromatic dinitro compound is expected to provide a new route for the one step preparation of the corresponding bis(azoxy) and bis(azo) compounds. The expectation was verified in the reaction of *p*-methylphenyl-IDMg with *p*- and *m*-dinitrobenzenes (**1** and **2**), bis(*p*-nitrophenyl)methane (**3**), bis(*p*-nitrophenyl) sulfide (**4**) and ether (**5**).



Scheme 1.

Scheme 2.

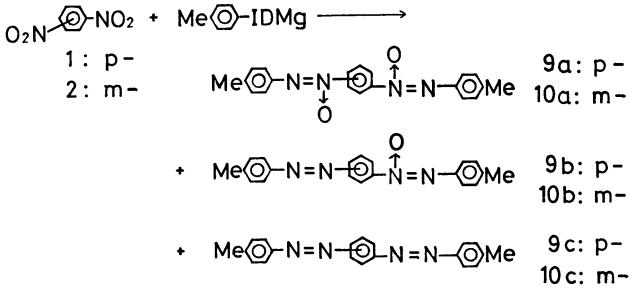


Similarly, the treatment of *p*- and *m*-nitrobenzaldehydes (**6** and **7**) as well as 4-nitro-4′-methylbenzophenone (**8**) with the same reagent is also expected to afford the corresponding azoxy azomethines and azo azomethines. Even by use of an excessive amount of the reagent, however, the reaction took place exclusively on the nitro group and not on the carbonyl group.

In this paper, the results of the IDMg reaction with the bifunctional nitro compounds, **1**—**8**, will be reported and explained in terms of their relative electron-accepting ability.

Results and Discussion

IDMg Reaction with p- *and* m-*Dinitrobenzenes.* In the reaction of *p*-dinitrobenzene, **1**, with five or six molar equivalents of *p*-methylphenyl-IDMg, the expected bis(azoxy) (**9a**), azoxy azo (**9b**), and bis(azo) (**9c**) products were obtained (Scheme 3 and Table 1).



Scheme 3.

The yields of the deoxygenative condensation products; **9a**, **9b**, and **9c**, are affected by the reaction conditions, especially by the temperature at which the addition is done (Expts 1—5). The yields were poor when the addition was carried out at 0 °C, and were improved by the addition at −78 °C. The formation of 4,4′-dimethylazobenzene is due to the oxidative coupling of the reagent molecules,[3] and that of an unidentifiable black material is due to the polymerization of the substrate initiated by one-electron reduction.[3] Their formation is reasonable, since the substrate **1** is highly electron-accepting.[5] The possible nitro azoxy product was not detected even by the treatment with the smaller excess of the reagent (Expt 2).

The reaction with *m*-dinitrobenzene, **2**, was carried out by adding its solution at −78 °C (Expts 6 and 7). The less electron-accepting **2**[5] gave the better combined yield of the bis(azoxy) (**10a**) and azoxy azo (**10b**) products, which were deoxygenated to afford **10b** and **10c**, respectively, by the treatment with

Table 1. Distribution of products in the reaction of p-MeC_6H_4-IDMg with p- and m-dinitrobenzenes

Expt No.	Substrate	[IDMg]/[Substrate]	Addition		Yields/%				
			Manner[a]	Temp °C	**9a**	**9b**	**9c**	(p-MeC_6H_4N=)$_2$	Recovered **1**

2	**1**	3	N[b]	0	−0	−0	−0	20	50
3	**1**	5	N	−78	20	13	0	17	10
4	**1**	6	R	0	0	6	18	23	16
5	**1**	6	R	−78	26	11	0	25	3
					10a	**10b**	**10c**		Recovered **2**
6	**2**	5	N	−78	43	15	0	18	—
7	**2**	10	N	−78	0	17	29	26	—

a) N and R designate "normal" and "reverse" additions respectively. b) The diluted THF solutions of the reagent and the substrate were used.

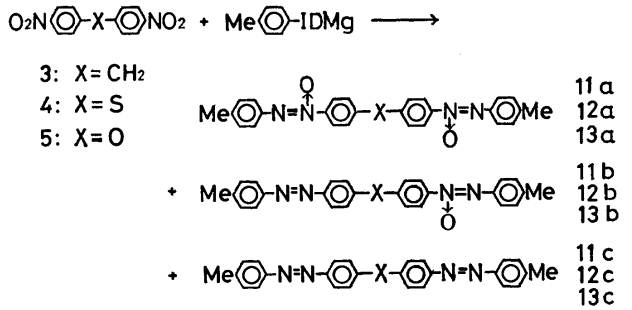
Table 2. Distribution of products in the reaction of p-MeC_6H_4-IDMg with bis-(p-nitrophenyl) compounds

Substrate	Yields/%[a]			
	Bis(azoxy)	Azoxy azo	Bis(azo)	(p-MeC_6H_4N=)$_2$
3($X=CH_2$)	26	31	9	25
4(X=S)	29	30	8	22
5(X=O)	27	32	10	29

a) Five molar equivalents of the reagent were used.

a larger excess of the reagent. The better yields of the condensation products in the reaction of **2** than those in the reaction of **1** suggests the importance of the combination of the electron-accepting and -donating abilities of the reactants.[6]

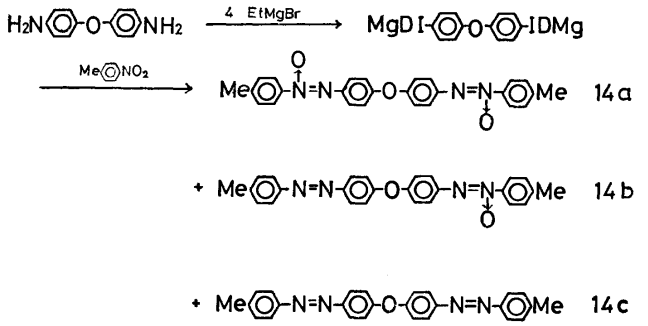
IDMg Reaction with Bis(p-nitrophenyl)methane, Bis(p-nitrophenyl) Sulfide and Ether. The bis(p-nitrophenyl) compounds, **3**, **4**, and **5**, the two nitro groups of which are located on the different phenyl groups, gave high combined yields of the corresponding bis(azoxy), azoxy azo, and bis(azo) products, **11a—c**, **12a—c**, and **13a—c** (Scheme 4 and Table 2).



Scheme 4.

The high combined yield of the products is ascribed to the moderate electron-accepting ability of **3**, **4**, and **5**. The electron-accepting effects of the individual nitro groups seem to be additive, but not synergic as in the case of **1**, since the formation of the unidentifiable black material is negligible and that of 4,4′-dimethylazobenzene *per* one nitro group is comparable to that obtained in the case of monofunctional nitroarenes.[3] The effect of the central atoms, C, S, and O, of the substrates on the distribution of the three types of the products is negligible.

The good result of the reaction of Scheme 4 forced the authors to examine the preparation and the reaction of bis(iminodimagnesium) reagents. An attempt to prepare the reagent from p-phenylenediamine by treating it with four molar equivalents of EtMgBr was unsuccessful: a voluminous white precipitate appeared and hardly any evolution of ethane[1] was observed. In contrast, bis(p-aminophenyl) ether gave the bis(iminodimagnesium) reagent. Its reaction with p-nitrotoluene(1.6 mol equiv., Scheme 5) gave the corresponding bis(azoxy) product (**14a**, 12%) and azoxy azo product (**14b**, 13%), which were isomeric with **13a** and **13b** respectively. A 22% of the substrate was recovered in this case.



Scheme 5.

IDMg Reaction with Nitrobenzaldehydes and a Nitrobenzophenone. It should be noted that the IDMg reaction with the substrates having nitro and carbonyl groups took place exclusively on the nitro group. The reaction of p-nitrobenzaldehyde, **6**, with five molar

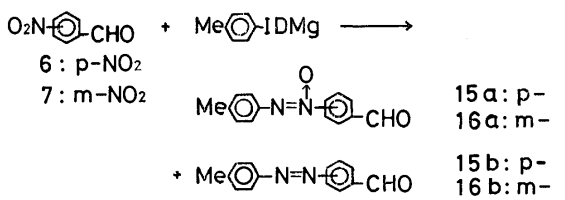
a) The azoxy and azo aldehydes, **15a**, **15b**, and **16b**, were identified by NMR; they were not purified. They were used for converting into the imino compounds.



Scheme 6.

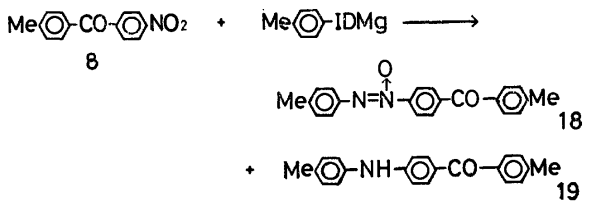
equivalents of *p*-methylphenyl-IDMg gave the corresponding azoxy and azo aldehydes, **15a** and **15b** (Scheme 6 and Table 3). Even by use of eight molar equivalents of the reagent, *m*-nitrobenzaldehyde, **7**, afforded solely an excellent yield of the azo aldehyde, **16b**. Neither azoxy azomethine nor azo azomethine were detected. In an attempt to convert the isolated **15b** into the corresponding azo azomethine by treating with the more electron-donating *p*-methoxyphenyl-IDMg, the substrate was recovered unchanged. The expected azo azomethine, **17**, was prepared quan-

17

titatively by the treatment of **15b** in refluxing dry benzene with *p*-methoxyaniline in the presence of *p*-toluenesulfonic acid.[7] For the purpose of converting an aromatic aldehyde into the aldimine, the IDMg method is not advisable:[2] *p*-chlorobenzaldehyde was converted into the aldimine in only a 32% yield by the treatment with 1.2 molar equivalents of *p*-methylphenyl-IDMg.

The inertness of the carbonyl functional group is consistent with the fact that the one-electron reduction of nitro-substituted benzophenones gives the ESR spectra assigned to the benzoyl-substituted nitrobenzene anion radicals.[9] The higher oxidizing ability of nitroarenes compared with that of diaryl ketones[10] also supports the present result.

4-Nitro-4′-methylbenzophenone, **8**, also gave products which originated from the reactions exclusively on the nitro group by the treatment with five molar equivalents of *p*-methylphenyl-IDMg (Scheme 7). The normal condensation product, **18**, and the replacement product, **19**, were obtained in 38% and



Scheme 7.

28% yields, respectively; the oxidative coupling product, 4,4′-dimethylazobenzene, was also isolated in 21% yield. The formation of **19** is reasonable, since the nitro group is responsible for the replacement in the reaction of 4-nitroquinoline *N*-oxide and related compounds with alkali alkoxides and alkanethiolates.[11] The present result, however, may be the first example for the replacement of nitro group in organomagnesium reactions.

All the results obtained in the reactions of Schemes 1—7 are preliminary ones, but they show the important role of the electron-accepting ability of the substrates.

Experimental

The melting points are uncorrected.

The bifunctional nitro compounds **1**—**7** were obtained commercially. The nitrobenzophenone, **8**, was prepared by p-nitrobenzoylation of toluene by the Friedel-Crafts method.

The procedures for the reactions and for the isolation of products were reported previously.[1-4]

The melting points, the results of elemental analyses, and the NMR data of the products **9**—**19** are summarized in Table 4. Among the NMR data, several aromatic proton signals consisting of two or three AB quartets are not assigned and the δ values are given in parentheses.

The support of this work by research grants from the Ministery of Education, Science and Culture (C-56540307) is gratefully acknowledged.

The Ion-exchange Chromatography of Imino Derivatives of Glycine

Katsuhiro KAWASHIRO,* Shiro MORIMOTO, and Hideyuki YOSHIDA

Department of Chemical Engineering, Faculty of Engineering, Tokushima University, Minamijosanjima, Tokushima 770

(Received April 15, 1982)

The resolution of the six imino derivatives of glycine (Gly) by ion-exchange chromatography is described. The imino compounds included iminodiacetonitrile (**1**), iminodiacetamide (**2**), iminodiacetic acid (**3**), α-(cyanomethylamino)acetamide (**4**), α-(cyanomethylamino)acetic acid (**5**), and α-(carbamoylmethylamino)acetic acid (**6**). A mixture of **1**—**6** was chromatographed along with Gly, glycinamide, aminoacetonitrile, and NH_3 with an automatic amino acid analyzer using Aminex A-4 resin column (0.25ϕ × 50 cm) and sodium citrate buffers. When the initial buffer of pH 3.25 was changed to pH 6.50 15 min after beginning the analysis, these ten components were completely resolved. The analysis was completed in about 4.5 h. The stability of **1**, **4**, and **5** in aqueous media at room temperature was also studied.

In connection with chemical evolution, Ponnamperuma and Woeller[1] demonstrated that aminoacetonitrile (AAN) could be formed by an electric discharge through an anhydrous mixture of methane and ammonia (a simulated Jovian atmosphere) which was considered to resemble the primitive atmosphere of the Earth. Consequently, the role of AAN in aqueous media, as a precursor to polypeptides and amino acids, became of primary importance.[2-4] Chadha *et al.*[3] studied the reaction of AAN in aqueous solutions of pH 9. When the reaction products were examined by ion-exchange chromatography, peptides such as diglycine were not detected. After the reaction products were hydrolyzed and derivatized for gas chromatography, they identified glycine (Gly), iminodiacetic acid (**3**), and a small amount of nitrilotriacetic acid by gas chromatography-mass spectrometry. Recently, we investigated the reaction of AAN in aqueous ammoniacal solutions. When the reaction mixtures were examined by ion-exchange chromatography, a number of ninhydrin reactive products were eluted along with Gly and glycinamide (Gly-NH_2). On the basis of the results obtained by Chadha *et al.*[3,4] these products were considered to be imino derivatives of Gly, as shown in Fig. 1. Therefore, the resolution of these imino compounds by ion-exchange chromatography was necessary for identification and determination of the reaction products of AAN.

6: $R_1=CONH_2$, $R_2=COOH$

Fig. 1. Imino derivatives of Gly.

Since an automatic amino acid analyzer based on ion-exchange chromatography was first devised by Spackman *et al.*[5] in 1958, not only the resolution of amino acids and related compounds but also analysis time has been much improved by many investigators. However, substances analyzed by this method have been limited to those of biological origin such as hydrolyzates of proteins, physiological fluids, and tissue extracts.[6] This paper deals with the resolution of **1**—**6** by ion-exchange chromatography.

Results and Discussion

Ion-exchange Chromatography. The six imino compounds, that is, iminodiacetonitrile (**1**), iminodiacetamide (**2**), **3**, α-(cyanomethylamino)acetamide (**4**), α-(cyanomethylamino)acetic acid (**5**), and α-(carbamoylmethylamino)acetic acid hydrobromide (**6**·HBr) were prepared in the present study as the authentic samples for ion-exchange chromatography. The latter three (**4**, **5**, and **6**·HBr) are new compounds.

Because AAN was considered to give not only the imino compounds (**1**—**6**) but also hydrolysis products such as Gly, Gly-NH_2, and NH_3 in aqueous media, the resolution of a synthetic mixture of these ten compounds with an amino acid analyzer was examined.

Figure 2 illustrates the resolution of them with a pH 3.25—6.50 sodium citrate buffer system. All the ten components were completely resolved from each other and the analysis time was about 4.5 h. A column of 0.25ϕ × 50 cm packed with a Bio-Rad spherical resin, Aminex A-4 (8% crosslinkage; particle size 20± 4 μm) was found to be adequate for the present analysis. Among the basic components, **4** was always eluted at the break-through point of the second buffer. The buffer change time of 15 min was found to be optimum; the elutions with a buffer change time longer than 15 min or shorter than 15 min, resulted in merely a

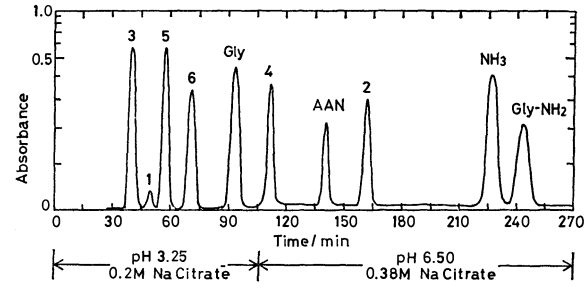

Fig. 2. Ion-exchange chromatogram of a mixture of imino derivatives of Gly (**1**—**6**) and related compounds. Conditions of chromatography are described in the Experimental Section. Charge amount of each component, 0.1 μmol. Elution was started using a pH 3.25 citrate buffer. A buffer change was made after 15 min to pH 6.50, and the break-through of the pH 6.50 buffer was observed at 108 min.

longer analysis time or the poor resolution of Gly and **4**, respectively.

As shown in Fig. 2, the components were eluted in a regular manner. Namely, compounds with the same *N*-substituent group (X) were eluted in the order of X–NH–CH_2–COOH (carboxylic acid), X–NH–CH_2–CN (nitrile), and X–NH–CH_2–$CONH_2$ (amide). For example, the compounds having carboxymethyl as an *N*-substituent group (X=CH_2–COOH) were eluted in the order of **3**, **5**, and **6**. The only exception is the case of the compounds (X=CH_2–CN), which were eluted in the order of **1** (nitrile), **5** (carboxylic acid), and **4** (amide). This reversed elution order of **1** and **5** could be explained in terms of the increased acidity of **1** due to a strong electron-attracting effect of the two cyano groups.

Figure 3 shows the elution behavior of the basic components with a pH 3.25—6.50 or a pH 3.25—5.28 citrate buffer system. Elution with a pH 3.25 buffer alone (D) resulted in a significantly longer analysis time, with the complete overlap of AAN and Gly–NH_2. The basic components, except for AAN and **2**, were eluted at almost constant positions regardless of the pH of a second buffer, so long as the buffer

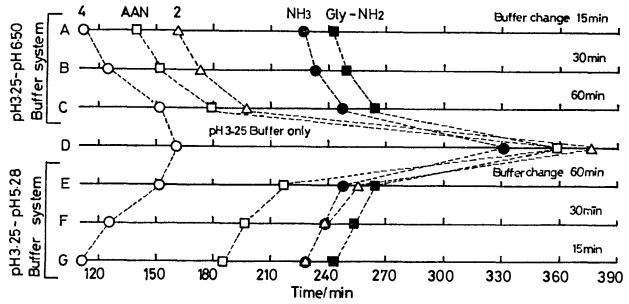

Fig. 3. Elution behavior of the basic components with various buffer systems.
Conditions of chromatography are described in the Experimental Section.

Table 1. Elution times and relative color constants of imino derivatives of Gly and related compounds[a)]

Compound	Elution time/min	Relative color constant[b)]
3	41	1.07
1	50	0.064
5	57	1.11
6	71	0.65
Gly	94	1.00
4	112	0.79
AAN	140	0.39
2	162	0.65
NH_3	227	1.23
Gly–NH_2	243	0.72

a) Conditions of chromatography are described in the Experimental Section. Elution was started using a pH 3.25 citrate buffer. A buffer change was made after 15 min to pH 6.50. b) The color constant refers to peak area per μmol of a compound. The peak area was calculated according to the conventional $H \times W$ method (Ref. 5). The color constant of Gly was 93.7 μmol^{-1}.

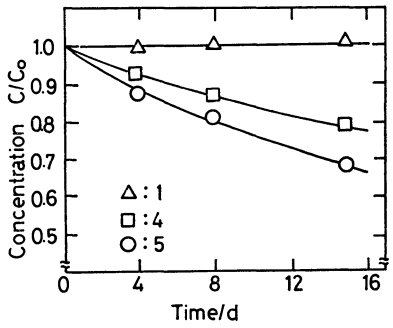

Fig. 4. Decomposition of α-amino nitriles (**1**, **4**, and **5**) in aqueous media (1 mM) at room temperature.

change time was unchanged. The elution times of AAN and **2** were very sensitive to the pH of a second buffer. Their elution was retarded remarkably with the pH 5.28 buffer, resulting in the poor resolution of NH_3, **2**, and Gly–NH_2 (E) or the complete overlap of NH_3 and **2** (F and G), in comparison with the elution with the pH 6.50 buffer. In this way, the basic components could be successfully resolved from each other by the use of the pH 3.25—6.50 buffer system.

Table 1 shows the elution times and the relative color constants of the ten components. It was evident that the color constant of **1** with ninhydrin was extremely poor compared with the other imino compounds, although the time of heating in the reaction bath of the amino acid analyzer was designed to be about 30 min.

Stability of the Imino Compounds in Aqueous Media. Among the imino compounds, α-amino nitriles such as **1**, **4**, and **5** were thought to be unstable in aqueous media due to the reverse Strecker reaction. Figure 4 shows the rate of decomposition of them in aqueous solutions (1 mM) (1 M=1 mol dm^{-3}) at room temperature. **4** and **5** were unstable and decomposed to 20.2 and 31.5%, respectively, in 15 d. Since **4** and **5** yielded Gly–NH_2 and Gly as the decomposition products, respectively, the unstability could be explained in terms of the reverse Strecker reaction as follows:

$$HN\begin{matrix}\diagup CH_2\text{–}CN \\ \diagdown CH_2\text{–}Y\end{matrix} + H_2O \longrightarrow H_2N\text{–}CH_2\text{–}Y + CH_2O + HCN$$

(Y=$CONH_2$ or COOH)

Unlike **4** and **5**, **1** was stable under these conditions. Hence, in the case of such unstable compounds, it is desirable to calibrate an amino acid analyzer with freshly prepared standard solutions.

Experimental

All the melting points were determined with a Yanagimoto micro melting point apparatus and were not corrected. IR spectra were taken with a Hitachi Model 285 Infrared spectrophotometer. ^{1}H-NMR spectra were measured with a Hitachi R-24B spectrometer using TMS as an internal reference. Thin layer chromatography was carried out on silica gel 60 F_{254}(Merck) using the following solvent system: *n*-BuOH–AcOH–H_2O (4:1:1, v/v). *S*-(*p*-methoxybenzyloxycarbonyl)-4,6-dimethyl-2-pyrimidinethiol(Z(OMe)–SDP) and

25% HBr–AcOH were obtained from Protein Research Foundation.

Ion-exchange Chromatography. Ion-exchange chromatography was carried out with a Sibata amino acid analyzer AA-600 under the following conditions: column, 0.25ϕ × 50 cm packed with Aminex A-4(Bio-Rad, 8%-crosslinked, sulfonic acid type cation exchange resin, particle size 20± 4 μm); flow rate of an eluent, 6 ml/h; flow rate of a ninhydrin solution,[5] 3 ml/h; jacket temperature, 30 °C; chart speed, 120 mm/h. Absorbance at 570 nm was measured by continuous photometry. Sodium citrate buffers of pH 3.25 (0.2 M Na), pH 5.28(0.35 M Na), and pH 6.50(0.38 M Na) were used as eluents. The former two buffers were obtained from Wako Pure Chemical Industries, Ltd. The pH 6.50 buffer was prepared according to the method of Moore *et al.*[7] using caprylic acid instead of phenol. Elution was started with the pH 3.25 buffer and the initial buffer was changed to a second buffer(pH 5.28 or 6.50) at an appropriate later time. A calibrated equimolar(0.1 μmol) mixture of the imino compounds(**1**—**5**, and **6**·HBr), Gly, Gly–NH_2·HBr, AAN·1/2 H_2SO_4, and NH_4·1/2 SO_4 was applied on the column of the amino acid analyzer.

Aminoacetonitrile Neutral Sulfate(AAN·1/2 H_2SO_4). Concd H_2SO_4(25.5 g, 0.25 mol) was gradually added to ethanol (EtOH) (125 ml). The temperature of the solution rose, but it was adjusted to 65—70 °C. Methyleneaminoacetonitrile (MAAN)[8] (34 g, 0.5 mol) was added gradually to it. In the beginning, MAAN dissolved, but after a certain point it ceased to dissolve. The mixture was warmed for 1 h(60 °C) on a water bath, and then kept in a refrigerator overnight. The precipitates were dissolved in H_2O(100 ml) and the undissolved material(MAAN) was removed by filtration. The product was precipitated by the addition of EtOH(600 ml) to the filtrate and then recrystallized from H_2O–EtOH; yield, 20 g(38%); mp, 160 °C(decomp)(lit,[9] mp, 165 °C); R_f, 0.27. Found: C, 23.03; H, 4.72; N, 26.76%. Calcd for $C_2H_5N_2O_2S_{0.5}$: C, 22.85; H, 4.79; N, 26.68%.

*Iminodiacetonitrile (**1**).* A solution of freshly distilled HCN(70 ml, 1.81 mol) and concd H_2SO_4(1 ml) in methanol (MeOH) (175 ml), was added to a suspension of MAAN (119 g, 1.75 mol) in MeOH (70 ml). The resulting suspension was warmed for 3 h(60 °C), and then refluxed at 75 °C for a further 30 min on a water bath, in a draft chamber. After the reaction mixture had been cooled to room temperature, the precipitates(MAAN) were removed by filtration. When the filtrate was cooled to 0 °C, **1** precipitated; this was processed with charcoal and then recrystallized from EtOH; yield, 85.7 g(52%); mp, 76—77 °C(lit,[10] 75 °C); R_f, 0.62.

*Iminodiacetamide (**2**).* A solution of dimethyl iminodiacetate hydrochloride(1.97 g, 10 mmol) in MeOH(15 ml) was treated with triethylamine (Et_3N) (1.4 ml, 10 mmol) at 0 °C. When diethyl ether(Et_2O) (60 ml) was added to the resulting solution, Et_3N·HCl precipitated and was removed by filtration. The filtrate was evaporated to give an oil (dimethyl iminodiacetate). Ammonolysis of the crude oil according to the method of Jongkees[11] gave **2**, which was recrystallized from MeOH: yield, 0.85 g(65%); mp, 141—143 °C(lit,[11] 143 °C); R_f, 0.17.

*Iminodiacetic Acid (**3**).* A solution of Gly(18.8 g, 0.25 mol) and chloroacetic acid(23.6 g, 0.25 mol) in 3 M LiOH (250 ml) was allowed to stand at room temperature for 6 d. When the solution was acidified with 6 M HCl(60 ml) under cooling, crystals precipitated; these were collected by filtration. The crystals(yield, 12.5 g; mp, 152—154 °C) were identified to be nitrilotriacetic acid by elementary analysis(Found: C, 37.53; H, 4.72; N, 7.47%. Calcd for $C_6H_9NO_6$: C, 37.70; H, 4.75; N, 7.33%. Lit,[12] mp, 142 °C). The filtrate was concentrated to give a syrup, which was dissolved in a minimum amount of H_2O. The half volume of the solution was applied on a column(Amberlite CG-120, acid form, 2ϕ × 90 cm), and then eluted with H_2O. The fractions containing **3** were collected and evaporated to give **3**. The remaining solution was also treated similarly. Recrystallization was performed from H_2O–EtOH; yield, 12.8 g(39%); mp, 225—228 °C(lit,[13] 225 °C); R_f, 0.09.

*α-(Cyanomethylamino)acetamide (**4**).* A mixture of Gly–NH_2·HBr(5.27 g, 34 mmol) and formalin(2.7 ml, 34 mmol) was cooled below 0 °C on an ice salt bath, and then a solution of NaCN(1.64 g, 34 mmol) in a minimum amount of H_2O was added dropwise with stirring. After the addition was completed, the stirring was continued for 3 h. The reaction mixture was extracted with ethyl acetate(AcOEt) (40 ml × 7), and the extract was dried (Na_2SO_4), filtered, and then evaporated to give **4**, which was recrystallized from AcOEt–Et_2O; yield, 0.90 g(27%); mp, 124—126 °C; R_f, 0.41: IR (KBr), 3380(NH), 2225(C≡N), and 1650 cm^{-1} (amide I); NMR(DMSO-d_6), δ=7.24, 7.05(2H, br, $CONH_2$), 3.63(2H, s, CH_2), 3.14(2H, s, CH_2), and 2.81(1H, br, NH). Found: C, 42.25; H, 6.07: N, 37.18%. Calcd for $C_4H_7N_3O$: C, 42.47; H, 6.24; N, 37.14%.

*Ethyl α-(Cyanomethylamino)acetate (**7**).*[14] A mixture of glycine ethyl ester hydrochloride(41.9 g, 0.3 mol) and formalin(25 ml, 0.3 mol) was cooled below 0 °C, and a solution of NaCN(14.7 g, 0.3 mol) in H_2O(30 ml) was added dropwise with stirring. After the addition was completed, the stirring was continued for 4 h. The reaction mixture was extracted with Et_2O(30 ml × 2), and the ethereal extract was dried (Na_2SO_4), filtered, and then evaporated to give a pale yellowish oil; yield, 32 g(75%); R_f, 0.49; NMR($CDCl_3$), δ= 4.20(2H, q, J=7 Hz, $C\underline{H}_2CH_3$), 3.59(2H, s, CH_2), 3.49 (2H, s, CH_2), 2.31(1H, s, NH), and 1.27(3H, t, J=7 Hz, $CH_2C\underline{H}_3$); ion-exchange chromatography (a pH 3.25—5.28 buffer system with the buffer change of 30 min), elution time 137 min.

*N-(p-Methoxybenzyloxycarbonyl)-α-(cyanomethylamino) acetic Acid Dicyclohexylammonium Salt (**8**·DCHA).* A mixture of **7** (7.10 g, 50 mmol), Z(OMe)–SDP(9.13 g, 30 mmol), and Et_3N(7 ml, 50 mmol) in $CHCl_3$ (50 ml) was stirred for 24 h at room temperature. The reaction mixture was washed with H_2O(25 ml × 5) and the $CHCl_3$ layer was dried(Na_2SO_4), filtered, and then evaporated to give a brown oil. The oily ethyl *N*-(*p*-methoxybenzyloxycarbonyl)-α-(cyanomethylamino)acetate was taken up in acetone(20 ml) and saponified as follows. 1 M NaOH(30 ml) was added to it and the resulting solution was stirred at room temperature for 2 h. After being acidified to pH 3 with 1 M HCl, the solution was extracted with AcOEt(50 ml × 5). The extract was washed with H_2O(50 ml × 3), dried(Na_2SO_4), filtered, and then evaporated to give a brown oil. The oil was dissolved in AcOEt(20 ml) and treated with DCHA(5 ml). When the solution was kept in a deep freezer overnight, **8**·DCHA precipitated and was recrystallized from $CHCl_3$–Et_2O; yield, 2.3 g(17%); mp, 152—154 °C; R_f, 0.61; IR (KBr), 2750—2400(NH_2^+), 2230(C≡N), and 1630 cm^{-1} (COO^-); NMR($CDCl_3$), δ=8.53(2H, br, NH_2^+), 7.45—6.70(4H, m, aromatic), 5.06(2H, s, CH_2O), 4.38(2H, s, CH_2), 3.90(2H, s, CH_2), 3.78(3H, s, OCH_3), and 2.90, 1.87—1.20(22H, m, cyclohexyl). Found: C, 65.12; H, 8.30; N, 8.86%. Calcd for $C_{25}H_{37}N_3O_5$: C, 65.34; H, 8.11; N, 9.14%.

*α-(Cyanomethylamino)acetic Acid (**5**).* To a suspension

of **8**·DCHA(1.0 g, 2.2 mmol) in AcOEt(50 ml) was added 0.2 M H_2SO_4 dropwise with shaking until the solution became free of suspended material. The AcOEt layer was washed with H_2O(20 ml×3), dried (Na_2SO_4), filtered, and then evaporated to give a pale brown oil. When the oil was dissolved in trifluoroacetic acid(3 ml) at 0 °C, the solution turned red. After 5 min, anisole(1 ml) was added to the solution; the mixture became colorless on standing at room temperature for 30 min. Et_2O(20 ml) was added and the precipitates were dissolved in H_2O(20 ml). After the undissolved materials had been removed by filtration, the filtrate was concentrated to a small volume. On the addition of EtOH and a large amount of Et_2O, free **5** precipitated; yield, 80 mg(32%); mp, 142—144 °C; R_f, 0.21: IR(KBr), 2750—2500(NH_2^+), 2250(C≡N, weak), and 1580 cm^{-1} (COO^-); NMR(DMSO-d_6), δ=6.48(2H, br, NH_2^+), 3.65 (2H, s, CH_2), and 3.31(2H, s, CH_2). Found: C, 41.95; H, 5.34; N, 24.91%. Calcd for $C_4H_6N_2O_2$: C, 42.11; H, 5.30; N, 24.55%.

*α-(Carbamoylmethylamino)acetic Acid Hydrobromide (**6**·HBr).* **8** prepared by decomposition of its DCHA salt(1.0 g, 2.2 mmol), was treated with anhydrous 25% HBr–AcOH(1.5 ml) at room temperature to give a clear solution with the evolution of CO_2. After 30 min, crystals were precipitated by the addition of Et_2O(30 ml); these were dissolved in H_2O (5 ml). After filtration, the solution was concentrated to a small volume and EtOH(10 ml) was added. When the solution was kept in a deep freezer, **6**·HBr precipitated and was recrystallized from H_2O–EtOH; yield, 180 mg (38%); mp, 211—213 °C; R_f, 0.42; IR(KBr), 2750—2600 (NH_2^+), 1740(COOH), and 1680 cm^{-1}(amide I); NMR (DMSO-d_6), δ=8.90(2H, br, NH_2^+), 7.90, 7.54(2H, br, $CONH_2$), 3.91(2H, s, CH_2), and 3.77(2H, s, CH_2). Found: C, 22.82; H, 4.39; N, 13.20%. Calcd for $C_4H_9N_2O_3Br$: C, 22.55; H, 4.26; N, 13.15%.

Decomposition of the Imino Compounds. An aqueous solution of each imino compound(1 mM) was prepared and allowed to stand at room temperature. An aliquot(0.1 ml) of the solution was analyzed with the amino acid analyzer at appropriate intervals. Decomposition products were identified by comparing their elution times with those of the authentic samples. **4** and **5** yielded Gly–NH_2(19.3%) and Gly(26.5%), respectively, on decomposition with H_2O in 15 d. The other imino compounds were found to be stable under these conditions.

(Received September 17, 1982)

Anion-catalyzed phase-transfer catalysis was evidenced in the diazo-coupling reactions of the arenediazonium ion with a range of diazophile components in liquid-liquid- and liquid-solid two-phase systems. The tetrakis[3,5-bis(trifluoromethyl)phenyl]borate ion was effective as an anionic catalyst to accelerate the reactions. Comparisons of the reaction rates in the two-phase system with those in solution systems indicated that the acceleration was due to the increased activity of the cationic reagent, partly by solubilization and partly by the dehydration of such cationic species in the nonpolar organic phase.

A great number of studies of phase-transfer catalysis (PTC) have appeared in the literature during the last decade.[1] All but a few applications thus far reported have been nucleophilic or base-mediated reactions catalyzed by an oleophilic organic cation, such as the tetraalkylammonium ion or the crown ether–metal complex. An electrophilic reaction may also proceed in a PTC manner if an appropriate anionic catalyst is provided. A few examples of this class have been verified in some reactions of the arenediazonium ion,[2] though such attempts at verification have not always been successful. This seems to have been due to the lack of an efficient anionic catalyst suitable for this purpose. In fact, very few stable organic anions have been known except for the conjugate bases of organic acids. Among them we directed our attention to the tetraphenylborate (TPB) anion as a possible anionic phase-transfer catalyst. The structural features of TPB were considered to be that the negative charge was formally localized on the central boron atom and that the hydrophilic-anion center was shielded by lipophilic phenyl ligands configured in a tetrahedrally symmetrical array.[3] Various types of homolog and their salts are conveniently discussed in the literature.

In the anion-catalyzed PTC process, the reactions were generally acid-mediated, and the leaving group upon the reaction was a proton or protonated species. In this respect, the catalyst anion had to be stable enough in an acid medium. Also, the reaction should be conducted in a nonpolar organic solvent immiscible with water in a manner like that formerly used in the traditional PTC process.

The TPB anion was, however, highly susceptible to proton-catalyzed decomposition,[4] and its solubility in nonpolar organic solvents was not always satisfactory for a phase-transfer catalyst.[5] Therefore, our efforts were focussed on improving the drawback of chemical instability[6] and, at the same time, attaining a higher solubility into the organic media by virtue of introducing a trifluoromethyl group on the phenyl rings of TPB.[7]

During the course of our studies aimed to producing the present tetrakis[3,5-bis(trifluoromethyl)phenyl]borate (TFPB) anion,[8] an application of the PTC process was reported in the acid-mediated hydrolysis of esters by the use of an ordianry TPB anion as a phase-transfer catalyst,[9] though it was shortly thereafter revealed to be false;[10] TPB is not long-lasting in such acid media.

The present paper will describe phase-transfer catalyzed diazo-coupling reactions, in which a typical onium ion acts as an electrophile, by the use of TFPB as a catalyst in two-phase systems consisting of a non-donating, inert organic phase and a solid or an aqueous one.[11] It should be noted that the present catalyst was contrived to be more oleophilic and especially durable in acid media than the parent TPB anion; sodium TFPB remained intact for more than 9 h in a vigorously stirred two-phase system of dichloromethane and 4 mol dm^{-3} sulfuric acid, and the second-order rate constants of the acid-catalyzed hydrolysis of TFPB and TPB salts in aqueous ethanol were 1.3×10^{-4} and 1.6×10^{-3} mol^{-1} dm^3 s^{-1} at 25 °C respectively. Under the present experimental conditions, therefore, the great majority of TFPB anions remain in the organic phase, and one can neglect the acid-catalyzed decomposition of TFPB by the proton which is liberated on the electrophilic aromatic substitution.

Results and Discussion

Diazo-coupling in a Liquid-solid PTC System. The dissolution of benzenediazonium tetrafluoroborate (**1**) into a benzene solution was followed by monitoring the absorbance of **1** at 300 nm. The absorbance of a supernatant containing sodium TFPB increased with the lapse of time and attained saturation within 1 h, while the dissolution rate varied with the fineness of the powdered **1**. Without the addition of sodium TFPB, we observed no indication of **1** being dissolved in the solvent; the absorbance was kept at nothing.

The suspension of the powdered **1** in a benzene solution of twice the molar amount of *N*,*N*-dimethylaniline (**2**) gave no color change, even upon vigorous agitation. The addition of a 20% molar amount of sodium TFPB to the suspension with moderate stirring at room temperature caused a rapid red-color development, where the added sodium TFPB was dissolved in the solution.[12] A 1-h reaction then afforded the coupling

** Present address: The Central Research Institute, Mitsui-Toatsu Chemical Co., Ltd., Kasama, Tozuka-ku, Yokohama 247.

product, 4-dimethylaminoazobenzene (**3**), in an 86% yield. In a similar manner, twice the molar amount of phenol (**4**) gave 4-hydroxyazobenzene (**5**) in a quantitative yield after a 3-h reaction in the presence of twice the molar amount of 2,6-dimethylpyridine (**6**). No diazo-coupling with phenol in the organic phase proceeded without the addition of a base such as **6**.[13]

The acceleration of the diazo-coupling rate can be attributed predominantly to the dissolution of the arenediazonium ion into the solvent by ion-pairing with the TFPB anion. The coupling reactions in the absence of the TFPB anion were negligible, though possibly taking place on the surface of the solid diazonium salt (**1**).

Diazo-coupling in a Liquid-liquid PTC System. In a two-phase system consisting of an aqueous 4-nitrobenzenediazonium tetrafluoroborate (**7**) and a dichloromethane solution of an equimolar amount of 9-ethylcarbazole (**8**), the vigorous agitation of the two-phase mixture resulted in a faint red coloration after a while, but no more color was developed by further, prolonged agitation. The addition of one-fifteenth the molar amount of sodium TFPB to the mixture immediately turned it dark red. The two-phase system formed no emulsion and was separated into two layers as soon as agitation stopped. After 3 h of continuous, vigorous stirring, the diazonium test by *N,N*-dimethylaniline was negative to the aqueous phase, and then the coupling product was isolated in an 80% yield. In a similar manner, the reactions of **7** with two kinds of diphenylamines, **9** and **10**, and three kinds of anisole derivatives, **11**, **12**, and **13**, gave the corresponding coupling products. The results are summarized in Table 1. A comparison of the latter three examples seemed to suggest a rather large substituent effect of diazophile components upon the reaction rate and yield. It is worthwhile noting that the coupling of **7** with **8** was found to afford the coupling product in a yield of less than a 2% after a 5-h reaction when the reaction was carried out in aqueous acetic acid.[14] From the comparisons of the yield and the reaction period, one can readily notice the efficiency of the present PTC system.

Diazotization and diazo-coupling could be conducted successively in one pot without any isolation of diazonium salt. The process was exemplified by PTC, consisting of a dichloromethane solution of **8** and an aqueous solution of 4-nitrobenzenediazonium salt, in the presence of a 1% molar amount of sodium TFPB. The conversion attained up to 94%, based upon the amount of sodium nitrite added after the 5-h reaction at room temperature. This procedure can provide a convenient method of diazo-coupling in general; it might be especially useful in reactions with the diazonium salts, which are too labile to be isolated.

Table 1. Phase-transfer catalyzed diazo-coupling in an aqueous-CH_2Cl_2 two-phase system[a]

Diazophile	Reaction time h	Yield[b] %
9-Ethylcarbazole (**8**)	3	80
Diphenylamine (**9**)	2	76
N-Methyldiphenylamine (**10**)	3	85
Anisole (**11**)	48	10[c,d]
m-Methylanisole (**12**)	12	50[d]
m-Methoxyanisole (**13**)	2	85[e]

a) The reaction was carried out at room temperature. b) Yield of the isolated product. c) A 10-fold molar excess of the diazophile was added. d) The aqueous phase was buffered at pH 7. e) The aqueous phase was not buffered, and the aqueous phase was found to be acid after the reaction.

Diazo-coupling in Homogeneous Phases. Kinetics and Mechanism. In connection with the diazo-coupling in liquid-liquid two-phase systems, the reaction rates were examined in homogeneous solution phases of aqueous and non-donating inert organic solvents separately. A solution of arenediazonium TFPB in such an organic solvent was prepared by ion exchange between the corresponding arenediazonium tetrafluoroborate in the solid state and sodium TFPB dissolved in the organic solvent to be examined. The kinetics of the diazo-coupling reaction of *N,N*-dimethylaniline (**2**) with benzenediazonium salt was followed under the pseudo-first-order conditions in the latter. A general expression of the reaction rate was given by Eq. 1, with the assumption that no exchange of the diazonium ion occurred between the ion pair of BF_4^- and that of $TFPB^-$ in the solution phase;

$$d[\text{Product}]_t/dt = k_1'[ArN_2^+ \cdot TFPB^-] + k_1''[ArN_2^+ \cdot BF_4^-], \quad (1)$$

where k_1' and k_1'' were the conditional rate constants concerning the respective diazonium salts. The ratio of $[ArN_2^+ \cdot BF_4^-]_{t=0}/[ArN_2^+ \cdot TFPB^-]_{t=0}$ in chloroform, for example, was estimated, from the ratio of $[\text{Product}]_{t=\infty}$ in the absence of the TFPB anion to that in the presence of the same anion, to be about 5%.

In the absence of TFPB salt, the first term was zero, irrespective of the reaction medium; then, assuming $[\text{Product}]_{t=0}=0$, we obtained:

$$\ln([\text{Product}]_{t=\infty}) - \ln([\text{Product}]_{t=\infty} - [\text{Product}]_t) = k_1''t. \quad (2)$$

Excellent pseudo-first-order kinetic plots were obtained according to Eq. 2 with a correlation coefficient (γ) greater than 0.99 in each system of the tetrafluoroborate with **2** as well as **4**.

An examination of the rate constants indicated that the reactions in dry organic solvents were second-order in **2**, while in aqueous buffers it was first-order also in **2**. These kinetic orders, in accordance with Bartsch's observation,[15] indicate that, in the dry organic phase, the reaction rate is determined by the stage of deprotonation from a σ-complex, and that the reaction requires an equimolar amount of the proton-accepting base, as is observed in the diazo-coupling of phenol in a solid-liquid PTC system. In the aqueous phase, the formation of the σ-complex would be the rate-determining step, and the subsequent deprotonation would proceed rapidly, promoted by a large excess of the water base. When the reaction was conducted in a wet chloroform which had been saturated in advance with an aqueous buffer such as would occur in an actual liquid-liquid PTC

Table 2. Rate constants of the diazo-coupling of *N,N*-dimethylaniline with benzenediazonium tetrafluoroborate (**1**) and -TFPB (**11**) in aqueous and organic solvents at 25 °C

Solvent	Third-order rate constant, k_3/mol^{-2} dm^6 s^{-1}		Second-order rate constant, k_2/mol^{-1} dm^3 s^{-1}
	1	**11**	**1**
Benzene	c)	7.1×10^4	—
Chloroform			
anhydrous	2.9×10^4	4.6×10^5	—
wet[a]	1.02×10^3	—	1.6
Aqueous buffer[b]	—	—	1.7×10^{-1}

a) Saturated with the aqueous buffer at 25 °C (*ca.* 6×10^{-2} mol dm^{-3} of water). b) pH 7.02. c) Not measurable due to the low solubility of **1**.

system, the kinetic behavior was again first-order in benzenediazonium salt, while the overall reaction order in **2** was not a simple one. Instead, the kinetic data were consistent with the rate expression of a sum of two terms, one being first-order, and the other, second-order, in **2**. The two terms conceivably correspond to the respective deprotonating paths simultaneously taking place in the solution, the former, to that by the water base present in the wet organic phase, and the latter, to that by **2** itself. The rate constants thus obtained are summarized in Table 2.

Comparisons of the rate constants concerning the fluoroborate (**1**) indicate that the k_3 in wet chloroform was reduced to 1/30 of that in the dry solvent, while the k_2 in the aqueous buffer was lowered to 1/15 of that in the wet chloroform, despite the increase in the water base in the former; the reduced reactivity can be ascribed to the stabilization of the cationic reagent due to hydration in such wet media.

It can also be seen that the presence of TFPB in a benzene solution caused a distinct difference in the reaction rate, since practically no arenediazonium ion was transferred into the organic phase without the TFPB catalyst. Also, a comparison of k_3 values of **1** and **11** in dry chloroform solutions indicates that the coupling reaction with the diazonium ion paired with TFPB proceeded about sixteen times faster. Comparisons of the k_1' and k_1'' values in the reactions with phenol of an equal concentration reveal a parallel tendency, with the rate three times faster. If the ratio of $[ArN_2^+\cdot BF_4^-]_{t=0}/[ArN_2^+\cdot TFPB^-]_{t=0}$ is taken into account, the contribution due to the second term in Eq. 1 can be neglected in practice. The observed acceleration caused by TFPB is presumably to be ascribed to the larger size of the counter anion upon ion pairing in nonpolar organic solvents.[16]

Kinetics and Mechanism of PTC. The kinetics in the solution phases suggested that the reaction scheme

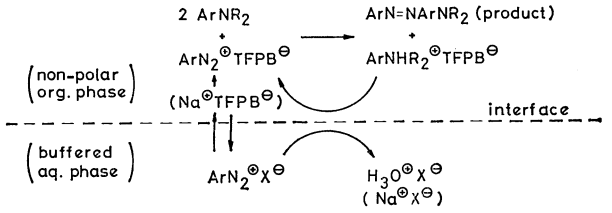

Fig. 1. PTC scheme of diazo-coupling reaction in a two-phase system.

of the present PTC cycle was as is illustrated in Fig. 1. At the beginning of the reaction, the diazonium ion was exchanged for the sodium ion of the catalyst at the interface, solubilized into the organic phase, and coupled with the diazophile dissolved therein, to give a product of azo dye;

$$(Na^+\cdot TFPB^-)_{org} + (ArN_2^+)_{aq} \overset{K_1}{\rightleftharpoons} (ArN_2^+\cdot TFPB^-)_{org} + (Na^+)_{aq}, \quad (3)$$

where

$$K_1 = [ArN_2^+\cdot TFPB^-]_{org}[Na^+]_{aq}/[Na^+\cdot TFPB^-]_{org}[ArN_2^+]_{aq} \quad (4)$$

and

$$[ArN_2^+\cdot TFPB^-]_{org} + [Diazophile]_{org} \xrightarrow{k_2} [Product]_{org} + [H_3O^+\cdot TFPB^-]_{org}, \quad (5)$$

where we assumed a slow coupling reaction relative to the mass-transfer between the two phases under an efficient stirring; the rate expression was then given by Eq. 6:

$$d[Product]_{org}/dt = k_2[ArN_2^+\cdot TFPB^-]_{org}[Diazophile]_{org}. \quad (6)$$

The liberated proton, which was in the form of an oxonium ion or some other protonated species, formed an ion pair with the TFPB anion to be transported to the interface; the proton was thrown out of the organic phase in exchange for the diazonium ion, which was used in the next PTC cycle:

$$[H_3O^+\cdot TFPB^-]_{org} + [ArN_2^+]_{aq} \overset{K_2}{\rightleftharpoons} [ArN_2^+\cdot TFPB^-]_{org} + [H_3O^+]_{aq}, \quad (7)$$

where

$$K_2 = [ArN_2^+\cdot TFPB^-]_{org}[H_3O^+]_{aq}/[H_3O^+\cdot TFPB^-]_{org}[ArN_2^+]_{aq}. \quad (8)$$

Provided the thermodynamic activities of the sodium and diazonium ions were maintained constant throughout the reaction period in an aqueous buffer, then the ratios of $[Na^+]_{aq}/[ArN_2^+]_{aq}$ and $[H_3O^+]_{aq}/[ArN_2^+]_{aq}$ were constant; they are represented by the symbols of Φ_1 and Φ_2 respectively.

Since the initial concentration of TFPB, Q_0, was given by Eq. 9, the concentration of the diazonium ion in the organic phase, $[ArN_2^+\cdot TFPB^-]_{org}$, was derived to be constant, as is given in Eq. 10, by com-

bining Eqs. 4, 8, and 9:

$$Q_0 = [Na^+ \cdot TFPB^-]_{org} + [ArN_2^+ \cdot TFPB^-]_{org} + [H_3O^+ \cdot TFPB^-]_{org}, \quad (9)$$

$$[ArN_2^+ \cdot TFPB^-]_{org} = Q_0/(\Phi_1/K_1 + \Phi_2/K_2 + 1). \quad (10)$$

In other words, the diazonium ion in the organic phase was supplied from the aqueous phase so fast, relative to the consumption rate by the reaction, that the concentration of the ion pair of $ArN_2^+ \cdot TFPB^-$ in the organic phase could be maintained at a steady level. Consequently, the reaction became apparently first-order only in the diazophile in the organic phase, as is expressed in Eq. 11:

$$d[Product]_{org}/dt = k_{app}[Diazophile]_{org}, \quad (11)$$

where;

$$k_{app} = k_2 Q_0/(\Phi_1/K_1 + \Phi_2/K_2 + 1) = k_2' Q_0. \quad (12)$$

Equation 12 indicated that the apparent first-order rate constant, k_{app}, was linearly proportional to the catalyst concentration, Q_0.

Since the total moles of diazophile and product was always equal to the initial moles of diazophile, the rate equation was then given by Eq. 13 or by Eq. 14 of an integrated form:

$$d[Product]_{org}/dt = k_{app}([Diazophile]_{org,0} - [Product]_{org}), \quad (13)$$

$$\ln([Diazophile]_{org,0}/([Diazophile]_{org,0} - [Product]_{org})) = k_{app}t. \quad (14)$$

The resulting formulations in the present process are quite analogous to those derived by Starks for the traditional cation-catalyzed PTC process.[17] The only essential difference is that each ionic species has a sign of charge which is opposite to that of the corresponding one in the traditional process.

Conditions such as those which Eqs. 11 and 13 were premised on could be accomplished in the diazo-coupling of 9-ethylcarbazole (**8**) in dichloromethane with a ten-fold excess of 4-nitrobenzenediazonium tetrafluoroborate (**7**) in an aqueous buffer in the presence of sodium TFPB if the reaction mixture was stirred at a speed such that the stirring was no longer rate-limiting.

The effect of stirring in the two-phase system is shown in Fig. 2. The initial rates were compared at various stirring speeds in the reaction of **8** with **1** in dichloromethane under an apparently first-order condition in **8**. The results indicated that, at a stirring speed higher than 400 min^{-1}, the reaction was no longer of an interfacial phenomena.

The kinetics of the formation of the azo dye from **7** and **8** was followed by monitoring the absorbance at 430 nm at 25.0 °C. Apparent first-order kinetic plots, mostly covering more than one half-life of the diazophile, were obtained with a correlation coefficient (γ) greater than 0.99, as is summarized in Table 3. The apparent rate constants thus obtained were linearly proportional to the catalyst concentration with a γ value of 0.998 in its range from 5.15×10^{-5} to 2.00×10^{-4} mol dm^{-3}, consistent with Eq. 12; the gradient of the correlation line gave the overall k_2' value of 8.9 mol^{-1} dm^3 s^{-1} in the present PTC system.

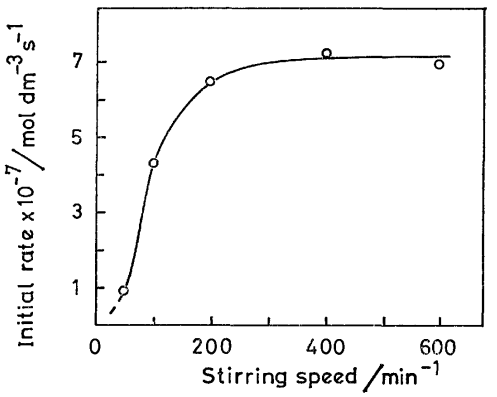

Fig. 2. Dependence of the initial reaction rate upon the stirring speed in the two-phase system.

The kinetics of the present model reactions in the two-phase system, though the diazophile and diazonium components examined fell within a rather limited range, indicated the catalyst turnover in the course of the PTC cycle and a remarkable acceleration of the *C*-coupling rate in non-donating organic solvents, irrespective of the reactivity of the diazophile component. Recently Griffiths and his co-workers reported on diazo-coupling in the PTC manner by the use of dodecylbenzenesulfonate (DBS) in a dichloromethane-aqueous buffer two-phase system.[2b] The DBS in their system, however, seems not always efficient as a phase-transfer catalyst; *e.g.*, PTC using DBS took 48 h to obtain a 44% yield from **8** and 4-nitrobenzenediazonium chloride, showing a great difference from the result of the present one-pot operation. A lower catalytic efficiency of DBS is consistent with the steric effect of an uncrowded anionic center of the sulfonate, which would favor the formation of a tight ion pair in nonpolar organic solvents and would consequently, decrease the reactivity of the counter cation. Also, they mentioned that, upon the diazo-coupling with arylamines in an anion-catalyzed PTC manner, the nucleophilicity of the amino nitrogen might affect the reaction site so as to cause *N*-coupling prior to *C*-coupling. However, such reaction behavior was unlikely so far as we have examined the present system; instead, *N*-coupling was seemingly observed only in

Table 3. Apparent first-order rate constants, k_{app}, in the diazo-coupling of 4-nitrobenzenediazonium salt with 9-ethylcarbazole in the two-phase system

$[TFPB^-]/10^{-5}$ mol dm^{-3}	5.15	7.7	10.0	15.0	20.0

cases of the absence of an effective proton-accepting base.

Experimental

Diazo-coupling in Liquid-solid PTC Systems. Into a stirred suspension of powdered benzenediazonium tetrafluoroborate (**1**)[18] (50 mg, 0.26 mmol) in benzene (10 ml) we added *N,N*-dimethylaniline (**2**) (66 mg, 0.55 mmol). The mixture was then colored pale yellow, but prolonged stirring caused no further reaction and gave no coupling product. Into a stirred mixture of the same compositions we added sodium TFPB (48 mg, 0.05 mmol). The mixture immediately turned red. We then kept stirring it at room temperature for 1 h. The resulting benzene layer was evaporated to dryness. The residual red solid was chromatographed on a silica-gel column; the fraction eluted with hexane gave yellow, crystalline 4-dimethylaminoazobenzene (49 mg, 86% yield) melting at 118 °C.[19]

The reaction with phenol was conducted in a similar manner except that an equimolar amount of 2,6-dimethylpyridine was added as a proton-accepting base. 4-Hydroxyazobenzene was obtained from a chromatographic fraction eluted with dichloromethane on a silica-gel column. Mp 154 °C.[20] The yield was quantitative when a double molar amount of phenol was used.

Diazo-coupling in Liquid-liquid PTC Systems. A mixture of an aqueous solution (25 ml) of 4-nitrobenzenediazonium tetrafluoroborate (**7**)[21] (70 mg, 0.3 mmol) and a dichloromethane solution (25 ml) of 9-ethylcarbazole (**8**) (55 mg, 0.3 mmol) and sodium TFPB (20 mg, 0.02 mmol) were agitated by means of a screw propeller rotating at 700 min^{-1} [22] for 3 h at room temperature; the aqueous layer was then negative to a diazonium test by *N,N*-dimethylaniline. The organic layer was evaporated to dryness. 9-Ethyl-3-(4-nitrophenylazo)carbazole (80 mg) was isolated from a chromatographic fraction eluted with dichloromethane on a silica-gel column. Recrystallization from methanol–dichloromethane gave red needles melting at 180—182 °C.[14] Found: C, 69.53; H, 4.72; N, 16.15%; *m/e*, 344 (M^+). The yield is tabulated in Table 1, together with those of the following reactions.

The reactions with diphenylamine (**9**) and *N*-methyldiphenylamine (**10**) were conducted in a similar manner to give 4-(4-nitrophenylazo)diphenylamine[23] of dark red needles melting at 160 °C[23] from methanol–dichloromethane (Found: C, 67.65; H, 4.15; N, 17.50%; *m/e*, 318 (M^+)) and 4-(4-nitrophenylazo)-*N*-methyldiphenylamine[24] of red needles melting at 174—175 °C from methanol-dichloromethane. Found: C, 68.46; H, 5.00; N, 16.79%; *m/e*, 332 (M^+). Calcd for $C_{19}H_{16}N_4O_2$: C, 68.66; H, 4.85; N, 16.86 %; M, 332. UV_{max} (CH_2Cl_2) 474 nm (ε 31900); ^{13}C-NMR ($CDCl_3$) δ=114.29, 122.77, 124.68, 125.61, 125.93, 126.22, 129.93, 144.99, 147.10, 147.62, 152.63, and 156.61; ^{1}H-NMR ($CDCl_3$) δ=3.40 (3H, s, =N-CH_3), 6.78 (2H of =N-C_6H_4-N_2-, d, J=5 Hz), 7.27 (5H, m, =N-C_6H_5), 7.77 (2H of =N-C_6H_4-N_2-, d, J=5 Hz), 7.80 (2H of -N_2-C_6H_4-NO_2, d, J=4.5 Hz), and 8.22 (2H of -N_2-C_6H_4-NO_2, d, J=4.5 Hz). The ^{1}H- and ^{13}C-NMR spectra were compatible with the assigned structure.

The reactions with anisoles were conducted in a mixture of 10 ml of a dichloromethane solution and 10 ml of an aqueous solution buffered with disodium hydrogenphosphate and potassium dihydrogenphosphate (2.0×10^{-3} mol dm^{-3} each) at pH 7.02. Each product was obtained from a chromatographic fraction eluted with dichloromethane on a silica-gel column. 4-(4-Nitrophenylazo)anisole; yellow crystallites melting at 140 °C.[25] MS: *m/e*, 257 (M^+). 4-(4-Nitrophenylazo)-3-methylanisole; red fibriles melting at 138 °C.[26] MS: *m/e*, 271 (M^+). 4-(4-Nitrophenylazo)-3-methoxyanisole; red fibriles melting at 155 °C.[27] Found: C, 58.28; H, 4.66; N, 14.56%; *m/e*, 287 (M^+).

Diazo-coupling in Liquid-liquid PTC System by One-pot Operation. The aqueous solution of diazonium salt was prepared by the addition of an aqueous sodium nitrite (0.170 g, 2.47 mmol, in 2 ml of water) to a solution of 4-nitroaniline (0.386 g, 2.80 mmol) in 2 mol dm^{-3} hydrochloric acid (7 ml) at 0 °C. After 1.5-h stirring, a nitrous acid test by the use of potassium iodide and starch was negative. The diazonium salt solution was stirred vigorously, together with a dichloromethane solution (20 ml) of 9-ethylcarbazole (**8**) (0.501 g, 2.57 mmol) and sodium TFPB (20 mg, 2.15×10^{-2} mmol). The absorbance of the azo dye was monitored at 430 nm. After a 5-h reaction, a diazonium test using *N,N*-dimethylaniline was negative to the aqueous phase, and the absorbance attained a plateau. The yield of azo dye was estimated by the absorbance to be 94%, based upon the amount of sodium nitrite added.

Kinetics in Solution Phases. A suspension of the diazonium salt (**1**) (10 mg, 0.05 mmol) in benzene or chloroform (50 ml) was shaken for 1 h at 25 °C with or without the addition of sodium TFPB (5 mg), the amount of which had previously been confirmed to be enough for the saturation in benzene,[12] while it dissolved completely in chloroform. The residual solid was filtered off if present. The benzene filtrate or chloroform solution was diluted with the same solvent to 10 times the original volume when TFPB was added. No dilution was needed in the absence of TFPB. An aliquot (2.00 ml) was placed in a septum-capped 10-mm photometric cell previously maintained at 25.0 °C. The absorbance was monitored immediately after the addition of a diazophile solution (1.00 ml) into the cell through the septum by means of a syringe.

The key bands for the determination of azo dyes in benzene and chloroform solutions were as follows: λ_{max} and (ε) for 4-dimethylaminoazobenzene, 410 nm (28000) and 410 nm (26000) respectively, and those for 4-hydroxyazobenzene, 345 nm (24000) and 345 nm (20000), respectively. The former azobenzene showed an ε value of 19000 at λ_{max} of 410 nm in a methanol–water (6:4 in volume) mixture; this value was used for the kinetic determinations of the azo dye in an aqueous solution buffered at pH 7.02. The resulting azo dye was less soluble in the aqueous solution, and the absorbance was followed until the reaction mixture became cloudy.

The kinetic dependence upon the concentration of *N,N*-dimethylaniline was examined in benzene, chloroform, and aqueous solutions, where the concentration ranges examined were 2.12—5.30×10^{-4}, 8—40×10^{-4}, and 1.0—5.0×10^{-3} mol dm^{-3} respectively; otherwise, the concentration was 3.80×10^{-4} mol dm^{-3}. Phenol (3.80×10^{-4} mol dm^{-3}) as a diazophile was added, together with an equimolar amount of 2,6-dimethylpyridine as a proton-accepting base. Plottings according to Eqs. 1 and 2 afforded k_1' value of 8.7×10^{-3} s^{-1} (γ=0.998) and k_1'' value of 2.7×10^{-3} s^{-1} (γ=0.991).

Kinetics in Liquid-liquid PTC Systems. An aqueous solution (25 ml) of 4-nitrobenzenediazonium tetrafluoroborate (**7**) (12 mg, 2.0×10^{-3} mol dm^{-3}), buffered with disodium hydrogenphosphate and potassium dihydrogenphosphate (2.0×10^{-3} mol dm^{-3} each) at pH 7.02 and a dichloromethane solution (25 ml) of 9-ethylcarbazole (**8**) (2.05×10^{-4} mol dm^{-3}) and sodium TFPB (5.15—20.0×10^{-5} mol dm^{-3}), both previously maintained at 25.0 °C, were put together all at once and stirred by means of a screw propeller rotating

at 700 min^{-1}. Every 2.0 min stirring was stopped, and a 100-μl portion was taken out of the dichloromethane layer. The aliquot was poured into the same solvent (3.0 ml), previously placed in a photometric cell, to determine the absorbance at 430 nm. The production of azo dye was plotted against the time lapse according to Eq. 14 to give the k_{app} for systems of different TFPB concentrations. The results are summarized in Table 3.

The plotting of k_{app} against the concentration of sodium TFPB gave a linear relationship with a γ value of 0.998, the gradient of the correlation line being 8.93 mol^{-1} dm^3 s^{-1}.

The authors wish to thank Professors Yukito Murakami and Toyoki Kunitake in the Department of Organic Synthesis, Kyushu University, for their informative criticism and advice in the discussion of the results.

Reaction of the Azomethine Moiety Buried in Bilayer Membranes[1)]

Yoshio Okahata,† Reiko Ando, and Toyoki Kunitake*
Department of Organic Syntheis, Faculty of Engineering, Kyushu University, Higashi-ku, Fukuoka 812
(Received September 22, 1982)

The reaction with water and amines of the azomethine moiety that is part of single-chain ammonium amphiphiles was examined. These amphiphiles form stable bilayer aggregates when they have the alkyl tail of C_7 or C_{12}. The reaction with water of the bilayer-forming amphiphiles ceases at the hydration stage and are 10—2000 times slower than those of the amphiphiles which do not form bilayers and undergo hydrolytic cleavage. The reactivity of the azomethine moiety in bilayers decreases with increasing distance from the membrane surface. The Arrhenius plots for the bilayer-forming amphiphiles show discontinuities at temperatures corresponding to phase transition of the respective bilayer (T_c). The apparent activation energy is larger at temperatures below T_c than at temperatures above T_c. This suggests that water penetration is facilitated in the fluid bilayer. The reaction with amines was affected by their solubility in the bilayer matrix, and poly(ethylenimine) gave a much reduced reaction rate when the azomethine moiety was buried deep in the bilayer matrix.

Organic reactions in the bilayer membrane matrix are attracting increasing attention in recent years, since the highly-organized bilayer matrix offers unique media for controlling reactions. A variety of double-chain surfactants have been shown to produce stable bilayer aggregates in dilute aqueous solution.[2-5)] Physicochemical properties of these bilayer membranes are intrinsically the same as those of the biolipid bilayer and, therefore, their unique properties have been examined in relation to catalysis of some organic reactions.[6)]

We showed previously that single-chain ammonium amphiphiles which possess the *N*-benzylideneaniline moiety (C_n–BB–C_m–N^+) in the hydrophobic portion produce stable bilayer aggregates in water.[7,8)] The aggregate morphology changes extensively with the molecular structure of the amphiphile. For instance, the stable bilayer structure is apparently not formed when the length of the alkyl tail is shorter than C_7. The linear amphiphiles (C_n–BB–N^+ and C_n–BB–C_m–N^+, n=7,12) form multi-walled bilayer vesicles, whereas an amphiphile with the bent rigid segment (p-C_{12}–BB–m-C_4–N^+) gives tubular aggregates.

The variation in morphology necessarily leads to the change in the packing and/or location of the *N*-benzylideneaniline moiety in the aggregate, which, in turn, may produce changes in its reactivity.

The bilayer aggregates of C_n–BB–C_m–N^+ are stable in neutral and alkaline solution; however, they slowly decompose in acidic media due to reaction at the *N*-benzylideneaniline moiety. This group readily reacts with amine nucleophiles, and the reactivity may also depend on the aggregate morphology. We describe in this paper reactions of the azomethine moiety that is part of the bilayer structure. The relation between aggregate morphology and reactivity, once established, would give important means to control organic reactions in aqueous media.

Experimental

Syntheses of amphiphiles containing the *N*-benzylideneaniline moiety(C_n–BB–N^+, C_n–BB–C_m–N^+) and aggregation behavior of these amphiphiles have been reported elsewhere.[7,8)] Electron microscopy was performed by using a Hitachi H-500 instrument.[7)] Differential scanning calorimetry was carried out with a Daini-Seikosha SSC-560 instrument. Sample solutions(1—2 wt%, 0.02—0.05 M)(1 M=1 mol dm^{-3}) were sealed in silver pans and the thermal measurement was repeated from 3 °C to 90 °C at a rate of 2 °C/min. The detail is described elsewhere.[9)]

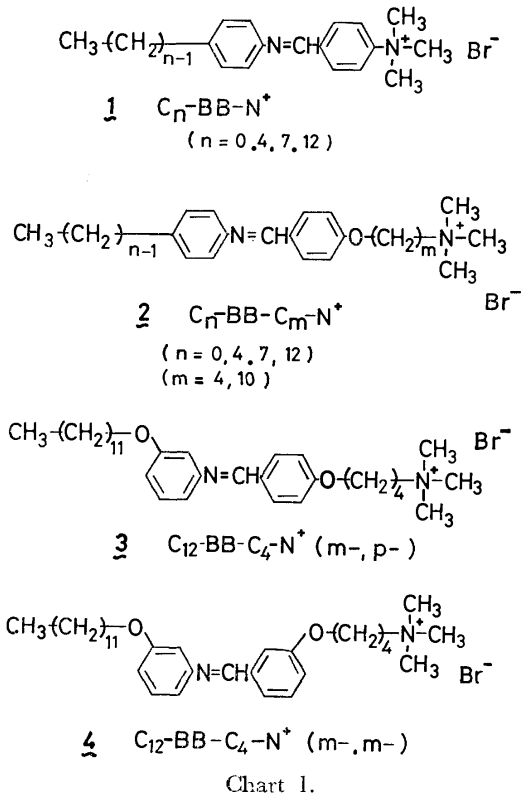

Chart 1.

Acid hydrolyses of aqueous C_n–BB–C_m–N^+ were performed usually at 30 °C, pH 5.5(0.02 M phosphate buffer) and μ=0.02(KCl). A stock solution(10^{-3}—10^{-2} M) of an amphiphile was prepared by sonication(Branson Sonifier 185) in a weakly alkaline solution(pH 9), and the reaction was initiated by adding 0.1—0.01 ml of this solution to an acidic buffer solution. The course of reaction was followed by disappearance of the absorption due to the azomethine linkage(-CH=N-) at 320 nm with a Hitachi 200 spectrophotometer. Pseudo first-order kinetics were observed up to at least 70—80% completion of the reaction, and apparent rate constants(k_{obsd}) were estimated. The pH

† Present address: Department of Polymer Science, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152.

of the reaction medium was maintained within ±0.05 during the reaction(HM-10B digital pH meter, Toa Electronics). The reaction with amines was followed in the same way.

Results

The Course of Reaction. The time course of the spectral change due to reaction of the C_{12}–BB–C_4–N^+ bilayer aggregate is shown in Fig. 1. C_{12}–BB–C_4–N^+ possesses absorption maxima at 280 nm and 320 nm. The latter peak that is attributable to the azomethine linkage[10,11] diminished with time. The absorption maximum and the spectral pattern were not influenced by the alkyl chain length (C_n and C_m). C_{12}–BB–C_4–N^+ in 50 v/v% EtOH–H_2O where the amphiphile does not form the bilayer aggregate gave the same spectral change as that of Fig. 1. It means that the spectra of C_n–BB–C_m–N^+ and C_n–BB–N^+ are not affected by the aggregate formation. Therefore, the spectrum of the amphiphile and the course of reaction are concluded to be identical irrespectively of the bilayer formation.

Acid hydrolysis of the azomethine linkage is initiated by proton addition to nitrogen followed by the rate-limiting nucleophilic attack of H_2O or OH^-, as shown in Eq. 1.[12] It is assumed that the same mechanism operates in the aqueous micelle[13] and in liquid crystalline media.[14]

$$-CH{=}N- \underset{\text{fast}}{\overset{H^+}{\rightleftharpoons}} -CH{=}\overset{+}{N}H- \underset{\text{slow}}{\overset{H_2O}{\rightleftharpoons}} -\underset{\displaystyle OH}{\underset{|}{CH}}-NH- \rightleftharpoons$$

$$-\underset{\displaystyle O^-}{\underset{|}{CH}}-\overset{+}{N}H_2- \rightleftharpoons -CHO + H_2N- \qquad (1)$$

Disappearance of the azomethine absorption at 320 nm that is used for following the reaction does not assure completion of Eq. 1. In the case of BB–N^+ and C_4–BB–C_4–N^+ which do not form bilayers, thin-layer chromatography of the reaction mixture indicated formation of the corresponding amines and aldehydes, and therefore, the reaction proceeds to completion according to Eq. 1. On the other hand, in the bilayer system, the reaction appears to stop at the hydration step from the following reasons: (1) The bilayer structure remains in electron micrographs after the reaction, as discussed below (Fig. 4b); (2) equimolar mixtures of the product amines and aldehydes do not give clear solution under the same conditions, although the reaction mixture remains clear after the reaction is over; (3) when the homogeneous reaction mixture is mixed with concentrated hydrochloric acid and refluxed, the product amine and aldehyde separate as white precipitates. Therefore, the reaction stops at the intermediate stage without the acid treatment. For these reasons, hydrolysis and hydration will not be discriminated in the subsequent discussion as long as the kinetics are concerned.

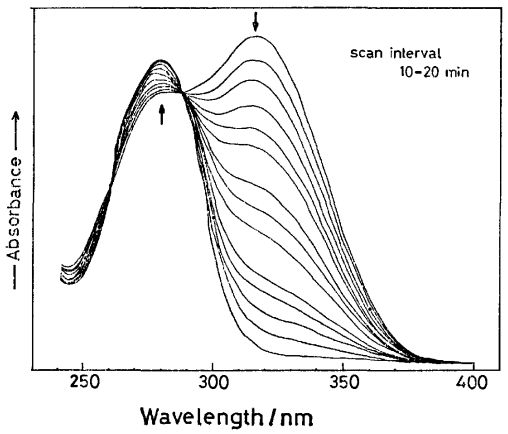

Fig. 1. Spectral change due to reaction of aqueous C_{12}–BB–C_4–N^+ bilayer.
30 °C, pH 3.4 (0.02 M acetate buffer), μ=0.02 (KCl), [C_{12}–BB–C_4–N^+]=1.0×10^{-4} M.

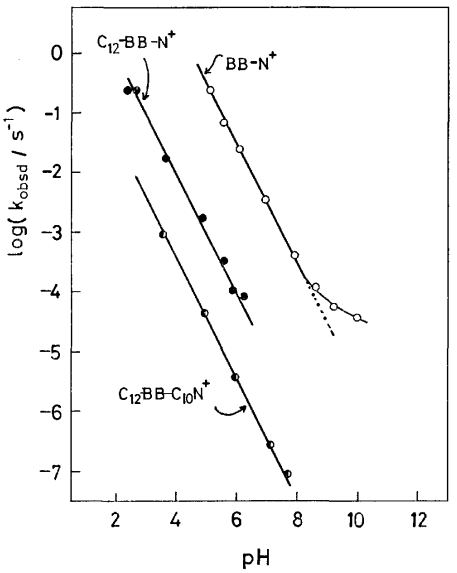

Fig. 2. pH-rate profiles of the reaction of C_n–BB–C_m–N^+.
30 °C, 0.02 M acetate buffer (pH 2—5), 0.02 M phosphate buffer (pH 6—7), 0.02 M borate buffer (pH 7—9), μ=0.02 (KCl), [C_{12}–BB–C_{10}–N^+]=6.0×10^{-5} M, [C_{12}–BB–N^+]=6.0×10^{-5} M, [BB–N^+]=6.0×10^{-4} M.

The pH-rate profile of the azomethine reaction was examined at pH 2 to 10 and those of BB–N^+, C_{12}–BB–N^+, and C_{12}–BB–C_{10}–N^+ are shown in Fig. 2 as typical examples. In all cases, log k_{obsd} decreases linearly with the slope of −1 at pH 2 to 8. This is consistent with the above-mentioned supposition that the reaction proceeds *via* the specific acid catalysis (Eq. 1). The upward curvature for BB–N^+ at pH 8—10 indicates the involvement of water or hydroxide catalysis. The catalytic effect of the basic buffer species (HBO_3^-, HPO_4^-, and $CH_3CO_2^-$) was negligibly small and the effective nucleophilic species is limited to water at buffer concentrations of 0.005 to 0.02 M. The subsequent experiments were conducted at pH 5.5 because of the experimental convenience.

Electron Microscopy. It is expected that the reaction alters the aggregate morphology drastically. An electron micrograph for an aqueous solution of C_{12}–BB–C_4–N^+ (5×10^{-3} M) is shown in Fig. 3a, which indicates the presence of multi-walled vesicles. A reacted sample for electron microscopy was obtained as follows: One ml of the same aqueous solution as that

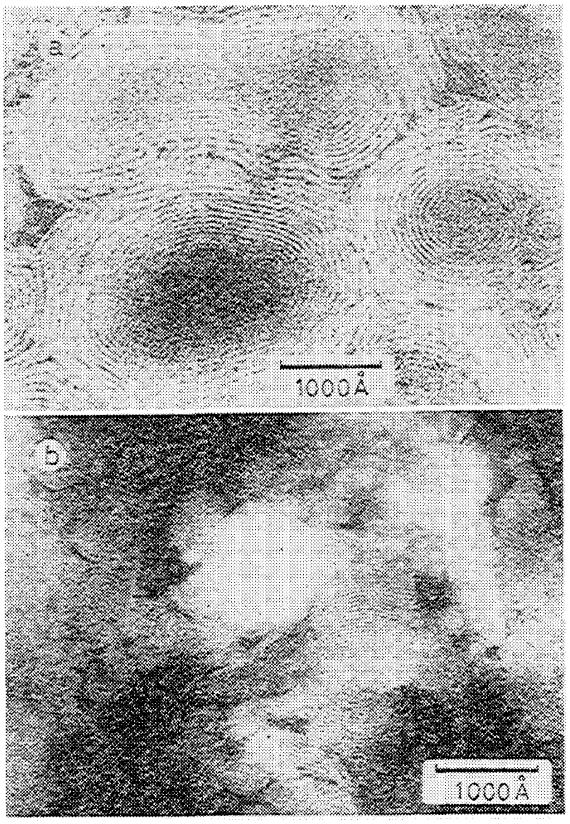

Fig. 3. Electron micrographs before (a) and after (b) reaction of C_{12}-BB-C_4-N^+ aggregates with water. Initial magnification, ×50,000, stained by uranyl acetate.

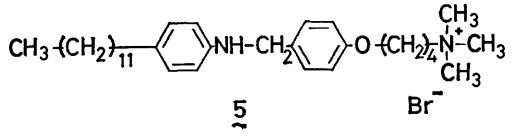
used for the rate measurement was adjusted to pH 1—2 by adding one drop of concentrated hydrochloric acid, and maintained at room temperature for 1 h. Complete disappearance of the absorption at 320 nm was confirmed, and the solution was stained with aqueous uranyl acetate (1 wt%). An electron micrograph for this sample is shown in Fig. 3b. The lamellar structure is preserved even after complete disappearance of the azomethine linkage.

As mentioned above, the acid-catalyzed reaction supposedly ceases to proceed at the hydration step of Eq. 1. The bilayer assemblage of the hydrated intermediate may suppress the subsequent cleavage step. It is interesting to note that the hydrogenation product of this amphiphile, **5**, gives tubular aggregates, in contrast to formation of lamellar aggregates by the hydration product.



5

Chart 2.

Amphiphile Structure and Reaction Rate. Figure 4 illustrates the dependence of the reaction rate on the amphiphile concentration. In Fig. 4a is given the concentration dependence for three amphiphiles whose total alkyl lengths (C_n+C_m) are 10 to 12. They react more slowly than BB-N^+ which does not have the

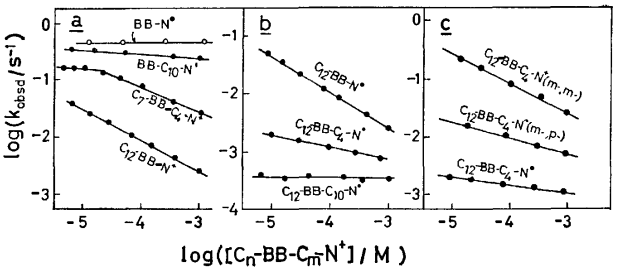


Fig. 4. Concentration dependence of the rate constant. 30 °C, pH 5.5±0.1 (0.02 M phosphate buffer), μ= 0.02 (KCl).

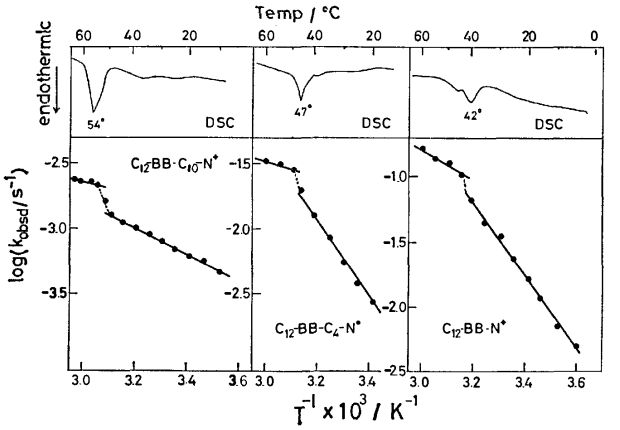

Fig. 5. Arrhenius plots of the reaction and DSC curves of C_{12}-BB-C_m-N^+ bilayers.
Reaction conditions: pH 4.3 (0.02 M acetate buffer), 0.02 M KCl, [C_{12}-BB-C_m-N^+]=6.1×10^{-5} M DSC samples: [C_{12}-BB-C_m-N^+]=1—2 wt% (2—5×10^{-2} M).

alkyl chain. It is interesting that the reaction rate varies considerably among the three amphiphiles in spite of their closely-related structures (only the distribution of the alkyl chain is different). The reaction rate is suppressed when the alkyl chain is localized in the tail portion (C_{12}-BB-N^+), but it is not so when the alkyl chain is localized in the spacer portion (BB-C_{10}-N^+). Figure 4b compares log k_{obsd} for C_{12}BB-C_m-N^+ in which the spacer length is varied. The rate as well as concentration dependence become smaller as the spacer is lengthened. The influence of the pattern of alkyl substitution at the rigid segment is shown in Fig. 4c. The meta substitution makes these amphiphiles more vulnerable to reaction than the para substitution.

Effect of Temperature. Reactions of aqueous bilayers of C_{12}-BB-C_m-N^+ (m=0, 4, 10) were performed at 0—60 °C. The corresponding Arrhenius plots are shown in Fig. 5. The three Arrhenius plots are made of two linear portions. The inflection regions are 40—45 °C, 45—50 °C, and 50—55 °C for C_{12}-BB-C_m-N^+ (m=0, 4, and 10), respectively. These temperature regions agree very closely to the endothermic region observed in the DSC measurement. The endothermic peaks are derived from the crystal-to-liquid crystal phase transition of the bilayer membrane.[7] Thus, the anomaly in the Arrhenius plots reflects the change

in the membrane physical state. In agreement with this supposition, aqueous BB–C_{10}–N^+ which does not form the bilayer structure and correspondingly gives no DSC peak gave linear Arrhenius plots.

Effect of Reaction Media. The reaction of C_{12}–BB–C_m–N^+ (m=0, 4, and 10) was examined in the bilayer matrix of dihexadecyldimethylammonium bromide ($2C_{16}N^+2C_1$), in the aqueous hexadecyltrimethylammonium bromide (CTAB) micelle, and in 50 v/v% EtOH–H_2O. The results are summarized in Table 1, in comparison with those of the single-component bilayer membrane. The k_{obsd} value decreased with increasing spacer lengths, when C_{12}-BB–C_m–N^+ were allowed to react as single-component bilayer membranes, in the $2C_{16}N^+2C_1$ bilayer or in the CTAB micelle. In contrast, the influence of the spacer length cannot be seen in the reaction in 50 v/v% EtOH–H_2O, and the k_{obsd} value is much larger in this medium than in other media. C_{12}–BB–C_m–N^+ would be molecularly dispersed in 50 v/v% EtOH–H_2O, and the azomethine moiety should be equally exposed to acid in spite of different spacer lengths, leading to the lack of the spacer effect. The observed influence of the spacer length in the other three media clearly indicates that C_{12}–BB–C_m–N^+ molecules are more or less organized in these media.

Table 1. Reaction of C_{12}-BB-C_m-N^+ (m=0, 4, and 10) in various microenvironments[a]

Medium	$10^4 \times k_{obsd}/s^{-1}$		
	C_0	C_4	C_{10}
Water	220	44	1.3
Aqueous $2C_{16}N^+2C_1$ bilayer	120	23	1.0
Aqueous CTAB micelle	480	100	8.2
50 v/v% EtOH-H_2O	1200	1400	1300

a) 30 °C, pH 5.5 (0.02 M phosphate buffer) μ=0.02 (KCl) [C_{12}-BB-C_m-N^+]=1.0×10^{-4}, [CTAB]=1.0×10^{-3} M, [$2C_{16}N^+2C_1$]=1.0×10^{-3} M.

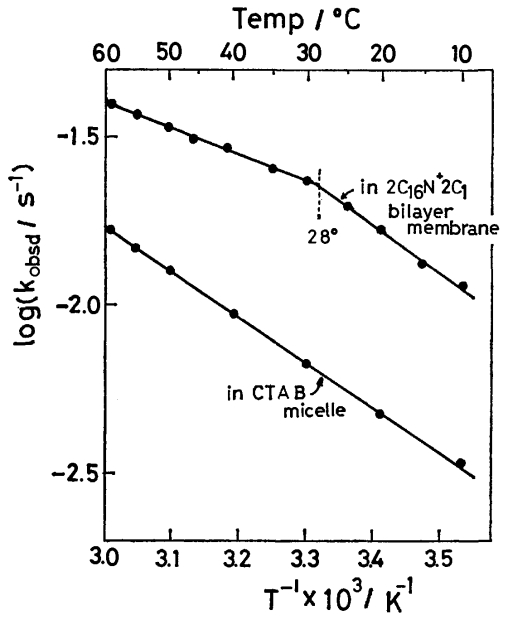

Fig. 6. Arrhenius plots of the reaction of C_{12}-BB-C_{10}-N^+ in the CTAB micelle and in the $2C_{16}N^+2C_1$ bilayer. 30 °C, pH 2.2, 0.02 M KCl, [C_{12}-BB-C_{10}-N^+]=6.0×10^{-5} M, [CTAB]=[$2C_{16}N^+2C_1$]=1.0×10^{-3} M.

Figure 6 illustrates the Arrhenius plots for the reaction of C_{12}–BB–C_{10}–N^+ in the $2C_{16}N^+2C_1$ bilayer and in the CTAB micelle. In the latter system the linear plots are observed, but the former system gives an inflection at *ca.* 28 °C. This temperature agrees with that of the crystal-to-liquid crystal phase transition of the $2C_{16}N^+2C_1$ bilayer.[9]

Reaction with Amines. Primary amines readily undergo the exchange reaction with Schiff bases. The exchange reaction with the azomethine moiety of aqueous C_{12}–BB–C_m–N^+ (m=0, 4, and 10) was examined in the presence of excess amines. The results are summarized in Fig. 7. The overall rate (k_{all} term) of disappearance of the azomethine moiety was corrected for the water reaction in the absence of amines (k_{obsd} term). Poly (ethylenimine) used is commercially available (MW 60000) and contains 25% primary, 50% secondary, and 25% tertiary amino groups.[15]

The rate constant increases linearly with the amine concentration, indicating occurrence of clean second-order reaction. The spacer length exerts relatively small influences in the reaction with benzylamine. The spacer effect is more apparent with dodecylamine as attacking nucleophile, although the reaction rates are smaller. In the case of poly(ethylenimine), the reactivities of C_{12}–BB–C_m–N^+ (m=4 and 10) are much smaller than that of C_{12}–BB–C_m–N^+ (m=0).

Discussion

Mode of Aggregation and Reactivity. The aggregation behavior of single-chain amphiphiles has been shown to be determined by five structural elements.[8] They are (1) flexible tail, (2) rigid segment, (3) hydrophilic head group, (4) spacer group, and (5) additional interacting group. In the case of the amphiphiles used in this study, three structural elements (length of flexible tail, spacer length and the mode of substitution at the rigid segment) are responsible for the change in the aggregation behavior.

The rate constants(k_{obsd}) at the amphiphile concentration of 1.0×10^{-4} M are summarized in Table 2, together with the aggregation behavior. The predom-

a) Aggregation behaviors are mostly quoted from Refs. 8 and 9. b) 30 °C, pH 5.5±0.1, μ=0.02(KCl), [C_n-BB-C_m-N^+] = 1.0×10^{-4} M.

inant factors which govern the reaction rate are (1) the extent of bilayer assemblage as determined by the tail length and the pattern of substitution at the rigid segment, and (2) the distance of the reacting group from the membrane surface as determined by the spacer length. The bilayer structure is not developed for the azomethine amphiphiles with alkyl tails shorter than C_7. These amphiphiles give largest k_{obsd} values (0.2—0.5 s^{-1}). It is noteworthy that C_4–BB–C_m–N^+ (m=4 and 10) and BB–C_{10}–N^+ are among the most reactive amphiphiles in spite of their extensive aggregation (though bilayer is not formed). This means that simple aggregation without amphiphile orientation do not lead to rate suppression. Comparisons shown in Figs. 4a and 4c also point to the same conclusion. Three amphiphiles (BB–C_{10}–N^+, C_7–BB–C_4–N^+ and C_{12}–BB–N^+) of Fig. 4a possess similar amounts of the alkyl chain and form equally huge aggregates (aggregate weight, 4—20 millions). However, their reactivities change drastically due to varying extents of orientation. The reactivities of amphiphiles with different patterns of substitution are compared in Fig. 4c. The molecular orientation in the aggregate as examined by electron microscopy becomes less ordered, as the meta substitution increases. The reaction rate becomes greater accordingly.

The influence of the distance of the reacting group from the membrane surface is found in Table 2 for several combinations. In the series of C_{12}–BB–C_m–N^+ (m=0, 4, and 10) which all give fully developed bilayers, the reaction rate decreases as the spacer becomes longer (see also Fig. 4b). The same trend is found for a series of less developed bilayers: C_7–BB–C_m–N^+ (m=0, 4, and 10). The spacer effect is similarly noticed when amphiphiles C_{12}–BB–C_m–N^+ are buried in the $2C_{16}N^+2C_1$ bilayer matrix and in the CTAB micelle (Table 1), but it totally disappears in 50 v/v% EtOH–H_2O. The ordered structure may persist in the CTAB micelle.

Additional examples of the spacer effect are obtained for Schiff-base exchange reaction of the azomethine bilayer with amines. As shown in Fig. 7, the reaction rate decreases with increasing spacer lengths, and the extent of the spacer effect (rate difference) varies with the structure of amines. Benzylamine produces the smallest spacer effect and the rate difference is largest for poly(ethylenimine). Benzylamine should be incorporated into the bilayer matrix relatively nonspecifically; hence, small spacer effects. Dodecylamine is expected to align better in the membrane matrix. This factor would lead to larger differences in relative rate. Poly(ethylenimine) is highly water-soluble, and would not readily penetrate into the bilayer matrix. In consistence with this supposition, the azomethine moiety near the membrane surface (no spacer) reacts much faster with the polymer than those buried in the membrane (spacer: C_4 and C_{10}).

As for the reactant orientation in the bilayer matrix, Czarniecki and Breslow examined the photosensitized hydrogen abstraction by benzophenones in the dihexadecyl phosphate bilayer.[16] They showed the bilayer lamella produced better orientation of the reagents than the bilayer vesicle, although the difference was not remarkable.

Membrane Physical State and Reactivity. The Arrhenius plots of the azomethine reaction show discontinuity near the phase transition of the respective membrane (Fig. 5). When the reaction was carried out in the $2C_{16}N^+2C_1$ bilayer, an inflection in the Arrhenius plots was found at T_c of the matrix membrane (Fig. 6). No inflection was observed in the CTAB micelle. Figure 8 is schematic illustrations of the membrane physical state. The component molecules are highly aligned and the molecular movement is suppressed in the gel(crystalline) state. However, the alignment becomes less ordered and the alkyl chain can assume multiple conformations in the liquid-crystalline state, although the bilayer structure is maintained. This change in the membrane physical state could produce the reactivity difference, and discontinuities observed in the Arrhenius plots (Fig. 5) may be related to coexistence of the two physical states during phase transition.

Table 3 summarizes the apparent activation energy

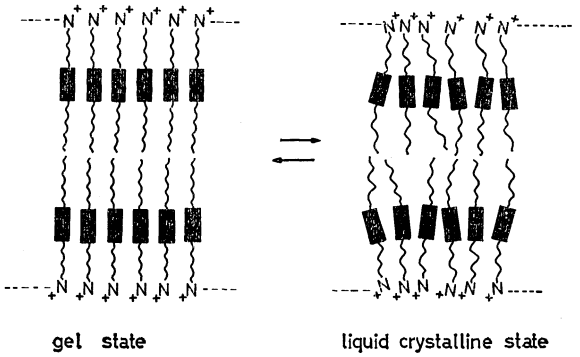

Fig. 8. Schematic illustrations of the phase transition of the C_n–BB–C_m–N^+ bilayer membrane.

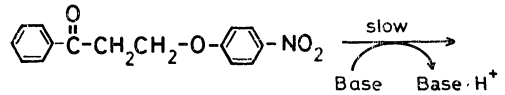
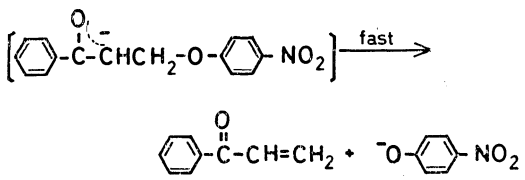
Table 3. Apparent activation energy of the reaction of C_{12}-BB-C_m-N^+ aggregates

Aggregate	E_a/kJ mol^{-1} Below T_c	Above T_c	ΔE_a
C_{12}-BB-N^+ bilayer	67	20	56
C_{12}-BB-C_4-N^+ bilayer	54	11	45
C_{12}-BB-C_{10}-N^+ bilayer	19	7.5	12
C_{12}-BB-C_{10}-N^+ in $2C_{16}N^+2C_1$ bilayer	16	12	4.2
C_{12}-BB-C_{10}-N^+ in CTAB micelle	(13)		—

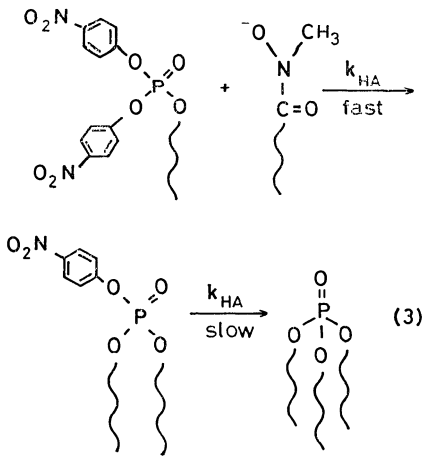
E_a of the reaction. In all the three single-component bilayers, the activation energy is greater in the temperature region below T_c than above T_c. This is not unexpected results, since the azomethine reactivity would certainly be suppressed in the rigid membrane matrix. In several reactions where reactants are buried in the membrane matrix, the activation energy increased in the temperature below T_c. For example, E_a was 167 and 84 kJ/mol at temperatures below and above T_c, respectively, in the case of proton abstraction of Eq. 2.[17] Nucleophilic displacement of a phosphate ester by hydroxamates (Eq. 3) gave similar E_a difference (88 and 59 kJ/mol)[18]





(2)

In the present system, the E_a values observed at temperatures above T_c are small and, correspondingly, its variation among different bilayers (C_{12}–BB–C_m–N^+, m=0, 4, and 10) is small. The E difference is much greater at temperatures below T_c. In both cases, E_a values become smaller as the spacer length is increased, and the E_a difference due to phase transition (ΔE_a) is 58 kJ/mol for the C_{12}–BB–N^+ bilayer and is only 12 kJ/mol for the C_{12}–BB–C_{10}–N^+ bilayer. It has been pointed out that longer spacers lead to stabilization of the bilayer structure.[8] The rate constant of the azomethine reaction decreases with the spacer length (Table 1). Thus, it is suggested that the temperature dependence is diminished for well-developed bilayers or when the reacting moiety is buried deep in the matrix. Interestingly, the concentration dependence of the reaction rate shows a pattern (Fig. 4b) analogous to that of the temperature effect in that the reaction of the C_{12}–BB–C_{10}–N^+ bilayer gives a much reduced concentration dependence relative to that of the C_{12}–BB–N^+ bilayer.



(3)

When C_{12}–BB–C_{10}–N^+ is buried in the $2C_{16}N^+2C_1$ matrix, the reactivity is much enhanced and an inflection in the Arrhenius plots is observed near T_c of the matrix membrane. The enhanced reactivity suggests that the cluster formation of C_{12}–BB–C_{10}–N^+, if present, is not significant. The inflection observed at T_c of the matrix membrane, not at T_c of the substrate itself, is not inconsistent with the cluster formation.

Conclusion

It is established in this investigation that the reactivity of a functional group is governed by molecular orientation (bilayer formation) in the aggregate, and if bilayer is formed, by distance from the membrane surface and membrane physical state. These results would provide valuable information on peculiar reactivities associated with bilayer characteristics.

Restricted Rotation Involving the Tetrahedral Carbon. XLVII. The "Positive" and the "Negative" Buttressing Effects on the Rotational Barriers in 9-(1,1-Dimethyl-2-phenylethyl)-1-halotriptycenes[1)]

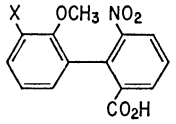
Gaku YAMAMOTO, Masahiko SUZUKI, and Michinori ŌKI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

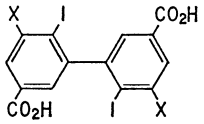
(Received October 9, 1982)

9-(1,1-Dimethyl-2-phenylethyl)-1,2,3,4-tetrahalotriptycenes (halogen=F, Cl, and Br) were synthesized and the kinetic studies of the rotational isomerization were made. The obtained data were compared with those for the corresponding 1-halo derivatives. The equilibrium constants (±*sc*/*ap*) for the tetrahalo compounds are smaller than those for the respective monohalo counterparts. The tetrafluoro compound isomerizes twice slower than the monofluoro one at 240 °C, showing the "positive" buttressing effect. Contrarily, the tetrachloro and the tetrabromo compounds isomerize 13 and 100 times, respectively, faster than the corresponding monohalo compounds at 175 °C, exhibiting the "negative" buttressing effect. These intriguing phenomena are discussed in terms of the molecular deformation in these congested compounds, which affects both the ground state and the transition state for rotation.

In 1934, Chien and Adams found that the presence of a substituent in 3′-position considerably reduces the rate of racemization of the optically active 2-carboxy-2′-methoxy-6-nitrobiphenyl (**1**),[2)] the degree of retardation being dependent on the 3′-substituent. The origin of the effect was not fully understood at that time. Later, Rieger and Westheimer found that 2,2′-diiodo-5,5′-dicarboxybiphenyl (**2a**) racemizes 30,000 times faster than 2,2′,3,3′-tetraiodo-5,5′-dicarboxybiphenyl (**2b**),



1



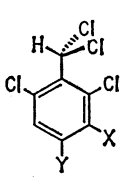
2a: X=H
2b: X=I

the enthalpies of activation being 21.0 and 27.3 kcal mol^{-1} (1 cal=4.18 J), respectively.[3)] These enthalpy values were satisfactorily reproduced by calculation in their pioneering works on molecular mechanics. The calculation revealed the origin of the retarding effects of the *m*-substituents, which is now recognized as the buttressing effect. In the planar transition state for racemization, the ortho groups bend away from each other to relieve the steric strain. Presence of a group in the neighboring meta position prevents the bending to some extent by "buttressing" the *o*-substituent, thus raising the transition state energy. The ground state in these compounds is considered almost free of strain, and the buttressing by the *m*-substituents docs not appreciably affect the ground state energy. Therefore, the buttressing effect operates to increase the energy barrier to racemization, which we refer to as the "positive" buttressing effect.

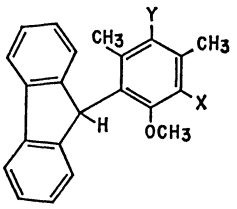
The buttressing effect on the energy barrier to internal rotation about an sp^2-sp^2 single bond is generally positive, because the ground state of the molecule is not much affected by the introduction of a buttressing substituent. However, when internal rotation about an sp^2-sp^3 or sp^3-sp^3 bond is concerned, the situation is somewhat different because the ground state usually suffers from some congestion.

If a substituent is introduced into the neighborhood of a congested site, it would increase the congestion and would raise the ground state energy. Since an energy barrier to rotation is a difference in energies between the ground and the transition states, if the change in the ground state energy is not negligible, it is possible that the buttressing effect either raises or lowers the barrier. The transition state is naturally more congested than the ground state and hence the buttressing effect should operate more effectively in the transition state than in the ground state: this results in the "positive" buttressing effect on the energy barrier, as is commonly observed.

Some examples of the buttressing effect on the energy barrier to rotation about an sp^2-sp^3 bond are known. The buttressed compound **3b** showed a higher barrier to rotation of the dichloromethyl group than **3a** ($\Delta G^{\ddagger}_{298}$: 15.4 *vs.* 14.9 kcal mol^{-1}).[4)] We observed the positive buttressing effect in 9-arylfluorenes (**4**) as



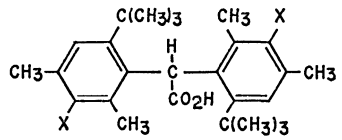
3a: X=H, Y=Cl
3b: X=Cl, Y=H



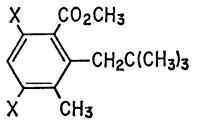
4

well. Free energies of activation for rotation at 329 K are 25.0 kcal mol^{-1} if X=Y=H, 25.9 kcal mol^{-1} if X=H and Y=Br, 26.5 kcal mol^{-1} if X=Br and Y=H, and 27.2 kcal mol^{-1} if X=Y=Br.[5)]

Though not definite, there are a few examples of the "negative" buttressing effect, namely, the lowering of the barrier by the presence of a buttressing substituents, in the literature. The barrier to racemization of optically active **5** decreases by the introduction of methyl groups in *m*-positions ($\Delta G^{\ddagger}_{298}$: 22.8 *vs.* 22.1 kcal mol^{-1}).[6)] Since there are two C–C$_{ar}$ bonds about which internal rotation is restricted, the observed barriers may not be mechanistically simple, although the authors attributed the retardation to the increase in the ground state energy.[6)] In compounds **6**, the

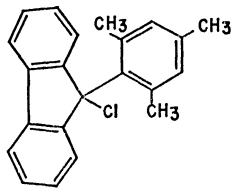


5: X=H or CH_3

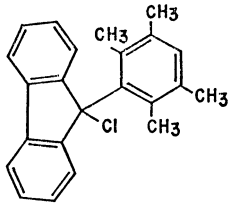


6: X=H or CH_3

rotational barrier of the neopentyl group is reduced by the presence of buttressing methyl groups ($\Delta G^{\ddagger}_{398}$: 14.6 *vs.* 13.8 kcal mol^{-1}).[7] In this case, the barrier reduction was ascribed to the change in conformation of the ester group because the ester moiety can no longer be coplanar with the benzene ring in the presence of the neighboring methyl group. The barrier to exchange of the diastereotopic *o*-methyl groups was suggested to be higher in compound **7** than in **8**.[8]



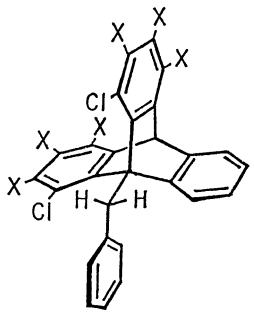
7



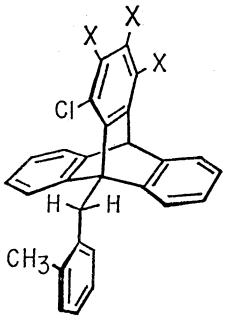
8

This fact was interpreted by the original authors in terms of sterically accelerated ionization followed by ion-pair return.[8] This conclusion was questioned from the results in solvent effect studies: the barriers showed no appreciable solvent dependence.[9] Thus one of the remaining possibilities is the restricted rotation about the C_9–C_{ar} bond which is subjected to the "negative" buttressing effect.

Several examples of the buttressing effect in sp^3-sp^3 systems have been found during the course of our studies on rotational barriers in 9-substituted triptycene derivatives. Dynamic NMR studies revealed that the barrier to the $+sc \rightleftarrows -sc$ interconversion in **9b** is 2.0



9a: X=H
9b: X=Cl



10: X=H or Cl

kcal mol^{-1} higher than in **9a** ($\Delta G^{\ddagger}_{c}$: 18.1 kcal mol^{-1} at 100 °C *vs.* 16.1 kcal mol^{-1} at 60 °C).[10] This suggests that the buttressing effect destabilizes the transition state to a greater extent than the ground state. A similar but less remarkable trend was also observed in the stereodynamics of compounds **10**.[11]

Recently we found an interesting dependence of the energy barrier to rotation upon the *peri*-substituent in 9-*t*-alkyltriptycenes.[12,13] In a series of 9-(1,1-dimethyl-2-phenylethyl)triptycene derivatives (**11**—**17**), the

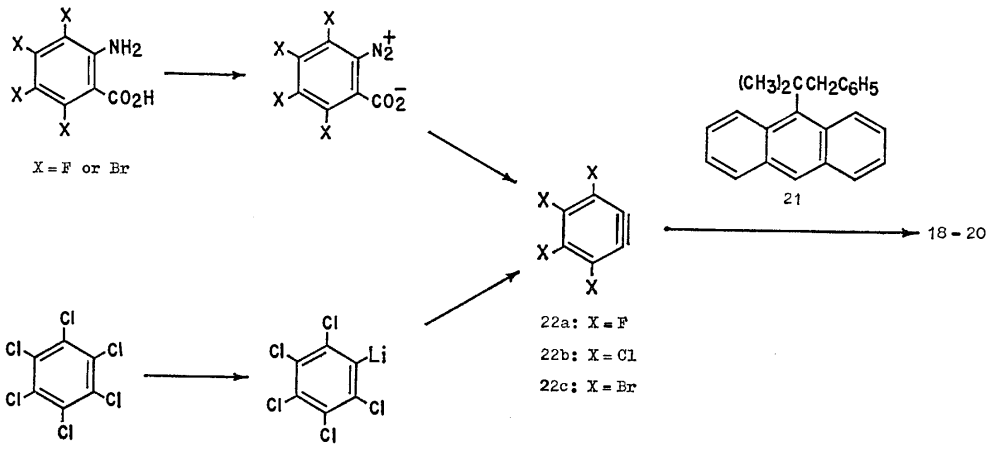
	X	Y	Z
11	H	Cl	H
12	F	H	H
13	Cl	H	H
14	Br	H	H
15	OCH_3	H	OCH_3
16	CH_3	H	CH_3
17	CF_3	H	H
18	F	F	F
19	Cl	Cl	Cl
20	Br	Br	Br

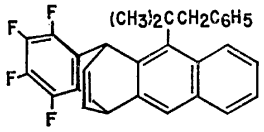
compounds with small *peri*-substituents, **12** and **15**, show higher barriers ($\Delta G^{\ddagger}_{500}$: 43.2 and 42.5 kcal mol^{-1}, respectively) than the *peri*-unsubstituted derivative **11** ($\Delta G^{\ddagger}_{500}$: 40.4 kcal mol^{-1}), but the *peri*-chloro compound **13** has almost the same barrier ($\Delta G^{\ddagger}_{500}$: 40.4 kcal mol^{-1}) as **11** and those with the even bulkier *peri*-substituent, **14**, **16**, and **17**, have lower barriers than **11**, the barrier height decreasing in this order ($\Delta G^{\ddagger}_{500}$: 39.2, 38.4, and 33.8 kcal mol^{-1}, respectively).[13] This implies that the presence of a bulky *peri*-substituent destabilizes the transition state to a lesser extent than the ground state.

It seemed interesting to investigate how the buttressing effect affects the energy barrier in these circumstances. We report in this paper the kinetic studies on the rotational barriers in 9-(1,1-dimethyl-2-phenylethyl)-1,2,3,4-tetrahalotriptycenes (**18**—**20**) to provide clear examples of the "negative" buttressing effect, comparing the data with those for the 1-halo counterparts **12**—**14** reported before.[13] The "positive" and the "negative" buttressing effects observed are discussed in terms of the molecular deformation in this highly congested system.[14]

Results

Syntheses. The tetrahalotriptycenes **18**—**20** were synthesized by reactions of 9-(1,1-dimethyl-2-phenylethyl)anthracene (**21**) with tetrahalobenzynes **22a**—**22c**. Tetrafluoro- and tetrabromobenzynes were generated by pyrolysis of the corresponding tetrahalo-2-diazoniobenzoates prepared from the respective anthranilic acids, while tetrachlorobenzyne was generated by pyrolysis of pentachlorophenyllithium prepared from hexachlorobenzene and butyllithium.[15] Reaction of either **22b** or **22c** with **21** afforded the *ap* atropisomer of the respective triptycene as a sole product.[17] Tetrafluorobenzyne (**22a**) reacted with **21** to give two products in a 3:2 ratio. The major product was the desired triptycene *ap*-**18**, and the minor one was assigned to a 1,4-adduct **23** by the ^{1}H NMR spectrum. As the chromatographic separation of **23** from *ap*-**18** seemed tedious, isolation of *ap*-**18** was performed by oxidative degradation of **23** with potassium permanganate followed by chromatography. The $\pm sc$ rotamers of **18**—**20** were isolated in pure forms from the equilibrated mixture of the rotamers by column chromatography. In each case, the $\pm sc$ rotamer eluted faster than the corresponding *ap* rotamer, in sharp contrast with the behavior exhibited by the 1-halo derivatives **12**—**14**, where the *ap* rotamers eluted faster.[13]





23

Kinetics. Kinetic measurements of rotamer isomerization were performed in 1-chloronaphthalene solutions according to the procedure described before.[13] Equilibrium and rate constants at several temperatures and the free energies of activation therefrom are compiled in Table 3. Allowance for the degeneracy of the $\pm sc$ rotamers is made in the calculations of the van't Hoff and the Eyring parameters, which are given in Table 1. Table 2 shows a comparison of the data with those of the 1-halo counterparts. Comparison is made at 240 °C for the fluoro pair and at 175 °C for the chloro and the bromo pairs. The reference temperatures are chosen because they are nearly the midpoints of the temperature range in which the kinetic measurements were made for each pair.

Discussion

Buttressing Effect on the Ground State Properties. A 9-*t*-alkyltriptycene is a highly congested molecule with some of the atoms in 9-*t*-alkyl group locating within the sum of the van der Waals radii from the triptycyl skeleton. Substitution at a *peri*-position increases the congestion so that the C_9–C_{alkyl} bond is forced to bend away from the *peri*-substituent. This feature was actually observed in the X-ray structure of 9-*t*-butyl-1,2,3,4-tetrachlorotriptycene.[18] It deserves to mention here that the 1,2,3,4-tetrachlorobenzo group is almost planar including the chloro groups. It would not have been possible to discuss the buttressing effect if the chloro groups deviated seriously from coplanarity. We assume the compounds in question take the similar structure. Then 9-(1,1-dimethyl-2-phenylethyl)-1,2,3,4-tetrahalotriptycenes (**18**—**20**) are supposed to be more crowded than the corresponding 1-halo compounds (**12**—**14**) in the vicinity of the axis bond.

A long-range spin-spin coupling is observed between the 1-fluorine and protons in the $\pm sc$-methyl group in any of the fluorine-containing atropisomers.[19] The coupling constant is larger in a tetrafluoro rotamer (9.2 Hz in *ap*-**18**, and 8.3 Hz in $\pm sc$-**18**) than in the corresponding monofluoro one (8.4 Hz in *ap*-**12** and 7.9 Hz in $\pm sc$-**12**), which may be the consequence of the closer proximity between the methyl group and the 1-fluorine in the tetrafluoro rotamers than in the monofluoro counterparts.

The buttressing effect in the ground state is manifested in the rotamer equilibrium. Table 2 shows that the equilibrium constants ($\pm sc/ap$) for the tetrahalo compounds are slightly smaller than those for the monohalo counterparts regardless of the kind of halogen. Increase in congestion by the presence of the buttressing halogens should cause a greater destabilization of the $\pm sc$ rotamer than the *ap* because the former has the bulkier benzyl group in the $\pm sc$ site. Thermodynamic data on **11**—**17** show that the equilibrium constant monotonously decreases as the bulkiness of the *peri*-substituent becomes larger. In this context, the buttressing effect in the ground state is understood as the increase in the effective bulkiness of the *peri*-halogen substituent in the tetrahalo compounds relative to the respective monohalo ones.

Buttressing Effect on the Rotational Barriers. Phenomenological Aspects: Plotting the barriers to rotation in 1-substituted 9-(1,1-dimethyl-2-phenylethyl)triptycenes **11**—**17** against the bulkiness (van der Waals radius) of the 1-substituent, we find a maximum at the 1-fluoro compound **12** and a gradually descending curve as the bulkiness increases.[13] This will imply that in compounds with a *peri*-substituent bulkier than fluorine, the presence of a buttressing substituent should lower the barrier, exhibiting the negative buttressing effect.

The tetrachloro compound **19** isomerizes 13 times faster than the monochloro counterpart **13** at 175 °C with the barrier drop of 2.3 kcal mol^{-1}, manifesting the negative buttressing effect. Even more conspicuous negative effect is found in the tetrabromo compound **20**, which isomerizes 100 times faster than the monobromo one **14** at 175 °C, the drop in the free energy of activation being 4.1 kcal mol^{-1}. Appearance of the negative effect in these compounds are in line with the expectation discussed above. A greater magnitude of the effect in the tetrabromo compound **20** than in the tetrachloro one **19** is also reasonable on the ground

TABLE 1. THERMODYNAMIC AND KINETIC PARAMETERS FOR 9-(1,1-DIMETHYL-2-PHENYLETHYL)-1,2,3,4-TETRAHALOTRIPTYCENES[a]

a) Only the equilibrium constant is obtained.

mentioned above, because both the buttressing and the buttressed halogens are bulkier in **20** than in **19**.

As for the tetrafluoro compound **18**, it is difficult to predict *a priori* the sign of the buttressing effect, since the 1-fluoro compound **12** gives a maximal barrier in the series of compounds **11**—**17**: the introduction of a buttressing substituent could lower the barrier, if a phantom substituent smaller than fluorine gives a real maximum in the series, and the reverse could occur if a phantom substituent a little bulkier than fluorine gives a maximum. In practice, the tetrafluoro compound **18** isomerizes twice slower than the monofluoro one **12** at 240 °C, exhibiting a small positive buttressing effect. This fact is an indication that a compound with a *peri*-substituent slightly bulkier than fluorine, if existed, should give a maximal barrier in a series of 1-substituted 9-(1,1-dimethyl-2-phenylethyl)triptycenes.

Analysis of the Barrier: Although the simple explanation in terms of the increase in the effective bulkiness of the *peri*-halogen substituent is possible for the observed buttressing effect, it turns out to be too rough in some cases. For example, the equilibrium constant for the tetrachloro compound **19** (0.44 at 175 °C) is almost identical with that for the monobromo compound **14** (0.43), and hence we can say that the 1-chlorine in **19** has almost the same effective bulkiness as the 1-bromine in **14**. However, the rotational barrier in **19** is lower than that in **14** by 1.0 kcal mol^{-1}. This implies that the buttressing effect on the energy barrier operates somewhat differently from that on the ground state and thus we must consider the effect on the transition state in some detail.

We have developed a hypothesis which uses a rigid rotor model to explain the observed dependence of the barrier on the bulkiness of the 1-substituent; that is, the lowering of the barrier with the increasing bulkiness of the *peri*-substituent should at least partly ascribed to lowering of the transition state energy.[13] The hypothesis states that a bulky *peri*-substituent in-

duces the deformation of the molecule typically manifested in the tilting of the axis bond of the 9-substituent away from the *peri*-substituent. If this feature is retained during the rotation about the axis bond, the maximal eclipsing interactions between the β-groups of the 9-substituent and the *peri*-substituent or hydrogens do not occur simultaneously at the three sites but sequentially with some time lags. Therefore, the transition state is not destabilized to such an extent that would be expected from the bulkiness of the *peri*-substituent, causing the decrease in the barrier. As the *peri*-substituent becomes bulkier, these time lags should become larger and hence the barrier should become lower, which was actually observed.

However this hypothesis still fails to explain the differential behavior observed in compounds **14** and **19**. The fact that **19** has a lower barrier to rotation than **14** suggests that the transition state for rotation in **19** is more "stabilized" than that in **14** relative to the respective ground state. A possible rationalization may be as follows. In order to relieve a large congestion in the transition state, 9- and *peri*-substituents further bend away from each other. While the 1-bromo group in **14** is prone to easy in-plane bending away from the 9-substituent, the bending of the 1-chloro group in **19** is restricted because of the buttressing effect. Hence the axis bond of the 9-substituent in **19** suffers a greater additional tilting than that in **14** on going from the ground to the transition state. This results in the larger time lags between the maximal eclipsing interactions in the transition state and thus the lower barrier in **19** than in **14**.

Thus we have to admit that the molecule is subjected to further deformation in the course of internal rotation for the better understanding of the buttressing effect. We conclude that the negative buttressing effect is originated from the fact that the transition state for rotation is less destabilized than the ground state upon introduction of a buttressing substituent.

Experimental

Melting points are not corrected. ^{1}H NMR spectra were obtained on a Hitachi R-20B (60 MHz) or a Varian EM-390 (90 MHz) spectrometer with tetramethylsilane as an internal reference. ^{19}F NMR spectra were recorded on a Varian EM-390 at 84.67 MHz with hexafluorobenzene as an internal reference, and the chemical shifts are given in ppm downfield from C_6F_6.

ap-*9-(1,1-Dimethyl-2-phenylethyl)-1,2,3,4-tetrafluorotriptycene* (ap-**18**). A solution of 1.05 g (5 mmol) of 1,2,3,4-tetrafluoroanthranilic acid[20] in 15 mL of dry acetone was added dropwise to a boiling solution of 764 mg (2.46 mmol) of 9-(1,1-dimethyl-2-phenylethyl)anthracene (**21**)[21] and 1 mL of isopentyl nitrite in 20 mL of dichloromethane during the course of 1 h. The mixture was heated under reflux for 1 h and evaporated. The residue was chromatographed through an alumina column. The desired triptycene *ap*-**18** and a by-product, which was assigned to the 1,4-adduct (**23**) by its ^{1}H NMR [($CDCl_3$, δ): 1.80 (3H, s), 1.86 (3H, s), 3.33 and 3.67 (2H, AB-q, J=13.2 Hz), 5.42 (1H, td J=1.7 and 6.0 Hz), 5.99 (1H, br d, J=6.2 Hz), 6.34 (1H, ddd, J=1.6, 6.2, and 7.2 Hz)], eluted together, which weighed 519 mg (47%). The mixture was dissolved in 20 mL of acetone and chilled to 0 °C, to which a solution of 190 mg of potassium permanganate in 15 mL of water was added dropwise. The mixture was stirred at 0 °C for 2 h and evaporated. The residue was extracted with dichloromethane and chromatographed through an alumina column with hexane as eluent affording 208 mg (19% based on **21**) of *ap*-**18** as colorless crystals, mp 192—194 °C (from benzene–hexane). Found: C, 78.76; H, 5.08%. Calcd for $C_{30}H_{22}F_4$: C, 78.59; H, 4.84%. ^{1}H NMR ($CDCl_3$, δ): 2.04 (6H, d, J=9.2 Hz), 3.87 (2H, s), 5.74 (1H, br d, J=1.6 Hz), 6.9—7.7 (11H, m), 8.08 (2H, m). ^{19}F NMR ($CDCl_3$): 2.96 (t, J=19.5 Hz, 2-F), 3.59 (ddd, J=22.0, 19.4, and 5.3 Hz, 3-F), 12.80 (dd, J=22.0 and 13.7 Hz, 4-F), 38.05 (br, 1-F).

±sc-*9-(1,1-Dimethyl-2-phenylethyl)-1,2,3,4-tetrafluorotriptycene* (±sc-**18**). The equilibrated mixture of the rotamers was chromatographed on alumina with hexane as eluent. The ±*sc* rotamer eluted faster than the *ap*, and was recrystallized from tetrahydrofuran–hexane, mp 203—204 °C. Found: C, 78.88; H, 4.66%. Calcd for $C_{30}H_{22}F_4$: C, 78.59; H, 4.84%. ^{1}H NMR ($CDCl_3$, δ): 1.95 (3H, d, J=8.3 Hz), 2.09 (3H, s), 2.61 (1H, d, J=14.1 Hz), 3.97 (1H, dd, J=14.1 and 2.4 Hz), 5.70 (1H, br d, J=1.6 Hz), 6.9—7.7 (12H, m), 7.81 (1H, m). ^{19}F NMR ($CDCl_3$): 3.24 (t, J=19.8 Hz, 2-F), 4.03 (ddd, J=22.9, 19.8, and 6.1 Hz, 3-F), 12.79 (dd, J=22.9 and 13.4 Hz, 4-F), 40.40 (br, 1-F).

ap-*1,2,3,4-Tetrachloro-9-(1,1-dimethyl-2-phenylethyl)triptycene* (ap-**19**). To a suspension of 3.68 g (12.9 mmol) of hexachlorobenzene in 200 mL of diethyl ether was added dropwise a solution of 13 mmol of butyllithium in hexane at −78 °C. The mixture was stirred at −78 °C until the solid had disappeared, to which an ethereal solution of 1.5 g (4.84 mmol) of **21** was added dropwise. The mixture was allowed to slowly warm up to room temperature, and then heated under reflux for 2 h. Column chromatography on alumina with hexane–benzene as eluent gave a mixture of *ap*-**19** and unidentified by-products, presumably polychlorobiphenyls. Repeated chromatographies and recrystallizations from tetrahydrofuran–methanol afforded a pure sample of *ap*-**19**, mp 283—285 °C. Found: C, 68.73; H, 4.25; Cl, 26.79%. Calcd for $C_{30}H_{22}Cl_4$: C, 68.72; H, 4.23; Cl, 27.05%. ^{1}H NMR ($CDCl_3$, δ): 2.36 (6H, s), 3.81 (2H, s), 6.12 (1H, s), 7.0—7.6 (11H, m), 8.08 (2H, m).

±sc-*1,2,3,4-Tetrachloro-9-(1,1-dimethyl-2-phenylethyl)triptycene* (±sc-**19**). The equilibrated mixture of the rotamers was chromatographed on alumina with benzene–hexane as eluent. ±*sc*-**19** eluted faster than *ap*-**19**. Recrystallization from tetrahydrofuran–hexane afforded pure ±*sc*-**19**, mp 231—232 °C. Found: C, 68.71; H, 4.17; Cl, 26.64%. Calcd for $C_{30}H_{22}Cl_4$: C, 68.72; H, 4.23; Cl, 27.05%. ^{1}H NMR ($CDCl_3$, δ): 2.12 (3H, s), 2.37 (3H, s), 4.13 and 4.37 (2H, AB-q, J=15.2 Hz), 6.11 (1H, s), 6.9—7.7 (11H, m), 7.92 (1H, m), 8.16 (1H, m).

ap-*1,2,3,4-Tetrabromo-9-(1,1-dimethyl-2-phenylethyl)triptycene* (ap-**20**). A solution of 2.7 g (6 mmol) of tetrabromoanthranilic acid[22] in 10 mL of 1,2-dimethoxyethane (DME) was added dropwise to a boiling solution of 486 mg (1.56 mmol) of **21** and 1 mL of isopentyl nitrite in 20 mL of DME during the course of 2.5 h. The mixture was heated under reflux for 1 h, evaporated and chromatographed on alumina with dichloromethane–hexane as eluent, affording 194 mg (18%) of *ap*-**20**, mp 291—293 °C (from tetrahydrofuran–hexane). Found: C, 51.30; H, 2.88%. Calcd for $C_{30}H_{22}Br_4$: C, 51.32; H, 3.16%. ^{1}H NMR ($CDCl_3$, δ): 2.51 (6H, s), 3.75 (2H, s), 6.24 (1H, s), 7.0—7.6 (11H, m), 8.10 (2H, m).

±sc-*1,2,3,4-Tetrabromo-9-(1,1-dimethyl-2-phenylethyl)triptycene*

(±sc-20). Addition of hexane to the equilibrated mixture of rotamers of **20** in 1-chloronaphthalene caused selective crystallization of *ap*-**20**, leaving the ±*sc*-enriched mixture in the mother liquor, which was chromatographed on alumina with hexane as eluent. The ±*sc* rotamer eluted slightly faster than the *ap*. The fractions containing almost pure ±*sc*-**20** was evaporated and recrystallized from tetrahydrofuran–hexane, affording a pure sample of ±*sc*-**20**, mp 223—225 °C. Found: C, 51.57; H, 3.28; Br, 45.55%. Calcd for $C_{30}H_{22}Br_4$: C, 51.32; H, 3.16; Br, 45.52%. ^{1}H NMR ($CDCl_3$, δ): 2.01 (3H, s), 2.57 (3H, s), 4.08 and 4.67 (2H, AB-q, J=15.5 Hz), 6.23 (1H, s), 6.9—7.7 (11H, m), 7.95 (1H, m), 8.15 (1H, m).

Kinetic Measurements. The experimental procedures described before[13] were followed. Relative populations of the rotamers were obtained by integrating the 1-fluorine signals for **18** and the *gem*-dimethyl signals for **19** and **20**. The liquids used for the boiling bath were shown in Table 3. The equilibrium constant for **20** at 202 °C was obtained in a conventional silicone oil bath.

Acyl Transfer from *S*-Monoacyldihydrolipoamide to Benzylamine in the Presence of Oxidizing Agents

Yoko Nambu,* Takeshi Endo, and Makoto Okawara

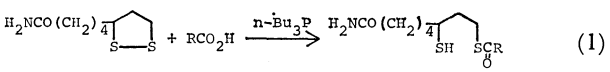
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227

(Received October 26, 1982)

Acyl transfer reaction from *N*-benzyl-8-*S*-(*p*-nitrobenzoyl)dihydrolipoamide to benzylamine was enhanced with oxidizing agents such as cobalt(II) ion or a soluble flavin under an oxygen atmosphere or with di-4-pyridyl disulfide, accompanied by the formation of *N*-benzyllipoamide.

Lipoic acid is known to work as an acyl carrier in the oxidative decarboxylation of α-keto acids in living systems through formation of active acyl intermediates, 6-*S*-acyldihydrolipoic acids which in turn acylate coenzyme A, and subsequent oxidation of the resultant dihydrolipoic acid to lipoic acid, enzymatically.

We have already reported that 8-*S*-monoacyldihydrolipoamides were synthesized by the reductive acylation of lipoamide with tributylphosphine in high yields (Eq. 1).[1]



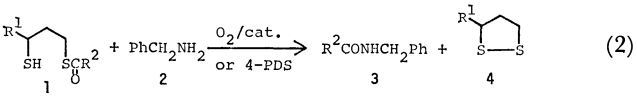
(1)

Further, we have found that acyl transfer from *S*-monoacyldihydrolipoamides to amine was accelerated by silver ion more effectively than that from *S,S'*-diacyl derivatives, caused by the activation of acyl group by silver ion bound to the neighboring mercapto group.

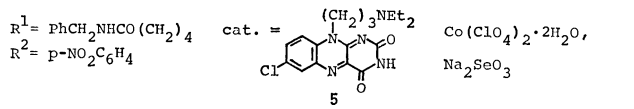
On the other hand, the acyl transfer from hydroquinone monobenzoates to alcohols has been reported to proceed oxidatively by use of oxidizing agents such as Ce^{4+}, Tl^{3+}, NBS, or Br_2,[3] and by electrochemical oxidation.[4]

These results suggested us to investigate the acyl transfer from *S*-monoacyldihydrolipoamide to amines in the presence of oxidizing agents for thiols, expecting that the activation of acyl group through two-electron oxidation of neighboring mercapto group to form amide and lipoamide. Various kinds of oxidizing agents are considered to be applied to the present case. However, by using some oxidizing agents which form S radicals rather than S cations from thiols, the dimerization of *S*-monoacylated dithiols might precede the activation of acyl groups, as reported in the iodine oxidation of 8-*S*-acetyldihydrolipoic acid in methanol[5] (Scheme 1).

We now report the acyl transfer from *N*-benzyl-8-*S*-(*p*-nitrobenzoyl)dihydrolipoamide (**1**) to benzylamine (**2**) in the presence of oxidizing agents such as an active flavin (**5**),[6] metal salts,[7] and di-4-pyridyl disulfide (4-PDS),[8] which are known to oxidize thiols to disulfides *via* the formation of complexes or adducts between oxidizing agents and thiols (Eq. 2).



(2)



Experimental

^{1}H-NMR spectra were recorded on a JEOL-PMX 60 NMR spectrometer using tetramethylsilane as an internal reference.

N-Benzyl-8-*S*-(*p*-nitrobenzoyl)dihydrolipoamide (**1**) and *N*-benzyl-*S,S'*-bis(*p*-nitrobenzoyl)dihydrolipoamide were prepared by the methods reported previously.[2b] An active flavin (**5**) was also prepared according to the procedure of King *et al.*[9] GLC analyses were carried out on a JEOL-1100 gas chromatograph (10% SE-30, stainless-steel column, 220 °C, N_2 carrier gas).

*Acyl Transfer Reaction from Monoacyl Derivative **1** to Benzylamine (**2**) in the Presence of Cobalt(II) Perchlorate as Catalyst.* To a THF solution (3 ml) of **1** (20 mg, 0.045 mmol) and amine **2** (0.1 ml, 0.9 mmol) was added cobalt(II) perchlorate (1.2 mg, 0.004 mmol) under an oxygen atmosphere and stirred for 15 h at room temperature. The reaction mixture was poured into ethyl acetate (50 ml), and the solution was washed with 0.1 M† HCl and saturated aqueous NaCl, then dried over $MgSO_4$. The solvent was removed under reduced pressure to obtain a solid residue. ^{1}H-NMR spectrum of the residue in $CDCl_3$ was measured to show a quantitative formation of *N*-benzyl-*p*-nitrobenzamide (**3**) and *N*-benzyllipoamide (**4**) compared with the authentic samples. The yield of amide **3** was calculated from the ratio of the ^{1}H-NMR signal of benzyl proton in **3** (δ=4.6) to the sum of benzyl protons in **1** and **4** (δ=4.4) to be 100% (Fig. 1). The residue obtained in the scale up experiment (two times of the above procedure) was chromatographed on silica gel with ethyl acetate to obtain amide **3** (18 mg, 78%) and **4** (19 mg, 71%). Authentic sample of **3** was prepared from *p*-nitrobenzoyl chloride and benzylamine mp 142.5—143.5 °C (from ethanol) (lit,[10] 141—142.5 °C); NMR ($CDCl_3$): δ 4.6 (2H, d, J=5.8 Hz, $PhCH_2$), 5.9 (1H, s, NHCO), 7.4 (5H, s, C_6H_5), 8.1 (4H, q, J=9.2 Hz, *p*-$NO_2C_6H_4$). Amide **4** was prepared by the method reported previously.[2c] NMR ($CDCl_3$): δ 1.5—2.0 (8H, m, $>CH_2$), 3.2 (2H, t, 5-membered CH_2–SS), 3.6 (1H, m, CH–SS), 4.4 (2H, d, J=5.7 Hz,

† 1 M = 1 mol dm^{-3}.

$PhCH_2$), 5.9 (1H, s, NHCO), 7.3 (5H, s, C_6H_5).

In case of other catalysts or 4-PDS, the reaction was carried out in the same procedure as described above.

Kinetic measurements were carried out by GLC analyses of the reaction solutions operated in the same way described above at 30 °C in the presence of *N*-cyclohexyl-*p*-nitrobenzamide as an internal standard for GLC analyses.

Acyl Transfer Reaction from Monoacyl Derivative **1** *to Methanol in the Presence of Oxidizing Agents.* The reaction was carried out in the same way as described above. Methanol (1 ml, 24 mmol) and triethylamine (0.13 ml, 0.9 mmol) were added instead of amine **2** and allowed to react for 15 h at room temperature. The residue was chromatographed on silica gel with ethyl acetate as eluent to afford methyl *p*-nitrobenzoate (**8**) identical with the authentic sample prepared from *p*-nitrobenzoyl chloride and methanol. The yield of ester **8** was calculated from the ratio of ^{1}H-NMR signal of methyl proton in **8** (δ=4.0) to that of benzyl protons in **1** and **4** (δ=4.4).

Results and Discussion

The acyl transfer reaction was carried out by treating monoacyl derivative **1** with excess benzylamine (**2**) in tetrahydrofuran (THF) in the presence of some oxidizing catalysts under an oxygen atmosphere, or in the presence of 4-PDS under a nitrogen atmosphere at 30 °C. The progress of the reaction was followed by GLC analyses of the acyl transfer product, *N*-benzyl-*p*-nitrobenzamide (**3**), in the reaction solution (Fig. 1). In every case, the formation of **3** followed first-order kinetics, and pseudo first-order rate constants, *k*, were obtained from the slopes of the first-order plots (Table 1). The yields of **3** were determined by ^{1}H-NMR method by carrying out the acyl transfer reaction at room temperature for 15 h, and the results were summarized in Table 1 together with those obtained by treating a diacyl derivative, *N*-benzyl-*S*,*S*′-bis(*p*-nitrobenzoyl)dihydrolipoamide, with amine **2**.

In the presence of excess amine **2**, amide **3** was obtained in 55% yield without oxidizing agents. No or slight enhancement was observed by bubbling oxygen gas into the reaction mixture or by adding a catalytic amount of Co(II) ion under a nitrogen atmosphere. On the other hand, the acyl transfer reaction was promoted by adding catalytic amounts of flavin (**5**), Co(II), or Se(IV) ion to the reaction mixture of monoacyl derivative **1** and amine **2** under an oxygen atmosphere, as observed both in the rate enhancements and the increase of yields in Table 1. Co(II)

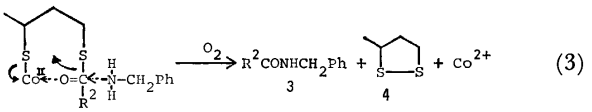
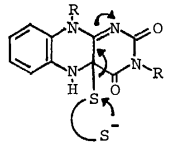
a) Conditions; monoacyl deriv. **1** 0.045 mmol (diacyl deriv. 0.023 mmol), amine **2** 0.9 mmol, cat. 0.004 mmol (4-PDS 0.045 mmol), THF 3 ml, room temperature, 15 h. b) Yields were determined by ^{1}H-NMR method as mentioned in experimental section. c) Kinetic measurements were carried out at 30 °C. d) *N*-Benzyl-*S*,*S*′-bis(*p*-nitrobenzoyl)dihydrolipoamide.

ion was the most effective catalyst to lead to the quantitative formation of amide **3** in the present reaction conditions. The ^{1}H-NMR spectrum of the products in the presence of Co(II) ion was shown in Fig. 2. Proton signal of mercapto group in **1** at $\delta=1.4$ (1H, d) disappeared completely by the reaction and new signals at $\delta=3.2$ (2H, d, $PhCH_2N$) appeared which suggested the quantitative formation of *N*-benzyllipoamide (**4**) accompanying the acyl transfer. However, only slight enhancement was observed by Co(II) ion catalyst in case of the acyl transfer reaction from diacyl derivative. Co(II) ion is known to catalyze the oxidation of dithiols to cyclic disulfides by oxygen effectively by way of complex formation.[7] It is presumed therefore that Co(II) ion catalyzed the acyl transfer oxidatively through the activation of acyl group by way of the complex formation with monoacyl derivative **1** as shown in Eq. 3.

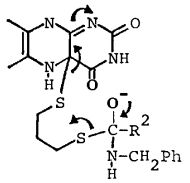


(3)

In the oxidation of dithiols by flavins, Loechler *et al.*[9] proposed the formation of a thiol-*C*(4a)-flavin adduct (**6**). Also in the present flavin catalyzed reaction, flavin (**5**) presumably enhanced the acyl transfer reaction oxidatively by the formation of adduct intermediate (**7**), and the reduced flavin formed might be reoxidized by oxygen to work catalytically.

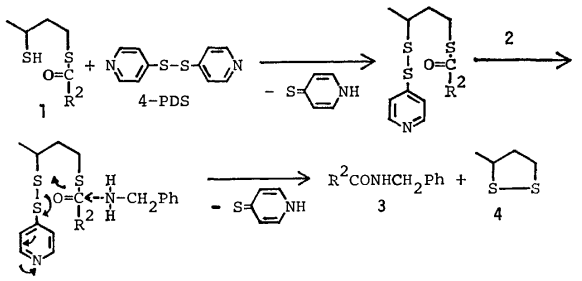


6



7

In he presence of 4-PDS as an oxidizing agent, acyl transfer reaction was enhanced most effectively to result in the quantitative formation of amide **3** and lipoamide **4**. The formation of 4(1*H*)-pyridinethione was ascertained from the UV spectrum of the reaction mixture (λ_{max}, 350 nm). Further 4-PDS is known to form reactive mixed disulfides with thiols very easily.[8] Therefore, the mechanism shown in Scheme 2 is proposed for the 4-PDS promoted acyl transfer reaction.



Scheme 2.

Table 2. Acyl transfer reaction from monoacyl derivative **1** to methanol[a]

Oxidizing agent	Yield of **8**/%[b]
None (N_2)	24
O_2/$Co(ClO_4)_2\cdot 2H_2O$	26
4-PDS	22
I_2	21

a) Conditions; monoacyl derivative **1** 0.045 mmol, methanol 24 mmol, Et_3N 0.9 mmol, cat. 0.004 mmol (4-PDS 0.045 mmol, I_2 0.05 mmol), room temperature, 15 h. b) Yields were determined by ^{1}H-NMR method as mentioned in experimental section.

The effect of oxidizing agents was further examined in case of the acyl transfer reaction from monoacyl derivative **1** to methanol. The reaction was carried out in the presence of various kinds of oxidizing agents and triethylamine (Et_3N). The results are shown in Table 2. No enhancement was observed for the formation of methyl *p*-nitrobenzoate (**8**) by adding oxidizing agents in the present reaction conditions, contrary to the reported results[5] where methanol was used as a solvent. The SH proton signal disappeared completely in ^{1}H-NMR spectrum of the reaction products. These results suggested that the dimerization of monoacyl derivative **1** preceded the enhancement of acyl transfer reaction in case of acyl transfer to weak nucleophiles such as alcohols.

The results in this study suggest that lipoamide might work as an acyl carrier in the synthesis of amides from carboxylic acids and amines by combining both the reductive acylation (Eq. 1) and the oxidative acyl transfer reaction (Eq. 2). We are planning to apply these reactions to a lipoamide immobilized on polystyrene beads to get a polymeric acyl carrier which is capable of recycle uses.

^{31}P NMR Study of Active Species for Ethylene Dimerization in σ-Aryl Nickel Complex–$AgClO_4$

Yoshimasa Ishimura, Ken-ichi Maruya,* Yoshiyuki Nakamura, Tsutomu Mizoroki, and Atsumu Ozaki

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227

(Received February 24, 1982)

$[NiBr(\sigma\text{-}C_6F_5)(PPh_3)_2]$ and $[NiCl(\sigma\text{-}C_6Cl_5)(PPh_3)_2]$ are active for ethylene dimerization in the presence of $AgClO_4$. The activity increases with increase in the amount of $AgClO_4$ and reaches maximum at $AgClO_4$/Ni-complex=2. Addition of excess $AgClO_4$ leads to marked decrease in activity with $[NiBr(\sigma\text{-}C_6F_5)(PPh_3)_2]$ but a little decrease with $[NiCl(\sigma\text{-}C_6Cl_5)(PPh_3)_2]$. ^{31}P NMR spectra of the active solution showed new resonance peaks due to $[Ni(ClO_4)(\sigma\text{-}C_6X'_5)(PPh_3)_2]$ and $[Ni(ClO_4)(\sigma\text{-}C_6X'_5)(PPh_3)]$ (X'=F,Cl), accompanying formation of AgX (X=Br,Cl) and $[Ag(ClO_4)(PPh_3)]$. Thus the role of $AgClO_4$ is to abstract halide anion and/or triphenylphosphine. The amount of $[Ni(ClO_4)(\sigma\text{-}C_6X'_5)(PPh_3)]$ is in good correlation with the rate of dimerization, which suggests this species to be catalytically active.

It has been shown that σ-aryl(halogeno)bis(triphenylphosphine)nickel(II), $[Ni(\sigma\text{-aryl})X(PPh_3)_2]$, is active for the dimerization of ethylene[1] and for the codimerization of ethylene with styrene[2] or 1,3-butadiene[3] in the presence of ether-boron trifluoride (1/1), $Et_2O\cdot BF_3$. During the course of our study on the effect of aryl ligands and $Et_2O\cdot BF_3$ on the dimerization, it has been found that $Et_2O\cdot BF_3$ combined with chloro(σ-pentachlorophenyl) bis (triphenylphosphine) nickel(II), $[NiCl(\sigma\text{-}C_6Cl_5)(PPh_3)_2]$, in the catalyst system can be effectively replaced by silver perchlorate, $AgClO_4$.[4] In the $[Ni(\sigma\text{-aryl})X(PPh_3)_2]$–$Et_2O\cdot BF_3$ system, the role of $Et_2O\cdot BF_3$ was suggested to form BF_3X^- and to abstract the phosphine ligand,[1] but no evidence to prove this has been reported. On the other hand, $AgClO_4$ is not so sensitive to water as $Et_2O\cdot BF_3$ and $[NiCl(\sigma\text{-}C_6Cl_5)(PPh_3)_2]$ is stabler than other σ-arylnickel(II) complexes such as $[NiBr(\sigma\text{-}C_6H_5)(PPh_3)_2]$ and $[NiBr(\sigma\text{-1-naphthyl})(PPh_3)_2]$.[5] The system comprising $[NiCl(\sigma\text{-}C_6Cl_5)(PPh_3)_2]$ and $AgClO_4$ is suitable to investigate the effects.

When chlorobis(methyldiphenylphosphine or dimethylphenylphosphine) (σ-pentachlorophenyl)nickel(II), $[NiCl(\sigma\text{-}C_6Cl_5)(PR_3)_2]$ (PR_3=$PMePh_2$ or PMe_2Ph), is treated with $AgClO_4$ in the presence of the ligand (L) such as lutidine, carbon monoxide, or water the corresponding cationic complex, $[Ni(\sigma\text{-}C_6Cl_5)(L)(PR_3)_2]ClO_4$ is isolated.[6,7] The reaction of the triphenylphosphine analogue, $[NiCl(\sigma\text{-}C_6Cl_5)(PPh_3)_2]$, with $AgClO_4$ is, however, too complicated to isolate the corresponding cationic complex, since the addition of excess $AgClO_4$ results in formation of triphenylphosphine–silver complex.[7] This suggests that $AgClO_4$ replaces the halide anion of the nickel complex with perchlorate anion and at the same time abstracts the triphenylphosphine ligand. Both bromobis (triphenylphosphine) (σ-pentafluorophenyl) nickel(II), $[NiBr(\sigma\text{-}C_6F_5)(PPh_3)_2]$,[8] and $[NiCl(\sigma\text{-}C_6Cl_5)(PPh_3)_2]$[4] are active for the dimerization of ethylene in the presence of $AgClO_4$. The reaction of $AgClO_4$ with $[NiBr(\sigma\text{-}C_6F_5)(PPh_3)_2]$ was investigated by means of ^{31}P NMR spectroscopy, suggesting a coordinatively unsaturated nickel complex, $[Ni(ClO_4)(\sigma\text{-}C_6F_5)(PPh_3)]$, to be an active species for the dimerization of ethylene.[8] This report is concerned with investigation of the reaction of $AgClO_4$ with $[NiCl(\sigma\text{-}C_6Cl_5)(PPh_3)_2]$ by means of ^{31}P NMR spectroscopy in addition to re-examination of the reaction with $[NiBr(\sigma\text{-}C_6F_5)(PPh_3)_2]$; the active species for the dimerization of ethylene is described.

Experimental

Materials. The preparation of nickel complexes and the purification of solvents were conducted in a nitrogen atmosphere, and they were kept under nitrogen. $[NiBr(\sigma\text{-}C_6F_5)(PPh_3)_2]$[9] and $[NiCl(\sigma\text{-}C_6Cl_5)(PPh_3)_2]$[10] were prepared according to the literature. Solvents were dried with diphosphorus pentaoxide (dichloromethane, chlorobenzene, and *o*-dichlorobenzene), metallic sodium (tetrahydrofuran and toluene), or metallic magnesium (ethanol) before distillation. Ethylene was distilled *in vacuo* at the Dry Ice temperature. Exact measurement of the amount of $AgClO_4$ was very hard because of its hygroscopicity. $AgClO_4$ was evacuated in a two-necked flask (50 ml) of known weight at 60 °C for 5 h, after which the flask was filled with nitrogen and weighed. It was kept as a toluene solution of 0.1, 0.2, or 0.5 mol/l.

Ethylene Dimerization. A typical reaction was performed as follows. To an *o*-dichlorobenzene solution (5 ml) of $[NiBr(\sigma\text{-}C_6F_5)(PPh_3)_2]$ (16.6 mg, 0.02 mmol) was added a toluene solution (0.2 ml) of $AgClO_4$ (0.1 mol/l). The solution was kept stirred at room temperature for 1 h, during which the color turned from yellow to reddish brown accompanying a formation of white precipitate. Then ethylene was introduced at 0 °C at 67 kPa of initial pressure and the pressure change was followed. After 1 h of the reaction the volatile material in the reaction flask was transferred into a sampling tube cooled at −196 °C *in vacuo* and analyzed by gas chromatography. The products corresponded to a butene mixture of equilibrium composition and no hexene was detected.

^{31}P NMR Measurements. ^{31}P NMR spectra were obtained on an Electron Optics Laboratory FX-100 spectrometer capable of operating in the pulsed Fourier transform mode at 40.26 MHz. In a typical experiment a toluene solution of $AgClO_4$ was added to a dichloromethane solution (2 ml) of $[NiBr(\sigma\text{-}C_6F_5)(PPh_3)_2]$ (33.2 mg, 0.04 mmol). The solution was filtered to remove the silver bromide formed before being put into an ampule. The chemical shifts were reported in ppm from the external PPh_3 reference (−5.86 ppm from 85% H_3PO_4).

Quantitative measurements were performed using $[NiCl(\sigma\text{-}$

$C_6Cl_5)(PPh_3)_2]$. To a chlorobenzene solution (2 ml) of the nickel complex (17.3 mg, 0.02 mmol) was added a toluene solution of $AgClO_4$. After stirring the solution at room temperature for 1 h, benzene-d_6 (0.2 ml) was added and the solution was filtered to remove the silver chloride. A chlorobenzene solution of triphenylphosphine was sealed into a capillary tube, which was fixed in the NMR tube. The integrated peak area was corrected by use of known concentrations of $[NiCl(\sigma\text{-}C_6Cl_5)(PPh_3)_2]$ in chlorobenzene. Amounts of the complexes and silver-phosphine complexes were evaluated by using the same correction factor as for $[NiCl(\sigma\text{-}C_6Cl_5)(PPh_3)_2]$.

Results and Discussion

Ethylene Dimerization with $[NiBr(\sigma\text{-}C_6F_5)(PPh_3)_2]$. Figure 1 shows a typical time course of ethylene dimerization catalyzed by $[NiBr(\sigma\text{-}C_6F_5)(PPh_3)_2]$-$AgClO_4$ system. Since the total yield of the butene

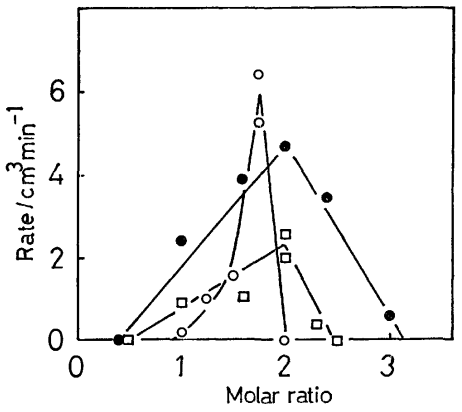

Fig. 2. Rate of ethylene dimerization as a function of molar ratio $AgClO_4$/Ni-complex at 0 °C.
a □: $[NiBr(\sigma\text{-}C_6F_5)(PPh_3)_2]$ (0.02 mmol) in *o*-di chlorobenzene (5 ml) soln, b ●: $[NiBr(\sigma\text{-}C_6F_5)(PPh_3)_2]$ (0.05 mmol) in *o*-dichlorobenzene (5 ml) soln, c ○: $[NiBr(\sigma\text{-}C_6F_5)(PPh_3)_2]$ (0.02 mmol) in dichloromethane (5 ml) soln.

mixture exceeded 97% and no other products such as hexene were detected, the rate of the absorption of ethylene corresponds to that of the ethylene dimerization. Thus the rate of dimerization is easily derived from a constant slope in Fig. 1. Figure 2 shows the dependence of the dimerization rate of ethylene in an *o*-dichlorobenzene solvent on the molar ratio of the nickel complex to $AgClO_4$. It can be seen that the catalyst does not show any activity at molar ratios smaller than 0.5. The catalytic activity increases with increase in the molar ratio from 0.5 to 2 and reaches the highest value at the molar ratio of 2. Beyond this ratio the catalytic activity decreases with increase in the ratio. The rate of dimerization depends also on the concentration of the nickel complex, but the dependence is not so simple. The higher concentration of the nickel complex results in the wider effective range of molar ratio, where the catalyst system is sufficiently active even at higher molar ratios than 2.5. When the same reaction was carried out in dichloromethane, the effective range was limited to 1 to 2 and the highest activity was obtained at the molar ratio of 1.75 (Fig. 2c). These results show that the molar ratio range for the catalyst system effective for the reaction is dependent on both the concentration of the nickel complex and the solvent used.

In order to clarify the effective component in the catalyst system, the reaction of the nickel complex with $AgClO_4$ was examined. When a toluene solution (0.2 ml) of $AgClO_4$ (0.1 mmol) was added to a dichloromethane solution (4 ml) of $[NiBr(\sigma\text{-}C_6F_5)(PPh_3)_2]$ (83 mg, 0.10 mmol), 16.0 mg of AgBr (85% based on the nickel complex) was precipitated. This shows that the following reaction is almost completed:

$$[NiBr(\sigma\text{-}C_6F_5)(PPh_3)_2] + AgClO_4 \longrightarrow [Ni(ClO_4)(\sigma\text{-}C_6F_5)(PPh_3)_2] + AgBr. \quad (1)$$

An addition of more than 0.2 mmol of $AgClO_4$ resulted in a formation of light greenish brown precipitate and a decoloration of the solution. The aqueous solution of the precipitate reacted with dimethylglyoxime to give a reddish brown precipitate. These results suggest that the addition of excess $AgClO_4$ decomposes the nickel complex to reduce the dimerization activity.

^{31}P NMR Spectra of $[NiBr(\sigma\text{-}C_6F_5)(PPh_3)_2]$-$AgClO_4$ *System.* The dichloromethane solution of $[NiBr(\sigma\text{-}C_6F_5)(PPh_3)_2]$ with or without $AgClO_4$ was monitored by ^{31}P NMR at −30 and −80 °C. As shown in Fig. 3b, the addition of an equimolar amount of $AgClO_4$ to the nickel complex leads to the disappearance of the resonance peak at 30.5 ppm due to the original nickel complex and to the appearance of a new resonance peak at 27.1 ppm. Since the reaction of $AgClO_4$ with the nickel complex at this molar ratio is expressed by Reaction 1, the new resonance peak at 27.1 ppm can be assigned to $[Ni(ClO_4)(\sigma\text{-}C_6F_5)(PPh_3)_2]$. Further addition of $AgClO_4$ up to 1.5 of molar ratio resulted in both the decrease in the resonance peak at 27.1 ppm and the increase in a resonance peak at 34.7 ppm along with the appearance of three broad resonance peaks at 13.3, 21.7, and 25.4 ppm (Fig. 3c). At the ratio of 2, the resonance peak

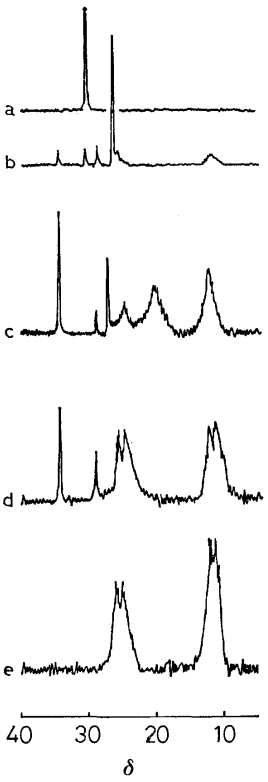

Fig. 3. ^{31}P NMR spectra of catalyst solution (0.02 mmol cat. ml) with different molar ratio $AgClO_4$/Ni-complex at −30 °C in dichloromethane (2 ml) soln. Molar ratios are as follows: a; zero, b;1, c;1.5, d;2, e;3.

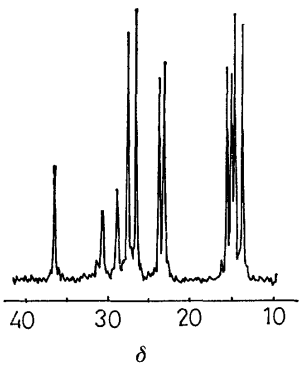

Fig. 4. ^{31}P NMR spectrum of Fig. 3 (c) at −80 °C.

at 27.1 ppm disappeared accompanying the decrease in the resonance peak at 34.7 ppm with the growth of the broad resonance peaks remaining (Fig. 3e). This sample gave eight sharp resonance peaks at −80 °C instead of broad ones. These resonance peaks are assigned to a couple of double doublet peaks due to (perchloro)(triphenylphosphine)silver(I), $[Ag(ClO_4)(PPh_3)]$, at 20.5 ppm ($^1J_{^{107}Ag,P}$=499.24 Hz, $^1J_{^{109}Ag,P}$ =577.34 Hz) and (perchloro)bis(triphenylphosphine)-silver(I), $[Ag(ClO_4)(PPh_3)_2]$, at 19.2 ppm ($^1J_{^{107}Ag,P}$= 317.97 Hz, $^1J_{^{109}Ag,P}$=367.80 Hz) according to the litterature,[11,12] where the broadness was induced by rapid exchange of the coordinated PPh_3. The disappearance of the resonance peak at 21.7 ppm in Figs. 3d and 3e may be ascribable to the transformation

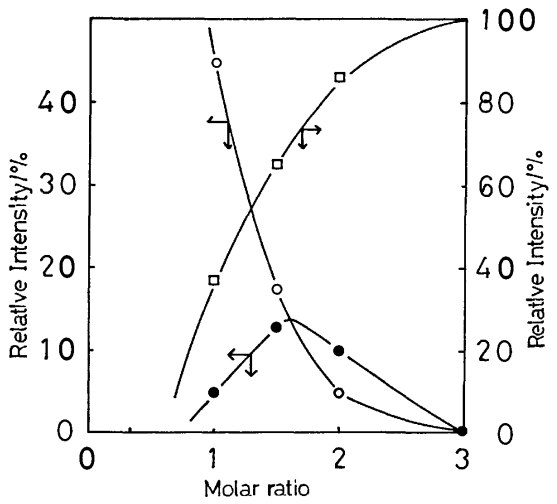

Fig. 5. Changes in relative intensities of resonances as a function of molar ratio $AgClO_4$/Ni-complex. □: Broad resonance peaks, ○: 27.1 ppm, ●: 34.7 ppm.

of $[Ag(ClO_4)(PPh_3)_2]$ into $[Ag(ClO_4)(PPh_3)]$ with increase in $AgClO_4$. The formation of these silver–phosphine complexes suggests the presence of a coordinatively unsaturated nickel complex according to the following reaction:

$$[Ni(ClO_4)(\sigma\text{-}C_6F_5)(PPh_3)_2] + AgClO_4 \longrightarrow [Ni(ClO_4)(\sigma\text{-}C_6F_5)(PPh_3)] + [Ag(ClO_4)(PPh_3)]. \quad (2)$$

Thus, the sharp resonance peak at 34.7 ppm in Figs. 3b, c, and d would be assigned to $[Ni(ClO_4)(\sigma\text{-}C_6F_5)(PPh_3)]$. The changes in relative intensity of the resonance peaks shown in Fig. 3 with increase in $AgClO_4$ added are summarized in Fig. 5. The intensity change of the resonance peak at 34.7 ppm well corresponds to the change in the dimerization rates shown in Fig. 2, suggesting that $[Ni(ClO_4)(\sigma\text{-}C_6F_5)(PPh_3)]$ would be an active species. The decrease in the active species must come from the abstraction of the second PPh_3 accompanied by the decomposition of the nickel complex, because the addition of excess $AgClO_4$ resulted in the formation of the precipitate of Ni(II) salts. The reason for the dependences of the dimerization rate on the solvent and the concentration of the nickel complex in higher molar ratios than 2 is not clear.

Ethylene Dimerization with $[NiCl(\sigma\text{-}C_6Cl_5)(PPh_3)_2]$. $[NiCl(\sigma\text{-}C_6Cl_5)(PPh_3)_2]$ as well as $[NiBr(\sigma\text{-}C_6F_5)(PPh_3)_2]$ is active for the ethylene dimerization in the presence of $AgClO_4$. As shown in Fig. 6, the rate of dimerization increases with increase in the molar ratio of $AgClO_4$ to $[Ni(ClO_4)(\sigma\text{-}C_6Cl_5)(PPh_3)_2]$, and reaches the highest at around 2 of the ratio in a similar manner as $[NiBr(\sigma\text{-}C_6F_5)(PPh_3)_2]$. However, differing from $[NiBr(\sigma\text{-}C_6F_5)(PPh_3)_2]$, the rate decreases only slightly with increase in the ratio up to 5. ^{31}P NMR spectra of the chlorobenzene solution of $[NiCl(\sigma\text{-}C_6Cl_5)(PPh_3)_2]$ and $AgClO_4$ showed three sharp resonance peaks at 25.0, 26.4, and 28.6 ppm due to nickel complexes along with two broad ones due to $[Ag(ClO_4)(PPh_3)]$. The resonance peak at 26.4 ppm is the one of the original nickel complex. As with

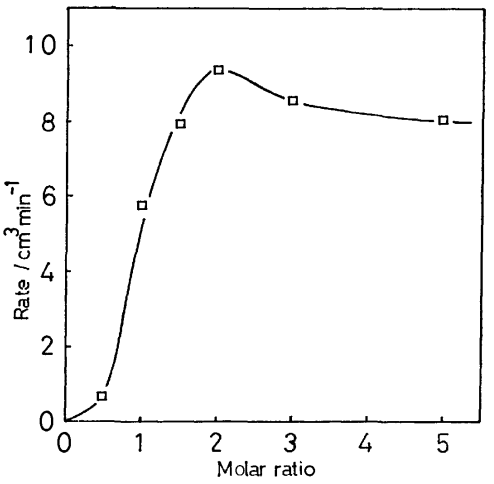

Fig. 6. Rate of ethylene dimerization as a function of molar ratio AgClO$_4$/Ni-complex.
[NiCl(σ-C$_6$Cl$_5$)(PPh$_3$)$_2$] (0.02 mmol) in chlorobenzene (2 ml) soln, react. temp 0 °C, initial ethylene pressure 67 kPa.

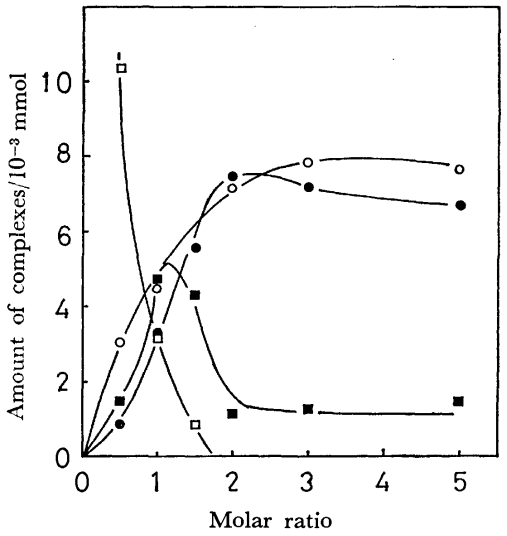

Fig. 7. Changes in the amount of complexes as a function of molar ratio AgClO$_4$/Ni-complex.
□: [NiCl(σ-C$_6$Cl$_5$)(PPh$_3$)$_2$], ■: [Ni(ClO$_4$)(σ-C$_6$Cl$_5$)-(PPh$_3$)$_2$], ●: [Ni(ClO$_4$)(σ-C$_6$Cl$_5$)(PPh$_3$)], ○: [Ag-(ClO$_4$)(PPh$_3$)].

the case of [NiBr(σ-C$_6$F$_5$)(PPh$_3$)$_2$], the resonance peak at 25.0 ppm can be assigned to [Ni(ClO$_4$)(σ-C$_6$Cl$_5$)-(PPh$_3$)$_2$] because the peak intensity was the highest at the molar ratio of 1. The resonance peak at 28.6 ppm would be assigned to [Ni(ClO$_4$)(σ-C$_6$Cl$_5$)(PPh$_3$)], because the intensity increases with compensation of the resonance peak at 25.0 ppm. Figure 7 shows the dependence of the intensity of the resonance peak at 28.6 ppm on the molar ratio, where the material balances of PPh$_3$ as estimated from each resonance peak

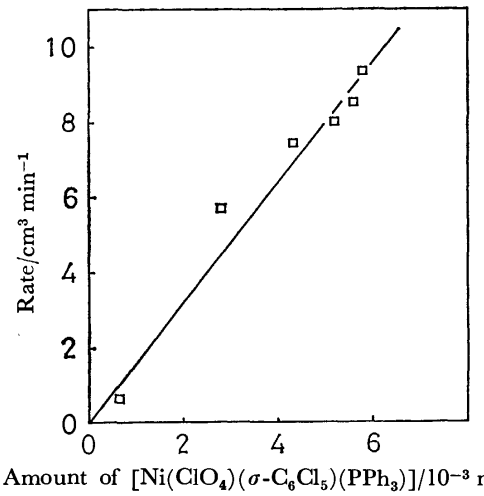

Fig. 8. Relationship between amount of [Ni(ClO$_4$)(σ-C$_6$Cl$_5$)(PPh$_3$)] and the rate of ethylene dimerization.

are not complete. This incompleteness is probably because of a loss caused in the procedure of filtration of the solution followed by ampuling the samples.

The dependence of the amount of [Ni(ClO$_4$)(σ-C$_6$Cl$_5$)(PPh$_3$)] on the molar ratio is analogous to the rate change shown in Fig. 6. Figure 8 shows the dependence of the rate on the amount of [Ni(ClO$_4$)-(σ-C$_6$Cl$_5$)(PPh$_3$)]. The clear linear relationship would suggest that [Ni(ClO$_4$)(σ-C$_6$Cl$_5$)(PPh$_3$)], which can afford two vacant sites on the nickel atom by dissociating the perchlorate anion, is an active species for the dimerization of ethylene. Although a real active species may be such a nickel hydride complex as has been assumed in the [Ni(σ-aryl)X(PPh$_3$)$_2$]-Et$_2$O·BF$_3$ system,[1] we have no evidence for the presence of any hydride species at present.

(Received March 20, 1982)

The electron-spin-resonance (ESR) spectra of three paramagnetic species trapped in single crystals of chloro(tetraphenylporphyrinato)cobalt(III) have been observed at 77 K. Using the ESR parameters obtained, one of them has been identified as the $[Co^{III}(tpp)]^{2+}\cdot(Cl^-)_2$ π cation radical, and the other two species, as $[Co^{II}(tpp)]$ which are influenced by axial ligation. From the angular variations in the hfcc due to the ^{59}Co, ^{14}N, and ^{35}Cl in the π cation radical, it has been found that the unpaired electron resides on the a_{2u} porphyrin π orbital and polarizes the Co and Cl atomic orbitals through a spin-polarization mechanism. Finally, the radical formation mechanisms in solution are briefly discussed, based on the results obtained from the single-crystalline measurements.

The role of the porphyrin-cation radicals in the chemical and biological behavior of metalloporphyrins has become very important. In the enzymatic reaction of horse-radish peroxidase (HRP) with peroxide, for example, it has been pointed out that the HRP I has an electronic configuration of Fe(IV) ($S=1$), with the porphyrin ring forming an a_{2u} π cation radical.[1] On the other hand, Dolphin *et al.*[2] showed how the organic macrocycles play important roles in biochemical systems in addition to those of the centrally coordinated metals.

It has been previously shown by ^1H FT-NMR[3] and ESR studies[4] that diamagnetic chloro(tetraphenylporphyrinato)cobalt(III) (**A**) (Fig. 1) in chlorinated solvents changes partially into paramagnetic species upon thermal and light activations. The formation of this species in the solutions occurs reversibly, with small enthalpy differences. This species was identified as a π cation radical of cobalt(III) tetraphenylporphyrin, $[Co^{III}(tpp)]^{2+}\cdot(Cl^-)_2$, using an electrochemical ESR technique[5]. The formation of the cation radical under ambient conditions can, therefore, be closely related to the enzymatic reactions of the metalloporphyrins mentioned above.

In the course of a crystallographic investigation of **A**[6] it was expected that the crystals grown from a solution including such paramagnetic species may trap the species. It may, therefore, be appropriate to elucidate in detail the electronic structure and the mechanism of its formation in solutions by using the single crystals trapping the species. In agreement with this expectation, we have succeeded in observing the ESR spectra of paramagnetic species trapped in the single crystals, one of which has been identified as the π cation radical. In order to clarify further the electronic structure of the radical, we have carried out a detailed ESR investigation of the single crystals.

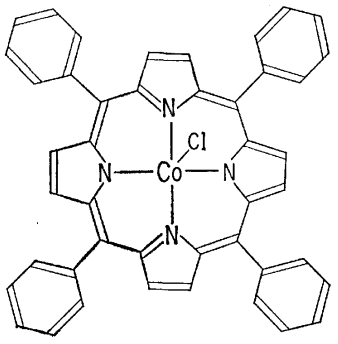

Fig. 1. Chloro($\alpha,\beta,\gamma,\delta$-tetraphenylporphyrinato)cobalt(III).

In this paper we will first describe the ESR parameters obtained from the angular dependences of the ESR spectra due to the paramagnetic species in the single crystals of **A**. Second, the electronic structure of the cation radical will be discussed in detail based on the parameters thus obtained and those in solutions reported previously. Finally, the mechanisms of its formation in solutions will be presented in relation to that of HRP I.

Experimental

A was prepared by using a method previously reported.[6] The compound obtained from the methanol solution was dissolved in chloroform or dichloromethane, and the solvent was allowed to evaporate slowly to yield violet and lustrous crystals of **A**. The purity of the crystals obtained was examined by means of elemental analysis and visible-spectrum measurements (Found: C, 73.40; H, 4.20; N, 7.84; Co, 8.24; Cl, 5.06%. λ_{max} (ε) in CH_2Cl_2: 544 nm(13200) and 406 nm(112000)). The spontaneous evaporation of the solvent gave crystals of various external forms; obelisk, pyramid, and bulky shapes. Previously the results of a X-ray analysis of the obelisk crystals were reported.[6] The successive refinement of the structure analysis[7] of these crystals made clear the existence of oxygen at the 6th ligand position.

Their crystal parameters, as determined by the X-ray diffraction method, are listed in Table 1. The pyramid and obelisk crystals were submitted to the ESR measurements. In the case of the obelisk crystal, the c axis was perpendicular to the porphyrin plane and parallel to the Co–Cl bond, which corresponds to the molecular symmetry axis and coincides with the long crystal axis. The basal plane of the pyramid crystal coincides with the molecular plane and is perpendicular to the c axis. The relationships between the a and b axes and the external forms are illustrated in Fig. 2. The angle between the a axis and one of the molecular symmetry axes parallel to the Co–N bond was 15°.[6] Such crystal habits were utilized for the single-crystal

Table 1. Crystal parameters of $Co^{III}(tpp)Cl$

Form	System	Lattice constants a/Å	c/Å	U/Å^3	Space group	Z	D_o	D_c
Obelisk	Tetragonal	13.693(2)	9.701(2)	1818.9(6)	14	2	1.34_7	1.324
Pyramid	Tetragonal	13.450(5)	9.792(3)	1771.4(11)	14	2	1.35_6	1.359

ESR measurements. Typical sizes of the obelisk and pyramid crystals used for the measurements were $0.1 \times 0.1 \times 0.3$ cm^3 and $0.2 \times 0.2 \times 0.1$ cm^3 respectively.

The ESR spectra were recorded on a JEOL X-band FE-3X ESR spectrometer. The spin concentrations of the paramagnetic species were determined from a comparison of the intensity of the signals with that of 2,2,6,6-tetramethyl-4-hydroxyl-1-piperidyl oxyl (98%) used as a standard. In order to obtain the ESR parameters of the paramagnetic species, the resonance magnetic field and the microwave frequency of each absorption line were measured using a JEOL ES-FC-4 NMR gaussmeter and a Takeda Riken TR5211 frequency counter respectively. The ESR parameters were determined by the best fitting of the experimental data with an equation derived by the second-order perturbation theory.[8] The computer simulation for the hyperfine structure analysis was carried out using a JEOL ES-9835 computer system.

Results and Discussion

The ESR Spectra of the Paramagnetic Species in the Single Crystal of A. It has already been determined from the magnetic susceptibility measurements that **A** is diamagnetic in the range from 77 K to room temperature.[6] Therefore, the ESR signals obtained from the crystals are regarded as those due to paramagnetic species trapped in the diamagnetic matrix. Figure 3 shows the ESR spectrum of the paramagnetic species in a pyramid crystal of **A** with the crystal setting of $H_0 \perp c$ at 77 K. The spectrum is composed of three signals, each of which has the hyperfine (hf) structure characteristic of ^{59}Co with $I=7/2$. Their microwave power and the temperature dependences of the signal intensities were different from one another. Therefore the spectrum was regarded as a superposition of the hf patterns due to three different species. Hereafter, we will call them α, β, and γ species, from right to left in the spectrum shown in Fig. 3. The relative intensities of these signals, that is, the relative amounts of these species, depended on the conditions of the crystallization and the external forms. The signal intensities due to these species in the pyramid crystal were of comparable orders of magnitude. On the other hand, the spectrum obtained from the obelisk crystal showed mainly the hf pattern due to the α species, as is shown in Fig. 4.

The angular variations in the absorption lines due to these species were measured on a plane including the c axis and on the ab plane which corresponds to the molecular plane of porphyrin. Table 2 lists the observed parameters of ^{59}Co in these species. The parameters obtained from the pyramid and obelisk crystals coincided with each other within the range of experimental errors. The g values of the β and γ

species are very similar to those of Co^{II}(tpp) in H_2-(tpp),[9] they are also listed in Table 2. The results are good enough to conclude that the β and γ species correspond to Co^{II}(tpp) in H_2(tpp), although the hfcc are a little different. The small deviations from the data reported earlier[9] may be due to slightly different perturbations from the axial ligands. The electronic configurations of Co^{2+} are very sensitive to axial ligands, as has already been pointed out.[10] The details of the discussion of the electronic structures of these species will be published elsewhere. The existence of the Co^{II} species in the crystals means their formation in solution, which provides an important clue to the mechanism of the formation of the π cation radical in solution, as will be described in the last section.

π Cation Radical of Cobalt(III) Tetraphenylporphyrin. The angular dependences of the ESR spectra of the α species were observed in the obelisk and pyramid crystals. The hf structure due to the α species in the pyramid crystal overlapped with those due to the β and γ species. Fortunately, the obelisk crystal showed mainly the signals due to the α species. Therefore, the angular dependence of the spectrum was measured by using the obelisk crystal.

The angular-dependent spectra of the α species on the ab plane and on the plane including the c axis are shown in Fig. 5. The spectra about the c axis (Fig. 5a) are angular-independent and have only eight hf lines due to ^{59}Co with an appreciably broad line width, the g value and the hfcc of ^{59}Co being 1.9980± 0.0001 and 1.25 mT respectively. On the other hand, in Fig. 5b, the eight hf lines for $H_0 \perp c$ gradually coalesce into one broad distorted line, as the angle between the direction of the magnetic field and the c axis, (θ), increases. The coalesced line at about θ= 40—50° splits into many lines at the higher angles. The small, sharp line at the center is due to an impurity in the crystal. It should be noted here that the g value is constant within the range of experimental errors (±0.0001) in this experiment. The spectrum for $H_0//c$ consists of 28 lines with a line-width (ΔH) of about 0.3 mT and with g=1.9981±0.0001. The spectrum simulation was carried out using one cobalt $a_{^{59}Co}$= 1.13 mT, four nitrogens $a_{^{14}N}$=0.56 mT, two chlorines $a_{^{35}Cl}$=0.57 mT ($a_{^{37}Cl}$=0.50 mT), and ΔH=0.40 mT,

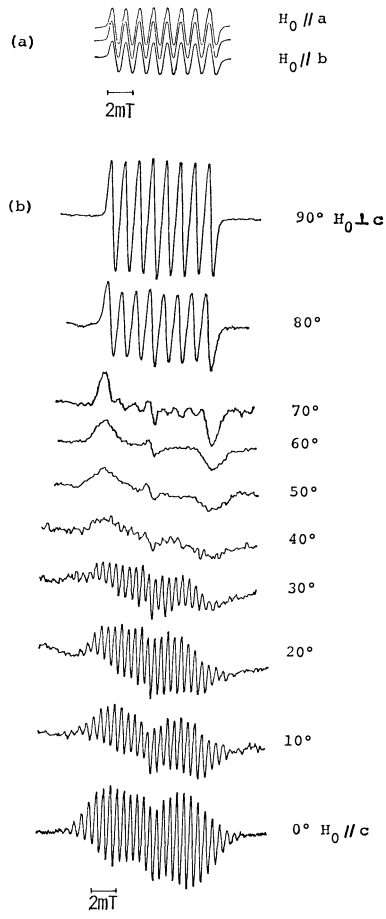

Fig. 5. The angular dependent ESR spectra of α species, (a): rotation about c axis, (b): rotation from the c axis to an axis perpendicular to the c axis.

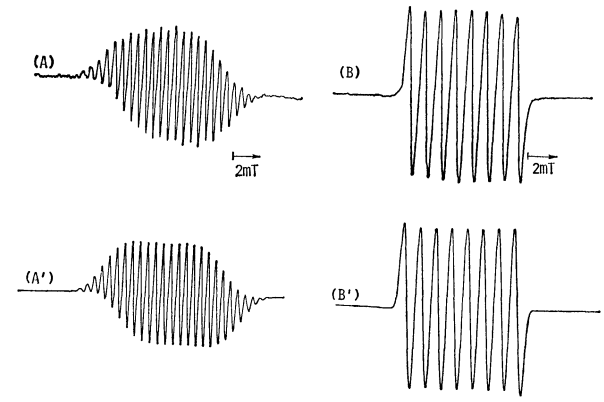

Fig. 6. The ESR spectra of the α species trapped in a single crystal of A at 77 K, (A) at $H_0//c$ and (B) at $H_0 \perp c$.
Simulation (A') assumes one cobalt a_{Co}=1.13 mT, four nitrogens a_N=0.56 mT, and two chlorines $a_{^{35}Cl}$= 0.57 ($a_{^{37}Cl}$=0.50) mT and (B') assumes one cobalt a_{Co}=1.18 mT.

which led to the best fit to the experimental data. The simulation spectra are shown in Fig. 6. The simulation at various angles was successively carried out by changing the parameters mentioned above, shown in Fig. 7, as functions of θ. The hfcc values of ^{14}N and $^{35}Cl(^{37}Cl)$ have a maximum at $\theta=0°$ ($H_0//c$) and a minimum at $\theta=90°$ ($H_0\perp c$), but that of ^{59}Co is almost independent of θ; its small anisotropic part has a maximum at $\theta=90°$ ($H_0\perp c$). The principal values of g and hfcc are also summarized in Table 2.

The g value obtained was isotropic and very close to that of the free electron (2.0023). The difference in these values is probably due to contributions from unoccupied orbitals of the cobalt atom. The isotropic parts of the ^{59}Co, ^{14}N, and $^{35}Cl(^{37}Cl)$ were also very close to those of the π cation radical of Co^{III}(tpp) obtained by the electrochemical oxidation of Co^{II}(tpp) of **A**.[5] Therefore, one can, from these data, identify the α species as the π cation radical of Co^{III}(tpp) coordinated by two chlorines.

Electronic Structure of the π Cation Radical of $[Co^{III}(tpp)]^{2+\cdot}$. It was well established that the neutral species Co^{II}(tpp) is paramagnetic, with an effective electron spin of 1/2 and with a square-planar $3d^7$ configuration, $(3d_\pi)^4$ $(3d_{xy})^2$ $(3d_{z^2})$. In the present case, the β and γ species showed the ESR parameters characteristic of this configuration. On the other hand, as we reported previously,[5] the π cation radical of $[Co^{III}(tpp)]^{2+\cdot}$, generated by electrochemical oxidations of Co^{II}(tpp) or **A** in solutions, has an electronic configuration described by a combination of diamagnetic Co^{3+} and paramagnetic tpp ligands, $(3d_\pi)^4$ $(3d_{xy})^2$ $(a_{2u})^1$. The a_{2u} π orbital has a spin distribution characterized by an appreciable localization (76%) at meso-carbons, followed by a 20% spin density at four nitrogens. This spin distribution of the π cation radical was experimentally confirmed by the observation of the angular dependent hfcc values of cobalt and four nitrogen atoms, $a_{Co}(\theta)$ and $a_N(\theta)$, in the single crystal, as is shown in Fig. 7.

The $a(\theta)$ is expressed by a combination of the isotropic (A_{iso}) and the anisotropic (A_{aniso}) parts of the hfcc:

$$a(\theta) = A_{aniso}(3\cos^2\theta - 1) + A_{iso} \quad (1)$$

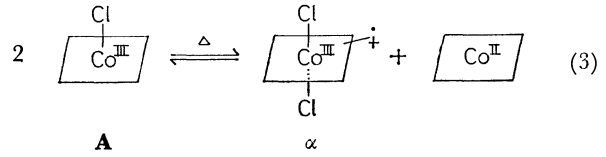
$$A_{iso} = (A_\parallel + 2A_\perp)/3 \quad (2)$$

where $A_\parallel$ and $A_\perp$ are the values of $a(\theta)$ at $\theta=0°$ and 90° respectively. The best fit of the equations to the experimental values, as is shown in Fig. 7, has lead to the values of $A^N_{iso}=0.26$ mT and $A^N_{aniso}=0.15$ mT. A^N_{iso} is very close to that of $[Co^{III}(tpp)]^{2+\cdot}(Cl^-)_2$ in solution (0.28 mT). This confirms the appropriateness of the identification of the α species as the π cation radical. From $A^N_{iso}=0.26$ mT, the spin density at the 2s orbital of nitrogen is calculated as $0.26/55.7=0.0047$ by using a theoretically estimated hfcc.[11] The anisotropic part in Eq. 1 provides also useful information about the contribution of the nitrogen orbitals to the a_{2u} orbital. First, $a_N(\theta)$ has a maximum at $\theta=0°$. This means that the axis of the $2p_z$ orbital of the nitrogen coincides with the c axis of the crystal. Second, the A^N_{aniso} is another measure of the spin density on the nitrogen $2p_z$ orbital. When we use the hfcc of the nitrogen $2p_z$ orbital of 1.7 mT[11] the spin density of one of the four nitrogen atoms ($\rho^N_{2p_z}$) is estimated as 0.088. This value coincides with that obtained from the spectra in solution (5 to 10%).

The chlorine hfcc showed the same angular dependence as the nitrogens; thus $A^{Cl}_{iso}=0.26$ mT and $A^{Cl}_{aniso}=0.15$ mT. A similar estimation of the spin density on the chlorine atom has lead to the values of $\rho^{Cl}_{3s}=0.0016$ and $\rho^{Cl}_{3p_z}=0.029$.[11] It should be noted here that the spin polarization in the $3p_z$ orbital is dominant. Although numerous ESR studies have revealed interactions of diamagnetic cations with aromatic anion radicals,[12] it was not until recently that the opposite interaction of diamagnetic anions with cation radicals[13] was detected. In order to clarify the mechanism of the interaction, it is instructive to compare the A^{Cl}_{iso} and A^N_{iso} in our system with those in some analogous systems, $[M^{II}(tpp)]^{+\cdot}Cl^-$: 0.152 and 0.151 mT for M=Mg, 0.162 and 0.166 mT for M=Zn, and 0.185 and 0.182 mT for M=Cd,[13] respectively. These data show clearly that A^{Cl}_{iso} depends linearly on A^N_{iso}, as in the case of A^{Co}_{iso} with A^N_{iso} reported previously. Therefore, it is concluded that the chlorine hfcc results from the spin polarization by the π electron on the nitrogen atoms.

The unpaired π electron on the nitrogen $2p_z$ orbital polarizes the four nonbonding orbitals of the nitrogens. A combination of these orbitals with total symmetry mixes well with the $3d_{z^2}$ and 4s orbitals of the cobalt atom. The ^{59}Co hfcc ($A^{Co}_{Iso}=1.16$ and $A^{Co}_{aniso}=-0.03$ mT) showed a small angular dependence, different from those due to ^{14}N and ^{35}Cl. The estimated spin densities, ρ^{Co}_{4s} and $\rho^{Co}_{3d_{x^2-y^2}}$ at the cobalt nucleus were $1.16/130.8=0.009$ and $-0.03/7.65=-0.04$ respectively, which were estimated based on the values of the hfcc calculated for the Co^0 configuration of $3d^74s^2$.[11] The spin density at the cobalt nucleus is of the same order of magnitude as those at the two chlorine nuclei. This means that the polarizations at these nuclei are a result of the first-order in the perturbation induced by the unpaired electron which resides on the nitrogen π orbital. Therefore, the other possibility that the electrons at the two chlorine nuclei are polarized through the cobalt atom, of the second-order in the effect, can be neglected. Figure 8 shows a schematical drawing of the spin polarization mentioned above with capable atomic orbitals. In summary, the unpaired π electron on four nitrogen atoms polarizes the electrons on two chlorine nuclei and the cobalt nucleus through the spin-polarization mechanism, the orders of the polarization being about 0.03 and 0.01 respectively.

On the Mechanism of the Cation Radical Formation. As described in the previous papers,[3,4] the π cation radical is formed by thermal activation in the chlorinated solvents. The formation of the species occurs reversibly with small enthalpy differences (ΔH). From the exponential portion of the temperature dependences of the spin concentration, ΔH was estimated to be 4 kJ mol^{-1} in tetrachloroethane and 10 kJ mol^{-1} in dichloromethane.[4] These results may indicate phenomenologically an equilibrium between the paramagnetic species (α, β, and γ) and the diamagnetic species, (**A**):



(3)

From the ESR measurements described above, it has been found that the crystals grown from the chlorinated solvents trap Co^{II}(tpp) (β and γ) in addition to the π cation radical (α). This fact apparently supports the hypothesis of Eq. 3. However, the detailed examination of Eq. 3 provides several possibilities as to the elementary reactions. The existence of oxygen in the atmosphere and the natural-light irradiation over the procedure of the sample preparations also induce the radical formation.

In conclusion, it should be understood that the observation of three paramagnetic species in our systems supports the apparent equilibrium of Eq. 3 described as a result of several reactions undetectable by the ESR techniques.

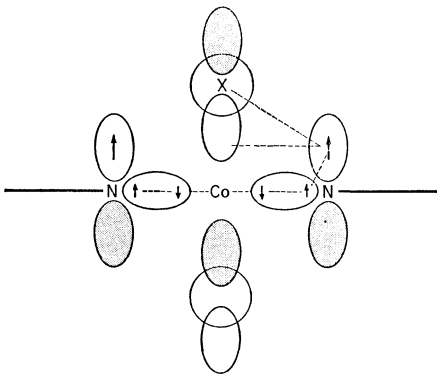


Fig. 8. Schematical drawing about the spin polarization on the cobalt, nitrogen, and halogen atoms in $[Co^{III}(tpp)]^{2+}\cdot(X^-)_2$.

Viscosities of Aqueous Solutions of Alkanoic Acids

Koichiro MIYAJIMA,* Masahiro SAWADA, and Masayuki NAKAGAKI

Faculty of Pharmaceutical Sciences, Kyoto University, Yoshida-shimoadachi-cho, Sakyo-ku, Kyoto 606

(Received April 1, 1982)

Viscosities of aqueous solutions of alkanoic acids including formic acid were measured by an Ostwald type viscometer at 15, 25, and 35 °C, and the viscosity B-coefficient and the temperature dependence of B-coefficient, dB/dT, were calculated. From the signs and the magnitudes of B_{st}, increment of B-coefficient arising from the change of water structure, and dB/dT, it was concluded that formic acid was a hydrophilic structure breaker, while acetic acid was neither a structure maker nor a structure breaker. Both propionic acid and butyric acid were the hydrophobic structure makers. The mechanism of structure breaking effect of carboxyl group was briefly discussed.

Various nonelectrolytes which have the groups such as –OH, $-NH_2$, and >CO form the hydrogen bond with water molecules in aqueous solutions, and more or less cause the change of the structure of water depending on the size and shape of the molecule. Urea and monosaccharides, for instance, are typical nonelectrolytes capable of hydrogen bond formation with water molecules. But their effects on the structure of water are quite different. Urea increases the water activity,[1] while glucose decreases it in aqueous solution.[2] This fact seems to be related to the geometry of the hydrogen bond between nonelectrolyte molecule and water molecule, and that between water molecules. Carboxyl group is also capable of forming hydrogen bond. Judging from the conformation of carboxyl group, the orientation of hydrogen bonds between carboxyl group and water molecules would not fit the orientation of hydrogen bond in the tridymite-like structure of water.

In a previous paper,[3] the effects of alkanoate ions on the structure of water were investigated by measuring the viscosities of aqueous solutions and it was concluded that the structure making effects of alkanoate ions did not arise from the hydration of carboxylate groups by the electrostriction, but from the hydrophobic hydration of alkyl groups. In other words, carboxylate group hardly influences the structure of water.

From these points of view, the viscosities of aqueous solutions of a homologous series of alkanoic acids including formic acid were determined at various temperatures. Based on the viscosity B-coefficients and their temperature dependences, the effects of alkanoic acids on the structure of water were discussed.

Experimental

Materials. Reagent grade alkanoic acids and hydrochloric acid were purchased from Nakarai Chemical Co. Ltd., and were used without further purification. These compounds were dissolved in water purified by redistillation and deionization with ion exchange resin.

Method. Viscosity measurement was carried out by an Ostwald type viscometer with an efflux time of *ca.* 360 s for water at 25 °C. Efflux time was measured with the Seiko stop watch 89 T to 0.01 s. At least five readings of the efflux time with variations not exceeding ±0.05 s were taken for each solution. Kinetic correction of viscometer was made by using the following equation:

$$\eta/d = \alpha t - \beta/t,$$

where η and d are the viscosity and density of the solution, t the efflux time in second. Pure water at 15, 25, and 35 °C was used as standard, and linear relation was obtained between η/dt and $1/t^2$. The values of α and β obtained from the intercept and the slope were 2.628×10^3 cP g^{-1} cm^3 s^{-1} and 15.00 cP g^{-1} cm^3 s, respectively. The effect of kinetic correction on the relative viscosity was observed in the high concentration region, and the difference of η_{rel} values before and after correction were within 0.3—0.5%. The temperature of the thermostat bath was controlled within ±0.03 °C.

Results

The relative viscosity, η_{rel}, of a nonelectrolyte solution below 0.1 mol dm^{-3} is expressed by Eq. 1.

$$\eta_{rel} = \eta/\eta_0 = 1 + Bc, \quad (1)$$

where η and η_0 are the viscosities of solution and solvent, respectively, and B is the viscosity B-coefficient, and c is the concentration in mol dm^{-3}. At higher concentration than 0.1 mol dm^{-3}, η_{rel} of nonelectrolyte is described by Eq. 2.

$$\eta_{rel} = 1 + Bc + Dc^2, \quad (2)$$

where D is a characteristic constant of the solute.

Alkanoic acid dissociates into proton and alkanoate anion in water. The alkanoic acids used in this experiment are formic acid, acetic acid, propionic acid and butyric acid, and their pK_a values are between 3.7—4.9 at 25 °C. Therefore, in dilute solution of alkanoic acid the dissociated ions also contribute to the viscosity of the solution. To remove the contribution of the dissociated species from the solution viscosity, two kinds of experiments were carried out. The viscosity of each alkanoic acid dissolved in 0.01 mol dm^{-3} aqueous solution of hydrochloric acid was determined by using 0.01 mol dm^{-3} of hydrochloric acid as a reference solution. The B-coefficient of the alkanoic acid was obtained from Eq. 3.

$$\eta/\eta_{HCl} = 1 + B'c, \quad (3)$$

where η and η_{HCl} are the viscosity of 0.01 mol dm^{-3} HCl solution of the alkanoic acid and that of 0.01 mol dm^{-3} HCl solution, respectively. B'-coefficient in Eq. 3 is the B-coefficient of alkanoic acid in aqueous 0.01 mol dm^{-3} HCl solution, where the amount of dissociated species of alkanoic acid is negligible. As shown in Fig. 1, linear relationships were obtained

between $(\eta/\eta_{HCl}-1)$ and c. B' values obtained from the slope are shown in Table 1.

At higher concentration than 0.1 mol dm^{-3}, where the concentration of dissociated species is considered to be negligible as compared to the undissociated species, Eq. 2 was applied to the determination of B-coefficients. Linear relationships were obtained between $(\eta/\eta_0-1)/c$ and c at 15, 25, and 35 °C as seen in Fig. 2. B and D coefficients obtained from the intercepts and the slopes are shown in Table 1. B values agree with B' values for three alkanoic acids at 25 °C, indicating that at higher concentration than 0.1 mol dm^{-3} the contribution of dissociated species to B-coefficient is negligible. Consequently it is evident that B and D values obtained from the measurements in high concentration region are those for undissociated species. These B values at 25 °C are also in fair agreement with Rupley's values,[4] which were calculated from the η values described in International Critical Table.

As stated previously,[3] B value of nonelectrolyte consists of two terms, B_{size} and B_{st}. B_{size} is the contribution of hydrodynamic obstruction effect of solute to B value and is usually evaluated from Einstein's viscosity equation for spherical colloidal particle on the assumption that the effective rigid volume of the solute is equal to the partial molal volume of the solute at infinite dilution. Thus B_{st}, the contribution of solute to the structure of water, is determined from Eq. 4.

$$B_{st} = B - 0.0025\overline{V}^\circ, \quad (4)$$

where $\overline{V}^\circ$ is generally the partial molal volume of solute at infinite dilution, but in this case we used the partial molal volume of undissociated species as $\overline{V}^\circ$.[9] B value *vs.* $\overline{V}^\circ$ curves for alkanoate ions and alkanoic acids are shown in Fig. 3 together with Einstein's relation (0.0025 $\overline{V}^\circ$). The solutes with the points above the dotted line are considered to be structure makers. B_{st} values obtained from Eq. 4 are shown in Table 2.

Another and more reliable criterion for the judgement of the solute effect on the structure of water is the sign and magnitude of temperature dependence of B value, dB/dT.[3] The values of dB/dT of four kinds of alkanoic acids at 25 °C obtained from the slopes in Fig. 4 are shown in Table 2 together with the values of B, B_{st}, and $\overline{V}^\circ$.

Discussion

As for formic acid, the sign of B_{st} is negative, while the sign of dB/dT is positive, indicating that it is a

structure breaker. The result that both values of B_{st} and of dB/dT for acetic acid are negative seems to be inconsistent with the criterion that structure maker has the positive sign of B_{st} and negative sign of dB/dT, and *vice versa* for structure breaker. However, judging from the absolute values of B_{st} and dB/dT, acetic acid may be neither a structure maker nor a structure breaker. Applying the criterion to propionic acid and butyric acid, both fall under the category of structure maker. The signs and magnitudes of B_{st} and dB/dT for a homologous series of alkanoic acids indicate that structure making effect of propionic acid and butyric acid originates from the hydrophobic group and not from the carboxyl group, because structure making effect of alkanoic acids increases with alkyl chain-length, and because formic acid with no alkyl group is clearly a structure breaker. From the similar study for sodium alkanoates, methyl group of acetate ion was found to increase the structure of water.[3] Therefore carboxyl group should be a structure breaker. The structure breaking effect of carboxyl group compensates for the structure making effect of methyl group in acetic acid, because the values of B_{st} and dB/dT are nearly zero for acetic acid. Propionic acid and butyric acid are hydrophobic structure makers.

D-coefficients of four alkanoic acids at 15, 25, and 35 °C are shown in Table 1. The variations of D-coefficients with alkyl chain-length and temperature are similar to those of B-coefficients except the temperature dependence of the coefficients for formic acid. Thomas extended the Einstein equation and showed that for colloidal suspensions the η_{rel} is given by[5]

$$\eta_{rel} = 1 + 2.5\phi + 10.05\phi^2$$
$$= 1 + 2.5\times10^{-3}Vc + 10.05\times10^{-6}V^2c^2, \quad (5)$$

where ϕ and V are the volume fraction and the molar volume of solute and c the concentration of solute in mol dm^{-3}. By assuming that $D=10.05\times10^{-6}\,\overline{V}^{\circ\,2}$, the values of D-coefficients at 25 °C were found to be 0.012, 0.027, 0.046, and 0.072 for formic acid, acetic acid, propionic acid, and butyric acid, respectively. Thomas's relation predicts the correct order of D-coefficient. But the magnitudes are too large, especially for formic acid and acetic acid. This fact suggests that D-coefficient relates to the volume of the solute, but another effect also contributes to the magnitude of D-coefficient.

Desnoyers *et al.*[6] pointed out that the solute-solute structural interaction and the solute-solvent interaction which were not accounted for by Bc term would greatly influence the magnitude of D-coefficient. As stated above, the structure making effects of propionic acid and butyric acid come from the hydrophobic hydration of alkyl-chain. The hydrophobic hydration increases with the solute concentration, resulting in the increase

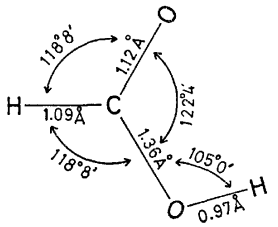

Fig. 5. Molecular structure of formic acid.

of the solution viscosity and consequently D-coefficient of solute. Such a structural interaction increases with alkyl chain-length and decreases with the increase of temperature. The small values of D-coefficients for formic acid and acetic acid may be due to an absence of such interaction.

Carboxyl group forms hydrogen bond with water like urea and saccharides. It is, however, important whether the formation of hydrogen bond between carboxyl group and water molecule promote the hydrogen bond between water molecules. The structure breaking effect of carboxyl group may be related to its molecular structure. The orientation of hydrogen bond in pure water may be tetrahedral as seen in the tridymite structure of ice. The molecular structure of formic acid is shown in Fig. 5 as a typical example of carboxyl group.[7] Roughly speaking, all atoms are in a plane, and three bond angles around the central carbon atom are nearly 120°. The structure of carboxyl group of alkyl homologous is similar to that of formic acid. Such a configuration of carboxyl group can hardly fit with the tridymite-like structure of water. In other words, the formation of hydrogen bonds between carboxyl group and adjacent water molecules would cause the disruption of hydrogen bond network of water. The situation is quite similar to urea.

The contribution of a methylene group to the value of B_{st} estimated from Eq. 6 is shown in Fig. 6.

$$B_{st}(CH_2) = B_{st}[H(CH_2)_nX] - B_{st}[H(CH_2)_{n-1}X], \quad (6)$$

where X is the terminal functional group shown in Fig. 6. The $B_{st}(CH_2)$ value of the methylene group adjacent to the terminal ionic group was more influenced than that of nonionic group. The small value of $B_{st}(CH_2)$ of methylammonium ion reflects the strong electrostriction of ammonium ion as pointed out by Zana.[8] It seems that the values of $B_{st}(CH_2)$ of these four kinds of alkyl derivatives converge to around 0.02—0.03 with increase of alkyl carbon chain.

In conclusion, carboxyl group is a weak structure breaker in contrast to carboxylate group, which is neither a structure maker nor a structure breaker. As for the alkanoic acids, the structure breaking effect of carboxyl group compensates for the hydrophobic structure making effect of methyl group of acetic acid, and alkanoic acids with more than two methylene groups become hydrophobic structure makers.

A Comparison between Ruthenium and Palladium with Regard to the Chemisorption of Carbon Monoxide on Metal Clusters Using Molecular Orbital Calculations

Masahiro KOBAYASHI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta-cho, Midori-ku, Yokohama, 227

(Received April 14, 1982)

Self-consistent charge extended Hückel calculations for systems consisting of 1—3 CO molecules chemisorbed on 8-atom and 10-atom clusters of Ru and Pd are reported. The binding energies and overlap populations between Pd and C are always smaller than those between Ru and C. It was found that the multiple types of bondings between 2—3 CO and a surface metal atom were less stable for Pd than for Ru.

Ruthenium and palladium exhibit different properties in CO adsorption, though they are the same type of platinum metal.

It is firmly established for Pd that the ratio of CO molecules chemisorbed to the surface atoms (CO/M_s) is less than unity and that there are two types of bonding (linear and bridge) between CO and surface metal atoms.[1]

We showed recently, however, that the ratio of chemisorbed CO molecules to the total metal atoms of Ru-supported catalysts was more than unity; consequently, CO molecules form multiple bonds with the surface atoms in the following manner:[2,3]

Hereafter, the (a) and (b) types will be called "twin" and "trine" respectively, and Ru^1, "multivalent metal atom", for the sake of convenience.

Further support has been afforded to our proposal that the stoichiometry of CO/Ru_s is more than unity using hydrogen uptake measurements.[4,5] Taylor[4] and Dalla Betta[5] found that the atomic ratio of the hydrogen uptake to the surface Ru atoms (H/Ru_s) was almost 1. This stoichiometry was confirmed by an examination of the data reported by Kubicka[6] and the new data obtained in the present laboratory.

The uptake of H_2 and CO obtained by using the same Ru–SiO_2 catalysts as in previous papers[2,3] and the calculated CO/H (molecule/atom) are summarized in Table 1. The CO/H values of Ru catalysts supported on various other carriers; Al_2O_3 as given by Dalla Betta,[7] TiO_2 as given by Tauster *et al.*,[8] and active carbon *etc.*, as given by Vannice and Garten,[9] have values greater than 1. These data are also summarized in Table 1. This means that CO molecules more than 1 combine with a surface Ru atom.

The IR studies of chemisorbed CO on Ru show that two CO molecules form the twin-type coordination with a Ru atom which is positively charged.[10,11] Thus, the charge or electronic properties of surface metal atoms would be influenced by CO chemisorption of the twin or trine type.

Politzer and Kasten successfully explained the characteristic features of electronic-charge transfer in the systems of Ni_n–CO, where the n values ranged from 1 to 9, by using the self-consistent-charge (SCC) approximation in the extended Hückel method.[12] The present investigation has been undertaken with the purpose of elucidating the difference between Pd and Ru catalysts in these CO-chemisorbed states in relation to the electronic charge transfer by means of the SCC extended Hückel approximation.

Procedure

Model Clusters. The crystal lattice of Pd metal is face-center-cubic (fcc), while that of Ru metal is hexagonal close-packed (hcp). The calculations have been performed for 10-atom clusters, as is shown in

TABLE 1. HYDROGEN AND CO ADSORPTION ON VARIOUS Ru CATALYSTS

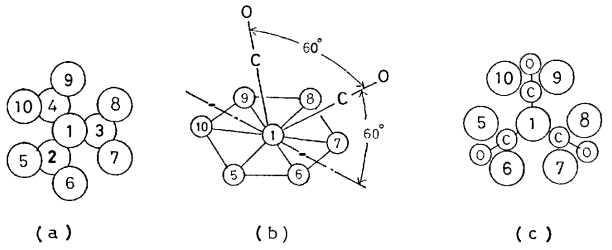

Fig. 1. Models for 10-atom cluster (a), M_{10}-$(CO)_2$ (b), and M_{10}-$(CO)_3$ (c).

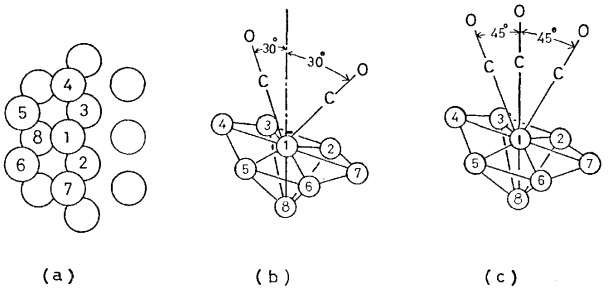

Fig. 2. Models for 8-atom cluster (a), M_8-$(CO)_2$ (b), and M_8-$(CO)_3$ (c).

Fig. 1(a). The atoms numbered 1 and 5—10 constitute the surface of Pd(111) or Ru(001). The atoms numbered 2, 3, and 4 correspond to the second layer.

It is presumed that the metal particles which are highly dispersed have the step sites, as is shown in Fig. 2(a). The model of the 8-atom cluster was also adopted. The atoms numbered 1, 4, and 7 constitute the edge of a stepped Pd(111) or Ru(001) surface. The 2, 3, and 8 atoms are second-layer with respect to the 1 and 4—7 atoms.

All the CO molecules bond to a central atom (numbered 1 in Figs. 1 and 2) through carbon atoms. In the present paper, models of the CO chemisorbed clusters are expressed, such as M_{10}–CO and M_8-$(CO)_2$. M is meant by Pd or Ru. The subscripts 10 and 8 indicate the clusters of Figs. 1 and 2 respectively. The subscripts of CO show the numbers of CO molecules adsorbed on the atom 1.

In M_{10}–CO, the C and O atoms are taken on the C_3-axis of C_{3v} symmetry. In M_{10}-$(CO)_2$ of Fig. 1 (b), two pairs of C and O are taken on the σ_h-plane of C_s symmetry, with the C–M–C angle of 60°. In M_{10}-$(CO)_3$ of Fig. 1(c), three pairs of C and O are taken on each of the three σ_v-planes of C_{3v} symmetry. Three C and atom 1 form a regular tetrahedral arrangement.

In M_8–CO, the atoms numbered 8, C, and O are taken on the C_2-axis of the C_{2v} symmetry. In M_8-$(CO)_2$ of Fig. 2 (b), the 1, 4, 7, and 8 atoms and two pairs of C and O are taken on one of the two σ_v-planes of the C_{2v} symmetry, with the C–M–C angle of 60°. In M_8-$(CO)_3$ of Fig. 2 (c), one of three CO is taken on the C_2-axis of the C_{2v} symmetry, with the C–M–C angle of 45°.

All the nearest-neighbor distances between metal atoms are taken as metallic values of 2.65 Å and 2.75 Å for Ru and Pd respectively. The Ru–C bond length is taken as 2.00 Å, which is close to that of 1.92 Å in $Ru_3(CO)_{12}$.[13] The two kinds of Pd–C bond length are taken as 2.00 Å for the sake of comparison with Ru, and as 2.25 Å; this brought about a desirable density of states in comparison with the UPS spectra. Palladium carbonyl complexes to be referred to for the Pd–C bond length are lacking. The C–O bond length is taken as 1.15 Å, which is identical with Politzer and Kasten's report[12] and close to the 1.128 Å of free CO.

Calculation. Computation was carried out by using the SCC extended Hückel method. Each molecular orbital, Ψ_i, is written as a linear combination of the occupied valence orbitals of various atoms:

$$\Psi_i = \sum_{jk} C_{ijk}\phi_{jk},$$

where ϕ_{jk} is an atomic orbital j on the atom k.

The diagonal elements of the Hamiltonian matrix, H_{ii}, are given in terms of the valence-state ionization energy according to the procedure of Basch, Viste, and Gray:[14]

$$-H_{ii} = A+BQ,$$

where Q is the charge on the atom. Basch *et al.*[14] applied A and B as functions of the average electron configuration as well as the atomic orbitals, but in the present paper A and B were adopted as functions of the atomic orbitals only, because of the difficult convergence and because of the insufficient spectroscopic data on Ru and Pd.[15] The A and B determined by spectroscopic data[15] as well as other input data are listed in Table 2.

The overlap elements, S_{ij}, were culculated by using Slater orbitals. The interactions among all the nearest-neighbor atoms are taken into account. The orbital exponents (ζ) obtained by Clementi *et al.*[16,17] were adopted except for 5s and 5p. The ζ_{5p} of Ru or Pd is lacking in Clementi's table,[17] but ζ_{5p} was postulated to be equal to ζ_{5s} according to Slater's rule. The ζ_{5s} and ζ_{5p} of Pd or Ru were determined as the minimum values so as not to give rise to negative eigenvalues of the determinant S_{ij}, since negative ones were produced when Clementi's ζ_{5s} was adopted. The ζ_{5s} and ζ_{5p} of Ru are accidentally coincident to those of Pd in two significant figures.

The off-diagonal elements of the Hamiltonian matrix were approximated by using Cusachs formula:[18]

$$H_{ij} = (1/2)S_{ij}(2-|S_{ij}|)(H_{ii}+H_{jj})$$

The calculation generally went through 5—35 iterations, giving a Mulliken charge distribution varying by less than 0.01 on each atom between successive cycles. As did Rein, Fukuda, Win, and Clark, we used the damping parameter in the iteration process to avoid divergence or oscillation;[19] convergence was forced by changing this damping parameter.

The density of states (DOS) was calculated from the converged coefficients, C_{ijk}, in every occupied level and multiplied by the Gaussian function, with a standard deviation of 2.0 eV. In the present paper, energy levels are expressed in values relative to the highest occupied molecular orbital (HOMO), which is taken as zero or the Fermi level (E_f). Fassaert and van der Avoird's paper[20] was referred to.

TABLE 2. PARAMETERS OF THE CALCULATION

Orbital exponents								
	Ru		Pd			C		O
4d	3.2032		3.4044		2s	1.6083		2.2458

a) In negative charge of Q.

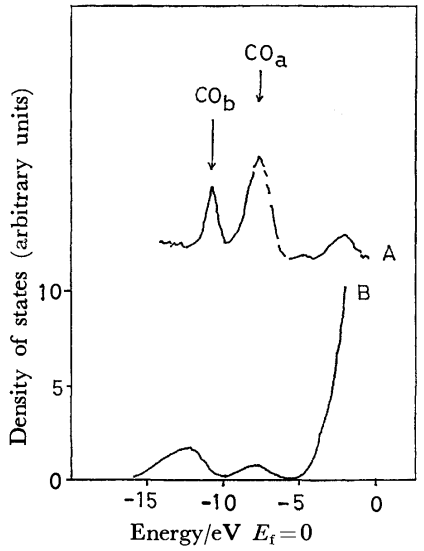

Fig. 3. Comparison between density of states for Ru_{10}–CO and UPS spectra of CO-covered Ru(001) surface. (A): UPS (He_{II}) spectra of Ru(001) covered 15 Langmuir CO, (B): density of states calculated for Ru_{10}–CO.

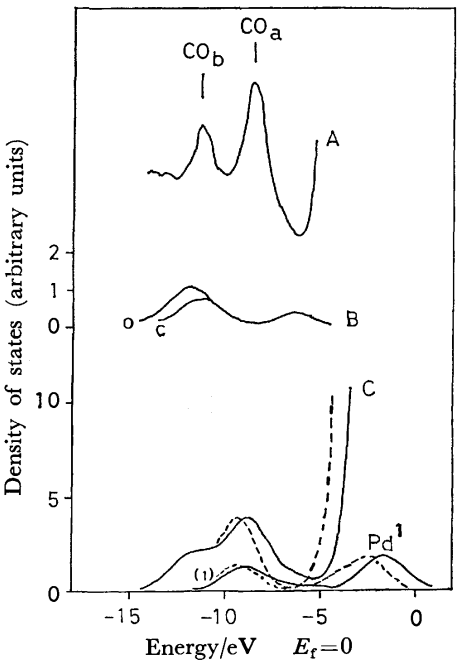

Fig. 4. Comparison between density of states for Pd_{10}–CO and UPS spectra of CO adsorbed Pd(111). (A): UPS (He_{II}) spectra of Pd(111) exposed to 2×10^{-7} Torr of CO, (B): density of states for C and O calculated in Pd_{10}–CO; (C): density of states for the whole and for central Pd^1 in Pd_{10}–CO (——) and Pd_{10} (----).

There were great differences in the total energies (ground states) of various models. It should be noted that the convergent states in the SCC approximation are not necessarily minimum in energy. The total energies will not be discussed in the present paper.

Results and Discussion

Density of States (DOS). The DOS values for Ru_{10}–CO are shown in Fig. 3, along with the UPS spectra of CO adsorbed Ru(001).[21] The DOS of the Ru_{10} cluster almost overlaps with that of Ru_{10}–CO over −5 eV and almost equals zero under −5 eV, so the DOS line is omitted in Fig. 3. The results of calculation agree with the UPS spectra on the CO_a band (−7.6 eV).

The DOS for Pd_{10}–CO (Pd–C=2.25 Å) and the Pd_{10} cluster are shown in Fig. 4, along with the UPS spectra of CO-adsorbed Pd(111).[22] In the case of Pd–C= 2.00 Å, the higher band (−7 or −6 eV) in the DOS of CO is very small; hence, the figure is omitted. The results of calculation agree with the UPS spectra on the CO_b band (−11.2 eV). The higher band (CO_a) in the DOS of CO (B in Fig. 4) agrees with the 5σ level obtained by Chen *et al.* in the SCF-XαSW calculation for Pd_5–CO.[23]

The DOS of the Ru_{10} cluster scarcely differs from that of Ru_{10}–CO, but the DOS of the Pd_{10} cluster (C in Fig. 4) has two important characteristcs. First, the DOS of the Pd_{10} cluster is widespread over a range lower than that of Ru_{10} and changes to a higher range upon adsorbing CO. Secondly, about half of the DOS of Pd^1 exists in a range lower than −5 eV, and this DOS is not influenced by the presence of CO. These

two characteristcs suggest that electrons of Pd_{10} are more stable and that fewer electrons take part in bonding with CO compared with Ru_{10}. This difference will be discussed numerically in the next section.

Population Analysis. Mulliken's atomic gross population (AGP), the atomic net population (ANP), the atomic bond population (ABP), and the atomic orbital-bond population (AOBP) were analyzed by using the converged C_{ijk} values. All the ANP properly have values less than the numbers of the valence electron on the atom. All the ABP of all the models except for Pd_{10}-$(CO)_3$ are positive, but negative ABP of Pd-Pd were contained in the Pd_{10}-$(CO)_3$; consequently, it can be presumed that such a state of chemisorption as in this model is not possible.

In the 10-atom cluster, M_{10}-$(CO)_2$ has C_s symmetry, unlike the other models. In the 8-atom cluster, M_8-$(CO)_3$ contains two different pairs of C and O atoms. Consequently, a detailed comparison among the same metal and the same cluster was omitted.

In AGP, the 10-atom cluster and 8-atom cluster systems are summarized in Tables 3 and 4 respectively. All the AGP of C (AGP-C) in the adsorbed CO are greater than the 3.695 of free CO. In Ru, all the AGP-C are greater than 4 (valence electrons of C). These results indicate the presence of an overall transfer of electrons from Ru to C, a so-called "back donation." In Pd_{10}-CO, the AGP-C of Pd-C=2.25 Å is greater than 4 and that of Pd-C=2.00 Å. This corresponds to the result of DOS presented above; that is, in Pd-C=2.00 Å, the higher band in DOS of CO is very small. The AGP-C values of Pd_{10}-$(CO)_2$, Pd_8-$(CO)_2$, and Pd_8-$(CO)_3$ are smaller than in all other models. The back donation can be taken as a measure of the strength of the bond between metal and carbon, so that the strength of the bond between a multivalent Pd and two or three C may be weak.

In the 8-atom cluster, all the AGP of oxygen have values greater than 6; that is, oxygen atoms have negative charges. This agrees with the general tendency found by another investigation.[12] In the 10-atom cluster, these AGP values of oxygen are less than 6. This suggests that the 8-atom cluster gives more suitable results of calculation.

In the AGP of a central atom, Ru^1 or Pd^1, without CO, those of the 8-atom cluster are greater than those of the 10-atom cluster, and they (8-atom cluster) are greater than the number of each valence electron (Ru: 8, Pd: 10). The transfer of electrons from the nearest-neighbor atoms to a central atom occurs and facilitates the back donation. Consequently, the step site (8-atom cluster) forms stronger bonds between metal and C, and also forms twin or trine easily. The values AGP−8.00 of Ru^1 are always greater than the values

AGP -10.00 of Pd[1] in all models. This indicates that the Ru–C bonding is more stable than that of Pd–C.

The binding energy (E_b) between the central metal atom and C, and the C–O stretching frequencies (ν) in various models are summarized in Table 5. The ν of C–O were evaluated by fitting the equation given by Baerends and Ros[24] to the ABP of CO. Except for M_{10}–CO and Ru_8–CO, the calculated ν values are close to the experimental values (1900—2200 cm^{-1}), so the SCC approximation seems reasonable. The discrepancies in the ν values of M_{10}–CO and Ru_8–CO are ascribed to Baerends's equation,[24] which was derived from carbonyl complexes. These complexes contain 4—6 CO, and neither Pd nor Ru was dealt with as a transition metal atom in the Baerends's paper.[24]

The binding energy, E_b is the E_{ab} value proposed by Pople *et al.*[25] These $|E_b|$ values decrease with an increase in the number of CO; that is, the bonding of twin or trine is weaker than linear bonding. The E_b values of Pd–C=2.00 Å properly have greater negative values than those of Pd–C=2.25 Å because of their shorter bond lengths. The E_b values of Ru–C always have greater negative values than the E_b values of Pd–C, and the E_b values of Pd–C=2.25 Å, which gives a result closer to the UPS spectra, are particularly small negative values, less than half those of Ru–C. On the whole, it is clear that the bonding of Pd–C, especially the bonding of twin or trine, is more unstable than that of Ru–C.

The ABP between the central metal atom and C in various models are summarized in Table 6, while the ABP between C and oxygen in various models are summarized in Table 7. The total ABP of Ru–C have greater values than those of Pd–C in each model. Contrary to the case of metal-C, the total ABP of CO in Ru are always smaller than those in Pd. The total ABP of CO in each model are always smaller than those of free CO. This shows that the overall increase in electron density between metal and C causes a decrease in the electron density between C and oxygen; this tendency agrees with the well-known description of transition-metal complexes involving car-

a) The averages of two different atoms in C_s symmetry. b) The averages of the central and side atoms.

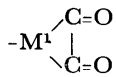
bonyl groups. In the 8-atom cluster, the total ABP of CO and ν increase, while those of metal-C decrease, with the number of CO. This tendency agrees with the view reported by Davydov and Bell[11] concerning the band shift of the IR spectra.

The ABP of π-orbitals in Pd–C are less than half those of Ru–C in every model. Since the ABP of π-orbitals result from the back donation of electrons from metals, the greater values of the ABP of π-orbitals as well as the total ABP in Ru–C show that Ru adsorbs CO more strongly than Pd.

The steep falls of the ABP (π-orbitals) in Pd_8-$(CO)_2$ and Pd_8-$(CO)_3$ and of the total ABP in Pd_{10}-$(CO)_2$ seem to explain why no experimental data of twin or trine types of CO chemisorption in Pd exist.

The AOBP between the 1 atom and C in various models are summarized in Table 8. In the AOBP of metal-C, remarkable differences between Pd and Ru are observed. The AOBP of the 4d-orbital in Ru–C are always more than double those in Pd–C. It seems an important factor for the stabilization of the bonding, especially, the bonding of twin or trine, that 4d-orbitals take part in the bond formation between metal and carbon. In Pd–C, the AOBP of 5s or 5p are greater than those of 4d. In the calculation of Chen *et al.*[23] for Pd_5–CO by the SCF-XαSW method, the ratio of the charge density in s, p, and d orbitals is 1:1:2. In the present calculations, the result for Pd_8–CO is close to that for Pd_5–CO obtained by Chen *et al.*[23] The great charge density of the d-orbital obtained by Chen *et al.*[23] arises from their taking the four Pd atoms as nearest neighbors. In the three hypothetical models Pd_8-$(CO)_2$, Pd_8-$(CO)_3$, and Pd_{10}-$(CO)_2$, the AOBP of 4d-orbitals are very small compared with Pd_8–CO. This is why twin or trine do not exist in CO-adsorbed Pd metal. The small AOBP of the 4d-orbital in Pd_{10}–CO have not yet been solved.

C–C Interaction. In the calculations described above, the overlap elements among carbon atoms were not taken into account. Further calculations were performed by placing the overlaps between carbon atoms in the matrix elements according to the following scheme of M_8-$(CO)_2$ and M_{10}-$(CO)_2$:



The various atomic populations of 10-atom and 8-atom clusters are summarized in Tables 9 and 10 respectively. The M^1–C bond length is taken as the same 2.00 Å in both Ru and Pd metals. The C–C bond length also results in a value of 2.00 Å when the M_8-$(CO)_2$ and M_{10}-$(CO)_2$ are used as models.

TABLE 9. THE ATOMIC POPULATION[a] OF M_{10}-$(CO)_2$ WITH A C–C BOND

Metal	AGP		Total ABP		AOBP	(M^1-C)
Ru	Ru^1	8.424	Ru-C	0.440	4d	0.181
	C	4.250	C-O	0.952	5s	0.092
	O	6.482	C-C	0.487	5p	0.166
Pd	Pd^1	9.945	Pd-C	0.228	4d	0.080
	C	4.132	C-O	1.010	5s	0.116
	O	6.368	C-C	0.541	5p	0.033

a) The values of carbon and oxygen are averages of two different atom in C_s symmetry.

TABLE 10. THE ATOMIC POPULATION OF M_8-$(CO)_2$ WITH A C–C BOND

Metal	AGP		Total ABP		AOBP	(M^1-C)
Ru	Ru^1	8.313	Ru-C	0.442	4d	0.184
	C	4.266	C-O	0.953	5s	0.097
	O	6.478	C-C	0.499	5p	0.160
Pd	Pd^1	9.904	Pd-C	0.232	4d	0.086
	C	4.089	C-O	1.014	5s	0.121
	O	6.356	C-C	0.561	5p	0.024

In all the evidence, the case taking the C–C overlap shows the same tendency as the preceding case taking no C–C overlap. The same discussion as in the preceding sections therefore holds.

The ABP of the C–C bond of the Pd cluster are greater than those of Ru contrary to the ABP of M^1–C. This is coincident with the tendency of the C–O bond.

The binding energies, E_b, values of M^1–C (E_{M-C}), of C–O (E_{C-O}), and of C–C (E_{C-C}) are summarized in Table 11. The $|E_{C-O}|$ and $|E_{C-C}|$ values of Ru are smaller than those of Pd. This tendency is comparable to that of ABP.

Concluding Remarks

Generally speaking, the experimental results show that no CO chemisorption of the twin or trine type is found on Pd, but is found on Ru metal.

Table 11. The binding energy of carbon atom in 8-atom and 10-atom clusters with a C–C bond

Cluster		E_{C-M}/eV	E_{C-O}/eV	E_{C-C}/eV
10-atom	Ru	−1.28	−8.87	−1.11
	Pd	−1.07	−10.58	−1.47
8-atom	Ru	−0.94	−8.86	−1.41
	Pd	−0.55	−10.42	−1.85

Calculations for the model Pd_{10}–$(CO)_3$ cluster gave negative ABP among the Pd atoms, suggesting that there is no trine type CO adsorption on the 10-atom Pd cluster.

From a comparison of Ru with Pd concerning twin-type adsorption on the 8-atom and 10-atom clusters, stability differences in bonding between two CO molecules and these metals were deduced, as is shown by the following inequality relationships:

1. AGP of $Ru^1 > 8$ (valence electron numbers of Ru)
   AGP of $Pd^1 < 10$ (valence electron numbers of Pd)
   This shows that an over-all donation to Ru^1 occurs more easily than to Pd^1.
2. AGP of C in Ru > 4
   AGP of C in Pd < 4
   This shows that an over-all back donation from Ru metal occurs more easily than from Pd metal.
3. (Total ABP of Ru–C) > (total ABP of Pd–C)
4. (AOBP of 4d in Ru–C) $\gg$ (AOBP of 4d in Pd–C)
5. ($|E_b|$ of Ru–C) > ($|E_b|$ of Pd–C)

All five of these relationships indicate that the twin-type CO adsorption on 8-atom and 10-atom Ru clusters are more stable than those on Pd. Thus, the calculated results account well for the experimental observations.

Conformational Changes of the Poly(α-L-glutamic acid)-Cu(II) Macromolecular Complexes in the pH Range of 4—7. A Light Scattering Study with Emphasis on Aggregation and Helix-coil Transitions

Tsutomu MASUJIMA†

Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730

(Received April 15, 1982)

The overall conformational changes of the macromolecular complex between poly(α-L-glutamic acid), poly(Glu), and Cu(II) in 0.15 M NaCl were investigated by means of the light scattering method at three mixing ratios of Glu residues to Cu^{2+}, R, (32, 16, and 8) in the pH range of 4—7. The root-mean-square radius of gyration and the weight-averaged molecular weight of poly(Glu) were determined by means of the Zimm plot, and those pH dependences show that the poly(Glu) shrinks in the course of the coil-to-helix transition and that it forms aggregates at pH values lower than 4.7, where helix formation is almost completed. In the presence of Cu^{2+} ions, the bound Cu(II) accelerates the shrinking of the poly(Glu) conformation and induces the aggregation in a high pH region, where the helix is imperfect. With the aid of theoretical treatments in the text, the aggregation scheme in the helix region was disclosed to be side-by-side, in which a 70—95% length of a helix overlaps one another. All these results and the pH dependence of the radius of gyration per poly(Glu) molecule were discussed in relation to the complex formation between Cu(II) and poly(Glu).

The poly(α-L-glutamic acid), poly(Glu), has been used extensively as a model substance of the proteins. Thus, the systems including both poly(Glu) and the transition-metal ions are interesting as models of the metallo-proteins or of the materials of the functional metal-polymer complex, and so they have been studied extensively.[1-19] In these transition-metal ions, the Cu(II) was shown to be rather unique in the induction of the conformational changes in poly(Glu),[2,11,14,16,17,19] the strength of the binding,[13,15-17] and the complicated complex formations.[12-18] Our recent work has clarified that three classes of complexes predominate either in the helix or extended-coil region, in the helix-coil intermediate transition region, or in the low-pH region, where the helix formation has already been completed.[15] The characteristic formation of the complex should be correlated with the conformational changes of poly(Glu). Since no definite conformation, however, was observed in the helix-coil intermediate region, a study of the conformational changes from other points of veiw is needed. One important point of view is that of the overall conformations of poly(Glu). The light scattering method is useful for this purpose, because it can discriminate the aggregation and the change in the scale of poly(Glu) by the use of the weight-averaged molecular weight, M_w, and the z-averaged root-mean-square radius of gyration, $\langle s^2 \rangle_z^{1/2}$, of poly(Glu) respectively.

Aqueous solutions of poly(Glu) or poly(Glu)–Cu(II) have been studied slightly by means of the light scattering method.[18,20,21] These studies have, though, been related to the aggregation[18,20] or have been only of the random coil of poly(Glu).[21] In the present study, poly(Glu)–Cu(II) macromolecular complexes at various pHs and various mixing ratios of Glu residues to Cu^{2+}, R, in 0.15 M (1 M=1 mol dm^{-3}) NaCl were investigated. With the observed values of M_w and $\langle s^2 \rangle_z^{1/2}$, the pH dependence of the overall conformational changes in poly(Glu) and the effect of Cu(II) binding on this changes were determined from the points of view of aggregation and the compactness of the poly(Glu) molecule. Furthermore, with the aid of some theoretical treatments developed (Theoretical), the equilibrium and the scheme (*e.g.*, side-by-side or head-to-tail) of aggregation, and the participation of H^+ ions in the aggregation were analyzed. Finally, the pH dependence of the extension per poly(Glu) molecule in the presence of Cu(II) was discussed in relation to the characteristic complex formations between poly(Glu) and Cu(II).

Experimental

Materials and Preparations of Poly(Glu) and Poly(Glu)–Cu(II) Solutions. Sodium poly(Glu), hereafter denoted simply as poly(Glu), was the same sample as has been described elsewhere.[11] The other chemicals were all of a reagent grade and were used without further purification. The preparation of the poly(Glu) and poly(Glu)–Cu(II) solutions prior to dialysis was the same as has been described previously.[15] The mixing ratio, R, defined as the molar residue concentration of poly(Glu) to the total concentration of Cu^{2+} ions, was adjusted by changing the amount of Cu^{2+} ions. Freshly redistilled, dust-free water was used for all preparations of solutions. The sample solutions were dialyzed against 2 l of a 0.15 M NaCl solution for 48 h. For a Cu^{2+} containing sample, an adequate amount of Cu^{2+} ions was also added to the outer-side solution prior to dialysis in order to diminish the change in the R of the inner-side solution in the course of dialysis. In this case, the concentration of the unbound Cu^{2+} was calculated on the basis of the data of equilibrium dialysis.[15] For the pH adjustment of a sample at a low pH (<4.5), H^+ ions were added indirectly from the outer-side solution in order to prevent the precipitation of poly(Glu). The dialyzed sample (inner side) was diluted with the outer-side dialysis solution when the concentration dependence of light scattering and the refractive index were measured. All the sample solutions were clarified by a careful and slow flow rate (1—3 ml/min) filtration[22] through a pair of 23 mmϕ Fuji micro filters FM-22 (0.22 μm pore) (Fuji Photo Film Co., Ltd., Japan), which adsorbed slight proteins (less than 1 μg/cm^2). The concentrations of poly(Glu) in all the samples after the light-scattering and refractive-index measurements were deter-

† Present address: Institute of Pharmaceutical Sciences, Hiroshima University School of Medicine, Kasumi 1-2-3, Minami-ku, Hiroshima 734.

mined by means of the micro-Biuret method with a precision of ±1% or less.[23] The value of 151.1 g/mol was used as the Glu residue mass throughout the experiments.

Light Scattering and Differential Refractive Index Measurements. The light scattering (L.S.) photometer was a Shimadzu type PG-21 apparatus, with a Takeda Riken digital multimeter, type TR-6855. The incident-light beam of the 436 nm wavelength of the Hg lamp was used. The cross section of the beam was 4×12 mm^2. The calibration of the instrument was achieved by the use of the freshly distilled benzene and standard polyethylene oxide of molecular weights of 8×10^4 and 15×10^4 (Toyo Soda SE-8 and SE-15 respectively; Toyo Soda Co., Ltd., Japan). The reference value of the R_{90} of benzene was 46.5×10^{-6} cm^{-1} (25 °C).[24] The intensities of the vertical and horizontal components of the scattered light at a given angle, θ, with a vertically polarized incident beam, $V_v(\theta)$ and $H_v(\theta)$ respectively, were calculated by means of the scattered-light intensities (without an analysing polarizer) with vertically (θ=30—135°), $U_v(\theta)$, and horizontally (90° only), $U_h(90)$, polarized incident beams as follows:[25,26]

$$V_v(\theta) = U_v(\theta) - H_v(\theta) \quad (1)$$

$$H_v(\theta) = U_h(90)/2. \quad (2)$$

Tomimatsu's method was followed for the correction of the back reflection of the cylindrical cell (38 mmϕ) (in a water jacket).[27] All L.S. measurements were carried out at 25±0.1 °C. The contributions of Cu^{2+} ions and the optical absorption of poly(Glu)–Cu(II) solutions ($\varepsilon\simeq20$ at most at 436 nm) to the scattered-light intensity were negligible.[28]

The differential refractive index, dn/dc, of a sample solution at 436 nm and at 25±0.1 °C was determined by the use of a Shimadzu differential refractometer (the Debye type) which has been modified in some respects. The method of detecting the slit image was changed to that with the photomultiplier. The Debye cell was capped to prevent the evaporation of the solvent, and the optical bench below the photomultiplier box was thermostated. In the measurements of both L.S. and dn/dc, the outer-side dialysis solution was used as a blank solution. The pH variation in the sample solution in the course of dilution was less than ±0.02 at pH≤5.5 and less than ±0.04 at pH>5.5.

The pH values of the sample solutions were determined on a Hitachi-Horiba Model N-5 pH meter after the L.S. and dn/dc measurements.

Theoretical

General Aggregation Models and the Variation in M_w. Two typical models can be assumed, called;
a) open association;

$$\begin{aligned} &M_1 + M_1 \overset{K_1}{\rightleftharpoons} M_2 \\ &M_2 + M_1 \overset{K_2}{\rightleftharpoons} M_3 \\ &\cdots\cdots\cdots\cdots \\ &M_{n-1} + M_1 \overset{K_{n-1}}{\rightleftharpoons} M_n \\ &\cdots\cdots\cdots\cdots \end{aligned} \quad (3)$$

and b) closed association;

$$nM_1 \overset{K'}{\rightleftharpoons} M_n, \quad (4)$$

where M_n is the n-mer of poly(Glu) and where K or K' is the equilibrium constant of association.[29] Since the precipitation of poly(Glu) is observed at pH values lower than 3.5, the aggregation process of poly(Glu) molecules seems to be of the former type, in which the value of n increases indefinitely. Since no definite correlating function has been found among the K values, all the steps in the open association are assumed to be equivalent, *i.e.*, identical K values, for a mathematically rigorous model;[29]

$$K_1 = K_2 = \cdots = K_n = \cdots = K. \quad (5)$$

This model implies an independence of the equilibrium constants from the degree of association.[29] Thus,

$$(K_1\cdot K_2\cdot \cdots \cdot K_{n-1} =)K^{n-1} = \frac{\gamma_n[M_n]}{(\gamma_1[M_1])^n}, \quad (6)$$

where γ_n is the activity coefficient of n-mer. As Ogston and Winzor showed in their theoretical study, $\gamma_n/{\gamma_1}^n$ in Eq. 6 can be regarded as 1 because of the self-cancellation of the activity coefficients in the equilibrium expression for the association of charged spherical or rod-shaped polymers.[30] In this case, Eq. 6 can be treated simply as;[31]

$$[M_n] = K^{n-1}[M_1]^n = [M_1]Y^{n-1}, \quad (7)$$

where

$$Y = K[M_1]. \quad (8)$$

The variation in $[M_n]/[M_1]$ with n at various parameters of Y is shown in Fig. 1. The figure shows that the weight-averaged molecular weight can be determined by the use of Y. The total molar concentration of unimers, C_0, included in unimers and multimers is;

$$C_0 = [M_1] + 2[M_2] + \cdots + n[M_n] + \cdots. \quad (9)$$

By combining Eqs. 7 and 9, we obtain;

$$C_0 = \frac{[M_1]}{(1-K[M_1])^2} = \frac{[M_1]}{(1-Y)^2}, \quad (10)$$

when $|Y|<1$. The weight-averaged molecular weight, M_w, which can be determined experimentally is;

$$M_w = \frac{M_1^2[M_1]\sum n^2(K[M_1])^{n-1}}{M_1C_0}, \quad (11)$$

when combined with Eq. 10, Eq. 11 was reduced;[29]

$$\frac{M_w}{M_1} = \frac{1+K[M_1]}{1-K[M_1]} = \frac{1+Y}{1-Y}. \quad (12)$$

These equations show that the observed values of M_w

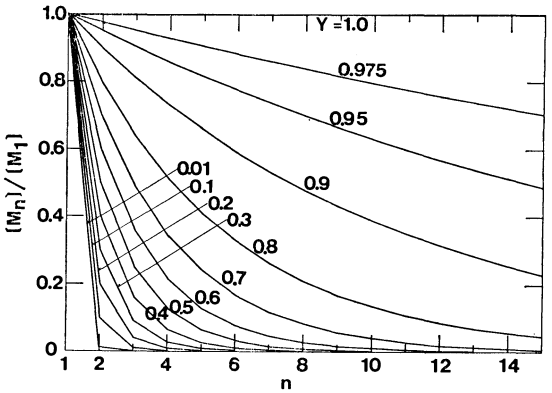

Fig. 1. The distribution curve of the molar concentration ratio of n-mer to unimer *vs.* n in the aggregated system at various assumed values of $Y(=K[M_1])$.

and M_1 give the value of Y by means of Eq. 12; then, with the values of Y and C_0, the values of $[M_1]$ and subsequently K can be determined by the use of Eqs. 8 and 10.

pH-Dependent Aggregation Models and the Variation in M_w. As will be shown later, the aggregation of poly(Glu) depends on the pH. This phenomenon shows that the binding of H^+ ions contributes to the aggregation. If the binding of mH^+ ions advances the one step of the open association, the following association process can be assumed as a first approximation;

$$\begin{aligned} &M_1' + M_1' + mH^+ \overset{K''}{\rightleftharpoons} M_2' \\ &M_2' + M_1' + mH^+ \overset{K''}{\rightleftharpoons} M_3' \\ &\cdots\cdots\cdots\cdots \\ &M_{n-1}' + M_1' + mH^+ \overset{K''}{\rightleftharpoons} M_n' \\ &\cdots\cdots\cdots\cdots . \end{aligned} \tag{13}$$

Then, just as in the preceding section,

$$[M_n'] = K''^{n-1}[M_1']^n((\gamma_{H^+}[H^+])^m)^{n-1}, \tag{14}$$

where γ_{H^+} is the activity coefficient of the H^+ ion. In this case, the following treatment is the same as in the previous open-association model when we regard Y as;

$$Y = K''[M_1'](\gamma_{H^+}[H^+])^m (= Y_H). \tag{15}$$

By combining Eqs. 14 and 10, we obtain;

$$\frac{Y_H}{(1-Y_H)^2} = C_0K''(\gamma_{H^+}[H^+])^m. \tag{16}$$

On electrochemical detection, $pH = -\log(\gamma_{H^+}[H^+])$. Thus,

$$\log\left(\frac{Y_H}{(1-Y_H)^2}\right) = \log(C_0K'') - m\cdot pH. \tag{17}$$

When we plot the pH dependence of the $\log(Y_H/(1-Y_H)^2)$, which can be determined by the data of M_w and M_1, the straight line gives the value of m from the slope and that of K'' from the intercept. When the curved plot is obtained, this model is unsuitable. Both K'' and m can be determined by the use of the two sets of data of M_w and pH by Eq. 17, but they should be nominal values in the curved plot.

Variation in the Mean-square Radius of Gyration in the Aggregate System. The variation in the mean-square radius of gyration, $\langle s^2\rangle_z$, with aggregation is more complicated than that of the M_w, because the variation in $\langle s^2\rangle_z$ is affected by the conformations of the polymer and $\langle s^2\rangle$ is z-averaged. In general,

$$\langle s^2\rangle_z = \frac{\sum n^2M_1^2Y^{n-1}\langle s_n^2\rangle}{\sum n^2M_1^2Y^{n-1}}, \tag{18}$$

where the open association is assumed and $\langle s_n^2\rangle$ is the mean-square radius of the gyration of the n-mer with the molecular weight of M_n. In the following, the conformation of the polymer should be assumed prior to the analysis.

1) Aggregation of Helices. In the association of helices, when the σ part (in length) of a helix overlaps with the unimer or multimer of the helix in a side-by-side or head-to-tail scheme, the length of the multimer, L, can be related with that of the unimer helix, L_1, by;

$$L = L_1(1+(n-1)(1-\sigma)). \tag{19}$$

Since the $\langle s_1^2\rangle$ of a helix equals $L_1^2/12$,[32] the $\langle s^2\rangle$ of aggregated n-helices, $\langle s_n^2\rangle$, is;

$$\langle s_n^2\rangle = \frac{L_1^2(1+(n-1)(1-\sigma))^2}{12} \tag{20}$$

$$= \langle s_1^2\rangle(1+(n-1)(1-\sigma))^2. \tag{21}$$

At $\sigma=0$, the head-to-tail aggregation scheme is assumed; on the other hand, at $\sigma=1$, the perfect side-by-side scheme is assumed. By combining Eqs. 18 and 21, we obtain;

$$\frac{\langle s^2\rangle_z}{\langle s_1^2\rangle} = \frac{\sum n^2Y^{n-1}(1+(n-1)(1-\sigma))^2}{\sum n^2Y^{n-1}}. \tag{22}$$

For the various σ values, the $(\langle s^2\rangle_z/\langle s_1^2\rangle)^{1/2}$ was calculated; it is plotted against Y and M_w/M_1 in Fig. 2 (a and b), which shows that the relation between $(\langle s^2\rangle_z/\langle s_1^2\rangle)^{1/2}$ and M_w/M_1 is almost linear.

2) Aggregation in the Helix-Coil Transition Region. Since the conformation of poly(Glu) changes in the helix-coil region, a general estimation of $\langle s^2\rangle_z$ is needed.

$$\langle s^2\rangle = \text{const}\cdot M^q, \tag{23}$$

where $q=2/3$, 1, and 2 for spheres, a Gaussian coil, and a thin rod respectively;[31] thus,

$$\frac{\langle s_n^2\rangle}{\langle s_1^2\rangle} = \left(\frac{M_n}{M_1}\right)^q (= n^q). \tag{24}$$

By combining Eqs. 18 and 24, we obtain;

$$\frac{\langle s^2\rangle_z}{\langle s_1^2\rangle} = \frac{\sum n^{2+q}Y^{n-1}}{\sum n^2Y^{n-1}}. \tag{25}$$

In Fig. 3, the value of $(\langle s^2\rangle_z/\langle s_1^2\rangle)^{1/2}$ is plotted against M_w/M_1 at the various q values assumed. In this case, it should be noted that there is an implicit assumption that $\langle s_n^2\rangle$ increases additively with n, just like the increment in the $\langle s^2\rangle$ of the unimers at various molecular-weights. When the association and the conformational changes occur simultaneously, the $(\langle s^2\rangle_z/$

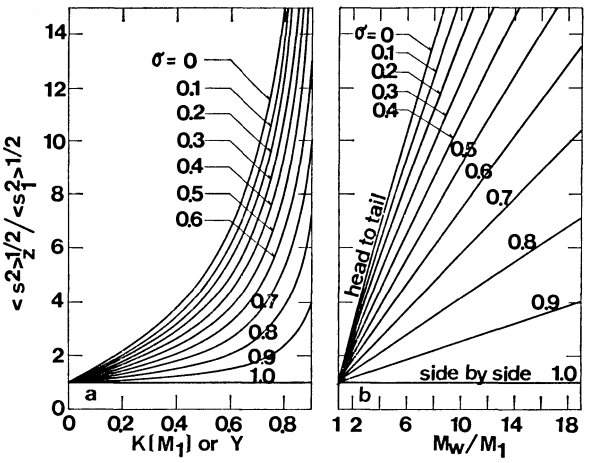

Fig. 2. The dependence of $\langle s^2\rangle_z^{1/2}/\langle s_1^2\rangle^{1/2}$ on (a) Y $(=K[M_1])$, and (b) M_w/M_1, at various overlapping parameters of σ, when the aggregation of helices is assumed to be the scheme of Eq. 22. The summation was carried out from $n=1$ to 100.

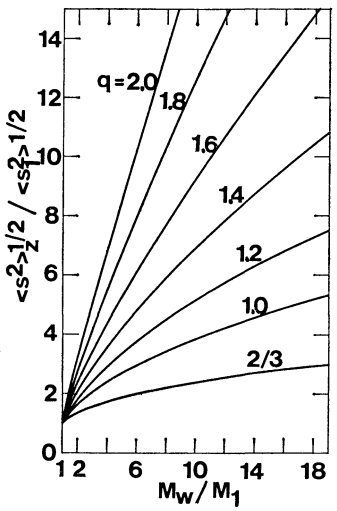

Fig. 3. The dependence of $\langle s^2\rangle_z^{1/2}/\langle s_1^2\rangle^{1/2}$ on M_w/M_1 at various conformational parameters of q, when the poly(Glu) is assumed to aggregate in the helix-coil transition region according to the scheme of Eq. 25. The summation was carried out from $n=1$ to 100.

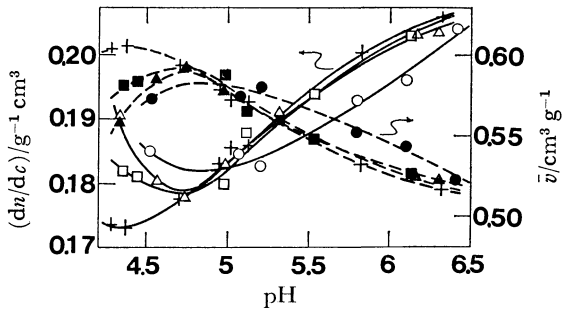

Fig. 4. The pH dependence of dn/dc (solid lines) and the partial specific volume (dashed lines) of poly(Glu) in 0.15 M NaCl solutions at various R of ∞ (poly-(Glu) only) (crosses), 32 (squares), 16 (triangles), and 8 (circles).

$\langle s_1^2\rangle)^{1/2}$ *vs.* M_w/M_1 curves will be very complicated.

Results and Discussion

pH Dependence of dn/dc and the Partial Specific Volume. Figure 4 shows the pH dependence of dn/dc and the partial specific volume, $\bar{v}$, of poly(Glu) in a 0.15 M NaCl solution at various R values. The value of $\bar{v}$ was calculated by means of Heller's equation using dn/dc;[33]

$$\bar{v} = 1.069 - 2.679\ (dn/dc), \tag{26}$$

as will be detailed in a subsequent paper.[19] The increment in $\bar{v}$ with the helix formation was interpreted as showing voids formed in the helix conformation and/or a change in the hydration of water accompanied by the transition.[34] In every case of R, almost all (more than 95%) the Cu^{2+} ions bind with poly(Glu) at pH values higher than 5, and then dissociate with a lowering of the pH.[15] The binding of the Cu^{2+} ion instead of two Na^+ ions should increase the n value; however, the value of dn/dc in the presence of Cu^{2+} ions decreases at a low R. Thus the decrease in dn/dc (increment of $\bar{v}$) in pH 5—6.5 at $R=8$ should be due to the helix formation of poly(Glu) induced by Cu(II).[15] The decrease in $\bar{v}$ at a low pH may show the exclusion of hydrated water on the aggregate formation. With the value of dn/dc and the Rayleigh ratio, the M_w and $\langle s^2\rangle_z^{1/2}$ of poly(Glu) were determined according to Zimm's method.[35]

Zimm Plots of Poly(Glu) at Various R and pH Values. The Rayleigh ratio, which is corrected for the optical anisotropy, $R'(\theta)$, was determined as follows:[25,26]

$$R'(\theta) = R_{V_V}(\theta) - (4/3)R_{V_h}(\theta). \tag{27}$$

Then,

$$K^*c/R'(\theta) = (1/M_w)(1+(16\pi^2/3\lambda^2)\langle s^2\rangle_z \times \sin^2(\theta/2)) + 2A_2c, \tag{28}$$

where K^* is the optical constant, c is the concentration of poly(Glu) (g/ml), λ is the wavelength of the incident beam (cm), and A_2 is the second virial coefficient.

Figure 5 shows the Zimm plots of poly(Glu) solutions at various R values and at pH 6.1—6.3. The almost linear plots seem to show that the molecular-weight distribution of the sample is rather narrow,[32] which is consistent with the results of electric birefringence ($M_w/M_n=1.13$).[36] The values of M_w obtained were 1.06×10^5, 1.22×10^5, and 1.79×10^5, the $\langle s^2\rangle^{1/2}$ values were 290, 250, and 210 Å, and the $A_2\times10^3$ values were 2.9, 1.5, and 0.93 at $R=\infty$, 16, and 8 respectively. The increment of M_w with the addition of Cu(II) shows the participation of Cu(II) in the formation of the aggregate at a high pH, while the decrease in $\langle s^2\rangle_z^{1/2}$ shows that the bound Cu(II) induces the shrinking of the poly(Glu) conformation.

Figure 6 shows the Zimm plot for poly(Glu) at various R values and at low pH (4.28—4.52), where the formation of the helix is completed.[15] The curvilinear plots should show that the molecular-weight distribution is dispersive or that the unimer and multimer of poly(Glu) coexist under these conditions.[32] However, the negative A_2 which is frequently seen in the aggregate systems was not observed, and the plot was almost linear in the experimented-on concentration

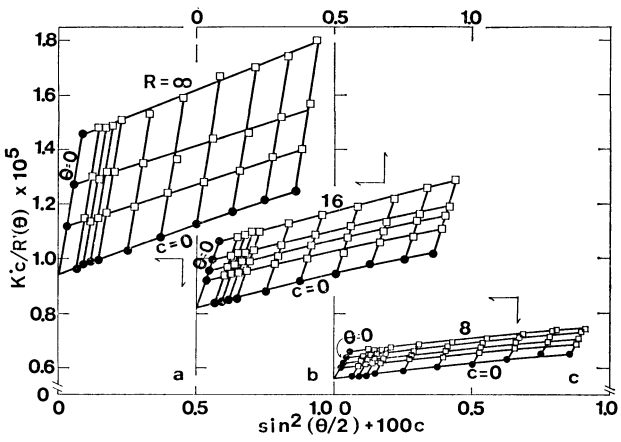

Fig. 5. The Zimm plots for poly(Glu) in 0.15 M NaCl solutions at high pH regions in (a) the absence ($R=\infty$) (pH 6.32) and (b,c) the presence of Cu^{2+} ions ((b) $R=16$ (pH 6.16) and (c) 8 (pH 6.09)).

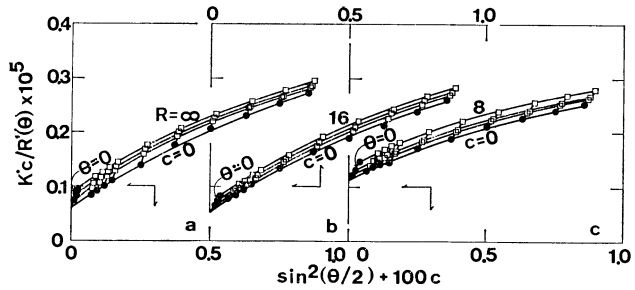

Fig. 6. The Zimm plots for poly(Glu) in 0.15 M NaCl solutions at low pH regions in (a) the absence (pH 4.28) and (b,c) the presence of Cu^{2+} ions ((b) $R=16$ (pH 4.34), and (c) 8 (pH 4.52)).

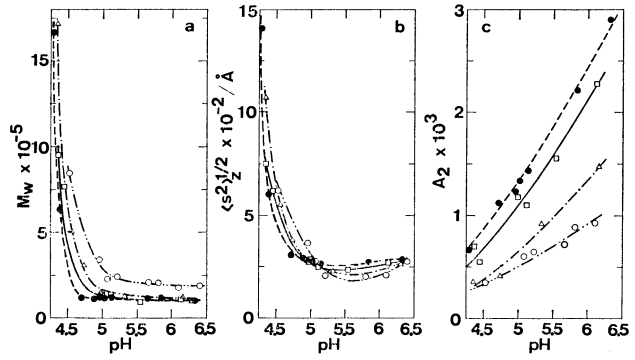

Fig. 7. The pH variation of (a) weight-averaged molecular weight, M_w, (b) z-averaged root-mean square of radius of gyration, $\langle s^2\rangle_z^{1/2}$, and (c) second virial coefficient, A_2, of poly(Glu) in the absence (--●--) and the presence ($R=32$ (—□—), 16 (—·△—·), and 8 (—··○—··)) of Cu^{2+} ions.

range. This may be mainly due to the large equilibrium constant of association[29] (noted later) of this system, in which the associated polymers hardly dissociate from each other with the decrease in the concentration. The value of A_2 was then determined by the slope of the linear region of the $\theta=0$ curve from the high concentration in the Zimm plot. The obtained values of M_w were 1.67×10^6, 1.72×10^6, and 8.47×10^5, while those of $\langle s^2\rangle_z^{1/2}$ were 1410, 1070, and 621 Å and those of $A_2\times10^3$ were 0.67, 0.36, and 0.35, at $R=\infty$, 16, and 8 respectively. In this pH range, the increment of M_w at any R shows that the aggregation of helices is induced by bound H^+ and Cu(II) ions.

pH Dependence of M_w, $\langle s^2\rangle_z^{1/2}$, and A_2. The values of M_w, $\langle s^2\rangle_z^{1/2}$, and A_2 thus determined at various R and pH values are plotted against the pH in Fig. 7. When the A_2, was not determined, the values of M_w and $\langle s^2\rangle_z^{1/2}$ were determined according to Eq. 27 with the light scattering data at one concentration and the interpolated A_2 value. Figure 7(a) shows the M_w *vs.* pH curves. The value of M_w is almost constant at pH values higher than 5.5 and at $R=\infty$ and 32. The M_w data in this region were averaged to 1.07×10^5, which was assumed to be the M_w of the unimer of poly(Glu), *i.e.*, M_1. The increment in M_w from this value means the aggregate formation. In the absence of Cu(II), the aggregation is formed rather drastically at pH values lower than 4.7, and the value of M_w increases to 1.67×10^6 at pH 4.28. With the addition of Cu(II) in a poly(Glu) solution, the starting pH of aggregate formation shifted to the high pH range at about 5, 6, and higher than 6.5 (not determined) at $R=32$, 16, and 8 respectively. The bound Cu(II) induces the aggregate formation of poly(Glu) at high pH values where the helix formation is imperfect. The M_w *vs.* pH curves at various R values seem finally to overlap with each other at some low pH value, because the Cu(II) dissociates from poly(Glu) with a lowering of the pH.[15]

Parallel with the M_w change, the variation in $\langle s^2\rangle_z^{1/2}$ with the pH is shown in Fig. 7(b). At $R=\infty$, the value of $\langle s^2\rangle_z^{1/2}$ decreases in the course of the transition from random coil to helix and then increases with the formation of helix and aggregation. In the presence of Cu^{2+} ions, $\langle s^2\rangle_z^{1/2}$ further decreases in the intermediate helix-coil transition region. The bound Cu(II) seems to induce the shrinking of the poly(Glu) conformation in the helix-coil region. In the low pH range, the value of $\langle s^2\rangle_z^{1/2}$ increases with further aggregate formation. The difference between the pH dependence of M_w and $\langle s^2\rangle_z^{1/2}$ at low pH values (in Figs. 7(a) and (b)) will be discussed later in relation to the aggregation scheme.

For the sample which has been dialyzed in equilibrium, the expression for A_2 is;

$$A_2=\frac{10^3}{2M_p^2}\left(\frac{Z^{*2}}{2m'}+\frac{\partial\ln\gamma_p^*}{\partial c}\right), \tag{29}$$
