This study investigates the flotation of uranium with four amidoxime-type surfactants ($R_{12}Ax$, $R_{16}Ax$, Ls8.6Ax, and Ls7.2Ax6.0Hx). Ls7.2Ax6.0Hx was prepared by the telomerization of acrylonitrile and acrylamide using 1-dodecanethiol as a solvent, followed by treatment with hydroxylamine. Uranium could be floated effectively at pH 5.0 with $R_{12}Ax$, $R_{16}Ax$, or a combination of Ls8.6Ax and a nonionic surfactant. The floatability for uranium present in sea water was 43% after the addition of 1 mg $R_{16}Ax$ and 90% after the addition of 30 mg $R_{12}Ax$. Ls7.2Ax6.0Hx formed a soluble complex, and 72% of the uranium present in sea water could be collected at pH 8.0 by foam fractionation using Ls7.2Ax6.0Hx. Little surfactant remained in the residual solution, and it was regenerated from an acidic solution dissolving the scum or froth.

Ion flotation has been examined as a method of collecting specific metal ions.[2] The collectors used in such flotation are generally a combination of complexing agents, precipitants, or adsorbents, and oppositely charged surfactants.[3,4] However, floatability is apt to vary with the collector-adding method or with the pH, and a small amount of the collector remains in the residual solution.[5] In a previous paper[1] we prepared surfactants with a complex radical and applied them to collectors. The collectors formed floatable complexes with heavy metal ions, and little remained in the residual solution when the HLB (hydrophilic–lipophilic balance) value of the complexes was 4—14.[1] However, the flotation for trace amounts of metal ions dissolved in an aqueous solution was not investigated.

Fetscher,[6] Tani *et al.*,[7] and Egawa *et al.*[8] have reported that amidoxime-type resins adsorb uranium selectively from an aqueous solution or sea water, so that amidoxime-type surfactants may be expected to act as uranium-floating collectors. To get further information on collectors, in this paper we study the recovery of uranium in a 10-ppb uranium solution and in sea water by means of ion flotation and foam fractionation, using four amidoxime-type surfactants: $R_{12}Ax$, $R_{16}Ax$, Ls8.6Ax, and Ls7.2Ax6.0Hx.

Experimental

Synthesis of Amidoxime-type Surfactants. $R_{12}Ax$(3-dodecyloxy)propionamide oxime), $R_{16}Ax$(3-(hexadecyloxy)propionamide oxime), and Ls8.6Ax(telomer containing 8.6 unit moles of the amidoxime group[9]) were obtained as has been described in a previous paper.[1] Ls7.2Ax6.0Hx(cotelomer containing 7.2 unit moles of the amidoxime group, 6.0 unit moles of the hydroxamic acid group, and an amide group[9]) was synthesized as follows:

1-Dodecanethiol(10.1—40.4 g), acrylonitrile(9.5—16.0 g,bp 76.0—77.0 °C), and acrylamide(12.5—21.4 g, bp_{25} 123.0—125.0 °C) were added to 80 cm^3 of ethanol in a three-necked flask equipped with a stirrer, a reflux condenser, and a thermometer. After the air had been purged with nitrogen for 30 min, 1 wt% of α,α'-azobisisobutyronitrile per weight of monomers was added to the reaction mixture and the mixture was stirred at 70 °C. The cotelomer containing a nitrile group and an amide group[9] (Ls–AN–Am) precipitated gradually within 3—4 h; the remaining mixture was stirred for an additional 5 h at 70 °C. After cooling to room temperature, Ls–AN–Am was filtered by suction, washed first with 100 cm^3 of ethanol and second with 50 cm^3 of ether, and then dried. Then Ls7.7AN21.3Am (cotelomer containing 7.7 unit moles of the nitrile group and 21.3 unit moles of the amide group, 2 g) and hydroxylamine hydrochloride (2.1—8.4 g, Wako GR) were dissolved in 30 cm^3 of *N,N*-dimethylformamide in the above-mentioned flask, and the mixture was stirred at 80 °C. Sodium carbonate, in an amount equivalent to the hydroxylamine hydrochloride, was added to the mixture for over 30 min, after which the mixture was stirred for an additional 3 h at 80 °C. The sodium chloride thus precipitated was filtered out by suction, and the filtrate was cooled to room temperature. The white cotelomer, Ls–Ax–Hx, precipitated by the addition of the filtrate to 100 cm^3 of 2-propanol was filtered, rinsed with 200 cm^3 of methanol, and dried.

Collectors. The behavior of the amidoxime-type surfactants used as collectors was compared with that of the hydroxamic acid-type surfactants,[10] an EDTA-type surfactant(*N*-(1-carboxyundecyl)ethylenediamine-*N,N',N'*-triacetic acid, R-edta),[11] and sodium dodecyl sulfate (SDS). The chemical formulas and abbreviations of the amidoxime-type surfactants and hydroxamic acid-type surfactants are presented in Fig. 1.

Sample of Uranium. An aqueous solution containing 10 ppb of uranium ions was prepared by dissolving uranyl nitrate(Wako GR) in deionized water. Sea water was taken at the sea-coast of Akase, Uto-gun, Kumamoto, in Jan., 1979, and was filtered to remove any impure particles.

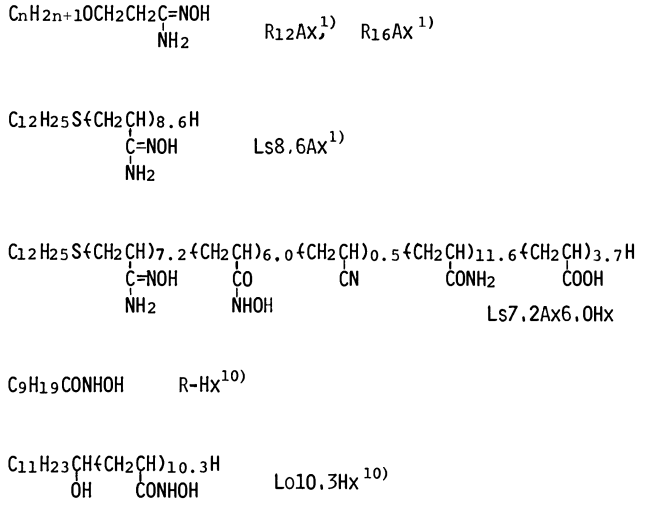

Fig. 1. Formulas and abbreviations.

Apparatus and Procedures. The flotation apparatus was the same as that previously reported.[1] A collector was added to 500 cm^3 of the sample of uranium in a flotation cell, and air, from which CO_2 had been removed with a NaOH solution, was passed into the sample through the glass filter at a rate of 30—40 cm^3/min for 20 min. The amount of uranium in the solution or in the scum was determined from the absorbance of the uranium–arsenazo III complex(660 nm).[12] The floatability(%) of uranium was calculated by the use of:

$$F = \frac{a_0 - a_1}{a_0} \times 100\%,$$

where a_0 and a_1 denote the initial and final concentrations of uranium in the solutions.

Results and Discussion

Synthesis of Ls7.2Ax6.0Hx. Ls–Ax–Hx was derived from Ls–AN–Am. Acrylonitrile was more difficult than acrylamide to introduce into the cotelomer, Ls–AN–Am. The IR spectrum of the compound prepared at 60 °C showed the absence of nitrile, even though the amount of acrylonitrile added was four times that of acrylamide. However, both acrylonitrile and acrylamide could be introduced into the cotelomer by raising the reaction temperature to 70 °C or 77 °C(bp of acrylonitrile), even in the monomer ratio of 1:1. The yield of cotelomer at 70 °C was more than that at 77 °C, and the elongation of the reaction time up to 3 h led to an increase in the yield. Therefore, the rest of the reactions were carried out for 5 h at 70 °C. The conditions for preparing Ls–AN–Am were listed in Table 1. The yields of cotelomer per monomer(acrylonitrile plus acrylamide) were all above 50%, and the plots of the fraction of 1-dodecanethiol(β) *vs.* the reciprocal of the polymerization degree(1/Pn) gave a straight line, as is seen in a usual chaintransfer reaction.[13]

The composition of the cotelomer was determined by means of its molecular weight (Corona 114 vapor pressure osmometer) and IR spectrum (Shimadzu IR-408). The IR spectrum of the cotelomer showed the characteristic absorptions of nitrile(ν_{CN} 2240 cm^{-1}), amide(ν_{CO} 1660, δ_{NH} 1610 cm^{-1}), and hydrocarbon(ν_{CH} 2920, 2850 cm^{-1}). The fraction of the cyano group and the carbamoyl group in the cotelomer was calculated from the absorption ratio for carbonitrile to carboxamide, based on the calibration curve made with the mixture of the nitrile-type telomer[1] and the amide-type telomer.[14] Moreover, the same structure was suggested by the ^1H NMR spectra integration(JEOL JMN-MH-100), as measured in a trifluoroacetic acid solvent with tetramethylsilane as the internal standard, *i.e.*, methyl(δ=0.89, 3H, t), methylene protons(δ=1.35, 20H) due to the dodecyl group, a broad peak of ethylene protons(δ=1.8—3.2), and carbamoyl protons(δ=7.5—7.7). The chemical formulas and results of the elementary analysis of four Ls–AN–Am are shown in Table 2. The calculated values of C, H, N, and S based on the chemical formulas agreed with the analytical data.

The carbamoyl group was introduced into the cotelomer to make the compound soluble even in a metallic solution. The four Ls–AN–Am in Table 2 were soluble in water, and stable foam was generated by bubbling air through the solution. The resulting

foam from the Ls7.7AN21.3Am solution was the richest, so that Ls7.7AN21.3Am was used for the next reaction. The amidoxime group resulted from the reaction of the cyano group with hydroxylamine. However, the carbamoyl group also reacted with hydroxylamine to give the hydroxamic acid group.[15] The conditions and yields of the reaction are shown in Table 3. All the yields were above 85%. The hydroxylamine used was 4.2—16.7 times the cyano group in molality, but a few unit moles of cyano group still remained in Ls-Ax-Hx. The amidoxime and hydroxamic-acid groups were identified by absorption at 265 nm and at 280 nm in an aqueous solution(pH 14).[1] The chemical formulas were determined by the use of the found C, H, N, S, Cl, and Na values of elementary analysis. The chemical formulas and elementary analysis are listed in Table 4.

Determination of Uranium. The amount of uranium in the aqueous solution, sea water, scum, or froth was determined from the absorbance of the arsenazo III- uranium complex(660 nm). Five cm^3 of 60 % HNO_3 was added to 500 cm^3 of the sample solution. The solution was shaken with 20 cm^3 of chloroform to remove any dissolved organic compounds and then concentrated to about 200 cm^3. To scum and froth, 2 cm^3 of 97% H_2SO_4 and 3 cm^3 of 60% HNO_3 were added. The mixture was heated till it became colorless, and then it was dissolved in 200 cm^3 of a 1% HNO_3 solution. After these pretreatments, the uranium was determined according to the procedure of Motojima *et al.*[12] To improve the lower limit of uranium detection, the volume of arsenazo III–31% perchloric acid solution was reduced from 10 cm^3 [12] to 4 cm^3 of the measurable minimum volume in a 1-cm cell. The 8-quinolinol was precipitated when extracted with that solution. Then the precipitate was filtered off. This reduction made the absorbance highly sensitive. The absorbance per 1 μg of uranium varied from 0.028[12] to 0.069; it was proportional to the amount of uranium within the range from 0 to 6 μg. The amount of uranium in 500 cm^3 of sea water was proved to be 1.50 μg (3.0 ppb) by the standard addition method. The addition of surfactants interfered little with the determination of uranium, because the amount of uranium in 500 cm^3 of sea water was proved to be 1.48 μg even when 0.5 g of $R_{12}Ax$ was added. It was presumed that the dissociation of the uranium–$R_{12}Ax$ complex and the formation of the uranium–arsenazo III complex proceeded quantitatively in a 31% perchloric acid solution.

Ion Flotation for 10 ppb Uranium Solution. It is well known that the resins containing the hydroxamic acid group[16] or the amidoxime group[6-8] adsorb uranium effectively. For comparison, the flotation for a 10 ppb uranium solution was examined with the above-mentioned collectors containing such groups.

The floatable pH range was 4—8, and the optimum pH was 5.0, with the amidoxime-type surfactants. The effects of amidoxime-type surfactants on the floatability of uranium at pH 5.0 are indicated in Fig. 2. The

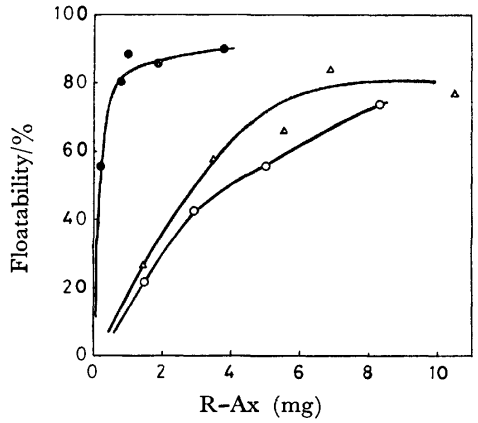

Fig. 2. Effects of R-Ax on the floatability of uranium. Uranium solution: 500 cm³; Concentration: 10 ppb; pH: 5.0. ○: $R_{12}Ax$, △: $R_{16}Ax$, ●: Ls8.6Ax+10 mg of nonionic surfactant.

highest floatability upon the addition of hydroxamic acid-type surfactants, R-edta, or SDS was as follows: 35%(pH 7.0) with 4.0 mg of R-Hx, 64%(pH 7.0) with both 2.1 mg of Lo10.3Hx and 10 mg of nonionic surfactant(Nissan nonion O-6), 51%(pH 7—8) with both 9.1 mg of R-edta and 10 mg of nonionic surfactant, and 21%(pH 7—8) with 20 mg of SDS.

It appears from these results and Fig. 2 that amidoxime-type surfactants were more effective than hydroxamic acid-type surfactants, R-edta, or SDS. The effect on flotation was $R_{12}Ax<R_{16}Ax<Ls8.6Ax$, as may be seen in Fig. 2, reversed to the solubility in water ($Ls8.6Ax<R_{16}Ax<R_{12}Ax$). Since $R_{12}Ax$ and $R_{16}Ax$ are floatable without any surfactant(Ls8.6Ax float with nonionic surfactant), it is considered that the amidoxime-uranium complexes are adsorbed or adhere to the excess of amidoxime-type surfactants and float with them. The HLB values of $R_{12}Ax$ and $R_{16}Ax$ calculated according to the Oda equation[17] were 5 and 4 respectively.

Ion Flotation for Uranium in Sea Water. The collectors used in uranium flotation are generally a combination of selective adsorbent and surfactant, or one of a selective complexing agent and the oppositely charged surfactant, *e.g.*, titanium dioxide and SDS, or arsenazo III and benzyldimethyltetradecylammonium chloride.[3,4] There has been no report on uranium flotation from sea water with a surfactant alone. Therefore, uranium flotation was investigated with amidoxime-type surfactants.

Flotation was carried out at the optimum pH of 5.0. The results are shown in Table 5. The floatability of uranium increased with the quantity of $R_{12}Ax$. In the case of $R_{16}Ax$ and Ls8.6Ax, known amounts of uranium(1, 2, and 3 μg) were further added to 500 cm³ of sea water. Although the amounts of the floatable uranium complexes increased, the floatability stayed approximately constant. The means of floatability were 44% with $R_{16}Ax$ and 47% with Ls8.6Ax, including the nonionic surfactant. Since the uranium complexes float, presumably because of the excess of the amidoxime-type surfactants, the floatability should increase with the increase in $R_{12}Ax$ and should not vary with the addition of uranium. The floatability coincided with the expectation, but the amount of uranium floated per gram of $R_{12}Ax$ decreased with the increase in $R_{12}Ax$, as may be seen in Table 5.

Flotation was carried out at the same pH as sea water(pH 8.0). The results are shown in Table 6. Amidoxime-type surfactants were also the most effective at pH 8.0, though the floatability at pH 8.0 was lower than at pH 5.0. Radioactive cobalt(^{60}Co) was also effectively floated at pH 5.0, as has been mentioned in a previous paper.[1] Because the isoelectric points

Ls8.6Ax	0.3+N[c]	3.0	45	0.20

a) 500 cm³ of sea water, pH adjusted to 5.0 with HNO_3. b) Uranium amount added to 500 cm³ of sea water. c) 10 mg of a nonionic surfactant. Note: Because of the trace amounts, the total amounts of uranium in sea water and scum were confirmed to be 1.50 μg after the flotation.

of amidoxime-type surfactants were presumed to be at pH 5.0, the differences between the floatability at pH 5.0 and that at pH 8.0 were considered to be due to the solubilities of amidoxime-type surfactants.

The residual amount of $R_{12}Ax$ and $R_{16}Ax$ in the sea water was then determined colorimetrically.[18] $R_{12}Ax$ and $R_{16}Ax$ were extracted with Orange II into chloroform at pH 1.0, and the absorbance of R–Ax–Orange II complexes in chloroform was measured at 485 nm. The residual amounts in sea water were 0.05 mg dm^{-3}(pH 5.0) and 0.06 mg dm^{-3}(pH 8.0) in $R_{12}Ax$, and less than 0.05 mg dm^{-3}(pH 5.0) and 0.05 mg dm^{-3} (pH 8.0) in $R_{16}Ax$.

Foam Fractionation of Uranium. Little of the used R-Ax remained in the sea water or the aqueous solution.[1] However, since the pH adjustment to 5.0 is unfavorable, the soluble amidoxime-type surfactant Ls–Ax–Hx was prepared and submitted to foam fractionation. The flotation effect for the 10-ppb uranium solution was observable in the range of pH 3.0—9.0. These floatability values were 52—56% with 40 mg of Ls7.2Ax6.0Hx. The floatability by Ls7.2Ax6.0Hx at pH 8.0 was 23% with 10 mg, 40% with 20 mg, and 56% with 40 mg.

The foam fractionation for uranium in sea water was also carried out(Fig. 3). Stable froth was formed by the addition of more than 30 mg of Ls7.2Ax6.0Hx, and the floatability of uranium was 67—70%. Even though sea water contains highly concentrated salts, the floatability was a little higher than that for the 10-ppb uranium solution. However, the effect varied with the content of the amidoxime group, and the floatability was about 30% with Ls5.1Ax3.9Hx. The floatability in foam fractionation is thought to be highly affected by the complexation and the bubbling ability. The largest amounts of uranium per gram of Ls7.2-Ax6.0Hx floated by foam fractionation were 106 μg/g for the 10-ppb uranium solution and 27 μg/g for sea water, lower than that by the ion flotation using R–Ax.

It is known that little collector for foam fractionation remains in an aqueous solution, since the foamy collector is adsorbed into the interface of the gas and the liquid and is almost completely removed as a froth.[19] The residual amount of Ls7.2Ax6.0Hx in sea water was determined at pH 8.0 by means of the less sensitive UV spectrum(235 nm), because Ls7.2Ax6.0-Hx could not be extracted with Orange II into chloroform. The sensitivity of this method was 0.5 mg/500 cm^3. The residual amount was below 0.5 mg/500 cm^3.

Foam fractionation can be expected to become more effective upon a modification of the apparatus or by a variation in the passing rate of air.[2]

Regeneration of Amidoxime-type Surfactants. The resulting scum or froth was dissociated to an amidoxime-type surfactant and a uranium solution by the addition of the acidic solution. Therefore, regeneration from the scum or froth was investigated after flotation. The hydrochloric acid solution(100 cm^3) prepared for pH prescription was added to the scum or froth and mixed for 5 min. $R_{12}Ax$ and $R_{16}Ax$ were extracted from the acidic solution with 15 cm^3 of chloroform, after which the chloroform was evaporated. Ls7.2Ax6.0Hx was floated as froth by foam fractionation from the acidic solution. The hydrophilic $R_{12}Ax$ in an acidic solution could be regenerated by both extraction and foam fractionation. However, the more hydrophilic Ls7.2-

( ): Floatability by original collectors.

Ax6.0Hx could not be extracted with chloroform. Furthermore, further flotation was carried out for other sea-water specimens using these regenerated amidoxime-type surfactants (Table 7). Uranium flotation with these surfactants was effective, even though a part of the surfactants might be lost because of adhering to the glass surface.

It is concluded from the above results that $R_{12}Ax$, $R_{16}Ax$, and Ls7.2Ax6.0Hx are excellent collectors for uranium flotation.

Studies on Thermodynamics for the Hydrolysis. II. The Temperature Effect on the Stereoselective Deacylation of Amino Acid Esters in Bilayer and Micellar Systems

Yōko Matsumoto and Ryuichi Ueoka*

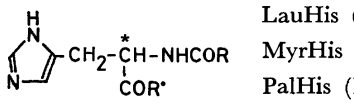
Department of Industrial Chemistry, Kumamoto Institute of Technology, Ikeda, Kumamoto 860

(Received March 7, 1983)

Stereoselective deacylations of *p*-nitrophenyl *N*-acyl-D(or L)-phenylalaninates(D(or L)-S_n; n=2, 12, and 16) and *N*-benzyloxycarbonyl-D(L)-phenylalaninates(D(L)-ZS) by the bilayer and micellar catalytic systems of L-histidine derivatives (LauHis, MyrHis, PalHis, LauHisLeu, and MyrHisLeu) and surfactants ($2C_mN2C_1Br$ with m=12, 14, and 16, CTAB, OTAC, and (*R*)-(+)-SUR_{16}) were performed. It is noteworthy that the temperature dependence of enantioselectivity for the deacylation of S_{12} having a long acyl chain is bell-shaped with maxima at 25 °C and 15—25 °C in the bilayer systems of MyrHis+$2C_{12}N2C_1Br$ and MyrHisLeu+$2C_{12}N2C_1Br$, respectively. On the other hand, the enantioselectivity for the S_{12} deacylation catalyzed by LauHisLeu in the presence of the CTAB micelles increases as temperature is lowered (the highest enantiomer rate ratio ($k^L_{a,obsd}/k^D_{a,obsd}$=12) is attained at 20 °C). The enantioselectivity for the deacylation of S_2 having a short acyl chain, however, is almost constant and considerably lowered in comparison with that for the deacylation of S_{12} in both the bilayer and micellar systems. According to the isokinetic temperature (β), the deacylation of S_n (n=2 and 12) and ZS in the bilayer systems might be entropy-driven, whereas that in the micellar systems might be enthalpy-driven. The stronger hydrophobic microenvironment of the bilayer systems in the ester-deacylation would probably be connected with the entropy-driven nature.

The stereoselective deacylation of *N*-protected amino acid *p*-nitrophenyl esters has recently received considerable attention,[1] and a relatively high stereoselectivity was attaind in the deacylation of diastereomeric dipeptide[2] and of *N*-acylamino acid esters with the dipeptide-type L-histidine derivative in the presence of cationic surfactants[3] or in bilayer systems.[4] However, there has been no report on thermodynamic specificity for the enantioselectivity in the deacylation of amino acid esters.

This study deals with the temperature dependence of catalytic efficiency and enantioselectivity for the stereoselective deacylation of *p*-nitrophenyl *N*-acyl-D(or L)-phenylalaninates (D(or L)-S_n; n=2, 12, and 16) and *N*-benzyloxycarbonyl-D(L)-phenylalaninates (D(L)-ZS) by the bilayer and micellar catalytic systems of L-histidine derivatives (LauHis, MyrHis, PalHis, LauHisLeu, and MyrHisLeu) and surfactants ($2C_mN2C_1Br$ with m=12, 14, and 16, CTAB, OTAC, and (*R*)-(+)-SUR_{16}) and has been performed in an attempt to discuss on the hydrophobic microenvironment of aggregates on the basis of isokinetic temperature (β).[5]



LauHis (R=$C_{11}H_{23}$, R′=OH)

Experimental

Materials. *p*-Nitrophenyl *N*-acyl-D(L)-phenylalaninates (D(L)-S_n; n=2, 12, and 16) were prepared by the previous method.[6,7]

p-Nitrophenyl *N*-Cbz-D(L)-phenylalaninates (D(L)-ZS) were prepared from *N*-benzyloxycarbonyl-D(L)-phenylalanine by the esterification of the CO_2H group with *p*-nitrophenol and dicyclohexylcarbodiimide in a way similar to the previous method.[8] Satisfactory results of elemental analysis were obtained for D(L)-ZS. D-ZS: mp 121.5—123.5 °C (lit,[8] mp 126—126.5 °C). Found: C, 65.88; H, 4.70; N, 6.67%. Calcd for $C_{23}H_{20}N_2O_6$: C, 65.70; H, 4.78; N, 6.66%. L-ZS: mp 119—120 °C (lit,[8] mp 126—126.5 °C). Found: C, 65.65; H, 4.73; N, 6.59%. Calcd for $C_{23}H_{20}N_2O_6$: C, 65.70; H, 4.78; N, 6.66%.

N-Dodecanoyl-L-histidine (LauHis), *N*-tetradecanoyl-L-histidine (MyrHis), and *N*-hexadecanoyl-L-histidine (PalHis) were prepared by reaction of L-histidine and the corresponding acid chlorides.[9] Satisfactory results of elemental analysis were obtained for LauHis,[7] MyrHis, and PalHis.[7] MyrHis: dp 196 °C (lit,[9] dp 192 °C). Found: C, 65.87; H, 9.61; N, 11.30%. Calcd for $C_{20}H_{35}N_3O_3$: C, 65.75; H, 9.59; N, 11.51%.

N-Dodecanoyl-L-histidyl-L-leucine (LauHisLeu) and *N*-tetradecanoyl-L-histidyl-L-leucine (MyrHisLeu) were prepared by reaction of L-histidyl-L-leucine with anhydrous dodecanoic acid and tetradecanoyl chloride, respectively. Satisfactory results of elemental analysis were obtained for LauHisLeu and MyrHisLeu. LauHisLeu: mp 194—196 °C. Found: C, 63.81; H, 9.17; N, 12.33%. Calcd for $C_{24}H_{42}N_4O_4$: C, 63.97; H, 9.39; N, 12.43%. MyrHisLeu: mp 212—214 °C. Found: C, 65.03; H, 9.63; N, 11.19%. Calcd for $C_{26}H_{46}N_4O_4$: C, 65.24; H, 9.69; N, 11.71%.

Didodecyldimethylammonium bromide ($2C_{12}N2C_1Br$), ditetradecyldimethylammonium bromide ($2C_{14}N2C_1Br$), and

dihexadecyldimethylammonium bromide ($2C_{16}N2C_1Br$) were prepared by reaction of *N,N*-dimethylalkylamine and the corresponding alkyl bromides in refluxing ethanol in the presence of sodium carbonate, and purified by repeated recrystallizations from ethyl acetate according to the previous method.[10] Satisfactory results of elemental analysis were obtained for $2C_{12}N2C_1Br$, $2C_{14}N2C_1Br$, and $2C_{16}N2C_1Br$. $2C_{12}N2C_1Br$: Found: C, 67.77; H, 12.20; N, 2.98%. Calcd for $C_{26}H_{56}NBr$: C, 67.50; H, 12.20; N, 3.03%. $2C_{14}N2C_1Br$: Found: C, 69.18; H, 12.52; N, 2.68%. Calcd for $C_{30}H_{64}NBr$: C, 69.44; H, 12.46; N, 2.70%. $2C_{16}N2C_1Br$: Found: C, 70.46; H, 12.49; N, 2.52%. Calcd for $C_{34}H_{72}NBr$: C, 71.02; H, 12.65; N, 2.44%.

Commercially available hexadecyltrimethylammonium bromide (CTAB) and octadecyltrimethylammonium chloride (OTAC) were recrystallized from an anhydrous ethanol–ether mixture.

(+) - Hexadecyldimethyl[(*R*) - α - methylbenzyl]ammonium bromide ((*R*)-(+)-SUR_{16}) was prepared by reaction of (*R*)-(+)-*N,N,*α-trimethylbenzylamine and hexadecyl bromide in accordance with the previous method.[11] Satisfactory results of elemental analysis were obtained.[7]

Determination of Rate Constants. Rates of *p*-nitrophenol liberation from *p*-nitrophenyl esters were measured at 400 nm with a Shimadzu UV-200 spectrophotometer. Each run was usually initiated by adding an acetonitrile solution (0.1 ml) of a substrate ester to a reaction medium of tris(hydroxymethyl)methanamine (Tris) buffer (3.4 ml) containing both nucleophile and surfactant. The reaction obeyed the usual pseudo-first-order rate law, and the apparent second-order rate constant ($k_{a,obsd}$) for the deacylation of ester substrate was evaluated by the following equation on the basis of triplicate runs:

$$k_{a,obsd} = (k_t - k_s)/[\text{nucleophile}]_0, \quad (1)$$

where k_t and k_s refer to the observed first-order rate constant for the deacylation of S_n with and without a nucleophile, respectively, and $[\text{nucleophile}]_0$ denotes the initial nucleophile concentration.

In the case of the bilayer catalytic systems, clear stock solutions were prepared by dissolving the nucleophile and the surfactant in Tris–KCl buffer by sonication (Bransonic 12, Yamato Scientific Co.) at 50 °C for 1 h, and used for kinetic measurements.

Results and Discussion

Since the reaction rate of D(L)-S_n (1×10^{-5} M; 1 M=1 mol dm^{-3}) deacylation with PalHis (5×10^{-5} M) attains a maximum in the presence of *ca.* 1×10^{-3} M (critical micelle concentration (cmc) $=5\times10^{-5}$ M)[12] $2C_{12}N2C_1Br$,[4b] the relative activity of nucleophiles will be discussed with the stereoselective deacylation of D-(L)-S_n (n=2 and 12) and D(L)-ZS with the above concentration of the nucleophiles (PalHis, MyrHis, and MyrHisLeu) and the bilayer surfactants ($2C_mN2C_1Br$; m=12, 14, and 16). On the other hand, the concentrations of the micellar surfactants (CTAB, OTAC, and (*R*)-(+)-SUR_{16}) were set above their cmc's.

Catalytic Efficiency. It is obvious that the hydrophobicity of nucleophiles and substrates play an important role in enhancing the catalytic efficiency and stereoselectivity for the deacylation of amino acid esters in micellar[1d] and bilayer[4d] systems. Thus, in this study, we have employed the reactants having a hydrophobic segment.

Rate constants ($k_{a,obsd}$) as a function of temperature for the deacylation of D(L)-S_n (n=2 and 12) and D(L)-ZS catalyzed by the bilayer catalytic systems of MyrHis+$2C_{12}N2C_1Br$ and MyrHisLeu+$2C_{12}N2C_1Br$

Table 1. Temperature dependence of rate constant ($k_{a,obsd}$/M^{-1} s^{-1}) for the deacylation of S_n catalyzed by MyrHis and MyrHisLeu in the presence of $2C_{12}N2C_1Br$[a,b]

a) pH 7.6, 3%(v/v) CH_3CN-H_2O, 0.083 M Tris buffer (0.083 M KCl), [LauHis]=[LauHisLeu]$=5\times10^{-5}$ M, [Sub]$=1\times10^{-5}$ M, and [CTAB]$=3\times10^{-3}$ M. b) Values in the parentheses are those for the deacylation of S_n catalyzed by LauHisLeu in the presence of CTAB. c) These values include the experimental error within ±6%.

are summarized in Table 1. The magnitude of rate enhancement increases in the orders L-S_{12}>L-ZS≫L-S_2 and D-S_{12}≳D-ZS≫D-S_2 in the deacylation of L- and D-enantiomers, respectively, over the temperature range of 10—35 °C in both the bilayer systems. These orders agree fairly well with the hydrophobicity of substrates. The catalytic efficiency of MyrHis is superior to that of MyrHisLeu. The difference in catalytic efficiency between MyrHis and MyrHisLeu would be attributable to the framework of both nucleophiles. Namely, it is deduced that the bulky leucine part in MyrHisLeu might reduce the catalytic efficiency due to the steric hindrance against the substrate-incorporation by the mixed bilayer membrane.

Table 2 shows the temperature dependence of $k_{a,obsd}$ for the deacylation of D(L)-S_n (n=2 and 12) catalyzed by LauHis and LauHisLeu in the CTAB micellar systems. The $k_{a,obsd}$ values increase linearly as temperature is raised for the deacylation of all the substrates and were used for calculating activation parameters. Nucleophile LauHis is superior in catalytic efficiency to the dipeptide-type nucleophile (LauHisLeu). The difference in catalytic efficiency between LauHis and LauHisLeu in the micellar system is similar to that between MyrHis and MyrHisLeu in the bilayer system. It is suggested that the steric hindrance of the leucine part in the nucleophile cannot be neglected with respect to the substrate-incorporation into the micellar matrix. The hydrophobicity of the substrate is almost reflected in the order of its reactivity. Especially, substrate L-S_{12} having a long acyl chain is fairly superior to L-S_2 having a short acyl chain as shown in Table 2. These results for both the bilayer and micellar systems imply that the hydrophobic interaction between substrate and nucleophile and the easiness of substrate-incorporation into the aggregates are of great importance to the enhancement of catalytic efficiency.

It is known that the extent of incorporation of a substrate into a micellar phase agrees reasonably well with its binding properties.[13] The binding constants of the long-chain substrates are fairly larger than those of the short-chain substrates in both the bilayer and micellar systems.[4b] This result suggests that the hydrophobic interaction between the former and the aggregates might be stronger than that between the latter and the aggregates and is reflected in the larger rate enhancement for the deacylation of the long-chain substrates (L-S_{12} and D-S_{12}) than that of the short-chain ones (L-S_2 and D-S_2) in almost all the catalytic systems in the present study as shown in Tables 1 and 2.

Stereoselectivity. Enantioselective parameters ($k^L_{a,obsd}/k^D_{a,obsd}$) as a function of temperature for the deacylations of S_n (n=2 and 12) and ZS in the bilayer systems of MyrHis+$2C_{12}N2C_1Br$ and MyrHisLeu+$2C_{12}N2C_1Br$ are shown in Figs. 1 and 2, respectively.

As Fig. 1 indicates, the temperature dependence of enantioselectivity for the deacylation of S_n (n=2 and 12) and ZS with MyrHis and $2C_{12}N2C_1Br$ is divided into the following three trends over the temperature range of 10—35 °C: (a) the enantioselectivity in the deacylation of S_{12} having a long acyl chain tends to decrease as temperature is raised with a maximum

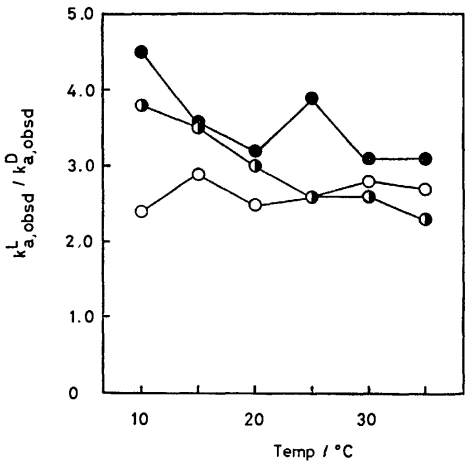

Fig. 1. Temperature dependence of enantioselectivity in the deacylation of S_n catalyzed by MyrHis with $2C_{12}N2C_1Br$.
pH 7.6, 3%(v/v) CH_3CN-H_2O, 0.083 M Tris-KCl buffer, [MyrHis]=5×10^{-5} M, [Sub]=1×10^{-5} M, [$2C_{12}N2C_1Br$]=1×10^{-3} M. ○: S_2, ●: S_{12}, ◑: ZS. The $k^L_{a,obsd}/k^D_{a,obsd}$ values include the experimental error within ±4%.

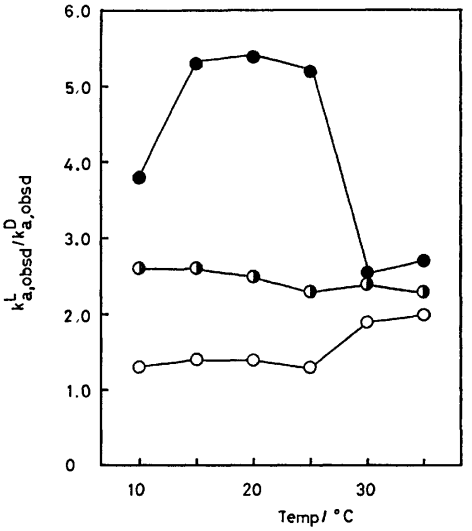

Fig. 2. Temperature dependence of enantioselectivity in the deacylation of S_n catalyzed by MyrHisLeu with $2C_{12}N2C_1Br$.
pH 7.6, 3%(v/v) CH_3CN-H_2O, 0.083 M Tris-KCl buffer, [MyrHisLeu]=3×10^{-5} M, [Sub]=1×10^{-5} M, [$2C_{12}N2C_1Br$]=1×10^{-3} M. ○: S_2, ●: S_{12}, ◑: ZS. The $k^L_{a,obsd}/k^D_{a,obsd}$ values include the experimental error within ±6%.

($k^L_{a,obsd}/k^D_{a,obsd}$=3.9) at 25 °C; (b) the $k^L_{a,obsd}/k^D_{a,obsd}$ value in the deacylation of ZS having a bulky side part decreases with rise in temperature; (c) the enantioselectivity in the deacylation of S_2 having a short acyl chain is almost constant ($k^L_{a,obsd}/k^D_{a,obsd}$=2.3—2.9) over the experimental temperature range. The difference in the temperature dependence of enantioselectivity among the deacylation of the three substrates (S_{12}, ZS, and S_2) would be attributed to the difference in the substrate-framework.

On the other hand, the temperature dependence for

the deacylation of S_n and ZS in the system of MyrHis-Leu+$2C_{12}N2C_1Br$ is different from that in the system of MyrHis+$2C_{12}N2C_1Br$ as shown in Fig. 2. It is especially worthy to note that the temperature dependence of enantioselectivity for the S_{12} deacylation is bell-shaped with a maximum ($k^L_{a,obsd}/k^D_{a,obsd}$=5.2—5.4) at 15—25 °C. The $k^L_{a,obsd}/k^D_{a,obsd}$ value for the deacylation of ZS is almost constant (2.3—2.6) over the whole temperature range examined, whereas that for the deacylation of S_2 is constant (1.3—1.4) in the temperature range of 10—25 °C and increases (1.9—2.0) at temperatures above 30 °C. Interestingly, the enantioselectivity for the deacylation of all the substrates (S_2, S_{12}, and ZS) employed converges at 30—35 °C.

These results for the bilayer and micellar systems suggest that the hydrophobic microenvironment would be changed delicately with temperature in the range of 10—35 °C and that the long-chain substrate (S_{12}) might be influenced by the change in microenvironment. At any rate, it is unique that the bilayer membrane system including the dipeptide-type nucleophile (MyrHisLeu+$2C_{12}N2C_1Br$) has displayed the high enantioselectivity in an adequate temperature range (15—25 °C) probably through a favorable hydrophobic interaction between the nucleophile (MyrHisLeu) and the substrate (D(L)-S_{12}). And, it is obvious that the leucine part of MyrHisLeu plays an important role in producing the high stereoselectivity.

Figure 3 and Table 2 show the temperature dependence of enantioselectivity for the deacylation of S_n (n=2, 12, and 16) in the micellar systems of PalHis+OTAC, LauHis+CTAB, and LauHisLeu+CTAB. Two interesting results were obtained: firstly, the temperature dependence of enantioselectivity for the S_{16} deacylation catalyzed by PalHis+OTAC is clearly bell-shaped with a maximum ($k^L_{a,obsd}/k^D_{a,obsd}$=3.6) at 30 °C and, secondly, the enantioselectivity for the S_{12} deacylation catalyzed by LauHisLeu+CTAB increases sharply as temperature is lowered. It is notable that the highest enantiomer rate ratio ($k^L_{a,obsd}/k^D_{a,obsd}$=12) is attained at 20 °C for the S_{12} deacylation in the micellar system of LauHisLeu+CTAB. This implies that the peculiar environments of the hydrophobic dipeptide (LauHisLeu) and the CTAB micelles, which are effective for the highly enantioselective deacylation of the hydrophobic substrate (S_{12}) at the lower temperature (20 °C), would be varied delicately as temperature is raised. The leucine part of LauHisLeu in the micellar system (CTAB) might play an important role in enhancing the enantioselectivity in common with that in the bilayer system (MyrHis-Leu+$2C_{12}N2C_1Br$). On the other hand, in the micellar systems of PalHis+OTAC and LauHis+CTAB, the stereoselectivity for the deacylation of S_n (n=2 and 12) remains almost constant over the temperature range of 20—35 (40) °C, though the magnitude of enantioselectivity for the long-chain substrate (S_{12}) is fairly larger than that for the short-chain substrate (S_2).

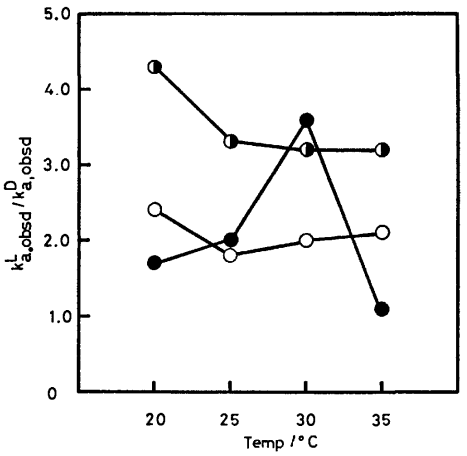

Fig. 3. Temperature dependence of enantioselectivity in the deacylation of S_n catalyzed by PalHis with OTAC.
pH 7.6, 3%(v/v) CH_3CN-H_2O, 0.083 M Tris-KCl buffer, [PalHis]=4×10^{-5} M, [S_n]=1×10^{-5} M, [OTAC]=8×10^{-4} M. ○: S_2, ◑: S_{12}, ●: S_{16}.
The $k^L_{a,obsd}/k^D_{a,obsd}$ values include the experimental error within ±3%.

Isokinetic Relationship. The isokinetic relationship appears to hold for the deacylation of D(L)-S_n (n=2 and 12) and D(L)-ZS in the bilayer and micellar systems from the relation between the entropy and enthalpy of activation on the basis of rate constant ($k_{a,obsd}$). The activation parameters (ΔG^*, ΔH^*, and ΔS^*) were evaluated by

$$\Delta G^* = 2.303RT \log (kT/hk_{a,obsd}) = \Delta H^* - T\Delta S^*, \quad (2)$$

where k and h stand for the Boltzmann and Planck constants, respectively. The linear relationship between the free energy of activation (ΔG^*) and the absolute temperature (T) is shown in Figs. 4 and 5. The ΔH^* and ΔS^* values obtained for the bilayer and micellar systems are summarized in Tables 3 and 4, respectively. Furthermore, the isokinetic temperatures (β) have been determined by plotting ΔH^* against ΔS^* according to Eq. (3)[5] and are summarized in Tables 3 and 4.

$$\Delta H^* = \Delta H^*_0 + \beta\Delta S^*, \quad (3)$$

where ΔH^*_0 is simply the intercept of ΔH^* correspond-

ing to ΔS^*.

It is known that hydrophobic interactions are mainly entropy driven, whereas lyophobic ones are mainly enthalpy driven.[14,15] On the other hand, it has been found that the β value based on apparent second-order rate constants ($k_{a,obsd}$) agrees fairly well with that based on k_m values for the simplified reaction ($M+S_n \overset{K_b}{\rightleftharpoons} MS_n \xrightarrow{k_m} P$; M, MS_n, and P stand for an aggregate composed of nucleophile and surfactant, an aggregate-substrate complex, and *p*-nitrophenol, respectively) in the deacylation of S_n (n=2, 12, and 16) with PalHis incorporated into OTAC micelles.[16] Then, we intend to discuss on the hydrophobic microenvironment for the stereoselective deacylation in the bilayer and micellar systems in terms of the β value obtained from the $k_{a,obsd}$ values in harmony with the k_m ones.

On the basis of the β value in connection with $\overline{T}$ (the average experimental temperature), the deacylation reaction in the bilayer systems may be governed by the entropy of activation in the temperature range of 10—40 °C, that is, $\overline{T}$ (296—306 K) exceeds β (245—269 K) in the bilayer systems of PalHis+$2C_{12}N2C_1Br$, MyrHis+$2C_{12}N2C_1Br$, MyrHisLeu+$2C_{12}N2C_1Br$, and PalHis+$2C_{14}N2C_1Br$, though β (302 K) is nearly equal to $\overline{T}$ (306 K) in the system of PalHis+$2C_{16}N2C_1Br$. This difference in β value between the systems of $2C_mN2C_1Br$ (m=12 and 14) and the $2C_{16}N2C_1Br$ system would be attributed to the difference in the state of bilayer phase. Namely, the bilayer systems of $2C_{12}N2C_1Br$ and $2C_{14}N2C_1Br$ and the system of $2C_{16}N2C_1Br$ are considered to be liquid crystals and a mixed state of liquid crystal and crystal over the experimental temperature range (see Table 3), respectively, in view of the phase transition temperature ($2C_{12}N2C_1Br$, 8 °C; $2C_{14}N2C_1Br$, 18 °C; $2C_{16}N2C_1Br$, 27 °C).[17] On the other hand, interestingly, the deacylation in the micellar systems may be governed by the enthalpy of activation in the temperature range of 20—40 (35) °C, that is, β (313—330 K) exceeds $\overline{T}$ (301—303 K) in the micellar systems of LauHis+

The difference in the driving parameter of activation ($\Delta S^{\ddagger}$ or $\Delta H^{\ddagger}$) for the deacylation reaction between the liquid-crystalline bilayer systems and the micellar ones would be attributable to the difference in the hydrophobic microenvironment of the aggregates. After all, it is concluded that the stereoselective deacylation in the liquid-crystalline bilayer systems would proceed through a stronger hydrophobic interaction between the reactants. So far, however, we have not found the relation between the β value and the catalytic efficiency and enantioselectivity.

We wish to thank Messrs. Akihiro Nakamura, Keizo Okada, and Toshihiro Kikuno for their technical assistance.

(Received March 24, 1983)

The band-structure parameters of organic conductors, $TSeT_2Cl$, TTT_2I_3, and $TSeT_2SCN$ (TSeT; 5,6:11,12-bis(diseleno)naphthacene; common name: tetraselenotetracene, and TTT; 5,6:11,12-bis(dithio)naphthacene; common name: tetrathiotetracene) were calculated using semiempirical molecular-orbital calculations. The longitudinal bandwidth W and the anisotropy parameter α of $TSeT_2Cl$ were obtained as 0.6 eV and 0.188 respectively. The shape of the Fermi surface, as calculated from the tight-binding theory and the large anisotropy parameter, agrees with its semimetallic nature at low temperatures. In TTT_2I_3, $W=0.56$ eV, and $\alpha=0.018$. This compound was regarded as a one-dimensional metal. The semiconductive conduction of $TSeT_2SCN$ was interpreted in terms of the small bandwidth, $W=0.26$ eV.

A number of highly-conducting complexes containing tetrathiotetracene (TTT) or tetraselenotetracene (TSeT) have been known, and their solid-state properties have been studied in some detail.[1,2] Among these compounds, $TSeT_2Cl$, $TSeT_2Br$, and $TSeT_2I$ show a high conductivity *ca.* $10^3\,\Omega^{-1}\,cm^{-1}$ at room temperature and retain their metallic conductivity down to 26 K.[3,4] Below this temperature the magnitude of the resistivity increases, but there is a tendency for $T\rightarrow 0$ to a finite value on the order of the room-temperature value. TTT_2I_3 also shows a high conductivity *ca.* $10^3\,\Omega^{-1}\,cm^{-1}$ at room temperature, but it has a conductivity maximum and its conductivity follows an activation process at low temperatures.[5] However, there is a considerable range of nonstoichiometry on iodine, and its physical properties suffer a serious influence from the disorder of the iodine sublattice.[5-8]

It is widely believed that an organic metal has a quasi-one-dimensional conduction band resulting from the π-π interaction of the planar organic molecules. However, the density-wave instabilities inherent in one-dimensional metals tend to destroy the metallic states of these compounds. The present authors have previously calculated the band-structure parameters of $TMTSF_2X$ and $(BEDT\text{-}TTF)_2ClO_4(C_2H_3Cl_3)_{0.5}$.[9-11] In the former, the authors concluded that the transverse transfer integrals, which are of the order of 0.1 of the longitudinal integrals, play an important role in the stabilization of the metallic states. On the other hand, $(BEDT\text{-}TTF)_2ClO_4(C_2H_3Cl_3)_{0.5}$ was regarded as a two-dimensional semimetal.

In the present investigation, the band-structure parameters of $TSeT_2Cl$ and TTT_2I_3 were calculated. To make a comparison, the calculation was also performed on an organic semiconductor, $TSeT_2SCN$. All these complexes have regular TSeT (or TTT) chains, and their conduction bands are three-quarters filled. In view of the calculated longitudinal bandwidths and the transverse interactions, their physical properties were also discussed.

Computation

The method of calculation was the same as has already been reported.[9-11] At first the molecular orbitals of a single molecule were calculated by the extended Hückel method using the parameters shown in Table 1.[12] Since the HOMO, which makes the conduction band in the crystal, is energetically separated enough from the other energy levels, as is shown in Fig. 1, only the overlaps of the HOMO's between the nearest-neighbor molecules were calculated. The transfer integrals t_i of the tight-binding theory are given from these overlaps S_i by the relation: $t_i=ES_i$, where E is a constant of the order of the ionization potential of the HOMO. From the energy level of the molecular orbital calculation (Fig. 1), in the present

paper E was assumed to be -10 eV. This value was also used in the calculations for the radical cation salts of TTF and BEDT–TTF when sulfur 3d orbitals were not included; it gave realistic magnitudes of transfer integrals which agrees well with the experimental results.[11] As will be discussed in the present paper, it also agrees consistently with various experiments on the salts of TTT and TSeT. The structural data were taken from the literature.[16–18]

Results and Discussion

$TSeT_2Cl$. The crystal structure of $TSeT_2Cl$ is shown in Fig. 2.[16] Because of the tetragonal symmetry, there are only two kinds of intermolecular interactions: the longitudinal interaction along the c axis, and the transverse interaction along the a axis. The calculated overlaps S, the bandwidth, and the anisotropy parameter α $(=t_\perp/t_{//})$ of the HOMO are shown in Table 2. The longitudinal bandwidth has been experimentally obtained as 0.6 eV from the magnetism.[3] This estimation agrees well with the results of the present calculation.

From the anisotropy of the conductivity, the anisotropy parameter can be roughly estimated using the following relation:[19]

$$\alpha = \left(\frac{t_\perp}{t_{//}}\right) \gtrsim \left(\frac{\sigma_\perp}{\sigma_{//}}\right)^{1/2}. \tag{1}$$

From the observed anisotropy of $TSeT_2Br$, $(\sigma_{//}/\sigma_\perp)=60$,[20] one obtains $\alpha=0.129$ ($t_a=0.077$ eV). The magnitude of the calculated $|\alpha|$ is slightly larger than this value.

From a standard tight-binding theory,[21] we obtained the following seqular equation for the conduction band.

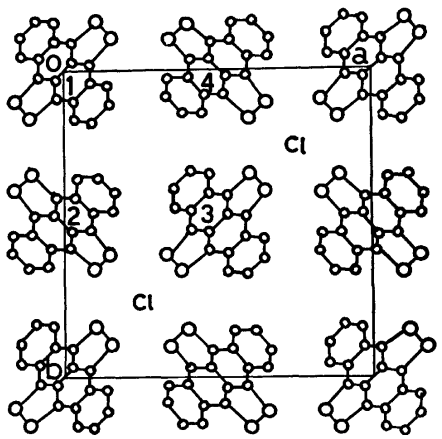

Fig. 2. Crystal structure of $TSeT_2Cl$, projection along c. The numbering of the molecules was used to derived Eq. 2.

Table 2. Band-structure parameters of $TSeT_2Cl$

Direction	Overlap	$4t_i$/eV	$\lvert\alpha_i\rvert$
c	-15.0×10^{-3}	0.60	
a	2.8×10^{-3}	-0.11	0.188

$$\begin{vmatrix} \lambda & \cos\frac{kb}{2}\cos\frac{kc}{2} & 0 & \cos\frac{ka}{2}\cos\frac{kc}{2} \\ \cos\frac{kb}{2}\cos\frac{kc}{2} & \lambda & \cos\frac{ka}{2}\cos\frac{kc}{2} & 0 \\ 0 & \cos\frac{ka}{2}\cos\frac{kc}{2} & \lambda & \cos\frac{kb}{2}\cos\frac{kc}{2} \\ \cos\frac{ka}{2}\cos\frac{kc}{2} & 0 & \cos\frac{kb}{2}\cos\frac{kc}{2} & \lambda \end{vmatrix} = 0, \tag{2}$$

$$\lambda = \frac{2t_c\cos kc-\varepsilon}{4t_a}.$$

This equation yields the dispersion relation:

$$\varepsilon(k) = 2t_c\left[\cos kc \pm 2\alpha\left(\cos\frac{ka}{2}\cos\frac{kc}{2} \pm \cos\frac{kb}{2}\cos\frac{kc}{2}\right)\right], \tag{3}$$

$$\alpha = t_a/t_c.$$

Since the conduction level is three-quarters filled, when $\alpha=0$ the Fermi surface consists of two pieces of fourfold degenerated planes at $k_F=\pm\pi/4c$. The shape of the Fermi surface depends only on the anisotropy parameter α. We numerically calculated their shapes for several values of α, as is shown in Fig. 3. When

$$\alpha = t_a/t_c = \frac{2}{8}\left(1-\cos\frac{\pi}{4c}c\right) = 0.07322,$$

one of the Fermi surfaces touches the $k_c=0$ plane, and if α is larger, a closed Fermi surface appears. At the calculated value of $\alpha=0.188$, two of the Fermi surfaces are closed, and though the other two remain open, they are seriously distorted. On the other hand, at the value of $\alpha=0.129$ obtained from the anisotropy of the conductivity of $TSeT_2Br$, one is closed, while the other three remain open. It is worth noting that, though the anisotropy parameter α of $TSeT_2Cl$ is only slightly larger than that of $TMTSF_2X$ (*ca.* 0.1),[9] the three-dimensional alignment and the larger number (8) of the neighbor molecules than that (4) of $TMTSF_2X$ effectively distort the Fermi surface.

From the anomaly of the magnetic susceptibility and the specific heat,[3,22] many authors have treated the transition at 26 K as of a Peierls type. Shchegolev and Yagubskii proposed a model where two of the four pairs of Fermi surfaces are nested, but the other two are unnested.[1] However, not only ideally planar Fermi surfaces, but also slightly distorted Fermi surfaces, can be effectively nested by a proper transfer vector.[23] Delhaes and his co-workers interpreted the properties below 26 K as a semimetallic state resulting from an imperfectly nested quasi-one-dimensional Fermi surface.[4] The observation of the anisotropic magnetoresistance also supports this interpretation.[20] The highly distorted Fermi surfaces in Fig. 3(d) agree with such semimetallic states. However, we are not certain whether a simple Peierls-type phase transition may occur on such a highly distorted Fermi surface as is shown in Fig. 3(d). A quantitative relation between the anisotropy and the Peierls transition in such a multi-band conductor remains unsolved.

In conclusion, we consider $TSeT_2Cl$ to be placed

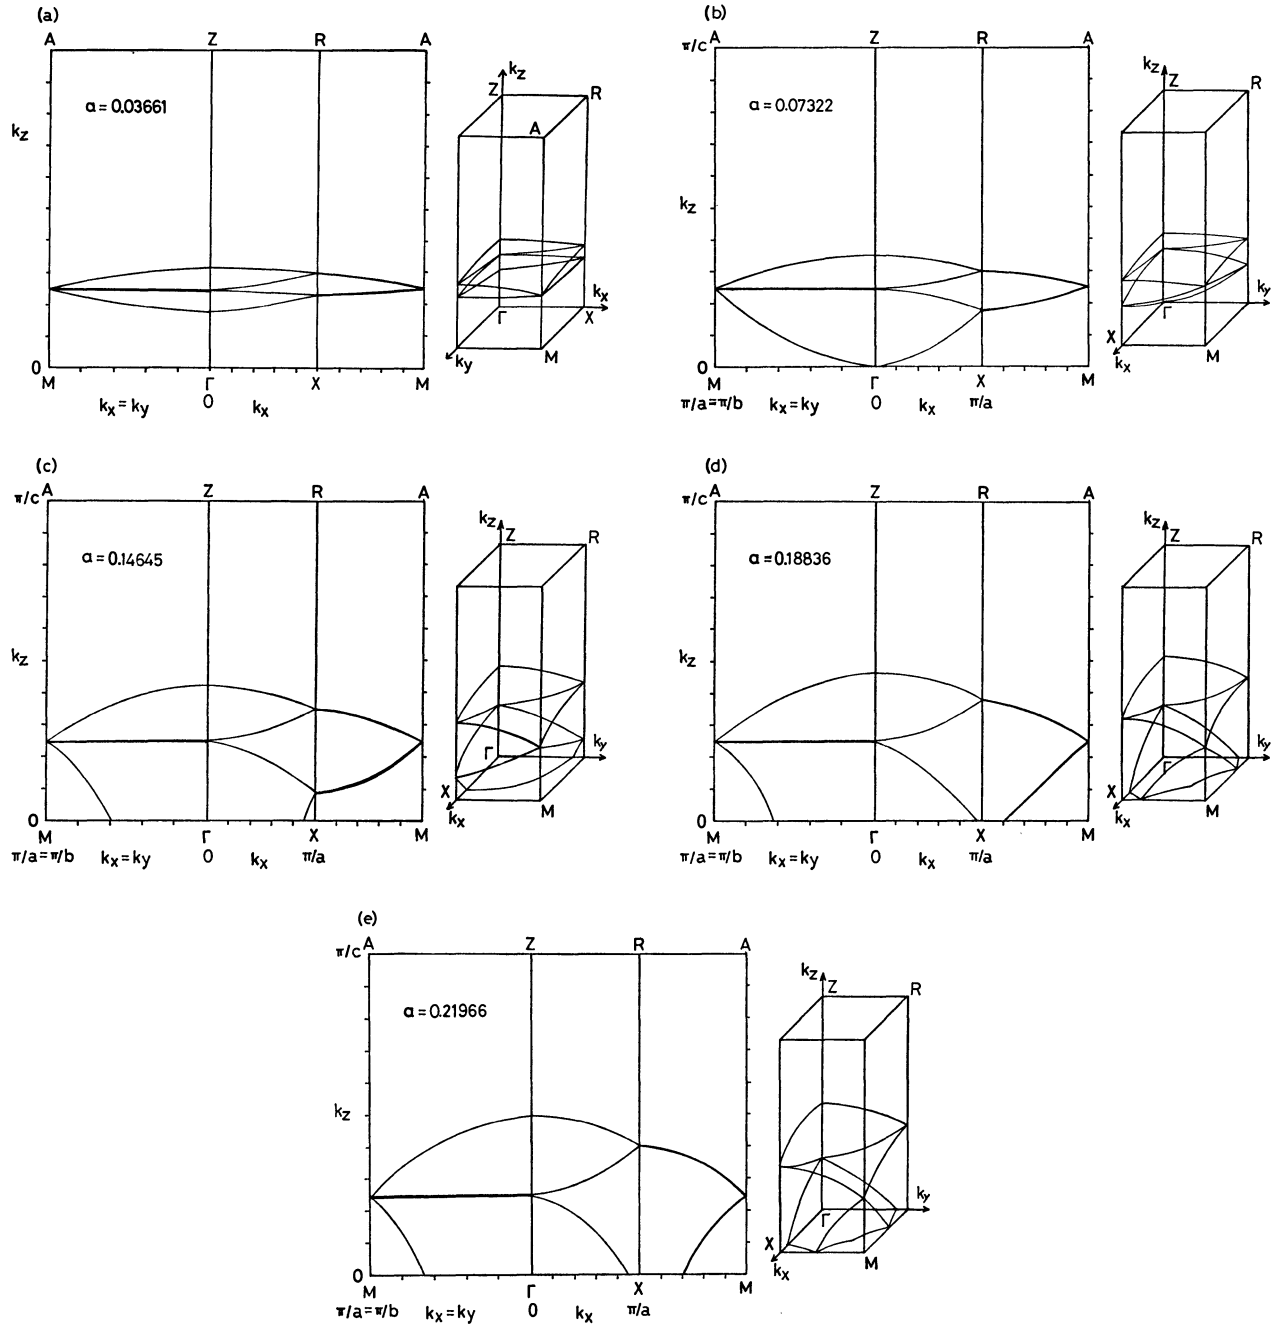

Fig. 3. Shape of the Fermi surfaces for various anisotropy parameters α, based on the dispersion of Eq. 3.

on the boundary between a one-dimensional metal and a three-dimensional metal.

TTT$_2$*I*$_3$. The crystal structure of TTT_2I_3 is shown in Fig. 4.[17] There are three kinds of intermolecular interactions. The calculated band-structure parameters are shown in Table 3. Since the magnetic susceptibility of TTT_2I_3 shows some temperature dependence, we cannot estimate the bandwidth directly from the magnetic data. However this fact qualitatively suggests that $U/4t$ in TTT_2I_3 is larger than that in $TSeT_2Cl$, and if the on-site Coulomb repulsion U is assumed to be unchanged, in TTT_2I_3 a slightly smaller bandwidth than that of $TSeT_2Cl$ is to be expected. There are some discrepancies as to the thermoelectric power because of the influence of disorder, but the bandwidth is estimated as 0.64 eV by Isett,[7] as 0.67 eV by Chaikin *et al.*,[24] as 0.7 eV by Khanna *et al.*,[8] and as 1.0 eV by Mihaly *et al.*[6] Since the magnitude of the thermoelectric power decreases with an increase in disorder,[8,24] we consider that the smallest W is the value free from the influence of disorder. Therefore, our calculated value agrees with the experimental results and can be regarded as the 'intrinsic' bandwidth free from disorder.

Though the shortest transverse S–S distance, 3.373 Å, along c is considerably smaller than the shortest longitudinal distance, 3.73 Å,[17] the calculated transverse overlap is much smaller than the longitudinal

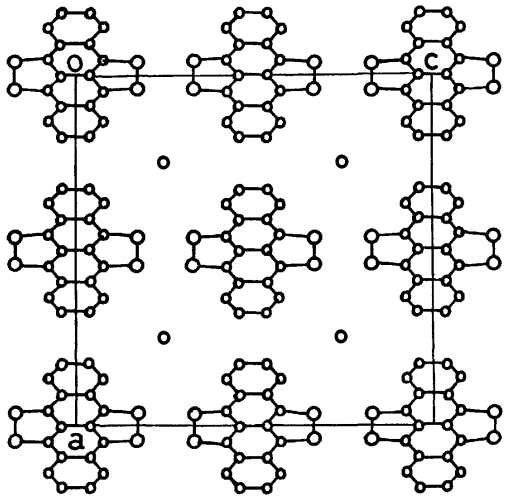

Fig. 4. Crystal structure of TTT_2I_3, projection along b.

Table 3. Band-structure parameters of TTT_2I_3

Direction	Overlap	$4t_i$/eV	$\|\alpha_i\|$
b	13.9×10^{-3}	−0.56	
c	-0.25×10^{-3}	0.010	0.018
a	0.064×10^{-3}	−0.0026	0.005

overlap and the anisotropy parameter, $\alpha=0.018$, is very small. It has been observed in the transverse interaction of TTF that the magnitude of the orbital overlap crosses zero between the σ-like and π-like overlap of the sulfur p-orbitals.[11] Because of the two similar sulfur atoms on the side of the molecule and the π-character of the HOMO, the change in the overlap between the two TTT molecules with side-by-side orientation is not very different from the case of TTF. Since the orientation between the two TTT molecules along c in TTT_2I_3 satisfies the crossover condition ($\phi=10°$ by the notation in Ref. 11, where ϕ is the angle between the molecular plane and the intermolecular transfer vector), t_c similarly happens to be small. Therefore, despite the relatively short transverse S–S distance, TTT_2I_3 has a highly-anisotropic band structure. This large anisotropy, $\alpha=0.018$, corresponds to that of the well-known organic metal, TTF–TCNQ ($\alpha=0.015$, for the largest transverse overlap).[19,25]

There are many pieces of evidence which suggest that the phase transition of TTT_2I_3 at 50 K is of a Peierls type. The magnetic susceptibility follows an exponential law with a gap 190 K below 50 K,[5,7] and the specific heat shows an anomaly of magnitude consistent with a mean-field model for a Peierls phase transition with correction for fluctuations.[26] The lack of the observation of distortion by X-ray scattering can be interpreted by the large scattering factor of iodine.[27] Though the influence of disorder seriously modifies the properties, especially those such as electrical conductivity and thermoelectric power, we regard TTT_2I_3 as essentially a quasi-one-dimensional metal, in which the bandwidth and the anisotropy parameter α are of about the same order as, or slightly larger than, those of TTF–TCNQ.

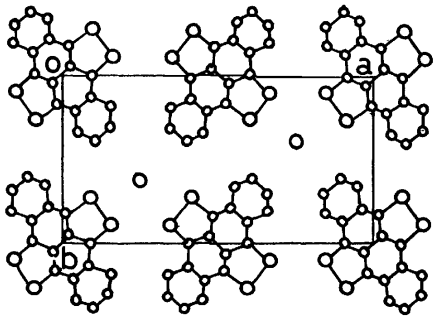

Fig. 5. Crystal sturcture of $TSeT_2SCN$, projection along c.

Table 4. Band-structure parameters of $TSeT_2SCN$

Direction	Overlap	$4t_i$/eV	$\|\alpha_i\|$
c	-6.6×10^{-3}	0.26	
a	-0.22×10^{-3}	0.0087	0.033
b	0.18×10^{-3}	−0.007	0.027

$TSeT_2SCN$. The crystal structure of $TSeT_2SCN$ is shown in Fig. 5.[18] Here again there are three kinds of intermolecular interactions. The calculated overlap and the bandwidths are shown in Table 4.

Though the degree of the occupancy of the TSeT chain is the same as that in $TSeT_2Cl$, its longitudinal conductivity is 20 Ω^{-1} cm^{-1} at room temperature and decreases with a lowering of the temperature.[18] This difference has been attributed to the larger interplanar separation (3.53 Å in $TSeT_2SCN$, and 3.37 Å in $TSeT_2Cl$), and to the pronounced anisotropy in the packing of the TSeT molecules which comes from the difference in the angle between the molecular plane and the chain direction.[18] The calculated small bandwidth and the small α reflect these structural differences. Though this anisotropy is large enough to produce a Peierls gap, it is more likely that the diffusive conduction occurs due to the larger electronic correlation in a narrowband conductor.

General Discussion. In the present paper, we neglected the interaction through anions. Since the Se–Cl distance, 3.024 Å, in $TSeT_2Cl$[16] and the Se–S distance, 3.160 Å, in $TSeT_2SCN$[18] are much shorter than the sum of the van der Waals radii, a considerable overlap of their orbitals is to be expected. These overlaps may contribute to the transport of electrons. Shchegolev and Yaguskii considered it as the dominant mechanism of the transverse interaction in $TSeT_2Cl$.[1] The contribution of such a transport to the transfer integral can be represented by a second-order perturbation theory as follows:

$$H_{ij}=\frac{H_{ia}H_{aj}}{E_a-E_o}, \tag{5}$$

where i and j represent the different organic molecules; E_a, the energy of the highest occupied level of the anion, and E_o, the energy of the HOMO. E_a-E_o is estimated to be usually of the order of several electron volts. In $TSeT_2Cl$, even if H_{ia} is assumed to be 10 times larger than the direct interaction, $W_a=0.01$ eV, H_{ij} is less than 0.05 eV. It is possible that this

second-order effect makes a considerable contribution to the transverse transport. However, it is unlikely that the calculated, not-small direct interaction is negligible compared with the indirect transport.

In summary, using semiempirical molecular orbital calculations, the present authors calculated the band-structure parameters of $TSeT_2Cl$, TTT_2I_3, and $TSeT_2SCN$. The bandwidth and the anisotropy parameter of $TSeT_2Cl$ are obtained as 0.6 eV and 0.188 respectively; this compound is considered to be on the boundary between a one-dimensional metal and a three-dimensional metal. In TTT_2I_3, the bandwidth is 0.56 eV and $\alpha=0.018$, and this compound is regarded essentially as a one-dimensional metal. On the contrary, the small bandwidth 0.26 eV of $TSeT_2SCN$ is considered to be responsible for the diffusive conduction.

Phosphorescence Studies of $^3\pi\pi^*$ Benzaldehyde, Acetophenone, and 1-Indanone in Benzoic Acid Host

Shin-ichi NAGAOKA and Noboru HIROTA*,†

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received March 26, 1983)

We have made a vibrational analysis of the phosphorescence spectra of benzaldehyde, deuterated benzaldehydes, acetophenone, and 1-Indanone in benzoic acid host. The emissions coming from different sites of benzaldehyde were separated with the help of microwave induced delayed phosphorescence (MIDP) spectroscopy. From the phosphorescence excitation spectra the locations of the $^3n\pi^*$ states were estimated to be about 2000 cm^{-1} above the $^3\pi\pi^*$ states. Contrary to the previous assignment, it was found that the aldehyde H wag is active in the spectra of benzaldehyde as in the cases of other host. The spectra of acetophenone and 1-indanone are similar to those obtained in other hosts, although the 0-0 bands are relatively stronger. The C=O stretching mode is, however, not clearly observable in all the systems studied here, suggesting that this mode is not active in the spectra of nearly pure $^3\pi\pi^*$ aromatic carbonyls. The main radiative mechanisms are discussed based on the present results and are compared with those of other aromatic carbonyls. Possible effects of hydrogen bonding on these properties are discussed.

The lowest excited triplet (T_1) states of aromatic carbonyls of the benzaldehyde type have mixed characters of $^3n\pi^*$ and $^3\pi\pi^*$ states. Their spectroscopic properties are interesting with regard to problems concerning the mixing of two nearby electronic states.[1,2] In recent years there have been considerable efforts to understand the details of the phosphorescence spectra of these molecules.[3–18] In order to fully understand the spectra of carbonyls with mixed characters, it seems desirable to understand first the spectra of pure $^3\pi\pi^*$ carbonyls.

Benzladehyde (abbreviated hereafter as BA) in benzoic acid (abbreviated as BAC), first studied by Koyanagi, Zwarich, and Goodman (KZG),[19] is nearly pure $^3\pi\pi^*$ in character because of the effect of hydrogen bonding. From a vibrational analysis of the phosphorescence spectrum KZG concluded that the aldehyde H wag mode is not active and that the couplings within the singlet manifold are more important than those in the triplet manifold, contrary to the cases of $^3\pi\pi^*$ benzladehydes in other hosts. It has also been a question whether or not the C=O stretching mode is present in the spectra of pure $^3\pi\pi^*$ aromatic carbonyls. Unfortunately the overlapping of the spectra coming from two sites and the presence of a broad background emission prevented KZG from making an unambiguous vibrational analysis. Here we have attempted to separate the emissions of the two sites using microwave induced delayed phosphorescence (MIDP) spectroscopy[20] and reexamined the spectrum of BA in BAC. We have also investigated the phosphorescence spectra of acetophenone (abbreviated as AP) and 1-indanone (abbreviated as 1ID) in BAC in order to see the general characteristics of the phosphorescence spectra of aromatic carbonyls of nearly pure $^3\pi\pi^*$ character.

It has been suggested that the properties of the $^3\pi\pi^*$ aromatic carbonyls of the benzaldehyde type are primarily determined by the energy separations between the $^3n\pi^*$ and $^3\pi\pi^*$ states.[21,22] However, an additional effect due to hydrogen bonding formation might be significant in the present systems. We also examine the magnetic and decay properties of the present systems in connection with those of the related $^3\pi\pi^*$ aromatic carbonyls.

Experimental

Sample Preparation. Commercially obtained BA and AP were purified by repeated distillations under reduced pressure. BA-d_1 (formyl hydrogen deuterated) and BA-d_6 obtained from Merck, Sharp, and Dohme of Canada were used without further purifications. 1ID was purified by recrystallization followed by zone refining. BAC used as host was purified by extensive zone refining. BAC crystals containing small amounts of BA, AP, and 1ID were grown by the Bridgman method. The initial concentrations of the guests in the melts were 2—3 wt%, but the actual concentrations in the crystals are considered to be very low. BAC crystals containing small amounts of anisole were used to obtain the BAC X-trap phosphorescence.

Phosphorescence and MIDP Spectra. The phosphorescence and MIDP spectra were taken at 4.2 K or 1.5 K with a zero field ODMR spectrometer similar to that described in a previous paper.[23] The light from a Xenon arc (XBO 900) or a mercury arc (Osram 500W) was filtered through a water solution saturated with $NiSO_4$ and a Toshiba UV transmitting filter (UVD33S). The phosphorescence emission was dispersed with a Spex 1704 spectrometer (blazed at 300 nm with linear dispersion of 0.83 nm/mm at 428.2 nm) and detected with an EMI 9502 photomultiplier. The phosphorescence intensities given in the tables were corrected for the wavelength dependence of the sensitivity of the detection system by the method given in Ref. 24 with quinine and 2-naphthol. In order to avoid the effect of polarization samples composed of small pieces were used to take the phosphorescence spectra. The polarization behavior of the emission was examined by observing the intensity variation of the phosphorescence with rotation of a polarizing sheet placed parallel to the ab plane of BAC crystal.

In the MIDP experiments microwaves generated by a HP 8900 series tunable microwave oscillator and amplified with a Hughes 1177H microwave amplifier were fed to the sample contained in a helix. In order to separate the spectra coming from the different sites microwave power corresponding to the transition frequency between the sublevels of one site was applied to produce MIDP signal. The

† Also at the Department of Chemistry, State University of New York at Stony Brook, N.Y. 11794.

MIDP signals generated at the rate of 0.5 Hz were lock-in detected with a PAR 128A lock-in amplifier, while the Spex spectrometer was scanned at the rate of 0.01 nm/s.

In order to take the phosphorescence excitation spectra the light from a 900 W Xenon arc was monochromatized by the Spex spectrometer and focused on the sample of the size of about $10\times5\times4$ mm which was immersed in liquid helium. The entire phosphorescence emission was monitored without using a monochromator.

Results and Discussion

Phosphorescence Excitation Spectra and the Locations of the $^1n\pi^*$ and $^3n\pi^*$ States. The phosphorescence excitation spectra of BA-d_1 in BAC and BAC X-trap obtained at 4.2 K are shown in Fig. 1. The triplet states of BA and AP in BAC host are generated by the direct absorption of the guests and the absorption of the host followed by the energy transfer to the guests.[25] Comparing the spectra of BAC containing BA or AP with that of BAC X-trap, we can assign the origins of the $S_1\leftarrow S_0$ and $S_2\leftarrow S_0$ transitions. The S_1 and S_2 states are considered to be $^1n\pi^*$ and $^1\pi\pi^*$ (^1L_b) states, respectively. The $T_2\leftarrow S_0$ ($^3n\pi^*$) transitions of the guests were not detected, presumably because the concentrations of the guests were very low. From the peak positions of the a_1 and b bands in Fig. 1 the origins of the $^1n\pi^*$ and $^1\pi\pi^*$ (^1L_b) states of BA-d_1 in BAC were located at 29500 and 32900 cm^{-1}, respectively. The $^1n\pi^*$ state is about 2700 cm^{-1} blue shifted compared with that in methylcyclohexane,[26] whereas the $^1\pi\pi^*$ (^1L_b) state is red shifted by 1500 cm^{-1}. The band a_2 is separated from the band a_1 by 1314 cm^{-1} and is assigned to the vibronic band associated with the C=O stretching vibration in the $^1n\pi^*$ state as in vapor and other hosts.[26] In taking the excitation spectrum of BA, emissions from the different sites were not distinguished. Therefore, the estimated energy separation has an ambiguity of about 200 cm^{-1}. Similarly, the energies of the $^1n\pi^*$ and $^1\pi\pi^*$ (^1L_b) states of AP in BAC were determined to be 29500 and 34000 cm^{-1}, respectively. The energy separations (ΔE_{TT}) between the $^3n\pi^*$ and $^3\pi\pi^*$ of the guests could not be determined directly from the present experiments, but approximate values may be obtained by noting that in the aromatic carbonyls of the benzaldehyde type the energy separations between the $^1n\pi^*$ and $^3n\pi^*$ states are about 1750 cm^{-1}.[21,27] ΔE_{TT} are then estimated using the $^3\pi\pi^*$ energies from the phosphorescence to be 2300 cm^{-1} for BA and 1750 cm^{-1} for AP. These values are much larger than those found for BA and AP in other systems.[26,28,29] This is presumably because hydrogen bonding increases the $^3n\pi^*$ and $^1n\pi^*$ energies. A smaller value of ΔE_{TT} and ΔE_{ST} (energy difference between $^1n\pi^*$ and $^3\pi\pi^*$ states) for AP than for BA probably indicates a weaker hydrogen bonding in AP.

Phosphorescence and ODMR Studies. The phosphorescence spectra of BA in the BAC host obtained at 4.2 K are shown in Fig. 2. In these spectra o and o′ peaks are the origins of the emissions coming from two sites as first suggested by Koyanagi *et al.* (KZG).[19] We designate the main vibronic bands using the notations adopted by KZG as much as possible. The phosphorescence spectrum of BA-d_6 in BAC reported by KZG has a broad background emission, but this emission could be eliminated easily by growing the crystals slowly from the melts.[30] It was found that the AP and 1ID spectra consist of the emissions from only one site (Fig. 3).

The o peak gives the ODMR signals at 4.35 and 0.48 GHz; the o′ peak at 4.23, 3.87, and 0.36 GHz in the case of BA-d_1. Deuteration effects on the ODMR frequencies are less than 0.06 GHz. In Table 1 we summarize the results of the ODMR study obtained at 1.5 K. The order of the sublevels is taken to be z, y, and x from the top.[22] It is notable that the energy separations between the z and y sublevels are very small. This situation is similar to that found

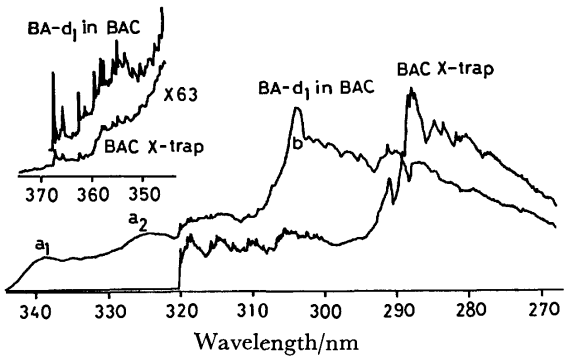

Fig. 1. Phosphorescence excitation spectra of BA-d_1 in BAC and BAC X-trap. The spectra shown in the upper left hand corner show the $T_1\leftarrow S_0$ absorption of BAC host.

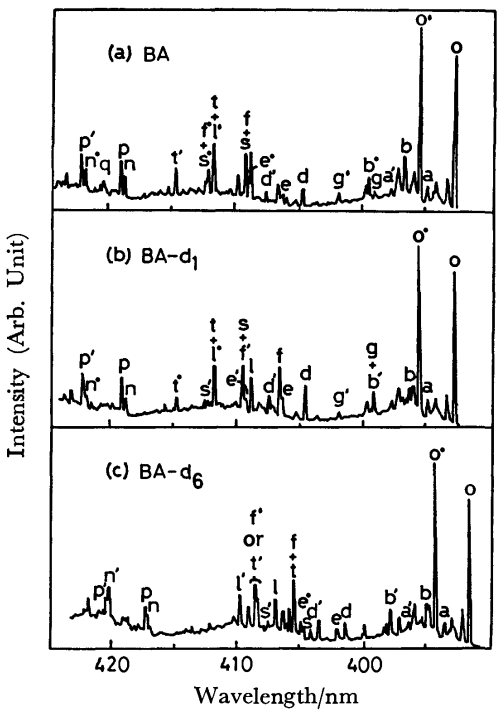

Fig. 2. Phosphorescence spectra of (a) BA, (b) BA-d_1, and (c) BA-d_6 in BAC. The spectra were taken with the slit width of 0.1 mm. No corrections for the peak intensities are made.

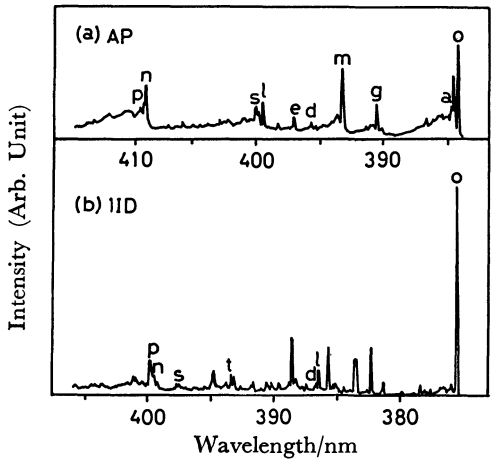

Fig. 3. Phosphorescence spectra of AP and 1ID in BAC. The spectra were taken with the slit width of 0.1 mm. No corrections for the peak intensities are made.

for AP in ethylene glycol water studied by Lamola.[31] In spite of the poor molecular symmetry the radiative and total decays of the site 1 BA, AP, and 1ID take place almost exclusively from the z sublevels. The EPR study showed that the z axis is along the C=O direction in the site 1 BA.[32] The x axis is perpendicular to the molecular plane. This is also considered to be true in the cases of AP and 1ID. On the other hand, the EPR study showed that as expected from the decay characteristics the z axis deviates from the C=O direction by 45° in the case of site 2 BA.[32]

We obtained the MIDP spectrum of the z sublevel for the site 1 and those of the z and y sublevels for the site 2 at 1.5 K. The representative spectra are shown in Fig. 4. It was not possible to separate the two emissions completely, but the contribution of the undesired emission was less than 20% of the desired one. We could easily identify the main vibrational

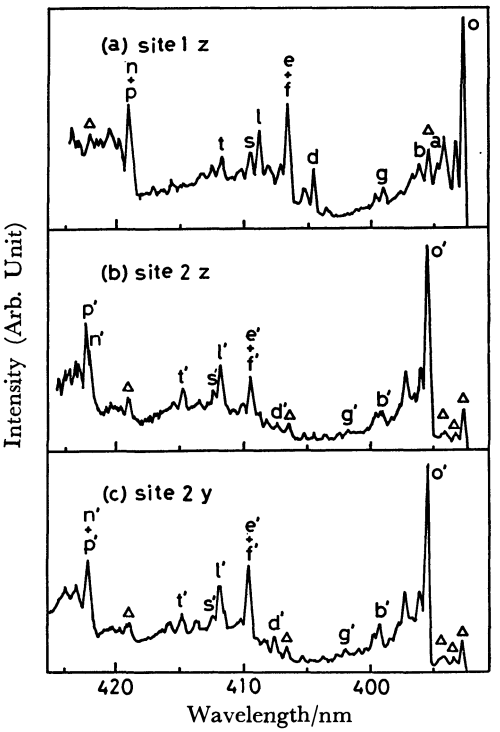

Fig. 4. MIDP specra of BA-d_1 in BAC. All spectra were taken with the slit width of 0.4 mm. The relative intensities of the peaks may not be accurate because of the use of long time constant. The peaks indicated with △ are due to the other site. (a) z sublevel spectrum of the site 1. (b) z subleved spectrum of the site 2. (c) y sublevel spectrum of the site 2.

bands of the emissions coming from the different sites. In Table 2 we give the results of our vibrational analysis. The analysis was made by comparison with the ground state vibrational frequencies given by Goodman *et al.*[33] The phosphorescence spectra of the site 1 and site 2 are slightly different from each other, but the difference is not large. Our assignments are mostly in agreement with those by KZG, but there are some important difference which are explained in the following.

The main difference is concerned with the assignments of the aldyhyde H wag (f) and ν_{19a} (s). KZG considered that the 0-1024 band (f) in the BA spectrum is due to the ν_{19a} vibration and the aldehyde H wag is not active. We think that this band is mainly due to the aldehyde H wag with a minor contribution from the ν_{19a} vibration, because we observe strong bands at 0-865 (f) and 0-870 (f+t) in the BA-d_1 and BA-d_6 spectra, which can be assigned to the aldehyde D wag. These vibrations are also very active in the site 2 spectra. In the MIDP spectra of BA-d_1 the band due to the ν_{19a} vibration is observable, but the intensity of this band is much weaker than that of the aldehyde D wag. This assignment is further supported by the observation that the polarization behavior of the 0-1024 band is similar to those of the other a″ bands such as CHO wag (b) and is different from those of the 0-0 and other a′ bands.[34] Among the a″ bands ν_{16b} and ν_4 vibrations seems to be less active than indicated by KZG.

a) The wave numbers in this table refer to vacuum. b) The relative intensities in this table are peak ones and their ambiguities are about 5%. c) The following peaks could be assigned to neither site 1 nor site 2. (numbers in the parenthesis are the relative intensities) 25034(2), 25000(4), 24624(6), and 23589(4). d) 25130(7), 25029(3), 24482(7), 24256(4), 24218(7), 24081(4), 24042(8), 23781(4), 23710(6), and 23589(6). e) 24082(4), 24809(4), 24763(4), 24253(6), 24169(5), 23976(7), 23923(6), and 23900(4).

Another important difference exists concerning the estimate of the intensity of the C=O stretching bands. According to the KZG assignment the C=O stretching bands have moderate intensities in the spectra of BA, BA-d_1, and BA-d_6. Although there is a 0-1680 (q) band of moderate intensity in the BA, there is no corresponding band in the BA-d_1 spectrum. Therefore, the C=O stretching band is likely to be very weak in the present systems. The C=O stretching band is also not clearly observable in the AP and 1ID spectra. The vibrations appearing in the AP spectrum are similar to those appearing in the spectra of AP X-trap[35] and AP in AP-d_8[19] except that the C=O stretching band is not clearly observable in AP in BAC. The common features of the spectra of BA and AP in BAC may be summarized as follows.

1) The 0-0 band is very strong.

2) The C=O stretching band is not clearly observable.

3) The main a′ modes associated with the ring vibrations are ν_1 (l), ν_{19a} (s), ν_{9b} (t), ν_{8b} (n), and ν_{8a} (p).

4) In addition to the a″ vibrations associated with the CHO and CH$_3$CO groups ν_{16a} (g), ν_{11} (d), and ν_{10a} (e) a″ ring modes have moderate intensities.

In connection with the observations recently made

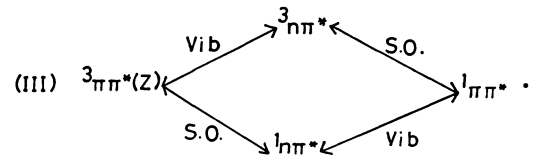
about the spectra of benzaldehyde, two points should be noted. One is about the intensity of the C=O stretching band. The C=O stretching vibration has been found widely in the phosphorescence spectra of the $^3\pi\pi^*$ aromatic carbonyls and it was suspected that it may have an intramolecular origin.[9] We have previously suggested that the appearance of this mode in the spectra of the $^3\pi\pi^*$ aromatic carbonyls is primarily due to the direct configurational mixing of the nearby $^3n\pi^*$ and $^3\pi\pi^*$ states caused by distortion and that it should not be active in the spectra of the nearly pure $^3\pi\pi^*$ aromatic carbonyls with large ΔE_{TT}.[5] The present result supports this suggestion further. Another point of interest is the relative intensities of the H wag and CHO torsion mode.[9] It was found that the intensity of the H wag is much stronger than that of the CHO torsion band as in the cases of many other $^3\pi\pi^*$ benzaldehydes.[12,25]

The phosphorescence spectrum of 1ID in BAC is also characterized by a very strong 0-0 band and a number of a″ vibronic bands with moderate to weak intensities. The vibrations appearing in the spectrum of 1ID in BAC are similar to those appearing in the 1ID X-trap spectrum,[33] but the relative intensity of the 0-0 band is much stronger in the BAC host. We made a vibrational analysis using infrared and Raman data.[36]

In the cases of BA, AP, and 1ID in BAC the phosphorescence takes place predominantly from the z sublevel. It was previously suggested that the z sublevel emissions of the $^3\pi\pi^*$ aromatic carbonyls are mainly due to the following three mechanisms.[5] (I) $^3n\pi^*$-$^3\pi\pi^*$ configurational mixing, (II) $^1n\pi^*$-$^3\pi\pi^*$ spin orbit coupling, (III) Herzberg-Teller vibronic spin orbit mechanism. However, the $^3n\pi^*$-$^3\pi\pi^*$ configurational mixing is not important in the present systems possibly because of large ΔE_{TT} and the planar structure of the T_1 states. Then the mechanism to produce the z sublevel emission at the 0-0 and the a′ band is,

$$\text{(II)}\ {}^3\pi\pi^*(z) \xleftrightarrow{\text{S.O.}} {}^1n\pi^* \xleftrightarrow{\vec{e}\,\vec{r}} S_0.$$

The Hertzberg-Teller vibronic spin orbit mechanism in both triplet and singlet manifolds gives rise to the a″ bands,



However, in view of the fact that ΔE_{TT} is smaller than the energy separations between the $^1n\pi^*$ and $^1\pi\pi^*$ states vibronic coupling within the triplet manifold is considered to be more important as in the other $^3\pi\pi^*$ benzladehydes.[5] The relative importance of the mechanism (III) with respect to that of (II) is reduced as ΔE_{TT} increases. This is the reason why the a″ vibronic bands are relatively weak compared with the 0-0 bands in the present systems. The phosphorescence spectra of the present systems are thus explained by the same radiative mechanisms as used previously to explain the other $^3\pi\pi^*$ aromatic carbonyls. It should be noted that the present mechanisms are essentially the same as those discussed for AP in ethylene glycol water by Lamola.[31]

The phosphorescence of the site 2 BA comes from both z and y sublevels with $k_z^r/k_y^r=0.71$ at the 0-0 band. Our EPR study showed that the z axis of the zero field tensor is 45° away from the C=O direction and this is the cause of the two sublevel activities in the site 2.[32] In fact, the y sublevel spectrum is quite similar to the z sublevel one. If the spin orbit mixing with the $^1n\pi^*$ state is responsible for the emissions from both y and z sublevels, the deviation of the z axis from the C=O direction is given by arctan $\sqrt{0.71}=40°$,[21] which is in reasonable agreement with the value determined by the EPR study.[33]

The EPR study showed that the spin distribution in the benzene ring of the T_1 state of BA in BAC is very similar to that of the T_1 state of benzonitrile. The T_1 states of BA in BAC and benzonitrile have similar quinonoid structures.[32,37] Then it may be expected that the modes associated with the benzene ring vibrations appearing in the phosphorescence spectra are similar in both systems. The phosphorescence spectrum of benzonitrile is simple consisting of the bands at 0-765, 0-1000, 0-1185, and 0-1610.[38] Indeed these bands have moderate intensities in the spectrum of BA in BAC.

Comparison with the Other $^3\pi\pi^*$ Carbonyls. The spectroscopic properties of BA, AP, and 1ID in BAC are mostly well explained by taking account of the fact that ΔE_{TT} are much larger than those of BA, AP, and 1ID in other hosts. However, there seem to be a few characteristics which are specific to the present systems.

It was shown previously that there is a good empirical correlation between the decay rate constant of the z sublevel of a $^3\pi\pi^*$ aromatic carbonyl and ΔE_{TT} or ΔE_{ST}.[21,22] This correlation with $\Delta E_{ST}=4050\ cm^{-1}$ predicts k_z of BA in BAC to be $17.6\ s^{-1}$, which is in good agreement with the observed $18\ s^{-1}$.[22] For a series of $^3\pi\pi^*$ aromatic carbonyls of the benzaldehyde type it was previously suggested that $k_y^r(0\text{-}0)/k_z^r(0\text{-}0)$ increases as ΔE_{TT} (ΔE_{ST}) increases.[5] There are a few carbonyls with large ΔE_{TT} in which $k_y^r(0\text{-}0)$ are even larger than $k_z^r(0\text{-}0)$.[39,40] Here, however, $k_y^r(0\text{-}0)/k_z^r(0\text{-}0)$ is very small in spite of rather large ΔE_{TT}. This is probably due to two causes. Firstly, $k_y^r(0\text{-}0)$ is very small. The fact that k_y of the site 1 BA and 1ID are much smaller than those of the other $^3\pi\pi^*$ aromatic carbonyls of the benzaldehyde type seems to indicate this. This shows that the radiative decay involving the spin-orbit mixing with the $^1\sigma\pi^*(^1\pi\sigma^*)$ state is not very effective in the present systems. Secondly, $k_z^r(0\text{-}0)$ is relatively large in the present systems probably because of the increased intensity of the $S_0\rightarrow S_1(^1n\pi^*)$ transition. Although we do not know the exact reason of the very small $k_y^r(0\text{-}0)/k_z^r(0\text{-}0)$ here, hydrogen bonding formation may be responsible.

The ZFS were determined by using the spin Hamiltonian, $H=-XS_x^2-YS_y^2-ZS_z^2$, with $D=-\frac{3}{2}Z$

and $E=\frac{1}{2}(Y-X)$. X, Y, and Z are the energies of the x, y, and z sublevels, respectively, with $X+Y+Z=0$. $|D|=0.0805$ cm^{-1} for BA-d_1, 0.0897 cm^{-1} for AP, and 0.0758 cm^{-1} for 1ID in BAC are rather small compared with those of the other $^3\pi\pi^*$ aromatic carbonyls. D is given as a sum of D_{SO} due to the second order effect of the spin orbit interaction and D_{SS} due to spin-spin interaction. D_{SO} is given approximately as[41,42]

$$D_{SO} = -G^2(1/\Delta E_{TT} - 1/\Delta E_{ST}).$$

Here G is the matrix element for the spin-orbit mixing between $^3n\pi^*$ and $^3\pi\pi^*$ states. G^2 was estimated to be $\approx$90, $\approx$60, and $\approx$20 cm^{-2} for a series of benzaldehydes, acetophenones, and 1-indanones.[21,22,43] With the values of ΔE_{TT} and ΔE_{ST} estimated in this work, these values give D_{SO} for BA, AP, and 1ID to be -0.017, -0.017, and -0.006 cm^{-1}, respectively. On the other hand, D_{SS} estimated for a series of benzaldehydes and 1-indanones are -0.11 cm^{-1} and -0.08 cm^{-1} from plots of D_{obs} *vs.* $1/\Delta E_{TT}-1/\Delta E_{ST}$.[21,22,43] These values predict D to be -0.127 and -0.086 cm^{-1}, respectively. The observed D are somewhat larger than these estimates. Our previous MO calculation showed that hydrogen bonding caused significant changes in the spin distribution on the carbonyl group.[31] D_{SS} and D_{SO} may be affected significantly through the changes in spin distribution.

We express our sincere thanks to Dr. Motohiko Koyanagi of Kyushu University for his helpful and critical discussions. Our thanks are also due to Dr. Seigo Yamauchi for valuable discussions, Mr. Yoshihiro Hirata for his help in the early stage of this work and Miss Yasuko Yamada for the correction of the wavelength dependence of the spectrometer and the polarization data. This work was partly supported by a Grant from the Ministry of Education, Science and Culture.

Decomposition of Methylamine over Ruthenium Black

Hideo ORITA, Shuichi NAITO,* Takaharu ONISHI,† and Kenzi TAMARU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received April 26, 1983)

The decomposition of methylamine over Ru black was investigated in the presence and absence of hydrogen, and the dependence of reaction rate on the pressures of reactants was also examined. Methylamine decomposes rapidly to gaseous ammonia and deposited carbon species (CH_x(a)) over clean Ru black in the absence of hydrogen. The hydrogenation of CH_x(a) after the decomposition of amines produced hydrocarbons in the range C_1—C_4 whose distribution was dependent on the way CH_x(a) was accumulated.

The reactions of aliphatic amines over some evaporated metal films (Ni, Fe, Pd, Pt, W, Co, V) were studied previously by Kemball and Moss,[1-3] and by Anderson and Clark.[4] Two most important reactions of methylamine have been considered to be (i) simple hydrocracking and (ii) disproportionation involving two amine molecules, which leave considerable amount of carbon on the catalysts.[1,4] On the other hand in the presence of hydrogen thermodynamics indicates that methylamine should be decomposed readily to methane and ammonia.

In the present work, ruthenium was chosen as a catalyst because of its high activity for ammonia synthesis and Fischer-Tropsch reaction, and the decomposition of methylamine over a ruthenium black was investigated in the presence and absence of hydrogen. The reaction mechanism has been discussed on the basis of the reaction kinetics and the nature of the carbon species deposited from amines.

Experimental

The catalytic reaction of amines was carried out in a conventional closed-circulation system, whose dead volume was 336 cm^3. The analysis of gas mixture was carried out by gas chromatography using Chromosorb 103 (3 m, 110—120 °C) for ammonia and amines, Molecular Sieve 5 A column (1.5 m, room temperature) for hydrogen and methane, and active alumina column (2 m, room temperature) for C_2—C_4 hydrocarbons.

The ruthenium black was purchased from Nippon Engelhard and was used as a catalyst after hydrogen reduction at 300 °C. After this treatment, no impurity was observed on the surface of ruthenium black by X-ray photoelectron spectroscopy. Methylamine was obtained from its hydrochloride solution and potassium hydroxide, followed by drying, purifying by vacuum distillation and out-gassing by freezing and pumping. Dried ethylamine (>99%) was purchased from Tokyo Kasei and was out-gassed before use. Hydrogen was purified by passing through a Deoxo catalyst (room temperature) and a liquid nitrogen cold trap.

Prior to each run of the reaction, the catalyst was reduced by hydrogen for 2 h and was evacuated for 1.5 h at 300 °C. The reaction temperature was fixed at 120±2 °C in order to prevent a secondary reaction. The exchange reaction with deuterium was investigated by IR, mass spectrometry, and gas chromatography (alumina+2% $MnCl_2$ column).

† Present address: Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Midori-ku, Yokohama 227.

Results and Discussion

Decomposition of Methylamine. The decomposition of methylamine over ruthenium black was investigated in the presence and absence of hydrogen, which are shown in Figs. 1 and 2, respectively. In the presence of hydrogen (Fig. 1a) ammonia and methane were produced simultaneously, but the amount of ammonia was more than that of methane. This indicates that carbon is deposited on the catalyst during the reaction. (The deposited carbon may be partially hydrogenated in the presence of hydrogen, which will hereafter be designated as CH_x(a).) The rate of reaction became slower as the reaction proceeded, and small amounts of hydrocarbons in the range of C_2—C_4 were also produced in the later stage if the reaction was prolonged. (The ratio of ethane to methane was ≈0.07.) After evacuation for about 5 min, the gas mixture of methylamine and hydrogen was introduced again to the catalyst on which CH_x(a) had been accumulated (Fig. 1b). Rapid production of ammonia was not observed this time, but ammonia and methane were produced proportionally and almost stoichiometrically. The formation of higher amines over ruthenium black was not observed although the production of larger amounts of higher amines have been reported over Pd, Pt, and W films.[1,4]

The decomposition of methylamine occurred readily even in the absence of hydrogen (Fig. 2a), producing ammonia and hydrogen, whereas the production of methane was not detected under this reaction condi-

tion, and the reaction was almost stopped after 1 h. After evacuation for 5 min, only hydrogen was introduced onto the catalyst (Fig. 2b). A large amount of methane was produced, whose rate of formation was almost equal to that of steady-state conditions.

The exchange reaction of ammonia or hydrogen with deuterium and the hydrogenation of olefins during hydrogenolysis of methylamine were very fast and finished within 10 min, which indicates that chemisorption of hydrogen is not inhibited even in the presence of methylamine.

The dependences of the formation of methane and ammonia on the pressures of methylamine and hydrogen were examined. The formation of methane and ammonia was independent of the pressure of methylamine, but increased with increasing the pressure of hydrogen. The dependence of the formation of methane on hydrogen pressure was determined to be 0.9± 0.1, but that of ammonia could not be estimated because of the scatter of data. The independency of amine pressure suggests that the surface must be substantially covered by adsorbed amine under the experimental conditions. The increase of the reaction rate with increasing hydrogen pressure suggests that the removal of CH_x(a) from the surface with hydrogen may be an important process.

On the basis of the above mentioned experimental results, the reaction mechanism is considered as shown in Fig. 3. The decomposition of methylamine occurs

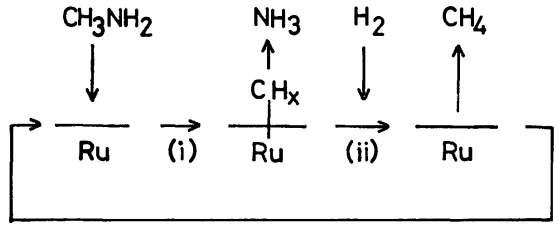

Fig. 3. Mechanism of hydrogenolysis of CH_3NH_2.

rapidly over freshly reduced ruthenium black even in the absence of hydrogen (step (i)), and then CH_x(a) is hydrogenated to methane slowly (step (ii)).

Hydrogenation of CH_x(a) after Various Reactions of Amines over Ruthenium Black. In order to investigate the nature of CH_x(a) produced from amines, the hydrogenation of CH_x(a) was carried out after various reactions of amines. The results are shown in Fig. 4 and Table 1. Main hydrogenation product was methane in all the cases, but the ratios of higher hydrocarbons to methane and the production rates were dependent on the way CH_x(a) was formed. The ratios of higher hydrocarbons to methane were larger in the hydrogenation of CH_x(a) produced from methylamine decomposition than that produced from the reaction of methylamine and hydrogen. This fact suggests that the CH_x(a) species produced from the reaction of methylamine and hydrogen is more easily hydrogenated to form methane than that from methylamine decomposition.

In the decomposition of methylamine and ethyl-

Reactions	Products of the hydrogenation of surface species						
	C_1	C_2	C_3	C_4	C_2/C_1	C_3/C_1	C_4/C_1
	Torr						
$CH_3NH_2 + H_2$ (20 h)[a)]	4.2	0.3	0.1	0.07	0.07	0.03	0.02
CH_3NH_2 decomp (4.5 h)[b),c)]	5.0	0.9	0.7	0.2	0.18	0.14	0.04
$C_2H_5NH_2$ decomp (4.5 h)[b),d)]	4.8	1.2	0.5	0.3	0.25	0.1	0.06

a) The time of hydrogenation is 50 min. b) Production of ammonia is almost stopped after 4.5 h. c) Amount of evolved ammonia is 28.7 Torr, and the time of hydrogenation is 50 min. d) Amount of evolved ammonia is 28.3 Torr, and the time of hydrogenation is 70 min.

amine, the same amount of ammonia was evolved, but when these CH_x(a) species were hydrogenated, smaller amount of methane and larger amount of ethane were produced in the case of ethylamine. Consequently, it is considered that CH_x(a) produced from the decomposition of ethylamine preserves the C–C bond to some extent. In the reaction of ethylene and hydrogen over clean ruthenium black at 120 °C, the hydrogenation of ethylene occurred rapidly and only a small amount of methane was produced. Therefore, the C–C bond is much more stable than the C–N bond over ruthenium black. Since CH_x(a) produced from amines has reactivity to produce C–C bonds, it may be similar to CH_x(a) species accumulated during CO–H_2 reaction over ruthenium metal.

(Received May 13, 1983)

Amorphous Ni–Ti and Ni–Zr alloys for their possible use in water electrolysis cathode materials were investigated. The hydrogen electrode reaction in 1 M NaOH (1 M=1 mol dm^{-3}) proceeds *via* the Volmer-Tafel reaction route with mixed rate-determining characteristics. The electrocatalytic activity is augmented significantly with a treatment of the alloy electrodes with aq HF. Thus, the exchange current density reaches 10^{-3} A cm^{-2} (apparent) at 303 K. The activation energy values are 9.4, 5.5, and 6.1 kcal mol^{-1} (1 cal=4.184 J) for the Volmer and Tafel step and the overall reaction, respectively. Surface analyses of the electrodes have indicated that such a high activity is caused by a stable porous Ni layer which is formed on the surface by the acid treatment. Such a porous Ni layer was not effectively formed if the alloys were in crystalline states.

Hydrogen is noted as a possible candidate for an energy carrier in the future as it is clean and fully recycleable substance of practically unlimited supply.[1] The energy system with hydrogen would consist mainly of three processes, the generation, transport or storage, and utilization. For its generation, the electrolysis of water is a simple and well established technique but, to make the technique economically practicable, improvements in electrode materials towards a minimized energy consumption are required.

Most of amorphous alloys prepared by a rapid quench from their melts, in general, possess high mechanical and corrosion resistant properties, and hence some of them have already been investigated for catalyst or electrode materials uses.[2,3] Also, a number of amorphous alloys, such as Ni alloys, containing, Ti, Zr, or Th, have been investigated towards hydrogen storage materials since they are not pulverized upon absorption and liberation of hydrogen and, in addition, have an improved amount and rate of absorption of hydrogen as compared with the corresponding crystalline alloys.[4] This indicates that there might be a possibility of using the amorphous alloys not only for a hydrogen evolving cathode but also for a hydrogen storage electrode.

One of the present authors investigated ealier the kinetics and mechanism of the hydrogen electrode reaction on Pd, a typical hydrogen absorbing metal.[5] It has been shown that the component overpotentials for each of the constituent steps are individually observable owing to the existence of a large amount of hydrogen stored in the electrode metal. Analysis of the overpotential rise and decay transient curves has shown that the hydrogen electrode reaction on Pd is comprised of two elementary steps, namely, Volmer and Tafel processes. The reaction rates of the elementary steps have thence been evaluated.

In this paper, we report the hydrogen electrode reaction characteristics of amorphous Ni–Ti and Ni–Zr alloys. In particular, the relationship between the electrodic property and the surface state of these electrodes will be discussed.

Experimental

Preparation of Electrodes. The amorphous alloys were prepared from the melts by a rapid quenching using a single roller type apparatus.[6] The specimens are of the following compositions, $Ni_{0.27}Ti_{0.73}$, $Ni_{0.33}Ti_{0.67}$, $Ni_{0.40}Ti_{0.60}$, $Ni_{0.25}Zr_{0.75}$, $Ni_{0.33}Zr_{0.67}$, $Ni_{0.50}Zr_{0.50}$, and $Ni_{0.65}Zr_{0.35}$. The crystalline Ni–Ti and Ni–Zr alloys were obtained by annealing the amorphous alloys at 873—1073 K for 30 min under a He atomosphere (20—30 kPa). The phase transition from the amorphous to the crystalline phase was monitored by observing changes of the electric conductivity and detected later by an X-ray diffraction analysis.

The specimens were in the shape of a ribbon, 0.6—1.4 mm in width, *ca.* 20 μm in thickness, and 1—2 cm in length, with the apparent surface area of 0.05—0.15 cm^2. Their ends were spot-welded to nickel wire which was in turn sealed into 8 mmϕ Pyrex glass tubings with epoxy resin ("Torr Seal" Varian Associates). These electrodes were treated with hot concentrated H_2SO_4, aqua regia, or 1 M HF solution in order to remove the oxide film on the surface (see below).

Electrochemical Measurements. The electrochemical measurements were carried out in a three compartment Pyrex glass electrolysis cell under a stream of H_2. A platinized Pt electrode was also used for comparison. The electrolytic solution, 1 M NaOH, was prepared from special grade NaOH (Merck Japan, Ltd.) with water from a Millipore pure water system. The temperature was controlled by a thermostat at 303 K except for the temperature dependence experiments. Details of the method and apparatus of the electrochemical measurements were described in a previous paper.[7]

X-Ray Photoelectron Spectroscopy. The surface analysis was performed by employing an ESCA apparatus (VG-III). Ar^+ bombardments were carried out at a condition of 800 eV and 3 μA cm^{-2} for 20 min in order to remove adsorbed carbon or hydroxyl groups from the surface of the alloys and to enhance the sensitivity of the detection. The spectra obtained were calibrated with the $4f_{7/2}$ peak from an Au plate which was employed as an internal standard. In order to avoid the overlap of the main spectra of Ti or Zr and Ni with their Auger signals, Al $K\alpha$ and Mg $K\alpha$ radiations were used for the Ni–Ti and Ni–Zr alloys, respectively.

Results and Discussion

Electrochemical Properties. The electrocatalytic activity of the amorphous Ni–Ti and Ni–Zr alloy electrodes in as-obtained form or after treatments with hot concentrated H_2SO_4 or aqua regia were very low and the reversible hydrogen electrode potential was not observed. However, when the samples, both the amorphous and crystalline alloys, were etched with a HF solution (1 M) for several minutes, the activity was strongly enhanced and the reversible potential was established. Alloys with relatively high Ni contents tended to require longer periods of time of the HF-treatment for the activation.

The galvanostatic overpotential rise transients give the rapidly growing overpotential component, η_1, which has the characteristics attributable to the Volmer process.[5,8] In Fig. 1 are shown the cathodic and anodic polarization behaviors with respect to η_1 on a series of the amorphous Ni–Ti alloys. The cathodic and anodic polarization curves appear to be essentially symmetrical with each other about the abscissa. This is expressed in terms of the symmetry factor β, which can be evaluated if we calculate the cathodic unidirectional current i_{-v}, by the relation,[5,8] $i_{-v}=i_{ov}\exp[-\beta F\eta/RT]=i/[1-\exp(F\eta/RT)]$. This is also shown in Fig. 1, a dashed line ($Ni_{0.27}Ti_{0.73}$), which gives almost a straight line with the slope of ≈ 95 mV or $\beta\simeq 0.63$. It is, therefore, concluded that η_1 represents the overpotential component responsible for an one electron transfer reaction, namely the Volmer (discharge) step.

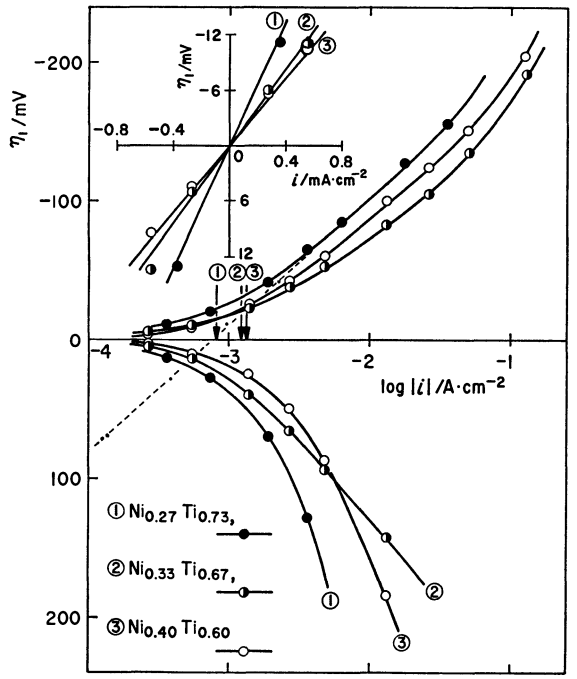

Fig. 1. Cathodic and anodic polarization behaviors of the rapidly rising overpotential component η_1 on a series of amorphous Ni-Ti alloys. The arrows on the abscissa indicate i_{ov} as evaluated from the linear plots (the inset figure) of η_1 *vs.* i near the reversible hydrogen electrode potential. 1 M NaOH, 303 K.

The exchange current density i_{ov} of the Volmer step has been evaluated[8] from the slope of a linear plot

†† The current density and the exchange current densities are given, unless otherwise stated, on the apparent unit area basis.

of η_1 *vs.* current density at low overpotentials (the polarization resistance, r_1) with $i_{oV}=(RT/F)/r_1$. On the amorphous Ni–Ti alloy electrodes, i_{oV} was found to be of the order†† of 10^{-3} A cm^{-2} and did not depend appreciably on the alloy composition. The values are indicated by the arrows on the abscissa in Fig. 1.

The overpotential decay transients at various time scales on the amorphous and crystalline $Ni_{0.33}Ti_{0.67}$ alloy electrodes are shown in Figs. 2(a) and 2(b), respectively. The overpotential on the amorphous electrode decayed rapidly up to about 1 sec but, after that, the decay rate was greatly diminished so as to require several minutes for its complete decay (Fig. 2(a)). On the crystalline alloy electrodes, on the other hand, the overpotential decayed much more rapidly and no plateau was observed on the transient curves (Fig. 2(b)). These observations suggest that the rate of hydrogen absorption into or liberation from the amorphous Ni–Ti alloys is very rapid as compared with the surface reaction, but that may not be the case with the crystalline alloys.

The slowly decaying overpotential component η_2' is defined at the moment of completion of the initial rapid overpotential decay upon the termination of the polarization current. This was readily evaluated on the amorphous Ni–Ti electrodes by extrapolating the plateau on the overpotential decay curves, such as that in Fig. 2(a), to $t=0$. Results are shown in Fig. 3, together with the total overpotential η on the amorphous or cyrstalline Ni–Ti alloys, and also η on a platinized Pt electrode. The slope of the Tafel lines for η_2' was around 30 mV and the exchange current density value, evaluated by $i_{oT}=(RT/2F)/r_2'$ where r_2' is the polarization resistance with respect to η_2', was around 0.4×10^{-3} A cm^{-2}. The fact that the latter value is not much different from i_{oV} reported above indicates that the hydrogen electrode reaction is of mixed rate-determining type.

The Tafel slope and the exchange current density values associated with η_2' suggest, along with the Tafel (H(a) recombination) step, a significant contribution to η_2' of the H_2 diffusion process in the solution phase. To see this, the diffusion overpotential in the present experimental system was evaluated separately using a Au electrode of a similar dimension. As the overpotential on Au decays very rapidly (time constant $\approx10^{-3}$ s) except for a component attributed to the concentration overpotential due to H_2 diffusion, the overpotential decay transients could reveal only the latter component (the time constant $\approx10^{0}$ s). Results indicated that the concentration overpotential is of comparable magnitude with η_2'. This means that i_{oT} as determined from η_2' is in fact for the Tafel-plus-diffusion processes and hence the intrinsic value for the Tafel step should be considerably greater than the value quoted above or given below in Table 1.

The linear portion of the Tafel line with respect to the total overpotential η in the cathodic region has the slope of about 120 mV and its extrapolation to $\eta=0$ gives the exchange current density $i_{o,ext}$ of the order of 10^{-3} A cm^{-2}. It has been shown earlier from a general analysis of the mixed rate-determining Volmer-Tafel reaction[8] that the kinetics at high cathodic overpotentials should practically be determined by the Volmer step. This means that the electrocatalytic activity of the electrode under (deep) cathodic polarization is approximately represented by i_{oV} and not i_o or i_{oT}. Indeed, comparison of Fig. 3 with Fig. 1 reveals that $i_{o,ext}$ is in fair agreement with i_{oV} reported above.

In Table 1 are summarized the exchange current densities and the double layer capacitance obtained on the amorphous or crystalline Ni–Ti alloys, a Ni wire (0.25 mmϕ), and a platinized Pt electrode.

The exchange current density i_o of the overall reaction on the amorphous Ni–Ti electrodes is calculated from i_{oV} and i_{oT} by the relation,

$$\frac{1}{i_o}=\frac{1}{i_{oV}}+\frac{1}{i_{oT}}.$$

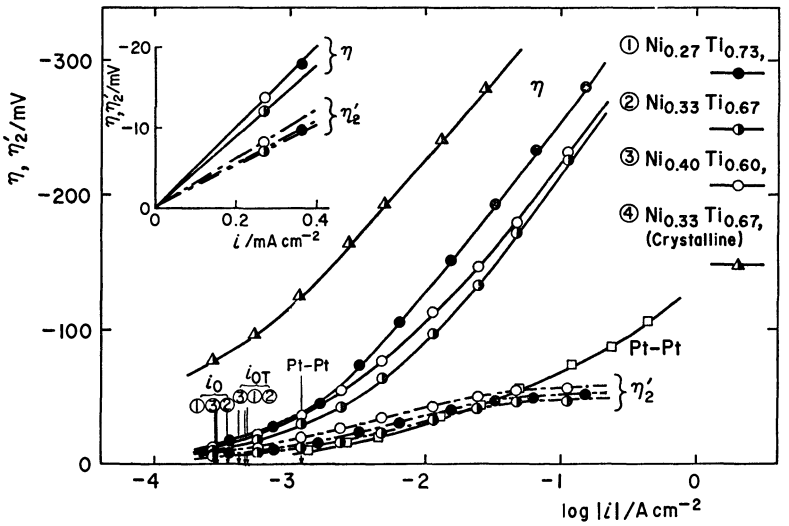

Fig. 3. Cathodic polarization behaviors of the total overpotential η and slowly decaying overpotential component η_2' on a series of amorphous and crystalline Ni–Ti alloy electrodes and on platinized Pt electrode. The arrows on the abscissa indicate i_o and i_{oT} obtained at low overpotentials (the inset figure). 1 M NaOH, 303 K.

Table 1. Exchange current densities[a] of the elementary steps and the overall reaction and the double layer capacitance on the cathodes of a series of Ni–Ti alloys in 1 M NaOH at 303 K

Composition	State	i_{oV} / mA cm^{-2}	i_{oT} / mA cm^{-2}	i_o / mA cm^{-2}	$i_{o,ext}$ / mA cm^{-2}	C / mF cm^{-2}
$Ni_{0.27}Ti_{0.73}$	Amorphous	0.82	0.47	0.28	0.83	2.3
$Ni_{0.33}Ti_{0.67}$	Amorphous	1.22	0.49	0.35	1.80	4.7
$Ni_{0.40}Ti_{0.60}$	Amorphous	1.32	0.37	0.29	1.60	2.1
$Ni_{0.33}Ti_{0.67}$	Crystalline				0.10	0.4
Ni	Crystalline				0.006	0.1
Pt–Pt	Crystalline			1.22		40.2

a) Per apparent unit area.

As mentioned above, i_o should not be identified with $i_{o,ext}$ in mixed rate-determining reactions such as in the present case ($i_o < i_{o,ext} \simeq i_{oV}$).

The evaluation of the step rates from the component overpotentials was not possible on the crystalline Ni–Ti electrode or on the Ni wire electrode. Accordingly, only $i_{o,ext}$ values are given, which may be compared with i_{oV}, at least approximately, as discussed above.

It is seen in Table 1 that the amorphous Ni–Ti alloy electrodes have electrocatalytic activities higher than the crystalline alloy electrode and far greater than that of the pure Ni electrode. The rate can further be increased if the H_2 diffusion rate were raised by improved stirring, *etc.* Even in the present stage, the activity is almost comparable with that of a smooth Pt electrode, particularly at low current densities.

It was seen that such a high electrocatalytic activity on the amorphous alloy electrodes were caused by a very large roughness factor value that was realized. The factor is evaluated from the capacitance values in Table 1 to be several hundreds, if one assumes a value of 18 μF cm^{-2} usually observed on Hg electrode to be the value per true unit area. Such an increase of the surface roughness factor must be a result of dissolution of the component metal Ti in the alloys by the treatment with hydrofluoric acid. If one counts $i_{o,ext}$ per true unit area on the amorphous and crystalline alloys, they are always in the range of 10^{-6}—10^{-5} A cm^{-2} (true) and are very close to that generally observed on smooth Ni electrodes. This is an indication that the electrocatalytic activity is caused by the layer of Ni and not by Ti.

The heat of activation determined from the Arrhenius plots of the exchange current densities (Fig. 4) on the amorphous $Ni_{0.33}Ti_{0.67}$ electrode was about 9.4, 5.5, and 6.1 kcal mol^{-1} for the Volmer and Tafel/diffusion step and the overall reaction, respectively. The value for the Volmer process was well comparable with the corresponding value of 8 kcal mol^{-1} observed on Pd.[8] The value for the Tafel/diffusion process is larger than *ca.* 3 kcal mol^{-1} anticipated for the diffusion process itself and thus indicates a significant contribution from the Tafel step which is likely[8] to be associated with some 6 kcal mol^{-1}.

The overpotential decay transients on the amorphous Ni–Zr alloy ($Ni_{0.33}Zr_{0.67}$) are shown in Fig. 2(c). The overpotential on both the amorphous and

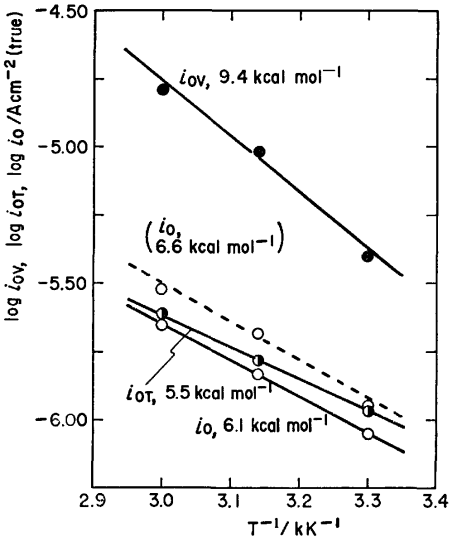

Fig. 4. Arrhenius plots of the exchange current densities and corresponding activation heats of the Volmer and Tafel step and the overall reaction on the amorphous $Ni_{0.33}Ti_{0.67}$ alloy electrode. The dashed-line and the value in the parenthesis represent those of i_o on the amorphous $Ni_{0.33}Zr_{0.67}$ alloy electrode. 1 M NaOH.

crystalline Ni–Zr alloys decayed rapidly with no plateau, and hence the kinetics of the component elementary reactions were not obtainable. Likewise, the evaluation of η_1 from the galvanostatic overpotential rise transients were not practicable.

The overall polarization characteristics on the amorphous or crystalline Ni–Zr alloys are shown in Fig. 5. It is seen that the electrodic characteristics are very similar with those of the Ni–Ti alloys. Thus, the slope of the Tafel line is around 120 mV and $i_{o,ext}$ is around 10^{-3} A cm^{-2}. One may hence conclude that the hydrogen electrode reaction on these alloys also proceeds *via* the Volmer-Tafel route with practically the same electrocatalytic activities, respectively, with the amorphous or crystalline Ni–Ti alloys reported above.

The polarization resistance around the reversible potential gives the values of i_o which are roughly in one order of magnitude smaller than $i_{o,ext}$. Along the line of arguments presented above, this fact may indicate that i_{oT} is at least several times smaller than

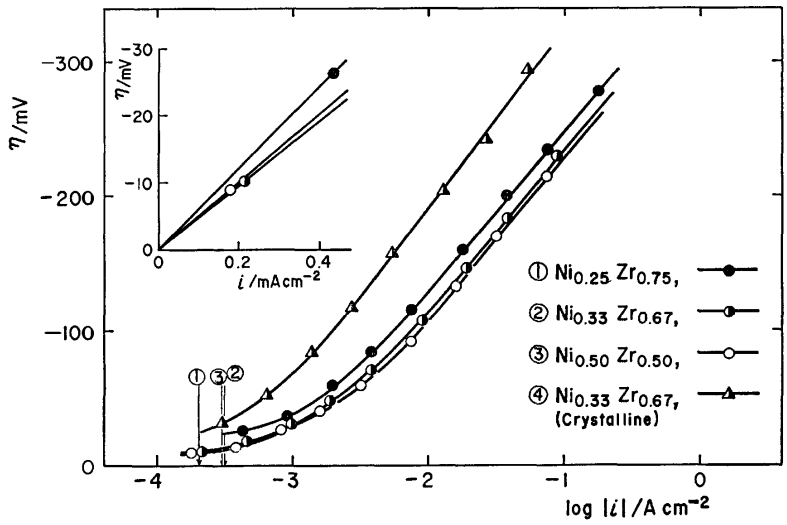

Fig. 5. Cathodic polarization behaviors of the total overpotential η on a series of the amorphous and crystalline Ni-Zr alloy electrodes. The arrows on the abscissa indicate i_0 obtained at low overpotentials (the inset figure). 1 M NaOH, 303 K.

Table 2. Exchange current densities[a] and double layer capacitance on the cathodes of a series of Ni–Zr alloys in 1 M NaOH at 303 K

Composition	State	i_0	$i_{0,ext}$	C
		mA cm^{-2}	mA cm^{-2}	mF cm^{-2}
$Ni_{0.25}Zr_{0.75}$	Amorphous	≈0.2	0.81	5.0
$Ni_{0.33}Zr_{0.67}$	Amorphous	≈0.3	1.10	4.1
$Ni_{0.50}Zr_{0.50}$	Amorphous	≈0.3	1.30	2.8
$Ni_{0.33}Zr_{0.67}$	Crystalline		0.34	0.9

a) Per apparent unit area.

i_{oV} and hence $i_o \simeq i_{oT}$. Values of i_o are hence evaluated by $i_o=(RT/2F)/r$ with $r=(d\eta/di)_{\eta\to 0}$ in a similar manner as i_{oT}. These are indicated by arrows in Fig. 5.

The exchange current density and the double layer capacitance obtained on a series of the amorphous Ni–Zr alloys and the crystalline $Ni_{0.33}Zr_{0.67}$ alloy are given in Table 2. Electrocatalytic activity measurements on $Ni_{0.65}Zr_{0.35}$ were unsuccessful because of its very low activity. The values of i_o on the amorphous Ni–Zr alloys was 0.2—0.3 mA cm^{-2}. As seen from Fig. 5, the electrocatalytic activity of the amorphous Ni–Zr alloys is considerably higher than that of the crystalline ones as in the case of the Ni–Ti systems. Also, it can be seen from Table 2 that the amorphous Ni–Zr alloys give nearly the same values of the double layer capacitance as on the amorphous Ni–Ti alloys and hence their true surface area is also very large.

The heat of activation was determined only for the overall reaction. It was 6.6 kcal mol^{-1} on the $Ni_{0.33}Zr_{0.67}$ alloy, as already shown in Fig. 4.

Surface Characterization. Surface analysis of the Ni–Ti or Ni–Zr alloy electrodes before and after the treatment with hydrofluoric acid were performed using the X-ray photoelectron spectroscopy (XPS) method. In Fig. 6 are recorded typical XPS spectrum patterns on the amorphous $Ni_{0.33}Ti_{0.67}$ and $Ni_{0.33}Zr_{0.67}$ alloys over a wide range of the binding energy. The non-treated (as-obtained) alloys, spectra a) ($Ni_{0.33}Ti_{0.67}$) and c) ($Ni_{0.33}Zr_{0.67}$), gave the signals with strong intensity of Ti or Zr and O, whereas the peaks to be assigned to Ni were very weak and almost undetectable. On the other hand, on the HF-treated samples, the

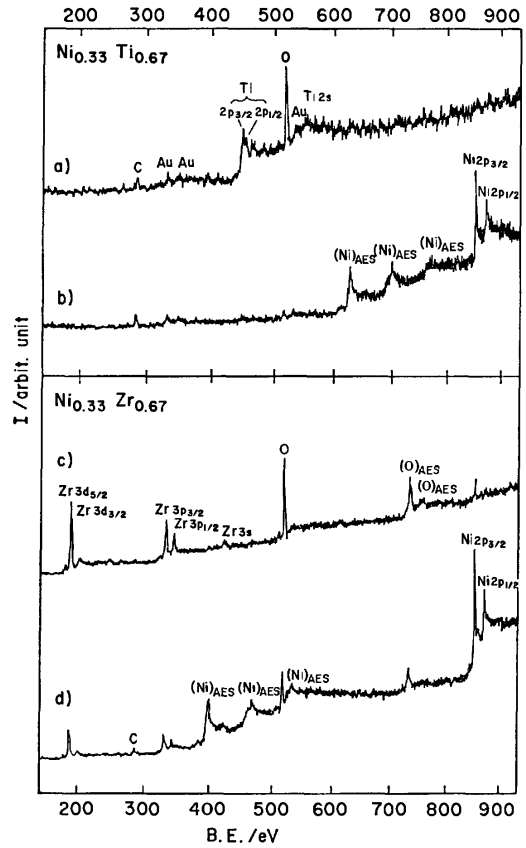

Fig. 6. XPS spectrum patters of the amorphous $Ni_{0.33}Ti_{0.67}$ and $Ni_{0.33}Zr_{0.67}$ alloys obtained with a wide range scan of the binding energy (*B.E.*=0—1000 eV). The X-ray source employed was Al $K\alpha$ for $Ni_{0.33}Ti_{0.67}$ and Mg $K\alpha$ for $Ni_{0.33}Zr_{0.67}$, respectively. a) and c), nontreated specimens; b) and d), HF-treated specimens.

XPS and Auger electron spectra from Ni increased remarkably while the signals of Ti or Zr were diminished (spectra b) and d)).

Figure 7 shows the XPS spectra ascribed to the Ti_{2p} or Zr_{3d} and the O_{1s} electrons from the nontreated amorphous $Ni_{0.33}Ti_{0.67}$ and $Ni_{0.33}Zr_{0.67}$ alloys. The signals of $Ti_{2p3/2}$ (or $Ti_{2p1/2}$) consists of three bands, as deconvoluted in Fig. 7, with the peak values around 455, 457, and 459 eV (or 461, 463, and 464.5 eV). These are attributable to metallic Ti or two oxides, Ti_2O_3 and TiO_2, on the basis of the data given in a handbook.[9] The Ti_2O_3 was probably formed from TiO_2 by the Ar^+ bombardments.[10] The $Ti_{2p3/2}$ and $Ti_{2p1/2}$ signals gave energy differences of 6.1 eV for metallic Ti or Ti_2O_3 and 5.6 eV for TiO_2. These values are in good agreement with the values in the literatures[9,11] for titanium in such valence states.

For the $Zr_{3d5/2}$ and $Zr_{3d3/2}$ electrons, there are each two bands respectively assigned to the Zr metal and its oxide (ZrO_2), with the peak positions about 179 or 182 eV for the former zirconium and about 183 or 185 eV for the latter one. The energy gaps of $Zr_{3d5/2}$ and $Zr_{3d3/2}$ were 2.3—2.4 eV as expected.[9] The O_{1s} signals are attributable to the lattice oxygens of Ti_2O_3, TiO_2, or ZrO_2. The XPS profiles similar to the Ti_{2p}, Zr_{3d}, or O_{1s} spectra in Fig. 7 were observed on the other amorphous or crystalline alloys.

The findings indicate that most of Ti or Zr on the surface of the alloys exists as dioxide, *viz.* TiO_2 or ZrO_2. On the other hand, the peak positions of $Ni_{2p3/2}$ and $Ni_{2p1/2}$ (≈853 and 870 eV) and the energy differences between these signals (≈17 eV) indicate that the nickel on the surface is metallic.

The surface atomic ratios, $C^S_{Ni/Ti}$ and $C^S_{Ni/Zr}$, were calculated from the integral peak intensity (I) of Ni_{2p} and $Ti_{2p3/2}$ or $Zr_{3d5/2}$, after taking into account their atomic sensitivity factors (S)[9] for X-ray in the following equation:

$$C^S_{Ni/M} = (I_{Ni}/S_{Ni})/(I_M/S_M), \quad M = Ti, Zr,$$

where the values employed were $S_{Ni}=5.4$, $S_{Ti}=1.1$, and $S_{Zr}=0.87$. The relationship between the surface and bulk Ni/Ti and Ni/Zr atomic ratios is shown in Fig. 8. It is seen that $C^S_{Ni/Ti}$ or $C^S_{Ni/Zr}$ values on the nontreated (amorphous and crystalline) samples are very low and entirely different from their bulk compositions. Thus, electrode surface is almost completely covered with a film of TiO_2 or ZrO_2. This explains why their electrocatalytic activity in the original form was so low that the reversible hydrogen electrode potential was hardly realized.

On the HF-treated alloys, the ratios $C^S_{Ni/Ti}$ and $C^S_{Ni/Zr}$ were found to be much higher than the values of $C^B_{Ni/Ti}$ and $C^B_{Ni/Zr}$ and this was particularly true on the amorphous alloys. It is conceivable that the concentration of Ni on the alloys would be increased by this treatment, above the level of its bulk composition, as hydrofluoric acid readily attacks the metal or oxides of Ti or Zr but not Ni. Further, the sufrace of the HF-treated alloys is very porous with the roughness factor as high as 300, as evaluated above from the

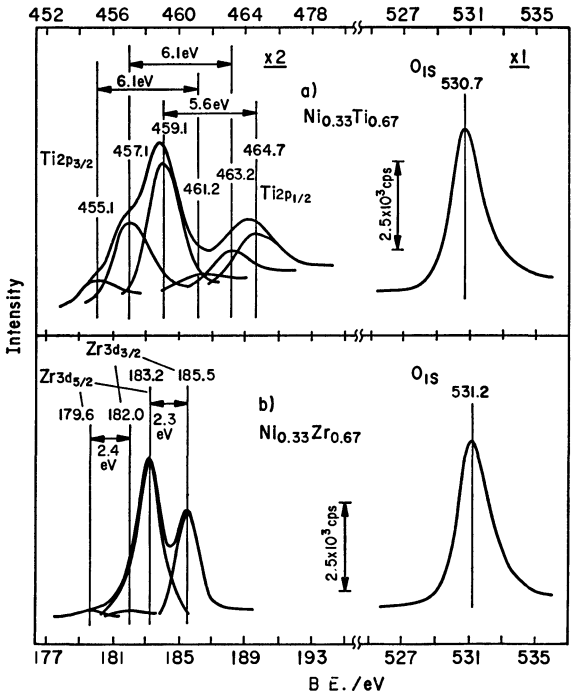

Fig. 7. XPS spectra of the Ti_{2p} or Zr_{3d} and the O_{1s} electrons from the amorphous $Ni_{0.33}Ti_{0.67}$ and $Ni_{0.33}Zr_{0.67}$ alloys (nontreated specimens). The X-ray source employed was Al $K\alpha$ for $Ni_{0.33}Ti_{0.67}$ and Mg $K\alpha$ for $Ni_{0.33}Zr_{0.67}$, respectively. The spectra of Ti_{2p} and Zr_{3d} were deconvoluted using Gaussian curves with reasonable half-band widths.

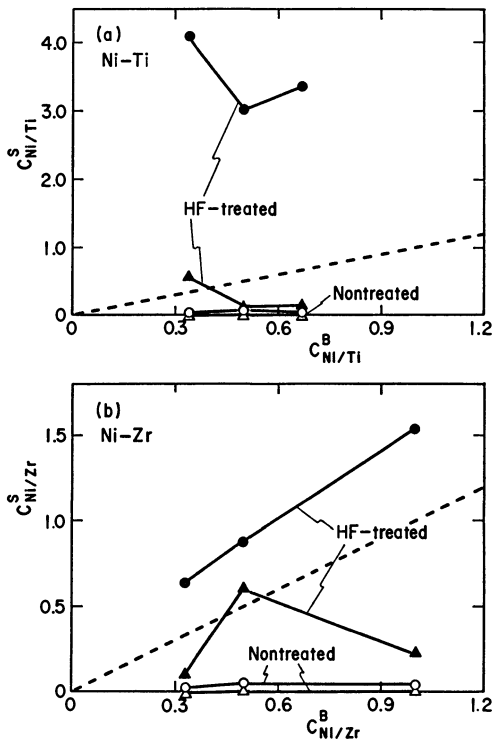

Fig. 8. Relationship between the surface and bulk atomic ratios ($C^S_{Ni/M}$ and $C^B_{Ni/M}$, M=Ti, Zr) of (a) Ni-Ti and (b) Ni-Zr alloys before and after the acid treatments. The dashed line represents a linear relationship of $C^S_{Ni/M}$ and $C^B_{Ni/M}$ when the surface concentration of the alloys is equal to the bulk one. Amorphous, ○ and ●; Crystalline, △ and ▲.

double layer capacitance (see Tables 1 and 2).††† The high electrocatalytic activity observed above is probably caused by the Ni-rich surface layer which is in the form of a Raney-type nickel. Indeed, the electrocatalytic activities per true unit area of the amorphous or cyrstalline Ni–Ti and Ni–Zr alloy electrodes are of the same order of magnitude with those on pure nickel electrodes.

It may be stressed that the amorphous, but not the crystalline, alloys could be readily brought to the state of very high roughness factor and hence of very high electrocatalytic activity by a simple acid treatment.

Conclusion

The amorphous Ni–Ti and Ni–Zr alloys after the treatment with aqueous HF have high electrocatalytic activity for the hydrogen electrode reaction in alkaline solutions. This is caused firstly by the removal of an inert film of TiO_2 of ZrO_2 from the surface, and secondly by producing a porous layer of Ni, which is stable on the amorphous alloys. Since the amorphous alloys in general show a high mechanical strength and high corrosion resistance, they can possibly be employed as water electrolysis cathode materials for hydrogen generation by water electrolysis.

††† The fact that the amorphous $Ni_{0.65}Zr_{0.35}$ alloy do not give an active electrode is likely to be due to a difficulty of removing Zr from the matrix by the acid treatments because of the high Ni content.

Mechanism of Quenching of SO_2 $\tilde{C}(^1B_2)$ by He, Ar, and N_2

Takefumi Oka
Nagaoka Technical College, Nagaoka, Niigata 940

(Received May 23, 1983)

Sulfur dioxide gas was excited to $\tilde{C}(^1B_2)$ state by steady illumination and the total intensity and the spectrum of the fluorescence were measured in the SO_2 pressure range of 0.1—1 Torr (1 Torr≈133.322 Pa) both in the absence and in the presence of He, Ar, and N_2 up to 600 Torr. The observed fluorescence spectrum was broad but the wavelength of the maximum intensity was found to be dependent upon excitation wavelength in the range of 240—220 nm. Addition of foreign gases caused the blue shift of the fluorescence spectrum. The Stern-Volmer plots were nonlinear for quenching by the foreign gases but linear for self-quenching. It was suggested that the foreign gas molecules cause not only vibrational deactivation but also collision induced transition between $^1B_2$ state and a nonemitting state and that the rate constants of the transition to the nonemitting state are larger from higher vibrational levels than from lower ones.

Sulfur dioxide has three absorption systems in the ultra-violet region. The first weak absorption system ($400>\lambda>340$ nm) is due to $\tilde{a}(^3B_1)$ state and plays an important role in photochemistry in the lower atmosphere. The second system ($340>\lambda>250$ nm) consists of a banded structure due to $\tilde{A}(^1A_2)$ state and an underlying continuum due to $\tilde{B}(^1B_1)$ state. The fluorescence from this system shows nonexponential decay, indicating a strong coupling of $\tilde{A}(^1A_2)$ with $\tilde{B}(^1B_1)$. These two systems have been extensively studied.[1-4,13,18] On the other hand, only a few studies have been reported about the third system ($250>\lambda>175$ nm). A group of absorption bands in this system was once classified into two electronic states, α_1 and α_2 by Duchesne and Rosen[5] ($\tilde{C}$ and $\tilde{D}$ in Herzberg's summary[6]). Recently Brand and his co-workers have assigned these bands to one electronic state $^1B_2$ on the basis of the rotational analysis.[7-9]

Okabe examined absorption and fluorescence excitation spectra of this system and suggested the occurrence of predissociation below 220 nm.[10] He estimated quenching rate constant of one of the bands (at 220.6 nm in Fig. 2) by Ar to be 5×10^{-11} cm^3 molecule^{-1} s^{-1} by the intensity reduction on addition of Ar of 400 Torr assuming Stern-Volmer mechanism.

Hui and Rice studied the decay of the ten vibronic bands between 230 and 210 nm and observed simple exponential decay.[11] They measured the lifetimes and quantum yields of the fluorescence. The quantum yield was nearly unity at longer wavelengths, but decreased as wavelength approached to 220 nm and dropped abruptly below 220 nm. This abrupt change supports the occurrence of the predissociation below 220 nm. Observed radiative lifetimes were 30—50 ns while a lifetime calculated from the oscillator strength was 9 ns.

Very recently, quantum beat in the decay of $^1B_2$ due to the coupling with the ground electronic state was observed in a supersonic free jet.[12] As for fluorescence emission spectrum, only a broad spectrum centered at 320 nm was reported.[13,14]

In the present paper, the experimental results of self-quenching and foreign gas quenching will be presented and collision induced coupling of $^1B_2$ state with another state will be suggested.

Experimental

The sample gases were handled in a conventional vacuum line with a mercury diffusion pump. Pressure was measured with a mercury manometer and an oil manometer.

The excitation light beam was obtained with a combination of Ushio 500W Xenon lamp and Ritsu MC-20L monochromator, and passed through a T-shaped fluorescence cell along the principal axis. The geometric size of the cell with three quartz windows is shown in Fig. 1. The outside wall of the cell excluding the windows was painted black. The intensity of the transmitted light was monitored with a photomultiplier (1p28) behind the cell.

The emission was observed through a side window of the cell with an uncooled photomultiplier(HTV R585). The total intensity observed without any optical filters was used for quenching study. The excitation bandpass($\Delta\lambda_{ex}$) was 0.2 nm. The length of the view zone along the principal axis of the cell was about 3 cm (Fig. 1). For the measurements of fluorescence spectra, the second monochromator (JASCO CT-25N) was placed in front of the side window of the cell. The bandpasses used were $\Delta\lambda_{ex}=4$ nm for the excitation monochromator and $\Delta\lambda_{em}=9$ nm for the emission monochromator. The quantum efficiency of R585 was not constant over the range of 250—400 nm.[15] However, the correction for this effect did not affect the foreign gas quenching data.

A photon counter (HTV-C767) was used to count the number of photons emitted. The output of the counter and the 1p28 photomultiplier was fed into a two pen strip chart recorder. The nominal emission intensities were corrected for variation of the intensity of the excitation beam by using the intensity monitored with 1p28.

Sulfur dioxide synthesized from Na_2SO_3 and H_2SO_4 was bubbled through H_2SO_4, dryed over P_2O_5 and distilled *in vacuo* at −80 °C.

Helium, argon, and nitrogen used here were of purity

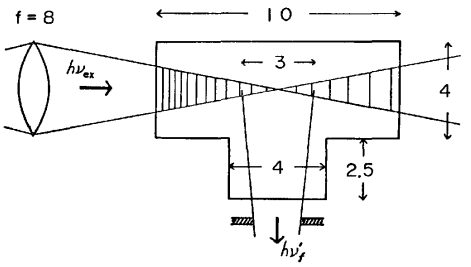

Fig. 1. Fluorescence cell. The unit of length is cm.

higher than 99.99% and passed through a liquid nitrogen trap before use. In the foreign gas quenching study, the cell was first filled with a certain pressure of SO_2 (mostly 0.8 Torr) and then a foreign gas of higher pressure (than 10 Torr) was added. The homogeneity of the mixture was confirmed by comparing the results obtained by this method with those of premixed sample. All the experiments were done at room temperature.

Results

Figure 2 shows the excitation spectrum of 0.9 Torr of SO_2 in the optical range of 240—216 nm. The vibrational assignment indicated in the figure is according to Brand.[6,8]

The bands located at wavelengths shorter than 225 nm could not be expressed by a combination of three normal modes because of the coupling of ν_1' and ν_3'. Quenching experiments were done with the resolved bands shown in Fig. 2. The emission spectra of 0.8 Torr SO_2 excited at various wavelengths are shown in Fig. 3. The emission spectra seemed to have structure[16] but the optical resolution in the present work ($\Delta\lambda_{ex}$=4 nm, $\Delta\lambda_{em}$=9 nm) was not high enough to resolve them. When the exciting light was changed to the longer wavelengths, the spectrum shifted to the blue.

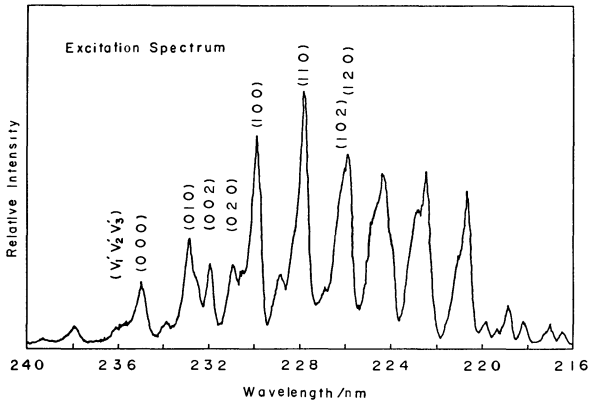

Fig. 2. Fluorescence excitation spectrum of $\tilde{C}^1B_2$ state. $p(SO_2)$=0.9 Torr and $\Delta\lambda_{ex}$=0.2 nm. The three figures in a parenthesis are a set of the vibrational quantum number of $^1B_2$ state, (v_1', v_2', v_3').

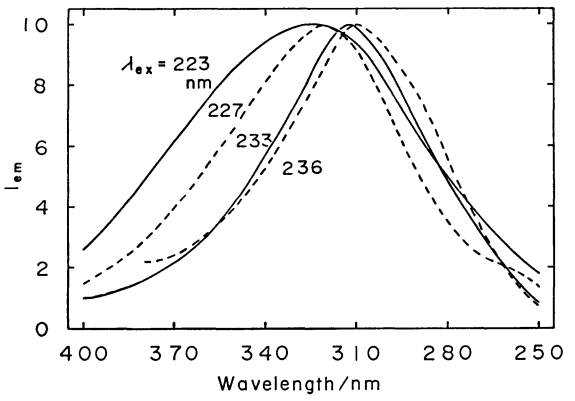

Fig. 3. Emission spectra excited at various wavelengths (λ_{ex}). $p(SO_2)$=0.8 Torr, $\Delta\lambda_{ex}$=4 nm, and $\Delta\lambda_{em}$= 9 nm. Spectra were not corrected for wavelength dependent sensitivity of the detection system.

The change of the emission spectrum due to the variation of SO_2 pressure from 0.1 to 1 Torr was negligibly small compared to that due to the high pressure foreign gas (*vide infra*). Foreign gas quenching of fluorescence excited at each vibronic band is shown in Fig. 4 for He, Fig. 5 for Ar, and Fig. 6 for N_2. The

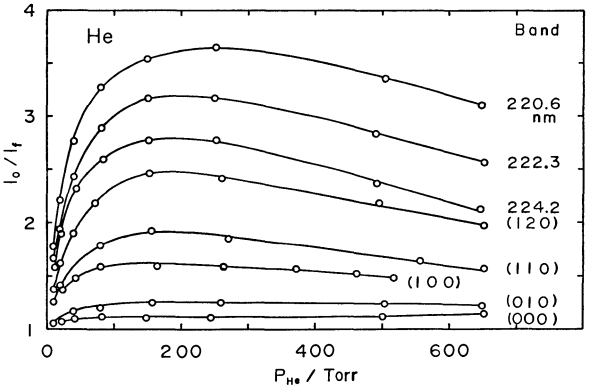

Fig. 4. Fluorescence quenching by He. $\Delta\lambda_{ex}$=0.2 nm and $p(SO_2)$=0.8 Torr. For the upper three curves, the bands are indicated by the wavelengths. I_f and I_0 are the fluorescence intensities with and without He, respectively.

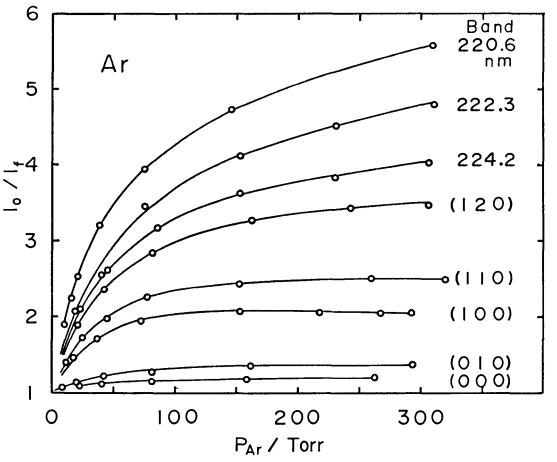

Fig. 5. Fluorescence quenching by Ar. See the legand of Fig. 4.

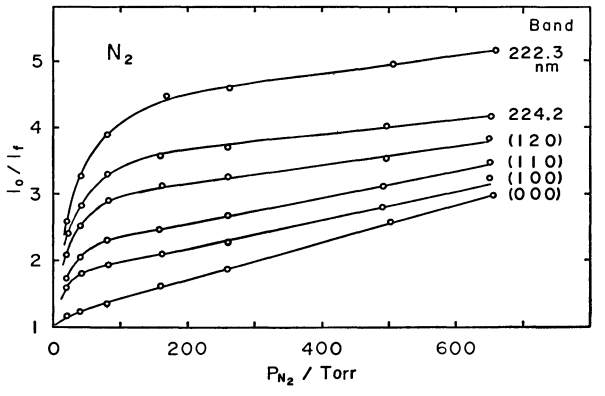

Fig. 6. Fluorescence quenching by N_2. See the legand of Fig. 4.

plots of I_0/I_F vs P_M are nonlinear, indicating that the quenching mechanism is not Stern-Volmer type.

As the foreign gas pressure increased from zero to about 200 Torr, intensity of emission decreased rapidly for all three gases. Above 200 Torr, the emission intensity showed different pressure dependence for the three gases, the intensity gradually increased for He, leveled off for Ar, and gradually decreased for N_2.[17]

The effects of addition of N_2 on the emission spectrum were the blue shift of the wavelength of emission maximum and the narrowing of the emission band width (Figs. 7-a,b).

The wavelength of maximum seems to converge to about 305 nm at the high pressure limit. The extent of the blue shift was large upon the excitation at shorter wavelengths.

The effects of addition of He and Ar on emission spectrum were similar to that of N_2. No difference among the three gases was observed upon the excitation at 233 nm. On the excitation at 223 nm, the efficiency of the effect decreased in the order of N_2, He, and Ar.

The self-quenching results of (110) band are compared in Fig. 8 for the cases in the absence and in the presence of high pressure argon. With Stern-Volmer mechanism, the straight lines with the same intercepts and with different slopes (larger in Ar) are expected. The plots in Fig. 8 show straight lines. However, the slope and the intercept in the presence of Ar are larger than those in the absence of Ar, though the difference in the intercepts is small. When He and N_2 were used in place of Ar, similar results were obtained. Table 1 summarizes the ratios of both the slope and the intercept in the presence of a foreign gas of about 200 Torr to those in the absence of the foreign gas.

Self-quenching was examined for each vibronic band of pure SO_2 in the SO_2 pressure range of 0.1—4 Torr. Self-quenching constants were determined as the ratio of intercept to slope in a plot of the type of Fig. 8 and are listed in the 2nd column of Table 3.

Discussion

Since the emission spectra were different for the excitation at different wavelengths as shown in Fig. 3, it can be said that the emitting species in pure SO_2 of 0.1—1 Torr is not vibrationally thermalized before the emission of fluorescence.

The blue shift of the emission spectra on the addition of the foreign gases can be interpreted as vibrational relaxation because the change of excitation level from higher to lower also caused the blue shift of the emission spectrum (Figs. 3 and 7). Since in the foreign gas quenching (Figs. 4—6) the rapid decrease followed by leveling off of the emission intensity as the foreign gas pressure increases from 0 to about 200 Torr is common to all the three gases, we may assume that

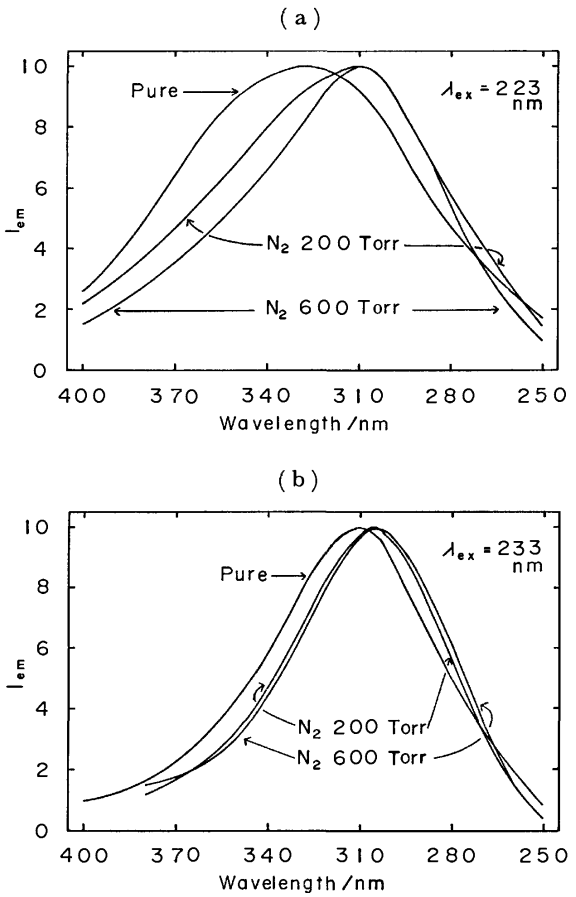

Fig. 7. Effect of addition of N_2 on the emission spectrum. $p(SO_2)$=0.8 Torr, $\Delta\lambda_{ex}$=4 nm, and $\Delta\lambda_{em}$ =9 nm. a) λ_{ex}=223 nm, b) λ_{ex}=233 nm.

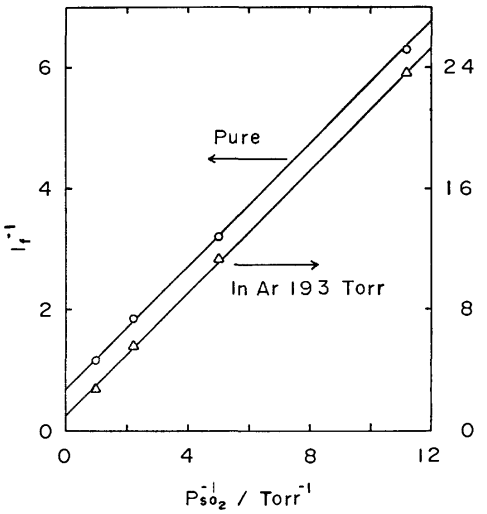

Fig. 8. Effect of Ar on self-quenching of (110) band. $\Delta\lambda_{ex}$=0.2 nm. I_f is corrected for the nonlinarity with respect to $p(SO_2)$.

TABLE 1. EFFECTS OF FOREIGN GASES ON SELF-QUENCHING OF (110) BAND

Foreign gas, M[a]	Intercept ratio[b]	Slope ratio[b]
He	1.1±0.1	2.9±0.1
Ar	1.3±0.1	4.2±0.1
N_2	1.4±0.1	4.1±0.1

a) p(M)=200 Torr and $p(SO_2)$=0.1—1.0 Torr. b) The intercept and the slope are those in the plot of $1/I_f$ *vs.* $1/p(SO_2)$.

this pressure dependence reflects the main structure of the foreign gas quenching mechanism.

Therefore, the mechanism we look for must be able to explain the following three features.

1) Foreign gases cause vibrational relaxation.

2) Fluorescence intensity decreases as foreign gas pressure increases and levels off above 200 Torr.

3) In the self-quenching, the plot of $1/I_f$ against reciprocal of SO_2 pressure is linear, and its slope is much larger in the presence of the foreign gas than in the absence of it while its intercept is only slightly larger in the presence of foreign gas.

First of all, we examine the equations for self- and foreign gas quenching expected with Stern-Volmer mechanism.

$$S + h\nu \xrightarrow{I_a} S^* \ (^1B_2, v'),$$
$$S^* \xrightarrow{k_r} S + h\nu'$$
$$S^* + S \xrightarrow{k_q} \text{self-quenching},$$
$$S^* + M \xrightarrow{k_m} \text{foreign gas quenching},$$

where S and M denote SO_2 and foreign gas molecules, respectively. I_a is the light intensity absorbed by SO_2 molecules at the view zone in the cell and is proportional to both the concentration of SO_2 and the incident light intensity I_l.

$I_a=\alpha I_l[S]$, where α is a proportional constant. Then the fluorescence intensity I_F is

$$I_F = k_r[S^*].$$

This mechanism leads to the equations;

$$I_0/I_f = 1 + \{k_m[M]/(k_r+k_q[S])\}, \quad (1)$$
$$1/I_f = [k_q+\{(k_r+k_m[M])/[S]\}]/(\alpha k_r), \quad (2)$$

where $I_f=I_F/I_l$, the fluorescence intensity relative to the incident light intensity, and I_0 is the value of I_f at $[M]=0$. Equation 2, when plotted I_f^{-1} *vs.* $[S]^{-1}$, gives a straight line with a slope $(k_r+k_m[M])/(\alpha k_r)$ and an intercept of $k_q/(\alpha k_r)$, and can explain the experimental results except for the slight dependence of the observed intercept on [M]. Equation 1 represents a straight line with a slope of $k_m/(k_r+k_q[S])$ in the plot of I_0/I_f *vs.* [M], while the experimental curves in Figs. 4—6 have slopes of decreasing functions of [M]. The vibrational relaxation is neither expected in this mechanism.

In the above mechanism, k_m is supposed to be a constant. However, if we would expect this mechanism to describe the experimental results, the slope, $k_m/(k_r+k_q[S])$, expected from Eq. 1 must be a decreasing function of [M] which approaches to zero at high pressure limit. We may attribute this [M] dependence to k_m. Secondly tested is the mechanism where vibrational relaxation takes place along with quenching processes. Higher vibrational levels are assumed to have larger quenching rate constants (k_m) than lower levels do. If Eq. 1 is applied to this system, the apparent k_m obtained would decrease as [M] increases because of vibrational relaxation. The following processes represent such a model where for simplicity only two levels are assumed.

$$S + h\nu \xrightarrow{I_a} S^*(1),$$
$$S^*(1) \xrightarrow{k_r} S + h\nu',$$
$$S^*(1) + S \xrightarrow{k_q} \text{self-quenching},$$
$$S^*(1) + M \xrightarrow{k_{m1}} \text{quenching}$$
$$\xrightarrow{k_v} S^*(0) + M,$$
$$S^*(0) \xrightarrow{k_r} h\nu' + S,$$
$$S^*(0) + S \xrightarrow{k_q} \text{self-quenching},$$
$$S^*(0) + M \xrightarrow{k_{m0}=0}$$
$$(k_{m1}>k_{m0}=0),$$

where $S^*(1)$ and $S^*(0)$ represent $v'=1$ and $v'=0$ levels of $^1B_2$ state respectively. The value of k_{m0} must be taken as zero otherwise emission intensity would not level off at high pressure of M. This mechanism leads to the Eqs. 1′ and 2′ below.

$$I_0/I_f = 1+\{k_m'[M]/(k_r+k_q[S])\}, \quad (1)'$$
$$k_m' = k_{m1}(k_r+k_q[S])/(k_r+k_q[S]+k_v[M]),$$

and when $k_q[S] \ll k_r+k_v[M]$,

$$1/I_f = [k_q\{1+k_{m1}k_v[M]^2/(k_r+k_v[M])^2\} +$$
$$k_r\{1+k_{m1}[M]/(k_r+k_v[M])\}/[S]]/(\alpha k_r). \quad (2)'.$$

This mechanism explains the first and second features but cannot explain the third feature because Eq. 2′ requires the slope and intercept in self-quenching increase by the same factor of $1+(k_{m1}/k_v)$ on addition of sufficiently high pressure of M. The origin of the failure of this mechanism is zero value of k_m at the lowest level. For the mechanism to be able to explain the third feature, k_m must be nonzero and et be a decreasing function of [M].

Then we hope to realize this situation by adding a back reaction of quenching process to the Stern-Volmer mechanism as follows;

$$S + h\nu \xrightarrow{I_a} S^*(^1B_2),$$
$$S^* \xrightarrow{k_r} S + h\nu',$$
$$S^* + S \xrightarrow{k_q} \text{self-quenching},$$
$$S^* + M \underset{k_m'}{\overset{k_m}{\rightleftarrows}} S^{**} + M,$$
$$S^{**} \xrightarrow{k_n'} \text{nonradiative decay},$$
$$S^{**} + S \xrightarrow{k_q'} \text{self-quenching},$$

where S^{**} denotes another electronic state. Again this mechanism does not contain electronic quenching processes of S^* and S^{**} to explain the leveling off of emission intensity at high pressures of M. This mechanism leads to the following equations 3 and 4.

$$I_0/I_f = 1 + [M]/(A+B[M]), \quad (3)$$

where

$$A = (k_r+k_q[S])/k_m \quad \text{and}$$
$$B = k_m'(k_r+k_q[S])/\{k_m(k_n'+k_q'[S])\},$$
$$1/I_f = \{k_q+(k_r+C[M])/[S]\}/(\alpha k_r), \quad (4)$$

where

$$C = k_m(k_n' + k_q'[S])/(k_n' + k_q'[S] + k_m'[M]).$$

Equation 4 can be approximated by Eq. 4', when

$$k_q'[S] \ll k_n' + k_m'[M], \quad (5)$$

$$1/I_f = [\{k_q + k_q'k_mk_m'[M]^2/(k_n' + k_m'[M])^2\} + \{k_r + k_mk_n'[M]/(k_n' + k_m'[M])\}/[S]]/(\alpha k_r). \quad (4)'$$

Equations 3 and 4' can explain the experimental results well. Fitting these equations to the experimental results, the quantities on the left-hand sides of the following equations can be experimentally determined.

$$k_m = (k_r + k_q[S])/A, \quad (6)$$

$$(k_n' + k_q'[S])/k_m' = A/B, \quad (7)$$

$$k_n'/k_m' = [M][k_m[M]/\{k_r(IR-1)\} - 1]^{-1}, \quad (8)$$

$$k_q'/k_m' = k_mk_q[M]^2(SR-1)/\{k_m[M] - k_r(IR-1)\}^2, \quad (9)$$

where IR and SR are respectively the ratios of the intercept and the slope of the self-quenching in the presence of foreign gas of [M] to those in the absence of it. It should be noted that the quantity of $(k_n' + k_q'[S])/k_m'$ can be obtained by the two independent ways, one with Eq. 7 and the other with a combination of Eqs. 8 and 9. The results of application of these equations to the data of (110) band are compared for the three gases in Table 2. It can be seen that the condition (5) is met and that Eqs. 7—9 are self-consistent. The results of application of Eqs. 6 and 7 to other levels are summarized in Table 3. It seems that k_m is smaller than k_q by an order and is an increasing function of vibrational energy.

Finally, by adding vibrational relaxation to the above mechanism, we have a mechanism that can explain all the three features. In this case, the quantities k_m and $(k_n' + k_q'[S])/k_m'$ in Table 3 must be interpreted as some sort of weighted averages over several levels.

In quenching by N_2, additional weak electronic quenching of S* and/or S** must be operating because continuous decrease of I_f was observed above 200 Torr as seen in Fig. 6. The recovery of I_f at high pressures observed in quenching by He (Fig. 4) cannot be explained by the proposed mechanism. The comparison of the quenching rate constant by Ar reported by Okabe with the k_m value of the present work is meaningless because Okabe's value was calculated with I_0/I_f at 400 Torr of Ar assuming Stern-Volmer mechanism. However, I_0/I_f values themselves in the two works coincide with each other within an experimental error.

Since the quantum beat in the fluorescence decay of $\tilde{C}(^1B_2)$ state due to the weak vibronic coupling of the state to the ground electronic state $\tilde{X}(^1A_1)$ has been observed,[12] the nonemitting state S** invoked in the proposed mechanism might be the ground state. To identify S** state, kinetic studies of $SO_2(^1B_2)$ in the presence of foreign gas are needed.

Table 2. The results of application of the proposed mechanism to (110) band

Gas M	k_m	$(k_n' + k_q'[S])/k_m'$	k_n'/k_m'	$k_q'[S]/k_m'$
	10^{-10} cm^3 molecule^{-1} s^{-1}	10^{18} molecule cm^{-3}		
He	0.67	1.0	1.0	0.06
Ar	0.91	1.4	1.3	0.16
N_2	1.3	0.91	0.86	0.14

$k_r = 3.1 \times 10^7$ s^{-1} from Ref. 11. $k_q = 1.25 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1} calcd from Q in Table 3.

The author wishes to thank Professors Shin Sato and Shigeru Tsunashima of Tokyo Institute of Technology and Dr. Shigeyoshi Arai of the Institute of Physical and Chemical Research for helpful discussions and encouragements.

†*Institute of Inorganic and Analytical Chemistry, University of Innsbruck, Innrain 52a, A-6020 Innsbruck, Austria*

(Received July 16, 1983)

The structure of *N,N*-dimethylformamide (DMF) was determined at 25 °C by means of X-ray diffraction using a θ-θ type X-ray diffractometer. The least-squares analysis of the reduced intensities results that a DMF molecule has a practically planar skeletal structure in the liquid state. Intramolecular structural parameters within a DMF molecule were determined as follows: C=O; 1.24 Å, N-C(CHO); 1.35 Å, and N-C(CH_3); 1.45 Å. The bond lengths are not appreciably different from those found in the gas phase, except for the C=O length, which is slightly longer by 0.04 Å in the liquid state than in the gaseous one. The radial distribution curve of DMF shows that the intermolecular arrangement of DMF molecules is practically fully disordered and no evidence has been found for the cluster formation of DMF molecules in the liquid state. The experimental result for the weak intermolecular interactions between DMF molecules is supported by *ab initio* MO-SCF calculations.

Structural studies of liquid amides have drawn considerable attentions of physical chemists and biochemists in connection with the conformation of amide moieties in polypeptides.[1-3] The structure of formamide has been extensively investigated in the liquid state,[4-9] as well as in the gaseous[10] and solid[11,12] phases. Theoretical considerations have also been carried out for the structure of formamide.[13,14] The molecular structure of *N,N*-dimethylformamide (DMF) has been determined in the gas phase by electron diffraction[15] and microwave[16] methods and they concluded that all atoms except hydrogen atoms at the methyl groups lay on one plane. The structure of DMF in the solid state has been studied for crystalline solvates,[17-19] but no crystal structure has been determined for pure DMF. Theoretical treatments for the molecular structure of DMF have also been done by some authors[2,20] for the electron distribution on the atoms within the DMF molecule. However, intermolecular interactions between DMF molecules have not been taken into the theoretical consideration.

Raman and infrared spectra of liquid DMF have been recorded by Fini and Mirone,[21] from which they concluded that DMF molecules formed clusters oriented in a partially ordered way. However, the cluster formation has not been conclusive from NMR measurements.[22-26] No X-ray study has been carried out so far for the structure of liquid DMF.

Since X-ray diffraction measurements can provide direct information for ordered structures of liquids, we aimed at investigating the liquid structure of DMF and comparing it with the structure of formamide examined in a previous work.[9]

Experimental

Reagents. Commercially available *N,N*-dimethylformamide of analytical grade was dried with Molecular Sieves (4A) and then distilled under a reduced pressure.

Method of Measurements and Analysis of Scattering Data. A sample solution was placed in a flat glass tray of 38 mm depth. X-Ray scattering measurements were carried out at (25±2) °C in a thermostatted room by using a JEOL θ-θ diffractometer with a bent LiF monochromator. Mo $K\alpha$ radiation (λ=0.7107 Å) was used. The scattered intensities were collected at discrete points over the s-range from 0.6 $Å^{-1}$ to 16.4 $Å^{-1}$ ($s=4\pi\lambda^{-1}\sin\theta$, where 2θ is the scattering angle). Details of the method of measurements have been described elsewhere.[27]

Experimental intensity data were corrected for background, absorption, double scattering, polarization and incoherent scatterings by the usual methods and then normalized to the absolute scale with respect to a stoichiometric unit volume V containing one DMF molecule.

The radial distribution curve was calculated by using a Fourier transform

$$D(r) = 4\pi r^2\rho_0 + 2r\pi^{-1}\int_{s_{min}}^{s_{max}} s\cdot i(s)\cdot M(s)\cdot\sin(sr)\mathrm{d}s, \quad (1)$$

were ρ_0 denotes the average scattering density, $M(s)$ a modification function of the form $[\sum n_i\{(f_i(0)+\Delta f_i')^2+(\Delta f_i'')^2\}/\sum n_i\{(f_i(s)+\Delta f_i')^2+(\Delta f_i'')^2\}]\cdot\exp(-0.01s^2)$. The s_{min} and s_{max} values are 0.6 $Å^{-1}$ and 16.4 $Å^{-1}$, respectively. The reduced intensities $i(s)$ were given as follows:

$$i(s) = I(s)_{obsd} - \sum n_i\{(f_i(s)+\Delta f_i')^2+(\Delta f_i'')^2\}, \quad (2)$$

and n_i is the number of atom i in the stoichiometric volume and $f_i(s)$ denotes the scattering factor of atom i at s. $\Delta f_i'$ and $\Delta f_i''$ are the real and imaginary parts of anomalous dispersion of atom i, respectively.

Theoretical reduced intensities were calculated by Eq. 3:

$$\begin{aligned} i(s) = \sum n_j[\sum n_{pq}\{(f_p(s)+\Delta f_p')(f_q(s)+\Delta f_q') \\ +\Delta f_p''\Delta f_q''\}\cdot\frac{\sin(sr_{pq})}{(sr_{pq})}\cdot\exp(-b_{pq}s^2)] \\ -\frac{4\pi R_j^3}{3V}\cdot\frac{3\{\sin(sR_j)-sR_j\cos(sR_j)\}}{(sR_j)^3} \\ \cdot\exp(-B_js^2)\cdot\{\sum n_i(f_i(s)+\Delta f_i')\sum n_j\cdot \\ (f_j(s)+\Delta f_j')+\sum n_i\Delta f_i''\sum n_j\Delta f_j''\}, \end{aligned} \quad (3)$$

where r_{pq}, b_{pq}, and n_{pq} stand for the distance, the temperature factor, and the frequency factor of the p-q atom-pair, respectively. R_j denotes the distance from an atom j beyond which a continuous electron distribution is assumed. A parameter B_j is introduced since the emergence of such a

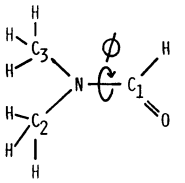

Fig. 1. The structure of DMF molecule.

continuous electron distribution around atom j is not sharp. Intramolecular interactions of all possible atom-pairs of DMF were calculated by using the first term of Eq. 3, while interactions between different molecules were approximated by using the second term of Eq. 3 on the assumption of the continuous electron distribution beyond the R_j values of each atom in one molecule. The R_j values were selected in order to obtain the best fit $s \cdot i(s)$ curve to the experimental one and assumed to be 2.50 Å for H and N atoms and 3.30 Å for O and C atoms by taking into consideration the interatomic distances found in the present work as will be shown later. The B_j values were set to be 0.05 Å^2 for all the atoms. The C–H bond length within a DMF molecule was fixed at 1.09 Å. The calculations were performed by using the KURVLR program.[28]

Distances of atom-pairs in the system were first assumed to be the same as those with the literature values reported from the electron diffraction measurement in the gas phase,[15] and then the structural parameters of the atom-pairs were refined by the least-squares method applied to the reduced intensities so as to minimize the error-square sum $U=\sum w\{i(s)-i(s)_{calcd}\}^2$, where the weighting function $w=I(s)_{obsd}^{-2}\cdot\cos\theta$. The NLPLSQ program was used for the calculations.[29]

For the sake of convenience of the discussion in the following section, we numbered the carbon atoms within a DMF molecule (Fig. 1).

Results and Discussion

The $s \cdot i(s)$ and radial distribution $(D(r)-4\pi r^2\rho_0)$ curves are shown in Figs. 2 and 3, respectively. The radial distribution curve of formamide is also shown in Fig. 3 for comparison.

Two distinct peaks are observed at 1.3 and 2.3 Å in the radial distribution curve of DMF (Fig. 3a). The former peak contains peaks due to the N–C_1, N–C_2, N–C_3, and C_1=O bonds within each DMF molecule, and the latter can be ascribed to the $C_1\cdots C_2$, $C_1\cdots C_3$, $C_2\cdots C_3$, and N···O nonbonding interactions. No significant peak is found in the range $r>3$ Å in the radial distribution curve of DMF, in contrast to that of formamide (see Fig. 3b).

NMR studies showed that a DMF molecule can rotate along the N–C_1 axis, although the free energy of activation of the rotation of the molecule is rather large (88 kJ mol^{-1}).[30] Therefore, we first attempted to postulate two possibilities of configuration of a DMF molecule; *i.e.*, a planar ($\phi=0°$) and a perpendicular ($\phi=90°$) structures (see Fig. 1). For the both model-structures we employed the least-squares calculation for the reduced intensities over the s-range from 3.5 Å^{-1} to 16 Å^{-1} in order to find structural parameters which can best reproduce the experimental $s \cdot i(s)$ values. In the course of the calculations we assumed a tetrahedral structure of the methyl groups within a DMF molecule and the C–H bond length to be 1.09 Å. The results obtained from the two models are compared with the experimental values in Fig. 2, and it is obvious that the planar model gives a much better fit to the experimental curve than the perpendicular one does. Moreover, when we introduced interatomic distances calculated from models at $\phi=30°$ and 60° as the initial values and allowed them to be optimized without fixing the rotation angle, the distances converged to the values resulted from the least-squares analysis at $\phi=0°$. Therefore, we concluded that the structure of a DMF molecule is practically planar. The final values of the bond distances thus obtained are listed in Table 1, together with the values found in the gaseous and solid states. The bond angles were estimated as follows: $\angle$N–C_1–O; (121±3)°, $\angle C_1$–N–$C_2=\angle C_1$–N–C_3; (116±4)°, and $\angle C_2$–N–C_3; (124±5)°.

The intramolecular bond distances of each atom-pair in DMF found in the liquid state are well consistent with those in the gas phase[15] except for the

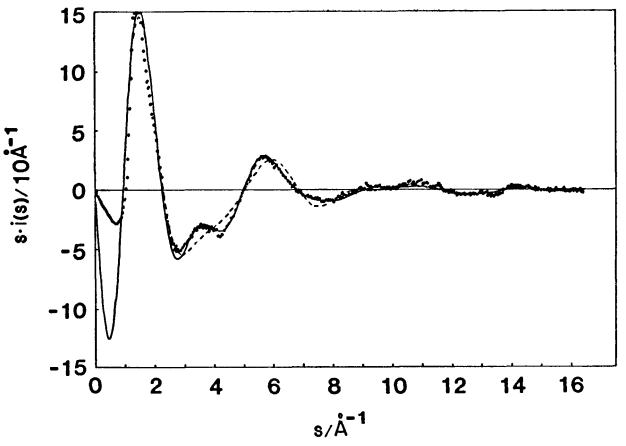

Fig. 2. The $s \cdot i(s)$ values of liquid DMF. Circles represent the $s \cdot i(s)$ values experimentally obtained. The solid line shows the theoretical $s \cdot i(s)$ values at $\phi=0°$ including those for interactions between atoms and electrons continuously distributed in the region of $r>R_j$. The dashed line shows the theoretical values at $\phi=90°$.

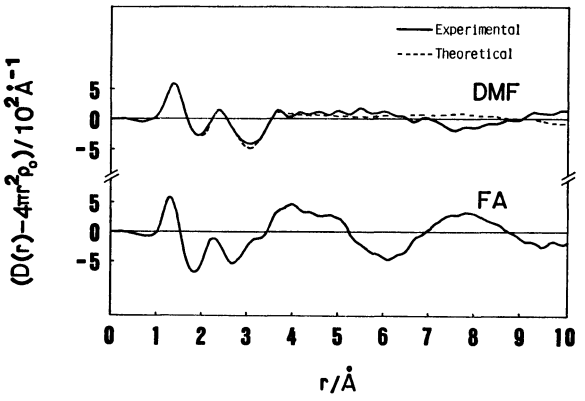

Fig. 3. Radial distribution curves $D(r)-4\pi r^2\rho_0$. (a) DMF. The solid and dashed lines represent experimental and theoretical curves, respectively. (b) Formamide.

TABLE 1. THE INTRAMOLECULAR DISTANCES (r) AND THE TEMPERATURE FACTORS (b) OF ATOM-PAIRS IN LIQUID DMF. THE VALUES IN PARENTHESES ARE THEIR STANDARD DEVIATIONS ESTIMATED (3σ). THE BOND LENGTHS WITHIN A DMF MOLECULE DETERMINED IN THE GAS PHASE AND IN A CRYSTALLINE SOLVATE ARE ALSO SHOWN

Atom-pair	Gas[15]	Liquid		Crystalline solvate[18]
	r/Å	r/Å	b/Å^2	r/Å
C_1=O	1.20	1.24(1)	0.003(1)	1.30
N-C_1	1.34	1.35(2)	0.002(1)	1.28
N-C_2	1.45	1.45(1)	0.004(1)	1.51
N-C_3	1.45	1.45(1)	0.004(1)	1.50

C=O bond length, which is slightly longer by 0.04 Å in the liquid state than in the gaseous one. The result may indicate a weak hydrogen-bonded interaction between DMF molecules. However, there are some discrepancies in the bond distances between in the liquid state and in a crystalline solvate,[18] probably because of strong ion-DMF interactions in the crystalline solvate compared with intermolecular interactions of DMF themselves in the liquid state.

In the radial distribution curve of DMF we do not find appreciable peaks in the range $r>3$ Å, in which we see still peaks due to intermolecular interactions of formamide molecules (Fig. 3). If we assumed a continuous electron distribution beyond R_j from each atom j within a DMF molecule, the reduced intensities calculated from Eq. 3 gave values which fitted satisfactorily with the experimental ones over the wide s-range of 1 Å^{-1} to 16 Å^{-1} (see solid line in Fig. 2). The radial distribution curve showed no distinct peak beyond $r=3$ Å, which indicated a practically random distribution of molecules in the system. Therefore, the result indicated that no significant interactions existed between molecules through, for instance, hydrogen bonds and thus the cluster formation of DMF molecules was not observed from the present X-ray diffraction work.

However, it is obvious that DMF molecules interact with each other to form a condensed phase at a room temperature. Therefore, we estimated the interaction energy between DMF molecules with the aid of the *ab initio* MO-SCF method by using some suitable structure models and minimal basis sets. The geometry of the DMF molecules was fixed at the experimental one obtained by the present work, and the distance between DMF molecules and the configuration of DMF associates were varied. The calculations were performed in a similar way as described previously.[9]

The dimer model used for the calculation is shown in Fig 4. At $\Theta=\Theta'=180°$, the dimer at $\Psi=0°$ was more stable by *ca.* 8.4 kJ mol^{-1} than that at $\Psi=180°$ when the intermolecular C-H···O distance was 3.2 Å. In the latter configuration the lowest energy of interaction was found at $\Theta=180°$ and $\Theta'=90°$ at $r_{C-H\cdots O}=$ 3.2 Å. At $\Theta'=120°$ a slightly higher energy of stabilization was estimated for the dimer, but the difference was too small (*ca.* 1 kJ mol^{-1}) to be significant.

The rotation barrier of the DMF dimer around the

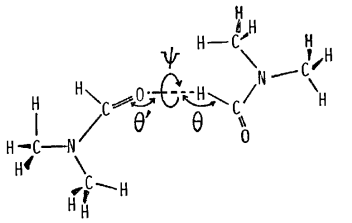

Fig. 4. The dimer model of DMF.

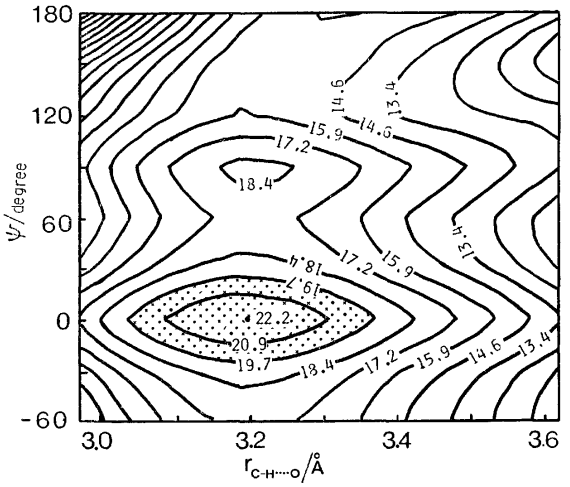

Fig. 5. The energy surface for the linear-dimer of DMF plotted against the C-H···O distance ($r_{C-H\cdots O}$) between molecules and the rotation angle Ψ around the C-H···O axis. The numbers indicated in the diagram show the stabilization energy of the dimer ($-\Delta E$) in kJ mol^{-1} units.

C-H···O axis at $\Theta=\Theta'=180°$ was calculated at various C-H···O distances. The energy surface diagram is plotted for varying bond distance $r_{C-H\cdots O}$ and rotation angle Ψ in Fig. 5. The numbers indicated in the diagram show stabilization energies of dimerization of DMF molecules ($-\Delta E$) in kJ mol^{-1} units. It is seen from the diagram that the configuration is most stable at $r_{C-H\cdots O}=3.2$ Å and $\Psi=0°$, but the curvature is so small that the bond distance and the rotation angle can change over the range ±0.15 Å and $\pm30°$, respectively, by the thermal energy (kT) at $T=300$ K. The crosshatched area in Fig. 5 indicates the region where the variation of the energy is smaller than the kT value at room temperature. The maximum stabilization energy of dimerization was estimated to be -22.2 kJ mol^{-1} (see Fig. 5), which is much smaller than the energies of hydrogen bonds of water molecules (-30 to -40 kJ mol^{-1}) and of formamide (-68 kJ mol^{-1}[19]). The ring-dimer structure of DMF was much less stable than the linear dimer examined above.

A chain-trimer connected by the C-H···O hydrogen bonds of DMF molecules had a similar stabilization energy (-23 kJ mol^{-1}) per bond as the linear dimer, and thus, no special stabilization is to be expected by the formation of oligomers. The vibrational amplitude of the C-H···O bond at room temperature was estimated to be about 0.23 Å from the surface of the stabilization energy of the trimer and the kT value. The amplitude of the trimer is practically the

same as that of the dimer (0.15 Å). Since the vibrational amplitude of DMF associates is fairly large, we may not expect to detect the associated species as discrete units in the liquid DMF. This conclusion is consistent with that obtained by the X-ray diffraction measurement demonstrated in the present study.

The present work has been financially supported by the Grant-in-Aid for Scientific Research (No. 57470054) from the Ministry of Education, Science and Culture. The Asahi Glass Foundation for Industrial Technology also financially supports the present work. The financial support by the Austrian Federal Ministry for Science and Research (Erl. Zl. 18.854/6—10/81) is also gratefully acknowledged.

Microwave Spectroscopy of Boron Chloride (BCl). The Chlorine Nuclear Quadrupole Coupling Constant

Yasuki Endo, Shuji Saito, and Eizi Hirota*
Institute for Molecular Science, Okazaki 444
(Received July 28, 1983)

The pure rotational spectrum of an unstable diatomic molecule, boron chloride (BCl), has been observed in the millimeter wave region. The BCl molecule was directly generated in a 3.7-m long free space absorption cell by a d.c. glow discharge in BCl_3. Rotational transitions of $^{11}B^{35}Cl$ and $^{11}B^{37}Cl$ in the ground vibrational state, which are split into a few components by the nuclear electric quadrupole interactions, have been observed and analyzed to yield molecular constants including the chlorine nuclear quadrupole coupling constant with high accuracy. The eQq constant thus determined is discussed along with those of other diatomic chlorides, to obtain information on the electronic structure of the molecules.

The chlorine nuclear quadrupole coupling constant [eQq(Cl)] has been determined in a number of molecules in the gas phase by means of microwave spectroscopy, and its significance for the electronic structure of the molecules has been explored in detail.[1] Thanks to recent developments in microwave spectroscopic techniques, several unstable molecules containing a chlorine nucleus have also been investigated; OCl,[2,3] CCl,[4] ClBO,[5] and NCl[6] are such examples. A diatomic molecule consisting of a second row element and a chlorine atom has the electron configuration in the ground state expressed as $KKL(5\sigma)^2(6\sigma)^2(2\pi)^4(7\sigma)^2(3\pi)^n$, where $n=1,2,3$, and 4 apply to CCl, NCl, OCl, and FCl.[7] As has been shown previously,[6] the eQq(Cl) constants of the molecules with $n=1$—4 fall on a smooth curve when they are plotted against n, the number of electrons in the 3π (HOMO) orbital, provided that the observed values of eQq for CCl, NCl, and OCl were corrected for π-electron back donation, as estimated from the magnetic hyperfine coupling constants. It is interesting to see whether the eQq(Cl) constant of BCl conforms with the prediction from those of other molecules; BCl is the first member with $n=0$ of this series.

The ground-state rotational and vibrational constants of BCl were first obtained by Herzberg and Hushley[8] from the analysis of the observed ultraviolet spectrum. Maki *et al.*[9] have recently observed vibration-rotation spectra of BCl by infrared diode laser spectroscopy in the 12-μm region. They generated BCl in the optical path by means of either a dc glow discharge or a 2450 MHz microwave discharge in BCl_3. They improved the accuracy of the ground-state constants over that of the previous study, but were unable to resolve the hyperfine structure. They have attempted to observe the pure rotational spectrum at around 80 GHz with a Stark-modulated microwave spectrometer without success.[9]

The present paper reports the observation of the rotational transitions of BCl and precise ground-state constants including eQq(Cl) obtained therefrom.

Experimental

The microwave spectrometer employed in the present study is a source modulation spectrometer with a free space absorption cell of 3.7-m length sealed with Teflon lenses at both ends.[10] The BCl molecule was generated directly in the cell by a dc glow discharge in BCl_3; BCl_3 was pumped continuously through the cell by a mechanical booster pump of 67 l s^{-1}. The optimum pressure for BCl_3 in the cell was about 20 mTorr (2.7 Pa) as measured by an uncalibrated Pirani gauge. The dc discharge current of 100 mA was required to obtain the S/N ratio sufficient for the measurement. We have also attempted to observe BCl lines using a 1-m long cell, where BCl was generated by a microwave discharge in BCl_3 in a side arm used as the inlet; the discharge products were rapidly pumped through the cell. Although the sample pressure (5 to 30 mTorr or 0.7 to 4.0 Pa) and the discharge current were carefully adjusted, we were unable to observe the BCl spectrum by this arrangement. This result indicates that BCl is short-lived and exists only in and near the discharged region.

Using the molecular constants of Maki *et al.*,[9] the frequency of the $J=4\leftarrow3$ transition of $^{11}B^{35}Cl$ was calculated to be about 163.3 GHz, and searching for this species was initiated in this region. A fairly strong absorption line with resolved hyperfine structure was observed at 13 MHz higher than that predicted for $J=4\leftarrow3$; its trace is shown in Fig. 1. It vanished immediately when the discharge was turned off, and was thus ascribed to a species of short life. Both the observed hyperfine structure and the short lifetime of the species indicated that the observed line is due to BCl. This assignment was confirmed by observing the corresponding transition of $^{11}B^{37}Cl$ and also the next lowest transition, $J=3\leftarrow2$. The $J=2\leftarrow1$ transition was found to be complicated because of additional splittings due to the ^{11}B nuclear quadrupole interaction, as exemplified by the trace shown in Fig. 2 (see also Table 1). The lowest $J=1\leftarrow0$ transition was also observed, but was too weak to measure the hyperfine components accurately.

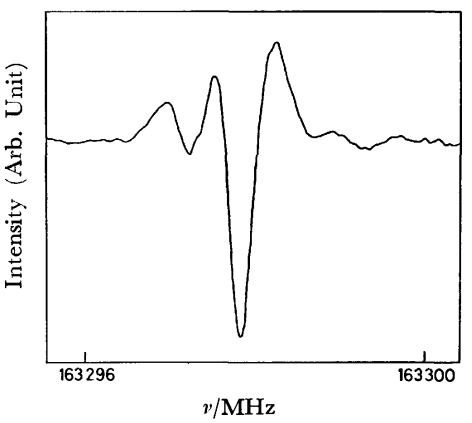

Fig. 1. The $J=4\leftarrow3$ transition of $^{11}B^{35}Cl$.

a) The weight for unresolved components is taken to be proportional to the square of the calculated relative intensity.

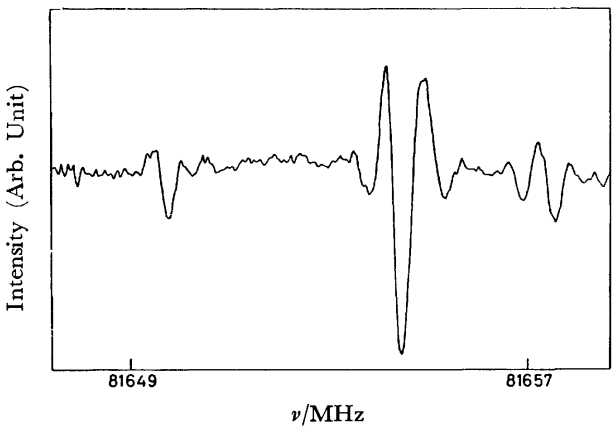

Fig. 2. The $J=2\leftarrow1$ transition of $^{11}B^{35}Cl$. The spectrum was synthesized from a few consecutive scans, each covering a region of 4 MHz.

The observed frequencies are listed in Table 1 with the assignment; each frequency was determined by taking the average of three up-sweep and three down-sweep measurements. A smaller number of lines were observed for $^{11}B^{37}Cl$ than for $^{11}B^{35}Cl$, because of poorer S/N ratio. The frequencies observed for $^{11}B^{37}Cl$ are given in Table 2. The standard deviation of the frequency measurement is less than 20 kHz except for a few weak lines.

Analysis of the Observed Spectrum

Because both nuclei in the BCl molecule show the quadrupole coupling interaction, a coupling scheme of the angular momenta, $\mathbf{F}_1=\mathbf{J}+\mathbf{I}(\mathrm{Cl})$ and $\mathbf{F}=\mathbf{F}_1+\mathbf{I}(^{11}\mathrm{B})$, was employed to analyze the hyperfine structure, where $\mathbf{J}$, $\mathbf{I}(\mathrm{Cl})$, and $\mathbf{I}(^{11}\mathrm{B})$ denote the rotational, Cl nuclear spin, and ^{11}B nuclear spin angular momenta, respectively; both $I(^{35,37}\mathrm{Cl})$ and $I(^{11}\mathrm{B})$ are 3/2. The $\Delta J=0$ matrix elements for the quadrupole coupling Hamiltonians, $\mathbf{H}_Q(\mathrm{Cl})$ and $\mathbf{H}_Q(\mathrm{B})$, are given by

$$\begin{aligned}&\langle I(\mathrm{Cl})JF_1'I(\mathrm{B})F'M_{F'}|\mathbf{H}_Q(\mathrm{Cl})|I(\mathrm{Cl})JF_1I(\mathrm{B})FM_F\rangle\\&=-\frac{1}{8}\delta_{F_1'F_1}\delta_{F'F}\delta_{M_{F'}M_F}\\&\times\frac{3C(C-1)-4J(J+1)I(\mathrm{Cl})[I(\mathrm{Cl})+1]}{(2J-1)(2J+3)I(\mathrm{Cl})[2I(\mathrm{Cl})-1]}eQq(\mathrm{Cl}),\end{aligned}\tag{1}$$

and

$$\begin{aligned}&\langle I(\mathrm{Cl})JF_1'I(\mathrm{B})F'M_{F'}|\mathbf{H}_Q(\mathrm{B})|I(\mathrm{Cl})JF_1I(\mathrm{B})FM_F\rangle\\&=-\delta_{F'F}\delta_{M_{F'}M_F}(-1)^{J+I(\mathrm{Cl})+F_1}[(2F_1+1)(2F_1'+1)]^{1/2}\\&\times\begin{Bmatrix}J & F_1 & I(\mathrm{Cl})\\ F_1' & J & 2\end{Bmatrix}(-1)^{I(\mathrm{B})+F_1+F}\\&\times\begin{Bmatrix}I(\mathrm{B}) & F_1 & F\\ F_1' & I(\mathrm{B}) & 2\end{Bmatrix}\left[\frac{J(J+1)(2J+1)}{(2J-1)(2J+3)}\right]^{1/2}\\&\times\left[\frac{[I(\mathrm{B})+1][2I(\mathrm{B})+1][2I(\mathrm{B})+3]}{I(\mathrm{B})[2I(\mathrm{B})-1]}\right]^{1/2}eQq(\mathrm{B})/4,\end{aligned}\tag{2}$$

where $C=J(J+1)+I(\mathrm{Cl})[I(\mathrm{Cl})+1]-F_1(F_1+1)$ and δ_{ij} and $\{\cdots\}$ denote Kronecker's delta and the Wigner 6j symbol, respectively. The matrix elements off-diagonal in J were ignored, since their contributions

were found to be small. All other $\Delta J=0$ matrix elements off-diagonal in F_1 were taken into consideration. The Hamiltonian matrix was then factorized into blocks of 4×4 dimension or smaller, and was numerically diagonalized in carrying out the least-squares analysis.

The observed frequencies of $^{11}B^{35}Cl$ were thus analyzed taking B_0, D_0, and $eQq(^{35}Cl)$ as adjustable parameters, while $eQq(^{11}B)$ was determined separately by simulation; the calculated spectrum was obtained by assuming a Lorentzian line shape with the line width and modulation width of 0.25 and 0.2 MHz, respectively. For $^{11}B^{37}Cl$ only B_0 and D_0 were determined since the number of the observed lines was small, while $eQq(^{37}Cl)$ was fixed to $eQq(^{35}Cl)$ multiplied by the ratio of the nuclear quadrupole moments for ^{37}Cl and ^{35}Cl (1/1.26878). The frequencies of unresolved hyperfine components were calculated by weighting each component in proportion to the square of the normalized relative intensity. The molecular constants thus determined are listed in Table 3, where B_0 and D_0 calculated from the Dunham coefficients reported by Maki *et al.*[9] are also included for comparison.

Discussion

The eQq(Cl) constants obtained for the XCl type molecules are given in Table 4, where X=B, C, N, O, and F. The same Table also includes the values for CCl, NCl, and OCl that are obtained by correcting for the effect of π-electron delocalization estimated using the observed magnetic hyperfine coupling constants. Figure 3 plots the observed and corrected eQq values, indicated by open circles and solid circles, respectively, against the electronegativity difference. As is seen, the corrected values fall on a curve which is slightly shifted from that calculated by a formula proposed by Gordy and Cook.[1] The observed eQq(Cl) value of BCl also fits well with the curve; in order to obtain a better fit, only 0.12 π-electrons are necessary to be transferred from Cl to B, in other words, the 2π molecular orbital is required to involve the B $2p_\pi$ orbital by 3%. The fairly small eQq constant of BCl is thus primarily ascribed to the large ionic character of the B-Cl bond; the ionic character is estimated to be 79—85% using the relation $i_C=1+eQq/eQq_{310}$,[1] where eQq_{310} denotes the value for an atomic p electron in the 3p orbital.

Table 4. Chlorine nuclear quadrupole coupling constants of XCl

X	n[a)]	eQq/MHz	$eQq^{corr.b)}$/MHz	
B	0	−16.74(11)	(−23)[c)]	Present
C	1	−34.26(16)	−60.10	Ref. 4
N	2	−63.13(18)	−87.16	Ref. 6
O	3	−87.95(23)	−105.73	Ref. 3
F	4	−145.871		

a) The number of electrons in the 3π orbital. b) Corrected for π-electron delocalization. See Ref 6. c) 0.12 π-electrons were assumed to be transferred from Cl to B.

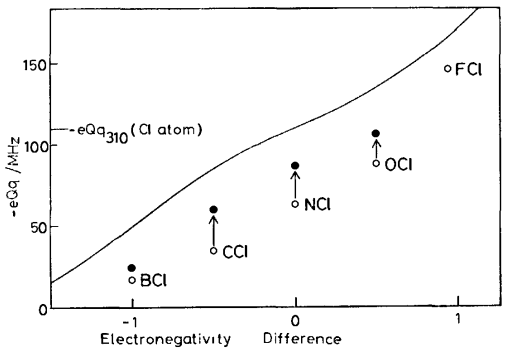

Fig. 3. The nuclear quadrupole coupling constants observed for second-row element chlorides *versus* the electronegativity difference. The observed values are shown by open circles, whereas the solid circles correspond to the corrected values. The arrows for OCl, NCl, and CCl designate the corrections for π-electron delocalization. For BCl the solid circle corresponds to 0.12 π-electron delocalization from Cl to B. The solid curve was calculated from a formula proposed by Gordy and Cook (see Ref. 1).

The B_0 constants of both $^{11}B^{35}Cl$ and $^{11}B^{37}Cl$ which Maki *et al.*[9] have reported differ from the present, more accurate values by four times their standard errors. The discrepancy may be ascribed to the fact that almost all transitions they observed belong to the R branch and the B_0 values are likely to be subjected to systematic errors.

We have also observed a few vibrational satellites. The relative intensity of these lines indicates the effective vibrational temperature of BCl in the discharge plasma to be much higher than the room temperature, namely 1000—2000 K.

Calculations in the present study were carried out at the Computer Center of the Institute for Molecular Science.

Phase Equilibria in the Ln_2O_3–V_2O_3–V_2O_5 (Ln=Eu and Yb) Systems at 1200 °C

Kenzo KITAYAMA,* Hidehiko SOU,† and Takashi KATSURA

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received February 18, 1983)

Phase equilibria in the systems, Eu_2O_3–V_2O_3–V_2O_5 and Yb_2O_3–V_2O_3–V_2O_5, were established at 1200 °C by changing the oxygen partial pressure from −0.68 (air) to −13.00 atm in terms of $\log P_{O_2}$. In the Eu_2O_3–V_2O_3–V_2O_5 system, $0.81Eu_2O_3 \cdot 0.19V_2O_5$ ($Eu_{1.62}V_{0.38}O_{3.38}$) was stable; in the Yb_2O_3–V_2O_3–V_2O_5 system, a new compound $Yb_7V_3O_{16}$ was stable; and in both systems Ln_2O_3, $LnVO_4$, $LnVO_3$, V_nO_{2n-1} (n=2—7), and VO_2 were stable under the present experimental conditions. On the basis of the established phase diagrams, Gibbs energies of these reactions, $31/50\ Eu_2O_3 + 19/50\ EuVO_3 + 19/100\ O_2 = Eu_{1.62}V_{0.38}O_{3.38}$, $EuVO_3 + 1/2\ O_2 = EuVO_4$, $2\ Yb_2O_3 + 3\ YbVO_3 + 1/2\ O_2 = Yb_7V_3O_{16}$, $Yb_7V_3O_{16} + O_2 = 2\ Yb_2O_3 + 3\ YbVO_4$, and $YbVO_3 + 1/2\ O_2 = YbVO_4$, were determined to be −58.9, −126.0, −134.0, −210.0, and −117.7 kJ respectively. $EuVO_4$, $Eu_{1.62}V_{0.38}O_{3.38}$, $YbVO_4$, $Yb_7V_3O_{16}$, V_2O_3, and VO_2 have nonstoichiometric compositions.

Phase equilibria in the Ln_2O_3–V_2O_3–V_2O_5 systems (Ln=Sm, Lu, Er, Gd, La, Nd, and Tm) at 1200 °C have been established[1-7] by changing the oxygen partial pressure from −0.68 (air) to −12.50 or −13.00 atm†† in terms of $\log P_{O_2}$. These studies established phase diagrams whose different patterns are a result of the fact that different compounds coexist under the experimental conditions. We also succeeded in obtaining the Gibbs energies of reactions presented in the diagrams, the crystallographic data of the ternary compounds, and the activities of the components in the solid solutions.

In the present studies, Eu_2O_3 and Yb_2O_3 were chosen as the Ln_2O_3. Especially, the system that consists of Yb_2O_3 was expected to form as interesting pattern as that of the Lu_2O_3 system,[2] because the existence of a pyrochlore type compound $Yb_2V_2O_7$ was well known[8] and its physical properties had been studied by many researchers.[8-11]

In the Eu_2O_3–V_2O_3 and Yb_2O_3–V_2O_3 systems, $EuVO_3$ and $YbVO_3$ were well known, but these systems have not yet been completely studied, because of V_2O_3 is unstable in air. The crystallographic properties of $EuVO_3$ and $YbVO_3$ have been investigated by McCarthy *et al.*[12] and Shin-ike *et al.*,[13] and it has been confirmed that these compounds belong to orthorhombic system, like the other lanthanoid vanadites except for $LaVO_3$ and $CeVO_3$.

The Eu_2O_3–V_2O_5 system was studied by Brusset *et al.*[14] and Kiparisov *et al.*[15] Brusset *et al.* studied in the temperature range from 600 °C to 1500 °C in air and found three compounds: $Eu_2O_3 \cdot V_2O_5$ ($EuVO_4$), $4Eu_2O_3 \cdot V_2O_5$ ($Eu_8V_2O_{17}$), and $5Eu_2O_3 \cdot V_2O_5$ ($Eu_{10}V_2O_{20}$), while Kiparisov *et al.* studied in the temperature region 500—1500 °C in air and found $Eu_2O_3 \cdot V_2O_5$ and $3Eu_2O_3 \cdot V_2O_5$. A discrepancy in two results exists regarding the stable compounds.

The Yb_2O_3–V_2O_5 system was also investigated by Brusset *et al.*[14] in the temperature range from 600 °C to 1500 °C in air; they found $Yb_2O_3 \cdot V_2O_5$, $4Yb_2O_3 \cdot V_2O_5$, and $5Yb_2O_3 \cdot V_2O_5$.

The crystallographic system of the $Yb_8V_2O_{17}$ is monoclinic[16,17] but that of $5Yb_2O_3 \cdot V_2O_5$ has not been determined, although a rough X-ray powder pattern had been presented by Brusset *et al.*[14] (Fig. 4 in Ref. 14).

The objectives of the present experiment are: (1) to establish the detail phase equilibria in these two systems at 1200 °C in order to confirm which compounds are stable under our experimental conditions, (2) to calculate the Gibbs energies of the reactions which appear in the established phase diagrams, and (3) to ascertain whether or not there exists a linear relationship between the Gibbs energies of the reaction, $LnVO_3 + 1/2\ O_2 = LnVO_4$, and the ionic radii of lanthanoid elements as found in Ln–Fe–O.[18]

Experimental

Analytical grades of Eu_2O_3 (99.9%), of Yb_2O_3 (99.9%), and of V_2O_5, made by heating the guaranteed grade of NH_4VO_3 at 500 °C in air about 24 h, have been used as the starting materials. Desired Eu_2O_3/V_2O_5 and Yb_2O_3/V_2O_5 mole ratios of samples were obtained by mixing the appropriate quantities thoroughly in an agate mortar under ethyl alcohol. The mixtures thus obtained were treated by the procedures described in the previous paper.[1] The apparatus and procedures for controlling the oxygen partial pressures and keeping a constant temperature, the method of the thermogravimetry, the criterion for an equilibrium establishment, and the method of the chemical analysis except for the analysis of vanadium in the presence of europium are the same as those reported in the previous papers.[1,19-23] To obtain the V contents coexisting with Eu, we deduced the weight of Eu_2O_3, which was obtained by the gravimetric method,[1] from the total weight, because Eu^{3+} is reduced to Eu^{2+}, and Eu^{2+} precipitates as $EuSO_4$[24] in the reduction of V^{5+} with Zn–amalgam.

Results and Discussion

Phase Equilibria. (1) The Eu_2O_3–V_2O_3–V_2O_5 System: Although europium oxide has several forms, such as Eu_2O_3, EuO, and Eu_3O_4,[25,26] only Eu_2O_3 is stable under the present experimental conditions.[26,27] Nine samples with Eu_2O_3/V_2O_5 mole ratios of 85/15, 82/18, 81/19, 8/2, 7/3, 6/4, 1, 35/65, and 2/8 were prepared to be used in the thermogravimetric experiment. In Fig. 1, the relationships between the

† Present address: Nippon Mining Co., Ltd., Kurami Works: 3 Kurami, Koza-gun, Kanagawa 253-01.

†† atm = 1.013×10^5 Pa.

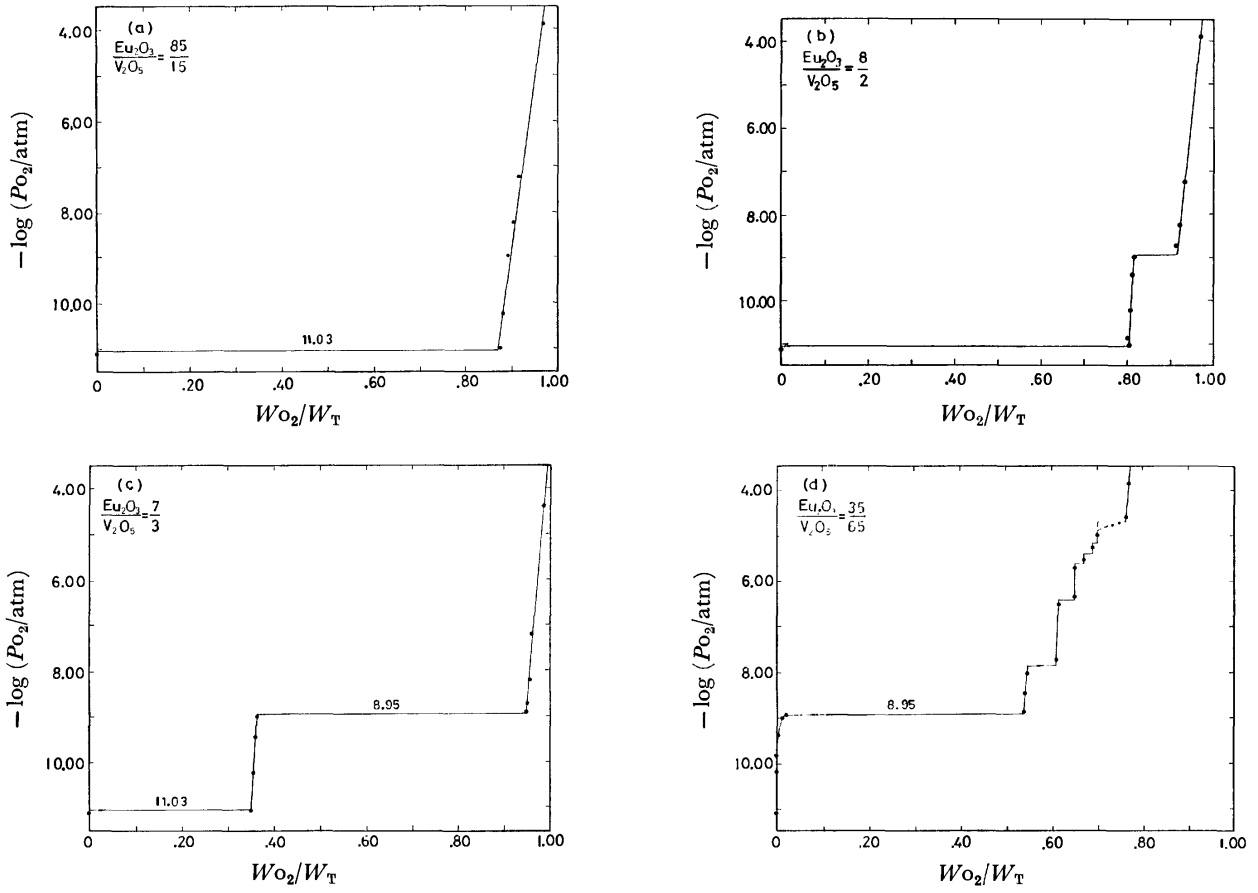

Fig. 1. The relationship between the oxygen partial pressure in $-\log(P_{O_2}/\text{atm})$ and the weight change of the sample in W_{O_2}/W_T.
(a) $Eu_2O_3/V_2O_5=85/15$, (b) $Eu_2O_3/V_2O_5=8/2$, (c) $Eu_2O_3/V_2O_5=7/3$, (d) $Eu_2O_3/V_2O_5=35/65$.

oxygen partial pressure, atm, on the ordinate and the weight change, W_{O_2}/W_T, on the abscissa are shown; here W_{O_2} is the weight gain of the samples from the reference weight in the atmosphere of $\log P_{O_2}=-13.00$ atm, and W_T is the total weight gain that the samples would get if V_2O_3 in the samples would change to V_2O_5. The experimental results of four samples, 85/15, 8/2, 7/3, and 35/65 are shown in Fig. 1 as representative. From Figs. 1a to 1c, it is apparent that abrupt weight changes occur at two oxygen partial pressures, -11.03 and -8.95 atm in $\log P_{O_2}$. These values correspond to the equilibrium oxygen partial pressures of the reactions described in Table 6. Fig. 1d shows a similar pattern to those of the samples of other systems.[1,3-7] which have the composition of Ln_2O_3/V_2O_5 mole ratios lower than unity. But the value of the oxygen partial pressure, $\log P_{O_2}=-8.95$, that corresponds to the equilibrium oxygen partial pressure of the reaction, $EuVO_3+1/2\ O_2=EuVO_4$, is different.

In Table 1 the results of the identification of phases are shown. In the first column are the compositions of the starting materials in mol%; in the second and third are shown the experimental conditions of the oxygen partial pressures in terms of $\log P_{O_2}$ in atm and the experimental duration in h; and in the fourth are the phases identified by X-ray powder diffractometer using Cu $K\alpha$ radiation.

Based upon the above experimental results, a phase diagram of the system at 1200 °C was drawn; This is shown in Fig. 2. The following phases are present under the present experimental conditions except for six compounds in the V_2O_3–V_2O_5 system; Eu_2O_3(R), $Eu_{1.62}V_{0.38}O_{3.38}$(A), $EuVO_4$(B), and $EuVO_3$(C). Compounds in the V_2O_3–V_2O_5 system are the same as those in the previous report.[1] $5Eu_2O_3\cdot V_2O_5$ reported by Brusset *et al.*[14] and $3Eu_2O_3\cdot V_2O_5$ reported by Kiparisov *et al.*[15] have not been confirmed under the present experimental conditions. The Compound A may correspond to the compound $4Eu_2O_3\cdot V_2O_5$ that Brusset *et al.* have reported. But under the present experimental conditions, this compound has no such round mole ratio as that written above. The straight line drawn by plotting the results of the thermogravimetry usually converges to a composition $0.81Eu_2O_3\cdot 0.19V_2O_5$, even considering the experimental errors. As is shown in Fig. 1b, the sample, $Eu_2O_3/V_2O_5=8/2$, has a pattern similar to that in Fig. 1c which shows the two equilibrium oxygen partial pressures. If compound A had the composition of $Eu_2O_3/V_2O_5=8/2$, the pattern should be the same one as that of Fig. 1a with one equilibrium oxygen partial pressure, $\log P_{O_2}=-11.03$. Compounds with the same $Ln_2O_3/V_2O_5=81/19$ mole ratio were found in other systems.[4,5] Figure 2 has a pattern similar to that of the Gd_2O_3–V_2O_3–V_2O_5 system.[4]

Compound A and $EuVO_4$ have nonstoichiometric

compositions. The following relationships between the oxygen partial pressure and the composition were found from the results of the thermogravimetry; $N_O/N_A = 8.71\times10^{-3}+5.18\times10^{-3}\log P_{O_2}$ for compound A and $N_O/N_B = 2.24\times10^{-3}+1.62\times10^{-3}\log P_{O_2}$ for $EuVO_4$ (B). Here N_O, N_A, and N_B mean the mole fractions of oxygen and of component A and B. Nonstoichiometry was not found for $EuVO_3$ under the present experimental conditions.

a) A: $Eu_{1.62}V_{0.38}O_{3.38}$.

Table 2 shows compositions of the compounds that were calculated from the results of the thermogravimetry, symbols of the compounds, stability ranges of the compounds in terms of $\log P_{O_2}$, and activities of the components in the solid solutions. Activities of each component in the solid solutions were calculated by using Gibbs-Duhem equation. The detailed method of calculation has been described in the paper of Kimizuka and Katsura.[22]

The lattice constants of the compound A were successfully determined with the aid of the assignment of $4Tm_2O_3\cdot V_2O_5$.[16] Lattice constants of the com-

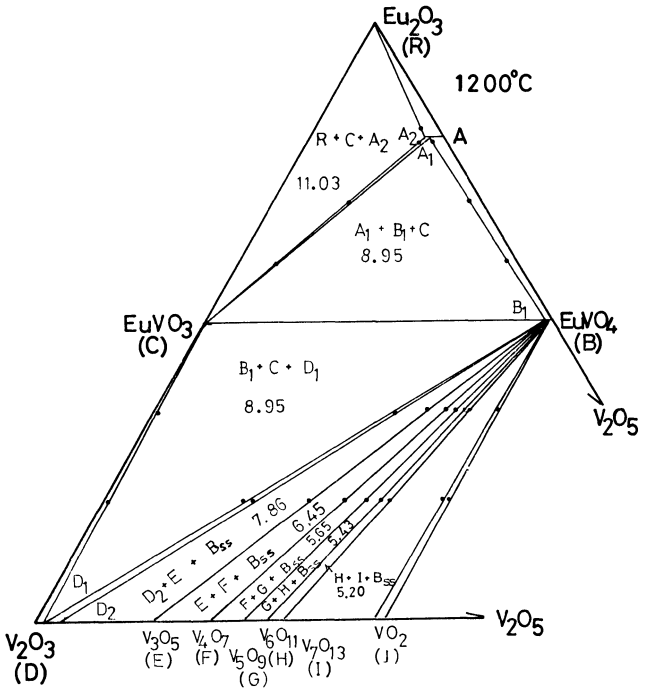

Fig. 2. Phase equilibria in the Eu_2O_3-V_2O_3-V_2O_5 system at 1200 °C. Numerical values in three solid phases regions are the equilibrium oxygen partial pressure in $-\log P_{O_2}$. Abbreviations are the same as those in Table 2.

pounds, A, $EuVO_4$, and $EuVO_3$ are tabulated in Table 3, together with those of previous reports.[12,13,27,28] Figures that are shown in the second column of the Table are the oxygen partial pressure used in preparation of samples. We could not discuss about the difference of the unit cell dimensions of two A samples because the experimental errors are too large. Present values for $EuVO_4$ are in good agreement with those of Schwarz,[28] but the values for $EuVO_3$ are slightly larger than those of McCarthy *et al.*[12]

(2) The Yb_2O_3–V_2O_3–V_2O_5 System: Yb_2O_3 is stable under the present experimental conditions.[22] Six samples with Yb_2O_3/V_2O_5 mole ratios of 8/2, 7/3, 6/4, 1, 35/65, and 2/8 were prepared to be used in the thermogravimetric experiments. Relationships between the oxygen partial pressure and the weight change, W_{O_2}/W_T, for three samples: 8/2, 6/4, and 2/8 are shown in Fig. 3 as representative cases. We find three equilibrium oxygen partial pressure: 9.55, 8.37, and 7.47 in $-\log P_{O_2}$ from Figs. 3a and 3b. Figure 3c shows a similar pattern to that in Fig. 1d except for the oxygen partial pressure, $\log P_{O_2} = -8.37$, for the reaction $YbVO_3 + 1/2\ O_2 = YbVO_4$.

In Table 4, the results of the identification of phases are shown. Based upon the above experimental results, a phase diagram at 1200 °C was drawn and is shown in Fig. 4. The following phases are present under the present experimental conditions, along with the six compounds in the V_2O_3–V_2O_5 system. Phases are: Yb_2O_3(R′), $Yb_7V_3O_{16}$(A′), $YbVO_4$(B′), and $YbVO_3$(C′). Compounds in the V_2O_3–V_2O_5 system are the same as those in the previous report.[1] The compound $Yb_7V_3O_{16}$ is new although the Ln/V/O mole ratio is identical with those of Lu[2] and Tm[7] systems. Compounds $4Yb_2O_3 \cdot V_2O_5$ and $5Yb_2O_3 \cdot V_2O_5$ reported by Brusset *et al.*[14,16] and the pyrochlore type $Yb_2V_2O_7$ reported by many authors[8–10] were not found under the present experimental conditions. This phase diagram is a new type.

Compounds $Yb_7V_3O_{16}$ and $YbVO_4$ have nonstoichiometric compositions. The following relationships between the oxygen partial pressure and the composition were obtained from the results of the thermogravimetry: $N_O/N_A' = 1.161 + 0.158 \log P_{O_2}$ for $Yb_7V_3O_{16}$ (A′) and $N_O/N_B' = 4.58 \times 10^{-3} + 2.59 \times 10^{-3} \log P_{O_2}$ for $YbVO_4$ (B′).

2.080	10	1.4659	11
1.9282	57	1.4317	12
1.9076	22		

In Table 2, the compositions of the compounds at various oxygen partial pressures, stability ranges of the compounds in terms of $\log Po_2$, the symbols of the compounds, and the activities of the components in the solid solutions are also tabulated.

The assignment of Miller's indices for the new compound, $Yb_7V_3O_{16}$, did not succeed. Relative intensities and spacings that were obtained by X-ray diffractometer with the powder sample are shown in Table 5, several weak peaks being omitted.

Lattice constants of the compounds, $YbVO_4$ and $YbVO_3$, are tabulated in Table 3, together with those of previous reports.[12,14,28,29] The lattice constants of $YbVO_4$, made in air, are in good agreement with those prepared at $\log Po_2=-7.20$ and with those of the previous reports. Present values of $YbVO_3$ are larger than those obtained by McCarthy *et al.*[12]

Calculation of Gibbs Energies of Reactions. On the basis of the established phase diagrams, Gibbs energies of reactions appearing in the systems, except for the reactions in the V_2O_3-V_2O_5 system, can be calculated by an equation, $\Delta G^\circ=-RT\ln K$, where the R is the

TABLE 6. GIBBS ENERGIES OF REACTIONS

Reaction	$-\log(P_{O_2}/\text{atm})$	$-\Delta G°/\text{kJ}$
$19/50\ EuVO_3+31/50\ Eu_2O_3+19/100\ O_2=Eu_{1.62}V_{0.38}O_{3.38}$	11.03±0.06	58.9±0.2

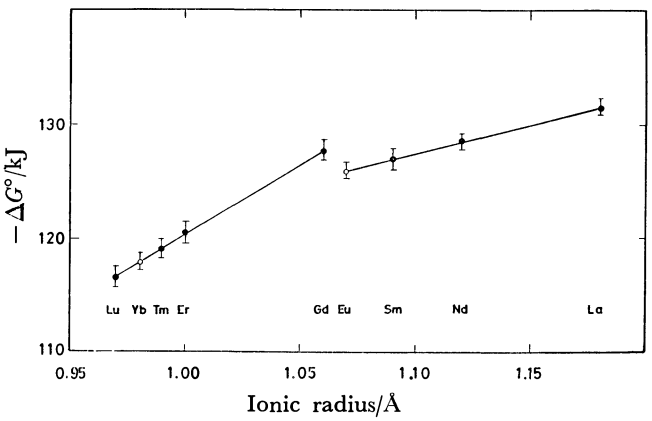

Fig. 5. The relationship between the ionic radius in 8 coordination number and the Gibbs energies of reaction, $LnVO_3+1/2\ O_2=LnVO_4$. The solid circles are the previous values and the open circles present values.

gas constant, the T the absolute temperature, and the K the equilibrium constant of each reaction. Reactions and the $\Delta G°$ values obtained are shown in Table 6, together with the equilibrium oxygen partial pressures. Activities of each component in the solid solutions whose activity is necessary for the calculations are listed in Table 2.

The Relationship between $\Delta G°$ and Ionic Radius. In the previous report,[7] the relationship between $\Delta G°$ values for the reaction $LnVO_3+1/2\ O_2=LnVO_4$ and the 8 coordinated ionic radius of lanthanoid elements was graphically shown. The series divided into two groups and the relationship is linear within each of the groups. The experimental results of the present systems are plotted in Fig. 5 with open circles together with the previous data shown as solid circles. Both open circles fit well on the lines which were drawn using the data of the previous experiments.

Crystal and Molecular Structure of μ-Imidazolato-bis{[tris(2-methylthioethyl)amine]copper(II)}perchlorate

Masatatsu Suzuki,* Ikuhiko Ueda, Hajime Kanatomi, and Ichiro Murase

Laboratory of Chemistry, College of General Education, Kyushu University, Ropponmatsu, Chuo-ku, Fukuoka 810

(Received April 14, 1983)

The structure of the title complex, $[Cu_2(NS_2\text{-}Me)_2im](ClO_4)_3$, has been determined by the single-crystal X-ray diffraction method, where NS_3–Me is tris(2-methylthioethyl)amine and im is imidazolate anion. The complex crystallizes in the monoclinic space group $P2_1/a$ with a unit cell with the dimensions of $a=13.114(3)$, $b=28.045(6)$, $c=10.481(2)$ Å, $\beta=98.70(2)°$, $V=3810.2(13)$ Å^3, and $Z=4$. The structure was solved by the heavy atom method. The residual R value was 0.0594 for 4431 independent reflections. The coordination geometries of the two copper atoms are different from each other; the Cu(1) is in a trigonal bipyramidal geometry with three sulfur atoms in the equatorial plane and two nitrogen atoms in the axial positions, while the coordination geometry of the Cu(2) can be best described as an intermediate between a trigonal bipyramid and a square pyramid. The intramolecular Cu(1)···Cu(2) distance is 5.930(2) Å. Temperature-dependent magnetic susceptibility data showed a strong antiferromagnetic exchange interaction with a coupling constant $-J=63$ cm^{-1}. The Cu(1)–N(1)–C(1) and Cu(2)–N(2)–C(1) angles, which have been considered to be related to the magnitude of the antiferromagnetic exchange interaction, are 132.1(5) and 127.0(6)°, respectively. The magnetism of the complex is discussed in connection with the structural data.

Recently, a number of di- and tetra-nuclear copper (II) complexes bridged by various imidazolate groups have been reported as possible models for the active site of bovine erythrocyte superoxide dismutase.[1-8] Those studies have shown that antiferromagnetic exchange interactions operate between copper(II) ions and their magnitudes are highly dependent on the structure of the Cu–im–Cu moiety.

In the previous study,[9] we reported that the imidazolate-bridged dinuclear copper(II) complexes with tripod ligand (L) having NS_3 or N_2S_2 donor set, $[Cu_2(L)_2im](ClO_4)_3$, exhibited antiferromagnetic interactions with coupling constants $(-J)$ of 58—66 cm^{-1}, where L is tris(2-alkylthioethyl)amine, 2-[bis(2-methylthioethyl)aminomethyl]pyridine, or *N,N*-bis-(2-methylthioethyl)ethylenediamine and im is imidazolate anion. The antiferromagnetic exchange interactions of those complexes are considerably strong compared with those of the other dinuclear complexes bridged by imidazolate itself.[2-8] Therefore, we are interested in the structure of the Cu–im–Cu moiety of the above complexes with tripod ligands containing sulfur atoms in connection with their magnetic properties.

In general, tripod ligands (L) such as tris(2-aminoethyl) amine (tren) tend to form trigonal bipyramidal copper(II) complexes, $[Cu(L)X]^{n+}$, with an additional unidentate ligand (X).[10-13] Previously, we demmonstrated that, in a series of $[Cu(NS_3\text{–}R)X]^{n+}$, the stereochemistry of the complexes depends on both alkyl substituent (R) and the unidentate ligand (X).[14] The electronic and esr spectra of the imidazole complex, $[Cu(NS_3\text{–}Me)Him](ClO_4)_2$, suggested that the complex has a square pyramidal structure. Thus the stereochemistry of the dinuclear complex with tripod ligand, NS_3–Me, is also interesting. In this paper, we have undertaken a single-crystal X-ray analysis of $[Cu_2(NS_3\text{–}Me)_2im](ClO_4)_3$.

Mikuriya *et al.*[15,16] demonstrated that the replacement of nitrogen donor atom by sulfur donor atom causes an increase in antiferromagnetic exchange interaction; the alkoxo-bridged dinuclear copper(II) complexes with SNO and NSO donor sets exhibit a stronger antiferromagnetic exchange interaction than the complexes with NNO donor set. An influence of the sulfur donor atom on the antiferromagnetic exchange interaction is also described.

Experimental

The complex was prepared by the method previously reported.[9] Recrystallization from an aqueous solution at room temperature afforded dark green prisms.

The diffraction data were measured on a Rigaku AFC-5 automated four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation. The unit-cell parameters were determined by the least-squares refinement based on 20 reflections. A crystal with approximate dimensions of $0.3\times0.2\times0.2$ mm^3 was used for intensity measurement. Crystal data: $Cu_2Cl_3S_6O_{12}N_4C_{21}H_{45}$, F.W.=971.4, monoclinic, space group $P2_1/a$, $a=13.114(3)$, $b=28.045(6)$, $c=10.481(2)$ Å, $\beta=98.70(2)°$, $V=3810.2(13)$ Å^3, $D_m=1.68$, $D_x=1.69$ g cm^{-3}, $Z=4$, and μ(Mo $K\alpha$)=17.4 cm^{-1}.

The intensity data were collected by θ-2θ scan technique with a scan rate of 8° min^{-1}. For weak reflections the peak scan was repeated up to three times depending on their intensities. Three standard reflections were monitored every 100 reflections and their intensities showed a good stability. A total of 7249 reflections with $2\theta<50°$ was collected and 4431 independent reflections with $|F_o|>3\sigma(|F_o|)$ were considered as "observed" and used for structure analysis. The intensity data were corrected for the Lorentz and polarization effects, but not for the absorption.

The structure was solved by the heavy-atom method. The positions of two copper atoms were obtained from the Patterson synthesis and those of the remaining 46 nonhydrogen atoms were obtained from successive Fourier syntheses. Refinement was carried out by the block-diagonal least-squares method. A difference Fourier synthesis gave several peaks around chlorine atoms of perchlorate ions, which were ascribed to the disordered oxygen atoms of perchlorate ions. The nonhydrogen atoms with occupancy factor larger than 0.5 were refined with anisotropic thermal parameters. Hydrogen atoms defined by the geometry of the complex were located at the calculated positions (C–H=1.09 Å)

Table 1. Fractional positional parameters ($\times 10^4$) and thermal parameters of non-hydrogen atoms with their estimated standard deviations in parentheses

b) Occupancy factors.

In the final cycles of the refinement, hydrogen atoms were included with isotropic thermal parameters (4.0 Å^2). The final value of R was 0.0594.

The difference Fourier map showed a peak (1.4 eÅ^3) near the S(6) atom which was probably due to the fact that the absorption correction had not been applied.

The atomic scattering factors and the anomalous dispersion corrections, $\Delta f'$ and $\Delta f''$, for Cu, Cl, S, O, N, and C, were taken from the international tables for X-ray Crystallography.[17] For the hydrogen atoms, the scattering factors were adopted from the tables of Stewart *et al.*[18] All the calculations were carried out on the FACOM M-200 computor at the Computor Center of Kyushu University by the use of a local version of the UNICS III[19,20] and the ORTEP[21] programs. The final positional parameters with their standard deviations are given in Table 1. Observed and calculated structure factors, anisotropic thermal parameters of the nonhydrogen atoms, and hydrogen atom coordinates have been deposited as a Document NO. 8351 at the Office of the Editor of Bull. Chem. Soc. Jpn.

Results and Discussion

A perspective drawing of the complex cation and the numbering system are illustrated in Fig. 1. Bond distances and angles are listed in Table 2.

The crystal structure consists of a discrete imidazolate bridged dinuclear cation, $[Cu_2(NS_3\text{-}Me)_2im]^{3+}$, and perchlorate anions. The intramolecular Cu(1)···Cu(2) distance is 5.930(2) Å. Each copper atom is five-coordinate. The coordination geometries of the Cu(1) and Cu(2) atoms are different from each other. The Cu(1) atom is in a trigonal bipyramidal coordination geometry, while the Cu(2) is in an intermediate between a trigonal bipyramid and a square pyramid (Fig. 2). In the former, the equatorial positions are occupied by three sulfur atoms and the axial positions

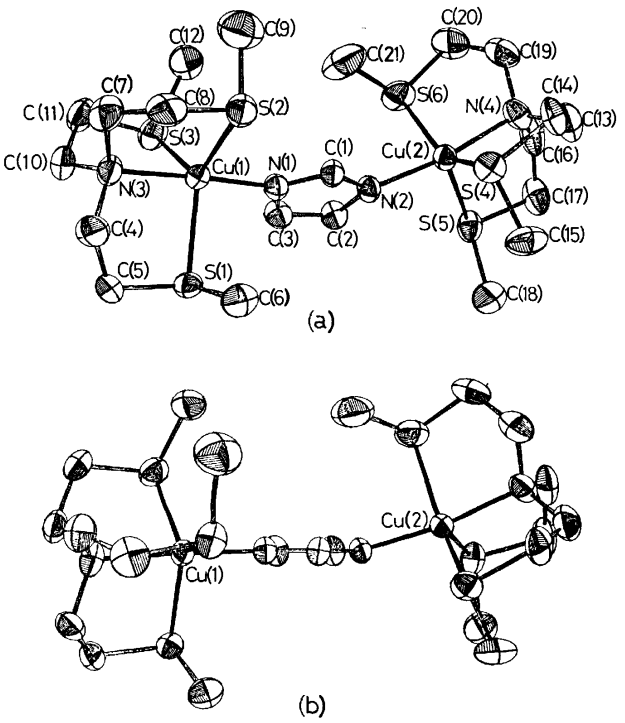

Fig. 1. Two views (a) and (b) of the complex cation, $[Cu_2(NS_3\text{-}Me)_2im]^{3+}$, showing the atomic numbering. The thermal ellipsoid was drawn at the 50% probability level.

by two nitrogen atoms. The three trigonal angles formed by S–Cu–S are close to 120°, *i.e.*, 121.11(9), 117.47(9), and 120.71(10)°, and the trigonal axis (N(1)–Cu(1)–N(3)) is nearly linear (177.1(3)°). The three equatorial Cu–S distances are 2.374(2), 2.423 (3), and 2.402(3) Å, which are in agreement with those in trigonal bipyramidal complexes with tripod ligand containing sulfur atoms, $[Cu(NS_3\text{–}Me)Br]ClO_4$ [22] and $[Cu(pam)SO_4]$[23] (pam=2-[bis(2-ethylthioethyl)-aminomethyl]pyridine). The Cu(1)–N(3) distance is comparable to Cu–N distances of the above complexes.

The Cu(1) atom does not exactly fit in the trigonal plane through S(1), S(2), and S(3), and is displaced 0.12 Å toward the direction of the bridging imidazolate. This type of displacement of the Cu atom is quite commom in the trigonal bipyramidal complexes with tripod ligands.[10–13]

The coordination geometry around the Cu(2) atom is an intermediate between a trigonal bipyramid and a square pyramid. The distorted nature from a trigonal bipyramid becomes evident from an examination of the S–Cu–S bond angles, 95.77(9), 117.71 (9), and 145.10(10)°. Viewing the structure as a square pyramid, N(2), N(4), S(4), and S(6) atoms form a basal plane, and the S(5) atom occupies the axial position. In a regular square pyramid, The S(4)–Cu(2)–S(6) and the N(2)–Cu(2)–N(4) angles should be 180°. In the typical square pyramidal complex, $K[Cu(NH_3)_5](PF_6)_3$[24], however, the corresponding angles are 164 and 167°, where the decrease

a) The angles around Cl(3) are omitted because of serious disorder.

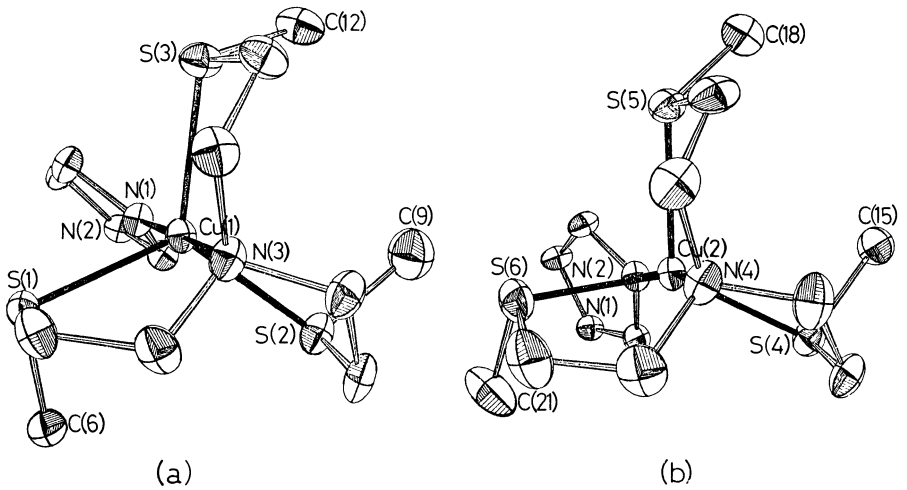

Fig. 2. Coordination geometries around the Cu(1) (a) and the Cu(2) (b) of $(Cu_2(NS_3\text{-}Me)_2im]^{3+}$.

in those angles from 180° is due to the displacement of the Cu atom from the basal plane toward the fifth ligand. In the present complex, the S(4)–Cu(2)–S (6) and the N(2)–Cu(2)–N(4) angles are 145.10(10) and 172.5(3)°, respectively. In general, the apical bonds are longer than the basal ones in square pyramidal complexes.[25] The S(5)–Cu(2) bond distance (2.500 (3) Å) is apparently longer than the S(4)–Cu(2) (2.345 (3) Å) and the S(6)–Cu(2) (2.392(3) Å). Thus the coordination geometry around the Cu(2) atom can be best described as an intermediate between a trigonal bipyramid and a square pyramid.

In general, tripod ligands tend to enforce a trigonal bipyramidal structure, *i.e.*, in the tren complexes, the range of the trigonal angles are from 105 to 140°.[10-13] The larger variation in the trigonal angles of the present complex may be due to the packing effects.

All of the bond distances and angles of the NS_3–Me ligands are within the range observed for $[Cu(NS_3\text{–}Me)Br]ClO_4$,[22] and $[Co(NS_3\text{–}Bu)Br]PF_6$.[26] All the five-membered chelate rings adopt gauche conformation with the exception of the Cu(2)–N(3)–C(19)–S(6) chelate ring which assumes envelop conformation. The torsion angles about C–C bonds of the chelate rings in the gauche conformation are in the range of 50.8—58.9°, while that in the envelop conformation is 35.2°.

The bond distances and angles of the imidazolate ring are in agreement with those previously reported.[3,4,6] The five atoms constituting the imidazolate ring lie within 0.009 Å of the best plane through them. The Cu(1) atom is 0.039 Å out of this plane and the Cu(2) atom deviates 0.603 Å from the plane on the opposite side, which is considerably larger than those previously reported.[3,4,27] Thus the Cu(2)–N(2) bond is bent out of the imidazolate plane (Fig. 1b). The angle of this bending is *ca.* 17°.

The Cu–N(imidazolate) bond distances are 1.968 (7) and 1.961(7) Å, which are quite normal.

Magnetism. Di- and tetra-nuclear copper(II) complexes bridged by various imidazolate groups show antiferromagnetic exchange interactions with coupling constants $(-J)$ ranging from *ca.* 0—90 cm^{-1}.[1,2,8] The magnitude of antiferromagnetic exchange interaction is a reflection of the interaction of the orbitals of the bridging ligand with copper orbitals in which the unpaired electrons reside; the extent of the overlap between the copper d orbitals and the appropriate orbitals of the bridging ligand, and the energy difference between those orbitals are two important factors which determine the J value.[2,8,28]

It has been suggested that a π-exchange mechanism is not important in the imidazolate-bridged copper(II) complexes.[2,4,8] Haddad and Hendrickson[2] demonstrated that, in a series of $[Cu_2(tren)_2Y]^{3+}$, (Y=benzimidazolate, imidazolate, or 2-methylimidazolate), the difference in antiferromagnetic exchange interactions mediated by a variety of the bridging imidazolates are related to the angle α (in the present complex, α is defined by the Cu(1)–N(1)–C(1) and Cu(2)–N(2)–C(1) angles). Increasing the angles α improves the overlap between the metal d orbitals and the σ orbitals of the bridging imidazolate, leading to an increase in $|J|$.

In addition, Dewan and Lippard[27] suggested that the angle θ between two Cu–N(imidazolate) vectors is also important in determining $|J|$. This angle can be also considered to be a measure of the extent of the overlap between the d orbitals and the σ molecular orbitals of the bridging imidazolate.

In the present complex, the values of α are 127.0(6) and 132.1(5)°, and that of θ is 145°. These values suggest that an overlap between the d orbitals and the σ molecular orbitals of the bridging imidazolate is not larger than those in $[Cu_2(tmdt)_2im(ClO_4)_2]ClO_4$[3] ($\alpha$= 129°, θ=143°, $-J$=25.8 cm^{-1}) (Table 3). Furthermore, the Cu(2)–N(2) bond significantly bends out of the imidazolate plane (*ca.* 17°). Thus, the effect of the overlap of the Cu–N bonds in a geometrical sense could not explain such a large $|J|$ value (63 cm^{-1}) of the present complex.

Kolks *et al.*[8] pointed out that the magnitude of the coupling constant is also proportional to the pK_a of imidazolium group. This was interpreted in terms of the energy change of the σ molecular orbitals of the bridging imidazolate groups. The higher the pK_a of the imidazolium is, the higher the energies of the σ

Table 3. Comparison of the copper-imidazolate geometry and coupling constant

a) Abbreviations for the ligands are bpim=4,5-bis[2-(2-pyridyl)ethyliminomethyl]imidazolate; pmdt=*N*,*N*,*N*′,*N*″,-*N*″-tetramethyldiethylenetriamine; tmdt=*N*,*N*,*N*′,*N*′-tetramethyldiethylenetriamine; L=30-membered macrocyclic Schiff base in Ref. 5,6; gly-glyO=glycylglycinate. b) The value given in Table 2 in Ref. 5 is 163°, which is incorrect.

molecular orbitals of the imidazolate become. This results in a decrease in energy separation between the d orbitals and the σ molecular orbitals, and an increase in $|J|$. One of the other possibilities of the large $|J|$ value of the present complex is the lowering of the d orbital energies compared with those of $[Cu_2(tmdt)_2im(ClO_4)_2]ClO_4$.[3] Mikuriya *et al.*[15,16] demonstrated that, in a series of the alkoxo-bridged dinuclear copper (II) complexes, the replacement of the nitrogen donor atom by the sulfur donor atom causes an increase of $|J|$. Although direct evidence is lacking, it seems that the sulfur donor atom has a larger effect which lowers the d orbital energy than the nitrogen donor atom.

We thank Proffesor S. Kida, Proffesor H. Okawa, Dr. Y. Nishida, and Dr. M. Mikuriya for allowing us to use automated diffractometer and for their helpful discussions.

Liquid-Liquid Distribution of 4-Acyl-3-methyl-1-phenyl-5-pyrazolones and Their Zinc Complexes

Shigeo UMETANI and Masakazu MATSUI*
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received April 18, 1983)

The distribution of eight 4-acyl-3-methyl-1-phenyl-5-pyrazolones and their zinc complexes between aqueous and cyclohexane phases was investigated. The acid dissociation constants and partition constants of the extractants were discussed in terms of a substituent effect. It was found that two series of examined reagents in which one has an aromatic substituent at the 4-position of 5-pyrazolone, and the other an aliphatic one give similar extraction constants. Since their acid dissociation constants are essentially the same, a relationship, $\log P_{MA}=2\log P_{HA}+\text{constant}$, is postulated. The extraction constant of a fluorinated reagent which has a considerably small pK_a value is also similar to that of the reagents having aliphatic substituents. Another relationship, $\log \beta_2=2pK_a+\text{constant}$, is postulated.

The solvent extraction system has been widely employed as a convenient separation and concentration method of metal cations, and the extraction mechanism has been investigated in terms of the nature of metal cations, the role of solvents, and the chelation and distribution behavior of ligands.

The previous papers indicate that 4-acyl-5-pyrazolones (Fig. 1), a kind of β-diketones, have several advantages.[1-3] First, metal ions are extractable from acidic media because the pyrazolones are strong acids, and secondly, various kinds of derivatives can be easily synthesized, an important point for the investigation on the extraction mechanism. Obvious substituent effects were observed in the extraction of europium and barium,[1] and in the synergistic extraction of alkaline earths,[2] europium and scandium.[3]

In the present paper, quantitative investigations are made on the distribution of 4-acyl-3-methyl-1-phenyl-5-pyrazolones and the extraction of their zinc complexes.

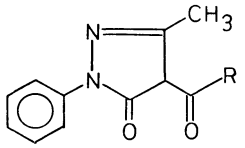

Fig. 1. 4-Acyl-3-methyl-1-phenyl-5-pyrazolones.

Experimental

Reagents. 4-Acyl-3-methyl-1-phenyl-5-pyrazolones were synthesized according to Jensen's method,[4] that is, from 3-methyl-1-phenyl-5-pyrazolone and the corresponding acid chloride or acid anhydride for the fluorinated ligand. The crude compounds were recrystallized from aqueous dioxane or methanol. Analytical data for these reagents are shown in Table 1. Zinc-65 was supplied by New England Nuclear, Boston, Mass. as a hydrochloric acid solution. This solution was once dried up and diluted with perchloric acid. Sodium perchlorate used to adjust the ionic strength (0.1) was recrystallized from water. All the other chemicals were chemically pure or reagent-grade materials.

Distribution of the Reagents. The experiments were performed in a 30 cm^3 glass-stoppered centrifuge tube. A cyclohexane solution containing pyrazolone (0.02 mol dm^{-3}) and an equal volume of the aqueous solution containing sodium perchlorate (0.1 mol dm^{-3}) and sodium acetate (0.01 mol dm^{-3}) as a buffer solution were shaken for 1 h in a thermostated room at 25±1 °C. The hydrogen ion concentration was controlled at a desired value with sodium hydroxide and perchloric acid. After the two layers had been separated centrifugally, the ligand concentration was measured spectrophotometrically. The ligand concentration in the aqueous phase was measured after the dilution with sodium hydroxide solution to complete the dissociation of the ligand. This anionic form which is stable enough for a few days, exhibits strong absorption at 250—300 nm. The sum of the ligand concentration determined in each phase coincided well with the initial concentration. The pH value of the aqueous phase was checked after extraction.

TABLE 1. ELEMENTAL ANALYSIS OF THE COMPOUNDS STUDIED

Reagent No.	R	Calcd (Found) (%) C	H	N	Mp θ_m/°C
1	Phenyl	73.37	5.07	10.07	92—92.5
		(73.54	4.99	10.22)	
2	2-Methylphenyl	73.96	5.52	9.58	111—112
		(73.64	5.52	9.33)	
3	3-Methylphenyl	73.96	5.52	9.58	94—95
		(73.72	5.39	9.38)	
4	4-Methylphenyl	73.96	5.52	9.58	100
		(74.01	5.46	9.66)	
5	2-Naphthyl	76.81	4.91	8.53	101
		(76.93	4.96	8.55)	
6	Propyl	68.83	6.60	11.47	45
		(68.78	6.59	11.66)	
7	Heptyl	71.97	8.05	9.33	61
		(72.17	8.09	9.25)	
8	Trifluoromethyl	53.34	3.33	10.36	146
		(53.55	3.30	10.56)	

Distribution of Zinc Complexes. A cyclohexane solution containing pyrazolone (0.02 mol dm^{-3}) and an equal volume of the aqueous solution containing Zn^{2+} (1×10^{-6} mol dm^{-3}), radioactive tracer (^{65}Zn), sodium perchlorate (0.1 mol dm^{-3}) and sodium acetate (0.01 mol dm^{-3}) were shaken for 1 h. After the two layers had been separated, 2 cm^3 of each phase was pipetted into a test tube and the radioactivities were counted.

Apparatus. Radioactivities were determined by counting with a Metro Electronics NaI (44.5 mm diam.×50.8 mm depth) well-type scintillation counter, model PbW-6, connected to a Metro automatic scaler, model SS-1060H. A Shimadzu UV-180 spectrophotometer was used for spec-

trophotometric measurements, and a Hitachi-Horiba F-7ss pH meter for pH measurements.

Results and Discussion

Data Processing. In a quantitative treatment for the distribution of the reagents, the acid dissociation constant, K_a, and the partition constant, P_{HA}, are defined as follows:

$$K_a = \frac{[H^+][A^-]}{[HA]},$$

$$P_{HA} = \frac{[HA]_o}{[HA]}, \quad (1)$$

where [HA] and [A^-] are the concentration of the neutral and anionic species of the extracting reagents in the aqueous phase, and the subscript o denotes the species in the organic phase. Thus, the distribution ratio of the reagents, D_{HA}, can be written as,

$$D_{HA} = \frac{[HA]_o}{[HA]+[A^-]},$$

or

$$D_{HA} = \frac{P_{HA}}{1+K_a[H^+]^{-1}}. \quad (2)$$

When the hydrogen ion concentration is high enough, D_{HA} agrees with P_{HA}, while log D_{HA} agrees with log $P_{HA}+pK_a-pH$ for low hydrogen ion concentrations.

The concentration of the anionic form can be described by using the initial ligand concentration, $[HA]_i$, as follows:

$$[HA]_i = [HA]_o + [HA] + [A^-],$$

$$[A^-] = \frac{[HA]_i}{1+[H^+](1+P_{HA})\cdot K_a^{-1}}. \quad (3)$$

When the divalent metal ion and the distribution ratio of the metal ion are denoted by M^{2+} and D_{MA}, the extraction constant, K_{ex}, can be written as follows:

$$M^{2+} + 2HA \rightleftharpoons MA_{2,o} + 2H^+,$$

$$K_{ex} = \frac{[MA_2]_o[H^+]^2}{[M^{2+}][HA]_o^2}. \quad (4)$$

The extraction constant can be rewritten by the chelate formation constants, β_2, and the partition constant of the chelates, P_{MA}, as follows:

$$\beta_2 = \frac{[MA_2]}{[M^{2+}][A^-]^2},$$

$$P_{MA} = \frac{[MA_2]_o}{[MA_2]},$$

$$K_{ex} = K_a^2\cdot\beta_2\cdot P_{MA}\cdot P_{HA}^{-2}. \quad (5)$$

Distribution of the Reagents. Figure 2 shows the distribution behavior of the reagents **1**, **7**, and **8** as a function of pH. The distribution curves are asymptotic to a constant value, log P_{HA}, at high hydrogen ion concentrations, and to a straight line with a slope of −1, *i.e.* the theoretical line (Eq. 2) at low hydrogen ion concentrations. The similar distribution behavior was also observed for other reagents. The results are summarized in Table 2. The acid dissociation constants increase in the order expected from the substituent effect,[1] but are essentially the same except for reagents **2** and **8**. Although the partition constants increase with the carbon number, the influence of increasing the carbon number is not always the same when aromatic substituents are compared with aliphatic ones. For instance, log P_{HA} for reagent **7** is much larger than for reagent **5**, whose carbon number is larger than that of reagent **7**.

Distribution of Zinc Complexes. A plot of log D_{MA} against log $[HA]_o$ for reagent **1** is shown in Fig. 3. A slope of 2 indicates that the extracted species is ZnA_2, and no further addition to this extracted form occurs in this ligand concentration range. Furthermore, dependence of log D_{MA} on pH and log [A^-]

has also been examined to confirm the availability of Eq. 4 and are shown in Figs. 4 and 5. The values of [A$^-$] can be obtained from Eq. 3. The plots of $\log D_{MA}$ against pH at a constant $[HA]_o$ gave straight lines with a slope of 2 for reagents **1** and **7**. The slope for reagent **8** is smaller than 2, for in this pH region log [A$^-$] increases no longer linearly with pH because of its strong acidity and low partition constant (see Table 2). Each plot of $\log D_{MA}$ against log [A$^-$] shows a straight line with a slope of 2 as seen in Fig. 5. The values of $\log K_{ex}$ and $\log P_{MA}\cdot\beta_2$ calculated from Eqs. 4 and 5 are summarized in Table 2 together with $pH_{1/2}$ (pH value at which 50% of the metal ion was extracted with 0.02 mol dm^{-3} of the reagent) and $\log K_a\cdot P_{HA}^{-1}$. As shown in Table 2, the values of $\log K_{ex}$ are close together for reagents **1**—**5** with aromatic substituents, and for reagents **6**—**8** with aliphatic ones. Figure 6 illustrates the plots for the relationship between $\log P_{MA}\cdot\beta_2$ and $\log K_a\cdot P_{HA}^{-1}$. Two straight lines with a slope of -2 are obtained for the two groups. The ligands with an aromatic substituent except for reagent **2** have similar values of K_a so that the values of β_2 are expected also to be similar to each other when other influences such as steric hindrance are negligible. On the basis of this assumption a relationship between P_{MA} and P_{HA} can be postulated from Fig. 6 as follows:

$$\log P_{MA} = 2\log P_{HA} + \text{constant}. \quad (6)$$

This relationship is also applicable to the aliphatic substituted group. Equation 6 is valid for the solvent extraction system of a reagent in various solvents[5] and of a solvent with various reagents.[6] Furthermore, reagent **8** which is a considerably strong acid also has a similar $\log K_{ex}$ value to reagents **6** and **7**. Since complex formation is the exchange reaction of a hydrogen ion for a metal ion, strong acidity may bring low chelation ability. On the basis of this assumption another relationship between K_a and β_2 can be postulated as follows:

$$\log \beta_2 = 2pK_a + \text{constant}. \quad (7)$$

Further investigation is required to confirm this relationship. The difference in the values of $\log K_{ex}$ between aromatic and aliphatic substituted groups may be caused by the stabilization of the complexes based on the aromatic resonance effect.

The Syntheses and Decompositions of Strontium and Barium Tetraphosphates

Makoto WATANABE,* Mioko MAEDA, and Tamotsu YAMADA

Department of Industrial Chemistry, Chubu Institute of Technology, Matsumoto-cho, Kasugai, Aichi 487

(Received April 25, 1983)

Strontium and barium tetraphosphates were made by hydrolyzing *cyclo*-tetraphosphate in a 5 mol dm^{-3} solution of sodium hydroxide, neutralizing the phosphate solution with 1 mol dm^{-3} hydrochloric acid, and then adding an aqueous solution of strontium or barium chloride to the solution. The P/M (M: Sr or Ba) ratio of the tetraphosphates was 1.3. The strontium and barium tetraphosphates were X-ray diffractometrically amorphous and contained about 23—14 and 14—8% of bound water depending on the washing conditions. They decomposed to phosphates having shorter chain lengths with the bond water in air at 25—30 °C or at a higher temperature. The decomposed phosphates were polymerized again above 150 °C and the products were mixtures of diphosphate and other polyphosphates.

The usual syntheses of polyphosphates have been made by some heating process. Organic acid anhydride, trichloroacetonitrile, and dicyclohexylcarbodiimide have been used as dehydrating agents.[1-6] It is still difficult to produce oligophosphates having chain lengths longer than the triphosphate by these methods. The compounds with the composition of $3MO \cdot 2P_2O_5$ (M: Sr, Ba, or Pb) were made by a heating method.[7-11] The barium and lead phosphates were confirmed to be tetraphosphate by paper chromatography. The strontium compound is not characterized yet. These compounds were slightly soluble in solvents, except for strongly acidic aqueous solutions, and the phosphates are readily hydrolyzed to phosphates having shorter chain lengths in the acidic solutions at room temperature. So it is difficult to use the phosphates for studying chemical properties. The present authors have reported the syntheses of calcium and magnesium tetraphosphates by a wet chemical process and have discussed the stability of the products.[12,13] The tetraphosphates were soluble in an aqueous disodium dihydrogen ethylenediaminetetraacetate dihydrate (EDTA) solution and can be used for studying chemical properties of the phosphates in an aqueous reaction system. This paper describes the syntheses of strontium and barium tetraphosphates by a wet chemical process and the thermal stability of the products.

Experimental

Synthetic Method. All the chemicals were of commercial reagent grade and were used without further purification. Sodium *cyclo*-tetraphosphate tetrahydrate was made by hydrolyzing α-P_2O_5 in water cooled below 15 °C with vigorous stirring and then by adding sodium chloride to the solution.[14] About 10 g of sodium *cyclo*-tetraphosphate tetrahydrate was added to 25 cm^3 of a 5 mol dm^{-3}-aqueous solution of sodium hydroxide, and the mixture was stirred at about 20 °C for 4 d. Most of the *cyclo*-phosphate was not dissolved in the sodium hydroxide solution, while the tetraphosphate produced by the hydrolysis of the *cyclo*-phosphate was well dissolved in the alkaline solution. Accordingly, the progress of the hydrolysis of the *cyclo*-phosphate to tetraphosphate was observed visually by the clarification of the solution. After being filtered, the solution was neutralized with 1 mol dm^{-3} hydrochloric acid to pH 10 at a temperature below 3 °C to prevent the hydrolysis of the tetraphosphate. An aqueous solution of strontium chloride or barium chloride, which was made by dissolving 20 g of strontium and barium chlorides in 20 and 50 cm^3 of water respectively, was added to the tetraphosphate solution. A white precipitate was filtered off, washed with cold water, ethanol, and acetone, and then dried under reduced pressure at 25 °C.

Paper Chromatography. One-dimensional paper chromatography was used for the identification of phosphates with acidic and basic developing solvents.[15] The acidic and basic solvents were used for the separation of chain and ring phosphates respectively. About 0.5 g of a sample was dissolved in 50 cm^3 of a 6% aqueous EDTA solution. About 8 mm^3 of the solution was spotted on Toyo No. 51A filter paper (2 by 50 cm). The development was carried out in a thermostat at 5 °C for 2 d. The determination of the phosphate on the chromatogram was made by the method described in our previous paper.[13]

Determination of Phosphorus, Strontium, and Barium in the Products. About 0.2 g of the strontium tetraphosphate and about 0.75 g of EDTA was dissolved in water and diluted to the mark by using a 100-cm^3 volumetric flask. About 0.5 g of the barium tetraphosphate was dissolved in a diluted hydrochloric acid solution and the total volume was made 100 cm^3 with water. The determination of phosphorus in the sample solutions was made by means of the molybdenum-blue method with Lucena-Conde and Prat's reagent.[16] The amounts of strontium and barium in the sample solutions were determined by the EDTA back titration and the gravimetric technique respectively.

X-Ray Diffractometry. The X-ray diffraction diagrams of the samples were taken with nickel-filtered Cu $K\alpha$ radiation by using a Toshiba X-ray diffractometer, ADG-102.

DTA and TG. The samples were heated at a heating rate of 5 °C min^{-1} with a Cho Balance $TRDA_1$-H-type apparatus.

IR Measurement. IR spectra of samples were recorded on a JASCO IR spectrophotometer, A-3, using the KBr disk method.

Determination of Bound Water. The amount of bound water in a sample was determined by the Karl Fisher method with an MK-AII apparatus by Kyoto Denshi.

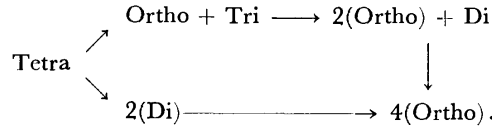
Decomposition in Air. The decomposition of the product at 25—30 °C in air was studied by paper chromatography, X-ray diffractometry, and IR spectrometry as described above.

Results and Discussion

Composition of the Product. The paper-chromatographic identification of the products showed that the products were composed of tetraphosphate. Strontium and barium ions had no serious effect on the development of the phosphates. The P/M (M:

Sr or Ba) ratios of the products were 1.30 and 1.33 for the strontium and barium salts respectively. Accordingly, the products were strontium tetraphosphate, $Sr_3P_4O_{13}$, and barium tetraphosphate, $Ba_3P_4O_{13}$. The strontium and barium phosphates contained about 23—14 and 14—8% of water respectively depending on the washing condition with ethanol and acetone. The products were X-ray diffractometrically amorphous.

Decomposition in Air at 25—30 °C. The stability of the tetraphosphates was studied in air at 25—30 °C. As Table 1 shows, the strontium tetraphosphate decomposed to phosphates having shorter chain lengths. The water contents in the decomposition product decreased as the passage of time, so the decomposition seemed to be caused by the bound water. The IR spectra of the decomposition products of the strontium tetraphosphate are shown in Fig. 1. The assignment of the absorptions is listed in Table 2. The intensity of the absorptions due to a $(PO_2)^-$ group decreased with the elapse of reaction time and finally disappeared. The result agrees well with that in Table 1. The following degradation process can be concluded from these results:



The decomposition product was amorphous even after 30 d. Since a part of the decomposition product of the barium tetraphosphate seemed to be insoluble in an aqueous EDTA solution, the decomposition of the phosphate could not be studied by the paper chromatography method. The IR spectra of the decomposition products of the barium tetraphosphate are shown in Fig. 2. The intensity of the absorption due to a $(PO_2)^-$ group decreased with time so the tetraphosphate seemed to decompose to phosphates with shorter chain lengths. The X-ray diffraction diagrams of the decomposition products of the phosphate are shown in Fig. 3. The decomposition product gave weak peaks at 16 d, and the intensity of the peaks increased with time. These peaks are all assigned to those of barium diphosphate–water (5/12), which is made by adding an aqueous barium chloride solution to an aqueous sodium diphosphate solution. The result agrees well with that of IR spectra. The water used for the decomposition of the phosphate may be the bound water in the product because, as Table 3 shows, the water content of the product decreased

with time.

DTA and TG. DTA and TG curves of the strontium tetraphosphate are given in Fig. 4. The samples as numbered on Fig. 4 were removed from a furnace, cooled in a silica-gel desiccator, and subjected to further analysis. The results are presented in Table 4 and Figs. 5 and 6. Samples No. 1 and No. 2 were soluble in water, but No. 3 was insoluble in water. So the composition of phosphates in No. 3 could not be studied by paper chromatography. A rapid weight loss of the product and a corresponding big endothermic peak were observed below 150 °C. This reaction seemed to be caused by removing the bound water and, as Table 4 shows, the decomposition of the tetraphosphate to phosphates having shorter chain lengths occurred at the same time. The succeeding gradual weight loss of the product from 150—380 °C is the condensation reaction of the decomposition product. Samples No. 1 and No. 2 were X-ray diffractometrically amorphous, but, as Fig. 6 shows, sample No. 3 gave X-ray diffraction peaks of α-$Sr_2P_2O_7$ (ASTM card, No. 24-1011) and $Sr_3P_4O_{13}$ (ASTM card, No. 20-1207). So the exothermic peak at about 540 °C may be due to the crystallization of the amorphous phosphates.

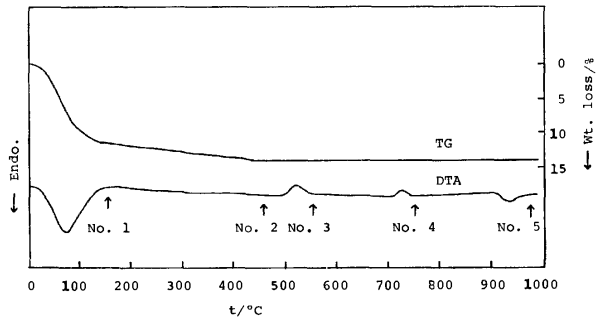

Fig. 7. DTA and TG curves of the barium tetraphosphate in air.

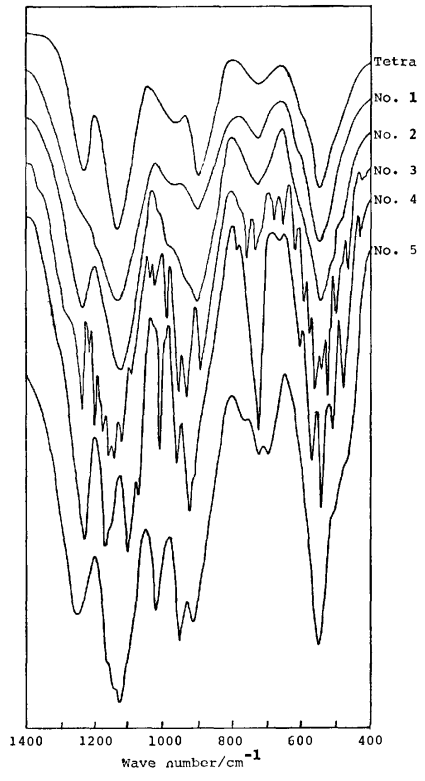

Fig. 8. IR spectra of the thermal decomposition products (Nos. 1—5) of the barium tetraphosphate in air.

The curves of DTA and TG measurements of the barium tetraphosphate are shown in Fig. 7. The tetraphosphate showed a rapid weight loss accompanied by a big endothermic peak. The process was considered to be caused by the elimination of the bound water. As Fig. 8 shows, the absorption of a $(PO_2)^-$ group disappeared in the IR spectrum of No. 2, while the sample still showed the absorptions of a P–O–P linkage. This means that the tetraphosphate decomposes to phosphates with shorter chain lengths and the main decomposition product is diphosphate. The gradual weight loss seemed to be due to the condensation of the decomposed phosphates since, as Fig. 8 shows, sample No. 3 showed the IR absorption of a $(PO_2)^-$ group at about 1240 cm^{-1}. Samples No. 1 and No. 2 were amorphous and No. 3 gave the unknown X-ray diffraction peaks shown in Fig. 9. So the exothermic peak around 520 °C is attributable to the crystallization of the phosphates. After the second

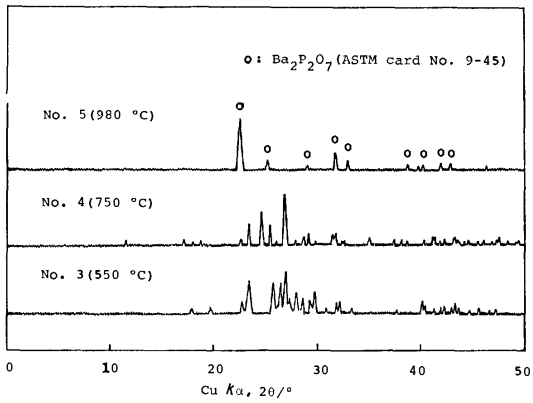

Fig. 9. X-Ray diffraction diagrams of the thermal decomposition products (Nos. 3—5) of the barium tetraphosphate in air.

exothermic peak, the sample gave different X-ray diffraction peaks. The small endothermic peak at about 930 °C was caused by melting of a part of the phosphates because the product was sintered after the endothermic reaction. The last product gave the X-ray diffraction pattern of barium diphosphate (ASTM card, No. 9-45), while the IR spectrum of No. 5 gave the absorption associated with a $(PO_2)^-$ group. Therefore, sample No. 5 was considered to be a mixture of crystalline barium diphosphate and amorphous polyphosphates having a middle-PO_4 group.

Preparation and Spectroscopic Characterization of Substituted Pentacyanoferrates(II) with Phosphine or Phosphite Ligands

Hidenari INOUE,* Masahiro SASAGAWA, Ekkehard FLUCK,† and Tsuneo SHIRAI

Department of Applied Chemistry, Faculty of Science and Technology, Keio University, 3-14-1, Hiyoshi, Kohoku-ku, Yokohama 223

†*Institut für Anorganische Chemie, Universität Stuttgart, Pfaffenwaldring 55, D-7000 Stuttgart 80, FRG*

(Received May 6, 1983)

Twenty-two substituted pentacyanoferrates(II) with the formula $Na_3[Fe(CN)_5PX_3]\cdot 2H_2O$ (PX_3 = phosphine or phosphite) have been prepared by ligand substitution of sodium amminepentacyanoferrate(II). The phosphite complexes show smaller isomer shifts than the phosphine complexes. The phosphine complexes involving an aryl or bulky phosphine exhibit larger quadrupole splitting than the phosphite complexes. These tendencies in Mössbauer parameters are discussed in terms of the π-acceptor capability of the phosphine and phosphite ligands. The linear dependence of the isomer shifts on both CN stretching frequencies and d-d transition energies is interpreted on the basis of the predominance of iron-to-phosphorus π back-donation.

Substantial interest continues in substituted pentacyanoferrates(II) prepared from hexacyanoferrates(II) by replacing one of the six cyanide ligands with a ligand having a nitrogen donor atom. In recent years a wide variety of substituted pentacyanoferrates(II) have been synthesized and extensively studied by Mössbauer,[1-3] ^{13}C NMR,[4-6] and X-ray photoelectron spectroscopy.[7-8] The focus of these spectroscopic studies is the Fe–N bond between the central iron(II) ion and the nitrogen-containing ligand. Substituted pentacyanoferrates(II) in which the sixth ligand is a phosphine or phosphite have received relatively little attention although they provide an excellent opportunity for investigating the Fe–P bond by spectroscopic methods. Spectroscopic investigations on these phosphine and phosphite complexes have been limited almost wholly to a few complexes having the phosphine as the sixth ligand of octahedral coordination.[9-10]

We have prepared a series of substituted pentacyanoferrates(II) of the type $Na_3[Fe(CN)_5PX_3]\cdot 2H_2O$, where PX_3 is a phosphine or phosphite ligands. The functional groups adjacent to the phosphorus ligand atom was varied systematically in order to understand the Fe–P bond on the basis of the σ-donor and π-acceptor properties of the phosphine and phosphite ligands. Another purpose of the present work is to learn how the functional groups attached to the donor phosphorus atom affect the electronic structure of the $[Fe(CN)_5PX_3]^{3-}$ moiety and how the coordination of the phosphine or phosphite ligand influences the Fe–C bonding between the iron(II) ion and the cyanide ligands.

Experimental

Materials. Sodium amminepentacyanoferrate(II) was prepared by a method in the literature.[11] Phosphine and phosphite ligands were purchased from Strem Chemicals Inc. and used without further purification. All solvents used were analytical reagent grade, except that the methanol used for measurement of the electronic spectra was spectrophotometric solvent grade obtained from Kanto Chemical Co., Inc.

Preparation of Compounds. Manupulations involving air-sensitive materials were performed in a nitrogen-filled glovebox. General aspects of the experimental techniques are similar to those described in the literature.[12] Typical procedures are described in detail here only for $Na_3[Fe(CN)_5P(CH_3)_3]\cdot 2H_2O$ and $Na_3[Fe(CN)_5P(OCH_3)_3]\cdot 2H_2O$. To a suspension of 1.0 g (3.1 mmol) of $Na_3[Fe(CN)_5NH_3]\cdot 3H_2O$ in 25 ml of methanol was added 0.28 g (3.7 mmol) of $P(CH_3)_3$. The reaction slurry was vigorously stirred in the dark at room temperature for 24 h. Filtration of the resultant heterogeneous reaction mixture afforded a yellow solution. Careful addition of 150 ml of diethyl ether to the filtrate caused a yellow solid to precipitate. This was filtered, recrystallized from methanol, and dried over silica gel. To a vigorously stirred suspension of 1.0 g (3.1 mmol) of $Na_3[Fe(CN)_5NH_3]\cdot 3H_2O$ in 25 ml of methanol was added 0.80 g (6.4 mmol) of $P(OCH_3)_3$. After stirring of the reaction slurry in the dark at room temperature for 24 h, the resulting yellow reaction mixture was filtered off. Diethyl ether (200 ml) was added to the filtrate to precipitate a pale yellow solid, which was filtered with a glass filter, recrystallized from methanol, and dried over silica gel. The compounds were identified by elemental analysis (C, H, and N), phosphorus spectrophotometry, and iron atomic absorption spectrophotometry.

Physical Measurements. Mössbauer spectra were obtained with a ^{57}Co source in palladium (The Radiochemical Centre, Amersham, England) using a Wissel constant-accelaration transducer coupled with a Canberra OMEGA-1 multichannel analyzer operated in time mode. The spectra obtained at 77 and 293 K were fitted to Lorentzian curves with an iterative least-squares computer program. The isomer shifts were referred to the symmetry center of six absorption lines of natural iron foil at 293 K. Infrared spectra were recorded with a Hitachi Perkin-Elmer Model 225 grating infrared spectrophotometer in the range 200 to 4000 cm^{-1} and with a JASCO A-3 infrared spectrophotometer in the range 330 to 5000 cm^{-1} using Nujol mulls and KBr pellets. Electronic spectra of the substituted pentacyanoferrates(II) in methanol solution were recorded on a JASCO UVIDEC-1 digital double-beam spectrophotometer in the range 200 to 800 nm using 1-cm quartz cells.

Results and Discussion

Preparation of Complexes. All the compounds were obtained as pale yellow, pale blue, or colorless fine crystalline powders. Two of twenty-two substituted pentacyanoferrates(II) were not obtained in a pure form. Among the phosphine ligands tris(4-di-

methylaminophenyl)phosphine failed to give pure $Na_3[Fe(CN)_5P(C_6H_4N(CH_3)_2)_3]\cdot 2H_2O$ because the ligand is only slightly soluble in methanol. A mixture of methanol and acetone (1:1) was used to improve the solubility of the ligand and the reaction product. However, the Mössbauer spectra of the products always gave a couple of quadrupole-splitting doublets, indicating that the desired product was contaminated. Among the phosphite ligands triphenyl phosphite appeared to undergo ester interchange with the solvent, *i.e.*, with methanol to yield four different types of phosphite complexes with mixed phosphites such as $P(OC_6H_5)_3$, $P(OC_6H_5)_2(OCH_3)$, $P(OC_6H_5)(OCH_3)_2$, and $P(OCH_3)_3$. The existence of these four pentacyanophosphiteferrate(II) species was confirmed by ^{31}P NMR spectroscopy because each coordinated phosphite ligand shows a characteristic chemical shift. When *N,N*-dimethylformamide was used in place of methanol as the solvent, the desired complex was contaminated by sodium pentacyano(*N,N*-dimethylformamide)ferrate(II). This contamination was confirmed by a comparison of Mössbauer parameters.

Effect of Axial Ligand on Isomer Shift. The series of complexes prepared here are suitable model compounds for studying the Fe–P bond without changing the type of coordination bonding, *i.e.*, the atomic orbital which participate in the Fe–P bond. Especially Mössbauer spectroscopy provides a sophisticated means to characterize the Fe–P bond in the present complexes. Typical Mössbauer spectra obtained are presented in Fig. 1. Most of our complexes gave a symmetric quadrupole-splitting doublet although the

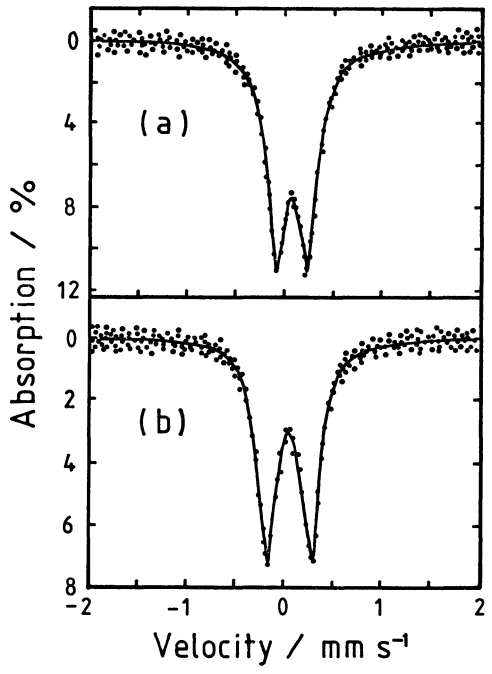

Fig. Typical Mössbauer spectra of (a) $Na_3[Fe(CN)_5P(CH_3)_3]\cdot 2H_2O$ and (b) $Na_3[Fe(CN)_5P(OC_2H_5)_3]\cdot 2H_2O$ at 77 K.

complexes having diphenylphosphine or phenylphosphine ligand showed an asymmetric doublet even at 77 K. In these complexes the higher velocity component of the quadrupole-splitting doublet was always stronger than the lower one, and this asymmetry remained even in measurements with finely ground powders. The Mössbauer parameters are summarized in Table 2. The isomer shifts at 77 K are more positive than those at 293 K due to the second-order Doppler shift. The isomer shifts obtained at 293 K range from −0.075 to 0.012 mm/s and fall into the range characteristic of low-spin iron(II) complexes.

In general the isomer shift in iron compounds increases with a decrease in total electron density at the iron nucleus.[13] Electrons other than s electrons do not contribute directly to the total electron density at the iron nucleus, *i.e.*, to the isomer shift, because of a negligibly small probability density at the nucleus. However, d electrons affect the total electron density at the iron nucleus through the so-called shielding effect. The change in the isomer shift is interpreted mainly by the following two mechanisms; ligand-to-metal σ donation and metal-to-ligand π back-donation. Both mechanisms increase the total electron density at the iron nucleus, and hence decrease the isomer shift of iron complexes. The decreasing tendency of isomer shifts is clearly associated with the σ-donor and π-acceptor capability of the ligand PX_3, *i.e.*, the electronic properties of functional group X attached to the phosphorus atom. An increased σ-donor capability of the phosphorus ligand increases the s-electron density at the iron nucleus through the formation of the phosphorus-to-iron σ bonding. Increased π-acceptor capability of the phosphorus ligand also increases the s-electron density at the nucleus through π back-donation from the iron d_π orbital to the vacant

a) With uncertainty of 0.005 mm/s.

phosphorus π or d_π orbitals. Therefore, the σ-donor capability can not be readily differentiated from the π-acceptor capability by the isomer shift value, which reflects only the total electron density at the iron nucleus.

The isomer shifts of phosphite complexes are smaller than those of phosphine complexes. This indicates that the higher the electronegativity of the atom adjacent to the phosphorus atom the larger the isomer shift of the complexes. The electron-attracting and electron-releasing power of the substituent at the 4 position of the triarylphosphines is associated with the Hammett substituent constant, which decreases in the order $-Cl>-F>-H>-CH_3>-OCH_3>-N(CH_3)_2$.[14] This order was expected to be directly connected with the isomer shifts observed for $Na_3[Fe(CN)_5PX_3]\cdot 2H_2O$, where PX_3 is an arylphosphine with a substituent at the 4 position. However, no significant linear correlation could be established between the isomer shift and the Hammett substituent constant. Thus the substituent X on the aryl group is located too far away to affect the electron density at the iron nucleus, *i.e.*, the isomer shift of the central iron atom *via* the mesomeric or inductive effect.

The isomer shift of the complexes involving a phenylphosphine increases clearly in the sequence: $P(C_6H_5)_3<P(C_6H_5)_2H<P(C_6H_5)H_2$. The substitution of a phenyl group for a hydrogen diminishes the π-acceptor capability of the phosphorus donor atom and decreases the iron-to-phosphorus π back-donation. Consequently, this decrease in the back donation agrees

with the increased isomer shift observed for the complex having the phenylphosphine.

Influence of Local Symmetry on Quadrupole Splitting. The symmetry group of the $[Fe(CN)_5PX_3]^{3-}$ moiety is approximated as C_{4v} if the geometry of the three functional groups directly attached to the phosphorus atom is ignored. In $Na_3[Fe(CN)_5PX_3]\cdot 2H_2O$ the symmetry around the iron nucleus is distorted from the O_h symmetry to which the $Fe(CN)_6^{4-}$ moiety of sodium hexacyanoferrate(II) belongs. The local site symmetry of the $[Fe(CN)_5PX_3]^{3-}$ moiety is reflected in the quadrupole splitting of the Mössbauer spectra. All the complexes of the type $Na_3[Fe(CN)_5PX_3]\cdot 2H_2O$ show quadrupole splitting, whereas the octahedrally symmetric sodium hexacyanoferrate(II) shows no quadrupole splitting at all.[15] The quadrupole splittings of $Na_3[Fe(CN)_5PX_3]\cdot 2H_2O$ are relatively small and typical of low-spin iron(II) complexes. They increase slightly on lowering the temperature to 77 K since the low-spin iron(II) complex usually has only a small valence contribution to the electric field gradient at the iron nucleus. The arylphosphine complex gives a larger quadrupole splitting than does the alkylphosphine complex. This is presumably due to the bulkiness of the aryl groups. The quadrupole splitting values of the phosphite complex, as well as the complex with a ligand intermediate between phosphine and phosphite, lie between those of arylphosphine and alkylphosphine complexes.

The quadrupole splitting is plotted against the isomer shift in Fig. 2. A linear plot was obtained (r=0.702) for the measurements at 77 K.[16] Good correlation was not found (r=0.505) for the measurements at 293 K, probably due to the pronounced contribution of the second-order Doppler effect to the isomer shift. The isomer shift data alone do not always reveal which is dominant, the σ-donation or the π back-donation, because both increase the electron density at the iron nucleus and consequently decrease the isomer shift. Despite their similar contribution to the isomer shift the linear dependence of the quadrupole splitting on the isomer shift provides a useful means of estimating

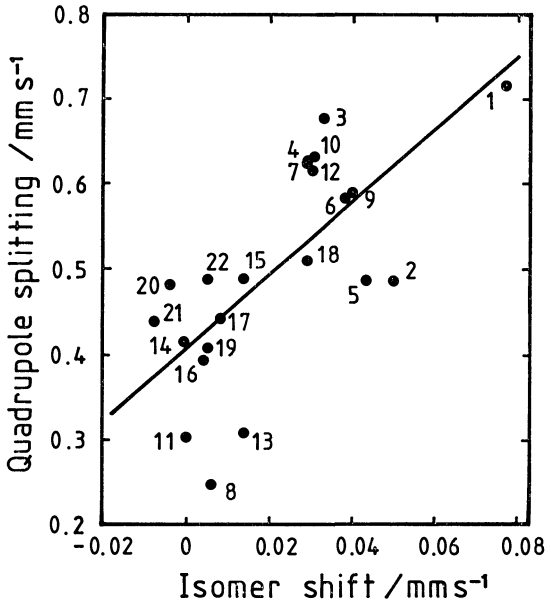

Fig. 2. Plots of quadrupole splittings against isomer shifts (at 77 K).

the relative importance of the σ-donor or π-acceptor capability.[17] The linear dependence with a positive slope demonstrates that the σ-donation is offset by the π-acceptor, *i.e.*, the π-acceptor capability is dominant in the present complexes.

Dependence of IR Frequencies on π-Acceptor Capability of Ligand PX_3. The infrared frequencies are summarized in Table 3. The ν_{CN} stretching modes referred to as $\nu_{CN}(1)$, $\nu_{CN}(2)$, and $\nu_{CN}(3)$ in Table 3 appeared in the range 2030—2100 cm^{-1}. The observation of two or three ν_{CN} stretching bands is consistent with the group-theoretical prediction that the point group of the $[Fe(CN)_5PX_3]^{3-}$ moiety is approximately C_{4v}. The dependence of the ν_{CN} stretching frequencies on the isomer shift is useful for estimating the π-acceptor capability of the ligand PX_3. As shown in Fig. 3, all the frequencies observed for the $\nu_{CN}(1)$, $\nu_{CN}(2)$, and $\nu_{CN}(3)$ stretching modes decrease as the isomer shifts increase. This decrease in the ν_{CN} stretching frequencies reflects the reduced Fe-to-P π back-donation. The stronger the π-acceptor capability of the ligand PX_3 is the more the d_π electrons of the central iron atom are withdrawn towards the ligand through π back-donation. Alternatively, the decreased electron density in the iron d_π orbitals is compensated for by increased electron flow from the cyanide ligands to the central iron atom through the inverse π back-donation. Thus the decreased electron population in the antibonding π^* orbitals of the cyanide ligands causes the ν_{CN} stretching frequencies to increase. The relative increase in the Fe-to-P back-donation gives rise to the increased total electron density at the iron nucleus because of the decreased shielding effect of its d_π electrons and hence leads to the decreased isomer shift. This indicates that the greatly increased π back-donation from the filled iron d_π orbitals to the phosphorus orbitals is not offset, even by the decreased π back-donation to the cyanide ligands. All the ν_{CN} stretching modes belonging to the two different species $2A_1+E$ showed the same tendency with regard to the dependence of the ν_{CN} stretching frequencies on the isomer shifts. The empty antibonding π^* orbitals of both axial and radial cyanide ligands participate in overlapping with the identical d_π orbitals to form the π bonding between Fe and C. Accordingly, the same tendency observed for three different ν_{CN} stretching modes is due to the synergetic effect of the d_π orbitals of the central iron atom on the axial and radial cyanide ligands.

The ν_{Fe-C} stretching and δ_{Fe-CN} bending modes appeared in the ranges 400—500 and 576—586 cm^{-1}, respectively. The ν_{Fe-C} stretching mode of the complexes with a phosphine ligand tends to show higher absorption frequencies than those with a phosphite ligand. This tendency agrees with the fact that the Fe-to-P back-donation is generally larger in phosphite complexes than in phosphine complexes. On the other hand, the absorption frequencies of the δ_{Fe-CN} bending modes were almost independent of the kind of phosphorus ligand. The ν_{Fe-P} stretching and δ_{Fe-P} bending modes are expected to be direct evidence for the Fe–P bonding. Unfortunately, no absorption band could be observed for our complexes, presumably because these absorption bands are of very weak intensity or lie outside of the present experimental region.

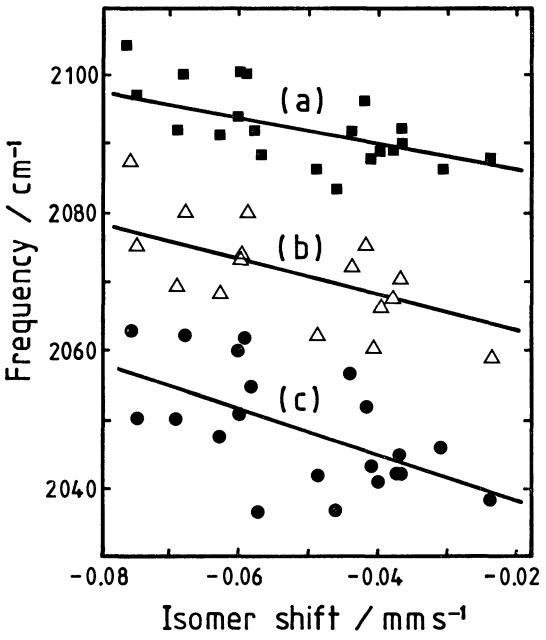

Fig. 3. Dependence of three different ν_{CN} stretching frequencies on isomer shifts. (a), (b), and (c) correspond to a regression line for the $\nu_{CN}(1)$, $\nu_{CN}(2)$, and $\nu_{CN}(3)$ stretching modes. Plots of compound No. 1 are not shown here due to its large positive isomer shift (at 293 K).

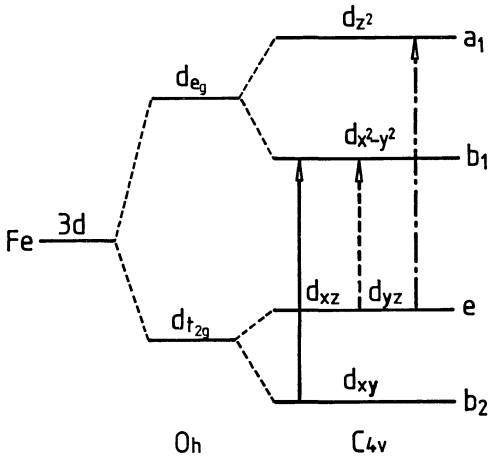

Fig. 4. Energy-term diagram for the $[Fe(CN)_5PX_3]^{3-}$ moiety. (a) $^1A_1 \rightarrow E(1)$ (—·—·—), (b) $^1A \rightarrow {}^1A_2$ (——), and (c) $^1A_1 \rightarrow E(2)$ (----).

Correlation between d-d Transition Energy and π Back-Donation. The absorption bands observed in the electronic spectra are presented in Table 4 together with their assignment. The electronic spectra of these complexes are so similar to those of the usual substituted pentacyanoferrates(II) that the absorption bands were assigned by comparison with the band assignment for substituted pentacyanoferrates(II) such as sodium pentacyanonitrosylferrate(II).[18] The partial energy-term diagram of the $[Fe(CN)_5PX_3]^{3-}$ moiety (symmetry group C_{4v}) is schematically shown in Fig. 4. A strong absorption band observed in the range 26×10^3—32×10^3 cm^{-1} is assigned to the transition $^1A_1 \rightarrow E(1)$ ($e \rightarrow a_1$). A relatively weak absorption band assigned to the transition $^1A_1 \rightarrow E(2)$ ($e \rightarrow b_1$) appeared in the range 15×10^3—21×10^3 cm^{-1}. A weak shoulder band around 25×10^3 cm^{-1} is assigned to the transition $^1A_1 \rightarrow {}^1A_2$ ($b_2 \rightarrow b_1$) although it is partially hidden by the strong absorption band resulting from the transition $^1A_1 \rightarrow E(1)$. The band position of the transition $^1A_1 \rightarrow {}^1A_2$ is hardly affected by the variation in the axial phosphine or phosphite ligand, while those of the other transitions, $^1A_1 \rightarrow E(1)$ and E(2), vary with the kind of axial ligand. This is due to the fact that both transitions $^1A_1 \rightarrow E(1)$ and E(2) involve the d_{xz} and d_{yz} orbitals directed towards the axial phosphine or phosphite ligand.

The transition energies of the d-d absorption bands are correlated with the isomer-shift values since both ligand field parameters and Mössbauer parameters are associated with the π-acceptor capability of the axial ligand.[19] The plots of the d-d transition energies *vs.* the isomer shift values are shown in Fig. 5. The energies of the transitions $^1A_1 \rightarrow E(1)$ and E(2) decrease as the isomer shifts increase, whereas the energy of the transition $^1A_1 \rightarrow {}^1A_2$ is almost independent of the variation in the isomer shifts as the axial phosphine or phosphite ligands are changed. This relationship between the d-d transition energies and the isomer shifts can be also explained on the basis of the Fe-to-P π back-donation. The energy level e (shown in Fig. 4) is lowered by the enhanced Fe-to-P π back-donation so that the energies of the transitions $^1A_1 \rightarrow E(1)$ and E(2) are increased and shifted to the higher frequency side.

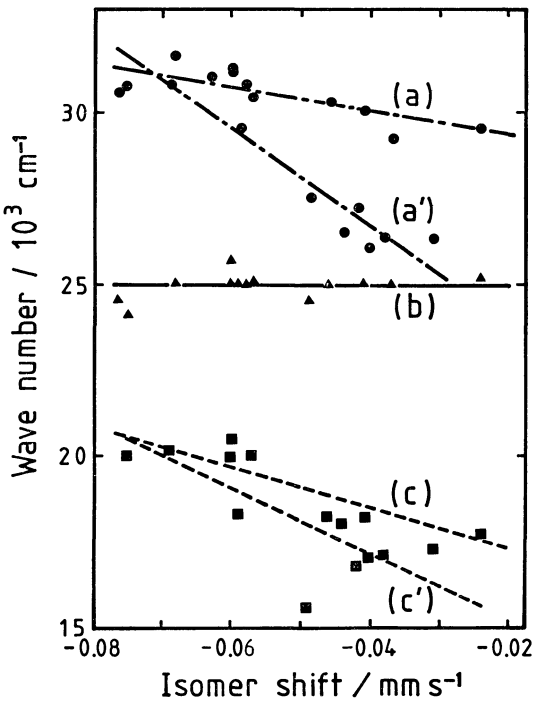

Fig. 5. Plots of d-d transition energies *vs.* isomer shifts (at 293 K). (a) and (c) are a regression line for alkylphosphine complexes, (a') and (c') for arylphosphine complexes, and (b) for both phosphine complexes. Plots of compound No. 1 are not shown here due to its large positive isomer shift.

A Complete Series of $[Co(acac)_x(en)_y(dmpe)_z]$ Complexes

Tomoji Ohishi, Kazuo Kashiwabara, and Junnosuke Fujita*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received June 1, 1983)

A complete series of $[Co(acac)_x(en)_y(dmpe)_z]$ complexes was obtained by preparing four new complexes, $[Co(acac)(dmpe)_2]^{2+}$, $[Co(en)_2(dmpe)]^{3+}$, $[Co(en)(dmpe)_2]^{3+}$, and $[Co(acac)(en)(dmpe)]^{2+}$, where acac, en, and dmpe denote an acetylacetonate ion, ethylenediamine, and 1,2-bis(dimethylphosphino)ethane, respectively. Except for $[Co(acac)(dmpe)_2]^{2+}$, the three new complexes were resolved into optical isomers by SP-Sephadex column chromatography. Absorption and circular dichroism spectra of all the complexes were recorded and compared with one another.

In a previous paper,[1] we reported ten $[Co(en)_x(tn)_y(tmd)_z]^{3+}$ ($x,y,z=0,1,2$, or 3; $x+y+z=3$) complexes as the first example of a complete series of the $[Co(AA)_x(BB)_y(CC)_z]$-type complexes, where en ($NH_2CH_2CH_2NH_2$), tn ($NH_2CH_2CH_2CH_2NH_2$), and tmd ($NH_2CH_2CH_2CH_2CH_2NH_2$) form a five-, six-, and seven-membered chelate ring, respectively upon coordination. This paper reports the second example of a complete series-complexes belonging to the same type. The complexes are those of the type, $[Co(acac)_x(en)_y(dmpe)_z]$, where acac (acetylacetonate ion), en, and dmpe (1,2-bis(dimethylphosphino)ethane) are typical chelate ligands with O,O, N,N, and P,P donor atoms, respectively. Of the ten complexes belonging to this series, known complexes are the series of $[Co(acac)_{3-n}(en)_n]^{n+}$ ($n=0,1,2,3$), $[Co(acac)_2(dmpe)]^+$,[2] and $[Co(dmpe)_3]^{3+}$,[3] and there remain four unknown complexes, $[Co(acac)(dmpe)_2]^{2+}$, $[Co(en)_2(dmpe)]^{3+}$, $[Co(en)(dmpe)_2]^{3+}$, and $[Co(acac)(en)(dmpe)]^{2+}$, all of which contain the dmpe ligand. Preparative work on such series-complexes comprised of ligands with remarkably different donor properties will be useful for elucidating such properties as stability or electronic spectra of metal complexes.

Experimental

1,2-Bis(dimethylphosphino)ethane, $(CH_3)_2PCH_2CH_2P(CH_3)_2$ was prepared by the literature method,[4] and handled under nitrogen atmosphere until it formed cobalt(III) complexes. Oxygen-free solvents were obtained by bubbling nitrogen for 20 min immediately before use. Absorption and circular dichroism (CD) spectra were recorded on a Hitachi 323 spectrophotometer and a JASCO J-40CS spectropolarimeter, respectively.

Preparation of Complexes. *$[Co(en)_2(dmpe)]Br_3\cdot H_2O$*: To a solution of $[Co(en)_3](ClO_4)_3$[5] (473 mg, 1.4 mmol) in oxygen-free dimethyl sulfoxide (100 cm³) were added dmpe (210 mg, 1.4 mmol) and active charcoal (100 mg). The mixture was stirred for a day at room temperature and filtered. The filtrate was diluted with water (1 dm³) and poured on a column (ϕ3.5 cm × 150 cm) of SP-Sephadex C-25. The product adsorbed was eluted with 0.2 mol dm^{-3} NaCl, giving three bands in the order of $[Co(en)(dmpe)_2]^{3+}$ (very small amount), $[Co(en)_2(dmpe)]^{3+}$, and $[Co(en)_3]^{3+}$. The effluent of the second band was diluted five times with water and poured again on a small column (ϕ3.5 cm × 10 cm) of SP-Sephadex C-25. The complex adsorbed was eluted with 1 mol dm^{-3} NaBr, and the effluent was concentrated in a vacuum desiccator over P_4O_{10} to yield yellow crystals, which were filtered, washed with cold methanol–diethyl ether (1:5), and air-dried. Yield: 92 mg (16%). Found: C, 20.46; H, 5.84; N, 9.25%. Calcd for $C_{10}H_{34}N_4CoBr_3OP_2=[Co(en)_2(dmpe)]Br_3\cdot H_2O$: C, 20.46; H, 5.84; N, 9.54%. The complex is soluble in water, methanol, and dimethyl sulfoxide, but insoluble in diethyl ether.

$[Co(en)(dmpe)_2]Br_3$: To a solution of *trans*-$[CoCl_2(dmpe)_2]ClO_4$[3] (300 mg, 0.57 mmol) in oxygen-free methanol (100 cm³) was added excess en (180 mg, 2.9 mmol). The mixture was stirred for a day at room temperature, and diluted with water (1 dm³). The solution was poured on a column (ϕ3.5 cm × 150 cm) of SP-Sephadex C-25. By elution with 0.2 mol dm^{-3} NaCl, the product adsorbed gave four bands in the order of *trans*-$[CoCl_2(dmpe)_2]^+$, $[Co(en)(dmpe)_2]^{3+}$, $[Co(en)_2(dmpe)]^{3+}$ (very small amount), and $[Co(en)_3]^{3+}$. Orange crystals of the desired complex were obtained from the effluent of the second band by the same method as that for $[Co(en)_2(dmpe)]^{3+}$. Yield: 67 mg (18%). Found: C, 25.15; H, 6.23; N, 4.19%. Calcd for $C_{14}H_{40}N_2Br_3CoP_4=[Co(en)(dmpe)_2]Br_3$: C, 25.52; H, 6.12; N, 4.25%. The complex is soluble in water, methanol, and dimethyl sulfoxide, but insoluble in diethyl ether.

$[Co(acac)(dmpe)_2](PF_6)_2$: To a solution of *trans*-$[CoCl_2(dmpe)_2]ClO_4$ (163 mg, 0.31 mmol) in oxygen-free methanol (100 cm³) was added Li(acac) (32.6 mg, 0.31 mmol). The color of the solution changed immediately from blue-green to orange. After 30 min the solution was diluted with water (1 dm³) and poured on a column (ϕ3.5 cm × 150 cm) of SP-Sephadex C-25. By elution with 0.2 mol dm^{-3} NaCl, only orange-yellow effluent was obtained. The effluent was evaporated to dryness under reduced pressure, and the residue was extracted with methanol. On addition of excess $NaPF_6$ (100 mg) in water (5 cm³) the extract gave orange crystals, which were filtered, washed with cold water, and air-dried. Yield: 168 mg (73%). Found: C, 26.97; H, 5.01%. Calcd for $C_{17}H_{39}CoF_{12}O_2P_6=[Co(acac)(dmpe)_2](PF_6)_2$: C, 27.29; H, 5.25%. The complex is soluble in methanol, ethanol, and acetonitrile, but hardly soluble in water.

$[Co(acac)(en)(dmpe)](PF_6)_2\cdot H_2O$: To an oxygen-free methanol solution (100 cm³) of $[Co(acac)_2(en)]PF_6$ (660 mg, 1.53 mmol) which had been prepared from $[Co(acac)_2(en)]ClO_4$[6] and $NaPF_6$ was added dmpe (230 mg, 1.53 mmol). The mixture was kept at 50 °C for 5 h, and then mixed with water (400 cm³) and diethyl ether (100 cm³) to extract unreacted dmpe into diethyl ether. The aqueous layer was diluted with water (1 dm³) and poured on a column (ϕ3.5 cm × 150 cm) of SP-Sephadex C-25. By elution with 0.2 mol dm^{-3} Na_2SO_4, $[Co(acac)_2(dmpe)]^+$ (red), $[Co(acac)(en)(dmpe)]^{2+}$ (orange-red), and $[Co(acac)(dmpe)_2]^{2+}$ (orange-yellow) were eluted accompanying with a few very small brown bands. The effluent of the second orange-red band was collected and evaporated to dryness under reduced pressure. To the residue was added a small amount of methanol to extract the complex. On addition of excess $NaPF_6$ (200 mg) in water (5 cm³) the extract gave orange-

red crystals, which were filtered, washed with cold water, and air-dried. Yield: 40 mg (4%). Found: C, 23.90; H, 5.16; N, 4.13%. Calcd for $C_{13}H_{33}N_2CoF_{12}O_3P_4$=[Co(acac)(en)(dmpe)]$(PF_6)_2\cdot H_2O$: C, 24.13; H, 4.83; N, 4.33%. The complex is soluble in methanol, ethanol, and acetonitrile, but hardly soluble in water.

Known complexes, $[Co(acac)_3]$,[7] $[Co(acac)_2(en)]ClO_4$,[6] $[Co(acac)(en)_2]I_2$.[8] $[Co(en)_3](ClO_4)_3$,[5] $[Co(acac)_2(dmpe)]PF_6$,[2] and $[Co(dmpe)_3](ClO_4)_3$[3] were prepared by the literature methods.

Optical Resolution of Complexes. *[Co(en)$_2$(dmpe)]$^{3+}$*: The complex was resolved by a chromatographic method with a column (ϕ3.5 cm × 120 cm) of SP-Sephadex C-25 and an eluent of 0.1 mol dm^{-3} $Na_2[Sb_2(d\text{-tartrate})_2]$. $[Co(en)_2(dmpe)]Br_3\cdot H_2O$ (*ca.* 30 mg) charged on the top of the column was resolved completely by elution with the eluent. From each effluent, the optically active complex was isolated as bromide by the same method as that for the racemate. The slow-moving enantiomer has been determined to be Λ-$(+)_{589}$-$[Co(en)_2(dmpe)]Br_3\cdot 1/2\ H_2O$ by X-ray analysis.[9]

[Co(acac)(en)(dmpe)]$^{2+}$: The complex was resolved by the same chromatographic method as the above. However, a poor separation between the bands of enantiomers was observed. The fractions having a constant value of $\Delta\varepsilon/\varepsilon$ were collected, diluted five times with water, and poured on a small column (ϕ1 cm × 10 cm) of SP-Sephadex C-25. The complex adsorbed was eluted with 0.2 mol dm^{-3} $NaPF_6$, and the effluent was used for the measurements of CD spectra without isolating the complex. The concentration of the complex was determined by reference to the ε values of the racemate. The active complex hexafluorophosphate is much more soluble in water than the racemic salt.

Other Complexes. The $[Co(en)(dmpe)_2]^{3+}$ and $[Co(acac)_2(dmpe)]^+$ complexes were resolved partially by the same chromatographic method as the above. No fractions having a constant value of $\Delta\varepsilon/\varepsilon$ were obtained. The column chromatographic method becomes less effective as the number of acac or dmpe ligand increases in the complex. No resolution was achieved for $[Co(acac)(dmpe)_2]^{2+}$.

Results and Discussion

Mixed complexes in the series of $[Co(acac)_{3-n}(en)_n]^{n+}$ can be easily prepared from the parent complexes by substitution reactions in fairly good yields; $[Co(acac)_2(en)]^+$ is prepared from $[Co(acac)_2(NO_2)_2]^-$ and en,[6] and $[Co(acac)(en)_2]^{2+}$ from $[CoCO_3(en)_2]^+$ [8] or $[CoCl(H_2O)(en)_2]^{2+}$ [10] and acac. However, most reactions of dmpe with a cobalt(III) complex accompany disproportionation or ligand scrambling, affording many complexes formed with dmpe and ligands contained in the starting complex. The reaction of $[Co(en)_3]^{3+}$ with dmpe in the ratio of 1:1 yields all complexes of the series, $[Co(en)_{3-n}(dmpe)_n]^{3+}$, and $[Co(en)_2(dmpe)]^{3+}$ is obtained in 16% yield. The formation of $[Co(en)(dmpe)_2]^{3+}$ is very small, and $[Co(dmpe)_3]^{3+}$ decomposes during the experiment of column chromatography. The reaction of *trans*-$[CoCl_2(en)_2]^+$ with dmpe also forms $[Co(en)_2(dmpe)]^{3+}$, but the yield is very poor, $[Co(en)_3]^{3+}$ and *trans*-$[CoCl_2(dmpe)_2]^+$ being formed in large amounts. The other mixed complex, $[Co(en)(dmpe)_2]^{3+}$ is obtained in 18% yield by the reaction of *trans*-$[CoCl_2(dmpe)_2]^+$ with excess en. The reaction with an equimolar amount of en is very slow, and on heating $[Co(en)_3]^{3+}$ and $[Co(dmpe)_3]^{3+}$ are formed as the major product. The (2-aminoethyl)dimethylphosphine (edmp) ligand also forms all complexes of the series, $[Co(en)_{3-n}(edmp)_n]^{3+}$ by reaction with *trans*-$[CoCl_2(en)_2]^+$.[11]

The $[Co(acac)(dmpe)_2]^{2+}$ complex is obtained in good yield by the reaction of *trans*-$[CoCl_2(dmpe)_2]^+$ with Li(acac) in the ratio of 1:1. The reaction takes place rapidly and gives no other complexes in detectable amount. The reaction of dmpe with $[Co(acac)_3]$ in the ratio of 1:1 yields all complexes of the series, $[Co(acac)_{3-n}(dmpe)_n]^{n+}$, the main product being $[Co(acac)_2(dmpe)]^+$.[2] Similar reactions of diphenylphosphine-type chelate ligands such as (2-aminoethyl)diphenylphosphine (edpp) or 1,2-bis(diphenylphosphino)ethane (dppe) with $[Co(acac)_3]$ give only bis(acac) complex, and no bis(edpp or dppe) complex is formed even in the presence of active charcoal.[12] The dmpe ligand is more reactive to Co(III) than edpp and dppe.

The $[Co(acac)(en)(dmpe)]^{2+}$ complex is obtained in 4% yield by the reaction of dmpe with $[Co(acac)_2(en)]^+$. The reaction between dmpe and $[Co(acac)(en)_2]^{2+}$ yields further less amount of the complex. In either reaction, $[Co(en)_3]^{3+}$, $[Co(acac)(dmpe)_2]^{2+}$, and $[Co(acac)_2(dmpe)]^+$ are formed in larger amounts.

While solid $[Co(dmpe)_3](ClO_4)_3$ is rather unstable in the air,[3] all of the dmpe complexes prepared in this study are stable in the solid state. Both $[Co(en)(dmpe)_2]^{3+}$ and $[Co(en)_2(dmpe)]^{3+}$ in aqueous solution are stable at room temperature, but decompose slowly on heating over 60 °C. The former complex in water in the presence of excess NaCl changes to *trans*-$[CoCl_2(dmpe)_2]^+$ by heating, but the latter complex decomposes to give Co(II) species under the same conditions. The $[Co(dmpe)_3]^{3+}$ complex in methanol containing excess Cl^- or Br^- also changes easily to *trans*-$[Co(Cl\text{ or }Br)_2(dmpe)_2]^+$.[3] In contrast to the en complexes, no changes occur for both $[Co(acac)(dmpe)_2]^{2+}$ and $[Co(acac)_2(dmpe)]^+$ in aqueous solution by heating at *ca.* 70 °C for several hours. Thus the acac ligand seems to stabilize more dmpe complexes than the en ligand does. An aqueous solution of $[Co(acac)(en)(dmpe)]^{2+}$ gives a small amount of Co(II) species and $[Co(acac)(dmpe)_2]^{2+}$ by heating.

In Fig. 1 are shown absorption spectra of $[Co(en)_{3-n}(dmpe)_n]^{3+}$ (n=0,1,2,3) together with those of related edmp complexes,[11] and in Fig. 2 absorption spectra of $[Co(acac)_{3-n}(en)_n]^{n+}$ (n=0,1,2,3), $[Co(acac)_{3-n}(dmpe)_n]^{n+}$ (n=1,2,3), and $[Co(acac)(en)(dmpe)]^{2+}$. In the Figures, short vertical lines are positions of the first absorption bands calculated by Yamatera's rule[13] using the observed values of the first absorption bands of $[Co(acac)_3]$, $[Co(en)_3]^{3+}$, and $[Co(dmpe)_3]^{3+}$. Table 1 lists spectral data in the d-d band region for ten complexes of the series, $[Co(acac)_x(en)_y(dmpe)_z]^{n+}$. The observed first absorption band maxima appear to agree with the calculated values for the series of $[CoN_nP_{6-n}]$, where *trans*-$[CoN_4P_2]$, *mer*-$[CoN_3P_3]$, *trans*-$[CoN_2P_4]$, and $[CoNP_5]$ are missing. Many attempts to prepare complexes of these types have been unsuccessful. The first three types have a *trans*(P,P) configuration which would make the complex unstable by the trans effect of a phosphine li-

TABLE 1. ABSORPTION AND CD SPECTRAL DATA OF $[Co(acac)_x(en)_y(dmpe)_z]^{n+}$ IN THE d-d BAND REGION

Complex	Absorption $\tilde{\nu}/10^3$ cm^{-1} (log ε)	CD $\tilde{\nu}/10^3$ cm^{-1} ($\Delta\varepsilon$)	Solvent

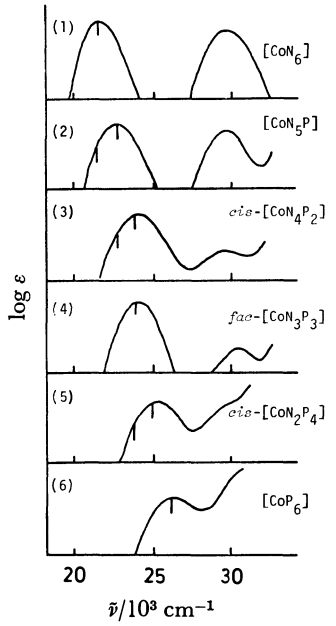

Fig. 1. Absorption spectra of (1) $[Co(en)]^{3+}$, (2) $[Co(en)_2(edmp)]^{3+}$, (3) $[Co(en)_2(dmpe)]^{3+}$, (4) *fac*-$[Co(edmp)_3]^{3+}$, (5) $[Co(en)(dmpe)_2]^{3+}$, and (6) $[Co(dmpe)_3]^{3+}$. Short vertical lines show the calculated band positions (see the text).

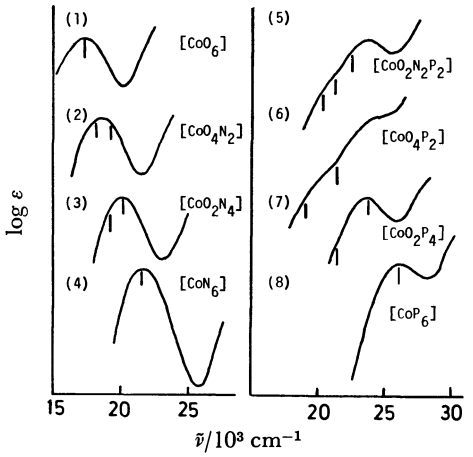

Fig. 2. Absorption spectra of (1) $[Co(acac)_3]$, (2) $[Co(acac)_2(en)]^+$, (3) $[Co(acac)(en)_2]^{2+}$, (4) $[Co(en)_3]^{3+}$, (5) $[Co(acac)(en)(dmpe)]^{2+}$, (6) $[Co(acac)_2dmpe)]^+$, (7) $[Co(acac)(dmpe)_2]^{2+}$, and (8) $[Co(dmpe)_3]^{3+}$. Short vertical lines show the calculated band positions (see the text).

gand.[11,14] For example, the reaction of edmp with *trans*-$[CoCl_2(dmpe)_2]^+$ did not yield $[Co(edmp)(dmpe)_2]^{3+}$ of the $[CoNP_5]$-type, giving *fac*-$[Co(edmp)_3]^{3+}$ and $[Co(dmpe)_3]^{3+}$ by disproportionation.

As shown in Fig. 1, the first absorption bands of $[CoN_nP_{6-n}]$ are shifted to the high energy side by replacing N with P, while the positions of the second absorption bands remain almost unchanged. As the result the energy difference between the two d-d bands becomes small as the number of P increases. The difference of *ca.* 3500 cm^{-1} for $[Co(dmpe)_3]^{3+}$ is only 43% of that for $[Co(en)_3]^{3+}$ (8100 cm^{-1}). When the decrease in energy difference is assumed to occur by an increasing covalent character of bonds between the phosphine ligand and Co(III),[15] it is concluded that the Co^{3+}–P bond has extremely strong covalent character as compared with the Co^{3+}–N bond. Some Co(III)–phosphite complexes have also small energy difference between the two d-d bands, $[Co\{P(OCH_2)_3CCH_3\}_6]^{3+}$ and $[Co\{P(OCH_3)_3\}_6]^{3+}$ being 5000 and 3300 cm^{-1}, respectively.[16]

While each of $[Co(acac)_{3-n}(en)_n]^{n+}$ (n=1,2) shows the first absorption band at nearly the same position as that expected from Yamatera's rule, $[Co(acac)_2(dmpe)]^+$ and $[Co(acac)(en)(dmpe)]^{2+}$ give spectra fairly different from those expected from the rule in this region (Fig. 2). Both complexes exhibit a peak around 23400 cm^{-1} on the high energy side of the expected positions. The $[Co(acac)(dmpe)_2]^{2+}$ complex also shows the absorption maximum at nearly the same position (23250 cm^{-1}), although the position coincides with that expected from the rule. The spectra of *cis*-$[Co(acac)_2(P)_2]^+$ (P=$P(CH_3)_3$, $P(CH_3)_2(C_6H_5)$) resemble that of $[Co(acac)_2(dmpe)]^+$.[2] The reason for these spectral properties remains unknown.

Figure 3 shows CD spectra of $[Co(en)_{3-n}(dmpe)_n]^{3+}$

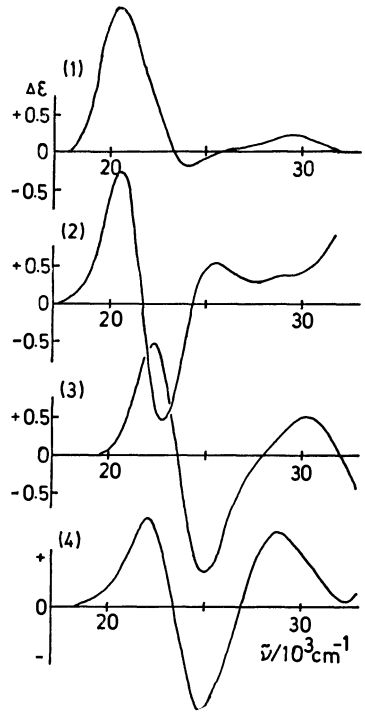

Fig. 3. CD spectra of (1) Λ-$[Co(en)_3]^{3+}$, (2) Λ-$[Co(en)_2(dmpe)]^{3+}$, (3) Λ-*fac*-$[Co(edmp)_3]^{3+}$, and (4) $(+)_{589}$-$[Co(en)(dmpe)_2]^{3+}$ (qualitative data, see the text).

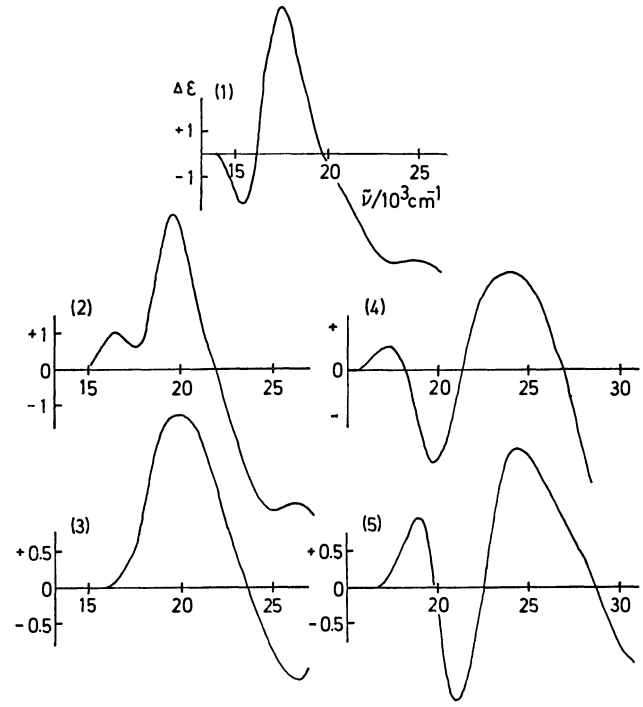

Fig. 4. CD spectra of (1) Λ-$[Co(acac)_3]$, (2) Λ-$[Co(acac)_2(en)]^{+}$, (3) Λ-$[Co(acac)(en)_2]^{2+}$, (4) $(+)_{589}$-$[Co(acac)_2(dmpe)]^{+}$ (qualitative data, see the text), and (5) $(+)_{589}$-$[Co(acac)(en)(dmpe)]^{2+}$.

(n=0,1,2) and *fac*-$[Co(edmp)_3]^{3+}$ [11] in the d-d band region. The spectrum of $[Co(en)(dmpe)_2]^{3+}$ is qualitative because of poor resolution. The absolute configurations of $[Co(en)_3]^{3+}$,[17] $[Co(en)_2(dmpe)]^{3+}$,[9] and *fac*-$[Co(edmp)_3]^{3+}$ [12] in the Figure have been determined to Λ by the X-ray method. These Λ-isomers give two CD components with different signs, (+) and (−) from the low energy side in the first absorption band region, although the negative components of the phosphine complexes are very strong as compared with that of Λ-$[Co(en)_3]^{3+}$. All the isomers give positive CD in the second absorption band region. The CD spectrum of $[Co(en)(dmpe)_2]^{3+}$ in the Figure has such characteristics of the Λ-isomer, and the complex can be assigned to Λ configuration. In column chromatographic resolution by use of SP-Sephadex C-25 and $Na_2[Sb_2(d\text{-tartrate})_2]$, the fast-moving enantiomer is Λ for $[Co(en)_3]^{3+}$ and *fac*-$[Co(edmp)_3]^{3+}$, while Δ for $[Co(en)_2(dmpe)]^{3+}$ and $[Co(en)(dmpe)_2]^{3+}$. No resolution has been achieved for $[Co(dmpe)_3]^{3+}$.

Figure 4 shows CD spectra of $[Co(acac)_{3-n}(en)_n]^{n+}$ (n=0,1,2), $[Co(acac)_2(dmpe)]^{+}$, and $[Co(acac)(en)(dmpe)]^{2+}$ in the d-d band region. The latter two complexes are enantiomers eluted faster in column chromatography. The CD spectrum of $[Co(acac)_2(dmpe)]^{+}$ is qualitative because of poor resolution. In the Figure, the absolute configuration of $[Co(acac)_3]$ has been determined to Λ by the X-ray method,[18] and those of $[Co(acac)_2(en)]^{+}$ [19] and $[Co(acac)(en)_2]^{2+}$ [20] assigned to the same Λ configuration on the basis of the CD spectra. These Λ-isomers as well as Λ-$[Co(en)_3]^{3+}$ give a positive main CD band in the first absorption band region. On the other hand, the CD spectra of $[Co(acac)_2(dmpe)]^{+}$ and $[Co(acac)(en)(dmpe)]^{2+}$ differ remarkably from those of Λ-$[Co(acac)_{3-n}(en)_n]^{n+}$, giving three CD components of (+), (−), and (+) signs from the low energy side in this region. This CD pattern, however, is quite similar to that of Λ-$[Co(en)_{3-n}(dmpe)_n]^{3+}$ (n=1,2), both of which show a strong negative CD component as seen in Fig. 3. The appearance of the strong negative components in $[Co(acac)_2(dmpe)]^{+}$ and $[Co(acac)(en)(dmpe)]^{2+}$ can also be attributed to the effect of substitution of one en ligand in $[Co(acac)_2(en)]^{+}$ and $[Co(acac)(en)_2]^{2+}$, respectively by the dmpe ligand. Thus both acac complexes containing dmpe in Fig. 4 can be assigned to Λ configuration.

Alkyd Resin Paint as a New Membrane Material of Ion-selective Electrode

Takashi KATSU,* Keiko TOGAWA, and Yuzaburo FUJITA
Faculty of Pharmaceutical Sciences, Okayama University, Tsushima, Okayama 700
(Received June 14, 1983)

A new membrane material, alkyd resin paint, was used for a silver iodide-based ion-selective electrode. The electrode was easily prepared in the laboratory by mixing silver iodide precipitate and alkyd resin paint. The electrode responded to both iodide and silver ions with the deviations from a Nernstian response due to adsorption and desorption of ions. Silver ions tended to adsorb more strongly on the electrode surface. The preparation and properties of the present electrode are described in view of an analytical utilization of the electrode.

Various membrane materials including silicone rubber, poly(vinyl chloride), and paraffin wax have been utilized for the precipitate-based ion-selective electrode.[1] We are interested in the development of a new electrode material which is easily prepared in a laboratory. The following conditions are required for the membrane materials of the precipitate-based ion-selective electrode:[2] (a) It is chemically inert and provides good adhesion for the sensor precipitates. (b) It is hydrophobic, tough, flexible, nonporous, and non-swelling in sample solution. Extensive swelling disrupts the active chain of the sensor precipitates.

In the present study, we chose alkyd resin paint as a membrane material, because it is most commonly utilized for outdoor painting, and it provides a chemically tough and weather-proof coating. In addition, it can well disperse the inorganic pigments in the paint medium.[3,4] This paper describes the use of the alkyd resin paint to a silver iodide-based ion-selective electrode. The electrode was prepared by the incorporation of silver iodide into the alkyd paint. This electrode responded well to both iodide and silver ions. The deviations from a Nernstian response, attributed to the adsorption and desorption of ions,[5] were observed at a lower concentration region. The characteristics of the electrode were discussed in view of an analytical utilization of the electrode.

Experimental

Reagents. Silver iodide was purchased from Rare Metallic Co., Ltd., and alkyd resin paint was a product of Nippon Oil and Fats Co., Ltd. (Glasstone No. 1000, Clear). Other chemicals used were all of analytical reagent grade. Water was distilled and deionized.

Preparation of Electrode. Figure 1 shows the silver iodide-based ion-selective electrode constructed in the present study. A copper plate (*ca.* 10 mm diameter, 0.5 mm thickness), which was connected to a shielded cable, was covered with a glass tube, and tightly attached using an epoxy resin adhesive. The exposed copper plate was polished with sandpaper, washed, and dried. Silver iodide was sieved through a 200-mesh screen after grinding in a mortar. Alkyd resin paint was diluted with toluene (20 w/w%) in order to decrease its viscosity. The silver iodide powder and the diluted paint were then blended on the copper plate, and the mixture was allowed to dry in air overnight. The mass ratio of the powder to the paint was not so critical, though the most favorable results were obtained with 15—20 mg of the powder and 20 ul of the diluted paint. The electrode

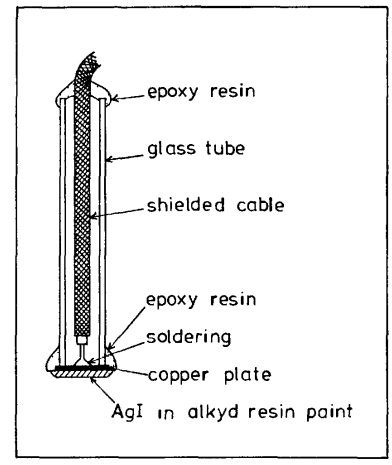

Fig. 1. Construction of electrode.

was used after being soaked for 2 h in 10^{-4} M† solution of potassium iodide.

Potential Measurements. The electrochemical cell assembly employed in this study is as follows: silver iodide-based ion-selective electrode/ test solution/ 1 M NH_4NO_3 (salt bridge)/ 0.01 M KCl/ Ag,AgCl. Usual glass containers were used for the stock of test solutions. The amount of test solution was 2 ml, and the ionic strength was maintained at 0.1 with KNO_3. An appropriate FET-operational amplifier (input resistance: $>10^{12}\,\Omega$) was used for the potential measurements. The measurements were carried out at room temperature. The solution was stirred with a magnetic stirrer. Between measurements, the electrode was rinsed several times with water and wiped.

Results and Discussion

Response Characteristics. Figure 2 shows the potential response to iodide ions of the present electrode. The calibration curves were measured from 10^{-7} M to 10^{-2} M of iodide ions, and three consecutive runs were performed. The lower detection limit of iodide ion was gradually interfered with repeated calibration measurements. Further deterioration of the detection limit, however, was not observed even when the electrode was continuously used. It was found that if the electrode was soaked in fresh 0.1 M KNO_3 solution for 10 min, the detection limit could easily be improved to the level in the original calibration. This means that some iodide ions in the electrolyte may weakly be adsorbed on the electrode surface, and such ions can not be eliminated by a conventional washing of

† 1 M=1 mol dm^{-3}.

the electrode.

To clarify the influence of the adsorption of ions on the electrode, we measured the potential response after the pretreatment with various concentrations of iodide ion. The electrode was immersed in a solution (2 ml) containing iodide ion for 3 min, rinsed with water, wiped, and then soaked in 10^{-7} M KI—0.1 M KNO_3 solution; the addition of 10^{-7} M KI in the solution afforded the reproducibility and the rapid response of the electrode potential. The potential-time responses of the electrode are shown in Fig. 3. It was found that the amount of the iodide ion released was nearly proportional to the pretreated concentration of iodide ion. Such a correlation seems to indicate that the adsorption and desorption occur at the electrode surface. The Freundlich adsorption isotherm is applicable to the adsorption from solution:

$$x = kC_{eq}^{1/n},$$

where x is the specific amount adsorbed, C_{eq} is the concentration at equilibrium, and k and $1/n$ are constants characterizing the substance adsorbed and adsorbing materials.[6] It is reasonable to postulate that C_{eq} and x can refer to the concentration of iodide ion pretreated and the amount released in 10^{-7} M KI solution, respectively. The log-log plots of x *vs.* C_{eq} gave the values of $k=2\times10^{-4}$ and $1/n=0.6$.

The above discussions should hold when the adsorbed iodide ions are completely desorbed by dipping the electrode into the solution. To see more directly the effect of the adsorption of iodide ion, we measured the potential response to silver ion after the pretreatment with iodide ion. A large negative deviation of the potential response to silver ion was observed immediately after the pretreatment of the electrode with iodide ions (Fig. 4(a)). A normal Nernstian response could be observed after the adsorbed iodide ion reacted completely with silver ion. However, when the electrode was immersed in fresh 0.1 M KNO_3 solution for 10 min prior to the measurement, such deviation was diminished (Fig. 4(b)). This observation was consistent with the result that the adsorbed iodide ion was easily desorbed by soaking the electrode into the solution, as already mentioned above.

In contrast, the response to iodide ion after the pretreatment with silver ion showed a large positive deviation even after the electrode was immersed in fresh 0.1 M KNO_3 (Fig. 5(b)). This seems to indicate that silver ions tend to adsorb more strongly on the electrode surface. It has been reported that metal ions adsorbed on the electrode can not be removed by dipping into water.[7] Effective removal has been accomplished only by physical rubbing with a cleanser.

It is now well known that the adsorption and desorption taking place at an electrode surface cause the deviations from a Nernstian response.[5] Adsorption and desorption phenomena interfere with the lower limit of detection; other sources of the deterioration

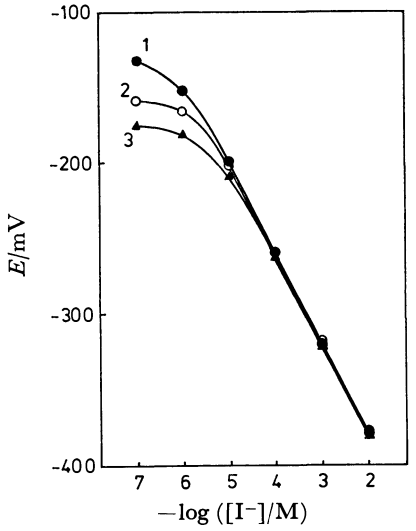

Fig. 2. Potential response to iodide ion. The calibration plots were measured in the order indicated. Three consecutive runs were performed.

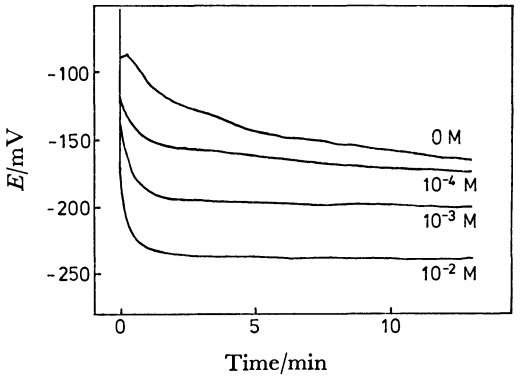

Fig. 3. Time course of the desorption of iodide ions after immersing the electrode in various concentrations of iodide ions for 3 min. The concentrations of the pretreatment are indicated in the figure. The electrode was soaked in a solution containing 10^{-7} M KI—0.1 M KNO_3.

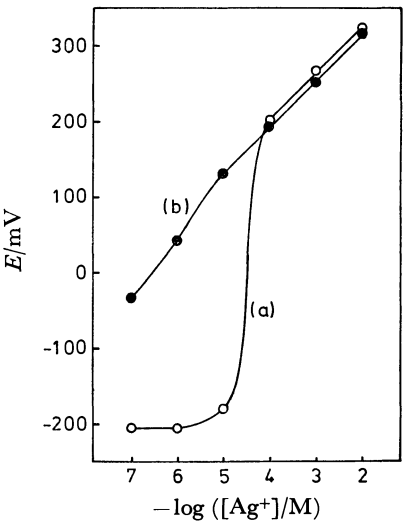

Fig. 4. Potential response to silver ion after the pretreatment of the electrode with 10^{-2} M iodide ion for 3 min. (a) Immediately after the pretreatment and conventional washing of the electrode. (b) After soaking in fresh 0.1 M KNO_3 solution for 10 min.

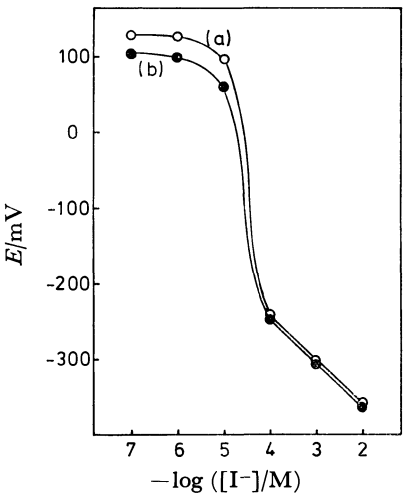

Fig. 5. Potential response to iodide ion after the pretreatment of the electrode with 10^{-2} M silver ion for 3 min. (a) Immediately after the pretreatment and conventional washing of the electrode. (b) After soaking in fresh 0.1 M KNO_3 solution for 10 min.

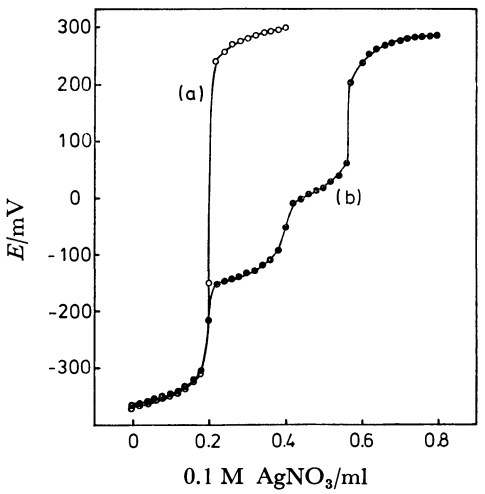

Fig. 6. Potentiometric titrations of iodide ion (a), and of a mixture of iodide, bromide, and chloride ions (b) at 0.01 M concentration in the presence of 0.1 M KNO_3.

(such as air oxidation of iodide ions) are also known.[8] It is quite natural to think that interference due to adsorption becomes more significant when the large surface area of the electrode and the small volume of the test solution are used. As for the iodide detection, if the present experiments were performed at iodide concentrations below 10^{-4} M (with 2 ml of test solution), it is unnecessary to consider the effects of adsorption and desorption because the interference at this concentration range is beyond the detection limit. Only when the measurement was transfered from higher (above 10^{-4} M) to lower concentrations, the cleaning of the electrode by soaking in a fresh solution without iodide ions was required.

Application to Potentiometric Titrations. Aside from the characteristics of the electrode, we tried an analytical utilization of the present electrode. Although an extensive application of the ion-selective electrode has been reported, the potentiometric titrations of iodide ion and of a mixture of iodide, bromide, and chloride ions were performed with the present electrode. A typical result is shown in Fig. 6. The well-defined S-shape of the titration curve and the large potential change at the end-point permitted accurate results, as was reported with silicone rubber membrane.[9] Potentiometric titrations could also be carried out in aqueous organic solvents (20% aqueous ethanol or acetone) and the halide content could be determined to be that obtained in aqueous solution.

Conclusion. The present paper describes the preparation and properties of the silver iodide-based ion-selective electrode with alkyd resin paint as a new membrane material. The experimental data presented here are almost compatible with the previous results; however, the most attractive point is ease of the preparation of the electrode in the laboratory. The electrode can be made without special treatments and techniques. Commercially available silver iodide and alkyd resin paint are blended on the metal surface. It is apparent that the present method will also be applied to the preparation of other electrodes by incorporating sensor precipitates into the alkyd resin paint.

The Solvent Effects on the Photochemical Isomerization of 5-Cyano-5*H*-benzocycloheptene

Hisako KOBAYASHI, Keizo TAKATOKU, Masahiko KATO,* and Toshio MIWA

Faculty of Science, Osaka City University, Sugimoto-3, Sumiyoshi-ku, Osaka 558

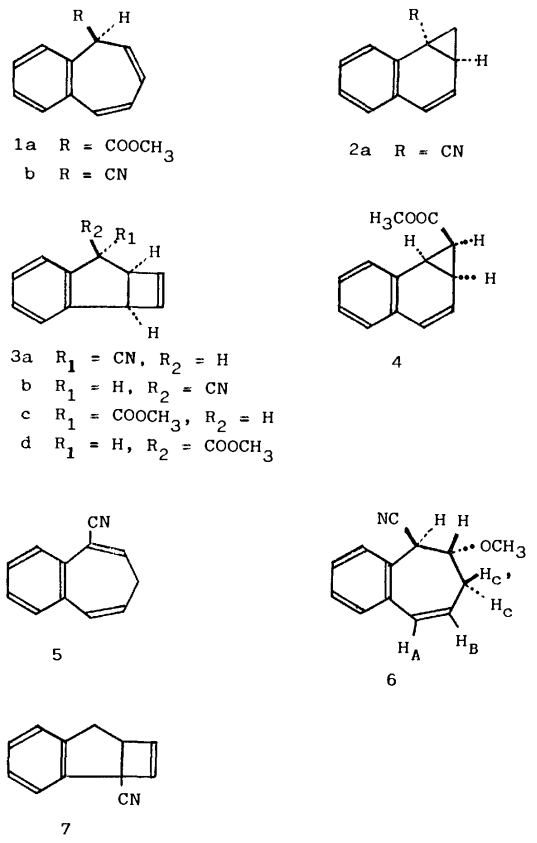
(Received October 18, 1982)

The photochemical reaction of 5-cyano-5*H*-benzocycloheptene (**1b**) has been studied kinetically in various solvents. The main reactions were (1) a 1,7-hydrogen shift, with simultaneous cyclization, to give 7b-cyano-1a,7b-dihydro-1*H*-cyclopropa[*a*]naphthalene and (2) a 4π-electrocyclic ring closure to give cyclobutenes. The former reaction was found to show rather complicated solvent effects, but the latter was accelerated in less polar solvents. The conformational equilibrium between *exo*- and *endo*-forms was also observed in the NMR spectra of **1b** under various conditions. From a consideration of the solvent effects on the product distribution, the ground-state conformations of **1b** could be reflected in the ratio of the *exo* and *endo* forms of the cyclization products.

The photochemistry of 5*H*-benzocycloheptenes (**1**) has been studied by Swenton *et al.*[1] and also by us.[2,3] As a result, it has been found that these molecules are rearranged principally in two directions; *i.e.*, the formation of benzonorcaradienes (**2**) *via* a 1,7-hydrogen shift and the formation of 2a,7a-dihydro-7*H*-cyclobut[*a*]indenes (**3**) by means of an electrocyclic ring closure.

In the case of the 5-methoxycarbonyl derivative (**1a**), a facile 1,7-migration of the substituent took place, instead of the 1,7-hydrogen migration, to give 1-*endo*-methoxycarbonyl-1a,7b-dihydro-1*H*-cyclopropa[*a*]naphthalene (**4**) exclusively.[3]

In this paper, we wish to report the photochemistry of 5-cyano-5*H*-benzocycloheptene (**1b**) in order to compare it with that of **1a**. The solvent effects on the conformational equilibrium and on the photochemical isomerization of **1b** have also been studied.



Scheme 1.

Results

The irradiation of **1b** in a methanol solution with the aid of a high-pressure mercury arc (UM-452) through a Pyrex filter for 1 h gave a mixture, **A**—**F**, consisting of **2a** (33%), **3a** (*exo*) (18%), **3b** (*endo*) (9%), **5** (5%), **6** (10%), and **7** (6%). They were separated by successive column and vapour-phase chromatography.

Structure of the Products. Compound **A** showed three signals characteristic of a three-membered ring proton and two olefinic proton signals in the NMR spectrum; it was identical with the known 7b-cyano-1a,7b-dihydro-1*H*-cyclopropa[*a*]naphthalene (**2a**).[4] Because of the difficulty of separating **B** from **C**, we studied them as a mixture. The NMR spectrum showed two sets of olefinic signals on the cyclobutene ring (**B**, δ 6.42 and 6.15; **C**, δ 6.52 and 6.28 ppm (AX type, J=2.7 Hz)), accompanied by benzylic proton signals characteristic of *exo*- and *endo*-2a,7a-dihydro-7*H*-cyclobut[*a*]indene (**3**) (**B**, δ 4.49 (bd); **C**, δ 4.32 ppm (d)).[5] We deduced **3a** structure for compound **B** and that of **3b** for **C**, because the NMR signals for the benzylic proton in 7-substituted 2a,7a-dihydro-7*H*-cyclobut[*a*]indene are quite indicative of the configuration, whether the substituent occupies the *exo* (broad doublet) or the *endo* position (doublet).[5] These assignments were confirmed by the methanolysis of the mixture to the easily separable corresponding methyl carboxylates, **3c** and **3d**. They were identical with those independently obtained through the sensitized irradiation of 5-methoxycarbonyl-5*H*-benzocycloheptene (**1a**).[6] Compound **D** showed an UV maximum (λ_{max}: 229 nm) characteristic of 7*H*-benzocycloheptenes and an IR absorption of the conjugated nitrile ($\nu_{C\equiv N}$: 2220 cm^{-1}). The NMR signals of the three olefinic and two aliphatic protons, together with their coupling patterns, determined the structure to be **5**.[4] Compound **E** had the molecular formula of $C_{13}H_{13}NO$, composed of one molecule each of the starting material and of methanol. This compound showed a UV spectrum similar to that of 6,7-dihydro-5*H*-benzocycloheptene,[7] while the NMR olefinic signals (2H, AB type, J_{AB}=12.2 Hz) showed a strong coupling only with the adjacent methylene protons (J_{AC}=2.2 Hz, $J_{AC'}$=

1.5 Hz, J_{BC}=4.4 Hz, $J_{BC'}$=5.4 Hz, $J_{CC'}$=18.3 Hz). Since the proton on C-6 showed a doublet of doublets of doublets (J=9.3, 5.4, 2.2 Hz) at δ 3.87 ppm and the one on C-5, a broad doublet (J=2.2 Hz) at δ 4.21 ppm, the methoxyl and cyano groups must be attached to C-6 and C-5 respectively, or *vice versa*. The structure (**6**) was deduced from the experiment with Siever's reagent on NMR measurements. Thus, in addition to a moderate shift for the signals of H-6, there was an extraordinary lower-field shift for the H-5 and H-7a, which defined the *cis* stereochemistry of both the hydrogens to the methoxyl group (Table 1). Such an enormous shift of the signal of H-7 is expected for the **6** structure.[8] As it had been reported that **2a** gives **5** as a primary photoproduct[4] and that the cyano group rarely migrates under photolytic conditions,[9] **1b** and/or **5** can logically be recognized as a precursor of **6**. Both would then possibly be photochemically isomerized to a constrained *trans*-form. It is well known that the dipolar additions of protic solvents to constrained olefins proceed readily.[10] Compound **F** has a molecular formula, $C_{12}H_9N$ (*m/e* 167 (M^+)) and shows characteristic olefinic AX-type signals (J_{AX}=2.7 Hz) of cyclobutene in the NMR spectrum. The lack of an NMR signal due to a benzylic proton on C_{2a} defined the structure (**7**) for compound **F**.

*Kinetic Studies of Photochemical Reactions of **1b** in Several Solvents.* In order to obtain further information about how the photochemical behavior of **1b** is changed by the solvents used in photolysis, we studied it comparatively in a merry-go-round apparatus in several solvents; methanol, *t*-butyl alcohol (protic polar), acetonitrile, dichloromethane (aprotic polar), and cyclohexane, benzene (aprotic nonpolar). Two runs were carried out for every solvent. With a longer period of irradiation, we obtained the product distributions shown in Fig. 1, while the results of the shorter-period irradiation are summarized in Table 2. From Fig. 1 it is obvious that the formation of **5** and **7** at the initial stage was so trivial that they were omitted from the table.

Among the solvents studied, the rate of the disappearance of **1b** (k_r) was the fastest in benzene, and the rates were almost all consistent with the first-order kinetics at the initial stage. Therefore, we related them to the decreasing rate of **1b** in benzene.

Discussion

Table 2 shows that, though there is no parallel relationship between the relative rates for the formation of **2a** and the solvent polarities, in all aprotic solvents except benzene and toluene the reaction proceeds faster as the polarities of the solvents increase, while the reaction is retarded in protic solvents.

On the other hand, it is obvious that the electrocyclic reaction to **3a** and **3b** proceeded faster as the polarity of the solvents decreased. The solvent effect observed here suggests the existence of different transition states (or energy surfaces) between the 1,7-hydrogen shift and the 4π-electrocyclic ring closure.

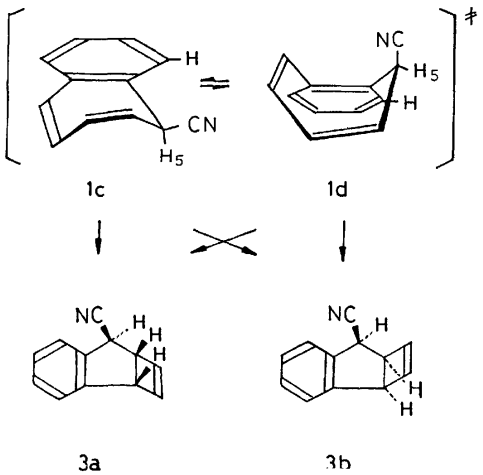
It is interesting to note that the ratio of k_{3b}/k_{3a} decreases gradually as the solvent polarities decrease.

This was not seen in the case of the cyclization of 5-methoxycarbonylmethyl-5*H*-benzocycloheptene, which gives an almost constant ratio of cyclization products in various solvents (*exo*:*endo*=95:5).[6]

It is well established that cycloheptatrienes exist in an equilibrium mixture of two tub conformations;[11] for example, the two conformers of 5-methoxy-6,7,8-triphenyl-5*H*-benzocycloheptene are separated by an energy barrier of 71 kJ/mol.[12] We estimated, by means of the ^1H and ^{13}C NMR spectra in dideuteriodichloromethane, that the energy barrier of the conformational flipping of the seven-membered ring of **1b** is equal to ΔG^* 40.2 kJ/mol at −73 °C and that the equilibrium between the two conformers with the cyano group in either the *quasi*-equatorial (**1c**) or the *quasi*-axial position (**1d**) is approximately equal to 81:19.[3]

The increase in the ratio of the *quasi*-equatorial form in **1b** compared with that of **1a** (52:48)[3] reflects the fact that the equilibrium is sensitive to the bulkiness of the substituents on C-5. **1c** and **1d** should interact with a polar solvent more strongly at the polar site than at any other part of the molecule. This interaction can be expected to affect the equilibrium between **1c** and **1d** by the increase in the steric repulsion between H-4 and cyano group and/or by the decrease in the solvation energy in **1d** compared with that in **1c**. The *quasi*-axial cyano group of **1d** is opened to solvation in every direction, but the *quasi*-equatorial cyano group of **1c** is blocked at the side facing a hydrogen on C-4. The solvation energy gained by **1d** must be much larger than that won by **1c**; therefore, the equilibrium between **1c** and **1d** moves toward **1d** as the polarity of the solvent increases (Scheme 2).

The photochemical reaction from its excited singlet is expected to proceed much faster than the ring inversion;[13] therefore, the ring closure of **1c** can be discriminated from that of **1d**. There are two possible disrotatory modes of 4π-electrocyclic-ring closure for the conformations. When we write the boat form in the upper concave, as is shown by **1d** in Scheme 2, one mode is a ring closure with the rotation of the bonds, from C-8 to C-9 and from C-7 to C-6, in the opposite and outer directions to give the cyclobutene, while the other is the ring closure with the rotation of the same bonds in the inner directions. In the former mode, the axial substituent in **1d** is transformed to the *endo* substituent, and the equatorial one, to the *exo* substituent. In the latter mode, the axial substituent is transformed to the *exo* substituent, and the equatorial one, to the *endo* substituent. Considering the energy relation along the reaction coordinate, it is possible that one of these cyclization modes is to be preferred to the other. Then the ring closure to either the pair of **3a** (*exo*) from **1c** and **3b** (*endo*) from **1d**, or the pair of **3a** from **1d** and **3b** from **1c**, will proceed easier than the other pair.[14] Then, if we could determine the ratio of the conformers in equilibrium, we would be able to evaluate k_{endo} using the ratio and k_{exo}. It seemed difficult, however, to estimate the conformer's ratio of **1b** by NMR at the low temperatures in the solvents used, other than dichloromethane-d_2, because of their higher melting points or of their increasing viscosities at low temperatures.



Scheme 2.

In order to clarify the conformational aspect, the NMR spectra of **1b** were measured in several solvents at room temperature. The chemical shifts of H-5 and H-9 are listed in Table 3, while the plots of $\delta H_9-\delta H_5$ *versus* k_{exo} are shown in Fig. 2. We noticed a rough trend for the less polar solvents to favor a larger separation of $\delta H_9-\delta H_5$ and a bigger k_{exo}, while the more polar ones favor less separation and a smaller k_{exo}.

Table 3. The chemical shifts of H_9 and H_5, and their differences

Solvent	δH_9	δH_5	$\delta H_9-\delta H_5$	
CD_3OD	7.33±0.2	4.34±0.2	2.99±0.4	(48.4%)[a]

TABLE 4. THE PERCENTAGES OF **1d** IN THE EQUILIBRIA FOR SEVERAL SOLVENTS, AND THE POLARITY PARAMETERS OF THE SOLVENTS

Solvent	Method I[a] (%)	Method II[a] (%)	$(J_{H_5-H_6})$ Hz	Mean value %	E_{T30} kJ mol^{-1}
CH_3OH[b]	48.4±5	46.5±5	(6.74±0.2)	47.5	232
CH_3CN	46.7	48.5	(6.79)	47.6	192
t-BuOH	31.1	26.0	(6.25)	28.6	184
CH_2Cl_2	19.0	26.0	(6.25)	22.5	172
C_6H_6	10.7	15.0	(5.99)	12.9	144
C_6H_{12}	7.9	7.0	(5.79)	7.5	142

a) Methods I and II are referred to the estimation methods, *i.e.*, the use of the chemical shifts (Method I) and the coupling constants, $J_{H_5-H_6}$ (Method II). b) The full deuterated solvents were used for NMR measurements.

Günther *et al.* reported the determination by means of ^{13}C NMR spectroscopy, of the ratio of the *quasi*-equatorial to the *quasi*-axial conformer of 7-cyano-1,3,5-cycloheptatriene in equilibrium as 79:21. Here, the chemical shifts of C-3 (or C-4) in the two conformers are identical with each other in the temperature range from −2.5 to −123 °C.[11] If we use the chemical shift of H-9, which is far from the cyano group, as the standard, the $\delta H_9 - \delta H_5$ becomes a chemical shift of H-5 from this standard, which has already been cancelled in the same magnitude as the solvent effect influencing H-9. As has been mentioned above, this chemical shift of H-5 is equal to a weight average of the chemical shifts of H-5 existing in **1c** and **1d**.[15] In order to check the propriety of this method, the difference in the chemical shifts between aromatic and benzylic protons of benzyl cyanide were examined and found to show satisfactory similarities (±0.1 ppm), except in benzene (+0.58 ppm).

When the chemical shifts at δ 3.56 (H-5 for **1c**) and δ 4.78 ppm (H-5 for **1d**) observed at a low temperature in CD_2Cl_2 are in effect as the standard at room temperature in CH_2Cl_2, the percentage of **1d** in the equilibrium in several solvents can be roughly estimated as is shown in Table 3 (Method I).

Another approach[16] to determine the equilibrium has been done by taking advantage of the difference in the spin-spin coupling constants of C-5 protons between **1c** (equatorial-CN) and **1d** (axial-CN). From the low-temperature NMR spectrum of **1b** in CD_2Cl_2, the signals due to equatorial H-5 (**1d**) (lower field) and to axial H-5 (**1c**) (higher field) are seen as broad doublets. Applying the computer program for the resolution of the overlapping peak into their components (Gaussian function) to those bands,[17] we obtained the coupling constants; $J_{endo-5,6}=5.63\pm0.2$, $J_{exo-5,6}=8.02\pm0.2$ Hz for **1b**.[18] From the NMR spectra of **1b** in several solvents, we get the weight-averaged coupling constants for the equatorial and for the axial H-5 of **1b**. We can then calculate the percentages of **1c** in **1b** from the coupling constants in several solvents (Table 4, Method II). The percentages thus obtained were parallel with those obtained from the chemical shifts; we used the mathematical mean values for the following calculations. The plots of the percentages of **1d** in **1b** *versus* the solvent polarity parameters, E_T,[19] in various solvents are shown in Fig. 3. A linear correlation was observed for every

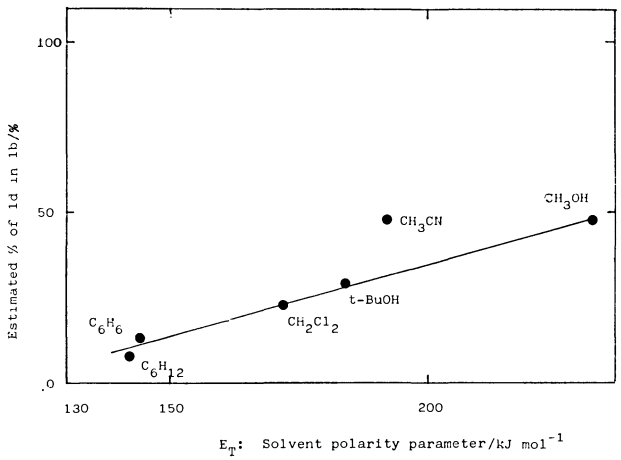

Fig. 3. Plots of the estimated percentage of **1d** against solvent polarity.

solvent excep acetonitrile, in which the cyano group of **1b** may have a strong affinity to the same group of the solvent.

As the conformers' ratios are obtained based on NMR data in CD_2Cl_2 at low temperatures, we used the kinetic data in dichloromethane as a standard. When the observed values of k_{exo} are divided by each respective molar fraction of **1c** in the same solvent, we obtain the values of k°_{exo}; the values of k_{exo} from pure **1c**. Similarly, if the observed value of k_{endo} (CH_2Cl_2) is divided by the molar fraction of **1d** in dichloromethane, we obtain the value of k°_{endo} (CH_2Cl_2): the value of k_{endo} from pure **1d** in dichloromethane. If we assume that the ratios of the reaction rate, $k^\circ_{endo}/k^\circ_{exo}$, were constant in every solvent, we can calculate the values of k°_{endo} for every solvent using the values of k°_{exo} and the ratio in CH_2Cl_2 (0.515). Further, we will be able to evaluate k_{endo} (calcd) in a solvent by the use of the k°_{endo} (calcd) and the molar fraction of **1d** in the same solvent. The calculated values of k_{endo} (calcd), listed in Table 5, are in satisfactory agreement with the observed values of k_{endo}. Therefore, it seems reasonable that the photochemical progenitors of **3a** (*exo*) and **3b** (*endo*) are **1c** and **1d** respectively. In other words, the interrelation between the estimated conformer ratio of the starting material in the equilibrium and the experimental product-ratio supports the allowed disrotatory ring closure with rotation at the conjugated double

Table 5. Comparison of the observed and the calculated parameters

bond in a 7-membered-ring tub conformation to the outer direction. This process corresponds to the pathway with the least torsional energy around the $C_5(sp^3)$–$C_6(sp^2)$ bond.

A clear solvent effect on the *anti-syn* ratio in the formation of the [2+2] adducts was seen in the case of the photochemical dimerization of 2-cyclopentenone.[20] The photochemical reactions which proceed under the control of the ground-state geometries have previously been observed in the ring opening of 1,3-cyclohexadiene derivatives;[21] the present case is the first example of such a reaction for a seven-membered ring analogue.

As has been mentioned above, rather complicated solvent effects on the formation of **2a** can not be understood from the control of the ground-state geometries of the starting material. It is possible to assume that the electronic polarization of **1b** to **8a** or **9** may have played a role in the transition state. The former (**8b**) was suggested by Swenton and his co-workers to explain the solvent effect on the same rearrangement of 7-substituted 5*H*-benzocycloheptenes,[1] and a similar polarization to the latter was proposed by Tezuka and Houk to clarify the substituent effects on the cyclization and 1,7-sigmatropic hydrogen shift of substituted cycloheptatrienes.[22] Interaction with protic solvents can be expected to retard the reaction, and enhancement of the charge separation by aprotic polar and benzenoid solvents may accelerate the reaction.[23]

Thus, we found that the photochemical isomerization of **1b** under direct irradiation was quite different from that of 5-methoxycarbonyl-5*H*-benzocycloheptene, which gave **4** exclusively.[3]

Experimental

General Procedure. The UV, IR, ^1H NMR, ^{13}C NMR, and mass spectra were recorded according to the methods given in the previous paper. A Varian Aerograph, model 90P, was used for the preparative VPC (Helium flow rate; 30—40 mL/min), while a Shimadzu Gas Chromatograph GC-4BM was used for the analytical purposes (Hydrogen flame detector). The columns used for separation were ϕ3.2 mm × 1.8 m columns charged with: A, 3% Silicone OV-17; B, Silicone SE-30, on Chromosorb WAW.

For irradiation of a volume of more than 100 mL, a solution charged in a vessel fitted with a quartz cooling jacket was purged with dry nitrogen for five min and then internally irradiated with an Ushio high-pressure mercury arc (UM-452) through a Pyrex filter. For small-scale irradiation (less than 15 mL), unless otherwise described, a solution charged in a drum-shaped Pyrex vessel with a ground glass joint fitted with a three-way cock was purged with dry nitrogen for five min and then dipped in ice water in a quartz-made Dewar bottle with a flat quartz window. The solution was then irradiated externally with an Ushio lamp (USH-500D) through a Toshiba filter (UV-31).

Synthesis of ***1b****.* Benzotropylium tetrafluoroborate, which had been derived from 2,3-benzotropone (3.24 g, 20.7 mmol),[2] in anhydrous acetonitrile (18 mL), was added, drop by drop, to sodium cyanide (910 mg, 18.6 mmol) in acetonitrile (12 mL) at 0 °C under a nitrogen atmosphere, and then the mixture was stirred for 30 min at room temperature. The mixture was filtered through Hyfrosupercel (a filter aid), and the filtrate was concentrated under reduced pressure. The residue taken up in ether (100 mL), washed successively with water and saturated brine, and dried. After the evaporation of the ether, the remaining oily products (2.88 g, 81%) were separated by column chromatography (silica gel 90 g/benzene), followed by preparative TLC with a multiple-developing technique (10% ether–hexane) to give **1b** (1.41 g, 8.43 mmol; 41%) and a mixture of 7-cyano-7*H*- and 7-cyano-5*H*-benzocycloheptene (*ca.* 95:5, 0.81 g, 4.84 mmol; 23%). The latter mixture was converted quantitatively into 7-cyano-5*H*-benzocycloheptene by passing it through a column of basic alumina (Merk; activity I/benzene). **1b** IR (liq film) ν_{max}: 3030, 2260, 1589, 1493, 893, 822 cm^{-1}. UV (95% C_2H_5OH) λ_{max} (log ε): 274.5 (3.89) nm. NMR (CCl_4) δ=3.76 (1H, dd, J=6.0, 1.3 Hz), 5.75 (1H, dd, J=9.5, 6.0 Hz), 6.19 (1H, ddd, J=9.5, 5.3, 1.3 Hz), 6.55 (1H, dd, J=11.8, 5.3 Hz), 7.20 (1H, d, J=11.8 Hz), 7.2—7.7 (4H, m). ^{13}C NMR ($CDCl_3$) δ=35.6, 119.1, 123.1, 125.3, 127.3, 128.0, 128.7, 129.9, 130.7, 134.3, 134.6 ppm. Found: C, 86.00; H, 5.41; N, 8.43%. Calcd for $C_{12}H_9N$: C, 86.20; H, 5.43; N, 8.38%. *7-Cyano-7*H*-benzocycloheptene.* IR (liq film) ν_{max}: 3040, 2260, 1638, 1492, 1445, 800, 770, 712 cm^{-1}. UV (95% C_2H_5OH) λ_{max}: 227 nm. NMR (CCl_4) δ=3.25 (1H, tt, J=6.0, 1.0 Hz), 5.76 (2H, dd, J=10.0, 6.0 Hz), 6.64 (2H, dd, J=10.0, 1.0 Hz), 7.25 (4H, s).

Photolysis of ***1b*** *in Methanol.* A solution of **1b** (171 mg, 0.99 mmol), dissolved in methanol (130 mL), was irradiated with a HPL through a Pyrex filter under a nitrogen atmosphere for 1 h. The usual work-up gave a mixture, which was then separated using preparative thin-layer chromatography with a multiple-development technique to give **1b** (28 mg, 16%), a mixture (2:1) of **3a** and **3b** (47 mg, 27%), and **6** (10 mg, 5%), in addition to a mixture of **2a**, **5**, and **7** (78 mg, 33, 5, 6%, respectively). The latter was further separated by preparative VPC (column B, 145 °C: retention time; **7**, 4.4 min; **2a**, 7.0 min; **5**, 8.4 min). The spectroscopic data of **2a** and **5** were identical with those of the authentic sample reported by Swenton.[4] **3a** NMR ($CDCl_3$) δ=3.9 (1H, m), 4.0 (1H, m), 4.49 (1H, bd), 6.15 (1H, dd, J=2.7, 0.7 Hz), 6.42 (1H, dd, J=2.7, 0.7 Hz), 7.25—7.46 (4H, m). **3b** NMR ($CDCl_3$) δ=3.8 (1H, m), 4.0 (1H, m), 4.32 (1H, d, J=3.0 Hz), 6.28 (1H, d, J=2.7

Identification of the Mixture of 3a and 3b. Into a solution of a mixture of **3a** and **3b** (2:1, 31 mg, 0.19 mmol), dissolved in anhydrous ether (1 mL) and methanol (1 mL), we passed dry hydrogen chloride at 0 °C for 2.5 h. After stirring further for 1 h at room temperature, water (5 mL) was added slowly to the solution under cooling. After sweeping off the hydrogen chloride by passing nitrogen into the solution, the solution was filtered and the filtrate concentrated to a small volume. The residue was extracted

with ether, and the ethereal extracts were washed successively with water and saturated brine, and then dried. The ether was evaporated, and the remaining crude product (30 mg) was purified by preparative TLC (10% ether–hexane) to give **3c** (20 mg, 53%) and **3d** (10 mg, 26%). The spectral data were identical with those of authentic samples of **3c** and **3d** described previously.[6] As a result, the structures of compounds **B** and **C** were established as **3a** and **3b** respectively.

*Photolysis of **1b** in Benzene.* A solution of **1b** (51 mg, 0.3 mmol), dissolved in benzene (11 mL), was irradiated externally for 4.8 h. The resulting solution was concentrated, and the residue (50 mg) was separated by preparative TLC (10% ether–hexane) to give **2a** (17.4 mg, 34%) and **3a** (11 mg, 21.5%). **3a** IR (liq film) ν_{max}: 3045, 2250, 1484, 1279, 830, 770, 740 cm^{-1}.

*Photolysis of a Mixture of **3a** and **3b** in Benzene.* A solution of a mixture (5 mg, 2:1) of **3a** and **3b** in benzene (11 mL) was irradiated externally for 2.5 h. The solution was then concentrated, and the residue (4.8 mg) was examined in terms of its NMR spectrum, which was found to be identical with that of the starting mixture.

*Photolysis of **3a** in Methanol.* A solution of **3a** (11 mg, 0.06 mmol), dissolved in methanol (11 mL), was irradiated externally for 3 h under ice cooling. After the evaporation of the solvent, the isolated material (8.4 mg) was examined in terms of its NMR spectrum. The spectrum revealed that it consists solely of **3a**.

*Kinetic Measurement of Photochemical Reaction of **1b**.* *Solvents*: The solvents used for photolysis were as follows. Methanol: The UV spectrum of a special-grade one was checked to confirm it to be transparent above 205 nm and was used without purification. Cyclohexane: A spectrophotometric grade of Merk's cyclohexane was used directly. Acetonitrile: A first-grade specimen was distilled over phosphoric pentoxide, then let stand over anhydrous potassium carbonate for more than one day, and distilled before use. Dichloromethane: A first-grade specimen was distilled over phosphoric pentoxide before use. Benzene: A first-grade substance was washed successively with concentrated sulfuric acid and water. This was dried over anhydrous calcium chloride and then distilled. After being dried over sodium wire, it was distilled before use. *t*-Butyl alcohol: A first-grade specimen was distilled over sodium before use.

Measurement: Each 1.0 mmol/dm^3 solution of **1b** was prepared in an appropriate solvent containing 0.10 mmol/dm^3 of hexadecane as an internal standard. Each test tube (ϕ1.5 cm × 16 cm) with a ground-glass male joint at the top was fitted with a cap made of female joint of the same size connected to a two-way cock and was then used for photolysis. Five of the tubes containing the same solution (5 mL) and two containing the benzene solution (5 mL) were arranged cylindrically in a circle (ϕ16.5 cm for short-period irradiation and ϕ11.5 cm for longer-period irradiation) at the same distance from the light source placed at the center (merry-go-round apparatus).[24] Before irradiation, purified nitrogen was passed through every solution for five minutes and the cocks were shut off. The photolysis was carried out with a high-pressure mercury lamp (UM-452) mounted in a quartz cooling jacket through a Pyrex filter under cooling (ice water; care must be taken not to keep the samples too cold; otherwise, they freeze). During irradiation, a test tube was taken out every definite number of minutes (see the text), and each 10 μL of the solution was examined by VPC (Column A, 130 °C; nitrogen-flow rate, 40 mL/min: retention time; hexadecane, 1.6 min; **7**, 3.2 min; **3a**, 3.6 min; **3b**, 4.15 min; **1b**, 4.8 min; **2a**, 5.0 min; **5**, 7.25 min). The product ratios were obtained by comparing the integrated curve areas as estimated using this equation: S=the height times the half-width of the curve. In some runs, uniform paper was cut into the curved areas, and their weights were compared. Both methods gave satisfactorily similar results within a 3% margin of error. The calibration curves for the pure samples, **1b**, **2a**, and **3a**, as separated by preparative VPC, was obtained similarly, and a linear relationship between the sample amounts and the integrated areas of the peaks was obtained. The ratio of the VPC intensities for **1b**, **2a**, and **3a** for samples of the same amount was 100:91:109 (including a 5% margin of error). As we could not obtain **3b** in the pure state, we assumed the intensity in VPC was the same as that of **3a**. The other materials in the product were not calibrated to their standards, but their VPC areas were directly compared with that of **1b**. Each datum was recalculated against that of the standard (hexadecane) as unity, and the two values were compared with each other. Two runs were carried out, one for a longer period of irradiation (up to 2 h) and the other for a shorter period of irradiation (up to 15 min). The results are summerized in Fig. 1 (longer-period irradiation) and Tables 2 and 6 (shorter-period irradiation).

This paper is dedicated to Emeritus Professor Takeo Sakan on the occasion of his 70th birthday. The authors wish to thank Dr. Yoshimasa Fukazawa of Tohoku University for valuable discussion and Mr. Jun-ichi Goda of our University for the elementary analysis.

The Reaction of Nitrile Oxides with Alkyl- and Alkyl-halo-substituted *p*-Benzoquinones

Shinsaku SHIRAISHI,* B. Shivarama HOLLA,† and Kiyoshi IMAMURA

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received December 14, 1982)

Various aromatic nitrile *N*-oxides, sterically stabilized and unstabilized ones, were allowed to react with several alkyl- and alkyl-halo-substituted *p*-benzoquinones with a view to studying the influence of quinone substituents on the mode of the addition reaction. Mono-, di-, and tri-substituted quinones with such substituents gave isoxazoline derivatives formed through addition of nitrile oxides to the C=C bond of the quinones. 2-Chloro-5- and -6-methyl-*p*-benzoquinones gave two kinds of C=C adducts, one formed through the addition to the C=C of methyl-substituted side and the other to that of chlorine-substituted side, and the latter adducts were not isolable due to the prompt dehydrochlorination forming the fully-conjugated isoxazoloquinones and subsequent C=O addition of another nitrile *N*-oxide forming spirodioxazole derivatives.

Nitrile *N*-oxide, a typical 1,3-dipole, reacts with various unsaturated compounds to give heterocycles.[1] The reactions of nitrile *N*-oxides with substituted *p*-benzoquinones, which have two kinds of potential reactive sites, *i.e.* C=C and C=O bonds, have been studied and reported in the previous papers.[2,3] All the tetrasubstituted quinones gave dioxazole derivatives through addition at the carbonyl site(s), while the disubstituted quinones gave dioxazole or isoxazoline derivatives depending on the substituents and substitution pattern. With a view to studying the influence of substituents on the mode of the addition of nitrile *N*-oxides to quinones, reactions of several alkyl- and alkyl-halo-substituted quinones with nitrile *N*-oxides have been investigated and the result is reported in this paper.

Results and Discussion

Several aromatic nitrile *N*-oxides (**1**) were allowed to react with various kinds of alkyl- and alkyl-halo-substituted *p*-benzoquinones (**2**). Three sterically stabilized nitrile *N*-oxides, *viz.*, 2,4,6-trimethylbenzonitrile *N*-oxide (MNO), 2,3,5,6-tetramethylbenzonitrile *N*-oxide (DNO), and 2,6-dichlorobenzonitrile *N*-oxide (CNO) were chosen for the reaction with quinones. The reactions were conducted in benzene using equimolar reactants at room temperature. The progress of the reaction was followed by thin layer chromatography (TLC) on silica gel plates. In most cases, isoxazoline derivatives were obtained as the main products in rather good yields. The result is summarized in Tables 1—3. The structure of the products were determined by IR, ^{1}H NMR, and mass spectra and elemental analyses. The isoxazoline derivatives formed have the structure as shown in Scheme 1. Trisubstituted olefinic double bond was the exclusive or at least the main reaction site to undergo the C=C addition forming the C–O bond between the oxygen atom of the nitrile oxide and the carbon atom bearing a substituent of the quinone moiety even in the reaction of methyl-*p*-benzoquinone, where the adduct **3a** (see Table 1) was the main product. This indicates that steric factors are less important for the site-selectivity of the addition reaction than electronic factors, though that is the governing factor in the reaction with 2-*t*-butyl-6-methyl-*p*-benzoquinone where the addition occurs selectively at the C=C bond of the methyl-substituted side. In the reaction of CNO with 2-*t*-butyl-5-methyl-*p*-benzoquinone, however, addition occurred at both sides to give a 2:1-mixture of the adduct on the less hindered side (**3d**) and that on the other side (**3m**). In the reaction of CNO with 2-isopropyl-5-methyl-*p*-benzoquinone, the formation ratio of the two isomers was determined to be 3:2 from the ^{1}H NMR spectrum of the crude reaction product, though the separation was not conducted.

The IR spectra of the most adducts showed either a broad or a split carbonyl absorption around 1670—1690 cm^{-1}. The IR spectra of some of the adducts from chlorine-substituted quinones, however, showed two distinct carbonyl absorptions around 1680 and 1700 cm^{-1}. The ^{1}H NMR spectrum of the product **3e** from 2,6-dimethyl-*p*-benzoquinone (26DMQ) and CNO shows three singlets at δ 7.32, 2.16, and 1.73, each integrating to three protons. The signals at δ 1.73 and 2.16 are assigned to the angular and olefinic methyl groups on the quinone moiety respectively, and the singlet at δ 7.32 is due to the three aromatic protons. The olefinic proton and the angular methine proton

resonate as each singlet at δ 6.70 and 4.44, respectively. The chemical shift of the angular methine signal shows undoutedly that the orientation of the addition reaction is such as indicated in Scheme 1.[4)] Similar ^{1}H NMR spectra are observed for all the CNO adducts and the spectral data are summarized in Table 4.

The reactions of DNO and MNO with quinones were slower in reaction rate than those of CNO; *e.g.* in the reaction of either DNO or MNO with 2,5-di-*t*-butyl-*p*-benzoquinone (25DBQ), the starting materials were recovered almost quantitatively even after a week and only a partial reaction was observed after a month. The addition products from DNO and MNO are also found to be isoxazoline derivatives. In the ^{1}H NMR spectra of the adducts, the signals due to the methyl protons of the quinone moiety overlapped with those originated from aromatic moiety in some cases, but all the adducts are characterized by the characteristic singlet due to the angular methine proton at δ 4.1—4.8, which confirm the isoxazoline structure of the same orientation in the addition reactions. The ^{1}H NMR spectral data are also summarized in Table 4.

In the mass spectra of the C=C adducts obtained from the reactions of the nitrile oxides with quinones, the molecular ion peak was generally very weak and the major peaks were due to the fragment ions. In most cases, the most intense signal is due to the fragment E (in some cases the fragment F). The molecular ion underwent initially the fragmentation with the loss of the angular alkyl substituent or the scission forming the fragment E. The fragments A, D, E, and F were always observed in the mass spectra of the 1:1-C=C adducts, and the structure of the fragment species were confirmed to be such by high resolution mass spectrometry. Some other fragmentation processes were observed. The major fragmentation modes were such as shown in Scheme 2. The adducts from CNO showed an intense peak of M^+-Cl, in some cases as the base peak, but the major fragmentation pattern was substantially similar.

The unstabilized nitrile *N*-oxides, generated just before the reaction in the same pot, reacted with 25DBQ at far faster rates than those of MNO or DNO to give two products in each reaction, the major one of which was identified to be the same type of C=C adduct as in the previous cases and the other was found to be a 1:2-adduct formed through the addition to both of the C=C double bonds. The results of the reaction and the characterization data of the products are summarized in Table 5.

The reactions of nitrile *N*-oxides with 2-chloro-6-(26CMQ) and -5-methyl-*p*-benzoquinones (25CMQ) were somewhat complex owing to the formation of two types of C=C adducts, one is the adduct formed by addition of the nitrile oxides on the C=C of methyl-substituted side and the other is that formed by addition on the opposite side. The former was isolable as formed but the latter was not due to the elimination of hydrogen chloride forming a fully-conjugated isoxazoloquinone and subsequent addition of another nitrile oxide onto the C=O of the isoxazoloquinone to form a spiro-dioxazole derivative. The isoxazoloquinone and the spiro-dioxazole derivatives were both isolated in the reaction of DNO with 26CMQ and characterized. The reactions of the combinations of the other nitrile oxides with 26CMQ or 25CMQ showed similar reaction patterns to that of DNO with 26CMQ but isolation of isoxazoloquinones or spiro-dioxazole derivatives except the isoxazoline derivatives was not successful. The reaction of DNO with 26CMQ gave an isoxazoline derivative **5e** in a 30% yield. The structure of **5e** is confirmed by the fact that the ^{1}H NMR spectrum showed two singlets at δ 4.30 and 1.73 having the intensities corresponding to one and three

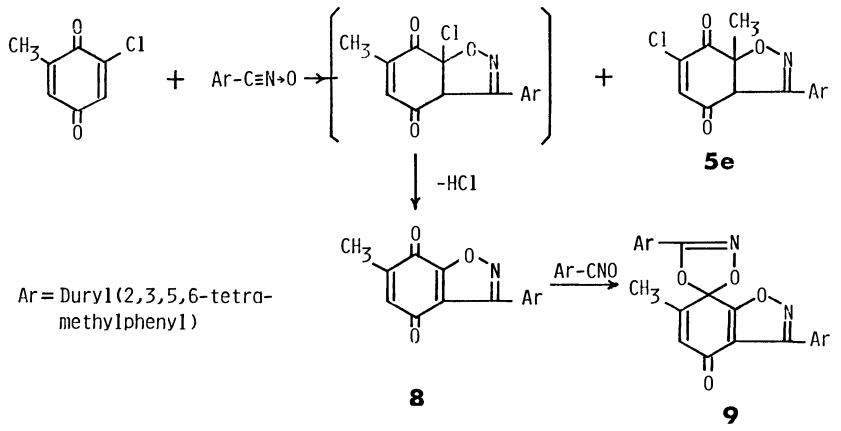

Scheme 3.

protons respectively, which are assigned to the angular methine and methyl protons. The signals due to the quinone olefinic methine and aromatic protons are overlapped and appeared as a singlet at δ 7.00. The methyl protons of the duryl moiety resonate as broad singlets at δ 1.84 and 2.22, the former integrating for three protons and the latter for nine protons and having an inflection at δ 2.17. This pattern is interpreted in terms of the hindered rotation of the duryl group and one of the 2,6-methyl groups being in a close proximity of the quinone moiety. The ^{1}H NMR spectral pattern is similar to those of the other isoxazoline derivatives shown in Table 3. Besides this isoxazoline derivative, isoxazoloquinone **8**, formed by the addition of DNO to the C=C bond at the other side and subsequent dehydrochlorination, and a spiro-dioxazole derivative **9**, formed by addition of another DNO to the C=O bond of **8**, were isolated in 7 and 15% yields, respectively. Their structures were also determined by NMR, IR, and mass spectra and elemental analyses. In the ^{1}H NMR spectrum of **8**, the duryl methyl protons are seen as two singlets of the same intensity at δ 2.28 and 1.94, while the methyl on quinone moiety appears at δ 2.22 as a singlet. No absorption characteristic of the angular methine proton was observed in the region of δ 4.0—5.0. The integration of the ^{1}H NMR spectrum of **9** clearly shows that the product is a 1:2-adduct of the quinone and the nitrile *N*-oxide. The olefinic proton of **9** resonates at δ 6.24, being upper field than that of **8** which appears at δ 6.64, while the olefinic methyl signal of **9** appears at δ 2.30, slightly lower field than that of **8**. Taking into consideration the shift pattern of the signals on C=O addition, this suggests that the second nitrile *N*-oxide added across the carbonyl group adjacent to the methyl substituent. If so, this also supports the orientation of the first addition of the nitrile *N*-oxide and is well consistent with the reactivity enhancement of carbonyl bond toward cycloaddition by adjacent oxygen substitution described in the previous paper.[2]

Experimental

All melting points are uncorrected. The ^{1}H NMR spectra were recorded with a JEOL MH-100 100 MHz NMR spectrometer and the mass spectra with a Hitachi RMU-7L high-resolution mass spectrometer.

Materials. Methyl-*p*-benzoquinone (MQ), 2-methyl-1,4-naphthoquinone (MNQ), and 2,5-di-*t*-butyl-*p*-benzoquinone (25DBQ) were obtained commercially and were used after recrystallization. 2,6-Dimethyl-*p*-benzoquinone (26DMQ), 2,5-dimethyl-*p*-benzoquinone (25DMQ), 2,3,5-trimethyl-*p*-benzoquinone (TMQ), 2-methyl-5-isopropyl-*p*-benzoquinone (25MPQ), 2-methyl-6-*t*-butyl-*p*-benzoquinone (26MBQ), 2-methyl-5-*t*-butyl-*p*-benzoquinone (25MBQ) 2,6-diisopropyl-*p*-benzoquinone (26DPQ) were prepared from the corresponding phenols by the procedures of McLamore[5] with some modifications.[6] 2-Chloro-6-methyl-*p*-benzoquinone (26CMQ) was prepared by chlorination of o-cresol and subsequent oxidation of the 4,6-dichloro-*o*-cresol.[7] 2-Chloro-5-methyl-*p*-benzoquinone (25CMQ) was prepared from 2-methyl-*p*-benzoquinone by its hydrochlorination and subsequent oxidation[8]. By adopting a similar procedure, 3-chloro-2,6-dimethyl-*p*-benzoquinone (26DMCQ) and 3-chloro-2,5-dimethyl-*p*-benzoquinone (25DMCQ) were prepared from 26DMQ and 25DMQ respectively. The stable nitrile oxides (MNO, DNO, and CNO) were prepared according to the Grundmann's procedure.[9]

Reactions of Quinones with Nitrile N-*Oxides. General procedure*: The reaction was carried out by dissolving the reactants in benzene in a concentration of 5 mmol/100 ml each and allowing the mixture to stand at ambient temperature for 3—7 d. The progress of the reaction was followed by TLC using silica gel plates (Merck). After an appropriate reaction period the solvent was removed by evaporation under reduced pressure and the residue was triturated with petroleum ether or methanol. The solid product thus obtained was subjected to column chromatography on silica gel (Wako gel C-100 or C-200) using benzene as an eluent. The nitrile *N*-oxide, the quinone and the product were eluted in that order. The fractions containing the products were collected and evaporated under reduced pressure to afford the product, which was purified by recrystallization from benzene or a mixture of benzene and petroleum ether or hexane. The reaction conditions, physical constants, analytical and IR data are tabulated in Tables 1—3. The ^{1}H NMR data are summarized in Table 4.

Reactions of Unstabilized Nitrile N-*Oxides with 2,5-Di-*t*-butyl-*p*-benzoquinone (25DBQ)*. A typical example follows: A solution of *p*-chlorobenzhydroxamoyl chloride (950 mg, 5 mmol) in CH_2Cl_2 (30 ml) was cooled to -10 °C in an ice-salt bath. Triethylamine (0.55 g, 5 mmol) in CH_2Cl_2 (20 ml) was slowly added to the above solution with stirring and maintaining the temperature below -5 °C. After the

addition of the amine, a solution of 25DBQ (1.1 g, 5 mmol) in CH_2Cl_2 (30 ml) was added dropwise during 15 minutes maintaining the temperature below 0 °C. The reaction mixture was allowed to stand at ambient temperature for 2 d and then the solvent was removed by evaporation to dryness under reduced pressure. The residue was extracted with benzene to leave triethylammonium chloride as white solid. The extract was concentrated and subjected to column chromatography on silica gel using benzene as an eluent. The first fraction gave 100 mg (4%) of colorless crystals of 1:2-adduct, **7a**, mp 189—190 °C. The second fraction contained 100 mg (8%) of the unreacted quinone. The third fraction yielded 1.65 g (88%) of 1:1-adduct, **6a**, which was recrystallized from a mixture of benzene–petroleum ether to give stout yellow needles, mp 151—152 °C. Characterization data are given in Table 5.

*Reaction of 2-Chloro-6-methyl-*p*-benzoquinone (26CMQ) with 2,3,5,6-Tetramethylbenzonitrile* N-*Oxide (DNO)*: A solution of 26CMQ (0.78 g, 5 mmol) and DNO (0.87 g, 5 mmol) in chloroform (200 ml) was stirred at room temperature for 3 d. The solvent was removed by evaporation under reduced pressure and the residue was triturated with methanol. A yellow solid was obtained. This was collected by filtration and subjected to column chromatography on silica gel using benzene as an eluent. The first fraction gave colorless crystals of **9**, which was recrystallized from ethanol into silky white needles (300 mg, 15%), mp 163—164 °C. IR(KBr) 1680 cm^{-1}($\nu_{C=O}$). ^1H NMR ($CDCl_3$) δ=7.12 (1H, s) and 7.08 (1H, s)(duryl aromatic), 6.24 (1H, s, quinone olefinic), 2.44 (6H, s, duryl methyl), 2.26 (15H, m, duryl and quinone methyl), 1.92 and 1.96 (6H, two s, duryl methyl). M^+ was not observed and the fragmentation pattern was almost the sum of those of the isoxazoloquinone **8** and DNO, showing the peaks at *m/e* 295.1247 (calcd for **8**: 295.1207) and 175.0978 (calcd for DNO: 175.0997).

Found: C, 74.16; H, 6.30; N, 6.17%. Calcd for $C_{29}H_{30}N_2O_4$: C, 74.02; H, 6.43; N, 5.95%.

The second fraction gave yellow micro needles of isoxazoloquinone, **8** (100 mg, 7%) on recrystallization from ethanol, mp 174—176 °C. IR(KBr) 1650 and 1670 cm^{-1} ($\nu_{C=O}$). ^1H NMR($CDCl_3$) δ=7.12(1H, s, duryl aromatic), 6.64(1H, s, quinone olefinic), 2.28(6H, s, duryl 2,6-methyls), 2.22(3H, s, quinone methyl), 1.94(6H, s, duryl 3,5-methyls).

Found: C, 73.43; H, 5.16; N, 4.79%; M^+, 295.1171. Calcd for $C_{18}H_{17}NO_3$: C, 73.20; H, 5.80; N, 4.74%; M, 295.1207.

The third fraction gave yellow flakes of isoxazoline derivative, **5e** (450 mg, 30%) on usual work-up and recrystallization from benzene–petroleum ether, mp 183—184 °C. The characterization data for **5e** are given in Tables 3 and 4.

*Reaction of 2-Methyl-5-*t*-butyl-*p*-benzoquinone (25MBQ) with CNO*: A solution of 25MBQ (0.89 g, 5 mmol) and CNO (0.94 g, 5 mmol) in benzene (100 ml) was stirred for 10 d at room temperature. Evaporation of the solvent left a solid, which was washed with petroleum ether to give 1.65 g (90%) of the product. The NMR spectrum of the crude product revealed this to be a mixture of two C=C adducts (the signals at 4.84 and 4.62 due to the angular methines of the two adducts in the ratio of 1:2. The crude product was recrystallized from benzene–petroleum ether and the two kinds of crystals were separated manually under a microscope, giving yellow microcubes of **3d** and pale yellow microneedles of **3m**. The characterization data are given in Tables 1 and 4.

Mechanism of the Photooxidation of and Photoepoxidation with Cyclic α-Diketones

Yasuhiko SAWAKI

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received Jauary 31, 1983)

The photooxidation of phenanthrenequinone (PhQ) under oxygen afforded diphenic acid and its peroxy acid, while acenaphthenequinone (AcQ) predominantly yielded 1,8-naphthalenedicarboxylic anhydride. The photolysis of PhQ or AcQ in the presence of olefins afforded predominantly 1:1 cycloadducts and the photoepoxidation was a very minor one accompanying significant amount of C–C cleavage of olefins. These results show that the photoreaction of PhQ or AcQ with olefins is very fast and competitive with the quenching and/or reaction with oxygen. The photoepoxidation of stilbene in the presence of dimethyl sulfoxide resulted in a high selectivity (>98%) for the *trans*-epoxide. The same was true for the epoxide formed in the coautoxidation of benzaldehyde and stilbene. These facts suggest that the photoepoxidation with cyclic α-diketones as a minor reaction proceeds chiefly by way of acylperoxyl radical, accompanying the epoxidation with peroxy acids produced concomitantly. Mechanisms of the photooxidation of and photoepoxidation with the cyclic diketones are discussed in comparison with the case of acyclic diketones.

Most of the sensitized photooxidation of olefins proceeds by way of a singlet oxygen reaction (*i.e.*, the Type II photooxidation).[1,2] Sometimes, epoxide formations have been observed to accompany some reactions with singlet oxygen.[3] Shimizu and Bartlett[4] reported a novel photoepoxidation with α-diketone and oxygen, which is quite different from the Type I photooxidation (*i.e.*, free radical autoxidations), singlet oxygen reactions or a recently found photooxidation *via* electron transfer.[5] The photoepoxidation with α-diketones has been utilized as a practical epoxidation method,[6] but there remains much to be clarified about the scope and mechanism of the photoreaction.

In the previous paper,[7] we suggested that the photoepoxidation with benzil or biacetyl proceeds *via* acylperoxyl radical (**2**) produced from the triplet diketone–oxygen adduct (**1**). The predominant formation of *trans*-epoxides[4a] and phenyl benzoates from the reaction of benzil in benzene[4c,7] are good evidence for the radical epoxidation *via* **2**. Recently, the photoepoxidation with acenaphthenequinone (AcQ) has been reported to afford a high yield of 1,8-naphthalenedicarboxylic anhydride.[8] However, the proposed mechanism is quite different from ours deduced from the reaction of acyclic α-diketones. Hence, it is interesting to decide whether such a specified mechanism is operating or not for cyclic α-diketones. Here we wish to report that the photooxidation of cyclic α-diketones is relatively ineffective ($\Phi \approx 0.005$) and the photoepoxidation of olefins is a rather minor reaction; the major pathway for the case of AcQ or phenanthrenequinone (PhQ) is a 1:1 cycloaddition between diketones and olefins. Recently, the radical epoxidation with **2** have been shown to occur in the photoepoxidation with benzoins and oxygen.[9]

Results and Discussion

In benzene benzil was photooxidized to yield benzoic acid (80%), perbenzoic acid (40—60%), and phenyl benzoate (30—50%) in addition to small amounts of biphenyl, benzoyl peroxide, and phenol.[7,10] The photooxidation rate of benzil was not altered by the addition of olefins, affording epoxides together with C–C cleavage products.[7] As described below, the photooxidation of cyclic α-diketones has been examined to compare with the acyclic benzil case.

PhQ. The photooxidation of PhQ in benzene afforded diphenic (**3**) and monoperoxydiphenic acids (**4**) in addition to 2,2′-biphenylcarbolactone (**5**) (1—2%) (Table 1). The formation of **5** may be formulated *via* the decarboxylation of **6** to yield **7** followed by the intramolecular cyclization. Phenyl diphenate, which corresponds to phenyl benzoate in the benzil case, could not be detected (*i.e.*, within 0.2% if any). Probably, the large steric effect of *o*-aroyl group in aroyloxyl radical **6** suppressed the radical aroyloxylation of benzene. Also we could detect neither diphenic anhydride **8** nor 2,2′-biphenyldicarbonyl peroxide **9** by GLC (*i.e.*, below 0.5% if any). For the GLC

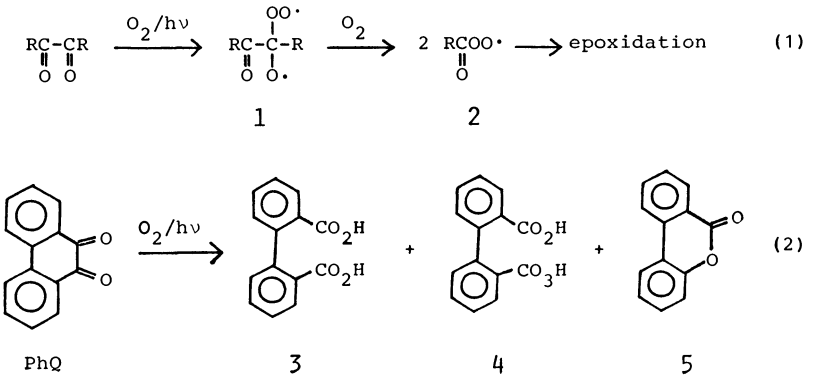

Table 1. Photooxidation of PhQ in benzene

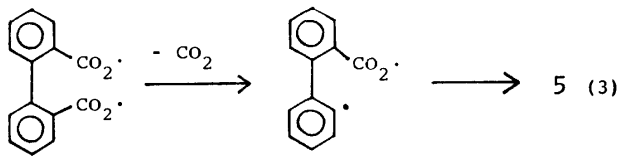
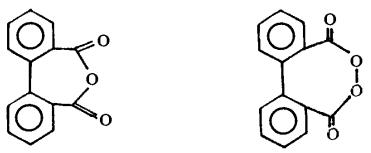
a) Irradiation of 2.5 mM PhQ through a Pyrex filter for 10—60 min under O_2 at 20 °C unless otherwise noted. b) Relative quantum yields from the decrease of PhQ as determined by UV absorbance at 420 nm. c) Products were determined by GLC. Allylic hydroperoxide were determined after the reduction with $NaBH_4$, and the acid after methylation with diazomethane. Peroxy acid **4** was titrated iodometrically. %Yields are based on PhQ. d) 1:1 Adducts of PhQ with olefins or THF. e) Absolute quantum yield is 0.0048. f) Not determined. g, h) Recovered olefins: cis/trans=0.35 and 4, respectively.



6 7 5 (3)



8 9

detection of diacyl peroxide **9**, we applied the facile reduction of **9** to **8** by triphenylphosphine.[11a] Since **9** is known to decompose thermally to afford **5**,[11b] some of **5** may be derived from **9**.

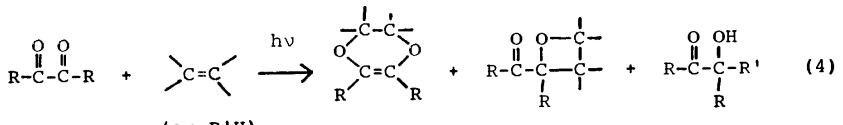
The photooxidation of PhQ in the presence of olefin resulted in the sharp decrease in diphenic acid formation and the major reaction changed to the cycloaddition between PhQ and olefins (Table 1). Since the oxygen quenching of triplet ketones is close to the diffusion-controlled rate (*e.g.*, 10^9 M^{-1} s^{-1}, 1 M= 1 mol dm^{-3}),[12] it is apparent that the cycloaddition between excited PhQ and olefins is likewise very fast. The photochemical 1,2-cycloaddition (**11**) or 1,4-addition (**10**) of PhQ is well known.[13] The isomer distributions of these cycloadducts are extensively studied and shown to change by olefins.[14] The photochemical 1,2-adducts such as **12** are also known for hydrogen donors, *e.g.*, ethers and aldehydes.[15]

The epoxide formation was only a minor reaction (2—10%) (Table 1). For cyclohexene, the ratio of epoxide:allylic hydroperoxide was *ca.* 1:10, which was approximately same with the ratio from AIBN-initiated autoxidation at 60 °C.[16] For the case of β-methylstyrene or stilbene, the yield of benzaldehyde, an oxidative C–C cleavage product, was higher than that of epoxides. Thus, it is apparent that the photoepoxidation with PhQ is not effective.

The quantum yield for the photooxidation of PhQ, irradiated at >320 nm in benzene, was Φ=0.0048, which is about one tenth of the benzil case (Φ=0.035).[7] For comparison, quantum yields were also determined under nitrogen; *i.e.*, Φ=0.71 (lit,[14a] 0.79) for the addition of PhQ to 2,3-dimethyl-2-butene and Φ= 0.95 (lit,[15b] 0.86) for the addition to THF, which are fairly consistent with the literature values as shown. The relative Φ values in Table 1 also suggest that the reaction with olefins or THF is fast and efficient. These will be discussed later.

AcQ. The photooxidation of AcQ gave anhydride **13** as a major product,[8,15b,17] 1,8-naphthalenedicarboxylic acid (**14**) being a minor one (Table 2).

The attempted photoepoxidation with AcQ was not efficient just like the PhQ case. Again, the predominant reaction was the cycloaddition of AcQ to olefins; the 1:1 adducts were a 2,3-dihydro-1,4-dioxin **10** for 1,2-dimethylcyclohexene and 2-acyloxetane **11** for the other olefins (see Experimental for details). The for-



(or R'H) 10 11 12 (4)

AcQ 13 14 (5)

mation of **10** from AcQ has been reported for 2,3-dimethyl-2-butene;[17] the formations of oxetane **11**[14c,d] and α-hydroxy ketone **12**[18] are also known.

Here, some should be noted for the discrepancy between the present results and the reported ones.[8] The relative quantum yields for the disappearance of AcQ was reported to be almost constant even in the presence of cyclohexene,[8] which is in sharp contrast to the present results in Table 2. We suppose that since the reported Φ values were determined by monitoring the formation of anhydride **13** by UV, the formation of cycloadduct **11** could not be detected because of the close similarity in UV spectra between AcQ and **11**.

Camphorquinone (CQ). The photooxidation of 2,3-bornanedione (CQ) in benzene was reported to yield many kinds of products involving a rather small amount of camphoric acid (**15**, 7%) and its anhydride (**16**, 3%).[19] The reported yields of **16** change with solvents, *e.g.*, 26% in MeOH,[20] 35% in xylene,[21] and predominant in CCl_4.[19]

The attempted photoepoxidation of β-methylstyrene and *trans*-stilbene with CQ resulted in poor yields (5—10%) of epoxide, accompanying C–C cleavage products. Cyclohexene (0.1 M) and CQ afforded 13% epoxide and 68% cyclohexenyl hydroperoxide, indicating again the radical autoxidation of olefin as a major reaction. Like PhQ or AcQ, the photoepoxidation with CQ is not effective.

Comparison of Cyclic and Acyclic α-Diketones. Quantum yields of the photooxidation in benzene are in the order of biacetyl≫benzil, CQ≫AcQ, PhQ, indicating much less effective photolysis for the cyclic diketones. For the photooxidation of benzil and biacetyl there is no accelerating effect by additives such as olefins, THF or *i*-PrOH; this suggests that the photochemical reactions with these additives are not so fast as those with oxygen. The same is true for cyclic diketone CQ. On the contrary, PhQ reacts very fast with olefins, THF or *i*-PrOH; for example, the photoreaction is 98-fold faster in the presence 20 vol% THF; similar trend is also observed for the case of AcQ (Table 2). As apparent in Tables 1 and 2, the accelerating effect is due to the fast formation of 1:1 adducts; thus, the photoepoxidation with these cyclic diketones is not effective.

The same features are also shown in the photoepoxidation of stilbene (Table 3). While considerably high yields (50—80%) of epoxide were obtained with benzil and biacetyl, the reaction with cyclic diketones resulted in only 4—7% yields, predominantly affording 1:1 cycloadducts. The photoepoxidation always afforded predominantly *trans*-epoxide (85—95% trans), and the trans % increases up to over 97% by adding dimethyl sulfoxide (DMSO). Similar effect of DMSO was observed for the coautoxidation of 0.05 M stilbene and 0.2 M benzaldehyde (initiated by α,α'-azobisisobutyronitrile at 60 °C); % trans increased from 65% to 98% by adding DMSO. It is well known that the coautoxidation of aldehyde and olefin affords a mixture of *cis*- and *trans*-epoxides, the epoxidizing species being acylperoxyl radical and peroxy acid.[22] These results suggest that the peroxy acid epoxidation is effectively reduced by DMSO[23] and the epoxidation by acylperoxyl radical proceeds with high selectivity (*i.e.*, >98%) for *trans*-stilbene oxide.

Here, some should be noted about the quenching by DABCO (1,4-diazabicyclo[2.2.2]octane). The results in Tables 1 and 2 show an effective quenching by DABCO for the diketone photooxidation.[24] However,

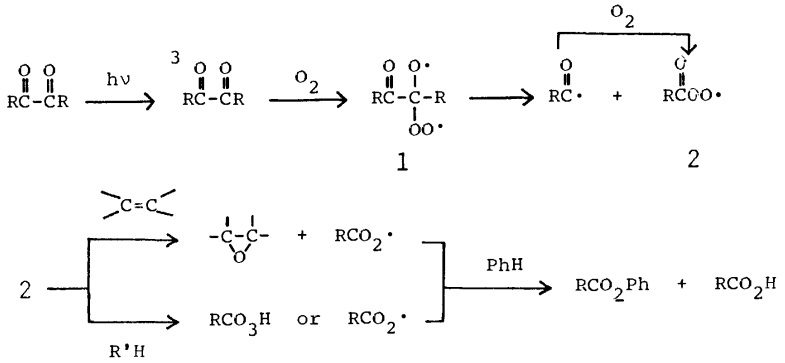
B) Coautoxidation with PhCHO-AIBN[h]				
trans-Stilbene	PhH	f)	(0:100)	Epoxidn.
cis-Stilbene	PhH	f)	(35:65)	Epoxidn.
cis-Stilbene	PhH (DMSO)	f)	(2:98)	Epoxidn.

a) Products were determined by GLC based on the consumed diketone. b) 0.1 M DMSO was added. c) Irradiation of 2 mM diketone and 0.05 M *trans*-stilbene solution through a Pyrex filter under O_2 (20 °C, 2 h). Recovered olefin: cis/trans=4—9. d) The cis/trans ratios were practically the same when *cis*-stilbene was used. e) 1:1 Adducts of diketone and olefin. See Tables 1 and 2. f) Not determined. g) Many products were detected by GLC, but not identified. h) Coautoxidation of 0.05 M stilbene and 0.2 M benzaldehyde was initiated by the thermal decomposition of AIBN (≈5 mM) at 60 °C.



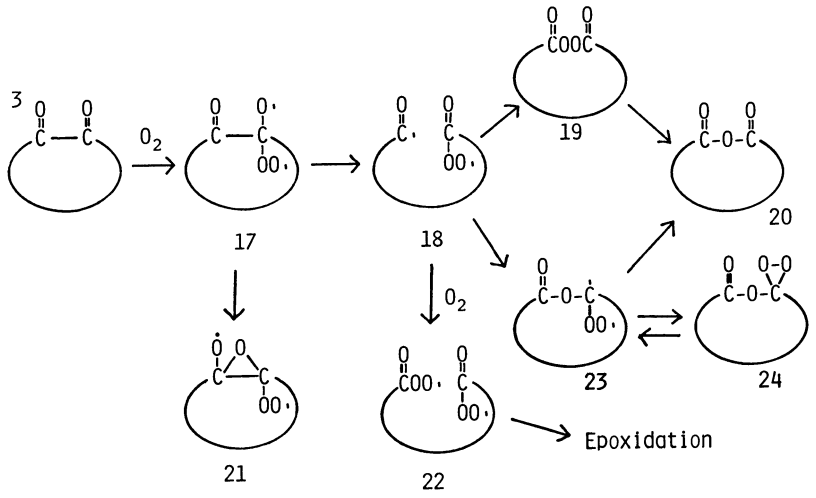
Scheme 1.

the apparent quenching by DABCO does not mean that the diketone photooxidation proceeds *via* a singlet oxygen reaction, since the photolysis of benzil was rather retarded by adding Methylene Blue or Rose Bengal, an efficient $^1O_2$ sensitizer. The addition of DABCO to PhQ in benzene resulted in weakly reddish solution with a few percent increase in the absorbance at >300 nm. Probably this indicates the formation of a C-T complex between PhQ and DABCO, which may act as an efficient energy accepter for the excited PhQ*, quenching the PhQ photolysis. This was ascertained by the fact that the cycloaddition of PhQ with cyclohexene is also efficiently quenched by DABCO. The same is probably true for the other diketones in Table 3, although no absorption due to C-T complex could be detected by UV.

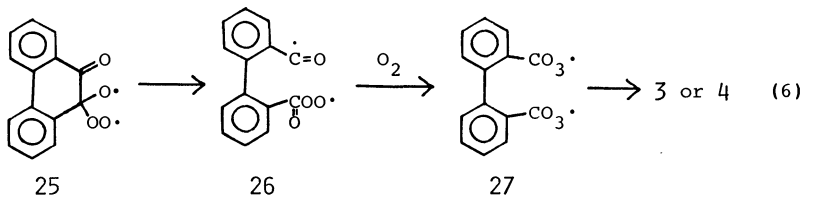
Mechanism. The photoepoxidation of acyclic α-diketones has been shown to proceed by way of Scheme 1.[7] A considerable amount of phenyl benzoate was obtained for the benzil photooxidation in benzene (*i.e.*, R=Ph).[7]

The photooxidation of AcQ affords anhydride as a major product. Similar anhydride formations are also known for the photooxidation of CQ[19–21] and other cyclic diketones.[20,25] Some possible routes for the formation of anhydride (**20**) from cyclic diketones may be written as Scheme 2. This mechanism is, in parts, similar to that reported by Koo and Schuster,[8] but essentially different in the fate of alkoxyl radical **17**. The β-scission of alkoxyl radical **17** to afford **18** is probably facile since the scission of acyl radical in α-acylalkoxyl radicals has been established to be very fast.[26] The conversion of **17** to **21**, as was suggested,[8] seems to be unfavorable on the basis of an energetic point of view that **21**, an oxirane diradical, would be much less stable than **17**, a ketone diradical. No formation of anhydride from PhQ also supports the pathway **17**→**18**.

The next choice is about the reactions of radical pair **18**. It seems to couple easily to diacyl peroxide **19**, but, **19** is not likely to afford smoothly anhydride **20**.[27] An alternative reaction of **18** is the intramolecular addition of acyl radical to carbonyl oxygen to afford **23**. Since the addition of acyl radical to carbonyls is known intermolecularly,[29] the intramolecular addition (*i.e.*, **18**→**23**) may proceed smoothly.



Scheme 2.



It is not certain that intermediate diradical **23** might be equilibriated with unstable dioxirane (**24**) or not. These unstable intermediate **23** and **24** are probably a poor O-transfer agent to olefins.[30] In the photooxidation of AcQ the formation of only small amount of diacid **14** indicates that intramolecular addition of acyl radical **18** to form **23** is much faster than the trapping by oxygen to afford **22** (*i.e.*, ultimately **14**). The anhydride formation in benzene is only 3% from CQ[19] and <1% from PhQ, suggesting that the anhydride formation from α-diketones is not a general or primary photochemical event.

In the photooxidation of PQ the predominant formation of diphenic acid (**3**) and peroxy acid (**4**) suggests that, after fast C–C scission in **25**, the resulting diradical **26** is effectively trapped by oxygen (Eq. 6). In other words, an intramolecular cyclization of **26** to **9** or to diradical **23** is much slower than the trapping of acyl radical **26** by oxygen. One reason for the unfavorable intramolecular coupling of **26** (or **18**) may be the free rotation of two aryl rings in **26**, which is not the case for AcQ or CQ of fixed carbon skelton. Another reason is probably due to spin multiplicity effect.[31] There are many cases where coupling products from triplet radical pairs are of much lower yields than those of corresponding singlet ones.[32] The present reaction of triplet quinones with oxygen would produce predominantly triplet or quintet diradical **25** and hence **26**.[33] Thus the ring closure of **26** to **9** becomes less efficient as observed.

In conclusion, the photooxidation of PhQ proceeds *via* the similar pathway (*i.e.*, **17**→**18**→**22**) as is the case for acyclic benzil, while AcQ gives anhydride probably by way of **17**→**18**→**23**→**20**. The photoepoxidation with cyclic α-diketones is not efficient, 1:1 cycloadditions being predominant. The epoxidation as a minor reaction affords chiefly *trans*-epoxide accompanying a significant amount of C–C cleavage products. The addition of DMSO results in much higher selectivity for *trans*-epoxide. These facts suggest that the photoepoxidation with cyclic α-diketones proceeds by way of acylperoxyl radical just as acyclic ones.

Experimental

Melting points were measured by a Yanagimoto micro melting point apparatus and are corrected. ^{1}H NMR spectra were recorded with a Hitachi R24-B spectrometer, IR spectra with a Perkin-Elmer 337 spectrometer, and UV with a Hitachi 124 spectrophotometer. GLC analysis were performed with a Yanagimoto G 180 gas chromatograph using two different 1 m columns: PEG 20M, 20% on Chamelite CK; Silicon OV-17, 5% on Shimalite W.

Materials. AcQ and PhQ were prepared according to literatures, mp 260 °C (lit,[34] 259—260 °C) and 205—208 °C (lit,[35] 209—210 °C), respectively. CQ was obtained by selenium dioxide oxidation of camphor in AcOH (reflux, 2 h), mp 198—199 °C (lit,[36] 198 °C). *cis*-Stilbene (95% pure) was obtained by benzil-sensitized photoisomerization of *trans*-stilbene. Other olefins were of commercial sources.

Photooxidation of PhQ. A typical procedure is as follows. A 5 ml benzene solution of 2.5 mM PhQ was irradiated under oxygen through a Pyrex filter using a medium pressure 300 W Hg lamp at *ca.* 20 °C. Products were determined by GLC directly and carboxylic acids were analyzed after methylation with diazomethane. Peroxy acid was titrated as described previously.[37] A small amount of 2,2′-biphenylcarbolactone **5** was detected by GLC, but diphenic anhydride was not. Diphenic acid was identified as dimethyl ester and also by the thermal conversion to diphenic anhydride.

The photoepoxidation of olefins with diketone was conducted similarly and resulting allylic hydroperoxides were determined after the reduction with $NaBH_4$ and MeOH. The results are listed in Table 1. Since the cycloaddition of PhQ with olefins has extensively studied,[13,14] the 1:1 adducts were not isolated.

Quantum yields for the photooxidation of PhQ were determined using trioxalatoferrate(III) actinometry[38] and/or a merry-go-round apparatus.

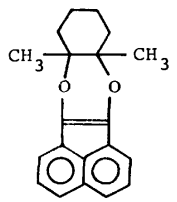
Photooxidation of AcQ. The photooxidation of AcQ was carried out similarly with the PhQ case. The GLC analysis showed a predominant formation of anhydride **13** together with a minor amount of diacid (**14**).

The photoepoxidation of olefins with AcQ were conducted similarly and the results are shown in Table 2. As exemplified below, the major photochemical reaction of AcQ with olefins is 1,2- or 1,4-cycloaddition to yield oxetanes (**11**) or **10**.

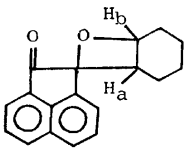
Photoreaction of AcQ with 1,2-Dimethylcyclohexene. A CH_2Cl_2 solution (20 ml) of AcQ (60 mg) and 1,2-dimethylcyclohexene (0.15 ml) was irradiated under air for 5 h. The NMR spectra of the crude reaction mixture indicated a single reaction product. Purification by passing through a Florisil column (20 g) using hexane–CH_2Cl_2 (9:1) afforded red dihydrodioxin **28** in *ca.* 60% yield, mp 134—136 °C. NMR (δ, CCl_4): 1.5—1.8 (m, 8H, methylenes), 1.39 (s, 6H, two methyl), and 7.2—7.5 (m, 6H, aromatic protons); UV (hexane): 465 and 485 (ε 520), 316 (5100), 303 (5700), and 228 nm (22000).

Found: C, 82.26; H, 7.33; O, 10.41%. Calcd for $C_{20}H_{20}O_2$: C, 82.15; H, 6.89; 10.95%.

The NMR and UV spectra are close to those of the corresponding dihydroxin from AcQ and 2,3-dimethyl-2-butene; NMR (δ), 1.37 and 7.2—7.5; UV, 450, 318, 306, and 230 nm.[17]



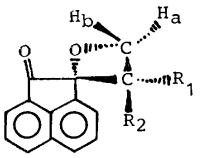
28



29

Photoreaction of AcQ with Cyclohexene. A similar reaction of AcQ with cyclohexene under air and column chromatography using hexane–CH_2Cl_2 (1:1) gave oxetane **29** in 65% yield. NMR spectra (δ, $CDCl_3$), 1.2—2.2 (m, 8H, methylenes), 3.10 (q, J=20 Hz, H_a), 5.5—5.8 (m, H_b) and 7.5—8.2 (m, 6H, aromatic protons); UV (hexane), 338 (ε 3300), 325 (sh, 3600), 310 (4420), 300 (sh, 3800), 277 (2700), and 223 nm (3600).

Photoreaction of AcQ with 1,1-Diphenylethylene. The 5 h irradiation of AcQ (60 mg) and olefin (120 mg) in CH_2Cl_2 (20 ml) under air yielded a single product as checked by NMR. Purification by passing through a Florisil column using CH_2Cl_2 and recrystallization from hexane–CH_2Cl_2 gave pure crystals of oxetane **30a** in 19% yield, mp 220—224 °C (decomp). NMR spectra (δ, $CDCl_3$), 5.53 (d, J=6 Hz, H_a), 6.10 (d, J=6 Hz, H_a) and 6.5—8.1 (m, 16H aromatic protons). IR (Nujol), 1730 cm^{-1} (C=O); UV (hexane), 342 (ε 3000), 325 (sh, 2780), 313 (3620), 300 (sh, 2850), 284 (sh, 3140), 254 (sh, 6750), and 223 nm (16000). The structure **30a** as shown was deduced from the NMR spectra in comparison to corresponding protons in oxetanes.[39]



30

a R_1 = R_2 = Ph

b R_1 = Me, R_2 = Ph

c R_1 = Ph, R_2 = Me

Photoreaction of AcQ with α-Methylstyrene. The irradiation of CH_2Cl_2 solution (25 ml) of AcQ (60 mg) and α-methylstyrene (0.3 ml) under air afforded 1:1 mixture of two oxetane isomers in the combined yield of over 90% as determined by NMR. The two isomers were separated by passing a Florisil column (50 ml) using hexane–CH_2Cl_2 (1:1). The earlier fractions gave 4 mg (6%) of pure oxetane **30b**, mp 102—108 °C; NMR (δ, CCl_4), 1.71 (s, 3H, CH_3), 4.93 (d, J=6 Hz, 1H, H_a), 5.38 (d, J=6 Hz, 1H, H_b) and 6.4—8.0 (m, 11H, aromatic protons).

The latter fractions, after the recrystallization from hexane–CH_2Cl_2, afforded pure oxetane **30c** in 6% yield, mp 161—161.5 °C; NMR (δ, CCl_4), 1.82 (s, 3H, CH_3), 4.40 (d, J=5 Hz, 1H, H_a), 5.82 (d, J=5 Hz, 1H, H_b) and 6.4—8.0 (m, 11H, aromatic protons). UV spectra in hexane are the same for **30b** and **30c**; 337 (ε 3020), 326 (sh, 2940), 312 (4140), 300 (3560), 284 (sh, 3200), 260 (sh, 5750), 252 (6680), and 223 nm (27000). IR (film): 1730 cm^{-1} (C=O).

Found: C, 88.88; H, 5.71%. Calcd for $C_{21}H_{16}O$: C, 88.98; H, 5.37%.

The Synthesis of (+)-Coleon A

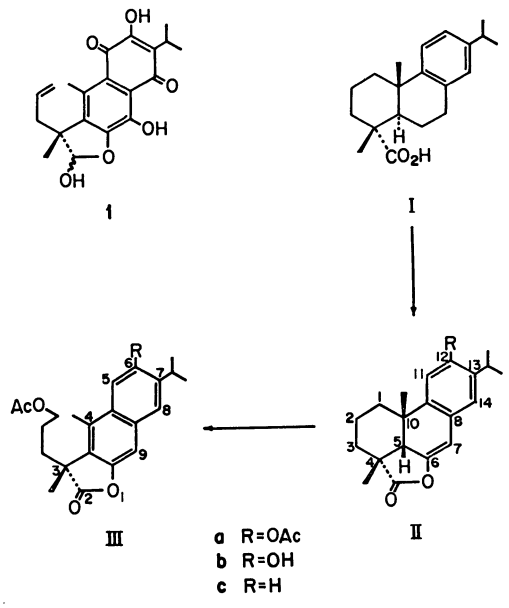
Takashi MATSUMOTO,* Sachihiko IMAI,* Takashi HIRATA, Yutaka FUKUDA, Tadashi YAMAGUCHI, and Kazuhiro INOUE

Department of Chemistry, Faculty of Science, Hiroshima University, Higashiseada-machi, Naka-ku, Hiroshima 730

(Received April 14, 1983)

Partial methylation of (*R*)-6-hydroxy-3-(3-hydroxypropyl)-7-isopropyl-3,4-dimethylnaphtho[2,3-*b*]furan-2(3*H*)-one followed by benzylation afforded the 6-benzyloxy-3-(3-methoxypropyl) derivative, which was converted into the 9-acetyl derivative by the series of reactions; sodium borohydride reduction, acetylation, alkaline hydrolysis, and Jones oxidation. This was oxidized with *m*-chloroperbenzoic acid to give the 9-acetoxy-5,8-quinone derivative, which was further converted into the 5,6,8,9-tetraacetoxy-3-(3-hydroxypropyl) derivative by hydrogenolysis, reductive acetylation, and demethylation. The tetraacetate in pyridine was treated with *o*-nitrophenyl selenocyanate in the presence of tributylphosphine and the resulting selenide was oxidized with hydrogen peroxide to give the 3-allyl derivative. This was converted into (+)-coleon A lactone by alkaline hydrolysis and subsequent oxidation. Finally, (+)-coleon A lactone was reduced with sodium borohydride to give (+)-coleon A which was also obtained by lithium aluminium hydride reduction of the 3-allyl derivative.

Coleon A (**1**),[1-3] a rare highly oxygenated 1,10-secoabietane derivative, has been isolated from the leaves of *Coleus igniarius* Schweinf. (Labiatae) by Eugster *et al.* In previous papers,[4,5] we have reported the novel conversion of 6-hydroxy-5βH-abieta-6,8,11,13-tetraen-18-oic acid 18,6-lactone derivatives (**IIa—c**) prepared from (+)-dehydroabietic acid (**I**), into the corresponding 1,10-secoabietane derivatives, (*R*)-3-(3-acetoxypropyl)-7-isopropyl-3,4-dimethylnaphtho[2,3-*b*]-furan-2(3*H*)-ones (**IIIa—c**). These 1,10-secoabietane derivatives **III** seemed to be useful intermediates for the synthesis of coleon A (**1**). In order to devise an efficient synthetic route for coleon A, some preliminary experiments were carried out on the introduction of oxygen functions into the naphthalene skeleton of **III** and the conversion of an acetoxypropyl side chain into an allyl group. The results were also reported in the preceding paper.[6] As an extension of the previous work, we now describe the synthesis of (+)-coleon A (**1**) starting from (*R*)-6-hydroxy-3-(3-hydroxypropyl)-7-isopropyl-3,4-dimethylnaphtho[2,3-*b*]furan-2(3*H*)-one (**2**).[6]



Partial methylation of **2**, prepared from (*R*)-6-acetoxy-3-(3-acetoxypropyl)-7-isopropyl-3,4-dimethylnaphtho[2,3-*b*]furan-2(3*H*)-one (**IIIa**),[2] with diazomethane and boron trifluoride etherate in ether at room temperature afforded the corresponding 6-hydroxy-3-(3-methoxypropyl) derivative (**3**). This was then converted into (*R*)-6-benzyloxy-7-isopropyl-3-(3-methoxypropyl)-3,4-dimethylnaphtho[2,3-*b*]furan-2(3*H*)-one (**4**) by treatment with benzyl chloride and anhydrous potassium carbonate in refluxing *N*,*N*-dimethylformamide. The compound **4** was also obtained from **2** by similar benzylation, followed by methylation of the resulting 6-benzyl ether (**5**). To introduce an acetyl group at C-9,[6] the lactone **4** was reduced with sodium borohydride in ethanol at room temperature and the resulting mixture of C-2 epimeric alcohols (**6**) immediately treated with acetic anhydride in the presence of boron trifluoride etherate at 0—5 °C to give the corresponding 2-acetoxy-9-acetyl derivative (**7**) [IR: 1748 (acetoxyl) and 1679 cm^{-1}(acetyl)]. The structure of **7** was supported by its ^{1}H NMR spectrum which showed singlet signals at δ 2.59 (3H) due to an acetyl and at δ 7.12 (1H) and 8.22 (1H) due to C-5 and C-8 protons. Hydrolysis of the acetoxyl group in **7** with sodium hydrogencarbonate in refluxing aqueous methanol afforded the hemiacetal derivative (**8**), which was oxidized with Jones reagent at 0—5 °C to give (*R*)-9-acetyl-6-benzyloxy-7-isopropyl-3-(3-methoxypropyl)-3,4-dimethylnaphtho[2,3-*b*]furan-2(3*H*)-one (**9**: 42% from **IIIa**). The IR spectrum of **9** showed absorption bands at 1803 (γ-lactone) and 1680 cm^{-1}(acetyl). In order to introduce oxygen functions at C-5, C-8, and C-9 in one stage, the acetyl compound **9** in dichloromethane was refluxed with *m*-chloroperbenzoic acid in the presence of *p*-toluenesulfonic acid monohydrate Purification of the crude product gave three *p*-quinone derivatives, **10** (22%), **11** (3%), and **12** (21%). The IR spectrum of **10** showed absorption bands at 1810 (γ-lactone), 1772 (acetoxyl), 1650 cm^{-1} (*p*-quinone), and its ^{1}H NMR spectrum showed signals at δ 1.17 (6H) and 3.27 (1H) due to an isopropyl, at δ 1.63 (3H) and 2.66 (3H) due to two methyls, at δ 2.42

(3H) due to an acetoxyl, at δ 3.20 (3H) due to a methoxyl, and at δ 5.27 (2H) and 7.2—7.5 (5H) due to a benzyl. These spectral data suggested the structure of **10** to be (*R*)-9-acetoxy-6-benzyloxy-2,3,5,8-tetrahydro-7-isopropyl-3-(3-methoxypropyl)-3,4-dimethylnaphtho[2,3-*b*]furan-2,5,8-trione. The IR spectra of **11** and **12** showed absorption bands at 1809 (γ-lactone), 1698 (acetyl), 1654 cm^{-1} (*p*-quinone), and at 3360 (hydroxyl), 1820 (γ-lactone), 1712 (acetyl), 1652 cm^{-1} (*p*-quinone), respectively. From these spectral data, the structures of **11** and **12** were assigned respectively to be (*R*)-9-acetyl-6-benzyloxy-2,3,5,8-tetrahydro-7-isopropyl-3-(3-methoxypropyl)-3,4-dimethylnaphtho[2,3-*b*]furan-2,5,8-trione and (*R*)-9-acetyl-2,3,5,8-tetrahydro-6-hydroxy-7-isopropyl-3-(3-methoxypropyl)-3,4-dimethylnaphtho[2,3-*b*]furan-2,5,8-trione. These structures were further supported by their ^1H NMR spectra (see Experimental section). In order to examine the effect of other substituents at C-6 for the *m*-chloroperbenzoic acid oxidation, the 6-methoxy (**14**) and 6-acetoxy (**15**) derivatives were also prepared as follows. Hydrogenolysis of **9** in acetic acid with 10% Pd–C at 60 °C afforded the corresponding 6-hydroxy compound (**13**); IR: 3590, 3310 br (hydroxyl), 1798 (γ-lactone), 1673 cm^{-1} (acetyl). The compound **13** was converted into **14** (57% from **9**) [IR: 1807 (γ-lactone), 1680 cm^{-1} (acetyl)] and **15** (96% from **9**) [IR: 1811 (γ-lactone), 1762 (acetoxyl), 1688 cm^{-1} (acetyl)] by methylation with methyl iodide and anhydrous potassium carbonate in refluxing acetone and by acetylation with acetic anhydride in pyridine. Oxidation of **14** with *m*-chloroperbenzoic acid and *p*-toluenesulfonic acid monohydrate in refluxing dichloromethane afforded the desired (*R*)-9-acetoxy-2,3,5,8-tetrahydro-7-isopropyl-6-methoxy-3-(3-methoxypropyl)-3,4-dimethylnaphtho[2,3-*b*]furan-2,5,8-trione (**16**: 11%) [IR: 1808 (γ-lactone), 1768 (acetoxyl), 1652 cm^{-1} (*p*-quinone)] together with its 9-acetyl derivative (**17**: 10%) [IR: 1808 (γ-lactone), 1700 (acetyl), 1657 cm^{-1} (*p*-quinone)]. The similar oxidation of **15** yielded only the Baeyer-Villiger oxidation product, (*R*)-6,9-diacetoxy-7-isopropyl-3-(3-methoxypropyl)-3,4-dimethylnaphtho[2,3-*b*]furan-2(3*H*)-one (**18**: 67%) [IR: 1800 (γ-lactone), 1763, 1754 cm^{-1} (acetoxyls)], and no *p*-quinone derivative. The structure of **18** was supported by its ^1H NMR spectrum, which showed singlet signals at δ 2.38 (3H) and 2.47 (3H) due to two acetoxyls, and at δ 7.64 (1H) and 7.75 (1H) due to C-5 and C-8 protons. The above oxidation of **9**, **14**, and **15** indicated that a benzyloxyl group at C-6 increased the yield of the desired acetoxy-*p*-quinone derivative: That is, the benzyloxy derivative **9** was superior to the methoxy (**14**) and acetoxy (**15**) derivatives in one-stage oxidation of C-5, C-8, and C-9. Hydrogenolysis of **10** with 10% Pd-C in acetic acid at 60 °C, followed by reductive acetylation with zinc and acetic anhydride in pyridine at room temperature yielded (*R*)-5,6,8,9-tetraacetoxy-7-isopropyl-3-(3-methoxypropyl)-3,4-dimethylnaphtho[2,3-*b*]furan-2(3*H*)-one (**19**: 76%).

Subsequently, the transformation of a methoxypropyl side chain into an allyl group was carried out as follows. Demethylation[7] of **19** with boron tribromide, sodium iodide, and 15-crown-5 in dichloromethane at

23

—30 °C under a stream of nitrogen afforded the 3-(3-hydroxypropyl) derivative (**20**). This was immediately treated with *o*-nitrophenyl selenocyanate and tributylphosphine in pyridine[8] at room temperature under a stream of nitrogen to give a selenide (**21**: 75% from **19**). Oxidation of **21** with 50% hydrogen peroxide in tetrahydrofuran at room temperature yielded (*R*)-5,6,8,9-tetraacetoxy-3-allyl-7-isopropyl-3,4-dimeth-

ylnaphtho[2,3-*b*]furan-2(3*H*)-one (**22**: 87%), whose ^{1}H NMR spectrum showed signals at δ 2.34 (6H), 2.38 (3H), and 2.39 (3H) due to four acetoxyls and at δ 2.79 (2H) and 4.85—5.6 (3H) due to an allyl. The allyl derivative **22** was then converted into (*R*)-3-allyl-2,3,5,8-tetrahydro-6,9-dihydroxy-7-isopropyl-3,4-dimethylnaphtho[2,3-*b*]furan-2,5,8-trione (**23**: 40%) [$[\alpha]_D$ +145° (EtOH); IR: 3325 (hydroxyls), 1808 (γ-lactone), 1647 cm^{-1} (*p*-quinone)] by hydrolysis with aqueous potassium hydroxide in refluxing methanol, followed by oxidation with oxygen and subsequent treatment with dilute hydrochloric acid. Reduction of **23** with sodium borohydride in aqueous ethanol afforded a mixture of C-2 epimeric alcohols (**1**: 75%), mp 140.5—141.5 °C, $[\alpha]_D$ +88° ($CHCl_3$); IR: 3580, 3495, 3305 (hydroxyls), 1657 cm^{-1} (*p*-quinone). Compound **1** was also obtained by reduction of **22** with lithium aluminium hydride in refluxing tetrahydrofuran in 34% yield. The physical and spectral data of the synthetic **1** and **23** were in good agreement with those of natural coleon A, mp 136—136.5 °C, $[\alpha]_D$ +80° ($CHCl_3$), and coleon A lactone, $[\alpha]_D$ +144° (EtOH). From the present study, the stetreochemistry of C-3 in coleon A (**1**) was conclusively assigned to be the *R*-configuration, which was previously suggested by Eugster[3,9] on the basis of the incorporation experiments using [2-^{14}C]mevalonic acid.

Experimental

All melting points are uncorrected. The IR spectra and optical rotations were measured in chloroform, and the ^{1}H NMR spectra in deuteriochloroform at 90 MHz, with tetramethylsilane as an internal standard, unless otherwise stated. The chemical shifts are presented in terms of δ values; s: singlet, bs: broad singlet, d: doublet, bd: broad doublet, t: triplet, m: multiplet. The column chromatography was performed using Merck silica gel (0.063 mm).

(R)-6-Benzyloxy-7-isopropyl-3-(3-methoxypropyl)-3,4-dimethylnaphtho[2,3-b]furan-2(3H)-one (4). (*R*)-6-Acetoxy-3-(3-acetoxypropyl)-7-isopropyl-3,4-dimethylnaphtho[2,3-*b*]furan-2(3*H*)-one (**IIIa**)[2] (16.50 g) was hydrolyzed by the known procedure[6] to give the crude (*R*)-6-hydroxy-3-(3-hydroxypropyl)-7-isopropyl-3,4-dimethylnaphtho[2,3-*b*]furan-2(3*H*)-one (**2**)[6] (13.10 g).

a): To a solution of the above crude **2** (13.10 g) in ether (400 ml) was added successively boron trifluoride etherate (6.40 ml) and a diazomethane ether solution (800 ml), which was prepared from *N*-methyl-*N*-nitrosourea (80 g) by the known procedure and dried over potassium hydroxide. The mixture was allowed to stand at room temperature for 30 min and then filtered to remove resinous material. The filtrate was washed with aqueous sodium hydrogencarbonate and brine, dried over sodium sulfate, and evaporated *in vacuo* to give the crude 6-hydroxy-3-(3-methoxypropyl) derivative (**3**) (13.80 g). IR: 3590, 3300br, 1785, 1620 cm^{-1}; ^{1}H NMR: δ=1.32 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.61 (3H, s, C_3-CH_3), 2.50 (3H, s, C_4-CH_3), 3.22 (3H, s, $-OCH_3$), 3.27 (2H, t, J=6 Hz, $-C\underline{H}_2OMe$), 3.44 (1H, m, $-C\underline{H}(CH_3)_2$), 6.68 (1H, br, C_6–OH, disappeared with D_2O), 7.23 (2H, s, C_5–H and C_9–H), 7.54 (1H, s, C_8–H).

A mixture of crude **3** (13.80 g), benzyl chloride (5.30 ml), and anhydrous potassium carbonate (58 g) in *N,N*-dimethylformamide (143 ml) was refluxed for 30 min. The mixture was poured into water, acidified with dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo* to give the crude **4** (17.75 g) which was used without purification in the next reaction. The crude **4** obtained from another experiment was purified by column chromatography on silica gel, using ether–benzene (1:9) as the eluent, to give pure **4**. $[\alpha]_D$ +40° (*c* 1.13); IR: 1800, 1645, 1628 cm^{-1}; ^{1}H NMR (CCl_4): δ=1.32 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.58 (3H, s, C_3-CH_3), 2.54 (3H, s, C_4-CH_3), 3.12 (3H, s, $-OCH_3$), 3.13 (2H, t, J=6 Hz, $-C\underline{H}_2OMe$), 3.47 (1H, m, $-C\underline{H}(CH_3)_2$), 5.18 (2H, s, $-OC\underline{H}_2Ph$), 7.17 (2H, bs, C_5–H and C_9–H), *ca.* 7.2—7.5 (5H, m, $-OCH_2C_6\underline{H}_5$), 7.51 (1H, s, C_8–H). Found: C, 77.64; H, 7.45%. Calcd for $C_{28}H_{32}O_4$: C, 77.75; H, 7.46%.

b): A mixture of the crude **2** (4.00 g) prepared from **IIIa** (4.99 g), benzyl chloride (2.15 ml), anhydrous potassium carbonate (17.0 g), and potassium iodide (2.10 g) in acetone (120 ml) was refluxed for 8 h and then allowed to stand overnight at room temperature. After the mixture had been filtered, the filtrate was evaporated *in vacuo* and the residue was diluted with ether. The ether solution was washed with aqueous sodium thiosulfate and brine, dried over sodium sulfate, and evaporated *in vacuo* to give the crude 6-benzyloxy derivative (**5**) (5.30 g). The crude **5** obtained from another experiment was purified by column chromatography on silica gel, using ether–benzene (1:9) as the eluent, to give pure **5**. $[\alpha]_D$ +41° (*c* 2.24); IR: 3430br, 1797, 1640, 1625 cm^{-1}; ^{1}H NMR: δ=1.35 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.53 (1H, br, –OH, disappeared with D_2O), 1.65 (3H, s, C_3-CH_3), 2.60 (3H, s, C_4-CH_3), 3.47 (2H, t, J=6 Hz, $-C\underline{H}_2OH$), 3.51 (1H, m, $-C\underline{H}(CH_3)_2$), 5.23 (2H, s, $-OC\underline{H}_2Ph$), 7.27 (2H, s, C_5–H and C_9–H), *ca.* 7.30—7.55 (5H, m, $-OCH_2C_6\underline{H}_5$), 7.58 (1H, s, C_8–H). Found: C, 77.76; H, 7.33%. Calcd for $C_{27}H_{30}O_4$: C, 77.48; H, 7.23%.

To a stirred solution of the crude **5** (5.30 g) in ether (290 ml) was added successively boron trifluoride etherate (2.9 ml) and a diazomethane ether solution (250 ml) which was prepared from *N*-methyl-*N*-nitrosourea (25 g) by the known procedure. After work-up as described for the preparation of **3**, crude **4** (5.49 g) was obtained.

(R)-9-Acetyl-6-benzyloxy-7-isopropyl-3-(3-methoxypropyl)-3,4-dimethylnaphtho[2,3-b]furan-2(3H)-one (9). *a)*: Sodium borohydride (3.33 g) was added portionwise to a stirred solution of the crude **4** (17.75 g, prepared from **3**) in ethanol (720 ml) with cooling in an ice-water bath. The mixture was stirred at this temperature for 1 h and then at room temperature for 15 h. After the excess hydride had been decomposed with acetone, the mixture was concentrated *in vacuo*, poured into dilute hydrochloric acid, and extracted with chloroform. The chloroform extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo* to give a mixture of the crude C-2 epimeric alcohols (**6**) (16.50 g) which was used without purification in the next reaction. IR: 3610, 3350br, 1628 cm^{-1}; ^{1}H NMR (CCl_4): δ=1.30 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.37 and 1.43 (3H, each s, C_3-CH_3), 2.50 (3H, s, C_4-CH_3), 3.18 and 3.23 (3H, each s, $-OCH_3$), *ca.* 3.1—3.3 (2H, m, $-C\underline{H}_2OMe$), 3.43 (1H, m, $-C\underline{H}(CH_3)_2$), 5.11 (2H, s, $-OC\underline{H}_2Ph$), 5.34 and 5.46 (1H, each s, *ca.* 1:3, C_2–H), 6.82 (1H, s, C_9–H), 7.10 (1H, s, C_5–H), *ca.* 7.2—7.5 (6H, m, C_8–H and $-OCH_2C_6\underline{H}_5$).

Boron trifluoride etherate (16.5 ml) was added to a stirred solution of the crude **6** (16.50 g) in acetic anhydride (330 ml) at 0—5 °C. The mixture was stirred at this temperature for 4 min, poured into a mixture of ice and aqueous sodium hydrogencarbonate, and extracted with chloroform. The chloroform extract was washed with brine, dried over sodium

sulfate, and evaporated *in vacuo* to give a crude epimeric mixture at C-2 of 2-acetoxy-9-acetyl-6-benzyloxy derivative (**7**) (20.00 g) which was used without purification in the next reaction. The crude **7** obtained from another experiment was purified by column chromatography on silica gel, using ether–benzene (8:92) as the eluent, to give pure C-2 epimeric mixture. IR: 1748, 1679 cm^{-1}; ^1H NMR (CCl_4): δ=1.32 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.43 and 1.50 (3H, each s, C_3-CH_3), 1.92 and 2.03 (3H, each s, $-OCOCH_3$), 2.53 (3H, s, C_4-CH_3), 2.59 (3H, s, C_9-COCH_3), 3.17 and 3.23 (3H, each s, $-OCH_3$), *ca.* 3.1—3.3 (2H, m, $-C\underline{H}_2OMe$), 3.45 (1H, m, $-C\underline{H}(CH_3)_2$), 5.16 (2H, s, $-OC\underline{H}_2Ph$), 6.38 and 6.47 (1H, each s, *ca.* 1:3, C_2-H), 7.12 (1H, s, C_5-H), *ca.* 7.2—7.5 (5H, m, $-OCH_2C_6\underline{H}_5$), 8.22 (1H, s, C_8-H). Found: C, 74.28; H, 7.51%. Calcd for $C_{32}H_{38}O_6$: C, 74.10; H, 7.39%.

A mixture of crude **7** (20.00 g) and sodium hydrogencarbonate (17.0 g) in methanol (1600 ml) and water (340 ml) was refluxed for 2 h. The mixture was concentrated *in vacuo* to *ca.* 500 ml, diluted with brine, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo* to give a crude epimeric mixture at C-2 of 9-acetyl-6-benzyloxy-2-hydroxy derivative (**8**) (17.30 g) which was used without purification in the next reaction. IR: 3610, 3325br, 1668 cm^{-1}; ^1H NMR (60 MHz, CCl_4): δ=1.31 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.28 and 1.37 (3H, each s, C_3-CH_3), 2.47 (3H, s, C_4-CH_3), 2.61 (3H, s, C_9-COCH_3), 3.12 and 3.18 (3H, each s, $-OCH_3$), *ca.* 3.0—3.3 (2H, m, $-C\underline{H}_2OMe$), 3.42 (1H, m, $-C\underline{H}(CH_3)_2$), 5.09 (2H, s, $-OC\underline{H}_2Ph$), *ca.* 5.2—5.5 (2H, m, C_2-H and $-OH$), 7.05 (1H, s, C_5-H), *ca.* 7.1—7.5 (5H, m, $-OCH_2C_6\underline{H}_5$), 8.13 (1H, s, C_8-H).

Jones reagent [2.5 M (1 M=1 mol dm^{-3}): 28.8 ml] was added dropwise to a stirred solution of crude **8** (17.30 g) in acetone (440 ml) at 0—5 °C. The mixture was stirred at this temperature for 15 min and the excess oxidant decomposed with methanol. The mixture was poured into brine and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (750 g), using ether–benzene (3:97) as the eluent, to give **9** (8.06 g: 42.4% from **IIIa**). This was recrystallized from methanol, mp 140 °C, $[\alpha]_D$ +28° (*c* 0.830); IR: 1803, 1680, 1623 cm^{-1}; ^1H NMR (CCl_4): δ=1.34 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.60 (3H, s, C_3-CH_3), 2.55 (3H, s, C_4-CH_3), 2.70 (3H, s, C_9-COCH_3), 3.12 (3H, s, $-OCH_3$), 3.15 (2H, t, J=6 Hz, $-C\underline{H}_2OMe$), 3.46 (1H, m, $-C\underline{H}(CH_3)_2$), 5.18 (2H, s, $-OC\underline{H}_2Ph$), 7.17 (1H, s, C_5-H), *ca.* 7.2—7.5 (5H, m, $-OCH_2C_6\underline{H}_5$), 8.16 (1H, s, C_8-H). Found: C, 76.00; H, 7.40%. Calcd for $C_{30}H_{34}O_5$: C, 75.92; H, 7.22%.

b): The crude **4** (5.49 g, prepared from **5**) was also subjected to a series of reactions in *a)* to yield **9** (2.35 g: 40.9% from **IIIa**).

Oxidation of ***9*** *with* m-*Chloroperbenzoic Acid.* A mixture of **9** (950 mg), *m*-chloroperbenzoic acid (90%: 1550 mg), and *p*-toluenesulfonic acid monohydrate (95 mg) in dichloromethane (47.5 ml) was refluxed for 3 h. The mixture was diluted with ether and the ether solution washed successively with aqueous potassium iodide, aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and brine. The dried solution was evaporated *in vacuo*. The residue was chromatographed on silica gel (100 g), using ether–benzene (1:99) as the eluent, to give (*R*)-9-acetoxy-6-benzyloxy-2,3,5,8-tetrahydro-7-isopropyl-3-(3-methoxypropyl)-3,4-dimethylnaphtho[2,3-*b*]furan-2,5,8-trione (**10**) (231 mg: 22.2 %). This was recrystallized from methanol, mp 147.5—148,5 °C, $[\alpha]_D$ +32° (*c* 3.32); IR: 1810, 1772, 1650, 1612, 1576 cm^{-1}; ^1H NMR: δ=1.17 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.63 (3H, s, C_3-CH_3), 2.42 (3H, s, $C_9-OCOCH_3$), 2.66 (3H, s, C_4-CH_3), 3.20 (3H, s, $-OCH_3$), 3.23 (2H, t, J=6 Hz, $-C\underline{H}_2OMe$), 3.27 (1H, m, $-C\underline{H}(CH_3)_2$), 5.27 (2H, s, $-OC\underline{H}_2Ph$), *ca.* 7.2—7.5 (5H, m, $-OCH_2C_6\underline{H}_5$). Found: C, 68.93; H, 6.15%. Calcd for $C_{30}H_{32}O_8$: C, 69.21; H, 6.20%.

Subsequent elution with ether–benzene (3:97) afforded (*R*)-9-acetyl-6-benzyloxy-2,3,5,8-tetrahydro-7-isopropyl-3-(3-methoxypropyl)-3,4-dimethylnaphtho[2,3-*b*]furan-2,5,8-trione (**11**) (32 mg: 3.2%), $[\alpha]_D$ +23° (*c* 3.12); IR: 1809, 1698, 1654, 1610, 1568 cm^{-1}; ^1H NMR: δ=1.17 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.62 (3H, s, C_3-CH_3), 2.55 (3H, s, C_9-COCH_3), 2.71 (3H, s, C_4-CH_3), 3.20 (3H, s, $-OCH_3$), 3.23 (2H, t, J=6 Hz, $-C\underline{H}_2OMe$), 3.29 (1H, m, $-C\underline{H}(CH_3)_2$), 5.32 (2H, s, $-OC\underline{H}_2Ph$), *ca.* 7.25—7.5 (5H, m, $-OCH_2C_6\underline{H}_5$). Found: C, 71.44; H, 6.48%. Calcd for $C_{30}H_{32}O_7$: C, 71.41; H, 6.39%.

Further elution with ether–benzene (1:9) afforded (*R*)-9-acetyl-2,3,5,8-tetrahydro-6-hydroxy-7-isopropyl-3-(3-methoxypropyl)-3,4-dimethylnaphtho[2,3-*b*]furan-2,5,8-trione (**12**) (171 mg: 20.6%), $[\alpha]_D$ +26° (*c* 0.35); IR: 3360, 1820, 1712, 1652, 1605, 1580 cm^{-1}; ^1H NMR: δ=1.27 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.62 (3H, s, C_3-CH_3), 2.57 (3H, s, C_9-COCH_3), 2.76 (3H, s, C_4-CH_3), 3.20 (3H, s, $-OCH_3$), 3.24 (2H, t, J=6 Hz, $-C\underline{H}_2OMe$), 3.30 (1H, m, $-C\underline{H}(CH_3)_2$), 7.79 (1H, bs, C_6-OH, disappeared with D_2O). Found: C, 66.37; H, 6.38%. Calcd for $C_{23}H_{26}O_7$: C, 66.65; H, 6.32%.

*(R)-9-Acetyl-6-hydroxy-7-isopropyl-3-(3-methoxypropyl)-3,4-dimethylnaphtho[2,3-b]furan-2(3H)-one (**13**).* A mixture of **9** (4.75 g) and 10% Pd–C (1.43 g) in acetic acid (47.5 ml) was submitted to catalytic hydrogenation with 1 atm hydrogen pressure at 60 °C. After the usual work-up, the crude product was chromatographed on silica gel (100 g), using ether–benzene (1:9) as the eluent, to give **13** (3.33 g: 86.5%). This was recrystallized from aqueous methanol, mp 158.5—159.5 °C, $[\alpha]_D$ +19° (*c* 2.42); IR: 3590, 3310br, 1798, 1673, 1615 cm^{-1}; ^1H NMR: δ=1.27 and 1.30 (each 3H, d, and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.64 (3H, s, C_3-CH_3), 2.47 (3H, s, C_4-CH_3), 2.77 (3H, s, C_9-COCH_3), 3.22 (3H, s, $-OCH_3$), 3.27 (2H, t, J=6 Hz, $-C\underline{H}_2OMe$), 3.30 (1H, m, $-C\underline{H}(CH_3)_2$), 6.07 (1H, br, $-OH$, disappeared with D_2O), 7.17 (1H, s, C_5-H), 8.09 (1H, s, C_8-H). Found: C, 71.67; H, 7.37%. Calcd for $C_{23}H_{28}O_5$: C, 71.85; H, 7.34%.

*(R)-9-Acetyl-7-isopropyl-6-methoxy-3-(3-methoxypropyl)-3,4-dimethylnaphtho[2,3-b]furan-2(3H)-one (**14**).* A mixture of **13** (193 mg), methyl iodide (142 mg), and anhydrous potassium carbonate (667 mg) in acetone (4.0 ml) was refluxed for 2 h. The mixture was filtered and the filtrate was evaporated *in vacuo*. The residue was extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate and brine, dried over sodium sulfate, and evaporated *in vacuo*. The crude product was purified by column chromatography on silica gel (20 g), using ether–benzene (3:97) as the eluent, to give **14** (131 mg: 65.4%). $[\alpha]_D$ +17° (*c* 1.87); IR: 1807, 1680, 1621, 1600 cm^{-1}; ^1H NMR: δ=1.30 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.67 (3H, s, C_3-CH_3), 2.67 (3H, s, C_4-CH_3), 2.77 (3H, s, C_9-COCH_3), 3.21 (3H, s, $-OCH_3$), 3.24 (2H, t, J=6 Hz, $-C\underline{H}_2OMe$), 3.42 (1H, m, $-C\underline{H}(CH_3)_2$), 3.97 (3H, s, C_6-OCH_3), 7.22 (1H, s, C_5-H), 8.13 (1H, s, C_8-H). Found: C, 72.60; H, 7.64%. Calcd for $C_{24}H_{30}O_5$: C, 72.33; H, 7.59%.

*(R)-6-Acetoxy-9-acetyl-7-isopropyl-3-(3-methoxypropyl)-3,4-dimethylnaphtho[2,3-b]furan-2(3H)-one (**15**).* The crude phenol **13** (872 mg) prepared from **9** (977 mg) was acetylated with acetic anhydride (4.4 ml) in pyridine (4.4 ml) at room

temperature for 12 h. After the usual work-up, the crude product was chromatographed on silica gel (100 g), using ether–benzene (1:9) as the eluent, to give **15** (844 mg: 96.1% from **9**). $[\alpha]_D$ +16° (*c* 2.88); IR: 1811, 1762, 1688, 1628, 1601 cm^{-1}; ^1H NMR: δ=1.30 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.66 (3H, s, C_3-CH_3), 2.39 (3H, s, $C_6-OCOCH_3$), 2.64 (3H, s, C_4-CH_3), 2.77 (3H, s, C_9-COCH_3), 3.13 (1H, m, $-C\underline{H}(CH_3)_2$), 3.20 (3H, s, $-OCH_3$), 3.23 (3H, t, J=6 Hz, $-C\underline{H}_2OMe$), 7.65 (1H, s, C_5-H), 8.28 (1H, s, C_8-H). Found: C, 70.20; H, 7.37%. Calcd for $C_{25}H_{30}O_6$: C, 70.40; H, 7.09%.

*Oxidation of **14** with* m-*Chloroperbenzoic Acid.* A mixture of **14** (1493 mg), *m*-chloroperbenzoic acid (90%: 2250 mg), and *p*-toluenesulfonic acid monohydrate (30 mg) in dichloromethane (75 ml) was refluxed for 3 h. The mixture was diluted with ether and the ether solution washed successively with aqueous potassium iodide, aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and brine. The dried solution was evaporated *in vacuo*. The residue was chromatographed on silica gel (150 g), using ether–benzene (2:98) as the eluent, to give (*R*)-9-acetoxy-2,3,5,8-tetrahydro-7-isopropyl-6-methoxy-3-(3-methoxypropyl)-3,4-dimethylnaphtho[2,3-*b*]furan-2,5,8-trione (**16**) (182 mg: 10.9%). $[\alpha]_D$ +24° (*c* 1.66); IR: 1808, 1768, 1652, 1613 cm^{-1}; ^1H NMR: δ=1.24 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.64 (3H, s, C_3-CH_3), 2.44 (3H, s, $C_9-OCOCH_3$), 2.68 (3H, s, C_4-CH_3), 3.20 (3H, s, $-OCH_3$), 3.24 (2H, t, J=6 Hz, $-C\underline{H}_2OMe$), 3.29 (1H, m, $-C\underline{H}(CH_3)_2$), 4.00 (3H, s, C_6-OCH_3).

Further elution gave (*R*)-9-acetyl-2,3,5,8-tetrahydro-7-isopropyl-6-methoxy-3-(3-methoxypropyl)-3,4-dimethylnaphtho[2,3-*b*]furan-2,5,8-trione (**17**) (153 mg: 9.5%), $[\alpha]_D$ +9.2° (*c* 2.18); IR: 1808, 1700, 1657, 1612, 1590, 1567 cm^{-1}; ^1H NMR: δ=1.24 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.62 (3H, s, C_3-CH_3), 2.57 (3H, s, C_9-COCH_3), 2.71 (3H, s, C_4-CH_3), 3.21 (3H, s, $-OCH_3$), 3.24 (2H, t, J=6 Hz, $-C\underline{H}_2OMe$), 3.31 (1H, m, $-C\underline{H}(CH_3)_2$), 4.05 (3H, s, C_6-OCH_3). Found: C, 66.97; H, 6.37%. Calcd for $C_{24}H_{28}O_7$: C, 67.27; H, 6.59%.

*Oxidation of **15** with* m-*Chloroperbenzoic Acid.* A mixture of **15** (954 mg), *m*-chloroperbenzoic acid (90%: 1544 mg), and *p*-toluenesulfonic acid monohydrate (119 mg) in dichloromethane (38 ml) was refluxed for 20 h. After the mixture had been treated as described for the preparation of **16**, the crude product was chromatographed on silica gel (100 g), using ether–benzene (8:92) as the eluent, to give (*R*)-6,9-diacetoxy-7-isopropyl-3-(3-methoxypropyl)-3,4-dimethylnaphtho[2,3-*b*]furan-2(3*H*)-one (**18**) (155 mg: 15.7%). $[\alpha]_D$ +21° (*c* 2.15); IR: 1800, 1763, 1754, 1652, 1619 cm^{-1}; ^1H NMR: δ=1.30 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.65 (3H, s, C_3-CH_3), 2.38 and 2.47 (each 3H and s, $C_6-OCOCH_3$ and $C_9-OCOCH_3$), 2.59 (3H, s, C_4-CH_3), 3.14 (1H, m, $-C\underline{H}(CH_3)_2$), 3.18 (3H, s, $-OCH_3$), 3.22 (2H, t, J=6 Hz, $-C\underline{H}_2OMe$), 7.64 and 7.75 (each 1H and s, C_5-H and C_8-H). Found: C, 68.14; H, 6.92%. Calcd for $C_{25}H_{30}O_7$: C, 67.85; H, 6.83%. Further elution with the same solvent gave a mixture of **18** and the starting **15** (567 mg, *ca.* 9:1 ratio). The total yield of **18** was *ca.* 67%.

*(R)-5,6,8,9-Tetraacetoxy-7-isopropyl-3-(3-methoxypropyl)-3,4-dimethylnaphtho[2,3-b]furan-2(3H)-one (**19**).* A mixture of **10** (414 mg) and 10% Pd–C (120 mg) in acetic acid (4.2 ml) was submitted to catalytic hydrogenation with 1 atm hydrogen pressure at 60 °C. The crude product, after the usual work-up, was dissolved in acetic anhydride (3.5 ml) and pyridine (3.5 ml) and then zinc powder (130 mg) was added at 0—5 °C. The mixture was stirred at this temperature for 5 min and at room temperature for 1 h, poured into aqueous sodium hydrogencarbonate, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (50 g), using ether–benzene (2:8) as the eluent, to give **19** (339 mg: 76.3 %). This was recrystallized from methanol, mp 243 °C, $[\alpha]_D$ +13° (*c* 2.80); IR: 1809, 1775, 1648, 1616 cm^{-1}; ^1H NMR: δ=1.26 (6H, bd, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.61 (3H, s, C_3-CH_3), 2.33 and 2.39 (each 6H and s, $C_5-OCOCH_3$, $C_6-OCOCH_3$, $C_8-OCOCH_3$, and $C_9-OCOCH_3$), 2.66 (3H, s, C_4-CH_3), 3.17 (3H, s, $-OCH_3$), 3.21 (3H, m, $-C\underline{H}_2OMe$ and $-C\underline{H}(CH_3)_2$). Found: C, 62.26; H, 6.19%. Calcd for $C_{29}H_{34}O_{11}$: C, 62.36; H, 6.14%.

*(R)-5,6,8,9-Tetraacetoxy-7-isopropyl-3,4-dimethyl-3-[3-(o-nitrophenylselenyl)propyl]naphtho[2,3-b]furan-2(3H)-one (**21**).* Boron tribromide dichloromethane solution (1 M: 1.5 ml) was added at −30 °C to a stirred solution of **19** (276 mg) and the 15-crown-5 dichloromethane solution (0.3 M: 9.9 ml) saturated with sodium iodide, under a stream of nitrogen. The mixture was stirred at −30 °C for 3 h. After the addition of aqueous sodium hydrogencarbonate, the mixture was diluted with ether and the ether solution was washed successively with aqueous sodium thiosulfate and brine. The dried solution was evaporated *in vacuo* to give the crude 3-(3-hydroxypropyl) derivative (**20**) which was used without purification in the next reaction. IR: 3530br, 3380br, 1808, 1775, 1648, 1615 cm^{-1}; ^1H NMR: δ=1.26 (6H, bd, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.63 (3H, s, C_3-CH_3), 1.74 (1H, br, –OH, disappeared with D_2O), 2.33 and 2.39 (each 6H and s, $C_5-OCOCH_3$, $C_6-OCOCH_3$, $C_8-OCOCH_3$, and $C_9-OCOCH_3$), 2.67 (3H, s, C_4-CH_3), 3.20 (1H, m, $-C\underline{H}(CH_3)_2$), 3.40 (2H, t, J=6 Hz, $-C\underline{H}_2OH$).

Tributylphosphine (0.53 ml) was added to a stirred mixture of the above crude **20** and *o*-nitrophenyl selenocyanate (457 mg) in pyridine (5.0 ml) at 0—5 °C under a stream of nitrogen. The mixture was stirred at room temperature for 30 min, evaporated *in vacuo*, and diluted with ether. The mixture was filtered to remove a yellow precipitate and the filtrate was evaporated *in vacuo*. The residue was chromatographed on silica gel (60 g), using ether–benzene (1:9) as the eluent, to give **21** (272 mg: 75.5%). IR: 1811, 1778, 1648, 1593, 1510, 1334 cm^{-1}; ^1H NMR: δ=1.27 (6H, bd, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.60 (3H, s, C_3-CH_3), 2.33, 2.34, 2.37, and 2.39 (each 3H and s, $C_5-OCOCH_3$, $C_6-OCOCH_3$, $C_8-OCOCH_3$, and $C_9-OCOCH_3$), 2.53 (3H, bs, C_4-CH_3), *ca.* 2.5—3.0 (2H, m, $-C\underline{H}_2SeC_6H_4-$), 3.20 (1H, m, $-C\underline{H}(CH_3)_2$), *ca.* 7.0—7.3 (3H, m) and *ca.* 8.05—8.3 (1H, m) ($-SeC_6\underline{H}_4-$).

*(R)-5,6,8,9-Tetraacetoxy-3-allyl-7-isopropyl-3,4-dimethylnaphtho[2,3-b]furan-2(3H)-one (**22**).* A mixture of **21** (272 mg) and 50% hydrogen peroxide (0.24 ml) in tetrahydrofuran (8.0 ml) was stirred at room temperature for 17 h. The mixture was diluted with brine and extracted with chloroform. The chloroform extract was washed successively with aqueous potassium iodide, aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and brine. The dried solution was evaporated *in vacuo*. The residue was chromatographed on silica gel (20 g), using ether–benzene (1:9) as the eluent, to give **22** (170 mg: 86.5%). This was recrystallized from benzene, mp 269—270 °C, $[\alpha]_D$ +79° (*c* 0.845); IR: 1816, 1780, 1652, 1620, 940 cm^{-1}; ^1H NMR: δ=1.27 (6H, bd, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.64 (3H, s, C_3-CH_3), 2.34 (6H, s), 2.38 (3H, s), and 2.39 (3H, s) ($C_5-OCOCH_3$, $C_6-OCOCH_3$, $C_8-OCOCH_3$, and $C_9-OCOCH_3$), 2.69 (3H, s, C_4-CH_3), 2.79 (2H, bd, J=7 Hz, $-C\underline{H}_2CH=CH_2$), 3.20 (1H, m, $-C\underline{H}(CH_3)_2$), *ca.* 4.85—5.6 (3H, m, $-CH_2C\underline{H}=C\underline{H}_2$). Found: C, 64.17; H, 5.76%.

Calcd for $C_{28}H_{30}O_{10}$: C, 63.87; H, 5.74%.

*(R)-3-Allyl-2,3,5,8-tetrahydro-6,9-dihydroxy-7-isopropyl-3,4-dimethylnaphtho[2,3-b]furan-2,5,8-trione (Coleon A Lactone) (**23**).* A mixture of **22** (200.2 mg) and aqueous potassium hydroxide (10%: 4.5 ml) in methanol (40 ml) was refluxed for 15 min and oxygen was then bubbled into it at room temperature for 30 min. The mixture was acidified with dilute hydrochloric acid, stirred at room temperature for 1 h, and extracted with ether. The ether extract was washed with brine, dried over magnesium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (15 g), using benzene as the eluent, to give **23** (54.7 mg: 40.4 %). $[\alpha]_D$ +145° (EtOH, *c* 0.780); IR: 3325, 1808, 1647, 1617, 928 cm^{-1}; ^1H NMR: δ=1.30 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.65 (3H, s, C_3-CH_3), 2.68 (3H, s, C_4-CH_3), 2.83 (2H, bd, J=6.5 Hz, $-C\underline{H}_2CH=CH_2$), 3.38 (1H, m, $-C\underline{H}(CH_3)_2$), *ca.* 4.87—5.60 (3H, m, $-CH_2C\underline{H}=C\underline{H}_2$), 7.98 (1H, bs, C_6-OH), 13.35 (1H, s, C_9-OH). Found: C, 67.60; H, 5.83%. Calcd for $C_{20}H_{20}O_6$: C, 67.40; H, 5.66%. The spectral data of **23** were in good agreement with those of natural coleon A lactone.

*Coleon A (**1**).* *a)*: A mixture of **23** (50.2 mg), sodium borohydride (33.0 mg), and water (0.4 ml) in ethanol (3.6 ml) was stirred at 0—5 °C for 1 h and then at room temperature for 20 h. The mixture was concentrated *in vacuo*, acidified with dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over magnesium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (5.0 g), using ether–benzene (15:85) as the eluent, to give the C-2 epimeric mixture (**1**) (38.1 mg: 75.5%). This was recrystallized from cyclohexane, mp 140.5—141.5 °C, $[\alpha]_D$ +88° (*c* 1.68); IR: 3580, 3495, 3305, 1657, 1612, 918 cm^{-1}; IR (CCl_4): 3505, 3300, 1658, 1614, 918 cm^{-1}; ^1H NMR: δ=1.28 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.44 and 1.50 (3H, each s, *ca.* 0.4:1 ratio, C_3-CH_3), 2.50 (2H, bd, J=6.5 Hz, $-C\underline{H}_2CH=CH_2$), 2.65 (3H, s, C_4-CH_3), 3.34 (1H, m, $-C\underline{H}(CH_3)_2$), *ca.* 4.9—5.25 (2H, m, $-CH_2CH=C\underline{H}_2$), 5.42—5.98 (1H, m, $-CH_2C\underline{H}=CH_2$), 5.78 and 5.90 (1H, each s, C_2-H), 8.13 (1H, s, C_6-OH), 13.48 (1H, s, C_9-OH). Found: C, 67.31; H, 6.32%. Calcd for $C_{20}H_{22}O_6$: C, 67.02; H, 6.19%.

b): A mixture of **22** (170.3 mg) and lithium aluminium hydride (61 mg) in dry tetrahydrofuran (8.0 ml) was refluxed for 2 h. The mixture was poured into ice-dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried over magnesium sulfate, and evaporated *in vacuo*. The residue was chromatographed on silica gel (10 g), using ether–benzene (15:85) as the eluent, to give **1** (39.8 mg: 34.3%), whose IR and ^1H NMR spectra were in good agreement with those of natural coleon A.

Semburins and Swertiols, Novel 2,8-Dioxabicyclo[3.3.1]nonanes and Their Precursory Alcohols, from *Swertia japonica* Makino

Tsutomu Sakai,* Yoshiko Nakagawa, Takashi Iwashita, Hideo Naoki, and Takeo Sakan

Suntory Institute for Bioorganic Research, Shimamoto-cho, Mishima-gun, Osaka 618

(Recived April 14, 1983)

The steam-volatile constituents of *Swertia japonica* Makino have been studied, and 71 components of the oil (comprising nearly 90% of the sample) have been identified. Structures of three novel 2,8-dioxabicyclo-[3.3.1]nonanes (semburin, isosemburin, and neosemburin) and their precursory alcohols (swertiol, isoswertiol, and isoneoswertiol) have been established by spectroscopic analysis and chemical transformation data. The presence of 2-*epi*-isoneoswertiol, which was named neoswertiol, was detected by GC/MS. This is the first time that the 2,8-dioxabicyclo[3.3.1]nonane skeleton has been encountered in natur al products.

In 1967, Motomura[1] reported the interesting observation that cats are attracted by volatile fractions of *Swertia japonica* Makino as well as by fractions of *Actinidia polygama* Miq.[2] and *Nepeta cataria* L.,[3] *etc.* During the course of our investigations on various plants which have a peculiar excitatory effect on cats and *Felidae*, we studied the volatile constituents of *Swertia japonica* Makino. *Swertia japonica* Makino (Gentianaceae; Japanese name, semburi) is a popular herb in Japan, the whole plant being widely used as a folk medicine for stomach complaints because of its characteristic strong bitter taste. The bitter principles of this plant have been studied by a number of workers.[4] However, until recently no detailed study of the volatile components had been carried out. In a previous paper,[5] we reported the isolation and structures of two novel 2,8-dioxabicyclo[3.3.1]nonanes, semburin and isosemburin, which constitute the major components isolated from the volatile oil. We now report the analysis of the volatile constituents by GC/MS, and the details of the isolation and structural elucidation of these and five new compounds.

Results and Discussion

Analysis of Volatile Constituents. The oils obtained by steam distillation of the fresh or air-dried *Swertia japonica* plant (collected in Miyagi Pref., 1980) and *via* methanol extraction of the air-dried commercial material showed similar gas chromatographic profiles. Figure 1 shows the gas chromatogram of the whole essential oil obtained from the air-dried commercial plant. This chromatogram was obtained by injecting 1.0 μl of the oil into a CP Wax 51 glass WCOT column. The column temperature was held initially at 100 °C for 10 min, then programmed at 2 °C per minute to 150 °C, and run isothermally at 150 °C until all the components had emerged.

Volatile constituents of *Swertia japonica* were identified as far as possible by GC/MS. The major components were isolated by preparative GC and by silica-gel column chromatography (CC) and their structures were confirmed by their spectral properties. Table 1 shows the compounds detected in the volatile oil.

Among the more than 110 component peaks observed in the chromatogram of the oil, seventy-one compounds were determined. Anethole and eugenol

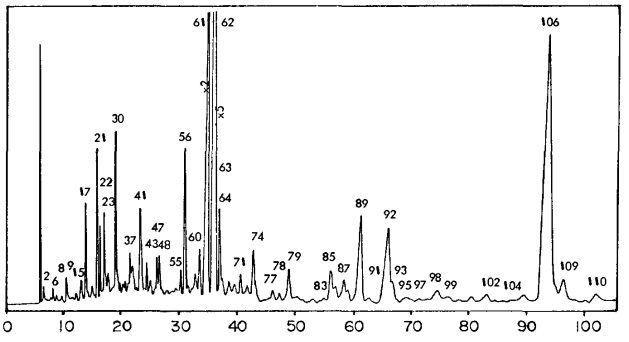

Fig. 1. Gas chromatogram of the volatile oil of *Swertia japonica* Makino.

(peaks 62 and 106) were the main components in the oil (32% of the oil). A fraction containing aromatic oxygenated compounds constituted 11.2% of the oil, followed by terpenic oxygenated compounds (8.5%), terpenic hydrocarbons (7.1%), and aliphatic oxygenated compounds (5.9%). The existence of three new oxides and four new alcohols, which we have named semburins and swertiols, was revealed by GC/MS in both the volatile oil and the methanol extract. Semburins (peak 56, 61, and 64) and swertiols (peaks 91, 92, 93, and 98) accounted for 11.8% and 5.0% of the oil, respectively. Furthermore, a new lactone (peak 109, 1.39% of the oil) was obtained.

Structures of Semburins. Three novel 2,8-dioxabicyclo[3.3.1]nonanes possessing the same molecular formula of $C_9H_{14}O_2$ were contained in a fraction eluted with ether–hexane (1:9) on silica gel CC. Each compound was isolated in the pure state by preparative GC and by repeated CC. The mass spectra of two major compounds (**1** and **2**) are almost identical, but differ slightly from that of the minor compound (**3**). (Scheme 1). The IR spectra of **1** and **2** are very similar and showed the absence of hydroxyl and carbonyl groups and the presence of a vinyl group. The IR spectrum of **3** is also similar to that of **1** and **2**, except for the absence of vinyl bands. These facts suggest that the second major compound **2** is a diastereoisomer of the major compound **1**, while the minor compound **3** is a double bond isomer of both **1** and **2**. These three new compounds have been named semburin (**1**), isosemburin (**2**), and

TABLE 1. CONSTITUENTS OF THE VOLATILE OIL FROM *Swertia japonica* MAKINO

Peak No.	Compound	Content % [a]	Peak No.	Compound	Content % [a]

a) Based on relative peak areas of the GC analysis of the volatile oil; GC on CP Wax 51 glass WCOT column (50 m×0.24 mm i.d.), 100 °C to 150 °C programmed at 4 °C/min. b) New compound.

neosemburin (**3**).

Semburin(**1**), $[\alpha]_D^{26}$ −2.0°, and isosemburin (**2**), $[\alpha]_D^{24}$ −8.0°, contain nine carbons: two CH_2's, one $=CH_2$, two OCH_2's, two CH's, one =CH, and one O–CH–O (^{13}C NMR). The IR and high resolution mass spectra of both **1** and **2** suggested the presence of a tetrahydropyran ring having a vinyl group: absorption bands at 3070, 1640, and 920 cm^{-1} (CH_2=CH) and fragment peaks at *m/z* 81.0320 ($C_5H_5O^+$, 98%), 109.0635 ($C_7H_9O^+$, 37%), and 124.0886 (M^+-CH_2O, 100%). These data coupled with the 360 MHz ^1H NMR and the 300 MHz ^1H–^1H 2-D chemical shift correlation spectra[6] (see Fig. 2), led to the 4-vinyl-2,8-dioxabicyclo[3.3.1]nonane skeleton for both semburin and isosemburin. The structure of **1** was confirmed by synthesis of (±)-**1**[7] *via* a pathway resembling its biogenesis from sweroside (**4**), a bitter principle of this plant. This synthesis verified the *cis* relationship of 4-H and 5-H. Furthermore, the absolute configuration at C-5 in both **1** and **2** was established as being identical with that of the asterisked carbon in structure **4** by synthesis of (−)-**1** and (−)-**2** from (*R*)-4-allyl-4-butanolide.[8] This synthesis also established that **1** and **2** are epimers.

The stereochemistry of **1** is evident from 360 MHz ^1H NMR analysis. Proton decoupling and 2-D *J* techniques[9] showed the presence of two W-type long range couplings between 5-H (δ 1.71)/1-H (δ 5.32)(1.5 Hz) and between 5-H/3′-H (δ 3.69)(2.0 Hz), indicating that the tetrahydropyran ring with the vinyl side-chain adopts a chair conformation. Irradiation of the 7′-H signal at δ 3.42 in **1** induced an NOE on the δ 1.36 9-H pattern, indicating a boat conformation for the other tetrahydropyran ring. Finally, the equa-

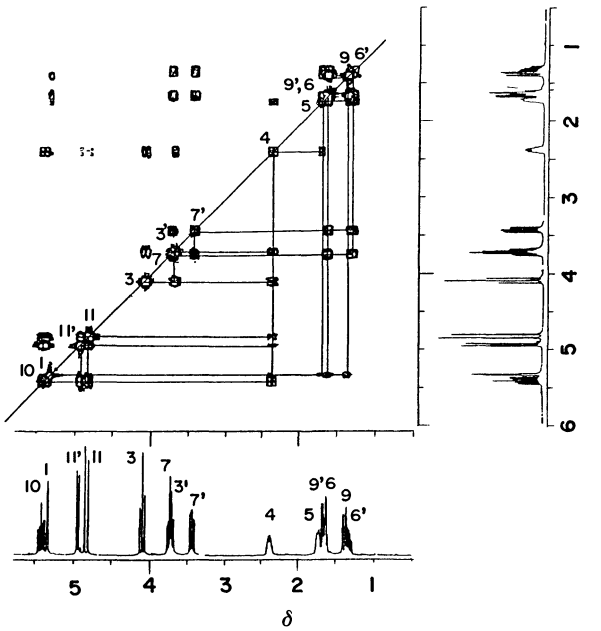

Fig. 2. ^1H–^1H 2-D chemical shift correlation map of semburin **1**.

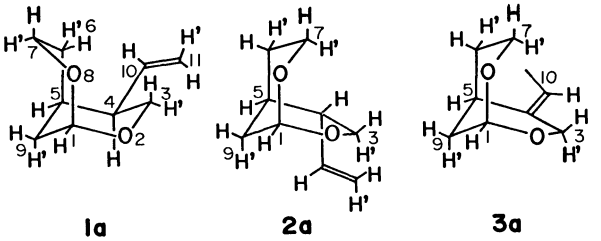
torial nature of the vinyl group was established by noting a 12 Hz diaxial coupling between 4α-H and 3β-H. The NMR data (Fig. 2) unequivocally led to structure **1** with the chair/boat conformation **1a**.

The conformation of **2** was deduced to be half-chair/chair **2a** by carrying out similar experiments. Two W-type couplings between 5-H (δ 1.57)/1-H (δ 5.31)(1.5 Hz) and between 9-H (δ 1.30)/4-H (δ 2.10) (1.5 Hz) were observed upon proton decoupling of **2**. Irradiation of the 7'-H signal at δ 3.46 induced an NOE on the 4-H signal at δ 2.10. The coupling constants of the dddd pattern of the 4-H signal ($J_{4,3}$= 9 Hz, $J_{4,3'}$=7 Hz) indicated the presence of an axial vinyl side-chain on a half-chair tetrahydropyran ring.

The third minor compound (**3**), neosemburin ($[\alpha]_D^{25}$ +8.3°), showed the presence of a CH_3CH=C group (δ 1.30, 3H, dddd; δ 5.08, 1H, dddq) instead of a CH_2=CH–CH group in its ^1H NMR spectrum. Decoupling studies of the 360 MHz ^1H NMR spectrum showed **3** to be 4-ethylidene-2,8-dioxabicyclo[3.3.1]-nonane. The absolute configurations of C-1 and C-5 are assumed to be the same as in **1** and **2**. The geometry of the trisubstituted double bond in **3** was assigned a *Z* configuration, since irradiation of the 3-H resonance at δ 4.10 and the 10-Me signal at δ 1.30 enhanced the 10-H (δ 5.08) and the 5-H (δ 2.49) patterns, respectively. A W-type coupling between 5-H (δ 2.49)/ 7-H (δ 3.52)(1.5 Hz) was observed, indicating the conformation of **3** also to be half-chair/chair **3a** as in the case of **2a**. (Fig. 3).

Structures of Swertiols. Two pairs of new isomeric compounds also possessing the semburin molecular formula ($C_9H_{14}O_2$) were contained in a fraction eluted with ether–hexane (3:7) on silica gel CC. Three of these have been isolated in the pure state by preparative GC and CC.

The major compound, isoswertiol (**5**)($[\alpha]_D^{24}$ +54.2°),



1a **2a** **3a**

Fig. 3.

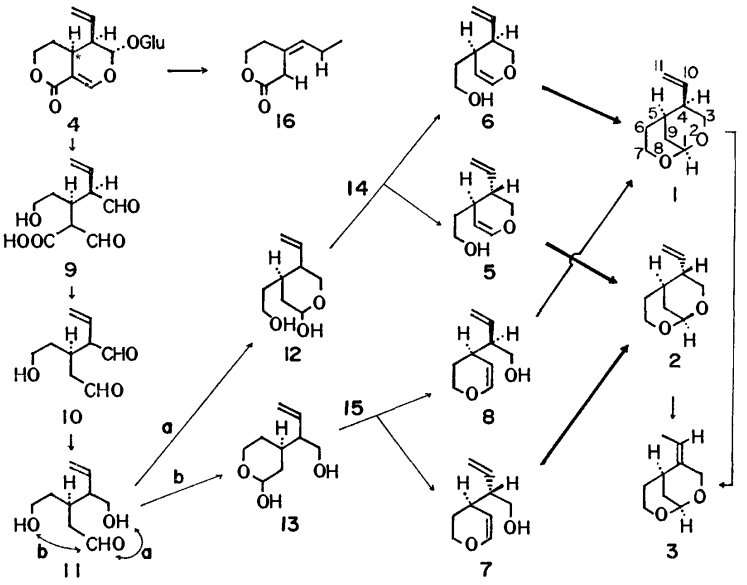
had IR absorption bands for a hydroxyl (3360 cm^{-1}), a vinyl (3020, 1640, and 920 cm^{-1}), and a CH=CH–O–CH_2 (1240 cm^{-1}) group. The ^{13}C and ^1H NMR spectra of **5** indicated the presence of a 3,4-dihydro-2*H*-pyran moiety (δ 3.52 and 3.81, each 1H, dd, 2-H_2; δ 6.39, 1H, dd, 6-H; δ 4.55, 1H, dd, 5-H; δ 2.01, 2H, m, 3-H and 4-H), and –CH_2CH_2OH (δ 1.20 and 1.56, each 1H, dddd, 7-H_2; δ 3.33, 2H, m, 8-H_2; δ 0.64, 1H, br s, OH) and CH=CH_2 groups (δ 5.40, 1H, ddd, 9-H; δ 4.92 and 4.93, each 1H, ddd, 10-H_2). The mass spectrum of **5** also supported the presence of these groups: *m/z* 109 (M^+–CH_2CH_2OH, 58%), 83 ($C_5H_7O^+$, 77%), and 54 ($C_4H_6^+$, 100%). On the basis of these data, **5** is 3-vinyl-4-(2-hydroxyethyl)-3,4-dihydro-2*H*-pyran. The smooth conversion of **5** into isosemburin (**2**) by treatment with *p*-toluenesulfonic acid confirmed the structure of **5**, and also established the absolute configurations at C-3 and C-4 in **5** to be the same as in **2**.

The minor compound (**6**) exhibited IR and mass spectra very similar to **5**. No NMR measurements were carried out due to the limited amount of sample. However, transformation of **6** into semburin (**1**) by treatment with *p*-toluenesulfonic acid established the structure of **6**, swertiol, as being the 3-epimer of isoswertiol (**5**).

The second major compound, isoneoswertiol (**7**)($[\alpha]_D^{22}$ −52.8°), had IR absorption bands for a hydroxyl (3340 cm^{-1}), a vinyl (3050, 1630, and 905 cm^{-1}), and a CH=CH–O–CH_2 (1240 cm^{-1}) group. The ^{13}C and ^1H NMR spectra of **7** showed the presence of a 3,4-dihydro-2*H*-pyran moiety (δ 3.66 and 3.74, each 1H, ddd, 2-H_2; δ 1.43, 2H, m, 3-H_2; δ 4.47, 1H, dddd, 5-H; δ 6.39, 1H, dd, 6-H), and –CH_2OH (δ 3.30, 1H, dd, 8-H; δ 3.49, 1H, br dd, 8-H; δ 0.80, 1H, br s, OH) and –CH=CH_2 (δ 5.40, 1H, ddd, 9-H; δ 4.89 and 4.97, each 1H, ddd, 10-H_2) groups. The mass spectrum also confirmed the presence of these groups: *m/z* 83 ($C_5H_7O^+$, 100%) and 124 (M^+–CH_2OH, 1.5%). These data indicated that **7** is 2-(3,4-dihydro-2*H*-pyran-4-yl)-3-buten-1-ol. The conversion of **7** into isosemburin (**2**) established the structure and the absolute configuration at C-2 and C-4'.

The remaining counterpart of the second pair could not be isolated, but was assumed to be the 2-epimer of isoneoswertiol (**7**); we named it neoswertiol (**8**), since its mass spectrum (by GC/MS) is identical with that of isoneoswertiol (**7**).

A possible biogenetic route from sweroside (**4**) to semburins (**1** and **2**) is illustrated in Scheme 1. Acid-catalyzed cleavage of sweroside (**4**) would provide the hydroxydial acid (**9**). Decarboxylation and racemi-



Scheme 1. Biosynthesis of semburins and swertiols from sweroside.

zation at the α-position of the carbonyl in **9** then gives the hydroxydials **10**, the reduction of which leads to epimeric diols **11**. Compound **11** is an important intermediate because the absolute configuration at C-5 in **4** remains unaltered. Cyclization of **11** in two directions **a** and **b** would provide two hemiacetals **12** and **13**. Semburins **1** and **2** could be obtained directly from both hemiacetals **12** and **13** by dehydration-cyclization, or *via* the dihydropyran alcohols **14** and **15**. These dihydropyran alcohols **14** and **15** correspond to the four new compound **5**—**8** isolated from both the volatile oil and the methanol extract of plant.

A number of studies concerning the role of loganin and secologanin in the biosynthesis of terpenoids and indole alkaloids have been reported, but possible key intermediates postulated in the biogenetic sequence from iridoids to alkaloids have not been isolated or confirmed. It is possible that the compounds discussed might be efficient precursors in the biosynthesis of the Corynanthe-type indole alkaloids.

Although the 2,8-dioxabicyclo[3.3.1]nonane skeleton has already been obtained as the aglycone of secologanin,[10] this is the first time it has been encountered in natural products.

Structure of a New Lactone ***16***. From the fraction containing swertiols, a new lactone (peak 109 in Table 1, 1.39% of the oil), 3-propylidene-5-pentanolide (**16**) was obtained. Its mass spectrum showed a molecular ion at *m/z* 140 corresponding to $C_8H_{12}O_2$. The IR and ^{1}H NMR spectra showed the presence of a δ-lactone moiety (1740 cm^{-1}) and a $CH_3CH_2CH{=}C$ group [δ 0.74 (3H, t, J=7.5 Hz), 1.59 (2H, ddq, J=7.5, 7.0, 1.0 Hz), and 4.86 (1H, ttt, J=7.0, 1.5, 1.5 Hz)]. Irradiation of the 3-H_2 signal at δ 2.87 induced an NOE on the 8-H_2 (δ 1.59) pattern. Thus, the configuration of the trisubstituted double bond was determined as *Z*. It is also presumed that this compound is derived from sweroside (**4**). (see Scheme 1)

Experimental

The IR spectra were obtained on a Hitachi EPI G2 infrared spectrophotometer as thin films between NaCl plates. The optical rotations were measured on a Perkin-Elmer 141 polarimeter. The NMR spectra were taken by Nicolet NT-360 (360 MHz ^{1}H NMR), Nicolet NT-300 (300 MHz ^{1}H–^{1}H 2-D J correlation), and JEOL FX-100 (^{13}C NMR). GC/MS spectra were determined with a Hitachi M-80 GC/MS spectrometer equipped with 50 m×0.24 mm i.d. glass WCOT column of CP Wax 51. The preparative GC conditions, using a model 920 Varian Aerograph fitted with a thermal-conductivity detector, were as follows: a 3 m× 10 mm aluminum column containing 10% Thermon 1500 on Chromosorb W; He carrier gas, 60 ml/min; oven temp at 130—150 °C.

Material and Isolation. Steam distillations of the fresh whole plant (3 kg, collected in Sendai, Miyagi Pref., Oct. 1980), its air-dried material (0.5 kg), and a commercial air-dried material (5 kg, collected in Tohoku District) gave, respectively, 0.37 g, 0.27 g, and 2.0 g of volatile oils. The commercial material (0.4 kg) was extracted with MeOH for 2 weeks. The crude extract (44.8 g) was obtained.

The volatile oil (2.0 g) of the commercial material was chromatographed on silica gel (70 g, 2.5 cm i.d.×60 cm column). Elution with hexane, hexane–ether mixture, ether, and MeOH gave 7 fractions: fraction I (hexane, 0.53 g), II (hexane–ether, 95:5, 0.12 g), III (9:1, 0.46 g), IV (85:15, 0.30 g), V (7:3, 0.19 g), VI (ether, 0.23 g), and VII (MeOH, 0.08 g). Fraction III was rechromatographed, yielding 3 fractions: III-1 (0.17 g), III-2 (0.13 g), and III-3 (0.15 g). Three semburins were contained in fraction III-3. Four swertiols were contained in fraction V. Each compound was isolated by prep. GC and CC: semburin, 5.0 mg, prep. GC Rt (oven temp 130°) 20.5 min; isosemburin, 1.5 mg, 16.0 min; neosemburin, 1.0 mg, 23.0 min; isoswertiol, 9.0 mg, 20 min (oven temp 150 °C); isoneoswertiol, 3.9 mg, 20 min; swertiol, 30 min.

Cyclic Phosphorylation Reaction of Diols with Tri(1-imidazolyl)phosphine

Takeo SHIMIDZU,* Kazushige YAMANA, Naoya KANDA, and Susumu KITAGAWA†

Division of Molecular Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

†*Department of Chemistry, Kinki University, Kowakae, Higashi-Osaka 577*

(Received April 22, 1983)

Tri(1-imidazolyl)phosphine (**1**) gave the cyclic phosphite quantitatively in the reactions with the diols possessing favorably placed hydroxyl groups in which the distance between the two oxygen atoms is 2.7—3.0 Å. The both five- and six-membered cyclic phosphites were obtained quantitatively from the reactions of the diols possessing flexible chains with **1**. The course of the selective formation of ribonucleoside 2′,3′-cyclic 1-imidazolylphosphonite was interpretated by the higher reactivity of **1** toward the 2′- or 3′-hydroxyl group than toward the 5′-hydroxyl group of ribonucleoside.

It is well-known that many active phosphorus compounds readily react with vicinal diols to give the cyclic phosphites.[1-7] Recently, we have developed a new sort of phosphorylating reagent such as tri(1-imidazolyl)phosphine (**1**) which reacts selectively with the 2′- and 3′-hydroxyl groups of ribonucleoside to give a ribonucleoside 2′,3′-cyclic 1-imidazolylphosphonite (**2a**).[8] This reaction was extended by the use of tri(azol-1-yl)phosphines and has been successfully adopted to the synthesis of oligoribonucleotides directly from unprotected ribonucleosides.[9,10] It is significant to elucidate the aspect of this cyclic phosphorylation reaction which is directed toward the use for a selective phosphorylation of some important substances possessing diol group, *e.g.* sugars, some steroids, *etc.* For this purpose, the reaction of some simple diols with **1** is performed. In this paper, we describe the cyclic phosphorylation reaction of diols with **1** in connection with the phosphorylation of the ribonucleosides.

Results and Discussion

We first focused our attention on the reaction of diols possessing different degree of distance between the reacting hydroxyl groups with **1**. Cyclohexanediols have a variety of stereoisomeric conformers. The distances between the two oxygen atoms in the diols can be calculated[11] and listed in Table 1. Compounds 1,2-cyclohexanediol, 1,3-cyclohexanediol, and 1,4-cyclohexanediol were allowed to react with equimolar amounts of **1** and then ethanol. The products were analyzed by ^{31}P NMR spectroscopy. All the cyclohexanediols were completely phoshorylated by the reaction with **1** at −78 °C within 5 min. The yields of cyclic phosphite derivatives are given in Table 1. Both *cis*- and *trans*-1,2-cyclohexanediol gave the five-membered cyclic phosphonite (**3a**) quantitatively. Inspection of models shows that the phosphonite ring can be formed readily both with the *cis*-diol having one axial and one equatorial hydroxyl(O–O distance, 2.96 Å), and the *trans*-diol having two equatorial hydroxyl groups(O–O distance, 2.96 Å). Neither of the two stereoisomeric(*cis* and *trans*) cyclic phosphonites is greatly strained and their formation can require little or no distortion of the cyclohexane ring from its

preferred chair conformation. On the other hand, of the two 1,3-cyclohexanediols, only the *cis*-compound having two axial hydroxyl groups (O–O distance, 2.53 Å), gave the six-membered cyclic phosphonite (**4a**), but *trans*-compound(O–O distance, 5.3 Å) did not give the cyclic phosphonite. Inspite of no distortion of the cyclohexane ring from the chair conformation, the yield(44%) of the six-membered cyclic phosphonite was less than that of the five-membered one. *cis*-1,4-Cyclohexanediol(O–O distance, 4.49 Å), and *trans*-1,4-cyclohexanediol(O–O distance, 5.70 Å) did not give the cyclic phosphonite. They yielded gel-like polymeric material. These results show that the selectivity of the cyclic phosphorylation reaction with **1** depends on the distance between the two oxygen atoms of the hydroxyl groups in diols; in the case of diols possessing the favorably adjacent hydroxyl groups, only the cyclic phosphorylation reaction proceeds, which involves the formation of the monophosphorylated diol and then the successive intramolecular reaction to give the cyclic phosphonite. When the two hydroxyl groups of diols are not favorably placed, the intermolecular reaction of the monophosphorylated diols leads to the formation of the polymer.

Further investigation on the reactions of benzenediol derivatives with equimolar amounts of **1** was carried out. The yields of the cyclic phosphite derivatives are shown also in Table 1. 1,2-Benzenediol(O–O distance, 2.72 Å) was favored to give the five-membered cyclic phosphonite (**3b**). The six-membered cyclic phosphonite from 1,3-benzenediol (O–O distance, 4.71 Å) was not obtained. 1,4-Benzenediol (O–O distance 5.44 Å) gave polymeric material.

The question arose whether a six-membered ring could be formed in the reaction of a nucleoside possessing the 5′- and 3′-hydroxyl groups(O–O distance, 3.73 Å) with **1**. To study this problem the reaction of thymidine with equimolar amount of **1** was performed. The result is shown in Table 1. Thymidine 3′,5′-cyclic phosphonite was not formed, but polymeric compounds were obtained. On the other hand, the reaction of 5′-monomethoxytrityluridine having free 2′- and 3′-hydroxyl groups(O–O distance, 2.77 Å) with equimolar amount of **1** gave only the five-membered cyclic phosphonite (**2b**), but no polymeric compound was obtained. It is concluded therefore that **1** gave the cyclic phosphites quantitatively in the reaction with diols possessing the favorably placed hydroxyl groups in which the distance between the two oxygen atoms is 2.7—3.0 Å.

Another problem was to examine the ease of the formation of five-membered cyclic phosphonite and six-membered one in the reaction of diols with **1**. The reaction of aliphatic diols which have flexible chains with equimolar amounts of **1** were carried out (−78 °C, 30 min). After the treatment with methanol, ^{31}P NMR spectra of the products show that the cyclic phosphites were formed quantitatively both from ethylene glycol and 1,3-propanediol. These results indicate that **1** has a potential activity to give the both five- and six-membered cyclic phosphonite (**5** and **6**) from the flexible chain diols. It was reported that, in the similar reactions, phosphorus trichloride,[1–3] triphenylphosphine,[4] and hexamethylphosphorous triamide[12] gave the cyclic phosphite in moderate yields. Therefore, from the practical point of view, **1** is useful for the preparation of cyclic phosphites.

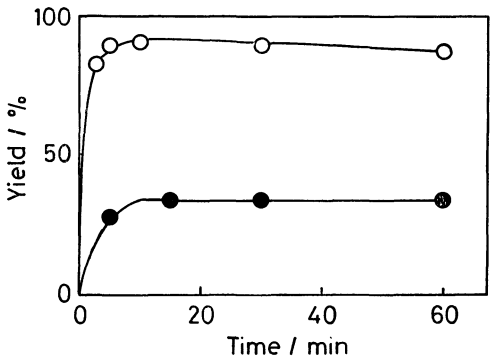

Fig. 1. The time course of the phosphorylation reaction of 5′-*O*-monomethoxytrityluridine and 2′,3′-*O*-isopropylideneuridine with tri(1-imidazolyl)phosphine. ○: 5′-*O*-Monomethoxytrityluridine, ●: 2′,3′-*O*-isopropylideneuridine.

We have already shown that, in the reaction of unprotected ribonucleoside, the ribonucleoside 2′,3′-cyclic 1-imidazolylphosphonite (**2a**) is formed by the selective attack of **1** to the 2′- and 3′-hydroxyl groups of ribonucleoside.[8–10] In order to examine the course of the selective formation of the ribonucleoside 2′,3′-cyclic 1-imidazolylphosphonite(**2a**), the reactivity of **1** toward the different hydroxyl groups(5′- or 2′,3′-OH) of ribonucleoside was investigated. The time course of the phosphorylation reaction of 5′-*O*-monomethoxytrityluridine and 2′,3′-*O*-isopropylideneuridine with equimolar amount of **1** was shown in Fig. 1. 5′-*O*-Monomethoxytrityluridine was phosphorylated to 90% within 3 min, whereas the rate of the phosphorylation of 2′,3′-*O*-isopropylideneuridine was considerably slow and the yield of the phosphorylated product was less than 35%. That is, the reactivity of **1** toward the 2′- and 3′-hydroxyl groups of ribonucleoside is much higher than toward the 5′-hydroxyl group. Consequently, it is considered that the formation of ribonucleoside 2′,3′-cyclic 1-imidazolylphosphonite (**2a**) is obviously kinetically controlled.

Experimental

High-performance liquid chromatography was carried out on a Shimadzu-Dupont LC 830 instrument using Partisil 10 SAX(ion exchange) column; the linear gradient was 0.001 M†† KH_2PO_4 to 0.3 M KH_2PO_4 containing 10% ethanol(3% min^{-1}) at 70 atm, or on a Shimadzu LC 3A instrument using Nucleosil 7C_{18}(reverse-phase) column; solvent was 2—20% CH_3CN in 0.1 M ammonium acetate(pH 6.0) at a flow rate of 1.0 ml min^{-1}. ^{31}P NMR spectra were recorded on a JEOL FX-200 instrument. ^{13}C NMR spectra were obtained on a JEOL FX-100 instrument.

Pyridine was distilled from *p*-toluenesulfonyl chloride, redistilled from calcium hydride, and stored over 4A molecular sieves. Tetrahydrofuran was refluxed in the presence of $LiAlH_4$ for overnight, distilled, and stored over 5A molecular sieves. Phosphorus trichloride was distilled and stored in

†† 1 M=1 mol dm^{-3}.

a brown ampule. Ethanol was distilled in the presence of benzene and stored over 3A molecular sieves. Methanol was distilled and stored over 3A molecular sieves. Imidazole, thymidine, *cis*- and *trans*-1,2-cyclohexanediol(*cis*:*trans*=67:33),[13] *trans*-1,2-cyclohexanediol, *cis*- and *trans*-1,3-cyclohexanediol(*cis*:*trans*=50:50),[13] *cis*- and *trans*-1,4-cyclohexanediol(*cis*:*trans*=44:56),[13] ethylene glycol, 1,3-propanediol, 1,2-benzenediol, 1,3-benzenediol, and 1,4-benzenediol were purchased from Nakarai Chemical Co. 5′-*O*-Monomethoxytrityluridine and 2′,3′-*O*-isopropylidene uridine were synthesized by the usual method.[14]

Tri(1-imidazolyl)phosphine. The preparation of tri(1-imidazolyl)phosphine was carried out under argon; phosphorus trichloride(300 μl, 3.45 mmol) was added dropwise to a solution of imidazole(1.41 g, 20.7 mmol) in 24 ml of tetrahydrofuran (THF). Then the mixture was stirred at 0 °C for 20 min. After the filtration of the imidazolium hydrochloride, the filtrate was used as a phosphorylating reagent. Tri(1-imidazolyl)phosphine was contained *ca.* 0.14 mmol in 1 ml of the filtrate. This phosphorylating reagent was stable at least for a week in anhydrous THF under argon.

Reaction with Cyclohexanediols. Generally, the reactions of cyclohexanediols with tri(1-imidazolyl)phosphine were carried out in THF; the reaction mixtures consisted of cyclohexanediols (400.8 mg, 3.45 mmol) in 5 ml of THF and tri(1-imidazolyl)phosphine (approximately equimolar amount to cyclohexanediols) in 24 ml of THF. The mixtures were stirred at −78 °C for 60 min and then evaporated to nearly dryness. The residues were dissolved in pyridine-d_5. The solutions were sealed into the NMR tube under argon and then analyzed by ^{31}P NMR.

Time Course of the Reaction with Cyclohexanediols. *trans*-1,2-Cyclohexanediol was reacted with tri(1-imidazolyl)phosphine under the same conditions above for 5, 15, 30, and 60 min. After these time intervals, the reaction mixtures were treated with excess ethanol at 0 °C for 30 min. The solutions were evaporated to nearly dryness and dissolved in benzene-d_6. They were sealed into the NMR tube and then analyzed by ^{31}P NMR. Similar experiments were done for *cis*- and *trans*-1,2-cyclohexanediol, and *cis*- and *trans*-1,3-cyclohexanediol.

Reaction with Glycols. Glycols (ethylene glycol, 62.1 mg, 1,3-propanediol, 76.1 mg; 1 mmol) were dissolved in THF (7 ml) and then cooled to −78 °C. To these solutions, tri(1-imidazolyl)phosphine (1.0 mmol) in 7 ml of THF was added and stirred for 30 min. After treatment of methanol (0.2 ml, 4.9 mmol), the solutions were evaporated to nearly dryness. The residue were dissolved in $CDCl_3$. The solutions were transferred into the NMR tube and then analyzed by ^{31}P NMR.

Reaction with Benzenediols. Benzenediols (30.8 mg, 0.28 mmol) were reacted with tri(1-imidazolyl)phosphine(equimolar amount to benzenediols) in 3 ml of THF at −78 °C for 60 min. The reaction mixtures were added to a solution of iodine (71.2 mg, 0.28 mmol) in 3 ml of THF–water(2:1, v/v) with a few drops of pyridine. Then the solutions were evaporated to dryness. The residues were dissolved in 1 ml of water and then analyzed by HPLC.

Reaction with Thymidine. Thymidine (36.2 mg, 0.1 mmol) was reacted with tri(1-imidazolyl)phosphine (equimolar amount to nucleoside) in 2.4 ml of pyridine–THF (1:4, v/v) at −78 °C for 60 min. After the oxidation with iodine and water, the mixtures were evaporated to dryness. The residues were dissolved in 1 ml of water and then analyzed by HPLC.

Reaction with 5′-O-Monomethoxytrityluridine and 2′,3′-O-Isopropylideneuridine. 5′-*O*-Monomethoxytrityluridine (72.3 mg, 0.14 mmol) was dissolved in 1.4 ml of pyridine–THF (5:2, v/v) and then cooled to −78 °C. To this solution, tri(1-imidazolyl)phosphine (equimolar amount to nucleoside) in 1 ml of THF was added and stirred. After the appropriate time intervals, the mixture was oxidized with iodine and water. The mixture was evaporated to dryness and dissolved in the buffer(20% CH_3CN) and then analyzed by HPLC. Similar experiment was done for 2′,3′-*O*-isopropylideneuridine under the same conditions. In order to confirm the cyclic structure, the phosphorylated derivative from 5′-*O*-monomethoxytrityluridine was treated with $ZnBr_2$ in methanol and then analyzed by HPLC. Only the peak due to uridine 2′,3′-cyclic phosphate was appeared.

Determination of Yields. Yields(%) of the cyclic phosphite derivatives from the reaction of tri(1-imidazolyl)phosphine with cyclohexanediols and glycols were determined by ^{31}P NMR spectroscopy. The cyclic structure was confirmed after the conversion of the cyclic 1-imidazolylphosphonite to the corresponding cyclic phosphites of which ^{31}P chemical shifts (downfield from external 85% H_3PO_4) were reported in the literatures.[15,16] 2-Ethoxy-4,5-(*cis*-1,2-cyclohexanedihydroxy)-1,3,2-dioxaphospholane (from **3a**): δ+136 ppm (lit,[15] δ+136 ppm); 2-ethoxy-4,5-(*trans*-1,2-cyclohexanedihydroxy)-1,3,2-dioxaphospholane (from **3a**): δ=139 (lit,[15] δ=139); 2-ethoxy-4,5-(*cis*-cyclohexanedihydroxy)-1,3,2-dioxaphosphorinane (from **4a**): δ=124 (lit,[15] δ=124); 2-methoxy-1,3,2-dioxaphospholane (from **5**): δ=132 (lit,[16] δ=132); 2-methoxy-1,3,2-dioxaphosphorinane (from **6**): δ=129 (lit,[16] δ=129).

The Vibrational Spectra and Thermodynamic Functions of 2,3-Dichloropyridine

Kanak Chandra Medhi

Department of Physics, Gauhati University, Gauhati-781014, India

(Received September 10, 1982)

The infrared spectrum in the vapor, liquid, solution, and solid phases and the laser Raman spectrum in the liquid state have been measured for 2,3-dichloropyridine. A complete vibrational assignment is given. Ideal gas state thermodynamic functions of the molecule are computed over the temperature range 200—1500 K.

The infrared spectrum of 2,3-dichloropyridine in solutions was measured by Green *et al.*,[1] and a vibrational assignment based on comparison with the related molecules was given. For evaluation of the thermodynamic properties, a precise knowledge of the fundamental frequencies is necessary. A study of the vapor-phase infrared spectrum and the polarized Raman spectrum is essential for an accurate vibrational assignment of the observed frequencies. There is, however, no previous report on the Raman and vapor-phase infrared spectra of this molecule. In extension of the previous work on the vibrational spectra of some substituted pyridines,[2-5] the infrared spectrum of 2,3-dichloropyridine in the vapor, liquid, solution and solid phases and the Raman spectrum in the liquid state have been studied in details in this work. The present measurements suggest some changes in the previous assignments.[1]

The present paper gives an essentially complete assignment of the observed frequencies based on the contours of the vapor-phase infrared bands, the state of polarization of the Raman lines and comparison with the assignments proposed for related molecules.[4-10] It also includes the ideal gas state thermodynamic functions of the molecule calculated on the basis of the present assignment.

Experimental

Pure sample of 2,3-dichloropyridine obtained from Schuchardt, Germany was purified by repeated sublimation under vacuum.

The Raman spectrum of the compound in the liquid state just above the melting point was recorded on a Cary 82 laser Raman spectrophotometer. The spectrum was excited by the 514.5 nm line (200 mW) of an argon ion laser. The polarization measurement was carried out by the method described previously.[5] The infrared spectrum in the region 4000—400 cm^{-1} in the vapor state, in nujol mull or polycrystalline film, in liquid film prepared from the melt of the substance and in solution in CCl_4 or CS_2 was measured using a Carl-Zeiss Specord IR 75 spectrophotometer after the calibration of the instrument had been checked by a polystyrene film run. A 9 cm heated gas cell equipped with KBr windows was used to record the vapor-phase spectrum. The far infrared spectrum in nujol mull in the region 500—30 cm^{-1} was obtained using a Perkin-Elmer Model 180 spectrophotometer.

Results and Discussion

The observed infrared and Raman frequencies of 2,3-dichloropyridine together with their approximate intensities and assignments are given in Table 3. The fundamental frequencies are collected in Table 4. Table 5 shows the calculated values of the thermodynamic quantities of the molecule over the temperature range 200—1500 K. The variations of these thermodynamic functions with temperature are represented graphically in Figs. 2 and 3.

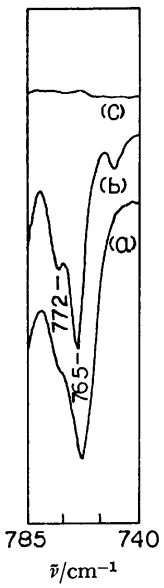

Fig. 1. Infrared spectrum of 2,3-dichloropyridine showing 772 and 765 cm^{-1} bands. a): Thin film (melt), (b): solution in CS_2, (c): pure CS_2.

The 2,3-dichloropyridine molecule belongs to the point group C_s and its twenty seven normal vibrations, which are active both in the Raman and infrared spectra, are distributed over the two symmetry species as

$$19a' + 8a''.$$

The a′ modes should be polarized and the a″ modes depolarized in the Raman spectrum. The principal moments of inertia of 2,3-dichloropyridine molecule and the asymmetry parameters $\kappa = \frac{2B-A-C}{A-C}$ and $\rho^* = \frac{A-C}{B}$, where A, B, and C are rotational constants, have been calculated (Table 1) with the following interatomic distances and bond angles assuming that the ring is a planar regular hexagon:

$r(C\text{-}C) = r(C\text{-}N) = 1.397$ Å, $r(C\text{-}H) = 1.084$ Å,
$r(C\text{-}Cl) = 1.717$ Å,
$\angle CCC = \angle CCN = \angle CCH = \angle CCl = 120°$,

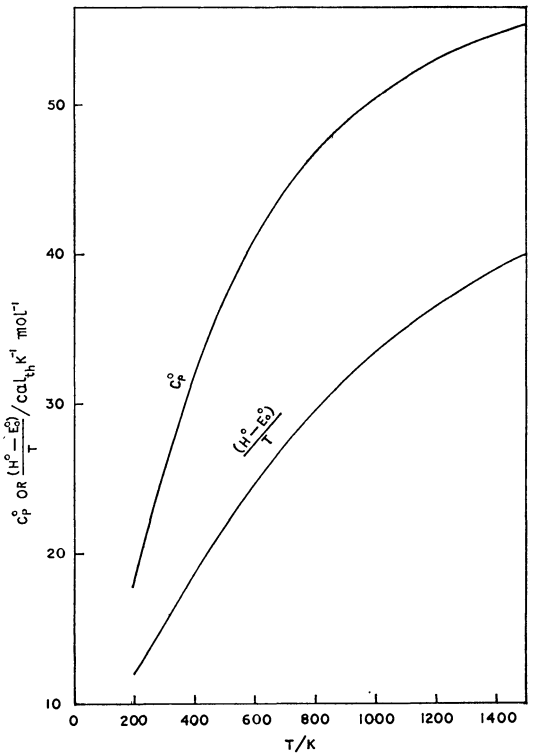

Fig. 2. Variation of heat capacity and enthalpy of 2,3-dichloropyridine with absolute temperature.

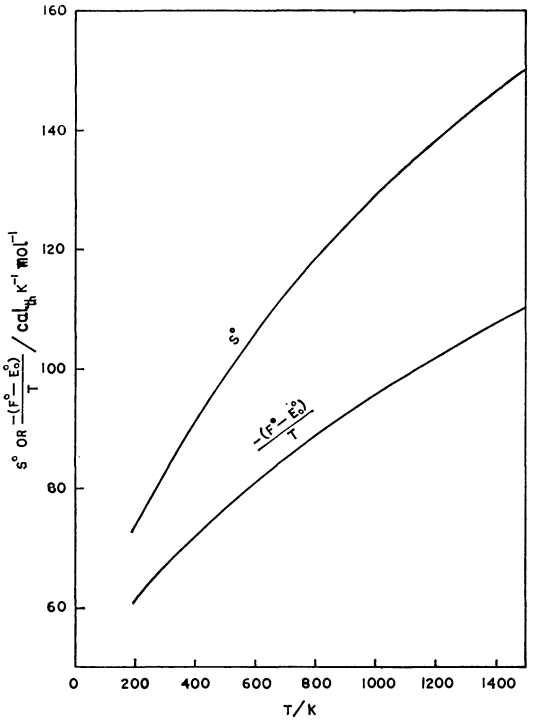

Fig. 3. Variation of entropy and free energy of 2,3-dichloropyridine with absolute temperature.

and by using the relative atomic masses recommended by IUPAC.[11] The PR separations of band envelopes in the vapor-phase infrared spectrum have been calculated at $T=346$ K by the method of Seth-Paul and Dijkstra,[12] and are included in Table 2 along with the observed separations.

Table 1. Principal moments of inertia[a] and the asymmetry parameters for 2,3-dichloropyridine

$I_x/10^{-47}$ kg m^2	$I_y/10^{-47}$ kg m^2	$I_z/10^{-47}$ kg m^2	κ	ρ^*
424.003	601.068	1025.070	−0.0048	0.8312

a) The z-axis is perpendicular to the plane of the ring.

Table 2. PR separations in the infrared vapor-phase band envelopes

Band type	PR separation $\tilde{\nu}$/cm^{-1}	
	Calcd	Obsd
A (∥)	10.7	10.0, 10.0
B (⊥)	8.1	8.0, 8.0, 8.0, 8.0
C (⊥)	16.1	16.0, 17.0

The infrared bands belonging to the species a″ should show C-contour with a PQR structure showing a sharp strong Q maximum but ill-defined P and R branches,[13] while those of species a′ will have A- or B- contour or contours of the hybrid type-AB.

Species a′. There are expected three frequencies in the C–H stretching region, and the polarized Raman lines at 3068 and 3054 cm^{-1} are assigned to these modes. The Raman shifts at 1562, 1552, 1436, 1398, and 1031 cm^{-1} are observed to be polarized; these are unambiguously identified as a′ fundamentals arising essentially from the stretching of the C–C (C–N) bonds. The infrared band at 1125 cm^{-1} shows type-B contour in the gas-phase spectrum, its Raman counterpart located at 1126 cm^{-1} being polarized. This may be attributed to the a′ mode involving stretching of the C–Cl bonds in agreement with the similar assignment proposed in the case of *o*-dichlorobenzene.[6]

A moderately intense infrared band has now been observed at 772 cm^{-1} which was not reported by the previous investigators[1] probably due to lack of proper resolution. In the present investigation the 772 cm^{-1} band is appearing as a shoulder on the higher wavenumber side of the 765 cm^{-1} band in the pure liquid state. The band is, however, clearly resolved in solution in CS_2 (Fig. 1). Though its Raman counterpart is not observed, it has been tentatively assigned as the a′ fundamental corresponding to the substituent-sensitive mode 12.[2,9] The infrared band at 517 cm^{-1} (present value) was assigned previously[1] to the a″ species. But the corresponding Raman line observed at 506 cm^{-1} appears to be polarized; it must therefore be assigned as an a′ fundamental. The observed frequency difference between the infrared band and the Raman shift may be due to the fact that the infrared band at 517 cm^{-1} is sharp, while the Raman line is weak and broad having its maximum at about 506 cm^{-1}. Moreover, its position is somewhat influenced by the neighbouring strong Raman line at 477 cm^{-1}. The remaining a′ fundamentals are identified with the polarized Raman lines at 1215, 1159, 1062, 652, 477, and 204 cm^{-1} and the infrared bands at 1298 and 763 cm^{-1} in agreement with the previous assignment.[1]

a) Ideal gas state at standard pressure of 1 atm. 1 cal$_{th}$=4.184 J.

Species a″. In the earlier work[1] the infrared frequencies at 426 and 351 cm^{-1} (present values) were assigned to the a′ class and the weak infrared band at 443 cm^{-1} to the a″ species. But the Raman spectrum reveals that the corresponding shifts at 428 and 353 cm^{-1} respectively are completely depolarized. They must therefore be assigned as a″ fundamentals arising respectively from the C–H and C–C–C out-of-plane deformations. The 443 cm^{-1} band may be explained as the combination band 250+202=452 cm^{-1} (A″) or the difference band 793−351=442 cm^{-1} (A′).

The infrared bands at 793 and 726 cm^{-1} showing type C contours in the gas phase and the depolarized Raman lines observed at 255 and 142 cm^{-1} are reasonably assigned to the a″ species. The infrared spectrum shows weak absorptions at 972 and 934 cm^{-1}. As in the case of other substituted pyridines, they are attributed to the C–H out-of-plane deformations. The assignments of these frequencies to the a″ species are in agreement with the previous assignments.[1]

Thermodynamic Functions

Ideal gas state thermodynamic functions of 2,3-dichloropyridine molecule have been calculated using the standard expressions[14] and the following wavenumbers of the fundamentals observed in the infrared and Raman spectra (where available, the vapor-phase frequencies are used):

3068, 3068, 3054, 1563, 1556, 1438, 1401, 1298, 1215, 1165, 1127, 1064, 1031, 971, 934, 792, 772, 763, 730, 650, 506, 474, 428, 353, 255, 204, and 142.

Thermodynamic contributions from over-all rotation and vibration are calculated on the basis of the above data and those given in Table 1 by assuming a rigid-rotator harmonic-oscillator approximation.

Physicochemical Studies of Alkali Metal Solutions in Tetrahydrofuran

Jacques Lacoste and François Schué*

Laboratoire de Chimie Macromoléculaire, Université de Sciences et Techniques du Languedoc, Place E. Bataillon, 34060 Montpellier Cedex, France

(Received December 21, 1982)

We have studied the rate of alkali metal dissolution in THF as a function of its nature and of the cryptand (C). The selectivity has been estimated through the equilibrium constant of the following equilibrium:

$$M^- + C \rightleftarrows M^+C + 2e^-_{solv}.$$

Both $\Delta H°$ and $\Delta S°$ for this reaction are negative. The entropy decrease reveals that the sum of the energies bonds between the cation and the ligand and the electrons and the solvent is higher than that necessary to desolvate and dissociate M^-.

Solutions of alkali metals in amines and ethers have been widely studied.[1-5, 12-14] The species which can exist in these solutions may be described by the following equilibria (1) to (3):[2]

$$2M_s \rightleftarrows M^+ + M^- \quad (1)$$

$$\uparrow\downarrow$$

$$M + e^-_{solv} \quad (2)$$

$$\uparrow\downarrow$$

$$M^+ + e^-_{solv} \quad (3)$$

An increase in the solvating power and dielectric constant of the solvent shifts all three equilibria to the right.

The use of a cation-complexing agent (C) seems to provide enough stabilization energy to yield solvated electrons in solvents in which the metals would otherwise be insoluble.[1] The effect of (C) may be represented by the following in addition to equilibria (1)—(3).

$$2M_{(s)} + C \rightleftarrows M^+C + M^- \quad (4)$$

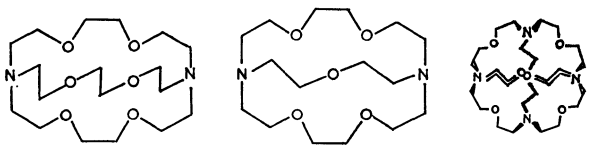
$$M^- + C \rightleftarrows M^+C + 2e^-_{solv} \quad (5)$$

Many complexing agents have been used which belong to the classes of crowns and cryptands.

In a preliminary note,[6] we have studied equilibria (4) and (5) from a kinetic point of view.

At the early stage of the reaction (short time of contact between a solution of (C) and M solid), the complexing agent is in excess with respect to the dissolved metal and, under certain conditions, it is possible to obtain the solvated electron without the presence of M^-. With increasing time of contact, most of the free C is consumed by reaction (4); reaction (5) is reversed, and the M^- species predominates.

In this work, we have studied in more detail both the kinetics of metal dissolution as a function of the nature of the alkali metal and of the complexing agent **1**, **2**, and **3** and the thermodynamic parameters of equilibrium (5).



1 **2** **3**

Experimental

The high reactivity of the species e^-_{solv} and M^- requires the use of high vacuum techniques and all glass apparatus.

All glassware was cleaned[2] first with an HF solution followed by a thorough rinsing with distilled water. The cells were filled with boiling aqua regia which was allowed to remain in the cell for at least 10 h. After rinsing with distilled water, the cell was dried in an oven overnight.

Tetrahydrofuran (THF) was first dried with potassium hydroxide and calcium chloride. After initial drying, it was distilled onto potassium and finally stored under vacuum over Na:K (1:3) alloy which yielded blue solutions.

The metals were vacuum-distilled in bulbs supplied with break-seals. The cation-complexing agents were recrystallized in hexane, dried and sealed off under vacuum.

The experiments were carried out in the apparatus described in Fig. 1 according to the following procedure: after evacuation, the metal was distilled from the side arm (a) to form a mirror on the walls of vessel A. Then the solvent, stored on a vacuum line, was distilled under vacuum into A. When the complexing agent (b) had been added, after a given time of contact (t_c) at −78 °C (methanol–Dry Ice refrigerating mixture), the solution was poured through the coarse frit (G2) into the thermostated quartz call B. Excess complexing agent could be added through break-seal (c).

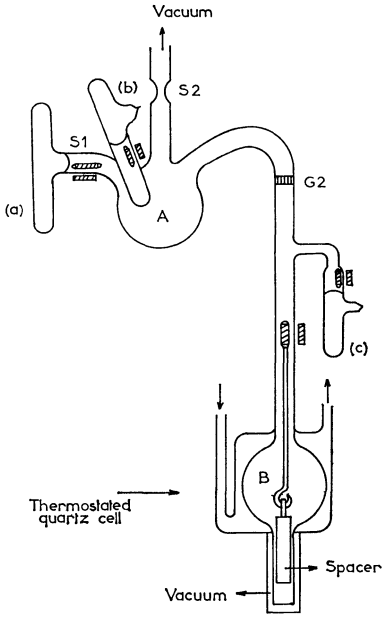


Fig. 1. Apparatus for the preparation and spectroscopic studies of alkali metal solutions.

Optical spectra were obtained with a Beckman DK-2A spectrophotometer. The spectroscopic parameters (λ_{max}, $d\varepsilon/dT$) were determined elsewhere.[7] The optical path-length of the cells was determined with standard solutions of potassium dichromate ($l=0.51+0.01$ and $l=0.057\pm 0.001$ cm). The total metal concentration in solution was estimated by flame photometry (Electrosynthese PHF 62 A). Temperature was controlled by means of an Ultra-kryostat Haake KT52.

Results and Discussion

Kinetics of Dissolution. In order to carry out this study, we used less complexing agent than total metal. If we consider only reaction (4), the ratio R can reach a limiting value of 0.5.

$$R = \frac{[C_o]}{[M]} \qquad (6)$$

$[C_o]$ and [M] represent the concentrations respectively of complexing agent and of metal in solution. The simultaneous presence of reactions (4) and (5) will allow values of R higher than 0.5. High values of the ratio R can be due either to a low complexation efficiency or to a short contact time (Figs. 2 to 5).

The use of compound **3** (Fig. 6), specific for cesium, increases the dissolution and one can observe a higher proportion of e_s^- for a short time of contact. This last study shows the intramolecular cavity cation selectivity.

Complexation Effect. The kinetic studies have shown the influence of the metal and the complexing agent on the rate of dissolution of alkali metals in

Cryptand III $=1.78\times10^{-4}$ mol dm^{-3}.

THF. For a better understanding of these phenomena, we have studied the behavior of these solutions in the presence of an excess of complexing agent.

For a constant ratio R, we can expect the equilibrium (5) to be more or less shifted to the right according to the ionization potential of the metal anion and the selectivity of the complexing agent. Figure 7 shows the optical spectra after addition of an excess of compound **1**. A remarkable $K^+ > Rb^+ > Cs^+ > Na^+$ complexation selectivity displayed by ligand **1** is noted. Cesium and rubidium are less complexed than potassium. This shows that the intramolecular cavity-cation selectivity prevails over the ionization potential of the metal anion in these cases.

This selectivity can be illustrated by the equilibrium constant of reaction (5) at −50 °C.

$$K_5 = \frac{[M^+C][e^-_{solv}]^2}{[M^-][C]} \qquad (7)$$

now, $[M^+C]=[M^-]+[e^-_{solv}]$ and $[C]=[C_0]-[M^+C]$ leading to:

$$K_5 = \frac{\{[M^-]+[e^-_{solv}]\}[e^-_{solv}]^2}{[M^-]\{[C_0]-([M^-]+[e^-_{solv}])\}} \qquad (8)$$

The values obtained have been plotted as a function of the cationic radius (Fig. 8), and confirm the high selectivity for K^+.

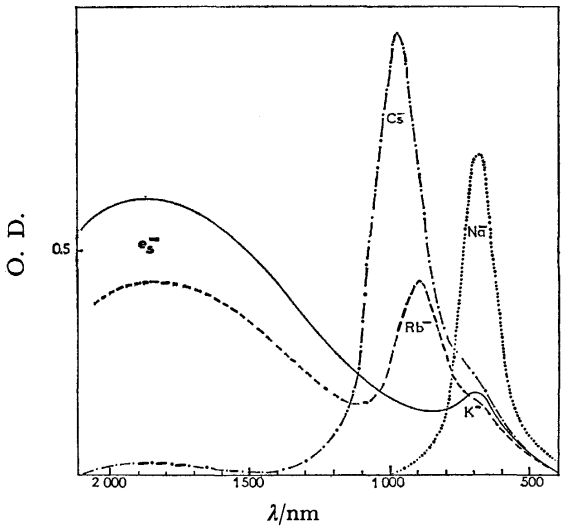

Fig. 7, Absorption spectra of sodium, potassium, rubidium and cesium in THF in the presence of cryptand **I** ($t=-50$ °C).
·····: Na, R=9.2, ——: K, R=4.6, ----: Rb, R=4.4, —·—·—: Cs, R=6.5.

The use of compounds **2** and **3** have marked effects on equilibrium (5). The Cs^+–**3** and K^+–**1** complexes are comparable; but that is not the case for the Na^+–**2** complex for which the high ionization potential of Na^- prevails.

Thermodynamic Parameters. A deeper understanding of the thermodynamics of cryptate formation may be provided by analysis of the enthalpy, $\Delta H°$, and entropy $\Delta S°$, of complexation. Such data have

recently become available for a number of macrobicyclic ligands.[10]

Figure 9 shows the influence of temperature on the absorption spectrum of a rubidium cryptand-I THF solution. Besides the shift of the equilibrium toward the formation of M^- with increasing temperature, we note that the temperature dependence of the position of the absorption bands prevents the presence of an isosbestic point.

Figure 10 represents the Vant Hoff plots and the thermodynamic relation (9) allows the estimation of the enthalpy $\Delta H°$ and entropy $\Delta S°$ for reaction (5).

$$-\frac{\Delta G°}{RT} = -\frac{\Delta H°}{RT} + \frac{\Delta S°}{R} = \log K_5 \qquad (9)$$

The data are given in Table 1.

Both enthalpies and entropies are negative. Negative enthalpies reveal that the sum of the energy of the bonds between the cation and the ligand and the electron and the solvent are higher than that necessary to desolvate and dissociate M^-.

The values observed are in agreement with the high values of the equilibrium constant K_5.

The entropy decrease can be explained by two kinds of complexation; the cation cryptand and the electron THF ones.

We wish to acknowledge support of this research by the Societé Nationale des Poudres et Exploisifs under Contracts N° 17.72 D, 13.73 D, 11.74 D, and 11.42 A.

Our special thanks go to Professor J. M. Lehn of the University of Strasbourg, for providing us with samples of the cryptand compounds and for useful discussions, to Professeur J. L. Dye of the Michigan State University of helpful exchanges of information and useful discussions, and to Dr. S. Bywater of the National Research Council of OTTAWA for useful discussions.

Infrared Spectra of Ammonia Adsorbed on Titanium Dioxide

Masao HINO* and Yasuko MIKAMI

Government Industrial Development Laboratory, Hokkaido, Tsukisamu-Higashi, Toyohira-ku, Sapporo 061-01

(Received October 2, 1982)

Synopsis. IR spectra of ammonia adsorbed on titanium dioxide were measured including those of partially deuterated ammonia. The results were compared with spectra reported in the literature.

A few papers have been published on IR spectra of ammonia adsorbed on TiO_2 studied with object of surface characterization.[1-3] Parfitt *et al.*[2] observed the spectra on a rutile surface and Primet *et al.*[3] on anatase including 10—15% of rutile. A good agreement is seen between the spectra observed by them. They attributed the observed bands to the two types of ammonia adsorbed on different Lewis acid sites. However, some differences are seen in the details of their assignments (Table 1, Assignments 1 and 2). The purpose of the present paper is to resolve the confusion in the assignments by the use of partially deuterated ammonia.

Experimental

Degussa Titanium dioxide p-25 (60% anatase, 40% rutile) was used as the sample. The self-supporting disk samples were initially heated at 450 °C for 5 h and cooled to room temperature in flowing oxygen, then evacuated in situ at 350 °C for 2 h, exposed to 40 Torr (1 Torr≈133.322 Pa) of oxygen at the same temperature for 0.5 h, and finally again evacuated at the same temperature for 0.5 h. Standard ammonia (Takachiho Co. Ltd.) was dried with sodium metal at a low temperature. Deuterated ammonia was distilled from a D_2O solution of ammonia-d_3 (99 atom%, E. Merck Darmstadt), and then dried in the same manner as for the ammonia. All the spectra were measured at room temperature. The IR cell was similar to that previously described,[4] and a JASCO-Model 402G spectrophotometer was used for the measurements.

Results and Discussion

The NH_3–TiO_2 adsorption system showed almost the same spectra as those reported by the previous authors.[2,3] Five absorption bands in the NH stretching region, and two bands in the deformation region were observed after pumping at room temperature (Table 1). Elevation of the evacuation temperature gave rise to the appearance of a new band around 1230 cm^{-1}. As a result of evacuation at 350 °C, all the above bands disappeared. After the surface OH groups were exchanged for OD groups by repetition of the introduction of ND_3 followed by evacuation

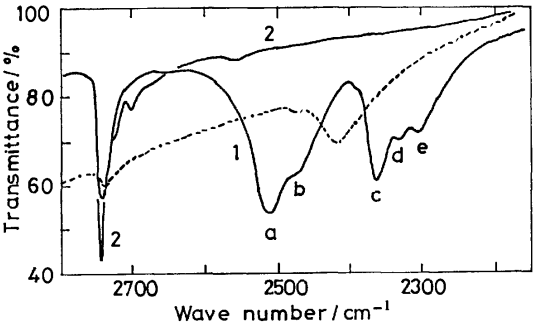

Fig. 1. Spectra of ammonia adsorbed on TiO_2 in the ND stretching region.
Full line: TiO_2–ND_3 system; evacuated at room temperature for 20 min (1), and at 350 °C for 3 h (2) after saturated with ND_3 gas at room temperature. Sample disk thickness was 40 mg/cm². Broken line: TiO_2-NH_2D system; evacuated at room temperature for 20 min after saturated with NH_3-ND_3 10.1 to 1.0 mixed gas at room temperature. Sample disk thickness was 140 mg/cm².

TABLE 1. IR BANDS OF AMMONIA ADSORBED ON TITANIUM DIOXIDE (STRETCHING REGION)

Band sign	νNH/cm^{-1}		νND/cm^{-1}		Assignment		
	NH_3	NHD_2	ND_3	NH_2D	(1)	(2)	(3)
a	3395		2520		ν_3	ν_3	ν_3
b	3345		2476		ν_1	ν_3	ν_3
		3285		2423			
c	3251		2372		ν_3	ν_1	ν_1
d	3188		2340		ν_1		$2\delta_4$
e	3151		2310			ν_1	ν_1

(1) Ref. 2, (2) Ref. 3, (3) this paper. Bands coupled with a L-shaped line mean that they are the pair of ν_3 and ν_1 of one type of the adsorbed ammonia.

at 350 °C, the spectra of ND_3 adsorbed on TiO_2 were measured (Fig. 1). The stretching bands correspond well to those of NH_3 adsorbed on TiO_2 (Table 1). Besides the D-shift, a small hump attributable to a combination band of ND_3 was detected at 3400 cm^{-1}. The bands at 2745, 2730, 2700, and 2675 cm^{-1} in Fig. 1 may be assigned to the surface OD groups on TiO_2.

Spectra of ammonia adsorbed on TiO_2 were measured for various H/D ratios. A typical result is shown in Fig. 1, using NH_3: $ND_3 \approx 10:1$ gas mixture, where NH_3: NH_2D: NHD_2: $ND_3 \approx 1000:300:30:1$. Hence, the bands in the νND region of the observed spectra are mainly due to adsorbed NH_2D. The result shows only a strong main band at 2423 cm^{-1} with a very small shoulder at 2482 cm^{-1} in the ND stretching region. The band at 2423 cm^{-1} is safely assigned to the νND of the adsorbed NH_2D; neither the NH_3-adsorbent system nor the ND_3-adsorbent system showed any band at this frequency (Fig. 1). For the NHD_2–TiO_2 system, the νNH band of the adsorbed NHD_2, which corresponds to the band at 2423 cm^{-1} for the NH_2D–TiO_2 system, was observed at 3285 cm^{-1}.

The fundamental νNH band of NHD_2 appears approximately at the mean frequency of ν_3 and ν_1 of NH_3, and the νND band of NH_2D appears between ν_3 and ν_1 of ND_3.

On the basis of these observations, the tentative assignments shown as "Assignment (3)" in Table 1 were made for the bands a—e. It is seen from the table that the proposed assignments are more consistent with those made by Primet *et al.*[3] than with those of Parfitt *et al.*[2] However, to confirm the assignments further experimental studies including considerations of hydrogen-bonding effect are necessary. The small shoulder at 2482 cm^{-1} may be attributed to the adsorbed species of NHD_2 which coexists in the mixed sample gas, or may suggest the existence of a small amount of another adsorbed species such as $-NH_2$ proposed by Parfitt *et al.*[2] near the frequencies of the bands a and b.

The Wavelength Dependence of the Photochemical Reaction of 9-Anthracenecarbaldehyde with 2-Methyl-2-butene

Fujio TANAKA and Shigeru YAMASHITA*

College of Integrated Arts and Sciences, University of Osaka Prefecture, Mozu-umemachi, Sakai, Osaka 591

(Received February 28, 1983)

Synopsis. Photochemical reaction of 9-anthracenecarbaldehyde with 2-methyl-2-butene was studied under irradiation of >410 and 366 nm. Oxetane formation is predominant in both the wavelength cases, as revealed through isolation of reaction products and examination of their NMR, mass, and UV spectra.

In recent years, photocycloaddition reaction of carbonyl compounds to olefins yielding oxetanes has been an interesting subject for many workers.[1] A wide variety of reaction mechanisms have been proposed with many kinds of excited species as photoreactive states depending on the combination of carbonyl compounds and olefins.

Generally speaking, mechanisms for the oxetane formation by photocycloaddition of excited carbonyl compounds with acyclic olefins have been elucidated for many cases, and several reviews have been published.[1l,1m]

The photochemical reaction of 9-anthracenecarbaldehyde (9-CHO-A) having the $T_1(\pi,\pi^*)$ state with olefins has been studied by many workers with diverse results. Yang[1d] observed an oxetane formation in an irradiation at <410 nm on a mixture of 9-CHO-A and 2-methyl-2-butene, while under an irradiation at longer than 410 nm no oxetane formation was observed and the main product was the dimer of 9-CHO-A. Though Warwick and Wells[8] ascertained a similar wavelength effect on the carbonyl photoreaction using 2,3-dimethyl-2-butene as olefin, the main product was found to be pinacol and not oxetane as reported by Yang. Porter and Suppan[9,10] found spectroscopically the photoreduction of the carbonyl group to occur regardless of irradiation wavelength and suggested that the lowest excited singlet state (S_1) is the reactive state. Hirayama[11] supported the reaction mechanism *via* the upper triplet state on the basis of a spectroscopic ground. It was pointed out[1n] that the irradiation at a longer wavelength (440 nm) was effective for the formation of oxetane in the case of 9-CHO-A with 2,3-dimethyl-2-butene, suggesting the necessity of reexamination of the previous result for the case of 9-CHO-A with 2-methyl-2-butene. However, no detailed description has been reported. At any rate, the effect of wavelength on the formation of oxetanes in the photochemical reaction of 9-CHO-A and simple olefins remains unclarified without any further reports concerning this point.

The diversity of the results obtained by the previous workers about the wavelength dependence of the reaction seems to be closely associated with the fact that oxetane, which is thought the most probable product, has not been isolated for identification under the irradiation of longer wavelengths. The isolation of oxetane was reported in only one case of shorter wavelength irradiation.[1d]

In the present work, we have reinvestigated the photochemical reaction of 9-CHO-A with 2-methyl-2-butene in order to isolate and identify the reaction products and to ascertain the wavelength dependence of the reaction. A solution containing 206 mg of 9-CHO-A in 50 ml of 2-methyl-2-butene was irradiated under the condition of λ>410 nm. All runs were carried out without deaeration since the absence of influence by oxygen was already confirmed.[1b,10,11]

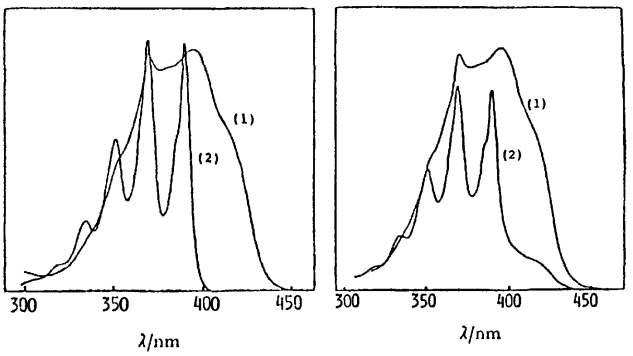

Fig. 1. The change of absorption spectrum by the irradiation of >410 nm(left) and 366 nm(right). (1): Before and (2): after the irradiation. The concentration for reaction is 2×10^{-2} M. The spectra were measured by diluting to 1/250 with hexane.

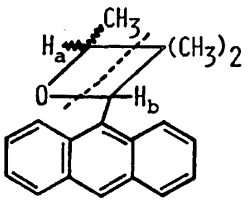
The absorption spectra obtained before and after the irradiation are shown in Fig. 1(left). The appearance of the band structure typical of the anthracene ring indicates that the carbonyl group is photoreduced keeping the anthracene ring unchanged.

In the process of trying to isolate reaction products, we found that the main product was unstable in neat or concentrated conditions while it was stable in dilute solution. The absorption band in the near UV region disappeared gradually as the degradation of the main product proceeded. With the lability of the main product taken into account, the separation of products from the reaction mixture was carefully performed by column chromatography (silica gel–benzene).

The main product (*ca.* 100 mg) thus obtained was an oily substance with a peak for the 0-0 band (λ_{0-0}) at 390 nm in hexane. The ^{1}H NMR spectrum of this compound shows a distinct signal of quartet at 4.70 ppm, assigned to H_a of the oxetane isomer **1** formed by the photoreaction of carbonyl compounds with 2-methyl-2-butene.[1b] The mass spectrum showing peaks at m/e=276 (the molecular ion of formula **1**) and 232 (the fragment ion shown by the broken line) also supports the molecular structure predicted on ^{1}H NMR.

As a minor product, an unidentified compound showing the absorption of λ_{0-0} at 386 nm and mass spectral peaks at m/e=276 and 259 was separated.

A similar experiment was carried out under irradiation of 366 nm. The change in absorption spectrum with the irradiation for 8 h is shown in Fig. 1 (right). Since the reaction product suffered a further photochemical change at this wavelength, the isolation



Formula **1**. H_a displays a ^1H NMR signal of quartet at 4.7 ppm. A broken line shows the fragmentation causing a peak of $m/e=232$ in the mass spectrum.

of products was performed before reaction of the entire 9-CHO-A had been completed.

The main product obtained by the 366 nm irradiation was found to be oxetane **1** again the same as the product obtained under the irradiation of $\lambda>410$ nm, as inferred from the absorption spectra and ^1H NMR spectra.

Thus the results obtained indicate that oxetane is formed in both the 366 nm and >410 nm excitations, no significant wavelength dependence being able to be observed.

Since the photodimer of 9-CHO-A posseses no absorption band in the wavelength region longer than 300 nm, the ratio of photoreaction of carbonyl to photodimerization is obtained from the absorption spectra before and after the photoreaction. The ratios for the irradiation of $\lambda>410$ nm were found 73/27 at 2×10^{-2} M (1 M=1 mol dm^{-3}) of 9-CHO-A and 86/14 at 2×10^{-3} M of 9-CHO-A. The photodimerization was negligible at concentrations lower than 2×10^{-4} M. The quantum yield of the photoreaction of carbonyl by the excitation with 436 nm was 3.4×10^{-2} at the concentration 2×10^{-3} M of 9-CHO-A. Potassium ferrioxalate was used as a chemical actinometer.

Under the experimental conditions of this work, the primary process is the photoexcitation of 9-CHO-A to its S_1 state followed by the intersystem crossing to the $T_n(n\pi^*)$ state located about 60 kcal/mol higher than the ground state.[11,8] The primary process from S_1 to T_n by intersystem crossing has also been found in the photochemical reaction of β,γ-unsaturated ketone.[12] When the triplet level of carbonyl compound is lower than that of olefin compound, oxetane formation has been found predominant since the energy transfer to olefin molecule causing dimerization of olefin is improbable. This reaction energetics has been seen in reactions of carbonyl compounds and norbonene. The same situation seems to be applicable in the present study on the 9-CHO-A and 2-methyl-2-butene system. The T_1 energy of 2-methyl-2-butene is supposed to be about 80 kcal/mol in view of T_1 levels of other olefins being higher than the above-mentioned $T_n(n\pi^*)$ state of 9-CHO-A.

Therefore, any energy transfer to olefins from 9-CHO-A is improbable and oxetane formation is predominant regardless of the exciting wavelengths as has been found in the present work.

Experimental

The preparation of 9-CHO-A was carried out according to the literature.[13] An ultra high pressure mercury lamp (Ushio USH 500) was used as the light source. The wavelengths of >410, 366, and 436 nm were isolated with Toshiba filters V-Y43, (UV35+UV-D1b), and (V-Y43+V40), respectively.

Isolation of Oxetane 1 and Spectroscopic Measurements. 2-Methyl-2-butene was evaporated from the irradiated solution, and the hexane-soluble part of the residue was chromatographed on silica gel using benzene as eluent. The main fractions following the degradation products were collected, and a check was made on the UV spectra of effluents. After the removal of benzene the hexane-soluble part was submitted to spectroscopic measurements. To reduce the degradation of oxetane, the chromatographic separations were performed on a smaller scale in UV and MS measurements where only a little sample was needed. The recorded ^1H NMR spectrum showed a fairly clear pattern, though the contamination due to degradation could not entirely be avoided: ^1H NMR (C_6D_6) δ=0.50 (CH_3 with a slight split by isomers), 1.20—1.28 (m, $2\times CH_3$), 4.70 (q, J=3.8 Hz, H_a), 6.98 and 7.08 (s, H_b isomers), and 7.18—8.25 (aromatic); MS (70 eV) *m/e* (%) 276 (2.5), 232 (72), 217 (100), and 206 (50), and (20 eV) 276 (16), 232 (57), 217 (60), and 206 (100); UV_{max}(hexane) 390, 369.5, 351 and 257 nm.

We wish to thank Drs. Setsuo Taniguchi, Shun-ichi Kawamura, and Mitsuo Chubachi of Radiation Center of Osaka Prefecture for the measurements of NMR and mass spectra.

Some Problems Associated with the Exact Solution Conformation of Poly(α-L-glutamic acid) as Determined by Optical Methods

Kiwamu YAMAOKA

Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730

(Received April 4, 1983)

Synopsis. By combining the experimental data on circular dichroism and light scattering, the helical conformation of poly(Glu) in 0.15 mol dm^{-3} NaCl solutions was estimated. The axial translation per residue was probably in the range of 1.2—1.3 Å for the unaggregated helix, while the persistence length was *ca.* 120 Å for the random-coil.

The conformation of poly(α-L-glutamic acid), poly(Glu), in aqueous solutions has been studied widely, since the optical and other physical properties are considered to be the primary reference for the α-helix and the random coil.[1] In order to determine an exact helical conformation, light scattering is a convenient means which gives both molecular weight M_r and overall length L.[2] Yet, there remain three major obstacles to identifying the conformation: (1) The pH region for the completion of helix formation should be known, (2) the α-helix is one of several helical conformations which poly(Glu) may take, and (3) a poly(Glu) sample is generally polydisperse with M_r and L. During the investigation of the macromolecular complex between poly(Glu) and Cu^{2+} ion, poly(Glu) was also studied by circular dichroism (CD), light scattering, viscosity, and other methods.[3—8] Based on these results, some hitherto mostly ignored difficulties, which are associated with the optical determination for the helical conformation of poly(Glu) in aqueous solutions, will be discussed.

Results and Discussion

Estimation of the Helix Fraction. Figure 1 shows the pH dependence of the molar ellipticity at 222.5 nm, $[\theta]_{222.5}$, for a poly(Glu) sample in 150 mM (1 M=1 mol dm^{-3}) NaCl solution. (Descriptions were given elsewhere on CD[3,8] and light scattering.[7]) Stepwise changes have been observed beyond experimental errors both in CD and ORD (at 233 nm) for poly(Glu) samples, which are derived either from poly(γ-benzyl L-glutamate)[3,8] or from poly(γ-methyl L-glutamate),[4,6] in solutions with and without added NaCl. (A similar change in CD was recently detected with a multipurpose technique.[9]) The helix fraction,[8] $f_h=([\theta]^c-[\theta])/([\theta]^c-[\theta]^h)$, can be evaluated from the CD data, where $[\theta]^c$ and $[\theta]^h$ are, respectively, the molar ellipticities for the states of coil and helix. This two-state expression has been verified by the principal-component-analysis method[5] and also by the presence of an isoelliptic point in the CD spectra of poly(Glu).[5,8] It should be noted that f_h does not necessarily denote the fraction of unaggregated helix molecules in a given poly(Glu) solution, because the CD is a short-range phenomenon and does not reflect the overall molecular shape.[1,10]

The first problem is the assignment of an appropriate value to $[\theta]^h$, since the formation of aggregates overlaps with the completion of monomeric helices.[7,8] A value of −36300 (pH=4.42) was used in a previous work,[8] by considering that the perfect helix is completed at point A, the onset of the second transition. However, the helix formation may as well be completed at the midpoint of the second transition (point B), for which $[\theta]^h=-38100$ and pH=4.31.[5] The oft-observed highest value of −40600 may equally be assigned to $[\theta]^h$ (pH=4.10), *i.e.*, point C.[1] This last procedure tacitly accepts the notion that the helix formation is not completed until aggregates are formed. The value of $[\theta]^c$ is 2650 (point D).

Helix Fraction and Root-mean-square Radius of Gyration. In Fig. 1, the square root of the z-average of the mean-square radius of gyration $\langle s^2\rangle_z^{1/2}$, obtained from light scattering,[7] is plotted against the helix fraction obtained from CD. Regardless of the choice of the point for completion of helix (A, B, or C), the value of $\langle s^2\rangle_z^{1/2}$ becomes minimum in the $(1-f_h)$ range of 0.7—0.8. The plots indicate that both helical and coiled segments coexist in a single poly(Glu) chain, excluding the possibility that completely helical and completely coiled molecules exist in varying equilibria in the coil-to-helix transition process (otherwise, the $\langle s^2\rangle_z^{1/2}$ *vs.* $(1-f_h)$ plot would be linear).[8]

The second problem is the assignment of a value of $\langle s^2\rangle_z^{1/2}$ to the perfect helix. As the helix formation is nearly completed ($f_h=0.9$), observed values of

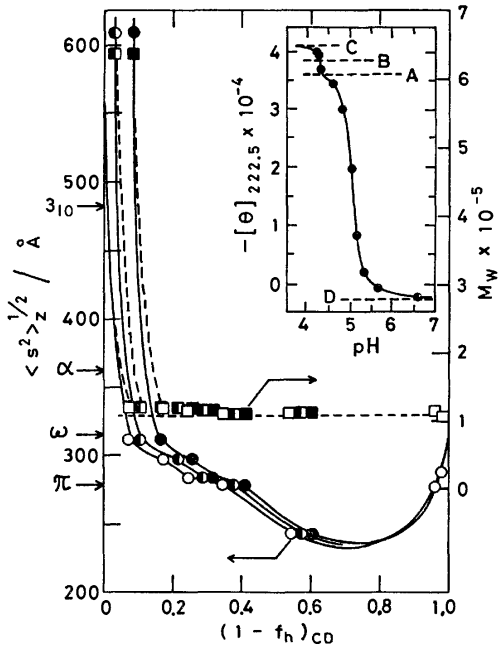

Fig. 1. Dependence of the square root of the z-average of the mean-square radius of gyration, $\langle s^2\rangle_z^{1/2}$, (circles) and the weight-average molecular weight, M_w, (squares) on the fraction of the poly(Glu) coil, $(1-f_h)_{CD}$, in the 150 mM NaCl solutions at 25 °C. The helical conformation is assumed to be completed at point A (open symbols), B (half-closed), or C (closed). Insert: the pH dependence of the molar ellipticity (deg cm^2 dmol^{-1}) at 222.5 nm.

$\langle s^2\rangle_z^{1/2}$ range between 305 and 450 Å, depending on the choice of point A, B, or C (Fig. 1). However, no definite value can be specified for the monomeric, perfect helix ($f_h=1$), because of a concomitant formation of aggregates, as envisaged in Fig. 1 by the change in weight-average molecular weights, M_w, which remain nearly constant at a value of 1.07×10^5 (pH>*ca.* 5) but sharply increase with a decrease in pH.[7] Nevertheless, the limiting value of $\langle s^2\rangle_z^{1/2}$ ($f_h\to 1$) is most likely between 280 and 320 Å.

Value of $\langle s^2\rangle_z^{1/2}$ and Conformation of Helix. The third problem is the estimation of the axial translation per residue, h, which defines the helical conformation (h=2.0 Å for the 3_{10}-, 1.5 A for the α-, 1.3 Å for the ω-, and 1.15 Å for the π-helix). For a long rodlike molecule with length L, $\langle s^2\rangle=L^2/12$,[2] but the poly(Glu) sample is polydisperse. Therefore, $\langle s^2\rangle_z$ must be divided by the z-average of the square of degree of polymerization, $\langle DP^2\rangle_z$, not by the weight-average $\langle DP^2\rangle_w$ (an oft-neglected fact), to calculate values of h. If $\langle s^2\rangle_z^{1/2}$ is divided by $\langle DP\rangle_w$, the value of h would be erroneously large. For a polydisperse sample in which each molecule is a rigid perfect helix,

$$h^2 = \langle L^2\rangle_z/\langle DP^2\rangle_z = 12\langle s^2\rangle_z/\langle DP^2\rangle_z$$
$$= 12m_0^2\langle s^2\rangle_z/M_{z+1}\cdot M_z, \quad (1)$$

where m_0 is the residue weight, M_{z+1} and M_z are the $(z+1)$- and z-average molecular weights. From electric birefringence on the same poly(Glu) sample,[11] the polydispersity, M_w/M_n, was estimated to be 1.12 for the unaggregated α-helix by assuming the Lansing-Kraemer distribution, from which the relation $(M_{z+1}\times M_z)^{1/2}=M_w(M_w/M_n)^{3/2}$ results.[12] In Fig. 1, the values of $\langle s^2\rangle_z^{1/2}$ calculated from Eq. 1 are indicated by arrows for four typical helices. The conformation of poly(Glu) now appears closer to the ω-helix (315 Å) rather than to the π-helix (270 Å) or the α-helix (363 Å). A viscometric study has led to the similar conclusion about the conformation.[8]

Persistence Length and Chain Flexibility. The persistence length q is a measure for the chain flexibility and is related to the radius of gyration.[13] According to Kratky and Porod,[14]

$$\langle s^2\rangle_i = 2qL_i[(1/6)-(q/2L_i)+(q/L_i)^2-(q/L_i)^3(1-e^{-L_i/q})] \quad (2)$$

for the ith molecule of contour length L_i. Since $\langle s^2\rangle_z=\sum N_iM_i^2\langle s^2\rangle_i/\sum N_iM_i^2$, it is a complicated average of the contour length.[15] As a first approximation, the z-average length L_z is utilized in place of L_i,[16] together with a simplified relation: $L_z=[h\times f_h+3.62\times(1-f_h)]\langle DP\rangle_z$.[8] Values of q and q/L_z were calculated at various helix fractions for different helical conformations (Table 1). The contour length L_z for the completely coiled poly(Glu) is 2870 Å ($=3.62\times 708\times 1.12$); yet, q is only *ca.* 120 Å, indicating that the poly(Glu) chain is highly coiled in the 150 mM NaCl (20-fold in excess of Glu residues) in contrast to the 7.5 mM NaCl solution.[8] The chain becomes very contracted at the onset of the coil-to-helix transition ($f_h\approx 0.2$), q being only *ca.* 75 Å, but it becomes stiffer as the helix fraction increases.

Table 1. The persistence length poly(Glu) in 150 mM NaCl[a]

$(f_h)_{CD}$		0	0.2	0.4	0.6	0.8
$\langle s^2\rangle_z^{1/2}$/Å		320[b]	240	237	268	290
q/L_z	α-[c]	0.0420	0.0294	0.0391	0.0777	0.172
	ω-	0.0420	0.0301	0.0418	0.0890	0.234
	π-	0.0420	0.0308	0.0440	0.0990	0.316
q/Å	α-	120.6	74.5	86.0	144.7	262.4
	ω-	120.6	75.3	89.2	157.3	327.3
	π-	120.6	76.4	91.8	167.9	412.0

a) The helical structure was assumed to be completed at point A. b) A extrapolated to $(1-f_h)_{CD}\to 1$. c) Three different helical conformations.

The fourth and barely touched problem is the possibility of kinked or broken points in a long helical backbone. For example, seven Glu residues forming a coil-segment in a poly(Glu) helix correspond to the 99% helix content. A 1% difference is utterly impossible to detect by optical methods, but such a single break may lower the overall chain length or the value of $\langle s^2\rangle_z^{1/2}$ considerably, making the shorter helix conformations only apparent. For a perfect helix, values of q/L_i should be infinitely large, but this can never be confirmed because of the exponential increase in length and molecular weight of aggregated helices.

Many thanks are due to Dr. T. Masujima and Messrs. H. Watanabe, T. Matsuda, K. Ueda, and K. Fukudome for their close collaboration.

(Received May 12, 1983)

Synopsis. A new sesquiterpene ($C_{15}H_{23}Br_2Cl$, mp 172—173 °C) isolated from *Laurencia nipponica* Yamada has been found to be (−)-obtusane by X-ray crystal structure analysis.

In continuing studies on the constituents of the red alga, *Laurencia nipponica* Yamada, collected at Akkeshi on the Pacific Coast of Hokkaido,[1] we have isolated a new sesquiterpene hydrocarbon (**1**). The ^1H and ^{13}C NMR spectra of **1** show a close resemblance to those of obtusane (**2**) isolated from *Laurencia obtusa*,[2] while the specific rotations of **1** and **2** are equal in magnitude but opposite in sign. These facts suggest that **1** may be the enantiomer of **2**. In order to establish the molecular structure of **1**, we have now carried out an X-ray crystal structure analysis.

Experimental

Isolation. *Laurencia nipponica* Yamada collected at Akkeshi, Hokkaido, was extracted with methanol. The neutral methanol extracts (*ca.* 1% of the half-dried alga) obtained by the conventional methods were chromatographed over alumina. The fraction eluted with hexane–benzene (1:1 volume ratio) was rechromatographed over silica gel to yield **1** (0.09% of the extracts); mp 172—173 °C (from diisopropyl ether), $[\alpha]_D^{22}$ −38.5° (*c* 0.55, $CHCl_3$); IR (Nujol) ν_{max} 3100, 1640, 1222, 1198, 1158, 1092, 1058, 1028, 972, 916, 876, 800, 778, 726, 664, 642, and 624 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ 0.96, 1.14, 1.83 (each 3H, s), 1.6—2.4 (10H, m), 4.45 (1H, dd, J=13 and 4 Hz), 4.72 (1H, dd, J=13 and 5 Hz), 4.87, and 5.26 (each 1H, s); ^{13}C NMR ($CDCl_3$, 50.1 MHz) δ 145.8 (=C〈), 114.9 (=CH_2), 68.4 (〉C〈), 68.0, 63.6 (each 〉CH–), 50.5, 44.0 (each 〉C〈), 40.5, 37.3, 35.9, 33.6, 25.7 (each –CH_2–), 24.0, 23.7, and 17.6 (each CH_3); MS *m/e* (rel intensity) 402, 400, 398, 396 (1:4:9:3, M^+), 321, 319, 317 (2:9:5, M^+–Br), 320, 318, 316 (2:9:4, M^+–HBr), 283, 281 (9:9, M^+–HBr–Cl), 239, 237 (3:18, M^+–HBr–Br), 201 (31, M^+–HBr–Br–HCl), 109 (98), 107 (22), 105 (30), 95 (66), 93 (38), 91 (30), 81 (23), 69 (100), 67 (28), 55 (19), and 41 (91). Found: *m/e* 399.9846. Calcd for $C_{15}H_{23}{}^{81}Br_2{}^{35}Cl$: M 399.9816. The melting point was uncorrected. The IR spectrum was measured on a Hitachi EPI-G2 spectrometer. The ^1H and ^{13}C NMR spectra were recorded on a JEOL FX-200 spectrophotometer, TMS being used as an internal reference. The low and high resolution mass spectra were obtained with a JEOL JMS-D300 spectrometer. The optical rotation was measured on a JASCO DIP-140 polarimeter.

X-Ray Measurement. A colorless single crystal cut into a cube with an edge of *ca.* 0.2 mm was used. The crystal data were as follows: $C_{15}H_{23}Br_2Cl$, mol wt 398.61, orthorhombic, space group $P2_12_12_1$, a=10.580(3), b=20.537(6), c=7.492(2) Å, Z=4, D_c=1.626 g cm^{-3}, μ(Mo $K\alpha$)=50.8 cm^{-1}. The cell dimensions and diffraction intensities were measured on a Rigaku four-circle diffractometer at the High Brilliance X-Ray Diffraction Laboratory of Hokkaido University, using graphite-monochromated Mo $K\alpha$ radiation (λ=0.71073 Å). The θ—2θ scanning technique was applied at a θ scan rate of 2° min^{-1}; the background was counted for 10 s at each end of the scan range. Three standard reflections, measured at intervals of every 100 reflections, showed a gradual decrease in intensity during the course of data collection; the final-intensity/initial-intensity ratios were *ca.* 0.91—0.98. The intensities were corrected for this damage to the sample as well as for the Lorentz and polarization factors, but not for the absorption or the extinction effect. In the range of 2θ values up to 50°, 1131 independent structure factors above the $3\sigma(F)$ level were selected for the structure determination.

Structure Determination

The structure was solved by the Monte Carlo direct method,[3] using the 20 reflections with the greatest $|E|$ values as the starting set. The seventhly-generated random phase set led to the correct solution; an E-map based on 499 phases revealed all the non-hydrogen atoms. After the structure had been well refined by the block-diagonal least-squares method with anisotropic temperature factors, the absolute configuration was determined by taking account of the anomalous dispersion of the halogen atoms for Mo $K\alpha$ radiation. The R ratio for the two enantiomeric structures, 1.10, excluded one of them at a 99.5% confidence level.[4] Since a difference Fourier map revealed all the hydrogen atoms, further least-squares refinements were carried out including the hydrogen atoms. For these refinements, the following weighting scheme was used:

$$w = 1/\{\sigma(F)^2 \exp(c_1X^2+c_2Y^2+c_3XY+c_4X+c_5Y)\},$$

where $X=|F_o|$ and $Y=\sin\theta/\lambda$. The c_1, c_2, c_3, c_4, and c_5 coefficients were evaluated from the $(\Delta F)^2$ distribution; $c_1=-0.208\times10^{-3}$, c_2=27.5, $c_3=-0.908\times10^{-2}$, c_4=0.0502, and $c_5=-25.0$. In this manner, the R value reached 0.050. The final atomic parameters are listed in Table 1.[5]

The calculations were done on a HITAC M-200H computer at the Hokkaido University Computing Center, using our own programs. The atomic scattering factors were taken from the International Tables.[6]

Results and Discussion

The molecular structure of **1** including the absolute configuration is shown in Fig. 1, while the bond distances and angles are given in Fig. 2. Thus, it is concluded that this new sesquiterpene is the enantiomer of obtusane,[2] *i.e.*, (−)-obtusane.

Each of the six-membered A- and B-rings has a

a) $B_{eq}=8\pi^2(u_1^2+u_2^2+u_3^2)/3$, where u_i is the root-mean-square deviation in the ith principal axis of the thermal ellipsoid.

chair conformation. The C(7)=C(14)H_2 and C(15)H_3 groups occupy the axial positions on the A-ring, while the Cl and Br(1) atoms and the C(11)Me_2 group take the equatorial orientations. Because of the *syn*-periplanar conformation (torsion angle, −7(2)°) of the C(1)–C(6)–C(7)=C(14) segment, the C(14)H_2 group is very close to the C(1)H_2–C(2)H part: C(1)···C(14), 2.87(2); C(2)···C(14), 3.17(2) Å. The difference of 5° between the C(6)–C(7)=C(14) and C(8)–C(7)=C(14) bond angles probably results from this steric repulsion. The Cl atom is gauche to both the Br(1) atom and the C(15)H_3 groups: Cl···Br(1), 3.430(4); Cl···C(15), 3.19(1) Å. These gauche interactions cause the C(3)–C(2)–Cl bond angle to be greater than the C(1)–C(2)–Cl angle by 4°. A similar bond-angle distortion is found also for the C(3)–C(15) bond; the C(2)–C(3)–C(15) angle is greater than the C(4)–C(3)–C(15) angle by 5°. On the other hand, in spite of the severe steric hindrance between the Cl and Br(1) atoms, the C(2)–C(3)–Br(1) bond angle is smaller than the tetrahedral angle, and is almost equal to the C(4)–C(3)–Br(1) and C(15)–C(3)–Br(1) angles. As was pointed out in a previous paper,[7] such a shrinkage of the C–C–halogen bond angles seems likely to be a property of tertiary chlorides and bromides.

The C(5)H_2 and C(13)H_3 groups are placed axially on the B-ring, while the Br(2) atom and the C(1)H_2 and C(12)H_3 groups are equatorially oriented. The Br(2) atom suffers gauche repulsions from both C(12)H_3 and C(13)H_3 groups: Br(2)···C(12), 3.23(1); Br(2)···C(13), 3.31(1) Å. Consequently, the C(11)–C(10)–Br(2) bond angle is greater than the C(9)–C(10)–Br(2) angle by 5°. The C(6)–C(11) distance is considerably longer than the standard C–C single-bond distance. Since both of the C(6) and C(11) atoms have three bulky groups, this bond lengthening is probably due to strong steric repulsions among these groups.

Production of Ethylene and Propylene by the Vapor-phase Catalytic Oxidative Dehydrogenation of Butane with Carbonyl Sulfide

Masamichi AKIMOTO,* Takashi SAKATANI, and Etsuro ECHIGOYA

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received May 24, 1983)

Synopsis. Ethylene and propylene were produced at high yields, additionally to butenes and butadiene, by the vapor-phase oxidative dehydrogenation of butane with COS over SiO_2, Al_2O_3, MgO, and TiO_2 catalysts at 873—923 K. The results of kinetic and mechanistic studies indicate that ethylene and propylene are produced by the oxidative dehydrogenation through a homolytic mechanism followed by β-scission of the carbon–carbon bond.

Carbonyl sulfide undergoes catalytic decomposition by either of the following two reactions.[1]

$$COS \rightarrow CO + S, \qquad xS \rightarrow S_x \ (x=2,\ 4,\ \text{and}\ 8), \quad (1)$$

$$2COS \rightarrow CO_2 + CS_2. \quad (2)$$

Since the dissociation by the first reaction evolves reactive sulfur atoms, many studies have been made on the use of COS as an oxidant for the oxidative dehydrogenation of lower paraffinic hydrocarbons and alkyl-substituted aromatics.[2,3] Some mechanistic studies have also been reported.[4,5] In our recent study on the vapor-phase oxidative dehydrogenation of ethylbenzene by COS over SiO_2, Al_2O_3, MgO, and TiO_2 catalysts, we showed that the role of the metal oxide catalysts is to decompose COS to CO+S, the formed sulfur (maybe sulfur atom) then dehydrogenating ethylbenzene in gaseous phase.[5] We also showed that in addition to the thermocatalytic mechanism proposed by Haas and Khalafalla[1] COS is decomposed to CO+S by the action of the reduction sites.[5] In the present paper, we report the production of ethylene and propylene by the vapor-phase catalytic oxidative dehydrogenation of butane with COS and discuss the mechanism of the formation of these two olefins. The catalytic oxidative dehydrogenation of ethane, propane, and isobutane with COS has been reported.[3,4] However, no studies have been reported on the catalytic oxidative dehydrogenation of butane with COS and hence no results have been reported of the formation of ethylene and propylene by the catalytic oxidative dehydrogenation with COS.

Experimental

Vapor-phase catalytic oxidative dehydrogenation of hydrocarbons was carried out using a conventional flow fixed-bed reactor under atmospheric pressure. The shape of reactor and method of reaction were the same as those in our previous paper.[5] Purchased COS of greater than 97.5 % purity and research grade paraffinic hydrocarbons(purity>99%) were used without further purification. The catalysts (32—60 mesh) were prepared by the calcination of their corresponding metal hydroxides at 1073 K (873 K for TiO_2) in air for 5 h. The surface areas determined by the conventional B.E.T. method were 167 $m^2 g^{-1}$ (SiO_2), 178 $m^2 g^{-1}$ (Al_2O_3), 40 $m^2 g^{-1}$ (MgO), and 48 $m^2 g^{-1}$ (TiO_2), respectively. The gaseous reaction products (paraffins, olefins, COS, CO, CO_2, and H_2S) were analyzed by gas chromatography using propylene carbonate (40 wt% on C-22, 17.0 m, room temperature), Porapak R(2.0 m, 363 K), and molecularsieve 13X(1.5 m, room temperature) as separating columns. Carbon disulfide was not analyzed.

Results and Discussion

Table 1 summarizes the catalytic results obtained in the oxidative dehydrogenation of butane with COS at 873 K. No reaction took place when the mixture of butane and N_2 (butane 30.0 vol%) was fed over these four metal oxide catalysts at 873 K. However, such olefins as ethylene and propylene were produced additionally to butenes and butadiene with an accompanying formation of H_2S when COS was added to the reacant mixture (Table 1. The yield of H_2S is not presented for the sake of simplicity). Both the conversions of butane and COS decreased with time, due to the formation of carboneceous materials at the surface of the catalysts,[5] and leveled off after a preliminary period of 5 h. However, it is evident that Al_2O_3 had the greatest catalytic activity at the initial stages of the reaction among these four metal oxide catalysts (Table 1,A). This greatest initial catalytic activity of Al_2O_3 correlates its greatest concentration of the reduction sites reported in our previous paper[5], suggesting the preferential role of the reduction sites in the catalytic decomposition of COS to CO+S. For some catalytic results, the conversion of butane was greater than the yield of sulfur (=[conversion of COS]×[COS decomposition to CO+S]) (Table 1, SiO_2-A,B, MgO-B, and TiO_2-B). It seems that sulfur was also evolved by the catalytic decomposition of

CS_2 formed during the catalytic oxidative dehydrogenation of butane by COS, as already seen in the reaction of ethylbenzene by COS.[5]

The most important finding that Table 1 provides is that ethylene and propylene were produced additionally to butenes and butadiene in the catalytic oxidative dehydrogenation of butane by COS. The combined yield of ethylene and propylene was high, 18.0—28.7% (selectivity 60.4—62.7%) and 8.7—16.5% (30.9—32.7%), over SiO_2 and Al_2O_3 catalysts, respectively, and the total selectivity to olefins was also high, 83.2—86.9%, over SiO_2 catalyst. It is to be noted that the yield of propylene was always greater than that of ethylene for all of the catalysts employed (Table 1). At 923 K, the combined yield of ethylene and propylene over SiO_2 catalyst determined after a preliminary period of 10 min increased to 60.3% (selectivity 64.1%) whereas that of butenes and butadiene remained nearly unchanged, 8.2%. In contrast to the reaction of butane, no such olefins as ethylene and propylene were produced when *trans*-2-butene was similarly reacted at 873 K (*e.g.*, SiO_2 catalyst, conversion 48.1%, total yield of butenes 33.2%, and yield of butadiene 10.0%).

In the oxidative dehydrogenation of butane by COS over SiO_2 catalyst at 873 K, the reaction order in butane was unity and that in COS was 0.2—0.3. Assuming the first order kinetics for the oxidative dehydrogenation of paraffinic hydrocarbons, the rate constant for the oxidative dehydrogenation of ethane, propane, and isobutane by COS over SiO_2 catalyst was determined at 873 K using an integral reactor (Table 2). The rate constant k for the paraffinic hydrocarbons follows the order: ethane<propane< isobutane. The order of the reactivity of these hydrocarbons is much more obvious when the value of the rate constant k is normalized to one most-reactive hydrogen (k', Table 2). That is, the reactivity of hydrogen for the oxidative dehydrogenation by sulfur follows the order: primary hydrogen < secondary hydrogen<tertiary hydrogen. This order of the reactivity of hydrogen correlates the value of the C–H bond dissociation energy (Table 2). As reported previously by Haag and Miale,[4] we may thus conclude that the oxidative dehydrogenation of these paraffinic hydrocarbons by sulfur proceeds through a homolytic mechanism. On the other hand, no formation of olefins other than isobutene in the reaction of isobutane (Table 2) indicates that no α-scission of the carbon-carbon bond took place during the oxidative dehydrogenation of paraffinic hydrocarbons by COS at 873 K.

Based on the above findings made in the present work, we propose the following reaction scheme for the oxidative dehydrogenation of butane by COS over these metal oxide catalysts. The oxidative dehydrogenation of butane by sulfur takes place mainly in gaseous phase and it proceeds more preferentially *via* an intermediate In_1 than *via* the another In_2, as indicated by the relative reactivity of the hydrogens (Table 2). The greater yields of propylene than ethylene and no formation of these two olefins from *trans*-2-butene found in the present work (Table 1) support this reaction scheme. The hydrogenation of hydrocarbon species does not take place extensively as seen in the small values of the combined yield of methane, ethane, and propane (Table 1). The hydrogens used for the hydrogenations must have been supplied from HS_x (maybe $x=1$ and/or 2). The mechanism of the formation of carboneceous materials at the surface of the catalysts remains unknown.

Chirality of Waugh-type Enneamolybdomanganate(IV) Heteropolyanion. Observation of a Pfeiffer Effect

Kenji NOMIYA, Ryoichi KOBAYASHI, and Makoto MIWA*

Department of Industrial Chemistry, Faculty of Engineering, Seikei University, Musashino, Tokyo 180

(Received March 14, 1983)

Synopsis. Enneamolybdomanganate(IV), $[Mn^{IV}Mo_9O_{32}]^{6-}$, so-called Waugh-type heteropolyanion, has a chirality based on the D_3 symmetry around an MnO_6 octahedron. Attempts to resolve the racemic polyanion have been unsuccessful. A Pfeiffer effect was observed for the tetrabutylammonium salt in organic media containing *l*-brucine sulfate as an environment substance. This is the third example of heteropolyanions which show an optical activity.

Waugh-type enneamolybdomanganate(IV) formulated as $[Mn^{IV}Mo_9O_{32}]^{6-}$ is an octahedral manganese (IV) complex with the Mo_9O_{32} ligand, which was prepared first as potassium and barium salts by Hall.[1] Absorption spectrum of the ammonium salt was measured first in aqueous solution by Shimura and Tsuchida,[2,3] and the absorption bands were assigned to d^3 ions by Baker and Weakley.[4] A structure determination of the ammonium salt, $(NH_4)_6[MnMo_9O_{32}]\cdot 8H_2O$, by the single-crystal X-ray diffraction technique has shown that an MnO_6 octahedron has the D_3 symmetry.[5] Thus, this complex should be chiral. However, all attempts to resolve the racemic complex have failed.[4] There may be several reasons: (1) relatively rapid racemization, (2) the potassium and ammonium salts dissolve only in water, and (3) all resolving agents tested sofar form insoluble diastereomers in water. In this work we prepared the quaternary ammonium salt of the complex which is soluble in organic solvents and observed the Pfeiffer effect in the presence of *l*-brucine sulfate as an environment substance. This is the third example of heteropolyanions which show an optical activity; the first is $(NH_4)_6[Co_2Mo_{10}O_{34}(OH)_4]\cdot 7H_2O$, which was resolved by Shimura and his co-workers,[6] and the second is $[(C_4H_9)_4N]_5H[P_2Mo_{18}O_{62}]$, chirality of which is shown by observing the Pfeiffer effect by Garvey and Pope.[7]

Experimental

Electronic absorption and CD spectra were measured on a Hitachi 340-spectrophotometer with computer key-board and on a JASCO J-40AS spectropolarimeter, respectively. IR spectra were recorded with a JASCO IR-G spectrophotometer. Measurements were made at room temperature. For IR spectra measurement in acetonitrile a KBr cell with 0.1 mm optical path was used.

Preparation. The orange-red complex was prepared according to the literature,[4] analyzed and formulated as $(NH_4)_6[MnMo_9O_{32}]\cdot 6H_2O$ (Found: H, 2.11; N, 5.05%. Calcd: H, 2.20; N, 5.10%). This complex salt was converted to the free acid by passing the aqueous solution through a cation-exchange resin (Dowex-50W, H form) column. The acid form of the complex is readily soluble in aqueous solution and stable except when it is left standing for a long time. An aqueous solution containing an equimolar amount of tetrabutylammonium bromide (9.75 g) and potassium chloride (2.25 g) was added to the free acid solution obtained from the starting ammonium salt (5 g). Pale brick-red precipitate was collected, washed several times with a small amount of water, and dried *in vacuo*. The complex is readily soluble in water and various organic solvents except for ethyl ether, and cannot be easily recrystallized. The complex is contaminated with yellow $Mo_6O_{19}^{2-}$ as an impurity, which shows chracteristic IR bands at 800 and 950 cm^{-1}. The impurity crystallizes out of the acetonitrile solution and is removed by filtration. The complex can be reprecipitated by adding excess isobutyl methyl ketone to the filtrate, although the yield is remarkably low. The complex thus obtained was formulated as $K_2[(C_4H_9)_4N]_4[MnMo_9O_{32}]\cdot 13H_2O$ (Found: C, 28.32; H, 5.63; N, 2.02%. Calcd: C, 28.34; H, 5.35; N, 2.07%). The potassium tetrabutylammonium salt is sufficiently stable in the solid state, while it decomposes in organic media after a long time.

Results and Discussion

Absorption spectra of the complex in the acetonitrile solutions (6.6×10^{-4} mol dm^{-3}), which contain various molar ratios of *l*-brucine sulfate as an environment substance, are shown in Fig. 1, together with that of the solution without *l*-brucine sulfate. The form

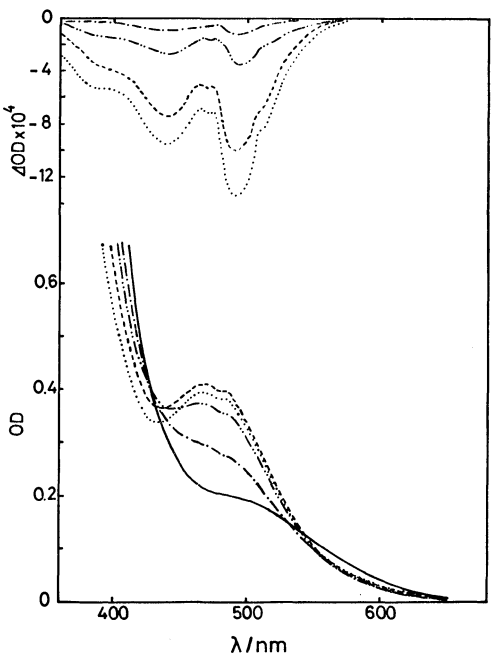

Fig. 1. Absorption and CD spectra of the tetrabutylammonium salt of $[MnMo_9O_{32}]^{6-}$ anion (6.6×10^{-4} mol dm^{-3}) in acetonitrile containing various moles of *l*-brucine sulfate. Molar ratios of brucine: complex are 2:1 (———), 4:1 (———), 6:1 (----) and 8:1 (·····). A full line shows the spectrum of the complex alone.

of the spectrum of the parent ammonium salt in an aqueous solution has been known to depend markedly on the pH.[4] The spectrum of the tetrabutylammonium salt in acetonitrile is similar to that of the ammonium salt at pH 2.9. As the molar ratio of brucine to the complex increases, the absorbance at 480 nm increases, with a double peak appearing at 468 and 484 nm. For the solution with the molar ratio of brucine higher than 4 the spectral change becomes very small. The double peak coincides with that of the ammonium salt observed in the aqueous solution of pH 3.5—4.9. The splitting is due to a trigonal distortion of the first spin-allowed transition ($^4T_{2g} \leftarrow {}^4A_{2g}$) in the d^3 octahedral MnO_6 ion.[4,8] Thus, the effect of *l*-brucine for the complex in acetonitrile resembles the pH-raising effect for the ammonium salt in an aqueous solution.

The circular dichroism (CD) spectra were observed for mixtures of the complex and *l*-brucine, the optical activity of which appeared only after the addition of *l*-brucine. They are also shown in Fig. 1. A remarkable change in the CD spectra is found for solutions with the molar ratio of brucine to the complex, 4:1, 6:1, and 8:1, whereas their absorption spectral change is very small. This is attributed neither to the induced CD accompanied with outer-sphere association, nor to the chemical reaction between the complex and *l*-brucine since the experiments were performed in a relatively low concentration ($\approx 10^{-3}$ mol dm^{-3}) of the latter. Conclusively, this is attributed to a shift of the equilibrium between two enantiomers of the racemic complex, *viz.* the Pfeiffer effect.

IR spectra have shown that the structure of polyanion-moiety depends significantly on the cation, and the bands of the tetrabutylammonium salt in 700—500 cm^{-1} were less split than those of the parent ammonium salt. This shows that a site symmetry of the tetrabutylammonium salt may be higher than that of the parent ammonium salt. IR spectrum of the acetonitrile solution of the tetrabutylammonium salt was also measured with and without *l*-brucine sulfate. When the molar ratio of brucine:complex is 4:1, the IR spectrum is close to that of the solid ammonium salt which has the D_3 symmetry around the MnO_6 octahedron. The IR spectrum in the absence of *l*-brucine is substantially unchanged from that of the solid tetrabutylammonium salt except for the sharpening of bands. These results indicate that the site symmetry of the complex ion is lowered to D_3 by the addition of *l*-brucine.

Further, DMF and *l*-strychnine sulfate were used as the solvent and the environment substance, respectively to demonstrate the Pfeiffer effect and the shift of the equilibrium toward the (+)-enantiomer of the complex. Unfortunately the equilibrium shift was not observed; only the shift toward the (−)-enantiomer by the Pfeiffer effect was shown. Besides, the observed CD was much reduced than that observed in the brucine-complex system in acetonitrile.

The CD spectrum of the brucine-complex system in acetonitrile, in which the (−)-enantiomer predominates, shows peaks at 510, 490, 470, 440, and 390 nm. The selection rule for the first and the second magnetic dipole transitions of the d^3 ion under the D_3 symmetry indicates that two transitions ($^4E \leftarrow {}^4A_2$ and $^4A_1 \leftarrow {}^4A_2$) for the first electronic transition, and only one transition ($^4E \leftarrow {}^4A_2$) for the second transition are allowed. Even if a contribution from spin-forbidden transitions is taken into account, the number of the CD peaks is too many. This may indicate that the electronic transitions are not pure d-d ones. Further investigation on the origin of the CD peaks is required.

Use of an Ion-selective Electrode as a Detector in Ion Pair Chromatography

Akinori Jyo,† Kenji Mori, and Nobuhiko Ishibashi*
Department of Applied Analytical Chemistry, Faculty of Engineering, Kyushu University, Fukuoka 812

(Received March 22, 1983)

Synopsis. A chloride ion-selective electrode was used as a detector for inorganic anions separated by ion pair chromatography. Excellent performance of the electrode detector was demonstrated by detection of chloride, iodide, and thiocyanate.

While ion pair chromatography has been widely used in the separation of charged organic species,[1] little has been reported for the separation of inorganic anions.[2,3] This is seemingly ascribable to limitation in detectors which directly respond to inorganic anions under the conditions of the chromatography. Although detectable species are limited, ion-selective electrodes will be useful for detection of anions which have no or weak light absorption in the UV and visible regions.[4]

This paper describes the use of a solid state type chloride ion-selective electrode as a detector for some inorganic anions in ion pair chromatography.

Experimental

An HPLC system with an ion-selective electrode detector was reported in detail in a previous paper.[5] An Orion 94-17A chloride ion-selective electrode was used. A baseline supporting electrolyte solution (BLSS), which depresses streaming potential and stabilizes baseline potential, was mixed to a column effluent by a post column technique. The BLSS used was an aqueous solution containing potassium nitrate(1.0 M, 1 M=1 mol dm^{-3}) and sodium chloride(3.0×10^{-5} M). A LiChrosorb RP-18(Merck) or ODS 6013(Kyowa Seimitsu) was packed in a stainless steel coulmn(100 mm × 2.1 mm i.d.). Samples were injected with a Hamilton microsyringe HP-305(5 μl). The mobile phase was an aqueous solution containing tetrabutylammonium sulfate and sulfuric acid. The mobile phase and BLSS were doubly filtered with Mitex and Millipore MF filters, before use. All chemicals were of reagent grade and were used as received.

Results and Discussion

Since a chloride ion-selective electrode of solid membrane type responds to most anions which form sparingly soluble silver salts, the separation and detection of these kinds of anions were tested. In order to determine an appropriate pH range of the mobile phase, chloride, iodide, and thiocyanate were separately eluted with a mobile phase of various pH. When the pH of the mobile phase was greater than 1.5, marked tailing was observed for elution of iodide and thiocyanate. As an example, detector responses for iodide are shown in Fig. 1. Thus, further studies were made maintaining the pH of the mobile phase below 1.5, although the cause of the tailing was not clear.

Figure 2 shows detection of chloride and thiocyanate. Both anions were successfully separated within 10 min. The complete separation of iodide from chloride and thiocyanate was difficult under the conditions examined. In Table 1, an example of reproducibility for detector responses is given. The reproducibility is comparable to that of conventional detectors. Figure 3 shows an analytical curve for chloride separated

from thiocyanate. The analytical curve is not linear. It shows slightly upward curvature. Lower detection limits are not examined, but it is not difficult to detect the anions down to orders of nano moles.

As is illustrated in this work, the chloride ion-selective electrode can be successfully used as one of the detectors in ion pair chromatography. Recently, reversed phase columns have drawn attention to the separation of charged inorganic species by ion pair chromatography[2,3] and by similar but somewhat different approaches.[6-8] Seemingly, ion-selective electrodes will be useful for expansion of this field, since problems encountered are detectors in chromatographic determination of inorganic species.

This work was supported by a grant of the Asahi Glass Foundation for Contribution of Industrial Technology.

Determination of Small Amounts of Carbazole in Anthracene by Synchronous Fluorescence Spectrometry

Motohisa FURUSAWA,* Masaki TACHIBANA, and Mamiko FUJISHIMA
Faculty of Engineering, Yamanashi University, Takeda, Kofu 400

(Received March 29, 1983)

Synopsis. After converting anthracene into the Diels-Alder adduct by the reaction with maleic anhydride, and converting the adduct into a water-soluble salt by hydrolysis with potassium hydroxide aqueous solution, carbazole is then extracted into 2,2,4-trimethylpentane together with other impurities. Then carbazole can be determined by synchronous fluorescence spectrometry without interference of the impurities.

Since commercially available anthracene contains carbazole as an impurity and its removal from anthracene is relatively difficult, a determination method of carbazole is required. For the determination of small amounts of carbazole in anthracene, several methods have been developed.[1-3] In the present paper separation of carbazole from anthracene and its determination by synchronous fluorescence spectrometry will be described. By this method, carbazole can be determined more rapidly and simply than previous methods. The determination limit is 10 ppm.

Experimental

Reagents. Maleic anhydride was purified by distillation. 2,2,4-Trimethylpentane used was of the "Spectro" grade.

Apparatus. All the measurements of synchronous fluorescence spectra were made on a Hitachi 650-40 fluorescence spectrophotometer equipped with a Hitachi 056 recorder. The spectral bandpass was set at 2 nm. A 150-W Xenon lamp was used as the exciting source. A $10\times10\times45$ mm^3 quartz cell was used. A Torika MA-1 mixer of Japan Torika Corp. was used as a shaker for the extraction.

Procedure. A mixture of 10 mg of the anthracene sample and 1 g of maleic anhydride was fused at 160 °C for 10 min in a 25-ml Kjeldahl flask (short neck) fitted with an air condenser. The reaction mixture was dissolved by adding 10 ml of 3 mol/l potassium hydroxide aqueous solution and heating with occasional shaking. After the solution had been cooled to room temperature, 10 ml of 2,2,4-trimethylpentane was added. The mixture was thoroughly shaken and allowed to stand for a while. The synchronous fluorescence spectrum of the 2,2,4-trimethylpentane phase was measured with a wavelength interval of 5 nm. Carbazole was determined from the intensity at 335 nm obtained by the base line method. As the standard, the synchronous fluorescence intensity of a 0.2 μg/ml carbazole solution was used. The calibration curve was prepared by using carbazole solutions containing 0—0.2 μg per ml.

Results and Discussion

Synchronous Fluorescence Spectrum. For the determination of carbazole, a wavelength interval of 3 nm is suitable under ordinary conditions.[4] For the determination of more minute amounts of carbazole, however, a larger wavelength interval is necessary for enhancement of the signal-to-noise ratio. From the experimental results, a wavelength interval of 5 nm was effective. The synchronous fluorescence spectrum of carbazole is shown in Fig. 1. The spectrum has a maximum at 335 nm.

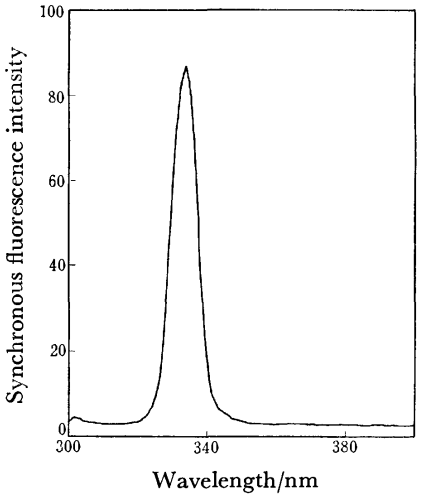

Fig. 1. Synchronous fluorescence spectrum of carbazole. Wavelength interval: 5 nm; solvent: 2,2,4-trimethylpentane.

Removal of Anthracene. The Diels-Alder reaction of anthracene with maleic anhydride was useful for the removal of anthracene as an adduct. Carbazole was separated together with other impurities by extraction into 2,2,4-trimethylpentane after the adduct had been converted into the water-soluble potassium salt by hydrolysis with potassium hydroxide aqueous solution. The Diels-Alder reaction was carried out by fusing the anthracene sample with maleic anhydride. To find the effect of heating time on the reaction, pure anthracene was fused with maleic anhydride by varying the heating time at 160 °C. Table 1 shows the residual amounts of anthracene in the 2,2,4-trimethylpentane phase evaluated by measuring the synchronous fluorescence intensity at 379 nm. Table 1 indicates that the reaction is completed within 5 min. It is recommended, therefore, that the sample is fused at 160 °C for 10 min.

Experiments using saturated hydrocarbons as the medium for the Diels-Alder reaction failed, because maleic anhydride did not dissolve satisfactorily in these solvents having desired boiling points.

Calibration Curve. A calibration curve of carbazole was linear over the concentration range from 0.01 to 0.2 μg/ml. As the standard a 0.2 μg/ml carbazole solution was used, and the coefficient of variation obtained in 20 measurements was 0.73%.

Effects of Impurities in Anthracene. Effects of disturbing substances due to absorption have been reported in the previous paper.[4] Acenaphthene shows the spectral interference, but the determination of a

Table 1. Effect of heating time on Diels-Alder reaction of anthracene with maleic anhydride

3	18.5	53	530
5	<1.0	<3	<30
5	<1.0	<3	<30
10	<1.0	<3	<30
10	<1.0	<3	<30
15	<1.0	<3	<30

a) As the standard, synchronous fluorescence intensity (wavelength interval=5 nm) at 379 nm of a 0.200 μg/ml anthracene solution was taken as 70 div.

0.2 μg/ml carbazole solution was not interfered with the presence of less than 8-fold amount of acenaphthene.

Determination of Carbazole in Synthetic Mixtures. The analytical results of synthetic mixtures are shown in Table 2, Nos. 1—11. Each mixture contains 0.1% of biphenyl, acenaphthene, fluorene, dibenzofuran, and phenanthrene and 0.01% of perylene, fluoranthene, naphthacene, chrysene, and 9,10-anthraquinone. Table 2, Nos. 1—11 indicate that the analytical results agree well with the contents of carbazole. Therefore, carbazole in anthracene can be determined by the present method.

Determination of Carbazole in Practical Samples. Carbazole in three kinds of commercial anthracene was determined by the present method, and the results were compared with the analytical results obtained by a spectrophotometric method.[1] As is shown in Table 2, Nos. 12—14, both results agree within experimental errors. The synchronous fluorescence spectra of the solutions used for the determination exhibited the characteristic signal of carbazole having a peak at 335 nm. In addition, the solutions did not show the absorption based on interfering impurities. Therefore, the method proposed in the present paper can be applied to practical samples of anthracene. The determination of carbazole by the conventional fluorimetry was unsuccessful because of the interference of other luminescent species.

The Precipitation-Spectrophotometric Determination of Dithionate Ions with Bis(diethylenetriamine)nickel(II) Chloride Solution[1)]

Tsugio SATO* and Taijiro OKABE

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Sendai 980

(Received May 19, 1983)

Synopsis. A solution containing dithionate ions is treated with bis(diethylenetriamine)nickel(II) chloride solution to precipitate dithionate as $[Ni(dien)_2]S_2O_6$ complex. After centrifugation, the concentration of nickel(II) ions in the supernatant is spectrophotometrically determined by dimethylglyoxime method. There is no interference from SO_4^{2-} SO_3^{2-}, $S_2O_3^{2-}$, $S_4O_6^{2-}$, $HN(SO_3)_2^{2-}$, S^{2-}, or Fe^{3+}.

Special attention has been recently devoted to the chemical behavior of dithionate because dithionate is often produced in various industrial processes using sulfite solutions, such as wet type desulfurization and hydrometallurgy, and causes pollution problems. However, the analysis of dithionate by classical methods such as redox titration[2,3)] or gravimetry[4)] after disproportionation of dithionate to sulfite and sulfate in hot acidic solutions that were used in previous studies are very tedious operations, especially in the cases where other sulfur compounds coexist.

Recently Marcu *et al.*[5)] reported that dithionate forms slightly soluble salts with metal(II) ethylenediamine complexes and with metal(II) 1,2-propanediamine complexes, where metals are nickel, cadmium, copper, and zinc. They have proposed a gravimetric method for determining dithionate as these amine complexes. The method can be used to determine dithionate in the presence of sulfite and sulfate, but high amounts of polythionates interfere. In the preceeding study,[6)] we have shown the solubility of many kinds of metal(II) alkylamine complexes and have reported that the solubility of $[Ni(dien)_2]S_2O_6$ is extremely small. Therefore, it may be more useful for the determination of dithionate ions. The present paper is concerned with a simple and selective spectrophotometric determination of dithionate ions using bis(diethylenetriamine)nickel(II) chloride as precipitant.

Experimental

Apparatus. The spectrophotometric measurements were made with a Hitachi 101 spectrophotometer.

Reagents. Sodium dithionate, potassium tetrathionate, and potassium imidobis(sulfate) were prepared by Pfanstiel's method,[7)] Martin's method,[8)] and Sisler's method,[9)] respectively.

Bis(diethylenetriamine)nickel(II) Chloride Solution: Dissolve 6.0 g of nickel(II) chloride hexahydrate in 150 cm^3 of distilled water, and add 50 cm^3 of diethylenetriamine and 800 cm^3 of ethyl alcohol.

Dimethylglyoxime Solution: Dissolve 1 g of dimethylglyoxime in 500 cm^3 of 0.25 M (M=mol dm^{-3}) sodium hydroxide solution.

All other chemicals were of analytical grade and were used without further purification.

Procedures. Transfer 5 cm^3 of sodium dithionate solution (0—20 mM) to a 15 cm^3 centrifuge tube, add 5 cm^3 of bis(diethylenetriamine)nickel(II) chloride solution, seal it to prevent evaporation of solvent and place the tube in an ice bath. After 30 min, remove the tube from the ice bath and centrifuge it at 2000 min^{-1} for 10 min. Transfer 100 mm^3 of supernatant to a 50 cm^3 volumetric flask, then add 2 cm^3 of 20 wt% potassium sodium tartrate solution, 0.5 g of ammonium peroxodisulfate, 1 cm^3 of dimethylglyoxime solution and 2.5 cm^3 of 5 M sodium hydroxide. Dilute the solution to the mark with distilled water. After 30 min, measure the absorbance of the solution at 465 nm in a 10 mm thick glass cell against a water blank.

Results and Discussion

The analytical method described above consists of the separation of dithionate as a slightly soluble bis(diethylenetriamine)nickel(II) dithionate complex by double decomposition as shown in Eq. 1, and the

$$Na_2S_2O_6 + [Ni(dien)_2]Cl_2 \longrightarrow [Ni(dien)_2]S_2O_6 + 2NaCl, \quad (1)$$

determination of nickel(II) ions remaining in the solution. For the determination of nickel(II) ion, dimethylglyoxime method[10)] was adapted because it seems to be the simplest method. Therefore in the present study, a series of tests was carried out to investigate the precipitation behavior of dithionate.

Four different organic solvents (dioxane, acetone, methyl alcohol, and ethyl alcohol) were tested for the precipitation of $[Ni(dien)_2]S_2O_6$ at 30 °C. The results are shown as Fig. 1. It is seen that solubility of $[Ni(dien)_2]S_2O_6$ under these experimental conditions is 1.47 mM in water, but rapidly decreases with increasing concentrations of organic solvents. Subsequently, ethyl alcohol–H_2O system was chosen because it showed the smallest solubility of $[Ni(dien)_2]S_2O_6$ complex. The solubility product of this complex in 40 vol% ethyl alcohol is 1.6×10^{-7}; hence, more than

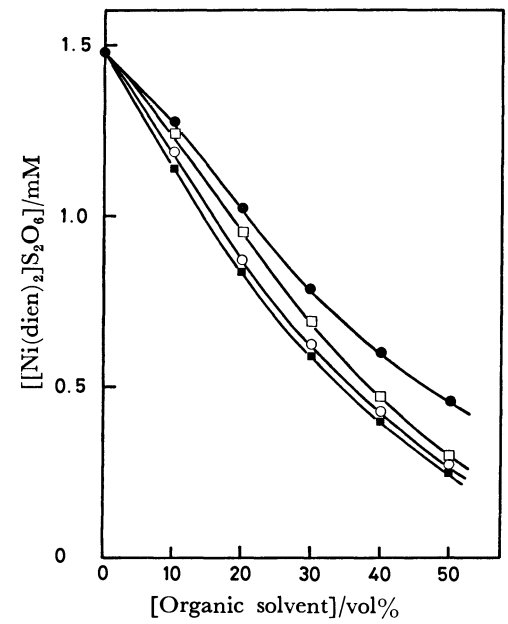

Fig. 1. Solubility of $[Ni(dien)_2]S_2O_6$ in mixed organic solvent–H_2O solutions. ●: Dioxane, □: acetone, ○: methyl alcohol, ■: ethyl alcohol, temperature: 30 °C, ionic strength: 0.5 M.

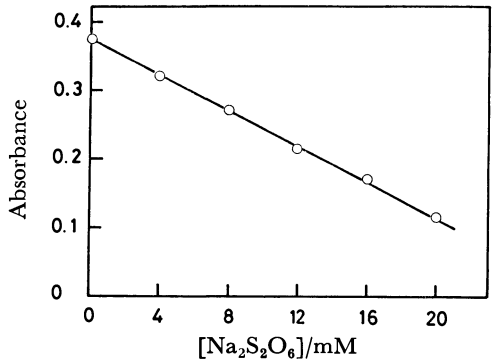

Fig. 3. Calibration curve.

99% of dithionate in the range of concentrations 2—20 mM can be precipitated by the above-mentioned procedure.

The effect of standing time in the precipitation step was examined and constant absorbances were obtained after standing for 15 min.

The absorbance was measured as a function of the pH value at double decomposition reaction in the range of pH 7.0—12.5. As is shown in Fig. 2, constant absorbances were obtained at pH values above 8.5. The precipitant, bis(diethylenetriamine)nickel-(II) chloride solution, contanins much free diethylentriamine, so that it is not necessary to neutralize the sample solutions unless the acid concentrations are more than 2.5 M.

On the basis of the above results, a standard procedure was evolved, by which the linear calibration graph was obtained in the range of dithionate concentrations in the sample solution 0—20 mM, as shown in Fig. 3. The coefficient of variation for the ten replicated experiments was satisfactory (2.5% for 15.4 mM of $S_2O_6^{2-}$).

The interferences due to various ions were also examined, as is shown in Table 1. Thiosulfate caused considerable errors, but no other compounds showed interference. It is significant that sulfite and sulfate which usually coexist with dithionate showed no interference even at such high concentrations as 800 mM. In the presence of thiosulfate, the amounts of dithionate found were larger than those added: it means that a part of thiosulfate coprecipitates with dithionate as nickel(II) diethylenetriamine complex. However, thiosulfate can be oxidized by iodide to tetrathionate

which shows no interference for the determination of dithionate. Therefore the interference due to thiosulfate may be overcome by modifying the procedure as follows. After the same volume (5 cm³) of the sample solution is placed in a 15 cm³ centrifuge tube, add 1 cm³ of adequate concentration of iodide solution to oxidize thiosulfate, and then carry out the same procedures. The results shown in Fig. 4 were thus as expected, and excess iodide showed no interference.

The Crystal and Molecular Structure of *trans*(*O*)·*mer*(*N*)-(*S*-(2-Aminoethyl)-L-homocysteinato)(glycinato)cobalt(III) Perchlorate

Ken-ichi OKAMOTO,* Masutaro SUZUKI, Hisahiko EINAGA,† and Jinsai HIDAKA

Department of Chemistry, University of Tsukuba, Sakura, Ibaraki 305

† *Institute of Materials Science, University of Tsukuba, Sakura, Ibaraki 305*

(Received May 20, 1983)

Synopsis. The crystal and molecular structure of the title complex, *trans*(*O*)·*mer*(*N*)-[Co(L-aehc)(gly)]$^+$, has been determined by the X-ray analysis. This isomer has *Δ* configuration. The sulfur donor atom of the coordinated L-aehc has *R* configuration and the six-membered N–S chelate ring takes a chair conformation.

When a quadridentate ligand, *S*-(2-aminoethyl)-L-homocysteinate (L-aehc), and a glycinate coordinate to a cobalt(III) ion, the possible geometrical isomers are four: *Δ-trans*(*O*)·*mer*(*N*), *Δ-cis*(*O*)·*mer*(*N*), *Δ-cis*(*O*)·*mer*(*N*), and *Δ-cis*(*O*)·*fac*(*N*).[1] In the *Δ* isomers, two conformations, chair and skew boat, are possible for the six-membered N–S chelate ring of the L-aehc. The *R*(*S*) coordination of the sulfur atom takes a chair-formed N–S chelate ring and the *S*(*S*) coordination takes a skew boat one. We reported that the sulfur donor atom in the *Δ-cis*(*O*)·*mer*(*N*) isomer takes the *R*(*S*) configuration and the six-membered N–S chelate ring takes a chair form.[2] The present work was attempted to investigate whether the six-membered N–S chelate ring of the L-aehc preferably takes a chair form (simultaneously *R*(*S*) configuration) in the *Δ-trans*(*O*)·*mer*(*N*) isomer or not. The first eluted isomer employed in this work can be assigned confidently as the *Δ-trans*(*O*)·*mer*(*N*) isomer from the explicit splitting of the first absorption band.[2-4] In this note, we wish to report the results of the determination of the crystal and molecular structure of the title compound. The absolute configuration of the sulfur donor atom and the conformation of the six-membered N–S chelate ring were determined.

Experimental

[Co(L-aehc)(gly)]Cl was prepared by the method in the literature[2] and chromatographed on the Dowex 50W-X8 (Na^+ form, 3 cm×40 cm) by eluting with 0.1 mol dm^{-3} NaCl aqueous solution. Four colored bands were eluted successively. The absorption and CD spectral measurements showed that the first eluate contained the *Δ-trans*(*O*)·*mer*(*N*) isomer. Then the first eluate was concentrated to a small volume with a rotary evaporator and the deposited NaCl was filtered off. By use of the anion exchange column (ClO_4^- form), the chloride salt in the eluate was converted into the perchlorate salt. Dark violet needle crystals were grown from an aqueous solution by adding ethanol. The cell dimensions and intensity data were measured on a Rigaku-denki four circle diffractometer (AFC-5) using Mo *Kα* (0.710730 Å) radiation. The crystal data are as follows; $CoC_8H_{17}N_3O_8SCl$, a=7.683 (2), b=16.304 (3), c=5.855 (1) Å, β=105.40 (2)°, V=707.1 (2) Å^3, monoclinic, space group $P2_1$, Z=2. The intensity data were collected by the ω-2θ scan technique up to 2θ=60°. A total of 2283 independent reflections with $|F_o|>3\sigma(|F_o|)$ were observed and employed in solving and refining the structure. No absorption correction was applied.

Structure Determination and Refinement

The structure was solved by the heavy atom method and refined by a full-matrix least-squares method using all the non-hydrogen atoms (program RFINE by L. W. Finger was used). The final residual values were R=0.055 and R_w=0.084, respectively. The absolute configuration was determined by an anomalous scattering technique. The atomic scattering factors for all the non-hydrogen atoms were taken from the literature.[5] When the refinements were carried out by use of a set of the atomic parameters containing the *Δ* configuration of the complex cation, the residual values converged to R=0.053 and R_w=0.083, respectively. On the contrary, the refinements in the enantiomeric atomic parameters (the *Δ* configuration) resulted in the residual values of R=0.058 and R_w=0.088, respectively. These facts indicate that the former is probably the correct choice, namely, the complex cation has the *Δ* configuration. This absolute configuration is supported from the result that the

asymmetric carbon atom of the L-aehc in the *Δ* configuration is in line with the known *S(C)* configuration.[6] The final positional parameters and equivalent isotropic temperature factors for the non-hydrogen atoms are listed in Table 1. Tables of structure factors, anisotropic temperature factors, bond lengths and angles, and the projected figure of the crystal structure are kept at the Chemical Society of Japan (Document No. 8344).

Results and Discussion

The perspective drawing of the present complex cation is shown in Fig. 1 (ORTEP program[7]). Each cobalt atom is surrounded by a sulfur, two trans oxygen and three meridional nitrogen atoms, as expected from the splitting pattern of the first absorption band of this complex cation (18.52 (ε=85.1) and 21.14 (ε=91.2)$\times 10^3$ cm^{-1}).[2-4] The complex cation is determined to be in the *Δ* configuration by anomalous scattering technique. The L-aehc coordinates to cobalt atom as a quadridentate and the asymmetric sulfur donor atom takes only *R* configuration. Therefore, the present complex cation is the *Δ-trans(O)·mer(N)-R(S)* isomer. The bond lengths and angles of the complex cation are similar to those for the cobalt(III) complexes with other sulfur-containing ligands and amino carboxylates.[2,3,8-12] The average Co–N distance for the nitrogen atoms is 1.958 Å and the Co–N3 distance bonded trans to the sulfur atom is 1.954 Å. This fact indicates that the trans effect due to the coordinated sulfur atom can not be recognized in the *Δ-trans(O)·mer(N)* isomer, as in the case of the cobalt (III) complexes with the thioether type ligands such as L-aehc in the *Δ-cis(O)·mer(N)* isomer,[2] *N,N'*-ethylenebis(*S*-methyl-L-cysteinate),[3] and 2-(methylthio)ethylamine.[13]

In order to investigate the conformation of the chelate rings, we calculated the displacements of relevant atoms from the chelate ring plane, which is defined by the central cobalt atom and two coordinated atoms in the chelate ring (Table 2). The six-membered N–S chelate ring of the L-aehc (N2–C2–C3–C4–S) takes a chair form, which consists of two almost parallel planes; dihedral angle for the two planes, N2–Co–S and C2–C3–C4, is 3.03°. Similar conformations have been also observed for *Δ-cis(O)·mer(N)-R(S)*-[Co(L-aehc)(gly)]$^+$ [1,2] and [Co(*S,S*-ebm)]$^+$,[11,12] where *S,S*-ebm denotes *N,N'*-ethylenebis(L-methioninate) whose six-membered chelate rings have the same framework as that of the L-aehc. The five-membered N–S chelate ring takes an envelope form with the *λ* conformation. The glycinate moiety of the L-aehc takes an envelope form with the *λ* conformation and the displacement of relevant atoms from the plane N2–Co–O1 does not differ much from that of the glycinate with the *δ* conformation in the present complex cation.

(Received June 8, 1983)

Synopsis. $[Co(C_{10}H_8NO)_2]\cdot H_2O$ ($C_{10}H_8NO^-$=2-methyl-8-quinolinolate ion) reacted with nitrogen monoxide in dichloromethane to give unstable compounds, $[Co(C_{10}H_8NO)_2(NO)_2]$ and $[NO]_3[Co(C_{10}H_8NO)_2(NO_3)(NO_2)]$ with liberation of dinitrogen oxide. The compounds were characterized by ^{15}N-isotopic effect observed on the IR spectra.

Nitrogen monoxide reacts with low-valent transition-metal complexes to give the nitrosyls or to cause a disproportionation of nitrogen monoxide.[1-3] Recently, one of the authors reported that $[Co(C_9H_6NO)_2]$ ($C_9H_6NO^-$=8-quinolinolate ion) reacted with nitrogen monoxide in dichloromethane at room temperature to give $[NO][Co^{III}(C_9H_6NO)_2(NO_3)(NO_2)]$ with liberation of dinitrogen oxide via $[Co^{III}(C_9H_6NO)_2(NO)]$.[4] The reaction involves a nitrosylation followed by an electrophilic attack of nitrogen monoxide on the coordinating nitrosyl group, and a disproportionation of nitrogen monoxide to $[NO]^+$, NO_3^-, and dinitrogen oxide.

In this paper, we report a reaction of $[Co(C_{10}H_8NO)_2]\cdot H_2O$ ($C_{10}H_8NO^-$ = 2-methyl-8-quinolinolate ion) with nitrogen monoxide in dichloromethane, pyridine, 10 vol% pyridine–DMF, or DMF.

The reaction was performed using a vacuum line, and the solid products were manipulated under nitrogen atmosphere as soon as possible. Starting material, $[Co(C_{10}H_8NO)_2]\cdot H_2O$ was synthesized by ordinary method. Nitrogen[^{15}N] monoxide was derived from potassium nitrate[^{15}N] (^{15}N atom%=99.7). The gaseous product was identified by mass spectrometer, and the IR bands and their ^{15}N-isotopic shifts.[5]

$[Co(C_{10}H_8NO)_2]\cdot H_2O$ (0.5 mmol) suspended in dichloromethane (20 cm^3) degassed by three cycles of freeze-pump-thaw was brought into contact with nitrogen monoxide (5 mmol), and stirred for 1 d at room temperature or for 7 d at *ca.* −20 °C. The suspended $[Co(C_{10}H_8NO)_2]\cdot H_2O$ changed from original orange to russet. The yield of the russet compound (**1**) was *ca.* 70% based on the starting material. The liberated gas was only dinitrogen oxide under the experimental conditions.

Compound **1** could not be purified since the compound in the solid state was gradually decomposed with liberation of nitrogen monoxide even under nitrogen atmosphere, and was also unstable in deoxygenated DMF or dichloromethane. The elementary analyses consisted with $Co_1C_{20}H_{16}N_7O_{10}$. Found: Co, 10.3; C, 42.3; H, 2.7; N, 17.5%. Calcd: Co, 10.3; C, 41.9; H, 2.8; N, 17.1%. The IR spectra of compound **1** at 80 K showed several absorption bands characteristic of nitrosyl cations, coordinating nitro, and nitrate ions in addition to the coordinating 2-methyl-8-quinolinolate ions, as shown in Fig. 1. The 2109(vs) cm^{-1} band shifted to 2040 cm^{-1} upon ^{15}N-substitution, and was assigned to the N–O stretching vibration due to the nitrosyl cations.[5] The 1280(w)[6], 820(sh)[6], 641(w), 582(w), and 422(w) cm^{-1} bands also shifted to 1260(sh)[6], 812(m), 635(w), 576(w), and 416(w) cm^{-1}, respectively, and were assigned to the symmetric N–O stretching of NO_3^-, the symmetric NO_2 deformation of NO_2^- or the rocking of NO_3^-, the antisymmetric or symmetric NO_2 deformation of NO_3^-, the NO_2 wagging of NO_2^-, and the Co–NO_2 stretching vibrations, respectively, from wave numbers of the bands and their ^{15}N-isotopic shifts.[4,5] The bands at 1330(sh)[6] cm^{-1} for the ^{14}N-labelled compound and at 1347(m) cm^{-1} for the ^{15}N-one could be assigned to the antisymmetric or symmetric N–O stretching of NO_2^-, and the antisymmetric N–O stretching of NO_3^-.

The elementary analyses and the IR spectra suggest that compound **1** is $[NO]_3[Co(C_{10}H_8NO)_2(NO_3)(NO_2)]$ containing monopositive cobalt ion. A number of nomopositive cobalt-complexes with π-acceptor ligands have been reported so far, and they are in general air-sensitive and diamagnetic.[7] On the other hand, as the ligands in compound **1** are not π-acceptor ones,[8] an electronic configuration of the cobalt ion in compound **1** is expected to be high-spin d^8. The effective magnetic moment of compound **1** was 3.7±0.1 BM (at 296 K), and was larger than the value, 2.8—3.5 BM observed for the first row transition-metal ions with high-spin d^8 configuration.[9] Hence, it is taken into consideration that compound **1** may be contaminated by paramagnetic substances such as the unreacted starting material or uncharacterized decom-

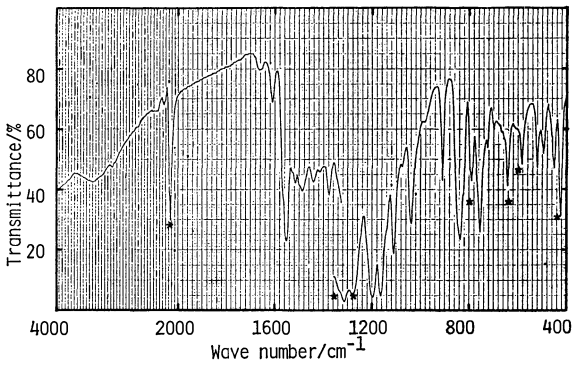

Fig. 1. IR spectrum of $[NO]_3[Co(C_{10}H_8NO)_2(NO_3)(NO_2)]$. * indicates the band shifted upon ^{15}N-substitution.

† Partly presented at 45th National Meeting of the Chemical Society of Japan, Tokyo, April 1982, Abstr., No. 1B37.

posed one, although it could not be confirmed.

After compound **1** had been filtered from the reaction solution stirred at *ca.* −20 °C, the solvent, dichloromethane, was removed in keeping the filtrate at lower than 0 °C to obtain violet product, $[Co(C_{10}H_8NO)_2(NO)_2]$ (**2**). Yield, 10%. Found: C, 53.6; H, 3.6; N, 12.3%. Calcd: C, 55.2; H, 3.7; N, 12.9%. Compound **2** was even more unstable than compound **1**, and could not be purified. The IR spectra showed that compound **2** was contaminated by compound **1**. The IR bands at 1840(vs) and 1760(vs) cm^{-1} shifted to 1805 and 1730 cm^{-1}, respectively, upon ^{15}NO-substitution. These bands could be assigned to the N–O stretching vibrations of the coordinating nitrosyl groups.[8] The wave number of the N–O stretching vibrations show that the formal oxidation number of the coordinating nitrosyl group is +I, and hence that of the cobalt is zero.[8] The N–O stretching vibrations for $[Fe(C_{10}H_8NO)(NO)_2]$ with the formal oxidation number of Fe^{-I} were observed at 1758 and 1685 cm^{-1}.[8] The N–O stretching bands for compound **2** are higher than those for the iron nitrosyl, which reflects that π^*-electron on the nitrosyl group is more drawn to the cobalt than to the iron due to difference of their nuclear charges.

The yields of compounds **1** and **2** were *ca.* 30 and 50%, respectively, in the case of stirring at *ca.* −20 °C for 1 d; the yield of compound **2** was larger than that of compound **1** in the initial stage of the reaction. Compound **2** reacted with nitrogen monoxide in dichloromethane to precipitate compound **1**. These suggest that $[Co(C_{10}H_8NO)_2]\cdot H_2O$ reacted with nitrogen monoxide to form compound **2**, and then it reacted further with nitrogen monoxide to precipitate compound **1** with liberation of dinitrogen oxide. However, it can not be denied that $[Co(C_{10}H_8NO)_2]\cdot H_2O$ reacted with nitrogen monoxide to produce compound **1** directly.

The Co^{II} in the starting material was reduced to Co^{I} or Co^{0} by nitrogen monoxide on the present study, while on the reaction of $[Co(C_9H_6NO)_2]$ with nitrogen monoxide, the Co^{II} was oxidized to Co^{III}.[4] The difference in the reaction of nitrogen monoxide with the cobalt ion seems to be due to electron-donating power of methyl groups in 2-methyl-8-quinolinolate ions.

A reaction of $[Co(C_{10}H_8NO)_2]\cdot H_2O$ with nitrogen monoxide in pyridine, 10 vol% pyridine–DMF, or DMF was tried on the same scale as in dichloromethane. In pyridine and the pyridine–DMF, $[Co(C_{10}H_8NO)_2]\cdot H_2O$ did not reacted with nitrogen monoxide, instead only the pyridine adduct being isolated. In DMF, $[Co(C_{10}H_8NO)_2]\cdot H_2O$ reacted with nitrogen monoxide to give a deep red solution with liberation of dinitrogen oxide. Deoxygenated diethyl ether (150 cm^3) was added to the solution to precipitate a russet product. However, the russet product did not give constant elementary analyses. The IR spectra of the compound was seemingly same as those of compound **1** except an addition of a 1660 cm^{-1} band assignable to the C–O stretching vibration of DMF to the spectra of compound **1**.

The authors wish to express their thanks to Dr. Mikio Tanaka of Nippon Medical School for measuring the mass spectra.

Mosomorphic Phenyl Benzoate and 1,3-Dioxane Derivatives Bearing Terminal Vinyl Group

Hiroyoshi KAMOGAWA,* Tomoki HIROSE, and Masato NANASAWA
Department of Applied Chemistry, Yamanashi University, Takeda 4, Kofu 400

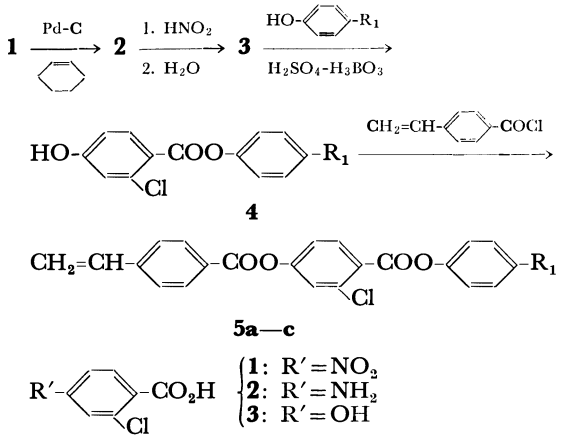
(Received January 18, 1983)

Synopsis. 4-Alkylphenyl 2-chloro-4-(4-vinylbenzoyloxy) benzoates and 2-phenyl-1,3-dioxane derivatives with terminal vinyl groups were synthesized. Most of the novel compounds obtained possess characteristic mesomorphic ranges.

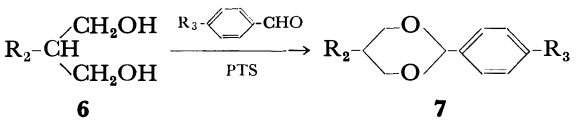
Some efforts have been made to incorporate vinyl groups into nematic liquid crystalline structures with intention of polymerizing the resulting vinyl monomers to obtain polymeric liquid crystals.[1] Besides the potentiality of these monomers as precursors to polymeric liquid crystals, the terminal rigid vinyl group bearing the sp^2-carbon atoms is itself expected to afford liquid-crystalline characteristics different from those of the corresponding compounds with alkyl and related flexible groups. With this intention, two series of novel vinyl compounds were prepared and their liquid-crystalline behavior was compared with that of the corresponding compounds with alkyl and related groups.

Vinyl compounds were prepared as follows:

(a)



(b)



Tables 1 and 2 summarize the yields and mesomorphic ranges of compounds **5** and **7**, respectively, in comparison with those of the corresponding compounds with alkyl and related groups.

All of the vinyl compounds listed in these tables, among which **5a—c** and **7a—f** have not been listed in literature as yet, are stable up to the isotropic ranges, presumably due to their long rodlike structures.

In the phenyl benzoate series (Table 1), the replacement of the alkyl group as R by the rigid vinyl group generally causes smectic ranges to appear prior to nematic ones with elevation of temperature, which is not general in the conventional **5**-type esters.[2] The

absence of smectic textures for compounds **5d** and **5f** having no chlorine atom may indicate that the effects of chain length and branching in R_1 on the smectic alignments of the molecules are predominant in the absence of the chlorine atom. Higher N—I transition temperatures were also recognized for compounds with unbranched R_1 (**5b** and **5c** *vs.* **5i** and **5k**).

In the dioxane series (Table 2), compounds wtih the 4-vinylbenzyl group as R_2, in spite of the presence of the rigid vinyl end, have much lower mesomorphic ranges than those with the alkylphenyl or alkoxyphenyl group (**7a** *vs.* **7k** and **7l**; **7b** and **7c** *vs.* **7m**), although the alkylbenzyl group is required for exact structural comparison. Compounds **7d** and **7e** also have lower melting points (below room temperature) than **7n**, **7o**, **7g**, and **7h**.

These results indicate that the introduction of the terminal rigid vinyl group into these two series of compounds does not interfere with the formation of mesomorphic structures at all, leading to characteristic

mesomorphic behavior, when appropriate chemical structures are adopted.

Experimental

Infrared, ^{1}H NMR, and mass spectra were recorded on a Hitachi 215 spectrophotometer, a JNM-PMX 60 spectrometer, and a Hitachi RMU-6 spectrometer, respectively, under standard conditions. Elemental analyses were carried out with a Perkin-Elmer 250 instrument. Mesomorphic ranges were determined by means of either a Yamato MP-21 melting point apparatus or an optical microscope, both equipped with crossed polarizers.

2-Chloro-4-hydroxybenzoic Acid (3). A known preparative procedure[2] was modified as follows: 2-Chloro-4-aminobenzoic acid (**2**; mp 205—207 °C; 9 g, 52 mmol), prepared by heating 2-chloro-4-nitrobenzoic acid (**1**) in ethanol under reflux for 2 h in the presence of 5% Pd–C and a large excess of cyclohexene and purified by recrystallization from water, was dissolved in a solution of sodium nitrite (4 g, 58 mmol) and sodium carbonate (4 g, 40 mmol) in water (250 ml). A solution of concd sulfuric acid (30 ml) in water (200 ml) was then added with ice cooling, and the resulting solution was further stirred for 15 min. Urea (1 g) was next added, and stirring was further continued at 50—60 °C for 7 h. The reaction mixture was then extracted with ether (200 ml). The orange organic layer was washed with water, dried over anhyd sodium sulfate, and evaporated *in vacuo* to leave the crude product. Recrystallizations from water provided pure needles (mp 203—206 °C; lit,[2] 206—208 °C) in 50% yield: IR(KBr) 1680 (C=O), 1590, 1570 (aromatic), 1400, 1290, and 1240 (OH) cm^{-1}; NMR ($CDCl_3$+DMSO-d_6) δ=6.8 (m, 2H, ArH) and 7.7—8.7 (m, 3H, ArH+OH+COOH).

4-Butylphenyl 2-Chloro-4-(4-vinylbenzoyloxy)benzoate (5b). 4-Vinylbenzoyl chloride (0.8 g, 5.0 mmol) was added to a solution of 4-butylphenyl 2-chloro-4-hydroxybenzoate (**4**; 1.4 g, 4.7 mmol), prepared from 2-chloro-4-hydroxybenzoic acid (**3**) and 4-butylphenol,[3] and 4-*t*-butylcatechol (50 mg) in dry pyridine (25 ml). After stirring at room temperature for 18 h, the reaction mixture was poured into an ice–water mixture and the product was isolated by filtration. Three-time recrystallizations from ethanol gave pure crystals: Found: C, 71.58; H, 5.32%. Calcd for $C_{26}H_{23}O_4Cl$: C, 71.80; H, 5.33%. IR (KBr) 1740, 1590, 980, and 910 cm^{-1}; NMR ($CDCl_3$+DMSO-d_6) δ=0.9—3.0 (m, 9H, C_4H_9), 5.4 (d, 1H), 5.8 (d, 1H), 6.7 (q, 1H), 7.3 (t, 8H), and 8.1 (d, 3H); MS (rel intensity) 435 (M^+, 5) and 298 (100).

Compounds **5a** and **5c** were prepared in the same manner with satisfactory analytical data.

2-Vinylbenzyl-1,3-propanediol (6). To a solution of sodium (2.3 g, 100 mmol) in absolute ethanol (100 ml) was gradually added with ice cooling first diethyl malonate (16.0 g, 100 mmol) and then a mixture of vinylbenzyl chloride (Seibi Chem. Co.; *m*/*p*=60/40; 15.2 g, 100 mmol) and 4-*t*-butylcatechol (1 g) with exclusion of moisture. The mixture was heated under reflux until it became no longer alkaline (about 2 h). The reaction mixture was then purified by distillation under reduced pressure to afford diethyl vinylbenzylmalonate (bp, 135 °C/3 mmHg) (1 mmHg=133.322 Pa) in 22% yield. The malonate (13.8 g, 50 mmol) was then heated under reflux for 2 h in anhyd ether in the presence of $LiAlH_4$ (3.8 g) with exclusion of moisture. The reaction mixture was worked up as usual to afford compound **6** in 93% yield: Found: C, 75.34; H, 8.11%. Calcd for $C_{12}H_{16}O_2$: C, 75.00; H, 8.33%. IR ($CHCl_3$) 3350—3200 (OH), 990 and 900 (vinyl) cm^{-1}; NMR ($CDCl_3$) δ=5.2 (d, CH_2=), 5.7 (d, CH_2=), and 6.7 (q, =CH–).

2-(4-Cyanophenyl)-5-(4-vinylbenzyl)-1,3-dioxane (7a). A solution of compound **6** (1.92 g, 10 mmol), 4-cyanobenzaldehyde (1.31 g, 10 mmol), 4-*t*-butylcatechol (0.1 g), and *p*-toluenesulfonic acid (PTS; 0.1 g) in benzene (100 ml) was heated under reflux for 7 h with a Dean-Stark trap fitted. The reaction mixture was washed with aq Na_2CO_3, then with water, dried over anhyd Na_2SO_4, and concentrated on a rotary evaporator to afford the crude product. Column chromatography (Wakogel C-300) using benzene as eluent and subsequent several recrystallizations from methanol provided colorless needles: Found: C, 78.34; H, 6.53: N, 4.85 %. Calcd for $C_{20}H_{19}NO_2$: C, 78.66; H, 6.27; N, 4.59%. IR (KBr) 2220 (CN), 990, 910 (vinyl), and 820 (1,4-disubstitution) cm^{-1}; NMR ($CDCl_3$) δ=2.4 (s, 3H, CH_2, CH), 3.3—4.4 (m, 4H, $2CH_2O$), 5.3 (d, 1H, CH_2=), 5.5 (s, 1H, –CH<O–O–), 5.8 (d, 1H, CH_2=), 6.7 (q, 1H, –CH=), and 6.9—7.9 (8H, ArH); MS 305 (M^+).

Compounds **7b** and **7c** were prepared in the same manner with satisfactory analytical data.

2-(4-Vinylphenyl)-5-(4-vinylbenzyl)-1,3-dioxane (7f). The same reaction procedure as that for **7a** was applied to **6** and vinylbezaldehyde, synthesized from vinylbenzyl chloride by the Sommlet reaction,[5] to afford colorless crystals: Found: C, 77.47; H, 6.79%. Calcd for $C_{21}H_{22}O_2$: C, 77.56; H, 6.82%. IR (KBr) 990, 900 (vinyl), and 840 (1,4-disubst.) cm^{-1}; NMR ($CDCl_3$) δ=2.4 (s, 3H, CH_2, CH), 3.3—4.5 (m, 4H, $2CH_2O$), 5.3 (d, 2H, $2CH_2$=), 5.4 (s, 1H, –CH<O–O–), 5.8 (d, 2H, $2CH_2$=), 6.7 (q, 2H, 2–CH=), and 6.9—7.6 (m, 8H, ArH); MS 306 (M^+).

Compounds **7d** and **7e** were prepared in the same manner with satisfactory analytical data.

Synthesis of Diphenyl-substituted Flavonoid Compounds on Both Benzene Rings

Hisashi MATSUMURA,† Toshio TSUCHIYA,†† and Kimiaki IMAFUKU*

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860

(Received January 29, 1983)

Synopsis. Condensation of *o*-hydroxyacetophenone and its 3- and 5-phenyl-substituted compounds with 2- or 4-methoxy-biphenyl-3-carbaldehyde gave six mono- and diphenyl-substituted 2′-hydroxychalcones (**5a—f**), which were cyclized with alkali to afford the flavanones. The chalcones **5a—f** were also converted to the corresponding flavones *via* chalcone bromides.

Little is known about phenyl-substituted flavonoid compounds, except for a few reports.[1] Previously, we reported the synthesis of 6- and 8-phenyl-substituted flavonoid compounds.[2] The present communication deals with the synthesis of flavonoid compounds having two phenyl groups in both benzene ring.

Scheme 1.

Results and Discussion

In starting materials, 3-acetylbiphenyl-4-ol and -2-ol (**4b** and **4c**) were prepared by the method described in the previous paper.[2] 4-Methoxybiphenyl-3-carbaldehyde (**3a**) was prepared by Duff's formylation[3] and methylation of biphenyl-4-ol (**1a**). Similarly, 2-methoxybiphenyl-3-carbaldehyde (**3b**) was newly obtained by formylation and methylation of biphenyl-2-ol (**1b**).

The *o*-hydroxyacetophenones (**4a—c**) were condensed with methoxy-substituted biphenyl-3-carbaldehydes (**3a** and **3b**) to afford mono- or diphenyl-substituted 2′-hydroxychalcones (**5a—f**) in good yields. The spectral data are summarized in Table 1. In the UV spectra, an introduction of the phenyl group at the 3-position exhibited no appreciable effect. On the other hand, the spectra of the 5-phenyl-substituted chalcones exhibited remarkable differences. In the NMR spectra, the signal (δ *ca.* 3.4) for the methoxyl protons of the 3-phenyl-substituted chalcones (**5b**, **d**, and **f**) shifted towards higher magnetic field than that (δ *ca.* 3.9) for the 5-phenyl-substituted chalcones (**5a**, **c**, and **e**). This might be caused by ring-current in the neighboring phenyl group.

The bromination of the chalcones **5a—f** gave the corresponding dibromides **6a—f** in good yields. These characteristic data are listed in Table 2.

The chalcones **5a—f** were heated in the presence of alkali to cyclize to flavanones **7a—f**. These spectral data are summarized in Table 3. The UV spectra of **7a** and **7b** exhibited no appreciable effect of the phenyl group at the 3′- and 5′-positions. In the UV spectra of **7c—f**, the phenyl group at the 6- and 8-positions caused bathochromic shift of the maximum at longer wavelength band. The NMR spectra showed

the typical ABX pattern of 2-, 3e-, and 3a-protons.

The chalcone dibromides **6a—f** were treated with alkali to afford the corresponding flavones **8a—f** in good yields. The characteristic data are summarized in Table 4. In the UV spectra of **8a** and **8b**, the phenyl group at the 3'-position exhibited no effect but the phenyl group at the 5'-position exhibited bathochromic shift of the maximum at longer wavelength band. The NMR spectra showed a sharp singlet peak for the 3-H proton at δ 6.9—7.1. The methoxyl protons of the 3'-phenylflavones (**8b, d**, and **f**) were also observed in higher magnetic field than those of 5'-phenylflavones (**8a, c**, and **e**).

Experimental

The IR, UV, and NMR spectra were taken on a JASCO 403G, a Hitachi EPS-3T, and a Hitachi R-24 (60 MHz) spectrometer, respectively.

*2-Methoxybiphenyl-3-carbaldehyde (**3b**).* Methylation of 2-hydroxybiphenyl-3-carbaldehyde (**2b**)[4] (2.4 g, 12 mmol) with dimethyl sulfate (1.5 g, 12 mmol) in acetone (100 ml) in the presence of potassium carbonate (1.7 g, 12 mmol) gave 2-methoxybiphenyl-3-carbaldehyde (**3b**) as colorless crystals (from methanol). Yield, 2.0 g (73%). Mp 53—54 °C, IR (KBr) 1680 cm^{-1}. Found: C, 79.36; H, 5.43%. Calcd for $C_{14}H_{12}O_2$: C, 79.22; H, 5.70%.

*4-Methoxybiphenyl-3-carbaldehyde (**3a**).* This compound also prepared in a similar manner to the preparative method of **3b**. Yield, 86%. Mp 77—78 °C (lit,[5] 76.5—77 °C).

*The Chalcones **5a—f**.* A solution of 2-hydroxyacetophenone (**4a—c**) (2.4 mmol) and 2- or 4-methoxybiphenyl-3-carbaldehyde (**3a, b**) (500 mg, 2.4 mmol) in ethanol (3 ml) was stirred at 50 °C in the presence of 60% potassium hydroxide solution (2.5 ml). The mixture was slightly acidified with 3 M hydrochloric acid (1 M=1 mol dm^{-3}) extracted with ether, and worked up to give the chalcone **5a—f**.

*The Chalcone Dibromides **6a—f**.* A bromine (320 mg, 2 mmol) solution in carbon tetrachloride (2 ml) was added dropwise to a solution of the chalcone **5a—f** (500 mg) in carbon tetrachloride (5 ml) at room temperature to afford the chalcone dibromide **6a—f** (from acetone).

*The Flavanones **7a—f**.* A solution of the chalcone **5a—f** (330—400 mg, 1 mmol) in acetone (8 ml) was refluxed for 90 min in the presence of 1% potassium hydroxide solution (0.5 ml). The mixture was concentrated and allowed to stand overnight to give a precipitate, which was chromatographed on an alumina column to afford the flavanone **7a—f** (from acetone).

*The Flavones **8a—f**.* To a suspended solution of the chalcone dibromide **6a—f** (450 mg) in acetone (2 ml) was added 20% potassium hydroxide solution (1 ml) at room temperature. The mixture was diluted with water and slightly acidified with 3 M hydrochloric acid to give a precipitate, which was chromatographed on a silica-gel column to afford the flavone **8a—f** (from acetone).

We are grateful to Sanko Chemical Co., Ltd. for a supply of biphenyl-2-ol and -4-ol.

A Stereoselective Synthesis of (3*E*,5*Z*)-3,5-Tetradecadienoic Acid (Megatomoic Acid), the Sex Attractant of the Black Carpet Beetle†

Sadao Tsuboi, Toshihide Masuda, and Akira Takeda*

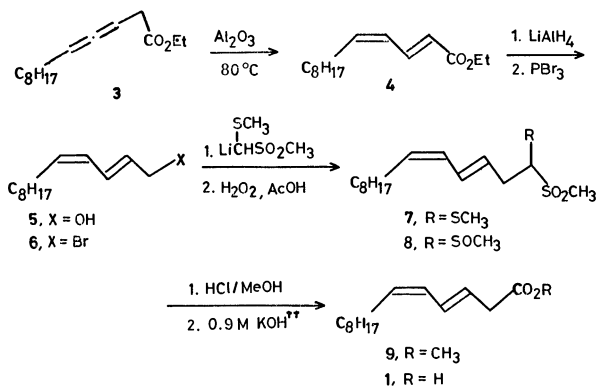
Department of Synthetic Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700

(Received February 27, 1983)

Synopsis. The total synthesis of (3*E*,5*Z*)-3,5-tetradecadienoic acid (megatomoic acid) is accomplished with 74% stereoselectivity through the use of stereoselective rearrangement of ethyl 3,4-tridecadienoate to ethyl (2*E*,4*Z*)-2,4-tridecadienoate with alumina and the extension of the carbon chain with methyl methylthiomethyl sulfone.

The sex attractant of the black carpet beetle, *Attagenus megatoma* (*Fabricius*), was identified as (3*E*,5*Z*)-3,5-tetradecadienoic acid (**1**) by Silverstein *et al.*,[1] to which they assigned the trivial name, megatomoic acid. The total synthesis of **1** has been reported by two groups.[2,3] In spite of reasonable overall yields, their sequences produce a significant amount of stereoisomers.[4] We present here a convenient and stereoselective synthesis of **1** starting with 1-undecyn-3-ol (**2**), which is superior to others[2,3] in its stereoselectivity (74%). The synthetic plan outlined in Scheme 1 was conceived with two strategic aspects: (1) to construct (2*E*,4*Z*)-2,4-dienoic ester (*e.g.*, ester **4**) from readily available materials, (2) to extend its carbon chain with the retention of the geometry. Ethyl (2*E*,4*Z*)-2,4-tridecadienoate (**4**), a key intermediate which fulfills these requirements was prepared in good yield by the highly stereoselective synthesis of (2*E*,4*Z*)-2,4-dienoates with alumina catalyst, as recently described by us.[5]

3,4-Dienoate **3** was prepared in 85% yield by the modified Claisen rearrangement of **2** with triethyl orthoacetate.[5] The thermal rearrangement of **3** with alumina gave 88% yield of (2*E*,4*Z*)-2,4-dienoate **4** of 97% purity.[6] A minor component was suggested to be (2*E*,4*E*)-isomer by comparison of the retention time of GLC.[5] Reduction of **4** with lithium aluminium hydride gave the corresponding alcohol **5** in 95% yield. The reaction of the allylic alcohol **5** with PBr_3 in petroleum ether afforded the desired bromide **6** in a reasonable yield. The conversion of **6** to carboxylate was attempted by various methods. The reactions of the Grignard reagent derived from **6** followed by carbonation resulted in the recovery of the starting material, or in the formation of unidentified materials. The reaction of **6** with sodium cyanide gave 3,5-tridecadienenitrile (**10**) in poor yields as stereoisomeric mixtures. The hydrolysis of **10** to the corresponding carboxylic acid, however, gave a trace of a carboxylic acid. On the other hand, the reaction of **6** with methyl methylthiomethyl sulfone[7] in the presence of butyllithium gave the corresponding product (**7**) with 81% purity in 46% yield,[8] while the reaction using a phase-transfer catalyst (PTC) resulted in poor yields of **7**. Compound **7** was oxidized with peracetic acid under mild conditions to give the sulfinyl sulfone **8**



Scheme 1.

as an oil. The subsequent treatment of **8** with concentrated hydrochloric acid in methanol gave methyl (3*E*,5*Z*)-3,5-tetradecadienoate (**9**) with 74% purity, in 30% yield from **7**. The desired product, megatomoic acid **1**, was obtained in 89% yield by the hydrolysis of **9** with 0.9 M potassium hydroxide. The spectral properties of the synthesized **1** were identical with those reported for the natural product.[1]

Experimental

The boiling points are uncorrected. Elemental analyses were carried out by Mr. Eiichiro Amano of our laboratory. Analytical determinations by GLC were performed on a Hitachi Model 163 gas chromatograph fitted with 10% Silicone SE-30 on Chromosorb W column (3 mm o.d. × 1 m). IR spectra were taken on a Hitachi Model EPI-S2 or a JASCO Model A-102 spectrometer. ^{1}H NMR spectra (60 MHz) were recorded with a Hitachi R-24 apparatus. ^{13}C NMR spectra (25 MHz) were obtained with JEOL LTD. JNM-FX 100 apparatus equipped with FT facilities, using $CDCl_3$ as solvent. 1-Undecyn-3-ol (**2**) was prepared by a method in the literature:[5b,9] bp 89 °C (5 mm); 71% yield, improved over the previously reported value.[5b]

(2E,4Z)-2,4-Tridecadien-1-ol (5). To a stirred mixture of 160 mg (4.2 mmol) of lithium aluminium hydride and 10 ml of dry ether was added dropwise a solution of 1.0 g (4.2 mmol) of **4** in 10 ml of dry ether at −40 °C. After 1.5 h, the reaction mixture was quenched with 400 mg of ethyl acetate, and neutralized with 10% HCl. The organic layer was extracted with ether, and the combined ethereal layers were washed with water and dried over $MgSO_4$. Removal of the solvent gave 780 mg (95%) of **5** containing 9% (2*E*,4*E*)-isomer by ^{13}C NMR: IR (neat) 3350 (OH), 1640 cm^{-1} (C=C); ^{1}H NMR (CCl_4) δ=0.92 (broad t, 3 H, J=4 Hz, CH_3), 1.27 (broad s, 12 H, $(CH_2)_6$), 2.13 (m, 2H, =CHC$\underline{H}_2$C$_7$H$_{15}$), 3.64 (s, 1H, OH), 4.09 (d, 2H, J=5.5 Hz, C$\underline{H}_2$OH), 5.10—6.08 (m, 3H, C$\underline{H}$=C$\underline{H}$CH=C$\underline{H}$CH$_2$OH), 6.45 (dd, 1H, J=10 and 15 Hz, C$\underline{H}$=CHCH$_2$OH); ^{13}C NMR

† Presented at the 45th National Meeting of the Chemical Society of Japan, Tokyo, April 1982, Abstr. No. 2, p. 887.

($CDCl_3$) δ=14.1 (d, CH_3), 22.8 (t, C_{12}), 27.9 (t, C_6), 29.4 (t), 29.6 (t), 29.8 (t), 32.0 (t, C_{11}), 63.0 (t, C_1), 126.6 (d, C_3), 128.0 (d, C_4), 132.0 (d, C_2), 132.6 (d, C_5). Found: C, 79.76; H, 12.08%. Calcd for $C_{13}H_{24}O$: C, 79.53; H, 12.32%.

(2E,4Z)-1-Bromo-2,4-tridecadiene (6). To a stirred solution of 600 mg (3.06 mmol) of **5** in 1.5 ml of petroleum ether was added dropwise a solution of 580 mg (2.15 mmol) of PBr_3 in 1.5 ml of petroleum ether at −15 °C for a period of 15 min. The mixture was stirred for 2 h at −15 °C and then overnight at room temperature. The reaction mixture was diluted with ice water (50 ml) and neutralized with dilute $NaHCO_3$. The organic layer was extracted with petroleum ether. The combined extracts were washed with water, and dried over $MgSO_4$. Removal of the solvent gave 624 mg (79%) of **6** as a clean oil: IR (neat) 1645 cm^{-1} (C=C); ^1H NMR (CCl_4) δ=0.92 (broad t, 3 H, J=4 Hz, CH_3), 1.25 (broad s, 12H, $(CH_2)_6$), 2.13 (m, 2H, =CH-C<u>H</u>$_2C_7H_{15}$), 3.91 (d, J=7.4 Hz, 2H, CH_2Br), 5.29—6.11 (m, 3H, C<u>H</u>=C<u>H</u>CH=C<u>H</u>CH_2Br), 6.47 (dd, 1H, J=10 and 15 Hz, C<u>H</u>=CHCH_2Br). Found: C, 60.47; H, 8.90 %. Calcd for $C_{13}H_{23}Br$: C, 60.23; H, 8.94%.

(3E,5Z)-1-Methylsulfonyl-1-methylthio-3,5-tetradecadiene (7). To a stirred solution of 342 mg (2.44 mmol) of methyl methylthiomethyl sulfone in 5 ml of dry THF was added dropwise 1.57 ml (2.43 mmol) of 1.55 M butyllithium (hexane) at −20 °C under a static N_2 atmosphere. The mixture was stirred for 90 min and then cooled at −65 °C. After gradual addition of 600 mg (2.32 mmol) of **6**, the mixture was stirred for 1 h at −65 °C and then for 12 h at 0 °C. It was poured into water (*ca.* 30 ml) and the organic layer extracted with ether. The dried ($MgSO_4$) ethereal layer was concentrated *in vacuo* to yield 765 mg of an oil. Column chromatography on silica gel (30 g) with hexane–ethyl acetate gave 337 mg (46%) of **7** as a clean, viscous oil containing 19% (3*E*,5*E*)-isomer by ^{13}C NMR:[10] IR (neat) 2910, 1300, 1160 cm^{-1} (SO_2); ^1H NMR ($CDCl_3$) δ=0.92 (broad t, 3 H, J=5 Hz, CH_3), 1.30 (broad s, 12H, $(CH_2)_6$), 1.9—2.5 (m, 2H, =CHC<u>H</u>$_2C_7H_{15}$), 2.33 (s, 3H, SCH_3), 2.60 (dd, 2H, J= 7 and 10 Hz, =CHC<u>H</u>$_2$CH<), 3.01 (s, 3H, SO_2CH_3), 3.62 (dd, 1H, J=4 and 10 Hz, >C<u>H</u>SO_2), 5.26—6.20 (m, 3H, C<u>H</u>=C<u>H</u>CH=C<u>H</u>CH_2CH<), 6.59 (dd, 1H, J=10 and 15 Hz, C<u>H</u>=CHCH_2CH<); ^{13}C NMR ($CDCl_3$) δ=14.1 (q, CH_3), 14.2 (q, CH_3), 22.7 (t, C_{13}), 27.8 (t, C_7), 29.2 (t), 29.4 (t), 29.6 (t), 30.3 (t, C_2), 31.9 (t, C_{12}), 36.7 (q, SO_2CH_3), 126.3 (d), 127.5 (d), 130.0 (d), 133.0(d). Found: C, 60.12; H, 9.54%. Calcd for $C_{16}H_{30}O_2S_2$: C, 60.33; H, 9.49%.

Methyl (3E,5Z)-3,5-Tetradecadienoate (9). A mixture of **7** (270 mg, 0.85 mmol), acetic acid (1.5 ml), and 35% hydrogen peroxide (0.1 ml, 1.1 mmol) was stirred for 2 d at room temperature in a dark room. The mixture was dissolved in CH_2Cl_2 and then treated with 3 g of potassium carbonate. After fitration, the filtrate was dried over $MgSO_4$. Removal of the solvents gave 254 mg of an oil, which was assumed to be (3*E*,5*Z*)-1-methylsulfonyl-1-methylsulfinyl-3,5-tetradecadiene (**8**).

A mixture of the above oil **8** (123 mg, 0.368 mmol), methanol (2 ml), and a catalytic amount of conc HCl was heated at reflux temperature for 6 h, and then poured into water (*ca.* 25 ml). The resulting mixture was extracted with ether, and the organic layer washed with water and dried over $MgSO_4$. Removal of the solvents yielded 100 mg of an oil which was purified by column chromatography on silica gel (4 g) with hexane–AcOEt as an eluent, giving 29 mg (30% from **7**, 32% from consumed **7**) of **9** (74% pure by ^{13}C NMR): ^{13}C NMR ($CDCl_3$) δ=14.0 (q, C_{14}), 22.6 (t, C_{13}), 27.7 (t, C_7), 29.2 (t), 29.4 (t), 29.5 (t), 31.8 (t, C_{12}), 38.0 (t, C_2), 51.8 (q, $CO_2\underline{C}H_3$), 124.3 (d), 127.5 (d), 129.2 (d), 132.4 (d), 172.0 (s, $\underline{C}O_2CH_3$). GLPC analysis [column temp, 150 °C; carrier gas, N_2 (1.0 kg/cm^2)] indicated that it consisted of two components with the retention times, 10.5 min (**9**, 74 parts) and 12.3 min (the (3*E*,5*E*)-isomer,[2] 26 parts). IR and ^1H NMR data of pure **9** obtained by preparative GLPC were identical with those in the literature.[2,3] Another fraction gave 15 mg of **7**, the spectral data of which were identical with those of the sample prepared above.

(3E,5Z)-3,5-Tetradecadienoic Acid (1). A mixture of 20 mg (0.084 mmol) of **9** purified by preparative GLPC and 0.3 ml of 0.9 M KOH in 90% MeOH was stirred at 25 °C for 5 h, and poured into cooled water. The mixture was acidified with 10% HCl, and the organic layer extracted with ether. The combined ethereal layers were washed with water and dried over $MgSO_4$. Removal of the solvent gave 17 mg (89%) of **1** as a viscous oil. IR and ^1H NMR data were identical with those of the authentic sample.[1]

Catalytic Epoxidation of Cyclohexene with *t*-Butyl Hydroperoxide in the Presence of Various Molybdenum Complexes

Masashi YAMAZAKI,† Hidetoshi ENDO,† Masato TOMOYAMA,† and Yasuhiko KURUSU*

(Received March 1, 1983)

Synopsis. A ligand can play an important role in the activity of the molybdenum-catalyzed epoxidation. Molybdenum complex was changed to the reactive intermediate through the reaction of catalyst with *t*-BuOOH. Oxalate, edta, and phenoxyl groups were selected as ligands. The phenoxyl group was most effective for the epoxidation. This effect was interpreted by the HSAB concept.

Epoxidations of olefins with hydroperoxide in the presence of molybdenum(VI) or (V) complexes have been reported by Trifilo *et al.*,[1] Sheldon,[2] and Gould *et al.*[3] Also, Henry presented a review about molybdenum compounds for epoxidation with hydroperoxide.[4]

Ziolkowski presented the oxalatomolybdenum(V) complex as a catalyst for epoxidation.[5] Mitchell[6] and Komura *et al.*[7] reported the properties and reactivity of oxalatomolybdenum(V) complexes. Ziolkowski *et al.* used oxalic, malonic, succinic, glutaric, adipic, oxoacid, water, pyridine, and anionites containing $-N(CH_3)_2$ and $-\overset{+}{N}(CH_3)_3\bar{Cl}$ groups as the ligands of the complex mentioned above.[8,9] In this paper, we report the relation between the reactivity and the ligand in case of epoxidation with molybdenum complexes.

1 was obtained in the usual way.[8] An exchange reaction of the ligand of oxalatomolybdenum(V) complex was carried out by the method reported by Komura and co-workers.[7] Epoxidation of cyclohexene with *t*-BuOOH was carried out in the presence of materials **1**—**8**. The reaction proceeded according to the reported scheme by Ziolkowski and Sobczak.[8,9] The results are shown in Table 1. Hydrazinium ion is more reactive than barium ion, proton, or pyridinium ion in the cationic ligands used in our experiments. Also, the complex with pyridine as the inner ligand shows higher reactivity. An induction period was observed in this case, since the formation of active intermediate was promoted by the reaction of *t*-BuOOH with oxalato complexes. The UV-spectrum of *t*-BuOOH and complex in benzene is shown in Fig. 1(a), where the absorption band is shown at 370 nm after 60 min. The time dependency of the spectrum of *t*-BuOOH–$H_2[Mo_2O_4(C_2O_4)_2(H_2O)_2]$ system is shown in Fig. 1(b). The maximum band was observed after 40 min. The formation of the reactive intermediate was inferred from Fig. 1(b).

Trifiro and co-workers reported the formation of the intermediate in the epoxidation of olefin with *t*-BuOOH and molybdenum complex.[1] They reported that when the bond between metal and ligand was stable, the activity of epoxidation was low. On the other hand, a weak bond complex was effective for the decomposition of hydroperoxide and the selectivity for epoxide became lower. Since Figs. 1(a) and (b) show that epoxides are obtained after the formation of an intermediate from *t*-BuOOH and molybdenum complex, it is interesting to apply method B[12] for molybdenum complex with ethylendiamintetraacetic acid (H_4edta), which is reported to be a stable compound by Trifiro.[1] The result obtained by method B is better than that obtained method A[12] in Table 2. After *t*-BuOOH and Mo^V–edta complex were allowed to react 4 h, cyclohexene was added to the reaction mixture. In the case of Mo^V–edta complex, pre-reaction of Mo^V–edta complex with *t*-BuOOH improved the reactivity. The high yield of cyclohexene epoxide was obtained at 73 °C. The rate of the epoxidation with Mo^{VI}–edta complex at 73 °C was slower than

TABLE 1. EPOXIDATION OF CYCLOHEXENE WITH *t*-BuOOH BY OXALATO-COMPLEXES

Table 2. Epoxidation by Mo^{V}- and Mo^{VI}-edta complex

Catalyst	Method[a]	Reaction conditions		Cyclohexene conversion/%	Epoxide	
		Time/min	Temp/°C		Selectivity/%	Yield/%
Mo(V)-edta	A	420	74	55.0	88.6	48.7
	B	240	73	74.7	101	83.6
Mo(VI)-edta	A	420	75	39.8	106	43.9

Reaction conditions: cat 0.1 mmol, cyclohexene 50 mmol, *t*-BuOOH 50 mmol, benzene 50 cm³. a) See Ref. 12.

Table 3. Epoxidation of cyclohexene by $Mo_2O_4(OH)_2(pHO)_2$ and $MoO_2(sala)_2$

Catalyst	Temp/°C	Decomp of *t*-BuOOH/%	Yield of epoxide/%	Selectivity/%
Mo-ph	8	18.3	15.7	86
	35	68.3	66.7	98
	44	81.3	76.9	94
$Mo(sala)_2$	10.5	31.0	33.6	100
	20	45.1	45.4	100
	31.5	66.3	55.5	84

Reaction conditions: cyclohexene 3.95 mmol/cm³, *t*-BuOOH 1.05 mmol/cm³, Mo-ph, 0.603 mmol/cm³, Mo-$(sala)_2$ 0.541 mmol/cm³, time 60 min, solv., benzene 25 cm³.

that of Mo^{VI}–edta complex, but the effect of pre-reaction of Mo^{VI}–edta complex with *t*-BuOOH was not observed. The epoxidation with Mo^{VI}–edta complex with *t*-BuOOH was not observed. The epoxidation with Mo^{V}–edta complex was inhibited in a polar solvent (*e.g.* CH_3CN). This may indicate the association of polar species to the active sites of the catalyst.

Ziolkowski proposed that the *t*-BuO–Mo bond participated in epoxidation, and that the coordination of the transition metal complexes for hydroxyl(–OH) or alkoxyl(–OR) oxygen occurred on active site.[13] Also, Sheldon reported that Mo^{VI}–1,2-diol system showed higher reactivity for epoxidation.[14] In order to examine this effect of the RO–Mo bond, di-μ-oxobis[hydroxo(oxo)(phenoxo) molybdenum(VI)] $[Mo_2O_4(OH)_2(phO)_2]$ and dioxobis[salicylaldehydatomolybdenum(VI)] $[MoO_2(sala)_2]$ were applied for the epoxidation of cyclohexene. The results are summarized in Table 2. In each case, selectivity and yield are higher than in other cases. The activation energy was calculated from the initial rates and at various reaction temperature (Table 3). $[Mo_2O_4(OH)_2(phO)_2]$ and $[MoO_2(sala)_2]$ were the most reactive catalysts, compared with the other catalysts cited in Table 3. The alkoxyl group is a hard base and the phenyl group is a soft base. Our information suggests that the phenoxyl group is a soft base and that MoO^{3+} is a hard acid.[10] So, it would be understandable that the interaction of Mo–Oph with *t*-BuOOH is most effective for the occurrence of an electrophilic hydroxyl group.

Experimental

Synthesis of Oxalate Complexes. $Ba[Mo_2O_4(C_2O_4)_2(H_2O)_2]\cdot 3H_2O$ (**1**), $H_2[Mo_2O_4(C_2O_4)(OH)_2(H_2O)_2]\cdot H_2O$ (**2**), $H_2[Mo_2O_4(C_2O_4)_2(py)_2]$ (**3**), $(pyH)_2[Mo_2O_4(C_2O_4)_2(H_2O)_2]\cdot 2H_2O$ (**4**), $(pyH)_2[Mo_2O_4(C_2O_4)_2(py)_2]$ (**5**), $Ba[Mo_2O_4(C_2O_4)_2(py)_2]\cdot 8H_2O$ (**6**), $HH_2NNH_3[Mo_2O_4(C_2O_4)_2(H_2O)_2]\cdot 2H_2O$ (**7**), $H_2[Mo_2O_4(C_2O_4)_2(H_2O)_2]\cdot 3H_2O$. These compounds were synthesized by the methods of Mitchell,[6] Komura,[7] and Ziolkowski.[8]

Di-μ-oxobis[oxohydroxydiphenoxymolybdate(VI)] $[Mo_2O_4(OH)_2phO_2]$, Dioxobis[salicylaldehydatomolybdenum(VI)] $[MoO_2(sala)_2]$: these compounds were synthesized in the usual way.

Table 4. Activation energy of the epoxidation with various Mo compound

Catalyst	Substrate	Solvent	E_a/kJ mol^{-1}
Mo-Powder	Cyclohexene	Cyclohexane	100.5[e]
Mo-y[a]	Cyclohexene	Cyclohexane	44.0[d]

(Received March 11, 1983)

Synopsis. By oxidation with molecular oxygen, photoadducts **2** of 1-(4-methoxyphenyl)-1a-phenyl-1a,7a-dihydro-1*H*-naphth[2,3-*b*]azirine-2,7-dione with olefins afforded cation radicals of **2** in acidic media such as CF_3CO_2H or $HClO_4$. On irradiation, the cation radicals gave ring enlarged isomers 10,11-bis(methoxycarbonyl)-1-phenyl-3,4-benzo-7,8-(3′-methoxybenzo)-9-azabicyclo[4.3.2]undec-3,7-diene-2,5-dione (**3**).

Photochemical reactions of cation radicals derived from title compound **2a** and its analogues were investigated. The substrate **2a** is a photoproduct of 1-(4-methoxyphenyl)-1a,7a-dihydro-1*H*-naphth[2,3-*b*]azirine-2,7-dione (**1**) and dimethyl fumarate.[1] The compound **2a** was inert photochemically in a neutral solvent,[1,7] but under aerated conditions in an acidic medium it produced immediately the cation radical. Upon irradiation the cation radical showed a ring enlargement reaction of a novel type unknown so far.

Results and Discussion

Immediately after yellow crystals of **2a** (160 mg) were dissolved into 20 ml of 70% $HClO_4$ or trifloroacetic acid the solution became purple coloured and the purple solution showed a strong ESR signal at $g=2.0032$ (Fig. 1). The radical species had a life time of several days at 0 °C. Under deaerated conditions neither purple colour nor ESR signal was observed in the solution. Upon exposure of the solution to air, the purple coloured radical showing ESR signal gradually appeared (Fig. 2). Accordingly, oxygen is responsible for the formation of purple coloured radicals. In a neutral air saturated solvent such as acetonitrile or benzene, **2a**—**i** did not afford the purple coloured radical.

The same purple coloured radicals were produced by electrolysis of **2a** in an acetonitrile solution containing 20 mM (1 M=1 mol dm^{-3}) of triethylammonium perchlorate or in trifluoroacetic acid containing 0.1 M of sodium acetate at platinum anode. (The half wave potentials of **2** were tabulated in Table 1). Consequently, the purple coloured radicals are undoubtedly cation radicals of **2**.

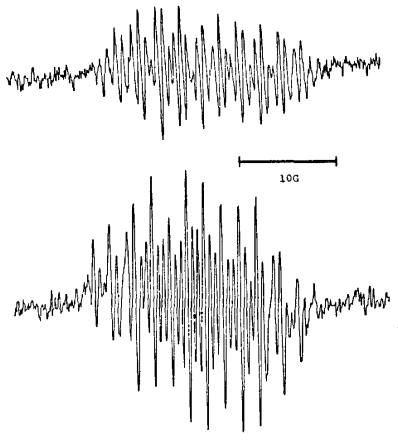

Fig. 1. ESR spectra of the cation radical of **2a** (upper) and **2b** (lower) in air saturated trifluoroacetic acid.

The reason why the cation radical could not be afforded in neutral solvents might be explained in terms of the pH dependence of oxidation reduction potential of oxygen. In acetonitrile the dominant reductive reaction of oxygen is

$$O_2 + e^- \rightleftharpoons O_2^-, \quad (1)$$

and the potential is −0.55 V (*vs.* normal hydrogen electrode (NHE)).[2] Thus produced super oxide anion affords hydrogen peroxide in a protic solvent.[3] In a strong acid such as 85% orthophosphoric acid, the domiannt reaction is reported to be

$$O_2 + 6H^+ + 4e^- \longrightarrow 2H_3O^+, \quad (2)$$

and the potential is +1.2 V (*vs.* NHE).[4] The potential difference between oxygen and **2a** can be calculated to be −1.50 V in acetonitrile and −0.14 V in trifluoroacetic acid.

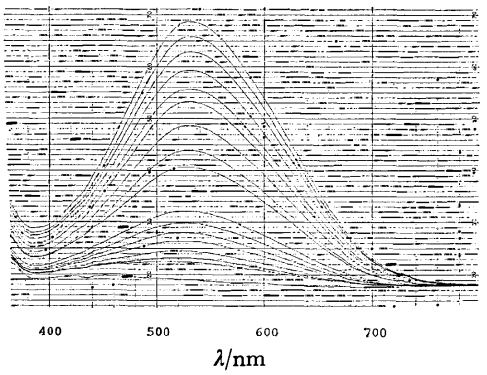

Fig. 2. Time dependent UV absorption change of **2a** in trifluoroacetic acid. Time interval is 5 min.

TABLE 1. STABLE CATION RADICALS

				Generated by oxygen[a]		Half wave potentials/V[b]

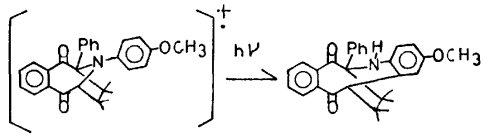
a) Oxidized in CF_3CO_2H. b) Determined by cyclic voltammetry using Ag^+/Ag as a reference electrode, and then converted to those *vs.* NHE by using $E^\circ(Ag^+/Ag) = 0.2225$ V. c) E=CO_2CH_3. d) Irreversible. e) The cation radical was not observed.

Table 2. Photoreaction of cation radical of **2**



3

	Yield %	Mp θ_m/C°	Characteristic ^{1}H-NMR chemical shift of **3** (δ)
2a	21	237—239.5	3.06(s, 3H), 3.41(s, 3H), 3.64(s, 3H)
2b	0		
2c	34	Oil	2.96(s, 3H), 3.59(s, 3H)
2d	20	Oil	3.60(s, 3H)

fluoroacetic acid based on the assumption that the reduction potential of oxygen in trifluoroacetic acid is the same as that in 85% orthophosphoric acid. Thus, the electron transfer from **2** to oxygen is far more favourable in the acidic media than in the neutral solvent.[5]

Further, photochemical reactions of cation radicals of **2** were investigated. As a typical example, **2a** (160 mg) was dissolved into 20 ml of 70% $HClO_4$ and irradiated for 30 h at 0 °C with light of longer wavelength than 480 nm using a filter (Toshiba VY-48) in order to irradiate only the cation radical. Colourless crystals crystallized out of the solution by irradiation. The remaining solution changed its colour into pale brown. The crystals were collected, and the solution was diluted with 100 ml of water. The colourless solids precipitated was filtered, washed with water, and then dissolved in dichloromethane. The dichloromethane solution was dried with $MgSO_4$ and passed through a short column of alumina using dichloromethane as an eluent. On standing the solution over nights at room temperature (≈25 °C) colourless crystals (mp 237—239.5 °C) were precipitated out. Total yield of the crystals was 21.0%. The remaining was a dark brown tarry matter. The structure of the product was compatible with **3a** depicted in Scheme 1.[8]

Since the HOMO of cation radical of **2a—i** presumably is nitrogen n-orbital and the LUMO might be π^* of *N*-aryl group, an electron at the nitrogen n-orbial may transfer to the π^* of *N*-aryl group on irradiation. As a result the π system of *N*-aryl group is charged in negative and nitrogen is doubly charged in positive. This charge separation is presumably a driving force of the rearrangement.

This type of the photochemical reaction is unique, because the photochemical reaction of cation radical has been scarcely reported.[6]

Experimental

Apparatus. ^{1}H-NMR spectra were recorded on a JEOL PS-100 spectrometer. Mass spectra were recorded on a Hitachi M-52 mass spectrometer. Infrared spectra were taken on a JASCO-402G spectrometer. UV-spectra were taken on a Shimadzu UV-200. Electron spin resonance spectra were taken on a JEOL PE-3X. Elemental analyses were performed at the microanalytical laboratory of Kyoto University. Melting points were measured on a Yanagimoto micro melting point apparatus and uncorrected.

Materials. Compound **1** was prepared from 2-phenyl-1,4-naphthoquinone and 4-methoxyphenylazide as reported previously.[1] Photochemical production of **2** is reported elsewhere.[7] Perchloric acid 70% was purchased from Nakarai Chemicals, LTD., and used without further purification. Trifluoroacetic acid was purchased from Nakarai Chemicals, LTD., and dried over phosphorous pentaoxide and distilled.

Physical Properties of 3. **3a**: ^{1}H-NMR ($CDCl_3$) δ= 3.06(3H, s, CO_2CH_3), 3.41 (3H, s, CO_2CH_3), 3.64 (3H, s, $NC_6H_5OCH_3$), 4.05 (1H, d, J=7 Hz), 4.48 (1H, d, d, J= 7.0, 8.5 Hz), 4.56 (1H, s, NH), 5.09 (1H, d, J=8.5 Hz), 6.54 (2H, d, J=9.0 Hz), 6.88 (1H, d, J=9 Hz), 7.2—8.0 (9H, m); IR (KBr) 3400 (NH), 1732, 1705, 1682 cm^{-1}; MS (16 eV) *m/e* (rel intensity) 501 (M^+; 100). 8) None of **3** was detected when the cation radical solution was left in the dark for a week, but only a dark tarry matter was produced.

The Reaction of Olefins with Malonic Acid in the Presence of Manganese(III) Acetate

Nobuyuki Ito, Hiroshi Nishino, and Kazu Kurosawa*

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860

(Received May 9, 1983)

Synopsis. The reaction of 1,1-diphenylethene with malonic acid in the presence of manganese(III) acetate gave 3,3,8,8-tetraphenyl-2,7-dioxaspiro[4.4]nonane-1,6-dione and 4,4-diphenyl-2-(2,2-diphenylethenyl)-4-butanolide. Similar reactions with 1,1-bis(4-methoxyphenyl)ethene, methylenecyclohexane, 2-phenylpropene, 1-octene, and cyclohexene yielded the corresponding 2,7-dioxaspiro[4.4]nonane-1,6-diones.

The formation of γ-lactone in the reaction of olefins with manganese(III) acetate (MA) in acetic acid (AcOH) has been reported.[1] Similar α-substituted γ-lactone formations have been observed when the reaction was carried out in the presence of propionic acid,[2] cyanoacetic acid, isobutyric acid, and succinic acid.[1] These results led us to examine the reaction of olefins with malonic acid in the presence of MA. When a mixture of 1,1-diphenylethene (**1a**) and malonic acid was oxidized with MA in AcOH, 3,3,8,8-tetraphenyl-2,7-dioxaspiro[4.4]nonane-1,6-dione (**2a**), 4,4-diphenyl-2-(2,2-diphenylethenyl)-4-butanolide (**3**), and benzophenone (**4**) were obtained. 1,1-Bis(4-methoxyphenyl)ethene (**1b**) and methylenecyclohexane (**1c**) gave the corresponding 2,7-dioxaspiro[4.4]nonane-1,6-diones (**2b** and **2c**). The reactions of 2-phenylpropene (**1d**), styrene (**1e**), and 1-octene (**1f**) yielded three isomeric 2,7-dioxaspiro[4.4]nonane-1,6-diones, (**2d'**, **2d''**, **2d'''**), (**2e'**, **2e''**, **2e'''**), and (**2f'**, **2f''**, **2f'''**). Their configurations could be determined on the basis of ^{1}H-NMR spectral analyses. The reaction of cyclohexene (**1g**) with malonic acid in the presence of MA gave cyclohexenyl acetate (**5**) and a mixture of dodecahydro-3,3'(2*H*,2'*H*)-spirobi[benzofuran]-2,2'-diones (**2g'**, **2g''**, and **2g'''**)(27%). In contrast to disubstituted olefins, the reaction of 1,1,2-triphenylethene (**1h**) with malonic acid in the presence of MA gave 1,1,2-triphenyl-1,2-ethanediol 2-acetate (**6**) and 3,4,4-triphenyl-4-butanolide (**7**).

Experimental

Reaction of Olefins with Malonic Acid in the Presence of MA. To a heated solution of olefin (2 mmol) and malonic acid (1 mmol) in AcOH (20 ml), MA[6] (4 mmol) was added. The solution was heated under reflux for 1—5 min. After water (100 ml) being added, the mixture was extracted with chloroform or dichloromethane. The solvent was removed *in vacuo* and the resulting crude product was separated on TLC with chloroform or benzene as the developing solvent, and in the cases of **2f** and **2g** further separation was made by HPLC, eluting with aqueous methanol.

Oxidation Products from 1,1-Diphenylethene[7] *(**1a**). 3,3,8,8-Tetraphenyl-2,7-dioxaspiro[4.4]nonane-1,6-dione (**2a**)*: Colorless needles: mp 284.5—285.0 °C (from benzene); 84% yield; IR ($CHCl_3$) 1770 (C=O) and 1793 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=2.62 (2H, d, J=13.5 Hz, 2×-HCH-), 3.03 (2H, d, J=13.5 Hz, 2×-HCH-), 7.24 (10H, s, 2×Ph), and 7.35 (10H, s, 2×Ph). Found: C, 80.87; H, 5.47%. Calcd for $C_{31}H_{24}O_4$: C, 80.85; H, 5.25%.

*4,4-Diphenyl-2-(2,2-diphenylethenyl)-4-butanolide (**3**)*: Colorless prisms; mp 165—166 °C (methanol); 5% yield; IR ($CHCl_3$) 1772 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=2.66 (1H, dd, J=12.7 and 11.4 Hz, -HCH-), 3.12 (1H, dd, J=7.8 and 12.7 Hz, -HCH-), 3.51 (1H, m, -CH<), 6.62 (1H, d, J=8.8 Hz, =CH-), and 7.01—7.41 (20H, m, 4×Ph). Found: *m/z* 416.17511. Calcd for $C_{30}H_{24}O_2$: M, 416.17763.

*Benzophenone (**4**)*: Colorless plates; mp 47—48 °C (methanol); 1%.

Oxidation Product of 1,1-Bis(4-methoxyphenyl)ethene[8] *(**1b**). 3,3,8,8-Tetrakis(4-methoxyphenyl)-2,7-dioxaspiro[4.4]nonane-1,6-dione (**2b**)*: Amorphous solid (methanol); 84% yield; IR ($CHCl_3$) 1768 (C=O) and 1790 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=2.54 (2H, d, J=13.0 Hz, 2×-HCH-), 2.94 (2H, d, J=13.0 Hz, 2×-HCH-), 3.72 (6H, s, 2×OCH_3), 3.80 (6H, s, 2×OCH_3), and 6.65—7.30 (16H, m, aromatic). Found: *m/z* 580.20720. Calcd for $C_{35}H_{32}O_8$: M, 580.20972.

Oxidation Product of Methylenecyclohexane[9] *(**1c**). 16,19-Dioxatrispiro[5.1.1.5.2.2]nonadecane-17,18-dione (**2c**)*: Colorless plates; mp 165—166 °C (methanol); 27% yield; IR ($CHCl_3$) 1758 (C=O) and 1774 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=1.0—2.4 (20H, 2×-$(CH_2)_5$-), 2.11 (2H, d, J=13 Hz, 2×-HCH-), 2.63 (2H, d, J=13 Hz, 2×-HCH-). Found: *m/z* 292.17128. Calcd for $C_{17}H_{24}O_4$: M, 292.16746.

Oxidation Products from 2-Phenylpropene[10] (**1d**). (3R*, 5R*,8R*)-3,8-Dimethyl-3,8-diphenyl-2,7-dioxaspiro[4.4]nonane-1,6-dione (**2d'**): Colorless needles; mp 162—163 °C (methanol); 10% yield; IR ($CHCl_3$) 1768 (C=O) and 1785 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=1.75 (6H, s, 2×CH_3), 2.17 (2H, d, J=13.4 Hz, 2×-HCH-), 2.68 (2H, d, J=13.4 Hz, 2×-HCH-), 7.14—7.43 (10H, m, 2×Ph); HPLC R_t (retention time)(eluent) 12.6 min (70% aqueous methanol). Found: m/z 336.12992. Calcd for $C_{21}H_{20}O_4$: M, 336.13600.

(3S*,5R*,8S*)-3,8-Dimethyl-3,8-diphenyl-2,7-dioxaspiro[4.4]-nonane-1,6-dione (**2d''**): Colorless needles; mp 218—219 °C (methanol); 19% yield; IR ($CHCl_3$) 1768 (C=O) and 1789 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=1.77 (6H, s, 2×CH_3), 2.72 (2H, d, J=13.4 Hz, 2×-HCH-), 3.24 (2H, d, J=13.4 Hz, 2×-HCH-), and 7.34—7.45 (10H, m, 2×Ph); HPLC R_t 8.3 min (70% aqueous methanol). Found: m/z 336.13550. Calcd for $C_{21}H_{20}O_4$: M, 336.13600.

(3R*,5R*,8S*)-3,8-Dimethyl-3,8-diphenyl-2,7-dioxaspiro[4.4]-nonane-1,6-dione (**2d'''**): Colorless plates; mp 98.5—99.5 °C (methanol); 39% yield; IR ($CHCl_3$) 1768 (C=O) and 1785 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=1.66 (3H, s, CH_3), 1.86 (3H, s, CH_3), 2.08 (1H, d, J=13.2 Hz, -HCH-), 2.79 (1H, d, J=13.5 Hz, -HCH-), 2.83 (1H, d, J=13.2 Hz, -HCH-), 3.20 (1H, d, J=13.5 Hz, -HCH-), 7.32 (5H, m, Ph), and 7.37 (5H, m, Ph); HPLC R_t 10.5 min (70% aqueous methanol). Found: C, 75.19; H, 6.02%. Calcd for $C_{21}H_{20}O_4$: C, 74.98; H, 5.99%.

Oxidation Products from Styrene (**1e**). (3R*,5R*,8R*)-3,8-Diphenyl-2,7-dioxaspiro[4.4]nonane-1,6-dione (**2e'**): Colorless plates; mp 162—163 °C (methanol); 9% yield; IR ($CHCl_3$) 1770 (C=O) and 1788 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=2.23 (2H, dd, J=13.5 and 9.0 Hz, 2×-HCH-), 3.09 (2H, dd, J=13.5 and 6.5 Hz, 2×-HCH-), 5.93 (2H, dd, J=9.0 and 6.5 Hz, 2×-CH<), and 7.33 (10H, s, 2×Ph); HPLC R_t 9.2 min (70% aqueous methanol). Found: m/z 308.10706. Calcd for $C_{19}H_{16}O_4$: M, 308.10486.

(3S*,5R*,8S*)-3,8-Diphenyl-2,7-dioxaspiro[4.4]nonane-1,6-dione (**2e''**): Colorless needles; mp 236—237 °C ($CHCl_3$); 30% yield; IR ($CHCl_3$) 1762 (C=O) and 1782 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=2.87 (2H, m, 2×-HCH-), 2.79 (2H, m, 2×-HCH-), 5.50 (2H, t, J=8.0 Hz, 2×-CH<), and 7.50 (10H, s, 2×Ph); HPLC R_t 6.3 min (70% aqueous methanol). Found: m/z 308.10564. Calcd for $C_{19}H_{16}O_4$: M, 308.10486.

(3R*,5R*,8S*)-3,8-Diphenyl-2,7-dioxaspiro[4.4]nonane-1,6-dione (**2e'''**): Colorless needles; mp 185—186 °C (benzene); 40% yield; IR ($CHCl_3$) 1768 (C=O) and 1786 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=2.15—3.37 (4H, m, 2×-CH_2-), 5.56 (1H, dd, J=10 and 7 Hz, -CH<), 5.86 (1H, dd, J=10 and 6 Hz, -CH<), 7.40 (5H, s, Ph), and 7.42 (5H, s, Ph); HPLC R_t 7.4 min (70% aqueous methanol). Found: C, 74.01; H, 5.23%. Calcd for $C_{19}H_{16}O_2$: C, 74.00; H, 4.99%.

Oxidation Products from 1-Octene (**1f**). (3S*,5R*,8S*)-3,8-Dihexyl-2,7-dioxaspiro[4.4]nonane-1,6-dione (**2f'**): Colorless needless; mp 116.5—118.0 °C (methanol); 4% yield; IR ($CHCl_3$) 1762 (C=O) and 1780 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=0.6—2.1 (26H, m, 2×-C_6H_{13}), 1.88 (2H, dd, J=13 and 9 Hz, 2×-HCH-), 2.75 (2H, dd, J=13 and 6 Hz, 2×-HCH-), 4.5—5.1 (2H, m, 2×-CH<); HPLC R_t 10.0 min (80% aqueous methanol). Found: m/z 324.23226. Calcd for $C_{19}H_{32}O_4$: M, 324.23006.

(3R*,5R*,8R*)-3,8-Dihexyl-2,7-dioxaspiro[4.4]nonane-1,6-dione (**2f''**): Colorless needles; mp 112.5—113.5 °C (methanol); 17% yield; IR ($CHCl_3$) 1762 (C=O) and 1782 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=0.7—2.1 (26H, m, 2×-C_6H_{13}), 2.41 (4H, d, J=8 Hz, 2×-CH_2-), and 4.42 (2H, br. q, J=8 Hz, 2×-CH<); HPLC R_t 6.6 min (80% aqueous methanol). Found: C, 75.53; H, 10.00%. Calcd for $C_{19}H_{32}O_4$: C, 75.34; H, 9.94%.

(3S*,5R*,8R*)-3,8-Dihexyl-2,7-dioxaspiro[4.4]nonane-1,6-dione (**2f'''**): Colorless needles; mp 110—111 °C (methanol); 19% yield; IR ($CHCl_3$) 1762 (C=O) and 1778 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=0.7—2.1 (26H, m, 2×-C_6H_{13}), 1.70—2.95 (4H, m, 2×-CH_2-), and 4.2—5.1 (2H, m, 2×-CH<); HPLC R_t 7.8 min (80% aqueous methanol). Found: m/z 324.23135. Calcd for $C_{19}H_{32}O_4$: M, 324.23006.

Oxidation Products from Cyclohexene (**1g**). (3R*,3aR*,3'aR*,7aR*,7'aR*)-Dodecahydro-3,3'(2H,2'H)-spirobi[benzofuran]-2,2'-dione (**2g'**): Colorless needles; mp 285—286 °C (methanol); IR ($CHCl_3$) 1766 (C=O) and 1792 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=1.10—1.85 (14H, m, 6×-CH_2- and 2×-CH<), 2.29 (2H, br. d, J=13.9 Hz, 2×-CH<), 2.50 (2H, m, $w_{1/2}$=22 Hz, 2×-HCH-), and 4.62 (2H, m, $w_{1/2}$=9 Hz, -OCH<); HPLC R_t 5.6 min (70% aqueous methanol). Found: m/z 264.13606. Calcd for $C_{15}H_{20}O_4$: M, 264.13616.

(3R*,3aS*,3'aR*,7aS*,7'aR*)-Dodecahydro-3,3'(2H,2'H)-spirobi[benzofuran]-2,2'-dione (**2g''**): Colorless needles; mp 190—191 °C (methanol); IR ($CHCl_3$) 1766 (C=O) and 1792 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=1.0—1.8 (13H, m, 6×-CH_2- and -HCH-), 2.20—2.35 (3H, m, 3×-HCH-), 2.50 (2H, m, $w_{1/2}$=24 Hz, 2×-CH<), 4.51 (1H, m, $w_{1/2}$=8 Hz, -OCH<), and 4.84 (1H, m, $w_{1/2}$=8 Hz, -OCH<); HPLC R_t 7.0 min (70% aqueous methanol). Found: m/z 264.13647. Calcd for $C_{15}H_{20}O_4$: M, 264.13616.

Dodecahydro-3,3'-(2H,2'H)-spirobi[benzofuran]-2,2'-dione (**2g'''**) (configuration is unknown): Colorless needles; mp 186—187 °C (methanol); IR ($CHCl_3$) 1770 (C=O) and 1792 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=1.1—2.0 (14H, m, 7×-CH_2-), 2.2—2.5 (3H, m, 2×-HCH- and -CH<), 2.67 (1H, m, $w_{1/2}$=24 Hz, -CH<), 3.99 (1H, m, $w_{1/2}$=27 Hz, -OCH<), and 4.50 (1H, m, $w_{1/2}$=13 Hz, -OCH<); HPLC R_t 6.0 min (70% aqueous methanol). Found: m/z 264.13625. Calcd for $C_{15}H_{20}O_4$: M, 264.13616.

Cyclohexenyl Acetate (**5**): Colorless liquid; 22% yield.

Oxidation Products from 1,1,2-Triphenylethene[11] (**1h**). 1,1,2-Triphenyl-1,2-ethanediol 2-Acetate (**6**): Colorless needles; mp 224.5—225.5 °C (benzene) (lit,[12] mp 217—219 °C); 22% yield; IR ($CHCl_3$) 1736 (OAc) and 3592 cm^{-1} (OH); ^{1}H-NMR ($CDCl_3$) δ=1.93 (3H, s, OAc), 2.27 (1H, s, OH), 6.68 (1H, s, -CH<), and 7.1—7.7 (15H, m, 3×Ph).

3,4,4-Triphenyl-4-butanolide (**7**): Pale yellow needles; mp 96.0—96.5 °C (methanol); 3% yield; IR ($CHCl_3$) 1776 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$) δ=2.75 (1H, dd, J=17 and 5 Hz, -HCH-), 2.93 (1H, dd, J=17 and 7 Hz, -HCH-), 4.46 (1H, dd, J=7 and 5 Hz, -CH<). Found: m/z 314.13397. Calcd for $C_{22}H_{18}O_2$: M, 314.13068.

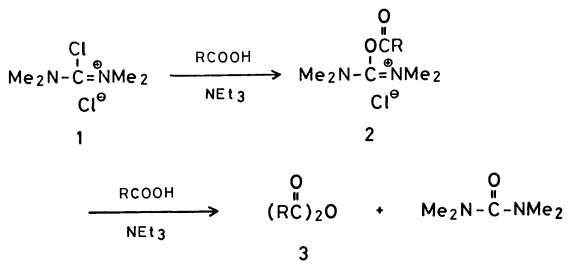
(Received May 9, 1983)

Synopsis. *N,N,N′,N′*-Tetramethylchloroformamidinium chloride reacted smoothly with a variety of carboxylic and phosphoric acids in the presence of a tertiary amine to give the corresponding acid anhydrides in high yields.

Acid anhydrides play an important role in organic syntheses as reactive intermediates, and they react with various nucleophiles such as alcohols,[1] amines,[2] aromatics,[3] and Grignard reagents[4] to give acylated compounds. On the other hand, pyrophosphates, anhydrides of phosphoric acid, are very important in biological activities as an energy source. Although many representative methods for the preparation of acid anhydrides reported so far are performed by the condensation of acids with acid chlorides,[5] one-step synthesis of acid anhydrides from acids requires a long reaction time and an elevated temperature[6] even if condensation reagents were used.[7] We now wish to report that *N,N,N′,N′*-tetramethylchloroformamidinium chloride (**1**) reacted smoothly with various kinds of acids in the presence of a tertiary amine under mild conditions to give the corresponding acid anhydrides in high yields.

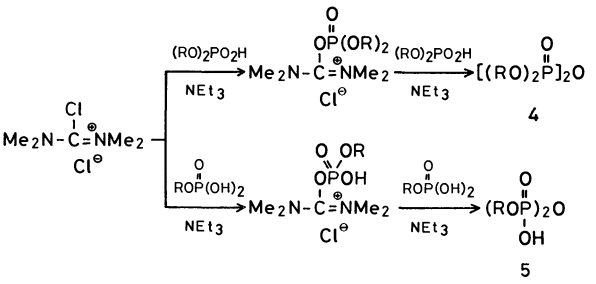
The condensation reagent, *N,N,N′,N′*-tetramethylchloroformamidinium chloride (**1**) is easily available by the reaction of *N,N,N′,N′*-tetramethylurea and oxalyl dichloride.[8] The reaction of the reagent with benzoic acid in dichloromethane was performed at −30 °C in the presence of triethylamine for 3 h, and then the reaction mixture was allowed to warm to 0 °C resulting in the formation of benzoic anhydride in 88% yield. The effect of some bases and solvents was examined in the preparation of benzoic anhydride. The use of triethylamine, tributylamine, and pyridine as a base in dichloromethane gave the anhydride in 88, 85, and 74% yields, respectively. When dichloromethane, chloroform, 1,2-dichloroethane, and acetonitrile were employed as a solvent in the presence of triethylamine, the yields of the anhydride were 88, 89, 87, and 74%, respectively. The reaction can be explained by the nucleophilic attack of the carboxylate anion to the acyloxyformamidium chloride (**2**) initially formed.



Scheme 1.

As shown in Table, aromatic carboxylic acids as well as aliphatic carboxylic acids were easily converted to the corresponding acid anhydrides (**3**) in high yields (runs 1—6), however bulky carboxylic acid and olefinic carboxylic acids required longer reaction time (runs 7—9).

Moreover, the present method was applied to the synthesis of pyrophosphate from mono- or disubstituted phosphates. Although these phosphorus compounds are dissolved well in tertiary amines such as triethylamine, such amines generally decrease the reaction rate in the phosphorylation using dicyclohexylcarbodiimide[9] or 1-imidazoylphosphonate.[10] On the contrary, the present method using *N,N,N′,N′*-tetramethylchloroformamidinium chloride in the presence of triethylamine gave tetraalkyl or tetraaryl pyrophosphates (**4**) in high yields from dialkyl or diaryl hydrogenphosphates under mild conditions and



Scheme 2.

Table 1. Synthesis of acid anhydrides from the corresponding acids

Run	Acid	Reaction temp/°C	Reaction time/h	Product	Yield %
1	Benzoic acid	−30→0	3	**3a**	88
2	4-Methoxybenzoic acid	−30→0	6	**3b**	86
3	1-Naphthoic acid	−30→0	5	**3c**	91
4	2-Furoic acid	−30→0	3	**3d**	84
5	Hexanoic acid	−30→0	5	**3e**	83
6	Cyclohexanecarboxylic acid	−30→0	7	**3f**	81

12	Dibutyl hydrogenphosphate	0→rt	2	**4c**	96
13	Phenyl dihydrogenphosphate	0→rt	18	**5**	61[b]

a) Determined by GLC. b) Isolated as the bis(cyclohexylammonium) salt.

in a short reaction time (runs 10—12). Further, application of the method to the synthesis of diphenyl dihydrogenpyrophosphate (**5**) from phenyl dihydrogenphosphate gave the desired compound, which was isolated as its bis(cyclohexylammonium) salt[11] in a moderate yield (run 13).

In conclusion, *N,N,N′,N′*-tetramethylchloroformamidinium chloride (**1**), which can be easily prepared from readily available tetramethylurea and oxalyl dichloride, is an effective condensation reagent for the one-pot synthesis of acid anhydrides from the corresponding acids in high yields under mild conditions.

Experimental

The ^{1}H NMR and IR spectra were taken with a Varian A-60D spectrometer and a Hitachi EPI-G2 spectrometer, respectively. Gas chromatography was carried out with a Yanaco G-180 chromatographic apparatus, using a ϕ 3 mm × 1 m, 15% SE-30 column. Acid anhydrides and pyrophosphates obtained were identified by comparison of their IR and ^{1}H NMR spectra with those of the respective authentic samples. Authentic samples of **3a**, **3e**, and **3i** were obtained from Nakarai Chem. Ltd., and other chemicals were prepared by reported methods: **3b**,[11] **3c**,[12] **3d**,[13] **3f**,[14] **3g**,[15] **3h**,[16] **4a**,[17] **4b**,[18] **4c**,[18] and **5**.[19]

*N,N,N′,N′-Tetramethylchloroformamidinium Chloride (**1**).* Oxalyl dichloride (0.30 ml, 3.5 mmol) was added into a solution of *N,N,N′,N′*-tetramethylurea (244 mg, 2.1 mmol) in 3 ml of 1,2-dichloroethane at room temperature. The reaction mixture was then stirred for 2 h at 60 °C. After removal of the solvent under a reduced pressure, the faint yellow solid residue was used in the following experiments without further purification.

*General Procedure for the Synthesis of Acid Anhydrides (**3a—c, h**).* *N,N,N′,N′*-Tetramethylchloroformamidinium chloride (2.1 mmol), a carboxylic acid (4.0 mmol), and triethylamine (4.0 mmol) were stirred in 6 ml of dichloromethane at −30 °C for 1 h. This reaction mixture was allowed to warm to 0 °C or room temperature for 2 h and stirred at the same temperature until the reaction completed. This mixture was washed with two 10 ml portions of saturated sodium hydrogencarbonate, dried over anhydrous magnesium sulfate, and concentrated under a reduced pressure. The residue was chromatographed on silica gel to give acid anhydride (**3a—c, h**).

*General Procedure for the Synthesis of Acid Anhydrides (**3d—f, i**).* *N,N,N′,N′*-Tetramethylchloroformamidinium chloride (2.1 mmol), a carboxylic acid (4.0 mmol), and triethylamine (4.0 mmol) were stirred in 6 ml of dichloromethane at −30 °C for 1 h. This reaction mixture was allowed to warm to 0 °C or room temperature for 2 h and stirred at the same temperature until the reaction completed. After removal of the solvent under a reduced pressure, a 5 ml portion of ether was added to the residue, and the mixture was filtered under argon. The residue was washed with three 3 ml portions of ether, and the combined filtrate was distilled under a reduced pressure (Kugelrohr apparatus). Bp: **3d**; 200 °C/20 mmHg, **3e**; 200 °C/20 mmHg, **3f**; 200 °C/0.3 mmHg, **3g**; 150 °C/20 mmHg, and **3i**; 200 °C/20 mmHg.

*General Procedure for the Synthesis of Pyrophosphate (**4a—c**).* *N,N,N′,N′*-Tetramethylchloroformamidinium chloride (2.1 mmol), a phosphate (4.0 mmol), and triethylamine (4.0 mmol) were stirred in 6 ml of dichloromethane at 0 °C for 1 h and further at room temperature for 2 h. After removal of the solvent under a reduced pressure, a 5 ml portion of ether was added to the residue and the mixture was filtered under argon. The residue was washed with three 3 ml portions of ether, and the combined filtrate was distilled under a reduced pressure (Kugelrohr apparatus). Bp: **4a**; 250 °C/0.3 mmHg, **4b**; 200 °C/0.3 mmHg, and **4c**; 250 °C/0.4 mmHg.

*Synthesis of Diphenyl Dihydrogenpyrophosphate (**5**) Isolated as the Bis(cyclohexylammonium) Salt.* *N,N,N′,N′*-Tetramethylchloroformamidinium chloride (2.1 mmol), phenyl dihydrogenphosphate (696 mg, 4.0 mmol), and triethylamine (409 mg, 4.0 mmol) were stirred in 6 ml of dichloromethane at 0 °C for 1 h and stirred at room temperature for 12 h. After removal of the solvent, 30 ml of water and a sufficient amount of sodium hydrogencarbonate were added to the residue to neutralize the acidic solution. To the solution was added aqueous cyclohexylamine (812 mg, 8.2 mmol) and the solution set aside at 0 °C. Bis(cyclohexylammonium) diphenyl pyrophosphate was separated and recrystallized from water as colorless needles (640 mg, 61%); mp 250—254 °C (lit,[19] mp 250—255 °C).

Partial financial support of this research by the Asahi Glass Foundation is greatly acknowledged.

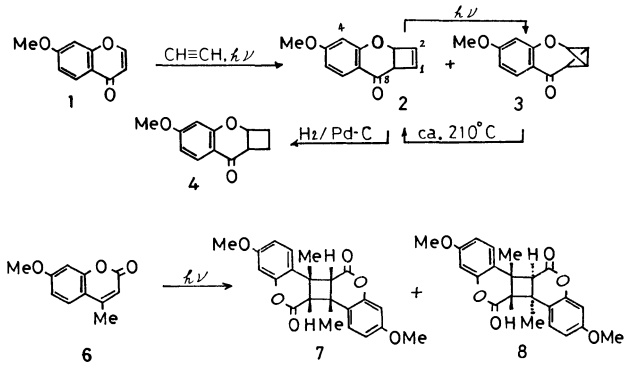
(Received May 16, 1983)

Synopsis. 7-Methoxychromone reacts photochemically with acetylene to form 5-methoxy-2a,8a-dihydro-8*H*-benzo[*b*]cyclobuta[*e*]pyran-8-one and its valence isomer. Photoaddition of acetylene to 6-methoxychromone and 7-methoxy-4-methylcoumarin did not proceed, but the latter underwent photodimerization to give the head-to-tail dimers.

In approach to the synthesis of trichothecane sesquiterpenes, we have reported that photochemical cycloaddition of α,β-unsaturated carbonyl compounds, such as 4a,5,6,7,8,8a-hexahydro-4a-methoxycarbonyl-7,7-ethylenedioxy-4-methylcoumarin with acetylene produced the 3,4-fused cyclobutene ring system in 62% yield, which was led to construct the five-menbered ring of trichothecane nucleus.[2] Our extensive interest is present in preparation of cyclobutene and cyclobutane skeleton from photochemical cycloaddition reaction of benzopyrones with several olefins, and in the development of construction of trichothecanes and trichothecane-like compounds *via* procedure containing the acid-catalysed rearrangement of the strained component. This paper describes preparation of the cyclobutane derivatives, acetylene adducts from 7-methoxychromone and coumarin dimers from 7-methoxy-4-methylcoumarin by photochemical cycloaddition,[3] respectively.

Irradiation of a solution of 7-methoxychromone (**1**) in acetone with bubbling introduction of acetylene using a 500-W high pressure mercury lamp through a Pyrex filter afforded 5-methoxy-2a,8a-dihydro-8*H*-benzo[*b*]cyclobuta[*e*]pyran-8-one (**2**) in 35% yield and its valence isomer, bicyclobutane (**3**) in 10% yield. These structures can be interpreted on the basis of the NMR spectral characteristics: for **2** ^{1}H-NMR signals of the two methine protons at δ 3.97 and 5.32 (each d, J=3 Hz) and the two olefin protons at 6.23 and 6.33 (each d, J=2 Hz), and ^{13}C-NMR signals at δ 54.8, 73.9, 140.0, and 140.7 due to C_{8a}, C_{2a}, C_1, and C_2 respectively, indicated the formation of cyclobutene ring system involving the 2,3-positions of the chromone and the formation of bicyclo[1.1.0]butane moiety in **3** was indicated by the ^{1}H-NMR signals due to the four methine protons at δ 2.51 (2H, t, J=3 Hz), 3.70—3.87 (1H, m), and 5.66 (1H, dt, J=2, 4 Hz), which were compatible with those of the bicyclobutane compound reported by Murata *et al.*[4] The gross structures of **2** and **3** were also supported by the mass spectrum, both of which showed intense peak at m/z 202 just to M^+.

Catalytic hydrogenation of **2** over Pd–C in ethanol yielded the cyclobutane derivative (**4**) in 72% yield. The confirmation of a cyclobutane ring in **4** was provided from the NMR spectra (the data are given in Experimental). Furthermore, we tried the isomerization between valence isomers **2** and **3** as follows.[5]



When a solution of **2** in acetone was irradiated, **3** was obtained in 33% yield. However, irradiation of **3** in acetone led to recovery of the starting material. Whereas the thermal reaction of **3** at 205—210 °C for 10 min gave **2** (26% yield) along with starting material.

In contrast to the photochemical activity of **1** with acetylene, neither 6-methoxychromone (**5**) nor 7-methoxy-4-methylcoumarin (**6**) was reactive toward acetylene. Consequently, **5** was almost recovered in the photochemical reaction. On the other hand, **6** dimerized upon direct irradiation in methanol to give the head-to-tail dimers, **7** (45% yield) and **8** (25% yield). Upon benzophenone-sensitized irradiation in benzene, **8** was prepared in 90—92% yield. There are two possible cycloutane photodimers of 4-methylcoumarin having the *syn* and *anti* head-to-tail configuration.[6] The assignment of *syn* and *anti* isomers were made on the basis of a NMR diamagnetic shielding effect, indicating that dimer **7** with the more highly shielded aromatic protons (δ 6.04, 6.66, and 7.10 for **7** and 6.70, 6.84, and 7.14 for **8**) has the *syn* configuration and dimer **8** with the more highly shielded methyl protons (δ 1.66 for **7** and 1.26 for **8**) corresponds to the *anti* configuration.[7]

Presently, the work is under the investigation of the acid-catalysed transformation of all synthetic cyclobutanes described here and their functionalized compounds in order to construct the five-menbered ring of trichothecane analogues.

Experimental

Melting points are uncorrected. IR spectra were measured in $CHCl_3$ with a Hitachi 260-50 spectrophotometer. ^{1}H-NMR and ^{13}C-NMR spectral data were obtained in $CDCl_3$ on a JEOL JNM MH-100 spectrometer (100 MHz) and a JEOL JNM-FX 60 Fourier transform spectrometer (60 MHz) operating at 15.1 MHz, respectively. Chemical shifts are reported in δ values downfield from TMS as an internal standard. Mass spectra were obtained on a JEOL JMS-D 300S spectrometer. All irradiations were performed

with a 500-W high pressure mercury lamp (Eikosha EHB-WI-500). Column chromatography was performed with Merck silica gel (0.063 mm).

Photoaddition of Acetylene to 7-Methoxychromone (1). A solution of **1** (550 mg) in acetone (400 ml) was irradiated through a Pyrex filter at 25—30 °C with bubbling introduction of acetylene for 5 h. After removal of the solvent under reduced pressure, the residue was subjected to column chromatography on silica gel using ethyl acetate–benzene (1:19) as eluent to give mainly three products, unidentified oil (*ca.* 30 mg), **3** (64 mg), **2** (220 mg), and **1** (160 mg) in the order of elution. **2**: Mp 96—97 °C (acetone–hexane); IR: 1665, 1615, and 1580 cm^{-1}; ^{1}H-NMR: 3.82 (3H, s, OCH_3), 3.97(1H, d, J=3 Hz, C_{8a}–H), 5.32(1H, d, J=3 Hz, C_{2a}–H), 6.23 (1H, d, J=2 Hz, C_1–H), 6.33 (2H, d, J=2 Hz, C_2– and C_4–H), 6.54 (1H, dd, J=2 and 11 Hz, C_6–H), and 7.81 (1H, d, J=11 Hz, C_7–H); ^{13}C-NMR: 54.8 (d, C_{8a}), 55.6 (q, OCH_3), 73.9 (d, C_{2a}), 101.4 (d, C_4), 110.2 (d, C_6), 112.4 (s, C_{7a}), 129.6 (d, C_7), 140.0 and 140.7 (each d, C_1 and C_2), 160.7 (s, C_{4a}), 166.3 (s, C_5), and 192.4 (s, C_8); MS: m/z 202 (M^+); Found: C, 71.27; H, 4.95%. Calcd for $C_{12}H_{10}O_3$: C, 71.28; H, 4.99%. **3**: Mp 66—68 °C (acetone–hexane); IR: 1660, 1610, and 1575 cm^{-1}; ^{1}H-NMR: 2.51 (2H, t, J=3 Hz, C_1– and C_2–H), 3.70—3.87 (1H, m, C_{8a}–H, overlapped with methoxyl peak), 3.87 (3H, s, OCH_3), 5.66 (1H, dt, J=2 and 4 Hz, C_{2a}–H), 6.43 (1H, d, J=3 Hz, C_4–H), 6.60 (1H, dd, J=3 and 9 Hz, C_6–H), and 8.00 (1H, d, J=9 Hz, C_7–H); ^{13}C-NMR: 15.6 (d, C_1 and C_2), 55.6 (q, OCH_3), 59.3 (d, C_{8a}), 85.8 (d, C_{2a}), 103.3 (d, C_4), 109.4 (d, C_6), 116.8 (s, C_{7a}), 132.6 (d, C_7), 157.4 (s, C_{4a}), 164.9 (s, C_5), and 200.9 (s, C_8); MS: m/z 202 (M^+); Found: C, 71.35; H, 4.93%. Calcd for $C_{12}H_{10}O_3$: C, 71.28; H, 4.99%.

Conversion between 2 and 3. a): A solution of **2** (100 mg) in acetone (300 ml) was irradiated at room temperature for 2 h through a Pyrex filter. Evaporation of the solvent, followed by silica-gel column chromatography of the residual oil gave **2** (12 mg) and **3** (33 mg).

b): 100 mg of **3** was prepared in a round bottom flask and heated at 205—210 °C for 10 min. This thermal reaction showed that a mixture of **2** (26 mg) and **3** (41 mg) was contained after separation by column chromatography on silica gel.

Hydrogenation of 2. A mixture of **2** (187 mg) and 5% Pd–C (50 mg) in ethanol (20 ml) was treated with H_2 at room temperature until equimolar H_2 was consumed. The mixture was filtered and concentrated *in vacuo*. Chromatographic separation of the residue through silica-gel coloumn eluting with benzene afforded **4** (128 mg, 72% yield) as colorless oil. IR: 1660, 1605, and 1570 cm^{-1}; ^{1}H-NMR: 1.88—2.78 (4H, m, 2 $-CH_2-$), 3.15—3.39 (1H, m, $-\overset{|}{C}OCH-$), 5.06 (1H, dd, J=8 and 16 Hz, $-O\overset{|}{C}H-$), 6.33 (1H, d, J=3 Hz, C_4–H), 6.56 (1H, dd, J=3 and 8 Hz, C_6–H), and 7.89 (1H, d, J=8 Hz, C_7–H); ^{13}C-NMR: 20.8 and 28.6 (each t, C_1 and C_2), 45.4 (d, C_{8a}), 55.5 (q, OCH_3), 72.5 (d, C_{2a}), 101.2 (d, C_4), 109.8 (d, C_6), 113.8 (s, C_{7a}), 128.9 (d, C_7), 161.5 (s, C_{4a}), 166.3 (s, C_5), and 193.1 (s, C_8); MS: m/z 204 (M^+); Found: C, 70.28; H, 5.94%. Calcd for $C_{12}H_{12}O_3$: C, 70.57; H, 5.92%.

Photoaddition of 7-Methoxy-4-methylcoumarin (6). a) In Methanol: A solution of **6** (300 mg) in methanol (500 ml) was irradiated at room temperature for 5 h through a Pyrex filter with introduction of acetylene. Usual work-up gave 480 mg of crude solid, which was taken up in a small amount of ethyl acetate and the insoluble material was filtered off, followed to recrystallization from acetone to give dimer **8** in 25% yield; mp 199—201 °C; IR: 1765, 1625, and 1585 cm^{-1}; ^{1}H-NMR: 1.26 (6H, s, 2 CH_3), 3.39 (2H, s, 2 $-\overset{|}{C}H-$), 3.87 (6H, s, 2 OCH_3), 6.70, 6.84, and 7.14 (each 2H, d, J=3 Hz, dd, J=3 and 9 Hz, and d, J=9 Hz, aromatic protons); MS: m/z 380 (M^+); Found: C, 69.27; H, 5.16%. Calcd for $C_{22}H_{20}O_6$: C, 69.46; H, 5.30%. The filtrate was concentrated in a rotary evaporator to afford **7** as a solid, which was further purified by column chromatography on silica gel with ethyl acetate–benzene (1:19), 140 mg (45% yield); mp 226—227 °C (methanol); IR: 1750, 1625, and 1585 cm^{-1}; ^{1}H-NMR: 1.66 (6H, s, 2 CH_3), 3.40 (2H, s, 2 $-\overset{|}{C}H-$), 3.65 (6H, s, 2 OCH_3), 6.04, 6.66, and 7.10 (each 2H, d, J=3 Hz, dd, J=3 and 9 Hz, and d, J=9 Hz, aromatic protons); MS: m/z 380 (M^+); Found: C, 69.21; H, 5.26%. Calcd for $C_{22}H_{20}O_6$: C, 69.46; H, 5.30%.

b) In Benzene with Benzophenone: Irradiation of a solution containing **6** (500 mg) and benzophenone (96 mg) in 300 ml of benzene with acetylene through a Pyrex filter at room temperature for 6 h, followed by chromatographic work-up on silica gel afforded **8** in 92% yield. However, the photoreaction by using conditions similar to those described above, changing reaction time, temperature, and solvent did not lead to yields of cycloadducts of acetylene to **6**.

(Received May 16, 1983)

Synopsis. (1 - Alkyl - 2 - hydroxyethyl)diphenylphosphine oxides were synthesized from the corresponding (1-alkyl-2-oxoethyl)diphenylphosphine oxides in excellent yields. The structures of 2-hydroxy derivatives and their acetates were confirmed by elemental and spectral analyses.

We have recently reported the synthesis of diphenylphospine oxide derivatives having a nitro group on the β-carbon atom of phosphorus, *i.e.*, (1-alkyl-2-nitroethyl)diphenylphosphine oxides, and the conversion of the nitro compound into the aldehyde compound by oxidation with ozone/methoxide method.[1,2] The present note deals with a convenient method for the synthesis of (1-alkyl-2-hydroxyethyl)diphenylphosphine oxides,[3,4] which have the partial structure of a phosphorus-sugar derivative, from (1-alkyl-2-oxoethyl)diphenylphosphine oxides by reduction with sodium tetrahydridoborate, and their conversion into the acetates.

Results and Discussion

Aldehydes 1, which were prepared from (1-alkyl-2-nitroethyl)diphenylphosphine oxides,[2] were transformed into 2-hydroxyethyl compounds **2** in excellent yields by treatment with sodium tetrahydridoborate in methanol under reflux as shown in Table 1.[5] Compounds **2** were characterized by microanalysis, IR, ^{1}H NMR, and MS.

$$\underset{\mathbf{1}}{Ph_2\overset{O}{\overset{\|}{P}}\text{-}\overset{R}{\overset{|}{C}}H\text{-}CH{=}O} \xrightarrow{NaBH_4/MeOH} \underset{\mathbf{2}}{Ph_2\overset{O}{\overset{\|}{P}}\text{-}\overset{R}{\overset{|}{C}}H\text{-}CH_2OH}$$

Yields of (2-hydroxyethyl)diphenylphosphine oxide derivatives were 31—81%[3] and 69—85%[4] in the reaction of lithium derivative of methyldiphenylphosphine oxide derivatives with carbonyl compounds such as aldehydes and ketones. 2-Hydroxyethylphosphonates were previously synthesized from vinylphosphonates by hydroboration in 50—65% yields.[6] Therefore, the present method is an improved one in preparation of phosphorus derivatives having a hydroxy group on the β-carbon atom.

2-Hydroxyethyl compounds **2** were acetylated in excellent yield with acetic anhydride in pyridine at room temperature.[7]

The structure of acetates **3** were determined by microanalysis, IR, ^{1}H NMR, and MS. The produced derivatives **3** clearly reconfirmed the structure of compounds **2**.

$$\mathbf{2} \xrightarrow{Ac_2O/Pyridine} \underset{\mathbf{3}}{Ph_2\overset{O}{\overset{\|}{P}}\text{-}\overset{R}{\overset{|}{C}}H\text{-}CH_2OAc}$$

The high yield and simple operation in preparation of (1-alkyl-2-hydroxyethyl)diphenylphosphine oxides show that the method provides a convenient preparative way to afford phosphorus compounds possessing a 2-hydroxyethyl group. This procedure will provide a new route to synthesize phosphorus-sugars.

Experimental

Apparatus. IR spectra were measured by a JASCO A-3 spectrophotometer. ^{1}H NMR spectra were run on a Hitachi R-20 (60 MHz) spectrometer. MS spectra were measured by a Hitachi RMU DMG GC-MS spectrometer. Liquid chromatography was carried out using a Toyo Scientific Industry UVICON-540M.

Materials. (1 - Alkyl - 2 - oxoethyl)diphenylphosphine oxides were prepared from (1-alkyl-2-nitroethyl)diphenylphosphine oxides.[2] Pyridine and acetic anhydride were purified before use.

*Synthesis of (2-Hydroxy-1-methylethyl)diphenylphosphine Oxide (**2a**, R=Me).* To a solution of (2-oxo-1-methylethyl)-diphenylphosphine oxide (**1a**, R=Me; 0.415 g, 1.6 mmol) in anhydrous methanol (25 ml) was added sodium tetrahydridoborate (0.612 g, 16 mmol) at room temperature, then the solution was refluxed for 16 h. A small amount of water was added to the reaction mixture and then it was refluxed for further 30 min. After the solution was neutralized with acetic acid, the solvent was removed off by a rotary evaporator and the residue was taken up into chloroform (40 ml). The chloroform solution was washed with water (20 ml×2) and dried over anhydrous sodium sulfate. Evaporation of the solvent *in vacuo* and recrystallization of the product from chloroform–cyclohexane gave (2-hydroxy-1-methylethyl)diphenylphosphine oxide (**2a**, 0.418 g) in 82% yield, mp 141—142 °C. ^{1}H NMR ($CDCl_3$) δ 1.22 (dd, J_{HH}=7.0 Hz, J_{HP}=16.0 Hz, CH_3), 2.4—3.0 (m, 1H, CH), 3.83 (dd, 2H, J_{HH}=5.0 Hz, J_{HP}=13.0 Hz, CH_2), 4.46 (s, 1H, OH), and 7.3—8.0 (m, 10H, Ph); IR ν_{max}^{KBr} 3200 cm^{-1} (OH); MS *m/e* 260 (M^+). Found: C, 68.96; H, 6.34%. Calcd for $C_{15}H_{17}O_2P$: C, 69.22; H, 6.58%. Found: *m/e* 260.0970. Calcd for $C_{15}H_{17}O_2P$: 260.0966.

*Synthesis of [1-(Hydroxymethyl)propyl]diphenylphosphine Oxide (**2b**, R=Et).* Treatment of a solution of **1b** (R=Et, 0.738 g, 2.71 mmol) in anhydrous methanol (25 ml) with sodium tetrahydridoborate (1.03 g, 27.1 mmol) followed by work-up and recrystallization from chloroform–cyclohexane gave product **2b** (0.660 g) in 89% yield, mp 105—106 °C. ^{1}H NMR ($CDCl_3$) δ 0.97 (t, 3H, J_{HH}=7.0 Hz, CH_3), 1.4—2.0 (m, 2H, J_{HH}=7.0 Hz, $CH_3C\underline{H}_2$), 2.1—2.7 (m, 1H, CH), 3.94 (dd, 2H, J_{HH}=5.0 Hz, J_{HP}=18.0 Hz, $C\underline{H}_2OH$), 5.77 (s, 1H, OH), and 7.4—8.1 (m, 10H, Ph); IR ν_{max}^{KBr} 3300 cm^{-1} (OH); MS *m/e* 274 (M^+). Found: C, 70.02; H, 6.93%. Calcd for $C_{16}H_{19}O_2P$: C, 70.06; H, 6.98%. Found: *m/e* 274.1138. Calcd for $C_{16}H_{19}O_2P$: 274.1123.

[1 - (Hydroxymethyl) - 2 - methylpropyl]diphenylphosphine oxide (**2c**, R=*i*-Pr) and (2-hydroxy-1-phenylethyl)diphenylphosphine oxide (**2d**, R=Ph) were synthesized by an analogous method mentioned above in 92 and 63% yields, respectively.

a) Satisfactory micro and milimass analyses were obtained.

*Synthesis of (2-Acetoxy-1-methylethyl)diphenylphosphine Oxide (**3a**, R=Me).* To a solution of **2a** (0.290 g, 1.1 mmol) in anhydrous pyridine (5 ml) was added acetic anhydride (3 ml), and the solution was stood for 24 h at room temperature. The reaction mixture was taken up into chloroform (40 ml). The extract was washed with water (20 ml×2) and was dried over anhydrous sodium sulfate. Evaporation of the solvent *in vacuo* and recrystallization of the product from carbon tetrachloride–cyclohexane gave **3a** (0.335 g) in 99% yield, mp 133—134 °C. ^{1}H NMR ($CDCl_3$) δ 1.22 (dd, 3H, J_{HH}=7.0 Hz, J_{HP}=16.0 Hz, CH_3), 1.79 (s, 3H, CH_3CO), 2.7—3.2 (m, 1H, J_{HH}=7.0 Hz, CH), 4.1—4.52 (m, 2H, CH_2), and 7.3—8.1 (m, 10H, Ph); IR ν_{max}^{KBr} 1740 cm^{-1} (CO); MS *m/e* 302 (M^+). Found: C, 67.47; H, 6.17%. Calcd for $C_{17}H_{19}O_3P$: C, 67.54; H, 6.33%. Found: *m/e* 302.1091. Calcd for $C_{17}H_{19}O_3P$: 302.1110.

*Synthesis of [1-(Acetoxymethyl)propyl]diphenylphosphine Oxide (**3b**, R=Et).* Treatment of **2b** (0.280 g, 1.02 mmol) in pyridine (5 ml) with acetic anhydride (3 ml) followed by work-up and recrystallization from carbon tetrachloride-cyclohexane gave product **3b** (0.256 g) in 80% yield, mp 108—109 °C. ^{1}H NMR ($CDCl_3$) δ 0.99 (t, 3H, J_{HH}=7.0 Hz, CH_3), 1.1—1.9 (m, 2H, $CH_3C\underline{H}_2$), 1.72 (s, 3H, CH_3CO), 2.4—3.0 (m, 1H, CH), 4.43 (dd, 2H, J_{HH}=7.0 Hz, J_{HP}= 13.0 Hz, CH_2O), and 7.2—8.1 (m, 10H, Ph); IR ν_{max}^{KBr} 1738 cm^{-1} (CO); MS *m/e* 316 (M^+). Found: C, 68.33; H, 6.50%. Calcd for $C_{18}H_{21}O_3P$: C, 68.34; H, 6.69%. Found: *m/e* 316.1259. Calcd for $C_{18}H_{21}O_3P$: 316.1228.

[1-(Acetoxymethyl)-2-methylpropyl]diphenylphosphine oxide (**3c**, R=*i*-Pr) was synthesized by an analorous method mentioned above in 99% yield.

(Received May 26, 1983)

Synopsis. 3-Arylsydnone-4-carboxamide oximes (**2**) were prepared from the corresponding 3-arylsydnone-4-carbonitriles and hydroxylamine in high yields. The amide oximes **2** reacted with orthoesters to give 3-aryl-4-(1,2,4-oxadiazol-3-yl)sydnones.

Many sydnone compounds have been found to have biological and pharmacological activities.[1-3] Some heterocyclic compounds are also well known to show such activities. It therefore must be interesting to synthesize sydnones having heterocyclic groups, but sydnones substituted directly by such groups (4-thiazolyl[3,4] and 4-sydnonyl[5,6] groups) at their 4-positions have been rarely reported. In this work, the preparation of sydnone compounds **2** with amidino-type groups, which are good precursors of heterocyclic groups, and the conversion of **2** into 4-(1,2,4-oxadiazol-3-yl)sydnones (**3**) were attempted.

Sydnone is a typical mesoionic compound and its chemical and physical properties are very unique.[1,7] Sydnone compounds seem to be fairly different from others in both reactivity and stability: Although a sydnone ring has a somewhat aromatic nature, the synthesis of sydnone compounds substituted by electron-releasing groups at the 4-position was unsuccessfully tried using some common reactions.[8-12] Therefore, both methods and conditions for the synthesis of sydnone compounds may often be restricted.

Results and Discussion

Nitriles are useful starting compounds for the preparation of amidines and imidic esters. However, the reaction of 3-phenylsydnone-4-carbonitrile (**1a**) with some nucleopliles did not give the corresponding addition products under conditions where common nitriles can react. The reaction of **1a** with free hydrazine at room temperature resulted in decomposition of **1a**, while hydrochlorides of hydrazine and aniline did not react in the presence of pyridine even at higher temperatures. The reaction with methanol in the presence of hydrogen chloride, so-called the Pinner reaction, also did not occur. These unsuccessful results may be due to the decrease of reactivity of the cyano group of **1a** by the electron-releasing nature[12] of the 4-position and/or instability of the desired products under the reaction conditions.

Only hydroxylamine hydrochloride could react with **1a—c** at room temperature in the presence of pyridine to give the corresponding 3-arylsydnone-4-carboxamide oximes (**2a—c**) in their free states in high yields, as shown in Table 1. This successful synthesis may be caused by such adequate basicities of hydroxylamine and **2** that the former can react with the cyano group and the latter can be present in the free state without decomposition. It is interesting to note that the electrophilic reaction of **1** might be sensitive to the basicity of neucleophile, product, and reaction medium.

The conversion of **2** prepared thus into 3-aryl-4-(1,2,4-oxadiazol-3-yl)sydnones (**3a—f**) was successfully carried out using the acid-catalyzed reaction with orthoesters (**4a—b**).[13] The reaction proceeded at room temperature (for 3 d) in the presence of sulfuric acid as a catalyst and **3** could be obtained in high yields, as shown in Table 2. Similar results could be obtained by using boron trifluoride etherate, instead of sulfuric acid, at higher temperature(90—100 °C) for shorter time(5 min).

The preparation of **2** in this work seems to be the

first report of the synthesis of sydnones substituted by an amidino-type group which may be a good precursor of longer carbon-nitrogen alternate and heterocyclic groups in addition to a 1,2,4-oxadiazol-3-yl group. The new type of sydnone compounds such as **2** and **3** is also expected to be biologically or pharmacologically active.

Experimental

3-Arylsydnone-4-carbonitriles (**1a—c**) were prepared from the corresponding 4-formylsydnones by the Schmidt reaction.[14]

Typical procedures for the preparation of **2** and **3** were as follows: To a suspension of **1a** (3.74 g, 0.02 mol) in 95% ethanol (50 ml)–pyridine (5 ml), hydroxylamine hydrochloride (2.10 g, 0.03 mol) in water (10 ml) was added with stirring. The stirring was continued for 3 days at room temperature. The resulting precipitates (**2a**) were collected by filtration, and concentration of the filtrate afforded additional **2a**. To a suspension of **2a** (0.44 g, 0.002 mol) in 95% ethanol (20 ml), **4a** (2 ml) and concentrated sulfuric acid (2 drops) were added. By a procedure similar to the preparation of **2a**, the crude product of **3a** was obtained and recrystallized from 95% ethanol. All the products, **2a—c** and **3a—f** were confirmed by spectral (IR, ^{1}H-NMR, and MS) and analytical data.

The compound, **2a**: ^{1}H NMR (DMSO-d_6) δ=9.92 (1H, s, OH), 7.73 (5H, s, aromatic), 5.91 (2H, s, NH_2); MS (70 eV), *m/e* 220 (M^+), 162 (M^+—NO—CO). Found: C, 49.34; H, 3.58; N, 25.34%. Calcd for $C_9H_8N_4O_3$: C, 49.10; H, 3.66; N, 25.45%.

(Received June 1, 1983)

Synopsis. The structure of a product from a reaction mixture of 2-(*p*-bromophenyl)-9*H*-imidazo[1,2-*a*]benzimidazole and 2,3,4,6-tetra-*O*-acetyl-*β*-D-glucopyranosyl bromide in the presence of NaI, hexamethyldisilazane, and $(NH_4)_2SO_4$ has been established as 3,4,6-tri-*O*-acetyl-1,2-*O*-[(1*S*)-1-[2-(*p*-bromophenyl)-9*H*-imidazo[1,2-*a*]benzimidazol-3-yl]ethylidene]-*α*-D-glucopyranose by means of X-ray crystal structure analysis.

In a series of synthesizing nucleoside analogs[1], we carried out the reaction of 2-(*p*-bromophenyl)-9*H*-imidazo[1,2-*a*]benzimidazole (**1**) and 2,3,4,6-tetra-*O*-acetyl-*β*-D-glucopyranosyl bromide (**2**).[2] From the reaction mixture, three compounds were separated, two of them were identified by means of NMR, IR, and UV, but the rest was not. In this paper, we describe the molecular structure of the compound(**3**) determined by X-ray analysis.

(3)

Experimental

A specimen of **3** with the approximate dimensions of 0.3×0.3×0.3 mm³ was used for the intensity measurements. The density was determined by the flotation methods in a mixture of petroleum ether and carbon tetrachloride. The cell constants were determined by the least-squares procedure from the 2*θ* values of 24 reflections measured on a diffractometer using monochromated Cu *Kα* radiation. Three dimensional intensity data were collected on a Fillips automatic four-circle diffractometer with graphite monochromated Cu *Kα* radiation. Background was counted for 5 s at both sides of each peak. Three standard reflections were measured every 100 reflections during the course of collection. A total of 4604 independent reflections were collected. Reflections having an intensity exceeding the corresponding standard deviations by a factor of three were treated as observed. 4201 reflections were retained and corrected for Lorentz and polarization factors but not for absorption factor. The crystal of compound **3** belongs to the triclinic, space group P1, and $Z=2$. $a=9.485(2)$, $b=20.080(2)$, $c=9.708(1)$ Å, $\alpha=100.31(2)$, $\beta=109.60(1)$, $\gamma=92.45(2)°$.

Determination and Refinement of the Structure. The structure was determined by the heavy atom method. All the non-hydrogen atoms in the asymmetric unit were obtained from the Fourier map phased by the two bromine atoms. The oxygen and nitrogen atoms were identified by the structural considetations. Refinement of atomic parameters was carried out by the full-matrix least-squares method, the quantity minimized being $\Sigma w(|F_o|-|F_c|)^2$, with $w=1.0$ for all the reflections used. The final ***R*** values was 0.069. The atomic scattering factors for C, O, N were given by Cromer and Mann,[3] and that for H by Stewart *et al.*,[4] and that for Br from International Tables for X-ray Crystallography.[5] The final atomic parameters and equivalent isotropic temperature factors are given in Table 1.†

Results and Discussion

The molecular framework is shown in Fig. 1. It is concluded that the product from the reaction **1** and **2**, has the structure **3**.

The asymmetric carbon C(17) is specified as (S), and it is thought that the reaction proceeded stereospecific. In the crystal, **3** was found to be a (1:1) mixture of rotational isomers (**3A** and **3B**), and torsional angles of C(1)–C(2)–C(17)–O(1) are 18.5° (for 3A) and −41.8° (for 3B) and N(2)–C(2)–C(17)–O(2) are −51.5° (for 3A) and 26.6° (for 3B), respectively.

Table 4. Dihedral angles between the planes

Dihedral	θ/° 3A	θ/° 3B
Benzene plane[C(4)–C(5)–C(6)–C(7)–C(8)–C(9)] and imidazole plane[C(3)–N(3)–C(4)–C(5)–N(2)]	0.6	1.6
Benzene plane[C(4)–C(5)–C(6)–C(7)–C(8)–C(9)] and imidazole plane[C(1)–C(2)–N(2)–C(3)–N(1)]	3.3	5.3
Two imidazole planes[C(3)–N(3)–C(4)–C(5)–N(2)] and [C(1)–C(2)–N(2)–C(3)–N(1)]	3.3	4.7
Benzene plane[C(10)–C(11)–C(12)–C(13)–C(14)–C(15)] and imidazole plane[C(1)–C(2)–N(2)–C(3)–N(1)]	41.8	42.7

In the heterocyclic moiety, one benzene ring and two imidazole rings are almost planar each other in the range of 0.6—5.3°, but the dihedral angles between the *p*-bromophenyl group and imidazole ring [C(1)–C(2)–N(2)–C(3)–N(1)] are 41.8° (for **3A**) and 42.7° (for **3B**) respectively.

The bond distances and angles are given in Table 2 and 3, respectively.

Two acetone molecules are found in an unit cell.

A view of **3A**, **3B** and acetone molecules defining the atom numbering is given in Fig. 1.

On the difference map, 8 peaks corresponding to two acetone molecules and the peaks corresponding to three acetyl groups showed broad peaks and some of their temperature factors are large. This is, in the case of acetyl group, presumably because of the rotation of acetyl groups around the axis C(20)–O(4)–, C(21)–O(6), and C(27)–O(8) respectively.

Palladium Catalyzed Reaction of Trimethylsilyltributyltin with α-Halo Ketones. Preparation of Enol Silyl Ethers

Masanori Kosugi, Takao Ohya, and Toshihiko Migita*
Department of Chemistry, Faculty of Technology, Gunma University, Kiryu, Gunma 376
(Received June 3, 1983)

Synopsis. The reaction of trimethylsilyltributyltin with α-halo ketone in the presence of a catalytic amount of palladium chloride plus twice molar amounts of trimethyl phosphite gave enol silyl ethers in good yields.

The most important method to form Si–C bonds involves the reaction between organosilicon halides and Grignard or organolithium reagents. An alternative method available is the reaction between disilane and organic halides in the presence of appropriate transition metal complexes.[1] Application of this reaction

$$RX + Me_3SiSiMe_3 \xrightarrow{[M]} RSiMe_3 + Me_3SiX$$

to α-halo ketone was recently reported by Moro-oka *et al.* to give the reductive dehalogenated product, ketone as a major product, except for the reaction with α-bromoacetophenone which gave enol silyl ether as a major product.[2]

Comparing with hexamethyldisilane, trimethylsilyltributyltin is expected to be a more reactive reagent, because Sn–Si bond is weaker than Si–Si bond. We carried out the palladium-catalyzed reaction of trimethylsilyltributyltin with α-halo ketones under various conditions, intending to increase the yield of enol silyl ether, and to reduce the yield of reductive dehalogenated product. This note which describes the results affords an example of the catalytic silylation of α-halo ketones by means of the compound related to disilane, although a number of other methods for the preparation of enol silyl ether are so far known.[3]

$$-\overset{\overset{O}{\|}}{C}-\overset{|}{C}-X + Bu_3SnSiMe_3 \xrightarrow{[Pd]} -C=C\begin{matrix}\diagup\\ \\ \diagdown\end{matrix} + Bu_3SnX \quad (OSiMe_3)$$

The reaction of trimethylsilyltributyltin with α-bromoacetophenone in the presence of tetrakis(triphenylphosphine)palladium was carried out at various reaction temperature. As Table 1 shows, lower the temperature, the yield of α-trimethylsiloxystyrene increased comparing with that of acetophenone, the reductive dehalogenated product. The optimum temperature was about 80 °C.

The distribution of the products depended also on the nature of the catalysts and the ligands used. As shown in Table 2, the best catalyst was π-allylpalladium or palladium chloride plus twice molar amounts of trimethyl phosphite. From the view point of availability and stability of the catalysts, palladium chloride plus trimethyl phosphite may be the most recommendable catalyst.

Since, under these conditions, α-trimethylsiloxystyrene was produced in good yield and the production of acetophenone was essentially suppressed, the method was applied to the reaction with various α-halo ketones, giving the results as shown in Table 3. Enol silyl ethers were produced in good yields together with a quite small amount of the reductive dehalogenated products. The yield descended as the halo ketone varied from primary to secondary, and then to tertiary. At lower reaction temperature, the yields of the product from secondary or tertiary bromide seemed to be improved.

The mechanism for this reaction may be analogous to that proposed by Moro-oka *et al.*[2]

Experimental

Boiling points are uncorrected. IR spectra were recorded on a Hitachi EPI-3G spectrophotometer. NMR spectra were recorded on a Varian EM-360 instrument. GLC analyses were carried out with an Ohkura 802 instrument, using columns (1.5 m) packed with 10% Silicone SF-96, 10% SE-30, 10% Apiezon Grease L, or 10% Carbowax-20M on Celite 545 (AW DMCS).

Materials. Trimethylsilyltributyltin,[4] bromoacetone,[5] 1-bromo-2-butanone and 3-bromo-2-butanone,[6] 1-bromo-3-methyl-2-butanone and 3-bromo-3-methyl-2-butanone,[6] 1-bromo-3,3-dimethyl-2-butanone,[7] α-bromoacetophenone,[8] 2-chlorocyclohexanone,[9] $Pd(PPh_3)_4$,[10] $PdCl_2(PPh_3)_2$,[11] $PdCl_2[P(o\text{-}tolyl)_3]_2$,[11] $PdCl_2[P(p\text{-}tolyl)_3]_2$,[11] $PdCl_2(PhCN)_2$,[12] $RhCl(PPh_3)_3$,[13] $NiCl_2(PPh_3)_2$,[14] and $[PdCl(C_3H_5)]_2$[15] were prepared by the methods described in literatures.

Reaction Procedures. Solutions of trimethylsilyltributyltin (1.2 mmol), α-halo ketone (1.0 mmol), and the catalyst (0.01 mmol) in benzene (0.5 ml) were degassed and sealed *in vacuo*. After heating for 5 h, the reaction mixtures were subjected in GLC. For the experiment in preparative scale, solutions of 30 times amounts of reactants and catalyst were prepared and heated under argon at 80 °C for 5 h. The products were isolated by distillation under reduced pressure.

Products. All the products are known compounds,[16,17] identification of which was based on their spectroscopic data recorded here.

2-Trimethylsiloxy-1-propene: IR (neat) 1640 and 900 (C=C), and 1030 cm^{-1} (Si–O–C). ^1H NMR (CCl_4) δ=0.18 (s, 9H), 1.72 (s, 3H), and 3.95 (s, 2H).

2-Trimethylsiloxy-1-butene: IR (neat) 1620 and 880 (C=C), and 1030 cm^{-1} (Si–O–C). ^1H NMR (CCl_4) δ=0.13 (s, 9H), 0.92 (t, J=7.6 Hz, 3H), 1.93 (q, J=7.6 Hz, 2H), and 3.89 (s, 2H).

2-Trimethylsiloxy-3-methyl-1-butene: IR (neat) 1630 and 860 (C=C), and 1010 cm^{-1} (Si–O–C). ^1H NMR (CCl_4) δ=0.20 (s, 9H), 0.96 (d, J=6 Hz, 6H), 2.10 (h, J=6 Hz, 1H), 3.84 (s, 1H), and 3.95 (s, 1H).

2-Trimethylsiloxy-3,3-dimethyl-1-butene: IR (neat) 1620 and 880 (C=C), and 1030 cm^{-1} (Si–O–C). ^1H NMR (CCl_4) δ= 0.18 (s, 9H), 1.05 (s, 9H), 3.85 (d, J=1 Hz, 1H), and 4.01 (d, J=1 Hz, 1H).

α-Trimethylsiloxystyrene. IR (neat) 1620 (C=C) and 1010 cm^{-1} (Si–O–C). ^1H NMR (CCl_4) δ=0.26 (s, 9H), 4.27 (d, J=1.7 Hz, 1H), 4.73 (d, J=1.7 Hz, 1H), and 7.00—7.58 (m, 5H).

1-Trimethylsiloxycyclohexene: IR (neat) 1670 and 898 (C=C), and 1190 cm^{-1} (Si–O–C). ^1H NMR (CCl_4) δ=0.15 (s, 9H), 1.31—1.73 (m, 4H), 1.73—2.18 (m, 4H), and 4.73 (m, 1H).

2-Trimethylsiloxy-2-butene: IR (neat) 1680 and 900 (C=C), and 1050 cm^{-1} (Si–O–C). ^1H NMR (CCl_4) δ=0.18 (s, 9H), 1.43 (d, q, J=6.6 and 1 Hz, 3H), 1.71 (m, 3H), and 4.41 (q,q, J=6.6 and 1 Hz, 1H).

2-Trimethylsiloxy-3-methyl-2-butene: IR (neat) 1680 and 905 (C=C), and 1010 cm^{-1} (Si–O–C). ^1H NMR (CCl_4) δ=0.10 (s, 9H), 1.55 (s, 6H), and 1.70 (s, 3H).

The Configurations of *N*-Methyl- and *N*-*t*-Butyl-α-methoxycarbonylmethanimine *N*-Oxides

Yoshinobu INOUYE,* Kazuharu TAKAYA, and Hiroshi KAKISAWA
Department of Chemistry, University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 305
(Received June 3, 1983)

Synopsis. *N*-Methyl-α-methoxycarbonylmethanimine *N*-oxide, *Z* configuration in crystal, was found to exhibit a facile equilibration with its *E*-isomer in solution. The configuration of *N*-*t*-butyl derivative was always *Z*.

Recently, we found that *N*-benzyl-α-methoxycarbonylmethanimine *N*-oxide (**1**) and its analogues exist in one configuration in the crystalline state but, in solution, exhibit a facile isomerization to give a mixture of *E*- and *Z*-isomers.[1] The configuration of **1** in the crystalline state have been proved to be *Z* by X-ray crystal analysis.[2]

In this paper, we wish report the geometrical structures of *N*-methyl- (**2**) and *N*-*t*-butyl-α-methoxycarbonylmethanimine *N*-oxides (**3**) in order to clarify the influence of a substituent on the nitrogen atom.

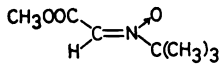
2Z **2E**



3

Experimental

Preparation of 2 and 3. According to the procedure of Winterfeldt and co-workers,[3] **2** and **3** were prepared from *N*-alkylhydroxylamine hydrochloride and methyl glyoxylate[4] in the presence of sodium acetate and calcium chloride.

2, Mp 69—71 °C (from benzene, lit,[3] mp 71 °C); ν (KBr): 1710 and 1230 cm^{-1}; λ_{max}(MeOH): 268 nm. Found: C, 40.98; H, 6.03; N, 11.96%. Calcd for $C_4H_7NO_3$: C, 41.02; H, 6.03; N, 11.96%.

3, Bath temp 110—120 °C/0.55 mmHg (1 mmHg≈133.322 Pa) (Kugelrohr dist): ν(film): 1720 and 1180 br cm^{-1}; λ_{max} (MeOH): 270 nm. Found: C, 52.98; H, 8.42; N, 8.66%. Calcd for $C_7H_{13}NO_3$: C, 52.81; H, 8.23; N, 8.79%.

^{1}H-NMR Measurements. ^{1}H-NMR spectra were obtained on a JEOL JNM-PMX60SI spectrophotometer and δ-values were calculated from the TMS as an internal standard (35 °C).

Discussion

The *N*-methyl derivative **2** had been already prepared in 1969 by Winterfeldt and co-workers[3] and the ^{1}H-NMR spectrum ($CDCl_3$) reported showed only three signals at δ 7.39, 3.82, and 3.66. These results suggested the absence of a geometrical isomer.

However, as shown clearly in Fig. 1, the spectra of **2** changed gradually with the elapse of time. The signal at δ 3.81 decreased, while a new peak appeared at δ 4.14 increased. The relative intensities of these two peaks remain constant after 40 min.

The signal at δ 4.14 is assignable to the *N*-CH_3 group in *E*-nitrone (**2E**) as the result of the deshielding effect of the neighboring methoxycarbonyl group.[1] Thus, the phenomena in Fig. 1 are explained by arguing that an initial *Z*-nitrone (**2Z**), which determines the crystal structure, isomerizes to the *E*-isomer (**2E**) when it dissolves in $CDCl_3$ and that, after 40 min, the system reaches the equilibrium mixture of both isomers. The *E*/*Z* ratio at equilibrium was calculated from the peak areas of δ 4.14 and 3.81 and the rate constant of isomerization was obtained from the *E*/*Z* ratios at different time. The results are summarized in Table 1.

From the Table, it is clear that the solvent polarity is significant in determining the *E*/*Z* ratio at equilibrium: the less polar the solvent polarity, the more predominant the *E*-isomer. Although the detailed mechanism of the stabilizing the two geometrical isomers in a given solvent is still unclear, the *Z*-isomer, which is anticipated[5] to have a larger dipole moment than the *E*-isomer, is thought to be more stabilized

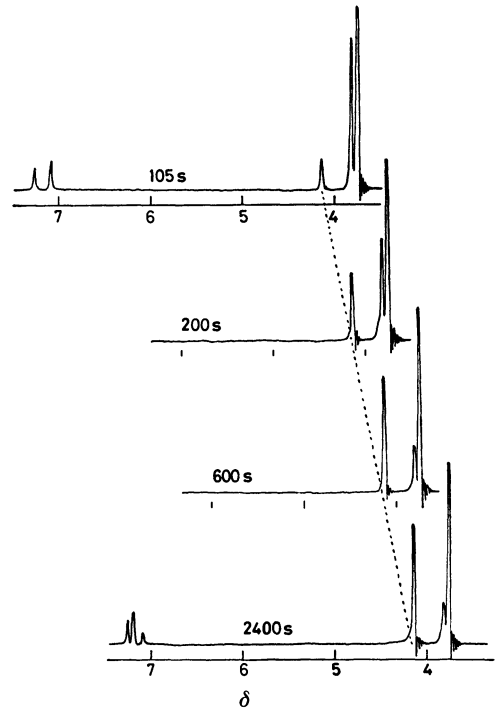


Fig. 1. Time-dependence of the intensities of methyl protons in the ^{1}H-NMR spectra of **2** in $CDCl_3$.

Table 1. The *E/Z* ratio and the rate constant of isomerization of **2**[a)]

Solvent	*E/Z*	k_Z/s^{-1}	k_E/s^{-1}
C_6D_6	6.0		
$CDCl_3$	3.8	2.4×10^{-3}	6.2×10^{-4}
CD_3OD	0.83	3.3×10^{-5}	4.0×10^{-5}
DMSO-d_6	0.67		

a) Measured at 0.08 mmol of **2** in 0.3 ml of each solvent.

in more polar solvents.

The rate constant in CD_3OD is smaller than that in $CDCl_3$. This can be partially explained by considering the hydrogen bonding between the nitrone oxygen and the solvent hydrogen (=N→O···H–O–R).

In the case of *N*-*t*-butyl derivative **3**, both ^{1}H-NMR (δ in $CDCl_3$: 7.25, 3.76, and 1.49) and ^{13}C-NMR (δ in $CDCl_3$: 161.3, 121.1, 74.8, 51.8, and 28.2) were simple and no changes were observed even when the temperature was raised to 62 °C. This shows that only one configurational isomer is present in solution. As a large NOE (35%) was observed between the olefinic proton and *t*-butyl protons,[6)] the configuration of the nitrone **3** was proved to be *Z*.

Various derivatives have been investigated; among these, *N*-alkyl-α-methoxycarbonylmethanimine *N*-oxides which have at least one hydrogen at the carbon attached to the nitrogen of the nitrone chromophore are apt to equilibrate into *E*- and *Z*-isomers in solution at room temperature.

Convenient Preparation of Methylthiomethyl *p*-Tolyl Sulfone Starting from Dimethyl Sulfoxide

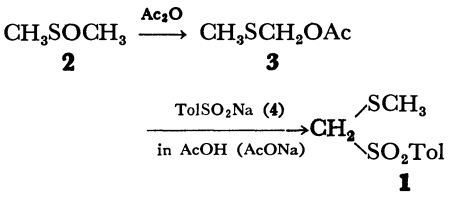
Katsuyuki OGURA,* Nobuhiro YAHATA, Jun-ichi WATANABE, Kazumasa TAKAHASHI, and Hirotada IIDA

Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoicho 1-33, Chiba 260

(Received June 4, 1983)

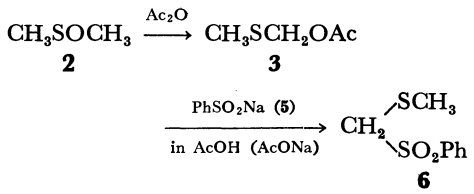
Synopsis. An efficient method for preparing methylthiomethyl *p*-tolyl sulfone was accomplished by the Pummerer reaction of dimethyl sulfoxide with acetic anhydride followed by treatment of the resulting acetoxymethyl methyl sulfide with sodium *p*-toluenesulfinate in the presence of sodium acetate in acetic acid.

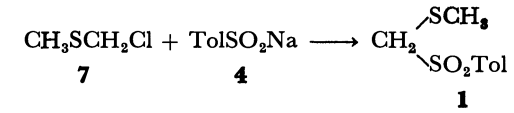
In a previous paper,[1] methylthiomethyl *p*-tolyl sulfone (**1**) was shown to be one of the most useful reagents for preparation of *S*-methyl α-oxo thiocarboxylates, carboxylic esters, five- and six-membered cycloalkanones, and α-methoxy-α-arylacetic esters.[2] With regard to formation of **1**, there has been only one report which describes the reaction of (*p*-tolylsulfonyl)acetone with *S*-methyl *p*-toluenethiosulfonate in the presence of sodium carbonate followed by hydrolysis to give **1**.[3] However, this does not seem to be suitable as a preparative method of **1** because these starting materials are not easily available. Hence, our effort was devoted to exploiting a convenient method for its synthesis; we have found an efficient route from inexpensive dimethyl sulfoxide (**2**) to **1** *via* acetoxymethyl methyl sulfide (**3**) in a "one-pot" fashion, as outlined in the following scheme.



First, the substitution of acetoxymethyl methyl sulfide (**3**)[4] with *p*-toluenesulfinate anion was investigated. Heating **3** together with sodium *p*-toluenesulfinate (**4**) in DMF at 80—90 °C afforded only a trace of **1**. Efforts were made to achieve a higher yield of **1** by variation of reaction conditions (solvent, temperature, time). Acetic acid was found to be the most suitable solvent. In acetic acid, the substitution reaction occurred at 100 °C, and **1** was produced in 65% yield after heating for 48 h. It may be reasonable to assume that acetic acid not only serves as an appropriate solvent for **4**, but enhances the capability of the acetoxyl group as a leaving group by protonation. Since **3** was obtained by the Pummerer reaction of dimethyl sulfoxide (**2**) with acetic anhydride where acetic acid is the only by-product, the employment of acetic acid as a solvent in the above substitution allows the synthesis of **1** from **2** to perform in one flask without isolation of the intermediate **3**. Thus, a mixture of **2** and acetic anhydride (1.3 mol-equiv. to **2**) was heated at 80 °C for 24 h, and, after addition of acetic acid and sodium *p*-toluenesulfinate (1.5 mol-equiv. to **2**), the resulting mixture was further heated at 100 °C for 26 h to give **1** in 57% yield. It was also found that the presence of sodium acetate (1 mol-equiv. to **2**) in the substitution step (**3**→**1**) increased the yield of **1** to 71%. Sodium acetate is thought to prevent production of *p*-toluenesulfinic acid, which affords *S*-*p*-tolyl *p*-toluenethiosulfonate and di-*p*-tolyl disulfide at an elevated temperature.

It should be noted that a combination of acetic anhydride, acetic acid, and sodium *p*-toluenesulfinate was crucial to the above reaction. As mentioned above, DMF is not suitable as a solvent. When propionic anhydride and propionic acid were employed, the yield of **1** was 15%. The use of sodium benzenesulfinate (**5**) in place of **4** gave methylthiomethyl phenyl sulfone (**6**), but the yield was lower (25—38% overall yield from **2**) in the presence or absence of sodium acetate. Furthermore, the reaction of chloromethyl methyl sulfide (**7**) with **4** in THF, DMF, or diglyme met with no success. In spite of many efforts, the maximum yield (22%) of **1** was attained when the reaction was carried out by stirring **4** and **7** in DMF at room temperature for 44 h (see also Experimental section).





Thus we have found that **1** can be conveniently prepared from inexpensive dimethyl sulfoxide by successive treatment with acetic anhydride and with commercially available sodium *p*-toluenesulfinate in one flask.

Experimental

Melting points were determined on a hot-stage microscope (Yanagimoto) and were uncorrected. ^{1}H NMR spectra were obtained on a Hitachi R-600 spectrometer. Infrared spectra were determined with a JASCO A-200 spectrometer.

One-pot Preparation of Methylthiomethyl p-*Tolyl Sulfone (1) from Dimethyl Sulfoxide (2)*: A mixture of **2** (9.25 g: 0.118 mol) and freshly distilled acetic anhydride (15.60 g: 0.153 mol) was heated at 80 °C for 24 h and then cooled to ambient temperature. Acetic acid (90 ml), sodium acetate (9.70 g: 0.118 mol), and sodium *p*-toluenesulfinate[5] (31.60 g: 0.178 mol) were successively added to the mixture, and the resulting

mixture was again heated at 100 °C for 26 h. After addition of brine (150 ml), the mixture was extracted with five 70-ml portions of dichloromethane. The extracts were combined, dried over anhydrous sodium sulfate, and evaporated under reduced pressure to give 27.20 g of pale yellow crystals containing a small amount of an oil. Recrystallization of these crystals from 95% ethanol afforded 13.31 g of **1** as colorless needles. The mother liquor was evaporated and subjected to a column chromatography on silica gel using hexane and benzene as eluents to give 4.88 g of **1** as colorless crystals. The total yield of **1** was 71%: mp 82—83 °C (lit,[3] 80 °C); ^{1}H NMR ($CDCl_3$) δ=2.29 (3H, s), 2.46 (3H, s), 3.93 (2H, s), 7.37 (2H, d, J=8 Hz), and 7.87 (2H, d, J=8 Hz); IR (KBr) 1295, 1160, 1117, 1018, 740, 542, and 507 cm^{-1}.

Calcd for $C_9H_{12}O_2S_2$: C, 49.98; H, 5.59%. Found: C, 50.09; H, 5.56%.

*Preparation of Methylthiomethyl Phenyl Sulfone (**6**)*: A mixture of dimethyl sulfoxide (1.04 g: 13.3 mmol) and acetic anhydride (1.76 g: 17.3 mmol) was heated at 80 °C for 24 h. After the mixture was cooled to ambient temperature, acetic acid (10 ml), sodium acetate (1.09 g: 13.3 mmol), and sodium benzenesulfinate (**5**) (3.27 g: 19.9 mmol) were added and the resulting mixture was heated at 100 °C for 26 h. The usual workup [addition of water and extraction with dichloromethane] and column chromatography on silica gel (eluted with hexane and benzene) gave 1.01 g (38% yield) of methylthiomethyl phenyl sulfone (**6**) as colorless crystals: mp 86.5—87.5 °C (from 95% ethanol); ^{1}H NMR ($CDCl_3$): δ=2.32 (3H, s), 3.96 (2H, s), and 7.48—8.09 (5H, m); IR (KBr) 1292, 1160, 1116, 1080, 741, 544, and 520 cm^{-1}.

Calcd for $C_8H_{10}O_2S_2$: C, 47.50; H, 4.98%. Found: C, 47.62; H, 4.96%.

*Conversion of Dimethyl Sulfoxide (**2**) to **1** Using Propionic Anhydride, Propionic Acid, and **4***: A mixture of **2** (1.27 g: (16.3 mmol) and propionic anhydride (2.84 g: 21.8 mmol) was heated at 80 °C for 24 h. After being cooled to room temperature, propionic acid (20 ml) and **4** (4.35 g: 24.4 mmol) were added and the resulting mixture was heated at 100 °C for 48 h. Water (40 ml) was added and the reaction mixture was extracted with five 40-ml portions of dichloromethane. The extracts were combined, washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure. Column chromatography on silica gel using hexane and benzene as eluents afforded 518 mg (15% yield) of **1**.

*Reaction of Chloromethyl Methyl Sulfide (**7**) with Sodium p-Toluenesulfinate (**4**)*: A mixture containing 7 (5.65 g: 58.6 mmol) and **4** (15.72 g: 88.3 mmol) in DMF (60 ml) was stirred at room temperature for 44 h. After addition of water (100 ml), the mixture was extracted with four 40-ml portions of dichloromethane. The extracts were combined, washed with water, dried over anhydrous sodium sulfate, and evaporated under reduced pressure. The residue was subjected to column chromatography on silica gel using hexane and benzene as eluents to give 2.84 g (22% yield) of **1**.

Several reaction conditions were also examined for the reaction of **7** with **4** (1.2—1.75 mol-equiv.), but the yields of **1** were low [70 °C/28 h in DMF, 19%; 40 °C/116 h in THF in the presence of n-$Bu_4N \cdot HSO_4$ (0.2 mol-equiv.), 11%; r.t./70 h in diglyme, 10%; r.t./70 h without solvent, 10%]

Charge-carrier Transport in Nematic 2-(*p*-Decyloxybenzylideneamino)-9-Fluorenone

Ken-ichi OKAMOTO,* Shu NAKAJIMA, Akira ITAYA, and Shigekazu KUSABAYASHI†
Department of Chemical Engineering, Faculty of Engineering, Yamaguchi University, Ube, Yamaguchi 755
†*Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565*
(Received January 8, 1983)

2-(*p*-Decyloxybenzylideneamino)-9-fluorenone (DBAF), with a large π-electronic group, showed a transient photocurrent induced by the strongly-absorbed light from a N_2 gas laser in the nematic, monotropic smectic, and isotropic liquid states. This photocurrent seemed to be due to the space-charge-limited current. The drift mobilities of the positive and negative charge carriers (μ_p and μ_n respectively) were determined from the peak time. The μ_n was ten times larger than μ_p, while the activation energies were identical. The modified Walden rule was valid in the nematic state ranging from 90 °C to 135 °C. The nematic mixtures of DBAF and *N*-(*p*-methoxybenzylidene)-*p*-butylaniline also showed a similar transient photocurrent, the magnitude of which increased significantly with an increase in the DBAF content. The mobilities were independent of the DBAF content and were nearly equal to those in nematic DBAF at the same viscosity, η: that is, $\mu_n = 3 \times 10^{-5}$, and $\mu_p = 2.5 \times 10^{-6}$ cm²/V s at $\eta = 0.026$ Pa s. These facts indicate that the nature of the carrier transport of the photoconduction is not electronic, but ionic. The O_2^- and the cation radical of DBAF are proposed as the ionic carrier species for both nematic DBAF and the nematic mixtures.

Charge-carrier transport in liquid crystals has been extensively studied over the last ten years and has been found to be of an ionic nature.[1-10] In most of the studies, either the voltage-pulse-injection method[1-4] or the polarity-inversion method[5,6] has been used to measure the carrier mobility. These methods, however, give no direct information as to the sign of the carriers. Yamashita and Amemiya have measured the drift mobility of the positive charge carriers photoinjected from an amorphous Se layer in nematic *N*-(*p*-methoxybenzylidene)-*p*-butylaniline (MBBA).[8] To our knowledge, this is the only case where the sign of the carriers migrating in a liquid crystal has been identified. On the contrary, the drift mobility in many organic solids has been measured separately for the positive and negative charge carriers. This is because the time-of-flight method is easily applied to the organic solids where the pulse-photocurrent is caused by pulsed strongly-absorbed light. Unfortunately, the liquid crystals investigated to date have not been photoconductive.

In the previous paper,[11] we found that nematic 2-(*p*-decyloxybenzylideneamino)-9-fluorenone (DBAF), which has a relatively large π-electronic group, showed photoconduction in its absorption region. In the present investigation, we measured the transient photocurrent induced by pulsed strongly-absorbed light to determine the drift mobility. We believe that this is the first report in which the drift mobilities have been determined separately for the positive and negative charge carriers in a liquid crystal.

Experimental

The DBAF was prepared as has been described previously.[11] The MBBA was obtained commercially and was purified with vacuum distillation. The sample was sandwiched between two nesa-coated glass electrodes with a Myler spacer 20—100 μm thick. Cells with a homogeneous alignment were prepared by means of the rubbing technique of the glass electrodes.[11] Caution was taken in preparing the cells so as not to heat the DBAF sample above 95 °C. The effective area of the cells was typically 1 cm². A nitrogen-gas laser (3 ns in pulse width) was irradiated on a cell set in a cryostat with an argon atmosphere. The induced photocurrent was observed through a series load resistor by means of a storage oscilloscope. Before the measurement, the dark current was cancelled out by means of a compensation circuit. The viscosity was measured with an Ostwald viscometer calibrated by using MBBA[12] and hexadecane[13] as standard samples.

Results and Discussion

Typical traces of the transient photocurrent are shown in Fig. 1. The attenuation coefficient of a nematic DBAF sample was evaluated to be 1.2×10^5 cm^{-1} at 337 nm from the molar extinction coefficient of its benzene solution (2.2×10^4 M^{-1} cm^{-1}). This value indicates that the exciting light is absorbed within the surface layer to a depth of less than 0.5 μm. The original photocarriers, which are supposed to be the cation radical of DBAF and the anion radical of either DBAF or an electron-acceptor impurity,[11] are generated in this surface layer. When the front electrode is

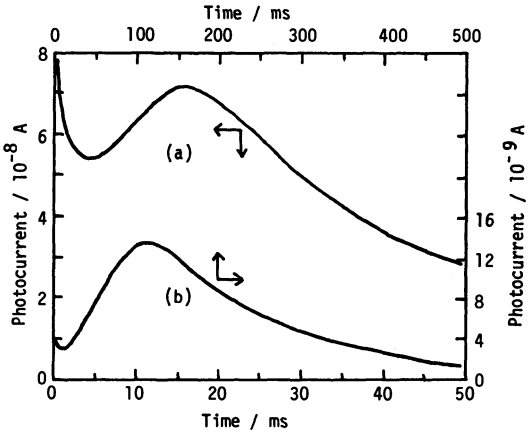

Fig. 1. Typical traces of transient photocurrent in nematic DBAF. (a) and (b): Negative- and positive-electrode illuminations, respectively. Applied voltage: 34 V, sample thickness: 30 μm, temperature: 97 °C.

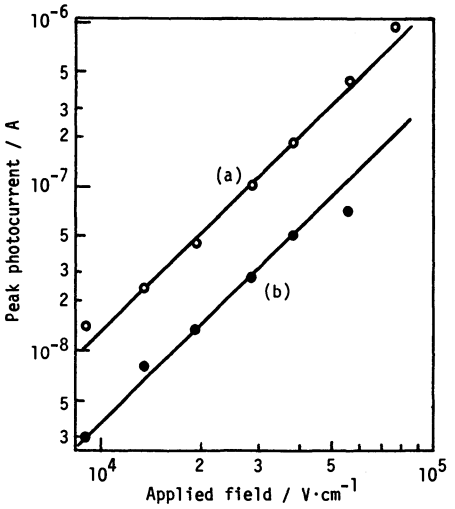

Fig. 2. Dependence of peak photocurrent on applied electric field. (a) and (b): Negative- and positive-electrode illuminations. Sample thickness: 50 μm, temperature: 97 °C.

positively biased, the positive-charge carriers can drift toward the back electrode, and *vice versa*. Thus, the transient photocurrent observed for the positive- or negative-electrode illumination is due to the positive- or negative-charge carriers respectively.

The transient photocurrent showed a peak, as may be seen in Fig. 1. The peak photocurrent was proportional to the square of the applied field, as shown in Fig. 2. It was roughly proportional to the inverse cube of the sample thickness. Judging from these facts, the observed transient photocurrent seems to be to the space-charge-limited current. The drift mobility, μ, was calculated from the peak time, t_p, according to Eq. 1;[14]

$$\mu = 0.79\, d^2/t_p\, V, \qquad (1)$$

where d is the sample thickness, and V, the applied voltage. Thus, the drift mobilities of the positive- and negative-charge carriers were determined separately and labelled μ_p and μ_n respectively.

The mobilities in nematic DBAF were independent of the sample thickness, but they were dependent on the applied electric field, as shown in Fig. 3. The μ_n was roughly proportional to the root of the field, while the μ_p increased at a much slower rate with an increase in the field. It has been suggested that the ionic mobility measured in high electric fields is probably overestimated because of the effect of the electrohydrodynamic (EHD) flow.[8,9] This suggests that the mobility in liquid crystals may be dependent on the field. The mobility in liquid crystals has, however, been reported to be independent of the field,[1-3,5-9] except in only one report.[4] Both μ_n and μ_p in the nematic mixtures of MBBA and DBAF, which will be mentioned below, were independent of the field, as shown in Fig. 3. The EHD flow was observed for both nematic DBAF and nematic mixtures of DBAF and MBBA in fields higher than about 2×10^3 V/cm. These facts suggest that the field dependence of the mobility in nematic DBAF is not due to the effect of the EHD flow. At present,

though, we have no explanation for this field dependence.

The temperature dependence of the mobilities at the field of 3.66×10^4 V/cm is shown in Fig. 4. The mobility data were reproducible unless the cell was heated up to the isotropic liquid state. In the nematic state, both

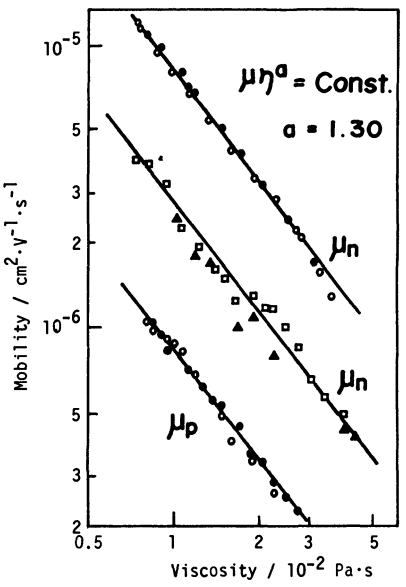

Fig. 5. Viscosity dependence of drift mobility in nematic state. Keys are identical with those in Fig. 4.

μ_n and μ_p had the same activation energy of *ca.* 0.54 eV. On the cooling runs, the mobilities showed a discrete change at the transition from the nematic phase to the smectic phase (88.7 °C), while their activation energies in the smectic state were nearly equal to those in the nematic state. The μ_n decreased abruptly and irreversibly at the transition from the nematic to the isotropic phase (138.7 °C). Once the cell was heated up to the isotropic liquid state, the μ_n in the nematic state as well as in the smectic one decreased to a third of its original value, as shown in Fig. 4, while the activation energy practically did not change.

The temperature dependence of the viscosity is also shown in Fig. 4. The activation energy of the viscosity was *ca.* 0.40 eV for both nematic and isotropic liquid states.

If the carrier transport is of an ionic nature, Walden's rule (Eq. 2) or its modification (Eq. 3) should be valid:[15]

$$\mu\eta = e/6r, \quad (2)$$

$$\mu\eta^a = \text{constant}, \quad (3)$$

where e is the electronic charge; r, the effective radius of the ionic carrier species, and a, an experimental constant close to unity. The mobility data for the nematic state shown in Fig. 4 were replotted against the viscosity in the bilogarithmic form according to Eq. 3. As shown in Fig. 5, straight lines with the same slope were obtained: they gave the a value as 1.3. It should also be noted that the modified Walden's rule is valid in the nematic state over the wide range from 90 °C to 135 °C.

The transient photocurrent in the nematic mixtures of MBBA and DBAF was also measured at the temperatures where the viscosity of the mixtures was roughly equal to that of DBAF at 97 °C (2.6×10^{-2} Pa s). Nematic MBBA did not show the transient photocurrent, although it absorbed the exciting light strongly. The nematic mixtures containing more than 10 mol% of DBAF showed a transient photocurrent similar to that shown in Fig. 1. The peak photocurrent increased about ten times with an increase in the DBAF content from 10 mol% to 30 mol%, indicating that the photocarriers were generated from the excited state of DBAF. On the other hand, the drift mobilities in the nematic mixtures were independent of the DBAF content and were nearly equal to those in nematic DBAF, as shown in Fig. 3; that is, $\mu_n=3\times10^{-5}$ and $\mu_p=2.5\times10^{-6}$ cm^2/V s at $\eta=2.6\times10^{-2}$ Pa s. This important fact indicates that the photocarriers do not migrate in nematic media by means of the electronic hopping process, but by means of the ionic process, and that the ionic carrier species are identical between nematic DBAF and the nematic mixtures of MBBA and DBAF.

In both nematic DBAF and the nematic mixtures of MBBA and DBAF, the effective radii of the negative ionic carriers were estimated from Eq. 2 to be *ca.* 1.1 Å. This value is quite small. In MBBA and 4,4′-azoxyanisole the radii of the ionic carriers have been estimated to be 2.1 and 1.1 Å respectively, and O^{2-} has been proposed as the negative carrier species.[3,7] The O_2^-, however, is the most probable negative carrier species in the present case for the following reasons. First, O_2 has the gaseous electron affinity of 0.44 eV,[16] which may be sufficient to accept an electron from the original negative photocarrier or the DBAF anion radical. Secondary, the effective radius of O_2^- has been reported to be 1.54 Å[17] or 1.4 Å.[18] These values are in fair agreement with the estimated value (1.1 Å). Third, it is well known that the carrier transport in liquid hydrocarbons changes from an electronic nature to an ionic one in the presence of only an extremely small amount of O_2.[19]

Once the cells were heated up to the isotropic liquid state with applying the electric field, the estimated radius of the negative ionic species changed from 1.1 Å to 4.1 Å. This suggests that an unknown degradation product acts as an electron trap instead of O_2.

In both nematic DBAF and the nematic mixtures of MBBA and DBAF, the radii of the positive ionic carriers were estimated from Eq. 2 to be 12.6 Å. This value is about ten times larger than that for the negative ones. 2-Amino-9-fluorenone, a probable impurity, is a candidate for the positive carrier species, because it may have an ionization potential sufficient to release an electron to the original positive photocarrier or the DBAF cation radical. It is, however, not probable that the 2-amino-9-fluorenone cation radical has an effective radius as large as 12.6 Å. Therefore, the DBAF cation radical itself seems to be the positive carrier species, actually migrating in the nematic media. For nematic MBBA, Yamashita and Amemiya have reported small μ_p values of $(6\text{—}9)\times10^{-6}$ cm^2/V s and proposed the MBBA cation radical as the positive carrier species.[8] Even in the nematic mixtures of MBBA and DBAF, the DBAF cation radical seems to be the positive carrier species, because the ionization potential of DBAF is smaller than that of MBBA.

It should be noted that μ_n is much larger than μ_p in the nematic state of MBBA,[3,8] DBAF, and their mixtures. A similar result was obtained for *N*-methyl-2-(*p*-hexyloxybenzylideneamino)-carbazole, which has a large π-electronic group;[20] that is, $\mu_n=1\times10^{-4}$ cm^2/V s

and $\mu_p = 1 \times 10^{-5}$ cm^2/V s in the nematic state at 122 °C. This is due to the significant difference in the effective radius of the carrier species between O_2^- and the corresponding cation radicals of the liquid crystal molecules. It may be considered that doping with an electron donor of a small molecular size increases μ_p appreciably.

Although being necessary to the occurrence of photoconduction, the presence of a π-electronic group in a liquid crystal molecule can not change the nature of carrier transport from ionic to electronic, as mentioned above. This can be explained as follows. For example, a DBAF molecule is composed of two parts. One is a fluorenone moiety which might serve as a hopping site. The other, a phenyl group with a long alkyloxy chain, is necessary to the presence of liquid crystal states. The latter part, which occupies the predominant space in the molecule, significantly reduces the electronic interaction between the large π-electronic groups. This is supported by the fact that the molecules having only the former part show electronic hopping transport in the liquid state, as has been reported for 2,4,7-trinitro-9-fluorenone[21] and benzene.[22]

Pressure-Volume-Temperature Relations of Supercooled Liquid and Glass of Triphenylchloromethane/*o*-Terphenyl Mixture

Motosuke NAOKI* and Manabu MATSUSHITA
Department of Textiles and Polymers, Faculty of Technology, Gunma University, Kiryu, Gunma 376
(Received February 14, 1983)

Volumetric data on the supercooled liquid state and on the glassy state are reported for a binary mixture of triphenylchloromethane and *o*-terphenyl. In the supercooled liquid state, the thermal expansivity, the isothermal compressibility, and their temperature dependences of the mixture are much samller than those of simple molecular liquids and are almost the same order of magnitude as those of polymer liquids. The glass of the mixture also closely resembles polymer glasses in the apparent thermodynamic properties. Some representative lattice-like liquid theories are applied to the pressure-volume-temperature relations of the supercooled liquid sample, with the aid of the principle of corresponding states.

Supercooling and glass transition phenomena are general in all sorts of molecules.[1] Since polymer liquids can easily be supercooled and vitrified, many experimental and theoretical studies on the glass transition of polymers have been proposed.[2,3] The polymer glass transition has been interpreted as arising from a large decrease in the intramolecular conformational entropy of the liquid as the temperature decreases.[3,4] The models adopted in the theory above, however, may not be appropriate for simple molecular liquids.

Recent molecular dynamic simulation studies give some insight into properties of supercooled liquids and glasses,[5] but the one-component monatomic glasses to be studied by such computer experiments are usually extremely difficult to prepare experimentally.

While many accurate measurements of volumetric properties of supercooled liquids and glasses of polymers have been reported,[6-12] such measurements are few for simple molecular liquids due to their low glass transition temperature and poor stabilities of the supercooled liquid states. It is well known that *o*-terphenyl[13] and its mixtures[14] can be supercooled and vitrified. The supercooled liquid of a mixture of triphenylchloromethane (TPCM) and *o*-terphenyl (oTP), TPCM/oTP, was found to be still more stable oTP alone.[15] In this paper, we attempt to measure the pressure-volume-temperature (*P-V-T*) relations of TPCM/oTP below the melting temperature up to 78.5 MPa. The volumetric properties thus obtained are compared with some simple liquid theories.

Experimental

Sample. Triphenylchloromethane (TPCM, the melting temperature $T_m = 113$ °C) and *o*-terphenyl (oTP, $T_m = 55.5$ °C) were purchased from Tokyo Chemical Industry Co. and were used without further purification. A mixture of TPCM/oTP with composition of 25/75 in weight ratio was used in the present study.

The supercooled sample contained in Pyrex test tube was stable over one month at room temperature, but, when the sample was in contact with mercury, it crystallized after about one week. In the present dilatometric experiments, the sample is contained in a small pouch made of thin natural rubber vulcanizate to avoid evolutions of internal stress in the glassy sample as the sample vitrifies. When the sample contained in the rubber pouch was in contact with mercury, it crystallized after about two weeks.

Equipment. Measurements of the *P-V-T* relations were carried out in a Pyrex dilatometer set in a pressure vessel which was immersed in an ethylene glycol/water bath controlled to an accuracy of ±0.02 K by use of a refrigerator (CC-100, Neslab). The temperature was controlled within ±0.004 K in the pressure vessel which was outlined elsewhere.[12] Silicone oil (KF-94, Shin-Etsu Chemical Co.) was used to transmit the hydrostatic pressure. The pressure was measured by a Heise bourdon tube gauge with an automatic compensator (Dresser Industries) and the temperature by a calibrated alumel-chromel thermocouple inserted in the pressure vessel.

A schematic diagram of the pressure dilatometer is shown in Fig. 1. The sample was separated from mercury and Pyrex glass chamber by a thin pouch made of natural rubber vulcanizate. When the sample was directly in contact with the chamber, the dilatometer was almost always broken due to strong adhesion of the sample to the chamber wall as the sample vitrified. Even if the dilatometer was not broken, a high internal stress stored in the glassy sample would result in a poor reproducibility of the volumetric data.

Variations of the sample volume in the dilatometer with temperature and pressure were obtained from changes in the mercury level in the dilatometer, which was read by measuring the emf of a variable transformer (150-9, Shinko Electric Co.)

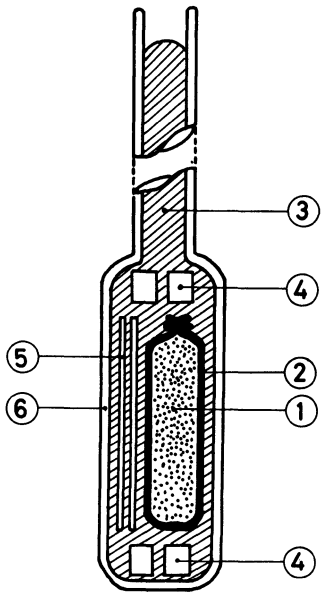

Fig. 1. Schematic diagram of pressure dilatometer.
1: Sample, 2: rubber pouch, 3: mercury, 4: pyrex stopper, 5: pyrex capillary, 6: pyrex chamber.

induced by a piece of Permalloy set on the top of mercury column. Pressure effects on the emf were negligibly small up to 100 MPa, but temperature effects were not.[12] The *P-V-T* data for mercury taken from Refs. 16 and 17 and a mercury-filled dilatometer were used to calibrate the temperature variation of the emf and to calculated the specific volume of the sample. Details of the pressure cell used and the treatments of data are given elsewhere.[12]

Experimental Procedure and Operations. TPCM and oTP were mixed at 130 °C. The sample was loaded in the rubber pouch at 70 °C, being degassed in slight vacuum. Then the sample was sealed by fastening the pouch with a band made of natural rubber vulcanizate. The rubber pouch and band had previously been purified by repeated sweeling with benzene and toluene and deswelling with methanol and acetone. Mercury was loaded in the dilatometer *in vacuo* at about −30 °C.

The density of the sample was measured at 30 °C by use of a picnometer of volume 25 ml. An isobaric cooling experiment to obtain T_g and the atmospheric V–T relation was carried out at about 1 K intervals in the liquid state and at about 0.5 K intervals in the glassy state with a continuous cooling rate of 0.24 K min^{-1} from 310 to 238 K. Then a heating experiment was carried out with a rate of 0.24 K min^{-1} from just above T_m of mercury (235.28 K) to 273 K.

Isothermal experiments in the supercooled liquid region were carried out to obtain the *P-V-T* relations at about 4 K intervals over a temperature range of 240—308 K. The pressure was changed in increments of 5.9 MPa in the 0.1—19.6 MPa region and in increments of 9.8 MPa in the 19.6—78.5 MPa region.

V-P relations of the glass vitrified by continuous cooling at a rate of 0.24 K min^{-1} were measured at about 1.5 K intervals from 235.5 K to 249.6 K. At lower temperatures, *V-P* relations under high pressures were not obtained due to crystallization of mercury. On the other hand, since the sample relaxed toward the equilibrium liquid state and slight retardations were observed in the volume at lower pressures near T_g, the pressure was not released in order to avoid the progressive retardation. The experiments for the glassy state were conducted as quick as feasible.

Although the sample penetrates into the natural rubber pouch, the excess mixing volume between TPCM/oTP and the pouch was ignored in the calculation of the specific volume v of the sample:

$$v_{app}(w+w_r) = wv + w_r v_r, \quad (1)$$

where v_{app} is the apparent average specific volume of the sample and the rubber pouch and band, v_r the specific volume of the pouch and band,[18] w the mass of the sample (1.1181 g), and w_r the total mass of the pouch and band (0.2653 g).

Results

Supercooled Liquid State. The results of the *P-V-T* experiments are summarized in Fig. 2. Each atmospheric isobar of the liquid volume from the heating experiment exactly falls on that from the cooling experiment above 254 K. The liquid state specific volume v is expressed by a quadratic equation in temperature T at each pressure P:

$$v = a_0 + a_1 T + a_2 T^2. \quad (2)$$

Values of a_0, a_1, a_2, and the standard deviation σ obtained by the least-squares method are listed in Table 1. The second derivatives a_2 are very small and the isobars of TPCM/oTP are very close to being linear in the supercooled liquid region. Thus the thermal expansivity α, $\alpha \equiv (\partial \ln v/\partial T)_p$, decreases with increasing temperature at all pressures in the present temperature region. Some examples of v and α calculated from Eq. 2 are shown in Figs. 3 and 4, respectively.

The *P-T* isochores calculated from Eq. 2 are shown

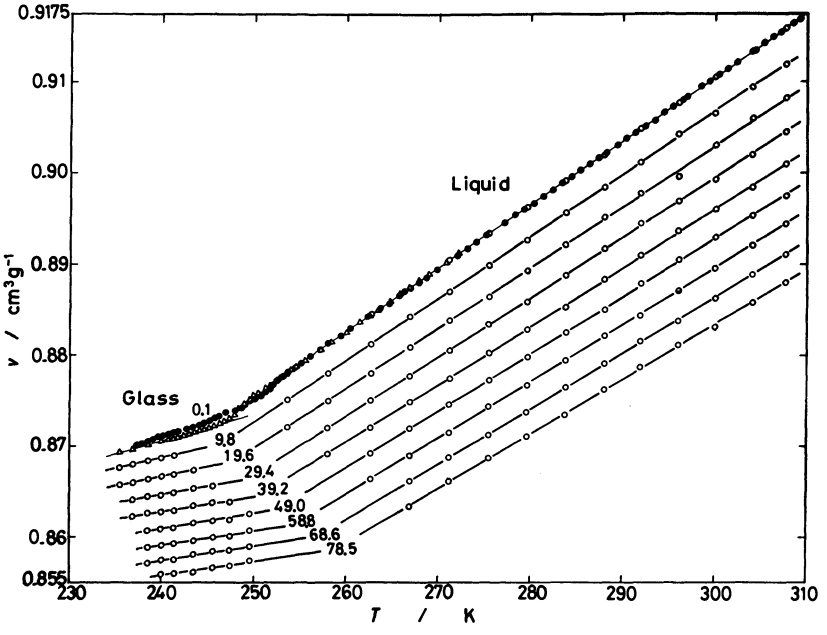

Fig. 2. Summary of *P-V-T* relations.

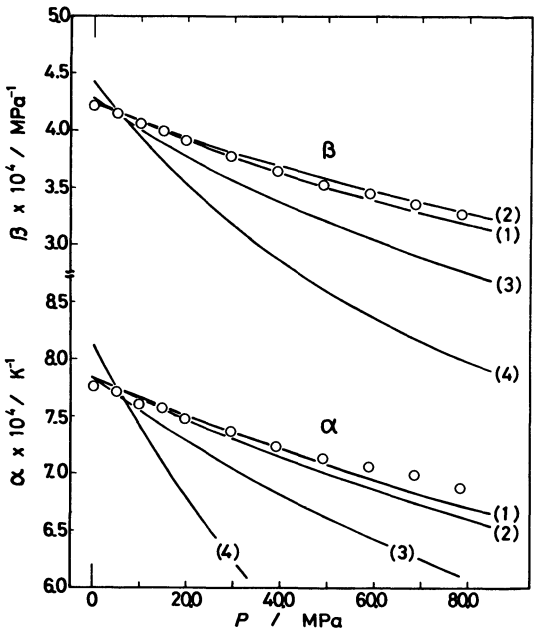

Fig. 4. Thermal expansivity and isothermal compressibility of supercooled liquid at 285 K. Indices of each line are the same as those in Fig. 3.

in Fig. 5. The isochores are approximately linear over the present experimental range. Thus the thermal pressure coefficient γ, $\gamma\equiv(\partial P/\partial T)_v$, of the supercooled TPCM/oTP, as well as most liquids,[19] is approximated as a function of volume only. Values of γ determined from slopes of the isochores are shown in Fig. 6. The variation of γ with volume is well represented by a linear equation:

$$\gamma = 11.159 - 10.350\,v \quad (\mathrm{K^{-1}\,MPa}), \tag{3}$$

with the standard deviation being 0.0033 K^{-1} MPa.

The isothermal compressibility β, $\beta\equiv-(\partial \ln v/\partial P)_T$, can be calculated from

$$\beta = \frac{\alpha}{\gamma}, \tag{4}$$

with α from Eq. 2 and γ from Eq. 3. The results are plotted as a function of pressure in Fig. 4. The values of α and β are smaller than those of ordinary molecular liquids[20] and poly(dimethylsioxane)[11,21] and very close to those of ordinary supercooled polymer liquids.[9-12]

The Tait equation is commonly written as[22]

$$\frac{v}{v_0} = 1 - C\ln\left(1+\frac{P-P_0}{B}\right), \tag{5}$$

where v_0 is the specific volume at the reference pressure P_0. Simha *et al.*[7,24] have shown that C can be assumed to have the universal value of 0.0894 and B can be expressed by

$$B = b_1 \exp(-b_2 T). \tag{6}$$

Values of b_1 and b_2 calculated by the least-squares

Table 2. Tait parameters

	C	b_1 / MPa	$b_2\times10^3$ / K^{-1}

method are listed in Table 2. The average deviation in v/v_0 is 2.5×10^{-4}, which exceeds the deviation in Eq. 2 on the whole. As can be seen in Fig. 4, α and β calculated from Eq. 5 (indexed by (1)) agree well with those from Eqs. 2, 3, and 4 (circles).

Glassy State. In the glassy and glass transition regions, *i.e.*, 239—254 K Each atmospheric V-T isobar from the cooling experiment does not fall on that from the heating experiment, as shown in Fig. 2. In this region, the relation time is very long and the cooling isobar may not attain the one of the thermal steady state due to bulkiness of the sample. The atmospheric glass transition temperature obtained from the intersection point of the heating isobar and the liquid isobar (Eq. 2) is 244.2 K.

We have calculated the glass volume at elevated pressures based on the heating isobar. The glassy state specific volume were also expressed by Eq. 2 at each pressure. Values of the constants and the standard deviation in Eq. 2 obtained by the least-squares method are shown in Table 3, where isobars at elevated pressures are approximated by linear expressions, since the numbers of the experimental points are not sufficient. Volumetric properties of the glass calculated from Eq. 2 are summarized in Fig. 7.

The Tait equation was also applied for the glassy state and the average deviation was obtained to be 3.5×10^{-4}. The P-T isochores calculated from the isobars, Eq. 2, and from the isotherms, Eq. 5, are shown in Fig. 5.

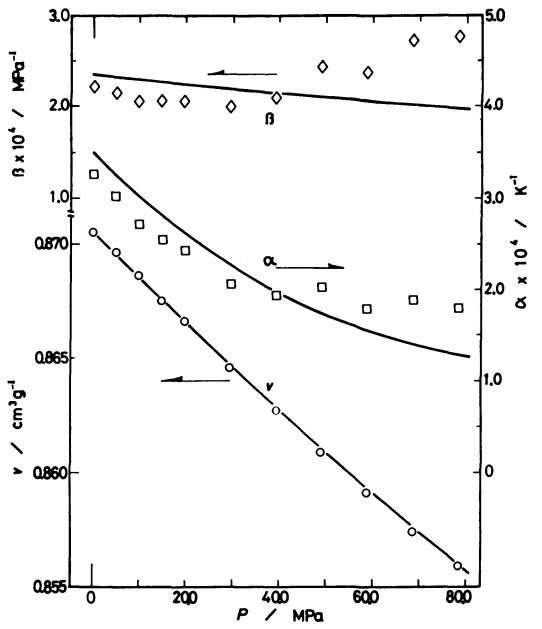

Fig. 7. Isotherms of specific volume (○), thermal expansivity (□), and isothermal compressibility (◇) in glassy state. Lines are calculations from Tait equation.

Values of γ determined from slopes of the isochores are shown in Fig. 6. Gamma from the isobars does not precisely agree with γ from the isotherms. A quadratic equation is applied to γ by the least-squares method:

$$\gamma = 1482.67 - 3489.57\,v + 2054.02\,v^2 \quad (\mathrm{K^{-1}\,MPa}), \tag{7}$$

where the standard deviation is 0.066 $\mathrm{K^{-1}}$ MPa.

As shown in Fig. 7, α calculated from Eqs. 5, 7, and 4 (solid line) approximately agrees with that from Eq. 2 (lozenges), but β from Eqs. 2, 7, and 4 (lozenges) considerably deviates from that from Eq. 5 (solid line). This implies the inconsistency involved in the empirical equations, Eqs. 2, 5, and 7. The inconsistency may arise from slow volumetric retardations of the glass towards an equilibrium liquid state.

Discussion

Comparison with Some Simple Equations of State for Supercooled Liquid. For the condensed liquid region, as an *empirical* or an *useful* equation of state, lattice-like liquid theories rather than more strict theories have widely used due to their simplicity and their quantitative success in liquids[24] and liquid mixtures.[25]

Prigogine, Trappeniers, and Mathot derived an equation of state for polymer liquids based on the Lennard-Jones and Devonshire cell model.[26,27] Its simplest form with a square-well approximation introduced by Nanda and Simha[28] is expressed as

$$\frac{\tilde{P}\tilde{v}}{\tilde{T}} = \frac{1}{1 - 2^{-1/6}\tilde{v}^{-1/3}} + \frac{\tilde{v}^{-4} - \tilde{v}^{-2}}{\tilde{T}}, \tag{8}$$

wihch is hereafter referred to as the PNS equation. $\tilde{P}$, $\tilde{v}$, and $\tilde{T}$ are the reduced quantities related to the ordinary configurational quantities such as P, v, and T through characteristic reduction parameters (with asterisk):

$$\tilde{P} = \frac{P}{P^*}, \quad \tilde{v} = \frac{V}{V^*}, \quad \tilde{T} = \frac{T}{T^*}. \tag{9}$$

Using Tonks' free volume[29] and a van der Waals type intermolecular potential energy, Flory, Orwall, and Vrij presented an equation of state:[30]

$$\frac{\tilde{P}\tilde{v}}{\tilde{T}} = \frac{1}{1 - \tilde{v}^{-1/3}} - \frac{1}{\tilde{v}\tilde{T}}, \tag{10}$$

which is hereafter referred to as the Flory equation.

Hole theories, which usually lead to equations of state of complex form, generally improve the cell theories in the low density region, but not in the high density region.[31] In the well condensed region such as the supercooled liquid state, little is expected for such hole theories without some adjustable parameters.[32] Therefore, we do not discuss them here.

Apart from the cell theories, the most primitive hole theory is constructed by adopting a random-mixing assumption on the distribution of occupied cells and empty cells:

$$\frac{\tilde{P}\tilde{v}}{\tilde{T}} = \tilde{v}\ln\frac{1}{1 - \tilde{v}^{-1}} - \frac{1}{\tilde{T}\tilde{v}}. \tag{11}$$

This is hereafter referred to as the Simple Hole equation. Based on this equation, Sanchez and Lacombe have proposed an equation of state for polymer liquids, which gives some qualitative success in polymer solution.[33]

From Eq. 9, αT and βP^* are expressed by

$$\alpha T = \left(\frac{\partial \ln \tilde{v}}{\partial \ln \tilde{T}}\right)_{\tilde{P}}, \tag{12}$$

$$\beta P^* = \left(\frac{\partial \ln \tilde{v}}{\partial \tilde{P}}\right)_{\tilde{T}}. \tag{13}$$

If the principle of corresponding states is applicable, αT and βP^* should be universal functions of the reduced quantities. At zero pressure, therefore, the theoretical αT *vs.* log $\tilde{v}$ curves should be shifted parallel to the log v axis to the experimental αT *vs.* log v curve. The shift factor corresponds to v^*. Similarly, the superposition of the theoretical αT curves parallel to the log T axis should give T^*. When T^* obtained above is employed, the superposition of the theoretical log βP^* curves parallel to the log β axis should give P^*. Results are summarized in Table 4.

The PNS equation approximately describes the variation of the thermal expansivity with pressure, *i.e.*, the variation of the compressibility with temperature, as shown in Fig. 4. This accordance can clearly be seen in Fig. 3. The PNS equation represents satisfactorily the *V-P* isotherms, while the Flory equation, as often demonstrated,[21,34] predicts appreciably less compressible than the experiments.

The Simple Hole equation, as naturally anticipated from its model which consists of gas-like molecules and

Table 4. Characteristic parameters for the liquid

Theory	v^* / cm³ g⁻¹	T^* / K	P^* / MPa

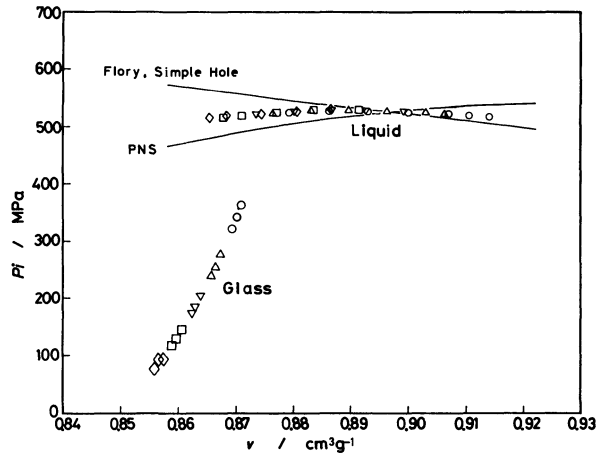

Fig. 8. Internal pressures of supercooled liquid and glass. Lines are theories.
○: 0.1, △: 19.6, ▽: 39.2, □: 58.8, ◇: 78.5 MPa.

vacuous cells, overestimates considerably the second and third derivatives of the thermodynamic free energies. The model might be suitable for the liquid state in a tolerably high temperature region.

In Fig. 8, the internal pressure P_i, $P_i = T_r - P$, calculated from Eq. 3 is shown as a function of volume. P_i has a maximum at about 0.89 $cm^3\ g^{-1}$. The maximum can be predicted by the Lennard-Jones potential (PNS equation), but a quantitative agreement with the experiments in the location of the maximum is not given. The van der Waals type potential seems to be appropriate in somewhat higher temperature region.

Glassy State. Several equations of state for glasses have been proposed.[12] However, the present experimental temperature range is considered to be too narrow to make a significant comparison with those theories.

The internal pressure P_i of the glass calculated from Eq. 7 is shown in Fig. 8. Values of P_i determined by using α from Eq. 2 and β from Eq. 5 are somewhat larger than those in Fig. 8 in the lower volume region, but the qualitative shape of the figure is unchanged. P_i of the glass is much smaller than that of the supercooled liquid. The glass P_i increases significantly with increasing volume. This behavior cannot be described by the van der Waals type potential. The Lennard-Jones potential may be appropriate for the TPCM/oTP glass as well as for the poly(vinyl chloride) glasses.[12]

Conclusion

The present study offers, probably for the first time as far as we know, the detailed data on the *P-V-T* relations in the supercooled liquid state and the glassy state of a relatively simple, global molecular liquid constituted by the triphenylchloromethane/*o*-terphenyl (25/75 in weight ratio) mixture.

The thermal expansivity, the compressibility, the thermal pressure coefficient, and their variations with temperature and pressure in the supercooled liquid region are apparently similar in magnitude to those of polymer liquids, rather than to those of simple molecular liquids above the melting temperature. The *P-V-T* relations of the supercooled liquid are fairly well represented by the Prigogine-Nanda-Simha equation of state. The lattice-like liquid model might be appropriate for the well condensed liquid state of normal liquids such as the supercooled liquid state.

The apparent thermodynamic properties of the TPCM/oTP glass are also very similar in magnitude to those of polymer glasses.

Viscosity *B*-Coefficients, Apparent Molar Volumes, and Activity Coefficients for α- and γ-Cyclodextrins in Aqueous Solutions

Koichiro MIYAJIMA,* Masahiro SAWADA, and Masayuki NAKAGAKI
Faculty of Pharmaceutical Sciences, Kyoto University, Yoshida Shimoadachi-cho, Sakyo-ku, Kyoto 606
(Received April 2, 1983)

The viscosities and densities at 15, 25, and 35 °C, and activity coefficients at 25 °C for the aqueous solutions of α- and γ-cyclodextrins were measured, and the results were interpreted in terms of solute-solvent and solute-solute interactions. The concentration and temperature dependences of viscosities and apparent molar volumes are almost similar to those of linear saccharides, *i.e.* maltose and maltotriose, indicating that α- and γ-cyclodextrins are structure forming solutes. However, the concentration dependences of activity coefficients of cyclodextrins are significantly different from those of maltose and maltotriose. The results were tentatively assigned to the formation of dimer in aqueous solutions.

Cyclodextrins are the condensed ring compounds of D-glucopyranoses through α-1,4-glucosidic linkage and are called α-, β-, and γ-cyclodextrins (CD) in accordance with the numbers of glucose residues, 6, 7 and 8, respectively. CD has been well-known to form inclusion complexes with a wide varieties of molecular species irrespective of hydrophobic or ionic in nature.[1]

In contrast to the numerous studies on the complex formation, the studies on the solution of CD seem to be sparse. However, the thermodynamic properties of aqueous solutions must play an important role on the complex formation, because the complex formation usually takes place in aqueous solution. Furthermore it is also interesting to compare the solution properties of CD with those of linear di- and trisaccharides reported previously.[2]

In these viewpoints, we determined the viscosity *B*-coefficients and the apparent molar volumes at 15, 25, and 35 °C, and the activity coefficients at 25°C for α- and γ-CD in aquous solutions, and discussed the effects of CD on the water structure.

Experimental

Materials. Reagent grade α- and γ-CD purchased from Nakarai Chemical Co. Ltd., were recrystallized twice from water according to French *et al.*[3] and were dried *in vacuo* for 5h at 110 °C before use. After drying, the water contents of crystalline compounds determined by the Carl Fisher method were found to be less than 0.2% for each CD. The concentration correction was made on every solution. Reagent grade sodium chloride purchased from Matsunaga Chemical Co. Ltd., was used after drying without purification. CD and sodium chloride solutions were prepared with water purified by distillation and deionization.

Methods. The viscosity and density measurements were carried out at 15, 25, and 35 °C by using the apparatus described in a previous paper.[2] Vapour pressure over aqueous solution was measured at 25 °C with an osmometer model 117 manufactured by Corona Electric Co. Ltd. Sodium chloride was used as a standard substance for the measurement of the instrument constant. The instrument constant thus obtained was almost unchanged in a set of measurements. But the constant was changed slightly in another set of measurements. Consequently, the instrument constant was determined for every set of measurements.

Results

Viscosity. The reletive viscosity, η_{rel} of a non-electrolyte solution can be expressed by

$$\eta/\eta_0 = \eta_{rel} = 1 + Bc + Dc^2, \quad (1)$$

where η_0 and η are the viscosities of the solvent and the solution, respectively, and c is the concentration in mol dm^3. B and D are the characteristic constants depending on the solute and the solvent at constant temperature and pressure. The plots of $(\eta_{rel}-1)/c$ *vs.* c for α- and γ-CD at 25 °C are shown in Fig. 1, indicating that Eq. 1 is valid up to about 0.05 mol dm^{-3}. The B and D coefficients determined from the intercepts and slopes at 15, 25, and 35 °C are listed in Table 1. The points in low concentration, which considerably deviate from the lines because of the experimental error, were neglected, and the standard deviation of each plot up to 0.05 mol dm^{-3} was calculated to be within 0.014 mol^{-1} dm^3. Therefore, the experimental errors in B and D are estimated to be less than 0.03 mol^{-1} dm^3 and 1.0 mol^{-2} dm^6, respectively.

The increment of B-coefficient arising from the structural change of water, B_{st}, may be obtained by

$$B_{st} = B - \nu V/1000. \quad (2)$$

The second term of the right hand side of Eq. 2 expresses the contribution of the hydrodynamic obstruction effect according to Einstein and Shimha.[4] On the assumptions that a certain number of water molecules is packed in a cavity and the shape of the molecule is approximated by an oblate ellipsoid, the ν value of α-CD was estimated on the basis of Scheraga's table[5] using the numerical value of axial ratio obtained from the molecular model,[6] resulting in 2.26. The molar volume of the oblate, V, is calculated by

$$V = \bar{V}^\circ + N\bar{V}_w, \quad (3)$$

where $\bar{V}^\circ$ and $\bar{V}_w$ is the partial molar volume of α-CD at infinite dilution and molar volume of water, respectively. N is the number of water molecules in the cavity. An α-cyclodextrin hexahydrate crystal contains two water molecules in the cavity.[7] By assuming that the number of water molecules in the cavity of α-CD molecule in solution state is the same as that in solid state, the value of B_{st} of α-CD was found to be 0.71. The B_{st} value of γ-CD could not be obtained because

TABLE 1. THE VALUES OF B, D, dB/dT, $\bar{V}°$ AND α^* FOR CYCLODEXTRINS

	Temp/°C	α-CD	γ-CD
B / mol^{-1} dm^3	15	2.50	3.90
	25	2.39	3.74
	35	2.24	3.62
D / mol^{-2} dm^6	15	8.6	17.4
	25	7.8	15.7
	35	7.8	14.7
$(dB/dT)\times10^2$ / mol^{-1} dm^3 K^{-1}	25	−1.3	−1.4
$\bar{V}°$ / cm^3 mol^{-1}	15	598.5	788.5
	25	606.0	803.0
	35	612.0	805.3
$\alpha^*\times10^3$ / cm^3 mol^{-1} K^{-1}	25	1.1	0.8

the N value is not available.

Figure 2 shows the temperature dependence of B values. As seen in Fig. 2, the value of B decreases with increase of temperature for both CDs. The values of dB/dT at 25 °C are shown in Table 1.

Density. Apparent molar volume of solute, ϕ_v, was calculated by

$$\phi_v = \frac{1000(d_0-d)}{cd_0} + \frac{M_2}{d}, \quad (4)$$

where d_0 and d are the densities of the solvent and the solution, respectively, and M_2 is the molecular weight of the solute. As shown in Fig. 3, ϕ_v at each temperature is linearly related to c:

$$\phi_v = \bar{V}° + b_v c, \quad (5)$$

where $\bar{V}°$ is the partial molar volme at infinite dilution and b_v is the empirical constant. The $\bar{V}°$ values obtained from the extrapolation of ϕ_v to $c=0$ are also shown in Table 1. The values of b_v for the CDs are positive at every temperature. In Fig. 3, the positive deviations of ϕ_v from the lines in low concentration may be due to experimental error. The standard deviation of each plot was within 0.3 cm^3 mol^{-1}, if the points deviating extremely in low concentration were neglected. The experimental error in $\bar{V}°$ is estimated to be less than 0.6 cm^3 mol^{-1}.

The temperature dependence of $\bar{V}°$ is shown in Fig. 4. The values of $\bar{V}°$ of α- and γ-CD increase nonlinearly with temperature, and the curves display upward curvatures. The thermal expansion coefficient, α^*, is defined by

$$\alpha^* = (\partial \bar{V}°/\partial T)_p/\bar{V}°. \quad (6)$$

The values of α^* at 25 °C are given in Table 1.

Activity Coefficient. The relations between the osmotic coefficient, ϕ, and the concentration in mol kg^{-1}, m, at 25 °C are shown in Fig. 5. By the least-squares fitting, ϕ's are expressed in terms of m as

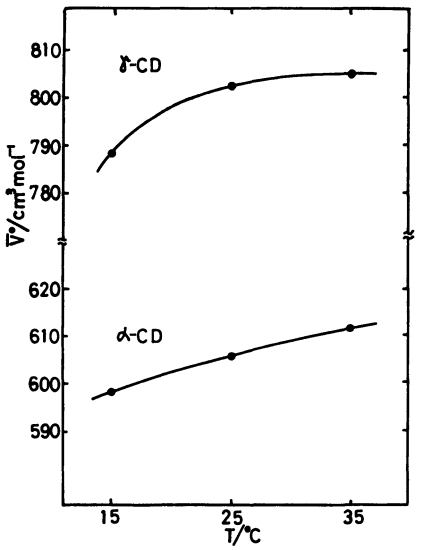

Fig. 4. Temperature dependence of $\bar{V}°$ for cyclodextrins.

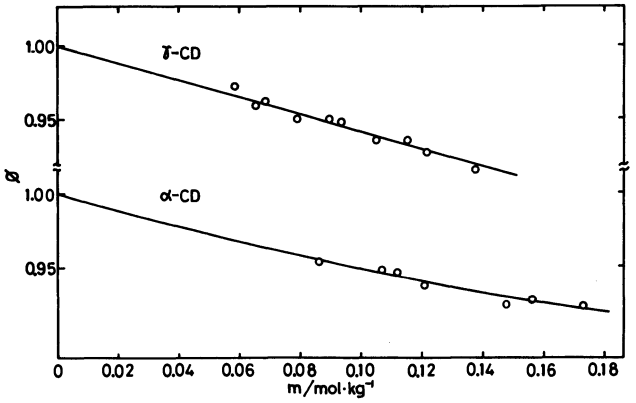

Fig. 5. Osmotic coefficients of cyclodextrins at 25 °C.

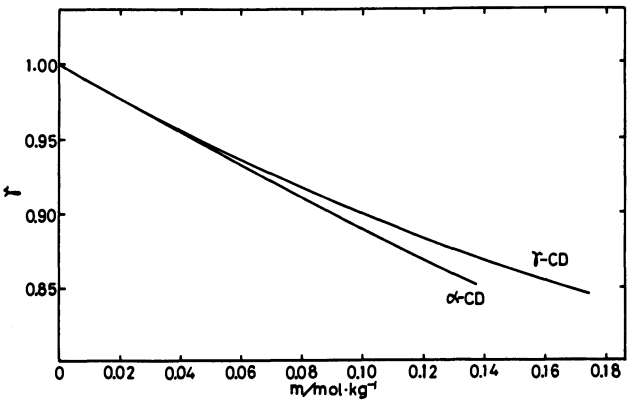

Fig. 6. Activity coefficients of cyclodextrins at 25 °C.

$$\left.\begin{aligned}\phi &= 1 - 0.585\,m \quad \text{for } \alpha\text{-CD},\\ \phi &= 1 - 0.588\,m + 0.789\,m^2 \quad \text{for } \gamma\text{-CD}.\end{aligned}\right\} \tag{7}$$

The activity coefficients, γ, were calculated from the osmotic coefficients by the following equation:

$$\ln\gamma = (\phi - 1) + \int_0^m \frac{\phi - 1}{m}\mathrm{d}m. \tag{8}$$

Introducing Eqs. 7 into Eq. 8, and integrating, we obtain

$$\left.\begin{aligned}\ln\gamma &= -1.170\,m \quad \text{for } \alpha\text{-CD},\\ \ln\gamma &= -1.176\,m + 1.148\,m^2 \quad \text{for } \gamma\text{-CD}.\end{aligned}\right\} \tag{9}$$

As seen in Figs. 5 and 6, the osmotic and activity coefficients decrease with increase of the concentration.

Discussion

As stated in a previous paper,[8] the signs and the magnitudes of B_{st} and $\mathrm{d}B/\mathrm{d}T$ are the useful criterion for the classification of solute property in water. As seen in Table 1, both α- and γ-CD are structure makers because of their negative $\mathrm{d}B/\mathrm{d}T$ values. The negative values of $\mathrm{d}B/\mathrm{d}T$ increase with the number of glucose regardless of linear[2] or cyclic, indicating that glucose residue has a structure forming ability. On the other hand, Hepler[9] proposed other criterion for the classification of solutes as structure makers or breakers. His criterion is that the structure making solutes have the positive sign of $(\partial^2\bar{V}°/\partial T^2)$ while the structure breaking solutes the negative sign. As shown in Fig. 4, the signs of $(\partial^2\bar{V}°/\partial T^2)$ for CDs are negative. If we adopt Hepler's criterion, CDs are structure breakers in disagreement with the conclusion obtained from B_{st} and $\mathrm{d}B/\mathrm{d}T$. As for hydrophilic nonelectrolytes, the values of $(\partial^2\bar{V}°/\partial T^2)$ for urea,[10] maltose and maltotriose[2] are negative, and that for D-glucose[2] is nearly zero. These experimental results are in conflict with Hepler's criterion, because it has been proved by many studies that urea is a structure breaker, while D-glucose, maltose and maltotriose are structure makers. Therefore, Hepler's criterion seems to be inapplicable to hydrophilic nonelectrolytes such as sugars and urea.

As seen in Fig. 7, the B-coefficients of linear maltodextrins[11] increase almost linearly with the degree of polymerization (n) and the point of the B-coefficients for cyclic dextrins, *i.e.* α- and γ-CD, locate below the B *vs.* n curve for linear maltodextrins. The shape and the size of the hydrated molecule or ion affect mainly the sign and magnitude of the B-coefficient. The partial molar volumes of linear polysaccharides are not so

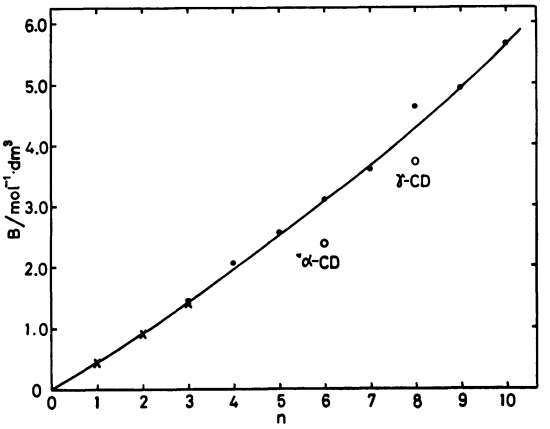

Fig. 7. Relation between B-coefficients and the number of glucose residues (n) for maltodextrins at 25 °C.
●: Calculated values from Thoma's table.[11] ×: Our values in a previous paper.[2] ○: Cyclodextrin.

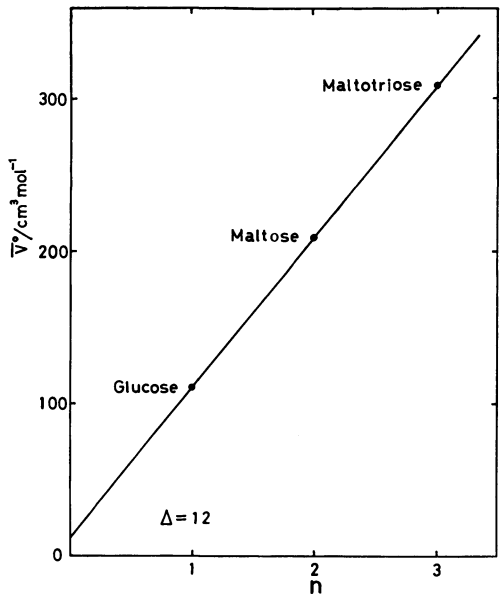

Fig. 8. Relation between $\bar{V}°$ and n at 25 °C.

much different from those of the corresponding cyclic dextrins as will be seen later, and the hydrodynamic rigid volumes of the cyclic types are lager than those of the linear types based on the assumption that the exchange of water molecules between cavity and bulk has no influence on the hydrodynamic process. This assumption is supported by the fact that the point for γ-CD is more close to the B *vs.* n curve than that for α-CD in Fig. 7, because γ-CD has a larger cavity than α-CD.[12] The above discussion leads to the conclusion that the small values of the B-coefficients for cyclic dextrins, as compared with those of the corresponding linear ones, are due to the difference in shape, *i.e.* rod-like and oblate type molecules.

The partial molar volume at infinite dilution of a linear polymer, $\bar{V}^{olin}(n)$, is expressed as

$$\bar{V}^{olin}(n) = n\bar{V}^{om} - (n-1)\Delta = n(\bar{V}^{om} - \Delta) + \Delta, \quad (10)$$

where n is the degree of polymerization, $\bar{V}^{om}$ the volume of the monomer *i.e.* D-glucose, and Δ is the volume change on the formation of the α-1,4 ether linkage. On the other hand, the partial molar volume at infinite dilution of a cyclic polymer, $\bar{V}^{ocyc}(n)$, is expressed as

$$\bar{V}^{ocyc}(n) = n\bar{V}^{om} - n\Delta. \quad (11)$$

The Δ value was found to be 12 cm^3 mol^{-1} form the intercept and the slope of the $\bar{V}^{olin}(n)$ *vs.* n curve as seen in Fig. 8. The value of $\bar{V}^{ocyc}(n)$ was calculated from Eq. 11 using the Δ value, resulting in 596 and 795 cm^3 mol^{-1} for α-CD and γ-CD, respectively. These calculated values are smaller than the experimental values of $\bar{V}^{ocyc}(n)$ by 10 to 8 cm^3 mol^{-1}. This result may be due to the formation of intramolecular hydrogen bonding[13] and the bulkiness of water in the cavity in which hydrophobic environment is formed.

The thermal expansion coefficient of α-CD at 25 °C is close to that of D-glucose (1.0×10^{-3}) and smaller than that of maltose (1.3×10^{-3}) or maltotriose (1.4×10^{-3}). This fact may be related to the torsional rotation around the α-1,4-linkage which brings about the increase of unstructured water having high thermal expansibility because D-glucose has no α-1,4-linkage and the rotations of glucose residues in the CD molecule are almost hindered. The small value of α^* of γ-CD may be due to the large cavity, in which bulky water is packed.

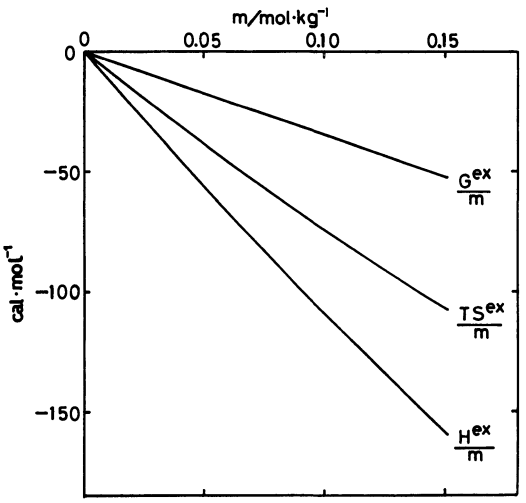

Fig. 9. Thermodynamic quantities of α-CD at 25 °C.

As seen in Figs. 5 and 6, the concentration dependences of the osmotic and activity coefficients for α- and γ-CD are strikingly different from those for linear oligosaccharides, such as maltose and maltotriose. The coefficients of the CDs decrease with increase of concentration. In general, the decrease in activity coefficients with the increase of concentration is possibly interpreted in terms of two different effects, *i.e.* structure breaking effect and the association of the solutes.

Using the data of the heat of dilution, ΔH^{dil},[14] excess thermodynamic quantities of α-CD are calculated from

$$G^{ex} = mRT(1 - \phi + \ln\gamma), \quad (12)$$

$$H^{ex} = -\Delta H^{dil}, \quad (13)$$

and

$$G^{ex} = H^{ex} - TS^{ex}. \quad (14)$$

As seen in Fig. 9, the sign of each quantity is negative, being opposite to that of D-glucose.[15] The negative sign of G^{ex} is based on the predominance of the negative value of H^{ex} over the negative value of TS^{ex}. The negative value of H^{ex} means the endothermic heat on the dilution process. Judging from the TS^{ex}/m *vs.* m curve in Fig. 9, excess partial molar entropy of water, $\bar{S}_w^{ex}$, would be positive, suggesting that the ordering of water molecules decreases with increase of solute concentration as far as solute-solute interactions are weak or absent. However, the possibility that the CD is a structure breaker would be small, because such a large decrease of γ in low concentration is unlikely to take place as a result of solute-solvent interaction alone, and α-CD is a hydrodynamically structure maker as stated in the preceding section.

From these considerations, we regard the positive value of $\bar{S}_w^{ex}$ as the result of the association of solute, and obtain the dimerization constant graphically using Eq. 13.[16]

$$K = (1 - \phi)/m\phi^2. \quad (13)$$

The K values of α- and γ-CD were found to be 0.66 and 0.55 mol^{-1} kg, respectively. These K values indicate that about 10 molecules out of 100 molecules form a dimer at 0.1 mol kg^{-1}.

The effect of the association of CD is considered to be reflected in Figs. 1 and 3. As mentioned above, B and $\bar{V}^\circ$ express the solute-solvent interactions at infinite dilution, where the association does not occur. The values of B and $\bar{V}^\circ$ are actually determined by the extrapolations of $(\eta_{rel}-1)/c$ and ϕ_v to $c=0$. Therefore, the discussions of the nature of CD based on these values are not influenced by the association of CD. On the other hand, D and b_v are regarded to express the solute-solute interactions. Accordingly, the effect of the association of CD is reflected in the values of D and b_v, *i.e.* the slopes of the lines in Figs. 1 and 3. But it is difficult to derive the evidences of the association of CD from the values of D and b_v, because these coefficients are also influenced by other complicated factors such as structural interactions.[17,18]

We have no other evidence that CD forms a dimer in aqueous solutions at the present stage. But some kinds of compounds are included in β-CD dimer of head to head type, in which two secondary OH groups of β-CD are hydrogen bonded.[19]

In conclusion, α- and γ-CD promote the structure of water and may possibly form a dimer in aqueous solutions, resulting in the increase of excess partial molar entropy of water.

Anharmonic Potential Functions and Intrinsic Reaction Coordinates of Polyatomic Molecules

Katsunosuke MACHIDA
Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606
(Received April 11, 1983)

A general method has been developed to describe the atomic motion along a given intrinsic reaction coordinate (IRC) in the vicinity of the potential minimum of a polyatomic molecule whose anharmonic force constants are known experimentally or theoretically. The components of the position vector of a configuration point on an IRC in the normal coordinate space are expanded as power series of the path length from the origin measured along the IRC. Explicit expressions of the expansion coefficients up to the third order have been given in terms of the normal frequencies and the anharmonic force constants with respect to the normal coordinates. The atomic loci along the IRC are given by transformation from the normal coordinates to the Cartesian displacements. Through application to formaldehyde and water, the method has proved to be useful to check if a given normal coordinate can be connected to any dissociation path on large distortion of the molecule.

The intrinsic reaction coordinate, hereafter abbreviated as IRC, has been introduced by Fukui in 1970 as a concept of fundamental importance in reaction dynamics of polyatomic molecules.[1] An IRC describes how a molecule is distorted when the atomic displacement associated with a chemical reaction proceeds with an infinitesimal rate. Determination of the IRC is an indispensable step in understanding the reaction mechanism. An IRC should coincide with one of the normal coordinates if the potential function which regulates the molecular vibrations around the equilibrium configuration is rigorously harmonic.[1,2] In actual molecules, however, presence of anharmonic terms in the potential leads to deviation of any IRC's from the normal coordinates defined at the potential minimum when the constituent atoms move away from the equilibrium positions. The non-linear relationship between an IRC and the normal coordinates should thus be described uniquely in terms of the anharmonic force constants. The present work has been initiated to search for such a relationship in a general form, and to utilize it to examine the behavior of an IRC near the minimum of an experimentally determined potential function of polyatomic molecules containing anharmonic terms.

Theory

Following the standard perturbation theory, we expand the potential function of a polyatomic molecule as a power series of its normal coordinates in the form

$$V = \frac{1}{2}\sum_i \lambda_i Q^{i2} + \frac{\varepsilon}{6}\sum_{ijk} K_{ijk}Q^iQ^jQ^k + \frac{\varepsilon^2}{24}\sum_{ijkl} K_{ijkl}Q^iQ^jQ^kQ^l + \cdots, \quad (1)$$

where λ_i is the ith frequency parameter related to the normal frequency ω_i in cm^{-1} and the light velocity c by

$$\lambda_i = (2\pi c\omega_i)^2,$$

and ε is an ordering parameter. In analysing spectroscopic data, the higher-order force constants are usually given in the system of the dimensionless normal coordinates. The cubic and quartic constants in this system, k_{ijk} and k_{ijkl}, are transformed to those in Eq. 1 through the relations

$$K_{ijk} = (1+\delta_{ij})(1+\delta_{ik}+\delta_{jk})(h/2\pi)^{3/2}(\lambda_i\lambda_j\lambda_k)^{1/4}k_{ijk} \quad (2)$$

and

$$K_{ijkl} = (1+\delta_{ij})(1+\delta_{ik}+\delta_{jk})(1+\delta_{il}+\delta_{jl}+\delta_{kl}) \times (h/2\pi)^2(\lambda_i\lambda_j\lambda_k\lambda_l)^{1/4}k_{ijkl}, \quad (3)$$

respectively, where h is Planck's constant and δ_{ij} is Kronecker's delta. Differentiating Eq. 1 with respect to Q^i leads to

$$(\partial V/\partial Q^i) = \lambda_i Q^i + \frac{\varepsilon}{2}\sum_{jk} K_{ijk}Q^jQ^k + \frac{\varepsilon^2}{6}\sum_{jkl} K_{ijkl}Q^jQ^kQ^l + \cdots. \quad (4)$$

Whenever the molecule is distorted along an IRC in the vicinity of the potential minimum, any pairs of non-degenerate normal coordinates, Q^i and Q^j, should satisfy the IRC equation[1]

$$dQ^i/(\partial V/\partial Q^i) = dQ^j/(\partial V/\partial Q^j), \quad (5)$$

or

$$(\partial V/\partial Q^i)dQ^j - (\partial V/\partial Q^j)dQ^i = 0. \quad (6)$$

The form of Eq. 5 is the same as that in the case of the mass-weighted Cartesian coordinates[2] because of the orthogonality condition between the two coordinate systems.

Now we suppose that there is an IRC which converges into the normal coordinate Q^i when the molecular configuration approaches that at the potential minimum. In order to specify the position of a configuration point moving on this IRC, we may take the distance from the origin to the point measured along the IRC, s^i, as an independent variable, and represent each element of the position vector in the normal coordinate space as a function of s^i satisfying Eq. 5. In the vicinity of the potential minimum, such a function may be expanded as a power series of s^i in the form

$$Q^j = a^j_i s^i + \frac{\varepsilon}{2}a^j_{it}s^{i2} + \frac{\varepsilon^2}{6}a^j_{iti}s^{i3} + \cdots. \quad (7)$$

Substituting Eq. 7 with $j=i$, j, k, and l into Eq. 4 and multiplying the result by the differential of Eq. 7, we obtain the first term of Eq. 6 as

$$(\partial V/\partial Q^i)dQ^j = [\lambda_i a_i^i a_i^j s^i + \frac{\varepsilon}{2}\{\lambda_i(2a_i^i a_{ii}^j + a_{ii}^i a_i^j) + a_i^j \sum_{kl} K_{ikl} a_i^k a_i^l\} s^{i2} + \frac{\varepsilon^2}{6}\{\lambda_i(3a_i^i a_{iii}^j + 3a_{ii}^i a_{ii}^j + a_{iii}^i a_i^j) + a_{ii}^j \sum_{kl} K_{ikl} a_i^k a_i^l + a_i^j(3\sum_{kl} K_{ikl} a_i^k a_{ii}^l + \sum_{klm} K_{iklm} a_i^k a_i^l a_i^m)\} s^{i3} + \cdots] ds^i. \quad (8)$$

The second term of Eq. 6 can also be expressed by Eq. 8 provided that the superscripts i and j of the a coefficients are interchanged with each other and the subscript i of the force constants λ and K's is replaced by j. Since Eq. 6 holds for any displacements of the nuclei along the IRC under consideration, the coefficient of each power of s^i in the left hand side should vanish separately. The linear term gives the relation

$$(\lambda_i - \lambda_j) a_i^i a_i^j = 0, \quad (9)$$

which implies that

$$a_i^j = 0, \quad (10)$$

when both the conditions $\lambda_i \neq \lambda_j$ and $a_i^i \neq 0$ hold. This property of IRC's has already been pointed out by Fukui *et al.*[2]

Prior to estimation of a_{ii}^j, we shall determine the first two coefficients of the expansion of Q^i in terms of s^i. It follows from the definition of s^i that

$$\sum_k (dQ^k)^2 = (ds^i)^2. \quad (11)$$

Substituting Eqs. 7 and 10 into Eq. 11 and taking the term not including s^i, we have

$$a_i^i = \pm 1, \quad (12)$$

where the plus sign may be adopted without loss of generality. Since the coefficient of the term linear in s^i in Eq. 11 vanishes while a_i^i does not, it should hold that

$$a_{ii}^i = 0. \quad (13)$$

Substituting Eqs. 8, 10, 12, and 13 into Eq. 6, and taking the term quadratic in s^i, we obtain

$$a_{ii}^j = K_{jii}/(2\lambda_i - \lambda_j). \quad (14)$$

The coefficients of the cubic term in the expansions of Q^i and Q^j are derived similarly from Eq. 11 as

$$a_{iii}^i = -\sum_k (a_{ii}^k)^2, \quad (15)$$

and from Eq. 8 as

$$a_{iii}^j = (K_{jiii} + 3\sum_k K_{jik} a_{ii}^k - 3K_{iii} a_{ii}^j)/(3\lambda_i - \lambda_j), \quad (16)$$

respectively. The denominators in Eqs. 14 and 16 indicate that the expansion of Q^j in power series of s^i cannot be accomplished when λ^j is an integral multiple of λ_i. The form of $Q^j(s^i)$ in such a case is given in Appendix.

Once the expansion coefficients in Eq. 7 are determined by using Eqs. 14—16, we can calculate the values of normal coordinates corresponding to any small values of s^i given arbitrarily. The atomic displacements along with the increase of s^i can then be traced by converting the normal coordinates into the Cartesians $\boldsymbol{X}$ according to

$$\boldsymbol{X} = \boldsymbol{L}_x \boldsymbol{Q}. \quad (17)$$

Since the same relation as Eq. 17 holds for the derivatives of X's and Q's with respect to s^i, it is also possible to evaluate the components of the principal normal of an IRC by differentiating Eq. 7 at a given point near the potential minimum. Similarly, the curvature of an IRC near the equilibrium is obtained from the second derivatives of Eq. 7.[3]

Application

Let us consider an isolated formaldehyde molecule undergoing a certain distortion which starts in the direction of the ν_6 mode at the equilibrium and proceeds as described by Eq. 7 in the normal coordinate space. The relevant expansion coefficients $a^j{}_{66}$ and $a^j{}_{666}$ are listed in Table 1 for two sets of force constants, Sets I and II, together with the frequency parameters λ_j which are common to the two sets. Set I was obtained previously by the least squares fitting of the observed values of 31 vibrational frequencies of H_2CO, HDCO, and D_2CO and 30 vibration-rotation interaction constants of H_2CO and D_2CO.[4] Set II was the same as Set I except that the cubic interaction constant between the CO stretching and the HCO deformation coordinates, $K_{R\phi\phi}$, was set equal to zero. This constant is given a relatively large absolute value, 0.963×10^{-8} N/rad^2, in Set I, so it is desirable to check its reality from a nonspectroscopic point of view. Since λ is nearly twice as large as λ_6, the denominator in Eq. 14 causes an appreciable difference in $a^2{}_{66}$ between Sets I and II, and even larger difference in $a^2{}_{666}$ results from the square of $a^2{}_{66}$ according to Eq. 15. Because of these differences, the in-plane normal coordinates calculated for Sets I and II exhibit quite different trends of the dependence on s^6 from each other as shown in Fig. 1. The energy for Set I increases more rapidly than that for Set II at larger values of s^6. The atomic displacements derived from the changes of Q^j's through Eq. 17 are shown in Fig. 2 together with a schematic view of the distorted molecule.

The IRC's of formaldehyde for the dissociation reaction

$$H_2CO \longrightarrow H_2 + CO$$

and the isomerization reaction

$$H_2CO \longrightarrow HC\text{–}OH$$

were studied by Yamashita *et al.* by means of an *ab initio* MO calculation.[5] For each of these reactions, the IRC traced from the transition point back to the starting

system converges into the ν_6 mode of formaldehyde. According to the present calculation, the spectroscopic data support the existence of an IRC which starts in the direction of the ν_6 mode at the equilibrium and proceeds toward the dissociation. In the framework of the harmonic approximation, the ν_6 mode is the CH_2 rocking mode in the course of which the two H–C=O angles close and open in turn. The hydrogen atom H_1 in Fig. 2 starts to close the H_1–C=O angle, but soon displays a

180° turn to move toward the correct direction for the dissociation. This reversal of the translation direction of H_1 takes place as a result of the increase of the contribution of the ν_2 mode and the corresponding decrease of that of the ν_6 mode in the IRC as shown in Fig. 1. Comparison between Sets I and II indicates that the turning point of H_1 is made nearer the equilibrium and the curvature around the turning point is increased by introduction of $K_{R\phi\phi}$. In Fig. 2, the locus of the hydrogen atom H_2 for Set I also shows a large curvature around the point where $s^6=17$ amu$^{1/2}$ pm. The turning of H_2 seems to be somewhat exaggerated, however, by errors associated with the truncation of Eq. 7 which contains large expansion coefficients.

Recently, very precise values of the ground state rotational constants of various isotopic species of formalde-

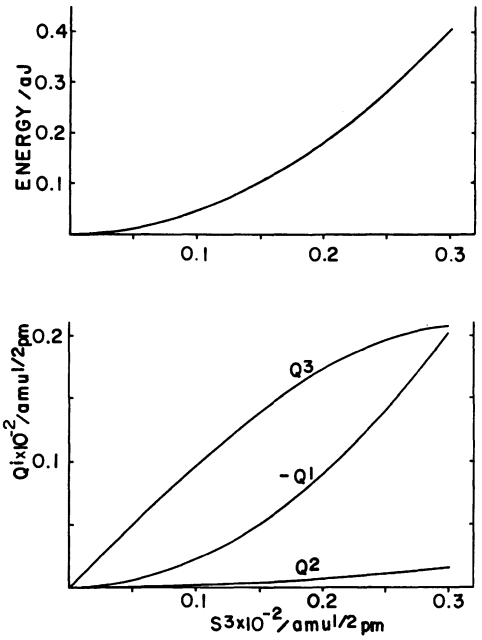

Fig. 4. Dependence of the potential energy and the normal coordinates on s^3 of water molecule.

hyde have been determined from the microwave spectra.[6-8] Some of them are compared with those calculated from Sets I and II in Table 2. Obviously, Set I is superior to Set II in reproducing the observed data, indicating the importance of the cubic constant $K_{R\phi\phi}$. For both Sets I and II, the mixing of the ν_5 mode takes place with the correct phase which brings about stretching of the C–H_1 bond, though the rate of the mixing is rather small compared with the result of the *ab initio* MO calculation.[5]

There are many normal modes for which the atomic path defined by Eq. 7 does not lead to any dissociation into molecular fragments. Figure 3 shows the atomic displacements of an isolated water molecule calculated by applying the same procedure as above to the ν_3 mode. The corresponding changes of the energy and the normal coordinates are plotted against s^3 in Fig. 4. The force constants were taken from the general quartic force field (iii) of Smith and Overend.[9] According to the sign of the coefficient $a^1{}_{33}$, the mixing of Q^1 and Q^3 in s^3 takes place with the opposite phase, leading to a sharp turning of the hydrogen atom H_2 in Fig. 3 which starts to stretch the O–H_2 bond at the potential minimum. Since the atom H_1 starts to approach the oxygen atom, the molecular distortion along s^3 cannot lead to any dissociation eventually. There are a number of symmetric triatomic molecules for which the antisymmetric stretching mode ν_a has a higher frequency than the symmetric stretching mode ν_s, and the relevant cubic constant K_{saa} is negative.[10] Absence of any IRC's which start in the direction of the antisymmetric stretching mode at the equilibrium should be a general feature for these molecules.

Combination of Eqs. 7 and 17 may thus be utilized for discussing whether a given normal coordinate is connected with any IRC's as well as for examining the behavior of an IRC in the vicinity of the equilibrium configuration of a molecule. Such an information offers important reference data in estimation of higher-order force constants, and should be useful to check the accuracy of a MO calculation when reliable force constants are available from a large number of experimental data.

The author is grateful to Professor R. G. Parr of the University of North Carolina, Dr. H. Nakatsuji and Dr. K. Yamashita of Kyoto University for valuable discussions. Numerical calculations were carried out with FACOM M200 and M382 computing systems at the Data Processing Center, Kyoto University and a HITAC M200H computing system at the Computer Center, Institute for Molecular Science.

Appendix

The behavior of the IRC starting in the direction of the ν_i mode in the normal coordinate space may be described by taking Q^i itself instead of s^i as the independent variable. In this case, we divide Q^j in orders of magnitude as

$$Q^j = Q^j_0 + \varepsilon Q^j_1 + \varepsilon^2 Q^j_2 + \cdots. \tag{A1}$$

Substituting Eq. 4 and Al into Eq. 6 and rearranging, we obtain a series of differential equations which should hold separately in order that the choice of ε is arbitrary. The zeroth order equation

$$dQ^j_0/\lambda_j Q^j = dQ^i/\lambda_i Q^i$$

is immediately integrated to give the general expression for meta IRC's given by Tachibana and Fukui,[11]

$$Q^j_0 = C_{0j} Q^{i\lambda_j/\lambda_i}. \tag{A2}$$

If we take only those solutions of the zeroth order equation which are identically zero by putting $C_{0j}=0$ in Eq. A2, the first order equation is written simply as

$$(dQ^j_1/dQ^i) = (\lambda_j Q^j_1/\lambda_i Q^i) + (K_{jii}/2\lambda_i)Q^i. \tag{A3}$$

By introducing the integrating factor

$$\exp\{-(\lambda_j/\lambda_i)\int(1/Q^i)dQ^i\} = Q^{i\,-\lambda_j/\lambda_i},$$

Eq. A3 can be solved to give

$$Q^j_1 = (1/2)K_{jii}(\ln Q^i/\lambda_i)Q^{i2}, \tag{A4}$$

for the case where $\lambda_j=2\lambda_i$ and

$$Q^j_1 = (1/2)K_{jii}(2\lambda_i - \lambda_j)^{-1} Q^{i2}, \tag{A5}$$

for the case where $\lambda_j \neq 2\lambda_i$. The solution of the second order equation is given similarly as

$$Q_2^j = (1/6)(K_{jiii} + 3\sum_k K_{jik}a_{ii}^k - 3K_{iii}a_{ii}^j)(\ln Q^i/\lambda_i)Q^{i2}, \quad \text{(A6)}$$

when $\lambda_j = 3\lambda_i$. The solution for the case where $\lambda_j \neq 3\lambda_i$ is obtained by replacing $(\ln Q^i/\lambda_i)$ in Eq. A6 with $(3\lambda_i - \lambda_j)^{-1}$. These solutions of the first and the second order equations can also be expressed as functions of s^i simply by replacing Q^i in Eqs. A4—A6 with s^i, since the expansion of Q^i with respect to s^i does not include the quadratic term: see Eq. 13. The coordinate Q^j is then given as the sum of $Q_1{}^j$ and $Q_2{}^j$ under the approximation up to the second order. When neither $2\lambda_i$ nor $3\lambda_i$ equals to λ_j, this sum becomes identical to the expansion derived in the text.

Mechanochemical Change in the Solid State of Hexobarbital

Akiko IKEKAWA* and Sohachiro HAYAKAWA†

Faculty of Pharmaceutical Sciences, Showa University, Hatanodai, Shinagawa-ku, Tokyo 142

†*Department of Applied Physics, Faculty of Science, Tokyo Institute of Technology, Oh-okayama, Meguro-ku, Tokyo 152*

(Received April 26, 1983)

The effect of ball-milling on X-ray diffraction diagrams, IR spectra, DTA and DSC thermograms of hexobarbital was investigated. It was found that the regularity at the crystal part changed upon ball-milling without any diluent. In addition to this change, an amorphous part increased upon ball-milling with microcrystalline cellulose (MCC). The solubility in a KH_2PO_4–Na_2HPO_4 buffer solution (pH 6.0) also increased upon ball-milling with MCC, though the solubility did not change without MCC. The analysis of IR spectra indicated that hydrogen bonds were formed between the C=O group of hexobarbital and the OH group of MCC upon ball-milling. Both the increase in the amorphous part and solubilization of hexobarbital upon ball-milling were attributed to the stabilization of the amorphous state caused by the interaction with MCC.

Previously, the change in the solid state of amobarbital upon ball-milling, both with and without any diluent, was investigated.[1-3] In this paper, the change in the solid state of hexobarbital upon ball-milling was discussed.

Experimental

The materials used were microcrystalline cellulose (MCC) described in a previous paper[4] and hexobarbital [5-(1-cyclohexenyl)-1,5-dimethyl-2,4,6(1*H*, 2*H*, 3*H*)-pyrimidinetrione] supplied from Teikoku Kagaku Sangyo Co.

A sample was inserted in a stainless-steel mill (in diameter of 10 cm and in capacity of 900 cm^3) containing 30 stainless-steel balls (with true density of 8.2 g/cm^3 and in diameter of 1.9 cm) and 10 balls of diameter of 2.5 cm. The mill was rotated at the velocity of 120 min^{-1}. The ball-milled samples are 10 g of MCC, 10 g of hexobarbital, a mixture of 1 g of hexobarbital and 9 g of MCC, and a mixture of 3 g of hexobarbital and 7 g of MCC.

The following measurements were carried out in the way reported previously; X-ray diffraction diagrams, DTA and DSC thermograms, IR spectra by the use of Nujol method, and particle size distribution of hexobarbital.[4] Solubility of hexobarbital in various samples in KH_2PO_4–Na_2HPO_4 buffer solution (pH 6.0, ionic strength 0.08) at 30 °C was obtained from the absorbance at 219 nm as described in the previous paper.[4]

Results and Discussion

Ball-milling without Any Diluent. X-Ray Diffraction: Figure 1 shows the effect of ball-milling without any diluent on X-ray diffraction diagrams of hexobarbital. The diffraction intensities of the lines at 8.4°, 11.1, 15.8, and 23.2° of 2θ decreased and those of the lines at 14.5 and 17.3° of 2θ increased by ball-milling. Fine powders were obtained on evaporation of an ethanol solution or a chloroform solution of hexobarbital under reduced pressure. The differaction diagram of the powders obtained from an ethanol solution was similar to the diagram for original hexobarbital, and the diagram for the powders obtained from a chloroform solution was similar to the diagram for ball-milled hexobarbital. It is clear from this fact that the change in the diffraction intensities in Fig. 1 is not attributed to the decrease in particle size. The locations of the lines were little influenced by ball-milling. The presence of polymorphs for hexobarbital has not been reported yet. These facts suggest that the regularity at the crystal part of hexobarbital changes by ball-milling.

The mean values of the lattice disturbance amplitude, $\overline{U_x''}$, were obtained, using all the combinations of the two of the diffraction intensities of the lines at 8.4, 11.1, 14.3, 15.8, 17.3, and 23.2—23.5° of 2θ.[5] As is shown in Fig. 2, $\overline{U_x''}$ was at a minimum at the ball-milling time around 1—5 h. Each line was indexed as is shown in Fig. 1, on the basis of the crystal structure reported by

Jean-Pierre Bideau *et al.* ($P2_1/c$, $a=16.79$ Å, $b=6.65$ Å, $c=11.02$ Å, $\beta=108°\ 17'$).[6] These results suggest that the regularity at the crystal part increases in the first stage of ball-milling and that the regularities in (110), ($1\bar{1}0$), ($2\bar{1}0$), and (210) planes increase more remarkably than those in the other planes. It is also shown that the regularity decreases upon ball-milling for more than 10 h.

The crystallinity obtained by the Ruland's method[7] was little influenced by ball-milling.

IR Spectra: Figure 3 shows the effect of ball-milling without any diluent on IR spectra of hexobarbital. The absorbances at 3240 and 1720 cm^{-1} regions increased upon ball-milling. The absorbance at each of the wave number, ν, was determined, assuming the transmittance on the straight line, passing through 3400 and 1900 cm^{-1} or 1900 and 900 cm^{-1}, to be 100%. In Fig. 4, $R_{\nu,\nu'}$ is the ratio of the absorbance at the wave number of ν to the absorbance at ν'. The $R_{3240,3210}$ and $R_{1720,1660}$ values increased and the $R_{\nu,1660}$ values ($\nu/cm^{-1}=1670$—1705, 1730—1740) decreased upon ball-milling.

In the IR spectra of barbituric acid derivatives, the band at 3000—3600 cm^{-1} region is assigned to be due to the NH stretching vibration. The absorption of free NH in the solid state of phenobarbital is observed at 3310 cm^{-1}, and this band shifts to lower frequency by hydrogen bonding. The three bands at 1600—1800 cm^{-1} region is assigned to the stretching vibrations of the C=O groups. In the spectra of hexobarbital, the highest frequency band at 1740—1750 cm^{-1} is assigned to the C=O group at the 2-position, the middle frequency band to the C=O group at the 4-position, and the lowest frequency band to the C=O at the 6-position. The absorption band due to the free C=O at the 4-position is around 1730 cm^{-1}, and the band due to the free C=O in the 6-position is around 1700 cm^{-1}. These bands shift to lower frequency by hydrogen bonding. It is also reported that the C=O group in the 6-position of hexobarbital forms hydrogen bonds with the NH group in the solid state.[8]

a) *bt* is the ball-milling time.

It is suggested from the above results that the 4-carbonyl groups free from hydrogen bonding with the NH groups increased by ball-milling. The bands at 1020—1060 cm^{-1} due to the skeletal vibration[8] also changed upon ball-milling; this is also considered to be due to the change in hydrogen bonding. As is shown in Figs. 2 and 4, the variation in $\overline{U_x''}$ with ball-milling is parallel to the variation in $R_{\nu,\nu'}$; this fact suggests that the variation in hydrogen bonding due to ball-milling is related to the variation in the regularity at the crystal part.

No difference was observed before and after ball-milling in the melting point, the heat of fusion, and the solubility of hexobarbital in KH_2PO_4–Na_2HPO_4 buffer solution (pH 6.0) at 30 °C.

Particle Size: In Fig. 5, D_{50} is a median diameter by

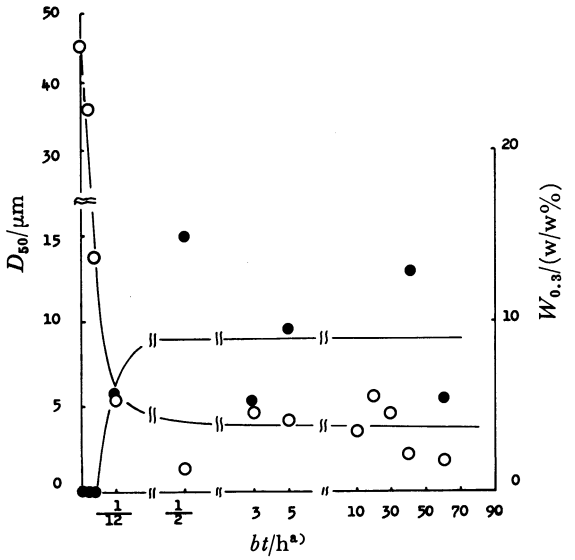

Fig. 5. Variation in particle size of hexobarbital with ball-milling in the absence of any diluent.
○: D_{50}, ●: $W_{0.3}$.
a) bt is the ball-milling time.

Content of hexobarbital; 30 w/w%.
1: A mixture of hexobarbital, ball-milled for 60 h without any diluent, and MCC ball-milled for 60 h without hexobarbital, 2: a mixture of hexobarbital and MCC ball-milled together for 60 h.
a) 2θ is the angle between the incident X-ray and the scattering X-ray.

weight base and $W_{0.3}$ is the weight fraction of the particles smaller than 0.3 μm in diameter. The D_{50} and $W_{0.3}$ values of hexobarbital varied in the first stage, and they stayed nearly constant after ball-milling for more than 30 min. The variations in D_{50} and $W_{0.3}$ with ball-milling were parallel to the variation in $\overline{U_x''}$ and $R_{\nu,\nu'}$ in the first stage. Probably, the change in the regularity at the crystal part becomes remarkable when the particles are broken.

Ball-milling with MCC. X-Ray Diffraction: The ratio of the diffraction intensity at 17.3° of 2θ to the intensity at 15.8° of 2θ increased at the first stage of ball-milling. As is shown in Fig. 6, the diffraction intensities for hexobarbital decreased gradually upon ball-milling with MCC. The crystallinity, x_{cr}, for hexobarbital ball-milled for 60 h without any diluent, was 0.92 as determined by the Ruland's method.[7] The x_{cr} values of hexobarbital in the ball-milled mixture with MCC were determined from the ratio of the intensity of the diffraction lines in the range of 10—20° of 2θ to the intensity for the mixture of hexobarbital (ball-milled for 60 h without any diluent) and MCC, for the diffraction lines were overlapped with those of MCC in the range of 20—30° of 2θ in the first stage of ball-milling. The x_{cr} value decreased upon ball-milling and the rate in the first stage was larger for the mixture containing larger amount of MCC. (Fig. 7)

Content of hexobarbital/(w/w%)	x_{cr}	$x_{cr\ heat}$
10	●	▲
30	○	△

a) bt is the ball-milling time.

Heat of Fusion: The heat of fusion, ΔH_{obsd}, for hexobarbital decreased from 27.6 kJ/mol to 6.7 kJ/mol upon ball-milling the mixture with MCC containing 30 w/w% of hexobarbital for 60 h. The peak of fusion of hexobarbital disappeared upon ball-milling the mixture containing 10 w/w% of hexobarbital for more than 30 h. The ΔH_{obsd} value did not change upon ball-milling without any diluent, though the regularity at the crystal part slightly changed. Assuming that ΔH_{obsd} for the amorphous part is zero, the crystallinity of hexobarbital ($x_{cr\ heat}$) is obtained from Eq. 1.

$$x_{cr\ heat} = (\Delta H_{obsd}/27.6) \times 0.93 \quad (1)$$

As is shown in Fig. 8, the $x_{cr\ obsd}$ values were nearly identical with the x_{cr} values.

Melting Point: In Fig. 8, T_1 is the temperature at which the peak of fusion starts, T_2 is the melting point, and T_3 is the temperature at the intersecting point of the base line and the extension of the line behind the peak. The peak of fusion of hexobarbital was broadened, and T_1, T_2, and T_3 were lowered by ball-milling with MCC, though the peak was not influenced upon ball-milling without any diluent. In Figs. 7 and 9, parallel relationship is seen between the lowering of these temperatures and the decrease in x_{cr} by ball-milling; this

a) *bt* is the ball-milling time.

result shows that the lowering of the temperatures is attributable to the increase in the amorphous part.

IR Spectra: Figure 10 shows the effect of ball-milling on IR spectra of the mixtures of hexobarbital and MCC. The absorbances around 1670—1730 and 1110 cm^{-1} regions increased upon ball-milling. The absorbance at 3400 cm^{-1} region also increased for the mixture containing 30 w/w% of hexobarbital. The band around 1670—1730 cm^{-1} corresponds to the stretching vibration of the C=O groups of hexobarbital.[8] In the IR spectra of the cellulose derivatives, the band around 3400 cm^{-1} region was assigned to the stretching mode of hydrogen-bonded OH groups.[9] The intensities and

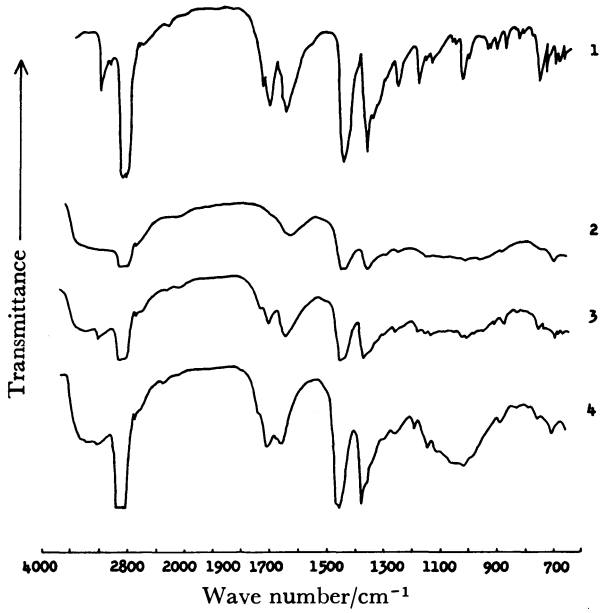

Fig. 10. Influence of ball-milling on IR spectra of a mixture of hexobarbital and MCC.
1: Hexobarbital ball-milled for 60 h without any diluent, 2: MCC ball-milled for 60 h without hexobarbital, 3: a mixture of "1" and "2" in the ration of 3 : 7 by weight, 4: a mixture of 3 g of hexobarbital and 7 g of MCC ball-milled together for 60 h.

frequencies of this band was reported to be affected by the difference in a hydrogen-bonding system.[10] The band at 1110 cm^{-1} was assigned to the C–O stretching mode, perphaps coupled to the C–C frequency. This band was also reported to change with the variation in the hydrogen-bonding system.[9-11] These facts indicate that hydrogen bonds are formed between the C=O groups of hexobarbital and the OH group of MCC. The variation in the skeletal vibration of hexobarbital around 1045 cm^{-1} is probably due to the change in the hydrogen bonds of the C=O groups.[8]

The absorbance at each of the wave numbers, ν, was determined, assuming that the transmittance on the straight line passing through 1850 and 800 cm^{-1} was 100%. In Fig. 11, $R_{1740,1660}$ was little influenced by ball-milling. $R_{\nu,1660}$ values (ν/cm^{-1}=1675—1735) were affected slightly in the first stage, and they increased after ball-milling for more than 10 h. This tendency was remarkable at the range of 1690—1700 cm^{-1}. These results show that the 4-carbonyl group of hexobarbital forms hydrogen bonds with MCC upon ball-milling and that the absorbance of hexobarbital at 1730 cm^{-1} shifts to the lower frequency.

Solubility: A suspension of the ball-milled mixture in KH_2PO_4–Na_2HPO_4 buffer solution (pH 6.0) was shaken at 30 °C, and the concentration of hexobarbital in the filtrate of the suspension was measured. The concentration stayed nearly constant after shaken for more than 15 min. In Fig. 12, c_{20min} is the concentration for the suspension shaken for 20 min. The c_{20min} value was little influenced in the first stage of ball-milling, and the value increased after ball-milling for more than 10 h. The variation in c_{20min} with ball-milling was parallel to the variation in $R_{\nu,1660}$ (ν/cm^{-1}=1665—1735)

The increase in the solubility of hexobarbital upon ball-milling is probably due to the interaction with MCC.

In the previous paper, amobarbital was ball-milled with such diluents as methylcellulose (MC) and dextran. Solubility of amobarbital in distilled water increased upon ball-milling with diluents, though it increased only slightly in the absence of any diluent. The analysis of the IR spectra indicated that hydrogen bonds were formed between the C=O groups of amobarbital and the OH groups of the diluents by ball-milling. MC and dextran are both soluble in distilled water. After the suspension of the mixture with MC or dextran in distilled water had been set aside for a week after the time of preparation, the solid state of amobarbital undissolved in the suspension was compared with the state before dissolution. From this comparison, it was shown that the presence of diluent in the ball-milled mixture prevented the amorphous part to be crystallized. It was concluded from the above results that the increase in the solubility of amobarbital upon ball-milling was attributed to the stabilization of the amorphous state caused by the interaction with diluents.[3] It is analogized from these results in the previous paper[3] that the increase in the amorphous part and in the solubility of hexobarbital upon ball-milling are both due to the stabilization of the amorphous state caused by the interaction with MCC, though these could not be confirmed experimentally because of poor solubility of MCC in distilled water.

The authors are grateful to Mrs. Mayumi Tobe, one of the members of the Analytical Center of Showa University, for the measurement of IR spectra.

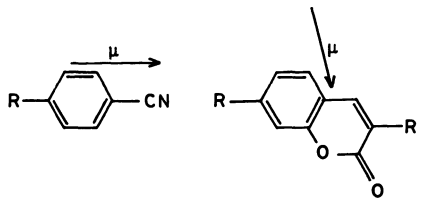
Thermal and Dielectric Properties of Liquid Crystals with a Coumarin Skeleton

Hidetsugu NAKAI, Shunsuke TAKENAKA,* and Shigekazu KUSABAYASHI
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565
(Received May 2, 1983)

In order to examine the liquid crystalline properties of coumain, 3-X- and 7-Y-substituted coumarins where X= cyano and *n*-alkoxycarbonyl, and Y=4-*n*-alkyl- and 4-*n*-alkoxybenzoyl, 4-alkoxycinnamoyloxy, 4′-alkyl- and 4′-alkoxy-4-biphenylylcarbonyloxy, and 4-(4-alkoxybenzoyloxy)benzoyloxy (**4**) groups have been prepared. The compounds with X=alkoxycarbonyl group tend to exhibit strong smectic properties, and compounds with X=cyano exhibit stable nematic phases, whereas the coumarin core seems to facilitate a lateral separation of molecules in the mesophase due to its large molecular breadth. The heptyloxy homolog of **4** exhibits a reentrant behavior of the C–N_{re}–S_A–N–I type. The thermal properties are discussed in terms of the polarity and polarizability of coumarin, and the molecular structure. The dielectric properties of the compounds have also been examined and discussed in terms of the polarity of the coumarin core.

An investigation of the physical properties of new liquid crystalline materials is important in studying the relationship between the structure of materials and their mesomorphic characteristics. Liquid crystalline materials with a polar group such as a cyano or a nitro give rise to some interesting behavior. A cyano group directed along the parallel direction with respect to the longer molecular axis induces a strong dipole moment along that direction. Liquid crystals with a cyano group as the terminal of the molecule have proved successful in electro optical devices employing the twisted nematic mode. On the other hand, a cyano group directed along the lateral direction with respect to the longer molecular axis induces a strong dipole moment along that lateral direction. Liquid crystals with a cyano group as a lateral substituent give rise to a negative dielectric anisotropy and have proved successful in electro-optical devices employing the dynamic scattering and guest-host modes.[1]



In usual mesogens, the polarity is important in determining not only the mesomorphic but also the dielectric properties. Benzonitrile has a strong dipole moment (3.9 D, 1 D=3.3356×10^{-30} C m) along the longer molecular axis, as is shown below.[2] On the other hand, coumarin is a benzene derivative with a lactone ring, which generates a strong dipole monent (4.48 D).[3] As the 3 and 7 positions of coumarin are substituted, however, the polarity will have some angles with respect to the longer molecular axis. In this paper, we wish to report the syntheses of new liquid crystalline materials involving coumarin; their thermal and dielectric properties will be discussed in terms of the characteristics of the coumarin core.

Experimental

Method. The transition temperatures were determined using a Nikon Model POH polarising microscope fitted with a Mettler FP 52 heating stage and a FP 5 control unit. The transition entropies were calculated by means of the equation; $\Delta S=\Delta H/T$, where the transition enthalpy, ΔH, was measured with a Daini-Seikosha SSC-560 differential scanning calorimeter, indium being used as a calibration standard, with a heating rate of 5 °C/min. The dielectric constants were measured by using a Ando-denki TR-10 precision capacitance-measurement system. The capacitor cell consisted of two indium oxide-coated glass electrodes separated by a 25 μ Mylar spacer. The cell temperature was controlled by means of a brass housing. The voltage applied was 0.4 V at 1 kHz. The alignment of molecules in the cell was achieved by applying a magnetic field of *ca.* 8 kG (1 G=10^{-4} T). The capacitor cell was calibrated by the use of highly purified benzene and acetonitrile.

Materials. Nematic 5 and ZLI-1083 were purchased from the Merck Co. The 4-(*n*-alkyl)benzoic acids and the aldehydes were purchased from the Kantokagaku Co. The 4-(*n*-alkoxy)benzoic acids and the aldehydes were purchased from the Tokyo Kasei Co.

3-Cyano-7-hydroxycoumarin. A mixture of 2,4-dihydroxybenzaldehyde (5 g, 0.036 mol) and malonitrile (2.4 g, 0.036 mol) in absolute ethanol (30 ml) and two drops of piperidine was heated with stirring at 70 °C for 1 h. The reaction mixture was then poured onto a 350-ml portion of 3.5 mol dm^{-3} hydrochloric acid, and the resulting solution was heated at 60 °C for 30 min. After cooling, the precipitates were collected by filtration and recrystallized from ethanol, giving 3-cyano-7-hydroxycoumarin as yellow needles, 3.6 g (53%); mp>270 °C.[4]

3-Pentyloxycarbonyl-7-hydroxycoumarin. A mixture of 2,4-dihydroxybenzaldehyde (11 g, 0.08 mol), dipentyl malonate (20.1 g, 0.082 mol), piperidine (0.8 ml), and three drops of acetic acid in absolute ethanol (25 ml) was refluxed for 5 h.[5] The reaction mixture was then poured onto hot water (50 ml) and left to stand for overnight. The precipitates that separated out were collected and recrystallized from methanol, giving 3-pentyloxycarbonyl-7-hydroxycoumarin as colorless needles, 6.0 g (27%).

The 3-alkyloxycarbonyl-7-hydroxycoumarins were prepared by a similar method.

The 4-alkyl- and 4-alkoxybenzoyl chlorides and the coumarins were reacted in a mixture of absolute pyridine and benzene (1 : 1) to give a homologous series of **1**.[6]

The 4-alkoxycinnamic acid chlorides, which had been obtained by the reaction of 4-alkoxybenzaldehydes and malonitrile, and the coumarins were reacted in a mixture of

absolute pyridine and benzene (1 : 1) to give a homologous series of **2**.

The 4-alkyl- and 4-alkoxy-4′-carboxybiphenyls were prepared by the method of Gray *et al.*[7] Series **3** were obtained by the condensation of 4-alkyl- and 4-alkoxy-4′-(chlorocarboyl)biphenyls and coumarins in a mixture of absolute pyridine and benzene (1 : 1).

The 4-(4-alkoxybenzyloxy)benzoic acids were obtained according to the method of van Meter *et al.*[8] Series **4** were obtained by the condensation of the 4-(4-alkoxybenzoyloxy)-benzoyl chlorides and 3-cyano-7-hydroxycoumarin in a mixture of absolute pyridine and benzene (1 : 1). 4-Pentylphenyl 4-(4-octylbenzoyloxy)benzoate was prepared by the method of Dubois *et al.*[9]

N-[4-[4-(Octyloxy)benzoyloxy]benzylidene]-4-cyanoaniline was prepared by the method of Demus *et al.*[10] The products were purified by column chromatography on silica gel, using a mixture of pet. ether and ether (95 : 5—90 : 10) as an elution solvent, followed by recrystallization from absolute ethanol.

The purity was checked by means of the elementary analysis; the results are shown in Table 1.

Results

The transition temperatures and entropies for Series **1**—**4** are summarized in Table 2—5. The virtual N–I transition temperature for **1c**, **1f**, and **1m** were evaluated[11] from the binary phase diagrams in Fig. 1. The nematic and smectic phases for the compounds with an alkoxycarbonyl group tend to exhibit a schlieren texture and fan shaped texture, respectively, between two glass plates.

The compounds with a cyano group tend to form the nematic and/or smectic phases with a homeotropic texture between two glass plates. To identify the

smectic phase, the binary-phase diagrams for several compounds were examined, as is shown in Figs. 1 and 2. Figure la indicates a phase diagrams for the binary mixture of 4-pentylphenyl 4-(4-octylbenzoyloxy)benzoate and **1c**, where both smectic A phases are miscible. This indicates that the smectic phase for **1c** can be assigned to the smectic A modification.[9] **4f** shows a reentrant property of the C–N_{re}–S_A–N–I type, which is confirmed by the binary-phase diagrams shown in Figs. 2c and 2d. The latent heats of the N_{re}–S_A and S_A–N transitions for **4f**—**h** are so small that these transitions could not be detected by means of the DSC thermograms. On the basis of these facts, we assume that the enthalpies for these transitions are less than 50 J mol^{-1}. The extrapolation of the N–I transition temperatures in Fig. 2c gives the N–I transition temperature of 295 °C for **4f**. Similarly, the N–I transition temperatures for **4g** and **4h** were evaluated as *ca.* 300 °C.

The values in the brackets are the virtual transition temperatures.

The dielectric constants were measured in a eutectic mixture of azoxy compounds (Merck nematic 5), since the present homologues have relatively high melting points. Figure 3 indicates the plots of the dielectric constants $\varepsilon_{//}$, $\varepsilon_{\perp}$, and $\Delta\varepsilon$ against the mole concentration of the coumarin compounds, where $\varepsilon_{//}$, $\varepsilon_{\perp}$, and $\Delta\varepsilon$ are the dielectric constants along the parallel and perpendicular directions with respect to the longer molecular axis, and the difference, respectively. In Fig. 3a, both $\varepsilon_{//}$ and $\varepsilon_{\perp}$ for **1c** can be seen to increase linearly in the range between 0 and 30 mol%, and to reach a plateau onward. The anisotropy also increases similarly in the range between 0 and 30 mol% of **1c** and then decrease monotonically thereafter, giving a maximum at 25 mol% of **1c**. **2c** also shows a similar trend. In Fig. 3b, both $\varepsilon_{//}$ and $\varepsilon_{\perp}$ for **1i** increase linearly with an increase in the concentration of **1i** in the range between 0 and 30 mol% of **1i**, though they tend to reach a plateau thereafter. A similar trend is also observed in **2f** and **4d**. Thus, the plots of the dielectric anisotropies against the mole

concentration for the present series have no linear correlation. The dielectric anisotropies at 15 mol% of the compounds are illustrated in Table 5.

Discussion

It has been known that the linearity, rigidity, and polarizability of a molecule are very important in determining the stability of the mesophase. From the structural point of view, the present series might be unfavorable for the stability of the nematic phase, since coumarin has a larger molecular breadth than phenyl and naphthyl groups, as is shown below.[12] Although coumarin elongates the molecular length of 1.5 Å compared with benzene, simultaneously the breadth around coumarin is larger by 1.7 times than that of benzene.

The thermal stability of the mesophase for the present series is compared with those of the other related series

(–C_6H_4– indicates a *p* phenylene group.)

Coumarin compounds **1a—f** with a alkoxycarbonyl group at the 3 position exhibit strong smectic properties in addition to the nematic ones. The thermal stability of the nematic phase is comparable with those for **9** and **10**. Similar trends are observed in Series **2** and **3**. For the homologous series, somewhat interesting trends are observed in the effect of chain length on the thermal stabilities of the nematic and smectic A phases. The S_A–N transition temperatures for **1c—e** and **3g—h** increase with an increase in the carbon number in the alkyl chain at the 7 position (see Tables 2 and 4). These trends are always present. By contrast, the S_A–N transition temperatures for **1a**, **1e**, **1f**, and **3b—f**, which involve the alkyl chain of the ethyl to the hexyl group at the 3 position of the coumarin core almost constant (see Tables 2 and 4). Simultaneously, the N–I transition temperatures rapidly decrease, showing a weak even-odd alternation. In this connection, the following facts are worthy of note. Firstly, it would be reasonable to assume that the coumarin facilitates the formation of the smectic order, since the strong dipole moment arising from the coumarin core is directed to the lateral direction of the molecule, and that it increases the lateral interactions. Secondly, the alkoxycarbonyl group at the 3 position of coumarin should be located on the coumarin plane due to steric hindrance between the alkoxycarbonyl and carbonyl groups at the 2 position of coumarin, thus increasing the molecular thickness. Therefore, the elongation of the alkyl chain in the alkoxycarbonyl group would facilitate the lateral separation of the molecules in the mesophase, rapidly decreasing the thermal stability of the nematic phase. Thereby, the increase in the alkyl chain length would not serve to enhance the S_A–N transition temperatures, since the lateral separation of the molecules inhibits any short-range interaction, a general requisite for the enhancement of the smectic properties.

When a cyano group is introduced at the 3 position, both S_A–N and N–I transition temperatures tend to decline for Series **1—4**, and the nematic properties become remarkable. For example, the N–I transition temperature for **1k** is higher than **5** by 64 °C and lower than **8** by only 15 °C, while the N–I temperature for **1i** is lower than **6** by 38 °C. On the other hand, the homologous series of **4** form a highly stable nematic phase. These facts indicate that the polarity and polarizability arising from the coumarin core involving the cyano group and the elongation of the rigid core of the molecule along the longer axis enhance the stability of the nematic phase, though the large molecular breadth around the coumarin core does not favor the nematic stability. An interesting trend is observed in the thermal properties for **1n** and **1o**. These do not exhibit a nematic phase, but these compounds have a cyano group at the terminal. These facts indicate that the alkoxycarbonyl group at the 3 position of coumarin decreases the N–I transition temperature as a result of the increased molecular thickness, as has been mentioned above. The homologous series of **4** have a highly stable nematic phase.

The smectic A phase commences from the heptyloxy homologue, and the heptyloxy homologue shows a reentrant behavior of the C–N_{re}–S_A–N–I type. As has been demonstrated by several authors,[16,17] the formation of a bimolecular complex is indispensable for the reentrant phenomena. It has been known that molecules exhibiting the reentrant behavior are constituted of plural phenyl rings combined by linkages such as –CH=N– or –COO–, with an alkoxy group of a suitable length as a terminal and a polar group such as a cyano or a nitro group indispensable to form a bimolecular complex.[18,19] In Fig. 1a, the S_A–N transition temperatures show an almost straight line, and both S_A phases are miscible, indicating that **1c** forms the smectic A phase with a monolayer organization of the molecules, because 4-pentylphenyl 4-(4-octylbenzoyloxy)benzoate has been known to form the smectic A phase.[25]

Both smectic A phases in Fig. 1b show a miscible relation with a convexity, indicating that the smectic A phase for **3a** also has a monolayer alignment of molecules. Therefore, it is impossible to expect the homologous series of **3** to exhibit the reentrant behavior. In fact, the homologous series do not exhibit the reentrant behavior, whereas they do show a wide range of the smectic A phase (Table 4).

In Fig. 1c, the smectic A phase for **2b** is miscible with that for **1n**, whereas the smectic A phase for **1n** is considered to form a bilayer type of alignment of the molecules, since the molecule has the cyano group as the polar terminal.[18,19] In Fig. 1d, on the other hand, the S_A–N transition temperatures show a remarkable depression between 40 and 60 mol% of **2o**, whereas both **1o** and **2f** have the cyano group as the terminal.

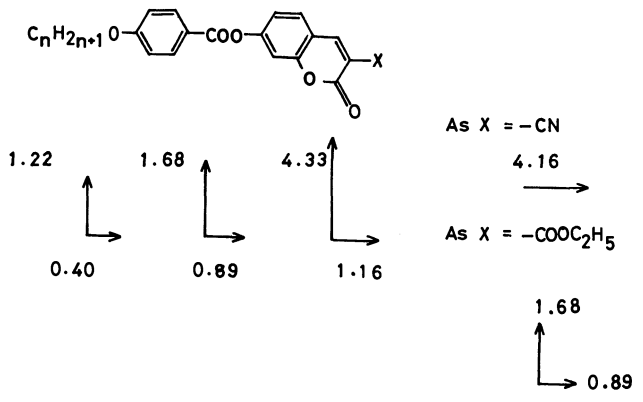
In Figs. 2a and 2b, the smectic A phases for **1f** and **1n** are miscible with that for **4f**. An interesting fact is that the reentrant N_{re}–S_A transition temperatures for **4f** increases with an increase in the concentration of **1f** but rapidly decrease thereafter, giving a maximum at 11

mol% of **4f** (Fig. 2a), whereas these temperatures rapidly decrease with an increase in the concentration of **11** (Fig. 2b). A tentative description of this trend is shown in Fig. 2c, where the monolayer smectic A phase for 4-pentylphenyl 4-(4-octylbenzoyloxy)benzoate is immiscible with the bilayer smectic A phase for **4f**. These facts indicate very clearly that a very subtle change in the molecular structure determines the affinity between the monolayer and bilayer-type smectic A phases. As we can see from Fig. 2d, the bilayer smectic A phase shows a remarkably constricted part at 60 mol% of **4f**, presumably as a result of the subtle difference in their molecular structures. Indeed, the smectic A phase with the monolayer alignment of molecules has been known usually to have an affinity with the bilayer one, but sometimes not.[20,21]

According to a concept of the miscibility relation between the monolayer and bilayer smectic A phases in the pure molecule, we can easily understand the reentrant phenomena.

The molecules with a polar terminal group such as cyano have been known to form the bimolecular complex in the mesophase and in an isotropic solution as a result of strong dipole-dipole interactions.[22,23] Such interactions form the bilayer alignment of the molecules in the smectic A phase. Usually, the bilayer smectic A phase is more stable than the monolayer one at higher temperatures. Therefore, the bilayer smectic A organization would vary in relation to the monolayer one with a lowering of the temperature. As the bilayer smectic A phase does not, thereby have a miscible relation with the monolayer one, we can expect the molecule to exhibit the reentrant phenomena. **4f** is just such a case. Further study is now underway.

Dielectric Propererties. It has been known that polarity is very important in determining the dielectric properties of a molecule. Therefore, we have to pay much attention to the polarity of coumarin. As has been mentioned above, coumarin has a larger dipole moment than benzonitrile, though the dipole moment in the present series is directed to the lateral direction of the molecule. We can roughly estimate the effective dipole moment, by the use of the usual method.[2,24]



Supposing the order parameter in the nematic phase to be 0.6, we can expect the molecule with X=H to show a negative dielectric anisotropy, since $\mu = -0.46$. The alkoxycarbonyl compounds can be expected to show small positive dielectric anisotropies, for the effective dipole moment is estimated to be +0.007. As the cyano group is introduced at the 3 position of coumarin, the effective dipole moment is estimated to have a value of 2.91, as the 3-cyano compounds can be expected large dielectric anisotropies. As the phenyl group in **1a—h** is replaced by a cyclohexane, we can expect to exhibit large negative dielectric anisotropies. Unfortunately, 3-alkoxycarbonyloxy-7-(4-alkylcyclohexylcarbonyloxy)-coumarins exhibited only smectic properties.[25]

In Fig. 3a, the plots of the dielectric constants *versus* the mole concentration show rather interesting trends. The anisotropy increases with an increase in the concentration of **1c** and decreases monotonically, giving a maximum at 25 mol%. The extrapolated value for **1c**, therefore, is −1.5, incline the calulated result. In this case, we assume that the monotonical decrease in the range between 25 and 100 mol% of **1c** is connected with the increases in the smectic order in the mixture, as shown is in Fig. 3a, and that **1c** has essentially a positive dielectric anisotropy. In Fig. 3b, the dielectric anisotropy for **1i** linearly increases with increasing the concentration of **1i** and tends to become a plateau, the curve having an forward convexity. Therefore, **1i** must have a large positive dielectric anisotropy.

As we can see by comparing the dielectric constants of butyl 6-[4-(hexyloxy)benzoyloxy]-2-naphthoate (**1c** and **2c**) in Table 5, the dipolarity arising from the coumarin core results in an increase to the same extent in the dielectric constants along both parallel and perpendicular directions of the molecule. As a result, the dielectric anisotropies for **1c** and **2c** are almost same as that for the naphthalene compound. As the alkoxycarbonyl group at the 3 position is replaced by the cyano, the dielectric constant along the parallel direction of the molecule tends to increase rapidly, though that along the perpendicular direction stays constant, resulting in large values of the dielectric anisotropy.

The Study of Metal Colloids Produced by Means of Gas Evaporation Technique. I. Preparation Method and Optical Properties in Ethanol

Keisaku KIMURA* and Shunji BANDOW
Instrument Center, Institute for Molecular Science, Myodaiji, Okazaki 444
(Received May 9, 1983)

Three new methods for the preparation of metal colloid in organic solvent are presented. These methods were the matrix isolation method, the gas flow-cold trap method and the gas flow–solution trap method; the latter was found to give a good colloid solution for the optical measurements. The metals reported are high purity Ag, Au, Cu, In, Al, Ca, Sn, and Pb. The stability of the colloid is dependent on the kind of metals: Al, In, Au, and Ag are stable, and Pb, Sn, Ca, and Cu are unstable. The optical absorption spectra of these sols were measured in ethanol solution in Ar atmosphere. They are discussed in relation to those reported on the solid matrix or on the solid substrate.

A considerable amount of literature is available on the optical properties of metal particles in solid matrix as well as in colloidal aqueous solution. The routine methods to make fine particles are that metals are evaporated on an inert substrate and/or rigid matrix in vacuo or that metals are dispersed in an aqueous solution by chemical reaction. The problem posed by the former procedure is the coagulation of particles. In the latter case, we could expect many advances in the study of colloid chemistry, if we can use organic liquids as solvents rather than aqueous solution. The optical spectra were measured at a low temperature for the metal fine particles dispersed on the solid matrix. Except an aqueous solution, there have been very few reports on the spectra of solution state because of the difficulty of the sample preparation.

Conventional chemical methods supply well dispersed particles in a colloid solution; the classical Mie theory[1] has been used to explain the absorption spectrum. Recent measurements of ultrafine particles[2] applied both classical and quantum theories to the optical properties of metal particles. However the measurements were limited to solid matrix and to aqueous solution. Therefore it is important for us to observe the spectra of many sorts of metal colloids in organic solvents with a wide range of dielectric constants. Moreover, it will be desirable to get a neat metal colloid solution especially for the study of the physical properties.

In this report, we will present new preparation methods of metal colloids in organic solvents without the use of chemicals such as redox reagents, polymers, electrolytes, glue or other kinds of colloid stabilizers. This method is applied to the measurement of the optical spectra of many metal colloid solutions, some of which are first reported here. The method is applicable not only to ethanol reported here but also to any organic solvent. In addition, this technique can be applied to many sorts of solids as described in this report.

Experimental

Three different preparation methods were examined. These are the matrix isolation method, the gas flow-cold trap method, and the gas flow-solution trap method. All methods are based on a gas evaporation technique.[3] The first one is the modification of that described by Wada and Ichikawa.[4] Therefore we will omit the detailed description of the method and simply show the apparatus used in Fig. 1.

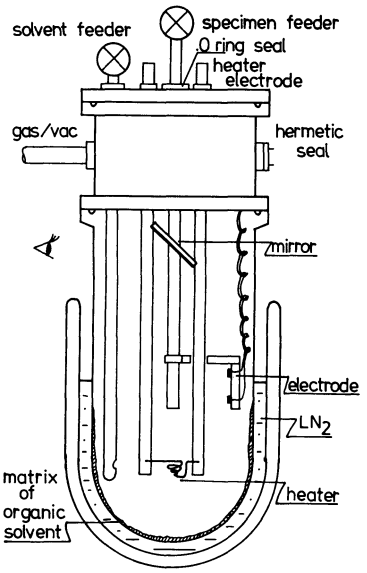

Fig. 1. The apparatus for the matrix isolation method. Organic solvent is introduced through solvent feeder to form matrix on the Pyrex glass dewar which is cooled by liquid nitrogen. Mirror enables us the observation of melting state of metals. Electrode was used to monitor the thickness of the metal layer.

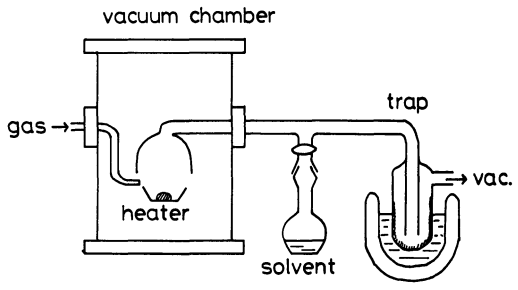

Fig. 2. The apparatus for the gas flow-cold trap method. One of the gas inlet is abbreviated in the Figure.

The gas flow-cold trap method is shown in Fig. 2. The fine particles are produced in a vacuum chamber in the atmosphere of helium gas flow. The chamber was once

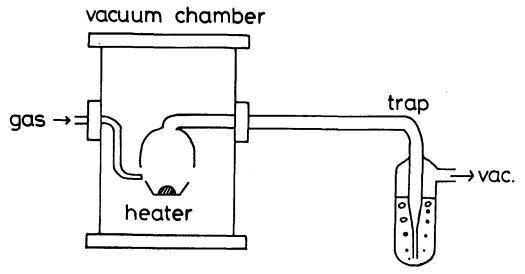

Fig. 3. The apparatus for the gas flow-solution trap method.

evacuated to 10^{-3} Torr (1 Torr≈133.322 Pa) prior to the introduction of helium gas. Under the constant flow of helium gas, a piece of metal was heated. The pressure of the chamber was varied in the range 10—50 Torr corresponding to the desired level of particle diameter. The chamber has two gas inlets, one of which is introduced to the back of tungsten heater to produce fine particles in high efficiency and the other is placed at the edge of the particle collector in order to enhance the collection yield of the particle. Argon was used for this inlet. The vapor of organic solvent which was completely degassed was introduced through the Teflon valve in the carrier gas stream and then trapped in the glass cold trap cooled with liquid nitrogen. After collection of fine particles, the trap was filled with Ar gas at 1 atmospheric pressure. The particle diameter was varied by changing the pressure of gas and the temperature of the heater.

The gas flow-solution trap method is shown in Fig. 3. Two kinds of gases were also used in this case, helium for the production of fine particles and argon for the collection and the carrier of fine particles. The procedure is the same as for the second case, except that the cold trap is replaced by the organic solvent which is cooled by cold ethanol; the temperature is −30——40 °C. The matrix isolation method and the gas flow-cold trap method sometimes gave coagulated samples and did not give a finely dispersed solution, on the other hand the gas flow-solution trap method made reproducible, well dispersed solutions. Therefore the results obtained by the latter method are mainly reported in this paper.

All spectra were obtained at room temperature in a conventional fused quartz rectangular optical cell except the vacuum evaporated film on a quartz substrate. The optical absorption spectra were recorded just after the preparation of colloid. Some metals were not stable even under these conditions, as described in the results. The metals reported are silver (99.9999%), gold (99.5%), copper (99.9999%), indium (99.999%), calcium (99.99%), aluminum (99.9999%), lead (99.9999%), and tin (99.9999%). Several organic solvents were tested: ethanol, methanol, tetrahydrofuran, cyclohexane, chlorocyclohexane, cyclohexanone, toluene, and benzene. Some solvents were found to be very reactive toward fine particles and the result of ethanol solution is presented in this report.

The optical absorption spectra of vacuum-evaporated thin films of the metals were also recorded as a reference. The metals were sublimed on the fused silica substrate in a vacuum at least 8×10^{-6} Torr. In the case of calcium, paraffin was sublimed onto the calcium film to prevent the air oxidation during the recording of the spectrum. The film thickness was monitored by a quartz oscillator film thickness gauge, Sloan DTM 200. The electron micrographs were taken by a Hitachi H 500H electron microscope used in the high resolution mode. The specimen were obtained by dropping the sample solution on the Cu grid coated by collosion film reinforced by carbon film. The silver aqueous colloid was prepared by the conventional chemical method. 0.1 M silver nitrate solution and 1% tannic acid solution were added to 500 ml distilled water and then 1% sodium carbonate solution was poured into the mixture with stirring at 70 °C. The resultant colloid solution was dialysed to distilled water overnight.

Results and Discussion

We examined many organic solvents, as stated in the experimental section, but confine ourselves here to the case of ethanol which has both protic and aliphatic properties.

Pb. Figure 4a shows the micrograph of deposited lead colloid on a carbon film taken by the usual transmission technique. The diameters of many particles lie in the region of 10 nm. Figure 4b shows the optical absorption spectra of lead colloid solution (dark brown) in Ar atmosphere. Two absorption maxima at 400 and 250 nm in a 10 nm thickness evaporated film reflect the spectra of the colloid solution. Three bands: 320 nm shoulder, 250 and 215 nm peaks in colloid was found to be time dependent. The 320 and 250 nm bands decreased with time, while the 215 nm peak increased with time. The 215 nm peak was observed in a less stable metal. It is most likely that this peak comes from the

product of the solvent-metal reaction. After 24 h, the dark brown coloration of the solution changed to transparent, resulting in the disappearance of the 320 nm peak.

Lead colloid bands were observed in Pb doped alkali halide crystals. Topa and Velicescu reported[5] that the colloid band appears at around 250 nm upon annealing the T-center. The computer calculation[6] on the bases of complete Mie equations agreed fairly well with the above experiment. The peak position depends on the diameter of the particle. Following the calculation, the 240 nm peak was obtained for 10 nm diameter lead colloid–NaCl system. More comprehensive studies were reported by Jain *et al.*[7] They also observed the Pb colloid band at 240 nm which coincided with the experimental result obtained by Topa and Velicescu. In addition to 240 nm band, they reported that a 214 nm band forms with heat treatment of KCl–Pb system. This band was ascribed to Pb° center. In our case, it is not reasonable to assume the existence of Pb atom in solution to explain the 215 nm peak.

Sn. In Fig. 5a is shown the micrograph of tin colloid. The diameters of many particles fall in the region of 15 nm. Figure 5b shows the spectra of tin colloid solution (dark brown). There is a complex band structure in the region of 240—440 nm of 5 nm thickness evaporated film, which also appears in colloid solution at the same spectral region. We also notice the 215 nm peak due to the solvent-metal reaction. It should be pointed out that the absorption still remains near the infrared region which suggests that the optical properties of this colloid has a bulk nature. The transmission and the reflectance spectra of tin particles isolated by MgF_2 were reported by Zeller and Kuse.[8] Strong absorption at the visible and near infrared was qualitatively explained by the Maxwell-Garnett theory.[9] Their result is basically consistent to our data. To complete the identification of the complex absorption band structure, detailed considerations including the surface plasmon and the interband transitions are needed.

(b)

Fig. 6. (a): Micrograph of aluminum colloid. (b): Absorption spectra of colloid solution (solid line) and 20 nm thickness evaporated film (dotted line) of aluminum.

Al. In Fig. 6a is shown the micrograph of aluminum colloid. The diameter of the majority is near 30 nm. Figure 6b shows the spectra of aluminum colloid solution (dark blue) together with that of 20 nm thickness evaporated film. Rather strong absorption exists even at 850 nm, although some may be due to scattering effects. There are two peaks at 215 and 250 nm, together with a broad band at around 550 nm. The solution was stable for one month, irrespective of the existence of the 215 nm peak. We assume this stability to be due to the formation of the passive state on the surface of the colloid. The calculation of the optical spectra based on

(b)

Fig. 8. (a): Micrograph of indium colloid. (b): Absorption spectra of colloid solution (solid line) and evaporated film (dotted line) of indium. The thickness of the film is 5 nm.

Mie's treatment was conducted for the system of Al–Al_2O_3.[10] The 250 nm absorption maximum was obtained for the particles of 10 nm and the 305 nm maximum for 20 nm diameter ones. The difference between the present study and their calculation may lie in the difference of dielectric constant. The spectrum of aluminum aqueous colloid solution prepared by the aerosol technique was reported by Petrov.[11] Only a broad band at 600 nm was observed in his study.

Ca. In Fig. 7a is shown the micrograph of calcium colloid. It is difficult to perceive any individual particles in the figure except traces. Figure 7b shows the spectra of calcium colloid solution (light blue) and the 35 nm thickness evaporated film. Calcium was not stable toward oxygen and water, therefore the evaporated film was coated with paraffin and then we measured the spectra. Even upon this treatment, the absorption decreased with time within ten to twenty minutes. The colloid solution was also unstable. The coloration changed to transparent within one hour in the Ar atmosphere, which indicates that the metal particle reacts with the alcohol. The formation of calcium colloid in CaF_2 crystal was reported by Orera and Alcara.[12] The absorption band at 550 nm in heavily electron irradiated samples and in additively colored crystals of CaF_2 is associated with colloidal calcium. These authors also calculated the optical absorption spectra using Mie's theory and obtained a good agreement between theoretical calculations and experimental results.[13] On the other hand, McLaughlan and Evans observed many bands between 300 and 700 nm on the X-irradiated doped CaF_2 crystal.[14] In the thin film, as shown by Fig. 7b, we have an absorption window in this region. In solution, the absorption minimum shifts to 320 nm and a new peak appears at around 250 nm. We notice that there are many bands between 350 and 850 nm, although they are obscured by the broad distribution of the size of the calcium colloid. The dielectric constant of the solvent and the diameter of the colloid is the main cause of the difference in the solution state and in the rigid matrix.

In. In Fig. 8a is shown the micrograph of indium colloid. The diameters of many particles are scattered from 10 nm to 80 nm. Figure 8b is the absorption spectra of indium colloid (light brown) and the evaporated film whose thickness is 5 nm. The colloid solution was very stable over several months. The optical absorption of indium granular deposits was reported for three samples with different thicknesses on the quartz substrate.[15] The position of the absorption maximum was nearly constant at 258 nm, irrespective of the differences in thickness: 3.5, 7, and 22 nm. The 258 nm peak shifts to 340 nm for the case of thin film (Fig. 8b). In solution, the absorption band seems to be comprised of two peaks: 280 and 400 nm maximum. The reason of this broad band is attributable to the wide diameter distri-

bution in the sols.

Cu. Figure 9a shows the micrograph of copper colloid. The diameter of the majority is near 5 nm. The optical absorption spectra of copper colloid (wine red) and the evaporated film are shown in Fig. 9b. There are two peaks at 220 and 570 nm and two shoulders at 240 and 380 nm. This colloid was not stable in an aerobic condition. The 570 nm peak disappeared within 30 min and the wine red color also disappeared. The 240 nm shoulder slightly increased in intensity at the same time. On the other hand, the colloid was relatively stable under the Ar atmosphere. However, the wine red color changed to yellow after one day. The spectrum of copper colloidal particles was measured in dodecane.[16] Three peaks at 220, 310, and 590 nm were observed. These observations resemble our spectrum closely. The 570 nm peak of copper fine particle was also observed by Abe *et al.* on the Ar matrix at liquid helium temperature.[17] It is noticeable that the room temperature colloid solution gives the same spectrum as that of the fine particles dispersed on low temperature matrices. The optical spectrum of the suspension of copper particles in water was measured by Petrov.[11] The two peaks observed at 380 and 590 nm may correspond to 380 and 570 nm peaks in the present study. The origin of the long wavelength peak (570 nm) is not clear: it could be assigned to an interband transition[17] or to an intraband transition.[11,16]

Au. In Fig. 10a is shown the micrograph of gold colloid. The diameters of many particles fall in the region from 10 nm to 5 nm. The optical absorption spectra of gold colloid solution (purple) is shown in Fig. 10b, together with that of the evaporated film whose thickness is 10 nm. This colloid is very stable over a month. The absorption spectra of aqueous gold sols and small particles deposited in glass were reported by Doremus.[18] In aqueous gold sols, there are two main peaks at 250 and 520 nm. The 520 nm peak was also found in the deposited particles (12 nm diameter) in glass. In ethanol gold sols, we found three peaks at 220, 250, and 540 nm. Generally speaking, these two sols are quite similar in their spectra, as was the case for the copper colloid, regardless of the difference in solvent and measurement temperature. Abe *et al.*[17] also measured the spectra of gold fine particles in Ar matrix at liquid helium temperature. There were two peaks at 520 and 380 nm. They assigned the 520 nm peak to surface plasmon absorption. Here, we will point again that the gas flow-solution trap method gives a simple and well dispersed particle system, similar to the result of the low temperature Ar matrix method.

Ag. The spectra of silver colloid are given in Fig. 11. For all three samples, the vacuum evaporated film (8.5 nm in thickness), ethanol sols (12 nm in diameter) and aqueous sols (6.4 nm in diameter), there are clear plasmon edges at 330 nm. Absorption peaks are different for three samples (the plasmon peaks are

at 420 nm to aqueous sol, at 405 nm to alcohol sol and at 680 nm to thin film) but the general feature is similar for the two sols. There are many reports on the optical properties of silver colloids. Doremus measured[19] the optical absorption spectra of silver particles in glass (the peak at 440 nm) and got a successful agreement with the calculation done using Mie's equation. Genzel *et al.* calculated the plasmon peak and halfwidth of the plasmon peak as a function of particle diameter based on a quantum mechanical model.[20] The peak position thus obtained is 407 nm for 10 nm particles. A gas evaporation technique was applied to the measurement of optical absorption of silver microcrystallites at low temperature.[1] The plasmon peak at 380 nm was explained by a classical model. The additional peaks at about 300—340 nm were ascribed to the Ag atom trapped in the matrix in low temperature. The absorption at the ultraviolet region observed in the silver colloid of the present report may be the contribution from the interband transitions.

Conclusion

A new colloid preparation method, the gas flow-solution trap method, was presented and described in detail. The presented method has three characteristics. One is the wide applicability to any metals/metal solid solutions with use of the same apparatus. It should be emphasized that this technique is not confined to metals but is applicable also to any thermally stable solid samples. The second is the simpleness of the system. This technique gives substantially a two-component pure system unless the metal does not react with solvent. The simpleness of the system may make it easy to understand the solid state properties of small metal particles in solution. The third one is that the colloid prepared by the present method is a sol, that is, the metal fine particles are in solution. This is a merit for the optical measurement in ultraviolet region, because the scattering effect is dominant in solid matrixes in this region.

This technique was applied to Pb, Sn, Al, Ca, In Cu, Au, and Ag metal colloids in ethanol solution. All metals gave well-dispersed colloids. The diameters of many samples fell in the region of 10 to 50 nm in the present experimental conditions. Some metal particles, Pb, Sn, Ca, and Cu were found to be unstable and others, Al, In, Au, and Ag, were stable. The optical spectra of these colloid solutions resembled the reported spectra of fine particles on matrix or on substrate, many of which were results of low temperatur measurements.

A ^{1}H and ^{31}P NMR Study of Phenylphosphonous Dichloride Partially Oriented in a Nematic Phase

Koji SAITO, Akihiro YOSHINO, Tadayoshi YOSHIDA, and Kensuke TAKAHASHI*
Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received June 10, 1983)

The ^{1}H and ^{31}P NMR spectra of phenylphosphonous dichloride dissolved in a nematic phase of *N*-(*p*-ethoxybenzylidene)-*p*-butylaniline (EBBA) have been analyzed, and the structure of the proton and phosphorus skeleton has been determined.

The NMR spectroscopy of molecules in the oriented phase has become a useful method of obtaining structural information about molecules since the first observation by Englert and Saupe.[1,2] In principle, the orientation parameters and the relative distances between the spin nuclei in a molecule can be determined by this technique.[3] The technique has been applied to many molecules containing various nuclei. However, only a few NMR studies have so far been reported on molecules containing the ^{31}P nucleus in the oriented phase.[3-7] This study will present the results of our own observation and analyses of the title substance dissolved in a nematic phase of *N*-(*p*-ethoxybenzylidene)-*p*-butylaniline (EBBA). The relative internuclear distances and the orientation parameters have been obtained.

Experimental

The phenylphosphonous dichloride (PPD) and EBBA were commercial in origin and were used without further purification.

The ^{1}H and ^{31}P NMR spectra of PPD in the isotropic phase were recorded at 60 and 24.28 MHz on a Hitachi R-20B spectrometer equipped with a R-204P attachment. In both cases, the spectra were obtained at 31.5±0.5 °C.

The ^{1}H and ^{31}P NMR spectra of PPD in an oriented phase were recorded on a Varian XL-200 spectrometer, operating both at 200 and 80.96 MHz for a 14.1 mol% solution in EBBA. Although there was a marked color change from colorless to yellow on the dissolving of PPD in EBBA, no chemical reaction occurred and the nematic solutions were stable for a week during the NMR measurements. The spectra were recorded with 32K data points using spectral widths of 20000 and 10000 Hz for the cases of ^{1}H and ^{31}P. Sixteen ^{1}H FIDs were accumulated without a lock for the proton spectrum, and 128 ^{31}P FIDs were accumulated with an external D_2O lock for the ^{31}P spectrum. In both cases, the sample was spun in the superconducting system. The probe temperature was about 22.5 °C. The average line-widths in the nematic phase were about 10 and 9 Hz for the ^{1}H and ^{31}P spectra respectively.

The calculation of the spectral and structural analyses were carried out by a HITAC E-600 minicomputer system installed in our laboratory.

Results and Discussion

Analyses of the Spectra. The ^{1}H NMR spectrum of PPD in the neat liquid consists of a large number of lines. Sixty-five lines were assigned. Analyses of the spectra were followed by a program, LAOCN3.[8] The results are given in Table 1. Sixty-five observed lines were assigned to the calculated values, with an RMS error of 0.08 Hz. The results were almost entirely consistent with those reported by Parr.[9] It was assumed that the phosphorus-proton couplings over three, four, and five bonds are positive. The numberings of the nuclei are shown in Fig. 1.

TABLE 1. ^{1}H NMR SPECTRAL PARAMETERS FOR PHENYLPHOSPHONOUS DICHLORIDE IN Hz

a) Parameters obtained for the neat liquid. b) Parameters obtained for a 14.1 mol% solution in EBBA.

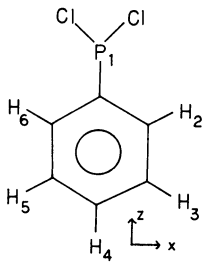

Fig. 1. Numbering system for phenylphosphonous dichloride.

The ^{1}H and ^{31}P NMR spectra of PPD in the nematic phase are given in Fig. 2. The spectra consisted of 55 and 18 resolved lines respectively. Eighty and 32 calculated lines were assigned for the observed ^{1}H and ^{31}P spectra, with an RMS error of 1.9 Hz. The results are also given in Table 1. The analyses of the spectra were followed by a program, LAOCN3D, which has been slightly modified from the LAOCN3+D program.[10] The indirect coupling constants were kept constant in the iteration calculation. The errors of the various parameters in Table 1 correspond to those given in the computer output.

The spectra calculated by varying the values of D_{12}, D_{13}, D_{26}, and D_{35}, while keeping $D_{12}+D_{13}$ and $D_{26}+D_{35}$ constant, were nearly identical. This means that only the sums ($D_{12}+D_{13}$ and $D_{26}+D_{35}$) can be determined with reasonable precision. When the difference between

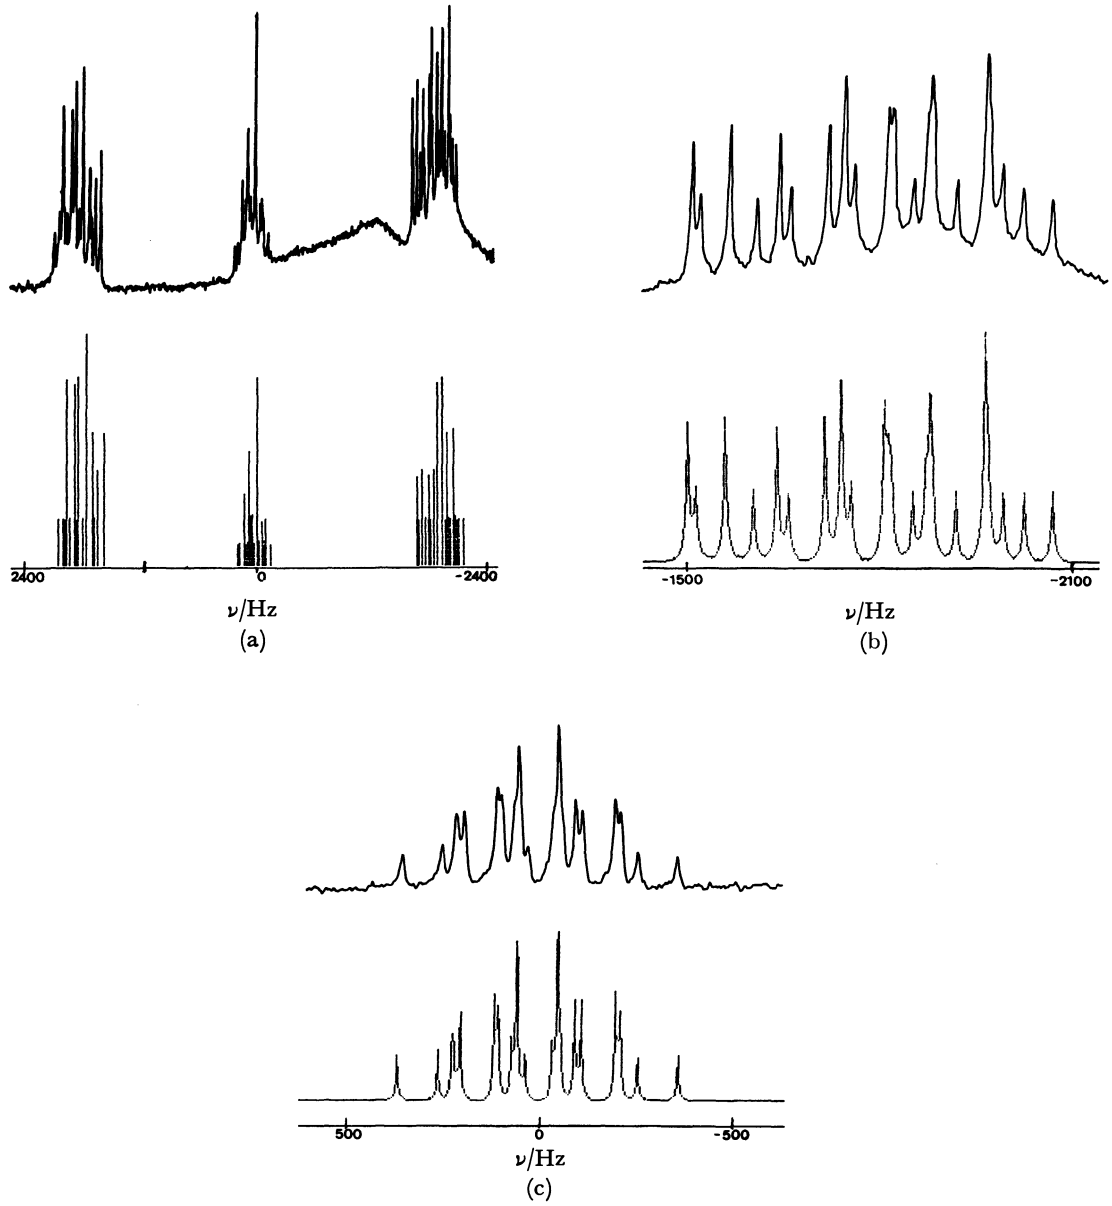

Fig. 2. Observed ^{1}H and ^{31}P NMR spectra of phenylphosphonous dichloride dissolved in EBBA. Calculated spectra are also given under the observed ones; (a) A whole observed ^{1}H spectrum accumulated 16 scans and a calculated stick spectrum, (b) an expanded upfield spectrum of (a) and a calculated one, (c) an observed ^{31}P spectrum accumulated 128 scans and a calculated one.

D_{26} and D_{35} is small, it is very difficult to differentiate D_{26} and D_{35} separately. However, a better agreement between the observed and the calculated spectra was obtained in the case of $D_{26}<D_{35}$.

Analyses of the Molecular Structure. PPD has been shown to be planar and to have a C_{2v} symmetry by means of an electron-diffraction study.[11] Therefore, there are only two diagonal-orientation parameters necessary to describe the molecular orientation. The three following assumptions were made before the analyses of the molecular structure: (1) the benzene ring forms a hexagonal plane; (2) molecular vibrations need not be taken into consideration; and (3) the anisotropies of the proton-phosphorus and proton-proton indirect couplings are negligible. Under these assumptions, the relative positions of the protons and the phosphorus can be determined from the direct proton-proton and proton-phosphorus couplings with the aid of the iterative program SHAPE.[12] The derived geometrical and orientation parameters are given in Table 2.

As may be seen in Table 2, the parameters derived from the present study agree with those from the electron-diffraction study within the limits of the standard deviation except in the case of the phosphorus atom. Two reasons for this discrepancy may be considered: (1) a vibration correction was not performed; or (2) the interatomic distances derived from NMR may deviate essentially from those of other methods.[3] The coordinates of the hydrogen atoms of PPD are in excellent agreement with those of phenylphosphonic

Table 2. Coordinates of the spin nuclei in phenylphosphonous dichloride in Å, and order parameters[a)]

Nucleus	X Coordinate	Z Coordinate
P	0.0	5.874 ± 0.029
	(0.0)[b)]	(5.74 ± 0.05)
H-2	2.182 ± 0.031	3.749 ± 0.054
	(2.16 ± 0.02)	(3.74 ± 0.02)
H-3	2.166 ± 0.031	1.249 ± 0.014
	(2.16 ± 0.02)	(1.25 ± 0.02)

H-5	−2.166 ± 0.031	1.249 ± 0.014
	(−2.16 ± 0.02)	(1.25 ± 0.02)
H-6	−2.182 ± 0.031	3.749 ± 0.054
	(−2.16 ± 0.02)	(3.74 ± 0.02)
S_{xx}	−0.06288 ± 0.00038	
S_{zz}	0.15689 ± 0.00013	

a) The calculated coordinates are based on the value of r(H-3, H-4), which is assumed to be 2.500 Å. b) The values in parentheses were calculated from the results obtained by means of the electron-diffraction method[11] (r(C–C)=1.413±0.008, r(C–H)=1.080±0.003, and r(C–P)=1.833±0.04 Å).

dichloride.[7] However, as far as the coordinate of the phosphorus atom is concerned, the C–P distance of PPD is much longer than that of phenylphosphonic dichloride.[7] The above difference can, though, be partly explained by the fact that the C–P(III) (trivalent phosphorus) distance is slightly longer than the C–P(V) (pentavalent phosphorus) distance reported in electron-diffraction studies.[13,14]

(Received June 15, 1983)

The interaction of 3,3′-diethylthiacarbocyanine iodide, a cationic dye, with sodium dodecyl sulfate (SDS), an anionic detergent, was studied as a function of the concentration of SDS ([SDS]) above and below the critical micelle concentration (cmc). The [SDS]-dependent fluorescence spectra, quantum yield and decay measurements revealed the deaggregation of the dye above the cmc and the formation of the dye–SDS aggregate below the cmc.

The photophysical and photochemical behavior of organic molecules in organized assemblies such as micelles[2,3)] has been receiving current attention from several viewpoints, such as (1) the influence of the micellar environment on the very fast photophysical process like rotational diffusion,[4)] (2) the photophysical study in relation to finding a good lasing system,[5,6)] (3) the measurement of the aggregation number of micelles,[7)] and (4) the construction of a model membrane system to mimic a biological system like chloroplasts, with special emphasis on the enhancement of the energy transfer and electron transfer efficiencies.[8–20)] The study of the spectroscopic properties of organic molecules in micellar media provides us with the basic properties of such a system which are useful in understanding many specific features of the system as mentioned above.

Many peculiarities have been noted for the spectroscopic properties of the dye with a detergent with the opposite charge around the critical micelle concentration (cmc). Pinacyanol, a cyanine dye, has been used in the "spectral change method" to determine the cmc of many detergents.[21)] Mataga and Koizumi[22,23)] studied the variation in absorption spectra and fluorescence quenching of the Rhodamine 6G (Rh-6G)–sodium dodecyl sulfate (SDS) system, which was dependent on the concentration of SDS ([SDS]), around the cmc. Mukerjee and Mysels[24)] studied absorption spectra of the pinacyanol–SDS system as a function of [SDS], and examined critically the "spectral change method" mentioned above. Lohoczki and Hevesi[9)] studied the variation of absorption spectra of the thionine–SDS system especially below the cmc (*i.e.* in the premicellar region). From further investigation of these peculiarities in the absorption and fluorescence spectra along with the fluorescence lifetime and quantum yield, detailed picture on the nature of dye–detergent interaction can be obtained.

In the present paper, the [SDS]-dependent variation in absorption and fluorescence spectra, quantum yield, and decay characteristics of 3,3′-diethylthiacarbocyanine iodide (DTC)–SDS system was studied, and the nature of the dye–detergent interaction was discussed. The structural formula of DTC is given in Fig. 1.

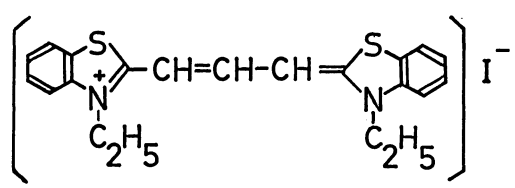

Fig. 1. Structural formula of 3,3′-diethylthiacarbocyanine iodide.

Experimental

Materials. DTC (Dojin Kagaku), Rhodamine B (Eastman-Kodak), and Rhodamine 101 (Exciton) were used without further purification. The purity of these dyes was checked by thin-layer chromatography. SDS (Nakarai, protein research grade), quinine sulfate (Wako), *m*-dimethylaminonitrobenzene, and 4-dimethylamino-4′-nitrostilbene (Nakarai) were used as received. Water was distilled twice. Sulfuric acid, benzene, hexane, *o*-dichlorobenzene, and ethylene glycol were of G. R. grade of Wako or Nakarai and were used as received.

Absorption and Fluorescence Spectra. Absorption spectra were measured by a Shimadzu UV-200 recording spectrophotometer. Fluorescence spectra were measured by a Hitachi 650-10S spectrofluorimeter with a Hamamatsu R928 photomultiplier (sensitive to 930 nm). Measurements were made at room temperature for aerated solutions.

Fluorescence Decay. In the measurement of fluorescence decay curves, the dye solution in a quartz spectrofluorimeter cell was pumped with the second harmonic of a Nd^{3+}: YAG laser. Fluorescence decay was measured with a Hamamatsu C979 streak camera, using a Nihon-shinkukogaku interference filter (579 nm), or a Toshiba VO56 or 57 cut-off filter. The time-scale of the streak camera was fully calibrated. All measurements were made at room temperature for aerated solutions. The results of three to nine shots on the same sample were averaged.

Quantum Yield Measurements. The fluorescence quantum yield (ϕ) of the dye solution was measured with reference to that of quinine sulfate standard solution (1×10^{-6} M† in 0.5 M H_2SO_4), $\phi_{st}=0.55$,[25)] using the formula[26)]

$$\frac{\phi}{\phi_{st}}=\frac{F}{F_{st}}\cdot\frac{A_{st}}{A}\cdot\frac{E_{st}}{E}\cdot\frac{n^2}{n_{st}^2}, \quad (1)$$

where F, A, E, and n are the integrated area under the fluorescence spectrum (corrected for the response function of the spectrofluorimeter), the absorbance/cm at the exciting wavelength, the intensity of the exciting light measured by a photocell (Hamamatsu S1133-01) corrected for its response function, and the refractive index of the sample solution, respectively. F_{st}, A_{st}, E_{st}, and n_{st} are the corresponding quantities of the

† 1 M=1 mol dm^{-3}, 1 mM=1×10^{-3} mol dm^{-3} in this paper.

standard solution. The exciting wavelength was 365 and 520 nm for quinine sulfate and DTC, respectively. All measurements were made at room temperature (25±2 °C) for aerated solutions. The relation $n \approx n_{st}$ was assumed. The response function of the spectrofluorimeter was measured using *m*-dimethylaminonitrobenzene (1×10^{-5} M in benzene–hexane mixture (30 : 70 in volume)) and 4-dimethylamino-4′-nitrostilbene (1×10^{-5} M in *o*-dichlorobenzene).[27,28] That of the photocell was measured using the solution of Rhodamine B in ethylene glycol. In order to check the accuracy of the present method of quantum-yield determination, the quantum yield of Rhodamine-101 was measured. The quantum yield of this dye has been known to be 1.0.[6,29] The quantum yield of Rhodamine 101 (6×10^{-6} M in ethanol) measured by the present method was 1.04—1.06. The accuracy (within *ca.* 10%) of the present method was thus proved.

Cmc Measurements. The cmc of SDS was determined conductometrically. The electrodes of the conductivity cell were platinum plates without platinum black. The temperature of the cell was kept at 25.0±0.1 °C. The bridge used was a Yanaco MY-8 Conductivity Outfit or a Yokogawa Hewlett-Packard 4255 A Universal Bridge. The cmc determined was 7.4±0.1 mM, in good agreement with the generally accepted published value (8.1 mM).[30]

Results

Absorption and Fluorescence Spectra of DTC and DTC–SDS. The absorption spectra of the aqueous solutions of DTC are shown in Fig. 3. For [DTC]$\lesssim 2.0 \times 10^{-5}$ M, the shape of the absorption band remained essentially the same and was quite similar to that of the methanol solution. The dye is present essentially as a monomer in these solutions. The dimer band at 510 nm became apparent for [DTC]$\gtrsim 5.0 \times 10^{-5}$ M. The ratio of the absorbance at 510 nm to that at 556 nm (A_{510}/A_{556}) increased with the concentration of the dye, while the corresponding ratio was essentially constant in methanol (See Fig. 3). The fluorescence maximum which appeared around 580 nm is due to the monomer of the dye. The absorption spectra of DTC–SDS solutions are shown in Fig. 4. The ratio A_{510}/A_{560} (the dimer band was found at 510 nm, and the monomer band at 560 nm) increased and then decreased with [SDS] for [SDS]<cmc, and decreased with [SDS] for [SDS]>cmc, as shown in Fig. 5. Comparison of Figs. 3 and 5 reveals two opposite action of SDS on DTC, *i.e.*, the aggregation of the dye below the cmc, and the deaggregation of the dye above the cmc. The fluorescence spectra of the DTC–SDS solutions are shown in Fig. 6. The fluorescence peak shifted to 594 nm. The shift of ≈14 nm compared with the aqueous solution is due to the micellar environment. It is to be noticed that the 594 nm peak appeared even at [SDS]=6.0 mM, *i.e.*, in the *premicellar* region. This shows the presence of some aggregate which provides the micelle-like

environment in this [SDS] region.

For [SDS] $=1$—4 mM, the absorption spectra are characterized with broad bands to the shorter wavelength of the dimer band and to the longer wavelength of the monomer band, as shown in Fig. 4. Fluorescence band in this [SDS] region appeared as a broad band with a peak around 655 nm, as shown in Fig. 6. Fine precipitate appeared around [SDS] $\cong 1$ mM when the dye concentration was high.

Fluorescence Quantum Yield. The variation of fluorescence quantum yield (ϕ) of DTC as a function of [SDS] is shown in Fig. 7. The obtained value $\phi=0.03$ in water is comparable with the reported values $\phi=$ 0.048 in ethanol,[31] or 0.042 in water–methanol (9 : 1).[32] Fluorescence quenching which is evident in the pre-

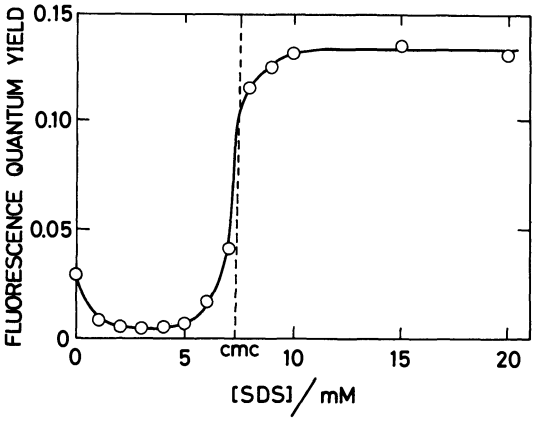

Fig. 7. Variation of fluorescence quantum yield of DTC as a function of [SDS], [DTC] $=2.0\times10^{-5}$ M.

micellar region must be the results of static and dynamic quenching of the monomer fluorescence by the presence of dimer and dye–SDS aggregate. The fluorescence quantum yield as compared with that in the aqueous solution is drastically enhanced by the addition of SDS above the cmc. This must be partly due to the deaggregation action of SDS micelles on the dye. However, this action alone cannot fully explain the observed enhancement of the fluorescence, because DTC molecules in the aqueous solution exist essentially as monomers at this [DTC] (2×10^{-5} M), as mentioned above in relation to the absorption spectra.

Fluorescence Decay. The nature of dye–detergent interaction is revealed most clearly in the fluorescence decay characteristics. The fluorescence decay curves for the aqueous solution ($\lambda_{max}=580$ nm) and SDS solutions ($\lambda_{max}=594$ nm) of DTC ([DTC] $=5.0\times10^{-5}$ M and 2.0×10^{-6} M) are shown in Figs. 8(a) and (b). An exponential decay with a lifetime of 100 ps was observed for the aqueous solution. The same decay behavior was observed over the whole concentration range studied (1.0×10^{-4}—2.0×10^{-6} M). It is comparable with that predicted by Roth and Craig[31] for methanol solution (150 ps). The observed decay is apparently that of the monomer, and the quenching by the dimer did not occur in these concentrations.

The decay behavior of the DTC (5.0×10^{-5} M)–SDS solutions (Fig. 8(a)) was found to depend largely on [SDS]. Such a large variation in the fluorescence decay behavior with [SDS] can be explained by comparison with the absorption and fluorescence spectra and by referring to the other cationic dye–SDS solutions (*e.g.* pinacyanol–SDS[12,14,24]). The fluorescence decay for [SDS] $=1.0\times10^{-2}$ M was exponential. Its lifetime, 410 ps, was much longer than that of the monomer in the aqueous solution (100 ps) mentioned above. Therefore, the decay behavior cannot be explained by the deaggregation effect alone.

For [SDS] $=8.0$ mM, the nonexponential decay behavior can be attributed to the presence of P_3, P_4, $\cdots$ micelles besides P_1 and P_2 micelles (P_1, P_2, $\cdots$ micelles are the micelles which incorporate one, two, $\cdots$, dye molecules). The distribution of dyes among micelles is usually treated in terms of Poisson statistics.[33] The

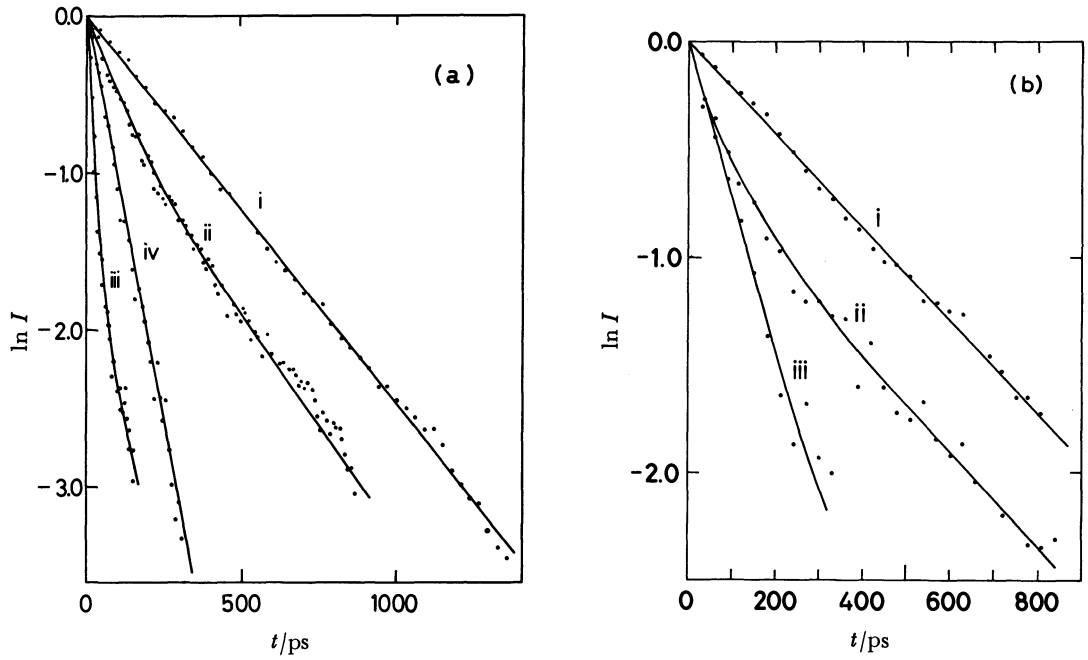

Fig. 8. Flourescence decay curves of DTC–SDS solutions.
(a) [DTC]=5.0×10^{-5} M, (i) [SDS]=1.0×10^{-2} M, (ii) 8.0×10^{-3} M, (iii) 5.0×10^{-3} M, (iv) 0 M; (b) [DTC]=2.0×10^{-6} M, (i) [SDS]=1.0×10^{-2} M, (ii) 5.0×10^{-3} M, (iii) 1.0×10^{-3} M. At [SDS]=8.0×10^{-3} M (not shown), the decay was almost identical to (i).

dye molecules in P_1 and P_2 micelles follow the monomer decay. Those in P_3, P_4, ··· micelles are, however, influenced by the quenching by dimers. The observed decay is the sum of the decays in P_1, P_2, P_3, ··· micelles and hence nonexponential.

For [SDS]=5.0 mM, the observed decay was very fast. Since the fluorescence band is a superposition of 594 and 655 nm fluorescence, where the latter seems to be enhanced by the energy transfer from the former, the decay must be composed of (1) that of the 594 nm fluorescence due to the dye molecules in the micelle-like environment (affected by the energy transfer mentioned above) plus (2) that of the 655 nm fluorescence. Apparently, the observed fast decay reflects only the decay of the component (1), since the component (2) is very weak compared with (1).

A similar [SDS]-dependent variation of fluorescence decays was observed for [DTC]=2.0×10^{-6} M (Fig. 8(b)). However, in this case each decay pattern appeared at the smaller [SDS] compared with the case of [SDS]=5.0×10^{-5} M. The slow decay with the lifetime ≈450 ps appeared at [SDS]=10.0 mM. An exponential decay with almost the same lifetime was observed at [SDS]=8.0 mM. The nonexponential decay (which is similar to the case of [DTC]=5×10^{-5} M and [SDS]=8 mM) appeared at [SDS]=5 mM. At [SDS]=1 mM the decay was very fast, as was observed for [DTC]=5×10^{-5} M and [SDS]=5 mM. A similar decay pattern which is dependent on both of [dye] and [SDS] has been reported for the acridine orange–SDS system.[12,34]

Discussion

The Effect of SDS on the Aggregation State of the Dye. The characteristics of the absorption and fluorescence spectra, fluorescence intensity and quantum yield of the dye–detergent systems as mentioned above reveal two opposite effects of SDS on the aggregation state of the dye, aggregation below the cmc and deaggregation above the cmc.

Dye–SDS Aggregate Formation in the Lower Premicellar Region. In the lower premicellar region ([SDS]= 1—4 mM), the very broad absorption band and the weak, long-wavelength fluorescence band at 655 nm show the presence of some aggregated state of the dye.

Two types of higher aggregate of cyanine dyes, H-aggregate and J-aggregate are known.[35] The former is characterized with an absorption band to the shorter wavelength of the dimer band, while the latter with the absorption band to the longer wavelength of the monomer band. Resonance fluorescence is peculiar to the J-aggregate. The H- and J-aggregate have different stack structure, head-to-head and head-to-tail, respectively. While some *meso*-substituted or benzo-fused derivatives of DTC show the strong tendency to form H- and J-aggregates,[36–38] DTC itself does not. This is evident from the absorption spectra (Fig. 2) which are composed of only monomer and dimer bands to the limit of highest concentration limited by the solubility of the dye in water.

Contrary to this behavior in aqueous solutions, DTC forms higher aggregate in SDS solutions in the lower premicellar region, as shown by the presence of broad

absorption bands to the shorter and longer wavelengths of the monomer and dimer bands (Fig. 4). Clearly, the aggregates in this case are composed of the dye and SDS, *i.e.* the DTC–SDS aggregates. Then, what is their composition like? How are they related to the H- and/or J-aggregate in the aqueous solution of the related compound?

For some dye–detergent systems with the opposite charge, *e.g.*, pinacyanol–SDS[12,14,24] and Acridine Orange–SDS,[34] the dye–detergent aggregate forms a large particle and precipitates from the solution around [SDS]≈1—2 mM. This is due to the 1 : 1 complex of the cationic dye (D^+) and the dodecyl sulfate anion (S^-), $(D^+S^-)_n$.[24] In the DTC–SDS system presently studied, very minute particles appeared in the solution when [DTC] was high (*e.g.* 1.0×10^{-5} and 5.0×10^{-5} M) and [SDS] was around 1 mM.[39] These must be due to the $(D^+S^-)_n$ type aggregate. The DTC–SDS aggregate characterized with the very broad absorption band and the 655 nm fluorescence will also be due to the essentially 1 : 1 complexes dispersed and stabilized in the aqueous solution by the addition of slight excess of SDS molecules.[24]

The emission spectra of the related dye, 3,3′-diethyl-9-methylthiacarbocyanine iodide, at 78 K in EPA matrix were studied by Cooper and Liebert.[40] To the longer wavelength of the monomer fluorescence peak at 562 nm, a group of three emission peaks was observed in the 580—760 nm region. A sharp band at 594 nm was assigned to the dimer emission, a broad low-intensity band at about 648 nm to the excimer emission, and a sharp band near 680 nm to the triplet—singlet transition (phosphorescence). By referring to this observation, the broad structureless emission band of the DTC–SDS solution in the lower premicellar region ([SDS]≈1—4 mM) can be most reasonably assigned to the excimer fluorescence of the dye molecule in the DTC–SDS aggregate.

Resonance Raman spectra of DTC–SDS solutions give further information on the structure of the DTC–SDS aggregate.[39] The relative intensities of Raman bands varied as a function of [SDS]. For [DTC]= 1×10^{-5} M, the relative band intensities at [SDS]= 2.5 mM were very similar to those of solid DTC (KBr disk). DTC molecules in the DTC–SDS aggregate must be in the aggregation state like that of the dye in the solid state.

Not only the electrostatic attraction between the dye cation (D^+) and the dodecyl sulfate anion (S^-), but also the hydrophobic interaction between the dye molecules and detergent molecules must be working in the stabilization of the DTC–SDS aggregate in the lower premicellar region. When the electrostatic interaction becomes dominant (at the lower [SDS] edge of this [SDS] region), the precipitation of $(D^+S^-)_n$ occurs. The hydrophobic interaction becomes increasingly dominant with [SDS]. DTC–SDS aggregates change into dye-rich induced micelles and then into the ordinary micelles with increasing [SDS], as will be discussed later.

Deaggregation and Immobilization of the Dye above the cmc. The deaggregation of the dye, an effect of SDS which is opposite to that in the lower premicellar region, is evident above the cmc by monomer-type absorption spectra. The deaggregation is apparently due to the distribution of the molecules among micelles. However, the fluorescence intensity much enhanced, the quantum yield much larger, and the fluorescence lifetime much longer than in the aqueous solution cannot be explained by the deaggregation effect alone, because the enhancement occurred even for [DTC] at which the dye is present essentially as a monomer in the aqueous solution.

The enhancement of fluorescence intensity compared with the aqueous solution was explained as due to the environmental change (the hydrophobic environment) and/or to the immobilization of dye molecules in the miceller media.[1] The enhancement of a similar nature has been reported in a recent communication by Humphry-Baker *et al.*[41] for a cyanine dye–SDS solution, and by Nakashima and Kunitake[42] for some cyanine dyes bound to synthetic bilayer membranes. The enhancement in these systems were attributed to the inhibition of the radiationless decay by the micellar environment which immobilize the cyanine dyes to some extent.

The immobilization effect of micelles on dyes is revealed in the rotational diffusion. This was studied by transient absorption by Lessing and von Jena.[4] They obtained the rotational relaxation time (τ_R) of a few nanoseconds in the micellar media, in contrast to that of a few hundred picoseconds in solvents of low viscosity.[43–45] Humphry-Baker *et al.*[41] examined the rotational motion in excited states by fluorescence polarization measurements, and calculated the rotational rate about one order of magnitude smaller in the micellar than in alcoholic solutions. The prevention of rotational motion is more evident in the bilayer system of Nakashima and Kunitake.[42] The values of τ_R were obtained for the aqueous and SDS ([SDS]=15 mM) solutions of DTC from the fluorescence polarization to be 380 ps and 1.9 ns, respectively.

Such an effect of micelles on the movement of dye molecules has sometimes been expressed in terms of the "microviscosity (or, microscopic viscosity)." For example, the microviscosities of SDS or hexadecyltrimethylammonium bromide (HTAB) micelles measured near room temperature are reported to be about 15—30 cP.[3] The dependence of fluorescence intensity of the dyes on the viscosity of solvents has been extensively studied.[46–54] This effect is especially evident for cyanine dyes.[49–54] It is known that cyanine dyes undergo photochemical cis-trans isomerization at the central methine chain.[50,54–58] This photoisomerization process is one of the important nonradiative decay channels in cyanine dyes. The suppression of this process in the micellar media can explain the observed large fluorescence enhancement of cyanine dyes.

Formation of Dye-rich Induced Micelles in the Higher Premicellar Region. It is to be noticed that this fluorescence enhancement effect was not limited to the region above the cmc. It was found even in the *higher* premicellar region (*i.e.*, [SDS]=*ca.* 4 mM-cmc). This is clearly due to the presence of the chemical entity which provides the dyes with a micelle-like environment.

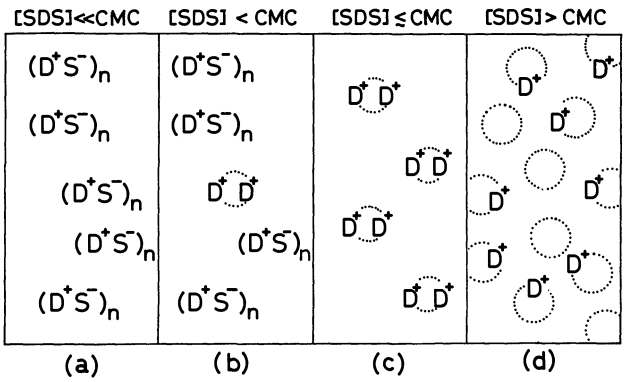

Fig. 9. A schematic model of the dye–detergent system with the opposite charge. See text for explanation.

In this [SDS] region the $(D^+ \cdot S^-)_n$-type 1 : 1 complex changes gradually with the [SDS] into the ordinary micelles above the cmc. The complex is successively diluted with SDS in this region. The presence of dye-rich induced micelles which incorporate a few dye molecules in the micelle-like aggregate in this [SDS] region has been proved by Mukerjee and Mysels for the pinacyanol–SDS system.[24] The energy-transfer efficiency between Rh-6G (donor) and DTC (acceptor) showed a maximum in this [SDS] region.[10] The fluorescence decay of the donor cannot be interpreted if the donor and acceptor are uniformly distributed in the solution, although [SDS] is *below* the cmc. Donor and acceptor molecules must be locally concentrated in dye-rich induced micelles.[11] The appearence of the maximum in the energy-transfer efficiency was found also in the Rh-6G–pinacyanol system,[12,14] for which the participation of dye-rich induced micelles in the energy transfer process is proved by the comparison with the absorption spectra. The maximum of electron-transfer efficiency also appeared in the premicellar region.[13,18]

Nature of Dye–Detergent Interaction. A schematic model of the dye–detergent system with the opposite charge is given in Fig. 9. In the lower premicellar region ([SDS]≅1—4 mM, (a) in the figure) the dye–detergent aggregate (with an essentially 1 : 1 composition, stabilized and dispersed in the aqueous solution by the addition of a slight excess of SDS) is formed. This aggregate is depicted as $(D^+S^-)_n$ in the figure for simplicity. This aggregate is successively diluted with SDS and changes into the dye-rich induced micelles in the higher premicellar region ([SDS]≅4 mM-cmc, (b) and (c) in the figure). The dye-rich induced micelles change into ordinary micelles above the cmc through further dilution with SDS ((d) in the figure).

Someone may argue that the presence of dye-rich induced micelles *below* the cmc is contradictory statement, and that the cmc itself must be lowered. However, the cmc is usually determined by the break of some *macroscopic* physical quantity like electrical conductivity. The addition of dye molecules to the SDS solution causes only a slight shift (*e.g.* by 0.1—0.4 mM) to the lower SDS region, as shown for Rh-6G–DTC–SDS,[10] acridine orange–SDS[34] or Rh-6G–pinacyanol–SDS.[14] The spectroscopic evidences for the presence of dye-rich induced micelles, *i.e.*, the absorption and fluorescence bands appearing at the wavelengths indicating micellar environment and the enhancement of the energy-[10–12,14] or electron-[13] transfer efficiency, are observed for [SDS] much lower the cmc thus newly determined for the dye–SDS system.

The presence of premicellar aggregates has been reported also for some metal complex cation-anionic detergent systems.[13,17–19,59–61] Ozeki *et al.*[61] carried out the measurements of surface tension and light scattering experiments for the $[Fe(phen)_3](ClO_4)_2$–SDS system (phen=1,10-phenanthroline), and clarified that (1) the shift of the cmc is rather small (7.6 mM to 7 mM) even in the presence of $[Fe(phen)_3](ClO_4)_2$ (5.0×10^{-5} M), and that (2) there is a threshold detergent concentration (C_{pre}) at which the formation of the premicellar aggregate starts far below the cmc (0.35 mM by the surface tension measurement). They stated that the hydrophobic interaction plays a very important part in the formation and stabilization of the premicellar aggregate. A similar mechanism of formation and stabilization by hydrophobic interaction must be present in our premicellar aggregates, *i.e.*, the essentially 1 : 1 complexes dispersed and stabilized in the aqueous solution by the addition of slight excess of SDS molecules which appeared in the lower premicellar region, and dye-rich induced micelles which appeared in the higher premicellar region.

The present authors are grateful to Dr. Yoshihumi Kusumoto of Kagoshima University for his cooperation in the earlier stage of this work. They are also grateful to Mr. Nobukazu Hata for his assistance in the quantum yield measurements. They are also grateful to Professor Shoichi Ikeda of Nagoya University for helpful discussions. This work is supported partly by the Joint Studies Program (1980—81) of the Institute for Molecular Science, and by the Grant-in-Aid No. 447006 from the Ministry of Education, Science and Culture.

Transient Intermediate Produced from 5-Aminouracil in Reaction with Dichloride Anion Radical

Takahiro MASUDA,* Ryoji GUNJI, Takako KIMURA, and Kotaro YAMAUCHI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158

(Received June 16, 1983)

A transient absorption, which is relatively long-lived, was found in a flash photolysis of aqueous potassium chloride containing 5-aminouracil. The transient absorption with a peak at about 335 nm was assigned to an intermediate produced from 5-aminouracil through a one-electron oxidation by dichloride anion radical. For the intermedicate, a possible structure is proposed to explain its long life-time. On the basis of the transient absorption, a determination of the rate constant for the reaction of 5-aminouracil with dichloride anion radical was carried out by use of a competition kinetics. The value of $(2.9\pm0.2)\times10^8$ dm^3 mol^{-1} s^{-1} was obtained as the rate constant on the basis of rate constants of several reference compounds. By comparing the values obtained by the competition method with those estimated by a direct analysis of the decay rate of dichloride anion radical, the validity of the competition method was examined.

In the course of our study on reactions of dichloride anion radical with pyrimidine derivatives,[1] a relatively long-lived transient absorption with a peak at about 335 nm was found in a flash photolysis of aqueous solutions of potassium chloride containing 5-aminouracil. It overlaps a transient absorption due to dichloride anion radical and obstracts the determination of the rate constant for the reaction of 5-aminouracil with dichloride anion radical by anaysis of the decay rate of the anion radical (a direct method).

Intermediate products of pyrimidine bases produced through reaction with dichloride anion radical have been suggested as π-cation radicals by ESR studies.[2,3] Absorption spectra of intermediate species formed from pyrimidine bases through reaction with oxidizing radical such as $SO_4^{-\cdot}$ or $Cl_2^{-\cdot}$ have been reported to have absorption maxima at 410 and 560 nm for uracil, 400 and 500 nm for thymine, and 410 nm for isoorotic acid.[2] However, no transient absorptions were observed in the time-scale of flash photolysis. It implies a fast decay of transient species responsible for the absorptions. A half-life of the transient intermediate formed from 5-aminouracil was estimated to be *ca.* 800 μs, which is considerably long compared with those for transient species from other bases and for dichloride anion radical.

In the present study, an assignment of transient absorptions was attempted by comparison of transient spectra observed under various conditions where different kinds of intermediate species are allowed to form. Furthermore, a competition method using a transient absorption at 330 nm was applied to the determination of the rate constant of 5-aminouracil with dichloride anion radical. With several referance compounds, the method was confirmed to give a reasonable value for the rate constant of 5-aminouracil with dichloride anion radical. The validity for wide application of the method was examined and discussed in terms of the reactivity of products produced from substrates and of a possible interaction between a substrate and 5-aminouracil in aqueous solutions.

Experimental

5-Aminouracil (abbreviated to 5AU) and other pyrimidine bases were obtained from Sigma Chemical Co. and peptides from Nutritional Biochemical Corp. as preparations of high purity. They were used without further purification. Potassium chloride and other chemicals were of reagent grade.

Solutions for irradiation were prepared with triply distilled water and adjusted to pH 7. The solutions were bubbled with dinitrogen monoxide, sulfur hexafluoride, or nitrogen for 20 min immediately before flash photolysis. A conventional type of apparatus was used for flash photolysis with 10 μs of 1/e duration and 200 J of input energy. Details were described in a previous paper.[4] Transient spectra were measured by a kinetic spectrophotometry. Calculation for kinetic analysis was carried out with the aid of microcomputers PC 8001 and 8801 (Nippon Electric Co.).

Results and Discussion

Transient Absorption Spectra. Transient absorption spectra of flash photolyzed aqueous solutions of 5-aminouracil were measured under several conditions (Fig. 1(a)). For the N_2O-saturated neutral solution of potassium chloride containing 5-aminouracil, absorption peaks at about 335 and 390 nm were observed at 150 μs after start of flash, while a peak at 335 nm was observed for the SF_6-saturated solution. For the acid solution (pH 3.15), a maximum was seen at 335 nm. The peak at 335 nm was also observed in the absence of potassium chloride. This suggests that the direct photoionization takes place to yield a similar intermediate.

In the N_2O-saturated neutral solution of potassium chloride containing a sufficient amount of 5-aminouracil, the following reactions are expected to proceed in flash photolysis:

$$Cl^- + h\nu \longrightarrow Cl\cdot + e^-, \quad (1)$$

$$Cl\cdot + Cl^- \longrightarrow Cl_2^{-\cdot}, \quad (2)$$

$$e^- + aq \longrightarrow e_{aq}^-, \quad (3)$$

$$e_{aq}^- + N_2O \longrightarrow N_2 + HO\cdot + OH^-, \quad (4)$$

$$HO\cdot + Cl^- \longrightarrow ClOH^{-\cdot}, \quad (5)$$

$$HO\cdot + 5AU \longrightarrow 5AUOH\cdot, \quad (6)$$

$$ClOH^{-\cdot} + 5AU \longrightarrow 5AUOH\cdot + Cl^-, \quad (7)$$

$$Cl_2^{-\cdot} + 5AU \longrightarrow 5AU^{+\cdot} + 2Cl^-. \quad (8)$$

In flash photolysis of the N_2O-saturated neutral solution of 5-aminouracil, Reaction 9, a direct photoionization, will occur, followed by Reactions 3, 4, and

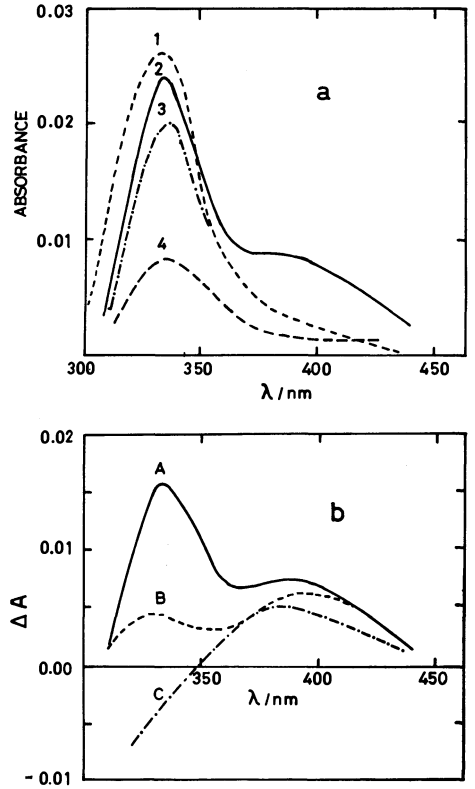

Fig. 1. Absorption spectra of the intermediates produced from 5-aminouracil in flash photolysis.
(a) Transient spectra measured at 150 μs after start of flash. $[5AU]=5\times10^{-5}$ mol dm^{-3}. 1: 1 mol dm^{-3} KCl, N_2O saturated, pH 3.15. 2: 1 mol dm^{-3} KCl, N_2O saturated, neutral pH. 3: 1 mol dm^{-3} KCl, SF_6 saturated, neutral pH. 4: N_2O saturated, neutral pH.
(b) Difference spectra. A: 2-4. B: 2-3. C: 2-1.

6; then the formation of a cation radical ($5AU^{+}\cdot$) and an OH-adduct (5AUOH·) is expected:

$$5AU + h\nu \longrightarrow 5AU^{+\cdot} + e^{-}. \quad (9)$$

When an acid solution of potassium chloride containing 5-aminouracil is photolyzed with N_2O-saturation, Reactions 10 and 11 will be added to Reactions 1—5 and 8:

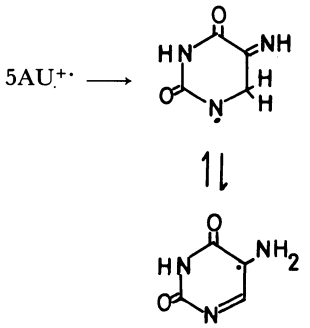
$$e^{-}_{aq} + H^{+} \longrightarrow H\cdot, \quad (10)$$

$$ClOH^{-\cdot} + H^{+} \longrightarrow Cl\cdot + H_2O. \quad (11)$$

Although an addition reaction of a hydrogen atom to 5-aminouracil can be expected in acid solutions, data on rate constants and concentrations indicate that Reaction 4 overwhelms Reaction 10, since the rate constants for Reactions 4 and 10 are reported to be 8×10^{9} [5] and $(2.2\text{—}2.4)\times10^{10}$ dm^3 mol^{-1} s^{-1},[6] respectively, and the concentrations of N_2O and H^+ are 2.5×10^{-2} and 7×10^{-4} mol dm^{-3}, respectively. Therefore, $5AU^{+\cdot}$ is considered as the main intermediate product formed from 5-aminouracil in the acid solution. In the SF_6-saturated solution of potassium chloride containing 5-aminouracil, Reaction 12 may occur in addition to Reactions 1—3 and 8:

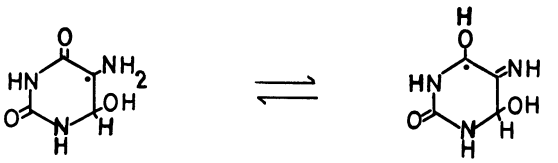
$$e^{-}_{aq} + SF_6 \longrightarrow SF_5\cdot + F^{-}. \quad (12)$$

The difference spectra shown in Fig. 1(b) can be well understood by combination of the above reactions. The absorption peaks at 335 and 390 nm are attributable to $5AU^{+\cdot}$ and 5AUOH·, respectively. Danziger *et al.*[7] reported that the OH-adduct of uracil shows an absorption maximum at 390 nm. Similarly Mayers *et al.*[8] indicated that the OH-adducts of uracil and thymine have absorption spectra with a maximum at 375 nm and that the second-order decay constants of the OH-adducts are 2.1×10^{9} dm^3 mol^{-1} s^{-1} for uracil and 2.2×10^{9} dm^3 mol^{-1} s^{-1} for thymine. The half-life was also estimated by the authors to be *ca.* 100 μs for 5×10^{-6} mol dm^{-3} of initial concentration. For the OH-adduct of 5-aminouracil studied in the present work, however, about 600 μs of half-life was obtained at the initial concentration of 3.5×10^{-6} mol dm^{-3}. Apparently the OH-adduct of 5-aminouracil is more stable than those of other bases. Bansal and Fessenden[2] and Sevilla *et al.*[3] have proposed structure of π-cation radicals produced from pyrimidine bases through reaction with oxidizing radicals on the basis of ESR studies. The structures correspond to neutral radicals with a high electron density at C-5, which are produced from cation radicals after deprotonation respectively. For the intermediate species of 5-aminouracil responsible for the absorption at 335 nm, therefore, deprotonated forms of the cation radical ($5AU^{+\cdot}$) can be considered. The possible structure is as follows:



(13)

The N-radical will be an explanation for the long life-time. An analogous argument with the OH-adduct leads to the following structure:



(14)

Competition Kinetics. Assuming a competition between Reactions 8 and 15, Eq. I can be derived:

$$Cl_2^{-\cdot} + S \longrightarrow 2Cl^{-} + \text{product(s)} \quad k_s, \quad (15)$$

$$\frac{A_0}{A} = 1 + \frac{k_s[S]_0}{k_8[5AU]_0}, \quad (I)$$

where A_0 and A represent the absorbances at 330 nm in the absence and presence of substrate, respectively, and $[S]_0$ and $[5AU]_0$ designate the initial concentrations of the substrate and 5-aminouracil, respectively. By plotting A_0/A against $[S]_0/[5AU]_0$, k_s/k_8 is obtained from the slope of a straight line. Equation I is valid when the dichloride anion radical converts to the intermediate

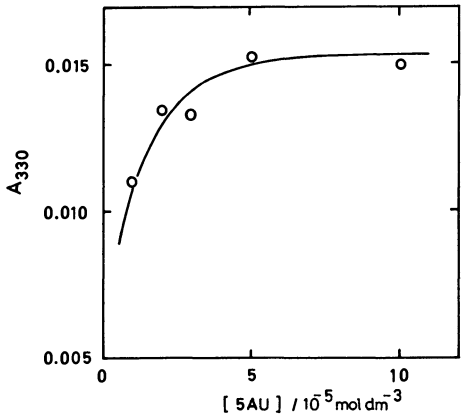


Fig. 2. Dependence of the absorbance at 330 nm of the intermediate of 5-aminouracil upon the concentration of 5-aminouracil.

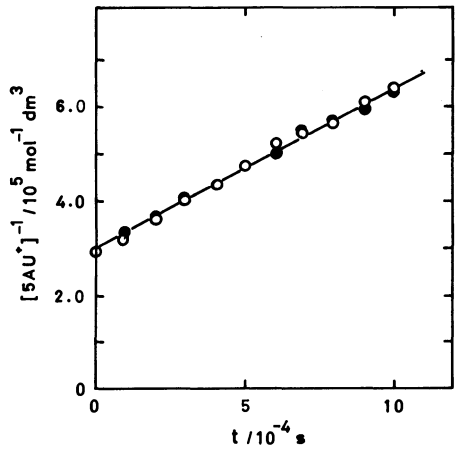

Fig. 3. Second-order decay of the intermediate of 5-aminouracil. ○: 5×10^{-5} mol dm^{-3} 5-aminouracil. ●: 10^{-4} mol dm^{-3} 5-aminouracil.

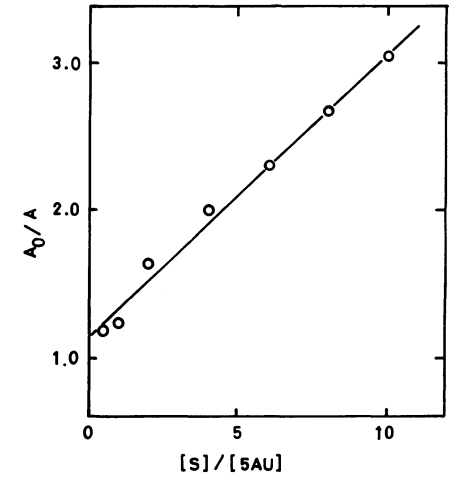

Fig. 4. Competition between 5-aminouracil and glycylnorvaline against the dichloride anion radicals.

of 5-aminouracil completely. The dependence of the absorbance at 330 nm on the concentration of 5-aminouracil (Fig. 2) and the decay rate of the intermediate of 5-aminouracil (Fig. 3) seem to confirm this condition. The absorbance at 330 nm was observed to reach the upper limit at *ca.* 5×10^{-5} mol dm^{-3}, as shown in Fig. 2. For 5×10^{-5} and 10^{-4} mol dm^{-3} solutions of 5-aminouracil, an identical decay rate of the intermediate was found (Fig. 3). The decay process obeys a second-order kinetics and the value of 5.8×10^{4} was obtained as $2k/\varepsilon$. The absorption coefficient of the intermediate of 5-aminouracil is estimated to be 6200 dm^3 mol^{-1} cm^{-1}, on the assumption that a complete conversion of dichloride anion radical to the intermediate at 10 μs after start of flash. Consequently the value of 3.6×10^{8} dm^3 mol^{-1} s^{-1} was obtained as $2k$. The result obtained by plotting A_0/A *vs.* $[S]_0/[5AU]_0$ supports the reliability of Eq. I. Figure 4 shows an example of competition plot obtained for glycylnorvaline.

Table 1. Rate constants for the reaction of dichloride anion radical with 5-aminouracil estimated by the competition method

Reference compound	Slope	k_8 / 10^8 dm^3 mol^{-1} s^{-1}
Cytosine	1.09	3.21
Thymine	1.06	3.02
Glycyl-α-amino-*n*-butyric acid	0.114	2.63
Glycylnorvaline	0.182	2.80
Glycylvaline	0.150	2.73
Glycylleucine	0.170	3.18
	Average	2.93 ±0.24

The rate constant of 5-aminouracil with dichloride anion radical can be estimated by using some reference compounds whose rate constants have been determined by the direct method.[1,9] The direct determination of rate constant for reaction with dichloride anion radical is based on analysis of the decay rate of dichloride anion radical.[1] Equation II is derived from Reactions 1, 2, 15, and 16:

$$Cl_2^{-\cdot} + Cl_2^{-\cdot} \longrightarrow Cl_2 + 2Cl^-, \quad (16)$$

$$\ln\frac{[Cl_2^{-\cdot}]_0(2k[Cl_2^{-\cdot}]+k_{ob})}{[Cl_2^{-\cdot}](2k[Cl_2^{-\cdot}]_0+k_{ob})} - k_{ob}t = 0, \quad (II)$$

where k_{ob} is equal to $k_s[S]$; $[Cl_2^{-\cdot}\ t]_0$ and $[Cl_2^{-\cdot}]$ are the concentrations of dichloride anion radical at time zero and t, respectively. $2k$ is the rate constant for Reaction 16. The concentration of the anion radical at time zero was assumed to be equal to the value obtained by applying an extrapolation of $1/[Cl_2^{-\cdot}]$ and t. Values of k_{ob} at given times were estimated by Eq. II. From the values estimated at every 10 μs from 50 to 100 μs after start of flash, an average value of k_{ob} was calculated for a given concentration of substrate. The average values of k_{ob} were plotted against the concentration of substrate and k_s was obtained from the slope. The result is summarized in Table 1. With six reference compounds, the value of $(2.9\pm0.2)\times10^{8}$ dm^3 mol^{-1} s^{-1} was obtained as k_8. The value shows a close agreement with the value of $(3.1\pm0.5)\times10^{8}$ dm^3 mol^{-1} s^{-1}, reported in a previous paper,[1] as estimated from data with cytosine, thymine, glycylleucine, and

Table 2. Comparison of rate constants estimated by the competition method with those determined by other methods

formate.

The rate constant for a given substrate with dichloride anion radical can be estimated by the competition method making use of k_8 as the reference. Results are shown in Table 2. Agreement of the values with those obtained by the direct method seems to be fairly good with some exceptions. The values reported by other authors are in general smaller than the present values. The values cited in the fourth column of Table 2 were determined by a pseudo-first-order kinetics with pulse radiolysis. Despite the low doses applied, neglect of Reaction 16 may cause an incorrect estimation, especially for relatively low concentrations of substrate. Furthermore, the analysis of the decay rate of dichloride anion radical would be disturbed by a new absorption due to an intermediate species from the substrate, if the absorption appears in the same region of wavelength with dichloride anion radical, because the time-scale of pulse radiolysis is much shorter than that of flash photolysis.

For formate ion, the value determined by the competition method differs from that by the direct method, but is in fairly good agreement with the value determined by pulse radiolysis. The reaction of dichloride anion radical with formate ion produces a carbon dioxide anion radical ($CO_2^{-\cdot}$):

$$Cl_2^{-\cdot} + HCOO^- \longrightarrow 2Cl^- + H^+ + CO_2^{-\cdot}. \quad (17)$$

$CO_2^{-\cdot}$ will react with dichloride anion radical to form carbon dioxide:

$$Cl_2^{-\cdot} + CO_2^{-\cdot} \longrightarrow 2Cl^- + CO_2. \quad (18)$$

Therefore, the reaction of formate ion with dichloride anion radical is complicated and the direct method is not appropriate to the substrate.

For uracil and 6-aminouracil, significant differences were observed between the values obtained by the competition and direct methods. An electron transfer from 5-aminouracil to a substrate cation (S^+) will be an explanation for the discrepancy. The electron transfer causes a decrease in reactivity of the substrate in appearance, when the competition kinetics is applied. However, a simulation by a computer indicated that the mechanism gives no linear correlation between A_0/A and $[S]_0/[5AU]_0$. Another explanation is the formation of a complex of 5-aminouracil with the substrate:

$$5AU + S \overset{K}{\rightleftharpoons} 5AU{\cdot}S, \quad (19)$$

$$5AU{\cdot}S + Cl_2^{-\cdot} \longrightarrow 5AU^{+\cdot} + S + 2Cl^- \quad k_c. \quad (20)$$

Assuming that the complex reacts with dichloride anion radical to give $5AU^{+\cdot}$ the following relation is derived:

$$A_0/A = 1 + \frac{k_8[S]}{k_8[5AU] + k_c[5AU{\cdot}S]}, \quad (III)$$

where [S], [5AU], and [5AU·S] designate the concentrations of a substrate, 5-aminouracil, and the complex at equilibrium, respectively; k_c is the rate constant for Reaction 20. When 5-aminouracil is converted to the complex completely, Eq. III is transformed to

$$A_0/A = 1 + \frac{k_s[S]}{k_c[5AU{\cdot}S]}, \quad (IV)$$

where [5AU·S] is equal to $[5AU]_0$ and [S] is the difference between $[S]_0$ and $[5AU]_0$, hence

$$A_0/A = \left(1 - \frac{k_s}{k_c}\right) + \frac{k_s[S]_0}{k_c[5AU]_0}. \quad (V)$$

When the ratio of the initial concentrations, $[S]_0/[5AU]_0$, is sufficiently large, the slope of the straight line obtained by plotting A_0/A *vs.* $[S]_0/[5AU]_0$ provides the value of k_c. For 6-aminouracil and uracil, 5.2×10^9 and 5.8×10^8 dm³ mol⁻¹ s⁻¹ were obtained as k_c, respectively. Using the equilibrium constant, K, as a parameter and the value of k_c, a simulation of Eq. III was carried out and 1.5×10^4 of K was found to give the best fitted curve in the case of 6-aminouracil, as shown in Fig. 5. For uracil, the best fitted curve was obtained for 10^4 of K. Although there is no confirmation for the formation of the complex, the resemblance of their structures suggests a possible interaction between them.

For the dicarboxylic acids, the agreement is fairly good between the two methods. Since the values of

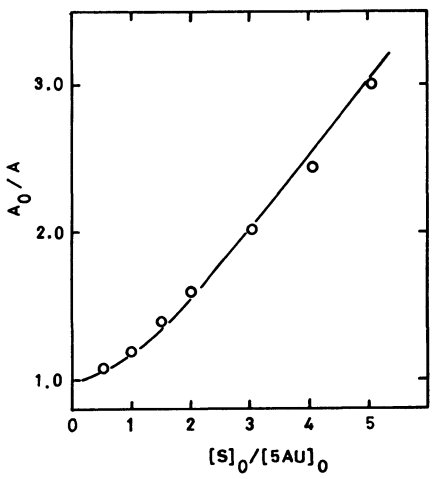

Fig. 5. Simulation of A_0/A *vs.* $[S]_0/[5AU]_0$ based on the mechanism of complex formation.
Substrate: 6-aminouracil.

1.4×10^6 and 2.5×10^6 $dm^3\ mol^{-1}\ s^{-1}$ were obtained as the rate constants for acetate and propionate,[11] the value for succinate seems reliable. In a previous study,[1] the partial rate constant for the 5, 6 double bond of uracil for the reaction with dichloride anion radical was estimated to be 2.2×10^8 $dm^3\ mol^{-1}\ s^{-1}$. For a compound containing a double bond, therefore, a value of the order of 10^8 can be expected as the rate constant of reaction with dichloride anion radical if the compound has no other reactive group than the double bond or no repressive one. The observed rate constants for the unsaturated carboxylic acids appear to be consistent with this argument. Maleate was found to be less reactive than fumarate toward dichloride anion radical. This implies that a stabilization due to the interaction between two carboxyl groups in the *cis*-form may cause a decrease in the reactivity of one electron oxidation.

The present work was supported by a Grant-in-Aid for Scientific Research No. 56580144 from the Ministry of Education, Science and Culture.

Thermodynamic Study for Dibenzo-24-crown-8 Complexes with Alkali Metal Ions in Nonaqueous Solvents

Yasuyuki TAKEDA
Department of Chemistry, Faculty of Science, Chiba University, Yayoi-chō, Chiba 260
(Received June 25, 1983)

Complex-formation constants (K_{ML^+}) of dibenzo-24-crown-8 (DB24C8) with alkali metal ions in acetonitrile and the solubility of DB24C8 in methanol, acetonitrile, and propylene carbonate were determined conductometrically and spectrophotometrically at 25 °C, respectively. The K_{ML^+} value sequences of the alkali metal ions with DB24C8 are $Na^+ > Cs^+ > K^+ = Rb^+$. Dibenzo-24-crown-8 shows no remarkable selectivity for the alkali metal ions in acetonitrile. Transfer activity coefficients of the DB24C8 complexes with alkali metal ions were calculated from these data and literature values of transfer activity coefficients of alkali metal ions. For the same alkali metal ion, the bulky DB24C8–alkali metal ion complex is more soluble in the aprotic solvents acetonitrile and propylene carbonate than in the protic solvent methanol as compared with the case of the alkali metal ion itself. The transfer activity coefficient of the DB24C8–alkali metal ion complex from methanol to acetonitrile is somewhat sensitive to the variation of the alkali metal ion in the DB24C8 cavity, whereas the mobility of the DB24C8–alkali metal ion complex at the same concentration in the solvents is not sensitive.

Selectivity and complexing ability of dibenzo-24-crown-8 (DB24C8) for metal ions, which were studied by means of solvent extraction[1] and conductometry,[2,3] were reported in the previous papers. For both conductance and solvent extraction systems, DB24C8 shows no peak selectivity for any alkali metal ion. However, DB24C8 reveals the pronounced extraction-selectivity for Ba^{2+} among all the alkali and alkaline earth metal ions. Behavior of the DB24C8–alkali metal ion complexes in methanol and propylene carbonate was conductometrically investigated.[2,3] In each case of methanol and propylene carbonate, mobilities of the complexes at the same concentration are nearly equal to each other. Furthermore, DB24C8 was used for separation of Ba^{2+} from Sr^{2+} by means of solvent extraction.[4]

In the present work, complex-formation constants of DB24C8 with alkali metal ions in acetonitrile and the solubility of DB24C8 in methanol, acetonitrile, and propylene carbonate were conductometrically and spectrophotometrically determined at 25 °C, respectively. Transfer activity coefficients of the DB24C8 complexes with alkali metal ions were calculated from these data and literature values of transfer activity coefficients of alkali metal ions. The behavior of the DB24C8 complexes with alkali metal ions in solutions was discussed in terms of the transfer activity coefficients and the mobility of the complexes.

Experimental

Materials. Dibenzo-24-crown-8 (Nisso Co., Ltd.) was dissolved in hexane, and filtered while hot. Then it was recrystallized three times from hexane and, prior to use, dried at 50 °C in a vacuum oven. Sodium and potassium perchlorates were purchased commercially. The method of preparing rubidium and caesium perchlorates, as well as that of purifying alkali metal perchlorates was previously described.[2] The method of purification of methanol,[2] acetonitrile,[5] and propylene carbonate[2] was as has previously been reported. For these solvents, the middle 70% of the distillate was used. The water contents of the purified acetonitrile and propylene carbonate determined by means of the Karl Fischer titration were less than 0.01%, and, for methanol, less than 0.03%. The conductivity of the final product of acetonitrile was less than $1.5\times10^{-7}\ \Omega^{-1}\ cm^{-1}$.

Apparatus and Procedure. The conductance measurements were made on a Fuso conductivity apparatus, model 362A, in a water bath thermostated at 25±0.005 °C. Two cells were used with cell constants of 0.05970_5 and 0.09393_4 cm^{-1}. The experimental procedure to obtain formation constants of DB24C8 complexes with alkali metal ions in acetonitrile was the same as those described in the previous paper.[2]

Dibenzo-24-crown-8 solubilities in methanol (225 nm), acetonitrile (275 nm), and propylene carbonate (275 nm) were determined spectrophotometrically at 25±0.02 °C. They are 6.5×10^{-3} M (1 M=1 mol dm^{-3}) in methanol, 1.0×10^{-1} M in acetonitrile, and 4.5×10^{-2} M in propylene carbonate.

Results and Discussion

From Fig. 1, the molar conductivity, Λ, *vs.* $[L]_t/[M]_t$ plots for each alkali metal system, where $[L]_t$ and $[M]_t$ denote the total concentrations of DB24C8 and an alkali metal ion respectively, show a monotonous decrease in Λ with an increase in the DB24C8 concentration. This indicates that the DB24C8 forms a complex with each alkali metal ion and the complexed cation is much less mobile than the corresponding alkali metal ion in

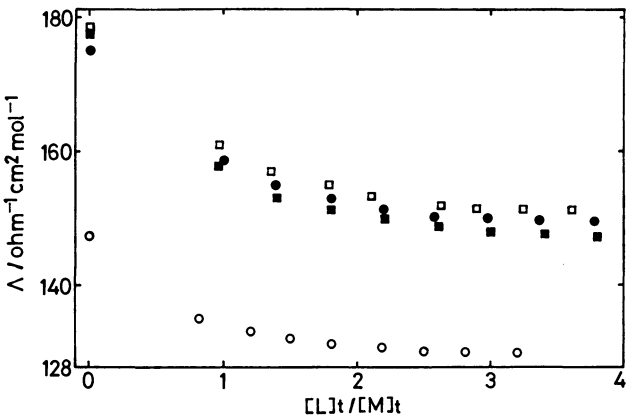

Fig. 1. Λ *vs.* $[L]_t/[M]_t$ curves for DB24C8–alkali metal perchlorate systems in acetonitrile at 25 °C.
○: Na^+, ●: K^+, □: Rb^+, ■: Cs^+, $[M]_t=5\times10^{-4}$ M.

acetonitrile.

It is assumed that the association between the cation and the perchlorate ion in acetonitrile is negligible under these highly dilute experimental conditions ($[M]_t=5\times10^{-4}$ M) and that the DB24C8 forms the 1 : 1 complexes with the alkali metal ions in acetonitrile. The equilibrium equation is written as

$$\begin{array}{ccccc} M^+ & + & L & \rightleftharpoons & ML^+ \\ \alpha[M]_t & & [L]_t-(1-\alpha)[M]_t & & (1-\alpha)[M]_t, \end{array} \quad (1)$$

where M^+, L, and α are the alkali metal ion, crown ether, and the fraction of free alkali metal ions. Thus, the complex-formation constant, K_{ML^+}, is defined by

$$\begin{aligned} K_{ML^+} &= [ML^+]/[M^+][L] \\ &= (1-\alpha)/\alpha[L]. \end{aligned} \quad (2)$$

The observed conductivity, κ, is given by

$$\kappa = \kappa_{MClO_4} + \kappa_{MLClO_4}, \quad (3)$$

where κ_{MClO_4} and κ_{MLClO_4} represent the conductivities of alkali metal perchlorate and alkali metal DB24C8 perchlorate, respectively. The molar conductivities are as follows

$$\begin{aligned} \Lambda_{MClO_4} &= \kappa_{MClO_4}/[M^+] \\ &= \kappa_{MClO_4}/\alpha[M]_t, \end{aligned} \quad (4)$$

$$\begin{aligned} \Lambda_{MLClO_4} &= \kappa_{MLClO_4}/[ML^+] \\ &= \kappa_{MLClO_4}/(1-\alpha)[M]_t, \end{aligned} \quad (5)$$

Λ_{MClO_4} and Λ_{MLClO_4} being the molar conductivities of alkali metal perchlorate and alkali metal DB24C8 perchlorate respectively. As a consequence of Eqs. 4 and 5, Eq. 3 can be transformed into

$$\begin{aligned} \Lambda &= \kappa/[M]_t \\ &= \alpha\Lambda_{MClO_4} + (1-\alpha)\Lambda_{MLClO_4}. \end{aligned} \quad (6)$$

Since the DB24C8 concentration was kept low during these experiments, corrections for viscosity changes were neglected. As a consequence of Eq. 6, Eq. 2 can be transformed into

$$K_{ML^+} = (\Lambda_{MClO_4}-\Lambda)/(\Lambda-\Lambda_{MLClO_4})[L], \quad (7)$$

where $[L]=[L]_t-[M]_t(\Lambda_{MClO_4}-\Lambda)/(\Lambda_{MClO_4}-\Lambda_{MLClO_4})$. The K_{ML^+} value can be obtained by the following procedure. The Λ_{MLClO_4} value is estimated from the Λ values at the points of large $[L]_t$ to $[M]_t$ ratios. Using this Λ_{MLClO_4} value, the K_{ML^+} value in Eq. 7 is calculated. The actual K_{ML^+} and Λ_{MLClO_4} values are calculated by a succesive approximation method. The $\log K_{ML^+}$ values are listed in Table 1.

Table 1. $\log(K_{ML^+}/\text{mol}^{-1}\,\text{dm}^3)$ values of DB24C8 with alkali metal ions at 25 °C

	Na^+	K^+	Rb^+	Cs^+
Acetonitrile	4.1	3.8	3.8	4.0
Propylene carbonate[3]	4.1_6	3.7_3	3.5_5	3.4_6
Methanol[2]	—	3.5_7	3.8_6	3.8_4

Dibenzo-24-crown-8 shows no remarkable selectivity for the alkali metal ions in acetonitrile. For both acetonitrile and propylene carbonate, although Na^+ is most strongly solvated and its size is the least favorable to the DB24C8 cavity of all the alkali metal ions (Na^+, K^+, Rb^+, and Cs^+), DB24C8 forms the most stable complex with Na^+. The differences in the free energies of the solvation of Na^+ and K^+, Na^+ and Rb^+, and Na^+ and Cs^+ are much smaller for acetonitrile and propylene carbonate than for the solvents such as water, methanol, DMF, and DMSO.[6] The solvation power of propylene carbonate and acetonitrile for Na^+ is the smallest of all these solvents.[6] Judging from the large size and the flexibility of DB24C8, Na^+ seems to have a suitable size for the favorable arrangement of the ether oxygen atoms for the metal ion trapped in the cavity. This may be the reason why the DB24C8 complex with Na^+ is the most stable in both acetonitrile and propylene carbonate.

Table 1 shows that stability of the DB24C8 complex with the same alkali metal ion slightly varies with the solvent. In general, only for aprotic solvents (acetonitrile (DN=14.1[7]) and propylene carbonate (DN=15.1[7])), a reverse correlation exists between the stabilities of the DB24C8–alkali metal ion complexes and the donor number, DN, of the solvent.

Transfer Activity Coefficient. The transfer activity coefficient, $\log {}^{S_1}\gamma^{S_2}(ML^+)$, of the DB24C8–alkali metal ion complex between the solvent S_1 and the solvent S_2 is calculated by Eq. 8.

$$\begin{aligned} \log {}^{S_1}\gamma^{S_2}(ML^+) = (\log K_{ML^+})_{S_1} - (\log K_{ML^+})_{S_2} + \log {}^{S_1}\gamma^{S_2}(L) \\ + \log {}^{S_1}\gamma^{S_2}(M^+) \end{aligned} \quad (8)$$

These data are summarized in Table 2.

Dibenzo-24-crown-8 is much more soluble in the aprotic solvents acetonitrile and propylene carbonate than in the protic solvent methanol (Table 2). Both dibenzo-18-crown-6 (DB18C6) and dibenzo-30-crown-

	K^+	-1.9	-1.8_1	-1.3_3	-1.3_5	-1.1_6	-0.5_5
	Rb^+	-1.8	-1.7_2	—	-1.2_2	-1.0_1	—
	Cs^+	-2.5	-2.1_4	—	-1.4_8	-1.1_2	—

a) Acetonitrile. b) Propylene carbonate. c) Methanol.

10 (DB30C10) show the same tendency as DB24C8. From Table 2, for both DB24C8 and DB18C6, the log ${}^{MeOH}\gamma^{S}(L)$ value is larger than the log ${}^{MeOH}\gamma^{S}(ML^+)$ value, and contrary holds for DB30C10, where S=AN and PC. This cannot clearly be explained at the present stage. However, possible reasons may be the difference in the strength of hydrogen bonds between CH_3OH-uncomplexed crown ether and CH_3OH-complexed crown ether, and the difference in the conformation between an uncomplexed crown ether and a complexed crown ether.

As can be seen from Table 2, for the same alkali metal ion, the bulky ML^+ is more soluble in an aprotic solvent than in a protic solvent as compared with the case of M^+.

In the case of DB24C8, log ${}^{MeOH}\gamma^{PC}(ML^+)$ values of alkali metal ions are nearly equal to one another, whereas the log ${}^{MeOH}\gamma^{AN}(ML^+)$ value of Cs^+ is relatively smaller than the others, and the log ${}^{PC}\gamma^{AN}(ML^+)$ value varies with the alkali metal ion trapped in the DB24C8 cavity (Na^+: -0.9_3, K^+: -0.6_5, Rb^+: -0.7_1, Cs^+: -1.0_2). This indicates that, for the CH_3OH–propylene carbonate system, the charge of the alkali metal ion held in the DB24C8 cavity is effectively shielded, and that, for the CH_3OH–acetonitrile and propylene carbonate–acetonitrile systems, the charge is not effectively screened. The actual Λ_{MLClO_4} values of DB24C8–alkali metal perchlorate systems in acetonitrile at 25 °C obtained in this work are as follows.

	Na	K	Rb	Cs
$[MClO_4]_t \times 10^{-4}$/mol dm^{-3}	4.998	5.075	5.255	4.945
$\Lambda_{MLClO_4}/\Omega^{-1}$ cm^2 mol^{-1}	145.2	145.5	145.7	144.0

These data show that the alkali metal ion held in the DB24C8 cavity is effectively shielded by the DB24C8 from the solvent. The same tendency for DB24C8 complexes with alkali metal ions has been reported for methanol[2] and propylene carbonate.[3] It follows from the above discussion that the transfer activity coefficient of the DB24C8–alkali metal ion complex is somewhat sensitive to the variation of the alkali metal ion in the DB24C8 cavity, whereas the mobility of the DB24C8–alkali metal ion complex at the same concentration is not sensitive.

Spectrophotometric Determination of Ruthenium(III) and Rhodium(III) with 9,10-Phenanthrenequinone Monoxime after Extraction into Molten Naphthalene

Abdul WASEY, Raj K. BANSAL, Masatada, SATAKE,*,† and Bal K. PURI
Department of Chemistry, Indian Institute of Technology, Hauz Khas, New Delhi-110016, India
†*Faculty of Engineering, Fukui University, Fukui-910, Japan*
(Received January 13, 1983)

9,10-Phenanthrenequinone monoxime has been used as a reagent for the spectrophotometric determination of ruthenium(III) and rhodium(III) after extraction into molten naphthalene. The extracted mixture of the metal complex and naphthalene was dissolved in chloroform and ruthenium and rhodium were determined spectrophotometrically. Beer's law holds in the concentration range of 0.2—4.1 μg/cm³ for ruthenium and 0.3—5.3 μg/cm³ for rhodium in 10 cm³ of the final solution. The molar absorptivities and Sandell sensitivities are calculated to be 9.70×10^3 l mol^{-1} cm^{-1} and 0.01 μg/cm² (660 nm) for ruthenium and 1.13×10^4 l mol^{-1} cm^{-1} and 0.009 μg/cm² (410 nm) for rhodium respectively. Aliquots containing 2.0 μg of ruthenium and 4.1 μg of rhodium give mean absorbances of 0.192 and 0.451 with standard deviations of 0.0017 and 0.0039, respectively. Interference of various ions has been studied and the method has been applied to the determination of ruthenium and rhodium in various synthetic mixtures. This procedure is also applied to the simultaneous determination of ruthenium and rhodium present together in a solution.

9,10-Phenanthrenequinone monoxime has been suggested as a possible analytical reagent by Trikha and Kamil in the spectrophotometric[1-3] and gravimetric[4] determination of some metals. Since both these metals form complexes with the reagent at a high temperature, ordinary liquid-liquid extraction is not applicable. Liquid-liquid extraction no doubt is a convenient technique for the separation and determination of metal ions, but it fails in the extraction of those metal ions which form complexes with the complexing agents at a high temperature or the solubility of their complexes is low at room temperature. In such cases, the metal complex is first precipitated at a high temperature and then extracted into a suitable organic solvent after cooling to room temperature.[5] Thus the method becomes time consuming. Fujinaga and co-workers have developed a method of extraction, *i.e.* "solid-liquid separation after liquid-liquid extraction" in which all the above mentioned difficulties are overcome.[6] The advantages of this technique over the liquid-liquid extraction have already been stated in a previous communication.[7] In the present work this technique has been applied to the extraction of ruthenium and rhodium with 9,10-phenanthrenequinone monoxime into molten naphthalene and their subsequent determination by spectrophotometric method after dissolution of the solid naphthalene containing the metal complex in chloroform. Interference of various ions has been studied and this method has been applied to the determination of these metals in various synthetic mixtures. Conditions have also been developed for the simultaneous determination of these metals in synthetic mixture since these metal complexes absorb at two different wavelengths.

Experimental

Reagents. 9,10-Phenanthrenequinone monoxime (molecular weight: 223) was prepared and purified according to the method given in the literature,[3] and its 0.001 M solution (1 M=1 mol dm^{-3}) was prepared in ethanol. Solutions of ruthenium(III) chloride and rhodium(III) chloride were prepared from samples (1 g ampule) in 1 M hydrochloric acid and standardized gravimetrically.[7] Buffer solution of sodium acetate (0.2 M)–acetic acid (0.2 M) of pH 5.2 was used for pH adjustment. Naphthalene and chloroform were of analytical reagent grade and tested spectrophotometrically before use. To study the interference of various ions, 5000 μg/cm³ of anion and 100 μg/cm³ of metal ion solutions were prepared in redistilled water.

Equipment. An Elico pH meter and Sp-700/500 spectrophotometer were used for measurements.

General Procedure. To an aliquot of each of the metal solution taken separately was added 1.0 cm³ of the reagent and the pH was adjusted with 2.0 cm³ of buffer solutions (Fig. 2). These solutions were transferred to stoppered round-bottomed flasks and 2.0 g of naphthalene was added to each. Temperature was raised to about 85—90 °C to melt naphthalene and the mixture was stirred vigorously with a magnetic stirrer-hot plate arrangement for 35 min for both the metals (Fig. 3). Naphthalene containing the metal complex was separated by filtration. If was dried in the folds of a filter paper and then dissolved in 10 cm³ of chloroform. This solution was dried with anhydrous sodium sulfate (2.0 g) and the absorbance was measured in a 1-cm cell at 660 nm for ruthenium and 410 nm for rhodium against a reagent blank. The calibration curves were constructed under similar conditions.

Results and Discussion

Absorption Spectra. The absorption spectra of 9,10-phenanthrenequinone monoxime and its ruthenium and rhodium complexes were recorded in naphthalene–chloroform solution against weter and reagent blank, respectively (Fig. 1). It was observed that both the complexes have two absorption peaks, *i.e.* 520—535 nm and 660 nm for ruthenium and 400—410 nm and 470—480 nm for rhodium. The reagent absorbed only slightly at 410 nm, while it absorbed negligibly at the other wavelengths. The simultaneous determination of ruthenium and rhodium is possible because of a large difference of their λ_{max} (Fig. 1). All the measurements were made at 660 nm for ruthenium and at 410 nm for rhodium.

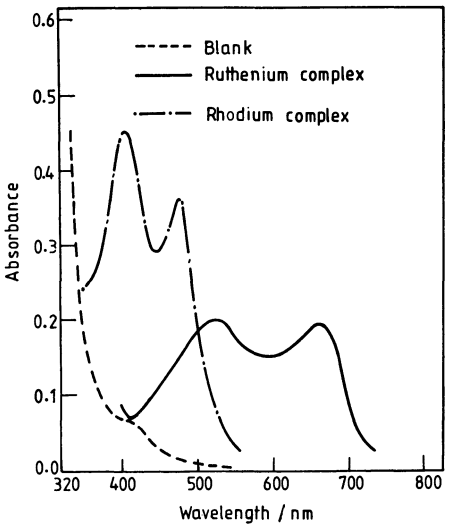

Fig. 1. Absorption spectra.
Reagent blank, 9-10 phenanthrenequinone monoxime (0.001 M): 1.0 cm³. Reference: water; Ru: 2.0 μg, pH: 5.2, Rh: 4.1 μg, pH: 5.2, reference: reagent blank. Naphthalene 2.0 g, chloroform: 10.0 cm³.

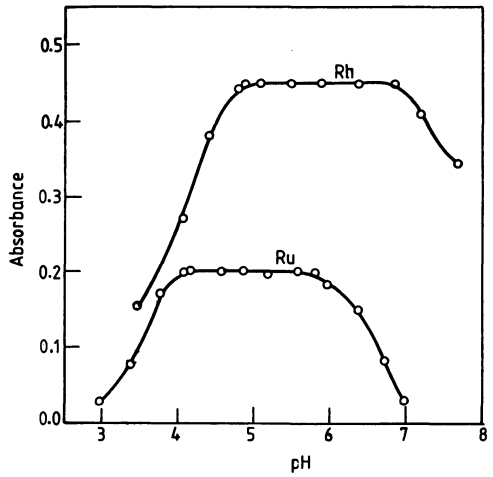

Fig. 2. Effect of pH.
Acetate concentration 1 M: 2.0 cm³. Ru: 2.0 μg, wavelength: 660 nm, Rh: 4.1 μg, wavelength: 410 nm, 9,10-phenanthrenequinone monoxime (0.001 M): 1.0 cm³, naphthalene: 2.0 g, chloroform: 10.0 cm³. Stirring time: 35 min, reference: reagent blank.

Effect of pH. Extraction behaviours of these metal-9,10-phenanthrenequinone monoximates were studied over a wide range of pH. Ruthenium was quantitatively extracted over the pH range of 4.1—5.8 and rhodium between 4.9—6.8. Extraction was incomplete beyond these pH ranges (Fig. 2).

Effect of Buffer Concentration. Extraction was carried out by varying the volume of 0.2 M sodium acetate–0.2 M acetic acid buffer (pH 5.2). It was observed that it has no effect on absorbance when the volume was varied between 1.0—5.0 cm³ per 30 cm³ of aqueous solution. Thus 2.0 cm³ of the buffer solution was used for subsequent studies.

Effect of Reagent Concentration. Extraction was carried out at optimum pH and at varying volumes of 0.001 M reagent solution. It was found to be quantitative in the volume range of 0.1—3.0 cm³ for ruthenium and 0.3—3.0 cm³ for rhodium. Thus 1.0 cm³ was used for further studies.

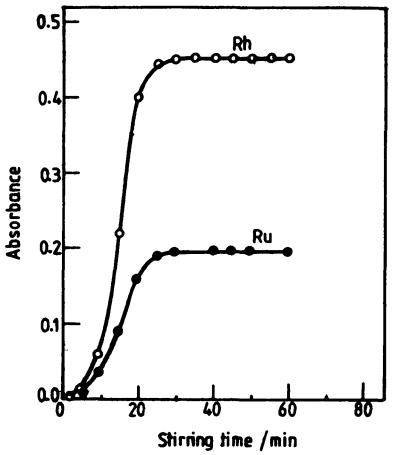

Fig. 3. Effect of stirring time.
Conditions were same as in Fig. 2.

Effect of Amount of Naphthalene. Extraction was carried out by varying the amounts of naphthalene from 0.2—4.0 g at optimum pH and keeping other parameters constant. With both metals the absorbance remained constant when the amount of naphthalene used was in the range of 1.3—3.5 g. The extraction was not complete with less than 1.3 g while above 3.5 g of naphthalene it was difficult to dissolve it in the limited quantity of chloroform (10 cm³). Thus 2.0 g of naphthalene was selected for further work.

Effect of Aqueous Phase Volume. Since the amount of naphthalene is small (2.0 g) as compared to that of the aqueous phase the effect of the volume of the latter on extraction was studied. Extraction was quantitative when the aqueous phase did not exceed 60 cm³.

Effect of Stirring Time. Since ruthenium and rhodium form complexes with reagent at a high temperature,[7] the effect of stirring time on extraction was examined. A mixture of naphthalene and the complex was stirred at different intervals of time with a magnetic stirrer-hot plate arrangement at 85—90 °C. It was found that the extraction was complete when the mixture was stirred for more than 30 min at this temperature in each case. (Fig. 3).

Effect of Standing Time. Absorbance of the extract in naphthalene–chloroform was constant for at least 24 h for ruthenium and 48 h for rhodium.

Effect of Electrolytes. Various electrolytes such as sodium chloride, sodium acetate, potassium chloride, and sodium nitrate (0.3—3.0 cm³ of 1.0 M) caused no improvement in extraction, indicating that the extraction was complete in the presence or in the absence of these electrolytes showing the absence of salting effect.

Composition of the Complex. The nature of ruthenium and rhodium-9,10-phenanthrenequinone monoximates in naphthalene–chloroform solution was studied by Job's method of continuous variation and mole-ratio method. This suggested that $[Ru^{II}(C_{14}H_8O_2N)_2]$ and $[Rh^{III}(C_{14}H_8O_2N)_3]$ complexes were

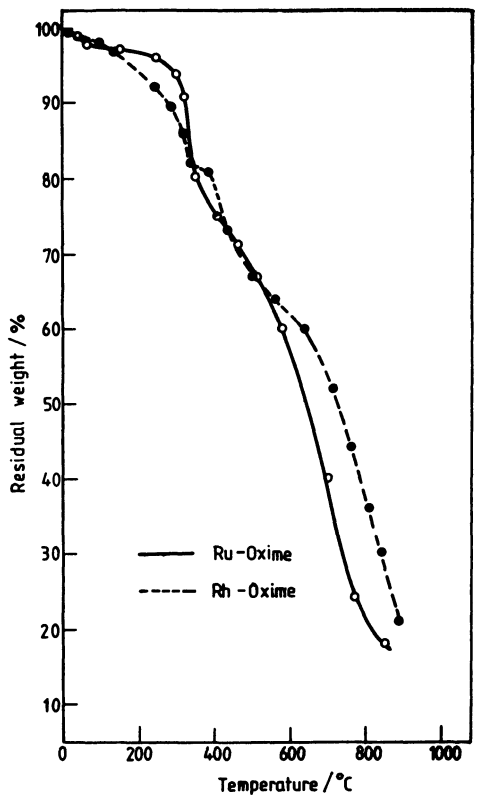

Fig. 4. Typical thermograms of the complexes. Complex (Ru or Rh): 5 mg; atmosphere: air: 20 cm³/min, heating rate: 10 °C/min.

extracted into molten naphthalene being the same as in liquid-liquid extraction.[8] It was reported by Trikha[8] that the elemental analysis of the complexes gave Ru: 18.5%, N : 5.10% corresponding to Ru : 18.54% N : 5.16% and Rh: 13.35%, N : 5.40% corresponding to Rh : 13.38%, N: 5.46 K, which also supports the above composition. Magnetic susceptibility of the isolated ruthenium and rhodium complexes have been determined by the Guoy procedure. It was found to be diamagnetic indicating it to be a spin paired square-planar ruthenium complex whereas the rhodium complex was found to be diamagnetic and thus a spin-paired octahedral complex. The infrared shows C=O and C=N stretching frequencies at 1600 and 1525 cm^{-1} in the free ligand. In the metal chelates these modes were observed at 1585 and 1520 cm^{-1} for ruthenium and 1580 and 1520 cm^{-1} for rhodium respectively. This further corroborates the composition stated above.

Thermal Stability of the Complex. The thermal stability of the complexes was determined by thermogravimetric analysis (TGA) by plotting the percentage residual weight against temperature (Fig. 4). The decomposition curve showed some plateaus which were indicative of constant weight representing stable phase over the particular temperature range (Experiment was performed on a Stanton Red-Croft TG-750 thermobalance in a air atmosphere at a heating rate of 10 °C/min). Successive plateaus probably correspond to the decomposition of water (100 °C), metal complex followed by the metal oxide. From the plot it was found that ruthenium and rhodium complexes indeed are thermally stable but the former decomposes at 270 °C while the latter at 360 °C.

Beer's Law and Sensitivity. Under the optimum conditions described above, calibration curves were constructed at 660 nm for ruthenium and 410 nm for rhodium. Beer's law was obeyed in the concentration range of 0.2—4.1 μg of ruthenium and 0.3—5.3 μg of rhodium in 10 cm³ of the chloroform solution. The

Table 5. Simultaneous determination of ruthenium and rhodium in synthetic mixture

Composition of the synthetic mixture (μg)	Ru and Rh taken (μg)	Ru and Rh found (μg)	Average (μg)	Error/%
Ru^{III}: 2.5, Rh^{III}: 5.0	Ru: 2.5	2.5, 2.5, 2.4, 2.5, 2.6	2.50	+0.0
Os^{VIII}: 30, Pd^{II}: 10, Au^{III}: 20, Pt^{IV}: 30.5	Rh: 5.0	5.0, 5.0, 5.0, 4.9, 5.0	4.98	+0.4

molar absorptivities and Sandell sensitivities were calculated to be 9.70×10^3 l mol^{-1} cm^{-1} and 0.01 μg/cm^2 for ruthenium and 1.13×10^4 l mol^{-1} cm^{-1} and 0.009 μg/cm^2 for rhodium. Solutions containing 2.0 μg of ruthenium and 4.1 μg of rhodium gave mean absorbances of 0.192 and 0.451 with standard deviations of 0.0017 and 0.0039 respectively.

Effect of Diverse Ions. Various ions were added individually to a solution containing 2.0 μg of ruthenium and 4.1 μg of rhodium and the general procedure was applied. Among the anions (Table 1), thiocyanate, citrate, tartrate, nitrite, oxalate, orthophosphate, and EDTA interfered with the determination of these metals but relatively low amounts could be tolerated. Of the meal ions (Table 3), interference of Fe^{III}, Co^{II}, Ni^{II} Cu^{II}, Pd^{II}, and Os^{VIII} has been eliminated by preextraction at room temperature in each case. For rhodium the interference of Ir^{III} was removed by masking with EDTA.

Determination of Ruthenium(III) and Rhodium(III) in Synthetic Mixtures. Synthetic mixtures were prepared containing both ruthenium and rhodium and aliquot of synthetic mixture was taken in a beaker, 1.0 cm^3 of ethanolic solution of the 9,10-phenanthrenequinone monoxime was added, the pH adjusted to 5.2 with acetate buffer solution and determined by the general procedure already described. The results are recorded in Tables 3 and 4.

On the basis of the absorption maximum of the complexes, these metals have been separated from each other (Fig. 1) and determined when present together. The results are summarized in Table 5.

The Stereochemistry and Reactivity of Metal-Schiff Base Complexes. VI. The Kinetics and Mechanism of Isomerization between Δ_L-β_2- and Λ_L-β_2-Diastereoisomers of *N,N'*-Ethylenebis(α-methylsalicylideneaminato)cobalt(III) Complexes with L-Amino Acid

(Received March 10, 1983)

The kinetics for isomerization between Δ_L-β_2- and Λ_L-β_2-diastereoisomers of [Co(α-Me-sal$_2$en)(L-aa)], where L-aa represents L-phe, L-met, L-ile, L-pro, *N*-Bz-L-ala, and *N*-Me-L-ala, were studied in methanol. The activation enthalpies (ΔH^*/kJ mol^{-1}) and the activation entropies (ΔS^*/J K^{-1} mol^{-1}) from the Δ_L-β_2-isomer (unstable form) to the Λ_L-β_2-isomer (stable form) were determined to be 86.6 and −9.6 for L-phe, 92.5 and +6.7 for L-met, 87.5 and −8.0 for L-ile, 100.4 and +28.0 for *N*-Bz-L-ala, and 102.9 and +18.4 for *N*-Me-L-ala, respectively. For L-pro-complex, the Δ_L-β_2-isomer is the stable form, and the enthalpy and entropy for isomerization from Λ_L-β_2- to Δ_L-β_2-isomers were 96.2 and 0.0. The isomerization was catalyzed by acids but not by bases, and was much faster than the substitution of coordinated L-amino acid. The H–D exchange of N–H proton of *N*-Me-L-ala-complex proceeded with almost the same rate as the isomerization. The isomerization showed strong solvent dependency; it was fast in a hydrogen-bonding solvent, but was quite slow in a weak- or nonhydrogen-bonding solvent. On the basis of these facts, proton-assisted and/or hydrogen-bonding solvent-assisted intramolecular mechanism *via* an intermediate is proposed, in which the Schiff base takes a planar configuration and the amino acid coordinates as a unidentate ligand with its carboxylate group.

Many studies have been directed toward the synthesis and the first order asymmetric transformation of Co(N$_4$)-complexes with a chiral amino acid, where (N$_4$) denotes a tetramine ligand such as (en)$_2$ and trien.[1–4] However, there are only a few studies for detailed isomerization mechanism among the diastereoisomers of these complexes.[5,6] This may be due to the inertness of Co(N$_4$)-complexes: charcoal is usually needed as a catalyst to promote the isomerization. On the other hand, we have recently found that cobalt(III) complexes containing a sal$_2$en-type Schiff base and L-amino acid, β_2-[Co(Schiff base)(L-aa)], easily isomerize in methanol to establish the equilibrium between Δ_L-β_2- and Λ_L-β_2-isomers.[7–12] This reaction is very interesting because the isomerization is quite fast as compared with that of Co(N$_4$)-complexes.

In order to elucidate the isomerization mechanism and the origin of the isomerization lability of cobalt(III)–Schiff base complexes, the isomerization kinetics for β_2-[Co(α-Me-sal$_2$en)(L-aa)] was studied.[13]

Experimental

Materials. The complex β_2-[Co(α-Me-sal$_2$en)(L-aa)] was prepared as previously reported.[7,9,10] The 1 : 1 mixture of Δ_L- and Λ_L-β_2-isomers of L-met-complex was obtained by the addition of a large excess of water to the methanol solution (*ca.* 1 M, 1 M = 1 mol dm^{-3}) of Λ_L-β_2-[Co(α-Me-sal$_2$en)(L-met)].[7] Found: C, 53.32; H, 5.78; N, 8.01%. Calcd for $CoC_{23}H_{28}N_3O_4S \cdot H_2O$: C, 53.18; H, 5.82; N, 8.09%. $[M]^{25}_{435} = +600°$ (soon after dissolution in methanol, $c = 1.0 \times 10^{-3}$ M). $[M]^{25}_{435} = -15400°$ (under equilibrium conditions in methanol). ^{1}H NMR: δ 2.67 (6H, S, CH_3–C=N), δ 1.85, 1.75 (3H, two S with equal intensity, –S–CH_3) (soon after dissolution in $CDCl_3$ + CD_3OD (8 : 1 in volume)).

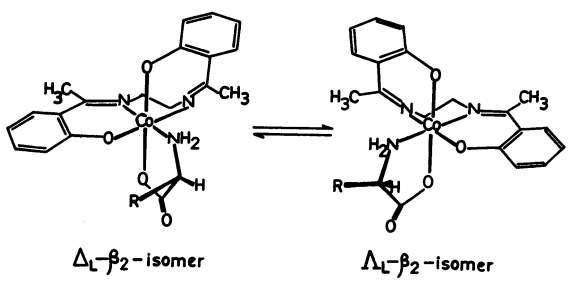

Fig. 1. Structures of two isomers of β_2-[Co(α-Me-sal$_2$en)-(L-aa)].

Reagent grade organic solvents were used after distillation. The other chemicals were reagent grade and used without further purification.

Kinetic Procedure. The complexes (2.5×10^{-5} mol) were dissolved in a given solvent (25 cm^3) at a given temperature, and, whenever necessary, other reagents were added. The mutarotation at 435 nm of the solutions was measured with 1 cm cell by the use of a thermostated cell-holder (the deviation of the solution temperature = ±0.1 °C). When the mutarotation was very slow, the solutions were placed in a thermostat bath, and picked up one by one at proper intervales. The rate constant was calculated from the slope of plots of $\ln(a_\infty - a_t)$ *vs.* time, where a_∞ and a_t are the optical rotations under the equilibrium conditions and at time t, respectively (see Appendix).

Measurements. The optical rotation at 435 nm was measured on a JASCO DIP-140 Polarimeter. The electronic absorption and circular dichroism spectra were recorded on a Hitachi 200-10 Spectrometer and a JASCO J-20 Spectropolarimeter, respectively. The ^{1}H NMR spectra were measured on a Hitachi R-20 Spectrometer.

Results and Discussion

The Kinetics of Isomerization of β_2-[Co(α-Me-sal$_2$en)(L-aa)] in Methanol. The isomerization rate of β_2-[Co(Schiff base)(L-aa)] complexes has been observed to depend strongly on the kind of the Schiff base ligand.[14] For *N,N'*-ethylenebis(4-phenyl-4-oxo-2-butaniminato) or *N,N'*-ethylenebis(α-phenyl-5-methylsalicylideneaminato), the isomerization is too fast to be

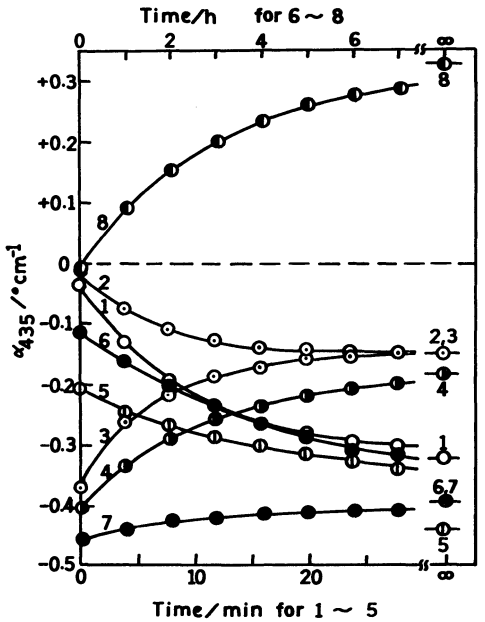

Fig. 2. Mutarotations of β_2-[Co(α-Me-sal$_2$en)(L-aa)] in methanol at 25 °C.
Complex concentration = 1.0×10^{-3} M. Cell length = 1.0 cm. 1: L-phe, 2: L-met (1 : 1 mixture), 3: L-met (pure Λ_L-β_2-isomer), 4: L-ile, 5: *N*-Bz-L-ala, 6: *N*-Me-L-ala (1 : 1 mixture), 7: *N*-Me-L-ala (pure Λ_L-β_2-isomer), 8: L-pro.

followed with a polarimeter at 25 °C in methanol, but for *N*,*N*'-ethylenebis(5, 5, 5-trifluoro-4-oxo-2-pentaniminato), the reaction is very slow. Since the Co(α-Me-sal$_2$en)-complex isomerizes with a suitable rate for rotational measurements, it was selected as the representative complex in this work.

The isomeric ratios of the complexes in the solid state are listed in Table 1. The complexes β_2-[Co(α-Me-sal$_2$en)(L-aa)] are isolated usually as the 1 : 1 mixture of Δ_L- and Λ_L-isomers or as the pure Λ_L-isomer. This is mainly due to the solubilities of the complexes. When the complexes were dissolved in methanol (Fig. 2), the solutions exhibited a mutarotation with a minus sign at 435 nm under the equilibrium conditions except for L-pro-complex. For L-pro-complex, the rotation has a plus sign. As has been reported previously,[7,9,10] during the mutarotation the absorption spectra do not show any obvious change, whereas the CD spectra an isosbestic point at about 470 nm. On the basis of the AB, CD, and ^{1}H NMR spectral studies and the X-ray analysis,[8,11] the following facts has been verified: 1) the mutarotation corresponds to the isomerization between $(+)_{435}$-Δ_L-β_2- and $(-)_{435}$-Λ_L-β_2-diastereoisomers, and neither decomposition nor the other reaction occurs in methanol; 2) the Λ_L-β_2-isomer predominates under the equilibrium conditions except for the L-pro-complex, for which the Δ_L-β_2-isomer is predominant.

In Fig. 2 both the 1 : 1 mixture and the pure Λ_L-β_2-isomer of the L-met-complex reached to the same optical rotation under the equilibrium conditions of mutarotation. A similar behaviour to the L-met-complex was observed for the *N*-Me-L-ala-complex. These facts clearly indicate that the present isomerization reaction belongs to a reversible one. In Fig. 3 the plots of $\ln(\alpha_\infty-\alpha_t)$ *vs.* time gave a straight line up to at least 90% completion of the isomerization, and the slopes were found to be independent of the complex concentration. Hence, the rate formula is expressed as follows:

$$\text{Rate} = k_{obsd}[\text{complex}], \quad (1)$$

Table 2. Activation parameters of isomerization of β_2-[α-Me-sal$_2$en) (L-aa)] in methanol

L-aa	pK_{a_1}	pK_{a_2}	$\Delta H^{\ddagger}$ (k_{+1}) kJ mol^{-1}	$\Delta S^{\ddagger}$ (k_{+1}) J K^{-1} mol^{-1}	$\Delta H^{\ddagger}$ (k_{-1}) kJ mol^{-1}	$\Delta S^{\ddagger}$ (k_{-1}) J K^{-1} mol^{-1}

where k_{obsd} represents the observed first order rate constant. The k_{obsd} values are summarized in Table 1. When the isomerization rate constant from Λ_L- to Λ_L-β_2-isomers is written as k_{+1}, and that from Λ_L- to Δ_L-β_2-isomers as k_{-1}, the k_{obsd} value is related to k_{+1} and k_{-1} by Eq. 2 as is shown in Appendix:

$$k_{obsd} = [(K+1)/K]k_{+1} = (K+1)k_{-1}, \quad (2)$$

where K denotes the isomeric ratio between Λ_L- and Δ_L-β_2-isomers, $K = [\Lambda_L\text{-}\beta_2\text{-isomer}]/[\Delta_L\text{-}\beta_2\text{-isomer}]$, under the equilibrium conditions. Equation 2 was confirmed from the fact that the k_{obsd} values for the 1 : 1 mixture and the pure Λ_L-β_2-isomer are identical in the cases of the L-met- and *N*-Me-L-ala-complexes. The K values were estimated from the CD intensity of the complexes as previously reported.[12] The K values and the k_{+1}, k_{-1} values thus obtained are summarized in Table 1.

The activation parameters were calculated from the temperature dependence of k_{+1} and k_{-1} values, and are given in Table 2. Table 2 indicates that 1) the activation enthalpy becomes generally large when the pK_{a_2} value of L-amino acid is large, and 2) the activation entropies of all the complexes are very small with plus or minus sign, suggesting similar isomerization mechanisms.

Effects of Water, Salts, Acids, Bases, and Amino Acids on the Isomerization in Methanol. The water content of the methanol solution gave no significant effect on the observed isomerization rates of all the complexes in the range from 1×10^{-3} to 1×10^{-1} M (complex concentration $=1\times10^{-3}$ M). However, when a large excess of water (5 M) was added to the methanol solution, the isomerization became somewhat faster (about 15%). This is due to the faster isomerization in water than in methanol (*vide infra*). $NaClO_4$ and CH_3COONa also gave no effect on the isomerization rates in the range from 1×10^{-3} to 2×10^{-1} M. This fact indicates that effects of the ionic strength is negligibly small.

The relationship between acetic acid concentration and the observed isomerization rate is illustrated in Fig. 4. The diagrams are linear at least up to 3×10^{-1} M of acetic acid for L-phe-, L-met-, L-ile-, and L-pro-complexes, and up to 3×10^{-2} M of acetic acid for *N*-Bz-L-ala- and *N*-Me-L-ala-complexes. The intercepts coincided with the k_{obsd} value in the absence of acetic acid. Hence, the k_{obsd} is expressed by

$$k_{obsd} = k_{obsd}^{MeOH} + k_{obsd}^{AcH}[CH_3COOH]. \quad (3)$$

The values of k_{obsd}^{AcH} are listed in Table 3. Acetic acid is a weak protic acid, and its catalytic effect on the isomerization is linear to the acetic acid concentration as observed above. Thus, the effect may be caused by the action of the acetic acid molecules.

When a large excess of acetic acid was added, the partial decomposition of the complexes occurred. The decomposition was confirmed from the changes of optical rotation and absorption spectra. Since the plots of $\ln(\alpha_\infty - \alpha_t)$ *vs.* time for the partial decomposition give a linear relation, the observed decomposition rates are listed in Table 3. The degree of decomposition increases in the folllowing order:

L-phe < L-pro = L-met < L-ile < *N*-Bz-L-ala < *N*-Me-L-ala.

In the presence of trichloroacetic acid, all the complexes isomerized quite rapidly, followed by decomposition to produce brown complexes with the loss of optical rotation, even in 1×10^{-2} M. The isomerization was too fast to follow. The decomposition rates are summarized in Table 3. Since trichloroacetic acid is a strong protic acid, its effect may be due to proton. In fact, the isomerization and decomposition were very fast

TABLE 3. VALUES OF k_{obsd}^{AcH}, ACID-BASE DECOMPOSITION RATES, AND SUBSTITUTION RATES OF AMINO ACIDS OF β_2-[Co(α-Me-sal$_2$en) (L-aa)] IN METHANOL AT 25 °C

L-aa	k_{obsd}^{AcH} / $M^{-1}\,s^{-1}$	Observed decomposition rate constants/s^{-1}				Substitution rate constants/s^{-1} with phenylalanine[b] (2×10^{-2} M)
		CH_3COOH (1 M)	Cl_3CCOOH (1×10^{-2} M)	KOH (1 M)	Pyridine (1 M)

a) Degree of decomoposition. b) Observed value. c) Partial substitution.

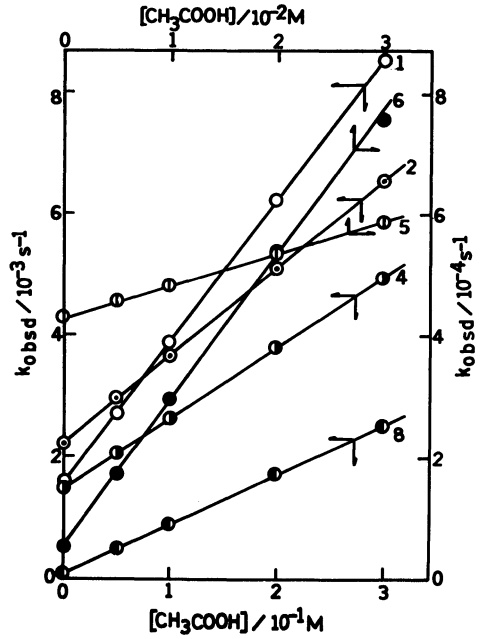

Fig. 4. Influence of acetic acid in methanol at 25 °C. 1: L-phe, 2: L-met (1 : 1 mixture), 4: L-ile, 5: *N*-Bz-L-ala, 6: *N*-Me-L-ala (1 : 1 mixture), 8: L-pro.

in the presence of HCl as well.

Bases such as KOH and pyridine gave no catalytic effect on the isomerization for KOH 1×10^{-3}—1×10^{-2} M, and for pyridine 1×10^{-3}—5×10^{-2} M except for *N*-Bz-L-ala- and *N*-Me-L-ala-complexes. For *N*-alkyl-L-ala-complexes partial decomposition occurred even in a low concentration of a base (*ca.* 2×10^{-3} M of the base). When a large excess of bases was added, all the complexes except for the L-pro-complex decomposed to form *trans*-[Co(α-Me-sal$_2$en)(base)$_2$]$^{\pm n}$. For the L-pro-complex only partial decomposition occurred, which was confirmed by the loss of optical rotation and spectral change. Since the plots of $\ln(a_\infty - a_t)$ *vs.* time gave a linear relation, the estimated decomposition rates are listed in Table 3.

The sensitivity of the base decomposition was observed to increase in the following order of amino acids:

L-pro < L-phe < L-met < L-ile < *N*-Bz-L-ala < *N*-Me-L-ala.

This order is almost the same as that for the decomposition under the acidic conditions.

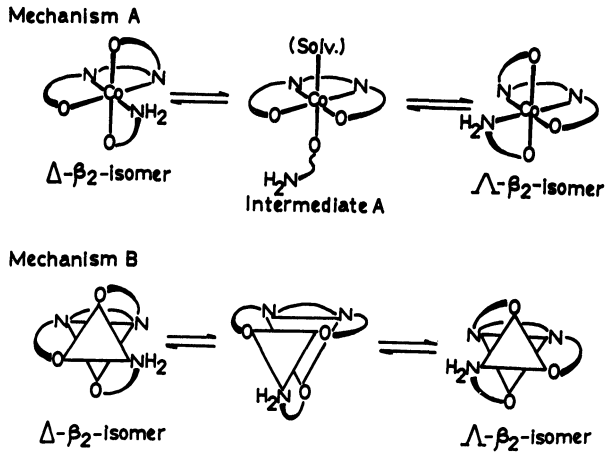

Fig. 5. Sterically possible isomerization mechanisms.

Free amino acids such as phenylalanine and proline gave no significant effect on the isomerization of all the complexes. However, when the complex solutions containing free amino acids were allowed to stand for a long time, substitution of the coordinated amino acidate ion occurred. Since the plots of $\ln(a_\infty - a_t)$ *vs.* time for the substitution with D-phenylalanine (L-phenylalanine in the case of L-pro-complex) gave a linear relation, the observed substitution rate can be estimated, and the first order rate constants observed are listed in Table 3. The substitution is much slower than the isomerization in all the complexes, indicating that the isomerization proceeds *via* an intramolecular mechanism.

From these results, it can be pointed out that the intramolecular isomerization mechanism of all the complexes should be quite similar because of their similar properties.

Isomerization Mechanism. A β_2-[Co(Schiff base)-(L-aa)] complex is composed of one quadridentate and one bidentate ligands. Hence, its intramolecular isomerization is sterically restricted as compared with that of tris(bidentate) complexes. Molecular models indicate that only two mechanisms in Fig. 5 are sterically possible, and a bond breaking mechanism between cobalt(III) and a carboxylate group of the amino acidate is sterically impossible. Mechanism **A** in Fig. 5 is a Co–N bond breaking mechanism with an intermediate in which the quadridentate Schiff base takes a planar configuration, and the amino acidate coordinates as a unidentate ligand with its carboxylate group. Mecha-

a) Value in $CD_3OD+CDCl_3$ (1:4).

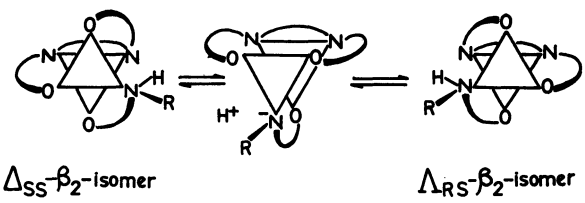

Fig. 6. *R-S* inversion of an asymmetric nitrogen atom in the twist mechanism.

nism **B** is a twist mechanism without a Co^{III}–ligand bond breaking. Since the activation enthalpy is correlated with pK_{a_2} value of the amino acid and the ionic strength effect on the isomerization is negligibly small, the Co–O bond breaking mechanism can safely be omitted, but it is quite difficult to distinguish between Mechanisms **A** and **B**.

In the case of *N*-alkyl-L-ala-complexes, however, Mechanism **B** is unlikely, because, 1) the *N*-alkyl-L-ala-complexes have an asymmetric nitrogen atom at the amino group.*** Therefore, not only the inversion between Δ- and Λ-configurations but also the inversion between *R*- and *S*-configurations of the asymmetric nitrogen atom are required in the isomerization between Δ_{SS}- and Λ_{RS}-β_2-isomers;[15] 2) the *R–S* inversion is impossible in Mechanism **B** without deprotonation of an N–H proton (Fig. 6).

If the deprotonation occurs during the isomerization, the H–D exchange rate of the N–H proton should be 10^2—10^3 times or more faster than the isomerization rate in Mechanism **B**.[16] On the other hand, in Mechanism **A**, the H–D exchange rate is expected to be comparable to the isomerization rate of the complex, because Mechanism **A** involves an intermediate in which the amino group is free from the cobalt(III) ion, and the H–D exchange rate of a free amino group is usually very fast. On the basis of these expectations, the H–D exchange rates for the *N*-Me-L-ala-complex were measured. Since the complex was hardly soluble in CD_3OD, a mixed solvent of CD_3OD and $CDCl_3$ (1 : 4 in volume) was used. The ^1H NMR spectral variation was shown in Fig. 5 of Ref. 10, and the ln-plots are shown in Fig. 7. The diagrams are linear up to at least 40% completion of the H–D exchange for the 1 : 1 mixture of Δ_{SS}- and Λ_{RS}-β_2-isomers and up to at least 80% completion for the pure Λ_{RS}-β_2-isomer. The first order H–D exchange rate constants thus obtained

*** The $(+)_{435}$-isomer of *N*-alkyl-L-ala-complexes used here corresponds to the Δ_{SS}-β_2-isomer, and the $(-)_{435}$-isomer to the Λ_{RS}-β_2-isomer.[10,15]

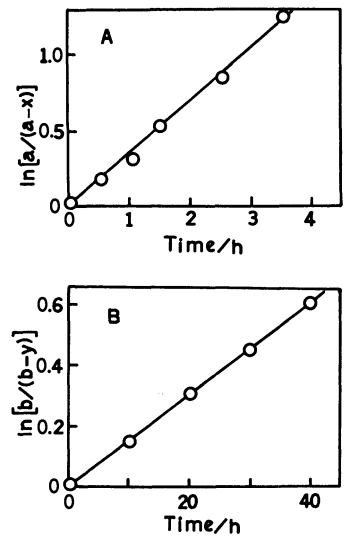

Fig. 7. ln-plots for H–D exchange of *N*-Me-L-ala-complex in mixed solvent of CD_3OD and $CDCl_3$ (1 : 4 in volume) at 35 °C.
A=1 : 1 mixture. B=Pure Λ_L-β_2-isomer. a=Initial concentration of Δ_L-β_2-isomer. x=Concentration of deuterated isomer at time *t*. b=Initial concentration of Λ_L-β_2-isomer. y=Concentration of deuterated isomer at time *t*.

are listed in Table 4. The isomerization rate constants in the mixed solvent of CH_3OH and $CHCl_3$ (1 : 4 in volume) were estimated from the mutarotation at 435 nm of the complex, and are given in Table 4.

Table 4 indicates that 1) the H–D exchange rate for the 1 : 1 mixture is almost the same as the isomerization rate (k_{+1}) from Δ_{SS}- to Λ_{RS}-β_2-isomers; 2) the H–D exchange rate for the pure Λ_{RS}-β_2-isomer is almost identical with the isomerization rate (k_{-1}) from Λ_{RS}- to Δ_{SS}-β_2-isomers. Thus, it can be concluded that Mechanism **A** is most probable as the isomerization mechanism of the *N*-Me-L-ala-complex. Since there is no reason that other amino acidato complexes take a different isomerization mechanism from that of the *N*-Me-L-ala-complex, all the complexes investigated here are concluded to isomerize *via* Mechanism **A**.

It has been observed that the formation of β_2-[Co(α-Me-sal$_2$en)(L-aa)] complexes from *trans*-[Co(α-Me-sal$_2$en)(O_2)] and L-amino acid proceeds *via* an intermediate similar to **A** in Fig. 5, and it is much faster than the isomerization of β_2-[Co(α-Me-sal$_2$en)(L-aa)].[9] These facts suggest that the formation of Δ_L- and Λ_L-β_2-isomers from Intermediate **A** in Fig. 5 is much faster than the isomerization. Accordingly, the rate deter-

TABLE 5. OBSERVED ISOMERIZATION RATES (k_{obsd}/s^{-1}) IN VARIOUS SOLVENTS AT 23.5 °C

a) First absorption maximum. b) A small amount of decomposition of complex occurred in CH_3COOH. c) Value in mixed solvent of H_2O and MeOH (2:3 in volume).

mining step of the isomerization is thought to be the formation process of *trans*-Intermediate **A** from Δ_L- and Λ_L-β_2-isomers.

Effect of Solvents on the Isomerization. In order to get further information, isomerizations in various solvents were investigated. The k_{obsd} values for the representative complexes are summarized in Table 5. From these measurements, the following tendencies were found: 1) the isomerization becomes faster in the following order of solvents: acetone, DMF, DMSO, THF, 1,4-dioxane, pyridine<aniline<BuOH<PrOH <EtOH<MeOH<*o*-cresol<H_2O<CH_3COOH; 2) the isomerization in acetone, DMF, DMSO, THF, 1,4-dioxane, and pyridine is quite slow or no isomerization occurs; 3) no decomposition of the complex occurred in pyridine and aniline, although the decomposition of the complex occurred in the mixed solvents of methanol and pyridine or aniline.

The isomerization is faster in the solvents having a hydrogen bonding proton than in weak- or nonhydrogen bonding solvents. Thus, hydrogen bonding solvents clearly assist the isomerization. As has been observed previously,[12] the hydrogen bonding occurs mainly at the phenolic oxygen atoms of a Schiff base ligand, and when the hydrogen bonding is stronger, the first absorption band of the complexes shifts to the lower energy side. This shift is caused by the lowering of the coordination ability of phenolic oxygen atoms due to the hydrogen bonding. A similar shift of the first absorption band was also observed in the present study, and when the shift was larger, the isomerization was faster. Therefore, it can be concluded that 1) the hydrogen bonding at the phenolic oxygen atoms of the Schiff base ligand assists the isomerization, and 2) the stronger the hydrogen bonding is, the more labile the isomerization is.

For the formation of Intermediate **A** in Fig. 5 from Δ_L- and Λ_L-β_2-isomers, not only the bond breaking between the cobalt(III) atom and the amino group of amino acidate ion but also the rearrengement of the coordinated Schiff base ligand from β- to *trans*-configurations is needed. And, for the rearrangement of the Schiff base ligand, a loosening of the Co^{III}–phenolic oxygen bond is necessary. Since the hydrogen bonding solvents are thought to act to make the Co^{III}–phenolic oxygen bond more loose, their effects may be to assist rearrengement of the Schiff base ligand. We think that the catalytic effect of protic acid should be similar to that of hydrogen bonding solvents, because it has been known that the protonation occurs at the phenolic oxygen atoms.[17]

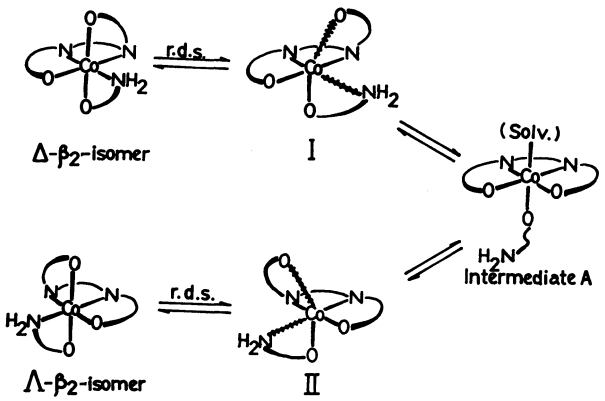

Fig. 8. Proposed isomerization mechanism.

On the basis of these results and above discussion, we propose an isomerization mechanism shown in Fig. 8. In Fig. 8, we assummed that 1) the rate controlling step is the formation of activated complexes **I** and **II**, and 2) the activated complexes take a structure in which two bonds, that between cobalt(III) and the amino group, and that between cobalt(III) and one of the phenolic oxygen atoms, are stretched.

The authors wish to express their deep thanks to Professor J. C. Bailar Jr., of University of Illinois for his encouragement.

Appendix

Derivation of the Rate Equation. When the isomerization rate constant from Δ_L- to Λ_L-isomers is written as k_{+1} and that from Λ_L- to Δ_L-isomers as k_{-1}, they can be expressed as follows:

$$k_{+1} = ([\Lambda_L]_\infty/at)\ln\{[\Lambda_L]_\infty/([\Lambda_L]_\infty-[\Lambda_L]_t\}, \quad (1)$$

$$k_{-1} = ([\Delta_L]_\infty/at)\ln\{[\Delta_L]_\infty/([\Delta_L]_\infty-[\Delta_L]_t)\}, \quad (2)$$

where, $[\Lambda_L]_t$, $[\Delta_L]_t$ and $[\Lambda_L]_\infty$, $[\Delta_L]_\infty$ represent the concentrations of Λ_L- and Δ_L-isomers at the time t, and at the equilibrium conditions, respectively, and a denotes the total complex

concentration. When the molar rotations of Λ_L- and Δ_L-isomers are expressed by $[M]_{\Lambda L}$ and $[M]_{\Delta L}$, respectively, the observed rotation (α_t) at the time t can be written as follows:

$$\begin{aligned}\alpha_t &= [M]_{\Lambda L}[\Lambda_L]_t d + [M]_{\Delta L}[\Delta_L]_t d \\ &= ([M]_{\Lambda L} - [M]_{\Delta L})[\Lambda_L]_t d + [M]_{\Delta L} ad \\ &= ([M]_{\Delta L} - [M]_{\Lambda L})[\Delta_L]_t d + [M]_{\Lambda L} ad, \end{aligned} \quad (3)$$

where, d is the cell length.

From Eq. 3, the following relations can be derived:

$$[\Lambda_L]_t = (\alpha_t - [M]_{\Delta L} ad)/([M]_{\Lambda L} - [M]_{\Delta L})d, \quad (4)$$

$$[\Delta_L]_t = (\alpha_t - [M]_{\Lambda L} ad)/([M]_{\Delta L} - [M]_{\Lambda L})d. \quad (5)$$

Similarly, $[\Lambda_L]_\infty$ and $[\Delta_L]_\infty$ can be written as follows:

$$[\Lambda_L]_\infty = (\alpha_\infty - [M]_{\Delta L} ad)/([M]_{\Lambda L} - [M]_{\Delta L})d, \quad (6)$$

$$[\Delta_L]_\infty = (\alpha_\infty - [M]_{\Lambda L} ad)/([M]_{\Delta L} - [M]_{\Lambda L})d. \quad (7)$$

When the isomeric ratio under the equilibrium conditions is expressed by

$$K = [\Lambda_L]_\infty/[\Delta_L]_\infty = k_{+1}/k_{-1}, \quad (8)$$

k_{+1} and k_{-1} in Eqs. 1 and 2 can be written as follows by the use of relations in Eqs. 4—8:

$$\begin{aligned} k_{+1} &= [K/(K+1)t] \\ &\times \ln\{[K/(K+1)]([M]_{\Lambda L} - [M]_{\Delta L})ad/(\alpha_\infty - \alpha_t)\}, \end{aligned} \quad (9)$$

$$\begin{aligned} k_{-1} &= [1/(K+1)t] \\ &\times \ln\{[1/(K+1)]([M]_{\Delta L} - [M]_{\Lambda L})ad/(\alpha_\infty - \alpha_t)\}. \end{aligned} \quad (10)$$

By transforming the Eqs. 9 and 10, Eqs. 11 and 12 are obtained:

$$\begin{aligned} \ln(\alpha_\infty - \alpha_t) &= -[(K+1)/K]k_{+1}t \\ &+ \ln\{[K/(K+1)]([M]_{\Lambda L} - [M]_{\Delta L})ad\}, \end{aligned} \quad (11)$$

$$\begin{aligned} \ln(\alpha_\infty - \alpha_t) &= -(K+1)k_{-1}t \\ &+ \ln\{[1/(K+1)]([M]_{\Delta L} - [M]_{\Lambda L})ad\}. \end{aligned} \quad (12)$$

When the values of $-[(K+1)/K]k_{+1}$ and $-(K+1)k_{-1}$ are designated as $k^{\Lambda\to\Delta}_{obsd}$ and $k^{\Lambda\to\Lambda}_{obsd}$, respectively, the following relationship can be derived by the use of Eq. 8:

$$k^{\Lambda\to\Delta}_{obsd} = -[(K+1)/K]k_{+1} = -(K+1)k_{-1} = k^{\Lambda\to\Lambda}_{obsd}. \quad (13)$$

Pyrolytic Sulfurization Gas Chromatography. XV. Simultaneous Determination of the Atomic Ratio between C, H, O, and N in an Organophosphorus Compound

Tadashi HARA,* Kaoru FUJINAGA,† Fujio OKUI, and Akihiro ARAI

Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602

†*Department of Chemistry, Faculty of Science, Shimane University, 1060 Nishikawatsu-cho, Matsue 690*

(Received April 1, 1983)

In order to confirm whether or not pyrolytic sulfurization gas chromatography can be applied to organophosphorus compounds, many kinds of organophosphorus compounds were examined; C-rich compounds gave satisfactory results while C-poor ones gave lower oxygen values. The application limit of this method to various organophosphorus compounds was determined by the use of the C/O value and a structural factor for a sample, and the application limit was established. The structural factor of a sample varied with the kind of X_1, X_2, X_3, and X_4 in the general formula $X_1X_2X_3P=X_4$, where X_1=OH, OR, R; X_2=OH, OR′, R′; X_3=OH, OR″, R″; and X_4=O, S.

With the objective of establishing a new organic elemental analysis method by which several elements can be simultaneously determined, pyrolytic sulfurization gas chromatography (PSGC) was originated[1] and has been studied[2–14] by the authors. The PSGC method is based on a combustion technique in sulfur vapor instead of the conventional one in an oxygen atmosphere; this makes possible the simultaneous determination of the atomic ratio between C, H, O, and N in an organic compound without weighing the sample. So far this method has been successfully applied to a normal organic compound,[1,2] a metal organic chelate,[3,13] a polymer,[5] and an organic halogen compound.[7,9]

In the field of conventional organic elemental analysis, oxygen in an organic compound containing metallic or non metallic elements cannot be analyzed with ease because a number of elements show a strong affinity for oxygen and are apt to form nonvolatile compounds such as their oxides or carbonates. On the contrary, the PSGC method makes possible the simultaneous determination of the atomic ratio between C, H, O, and N even in a compound containing the above-mentioned elements because they are converted into their sulfides. Though the effects of many coexistent elements on the determination of C, H, O, and N have been discussed and clarified, the effect of phosphorus as a coexistent element still remained unsolved in the previous studies.[3,13] Moreover, the determination of oxygen in an organophosphorus compound by the conventional organic elemental analysis method is difficult. Therefore, the present study has been carried out to confirm whether or not the PSGC method can be applied to various types of organophosphorus compounds. Fifteen kinds of organophosphorus compounds were analyzed by the PSGC method; C-rich compounds gave satisfactory results but C-poor ones gave low oxygen values. This was explained by the assumption that the phosphorus oxides produced from phosphorus and oxygen in a sample are reduced to phosphorus sulfide by carbon in a C-rich compound sample, but not in a C-poor compound sample. On the other hand, some experimental results could not be explained by the C/O value alone. In these cases, the application limit of the PSGC method to various organophosphorus compounds was decided by the use of the C/O value and a structural factor for the sample. The structural factor of a sample varied with the kind of X_1, X_2, X_3, and X_4 in the general formula $X_1X_2X_3P=X_4$ where X_1=OH, OR, R; X_2=OH, OR′, R′; X_3=OH, OR″, R″; and X_4=O, S.

Experimental

Apparatus and Reagents. The apparatus and reagents used in this experiment were the same as those reported previously. A definite amount of sample was taken using a Shimadzu microbalance MDP-5.

Samples. Eleven kinds of organophosphorus compounds, sample numbers 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, and 12 (shown in Table 1) were synthetic ones provided by Professor Isao Furukawa at Doshisha University. Other samples were of reagent grade. These samples were, if necessary, purified by recrystallization from appropriate solvents. The composition and purity of the samples were confirmed by CH and/or CHN analysis carried out in the Elemental Analysis Center of the Pharmaceutical Department of Kyoto University (Table 1).

Procedure. A 0.3—0.5 mg of sample and 5 mg of purified sulfur[4] was inserted into a quartz tube (2.5 mm i.d., 3.5 mm o.d., and 100 mm long), one end of which was previously closed. The air inside the tube containing the sample and S was displaced with He for 10 min at the flow rate of 100 cm³/min, followed by sealing the other end of the tube. The ampule thus obtained was treated for 10 min at 600 °C and for 30 min at 950 °C. The reaction products, carbon dioxide, carbonyl sulfide, carbon disulfide, hydrogen sulfide, and nitrogen, in the ampule were analyzed gas-chromatographically by crushing the ampule in the flow of the gas chromatograph, followed by calculation of the atomic ratio between C, H, O, and N in the sample in the same way as that reported previously.[2] The precision of the PSGC had been reported in the previous paper.[14]

Results

Analytical Results of Various Organophosphorus Compounds. Various organophosphorus compounds were analyzed by the PSGC method; the results are shown in Table 2. As can be seen from Table 2, C-rich compounds gave satisfactory results, but C-poor compounds such as samples 11, 13, 14, and 15 did not. In the PSGC

method, each content of C, H, O, and N in a sample is calculated by normalizing their total contents to 100%. In order to clarify which element was influenced by phosphorus as a coexistent element, the atomic ratios of H, O, and N to C were calculated; it became apparent that only the content of O was influenced by phosphorus. This may be explained by the assumption that phosphorus oxide produced from phosphorus and oxygen in a sample is reduced by carbon in a C-rich compound sample, but not in a C-poor compound sample. The white powder, which was presumed to be a phosphorus oxide, was observed in the ampule of the latter case after pyrolytic sulfurization.

Relationship between the Analytical Results and the C/O Value. The atomic ratio of C to O (the C/O value) was defined as an indication of the reducing power for the phosphorus oxide to explain the above-mentioned results. The relationship between the error of oxygen in each analytical result of organophosphorus compound and the C/O value calculated from each sample was shown in Fig. 1. Figure 1 shows that the PSGC method can be applied to organophosphorus compounds in which the C/O value exceeds about 3 and the negative error in oxygen value increases with a decreasing C/O value less than about 3. However, the fact that sample 11 (C/O=3.0) did not give a satisfactory result while sample 12 (C/O=2.7) did give a satisfactory result cannot be explained by the C/O value alone. Therefore, another factor must also be taken into consideration to clarify the application limit of the PSGC method to organophosphorus compounds. It is discussed below.

Discussion

Effect of the Chemical Structure of a Sample on the Analytical Result. Since the application limit of the PSGC method to organophosphorus compounds could not be decided exactly by the C/O value alone as mentioned above, the chemical structure of a sample was investigated as another factor of deciding the application limit to organophosphorus compounds in which the oxidation number of phosphorus is +5 in the following manner. Three kinds of mixed samples with the C/O values of 1—7 were prepared as model compounds by the use of the following pairs; sample 1 and sucrose, sample 5 and sucrose, and sample 15 and anthracene, respectively. These samples were analyzed by the PSGC method; each relationship between the analytical value of oxygen in each sample and its C/O value is shown in Fig. 2, where all analytical values of C, H, and N were

confirmed to be correct from the atomic ratios of H and N to C. As can be seen from Fig. 2, the errors of oxygen decrease with an increasing C/O value, but the numerical values of the oxygen error are different from one another even at the same value of C/O. This is attributed to the difference of the chemical structure of the sample, that is, satisfactory results are obtained for the following samples; 1) sample 15 as an addition compound of phosphoric acid when the C/O value is more than 5.5, 2) sample 5 as a derivative of phosphinic acid when the C/O value is more than 2, and 3) sample 1 as a derivative of phosphonothioic acid containing no oxygen when the C/O value is more than 1. Thus the analytical result of oxygen is influenced by the substituent groups bonding to phosphorus, –OH, –OR, and –R (R indicates a hydrocarbon group), in that order. From the results of this experiment, the application limit of the PSGC method to organophosphorus compounds may be explained by the use of two factors; the C/O value and the chemical structure.

Application Limit of the PSGC Method to Organophosphorus Compounds. In order to clarify the application limit of the PSGC method to organophosphorus compounds, the relationship between each analytical result of organophosphorus compound and above-mentioned two factors was investigated; the results are shown in Table 3. In Table 3, substituent groups bonding to phosphorus (V) as a structural factor are vertically enumerated in the order of their interferences and the C/O values are arranged horizontally, followed by marking + at the corresponding position for the sample giving a satisfactory result and by marking − for one giving a negative error of oxygen. In addition, both the positions giving satisfactory results for phosphoric acid, C/O=5.5 in structure A, and for phosphonothioic acid, C/O=1 in structure J, were linked with a broken line. This broken line indicates the application range of the PSGC method, that is, the sample satisfying the

conditions under the broken line may be analyzed by the PSGC method without any exceptions.

Judging from the results obtained by the present study and the difficulties in oxygen analysis of an organophosphorus compound by the conventional method, the utility of the PSGC method in analysis of an organophosphorus compound is obvious even though its applicable region is restricted by the application limit.

The authors wish to express their thanks to Professor Isao Furukawa, Doshisha University, for the supply of 11 kinds of organophosphorus compounds.

Circular Dichroism of Chromium(III) Complexes. VIII. Circular Dichroism Spectra of Mixed Diamine Complexes of *trans*-$[CrF_2(N)_4]^+$ Type

Sumio KAIZAKI

Department of Chemistry, Faculty of Science, Nara Women's University, Nara 630

(Received May 28, 1983)

The ligand field absorption and circular dichroism (CD) spectra were examined not only for *trans*-difluoro bis(diamine)chromium(III) complexes with two identical chiral diamines but also for nine new mixed diamine complexes of the same type with different diamines, which were ethylenediamine, trimethylenediamine, (*R*)- and (*S*)-propylenediamine, (1*R*, 2*R*)-1,2-cyclohexanediamine, (2*R*, 4*R*)- and (2*R*, 4*S*)-2,4-pentanediamine. The additivity of the CD contributions from the individual chiral diamines were substantiated for most of these complexes. On this basis, the conformational and the vicinal CD contribution due to puckered diamine rings and asymmetric carbon atoms, respectively, were differentiated, and the CD origins of all the present complexes were discussed in connection with stereochemistry.

It has been considered that there are two stereochemical sources from which the circular dichroism (CD) of so-called praseo type complexes with chiral diamines arises: The conformational effect due to puckered chelate rings and the vicinal effect due to asymmetric atoms on ligands. Hawkins *et al.*[1] suggested that the CD spectra of *trans*-$[CoCl_2(diamine)_2]^+$ with (*R*)-propylenediamine (*R*-pn) and (1*R*,2*R*)-1,2-cyclohexanediamine (*R*,*R*-chxn) are contributed exclusively by the conformational effect rather than by the vicinal effect. This has been supported by the CD studies on Co^{III} complexes with analogous chiral diamines.[2,3] More explicit information about the CD origins of *trans*-$[MX_2(N)_4]$ type complexes will be afforded by the CD spectra of mixed diamine complexes of this type with different diamines; it may become feasible to test the additivity of the CD contributions from individual chiral diamines and moreover to differentiate between the conformational and the vicinal effect in this type of complexes. However, there has been no investigation on the CD spectra of mixed diamine complexes with *R*-pn, *R*,*R*-chxn, or (2*R*,4*R*)-2,4-pentanediamine (*R*,*R*-ptn), though a few CD studies in such a system have been reported on *trans*-$[CoCl_2(N)_4]^+$ containing *N*,*N*'-dimethylethylenediamine and the related diamines.[4,5] For this purpose, chromium(III) complexes are considered to be suitable, because a few mixed diamine chromium(III) complexes of the same type have already been prepared[6] and because the CD spectra in the first ligand field band region of Cr^{III} complexes behave similarly to those of Co^{III} complexes.

In this paper, the synthetic method for the known *trans*-difluoro mixed diamine chromium(III) complexes[6] is applied to the preparation for nine new Cr^{III} complexes with different diamines, which are pairs of *R*- and *S*-pn or ethylenediamine (en) with trimethylenediamine (tn), *R*,*R*-chxn, *R*,*R*-ptn, or (2*R*,4*S*)-2,4-pentanediamine (*R*,*S*-ptn). The ligand field absorption and CD spectra of these complexes are discussed in comparison with those of the same type complexes containing two identical chiral diamines. It is demonstrated that the CD contributions from the individual chiral diamines to the complexes are almost separable and additive except for such complexes as the bis(*R*-pn) and the bis(*R*,*R*-chxn) one, and that the conformational and the vicinal CD contributions from the chiral diamines are separated. The anomalous CD behavior of the bis(*R*-pn) and the bis(*R*,*R*-chxn) complexes is interpreted in terms of an additional chirality due to donor nitrogen atom distortions.

Experimental

Preparation of Ligands. The chiral diamines used were obtained by the methods described previously: *S*- and *R*-pn,[7] *R*,*R*-chxn,[8] *R*,*R*-ptn·2HCl,[2] and *R*,*S*-ptn·2HCl.[2]

Preparation of Complexes. *1)* trans-$[CrF_2(R\text{-}pn)_2]ClO_4$, trans-$[CrF_2(R,R\text{-}chxn)_2]Cl\cdot H_2O$, *and* trans-$[CrF_2(R,R\text{-}ptn)_2]ClO_4$: These complexes were prepared according to the literature methods for the *R*-pn, *R*,*R*-chxn complexes,[9] and *R*,*R*-ptn complex.[10] The *R*,*R*-chxn complex was originally isolated as the perchlorate salt and then converted to the chloride salt with an anion exchange resin of chloride form in a batchwise operation. Found: C, 38.71; H, 8.21%. Calcd for $[CrF_2(R,R\text{-chxn})_2]Cl\cdot H_2O$: C, 38.76; H, 8.13%.

2) trans-$[CrF_2(en)(R\text{-}pn)]Br\cdot H_2O$, trans-$[CrF_2(tn)(R\text{-}pn)]Br\cdot 1.5H_2O$, trans-$[CrF_2(R\text{-}pn)(R,R\text{-}chxn)]Br$, *and* trans-$[CrF_2(S\text{-}pn)(R,R\text{-}chxn)]Br\cdot 0.5H_2O$: The preparation of these mixed diamine complexes were carried out by the method of Vaughn and Marziwski[6] except that the chiral diamines (*R*-, *S*-pn, and *R*,*R*-chxn) were used instead of the racemic ones. Although they obtained only one isomer (*cis* one) for $[CrF_2(pn)(dach)]Br\cdot H_2O$ where pn and dach stand for *rac*-pn and *rac*-chxn, respectively, another isomer (*trans* one) of the corresponding complexes with the chiral diamines could be isolated after the reaction at about 50 °C. Found: C, 18.20; H, 6.16; N, 17.57%. Calcd for $[CrF_2(en)(R\text{-pn})]Br\cdot H_2O$: C, 18.64; H, 6.26; N, 17.39%. Found: C, 20.88; H, 6.65; N, 16.28%. Calcd for $[CrF_2(tn)(R\text{-pn})]Br\cdot 1.5H_2O$: C, 20.89; H, 6.72; N, 16.23%. Found: C, 31.18; H, 6.81%. Calcd for $[CrF_2(R\text{-pn})(R,R\text{-chxn})]Br$: C, 30.18; H, 6.75%. Found: C, 28.63; H, 6.69%. Calcd for $[CrF_2(S\text{-pn})(R,R\text{-chxn})]Br\cdot 0.5H_2O$: C, 29.44; H, 6.86%.

3) trans-$[CrF_2(en)(R,R\text{-}chxn)]Br\cdot 2H_2O$: This was prepared with use of *trans*(F)-$[CrF_2(H_2O)_2(en)]Br$[11] by a similar method to that for *trans*-$[CrF_2(R\text{-pn})(R,R\text{-chxn})]Br$. Found: C, 24.71; H, 6.60; N, 14.55%. Calcd for $[CrF_2(en)(R,R\text{-chxn})]Br\cdot 2H_2O$: C, 25.27; H, 6.89; N, 14.74%.

4) trans-$[CrF_2(en)(R,R\text{-}ptn)]Br\cdot H_2O$, trans-$[CrF_2(R\text{-}pn)(R,R\text{-}ptn)]Br\cdot H_2O$, trans-$[CrF_2(S\text{-}pn)(R,R\text{-}ptn)]Br\cdot 1.5H_2O$, *and* trans-$[CrF_2(R\text{-}pn)(R,S\text{-}ptn)]Br\cdot H_2O$: Pure sodium (0.3 g) was dissolved in 8 cm^3 of absolute ethanol. To this solution was added 1.1 g of *R*,*R*-ptn·2HCl or *R*,*S*-ptn·2HCl by portions; then white powder of sodium chloride was precipitated during vigorous stirring. After it was removed by

filtration and washed with a small amount of ethanol, *trans*(F)-[$CrBrF_2(H_2O)$(*R*-pn)] (or *trans*(F)-[$CrBrF_2(H_2O)$(*S*-pn)]) (1.7 g) or *trans*(F)-[$CrF_2(H_2O)_2$(en)]Br (1.7 g) was added to the filtrate and washings. The mixture was warmed on a water bath at about 50 °C for several hours. Then pink orange precipitate was obtained. After cooling in an ice bath, it was filtered off and recrystallized from methanol by the addition of ether. Found: C, 23.29; H, 6.81; N, 15.96%. Calcd for [CrF_2(en)(*R*,*R*-ptn)]Br·H_2O: C, 24.00; H, 6.91; N, 16.00%. Found: C, 25.88; H, 7.11; N, 15.23%. Calcd for [CrF_2(*R*-pn)(*R*,*R*-ptn)]Br·H_2O: C, 26.38; H, 7.20; N, 15.38%. Found: C, 25.72; H, 7.40; N, 15.20%. Calcd for [CrF_2(*S*-pn)(*R*,*R*-ptn)]Br·1.5H_2O: C, 25.74; H, 7.29; N, 15.01%. Found: C, 25.97; H, 7.35; N, 15.30%. Calcd for [CrF_2(*R*-pn)(*R*,*S*-ptn)]Br·H_2O: C, 26.38; H, 7.20; N, 15.38%.

Measurements. The electronic absorption spectra were measured by a Shimadzu UV-200S spectrophotometer. The CD spectra were recorded with a JASCO MOE-1 spectropolarimeter. These measurements were made on aqueous solutions ranging in concentration from 4×10^{-3} to 6×10^{-3} mol dm^{-3} at room temperature.

Results and Discussion

1) Absorption Spectra. The absorption spectral data of the present complexes are given in Table 1. Their positions and intensities are similar to those of *trans*-[$CrF_2(en)_2$]$^+$. Thus, it is apparent that these complexes have a *trans* geometrical structure.

The first ($^4T_{2g}\leftarrow{}^4A_{2g}$) and the second ($^4T_{1g}\leftarrow{}^4A_{2g}$) ligand field transition split into two components respectively; they have been assigned to the $^4E(^4T_{2g})$, $^4B_2(^4T_{2g})$, $^4E(^4T_{1g})$, and $^4A_2(^4T_{1g})$ states in D_4 symmetry from the longer wavelength side.[12] The absorption band intensities for *trans*-difluoro complexes with two identical diamines are found to be similar to one another, whereas those with different diamines give larger molar absorptivities than the former group of the complexes (Table 1). Such an intensity difference between the former and the latter group of the complexes is observed more clearly and more reliably for the $^4B_2$ and $^4A_2$ nondegenerate components than for the two ^4E components, because these nondegenerate components always exhibit prominent band peaks but not shoulders nor plateaus. On the theoretical basis, it has been pointed out that the absorption band intensities of the $^4B_2$ and $^4A_2$ components depend on the ligands on the xy plane; *i.e.*, the $(N)_4$ ligands in *trans*-[$CrF_2(N)_4$]$^+$ type complexes.[13] As seen through the absorption band intensities of the complexes with two identical diamines, the hyperchromic properties of the five- and six-membered diamines seem to be similar to one another. Therefore, the increase in intensity for the mixed diamine complexes is not caused by the hyperchromic properties of the diamines, but this may be responsible for the descent from D_2 to C_2 symmetry of the $(N)_4$ plane in these complexes.

2) CD Spectra. The CD spectra of the present complexes are given in Figs. 1 and 2, and their data are summarized in Table 2. Since the CD spectrum of *trans*-$[CrF_2(R,R\text{-chxn})_2]^+$ resembles that of *trans*-$[CrF_2(R\text{-pn})_2]^+$ (Fig. 1 and Table 2), it appears that the overall CD of these complexes arise mainly from the conformational effect due to the λ ring conformation[10] rather than from the vicinal effect as found for the CD spectra of Co^{III} complexes.[1-3] From this result, it might be predicted that the CD spectrum of *trans*-$[CrF_2(en)(R\text{-pn})]^+$ should be similar to that of *trans*-$[CrF_2(en)(R,R\text{-chxn})]^+$, and that *trans*-$[CrF_2(S\text{-pn})(R,R\text{-chxn})]^+$ should give negligibly weak CD. These are not observed for the present complexes. That is, the CD intensity of *trans*-$[CrF_2(en)(R,R\text{-chxn})]^+$ is twice as strong as that of *trans*-$[CrF_2(en)(R\text{-pn})]^+$, and *trans*-$[CrF_2(S\text{-pn})(R,R\text{-chxn})]^+$ gives appreciable CD intensity (Fig. 1 and Table 2). These facts indicate that each contribution of the *R*-pn and *R,R*-chxn ligands to optical activity of the mixed diamine complexes differs significantly from that of the bis(*R*-pn) and the bis(*R,R*-chxn)-complex. In order to examine the difference in CD behavior between the complexes with identical diamines and those with different diamines in more detail, the separation of each CD contribution from the *R*-pn and the *R,R*-chxn ligand to the mixed diamine complexes is attempted by the addition and the substraction of the CD curves of *trans*-$[CrF_2(R\text{-pn})(R,R\text{-chxn})]^+$ and *trans*-$[CrF_2(S\text{-pn})(R,R\text{-chxn})]^+$. The same treatment is carried out for *trans*-$[CrF_2(R\text{-pn})(R,R\text{-ptn})]^+$ and *trans*-$[CrF_2(S\text{-pn})(R,R\text{-ptn})]^+$. The CD contributions of the chiral diamines thus obtained correspond to the CD curves of *trans*-$[CrF_2(rac\text{-pn})(R,R\text{-chxn})]^+$ and *trans*-$[CrF_2(R\text{-pn})(rac\text{-chxn})]^+$ for the former case, and to those of *trans*-$[CrF_2(rac\text{-pn})(R,R\text{-ptn})]^+$ and *trans*-$[CrF_2(R\text{-pn})(rac\text{-ptn})]^+$ for the latter case. They are compared with each other in Figs. 1 and 2. The CD contribution from the *R,R*-chxn to *trans*-$[CrF_2(rac\text{-pn})(R,R\text{-chxn})]^+$ and that from the *R,R*-ptn to *trans*-$[CrF_2(rac\text{-pn})(R,R\text{-ptn})]^+$ are identical with the overall CD curve of *trans*-$[CrF_2(en)(R,R\text{-chxn})]^+$ and that of *trans*-$[CrF_2(en)(R,R\text{-ptn})]^+$ (and also one half that of *trans*-$[CrF_2(R,R\text{-ptn})_2]^+$), respectively. For *trans*-$[CrF_2(R\text{-pn})(rac\text{-chxn})]^+$, the CD contribution from the *R*-pn is similar to that from the *R*-pn to *trans*-$[CrF_2(R\text{-pn})(rac\text{-ptn})]^+$, especially in the region of the longer wavelength CD component, but does not agree appreciably with the CD curve of *trans*-$[CrF_2(en)(R\text{-pn})]^+$, *trans*-$[CrF_2(tn)(R\text{-pn})]^+$, and one half that of *trans*-$[CrF_2(R\text{-pn})_2]^+$. Accordingly, it can be seen that the CD contributions of the chiral diamines to the present complexes are separable and additive except for the cases of the bis(*R*-pn), bis(*R,R*-chxn), and the mono(*R*-pn) complexes with ethylenediamine and trimethylenediamine. In view of such additivity of the CD for the complexes, there may be no significant interaction between two different diamines in the complexes; free puckering of the ethylenediamine ring occurs for *trans*-$[CrF_2(en)(R,R\text{-chxn})]^+$ and *trans*-$[CrF_2(en)(R,R\text{-ptn})]^+$ in solution. As to *trans*-$[CrF_2(tn)(R\text{-pn})]^+$, the CD spectrum is quite identical with the CD of *trans*-$[CrF_2(R\text{-pn})(R,S\text{-ptn})]^+$, but differs from that of *trans*-$[CrF_2(R\text{-pn})(rac\text{-ptn})]^+$ (Fig. 2). This fact suggests that the coordinated trimethylenediamine takes the same conformation as the *R,S*-ptn ligand, which has been determined to have a chair form by the X-ray structural analysis of $(+)_{560}$-$[Co(ox)(R,S\text{-ptn})_2]ClO_4\cdot H_2O$.[14] This will be substantiated more evidently by the CD study on *trans*-$[Cr(ONO)_2(R\text{-pn})(R,S\text{-ptn})]^+$ and *trans*-$[Cr(ONO)_2(tn)(R\text{-pn})]^+$ as discussed in a subsequent paper.[15] The CD behavior of *trans*-$[CrF_2(en)(R\text{-pn})]^+$ may be interpreted as follows. From a similarity in absorption

band intensity between *trans*-$[CrF_2(en)(R\text{-pn})]^+$ and *trans*-$[CrF_2(R\text{-pn})_2]^+$ (Table 2) and from good coincidences in shape and size between the *R*-pn and ethylenediamine rings in complexes as revealed by X-ray structural analyses,[16,17] it is supposed that the effective symmetry of the $(N)_4$ plane in the former mono(*R*-pn) complex is similar to the D_2 symmetry of the rectangular $(N)_4$ plane in the latter bis(*R*-pn) complex as seen through the Section *1)*. In this case, the steric interaction between the *R*-pn and ethylenediamine ligands may occur owing to the proximity between the amine protons of the ethylenediamine and the adjacent ones of the *R*-pn. Meanwhile, there may be no significant interaction in the lower C_2 symmetry complexes with nonidentical diamines having the different N–Cr–N angles as noted above, probably because the deformation of the $(N)_4$ planes from the rectangle to the trapezoid may decrease the crowding between the two diamine moieties. This interaction appears to cause restricted puckering of the ethylenediamine ring, resulting in some CD contribution from the ethylenediamine ligand to this mixed diamine complex. This seems to be the reason why the CD spectrum of *trans*-$[CrF_2(en)(R\text{-pn})]^+$ differs from one half of the CD of the bis(*R*-pn) complex and from the CD contribution of the *R*-pn to *trans*-$[CrF_2(R\text{-pn})(rac\text{-chxn})]^+$ and *trans*-$[CrF_2(R\text{-pn})(rac\text{-ptn})]^+$.

The longer wavelength CD component of *trans*-$[CrF_2(rac\text{-pn})(R,R\text{-chxn})]^+$ is more than twice as intense as that of *trans*-$[CrF_2(R\text{-pn})(rac\text{-chxn})]^+$ and *trans*-$[CrF_2(R\text{-pn})(rac\text{-ptn})]^+$ (Figs. 1 and 2). Such a difference in CD contribution between the *R*-pn and the *R,R*-chxn ligand may be understood by the differentiation between the conformational and the vicinal effect. For this purpose, it is assumed that the CD contributions of the chiral diamines consist of the conformational effect ($\Delta\varepsilon(\lambda)$ for the *R*-pn and the *R,R*-chxn ligand; $\Delta\varepsilon(\lambda')$ for the *R,R*-ptn ligand) and the vicinal effect ($\Delta\varepsilon(R)$ for all these three diamines) as expressed in the following equations,

$$\Delta\varepsilon(R\text{-pn}\cdot R,R\text{-chxn}) = 3\Delta\varepsilon(R) + 2\Delta\varepsilon(\lambda),$$

$$\Delta\varepsilon(S\text{-pn}\cdot R,R\text{-chxn}) = \Delta\varepsilon(R),$$

$$\Delta\varepsilon(R\text{-pn}\cdot R,R\text{-ptn}) = 3\Delta\varepsilon(R) + \Delta\varepsilon(\lambda) + \Delta\varepsilon(\lambda'),$$

$$\Delta\varepsilon(S\text{-pn}\cdot R,R\text{-ptn}) = \Delta\varepsilon(R) - \Delta\varepsilon(\lambda) + \Delta\varepsilon(\lambda'),$$

where the *R* configuration of asymmetric carbons requires the λ conformation due to the equatorial preference of alkyl-substituents on ligands, and $\Delta\varepsilon(R) = -\Delta\varepsilon(S)$ and $\Delta\varepsilon(\lambda) = -\Delta\varepsilon(\delta)$. From the above equations, the conformational and the vicinal CD contribution are obtained as shown in Fig. 3. The considerable CD contribution from the vicinal effect due to the *R* configuration for the *R*-pn and the *R,R*-chxn ligand leads to the difference in CD contribution between the *R*-pn and the *R,R*-chxn ligand. It is noted that the net CD signs in the first ligand field $^4T_{2g} \leftarrow {}^4A_{2g}$ transition for the conformational contributions of both the *R*-pn(*R,R*-chxn) and the *R,R*-ptn ligand are the same as each other and are opposite to those for the vicinal contributions as seen in Fig. 3. The net CD signs for the λ conformation and the *R* configuration of asymmetric carbons, negative and positive, respectively, are consistent with the predicted ones in terms of the regional (hexadecadal) rule.[18] It is considered unlikely that the conformational and the vicinal CD contribution in the mixed diamine complexes with different diamines are much different from those in the bis(*R*-pn) and the bis(*R,R*-chxn) complexes. Thus, the inconsistency in CD behavior between the mixed diamine complexes and the bis(*R*-pn), bis(*R,R*-chxn) complexes may be explained on the assumption of an additional chirality probably due to donor nitrogen atom distortions in the latter complexes. As shown in Figs. 1 and 2, the CD spectrum of *trans*-$[CrF_2(R\text{-pn})_2]^+$ is more intense than twice the CD contribution of the *R*-pn to *trans*-$[CrF_2(R\text{-pn})(rac\text{-chxn})]^+$ or the calculated CD curve contributed solely from the conformational and the vicinal effects (*i.e.*, $2\Delta\varepsilon(R)+2\Delta\varepsilon(\lambda)$), whereas the CD spectrum of *trans*-$[CrF_2(R,R\text{-chxn})_2]^+$ is less intense than twice the CD contribution of the *R,R*-chxn to *trans*-$[CrF_2(rac\text{-pn})(R,R\text{-chxn})]^+$ or the calculated CD curve (*i.e.*, $4\Delta\varepsilon(R)+2\Delta\varepsilon(\lambda)$). This observation suggests that the CD contributions from an additional chirality to the bis(*R*-pn) and the bis(*R,R*-chxn) complex are not equivalent and opposite in sign to each other; positive and negative CD being contributed to the bis(*R*-pn) and the bis(*R,R*-chxn) complexes, respectively. The regional rule predicts that such an additional CD contribution is induced by donor nitrogen atoms which are skewed away from ideal octahedral edges in such a way that they lie in the same sector as the ring alkyl group ($-CH_2CH-$) for the bis(*R*-pn) complex and as the *C*-alkyl substituents for the bis(*R,R*-chxn) complex as depicted in Fig. 4. Similar displacement of the donor nitrogen atoms in the *R*-pn complex has been found by the X-ray structural crystallography of *trans*-$[CoCl_2(R\text{-pn})_2]Cl\cdot HCl\cdot H_2O$[14] as pointed out previously.[2,19] It is likely that such a distortion arises from the steric interaction between the identical diamines in the bis(*R*-pn) and the bis(*R,R*-chxn) complex. For *trans*-$[CrF_2(en)(R\text{-pn})]^+$, which encounters a similar situation to the bis(*R*-pn) complex as noted above, the crowding between the diamine moieties may be released by shifting the conformational equilibrium of the ethylenediamine ring puckering and/or by distorting the donor nitrogen atoms. For other mixed diamine complexes with

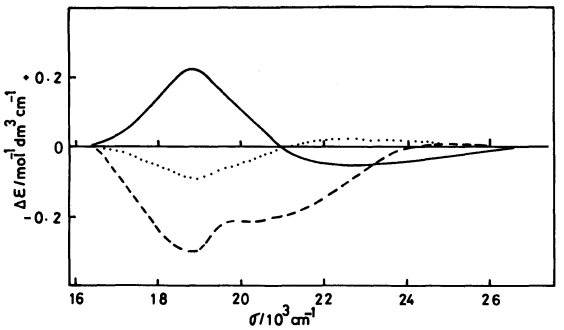

Fig. 3. The CD contribution from the vicinal effect due to the configuration of asymmetric carbons ($\Delta\varepsilon(R)$) (——); the CD contribution from the conformational effect due to five-membered chelate rings (*R*-pn and *R,R*-chxn) ($\Delta\varepsilon(\lambda)$) (·····) and of a six-membered one (*R,R*-ptn) ($\Delta\varepsilon(\lambda')$) (------).

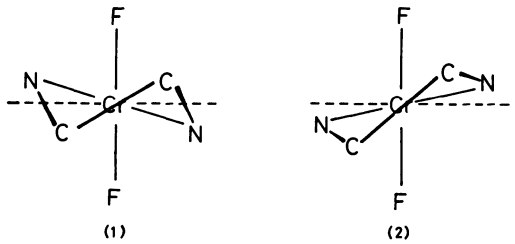

Fig. 4. Proposed donor nitrogen atom displacements from ideal octahedral edges for *R*-pn(1) and *R,R*-chxn (2) rings.

nonidentical diamines, it is plausible that there seems to be no observable CD contribution from the donor nitrogen atom distortions, because of no appreciable steric interaction between the different diamines in these complexes as mentioned above.

The author wishes to thank Prof. Yoichi Shimura of Osaka University for making the CD spectra available for this work. The present study was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

Circular Dichroism of Chromium(III) Complexes. IX. Circular Dichroism Spectra and Stereochemistry of Dinitritobis-(diamine)chromium(III) Complexes

Sumio KAIZAKI

Department of Chemistry, Faculty of Science, Nara Women's University, Nara 630

(Received May 28, 1983)

The circular dichroism (CD) spectra of optically active dinitritobis(diamine)chromium(III) complexes were measured in the visible and near-ultraviolet region, where the diamines used were ethylenediamine, trimethylenediamine, (*R*)-propylenediamine, (1*R*, 2*R*)-1,2-cyclohexanediamine, (2*R*, 4*R*)- and (2*R*, 4*S*)-2,4-pentanediamine. The stereochemistry and the conformational (rotational) isomerism of coordinated nitrito ligands were discussed on the basis of the solvent-dependent CD spectra in the near-ultraviolet region of an intraligand absorption band localized on nitrito ligands. It is proposed that the CD variation in the intraligand transition region among the complexes concerned is responsible for the chiral arrangement of nitrito ligands. Further, the conformation of trimethylenediamine chelate in the *trans*-dinitrito-(*R*)-propylenediamine complex is determined to take a chair form in comparison with the CD behavior of the corresponding (2*R*, 4*S*)-2,4-pentanediamine complex.

There have been few studies on stereochemistry of unidentate ligands in complexes. A new conformational or rotational isomerism of coordinated unidentate ligands has been first discovered for "brown" and "yellow" crystal forms of *mer*-$[Co(NO_2)_3(NH_3)(en)]$[1] and established by X-ray structural analyses.[2] Since these isomers show the identical physical properties in solution,[1] it is difficult to recognize such a conformational isomerism in solution. It has been proposed that the solvent-dependent CD variation in the first ligand field band region of some dianionotetraamine Co^{III} complexes is responsible for optical activity due to rotational conformations of unidentate aniono ligands such as NO_2^- and N_3^-.[3] However, CD spectra in the d-d band region are not appropriate for the investigation on stereochemistry of unidentate ligands in various circumstances brought about by different chelate rings, because they are susceptible to ring conformations and geometrical configurations of complexes. CD spectra associated with intraligand transitions of unidentate ligands will provide the stereochemical information about such unidentate ligands themselves. For instance, it has been found that for organic nitrites several well-defined vibronic CD peaks observed in the nitrite chromophore region (400—350 nm) are sensitive to the stereochemical environments around nitrites.[4] In the corresponding region of oxygen-bonded nitritochromium(III) complexes, some inflections of the vibronic structure overlapping with a broad absorption band envelope due to the second d-d transition have been observed in dipolar aprotic solvents; they are ascribed to the intraligand $n\rightarrow\pi^*$ transition localized on the coordinated nitrito ligands.[5] In addition to such spectral properties, taking into account the fact that nitrito Cr^{III} complexes are relatively stable and do not isomerize to N-bonded nitro complexes, the CD spectra in the intraligand transition region of these complexes may be useful for the stereochemical investigation of unidentate ligands. In a previous letter,[6] the CD spectra in the intraligand band region of optically active *cis*- and *trans*-dinitritobis(diamine)-chromium(III) complexes have been explained in terms of the chiral arrangements of nitrito ligands. In this paper, the intraligand CD spectra of mononitrito and dinitrito chromium(III) complexes of various diamines are examined in order to assess the effect of the stereochemical environment around the coordinated diamine chelate rings on the rotational isomerism of coordinated nitrito ligands, where the diamines used are ethylenediamine(en), trimethylenediamine(tn), (*R*)-propylenediamine(*R*-pn), (1*R*, 2*R*)-1, 2-cyclohexanediamine(*R*,*R*-chxn), (2*R*,4*R*)- and (2*R*,4*S*)-2,4-pentanediamine(*R*,*R*-ptn and *R*,*S*-ptn).

Experimental

Preparation of Complexes. *1)* trans-$[Cr(ONO)_2(diamine)_2]ClO_4$: *trans*-Difluorobis(diamine) complexes were obtained as starting materials by the methods described elsewhere.[7-9] These difluoro complexes were converted into *trans*-dibromobis-(diamine)chromium(III) bromides by dissolving the difluoro complexes in 3.5 M (1 M=1 mol dm^{-3}) methanolic hydrogen bromide solutions.[8] The nitrito complexes were obtained as anhydrous perchlorate salts by the reaction with lithium nitrite in weakly acidified solutions after aquating the corresponding dibromo complexes at about 60 °C for 5 min, and then by the addition of an excess amount of lithium perchlorate. The complexes were recrystallized from acetonitrile by the addition of ether.

2) trans-$[CrF(ONO)(R,R\text{-}chxn)_2]ClO_4\cdot 0.5LiClO_4$: This mono nitrito complex was prepared by a similar method to that for *trans*-$[CrF(ONO)(en)_2]ClO_4$.[10]

3) $(+)^{Ag}_{480}$-cis-$[Cr(ONO)_2(en)_2]ClO_4$ *and* $(+)^{Ag}_{480}$-cis-$[Cr(ONO)_2(tn)_2]ClO_4\cdot 0.5LiClO_4$: As starting materials, the corresponding *cis*-dichloro complexes were prepared and resolved into the optical isomers according to the reported methods.[11-13] The less soluble $(+)^{Ag}_{520}$-optical isomers of these *cis*-dichlorobis(diamine)chromium(III) 3-bromo-*d*-camphor-8-sulfonate were aquated with an appropriate amount of silver nitrate in an ice-cold solution. After silver chloride was removed, the perchlorate salts of the corresponding dinitrito complexes were isolated by the successive addition of lithium nitrite and lithium perchlorate below 5 °C. Although the racemization of these optically active *cis*-bis-(diamine) complexes should be taken into consideration, the CD intensity in the first band region is found to be comparable to that of other *cis*-$[CrX_2(en)_2]^+$ type complexes.[13] Thus, it appears that the racemization of the dinitrito complexes is not significant during the preparation.

TABLE 1. ANALYTICAL DATA OF THE COMPLEXES

The elemental analyses of the complexes are presented in Table 1.

Measurements. Absorption and CD spectra were recorded with a Shimadzu UV-200S spectrophotometer and a JASCO MOE-1 spectropolarimeter, respectively. All the solvents used are of spectrograde. The concentrations of the complexes were 2×10^{-3} to 4×10^{-3} M. CD measurements in KBr disks were carried out by a similar procedure to that of Bosnich *et al.*[14]

Results and Discussion

Stereochemistry of Nitrito Ligands. The geometrical structures of the dinitritobis(diamine)chromium(III) complexes are assigned by comparing their visible and near-ultraviolet absorption spectra with those of the known *cis*- and *trans*-dinitritobis(ethylenediamine)chromium(III) complexes;[5] the geometrical structure is retained on the anation of the corresponding diaqua complexes with nitrite ions in acidic solutions. As shown in Fig. 1, the first d-d absorption bands of *cis*- and *trans*-isomers of the complexes differ from each other, while the isomers give a similar spectral behavior in the second

d-d band region where the n→π^* intraligand transition within nitrito ligands occurs. Some characteristic inflections on this absorption band are observed for *cis*- and *trans*-dinitritobis(diamine)chromium(III) complexes in aprotic solvents such as *N,N*-dimethylformamide (DMF).[5] On their CD spectra in the region from 24000 to 30000 cm^{-1}, more marked characteristics of the intraligand transition are recognized in aprotic solvents than those on the absorption spectra.[6] The CD spectra of the complexes in DMF give more remarkable and well resolved peaks, of which each position corresponds to that of the absorption spectra as seen in Fig. 1. The absorption maxima and CD extrema consist of the progression of about 1000 cm^{-1}, originating from 25000 cm^{-1}, due to the N–O stretching vibration as found in the vibronic structure of $NaNO_2$ crystals.[15] The intensity distribution of the CD spectra is found to be in line with that of alkyl nitrites.[4] Therefore, each vibronic CD component in this region is certainly associated with the intraligand n→π^* transition of the coordinated nitrito ligands in the complexes. Figures 2—4 show the remarkable solvent-dependent variation of the CD spectra of some complexes. It is found that the intensity enhancement of the vibronic CD components is more pronounced than that of the CD in the first d-d band region. As shown in Figs. 2 and 3, a positive CD band in the second band region at about 27500 cm^{-1} for *trans*-dinitritobis(diamine) complexes in H_2O may correspond to the second ligand field ($^4T_{1g}$←$^4A_{2g}$) transition, because this lies at the expected position for the $^4E_g(D_{4h})$ component of the $^4T_{1g}$ parentage and in general *trans*-dihalogenobis(diamine)chromium(III) complexes with *R*-pn and *R,R*-ptn ligands give a positive CD component due to the second ^4E_g←$^4B_{1g}$ transition.[8] This suggests that the vibronic CD components of the *trans*-bis(*R*-pn) complex undergo sign inversions by changing the solvent from water to aprotic solvents in contrast with the CD behavior of the *trans*-bis(*R,R*-ptn) complex where no CD sign inversion occurs with solvent change. In addition to these CD behavior, the considerable CD intensity enhancement of *trans*-bis(diamine) complexes in aprotic solvents as shown in Figs. 2 and 3 will also support the exclusive contribution of optical activity associated with the intraligand transition within nitrito ligands to the vibronic CD components.

It is noted that the signs of the intraligand CD spectra for the *trans*-bis(*R*-pn) and -bis(*R,R*-ptn) complexes are opposite to each other though the diamines have the same absolute configuration, and also that the CD behavior of the $(+)^{\Delta\varepsilon}_{480}$-*cis*-bis(en) complex differs from that of the $(+)^{\Delta\varepsilon}_{480}$-*cis*-bis(tn) complex as well as that of the *trans*-bis(diamine) complexes as seen in Figs. 2—5. Such differences in intraligand CD among these complexes may be attributed to the different stereochemical environment experienced by nitrito ligands in the complexes. There are two possible coordination modes of unidentate nitrito ligands with respect to the rotation about the (O)N–O(Cr) bond. As revealed in $[Cr(ONO)(NH_3)_5](ClO_4)_2$ and other nitrito metal complexes by X-ray structural analyses,[16,17] a nitrito ligand in a

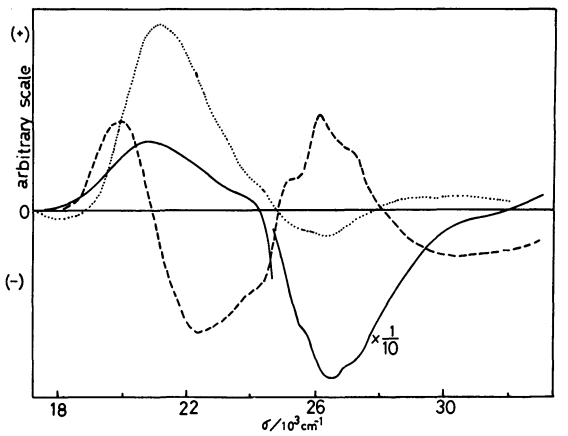

Fig. 6. CD curves of *trans*-$[Cr(ONO)_2(R\text{-pn})_2]ClO_4$ (——), *trans*-$[Cr(ONO)_2(R,R\text{-ptn})_2]ClO_4$ (------), and $(+)^{A}_{480}$-*cis*-$[Cr(ONO)_2(en)_2]ClO_4$ (·····) in a KBr disk.

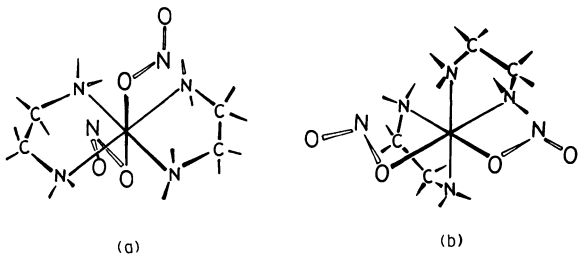

Fig. 7. Proposed configurations due to rotamer conformations of two nitrito ligands in (a) *trans*-$[Cr(ONO)_2(R\text{-pn})_2]ClO_4$ and (b) $(+)^{A}_{480}$-*cis*-$[Cr(ONO)_2(en)_2]ClO_4$ with a $\Lambda(\delta\delta)lel_2$ configuration. The methyl group of *R*-pn and all protons are omitted for clarity.

complex prefers the trans form to the cis one, minimizing the steric interaction with the amine ligands. With this coordination mode, the rotation of nitrito ligands about the Cr–O(NO) bond seems to have immediate influence on optical activity of the intraligand transition localized on nitrito ligands. Restricted rotation can form rotamers of different conformations at equilibrium and can produce new chirality with respect to the whole molecule, while complete free rotation can contribute little to optical activity. In the latter case, the intraligand transition acquires the rotational strength only through so-called "vicinal effect" which originates from the chiral diamine chelates. It is probable that the equilibrium of such rotamers depends on a given stereochemical circumstance around nitrito ligands. The interaction between the nitrito ligands and the diamine chelate rings in dinitritobis(diamine) complexes may play an important role in the formation of the predominant rotamer conformations for nitrito ligands. It has been found in *trans*-$[Ni(ONO)_2(Me_2NC_2H_4NH_2)_2]$ and -$[Zn(ONO)_2(Me_2NC_2H_4NH_2)_2]$ by X-ray analyses[18,19] that the nitrito nitrogen atoms are located around the amine nitrogen atoms in which the nearest protons are equatorial. This suggests that the congestion brought about by the diamine chelate rings around the nitrito ligands is released in the neighbourhood of the amino equatorial NH protons where the predominant rotamers can settle beacause the equatorial protons are more distant from the nitrito nitrogen atoms than the axial protons; thus the steric interaction between them decreases. In view of the fact that the intraligand CD spectrum in a KBr disk of *trans*-$[Cr(ONO)_2(R\text{-pn})_2]ClO_4$ is about ten times as intense as the CD in the first d-d band region as shown in Fig. 6, the nitrito ligands are expected to take a chiral configuration. It is supposed that in the solid state of this complex two nitrito ligands are arranged in such a way that their nitrogen atoms are located near the NH equatorial protons of (*R*)-propylenediamines with the λ ring conformation as shown in Fig. 7. Since such an arrangement results in configurational chirality with respect to the intraligand transition of nitrito ligands, the CD intensity in this region is expected to be enhanced. On the other hand, according to the empirical method based on the CD in the first d-d band region,[13a] $(+)^{A}_{480}$-*cis*-$[Cr(ONO)_2(en)_2]ClO_4$ is assumed to take a Λ absolute configuration, presumably with a stable $\delta\delta(lel_2)$ conformation of the ethylenediamine rings. Then, the location of the nitrito nitrogen atoms in the vicinity of the NH equatorial protons for the ethylenediamine chelates gives rise to the achiral configuration in which two nitrito ligands lie in the same plane as the CrN_2O_2 one as depicted in Fig. 7. The proposed rotamer configuration is deduced from the fact that the intraligand CD of $(+)^{A}_{480}$-*cis*-bis(en) complex perchlorate in a KBr disk is much weaker than the CD in the first d-d band region as shown in Fig. 6.

In solution, the solvent effect on the distribution of the rotamer conformations must be taken into account, since the intraligand CD spectra of the present complexes vary remarkably with solvent as compared with the CD in the first d-d band region. As shown in Figs 2—4, the fine structures of the CD spectra in the corresponding region become more resolved, sharper, and more amplified with solvent in the order, formamide< *N*-methylforamide(NMF)<DMF< *N*,*N*-dimethylacetamide (DMA). This order for the CD variation is in accordance with the increasing order of the donor number of solvents,[20] and is similar to the order derived from the solvent-dependent CD and NMR study of cobalt(III) complexes by Hawkins *et al.*[21] They postulated the stereoselective solvation to the amino NH equatorial protons in the complexes. As shown in Figs. 2 and 3, more marked CD enhancement is observed in DMA than in DMF, though the donor number of

DMA (27.8) is not much different from that of DMF (26.6). This implies that the bulkiness as well as the donor number of the solvents is responsible for the optical activity associated with the intraligand transition in nitrito ligands, solvation in DMA being more stereoselective. As proposed for the solvent-dependent CD spectra of cobalt(III) complexes,[3] such stereoselective solvation in the present complexes will form more chirally defined second coordination spheres and will assist more restricted rotation of nitrito ligands in making their predominant rotamer conformations in the increasing order of the bulkiness as well as the donor number of the solvents, enhancing optical activity in the intraligand transition region. In acetonitrile, the intraligand CD spectrum of the *trans*-bis(*R*-pn) complex is similar to that in DMF, whereas the *trans*-bis(*R,R*-ptn) complex gives a quite different CD pattern in this solvent from that in DMF as shown in Fig. 3. In the last case, the CD diminishes considerably, but still exhibits the prominent vibronic structure. This fact together with the sign inversion of the intraligand CD behavior for the *trans*-bis(*R*-pn) and the *trans*-bis(*R,R*-ptn) complex reflects a subtle difference in the stereochemical circumstance containing the first solvation sphere around nitrito ligands between these complexes. The different disposition of the amino NH equatorial protons in the complexes may impose the different orientation of higher order on the solvent molecules or may cause the formation of different chirally defined second coordination spheres. Judging from the fact that the intraligand CD intensity of the *trans*-bis(diamine) complexes in aprotic solvents is much stronger than that in water and that of the optically active *cis*-bis(diamine) complexes in aprotic solvents, chiral configurations caused by restricted rotation of two nitrito ligands in the *trans*-bis(diamine) complexes as in the case of the solid state may be retained to some extent even in solutions. This postulate is confirmed by comparing the CD intensity of *trans*-$[CrF(ONO)(R,R\text{-chxn})_2]^+$ with that of *trans*-dinitritobis(*R,R*-chxn) complex in DMF. The CD spectrum of the mononitrito complex is found to be much weaker by about one sixth than that of the dinitrito complex as shown in Fig. 8. A comparison of the CD for *trans*-$[Cr(ONO)_2(en)(R\text{-pn})]^+$ and -$[Cr(ONO)_2(en)(R,R\text{-ptn})]^+$ with that for *trans*-$[Cr(ONO)_2(R\text{-pn})_2]^+$ and -$[Cr(ONO)_2(R,R\text{-ptn})_2]^+$, respectively, also ensures the chiral arrangement of two nitrito ligands in the complexes; *i.e.*, the intraligand CD intensities of the mono(*R*-pn) and mono (*R,R*-ptn) complexes are not half but about one fourth as weak as those of the corresponding *trans*-bis(*R*-pn) and -bis(*R,R*-ptn) complexes as seen in Figs. 2, 3, 9, 10. These findings are contrary to the anticipation that the vicinal CD contribution from the chirality in diamine ligands (configurations of asymmetric carbons and conformations of chelate rings) is proportional to the number of chiral ligands and/or nitrito chromophores in the absence of the chirality due to the rotational arrangements of two nitrito ligands.

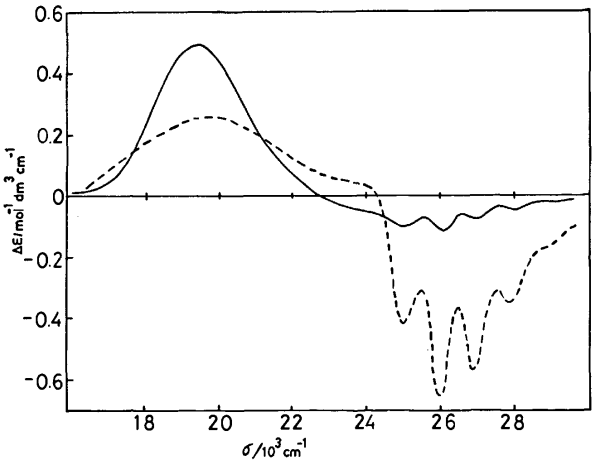

Fig. 8. CD curves of *trans*-$[CrF(ONO)(R,R\text{-chxn})_2]ClO_4$ (——) and *trans*-$[Cr(ONO)_2(R,R\text{-chxn})_2]ClO_4$ (------) in DMA.

Even though the rotamer conformations of the nitrito ligands in the complexes in solutions are much less rigid and much more flexible than in the solid state, it might be expected that due to the intra- and intermolecular interactions of nitrito ligands with diamine chelates and/or the solvation molecules the most probable location of nitrito ligands at equilibrium is in the neighbourhood of amino nitrogen atoms along the line connecting between equivalent symmetry-related (by a C_2 axis) NH equatorial protons where nitrito ligands would

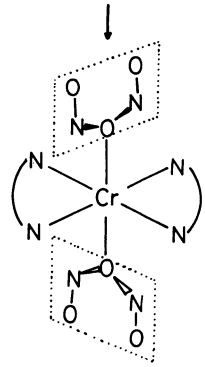

Fig. 11. The most probable paired locations of nitrito ligands at two equivalent symmetry-related sites near equatorial NH protons of diamines; the disorder over the pairs results in forming the planes.

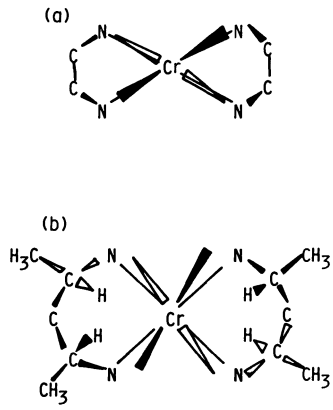

Fig. 12. View along the (ON)O–Cr–O(NO) bond axis from the arrow of Fig. 11 for *trans*-bis(*R*-pn) complex (a) and *trans*-bis(*R*,*R*-ptn) complex (b); the shaded and open elongated triangles indicate the upper and lower nitrito ligands, respectively.

rotate more sluggishly and reside for a longer time than anywhere else. In other words, it seems that the time-averaged orientation of two nitrito ligands results in the formation of two planes as shown in Fig. 11. Non-orthogonality and non-coplanarity of the two planes are expected to induce a new chirality. Construction of molecular models shows that the dihedral angles between the planes are sensitive to the N–Cr–N chelate angles of diamines and/or the crowding brought about by the chelate ring backbone. For the *trans*-bis(*R*-pn) complex, the dihedral angles may be smaller than 90°, because the chelate N–Cr–N angles of five-membered diamine rings are usually about 85°. On the other hand, the *trans*-dinitritobis(*R*,*R*-ptn) complex may give the angle of larger than 90°, due mainly to the steric interaction between the nitrito nitrogen atoms and the axially oriented protons on 2- and 4-carbons of the skew boat *R*,*R*-ptn chelate ring by which the nitrogen atoms might be pushed away from over the chelate plane as shown in Fig. 12. Then such chiral arrangements composed of the nitrito ligand planes in the *R*-pn and *R*,*R*-ptn complexes have the enantiomeric relation to each other in an approximate manner as depicted in Fig. 12. Thus, it is plausible that this enantiomeric pair causes

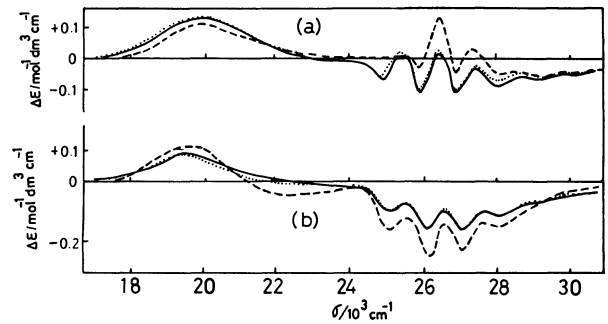

Fig. 13. CD curves of *trans*-[Cr(ONO)$_2$(tn)(*R*-pn)]ClO$_4$ (——) and *trans*-[Cr(ONO)$_2$(*R*-pn)(*R*,*S*-ptn)]ClO$_4$ (·····), and the CD curves calculated by Eq. 1 for *trans*-[Cr(ONO)$_2$(*R*-pn)(*rac*-ptn)]$^+$ (------) in DMA (a) and in acetonitrile (b).

the sign inversion of the intraligand CD components between the *R*-pn and *R*,*R*-ptn complexes.

Conformation of Diamine Chelates. In order to examine the additivity of the CD contributions from the different chiral diamines in a complex and to reveal ethylenediamine and trimethylenediamine chelate ring conformations in the mixed diamine complexes in aprotic solvents, the CD curves of *trans*-[Cr(ONO)$_2$-(*R*-pn)(*rac*-ptn)]$^+$ and -[Cr(ONO)$_2$(*rac*-pn)(*R*,*R*-ptn)]$^+$ are calculated by using the following equations:

$$\Delta\varepsilon(R\text{-pn}\cdot rac\text{-ptn}) = 1/2\{\Delta\varepsilon(R\text{-pn}\cdot R,R\text{-ptn}) - \Delta\varepsilon(S\text{-pn}\cdot R,R\text{-ptn})\}, \quad (1)$$

$$\Delta\varepsilon(rac\text{-pn}\cdot R,R\text{-ptn}) = 1/2\{\Delta\varepsilon(R\text{-pn}\cdot R,R\text{-ptn}) + \Delta\varepsilon(S\text{-pn}\cdot R,R\text{-ptn})\}. \quad (2)$$

As shown in Fig. 13, the CD curves of *trans*-[Cr(ONO)$_2$-(tn)(*R*-pn)]$^+$ in acetonitrile and DMA are almost identical with those of *trans*-[Cr(ONO)$_2$(*R*-pn)(*R*,*S*-ptn)]$^+$ in those solvents, respectively, but not with those of *trans*-[Cr(ONO)$_2$(*R*-pn)(*rac*-ptn)]$^+$. This means that the ring conformation of the coordinated trimethylenediamine in the dinitrito complex takes the same chair form as that in the *R*,*S*-ptn complex as has been revealed from the CD study of *trans*-difluorobis(diamine) complexes.[7] It appears that the CD difference in the intraligand band region between the *rac*-ptn and *R*,*S*-ptn (or tn) dinitrito complexes reflects the subtle difference in the first and/or the second coordination sphere arising from the skew boat and chair conformations of the six-membered chelate rings. The CD curve calculated by Eq. 2 in acetonitrile is similar to the CD curve of *trans*-[Cr(ONO)$_2$(en)(*R*,*R*-ptn)]$^+$, but the CD of this ethylenediamine complex in DMA differs from the calculated one of the *rac*-pn complex with *R*,*R*-ptn in DMA as shown in Fig. 14. In view of this fact, the ethylenediamine chelate ring in the *trans*-dinitrito complex in acetonitrile may have the same conformation as the *rac*-propylenediamine in *trans*-[Cr(ONO)$_2$(*rac*-pn)-(*R*,*R*-ptn)]$^+$; free puckering of the ethylenediamine may occur in acetonitrile as found for the CD spectrum of *trans*-[CrF$_2$(en)(*R*,*R*-ptn)]$^+$ in water.[7] In DMA, it is likely that the stereoselective solvation of bulky DMA with the amine NH protons gives rise to the displacement of the conformational equilibrium of the ethyeledi-

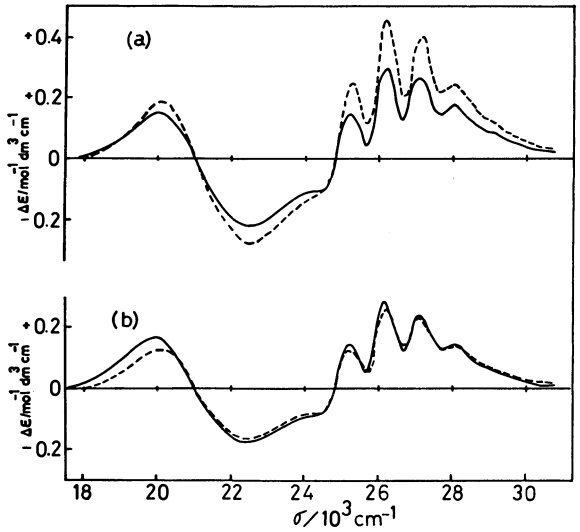

Fig. 14. CD curves of *trans*-[Cr(ONO)$_2$(en)(*R*,*R*-ptn)]-ClO_4 (——) and the CD curves calculated by Eq. 2 for *trans*-[Cr(ONO)$_2$(*rac*-pn)(*R*,*R*-ptn)]$^+$ (------) in DMA (a) and in acetonitrile (b).

amine ring puckering in *trans*-[Cr(ONO)$_2$(en)(*R*,*R*-ptn)]$^+$. In other words, the CD contribution from different diamines to *trans*-dinitrito mixed diamine complexes with nonidentical diamines are separable and additive in acetonitrile but not in DMA.

The author wishes to express his thanks to Prof. Yoichi Shimura of Osaka University for the guidance of this study and for making the CD spectra available for the present work. This study was supported by a Grant-in-Aid for Scientific Research No. 354223 from the Ministry of Education, Science and Culture.

Development of Hydrogen Ion Selective Electrode with Lithium Phosphate Glasses for the Use in Solutions Containing Hydrofluoric Acid

Tsuyoshi NOMURA* and Genkichi NAKAGAWA
Laboratory of Analytical Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya, 466
(Received June 2, 1983)

In order to determine reproducible and stable potential response conditions of the hydrogen ion in hydrofluoric acid solutions, lithium phosphate glass membranes of various constituents were developed. The glass membranes contained various metal oxides: Ag_2O, Li_2O, P_2O_5, MgO, BeO, WO_2, and Al_2O_3. The response characteristics of the glass electrode depend strongly on the glass compositions. For the examination of the selectivity coefficient and the electrode function of hydrogen ion activities, the glass composition of 10 Ag_2O : 20 Li_2O : 50 P_2O_5 : 10 MgO : 10 WO_2 is the most suitable one. The potential response is linear over the hydrogen ion activities of ($10^{0.3}$—10^{-4}) mol/dm^3, and has a slope of 44.5 mV/decade change in the hydrogen ion activity at 20 °C. The dynamic response time was within a minute in the range 10^{-1} to 10^{-4} mol/dm^3. The intereference of the various cations on the activity of about 0.1 mol/dm^3 can be ignored during the determination of the hydrogen ion activities at pH below 3. Physical and chemical properties, such as glass transition temperature, softening temperature, thermal expansion, membrane resistance, and chemical durability were measured and compared with those of other glasses.

It is well known that various types of the ion selective glass electrode are available; almost all of these are made of alkali silicates.[1,2] However, these electrodes show a serious disadvantageous point: They are earsily corroded chemically by hydrofluoric acid. Some anomalous behavior of the common glass electrode in solutions containing hydrofluoric acid has been discussed.[3] In the hydrofluoric acid solution, the hydrogen ion activities have been measured with a metallic antimony electrode or the cation exchange membrane electrode.[4]

Phosphate glasses containing iron oxide[5] have been investigated as materials of the cation selective membrane electrode for alkaline earth cations. Moreover, it is known from the literature[6] that the glasses made from aluminium and lithium metaphosphate were studied and their potential responses to hydrogen ions were found. However, the chemical durability and the dependence of the potential response in the hydrofluoric acid solutions have not been published in detail.

We have already studied the properties of alkali-free magnesium phosphate glasses and their application to the ammonia selective electrode.[7] In the present work, we studied the physical and chemical properties of the lithium phosphate glasses containing various metal oxides, such as Ag_2O, MgO, BeO, WO_2, and Al_2O_3, and the application of the electrode membrane to determine the hydrogen ion activities in the hydrofluoric acid solution.

Experimental

Preparation of the Glass Membrane. Orthophosphoric acid (85%), silver carbonate, lithium carbonate, tetramagnesium tricarbonate dehydroxide, tungsten dioxide, aluminium hydroxide, and beryllium oxide were used to prepare the glasses. All the chemical except silver carbonate were of a reagent grade. The preparation procedures of the phosphate glasses and the glass membrans have been described previously.[7] The chemical compositions of some of the tested glasses are shown in Table 1.

Glass Transition Temperature, Softening Temperature, and Thermal Expansion of Lithium Phosphate Glasses. Glass transition temperature (T_g, °C) softening temperature (T_s, °C) and thermal expansion (α, cm °C^{-1}) were measured with a Shimadzu TM-30 type dilatometer. All dilatometer measurements were carried out at 3 °C/min of the sample heating rate.

Chemical Durability and Membrane Resistance of the Glasses. The chemical durability of the tested glasses was measured by the following method. A glass film (surface area, about 3×10^2 mm^2) was weighted and placed in a 100 ml portion of 0.5 mol/dm^3 hydrofluoric acid and 0.6 mol/dm^3 sulfuric acid mixtures, allowed to stand for 60 d at about 30 °C, and the weight loss per unit area of the glass membrane was measured.

The resistance of the lithium phosphate glass membrane was measured by a Toa Denpa SM-9E type megaohm meter, because the resistance of the tested glass membrane is relatively low compared to that of the alkali silicate glasses.

Measurements of the Membrane Potentials. The glass elec-

trode was prepared by tightening the glass disk with a Silicone rubber O-ring and a plastic holder at the end of the cyclindrical plastic tube, which was filled with 0.1 mol/dm^3 $NaNO_3$ solution. The Ag/AgCl reference electrode was a double junction type, DKK 4400, with a salt bridge of 0.1 mol/dm^3 $NaNO_3$ internal solution; the acid error of the reference electrode is removed.

Figure 1 shows the completed assembly of the electrode system for the determination of hydrogen ion activity. The responses of each glass membrane were observed by measuring the potential *vs.* a Ag/AgCl reference electrode with a DKK IOC-10 ion-meter connected with a Sekonic model SS-250F recorder. In order to obtain a reproducible electrode potential, the electrodes were polished with waterproof silicon carbide paper No. 1000, and then preconditioned before use in distilled water for 1 d. The hydrogen ion activities for the proper quantities of nitric acid or nitric acid in the solution containing hydrofluoric acid and sodium nitrate mixtures were measured with a commercially available pH electrode, and then the electrode potentials which has been measured by the glass membranes tested in the same composition of the solutions were converted into the hydrogen ion activities. The activities of various cations except for hydrogen ion were calculated from the concentration by means of the activity coefficients tabulated by Kielland.[8]

Results and Discussion

Physical and Chemical Properties of Glasses. Some physical and chemical properties, such as glass transition temperature, softening temperature, thermal expansion, membrane resistance, and chemical durability of some lithium phosphate glasses in hydrofluoric acid solution are summarized in Table 2.

When we compared the values of T_g and T_s of those of the tested glasses and the usual silicate glasses, the tested glasses showed much lower values. However, all the values of the thermal expansion among these glasses were very similar.

When some Ag_2O is included in the glass constituents, the mixtures are easily glass forming, and show very low resistance.[9] However, the presence of Al_2O_3 has a negative effect on the chemical durability and the glass completely dissolved after standing for 60 d. The tested glasses which contain MgO or WO_2 were found to be more soluble in the hydrofluoric acid solution, but the glasses containing both MgO and WO_2 gave better results as for the chemical durability. Contrary to this result, however, the glasses containing both MgO and WO_2 increased in membrane resistance.

Potential Response of the Lithium Phosphate Glass Membranes. Figure 2 shows the potential response of the $10Ag_2O : 50P_2O_5 : 20Li_2O : 10MgO : 10WO_2$ glass membrane (Glass No. 4) to hydrogen ion activities in the solution containing 0.01 mol/dm^3 sodium nitrate and 0.05 mol/dm^3 hydrofluoric acid.

The potential response for the two experimental conditions was observed on the same calibration curve. The response for the hydrogen ion activity was linear over the range of ($10^{0.3}$—10^{-4}) mol/dm^3. The average slope was computed as 44.5 mV/decade change at 20 °C. Responses of the electrodes are reproducible, and electrode potentials are the same within 2 mV. The dynamic response time[10] for the change of the hydrogen ion activity was within a minute in the range 10^{-1} to 10^{-4} mol/dm^3, but was a few minutes above 10^{-1} mol/dm^3. Therefore, the steady state is defined as a potential stable to less than 1 mV drift in 2 min.

At the hydrogen ion activities below 10^{-6} mol/dm^3, however, the slope of the electrode potential *vs.* hydrogen ion activities falls to almost zero, and the electrode ceases to be functional. The tested glass membranes responded to the hydrogen ion activities within a certain range, but the slope was smaller than the value predicted by the Nernst expression.

From the dissociation constant[11] of the hydrofluoric acid, $a_{H^+} \cdot a_{F^-}/a_{HF} = 10^{-3.2}$, the hydrofluoric acid mole-

7	21.3	—	—	—	—	—

cules exist at pH values below 3.0. Therefore, when the measurements of the pH value are performed with a commercially available pH electrode in the hydrofluoric acid solution, a reproducible electrode potential cannot be expected over long times, due to the dissolution of the electrode surface. However, the electrode potentials of the lithium phosphate glasses are more stable and reproducible than that of the alkali silicate glasses.

Response Behavior of Glass Membrane of Various Compositions. The response characteristics of lithium phosphate glass electrodes depend upon the glass composition. Therefore, the experiments of the electrode response were carried out with the glasses containing fixed quantities of P_2O_5 at 50 mol% and a varied quantities of the other metal oxide.

The glasses not containing Ag_2O show a small potential response to hydrogen ion activity and an unstable electrode potential in the hydrofluoric acid solution. Therefore, the presence of Ag_2O in the glass structure may contribute to the greater mobility of cations in the glass membrane and to the reproducibility of the electrode potential.[2] However, the presence of Al_2O_3 decreases the chemical durability in the hydrofluoric acid solution and the glass electrode is not responded to the hydrogen ion activities for the same behavior as in the case of silicate glasses.[12]

The electrode function of the hydrogen ion activities and the selectivity coefficients of the other cations for the lithium phosphate glass electrodes are shown in Table 3.

Selectivity Coefficient of Hydrogen Ion for the Other Cations. The interferences of various cations on the concentration of about 0.1 mol/dm^3 can be ignored for the measurement of the hydrogen ion activities at pH values below 3.

The selectivity coefficients of lithium phosphate glass electrodes with respect to a number of cations were determined by the mixed solution method.[13] Values of the selectivity coefficient are obtained by measuring the electrode potential in solutions containing fixed quantities of the interfering ion (0.1 mol/dm^3) and a varied activity of the hydrogen ion.

It is apparent that the selectivity coefficients for the interfering cations and the electrode function of hydrogen ion activities are better for glass electrode No. 4 than the others.

We wish to thank Prof. Yoshihiro Abe for his valuable advice.

An X-Ray Diffraction Study on the Structures of Mono(glycinato)nickel(II) and Tris(glycinato)nickelate(II) Complexes in Aqueous Solution

Kazuhiko Ozutsumi and Hitoshi Ohtaki*

Department of Electronic Chemistry, Tokyo Institute of Technology at Nagatsuta, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received June 15, 1983)

The structures of mono(glycinato)nickel(II) and tris(glycinato)nickelate(II) complexes in aqueous solution were determined by the X-ray diffraction method. From the analysis of the radial distribution curve of solution A, in which the hexaaqua- and mono(glycinato)nickel(II) ions coexisted (the mole ratio $C_{gly}/C_{Ni}=0.792$, where C_i denotes the total concentration of species i), we found that the mono(glycinato)nickel(II) complex combined with four water molecules at the distance of (2.08±0.01) Å, the bond being longer than the Ni–OH_2 bond (2.04 Å) within the $[Ni(OH_2)_6]^{2+}$ ion. The Ni–O and Ni–N bond lengths within the mono(glycinato)nickel(II) complex were essentially the same and (2.09±0.02) Å. Therefore, the mono(glycinato)nickel(II) ion has a practically regular octahedral structure. The nonbonding Ni···C distance was also determined to be (2.87±0.02) Å. The X-ray scattering data of solutions having the C_{gly}/C_{Ni} mole ratio of 3.24 (solution B) and 3.94 (solution C), in both of which almost all nickel(II) ions formed the $[Ni(gly)_3]^-$ complex, showed that the tris(glycinato)nickelate(II) complex had a slightly distorted octahedral structure with the Ni–O and Ni–N bond lengths of (2.03±0.01) Å and (2.14±0.01) Å, respectively. The nonbonding Ni···C(COO), Ni···$C(CH_2)$ and Ni···O(O=C) distances were (2.82±0.02) Å, (2.96±0.02) Å, and (4.07±0.03) Å, respectively.

Structures of chelate compounds of some transition metal ions were first determined for ethylenediamine complexes in aqueous solutions.[1-4] The chelate effect on the formation of the ethylenediamine complexes was discussed in connection with the structural data of the complexes determined by the X-ray diffraction experiments by comparing them with the structures of ammine complexes of the relevant metal ions.[5]

A large number of crystallographic data have been accumulated for aminocarboxylato complexes.[6] However, compounds so far studied by the X-ray crystallography were mostly non-charged ones, which were relatively easy to prepare single crystals. Therefore, usually the structure of only one compound has been known in a series of compounds of a metal ion having one kind but different numbers of ligands. In X-ray analysis of solutions a restriction of preparing a single crystal is eliminated, although another restriction for solubility of compounds may be introduced, instead.

Glycine is one of the most interesting and important compounds among chelating reagents. It is the most fundamental unit in the formation of proteins. Some metal ions, which react as catalysts in biochemical reactions, are often combined with amino acid residues within proteins. Therefore, structural data of aminocarboxylato complexes must be very important in elucidating mechanisms of biochemical reactions.

In the present study we aimed at determining the structures of the mono(glycinato)nickel(II) and tris(glycinato)nickelate(II) complexes in aqueous solution by the X-ray diffraction method. The bis(glycinato)nickel(II) complex is not soluble enough to determine the structure in an aqueous solution; instead, the structure has been determined in crystal.[7]

Experimental

Preparation and Analysis of Sample Solutions. All chemicals used were of reagent grade. Since it was difficult to achieve a high value of the average ligand number of the nickel(II)–glycine solutions by adding glycine to a nickel(II) salt solution at a high pH, we mixed diaquabis(glycinato)nickel(II) with sodium glycinate in water at a suitable pH for preparing solutions in which the tris(glycinato)nickelate(II) complex formed as the main species (solutions B and C). A solution of a relatively low ligand number, in which the mono(glycinato)nickel(II) complex was formed as a predominant species, was prepared by mixing a nickel(II) nitrate solution with crystals of the bis(glycinato)nickel(II) complex (solution A).

Bis(glycinato)nickel(II) was prepared by dissolving freshly precipitated nickel(II) carbonate to an aqueous glycine solution, and then recrystallized from water. *Sodium glycinate* was obtained by mixing sodium hydroxide and glycine in methanol and then recrystallized from methanol. *Nickel(II) nitrate* of reagent grade was recrystallized from water.

The total concentration of nickel(II) ions (C_{Ni}) in the sample solutions was gravimetrically determined as bis(dimethylglyoximato)nickel(II). The total glycine concentration (C_{gly}) of the solutions was determined by the Kjeldahl method. Concentrations of nitrate ions in solution A and of sodium ions in solutions B and C were estimated from the material balance of ions in the solutions. Densities of the sample solutions were measured pycnometrically. The composition of the solutions is given in Table. 1.

X-Ray Scattering Measurements. X-Ray scattering measurements were carried out with a JEOL θ-θ diffractometer by using

Table 1. The composition (mol dm^{-3}) and stoichiometric volume V per nickel atom in the solutions

	A	B	C

Mo $K\alpha$ radiation (λ=0.7107 Å) in a room thermostated at (25±1) °C. The accessible range of scattering angle (2θ) was 2—140°. Times requiring to accumulate 120000 counts were recorded at each angle of measurements. The method of measurements and data treatments were described in previous papers.[1-5,8,9] All calculations were performed by using programs KURVLR[10] and NLPLSQ.[11] Computers at the Tokyo Institute of Technology was mainly used, but a part of the computation was carried out at the Institute for Molecular Science in Okazaki.

Results and Discussion

According to the stability constants of nickel(II)–glycine complexes[12] and the low solubility of the bis(glycinato)nickel(II) (about 0.12 mol dm^{-3}) so far reported in the literature, we can expect that comparable amounts of $[Ni(OH_2)_6]^{2+}$ and $[Ni(gly)]^+$ ions coexist in solution A, while almost all nickel(II) ions are present as the $[Ni(gly)_3]^-$ complex in solutions B and C. In solution B the concentration of sodium ions is smaller than that in solution C, and therefore, the C_{H_2O}/C_{Na} ratio in the former solution is about a double of that in the latter (see Table 1).

The observed $s\cdot i(s)$ and $D(r)$ curves of the solutions are shown in Figs. 1 and 2, respectively.

The structure of glycine has been determined crystallographically.[13,14] Since the intramolecular bond lengths within the glycinate ion in the bis(glycinato)nickel(II) are essentially the same as those in glycine, we assumed that the intramolecular bond distances within the glycinate ions coordinated to the central nickel(II) ion were independent of the complexes and the same as those reported in the literature.[7,13,14] The parameter values of water molecule, glycinate and nitrate ions used for the computations are summarized in Table 2. The numbering of the atoms within the glycinate ion coordinated to the nickel(II) ion is shown in Fig. 3.

Solution A. According to the stability constants of the nickel(II)–glycine complexes in the literature,[12] approximately the same amounts of $[Ni(OH_2)_6]^{2+}$ and $[Ni(gly)]^+$ ions may be formed in this solution. However, it should be noted that the stability constants determined in relatively dilute solutions may not be correctly applicable to calculations of distributions of the $[Ni(OH_2)_6]^{2+}$ and $[Ni(gly)]^+$ complexes in a concentrated solution like the sample solution in the present study.

The radial distribution curve of solution A is given in Fig. 2A. Figure 4 also represents the $D(r)$ function and the differential radical distribution curve, $D(r)-4\pi r^2\rho_0$, of solution A, where ρ_0 denotes the average scattering density in the stoichiometric volume V of the solution per Ni atom, as well as theoretical peak shapes of each atom pair in the system, for which we will discuss in the following section.

The broad and small peak around 1.3 Å observed in the $D(r)$ and $D(r)-4\pi r^2\rho_0$ curves (Fig. 4, a and e, respectively) is due to the O–H bonds within water molecules, the N–O bonds within nitrate ions and the N–H, C–H, C_1–C_2, C_2–N, $C_1\cdots O_1$, and $C_1\cdots O_2$ bonds within glycinate ions. The second peak at 2.1 Å is attributed to interactions between nickel and ligand atoms in the first coordination shell of the complexes. Nonbonding $C_1\cdots N$, $C_2\cdots O_1$, $C_2\cdots O_2$, and $O_1\cdots O_2$

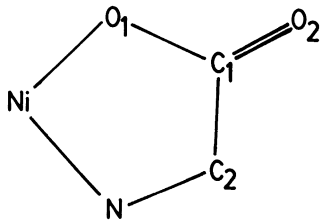

Fig. 3. The numbering of the atoms within the glycinate ion coordinated to the nickel(II) ion.

interactions within glycinate ions and O...O interactions within nitrate ions may also contribute, in part, to the peak (see Fig. 4, b—d). The third peak appearing at about 2.9 Å may be composed of peaks owing to nonbonding Ni⋯C_1 (and also Ni⋯C_2) pairs within the mono(glycinato)nickel(II) complex, interactions between the ligand atoms in the first coordination sphere of the complex, and to the O⋯O contacts in the bulk water.

The peak at 2.1 Å was well explained by assuming that all nickel atoms in the solution have six oxygen and nitrogen atoms in the first coordination sphere, independent of the concentration ratio of the $[Ni(OH_2)_6]^{2+}$ to $[Ni(gly)]^+$ ions. Since the Ni–O_1 and Ni–N bonds are hardly distinguishable by the X-ray diffraction analysis as previously pointed out,[3] the result suggests that all nickel(II) ion in the solution have six ligand atoms and thus the $[Ni(gly)]^+$ complex should have additional four oxygen atoms in its first coordination sphere at the distance of about 2.1 Å. Therefore, we can conclude that the mono(glycinato)nickel(II) complex is described as $[Ni(gly)(OH_2)_4]^+$ and has an almost regular octahedral structure.

In order to refine the structural parameters of the mono(glycinato)nickel(II) ion in the solution, we first assumed that concentrations of both the $[Ni(OH_2)_6]^{2+}$ and $[Ni(gly)(OH_2)_4]^+$ ions are 50 mol%, and the least-squares method was employed to the refinement of the

Table 3. Results of the least-squares refinements of solution A

Parameter values refined were bond distances (r/Å) and temperature factors (b/Å^2). Standard deviations are given in parentheses.

Interaction	Parameter	A-I (s>4.5 Å^{-1})	A-II (s>7.0 Å^{-1})
Ni–OH_2	r	2.08 (1)	2.08 (1)

a) The values were kept constant during the calculation.

structural parameters of the $[Ni(gly)(OH_2)_4]^+$ ion at the fixed composition of the solution. In this calculation the structural parameters of the $[Ni(OH_2)_6]^{2+}$ ion were quoted from the work by Ohtaki *et al.*[15] and fixed at the literature values. The structural parameters of the bulk water were taken from the work by Narten.[16]

Two types of the least-squares method were carried out in the present case (Table 3). In the A-I type calculation, the intensity data in the range s>4.5 Å^{-1} were used and the contribution of the O⋯O contacts in the bulk water was taken into account in the course of the refinement. On the other hand, in the A-II calculation the O⋯O interactions in the bulk water were not taken into consideration, and the intensity data used for the calculation were those in the range s>7.0 Å^{-1}, where the long-range interactions did not significantly contribute to the calculation. Since oxygen and nitrogen atoms have similar scattering factors over the whole angle range, the lengths of the Ni–O_1 and Ni–N bonds were not determined separately with reasonable certainties by the least-squares method. Therefore, we assumed that the Ni–O_1 and Ni–N bonds have the same structural parameters in the present stage of calculations. The results obtained by the A-I and A-II type calculations were very similar (see Table 3), and thus the Ni–OH_2 bond length within the $[Ni(gly)(OH_2)_4]^+$ complex was determined to be 2.08 Å and the lengths of the Ni–O_1 and Ni–N bonds were estimated to be 2.09 Å. Even if we changed the concentration ratio of $[Ni(OH_2)_6]^{2+}$ to $[Ni(gly)(OH_2)_4]^+$ from 30 : 70 to 70 : 30, no significant improvement of the result was achieved under the present assumption of the same length of the Ni–O_1 and Ni–N bonds.

A possibility of different lengths of the Ni–O_1 and Ni–N bonds may not still be well eliminated by the above calculation, because the initial values, in which the Ni–O_1 and Ni–N bonds are assumed to have the same length, may give a very shallow minimum of the error-square sum in the course of the least-squares refinement of the structural parameters and the param-

eter values may not be well floated to reach a set of the best values. Therefore, at the next step of the refinement of the result, we stepwise changed the initial values of the lengths of the Ni–O_1 and Ni–N bonds, as well as the mole ratio of $[Ni(OH_2)_6]^{2+}$ to $[Ni(gly)(OH_2)_4]^+$. In this case, we assumed that the Ni–OH_2 bond was 2.08 Å and the temperature factor of the bond was stepwise changed from 0.003 Å^2 to 0.006 Å^2. The temperature factors of the Ni–O_1 and Ni–N bonds were fixed at 0.003 Å^2, which was found from the analysis of the structure of the tris(glycinato)nickelate(II) complex in solutions B and C, as will be described in the later section. Although the value was smaller than that estimated from the least-squares method in Table 3, we considered that the temperature factor of 0.003 Å^2 for the Ni–O_1 and Ni–N bonds was more reliable one than 0.005—0.006 Å^2 in Table 3, because the former value of the temperature factor was determined in solutions B and C in which the $[Ni(gly)_3]^-$ complex existed as the main species and the structure of the complex was more accurately analyzed than that of the $[Ni(gly)(OH_2)_4]^+$ complex coexisting with $[Ni(OH_2)_6]^{2+}$. Moreover, we can expect that the temperature factors of the Ni–O_1 and Ni–N bonds within the $[Ni(gly)(OH_2)_4]^+$ complex may not be greatly different from those within the $[Ni(gly)_3]^-$ ion.

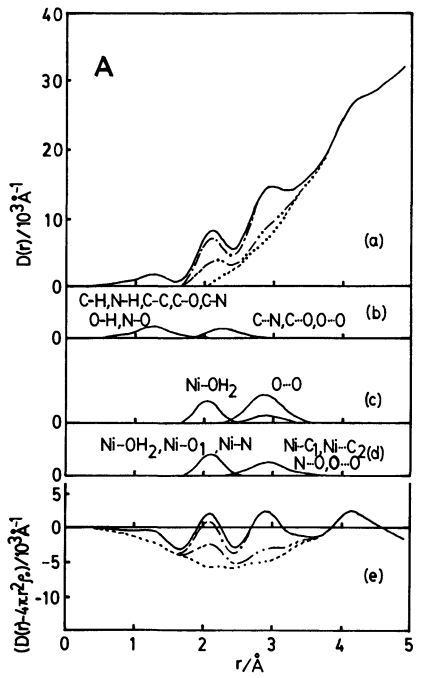

Fig. 4. (a) The radial distribution curve for solution A. (b) The theoretical peaks for O–H bonds within water molecule, intramolecular interactions within glycinate ion, and N–O and O···O pairs within nitrate ion. (c) The theoretical peak shapes calculated for Ni–OH_2 and O···O pairs within the hexaaquanickel(II) complex and O···O contacts of water molecules in the bulk. (d) The theoretical peak shapes owing to Ni–OH_2, Ni–O_1, Ni–N, Ni···$C_{1,2}$, N···O, and O···O pairs within the mono-complex. (e) The corresponding $(D(r)-4\pi r^2\rho_0)$ curve to the $D(r)$ in (a). The chain, double chain and dashed lines show the residual curves after subtraction of the theoretical peaks in (b), (c), and (d), respectively.

In the course of the refinement of the structural parameters of the $[Ni(gly)(OH_2)_4]^+$ ion, we extracted the second peak of the radial distribution curve given in Fig. 2A. By subtracting intramolecular interactions of water molecules, glycinate and nitrate ions, we can obtain the radial distribution curve which contains the only peaks ascribed to interatomic distances within the complexes around 2.1 Å and to longer range interatomic interactions in the region of larger r values. The peak at about 2.1 Å (the second peak in the original $D(r)$ curve) was extracted from the residual radial distribution curve by assuming a symmetrical shape of approximately Gaussian (Fig. 5). Since we could expect that the peak consisted of peaks owing to the Ni–OH_2 bonds within the $[Ni(OH_2)_6]^{2+}$ ion, Ni–OH_2, Ni–O_1, and Ni–N bonds within the $[Ni(gly)(OH_2)_4]^+$ complex, the refinement of the structural parameters of the $[Ni(gly)(OH_2)_4]^+$ ion was carried out in order to minimize the error-square sum defined by Eq. 1 at various sets of the temperature factor of the Ni–OH_2 bond, lengths of the Ni–O_1 and Ni–N bonds and the mole ratio of $[Ni(OH_2)_6]^{2+}$ to $[Ni(gly)(OH_2)_4]^+$.

$$U = \sum w\{D(r)^{2nd\ peak}_{calcd} - D(r)^{2nd\ peak}_{obsd}\}^2 \quad (1)$$

Here $D(r)^{2nd\ peak}$ denotes the $D(r)$ values at the second peak of the radial distribution curve extracted from the original curve by the procedure mentioned above. w is given as $\exp(-\alpha\cdot\Delta l^2)$, where $\Delta l = r_0 - r$ and r_0 represents the r-value at the center of the second peak. In this calculation we assumed that the r_0 value was 2.08 Å. The value α was estimated from the half-width of the second peak extracted.

In the course of the present calculations we fixed the values of all the structural parameters of the $[Ni(OH_2)_6]^{2+}$ ion at the literature values,[15] as well as the length of the Ni–OH_2 bond at 2.08 Å and the temperature factors of the Ni–O_1 and Ni–N bonds at 0.003 Å^2.

The minimum error-square sum was obtained for the set in which the temperature factor of the Ni–OH_2 bond within the $[Ni(gly)(OH_2)_4]^+$ was 0.003 Å^2. In Table 4 are summarized values of the error-square sums for various sets of the lengths of the Ni–O_1 and Ni–N bonds and the mole ratio of $[Ni(OH_2)_6]^{2+}$ to $[Ni(gly)$-

Table 4. Result of the analysis of the second peak in the $D(r)$ curve of solution A

Error-square sums ($U\times 10^{-5}$/Å^{-2}) were calculated according to the equation in the text. The Ni–OH_2 bond distance and all the temperature factors within the mono-complex were kept constant at 2.08 Å and 0.003 Å^2, respectively, in the course of the calculation.

		Mole fraction				
		Ni^{2+} = 0.3	0.4	0.5	0.6	0.7
		$Ni(gly)^+$ = 0.7	0.6	0.5	0.4	0.3
Bond distance r/Å		$U\times 10^{-5}$/Å^{-2}				
Ni–O_1	2.05	4.7	4.3	5.0	6.7	9.3
Ni–N	2.13					
Ni–O_1	2.07	4.6	4.1	4.7	6.4	9.0
Ni–N	2.11					
Ni–O_1	2.09	4.5	*4.0*	4.6	6.2	8.8
Ni–N	2.09					

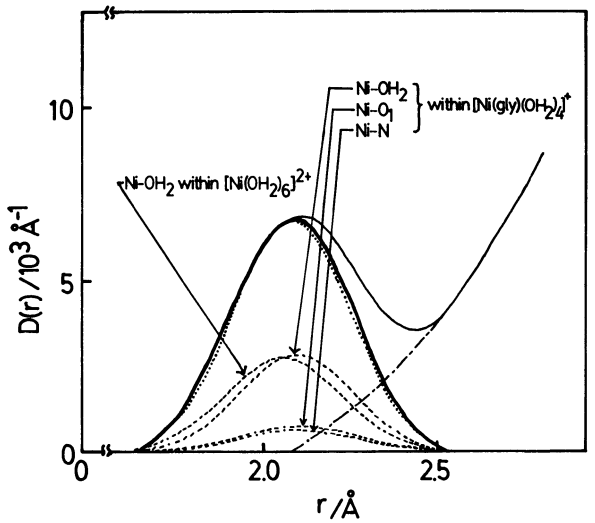

Fig. 5. The second peak of the radial distribution curve for solution A. The thin and thick solid lines represent the experimental and extracted $D(r)$ curves, respectively, and the chain line indicates the residual curve after extraction. The theoretical peak shapes owing to the Ni–OH_2 bonds within the $[Ni(OH_2)_6]^{2+}$ ion and Ni–OH_2, Ni–O_1, and Ni–N bonds within the $[Ni(gly)(OH_2)_4]^+$ ion are shown by dashed lines. The dotted line represents the peak shape by summing up ones shown by dashed lines.

$(OH_2)_4]^+$ at the value of 0.003 Å² for the temperature factor of the Ni–OH_2 bond.

In Fig. 5 was shown the coincidence of the experimentally obtained curve (the peak extracted by the procedure described previously) with the calculated shape by summing up shapes owing to the Ni–OH_2 interactions within the $[Ni(OH_2)_6]^{2+}$ ion and to the Ni–OH_2, Ni–O_1, and Ni–N bonds within the $[Ni(gly)(OH_2)_4]^+$ complex.

From the result we concluded that the Ni–O_1 and Ni–N bonds within the $[Ni(gly)(OH_2)_4]^+$ have practically the same length of 2.09 Å and thus the $[Ni(gly)(OH_2)_4]^+$ complex is essentially regular octahedral. The mole ratio of the $[Ni(OH_2)_6]^{2+}$ to the $[Ni(gly)(OH_2)_4]^+$ ions was approximately 40 : 60 in the present solution.

Solutions B and C. In solutions B and C, the tris(glycinato)nickelate(II) complex may be present as the main species. The radial distribution curves obtained for solutions B and C are shown in Fig. 2. They are very similar in shape, but it should be noted that the radial distribution curve of solution C has a small hump at about 3.4 Å, the concentration of sodium ions in solution C being higher than in solution B.

The radial ($D(r)$) and differential radial ($D(r)-4\pi r^2\rho_0$) distribution curves are shown in Fig. 6, a and e, respectively, for solution B. In the curves we see four peaks at 1.3, 2.2, 3.0, and 4.0 Å.

The peak at 1.3 Å can be ascribed to the O–H bonds within water molecules and N–H, C–H, C_1–C_2, C_2–N, $C_1\cdots O_1$, and $C_1\cdots O_2$ bonds within glycinate ions. The second peak consists mainly of interactions between nickel atoms and oxygen and nitrogen atoms within the glycinate ions coordinated. Nonbonding $C_1\cdots N$, $C_2\cdots O_1$, $C_2\cdots O_2$, and $O_1\cdots O_2$ interactions within

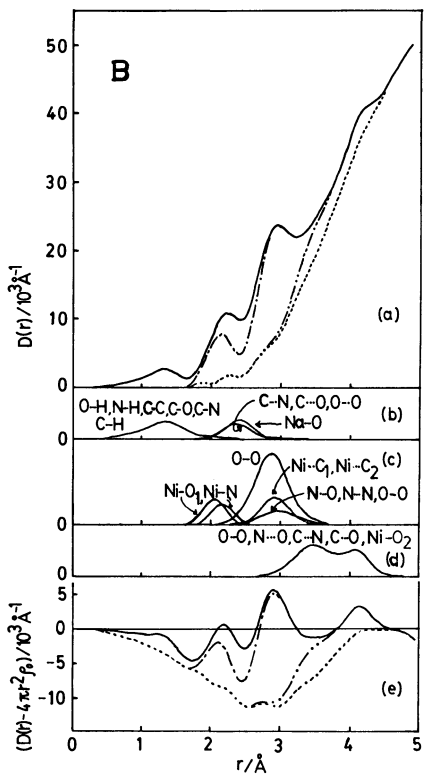

Fig. 6. (a) The radial distribution curve for solution B. (b) The theoretical peak shapes calculated for the O–H bonds within water molecule, the intramolecular interactions within glycinate ion, and Na–O pairs within hydrated sodium ion. (c) The theoretical peaks for Ni–O_1, Ni–N, Ni$\cdots C_{1,2}$, N$\cdots$O, N$\cdots$N, and O$\cdots$O pairs within the tris-complex and O$\cdots$O contacts of water molecules in the bulk. (d) The theoretical peaks for O$\cdots$O contacts within hydrated sodium ion and Ni$\cdots O_2$, N$\cdots O_2$, $C_{1,2}\cdots$N, and $C_{1,2}\cdots O_1$ pairs within the tris-complex. (e) The corresponding ($D(r)-4\pi r^2\rho_0$) curve to the $D(r)$ in (a). The chain, double chain, and dashed lines indicate the residual curves after subtraction of the theoretical peaks in (b), (c), and (d), respectively.

glycinate ions also contribute, in part, to the peak. The Na–O pairs within the hydrated sodium ions should have the bond length of about 2.4 Å,[17] which might also appear in this region in the $D(r)$ curve. The third peak may be composed of peaks due to nonbonding interactions between nickel and carbon atoms of the carboxylato and methylene groups within the glycinate ions coordinated, between ligand atoms in the coordination sphere of the $[Ni(gly)_3]^-$ complex, and between oxygen atoms in the bulk water. In the fourth peak at about 4 Å, nonbonding Ni$\cdots O_2$ and other long-range interactions may be included.

As we have pointed out in the previous section, we found a small hump at about 3.4 Å in the radial distribution curve of solution C, in which a higher concentration of sodium ions was contained than in solution B. This fact suggests that the hump may be due to interactions within hydrated sodium ions.

At the first step of analysis of the radial distribution curve of solution B, as well as that of solution C, we first

subtracted peak shapes of known interatomic distances within glycinate ions and the bulk water (Fig. 6b). The interaction between sodium ion and water molecules hydrated must also be taken into account in the calculation.

The structure of hydrated sodium ion has been determined in solutions of relatively low[17] and high[18] concentrations. Caminiti *et al.*[17] showed that a sodium ion had six water molecules in the first coordination shell at the distance of 2.41 Å. Calculations by using molecular dynamics simulations for the structure of *ca.* 0.5—2 mol dm^{-3} aqueous solutions of sodium chloride led to the hydration number of about 6—8 for sodium ions.[18] On the other hand, Maeda and Ohtaki found that the hydration number of sodium ion was four in a 7 mol dm^{-3} NaI solution.[19] If sodium ion has six water molecules coordinated in the form of a regular octahedron, we can expect to find the nonbonding water–water distance within the hydrated sodium ion at about 3.4 Å ($=2.4\text{ Å}\times\sqrt{2}$). On the other hand, in the four-coordinated sodium ion with water molecules, the nonbonding water-water interactions within the hydration shell of the sodium ion may appear at about 3.9 Å ($=2.4\text{ Å}\times\sqrt{8/3}$).

If we assumed the tetrahedral structure of the hydrated sodium ion in the solution and subtracted the intramolecular interactions within the hydrated ion from the radial distribution function, a peak remained at about 3.4 Å in the $D(r)$ curve of both solutions B and C, which was not satisfactorily explainable by possible atom pairs in the system. However, when the octahedral structure was assumed for the hydrated sodium ion, the radial distribution curves of both solutions B and C were well interpreted in terms of peak shapes of all the possible combinations of atom pairs shorter than 4 Å, as will be described in more detail in the later section.

Thus, we concluded that sodium ion has six water molecules at the distance of 2.40 Å in such solutions of relatively low concentrations as those in the present case.

When we subtracted the peak shapes of the Na–O interactions within the hexa-hydrated sodium ions and intramolecular bonding and nonbonding interactions within glycinate ions and water molecules (see Fig. 6b), we found a peak remaining at about 2.1 Å. The peak must be ascribed to the Ni–O_1 and Ni–N interactions within the $[Ni(gly)_3]^-$ complex. The shape of the peak was quite symmetrical. However, it was difficult to reproduce the peak shape by a single Gaussian curve which was constructed from the Ni–O_1 and Ni–N bonds with the same length, because the temperature factor of the bonds become unreasonably large (0.01—0.02 Å^2). Therefore, we assumed that the peak at 2.1 Å consisted of two peaks of Ni–O_1 and Ni–N bonds with different lengths. By a trial-and-error method the peak was separated into two, one had the peak position at 2.04 Å and the other was centered at 2.15 Å; the value of the temperature factors of the both bonds seemed to be reasonable ($\simeq$0.003 Å^2).

It is not straightforward to identify which peak corresponds to the Ni–O_1 or Ni–N bond. It has been found in crystal of *fac*-$[Cr(gly)_3]\cdot H_2O$ that the metal-oxygen bond is shorter than the metal-nitrogen bond within the complex.[20] The fact that the metal-oxygen bond is shorter than the metal-nitrogen bond has been found by many crystallographic investigations of various glycinato complexes. When we make a model structure of the $[Ni(gly)_3]^-$ ion by using three glycinate ions and one nickel(II) ion of an ionic radius of about 0.69 Å,[21] the glycinate ions are largely deformed and strained if we assume that the Ni–O_1 bond is longer than the Ni–N bond. On the other hand, the structural model having the Ni–O_1 bond of about 2.04 Å and the Ni–N bond of about 2.15 Å shows no large deformation in the bond angles within the glycinate ions. Therefore, we concluded that the peak at 2.04 Å is attributed to the Ni–O_1 bond, while the other peak at 2.15 Å is ascribed to the Ni–N bond within the tris(glycinato)-nickelate(II) complex.

The structural parameters of the tris(glycinato)-nickelate(II) complex were finally refined by the least-squares method by inserting the values for each interatomic interaction estimated by the trial-and-error method previously described as the initial values. The least-squares refinement of the structural parameters of the $[Ni(gly)_3]^-$ ion was performed by using $s\cdot i(s)$ data over the range $s>4$ Å^{-1}. In the refinement three types of calculations were carried out on slightly different assumptions.

In the B-I calculation all the distances and the temperature factors listed in Table 5 were refined by

Table 5. Results of the least-squares refinements of solution B

Parameter values refined were bond distances (r/Å), temperature factors (b/Å^2), and frequency factors (n). Standard deviations are given in parentheses.

Interaction	Parameter	B-I	B-II	B-III
Ni–O_1	r	2.039 (4)	2.034 (4)	2.031 (4)

$[Ni(gly)(OH_2)_2]$ [b]	2.10	2.06	2.08
$[Ni(gly)_3]^-$	—	2.03	2.14

a) Ref. 15. b) Ref. 7.

keeping all the frequency factors constant. In the B-II treatment some interatomic interactions of relatively long distances were allowed to remain unchanged. The B-III calculation was carried out on similar assumptions given at the B-II calculation except for the frequency factors of some atom-pairs floated in the course of the refinement. All the calculations gave quite similar results, and we adopted the values obtained by the B-I type calculation as the final ones for the tris(glycinato)-nickelate(II) complex in solution B.

In the course of the calculation the existence of the *fac*- and *mer*-isomers of the tris(glycinato)nickelate(II) complex was taken into account. However, since the difference between the isomers was so small, the introduction of the existence of the isomers did not improve the result.

For solution C a similar procedure of calculations were performed to obtain the structural parameters of the tris(glycinato)nickelate(II) complex in the solution in order to examine reproducibility of the result. The interatomic distances found for the $[Ni(gly)_3]^-$ complex in solution C are listed in Table 6, together with those obtained in solution B. The proposed values of the bond lengths within the tris(glycinato)nickelate(II) complex are also given in the table.

In Table 7 we summarized the lengths of the Ni–OH_2, Ni–O_1, and Ni–N bonds within the hexaaqua-, tetraaquamono(glycinato)- and diaquabis(glycinato)nickel(II) and tris(glycinato)nickelate(II) complexes.

It can be noted that the Ni–OH_2 distance increases with the increased number of glycinate ions coordinated. The same trend may be seen for the Ni–N bond. On the contrary, the Ni–O_1 distance decreases with the increase in the number of glycinate ions in the coordination sphere of nickel(II) ion. The result suggests that the electrostatic interaction between the central nickel (II) ion and a charged donor atom is enhanced, while the coordination interaction between the metal ion and an uncharged donor atom weakens.

The work has been financially supported, in part, by the Grant-in-Aid for Scientific Research No. 57470054 from the Ministry of Education, Science and Culture. The financial aid by the Asahi Glass Foundation for Industrial Technology is also acknowledged. A part of the computer calculations carried out in the present work has been performed at the Institute for Molecular Science in Okazaki.

Hydrophobic Vitamin B_{12}. I. Preparation and Axial Ligation Behavior of Hydrophobic Vitamin B_{12r}†

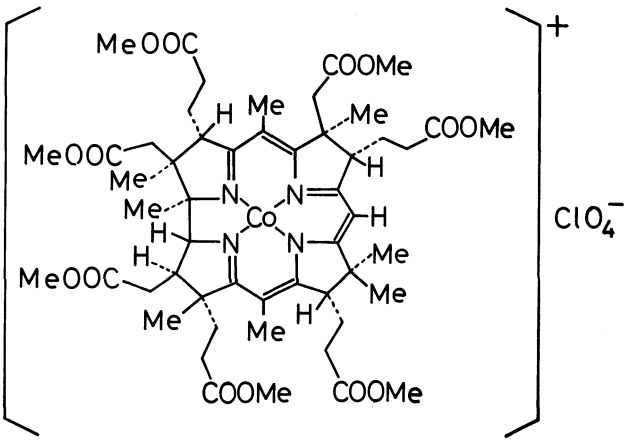
Yukito Murakami,* Yoshio Hisaeda, and Akiro Kajihara
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812
(Received June 22, 1983)

Heptamethyl cobyrinate perchlorate, [Cob(II)ester]ClO_4, was prepared in a good yield from cyanocobalamin. This hydrophobic complex is structurally comparable to the base-off form of vitamin B_{12r}. Thermodynamic parameters (ΔG, ΔH, and ΔS) for axial ligation of [Cob(II)ester]ClO_4 with various amines in dichloromethane and toluene were determined by electronic spectroscopy. The isoequilibrium temperatures obtained from plots of ΔH *vs.* ΔS were 194 ± 20 and 317 ± 20 K in dichloromethane and toluene, respectively. The equilibrium is primarily controlled by entropy at ordinary temperatures and the log K_1 value varies sensitively along with the change in pK_a of amine in dichloromethane, while the equilibrium values were almost invariant to the choice of amine in toluene because the measurements were carried out near the isoequilibrium temperature. The log K_1 value for [Cob(II)ester]ClO_4, different from the case of cobalt(II)–porphyrin complexes, depends on the nature of solvent used and undergoes wide variations. The possible functions of equatorial ligands involved in these two different complexes in the axial ligation behavior were discussed.

We have prepared previously the cobalt complex of 1,19-dimethyl-AD-didehydrocorrin (Hbdhc), having additional double bonds at peripheral positions and an additional angular methyl group compared with the parent corrinoid, and investigated its structural properties from the viewpoint of vitamin B_{12} chemistry.[1] The bdhc complex is quite analogous to the corrinoid as far as the electronic properties are concerned on the basis of its spectroscopic, electrochemical, and axial coordination behaviors. On the other hand, the angular methyl groups in the complex exert an unusually large steric effect in the bimolecular reactions of Co^I(bdhc) with alkyl donors which result in the formation of an alkyl–cobalt bond. Even though the bdhc complex is considered to be a good B_{12} model, it does not catalyze the 1–2 migration as observed with vitamin B_{12}. This may indeed be due to the steric repulsion of the angular methyl groups which prevents the initially formed alkyl fragments upon C–Co cleavage from staying close to the cobalt. In order to improve these situations, it is necessitated to develop another good vitamin B_{12} model.

The model studies of coenzyme B_{12}-dependent enzymatic reactions have been carried out in aqueous media[2] since vitamin B_{12} is soluble in water but hardly in apolar solvents. In order to simulate the functions of vitamin B_{12} as exerted in the hydrophobic active sites of enzymes concerned, however, vitamin B_{12} needs to be modified so that the model studies can be carried out in ordinary apolar organic solvents. Therefore, we synthesized in this work heptamethyl cobyrinate by converting amide groups of vitamin B_{12} into ester ones. Heptamethyl cobyrinate involving cobalt(II) has been prepared by Werthemann *et al.* and isolated as the iodo-adduct.[3] In the present work, we prepared heptamethyl cobyrinate perchlorate, [Cob(II)ester]ClO_4, in a good yield according to some modified method. This complex is structurally comparable to vitamin B_{12r} in the base-off form, but much more stable in solution and solid states and much less readily oxidized in the air than vitamin B_{12r} itself.

Physicochemical data for vitamin B_{12r} are lacking because B_{12r} is readily oxidized to B_{12a} in the air,[4] even though such information is important for characterizing its catalytic functions. Therefore, axial ligation constants and thermodynamic parameters for the reaction of [Cob(II)ester]ClO_4 with some pyridines, imidazoles, and aliphatic amines were evaluated in organic solvents under nitrogen atmosphere, and compared with the corresponding data for (5,10,15,20-tetraphenylporphinato)cobalt(II), Co^{II}(tpp).



[Cob(II)ester] ClO_4

Experimental

Materials. Cyanocobalamin was purchased from Nakarai Chemicals and used without further purification. Dicyanocobyrinic acid heptamethyl ester, $(CN)_2$Cob(III)ester, was prepared from cyanocobalamin according to the method of Werthemann *et al.*,[3] purified by thin-layer chromatography on silica gel (Kiesel gel 60H) with chloroform–methanol (9 : 1 v/v), and reprecipitated from benzene upon addition of hexane. The product was identified by electronic, IR, ^{1}H-NMR, and ^{13}C-NMR spectroscopy[5,6] as well as by elemental analysis. (5,10,15,20-Tetraphenylporphinato)cobalt(II), Co^{II}(tpp), was prepared after the method of Alder *et al.*,[7] purified by liquid chromatography on a column of silica gel (Wakogel C-100) with chloroform as an eluant followed by recrystallization from

† Contribution No. 702 from this Department.

chloroform, and identified by electronic and IR spectroscopy as well as by elemental analysis.

Heptamethyl Cobyrinate Perchlorate, [Cob(II)ester]ClO_4. $(CN)_2$Cob(III)ester (50 mg, 4.6×10^{-5} mol) was dissolved in 40 ml of dichloromethane, and the resulting purple solution was treated with 25 ml of 30% aqueous perchloric acid. The orange dichloromethane layer was separated from the acidic aqueous layer and washed with distilled water. After being dried over sodium sulfate, the organic layer was evaporated to dryness at room temperature to obtain monocyanocobyrinic acid heptamethyl ester, [(CN)(H_2O)Cob(III)ester]ClO_4, in a nearly quantitative yield. The monocyano-complex, [(CN)-(H_2O)Cob(III)ester]ClO_4, was dissolved in 50 ml of methanol, and 50 ml of distilled water was added to this solution. The solution was deoxygenated by bubbling nitrogen gas through it for 30 min, and treated with 1.0 g of sodium tetrahydroborate and 15 ml of distilled water with vigorous shaking and frequent venting under nitrogen atmosphere. At the instance that the color of solution changed to dark green, 3 ml of 60% aqueous perchloric acid was added carefully to decompose excess sodium tetrahydroborate and to convert Cob(I)ester into Cob(II)-ester. The resulting cobalt complex was extracted with dichloromethane and washed with distilled water. After being dried over sodium sulfate, the dichloromethane solution was evaporated to dryness at room temperature. The residue was reprecipitated four times from benzene upon addition of hexane to afford fine brown crystals: yield 45 mg (87%); λ_{max} (CH_2Cl_2) 266 (ε 1.90×10^4), 316 (2.35×10^4), 403 (0.63×10^4), and 468 nm (1.21×10^4); IR (KBr) 1730 (ester C=O), and 1100 and 620 cm^{-1} (ClO_4^-).

Found: C, 54.68; H, 6.41; N, 5.00%. Calcd for $C_{52}H_{73}ClCoN_4O_{18}$: C, 54.95; H, 6.47; N, 4.93%.

Spectroscopic Measurements. Electronic absorption spectra were recorded on a Hitachi 340 or a Hitachi 220A spectrophotometer. ESR spectra were obtained with a JEOL JES-ME-3 X-band spectrometer equipped with a 100-kHz field modulation unit; a standard MgO/Mn^{II} sample calibrated with a NMR magnetometer was employed for calibration of the magnetic field.

Measurements of Equilibrium Constants and Thermodynamic Calculations. Liquid amines were distilled and solid amines were sublimed at 60 °C/1.33 Pa before use. Dichloromethane and toluene purified and dried according to the standard procedures[8] were redistilled and degassed by bubbling nitrogen gas through them before use. An equilibrium constant for coordination of an amine base to [Cob(II)ester]ClO_4 in dichloromethane was determined by measuring spectral change of a series of solutions containing the cobalt complex (*ca.* 8×10^{-5} mol dm^{-3}) and varying amounts of an amine base under nitrogen atmosphere. Upon addition of each of pyridines, imidazoles, and aliphatic amines, the visible peak at 468 nm decreased in intensity along with slight shift to longer wavelength, and clear isosbestic points were observed. Equilibrium constants were calculated by Eq. 1.

$$\log[(A_0-A)/(A-A_\infty)] = n\log[B] + \log K_n \quad (1)$$

Here, A designates an absorbance at a given concentration of an amine base ([B]), A_0 is an absorbance at [B]=0, and A_∞ stands for a limiting absorbance in the presence of a sufficient amount of a base. The values of log K_n, measured at three or four different temperatures over the 10—30 °C range, were used to evaluate ΔH and ΔS values. As for [Cob(II)ester]ClO_4 in toluene, and Co^{II}(tpp) in dichloromethane and toluene, the equilibrium constants were also calculated according to the same method on the basis of absorbance changes at 470 nm for the former complex and 527.5 nm for the latter.

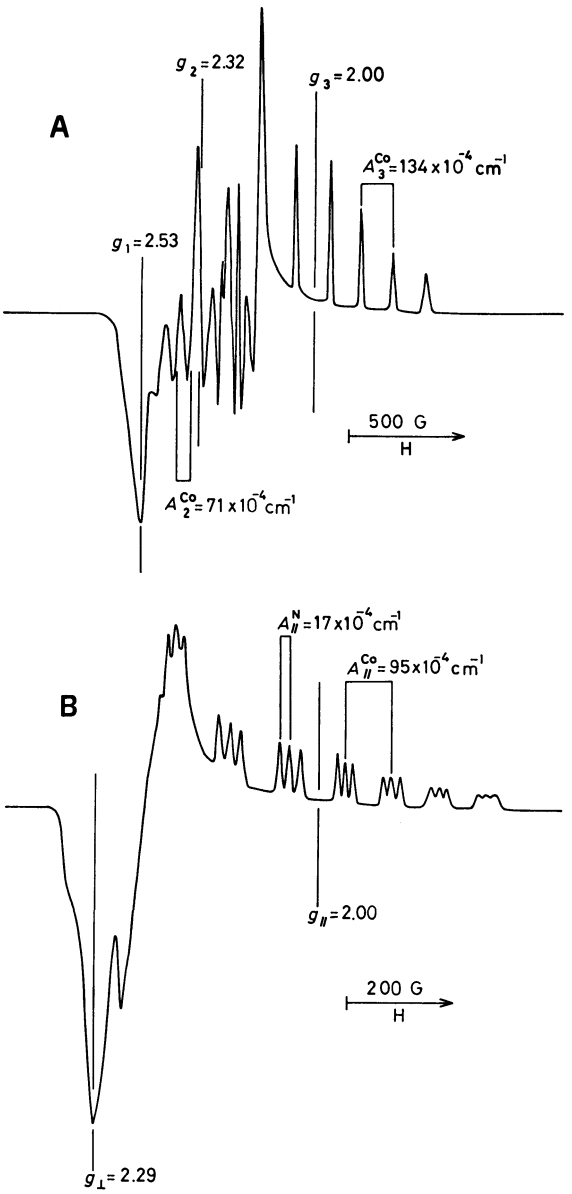


Fig. 1. ESR spectra of [Cob(II)ester]ClO_4 in chloroform–benzene (2 : 1 v/v) at 77 K: A, 9×10^{-3} mol dm^{-3} [Cob(II)ester]ClO_4; B, 9×10^{-3} mol dm^{-3} [Cob(II)-ester]ClO_4 and 4.5×10^{-2} mol dm^{-3} pyridine.

Results and Discussion

ESR spectra of [Cob(II)ester]ClO_4 in base-off and base-on forms are shown in Fig. 1. The spectra and the corresponding spin Hamiltonian parameters are comparable to those of aqueous vitamin B_{12r}.[9,10] Electronic spectra of the present complex also show similar features as observed for aqueous vitamin B_{12r}.[11]

The spectral change upon addition of a base to [Cob-(II)ester]ClO_4 is typically shown in Fig. 2. The corresponding straight line plots on the basis of Eq. 1 are given in Fig. 3; $n=1.00\pm0.05$. This indicates that only one molecule of the base is coordinated to one molecule of the complex under the present conditions, being consistent with the ESR data (Fig. 1). The equilibrium constants and thermodynamic parameters are summarized in Table 1 for the reaction of [Cob(II)ester]-

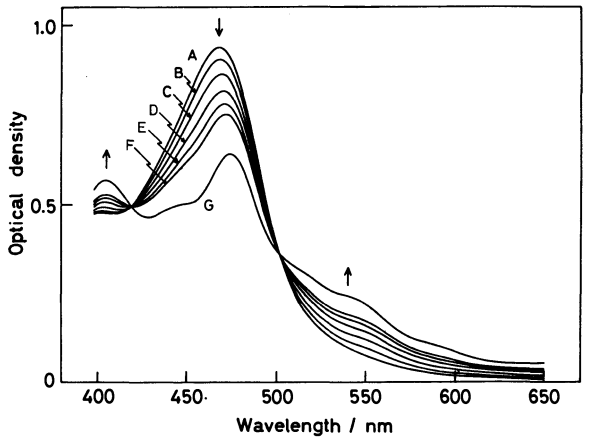

Fig. 2. Spectral change at 18.6 °C for the reaction of [Cob(II)ester]ClO_4 in dichloromethane with morpholine at various concentrations: A, 0; B, 7.62×10^{-5}; C, 2.28×10^{-4}; D, 4.56×10^{-4}; E, 7.59×10^{-4}; F, 1.19×10^{-3}; G, 1.32×10^{-1} mol dm^{-3}. Trends of spectral change with increase in base concentration are shown by arrows.

ClO_4 with various bases in dichloromethane and toluene.

The linear correlations are observed between log K_1 and pK_a[12] values for the axial ligation of [Cob(II)ester]-ClO_4 with various bases as shown in Fig. 4 specifically in dichloromethane: a single straight line correlation for each of the three different types of amine bases; imidazoles, pyridines, and aliphatic amines. The log K_1 value for the reaction with 2-methylpyridine deviates largely from the corresponding correlation line apparently due to a steric hindrance caused by the 2-methyl group. The stability order with respect to the type of amine base is in an increasing sequence: aliphatic amines, pyridines, and imidazoles. However, this order cannot be directly correlated with the nature and strength of cobalt-nitrogen bond even though such explanation is a tempting one,[13] since the entropy effect must be taken into account. An increment in $-\Delta G$ (from 21.1 to 25.6 kJ mol^{-1}) is accompanied by a decrement in $-\Delta H$ (from 44 to 36 kJ mol^{-1}) for the

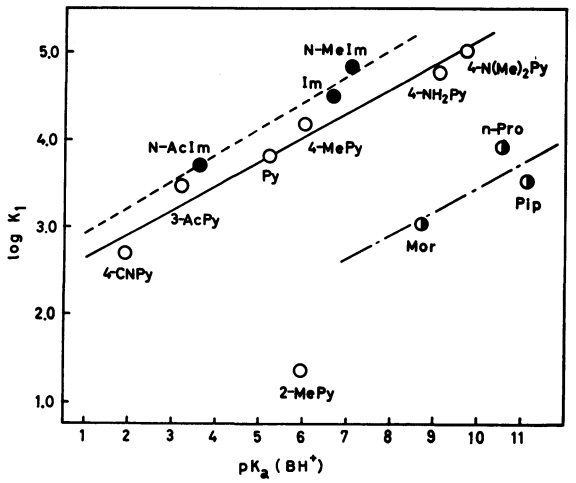

Fig. 4. Correlations between log K_1 and amine basicity for the reaction of [Cob(II)ester]ClO_4 with various bases in dichloromethane at 23.5 °C; K_1 in mol^{-1} dm^3.

reaction of the complex with imidazole derivatives in dichloromethane (Table 1). Such trends are also noted for the reaction with aliphatic amines and some pyridine bases in the same solvent (Table 1). The thermodynamic parameters for ligand coordination in the liquid state seem to reflect the interaction modes of a medium with the metal complex and a coordinating ligand. Such modes must be intensively correlated with the extent of charge delocalization within the metal complex as well as with the extent of steric interaction between a base and the complex. Thus, the enthalpy and entropy parameters were treated on the basis of isoequilibrium relationship.[14,15]

The enthalpy and entropy changes are linearly correlated by Eq. 2.

$$\Delta H = \Delta H_0 + \beta\,\Delta S \quad (2)$$

Here, ΔH_0 is the ΔH value corresponding to $\Delta S=0$, and β denotes the isoequilibrium temperature. Combination of Eq. 2 with the correlation, $\Delta G=\Delta H-T\,\Delta S$, gives the following equations.

$$\Delta G = (T/\beta)\Delta H_0 + (1 - T/\beta)\Delta H \quad (3)$$
$$\Delta G = \Delta H_0 + (\beta - T)\Delta S \quad (4)$$

Consequently, the variation of the free energy change ($\Delta\Delta G$) along with the axial coordination of amines is given by either Eq. 5 or 6, and $\Delta\Delta G$ is concerned with a temperature range under measurements with respect to β.

$$\Delta\Delta G = (1-T/\beta)\Delta\Delta H \quad (5)$$
$$\Delta\Delta G = (\beta-T)\Delta\Delta S \quad (6)$$

Plots of ΔH *vs.* ΔS are shown in Fig. 5 (refer to Table 1). As regards the data obtained in dichloromethane, all points appear to lie along the same line irrespective of the nature of base except for the sterically hindered one (2-MePy): correlation coefficient, 0.99; β, 194$\pm$ 20 K. It is not surprising, therefore, that increments in ΔG are accompanied by decrements in ΔH at the temperature range of present study which is about 100 K above the isoequilibrium temperature. The stability order for the axial ligation of [Cob(II)ester]ClO_4 (see Fig. 4) decreases in the order: imidazoles, pyridines,

and aliphatic amines. Dichloromethane is considered to be inert for metal-coordination and interaction with the corrin skeleton. Thus, such stability sequence seems to be concerned with the extent of steric interaction between the cobalt complex and amine bases. Further, space-filling molecular models indicate that serious van der Waals repulsion can be generated between the hydrogen atoms bound to the carbons α to the nitrogen atom of the aliphatic amines and the angular hydrogen atom bound to the carbon atom at 19 position of [Cob(II)ester]ClO_4. The molecular models show that the restriction of rotation about the carbon–nitrogen bond decreases in the order: cyclic aliphatic amines, pyridine derivatives, and imidazole derivatives. This is attributed to the interactions between an amine base and the side chains of [Cob(II)ester]ClO_4 and

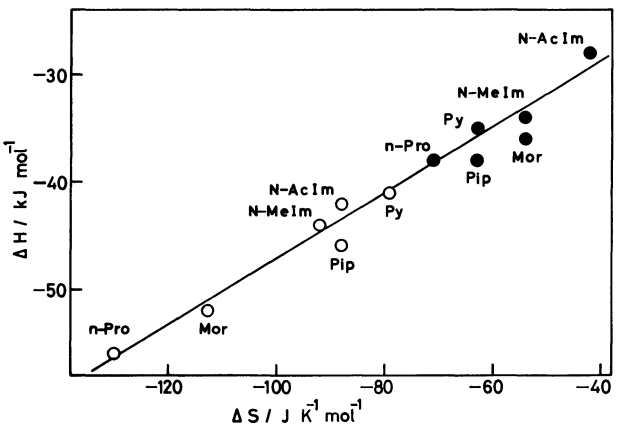

Fig. 6. Plots of ΔH *vs.* ΔS for the reaction of Co^{II}(tpp) with amines in dichloromethane (○) and toluene (●). The solid line is based on the least squares calculation applied to all points.

between the hydrogen atoms bound to α-carbon atoms of amines and the angular hydrogen of the cobalt complex.

In toluene, the enthalpy–entropy relationship with a correlation coefficient of 0.99 (Fig. 5) gives $\beta = 317 \pm 20$ K. The isoequilibrium temperature is very close to the temperature range for present measurements. As a consequence, the values of $\log K_1$ are nearly invariant to the choice of amine in contrast to those observed in dichloromethane.

Thermodynamic parameters for the reaction of Co^{II}(tpp) with various amines in dichloromethane and toluene are tabulated in Table 2. The values of $\log K_1$ are nearly invariant to the choice of amine or solvent. Plots of ΔH *vs.* ΔS for determination of the isoequilibrium temperatures in both solvents are shown in Fig. 6. All points appear to lie along the same line: correlation coefficient, 0.98; β, 300 ± 20 K. Calculations for each individual solvent system result in isoequilibrium temperatures of 301 ± 30 and 327 ± 50 K for dichloromethane and toluene, respectively. Because the isoequilibrium temperatures are obviously close to room temperature, the $\log K_1$ value for axial ligation of Co^{II}(tpp) in dichloromethane and toluene is insensitive to the change in pK_a of amine. The results obtained for Co^{II}(tpp) are comparable to those for [5,10,15,20-tetrakis(*p*-methoxyphenyl)porphinato]cobalt(II), Co^{II}(t(*p*-CH_3O)pp).[16] Axial ligation constants for the reaction of Co^{II}(t(*p*-CH_3O)pp) with pyridine, piperidine, and *N*-methylimidazole in several solvents have been reported to be nearly constant at room temperature. This was attributed to the fact that the reaction was carried out near the isoequilibrium temperature (320 ± 24 K). Being consistent with the previous and present results, plots of ΔH *vs.* ΔS result in a single line correlation for the axial ligation of a cobalt(II)–porphyrin complex, irrespective of the nature of amines and solvents. On the other hand, the correlation of ΔH *vs.* ΔS for the axial ligation of [Cob(II)ester]ClO_4 apparently depends on the nature of solvent employed (Fig. 5). The present complex, [Cob(II)ester]ClO_4, involves the monoanionic corrin moiety as its equatorial ligand while Co^{II}(tpp) has the dianionic porphyrin ligand. The positive charge in the former complex is supposed to be delocalized throughout the whole molecule and the π-π interaction of charge-transfer type between the equatorial ligand and toluene is expected along with the reduction of axial ligation ability as a consequence. Such interaction is apparently not expected with dichloromethane.

In conclusion, the isoequilibrium relationship applies to axial ligation of [Cob(II)ester]ClO_4 in a manner as demonstrated for cobalt(II)– and iron(II)–porphyrin complexes.[13,16,17] In dichloromethane which has no tendency to interact with [Cob(II)ester]ClO_4, the equilibrium constant is primarily controlled by entropy at ordinary temperatures and the $\log K_1$ value varies sensitively along with the change in pK_a of amine. The $\log K_1$ value for the present hydrophobic vitamin B_{12r}, in contrast to that for cobalt(II)–porphyrin complexes, depends on the nature of medium. This suggests that the axial ligation equilibrium of vitamin B_{12} changes widely with the microenvironmental property in the enzyme active sites.

Oxidized Rubredoxin Models. II. Iron(III) Complexes of Z-Cys-Pro-Leu-Cys-OMe and Z-Cys-Thr-Val-Cys-OMe[1)]

Michio NAKATA, Norikazu UEYAMA, Toshitsugu TERAKAWA, and Akira NAKAMURA*
Department of Macromolecular Science, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received July 5, 1983)

Fe(III) complexes of cysteine-containing peptides such as Z–Cys–Pro–Leu–Cys–OMe and Z–Cys–Thr–Val–Cys–OMe corresponding to the Fe binding amino acid sequences in *Cl. pasteurianum* rubredoxin were prepared in solution and characterized by the absorption, circular dichroism (CD), and magnetic circular dichroism (MCD) spectra and were compared with those of the Fe(III) complexes of Z–Cys–Ala–Ala–Cys–OMe, Z–Ala–Cys–OMe, and Z–Cys–Ala–Cys–OMe. These model compelxes exhibited the existence of an electronic configuration and a core structure similar to that of native rubredoxin. The thermal stabilities of the Fe(III) peptide complexes decrease in the following order, Z–Cys–Thr–Val–Cys–OMe$>$Z–Cys–Ala–Ala–Cys–OMe$>$Z–Cys–Pro–Leu–Cys–OMe $\simeq$Z–Ala–Cys–OMe$\gg$Z–Cys–Ala–Cys–OMe.

Rubredoxin playing significant roles in biological electron transfer and oxygenation reactions has one $[Fe(S\text{–}Cys)_4]^{-,2-}$ (S–Cys denotes cysteinyl thiolate, –NH–CH(CH_2S^-)–CO–) as an active site.[2,3)] The X-ray analysis of oxidized rubredoxin from *Clostridium pasteurianum* has revealed that the Fe(III) is coordinated by two thiolates of –Cys(6)–Pro–Leu–Cys(9)–sequence and other two thiolates of –Cys(39)–Thr–Val–Cys(42)–sequence with a distorted tetrahedral geometry.[4)]

Importance of –Cys–A–B–Cys– has been discussed on the contribution to the stabilities of the chelate rings, the determination of the geometries around the metal ions, and the origins of catalytic activities. Christou *et al.* reported the Fe(III) complexes of Ac{Gly–Cys–Gly}$_n$$NH_2$ (n=1—4) in which two Gly residues were interposed between Cys residues. The Gly residues have the least sterical restriction on the peptide conformations.[5)]

Any substituent on the peptide chain will restrict the conformations and will result in preference of one of them.

Thus, our previous paper reported the absorption, CD, MCD, and electron paramagnetic resonance (EPR) spectral analyses of Fe(III) complexes of Z–Cys–Ala–Ala–Cys–OMe and Z–Ala–Cys–OMe.[1)] The tetrapeptide complex exhibited a relatively stable structure with the hairpin turn conformation of the tetrapeptide. It may be indispensable to the function of rubredoxin that the –Cys–A–B–Cys– sequences consist of amino acid residues with bulky side chains such as Pro, Leu, Val, and Thr residues.

In this paper, we describe the preparation and the characterization of Fe(III) complexes of Z–Cys–Thr–Val–Cys–OMe corresponding to the Fe(III) binding sequences in *Cl. pasteurianum* rubredoxin. For comparison, thermal stabilities of an artificial sequence, Z–Cys–Ala–Cys–OMe, in addition to those of Z–Cys–Ala–Ala–Cys–OMe and Z–Ala–Cys–OMe mentioned previously[1)] were investigated with visible spectra. Characteristic properties dependent on the identity of A and B residues in these Cys–A–B–Cys sequences will be discussed.

Experimental

All operations were carried out under argon atmosphere. Dimethyl sulfoxide and triethylamine were degassed and distilled before use. Iron(III) chloride hexahydrate was of commercial grade. Syntheses of the cysteine-containing peptides are described elsewhere.[6)]

Preparations of Fe(III) Complexes. The Fe(III) complexes of the peptides were prepared by the same manner reported by Christou *et al.*[7)] A Me_2SO solution of $FeCl_3\cdot 6H_2O$ and 4 molar equivalents of the cysteine-containing peptide based on its SH-content was treated with triethylamine to give a deep red-violet solution of the Fe(III) complex of the corresponding peptide, which was used for physical measurements without further purifications. $[Et_4N][Fe(S_2\text{-}o\text{-}xyl)_2]$ (S_2-*o*-xyl=*o*-xylene-α,α'-dithiolate) was prepared according to the literature.[8)]

Physical Measurements. Absorption spectra were recorded on a JASCO UVIDEC-5A spectrophotometer. CD and MCD spectra were measured using a JASCO J-40 spectropolarimeter equipped with an electromagnet. The magnetic field was calibrated with an aqueous $K_3[Fe(CN)_6]$ solution.[9)] Calibration of the spectropolarimeter was performed with *epi*-androsterone in dioxane.[10)] The values of ε and $\Delta\varepsilon$ were given in the unit of $M^{-1}\,cm^{-1}$ and $\Delta\varepsilon_M$ in $M^{-1}\,cm^{-1}\,T^{-1}$ where M expresses molar concentration of Fe(III) g-atom. The MCD spectra of the peptide complexes were corrected for the zero-field circular dichrosim.

EPR spectra were recorded at 77 K on a JEOL JESFE 1X with 100 KHz magnetic field modulation using Mn(II) as g-marker (g=1.981).

Results

Spectral Properties of Fe(III) Complexes of Cysteine-containing Peptides. In order to elucidate core structures of the Fe(III) complexes of a series of cysteine-containing peptides, absorption, MCD, and CD spectra of the Fe(III) peptide complexes were investigated in Me_2SO. Table 1 lists the near UV-visible absorption, MCD, and CD spectra of the Fe(III) complexes of Z–Cys–Thr–Val–Cys–OMe and Z–Cys–Pro–Leu–Cys–OMe. For the sake of comparison, those of $[Et_4N][Fe(S_2\text{-}o\text{-}xyl)_2]$ and oxidized rubredoxin from *Cl. pasteurianum*[11–13)] are also represented in Table 1.

The Fe(III) complexes of the peptides exhibited absorption maxima at 330—350 nm and $\approx$500 nm, which were assigned to the ligand-to-metal charge-transfer transitions.[14,15)] The absorption spectra of $[Fe(S_2\text{-}o\text{-}xyl)_2]^-$ and oxidized rubredoxin showed similar spectral features to those of the Fe(III) peptide com-

plexes although several additional bands were observed (Table 1).

The MCD spectra of the Fe(III) peptide complexes were highly structured and much more informative than the absorption spectra. The MCD spectrum of oxidized rubredoxin was characterized by Ulmer *et al.* and they pointed out that two dispersion type bands with cross-over points at 382 and 495 nm are assignable to the Faraday A-term, and a negative and a positive bell-shaped bands at 347 and 565 nm to the Faraday B-term corresponding to the absorption maxima at 353, 380, 493, and 560 nm (Table 1).[12] A positive band at 309 nm was not assigned. According to the assignments for rubredoxin[11] and its model complexes with alkanedithiols,[16] tentative assignments for the peptide complexes and $[Fe(S_2\text{-}o\text{-}xyl)_2]^-$ were carried out and are summarized in Table 1. All of the Fe(III) peptide complexes had dispersion type bands with cross-over points at 380—390 nm and positive MCD shoulders at 550—585 nm corresponding to those of the native protein at 382 and 565 nm whereas the peptide complexes had no definite absorption maxima at these regions. On the other hand, $[Fe(S_2\text{-}o\text{-}xyl)_2]^-$ had no cross-over point at 380—390 nm. Among the peptide Fe(III) complexes examined, Z–Cys–Pro–Leu–Cys–OMe and Z–Cys–Ala–Ala–Cys–OMe complexes exhibited negative Faraday effects at 350 and 355 nm, respectively, similar to rubredoxin. The complexes of other peptides did not show such negative ones.

The CD spectra of the Fe(III) peptide complexes

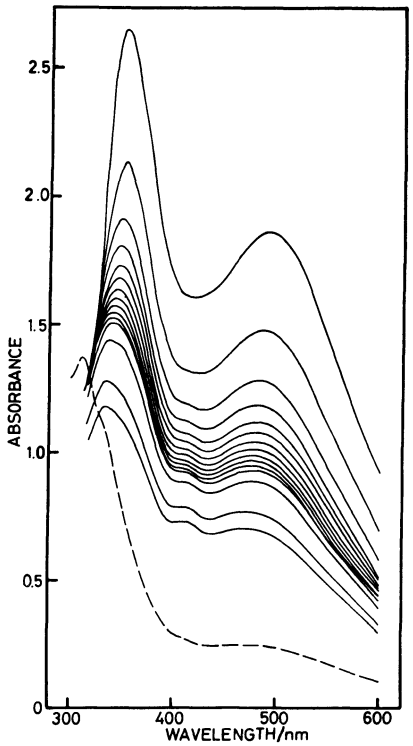

Fig. 1. Spectral change of Fe(III) complex of Z-Cys-Pro-Leu-Cys-OMe. Each spectrum from upper to lower indicates that measured after 10, 71, 130, 187, 254, 314, 383, 453, and 530 s, 10, 11, 13, 24, and 30 min from the complex formation. The broken-line indicat esthe spectrum after 13 h.

also revealed many transitions involved in the charge-transfer region as shown in Table 1. The tetrapeptide Fe(III) complexes especially Z-Cys-Ala-Ala-Cys-OMe complex previously reported,[1] exhibited spectral pattern similar to that of rubredoxin at wavelength longer than 400 nm although the magnitude of the Cotton effects was *ca.* 1/10. On the other hand, tri- and dipeptide Fe(III) complexes exhibited the CD spectra entirely different from those of the tetrapeptide complexes or rubredoxin.

Thermal Stabilities of Fe(III) Complexes of Cysteine-containing Peptides. Under anaerobic conditions, the Fe(III) complexes of the cysteine-containing peptides were unstable as reported by Christou *et al.*[6] Intense red-violet color of the Fe(III) complexes observed immediately after the addition of triethylamine faded gradually due to oxidations of the ligands by the Fe(III) ion. The spectral changes were followed in the time course. A typical example is shown in Fig. 1 for the Z-Cys-Pro-Leu-Cys-OMe complex. After 13 h, the spectrum is broken line of Fig. 1 and further change was observed. The spectrum was similar to that of the Fe(II) complex of Z-Cys-Pro-Leu-Cys-OMe which will be described elsewhere. The following reaction must be taking place:

$$4[Fe^{III}(Z\text{-cys-Pro-Leu-cys-OMe})_2]^{2-} \longrightarrow 3[Fe^{II}(Z\text{-cys-Pro-Leu-cys-OMe})_2]^{2-} + 1/2n\,(Z\text{-Cys-Pro-Leu-Cys-OMe})_n + 1/4\,Fe^{II}.$$

Half-life time for each peptide complexes was obtained by monitoring the absorbance maximum at around 500 nm, which is listed in Table 2. The results indicate that the Fe(III) complexes of Z-Cys-Thr-Val-Cys-OMe and Z-Cys-Ala-Ala-Cys-OMe are less unstable among the complexes examined by us. In contrast, the Fe(III) state of rubredoxin is stable at ambient temperature in an aqueous solution.

TABLE 2. HALF-LIFE TIMES OF Fe(III) COMPLEXES OF CYSTEINE-CONTAINING PEPTIDES

Ligand	Half-life times/min	λ_{max}/nm
Z-Cys-Thr-Val-Cys-OMe	25	495
Z-Cys-Pro-Leu-Cys-OMe	7	490
Z-Cys-Ala-Ala-Cys-OMe	16	495
Z-Cys-Ala-Cys-OMe	1	500
Z-Ala-Cys-OMe	5	495

Conditions: in Me_2SO at 33 °C.

Discussion

Structures of $[Fe^{III}S_4]$ *Cores.* The absorption, MCD, and EPR spectra of the Fe(III) peptide complexes led the conclusion that the peptide complexes have mononuclear tetrahedral $[Fe^{III}S_4]$ cores. A formation of binuclear core, $[Fe^{III}{}_2S_8]$, involved in $[Fe^{III}(SCH_2\text{-}CH_2S)_2]_2{}^{2-}$ [17] was ruled out by the MCD spectra. The Fe(III) complex of 1,2-ethanedithiolate exhibited no dispersion type band at around 490 nm but a small positive band at 427 nm and a negative one at 590 nm which were ascribed to the Faraday B-term.[16] The previous paper[1] also indicated that the ESR signals of the Fe(III) complexes of Z-Cys-Ala-Ala-Cys-OMe and Z-Ala-Cys-OMe arise from $S=5/2$ ground state (Fe(III)d^5 high spin) under approximately tetrahedral environments coordinated with four cysteinyl thiolates.

Although the peptide complexes had the similar MCD spectral features from 400 to 700 nm, they exhibited different spectral properties from 300 to 400 nm. They could be divided into two groups. One is the Fe(III) complexes of Z-Cys-Pro-Leu-Cys-OMe and Z-Cys-Ala-Ala-Cys-OMe which have a negative Faraday B-term at around 350 nm and the other has

TABLE 3. CHARGE-TRANSFER BANDS OF Fe(III) COMPLEXES OF CYSTEINE-CONTAINING PEPTIDES[a)]

no such a band at 300—400 nm.

A simple molecular orbital consideration gives a clue to interpret the charge-transfer spectra. A qualitative molecular orbital diagram for tetrahedral Fe(III) complexes is illustrated in Fig. 2, which shows the highest ligand level (L), the Fe(III) d levels, and allowed charge-transfer transitions. The molecular orbitals are constructed by a basis set consisting of 3d, 4s, and 4p of Fe(III) and 3s and 3p of S.[18)] The transition energies estimated from the MCD spectra of the peptide complexes are listed in Table 3. The transitions were assigned to those from the highest occupied ligand π or nonbonding orbitals to the half occupied metal d orbitals according to the literature.[15)] The orientations of the lone pairs on the cysteinyl S atom are shown schematically in Fig. 3. There are two lone pairs; one is perpendicular to the Fe–S–C_β plane (π-type) and the other in the plane (nonbonding type). As shown in Fig. 2 and Table 3, the transitions at around 350 nm (28600 cm^{-1}) were assignable to those from the occupied ligand orbitals ($3t_2$) to the half-occupied metal t_2 orbitals ($4t_2$). The MCD spectral characteristics sensitively reflect differences of the orientation of the π-orbitals on S atom toward Fe(III) ion (Fig. 3b). The orientation of the π-type S lone pair toward the Fe(III) ion change the energies of the Fe d_{xy} and d_{yz} as described by Bair and Goddard III.[19)] The nonbonding orbital on the S atom does not affect the Fe d orbitals in a manner observed for the π-type orbital. Thus, the MCD spectral differences in 300—400 nm region are related to the differences in the electronic states of the Fe(III) t_2 orbitals affected by the lone pairs of the S atom, mainly π-orbitals, whose orientation is determined by steric disposition of the S–C_β bond relative to the Fe–S bond as shown in Fig. 3. Conformational restriction of the peptide ligands determines these orientations and, hence, electronic structures of the $[Fe^{III}S_4]$ cores.

Chemical environments surrounding the $[Fe^{III}S_4]$ core are also important in determining properties of the core. For example, the MCD spectrum of $[Fe(S_2\text{-}o\text{-xyl})_2]^-$ exhibited entirely different feature within 300—400 nm from those of the peptide complexes and rubredoxin (Table 1) in spite of the similarities of the $[Fe^{III}S_4]$ core structures as confirmed by the X-ray structural analyses.[3,8)]

Although the absorption and MCD spectra of the peptide Fe(III) complexes did not show remarkable differences among a series of the peptide ligands examined, their CD spectra exhibited different spectral profiles as shown in Table 1. The Cotton effects in the charge-transfer region are originated with chiral charge-transfer from thiolate to Fe(III) influenced by asymmetric α-carbons of the peptide ligands. Spatial distribution of the asymmetric carbons is crucial in determining the CD spectral features. Restricted conformation of the peptide ligands around the metal ion will result in large Cotton effects. Therefore, chelate ring formation is related to the large Cotton effects.

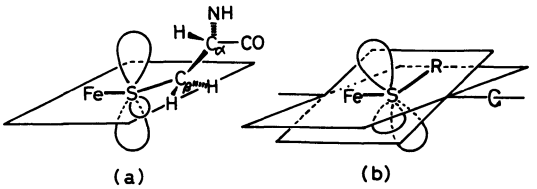

Fig. 3. (a) Schematic representation of lone pairs on S atom in $[Fe(S\text{–}Cys)_4]$ core. (b) Rotation about Fe–S bond in (a).

According to the above criteria, the Fe(III) complex of Z–Cys–Thr–Val–Cys–OMe, Z–Cys–Pro–Leu–Cys–OMe, and Z–Cys–Ala–Ala–Cys–OMe have *S,S*-chelate structures when comparisons were made with the CD spectrum of the Fe(III) complex of Z–Ala–Cys–OMe. The tetrapeptide complexes had the stronger Cotton effects; 10—50 times greater than the dipeptide complex (Table 1). The tripeptide complex shows about half CD strength of the tetrapeptide (Table 1). Further studies are required to determine the *S,S*-chelation of the tripeptide to Fe(III) ion.

Comparisons between Fe(III) Complexes of Cysteine-containing Peptides and Oxidized Rubredoxin. Relationships of the properties of the $[Fe^{III}S_4]$ cores with the spectral arrangement of the cysteine-containing peptides among the peptide Fe(III) complexes and oxidized rubredoxin will be discussed in terms of the spectral characteristics as diagnostic tools. A given orientation of the S–C_β bond around the Fe–S bond fixes location of the lone pairs on the S atom and, consequently, determines the electronic state of the $[Fe^{III}S_4]$ core, which is reflected sensitively by the MCD spectra as discussed above. Therefore, similarity of the MCD spectra between the Fe(III) complexes of Z–Cys–Pro–Leu–Cys–OMe or Z–Cys–Ala–Ala–Cys–OMe and rubredoxin (Table 1) allows us to conclude that they have similar $[Fe^{III}S_4]$ core electronic structures

controlled by the orientations of the S–C_β bonds around the Fe–S bonds. The other peptide complexes presumably have somewhat different orientations of the S lone pairs, especially π-type orbitals, which influence their MCD spectra in the $3t_2$–$4t_2$ transitions (Fig. 2).

The CD spectral resemblances between the peptide Fe(III) complexes and the native protein mean the similar arrangements of the asymmetric α-carbons between them as well as the similar orientations of the S–C_β bonds (Fig. 3a). From such a point of view, the Fe(III) complex of Z–Cys–Ala–Ala–Cys–OMe has spatial arrangement of the peptide ligands closely similar to rubredoxin around the [$Fe^{III}S_4$] core. The other tetrapeptide, Z–Cys–Thr–Val–Cys–OMe or Z–Cys–Pro–Leu–Cys–OMe, could not reproduce the CD spectral characteristic of rubredoxin completely. Cooperative effects of the both tetrapeptide units or whole protein environments seem to be important for subtle adjustments of the active site properties of native rubredoxin.

Thermal Stabilities of Fe(III) Complexes of Cysteine-containing Peptides. The thermal stabilities of the Fe(III) peptide complexes followed in the order (Table 2): Z–Cys–Thr–Val–Cys–OMe>Z–Cys–Ala–Ala–Cys–OMe>Z–Cys–Pro–Leu–Cys–OMe>Z–Ala–Cys–OMe>Z–Cys–Ala–Cys–OMe. It is interesting that the Fe(III) complex of Z–Cys–Pro–Leu–Cys–OMe, although having one of the Fe binding peptide units of rubredoxin, is somewhat less stable under these conditions. On the other hand, the Fe(III) complex of Z–Cys–Thr–Val–Cys–OMe had fairly good stability toward the oxidation of the thiolate ligand. Steric effects caused by different conformations of the two tetrapeptides in the Fe(III) complexes presumably resulted in such differences in their thermal stabilities, which were supported by their CD spectra. A recent synthesis of thermally stable $[Fe^{III}(SC_{10}H_{13})_4]^-$ ($C_{10}H_{13}S^-$= 2,3,5,6-tetramethylbenzenethiolate) revealed that the steric and conformational properties of the thiolate ligands are crucial in accounting for the stabilities of Fe(III) thiolate complexes because the synthesis of the corresponding benzenethiolate derivative has not been successful.[20] Importance of the steric and conformational effects on the cysteine-containing peptide ligands is supported by the fact that reconstituted adrenodoxin containing one Fe(III) ion at its active site, which exhibits oxidized rubredoxin-like spectra, is unstable in the Fe(III) state.[21] Adrenodoxin, which is one of the iron–sulfur proteins, has a [$Fe_2S^*_2$] core (S* denotes inorganic sulfide) chelated by two tetrapeptide units as Cys(52)–Ser–Thr–Cys(55) and Cys(92)–Glu–Ile–Cys(95) with the cysteinyl thiolates in its native state.[21] On the reconstitution, one Fe(III) ion will be accommodated by these cysteinyl thiolate ligands, but the [$Fe^{III}S_4$] core is not stabilized by the tetrapeptide units in the active site of adrenodoxin.

We thank Professor Masahiro Hatano and Dr. Tsunenori Nozawa for useful discussion of CD and MCD spectra. The present work was supported by a Grant-in-Aid from the Ministry of Education, Science and Culture.

Asymmetric Synthesis of α-Deuterated α-Amino Acids through Nonenzymatic Transamination Reaction and the Determination of Their Enantiomeric Excesses

Yoji TACHIBANA,† Makoto ANDO, and Hiroyoshi KUZUHARA*
The Institute of Physical and Chemical Research, Wako, Saitama 351

(Received April 13, 1983)

Optically active α-deuterated α-amino acids were prepared in methanol-*d* through Zn^{2+}-catalyzed transamination reaction between the chiral pyridoxamine analogs, (*R*)- or (*S*)-15-aminomethyl-14-hydroxy-5,5-dimethyl-2,8-dithia[9](2,5)pyridinophane and various α-keto acids with enantiomeric excesses ranging from 40 to 94%. Aliphatic α-keto acids gave α-deuterated α-amino acids, whereas aromatic ones possessing a methylene group between the carbonyl group (ketone) and the aromatic ring underwent concomitant deuterium substitution at the active methylene group to give the amino acids deuterated at both α- and β-positions of the carboxyl group. The use of the (*S*)-pyridoxamine analog gave the (*R*)-deuterated α-amino acids in excess and *vice versa*. The enatiomeric excesses of the amino acids were determined through the analyses of ^1H NMR spectra of the Schiff bases produced by the condensation of the amino acids with the chiral pyridoxal analog, (*R*)- or (*S*)-15-formyl-14-hydroxy-2,8-dithia[9]-(2, 5)pyridinophane. The azomethine protons of the diastereomeric Schiff bases were clearly resolved in the spectrum and their intensities well reflected the amount of the diastereomers.

Chiral α-amino acids labelled at α- or β-position of the carboxyl group have been valuable for determinig the steric course of a variety of biosynthetic transformations and conformational analyses of peptides.[1-3] However, there are only a few reports concerning the preparation of these deuterated amino acids.[4-6]

In the course of our continuous study of vitamin B_6-dependent enzyme models, we have recently reported the asymmetric synthesis of α-amino acids through the enantioselective transamination reaction between the chiral pyridoxamine analogs with a pyridinophane structure, (*R*)- or (*S*)-15-aminomethyl-14-hydroxy-5,5-dimethyl-2,8-dithia[9](2,5)pyridinophane ((*R*)- or (*S*)-**1**) or (*S*)-15-aminomethyl-14-hydroxy-2,8-dithia[9](2,5)-pyridinophane ((*S*)-**2**), and various α-keto acids in the presence of Zn^{2+}.[7,8] We have also found that the α-proton of the amino acids comes directly from the methanol employed as solvent in the nonenzymatic transamination reaction.[9] In the present paper, we wish to describe the extended application of the nonenzymatic transamination system to the asymmetric synthesis of α-deuterated α-amino acids by employing methanol-*d* as the solvent and the determination of their enantiomeric excesses by analyzing the ^1H NMR spectra of the Schiff bases prepared from the deuterated amino acids and a chiral pyridoxal analog, (*R*)- or (*S*)-15-formyl-14 hydroxy-2,8-dithia[9](2,5)pyridinophane ((*R*)- or (*S*)-**3**).[10]

Results and Discussion

The nonenzymatic transamination reactions in methanol-*d* (MeOD) were slower than those in methanol and took several days to be completed because of the solvent isotope effect.[11] The isolation of the deuterated α-amino acid produced was carried out in a similar way to that described previously for the general preparation of amino acids.[7] The NMR spectra of the products showed that aliphatic α-keto acids such as pyruvic acid, 3-methyl-2-oxobutanoic acid, and 4-methyl-2-oxopentanoic acid gave the corresponding α-deuterated α-amino acid through reaction with the pyridoxamine analog ((*R*)- or (*S*)-**1**) in the presence of Zn^{2+}. On the other hand, the employment of aromatic α-keto acids such as phenylpyruvic acid and indole-3-pyruvic acid under the same reaction conditions resulted in the corresponding amino acids deuterated at both α- and β-positions of their carboxyl group (Fig. 1). The NMR spectra of deuterated leucine, valine, and phenylalanine are shown in Figs. 2,3, and 4. The results of the elemental analyses and mass spectra of these deuterated α-amino acids are shown in Table 1. Deuteration of the active methylene group between the keto and the aromatic groups of sodium phenylpyruvate or sodium indole-3-pyruvate took place spontaneously even if the pyridoxamine analog and the metal ion were absent. However, the chelated ketimine group formed in the presence of the pyridoxamine analog and the metal ion is more electron-withdrawing than the original keto group and more strongly prompts elimination of the protons from the neighboring methylene group, resulting in deuterio substitution at that place.

Determination of the enantiomeric excess of the deuterated amino acids was not easy because the specific rotations of the authentic specimens were unknown. The utilization of the diastereomeric Schiff base mixture produced by condensation of the deuterated amino acids with some chiral aldehydes might be a promising way for the enantiomeric excess determination. Our pyridoxal analog ((*R*)- or (*S*)-**3**) could

be regarded as a candidate for the chiral aldehyde because **3** readily condensed with free amino acids in methanol at room temperature to give an aldimine type of Schiff base. We confirmed that no racemization of the general amino acid moieties in the Schiff bases took place under such mild conditions, since the amino acids recovered after acidic hydrolysis of the Schiff bases retained the full original chirality. Judging from the isotope effect, these results obtained by using general chiral amino acids would be also applicable to deuterated amino acids. Therefore, the deuterated amino acids obtained were converted into Schiff bases by condensation with (*R*)- or (*S*)-**3**. Figure 5 shows the 400 MHz ^{1}H NMR spectrum of the C_6D_6 solution of the diastereomeric mixture of the Schiff bases resulted from the reaction of the racemic α-deuterated leucine with (*R*)-**3** in methanol. The signals at δ 8.77 (b) and δ 9.00 (d) were assigned to the aldimine protons of the pyridoxal analog moiety.[12–16] The signals at δ 8.02 (a), δ 8.17 (c), and δ 8.26 (e) should be assigned to the 6-H protons on the pyridine ring.[17–18] The assignment of those signals (b—e) was confirmed by comparing them with the NMR spectra of the Schiff bases prepared from authentic sample of general (*S*)- or (*R*)-leucine and (*R*)-**3**, respectively.[19] The Schiff

a) δ from TMS in C_6D_6 (400 MHz). b) The high-field shift of the peaks is probably due to the anisotropic effect of the phenyl ring.

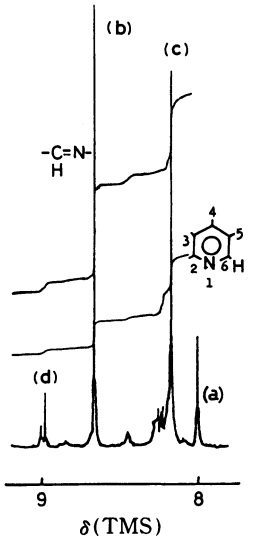

Fig. 6. ^1H 400-MHz NMR spectrum of C_6D_6 solution of the Schiff bases derived from (*R*)-**3** and deuterated leucine enriched in *S*-configuration in a molar ratio of 1.2/1 in MeOH (TMS internal standard). The signals (a—d) are; (a): 6-H proton of (*R*)-**3**, (b), (d): azomethine protons of **5** and **6**. (c): 6-H proton of **5**.

bases produced from (*S*)- or (*R*)-leucine and (*R*)-**3** can be isolated and characterized by elemental analyses, IR, and NMR spectra. When (*S*)-leucine was condensed with (*R*)-**3**, the resulting Schiff base revealed the azomethine and the pyridine ring protons at δ 8.73 and δ 8.13, respectively. When (*R*)-leucine was condensed with (*R*)-**3**, the signals for the azomethine and the pyridine ring protons appeared at δ 9.00 and 8.20. Therefore, the signals, (b) and (d), should be assigned to the azomethine protons of the Schiff bases containing (*S*)- and (*R*)-deutero leucine residues, respectively. In the same manner, the signals, (c) and (e), were apparently assignable to the protons of the pyridine ring of the Schiff bases constructed from (*S*)- and (*R*)-α-deuterated leucines, respectively. The difference of the chemical shifts between signals (b) and (d) was δ 0.23 which was enough resolution to make the accurate integration of each signal possible. Accordingly, the enantiomeric excess of the α-deuterated leucine obtained through the transamination reaction in MeOD was calculated from the ratio of the integrated intensities of the two diastereotopic azomethine protons, (b) and (d). Figure 6 shows the 400-MHz NMR spectrum of the Schiff bases prepared from the α-deuterated leucine, the product of transami-

nation reaction using (*R*)-**1**, and (*R*)-**3**. Apparent predominance of the intensity of the signal at δ 8.77 over that at δ 9.00 indicates that the transamination reaction gave (*S*)-α-deuterated leucine in excess. The enantiomeric excess was calculated as described above. Similarly, the employment of (*S*)-enantiomer of **1** gave (*R*)-α-deuterated leucine in excess. The diastereotopic azomethine protons of Schiff bases prepared from the deuterated phenylalanine and valine, and (*R*)-**3** were also clearly resolved in the 400-MHz NMR spectra (Table 2). Consequently, the enantiomeric excess of the deuterated phenylalanine and valine could be determined as has been described in the case of the deuterated leucine. These results are shown in Table 3. The (*S*)-enantiomer of the pyridoxal analog (**3**) was also employed for quantitative measurement of enantiomeric excess of the deuterated amino acids. The enantiomeric excess of the deuterated alanine and tryptophane could not be determined by this procedure because of the overlapping of the diastereotopic azomethine protons.

This method can be applied to the determination of the enantiomeric excess of amino acids in general. Table 4 compares the enantiomeric excesses of several amino acids determined by the measurement of the optical rotations and by the NMR method described above. The results obtained by the two methods are consistent, confirming the reliability of the NMR method for the determination of enantiomeric excesses of amino acids.

Experimental

The melting points were determined with a Yamato capillary melting point apparatus and are uncorrected. The optical rotations were measured with a Perkin-Elmer 241 MC polarimeter. The IR spectra were recorded on a Shimadzu IR-27 instrument. Mass spectra were recorded on a Hitachi M-80 mass spectrometer. The ^1H NMR spectra were recorded with a Varian HA-100D apparatus or a Japan Electron Optics Laboratory JEOL FX-400 with TMS or DSS as the internal standard. Chiral pyridoxamine analogs, (*R*)- or (*S*)-15-aminomethyl-14-hydroxy-5,5-dimethyl-2,8-dithia[9](2,5)pyridinophane ((*R*)- or (*S*)-**1**),[20] and chiral pyridoxal analogs, (*R*)- or (*S*)-15-formyl-14-hydroxy-2,8-dithia[9](2,5)pyridinophane ((*R*)- or (*S*)- **3**),[10] were prepared as reported previously. Microanalyses of deutérated amino acids obtained by the conventional C and H method gave the total H+D percentages as determined by the weight of H_2O and HOD formed. The determined values of H+D were calculated from the weight of H_2O+HOD produced on the assumption that the H : D atomic ratio was that of the compound analyzed.

Preparation of Deuterated Amino Acid. A typical procedure for the preparation of the deuterated amino acid is described in the following. A mixture of sodium 4-methyl-2-oxopentanoate (106 mg, 0.70 mmol), $Zn(ClO_4)_2 \cdot 6H_2O$ (67 mg, 0.18 mmol), and pyridoxamine analog ((*R*)-**1**) (112 mg, 0.36 mmol) was stirred in methanol-*d* (100 ml) at room temperature for 4 d. The methanol-*d* solution was acidified to pH 1 with 1 M hydrochloric acid (1 M=1 mol dm^{-3}) and evaporated *in vacuo*. Distilled water (50 ml) was added to the residue and the resulting mixture was extracted with ethyl acetate (200 ml) to remove the pyridoxal analog ((*R*)-**4**) produced. The aqueous layer was placed on Dowex-50 (H^+ form, 50 ml) column and eluted with distilled water (1000 ml) and 0.1 M aqueous ammonium hydroxide successively. The ammonium hydroxide effluent was evaporated *in vacuo* and the residue was redissolved in distilled water (10 ml). The solution was put on Amberlite IRC-50 (H^+ form, 15 ml) column and eluted with distilled water in order to remove trace of pyridoxamine analog ((*R*)-**1**). The effluent was concentrated to dryness *in vacuo* to give α-deuterated leucine (31.4 mg).

Determination of the Enantiomeric Excesses. A typical procedure for the determination of the enantiomeric excesses of the deuterated amino acids is exemplified by the case of leucine: a methanol solution (5 ml) of (*R*)-**3** (20.4 mg, 0.07 mmol) and the deuterated leucine (7.9 mg, 0.06 mmol) obtained was stirred at room temperature overnight and evaporated. The resulting residue was dissolved in C_6D_6 (1 ml) and the solution underwent recording the NMR spectrum at 400 MHz.

Spontaneous Deuteration at the β-Position of the Aromatic α-Keto Acids. Sodium phenylpyruvate (100 mg) was dissolved in methanol-d_4 (5 ml) and stirred at room temperature. The aliquots of the solution were taken for recording ^{1}H NMR spectrum (100 MHz). The ratio of the deuteration of the β-protons of the keto acid was determined by comparing the integral intensity of the β-protons with that of phenyl ring protons of the keto acid. The β-protons of sodium phenylpyruvate were gradually deuterated (44% at 24 h, 52% at 48 h, and 100% at 144 h, respectively). The β-protons of sodium indole-3-pyruvate were completely deuterated at 48 h.

Preparation of Schiff Base from General α-Amino Acid and Chiral Pyridoxal Analog. A mixture of (*S*)-leucine (66 mg, 0.5 mmol) and (*R*)-**3** (142 mg, 0.5 mmol) was stirred in methanol (150 ml) at room temperature overnight. After the methanol was recovered *in vacuo*, the resulting residue was extracted with benzene and the benzene solution was concentrated to about 10 ml. To the solution hexane was added gradually until a precipitate separated out. The precipitate was collected and recrystallized from a mixture of benzene and hexane to give the Schiff-base of (*R*)-pyridoxal analog-(*S*)-leucine in 65% yield: mp 100—102 °C. $[\alpha]_D^{23}$ +231° (*c* 0.13, $CHCl_3$). IR (KBr disk) 1715 (C=N) and 1625 cm^{-1} (C=O): ^{1}H NMR (400 MHz, C_6D_6) δ=8.73 (1H, s, C=N) and 8.13 (1H, s, 6-H). Found: C, 57.58; H, 7.28; N, 7.07; S, 16.41%. Calcd for $C_{19}H_{28}N_2O_3S_2$: C, 57.58; H, 7.06; N, 7.07; S, 16.18%.

The authors are grateful to Dr. Haruo Homma and his staff for performing elementary analyses, and to Dr. Jun Uzawa and Mrs. Tamiko Chijimatsu for ^{1}H NMR spectra measurement.

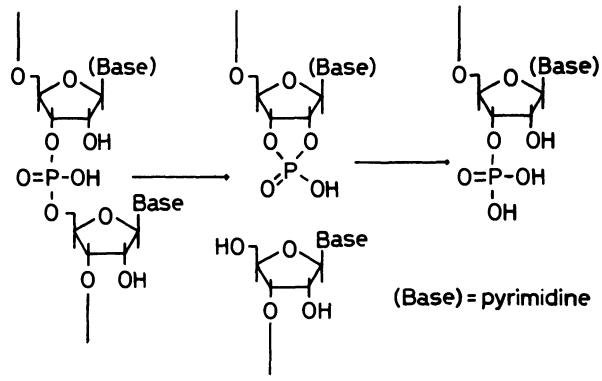
Synthesis and Properties of Cationic Polynucleotide Analog Binding RNase A

Takeo SHIMIDZU,* Akira MURAKAMI, and Kazushige YAMANA
Division of Molecular Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606
(Received April 22, 1983)

A new type of cationic polynucleotide analog binding RNase A and its related compounds were synthesized from an insoluble cross-linked poly(4-vinylpyridine). The cross-linked poly(4-vinylpyridine) was converted into an aldehyde derivative by the reaction with cyanogen bromide. The aldehyde derivative was used for the binding of RNase A and 9-(2-aminoethyl)adenine through their amino groups. The cationic adenine polynuleotide analog binding RNase A favorably interacted with nucleotides containing uracil base through the base-specific interactions. This analog showed the considerable selectivity in the hydrolysis of uridine polynucleotide owing to the template effect.

Several cationic polynucleotide analogs have been synthesized[1-3] and their interactive properties with nucleic acid bases,[4] nucleotides,[2,3,5] polynucleotides,[4] and nucleotide analogs[6,7] have also been investigated. In these studies, the mode of interactions was predominantly the base-base stacking. On the other hand, the complementary base-base interaction was pronounced in the interactions between polynucleotides and mononucleotide analogs with positive charge.[8] It was deduced that the ionic field originating from polynucleotide or its analogs makes a large contribution to the base-base interaction: the catinic field contributes to the base stacking interaction, on the other hand, the anionic one contributes to the hydrogen bonding in the complementary base-base interaction. This evidence for the contribution of the ionic field has been found in the interaction of nucleotides and nucleotide analogs in the presence of polyelectrolytes.[6,7] The mode of the base-base interaction was also affected by the hydrophobic polymer domain. The cross-linked cationic polynucleotide analogs have a tendency to interact with the complementary nucleotide.[5] The template-directed syntheses of oligonucleotides were carried out and homogeneous oligonucleotides, in which the base units are complementary to those in the polymeric "template," were found in considerable amounts, whereas scarcely any homogeneous oligomers consisting of the other nucleotide units were observed.[9]

It is expected that cross-linked cationic polynucleotide analogs, which played a role of the template, would have the ability to control the substrate specificity of enzymes which hydrolyze nucleic acids. RNase A is specific for both uracil and cytosine ribonucleotide linkages, *i.e.*, those cleaving cyclic 2′,3′-pyrimidine nucleotide residues either singly or at the termination of purine nucleotide chains[10] (Scheme 1). In order to control the substrate specificity or base specificity of RNase A, we have first time tried to bind RNase A on a cross-linked cationic polynucleotide analog. The analog consists of adenine base which is the complementary base to uracil. In this paper we describe the catalytic properties of the cationic polynucleotide analog binding RNase A in the hydrolysis of pyrimidine nucleotide linkages. This analog shows the consider able selectivity in the hydrolysis of uridine polynucleotide.



Scheme 1.

Results and Discussion

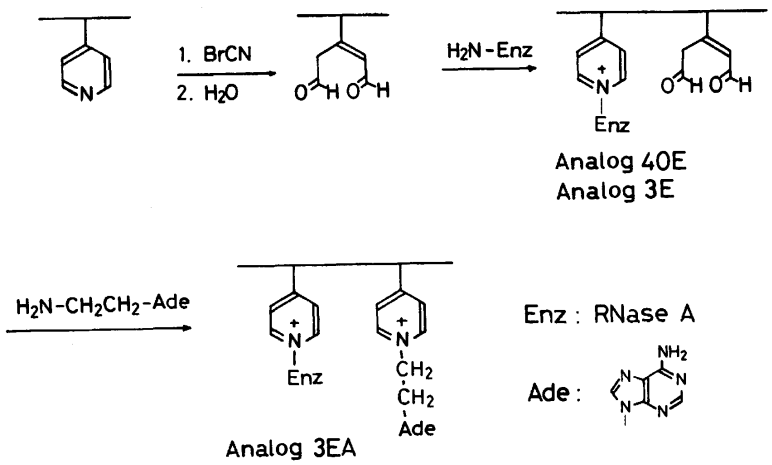
A new type of cationic polynucleotide analog binding RNase A[11] and its related compounds were synthesized from an insoluble cross-linked poly(4-vinylpyridine), according to the following scheme (Scheme 2). The cross-linked poly(4-vinylpyridine) was converted to an aldehyde derivative by the reaction with cyanogen bromide.[12] The aldehyde derivative formed was used for the binding of RNase A through its ε-amino groups and of 9-(2-aminoethyl)adenine. Excess formyl groups were reduced with borohydrides. The amounts of RNase A and adenine residue bound to poly(4-vinylpyridine), together with their abbreviations, were shown in Table 1.

In order to examine the interactive property or the template effect of the cationic polynucleotide analog binding RNase A, Analog 3EA, the affinity of the pyrimidine nucleotides with Analog 3EA and its related

TABLE 1. THE AMOUNTS OF RNase A AND ADENINE RESIDUE BOUND TO POLY(4-VINYLPYRIDINE)

	RNase A	Adenine residue
	μmol/g of dry Analog	mmol/g of dry Analog
Analog 40E[a]	0.47	—
Analog 3E[b]	0.29	—
Analog 3EA[b]	0.29	0.34

Cationic polynucleotide analog binding RNase A and its related compounds were synthesized from; a) 40% cross-linked poly(4-vinylpyridine) and b) 3% cross-linked poly(4-vinylpyridine).



Scheme 2.

TABLE 2. ADSORPTION OF PYRIMIDINE NUCLEOSIDE 2′,3′-CYCLIC PHOSPHATE[a] ON ANALOG[b]

System	$\frac{\text{Adsorbed nucleotide}}{\text{Initial nucleotide}} \times 100$
Analog 3E–Cp>	0.2
Analog 3E–Up>	2.5
Analog 3EA–Cp>	4.4
Analog 3EA–Up>	8.1

a) Nucleotide, 1.7×10^{-2} mol dm^{-3}. b) Analog, 8 mg.

compound, Analog 3E, was investigated. A solution of uridine 2′,3′-cyclic phosphate (Up>) or cytidine 2′,3′-cyclic phosphate (Cp>) was added to the analogs and then the mixture was shaken. The amount of adsorbed nucleotides on the analog was determined by UV absorbance of the supernatant. The results are shown in Table 2. Analog 3EA favorably interacts with Up>, which is caused by the specific interaction of bases.

Hydrolyses of pyrimidine nucleoside 2′,3′-cyclic phosphates in the presence of the cationic polynucleotide analog binding RNase A, Analog 3EA, its related compounds, Analog 40E, Analog 3E, and the native RNase A were carried out at 25 °C in 0.1 M† phosphate buffer (pH 7.0). The steady-state kinetic parameters are summarized in Table 3. When RNase A was immobilized on the 3% cross-linked poly(vinylpyridine), the apparent K_m values of Analog 3E in the hydrolyses of the both substrates were smaller than those of the native RNase A. It is suggested that the analog promotes the binding of the substrates. Analog 3E having a positive charge which is resulted from the immobilization of RNase A interacts with the anionic substrates through the coulombic attractive force. This interaction may promote the complex formation between the enzyme and the anionic substrates. On the contrary, by the immobilization of RNase A on the highly cross-linked poly(vinylpyridine) (40%), Analog 40E, the interaction with the substrates was slightly lower than that of the native RNase A. The k_{cat} and V_{max} values of Analog 3E in the hydrolyses of the both substrates were considerably smaller than those of the native RNase A. This means that the catalytic activity of RNase A was reduced by the immobilization on the cross-linked poly(4-vinylpyridine). That k_{cat} and V_{max} of Analog 40E in the hydrolysis of Cp> was close to those of Analog 3E shows the less effect of the degree of cross-linking on the catalytic activity. Of the cationic polynucleotide analog binding RNase A, Analog 3EA, the adenine residue showed no significant effect on the K_m, k_{cat}, and V_{max} values in the hydrolyses of not only Cp>, but also Up>. The results that Analog 3EA adsorbs the larger amount of Up> and shows no specificity in the hydrolysis of Up> indicate that the substrates are mainly adsorbed on Analog 3EA at the adenine residues which are relatively remote from the active center of the immobilized enzyme RNase A.

and 3′-5′ dicytidine monophosphate (CpC) in the presence of Analogs 3EA and 3E were carried out at 25 °C in 0.1 M phosphate buffer (pH 7.0) for 2 h. The hydrolyzed products were analyzed by HPLC. The results are shown in Table 4. CpC was hydrolyzed in the presence of both Analog 3EA and Analog 3E to the almost similar composition of the products, Cp>, Cp, and C. Similary, the distribution of the products in the hydrolysis of UpU by Analog 3EA and Analog 3E was not significantly different. These results show that Analog 3EA has no specificity in the hydrolyses of both UpU and CpC.

This feature was drastically changed in the hydrolysis of Poly U and Poly C as substrates. The results are shown in Table 5. Poly C was hydrolyzed in the presence of Analog 3EA to Cp, Cp>, CpCp, and CpCpCp. The amounts of CpCp and CpCpCp were slightly larger than those in the case of Analog 3E. On the other hand, the amounts of the products, UpUp> and UpUpUp, in the hydrolysis of Poly U by Analog 3EA were one-half to one-forth of those by Analog 3E. That is, the hydrolysis rate of Poly U by Analog 3EA is much higher than by Analog 3E. These results imply that there is no effect of adenine residue on the hydrolysis of Poly C but a considerable effect on Poly U hydrolysis. This effect is considered as follows; Poly U adsorbs on Analog 3EA through the complementary base-base interaction and it approaches to the active center of RNase A bound to Resin 3EA, for the polynucleotides having a long chain are easy to approach to the active center of the enzyme, even though the adsorption site of substrates is apart from the active center. The present study shows that the new type of cationic polynucleotide analog binding RNase A controls the substrate specificity of enzyme through the template effect.

Experimental

Materials. RNase A (Bovine Pancrease) was perchased from Sigma Chemical Co. 9-(2-aminoethyl)adenine was synthesized by the reported method.[13] 3% and 40% cross-linked poly (4-vinylpyridine) was synthesized by the copolymerization of 4-vinylpyridine with divinylbenzene. Up>, Cp>, UpU, CpC, Poly U (M. W.=10000) and Poly C (M. W.=10000) were obtained from Sigma Chemical Co.

Preparation of Cationic Polynucleotide Analog Binding RNase A and Its Related Compounds. *a) Analog 40E*: 3 g of 40% cross-linked poly(4-vinylpyridine) was reacted with 1.5 g of cyanogen bromide in 10 cm^3 of anhydrous dioxane at room temperature for 15 min. Water was then added and the mixture was stirred for 90 min at room temperature. The gel was filtered and washed with cold water. 1.5 g of the activated gel was stirred overnight in a solution of RNase A (20 mg) in 4 cm^3 of 0.05 M phosphate buffer, pH 5.0, at 10—12 °C. The gel was then treated with 1% $NaBH_4$ at room temperature for 10 min and then washed with the phosphate buffer.

b) Analog 3E: 2.6 g of 3% cross-linked poly(4-vinylpyridine) was reacted with 2.5 g of cyanogen bromide in 10 cm^3 of anhydrous dioxane at room temperature for 15 min. After the treatment with water for 60 min, the gel was washed with cold water. 0.5 g of the activated gel was stirred overnight in a solution of RNase A (23 mg) in 2 cm^3 of 0.05 M phosphate buffer, pH 5.0, at 4 °C. The gel was then treated with 1% $NaBH_4$ at room temperature for 10 min and then washed with the phosphate buffer.

c) Analog 3EA: $NaBH_4$-untreated Analog 3E was reacted with 50 mg of 9-(2-aminoethyl)adenine in the same buffer at 4 °C for overnight. Then, the gel was treated with 1% $NaBH_4$ at room temperature for 10 min and then washed with the phosphate buffer.

The Amount of RNase A and Adenine Residue Bound to Polynucleotide Analog. The amount of RNase A on Analog was determined as follows. Analog was treated with 6 M HCl at 50 °C for 6 h and the amount of released tyrosine was measured at 294 nm ($\varepsilon=2.39\times10^3$). Calculation was carried out on the fact that RNase A (M. W.=13700) contains 6 tyrosine residues.[14] The amount of adenine residue on Analog 3EA was determined from the amount of the unreacted 9-(2-aminoethyl)adenine in the washing of the reaction mixture.

Adsorption of the Substrate on Analog. A solution of the substrate (1.7×10^{-5} mol) in 0.1 M phosphate buffer, pH 7.0,

Table 5. Hydrolyses of polynucleotides[a] by Analogs 3E[b] and 3EA[b]

	Yield of product / %				
	Cp	Cp>	CpCp	CpCp>	CpCpCp
Analog 3E–Poly C	53.6	38.2	4.9	Trace	4.0
Analog 3EA–Poly C	43.4	42.3	5.7	Trace	8.6
	Yield of product / %				
	Up	Up>	UpUp	UpUp>	UpUpUp
Analog 3E–Poly U	20.3	37.0	10.7	24.6	7.7
Analog 3EA–Poly U	25.8	47.4	11.0	13.6	1.9

Reactions were carried out at 25 °C for 2 h. a) Polynucleotide, 3.7×10^{-3} mol dm^{-3}. b) Enzyme on Analog, 1.6×10^{-5} mol dm^{-3}.

(1.0 cm^3) was added to Analog (8 mg). The difference between the initial and the final (5 min after) optical densities of the supernatant was measured by UV spectroscopy at 260 nm. Thus, the apparent adsorption of the substrate on Analog was estimated.

Activity of RNase A Bound to Polynucleotide Analog. Up>, Cp>, UpU, CpC, Poly U, and Poly C were used for substrates. Hydrolyses of these substrates in the presence of Analog was carried out in 0.1 M phosphate buffer, pH 7.0, at 25 °C. Analysis of hydrolytic products was done on a HPLC(Partisil 10 SAX column; 0.001 M KH_2PO_4—0.3 M KH_2PO_4 containing 10% EtOH, a linear gradient).

a) Experiment in Table 3: Hydrolysis was carried out in a mixture of substrate (Up> and Cp>) (2.2×10^{-8}—4.1×10^{-7} mol), 0.1 M phosphate buffer pH 7.0 (0.1 cm^3), and Analog (15 mg for Analog 40E, 30 mg for Analogs 3E and 3EA). After incubation at 25 °C for 30 min, the products were filtered by Milipore Filter (Type HA, 0.45 μm) and analyzed by HPLC. Control experiment for soluble RNase A was done in a mixture of the substrates (2.2×10^{-8}—4.1×10^{-7} mol), 0.1 M phophate buffer pH 7.0 (0.1 cm^3), and the enzyme (final concentration, 4.0×10^{-5} mol dm^{-3}) at 25 °C for 5 min. Analysis of the products were the same as for Analog. Thus, the kinetic constants were determined by the Michaelis-Menten method.

b) Experiments in Tables 4 and 5: Hydrolysis was carried out in a mixture of substrates (2.3×10^{-3} mol for dinucleotide monophosphate, 3.7×10^{-3} mol for polynucleotide), 0.1 M phophate buffer, pH 7.0, (0.1 cm^3), and Analog (5 mg). After incubation at 25 °C for 2 h, the products were filtered by Milipore Filter (Type HA, 0.45 μm) and analyzed by HPLC.

^{13}C NMR Signal Assignments of Herqueinone and Its Phenalenone Derivatives

Takayuki Suga,* Takamitsu Yoshioka, Toshifumi Hirata, and Tadashi Aoki
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received April 27, 1983)

The full assignments of the ^{13}C NMR signals of the herqueinone-type phenalenone, herqueinone, were established by a combination of the single-frequency off-resonance decoupling technique and the ^{13}C-enrichment technique using the ^{13}C-labeled tracer. Furthermore, the full assignments of the ^{13}C NMR signals of deoxyherqueinone-type, dihydroherqueinone-type, and xanthoherqueinone-type phenalenone were completed on the basis of the application of the chemical shift rule and the mutual comparison of their chemical shifts.

The red pigments of *Penicillium herquei*,[1-3] such as herqueinone (**2**), atrovenetin (**4**), and deoxyherqueinone (**5**), are compounds having a phenalenone skeleton (**1**) and a 1,2,2-trimethyltetrahydrofuran ring.†,[3-14]

The biosynthetic mechanism for the formation of the phenalenone skeleton of deoxyherqueinone (**5**) was clarified by feeding experiments with ^{14}C- and ^{13}C-labeled acetates.[15-18] On the other hand, the feeding experiment of ^{13}C-labeled malonate indicated that the trimethylfuran ring of herqueinone-type pigments was biologically formed from mevalonic acid.[17,18] However, a biosynthetic mechanism for the formation of the trimethylfuran ring fused to the phenalenone skeleton is still unknown. Before clarifying the mechanisms of the prenylation and the cyclization of its prenyl chain, it was necessary to complete the full assignments of the ^{13}C NMR signals of herqueinone (**2**) and its derivatives (**3**) and (**5**)—(**13**). We have now established the full assignments of the ^{13}C NMR signals of these phenalenones by use of the decoupling techniques and the ^{13}C-enrichment technique.

† This is abbreviated as trimethylfuran ring hereinafter.

Results and Discussion

The phenalenones derived from herqueinone (**2**) were classified into four groups, such as herquinone-type, deoxyherqueinone-type, dihydroherqueinone-type, and xanthoherqueinone-type phenalenones, on the ground of their structures. The assignments of the ^{13}C NMR signals of these four types of phenalenones were completed as follows.

Herqueinone-type Phenalenones. The proton noise decoupling ^{13}C NMR spectra of herqueinone (**2**) exhibited 20 signals in [$^2H_6$]dimethyl sulfoxide and [$^2H_5$]pyridine solutions. The signals at δ_c 131.3, 109.2, 178.6, 78.9, 150.7, and 138.8 were assigned to C-1, C-2, C-3, C-4, C-8, and C-13, respectively, on the basis of the application of the chemical shift rule[19,20] and the comparison of the ^{13}C chemical shifts of **2** with those of the corresponding carbon atoms of previously reported deoxyherqueinone diacetate (**7**).[17,18] Furthermore, the ^{13}C NMR signals due to the protonated carbon atoms at the 12-, 14-, 15-, 1′-, 2′-, 4′-, and 5′-positions were completely assigned by use of Birdsall's method,[21] as shown in Fig. 1. Consequently, the signals at δ_c 122.8, 59.9, 18.6, 95.9, and 15.9 were assigned to C-12, C-15,

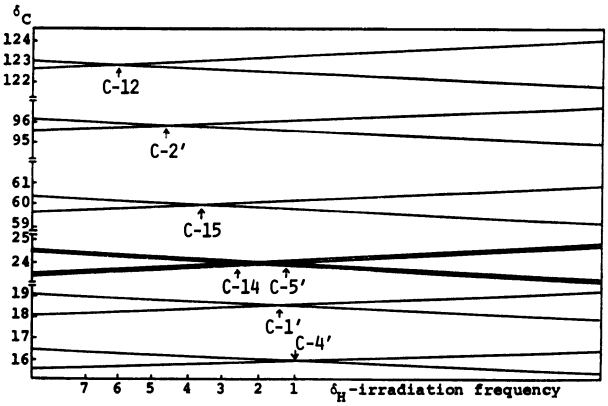

Fig. 1. Birdsall plot of SFORD data for herqueinone (**2**).

C-1′, C-2′, and C-4′, respectively. The signals of C-5′ and C-14 overlapped each other at δ_c 23.8. On the other hand, the distinction between the signals for C-5 and C-11, C-6 and C-10, and C-7 and C-9 was difficult, because of the symmetry of the phenalenone skeleton. However, we succeeded in full assignments of these signals as follows. First, the assignments of the signals due to C-6 and C-10 were completed by the gated decoupling method; the spectrum in the presence of D_2O exhibited $^3J_{CH}$ (4 Hz) at δ_c 103.2 to the aromatic proton on C-12 and the singlet signal at δ_c 102.7, and the signals at δ_c 102.7 and 103.2 were evidently assigned to C-6 and C-10, respectively. Next, the distinction between the signals for C-5 and C-11 and C-7 and C-9, in addition to C-6 and C-10, at the symmetrical positions of the molecule was performed by diagnosis of the ^{13}C–^{13}C spin couplings due to the nine acetate units in the molecule of ^{13}C-enriched herqueinone (**2**) biosynthesized by incorporation of [1,2-$^{13}C_2$]acetate in *P. herquei*. As the incorporation pattern of seven acetate units in the phenalenone skeleton of deoxyherqueinone (**5**) biosynthesized from [1,2-$^{13}C_2$]acetate in *P. herquei* has been previously established,[17,18] the carbon skeleton of the molecule of herqueinone (**2**) should be occupied by the ^{13}C–^{13}C spin coupling pairs originating from [1,2-$^{13}C_2$]acetate as shown in Fig. 2. The ^{13}C NMR spectra of the ^{13}C-enriched herqueinone (**2**) showed the nine ^{13}C–^{13}C spin couplings as shown in Table 1. Analysis of the coupling constants established the assignments of the signals for C-5, C-6, C-9, C-10, and C-11 which constituted the coupling pairs with C-4, C-7, C-8, C-1, and C-12, respectively Thus, the full assignments of the ^{13}C NMR signals of herqueinone (**2**) were completed.

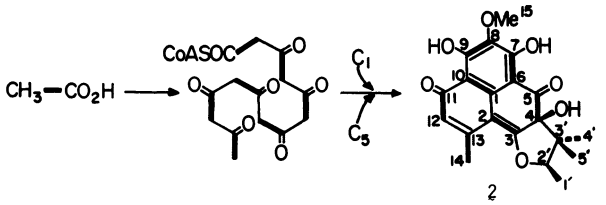

Fig. 2. ^{13}C incorporation pattern of the acetate units (—) in herqueinone (**2**).

TABLE 1. ^{13}C–^{13}C SPIN COUPLINGS IN THE ^{13}C NMR SPECTRUM OF HERQUEINONE (2) BIOSYNTHESIZED FROM [1,2-$^{13}C_2$]ACETATE[a]

Carbon	δc[b]	$^1J_{CC}$	Carbon	δc[b]	$^1J_{CC}$
1	131.3	80	11	186.4	56

8	150.7	42	3′	43.1	36[c]
9	163.0	44	4′	15.9	37
10	103.2	79	5′	23.8	0

a) These δc and $^1J_{CC}$ values differ from those described in Ref. 7, but these are the corrected after careful reexamination. b) Taken in [$^2H_6$]DMSO containing TMS as an internal standard (δ_{TMS}=0.0) : number of scan; 29253 times. c) These $^1J_{CC}$ values were obtained in [$^2H_5$]pyridine.

The chemical shifts of the ^{13}C NMR signals of bromoherqueinone (**3**) were in fair agreement with those of **2** except for that of the conjugated carbonyl group at the 11-position. The C-11 signal of **3** shifted to higher-field by about 5 ppm in comparison with that of **2**. This higher-field shift might be caused by the reason why the halogenation at the neighboring position of the conjugated carbonyl group breaks up slightly the conjugated system. Such a higher-field shift has been observed on the ^{13}C NMR spectrum of 3-bromo-5-hydroxy-1,4-naphthoquinone.[22]

Deoxyherqueinone-type Phenalenones. Deoxygenation at the 4-position of herqueinone (**2**) gave deoxyherqueinone (**5**), which was then converted into the corresponding dimethyl ether (**6**) and diacetate (**7**). The ^{13}C chemical shifts of the diacetate (**7**) were in fair agreement with those of the deoxyherqueinone diacetate described previously in the literature.[17,18] These described chemical shifts were supported by examination of the assignments of the protonated carbon atom signals by use of Birdsall's method.[21] For the signals at δc 163.5 and 159.6 in the ^{13}C NMR spectrum of **5**, these were assigned to C-9 and C-11, respectively, by considering the acetylation shift between the signals of **5** and **7**. The signals of C-9 and C-11 overlapped at δ_c 161.5 in the ^{13}C NMR spectrum of **6**. The assignments of the other ^{13}C NMR signals of **5** and **6** were completed by comparing the signals with those of the corresponding carbon atoms of **7**.

Dihydroherqueinone-type Phenalenones. Herqueinone (**2**), on hydrogenation followed by methylation, gave dihydroherqueinone monomethyl ether (**8**) and dimethyl ether (**10**). Acetylation of **8** afforded the diacetate (**9**) with two acetoxyl groups at the 7- and 11-positions. On the other hand, acetylation of **10** gave the monoacetate (**11**) with an acetoxyl group at the 11-position and diacetate (**12**) with two acetoxyl groups at the 4- and 11-positions.

The ^{13}C NMR signal of C-3 of these dihydroherqueinone-type phenalenones (**8**—**12**) was assigned by use of the off-resonance decoupling technique. The signals of C-9 and C-11 of **8** were assigned on the basis of the higher-field shift of about 10 and 30 ppm, respectively, in comparison with those of **2**. The other signals of **8** were assigned by comparison of the chemical shifts with those of the corresponding carbon atoms of **2**. On the other hand, the assignments of the signals for C-7 of **9**—**12** and for C-11 of **9**, **11**, and **12** were completed on the basis of the higher-field shifting on methylation or acetylation. The other ^{13}C signals of dihydroherqueinones (**9**—**12**) were assigned by comparison of the chemical shifts with those of the corresponding carbon atoms of **2** and **8**.

It is interesting to note that the ^{13}C NMR signal of C-1′ of deoxyherqueinones (**5**—**7**) and the signal of C-5′ of dihydroherqueinones (**8**—**12**) appear at a higher field in comparison with those of the corresponding carbon atoms of herqueinone (**2**), while the signals of C-4′ and C-5′ of deoxyherqueinones (**5**—**7**) appear

a) Taken in [^{2}H$_6$]DMSO (δ_{TMS}=0.0): number of scan; *ca.* 1500—4300 times. b) Taken in [^{2}H$_5$]pyridine. c and d) Values in any vertical column may be interchanged although those given here are preferred.

at a lower field in comparison with those of **2**. These seem to be due to the difference in the influence of the anisotropy[23] caused by the phenalenone ring. The plane angle formed by the phenalenone skeleton and the trimethylfuran ring of the deoxyherqueinones (**5**—**7**) is about 180° in model.[24] Therefore, the anisotropic effect to the C-1′ methyl group of deoxyherqueinones (**5**—**7**) may be greater than that in the case of herqueinone (**2**), whereas the effect to the C-4′ and C-5′ methyl groups may be less than that in that case. On the other hand, the plane angle of dihydroherqueinones (**8**—**12**), is smaller than that in the case of herqueinone (**2**). Therefore, the C-4′ and C-5′ methyl groups of **8**—**12** may be equally influenced by the anisotropy of the carbonyl group and the aromatic rings.

Xanthoherqueinone-type Phenalenone. The ^{13}C NMR chemical shifts of xanthoherqueinone (**13**) were in fair agreement with those of the phenalenone skeleton of **5**, except for the signals of phenolic carbon atoms at the 3-, 4-, and 5-positions. These signals appeared at δC 152.3, 130.1, and 165.4 and were assigned to the phenolic carbon atoms, respectively, by application of the chemical shift rule.

The final assignments of the ^{13}C NMR signals of herqueinone (**2**) and its derivatives (**3**) and (**5**—**13**) are given in Table 2.

Experimental

The fungal culture of *Penicillium herquei* Bainer and Sartory (IFO 7904) was obtained from the Institute for Fermentation.†† Sodium [1,2-^{13}C$_2$]acetate was purchased from the British Oxygen Company Co. Ltd. The ^{1}H NMR spectra were taken, with TMS as an internal standard, at 60 and 90 MHz. The ^{13}C NMR spectra were obtained on a Hitachi R-42 FT NMR spectrometer at 22.631 MHz at 35 °C in an 8 mm spinning tube; precisions of δ_c are about $\pm$0.1. FT measurement conditions were as follows: spectral width, 250 ppm; filtering, 6 KHz; pulse width, 45°; pulse interval, 1.800 s; number of data points, 8000. The series of single-frequency off-resonance decoupling ^{13}C NMR spectra of herqueinone (**2**) and deoxyherqueinone diacetate (**7**) were recorded with the ^{1}H decoupling frequency set at ten different points started from the upfield to the downfield in increments of about 100 Hz in the ^{1}H NMR region (Fig. 1). The gated decoupling with NOE was measured by a JEOL FX-200 FT NMR spectrometer at 50.150 MHz at 0 °C in a 5 mm spinning tube: pulse width, 45°; pulse interval, 6.00 s; number of data points, 8000; precisions of δ_C, $\pm$0.02. The EI-MS spectra were obtained on a Hitachi RMU-6L mass spectrometer at 70 eV. Analytical and preparative TLC were carried out on Merck 60 GF$_{254}$ silica-gel plates which were 0.25- and 0.5 mm-thick, respectively.

Isolation of Herqueinone. The spores, obtained from the preculture of *P. herquei* on the malt extract-agar medium, were

a) Taken in the neat film.

inoculated to the Raulin-Thom solution.[2] After inoculation, this culture of *P. herquei* was incubated at 25 °C for 25 d. The mycelia produced on the medium were filtered off, and immersed in EtOAc. On the other hand, the filtered medium was acidified to pH 5, and extracted with EtOAc. This EtOAc extract of the medium was combined with the EtOAc extract of the mycelia, because the two EtOAc extracts exhibited the same behavior on TLC. The combined EtOAc extract (*ca.* 5 g), after removal of the solvent, was subjected to centrifugal liquid chromatography on silica gel (3 mm in thickness and 10 cm in radius) with EtOAc–hexane (1 : 4 v/v) as solvent to give a red powder (310 mg). Recrystallization of this red powder from EtOH gave herqueinone (**2**) (275 mg) as red needles: mp 217—218 °C (lit,[8] 218—222 °C); $[\alpha]_D^{25}$ +374° (c 1.68, $CHCl_3$) (lit,[8] $[\alpha]_D$ +300° ($CHCl_3$)); IR (Nujol) 3300 (OH), 1640 and 1626 (C=O), 1591 and 1512 (aromatic C=C), 1247 and 1039 (C–O–C), and 1100 cm^{-1} (cyclic C–O–C); IR (0.0002M, CCl_4) 3315 cm^{-1} (intramolecular hydrogen bonded OH); UV_{max} (cyclohexane) 450 (log ε 4.45), 307 (5.60), 254 (5.08), and 223 nm (5.34); ^1H NMR ([$^2H_6$]DMSO) δ=6.28 (1H, d, J=1.5 Hz, 12-H), 4.83 (1H, q, J=6.5 Hz, 2′-H), 3.80 (3H, s, 15-H_3), 2.50 (3H, d, J=1.5 Hz, 14-H_3), 1.55 (3H, d, J=6.5 Hz, 1′-H_3), 1.40 (3H, s, 5′-H_3), and 1.00 (3H, s, 4′-H_3); MS m/z (rel intensity) 372 (M^+, 100%) and 341 (M^+-OCH_3, 68).

Found: C, 64.51; H, 5.49%. Calcd for $C_{20}H_{20}O_7$: C, 64.51; H, 5.41%.

Preparation of ^{13}C-enriched Herqueinone. Sodium [1,2-$^{13}C_2$]acetate (270 mg, 92% enriched) dissolved in distilled water (5 ml) was added into each of 5 flasks which contained a 14-d old culture (200 ml) of *P. herquei*. After further cultivation for 11 d, the usual work-up of the cultures gave the sample of ^{13}C-enriched herqueinone (**2**) (44 mg), with about 31% ^{13}C-abundance at each labeled position. The ^{13}C–^{13}C spin couplings in the ^{13}C NMR spectra of the ^{13}C-enriched **2** were determined, and the results are given in Table 1.

Preparation of the Phenalenone Derivatives. According to the method givin in the literature,[3] bromoherqueinone (**3**) and deoxyherqueinones (**5**—**7**) were derived from herqueinone (**2**) as follows. Bromination of **2** with Br_2 gave bromoherqueinone (**3**). Deoxygenation of **2** with Zn dust gave deoxyherqueinone (**5**). Furthermore, **5** was methylated with CH_2N_2 to give the dimethyl ether (**6**), and acetylated with the acetic anhydride–pyridine mixture to give the diacetate (**7**). The dihydroxyherqueinones (**8**—**12**) were also derived from **2** following the method given in the literature[8] as follows. Methylation of the product, obtained by hydrogenation of **2** in the presence of Pd–C, gave dihydroherqueinone methyl ethers (**8**) and (**10**). These methyl ethers were acetylated with the acetic anhydride–pyridine mixture to give the acetates (**9**) and (**11**), and with the acetic anhydride–*p*-toluenesulfonic acid mixture to give the diacetate (**12**). Xanthoherqueinone (**13**) was derived from **2** by acid-hydrolysis under the same conditions as described in the literature.[2]

The physical and analytical data of these phenalenones (**3**)

Photochemical Reactions of 2-(Dimethylcarbamoyl)quinolines

Isao ONO* and Norisuke HATA
Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157

(Received August 19, 1983)

2-(Dimethylcarbamoyl)quinolines are converted into 2-(methylaminoacetyl)quinolines (**2**) and 2-methyl-1*H*-pyrrolo[3,4-*b*]quinolin-3(2*H*)-ones (**3**) by irradiation in a nitrogen atmosphere. The reaction was quite efficient in acetonitrile but inefficient in hydrocarbon solvents and ethanol. The introduction of a chlorine atom to the 4-position of a quinoline nucleus caused an increase of the yield of **3** in company with a decrease of the yield of **2**. On the other hand, irradiation in an oxygen atmosphere afforded 2-(methylcarbamoyl)quinolines as a main product but **2** and **3** were minor products. The results of quenching and sensitization experiments confirmed that the triplet π,π^* state was responsible for the formation of those products. It is suggested that the reaction involves zwitterionic intermediates formed *via* Type II hydrogen abstraction by the ring nitrogen from the *N*-methyl group.

The photochemical behavior of cyano-substituted quinolines and isoquinolines has been a subject of continuing interest in our laboratory since we found that 2-quinolinecarbonitriles undergo the photochemical replacement of the cyano group by a hydroxyalkyl group in an alcoholic solvent.[1] Recently, this reaction was proved to proceed *via* a singlet radical pair formed by hydrogen abstraction by the ring nitrogen from the hydrogen-bonded alcohol.[1e] However, photochemical studies of the quinolines bearing an electron-withdrawing substituent other than the cyano group are few and the photochemical behavior of *N*-alkyl amides substituted on azanaphthalenes is still ambiguous, although α-cleavage of alkyl amides such as the case of *N*-hexylhexanamide is well known.[2] Therefore, we investigated the photochemical reactions of 2-(dimethylcarbamoyl)-quinolines (**1**) in several solvents. We discuss the nature of the intermediates involved in this reaction and the reaction pathway.

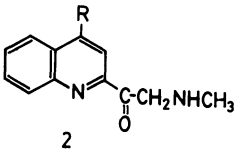
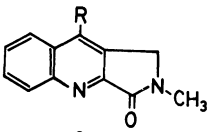
1c : R=Cl

Identification and Chemical Yields of Products. Irradiation of 2-(dimethylcarbamoyl)quinolines **1a—c** in a nitrogen atmosphere resulted in the formation of two products, **2** and **3**. The product **2** has the UV spectra of a quinoline type and its IR spectra show weak absorption by NH stretching at 3350 cm^{-1} and CO absorption at 1680 cm^{-1}. On the NMR spectra, the signals due to the methyl and methylene groups were found as doublet lines at 2.85 and 4.62 ppm, respectively. On the basis of these data, in addition to mass spectra and elemental analysis, **2** was determined to be 2-(methylaminoacetyl)quinoline. For the product **3**, the NMR signals due to the methyl and methylene groups were observed as singlet peaks, and it was found that one proton of the aromatic protons disappeared. The mass spectra showed that the molecular weight of **3** was less by two than that of **1**. The presence of the CO group was confirmed by the IR spectra. Hence, **3** was reasonably deduced to be 2-methyl-1*H*-pyrrolo-[3,4-*b*]quinolin-3(2*H*)-one.



2



3

2a, 3a : R=H
2b, 3b : R=CH3
2c, 3c : R=Cl

As shown in Table 1, the yield distribution of **2** and **3** in acetonitrile or benzene remarkably changed by introduction of the chloro substituent at the 4-position of a quinoline nucleus, but there was no significant effect by the methyl substituent. That is, the irradiation of **1a** and **1b** produced **2** as a major product and **3** as a minor one, while in the case of **1c** the yield of **2c** decreased extremely and that of **3c** increased. On the other hand, the yields of both products were very low in cyclohexane and ethanol.

Irradiation of **1** under an oxygen atmosphere gave 2-(methylcarbamoyl)quinolines (**4**) as a major product, and **2** and **3** as the minor products (Table 2). Identification of **4** was made by comparison with an authentic sample prepared according to the literature.[3] The

irradiation of acetonitrile solution of **1a** containing propylamine produced **4a** and 2-(propylcarbamoyl)-quinoline **4d** in 24 and 14% yields, respectively.

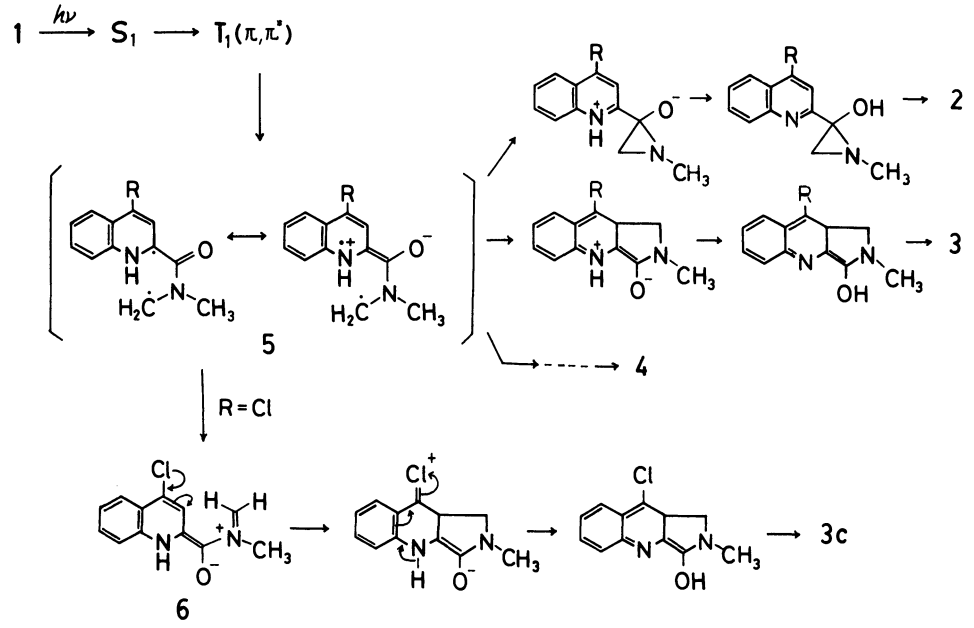
Emission and Absorption Spectra of 1. The phosphorescence spectra of **1** could be measured in methylcyclohexane and ethanol at 77 K (Table 3), although no fluorescence was observed in either solution. From the first maxima of the spectra, the triplet excitation energy (E_T) was determined to be about 250 kJ mol^{-1}, which is higher than that of 1,3-cyclohexadiene (E_T=219 kJ mol^{-1}) and lower than that of benzophenone (E_T=289 kJ mol^{-1}). This long phosphorescence lifetime, over 1 s, indicates that the T_1 state of **1** can be assigned to $^3\pi,\pi^*$ type. The UV spectra of **1** was similar to that of quinoline, but not to that of 2-quinolinecarbonitrile, suggesting that the carbamoyl substituent conjugates with a quinoline nucleus to only a small extent. This implies that the excitation energy of **1** may be localized in a quinoline moiety, namely the $T_1(\pi,\pi^*)$ is the excited state of the quinoline nucleus.

Triplet Sensitization. A solution of **1** in deaerated acetonitrile or benzene containing benzophenone was irradiated with 366 nm light for 20 h. As a result, **2** and **3** were obtained in a product distribution similar to that in the case of the direct photolysis (Table 4). On the other hand, benzophenone sinsitization of **1a** in acetonitrile in the presence of oxygen gave **4a** in a 18% yield besides 25% of **2a** and a small amount of **3a**. This fact suggests that the triplet state is responsible for the formation of **4** as well as for **2** and **3**, and that the reaction to **4** involves an oxidation process.

Quantum Yields and Triplet Quenching. The quantum yields of both the disappearance (Φ_d) and the formation (Φ_f) for the photochemical reactions of **1a** and **1c** were determined under a nitrogen atmosphere; the results are given in Table 5. The quantum yields for the formation of **2a** and **3c** were larger in acetonitrile than in benzene, and became very low in cyclohexane and ethanol. The measurements for the minor products **3a** and **2c** were not attempted in this experiment, because those yields were too low to be precisely evaluated.

Next, the quantum yields in the presence of 1,3-cyclohexadiene were determined in deaerated acetonitrile. The Stern-Volmer plots are shown in Fig. 1. The linear relation of the plots for the quantum yields of **2a** and **3c** indicates that both products were formed through the $T_1(\pi,\pi^*)$ state. The quenching constants were estimated from the slopes to be 1.6×10^4 dm^3 mol^{-1} for **2a** and 1.0×10^4 dm^3 mol^{-1} for **3c**. The quenching constants for the quantum yields of disappearance evaluated from the linear portion of the plots were 1.2×10^4 dm^3 mol^{-1} for **1a** and 0.7×10^4 dm^3 mol^{-1} for **1c**. No large difference between the constants for formation quantum yield and for disappearance quantum yield indicates that, even if any reaction proceeds *via* the excited singlet state, it may be quite inefficient.

Reaction Mechanism. The primary step of the reaction of **1** may be γ-hydrogen abstraction by the ring nitrogen in the $T_1(\pi,\pi^*)$ state. Considering that the product formation is more effective in acetonitrile than in the hydrocarbon solvents, the reaction is expected to proceed *via* an ionic intermediate. Such a solvent effect and the chloro substituent effect on the reaction may be explained in terms of the mechanism involving zwitterionic intermediates, as shown in Scheme 1.



Scheme 1.

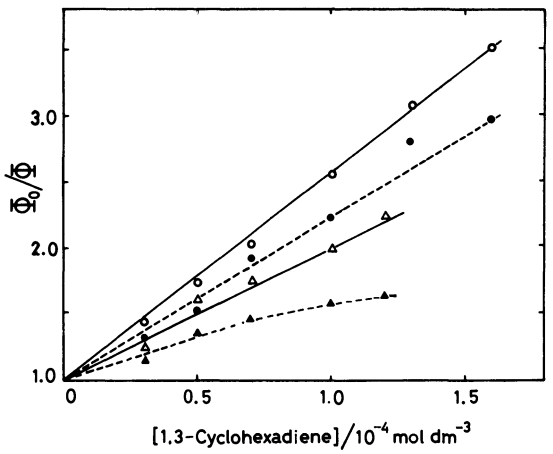


Fig. 1. Stern-Volmer plots for 1,3-cyclohexadiene quenching of the photochemical reactions of **1a** and **1c** in acetonitrile.
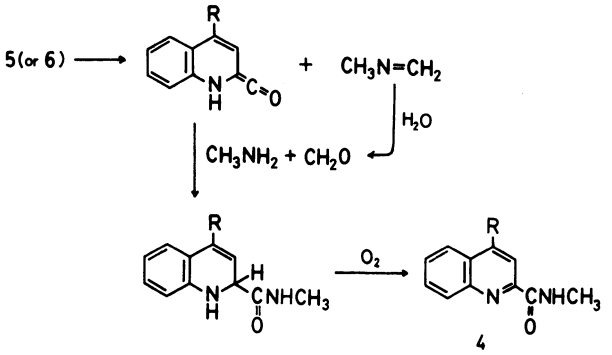
—○—: Formation of **2a**, ···●···: disappearance of **1a**,
—△—: formation of **3c**, ···▲···: disappearance of **1c**.

The intermediate **5** formed by the γ-hydrogen abstraction is in a resonance form of diradical and zwitterionic structures. The products **2** and **3** may be formed not *via* diradical structure but *via* zwitterionic one, because the contribution of the latter structure increases in a polar solvent, acetonitrile. The prominent increase of the yield of **3c** could be rationallized by assuming that the reaction **1c**→**3c** proceeds through a zwitterion **6**; the mesomery effect of the chlorine atom promotes the electron density on the carbon atom at the 3-position of a quinoline nucleus, which would be favorable for the cyclization of **6** followed by the formation of **3c**. Aoyama *et al.* have clarified that Type II cyclization of α-oxoamides occurs *via* zwitterion intermediates analogous to the type of **6** and that the zwitterions were stabilized in protic solvents.[4a] This explains the result that the yield of **3c** is larger in acetonitrile. The lower yields of the products **2** and **3** in ethanol may be attributed to the formation of a hydrogen bond between the ring nitrogen and the solvent. Such hydrogen-bonding is expected to suppress intramolecular hydrogen abstraction by the excited ring nitrogen. Previously, we have reported that 2-quinolinecarbonitriles undergo photochemical substitution derived from hydrogen abstraction by the ring nitrogen from the solvent alcohol.[1] However, we could not find the corresponding reaction in the case of **1**.

The formation of **4** is explained by assuming the decomposition of **5** to ketenes and imines. The decomposition is possible from both diradical and zwitterionic structures, and also from the zwitterion **6**. It is well known that such ketenes and imines are responsible for the formation of *N*-monosubstituted amides in the presence of moisture. For example, the photochemical reaction of *N*,*N*-diisopropylmethacrylamide was reported to give *N*-isopropylbutyramide *via* the dimethylketene and the corresponding imine.[4b] The photochemical formation of 2-(propylcarbaboyl)quinoline **4d** from **1a** in the presence of propylamine supports the reaction mechanism. The fact that **4** was formed only in the presence of oxygen indicates that it may be necessary for the oxidation of dihydroquinolines to **4**.



4-Acylpyrimidines were suggested to undergo γ-hydrogen abstraction by the ring nitrogen and Type II elimination by the carbonyl group in each n,π^* triplet state situated close together.[5] The carbamoyl group of **1** is easily deduced to possess the ^{3}CT state on the analogy of the fact that a formamid has an excited intramolecular charge transfer state.[6] If the ^{3}CT state lies close to the $T_1(\pi,\pi^*)$ state, the hydrogen abstraction by the carbonyl group from the *N*-methyl group may occur by way of an electron transfer mechanism well known for the photoreduction of amino ketones[7] and give a 1,3-biradical, which could also account for the formation of **2** and **3**. However, such a hydrogen transfer through the five-membered transition state is ineffective and there are few reports.[8] Therefore, hydrogen abstraction by the ring nitrogen is thought to be a more reasonable mechanism for the reaction of **1**.

Experimental

The NMR spectra were determined in $CDCl_3$ on a Hitachi-Perkin Elmer R-20, using TMS as an internal standard. The mass spectra were measured by a Hitachi RMU-6M or a Hitachi M-80 A double focus mass spectrometer. The IR spectra were taken on a JASCO A-302 and UV spectra were measured on a Shimadzu UV-220. The phosphorescence spectra were recorded with a Hitachi MPF-2A.

Materials. All solvents used in the irradiation experiment were reagent grade from Wako Pure Chemical Industry. Acetonitrile was refluxed in the presence of phosphorus pentaoxide for 10 h and distilled. Cyclohexane was used after purification by silica gel chromatography. Ethanol and benzene were used without further purification. 1,3-Cyclohexadiene and benzophenone from Tokyo Kasei Kogyo Co. were purified by distillation or recrystallization from ethanol, respectively. 2-(Dimethylcarbamoyl)quinoline **1a**—**c** were prepared by treating the corresponding 2-quinolinecarboxylic acids with $SOCl_2$ and dimethylamine.[3] The carboxylic acids were obtained from the basic hydrolysis of 2-quinolinecarbonitriles[9] synthesized by Reisert reaction of quinoline, 4-methylquinoline, and 4-chloroquinoline *N*-oxides which were prepared by the methods given in the literature.[10] **1a** and **1b** were purified by alumina chromatography, using a mixture of chloroform and diethyl ether as an eluent, and **1c** was recrystallized from a mixture of hexane and ethanol.

*2-(Dimethylcarbamoyl)quinoline (**1a**).* Colorless liquid; NMR δ=3.15 (3H, s, CH_3), 3.21 (3H, s, CH_3), 7.40—8.34 (6H, m, ArH); MS *m/e* 200 (M^+); IR (neat) 3050, 2910, 1670 (CO) cm^{-1}.

*2-(Dimethylcarbamoyl)-4-methylquinoline (**1b**).* Colorless liquid; NMR δ=2.62 (3H, s, CH_3 on ring), 3.15 (3H, s, *N*-CH_3), 3.18 (3H, s, *N*-CH_3), 7.34—8.24 (5H, m, ArH); MS *m/e* 214 (M^+); IR (neat) 3050, 2940, 1650 (CO) cm^{-1}.

*2-(Dimethylcarbamoyl)-4-chloroquinoline (**1c**).* Mp 64—65 °C; NMR δ=3.21 (6H, s, $(CH_3)_2$), 7.32—8.33 (5H, m, ArH); MS *m/e* 236/234 (M^+); IR (KBr) 3050, 2950, 1650 (CO) cm^{-1}.

*General Procedure of Direct Irradiation of **1**.* **1a**—**c** (200 mg) dissolved in 70 cm^3 of acetonitrile, benzene, cyclohexane, or ethanol were irradiated in a Pyrex vessel with a 100 W high pressure immersion mercury lamp (Riko Kagaku Sangyo Co.) in a nitrogen or oxygen atmosphere for 20 h. After the evaporation of the solvent, the residue was chromatographed on silica gel (Wakogel C-300). Elution with a mixture of chloroform and diethyl ether separated **2**, **3**, and **4**. Liquid products were purified on thin-layer chromatography of Kieselgel (PF_{254}, Merck) by being developed with the same eluent.

*2-(Methylaminoacetyl)quinoline (**2a**).* Colorless liquid; NMR δ=2.85 (3H, d, J=6.0 Hz, NHC$\underline{H}_3$), 4.62 (2H, d, J=9.1 Hz, C$\underline{H}_2$NH), 7.00—8.41 (7H, m, ArH and NH); MS *m/e* 200 (M^+); IR (neat) 3400 (broad), 3350 (NH), 3070, 2950, 1680 (CO) cm^{-1}. Found: C, 69.83; H, 6.14; N, 13.06%. Calcd for $C_{12}H_{12}N_2O$ 1/3 H_2O: C, 69.90; H, 6.15; N, 13.59%.

*2-(Methylaminoacetyl)-4-methylquinoline (**2b**).* Mp 80—81 °C (from hexane–ethanol); NMR δ=2.69 (3H, s, CH_3 on ring), 2.93 (3H, d, J=6.2 Hz, NHC$\underline{H}_3$), 4.72 (2H, d, J=9.1 Hz, C$\underline{H}_2$NH), 7.09—8.40 (6H, m, ArH and NH); MS *m/e* 214 (M^+); IR (KBr) 3330 (NH), 3050, 2940, 1675 (CO) cm^{-1}. Found: C, 72.77; H, 6.59; N, 13.09%. Calcd for $C_{13}H_{14}N_2O$: C, 72.90; H, 6.54; H, 13.08%.

*2-(Methylaminoacetyl)-4-chloroquinoline (**2c**).* Colorless liquid; NMR δ=2.99 (3H, d, J=7.0 Hz, NHC$\underline{H}_3$), 4.75 (2H, d, J=8.9 Hz, C$\underline{H}_2$NH), 7.33—8.45 (6H, m, ArH and NH); MS *m/e* 236/234 (M^+); $C_{12}H_{11}N_2OCl$ was determined with a Hitachi M-80 A double focus mass spectrometer; IR (neat) 3350 (NH), 3080, 2940, 1680 (CO) cm^{-1}.

*2-Methyl-1H-pyrrolo[3,4-b]quinolin-3(2H)-one (**3a**).* Mp 198 °C (from ethanol); NMR δ=3.22 (3H, s, CH_3), 4.48 (2H, s, CH_2), 7.18—8.50 (5H, m, ArH), MS *m/e* 198 (M^+); IR (KBr) 3050, 2940, 1680 (CO) cm^{-1}. Found: C, 72.11; H, 5.02; N, 13.97%. Calcd for $C_{12}H_{10}N_2O$: C, 72.73; H, 5.05; N, 14.14%.

*2,9-Dimethyl-1H-pyrrolo[3,4-b]quinolin-3(2H)-one (**3b**).* Mp 178 °C (from ethanol); NMR δ=3.12 (3H, s, CH_3 on ring), 3.25 (3H, s, *N*-CH_3), 4.47 (2H, s, CH_2), 7.20—8.34 (4H, m, ArH); MS *m/e* 212 (M^+); $C_{13}H_{12}N_2O$ was determined with a Hitachi M-80 A double focus mass spectrometer; IR (KBr) 3080, 2930, 1680 (CO) cm^{-1}.

*9-Chloro-2-methyl-1H-pyrrolo[3,4-b]quinolin-3(2H)-one (**3c**).* Mp 166 °C (from ethanol); NMR δ=3.26 (3H, s, CH_3), 4.46 (2H, s, CH_2), 7.34—8.48 (4H, m, ArH); MS *m/e* 234/232 (M^+); IR (KBr) 3050, 2910, 1690 (CO) cm^{-1}. Found: C, 61.62; H, 3.93; N, 11.91%. Calcd for $C_{12}H_9N_2OCl$: C, 61.94; H, 3.87; N, 12.04%.

The structures of **4a**—**d** were determined by the comparison with the authentic sample synthesized according to the same method as that used for the preparation of **1**.[3]

*2-(Methylcarbamoyl)quinoline (**4a**).* Mp 118 °C (from ethanol); NMR δ=3.12 (3H, d, J=5.1 Hz, NHC$\underline{H}_3$), 7.41—8.31 (7H, m, ArH and NH); MS *m/e* 186 (M^+); IR (KBr) 3350 (NH), 3080, 2960, 1660 cm^{-1}.

*2-(Methylcarbamoyl)-4-methylquinoline (**4b**).* Mp 109 °C (from ethanol); NMR δ=2.76 (3H, s, CH_3 on ring), 3.18 (3H, d, J=5.4 Hz, NHC$\underline{H}_3$), 7.40—8.35 (6H, m, ArH and NH); MS *m/e* 200 (M^+); IR (KBr) 3330 (NH), 3090, 2940, 1660 (CO) cm^{-1}.

*2-(Methylcarbamoyl)-4-chloroquinoline (**4c**).* Mp 140 °C (from ethanol); NMR δ=3.11 (3H, d, J=5.5 Hz, NHC$\underline{H}_3$), 7.37—8.42 (6H, m, ArH and NH); MS *m/e* 222/220 (M^+); IR (KBr) 3350 (NH), 3080, 2950, 1660 (CO) cm^{-1}.

*2-(Propylcarbamoyl)quinoline (**4d**).* Colorless liquid; NMR δ=0.978 (3H, t, J=6.6 Hz, $CH_2C\underline{H}_3$), 1.34—2.04 (2H, m, $CH_2C\underline{H}_2CH_3$), 3.49 (2H, q, J=7.6 Hz, NHC$\underline{H}_2CH_2$), 7.44—8.43 (7H, m, ArH and NH); MS *m/e* 214 (M^+); IR (neat) 3380 (NH), 3050, 2950, 1670 (CO) cm^{-1}.

Triplet Sensitization. Acetonitrile or benzene solution (110 cm^3) containing **1** (0.05 g) and benzophenone (0.1 g) was irradiated for 20 h with 366 nm light through a UV-35 Toshiba filter from a 500 W high pressure mercury lamp (USH-500D, Ushio Electric Inc.). The products were isolated by thin-layer chromatography of Kieselgel (PF_{254}, Merck), using a mixture of chloroform and diethyl ether.

Quantum Yield Determination. A deaerated solution con-

taining 3×10^{-4} mol dm^{-3} **1a** or **1c** was irradiated at 313 nm in a quartz cylindrical cell (5-cm in diameter and 1-cm in length), using a USH-500D lamp as a light source. The 313-nm line was isolated by a combination of a $NiSO_4$ solution with UV-29 and UVD-33S filters. The light intensity was determined by means of a potassium trioxalatoferrate(III) actinometer. The amount of the products (**2a** and **3c**) and consumed starting materials (**1a** and **1c**) were determined spectrometrically after the separation by a silica-gel column (chloroform was used as an eluent). Conversions ranged from 10 to 20%.

Asymmetric Reduction with C_1- and C_2-Symmetric NADH Model Compounds Containing Chiral 1,1′-Binaphthyls

Masaki AMANO, Motoshi WATANABE, Naomichi BABA, Jun'ichi ODA,* and Yuzo INOUYE
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received May 28, 1983)

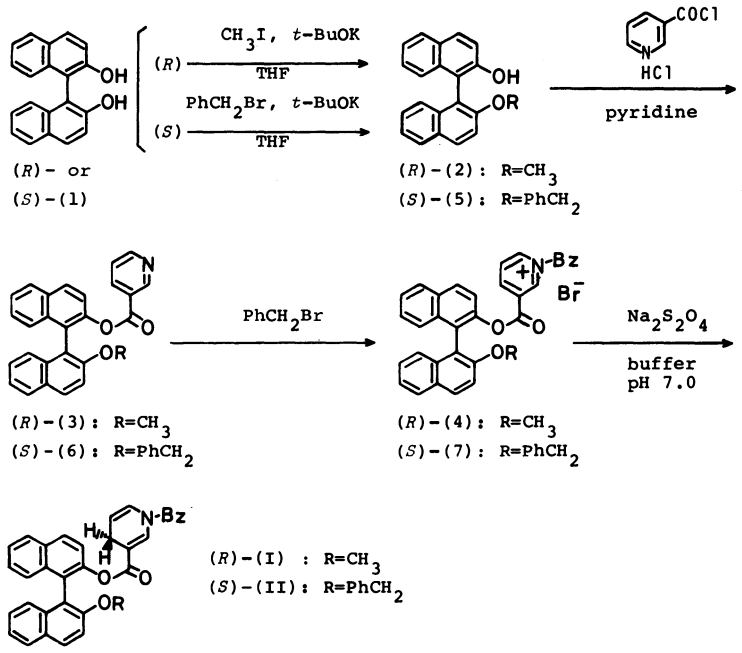
The present study deals with Mg-catalyzed asymmetric reduction of ethyl benzoylformate by the use of C_2-symmetric NADH model compounds in which axial dissymmetry(chiral 1,1′-binaphthyl derivatives) was introduced as a chiral source for the first time and the results were compared with those obtained by the corresponding C_1-symmetric models bearing the same chiral center. Better e.e.'s of the reduction product were obtained by the use of NADH models having C_2-symmetry than does the corresponding C_1-symmetric ones. Further, the kind of bonding as well as the distance between chiral binaphthyl and the reaction center affected the stereochemical course of hydrogen transfer.

Recently some intriguing works have been reported concerning salient effect of C_2-symmetry on the asymmetric synthesis for improving stereoselectivity. The study includes alkylation of enamines,[1] asymmetric reduction of prochiral carbonyl substrates by the use of lithium aluminium hydride modified with chiral 1,1′-binaphthyl,[2] borane–amine complexes modified with optically pure 1,1′-binaphthyl[3] and bis(NADH) model compound,[4] and Michael addition reactions catalyzed by C_2-symmetric chiral crown complexes.[5] However, at present, it is a question that what structure of the chiral reactant(s) is necessary for manifestation of the C_2-symmetry effect in general.

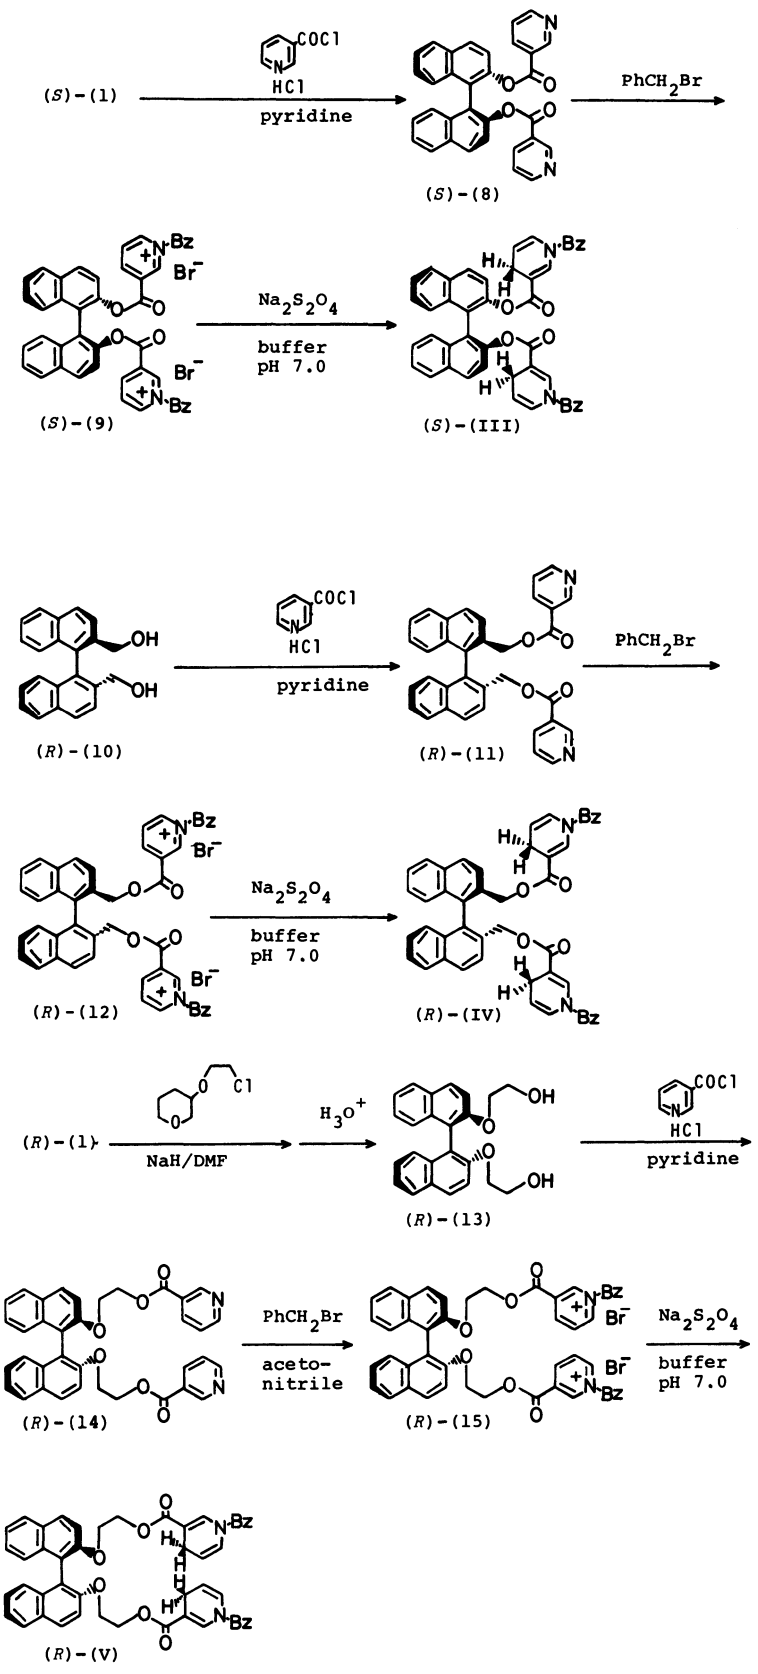
In the present study, we intended to design C_2-dissymmetric[6] NADH model compounds which have a C_2-axis passing through the center of the molecule and have diastereotopic hydrogens at the reaction center. For this purpose, a class of chiral 1,4-dihydropyridines were prepared in which axially dissymmetric binaphthyls were introduced for the first time as a chiral moiety instead of centro-asymmetry, and asymmetric reduction of ethyl benzoylformate was conducted therewith. The results were compared with those obtained by the use of the corresponding C_1-symmetric NADH models bearing the same chirality and the effect of C_2-symmetry was assessed. In addition, influence of polar functional groups, bonding mode of dihydropyridine and chiral binaphthyls as well as the distance between the reaction center and the binaphthyl moiety on the stereoselectivity were discussed.

Results and Discussion

Synthesis of C_1- and C_2-Symmetric NADH Model Compounds (NAH) with Chiral Binaphthyls. In the molecular design for constructing the axially dissymmetric NADH model compounds, enantiomeric 1,1′-bi-2-naphthols, 1,1′-bi-2-naphthylamines and 2,2′-bis-(hydroxymethyl)-1,1′-binaphthyls were introduced as the chiral center of choice. These chiral sources were prepared from 2-naphthol and 2-methylnaphthalene according to the literature.[7-9] The synthetic route for final 1,4-dihydropyridines were shown in Scheme 1 for (*R*)-(**I**) and (*S*)-(**II**), Scheme 2 for (*S*)-(**III**), (*R*)-



Scheme 1.



Scheme 2.

(**IV**), and (*R*)-(**V**), Scheme 3 for (*S*)-(**VI**), (*S*)-(**VII**), and (*S*)-(**VIII**). In particular, in the last step of synthesis of NADH models (**I**—**V**) possessing ester bonding, the sodium dithionite reductions were carried out in a phosphate buffer adjusted at pH 7.0 to avoid ester hydrolysis under the conventional basic conditions. All the C_1- and C_2-symmetric NADH models thus prepared were featured by their fluorescence on tlc and also

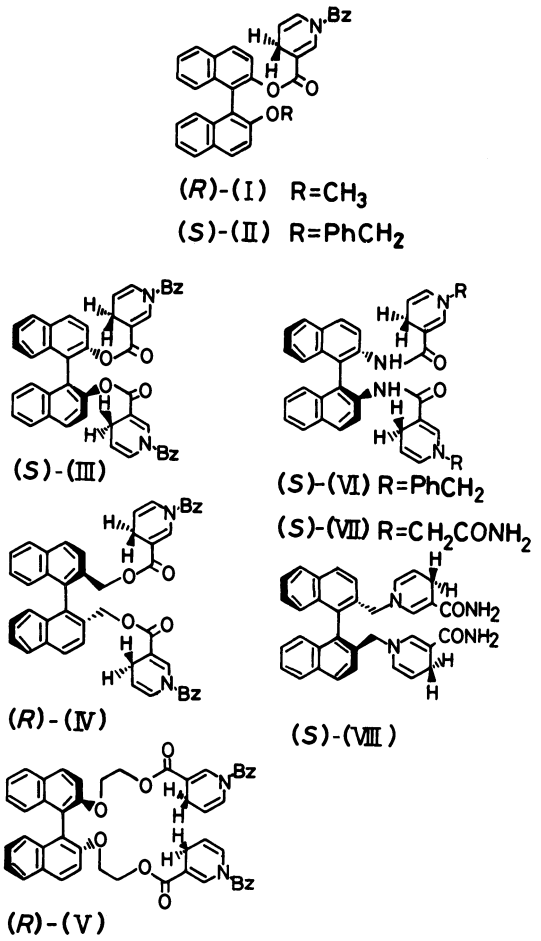
fully substantiated by their NMR and UV spectra.

Asymmetric Reduction of Ethyl Benzoylformate with Present NADH Models. In the present study, the magnesium perchlorate-catalyzed asymmetric reduction of ethyl benzoylformate was preferred as the model system of choice since considerable amount of informations have already been accumulated from both mechanistic and stereochemical aspects,[10] which would make the analysis of the experimental results easier. The results from the asymmetric reductions of ethyl benzoylformate at the ratio of $Mg(ClO_4)_2$: NAH=1 : 2 (mol : mol) by the use of the NADH models (**I**—**VIII**) were listed in Table 1.

The reductions of ethyl benzoylformate by the use of (*R*)-(**I**) and (*S*)-(**II**), both of C_1-symmetry, gave the reduction products (*R*)- and (*S*)-ethyl mandelate in 10 and 9% e.e. respectively (runs 1 and 2). The rather moderate optical yield may partially be ascribed to the ester function as pointed out by Ohno in the system involving chiral 1,4-dihydropyridine with *l*-menthyl group linked by the amide, ester or carbonylmethylene group.[11] The free rotation about the ester bond could



also be responsible for the low stereoselectivity. On the other hand, the model reaction using C_2-symmetric (*S*)-(**III**) even with the same ester bondings gave (*R*)-mandelate in much higher e.e. (43.2%) clearly suggesting that individual dihydropyridines hinder the free rotations around the ester bonds each other rendering a decrease of the number of conformations at the stereochemical determining stage. As will be shown later in this section, the interaction of dihydropyridylcarbonyloxy group with magnesium ion seems to be little as judged from UV spectrometry. So that, the augmentation of the optical yield caused by introducing a C_2-symmetry axis could possibly be ascribed to the enhanced access of the substrate to one specific face of dihydropyridine moiety by steric requirement, as were demonstrated by Whitesell in the enamine alkylation[1] and Inouye in the bis (NADH) model reaction.[4] In the model (*S*)-(**III**), the two dihydropyridine nuclei disposed in C_2-symmetry on the chiral binaphthyl may expose the specific one of their faces toward outside, permitting the access of substrate from the outside to the faces predominantly. However, when dihydropyridine moieties are removed from the chiral binaphthyls, as the cases with (*R*)-(**V**) the steric effect of chiral binaphthyls on the dihydropyridines may be diminished. Actually, observed e.e. by the use of (*R*)-(**IV**) and (*R*)-(**V**) steeply decreased giving 8.8%-(*S*) and 5.7%-(*R*) product respectively. It is also noteworthy that both the reductant (*S*)-(**III**) and (*R*)-(**V**) gave the same (*R*)-mandelate. Thus, the product stereochemistry was reversed by removing the reaction center from the binaphthyl moiety.

The model (*S*)-(**VI**) differs from (*S*)-(**VIII**) in that the binaphthyl was linked at 3-position of the dihydropyridine for the former whereas at N_1-position for the latter. Interesting is a result from this difference that product configuration was dramatically reversed from (*R*)-45.6% to (*S*)-43.5%.

Stereochemical behavior of (*S*)-(**III**) and (*S*)-(**VI**) reductants in the asymmetric reductions were further examined in detail. The reduction of ethyl benzoylformate by the use of these two models were conducted in the presence of varying amounts of magnesium perchlorate and the optical yields were plotted against the catalyst amount. As shown in Fig. A-1 and B-1, with the reductant (*S*)-(**III**), the e.e.'s remained constant in contrast to the case with (*S*)-(**VI**) where the e.e.'s changed greatly by variation of the catalyst amount with a maximum optical yield (45.6%) at $Mg(ClO_4)_2$/(**VI**)=0.5. However, the maximum values with the both reductants were very similar. Furthermore, the reduction with (*S*)-(**VI**) showed a dependence of e.e. on the reaction conversion as shown in Fig. B-2, whereas such was not the case with (*S*)-(**III**) (Fig. A-2). The two markedly different stereochemical behaviors between these models should obviously be ascribed to the difference in electronic nature of the ester and the amide functions. In fact, as revealed by UV spectroscopy, the reductant (*S*)-(**VI**) showed a spectral change with varying amounts of magnesium perchlorate (Fig. B-3), while no change was observed for (*S*)-(**III**) indicating that the amide functions interact to some extent with magnesium ion[12] in contrast to the ester functions (Fig. A-3). Accordingly, the chelative properties of the amide group must be responsible for the dependence of e.e. on the catalyst amount and on the reaction conversion observed in the asymmetric reduction with the model (*S*)-(**VI**). From this view, the C_2-symmetric diester reductant (*S*)-(**III**) could be regarded as a reasonable model to demonstrate unequivocally the importance of C_2-symmetry for the stereoselectivity since the electronic factor involving chelative interaction of the model (*S*)-(**III**) with magnesium ion seems to be negligible for the stereochemical course of the hydrogen transfer as described above.

In the present study, axial chirality was transferred successfully for the first time to centro-chirality of the reduction product in NADH model systems and the importance of C_2-symmetry for stereospecificity was unambiguously demonstrated by the use of the model (*S*)-(**III**) derived from optically active binaphthyl. In the diamide model (*S*)-(**VI**), the chelative interaction with magnesium ion was found to be significant and responsible for the dependence of e.e. on the catalyst amount as well as the reaction conversion.

Also, of interest was a finding that the product stereochemistry including configurational reversal was found to be greatly dependent on the bonding site of the dihydropyridine (N_1-position in **VIII** and 3-position in **I**—**VII**) to chiral moiety and also on the distance between the binaphthyls and the reaction center.

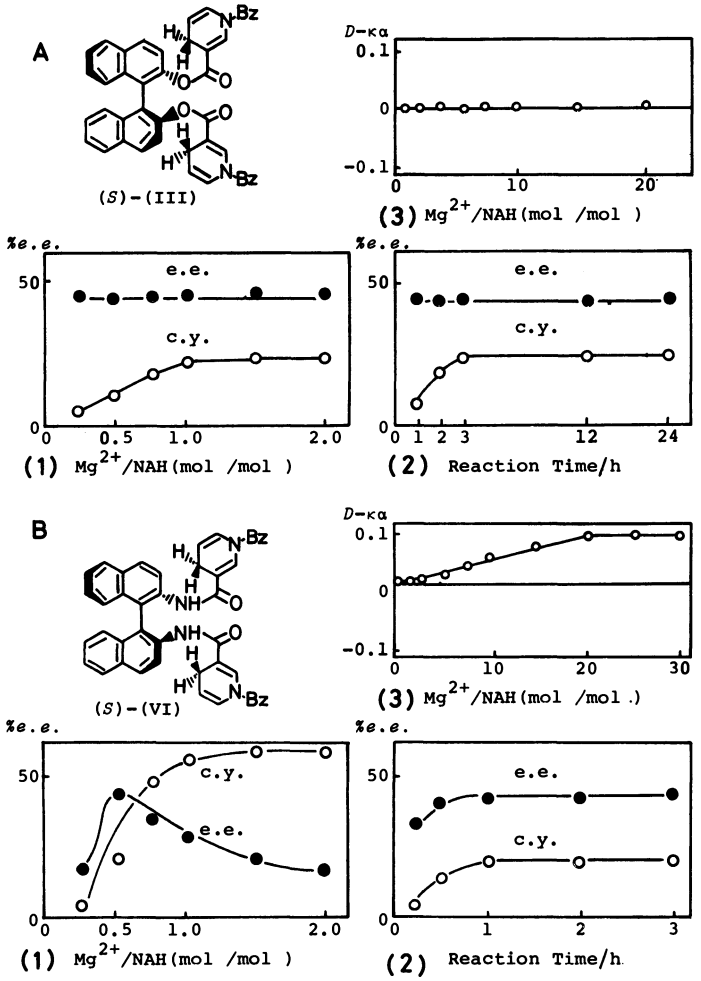


Fig. 1. Dependence of e.e. on the catalyst amount and the reaction conversion in the asymmetric reductions of ethyl benzoylformate with (*S*)-(**III**) and (*S*)-(**VI**), and determination of the mole ratio in the complexes of these models with magnesium perchlorate by UV spectroscopy.

Experimental

General. IR spectra were recorded with a Hitachi 215 spectrometer, ^{1}H-NMR spectra with a Varian EM-360 spectrometer with tetramethylsilane as internal standard. UV spectra were recorded on a Hitachi 340 spectrometer. Optical rotations were measured with a Perkin-Elmer 241 polarimeter. VPC analyses were performed on a Shimadzu GC-4CM instrument with 15% polyethylene glycol succinate(PEGS) on Chromosorb W at 180 °C. Preparative VPC analyses were on Varian Aerograph Model 920 with alminum column (3 m) packed with 15% Apiezone L at 190 °C.

Ethyl benzoylformate from commercial source was purified by chromatography (Kieselgel 60, 70—230 mesh) eluted by benzene, followed by distillation. Anhydrous magnesium perchlorate was kept in a vacuum desiccator over phosphorus pentoxide. Acetonitrile was distilled over phosphorus pentoxide. Ethanol was distilled over calcium hydride.

General Procedure for Asymmetric Reduction. A mixture of ethyl benzoylformate, NADH model compound (NAH) and magnesium perchlorate in dry acetonitrile (10 ml/1.0 mmol) was stirred at room temperature under nitrogen atmosphere in the dark, after which water (1 ml) was added to the reaction mixture. The mixture was stirred for 5 min at room temperature, and extracted with dichloromethane. The organic phase was evaporated *in vacuo*. The residue was chromatographed on TLC (Kieselgel G nach Stahl, Type 60) with benzene. The purity of the alcohol obtained was confirmed by VPC and ^{1}H-NMR.

Chemical yields were determined by VPC. Optical yields were calculated from optical rotations of the isolated ethyl mandelate based on the reported maximum rotation of enantiomerically pure ethyl mandelate, $[\alpha]_D^{25}$ $\pm$104.4° in ethanol.[13]

(R)-2-Hydroxy-2'-methoxy-1,1'-binaphthyl (R)-(2): A mixture of (*R*)-1,1'-bi-2-naphthol (**1**) (3.0 g, 10.5 mmol, $[\alpha]_D^{25}$ +31.5°, *c* 1.03, THF) and *t*-BuOK (1.8 g, 10.5 mmol) in 200 ml of dry THF was stirred under nitrogen atmosphere and methyl iodide (1.49 g, 10.5 mmol) in 50 ml of dry THF was added dropwise. The mixture was heated under reflux for 15 h, cooled and concentrated under reduced pressure. The residue was partitioned between dichloromethane and saturated sodium carbonate solution. The organic layer was washed with brine, dried and the solution was evaporated under reduced pressure to give an oil which was purified by silica-gel column chromatography with benzene elution; yield 1.94 g (61.6%), $[\alpha]_D^{25}$ +38.59° (*c* 0.99, THF), ^{1}H-NMR (chloroform-d_1): δ=3.86 (3H, s, $-CH_3$), 5.03 (1H, s, -OH), 7.15—8.30 (12H, m, aromatic protons).

(R)-2-Methoxy-2'-(3-pyridylcarbonyloxy)-1,1'-binaphthyl (R)-(3): To a solution of nicotinoyl chloride hydrochloride (1.8 g, 10.1 mmol) in pyridine (50 ml), (*R*)-(**2**) (2.0 g, 6.7 mmol) was added and the mixture was stirred at room temperature overnight, followed by reflux for 2 h. After cooling, evaporation under reduced pressure gave a residue, which was partitioned betweed dichloromethane and saturated sodium carbonate solution. The aqueous layer was extracted with dichloromethane. The organic layer was washed with brine, dried and chromatographed on silica-gel column chromatography with dichloromethane solution; yield 2.5 g (92.5%), $[\alpha]_D^{25}$ +29.10° (*c* 1.00, THF), ^{1}H-NMR (chloroform-d_1): δ= 3.73 (3H, s, $-CH_3$), 7.00—8.20 (14H, m, aromatic and pyridine protons), 8.40—8.80 (2H, m, pyridine).

(S)-2-Benzyloxy-2'-hydroxy-1,1'-binaphthyl (S)-(5): Benzyl ether (*S*)-(**5**) was prepared in the same manner with (*S*)-(**2**) from (*S*)-1,1'-bi-2-naphthol (3.0 g, 10.5 mmol) and benzyl bromide (1.80 g, 10.5 mmol); yield 2.6 g (66.0%), $[\alpha]_D^{25}$ −58.61° (*c* 1.034, THF), mp 93 °C, ^{1}H-NMR (chloroform-d_1): δ=4.96 (1H, s, -OH), 5.10 (2H, s, $-CH_2-$), 6.90—8.20 (17H, m, aromatic protons).

(S)-2-Benzyloxy-2'-(3-pyridylcarbonyloxy)-1,1'-binaphthyl (S)-(6): (*S*)-(**6**) was prepared in the same manner with (*R*)-(**3**) from (*S*)-(**5**) (2.4 g, 6.4 mmol) and nicotinoyl chloride hydrochloride (1.7 g, 9.5 mmol); yield 3.1 g (100%), $[\alpha]_D^{25}$ −44.73° (*c* 2.28, ethanol), ^{1}H-NMR (chloroform-d_1): δ=5.10 (2H, s, $-CH_2-$), 7.00—8.30 (14H, m, aromatic and pyridine protons), 8.60—8.80 (2H, m, pyridine).

(S)-2,2'-Bis(3-pyridylcarbonyloxy)-1,1'-binaphthyl (S)-(8): To a mixture of nicotinoyl chloride hydrochloride (22 g, 124 mmol) in a solution of triethylamine (25 g) in dichloromethane (200 ml), was added a dichloromethane solution (200 ml) of (*S*)-1,1'-bi-2-naphthol (**1**) (15 g, 52 mmol) and refluxed for 1 h, cooled and washed with saturated sodium carbonate solution and brine, dried over anhydrous sodium sulfate, followed by concentration under reduced pressure. The residue was chromatographed on silica-gel column with ethyl acetate as eluent to give pure (*S*)-(**8**); yield 21.0 g (81%), $[\alpha]_D^{25}$ −79.5° (*c* 1.00, ethanol), ^{1}H-NMR (chloroform-d_1): δ=7.05—8.20 (16H, m, aromatic and pyridine protons), 8.60—8.90 (4H, m, pyridine).

(R)-2,2'-Bis(3-pyridylcarbonyloxymethyl)-1,1'-binaphthyl (R)-(11): Binaphthyl derivative (*R*)-(**11**) was prepared in the same manner with (*S*)-(**8**) from (*R*)-2,2'-bis(hydroxymethyl)-1,1'-binaphthyl (**10**)[9] (1.1 g, 3.5 mmol) and nicotinoyl chloride hydrochloride (1.45 g, 8.4 mmol); yield 1.1 g (66.0%). In the preparation of this compound, the diol[optical purity 81%, $[\alpha]_D^{25}$ +68.0° (*c* 0.98, acetone)] was used. $[\alpha]_D^{25}$ +9.28° (*c* 1.00, chloroform), ^{1}H-NMR (chloroform-d_1): δ=5.27 (2H, s, $-CH_2-$), 7.17—8.20 (16H, m, aromatic and pyridine protons), 8.50—9.20 (4H, m, pyridine).

(R)-2,2'-Bis(2-hydroxyethoxy)-1,1'-binaphthyl (R)-(13): To a solution of (*R*)-1,1'-bi-2-naphthol (**1**) (1.0 g, 3.5 mmol: $[\alpha]_D^{25}$ +31.9° (*c* 1.00, THF) in DMF (20 ml) was added NaH (390 mg, 8.13 mmol, 50% oil emulsion). The mixture was heated to 70 °C with stirring under nitrogen atmosphere. After 1 h, 2-chloroethyl tetrahydro-3-pyranyl ether (1.32 g, 8.02 mmol) was added. The reaction mixture was stirred at 70 °C for 48 h in a nitrogen stream, cooled and shaken with 100 ml of water. The mixture was extracted with dichloromethane, and the combined organic layer was washed with water, dried, and concentrated. To the residue, dichloromethane (50 ml), methanol (25 ml) and 7 drops of concd hydrochloric acid was added and stirred for 1 h at room temperature. The reaction mixture was neutralized with saturated sodium hydrogencarbonate solution, washed with water, dried over anhydrous sodium sulfate and concentrated. The residue was crystallized from benzene–hexane; yield 920 mg (70%), $[\alpha]_D^{25}$ −21.6° [7] (*c* 1.01, THF), ^{1}H NMR (chloroform-d_1): δ=2.30 (2H, br, -OH), 3.60 (4H, m, $-CH_2O-$), 4.13 (4H, m, $-OCH_2-$), 6.80—8.20 (12H, m, aromatic protons), MS *m/e* (M^+) 374.

(R)-2,2'-Bis[2-(3-pyridylcarbonyloxy)ethoxy]-1,1'-binaphthyl (R)-(14): (*R*)-(**14**) was prepared in a similar procedure to the preparation of (*S*)-(**8**) from (*R*)-(**13**) (2.74 g, 7.32 mmol) and nicotinoyl chloride hydrochloride (5.48 g, 30.8 mmol); yield 4.1 g (96.0%), $[\alpha]_D^{25}$ −50.58° (*c* 1.02, THF), ^{1}H-NMR (chloroform-d_1): δ=4.30 (8H, s, $-CH_2CH_2-$), 7.10—8.05 (16H, m, aromatic and pyridine protons), 8.66—9.00 (4H, m, pyridine), MS *m/e* (M^+) 584.

(S)-2,2'-Bis(3-pyridylcarbonylamino)-1,1'-binaphthyl (S)-(17): To a solution of nicotinoyl chloride hydrochloride (7.0 g, 39.3 mmol) in pyridine (100 ml), (*S*)-1,1'-bi-2-naphthylamine (**16**)[8] (4.85 g, 17.1 mmol) was added and heated at 80 °C for 1 h. After the period, the mixture was cooled, followed by addition of saturated sodium hydrogencarbonate solution. The mixture was extracted with chloroform and the organic layer was washed with brine, dried over anhydrous sodium sulfate, concentrated and the residue was crystallized from ethyl acetate–benzene to give pure (*S*)-(**17**); yield 6.20 g (73.5%), $[\alpha]_D^{25}$ −127.08° (*c* 1.008, chloroform), IR ν (cm^{-1}, KBr): 3300—3500 ν (N-H), 1680 ν (C=O), 680—820 δ (aromatic C-H), ^{1}H-NMR (chloroform-d_1): δ=7.0—8.7 (22H, m, aromatic and pyridine protons and NH).

The Preparation of Oxidized Forms (R)-(4), (S)-(7), (S)-(9), (R)-(12), (R)-(15), (S)-(18), (S)-(19), and (S)-(21). The bromides (*R*)-(**4**), (*S*)-(**7**), (*S*)-(**9**), (*R*)-(**12**), and (*R*)-(**15**) were prepared by the use of stoichiometric amount of benzyl bromide without solvent to avoid cleavage of ester linkage by solvolysis. The salt, (*S*)-(**18**) was prepared by heating with benzyl bromide in acetonitrile. These quaternized salts were submitted as such to the sodium dithionite reduction without further purification. The amide, (*S*)-(**17**) was quaternized with chloroacetamide by heating in acetonitrile for 30 min. The residue, (*S*)-(**19**) obtained by the distillation of the solvent was submitted as such to the reduction with sodium dithionite. The salt, (*S*)-(**21**), was prepared by heating a solution of (*S*)-2,2'-bis(bromomethyl)-1,1'-binaphthyl (**20**)[9] (1.1 g, 2.5 mmol) and nicotinamide (555 mg, 4.6 mmol) in DMF (20 ml) at 70 °C overnight. The reaction mixture was added dropwise into ethanol (100 ml) to give colorless precipitate which was washed with ether over phosphorus pentoxide; yield 1.69 g (93.6%).

General Preparation of 1,4-Dihydropyridines by the Reduction with Sodium Dithionite. i) Preparation of (R)-(1), (S)-(11), (S)-(111), (R)-(IV), and (R)-(V): The quaternized salt (6.0 mmol) was dissolved in DMF (10 ml) and the solution was added to 0.25 M (1 M = 1 mol dm^{-3}) sodium phosphate buffer (1 l, pH 7.0) containing sodium dithionite (147 mmol) and stirred at room temperature under nitrogen atmosphere. After 15 min, the flocculent material separated out of the solution was filtered, washed with water. The reductant was purified by silica-gel column chromatography with dichloromethane elution.

(R)-2-Methoxy-2'-(1-benzyl-1,4-dihydro-3-pyridylcarbonyloxy)-1,1'-binaphthyl (R)-(I); Yield 61.1% $[\alpha]_D^{25}$ +69.3° (*c* 1.03, acetonitrile), UV λ_{max} (acetonitrile): 360—361 nm (ε_{max} 8696), IR ν (cm^{-1}, KBr): 1700 ν (C=O), 680—820 δ (aromatic C-H), ^{1}H-NMR (chloroform-d_1): δ=2.90 (2H, m, pyr-C_4-2H), 3.80 (3H, s, $-OCH_3$), 4.03 (2H, s, $-CH_2Ph$), 4.76 (1H, m, pyr-C_5-H), 5.66 (1H, br, pyr-C_6-H), 6.50 (1H, m, pyr-C_2-H), 7.10—8.33 (22H, m, aromatic protons).

(S)-2-Benzyloxy-2'-(1-benzyl-1,4-dihydro-3-pyridylcarbonyloxy)-1,1'-binaphthyl (S)-(II); Yield 88.9%, $[\alpha]_D^{25}$ −67.4° (*c* 1.005, acetonitrile), UV λ_{max} (acetonitrile): 361 nm (ε_{max} 8584), IR ν (cm^{-1}, KBr): 1700 ν (C=O), 1600 ν (C=C), 1150 ν (C-O-C).

680—820 δ (aromatic C–H), ^{1}H-NMR (chloroform-d_1): δ= 2.86 (2H, m, pyr–C_4–2H), 3.85 (2H, s, –NCH_2Ph), 4.65 (1H, m, pyr–C_5–H), 5.00 (2H, s, –OCH_2Ph), 5.50 (1H, m, pyr–C_6–H), 6.30 (1H, m, pyr–C_2–H), 6.80—8.20 (22H, m, aromatic protons).

(S)-2, 2'-Bis(1-benzyl-1, 4-dihydro-3-pyridylcarbonyloxy)-1, 1'-binaphthyl(S)-(III); Yield 42.0%, $[\alpha]_D^{25}$ −9.6° (*c* 1.05, ethanol), UV λ_{max} (ethanol): 362 nm (ε_{max} 17167), IR ν (cm^{-1}, KBr): 1740 ν (C=O), 1595 ν (C=C), 660—890 δ (aromatic C–H), ^{1}H-NMR (chloroform-d_1): δ=2.73 (4H, m, pyr–C_2–2H), 3.96 (4H, s, –CH_2Ph), 4.63 (2H, m, pyr–C_5–H), 5.50 (2H, m, pyr–C_6–H), 6.50 (2H, m, pyr–C_2–H), 6.90—9.10 (22H, m, aromatic protons).

(R)-2, 2'-Bis(1-benzyl-1, 4-dihydro-3-pyridylcarbonyloxymethyl)-1, 1'-binaphthyl(R)-(IV); Yield 17.1%, $[\alpha]_D^{25}$ +42.54° (*c* 0.992, ethyl acetate), UV λ_{max} (ethyl acetate): 357 nm (ε_{max} 13570), ^{1}H-NMR (chloroform-d_1): δ=3.03 (4H, m, pyr–C_4–2H), 4.24 (4H, s, –CH_2Ph), 4.90 (4H, s, CH_2O–), 4.50—5.20 (2H, m, pyr–C_5–H), 5.67 (2H, m, pyr–C_6–H), 6.93 (2H, m, pyr–C_2–H), 7.00—8.20 (22H, m, aromatic protons).

(R)-Bis[2-(1-benzyl-1, 4-dihydro-3-pyridylcarbonyloxy)ethoxy]-1, 1'-binaphthyl (R)-(V); Yield 60.0%, $[\alpha]_D^{25}$ +56.4° (*c* 1.08, acetonitrile), UV λ_{max} (acetonitrile): 355 nm (ε_{max} 12530), IR ν (cm^{-1}, KBr): 1680 ν (C=O), 1600 ν (C=C), 700—840 δ (arcmatic C–H), ^{1}H-NMR (chloroform-d_1): δ=3.00 (4H, m, pyr–C_4–2H), 4.20 (8H, d, J=2 Hz, –CH_2CH_2–), 4.80 (2H, m, pyr–C_5–H), 5.73 (2H, m, pyr–C_6–H), 6.70 (2H, m, pyr–C_2–H), 7.10—8.10 (22H, m, aromatic protons).

ii) Preparation of (S)-(VI), (S)-(VII), and (S)-(VIII): To a solution of sodium hydrogencarbonate (230 ml) in water (634 ml) saturated with carbon dioxide up to pH 8.0, sodium dithionite (72.8 mmol) and the quaternized salt (3.79 mmol) in methanol (238 ml) were added and kept in the dark overnight. After the period, the solid separated material was filtered and dried over phosphorous pentoxide.

(S)-2, 2'-Bis(1-benzyl-1, 4-dihydro-3-pyridylcarbonylamino)-1, 1'-binaphthyl (S)-(VI); Yield 91.7%, $[\alpha]_D^{25}$ +112.2° (*c* 0.50, acetonitrile), UV λ_{max} (acetonitrile): 363 nm (ε_{max} 21162), ^{1}H-NMR (chloroform-d_1): δ=2.26 (4H, m, pyr–C_4–2H), 4.13 (4H, s, –CH_2Ph), 4.40 (2H, m, pyr–C_5–H), 5.53 (2H, m, pyr–C_6–H), 6.83 (2H, m, pyr–C_2–H), 6.90—8.15 (22H, m, aromatic protons).

(S)-2, 2'-Bis(1-carbamoylmethyl-1, 4-dihydro-3-pyridylcarbonylamino)-1, 1'-binaphthyl (S)-(VII); Yield 23.7%, $[\alpha]_D^{25}$ +74.73° (*c* 0.182, chloroform), UV λ_{max} (chloroform): 362 nm (ε_{max} 20370), ^{1}H-NMR (chloroform-d_1): δ=2.33 (4H, m, pyr–C_4–2H), 3.66 (4H, s, –CH_2–), 4.53 (2H, m, pyr–C_5–H), 5.65 (2H, m, pyr–C_6–H), 6.83 (2H, s, pyr–C_2–H), 7.20—8.50 (22H, m, aromatic protons).

(S)-2, 2'-Bis(3-carbamoyl-1, 4-dihydro-1-pyridylmethyl)-1, 1'-binaphthyl (S)-(VIII); Yield 55.9%, $[\alpha]_D^{25}$ −197.5° (*c* 0.99, dichloromethane), UV λ_{max} (dichloromethane): 356 nm (ε_{max} 12000), ^{1}H-NMR (chloroform-d_1): δ=2.27 (4H, m, pyr–C_4–2H), 3.97 (4H, s, –CH_2N), 4.60 (2H, m, pyr–C_5–H), 5.53 (2H, m, pyr–C_6–H), 5.60 (4H, s, NH_2), 6.67 (2H, d, J=2 Hz, pyr–C_2–H), 6.90—8.20 (12H, m, aromatic protons).

This work was supported in part by a Grant-in-Aid (No. 57560125) from the Ministry of Education, Science and Culture to which we are deeply grateful.

The Base-catalyzed Condensation Reaction of Dimethyl Malonate with 5-Chloro-2-methoxytropone and 2,5-Dichlorotropone. On the Solvent Effect for the Sites of the Reaction[1)]

Tetsuo NOZOE,*,† Hitoshi TAKESHITA,*,†† and Kozo TAJIRI††

(Received June 16, 1983)

The sites of the nucleophilic attack of the base-catalyzed condensation of dimethyl malonate with 5-chloro-2-methoxytropone were solvent-dependent; the normal substitution product was predominant in benzene, but the *ciné*-substitution products were exclusive in methanol. With 2,5-dichlorotropone, the *ciné*-reaction products were exclusive in both solvents.

One of the most remarkable features on the nucleophilic substitution reaction of troponoid chemistry is a frequent occurrence of the abnormal substituion, or *ciné*-reaction,[2,3)] which means a reaction in which the leaving group on the aromatic ring is not located on the attacking site of the nucleophile. To date, many examples of such reactions have been recorded.[4)] This fundamental feature is important in order to understand the complicated mode of ring-closure in the azulene synthesis from the reactive troponoids.[5,6)] The condensation of troponoids with dimethyl malonate or ethyl acetoacetate is known to give, in the *ciné*- and/or normal mode, oxazulanones, 2*H*-cyclohepta[*b*]furan-2-ones,[7)] while, the methyl cyanoacetate and malononitrile, cyano derivatives, are known to give the functionalized azulene derivatives as major products.[8)] Moreover, the syntheses of the azulene derivatives from oxazulanones have been developed; *i.e.*, the consecutive condensation of some oxazulanones with active methylene derivatives[9)] and heating with various enamines.[10)] In view of the capability of introducing various kinds of functional groups to both five- and seven-membered rings of azulenes, these make the oxazulanones important as the starting materials. This paper will describe the solvent dependency of the *ciné*-reaction encountered in the formation of 2*H*-cyclohepta[*b*]furan-2-ones from 5-chlorotropolone derivatives, 5-chloro-2-methoxytropone (**1**) and 2,5-dichlorotropone (**2**), with dimethyl malonate.

8: X=CH(COOMe)$_2$, Y=H
9: X=Cl, Y=OMe

Scheme 1.

First of all, when a methanol solution of **1** was allowed to react with dimethyl malonate in the presence of sodium methoxide, a somewhat complicated reaction with a time-dependent product distribution occurred at 30 °C. After separation of the product mixture by the silica-gel column or high-pressure liquid chromatography, **3**—**10** were isolated and characterized. A minor product, **3**, was shown to be 6-chloro-3-methoxycarbonyloxazulanone (I: X=Cl) on the basis of the ^{1}H-NMR spectroscopy, and **4** was also identified to be 5-chloro-3-methoxycarbonyloxazulanone (II: X=Cl, Y=H). On the other hand, the major product, **5** (47%), was halogen-free, and its ^{1}H-NMR spectrum revealed a signal of another methoxyl group, introduced by a nucleophilic attack; it was the major product when the reaction was continued for a prolonged period, up to 8 h. In fact, **5** could be prepared from **4** by sodium methoxide at room temperature.

Therefore, **5** is 5-methoxy-3-methoxycarbonyloxazulanone (II: X=MeO, Y=H). Similarly, **6** was shown to be 6-methoxy-3-methoxycarbonyloxazulanone (I: X=MeO) by chemical correlation with **3**, and **7** and **8** correspond to the malonic ester derivatives from **3** and **4** (I and II: X=CH(COOMe)$_2$, Y=H).

The structure of **9** was determined to be 5-chloro-8-methoxy-3-methoxycarbonyloxazulanone (II: X=Cl, Y=OMe) by its mass spectrum [*m/e*, 268, 270 (M$^+$, $C_{12}H_9O_5Cl$)] and the ^{1}H-NMR analysis: A low-field signal at δ 9.09 indicated the presence of a chlorine atom at C-5, and its broadened shape due to a long-range coupling indicated the presence of a hydrogen atom at C-6. This was further confirmed by comparison of the chemical shifts of C-7 proton with **6** [δ=6.79 (dd, J=11, 2.5 Hz)]; therefore, another methoxyl group of **9** is at the C-8.

The remaining product, **10**, is the monodecarboxylated derivative of **7** (I: X=CH$_2$COOMe).

The base-catalyzed condensation reaction of **1** with dimethyl malonate in benzene solution was slower than that in methanol, and the product distribution was considerably different. The major product in this case was the normal condensate, **3** (64%), which was

a) By first-order analysis the coupling constants could not be determined, due to overlapping of signals.

accompanied by **4**, **7**, and **9**. Formation of a chloro methoxy derivative, **9**, in this inert solvent can be explained only in terms of the *ciné*-reaction *via* intermediary adduct **A** which was followed by an auto-oxidative dehydrogenation. An alternative explanation, *i.e.*, a nucleophilic introduction of methoxyl group on the C-8 position of **4** followed by a dehydrogenation, is not true since, as mentioned above, **4** was exclusively converted to **5**. Such a behavior has precedence in the condensation of 2-(*p*-tolylsulfonyloxy)tropone with some active methylene reagents.[11]

Furthermore, the product distribution in the reaction of **2** in a mixed solution of benzene–ether (1 : 1)[12] revealed an intermediary figure to those in methanol and in benzene. Occurrence of **3**—**5**, and **7** was directly confirmed by isolations.

Subsequently, the same reaction was carried out with **2** and dimethyl malonate. In methanol, the major product was **4** (62%) which was accompanied by a minor product, **5** (16%). No other compound was detected other than the recovered tropone, **1** (17%); the condensation thus occurred exclusively with the *ciné* mode. The reaction in benzene also produced the *ciné*-reaction products, **4** (65%) and **8**, together with the recovered **1** (8%). As expected, the reaction in a mixed solution of benzene–ether disclosed similar features to the results obtained from the reaction in methanol; it gave **4** (65%) and **5**.

Therefore, the results disclosed a solvent dependence in the reaction of **1** and dimethyl malonate, where the *ciné*-reaction was favored in the protic solvent, but in nonpolar aprotic solvent the normal substitution reaction was predominant. On the other hand, the reaction of **2** and dimethyl malonate exclusively gave the *ciné*-reaction products in every case.

Consequently, the reaction of **1** and dimethyl malonate is solvent-dependent; in methanol, the predominant process was the *ciné*-reaction, but in benzene, the reverse was true. It is known that in many cases encountered in the troponoid field, thoroughly different product distributions have arisen from slightly different reaction conditions; therefore, one must be careful in

drawing conclusions based on a single fact. However, in the present case, it is certain that the nature of solvents decided the course of the reaction. In methanol, the nucleophile, dimethyl sodiomalonate, should be tightly solvated, while, in benzene the reagent is rather naked. As results, nucleophilic attack by the solvated bulky reagent to C-2 position, the substituted site, might become unfavorable due to a steric hindrance.

The reaction of **2** with dimethyl malonate always proceeded in the exclusive *ciné*-mode.

The case-catalyzed condensation of **1** and **2** with other active methylene compounds, methyl acetoacetate and methyl *p*-nitrophenylacetate, gave other interesting features; these results will be presented in an independent paper.

Experimental

Throughout the study, the NMR spectra were measured by a JEOL FX-100 Model spectrometer in $CDCl_3$ solutions unless otherwise mentioned, and the chemical shifts were expressed in the δ unit from the internal standard, TMS. The UV spectra were measured in methanol solutions using a Hitachi Model 124 spectrometer. The IR spectra were measured with a JASCO Model A-102 spectrometer in either CCl_4 solutions or with KBr disks. High-resolution mass spectra were taken by JEOL OlSG Model spectrometer, and the figures were obtained by visual reading on the photographic plates.

*The Condensation Reaction of 5-Chloro-2-methoxytropone (**1**) and Dimethyl Malonate in Methanol.* Anhydrous methanol (25 cm³) containing dimethyl malonate (775 mg), NaOMe (285 mg) and **1** (500 mg) was warmed to 30 °C with stirring. The reaction was monitored by an occasional check of high-pressure liquid chromatogram (polasil T/ethyl acetate–hexane). After 8 h, the solvent was removed by evaporation, and the residue was neutralized with dil HCl and chromatographed on a silica-gel column to give three fractions of product mixture: From benzene–ether (80 : 20), a mixture of **3** and **4** (**a**, yellow solid, 59 mg), was at first eluted, and subsequently, a mixture of **5**, **8**, and **7** (**b**, yellow solid, 307 mg), was obtained; from the latest fractions, a mixture of **6**, **9**, and **10** (**c**, yellow solid, 77 mg), was obtained together with recovered **1** (89 mg).

Further fractionation of these products was performed by high-pressure liquid chromatography (micropolasil/ethyl acetatehexane): Thus, from the fraction **a**, analytical samples of **3**, 6-chloro-3-methoxycarbonyloxazulanone (yellow needles; mp 250—251 °C [Found: C, 55.18; H, 2.94%. Calcd for $C_{11}H_7O_4Cl$: C, 55.37; H, 2.96%. δ(C) = 51.9, 116.5, 129.3, 134.4, 140.7, 145.8, 153.0, 157.3, 163.5, and 164.4], 20 mg (3%)), and **4**, 5-chloro-3-methoxycarbonyloxazulanone (yellow needles; mp 172—173 °C [Found: C, 54.95; H, 2.98%. δ(C) = 51.8, 97.0, 117.4, 129.0, 135.1, 135.3, 147.8, 151.5, 158.5, 163.3, and 169.3], 38 mg (7%)) were isolated.

Similarly, analytical samples of **5**, **8**, and **7** were isolated from the fraction **b**, and showed the following properties: **5**, 5-methoxy-3-methoxycarbonyloxazulanone (yellow needles; mp 200—201 °C [Found: C, 61.47; H, 4.05%. Calcd for $C_{12}H_{10}O_5$: C, 61.54; H, 4.03%. δ(C) = 51.5, 56.6, 94.1, 108.1, 115.1, 129.3, 134.3, 153.7, 157.3, 164.8, 165.2, and 168.4], 265 mg (47%)), **8**, 3-methoxycarbonyl-5-[bis(methoxycarbonyl)methyl]oxazulanone (yellow needles; mp 181.5—182 °C [Found: C, 57.44; H, 4.18%; M.W., 334.0647. Calcd for $C_{16}H_{14}O_8$: C, 57.49; H, 4.22%; M. W., 334.0689], 27 mg (3%)), and **7**, 3-methoxycarbonyl-6-[bis(methoxycarbonyl)-methyl]oxazulanone (yellow crystals; mp 170—171 °C[Found: C, 57.35; H, 4.28%; M. W., 334.0652], 14 mg (2%)).

Preparative thin-layer chromatography (PTLC) of the fraction **c** gave **9**, 5-chloro-8-methoxy-3-methoxycarbonyloxazulanone (yellow needles; mp 231—232 °C [Found: C, 53.54; H, 3.37%; M. W., 268.0148. Calcd for $C_{12}H_9O_5Cl$: C, 53.65; H, 3.38%; M. W., 268.0139], 30 mg (5%)), **10**, 3-methoxycarbonyl-6-(methoxycarbonylmethyl)oxazulanone (yellow needles; mp 170—171 °C [Found: C, 60.80; H, 4.28%; M. W., 276.0615. Calcd for $C_{14}H_{12}O_6$: C, 60.87; H, 4.38%; M. W., 276.0634], 7 mg (1%), and **6**, 6-methoxy-3-methoxycarbonyloxazulanone (yellow crystals; mp 250—251 °C [Found: C, 61.44; H, 4.09%. Calcd for $C_{12}H_{10}O_5$: C, 61.54; H, 4.30%], 38 mg (7%)).

*The Condensation Reaction of **1** and Dimethyl Malonate in Benzene.* An anhydrous benzene (25 cm³) solution of dimethyl malonate (775 mg), NaOMe (285 mg), and **1** (500 mg) was warmed at 30 °C with stirring. After 8 h, the solvent was removed *in vacuo* at room temperature, and the residue was extracted with chloroform and dil HCl. The organic extracts were chromatographed on a silica-gel column to give a mixture of **3** and **4** (417 mg), **7** (48 mg; 7%), **9** (20 mg; 3%), and the unreacted **1** (120 mg; 24%). Separation of **3** and **4** was made by repeated silica-gel column chromatography; the yields were 340 mg (64%) for **3**, and 65 mg (11%) for **4**.

*The Condensation of **1** and Dimethyl Malonate in a Mixture of Benzene and Ether.* NaOMe (120 mg) and dimethyl malonate (375 mg) were dissolved in anhydrous ether (20 cm³) and mixed with benzene solution (20 cm³) of **1** (350 mg) and kept at 30 °C for 8 h. The mixture was then treated with dil HCl, and extracted with ethyl acetate. The organic extracts were chromatographed on a silica-gel column to give a yellow solid, **3** (175 mg; 47%), **4** (40 mg; 11%), **5** (9.5 mg; 3%), **7** (4.5 mg; 1%), and the recovered **1** (85 mg; 24%).

*The Condensation of 2,5-Dichlorotropone (**2**) with Dimethyl Malonate in Methanol.* A methanol solution (50 cm³) of **2** (505 mg, NaOMe (280 mg), and dimethyl malonate (450 mg) was kept at 30 °C for 8 h, although disappearance of **2** was already recognized after 1.5 h on a high-pressure liquid chromatogram. After evaporation of the solvent *in vacuo* at room temperature, the residue was treated with dil HCl, and extracted with ethyl acetate. Silica-gel column chromatography of the mixture afforded **4** (245 mg; 62%), **5** (90 mg; 16%), and the recovered **1** (60 mg; 17%).

*The Condensation of **2** with Dimethyl Malonate in Benzene.* Anhydrous benzene (50 cm³) containing dimethyl malonate (300 mg), NaOMe (110 mg), and **2** (200 mg) was kept at 30 °C for 8 h. The reaction was somewhat slower than in methanol; it took 4 h to consume **2**. The mixture was washed with dil HCl and extracted with ethyl acetate. Silica-gel column chromatography of the mixture afforded **4** (165 mg; 65%) and **8** (10 mg; 3%), along with **1** (15 mg; 8%).

*The Condensation of **2** and Dimethyl Malonate in a Mixture of Benzene and Ether.* To an anhydrous ether solution (20 cm³) of dimethyl malonate (375 mg) and NaOMe (110 mg), a benzene solution (20 cm³) of **2** (230 mg) was added at once, and kept at 30 °C for 8 h. The mixture was then acidified by dil HCl, and extracted with ether. The silica-gel column chromatography of the mixture gave **4** (280 mg; 65%), and **5** (8 mg; 2%), together with **1** (15 mg; 4.5%).

*The Further Conversion of **4** into **5**.* A Methanol solution (10 cm³) containing **4** (10 mg) and NaOMe (2 mg) was kept at room temperature for 24 h. The mixture was diluted with aqueous HCl and extracted with ether. The NMR analysis of the organic fractions confirmed the presence of **5**, but of no other product.

*The Conversion of **3** to **6**.* A methanol solution (10 cm³) of **3** (15 mg) was similarly treated with NaOMe (2 mg) for 24 h. The NMR analysis of the product confirmed the

exclusive formation of **6**.

*Formation of **8** from **4**.* A benzene solution (5 cm^3) of **4** (20 mg) was treated with **2** (50 mg) and NaOMe (1 mg) at 30 °C for 8 h. From the mixture, only **8**, 6 mg, was separated by PTLC.

*Formation of **7** from **3**.* A benzene solution (5 cm^3) of **3** (10 mg) and **2** (20 mg) with NaOMe (1 mg) was heated at 30 °C for 8 h. The mixture was fractionated by means of PTLC to afford **7** (4 mg). No other compound was detectable.

Constituents of the Root Bark of *Ailanthus altissima* SWINGLE. Isolation and X-Ray Crystal Structures of Shinjudilactone and Shinjulactone C and Conversion of Ailanthone into Shinjudilactone[1]

Masami ISHIBASHI, Takahiko TSUYUKI, Tatsushi MURAE, Hiroshi HIROTA, Takeyoshi TAKAHASHI,* Akiko ITAI,† and Yoichi IITAKA†

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

†*Department of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113*

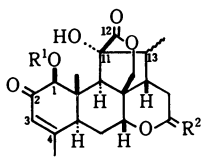
(Received June 23, 1983)

Two new quassinoids, shinjudilactone and shinjulactone C were isolated from the root bark of *Ailanthus altissima* SWINGLE and their structures were established to be 1β,11α-dihydroxy-2,16-dioxo-13(12→11α)*abeo*-picras-3-en-12,20-olide and 1α,12α : 5α,13α-dicyclo-1β,12β,20-trihydroxy-9β*H*-picras-3-ene-2,11,16-trione, respectively, by X-ray diffraction analysis. Shinjudilactone was prepared from ailanthone by benzilic acid rearrangement.

Quassinoids, bitter principles isolated from Simaroubaceous plants, have been extensively investigated from the interest in anti-tumor activity and structure determination,[2] and some of them have been shown to exhibit useful biological activities.[3] Recently these quassinoids have attracted much attention as synthetic target molecules.[4]

In Japan there grow two species of plants belonging to Simaroubaceae, *Picrasma ailanthoides* PLANCHON (=*P. quassioides* BENN, Japanese name : Nigaki) and *Ailanthus altissima* SWINGLE (=*A. glandulosa* DESF., Japanese name: Shinju or Niwaurushi) and these plants are known to contain bitter principles in leaves, barks, trunks, and roots. The bitter principles of *P. ailanthoides* have been investigated by us[2b] and by Takemoto *et al.*[5] and more than twenty quassinoids have been isolated. As a continuation of our work on bitter principles of Simaroubaceous plants in Japan, we examined the bitter principles of *A. altissima*. We wish to report on the X-ray crystal structures of new quassinoids, shinjudilactone (**1**) and shinjulactone C (**2**) isolated from root barks of the plant.

The half-dried root bark of *A. altissima*, defatted with petroleum ether, was continuously extracted with ethyl acetate and the extract was separated to afford seven



1 R^1=H, R^2=O; 13α-CH_3

4

Concentrated aqueous extract of the root bark of this plant was continuously extracted with dichloromethane. The organic layer was evaporated to give a residue, which was subjected to separation by silica-gel column chromatography to afford two new quassinoids, shinjudilactone (**1**) and shinjulactone C (**2**) in 0.01% and 0.001% yields, respectively, together with known chaparrolide,[15] chaparrinone (**4**),[16] shinjulactone B,[17] amarolide, ailanthone (**3**), glaucarubinone, and $\Delta^{13(18)}$-dehydroglaucarubolone.

Shinjudilactone (**1**), a bitter quassinoid, crystallized from ethyl acetate-methanol as colorless needles, mp 274—276 °C and $[\alpha]_D^{23}$ +102° (pyridine). Elemental analysis and high-resolution mass spectrum indicate the formula $C_{20}H_{24}O_7$. The spectral examination showed the presence of hydroxyl(s) (IR 3250 cm^{-1}), two carbonyls (ester or lactone moieties) (IR 1745 and 1735 cm^{-1}; ^{13}C NMR δ 170.6 and 173.5), a proton at the lactone terminus (^1H NMR δ 4.808, t), an α,β-unsaturated ketone (IR 1670 cm^{-1}; UV 238 nm; ^{13}C NMR δ 196.9), a tertiary methyl, a secondary methyl, and a vinyl methyl (^1H NMR δ 1.235, s, δ 1.240, d, and δ 1.798, br s, respectively).

On methylation with diazomethane, shinjudilactone (**1**) gave *O*-methylshinjudilactone (**5**), mp 291—294 °C, which still showed an absorption band at 3400 cm^{-1} due to a hydroxyl group, indicating the presence of two hydroxyl groups for **1**. Treatment of **1** with acetic anhydride and pyridine at room temperature gave a monoacetate (**6**), which showed a singlet signal at δ 5.78 due to a proton attached to the acetoxy-bearing carbon atom and an IR absorption band due to a hydroxyl group at 3480 cm^{-1}. The hydroxyl group was shown to be tertiary, because no diacetate was produced by acetylation under drastic conditions. Shinjudilactone (**1**) was reduced with sodium borohydride to afford a hemiacetal (**7**), which showed a multiplet signal due to a hemiacetal-methine proton at δ 5.68. The IR spectrum (1740 cm^{-1}) of **7** showed a lactone grouping still remained intact, indicating that **1** possesses two lactone groupings. Seven oxygen atoms of **1** were thus

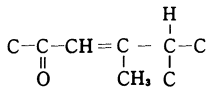
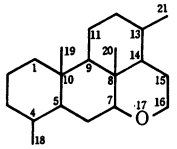
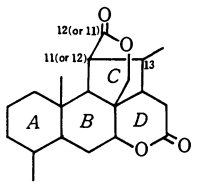
a) Measured in a pyridine-d_5 solution. b) Measured in a dimethyl-d_6 sulfoxide solution (Ref. 16b).



A



B



C

characterized. These findings indicate pentacyclic skeleton for **1**.

^1H NMR spectrum of shinjudilactone (**1**) showed that an olefinic proton resonating at δ 6.095 is coupled with a vinyl methyl and also with a methine proton at an allylic position with a coupling constant J=2.5 Hz, the presence of the same partial structure (**A**) as that of chaparrinone (**4**) being suggested for **1**. The assignment of signals in the ^{13}C NMR spectrum of **1** was carried out by comparison with signals of **4**[16b] (Table 1). It is inferred that the easily reducible lactone grouping should be located in the D ring[18] and the other one in the C ring. Shinjudilactone (**1**) could not be formulated based on the normal picrasane skeleton (**B**),[19] but should possess a migrated picrasane skeleton, a 13(12→11α) or 9(11→12)*abeo*-picrasane dilactone structure (**C**). Formation of **1** from ailanthone (**3**) could be reasonably explained by biogenetic consideration (*vide infra*).

Unambiguous proof for the proposed structure (**1**) of shinjudilactone was provided by X-ray diffraction analysis. The crystal of **1** belongs to a monoclinic space group $P2_1$ with the cell parameters of a=7.446(2), b=18.241(8), c=6.679(2) Å, and β=109.39(6)°. There are two molecules in the unit cell. Intensity data were collected on a Philips PW1100 automatic four-circle diffractometer using monochromated Cu $K\alpha$ radiation. A total of 1739 independent structure factors with $F_o \geq 2.5\ \sigma(F_o)$ within 2θ=156° were obtained by the 2θ-θ scanning mode. The structure was solved by the direct method using MULTAN program. An E-map revealed the positions of all the non-hydrogen atoms, and the hydrogen atoms were located in a difference electron density map. The structure was refined by the block-diagonal least-squares calculations

assuming anisotropic thermal motions for non-hydronge atoms and isotropic ones for hydrogen atoms. The final *R*-factor was 0.036. The final atomic coordinates are listed in Table 2 and bond lengths and bond angles are listed in Tables 3 and 4.[20] The computer-generated perspective drawing of molecule **1** is shown in Fig. 1.

Thus the structure of shinjudilactone (**1**) is shown to be formulated as 1β,11α-dihydroxy-2,16-dioxo-13(12→11α)*abeo*-picras-3-en-12,20-olide. The same rearranged skeleton could be derived by a 9(11→12)*abeo*-type rearrangement (*vide infra*).

Shinjulactone C (**2**), mp 292 °C (decomp), $[\alpha]_D^{23}$ −344° (pyridine), exhibited no bitter taste and the molecular formula, $C_{20}H_{22}O_7$, was determined by high resolution mass spectrum. The IR (*ca.* 3480, 1775, 1720, and 1650 cm^{-1}) and UV (λ_{max} 248 nm) spectra reveal the presence of hydroxyl(s) and three carbonyls, one of which is assigned to be an α,β-unsaturated ketone. The unsaturated carbonyl group is inferred to be located in the A ring; the mass spectrum of **2** afforded a prominent fragment peak at *m/e* 151 $(C_9H_{11}O_2)^+$ probably due to a tropylium ion (**D**), suggesting the presence of a partial structure (**E**), because the fragment ion **D** is observed in the mass spectrum of ailanthone (**3**).[8b] ^{1}H NMR spectrum (Table 5) of **2** showed the presence of two tertiary methyls (δ 1.092 and δ 1.306, each s), a vinyl methyl (δ 2.019, d), two methine protons (δ 2.900, s and δ 2.170, ddd), a lactone-terminus proton (δ 5.235, ddd),

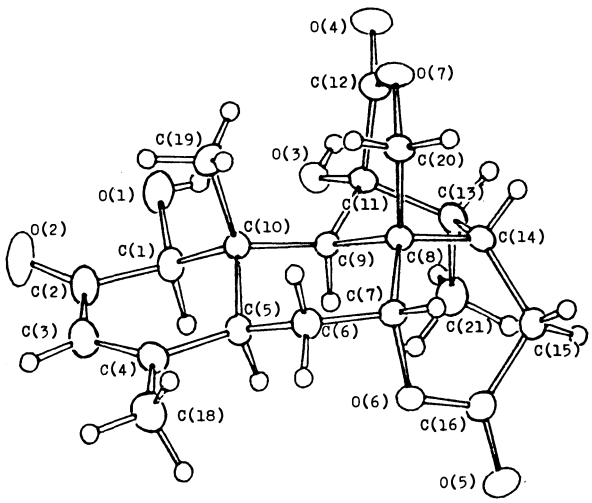

Fig. 1. Perspective view of shinjudilactone (**1**).[a]
a) For clarity hydrogen atoms are represented by spheres of arbitrary radius.

and an olefinic proton (δ 6.497, d). The lactone-terminus proton was shown to couple with the methine proton at δ 2.170 with a coupling constant J=2.5 Hz.

Four oxygen atoms were thus explained by the presence of a lactone, an α,β-unsaturated ketone, and an isolate ketone. The remaining three oxygen atoms were shown to be hydroxyl groups, one of which was shown to be primary by the following evidence. ^{1}H NMR (δ 4.052

■ denotes a carbon atom.

and δ 4.090, each d) and ^{13}C NMR (δ 60.2, t) spectra and a fragment ion at *m/e* 343 due to $(M-CH_2OH)^+$ suggest the presence of a primary hydroxyl group. Acetylation of shinjulactone C (**2**) gave a monoacetate (**8**) and a diacetate (**9**). The primary hydroxyl group of **2** easily reacts with formic acid at room temperature to afford a formate (**10**), which, on refluxing with 50% formic acid, gave the starting shinjulactone C (**2**). In the ^{1}H NMR spectrum of monoacetate (**8**), an AB quartet signal (δ_A 4.47 and δ_B 4.59, J_{AB}=12 Hz) was observed, suggesting that the $-CH_2OH$ group had been acetylated. The diacetate (**9**), yield of which increased by prolonged reaction time, showed that an absorption band at *ca.* 3450 cm^{-1} due to a hydroxyl group still remained in the IR spectrum. In our recent study,[21] the diacetate (**9**) was prepared from ailanthone (**3**) and was shown to be a 12,20-di-*O*-acetyl derivative. Two signals (δ 88.3 and δ 93.6, each s) due to carbon atoms bearing a tertiary hydroxyl group were observed in the ^{13}C NMR spectrum of **2**. The absence of coupling between olefinic and allylic protons due to the structure moiety (**A**) was shown for **2**. From these observations, a partial structure (**F**) was suggested for shinjulactone C.

^{13}C NMR spectrum (Table. 6) and discussion developed above indicating that shinjulactone C (**2**) possesses a hexacyclic skeleton, two carbon atoms at C-1 and C-5 in the partial structure (**F**) must connect with different carbon atoms respectively. The following

Table 6. ^{13}C NMR Spectrum of shinjulactone C (**2**)

Assignment of carbon atom		Number of carbon atom	δ-value (pyridine-d_5)
>C=O	(isolated)	1	209.8 s
	(conjugated)	1	195.2 s
	(lactone or ester)	1	170.8 s
>C=C<	(tetrasubstituted)	1	165.9 s
>C=CH-	(trisubstituted)	1	127.8 d

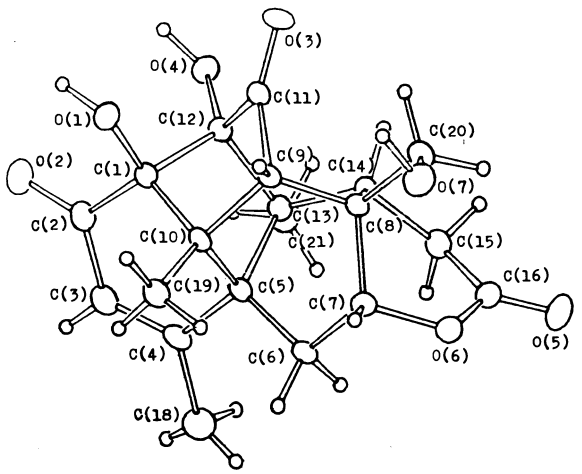

Fig. 2. Perspective view of shinjulactone C (**2**).[a]
a) For clarity hydrogen atoms are represented by spheres of arbitrary radius.

of a singlet signal due to a tertiary methyl at δ 1.306, signals at δ 6.497 ($\gtrless C=C_{(3)}-H$) and δ 2.019 ($C=\overset{1}{C}_{(4)}-CH_3$) showed increase in area. These enhancement in area due to NOE had never been observed in the usual picrasane derivatives. However, since further information for the structure elucidation of shinjulactone C (**2**) could be obtainable by neither spectral nor chemical investigation, single crystal X-ray diffraction analysis was carried out. Shinjulactone C (**2**) crystallized from acetone in orthorhombic space group $P2_12_12_1$ with the cell parameters of $a=13.247(6)$, $b=13.331(6)$, and $c=9.596(4)$ Å. Four molecules are contained in the unit cell. Intensity data were measured and the structure was solved and refined in the same manner with shinjudilactone (**1**) as described before. The 1831 independent reflections with $F_o \geq 2.5\ \sigma(F_o)$ were used for structure determination. The structure was refined to give the R-factor of 0.073 including all hydrogen atoms. Final atomic coordinates are listed in Table 7 and bond lengths and bond angles are listed in Tables 8 and 9.[20] Figure 2 shows a computer-generated drawing of the molecule **2**, showing to be formulated as 1α,12α : 5α,13α-dicyclo-1β,12β,20-trihydroxy-9βH-picras-3-ene-2,11,16-trione.

The structure elucidation of shinjudilactone (**1**) and shinjulactone C (**2**) has revealed that these new quassinoids possess modified picrasane skeletons. Since it seems possible that these modified quassinoids are biogenetically derived from ailanthone (**3**), conversion of **3** into shinjudilactone (**1**) was then investigated. The skeletal rearrangement of C ring of ailanthone (**3**) would be possible through two pathways *in vivo* (Scheme 1). Path **a** is initiated by protonation to $\Delta^{13(21)}$-double bond of **3**, followed by hydride shift to provide a cation at C-12. An *O*-terminus of a hemiacetal-bridge may shift from C-11 to the C-12 cationic center to give a cation at C-11. Each one of these cations could undergo ring-contraction followed by deprotonation to give **1**. The other path **b** comprises benzilic acid rearrangement of an intermediate α-diketone (**11**). Since a hydroxide ion is accessible to either C-12 or C-11 of the α-diketone (**11**), 13(12→11α)*abeo*-type or 9(11→12α)*abeo*-type rearrangement similar to those in the path **a** is considered. The resulting hydroxy carboxylic acid undergoes lactonization to furnish shinjudilactone (**1**).

According to these considerations, chemical conversion of ailanthone (**3**) into shinjudilactone (**1**) was investigated. The reaction did not occur under acidic conditions using *p*-toluenesulfonic acid, hydrochloric

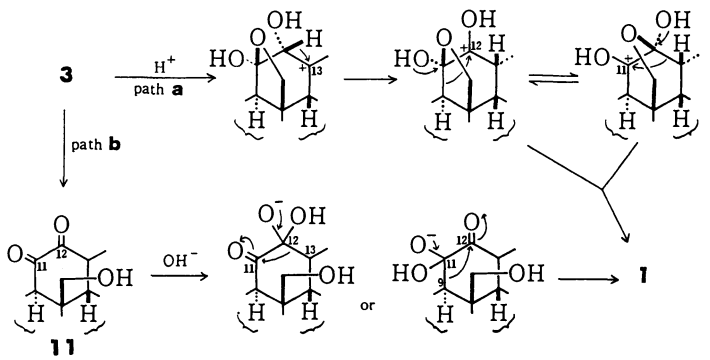
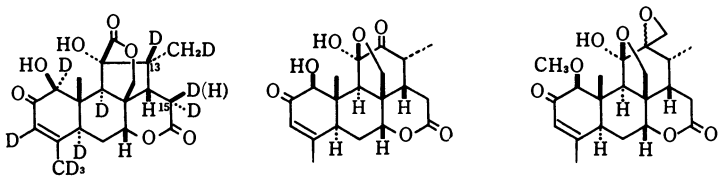


Scheme 1.

acid, acetic acid–hydrochloric acid, or iron(III) chloride–hydrochloric acid, while a very complex mixture was obtained in the reaction of **3** with boron trifluoride etherate in benzene or dichloromethane, no shinjudilactone (**1**) being detected in the reaction mixture by TLC examination.

Reactions under alkaline conditions such as sodium hydroxide in water, potassium hydroxide in methanol, and barium hydroxide in pyridine, gave extremely polar products, structures of which could not be identified. However, ailanthone (**3**) was treated with sodium hydrogencarbonate in boiling aqueous methanol and then the reaction mixture was acidified with hydrochloric acid to give a reaction mixture nearly quantitatively, showing two spots on TLC. Separation of the mixture afforded two compounds in a ratio of 1 : 1, one of which was found to be shinjudilactone (**1**) and the other with a lower R_f value on TLC was determined to be a 13β-epimer (**12**) of **1** by spectral investigation (see Experimental). Reaction of **3** with sodium carbonate under the same conditions as above gave the same reaction mixture, but accompanied by a



13 14 15

small amount of by-products.

Formation of shinjudilactone (**1**) from ailanthone (**3**) has been thus demonstrated, although it remained unresolved whether the reaction proceeds through 13(12→11)*abeo*-type or 9(11→12)*abeo*-type rearrangement. The pathway through benzilic acid rearrangement is also supported by i) labeling experiment and ii) isolation of an intermediate.

i) Treatment of ailanthone (**3**) with $NaDCO_3$ in boiling D_2O–CH_3OD and the reaction product was treated with dilute hydrochloric acid to afford labeled shinjudilactone and its 13-epimer. The labeled shinjudilactone was shown to be an undecadeuterio derivative (**1**-d_{11}) containing a decadeuterio derivative (**1**-d_{10}). The labeled positions were determined by ^1H NMR measurement at 400 MHz and shown in the structure **13**. Ten hydrogen atoms were completely replaced with deuterium atoms and a multiplet signal at δ 2.70 due to the $C_{(15\beta)}$–H was observed, accounting for the presence of **1**-d_{10}. The presence of a deuterium atom at C-9 implies the formation of a carbonyl group at C-11 followed by enolization, which is favorable to the path **b**, during the reaction. The location of a deuterium atom at C-13β of **1**-d_{11} would reject a direct hydride transfer mechanism from C-12β to a cationic center at C-13 as depicted in the path **a**. ii) Ailanthone (**3**) was isomerized by heating in pyridine for 10 h to afford a hemiacetal, for which the structure (**14**) could be assigned by ^1H and ^{13}C NMR measurement. The structure of hemiacetal moiety of **14** was confirmed by ^{13}C–^1H long range selective decoupling experiment measured at 90 MHz. When the ^1H signal due to $C_{(9)}$–H at δ 2.88 was irradiated, the ^{13}C signal at δ 108.15 became sharp, but ^{13}C signal at δ 207.46 still remained broad, being coupled with a proton at C-13. This observation leads to the conclusion that the hemiacetal carbon resonating at δ 108.15 and the carbonyl carbon at δ 207.46 are located in C-11 and C-12 positions, respectively. The fact that $C_{(9)}$–H kept α-configuration intact[22] was demonstrated by NOE experiment measured at 400 MHz. On irradiation at δ 2.88 due to $C_{(9)}$–H, signal due to $C_{(1)}$–H (δ 4.42) increased in area by 15%, while neither signal due to $C_{(7)}$–H (δ 4.79) nor due to $C_{(20)}$–H_2 (δ 4.15 and δ 4.46) showed NOE enhancement.

The structure (**14**), which is equivalent to the hypothetical α-diketone (**11**), has been proposed for isoailanthone by Polonsky *et al.*[8b] Isoailanthone was prepared by treatment of **3** with dilute alkali, but neither detailed description nor spectral data of isoailanthone was given. Only spectral data of its 1-*O*-methyl derivative prepared by methylation with diazomethane were registered.[8b] The hemiacetal (**14**) was then treated with diazomethane to yield a product, which however was suggested to be a 12-spirooxirane-derivative (**15**) from the spectral examination (see Experimental). This compound (**15**) is not identical with 1-*O*-methylisoailanthone. The reason why the disagreement occurred is obscure and further investigation is now in progress. On treatment with sodium hydrogencarbonate in boiling aqueous methanol, the hemiacetal (**14**) gave shinjudilactone (**1**) and its 13-epimer (**12**).

It would be suggestive that shinjudilactone (**1**) is synthesized biogenetically from ailanthone (**3**) or its equivalent through a path similar to the benzilic acid rearrangement. Recently Ochi *et al.*[23] have isolated a 6-epi-*ent*-gibberellane derivative, rabdoepigibberellolide, from *Rabdosia shinkokianus* Hara and suggested its biogenetic pathway from rabdosianin A through benzilic acid rearrangement.

Although biogenesis of shinjulactone C (**2**) with an unusual hexacyclic 1α,12α : 5α,13α-dicyclo-9β*H*-picrasane skeleton, is still unknown, a biogenetic precursor with a normal picrasane skeleton, such as ailanthone (**3**), would undergo an inversion of a chiral center at C-9 position prior to the bond-formation between C-1 and C-12 and between C-5 and C-13. Further investigation is now in progress.

Experimental

General Procedures. All melting points were measured on a Mel-temp capillary melting point apparatus (Laboratory Devices) and uncorrected. Optical rotations were determined on a JASCO polarimeter DIP-181. Ultraviolet absorption (UV) spectra and infrared (IR) spectra were measured on a Hitachi 340 and a Hitachi 260-30 spectrometer, respectively. Mass (MS) spectra were run on a Hitachi RMU-6 Tokugata mass spectrometer and high-resolution mass spectra on a JEOL JMS-D300 mass spectrometer operating at 70 eV. Proton nuclear magnetic resonance (^1H NMR) spectra (90 MHz) were taken using a Varian EM 390 and carbon-13 nuclear magnetic resonance (^{13}C NMR) spectra (22.5 MHz) JEOL FX 90Q unless otherwise stated. Measurement of ^1H NMR spectra at 400 MHz and ^{13}C NMR spectra at 100 MHz was carried out on a JMN GX 400 (JEOL) spectrometer. Chemical shifts were expressed in ppm downfield from tetramethylsilane as an internal standard (δ value) and coupling constants in Hz. Thin-layer chromatography (TLC) was carried out on Kieselgel 60 GF_{254} coated in 0.25 mm- or 0.5 mm-thickness or on TLC plates Silica Gel F_{254} with Concentration Zone (E. Merck). Wakogel C-200 (Wako), Silicic acid AR (Mallinckrodt) or Celite No. 545 (Wako) was used for column chromatography.

Plant Materials. Roots of *Ailanthus altissima* Swingle were collected twice at the Botanical Gardens, Faculty of Science, the University of Tokyo in January 1980 and 1981. Bark was stripped off from the root, air-dried, and chipped to afford 3.2 and 10 kg of materials, respectively.

Extraction and Separation. *i) Extraction with Ethyl Acetate*: The root bark (3.2 kg), defatted with petroleum ether (18 l) for 6 h, was extracted twice with ethyl acetate (18 l) for 6 h and then with methanol (18 l) for 6 h. Since the bitter taste was mainly exhibited in the ethyl acetate-extract, which was subjected to further separation. Non-bitter solids, precipitated from the extract on standing, were filtered off and the filtrate was concentrated to give a residue (30 g), which was partitioned between dichloromethane and aqueous methanol.

Column A: The aqueous methanol layer, on evaporation, gave a bitter residue (*ca.* 11 g), 3.5 g of which was subjected to column chromatographic separation (C-200, 180 g), eluted with chloroform (each 360 ml) containing following percentage of methanol: 1, 5, 10, 20, 40, 60, and 100%, and 28 fractions (each 90 ml) were collected. Elution with chloroform containing *ca.* 5% methanol afforded a small quantity of bitter principles, which were inferred to be a mixture of amarolide and amarolide 11-acetate by TLC examination (developed with 5% methanol–chloroform). Further confirmation was carried out by comparison with authentic samples, both of which were isolated from methanol extract of the root bark of the plant in *ca.* 0.01% yield, respectively.

Column B: Fraction 13 (2.1 g) of Column A was further separated by dry column chromatography (C-200, 420 g). A mixture (2 : 1) of benzene–acetone was passed through the column and 16 fractions (each 420 ml) were collected. Recrystallization of fractions 7—16 from ethyl acetate gave ailanthone (**3**; 1.2 g).

Column C: Fractions 3—6 (450 mg) of Column B were combined and separated by dry column chromatography (C-200, 140 g), eluting with 5% methanol–containing chloroform. Ten fractions (each 70 ml) were collected and a small quantity of ailanthone (**3**) was obtained from fractions 6—10. Fractions 3—5 were combined and separated by preparative TLC developed with benzene–acetone (1 : 1) and then with methanol–chloroform (1 : 9) to give ailanthone (**3**; trace), glaucarubinone (27 mg), and $\Delta^{13(18)}$-dehydroglaucarubinone (40 mg).

Column D: The dichloromethane layer obtained by the partition was evaporated to afford a bitter residue (19 g), 17 g of which was subjected to separation by column chromatography (C-200, 900 g). After elution with chloroform–benzene (1 : 1, 1.8 l) and chloroform (1.8 l), following solvents were successively passed through the column: 1%-, 2%-, 4%-, 8%-, 16%-, and 32%-methanol in chloroform (each 1.8 l) and 18 fractions (each 900 ml) were collected.

Column E: Fraction 15 (3.5 g) of Column D was chromatographed over silica gel (C-200, 300 g) eluting with benzene–acetone (3 : 2) to give 20 fractions (each 300 ml).

Column F: Fraction 16 (0.5 g) of Column A was chromatographed over silica gel (C-200, 100 g) eluting with benzene–acetone (1 : 1) to 10 fractions (each 100 ml).

Column G: Fractions 5—17 of Column E and fractions 7—14 of Column F were combined to afford a residue (450 mg) on evaporation, which was dissolved in chloroform, passed though a column packed with a mixture of silicic acid (23 g) and Celite (23 g). Elution with chloroform (92 ml) and 1%-, 2%-, 5%-, 10%-, 20%-, and 50%-methanol in chloroform (each 92 ml) afforded 25 fractions (each 23 ml). Recrystallization of fraction 20 from methanol gave shinjulactone A (7 mg). Fractions 17—19 were purified by preparative TLC developed with 10% methanol in chloroform to give $\Delta^{13(18)}$-glaucarubolone (20 mg).

ii) Extraction with Water: The air-dried root bark (10 kg) was extracted with hot water (90 °C, 20 l) overnight. The extraction was repeated twice and the aqueous extracts were combined and evaporated *in vacuo* to give a concentrated extract (*ca.* 5 l). The extract was divided into three portions, each of which was extracted continuously with dichloromethane (1 l) overnight and the extraction was repeated four times. Evaporation of the combined dichloromethane extract gave a residue (45 g).

Column H: The residue (40 g) above obtained, was chromatographed over silica gel (C-200, 1.3 kg) and eluted with 1%-, 2%-, 4%-, 8%-, 16%-, 32%-, and 64%-methanol in chloroform (each 2.6 l). Eighteen fractions (each 1.3 l) were collected and following residues were obtained on evaporation; fr 7 (5.6 g), fr 8 (4.0 g), fr 9 (1.8 g), fr 10 (4.4 g), fr 11 (3.2 g), fr 12 (3.7 g), fr 13 (3.0 g), fr 14 (3.3 g), fr 15 (5.3 g), and fr 16 (2.4 g).

Column I: Fraction 7 of Column H was subjected to separation by dry column chromatography (C-200, 560 g) and a mixture of benzene–acetone (4 : 1) was passed to afford 46 fractions (each 140 ml). Fractions 12 and 13 gave amarolide. Recrystallization of fractions 27—35 from methanol afforded shinjudilactone (**1**; 70 mg).

Column J: The mother liquor obtained from the recrystallization of shinjudilactone (**1**) afforded a residue (500 mg), which was chromatographed over silica gel (C-200, 100 g, eluted with 5% methanol in chloroform) and then silicic acid (70 g, eluted with 2.5% methanol in dichloromethane) to afford chaparrinone (**4**; 18 mg).

Column K: Recrystallization of fraction 8 (4.0 g) of Column H from methanol–chloroform afforded shinjudilactone (**1**; 200 mg) in needles and mother liquor, which gave a residue (3.8 g) on evaporation. The residue was chromatographed over silica gel (C-200, 600 g) and a mixture of benzene and ethanol (9 : 1) was passed to afford 12 fractions (each 400 ml). From fractions 7—12, shinjudilactone (**1**; 900 mg) was obtained by crystallization from methanol.

Column L: Fraction 10 of Column H was chromatographed over silica gel (C-200, 500 g, dry; elution with benzene–acetone (3 : 1)) and 36 fractions (each 200 ml) were obtained. Fractions 22—29 afforded ailanthone (**3**; *ca.* 1 g).

Column M: Fraction 14 of Column H was separated by column chromatography (C-200, 350 g) eluted with a lower phase of a mixture, chloroform–methanol–water (150 : 25 : 6) to give 27 fractions (each 100 ml). From fractions 13—16, $\Delta^{13(18)}$-dehydroglaucarubolone (100 mg) was obtained by crystallization from acetone.

Column N: Fractions 18—21 (380 mg) of Column L were dissolved in chloroform and the solution was passed through a column of silica gel (C-200, 200 g) and the following solvents were passed: chloroform (200 ml), 1%-methanol in chloroform (400 ml), 3%- (400 ml), and 5%- (800 ml). Eighteen fractions (each 100 ml) were collected and fractions 11—14 gave shinjudilactone (**1**; 50 mg) and fraction 16 afforded glaucarubinone (50 mg) after purification by preparative TLC developed with 3% methanol in ethyl acetate.

Column O: Fraction 11 of Column H was separated by column chromatography (C-200, 400 g) eluted with 1%-methanol in ethyl acetate (800 ml) and then with 2%- (1600 ml) to give 15 fractions (each 160 ml). Fractions 8—14 were dissolved in chloroform and passed through a dry column of silica gel (C-200, 300 g). Chloroform (300 ml), 2%-methanol in chloroform (600 ml), and 4%-(2050 ml) were successively passed to afford 39 fractions (each 75 ml). Fractions 17—22 consisted of mainly ailanthone (**3**) and fractions 31—36 afforded shinjulactone B (11 mg) after purification by preparative TLC developed with 5% methanol in chloroform.

Column P: Fraction 13 of Column H was subjected to partition chromatography over silica gel (C-200, 500 g, dry). Eluting solvent consisted of a 1 : 1 (v/v) mixture of a lower layer of dichloromethane–methanol–water (100 : 25 : 6) and

dichloromethane. Eighteen fractions (each 200 ml) were collected. Recrystallization of fractions 6 and 7 from acetone gave chaparrolide (*ca.* 200 mg). Shinjulactone C (**2**; *ca.* 20 mg) was obtained from the mother liquor by recrystallization from acetone.

Since separation of quassinoids in the root bark of *A. altissima* was difficult and therefore separation procedures were very complicated, it is impossible to describe all procedures carried out in this experiment. The contents of each quassinoids are estimated by summing up amounts obtained in various separation routes and are shown in Table 10.

Shinjudilactone (1). Colorless needles crystallized from ethyl acetate–methanol, mp 274—276 °C; $[\alpha]_D^{23}$ +102° (*c* 0.76, C_5H_5N); IR (KBr) *ca.* 3250, 1745, 1735, 1670, and 1620 cm^{-1}; UV (EtOH) 238 nm (ε 10800); ^1H NMR (Table 5); ^{13}C NMR (Table 1); MS *m/e* (%) 376 (M^+; 80), 358 (20), 347 (30), 332 (60), 303 (98), 288 (75), and 95 (100); Found: *m/e* 376.1509. Calcd for $C_{20}H_{24}O_7$: M 376.1520. Found: C, 62.03; H, 6.74; Calcd for $C_{20}H_{24}O_7 \cdot 1/2\ H_2O$: C, 62.33; H, 6.54%.

1-O-Methylshinjudilactone (5). Shinjudilactone (**1**; 30 mg) in methanol (10 ml) was treated with diazomethane in ether and the reaction mixture was allowed to stand overnight. After the usual work-up, the reaction product was purified by preparative TLC developed with 3% methanol–chloroform to give 1-*O*-methylshinjudilactone (**5**; 15 mg); mp 291—294 °C (from methanol); $[\alpha]_D^{23}$ +53.5° (*c* 0.27, $CHCl_3$); IR (Nujol) 3400, 1745, 1720, 1680, and 1630 cm^{-1}; UV (EtOH) 239.5 nm (ε 5400); ^1H NMR ($CDCl_3$) δ 1.05 (3H, s; $C_{(10)}$–CH_3), 1.11 (3H, d, J=7 Hz; $C_{(13)}$–CH_3), 1.95 (3H, br s; $C_{(4)}$–CH_3), 3.63 (1H, s; $C_{(1)}$–H), 3.75 (3H, s; CH_3O), 4.00 and 4.52 (each 1H, d, J=11.5 Hz; $C_{(20)}$–H), 4.52 (1H, t, J=2.5 Hz; $C_{(7)}$–H), 5.98 (1H, m; $C_{(3)}$–H), and 6.08 (1H, s; OH); MS *m/e* (%) 390 (M^+; 60), 360 (100), 345 (50), 330 (20), 301 (10), and 288 (45); Found: *m/e* 390.1659. Calcd for $C_{21}H_{26}O_7$: M 390.1677.

1-O-Acetylshijudilactone (6). Shinjudilactone (**1**; 20 mg) was acetylated with acetic anhydride (2 ml) in pyridine (2 ml) at room temperature for 9 h. Addition of methanol and the usual work-up afforded 1-*O*-acetylshinjudilactone quantitatively, mp 269—272 °C (from methanol); IR (Nujol) 3480, 1730, 1680, and 1630 cm^{-1}; UV (EtOH) 240 nm (ε 8000); ^1H NMR (C_5D_5N) δ 1.12 (3H, d, J=7 Hz; $C_{(13)}$–CH_3), 1.36 (3H, s; $C_{(10)}$–CH_3), 1.77 (3H, br s; $C_{(4)}$–CH_3), 2.25 (3H, s; –$OCOCH_3$), 4.26 and 4.73 (each 1H, d, J=12 Hz; $C_{(20)}$–H), 4.64 (1H, t, J=3 Hz; $C_{(7)}$–H), 5.78 (1H, s; $C_{(1)}$–H), and 6.05 (1H, m; $C_{(3)}$–H); MS *m/e* (%) 418 (M^+; 30), 400 (25), 358 (95), 330 (40), and 60 (100); Found: *m/e* 418.1678. Calcd for $C_{22}H_{26}O_8$: M 418.1628.

Reduction of 1 with Sodium Borohydride. To a solution of shinjudilactone (**1**; 30 mg) in ethanol (10 ml) kept at 0 °C, sodium borohydride (6 mg) in ethanol (2 ml) was added and the mixture was stirred for 4 h at 0 °C. Acetic acid (1 ml) was added and the solvents were evaporated *in vacuo* to afford a residue, which was dissolved in a mixture of dichloromethane (10 ml) and brine (10 ml). Extraction with dichloromethane (10 ml×3), evaporation *in vacuo*, and crystallization from methanol gave a hemiacetal (**7**; 20 mg), mp 276—277.5 °C; IR (Nujol) *ca.* 3300, 1740, 1660, and 1610 cm^{-1}; UV (EtOH) 240 nm (ε 11500); ^1H NMR (C_5D_5N) δ 1.13 (3H, d, J=6 Hz; $C_{(13)}$–CH_3), 1.17 (3H, s; $C_{(10)}$–CH_3), 1.76 (3H, br s; $C_{(4)}$–CH_3), 4.20 and 4.43 (each 1H, d, J=12 Hz; $C_{(20)}$–H), 4.26 (1H, t, J=3 Hz; $C_{(7)}$–H), 4.35 (1H, s; $C_{(1)}$–H), 5.68 (1H, m; $C_{(16)}$–H), and 6.04 (1H, m; $C_{(3)}$–H); MS *m/e* (%) 378 (M^+; 20), 360 (70), 345 (40), 334 (40), and 316 (100); Found: *m/e* 378.1681. Calcd for $C_{20}H_{26}O_7$: M 378.1679.

Shinjulactone C (2). Colorless prisms crystallized from acetone, mp 292 °C (decomp); $[\alpha]_D^{23}$ −344° (*c* 0.46, C_5H_5N); IR (KBr) *ca.* 3480, 1775, 1720, 1650, 1620 (sh), 1390, and 1190 cm^{-1}; UV (MeOH) 248 nm (ε 10600); ^1H NMR (Table 5); ^{13}C NMR (Table 6); MS *m/e* (%) 374 (M^+; 100), 356 (5), 343 (20), 315 (10), and 151 (60); Found: *m/e* 374.1379. Calcd for $C_{20}H_{22}O_7$: M 374.1366.

Acetylation of Shinjulactone C (2). *i)* Shinjulactone C (**2**; 20 mg) was treated with acetic anhydride (5 ml) and pyridine (5 ml) at room temperature overnight. After methanol (5 ml) was added, the reaction mixture was evaporated *in vacuo* to give a residue, which was shown to be a 7 : 3 mixture of a monoacetate (**8**) and a diacetate (**9**) by TLC examination. Acetylation of the mixture was repeated under the same conditions as above and the acetylation product was separated by preparative TLC developed with 10% methanol–chloroform to give the monoacetate (**8**; 1 mg) and the diacetate (**9**; 20 mg). *ii)* A mixture of shinjulactone C (**2**; 10 mg) and acetic acid (5 ml) was heated under reflux for 15 h to afford the monoacetate (**8**) quantitatively. 20-*O*-Acetylshinjulactone C (**8**): mp 131—134 °C (from acetone–hexane); $[\alpha]_D^{22}$ −222° (*c* 0.13, $CHCl_3$); IR (Nujol) *ca.* 3450, 1770, 1740 (br), 1660, 1620 (sh), and 1240 cm^{-1}; UV (EtOH) 245 nm (ε 14000); ^1H NMR (C_5D_5N) δ 1.11 (3H, s; $C_{(13)}$– or $C_{(10)}$–CH_3), 1.30 (3H, s; $C_{(10)}$– or $C_{(13)}$–CH_3), 1.96 (3H, s; –$OCOCH_3$), 2.03 (3H, br s; $C_{(4)}$–CH_3), 2.49 (1H, s; $C_{(9)}$–H), 4.47 and 4.59 (each 1H, d, J=12 Hz; $C_{(20)}$–H), 5.02 (1H, m; $C_{(7)}$–H), and 6.47 (1H, br s; $C_{(3)}$–H); ^1H NMR ($CDCl_3$) δ 0.99 (3H, s; $C_{(13)}$– or $C_{(10)}$–CH_3), 1.03 (3H, s; $C_{(10)}$– or $C_{(13)}$–CH_3), 2.08 (6H, s; $C_{(4)}$–CH_3 and –$OCOCH_3$), 4.07 (2H, s; $C_{(20)}$–H_2), 4.63 (1H, m; $C_{(7)}$–H), and 6.35 (1H, br s; $C_{(3)}$–H); MS *m/e* (%) 416 (M^+; 25), 398 (10), 388 (8), 374 (8), 356 (100), 193 (30), and 151 (10); Found: *m/e* 416.1464. Calcd for $C_{22}H_{24}O_8$: M 416.1469. 12,20-Di-*O*-acetylshinjulactone C (**9**): mp 152—154 °C (from acetone–hexane); $[\alpha]_D^{21}$ −200° (*c* 0.24, $CHCl_3$); IR (Nujol) *ca.* 3450, 1780, 1740 (br), 1665, 1620 (sh), and 1220 cm^{-1}; UV (EtOH) 245.5 nm (ε 9600); ^1H NMR (C_5D_5N) δ 1.14 (6H, s; $C_{(13)}$– and $C_{(10)}$–CH_3), 1.71 (3H, br s; $C_{(4)}$–CH_3), 1.94 and 2.06 (each 3H, s; –$OCOCH_3$), 2.57 (1H, s; $C_{(9)}$–H), 4.42 and 4.51 (each 1H, d, J=12 Hz; $C_{(20)}$–H), and 6.52 (1H, br s; $C_{(3)}$–H); ^1H NMR ($CDCl_3$) δ 0.99 (3H, s, $C_{(13)}$– or $C_{(10)}$–CH_3), 1.00 (3H, s; $C_{(10)}$– or $C_{(13)}$–CH_3), 2.06 and 2.13 (each 3H, s; –$OCOCH_3$), 2.10 (3H, br s; $C_{(4)}$–CH_3), 4.10 (2H, s; $C_{(20)}$–H_2), 4.63 (1H, m; $C_{(7)}$–H), and 6.37 (1H, br s; $C_{(3)}$–H); ^{13}C NMR (C_5D_5N) δ 12.3 q, 13.3 q, 20.0 q, 20.3 q, 22.6 q, 29.8 t, 29.8 t, 35.4 d, 42.4 s, 51.0 s, 52.7 d, 55.0 s, 56.2 s, 63.5 t, 72.6 d, 86.4 s, 97.5 s, 128.4 d, 165.5 s, 169.7 s, 170.0 s, 170.0 s, 193.2 s, and 201.0 s; MS *m/e* (%) 458 (M^+; 12), 430 (10), 416 (100), 398 (20), 193 (60), and 151 (58); Found: *m/e* 458.1590. Calcd for $C_{24}H_{26}O_9$: M 458.1587.

Formylation of Shinjulactone C (2). A solution of shin-

Shinjulactone C (**2**)	—	0.001

julactone C (**2**; 12 mg) in formic acid (5 ml) was stirred at room temperature for 2 h. Evaporation of the solvent *in vacuo* afforded 20-*O*-formylshinjulactone C (**10**) quantitatively, mp 268—271 °C (from acetone); IR (KBr) *ca.* 3450, 1770, 1730 (br), 1660, and 1180 cm^{-1}; ^1H NMR (C_5D_5N) δ 1.10 (3H, s; $C_{(13)}$- or $C_{(10)}$-CH_3), 1.27 (3H, s; $C_{(10)}$- or $C_{(13)}$-CH_3), 2.00 (3H, br s; $C_{(4)}$-CH_3), 2.49 (1H, s; $C_{(9)}$-H), 4.44 and 4.57 (each 1H, d, J=12 Hz; $C_{(20)}$-H), 4.96 (1H, m; $C_{(7)}$-H), 6.45 (1H, br s; $C_{(3)}$-H), and 8.25 (1H, s; H-CO); MS *m/e* (%) 402 (M^+; 100), 374 (10), 359 (10), 343 (15), 297 (20), and 151 (40); Found: *m/e* 402.1293. Calcd for $C_{21}H_{22}O_8$: M 402.1313.

Hydrolysis of 20-O-Formylshinjulactone C (10). The formate (**10**; 12 mg) was heated under reflux with a mixture of formic acid (3 ml) and water (3 ml) for 5 h to afford shinjulactone C (**2**) quantitatively.

Conversion of Ailanthone (3) into Shinjudilactone (1). *i)* Ailanthone (**3**; 21 mg) in a mixture of methanol (2 ml) and water (2 ml) was heated with sodium hydrogencarbonate (5 mg) under reflux for 30 min. The reaction mixture was acidified with concd hydrochloric acid (2 drops), evaporated to concentrated solution (*ca.* 1 ml) under reduced pressure, and extracted with dichloromethane. After usual work-up, a residue (20 mg) was subjected to separation by preparative TLC developed with chloroform–methanol (19 : 1) to afford shinjudilactone (**1**; 10 mg) and 13-epishinjudilactone (**12**; 10 mg), mp 263—266 °C (from methanol–ethyl acetate); $[\alpha]_D^{23}$ +48° (*c* 0.57, C_5H_5N); IR (KBr) *ca.* 3300, 1745, 1675, 1620, 1250, and 1180 cm^{-1}; UV (EtOH) 239 nm (ε 10300); ^1H NMR (C_5D_5N) δ 1.19 (3H, d, J=6 Hz; $C_{(13)}$-CH_3), 1.20 (3H, s; $C_{(10)}$-CH_3), 1.77 (3H, br s; $C_{(4)}$-CH_3), 4.22 (1H, s; $C_{(1)}$-H) 4.25 and 4.66 (each 1H, d, J=12 Hz; $C_{(20)}$-H), 4.65 (1H, t, J=2 Hz; $C_{(7)}$-H), and 6.06 (1H, m; $C_{(3)}$-H); ^{13}C NMR (C_5D_5N) δ 9.8, 11.4, 22.2, 27.0, 29.3, 41.9, 42.5, 42.8, 44.5, 48.3, 51.0, 74.3, 76.0, 76.6, 83.5, 126.3, 161.8, 170.9, 175.7, and 196.7; MS *m/e* (%) 376 (M^+; 8), 358 (6), 347 (8), 340 (10), 312 (45), 294 (40), 268 (100), and 253 (60); Found: *m/e* 376.1532. Calcd for $C_{20}H_{24}O_7$: M 376.1520.

ii) Reaction of ailanthone (**3**) with sodium carbonate in boiling aqueous methanol afforded the same reaction mixture of **1** and **12**, but accompanied with a formation of a small amount of by-products.

iii) Reactions of ailanthone (**3**) under following conditions were carried out, but all attempts were not successful; a) *p*-toluenesulfonic acid in tetrahydrofuran, reflux for 48 h, b) 2 M† hydrochloric acid in methanol, room temperature for 12 h and then reflux for 12 h, c) acetic acid-2 M hydrochloric acid in water, room temperature overnight, and then reflux overnight, d) 2 M hydrochloric acid–iron (III) chloride in water, reflux overnight, e) boron trifluoride etherate in benzene or dichloromethane, room temperature overnight, and f) sodium hydroxide in water, potassium hydroxide in methanol, or barium hydroxide in pyridine, reflux overnight.

Conversion of Ailanthone (3) into Undecadeuterioshinjudilactone (1-d_{11}). A mixture of ailanthone (**3**; 21 mg), $NaDCO_3$ (5 mg), D_2O (2 ml), and CH_3OD (2 ml) was heated under reflux for 30 min. The reaction mixture was acidified with concd hydrochloric acid (2 drops) and worked-up as usual to give a crude deuteriated product (20 mg), from which undecadeuterioshinjudilactone (**1**-d_{11}; 10 mg) was separated by preparative TLC. **1**-d_{11}: ^1H NMR (400 MHz, C_5D_5N) δ 1.22 (2H, br s; $C_{(13)}$-CH_2D), 1.23 (3H, s; $C_{(10)}$-CH_3), 2.06 (1H, br d, J=14 Hz; $C_{(6\beta)}$-H), 2.26 (1H, br s; $C_{(14)}$-H), 2.28 (1H, dd, J=14 Hz and 2.5 Hz; $C_{(6\alpha)}$-H), 2.70(0.5 H, m; $C_{(15\beta)}$-H), 4.28 and 4.78 (each 1H, d, J=11.5 Hz; $C_{(20)}$-H), and 4.78 (1H, t, J=2.5 Hz; $C_{(7)}$-H); MS *m/e* 387, 386, 367, 342, 100, and 68.

† 1 M = 1 mol dm^{-3}.

Isomerization of Ailanthone (3) into Hemiacetal (14). Ailanthone (**3**; 30 mg) in pyridine (5 ml) was refluxed for 10 h and the reaction product was separated by preparative TLC to give a hemiacetal (**14**; 20 mg), mp 166—169 °C (from acetone–benzene); IR (KBr) 3450, 1740, 1680, 1240, and 1050 cm^{-1}; UV (EtOH) 238 nm (ε 8100); ^1H NMR (C_5D_5N) δ 1.03 (3H, d, J=8 Hz), 1.58 (3H, s), 1.76 (3H, br s), 2.83 (1H, s), 4.12 and 4.43 (each 1H, d, J=9 Hz), 4.76 (1H, t, J=2.5 Hz), and 6.06 (1H, m); ^{13}C NMR (C_5D_5N) δ 10.21, 10.40, 22.30, 26.14, 28.80, 40.64, 42.07, 43.51, 46.05, 46.73, 51.20, 72.82, 77.64, 84.11, 108.15, 126.35, 161.46, 169.12, 196.79, and 207.41; MS *m/e* (%) 376 (M^+; 15), 358 (16), 332 (29), 303 (46), and 95 (100); Found: *m/e* 376.1514. Calcd for $C_{20}H_{24}O_7$: M 376.1520.

Methylation of hemiacetal (**14**; 20 mg) in tetrahydrofuran (5 ml) with an excess of diazomethane in ether at room temperature overnight gave a reaction mixture, which was subjected to separation by preparative TLC to afford an *O*-methyl oxirane derivative (**15**; 7 mg), mp 274—277 °C (from acetone–hexane), $[\alpha]_D^{22}$ −65° (*c* 0.46, $CHCl_3$); IR (Nujol) 3220, 1730, 1680, and 1240 cm^{-1}; UV (EtOH) 238 nm (ε 9500); ^1H NMR ($CDCl_3$) δ 0.81 (3H, d, J=7 Hz; $C_{(13)}$-CH_3), 1.29 (3H, s; $C_{(10)}$-CH_3), 1.95 (3H, br s; $C_{(4)}$-CH_3), 2.63 (1H, s; $C_{(9)}$-H), 2.57 and 3.26 (each 1H, d, J=5.5 Hz; -CH_2-), 3.56 (1H, s; $C_{(1)}$-H), 3.70 (3H, s; -OCH_3), 3.80 and 4.07 (each 1H, d, J=9 Hz; $C_{(20)}$-H), 4.49 (1H, t, J=2.5 Hz; $C_{(7)}$-H), 6.00 (1H m; $C_{(3)}$-H), and 7.45 (1H, s; -OH); ^{13}C NMR ($CDCl_3$) δ 9.8 q, 10.3 q, 22.5 q, 25.7 t, 28.7 t, 29.3 d, 42.8 d, 43.3 d, 44.7 s, 45.5 t, 46.3 s, 49.3 d, 61.5 q, 64.5 s, 72.1 t, 78.0 d, 93.4 d, 106.7 s, 127.0 d, 160.4 s, 169.8 s, and 195.0 s; MS *m/e* (%) 404 (M^+; 100), 374 (60), and 165 (80); Found: *m/e* 404.1855. Calcd for $C_{22}H_{28}O_7$: M 404.1835.

Conversion of Hemiacetal (14) into Shinjudilactone (1) and Its 13-Epimer (12). Hemiacetal (**14**; 16 mg) was heated with sodium hydrogencarbonate (10 mg) in aqueous methanol (4 ml) for 30 min to afford a mixture (11 mg) of shinjudilactone (**1**) and its 13-epimer (**12**). The physical and spectral data of these compounds, after separation by preparative TLC, were completely identical with those of authentic samples, respectively.

Inhibitory Activities. Inhibitory effects (ID_{50}) against HeLa cells were >10 μg/ml, >10 μg/ml, and 0.01—0.1 μg/ml for shinjudilactone (**1**), shinjulactone C (**2**), and ailanthone (**3**), respectively.

The authors wish to thank Dr. Wataru Tanaka and Dr. Kunihiro Niijima of Nippon Kayaku Co., for extraction of materials and the biological assay and Mr. Eiichi Ishii of the Botanical Gardens, Faculty of Science, The University of Tokyo, for collecting *Ailanthus altissima* Swingle. They also would like to thank Mr. Kazuhiro Matsushita of JEOL Co., for measurement of NMR spectra.

(Received June 29, 1983)

The structure of a new bitter principle, shinjulactone A, isolated from *Ailanthus altissima* SWINGLE was determined to be 11β,20-epoxy-1β,2α,11α,12α-tetrahydroxypicrasa-3,13(21)-dien-16-one and the configuration of a hydroxyl group at C-12 of ailanthone was revised to α-orientation by X-ray analysis.

Bitter principles of Simaroubaceous plants have been extensively investigated and a number of quassinoids have been reported.[2] In connection with our studies on bitter principles of *Picrasma ailanthoides* PLANCHON,[3] constituents of *Ailanthus altissima* SWINGLE (=*A. glandulosa* DESF.; Japanese name: Shinju or Niwaurushi) grown in Japan were examined and some of new picrasane derivatives were reported.[4-7] This paper deals with structural elucidation of a new bitter principle, shinjulactone A (**1**), isolated from the stem bark of the plant and also describes structural revision of ailanthone (**2**), a main bitter principle of the plant.

Concentrated methanolic extract of the stem bark of *A. altissima* was separated by silica-gel column chromatography to afford ailanthone (**2**)[8,9] in 0.05% yield and a crude new quassinoid together with other bitter principles. The new quassinoid was subjected to further separation by silicic acid-Celite column chromatography and crystallization to afford a new cytotoxic[10] bitter principle, shinjulactone A (**1**) in 0.002% yield.

Shinjulactone A (**1**), mp 245—245.5 °C (decomp) was shown to have a molecular formula, $C_{20}H_{26}O_7$ by high-resolution mass spectrum, and the IR and UV spectra showed the presence of hydroxyl(s) and δ-lactone and the absence of an α,β-unsaturated carbonyl group. Comparison of the ^1H and ^{13}C NMR spectra of **1** with those of ailanthone (**2**) could lead to the structure (**1**) for shinjulactone A except for the configuration of hydroxyl groups (see Tables 1 and 2).

The configuration of the hydroxyl groups at C-1 and C-12[11] could be established for **1** by NOE measurement operated at 270 MHz. On saturation of the signal due to $C_{(1)}$–H, the signals due to $C_{(9\alpha)}$–H and $C_{(5\alpha)}$–H showed increase by 12 and 5%, respectively. When the resonance frequency of $C_{(9\alpha)}$–H was irradiated, increase of signals due to $C_{(1)}$–H and $C_{(5\alpha)}$–H by 9 and 6% was observed, respectively. These observations imply the $C_{(1\alpha)}$–H and $C_{(1\beta)}$–OH orientations. On irradiation at the frequency of $C_{(12)}$–H, counterpart signals resonating in high field of an AB quartet signal due to $C_{(20\beta)}$–hemiacetal bridge methylene resulted in increase by 4%. Thus the orientation of the $C_{(12)}$–H was determined to be in β-orientation. The configuration of the hydroxyl group at C-2 was determined by differential NOE measurement operated at 400 MHz; on saturation of the singlet signal at δ 1.68 due to $C_{(10\beta)}$–CH_3, the multiplet signal at δ 4.62 due to $C_{(2)}$–H caused increase in area, indicating the $C_{(2\beta)}$–H and $C_{(2\alpha)}$–OH orientation. From these observations, the structure (**1**) having 1β-OH, 2α-OH, and 12α-OH configurations, is proposed for shinjulactone A.

In regard to the configuration at C-12, however, a

discrepancy between shinjulactone A and ailanthone arose. Two different structures (**3** and **4**) have been proposed for ailanthone so far. A hemiacetal structure (**3**), in which the $C_{(12)}$-OH was assigned to be β-equatorial, has been proposed for ailanthone by Polonsky *et al.*;[9] ailanthone was hydrogenated and followed by acetylation to afford dihydroailanthone triacetate (**5**), whose coupling constant between $C_{(12)}$-H and $C_{(13)}$-H was 8 Hz. A comparison of the coupling constant with that ($J_{12,13}$=3 Hz) observed in chaparrinone triacetate (**6**) led to the conclusion that the orientations of the $C_{(12)}$-OH groups of ailanthone and chaparrinone (**7**) were β-equatorial and α-axial configurations, respectively. On the other hand, Casinovi *et al.*[8b] proposed a $C_{(11)}$-keto structure (**4**) with 12α(axial)-OH configuration.

The structure of ailanthone was reinvestigated by NOE measurement of ^{1}H NMR spectrum in pyridine-d_5 solution and the $C_{(12)}$-H was suggested to be in β-equatorial disposition; on irradiation at δ 4.46 due to $C_{(12)}$-H, a signal resonating at δ 5.28 due to one of olefinic protons at C-21 showed an increase by 6%, and the irradiation at δ 5.28 resulted in increase in area of the signal due to $C_{(12)}$-H by 10%.

In order to establish the structure of ailanthone unambiguously, a single crystal obtained from chloroform–methanol solution was subjected to X-ray diffraction analysis. The crystal belongs to an orthorhombic space group $P2_12_12_1$, and the lattice parameters are a=17.067(8), b=16.608(8), and c=6.594(2) Å with four ailanthone molecules and four water molecules in a unit cell. Intensity data were measured on a PW1100 four-circle diffractometer using Cu $K\alpha$ radiation monochromated by a graphite plate. A total of 1874 independent structure factors with $F_o \geq 2.5\,\sigma(F_o)$ within 2θ=156°

a) $B_{eq} = 8\pi^2(u_1^2+u_2^2+u_3^2)/3$.

were obtained by $2\theta-\theta$ scanning mode. The structure was solved by the direct method using MULTAN program and was refined by the block-diagonal least-squares method. All hydrogen atoms, except for those of O(3) hydroxyl and water molecule, were located in a different electron density map. The final R-value was 0.043 using anisotropic temperature factors for the non-hydrogen atoms and isotropic ones for hydrogen

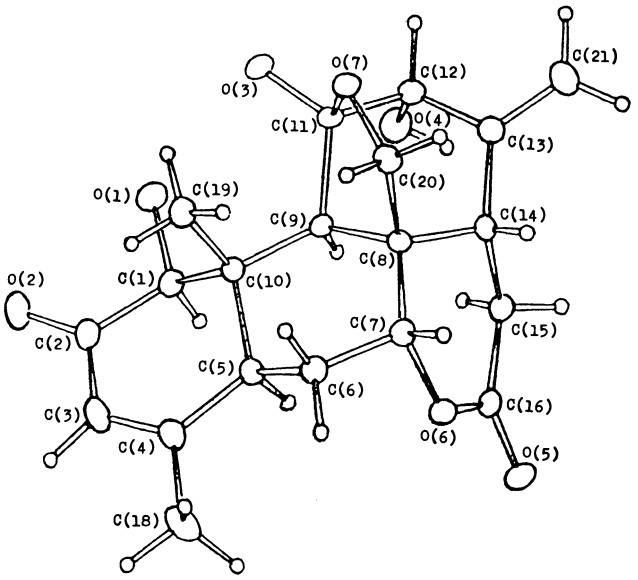

Fig. 1. Perspective view of ailanthone (**2**).[a]
a) For clarity hydrogen atoms are represented by spheres of arbitrary radius.

atoms. The final atomic coordinates are listed in Table 3 and bond lengths and bond angles are listed in Tables 4 and 5.[12] The hemiacetal structure and the $C_{(12\alpha)}$–OH configuration were clearly established as shown in Fig. 1. Molecules were strongly linked by the four hydrogen bondings, one is an intermolecular hydrogen bond between O(2) carbonyl and O(4) hydroxyl, and the others are between water and O(1) hydroxyl, O(3) hydroxyl, and O(5) lactone carbonyl in the three different ailanthone molecules. The distances are 2.843(4), 2.709(3), 2.861(3), and 3.007(4) Å, respectively.

The structure of ailanthone was thus shown to be revised to 11β,20-epoxy-1β,11α,12α-trihydroxypicrasa-3,13(21)-dien-2,16-dione (**2**) and the X-ray analysis also proved that the C-ring exists in a chair conformation. Therefore, when the hydrogenation occurs from

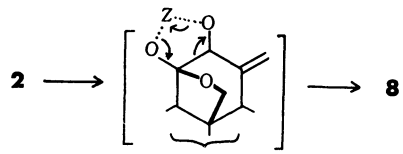
α-side, the *exo*-methylene group would produce a β-axial methyl group at C-13. Since the β-axial methyl group at C-13 would bring about an unstable diaxial relationship with the 12α-axial hydroxyl group, it seems most likely that an inversion of the C-ring occurs to adopt a stable boat conformation. The ring-inversion resulted in a large dihedral angle between 12-H and 13-H, which could reasonably explain the large coupling constant ($J_{12,13}$=8 Hz) for dihydroailanthone triacetate (**5**) stated above.[9]

The structure, 11β,20-epoxy-1β,2α,11α,12α-tetrahydroxypicrasa-3,13(21)-dien-16-one (**1**) proposed for shinjulactone A, was further confirmed by chemical conversion of **1** into **2**. Shinjulactone A (**1**) was oxidized with manganese dioxide in dichloromethane at room temperature to give two products, one of which was found to be identical with ailanthone (**2**). The other was identical with an oxidation product of ailanthone (**2**) with lead tetraacetate. The molecular formula, $C_{20}H_{22}O_7$, was determined by high resolution mass spectrum, and the UV and IR spectra suggest the presence of an α-substituted α,β-unsaturated aldehyde group (λ_{max} 221 nm and ν_{max} 2850 and 1685 cm^{-1}), an α,β-unsaturated ketone (λ_{max} 238 nm and ν_{max} 1685 cm^{-1}), and δ- and γ-lactone groupings (ν_{max} 1730 and 1775 cm^{-1}, respectively). Examination of ^{1}H and ^{13}C NMR spectra (Tables 1 and 2) and mass spectrum (see Experimental) and mechanistic consideration (Fig. 2) lead to the formulation of an 11,12-seco structure (**8**) for the



Z: oxidizing agent

Fig. 2.

oxidation product. On treatment with methanol, the compound (**8**) easily afforded a hemiacetal (**9**). The spectral data of **9** were compatible with the suggested structure.

Experimental

General Procedure. All melting points were measured on a Mel-temp capillary melting point apparatus (Laboratory Devices) and uncorrected. Optical rotations and circular dichroism (CD) were determined on a JASCO polarimeter DIP-181 and a JASCO Model J-15 spectrometer, respectively. Ultraviolet absorption (UV) and infrared (IR) spectra were measured on a Hitachi 340 and a Hitachi 260-30 spectrometer, respectively. Mass (MS) spectra were run on a Hitachi RMU-6 Tokugata mass spectrometer and high-resolution mass spectra on a JEOL JMS-D300 mass spectrometer operating at 70 eV. Proton nuclear magnetic resonance (^{1}H NMR) spectra were taken using a Varian EM390 (90 MHz), JEOL FX90Q (90 MHz), Brucker WH 270 (270 MHz), and JEOL FX400 (400 MHz). Carbon-13 nuclear magnetic resonance

(^{13}C NMR) spectra were taken on a JEOL FX90Q (22.5 MHz) and a JEOL FX100 (25 MHz). Chemical shifts were expressed in δ (ppm) downfield from tetramethylsilane as an internal standard and coupling constants in Hz. Thin-layer chromatography (TLC) was carried out on Kieselgel 60 GF_{254} coated in 0.25 mm- or 0.5 mm-thickness. Wakogel C-200 (Wako), Silicic acid AR (Mallinckrodt) or Celite No. 545 (Wako) was used for column chromatography. Analytical high performance liquid chromatography (HPLC) was carried out on a Waters Chromatograph ALC/GPS 202/401 at room temperature (column: μBondapack C_{18}; solvent system: MeOH–H_2O, 1 : 1; flow rate: 1.1 ml/min).

Plant Material. Stem bark of *Ailanthus altissima* was collected at the Botanical Gardens, Faculty of Science, The University of Tokyo in July 1979. The bark was air-dried and chipped to afford 9.3 kg of the materials.

Extraction and Separation. The stem bark (9.3 kg) was extracted three times with hot methanol (18 l×3) for 8 h. The combined extracts (*ca.* 50 l) were evaporated under reduced pressure and the residue was treated three times with hot petroleum ether (1.5 l×3) to give a bitter residue (737 g). A part (220 g) of the residue, dissolved in a solution of chloroform (180 ml) and methanol (1.3 l), was adsorbed on silica gel (300 g) and then solvents were removed *in vacuo*. The silica gel was placed on the top of a column of silica gel (2 kg), and the following solvents were passed through the column; chloroform (4 l), 1, 2, 4, 8, 16, 32, 64, and 80% methanol in chloroform (each 4 l), and finally methanol (2 l). The fractions 17 and 18 (each fraction; 1 l) were combined and subjected to fractional crystallization from methanol to give ailanthone (**2**; *ca.* 1.1 g).

The fraction 21 was evaporated and the residue was dissolved in hot methanol. After cooling, the precipitates (mainly sitosteryl glycoside) were filtered off and the filtrate was evaporated, dissolved in chloroform, and subjected to separation by a column of silicic acid and Celite, eluting with 1, 2, 5, 10, 20, and 50% methanol in chloroform. Fractions eluted with 20% and 50% methanol in chloroform were combined and crystallized from chloroform–methanol to give shinjulactone A (**1**; 40 mg). Separation of the fraction 22 under the same conditions afforded additional 17 mg of **1**.

Ailanthone (2). Mp 234—235 °C (lit,[9] mp 234—238 °C), $[\alpha]_D^{20}$ +9.2° (EtOH) (lit,[9] $[\alpha]_D$ +12.5° (EtOH)); CD $[\theta]_{310}$ +977 and $[\theta]_{260}$ +1379.

Shinjulactone A (1). Mp 245—245.5 °C (decomp, from MeOH and $CHCl_3$); $[\alpha]_D^{20}$ +2° (*c* 0.97, C_5H_5N); IR (Nujol) 3500, 3400, and 1740 cm^{-1}; ^{1}H NMR and ^{13}C NMR (Tables 1 and 2); MS *m/e* (%) 378 (M^+; 52), 363 (64), 360 (100), 345 (66), 342 (13), and 316 (100); Found: *m/e* 378.1634. Calcd for $C_{20}H_{26}O_7$: M 378.1679.

Oxidation of 1 with Manganese Dioxide. A solution of shinjulactone A (**1**; 14 mg) in dichloromethane (10 ml) was treated with manganese dioxide (200 mg, prepared by Attenburrow's procedure[13]) for 21 h at room temperature. After the usual work-up, the reaction mixture was separated by preparative TLC developed with methanol–chloroform (1 : 19). Ailanthone (**2**; 3.6 mg) was identified by HPLC (R_t= 6.4 min), MS, and FT-^{1}H NMR. The aldehyde (**8**; 0.7 mg) was identical with the oxidation product of **2** with lead tetraacetate (*vide infra*). Treatment with methanol in the presence of silica gel, the aldehyde (**8**) was converted into a hemiacetal (**9**), mp 203—205 °C (from acetone); IR (KBr) 3450, 1770 (sh), 1740, 1680, and 1035 cm^{-1}; UV (EtOH) 238 nm (ε 10000); ^{1}H and ^{13}C NMR (Tables 1 and 2); MS *m/e* 406 (M^+; 7), 388 (3), 374 (15), 356 (6), 151 (32), and 91 (100); Found: *m/e* 406.1632. Calcd for $C_{21}H_{26}O_8$: M 406.1627.

Oxidation of 2 with Lead Tetraacetate. Ailanthone (**2**; 26 mg) was treated with lead tetraacetate (36 mg) in 90% aqueous acetic acid (3 ml) at room temperature for 1 h. The reaction product was worked up as usual to afford the aldehyde (**8**) in a quantitative yield, mp 211—214 °C (from acetone); IR (KBr) 3450, 1775, 1730, 1685, and 1240 cm^{-1}; UV (EtOH) 238 nm (sh, ε 9700) and 221 nm (ε 12000); ^{1}H and ^{13}C NMR (Tables 1 and 2); MS *m/e* (%) 374 (M^+; 55), 356 (25), 346 (90), 246 (35), and 151 (100); Found: *m/e* 374.1362. Calcd for $C_{20}H_{22}O_7$: M 374.1366.

The authors wish to thank Professor J. Polonsky of C. N. R. S., France, for measurement of ^{1}H NMR spectrum of ailanthone. They also thank Mr. Kazuhiro Matsushita of JEOL Co. Ltd. for measurement of NMR spectra and Mr. Eiichi Ishii of the Botanical Gardens, Faculty of Science, The University of Tokyo, for collecting *Ailanthus altissima* Swingle.

(Received June 24, 1983)

N-Acetyl-L-Leu–X–L-Pro–L-Val methylamides (**IIa**: X=D-Ala, **IIb**: X=Gly, **IIc**: X=L-Ala) were synthesized and subjected to CD and ^{1}H NMR measurements to study the β-turn preferences of these peptides. Temperature dependences of L-Val^4–NH proton chemical shifts in CD_3OH solution were in the order of **IIa**<**IIb**<**IIc**, suggesting that the populations of the β-turn conformer with 4→1 hydrogen bonding were in the order of **IIa**>**IIb**>**IIc**. This order of β-turn preferences coincides with the order of the magnitudes of the Cotton effects in the CD spectra of the chromophoric derivatives, *N*-(2,4-dinitrophenyl)tetrapeptide *p*-nitroanilides, having the same sequences. This agreement supports the validity of the chiroptical method to study turn tendency of tetrapeptide sequences using chromophoric derivatives reported previously.

CD spectra of *N*-(2,4-dinitrophenyl)tetrapeptide *p*-nitroanilides (Dnp–tetrapeptide–pNA's)[2] exhibit characteristic Cotton effects above 250 nm when they take β-turn conformations. Exciton coupling of the electric transition moments of the two chromophores were assumed to explain the spectra, and the magnitudes of the Cotton effects near 310 and 350 nm were shown to reflect well the β-turn preference of the derivatives.[3] In the case of model peptides (Dnp-L-Leu–X–L-Pro–L-Val–pNA; **Ia**: X=D-Ala, **Ib**: X=Gly, **Ic**: X=L-Ala) related to the β-turn part of gramicidin S (GS), β-turn preferences of the tetrapeptide derivatives (**Ia**>**Ib**>**Ic** ≈0) had strong correlation with antibiotic activities of the GS analogs having the same tetrapeptide sequences at their β-turn parts.[3–5]

A question was raised, however, whether such chiroptical method using chromophoric derivatives as mentioned above reveals the conformational characteristics of the original peptide sequences lacking those chromophoric groups. To answer the question we attempted syntheses and conformational analyses of some *N*-acetyltetrapeptide methylamides (Ac-L-Leu–X–L-Pro–L-Val–NHMe; **IIa**: X=D-Ala, **IIb**: X=Gly, **IIc**: X=L-Ala) related to the β-turn part of GS, and the results were compared with those of Dnp–tetrapeptide–pNA (**Ia**—**c**) having the same tetrapeptide sequences.

Results and Discussion

Syntheses of Peptides (IIa—c). *N*-Acetyltetrapeptide methylamides (**IIa**—**c**) were synthesized by usual solution-phase procedures according to the scheme shown in Fig. 1. Boc–D-Ala–L-Pro–OH[6] and H–L-Val–NHMe were coupled by EDC method to afford Boc–D-Ala–L-Pro–L-Val–NHMe (**IIIa**), which was treated with hydrogen chloride in formic acid. H–D-Ala–L-Pro–L-Val–NHMe·HCl (**IVa**·HCl) obtained was coupled with Boc–L-Leu–ONSu to afford Boc–L-Leu–D-Ala–L-Pro–L-Val–NHMe (**Va**), which was converted to Ac–L-Leu–D-Ala–L-Pro–L-Val–NHMe (**IIa**) by deprotection and subsequent treatment with Ac–ONp. Compounds **IIb** and **IIc** were prepared by a similar manner to that described for the synthesis of **IIa**. Purities of the synthetic peptides were confirmed by TLC with three solvent systems, elemental analyses, amino acid analyses, and also 270 MHz ^{1}H NMR.

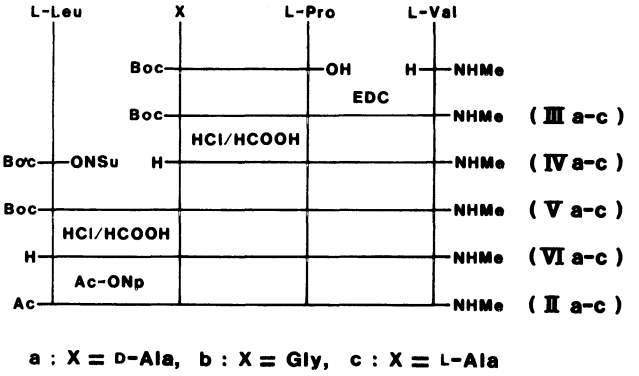

Fig. 1. Synthetic scheme of *N*-acetyltetrapeptide methylamides (**IIa**—**c**).

CD Measurements. CD spectra of **IIa**—**c** were measured in H_2O and in CH_3OH solutions (Fig. 2). In H_2O solution, all the CD spectra showed a minimum near 200 nm (Fig. 2A), suggesting that all the Ac–tetrapeptide–NHMe were in random conformations. Certainly, the magnitudes of Cotton effects (**IIa** : **IIb** : **IIc**=2 : 3 : 4) can be explained by difference in the configurations of component amino acid residues. On the other hand, in CH_3OH solution (Fig. 2B), the magnitudes of the Cotton effects were not so dependent on the configuration of second amino acid residues, and the CD minima were shifted to longer wavelength (**IIa**: 204 nm, **IIb**: 202.5 nm, **IIc**: 201 nm). It is of interest to note that the order of CD minima positions of Ac–tetrapeptide–NHMe (**IIa**—**c**) in CH_3OH solution was the same as that of Dnp–tetrapeptide–pNA near 200 nm (**Ia**: 205 nm, **Ib**: 201.5 nm, **Ic**: 200 nm) in CH_3OH solution (Fig. 2C).

^{1}H NMR Measurements. ^{1}H NMR (270 MHz) of **IIa**—**c** was measured in H_2O and in CD_3OH solutions. All the spectra showed two sets of resonances for most of the protons due to the cis-trans isomerism for the X–L-Pro bonds. The minor set of resonances (<10%) was assigned to the cis isomer from the results of related compounds (**Ia**—**c**).[5] Detailed discussions are described

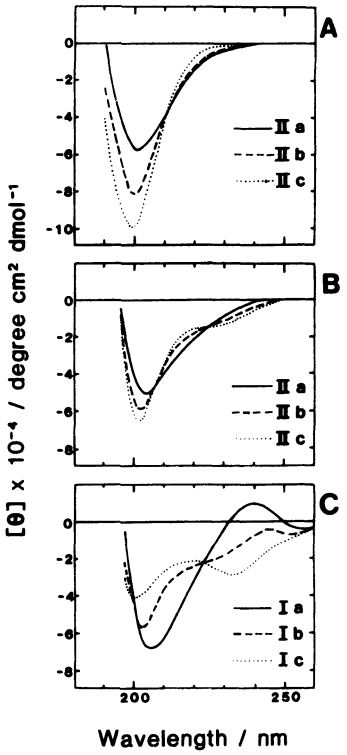

Fig. 2. CD spectra of **IIa—c** in H_2O (A) and in CH_3OH (B) solutions and of **Ia—c** in CH_3OH (C) solutions.

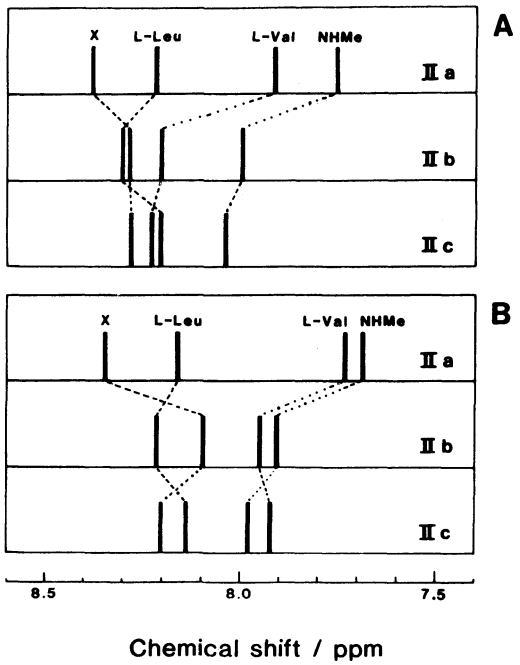

Fig. 3. Chemical shifts of amide protons in major conformer of Ac-L-Leu-X-L-Pro-L-Val-NHMe (**IIa—c**) in H_2O (A) and in CD_3OH (B) solutions.

hereafter for the major (trans) conformers.

Chemical shifts of NH protons of **IIa** spread over a wider range as compared with those of **IIc** which showed ordinary values (Fig. 3). The D-Ala residue of **IIa** showed smaller spin-coupling constant ($^3J_{NH-C_\alpha H}$=5.15 Hz) than the other residues (6—8 Hz) in CD_3OH

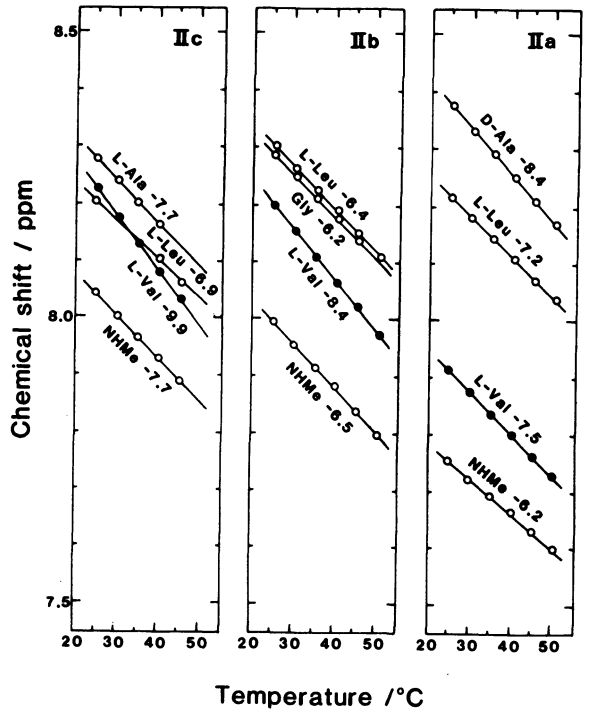

Fig. 4. Temperature dependences of amide proton chemical shifts of major conformers of **IIa—c** in H_2O solutions. Numbers on the lines refer to $10^3\times$ temperature coefficient in ppm $°C^{-1}$.

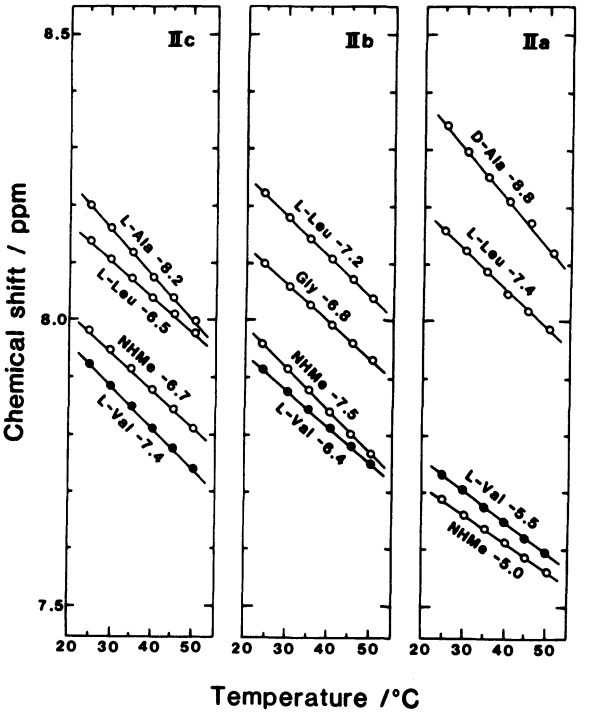

Fig. 5. Temperature dependences of amide proton chemical shifts of major conformers of **IIa—c** in CD_3OH solutions. Numbers on the lines refer to $10^3\times$ temperature coefficient in ppm $°C^{-1}$.

solution, suggesting that the ϕ angle of the D-Ala residue was fixed to a certain extent in CD_3OH solution, whereas the L-Ala residue of **IIc** showed such spin-coupling constant (6.25 Hz) as to be typical to free rotation.

These results suggest that **IIa** has some ordered conformation while **IIc** has unordered one.

The temperature dependences of chemical shifts of amide proton resonances are useful for distinguishing between "exposed" and "intramolecularly hydrogen-bonded" amide proton;[7] exposed protons exhibit larger temperature coefficients than hydrogen-bonded amide protons. All the NH proton resonances of **IIa—c** showed large temperature dependence of chemical shifts in H_2O solution (Fig. 4). In CD_3OH solution (Fig. 5), however, L-Val–NH proton of **IIa** showed a little smaller temperature dependence (-5.5×10^{-3} ppm $°C^{-1}$) than the other NH protons except for NHMe proton, suggesting that the L-Val–NH proton of **IIa** was involved in a weak hydrogen bonding. The fixation of ϕ angle of D-Ala residue of **IIa** suggests that the folded conformation of **IIa** in CD_3OH solution is β-turn conformation with 4→1 hydrogen bonding (L-Leu[1]–CO ···HN–L-Val[4]). The L-Val–NH proton of **IIb** also showed smaller temperature dependence than the other NH protons, but the value (-6.4×10^{-3} ppm $°C^{-1}$) was larger than that of **IIa**. In the case of **IIc**, the L-Val–NH proton showed large temperature dependence (-7.4×10^{-3} ppm $°C^{-1}$). The results of temperature dependences in CD_3OH solutions suggest that the populations of β-turn conformer with 4→1 hydrogen bond concerned by the L-Val–NH group are in the order of **IIa**>**IIb**>**IIc**≈0, although at a quite lower levels than that of Dnp–tetrapeptide–pNA (**Ia—c**); for example, the L-Val–NH proton of **Ia** showed such a small temperature dependence as -2.72×10^{-3} ppm $°C^{-1}$ in CD_3OH solution.[3,5] The small temperature dependence shown by the NHMe proton chemical shift of **IIa** in CD_3OH solution suggests the coexistence of another β-turn conformation having L-Pro–L-Val sequence at the internal position, since L-Pro residue has high bend positional potential at the second $(i+1)$ position of β-turn in the table proposed by Chou and Fasman on the basis of statistical analysis of the X-ray crystallographic data of 29 globular proteins.[8]

β-Turn Preference of Tetrapeptides. CD and NMR spectra of Ac–tetrapeptide–NHMe (**IIa—c**) did not show such large sequence dependences as those found in Dnp–tetrapeptide–pNA (**Ia—c**).[3,5] However, **IIa** and **IIb** are considered to have some populations of β-turn conformer in CH_3OH solution although they seem to take random conformations in H_2O solution. In addition, the order of population of β-turn conformer (**IIa**>**IIb**>**IIc**≈0) was the same as that of Dnp–tetrapeptide–pNA (**Ia—c**). These agreements suggest that introduction of Dnp and pNA groups amplify the intrinsic β-turn preference of parent tetrapeptide without affecting the order of β-turn preferences by stabilization of the β-turn conformer due to the attractive interaction of the two terminal chromophores. Consequently, CD spectra of Dnp–tetrapeptide–pNA are considered to be available for the study of β-turn preferences of the tetrapeptide sequences. Conformational energy calculation of *N*-acetyldi- or tetrapeptide methylamides also supported the validity of the chiroptical method.[9]

Experimental

Syntheses of Peptides. All the melting points were measured on a Yanagimoto micro melting point apparatus and uncorrected. TLC's were carried out on Merck silica gel 60 F_{254} plates with the following solvent systems: R_f^1, $CHCl_3$–CH_3OH (5 : 1, v/v); R_f^2, $CHCl_3$–CH_3OH–AcOH (95 : 5 : 1, v/v); R_f^3, *n*-BuOH–AcOH–pyridine–H_2O (4 : 1 : 1 : 2, v/v). Optical rotations were measured on an Union automatic polarimeter PM-201. Amino acid analyses of peptides were performed by Durrum D-500 amino acid analyzer after hydrolysis in 6 M (1 M=1 mol dm^{-3}) HCl at 105 °C for 20 h. Yields and analytical data of synthetic peptides are summarized in Table 1.

Boc-D-Ala-L-Pro-L-Val-NHMe (IIIa). To a chilled solution of Boc-D-Ala-L-Pro-OH·DCHA (1.40 g, 3 mmol) and H-L-Val-NHMe·HCl (0.50 g, 3 mmol) in $CHCl_3$ (12 ml)

a) *c* 1, CH_3OH. b) 1/2 H_2O. c) 1/4 H_2O.

was added EDC·HCl (0.58 g, 3 mmol), and the reaction mixture was stirred for 1 h at 0 °C and overnight at room temperature. Insoluble materials (DCHA·HCl) were removed by filtration and the filtrate was evaporated under reduced pressure. The residue was dissolved in EtOAc, and the solution was washed successively with 10% citric acid, 4% $NaHCO_3$, and H_2O, dried (Na_2SO_4), and evaporated. Addition of ether and petroleum ether to the residue gave crystals, which were recrystallized from EtOAc–ether–petroleum ether; yield, 986 mg (81%).

Compounds **IIIb** and **IIIc** were prepared by the similar manner to that described for **IIIa**.

H–D-Ala–L-Pro–L-Val–NHMe·HCl (IVa·HCl). Compound **IIIa** (398 mg, 1 mmol) was dissolved in 0.1 M hydrogen chloride in formic acid (12 ml). The soultion was allowed to stand for 30 min at room temperature and evaporated. Addition of ether to the residue gave highly hygroscopic crystals, which were used for the next reaction without further treatment; yield, 335 mg (100%); R_f^1 0.06, R_f^3 0.59.

Compounds **IVb, c** and **VIa—c** were prepared by a similar manner to that described for **IVa**: **IVb**; R_f^1 0, R_f^3 0.54: **IVc**; R_f^1 0.05, R_f^3 0.53: **VIa**; R_f^1 0.23, R_f^3 0.71: **VIb**; R_f^1 0.10, R_f^3 0.65: **VIc**; R_f^1 0.21, R_f^3 0.70.

Boc–L-Leu–D-Ala–L-Pro–L-Val–NHMe (Va). To a chilled solution of **IVa**·HCl (335 mg, 1 mmol) and TEA (0.14 ml, 1 mmol) in DMF (10 ml) was added Boc–L-Leu–ONSu (327 mg, 1.2 mmol), and the reaction mixture was stirred for 1 h at 0 °C and overnight at room temperature. A few drops of 1-(2-aminoethyl)piperazine were added to the solution, which was evaporated after being stirred further for 30 min at room temperature. The residue was dissolved in EtOAc and the solution was treated as described for **IIIa**. The crude product was dissolved in CH_3OH (3 ml) and applied to a column (3 cm × 170 cm) of Sephadex LH-20 and eluted with CH_3OH. The fractions containing the desired product detected by UV absorption and TLC were collected and evaporated, and the residue was crystallized by additions of ether and petroleum ether and recrystallized from EtOAc–ether–petroleum ether; yield, 379 mg (74%).

Compounds **Vb** and **Vc** were prepared by the similar manner to that described for **Va**.

Ac–L-Leu–D-Ala–L-Pro–L-Val–NHMe (IIa). To a chilled solution of **VIa**·HCl (224 mg, 0.5 mmol) and TEA (0.11 ml, 0.75 mmol) in DMF (2 ml) was added Ac–ONp (109 mg, 0.6 mmol), and the reaction mixture was stirred for 1 h at 0 °C and overnight at room temperature and evaporated. The residue dissolved in a mixture (5 ml) of $CHCl_3$ and CH_3OH (19 : 1, v/v), was applied to a column (1.8 cm × 30 cm) of silica gel 60 (Merck) and eluted with the same solvent. The fractions containing the desired product detected by TLC were collected and evaporated. The crude product was further purified by column chromatography with Sephadex LH-20 as described for **Va**. The product was recrystallized from CH_3OH–EtOAc; yield, 186 mg (82%).

Compounds **IIb** and **IIc** were prepared by the similar manner to that described for **IIa**.

CD Measurements. CD spectra were measured on a JASCO J-40A automatic recording spectropolarimeter in a quartz cell of 1-mm path length at the concentration of 0.2 mM at room temperature (23±2 °C).

^1H NMR Measurements. ^1H NMR spectra were recorded on a Brucker WH-270 spectrometer (270 MHz for ^1H), equipped with a Brucker B-ST-100/700 temperature control unit at the concentration of 5 mM at 23 °C unless otherwise mentioned. Chemical shifts were measured from the internal standard of DSS. The spectra were assigned by spin-decoupling, H–D exchange of NH protons and saturation transfer (between the two conformers).

The authors wish to express their thanks to Professor Tatsuo Miyazawa of The University of Tokyo and Associate Professor Masao Kawai of the Nagoya Institute of Technology for their helpful discussions. Thanks are also due to the members of Analytical Department of System Engineering Laboratory, Mitsubishi Chemical Industries Ltd., for elemental analyses.

Studies on Heterocyclic Analogs of Azulenes. XI.[1] Syntheses and Cycloadditions of Cyclohepta[4,5]pyrrolo[1,2-*a*]imidazoles and Cyclohept[*d*]imidazo[1,2-*a*]imidazoles

Noritaka ABE,* Tarozaemon NISHIWAKI,* Hideko YAMAMOTO, and Noboru KUNISHIGE
Department of Chemistry, Faculty of Sciences, Yamaguchi University, Yamaguchi 753
(Received June 25, 1983)

Cyclohepta[4,5]pyrrolo[1,2-*a*]imidazoles (1,3a-diazacyclopent[*a*]azulenes) (**2**) and cyclohept[*d*]imidazo[1,2-*a*]imidazoles (1,3a,9-triazacyclopent[*a*]azulenes) (**6**) were synthesized from 2-aminocyclohepta[*b*]pyrroles and 2-aminocycloheptimidazole, respectively, in moderate to good yields. Reactions of **2** and **6** with reactive acetylenes gave 2-azacyclohepta[*ef*]cycl[3.2.2]azines together with bis(1,3a-diazacyclopent[*a*]azuleno)[1,7]diaza[12]annulenes (**4**) and 2,3-diazacyclohepta[*ef*]cycl[3.2.2]azines together with bis(1,3a,9-triazacyclopent[*a*]azuleno)[1,7]diaza[12]-annulenes (**8**), respectively. Reactions of **2** and **6** with electron deficient olefins gave **4** and **8**, respectively. These reactions proceeded regioselectively *via* 1,10-dipolar intermediates.

The cyclazine systems have attracted attentions for their interesting physical and chemical properties,[2] whose efficient synthetic method is the cycloaddition to adequate N-bridged heterocycles [*e.g.* cycloaddition of indolizines with dimethyl acetylenedicarboxylate leads to cycl[3.2.2]azines[3-5]]. In the course of our studies on azaazulenes,[6] we investigated the syntheses of cata-condensed 1-azaazulenes and 1,3-diazaazulenes, which would provide a convenient synthetic route to novel cyclazines. In this paper, we report the syntheses and cycloadditions of cyclohepta[4,5]pyrrolo[1,2-*a*]-imidazoles and cyclohept[*d*]imidazo[1,2-*a*]imidazoles, which furnished novel cyclazines and condensed [1,7]-diaza[12]annulenes.

Syntheses and Cycloadditions of 1,3a-Diazacyclopent[a]-*azulenes.* Treatment of 2-amino-1-azaazulene (2-aminocyclohepta[*b*]pyrrole) (**1a**)[7,8] with α-bromoacetophenone in abs ethanol, followed by the treatment with potassium carbonate in aq ethanol in one pot gave **2a** in a 49% yield. The structure of **2a** was deduced to be 2-phenyl-1,3a-diazacyclopent[*a*]azulene (2-phenylcyclohepta[4,5]pyrrolo[1,2-*a*]imidazole) on the basis of elemental analyses and spectral data. In a similar manner, compounds **2b**—**e** were obtained by the reaction of **1a**—**c** with α-bromoacetophenone or 2-bromo-4′-methylacetophenone in abs ethanol or 1-butanol fol-

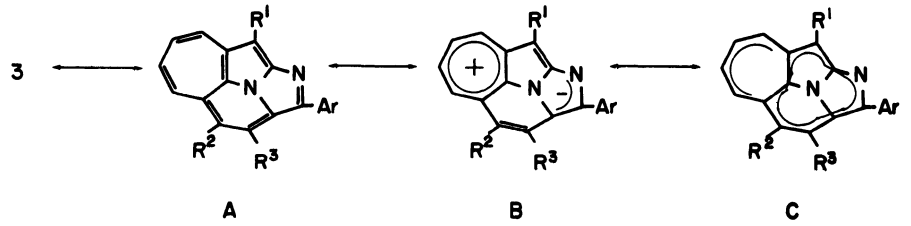
a) Taken for $CHCl_3$ solutions.



lowed by the treatment with potassium carbonate in moderate to good yields.

The compound **2c** was deesterified by hydrolysis with potassium hydroxide followed by decarboxylation with hot hydrobromic acid to give **2a**.

Reactions of **2** with reactive acetylenes gave 1 : 1-adducts (**3**) together with 2 : 2-adducts (**4**). In the reactions of **2** with electron deficient olefins, dehydrogenations were accompanied, and only 2 : 2-adducts (**4**) were isolated. These results were listed in Table 1.

The 1 : 1-adducts (**3**) were highly fluorescent crystals and were characterized as 2-azacyclohepta[*ef*]cycl[3.2.2]-azines on the basis of spectroscopic properties (Tables 2, 3, and 6) as well as elemental analyses (Table 7). Deesterification of **3e** and **3j** were attained by hydrolysis with potassium hydroxide followed by heating with copper in quinoline, and compounds **3p** and **3q** were obtained in good yield, respectively. The seven-membered ring protons of **3p** were seen at δ 7.73 (ddd, J=8.0, 7.0, and 1.5 Hz, H-5), 7.78 (ddd, J=8.0, 7.0, and 1.5 Hz, H-6), 8.32 (ddd, J=8.0, 1.5, and 0.5 Hz, H-4), and 8.57 (ddd, J=8.0, 1.5, and 0.5 Hz, H-7) in its 200 MHz ^{1}H NMR spectrum. Two pairs of doublets at δ 7.73 and 7.77 (J=4.0 Hz) were assignable to H-9 and H-8 protons, respectively. Although the low field resonated chemical shift of protons of **3p** intimates that **3p** should be inherently aromatic, the contribution of the resonance form **A** should be predominant, since the coupling constants of seven-membered ring protons imply somewhat of bond-alternation and the value of coupling constant of H-8 and H-9 is rather small (J=4.0 Hz). In the ^{13}C NMR spectrum of **3p**, signals of C-8 and C-9 carbons were seen at δ 113.9 (d) and 110.4 (d) and signals of seven-membered ring carbons (C-4, 5, 6, and 7) were seen at δ 130.5 (d), 123.0 (d), 125.9 (d), and 129.6 (d), respectively, and these observations also accord with the structure.

The 2 : 2-adducts (**4**) were characterized as bis(1,3a-

a) Taken for $CHCl_3$ solutions.

diazacyclopent[*a*]azuleno)[1,7]diaza[12]annulenes by means of their spectroscopic data (Tables 4, 5, and 6) as well as elemental analyses and mass spectra (Table 7). Deesterifications of **4e** and **4j** were attained by hydrolysis with potassium hydroxide followed by decarboxylation with copper in quinoline under heating, and **4p** and **4q** were obtained, respectively. The ^{1}H NMR spectra of **4p** and **4q** show two pairs of doublets at δ 7.05 and 8.03 (J=9.0 Hz) and at δ 7.10 and 8.06 (J=9.0 Hz), respectively, and their IR spectra show absorptions at 725 and 720 cm^{-1}, respectively. These facts denote that the configuration of ethylene bridge of **4** should be cis-one.

The regiochemistry of the reaction was attained by the reaction of **2** with the dissymmetrical acetylene (MP) or olefins (MA or EA). In the ^{1}H NMR spectrum of **3b**, the H-7 proton resonated at rather lower field (δ 9.85) than that of **3p** (δ 8.57), which would be under the deshielding effect of the ester group at C-8. The H-6 proton of **4b** also resonated at lower field (δ 8.30) than that of **4p** (δ 6.90).[9] It is conceivable that 1,10-dipolar intermediates (**D**), which were produced by the electrophilic attack of the acetylenes at the C-3 position of **2**,[10] cyclized at C-5 position to give **3** or reacted at C-5 position of another molecule (**D**) each other to give **4**. The reactions of **2** with olefins should proceed in a similar manner with the case of acetylenes, but it is

a) At 200 MHz. b) At 90 MHz. c) At 60 MHz. d) At 100 MHz. e) Two peaks are degenerated.

D

obscure which step dehydrogenations occured.

Syntheses and Cycloadditions of 1,3a,9-Triazacyclopent[a]*azulenes.* Treatment of 2-amino-1,3-diazaazulene (2-aminocycloheptimidazole) (**5**)[11] with *α*-bromoacetophenone in abs ethanol gave 2-amino-1-phenacylcycloheptimidazolium bromide in an 80% yield. Cyclization to 2-phenyl-1,3a,9-triazacyclopent[*a*]azulene (2-phenylcyclohept[*d*]imidazo[1,2-*a*]imidazole) (**6a**) was attained by the treatment of the salt with potassium carbonate in hot aq ethanol in a 76% yield. Similarly, **6b** was obtained by the treatment with 2-bromo-4′-methylacetophenone followed by the treatment with potassium carbonate in a 64% yield. In analogy with the reactions of **2a**, compounds **6a** and **6b** reacted with reactive acetylenes to give 1 : 1-adducts (**7**) and 2 : 2-adducts (**8**), and with electron deficient olefins to give 2 : 2-adducts (**8**). These results were listed in Table 1. The structures of 1 : 1-adducts (**7**) were assigned to 2,3-diazacyclohepta[*ef*]cycl[3.2.2]azines and 2 : 2-adducts to bis(1, 3a, 9-triazacyclopent[*a*]azuleno)[1, 7]diaza[12]-

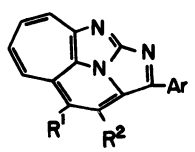
a) At 90 MHz. b) At 60 MHz. c) At 100 MHz.

annulenes on the basis of their spectroscopic properties (Tables 2, 3, 4, 5, and 6) as well as elemental analyses (Table 7).

Compounds **7a** and **7c** were deesterified by the treatment with potassium hydroxide followed by heating with copper in quinoline to give **7m**. Similarly, **7i** was deesterified to give **7n**. In the ^{1}H NMR spectrum of **7m**, seven-membered ring protons (H-4, H-5, H-6, and H-7) were seen at δ 8.48, 7.80, 7.91, and 8.56, respectively, with the vicinal coupling constants ($J_{4,5}$=$J_{6,7}$=8.5 Hz and $J_{5,6}$=7.0 Hz). Two pairs of doublets assignable to H-8 and H-9 protons were seen at δ 7.57 and 7.78 (J=4.0 Hz), respectively. These facts suggest that the resonance form **E** has large contribution in analogy with the case of **3**.

The compounds **8c** and **8i** were also deesterified and gave **8m** and **8n**, respectively. In the ^{1}H NMR spectra of **8m** and **8n**, two pairs of doublets were seen at δ 7.05 and 8.03 (J=9.0 Hz) and at δ 6.95 and 7.83 (J=9.0 Hz), respectively, and in their IR spectra, absorptions at 710 and 715 cm^{-1}, respectively, were seen. These results show that the configurations of ethylene bridge of **8** should be cis-one in similar to that of **4**.

The regiochemistry of the reaction was again attained by the reaction with dissymmetrical acetylene (MP) or olefins (MA, EA, or AN), and it is conceivable that 1,10-dipolar species should be intermediates.



E

a) At 20 MHz. b) At 25 MHz. c) Two peaks degenerated. d) Four peaks degenerated. e) Three peaks degenerated. f) Assignments may be reversed.

Experimental

Melting points were uncorrected. ^1H NMR spectra were taken on JEOL JNM-FX 200 (200 MHz), JEOL JNM FX-100 (100 MHz), Varian EM-390 (90 MHz), and Hitachi R-24B (60 MHz) spectrometers using deuteriochloroform as solvent (TMS as internal standard), unless otherwise stated. ^{13}C NMR spectra were taken on JEOL JNM FX-100 (25 MHz) and Varian FT-80A (20 MHz) spectrometers using deuteriochloroform as solvent (TMS as internal standard). Mass spectra were determined with a Hitachi M-80 instrument by means of field desorption ionization methods. IR spectra were recorded for Nujol mulls and electronic spectra for ethanol solutions, unless otherwise stated. Column chromatography was performed on Kieselgel 60. Recorded yields are based on the material after recrystallization.

Abbreviations. DMAD (dimethyl acetylenedicarboxylate), DEAD (diethyl acetylenedicarboxylate), MP (methyl propiolate), DBA (dibenzoylacetylene), EA (ethyl acrylate), MA (methyl acrylate), DMM (dimethyl maleate), AN (acrylonitrile), TMS (tetramethylsilane).

Materials. 2-Aminocyclohepta[*b*]pyrrole (**1a**)[7,8] and 2-aminocycloheptimidazole (**5**)[11] were prepared as reported.

Sythesis of ***1b***. A mixture of ethyl 2-chlorocyclohepta[*b*]pyrrole-3-carboxylate (5.00 g, 21.0 mmol) in 20 ml of presaturated ethanolic ammonia in a sealed tube was heated at 160 °C for 3 h. The reaction mixture was poured into water and extracted with chloroform. The extract was dried (Na_2SO_4) and evaporated under reduced pressure. The residue was chromatographed. Elution with benzene–chloroform (1 : 1) gave starting material (0.799 g, 16%). Elution with chloroform–ethyl acetate (2 : 1) gave **1b** (3.50 g, 76%), which crystallized from ethanol as yellow needles (2.79 g, 61%), mp 150—151 °C, (lit,[12,13] mp 150—151 °C); λ_{max} 247 nm (log ε 4.13), 287 (4.55, sh), 293 (4.58), 320 (3.89, sh), 365 (3.85), 424 (3.64, sh), and 432 (3.66); IR 3400, 3250, 3120, and 3050 (NH), and 1655 (ester C=O), and 1630 cm^{-1} (C=N); ^1H NMR (60 MHz) δ=1.44 (3H, t, J=7.0 Hz, Me), 4.42 (2H, q, J=7.0 Hz, OCH_2), 7.10—7.40 (2H, m, N<u>H</u>, exchangeable), 7.40—7.80 (3H, m, H-5, 6, and 7), 8.02 (1H, dm, J=10.0 Hz, H-8) and 8.80 (1H, dm, J=10.0 Hz, H-4). Found: C, 66.33; H, 5.52; N, 13.12%. Calcd for $C_{12}H_{12}N_2O_2$: C, 66.65; H, 5.59; N, 12.96%.

Synthesis of ***1c***. A mixture of 2-chlorocyclohepta[*b*]pyrrole-3-carbonitrile (12.34 g, 65.5 mmol) in 20 ml of presaturated ethanolic ammonia in a sealed tube at 160 °C for 5 h, and worked up as above. Elution with benzene–chloroform (1 : 1) gave starting material (2.36 g, 19%). Elution with chloroform–ethyl acetate (4 : 1) gave **1c** (5.61 g, 51%), which crystallized from ethanol–dichloromethane as yellow needles (4.95 g, 45%), mp 237—238 °C; λ_{max} 242 nm (log ε 4.11, sh), 250 (4.12), 284 (4.53), 291 (4.53), 320 (3.95, sh), 366 (3.86), 423 (3.54), and 433 (3.54); IR 3380, 3300, 3200, and 3150 (NH), and 2200 and 2170 (C≡N), and 1640 cm^{-1} (C=N); ^1H NMR (60 MHz) δ=5.65—6.15 (2H, m, N<u>H</u>$_2$, exchangeable), 7.45—7.85 (3H, m, H-5, 6, and 7), and 7.90—8.35 (2H, m, H-4 and 8). Found: C, 71.21; H, 3.98; N, 25.00%. Calcd for $C_{10}H_7N_3$: C, 70.99; H, 4.17; N, 24.84%.

Synthesis of ***2a***. A mixture of **1a** (1.11 g, 7.71 mmol)

a) Recrystallized from ethanol. b) Recrystallized from cyclohexane-dichloromethane. c) Recrystallized from cyclohexane.

and α-bromoacetophenone (1.50 g, 7.73 mmol) in abs ethanol (30 ml) was heated under reflux for 8 h. To this mixture, water (10 ml) and potassium carbonate (2.13 g, 15.4 mmol) were added, and the mixture was heated under reflux for 1 h and evaporated to dryness under reduced pressure. The residue was dissolved into water and extracted with chloroform. The extract was washed with water, dried over Na_2SO_4, evaporated, and the residue was chromatographed. Elution with benzene–chloroform (1 : 1) gave **2a** (1.205 g, 64%), which was crystallized from cyclohexane–dichloromethane to give brown prisms (0.925 g, 49%), mp 147—148 °C; λ_{max} 247 nm (log ε 4.28), 260 (4.23, sh), 320 (4.61), 340 (4.45, sh), 384 (3.57), 404 (3.63), 429 (3.58), 470 (2.70), 505 (2.76), 545 (2.74), 587 (2.61, sh), and 650 (2.28, sh); IR 740 and 690 cm^{-1} (phenyl); ^1H NMR (60 MHz) δ=6.80 (1H, s, H-10), 6.65—7.10 (3H, m, H-6, 7, and 8), 7.30—7.60 (3H, m, phenyl), 7.60—7.90 (2H, m, H-5 and 9), 7.97 (1H, s, H-3), and 7.90—8.20 (2H, m, phenyl); δ (CF_3CO_2H)=7.15 (1H, s, H-10),

7.45—8.30 (8H, m, H-6, 7, 8, and phenyl), 8.35 (1H, s, H-3), 8.53 (1H, dm, J=9.0 Hz, H-9), and 8.69 (1H, dm, J=9.0 Hz, H-5). Found: C, 83.47; H, 4.85; N, 11.32%. Calcd for $C_{17}H_{12}N_2$: C, 83.58; H, 4.59; N, 11.47%.

Synthesis of 2b. A mixture of **1a** (0.500 g, 3.47 mmol) and 2-bromo-4′-methylacetophenone (0.730 g, 3.51 mmol) in abs ethanol (20 ml) was heated under reflux for 10 h. Water (5 ml) and potassium carbonate (0.960 g, 6.96 mmol) were added to this mixture, then the mixture was heated under reflux for 1 h and worked up as above. Chloroform eluted **2b** (0.569 g, 63%), which was crystallized from cyclohexane–dichloromethane to give brown scales (0.425 g, 47%), mp 165—166 °C; λ_{max} 250 nm (log ε 4.28), 264 (4.28), 325 (4.61), 345 (4.48, sh), 385 (3.60), 405 (3.64), 429 (3.55), 470 (2.75), 505 (2.79), 545 (2.77), 587 (2.65, sh), and 650 (2.39, sh); IR 820 cm^{-1} (phenyl); ^{1}H NMR (90 MHz) δ=2.35 (3H, s, Me), 6.72 (1H, s, H-10), 6.50—7.00 (3H, m, H-6, 7, and 8), 7.14 (2H, d, J=8.0 Hz, H-*m*-phenyl), 7.31 (1H, dm, J=9.5 Hz, H-5), 7.54 (1H, dm, J=10.5 Hz, H-9), 7.76 (2H, d, J=8.0 Hz, H-*o*-phenyl), and 7.82 (1H, s, H-3). Found: C, 83.59; H, 5.23; N, 10.65%. Calcd for $C_{18}H_{14}N_2$: C, 83.69; H, 5.46; N, 10.84%.

Synthesis of 2c. A mixture of **1b** (4.240 g, 19.6 mmol) and α-bromoacetophenone (4.190 g, 21.6 mmol) in 1-butanol (30 ml) was heated under reflux for 20 h, then evaporated to dryness. To the residue, water (40 ml), ethanol (60 ml), and potassium carbonate (5.400 g, 39.3 mmol) were added, and the mixture was heated under reflux for 1 h, and evaporated. The residue was dissolved into water and extracted with chloroform. The extract was washed, dried (Na_2SO_4), and evaporated. The residue was chromatographed. Elution with benzene–chloroform gave **2c** (2.603 g, 42%), which was crystallized from cyclohexane–dichloromethane to give brown needles (1.887 g, 30%), mp 160—161 °C; λ_{max} 253 nm (log ε 4.41), 280 (4.09, sh), 340 (4.36), 355 (4.33, sh), 442 (3.60), 455 (3.59, sh), 530 (2.76, sh), 575 (2.56, sh), and 640 (1.98, sh); IR 1685 (ester C=O), and 740 and 695 cm^{-1} (phenyl); ^{1}H NMR (60 MHz) δ=1.57 (3H, t, J=7.0 Hz, Me), 4.60 (2H, q, J=7.0 Hz, OCH_2), 7.25—7.65 (6H, m, H-6, 7, 8, and phenyl), 7.93 (1H, dm, J=10.0 Hz, H-5), 8.07 (1H, s, H-3), 7.95—8.20 (2H, m, phenyl), and 9.33 (1H, dm, J=10.0 Hz, H-9). Found: C, 75.78; H, 4.92; N, 8.86%. Calcd for $C_{20}H_{16}N_2O_2$: C, 75.93; H, 5.10; N, 8.86%. Elution with chloroform–ethyl acetate (2 : 1) gave **1b** (1.725 g, 41%).

Synthesis of 2d. A mixture of **1b** (4.463 g, 20.6 mmol) and 2-bromo-4′-methylacetophenone (4.645 g, 20.6 mmol) in 1-butanol (30 ml) was heated under reflux for 20 h and evaporated. To this residue, water (10 ml), ethanol (90 ml), and potassium carbonate (5.710 g, 41.3 mmol) were added, and the mixture was heated under reflux for 1 h, and worked up as for **2c**. Elution with benzene–chloroform (1 : 1) gave **2d** (4.127 g, 60.5%), which was crystallized from cyclohexane–dichloromethane to give brown needles (2.475 g, 36%), mp 133—134 °C; λ_{max} 254 nm (log ε 4.42), 280 (4.11, sh), 347 (4.47), 360 (4.45, sh), 445 (3.68), 455 (3.68, sh), 530 (2.85, sh), 590 (2.53, sh), and 630 (2.19, sh); IR 1680 (ester C=O) and 810 cm^{-1} (phenyl); ^{1}H NMR (60 MHz) δ=1.53 (3H, t, J=7.0 Hz, Me), 2.38 (3H, s, Me), 4.55 (2H, q, J=7.0 Hz, OCH_2), 7.23 (2H, d, J=8.0 Hz, H-*m*-phenyl), 7.25—7.60 (3H, m, H-6, 7, and 8), 7.85 (1H, dm, J=10.0 Hz, H-5), 7.93 (2H, d, J=8.0 Hz, H-*o*-phenyl), 7.97 (1H, s, H-3), and 9.25 (1H, dm, J=10.0 Hz, H-9). Found: C, 76.64; H, 5.67; N, 8.09%. Calcd for $C_{21}H_{18}N_2O_2$: C, 76.35; H, 5.49; N, 8.48%. Elution with chloroform–ethyl acetate (2 : 1) gave **1b** (1.581 g, 36%).

Synthesis of 2e. A mixture of **1c** (1.210 g, 7.16 mmol) and α-bromoacetophenone (1.930 g, 7.16 mmol) in 1-butanol (30 ml) was heated under reflux for 100 h, and evaporated under reduced pressure. To the residue, ethanol (90 ml), water (10 ml), and potassium carbonate (1.980 g, 14.3 mmol) were added, and the mixture was heated under reflux for 1 h, and worked up as for **2c**. Elution with benzene–chloroform (1 : 1) gave **2e** (0.608 g, 32%), which was crystallized from ethanol–dichloromethane to give brown prisms (0.291 g, 15%), mp 256—257 °C; λ_{max} ($CHCl_3$) 247 nm (log ε 4.43), 280 (4.18, sh), 342 (4.45), 355 (4.42, sh), 435 (3.62), 457 (3.63), 507 (2.95, sh), 546 (2.83, sh), 595 (2.65, sh), and 650 (2.29, sh); IR 2200 (C≡N), and 740 and 695 cm^{-1} (phenyl); ^{1}H NMR (60 MHz) δ (CF_3CO_2D)=7.50—7.95 (5H, m, phenyl), 8.20—8.60 (3H, m, H-6,7, and 8), 8.54 (1H, s, H-3), 9.05 (1H, dm, J=10.0 Hz, H-5), and 9.18 (1H, dm, J=10.0 Hz, H-9). Found: C, 80.27; H, 3.93; N, 15.43%. Calcd for $C_{18}H_{11}N_3$: C, 80.28; H, 4.12; N, 15.60%.

Deesterification of 2c. A mixture of **2c** (0.316 g, 1.00 mmol) and potassium hydroxide (0.56 g, 10.0 mmol) in ethanol (30 ml)–water (20 ml) was heated under reflux for 1 h. The reaction mixture was diluted with water and acidified with 1 M aq hydrochloric acid (1 M=1 mol dm^{-3}). The resulted precipitate was filtered and dried to give the corresponding carboxylic acid [0.262 g, 90%, mp 181—182 °C (decomp)]. A suspension of the carboxylic acid (0.140 g, 0.49 mmol) in 48% hydrobromic acid (10 ml) was heated under reflux for 1 h, then poured into water, and neutralized with sodium carbonate, and extracted with chloroform. The extract was washed with water, dried (Na_2SO_4), and evaporated. The residue was chromatographed with benzene–chloroform (1 : 1) to give **2a** (0.037 g, 31%).

General Procedure for the Reactions of 2 with Acetylenes. A mixture of **2** (2.00 mmol), the acetylene (4.00 mmol), and the solvent (30 ml) was heated under reflux under the conditions specified in Table 1, and evaporated under reduced pressure. Chromatography of the residue with benzene–chloroform (1 : 1) gave **3** and **4**, successively. Analytical data are listed in Table 7 and spectroscopic data in Tables 2—5, and 6.

General Procedure for the Reactions of 2 with Olefins. A mixture of **2** (2.00 mmol), the olefin (20.0 mmol), and the solvent (30 ml) was heated under reflux under the conditions specified in Table 1 and evaporated to dryness under the reduced pressure. Chromatography of the residue with benzene–chloroform (1 : 1) gave **4**. Analytical data are listed in Table 7 and spectroscopic data in Tables 4, 5, and 6.

Deesterification of 3 and 4. A solution of **3e** (0.190 g, 0.42 mmol) and potassium hydroxide (0.90 g, 16 mmol) in ethanol (40 ml)–water (20 ml) was heated under reflux for 3 h. The reaction mixture was poured into water (250 ml), acidified with 1 M aq hydrochloric acid, and resulted precipitate was filtered to give the corresponding tricarboxylic acid (0.147 g, 88%, mp>300 °C). A mixture of the carboxylic acid (0.147 g, 0.37 mmol) and copper-powder (0.10 g) in quinoline (5 ml) was heated under reflux for 1 h. The reaction mixture was filtered off, and copper-powder was washed with chloroform. The combined filtrate was washed with 1 M aq hydrochloric acid followed by water, dried (Na_2SO_4), and evaporated. The residue was chromatographed with chloroform to give **3p** (0.098 g, 99%), which crystallized from cyclohexane as yellow needles (0.074 g, 75%), mp 197—199 °C; λ_{max} 239 nm (log ε 4.36), 260 (4.34, sh), 270 (4.40, sh), 281 (4.51, sh), 288 (4.54), 295 (4.47, sh), 320 (3.75), 357 (4.26), 374 (4.36), 417 (3.95), and 440 (4.07); ^{1}H NMR (200 MHz) δ=7.50—7.70 (3H, m, phenyl), 7.73 (1H, ddd, J=8.0, 7.0, and 1.5 Hz, H-5), 7.73 (1H, d, J=4.0 Hz, H-9), 7.77 (1H, d, J=4.0 Hz, H-8), 7.78 (1H, ddd, J=8.0, 7.0, and 1.5 Hz, H-6), 8.32 (1H, ddd, J=8.0, 1.5, and 0.5 Hz, H-4), 8.33 (1H, s, H-3), 8.45—8.55 (2H, m, phenyl), and 8.57 (1H, ddd, J=8.0, 1.5, and 0.5 Hz, H-7). Found: C, 84.75; H, 4.58; N, 10.28%. Calcd for $C_{19}H_{12}N_2$:

C, 85.05; H, 4.51; N, 10.44%.

In a similar manner, **3j**, **4e**, and **4j** gave **3q** (85%), **4p** (54%), and **4q** (50%), respectively.

3q: Yellow needles (from cyclohexane), mp 235 °C; λ_{max} 242 nm (log ε 4.71), 260 (4.65, sh), 271 (4.60, sh), 280 (4.69, sh), 290 (4.77), 300 (4.77), 323 (4.15), 359 (4.59), 375 (4.66), 415 (4.26), and 438 (4.36); ^{1}H NMR (60 MHz) δ=2.46 (3H, s, Me), 7.35 (2H, d, J=8.0 Hz, H-*m*-phenyl), 7.60—7.90 (4H, m, H-5, 6, 8, and 9), 8.22 (1H, dm, J=9.0 Hz, H-4), 8.25 (1H, s, H-3), 8.35 (2H, d, J=8.0 Hz, H-*o*-phenyl), and 8.50 (1H, dm, J=9.0 Hz, H-7). Found: C, 85.11; H, 4.83; N, 9.91%. Calcd for $C_{20}H_{14}N_2$: C, 85.09; H, 5.00; N, 9.92%.

4p: Violet needles (from cyclohexane–dichloromethane), mp 157—158 °C; λ_{max} 237 nm (log ε 4.77), 262 (5.01), 285 (4.38, sh), 344 (4.60), 360 (4.51), 384 (4.21, sh), 403 (4.46), 427 (4.46), 485 (3.58, sh), 515 (3.70), 547 (3.70), 590 (3.50), and 645 (2.94, sh); IR 725 cm^{-1} (*cis* HC=CH); ^{1}H NMR (60 MHz) δ=6.23 (2H, ddd, J=10.5, 8.0, and 2.0 Hz, H-8), 6.73 (2H, ddd, J=10.5, 8.0, and 2.5 Hz, H-7), 6.90 (2H, dd, J=10.5 and 2.0 Hz, H-6), 7.05 (2H, d, J=9.0 Hz, H-olefin), 7.27 (2H, s, H-10), 7.15—7.60 (6H, m, phenyl), 7.60 (2H, dd, J=10.5 and 2.5 Hz, H-9), 8.03 (2H, d, J=9.0 Hz, H-olefin), and 8.05—8.30 (4H, m, phenyl). Found: C, 85.27; H, 4.47; N, 10.56%. Calcd for $C_{38}H_{24}N_4$: C, 85.05; H, 4.51; N, 10.44%.

4q: Dark green needles (from cyclohexane), mp 159.5—162 °C; λ_{max} 240 nm (log ε 4.75), 264 (4.98), 287 (4.44, sh), 345 (4.55), 363 (4.48), 386 (4.27, sh), 406 (4.41), 428 (4.38), 487 (3.57, sh), 520 (3.62), 553 (3.63), 592 (3.47), and 650 (3.03, sh); IR 720 cm^{-1} (*cis* HC=CH); ^{1}H NMR (60 MHz) δ=2.42 (6H, s, Me), 6.27 (2H, ddd, J=10.5, 8.0, and 2.0 Hz, H-8), 6.69 (2H, ddd, J=10.5, 8.0, and 2.0 Hz, H-7), 6.90 (2H, d, J=9.0 Hz, H-olefin), 7.27 (4H, d, J=8.0 Hz, H-*m*-phenyl), 7.33 (2H, s, H-10), 7.41 (2H, dd, J=10.5 and 2.0 Hz, H-9), 8.06 (2H, d, J=9.0 Hz, H-olefin), and 8.09 (4H, d, J=8.0 Hz, H-*o*-phenyl). Found: C, 84.91; H, 4.98; N, 9.64%. Calcd for $C_{40}H_{28}N_4$: C, 85.09; H, 5.00; N, 9.92%.

Synthesis of ***6a***. A mixture of **5** (2.00 g, 13.8 mmol) and *α*-bromoacetophenone (2.74 g, 14.1 mmol) in abs ethanol (50 ml) was heated under reflux for 7 h, then cooled overnight to give 2-amino-1-phenacycloheptimidazolium bromide (3.74 g, 80%), which crystallized from ethanol as colorless prisms (mp 230—231 °C. Found: C, 55.64; H, 4.33; N, 11.96%. Calcd for $C_{16}H_{14}BrN_3O$: C, 55.83; H, 4.10; N, 12.21%). A mixture of the salt and potassium carbonate (3.25 g, 24.1 mmol) in ethanol (90 ml)–water (10 ml) was heated under reflux for 2 h, and worked up as for **1a**. Elution with chloroform–ethyl acetate (4 : 1) gave **6a** (2.19 g, 76%), which was crystallized from ethanol to give brown needles (1.970 g, 68%), mp 244—245 °C; λ_{max} 232 nm (log ε 4.50), 245 (4.42, sh), 334 (4.70), 421 (3.62), and 428 (3.60, sh); IR 735 and 685 cm^{-1} (phenyl); ^{1}H NMR (100 MHz) δ=7.20—7.50 (3H, m, phenyl), 7.55—7.80 (3H, m, H-6, 7, and 8), 7.94 (1H, s, H-3), 7.90—8.05 (2H, m, H-*o*-phenyl), 8.05 (1H, dm, J=11.0 Hz, H-5), and 8.40 (1H, dm, J=11.0 Hz, H-9), δ (CF_3CO_2D)=7.50—7.90 (5H, m, phenyl), 8.43 (1H, s, H-3, exchangeable), 8.60—9.00 (3H, m, H-6, 7, and 8), and 9.20—9.60 (2H, m, H-5 and 9). Found: C, 78.52; H, 4.49; N, 17.21%. Calcd for $C_{16}H_{11}N_3$: C, 78.35; H, 4.52; N, 17.13%.

Synthesis of ***6b***. A mixture of **5** (2.00 g, 13.8 mmol) and 2-bromo-4′-methylacetophenone (2.94 g, 13.8 mmol) in abs ethanol (40 ml) was heated under reflux for 5 h, then cooled overnight. Resulted precipitates were collected by filtration to give 2-amino-1-(*p*-methylphenacyl)cycloheptimidazolium bromide (3.82 g, 77%), which crystallized from ethanol as colorless needles [mp 257 °C (decomp). Found: C, 56.76; H, 4.43; N, 11.88%. Calcd for $C_{17}H_{16}BrN_3O$: C, 57.00; H, 4.50; N, 11.73%]. A mixture of the salt (4.65 g, 13.0 mmol) and potassium carbonate (3.59 g, 26.0 mmol) in ethanol (225 ml)–water (25 ml) was heated under reflux for 2 h and worked up as for **1a**. Elution with chloroform gave **6b** (2.786 g, 83%), which was crystallized from ethanol–dichloromethane to give brown needles (1.903 g, 57%), mp 272—275 °C (decomp); λ_{max} 235 nm (log ε 4.42), 255 (4.31), 338 (4.60), 423 (3.56), and 428 (3.54, sh); IR 820 cm^{-1} (phenyl); ^{1}H NMR (60 MHz) δ (CF_3CO_2D)=2.48 (3H, s, Me), 7.41 (2H, d, J=8.0 Hz, H-*m*-phenyl), 8.03 (2H, d, J=8.0 Hz, H-*o*-phenyl), 8.37 (1H, s, H-3, exchangeable), 8.65—9.00 (3H, m, H-6, 7, and 8), and 9.20—9.60 (2H, m, H-5 and 9). Found: C, 78.77; H, 5.18; N, 15.94%. Calcd for $C_{17}H_{13}N_3$: C, 78.74; H, 5.05; N, 16.20%.

General Procedure for the Reactions of ***6*** *with Acetylenes.* A mixture of **6** (2.00 mmol), the acetylene (4.00 mmol), and the solvent (50 ml) was heated under reflux under the conditions specified in Table 1 and evaporated to dryness under reduced pressure. Chromatography of the residue with benzene–chloroform (1 : 1) gave **7** and **8**, successively. Analytital data are listed in Table 7 and spectroscopic data in Tables 2, 3, 4, 5, and 6.

General Procedure for the Reactions of ***6*** *with Olefins.* A mixture of **6** (1.00 mmol), the olefin (10.0 mmol), and the solvent (30 ml) was heated under reflux under the conditions specified in Table 1 and evaporated to dryness under reduced pressure. Chromatography of the residue with benzene–chloroform (1 : 1) gave **8**. Analytical data are listed in Table 7 and spectroscopic data in Tables 4 and 5.

Deesterification of ***7*** *and* ***8***. A solution of **7a** (0.400 g, 1.04 mmol) and potassium hydroxide (0.58 g, 10.4 mmol) in ethanol (30 ml)–water (20 ml) was heated under reflux for 2 h. The reaction mixture was poured into water (200 ml), acidified with 1M aq hydrochloric acid. Resulted precipitate was filtered to give the corresponding dicarboxylic acid as yellow powder (0.350 g, 97%, mp>300 °C). A mixture of the carboxylic acid (0.350 g, 0.98 mmol) and copper-powder (0.10 g) in quinoline (5 ml) was heated under reflux for 1 h and worked up as for **3p**. Elution with chloroform gave **7m** (0.175 g, 66%), which was crystallized from ethanol–dichloromethane to give yellow needles (0.142 g, 54%), mp 204—206 °C; λ_{max} 234 nm (log ε 4.35), 261 (4.38), 282 (4.43), 291 (4.40), 322 (3.93), 335 (4.01), 364 (4.23), 380 (4.21, sh), 438 (4.08), and 462 (4.15); IR 745 and 680 cm^{-1} (phenyl); ^{1}H NMR (200 MHz) δ=7.57 (1H, d, J=4.0 Hz, H-8), 7.63 (1H, s, H-3), 7.58—7.70 (3H, m, phenyl), 7.78 (1H, d, J=4.0 Hz, H-9), 7.80 (1H, ddd, J=8.5, 7.0, and 1.5 Hz, H-5), 7.91 (1H, ddd, J=8.5, 7.0, and 2.0 Hz, H-6), 8.48 (1H, ddd, J=8.5, 2.0, and 0.5 Hz, H-4), 8.50—8.57 (2H, m, phenyl), and 8.56 (1H, ddd, J=8.5, 1.5, and 0.5 Hz, H-7). Found: C, 80.04; H, 3.85; N, 15.53%. Calcd for $C_{18}H_{11}N_3$: C, 80.28; H, 4.12; N, 15.60%.

In a similar manner, **7c**, **7i**, **8c**, and **8i** gave **7m** (94%), **7n** (44%), **8m** (51%), and **8n** (55%), respectively.

7n: Yellow needles (from cyclohexane–dichloromethane), mp 213—215 °C; λ_{max} 237 nm (log ε 4.36), 262 (4.39), 285 (4.36), 294 (4.37), 327 (3.98, sh), 340 (4.10, sh), 367 (4.33), 377 (4.32, sh), 440 (4.07), and 460 (4.20); IR 825 and 815 cm^{-1} (phenyl); ^{1}H NMR (60 MHz) δ=2.44 (3H, s, Me), 7.31 (2H, d, J=8.0 Hz, H-*m*-phenyl), 7.51 (1H, d, J=8.5 Hz, H-8), 7.50—8.00 (3H, m, H-5, 6, and 7), 8.32 (1H, d, J=8.5 Hz, H-9), 8.34 (2H, d, J=8.0 Hz, H-*o*-phenyl), and 8.43 (1H, dm, J=10.0 Hz, H-4). Found: C, 80.26; H, 4.43; N, 14.82%. Calcd for $C_{19}H_{13}N_3$: C, 80.55; H, 4.62; N, 14.83%.

8m: Brown needles (from cyclohexane–dichloromethane), mp 224—225 °C; λ_{max} 238 nm (log ε 4.91), 250 (4.87, sh), 266 (4.75, sh), 277 (4.66, sh), 328 (4.70), 340 (4.66, sh), 415 (4.53, sh), 437 (4.70), 525 (3.78, sh), 555 (3.81), 585 (3.72, sh), and

640 (3.25, sh); IR 740 and 680 (phenyl), and 710 cm^{-1} (*cis* HC=CH); ^1H NMR (60 MHz) δ=6.23 (2H, ddd, J=10.5, 8.0, and 2.0 Hz, H-8), 6.73 (2H, ddd, J=10.5, 8.0, and 2.5 Hz, H-7), 6.90 (2H, ddd, J=10.5, 2.0, and 0.5 Hz, H-6), 7.05 (2H, d, J=9.0 Hz, H-olefin), 7.27 (2H, s, H-10), 7.15—7.60 (6H, m, phenyl), 7.60 (2H, ddd, J=10.5, 2.5, and 0.5 Hz, H-9), 8.03 (2H, d, J=9.0 Hz, H-olefin), and 8.05—8.30 (4H, m, phenyl). Found: C, 80.02; H, 3.97; N, 15.30%. Calcd for $C_{36}H_{22}N_6$: C, 80.28; H, 4.12; N, 15.60%.

8n: Dark brown needles (from cyclohexane–dichloromethane), mp 216—217 °C; λ_{max} 239 nm (log ε 4.86), 250 (4.79, sh), 266 (4.66, sh), 281 (4.42), 335 (4.65), 343 (4.62, sh), 418 (4.51, sh), 440 (4.69), 530 (3.78, sh), 560 (3.82), 595 (3.72, sh), and 647 (3.26, sh); IR 810 (phenyl) and 715 cm^{-1} (*cis* HC=CH), ^1H NMR (60 MHz) δ=2.37 (6H, s, Me), 6.60—7.15 (6H, m, H-6, 7, and 8), 6.95 (2H, d, J=9.0 Hz, H-olefin), 7.14 (4H, d, J=8.0 Hz, H-*m*-phenyl), 7.75 (2H, dm, J=10.0 Hz, H-9), 7.83 (2H, d, J=9.0 Hz, H-olefin), and 7.93 (4H, d, J=8.0 Hz, H-*o*-phenyl). Found: C, 80.41; H, 4.49; N, 14.55%. Calcd for $C_{38}H_{26}N_6$: C, 80.55; H, 4.62; N, 14.83%.

We thank Dr. Masafumi Yasunami (Tohoku University) and Dr. Akira Mori (Kyushu University) for the high resolution NMR spectra. This work was supported by a Grant-in-Aid for Scientific Research (No. 56470021) from the Ministry of Education, Science and Culture.

(Received January 6, 1983)

The crystallization mechanism for zeolite was investigated. Tetraethyl orthosilicate and silica sol were used as silica sources. Many kinds of solid phases were obtained at various reaction times. These solid phases were characterized by analyses for chemical compositions, X-ray diffraction, adsorption of nitrogen gas and water vapor, and IR spectroscopy. The results obtained suggest that the solid phase derived from tetraethyl orthosilicate at an early stage of reaction is composed of slightly ordered skeletons. In addition, during aging of gel at room temperature, the structure of the solid phase of gel undergoes a rearrangement to form a crystalline structure. On the other hand, the gel phase obtained from silica sol is predominantly made up by the coagulation of disordered aluminosilicate polymers or silicic polymers. These gel phases act as a precursor, and a part of the gel dissolved into the liquid phase and the dissolved species are converted into crystals in the liquid phase. Thus, the silica sources influence the structure of gel and crystals. In general, the crystallization mechanism is strongly influenced by the starting materials, especially by the silica sources.

Many investigation on the mechanism and kinetics of zeolite crystallization have been done in recent years. These investigations are concerned with autocatalysis[1] and effects of temperature,[2] alkalinity,[2,3] and seeding,[1] and kinetically have dealt with the conversion from amorphous substances to crystals[4-9] and induction periods with respect to the distribution of chemical species in liquid and solid phases.[10-12] In addition, Raman[5] and IR[13,14] spectra of liquid and solid phases of gel were analyzed in order to understand the zeolite crystallization.

However, because of complex reactions of aluminosilicate in liquid and solid phases, the process of zeolite crystallization has not yet been made clear.

Schwochow and Heinze[15] reported that zeolite A, sodalite, zeolite P, and faujasite were crystallized from a liquid phase which had been separated from an aluminosilicate gel phase during a crystallization process. Zhdanov[11] revealed that the liquid phase of aluminosilicate gel influenced properties and compositions of crystals formed.

On the other hand, many investigations have revealed that the crystallization of zeolite occurs in the solid phase of gel through rearrangement of alumonisilicate framework. For example, Khatami and Flanigen[16] observed that the crystallization of gel phase occurred in the absence of liquid phase. After all, at the present stage there have been proposed two mechanisms for the zeolite crystallization based on two representative hypotheses. The first mechanism is based on a crystallization to occur in a solid phase. During the aging of this solid phase a rearragement of the aluminosilicate framework leads the amorphous gel to crystals. This mechanism is supported by Breck and Flanigen,[7] McNicol *et al.*,[17] and Aiello *et al.*[18]

The other mechanism is based on a crystallization to occur in a liquid phase; the constituents of zeolite are caused to be dissolved into a liquid phase *via* their precursors, amorphous gel phases, and then zeolite is made crystallized in a liquid phase. This mechanism is supported by Kerr,[1] Ciric,[9] Culfaz and Sand,[4] and Kacirek and Lechert.[19]

In our previous papers we reported that syntheses of zeolite A[20] and zeolite X[21] using tetraeth l orthosilicate as a silica source could proceed easily. These zeolites, in crystal, had a high purity and a high crystallinity. In addition, we investigated the difference between the distributions of component concentrations in the solid and liquid phases during processes of zeolite crystallization using tetraethyl orthosilicate, silica sol,[21] or sodium metasilicate.[22] These results suggested that at the beginning of reaction, the difference in the silica sources has an influence on chemical states of the soluble species of constituents of zeolite in the liquid phase, together with a significant influence on the nucleation of zeolite crystals, growth steps of aluminosilicate, and properties of crystals produced.

In the present study, solid phases were sampled out of reaction systems at various reaction times. These solid phases were characterized by chemical analysis, X-ray diffraction, adsorption of nitrogen gas and water vapor, and IR spectra. These results were compared with earlier results.[21]

Experimental

Materials. The silica sources used were a commercial tetraethyl orthosilicate (Nakarai Chemical Co. Ltd.) purified by distillation, and a silica sol which had been prepared by diluting a Snowtex 40 (Nissan Chemical Co. Ltd.) with distilled water to double the volume. The alumina source used was a sodium aluminate solution which had been synthesized from Al plate (99.99%, Nakarai Chemical Co. Ltd.) and sodium hydroxide solution. A sodium hydroxide solution (5 mol dm^{-3}) was used as excess alkaline solution. These starting materials were described in detail elsewhere.[21]

Preparation of Specimens. The molar ratios of SiO_2/Al_2O_3, Na_2O/SiO_2, and H_2O/Na_2O adopted for the preparation of mixtures of starting materials were 8, 6, and 50, respectively, which correspond to the formula $48Na_2O \cdot Al_2O_3 \cdot 8SiO_2 \cdot 2400H_2O$. These ratios have been established as falling in the region providing optimum conditions for the synthesis of zeolite X.[23]

The procedure of synthesis was as follows. Tetraethyl orthosilicate was added to a sodium aluminate solution in a flask, and the mixture was stirred by an ultra sonic generator (40 kHz) for 20 min. A mixture of sodium hydroxide solution and distilled water was added to the flask and allowed to be stirred mechanically for 6—72 h at room temperature. To prevent evaporation the flask was equipped with a glass tubing with both ends open, and it was heated in an air oven at 85 °C for 74—96 h. After a fixed time, the solid and liquid phases of reaction mixture were separated with a centrifuge. The supernatant solution of the liquid phase was pipetted out as a specimen of the liquid phase. The solid phase was filtered and washed with distilled water until the pH of washings reached 10.5 and then dried at 110 °C for 24 h.

Analyses. Analyses of liquid and solid phases were made as follows. The colorimetric method, *i.e.*, the molybosilicic acid yellow method, and a Hitachi spectrophotometer model 100-30 were applied to determining silica concentrations. Flame photometry using a Hitachi atomic absorption analyzed model 208 was applied to determining sodium concentrations. Aluminium concentrations were determined by the chelatometric titration using EDTA and Zn standard solutions and an XO indicator.

Adsorption. The adsorption of nitrogen gas was subjected to volumetric measurements at the boiling point of liquid nitrogen and the adsorption of water vapor to gravimetric measurements at 25 °C. The pretreatment of specimens was carried out as follows. After being kept at 110 °C for 24 h, the specimen was heated at 300 °C for 2 h under atmospheric pressure, and degassed under vacuum (at 10^{-5} mmHg) (1 mmHg≈133.322 Pa) for 30 min prior to the adsorption.

IR Spectra. Infrared transmission spectra were measured by the KBr wafer technique according to the study by Flanigen and Khatami.[13] Every wafer contained 1 mg of solid phase in 300 mg of KBr. Spectra were recorded on a Hitachi infrared spectrometer model 260-50.

Crystallinity. Products were identified by the powder X-ray diffractometry using a Toshiba X-ray diffractometer model ADG 301 (Cu *Ka*, Ni filter, 30 kV, 20 mA, G. M. detector) and a JEOL model JDX-7E (Cu *Ka*, Ni filter, 30 kV, 20 mA, scintillation counter). The crystallinity was determined by the X-ray diffraction method with an LMS 13X as reference.

Results

Crystallinity. The solid phase derived from tetraethyl orthosilicate remained amorphous for initial 75 h after the beginning of reaction, but began to include crystals at 76 h. The solid phase derived from silica sol remained amorphous for initial 74 h, but began to inculude crystals at 75 h. Table 1 shows the change in crystallinity with reaction time. The change in crystallinity proceeded very rapidly immediately after crystals were recognized in the solid phase from either tetraethyl orthosilicate or silica sol, and the rate of crystallization decreased after a few hours. Then, the crystallinity was kept almost constant.

The crystals derived from tetraethyl orthosilicate and from silica sol showed relative crystallinities of 120 and 75%, respectively, and the interplanar spacings of planes (111) as measured by X-ray diffraction were 14.27—14.25 and 14.23—14.14 Å, respectively. The crystal derived from silica sol increased in interplanar spacing

with increasing crystallinity.

Adsorption of Nitrogen Gas. Figures 1 and 2 show nitrogen gas adsorption isotherms for solid phases. The solid phases are grouped in three types according to the stage of their formation: the initial amorphous stage (6E—75E, 6C—74C), the early stage of crystallization (76E, 75C), and the full-crystallization stage (78E—96E, 76C—96C). The solid phase derived from tetraethyl orthosilicate shows the isotherms that run nearly parallel with the axis of relative pressure. Although the amorphous phases adsorb little nitrogen, the amount adsorbed increased rapidly immediately after the crystals began to be observed.

On the other hand, the solid phases derived from silica sol show adsorption isotherms a little different from those for tetraethyl orthosilicate. The amorphous state (6C—74C) shows somewhat a steep slope as compared with the former at lower relative pressures. The amount adsorbed is 25—40 ml/g in contrast to the solid phases (6E—75E) which adsorb little. This does not result from a difference, if any, in the developments of internal structure, but actually has arisen from different distributions of particle size. The particle sizes measured with a particle size analyzer and a scanning electron micrograph were 1.5—25 μm (av 6.6 μm) for 72E and 0.25—10 μm (av 2.4 μm) for 74C. The solid phases derived from silica sol indicate distributions of smaller particles.

At lower relative pressures, the slopes to the adsorption isotherms for the crystalline phases (75C—96C) are similar to those for tetraethyl orthosilicate (76E—96E). Although the amount adsorbed by the latter is *ca.* 160—170 ml/g, the former adsorb *ca.* one third of this value, *i.e.*, 50—70 ml/g. Such characteristics of adsorption isotherms are influenced by the presence of a large amount of an amorphous substance, aluminosilicate gel, which is always contaminated.

The monolayer capacity and specific surface area were calculated with the Langmuir or BET equation. The results of calculation are shown in Table 2. The outer and inner surface areas are tabulated in the same table. These values were evaluated by fitting the Frenkel-Halsey-Hill equation[24,25] to experimental data.

The change in inner and outer specific surface areas is shown in Fig. 3. The solid phases derived from tetraethyl orthosilicate remained amorphous for initial 75 h of reaction time, so that these solid phases adsorb so little as to give an inner specific surface area of zero. Their outer specific surface areas are 4—5 m^2/g. The solid phase which contained crystals rapidly increased in specific surface area with reaction time, up to over 700 m^2/g. Nearly 95% of this value is dependent on the inner structure of crystals. The remaining *ca.* 5% is attributable to the outer free surface of solid phase. On the other hand, in spite of the amorphous state, the amount adsorbed by the solid phases derived from silica sol is nearly 100—150 m^2/g, with no inner specific surface area detected. The specific surface area did not remarkably increase with reaction time after crystalline substances had appeared. Their values are *ca.* 250—300 m^2/g.

The outer specific surface area decreases slightly after the solid phase begins to crystallize. But it occupies *ca.* 15—25% of the total specific surface area. Its value is 40—70 m^2/g, and the outer surface areas for the solid phases derived from silica sol are larger than those for tetraethyl orthosilicate. It may be considered that in the course of crystallization the size of crystals can grow to some extent. Because of the crystals being contaminated with a large amount of amorphous substances as mentioned above, their outer surface areas amount to a larger portion of the total surface area.

Adsorption of Water Vapor. The diameter of water molecule (2.7 Å at 25 °C) is smaller than that of nitrogen molecule (3.64 Å at −196 °C). Water molecule is polar and is expected to be adsorbed fully on fine

structures of zeolite. Therefore, the method using water molecule is more effective for the study on the change in the solid phase than the method using nitrogen gas only. Some of the adsorption isotherms obtained are shown in Fig. 4. The crystals (96E, 84E) adsorb water vapor in fairly large quantities, and the slopes to adsorption isotherms are smooth, as compared with those for the crystals derived from silica sol. The amorphous substance (72E) adsorbs little water vapor.

On the contrary, the amorphous substance (72C) adsorbs water vapor in a fairly large quantity at lower relative pressures. Such a trend of adsorption isotherms is similar to that observed in the case of nitrogen adsorption by amorphous solid phases. The specific surface areas evaluated from the water vapor adsorption have revealed that the solid phases (96E, 84E) have larger values than the solid phases (96C, 84C). The high crystalline phases (96E, 84E, 96C) have larger specific surface areas by *ca.* 200—250 m^2/g than the corresponding values determined by nitrogen adsorption. Similarly the solid phases (84C, 72C) also have indicated larger values by *ca.* 100—150 m^2/g.

IR Spectra. A systematic study of infrared spectra for the characterization of zeolite frameworks with respect to crystal structure has been done by Flanigen and Khatami.[13,26] They pointed out that the mid-infrared region (1300 to 250 cm^{-1}) contains the fundamental vibrations of the framework of zeolite. The mid-infrared vibrations of zeolite were classified into two groups by them. One is the internal vibrations that are insensitive to change in the framework structure, and the other is the external vibrations that are sensitive to change in the framework.

The change in infrared spectra in going from the amorphous solid phase to crystals are shown in Figs. 5 and 6. The features of the spectra obtained for the specimens derived from tetraethyl orthosilicate are as follows:

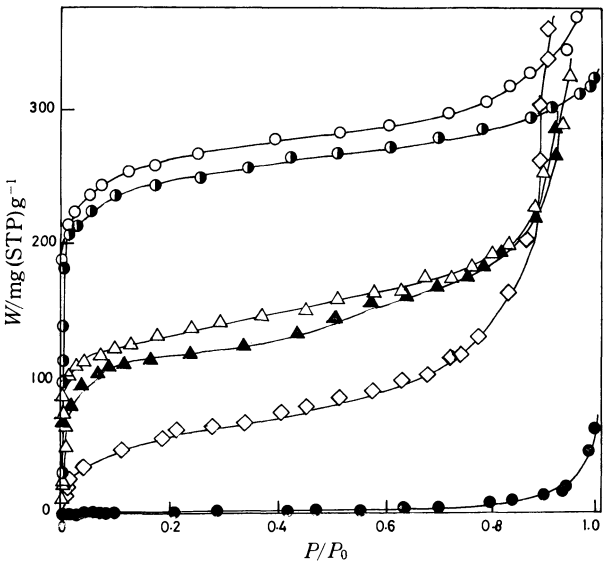

Fig. 4. Adsorption isotherms of water vapor at 25 °C. 96E: ○, 84E: ◑, 72E: ●, 96C: △, 84C: ▲, 72C: ◇. E: Tetraethyl orthosilicate, C: silica sol. Number: reaction time.

1) The spectra for earlier stages (6E, 24E) bear a resemblance to those of the crystals of high crystallinity.

2) The strongest vibration around 1000 cm^{-1} that is common to all zeolites and assigned to an asymmetric stretching mode ←OT→←O (T represents Si or Al) is found near 1000 cm^{-1} (6E—75E), but the frequency shifts to 980 cm^{-1} (76E—96E). The change in frequency shift is much less than that for the spectra of the solid phases derived from silica sol.

3) The amorphous specimens show very weak and broad bands around 580 cm^{-1}. The feature of this band in this region has a clearer pattern than the corresponding spectra for silica sol. The band in 650—500 cm^{-1} is assignable to a double 6-ring. But this band is obscure as compared with other bands in the spectrum. The crystals (76E—96E) show the clear band due to the double 6-ring around 560 cm^{-1}. The change in these bands suggests that the amorphous solid phases in the gel are composed of frameworks of secondary building units loosely cross-linked with aluminosilicate anions; therefore, the solid phases are converted from the amorphous solid state to a crystalline substance through the rearrangement of the bonds of aluminosilicate

polymers by the interaction between the solid and liquid phases of gel.

4) The band at 880 cm^{-1} assigned to Si–OH is found with the specimens (6E—76E). This band is no longer found with the specimens (78E—96E). This suggests that the amorphous solid state is caused to change into crystals that have high crystallinity through the combination of secondary building units with aluminosilicate polymers.

5) The spectral shape of the strongest asymmetric stretching around 1000 cm^{-1} is almost the same for all the specimens, in contrast with those derived from silica sol.

On the other hand, the features of the spectra for the specimens derived from silica sol are as follows:

1) The spectra are classified into three groups. The first group is for the amorphous substances obtained at earlier stages of reaction (6C, 24C). The second is for the specimens which have undergone aging for a pretty long term (48C, 72C, 74C). The third is for the crystalline substances. The infrared spectra of the first group have very simple patterns.

2) The first group has the strongest band around 1120 cm^{-1}, shifting to lower frequencies, 1040 and 1020 cm^{-1} for 48C and 72C, respectively. As a whole, the specimens (6C—72C) show broad spectra composed of many bands. This suggests that the solid phase consists of a large quantity of silica; in addition, it contains many varieties of siloxane and Al–O–Si bonds contaminated with the zeolite framework. This band is observed around 1000 cm^{-1} for 74C and around 990 cm^{-1} for 75C and 76C. The band is remarkably shifted to lower frequencies, as compared with the band observed in the case of tetraethyl orthosilicate.

3) The bands for the double 6-ring and pore opening have been observed in the specimen (75C) for the first time.

4) The band for the Si–OH vibration around 880 cm^{-1} is still observed in the crystalline specimen (78C). It becomes weak as the crystallization proceeds. But the very weak band remains in the spectra of crystals. On the contrary, no trace of that band is observed in the spectra of the crystals derived from tetraethyl orthosilicate. This suggests clearly that the former crystals will not grow sufficiently, and that they includes some nonbonding structures and amorphous substances

Discussion

In our previous study[21] on the mechanism of zeolite crystallization, we investigated the difference in constituents between the liquid and solid phases which had been derived from tetraethyl orthosilicate, sodium metasilicate, and silica sol as silica sources with various reaction times. In order to clarify the chemical bonding state of constituents in the solid phases, the dissolution of constituents of the solid phase into hydrochloric acid solution and the relative concentration of constituents dissolved were surveyed.

According to the findings obtained, the change in constituents of both the liquid and solid phases derived from silica sol is abrupt as compared with the solid phases derived from tetraethyl orthosilicate and sodium metasilicate. The X-ray amorphous phases derived from silica sol consists of silica predominantly, and alumina or soda is hardly incorporated in the framework. The change in constituents of both the liquid and solid phases derived from tetraethyl orthosilicate is slow, and as a whole the behavior of all constituents is similar to one another. X-Ray amorphous phases obtained at earlier stages of reaction bear a marked resemblance to crystals with respect to constituents. A similarity among the solid phases obtained at various reaction times is found in respect of the dissolution of constituents of the solid phase into hydrochloric acid solution. On the contrary, every solid phase derived from silica sol shows a markedly different behavior of dissolution.[21] These results suggest that the framework structure and chemical-bond features of the solid phases are markedly dependent on the silica sources used. The X-ray amorphous phase derived from tetraethyl orthosilicate is composed of somewhat similar ordered skeletons of aluminosilicate which constitute the chemical structure of crystalline phase. On the other hand, the coexistent phase derived from silica sol is composed of disordered skeletons of aluminosilicate.

It is considered that these results are due to the difference in both the gelation kinetics and the structure of aluminosilicate at the beginning of reaction. Thus, in the case of tetraethyl orthosilicate, the gelation kinetics is governed by the polymerization of ordered aluminosilicate which has grown up in the solution. On the contrary, in the case of the solid phase derived from silica sol, the dominant factor governing the gelation kinetics is the aggregation of disordered aluminosilicate polymers.

In spite of the solid phase consisting of disordered aluminosilicate skeletons derived from silica sol, the beginning of crystallization occurs about one hour earlier than in the case of tetraethyl orthosilicate. As shown in Table 1, the crystallization does not proceed so far as expected, and the crystallinity is *ca.* 60—70% in contrast with that derived from tetraethyl orthosilicate. This suggests that in the case of silica sol, the gelation kinetics is governed by the aggregation of aluminosilicate polymers and silicic polymers at the beginning of reaction, so that the nucleation of crystals takes place more rapidly so as to make the number of nuclei more than in the case of tetraethyl orthosilicate which is hydrolyzed slowly. These trends are consistent with the fact that the X-ray amorphous phase derived from silica sol is very viscous at the beginning of reaction. On the contrary, the X-ray amorphous phases derived from tetraethyl orthosilicate consists of particles of larger sizes.

Because the silica sol was originally prepared by dispersion of silicic polymer in water, it may be considered that the reaction of depolymerization-polymerization of silicic polymer during zeolite crystallization proceeds insufficiently. Therefore, the crystals obtained with silica sol are caused to include the aluminosilicate which will not participate in the crystal framework. In addition, it may be considered that the crystals formed have a fairly silica-rich structure. This is suggested from the fact that the diffractive angle 2θ of

X-ray diffraction peak (642) have values in the region 26.74—26.75° (lattice constant, a_0: 24.94—24.93 Å) for the specimens obtained from tetraethyl orthosilicate and in the region 26.81—26.84° (a_0: 24.88—24.85 Å) for the specimens obtained from silica sol. These results are consistent with the relation found between the Si/Al molar ratio and the lattice constant.[7] In addition, these results correspond also to the results[21] concerning the difference in constituent distribution between the liquid and solid phases.

According to the above discussion, the X-ray amorphous phase derived from tetraethyl orthosilicate is considered to have a structure of ordered skeletons, and therefore the development of cavities and channels in the solid phase may be expected at earlier stages of reaction. But it has been proved that any sufficient development of cavities and channels, which is detectable through the adsorption for nitrogen gas or water vapor, will not proceed in the amorphous solid state. This means that any crystallographic internal structures characteristic of zeolite cannot fully be constructed until crystals become recognized by X-ray diffraction.

Both the crystallinity and the amount adsorbed increase with reaction time, and the approximate specific surface areas evaluated for the crystals are 450 m^2/g for 76E, 710 m^2/g for 96E, 140 m^2/g for 75C, 250 m^2/g for 76C, and 360 m^2/g for 84C. These results suggest that the inner structure of the crystals derived from tetraethyl orthosilicate will grow about 2 to 3 times as much as that of the crystals derived from silica sol. The former crystals indicate a large difference between their specific surface areas measured with nitrogen gas and water vapor. These results show that the inner structure, especially the structure of micro pore, grows to a considerable extent in the crystals derived from tetraethyl orthosilicate as compared with those derived from silica sol. The different development of inner structure is in accord with the results concluding different degrees of crystallinity and different constituent distribution in both liquid and solid phases.

The infrared bands, called "external linkages"[13] and sensitive to the change in framework structure, become apparently detectable immediately after crystals have become observed. The spectrum obtained for the solid phase derived from each of the silica sources shows a very characteristic pattern. It is derivable from the change in spectra with reaction time that each solid phase is formed *via* its unique reaction mechanism.

The results obtained in the present study are in good agreement with the conclusion drawn in earlier tudies[21,22] that the X-ray amorphous phases obtained from tetraethyl orthosilicate at earlier stages are essentially identical with crystals.

The nucleation and nuclear growth are the most important steps for obtaining highly crystalline zeolites. The X-ray amorphous phases formed from tetraethyl orthosilicate are even initially composed of highly ordered structures; the subsequent interaction between the liquid and solid phases serves to raise the crystallinity during the aging time at room temperature. It thus follows that the crystals have high crystallinity and high purity. On the other hand, the X-ray amorphous phase derived from silica sol contains amorphous substances which cannot easily be removed from the solid phase during the aging time. Such behavior results from the structural characteristic of the gel itself. It may be considered that the X-ray amorphous phase derived from silica sol is made up predominantly *via* coagulation of aluminosilicate polymers or silicic polymers; that is, the amorphous substance as a precursor is allowed to deposit in the liquid phase. In addition, the constituent of zeolite is caused to get out of the gel during the aging time and the bond of Al–O–Si is formed newly. This is why the crystal phase coexists with a large amount of amorphous substance.

Breck[27] pointed out that the composition and structure of gel are controlled by the size and structure of polymerizing species. Since silicate may vary in chemical composition and molecular weight distribution, different silicate solutions may result in different gel structures. Therefore the gelation may control the nucleation of zeolite crystals. This sequence has strongly been supported in this study. In the zeolite synthesis, the kind of starting materials, particularly silica source, and the chemical state of gel phase strongly influence the crystallization mechanism.

The authors wish to express their thanks to Messrs. Hiroyasu Aoi and Kōzi Kitagawa for their assistance during the experiment.

(Received January 13, 1983)

ESR spectra of single crystals of silver(I) nitrate–butanedinitrile(1/1) were measured at 77 K. Two paramagnetic centers, $-CN\cdots Ag^{2+}\cdots NC-$ and $NO_3^{2-}\cdots Ag^+$, appeared simultaneously on X-irradiation at 77 K. The principal values of the g value (g) and the hyperfine coupling constants (A in the units of 10^{-4} cm^{-1}) were $g_1=2.050$, $g_2=2.053$, and $g_3=2.302$, $A(Ag)_1=21.8$, $A(Ag)_2=22.0$, $A(Ag)_3=34.9$, $A(N)_1=15.3$, $A(N)_2=15.9$, and $A(N)_3=14.0$ for the first center, and $g_{//}=2.001$, $g_\perp=2.006$, $A(Ag)_{//}=20.3$, $A(Ag)_\perp=17.4$, $A(N)_{//}=59.4$, and $A(N)_\perp=32.8$ for the second center. When the crystals X-irradiated at 77 K were exposed to visible light, the two centers disappeared simultaneously and the NO_2 radicals increased. When the crystals X-irradiated at 77 K were warmed to room temperature, the first center changed to a new paramagnetic center, in which the unpaired electron coupled with a silver nucleus, two equivalent nitrogen nuclei, and a proton.

Silver(I) ion, Ag^+, can act as an electron donor or electron acceptor. Many studies have shown that Ag^0, Ag^{2+}, Ag_2^+, and Ag_2^{3+} are easily formed from Ag^+ ions in irradiated crystals and frozen solutions at low temperatures.[1-4] Mosley and Moulton have shown that, when silver nitrate crystals are X-irradiated at 77 K, the Ag^+ ions are converted to Ag^{2+} ions and NO_3^- ions to NO_3^{2-} ions, indicating that electrons delivered from Ag^+ ions are trapped on NO_3^- ions.[3]

This paper describes the results of ESR studies on X-irradiated single crystals of silver (I)nitrate–butanedinitrile(1/1), $AgNO_3\cdot NCCH_2CH_2CN$. In the crystals, Ag^{2+} and NO_3^{2-} were primarily produced by X-irradiation at 77 K. The structures and spin densities in these two paramagnetic species were estimated. Electron transfers from Ag^+ to NO_3^- by X-ray excitation and from NO_3^{2-} to Ag^{2+} by visible light excitation were established.

Experimental

Single crystals of silver(I) nitrate–butanedinitrile(1/1) were prepared. Dry silver nitrate (about 10 g) dissolved in butanedinitrile (about 24 g) at 70 °C. After the solution was cooled slowly to room temperature in the dark, single crystals with dimensions of about $4\times3\times1$ mm^3 were obtained (mp 76 °C).[5] Calcd for $AgNO_3\cdot NCCH_2CH_2CN$: C, 19.2; H, 1.6; N, 16.8%. Found: C, 19.6; H, 1.6; N, 17.0%. Figure 1 shows the crystal form. An orthogonal set of axes a′, b′, and c′ were chosen for analysis of the ESR spectra. The crystal has a cleavage plane parallel to the a′b′ plane.

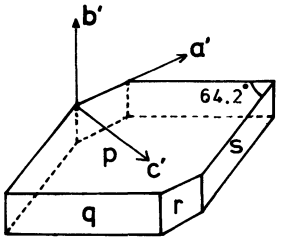

Fig. 1. The crystal form of $AgNO_3\cdot NCCH_2CH_2CN$. Interfacial angles ∠pq, ∠pr, and ∠ps are 90°.

The crystals were irradiated with X-rays at 77 K to an extent of about 0.2 Mrad. The ESR spectra of the crystals were recorded at 10° intervals in the a′b′, b′c′, and c′a′ planes at 77 K with a Varian model V-4501 X-band spectrometer. ESR measurements were also carried out on crystals that had been irradiated with X-rays at 77 K and subsequently illuminated with light from a 40 W tungsten filament lamp at 77 K, and on crystals that had been X-irradiated and successively warmed to room temperature for a minute and then cooled again to 77 K.

Figure 2 shows a typical ESR spectrum of the single crystal X-irradiated at 77 K. A group of lines at the lower magnetic field side will be attributed to the magnetic species $-CN\cdots Ag^{2+}\cdots NC-$, which we refer to as Ag^{2+} (a) center. A sextet at the high field side will be assigned to $NO_3^{2-}\cdots Ag^+$, which we refer to as NO_3^{2-}–Ag^+ center, and a sharp triplet (designated as p, p′, and p″) to NO_2.

Results and Discussion

Ag^{2+}(a) Center. The absorption lines at the lower field side consist of two quintets. The intensity ratio of the lines of the quintet is 1 : 2 : 3 : 2 : 1. These

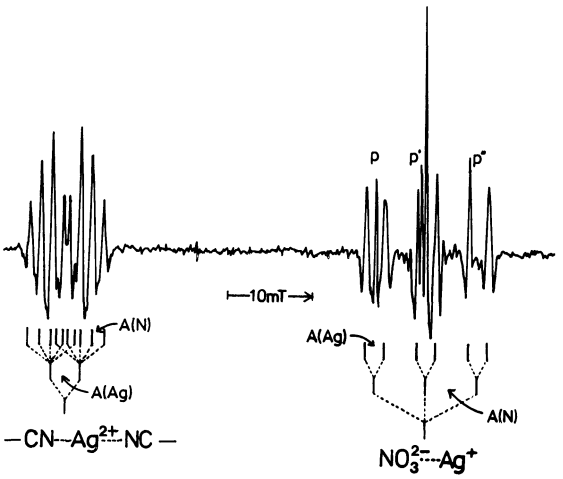

Fig. 2. Second derivative ESR spectrum of the X-irradiated single crystal of $AgNO_3\cdot NCCH_2CH_2CN$ with the magnetic field parallel to the c′ axis. The irradiation and ESR measurements were carried out at 77 K. The strongest line is due to DPPH.

†† Present address: Engineering Research Laboratory, Toray Industries, Inc., Tebiro, Kamakura 248.

Table 1. Principal values of the tensors, g, A(Ag) and A(N) for the Ag^{2+} (α) center

Principal values[a]			Principal axis
g	$A/10^{-4}$ cm^{-1}		
$g_1 = 2.050$	$A(Ag)_1 = 21.8$	$A(N)_1 = 15.3$	||a′
$g_2 = 2.053$	$A(Ag)_2 = 22.0$	$A(N)_2 = 15.9$	||b′
$g_3 = 2.302$	$A(Ag)_3 = 34.9$	$A(N)_3 = 14.0$	||c′

a) Estimated errors are 0.0005 for g and 0.5×10^{-4} cm^{-1} for A(Ag) and A(N).

lines are explained in terms of an unpaired electron interacting with a silver nucleus ($I=1/2$) as well as two equivalent nitrogen nuclei ($I=1$). Analysis of angular dependence of the spectra determined the principal elements of the tensor of the g value and the hyperfine coupling constants for the silver nucleus, A(Ag), and for the nitrogen nuclei, A(N). The results are given in Table 1. A splitting of lines due to the presence of the two abundant isotopes of silver (^{107}Ag and ^{109}Ag) could not be detected. Therefore A(Ag) in the table is the value averaged for the two isotopes. All the tensors are axially symmetric within experimental error about the c′ axis. We refer to the symmetric axis as the z axis and the axes perpendicular to it as the x and y axes.

The axial symmetry in the tensors g and A(Ag) can be accounted for by the existence of a tetragonal crystalline field at the Ag^{2+} ion,[9,10] which has been confirmed in many stable Ag^{2+} complexes. The observed relation, $g_3(g_z)>g_2\simeq g_1\simeq2$, suggests that the unpaired electron is primarily in the $4d_{x^2-y^2}$ orbital of the silver ion. The tetragonal field probably arises from the surrounding four ligands on the corners of a square plane perpendicular to the symmetry axis (the z axis). The most probable model for the $Ag^{2+}(\alpha)$ center is as follows. The Ag^{2+} ion is surrounded by two nitrogen atoms of CN groups on the x axis and by two oxygen atoms of nitrate ions on the y axis. Additional two oxygen atoms must be situated at a greater distance on the z axis. This model is consistent with the crystal structure of $2AgNO_3\cdot NCCH_2CH_2CN$, where the Ag^+ ion is linked to a CN group and surrounded by four oxygen atoms.[6]

Since superhyperfine structure due to two nitrogen atoms was observed, the unpaired electron must be delocalized on these atoms. The ground state molecular orbital for the unpaired electron is expressed by

$$\psi = \alpha\phi_0 - \sqrt{1-\alpha^2}\,\psi', \tag{1}$$

where ϕ_0 is the $4d_{x^2-y^2}$ atomic orbital of Ag^{2+} and ψ' is the appropriate normalized wavefunction of the ligands. Here the overlap integral between ϕ_0 and ψ' has been neglected. The silver hyperfine coupling constants are given by[7]

$$A_{//} = K + \left(\Delta g_{//} + \frac{3}{7}\Delta g_{\perp} - \frac{4}{7}\alpha^2\right)P, \tag{2}$$

$$A_{\perp} = K + \left(\frac{11}{14}\Delta g_{\perp} + \frac{2}{7}\alpha^2\right)P, \tag{3}$$

where $\Delta g_{//}$ and $\Delta g_{\perp}$ are the g shift from 2.0023 due to admixture of excited states, P is the hyperfine interaction parameter

$$P = g_e\mu_B g_{Ag}\mu_n \langle\phi_0|r^{-3}|\phi_0\rangle, \tag{4}$$

and K is a constant term mainly due to the core polarization which depends strongly on the spin density in ϕ_0 and ψ'.[8] Using the value of -68.76×10^{-4} cm^{-1} for P,[9] and the observed values of $|A_{//}|=A(Ag)_3$, $|A_{\perp}|=|A(Ag)_1+A(Ag)_2|/2$, $g_{//}=g_3$, and $g_{\perp}=(g_1+g_2)/2$, one obtains 0.549 for α^2 and 35.4×10^{-4} cm^{-1} for K.

The wavefunction, belonging to two nitrogen atoms, in the molecular orbital ψ can be written as

$$\sqrt{1-\alpha^2}\,\psi' = \cdots C_s[\phi_{2s}(N_1)+\phi_{2s}(N_2)] + C_p[-\phi_{2p}(N_1)+\phi_{2p}(N_2)]+\cdots, \tag{5}$$

where $\phi_{2s}(N_1)$, $\phi_{2p}(N_1)$, $\phi_{2s}(N_2)$, and $\phi_{2p}(N_2)$ are the 2s and 2p atomic orbitals of the nitrogen atoms 1 and 2. The nitrogen hyperfine coupling constants are given by

$$A_{xx}(N_1) = A_{xx}(N_2) = C_s^2A_{2s}(N) + 2C_p^2B_{2p}(N), \tag{6}$$

$$A_{yy}(N_1) = A_{zz}(N_1) = A_{yy}(N_2) = A_{zz}(N_2) = C_s^2A_{2s}(N) - C_p^2B_{2p}(N), \tag{7}$$

where $A_{2s}(N)=519\times10^{-4}$ cm^{-1} and $B_{2p}(N)=15.5\times10^{-4}$ cm^{-1}.[9] The coupling tensor is axial symmetric about the x axis and $A_{//}$ is larger than $A_{\perp}$. On the contrary the observed nitrogen coupling tensor is axial symmetric about the z(c′) axis and $A_{//}$ is smaller than $A_{\perp}$ (Table 1).

This discrepancy leads us to assume that there are at least two Ag^{2+} centers having the z axes parallel to each other but the x axes perpendicular to each other. Then the hyperfine coupling constants for N_1 and N_2 will be different. If the line widths are large, the observed nitrogen coupling constant must be the average value for N_1 and N_2, *i.e.*,

$$A_{\perp}(N) = \sqrt{[A_{xx}(N)^2+A_{yy}(N)^2]/2}, \tag{8}$$

and

$$A_{//}(N) = A_{zz}(N). \tag{9}$$

Using the values of $A_{//}(N)=14.0\times10^{-4}$ cm^{-1} and $A_{\perp}(N)=15.6\times10^{-4}$ cm^{-1}, one obtains $A_{xx}(N)=17.1\times10^{-4}$ cm^{-1}, $C_s^2=0.029$ and $C_p^2=0.067$. Therefore the spin density is 0.192 on the N_1 and N_2 atoms and 0.549 on the Ag atom, and the rest of 0.259 probably on the two oxygen atoms on the y axis.

If one neglects the in-plane and out-of-plane π-bonding between the Ag atom and ligand atoms, the principal values of the g tensors are given by

$$g_{//} = g_z = 2.0023 - 8\lambda\alpha^2/E_1, \tag{10}$$

$$g_{\perp} = g_x = g_y = 2.0023 - 2\lambda\alpha^2/E_2, \tag{11}$$

where λ is the spin-orbit coupling constant for an Ag^{2+} ion (-1844 cm^{-1}), and E_1 and E_2 are the energy separation of the d_{xy} and $d_{xz}(d_{yz})$ levels from the $d_{x^2-y^2}$ level, respectively.[7,9,11] Substituting the values of 2.302 and 2.0515 for $g_{//}$ and $g_{\perp}$, respectively, in Eqs. 10 and 11, one finds that E_1 and E_2 are 2.70×10^{-4} cm^{-1} (370 nm) and 4.11×10^{-4} cm^{-1} (243 nm), respectively. Unfortunately, the optical absorption data for the $Ag^{2+}(\alpha)$ center are not available. The spin densities on the silver atoms and nitrogen atoms of typical Ag^{2+} complexes are summarized in Table 2.[8,11–13] The spin density on the nitrogen atoms indicates that the σ-bonding between the Ag^{2+} ion and the nitrogen atom of cyano groups is weaker than that between the Ag^{2+} ion and aromatic nitrogen atoms.

	Direction cosines of the parallel axis in the a'b'c' system are (0.00, $\pm$0.14, 0.99).			

NO_3^{2-}–Ag^+ center have two sets of sextets when the magnetic field is in general directions. They merge into a single sextet when the magnetic field is in the a'b' or a'c' plane. Similar spectra have been observed in irradiated silver nitrate crystals and assigned to NO_3^{2-}–Ag^+, referred to as an $AgNO_3^-$ center.[3] The sextet, which consists of six lines with equal intensity (Fig. 2), arises from a hyperfine interaction with a nitrogen nucleus and a silver nucleus. The angular dependence of the g value and the coupling constants for the nitrogen and silver nuclei, A(N) and A(Ag), were analyzed to give their principal elements listed in Table 3. The principal values are similar to those of $AgNO_3^-$ trapped in silver nitrate crystals.[3] Furthermore, the principal values of A(N) are in good agreement with those of the nitrogen nucleus in NO_3^{2-} trapped in KNO_3 and other compounds.[14]

We discuss below the electronic structure of the NO_3^{2-}–Ag^+ center. The fact that A(Ag) is nearly isotropic indicates that the Ag atomic orbital in which the unpaired electron partly spends its time contains s character. If the unpaired electron localizes only on the 5s orbital, the average hyperfine interaction for $^{107}Ag^0$ and $^{109}Ag^0$ is 424×10^{-4} cm^{-1}.[9] The spin density on the 5s orbital of Ag in the NO_3^{2-}–Ag^+ center is 18.8/424, or 0.04.

The ion radical NO_3^{2-} has a pyramidal form with the nitrogen atom on the vertex. The unpaired electron occupies an sp^n hybrid orbital,

$$\phi = C_s\phi_{2s}(N) + C_p\phi_{2p}(N), \quad (12)$$

which extends along the C_3 symmetry axis (x axis). Here $\phi_{2s}(N)$ and $\phi_{2p}(N)$ are the 2s and $2p_x$ atomic orbitals of the nitrogen atom. Then the principal values of the A(N) are given by Eqs. 6 and 7. From the observed values in Table 2, the spin densities on the 2s and 2p orbitals are calculated to be 0.077 and 0.52, respectively. The remaining spin density of 0.37 would be distributed mainly on the three oxygen atoms. The bond angle $\angle$ONO for the pyramidal NO_3^{2-} ion is given by

$$\theta = \cos^{-1}\left(\frac{1.5}{2\xi^2+3} - \frac{1}{2}\right), \quad (13)$$

where $\xi^2 = C_p^2/C_s^2$.[14] The observed value of 6.69 for ξ^2 predicts that θ is 114°.

Optical and Thermal Conversion of $Ag^{2+}(\alpha)$ and NO_3^{2-}–Ag^+ Centers. When the crystals of $AgNO_3 \cdot NCCH_2CH_2CN$ X-irradiated at 77 K were exposed to light from a tungsten filament lamp at the same temperature, ESR signals of the $Ag^{2+}(\alpha)$ and NO_3^{2-}–Ag^+ centers disappeared in half an hour. During the exposure the intensity of a triplet (p, p', p'' in Fig. 2) increased. The magnetic species responsible for the triplet are reasonably identified as NO_2 because the observed g value (1.994—2.006) and hyperfine splitting of nitrogen ($(41-60) \times 10^{-4}$ cm^{-1}) are similar to those reported for NO_2 trapped in other compounds.[14]

These two paramagnetic centers, $Ag^{2+}(\alpha)$ and NO_3^{2-}–Ag^+, simultaneously appeared on X-ray irradiation and disappeared on visible light irradiation; this is explained as follows : At 77 K an electron is liberated from an Ag^+ ion through excitation by X-rays, it migrates in the lattice, and is trapped by an NO_3^- ion. This process gives rise to these two centers. The trapped electron in NO_3^{2-}–Ag^+ center is released by optical excitation and recombines with the hole on the $Ag^{2+}(\alpha)$ center. Some of the NO_3^{2-}–Ag^+ centers may be degraded into NO_2 during the irradiation.

When the crystals X-irradiated at 77 K were warmed to room temperature for a minute, the $Ag^{2+}(\alpha)$ center changes into a new Ag^{2+} center, which is designated as $Ag^{2+}(\beta)$ center. Figure 3 illustrates the ESR spectrum of the $Ag^{2+}(\beta)$ center, which is explained by an unpaired electron delocalized over an Ag^{2+} ion, two equivalent

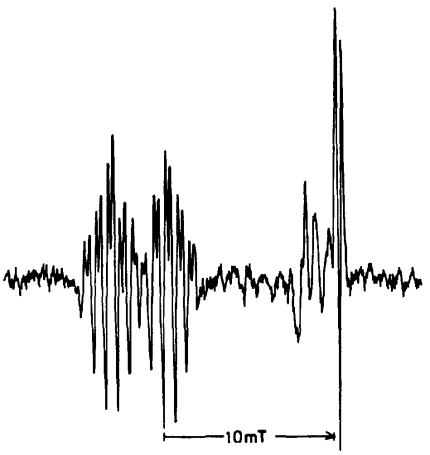

Fig. 3. Typical second derivative spectrum of the $Ag^{2+}(\beta)$ center. The magnetic field was applied in the a'c' plane, making an angle of 45° with the a' axis.

nitrogen atoms and a proton. The principal elements of the g tensor and hyperfine coupling tensors are tabulated in Table 3. The $Ag^{2+}(\beta)$ center has spin Hamiltonian parameters different from those for the $Ag^{2+}(\alpha)$ center. This fact suggests that the configuration of the ligands in the $Ag^{2+}(\alpha)$ center is altered irreversibly through thermal reorientation, giving rise to the $Ag^{2+}(\beta)$ center.

Crystal Structure and Orientation of Radicals. Two sets of ESR spectra were generally observed for the NO_3^{2-}–Ag^+ and $Ag^{2+}(\beta)$ centers. The angular dependence of these spectra are inherent in radicals trapped in a monoclinic crystal. The unique axis of the crystal must be parallel to the b′ or c′ axis. The observed interfacial angles ∠ps, ∠pq, and ∠pr are 90°, strongly suggesting that the b′ axis is the unique axis. Only one set of ESR spectra was observed for the $Ag^{2+}(\alpha)$ center. It indicates that the Ag^{2+} ion is on the symmetry axis of the unit cell. For the $Ag^{2+}(\alpha)$ center, the direction along N–Ag–N is perpendicular to the c′ axis. The C_3 symmetry axis of NO_3^{2-} in NO_3^{2-}–Ag^+ center lies on the b′c′ plane and makes an angle of 62° with the b′ axis. The infrared study of $AgNO_3 \cdot NCCH_2CH_2CN$ showed that butanedinitrile molecule assumes the *trans* rotomeric conformation and forms a bridge between two silver atoms.[5] These facts give some structural information for the parent (undamaged) complex, the structure of which is not known.

Studies of Polystyrene-based Ion Exchange Fiber. I. The Preparation and Fundamental Characteristics of Polystyrene-based Ion Exchange Fiber†

Toshio Yoshioka* and Masaharu Shimamura
Fibers Research Laboratories, Toray Industries, Inc., Sonoyama, Otsu 520
(Received February 28, 1983)

A polystyrene-based ion exchange fiber which has a large ion exchange capacity (*ca.* 2.5 mequiv g^{-1}) and a high mechanical strength (*ca.* 1.4 g d^{-1}) has first been prepared by using an islands-in-a-sea type composite fiber, the sea ingredient predominantly comprised of polystyrene for ion exchange and the island ingredient comprised of fiber-forming polypropylene for reinforcement, as the starting material; it can be used in an arbitrary form. It was found that the resulting fiber has two fundamental characteristics; the ion exchange rate for metal ions is extremely high, and the capacity of adsorbing the macromolecular ionic substance is exceedingly large, compared with ordinary ion exchange resins. The diffusion equation of ion exchange in the case of a cylindrical, endless fiber was solved by a modification of the method used for a spherical resin in a simple system. The former results are interpreted in terms of their solutions for two limiting cases. The latter results are explained by the fact that the surface-area ratio of the fiber to the resin is about ten.

There have been many investigations regarding the method of preparing ion exchange fiber, which has a large surface area per unit of weight and can be used in an arbitrary form.[1-6] These characteristics, however, have scarcely been studied because it is difficult to prepare ion exchange fiber which satisfies the following indispensable conditions:

(1) The ionic group and the basic polymer should be chemically stable.

(2) The ion exchange capacity should be large enough.

(3) The mechanical strength should be sufficiently high.

We have investigated ion exchange fiber which satisfies the above-mentioned three conditions and studied its characteristics. Polystyrene-based ion exchangers have already been selected from many polymer-based exchangers, as they satisfy the first two conditions, (1) and (2), and used industrially in the form of resin or film. Polystyrene has been well studied because it is suitable to the addition not only of ionic groups, but also of various functional groups. This has, therefore, been chosen as our basic polymer for the introduction of the ionic group. Polystyrene fiber, however, possesses so poor a mechanical strength as to be changed into various forms. It is also liable to break into fine particles when the ionic group is introduced, and thus does not satisfy the (3) condition.

The adoption of an additional fiber-forming polymer for reinforcement has been examined in order to satisfy the (3) condition. As a result, polystyrene-based ion exchange fiber, which satisfies the three conditions, has first been prepared by the introduction of a crosslinking group and an ion exchange group into the polystyrene part by chemically treating an islands-in-a-sea type composite fiber, the sea ingredient predominantly comprised of polystyrene for ion exchange and the island ingredient comprised of fiber-forming polypropylene for reinforcement.[7,8] The present authors would like to report here on this ion exchange fiber (abbrev. IONEX). This fiber was applied to the exchange of metal ions and to the adsorption of a caramel pigment from a sucrose solution. From these results, the fundamental characteristics of the fiber will also be discussed.

Experimental

Forty parts of polystyrene and 10 parts of polypropylene for the sea ingredient and 50 parts of polypropylene for the island ingredient were melt-spun at 255 °C into composite filaments having an islands-in-a-sea type sectional structure in which the number of islands was sixteen. The composite filaments were drawn five times as long as their original length in a conventional manner. The diameters of the sea and the islands of the resulting filaments were 24 and 4.2 μm respectively.

Ten grams of the filaments were crossinked in 100 ml of a solution consisting of 5 wt% paraformaldehyde, 25 wt% acetic acid, and 70 wt% concentrated sulfuric acid. A strong cation IONEX was obtained by the sulfonation of the crosslinked (90 °C, 4 h) filaments (10 g) in a solution comprised of 200 ml of trichloroethylene and 8 ml of chlorosulfonic acid at 20 °C for 2 h. Ten grams of the crosslinked (80 °C, 2 h) filaments were chloromethylated in a solution comprised of 100 ml of chloromethyl methyl ether and 10 ml of stannic chloride at 30 °C for 4 h. A strong anion IONEX was obtained by the quaternization of the chloromethylated filaments (10 g) in 100 ml of a 30 wt% trimethylamine aqueous solution at 30 °C for 1 h.[7-9]

The concentration of the calcium ion was determined by the EDTA methods. The color value (C.V.) was measured by means of a 1-cm cell at 410 nm both before and after the decoloration treatment. The resulting color values were referred to "*A*" and "*B*" respectively. Then the decoloration ratio was calculated by means of the following equation:

$$\text{Decoloration ratio}(\%) = \frac{A-B}{A} \times 100.$$

Results and Discussion

Preparation and Fundamental Properties. The process of preparing the ion exchange fiber is shown in Fig. 1. Polystyrene (PSt) was used as the basic polymer for the ion exchange, while polypropylene (PP), which exhibits

† A preliminary report of this work was presented in *Polym. Prepr. Jpn.*, **31**, 2025 (1982).

Fig. 1. Process of preparing the polystyrene-based ion exchange fiber (IONEX).

an enhanced resistance to chemicals, was used as the fiber-forming polymer for reinforcement. In the case of using as the starting material a blend fiber made from a uniform blend of PSt and PP, the ion exchange rate and the adsorption capacity of the resulting fiber are lowered when the amount of PP exceeds 50%; the fiber, on the other hand, becomes very poor in mechanical strength when the amount of PP is less than 50%. A sheath-core type composite fiber, which consists of PSt for the sheath ingredient and PP for the core ingredient, is not good as the starting material because of its poor resistance to separation between the two phases. An islands-in-a-sea type composite fiber which consists of PSt for the sea ingredient and PP for the island ingredient could provide a suitable ion exchange fiber, IONEX, which exhibits an enhanced ion exchange rate, adsorption capacity, mechanical strength, and resistance to separation.[7] A schematic cross-sectional drawing of the composite fiber is shown in Fig. 2. A composite fiber which consists of PSt mixed with a small amount of PP for the sea ingredient and PP for the island ingredient was finally used to enhance further the resistance to separation.[8] The methods of chemical reaction to the polystyrene part are shown in Fig. 3.

The strength, elongation, ion exchange capacity, and water content of several filamentary IONEX are summarized in Table 1. The ion exchange capacities of IONEX Nos. 1—4 correspond to 94, 88, 86, and 82% of the theoretically calculated values respectively. When a crosslinking group and an ionic group are introduced, the tensile strength of the resulting filaments becomes lower than the value estimated in consideration of the weight increase from the data on the original filaments; that is, the tensile strength per filament of the original filament was 12.9 g, and those of the crosslinked filament, the chloromethylated filament, and the strong anion exchange filament were 12.0, 11.9, and 10.5 g respectively. No change in the capacity or the water content was recognized, even if the strong cation or anion IONEX was repeatedly used ten times in the following treatment: add to 1 M (1 M=1 mol dm^{-3}) hydrochloric acid or sodium hydroxide, wash with deionized water, add to 1 M sodium chloride, and finally wash with deionized water. From these results, it can be presumed

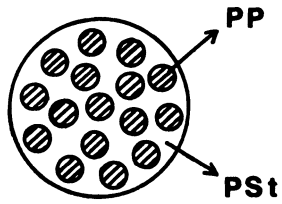

Fig. 2. Schematic cross sectional drawing of the composite fiber.

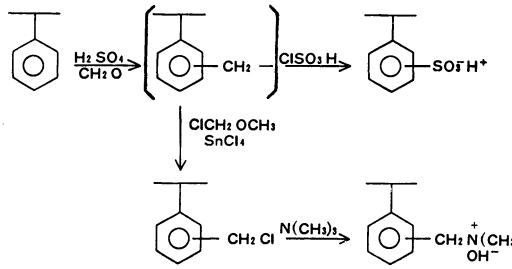

Fig. 3. The methods of chemical reaction to polystyrene part.

that a methylene bond is formed between phenyl rings by the crosslinking reaction and that then the resulting filament is strongly crosslinked and insolubilized.[9] IONEX with an arbitrary water content can be obtained by chosing the conditions of the crosslinking reaction. The acidity or basicity of a strong cation or anion IONEX is almost equal to that of polystyrene-based ion exchange resin. IONEX in an arbitrary form, such as staple fibers, cut fibers, needle punched felts, nonwoven fabrics, woven fabrics, knitted fabrics, braids, and papers, can also be obtained by processing the filaments before the chemical reaction; it can then be prepared so as to have the same capacity and water content as the filamentary form by controlling the processing density. Figure 4 presents a strong cation IONEX in a form of the cut fibers.

Exchange of Metal Ions. A strong cation exchanger of 6.6 mequiv in the Na form was added to 250 ml of a 0.008 M $CaCl_2$ aqueous solution containing 50 wt% sucrose; it was then strongly shaken at 20 °C. Similarly, a strong cation exchanger of 5.7 mequiv in the Ca form was added to 250 ml of a 1 M NaCl aqueous solution, and then the mixture was strongly shaken. The fractional attainment of equilibrium was evaluated in those two cases by measuring the calcium-ion concentration in the solution at several intervals. The results are shown in Figs. 5 and 6 respectively. A commercially available strong cation exchange resin and strong cation

IONEX No. 1 were used as cation exchangers.

According to the rate laws of ion exchange in a simple system, the fractional attainment of equilibrium $U(t)$ within a spherical resin with a radius of r_0 can be described in the two limiting cases of ideal film and ideal particle diffusion control respectively by the following equations:[10]

$$U(t) = 1 - \exp\left(-\frac{3DCt}{r_0\delta\bar{C}}\right), \tag{1}$$

$$U(t) = 1 - \frac{6}{\pi^2}\sum_{n=1}^{\infty}\frac{1}{n^2}\exp\left(-\frac{\bar{D}\pi^2n^2t}{r_0^2}\right). \tag{2}$$

The signification of the symbols in the above equations has been described in Ref. 10. The half-times, $t_{1/2}$, of ion exchange are calculated from Eqs. 1 and 2 respectively as follows:[10]

$$t_{1/2} = 0.230\, r_0\delta\bar{C}/DC, \tag{3}$$

$$t_{1/2} = 0.030\, r_0^2/\bar{D}. \tag{4}$$

We could solve the diffusion equation in the case of an endless fiber with a radius of r_f by the modification of the method used for a spherical resin; we could thus obtain the fractional attainment of equilibrium in the two limiting cases as, respectively:

$$U(t) = 1 - \exp\left(-\frac{2DCt}{r_f\delta\bar{C}}\right), \tag{5}$$

$$U(t) = 1 - \sum_{n=1}^{\infty}\frac{4}{x_n^2}\exp\left(-\frac{\bar{D}_f x_n^2 t}{r_f^2}\right). \tag{6}$$

where $\bar{D}_f$ is the interdiffusion coefficient in the ion exchange fiber and where the quantities x_n are the roots of the equation $J_0(x)=0$, in which $J_0(x)$ is the zero-order Bessel function. The half-times of ion exchange were finally derived from Eqs. 5 and 6 as follows:

$$t_{1/2} = 0.345\, r_f\delta\bar{C}/DC, \tag{7}$$

$$t_{1/2} = 0.065\, r_f^2/\bar{D}_f. \tag{8}$$

Although the diffusion equations have been solved under several conditions, the solutions can be applied to our experimental results in the case of a relative comparison between the fiber and the resin. The results in Fig. 5 are considered to correspond to the case of film diffusion control, since the concentration of the solution is sufficiently low: $C \ll 0.1$ M. The ratio of the half-time of the resin to that of the fiber can be calculated to be 11 from Eqs. 3 and 7 when $r_0=250$ μm and $r_f=15$ μm. The ratio obtained from the experimental data is, however, 25, almost twice as high as the calculated ratio. This fact may be interpreted owing to film diffusion control in terms of the increase in the surface area per unit of capacity of IONEX by the amount of the polymer for reinforcement. On the other hand, the results in Fig. 6 are considered to correspond to the case of particle diffusion control, since the concentration of the solution is sufficiently high: $C \gg 0.1$ M; the ratio can similarly be calculated to be 128 from Eqs. 4 and 8 if $\bar{D}=\bar{D}_f$ is assumed. The ratio obtained from the experimental data, however, is in the range of from 50 to 70 and is about half the calculated ratio. The results can be interpreted on the assumption that the polymer for reinforcement disturbs the diffusion of ions because of the particle diffusion control.

Adsorption of a Caramel Pigment. Two grams of a strong anion exchanger in the Cl form was added to 200 ml of a 50 wt% sucrose aqueous solution containing a commercially available caramel pigment (C.V. 0.92); the mixture was then stirred at 60 °C. The data of the

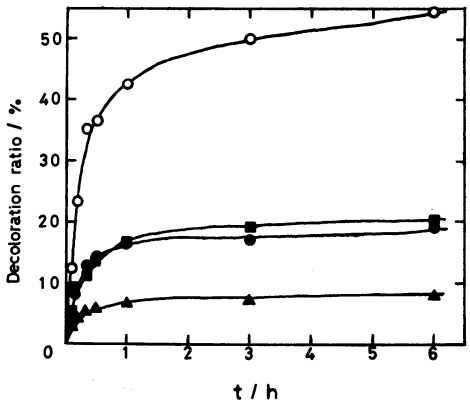

Fig. 7. Decoloration ratio as a function of time. Decoloration of 50 wt% sucrose solution containing caramel pigment (200 ml, C.V. 0.92) by Cl form anion exchanger (2.0 g) at 60 °C.

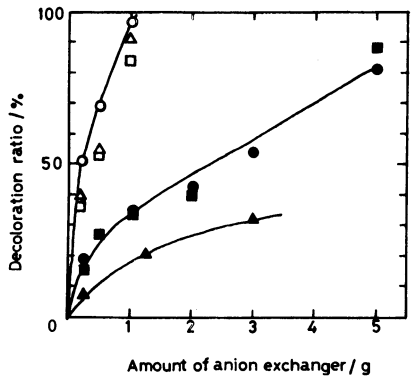

Fig. 8. Decoloration ratio *vs.* amount of anion exchanger. Decoloration of 50 wt% sucrose solution containing caramel pigment (25 ml, C.V. 0.92) by Cl form of anion exchanger (60 °C, 6 h). ○: IONEX No. 2, △: IONEX No. 3, □: IONEX No. 4, ●: IRA-401, ▲: IRA-400, ■: IRA-900.

decoloration ratio as a function of the time are shown in Fig. 7. It is apparent that the decoloration rate by the fiber is much greater than that by the three resins. This indicates that the effective capacity of the fiber to adsorb the caramel pigment is much larger than that of the resins, in spite of the fact that the ion exchange capacity of the fiber is about two thirds that of the resins.

Next, a strong anion exchanger in the Cl form was added to 25 ml of the same sucrose solution, and the mixture was shaken at 60 °C for 6 h. The correlation between the amounts of various anion exchangers and the decoloration ratio is shown in Fig. 8. This shows that the fibers have from seven to ten times as large an effective capacity of adsorbing the pigment as the low-crosslinked-type and the MR-type resins and, further, forty times as large a capacity as the standard-crosslinked-type resin. No large difference in the effective capacity was not observed between the strong anion IONEX Nos. 2—4. These results can be explained by the fact that the surface-area ratio of the fiber to the resin ($2r_0/3r_f$) is about ten, since the caramel pigment of a macromolecular weight cannot diffuse into the exchangers and can be adsorbed only near their surface. The reason why the low-crosslinked-type resin is superior to the standard-crosslinked-type resin is probably the small diffusion of the pigment into the former exchanger. Furthermore, the effective capacity of the MR-type resin is almost equal to that of the low-crosslinked-type resin, although it is said that the former resin has a large inner surface area of 30—100 $m^2 g^{-1}$. The reason for this is considered to be that the crosslinking degree of the MR-type resin is so high that the pigment cannot diffuse into the gel at all.

Conclusion

1. An excellent polystyrene-based ion exchange fiber which sufficiently satisfies the three indispensable conditions mentioned above was obtained by using the islands-in-a-sea type composite fiber as the starting material.
2. It was found that the resulting fiber has two fundamental characteristics; the ion exchange rate for metal ions is extremely high, and the capacity of adsorbing the macromolecular ionic substance is exceedingly large, compared with ordinary ion exchange resins.
3. The former results are interpreted in terms of the rate laws of ion exchange for the two limiting cases of ideal film and ideal particle diffusion control in a simple system. The latter results are explained by the fact that the fiber has a very large surface area in comparison with that of the resins.

The authors would like to express their appreciation to Dr. Tatsuro Kawaguchi, Mr. Michihiko Tanaka, and Dr. Masaki Nishino for their continuous encouragement throughout this work. They are also much obliged to Mr. Kazuo Teramoto for his advice on the chemical treatments and to Mr. Seiichi Yoshikawa and his collaborators for the preparation of the composite fibers. The authors also wish to thank Toray Industries, Inc., for making this study possible.

(Received May 6, 1983)

The penetration of water soluble polymers into lecithin monolayers was investigated for the random copolymers of L-lysine and L-leucine at various compositions in order to discuss the effect of hydrophobicity and charge density of the copolymers on their interaction with lipid monolayers. Compared to the penetration of the amino acids(L-lysine and L-leucine), the copolymer penetrated at very low concentration whereas the monomer (amino acid) did not. The amount of copolymer penetration increased significantly when the leucine fraction of a copolymer, X_{Leu}, was larger than 0.3, while little penetration occurred when X_{Leu} was smaller than 0.25. From these facts, it has been concluded that the penetration of lysine–leucine copolymers was not only attributed to the hydrophobicity or the charge density of copolymer molecules, but also to specific surface effects such as (1) the enhanced penetration of macromolecules by the preceded penetration of polymer segments of the same molecule, or (2) the formation of a compact α-helical structure as the result of the restricted motion of the segment near the lipid surface.

It has been widely accepted that biomembranes essentially consist of lipid bilayers in which proteins are dissolved.[1] Although the composition of membrane lipids depends on the kind of membranes, one of the typical constituents may be phospholipids.[2] From this point of view, the interaction between phospholipids and proteins has been studied by the use of phospholipid monolayers as a model of lipid membranes.[3,4]

Since the structure of a protein is complex, synthetic polypeptides have been used in many studies as models for proteins.[5–9] Polylysine is one of the basic polypeptides, and the dissociation of the ε–amino group in a lysine residue is known to vary with pH or on the addition of alcohols or electrolytes to the solution.[10–16] In solutions of neutral pH, polylysine has a positive charge due to the protonation of ε-amino groups. It is found that a strong interaction occurs between polylysine and lipids and causes aggregation by forming lipid–peptide complexes or clusters if the phospholipids are acidic such as phosphatidylserine or phosphatidic acid.[17,18] It is considered that this is due to electrostatic interaction occuring at the negatively charged lipid monolayer surface because polylysine does not interact with the neutral phospholipids like lecithin. However, electrostatic interaction between polylysine and zwitterionic phospholipids such as lecithin has been reported in recent liposomal studies, being weak but not negligible.[19] A similar interaction also occurs between neutral phospholipids and acidic polypeptides like polyglutamic acid.[20] Moreover, Campbell *et al.* have also indicated the existence of hydrophobic interaction between polylysine and lecithin.[19] From this standpoint, the author's interest is focussed on the penetration of polylysine into lecithin monolayers.

Many apolar amino acids as well as polar exist in a protein molecule. Not only homopolymers such as polylysine but also copolymers which involve both ionic and apolar chains should be regarded as models for the actual protein molecules. Leucine is an apolar amino acid since it does not have any ε-amino groups in the hydrocarbon chain, although it has six carbon atoms in the monomer residue, which is the same as lysine. Therefore, lysine–leucine copolymers of varying hydrophobicity or charge density are obtained by changing the lysine–leucine ratio.

The penetration of amino acids like lysine, leucine and norleucine into lecithin monolayers was discussed in our previous work.[21–23] In this paper, random copolymers consisting of lysine and leucine were used and the penetration of these copolymers into lecithin monolayers was investigated in order to study the effect of the hydrophobicity and the charge density of the copolymer on its penetration into lipid monolayers.

Experimental

Materials. Table 1 shows the lysine–leucine copolymers used in this experiment. Polylysine (poly-L-Lys·HCl) was purchased from the Protein Research Foundation, and the molecular weight was estimated from the viscosity measurement according to Yaron and Berger.[24] The other copolymers [poly(Lys^{x}Leu^y)$_n$ (HCl)$_{xn}$] in Table 1 were supplied from the Cardiovascular Research Institute, University of California. These copolymers were all water soluble. L-α-Dimyristoyl phosphatidylcholine (DMPC) from the Sigma Chemical Company was used without further purification. Chloroform was used as the spreading solvent.

Surface-tension Measurement. The surface tension of the aqueous copolymer solution, γ_{cop}, was measured by the capillary-rise method, and the surface pressure of copolymers, F_{cop}, was obtained by means of Eq. 1:

$$F_{cop} = \gamma_0 - \gamma_{cop}, \quad (1)$$

where γ_0 is the surface tension of pure water. The temperature

Table 1. Characterization of copolymers of L-lysine and L-leucine

Composition		MW	Degree of polymerization ($\overline{DP}$)
Lys	Leu		
1.0	0	66000	359
0.859	0.141	94000	534
0.829	0.171	102000	586
0.800	0.200	85000	491
0.751	0.249	88000	518
0.664	0.336	56000	337
0.616	0.384	43000	264

of the solution was kept at 25±0.5 °C.

Surface-pressure Measurement. The surface pressure of the DMPC monolayer was measured by Wilhelmy's plate method. Since the surface tension of a solution is not always equal to that of pure water, the surface pressure, F, was calculated by means of Eq. 2:[25]

$$F = \gamma_0 - \gamma = F' + F_{cop}, \quad (2)$$

where γ is the surface tension of a copolymer solution covered with a lipid monolayer, while F' is the practical surface pressure defined by:

$$F' = \gamma_{cop} - \gamma, \quad (3)$$

and is measured directly by Wilhelmy's plate method as the decrease in the surface tension of a copolymer solution upon the spreading of a lecithin monolayer. That is:

$$F' = (T_{cop} - T)/l, \quad (4)$$

where l is the length around the horizontal cross section of the plate. The forces acting on the Wilhelmy plate, T_{cop} and T, were measured as follows. A copolymer solution of 57 cm³ was poured into a trough (5.0×20.0×0.4 cm³) coated with Teflon, and was kept in thermostatted air at 25±0.5 °C. After the surface of the copolymer solution was swept by a barrier covered with a Teflon sheet, the lower end of a ground glass plate, vertically suspended, was touched to the liquid surface and the vertical pull force acting on the plate, T_{cop}, was measured by means of a Shimadzu T-NR torsion balance. A lipid monolayer was then spread from an Agla micrometer syringe (accuracy ±0.0002 cm³) and left for 5 minutes. The force acting on the plate, T, was then measured by compressing the monolayer with a barrier. The values of T_{cop} and T were measured several times, respectively, until the equilibrium values were obtained. The experimental error of the measurement was within ±0.1 mN m⁻¹.

Results

Surface Tension of a Copolymer Solution. Figure 1 shows the surface tension of polylysine and various copolymer solutions. It is seen that the surface tension decreases with the increase in the concentration, C_2, for all copolymer solutions, and it also decreases with the leucine content of copolymer. This is attributable to the fact that the higher the leucine content, the more hydrophobic and less electrically charged the molecule becomes. The surface concentration of the copolymer is, therefore, higher at higher content of leucine or lower content of lysine, since lysine is more hydrophilic and positively charged due to its ε-ammonium group.

Surface Pressure-Area Curves of the DMPC Monolayers. The relation between the surface pressure, F, and the area per molecule of lecithin, A_3, spread on polylysine solutions is shown in Fig. 2. The curve shifted to a higher surface pressure region at higher C_2, indicating that the penetration of polylysine into the lecithin

monolayers occurred. Figures 3 and 4 show the surface pressure-area curves of lecithin monolayers spread on leucine-containing copolymer solution, namely, poly-($Lys^{0.800}Leu^{0.200}$)$_n$ in Fig. 3 and poly($Lys^{0.616}Leu^{0.384}$)$_n$ in Fig. 4, respectively. The curve also shifts to a higher surface pressure region with higher C_2, similar to the case of polylysine (Fig. 2), although the extent of the shift differs in each case. The shifts were also observed for other lysine–leucine copolymers [poly($Lys^{0.857}Leu^{0.143}$)$_n$, poly($Lys^{0.751}Leu^{0.249}$)$_n$, and poly($Lys^{0.664}Leu^{0.336}$)$_n$], though not shown in the figure. Our previous studies of the penetration of amino acids[21-23] also showed similar shift of the curves to a higher surface pressure region, however, the shift was not appreciable unless the concentration of the amino acids was about ten to one hundred times higher than that of the polypeptides. This may be attributable to the fact that the penetration of one part of the polymer residues restricts the other part of the polymer molecule in the vicinity of the surface. The penetration of polymer molecules is therefore found at very low concentrations where the monomer penetration does not occur.

Effect of the Copolymer Composition on Its Penetration into Lecithin Monolayer. The increase in the surface pressure, ΔF, caused by the penetration of polymer molecules into lipid monolayer,

$$\Delta F = F - F_0, \quad (5)$$

is considered to be a measure of the interaction of the polymer with membranes,[26] where F and F_0 are the surface pressure at a given area per molecule of lecithin respectively with and without polymer in the aqueous solution. The typical results of ΔF are shown in Fig. 5 against the polymer concentration, C_2, where the area per molecule of lecithin, A_3, is 90×10^{-2} nm^2. It is seen from this figure that the values of ΔF increases with the polymer concentration, C_2, and that the shape of the ΔF *vs.* C_2 relations are independent of the mole

fraction of leucine in the copolymer, X_{Leu}, provided X_{Leu} is smaller than 0.25. However, ΔF becomes large when X_{Leu} is larger than 0.34. This behavior was also observed at other values of A_3, although the value of ΔF was smaller at larger A_3 value, as is shown in Fig. 6 when C_2 is 0.5 g dm^{-3}.

Discussion

It is considered that polypeptides with electric charge, such as polylysine, are more hydrophilic, and, therefore, the interaction of these polypeptides with phospholipids like lecithin is weaker than for polypeptides without net charge. The charge density or hydrophilicity of polylysine decreases at a higher pH (about 10) since the ε-ammonium groups are deprotonated ($-NH_3^+ \rightarrow -NH_2$). It also decreases on the addition of perchlorate (ClO_4^-) due to the specific shielding effect on the positive charge ($-NH_3^+$).[12,15] In fact, the increase in the surface pressure of the lecithin monolayer, ΔF, was enhanced under these conditions as established in our work (unpublished data).

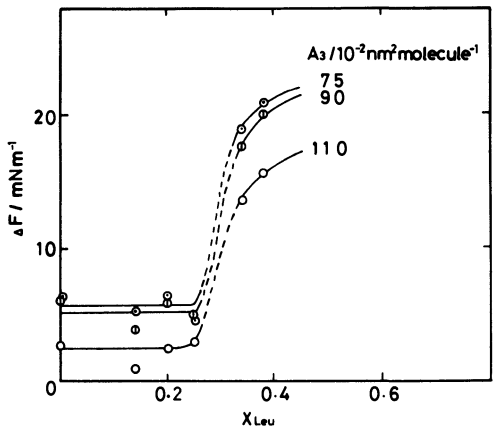

Fig. 7. The increase in surface pressure, ΔF, against the leucine fraction, X_{Leu}, where copolymer concentration, C_2, is 0.5 g dm^{-3}.

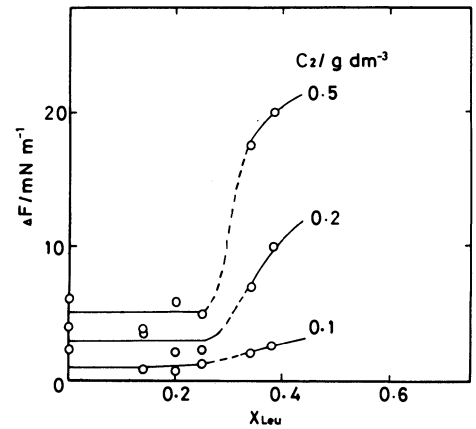

Fig. 8. The increase in surface pressure, ΔF, against the leucine fraction, X_{Leu}, at constant area per molecule of lecithin ($A_3=90\times10^{-2}$ nm^2).

The surface pressure increase, ΔF, due to the penetration was plotted against the leucine fraction, X_{Leu}, of the copolymer in Fig. 7 at a constant concentration of 0.5 g dm^{-3}. The ΔF values did not appreciably change when the leucine fraction, X_{Leu}, is from 0 to 0.25, irrespective of the area per molecule of lecithin, A_3. However, a remarkable increase was found in the vicinity of 0.3 of X_{Leu}, and the increase was again restrained when X_{Leu} exceeded 0.34. This remarkable increase in ΔF, however, does not occur at a small polymer concentration (0.1 g dm^{-3}), but it occurs when polymer concentration, C_2, is larger than 0.2 g dm^{-3}, as is shown in Fig. 8 for the area per molecule of lecithin of 90×10^{-2} nm^2.

In the copolymers of lysine and leucine, the charge density and hydrophilicity decrease with the increase in leucine fraction, and the penetration of these polymers into lecithin monolayers is expected to occur more easily. The amount of penetration of lysine–leucine copolymers into lecithin monolayers, however, did not change appreciably when the leucine fraction, X_{Leu}, is less than 0.25, but increased remarkably when X_{Leu} exceeded 0.3, as was described before. Accordingly, the penetration of these polymers is not only enhanced by the increase in hydrophobicity, the decrease in the charge density.

It is claimed that an α-helical structure is formed in lysine–leucine copolymers when the leucine fraction is large, because of the α-helix stabilizing effect of leucine.[27] A possible reason for the characteristic penetration as described above is that the transition from a coiled form to an α-helical structure occurs at a leucine fraction larger than about 0.3. According to circular dichroism, all the copolymers (leucine fraction, from 0 to 0.384) are in coiled forms in aqueous solution under our experimental conditions (pH≈5, in salt-free water). The remarkable increase in surface pressure is, therefore, not attributable to the conformational change of the polymers in the bulk solution.

The effect of the interface on the penetrability of these lysine–leucine copolymers into lecithin monolayer should be finally considered. D. Bach *et al.* have investigated the interaction of basic polypeptides consisting of two different amino acids with phospholipid vesicles by circular dichroism measurements and have reported the occurrence of a conformational change of these copolymers at a lipid surface.[9] In our experiment, the penetration of a part of the polymer segments to the lecithin monolayers restricts the other segments of the same macromolecule to a limited thermal motion in the vicinity of the surface. It is possible, therefore, that these restricted segments penetrate into lecithin monolayers more easily than when these segments are free in the bulk solution. It is, therefore, reasonable that the penetration of these copolymers occurs at such a low concentration where the monomers (residue amino acids) cannot penetrate appreciably. Moreover, the α-helical structure of the polypeptide is considered to be easily formed under the limited motion on the lipid surface, in comparison with the case where they are free in the bulk solution. More than one leucine residue are contained in one period of an α-helical spiral when the leucine fraction, X_{Leu}, is larger than 0.3, since there are 3.6 residues per α-helical unit. It is expected, therefore, that the α-helical structure is stabilized by the hydrophobic binding between leucine residues, which induces the contraction of polymer molecules, and the increase in penetration into the monolayer.

We wish to express our sincere thanks to Professor Dr. J. T. Yang. This work was supported in part by USPH5 GM-10880 (J. T. Yang). We are also grateful to Dr. K. Ikeda for helpful discussions concerning the circular dichroism spectra.

(Received June 4, 1983)

The *s-trans*-diene coordination in $(\eta^5\text{-}C_5Me_5)_2Zr$(butadiene) and the *s-cis*-diene coordination in $(\eta^5\text{-}C_5Me_5)_2Zr$-(isoprene) were confirmed by the ^1H- and ^{13}C-NMR spectral studies. The reaction of 2,4-dimethyl-3-pentanone with these complexes occurred regio- and stereoselectively to give $(\eta^5\text{-}C_5Me_5)_2ZrOC(i\text{-}Pr)_2CH_2CR{=}CHCH_2$ (**5**: R=H, **6**: R=Me). The X-ray crystal structure analysis of **5** and **6** revealed the (*Z*)-configuration with respect to the olefin part. Crystal data for **5**: monoclinic, space group $P2_1/n$ with $Z=4$, $a=11.650(2)$, $b=17.791(3)$, $c=13.612(2)$ Å, $\beta=92.20(2)°$, $R=0.111$ for 4308 non-zero reflections. Crystal data for **6**: monoclinic, space group $P2_1/n$ with $Z=4$, $a=10.279(3)$, $b=30.177(4)$, $c=9.955(2)$ Å, $\beta=108.67(2)°$, $R=0.104$ for 3526 non-zero reflections.

The unusual versatility of organozirconium complexes has led to many important developments in organic synthesis. In the preceding papers, we have reported that $(\eta^5\text{-}C_5H_5)_2Zr$(*s-cis*-isoprene) readily reacts with saturated or unsaturated ketones, aldehydes or esters; these reactions result in the regioselective C–C bond formation at the C_1 atom of the coordinated isoprene.[1,2] Stereochemical pathways for this reaction are of interest in understanding the unique chemical properties of the zirconium complexes. Two pathways are conceivable: a) insertion of carbonyl compound to the M–C bond with retention of the *s-cis*-diene conformation and b) insertion after conversion to the *s-trans*-diene coordination. Selective preparation of the *s-cis* and the *s-trans* zirconium-diene complexes is necessary to settle this problem. Though preparations of the *s-cis* and *s-trans* isomers of $(\eta^5\text{-}C_5H_5)_2Zr$(butadiene) complexes were recently reported by Erker[3,4] and by us,[5] purification of the respective isomers is difficult due to the existence of rapid equilibration between them. A thermally stable *s-trans* isomer of the butadiene complex was found to be obtained exclusively when the C_5H_5 ligand was replaced with C_5Me_5 ligand. The corresponding isoprene complexes, $(\eta^5\text{-}C_5R_5)_2Zr$(isoprene) (R=H, Me), assume the *s-cis*-diene coordination irrespective of the ligand. These findings prompted us to examine the reaction of carbonyl compounds with the *s-cis*- and the *s-trans*-diene complexes to define the stereochemical course by means of the X-ray structure analysis and chemical characterization.

Experimental

All manipulations were conducted with Schlenk technique under argon atmosphere. The reagents and solvents were dried over appropriate drying agents and distilled before use. $(C_5Me_5)_2ZrCl_2$[6] and enediylmagnesiums[7] were prepared according to usual methods. Regioselectivity was determined by gas chromatographic analysis of hydrolysis products with a Yanagimoto Model G-80 gas chromatograph using a column packed with Silicone DC-550 on Uniport B. NMR spectra were recorded on a Varian XL-100 instrument with a VFT-100-620L Fourier transform accessory and analyzed with a Varian spin simulation program. Mass spectra were recorded on a JEOL Model JMS OlSG-2 spectrometer. IR and electronic spectra were obtained on a Hitachi EPI-2 spectrometer and a JASCO Model UVIDEC-5A spectrometer, respectively.

Preparation of $(C_5Me_5)_2Zr$(s-trans-*butadiene*) (**1**). To a stirred solution of $(C_5Me_5)_2ZrCl_2$ (508 mg, 1.17 mmol) in 10 ml THF was added a THF slurry of 2-butene-1,4-diylmagnesium ($f=0.32$, 4.5 ml, 1.44 mmol) at −78 °C. The mixture was gradually warmed up to room temperature (25 °C). After stirring for 1 h, the solvent was evaporated under reduced pressure. The residue was extracted with hexane (25 ml) and salts were separated with a centrifuge to give an orange solution. After the solution was concentrated to *ca.* 1 ml, crystallization was carried out at 0 °C to give **1** as orange crystals. Yield 76% (370 mg, 0.89 mmol). Mp 196 °C, UV (hexane) λ_{max} (ε): 354 nm (1.61×10^3), 450 nm (4.33×10^2); IR (hexane) 1431, 1258, 1157, 1023, 944 and 803 cm^{-1}; MS (EI, 70eV), *m/e* 414 (M^+, ^{90}Zr); Found: C, 69.08; H, 8.50%. Calcd for $C_{24}H_{36}Zr$: C, 69.33; H, 8.73%.

Preparation of $(C_5Me_5)_2Zr$(s-cis-*isoprene*) (**2**). $(C_5Me_5)_2ZrCl_2$ (1.73 g, 4.0 mmol) was treated with 4.4 mmol ($f=0.17$, 26 ml) of 2-methyl-2-butene-1,4-diylmagnesium in essentially the same manner as described for **1**. Recrystallization from hexane gave **2** in 82% yield (1.41 g). Mp 208 °C. UV (hexane) λ_{max} (ε): 332 nm (2.54×10^3), 395 nm (1.12×10^3); IR (hexane) 1432, 1257, 1172, 1025 and 805 cm^{-1}; MS (EI, 70 eV), *m/e* 428 (M^+, ^{90}Zr); Found: C, 69.80; H, 8.87%. Calcd for $C_{25}H_{38}Zr$: C, 69.87; H, 8.91%.

*Reaction of **1** with 2,4-Dimethyl-3-pentanone.* To a benzene solution (5 ml) of **1** (1.25 g, 3.0 mmol) was added 2,4-dimethyl-3-pentanone (480 mg, 4.0 mmol). The color of the solution gradually turned into pale yellow. The insertion reaction became complete by stirring the mixture for 10 h at 30 °C or for 2 h at 80 °C, as revealed by gas chromatographic analysis. Concentration of solution to 1 ml resulted in the precipitation of complex **5** as yellow powder in >95% yield. Single crystals for X-ray structure analysis were obtained by recrystallization from hexane. Mp 206—211 °C; ^{1}H-NMR (C_6D_6) δ=1.18 (d, 6, J=7.0 Hz, CH(C$\underline{H}_3$)$_2$), 1.22 (d, 6, J=7.0 Hz, CH-(C$\underline{H}_3$)$_2$), 1.40 (d, 2, J=8.0 Hz, ZrC$\underline{H}_2$), 1.96 (m, 2, C$\underline{H}$-(CH$_3$)$_2$), 2.09 (d, 2, J=8.5 Hz, ZrCH$_2$CH=CH-C$\underline{H}_2$), 5.15 (dt, 1, J=8.5 and 11.0 Hz, ZrCH$_2$CH=C$\underline{H}$), 6.65 (dt, 1, J=8.0 and 11.0 Hz, ZrCH$_2$C$\underline{H}$=CH), 1.91 (s, C_5Me_5); ^{13}C-NMR (C_6D_6) δ=12.3 ($C_5\underline{Me}_5$), 20.6, 22.3 (CH(C$\underline{H}_3$)$_2$), 37.7 (ZrCH$_2$), 39.9 (C$\underline{H}$(CH$_3$)$_2$), 46.2 (ZrCH$_2$CH=CHC$\underline{H}_2$), 94.5 (ZrO$\underline{C}$(*i*-Pr)$_2$), 115.3 (ZrCH$_2$CH=$\underline{C}$H), 119.0 ($\underline{C}_5$Me$_5$), 138.6 (ZrCH$_2$-$\underline{C}$H=CH); MS (FD, 70 eV), *m/e* 528 (M$^+$, ^{90}Zr); Found: C, 70.10; H, 9.65%. Calcd for $C_{31}H_{50}OZr$: C, 70.26; H, 9.51%.

*Reaction of **2** with 2,4-Dimethyl-3-pentanone.* To a benzene solution (5 ml) of **2** (1.29 g, 3.0 mmol) was added 2,4-dimethyl-3-pentanone (480 mg, 4.0 mmol) at 25 °C. After the mixture was stirred at 25 °C for 10 h and the solution was concentrated, complex **6** was obtained as pale yellow crystals in 95% yield. A single crystal for the X-ray diffraction was prepared by recrystallization from benzene. Mp 239—243 °C; ^{1}H-NMR (C_6D_6) δ=1.20 (d, 12, J=7.0 Hz, CH(C$\underline{H}_3$)$_2$), 1.31 (d, 2, J=8.5 Hz, ZrC$\underline{H}_2$), 1.91 (s, 30, C_5Me_5), 2.0 (m, 2, C$\underline{H}$(CH$_3$)$_2$), 2.09 (bs, 3, CH=C(C$\underline{H}_3$)), 2.13 (bs, 2, CH=C-(CH$_3$)C$\underline{H}_2$), 6.61 (t, 1, J=8.5 Hz, ZrCH$_2$C$\underline{H}$=C); ^{13}C-NMR (C_6D_6) δ=12.3 ($C_5\underline{Me}_5$), 20.7, 22.4 (CH(C$\underline{H}_3$)$_2$), 27.5 (CH=C(C$\underline{H}_3$)), 39.6 (C$\underline{H}$(CH$_3$)$_2$), 41.3 (ZrC$\underline{H}_2$), 47.0 (CH=C(CH$_3$)-C$\underline{H}_2$), 93.2 (ZrO$\underline{C}$(*i*-Pr)$_2$), 118.8 ($\underline{C}_5$Me$_5$), 121.0 (CH=$\underline{C}$-(CH$_3$)), 135.1 (C$\underline{H}$=C(CH$_3$)); MS (FD, 70eV), *m/e* 542 (M$^+$, ^{90}Zr); Found: C, 70.60; H, 9.66%. Calcd for $C_{32}H_{52}OZr$: C, 70.65; H, 9.64%.

*Hydrolysis of **5**.* To the complex **5** (1.06 g, 2.0 mmol) in diethyl ether solution (20 ml) was added acetic acid (1 ml), 4 mol dm^{-3} aq HCl or aq H_2SO_4 at 20 °C. After neutralization with aq $NaHCO_3$, the resulting 2-methyl-3-isopropyl-6-hepten-3-ol was isolated by distillation (120 °C/2 mmHg, 1 mmHg≈133.322 Pa). Isolated yield, 85%. When the complex **5** was hydrolyzed with 0.1 mol dm^{-3} aq NaOH, a mixture of 2-methyl-3-isopropyl-6-hepten-3-ol (35%) and 2-methyl-3-isopropyl-5-hepten-3-ol (65%) was obtained. The geometry of the latter could not be determined due to the failure in separation of the respective isomers using a preparative gas chromatograph. Therefore, the ^{1}H-NMR assignment of the latter was made with reference to the spectrum of 2-methyl-3-isopropyl-6-hepten-3-ol obtained by acid hydrolysis.

2-Methyl-3-isopropyl-6-hepten-3-ol: IR (neat) 3490, 3078, 2960, 1640, 1467, 1383, 1095, 992, 968, 950, and 908 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=0.95, 0.97 (d, 12, J=7.0 Hz, CH(C$\underline{H}_3$)$_2$), 1.48—2.25 (m, 7, others), 4.84—5.20 (m, 2, CH=C$\underline{H}_2$), 5.60—6.05 (m, 1, C$\underline{H}$=CH$_2$); ^{13}C-NMR ($CDCl_3$) δ=17.4, 17.6 (CH(C$\underline{H}_3$)$_2$), 28.8 (C$\underline{H}_2$COH), 33.0 (CH$_2$=CHC$\underline{H}_2$), 34.2 (C$\underline{H}$(CH$_3$)$_2$), 77.0 (COH), 114.1 (C$\underline{H}_2$=CH), 139.3 (CH$_2$=C$\underline{H}$); MS (EI, 70 eV) 170 (M$^+$); Found: C, 77.50; H, 13.02%. Calcd for $C_{11}H_{22}O$: C, 77.58; H, 13.02%.

2-Methyl-3-isopropyl-5-hepten-3-ol: ^{1}H-NMR ($CDCl_3$) δ=0.93, 0.95 (d, 12, J=7.0 Hz, CH(C$\underline{H}_3$)$_2$), 1.40—2.50 (m, 8, others), 5.40—5.70 (m, 2, C$\underline{H}$=C$\underline{H}$).

*Hydrolysis of **6**.* When the complex **6** was hydrolyzed with 0.1 mol dm^{-3} aq NaOH in diethyl ether at 20 °C, a mixture of (*Z*)-2,5-dimethyl-3-isopropyl-5-hepten-3-ol (97%) and 2,5-dimethyl-3-isopropyl-6-hepten-3-ol (3%) was obtained in 99% GC yield, while the protolysis with acetic acid gave 2,5-dimethyl-3-isopropyl-6-hepten-3-ol (94% isomeric purity) in 95% yield. The (*Z*)-structure was determined from the NOE measurement (8%) in $CDCl_3$ at 30 °C.

(Z)-2,5-Dimethyl-3-isopropyl-5-hepten-3-ol: IR (neat) 3560, 2960, 1467, 1383, 994, and 813 cm^{-1}. ^{1}H-NMR ($CDCl_3$) δ=0.97, 0.99 (d, 12, J=6.5 Hz, CH(C$\underline{H}_3$)$_2$), 1.32 (s, 1, OH), 1.65 (d, 3, J=7.0 Hz, C$\underline{H}_3$CH=), 1.84 (bs, 3, CH=C(C$\underline{H}_3$)), 1.95 (sept, 2, J=6.5 Hz, C$\underline{H}$(CH$_3$)$_2$), 2.30 (bs, 2, CH=C(CH$_3$)C$\underline{H}_2$), 5.40 (q, 1, J=7.0 Hz, CH$_3$C$\underline{H}$=); ^{13}C-NMR ($CDCl_3$) δ=14.3 (C$\underline{H}_3$CH=), 17.8, 18.5 (CH(C$\underline{H}_3$)$_2$), 26.5 (CH=C(C$\underline{H}_3$)), 34.8 (CH=C(CH$_3$)C$\underline{H}_2$), 35.1 (C$\underline{H}$(CH$_3$)$_2$), 78.4 (COH), 123.5 (CH$_3$C$\underline{H}$=), 133.7 (CH=$\underline{C}$(CH$_3$)); MS (EI, 70 eV) 184 (M$^+$); Found: C, 78.07; H, 13.00%. Calcd for $C_{14}H_{24}O$: C, 78.20; H, 13.11%.

2,5-Dimethyl-3-isopropyl-6-hepten-3-ol: ^{1}H-NMR ($CDCl_3$) δ=0.90—1.05 (m, 15, CH(C$\underline{H}_3$)$_2$ and CH$_2$=CHCH$_2$CHC$\underline{H}_3$), 1.50—2.50 (m, 6, others), 4.80—5.20 (m, 2, CH=C$\underline{H}_2$), 5.55—6.10 (m, 1, C$\underline{H}$=CH$_2$).

*Crystal Structure Determination of **5** and **6**.* *Crystal Data for* [(*C*$_5$*Me*$_5$)$_2$*ZrOC*(*i*-*Pr*)$_2$*CH*$_2$*CH*=*CHCH*$_2$] (**5**): $C_{31}H_{50}OZr$, M=530.0, monoclinic, space group $P2_1/n$, a=11.650(2), b=17.791 (3), c=13.612(2) Å, β=92.20(2)°, U=2819.3(9) Å^3, Z=4, D_c=1.248 g cm^{-3}, μ(Mo $K\alpha$)=4.06 cm^{-1}, F(000)=1136.

Crystal Data for [(*C*$_5$*Me*$_5$)$_2$*ZrOC*(*i*-*Pr*)$_2$*CH*$_2$*CMe*=*CHCH*$_2$] (**6**): $C_{32}H_{52}OZr$, M=544.0, monoclinic, space group $P2_1/n$, a=10.279(3), b=30.177(4), c=9.955(2) Å, β=108.67(2)°, U=2925.3(11) Å^3, Z=4, D_c=1.235 g cm^{-3}, μ(Mo $K\alpha$)=3.93 cm^{-1} F(000)=1168.

Data Collection and Structure Analysis: The X-ray diffraction data were collected on a Rigaku automated four-circle diffractometer with Zr-filtered Mo $K\alpha$ radiation. As the compounds are very air-sensitive, the crystals were sealed in thin-walled glass capillary tubes under argon atmosphere. The crystals with dimensions of 0.50×0.50×0.30 mm for **5** and 0.45×0.40×0.35 mm for **6** were used for the data measurements. The integrated intensities were measured by the θ-2θ scan technique with background countings at each end of the scan range for 5 s. The total numbers of reflections measured were 6478 for **5** (2θ up to 55°) and 5134 for **6** (2θ up to 50°), among which non-zero reflections are 4308 and 3526, respectively. Three monitor reflections were measured for each block of 61 reflections to check for radiation damage and for any change in orientations of the crystals. No radiation damage of the crystals was found. The measured intensities were corrected for Lorentz and polarization effects but not for absorption, because of the relatively small absorption effects of these compounds for Mo $K\alpha$ radiation.

The crystal structures were solved by the conventional heavy atom method and refined by the block-diagonal least-squares (*HBLS*-V).[8] The atomic scattering factors were taken from the International Tables for X-Ray Crystallography.[9] Hydrogen atoms were searched for on the difference Fourier maps calculated after the anisotropic refinements of non-hydrogen atoms. Methyl hydrogen atoms, however, could not be located on the maps and were excluded in the final stage of refinements. The weighting scheme applied was $w=[\sigma(F_o)^2+a|F_o|+b|F_o|^2]^{-1}$ for non-zero reflections and $w=c$ for zero reflections, respectively. The final R indices defined by $R=\sum(|F_o|-|F_c|)/\sum|F_o|$ were 0.111 (non-zero reflections) and 0.219 (all reflections) for **5**, and 0.104 and 0.202 for **6**, respectively. The weighted R indices defined by $R_w=[\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2]^{1/2}$were 0.160 for **5** with the weighting parameters of a=0.368, b=0.00002, and c=0.014, and 0.094 for **6** with a=0.503, b=−0.002, and c=0.011, respectively. The

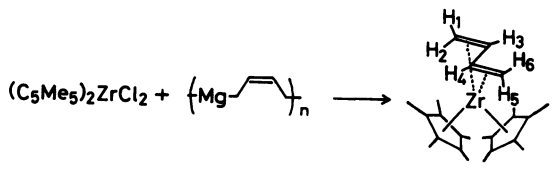
Results and Discussion

NMR Studies on the $(C_5Me_5)_2Zr$(diene) Complexes. Most mononuclear transition metal complexes of acyclic or cyclic dienes assume the *s-cis*-η^4-diene coordination. However, we and Erker *et al.* recently found by X-ray analysis that the *s-trans* coordination is possible for 1,4-diphenyl-1,3-butadiene[11] and butadiene[3,4] when these are coordinated to $(C_5H_5)_2Zr$ fragments. More recently, preparation of the corresponding hafnium-*s-trans*-butadiene complex has been reported.[12] A photochemically generated $(C_5H_5)_2Zr$(*s-trans*-butadiene) complex is thermally unstable and is readily converted to the *s-cis*-diene complex at ambient temperature.[3] Seeking for preparation of thermally stable *s-trans*-butadiene complexes, we have found that the 1 : 1 reaction of $(C_5Me_5)_2ZrCl_2$ with 2-butene-1,4-diylmagnesium predominantly gave a pure *s-trans* isomer (>99%), $(C_5Me_5)_2Zr$(*s-trans*-butadiene) (**1**), in good yield (Eq. 2).



(2)

1

The *s-trans* structure was confirmed by iterative computer simulation of the ^{1}H-NMR spectrum (Table 2). The magnitude of the proton-proton coupling constant, 16.0 Hz for $J_{3,4}$, clearly shows that the complex **1** has the *s-trans* structure. This value is consistent with the values of 15—16 Hz observed for the *s-trans* isomer of $(C_5H_5)_2Zr$(butadiene) and $(C_5H_5)_2Zr$(1,4-diphenyl-1,3-butadiene).[5] The coupling constant of $J_{3,4}$ for the *s-cis* isomer is known to be 8.0 Hz for $(C_5H_5)_2$-Zr(*s-cis*-butadiene) (**3-*s-cis***). Chemical shift values for **1** are also comparable with those for $(C_5H_5)_2Zr$(butadiene) (**3-*s-trans***).[5]

The corresponding isoprene complex, $(C_5Me_5)_2Zr$-(isoprene) **2**, was prepared in the same way (Eq. 3) and the geometry was determined to be *s-cis* based upon the ^{1}H-NMR chemical shift values (Table 2). It is noteworthy that the spectrum of **2** was not changed by

†† Tables of observed and calculated structure factors and anisotropic thermal parameters are deposited as Document No. 8348 at the Chemical Society of Japan.

TABLE 2. ^{1}H-NMR PARAMETERS FOR COMPLEXES **1** AND **2** OBTAINED BY COMPUTER SIMULATION[a)]

Complex	Chemical shift, ν/ppm							
	H_1	H_2	H_3	H_4	H_5	H_6	ν_{CH_3}[b)]	ν_{CH_3}[c)]
1	2.75	1.21	2.14	2.14	2.75	1.21	—	1.69
2	0.87	0.87	5.74	—	0.75	0.75	1.92	1.85

Complex	Coupling constant, J/Hz										
	$J_{1,2}$	$J_{1,3}$	$J_{2,3}$	$J_{3,4}$	$J_{4,5}$	$J_{4,6}$	$J_{5,6}$	$J_{1,5}$	$J_{2,6}$	$J_{3,5}$	$J_{3,6}$
1	−4.2	7.3	16.2	16.0	7.3	16.2	−4.2	1.0	0.2	−0.5	−1.2
2	−5.0	4.8	4.8	—	—	—	−5.0	0.6	0.6	−0.8	−0.8

a) Spectra were observed at 100 MHz in toluene-d_8 at 30 °C. Chemical shifts were calibrated by using the internal benzene peak, assumed to be 7.20 ppm. The numbering system follows that shown in Eqs. 2 and 3. b) Methyl proton signals of isoprene. c) Methyl proton signals of C_5Me_5 group.

TABLE 3. ^{13}C-NMR CHEMICAL SHIFT VALUES (ν/ppm) AND ^{13}C–^{1}H COUPLING CONSTANTS (IN PARENTHESES, J/Hz) FOR **1** AND **3**[a)]

Complex	Temp/°C	$C_1(C_4)$	$C_2(C_3)$	Ligand	$\Delta(C_2-C_1)$
1	30	64.95 (146.0)	100.71 (143.9)	10.45 (125.7) [Me] 108.64 [ring]	35.76
1	−50	64.54 (150.5)	100.57 (148.9)	10.37 (125.7) [Me] 108.05 [ring]	36.03
3-s-trans	30	57.72 (145.3)[b)] (156.3)[c)]	94.56 (148.9)	100.79 (172.1)	36.84
3-s-cis	30	48.35 (144.7)	110.86 (153.8)	98.08 (170.9)	62.52
3-s-trans	−50	57.66	94.09	97.92	36.73
3-s-cis	−50	48.29	110.38	102.41	62.09

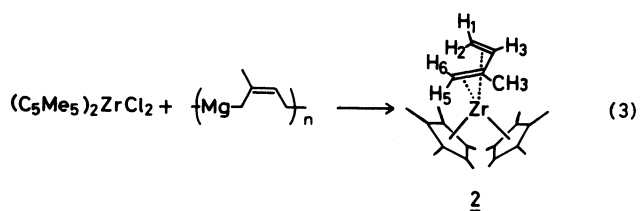
a) Spectra were recorded at 25.2 MHz in toluene-d_8 and chemical shifts were calibrated by using internal toluene peak (CH_3-proton signal), assumed to be 19.20 ppm. b) Coupling constant between ^{13}C at $C_1(C_4)$ and terminal proton at the *syn*-position with respect to the proton at $C_2(C_3)$. c) Coupling constant for ^{13}C–^{1}H at *anti*-position (see Ref. 22 for the assignment).

TABLE 4. ^{13}C-NMR CHEMICAL SHIFT VALUES AND ^{13}C–^{1}H COUPLING CONSTANTS (IN PARENTHESES) FOR **2** AND **4**[a)]

Complex	Temp °C	C_1	C_2	C_3	C_4	C_5[d)]	Ligand	$\Delta(C_3-C_4)$
2	30	45.96 (123.9)	136.65	124.68 (148.9)	47.37 (123.0)	30.68 (127.0)	10.04 (126.1) [Me] 115.85 [ring]	77.31
2	−50	44.82 (123.3)	136.76	124.62 (141.6)	46.29 (122.1)	31.06 (123.3)	9.94 (126.1) [Me] 115.36 [ring]	78.33
4	30	46.67 (143.4)	122.19	109.83 (156.3)	52.19 (140.4)	27.81 (125.7)	101.22 (170.9)	57.64
4	−50	46.45 (157.5)[b)] (128.2)[c)]	121.48	109.51 (153.8)	51.87 (157.5)[b)] (128.2)[c)]	27.81 (125.7)	99.11 (172.1) 102.68 (170.9)	57.64

a) Recorded at 25.2 MHz in toluene-d_8. Chemical shift values are expressed by ppm and coupling constants by Hz. Assignments of each atom were made with reference to the ^{1}H NMR chemical shift values (see. Ref. 5a). b) Coupling constant for ^{13}C–^{1}H at the *syn*-position with respect to the proton at C_2 or C_3 atoms (see Ref. 22). c) Coupling constant for ^{13}C–^{1}H at the *anti*-position with respect to the proton at C_2 or C_3 atoms. d) Methyl carbon of isoprene.

lowering the temperature from 50 °C to −70 °C while $(C_5H_5)_2Zr$(isoprene) **4** showed the limiting η^4-diene structure when it was cooled to −30 °C, as reported previously.[5)] This behavior indicates enhanced fluxionality of **2** compared to that of **4**.



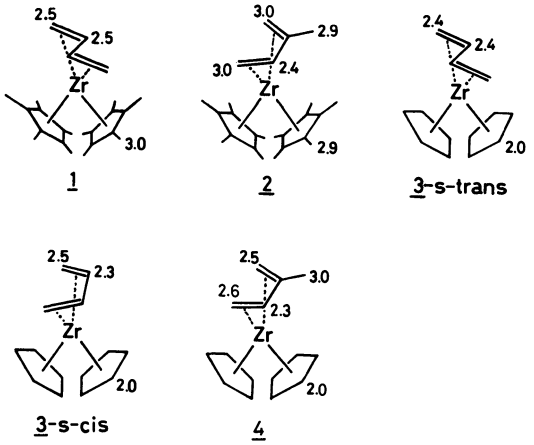
(3)

2

The geometry of **1**, **2**, ***3-s-cis***, ***3-s-trans*** and **4** was also confirmed by the ^{13}C-NMR spectra. Chemical shift values and the ^{13}C–^{1}H coupling constants for **1**, ***3-s-cis*** and ***3-s-trans*** are given in Table 3 and those for **2** and **4** are given in Table 4. It is apparent from these data that the chemical shift difference, $\Delta(C_2-C_1)$, between terminal carbons $C_1(C_4)$ and central carbon atoms $C_2(C_3)$ is rather small (*ca.* 36 ppm) for the *s-trans*-diene complexes, **1** and ***3-s-trans***, while the corresponding difference, $\Delta(C_3-C_4)$, for the *s-cis*-diene complexes **2**, **4** and $\Delta(C_2-C_1)$ for ***3-s-cis*** is significantly larger (57.6—

77.3 ppm) regardless of temperature. Thus, geometries are readily determined from chemical shift differences. It is important to note here that the ^{13}C chemical shift values of **4** at 30 °C for the fluxional diene molecule are essentially the same as the values for the η^4-coordinated diene observed at −50 °C. This result suggests that most of the coordinated isoprene remains η^4-bonded even when some of it is flipping. Such information could not be obtained from the ^1H-NMR spectrum since the proton signals of **4** coalesce at 0——30 °C.

The ^{13}C–^1H coupling constant offers important information on the extent of hybridization in the diene carbons. Based upon Newton's semiempirical rule,[13] it is possible to calculate the *s*-% of carbon atoms of the dienes and hence the hybridization. The hybridization approximated by $n=(1-s)/s$ for sp^n is shown below. The sp^3 character of CH_2 carbon at isoprene termini of **2** is higher than that of **4**. Thus, greater contribution of the zirconacyclopent-3-ene structure was inferred for **2** when compared with that of **4**. This will account for the higher fluxionality of **2**. The sp^3 character of carbon atoms at *s-trans*-diene termini of **1** is smaller than that of the terminal atom of the *s-cis*-diene complex **2**, indicating that the Zr–C_1 and Zr–C_4 σ-bonding of **1** is less than that of **2**. The sp^n parameter for $C_1(C_4)$ atoms of **3-*s*-*trans*** and **4** (at −50 °C) was obtained from the avaraged coupling constant values of ^{13}C–^1H(*syn*) and ^{13}C–^1H(*anti*). See footnote in Tables 3 and 4 and Ref. 22 for the assignment.



*Molecular Structures of **5** and **6**.* Single crystals of 1,2-oxazirconacyclohept-4-enes (**5** and **6**) were prepared by the 1 : 1 reaction of $(C_5Me_5)_2Zr$(*s-trans*-butadiene) **1** or $(C_5Me_5)_2Zr$(*s-cis*-isoprene) **2** with 2,4-dimethyl-3-pentanone at 30 °C in benzene to define the stereochemistry of the insertion reaction in terms of X-ray crystal structure analysis.

The molecular structures of **5** and **6** determined in this work are shown in Figs. 1 and 2 which give the *ORTEP* drawings[14] together with the atomic numberings. The bond distances and angles are listed in Table 5. The molecular structure of **5** shows that the 2,4-dimethyl-3-pentanone inserts regioselectively into the bond between zirconium and one of terminal carbon atoms of butadiene [Zr–C(4) bond]. The molecular structure of **6** shows that the insertion of ketone with

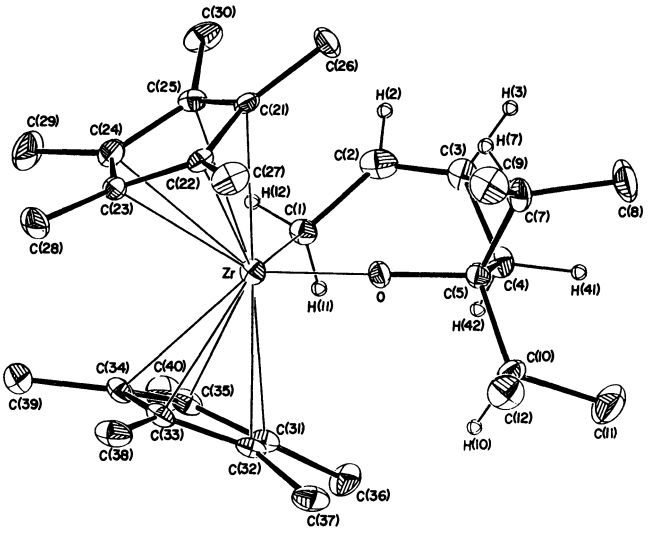


Fig. 1. Molecular structure of $[(C_5Me_5)_2ZrOC(i\text{-}Pr)_2\text{-}CH_2CH{=}CHCH_2]$ (**5**) with the numbering scheme of the atoms. Thermal ellipsoids for non-hydrogen atoms are drawn at the 20% probability level. Hydrogen atoms are shown as the spheres with arbitrary temperature factor of 1.0 Å².

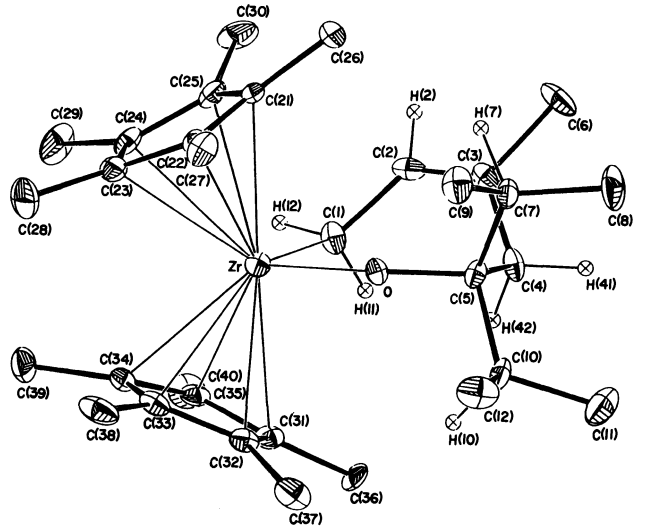

Fig. 2. Molecular structure of $[(C_5Me_5)_2ZrOC(i\text{-}Pr)_2\text{-}CH_2CMe{=}CHCH_2]$ (**6**) with the numbering scheme of the atoms. Drawing parameters are same as those for Fig. 1.

$(C_5Me_5)_2Zr$(isoprene) occurred into the bond between zirconium and C_1 atom of isoprene [C(4) atom in Fig. 2]. Thus, the insertion occurred regioselectively into the sterically hindered Zr–C(4) bond rather than into the less hindered Zr–C(1) bond. These molecular structures coincided with the oxametallacycloheptene structures determined by the mass and ^1H-NMR spectra (see Experimental) and the structures of the base hydrolysis products.

The overall geometry of complexes **5** and **6** is essentially the same. The zirconium atom is coordinated with two C_5Me_5 ligands and bonded with the C(1) atom of the diene part and the oxygen atom of the ketone part

in a pseudo-tetrahedral manner. The Zr–C(1) lengths, 2.294(10) Å in **5** and 2.311(14) Å in **6**, are similar to the Zr–C(alkyl) distances in $(\eta^5\text{-}C_9H_7)_2Zr(CH_3)_2$ [2.255(5) Å],[15] $(\eta^5\text{-}C_5H_5)_2Zr(CH_2SiMe_3)_2$ [2.279(4) Å],[16] and $(\eta^5\text{-}C_5H_5)_2Zr(CH_2CMe_3)_2$ [2.288(10) Å],[16] and also to the Zr–C (terminal) distance in $(\eta^5\text{-}C_5H_5)_2$-Zr(2,3-dimethylbutadiene) [2.300 Å].[3] The Zr–O distances are 1.961(7) and 1.964(8) Å for **5** and **6**, respectively. These distances are slightly shorter than the expected Zr–O single bond distance estimated from the sum of the covalent radii for zirconium (1.45—1.48 Å) and oxygen (0.66 Å). The Zr–O–C(5) angles have relatively large values of 155.2(7)° for **5** and 156.5(8)° for **6**, respectively. The C(2)–C(3) bond distances, 1.313(17) Å in **5** and 1.324(20) Å in **6**, show that these bonds are the localized carbon–carbon double bonds, whose standard value is 1.337±6 Å.[17] The interatomic distances between zirconium and C(2) and/or C(3) atoms [Zr–C(2): 3.144(13) Å in **5**, 3.177(14) Å in **6**; Zr–C(3): 3.702(11) Å in **5**, 3.729(14) Å in **6**] indicate that there is no direct interaction between zirconium and the C(2)–C(3) double bond. Thus, the oxametallacycloheptene part in these complexes is described as having the 1,2-oxazirconacyclohept-4-ene structure.

The characteristic views of the molecular structure of **6** are shown in Figs. 3 and 4. The corresponding views of **5** are essentially the same as those of **6** in these Figures. The most interesting features in the oxametallacycloheptene part in these complexes are the conformations of C(1)–C(2)–C(3)–C(4) moieties, which correspond to the 1,3-dienes in the original complexes into which the ketone inserts. The torsional angles about C(2)–C(3) double bonds, C(1)–C(2)–C(3)–C(4), are 0.0° in **5** and 2.3° in **6**, respectively. Thus, the C(1) to C(4) moiety takes the *s-cis* structure in both complexes. The oxametallacycloheptene parts in **5** and **6** are divided into two planar moieties, the plane of diene moiety [C(1) to C(4), including also C(6) in **6**] and the approximate plane defined by C(1), Zr, O, C(5), and C(4) with the maximum atomic deviations from the plane of 0.088 Å in **5** and 0.051 Å in **6**, the dihedral angles being 62.7° in **5** and 61.1° in **6**, respectively. All the methyl groups in 2,4-dimethyl-3-pentanone moieties locate away from the oxametallacycloheptene part to release the possible nonbonded interatomic repulsions in both complexes.

The mean distances between zirconium and carbon atoms of C_5Me_5 ligands are 2.623 Å in **5** and 2.621 Å in **6**, and those between zirconium and the centroids of C_5Me_5 ligands [d_1 and d_2 in Fig. 4] are 2.331 Å in both complexes. These distances are slightly longer than the corresponding distances in $(\eta^5\text{-}C_5H_5)_2ZrCl_2$[18] of 2.522(2) and 2.20 Å or those in $(\eta^5\text{-}C_5H_5)_2Zr(CHPh_2)_2$[16] of 2.513(15) and 2.22 Å. The CCP(1)–Zr–CCP(2) [CCP(1) and CCP(2), which are the centroids of C(21) to C(25) and C(31) to C(35)] angles [θ_1 in Fig. 4], 129.0° in **5** and 129.4° in **6**, are similar to those in $(\eta^5\text{-}C_5H_5)_2Zr(CHPh_2)_2$[19] [128.4°], $(\eta^5\text{-}C_5H_5)_2ZrF_2$[20] [127.8°], and $(\eta^5\text{-}C_5H_5)_2Zr$(2,3-dimethylbutadiene)[3] [124°]. Figure 3 shows that the two C_5Me_5 ligands are in a staggered conformation so as to release the nonbonded repulsion between the methyl groups of facing C_5Me_5 ligands. However, all the methyl groups in C_5Me_5 ligands in **5** and **6** bend back from the zirconium atom with the angular deviations from the C_5 plane [θ_3 or θ_4 in Fig. 4] of 3.7 to 16.1° [av. 10.2°] in CP(1) [ring defined by C(21) to C(25)] and of 7.2 to 15.2° [av. 10.2°] in CP(2) [ring defined by C(31) to C(35)] for **5**, and of 6.1 to 14.6° [av. 9.9°] in CP(1) and of 5.9 to 15.7° [av. 9.6°] in CP(2) for **6**, respectively. Some short contacts are found between these methyl groups, resulting in the large angular deviations from the C_5

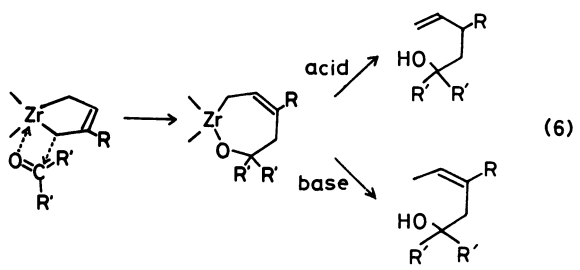
(5)

rings: C(28)···C(38) 3.288(20) Å, θ_3 16.1° [C(28)], θ_4 12.2° [C(38)] in **5**, and 3.329(25) Å, θ_3 14.6° [C(28)], θ_4 8.1° [C(38)] in **6**; C(29)···C(39) 3.344(23) Å, θ_3 9.5° [C(29)], θ_4 15.2° [C(39)] in **5**, and 3.327(28) Å, θ_3 7.3° [C(29)], θ_4 15.7° [C(39)] in **6**. Some short contacts are also found between the methyl groups in the C_5Me_5 ligands and the oxametallacycloheptene part; C(1)··· C(30) 3.262(17) Å in **5** and 3.273(22) Å in **6**; C(9)··· C(26) 3.588(18) Å in **5** and 3.635(23) Å in **6**; and C(12)···C(37) 3.372(20) Å in **5** and 3.374(26) Å in **6**. The shortest nonbonded contact of the methyl group on C(3) in **6** is the C(6)···C(7) of 3.392(22) Å.

The comparison between the molecular structures of **5** and **6** showed that these complexes take essentially the same structure in spite of the different coordination modes of the 1,3-diene in $(\eta^5\text{-}C_5Me_5)_2Zr$(butadiene) and $(\eta^5\text{-}C_5Me_5)_2Zr$(isoprene).



Crystal Structures of ***5*** *and* ***6***. The crystal structures of **5** and **6** are shown in Figs. 5 and 6, respectively. No intermolecular nonbonded contact shorter than 3.5 Å is found between the non-hydrogen atoms in either crystal structure.

Pathways for Regio- and Stereoselective Reaction of Ketones with s-cis *and* s-trans *Zirconium–Diene Complexes*. It is evident from the X-ray work that both the *s-cis*-diene and the *s-trans*-diene complexes gave oxametallacycloheptenes with (*Z*)-structure. Thus, the insertion of ketone caused the conversion of butadiene from *s-trans* to *s-cis* and the retention of isoprene in *s-cis* structure The interconversion occurs presumably *via* 1,2-η^2-diene metal species with 16e configuration and the process *via* 1,4-η^2-diene metal species (16e) can be ruled out (Eq. 5).

Since the Zr-η^4-diene complex has 18e configuration and leaves no vacant coordination site, the insertion of 2,4-dimethyl-3-pentanone may take place after its conversion to zirconacyclopent-3-ene structure with 16e configuration. Direct conversion of η^2-diene species to metallacyclopentene can not be ruled out when a ketone is present in the system. An MO calculation predicts that wedged $(C_5H_5)_2M$ fragment has three in-plane orbitals of d-character.[21] The $2a_1$ and b_2 orbitals are used for forming the zircona ring and the remaining vacant orbital ($1a_1$) may be used for the coordination of the ketone. Therefore, a zircona ring coordinated through oxygen atom of carbonyl group may be postulated as the intermediate. Insertion of ketone will then take place *via* four-centered transition state (Eq. 6). Hydrolysis of **6** with protic acid (aq HCl) gave 2,5-dimethyl-3-isopropyl-6-hepten-3-ol but hydrolysis with bases such as aq NaOH and Et_2NH gave (*Z*)-2,5-dimethyl-3-isopropyl-5-hepten-3-ol quantatively, in line with the X-ray structure. The high regioselectivity observed in the formation of **6** is explained by the inductive effect of the methyl group of isoprene, which causes the higher negative charge on the C_1 atom.

Other ketones, such as 2-propanone or 3-pentanone, and aldehydes such as ethanal or propanal, also react with **1**—**4** in the same fashion (these will be published in a separate paper). Therefore, the present reaction mechanism seems applicable in general for these reactions.

Support of this study by Grant-in-Aid for Scientific Research (No. 57550500) and Special Project Research (No. 57218014) from the Ministry of Education, Science and Culture, is acknowledged.

Racemization of Optically Active Amino Acid Salts and an Approach to Asymmetric Transformation of DL-Amino Acids

Chikara HONGO,* Ryuzo YOSHIOKA, Masanori TOHYAMA, Shigeki YAMADA,† and Ichiro CHIBATA††

Research Laboratory of Applied Biochemistry, Tanabe Seiyaku Co., Ltd., 16-89, Kashima-3-chome, Yodogawa-ku, Osaka 532

(Received June 13, 1983)

In connection with optical resolution of DL-amino acids, the racemization process of optically active amino acid salts was studied. A wide variety of salts of optically active amino acids with sulfonic acids or mineral acids could be racemized by heating in a medium of acetic acid at 80—100 °C for 1 h in the presence of 0.1 molar equivalents of an aldehyde and free DL-amino acid. From the reaction mixture, the racemized DL-amino acid salts were recovered in high yield (86—92%) and in high purity. An asymmetric transformation between two enantiomers of amino acid salt was attempted by the combination of preferential crystallization of the desired enantiomer and racemization of the antipode in the liquid phase. DL-Alanine *p*-chlorobenzenesulfonate was partially converted to L-isomer (yield 16%, optically purity 97%). Another approach was carried out by transformation between two diastereoisomeric salts. The combination of selective precipitation of less soluble diastereoisomeric salt and epimerization of soluble diastereoisomeric salt allowed DL-phenylglycine *d*-camphor-10-sulfonate to be partially converted to D-phenylglycine *d*-camphor-10-sulfonate (yield 68%, optical purity 96%).

Because of our interest in practical production of optically active amino acids, we have been studying the optical resolution of DL-amino acids and the racemization of the unwanted enantiomer obtained by the optical resolution process. A previous paper[1] proposed a new and facile method: Racemizing optically active amino acids in acetic acid solution in the presence of an aldehyde.

Now we extend this racemization method to the salts of optically active amino acids. The optical resolution is usually carried out in the form of salts of amino acids and the unwanted enantiomers are also obtained in the form of salts. For instance, chemical resolution is achieved by the formation of the diastereoisomeric salts, and preferential crystallization procedure can be applied to many amino acids by converting them to suitable salts such as DL-alanine *p*-chlorobenzenesulfonate,[2] DL-serine *m*-xylene-4-sulfonate,[2] DL-tryptophan *p*-phenolsulfonate,[3] DL-6-chlorotryptophan methanesulfonate,[3] and DL-*p*-hydroxyphenylglycine *o*-toluenesulfonate,[4] *etc.* If the racemization of the unwanted enantiomers can be easily accomplished in the form of the salts, the racemized DL-amino acid salts themselves can be advantageously reused as the starting material for the optical resolution. However, the racemization of the salts of amino acids is generally more difficult than that of free amino acids, although only a few salts[2,4] of optically active amino acids could be racemized by heating in water at a much higher temperature under high pressure. In this work, we could find a practical method for the racemization of various amino acid salts.

We attempted to apply this racemization method to an asymmetric transformation[5] of DL-amino acid salts by a simultaneous combination of the optical resolution and the racemization. The present paper describes the racemization of the salts of various amino acids and an approach to an asymmetric transformation of DL-phenylglycine and DL-alanine by using the present racemization method.

When the salts of L-amino acids were heated at 100 °C for 1 h in a medium of acetic acid in a manner similar to the racemization of free amino acids which is described in the previous report,[1] we found that the racemization of various amino acid salts was also accelerated by the addition of 0.1 molar equivalent of salicylaldehyde, but the rate of racemization was smaller than that in the case of free amino acids. When 0.1 molar equivalent

5-Nitrosalicylaldehyde	14	76[c)]	42	86[c)]
Furfural	23	91[b)]	74	100[b,c)]

a) The reactions were carried out at 100 °C for 1 h in acetic acid. The amounts of aldehyde and DL-amino acid used were 0.1 molar equivalents. b) A 0.2 molar equivalent of DL-amino acid was used. c) A ninhydrin positive spot of degradation product was detected by TLC of the reaction mixture.

of free DL-amino acid corresponding to the L-amino acid moiety of the salt was added into the reaction system together with salicylaldehyde, the racemization of the amino acid salts was found to be greatly accelerated. These results are shown in Table 1. The content of amino acid in the reaction mixtures was confirmed to be almost 100% without significant decomposition. The racemization mechanism of amino acid salts seems to be the same as that of free amino acids. Namely, a part of amino acid moiety of optically active amino acid salt leads to the free state by adding free DL-amino acid and the free optically active amino acid is racemized by an imine formation from the amino acid and aldehyde, as described in our previous report. In the case of L-lysine *p*-aminobenzenesulfonate, the racemization was accelerated by only the addition of salicylaldehyde and the addition of free DL-amino acid was not effective. This seems to be because the α-amino group in lysine *p*-aminobenzenesulfonate exists already in the free state (uncharged form) predominantly without the addition of free amino acid. The effect of the kind of aldehyde on the racemization of L-alanine benzenesulfonate and L-methionine hydrochloride was examined at 100 °C for 1 h in glacial acetic acid. The results are shown in Table 2. Various aldehydes, such as aliphatic or aromatic aldehydes, accelerated the racemization of amino acid salts under the coexistence of free DL-amino acid. The effect of the amount of salicylaldehyde on the racemization of L-alanine benzenesulfonate and L-methionine hydrochloride was examined at 100 °C for 1 h under the coexistence of 0.2 molar equivalent of DL-alanine or DL-methionine in glacial acetic acid. The effect of the amount of free DL-leucine on the racemization of L-leucine benzenesulfonate was examined at 100 °C for 30 min or 3 h in the presence of 0.1 molar equivalent of salicylaldehyde in glacial acetic acid. The results are shown in Tables 3 and 4. Salicylaldehyde and free DL-leucine exerted their effects in the use of 0.001 molar equivalent and gave a sufficient racemization degree in the use of 0.05 molar equivalent.

Table 3. Effect of amount of salicylaldehyde[a)]

Molar equivalent of salicylaldehyde	Racemization degree/%	
	L-Alanine·BS	L-Methionine·HCl
0	0	9
0.001	13	15
0.005	48	53
0.01	70	71
0.05	100	100
0.1	100	100

a) The reactions were carried out in the presence of 0.2 molar equivalent of DL-amino acid at 100 °C for 1 h.

Table 4. Effect of amount of DL-leucine on the racemization of L-leucine benzenesulfonate[a)]

Molar equivalent of DL-leucine	Racemization degree/%	
	30 min	3 h
0	2	27
0.001	4	34
0.005	6	43

a) The reactions were carried out at 100 °C for 2 h. b) BS, Benzenesulfonate; pTS, *p*-toluenesulfonate; pCBS, *p*-chlorobenzenesulfonate; oTS, *o*-toluenesulfonate. c) A 3 g amount of L-amino acid salt was used throughout. d) SA, Salicylaldehyde. e) Free DL-amino acid corresponding to L-amino acid moiety of the salt. f) No impurity was detected by TLC. g) Based on L-amino acid salt plus coexisting DL-amino acid. h) AcOH/water: 95/5(v/v). i) A 0.2 molar equivalent of SA was used. j) A 0.4 molar equivalent of DL-*p*-hydroxyphenylglycine was used.

obtained in high yield (86—92%) and in such high purity that no by-product was detected by thin-layer chromatography. The racemization method presented here seems to be a simple and practical way.

Ordinarily, the optical resolution of DL-amino acids is carried out under the conditions in which the amino acid is optically stable. On the contrary, we carried out the optical resolution of DL-amino acid under the racemization conditions described above in order to achieve an asymmetric transformation by a combination of optical resolution and simultaneous racemization (or epimerization). This type of asymmetric transformation is interesting because of its practical applications.[6-13]

An asymmetric transformation was carried out between two enantiomers by a combination of preferential crystallization and racemization. DL-Alanine can be resolved by preferential crystallization procedure in the form of *p*-chlorobenzenesulfonate.[2] This resolution method was combined with the present racemization method. Namely, a supersaturated solution consisting of DL-alanine *p*-chlorobenzenesulfonate (45.0 g), DL-alanine (2.0 g), salicylaldehyde (1.0 g), and glacial acetic acid (50 ml) was seeded with the crystals of L-alanine *p*-chlorobenzenesulfonate (0.5 g) and was gently stirred at 100 °C for 90 min. The precipitated crystals were quickly collected to give L-alanine *p*-chlorobenzenesulfonate (8.0 g), optical purity 97%, yield 16.7% (based on starting DL-salt). The mother liquor did not show any optical rotation. The results show that the preferential crystallization of L-alanine *p*-chlorobenzenesulfonate and the racemization of unseeded D-alanine *p*-chlorobenzenesulfonate took place at the same time, and that 7.3 g of L-alanine *p*-chlorobenzenesulfonate was transformed from DL-alanine *p*-chlorobenzenesulfonate existing as a supersaturation state.

Another approach was carried out by transformation between two diastereoisomeric salts. It is known that DL-phenylglycine can be chemically resolved by *d*-camphor-10-sulfonic acid as a resolving agent.[14] This resolution method was combined with the present racemization method. Namely, a mixture of DL-phenylglycine (15.1 g), *d*-camphor-10-sulfonic acid (22.1 g) and salicylaldehyde (0.24 g) was stirred in glacial acetic acid (70 ml) at 80 °C for 4 h. The precipitated crystals were collected to give D-phenylglycine *d*-camphor-10-sulfonate (26.1 g), optical purity 95.9%, yield 68.1% (based on DL-phenylglycine). The result shows that the selective precipitation of the less soluble D-phenylglycine *d*-camphor-10-sulfonate and the epimerization of the soluble L-phenylglycine *d*-camphor-10-sulfonate took place at the same time.

The proposed racemization method and asymmetric transformation of amino acids seem to be very promising for industrial applications. The asymmetric transformation is under investigation.

Experimental

Materials and Analyses. Analytical standard grade amino acids manufactured by our company, Tanabe Seiyaku Co., Ltd., were used. All aldehydes and other chemicals were obtained from Tokyo Kasei Kogyo Co., Ltd. The salts of L-amino acids were prepared as described in previous reports.[2-4] Optical rotations were measured with a Perkin-Elmer 141 automatic polarimeter. Decomposition of amino acids was checked by thin-layer chromatography (solvent system: 1-butanol–acetic acid–water, 4: 1: 1, vol/vol/vol; plate: Merck's precoated Kieselgel $60F_{254}$). An accurate quantitative determination of amino acids was made by a Hitachi KLA-3B amino acid analyzer (resin, Hitachi Custom Resin; eluting buffer, citrate buffer [pH 3.25]; column temperature, 55 °C).

Procedure of Racemization. Unless otherwise noted, the racemization was carried out as follows. A mixture of L-amino acid salt (0.1 g), 0.1 molar equivalent of aldehyde (3—8 μl), 0.1 molar equivalent of DL-amino acid (3—8 mg) corresponding to the L-amino acid moiety of the salt, and glacial acetic acid (3.0 ml) was heated in a sealed tube at 100 °C for 1 h and was shaken occasionally. The conditions were varied according to each experimental design. After the reaction, the reaction mixture was diluted with 1 M hydrochloric acid (5 ml). Optical rotation of the solution was measured. The racemization degree was calculated as follows:

$$\frac{\text{Initial optical rotation} - \text{final optical rotation}}{\text{initial optical rotation}} \times 100.$$

The reaction mixtures were checked by thin-layer chromatography or amino acid analyzer in order to determine whether or not the simultaneous decomposition of amino acid had occurred.

Preparation of DL-Amino Acid Salts by Racemization. A mixture of L-amino acid salt (3.0 g), 0.1 molar equivalent of salicylaldehyde (0.11 to 0.22 g, 0.2 molar equivalent for L-*p*-

hydroxyphenylglycine *o*-toluenesulfonate), 0.1 molar equivalent of free DL-amino acid (0.10 to 0.59 g, 0.4 molar equivalent for L-*p*-hydroxyphenylglycine *o*-toluenesulfonate) corresponding to the L-amino acid moiety of the salt, and acetic acid (6 ml, 50 ml for L-*p*-hydroxyphenylglycine *o*-toluenesulfonate) was stirred at 100 °C for 2 h. After the reaction, 0.1 molar equivalent of sulfonic acid or hydrochloric acid corresponding to the acid moiety of the salt was added in the reaction mixture in order to recover the free DL-amino acid existing in the reaction mixture as the corresponding amino acid salt. Then the reaction mixture was concentrated to dryness. The residual crystals were suspended in acetone (5—15 ml). The precipitated crystals were collected, washed with acetone, and air-dried at 55 °C. The L-amino acid salts used were L-alanine benzenesulfonate, L-alanine *p*-toluenesulfonate, L-leucine benzenesulfonate, L-methionine *p*-chlorobenzenesulfonate, and L-*p*-hydroxyphenylglycine *o*-toluenesulfonate. The yields and the purities of the separated amino acid salts are shown in Table 5.

Asymmetric Transformation of DL-*Alanine.* DL-Alanine *p*-chlorobenzenesulfonate (45.0 g), DL-alanine (2.0 g), and salicylaldehyde (1.0 g) were dissolved in glacial acetic acid (50 ml) at 120 °C. The solution was maintained at 100 °C, was seeded with finely pulverized crystals of L-alanine *p*-chlorobenzenesulfonate (0.5 g), and was gently stirred. During the reaction, the crystal growth of seeded L-isomer was observed. After 90 min, the precipitated crystals were quickly collected by filtration, washed with a small amount of glacial acetic acid, and dried to give L-alanine *p*-chlorobenzenesulfonate (8.0 g), $[\alpha]_D^{25}$ +3.5° (*c*=2, water), optical purity 97%, yield 16.7% (based on starting DL-salt). After the separation of the first crop, the second crop was crystallized by adding water (15 ml) and by stirring at room temperature and was collected by filtration to give DL-alanine *p*-chlorobenzenesulfonate (12.2 g), $[\alpha]_D^{25}$ 0.0° (*c*=2, water). The mother liquor did not show any optical rotation. Therefore, we subtract 0.5 g of seeded L-isomer from the net weight of L-isomer obtained above, and find that 7.3 g of L-alanine *p*-chlorobenzenesulfonate was transformed from DL-alanine *p*-chlorobenzenesulfonate existing as a supersaturation state.

Asymmetric Transformation of DL-*Phenylglycine.* DL-Phenylglycine (15.1 g, 100 mmol), *d*-camphor-10-sulfonic acid (22.1 g, 95 mmol), and salicylaldehyde (0.24 g, 2 mmol) were added into glacial acetic acid (70 ml). The mixture was stirred at 80 °C for 4 h. The reaction system was heterogeneous during the reaction. To the reaction mixture, *d*-camphor-10-sulfonic acid (1.1 g, 5 mmol) was added and the mixture was stirred at 20 °C for 2 h. The precipitated crystals were collected by filtration and dried to give D-phenylglycine *d*-camphor-10-sulfonate (26.1 g), $[\alpha]_D^{25}$ −47.1° (*c*=2, *N*-HCl), optical purity 95.9% (based on D-*d* salt $[\alpha]_D^{25}$ −49.7° (*c*=2, *N*-HCl) and DL-*d* salt $[\alpha]_D^{25}$ +13.6° (*c*=2, *N*-HCl)), yield 68.1% (136.2% based on D-form contained in DL-phenylglycine *d*-camphor-10-sulfonate).

D-Phenylglycine *d*-camphor-10-sulfonate (25.0 g) obtained above was recrystallized from water (120 ml) containing *d*-camphor-10-sulfonic acid (0.5 g) to give optically pure D-phenylglycine *d*-camphor-10-sulfonate (18.5 g), $[\alpha]_D^{25}$ −49.7° (*c*=2, *N*-HCl). The pure salt (18.0 g) was dissolved in water (70 ml) at an elevated temperature. The solution was adjusted to pH 6 with 10 M sodium hydroxide and allowed to stand in a refrigerator overnight. The precipitated crystals were collected, washed with water, and dried to give D-phenylglycine (6.6 g), $[\alpha]_D^{25}$ −168.5° (*c*=1, 5*N*-HCl).

Chemiluminescences in the Carbon Monoxide-Active Nitrogen System

Nobuaki WASHIDA, Hiroshi BANDOW, and Gen INOUE

Division of Atmospheric Environment, The National Institute for Environmental Studies, P. O. Tsukuba-gakuen, Ibaraki 305

(Received June 24, 1983)

Chemiluminescences produced in the reaction of CO with active nitrogen were measured in the region from infrared to vacuum ultraviolet. The infrared emission from vibrationally excited CO was measured by means of a FTIR spectrometer. A vibrationally excited CO up to $v''=18$ was observed. The quenching and relaxation of vibrationally excited CO were measured by the addition of other gasses. The formation of carbon atoms was observed by the absorption of carbon resonance lines, and the recombination reaction of $C+N+M\longrightarrow CN^*+M$ is proposed as the mechanism of the violet and red emission of CN. The reaction of $CO^*(a^3\Pi)+CO^*\longrightarrow C+CO_2$ is proposed as the carbon-atom source. The emission of the fourth positive band of CO was observed in the vacuum UV region. The effect of self-absorption by the vibrationally excited CO was reduced by the addition of CO_2. It is suggested that the apparent abnormal vibrational distribution in $CO(A^1\Pi)$ can be reduced by considering the effect of the quenching of $CO(A^1\Pi)$.

The reactions of active nitrogen with other gases are well known[1-4] to produce a variety of chemiluminescences and are widely used in studies of both the spectroscopy of molecules and chemical reactions. Over 1500 papers related to active nitrogen reactions have been published. Suggested active species in the active nitrogen have included N atoms (usually $N(^4S)$, the ground state, and in some special cases excited states, such as $N(^2D)$ and $N(^2P)$), metastable excited states of N_2, such as $N_2(A^3\Sigma_u^+)$ and $N_2(A^1\Pi_g)$, and the vibrationally excited ground state of N_2. One well-known CN radical chemiluminescent reaction in the active nitrogen-hydrocarbon system is the case of the reaction initiated by the N-atom attack on hydrocarbon.[2,4] On the other hand, the chemiluminescent reaction in the active nitrogen-CO system is the case of energy transfer from electronically excited N_2 to CO, because the bond-dissociation energy of CO is very large (11.09 eV) and CO cannot be decomposed by a direct reaction with N atoms.

In the case of the active nitrogen-CO system, the chemiluminescences reported are infrared emission from the vibrationally excited CO,[5,6] visible emission from CN radicals in both $A^2\Pi$ and $B^2\Sigma^+$ states,[7] and the fourth positive band emission from $CO(A^1\Pi)$[8-10] in the vacuum UV region. Studies of the mechanism of these emission bands are interesting because these emissions are produced by energy transfer in various electronic states of N_2 and CO. In the present study, emissions produced in the active nitrogen-CO system are measured by using the same flow reactor in order to study the correlation of each emission band. Several new results concerning the formation mechanism of chemiluminescences will be reported.

Experimental

The discharge flow-system used is illustrated in Fig. 1. The cylindrical Pyrex flow tube is 21.2 mm i.d., 500 mm in length, and sealed off at one end by a lithium fluoride window. The length of reaction zone can be varied by sliding the inlet tube (6 mm o.d.) in an O-ring seal. CO gas enters the main flow through four radially directed holes at the end of the inlet tube. Active nitrogen is generated by flowing nitrogen or a nitrogen-argon mixture at rates between 8 and 9 m s^{-1} and at pressures between 2 and 6 Torr (1 Torr≈133.322 Pa) through a microwave discharge (2450 MHz). The N-atom densities are measured by the well-known NO-titration technique. Quenching gases, such as CO_2 and N_2O, are added from three inlet

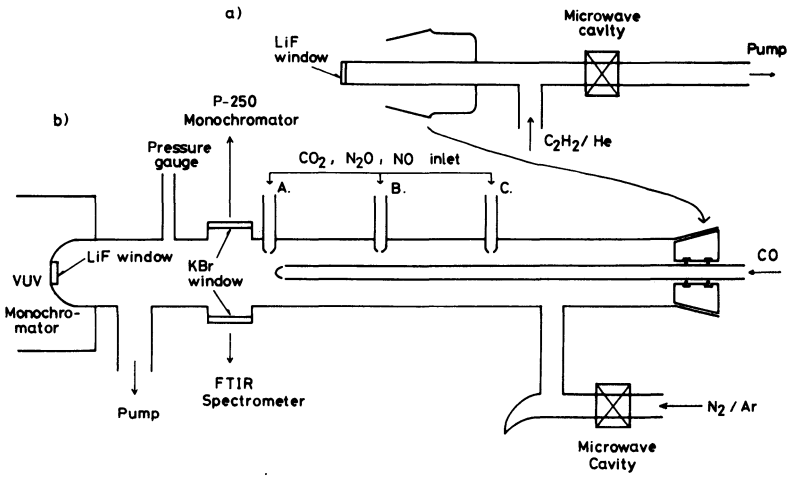

Fig. 1. Schematic diagram of experimental setup.
a) Carbon lamp. b) Discharge flow reactor.

ports, A, B, and C. The interval of each inlet port is 50 mm. In most cases, the C inlet port is used. The infrared emission spectra are measured side-on by means of a Nicolet 7199 FTIR spectrometer through a KBr window. The detector used was a liquid nitrogen cooled Hg–Cd–Te detector, which is sensitive from 800 to 4000 cm^{-1}. In the present study, in order to cut the strong thermal emission appearing below 1500 cm^{-1}, a sapphire filter (transmitting above 1600 cm^{-1}) was set in front of the detector. Therefore, the emission spectra from 1600 to 4000 cm^{-1} could be detected. The visible emission spectra were measured on another side by means of a 0.25 m monochromator (Nikon P-250, 1200 grooves/mm grating blazed at 300 nm) equipped with a photomultiplier (Hamamatsu R-636), a photon-rate meter, and a strip chart recorder. The vacuum UV emission spectra were measured at the end of the flow tube through a LiF window by means of a 0.3 m vacuum-ultraviolet monochromator (McPherson model 218) with a grating blazed at 150 nm (2400 grooves/mm), combined with a solar-blind photomultiplier (Hamamatsu R-976, MgF_2 window), which is sensitive from 115 to 320 nm.

The carbon atoms produced in the reaction of active nitrogen with CO were monitored photoelectrically through the axis of the flow tube by means of the attenuation of the carbon-atom resonance lines at 156.1 or 165.7 nm. A carbon-resonance lamp was attached at the other end of the flow tube in place of the movable inlet. In this case, CO was added from the side inlet port, B. A microwave-powered carbon-resonance lamp using a mixture of a few percent of acetylene in flowing helium was used.[11,12]

The spectral sensitivity of the P-250 monochromator with associated photomultiplier was determined by using a calibrated tungsten lamp. The wavelength calibration of the relative sensitivity of the VUV monochromator detecting system was achieved by measuring the intensities of the Lyman bands emitted from a discharge in argon with a trace amounts of H_2O.[13] The total and partial pressures of the gases were measured with an MKS Baratron gauge. All the measurements were done at room temperature, 298±3 K.

The gases, used without further purification, were N_2 (Nippon Sanso, 99.9995%), Ar (Nippon Sanso, 99.9995%), CO_2 (Nippon Sanso, 99.5%), N_2O (Takachiho, 99.9%), and NO (Matheson, 99.5%). The CO (Takachiho, 99.95%) was used after passing it through a hot quartz tube (800 °C) and a column packed with Molecular Sieve in order to remove any metal carbonyls.

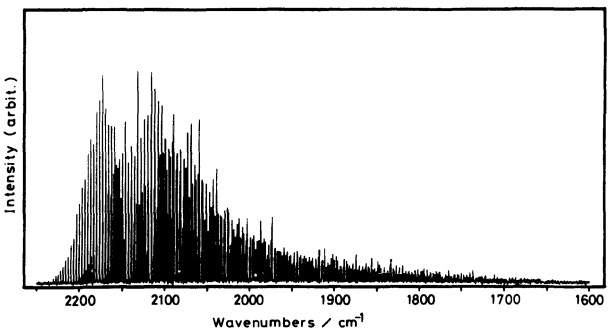

Fig. 2. High resolution (spectral resolution 0.25 cm^{-1}) infrared emission spectrum of vibrationally excited CO in the fundamental region. The spectrum was observed in the reaction of active nitrogen (microwave discharge of N_2, 2 Torr, and Ar, 2 Torr, mixture) with CO, 70 mTorr.

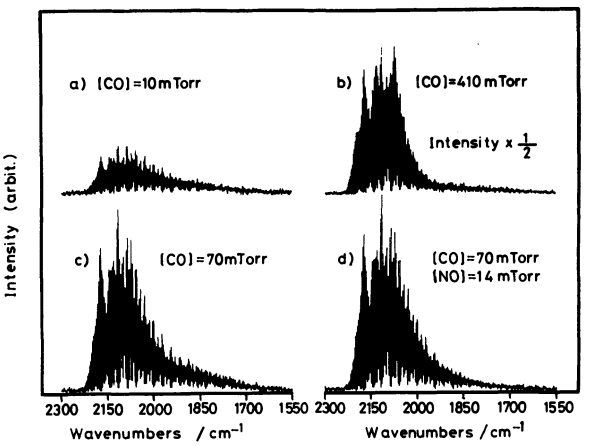

Fig. 3. Changes of the spectral distribution of the infrared emission of vibrationally excited CO by pressures of CO and the addition of NO. Active nitrogen was produced in the microwave discharge of N_2 (2 Torr) and Ar (2 Torr) mixture ([N]=4.2 mTorr). Spectral resolution is 1 cm^{-1}. a) 10 mTorr of CO was added. b) 410 mTorr of CO was added. Spectral intensity should be doubled. c) 70 mTorr of CO added. d) 14 mTorr of NO was added in addition to 70 mTorr of CO.

Results

A. Infrared Emission from the Vibrationally Excited CO. The high-resolution (spectral resolution 0.25 cm^{-1}) infrared emission spectrum of the vibrationally excited CO in the fundamental region is shown in Fig. 2. The spectrum was measured after 70 mTorr of CO had been added to the active nitrogen flow (4.2 Torr of total pressure) at a point 100 mm upstream from the observing point. Emissions from the vibrationally excited CO up to $v''=18$ could be observed.

The effects of the vibrational relaxation by CO and NO were also measured; they are shown in Fig. 3. Figures 3 (a) and (b) show the emission spectra when 10 and 410 mTorr, respectively, of CO were added to the active nitrogen flow. In these cases, the spectral resolution was 1 cm^{-1}. It should be clear that vibrational relaxations occur efficiently at high v'' levels. Figures 3(c) and (d) show the spectra in, respectively, the absence and presence of NO (14 mTorr) in the CO (70 mTorr)-active nitrogen flow. Relaxations can be observed very slightly in the high v'' levels. In these cases, the concentration of N atoms was 4.2 mTorr; *i.e.*, the color of the afterglow was changed from yellow (N_2 first positive-band emission due to N+N recombination) to green (NO_2 afterglow due to NO+O recombination) at the point of 4.2 mTorr NO addition. Therefore, vibrationally excited CO was still present even after all the N-atoms had been converted to O-atoms by the reaction of $N+NO \longrightarrow N_2+O$. This suggests that the formation of the vibrationally excited CO does not originate in the N-atom reaction. The integrated emission-band intensity as a function of the CO concentration is shown in Fig. 4 by solid circles. The total emission intensity increased with an increase in the CO concentration until it reaches a saturation point at about 300 mTorr of CO. The integrated-band intensity when NO was added to 70 mTorr of CO is shown by open circles in

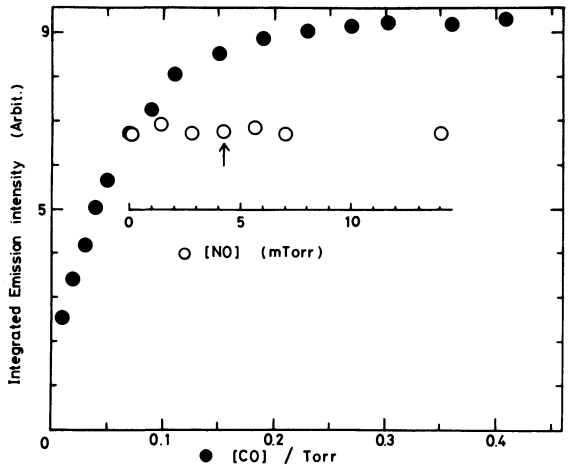

Fig. 4. Integrated intensity of infrared emission of CO as a function of the partial pressure of CO (solid circles). Intensities when NO was added in addition to 70 mTorr of CO are shown by open circles. An arrow indicates the titration point of N atoms. Active nitrogen was produced in the microwave discharge of N_2 (2 Torr) and Ar (2 Torr) mixture ([N]=4.2 mTorr).

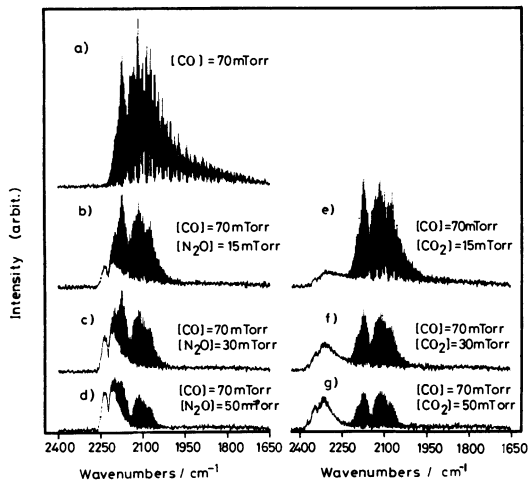

Fig. 5. Relaxation and quenching of the vibrationally excited CO by the addition of N_2O and CO_2. Spectral resolution is 1 cm^{-1}. Emissions appeared in (b)—(d) in the 2250—2100 cm^{-1} region are emissions from the vibrationally excited N_2O. Emissions appeared in (e)—(g) in the 2400—2200 cm^{-1} region are emission from the vibrationally excited CO_2. Active nitrogen was produced in the microwave discharge of N_2 (2 Torr) and Ar (2 Torr) mixture ([N]=4.2 mTorr).

Fig. 4. The total band intensity was not changed by the addition of NO. The arrow in Fig. 4 indicates the titration point of the nitrogen atoms.

The relaxation and quenching of the vibrationally excited CO occurred much more effectively upon the addition of N_2O and CO_2. Variations in the band profiles are shown in Fig. 5. The infrared emission bands of N_2O and CO_2 in the fundamental region appear with a decrease in the CO emission band. Further, highly vibrationally excited CO is quenched much more effectively. In both cases, when more than 150 mTorr of N_2O and CO_2 were added, the emission of CO was

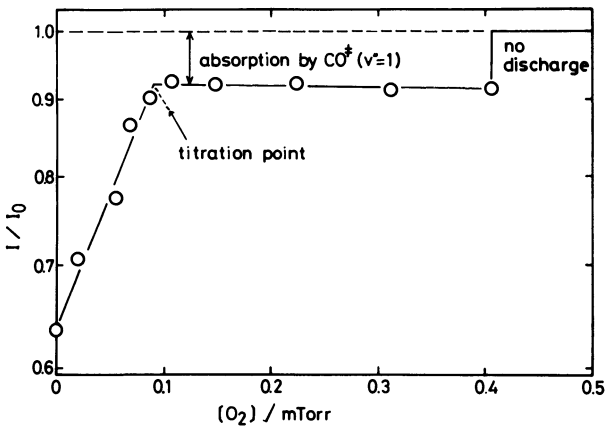

Fig. 6. Relative carbon atom absorption *versus* O_2 partial pressure (scale of ordinate is logarithmic). The 165.7 nm carbon atomic line was used to measure the resonance absorption of carbon atoms when 6 mTorr of CO was reacted with active nitrogen. "NO discharge" is the case when microwave discharge of the N_2 (2 Torr)–Ar (2 Torr) mixture was turned off.

quenched completely, only emissions of N_2O and CO_2 remaining.

B. Visible Emission and Carbon Atoms in the CO–Active Nitrogen Mixture. When CO was added to the straw yellow Lewis–Rayleigh afterglow of active nitrogen, the color changed slightly to deep blue. This chemiluminescence resembles the so-called "blue flame" observed in the reactions of active nitrogen with hydrocarbons[14] or C_2N_2.[15] That is, emissions of CN violet ($B^2\Sigma^+ \longrightarrow X^2\Sigma^+$) and CN red ($A^2\Pi \longrightarrow X^2\Sigma^+$) bands were observed, and strong tail bands appeared in the B→X bands, with a maximum at $v'=7$ and extending up to $v'=15$, just as in the cases of hydrocarbons[14] and C_2N_2.[15]

The existence of carbon atoms was observed by means of the resonance absorption of the carbon resonance lines. As will be described below, the chemiluminescence of the fourth positive band of CO ($A^1\Pi \longrightarrow X^1\Sigma^+$) was observed. The resonance lines of the carbon lamp, 156.1 and 165.7 nm, partially coincide with the 0-2 and 1-1 bands of the fourth positive emission respectively. However, under less than 10 mTorr of CO, the emission intensity of the fourth positive band is quite weak in comparison with that of resonance lines from the carbon lamp. Vibrationally excited CO was produced in the system, as has been mentioned before. The 0-2 and 1-1 bands in the A←X transition of CO absorb the resonance lines from the carbon lamp. In order to obtain the resonance absorption only by carbon atoms, a small amount of O_2 (less than 1 mTorr) was added to the system.[12,16] The carbon atoms in the system were consumed by the reaction of $C+O_2 \rightarrow CO+O$. On the other hand, the vibrationally excited CO was not quenched by less than 1 mTorr of O_2. A typical titration of carbon atoms by O_2 at 165.7 nm is shown in Fig. 6. The absolute steady-state concentrations of carbon atoms (0.02—0.1 mTorr, depending on the CO partial pressure) were determined by means of this O_2 titration method.[12,16] The intensity of the CN violet-band emission was proportional to the carbon-atom

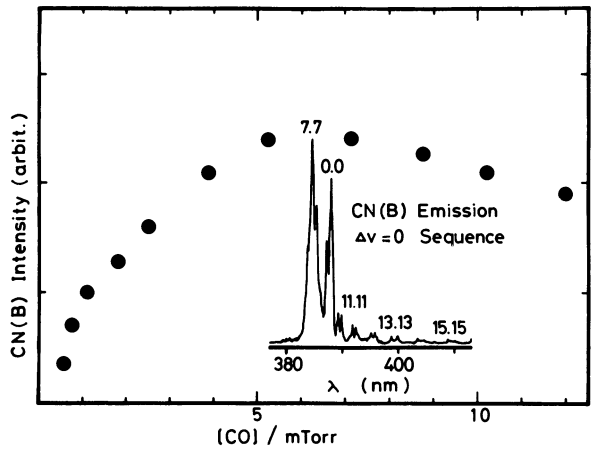

Fig. 7. Intensity of the CN violet emission band of $\Delta v=0$ sequence as a function of the pressure of CO. Spectrum shown is the CN violet emission of $\Delta v=0$ sequence. Concentration of nitrogen is constant ([N] = 4.2 mTorr).

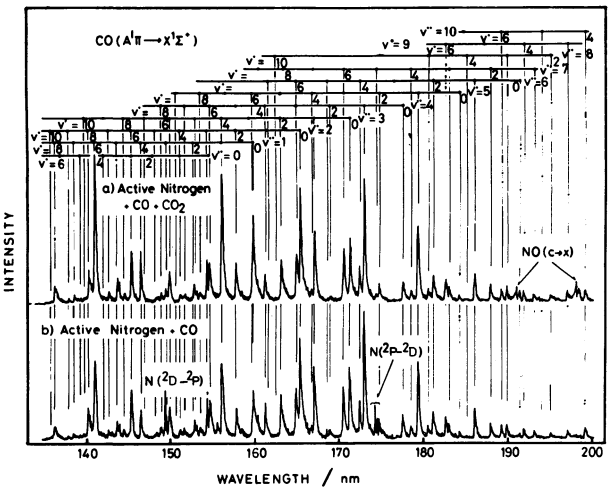

Fig. 8. Fourth positive band emission of CO observed in the reaction of active nitrogen with CO. Spectral resolution is 2 nm. Active nitrogen was produced in the microwave discharge of N_2 (3.5 Torr) and Ar (2.0 Torr) mixture ([N] = 5.7 Torr). a) [CO] = 410 mTorr and [CO_2] = 110 mTorr, b) [CO] = 410 mTorr and CO_2 is absent.

concentration; *i.e.*, the intensity of the violet emission decreased with a decrease in the carbon atoms upon the addition of O_2. These results suggest that the formation mechanism of the CN emission bands is quite similar to that proposed in the case of the "blue-flame conditions" of the active nitrogen–hydrocarbon reactions.[15,16] As will be described later, the formation mechanism of the CN emission bands proposed in the blue-flame condition is the recombination mechanism of C+N+M.

Figure 7 shows the intensity of the CN violet emission band of the $\Delta v=0$ sequence as a function of the partial pressure of CO. The intensity approaches a maximum at about 6 mTorr of CO. At 6 mTorr of CO, the intensity of the first positive-band emission of N_2 was not reduced. Therefore, it is probable that the precursor of the CN violet emission is not a nitrogen atom, but a

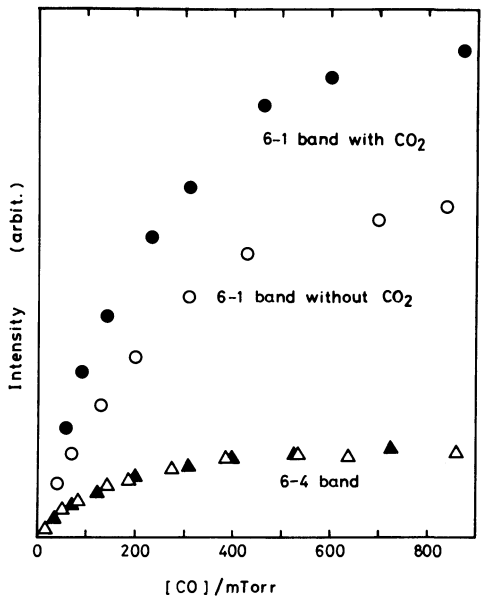

Fig. 9. CO($A^1\Pi \rightarrow X^1\Sigma^+$) intensities *vs.* partial pressure of CO. ●; 6-1 band in the presence of CO_2 (90 mTorr), ○; 6-1 band in the absence of CO_2, △; 6-4 band in the presence of CO_2 (90 mTorr), ▲; 6-4 band in the absence of CO_2. The condition of active nitrogen is as same as the case in Fig. 8.

metastable excited N_2 atom. The dependences of the CN red emission intensity and the concentration of the C atoms on the partial pressure of CO are similar to the case of the CN violet emission (Fig. 7).

C. Vacuum Ultraviolet Emission of CO. The fourth positive-band emission of CO was observed in the vacuum UV region as has been reported by Fontijn *et al.*[9] and by Golde *et al.*[10] The spectra measured are shown in Fig. 8. Figure 8(b) shows the CO($A^1\Pi \longrightarrow X^1\Sigma^+$) emission spectrum observed in the CO–active nitrogen system. Emission bands up to $v'=8$ were observed clearly, as was suggested by Golde *et al.*[10] In addition, very weak bands from $v'=9$ and 10 were observed in the present study. When 100 mTorr of CO_2 was added to the system, the intensities of several bands increased, as is shown in Fig. 8 (a). The increment occurred mostly in the $v''=1$ and 2 sequences. A similar result was obtained when N_2O was added to the system. Those results can be explained by the self-absorption by the vibrationally excited ground-state CO produced in the reaction of active nitrogen with CO. As is shown in Fig. 5, vibrationally excited CO was quenched by the addition of CO_2 and N_2O. The absence of any emission band in the $v''=0$ sequence is a result of the self-absorption by CO in the ground state.

The emission-intensity dependencies of the 6-1 and 6-4 bands on the partial pressure of CO are shown in Fig. 9. The open symbols in Fig. 9 show the emission intensity when CO was reacted with active nitrogen, while the solid symbols show the results when 90 mTorr of CO_2 was added to the system. It should be clear that the apparent intensity of the 6-1-band emission increased upon the addition of CO_2, while the intensity of the 6-4 band did not change when CO_2 was added. This can

be explained by the fact that there was a large amount of CO in the ground electronic state populated at $v''=1$ and a lesser amount at $v''=4$. The intensity of the emission bands increased up to about 1 Torr of CO. This suggests that a precursor to produce the fourth positive emission would be different from that in the case of CN-emission bands.

The increases in the 6-1-band intensity upon the addition of CO and CO_2 are shown in Fig. 10. In this case, CO_2 was added to the 700 mTorr of CO. The emission intensity increases up to a maximum at the addition of about 90 mTorr CO_2, and after that it decreases rapidly. Probably the decrease results from the quenching of $CO(A^1\Pi)$ or a precursor by CO_2.

The atomic lines of the nitrogen atoms appearing in Fig. 8(b) might be produced by the energy transfer from N_2 in the excited state to nitrogen atoms. The emission bands of NO shown in Fig. 8(a) are produced by the reaction of CO_2 with active nitrogen.[17]

Discussion

A. Infrared Emission from the Vibrationally Excited CO. The formation of vibrationally excited ground-state N_2 in the active nitrogen produced in the discharge of nitrogen was first inferred by Evans and Winkler[18] from chemical studies. The physical evidences were reported by Kaufman and Kelso[19] by means of temperature measurements and by Dressler[20] using the vacuum-UV-absorption of N_2. Tanaka *et al.*[21] extended the vacuum-UV-absorption measurements and observed transitions originating from levels up to $v''=29$ of the ground electronic state. Vibrational-energy transfer from vibrationally excited N_2 to CO was first suggested by Legay,[5] who measures the IR emission from CO. In the present study, the finding that the intensity of the IR emission of CO did not depend on the concentration of nitrogen atoms (Figs. 3 and 4) is consistent with the energy-transfer mechanism. As is shown in Fig. 4, since vibrationally excited N_2 is not quenched by the addition of NO, the system can be used as the source of the vibrationally excited N_2 under N-atom-free conditions.

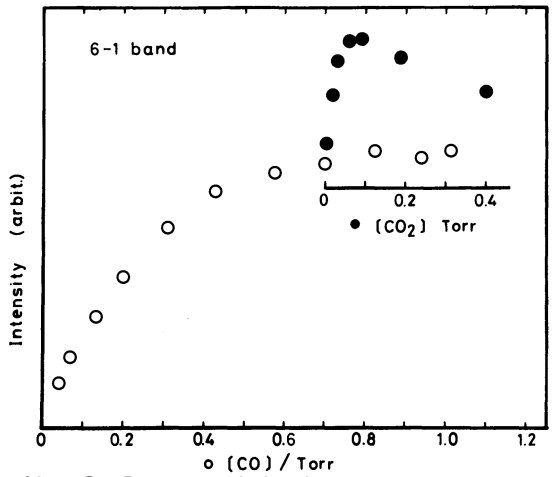

Fig. 10. ○; Increase of the 6-1 band intensity by the addition of CO and CO_2. ●; CO_2 was added to the 700 mTorr of CO. The conditions of active nitrogen are the same as the case in Fig. 8.

The rotational and vibrational temperatures of CO in the active nitrogen have been reported[5,6] to be 300—400 and 4000—8000 K respectively. It has also been reported that the rotational population[6] shows a Boltzmann distribution, while the vibrational population shows a non-Boltzmann distribution,[6,22] which coincides with a Treanor-type distribution.[23] In the present study, vibrationally excited CO up to $v''=18$ was observed.

An infrared emission due to the energy transfer from the vibrationally excited N_2 to CO_2[24] and N_2O[25] has also been reported. In the present study, emissions from CO_2 and N_2O were measured when CO_2 or N_2O was added to active nitrogen directly. Increases in the emission intensities as functions of CO_2 or N_2O were faster than in the case of CO, although the rate of self-quenching was also faster. Therefore, the decrease in the CO emission upon the addition of CO_2 or N_2O (shown in Fig. 5) results from both vibrational-energy transfer from N_2 to CO_2 or N_2O in competition with CO and the quenching of vibrationally excited CO by CO_2 or N_2O; the former process is preferable because of the excellent energy matching.

The amounts of the vibrationally excited N_2 or CO at $v''=1$ have been estimated[10,20] to be 5—10% of those at $v''=0$. In the present study, the emission intensity of the CO in the active nitrogen was compared with the infrared emission intensity of the CO produced in the $C+O_2\rightarrow CO+O$ system[26] (O_2 was added to the active nitrogen–C_2H_2 system). From the intensity ratio of the CO–active nitrogen to the C_2H_2, O_2–active nitrogen system, the amount of the vibrationally excited CO in the CO–active nitrogen system was estimated to be 10% or more of the CO at $v''=0$. In this estimation, it was assumed that the concentration of the vibrationally excited CO was equal to the concentration of carbon atoms in the C_2H_2, O_2–active nitrogen system. The value of 10% is interesting because the yield of the singlet oxygen, $O_2^*(a^1\Delta_g)$, produced in the discharge of O_2 is also about 10% of the O_2 in the ground electronic state.

A very large amount of vibrationally excited N_2 can be produced in the discharge of N_2, and a part of it is very highly excited. The vibrational energy transfer from N_2 to other molecules occurred very efficiently. Therefore, these vibrationally excited species can play a role in the chemiluminescent reactions of active nitrogen flames, although there have been no reports that the vibrationally excited N_2 is a precursor of the chemiluminescence in the active nitrogen flames.

B. Visible Emission of $CN(A^2\Pi$ and $B^2\Sigma^+)$. The spectral distribution of the CN violet band ($B^2\Sigma^+\longrightarrow X^2\Sigma^+$) is quite similar to that observed under blue-flame conditions in the active nitrogen–hydrocarbon system. Under the blue-flame conditions, the formation mechanism of the CN chemiluminescences has been suggested[15] to be a recombination reaction of C+N+M:

$$C(^3P) + N(^4S) + M \longrightarrow CN^*(C^4\Sigma^+) + M, \quad (1)$$

$$CN^*(C^4\Sigma^+) + M \longrightarrow CN^*(B^2\Sigma^+) + M, \quad (2)$$

$$CN^*(B^2\Sigma^+) \longrightarrow CN(X^2\Sigma^+) + h\nu(\text{violet band}), \quad (3)$$

$$CN^*(B^2\Sigma^+)\,M \longrightarrow CN^*(A^2\Pi) + M, \quad (4)$$

$$CN^*(A^2\Pi) \longrightarrow CN(X^2\Sigma^+)\,h\nu(\text{red band}). \quad (5)$$

The unusual intensity distribution in the vibrational structure of CN cmission bands could be explained[4,15] by the crossing of potential energy curves between $C^4\Sigma^+$ and $B^2\Sigma^+$ states.

Young and Morrow[7] have measured the CN-emission bands in the CO–active nitrogen system and proposed the following mechanism:

$$N_2^*(B^2\Pi \text{ or } W^3\Delta_u) + CO \longrightarrow CN + NO, \quad (6)$$

$$N_2^*(^5\Sigma_g^+) + CN \longrightarrow N_2 + CN^*(B^2\Sigma^+). \quad (7)$$

The mechanism of Young and Morrow can, however, be refuted by the following results in the present study: 1) If NO is produced by Reaction 6, emission bands of NO (γ, β, δ) can be observed in the active nitrogen system. However, no emission band from NO was observed here; 2) the formation of carbon atoms was observed, and the intensity of the CN violet emission was proportional to the steady-state concentration of the carbon atoms, just as in the case of the blue-flame conditions of the hydrocarbon system; 3) when a small amount of O_2 was added to the system and carbon atoms were consumed by the reaction of $C+O_2 \rightarrow CO+O$, the CN emission bands disappeared; 4) as is shown in Fig. 7, the intensity of the CN violet band approaches its maximum at 6 mTorr of CO. Under 6 mTorr of CO, the first positive band emission of N_2 is little reduced, *i.e.*, $N_2^*(B^3\Pi)$ is little quenched. Therefore, if the CN violet emission is produced by Reaction 7 subsequent to Reaction 6, the intensity maximum of CN emission should appear at a much larger amount of CO; 5) the potential energy curve of $N_2^*(^5\Sigma_g^+)$[27] is nearly repulsive. It is, then, very unlikely that the $N_2^*(^5\Sigma_g^+)$ is a precursor of the CN emission; 6) the unusual spectral distribution of the CN violet band can not be explained by the energy-transfer mechanism.

It was found that the purification of CO is very important in the present study. Usually, the CO gas in the cylinder contains a large amount of metal carbonyls. In the present study, as has been mentioned in the Experimental section, the CO was purified carefully. When CO was used without purification, the pink orange flame[15] appeared stronger than the blue flame, and the 0-0 band was much stronger than the 7-7 band in the CN violet system. These phenomena probably resulted from the reaction of metal carbonyls with active nitrogen. In the previous work by Young and Morrow, the procedure of the purification was not described.

The formation mechanism of carbon atoms in the CO–active nitrogen system can not be determined directly. The most probable mechanism is, however, the energy-transfer process from the metastable $N_2^*(A^3\Sigma_u^+)$, which can be produced by the recombination of nitrogen atoms:

$$N + N + M \longrightarrow N_2^*(A^3\Sigma_u^+), \quad (8)$$

$$N_2^*(A^3\Sigma_u^+) + CO \longrightarrow CO^*(a^3\Pi) + N_2, \quad (9)$$

$$CO^*(a^3\Pi) + CO \longrightarrow C(^3P) + CO_2. \quad (10)$$

Carbon atoms are reproduced by Reaction 11 subsequent to Reactions 3 and 5:

$$CN + N \longrightarrow C + N_2. \quad (11)$$

The energy-transfer process in Reaction 9 is known[28] to occur very efficiently. The quenching of $CO^*(a^3\Pi)$ by $CO(X^1\Sigma^+)$ has been suggested[29,30] to occur by means of Reaction 10, which is exoergic by $\simeq$8 kcal/mol (1 cal $=$4.814 J). However, no direct experimental verification of Reaction 10 has been made. If the carbon atoms are produced by Reaction 10, the intensity of the CN emission should be proportional to $[CO]^2$. However, as is shown in Fig. 7, the CN emission intensity is not proportional to $[CO]^2$. Another possible process is that the $CO^*(a^3\Pi)$ reacts with the highly vibrationally excited CO more rapidly:

$$CO^*(a^3\Pi) + CO^*(\text{high } v'') \longrightarrow C + CO_2. \quad (12)$$

The concentration of high v'' states might approach their maximum concentration under a low CO concentration, and after that, $[CO^*(\text{high } v'')]$ might be in its steady-state concentration because of the competition with the quenching processes. Therefore, if Reaction 12 occurs only in the very high v'' states, the carbon atoms formed (the intensity of CN emission) is proportional to the concentration of CO. Also, if there is a deactivation process such as Reaction 13, the dependence of the CN emission intensity on the CO concentration shown in Fig. 7 can be understood:

$$CO^*(a^3\Pi) + CO \longrightarrow CO + CO \quad (13)$$

When several mTorr of CO_2 were added to the system, the CN emission was reduced efficiently. Since the rate of the reaction of carbon atoms with CO_2 has been reported[31] to be very slow, slower than 10^{-15} cm^3 molecule^{-1} s^{-1}, the reduction of the CN emission does not result from the consumption of carbon atoms. The rate of the quenching of $N_2^*(A^3\Sigma_u^+)$ by CO_2 has been reported[28] to be slow, about 5500 times slower than CO. The quenching rate of $CO^*(a^3\Pi)$ by CO_2[32] is 20 times slower than CO. Probably, then, the reduction of CN emission is caused by the quenching of highly excited CO by the addition of CO_2; Reaction 12 is proposed as the source of the carbon atoms.

C. Vacuum Ultraviolet Emission of CO. Since the absolute transition probability of each transition in the fourth positive band of CO has been reported,[33] the

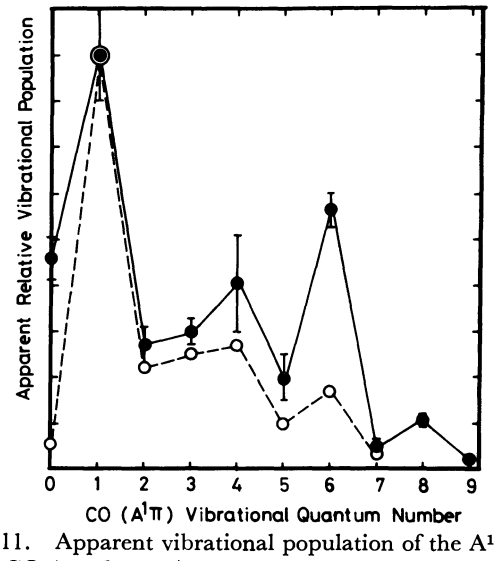

Fig. 11. Apparent vibrational population of the A^1 state of CO (see the text).

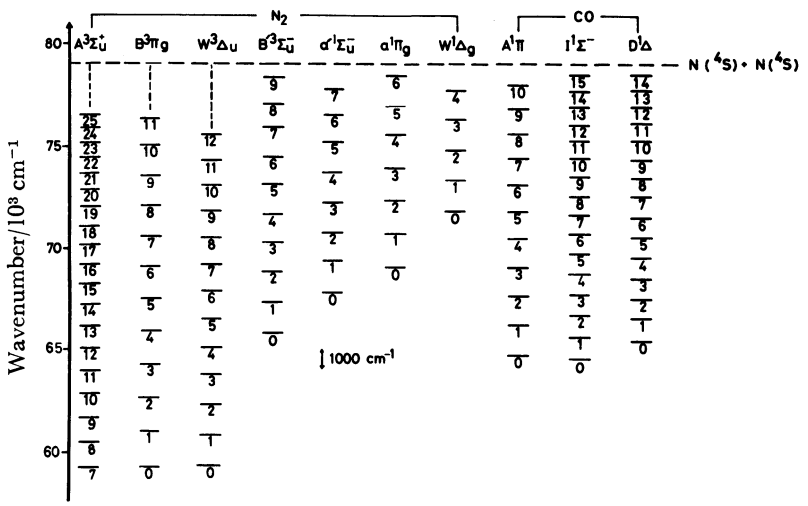

Fig. 12. Energy level diagram for electronically excited N_2 and CO. The energy of $N(^4S)+N(^4S)$ is 79030.4 cm^{-1}.

apparent vibrational population of the $A^1\Pi$ state of CO was calculated from the emission intensity of each band shown in Fig. 8(a). The results are shown in Fig. 11 by solid circles, which are the averages of several transitions. The error bars show the scattering of values. The results show that the widely separated $v'=1$ and $v'=6$ are formed most rapidly, as has previously been reported by Golde and Thrush.[10] In order to explain this mode of formation, they suggested an indirect energy transfer involving the collisional crossing from another excited state of CO, such as:

$$N + N + M \longrightarrow N_2^*(a^1\Pi_g) + M, \quad (14)$$

$$N_2^*(a^1\Pi_g) + CO \longrightarrow CO^*(I^1\Sigma^-) + N^2, \quad (15)$$

$$CO^*(I^1\Sigma^-) + M \longrightarrow CO^*(A^1\Pi) + M, \quad (16)$$

in addition to the direct energy-transfer process:

$$N_2^*(a^1\Pi_g) + CO \longrightarrow CO^*(A^1\Pi) + N_2. \quad (17)$$

Since the levels $CO^*(I^1\Sigma^-)$, $v'=2$, and $v'=9$, are perturbed by $CO^*(A^1\Pi)$, $v'=1$, and $v'=6$ respectively,[34] Golde and Thrush proposed the $CO(I^1\Sigma^-)$ rather than $CO(D^1\Delta)$ as a dominant precursor. Further, for the population of low levels of $CO(A^1\Pi)$, they suggested energy transfer from $N_2^*(a'^1\Sigma_u^-)$ to CO:

$$N_2^*(a'^1\Sigma^-) + CO \longrightarrow CO^*(A^1\Pi) + N_2. \quad (18)$$

An energy-level diagram for electronically excited N_2 and CO in which energy transfer can occur is shown in Fig. 12. The diagram is based on the molecular constants for N_2[27] and CO[35,36] previously reported. Since the energy of $N(^4S)+N(^4S)$ is 225.958 kcal/mol, *i.e.*, 79030.4 cm^{-1},[37] $CO^*(A^1\Pi)$ can populate energetically up to $v'=10$ if it is formed by the energy transfer from N_2^*.

The population shown in Fig. 11 by solid circles does not include the effects of quenching and relaxation processes in the $CO^*(A^1\Pi)$ state. The quenching cross-sections of $CO(A^1\Pi)$ by several gases previously reported[38,39] are very large (3.3 and 44 $Å^2$ for Ar and N_2 respectively at low v' levels, and 200, 80, and 120 $Å^2$ for CO, N_2, and CO_2 respectively at $v'=13$). Under the present experimental conditions (with a total pressure of about 6 Torr), the quenching process is competitive enough with the emission processes, although the radiative lifetime of the $A^1\Pi \rightarrow X^1\Sigma^+$ transition of CO is very short ($\approx$10 ns).[40] The quenching cross-sections of $CO^*(A^1\Pi)$ in individual vibrational levles ($v'=0$—8) have been reported[41] only in cases of rare gases. The quenching cross-section by rare gas is largest at $v'=1$ and smallest at $v'=0$ and 6. Since there have been no reports on quenching cross-sections by N_2, CO, and CO_2 in individual vibrational levels, the populations shown in Fig. 11 by solid circles were multiplied by the relative quenching cross-section by Ar at the individual vibrational levels and normalized at $v'=1$. The results are shown by open circles in Fig. 11. The population at $v'=6$ decreased, and the population became centered at $v'=1$. Of course, the above treatment is not correct. Correction should be done using the values of N_2, CO, and CO_2; in addition, the effect of vibrational relaxation should be considered. However, the results suggest that the formation of $CO(A^1\Pi)$ might be explained by direct-energy transfer from the excited state of N_2, Reactions 17 and 18, without a precursor of $CO^*(I^1\Sigma^-)$. The high population at $v'=1$ in $CO^*(A^1\Pi)$ may be explained by the energy transfer from $N_2^*(a'^1\Sigma_u^-)$ at $v'=0$, Reaction 18. Concerning the $a'^1\Sigma_u^-$ state of N_2 in the active nitrogen, it has been reported[42] that no emission band except that from the $v'=0$ level was observed in the $N_2(a'^1\Sigma_u^- \longrightarrow X^1\Sigma_g^+)$ system, although emissions from the $v'=0$—6 levels were observed in the $a^1\Pi_g \rightarrow X^1\Sigma_g^+$ system.[42,43]

A Study of Inorganic Ion Exchangers. VII.[1] The Synthesis of γ-$NH_4ZrH(PO_4)_2$ and Ion-exchange Properities of γ-$Zr(HPO_4)_2\cdot 2H_2O$

Etsuro KOBAYASHI
National Chemical Laboratory for Industry, Yatabemachi, Tsukuba-gun, Ibaraki 305
(Received March 9, 1983)

The conditions for the synthesis of γ-$NH_4ZrH(PO_4)_2$ and the ion-exchange properties of γ-$Zr(HPO_4)_2\cdot 2H_2O$ were investigated. The influence of the mole ratio of MH_2PO_4 (M=Na, K, and NH_4) to $ZrOCl_2$ on the formation of γ-zirconium phosphate using NaH_2PO_4 as MH_2PO_4 was such that the γ-form was obtained not in the NaH_2PO_4/$ZrOCl_2$ mole ratio of 4, but in are of 8.3 or more. In case of the Na or K salt, a non-stoichiometric compound, $M_xZrH_{2-x}(PO_4)_2$, was obtained. When using the NH_4 salt, a stoichiometric compound was synthesized at 120—280 °C in accordance with the following equation: $ZrOCl_2+NH_4H_2PO_4\longrightarrow NH_4ZrH(PO_4)_2+NH_4Cl+HCl+H_2O$. Using an autoclave lined with Hastelloy-B and equipped with a stirrer, the synthesis was carried out by a reaction at 150—160 °C for 18—54 h. γ-$Zr(HPO_4)_2\cdot 2H_2O$ was prepared from $NH_4ZrH(PO_4)_2$, and its ion-exchange capacity at pH 4.5 and selectivity quotient toward alkali metals and ammonium ions were measured. The measured values increased in the order of $Li^+<Cs^+<Na^+<K^+<NH_4^+$.

The crystalline phosphates of quadrivalent metals are generally prepared by reflux or a hydrothermal reaction of amorphous phosphate with phosphoric acid of a suitable concentration. The method for synthesizing γ-zirconium(IV) bis(hydrogenphosphate) dihydrate (γ-$Zr(HPO_4)_2\cdot 2H_2O$ or γ-zirconium phosphate) is somewhat different from the above process. Clearfield *et al.*[2] carried out the reflux of a zirconium phosphate gel in a mother liquor comprised of a concentrated NaH_2PO_4 and HCl solution. Yamanaka *et al.*[3] reported the region of the formation of $NaZrH(PO_4)_2$ and the structural model of γ-$Zr(HPO_4)_2\cdot 2H_2O$. They carried out a hydrothermal reaction of phosphate gel with a weakly acidified aqueous solution of sodium phosphate to obtain γ-zirconium phosphate, they found that the region of the formation of the γ-form was within the pH values of 1.5—4.0 at 180—230 °C.

In the present work, through the heating of a mixture of $ZrOCl_2\cdot 8H_2O$, MH_2PO_4 (M=Na, K, or NH_4) and water in a sealed glass tube, $MZrH(PO_4)$ was formed above 120 °C. Consequently, the mole ratios of MH_2PO_4 to $ZrOCl_2$ (M/Zr) and the reaction temperatures were investigated in order to determine whether or not the ammonium salt had a tendency to form a stoichiometric compound more easily than sodium and potassium salt; it was possible to directly synthesize $MZrH(PO_4)_2$ using an autoclave. In addition, the ion-exchange properties of γ-$Zr(HPO_4)_2\cdot 2H_2O$ toward Li^+, Na^+, K^+, Cs^+, and NH_4^+ were studied.

Experimental

Synthesis of $MZrH(PO_4)_2$. In a 20-cm³ hard glass tube were placed 1.61 g of $ZrOCl_2\cdot 8H_2O$, 2.4—9.5 g of MH_2PO_4 (M=Na, K, or NH_4) and 5 cm³ of water. The contents were thoroughly shaken, and the tube was sealed. From 2—4 such sealed tubes were prepared under various conditions (the type of MH_2PO_4 and mole ratio of M/Zr) and placed in a 200-cm³ stainless steel autoclave. To the autoclave was added 80 cm³ of water to prevent any rupture of the tubes. The contents of the tubes were heated to specified temperatures (120—280 °C), and the resulting products in the tubes were separated from the mother liquors, washed thoroughly with water, and dried at 20 °C in a relative humidity of 75%, or at 105 °C. On the other hand, 16.1 g of $ZrOCl_2\cdot 8H_2O$, 46 g of $NH_4H_2PO_4$ and 100 cm³ of water were directly charged in to a 300-cm³ autoclave lined with Hastalloy-B (Mitsubishi Kinzoku Co.). The mixture was made to react for 18—54 h with stirring (180 min^{-1}) at 120—165 °C. The product thus formed was repeatedly washed with water, separated by a centrifugal separator, and dried. γ-$Zr(HPO_4)_2\cdot 2H_2O$ was obtained by the ion-exchange treatment of γ-$NH_4ZrH(PO_4)_2$.

Analysis. The composition of the reaction products was analyzed according to a previously reported method.[4] The amount of H_2O was determined on the basis of the weight loss of the heated product at 800 °C (in the case of the $NH_4ZrH(PO_4)_2$, the amount of NH_3 was calculated from the weight loss on heating). The Na_2O and K_2O were measured according to the flame-photometering method. The NH_3 was determined by Kjeldahl's method. The empirical values of P_2O_5 and ZrO_2 in the reaction products of $MZrH(PO_4)_2$ synthesized in the present study were almost 1 : 1 in mole ratio. Accordingly, the amounts of the two components were also obtained by dividing the residual amount (R%) derived from the following equation by the proportion of the formula weight of P_2O_5 and ZrO_2:

$$100\%-H_2O\%-M_2O\% \text{ (or } NH_4\%)=R\%.$$

X-Ray diffraction was then performed with a Shimadzu Seisakusho diffractometer under the conditions of Cu $K\alpha$, 30 kV P, and 20 mA.

Ion-exchange Capacity. The ion-exchange titration curves and ion-exchange values were obtained according to a previously reported method.[5]

Results and Discussion

Formation of γ-$MZrH(PO_4)_2$. In the previously reported reaction methods,[2,3] much more sodium phosphate was used than a soluble zirconium salt (M/Zr=20), and the adjustment of the pH value was necessary for the formation of γ-$MZrH(PO_4)_2$.

The Mole Ratios of $MH_2PO_4/ZrOCl_2$: Table 1 shows the synthesis conditions and analytical values of the γ-zirconium phosphate obtained by the reaction of $ZrOCl_2$ with NaH_2PO_4 or KH_2PO_4. Table 2 gives the same data for the γ-ammonium zirconium(IV) hydrogen bis(phosphate) obtained by the reaction of $ZrOCl_2$ with $NH_4H_2PO_4$.

In Expt No. 1 in Table 1, a mixture of NaH_2PO_4 and Na_2HPO_4 was used as the phosphate. The pH value of the mother liquid, 4.26, was thus somewhat higher[3]

in the formation of γ-zirconium phosphate. In fact, no diffraction peak characterizing the γ-$NaZrH(PO_4)_2$ was detected in the X-ray diffraction pattern. Neither was the diffraction peak characterizing the γ-form found in the X-ray diffraction pattern of the reaction product in the second experiment at a Na/Zr mole ratio of 4. Howevere in Expts No. 3 and 4 at M/Zr mole ratios of 8.3 and 16.6 respectively, the formation of γ-zirconium phosphate apparently took place, since peaks appeared at 11.7, 6.36, 4.57, 4.41, 3.91, 3.81, 3.17, 2.87, and 2.54 Å (Å$=10^{-10}$ m) in the X-ray diffraction patterns. It was found, therefore, that the amount of NaH_2PO_4 could be reduced to less than half of that previously reported.

The influence of the mole ratio of NH_4/Zr was investigated also when the ammonium salt was used. The results are shown in Expts No. 1—4 in Table 2, while the X-ray diffraction patterns of the reaction products are shown in Fig. 1.

As the mole ratio of NH_4/Zr increased, the diffraction peak at 11.3 Å (7.8°) characterizing γ-$NH_4ZrH(PO_4)_2$ was intensified. The mole ratio of NH_3 in the product from Expt No. 1 was 0.6 and the mole ratio of NH_4/Zr was small. With an increase in the mole ratio of M/Zr, however, that of NH_3 reached 1.0, and a stoichiometric compound, $NH_4ZrH(PO_4)_2$, was formed. In the case of the Na salt, the mole ratios of Na_2O in the reaction products were 0.3 or less, as is shown in Table 1, and products of an indefinite $Na_{0.2-0.6}ZrH_{1.8-1.4}(PO_4)_2$ composition were obtained.

In the processes previously reported, hydrochloric acid was added to the reaction solutions[2,3] or the solutions were adjusted to pH 2.[3] The pH value of an aqueous solution of MH_2PO_4 (M=Na, K, or NH_4) showed 4—4.5, and the pH value of an aqueous solution equilibrated with $MM'H(PO_4)_2$ (M'=Ti or Zr), obtained by the ion-exchange of $M'(HPO_4)_2$ and MOH, also showed 4—4.5.

The reaction giving rise to the formation of the γ-zirconium phosphates can be written as follows:

$$ZrOCl_2+2MH_2PO_4 \longrightarrow MZrH(PO_4)_2+MCl+HCl+H_2O.$$

In this reaction, since HCl is liberated into the aqueous solution, the pH values were expected to become less than 4. In fact, the pH values of the mother liquors following the termination of the reaction inevitably showed the expected pH values (2.5—3.5).

Reaction Temperature: The reactions between $ZrOCl_2$ and KH_2PO_4 in Expts No. 5—8 are shown in Table 1. As with the Na-product, the K-product was also low in M_2O (K_2O) content, and a product of an indefinite $K_{0.2-0.8}ZrH_{1.8-1.2}(PO_4)_2$ composition was obtained. No correlation was observed between the X-ray diffraction peak intensity of 11.0 Å characterizing the γ-potassium zirconium(IV) hydrogen bis(phosphate) and the reaction temperature. As has been described above, the ease with which the crystalline γ-zirconium phosphates were produced as stoichiometric compounds reacting $ZrOCl_2 \cdot 8H_2O$ with MH_2PO_4 is considered to be in the order of the NH_4-product Na-product K-product.

The reaction temperatures were investigated for the NH_4-products; the results from Expts No. 5, 6, 3, and 7 are shown in Table 2. The mole ratios of NH_3 in the products ranged from 0.8—1.0 at 120—280 °C, and products of approximately a $NH_4ZrH(PO_4)_2$ composition were obtained. In the X-ray diffraction patterns of the NH_4 salt, the diffraction-peak intensity of 11.3 Å characterizing γ-$NH_4ZrH(PO_4)_2$ increased with an elevation of the reaction temperature.

Synthesis in the Autoclave. For the purpose of developing an industrial method for synthesizing γ-zirconium phosphates as compounds with a layer structure, the reaction between $ZrOCl_2$, $NH_4H_2PO_4$ and water was carried out in autoclave equipped with a stirrer and lined with Hastelloy-B (Ni: 67, Mo: 28, and Fe: 5%).

TABLE 3. ION-EXCHANGE PROPERTIES OF γ-ZIRCONIUM(IV) BIS(HYDROGENPHOSPHATE) IN SOLUTIONS TO ALKALI METAL AND AMMONIUM IONS

Ion	Equilibrium capacity at pH 4.5 Q^A/mequiv g^{-1}	Saturation capacity at pH 4.5 Q°/mequiv g^{-1}	Selectivity quotient K_H^M	Mole fraction Q^A/Q°	Absorption quantity A/%	Distribution coefficient K_D/ml g^{-1}
Li	0.36	1.80	0.04	0.20	14.4	8.42
Na	0.74	2.40	0.19	0.31	29.6	21.0

NH_4	1.69	2.70	3.26	0.62	66.8	100.5

Selectivity quotient: $K_H^M = \frac{(M^+)I}{(H^+)I} \cdot \frac{(H^+)S}{(M^+)S} = \frac{Q^A}{Q^\circ - Q^A} \cdot \frac{Q^A}{C - Q^A}$. Absorption quantity : $Q^A/C\ 100 = A$. Distribution coefficient: $K_D = A/I \cdot S(100-A)$. C: Initial quantity of MCl (2.5 mequiv). S: MCl solution (25 ml). I: Ion-exchanger (0.5 g).

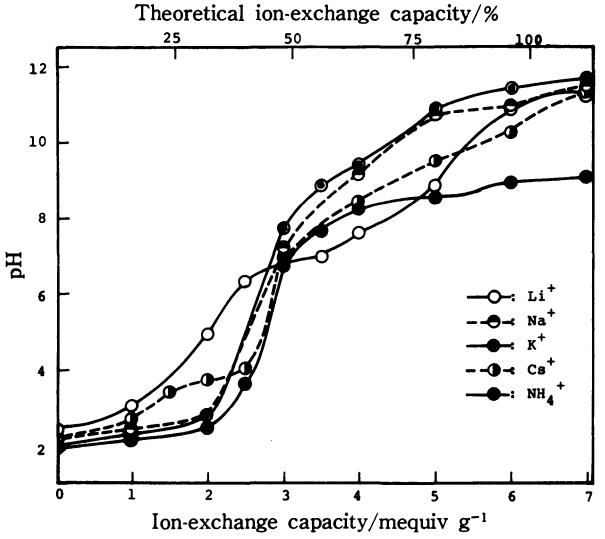

Fig. 2. Alkali metal and ammonium ion-exchange titration curves of γ-$Zr(HPO_4)_2 \cdot 2H_2O$.

The results are shown in Table 2.

The reaction temperature was maintained within 120—165 °C to prevent the corrosion of the metallic vessel. The reaction time of the contents under agitation could be significantly shortened compared to that required for a stationary state. Judging from the X-ray diffraction patterns of the products, a crystalline product was obtained after a reaction period of 18 h. The crystallization of the products (Nos. 9, 10, and 11) was brought to completion with an additional reaction time. When γ-zirconium phosphates are synthesized in the autoclave and the container is attacked above 180 °C, there is a chance that the reaction product may react with metal ions. Thus, a reaction temperature of about 150 °C was considered the most appropriate.

Ion-exchange Properties. Since γ-$Zr(HPO_4)_2 \cdot 2H_2O$ is present to a greater extent in the interlayer spacing (12.2 Å), it is considered void of selectivity as an ion-exchanger. With regard to the inorganic ion-exchange properties of this compound, therefore, there is no literature available except for one report by Clearfield *et al.*[2] They converted the γ-form into the β-form as a complete anhydride, and obtained ion-exchange titration curves of Cs^+, Na^+, and Ba^{2+} using the β-form. In the present study, ion-exchange titration curves of γ-$Zr(HPO_4)_2 \cdot 2H_2O$ toward alkali metal (Li, Na, K, Cs) and ammonium ions were measured in order to reconsider γ-$Zr(HPO_4)_2 \cdot 2H_2O$ as an ion-exchanger. The results are shown in Fig. 2. In the titration curves, the ion-exchange capacity up to pH 4.5 was arbitrarily defined as the saturation ion-exchange capacity (Q°).[5] On the other hand, an equilibrium ion-exchange capacity (Q^A) up to pH 4.5 was also obtained using the method of the previous report.[5] Table 3 showns the values for the selectivity quotient (K_H^M), the adsorption quantity (A), and the distribution coefficient (K_D) calculated from both ion-exchange capacities. In the ion-exchange titration curves of Fig. 2, the theoretical value for a 100% ion exchange of the two hydrogens in γ-$Zr(HPO_4)_2 \cdot 2H_2O$ corresponds to 6.25 mequiv/g. When the two hydrogens are theoretically 100%-ion-exchanged with Li^+, Na^+, K^+, or Cs^+, the pH values of the aqueous solution are each about 11. γ-$Zr(HPO_4)_2 \cdot 2H_2O$ tends to be attacked in such an alkaline solution. On the other hand, the pH value of the solution is 8.9 in the case of ion-exchange with NH_4^+; thus, there is little fear of γ-$Zr(HPO_4)_2 \cdot 2H_2O$ being attacked. An analysis of the ion-exchanger, however, indicated that about 65% of the ion-exchange was actually carried out. The values of Q^A, Q°, K_H^M, A, and K_D at pH 4.5 were, respectively, in the order of $Li^+ < Cs^+ < Na^+ < K^+ < NH_4^+$. That is, Li^+, with a smaller radius, was hydrated to the greatest extent, causing it to appear to have a large radius; thus, the ion-exchange quantity of the hydrated ion was small. Cs^+ was not hydrated, but was itself larger than Na^+, K^+, or NH_4^+. Consequently, the ion-exchange quantity of this ion was less than those of the other ions. NH_4^+ was not so high in selective ion-exchange compared with alkali metal ions, but was highest with respect to ion-exchange capacity. This point is of interest in consideration of the fact that NH_4^+ salt more easily forms stoichiometric compounds than the Na and K salts in the synthesis of γ-zirconium phosphates.

X-Ray Diffraction Study on the Coordination Structure of Chlorocopper(II) Complexes in Highly Concentrated Methanolic $CuCl_2$ Solution

Mitsuyoshi Ichihashi, Hisanobu Wakita,* and Isao Masuda

Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma, Jonan-ku, Fukuoka 814-01

(Received May 6, 1983)

The structures of the solute complexes existing in methanolic $CuCl_2$ solutions with the concentrations of 1.055—3.250 mol dm^{-3} were investigated by X-ray diffraction analysis. The solute complexes which were predominantly present could be formulated as $[CuCl_n(CH_3OH)_{6-n}]$ ($n=1$—3); they have an axially elongated octahedral structure including Cl^- at the equatorial site. The Cu–O bond distance was 2.230—2.238 Å. Methanol molecules were coordinated at the equatorial site with the Cu–O bond distance of 1.926—1.950 Å and at the axial site with that of 2.423—2.473 Å. When the initial concentration of $CuCl_2$ was kept within the range examined here, almost all of the Cu^{2+} ions formed chloro complexes.

Solution X-ray diffraction investigations have established that the stereo structure of the hexaaqua complex existing in aqueous $CuSO_4$ and $Cu(ClO_4)_2$ solutions is characteristic for the elongated octahedral geometry having two axial bonds with the longer distance (2.34—2.43 Å) and four equatorial bonds with the shorter distance (1.94—1.98 Å).[1,2] In concentrated aqueous $CuBr_2$ solutions (1.016—4.364 mol dm^{-3}), the coordination of Br^- ion was demonstrated to occur at the equatorial sites.[3] As for an aqueous $CuCl_2$ solution (2.952 mol dm^{-3}), Magini proposed from the investigation by X-ray diffraction analysis the presence of a monomeric complex which included two Cl^- ions at the equatorial sites,[4] similar to the above bromo complex. On the other hand, Wertz *et al.* reported the polymeric complexes to be present in aqueous $CuCl_2$ solutions (3.18 and 4.35 mol dm^{-3});[5] in these complexes the Cl^- ion bridged between two Cu^{2+} ions.

Since the coordination ability of methanol molecules is generally expected to be lower than that of water, the Cl^- ion may have a higher coordination ability than solvent molecules in methanol than in water. In fact, it was shown by the X-ray diffraction analysis that in methanolic $FeCl_3$ (6.0 and 11.0 mol kg^{-1}) and $CoCl_2$ (3.91 mol kg^{-1}) solutions, polymeric species bridged through Cl^- ions were present.[6] On the other hand, in aqueous $FeCl_3$ (2.332 mol dm^{-3}) and $CoCl_2$ (2.973 mol dm^{-3}) solutions, only the monomeric octahedral complex was known to be present in the form of either a mono- or a dichloro complex including H_2O molecules as another ligand.[4,7]

These facts suggest the increased coordination ability of Cl^- ion in methanol than in water. Accordingly, if a polynuclear chlorocopper(II) complex species were present, it might be demonstrated more distinctly with a methanolic $CuCl_2$ solution. In the present investigation the X-ray diffraction analysis has been carried out for concentrated methanolic $CuCl_2$ solutions. Observed $D(r)$ curves have been well explained by assuming that the solutions predominantly include three complexes, formulated as $[CuCl_n(CH_3OH)_{6-n}]$ where $n=1$, 2, and 3, in nearly equivalent amounts; the complexes have a distorted octahedral structure and the equatorial sites are occupied preferentially by Cl^- ions. The existence of a polymeric species was improbable.

Experimental and Data Treatment

Sample Solutions. Commercially available $CuCl_2\cdot 2H_2O$ crystals were recrystallized from distilled water. The hydrate was dehydrated by keeping it at 100 °C, *in vacuo*, for 48 h. The sample solutions were prepared by dissolving the anhydrous $CuCl_2$ into anhydrous methanol. The copper ion concentration of the solutions was determined by EDTA titration method. The chloride ion concentration was calculated from the copper concentration. The amount of methanol in the solution was calculated from the copper ion concentration and from the density determined pycnometrically. The composition of the sample solutions is given in Table 1.

X-Ray Diffraction Measurements and Data Treatments. The measurements and the data treatments were carried out as described elsewhere.[3,8] The time required for accumulating 80000 counts was recorded for solutions A and B, and that for 40000 counts for solution C. The $s\cdot i(s)$ curves in Fig. 1 with circles were obtained by multiplying the observed reduced intensities $i(s)$ by the s value ($s=4\pi\sin\theta/\lambda$).

The radial distribution function was calculated from the reduced intensities $i(s)$ according to Eq. 1:

$$D(r) = 4\pi r^2\rho_0 + \frac{2r}{\pi}\int_0^{15} s\cdot i(s)\cdot M(s)\cdot\sin(r\cdot s)\mathrm{d}s. \qquad (1)$$

In Eq. 1, $\rho_0=[\sum_i n_i f_i(0)]^2/V$. It denotes the average scattering power per unit volume V. $M(s)=[\sum_i n_i f_i(0)^2]/[\sum_i n_i f_i(s)^2]\times\exp(-0.01s^2)$; r is the distance in Å. The theoretical intensities, $i(s)_{\mathrm{calcd}}$, of the interactions for the given pairs of the atoms were calculated from Eq. 2:

$$i(s)_{\mathrm{calcd}} = \sum_i^{i\neq j}\sum_j n_{ij}\cdot f_i(s)\cdot f_j(s)\frac{\sin(r_{ij}\cdot s)}{r_{ij}\cdot s}\exp(-b_{ij}\cdot s^2), \qquad (2)$$

where $f_i(s)$ and $f_j(s)$ are the scattering factors of atoms i and j; and n_{ij}, r_{ij}, and b_{ij} are the frequency factor, the distance (Å), and the temperature factor (Å^2) of the interactions between atoms i and j. Least-squares refinements of the above structural parameters n, r, and b were made by the use of the NLPLSQ program[1] utilizing a selected s (Å^{-1}) range so as to

Results and Discussion

The $D(r)$ curves for solutions A, B, and C are given in Fig. 2. These show a common pattern exhibiting a shoulder around 1.0 Å, two distinct peaks with the maxima at 1.5 and 2.3 Å, and a shoulder between 3.0—3.5 Å.[9] The shoulder around 1.0 Å and the peak at 1.5 Å can be attributed to free and complexed CH_3OH molecules; the former is caused by the C—H and O—H interactions and the latter by the C—O interaction. In $D(r)$ curves obtained for methanol or methanolic solutions, the peak due to the C—O interaction has ordinarily been seen around 1.5 Å.[10] The shoulder located in the 3.0—3.5 Å region, judging from the position, may be ascribed to the mutual interactions among the ligands which are bound in the first coordination sphere and to the interactions between these ligands and the solvent CH_3OH molecules. The peak at 2.3 Å could be most informative for the interactions between Cu^{2+} and the ligands including CH_3OH and Cl^-. This peak appears to be quite symmetric, but, as will be discussed below, it can not be ascribed to solely one sort of interaction.

In order to analyze the $D(r)$ curve quantitatively, the area of the above peak has been taken into account. By supposing tentatively the presence of only one species of complex as $[Cu(CH_3OH)_6]^{2+}$,[11] the calculated peak area due to the six Cu–O interactions amounts to only 6/8 of the observed one, as shown in Fig. 3. Similarly, supposing only $[Cu(CH_3OH)_4]^{2+}$ to be present, the calculated peak area was not coincident with the observed one. Therefore, it appears necessary to accept the occurrence of the coordination of Cl^- to Cu^{2+} ion. In fact, Doe and Kitagawa recently reported that the stepwise formation constants of the chloro-copper complex species in methanol are $K_1 = 1.2 \times 10^5$, $K_2 = 2.5 \times 10^3$, and $K_3 = 1.7 \times 10^3$ (mol^{-1} dm^3).[12] On the basis of these data, the amounts of the complex species that include unitary bonding as $CuCl^+$, $CuCl_2$, and $CuCl_3^-$ are calculated to be 30.5, 37.6, and 31.5%, of the initial Cu^{2+} concentration in solutions A—C.[13] In addition, a survey of the bond distance data for the numerous chloro-copper(II) complex crystals suggested the following:

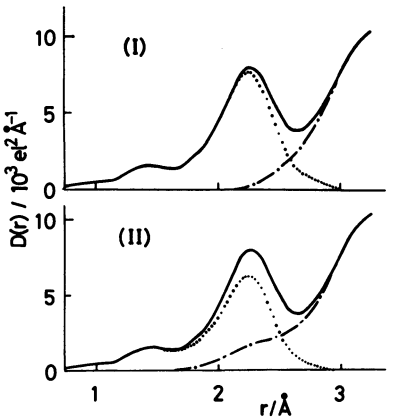

Fig. 3. Residual (—·—) $D(r)$ curves obtained by subtracting calculated $D(r)$ curves (·····) from observed $D(r)$ curve (——) for solution C.
(I); Calculated $D(r)$ curve is obtained by assuming the formation of "$CuCl_2(CH_3OH)_4$". (II); Calculated $D(r)$ curve is obtained by assuming the formation of $[Cu(CH_3OH)_6]^{2+}$.

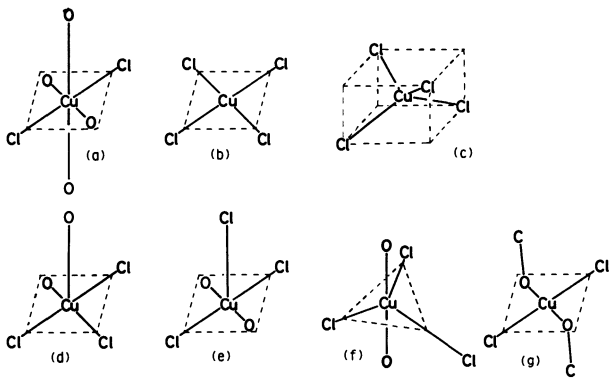

Fig. 4. Assumed structural models.

If the Cu^{2+} ion in methanolic solution had two sorts of coordination distances, one shorter and the other longer, and if it coordinated Cl^- ion with the longer one, the interaction due to such Cu—Cl bonding could be expected to appear at 2.6—3.0 Å. But, actually, no such peak appeared on the $D(r)$ curves in Fig. 2, so occurrence of the bonding in the above manner is unlikely. By taking into account the stability data, we assumed that the complexes including the unitary $CuCl^+$, $CuCl_2$, and $CuCl_3^-$ bonds are present in an elongated octahedral form wherein the Cu^{2+} ion coordinated the Cl^- ion with a bond distance shorter than 2.6 Å. These complexes are generally formulated as $[CuCl_n(CH_3OH)_{6-n}]$ (n=1—3), and on the basis of the stability data the mean composition of the complexes with n=1—3 existing in the solutions may be represented with a formula "$CuCl_2(CH_3OH)_4$". Therefore, the calculation of the peak area was carried out on "$CuCl_2(CH_3OH)_4$". As shown in Fig. 3, the calculated peak area agreed well with the observed one.

The structural model shown in Fig. 4-a was depicted. The model has axially elongated octahedral geometry and possesses two O atoms and two Cl^- ions at the equatorial sites, with the bond distances of 1.95 and 2.25 Å, respectively, and the other two O atoms at the axial sites with the bond distance of 2.45 Å. In order to determine the parameter values (n, r, and b values), the $s\cdot i\,(s)_{calcd}$ curves were calculated from Eq. 2 by employing a set of the parameter values selected tentatively for the Fig. 4-a. The refinements of these values were carried out by a least-squares method so that these gave an $s\cdot i\,(s)_{calcd}$ curve which agreed with the observed $s\cdot i\,(s)$ curve in the region of $s>5$ Å^{-1}. It was found that using the model, Fig. 4-a, the calculated $D(r)$ curve show a peak at 2.3 Å with the peak area closely agreed with the observed one. And, as shown in Fig. 1, a good agreement between the calculated and observed $s\cdot i(s)$ curves is seen in the region of $s>4$ Å^{-1}. The final parameter values used in these calculations are given in Table 2: it is noteworthy in Table 2 that the n values for the interactions, Cu-Cl, Cu-O (equatorial), and Cu-O (axial), are always nearly 2; this is consistent with the assumed six-coordinate complex. In Fig. 5 the smoothing of the observed $D(r)$ curves for solution C is demonstrated. The subtraction of the peaks due to the interactions expected for the model, Fig. 4-a, from the observed $D(r)$ curve gives finally a residual curve which is satisfactorily smooth.

Table 2. Structural parameter values of the $[CuCl_n(CH_3OH)_{6-n}]$(n=1—3) complexes

Solution (mol dm^{-3})	Parameter[a)]	Interaction		
		Cu–O_{eq}	Cu–O_{ax}	Cu–Cl_{eq}
A	r	1.950	2.458	2.230
(1.055)	b	0.0011	0.0084	0.0031
	n	2.109	1.938	2.019
B	r	1.947	2.423	2.236
(2.575)	b	0.0016	0.0072	0.0025
	n	1.982	2.089	2.085
C	r	1.926	2.473	2.238
(3.251)	b	0.0015	0.0074	0.0021
	n	1.919	2.023	2.048

a) r: Bond distance, Å; b: temperature factor, Å^2; n: frequency factor; eq, equatorial; ax, axial.

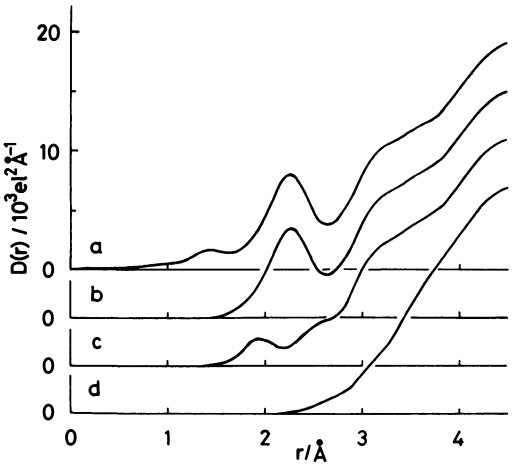

Fig. 5. Smoothing of $D(r)$ curve.
(a); $D(r)$ curve for solution C. (b); Obtained by subtracting the calculated peak due to the interactions within the methanol molecules from curve (a). (c); Obtained by subtracting the calculated peak due to the Cu–Cl_{eq} interactions from curve (b) (the clear peaks due to the Cu–O_{eq} and Cu–O_{ax} interactions are left at about 1.9 and 2.5 Å). (d); Final residual curve obtained by subtracting from curve (c) the calculated peaks due to the Cu–O_{eq} and Cu–O_{ax} interactions along with those due to the other expected intramolecular interactions (*cf.* Fig. 4-a).

A similar result of the $D(r)$ curve analysis could be deduced for the solution which was considered to include nearly equivalent amounts of the three complexes of n=1—3 in $[CuCl_n(CH_3OH)_{6-n}]$. It may be said from the formation data that almost all of the Cl^- ions are consumed for the above complexation; this makes the presence of chloro-bridged polymeric complexes improbable, for such polymer formation results in the presence of free Cl^- ions in the solution. In the concentrated methanolic 1.055—3.250 mol dm^{-3} $CuCl_2$ solutions, therefore, three monomeric complexes of the formula, $[CuCl_n(CH_3OH)_{6-n}]$ (n=1—3), were predominantly present; these possessed the axially elongated octahedral structure and coordinated the Cl^- ion equatorially.

The other structural models, b—g in Fig. 4, were also examined. As long as one considered the peak area and position of $D(r)$ curve, these models gave rise a peak with area and position similar to those of the observed peak at 2.3 Å. However, all of these models had to be discarded for the following reason. The temperature factors (b value) of the Cu–Cl bonding for the models b, c, and d were 0.02, 0.03, and 0.01 Å^2; these are too large, as compared with 0.0052 Å^2, a value known for the equatorial Cu–Cl bonding.[4] In the models e, f, and g, the b values, 0.0023—0.0032 Å^2, were not necessarily unreasonable, but these models had to be rejected for the following reasons. In model e, one of the Cl^- ions has to be at the apex apart from the Cu^{2+} ion with a very short distance, 2.45 Å, which is not plausible for the axial Cu–Cl bond distance. In model f, the Cu^{2+} ion binds two O atoms, two Cl^- ions, and one Cl^- ion with the distances of 1.95, 2.25, and 2.45 Å, respectively. This geometry resembles that in the $CuCl_2 \cdot 2DMSO$ crystal.[14] And this model gave an $s \cdot i\ (s)_{calcd}$ curve which fit the observed one well. But, the residual distribution curve obtained by using the model was not satisfactorily smooth in the 3—4 Å region. Model g gave an $s \cdot i\ (s)_{calcd}$ curve similar to that obtained by using model a. However, this geometry forces the the $\angle$Cu–O–C to be about 91°: This is not probable for the methanol molecule coordinated to the metal ions. The $\angle$Hg–O–C is 117° in the $HgCl_2 \cdot 2CH_3OH$ crystal,[15] and the $\angle$Cu–O–C is 119.5° in the $[Cu_2\{(CH_3)_2N(CH_2)_3NH(CH_2)_2O\}_2(CH_3OH)_2](ClO_4)_2$ crystal.[16]

9) The $D(r)$ curves reported by Wertz *et al.*[5] for the aqueous $CuCl_2$ solutions (3.18 and 4.35 mol dm^{-3}) showed five peaks at 1.95, 2.43, 3.2, 3.9, and 5.1 Å and one shoulder at 4.4 Å. They ascribed the peak at 3.9 Å to "secondary" Cu···O and Cu···Cl interactions between adjacent unitary molecules in the chloro-bridged polymeric complexes. On the $D(r)$ curves of the methanolic solutions subjected to our investigation, no peak around 3.9 Å was observed to appear.

Tetraammineplatinum(II)-Hydrogen Ion Exchange on α-Zirconium Phosphate and the Characterization of Its Complex Cation Form[1)]

Yoshitsugu HASEGAWA* and Giichi YAMAMINE

Department of Industrial Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Nakamachi, Koganei, Tokyo 184

(Received May 18, 1983)

The tetraammineplatinum(II)–hydrogen-ion exchange on α-zirconium phosphate has been investigated. The ion-exchange process was examined by measuring the change in the pH values of the supernatants. α-Zirconium phosphate loaded with tetraammineplatinum(II) was characterized by means of chemical analysis, X-ray diffractometry, infrared spectroscopy, and thermal analysis. The ion-exchange reaction proceeded more easily than the hexaaminecobalt(III)–hydrogen-ion exchange, and about 50% of the hydrogen ions in α-zirconium phosphate were replaced by tetraammineplatinum(II). The interlayer distance of the exchanger expanded from 7.60 to 10.7 Å.

α-Zirconium phosphate $Zr(HPO_4)_2 \cdot H_2O$ (α-ZP) has ion-exchange properties and catalytic activities. Though the great majority of work on α-ZP has dealt with the ion exchange, some catalytic properties have been studied.[2)] Also, it has been pointed out that α-ZP can be used as a catalytic support.[3)] In this case, the catalyst may be prepared as follows: Metal cations are exchanged with the protons in α-ZP and then reduced to a metallic state. The resultant catalyst may have two functional components, a metal and an acidic hydrogen; that is, it may work as a bifunctional catalyst, especially when the metal is one of the platinum group.[4)]

On the other hand, α-ZP has a layered structure and can form many intercalation compounds.[5)] Since salt forms of α-ZP also have a layered structure, a specific reaction can be expected between those layers.

The ion-exchange properties of α-ZP are influenced by its crystallinity, which depends on the method of preparation.[6)] When α-ZP is applied to a catalyst or a catalytic support, it is not necessary for α-ZP to be highly crystalline. The direct precipitation method has been employed during the course of these investigations so as to avoid differences due to the crystallinity. In the previous paper it was found that the hexaamminecobalt(III) ion, which is large, can exchange with the protons in α-ZP under suitable conditions.[7)] In this work, the tetraammineplatinum(II)–hydrogen-ion exchange was studied by the batch method, and the exchanger loaded with the complex cation (ZP–Pt) was characterized by means of chemical analysis, X-ray powder diffractometry, infrared spectroscopy, and thermal analyses.

Experimental

Preparation of α-ZP and Tetraammineplatinum(II) Chloride. The α-ZP was prepared by the direct precipitation method.[8)] The tetraammineplatinum(II) chloride was prepared according to the method of Kukuskine and Dkhara.[9)] Identification was made by elemental analysis and X-ray powder diffraction. The residue (ash) is assumed to be platinum metal. Found: Pt, 55.45; N, 15.91; H, 3.69; Cl, 19.39%. Calcd for $[Pt(NH_3)_4]Cl_2 \cdot H_2O$: Pt, 55.45; N, 15.91; H, 3.43; Cl, 20.14%. Though the X-ray diffraction pattern of $[Pt(NH_3)_4]Cl_2 \cdot H_2O$ has been previously presented,[10)] it differs from the one obtained in this work. This difference is caused by the facts that (1) only the strong reflections were recorded in the file, (2) the intensity of some diffraction peaks varied under the present experimental conditions, and (3), consequently, some peaks not listed in the file were observed as strong ones in this work. Cox analyzed the crystal structure of the complex and gave the lattice constants as $a_0 = 7.39 \pm 0.02$ and $c_0 = 4.21 \pm 0.02$ Å, and the space group as $P4/mmn$.[11)] Cox and Prestone later corrected a_0 to 14.76 Å.[12)] Since the diffraction peaks observed were indexed according to these constants in either case, the complex prepared was identified as $[Pt(NH_3)_4]Cl_2 \cdot H_2O$.

Ion Exchange. The ion-exchange procedures were similar to those reported previously.[7)] The concentration of the complex was 0.02 mol dm^{-3}, the reaction time, 48 h, and the reaction temperature, 25 °C.

Chemical Analysis. A weighed amount of ZP–Pt was mixed with sodium peroxide powder. Twenty-five ml of water were added to the mixture in an ice bath. The slurry thus obtained was placed on a water bath and heated for several hours. Then, the precipitate was filtered off and dissolved in hydrochloric acid. Zirconium was precipitated as cupferrate from the solution and determined gravimetrically. The filtrate was neutralized with hydrochloric acid and then another 5 ml of the acid were added to it. Platinum was separated as platinum sulfide by using thioacetamide as a homogeneous precipitant. The phosphorus was determined according to the literature.[13)]

Thermal Analysis. The differential scanning calorimetric (DSC) data were obtained with a Rigaku differential scanning calorimeter. Evolved gas analysis (EGA) was carried out with a Shimadzu pyrolyser-gas chromatograph.[14)] The thermogravimetric (TG) curve was obtained with a Shimadzu thermal analyser DT-30 at a heating rate of 10 °C/min under a herium stream.

Structural Study. The structural change in the exchanger was measured by means of X-ray diffractometry. The powder patterns were recorded with a Rigaku Denki Geigerflex diffractometer, using Ni-filtered Cu Ka ($\lambda = 1.542$ Å). The infrared (IR) spectra were measured on a JASCO DS-403G grating spectrophotometer.

Results and Discussion

Ion Exchange. The pH value of the supernatant solution was used as an indicator to ascertain the degree of the reaction. Figure 1 shows the pH change in the supernatant. In the first ion-exchange run, about 24% of the protons in α-ZP exchanged with the complex cation. The pH values rose, and the amount of the exchange per run decreased as the ion exchange proceeded. Then, the values reached the pH of the original solution. This ion exchange progressed more extensively than that for the hexaamminecobalt(III)–hydro-

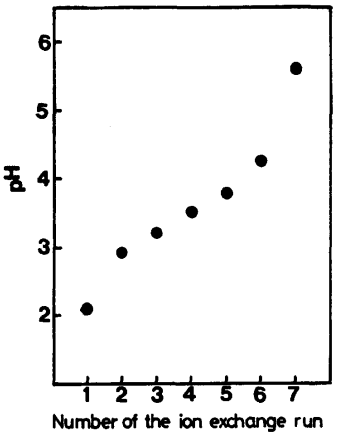

Fig. 1. pH change in the supernatant with the ion-exchange run.

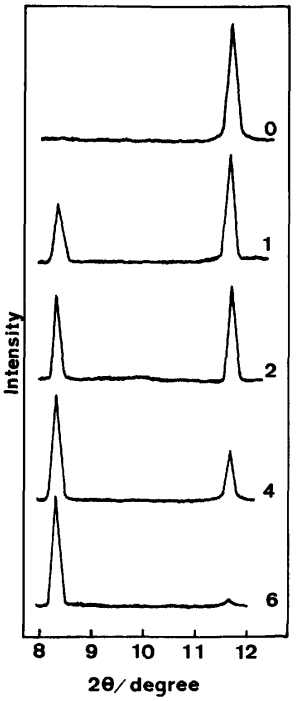

Fig. 2. Change in X-ray powder pattern of the exchanger. Numerals correspond to those of the ion-exchange runs in Fig. 1.

gen ion.[7] This difference may be explained on the basis of the size of the exchanging cation (see below).

In order to investigate the stoichiometry of the ion exchange, the composition of ZP–Pt was determined. Found: Zr, 20.2 (1.00); PO_4, 41.7 (1.96); Pt, 22.1 (0.51); N, 5.91 (1.89); H, 2.22 (9.83); weight loss by ignition, 17.9%. Calcd for $Zr[Pt(NH_3)_4]_{0.5}H(PO_4)_2 \cdot 1.5H_2O$: Zr, 20.7; PO_4, 43.1; Pt, 22.1; N, 6.53; H, 2.29; weight loss, 17.7%. In the parentheses are given the molar ratios of each element to zirconium. Since the ratio of nitrogen to platinum is equal to 3.7 and the hydrogen content agrees with the theoretical one, it can be said that $[Pt(NH_3)_4]^{2+}$ exchanges with two protons.

Structural Studies. Figure 2 shows the change in the X-ray diffraction patterns of the exchangers. The first peak at 8.3° (interplanar spacing of 10.7Å) appeared at the beginning of the ion exchange, and its intensity increased with the progress of the ion exchange. The intensity of the second peak decreased until it almost disappeared at the final stage of the ion exchange. The interplanar spacings of ZP–Pt are shown in Table 1.

TABLE 1. INTERPLANAR SPACINGS (*d*-VALUES) OF ZP–Pt

d/Å	I/I_0	*d*/Å	I/I_0
10.64	83	2.84	4
9.97	4	2.82	4
5.37	100	2.69	16
5.01	10	2.63	10
4.55	7	2.52	15
4.24	4	2.41	13
4.22	5	2.16	6
4.00	20	2.07	5
3.81	70	1.89	14
3.61	26	1.83	8
3.22	8	1.80	6
3.08	11	1.71	9
3.00	7	1.54	7

It is known that the interlayer distance of α-ZP depends on the cations present between layers. The first and the second peak correspond to the interlayer distances of ZP–Pt and α-ZP. If the ammonias coordinating to platinum are abstracted directly by α-ZP, or if they contribute to the ion exchange as ammonium ions, the ammonium form of α-ZP must be formed and the peak at 9.4° must be observed. As is shown in Fig. 2, this peak was not present in the present diffractograms.

Since the crystal structure of the salt forms of α-ZP has not been analyzed, the relationship between the interlayer distance and the counter-ion size is not clear. Generally, the interlayer distance increases with the size of the counter-ion. One of the salt forms, $ZrNaH(PO_4)_2 \cdot 5H_2O$ (monosodium form), has the interlayer distance of 11.8 Å[15]. The sodium ion was bonded to about four water molecules at the distance of 2.4 Å in a concentrated aqueous sodium iodide solution.[16] Assuming that the sodium ion in α-ZP retains the same structure as in the solution, the sphere with a diameter of 7.6 Å may be said to be present between the layers of the monosodium form. In hexaamminecobalt(III) ammonias coordinate octahedrally, and the complex cation can be assumed to be a sphere with a diameter of 7.6 Å.[17] The interlayer distance of ZP–Co was 11.2 Å (ZP-Co is α-ZP loaded with $[Co(NH_3)_6]^{3+}$).[7] The two interlayer distances are almost equal, in accordance with the size of the cations present. According to Cox, tetraammineplatinum(II) has a square planar structure, and the length of the side and the thickness can be estimated to be 5.7 and 2.8 Å respectively.[11] The platinum complex cation can be arranged between layers in three manners, namely, perpendicular, inclined, and parallel to the layer of α-ZP. The interlayer distance of ZP–Pt was 10.6 Å, slightly shorter than that of ZP–Co. This suggests that the plane of tetraammineplatinum(II) is not parallel to the layer of α-ZP.

The IR spectra of ZP–Pt and the ammonium form of α-ZP are shown in Fig. 3. The absorption bands whcih are

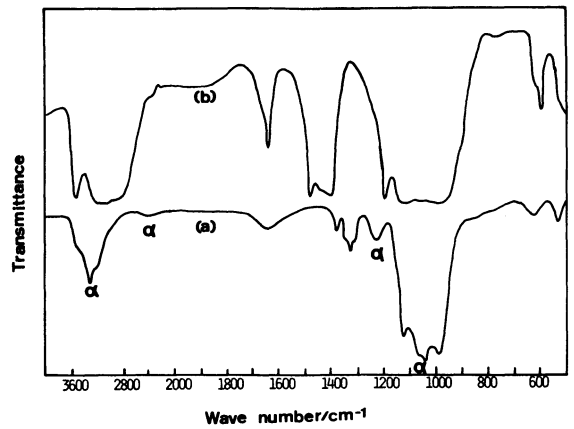

Fig. 3. IR spectrum of ZP-Pt (a) and the ammonium form of α-ZP (b).

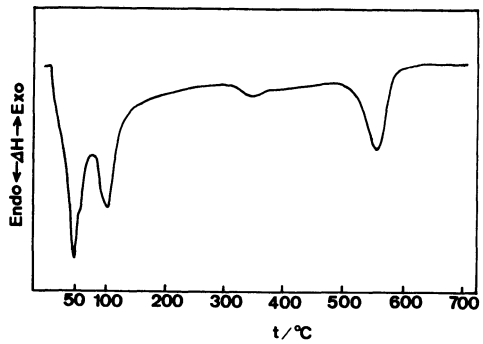

Fig. 4. DSC curve of ZP-Pt.

assigned by Horsley *et al.* are denoted by the symbol *a* in the figure.[18] The ammonia in tetraammineplatinum(II) ion gave absorptions at 3130, 1630, 1570, 1370, 1352, 1333, and 840 cm^{-1}.[19] The spectrum of ZP-Pt was composed of that of α-ZP and the tetraammineplatinum(II), except for the absorptions at 840 and 1570 cm^{-1}. These bands were assigned to the degenerate deformation and the rocking vibration of ammonia. According to Fujita *et al.*, the rocking vibration is sensitive to the kind of outer ion and the hydrogen bonding, and the absorption band is shifted to higher frequencies by these effects.[20] In ZP-Pt the ammonias form hydrogen bonds with the surrounding phosphate groups; consequently, the rocking vibration shifted and overlapped with the absorption bands of phosphate in the 900—1200 cm^{-1} region. It is considered that the absorption of 1570 cm^{-1} was shifted by the same cause and was observed in the 1500—1700 cm^{-1} region as a single band.

Thermal Studies. The DSC curve is shown in Fig. 4. The thermal decomposition took place in four steps, all of them endothermic. The evolution of ammonia was examined for each step. Ammonia was detected only at the third step. When ZP-Pt was decomposed in static air, the third step was observed as exothermic. This shows that the evolved ammonias were oxidized at the surface of a platinum crucible.[21] The ZP-Pt turned black after the third step, indicating that the platinum(II) ion in the solid was reduced to platinum(0) during the thermal decomposition and that nitrogen gas was evolved.

Table 2. Weight loss of ZP-Pt upon heating

t/°C	Experimental(%)	Theoretical(%)
200	8.39	6.13
420	13.4	13.6
600	17.9	17.7

In Table 2 the weight loss by heating is shown. Assuming that the possible decomposition pathways are as in the following scheme, the theoretical values are obtained. The experimental values agreed well with the theoretical ones at 420 and 600 °C, but the agreement is poor for the decomposition at 200 °C. At present it is impossible to give a proper interpretation of this disagreement.

$$Zr[Pt(NH_3)_4]_{0.5}H(PO_4)_2\cdot 1.5H_2O(ZP\text{-}Pt) \xrightarrow{\approx 200\,^\circ C}$$
$$Zr[Pt(NH_3)_4]_{0.5}H(PO_4)_2\ (I) \xrightarrow{\approx 420\,^\circ C} ZrPt(0)(HPO_4)_2\ (II)$$
$$\xrightarrow{\approx 600\,^\circ C} ZrPt(0)P_2O_7\ (III)$$

Scheme 1.

Compounds (II) and (III) were amorphous. The presence of zirconium pyrophosphate could not be detected. When ZP-Pt was heated to about 900 °C in a crucible and then examined by means of X-ray diffractometry, broad peaks were present at $2\theta=39.6$ and 46.4°. These correspond to the (111) and (200) planes of platinum metal.[22]

The authors wish to express their thanks to Mr. Yukihiro Takekawa for the IR measurements and to Professor Isao Tomita, Tokyo University of Fisheries, for the measurement of the TGA data.

A Chromatographic Study of the Acidic Hydrolysis of *cyclo*-Hexa- and *cyclo*-Octaphosphate

Genichiro KURA

Department of Chemistry, Fukuoka University of Education, Akama, Munakata, Fukuoka 811-41

(Received May 23, 1983)

The hydrolysis rate of inorganic *cyclo*-hexa- and *cyclo*-octaphosphate in 0.1 mol dm^{-3} HCl was determined by means of anion-exchange chromatography. The phosphorus content in the column effluent was determined automatically by the use of the Mo^{V}–Mo^{VI} reagent. The hydrolysis reactions were first-order. The rate constant decreases from *cyclo*- tri- to *cyclo*-hexaphosphate with the increased ring, however, that of *cyclo*-octaphosphate increases again. This increase is thought to be due to the stronger proton affinity of *cyclo*-octaphosphate. The Arrhenius activation energies for *cyclo*-hexa- and *cyclo*-octaphosphate hydrolysis were 91.5 and 96.9 kJ mol^{-1} respectively.

Of the condensed cyclic phosphates, six-membered *cyclo*-tri- and eight-membered *cyclo*-tetraphosphate have been known since the 19th century.[1] Investigations of the higher-membered cyclic phosphates have, however, progressed only slowly.[2–5] We have recently reported some chemical properties of these phosphates.[6–10] These phosphates are very important electrolytes because of their high negative charge on relatively compact structure. When using these anions in the aqueous state for various purposes, for example, as a complexing agent with various cations or a food additive in place of higher-membered linear phosphates, their hydrolysis properties, which have rarely been described, must be known clearly.

The hydrolysis reaction of *cyclo*-tri- and *cyclo*-tetraphosphate have been reported by several authors.[11,12] However, most investigators have used paper chromatography as an analytical tool. As has previously been pointed out by us, though, it is difficult to obtain reliable data on hydrolysis kinetics by this technique.

We ourselves have applied anion-exchange chromatography to the analysis of the hydrolysis products of *cyclo*-tri-[13] and *cyclo*-tetraphosphate.[14] The phosphorus content in the column effluents was determined automatically by the use of the Mo^{V}–Mo^{VI} reagent. From the chromatograms of the hydrolysis products, the kinetic data of *cyclo*-tri- and *cyclo*-tetraphosphate in a 0.1 mol dm^{-3} hydrochloric acid solution were obtained.

In both cases, the chromatographic run of each hydrolysis sample was finished within 50 min. Our analytical method is thought to be more fitting than the paper chromatographic method in terms of rapidity and reliability.

For *cyclo*-tetraphosphate hydrolysis studies, various experimental conditions were examined for the separation of parent compound and the hydrolysis products-linear tetra-, tri-, di- and monophosphates. Finally, suitable conditions for than purpose were found.

Similar analytical conditions for the *cyclo*-tetraphosphate hydrolysis products were also examined for studies of the hydrolysis of twelve-membered *cyclo*-hexaphosphate and sixteen-membered *cyclo*-octaphosphate.

Futhermore, the hydrolysis reaction of these cyclic phosphates might be utilized in the preparation of higher-membered linear phosphates which are their hydrolysis products.

In this paper, linear and cyclic phosphate are abbreviated as P_n and P_{nm} respectively, where n is the degree of polymerization.

Experimental

Materials. As an anion-exchanger, Hitachi Custom Ion-exchange Resin 2630 was used.

The sodium *cyclo*-hexa- and *cyclo*-octaphosphate was prepared by the methods of Griffith and Buxton[4] and Schülke[5] respectively.

Chromatographic System. The system is shown in Fig. 1. Pump A is a part of the Hitachi Model 635 liquid chromatograph. Pump B is a Model KHU-W-52 apparatus made by the Kyowa Seimitsu Co.

As eluents, a mixture of 0.4 mol dm^{-3} of potassium chloride and 0.005 mol dm^{-3} EDTA (2Na salt), the pH of which has been adjusted to 10.2 with a sodium hydroxide solution, was used. In this eluent, EDTA acts as the buffer reagent, while the masking reagent of the metal ions present as an impurity.

Hydrolysis. The initial concentration of the *cyclo*-hexa- and *cyclo*-octaphosphate solution to be hydrolysed was adjusted to 1.25×10^{-3} mol dm^{-3}.

Hydrochloric acid was added to each solution at a concentration of 0.1 mol dm^{-3}, and the hydrolysis reaction was performed in a water bath, the temperature of which was maintained within ± 0.1 °C. At measured time intervals, samples of a few cubic centimeters were withdrawn and neutralized with the same volume of a 0.1 mol dm^{-3} sodium hydroxide solution at nearly 0 °C.

The present author ascertained that the hydrolysis reaction of *cyclo*-hexa- and *cyclo*-octaphosphate in a neutral solution does not occur at a low temperature. For example, the hydrolysis products of both phosphates were not observed when the phosphates were boiled for 1 h in a neutral solution.

The sample solution were stored in a refrigerator until taken out for analysis.

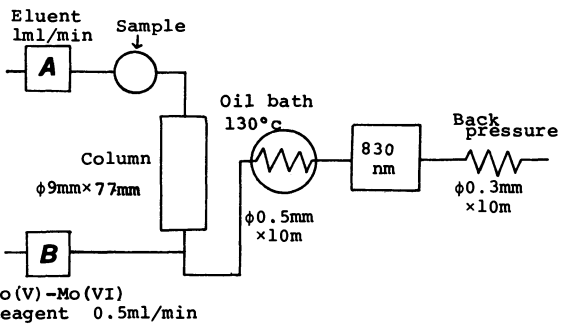

Fig. 1. Flow diagram of chromatograph and detection system.

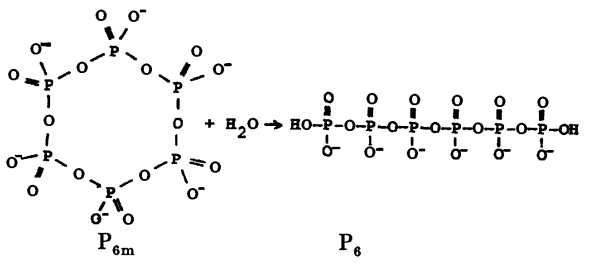
Results and Discussion

When *cyclo*-hexaphosphate is hydrolysed as shown in Eq. 1, the initial hydrolysis product is linear hexaphosphate; it can also be hydrolysed to lower linear phosphates and probably to *cyclo*-triphosphate.



P_{6m} P_6

$$P_6O_{18}^{6-} + H_2O \rightarrow H_2P_6O_{19}^{6-} \rightarrow P_5 \rightarrow P_4 \rightarrow P_3 \rightarrow P_2 \rightarrow P_1 \quad (1)$$

It is necessary to separate the parent compound and the seven hydrolysis products for the determination of the hydrolysis rate. Anion-exchange chromatography was thought to be best fitted for this purpose. The present author has, with the use of Hitachi Custom Ion 2630 resin applied anion-exchange chromatography to the analysis. As reported in our previous paper[14] on the separation of *cyclo*-tetraphosphate and its hydrolysis products, the distribution ratio of cyclic phosphates on the anion-exchange resin is not affected by the variation in the pH when the chloride-ion concentration of an eluent is constant. In the case of linear di- and triphosphate, their distribution ratios decrease appreciably with the increase in the pH at a constant chloride concentration.[15] From the retention volume on the column presented in our previous paper,[14] it was found that the distribution ratio of linear tetraphosphate also decreases with the increase in pH. From this fact, it was expected that the increase in the pH in the eluent might result in the achievement of a separation between *cyclo*-hexaphosphate and its hydrolysis products, which is impossible in the lower-pH range. Therefore, a mixture of *cyclo*-hexaphosphate and polyphosphate glass ($\bar{n}=10$) was eluted on the column with the use of 0.4 mol dm^{-3} KCl at pH 10.2 as the eluent.

The resulting chromatogram is shown in Fig.2. At least, linear phosphates with the polymerization degree less than eight were eluted in stages earlier than *cyclo*-hexaphosphate. The peak volume of an elution curve of *cyclo*-triphosphate as a hydrolysis product was about 75 cm^3 under these conditions.

The hydrolysis products of *cyclo*-hexaphosphate were analyzed under these chromatographic conditions.

cyclo-Octaphosphate of the sixteen-membered ring was eluted 10 cm^3 later than *cyclo*-hexaphosphate. Consequently, *cyclo*-octaphosphate and its hydrolysis products were successfully separated under the same elution conditions.

As discussed in our earlier papers, first-order hydrolysis-rate constants of *cyclo*-tri- and *cyclo*-tetraphosphate in a 0.1 mol dm^{-3} HCl solution varied with their initial concentration up to the relatively lower-concentration region. The hydrolysis rates of *cyclo*-hexa- and *cyclo*-octaphosphate were measured by changing those initial concentrations. A constant rate constant was obtained when the initial concentrations of both phosphates were lower than 2.5×10^{-3} mol dm^{-3}.

In the following hydrolysis experiments, the initial concentration of the parent compound was fixed at 1.25×10^{-3} mol dm^{-3}. We have presumed that the variation in the rate constant with the initial concentrations is due to the change in the hydrogen concentration in a test solution as the hydrolysis reaction proceeds.

An example of chromatograms of the hydrolysis products of *cyclo*-hexaphosphate in 0.1 mol dm^{-3} HCl at 40 °C is shown in Fig. 3. It was confirmed by a separate experiment that the area of the chromatogram of the *cyclo*-hexaphosphate thus obtained *versus* the phosphate concentration known gave a straight line passing through the point of origin. From the chromatograms of the hydrolysis products, the hydrolysis rate was calculated. The area of the chromatograms of the hydrolysis sample was automatically estimated by connecting an output terminal from the spectrophotometer to a SORD Mark IIIB micro computer through an A-D converter.

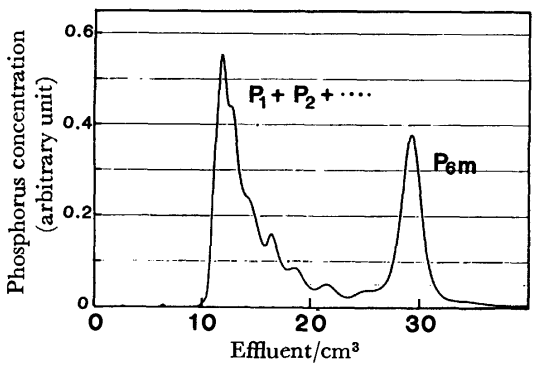


Fig. 2. Elution chromatogram of *cyclo*-hexaphosphate and linear oligophosphates mixture with 0.4 mol dm^{-3} potassium chloride solution (pH 10.2).

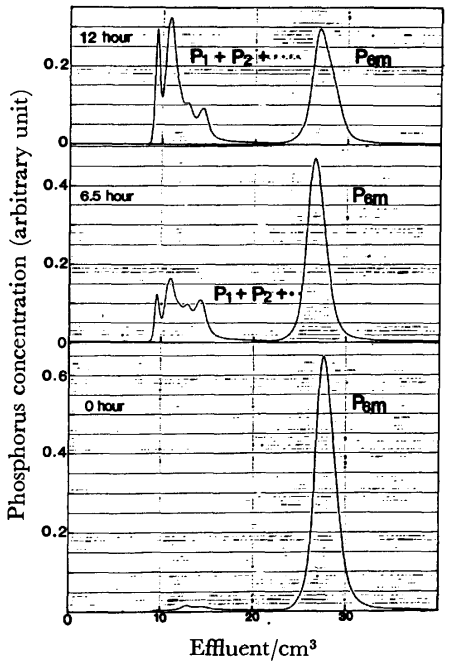

Fig. 3. Chromatograms of hydrolysis samples of *cyclo*-hexaphosphate in 0.1 mol dm^{-3} hydrochloric acid at 40 °C.

As was pointed out in the earlier papers,[13,14] the hydrolysis reactions of condensed phosphates have been known to be first-order. Let the total concentration of *cyclo*-hexaphosphate be c; the hydrolysis rate, $-dc/dt$, can thus be written as;

$$-\frac{dc}{dt} = k_0[P_6O_{18}^{6-}] + k_1[HP_6O_{18}^{5-}] + k_2[H_2P_6O_{18}^{4-}] + k_3[H_3P_6O_{18}^{3-}] + k_4[H_4P_6O_{18}^{2-}] + k_5[H_5P_6O_{18}^{-}] + k_6[H_6P_6O_{18}], \quad (2)$$

where $k_i (i=0—6)$ are rate constants for individual protonated species. If the molar fractions of the protonated species are written as X_6 for $H_6P_6O_{18}$, X_5 for $H_5P_6O_{18}^{-}$, and so on, the hydrolysis rate can be written as;

$$-\frac{dc}{dt} = (k_0X_0 + k_1X_1 + k_2X_2 + k_3X_3 + k_4X_4 + k_5X_5 + k_6X_6)c = k_{obsd}c, \quad (3)$$

where;

$$k_{obsd} = k_0X_0 + k_1X_1 + k_2X_2 + k_3X_3 + k_4X_4 + k_5X_5 + k_6X_6.$$

When the hydrogen-ion concentration is constant, k_{obsd} should be constant. Accordingly, from the first-order hydrolysis rate equation (3), if $[P]_0$ and $[P]_t$ are denoted as the concentrations of *cyclo*-hexaphosphate at time 0 and t respectively, $\log([P]_t/[P]_0)$ *versus* t plots should give a straight line.

Similar treatments are possible for the *cyclo*-octaphosphate hydrolysis reaction.

$\log([P]_t/[P]_0)$ *versus* t plots for *cyclo*-hexa- and *cyclo*-octaphosphate hydrolysis at various temperatures are shown in Figs. 4 and 5. Good straight lines were obtained, hence, the hydrolysis reactions of both phosphates are first-order. The apparent first-order rate constants, k_{obsd}, and half-lives, $t_{1/2}$, at various temperatures are shown in Table 1.

From the k_{obsd} at the various temperatures examined, the linear Arrhenius plots shown in Fig. 6 were obtained. The Arrhenius activation energies, *Ea*, were 91.5 and 96.9 kJ mol^{-1} for *cyclo*-hexa- and *cyclo*-octaphosphate respectively, nearly equivalent to those obtained for

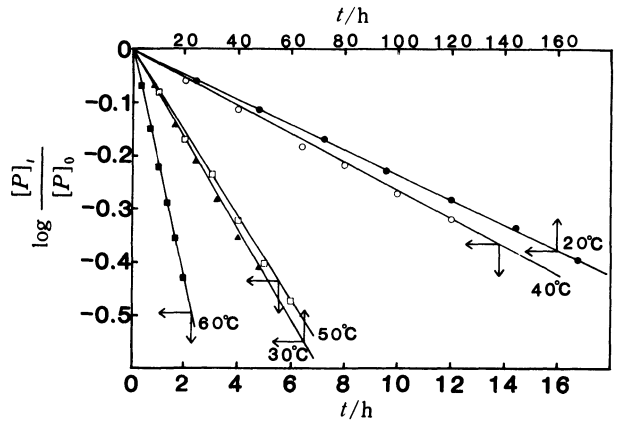

Fig. 4. Hydrolysis rate of *cyclo*-hexaphosphate in 0.1 mol dm^{-3} hydrochloric acid at various temperatures.

	$t_{1/2}$/h	128	35.4	11.4	3.82	1.40
P_{8m}	k_{obsd}/h^{-1}	1.17×10^{-2}	4.31×10^{-2}	0.153	0.486	1.39
	$t_{1/2}$/h	59.3	16.1	4.53	1.43	0.500

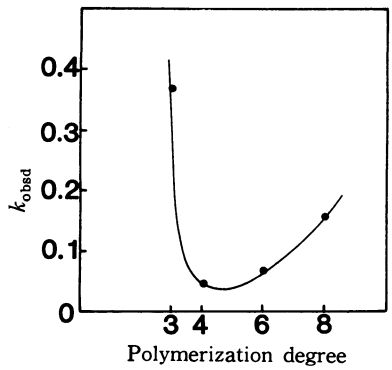

Fig. 7. First order rate constants as a function of polymerization degree in 0.1 mol dm^{-3} hydrochloric acid at 40 °C.

other condensed phosphates in acidic media.

The apparent rate constants, k_{obsd}, of *cyclo*-hexa- and *cyclo*-octaphosphate in 0.1 mol dm^{-3} HCl at 40 °C are plotted *versus* their polymerization degree in Fig. 7, along with the data for *cyclo*-tri- and *cyclo*-tetraphosphate reported in our previous papers.[13,14] This graph has a minimum at a polymerization degree near 5. This fact can be explained as follows. The present author has not obtained sufficient data on cyclic phosphate hydrolysis in alkaline media; however, from Ref. 3, it can be presumed that the stability of the ring structure of cyclic phosphate in an alkaline solution increases with an increase in the ring size. On the other hand, the hydrolysis rates of condensed phosphates are accelerated very much by the proton which binds to the phosphates. The bonding of the hydrogen ion to the oxygen atom involved in the phosphate tetrahedron renders the phosphorus atom more positive by reducing the electron density around that atom and more susceptible to nucleophilic attack by water molecules. As has been reported in our previous paper,[9] the degree of bonding with the hydrogen ion increase with an increase in the size of the ring. Accordingly, an increase in proton affinity would result in an increase in the k_{obsd}.

From the two opposite effects increasing and decreasing k_{obsd} presented above, k_{obsd} comes to have a minimum near the pentamer under acidic conditions.

Studies of the Selective *O*-Alkylation and Dealkylation of Flavonoids. VI.[1] Demethylation of 8-Hydroxy-5,7-dimethoxyflavones with Anhydrous Aluminum Chloride or Bromide in Acetonitrile

Tokunaru Horie,* Hiroki Kourai, and Nobuhisa Fujita

Department of Applied Chemistry, Technical College of Tokushima University, Minamijosanjima-cho, Tokushima 770

(Received June 6, 1983)

The demethylation of seven 8-hydroxy-5,7-dimethoxyflavones with anhydrous aluminum chloride or bromide in acetonitrile was studied and the following results were obtained. (1) Anhydrous aluminum chloride in acetonitrile selectively split the 5-methoxyl group without cleavage of the 7-methoxyl group, and seven 5,8-dihydroxy-7-methoxyflavones were quantitatively synthesized by the demethylation. (2) In the demethylation with anhydrous aluminum bromide, the 5- and 7-methoxyl groups on 4′,5,7-trimethoxy- and 3′,4′,5,7-tetramethoxy-8-hydroxyflavone were selectively split to give the corresponding 5,7,8-trihydroxyflavones in good yield. However, the demethylation was not accessible to the synthesis of 5,7,8-trihydroxy-3′,4′,5′-trimethoxyflavone, 4′,5,7,8-tetrahydroxy-3′-methoxy-, and 3′,5,7,8-tetrahydroxy-4′-methoxyflavone, because of the cleavage of the methoxyl groups on the B ring. The synthesized flavones were employed for the identification of the two natural flavones, which were proposed to be 4′,5,8-trihydroxy-7-methoxyflavone and 4′,5,8-trihydroxy-3′,7-dimethoxyflavone. The former, salvitin, was revised to 4′,5,7-trihydroxy-6-methoxyflavone and the latter seemed to be 4′,5,7-trihydroxy-3′,8-dimethoxyflavone.

In 1975, Gupta *et al.*[2] identified salvitin, isolated from *Salvia plebeia*, as 4′,5,8-trihydroxy-7-methoxyflavone (**1b**) on the basis of the spectral data and the synthesis by the two methods: the nuclear oxidation of 4′,5-dihydroxy-7-methoxyflavone and the oxidative demethylation of 4′-benzyloxy-5,7,8-trimethoxyflavone with nitric acid *via* the corresponding 5,8-quinone derivative. On the basis of the UV and MS data, Whalen *et al.*[3] claimed that one of the natural flavones which were isolated from *Solanum* section *Androceras* was 4′,5,8-trihydroxy-3′,7-dimethoxyflavone (**1d**). Recently, two natural flavones, 5,7,8-trihydroxy-4′-methoxyflavone (**2a**)[4] and 4′,5,7,8-tetrahydroxy-3′-methoxyflavone (**2d**)[3] were also isolated in the form of glycosides. A convenient method for synthesizing 5,8-dihydroxy-7-methoxyflavones (**1**) and 5,7,8-trihydroxyflavones (**2**) such as the above natural flavones seems to be the oxidative demethylation[2,5] of 5,7,8-trioxygenated flavones using nitric acid. However, little 5,8-dihydroxy-4′,7-dimethoxyflavone (**1a**) was synthesized from 4′,5,7,8-tetramethoxyflavone[6] by use of this method.

On the other hand, we had reported that 5,6-dihydroxy-7-methoxyflavones (**4**) and 5,6,7-trihydroxyflavones (**5**) were synthesized from 6-hydroxy-5,7-dimethoxyflavones (**3**) by the demethylation with anhydrous aluminum chloride in acetonitrile.[7] The results suggest that **1** and **2** may be synthesized from 8-hydroxy-5,7-dimethoxyflavones (**6**), isomers of **3**. Hence the selective demethylation of **6** with anhydrous aluminum chloride or bromide was studied, and it was found that **1a**—**g** and **2a**, **c** were synthesized from the corresponding **6** in high yield. In this paper, we report on the demethylation of **6**, the characterization of **1** and **2**, and the identification of the two natural flavones which were proposed as 5,8-dihydroxy-7-methoxyflavones (**1b** and **1d**).

Results and Discussion

Syntheses of 8-Hydroxy-5,7-dimethoxyflavones (6). The 2-benzyloxyl group on 2,3-bis(benzyloxy)-4,6-dimethoxyacetophenone (**8**), which was easily derived from 2,3-dihydroxy-4,6-dimethoxyacetophenone (**7**),[8] was selectively split with hydrochloric acid in acetic acid to give 3-benzyloxy-2-hydroxy-4,6-dimethoxyacetophenone (**9**) in good yield. But the partial benzylation of **7** with benzyl chloride-anhydrous potassium carbonate in acetone or *N*,*N*-dimethylformamide did not give **9** in favorable yield because of the formation of by-products. The benzoates, derived from **9** with substituted benzoyl chlorides, were converted into the diketone derivatives (**10**) by the Baker-Venkataraman rearrangement with potassium hydroxide in anhydrous pyridine. Cyclization of **10** with anhydrous sodium acetate in acetic acid easily led to 8-benzyloxy-5,7-dimethoxyflavones (**11**) which were quantitatively converted into **6** by the hydrogenolysis with palladium on charcoal.

Demethylation of 8-Hydroxy-5,7-dimethoxyflavones (6) with Anhydrous Aluminum Chloride in Acetonitrile. In the previous paper,[9] we reported that the 5-methoxyl group on the acetates of 6-hydroxy-5,7,8-trimethoxyflavones was quantitatively split to give 5,6-dihydroxy-7,8-dimethoxyflavones with about 5% (w/v) anhydrous aluminum chloride in acetonitrile at 80 °C. But under the same conditions, few of the 5-methoxyl groups on **6a** and its acetate (**12a**) were split. On the other hand, the 7-methoxyl group on **6a** was not completely split with about 30% (w/v) anhydrous aluminum chloride in acetonitrile, in contrast to that of 6-hydroxy-5,7,8-trimethoxyflavones[9] and **3**.[7] Therefore, **1a**—**g** were easily synthesized from **6** in quantitative yield under the following conditions: about 10% (w/v) anhydrous aluminum chloride in acetonitrile at 70 °C for 10 h.

The benzyloxyl groups on **11** were also split to give **1** under the above conditions. However, the high performance liquid chromatograms (HPLC) of the demethylated products from the flavones (**6b**, **d**, **e**, and **f**) which had benzyloxyl groups on the B ring indicated the existence of by-products having longer retention time than that of **1**. Consequently, for the synthesis of **1**, the demethylation of **6** was better than that of **11**.

The ^{1}H NMR data for the hydroxyflavones (**1** and **6**) (in DMSO) and the acetates (**13**) of **1** (in $CDCl_3$) are shown in Tables 1 and 2. The C_3- and C_6-proton

signals listed in these Tables were assigned on the basis of the NOE experiment for **1a** and **13a**: the integrated intensities of the singlets at δ 6.52 for **1a** and δ 6.67 for **13a** increased about 28 and 22% respectively, when the methoxyl groups were saturated by double irradiation. The C_6-proton on **1** is not affected by their substituents on the B ring and its signals are in the narrow range of δ 6.51 to 6.54, while the C_3-proton is slightly affected and its signals are in the slightly wider range of δ 6.65 to 7.02. These phenomena are also observed in the spectra for **6** and **13**. On the other hand, the signals for C_6-proton on **13** in $CDCl_3$ are in the range of δ 6.67 to 6.69 and the range shifts about 0.15 ppm lower than that of **1** in DMSO (δ 6.51—6.54). These δ values for **1** and **13** are distinct from those for 5,7-dihydroxy-8-methoxyflavones (**14**)[10-12] (C_6–H, $\delta\approx$6.3; acetates, $\delta\approx$6.8) or 5,7-dihydroxy-6-methoxyflavones (**15**)[13,14] (C_8–H, $\delta\approx$6.6; acetates, $\delta\approx$7.3).

In the UV spectra for **1**, Bands I and II are seen at about 330 and 280 nm respectively, as shown in Table 3. These bands undergo bathochromic shift by the addition of aluminum chloride and the spectra consist typically of four major absorption peaks. The properties are greatly different from those of 5,6,7-trihydroxyflavone derivatives such as **15**[13,14] or **4**[7,15] However, the UV data for the flavones (**1**) are essentially identical with those for the corresponding 5,7-dihydroxy-8-methoxyflavones (**14**),[10-12] the isomers of **1**, but a little differences were observed at 300—330 nm in the presence of aluminum chloride.

On the other hand, Bands I and II for the 5,7-dihydroxyflavones (**14**) are shifted bathochromically by the addition of sodium acetate,[10-12] but these bands for the 5,8-dihydroxyflavones (**1a**, **c**, **e**, and **g**) which have not the 4'-hydroxyl group do not show any bathochromic shift. In the UV spectra for the 5,8-dihydroxyflavones (**1b**, **d**, and **f**) having the 4'-hydroxyl group, Band II which associates with absorption involving the A ring benzoyl system do not also shift bathochromically by the addition of sodium acetate, but Band I undergoes a bathochromic shift and splits into two typical absorption peaks: one has the same wavelength as Band I and the other is in a range of 390—410 nm (Table 3).

*Demethylation of 8-Hydroxy-5,7-dimethoxyflavones (**6**) with Anhydrous Aluminum Bromide in Acetonitrile.* In the HPLC of 5,6,7-trioxygenated flavones, their retention times have been known to decrease with increasing numbers of hydroxyl groups except for 5-hydroxyl

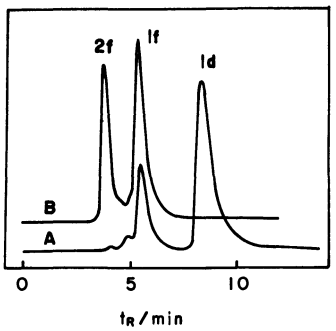

Fig. 3. HPLC of demethylated products from **6d** with anhydrous aluminum bromide in acetonitrile at 50 °C for 2 h (A) and 12 h (B).
Same conditions as in Fig. 1.

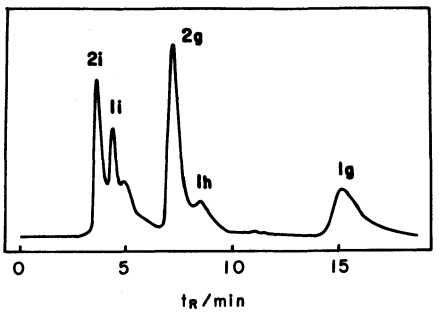

Fig. 4. HPLC of demethylated product from **6g** with anhydrous aluminum bromide in acetonitrile at 50 °C for 12 h.
Same conditions as in Fig. 1.

group.[16] The high performance liquid chromatography may be very useful for the separation of the demethylated products. Therefore, the demethylation of **6** with anhydrous aluminum bromide in acetonitrile was investigated in order to find a suitable method for the syntheses of 5,7,8-trihydroxyflavones (**2**) by the chromatography. The HPLC obtained are shown in Figs. 1—4.

The HPLC of the demethylated products from **6a** in the atmosphere showed the presence of three components (Fig. 1, Curve A). These components were identified as 5,7,8-trihydroxy-4′-methoxyflavone (**2a**), 6-bromo-5,7,8-trihydroxy-4′-methoxyflavone (**17**), and **1a** respectively, on the basis of the ^1H NMR and UV data (Tables

1—3). The amount of the bromoflavone (**17**) increased with increasing reaction time, but apparently decreased in nitrogen atmosphere (Fig. 1, Curve B). The 4'-methoxyl group of **6a** was stable under these demethylation conditions, so that 4',5,7,8-tetrahydroxyflavone (**2b**)[17] in the demethylated products was not detected by the high performance liquid chromatography. These results show that the 5- and 7-methoxyl groups of **6a** are selectively split with anhydrous aluminum bromide in nitrogen atmosphere to give **2a** in good yield.

The 5- and 7-methoxyl groups of **6c** were also selectively split under the above conditions to give **2c** as a main product. However, the HPLC of the demethylated product from **6c** showed small peaks which had shorter retention times than that of **2c** (Fig. 2). These small peaks are presumed to be those of the demethylated products of **2c**.

In the HPLC of the demethylated product from **6d**, the components of main peaks (R_t 3.8, 5.4, and 8.2 min) were identified as 3',4',5,7,8-pentahydroxyflavone (**2f**),[18] **1f**, and **1d** respectively, and the small peak (R_t 4.9 min) which is observed as a shoulder peak is estimated to be that of 4',5,7,8-tetrahydroxy-3'-methoxyflavone (**2d**) (Fig. 3). These results indicate that the 3'-methoxyl group is more easily split than the 7-methoxyl group and that the methoxyl groups of **6d** are split in the following order: 5, 3', and 7.

Similarly **6e**, an isomer of **6d**, was demethylated to **2f** *via* **1f**, but the 4'-methoxyl group was more easily split than the 3'-methoxyl group on **1d**. These results indicate that the hydroxyl group promotes the cleavage of adjacent methoxyl group. The cleavage of the methoxyl group with anhydrous aluminum bromide seems to proceed *via* the formation of a cyclic aluminum complex between the hydroxyl group and the methoxyl oxygen atom adjacent to each other.[19] However, the cleavage of 7-methoxyl group was clearly slower than that on the B ring of **1d** or **1e**, even though both of the methoxyl groups have an adjacent hydroxyl group. One of the causes of the difficulty in the cleavage of 7-methoxyl group may be that the 8-hydroxyl group has a tendency to form the cyclic aluminum complex with the ether oxygen atom at 1 position on the flavone nucleus.

On the other hand, the HPLC of the demethylated product from **6g** which has three methoxyl groups adjacent to each other showed the presence of many components (Fig. 4). The five main components were identified as 3',4',5,5',7,8-hexahydroxyflavone (**2i**), 3',4',5,5',8-pentahydroxy-7-methoxyflavone (**1i**), 5,7,8-trihydroxy-3',4',5'-trimethoxyflavone (**2g**), 4',5,8-trihydroxy-3',5',7-trimethoxyflavone (**1h**), and **1g** respectively (Tables 1—3). These results suggest that **6g** is demethylated to form **2i** *via* **1g** by the following two pathways because of a small difference of the rate of cleavage between the 7- and 4'-methoxyl groups: **6g**→**1g**→**2g**→**2i** and **6g**→**1g**→**1h**→**1i**→**2i**. Therefore, it seems that the flavones, **1g**, **2g**, **1i**, and **2i**, in the HPLC are observed as main peaks and that the flavones having the methoxyl groups adjacent to a hydroxyl group on the B ring such as **1h** are observed as small peaks.

From these results, it is suggested that the 5,7,8-trihydroxyflavones (**2**) which had one or two methoxyl groups on the B ring were easily synthesized by the demethylation of **6** with anhydrous aluminum bromide in acetonitrile.

The C_6-proton signals of the ^{1}H NMR for 5,7,8-trihydroxyflavones (**2**) and its acetates (**16**) appear at δ 6.26—6.29 and δ 6.93—6.95 respectively (Tables 1 and

2). These chemical shifts resemble those of the C_6-proton for 5,7-dihydroxy-8-methoxyflavones (**14**)[10-12] ($\delta \approx 6.3$) and its acetates ($\delta \approx 6.8$), but differ apparently from those of the C_8-proton for 5,6,7-trihydroxyflavones (**5**)[7] ($\delta \approx 6.6$) and its acetates ($\delta \approx 7.45$).

The UV spectra for **2** in ethanol or ethanol–aluminum chloride are similar to those for the corresponding **1**. However, Bands I and II in ethanol for **2** approach more closely to each other than those for the corresponding **1**. Therefore, in the presence of sodium acetate, the bathochromic shift of Band II which is associated with the 7-hydroxyl group on **2** is not clearly observed because of the overlap with neighboring Band I (Table 3).

Identification of the Two Natural Flavones. The structure of salvitin, isolated from *Salvia plebeia*, has been confirmed to be 4′,5,8-trihydroxy-7-methoxyflavone (**1b**) on the basis of the spectral data and the synthesis.[2] The properties of salvitin, however, were not identical with those of **1b** synthesized by us (Table 4). The singlet peak at δ 7.4 in the ^{1}H NMR for salvitin triacetate is assigned to the C_8-proton on 5,7-diacetoxy-6-methoxyflavones[13,14] or 5,6,7-triacetoxyflavones.[7] In addition, the UV data for salvitin are similar to those of 4′,5,7-trihydroxy-6-methoxyflavone[13] (**15b**). These results suggest that the structure of salvitin is **15b**, an isomer of **1b**. The physical data of salvitin and its triacetate are shown to be identical with those of **15b** and its triacetate[13] as shown in Table 4. Consequently, the structure of salvitin was found to be 4′,5,7-trihydroxy-6-methoxyflavone (dinatin[20]) (**15b**).

Whalen *et al.*[3] have proposed that the structure of one of the natural flavones, isolated from *Solanum* section *Androceras*, is 4′,5,8-trihydroxy-3′,7-dimethoxyflavone (**1d**) on the basis of the UV and MS data. They claimed that the structure of the natural flavone was not 4′,5,7-trihydroxy-3′,8-dimethoxyflavone (**14d**) but **1d** on the basis of the following facts: "Substitution of the C_7-hydroxyl group was demonstrated by the failure of Band II to show a bathochromic shift in NaOAc relative to MeOH". However, in the presence of sodium acetate, the bathochromic shift of Band II for **1d** synthesized is not exhibited, and the UV data are obviously different from those for the natural flavone as shown in Table 5. Moreover, the UV data for the natural flavone in the presence of aluminum chloride are similar to those for **14d**[12] rather than those for **1d**. These results suggest that the natural flavone is **14d**.

Experimental

All the melting points were determined in glass capillaries and were uncorrected. The ^{1}H NMR spectra were measured with a Hitachi R-24 spectrometer (60 MHz), using tetramethylsilane as an internal standard, and chemical shifts were presented in δ values. The UV spectra were taken on a Hitachi 124 spectrophotometer. The high performance liquid chromatographic analysis carried out with a Hitachi 635 instrument, using a column (2.1×500 mm) packed with Hitachi gel # 3011, methanol as a eluent, and a UV monitor at 338 nm.[16] For the separation of the demethylated products, a column (20×600 mm) packed with Hitachi gel # 3019 using methanol was employed.

3-Benzyloxy-2-hydroxy-4,6-dimethoxyacetophenone(9). A mixture of the acetophenone (**7**)[8] (10 g), benzyl chloride (30 ml), and anhydrous potassium carbonate (56 g) in *N,N*-dimethylformamide (60 ml) was gently refluxed for 3 h, and then water was added to the reaction mixture. After the excess of benzyl chloride was removed by steam distillation under reduced pressure, the oily material was extracted with ether. The ethereal solution was washed with water. The solvent was completely evaporated to give crude dibenzyl ether (**8**) as brown oil.

The crude dibenzyl ether was dissolved in acetic acid (100 ml) containing concentrated hydrochloric acid (10 ml) and then allowed to stand for 85 min at room temperature. After the solution was diluted with water, separated crystals were

collected, washed with ether–hexane (1 : 1), and then recrystallized from methanol as pale yellow prisms, mp 95—97 °C; yield 11.4 g (80%). Found: C, 67.58; H, 5.99%. Calcd for $C_{17}H_{18}O_5$: C, 67.59; H, 6.00%.

*3-Benzyloxy-2-hydroxy-4,6-dimethoxy-ω-benzoylacetophenones (**10a**—**g**).* A mixture of **9** (3.0 g; 9.9 mmol) and the substituted benzoyl chloride (11—12 mmol) in pyridine (6 ml) was heated at 120 °C for 2 h. The cooled reaction mixture was poured into a mixture of ice, hydrochloric acid, and ether, and then stirred till the separated oily material changed into a precipitate. The precipitate was collected, washed with water, and dried to give crude benzoate.

A mixture of the crude benzoate and powdered potassium hydroxide (4 g) in pyridine (15 ml) was stirred for 4 h at 60 °C, and then poured into a mixture of ice and hydrochloric acid. The separated precipitate was treated with a sodium carbonate solution and then recrystallized to give **10a**—**g** (Table 6).

*8-Benzyloxy-5,7-dimethoxyflavones (**11a**—**g**).* A mixture of **10** (3 g) and anhydrous sodium acetate (4 g) in acetic acid (20 ml) was heated at 140 °C for 4h, and then water was added to the mixture. The separated precipitate was recrystallized to give **11a**—**g** (Table 7).

*8-Hydroxy-5,7-dimethoxyflavones (**6a**—**g**).* Flavone (**11**) (500 mg) was hydrogenated over palladium on charcoal (10%; 200 mg) in ethyl acetate (150 ml)–methanol (150 ml) till the uptake of hydrogen ceased. After the catalyst was filtered off, the filtrate was evaporated. The residue was recrystallized to give **6a**—**g** (Table 8).

*8-Acetoxy-4′,5,7-trimethoxyflavone (**12a**):* colorless needles from methanol, mp 205—206 °C. Found: C, 64.58; H, 4.79% Calcd for $C_{20}H_{18}O_7$: C, 64.86; H, 4.90%.

*5,8-Dihydroxy-7-methoxyflavones (**1a**—**g**).* A mixture of **6** (100 mg) and anhydrous aluminum chloride (1 g) in acetonitrile (10 ml) was heated at 70 °C for 10 h, and then a 0.5% hydrochloric acid (50 ml) was added to the reaction mixture. The mixture was warmed at 60 °C for 1—2 h, and then allowed to stand overnight in a refrigerator. The separated precipitate was recrystallized to give **1a**—**g** (Table 9).

Acetates (**13a**—**g**) of **1a**—**g** were synthesized by a hot acetic anhydride–pyridine method (Table 11).

*Demethylation of 8-Hydroxy-5,7-dimethoxyflavones (**6a**, **c**, **d**, **e**, and **g**) with Anhydrous Aluminium Bromide in Acetonitrile.* Flavone (**6**) (100 mg) was dissolved in a solution of anhydrous aluminum bromide (2 g)–acetonitrile (5 ml) and heated at 50 °C for 12—48 h. To the reaction mixture, a 0.5—1% hydrochloric acid (*ca.* 50 ml) solution was added, and the mixture was warmed at 60—70 °C for 10—20 min. The separated precipitate was extracted with ethyl acetate. The extract was washed with water and evaporated. The residue was analyzed by a high performance liquid chromatograph and then separated into each component (Tables 9 and 10).

Acetates (**16**) of **2** were synthesized by a hot acetic anhydride-pyridine method (Table 11).

Studies of Peptide Antibiotics. XLV.[1] Syntheses of Gramicidin S-like Analogs with Macro-ring Structures[2]

Setsuko Ando,* Hideo Takiguchi, and Nobuo Izumiya†

Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma, Jonan-ku, Fukuoka 814-01

†*Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812*

(Received June 24, 1983)

Three cyclic tetradecapeptides related to gramicidin S (GS): *cyclo*(–Leu–Orn–Leu–Orn–Leu–D-Phe–Pro–)$_2$, *cyclo*(–Leu–Orn–Leu–Orn–Leu–D-Phe–Sar–)$_2$, and *cyclo*(–Leu–Orn–Leu–Orn–Leu–D-Phe–Gly–)$_2$, were synthesized to investigate the contributions of the ring size of cyclic peptides and of the number of the basic amino acid residues to the antibacterial activity. The protected cyclic tetradecapeptides were synthesized through a cyclization reaction of the linear tetradecapeptide azide in pyridine. Hydrogenolysis of the protected cyclic peptides afforded crystalline tetrahydrochlorides of the analogs. The homogeneity of the analogs was ascertained by TLC, paper electrophoresis, and elemental analysis. In the experiment of circular dichroism, the two analogs with 7,7′-Pro or 7,7′-Sar gave spectra similar in shape to that of GS, while the analog with 7,7′-Gly gave a slightly different spectrum from that of GS. The antibacterial assays showed that the analog with 7,7′-Pro exhibited considerable activities against the microorganisms tested, particularly against Gram-negative bacterias such as *Escherichia coli* and *Shigella sonnei*. On the other hand, the analogs with 7,7′-Sar or 7,7′-Gly exhibited weaker activities than that of GS.

For investigation of the relationship between the structure and the antibacterial activity, we have designed model compounds (Fig. 1). The following modifications to the Gramicidin S (GS) structure were made: (1) The number of amino acid residues in the cyclic peptides was increased from 10 to 14. (2) The number of ornithyl residues was increased from 2 to 4. (3) In addition to the prolyl residues at 7,7′-position, the prolyl residues were replaced by sarcocyl residues or glycyl residues.

Model compounds: *cyclo*(–Leu–Orn–Leu–Orn–Leu–D-Phe–Pro–)$_2$ (**P-12**), *cyclo*(–Leu–Orn–Leu–Orn–Leu–D-Phe–Sar–)$_2$ (**S-12**), and *cyclo*(–Leu–Orn–Leu–Orn–Leu–D-Phe–Gly–)$_2$ (**G-12**), have been synthesized. The present paper will describe the syntheses and the antibacterial properties of these compounds.

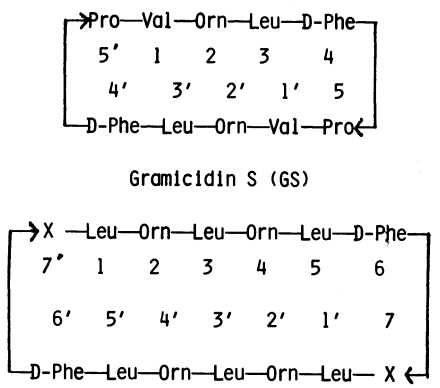

Fig. 1. Structures of GS and GS-like analogs [X=Pro (**P-12**), X=Sar (**S-12**), X=Gly (**G-12**)].

Routes for syntheses of **P-12·4HCl**, **S-12·4HCl**, and **G-12·4HCl** are outlined in Fig. 2. Boc-dipeptide ester (**1**) was prepared by means of the MA method[3] and the ester was converted into a hydrazide (**2**). Boc-pentapeptide esters (**S-3** and **G-3**) were prepared by the condensation of the azide derived from **2** with H–Leu–D-Phe–Sar–OEt·HCl[4] or H–Leu–D-Phe–Gly–OEt·HCl.[5] Pentapeptide ester hydrochlorides (**P-4**, **S-4**, and **G-4**) were derived from Boc–Leu–Orn(*Z*)–Leu–D-Phe–Pro–OEt[6] or Boc-pentapeptide ester (**S-3** and **G-3**) by the removal of the Boc group. Boc-heptapeptide esters (**P-5**, **S-5**, and **G-5**) were prepared by the condensation of the azide from **2** with the pentapeptide ester hydrochlorides (**P-4**, **S-4**, and **G-4**). The Boc-heptapeptide hydrazides (**P-6**. **S-6**, and **G-6**) were prepared from **P-5**, **S-5**, and **G-5** by treatment with hydrazine. Heptapeptide ester hydrochlorides (**P-7**, **S-7**, and **G-7**) were obtained from a part of **P-5**, **S-5**, and **G-5** by treatment with HCl in formic acid. Boc-tetradecapeptide esters (**P-8**, **S-8**, and **G-8**) were prepared by the condensation of the azide derived from **P-6**, **S-6**, and **G-6** with **P-7**, **S-7**, and **G-7**, respectively. For its cyclization, the compounds (**P-8**, **S-8**, and **G-8**) were converted into hydrazides (**P-9**, **S-9**, and **G-9**), and then by the removal of Boc group, the tetradecapeptide hydrazide dihydrochlorides (**P-10**, **S-10**, and **G-10**) were obtained. The azides derived from **P-10**, **S-10**, and **G-10** were treated with a large amount of pyridine, and the resulting *Z*-substituted cyclic tetradecapeptides (**P-11**, **S-11**, and **G-11**) were purified by passing them through columns of Dowex 50 and 1, and Sephadex LH-20. The compounds (**P-11**, **S-11**, and **G-11**) were confirmed to be the monomers by measuring molecular weights, CORONA Osmometer type 117 was used. The desired cyclic tetradecapeptides (**P-12**, **S-12**, and **G-12**) were afforded as crystalline tetrahydrochlorides by means of hydrogenolysis of **P-11**, **S-11**, and **G-11**. The compounds (**P-12**, **S-12**, and **G-12**) are more soluble in water than GS. The homogeneity o **P-12**, **S-12**, and **G-12** was ascertained by TLC, paper electrophoresis, and elemental analysis.

The CD spectra of **P-12**, **S-12**, **G-12**, and GS were measured with methanol as a solvent (Fig. 3). The CD spectra of **P-12** and **S-12** have similar patterns to that of GS, but the troughs of **P-12** and **S-12** are shallower than that of GS. The result suggests that the conformation of **P-12**, and **S-12** may be similar to that of GS. For the comformation of **P-12** and **S-12**, we attempted to construct a model with the antiparallel β-form as a possible structure (Fig. 4). Since the CD spectrum of **G-12** is a little different from that of GS, the conformation of **G-12** may be different.

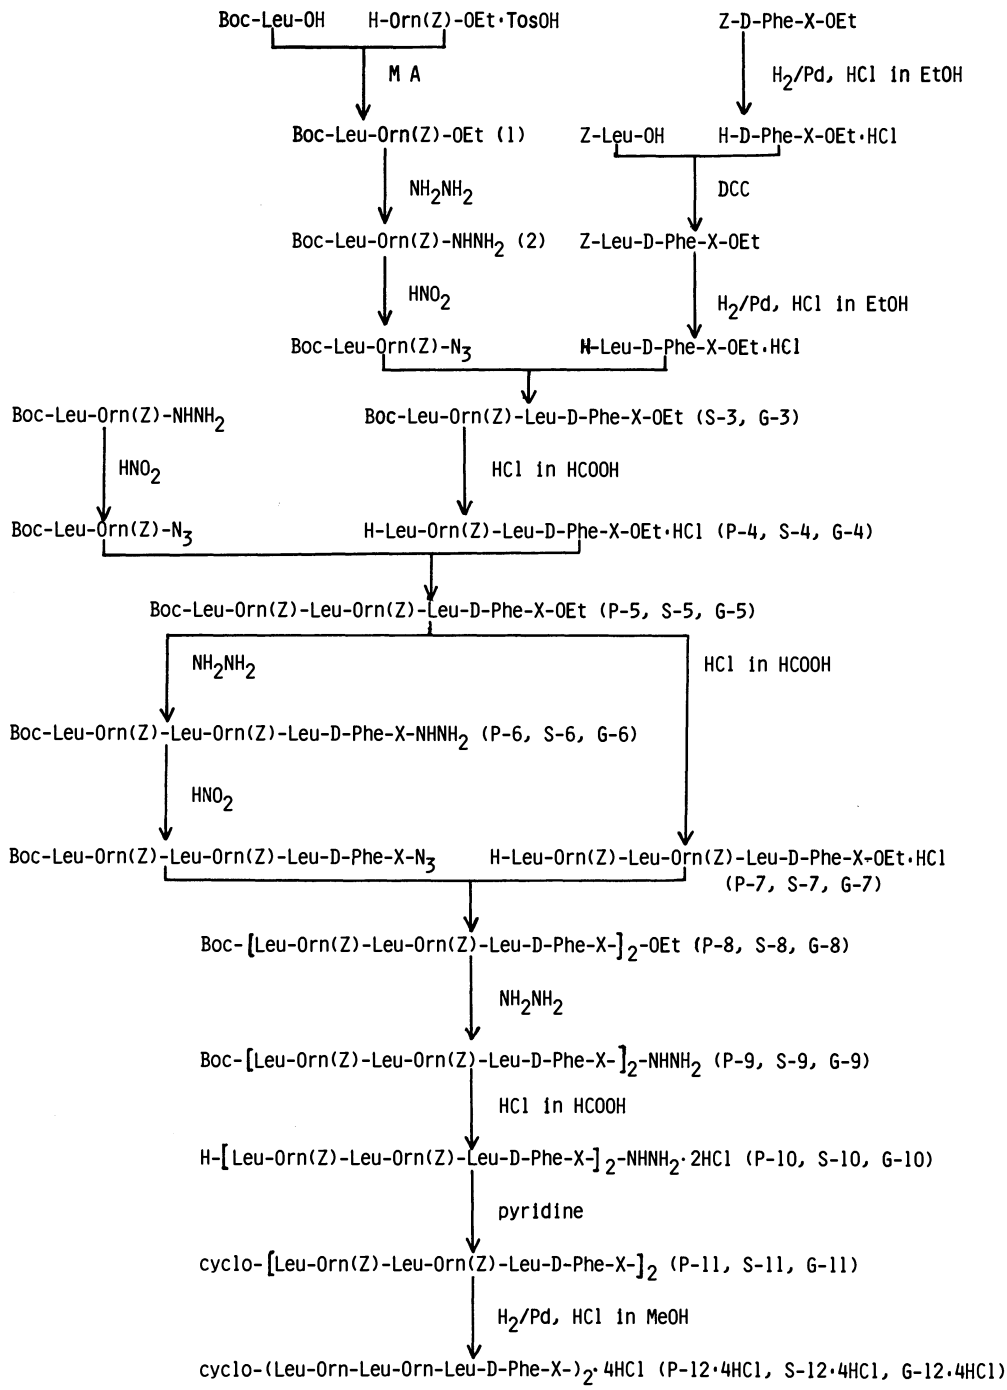

Fig. 2. Syntheses of GS-like analogs with four ornithyl residues [X=Pro (**P-12**), X=Sar (**S-12**), X=Gly (**G-12**)].

The antibacterial activities of **P-12**, **S-12**, **G-12**, and GS toward several microorganisms are listed in Table 1. It was found that the compound **P-12** exhibited considerable activity against the microorganisms tested, the compound **S-12** exhibited one-half activity compared with that of **P-12**, and the compound of **G-12** exhibited little activity. In particular, it is interesting that **P-12** has a marked inhibition against Gram-negative bacterias such as *E. coli* and *S. sonnei*. The ornithylleucyl copolymer[7] reported before exhibited a strong activity against *E. coli*. The result suggests that the ornithylleucyl residues contribute largely to the increase in activity against Gram-negative bacteria. [5,5'-Sar]-GS[4] and [5,5'-Gly]-GS[5,8] exhibited considerable antibacterial activity, but the synthesized analog (**S-12**) exhibited weaker activity, and **G-12** did not exhibit any activity. In particular, the contribution of prolyl residue was significant against the antibacterial activity. In addition, from the fact that the macro-ring analog such as **P-12** exhibited strong activities, it was found that the ring size is not always limited to 10 amino acid residues such as GS for the appearance of the activity.

Table 1. Antibacterial activities of GS-like analogs (**P-12**, **S-12**, and **G-12**) and GS[a]

Organism	P-12	S-12	G-12	GS[b]
Staphylococcus aureus	12.5	50	>100	3.13

Experimental

All melting points are uncorrected. Prior to analysis, compounds were dried over phosphorus pentaoxide at 80 °C and 2 mmHg††, except linear tetradecapeptide derivatives and cyclic tetradecapetides. TLC was carried out on the Merck silica gel G with the following solvent system: R_f, 1-butanol–acetic acid–pyridine–water (4 : 1 : 1 : 2, v/v).

*Boc–Leu–Orn(Z)–OEt (**1**).* To a solution of Boc–Leu–OH (7.63 g, 33 mmol) and triethylamine (4.67 ml, 33 mmol) in tetrahydrofuran (40 ml) was added isobutyl chloroformate (4.37 ml, 33 mmol) at −5 °C. After 15 min, a mixture of H–Orn(Z)–OEt·TsOH (13.7 g, 29.3 mmol) and triethylamine (4.15 ml, 29.3 mmol) in chloroform (50 ml) was added. The mixture was left to stand overnight at room temperature, evaporated *in vacuo*, and the oily residue was dissolved in ethyl acetate (150 ml). The solution was washed successively with 4% $NaHCO_3$, 0.5 M††† citric acid, and water, and then dried (Na_2SO_4). The filtrate which separated from the salt was concentrated *in vacuo*. The product which precipitated upon the addition of ether and petroleum ether was collected and washed with the same solvent; yield, 14.4 g (97%); mp 78—80 °C; $[\alpha]_D^{25}$ −14° (*c* 1, DMF); R_f 0.95.

Found: C, 61.22; H, 8.42; N, 8.07%. Calcd for $C_{26}H_{41}O_7N_3$: C, 61.52; H, 8.14; N, 8.28%.

*Boc–Leu–Orn(Z)–NHNH$_2$ (**2**).* A solution of **1** (14.4 g, 28 mmol) and hydrazine hydrate (27.6 ml, 568 mmol) in DMF (60 ml) was allowed to stand at room temperature for 7 d. The excess hydrazine was evaporated *in vacuo*, and then water (150 ml) was added to the residue. The resulting solid was collected by filtration; yield, 11.9 g (85%); mp 141—142 °C; $[\alpha]_D^{25}$ −24° (*c* 1, AcOH); R_f 0.85.

Found: C, 57.41; H, 8.25; N, 13.93%. Calcd for $C_{24}H_{39}O_6N_5 \cdot 1/2\ H_2O$: C, 57.35; H, 8.02; N, 13.93%.

*Boc–Leu–Orn(Z)–Leu–D-Phe–Sar–OEt (**S-3**).* A solution of **2** (6.43 g, 13 mmol) dissolved in DMF (30 ml) was cooled to −22 °C. To this solution, 3.40 M HCl in dioxane (11.5 ml, 39 mmol) and isopentyl nitrite (1.95 ml, 14.3 mmol) were added. After 10 min, the solution was neutralized with *N*-methylmorpholine (4.31 ml, 39 mmol). To this solution was added a chilled solution of H–Leu–D-Phe–Sar–OEt·HCl[4] (5.46 g, 13.2 mmol) and *N*-methylmorpholine (1.61 ml, 14.5 mmol) in DMF (30 ml). The reaction mixture was stirred at 0 °C for 7 d and evaporated *in vacuo*. The residual solid was triturated with 0.5 M citric acid, and then allowed to stand in a refrigerator. The solid was collected by filtration and washed successively with 4% $NaHCO_3$, 0.5 M citric acid and water; yield, 9.59 g (88%); mp 140—141 °C; $[\alpha]_D^{25}$ −15° (*c* 1,

DMF); R_f 0.98.

Found: C, 63.08; H, 8.26; N, 10.02%. Calcd for $C_{44}H_{66}O_{10}N_6$: C, 62.99, H, 7.93, N, 10.02%.

Boc-Leu-Orn(Z)-Leu-D-Phe-Gly-OEt (**G-3**). This compound was prepared from **2** (1.58 g, 3.4 mmol) and H-Leu-D-Phe-Gly-OEt·HCl[5] (1.39 g, 3.5 mmol) as described for the preparation of **S-3**. The product was obtained as an oil; yield, 1.67 g (63%); R_f 0.95.

H-Leu-Orn(Z)-Leu-D-Phe-Pro-OEt·HCl (**P-4**). The compound Boc-Leu-Orn(*Z*)-Leu-D-Phe-Pro-OEt[6] (4.33 g, 50 mmol) was dissolved in 0.183 M HCl in formic acid. After being left to stand at room temperature for 30 min, the solution was evaporated to dryness. The residual oil was treated with ether, but still was obtained as an oily substance; yield, 4.01 g (100%); R_f 0.83.

H-Leu-Orn(Z)-Leu-D-Phe-Sar-OEt·HCl (**S-4**). This compound was prepared from **S-3** (8.39 g, 10 mmol) as described for the preparation of **P-4**. The product was obtained as an oil; yield, 7.75 g (100%); R_f 0.77.

H-Leu-Orn(Z)-Leu-D-Phe-Gly-OEt·HCl (**G-4**). This compound was prepared from **G-3** (1.72 g, 2 mmol) as described for the preparation of **P-4**. The product was obtained as an oil; yield, 1.52 g (100%); R_f 0.93.

Boc-Leu-Orn(Z)-Leu-Orn(Z)-Leu-D-Phe-Pro-OEt (**P-5**). A solution of **2** (2.47 g, 5.0 mmol) dissolved in DMF (20 ml) was cooled to −22 °C. To this solution, 3.40 M HCl in dioxane (4.41 ml, 15 mmol) and isopentyl nitrite (0.74 ml, 5.5 mmol) were added. After 15 min, the solution was neutralized with *N*-methylmorpholine (1.67 ml, 15 mmol). To this solution was added a chilled solution of **P-4** (4.01 g, 5.0 mmol) and *N*-methylmorpholine (0.61 ml, 5.5 mmol) in DMF (20 ml). The reaction mixture was stirred at 0 °C for 7 d and evaporated *in vacuo*. The residual solid was triturated with 0.5 M citric acid, and then allowed to stand in a refrigerator. The solid was collected by filtration and dissolved in ethyl acetate (200 ml). The solution was washed successively with 4% $NaHCO_3$, 0.5 M citric acid, and water, and then dried (Na_2SO_4). The filtrate separated from the salt was evaporated *in vacuo*. The resulting crystals were collected by filtration with the aid of ether–petroleum ether; yield, 3.60 g (59%); mp 190—195 °C; R_f 0.98.

H-[Leu-Orn(Z)-Leu-Orn(Z)-Leu-D-Phe-Pro]$_2$-NHNH$_2$·2HCl (**P-10**). The compound **P-9** (1.38 g, 0.6 mmol) was dissolved in 0.183 M HCl in formic acid (7.90 g, 1.44 mmol). After being left to stand at room temperature for 30 min, the solution was evaporated to dryness. The product was obtained as an oily form; yield, 1.36 g (100%); R_f 0.90.

H-[Leu-Orn(Z)-Leu-Orn(Z)-Leu-D-Phe-Sar]$_2$-NHNH$_2$·2HCl (**S-10**). This compound was prepared from **S-9** (2.33 g, 1.0 mmol) as described for the preparation of **P-10**. The product was obtained in an oily form; yield, 2.20 g (100%); R_f 0.90.

H-[Leu-Orn(Z)-Leu-Orn(Z)-Leu-D-Phe-Gly]$_2$-NHNH$_2$·2HCl (**G-10**). This compound was prepared from **G-9** (2.51 g, 1.1 mmol) as described for the preparation of **P-10**. The product was obtained as an oily substance; yield, 2.31 g (96%); R_f 0.79.

cyclo[-*Leu-Orn(Z)-Leu-Orn(Z)-Leu-D-Phe-Pro-*]$_2$ (**P-11**). A solution of **P-10** (1.36 g, 0.66 mmol) in DMF (40 ml) was chilled to −22 °C. To this solution 3.40 M HCl in dioxane (0.41 ml) and isopentyl nitrite (0.09 ml, 0.66 mmol) were added. After 5 min, the solution was added dropwise into pyridine (300 ml) at 0 °C for 5 min, and stirring was continued for 3.5 h at 0 °C. It then was stirred for 55 h at 5 °C. After the solvent was removed, the residue was dissolved in a mixture of methanol and water (450 ml, 8 : 1, v/v). The solution was passed through two columns, of Dowex 1 (OH^- form) and 50 (H^+ form). The columns were washed with the same solvent (900 ml), and the effluent was evaporated to dryness. The residue was collected by filtration with the aid of water. For purification, the solution of the crude product in DMF (3 ml) was applied to a column (2.5×84.5 cm) of Sephadex LH-20, and the development continued with DMF. Elution was carried out at room temperature, at a flow rate of 24 ml per h. The peptide content in the fractions was determined with LKB 2138 Uvicord S (at 254 nm). The fractions containing the desired product were evaporated, and the product was collected by filtration with the aid of water; yield, 128 mg (53%); mp 184—188 °C; $[\alpha]_D^{25}$ −141° (*c* 0.1, MeOH); R_f 0.98.

cyclo(-*Leu-Orn-Leu-Orn-Leu-D-Phe-Gly-*)$_2$·4HCl (**G-12·4HCl**). This compound was prepared from **G-11** (96 mg, 0.05 mmol) as described for the preparation of **P-12**; yield, 44.6 mg (68%); mp 141—143 °C; $[\alpha]_D^{25}$ −48° (*c* 0.05, MeOH); R_f 0.77.

Found: C, 49.82; H, 8.53; N, 13.25%. Calcd for $C_{78}H_{134}O_{14}N_{18}Cl_4\cdot 10H_2O$: C, 50.10; H, 8.30; N, 13.48%.

Electrophoresis. Electrophoresis on Toyo Roshi No. 52 paper was carried out with a solvent system: formic acid–acetic acid–methanol–water (1 : 3 : 6 : 10, v/v; pH 1.8) for 2 h at 500 V/30 cm. The mobilities toward the cathode of **P-12**, **S-12**, and **G-12** were comparable with that of GS; the ratios of the mobilities of **P-12**, **S-12**, and **G-12** *vs.* GS were 1.10, 1.16, and 1.20, respectively.

CD Measurement. The measurement of CD was performed with a JASCO Model J-40 over a wavelength range of 195 to 260 nm in methanol as a solvent. In Fig. 3 are shown the CD spectra of **P-12**, **S-12**, **G-1 2**, and GS.

Microbiological Assays. The minimum amount of the compounds (**P-12**, **S-12**, **G-12**, and GS) necessary for the complete inhibition of growth was determined by a dilution method. The results are shown in Table 1.

Molecular Weight Measurement. The molecular weight measurement of the *Z*-substituted cyclic tetradecapeptides (**P-11**, **S-11**, and **G-11**) was carried out by the use of a CORONA Osmometer type 117, in DMF as a solvent. The values of molecular weight **P-11**, **S-11**, and **G-11** were 2022, 1997, and 1958; the calculated values were 2160, 2108, and 2080 respectively.

The authors wish to express their thanks to the staff members of Takeda Chemical Industries, Ltd,. for the microbiological assays. The authors are also indebted to Associate Professor Hiroshi Nishikawa for his kind advice and valuable discussion. The present work was partially supported by a grant from the Central Research Institute of Fukuoka University.

Mechanisms of Singlet and Triplet Sensitized Decomposition of Bis(2-phenylbenzoyl) Peroxide

(Received June 28, 1983)

Bis(2-phenylbenzoyl) peroxide (2-PhBPO) was found to decompose on singlet and triplet sensitized irradiations in benzene and carbon tetrachloride. The quantum yields were determined to be 0.48 and 0.43 on direct excitation and chrysene sensitization in benzene, respectively, and 0.62 and 0.60 on benzophenone and 3′-methoxyacetophenone sensitizations in carbon tetrachloride, respectively. The reaction mechanisms are discussed from the standpoint of the modes of bond cleavage.

Many organic peroxides have been known to decompose on heating[1] and on irradiation;[2] however, the mechanism for their photolyses has not been well understood.

Previously, dibenzoyl peroxide (BPO) was shown to decompose on direct irradiation and on singlet sensitization employing polycyclic aromatic hydrocarbons as sensitizers.[3–14] On direct and singlet sensitized photolyses BPO affords a moderate amount of phenyl benzoate, a geminate product,[12–14] in contrast with its thermolysis which produces a very low yield of the geminate product.[15,16] Through mechanistic investigations, it has been proposed that the direct and singlet sensitized irradiations of BPO result in simultaneous or successive cleavage of the peroxide linkage and carbon-(carbonyl)-carbon(aromatic) bond to give a geminate pair of a benzoyloxyl and phenyl radicals which easily recombine into the geminate product,[14] whereas thermolysis of BPO is known to lead to homolytic cleavage of the peroxide linkage to give two benzoyloxyl radicals.[15,16]

In the course of extending the investigation on photochemistry of organic peroxides, bis(2-phenylbenzoyl) peroxide (2-PhBPO) was found to decompose on direct, singlet sensitized, and also triplet sensitized irradiation as well as thermolysis, the latter being known to give biphenyl-2,2′-carbolactone and 2-phenylbenzoic acid as main products.[17]

This paper describes the mechanism of photochemical decomposition of 2-PhBPO and discusses the modes of its bond cleavage depending on the reaction conditions.

Results

Products from Photochemical and Thermal Decomposition of 2-PhBPO. 2-PhBPO (0.02 mol/dm³) was irradiated with 366-nm light at 20 °C without sensitizer in benzene and carbon tetrachloride, in the presence of chrysene (0.002 mol/dm³) as a singlet sensitizer in benzene, and in the presence of benzophenone (0.02 mol/dm³) as a triplet sensitizer in benzene and carbon tetrachloride. The irradiation was continued until the peroxide completely decomposed. As a control, 2-PhBPO (0.02 mol/dm³) was thermolyzed in benzene at 80 °C and in carbon tetrachloride at 78 °C. The products are summarized in Table 1.

Effect of Temperature on the Products Arising from Thermolysis and Photolysis of 2-PhBPO. To examine the effect of temperature on the yields of products, 2-PhBPO (0.02 mol/dm³) was irradiated in benzene in the absence of any sensitizer and in the presence of chrysene (0.002 mol/dm³) and benzophenone (0.05 mol/dm³) at 30 and 40 °C, and thermolyzed in benzene at 60 and 70 °C. The results are collected in Table 2 together with those at 20 °C (photolyses) and 80 °C (thermolysis).

Quantum Yields for Photochemical Decomposition of 2-PhBPO. Quantum yields, Φ, for decomposition of 2-PhBPO were determined at various concentrations of 2-PhBPO on direct irradiation in benzene with 313-nm

Table 1. Yields of products in photolysis and thermolysis of bis(2-phenylbenzoyl) peroxide (0.02 mol/dm³) in benzene and carbon tetrachloride (mol/mol peroxide)

light, on singlet sensitization by chrysene in benzene with 366-nm light, and on triplet sensitization in carbon tetrachloride by benzophenone with 366-nm light and by 3′-methoxyacetophenone with 313-nm light. An attempted use of 2-benzoylnaphthalene as a triplet sensitizer on 366-nm irradiation did not result in sensitization. For the sensitized decomposition the Stern-Volmer relationship held between the reciprocal of quantum yield and the reciprocal of peroxide concentration. In addition, an attempt was made to examine effects of naphthalene on direct irradiation of 2-PhBPO with 313-nm light in benzene under the conditions in which most incident light was absorbed by the peroxide. The results are depicted in Figs. 1—5. Table 3 summarizes the limiting quantum yields, Φ_{lim}, the quantum yields extrapolated to the infinite concentration of the peroxide or naphthalene, along with the related quantities.

Quenching of the Excited States of Sensitizers by 2-PhBPO. Fluorescence of chrysene was quenched by varying concentrations of 2-PhBPO in benzene under argon to give a linear Stern-Volmer relationship with $k_q\tau_s$ of 330 dm³/mol, which, combined with the lifetime, τ_s, of singlet chrysene without the peroxide in benzene under argon, 39 ns, affords the quenching rate constant, $k_q=8.5\times10^9$ dm³ mol^{-1} s^{-1}.

Phosphorescence of benzophenone was quenched by 2-PhBPO, biphenyl, and phenyl 2-phenylbenzoate in carbon tetrachloride under argon at room temperature to show linear Stern-Volmer relationships with $k_q\tau_T$'s of 1.3×10^4, 1.3×10^4, and 3.8×10^3 dm³/mol, respectively. These values, divided by the lifetime of triplet benzophenone determined in the absence of the quenchers under otherwise similar conditions as above, 6 μs, lead to the quenching rate constants of 2-PhBPO, biphenyl, and phenyl 2-phenylbenzoate, $k_q=2.2\times10^9$, 2.2×10^9, and 6.3×10^8 dm³ mol^{-1} s^{-1}, respectively.

Discussion

Singlet Sensitization. 2-PhBPO was decomposed by sensitization with singlet excited chrysene. Fluorescence of chrysene was quenched by 2-PhBPO at a rate constant which is close to the diffusion-controlled rate constant, 8.5×10^9 dm³ mol^{-1} s^{-1}. However, singlet excitation transfer from chrysene to 2-PhBPO cannot take place, since the singlet excitation energy of chrysene, 79 kcal†/mol,[18] would not be sufficient to excite 2-PhBPO possessing the singlet excitation energy of 90—100 kcal/mol as estimated from its absorption spectrum. Therefore, it is probable that 2-PhBPO quenches singlet excited chrysene through formation of an exciplex as previously reported on BPO.[12]

Accordingly, the singlet sensitized decomposition of 2-PhBPO will proceed through the following mechanism as proposed for BPO[12] with rate constants denoted for the corresponding processes, where D and P represent a sensitizer and 2-PhBPO, respectively.

The Stern-Volmer plot (Fig. 1) fits equation 6 derived from Scheme 1.

The $k_q\tau_s$ value, 300 dm³/mol, obtained from Fig. 1,

† 1 cal=4.184 J.

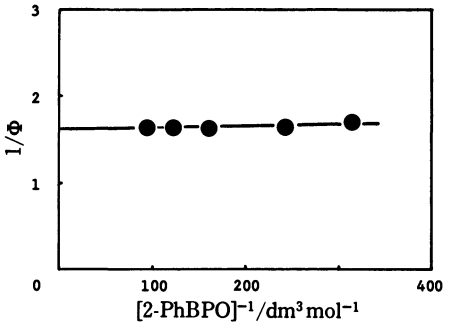

Fig. 2. Stern-Volmer plot for benzophenone-sensitized decomposition of bis(2-phenylbenzoyl) peroxide on irradiation with 366-nm light in carbon tetrachloride.

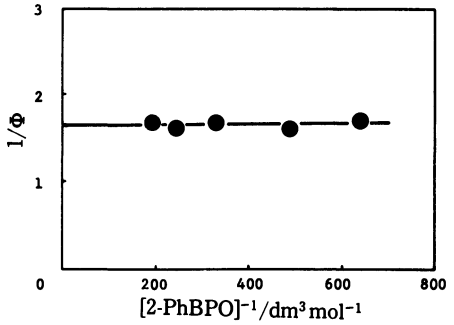

Fig. 3. Stern-Volmer plot for 3′-methoxyacetophenone-sensitized decomposition of bis(2-phenylbenzoyl) peroxide on irradiation with 313-nm light in carbon tetrachloride.

$$D \cdot \xrightarrow{h\nu} {}^1D^* \quad (1)$$

$${}^1D^* \xrightarrow{1/\tau_s} D \quad (2)$$

$${}^1D^* + P \xrightarrow{k_q} ({}^1D^*P) \quad (3)$$

$$({}^1D^*P) \xrightarrow{k_r} \text{Free radicals} + D \quad (4)$$

$$({}^1D^*P) \xrightarrow{k_d} D + P \quad (5)$$

Scheme 1.

$$1/\Phi = (1+k_d/k_r)(1+1/k_q\tau_s[P]) \quad (6)$$

agrees well with the $k_q\tau_s$ value, 330 dm³/mol, determined from the fluorescence quenching.

Triplet Sensitization. Among the sensitizers examined, benzophenone and 3′-methoxyacetophenone carrying the triplet excitation energies of 69 and 72 kcal/mol,[18] respectively, effectively sensitized decomposition of the peroxide; however, 2-benzoylnaphthalene with the lower triplet energy, 60 kcal/mol,[18] failed to sensitize. In view of the fact that 2-PhBPO quenched triplet benzophenone at a rate constant which is close to the diffusion-controlled rate constant, 2.2×10^9 dm³ mol^{-1} s^{-1}, the above result shows that the triplet energy of 2-PhBPO must be much higher than that of 2-benzoylnaphthalene and slightly lower than that of benzophenone. Phosphorescence of 2-PhBPO was not detected in EPA at 77 K; however, it is reasonable to assume that 2-PhBPO has nearly the same triplet energy as biphenyl and 2-phenylbenzoic acid, both of which exhibited in EPA at 77 K phosphorescence corresponding to the triplet energy of 67 kcal/mol.[18] Therefore, the triplet sensitized decomposition of 2-PhBPO will proceed as shown in the following scheme which involves energy transfer from the triplet excited sensitizer to the peroxide resulting in the triplet excited state of the peroxide and its decomposition into free radicals, where Φ_{ST} is the quantum yield for intersystem crossing of the sensitizer.

$$D \xrightarrow{h\nu} {}^1D^* \xrightarrow{\Phi_{ST}} {}^3D^* \quad (7)$$

$${}^3D^* \xrightarrow{1/\tau_T} D \quad (8)$$

$${}^3D^* + P \xrightarrow{k_q} {}^3P^* + D \quad (9)$$

$${}^3P^* \xrightarrow{k_r} \text{Free radicals} \quad (10)$$

$${}^3P^* \xrightarrow{k_d} P \quad (11)$$

Scheme 2.

The above mechanism leads to the following Stern–Volmer relationship.

$$1/\Phi = (1/\Phi_{ST})(1+k_d/k_r)(1+1/k_q\tau_T[P]) \quad (12)$$

The Stern-Volmer plots for photolyses sensitized by benzophenone and 3′-methoxyacetophenone (Figs. 2 and 3) exhibited linear relationships to give $k_q\tau_T$ values. The $k_q\tau_T$ value thus obtained for benzophenone, 6.9×10^3 dm³/mol, agrees fairly well with that obtained from phosphorescence quenching, 1.3×10^4 dm³/mol. These results support Scheme 2.

As to the triplet excitation transfer from sensitizers to the peroxide, it is noticeable that phenyl 2-phenylbenzoate and biphenyl quench triplet benzophenone almost as efficiently as 2-PhBPO. Accordingly, triplet excitation of benzophenone must be transferred to the biphenyl moieties of 2-PhBPO and phenyl 2-phenylbenzoate.

The resulting triplet state of 2-PhBPO will dissipate its electronic excitation through cleavage of the peroxide bond with a probability corresponding to the limiting quantum yield, $\Phi_{lim}=k_r/(k_r+k_d)$, which is nearly 0.6 for both benzophenone and 3′-methoxyacetophenone sensitizations. It is noticeable that this value is in the same magnitude as the quantum yields reported by Leffler and Miley[19] for the decomposition of dibenzoyl peroxides substituted with a benzophenone moiety as an intramolecular sensitizing chromophore. Since the activa-

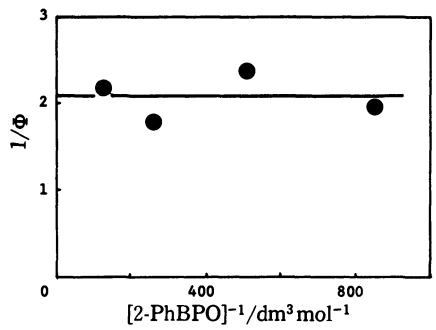

Fig. 4. Reciprocal plot of quantum yield for decomposition of bis(2-phenylbenzoyl) peroxide *vs.* concentration of the peroxide on irradiation with 313-nm light in benzene.

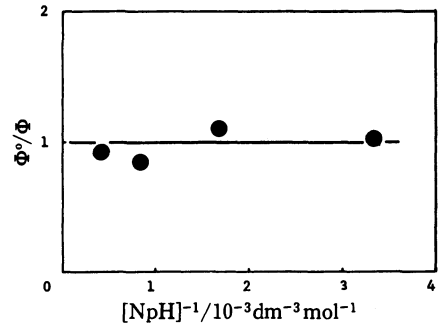

Fig. 5. Plot of relative quantum yield for decomposition of bis(2-phenylbenzoyl) peroxide *vs.* reciprocal concentration of naphthalene on irradiation with 313-nm light in benzene.

tion energy for homolytic cleavage of the peroxide bond is estimated to be around 30 kcal/mol[15,16] the excitation energy of the biphenyl moiety, 67 kcal/mol, must be sufficient to induce cleavage of the peroxide bond in view of the results on triplet sensitized decomposition of aromatic oxime esters, RR'C=NOCOR", in which only the aromatic moieties, RR'C=, with sufficient triplet energies can induce cleavage of the N–O bond.[20,21]

Direct Irradiation. Direct irradiation of 2-PhBPO in benzene leads to decomposition of the peroxide with a quantum yield of nearly 0.5. As Fig. 4 indicates, the quantum yield was almost unchanged with nearly six fold increase in peroxide concentration. On addition of naphthalene in concentrations varying more than eight times, the quantum yield was essentially unchanged (Fig. 5). This result shows that direct irradiation leads to decomposition of the peroxide either from the singlet excited state or from a triplet state with a lifetime shorter than 10^{-6} s; the triplet state of 2-PhBPO, if its lifetime were longer than 10^{-6} s, should be efficiently quenched by naphthalene, since the quenching must be exothermic.

Mechanism of the Photolyses. As Table 1 indicates, photolyses of 2-PhBPO gave similar products as those resulting from thermolysis in the same solvent. Formation of most products from the photolyses can be understood by the mechanism as reported for the thermolysis, in which the peroxide undergoes homolytic cleavage of the peroxide linkage to give 2-phenylbenzoyloxyl radicals followed by their reactions.[17] However, careful inspection of Table 1 shows that the triplet sensitized photolysis gave lower yields of both carbon dioxide and the products derived from 2-biphenylyl radicals like biphenyl, *o*-terphenyl, and 2-chlorobiphenyl, and on the other hand, a higher yield of biphenyl-2,2'-carbolactone than the direct irradiation and singlet sensitization.

In view of the fact that the direct irradiation and singlet sensitization of BPO induce cleavage of its two bonds, the peroxide bond and the linkage between the carbonyl carbon and aromatic carbon, to give benzoyloxyl and phenyl radicals along with carbon dioxide,[14] it is reasonable to assume that 2-PhBPO, on direct irradiation and singlet sensitization, tends to undergo the two-bond cleavage, whereas, on triplet sensitization as well as on thermolysis, the peroxide undergoes only the usual cleavage of the peroxide bond.[15,16] Thus, direct irradiation and singlet sensitization accelerates production of carbon dioxide and 2-biphenylyl radicals more efficiently than triplet sensitization, ultimately giving higher yields of the products arising from 2-biphenylyl radicals, and, on the contrary, affording lower yields of the products derived from 2-phenylbenzoyloxyl radicals such as biphenyl-2,2'-carbolactone and 2-phenylbenzoic acid.

Temperature effects on product yields are not remarkable, particularly in the direct and chrysene-sensitized photolyses, which seems to be consistent with the mechanism involving the two-bond cleavage. On the other hand, on triplet sensitization and thermolysis, the yields of biphenyl and *o*-terphenyl resulting from 2-biphenylyl radicals increase with increasing temperature. These must be due to enhanced decarboxylation of 2-phenylbenzoyloxyl radicals at higher temperatures. The yields of the lactone and acid decrease in the thermolysis, but increase in the triplet sensitization with increasing temperature. This behavior of 2-phenylbenzoyloxyl radicals indicates that their cyclization and disproportionation proceed with lower activation energies than the decarboxylation.[22]

Experimental

Materials. Bis(2-phenylbenzoyl) peroxide (2-PhBPO) was prepared from 2-phenylbenzoic acid and hydrogen peroxide in the presence of dicyclohexylcarbodiimide,[23] and recrystallized from dichloromethane–methanol. Chrysene and naphthalene were purified by column chromatography and crystallization. Benzophenone and 2-benzoylnaphthalene were recrystallized three times from ethanol. 3'-Methoxyacetophenone was distilled under reduced pressure. Benzene was distilled before use and carbon tetrachloride was purified by the method of Steel and coworkers.[24]

Photolysis. A solution of 2-PhBPO (0.02 mol/dm³) in benzene or carbon tetrachloride (3 ml) in the absence of any sensitizer or in the presence of chrysene (0.002 mol/dm³) or benzophenone (0.05 mol/dm³) in a Uranium glass tube was deaerated by bubbling of argon, and irradiated for five times half-life periods determined by iodometry with a 1 kW high pressure mercury lamp immersed in a Pyrex cooling bath and further surrounded by Toshiba UV-D36A glass filters using a merry-go-round type Riko Rotary photochemical Reactor. Products were determined by GLPC analyses on a Shimadzu GC 4CM gas chromatograph equipped with a flame ionization detector. The following columns were used for quantitative analyses: Diethylene glycol succinate (2%) with H_3PO_4

(0.5%), Thermon 3000 (2%). Carbon dioxide was determined gravimetrically using an Ascarite tube.

Thermolysis. A solution of 2-PhBPO (0.02 mol/dm^3) in benzene or carbon tetrachloride (3 ml) in a Pyrex tube was degassed by the usual freeze-thaw cycles and heated in an air bath constantly maintained at a given temperature (60, 70, 78, and 80 °C) for five times half-life periods. The products were similarly analyzed by GLPC.

Quantum Yields. Quantum yields for photolyses of 2-PhBPO (0.001—0.008 mol/dm^3) were measured in benzene in the absence of any additive or in the presence of naphthalene ($(0.3—2.4)\times10^{-3}$ mol/dm^3) and in carbon tetrachloride in the presence of 3'-methoxyacetophenone (0.06 mol/dm^3) by irradiating with 313 nm light isolated from a 100 W high pressure mercury lamp through a Toshiba UV-D33S glass filter and a K_2CrO_4 solution filter, and in benzene in the presence of chrysene (0.002 mol/dm^3) or 2-benzoylnaphthalene (0.02 mol/dm^3) and in carbon tetrachloride in the presence of benzophenone (0.02 mol/dm^3) by irradiating with 366 nm light isolated through a Toshiba UV-D36A glass filter. Disappearance of the peroxide was determined on a JASCO Trirotar HPLC with a 15 cm ODS column. Conversion of the peroxide was less than 15%. More than 95% of the incident light was absorbed by the sensitizer except the case of chrysene, by which *ca.* 80% of the light was absorbed.

Quenching Rate Constants. Fluorescence of chrysene (3×10^{-4} mol/dm^3) was measured in the presence of 2-PhBPO ($(0—6)\times10^{-3}$ mol/dm^3) in benzene under argon on a Hitachi 650-10S fluorescence spectrophotometer. Phosphorescence of benzophenone (0.01 mol/dm^3) was measured in the presence of 2-PhBPO ($(0—4)\times10^{-5}$ mol/dm^3), biphenyl ($(0—1.6)\times10^{-4}$ mol/dm^3), and phenyl 2-phenylbenzoate ($(0—1.6)\times10^{-4}$ mol/dm^3). Fluorescence lifetime of chrysene and phosphorescence lifetime of benzophenone were measured at room temperature by single photon counting technique on an Applied Photophysic SP-3X.

Stereoselective Epoxidation of Allylic Alcohols and Dehydrogenative Oxidation of Secondary Alcohols by Means of *t*-Butyl Hydroperoxide and Aluminium Reagents

Kazuhiko TAKAI, Koichiro OSHIMA,* and Hitosi NOZAKI

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received July 4, 1983)

Treatment of a solution of geraniol and $(t\text{-BuO})_3Al$ in benzene with *t*-BuOOH at 5 °C gives (2*R**, 3*R**)-2,3-epoxy-3,7-dimethyl-6-octenyl acetate in 83% yield after acetylative workup. Eight allylic alcohols are converted to α,β-epoxy alcohols in preparative yields. The epoxidation of secondary (*E*)-allylic alcohols shows opposite stereoselectivities to *t*-BuOOH–$VO(acac)_2$ system. Asymmetric epoxidation with a chiral hydroxamic acid as a ligand gives unsatisfactory degrees of enantiomeric excess. The same system can also convert secondary alcohols into ketones in excellent yields, while primary ones react very slowly.

The versatility of the epoxide functionality in synthesis makes further advances in stereoselective acyclic epoxidation to be of particular interest.[1] Conventional oxidation with organic peracids[2] or epoxidation with *t*-butyl hydroperoxide in the presence of transition metal catalysts,[3,4] for example, $VO(acac)_2$, $Mo(CO)_6$, and $Ti(OPr^i)_4$, is suitable for such purpose.[5] We wish to report that *t*-BuOOH–$(t\text{-BuO})_3Al$ system effects stereoselective epoxidation of allylic alcohols as well as dehydrogenative oxidation of secondary alcohols to ketones.[6]

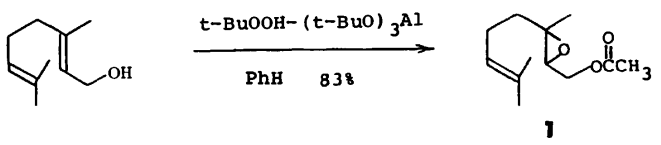
Trialkylaluminium compounds interact energetically with alkyl hydroperoxides to form organoaluminium peroxides.[7] The utility of these products as an oxidizing reagent, however, has been limited[8] because of their instability. They can react with the host trialkylaluminium compounds themselves or alternatively undergo intramolecular rearrangement.[9] We have found that the organoaluminium peroxide prepared *in situ* from *t*-BuOOH and $(t\text{-BuO})_3Al$ has proved to be effective for the title oxidation.[10]

Treatment of a solution of geraniol and $(t\text{-BuO})_3Al$ in benzene with *t*-BuOOH at 5 °C gave (2*R**, 3*R**)-2,3-epoxy-3,7-dimethyl-6-octenyl acetate (**1**) in 83% yield

TABLE 1. EPOXIDATION OF OLEFINIC ALCOHOLS WITH *t*-BuOOH–$(t\text{-BuO})_3Al$[a]

Run	Alcohol	Reaction conditions		Yield[b] %	Product		*t*-BuOOH–$VO(acac)_2$[d]	
		Temp/°C	Time/h		*threo*[c] (*trans*) (%)	*erythro*[c] (*cis*) (%)	*threo* (*trans*) (%)	*erythro* (*cis*) (%)
1		25	5	70	42	58	20	80
2		25	4	78	71	29	15	85
3		25	6	80	13	87	2	98
4		5	6	78	64	36	29	71
5		5	4	80	>99.5	<0.5	86	14
6		5	3	72	<0.5	>99.5	2	98
7		5	3	82	<0.5	>99.5	2	98
8		5	10	80	83	17	29	71[e]

a) All reactions were performed in benzene solution containing the substrates (2.0 mmol), $(t\text{-BuO})_3Al$ (3.0 mmol), and *t*-BuOOH (4.0 mmol). b) Isolated yields are underlined, all others are by GLPC relative to internal standard. Epoxy alcohols were acetylated *in situ* prior to analysis in Runs 5, 6, and 7. c) The resulting mixtures of epoxy alcohols, epoxy acetates, or epoxy alcohol trimethylsilyl ethers were analyzed by GLPC. d) Cited from Ref. 4a. e) Cited from Ref. 21.



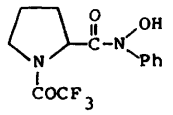
1

Scheme 1.

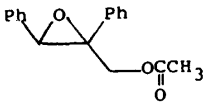
after acetylative workup (Scheme 1). Epoxidation of 6,7-olefinic linkage was not observed analogously as the *t*-BuOOH–$VO(acac)_2$ oxidation.

The results are shown in Table 1, together with the recorded selectivity of the Sharpless' *t*-BuOOH–$VO(acac)_2$ oxidation for comparison.[4a] Cyclohexenols with *Z*-configuration were preferentialy oxidized to cis epoxide by both methods commonly (Runs 6 and 7). The striking difference, however, has been observed in Runs 2, 4, and 8. The present aluminium reagent converted (*E*)-allylic alcohols predominantly into threo isomers which are less favored products in the vanadium one.

Asymmetric epoxidation[11] was examined with a chiral hydroxamic acid (**2**) as a ligand. A chiral aluminium reagent was prepared by treating trimethylaluminium with 1.2 equiv of **2** in benzene and used *in situ*. Epoxidation of geraniol with *t*-BuOOH and the reagent gave **1** in 34% e.e., whereas the reaction of 2,3-diphenyl-2-propen-1-ol gave **3** in 38% e.e.



2



3

The Oppennauer oxidation employing aluminium as a key atom is one of the useful methods for mild oxidation.[12] Recently Posner has reported selective oxidation of alcohols by means of Al_2O_3–Cl_3CCHO system.[13] The present system has provided another means of oxidizing secondary alcohols into corresponding ketones with excellent yields as shown in Table 2. Allylic secondary alcohols gave epoxy ketones in one pot (**Runs** 5 and 6).

Meanwhile, primary alcohols, such as 1-dodecanol reacted much more slowly[14] and required prolonged period (2 d) afford a complex mixture which contained dodecanal (13% yield) and 1-dodecanol (54% recovery). Under the conditions described for the oxidation of secondary alcohols, many functional groups were inert. For example, 1-iodododecane, methyl dodecanoate, phenylacetylene, anisole, and dodecanal diethylene acetal were recovered unchanged in 95, 95, 98, 98, and 86% yields, respectively, after exposure to the oxidant.

Experimental

The IR spectra were determined on a Shimadzu IR-27-G spectrometer; the mass spectra, on a Hitachi M-80 machine; and the NMR spectra, on a Varian EM-360 spectrometer. The chemical shifts are given in δ, with TMS as the internal standard. The analyses were carried out by the staff at the Elemental Analyses Center of Kyoto University. Benzene was dried on sodium and distilled. *t*-Butyl hydroperoxide (70% aqueous solution) was purchased from Nakarai and used without further purification. All the experiments were carried out under an argon atmosphere. Purification of products were performed by preparative thin layer chromatography (TLC) or column chromatography on silica gel (Merck Kieselgel 60). Analytical GLPC was performed with a Yanagimoto GCG-550-F or Shimadzu GC-4CPT. Preparative GLPC was performed with a JEOL-JGC-20K apparatus.

The *threo/erythro* nomenclature for the relative configuration of two adjacent asymmetric centers of α,β-epoxy alcohols was determined according to the Noyori's formalism.[15]

Epoxidation of Allylic Alcohols by Means of t-*BuOOH–*(t-*BuO)*$_3$-*Al Reagent.* *t*-Butyl hydroperoxide (70%, 0.51 g, 4.0 mmol) was added at 5 °C (or 25 °C) to a stirred solution of an allylic alcohol (2.0 mmol) and $(t\text{-BuO})_3Al$ (0.74 g, 3.0 mmol) in benzene (10 ml). The resulting mixture was stirred at this temperature for an appropriate time described in Table 1. The reaction mixture was acetylated *in situ* for the entry 5, 6, and 7 by treating with acetic anhydride (1.02 g, 10 mmol) and pyridine (0.79 g, 10 mmol) at 25 °C for 1 h. The whole was

TABLE 2. OXIDATION OF SECONDARY ALCOHOLS WITH *t*-BuOOH–$(t\text{-BuO})_3Al$

Run	Alcohol	Reaction conditions[a] Temp/°C	Time/h	Product	Yield[b] %
1	$PhCH(OH)CH_3$	25	6	$PhCOCH_3$	90
2	Cyclododecanol	25	18	Cyclododecanone	85
3	2-Octanol	25	12	2-Octanone	(100)
4	4-*t*-Butylcyclohexanol	25	15	4-*t*-Butylcyclohexanone	85
5		80[c]	6		47
6		80[c]	9		48

a) Reactions were performed in benzene solutions (10 ml) containing the substrates (2.0 mmol), $(t\text{-BuO})_3Al$ (3.0 mmol), and *t*-BuOOH (4.0 mmol). b) Except the case of 2-octanol where yield was determined by GLPC, all yields were isolated ones. c) *t*-BuOOH (8.0 mmol) and $(t\text{-BuO})_3Al$ (5.0 mmol) were used.

diluted with ether (10 ml), poured into 1 M †hydrochloric acid (20 ml), and extracted with ether. The organic layer was washed with aq $NaHSO_3$ (15 ml), aq $NaHCO_3$ (20 ml), and brine (2×20 ml), dried over anhydrous Na_2SO_4, and concentrated. The crude product was purified by silica-gel column chromatography (hexane–ethyl acetate) or preparative GLPC.

(2R, 3R*)-2,3-Epoxy-3,7-dimethyl-6-octenyl Acetate (1).*[48] Bp 94 °C (bath temp, 1 Torr, 1 Torr=133.322 Pa); IR (neat): 2940, 2350, 1750, 1460, 1375, 1230, 1038 cm^{-1}; NMR (CCl_4): δ=1.27 (s, 3H), 1.03—2.40 (m, 4H), 1.60 (s, 3H), 1.66 (s, 3H), 2.03 (s, 3H), 2.77 (t, J=6 Hz, 1H), 3.77—4.27 (m, 2H), 5.00 (bt, J=7 Hz, 1H); MS *m/e* (%): 212 (M^+, 1), 134 (11), 109 (74), 82 (31), 69 (50), 43 (100).

Conversion of threo- *and* erythro-*1,2-Epoxy-3-butanol*[16] *to* threo- *and* erythro-*2,3-Octanediol Acetonide.* This procedure was used to determine the ratio of *threo* and *erythro* epoxides produced by the oxidation of 3-buten-2-ol, because the separation of the diastereomeric epoxy alcohols by GLPC was not ideal.

Copper(I) iodide (12 g, 60 mmol) was suspended in anhydrous ether (150 ml). To this cooled (−20 °C) and stirred suspension was added butyllithium (1.7 M solution in hexane, 71 ml, 0.12 mol) dropwise over a period of 1 h. The mixture was allowed to stir for an additional 30 min, and then an etheral solution (30 ml) of a mixture of *threo*- and *erythro*-1,2-epoxy-3-butanols (approximately 7.5 mmol) was added at −20 °C. The whole was allowed to warm to 0 °C over a period of 1 h. The mixture was quenched by cautiously adding a sat. ammonium chloride solution. The copper salts were filtered off and the organic layer was washed twice with brine (40 ml), dried over anhydrous $MgSO_4$ and concentrated. The crude mixture of the diols was dissolved in acetone (10 ml). Perchloric acid (70%, 4 drops) was added to this and the resulting mixture was stirred at 25 °C for 1 h. The reaction mixture was quenched with 20% sodium hydroxide (2 ml) and extracted three times with hexane. The organic layer was separated and subjected to GLPC analysis (3% OV-17, 2 m, 65 °C) to show two peaks, T_r=6.2 min (*threo*-isomer, 42%) and T_r=8.7 min (*erythro*-isomer, 58%). *threo*-2,3-Octanediol acetonide: Bp 52 °C (bath temp, 3 Torr); IR (neat): 2948, 2880, 1464, 1382, 1248, 1180, 1100, 862 cm^{-1}; NMR (CCl_4): δ=0.90 (bt, J=6 Hz, 3H), 1.14 (d, J=6 Hz, 3H), 1.27 (s, 6H), 1.15—1.58 (m, 8H), 3.20—3.70 (m, 2H); MS *m/e* (%): 171 (M^+-CH_3, 100), 111 (18), 86 (56), 69 (74), 59 (32); Found: C, 70.89; H, 12.11%. Calcd for $C_{11}H_{22}O_2$: C, 70.92; H, 11.90%. *erythro*-2,3-Octanediol acetonide: Bp 60 °C (bath temp, 3 Torr); IR (neat): 2940, 2860, 1460, 1376, 1240, 1215, 1080, 855 cm^{-1}; NMR (CCl_4): δ=0.92 (bt, J=6 Hz, 3H), 1.05 (d, J=6 Hz, 3H), 1.22 (s, 6H), 1.00—1.62 (m, 8H), 3.75—4.18 (m, 2H); MS *m/e* (%): 171 (M^+-CH_3, 49), 129 (25), 86 (44), 69 (100), 59 (54); Found: C, 71.07; H, 12.09%. Calcd for $C_{11}H_{22}O_2$: C, 70.92; H, 11.90%.

threo- *and* erythro-*1,2-Epoxy-4-methyl-3-pentanol.*[16] The crude product was treated with *N*-(trimethylsilyl)imidazole (1.1 equiv) in dichloromethane. GLPC analysis (20%, PEG 6000, 2 m, 80 °C) of the resulting trimethylsilyl ethers indicated two peaks, T_r=7.8 min (*threo*-isomer, 71%) and T_r=7.0 min (*erythro*-isomer, 29%), which could not separated completely. The analytically pure samples of both isomers were prepared by preparative GLPC (20% PEG 6000). *threo*-Alcohol trimethylsilyl ether: Bp 67 °C (bath temp, 25 Torr); IR (neat): 2960, 1248, 1085, 928, 836 cm^{-1}; NMR ($CDCl_3$): δ=0.13 (s, 9H), 0.92 (d, J=6 Hz, 3H), 0.95 (d, J=6 Hz, 1H), 1.79 (dqq, J=5, 6, 6 Hz, 1H), 2.55—2.59 (m, 1H), 2.81 —2.83 (m, 1H), 2.91—2.93 (m, 2H); MS *m/e* (%): 173 (M^+-CH_3, 33), 145 (100), 75 (59), 73 (58). *erythro*-Alcohol trimethylsilyl ether: Bp 68 °C (bath temp. 25 Torr); IR (neat): 2970, 1472, 1250, 1068, 875, 838 cm^{-1}; NMR ($CDCl_3$): δ=0.13 (s, 9H), 0.92 (d, J=6 Hz, 3H), 0.95 (d, J=6 Hz, 3H), 1.79 (dqq, J=5, 6, 6 Hz, 1H), 2.61—2.72 (m, 2H), 2.85—2.95 (m, 1H), 3.34 —3.41 (m, 1H); MS *m/e* (%): 173 (M^+-CH_3, 4), 145 (63), 81 (10), 75 (45), 73 (100).

threo- *and* erythro-*1,2-Epoxy-2-methyl-3-heptanol.*[17] TLC (CH_2Cl_2–ether, 5 : 1) of the product derived from epoxidation of 2-methyl-1-hepten-3-ol indicated two spots, R_f=0.33 (*threo*-isomer, 13%) and R_f=0.43 (*erythro*-isomer, 87%). The *threo*/*erythro* isomer ratio was determined by GLPC (5% PEG 20M, 2 m, 85 °C), which showed two peaks at 26.0 min (*threo*-isomer) and at 15.0 min (*erythro*-isomer). The analytically pure samples of both isomers were prepared by preparative TLC. *threo*-Isomer: Bp 80 °C (bath temp, 1 Torr); IR (neat): 3450, 2940, 1460, 1050, 900, 874 cm^{-1}; NMR (CCl_4): δ=0.80—1.03 (bt, J=6 Hz, 3H), 1.27 (s, 3H), 1.15—1.55 (m, 6H), 2.15 (bs, 1H), 2.49 (d, J=5 Hz, 1H), 2.63 (d, J=5 Hz, 1H), 3.00—3.30 (m, 1H); MS *m/e* (%): 129 (M^+-CH_3, 1), 101 (11), 87 (16), 72 (40), 71 (87), 69 (37), 58 (100). *erythro*-Isomer: Bp 80 °C (bath temp, 1 Torr); IR (neat): 3460, 2960, 2940, 1460, 900, 788 cm^{-1}; NMR (CCl_4): δ=0.82—1.06 (bt, J=6 Hz, 3H), 1.06—1.78 (m, 6H), 1.28 (s, 3H), 2.00 (bs, 1H), 2.45 (d, J=5 Hz, 1H), 2.76 (d, J=5 Hz, 1H), 3.42—3.60 (m, 1H); MS *m/e* (%): 129 (M^+-CH_3, 1), 101 (9), 72 (28), 71 (70), 69 (32), 58 (100).

threo- *and* erythro-*(3R*, 4R*)-3,4-Epoxy-2-pentanol.*[18] Treatment of the crude epoxides derived from (*E*)-3-penten-2-ol with *N*-(trimethylsilyl)imidazole (1.1 equiv) in dichloromethane gave the trimethylsilyl ethers, which were analyzed by GLPC (10% PEG 20M, 2 m, 70 °C). GLPC indicated two peaks, T_r=7.8 min (*threo*-isomer, 64%) and T_r=6.6 min (*erythro*-isomer, 36%). The analytically pure samples were prepared by preparative GLPC (20% PEG 20M). *threo*-Alcohol trimethylsilyl ether: Bp 54 °C (bath temp, 13 Torr); IR (neat): 2960, 1450, 1370, 1248, 1098, 1052, 1012, 954, 890, 838, 750 cm^{-1}; NMR ($CDCl_3$): δ=0.12 (s, 9H), 1.19 (d, J=6 Hz, 3H), 1.30 (d, J=4 Hz, 3H), 2.64 (dd, J=2, 6 Hz, 1H), 2.85 (dq, J=2, 6 Hz, 1H), 3.56 (dq, J=6, 6 Hz, 1H); MS *m/e* (%): 159 (M^+-CH_3, 53), 117 (80), 115 (100), 73 (94). *erythro*-Alcohol trimethylsilyl ether: Bp 56 °C (bath temp, 12 Torr); IR (neat): 2960, 1450, 1370, 1248, 1094, 1004, 892, 836, 775 cm^{-1}; NMR ($CDCl_3$): δ=0.10 (s, 9H), 1.22 (d, J=6 Hz, 3H), 1.29 (d, J=5 Hz, 3H), 2.58 (dd, J=2, 5 Hz, 1H), 2.90 (dq, J=2, 5 Hz, 1H), 3.59 (dq, J=6, 6 Hz, 1H); MS *m/e* (%): 159 (M^+-CH_3, 50), 117 (92), 115 (100), 73 (84).

threo-*3,4-Epoxy-4-methyl-2-pentanol.*[18] GLPC analysis (5% PEG 20M, 2 m, 65 °C) showed that the product was homogeneous, having a retention time of 13.6 min: *threo*-Isomer: Bp 75 °C (bath temp, 15 Torr); IR (neat): 3450, 2970, 1720, 1378, 1112, 1070, 1030, 890, 868, 805 cm^{-1}; NMR (CCl_4): δ=1.16 (d, J=6 Hz, 3H), 1.28 (s, 3H), 1.30 (s, 3H), 2.57 (d, J=7 Hz, 1H), 3.33 (bs, 1H), 3.53 (dq, J=7, 6 Hz, 1H); MS *m/e* (%): 116 (M^+, trace), 72 (6), 59 (100), 58 (33), 57 (38), 45 (31).

Cf. erythro-Isomer:[18] Bp 76 °C (bath temp, 15 Torr); T_r= 19.1 min (5% PEG 20M, 2 m, 65 °C); IR (neat): 3450, 2970, 1645, 1380, 1112, 946, 906, 790 cm^{-1}; NMR (CCl_4): δ=1.25 (d, J=6 Hz, 3H), 1.27 (s, 3H), 1.30 (s, 3H), 1.55 (bs, 1H), 2.42 (d, J=7 Hz, 1H), 3.57 (dq, J=7, 6 Hz, 1H); MS *m/e* (%): 101 (M^+-CH_3, 1), 72 (6), 59 (100), 58 (27), 57 (33), 45 (34).

cis-*2,3-Epoxy-1-cyclohexanol.*[19] Bp 88 °C (bath temp, 18 Torr); IR (neat): 3300, 2950, 1650, 1420, 1058, 938, 846 cm^{-1}; NMR (CCl_4): δ=1.03—2.25 (m, 7H), 3.03—3.33 (m, 2H), 3.63—4.10 (m, 1H); MS *m/e* (%): 114 (M^+, 3), 96 (20),

† 1 M=1 mol dm^{-3}.

70 (100), 68 (32), 67 (48), 57 (96).

A small aliquot was acetylated with acetic anhydride and pyridine. GLPC analysis (10% PEG 20M, 2 m, 125 °C) indicated a peak (T_r=12.4 min) due to the *cis*-epoxy acetate. A peak at 9.8 min, corresponding to the *trans*-isomer prepared independently,[19] was absent.

cis-3,4-Epoxy-1-cyclohexanol.[20] Bp 79 °C (bath temp, 16 Torr); IR (neat): 3370, 2950, 1670, 1440, 1260, 1065, 990, 818, 792 cm^{-1}; NMR (CCl_4): δ=1.00—2.35 (m, 7H), 2.96—3.12 (m, 2H), 3.40—3.78 (m, 1H); MS *m/e* (%): 114 (M^+, trace), 95 (5), 71 (44), 70 (94), 57 (56), 42 (100).

After acetylation, the *cis/trans* isomer ratio was determined by GLPC (3% Silicone OV-17, 2 m, 75 °C), which indicated one peak at 40 min corresponding to the *cis*-epoxy acetate. The absence of *trans*-isomer[20] (T_r=36 min) was confirmed by the comparison with the authentic sample.

cis- *and* trans-*2,3-Epoxycyclododecanol.*[21] The two isomers were separated by column chromatography (hexane–ether, 5 : 1) on silica gel. *cis*-Isomer: Bp 81 °C (bath temp, 0.1 Torr); R_f=0.43 (hexane–ether, 1 : 1); IR (neat): 3350, 2950, 1462, 1448, 912, 870, 674 cm^{-1}; NMR (CCl_4): δ=0.97—2.27 (m, 19H), 2.72 (t, J=2 Hz, 1H), 2.90 (dt, J=10, 2 Hz, 1H), 3.85—4.08 (m, 1H); MS *m/e* (%): 198 (M^+, trace), 121 (24), 111 (38), 98 (52), 95 (67), 82 (83), 81 (87), 67 (65), 57 (100). *trans*-Isomer: Bp 83 °C (bath temp, 0.1 Torr); R_f=0.23 (hexane–ether, 1 : 1); IR (neat): 3450, 2950, 1475, 1465, 1040, 896, 788 cm^{-1}; NMR (CCl_4): δ=0.93—2.32 (m, 18H), 2.63 (bs, 1H), 2.53—2.88 (m, 2H), 2.90—3.18 (m, 1H); MS *m/e* (%): 198 (M^+, trace), 121 (17), 111 (28), 98 (41), 95 (59), 82 (71), 81 (72), 57 (100).

Asymmetric Epoxidation of Allylic Alcohols with a Chiral Aluminium Compound and t-*BuOOH.* The chiral ligand **2** was prepared by acylation of *N*-phenylhydroxylamine with *N*-trifluoroacetyl-(*S*)-prolyl chloride according to the literature.[22] **2**: $[\alpha]_D^{25}$ −61.3 (*c* 1.5, acetone). To a stirred solution of trimethylaluminium (1.0 M solution in hexane, 3.0 ml, 3.0 mmol) in benzene (15 ml) was added at 25 °C a benzene solution of **2** (1.1 g, 3.6 mmol) and the whole was stirred at the same temperature for 1 h. Then allylic alcohol (2.0 mmol) and *t*-butyl hydroperoxide (70%, 0.51 g, 4.0 mmol) were added successively and the resulting mixture was heated to reflux for an additional 3 h. After acetylation and a usual workup as mentioned before, the crude product was purified by preparative TLC.

1: $[\alpha]_D^{25}$ −8.6 (*c* 1.5, acetone). **3**: $[\alpha]_D^{25}$ −16.7 (*c* 0.6, CCl_4). Enantiomeric excess of these products were also checked by NMR with Eu(hfc)$_3$ shift reagent.

(2R, 3R*)-2,3-Epoxy-2,3-diphenylpropyl Acetate (3).*[11c] Mp 42.0 °C (hexane); IR (KBr): 1748, 1504, 1454, 1220, 1035, 745, 695 cm^{-1}; NMR (CCl_4): δ=1.98 (s, 3H), 4.16 (s, 1H), 4.23 (d, J=12 Hz, 1H), 4.50 (d, J=12 Hz, 1H), 6.80—7.20 (m, 10H); MS *m/e* (%): 225 (M^+-COCH_3, 1), 167 (10), 162 (28), 120 (100), 107 (38), 103 (26), 43 (48); Found: C, 75.98; H, 6.00%. Calcd for $C_{17}H_{16}O_3$: C, 76.10; H, 6.01%.

Oxidation of Secondary Alcohols by Means of t-*BuOOH–(*t-*BuO)$_3$Al Reagent.* To a stirred solution of a secondary alcohol (2.0 mmol) and (*t*-BuO)$_3$Al (0.74 g, 3.0 mmol) in benzene (10 ml) was added at 25 °C a benzene solution of *t*-BuOOH (0.44 g, 4.0 mmol). The resulting mixture was stirred at 25 °C for an appropriate time described in Table 2. The mixture was diluted with ether (10 ml) and poured into 1 M hydrochloric acid (20 ml). The separated organic layer and ether extracts were washed with aq $NaHSO_3$ (15 ml), aq $NaHCO_3$ (20 ml), and brine (2×20 ml), dried over anhydrous sodium sulfate, and concentrated. The crude product was purified by column chromatography (hexane–ethyl acetate) on silica gel (20 g).

The yield of 2-octanone was determined by GLPC (10% PEG 20M, 2 m, 50 °C) using dodecane as the internal standard.

Preparation of α,β-Epoxy Ketones by Means of t-*BuOOH–(*t-*BuO)$_3$Al Reagent.* A solution of an allylic secondary alcohol (2.0 mmol) and (*t*-BuO)$_3$Al (1.2 g, 5.0 mmol) in benzene (10 ml) was treated with a benzene solution of *t*-butyl hydroperoxide (70%, 1.0 g, 8.0 mmol) at 80 °C for 6 (9) h. After a usual workup, the crude product was purified by column chromatography (hexane–ethyl acetate) on silica gel (20 g).

(2R, 3R*)-2,3-Epoxycyclododecanone.* Mp 42.5 °C (hexane); IR (CCl_4): 2930, 1722, 1465, 1428 cm^{-1}; NMR (CCl_4): δ=0.95—1.93 (m, 15H), 1.95—2.40 (m, 2H), 2.63—3.00 (m, 2H), 3.30 (d, J=1.5 Hz, 1H); MS *m/e* (%): 196 (M^+, 4), 153 (12), 111 (53), 98 (92), 84 (90), 55 (100); Found: *m/e* 196.1464. Calcd for $C_{12}H_{20}O_2$: M, 196.1464.

(2R, 3S*)-2,3-Epoxy-1-phenyl-1-butanone.* Bp 123 °C (bath temp, 1 Torr); IR (neat): 2960, 1698, 1602, 1588, 1456, 1412, 1230, 940, 702 cm^{-1}; NMR (CCl_4): δ=1.16 (d, J=5 Hz, 3H), 3.32 (dq, J=5, 5 Hz, 1H), 3.97 (d, J=5 Hz, 1H), 7.15—7.63 (m, 3H), 7.83—8.15 (m, 2H); MS *m/e* (%): 162 (M^+, 12), 147 (8), 105 (100), 77 (35); Found: *m/e* 162.0704. Calcd for $C_{10}H_{10}O_2$: M, 162.0681.

(Received July 9, 1983)

The effects of basic amino acid residues on the base stacking of nucleotides have been studied to clarify the nature of interaction between histones and DNA's. For this purpose, lysine and arginine derivatives were used as models for basic amino acid residues in histone. The base stacking association of 2′-deoxyguanosine 5′-monophosphate(5′-dGMP) in aqueous solution has been studied by the measurement of the concentration dependence of ^{1}H NMR chemical shifts of 5′-dGMP both in the absence and in the presence of the basic amino acid derivatives at different pH's. We clarified that the lysine favors the base stacking association of 5′-dGMP through the interaction with the phosphate group(s), while an excess of the arginine destabilizes the stacking aggregates through the interaction with the base moiety. We also clarified that the ionization of the phosphate group destabilizes the stacking association of 5′-dGMP both in the absence and in the presence of the basic amino acids.

To investigate the interaction of basic protein with nucleic acid, there has been studied many model systems consisting of basic oligo- or polypeptides and polynucleotides, nucleic acids, or its components by physicochemical methods.[1-9] The binding of histones to DNA has been clarified to occur mainly through an electrostatic linkage between basic amino acid residues such as lysine and arginine, and the DNA phosphate groups.[4,9] Wagner and Arav[1] have used equilibrium dialysis to study the binding of the various nucleotides to poly(L-lysine) and poly(L-arginine) at pH 7. Their results showed that there is some specificity in the interaction between the nucleotides and basic polypeptides. In particular, the binding constant of uanine nucleotide with poly(L-arginine) is much larger than that with poly(L-lysine). Rifkind and Eichhorn[2] have studied, using optical rotatory dispersion, the interaction of various ribonucleotides with poly(L-lysine) and poly(L-arginine) and shown that the guanosine nucleotide stacks more weakly in the presence of poly(L-arginine) than in the presence of poly(L-lysine).

Free nucleic acid bases and their derivatives are known to aggregate in aqueous solution. In these aggregations, as shown by ^{1}H NMR measurements, the planar bases are arranged in parallel with each other to take so-called stacking mode.[10-15] The stacking interaction has been extensively studied for nucleosides and nucleotides,[10-19] because the stacking contributes dominantly to the stability of the secondary structures of DNA and other polynucleotides.[12,13,19-21]

No attempt has so far been made to study the effect of basic amino acids on the base stacking interaction of nucleotides. It seems that the study of this effect would promote the understanding of a local interaction at lysine- or arginine-rich regions in nucleohistone. A study on the nucleotide having guanine base can also provide the information relevant to the specific interaction of the nucleotide with poly(L-arginine). In this work, we will first study the base stacking association of 2′-deoxyguanosine 5′-monophosphate(5′-dGMP) at acidic, neutral, and alkaline pH's by means of ^{1}H NMR, since no detailed study has so far been reported. The effect of phosphate ionization on a base stacking association will be discussed. On the basis of these results, we will study the effect of lysine and arginine derivatives, N_α-acetyl-L-lysine methyl ester(Ac–Lys–OMe) and N_α-acetyl-L-arginine methyl ester(Ac–Arg–OMe), at each pH. For the sake of comparison, 2′-deoxyadenosine 5′-monophosphate(5′-dAMP), 2′-deoxyadenosine (2′-dAdo), and 2′-deoxyguanosine(2′-dGuo) will be also studied.

Experimental

Materials. All samples were purchased from Sigma Chemical Co. Sodium salts of 5′-dGMP and 5′-dAMP were treated with Chelex-100(Bio-Rad Laboratories). The lysine and arginine derivatives, free acid of 5′-dGMP, and nucleosides (2′-dAdo and 2′-dGuo) were used without further purification. Deuterium oxide(D_2O) and perdeuterated dimethyl sulfoxide($(CD_3)_2SO$) used as solvents, were purchased from Merck Sharp and Dohme, Canada Ltd.

NMR Measurements. Fourier transformed ^{1}H NMR spectra were taken on a JEOL PS-100 NMR spectrometer equipped with a PFT-100 Fourier transform system and a JEOL EC-100 computer. The spectrometer was field-frequency locked on deuterium resonance of D_2O or $(CD_3)_2SO$ used as solvent. Digital resolution was 0.24 Hz. The methyl signal of 2-methyl-2-propanol was used as an internal reference for monitoring the chemical shifts. This signal is known to be shifted to upfield in the presence of high concentration of aromatic solutes.[22] This shift is, however, negligibly small in the experimental concentration range (up to 0.25 M for the nucleotides, 1 M = 1 mol dm^{-3}).

All spectra were recorded at 30 °C. A JES VT-3 temperature controller was used for the stabilization, with accuracy of ±2 °C.

NMR samples were prepared in D_2O containing 5×10^{-3} M EDTA (ethylenediaminetetraacetic acid). An addition of EDTA did not affect ^{1}H chemical shifts. The pH of solution was adjusted to a desired value by an addition of very small amount of concentrated DCl and/or NaOD solution in D_2O. The pH value was measured, with an accuracy of ±0.01 pH unit, both before and after the NMR measurement with a TOKO TP-101 pH meter fitted with combination electrode of Type CE-103 which can be inserted to NMR sample tube. No correction was made for the deuterium isotope effect on pH value. Concentrations were determined by dry weight and then adjusted to the desired values by dilution using a volumetrically variable pipette 4710 (Eppendorf).

The data of chemical shifts were analyzed by using a Sharp MZ-80B personal computer: the observed variation of the chemical shift with concentration was fitted to an equation by

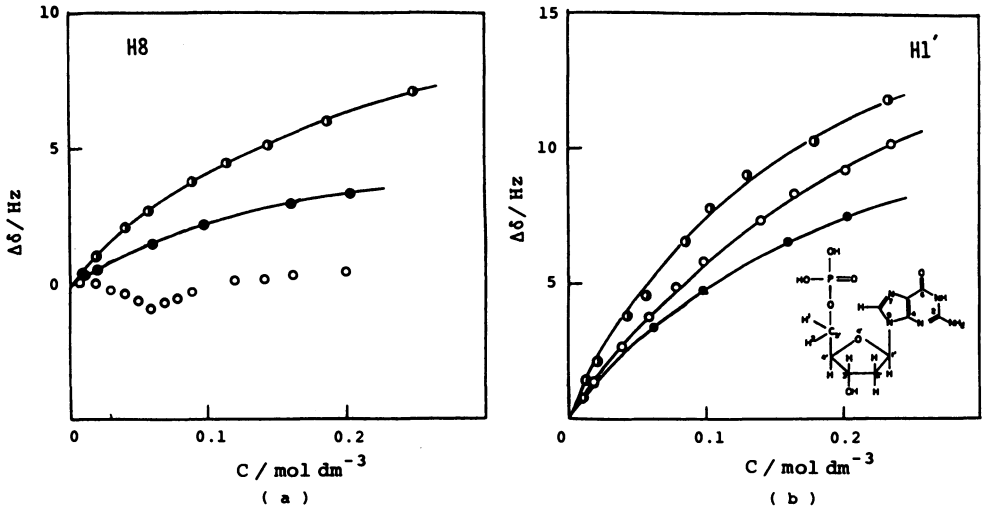

Fig. 1. Effect of pH on the base stacking association of 5′-dGMP. ^{1}H chemical shift differences $\triangle\delta$ are displayed for the H-8(a) and H-1′(b) as a function of 5′-dGMP concentration C at pH 4.0 (○), 6.6 (◑), and 9.0 (●), where $\triangle\delta$ is the chemical shift of a particular proton at each concentration referenced to that at an infinite dilution and a positive value represents an upfield shift.

using a Newton-Gauss nonlinear least-squares method.

Results

The Self-association of 5′-dGMP. We used the resonance of the base proton in position 8(H-8) and that of the ribose proton in position 1′(H-1′) (see Fig. 1), as a probe for studying the concentration dependence of intermolecular association of 5′-dGMP. The resonance of H-2 proton was further used in the experiment for 5′-dAMP. In Fig. 1 is shown the concentration dependence of the ^{1}H chemical shift differences ($\Delta\delta$) of the 5′-dGMP protons H-8(a) and H-1′(b) at pH 4.0, 6.6, and 9.0, where $\Delta\delta$ is the chemical shift of a particular proton at each concentration referenced to that at an infinite dilution and a positive value represents an upfield shift. These three pH's were chosen to correspond to monoanionic, pK, dianionic states of the phosphate group of 5′-dGMP. From the titration experiment of ^{31}P chemical shift of 5′-mononucleotides,[35] the phosphate group is mono and dianion at pH 4.0 and 9.0, respectively. The pH value of 6.6 is close to the pK value for the secondary ionization of the phosphate group. At pH 6.6 and 9.0, upfield shifts were observed with increasing concentration, indicating an increase of the fraction of the base stacking association.[10–15] The concentration dependence of these ^{1}H chemical shifts has been analyzed by applying the isodesmic model of indefinite non-cooperative stacking.[23] In this model, the relationship between the observed chemical shift difference ($\Delta\delta$) and total concentration (C) is given by

$$(\Delta\delta/C)^{1/2} = (K/2\Delta\delta_D)^{1/2} \times (2\Delta\delta_D - \Delta\delta), \quad (1)$$

where $\Delta\delta = \delta_0 - \delta_{obsd}$, δ_0 and δ_{obsd} are the chemical shifts of the investigated proton at an infinite dilution and at each concentration, $\Delta\delta_D$ the dimerization shift, and K the association constant. The observed chemical shift displacements for both protons at pH 6.6 and 9.0 were consistent with this model.

At pH 4.0, the H-8 base proton resonance shifts little with increasing concentration, while the H-1′ ribose proton resonance shifts significantly to upfield. The results indicate that there are other interactions in addition to the base stacking association and the interaction sites are in the base moiety of 5′-dGMP. The unique shift of H-8 proton at pH 4.0 may be specific to the nucleotide having guanine base, since the H-8 base proton resonance of 5′-dAMP shifted to upfield with increasing concentration at pH 4.0.

In order to understand an interaction other than base stacking, we have also studied the concentration de-

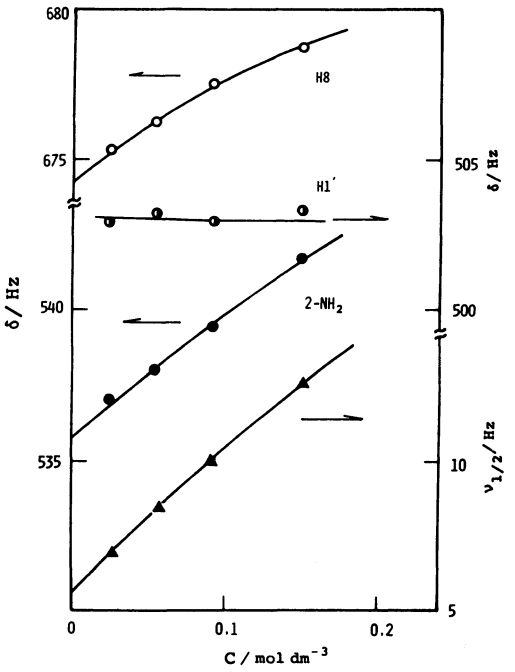

Fig. 2. ^{1}H chemical shifts δ from 2-methyl-2-propanol for the 5′-dGMP protons H-8 (○), H-1′ (◑), and 2-NH_2 (●) and the half-width $\nu_{1/2}$ of 2-NH_2 (▲) as a function of 5′-dGMP concentration C in $(CD_3)_2SO$.

TABLE 1. EFFECTS OF pH AND Ac–Lys–OMe ON THE ASSOCIATION CONSTANTS (K/M^{-1})[a] FOR THE BASE STACKING OF 5′-dGMP AND 5′-dAMP[b] ACCORDING TO THE ISODESMIC MODEL

pH	5′-dAMP			5′-dGMP		[Ac–Lys–OMe]/[5′-dGMP]=0.5		[Ac–Lys–OMe]/[5′dGMP]=1	
	H8	H2	H1′	H8	H1′	H8	H1′	H8	H1′
4.0	6.9	6.3	6.0	—[c]	1.5	6.2[d]	6.0[d]	7.1[d]	7.6[d]
6.6	4.6	4.2	4.5	2.7	3.0	3.4	3.5	4.3	4.4
9.0	3.7	3.3	3.2	1.9	2.0	2.9	3.2	2.7	3.0

a) Estimated errors for these association constants are 10—15%. b) Measurement for pH effect only. c) Not determined. d) For concentration below 0.06 M.

pendence of ^1H chemical shifts and line width of 5′-dGMP in $(CD_3)_2SO$ (Fig. 2). It is known that the base stacking association is negligibly small in this solvent.[24] The resonance position of H-1′ ribose proton is independent of concentration as expected. The resonance of 2-NH_2 shifts to downfield and its line width increases with increasing concentration, indicating the formation of hydrogen bond including 2-NH_2 group. Parallel to this variations, the resonance of H-8 proton shifts to downfield.

In Table 1 are shown the effects of pH on the association constants for the stacking of 5′-dGMP and 5′-dAMP estimated by applying the isodesmic model. The association constants obtained from the chemical shift displacements of H-8 base protons agree well with those from the H-1′ ribose protons, indicating that the variations of ^1H chemical shifts of both protons reflect the degree of stacking association. The association constants for stacking of both nucleotides decrease with increasing pH, except for 5′-dGMP at pH 4.0.

For comparison, 2′-dAdo, lacking 5′-monophosphate group, has been studied. In Fig. 3 is shown the pH dependence of 2′-dAdo protons (H-8, H-2, and H-1′) at various concentration up to dissolvable limit 0.04 M. The chemical shifts of all protons do not change in the range of pH 5 to 9 and this constancy is kept over the concentration range studied here. The downfield shifts of the base proton resonances observed for the nucleotides with decreasing pH below 5 can be attributed to the protonation of the base.[11,25]

Effect of the Lysine on the Stacking of 5′-dGMP. In Fig. 4 is shown the concentration dependence of ^1H chemical shifts (H-8 and H-1′) of 5′-dGMP at pH 4.0, 6.6, and 9.0 in the 2 : 1 mixture of 5′-dGMP and Ac–Lys–OMe. At pH 6.6 and 9.0, upfield shifts are observed with increasing concentration, which is consistent with the isodesmic model. This indecates that the lysine does not disturb the indefinite non-cooperative stacking of the base of 5′-dGMP. Even at pH 4.0, upfield shifts are also observed for both protons, unlikely in the case of 5′-dGMP alone. This indicates that the lysine interacts with 5′-dGMP.

In Table 1 is also shown the effect of the lysine on the association constants of 5′-dGMP. At pH 6.6, the association constants obtained from the H-8 and H-1′ protons increase in the presence of the lysine and with an increase of its population. The lysine, therefore, participates in the base stacking association.

Effect of the Arginine on the Stacking of 5′-dGMP. In Fig. 5 is shown the concentration dependence of ^1H chemical shifts of 5′-dGMP at molar ratios [Ac–Arg–OMe]/[5′-dGMP]=0 (5′-dGMP alone), 0.5, 1.0, and 2.0 at pH 4.0. The resonance of the base proton H-8 shifts to upfield with concentration in the presence of the arginine, similar to that in the presence of the lysine. The magnitudes of shift differences ($\Delta\delta$) of the ribose proton H-1′ increase in the presence of the arginine at lower 5′-dGMP concentration ($\approx$0.08 M). The arginine interacts with 5′-dGMP and participates in increase the fraction of stacking aggregates, similar to the case of the lysine.

At 5′-dGMP concentration higher than 0.1 M, the magnitudes of shift differences of the H-8 and H-1′

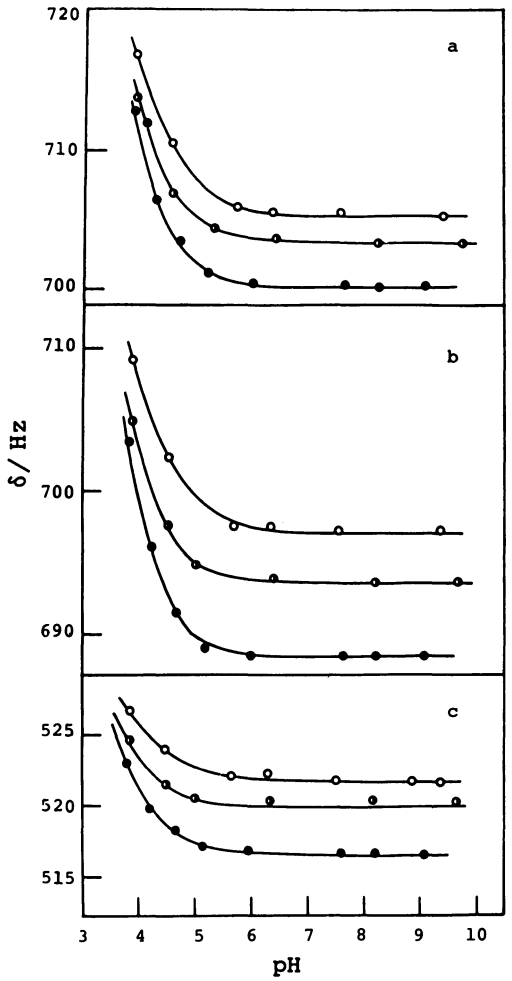

Fig. 3. ^1H chemical shifts δ *vs.* pH for protons H-8(a), H-2(b), and H-1′(c) of 2′-dAdo at 0.8×10^{-2} M (○), 2.2×10^{-2} M (◑), and 4×10^{-2} M (●).

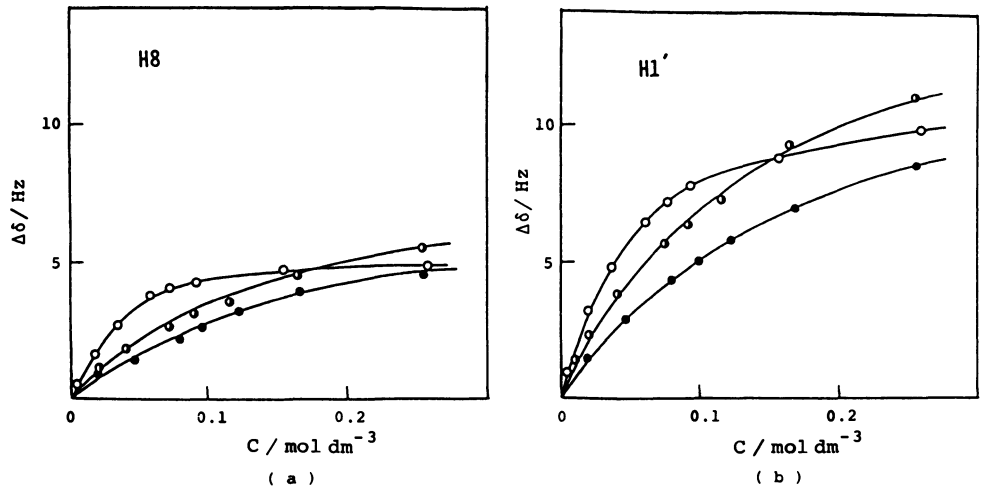

Fig. 4. Effect of pH on the self-association of 5′-dGMP at molar ratio [Ac–Lys–OMe]/[5′-dGMP]=0.5. ^{1}H chemical shift differences $\triangle\delta$ are displayed for the H-8(a) and H-1′(b) protons as a function of 5′-dGMP concentration C at pH 4.0 (○), 6.6 (◑), and 9.0 (●).

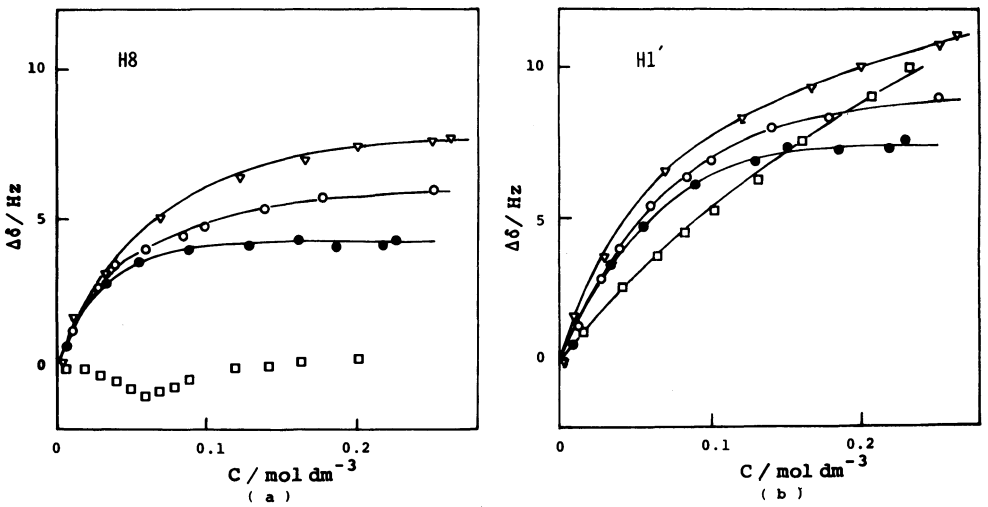

Fig. 5. Effect of the arginine on the self-association of 5′-dGMP at pH 4.0. ^{1}H chemical shift differences $\triangle\delta$ are displayed for the H-8(a) and H-1′(b) protons as a function of 5′-dGMP concentration C at molar ratios [Ac–Arg–OMe]/[5′-dGMP]=0(5′-dGMP alone) (□), 0.5 (▽), 1.0 (○), and 2.0 (●).

Table 2. Effects of pH and Ac–Arg–OMe on the association constants (K/M^{-1})[a] for the base stacking of 5′-dGMP according to the isodesmic model

[Ac–Arg–OMe]/[5′-dGMP]	H-8			H-1′		
	pH 4.0	pH 6.6	pH 9.0	pH 4.0	pH 6.6	pH 9.0
0[b]	—[c]	2.7	1.9	1.5	3.0	2.0
0.5	8.4	5.0	4.3	8.6	5.5	3.8
1.0	9.5[d]	5.2	4.1[e]	9.1[d]	5.8	3.7[e]
2.0	9.3[g]	5.5[f]	4.6[f]	8.9[g]	6.0[f]	4.1[f]

a) Estimated errors for these association constants are 15—20%. b) 5′-dGMP alone. c) Not determined. d—g) Concentration ranges of 5′-dGMP applied to the isodesmic model: (d) 0.18 M, (e) 0.15 M, (f) 0.09 M, (g) 0.06 M.

protons decrease and the chemical shifts tend to finite values with increasing molar ratio of the arginine to 5′-dGMP. These differences can be regarded as significant, since the experimental errors are within 0.5 Hz. This result indicates that the increase of the fraction of stacking aggregates of 5′-dGMP with increasing concentration is depressed at higher molar ratio of the arginine.

Similarly, at pH 6.6 and 9.0, the magnitudes of shifts observed for both protons at higher 5′-dGMP concentration decrease with increasing molar ratio of the arginine to 5′-dGMP. The isodesmic model cannot be

applied to these ^1H chemical shift variations. This is different from the case of the lysine where the chemical shift variations of both protons at pH 6.6 and 9.0 obey the isodesmic model. These results indicate that the differences between the arginine and the lysine could not be explained by the difference in electrostatic interactions alone.

In Table 2 are shown the effects of the arginine on the stacking association constants at each pH and the concentration ranges where the isodesmic model is applicable. The applicable concentration ranges were determined from plots of $(\Delta\delta/C)^{1/2}$ against $\Delta\delta$ (Eq. 1). These plots give a straight line up to an upper limit of concentration which is applicable to the isodesmic model. When the arginine is added to the 5'-dGMP solution at the ratio of [Ac–Arg–OMe]/[5'-dGMP]=0.5, the association constant (K) increases, similar to the case of the lysine. The K values at [Ac–Arg–OMe]/[5'-dGMP]=1.0 in the concentration ranges where the isodesmic model is applicable are, however, the same as those at [Ac–Arg–OMe]/[5'-dGMP]=0.5 within an experimental error. The K values are not increased by further addition of the arginine. The 5'-dGMP concentration ranges applied at [Ac–Arg–OMe]/[5'-dGMP]=2 are more restricted (Table 2, footnote (f)—(g)). These results indicate that the increase of the fraction of stacking aggregates is depressed in the presence of an excess of the arginine at all pH studied here.

Discussion

Self-association of 5'-dGMP at pH 4.0. The unique variation of chemical shift of H-8 proton with concentration at pH 4.0 (Fig. 1) could be interpreted by the formation of planar interbase association, because a guanine base is unusual among nucleic acid bases in its ability to make a self-associated regular structure with higher stability.[15,26–32] Gelation of aqueous solution of guanosine 5'-monophosphate (5'-GMP) takes place in acidic pH.[26,27] The gel structure of 5'-GMP at acidic pH consists of helically arranged stacks of planar tetramer units formed by hydrogen bonding (N-1 and 2-NH_2 as donors, O-6 and N-7 as acceptors).[21] Since the electron density at N-7 of the guanine base is large at acidic pH,[25,33,34] the N-7 of 5'-dGMP becomes also a stronger proton acceptor at pH 4.0 as compared with that at higher pH. Although 5'-dGMP, unlike 5'-GMP, does not form an ordered self-structure with applicable stability, the weak planar interbase association of 5'-dGMP could occur in acidic solution.

The effect of hydrogen bonding including 2-NH_2 on the chemical shift of H-8 proton, where the 2-NH_2 proton is the hydrogen bond donor for N-7 in planar interbase aggregate,[27–32] has been studied for 5'-dGMP in $(CD_3)_2SO$ (Fig. 2). With increasing the fraction of the interbase association by hydrogen bonding, the H-8 resonance shifts to downfield. This indicates that the formation of interbase hydrogen bonds including N-7(acceptor for 2-NH_2 proton) deshields the H-8 proton.

In aqueous solution, the hydrogen bonding becomes weak by simultaneous hydration of proton donor and acceptor groups, but the planar interbase association may be strong, since 5'-GMP forms gel even in aqueous solution.

The above results indicate that at pH 4.0, the deshielding of H-8 proton by planar interbase association can offset the upfield shift due to the base stacking association. There is, therefore, interbase association in addition to the base stacking association in the solution of 5'-dGMP at pH 4.0.

Effect of pH on the Base Stacking Association of Nucleotides. At the region of pH 6.6 to 9.0, the effect of pH is on the deprotonation of the phosphate group of nucleotides.[11] The association constants (K) for stacking of both 5'-dGMP and 5'-dAMP decrease with increasing pH (Table 1). These are possibly due to the increase of electrostatic repulsion between negatively charged phosphate groups in stacked aggregates. Scheller *et al.*[36] indicated that the tendency of self-stacking decreases in a series of adenosine$\gg AMP^{2-} > ADP^{3-} \approx ATP^{4-}$. The deprotonation of the phosphate group causes a decrease of stacking affinity by an increase of the intrinsic intermolecular electrostatic repulsion.

This interpretation is confirmed by comparison of 5'-dAMP and 2'-dAdo lacking 5'-monophosphate: the association constant (K) of 5'-dAMP decreases with increasing pH (Table 1), while 2'-dAdo does not induce the change of chemical shifts of all protons studied (H-8, H-2, and H-1') from pH 5 to 9 and this constancy is kept over the concentration range in this experiment (Fig. 3), that is, constancy of K value in this range of pH. The chemical shift of 2'-dGuo also did not change in the pH range up to dissolvable limit of concentration 0.01 M (not illustrated). The effect of charge of phosphate group is, thus, significant on the base stacking association.

Effects of Lysine and Arginine on the Self-association of 5'-dGMP. In the presence of the lysine or arginine derivative, monotonous upfield shifts are observed for H-8 and H-1' protons of 5'-dGMP even at pH 4.0 (Figs. 4 and 5), indicating that the base stacking association is easier to take place than the planar interbase association. The binding of lysine or arginine with 5'-dGMP results in the depression of the planar interbase association. Possibly, the interactions between these basic amino acids and 5'-dGMP include coulombic attraction and/or hydrogen bonding between the protonated ε-amino group ($pK \simeq 10$) of the lysine or the guanidinium group ($pK \simeq 11$) of the arginine and monoanionic phosphate group (s) in the stacked 5'-dGMP aggregates.

When the lysine is added to the 5'-dGMP solution at pH 6.6, the affinity of base stacking increases (Table 1). This increment is due to the neutralization of the negatively charged phosphate group by the positively charged ε-amino group of the lysine which reduces the intermolecular electrostatic repulsion between phosphate groups in the stacked 5'-dGMP. At pH 9.0, the association constant does not increase by an addition of the lysine. Since the degree of protonation ($pK \simeq 10$) of the lysine at pH 9.0 is low compared to that at lower pH, the addition of the lysine has a less effect on the stacking association of 5'-dGMP.

When an excess of the arginine is added to the 5'-dGMP solution at all pH studied, the increase of stacking

fraction with increasing concentration is depressed (Fig. 5 and Table 2). It is known that a guanidinium group of arginine can associate through hydrogen bonding with a guanine base.[37,38] An excess of the arginine can interact with the guanine base as well as the phosphate group of 5′-dGMP. On the other hand, the guanidinium cation is known to reduce a hydrophobic interaction.[39] This, leads to a reduction of fraction of the stacking aggregates, since the hydrophobic interaction contributes to the stabilization of stacking aggregates.[14,40] The hydrophobic interaction is more effective in the multiple stacked bases. We conclude, therefore, that the depression of stacking association is due to the interaction between the guanidinium group of the arginine and the guanine base of 5′-dGMP. From this interpretation, one could explain the fact that the stacking of guanine nucleotide occurs much less in the presence of poly(L-arginine) than in the presence of poly(L-lysine).[2]

Reduction of Sulfonic Acids and Related Organosulfur Compounds with Triphenylphosphine-Iodine System

Shigeru OAE*,† and Hideo TOGO

Department of Chemistry, The University of Tsukuba, Sakura, Niihari, Ibaraki 305

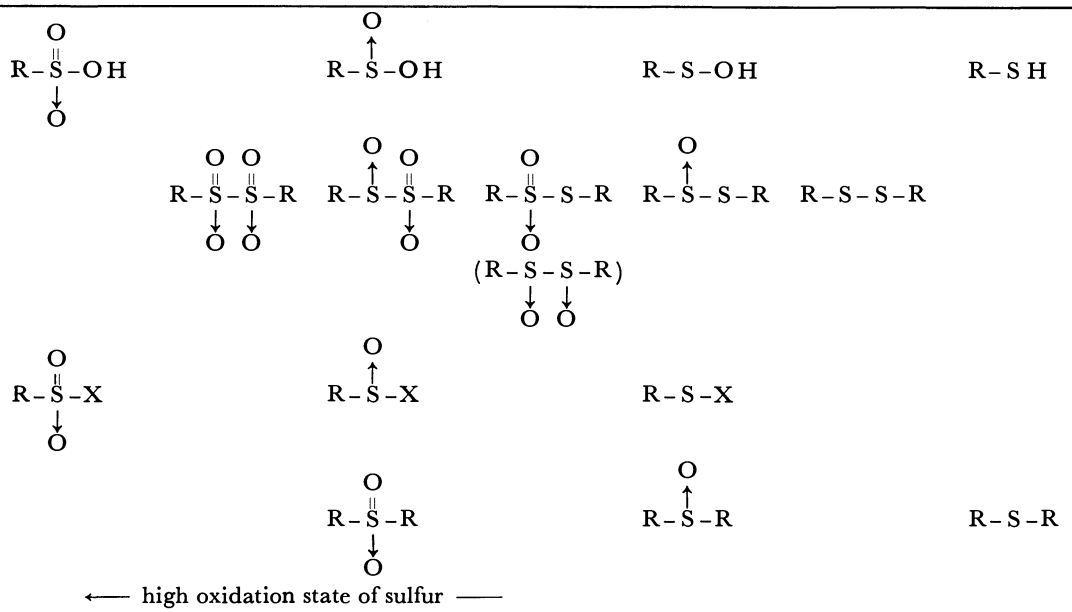
(Received July 18, 1983)

Arenesulfonic acids, their sodium salts, and alkyl arenesulfonates can be reduced readily to the corresponding arenethiols quantitatively by treatment with a mixture of triphenylphosphine and a catalytic amount of iodine, while alkanesulfonic acids, sulfinic acids, disulfides, thiosulfonic *S*-esters, and sulfonates are also readily reduced to the corresponding thiols similarly. Upon treatment with a mixture of triphenylphosphine and excess iodine, however, these aliphatic sulfur compounds are converted eventually to the corresponding alkyl iodides. The relative reactivities of these sulfonyl derivatives in the reaction with the triphenylphosphine–iodine system are the following. Aromatic series: $ArSO_2Cl$, $ArSO_2SAr' > ArSO_2H > ArSO_3R > ArSO_3^-HNBu_3^+$ (or PyH^+) $> ArSO_3H > ArSO_2SO_2Ar \gg ArSO_2CH_2C(CH_3)_3$, $ArSO_3Ar'$. Aliphatic series: RSO_2Cl, RSO_2SR', $RSO_2^-HNBu_3^+ > RSO_3^-HNBu_3^+ > RSSR$, $RSO_2H > RSO_3H > RSH > RSO_3R'$. In these reactions, the arenesulfonic acids bearing electron-donating substituents can be reduced more readily than those having electron-withdrawing substituents.

Organosulfur compounds can have several oxidative states, and the systematic representation of those compounds is shown in the Table 1 in which various sulfur compounds are arranged in order of the decrease of oxidation state from left to right hand side.[1] Sulfur atom in the sulfonic acid is in the highest oxidation state. Since the disulfone is formally a dehydrated condensation product between the sulfonic acid and the sulfinic acid, it is placed at the position between these two compounds in the Table. The sulfinylsulfone occupies the same position as the sulfinic acid, since the sulfinylsulfone is formed by dehydration of the sulfinic acid. While the thiosulfonic *S*-ester and the *α*-disulfoxide are also placed in the same position, the thiosulfinic *S*-ester and the disulfide are assigned at the different oxidation states as shown in Table 1.

Among these compounds, the sulfonic acid is exceptionally stable and inert to most reducing agents hitherto known, and no good method has been found to reduce sulfonic acids in one step. Reduction of other oxidized sulfur compounds can be found in numerous literatures, most of which are, however, rather fragmentary works done only for synthetic interests. Thus no systematic investigation on the reduction of these organic sulfur compounds has been carried out. Meanwhile, sulfonation of hydrocarbon has been a very important industrial process to introduce a sulfur functional group into organic compounds. Meanwhile sulfonic acids are so widely used in general chemical industries and also in laboratory organic syntheses, and hence a good method to reduce sulfonic acids has long been invoked, since synthetic chemistry using organosulfur compounds has recently been developed extensively. The purpose of this work is to discover a new reducing system powerful enough to reduce even organic sulfonic acids and also to investigate systematically the modes of deoxygenation of all these common oxidized organic compounds with the same reducing agent.

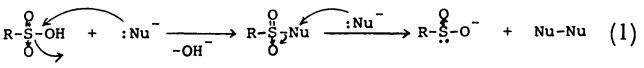
TABLE 1. OXIDOREDUCTION TABLE FOR ORGANOSULFUR COMPOUNDS



X: Halogens, NR^1R^2, OR.

† Present address: Okayama University of Science, 1-1 Ridai-cho, Okayama 700.

Direct electron transfer from alkali metal and related compounds to sulfonic acid has been known to lead mainly to reductive cleavage of C–S bond[2] (C–S bond dissociation energy: ≈293 kJ/mol[3]). Therefore, the deoxygenative reduction of the sulfonic acid would have to proceed stepwise *via* the initial nucleophilic displacement of OH group of the sulfonic acid by a good leaving group, followed by subsequent nucleophilic attack on the leaving group by the second nucleophile as shown in Eq. 1.

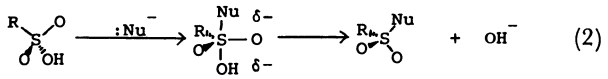


(1)

However, unfortunately such a nucleophilic substitution of OH^- group of the sulfonic acid does not readily proceed. Followings are some of the reasons why the sulfonic acid is so inert toward common reducing agents.

1) The sulfonic acid is so strong that it gives away proton to the nucleophilic reducing agent which upon protonation becomes no longer an effective nucleophile, while the deprotonated sulfonate anion possesses negatively charged three oxygen atoms which repel even strong nucleophiles to approach the central sulfur atom.

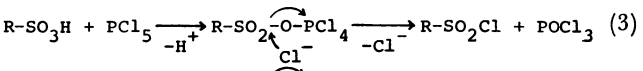
2) The reactivities of sulfonic acids and derivatives in nucleophilic displacements would be somewhat reduced since there would be unfavorable lone pair-lone pair repulsion between the nucleophile and two very electronegative oxygens at equatorial positions at the transition state of the trigonal bipyramide structure for the reaction. The sulfinic acid and its derivatives, having only one polarized oxygen atom on the sulfur and relatively weak S–O linkages, is more reactive in the nucleophilic displacement.



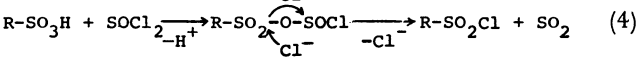
(2)

3) The poor leaving ability of OH group may also be partly responsible for the low reactivity of the sulfonic acid toward most nucleophiles.

However, the sulfonic acid can be made more reactive by replacing hydrogen by a suitable electron-withdrawing Y group to form RSO_2–OY upon treatment with a good condensing agent, XY. Indeed, nucleophilic displacement of OH group from the sulfur atom of sulfonic acid is very difficult, however, once RSO_2OY is formed, nucleophilic displacement of OY group in RSO_2OY by hard nucleophiles proceeds rather readily. Chlorination of sulfonic acids with PCl_5[4] or $SOCl_2$[5] is a good example (Eqs. 3 and 4) of transformation of sulfonic acids to RSO_2OY species. Obviously the formation of very stable phosphoryl chloride or SO_2 is the driving force of the reaction.

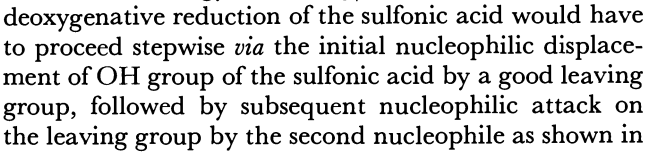


(3)



(4)

Thus, the key step of the reduction of the sulfonic acid represented by Eq. 5 is the activation of leaving OH group by the introduction of Y group on the sulfonyl oxygen, while Y should be an electron-withdrawing group and hence YO^- ought to be an excellent leaving group in the subsequent nucleophilic displacement. Once the intermediate (I) is formed, subsequent reactions are quite facile.



(5)

For example, sulfonyl chloride,[6] sulfonamide,[7] sulfonate,[8] thiosulfonic *S*-ester,[9] and sulfonic anhydride[10] (Nu=Cl, NRR′, OR, SR, and OSO_2R, respectively) are all intermediates of this type (I) which can be reduced to the corresponding thiols by common reducing agents. Thus, the success of the reduction of the sulfonic acids depends entirely upon a choice of XY and Nu^- to promote the reaction shown in Eq. 5. The first example of one pot reduction of sulfonic acids to thiols was recently reported from this laboratory, by using $(CF_3CO)_2O/(n\text{-}Bu)_4N^+I^-$, $X=CF_3CO_2^-$, $Y=CF_3CO$, $Nu^-=I^-$ shown in Eq. 5. This method is the first break through in the direct deoxygenative reduction of sulfonic acids, however, it not only requires a large excess of expensive reagents but also affords a mixture of reduction products, *i.e.* thiols and thiol trifluoroacetate.[11] More recently, G. A. Olah *et al.* reported the reduction of sulfonic acids to the corresponding disulfides with BX_3(X=Cl, Br, I)/KI.[12]

A series of extensive investigations on these basic problems have provided us a few other useful one-pot procedures to reduce sulfonic acids. Among those, the reducing system consisted of triphenylphosphine and iodine is quite convenient for reducing arenesulfonic acids to the corresponding arenethiols and also for reductive conversion of alkanesulfonic acids and related compounds to the corresponding alkyl iodides in one-pot reaction. This paper gives detailed accounts of these reductions.

Although triphenylphosphine is known to be a relatively strong reducing agent, it does not react directly with sulfonic acids. Triphenylphosphine has a strong oxygen affinity and hence if Ph_3P^+ group is introduced as Y in Eq. 5, even a weak nucleophile may attack the sulfonyl sulfur atom because of the excellent leaving ability of triphenylphosphine oxide. Meanwhile, the mixture of triphenylphosphine with halogen[13] and that of triphenylphosphine and disulfide[14] respectively are known to give phosphonium salts. Several reactions are known to utilize such phosphonium salts, *e.g.*, the conversion of alcohol and phenol derivatives to the corresponding halides by treatment with phosphine and halogen,[15] the desulfurization of disulfides to the corresponding sulfides with phosphine,[14,16–18] the condensation of carboxylic acids and alcohols or amines to the corresponding esters or amides[19] by treatment with a mixture of phosphine and diaryl disulfide,[20–22] diselenide,[23] or halogen and also the conversion of alcohols to sulfides with a mixture of phosphine and disulfide.[24] Thus a mixture of triphenylphosphine and a catalytic amount of iodine was our choice system for the reduction, (Eq. 5), in which not only RSO_2–OY ($Y=Ph_3P^+$) is easily generated from the reaction be-

tween the reagent and the sulfonic acid but also iodide is a relatively strong reducing agent enough to reduce the sulfonyl derivatives.[10,11,25]

Results and Discussion

Reduction of Arenesulfonic Acids, Their Sodium Salts, and Alkyl Arenesulfonates with Triphenylphosphine and Iodine.[26] Triphenylphosphine is known to react with iodine to afford iodotriphenylphosphonium iodide[13,27] which would behave as a halogenating agent of sulfonic acids like phosphorus pentachloride (Eq. 3), while hydrogen iodide formed may act as a reducing agent. Based on this assumption, the reaction between sulfonic acids and Ph_3P/I_2 was investigated. Meanwhile, the successful conversion of alcohols and thiols to the corresponding halides with halotriphenylphosphonium halide has also prompted us to examine this reduction. As soon as triphenylphosphine was dissolved into a benzene solution which contained iodine, iodine color disappeared immediately giving a pale yellow solution of iodotriphenylphosphonium iodide. Upon treatment of p-toluenesulfonic acid with this reagent in refluxing benzene, the expected reduction of the sulfonic acid proceeded smoothly and p-toluenethiol was obtained nearly quantitatively. Even when the amount of iodine was reduced, the yield of the thiol was not reduced but the reaction required a prolonged period to complete, suggesting that iodine catalyzes the reduction of the sulfonic acid with triphenylphosphine. Thus, the whole reaction between arenesulfonic acids and triphenylphosphine in the presence of iodine can be expressed by Eq. 6.

$$ArSO_3H + 3\,Ph_3P \xrightarrow{I_2} Ar\text{-}SH + 3\,Ph_3PO \quad (6)$$

Since the reagent readily reacts with water, eventually affording triphenylphosphine oxide and hydrogen iodide, the sulfonic acid was carefully dehydrated by azeotropic distillation with benzene just before subjecting to the reduction in refluxing benzene. The results are summarized in Table 2. Neither triphenylphosphine alone nor iodide anion reacts with the arenesulfonic acid at all. The initial reaction is undoubtedly the reaction of the arenesulfonic acid with iodotriphenylphosphonium iodide to generate the (arylsulfonyloxy)triphenylphosphonium iodide as an incipient intermediate which receives subsequently nucleophilic attack of gegen ion, I^-, at the sulfonyl sulfur atom to form the arenesulfonyl iodide as shown in Eqs. 7—9.

$$Ph_3P + I_2 \rightleftharpoons Ph_3\overset{+}{P}\text{-}I\ I^- \quad (7)$$

$$ArS\text{-}O\text{-}\overset{+}{P}Ph_3\ I^- \longrightarrow ArSI + Ph_3PO \quad (15)$$

$$ArSI + Ph_3\overset{+}{P}\text{-}I\ I^- \longrightarrow ArS\text{-}\overset{+}{P}Ph_3\ I^- + I_2 \quad (16)$$

$$ArS\text{-}\overset{+}{P}Ph_3\ I^- + HI \longrightarrow ArSH + Ph_3\overset{+}{P}\text{-}I\ I^- \quad (17)$$

$$ArSO_2I + Ph_3P \longrightarrow ArSO_2^-\ Ph_3\overset{+}{P}\text{-}I \longrightarrow ArSO\text{-}O\text{-}\overset{+}{P}Ph_3\ I^- \longrightarrow ArSOI + Ph_3PO \quad (18)$$

$$ArSOI + Ph_3P \longrightarrow ArSO^-\ Ph_3\overset{+}{P}\text{-}I \longrightarrow ArS\text{-}O\text{-}\overset{+}{P}Ph_3\ I^- \longrightarrow ArSI + Ph_3PO \quad (19)$$

The arenesulfonyl halide is known to be reduced with hydrogen iodide[28] to afford the diaryl disulfide, and also can be reduced by triphenylphosphine alone to give a mixture of the diaryl disulfide and the arenethiol.[29] Thus, two paths are conceivable for the reduction of the arenesulfonyl iodide. One path involves the initial nucleophilic attack of iodide anion on the arenesulfonyl iodide to afford iodine and the sulfinic acid which is eventually reduced to the diaryl disulfide *via* the arenesulfenic acid by the same reaction cycles through

which the arenesulfonic acid is converted to the arenesulfonyl iodide as shown in Eqs. 7—9. Another conceivable process involves nucleophilic attack of triphenylphosphine on the arenesulfonyl iodide to result in the formation of the same reaction intermediate, the (arylsulfinyloxy)triphenylphosphonium iodide, obtained in the former path, as shown in Eqs. 18 and 19. In order to clarify which nucleophilic reagent, iodide anion or triphenylphosphine initiated the reduction of the arenesulfonyl iodide, the sulfonyl iodide was treated with either triphenylphosphine alone or hydriodic acid respectively. However, since the reduction was found to proceed in both systems readily, it could not be concluded which process predominates over the other. Probably both processes are participating concurrently. The extremely fast reduction of the arenesulfonyl iodide is clearly evidenced by the fact that no probable intermediate can be detected during the reactions of the arenesulfonic acid with Ph_3P/I_2 system, since the initial conversion of sulfonic acid to the sulfonyl iodide is undoubtedly one of the slowest steps of this multi-step reduction of the sulfonic acid to the thiol. One interesting observation is that the reduction is accelerated considerably by the presence of such an amine as tributylamine (Table 2), which can readily dissociate the arenesulfonic acid to the corresponding sulfonate anion to facilitate the reduction. Therefore, tetraethylammonium benzenesulfonate, which is soluble in benzene under our reaction conditions, can be readily reduced to benzenethiol in a high yield. The effect of polar substituent on aromatic ring observed in the reduction of the arenesulfonic acid also indicates that the sulfonic acid bearing an electron-donating substituent was found to be reduced more readily than the one having an electron-withdrawing substituent as shown in Fig. 1. This also suggests that the reaction shown by Eq. 8′ is the rate-determining step of the reduction.

Though the arenesulfinic acid can be reduced very slowly with triphenylphosphine alone, the addition of iodine accelerates this reduction remarkably to give the corresponding arenethiol quantitatively (Table 3). While sodium arenesulfinate cannot be reduced at all with triphenylphosphine alone, the triphenylphosphine/iodine system can reduce the sulfinate readily to the arenethiol and diaryl disulfide even in the absence of any phase-transfer catalyst.

The arenesulfonyl chloride and the *S*-aryl arenethiosulfonate can be readily reduced with triphenylphosphine alone, or better with the mixture of triphenylphosphine and iodine (Table 4).

Alkyl arenesulfonates were found to react smoothly with Ph_3P/I_2 in benzene forming alkyl iodides and diaryl disulfides. The disulfides were converted ultimately to the arenethiols upon treatment with triphenylphosphine and water (Table 5).

$$2\ ArS(=O)-OR + 6\ Ph_3P + I_2 \longrightarrow (ArS)_2 + 2\ RI + 6\ Ph_3PO \quad (20)$$

$$(ArS)_2 + Ph_3P + H_2O \longrightarrow 2\ ArSH + Ph_3PO \quad (21)^{30)}$$

On the other hand, both aryl arenesulfonates and neopentyl arenesulfonates were found to be quite inert in this reducing system even under prolonged reaction times as shown in Table 5. Obviously the reaction of Eq. 20 is initiated by the nucleophilic displacement (S_N2) at the alkyl carbon with iodide anion to form the alkyl iodide and arenesulfonate anion which is further reduced to arenethiol by Ph_3P/I_2. Due to the lack of reactivity at aromatic carbon and steric hindrance of neopentyl group, both aryl arenesulfonates and neopentyl arenesulfonates resist the nucleophilic attack of iodide

After this reaction, the mixture of about 200 mg of water and 1 ml of dioxane was added and refluxed for 0.5—1.0 h. b) Starting material was recovered in 85% yield. c) Starting material was recovered in 86% yield.

anion and no reaction appears to start even after a prolonged treatment with Ph_3P/I_2. Interestingly, pentyl benzenesulfonate, an alkyl arenesulfonate, reacted readily with tetrabutylammonium iodide in benzene affording tetrabutylammonium benzenesulfonate and pentyl iodide, whereas, under similar conditions phenyl benzenesulfonate did not react with tetrabutylammonium iodide.

$$C_6H_5SO_3CH_2(CH_2)_3CH_3 + Bu_4N^+I^- \xrightarrow[\text{benzene reflux}]{10\text{ min}} Bu_4N^+\,C_6H_5SO_3^- + CH_3(CH_2)_4I \quad 100\% \qquad (22)$$

$$p\text{-}CH_3C_6H_4SO_3C_6H_5 + Bu_4N^+I^- \xrightarrow[\text{benzen reflux}]{15\text{ min}} \text{no reaction} \qquad (23)$$

When bromine was used instead of iodine as the catalyst in the reduction of p-toluenesulfonic acid with triphenylphosphine, the yield of the thiol was found to be low (Table 2). Although tributylphosphine is a stronger nucleophile than triphenylphosphine, only 33% of p-toluenethiol was obtained along with unidentified side products upon treatment of the sulfonic acid with Bu_3P/I_2 (Table 2).

Phosphorus trichloride and phosphonic acid also gave only small amounts of diaryl disulfides and arenethiols, respectively, upon treatment of arenesulfonic acids in the presence of iodine.

$$p\text{-}CH_3C_6H_4SO_3H\cdot H_2O \xrightarrow[\text{neat 3 h reflux}]{I_2/PCl_3} (p\text{-}CH_3C_6H_4S)_2 \quad 18\%$$

$$p\text{-}CH_3C_6H_4SO_3H\cdot H_2O \xrightarrow[CH_3CN\ 4.5\text{ h reflux}]{I_2/H_3PO_3} p\text{-}CH_3C_6H_4SH \quad 25\%$$

Inspection of data in Tables 2 and 5 reveals that the reduction of arenesulfonic acids takes place more slowly than alkyl arenesulfonates. This may mean that arenesulfonate anions are more reactive than arenesulfonic acids in the reaction with the reducing system, Ph_3P/I_2. The treatment of alkyl arenesulfonates with iodide ion involves the initial facile nucleophilic attack of iodide ion on alkyl group, eventually affording arenesulfonate anions as primary intermediates. Similarly, tertiary amine have already been found to accelerate the reduction of arenesulfonic acids with Ph_3P/I_2. All these observations, *i.e.* the higher reactivities of arenesulfonic acids bearing electron-donating substituents in the reduction, the acceleration of the reduction by addition of amine, and the facile rates of reduction of both arenesulfonates and tetraethylammonium arenesulfonates suggest clearly that the rate-determining step is the nucleophilic substitution of the sulfonate anion, which is a gegen anion, on the central phosphorus atom of iodotriphenylphosphonium cation to form (arylsulfonyloxy)triphenylphosphonium iodide which has a P–O–S linkage (Eq. 8′).

Sodium arenesulfonate did not react with Ph_3P/I_2 in benzene at all because of its insolubility, however, it was smoothly reduced to the thiol in the presence of such a phasetransfer catalyst as 18-crown-6. The rate of the reaction was found to depend on the amount of the phase transfer catalyst (Table 6). Thus, this reducing procedure is quite useful, since sulfonic acids are usually available in the form of sodium salts in industry. However p-aminobenzenesulfonic acid, arenesulfonamides, and sulfones were not reduced by our systems even at high temperatures and under prolonged heating in other common solvents. The unsuccessful reduction of p-aminobenzenesulfonic acid and arenesulfonamide is believed to be due to the lack of solubilities of these compounds in such solvents as benzene, acetonitrile and dioxane, which were used in the actual reduction.

Diphenyl disulfone of which the central sulfur is highly sterically hindered, is very inert to triphenylphosphine or

This reaction proceeds by the initial nucleophilic attack of iodide anion, which is formed by the reaction of triphenylphosphine and iodine, on the central sulfur atom of diphenyl disulfone to give benzenesulfonyl iodide and benzenesulfinate which can be readily reduced by triphenylphosphine/iodine system.

Finally, since triphenylphosphine/carbon tetrachloride system was known to form phosphonium salt,[31)] arenesulfonic acids were treated with this Ph_3P/CCl_4 system. Actually, the corresponding diaryl disulfides were obtained, but the yields were in general only 40% to 50% [arenesulfonic acid/Ph_3P=2/8(mmol)] when the reduction was carried out in the mixture of 1 ml of carbon tetrachloride and 5 ml of benzene under refluxing condi-

tions for 1.5 h.

Reductive Conversion of Alkanelfonic Acids, Sulfinic Acids, Thiols, Disulfides, Thiosulfonic S-Esters, and Sulfonates to the Corresponding Alkyl Iodides with Triphenylphosphine/Iodine.[32] When this reducing system was applied for the reduction of 1-pentanesulfonic acid, 1-pentanethiol which was the expected product, was not obtained, but pentyl iodide was the sole product obtained, when one equivalent amount of iodine was used.

$$RSO_3H + 4\,Ph_3P + I_2 \longrightarrow RI + 3\,Ph_3PO + Ph_3PS + HI \quad (24)$$

1-Pentanesulfonic acid is considered to be reduced at first to dipentyl disulfide or 1-pentanethiol as in the case of arenesulfonic acids. The subsequent multi-step reaction of either the disulfide or the thiol with Ph_3P/I_2 would afford eventually the iodide. In separate experiments, both 1-pentanethiol and dipentyl disulfide were found to be converted to pentyl iodide quantitatively upon treatment with Ph_3P/I_2.

$$RSSR + 2\,Ph_3\overset{+}{P}\text{-}I\ I^- \longrightarrow 2\,R\text{-}S\text{-}\overset{+}{P}Ph_3\ I^- \longrightarrow 2\,RI + 2\,Ph_3PS \quad (25)$$

$$RSH + Ph_3\overset{+}{P}\text{-}I\ I^- \longrightarrow R\text{-}S\text{-}\overset{+}{P}Ph_3\ I^- + HI \longrightarrow RI + Ph_3PS \quad (26)$$

It is worthy to note that even sterically-hindered *d*-camphor-10-sulfonic acid was successfully converted to the corresponding optically active 10-iodo-*d*-camphor. The formation of the corresponding thiol as the intermediate is shown in Fig. 2. 1-Pentanethiol was not detected in the direct conversion of 1-pentanesulfonic acid to pentyl iodide in the reduction with Ph_3P/I_2, since sterically unhindered 1-pentanethiol is so reactive, whereas *d*-camphor-10-thiol was actually isolated in a maximum yield of about 15% in the conversion of *d*-camphor-10-sulfonic acid to 10-iodo-*d*-camphor with Ph_3P/I_2. Since the *d*-camphor-10-thiol has a neopentyl

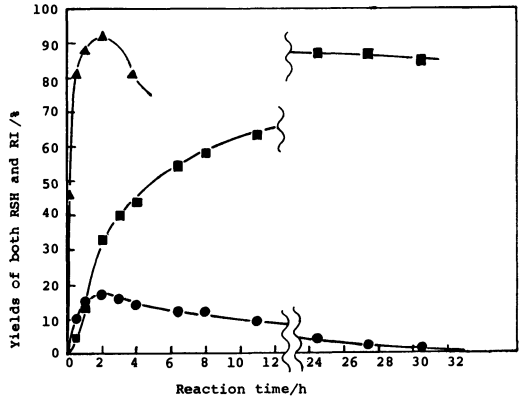

Fig. 2. Reaction of RSO_3H with Ph_3P/I_2 in Benzene under Reflux Conditions.

▲: $CH_3(CH_2)_4I$, ●:  , ■: 
[$RSO_3H/Ph_3P/I_2$=2/10/4(mmol), R=$CH_3(CH_2)_4$– and].

structure, further desulfurization (S_N2) reaction is rather slow. Therefore, we can detect *d*-camphor-10-thiol during the reductive conversion of *d*-camphor-10-sulfonic acid to the corresponding iodide. 1-Pentanesulfinic acid reacted more readily with Ph_3P/I_2 than 1-pentanesulfonic acid, both affording pentyl iodide. 1-Octanesulfonyl chloride gave a mixture of octyl iodide (major) and octyl chloride (minor), while the reaction of the same compound with triphenylphosphine alone proceeded also smoothly at room temperature in benzene to give octyl chloride in 80% yield (Eq. 27). Results of all these reactions are summarized in Table 7. *d*-Camphor-10-sulfonyl chloride can also be converted to the corresponding iodide upon heating with Ph_3P/I_2.

$$RSO_2Cl + 3\,Ph_3P \longrightarrow RCl + 2\,Ph_3PO + Ph_3PS \quad (27)$$

Reaction of both alkyl alkanesulfonates and *S*-alkyl alkanethiosulfonates with Ph_3P/I_2 proceeded smoothly to give alkyl iodides quantitatively upon treatment with Ph_3P/I_2 (Table 8).

$$RSO_2SR' + 4\,Ph_3P + I_2 \longrightarrow RI + R'I + 2\,Ph_3PO + 2\,Ph_3PS \quad (28)$$

$$RSO_2OR' + 4\,Ph_3P + I_2 \longrightarrow RI + R'I + 3\,Ph_3PO + Ph_3PS \quad (29)$$

$$RSO_2SAr + 3\,Ph_3P + I_2 \longrightarrow RI + ArSH + 2\,Ph_3PO + Ph_3PS + HI \quad (30)$$

Nucleophilic substitution on alkyl group, R′, by iodide ion is undoubtedly involved in the initial step of the reaction of the sulfonate (Eq. 29), while there are two possible paths to initiate the reaction of *S*-alkyl alkanethiosulfonate (Eq. 28), *i.e.* nucleophilic substitution on the sulfenyl sulfur and that on alkyl carbon. The *S*-aryl alkanethiosulfonate reacts with Ph_3P/I_2 quite readily to form the alkyl iodide and the arenethiol. This reaction should also be initiated by the nucleophilic displacement on the sulfenyl sulfur of the substrate with either triphenylphosphine or iodide anion. Since the reactions of both *S*-alkyl alkanethiosulfonate and *S*-aryl alkanethiosulfonate with Ph_3P/I_2 proceed much more readily than the reaction of alkyl alkanesulfonate under the same conditions, the reactions of the former two thiosulfonic *S*-esters are undoubtedly initiated by nucleophilic substitution on the divalent sulfur. Both iodide anion and triphenylphosphine being just as strong nucleophiles for divalent sulfur, it is hard to conclude which nucleophile plays an important key role in initiating of the reaction. The rate-determining step of the reaction of alkanethiols, sulfinic acids, and sulfonic acids are presumed to be the nucleophilic attack of conjugate bases of these organosulfur compounds on the phosphorus atom of iodotriphenylphosphonium ion,[33,34] as discussed in the former section which deals with the reduction of arenesulfonic acids. In accordance with this assumption, these reactions were markedly accelerated by the presence of amines (Table 7) while the reduction of the other aprotic derivatives were not affected by the addition of base. The reaction is quite useful in conversion of alkanesulfonic acids, thiosulfonic *S*-esters, sulfonates, disulfides, thiols, and sulfonyl chlorides to the corresponding alkyl iodides quantitively under mild conditions in one-pot treatment.

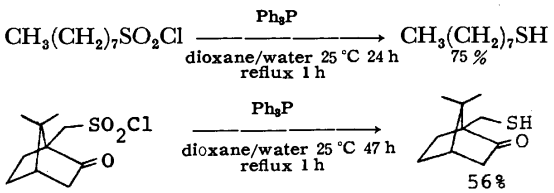
a) GLC yields (20 % OV-1, 10 m glass column). b) The mixture of benzene and dichloromethane was used as a solvent. c) After this reaction, the mixture of 0.5 ml of water and 2.5 ml of dioxane was added. Benzenethiol was obtained in 89% yield.

Finally, various alkanesulfonyl chlorides were found to be converted to the corresponding iodides by Ph_3P/I_2 system, however these sulfonyl chlorides were able to be converted to the corresponding chlorides with Ph_3P alone. Meanwhile, in an interesting and useful reaction, the corresponding thiols can be obtained in the reduction of alkanesulfonyl chlorides with Ph_3P/H_2O systems as shown by the following examples.



Experimental

Conversion of Sodium Sulfonate to the Corresponding Sulfonic Acid. The cation exchange resin which was converted to the protonated form by flowing 1 mol dm^{-3} aqueous HCl solution packed in a column [Dowex 50w-x8 200—400 mesh, H-form, Muromachi Kagaku Co.] was used.

GLC. Hitachi-163 Gas Chromatograph (20% OV-1 1m glass column) was used.

Reduction of Arenesulfonic Acid with Ph_3P/I_2 System. A mixture of 380 mg (2 mmol) of *p*-toluenesulfonic acid monohydrate and 5 ml of benzene was added into a reactor which was equipped with a cooler and a calcium chloride tube and then refluxed. The sulfonic acid was carefully dehydrated to completely dry prior to the reaction by way of azeotropic distillation with benzene. After 2620 mg (10 mmol) of triphenylphosphine was added to this dried sulfonic acid, the reactor was equipped with another cooler and an argon or nitrogen balloon, and substituted with this inert gas with a vacuum pump for 20 to 30 min at room temperature. Then, 5 ml of dry benzene and 254 mg (1 mmol) of iodine were added into this mixture and the whole mixture was stirred and refluxed (bath temperature 90—100 °C) for 2.5 h. The reaction was followed by GLC. After the reaction was complete, a mixture of 3 ml of water and 3 ml of dioxane was added to this reaction mixture which was refluxed for 1.0—0.5 h to decompose a small excess of triphenylphosphine–iodine complex to triphenylphosphine oxide and hydrogen iodide. The solution was poured into benzene and the benzene solution was washed with water for three times, and then dried ($MgSO_4$). *p*-Toluenethiol was obtained by GLC in 89% yield. After benzene was evaporated, the residue was separated through silica-gel column chromatography (Kieselgel-60, 70—230 mesh, MERCK, eluent: $CHCl_3$). A mixture of *p*-toluenethiol and a small excess of triphenylphosphine was obtained from fraction-1, and 2133 mg (128%) of triphenylphosphine oxide was obtained from fraction-2. Fraction-1 was separated further through silica-gel column chromatography (eluent: benzene/hexane=1/5=v/v) to give *p*-toluenethiol (R_f=0.5) in 54% yield. This was identical with commercially available authentic compound. The low yield of *p*-toluenethiol isolated as compared with that of GLC yield is believed to be due to the high volatility of the thiol. Ph_3PO mp 154—155 °C (lit,[35] 154—157 °C).

Reduction of Arenesulfonic Acid with Ph_3P/I_2/Amine System. Triphenylphosphine (2100 mg, 8 mmol) was added into the carefully dehydrated 380 mg (2 mmol) of *p*-toluenesulfonic acid of which reactor was equipped with a cooler and an argon or nitrogen balloon and substituted thoroughly with this inert gas with a vacuum pump. Then, after 5 ml of dry benzene and 254 mg (1 mmol) of iodine was added to this mixture, 371 mg (2 mmol) of tributylamine was finally added to this mixture This reaction mixture was stirred and refluxed for 20 min, following the reaction by GLC. Then a mixture of 3 ml of water and 3 ml of dioxane was added to this reaction mixture which was refluxed for 5 min. *p*-Toluenethiol was obtained in 95% yield by GLC.

Reduction of Sodium Arenesulfonate with Ph_3P/I_2/18-Crown-6 System. After 460 mg (2 mmol) of sodium 2-naphthalenesulfonate was dissolved in 5 ml of benzene, the mixture was refluxed and dehydrated to nearly completely dry by the same method. Triphenylphosphine 2620 mg (10 mmol) and 264 mg (1 mmol) of 18-crown-6 were added to this sodium salt. The reactor was equipped with a cooler and an argon or nitrogen balloon. After substitution with the inert gas by vacuum pumping, 5 ml of dry benzene and 508 mg of iodine were added to this mixture which was stirred and refluxed for 36 h. After the reaction, a mixture of 2-naphthalenethiol and di-2-naphthyl disulfide were detected by GLC. Di-2-naphthyl disulfide was converted to the 2-naphthalenethiol by addition of a mixture of 200 mg of water and 2 ml of dioxane and the reaction mixture was refluxed for 1 h. The reaction mixture was then treated in a similar way as in the case of arenesulfonic acids. 2-Naphthalenethiol was obtained in 95% yield and isolated in 93% yield, however the amount of triphenylphosphine oxide was not determined.

Competitive Reduction of para-Substituted Benzenesulfonic Acids with Ph_3P/I_2 System. A mixture of 190.2 mg (1 mmol) of *p*-toluenesulfonic acid, 176 mg (1 mmol) of benzenesulfonic acid, and 192.5 mg (1 mmol) of *p*-chlorobenzenesulfonic acid was dissolved in 5 ml of benzene in a reactor which was equipped with a cooler and a $CaCl_2$ tube, and the whole mixture was refluxed. All these sulfonic acids were dehydrated nearly

completely dry prior to the reaction by way of azeotropic distillation with benzene. After 3144 mg (12 mmol) of triphenylphosphine and 154 mg (1 mmol) of biphenyl (standard compound) were added to this dry sulfonic acids, the reactor was equipped with a cooler and a nitrogen balloon, and substituted with this inert gas. Then, 254 mg (1 mmol) of iodine and 6 ml of dry benzene were added to this mixture which was then stirred at 72—73 °C. A small portion (0.1 ml) of the reaction mixture was picked up by a microsyring and quenched with a mixture of water–dioxane–benzene (v=1/1/2) every fixed time interval (3, 5, 10, 30, 60, and 120 min from the initial time, respectively). The yields of three thiols obtained in every case, were determined by comparison of GLC curve with the predetermined calibration curve.

Reduction of Arenesulfonate with Ph_3P/I_2 System. Pentyl *p*-toluenesulfonate (484 mg, 2 mmol) and 2100 mg (8 mmol) of triphenylphosphine were added into a reactor which was equipped with a cooler and an argon or nitrogen balloon and substituted with this inert gas with a vacuum pump. Then, 5 ml of dry benzene and 381 mg (1 mmol) of iodine were added into this mixture which was refluxed and stirred for 10 min. The starting ester was no longer present by this time upon analysis with GLC and TLC (silica gel R_f=0.3 eluent: benzene), and *p*-toluethiol, di-*p*-tolyl disulfide, and pentyl iodide were resulted. After the reaction, the mixture was treated in the same manner as in the case of the reduction of arenesulfonic acid. The yields of the reaction products were determined by GLC (20% OV-1). *p*-Toluenethiol 95%. Pentyl iodide 90%. Authentic pently iodide was obtained by the known method. Pentyl iodide bp 157 °C/760 Torr (lit,[36] 157 °C/760 Torr, 1 Torr=133.322 Pa).

Synthesis of p-*Toluenesulfonyl Iodide.* *p*-Toluenesulfonyl iodide was obtained by a known method. Rock-crystals of mp 85—86 °C (decomp) were obtained (lit,[37] 84—85 °C).

Reductive Conversion of d-*Camphor-10-sulfonic Acid with Ph_3P/I_2 System.* The reaction was carried out under dry nitrogen atmosphere in a two-necked flask with a reflux condenser. To 8 ml of dry benzene solution of a mixture of *d*-camphor-10-sulfonic acid, 464 mg (2 mmol), and triphenylphosphine (2620 mg, 10 mmol), was added solid iodine 1524 mg (6 mmol) at room temperature. Then the mixture was refluxed for 9 h in nitrogen atmosphere. Benzene was added to the resultant mixture which was then washed with water. The organic layer was dried ($MgSO_4$) and the solvent was evaporated. The residue was then subjected to column chromatography on silica gel (eluent: benzene) in order to separate triphenylphosphine sulfide [R_f=0.5, yield 60%, mp 162—163 °C (lit,[38] 162—164 °C)], 10-iodo-*d*-camphor (R_f=0.4), and triphenylphosphine oxide [R_f=0.1, yield 90%, mp 154—155 °C (lit,[35] 154—157 °C)]. 10-Iodo-*d*-camphor was obtained in 87% (GLC) yield and was isolated in 67% yield: mp 71 °C; $[\alpha]^{25}$ −20.6 (*c* 1, $CHCl_3$); IR (KBr) 1735 (C=O), 1375, and 1390 cm^{-1}; NMR (CCl_4) δ=0.9 (3H, s), 1.1 (3H, s), 3.05 (1H, d, J=10.5 Hz), 3.35 (1H, d, J=10.5 Hz), and 1.0—2.4 (7H, m); Found: C, 43.29; H, 5.38; I, 45.74%. Calcd for $C_{10}H_{15}OI$: C, 43.18; H, 5.43; I, 45.62%.

Reductive Conversion of Alkanesulfonate with Ph_3P/I_2 System. Pentyl 1-octanesulfonate (529 mg, 2 mmol) and 2882 mg (11 mmol) of triphenylphosphine were added to a reactor which was equipped with a condenser and a nitrogen balloon and substituted with dry inert gas with a vacuum pump. Then, 8 ml of dry benzene and 1778 mg (7 mmol) of iodine were added to this mixture which was refluxed and stirred for 5 h. After the reaction, a mixture of 200 mg of water and 1 ml of dioxane was added into this mixture. The yields of reaction products were determined by GLC. Octyl iodide 95% bp 110 °C/23 Torr (lit,[39] 226 °C/760 Torr). Pentyl iodide 95%.

Preparation of d-*Camphor-10-thiol.* *d*-Camphor-10-sulfonic acid (10 g, 42 mmol) was dissolved in 15 ml of chloroform and then 18 g (86 mmol) of phosphorus pentachloride was added slowly. After this mixture was refluxed for 2 h, it was poured into 100 ml of chloroform which was then washed with water for 4 times, dried ($MgSO_4$) and evaporated to give *d*-camphor-10-sulfonyl chloride in 69% yield. Mp 65—67 °C (lit,[40] 67—68 °C). *d*-Camphor-10-sulfonyl chloride, 3 g (12 mmol) and 12.6 g (48 mmol) of triphenylphosphine were dissolved into a mixture of 40 ml of dioxane and 10 ml of water and the whole mixture was stirred for 47 h at room temperature, and then refluxed for 1 h. After the reaction, the mixture was separated through silica-gel column chromatography using benzene as eluent to give *d*-camphor-10-thiol in 56% yield. Mp 65—66 °C; TLC (eluent: benzene) R_f=0.2—0.3; IR (KBr) 1375, 1385, 1730 (C=O), and 2560 cm^{-1} (SH); NMR (CCl_4) δ=0.95 (3H, s), 1.05 (3H, s), 1.2—2.6 (8H, m), 2.73 (1H, d, J=6 Hz), and 2.95 (1H, d, J=6 Hz); Found: C, 65.24; H, 8.72; S, 17.24%. Calcd for $C_{10}H_{16}OS$; C, 65.17; H, 8.75; S, 17.40%.

Monitoring the Reaction of Alkanesulfonic Acid with Ph_3P/I_2. *d*-Camphor-10-sulfonic acid (464 mg, 2 mmol), 2620 mg (10 mmol) of triphenylphosphine, and 308 mg (2 mmol) of biphenyl (standard) were dissolved in 10 ml of dry benzene, into which 1016 mg (4 mmol) of iodine was then added and the solution was refluxed under nitrogen atmosphere. At fixed time intervals, 0.1 ml of the reaction mixture was picked up by a microsyringe and quenched with a mixture of water and benzene (v/v=1/1). The yields of the thiol and the iodide obtained in every case were determined by comparison of the GLC (SE-30) curve with the predetermined calibration curve. In the case of 1-pentanesulfonic acid, the corresponding thiol was not present in any sample under these conditions.

Preparation of Thiosulfonic S-*Esters.* Thiosulfonic *S*-esters were prepared by a known method[41,42] which is the reaction of arenesulfenyl chloride, that was prepared by treating a thiol or a disulfide with gaseous Cl_2 in CCl_4 at 0 °C, with sulfinic acid in the presence of pyridine in CCl_4 at 0 °C in 80—90% yield. *S*-Phenyl benzenethiosulfonate mp 44—45 °C (lit,[41] 44—45 °C). *S*-*p*-Tolyl *p*-toluenethiosulfonate mp 72—74 °C (lit,[42] 76 °C).

Preparation of Sulfonates. Sulfonates were prepared by a known method,[43–46] which is the reaction of sulfonyl chloride with alcohol in a mixture of benzene and acetonitrile in the presence of pyridine at room temperature, in 50—60% yields.

Phenyl *p*-toluenesulfonate mp 92—93 °C (lit,[43] 93 °C).

neo-Pentyl *p*-toluenesulfonate mp 46—47 °C (lit,[44] 48 °C).

Pentyl benzenesulfonate bp 138—140 °C/1 Torr (lit,[45] 136—138 °C/1 Torr).

Pentyl *p*-toluenesulfonate bp 167—168 °C/3 Torr (lit,[46] 169—170 °C/3 Torr).

Pentyl 1-octanesulfonate TLC (eluent: benzene) R_f=0.4—0.5; IR (NaCl) 1340 (SO) and 1160 cm^{-1} (SO); NMR (CCl_4) δ=4.1 (2H, t, J=6 Hz), 3.0 (2H, t, J=6.7 Hz), and 2.1—0.7 (24H, m); Found: C, 59.13; H, 10.55; S, 11.94%. Calcd for $C_{13}H_{28}SO_3$: C, 59.05; H, 10.67; S, 12.12%.

Preparation of Sulfinic Acids. *p*-Chlorobenzenesulfonyl chloride (5 g, 23.7 mmol) and 18 g (71.1 mmol) of sodium sulfite heptahydrate were added into 100 ml of water. The reaction mixture was kept at a temperature ranging 70—80 °C for 5 h. After the reaction, this water solution was washed with chloroform twice, acidified with excess concd HCl solution, cooled and filtered. The white precipitate was recrystallized from water yielding *p*-chlorobenzenesulfinic acid in a high yield (79%).

p-Chlorobenzenesulfinic acid mp 95—97 °C (lit,[47] 98—99 °C).

1-Octanesulfinic acid can also be obtained from 1-octane-

sulfonyl chloride by the similar procedure and identified as methyl octyl sulfone in 57% yield.

Methyl octyl sulfone mp 62—63 °C (lit,[48] 62 °C).

p-Toluenesulfinic acid and benzenesulfinic acid were obtained by acidification of the corresponding sodium arenesulfinates which were obtained as commercial samples. The white precipitates were recrystallized from water yielding the corresponding arenesulfinic acids.

Benzenesulfinic acid mp 78—80 °C (lit,[47] 81.5—83 °C).

p-Toluenesulfinic acid mp 84—85 °C (lit,[47] 84—85 °C).

1-Pentanesulfinic acid was prepared by a well known hydrolysis of 1-pentanesulfinyl chloride, which was prepared by treating dipentyl disulfide with chlorine in acetic anhydride in a mixture of ether and water at 0 °C in the presence of pyridine at the range of −20 °C to −10 °C in 77% yield. 1-Pentanesulfinic acid was identified as pentyl 2,4-dinitrophenyl sulfone by treating with 2,4-dinitrochlorobenzene.

Pentyl 2,4-dinitrophenyl sulfone (quantitative yield) mp 84 °C (lit,[49] 83 °C).

Preparation of S-*Alkyl Thiosulfonates.* *S*-Octyl 1-octanethiosulfonate and *S*-pentyl 1-pentanethiosulfonate were prepared by treating the corresponding disulfide with hydrogen peroxide in acetic acid at room temperature in nearly quantitative yields.

S-Pentyl 1-pentanethiosulfonate TLC (eluent: benzene) R_f= 0.5; IR (NaCl) 1120 (SO) and 1320 cm^{-1} (SO); NMR (CCl_4) δ=0.7—2.2 (18H, m), and 2.9—3.4 (4H, m); Found: C, 50.49; H, 9.34%. Calcd for $C_{10}H_{22}O_2S_2$: C, 50.38; H, 9.30%.

S-Octyl 1-octanethiosulfonate TLC (eluent: benzene) R_f= 0.5; IR (NaCl) 1120 (SO) and 1320 cm^{-1} (SO); NMR (CCl_4) δ=0.7—2.2 (30H, m), and 2.9—3.4 (4H, m); Found: C, 59.77; H, 10.68%. Calcd for $C_{16}H_{34}O_2S_2$: C, 59.57; H, 10.62%.

S-Phenyl 1-pentanethiosulfonate was prepared by treating benzenesulfenyl chloride with 1-pentanesulfinic acid in CCl_4 at 0 °C in the presence of pyridine. *S*-Phenyl 1-pentanethiosulfonate was obtained in a quantitative yield.

S-Phenyl 1-pentanethiosulfonate TLC (eluent: benzene) R_f =0.4; IR (NaCl) 1120 (SO) and 1320 cm^{-1} (SO); NMR (CCl_4) δ=0.7—2.2 (9H, m), 2.9—3.3 (2H, t, J=7.5 Hz), and 7.2—7.7 (5H, m); Found: C, 54.07; H, 6.58%. Calcd for $C_{11}H_{16}O_2S_2$: C, 54.16; H, 6.59%.

Reaction of Alkanesulfinic Acid with Ph_3P/I_2. 1-Pentanesulfinic acid, 272 mg (2 mmol), was dissolved in a mixture of 5 ml of dry benzene and 5 ml of dichloromethane. Then, 1730 mg (6.6 mmol) of triphenylphosphine and 762 mg (3 mmol) of iodine were added to this mixture. The reaction was carried out for 2 h at room temperature. After the reaction, 1-pentyl iodide formed was obtained in 95% yield by GLC.

Reaction of Alkanesulfonyl Chloride with Ph_3P. 1-Octanesulfonyl chloride, 425 mg (2 mmol), was dissolved in 5 ml of benzene and then 2100 mg (8 mmol) of triphenylphosphine was slowly added. The reaction was carried out at room temperature for 20 min. 1-Octyl chloride was obtained in 80% yield (GLC).

Reaction of Arenesulfonic Acid with Ph_3P/CCl_4. Triphenylphosphine, 2100 mg (8 mmol), was added into the carefully dehydrated 380 mg (2 mmol) of *p*-toluenesulfonic acid in a reactor which was equipped with a cooler and a nitrogen balloon, and substituted thoroughly with this gas. Then, 1 ml of carbon tetrachloride, which was dissolved in 5 ml of benzene, was added to this mixture. The mixture was refluxed for 1.5 h. After the reaction, triphenylphosphine was not present. Di-*p*-tolyl disulfide was obtained in 57% yield by GLC. The yields of triphenylphosphine oxide and other minor unknown products were not determined.

Reaction of Sulfonic Acid with PCl_3/I_2. *p*-Toluenesulfonic acid monohydrate, 380.4 mg (2 mmol), and 762 mg (3 mmol) of iodine were added into a reactor which was equipped with a cooler and a calcium chloride tube. Then, 7850 mg (57.3 mmol) of phosphorus trichloride was added to this mixture, which was refluxed for 3 h. After the reaction, di-*p*-tolyl disulfide was obtained in 18% yield by GLC.

Reaction of Sulfonic Acid with H_3PO_3/I_2. *p*-Toluenesulfonic acid monohydrate, 381 mg (2 mmol), was dissolved in 10 ml of acetonitrile, and then 1016 mg (4 mmol) of iodine and 2000 mg (24.4 mmol) of phosphonic acid were added to the mixture which was refluxed for 4.5 h under nitrogen atmosphere. After the reaction, *p*-toluenethiol was obtained in 25% yield by GLC.

Reaction of Diphenyl Disulfone with Ph_3P/I_2. Diphenyl disulfone, 200 mg (0.71 mmol), was dissolved in a mixture of 3 ml of dry acetonitrile and 10 ml of dry benzene and then 1300 mg (5 mmol) of triphenylphosphine and 179 mg (0.71 mmol) of iodine were added into this mixture. The reaction mixture was refluxed for 20 h under nitrogen atmosphere. The reaction was followed by GLC (eluent: benzene $C_6H_5SO_2SO_2C_6H_5$, R_f=0.3). After the reaction, a mixture of 1 ml of water and 2 ml of dioxane was added and the mixture was heated for 1 h. Benzenethiol was obtained in 91% yield (GLC). Diphenyl disulfone was prepared by a known method, which is the oxidation of benzenesulfinic acid by $KMnO_4$ in acetic acid, in 5% yield.

Diphenyl disulfone mp 196—197 °C (lit,[52] 196—196.5 °C).

Other Compounds. 1-Naphthalenethiol 160—165 °C/35 Torr (lit,[50] 142—142.5 °C/7 Torr, 85—88 °C/0.27 Torr). NMR (CCl_4) δ=3.4 (1H, s), and 7.05—8.30 (7H, m). 2,4-Dimethylbenzenethiol 74—76 °C/4 Torr (lit,[51] 80.5 °C/9 Torr, 93 °C/12 Torr) NMR (CCl_4) δ=2.2 (6H, s), 2.9 (1H, s), and 6.5—7.0 (4H, m).

Reduction of Organic Sulfonic Acids, Sodium Sulfonates, and Sulfonic Esters to the Corresponding Disulfides with Polyphosphoric Acid Derivatives, Potassium Iodide and Tetrabutylammonium Iodide System

Shigeru OAE*,† and Hideo TOGO

Department of Chemistry, The University of Tsukuba, Sakura, Niihari, Ibaraki 305

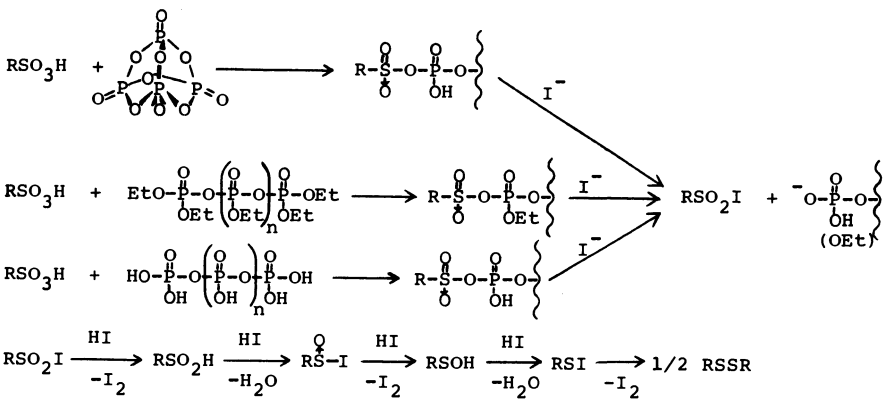
(Received July 18, 1983)

Organic sulfonic acids, sodium sulfonates, and alkyl sulfonates were readily reduced to the corresponding disulfides in moderate yields upon treatment with a mixture of a polyphosphoric acid derivative and iodide. In these reactions, formation of mixed anhydrides each having a P–O–S linkage is the key step, and subsequent attack of iodide on the sulfur atom gives the corresponding sulfonyl iodides which are reduced further exothermally to the disulfides with hydrogen iodide. Actually, *p*-toluenesulfonyl chloride was isolated in the reaction of *p*-toluenesulfonic acid and polyphosphoric acid derivatives with chloride ion. The competitive reduction of various aromatic sulfonic acids reveals that an aromatic sulfonic acid bearing an electron-donating para-substituent is more readily reduced to the disulfide than that which has an electron-withdrawing para-substituent.

The reduction of organic sulfonic acid which is in the highest oxidative state among all organosulfur compounds is one of the most challenging problems in organosulfur chemistry. Sulfonic acids, however, can be reduced in multi-step processes through initial conversion of sulfonic acids to the corresponding sulfonyl derivatives, *i.e.* sulfonyl halide,[1] sulfonic anhydride,[2] sulfonic ester,[3] and sulfonamide[4] and subsequent reduction of these derivatives with reducing agents to the corresponding thiols or thiol derivatives. Recently, there have appeared three procedures which can reduce sulfonic acids directly to the corresponding disulfides or thiols in one-pot process.[5-7] Each of these three procedures is epochal, and quite useful, since in a one-pot process reduction of various sulfonic acids and its derivatives to thiols or disulfides can be achieved. However, these reactions have some drawbacks, since the reagents used in these procedures, *i.e.* $(CF_3CO)_2O/(n\text{-}Bu)_4NI$,[5] Ph_3P/I_2 (catalyst),[6] $Ph_3P/(ArS)_2$(catalyst),[8] and BX_3-(X=Cl, Br, I)/KI[7] systems are either in large excess or by no means cheap. Another facile procedure to reduce both arene- and alkanesulfonic acids to the corresponding disulfides as the sole products has been found by us who used cheap reagents, such as polyphosphoric acid (PPA), ethyl polyphosphate (PPE), tetraphosphorus decaoxide (P_4O_{10}) and iodide ion, in organic media This paper gives a full account of this direct reduction of sulfonic acids.

Results and Discussion

Arene- and alkanesulfonic acids used in this investigation are listed in Tables 1, 2, and 3, while the sulfonic esters are summarized in Table 4. The condensing reagents used were tetraphosphorus decaoxide, polyphosphoric acid, and ethyl polyphosphate,[9] while acetonitrile and sulfolane are the choice solvents in the reduction with P_4O_{10}/I^- and PPA/I^- systems respectively because of the solubility of polyphosphoric acid derivatives, whereas acetonitrile, sulfolane, and chloroform were the choice solvents in the reduction with PPE/I^- system. Of the three systems, the reduction with P_4O_{10}/I^- or PPE/I^- gives the corresponding disulfides in higher yields than that with PPA/I^- system in the presence of $(n\text{-}Bu)_4NI$, whereas, in the absence of $(n\text{-}Bu)_4NI$ the yields of the disulfides are more satisfactory in the reduction with PPA/I^- than those with the former systems. It is worthy to note that *d*-camphor-10-sulfonic acid, which is a highly sterically hindered alkanesulfonic acid, was also reduced to the corresponding disulfide in a high yield, though the reaction was substantially slow. In this reduction, the sulfonyl iodide is considered to be the



Scheme 1.

key intermediate which is stepwisely reduced further very readily to the corresponding sulfinyl and sulfenyl iodides which are eventually reduced to the symmetrical disulfide[10] as shown in Scheme 1. Indeed, *p*-toluenesulfonyl chloride was obtained in 48 and 28% yields respectively when potassium chloride, which has no reducing ability at all, and tetraethylammonium chloride were added into the mixture of either P_4O_{10} or PPE and *p*-toluenesulfonic acid in acetonitrile. Meanwhile, *p*-toluenesulfonyl iodide, which was prepared from the reaction of sodium *p*-toluenesulfinate and iodine in a mixture of benzene and water, was found to be reduced exothermically to the corresponding disulfide by hydroiodic acid in a high yield in dioxane.

Competitive reduction of an equimolar mixture of para-substituted benzenesulfonic acids, *i.e.* *p*-chlorobenzene-, benzene-, and *p*-methylbenzenesulfonic acids, with the PPA/KI/$(n\text{-}Bu)_4NI$ (catalyst) system was carried out. Since the mixture of $C_6H_5SSC_6H_5$, $C_6H_5SSC_6H_4\text{-}p\text{-}C_6H_5SSC_6H_4Cl\text{-}p$, $p\text{-}CH_3C_6H_4SSC_6H_4CH_3\text{-}p$, $p\text{-}CH_3C_6H_4SSC_6H_4Cl\text{-}p$, and $p\text{-}ClC_6H_4SSC_6H_4Cl\text{-}p$ was not readily separated or determined, the mixture of these disul-

These data reveal clearly that, in the reduction of para-substituted benzenesulfonic acids, benzenesulfonic acid bearing an electron-donating substituent such as methyl group is more readily reduced than that has an electro-withdrawing group such as chloro group. Apparently, the rate-determining step is the formation of a mixed anhydride bearing $-\overset{\overset{O}{\|}}{\underset{|}{P}}-O-\overset{\overset{O}{\|}}{\underset{|}{S}}-$ bond which is formed by nucleophilic attack of sulfonic acid on the polyphosphoric acid derivative.

The same reduction procedure has been found to be successfully applied for the reduction of sulfonic esters (Table 4). Alkyl arene- and alkanesulfonates were found to react with these systems under similar conditions to give the corresponding alkyl iodides and disulfides. Alkyl iodide was usually obtained quantitatively by this reaction after about 15 minutes; however, the yield of the corresponding disulfide was very poor in the early stage of the reaction. These observations suggest that the initial step is the S_N2 attack of iodide on the α-carbon of alkyl sulfonates to form the alkyl iodides and the sulfonate anions which are then reduced further to the corresponding disulfides in a slow reaction with the polyphosphoric acid derivative/iodide system. Thus, the initial S_N2 reaction by the attack of iodide on the alkyl group is quite fast; however, the reduction of the sulfonate anion formed is relatively slow. Actually, benzenesulfonate was found to react readily with tetrabutylammonium iodide in benzene to afford tetrabutylammonium benzenesulfonate and pentyl iodide, whereas phenyl p-toluenesulfonate was not found to react with tetrabutylammonium iodide at all. On the other hand, phenyl p-toluenesulfonate, an aryl arenesulfonate was found to be quite inert in the same treatment with these reducing systems even under much harder conditions. In the case of phenyl p-toluenesulfonate, an aryl arenesulfonate, the initial nucleophilic attack of iodide on aromatic ipso carbon is so sluggish that the reduction does not proceed.

Experimental

Materials. PPA, potassium iodide, tetraphosphorus decaoxide, p-toluenesulfonic acid, sodium p-toluenesulfonate potassium chloride, sodium benzenesulfonate, sodium 2,4-dimethylbenzenesulfonate, p-toluenesulfonyl chloride, and d-camphor-10-sulfonic acid were all from Wako Chemicals Co. Tetrabutylammonium iodide, p-chlorobenzenesulfonic acid, benzenesulfonic acid, sodium 1-octanesulfonate, tetraethylammonium chloride, and ethyl benzenesulfonate were from Tokyo Kasei Co.

Conversion of Sodium Sulfonate to the Corresponding Sulfonic Acid. The cation exchange resin which was converted to the protonated from by flowing 1 mol dm^{-3} aqueous HCl solution through a column (Dowex, 50w-x8, 200—400 mesh H-form, Muromachi Kagaku Co.) was used to convert sodium sulfonate to the corresponding sulfonic acid.

Preparation of Ethyl Polyphosphate. Ethyl polyphosphate, PPE, was prepared according to the known method[9)] using tetraphosphorus decaoxide and dry diethyl ether. A colorless syrupy (hard) ester which is very sensitive to moisture, was obtained.

General Procedure for Reduction of the Sulfonic Acid to the Corresponding Disulfide. Potassium iodide, 8 g, (48 mmol) and tetrabutylammonium iodide 583 mg (1.5 mmol) were added into a mixture of PPE 24 g (48 mmol) and a sulfonic acid, *e.g.*, d-camphor-10-sulfonic acid 1.39 g (6 mmol). Then, into this mixture, 20 ml of dry chloroform was added. The whole mixture was stirred and refluxed for 5 h under nitrogen atmosphere. Then 10 ml of water was added to this mixture and the mixture was refluxed for 1 h. The reaction mixture was poured into benzene (100 ml), and washed with water for 3 times. The benzene solution was washed with 0.5 mol dm^{-3} sodium thiosulfate solution and dried ($MgSO_4$). The solvent was evaporated and the crude product, *i.e.* the disulfide was chromatographed on a silica-gel column with benzene (R_f= 0.2, eluent; benzene). Removal of the solvent afforded 10,10'-dithiobis(d-camphor) as colorless crystals in 74% yield (817 mg). Mp 236—238 °C; $[\alpha]_D^{25}$ −103.66° (c 1, $CHCl_3$); IR (KBr) 1730 cm^{-1} (C=O); NMR ($CDCl_3$) δ=0.90 (3H, s), 1.05 (3H, s), 2.75 (1H, d, J=13.5 Hz), 3.20 (1H, d, J=13.5 Hz), and 2.5—1.1 (7H, m); Found: C, 65.33; H, 8.25; S, 17.27%. Calcd for $C_{20}H_{30}S_2O_2$: C, 65.53; H, 8.24; S, 17.49%. Reduction of other sulfonic acids to the corresponding disulfides with the polyphosphoric acid derivative/iodide system were conducted in the same manner.

Di-p-tolyl disulfide mp 44—45 °C (lit,[11)] 46 °C).

Bis(p-chlorophenyl) disulfide mp 70—71 °C (lit,[12)] 73. °C)

Bis (2,4-dimethylphenyl) disulfide bp 180—186 °C/2—2.5 Torr (1 Torr=133.322 Pa) IR (NaCl) 540 and 800 cm^{-1};

NMR (CCl_4) δ=2.24 (3H, s), 2.33 (3H, s), and 3.4—2.6 (3H, m); Found: C, 69.69; H, 6.65; S, 23.58%. Calcd for $C_{16}H_{18}S_2$: C, 70.02; H, 6.61; S, 23.36%.

Dioctyl disulfide and diphenyl disulfide were identical to the authentic commercial samples.

Trapping Experiment of Sulfonyl Function. Tetraphosphorus decaoxide (1600 mg, 11.27 mmol) and 381 mg (2 mmol) of *p*-toluenesulfonic acid were dissolved in 5 ml of dry acetonitrile and the reaction mixture was heated (60—65 °C) for 1.5 h under nitrogen. Then, 33 mg (0.2 mmol) of tetraethylammonium chloride, 746 mg (10 mmol) of potassium chloride and 5 ml of dry acetonitrile were added to this reaction mixture at 0 °C and the mixture was kept standing for 3 h at room temperature. Then, the mixture was poured into 100 ml of benzene and the benzene solution was washed with water for three times, and then dried ($MgSO_4$). When the solvent was evaporated, *p*-toluenesulfonyl chloride was obtained in 48% yield (GLC); the isolated yield was 43%. The sulfonyl chloride was identical to the authentic sample of *p*-toluenesulfonyl chloride both in GLC and TLC. In the reduction with the PPE system, PPE, 6 g and 381 mg (2 mmol) of *p*-toluenesulfonic acid were dissolved in 5 ml of dry acetonitrile and the mixture was heated for 1 h at about 70 °C under nitrogen. Then, at 0 °C 33 mg of tetraethylammonium chloride and 746 mg (10 mmol) of potassium chloride were added to the reaction mixture which was kept standing for 2.5 h at room temperature. After the reaction, a similar treatment as that with P_4O_{10}, gave *p*-toluenesulfonyl chloride in 28% yield (GLC).

Preparation of p-*Toluenesulfonyl Iodide.* Treatment of sodium *p*-toluenesulfinate dihydrate with iodine according to a known method gave *p*-toluenesulfonyl iodide nearly quantitatively. Mp 85—86 °C (decomp) (lit,[13] 84—85 °C).

Reduction of p-*Toluenesulfonyl Iodide with Hydriodic Acid to Di*-p-*tolyl Disulfide.* *p*-Toluenesulfonyl iodide (300 mg, 1.06 mmol) was dissolved in 3 ml of dioxane and then 4 ml of hydriodic acid (57%) was slowly added to this mixture at room temperature. An exothermic reaction occurred affording di-*p*-tolyl disulfide. After 1 h the mixture was poured into benzene and the benzene solution was washed with water twice, 0.5 mol dm^{-3} $Na_2S_2O_3$ solution, and dried ($MgSO_4$). ($MgSO_4$). Only di-*p*-tolyl disulfide was obtained in 79% yield (GLC).

*Competitive Reaction of Arenesulfonic Acids with PPA/KI/*n-Bu_4NI*(Catalyst).* *p*-Toluenesulfonic acid, 190.2 mg (1 mmol), 176 mg (1 mmol) of benzenesulfonic acid, and 192.2 mg (1 mmol) of *p*-chlorobenzenesulfonic acid were dissolved in 10 ml of sulfolane, then 8100 mg of PPA, 3984 mg (24 mmol) of potassium iodide, 184 mg (0.5 mmol) of tetrabutylammonium iodide and 154 mg (1 mmol) of biphenyl were added to this mixture and the whole mixture was stirred (95—100 °C) for 4 h. The reaction was followed by GLC. After the reaction, 5 ml of water was added into the mixture which was then heated for 0.5 h. The solution was poured into benzene and the benzene solution was washed with water for 3 times, then with 0.5 mol dm^{-3} solution of $Na_2S_2O_3$ and dried ($MgSO_4$). The solution was found to contain only the mixture of disulfides *i.e.* $C_6H_5SSC_6H_5$, $C_6H_5SSC_6H_4CH_3$-*p*, $C_6H_5SSC_6H_4Cl$-*p*, *p*-$CH_3C_6H_4SSC_6H_4CH_3$-*p*, *p*-$CH_3C_6H_4SSC_6H_4Cl$-*p*, *p*-$ClC_6H_4SSC_6H_4Cl$-*p* which are converted to the corresponding thiols by treating with a mixture of triphenylphosphine or tributylphosphine (2 mmol) and water in a mixture solvent of benzene and dioxane over night at room temperature. The yields of the mixture of three thiols were determined with GLC. *p*-Toluenethiol, 71%; benzenethiol, 60%; *p*-chlorobenzenethiol, 34%.

In the reduction with the P_4O_{10} system, a mixture of three different para-substituted benzenesulfonic acids each with 1 mmol was dissolved in 20 ml of dry acetonitrile, and then 3000 mg (21 mmol) of P_4O_{10}, 3984 mg (24 mmol) of potassium iodide, and 184 mg (0.5 mmol) of tetrabutylammonium iodide were added to this mixture which was then refluxed for 7 h. After the reaction, a similar work-up procedure afforded a mixture of three para-substituted benzenethiols. The yields of these thiols were determined by GLC (SE-30, 1 m glass column) to be the following: *p*-toluenethiol, 50%; benzenethiol 50%; *p*-chlorobenzenethiol, 26%.

Preparation of Sulfonates. Treatment of organic sulfonyl chlorides with a choice alcohol according to a known procedure[14] gave various organic sulfonates. The yields of sulfonates are usually 50—60%.

Pentyl benzenesulfonate: 138—140 °C/1 Torr (lit,[14] 136—138 °C/1 Torr).

Pentyl *p*-toluenesulfonate: Mp 167—168 °C/3 Torr (lit,[15] 169—170 °C/3 Torr).

Phenyl *p*-toluenesulfonate: Mp 92—93 °C (lit,[17] 93 °C).

Pentyl 1-octanesulfonate: TLC (eluent: benzene) R_f=0.4—0.5; IR (NaCl) 1340 (SO_2) and 1160 cm^{-1} (SO_2); NMR-(CCl_4) δ=4.1 (2H, t, J=6.0 Hz), 3.0 (2H, t, J=6.7 Hz), and 2.1—0.7 (24H, m); Found: C, 59.13; H, 10.55; S, 11.94%. Calcd for $C_{13}H_{28}O_3S$: C, 59.05; H, 10.67; S, 12.12%.

Reduction of Sulfonate with Polyphosphoric Acid Derivative/Potassium Iodide/Tetrabutylammonium Iodide System. PPA, 5408 mg (16 mmol), 2656 mg (16 mmol) of potassium iodide, and 484 mg (2 mmol) of pentyl *p*-toluenesulfonate were dissolved in 10 ml of sulfolane, and then 74 mg (0.2 mmol) of tetrabutylammonium iodide and 308 mg (2 mmol) of biphenyl (standard material) were added to this mixture, which was then heated ($\approx$93 °C) with stirring under nitrogen. After 15 min, the starting ester was found to have disappeared upon GLC analysis and pentyl iodide was formed in 89% yield upon determination with GLC, but the yield of disulfide was still very poor during this period. After 12 h, 10 ml of water was added to this mixture and heated for 0.5 h. The mixture was poured into benzene which was then washed with water for three times, again with 0.5 mol dm^{-3} $Na_2S_2O_3$ solution and dried ($MgSO_4$). Thus, di-*p*-tolyl disulfide was obtained in 54% yield (GLC), and the yield of pentyl iodide was found to remain unchanged as compared with that, estimated after 15 min. Pentyl iodide 157 °C/760 Torr (lit,[16] 157 °C/760 Torr).

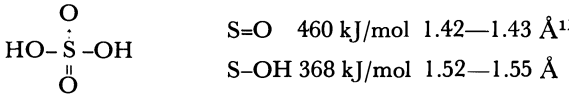
Biomimetic Reduction of Sulfuric Acid

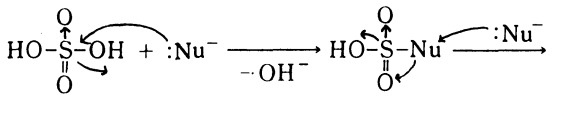
Shigeru OAE*,† and Hideo TOGO
Department of Chemistry, The University of Tsukuba, Sakura, Niihari, Ibaraki 305
(Received July 18, 1983)

Sulfuric acid and sodium sulfate were readily reduced to elemental sulfur and hydrogen sulfide upon treatment with a mixture of either one of polyphosphoric acid derivatives, PPE, PPA, and P_4O_{10}, which can form a mixed anhydride having –P–O–S– linkage, and iodide or thiol. Sulfur dioxide, which is undoubtedly one of important intermediates, was trapped by *p*-tolyllithium to afford *p*-toluenesulfinic acid which was converted to *p*-tolyl methyl sulfone upon treatment with methyl iodide, though the yield was low. Sulfur trioxide which has been postulated as the key intermediate in the biological reduction of inorganic sulfate, was also trapped by mesitylene to give mesitylenesulfonic acid in a high yield. The reduction of sulfate to elemental sulfur and hydrogen sulfide is considered to proceed through the course which resembles the biological reaction path involved in the assimilatory metabolism of inorganic sulfate in microorganisms and plants.

Inorganic sulfate which is in the highest oxidative state of sulfur atom is one of the most inert species toward any reducing agent among the naturally occurring sulfur compounds, and hence clean reduction of inorganic sulfate by any chemical means under mild conditions has been considered to be most difficult.



The deoxygenative reduction of sulfuric acid may proceed stepwise *via* an initial nucleophilic displacement of OH group of sulfuric acid by a leaving group, followed by subsequent nucleophilic attack on the leaving group bya second nucleophile as shown in Eq. 1.



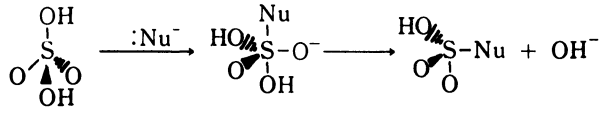
(1)

$HO^- + Nu\text{-}Nu + SO_2$

However, such a simple nucleophilic replacement of OH group of sulfuric acid does not seem to proceed readily, due mainly to the following reasons.

a) Sulfuric acid is a very strong acid which can dissociate so readily to divalent sulfate ion by supplying two protons to the attacking nucleophile that the nucleophile eventually loses the nucleophilic reducing ability due to the protonation to the lone electron pair of the nucleophile. Divalent sulfate ion, bearing two negative charge, may also no longer readily receive nucleophilic attack at its central sulfur atom due to the charge repulsion.

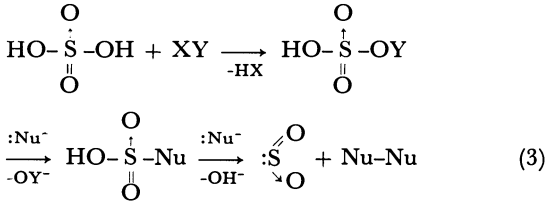
b) Even undissociated sulfuric acid would resist the nucleophilic attack, due to the steric hindrance and electronic repulsion by four oxygen atoms bound to the central sulfur, while three electronegative oxygens must be placed in the unfavorable equatorial position in the transition state of the substitution as shown in Eq. 2.



(2)

† Present address: Okayama University of Science, 1-1 Ridai-cho, Okayama 700.

c) The leaving ability of OH group is rather poor in most nucleophilic substitution reactions. Therefore, it would be necessary to substitute proton by some other elctron-withdrawing group by treatment with some condensing reagent XY to activate the central sulfur to receive nucleophilic attack as shown in Eq. 3.



(3)

Meanwhile, many plants, microorganisms are known to reduce inorganic sulfate to some sulfur-containing amino acids as shown below[2)] *via* sulfite and sulfide in the assimilatory metabolism. The biological reduction of sulfate consists of the following two key steps, *i.e.* the conversion of sulfate to a mixed anhydride, APS or PAPS, to activate sulfate, and the subsequent nucleophilic attack of a certain protein-thiol on the sulfur atom of APS or PAPS to generate the protein-bound thiosulfate. Then, the sulfenyl sulfur of the protein-bound thiosulfate can be easily displaced by other mercapto group in the enzyme to give sulfite which is ultimately reduced to hydrogen sulfide, or the sulfonyl group of the protein-bound thiosulfate is reduced by thiosulfate reductase to form R^1SS^- or R^2SS^-. This paper describes the first successful chemical model reactions for the assimilatory biological reduction of inorganic sulfate.

Results and Discussion

Since the essential part of ATP which takes part in the biological reduction of sulfate is the triphosphate linkage, polyphosphoric acid (PPA), ethyl polyphosphate (PPE),[3)] and tetraphosphorus decaoxide are considered to be use as ATP model compounds. When sulfuric acid was added to either one of these polyphosphoric acid derivatives, we observed mild evolution of heat, probably due to the formation of bond, which is the essential part of the mixed anhydride. Iodide is known

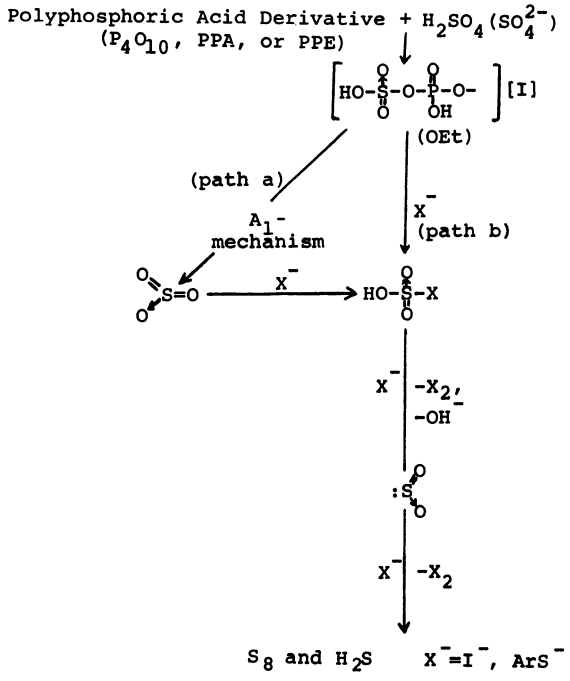
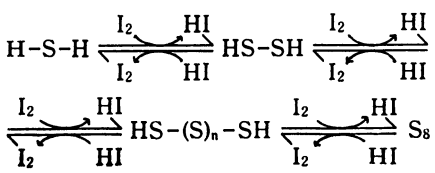
to be a facile reducing agent which can reduce oxidized organosulfur derivatives such as sulfoxides,[4] sulfinic acids,[5] sulfonyl halides,[6] thiosulfonic *S*-esters,[7] and sulfonic acids[8] to divalent organosulfur compounds, forming iodine, in a similar manner as in the case with thiols[9] which are readily oxidized to disulfides and play the most important role in the reduction of sulfate in microorganisms and plants. Although it is desirable to use thiols in order to mimic the biological reduction of sulfate, since iodide may not be present in nature, iodide is a little more reactive than thiols and the reaction is conveniently followed. Meanwhile, many reactive thiols can often forms mixed disulfides or polysulfides which are not readily separated for characterization, and hence iodide was used for the reduction at first for a detailed observation of the simple reduction and then thiols were used. The chemical behavior of iodide in the reduction is very similar to that of thiols. Sulfuric acid is, however, very inert and not reduced by iodide or thiols alone. Only in the presence of such condensing



Scheme 1.

agents as polyphosphoric acid derivatives, sulfate was reduced to sulfide with either iodide or thiols. The solvents used for the reactions with PPA and P_4O_{10} were dry sulfolane and acetonitrile respectively, since both solvents can readily dissolve these polyphosphoric acid derivatives, however, common polar aprotic solvent such as acetonitrile or chloroform can also be used in the reaction with PPE because of its high solubility in these solvents.

The results obtained in reduction of sulfuric acid are shown in Table 1. The products were elemental sulfur and hydrogen sulfide. Under acidic conditions, thiol group (*i.e.* hydrogen sulfide) and polysulfide (*i.e.* elemental sulfur) are in an equilibrium as shown in Eq. 4 (generally, thiol is oxidized by iodine in the presence of a base, *e.g.* pyridine or amine). Therefore the reduction products obtained were a mixture of hydrogen sulfide and elemental sulfur. The rather low yields of the reduction products are mainly due to the difficulty of purification and isolation of these products from the reaction mixture. In the absence of *n*-$Bu_4N^+I^-$, the yields of the reduction products were markedly decreased. In the runs 1, 2, 3, 4, and 5, the reduction to sulfur was carried out in one flask, whereas, in the runs A, B, and C, while the reduction was carried out in one flask, nitrogen gas was introduced into the flask to drive out evolving hydrogen sulfide into another flask which contained a dry benzene solution of DCC that can trap hydrogen sulfide to afford the thiourea derivative. Generally, when iodide ion was added into a mixture of sulfuric acid and any one of the polyphosphoric acid



(4)

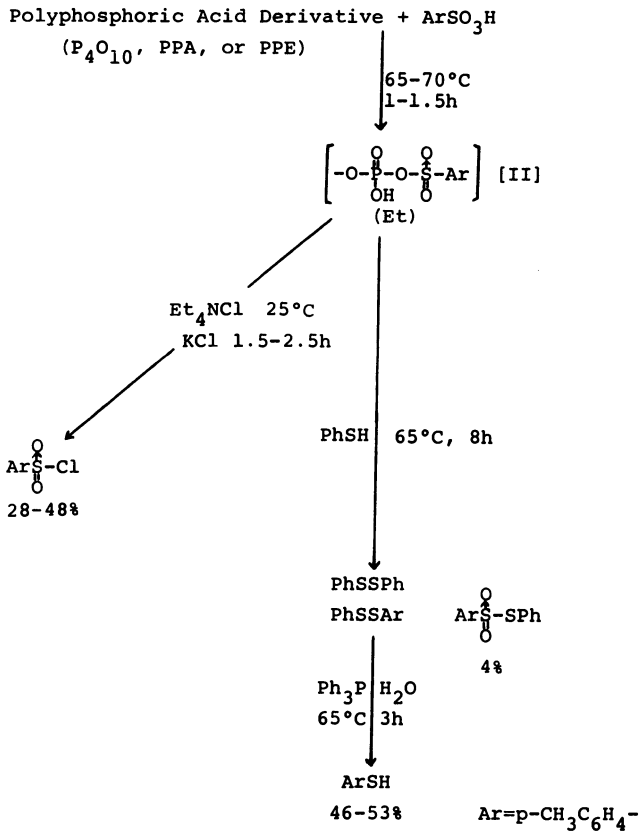


Fig. 2. Reduction of $ArSO_3H$ to ArSH by polyphosphoric acid derivative/PhSH.

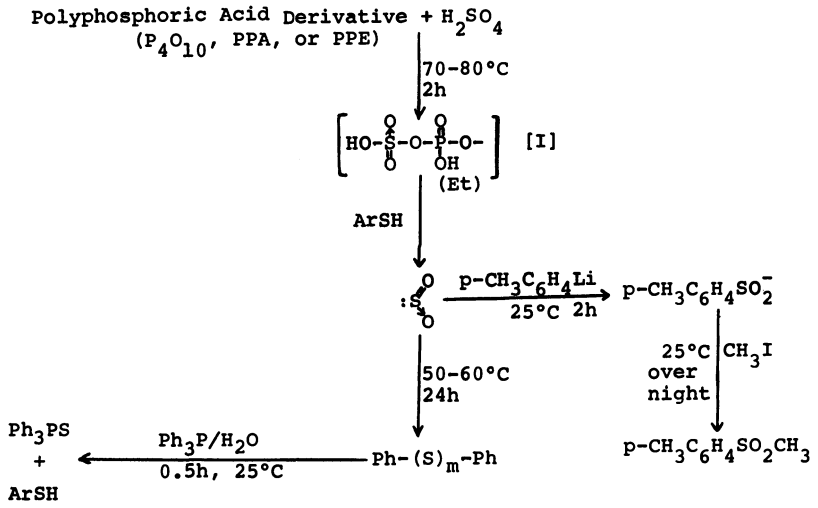
derivatives, the formation of hydrogen sulfide gas was easily detected.

Both elemental sulfur and the thiourea can be readily identified by comparison with the authentic samples (TLC, mp).

Inspection of the data in the Table reveals that PPA is the best model substrate for ATP, and gave sulfur and hydrogen sulfide in the highest yields. The rather low yields of reduction species in the reaction with either P_4O_{10} or PPE are believed to be due to the subsequent reaction between hydrogen sulfide formed and P_4O_{10}, which is a strong proton acceptor, or PPE which is an effective alkylating agent. The postulated mechanism is shown in Scheme 1. In this Scheme, [I] is believed to be the key intermediate in the presence of excess of any polyphosphoric acid derivative. Sulfite is also one of the intermediate, which is eventually reduced to elemental sulfur in a high yield in the reaction with a mixture of PPA and KI under similar conditions. The formation of intermediate[I] may be supported by a trapping experiment described in the reduction of sulfonic acid with the same system.[10] Namely, when chloride ion was added into the reaction mixture of polyphosphoric acid derivative and *p*-toluenesulfonic acid, *p*-toluenesulfonyl chloride was obtained as Fig. 2. However, isolation of chlorosulfuric acid in the reaction of the intermediate [I] with chloride anion was not achieved because of its rather high reactivity. Thus, only in the reaction of arenesulfonic acid we could isolate the sulfonyl chloride by treating the intermediate [II] with chloride.

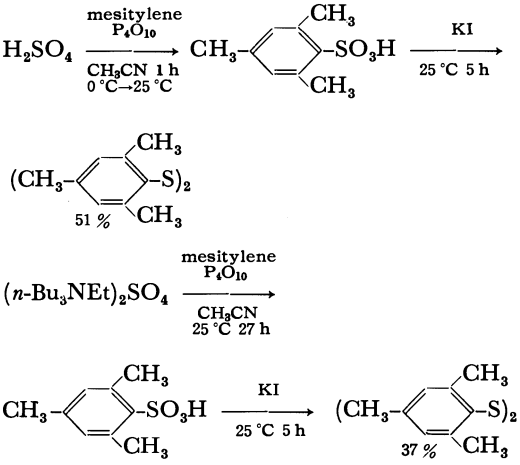


Scheme 2.

Sulfur dioxide is also an intermediate; however, it is so readily reduced by hydrogen iodide that it is difficult to trap SO_2 when iodide ion is used as the reducing agent. Instead of using iodide, excess thiophenol can be added as the reducing agent into the mixture of polyphosphoric acid derivative and sulfuric acid. Thus, sulfuric acid was reduced by thiophenol to afford diphenyl polysulfide of which middle sulfur atoms are derived from sulfuric acid. The polysulfide was then converted to thiophenol and triphenylphosphine sulfide upon of triphenylphosphine. Though the yield of the triphenylphosphine sulfide was low (2%), the combined sulfur atom of triphenylphosphine sulfide is obviously derived from sulfuric acid. The rather low yield of divalent sulfur is due to the fast reaction of thiophenol and polyphosphoric acid derivative as compared to the reduction of compound [I] by thiophenol.

Since thiophenol is a mild reducing agent as compared to hydrogen iodide, sulfur dioxide was successfully trapped by *p*-tolyllithium, when SO_2 gas formed was driven out into an ether solution of *p*-tolyllithium to afford *p*-toluenesulfinate which was then converted to the sulfone by treating with methyl iodide, though the yield of the sulfone was poor ($\simeq$1%). Although the yields of the reduction products are not high, the successful reduction of sulfuric acid and sulfate to sulfides in this biomimetic reduction with polyphosphoric acid derivatives with iodide or thiols, and the trapping of sulfur dioxide under mild conditions would be the first reported experiment which can successfully mimic the biological assimilatory sulfate reduction. In the reduction, two path (**a** and **b**) are conceivable for the reaction of compound [I] with nucleophile (I^-, PhSH). While path **b** may be unfavorable due to the stereo-electronic repulsion between the nucleophile and negative oxygen poles of bulky sulfate group of [I] at the transition state of the S_N2 reaction on the sulfur atom of [I], path **a** would be quite likely since hydrogen bound to the oxygen atom of [I] is extremely acidic.

Thus, 1,2-elimination reaction of [I] to form sulfur trioxide and phosphoric acid by Eleb process should take place quite readily.[11] Sulfur trioxide thus formed may react with iodide or arenethiol to afford iodosulfuric acid, or thiosulfuric acid either of which is considered to be subsequently reduced readily with iodide or thiols to afford sulfite. Sulfite ion (*i.e.* SO_2 in acidic conditions) is reduced further very readily with these systems to sulfide.[12] Actually, in one of our trapping experiments, sulfur trioxide was nicely trapped by mesitylene to give mesitylenesulfonic acid in the reaction of tetraphosphorus decaoxide and sulfuric acid under acidic conditions and also in the reaction between tetraphosphorus decaoxide and bis(tributylethylammonium) sulfate,



which are both neutral respectively. In a blank experiment, in the absence of tetraphosphorus decaoxide, *i.e.* the mixture of mesitylene and sulfuric acid, or the mixture of mesitylene and bis(tributylethylammonium) sulfate under similar conditions, the corresponding mesitylenesulfonic acid was not obtained. Earlier, Eiki and Tagaki[13] and Benkovic and Hevey[14] reported independently that the nucleophilic substitution of phenyl phosphatosulfate (PPS), a APS or PAPS model compound, similar to [I] in our experiment, by OH^- ion proceeded sluggishly, however, hydrolysis of PPS easily took place in acidic media or in the presence of some metal ions in aprotic solvents such as DMF. These results together with our results suggest clearly the elimination-addition mechanism involving the formation of sulfur trioxide in the acidic media (path **a**) as shown Scheme 1.

Experimental

Materials. PPA, potassium iodide, mesitylene, sulfuric acid, tributylamine, diethyl sulfate, tetraphosphorus decaoxide, and dicyclohexylcarbodiimide are all from Wako Chemicals Co., tetrabutylammonium iodide was from Tokyo Kasei Co., and sodium sulfite was obtained from Kanto Kagaku Co.

Ethyl Polyphosphate. Ethyl polyphosphate was prepared by a known method.[15] Tetraphosphorus decaoxide, 150 g, was added into a solution of 300 ml of dry ether and 150 ml of dry chloroform. The mixture was refluxed for 4 d under N_2 (bath temperature 50 °C). As the reaction proceeded, the crystalline P_4O_{10} faded away to give a homogeneous liquid. After completion of this reaction, the liquid phase was decanted into a flask in a dry box. Then the solution was evaporated to a colorless syrup. The residue was then dried by vacuum pump for 36 h at 40 °C. A colorless syrupy (hard) ester which is very sensitive to moisture, was obtained. NMR ($CDCl_3$) δ=1.9—1.5 (3H, m) and 4.2—5.0 (2H, m).

Reduction of Sulfuric Acid with PPA/KI/n-$Bu_4N^+I^-$ (cat) System to Sulfide. Polyphosphoric acid, 10 g (29.7 mmol, M.W. =338) and 4.93 g (29.7 mmol) of potassium iodide were added into 6 ml of dry sulfolane. Then, 300 mg (2.97 mmol) of sulfuric acid was added into this mixture, into which finally 184 mg (0.5 mmol) of tetrabutylammonium iodide was added. The reaction was carried out for 8 h at 75 °C with stirring under nitrogen atmosphere. The odor of hydrogen sulfide was clearly detected. After the reaction, 10 ml of water was added and the mixture was heated under similar conditions for 0.5 h in order to hydrolyze excess PPA. The reaction mixture was poured into benzene which solution was washed with water for 3 times, dried ($MgSO_4$), filtrated and the filtrate was evaporated. The residue was subjected to TLC (MERCK, silica gel type-60), separated with benzene to exclude iodine, then 55 mg of sulfur was obtained and identified by comparison with authentic sulfur (TLC R_f=0.7, eluent; benzene) mp 112—114 °C (lit,[16] 115 °C). After recrystallization with a mixture of benzene and hexane, the yield of sulfur was 58%.

Hydrogen Sulfide Trapping in PPA/KI/n-$Bu_4N^+I^-$ (cat) System. Reactor A: PPA (10 g) and 4.93 g (29.7 mmol) of potassium iodide were added into 6 ml of dry sulfolane. Then, 300 mg of sulfuric acid was added and finally 184 mg (0.5 mmol) of tetrabutylammonium iodide was added into this mixture.

Reaction B: Dicyclohexylcarbodiimide 18.4 g (9 mmol) was dissolved in 10 ml of dry benzene in a flask which was equipped with empty balloon.

Reactor B was jointed reactor A with a glass tube. The content in reactor A was stirred and heated for 4 h at 75 °C under slow flowing of nitrogen gas. While the reaction mixture in reactor B was stirred at room temperature, nitrogen and hydrogen sulfide were introduced into the reactor B. After the reaction, 10 ml of water was added to the reactor A and the mixture was heated under similar conditions for 1 h. The reaction mixture in reactor A was poured into benzene and washed with water for 3 times, dried ($MgSO_4$), filtrated and evaporated. The residue was separated by TLC with benzene to give sulfur. From the reactor A, 40 mg of sulfur was obtained. Yield 42%. In a separative experiment, 10 ml of water was added into the reactor B to quench any excess of dicyclohexylcarbodiimide to urea and the mixture was kept standing for a few hours. The mixture was poured into benzene which solution was washed with water, dried ($MgSO_4$), and benzene was evaporated. The residue was separated through silica-gel column with chloroform. *N,N'*-Dicyclohexylthiourea (103 mg, yield 15%), TLC (eluent; $CHCl_3$) R_f=0.3—0.4; IR (KBr) 1540, 3275, 1490 and 1220 cm^{-1}; mp 182—184 °C (lit,[17] 182—182.5 °C). A similar procedure with a similar molar ratio was used in the reduction of sodium sulfate in PPA system.

Trapping of Sulfur Trioxide in P_4O_{10} by Mesitylene I. Tetraphosphorus decaoxide, 2100 mg (15 mmol), was added into 6 ml of dry acetonitrile into which 2 ml of mesitylene was then added. The mixture was cooled down to 0 °C and 300 mg (2.97 mmol) of sulfuric acid was added into this mixture. The mixture was stirred for 1 h at room temperature (0 °C→ 25 °C) under nitrogen atmosphere. Then, 4903 mg (29.7 mmol) of potassium iodide, 184 mg (0.5 mmol) of tetrabutylammonium iodide and 4 ml of dry acetonitrile were added into this reaction mixture which was stirred for 5 h at room temperature under nitrogen. Since the isolation of mesitylenesulfonic acid is difficult in our system, the sulfonic acid was reduced to the disulfide with P_4O_{10}/KI system under mild conditions. Thus, mesitylenesulfonic acid was converted to dimesityl disulfide. After the reaction, 10 ml of water was added and the mixture was stirred for 1 h. The reaction mixture was poured into benzene which solution was washed with water for three times, 0.5 mol dm^{-3} of $Na_2S_2O_3$, once, again with water and dried ($MgSO_4$).

Dimesityl disulfide, which was derived from mesitylenesulfonic acid, was obtained in *ca.* 50% by GLC (OV-1, 1 m glass column). Authentic dimesityl disulfide was obtained by reducing mesitylenesulfonyl chloride with lithium aluminum hydride in dry diethyl ether for 1 h (0 °C→25 °C) to mesitylenethiol which was oxidized further to dimesityl disulfide with iodine and pyridine at room temperature in 81% yield. Mp 124—125 °C (lit,[18] 125 °C).

Trapping of Sulfur Trioxide in P_4O_{10} by Mesitylene II. Bis(tributylethylammonium) sulfate, 588 mg (1.2 mmol) was dissolved in 5 ml of dry acetonitrile and 2 ml of mesitylene was added to this mixture. Then, 1200 mg (8.4 mmol) of tetraphosphorus decaoxide was added and the whole mixture was stirred for 27 h at room temperature under nitrogen atmosphere. Potassium iodide, 1860 mg (11.2 mmol), was added into this mixture, into which 5 ml of acetonitrile was added and the whole mixture was stirred for 5 h at room temperature. Bis(tributylethylammonium) sulfate obviously plays the role of of phase-transfer catalyst. Then, 10 ml of water was added at 0 °C into the mixture which was stirred for 1 h at room temperature. The mixture was poured into benzene. The organic layer was separated and washed with water for three times, with 0.5 mol dm^{-3} of $Na_2S_2O_3$, once again with water once and dried ($MgSO_4$). Dimesityl disulfide was obtained in 37% yield (GLC, SE-30, 1 m glass column).

Trapping of Sulfonyl Group in $ArSO_3H/P_4O_{10}/KCl$ System. Tetraphosphorus decaoxide, 1600 mg (11.27 mmol), was added into 5 ml of dry acetonitrile, into which 381 mg (2 mmol) of *p*-toluenesulfonic acid was added. The mixture was heated and stirred for 1.5 h at 60—65 °C under nitrogen atmosphere. Then, 33 mg (0.2 mmol) of tetraethylammonium chloride, 746 mg (10 mmol) of potassium chloride were added into the reaction mixture at 0 °C and the mixture was stirred for 3 h at room temperature. After the reaction, the mixture was poured into benzene and washed with water for 3 times, then dried ($MgSO_4$). *p*-Toluenesulfonyl chloride was obtained in 48% yield (GLC), isolated in 43% yield. In the reaction with PPE, (PPE=6 g, *p*-$CH_3C_6H_4SO_3H\cdot H_2O$=381 mg), the yield of *p*-toluenesulfonyl chloride was 28% under similar conditions.

Reduction of $ArSO_3H$ to ArSH with PPA/Ar'SH System. PPA, 6 g, and 381 mg of *p*-toluenesulfonic acid were added into 5 ml of dry sulfolane, which was stirred and heated for 1.5 h at 90 °C under nitrogen atmosphere (the initial step). Then 2 ml of thiophenol was added to this mixture, and the reaction

mixture was kept at 90 °C for 3 h (the latter step). After the reaction, 10 ml of water was added, then the mixture was poured into benzene, which solution was washed with water for three times, and dried ($MgSO_4$). A mixture of diphenyl disulfide and phenyl *p*-tolyl disulfide was obtained. Very little di-*p*-tolyl disulfide was formed. *S*-Phenyl *p*-toluenethiosulfonate was not formed. The mixture was purified by column chromatography through silica gel(eluent; benzene/hexane=1/1=v), and the disulfides obtained were converted to the corresponding thiols by the addition of the mixture of Ph_3P/H_2O/dioxane. The yield of *p*-toluenethiol was 53% (GLC). In the reduction with PPE (PPE=7 g, *p*-$CH_3C_6H_4SO_3H \cdot H_2O$=381 mg), both the initial step and the latter step required 1.5 h/65 °C and 8 h/65 °C respectively. The reaction mixture was then treated similarly and nearly a similar result was achieved. *p*-Toluenethiol 46%. *S*-Phenyl *p*-toluenethiosulfonate 4% mp 78—80 °C (lit,[19] 78 °C).

Trapping of Sulfur Dioxide with p-*Tolyllithium. Reactor A (Step 1)*: PPE (10 g) was added to 800 mg (8 mmol) of sulfuric acid which reactor was heated and stirred at 80 °C for 1 h under nitrogen atmosphere.

Reactor B (Step 2): Lithium, 280 mg (40 mmol), was added into 5 ml of dry ether into which 5 ml of dry ether solution containing 5.1 g (30 mmol) of *p*-bromotoluene was added.[20] The mixture was stirred for a few hours under nitrogen atmosphere.

Step 3: Reactors A and B were jointed by a glass tube. Thiophenol, 3 ml, was added into the reactor A at room temperature. Then each solution in the reactors A and B was stirred for 2 h at room temperature under nitrogen atmosphere. After the reaction, the reaction mixture in reactors A and B was poured into water and washed with benzene for three times. The water was evaporated, the solution was concentrated, and excess methyl iodide was added into the mixture which was stirred over night (H_2O/EtOH=1/1=v). *p*-Tolyl methyl sulfone, 11.4 mg, was obtained. Mp 84—85 °C (lit,[21] 87 °C).

In the case of PPA, step 1 (PPA=10 g, H_2SO_4=840 mg) 2 h/70—80 °C.

Step 2: (Li=280 mg, *p*-$CH_3C_6H_4Br$=5130 mg, Et_2O=15 ml) a few hours/r.t.

Step 3: The mixture of 2 ml of thiophenol and 6 ml of sulfolane was added to reactor A and was stirred for 2 h at room temperature. The similar procedure and reaction conditions were used. *p*-Tolyl methyl sulfone, 10 mg, was obtained.

Reduction of Sulfuric Acid by Thiophenol in PPA. A mixture of PPA (10 g) and 0.8 g of sulfuric acid was heated under stirring for 2 h at 80 °C in nitrogen atmosphere. Then, 5 ml of thiophenol was added into this mixture which was stirred for 24 h at 50—60 °C. After the reaction, 10 ml of water was added and the mixture was poured into benzene, which solution was washed with water for three times, and dried ($MgSO_4$)

Triphenylphosphine 786 mg (3 mmol) was then added to this benzene solution, and 46 mg of triphenylphosphine sulfide was obtained. Triphenylphosphine sulfide was not obtained at all in the reaction of triphenylphosphine and diphenyl disulfide or thiophenol. Sulfur and diaryl polysulfide are known to be desulfulized by triphenylphosphine to give only triphenylphosphine sulfide, and arenethiol, respectively.

Triphenylphosphine sulfide mp 162—163 °C (lit,[22] 162—164 °C).

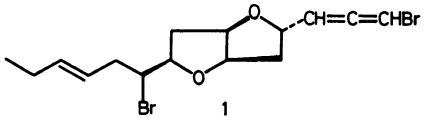
Structures of Halogenated Chamigrene Derivatives, Minor Constituents from the Red Alga *Laurencia nipponica* Yamada[1)]

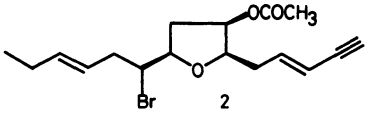
Minoru Suzuki, Makoto Segawa, Teruaki Suzuki, and Etsuro Kurosawa*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received August 5, 1983)

Three halogenated chamigrane-type sesquiterpenes have been isolated as the minor metabolites from the red alga *Laurencia nipponica*, collected at Sannai, near Wakkanai. The absolute structures of these compounds were confirmed by spectral and chemical methods.

In the course of our continuing studies on the constituents of the red alga *Laurencia nipponica* Yamada ("Ura-sozo") collected at various locations in warm and cold current regions in Hokkaido, the diversity of the secondary metabolites of this species has been found to be dependent upon growth localities.[2)] As part of further investigations of this alga, we turned our attention to the specimens in Northern Hokkaido (Dohoku) and collected at Sannai, Soya point, near Wakkanai, Hokkaido. This specimen displayed the presence of kumausallene (**1**) and *trans*-kumausyne (**2**) as the principal metabolites, which have recently been isolated from *L. nipponica* collected at Kumausu, near Otaru, Hokkaido.[3)] Furthermore, several known and unknown sesquiterpenes have also been isolated as the minor metabolites. In this paper we report the structures of three halogenated chamigrane-type sesquiterpenes.



1



2

Repeated column chromatography of the neutral methanol extracts yielded a halogenated sesquiterpene hydrocarbon **3** (1.6% of the extracts)and halogenated sesquiterpene alcohols **4** (2.0%) and **5** (1.7%) along with kumausallene (**1**) (12%) and *trans*-kumausyne (**2**) (16%).

The halogenated sesquiterpene hydrocarbon, **3**, $C_{15}H_{23}Br_2Cl$ (*m/z* 402, 400, 398, and 396; M^+), mp 76—77 °C, $[\alpha]_D^{15}$ +30.6°, showed in its IR and ^1H NMR spectra the presence of a *gem*-dimethyl group [ν_{max} 1390 and 1380 cm^{-1}; δ 0.96 and 1.15 (each 3H, s)], a tertiary methyl group [δ 1.70 (3H, s)], two halomethine groups [δ 4.45 (1H, dd, J=12, 5 Hz) and 4.72 (1H, dd, J=12, 5 Hz)], and an exomethylene group [ν_{max} 1640 and 908 cm^{-1}; δ 4.87 and 5.26 (each 1H, s)]. Comparison of the ^1H and ^{13}C NMR spectra of **3** with those[4,5)] of 2,10-dibromo-3-cholro-α-chamigrene (**6**) previously isolated from *L.* species,[4)] seemed to indicate **3** to be 2,10-dibromo-3-chloro-β-chamigrene. Confirmation of the structure of **3** was obtained by the following chemical correlation. Hydrogenation of **3** over PtO_2 in ethanol gave the dihydro derivative which was identical with the hydrogenation product (**7**)[4b)] of **6** in all respects, thus indicating that this compound is (2*S*)(3*S*)(10*R*)-2,10-dibromo-3-chloro-β-chamigrene (**3**). The IR, ^1H NMR, and mass spectral properties of **3** are almost identical with those of nidificene previously isolated from *L. nidifica*,[6)] showing that these compounds appear to be the same material.[7)]

One of the sesquiterpene alcohols, **4**, $C_{15}H_{23}OBr_2Cl$ (*m/z* 418, 416, 414, and 412; M^+), oil, $[\alpha]_D^{17}$ +3.33°, showed in its ^1H NMR spectrum the presence of three tertiary methyl groups, including *gem*-dimethyl group, at δ 0.91, 1.17, and 1.71 (each 3H, s), an α-proton to hydroxyl group at δ 4.43 (1H, dd, J=3, 3 Hz), two halomethine protons at 4.73 (1H, dd, J=13, 4 Hz) and 4.74 (1H, dd, J=11, 5.5 Hz), and exomethylene protons at 5.06 and 5.46 (each 1H, sharp s). Acetylation of **4** with acetic anhydride in pyridine afforded the corresponding acetate **8**, $C_{17}H_{25}O_2Br_2Cl$, ν_{max} 1740 and 1238

12

cm^{-1}; δ 5.41 (dd, J=4, 3 Hz), which regenerated the parent alcohol on mild saponification with K_2CO_3 in methanol. Furthermore, **4** was subjected to Jones or pyridinium chlorochromate oxidation to yield, with concomitant dehydrobromination, dienone **9**, $C_{15}H_{20}OBrCl$, ν_{max} 1672 cm^{-1}; λ_{max} 233 nm (ε 6300); δ 1.02, 1.05 (total 3H), 1.20 (3H, s), 1.69 (3H, s), 4.26 (0.4H, dd, J=12, 4 Hz), 4.69 (0.6H, dd, J=13, 5 Hz), 5.38 (1H, s), 5.95 (0.6H, d, J=10 Hz), 5.98 (0.4H, d, J=10 Hz), 6.16 (1H, s), and 6.51 (1H, d, J=10 Hz). The ^1H NMR spectrum of **9** suggests that this dienone exists at room temperature as an equilibrium mixture of two conformational isomers, which is supported by the observation of distinct temperature dependence in the ^1H NMR spectra (toluene-d_8) at various temperature.[8] In view of the above-mentioned data coupled with comparison of spectral properties of **3** and **4**, formula **4** could readily be proposed for this alcohol. The equatorial nature of the proton at C-8 was suggested by its J-values in the ^1H NMR spectra of **4** and **8**. The structure of **4**, including the absolute configuration, was established by derivation from 2,10-dibromo-3-chloro-7,8-epoxychamigrane (**10**) which was the major metabolite of Atsuta's *L. nipponica*.[4c,d] Treatment of **10** with *p*-toluenesulfonic acid in warm benzene gave **4** in 53% yield. Therefore, the structure of this alcohol is represented by formula **4**, which is the first example of halochamigrane derivatives from the genus *Laurencia* with a hydroxyl group at C-8.

Another sesquiterpene alcohol, **5**, $C_{15}H_{24}OBr_2$ (*m/z* 382, 380, and 378; M^+), oil, $[\alpha]_D^{18}$ −27.0°, revealed very similar IR, ^1H and ^{13}C NMR spectra to those of glanduliferol (**11**),[4b] indicating that **5** must be bromohydrin at C-2 and C-3 instead of chlorohydrin at C-2 and C-3 in glanduliferol (**11**). This was confirmed by the following reaction. Treatment of **5** with 5% methanolic KOH at room temperature gave 10-bromo-2,3-epoxy-α-chamigrene (**12**) as same as in the case of **11**.[4b] Recently Fukuzawa *et al.* reported that 2,10-dibromo-3-hydroxy-α-chamigrene has been isolated as a crystalline state (mp 58—59 °C, $[\alpha]_D^{20}$ −34.2°) from *L. nipponica* collected at the inside of Kabutoiwa, Oshoro Bay.[9] Unambiguously our alcohol was found to be identical with Fukuzawa's sample by comparison of the spectral data.

Previously we have isolated glanduliferol (**11**) from the specimen of *L. nipponica* (*L. glandulifera*)[10] collected at the outside of Kabutoiwa, Oshoro Bay, in August 1963 and 1964. The finding of 2,10-dibromo-3-hydroxy-α-chamigrene (**5**) from Oshoro's *L. nipponica* prompted us to reinvestigate the specimen collected at the outside of Kabutoiwa. Interestingly the specimens collected in 1978 (August)[11] and 1983 (June) revealed the presence of **5** instead of glanduliferol (**11**).

Experimental

The melting point was uncorrected. The IR spectra were measured on a JASCO A-102 spectrometer. The ^1H and ^{13}C NMR spectra were recorded on a JEOL JNM-FX100 spectrometer, TMS being used as an internal reference in $CDCl_3$. The UV spectra was obtained with a Shimadzu UV-240 spectrophotometer. The low and high resolution mass spectra were recorded on a JEOL JMS-D300 spectrometer. The optical rotations were measured on a JASCO DIP-140 polarimeter in $CHCl_3$. Aluminium oxide (Merck, activity II-III) and silica gel (Merck, Kieselgel 60, 70—230 mesh) were used for column chromatography. Silica gel 60 F_{254} (Merck) was used for thin-layer chromatography. All known compounds were identified by comparison of the spectral data with those of the authentic specimens.

Isolation. *Laurencia nipponica* Yamada was collected early in July, 1981, at Sannai, Soya point, near Wakkanai, Hokkaido. The neutral methanol extracts (2.0 g) (*ca.* 1% of the half-dried alga) obtained by the conventional methods were fractionated by column chromatography over alumina. The fraction eluted with hexane was rechromatographed on silica-gel column to yield isodihydrolaurene (7 mg),[4c] laurene (10 mg),[12] and α-bromocuparene (5 mg).[13] The fraction eluted with hexane–benzene (1 : 1) was further chromatographed on silica-gel column to yield 2,10-dibromo-3-chloro-β-chamigrene (**3**) (32 mg), selin-4(14)-en-5α-ol (30 mg),[14] and kumausallene (**1**) (100 mg).[3] The fraction eluted with benzene was further subjected to silica-gel column chromatography to give kumausallene (**1**) (140 mg) and *trans*-kumausyne (**2**) (320 mg).[3] The fraction eluted with ethyl acetate was repeatedly chromatographed on silica-gel column to give laurenisol (6 mg),[11] an unidentified alcohol (80 mg), 2,10-dibromo-3-chloro-8-hydroxy-β-chamigrene (**4**) (40 mg), 2,10-dibromo-3-hydroxy-α-chamigrene (**5**) (34 mg), and deacetylkumausyne (55 mg).[3]

2,10-Dibromo-3-chloro-β-chamigrene (3): Mp 76—77 °C (from hexane); $[\alpha]_D^{15}$ +30.6° (*c* 1.40); IR (CCl_4), ν_{max} 3080, 1640, 1390, 1380, 1306, 1295, 1200, 1158, 1093, 1060, 992, 970, 908, and 863 cm^{-1}; ^1H NMR, δ 0.96 (3H, s), 1.15 (3H, s), 1.70 (3H, s), 1.8—2.6 (10H, m), 4.45 (1H, dd, J=12 and 5 Hz), 4.72 (1H, dd, J=12 and 5 Hz), 4.87 (1H, s), and 5.26 (1H, s); ^{13}C NMR, δ 16.4 (q), 22.5 (q), 23.1 (q), 24.4 (t), 32.4 (t), 34.8 (t), 37.6 (t)×2, 42.7 (s), 50.0 (s), 60.3 (d), 62.5 (d), 70.7 (s), 113.6 (t), and 144.5 (s); MS (70 eV), *m/z* (rel intensity) 402, 400, 398, 396 (2 : 9 : 13 : 6; M^+), 387, 385, 383, 381 (1 : 4 : 6 : 3; M^+-CH_3), 321, 319, 317 (5 : 19 : 15; M^+-Br), 283, 281 (29 : 27; $M^+-Br-HCl$), 201 (47; $M^+-Br-HBr-HCl$), 109 (100), 95 (73), 69 (99), and 41 (99). Found: *m/z* 399.9855. Calcd for $C_{15}H_{23}{}^{79}Br^{81}Br^{37}Cl$: M, 399.9808.

2,10-Dibromo-3-chloro-8-hydroxy-β-chamigrene (4): Colorless oil; $[\alpha]_D^{17}$ +3.33° (*c* 1.20); IR (film), ν_{max} 3400, 3097, 1630, 1394, 1376, 1348, 1300, 1165, 1150, 1132, 1098, 1040, 1010, 975, 925, 895, 812, and 712 cm^{-1}; ^1H NMR, δ 0.91 (3H, s), 1.17 (3H, s), 1.71 (3H, s), 2.0—2.5 (9H, m), 4.43 (1H, dd, J=3 and 3 Hz), 4.73 (1H, dd, J=13 and 4 Hz), 4.74 (1H, dd, J=11 and 5.5 Hz), 5.06 (1H, s), and 5.46 (1H, s); ^{13}C NMR, δ 17.4 (q), 23.9 (q), 24.3 (q), 26.7 (t), 39.6 (t)×2, 42.4 (t), 43.8 (s), 50.8 (s), 60.1 (d), 61.6 (d), 71.9 (s), 76.0 (d), 118.1 (t), and 146.5 (s); MS, *m/z* 418, 416, 414, 412 (0.2 : 1 : 1.4 : 0.7; M^+), 400, 398, 396, 394 (0.5 : 2.3 : 3.3 : 1.4; M^+-H_2O), 380, 378, 376 (0.5 : 0.9 : 0.5; M^+-HCl), 347, 345, 343 (3 : 4.5 : 2; $M^+-H_2O-HCl-CH_3$), 337, 335, 333 (5 : 19 : 16; M^+-Br), 319, 317, 315 (11 : 46 : 35; M^+-H_2O-Br), 299, 297 (27 : 28; $M^+-Br-HCl$), 217 (17; $M^+-HBr-HCl-Br$), 199 (34; $M^+-Br-HBr-HCl-H_2O$), 157 (29), 147 (28), 119 (40), 107 (38), 105 (45), 93 (100), 91 (43), 69 (69), and 41 (89). Found: *m/z* 395.9686. Calcd for $C_{15}H_{21}{}^{79}Br^{81}Br^{35}Cl$: $M-H_2O$, 395.9681.

2,10-Dibromo-3-hydroxy-α-chamigrene (5): Colorless oil; $[\alpha]_D^{18}$ −27.0° (*c* 2.13); IR ($CHCl_3$), ν_{max} 3570, 1397, 1385, 1342, 1130, 1108, 1095, 1070, 1045, 1015, 990, 980, 928, and 837 cm^{-1}; ^1H NMR, δ 0.95 (3H, s), 1.23 (3H, s), 1.35 (3H, s), 1.98 (3H, finely splitted m), 1.5—2.3 (7H, m), 2.4—2.7 (2H, m), 4.56 (1H, dd, J=10 and 7.5 Hz), 4.77 (1H, dd, J=10 and 8.5 Hz),

and 5.21 (1H, m); ^{13}C NMR, δ 17.3 (q), 22.2 (q), 24.7 (q), 25.9 (q), 31.6 (t), 35.9 (t), 36.3 (t), 39.1 (t), 42.7 (s), 48.2 (s), 61.3 (d), 66.3 (d), 72.0 (s), 122.3 (d), and 140.1 (s); MS, *m/z* 382, 380, 378 (0.2 : 0.4 : 0.2 : M^+), 301, 299 (17 : 17; M^+-Br), 283, 281 (25 : 25; M^+-Br-H_2O), 201 (71; $M^+-Br-HBr-H_2O$), 159 (59), 149 (58), 147 (74), 145 (98), 133 (49), 119 (55), 109 (61), 105 (70), 93 (54), 91 (76), 69 (53), 55 (68), 43 (100), and 41 (97); Found: *m/z* 301.1007. Calcd for $C_{15}H_{24}O^{81}Br$: M−Br, 301.0992.

Hydrogenation of ***3***. The hydrogenation of **3** (12.6 mg) was performed in ethanol (2.0 ml) over PtO_2-catalyst. After removal of the catalyst and the solvent, the residual oil was chromatographed on a silica-gel plate to give **7** (7.0 mg); $[\alpha]_D^{21}$ +47.5° (*c* 0.65); The IR, ^{1}H NMR, and mass spectra were identical with those of authentic 2,10-dibromo-3-chlorochamigrane.[4b]

Acetylation of ***4***. Acetylation of **4** (12 mg) was carried out with acetic anhydride in pyridine in the usual manner. The acetylated product was purified by column chromatography on silica-gel to give **8** (11 mg); colorless oil; $[\alpha]_D^{17}$ −15.4° (*c* 0.34); IR (film), ν_{max} 3110, 1740, 1635, 1392, 1370, 1348, 1238, 1190, 1167, 1148, 1130, 1093, 1023, 930, 908, 877, 808, 730, and 715 cm^{-1}; ^{1}H NMR, δ 0.92 (3H, s), 1.19 (3H, s), 1.71 (3H, s), 2.02 (3H, s), 2.1—2.5 (8H, m), 4.61 (1H, dd, *J*= 12 and 6.5 Hz), 4.67 (1H, dd, *J*=13 and 5 Hz), 5.20 (1H, s), 5.41 (1H, dd, *J*=4 and 3 Hz), and 5.64 (1H, s); MS, *m/z* 458, 456, 454 (0.2 : 0.2 : 0.1; M^+), 418, 416, 414, 412 (0.1 : 0.4 : 0.6 : 0.3; $M^+-C_2H_2O$), 400, 398, 396, 394 (0.4 : 1.5 : 2 : 1; M^+-CH_3COOH), 379, 377, 375 (0.2 : 0.4 : 0.3; M^+-Br), 337, 335, 333 (0.2 : 0.5 : 0.5; $M^+-C_2H_2O-Br$), 319, 317, 315 (7 : 87 : 56; $M^+-Br-CH_3COOH$), 199 (27), 157 (13), 119 (19), 107 (22), 105 (25), 93 (15), 91 (20), 69 (27), 43 (100), and 41 (36).

Saponification of ***8***. A soln of **8** (2.7 mg) and potassium carbonate (9.6 mg) in methanol (0.3 ml) was allowed to stand at room temp for 20 min and then worked up in the usual way to give **4** (2.3 mg); The IR and ^{1}H NMR spectra were identical with those of natural alcohol (**4**).

PCC Oxidation of ***4***. To a suspended soln of pyridinium chlorochromate (10 mg) in CH_2Cl_2 (0.1 ml) was added a soln of **4** (16 mg) in CH_2Cl_2 (0.1 ml). The reaction mixture was allowed to stand at room temp for 2 h. After addition of ether, filtration, and washing with ether, the combined organic soln was passed through a short pad of Frorisil, and then the solvent was removed to leave a residual oil, which was chromatographed on a silica-gel plate to give **9** (4.1 mg) as a pale yellow oil; $[\alpha]_D^{20}$ −10.7° (*c* 0.38); UV (EtOH), λ_{max} 233 (ε 6300), and 200 nm (ε 5300); IR (film), ν_{max} 1672, 1620, 1397, 1385, 1352, 1315, 1253, 1220, 1162, 1095, 1065, 945, 845, 820, and 752 cm^{-1}; ^{1}H NMR, δ 1.02, 1.05 (each s, total 3H), 1.20 (3H, s), 1.69 (3H, s), 4.26 (0.4H, dd, *J*=12 and 4 Hz), 4.69 (0.6H, dd, *J*=13 and 5 Hz), 5.38 (1H, s), 5.95 (0.6H, d, *J*=10 Hz), 5.98 (0.4H, d, *J*=10 Hz), 6.16 (1H, s), and 6.51 (1H, d, *J*=10 Hz); MS, *m/z* 334, 332, 330 (5 : 18 : 16; M^+), 319, 317, 315 (1 : 5: 4; M^+-CH_3), 297, 295 (3 : 3; M^+-Cl), 253, 251 (13 : 37; M^+-Br), 215 (79), 199 (62), and 96 (100).

Jones Oxidation of ***4***. To a soln of **4** (10.3 mg) in acetone (4.0 ml) was added two drops of Jones reagent. After the usual work-up, the residual oil was chromatographed on a silica-gel plate to give **9** (7.0 mg).

Conversion of ***10*** *into* ***4***. To a soln of **10** (32.4 mg) in benzene (0.5 ml) was added a piece of TsOH, and the mixture was stirred for 20 min at 60 °C (bath temp). The reaction mixture was worked up as usual to leave an oily residue, which was chromatographed on silica-gel column to give **4** (17.1 mg); $[\alpha]_D^{17}$ +3.94° (*c* 0.86); The IR, ^{1}H NMR, and mass spectra were identical with those of natural **4**.

Conversion of ***5*** *into* ***12***. A soln of **5** (4.9 mg) in 5% methanolic KOH (0.3 ml) was allowed to stand at room temp for 30 min. After being treated by the usual method, the resulting oil was purified by chromatography on a silica-gel plate to afford **12** (3.8 mg); $[\alpha]_D^{20}$ −75.6° (*c* 0.21); The IR and ^{1}H NMR spectra were identical with those of authentic 10-bromo-2,3-epoxy-α-chamigrene.[4b]

We are grateful to Prof. K. L. Erickson, Clark University, for the spectral data of nidificene, and also to Dr. Akio Fukuzawa, Hokkaido University, for the spectral data of 2,10-dibromo-3-hydroxy-α-chamigrene and valuable suggestions.

Studies on Salt Hydrates for Latent Heat Storage. IV. Crystallization in the Binary System CH_3CO_2Na-H_2O

Takahiro WADA,* Fumiko KIMURA, and Yoshihiro MATSUO
Central Research Laboratory Matsushita Electric Industrial Co. Ltd., 1006 Kadoma, Osaka, 571
(Received February 21, 1983)

In the binary system CH_3CO_2Na–H_2O, crystallization temperature on slow cooling from a melt, glass transition temperature and crystallization temperature on slow heating from a quenched vitrified solid were measured by varying the CH_3CO_2Na concentration. The crystallization behaviour in the binary system CH_3CO_2Na–H_2O is characterized as follows; (1) crystallization region of ice extends into the CH_3CO_2Na-rich side from the eutectic composition, (2) a hard crystallization region exists in the composition between CH_3CO_2Na 35wt% and 40wt%, (3) the crystallization temperature range of $CH_3CO_2Na \cdot 3H_2O$ is from −50 °C to −30 °C and very narrow.

Sodium acetate trihydrate ($CH_3CO_2Na \cdot 3H_2O$) has recently attracted attention as a useful heat stroage material because of its large latent heat of fusion (about 264 J/g).[1,2] The $CH_3CO_2Na \cdot 3H_2O$ melt tends to supercool even when it is cooled considerably below its melting point (58.4 °C).[3,4] Such a supercooling phenomenon impaired its practical application.[5] Therefore, in order to develop latent heat storage materials using salt hydrates such as $CH_3CO_2Na \cdot 3H_2O$, Kimura[6] studied the supercooling phenomena of some salt hydrates from the viewpoint of the chemical potential difference of water molecules in molten and crystalline states. Wada and Yamamoto[7] have searched for crystal nucleation catalysts of $CH_3CO_2Na \cdot 3H_2O$ and found $Na_4P_2O_7 \cdot 10H_2O$.

The phase diagram of the binary system CH_3CO_2Na–H_2O based on data from Seidell's compilation[8] is shown in Fig. 1. A dashed line in Fig. 1 is the liquidus line of metastable CH_3CO_2Na. It is clear from the phase diagram that H_2O and $CH_3CO_2Na \cdot 3H_2O$ form an eutectic mixture melting at −18 °C, with the composition of 23 wt% CH_3CO_2Na and 77 wt% H_2O.

This paper reports a quantitative investigation of the crystallization behavior of the binary system CH_3CO_2Na–H_2O, where crystallization temperature on slow cooling from a melt (t_c), glass transition temperature (T_g), and crystallization temperature on slow heating from a quenched vitrified solid (T_c) were measured by varying the CH_3CO_2Na concentration.

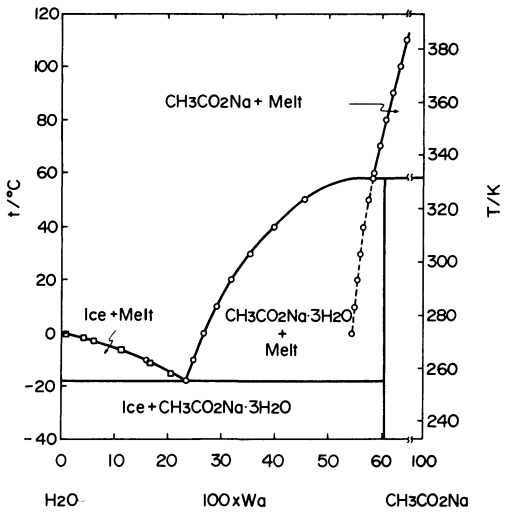

Fig. 1. Phase diagram of the binary system CH_3CO_2Na–H_2O.
○: The data obtained by Green,[9] □: the data obtained by Sidgwick and Gentle.[10]

Experimental

Sodium acetate trihydrate was of a guaranteed grade reagent from Wako Pure Chemical Industry. Weighed quantities of $CH_3CO_2Na \cdot 3H_2O$ and distilled water, 30 g in total, were placed in a glass vessel with a stirring bar. The sample temperature was measured by a chromel–alumel thermocouple attached to the inner wall of the glass vessel which was sealed and immersed in a water bath. In order to obtain reproducible data, the sample was heated to a temperature which is about 10 °C higher than its liquidus temperature and was stirred to a homogeneous melt.[11] Then, the melt was cooled at the rate of about 5 °C/min by consecutive addition of ice to the water bath. When the temperature of the melt reached to 20 °C, the vessel was transferred from the water bath to an ethanol bath. Cooling was continued to −70 °C at the rate of about 5 °C/min by consecutive addition of solid carbon dioxide to the ethanol bath. In such a slow cooling process, crystallization of the sample was detected by a sudden rise in temperature of the melt and by visual inspection. The viscosity of melts increased on cooling, which contained CH_3CO_2Na more than $W_a = 0.35$ (W_a is the mass fraction of CH_3CO_2Na), and sometimes the magnetic stirrer failed to operate the stirring bar. The measurement was performed three times for each sample. In this manner, t_c was measured as a function of the CH_3CO_2Na concentration. Figure 2 shows the average and the range of crystallization temperatures obtained by the present measurements.

Temperatures, T_g and T_c were measured as a function of the CH_3CO_2Na concentration by the differential scanning calorimetry (DSC). The DSC measurement was performed by using an SSC 560S DSC (Daini Seikosha Co.), heat-flux DSC. One drop of a melt (about 10 mg) was placed in a 15 μl silver crucible. This crucible was sealed and immersed in a water bath, whose temperature was about 10 °C higher than a liquidus temperature of the sample. After thirty minutes, the crucible was transferred into liquid nitrogen. The overall cooling rate was about 1000 K/min. DSC measurements were performed at a heating rate of 5 °C/min from −130 °C to 70 °C. This DSC system was calibrated by using ice (mp: 0.0 °C), chloroform (mp: −63.5 °C), acetone (mp: −94.3 °C), and ethanol (mp: −114.2 °C) as standards, and the measurements were made two times for each sample.

Results and Discussion

Crystallization Temperature on Slow Cooling from a Melt

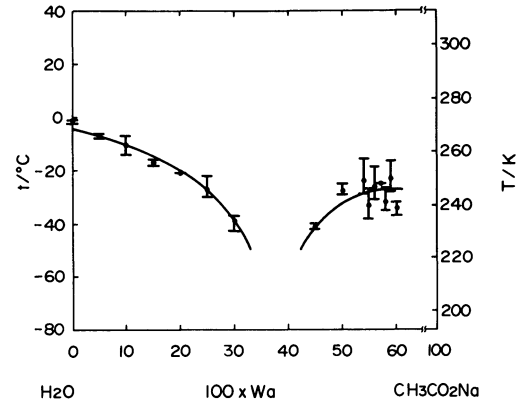

Fig. 2. Crystallization temperature on slow cooling (t_c) in relation to the CH_3CO_2Na concentration.

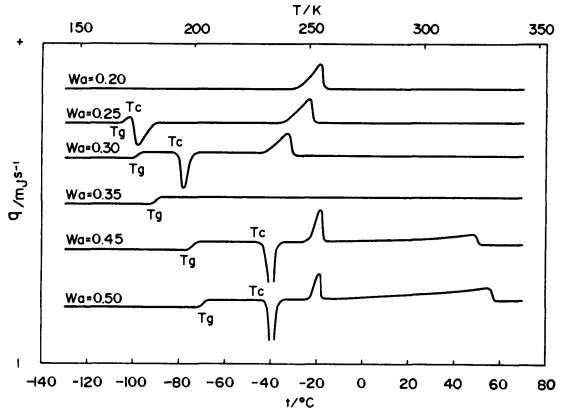

Fig. 3. DSC curves for some quenched samples of the system CH_3CO_2Na–H_2O.

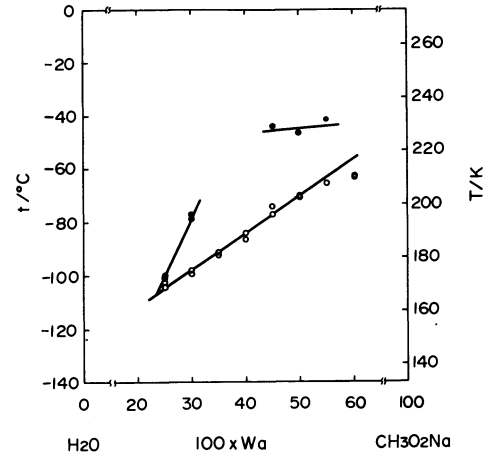

Fig. 4. Glass transition temperature (T_g) and crystallization temperature on slow heating (T_c) in relation to the CH_3CO_2Na concentration.
○: T_g, ●: T_c.

(t_c). The t_cs obtained are shown in Fig. 2. The number on the abscissa, $100 \times W_a$, is the weight percentage of CH_3CO_2Na in the system. The samples of $W_a=0.35$ and $W_a=0.40$ did not crystallize in all the runs.

In the water-rich side of the eutectic composition, the t_c curve lies about 5 °C lower than the liquidus line of H_2O, ice crystallizing first from the melt. Interestingly, the t_c curve extends beyond the eutectic composition into the CH_3CO_2Na-rich side. Therefore, the crystals that separated out first from the melt in the CH_3CO_2Na-rich side of the eutectic composition ($W_a=0.30$) is not $CH_3CO_2Na \cdot 3H_2O$, but ice.

From Fig. 2, it is also clear that t_cs of the melts containing CH_3CO_2Na more than $W_a=0.45$ are about 90 °C lower than the liquidus line, *i.e.*, supercooling of these samples is about 90 °C. $CH_3CO_2Na \cdot 3H_2O$ separated out first from both melts of $W_a=0.45$ and $W_a=0.50$, but for the samples containing CH_3CO_2Na more than $W_a=0.54$, anhydrous CH_3CO_2Na crystals separated out from their melts at the temperature about 10 °C lower than their liquidus temperarures, followed by crystallization of $CH_3CO_2Na \cdot 3H_2O$. Anhydrous CH_3CO_2Na crystals were identified by X-ray diffraction. Since the t_c curve varies continuously with the CH_3CO_2Na concentration between $W_a \times 0.45$ and $W_a=0.603$ ($CH_3CO_2Na \cdot 3H_2O$), the curve in Fig. 2 also suggests that anhydrous CH_3CO_2Na crystals (separated out first) have little influence on the subsequent crystallization of $CH_3CO_2Na \cdot 3H_2O$.

Glass Transition Temperature (T_g) DSC curves for some quenched samples are illustrated in Fig. 3, where q is heat flux. T_g and T_c are plotted against the CH_3CO_2Na concentration in Fig. 4. The melt with $W_a=0.25$ vitrified by quenching, but that with $W_a=0.20$ did not, and this result was confirmed by visual observation of these samples in a 3 mm diameter pyrex glass tubes put into liquid nitrogen. This observation shows that the glass forming composition is limited on the CH_3CO_2Na-rich side from the eutectic composition ($W_a=0.23$). This is due to the difficulty of crystal nucleation of $CH_3CO_2Na \cdot 3H_2O$.

In Fig. 4, T_g varies linearly with the CH_3CO_2Na concentration, and those of the samples containing CH_3CO_2Na more than $W_a=0.55$ lie below the T_g line. This deviation results from the decrease of the CH_3CO_2Na concentration caused by separation of CH_3CO_2Na crystals from the quenched samples, which is confirmed by visual observation using thin glass tubes. Williams and Angell,[12] and Kanno *et al.*[13] have reported that T_g of the sample with $W_a=0.313$ ($CH_3CO_2Na \cdot 10H_2O$) is −99 and −102 °C, respectively. The T_g estimated from our data is −96 °C and in good agreement with the reported data. The extrapolation of the obtained T_g to pure water gives −140 °C as the T_g of glassy water. Angell and Sare[14] also gave a similar value (−138 °C) from the studies on a large number of aqueous electrolyte solutions. This value is almost identical with the glass transition temperature (−139 °C) obtained for amorphous solid water prepared by the vapor deposition method.[15] The extrapolation to pure $CH_3CO_2Na \cdot 3H_2O$ gives −56 °C as the T_g of glassy $CH_3CO_2Na \cdot 3H_2O$. This value is close to T_g of $Na_2S_2O_3 \cdot 5H_2O$ ($T_g=-42$ °C)[16] and $Ca(NO_3)_2 \cdot 4H_2O$ ($T_g=-54$ °C).[14]

Crystallization Temperature on Slow Heating from a Quenched Sample (T_g) The quenched samples with $W_a=0.25$ and $W_a=0.30$ always crystallize on heating after the glass transition. T_c of the sample with $W_a=0.313$ ($CH_3CO_2Na \cdot 10H_2O$) has been reported to

be −73 °C by Kanno *et al.*,[12] which is in good agreement with T_c estimated from our data, −72 °C. The DSC curves show that the melting points of the samples with W_a=0.25 and W_a=0.30 are at −22 and −31 °C, respectively. These melting points are lower than the eutectic point, −18 °C, and lie on the extrapolated liquidus line of H_2O. As shown in Fig. 3, the samples with W_a=0.25 and W_a=0.30 do not show the endothermic peak of $CH_3CO_2Na\cdot3H_2O$ melting. Therefore, ice is the only compound crystallized from the melts with W_a=0.25 and W_a=0.30. This result is similar to the crystallization behaviour observed on slow cooling of the melt.

The quenched samples with W_a=0.35 and W_a=0.40 did not crystallize on heating twice. As mentioned above, these samples did not crystallize on cooling either. These results show that these samples have a stable solution structure with hard crystallization.

The quenched samples with W_a=0.45, W_a=0.50, and W_a=0.55 crystallized only once in two runs. For these cases, T_cs are between −40 and −50 °C as shown in Fig. 4. $CH_3CO_2Na\cdot3H_2O$ (W_a=0.603) did not crystallize on heating in two runs.

The phase diagram of the binary system CH_3CO_2Na–H_2O(Fig. 1), t_c cuves (Fig. 2), and T_g line and T_c curves (Fig. 4) are summarized in Fig. 5. In the temperature region demarcated by t_c and T_c curves, ice or $CH_3CO_2Na\cdot3H_2O$ is considered to crystallize from the melt in the present experimental conditions. The crystallization behavior of the binary system CH_3CO_2Na–H_2O is characterized as follows: (1) the crystallization region of ice extends into the CH_3CO_2Na-rich side from the eutectic composition, (2) a hard crystallization region exists in the composition between W_a=0.35 and W_a=0.40, (3) the crystallization temperature range of $CH_3CO_2Na\cdot3H_2O$ is from −50 °C to −30 °C and very, narrow.

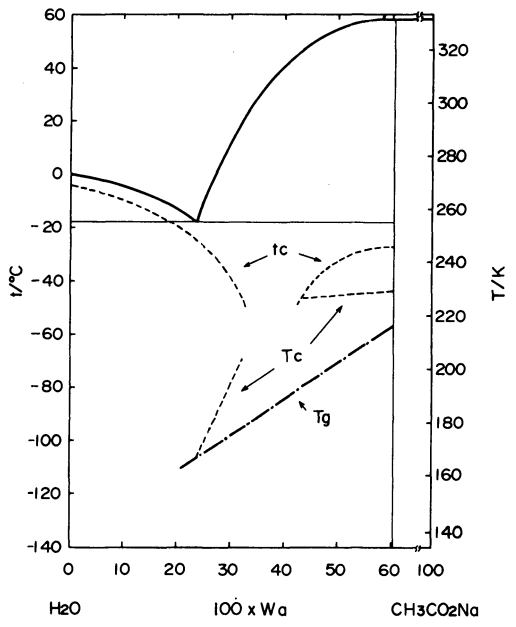

Fig. 5. Crystallization temperature curves (t_c and T_c curves), and glass transition temperature line shown in the phase diagram of the binary system CH_3CO_2Na–H_2O.

The crystallization temperature is generally influenced by the heating or cooling rate, quantity and purity of the sample and stirring method, *etc.* In measuring t_c, if the cooling rate is slower than 5 °C/min or the sample quantity is larger than 30 g, t_cs will be higher than the obtained values. In measuring T_c, if the heating rate is slower than 5 °C/min or the sample quantity is larger than about 10 mg, T_cs will be lower than the obtained values. Therefore, crystallization temperature breadths of ice and $CH_3CO_2Na\cdot3H_2O$ are expected to be wider than those shown in Fig. 5.

The authors wish to express their thanks to Dr.Ryoichi Kiriyama for his useful discussions and Drs. Tsuneharu Nitta, Eiichi Hirota, and Masanari Mikoda for their continuous encouragements. The authors are grateful to Dr. Ryoichi Yamamoto for his discussions throughout this work.

Electrical Dark- and Photo-conductivities of 2-(*p*-Decyloxybenzilideneamino)-9-fluorenone in the Nematic State

Ken-ichi Okamoto,* Shu Nakajima, Michiko Ueda, Akira Itaya, and Shigekazu Kusabayashi†
Department of Chemical Engineering, Faculty of Engineering, Yamaguchi University, Ube, Yamaguchi 755
(Received October 1, 1982)

The electrical conductivity of 2-(*p*-decyloxybenzylideneamino)-9-fluorenone (DBAF), which has a large π-electronic group, was investigated in the nematic state. The dark conductivity showed a positive anisotropy and was attributed to ionic conduction. The photocurrent was observed in the absorption region of DBAF and was enhanced by doping with 2,4,7-trinitro-9-fluorenone. The photocarriers seem to be generated from the excited state of DBAF by one photonic process.

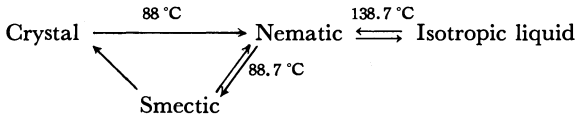
Electrical dark-conductivity in liquid crystals has been studied extensively[1-5] and attributed to ionic conduction on the basis of both the conductivity anisotropy[2,3] and the temperature dependence of the carrier mobility.[4,5] On the contrary, photoconductivity in liquid crystals has never been reported until now except for the photocurrent due to the photoinjection of charge carriers from an electrode.[6,7] This is probably because the liquid crystals investigated to data have had only small π-electronic groups, such as a benzene ring. In this paper, we investigated the dark- and photo-conductivities of 2-(*p*-decyloxybenzylideneamino)-9-fluorenone (DBAF), which has a large π-electronic group, in the nematic, monotropic smectic, and isotropic liquid states.

Experimental

The DBAF was prepared according to the literature[8] and was recrystallized several times from an absolute ethanol solution. The purity of the DBAF was satisfactory, judging from the analysis by means of differential scanning calorimetry and high-performance liquid chromatography. The *p*-methoxybenzylidene-*p*-butylaniline (MBBA) was obtained commercially and was purified by means of high-vacuum distillation. The sample was sandwiched between two nesa-coated glass electrodes with a Myler spacer 20—100 μm thick. The effective area of the cells was typically 1 cm^2. The capacitance and DC conductivity measurements were carried out under an argon atmosphere.

Results and Discussion

The phase transitions were as follows:



Alignment of the Molecules in Nematic State. The magnetic field aligns the long axes of the liquid crystal molecules along its direction.[9] Figure 1 shows the variation in the specific dielectric constant ε with the magnetic field H. A homogeneous or homeotropic alignment of the molecules in the nematic state was achieved by the magnetic field of 0.4 T perpendicular to or parallel to the applied electric field E. The negative dielectric anisotropy of DBAF ($\Delta\varepsilon = -1.65$ at 100 °C) is larger than that of such typical Schiff-base-type liquid crystals as MBBA,[2,9] because of the presence of a carbonyl group nearly perpendicular to the long molecular axis.

Dark Conductivity. The dark conductivity σ was measured for the homogeneous or homeotropic alignment, and labelled $\sigma_\perp$ or $\sigma_{//}$ respectively. The dark current obeyed Ohm's law in the fields less than 10^4 V/cm in every state. Figure 2 shows the temperature dependence of the dark conductivity and its anisotropy ratio, $R = \sigma_{//}/\sigma_\perp$. At the crystal-nematic phase transition, σ increased abruptly and showed a sharp peak which disappeared with an increasing voltage. This peak current seems to be caused by the abrupt change in the direction of the dipole-moment due to the change in molecular direction at the phase transition.[5] At the nematic-isotropic transition, $\sigma_{//}$ decreased appreciably, while $\sigma_\perp$ hardly changed. In the nematic state, σ was in the order of 10^{-10} Ω^{-1} cm^{-1} and ΔE_a was 0.5 eV. These values of σ and ΔE_a are comparable to those reported for typical nematic liquid crystals.[1-4] The temperature dependence of R is also similar to that reported for the Schiff-base-type liquid crystals;[2,3] that is, R is larger than unity in the nematic state, although it, because of a pretransitional effect, decreases below unity when approaching the transition to a smectic state. These results indicate that the dark conductivity of DBAF in nematic and isotropic states is caused by the ionic mechanism previously reported for conventional liquid crystals,[2-5,10] in spite of the presence of a large π-electronic group.

Photoconductivity in Nematic State. The stady-state photocurrent was reached in a few minutes when a cell was irradiated. Although the photocurrent in the crystal state obeyed Ohm's law, that in the nematic state showed a very complicated dependence on the field, as shown in Fig. 3. After reaching a maximum, the photocurrent decreased and then levelled off with an increasing field. At present, we have no explanation for this behavior; therefore, we restricted the experiments to the low-field range where the photocurrent increased roughly linearly with an increasing field. The photocurrent was roughly proportional to the light intensity and was observed in the spectral region of DBAF, as shown in Fig. 4, indicating that the photocurrent is caused by the light absorption of DBAF itself. The photocurrent increased step-by-step by a factor of 100 at the crystal-nematic phase transition, and it was almost independent of the temperature in the nematic state.

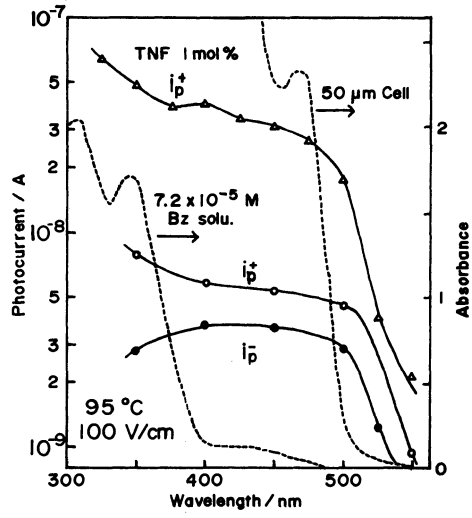

Fig. 4. Spectral dependence of the photocurrent and the absorption spectra.
Light intensity was 1×10^{15} photons/cm² s. The dotted lines were the absorption spectra of the benzene solution and of a cell of 50 μm thickness. —○—, —●—: An undoped cell, —△—: a cell doped with 1 mol% of TNF.

Although nematic MBBA did not show the photocurrent, the nematic mixtures of MBBA containing more than 10 mol% of DBAF showed the photocurrent in the absorption region of DBAF. The photocurrent increased appreciably with an increase in the DBAF content, but it was too small to be measured in detail. More detailed measurements were done for the pulse photoconduction induced by a N_2 gas laser and will be reported elsewhere.[11]

DBAF formed a charge-transfer complex with a strong electron acceptor. 2,4,7-Trinitro-9-fluorenone (TNF) was chosen as an acceptor, because it was fairly soluble in the nematic phase of DBAF. The complex of DBAF with TNF showed a charge-transfer absorption band at 485 nm in a dichloroethane solution. Doping with TNF by 1—5 mol% enhanced the photocurrent for the positive-electrode illumination (abbreviated as i_p^+) by a factor of 4—10, as shown in Figs. 3 and 4, while it hardly changed either the dark current or the photocurrent for the negative-electrode illumination (i_p^-).

The following photocarrier-generation process for nematic DBAF and its mixture with MBBA is suggested from the results presented above, with reference to the processes previously proposed for aromatic molecules in solutions[12,13] and in amorphous films.[14] In the first step, DBAF molecules absorb light, creating a molecular excited state. An excited DBAF molecule can react with either the electrode or an electron acceptor molecule, such as TNF and O_2, to give the original photocarriers. The original photocarrier species may thus be supposed to be the cation radical of DBAF and the anion radical of either DBAF or an electron

acceptor. The nature of the carrier-transport process (ionic diffusion or electronic hopping) in the photoconduction is still in question and so is under investigation.[11]

Synopsis. The complexation of 18-crown-6 with primary ammonium chlorides [$H(CH_2)_nNH_3Cl$, $n=0$, 1, 2, and 4] caused an increase in volume, which was attributable to the dehydration of the ammonium moieties. On the other hand, the apparent molal volumes of $(CH_3)_{4-n}NH_nCl$ ($n=0$—2) were not affected appreciably by the presence of the crown ether, and their complex stability seemed to be insignificant.

A positive change in volume was found for the formation of aqueous complexes between crown ethers and metallic cations, and this increase was attributed to the partial dehydration of the guest ions.[1,2] The volumetric behavior of several ammonium chlorides was investigated in aqueous 18-crown-6 solutions in order to obtain information about the change in the dissolution state of these solutes during complexation.

Experimental

The following chemicals were obtained from the indicated suppliers: NH_4Cl (99%), CH_3NH_3Cl (99%), $(CH_3)_2NH_2Cl$ (99%), $(CH_3)_3NHCl$ (98%), $(CH_3)_4NCl$ (99%) (Nakarai Chemicals); $C_2H_5NH_3Cl$ (99%), n-$C_4H_9NH_3Cl$ (99%) (Tokyo Chemical Industry Co.); 18-crown-6 (99%) (Aldrich Chemical Co. and Nippon Soda Co.). The NH_4Cl, the CH_3NH_3Cl, and the other salts were recrystallized twice from ethanol–water, ethanol–methanol, and ethanol–acetone mixtures respectively and dried under a vacuum at 50—55 °C for 24 h. The 18-crown-6 was dissolved in acetonitrile, and the resultant adduct was precipitated from the solution by cooling in an ice–acetone bath.[3] The weakly bound acetonitrile was removed under a vacuum at 30—35 °C for 24 h. The purified product had a melting point of 39.2—40.5 °C, in satisfactory agreement with the literature values of 39—40 °C[4] and 39.5—40.5 °C.[5] The water was distilled and deionized before use.

The solution densities were measured at 25.00±0.002 °C on an Anton Paar densimeter, Model 60/601, with an accuracy of $\pm 2\times10^{-6}$ g cm^{-3}. Each set of measurements was made on condition that X_w (see below) was maintained constant. The apparent molal volumes (ϕ_v) were calculated from the following equation:

$$\phi_v = (d_0-d)/mdd_0X_w + M/d,$$

where M is the molecular weight of an ammonium salt; m, its molality; X_w, the weight fraction of water in a binary solution consisting of water and crown ether; d_0, the density of this binary solution or that of pure water when $X_w=1$, and d, the density of a ternary solution prepared by the addition of the ammonium salt to the binary solution, the weight fraction of water of which is X_w.

Results and Discussion

The ϕ_v values of alkylammonium chlorides in water were fitted into the Redlich-Meyer equation:

$$\phi_v = \bar{V}^\circ + S_v\sqrt{c} + b_vc,$$

where $\bar{V}^\circ$ is the limiting partial molal volumes of the salts; c, the molar concentration; S_v, the Debye-Hückel limiting slope, and b_v, an empirical constant. The values of $\bar{V}^\circ$/cm^3 mol^{-1} and b_v/cm^3 dm^3 mol^{-2} thus obtained were 53.87 and -0.4_0, 72.43 and -1.0_8, 90.62 and -0.9_3, 107.51 and -1.6_6, 71.24 and -0.9_1, and 103.39 and -1.8_7 for CH_3NH_3Cl, $(CH_3)_2NH_2Cl$, $(CH_3)_3NHCl$, $(CH_3)_4NCl$, $C_2H_5NH_3Cl$, and n-$C_4H_9NH_3Cl$ respectively. These values were in excellent agreement with other reported values.[6,7] The ϕ_v values of NH_4Cl in water were taken from the data in the literature.[8] The ϕ_v of 18-crown-6 in water (ϕ_{CR}) was given by:

$$\phi_{CR}/\text{cm}^3\,\text{mol}^{-1} = 223.26 - 2.9_4\, m_{CR}/\text{mol kg}^{-1},$$

where m_{CR} is the molality of 18-crown-6.

As is shown in Fig. 1, the presence of the crown ether causes a large increase in ϕ_v. Similar results were obtained for the ϕ_v of methylammonium, ethylammonium, and butylammonium chlorides. In contrast, the ϕ_v of NH_4Cl was hardly affected by the presence of triethylene glycol dimethyl ether, in which system the complex formation need not be considered. These findings lead to the conclusion that the complexation between the cations and the crown ether causes a volume increase, the origin of which will be discussed below.

For this purpose, the ϕ_v of the complex ($\phi_{complex}$) should be estimated. In ternary solutions of water, ammonium or alkylammonium chloride (MCl), and crown ether (CR), the following equilibrium exists:

$$M^+ + Cl^- + CR \rightleftharpoons [M\cdot CR]^+ + Cl^-.^{9)}$$

The apparent molal volumes determined therefore contain a contribution from the complexed species. The $\phi_{complex}$ was estimated on the basis of the additivity of the apparent molal volumes:

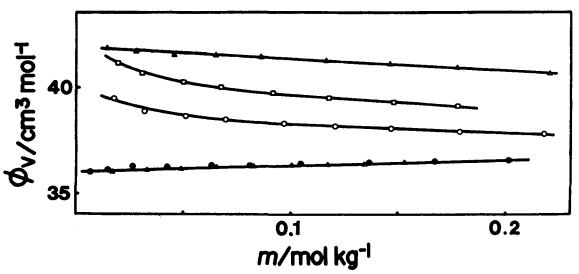

Fig. 1. Apparent molal volumes of NH_4Cl against its molality at 25 °C.
▲: In water, ○, □, and △: in 0.04996, 0.09085, and 0.2112 mol kg^{-1} aqueous 18-crown-6 solutions, respectively, ●: in 0.04915 mol kg^{-1} aqueous triethylene glycol dimethyl ether solution.

Table 1. Volume increase for the formation of 18-crown-6 complexes

Guest molecule	NH_4Cl	CH_3NH_3Cl	$CH_3CH_2NH_3Cl$	$CH_3(CH_2)_3NH_3Cl$	$CH_3(CH_2)_5NH_3Cl$[a]
ΔV/cm^3 mol^{-1}	6.9	2.4	2.5	2.9	3.1

a) Ref. 16.

$$(m_{MCl}+m_{CR})\Phi_v = m_{MCl}(1-\alpha)\phi_{MCl} + (m_{CR}-\alpha m_{MCl})\phi_{CR} + \alpha m_{MCl}\phi_{complex},$$

in which Φ_v is the mean apparent molal volumes of ternary solutions, m_{MCl} and m_{CR} are the total concentrations (including the complexed species) of MCl and CR in the ternary solutions respectively, ϕ_{MCl} and ϕ_{CR} are the apparent molal volumes of the solute species in water at the ionic strength of m_{MCl}, and α is the fraction of MCl in the complexed state. The values of α were calculated from the reported values of stability constants.[10] The $\phi_{complex}$ was evaluated on the additional assumption that the ϕ_{CR} does not depend on the ionic strength in solutions. Since the $\phi_{complex}$ thus obtained had a slight dependence on the ionic strength and the concentration of the crown ether, the partial molal volume at an infinite dilution ($\bar{V}^\circ_{complex}$) was determined by the extrapolation of $\phi_{complex}$ to $\sqrt{m_{MCl}}=0$ and $m_{CR}=0$. Table 1 tabulates the changes in volume for the complex formation, $\Delta V=\bar{V}^\circ_{complex}-(\bar{V}^\circ_{MCl}+\bar{V}^\circ_{CR})$.

The conventional heavy-atom technique has revealed the crystal structure of the 18-crown-6–NH_4Br complex, in which the ammonium cation is too large to fit into the cavity of the crown ether and the nitrogen atom makes three hydrogen bondings through its hydrogen atoms with the three oxygen atoms of the crown ether. Presumably a similar structure holds for the complex in solutions; this also seems to be the case for the primary alkylammonium ion complexes under investigation, as has been generally accepted on the basis of the examination of the CPK molecular models of possible complexes.[12,13] It is highly possible that the dense structure of water molecules electrostricted around the ammonium moieties is released during complexation because of the hydrogen bonding between the host and guest molecules. This process should, therefore, be accompanied by an increase in volume. A volume change caused by the dehydration of ions can be evaluated from their intrinsic and partial molal volumes.[14] For an ammonium ion was obtained an increase of 7.5 cm^3 mol^{-1}, which is comparable to the ΔV value in Table 1. This indicates that the main contribution to ΔV is the removal of water molecules from around the ammonium ion on complexation, although it is still possible for the complexed ion to contact water in the direction perpendicular to the plane of the crown-ether ring. The effect of the crown ether itself on ΔV is, though still obscure, probably small.

The substitution of a CH_3 group for H on NH_4^+ leads to a marked decrease in ΔV values. The hydrophobic residue, because of its bulkiness, occupies a volume where, in the case of the formation of the 18-crown-6 complex with NH_4^+, some water molecules to be dehydrated are located, thus leading to a decrease in ΔV. An alternative or an additional reason is that the water to be released from near the CH_3 group is not so dense as the electrostricted molecules. A similar situation is to be expected for the complex formation of the other *n*-alkylammonium ions, so nearly the same values of ΔV were obtained.

In contrast to the volumetric behavior of primary ammonium salts, only a slight decrease was found for the ϕ_v values of dimethylammonium, trimethylammonium, and tetramethylammonium ions in the presence of the crown ether. This finding suggests the insignificant stability of complexes with these cations,[15] for which the reduction in the number of hydrogen bondings available for the host-guest interaction may be responsible.

The authors wish to thank Masao Sakurai of Hokkaido University for his valuable discussions on the subject of this paper.

Reduction of Macrocyclic Cobalt(III) Complex Photosensitized by Tris(2,2′-bipyridine)ruthenium(II)

Yoshimi KURIMURA* and Emiko ENDO
Department of Chemistry, Ibaraki University, Mito, Ibaraki 310

(Received May 2, 1983)

Synopsis. The photosensitized reduction of macrocyclic cobalt(III) complex, $[Co(N_4)(OH_2)_2]^{3+}$ (N_4=Me_6[14]-4,11-dieneN$_4$), occurs rapidly in an anaerobic $[Ru(bpy)_3]^{2+}$/$[Co(N_4)(OH_2)_2]^{3+}$/triethanolamine solution. The mechanistic implications of the photosensitized reaction are discussed.

Several studies have been carried out on the electron-transfer quenching of the excited state of $[Ru(bpy)_3]^{2+}$ (bpy=2,2′-bipyridine), $*[Ru(bpy)_3]^{2+}$, by several quenchers.[1] However, very little attention[2] seems to have been paid to the "net" reduction of the metal complex which gives the product having a potentially high redox power and reversible redox property. It may be important to find efficient charge-separation systems as a prototype model for solar energy conversion.

In this paper the $[Ru(bpy)_3]^{2+}$ photosensitized reduction of macrocyclic cobalt(III) complex is described.

Experimental

$[Ru(bpy)_3]Cl_2\cdot 6H_2O$[3] and $[Co(N_4)(OH_2)_2](ClO_4)_3$[4] ($N_4$= 5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradeca-4,11-diene which is usually abbreviated as Me_6[14]4,11-dieneN$_4$) were synthesized in a manner similar to that described elsewhere. Reactant solutions of the cobalt(III) complex were prepared under nitrogen atmosphere shortly before use. Solution of the reduced species of the cobalt(III) complex, $[Co(N_4)(OH_2)_2]^{2+}$, was prepared by the reduction of the cobalt(III) complex by excess of ascorbate in an anaerobic solution at pH 6. The hydrogen ion concentration in the reactant solutions was adjusted using dilute perchloric acid and/or dilute sodium hydroxide solution without buffer reagents because the absorption spectra of the cobalt(III) and cobalt(II) complexes were found to be affected by both the pH and the concentration of the dissolved salts such as acetate and phosphate. Acid dissociation constants of $[Co(N_4)(OH_2)_2]^{3+}$ were determined by pH titration using a Hitachi-Horiba Model F-5 pH meter. Steady state irradiation was carried out using 150-W slide projector with UV cut-off filter (Kenko Skylight L-40, UV). The solution in the photometer cell (10 mm × 10 mm) in a cell holder (25±0.2 °C) was deoxygenated by introducing pure nitrogen prior to the photolysis. Development of the photoproduct was monitored by taking absorption spectra on Hitachi Model 320 spectrophotometer. Comparison measurements were carried out on the same day.

Results and Discussion

The acid dissociation constants of $[Co(N_4)(OH_2)_2]^{3+}$ defined by $K_1=[Co(N_4)(OH_2)(OH)^{2+}][H^+]/[Co(N_4)(OH_2)_2{}^{3+}]$ and $K_2=[Co(N_4)(OH)_2{}^+][H^+]/[Co(N_4)(OH_2)(OH)^{2+}]$ were determined to be $10^{-3.95}$ and $10^{-8.85}$ respectively (μ=0.3, 25 °C). The molar absorptivity (ε) of $[Co(N_4)(OH_2)_2]^{2+}$ was determined from the slope of the straight line of the absorbance *vs.* $[Co^{II}]$ plot: λ_{max} 442 nm (ε=78 M^{-1} cm^{-1}, 1 M=1 mol dm^{-3}) at pH 6.3.

The photosensitized reduction of the cobalt(III) complex was carried out at pH 6.3 and μ=0.25 ($NaClO_4$), At this pH, predominant cobalt(III) species and the donor species are $[Co(N_4)(OH_2)(OH)]^{2+}$ (*ca.* above 99%) and the monoprotonated species of triethanolamine (above *ca.* 98%, pK_a 7.90[5]) respectively. A typical example of the spectral change (Fig. 1) shows an increase in the absorption band intensity due to the cobalt(II) complex (λ_{max} 442 nm) with the irradiation time. The concentration of the cobalt(II) in the irradiated solution was determined using an equation: $[Co^{II}]=(A_0-A_t)/(\varepsilon_3-\varepsilon_2)$ where A_0 is the absorbance at time 0, A_t, that at time t, and ε_3 (46 M^{-1} cm^{-1}) and ε_2 (16 M^{-1} cm^{-1}) are the molar absoptivities of the cobalt(III) and cobalt(II) complexes respectively at 530 nm. The reduction rates of the cobalt(III) were determined from the slopes of $[Co^{II}]$ *vs.* irradiation time plots in the initial stages. A plot of the reduction rate *vs.* [TEOA] (TEOA=triethanolamine) showed that the rate almost levelled at above 2×10^{-2} M TEOA. It was also found that the rate increases as $[Co^{III}]$ increases ($[Co^{III}]\lesssim 7.0\times10^{-3}$ M).

The main feature of the photosensensitized reduction of the cobalt(III) complex are rationalized by Eqs. 1—5:

$$[Ru(bpy)_3]^{2+} \xrightarrow{h\nu} *[Ru(bpy)_3]^{2+}, \quad (1)$$

$$*[Ru(bpy)_3]^{2+} \xrightarrow{k_2} [Ru(bpy)_3]^{2+} + h\nu' + \Delta, \quad (2)$$

$$*[Ru(bpy)_3]^{2+} + [Co(N_4)(OH_2)(OH)]^{2+} \xrightarrow{k_3} [Ru(bpy)_3]^{3+} + Co^{II}, \quad (3)$$

$$[Ru(bpy)_3]^{3+} + Co^{II} \xrightarrow{k_4} [Ru(bpy)_3]^{2+} + [Co(N_4)(OH_2)(OH)]^{2+}, \quad (4)$$

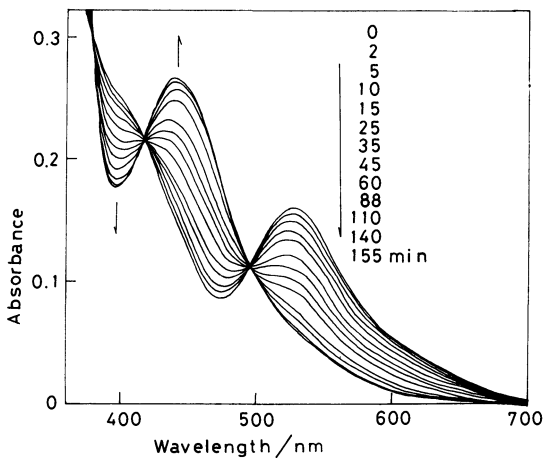

Fig. 1. Spectral change of the solution containing 2.0×10^{-5} M $[Ru(bpy)_3]^{2+}$, 3.0×10^{-3} M $[Co(N_4)(OH_2)_2]^{2+}$, and 0.10 M TEOA at pH 6.3, μ=0.25, and 25 °C. Reference: 2.0×10^{-5} M $[Ru(bpy)_3]^{2+}$.

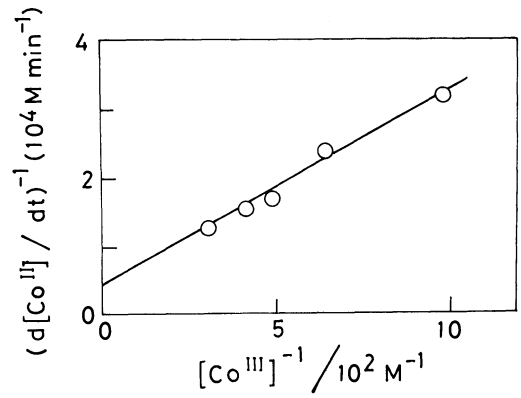

Fig. 2. A plot of $(d[Co^{II}(N_4)]/dt)^{-1}$ *vs.* $([Co(N_4)(OH_2)(OH)]^{2+})^{-1}$. 2.0×10^{-5} M $[Ru(bpy)_3]^{2+}$, 0.10 M TEOA

$$[Ru(bpy)_3]^{3+} + TEOA \xrightarrow{k_5} [Ru(bpy)_3]^{2+} + TEOA_{ox}, \quad (5)$$

where $TEOA_{ox}$ is the oxidized species of TEOA.

The rate equation resulting from this mechanism, assuming a steady-state concentrations for $*[Ru(bpy)_3]^{2+}$ and $[Ru(bpy)_3]^{3+}$, is given by

$$\frac{d[Co^{II}]}{dt} = \left(\frac{\phi I_{abs} k_3[Co^{III}]}{k_2+k_3[Co^{III}]}\right)\left(\frac{k_5[TEOA]}{k_4[Co^{II}]+k_5[TEOA]}\right), \quad (6)$$

where ϕ is the quantum yield for generation of cobalt(II); I_{abs}, the light intensity absorbed by $[Ru(bpy)_3]^{2+}$ in the system; k_2, k_3, k_4, and k_5 are the rate constants for the corresponding reactions. The rate constant k_3 is given by $k_3=k_qF$ where k_q is the rate constant for the quenching of $*[Ru(bpy)_3]^{2+}$ by $[Co(N_4)(OH_2)(OH)]^{2+}$ and F, a portion of the reduction of the cobalt(III) in the quenching process. It may be resonable to assume that $F=1$[6] and $k_4\,[Co^{II}] \ll k_5[TEOA]$[8] for a sufficient excess of TEOA and at the initial stage of the reaction. Thus, we obtain

$$\frac{d[Co^{II}]}{dt} = \frac{\phi I_{abs} k_3[Co^{III}]}{k_2+k_3[Co^{III}]}, \quad (7)$$

which after rearrangement will give

$$\left\{\frac{d[Co^{II}]}{dt}\right\}^{-1} = \frac{1}{\phi I_{abs}}\left(1+\frac{k_2}{k_3[Co^{III}]}\right). \quad (8)$$

A plot of $(d[Co^{II}]/dt)^{-1}$ *vs.* $[Co^{III}]^{-1}$ gives a straight line (Fig. 2). The value of k_2/k_3 ($=6.1\times10^{-3}$ M) can be calculated from the slope/intercept value of the plot. Using $k_2=1.7\times10^6$ s^{-1},[1a] we obtain $k_3=2.7\times10^8$ M^{-1} s^{-1}.

When the irradiated solution (2.0×10^{-5} M $[Ru(bpy)_3]^{2+}$], 3.0×10^{-3} M cobalt(III), 0.10 M TEOA, 50 min) was flushed with oxygen, the resulting spectrum became similar to that of the initial solution, suggesting that the cobalt(II) species generated by the irradiation were reoxidized to the initial species. Such a complex as $[Co(N_4)(OH_2)_2]^{3+}$ having a reversible redox property and relatively high reducing power may be important for making efficient charge separation system for solar energy conversion.

8) Under the conditions employed (2.0×10^{-5} M $[Ru(bpy)_3]^{2+}$, 3.0×10^{-3} M cobalt(III), and 0.10 M TEOA), the "back-reaction" may be ignored because the curve for the plot of the rate *vs.* [TEOA] levels off above *ca.* 0.05 M TEOA.

^{57}Fe Spin-lattice Relaxation Time of $Fe(CO)_5$ and Ferrocene

(Received May 30, 1983)

Synopsis. Spin-lattice relaxation times (T_1's) of ^{57}Fe were determined by the inversion recovery method to be 80 ($\pm$10) s at 293 K and 4 ($\pm$1) s at 303 K for $Fe(CO)_5$ and ferrocene, respectively. Predominant relaxation mechanisms were considered to be chemical shift anisotropy and spin-rotation for the former and the latter complexes, respectively.

Although chemical shifts of ^{57}Fe NMR of many iron complexes have been determined by a combination of pulse FT techniques with large sample tubes and a high magnetic field,[1] little has been known about the relaxation processes, which are important to understand the molecular dynamics of the complexes. ^{57}Fe nucleus with nuclear spin of one half and low natural abundance was believed to have a long relaxation time. Recently we have succeeded in determining the spin-lattice relaxation times of $Fe(CO)_5$ (pentacarbonyliron(0)), and ferrocene (bis(η-cyclopentadienyl)iron(II)). The relaxation time of ferrocene was fairly short as compared with that of $Fe(CO)_5$. Possible relaxation mechanisms to explain these results are discussed.

Experimental

Materials. $Fe(CO)_5$ was purchased from Strem Chemicals, Inc. Ferrocene was obtained from Wako Chemicals, Inc. as a guaranteed grade reagent and purified by recrystallization from benzene. Benzene-d_6 was purchased from E. Merck Japan Ltd.

Measurements. The NMR spectra of ^{57}Fe were measured with a Bruker CXP-300 FT-NMR spectrometer. The static field $B_0=7.05$ T (corresponding to a 300 MHz proton Larmor frequency) gave resonance frequencies around 9.7 MHz for the ^{57}Fe nuclei, and was internally locked on a ^2H signal of solvent, except for $Fe(CO)_5$ which was measured as neat liquid without lock. The 90° pulse width was determined to be 180 μs, which afforded a H_1 field of 10.1×10^{-4} T. A Bruker temperature controller (B-VT-1000) was employed and calibrated by measuring the proton frequency differences between the resonances of ethyl alcohol.[2] The NMR spectra of ^{57}Fe for neat $Fe(CO)_5$ and ferrocene in benzene-d_6 solution (1 mol dm^{-3}) were measured at 293 and 303 K at its natural abundance with a sample tube of 15 mm diameter. The ferrocene solution was degassed before the NMR measurements.

Results and Discussion

$Fe(CO)_5$ and ferrocene gave NMR signals at 9.71568 and 9.73056 MHz, respectively. The ratios of these values to the resonance frequency of $GeCl_4$ (ν(Fe)/ν(Ge)) were 0.928155 and 0.929576 which coincide well with the values in the reference,[1] 0.92815542 and 0.9295803. The half linewidths of the NMR signals were 1.0 and 2.6 Hz for $Fe(CO)_5$ and ferrocene, respectively.

Measurements of spin-lattice relaxation times were achieved by the inversion recovery method combined with a Fourier transform (IRFT). Since the spin-lattice relaxation time, T_1, for the ^{57}Fe NMR of $Fe(CO)_5$ was expected to be around 100 s, the recycle time was taken to be 800 s. The results are shown in Fig. 1. The plot of $-\ln((A_\infty-A_\tau)/2A_\infty)$ *versus* τ, where A_τ and A_∞ are the amplitude of the NMR signal partially relaxed for an inter-pulse time τ, and the amplitude at thermal equilibrium, yielded a T_1 value of 80 ($\pm$10) s.

The partially relaxed NMR spectra for ferrocene in benzene-d_6 solution are shown in Fig. 2. The plot of $-\ln((A_\infty-A_\tau)/2A_\infty)$ *versus* τ gave a T_1 value of 4 ($\pm$1) s.

Since no abundant spin is present in $Fe(CO)_5$, the only possible ways of relaxation are the spin-rotation and/or the chemical shift anisotropy mechanism.[3] Hence, it is reasonable for the system to have a spin-lattice relaxation time as long as 80 s.

Ferrocene in benzene-d_6 solution had a spin-lattice relaxation time much shorter than that of $Fe(CO)_5$, the reasons for this are now discussed.

In order to determine the rotational correlation time of ferrocene, the spin-lattice relaxation time of the ^{13}C nucleus of ferrocene was measured for the same solution for which the T_1 values of the ^{57}Fe nucleus had been determined. The T_1 values for the ^{13}C nucleus of ferrocene were 12.3 and 10.0 s at 303 and 293 K, respectively, which are in reasonable agreement with the reference values[4] (14.3 s at 311 K). The ^{13}C nucleus directly bound with one or more proton(s) is relaxed predominantly through the dipolar mechanism.[5] Hence the ^{13}C nucleus of ferrocene is presumed to be relaxed by

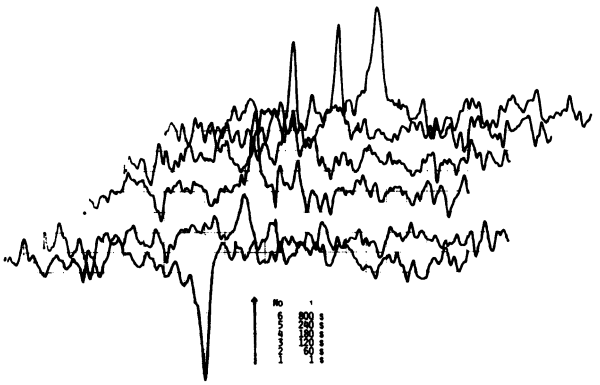

Fig. 1. The partially relaxed ^{57}Fe NMR spectra for $Fe(CO)_5$. The duration of 90° pulse was 180 μs at a transmitter gain with peak to peak voltage of 200 V. The recycle time was 800 s. The inter-pulse time (τ) values were 1, 60, 120, 180, 240, and 800 s from the bottom to the top spectra. Sweep width: 100 Hz, memory size: 8×10^3 words, line-broadening: 1 Hz, number of transients: 52, temperature: 293 K.

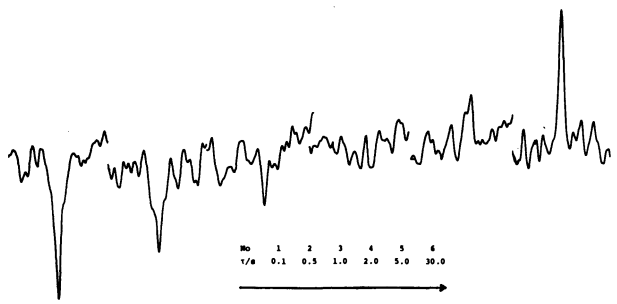

Fig. 2. The partially relaxed ^{57}Fe NMR spectra for ferrocene in benzene-d_6 solution (1 mol dm^{-3}). The duration of 90° pulse was 180 μs at a transmitter gain with peak to peak voltage of 200 V. The recycle time was 30 s. The inter-pulse time (τ) values were 0.1, 0.5, 1.0, 2.0, 5.0, and 30 s. Sweep width: 150 Hz, memory size: 8×10^3 words, linebroadening: 1 Hz, number of transients: 520, temperature: 303 K.

the dipole (^{57}Fe) and dipole (^{1}H) interaction mechanisms. The spin-lattice relaxation time for the dipolar interaction mechanism, T_1^{dd}, for a nucleus I being relaxed by a nucleus S under the extreme narrowing conditions can be written as[6]

$$1/T_1^{dd} = (\mu_0^2\gamma_I^2\gamma_S^2\hbar^2/12\pi^2)S(S+1)\Sigma(1/r^6)\tau_r, \quad (1)$$

where μ_0, γ, S, r, and τ_r are magnetic permeability in vacuum, magnetogyric ratio, spin quantum number for the nucleus S, distance between the nuclei I and S, and a rotational correlation time, respectively. Taking the above experimental T_1 value as the T_1^{dd}, and using Eq. 1 and the bond distance (1.095 Å) between ^{13}C and ^{1}H,[7] we can calculate the rotational correlation time, τ_r, to be 3.0×10^{-12} s at 303 K. Under the assumption that the ^{57}Fe nucleus of ferrocene has a rotational correlation time similar to that for the ^{13}C nucleus, and that the ^{57}Fe nucleus is relaxed by the dipolar mechanism, the spin-lattice relaxation time of the ^{57}Fe nucleus was calculated to be 2.2×10^4 s from Eq. 1 and the structure of ferrocene.[7] This value, which is far from the experimentally observed one (4 s), therefore, indicates that other relaxation mechanisms should be considered for the relaxation of the ^{57}Fe nucleus in ferrocene.

The spin-lattice relaxation time for the chemical shift anisotropy mechanism (T_1^{CA}) can be expressed by

$$1/T_1^{CA} = (2/15)\gamma_I^2H_0^2\Delta\sigma^2\tau_r, \quad (2)$$

under the extreme narrowing condition.[8] The chemical shift anisotropy ($\Delta\sigma$) necessary to explain the observed T_1 value (4 s) was calculated to be 2.0×10^4 ppm, under the assumption that the rotational correlation time, τ_r, for the ^{57}Fe nucleus is similar to that determined for the ^{13}C nucleus. This value appears to be one order of magnitude too large as compared with $\Delta\sigma$ values experimentally determined for other metallocenes (*e.g.*, 6400 ppm for $[Co^{III}(C_5H_5)_2]NO_3$[9]). Therefore the relaxation of the ^{57}Fe nucleus in ferrocene can not be explained by the chemical shift anisotropy mechanism only. Accordingly another relaxation mechanism, *i.e.*, spin-rotation mechanism, will play an important role in the relaxation of ^{57}Fe nucleus. The temperature dependence of the ^{57}Fe relaxation time of ferrocene which showed a longer value at lower temperature (5 s at 293 K) supported this conclusion.[7]

For the relaxation of the ^{13}C nucleus of $Fe(CO)_5$, it was reported that the chemical shift anisotropy was the predominant mechanism and that the rotational correlation time τ_r was 5×10^{-12} s at 293 K.[3] By use of this correlation time for the ^{57}Fe nuclei of $Fe(CO)_5$, the chemical shift anisotropy necessary to explain the experimental T_1 value (80 s) was calculated to be 4000 ppm from Eq. 2. Although this value is somewhat larger than that observed for other metal carbonyls ($\Delta\sigma=1400$ ppm for $[Mn(CO)_5Cl]$[10]), the chemical shift anisotropy mechanism will be predominant in the relaxation for the ^{57}Fe NMR of $Fe(CO)_5$.

This work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture, and by a grant from Nissan Science Foundation to M. H.

Effects of the Oxyethylene Chain Length of Fluorocarbon Surfactants on Demixing of Micelles of Fluorocarbon and Hydrocarbon Surfactants

Noriaki FUNASAKI,* Sakae HADA, and Saburo NEYA
Kyoto College of Pharmacy, Yamashina-ku, Kyoto 607
(Received July 4, 1983)

Synopsis. The critical mole fraction of hydrocarbon surfactant decreases with an increase in the oxyethylene unit of either fluorocarbon surfactant or hydrocarbon surfactant. This tendency is explicable in terms of regular solution theory if the depth of water penetration into the micellar interior is assumed to increase with an increase in the oxyethylene unit.

Under certain conditions, fluorocarbon and hydrocarbon surfactants are partially miscible in their mixed micelles, forming two kinds of mixed micelles with different compositions.[1] We reported the effects of hydrophobic and hydrophilic groups of hydrocarbon surfactant on the critical solution points of such micellar systems.[2]

According to regular solution theory, the critical mole fraction x_{cH} of the binary liquid system consisting of the nonpolar compounds, F and H, can be written as[3]

$$x_{cH} = [1-(1-q+q^2)^{1/2}]/(1-q), \quad (1)$$

where q is the ratio of molar volumes, *viz.* v_F/v_H. When we attempt to apply Eq. 1 to a mixed micelle, there is still an uncertainty as to volumes to be employed; the total molar volume or the molar volume of the hydrophobic group. To solve this problem, we investigate the effect of fluorocarbon surfactants on the critical solution points.

Experimental

The nonionic fluorocarbon surfactant, NFE7 ($[(CF_3)_2CF]_2C=C(CF_3)O(CH_2CH_2O)_nCH_3$, averaged $n=7$), was donated by Neos Company. This specimen is not homogeneous with respect to oxyethylene units. The nonionic hydrocarbon surfactant, heptaethylene glycol monododecyl ether (DE7), was obtained from Nikko Chemicals as at least 99% pure. The detail of surface tension measurements has been reported elsewhere.[2]

Results and Discussion

The surface tension method was used to determine the mutual solubility in micelles. In Fig. 1a, the surface tension of aqueous solutions of mixed NFE7 and DE7 is plotted against the mole fraction x_H of DE7 in the whole system. The total surfactant concentration is in a range of 1 to 1.3 mmol dm^{-3}, which is much higher than the critical micelle concentrations (cmc) of NFE7 and DE7, *viz.* 0.025 and 0.08 mmol dm^{-3}. These cmc values of NFE7 and DE7 decreased slightly with rising temperature. The cmc's of their mixtures are slightly larger than predictions from ideal mixing of these surfactants. Under these conditions, therefore, almost all of the surfactant molecules added form micelles and consequently the composition of the surfactants added is very close to that of micellized surfactants.

In the plateau region of the surface tension *vs.* composition curve, two kinds of mixed micelles coexist in a solution.[2] From two limits of this plateau region, we can determine mutual solubilities in the micelles. Further we can determine the solubility-temperature diagram for the NFE7 and DE7 system from Fig. 1a. This kind of diagram represents a coexistence curve for the comicellar system similar to that of the binary liquid system. In Fig. 1b, the coexistence curve of mixed micelles of DE7 and NFE18 is included for comparison. From a coexistence curve and the locus of its midpoints, we can determine the critical composition x_{cH} and the critical solution temperature T_c. Thus, from Fig. 1b, we obtained the values of x_{cH} and T_c for the NFE18–DE7 and NEF7–DE7 systems. In Table 1, these values are shown together with those of other systems.[2]

In Table 1, NFE18 ($[(CF_3)_2CF]_2C=C(CF_3)O(CH_2CH_2O)_{18}CH_3$) and DE9 (nonaethylene glycol monododecyl ether) are not homogeneous samples with respect to oxyethylene units but DE5 (pentaethylene glycol monododecyl ether) is homogeneous (99%). The T_c value is found to decrease with an increase in the oxyethylene unit of either fluorocarbon surfactant or hydrocarbon surfactant (Table 1). Further, it is noted that this T_c decreasing (solubility increasing) ability of an oxyethylene unit of NFE is greater than that of DE. As is evident from comparison of the NFE7–DE7 and NFE18–DE7 systems, x_{cH} decreases with an increase in the oxyethylene unit of NFE.

From Eq. 1, we can calculate the critical mole fraction

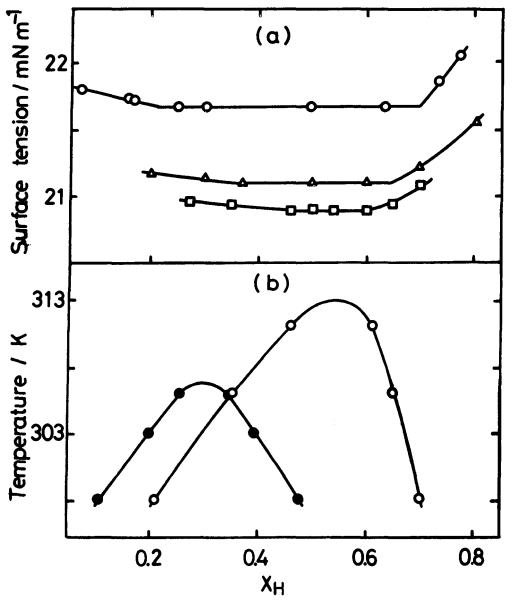

Fig. 1. (a) Surface tensions of aqueous solutions of mixed NFE7 and DE7 as a function of the mole fraction of DE7 at three temperatures (K): ○, 298.2; △, 303.2; □, 311.2. (b) Coexistence curves of two kinds of mixed micelles for the NFE7–DE7 (○) and NFE18–DE7 (●) systems.

Table 1. Observed x_{cH} and T_c and calculated x_{cH} by using different v's

System	Observed		Calculated x_{cH}		
	x_{cH}	T_c/K	v_t	v_α	v_β
NFE7–DE7	0.550	313.3	0.530	0.527	0.499
NFE18–DE5	0.506	310.3	0.774	0.527	0.499
NFE18–DE7	0.300	307.0	0.731	0.527	0.499
NFE18–DE9	0.283	299.2	0.689	0.527	0.499

of hydrocarbon surfactant by employing the different molar volumes; v_t, v_α, and v_β. The v_t denotes the total molar volume of a surfactant. The demixing of micelles of fluorocarbon and hydrocarbon surfactants is ascribed mainly to the interaction of fluorocarbon and hydrocarbon chains in the micelle. Therefore, the molar volume of the hydrophobic group, v_t, may be used instead of v_α. However, water may penetrate into the micellar interior; the number of wet carbon atoms adjacent to a hydrophilic group may be zero,[4] one or two,[5] or several.[6] If water penetrates into the micellar interior up to the α-carbon atom of the hydrophobic group, then the molar volume of the dry hydrophobic group from β- through ω-carbon atoms, v_β, must be used for v_α. Molar volumes v_t, v_α, and v_β of NFE7 are estimated from the observed v_t values of NFE18, DE's, and related compounds at 298.2 K, as already made for NFE18 and DE's.[2] We used the following values (cm^3 mol^{-1}); $v_t(DE5)=408.3$, $v_t(DE7)=485.4$, $v_t(DE9)=562.5$, $v_t(NFE7)=526.3$, $v_t(NFE18)=965.8$, $v_\alpha(DE5)=v_\alpha(DE7)=v_\alpha(DE9)=210.9$, $v_\alpha(NFE7)=v_\alpha(NFE18)=226.9$, $v_\beta(DE5)=v_\beta(DE7)=v_\beta(DE9)=194.7$, and $v_\beta(NFE7)=v_\beta(NFE18)=194.3$.

As the number of oxyethylene units of hydrocarbon surfactants increases, keeping the fluorocarbon surfactant (NFE18) constant, x_{cH} decreases. Apart from the direction, the magnitude in this change is inexplicable by using any of v_t, v_α, and v_β. Hence, we proposed a hypothesis which explains this discrepancy in x_{cH} between theory and experiment; we assumed a deeper penetration of water into the micellar interior with an increase in the oxyethylene unit.[2] The present data on the NFE7–DE7 system support this hypothesis. As is evident from Table 1, the x_{cH} value of the NFE18–DE7 system is smaller than that of the NFE7–DE7 system. This contradicts the theoretical results obtained by using any of v_t, v_α, and v_β. As the number of oxyethylene units increases, the surface area per surfactant molecule in the micelle increases and consequently water is likely to penetrate into the micellar interior more deeply. Therefore x_{cH} can decrease with an increase in the oxyethylene unit of fluorocarbon surfactants and this tendency is actually observed. This interpretation is also consistent with the fact that T_c decreases with an increase in the oxyethylene unit of either fluorocarbon surfactant or hydrocarbon surfactant.

Although the depth of water penetration into the micellar interior is still a matter of controversy,[4-6] the level of the α-carbon atom of dodecyl sulfates is most probable, as deduced from small angle neutron scattering.[7] The present results seem to support a shallow water penetration model in which the penetration depth depends on the number of oxyethylene units.

Thanks are due to Neos Company for a sample of NFE7 and to Nikko Chemicals for a sample of DE9.

Preparations and Strucutures of Silver(I) Complexes with *cyclo*(Glcyl-L-histidyl), *cyclo*(L-Methionyl-L-histidyl), and *cyclo*(L-Histidyl-L-histidyl)

Yoshitane KOJIMA,* Tetsushi YAMASHITA, Yoshio ISHINO,† Tsuneaki HIRASHIMA,† and Toshio MIWA

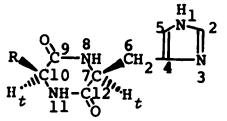
(Received March 14, 1983)

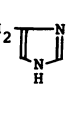
Synopsis. The structures of silver(I) complexes with *cyclo*(glycyl-L-histidyl), *cyclo*(L-methionyl-L-histidyl), and *cyclo*-(L-histidyl-L-histidyl) were examined using ^1H and ^{13}C NMR. The NMR measurements suggest that the silver(I) ion links to the sulfur atom of thioether and the nitrogen atom of imidazole group of the above cyclic peptides, but not to their amide groups.

The present authors have used a copper(II) complex with *cyclo*(L-histidyl-L-histidyl) (**3**) and a silver(I) complex with *cyclo*(L-methionyl-L-methionyl) (**4**) as simple model compounds[1] for studying metalloproteins and metalloenzymes, in which the ligating groups for metal ions are the functional groups of the side chains of peptides, but not the amide groups. In our previous papers,[1] the coordinations of the imidazole (Im) group of histidyl residue to the copper(II) ion and of the thiother group of the methionyl residue to the silver(I) ion were confirmed using ^1H NMR and X-ray crystal analysis. Other workers[2] have investigated the conformations of cyclic dipeptides using NMR and X-ray measurements, and have found that the cyclic dipeptides containing histidine, phenylalanine, and tyrosine prefer a folded form, in which the aromatic ring of the side chain of the peptide lies over 2,5-piperazinedione. This paper will report the preparations and characteristics of silver(I) complexes with cyclic dipeptides containing Im and thioether groups. *cyclo*(Glycyl-L-histidyl) (**1**), *cyclo*-(L-methionyl-L-histidyl) (**2**), and **3** were used as ligands in this experiment.



1: R=H$_c$

2: R=CH$_2$CH$_2$SCH$_3$



Experimental

Materials. **1**,[3] **2**,[4] and **3**[1a] were prepared according to the methods reported earlier. *cyclo*(Glycyl-glycyl)(**5**) and silver(I) salts(perchlorate, nitrate, and hexafluorophosphate) obtained commercially were used without further purification.

Preparations of Silver(I) Complexes. A mixture of **1** (0.50 mmol) and silver(I) perchlorate (0.53 mmol) was completely dissolved in hot water (50 cm^3) with stirring. After standing at room temperature for a few days, the precipitate was filtered off and recrystallized from water. Other complexes were similarly obtained by the procedure described above. Table 1 shows the values of the elemental analyses and melting points of silver(I) complexes with **1**, **2**, and **3**.

Measurements. The ^1H and ^{13}C NMR data of silver(I) complexes and their corresponding ligands were obtained in D_2O at 27, 40, and 50 °C, using sodium 3-trimethylsilyl-1-propanesulfonate as the internal reference. The molecular weights of silver(I) complexes with **1** and **2** were measured in H_2O at 56 °C, using urea as the standard material. JEOL FX-100 and FX-90Q (for ^1H and ^{13}C NMR spectra) apparatuses and a Knauer Vapor-pressure Osmometer (for molecular weight) were used for the measurements of the samples.

Results and Discussion

Table 2 shows the chemical shifts of the protons of ligands and their corresponding silver(I) complex ions. As is shown in Table 2, 10-H$_c$ (δ=3.13) and 10-H$_t$ (δ=3.72) of **1** absorb at a higher field than the methylene proton (δ=4.00) of **5** because of the magnetic shielding effect[2a] of the Im ring, showing that **1** exists as a folded form. The chemical shifts (δ=3.13 and 3.77) of 10-H$_c$ and 10-H$_t$ of [Ag(**1**)$_2$]$^+$(**A-1**) are almost the same as those of **1**, so a preferred form for **A-1** is a folded one. Table 2 also describes how the 13-H (δ=1.05—1.43 and 1.46—1.90) of **2** absorbs at a higher field than the β-methylene (δ=2.10—3.00) of **4**[1b] because of the magnetic anisotropy of the Im ring, indicating that **2** prefers a folded form. Though the peaks of 13-H of **2** are complicated and unresolved, the values of the chemical shifts are used for elucidating the conformation of [Ag(**2**)]$^+$ (**A-2**). The possibility that **A-2** favors a folded form is suggested by the small difference between the chemical shifts of 13-H of **2** and those (δ=1.49—1.97) of **A-2**. The downfield shift ($\Delta\delta$=0.32) of the 14-H and 15-H of **A-2** from **2** supports the coordination of the S atom to the silver(I) ion.[1b] The differences ($\Delta\delta$=0.86 and 0.46) in the chemical shifts of 6-H between **3** and

	2-C	4-C	5-C	6-C	7-C	9-C	10-C	12-C	13-C	14-C	15-C
1[b]	138.8	134.1	120.7	33.8	57.5	171.2	46.0	172.3	—	—	—
A-1[b]	140.9	134.9	120.5	35.0	57.3	171.1	45.9	171.9	—	—	—
	(2.1)	(0.8)	(−0.2)	(1.2)	(−0.2)	(−0.1)	(−0.1)	(−0.4)			
2[b]	138.5	133.8	121.2	33.1	57.6	171.4	56.1	171.9	35.3	30.4	16.7
A-2[b]	140.4	134.9	121.6	33.8	57.6	171.6	55.9	171.6	36.5	33.0	20.0
	(1.9)	(1.1)	(0.4)	(0.7)	(0.0)	(0.2)	(−0.2)	(−0.3)	(1.2)	(2.6)	(3.3)

a) $\Delta\delta$ = δ(Ag(I) complex) − δ(free ligand). b) **1** and **A-1** were measured at 27 °C, while **2** and **A-2** were done at 40 °C.

$[Ag(\mathbf{3})]^+$ (**A-3**) are considerably larger than those ($\Delta\delta$= 0.12—0.15) between **1** and **A-1** or **2** and **A-2**. This distinct downfield shift of **A-3** from **3** suggests that there is no magnetic shielding effect of the Im group, so that **A-3** prefers an unfolded form in which the Im group lies away from the 2,5-piperazinedione. Table 2 suggests that each 1- or 3-N atom of the Im groups of **1**, **2**, and **3** coordinates to the silver(I) ion because the downfield shifts ($\Delta\delta$=0.19, 0.21, and 0.33) of 5-H of **A-1**, **A-2**, and **A-3** from **1**, **2**, and **3**, and those ($\Delta\delta$=0.28, 0.30, and 0.15) of 2-H are observed, respectively.

The ^{13}C NMR data of **1**, **2**, **A-1**, and **A-2** are given in Table 3; those of **3** and **A-3** could not be obtained because of their low solubilities. Table 3 suggests that the 1- or 3-N atom of each Im group of **1** and **2** coordinates to the silver(I) ion, because the downfield shifts ($\Delta\delta$=0.8 or 1.1) of the 4-C of **A-1** or **A-2** from **1** or **2** and those ($\Delta\delta$=2.1 or 1.9) of 2-C are observed. The coordination of the S atom of **2** to the silver(I) ion is also confirmed by the marked downfield shifts ($\Delta\delta$=2.6 and 3.3) of the 14-C and 15-C of **A-2** from **2**. Table 3 indicates that no O atoms of the 2,5-piperazinedione of **1** and **2** coordinates to the silver(I) ion, for no distinct shifts of the 7-C, 9-C, 10-C, and 12-C of **A-1** or **A-2** from **1** or **2** are observed. As is shown in Table 2, this suggestion is also supported by the small shift ($\Delta\delta$=0.09 or −0.04) of the 7-H$_t$ of **A-1** or **A-3** from **1** or **3** and that ($\Delta\delta$=0.05 or 0.07) of the 10-H$_t$ of **A-1** or **A-2** from **1** or **2**.

The molecular weights (300 and 331) for **A-1** and **A-2** show **A-1** as a monomeric form, $[Ag(\mathbf{1})_2]^+ + NO_3^-$ (596/2=298), and **A-2** as a dimeric one, $\{[Ag(\mathbf{2})]_2\}^{2+} + 2ClO_4^-$ (951/3=317). The molecular weight of **A-3** could not be measured because of its extremely low solubility, suggesting that **A-3** prefers a polymeric form.

The results obtained in this paper suggest that the 1- or 3-N atom of the Im group and the S atom of thioether in **2** coordinate linearly to the silver(I) ion. In the cases of **1** and **3**, each silver atom is coordinated linearly to each 1- or 3-N atom of two Im groups.

The authors wish to thank Mr. Junichi Gohda for elemental analyses.

Succinate-complexed Octacalcium Phosphate

Hideki MONMA* and Masaru GOTO
National Institute for Research in Inorganic Materials, 1-1 Namiki, Sakura-mura, Niihari-gun, Ibaraki 305
(Received May 4, 1983)

Synopsis. A succinate-complexed calcium phosphate has been synthesized by conducting the hydrolysis of α-tricalcium bis(phosphate) in the presence of succinate ions. The organic substance is considered to be introduced into the structure of the hydrolysis product, *i.e.*, octacalcium bis(hydrogenphosphate) tetrakis(phosphate) pentahydrate, through the replacement of HPO_4^{2-} by $C_4H_4O_4^{2-}$.

Octacalcium bis(hydrogenphosphate) tetrakis(phosphate) pentahydrate (OCP), $Ca_8(HPO_4)_2(PO_4)_4\cdot 5H_2O$, is, structurally related to hydroxyapatite (HAp) and is a precursor in the formation of HAp in bones, teeth, and urinary calculi. The structure of OCP is composed of alternative stackings of an "apatitic layer" (A-layer) with the composition of $Ca_{12}(PO_4)_8\cdot 2H_2O$ and a "hydrated layer" (B-layer) of $Ca_4(HPO_4)_4\cdot 8H_2O$ which is compositionally the same as brushite ($CaHPO_4\cdot 2H_2O$).[1] HAp and other calcium phosphates have been widely studied in interactions with organic compounds related to biological, biomaterial, and bio-chromatographic problems. According to these studies, various organic substances have been shown to be adsorbed or ion-exchanged on the surface of calcium phosphates, however in one instance there is a possibility that glycine might be introduced into the HAp structure.[2] Generally it would be reasonable to consider that organic molecules or ions are difficult to introduce into calcium phosphates, because of their large size and steric conformations. Here, although the OCP structure is not classified normally into so-called layered compounds consisting of layers bound to each other weakly by van der Waals force or hydrogen bonds, we would expect from structural considerations that OCP must behave more actively towards organic compounds than HAp and other calcium phosphates and might incorporate some organic substances into the B-layer. In this work, we present data supporting the idea that succinate ions can be introduced into the B-layer.

Experimental

Powdery α-tricalcium bis(phosphate) (α-TCP), α-$Ca_3(PO_4)_2$, was used for the synthesis of a reference OCP (ref-OCP) and a succinate-containing OCP (succinate-OCP). The α-TCP was prepared by heating an equimolar mixture of γ-$Ca_2P_2O_7$ and $CaCO_3$ at 1200 °C for 1 h.[3] The ref-OCP was prepared by the hydrolysis of α-TCP in a 0.5 M (1 M=1 mol dm^{-3}) sodium acetate solution of 50 °C at a pH of 5.4±0.1 for 3 h. This procedure was a modification of the method developed previously.[4] The succinate-OCP was prepared by conducting the hydrolysis in the presence of 0.25 M succinate ions at 40 °C and at an initial pH of 6.0±0.1 for 3 h. The resulting OCP samples were dried at 40 °C and their products calcined at several temperatures were examine by X-ray diffraction, heating weight loss and Ca/P ratio. The chemical analyses for CaO and P_2O_5 were performed by a chelatometric EDTA titration method and a spectrophotometric molybdovanadophosphate method, respectively. The basal spacing of the OCP structure was taken from the (100) reflection.

Results and Discussion

A change in the basal spacing was observed for the succinate-OCP, and this is the most direct and reliable indication of the introduction of succinate into the OCP structure. Table 1 lists the basal spacings, Ca/P ratios of the ref-OCP and succinate-OCP with some relevant data. The data about the ref-OCP were admitted within experimental errors as those of OCP having adsorbed water. The succinate-OCP showed an expansion in basal spacing and an increased in Ca/P ratio, compared with the ref-OCP. Such changes keeping the OCP structure suggested that the replacement of HPO_4^{2-} by $C_4H_4O_4^{2-}$ took place within the structure, not on the surface. From a structural point of view on the OCP unit-cell structure,[1] it was speculated that two of the four HPO_4^{2-} groups within the B-layer seemed more exchangable than the other two HPO_4^{2-} groups which were considered to be tightly bound by sharing one oxygen of HPO_4^{2-} in the A-layer. Therefore, the two HPO_4^{2-} groups would posses a comparatively high probability for the replacement. A general formula was established to be $Ca_8(HPO_4)_{2-z}(PO_4)_4(C_4H_4O_4)_z\cdot mH_2O$ $z=0—1$. The succinate-OCP had the composition $Ca_8(HPO_4)_{1.17}(PO_4)_4(C_4H_4O_4)_{0.83}\cdot 5.5H_2O$. Here, the value of z was determined from the Ca/P ratio (1.55), and m was estimated by distributing the residual amount (19.5%), except the analytical amounts of Ca (31.8%) and PO_4 (48.7%), among 1.17(H), 0.83 ($C_4H_4O_4$), and $m(H_2O)$. Similarly, the ref-OCP was $Ca_8(HPO_4)_2(PO_4)_4\cdot 5.1H_2O$. Repeated runs with a little difference in initial pH seemed to cause sensitively variations within the ranges $0.7\lesssim z<1.0$ and $5\lesssim m\lesssim 7$.

Table 1. Charactors of succinate-OCP in comparison with ref-OCP

Prepared OCP	Basal spacing d_{100}/Å	Ca/P (mole ratio)	Weight loss/%[a]			Calcination product by X-ray[a]		Composition[b]	
			400 °C	700 °C	900 °C	700 °C	900 °C	z	m

Absolute Configurations Assigned to Some Octahedral *cis*-Bis(diamine)cobalt(III) Complexes on the Basis of Their Stereoselective Interactions in Solution

Katsuhiko MIYOSHI, Kenzo WATANABE, Yoshihisa TODA, and Hayami YONEDA*

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-senda-machi, Naka-ku, Hiroshima 730

(Received June 21, 1983)

Synopsis. Absolute configurations are assigned to some cationic *cis*-$[Co(diamine)_2(X)(Y)]^{n+}$-type complexes by detecting the direction of the chiral equilibrium shift induced for $[Cr(ox)_3]^{3-}$ in the presence of these chiral complexes in water–dioxane mixtures. The assignments are found all consistent with those made earlier by CD spectra.

In our previous work,[1] it was established that the Δ isomer of $[Cr(ox)_3]^{3-}$ is gradually enriched when the racemate is mixed with Λ-*cis*-$[M(diamine)_2(X)(Y)]^{n+}$-type complexes (M=$Co^{3+}$ or Cr^{3+}, diamine=ethylenediamine (en) or trimethylenediamine (tn), and X and/or Y=anionic ligand) in water–dioxane mixtures. This implies that a heterochiral[2] combination (Δ-Λ or Λ-Δ) is favored over a homochiral one (Δ-Δ or Λ-Λ) in the stereoselective interaction between $[Cr(ox)_3]^{3-}$ and *cis*-$[M(diamine)_2(X)(Y)]^{n+}$ in solution, and that the above phenomenon called the Pfeiffer effect[3] provides a new technique for assigning the absolute configuration to these optically stable, cationic complexes. In the present study, an attempt is made to extend the applicability of the above technique to other *cis*-$[M(diamine)_2(X)(Y)]^{n+}$-type complexes.

Experimental

Preparation of Complexes. The following complexes were prepared and resolved as described by earlier workers; *cis*-$[Co(CN)(X)(en)_2]^{n+}$ (X=NO_2^-, Cl^-, Br^-, and OH_2),[4] *cis*-$[Cr(CN)_2(en)_2]^+$,[5,6] *cis*-$[Co(Cl)(RNH_2)(en)_2]^{2+}$ (R=CH_3 and C_2H_5),[7] *cis*-$[Co(Cl)(RNH_2)(tn)_2]^{2+}$ (R=H and CH_3),[8] *cis*-$[Co(NCS)_2(tn)_2]^+$,[9] $[Co(gly)(tn)_2]^{2+}$,[10] *cis*-$[Co(Cl)(OH_2)(en)_2]^{2+}$,[11,12] *cis*-$[Co(NO_2)(OH_2)(en)_2]^{2+}$,[11] *cis*-$[Co(Cl)(NCS)(en)_2]^{2+}$,[13] and *cis*-$[Co(NCS)(OH_2)(en)_2]^{2+}$.[11] The purity of these complexes was checked by both ion-exchange chromatography and absorption and/or CD spectra. The λ_{max} of the first d-d band for *cis*-$[Co(CN)(NO_2)(en)_2]^+$ was reported to be 437 nm in Ref. 4, but our sample had an absorption maximum at 423—424 nm. As judged from the λ_{max} values for the *cis*-dinitro (439 nm) and *cis*-dicyano (400 nm) complexes, the value reported in Ref. 4 is probably in error.

Detection of Pfeiffer Effect. The Pfeiffer effect of $[Cr(ox)_3]^{3-}$ was detected in the same manner as before.[1] That is, the sample solution was prepared by adding aqueous racemic $K_3[Cr(ox)_3]\cdot 3H_2O$ (8×10^{-5} mol) to the above optically active complex (2×10^{-4} mol) in a volumetric flask (10 ml) to which 3 ml of dioxane was added. After it was kept standing overnight in the dark, it was passed through a cation-exchange column (Dowex 50 W X1, Na^+-form) to remove the optically active, cationic complex added as an environment substance.[3] The absorption and CD spectra of the effluent were recorded as quickly as possible on a Shimadzu UV-200 and a JASCO J-40CS spectrometers, respectively. The direction and degree of the equilibrium shift in initially racemic $[Cr(ox)_3]^{3-}$ were determined by comparing the sign and intenity of the CD spectrum thus recorded with those of optically pure $[Cr(ox)_3]^{3-}$.[14]

Results and Discussion

In Table 1 is listed the enantiomer of $[Cr(ox)_3]^{3-}$ enriched when *cis*-$[M(diamine)_2(X)(Y)]^{n+}$-type complexes given in the first column are employed as a chiral environment substance in water–dioxane mixtures. Except for the last two tn complexes, a Λ configuration

Table 1. Absolute configuration of enriched isomer of $[Cr(ox)_3]^{3-}$

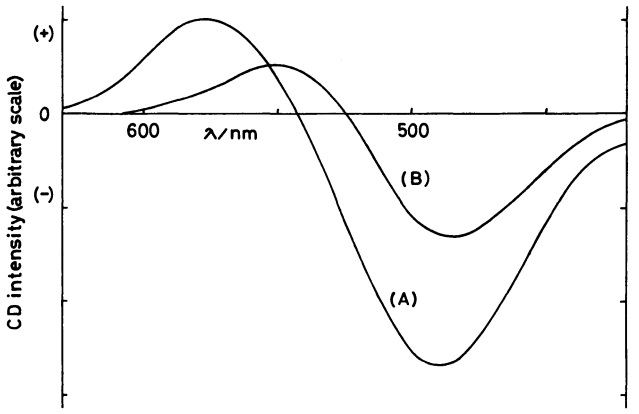

Fig. 1. CD patterns of $(-)^{CD}_{490}$-*cis*-$[Co(Cl)(CH_3NH_2)(tn)_2]^{2+}$ (A) and of $(-)^{CD}_{485}$-*cis*-$[Co(CH_3NH_2)_2(tn)_2]^{3+}$ derived therefrom (B).

has been assigned to these bis(diamine) complexes mainly on the basis of their CD spectra in the first d-d band. It is evident in Table 1 that the chiral equilibrium of $[Cr(ox)_3]^{3-}$ is always displaced toward its Δ enantiomer in the presence of Λ-*cis*-$[M(diamine)_2(X)(Y)]^{n+}$-type complexes. The enantiomer excess actually attained at equilibrium is around 1.0 and 1.5% under the present experimental conditions for uni- and bi-valent environment substances, respectively, in keeping with our previous results.[1] If the heterochiral combination (Δ-Λ or Λ-Δ) is favored as before, it is concluded that the absolute configurations assigned earlier to these complexes are all consistent with our present experimental results.

The last two bis(tn) complexes have already been resolved,[8] but the absolute configuration is not yet assigned to them. In Fig. 1 is shown the CD pattern of partially resolved $(-)^{CD}_{490}$-*cis*-$[Co(Cl)(CH_3NH_2)(tn)_2]^{2+}$ forming a less-soluble diastereomer with bis[μ-(+)-tartrato(4−)]bis[arsenate(III)]$^{2-}$ ion. The corresponding ammine complex exhibits a similar CD pattern as expected. These tn complexes have a negative major CD component at the higher energy side, suggesting a Δ configuration.[15] Our experimental results, however, lead us to assign a Λ configuration to these complexes, since they enrich the Δ enantiomer of $[Cr(ox)_3]^{3-}$. Then, $(-)^{CD}_{490}$-*cis*-$[Co(Cl)(CH_3NH_2)(tn)_2]^{2+}$ was converted to the corresponding bis(methylamine) complex by refluxing it in liquid methylamine, followed by purification with use of ion-exchange chromatography. Figure 1 clearly shows that the CD pattern of the bis(methylamine) complex thus derived is quite similar to that of Λ-*cis*-$[Co(NH_3)_2(tn)_2]^{3+}$ reported by Sano *et al.*[16] This observation is consistent with our present assignment made by the Pfeiffer effect, if so-called Walden inversion does not take place in the above substitution reaction as in the reaction of $(+)_D$-*cis*-$[Co(Cl)(NH_3)(en)_2]^{2+}$ with NH_3 to give $(+)_D$-*cis*-$[Co(NH_3)_2(en)_2]^{3+}$.[11] Thus, the criteria proposed by McCaffery *et al.*[13–15] for predicting the absolute configuration on the basis of the CD spectra, seem not to hold for these complexes with six-membered tn chelates, though they are fairly valid for the *cis*-$[M(X)_2(tn)_2]^+$-type complexes[17] as well as for $[M(acac)(tn)_2]^{2+}$,[18] $[Co(gly)(tn)_2]^{2+}$,[10] and $[M(ox)(tn)_2]^+$.[19]

In this way, our newly proposed technique serves well as a useful means to predict the absolute configuration of *cis*-$[M(diamine)_2(X)(Y)]^{n+}$-type complexes in which X and/or Y are anionic ligands and M may be other than Co^{3+} or Cr^{3+}. As a result, the Pfeiffer effect is applicable to deduce the absolute configuration of not only optically labile complexes[3,20,21] whose chiral equilibria are to be displaced, but also optically stable complexes when they are employed as an environment substance.

(Received July 5, 1983)

Synopsis. Sulfide ion was converted to Methylene Blue through the reaction with *N,N*-dimethyl-*p*-phenylenediamine in the presence of iron(III) ion. The dye produced was fixed by batch method onto the coagulated mixture of finely divided anion and cation exchange resins. The coagulated material was collected by filtration on a filter paper as a disk of thin layer, which was then soaked in an acetate buffer solution, and subjected to the spectrophotometric analysis. The calibration graph was linear over the range 1.03—10.3 nmol of sulfide. The method was applied to some hot spring waters.

The most familiar method for the determination of sulfide is the Methylene Blue method,[1,2] which was recommended by Emil Fisher as early as 1883.[3] The sensitivity of the method is rather high but the enrichment is usually required for the determination of trace amounts of sulfide in water. Recently, a flotation method was reported,[4] in which the Methylene Blue formed through the reaction of sulfide with *N,N*-dimethyl-*p*-phenylenediamine in the presence of iron(III) ion was separated by flotation with sodium dodecyl sulfate. Down to 2 μg of sulfide in 1-dm³ sample solution was determined.

In the present paper, the coagulated ion-exchanger colorimetry[5,6] is examined for the Methylene Blue method. The colored compound is concentrated in the thin layer of mixed ion exchange resins by a factor greater than 700 and determined spectrophotometrically.

Experimental

Reagents. A 0.1 w/v% solution of *N,N*-dimethyl-*p*-phenylenediammonium sulfate (abbreviated as DPDA, Wako Pure Chemicals) was prepared by dissolving 0.1 g of the reagent in 100 ml of 5 mol dm^{-3} sulfuric acid. A 0.1 mol dm^{-3} iron(III) chloride solution was prepared by dissolving 2.7 g of iron(III) chloride hexahydrate in 50 ml of hydrochloric acid and then diluting to 100 ml with water. An aqueous 1.0% zinc(II) acetate solution was prepared. The crystals of sodium sulfide nonahydrate, $Na_2S \cdot 9H_2O$, were rinsed with a small amount of water and dried and stored under nitrogen atmosphere. A 0.01 mol dm^{-3} sulfide solution was prepared by dissolving dried reagent in oxygen-free water and standardized immediately before use by iodometry. The sulfide standard solution was prepared fresh every time when the determination was carried out. The solution was diluted 100 times with oxygen-free water and further 100 times with the zinc(II) acetate solution to give a 1.0 μmol dm^{-3} solution. Methylene Blue used was a Merck product for microscopy. The reagent was dried for 4 h at 105 °C, and aqueous 1.0 mmol dm^{-3} stock solution was prepared.

Ion Exchange Resin Suspension. The macroreticular type ion exchangers, Amberlyst 15 and A-27 (Rohm and Haas), were used in RSO_3H and $RN(CH_3)_3Cl$ forms, respectively. The cation exchange resin suspension (CRS) and anion exchange resin suspension (ARS) were prepared according to the method reported.[7] The exchange capacities were 11.8 μequiv ml^{-1} for CRS and 7.0 μequiv ml^{-1} for ARS. When a 2.0-ml portion of CRS was mixed with 4.0 ml of ARS, both resins were coagulated completely with each other and the mixed resins were easily and quantitatively collected on a filter paper.

Apparatus. A Shimadzu UV 140-01 spectrophotometer was used. A Toyo KG-25 filter holder was used with filter papers of No. 5B (Toyo Roshi). A vaccum guage used was a NRK product, type STV-75.

General Procedure. A 25-ml portion of the zinc(II) acetate solution was placed in a 100-ml separatory funnel, and a sample solution containing less than 10.3 nmol of sulfide was added, and then the solution was diluted to 50 ml with the zinc(II) acetate solution. A 5-ml portion of DPDA solution and 1 ml of the iron(III) chloride solution were quickly added and the reaction mixture was shaken vigorously for 1 min and allowed to stand for 60 min. A 4.0-ml portion of ARS and 2.0 ml of CRS were then added to the solution and the mixture was shaken for 10 min. The resulting coagulated resins were collected on the filter strip placed on the holder by filtration with suction (600 mmHg). A disk of colored thin layer, 17 mm in diameter and about 0.3 mm in thickness, was formed. The filter strip supporting the thin layer was soaked in the acetate buffer solution (pH 4.6) for 15 min, and it was fixed on a glass plate on the one side of cell holder which is nearer to the light source. The absorbance was measured at 675 nm against the dry filter paper or another white paper. Another disk of thin layer was prepared without addition of sulfide and the absorbance corresponding to the reagent blank including the resins was also measured. The net absorbance of Methylene Blue in the resin phase was determined by substruction. Fundamental experiments were performed according to the above procedure with the exception that the pure Methylene Blue solution was used instead of the standard sulfide solution.

Results and Discussion

Adsorption of Methylene Blue. Methylene Blue was found to be strongly fixed on the cation exchange resin. The cation exchange resin was coagulated with anion exchange resin to form a bulky material and separated from the bulk solution within 8 min. The disk of colored thin layer with a smooth surface was obtained on the filter paper. The volume of resin phase being about 0.07 cm³, Methylene Blue was concentrated from 50 ml of the reaction mixture by a factor greater than 700.

Adsorption Spectrum. The absorption spectrum of Methylene Blue in the resin phase was slightly shifted to longer wavelength compared with that in solution (Fig. 1). The effect of pH was studied. The pH of initial solution, from which Methylene Blue was fixed on the mixed resins, was kept at 0.8, and the resulting thin layer was soaked for 15 min in the solutions with various

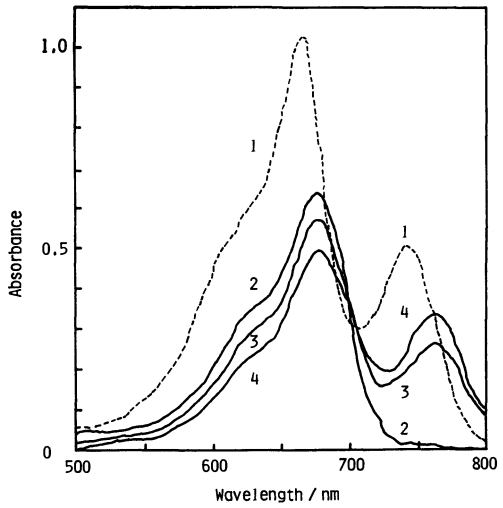

Fig. 1. Effect of pH on the absorption spectra of 6 nmol of Methylene Blue on the thin layer of mixed resins. The absorbance was measured after soaking the thin layer for 15 min in varying pH solutions; 2) 4.62, 3) 1.04, 4) 0.80. Dotted line (1) indicates the absorption spectrum of 20 μmol dm^{-3} Methylene Blue solution at pH 0.80 in a 1-cm cell.

Table 1. Effect of foreign ions on the determination of 6.25 nmol of sulfide ion

Compound	Added amount / μmol	Absorbance at 675 nm	Error / %
None	—	0.327	—
$NaNO_2$	0.06	0.320	−2.1
	0.60	0.319	−2.4
	6.00	0.196	−41.9
$NaHSO_3$	6.00	0.325	−0.6
$HSCH_2COONa$	6.56	0.354	+8.2

Table 2. Determination of sulfide in hot spring water

Sampling place	Sample amounts / ml	Absorbance at 675 nm	Sulfide found / ng S ml^{-1}
Shirogane	4.0	0.244	35.6
(pH = 6.76)	6.0	0.362	35.2
	6.0	0.364	35.4
	8.0	0.458	33.4
	8.0	0.496	36.2
			35.2±1.3[a)]
Nakagoya	0.5	0.488	569.5
(pH=9.11)	0.5	0.468	546.1
	0.5	0.476	555.5
			557.0±29.3[a)]

a) 95% confidence limits.

pH values. With increasing pH, the absorbance at the maximum of 675 nm increased, while that of 760 nm decreased, which indicates that the latter absorption maximum is due to the protonated Methylene Blue.[1)]

Effect of Soaking Time. When the thin layer was soaked in the acetate buffer solution of pH 4.6, the absorbance of Methylene Blue at 675 nm increased gradually and reached a constant value within 10 min. Thereafter the coloration was stable for at least 60 min. The use of acetate buffer soaking solution is advantageous for the sensitivity and stability of the coloration.

Standing Time of Reaction Mixture. When the color developing reagents were added to the test solutions with and without sulfide, a violet color appeared immediately in both solutions. The blank coloration faded gradually and after 60 min, the lower blank value and the stable coloration of Methylene Blue were obtained.

Calibration Graph. The calibration graph showed a good proportionality over range 1.03—10.3 nmol of sulfide, with absorbance ranging from 0.054 to 0.543. The relative standard deviations were 8.5% (n=4) for 1.03 nmol and 1.5% (n=5) for 10.3 nmol of sulfide. The yield of Methylene Blue from sulfide was estimated by comparing the slope of calibration curve with that of pure Methylene Blue. The reaction yield was calculated to 52.5%, while the value reported by Gustafsson was 66.7%.[1)]

Effect of Foreign Ions. As summarized in Table 1, a large amount of nitrite gave a serious negative error, which is due to the reduction of iron(III) ion.[4)] Mercaptoacetate gave a positive error.[8)]

Determination of Sulfide in Hot Spring Water. The sample waters were clear enough and so directly subjected to the analysis. The sulfide was precisely determined in the varying sample aliquots (Table 2). The pH of sample water at Nakagoya was higher than that at Shirogane, and the former contained sulfide in higher concentration than the latter.

Cycloaddition of Diphenylcyclopropenone with Carboximidate, Carboximidamide, and Carboximidothioate

Hiroshi YOSHIDA,* Shingo SOGAME, Shoichi BANDO, Shosuke NAKAJIMA, Tsuyoshi OGATA, and Kiyoshi MATSUMOTO†

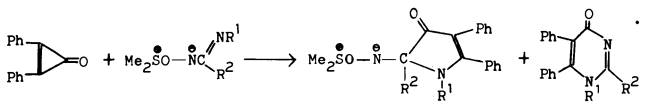
Department of Applied Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu 432

†College of Liberal Arts and Sciences, Kyoto University, Sakyo-ku, Kyoto 606

(Received March 23, 1983)

Synopsis. The reaction of diphenylcyclopropenone with $R^1N{=}C(R^2)X$ (**2**) (R^1, R^2=alkyl, aryl, X=MeO, EtO, MeS, or Me_2N) gave 2-pyrrolin-4-one (**3**) in good yield. The less reactive carboximidothioate (**2**, R^1=4-MeC_6H_4, R^2=Ph, X=MeS) yielded isomeric 3-pyrrolin-2-one together with **3**.

In a previous paper[1] we have reported the reaction of *N*-imidoyl sulfoximide with diphenylcyclopropenone to yield the sulfoximide substituted with pyrrolinone ring together with pyrimidinone *via* [2+3] and [3+3]cycloaddition reactions:



Eicher and his coworkers have reported that ketimine reacts with diphenylcyclopropenone **1** to yield 2-pyrrolin-4-one derivative by [2+3]cycloaddition reaction.[2] However, no work has been undertaken on the *N,N,N'*-trisubstituted carboximidamide, carbiximidate, and carboximidothioate (**2**). In this paper we report the reactivities of these compounds with diphenylcyclopropenone.

An equimolar mixture of **1** and **2** in benzene (reaction at 80 °C) or xylene (over 100 °C) was heated at suitable temperature. The reaction was followed by TLC. The products isolated by column chromatography were 2-pyrrolin-4-one (**3**), but in the case of **2j**, **3j**, and 3-pyrrolin-2-one (**4j**) were obtained. The yields of **3** and **4** and their physical properties are summarized in Table 1.

The structures of the products were elucidated on the basis of their elemental analyses, ^{1}H-NMR and mass spectroscopic studies as well as chemical transformations. Mass spectra of **3c**, **3g**, and **3j** showed peaks corresponding to the groups PhC=C(Ph)–NR^1 together with the parent peaks. Although **4j** showed a peak corresponding to PhC=C(Ph)–CPh, no such peak was observed for **3j**.

Some products were subjected to drastic hydrolysis. On treating with hot mixture of aqueous acetic and sulfuric acids, **3b**, **3e**, **3g**, **3i**, and **3j** gave the known triphenylfuranone (**5**)[2c] in moderate yields, while the isomer **4j** yielded the acid **6**.[3]

It has been reported that *N*-methyl and *N*-phenylketimines react completely with **1** in boiling 1,2-dimethoxyethane (at about 83 °C) within 20 min and 2—5 h respectively.[2c] Table 1 indicates that the reactivity of **2** decreased in orders on R^1: alkyl>aryl, X: NMe_2> OMe, and OEt>SMe. Although the reactivities of **2** were lower than those of ketimines, the electron-releasing effects of substituents on R^1 and X would account for the reactivities of **2**. Nucleophilic attack of the imino nitrogen on the cyclopropenone **1** gave **3** or **4** depending on the attacking site. The major products were 2-pyrrolin-4-ones (**3**) whereas the less reactive **2j** showed lower selectivity under more drastic conditions giving a mixture of **3j** and **4j**. In conclusion, the reaction of **1** with

2 has proven to be a useful method for the preparation of 2-pyrrolin-4-ones (**3**).

Experimental

General. Melting points are uncorrected. ^{1}H-NMR spectra were recorded on a Hitachi Perkin Elmer R-24 (60 MHz) spectrometer using TMS as an internal standard, and mass spectra on a Hitachi RMU-7M mass spectrometer.

Preparation of Carboximide, Carboximidate, and Carboximidothioate. The compounds **2** were prepared by the usual methods.[4] Carboximidamides **2d**, **e**, **h**, **k**, and **21** were obtained from the corresponding imidoyl chlorides and excess dimethylamine in benzene. Carboximidates **2b**, **f**, **g**, and **2i** were prepared from the imidoylchlorides and sodium alkoxide in alcohol. Carboximidothioates **2a**, **c**, and **2j** were obtained by the reaction of the corresponding thioamides with methyl iodide followed by treatment with aqueous sodium hydroxide. The purity of the products was confirmed by ^{1}H-NMR. New compounds were as follows: **2h** (85%): oil; ^{1}H-NMR ($CDCl_3$) δ=2.04 (3H, s, Me), 2.83 (6H, s, Me_2N), and 6.2—7.6 (9H, m, Arom); *m/e* 238 (M^+). **21** (93%): oil; ^{1}H-NMR ($CDCl_3$) δ=2.17 (3H, s, Me), 2.89 (6H, s, Me_2N), and 6.4—7.4 (9H, m, Arom); *m/e* 238 (M^+).

The Reaction of 1 with 2. A solution of **1** (1.5 mmol) and **2** (2 mmol) was refluxed in a minimum amount of benzene or xylene (3—5 cm^3). The reaction was checked by TLC (aluminum oxide, petroleum ether : ethyl acetate, 1 : 1, v/v) until **1** reacted completely. After cooling, the mixture was chromatographed over silica gel (petroleum ether : ethyl acetate, 4 : 1, v/v). The products were crystallized from appropriate solvents.

Hydrolyses of 3 and 4. In a boiling mixture of acetic acid and sulfuric acid in water (50 : 1 : 25, v/v, 5 cm^3) pyrrolinone (50 mg) was hydrolyzed for 2 d. The resulting mixture was poured into water and extracted with chloroform. The extract was dried over sodium sulfate and evaporated under reduced pressure. **3b**, **e**, **g**, **i**, and **3j** gave triphenyl-3-(2*H*)-furanone **5**: mp 191—192 °C (lit, mp 192—193 °C).[2c] In contrast **4j** yielded the acid **6**: mp 172—174 °C (lit, mp 172 °C).[3]

(Received June 22, 1983)

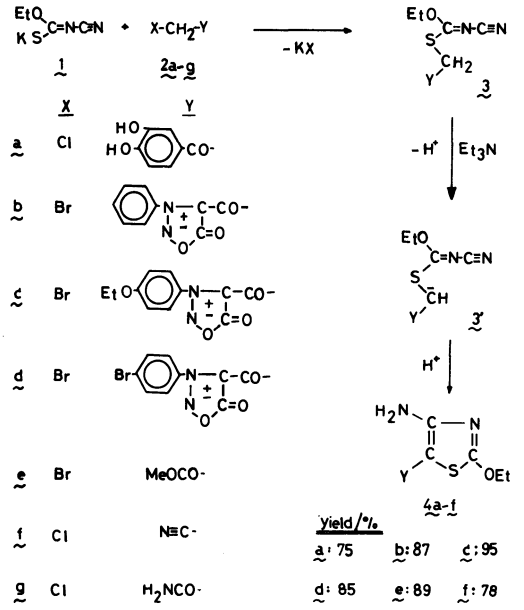
Synopsis. α-Halo derivatives of ketones, ester, and nitrile reacted readily with potassium ethoxythiocarbonylcyanamide to provide the corresponding 4-amino-2-ethoxythiazole compounds in good yields, while α-halo amide did not. In a similar manner, α,α′-dihalo ketone reacted with 2 equiv of alkoxythiocarbonylcyanamide and *S*-methyl *N*-cyanocarbamodithioate salts to give the corresponding bis(4-amino-5-thiazolyl) ketones.

Cyanamide derivatives are very useful for synthesis of heterocyclic compounds having nitrogen atoms. In the course of our synthetic studies[1-7] of heterocyclic compounds using cyanamide derivatives, we have found a novel synthetic reaction of 4-aminothiazole compounds from potassium ethoxythiocarbonylcyanamide (**1**) and α-halo ketones.[7] The reaction should be interesting from an aspect that few studies[8] on the synthesis of 4-aminothiazoles have been reported, while a number of 2-aminothiazoles have been known. In addition, the reaction may be useful for the preparation of 4-aminothiazoles having unstable substituents, since it can proceed under quite mild reaction conditions.

In this work, we attempted some extensions of the reaction to more complicated α-halo ketones and α-halo derivatives of compounds other than ketones.

Results and Discussion

The reaction of **1** with **2** easily proceeded at room temperature eliminating potassium halide to form stable intermediate (**3**), and then **3** underwent the base-catalyzed cyclization to be converted into the final product (**4**), as shown in Scheme 1. In the course of the reaction, **3** was not isolated from the reaction mixture and one-pot reaction was carried out.

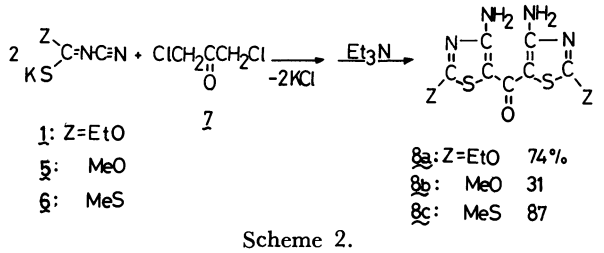


Scheme 1.

4-Aminothiazole (**4a**) having hydroxyl groups could be obtained in a fairly good yield from the corresponding α-halo ketone (**2a**).

Althogh sydnone compounds are generally interesting in their chemical, physical and biological properties,[9] their syntheses seem to be limited.[10,11] For instance, a few works dealing with the successful synthesis of sydnones having heterocyclic substituents have been reported: Only 4-(4-thiazolyl)[12] and 4-(1,2,4-oxadiazol-3-yl)sydnones[11] could be prepared in our previous works. In this point, the reaction of **1** with 3-aryl-4-(bromoacethyl)sydnone (**2b—d**) under such mild conditions, where a sydnone ring itself did not decompose, was successfully tried to prepare the corresponding 4-amino-5-thiazolyl 3-ary-4-sydnonyl ketones (**4b—d**).

The reaction was also extended to α,α′-dihalo ketone (1,3-dichloro-2-propanone, **7**) and consequently the corresponding bis(4-amino-5-thiazolyl)ketones (**8a—c**) were obtained in 31—87% yields using 2 equiv of cyanamide salts (**1**, **5**, and **6**), as shown in Scheme 2.



Scheme 2.

At the second stage of the investigation, the reaction was also extended to α-halo derivatives of compounds other than ketones. As shown in Scheme 1, α-halo ester (**2e**) and nitrile (**2f**) reacted with **1** to give the corresponding 4-aminothiazole compounds (**4e**, **f**) in high yields, while α-halo amide (**2g**) gave only the intermediate (**3g**) which could not cyclize under the conditions used. Since the initiation step of the cyclization seems to be carbanion (**3′**) formation from **3** by base-catalyzed proton abstraction, no occurrence of the cyclization of **3g** may be due to weaker electron-withdrawing effect of an amide group than the others.

Experimental

*3,4-Dihydroxyphenyl 2-Ethoxy-4-amino-5-thiazolyl Ketone (**4a**).*

To a stirred solution of 0.84 g (5 mmol) of potassium ethoxythiocarbonylcyanamide (**1**)[13] in 5 ml of acetone was gradually added a solution of 0.93 g (5 mmol) in 10 ml of acetone at room temperature. After 2 h of stirring, 0.31 ml of triethylamine was added to the reaction mixture. After additional 2 h of stirring, the reaction mixture was evaporated to dryness and the residue was mixed with water. The insoluble oily material was solidified with small amount of methanol and the resulting solid was collected by filtration. The yield was 1.05 g (75%). Recrystallization from aq. methanol provided 0.90 g (64%) of pure **4a**: mp 201—202 °C; IR (KBr) 1640 cm^{-1} (C=O); NMR (DMSO-d_6) δ=1.33 (t, 3H, $C\underline{H}_3CH_2$), 4.37 (q, 2H, $CH_3C\underline{H}_2$), 6.58—7.00 (m, 3H, Ar–H), 7.90 (s, 2H, $N\underline{H}_2$), and 9.00 (broad s, 2H, O<u>H</u>). Found: C, 51.42; H, 4.01; N, 9.97%. Calcd for $C_{12}H_{12}N_2O_4S$: C, 51.42; H, 4.32; N, 9.99%.

*4-Amino-2-ethoxy-5-thiazolyl 3-Phenyl-4-sydnonyl Ketone (**4b**).* To a stirred solution of 0.42 g (2.5 mmol) of **1** in 5 ml of acetone was gradually added a solution of 0.71 g (2.5 mmol) of 4-bromoacetyl-3-phenylsydnone[12] in 10 ml of acetone at room temperature. After 1 h of stirring, 0.1 ml of triethylamine was added to the reaction mixture. After additional 0.5 h of stirring, the reaction mixture was evaporated to dryness under reduced pressure. The residue was mixed with water and insoluble material was collected by filtration. The yield was 0.72 g (87%). Recrystallization from methanol provided 0.60 g (72%) of pure **4b** as yellow needles: mp 172—173 °C; IR (KBr) 1775 and 1605 cm^{-1} (C=O); NMR (DMSO-d_6) δ=1.37 (t, 3H, $C\underline{H}_3CH_2$), 4.40 (q, 2H, $CH_3C\underline{H}_2$), 7.50 (s, 5H, Ar–H), and 8.00 (s, 2H, $N\underline{H}_2$); MS *m/e* 332 (M^+). Found: C, 50.50; H, 3.59; N, 16.73%. Calcd for $C_{14}H_{12}N_4O_4S$: C, 50.60; H, 3.70; N, 16.86%.

*4-Amino-2-ethoxy-5-thiazolyl 3-(p-Ethoxyphenyl)-4-sydnonyl Ketone (**4c**).* In a similar manner, **4c** was obtained from **2c** in 95% yield. Recrystallization from ethanol provided pure **4c** as yellow needles: mp 171—172 °C; IR (KBr) 1775 and 1605 cm^{-1} (C=O); NMR (DMSO-d_6) δ=1.37 (t, 6H, $C\underline{H}_3CH_2$), 4.08 (q, 2H, $C\underline{H}_2OC_6H_4$), 4.43 (q, 2H, $CH_3C\underline{H}_2$), 7.02 (d, 2H, Ar–H), 7.52 (d, 2H, Ar–H), and 8.10 (s, 2H, $N\underline{H}_2$): MS *m/e* 376 (M^+). Found: C, 50.95; H, 4.18; N, 14.75%. Calcd for $C_{16}H_{16}N_4O_5S$: C, 51.06; H, 4.29; N, 14.89%.

*4-Amino-2-ethoxy-5-thiazolyl 3-(p-Bromophenyl)-4-sydnonyl Ketone (**4d**).* In a similar manner, **4d** was obtained in 85% yield. Recrystallization from ethanol provided pure **4d** as yellow needles: mp 163—164 °C; IR (KBr) 1775 and 1605 cm^{-1} (C=O); NMR (DMSO-d_6) δ=1.33 (t, 3H, $C\underline{H}_3CH_2$), 4.42 (q, 2H, $CH_3C\underline{H}_2$), 7.65 (q, 4H, Ar–H), and 8.19 (s, 2H, $N\underline{H}_2$): MS *m/e* 410 (M^+) and 412 (M^++2). Found; C, 40.98; H, 2.47; N, 13.61%. Calcd for $C_{14}H_{11}N_4O_4SBr$: C, 40.89; H, 2.70; N, 13.62%.

*4-Amino-2-ethoxy-5-methoxycarbonylthiazole (**4e**).* By the procedure similar to the preparation of **4b**, **4e** was obtained from methyl bromoacetate. The yield was 89%. Recrystallization from 20% aq methanol provided pure **4e** as colorless needles (83%): mp 80 °C; IR (KBr) 1620 cm^{-1} (C=O); NMR ($CDCl_3$) δ=1.37 (t, 3H, $C\underline{H}_3CH_2$), 3.65 (s, 3H, $C\underline{H}_3O$), 4.35 (q, 2H, $CH_3C\underline{H}_2$), and 5.70 (broad s, 2H, $N\underline{H}_2$); MS *m/e* 202 (M^+). Found: C, 41.30; H, 4.81; N, 13.65%. Calcd for $C_7H_{10}N_2O_3S$: C, 41.58; H, 4.98; N, 13.85%.

*4-Amino-5-cyano-2-ethoxythiazole (**4f**).* By the same procedure described above, **4f** was obtained from chloroacetonitrile. The yield was 78%. Recrystallization from methanol provided pure **4f** (60%); mp 148—149 °C IR (KBr) 2180 cm^{-1} (C≡N); NMR ($CDCl_3$) δ=1.43 (t, 3H, $C\underline{H}_3CH_2$), 4.44 (q, 2H, $CH_3C\underline{H}_2$), and 4.90 (broad s, 2H, $N\underline{H}_2$); MS *m/e* 169 (M^+). Found: C, 42.65; H, 3.90; N, 24.91%. Calcd for $C_6H_7N_3OS$: C, 42.59; H, 4.17; N, 24.83%.

*Reaction of **1** with Chloroacetamide.* The reaction was performed in a similar manner. After the reaction, the precipitating salt (KCl) was removed by filtration and the filtrate was concentrated to dryness provided **3g** in 100% yield. Recrystallization from methanol provided pure **3g**; mp 163—164 °C; IR (KBr) 2210, 2180 (C≡N) and 1660 cm^{-1} (C=O); MS *m/e* 187 (M^+). Found: C, 38.10; H, 4.84; N, 22.07%. Calcd for $C_6H_9N_3O_2S$: C, 38.49; H, 4.85; N, 22.44%.

*Bis(4-amino-2-ethoxy-5-thiazolyl) Ketone (**8a**).* The preparative procedure was described in the previous paper.[7]

*Bis(4-amino-2-methoxy-5-thiazolyl) Ketone (**8b**).* By the procedure similar to the preparation of **4** and **8a**, the reaction was carried out using 0.62 g (4 mmol) of potassium methoxythiocarbonylcyanamide (**5**),[3] 0.25 g (2 mmol) of 1,3-dichloro-2-propanone, and 0.1 ml of triethylamine in 10 ml of acetone. After the reaction, the reaction mixture was evaporated and the remaining residue was mixed with water. The insoluble oily material was separated from water and the oil was solidified with methanol, giving 0.18 g (31%) of crude **8b**. Recrystallization from DMF provided pure **8b**: mp 208—209 °C; IR (KBr) 3380, 3280 (NH) and 1600 cm^{-1} (C=O); NMR (DMSO-d_6) δ=3.97 (s, 6H, $C\underline{H}_3$) and 7.57 (s, 4H, $N\underline{H}_2$); MS *m/e* 286 (M^+). Found: C, 38.04; H, 3.49; N, 19.38%. Calcd for $C_9H_{10}N_4O_3S_2$: C, 37.75; H, 3.52; N, 19.57%.

*Bis(4-amino-2-methylthio-5-thiazolyl) Ketone (**8c**).* In a similar manner as above, the reaction was carried out using 1.70 g (10 mmol) of potassium *S*-methyl *N*-cyanocarbamodithioate (**6**),[3] 0.64 g (5 mmol) of 1,3-dichloro-2-propanone, and 0.4 ml of triethylamine. After work-up, 1.39 g (87%) of crude **8c** was obtained. Recrystallization from DMF–methanol provided pure **8c**: mp 250—251 °C; IR (KBr) 3480, 3370, 3300, 3250 (NH) and 1580 cm^{-1} (C=O); NMR (DMSO-d_6) δ=2.70 (s, 6H, $C\underline{H}_3$) and 7.66 (s, 4H, $N\underline{H}_2$); MS *m/e* 318 (M^+). Found: C, 33.83; H, 3.05; N, 17.58%. Calcd for $C_9H_{10}N_4OS_4$: C, 33.95; H, 3.17; N, 17.59%.

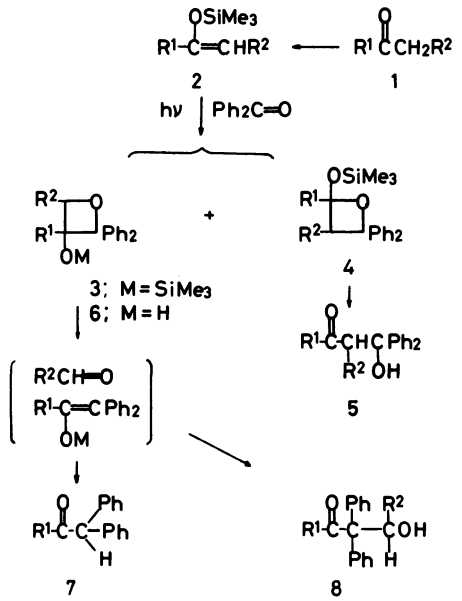
Synthesis of 2,2-Diphenyl-3-oxetanol Derivatives and Their Thermal or Acid-catalyzed Decomposition

Nobujiro SHIMIZU,* Shintaro YAMAOKA, and Yuho TSUNO
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812
(Received June 27, 1983)

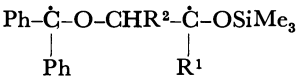
Synopsis. A series of five different 2,2-diphenyl-3-oxetanols was synthesized by photocycloaddition of benzophenone and enol trimethylsilyl ethers followed by protolysis of the resultant 3-trimethylsiloxyoxetanes. Thermal cleavage and acid-catalyzed rearrangement of these oxetanes are described.

Synthesis of 3-oxetanols has been accomplished by only a very limited number of methods.[1,2] A cycloaddition reaction of a carbonyl group and an enol would provide another simple synthetic route. The present work deals with the photocycloaddition of benzophenone and enol trimethylsilyl ethers of aliphatic ketones **1**, and subsequent regioselective decomposition of the resultant 3-siloxy and hydrxyoxetanes.



a; R1 = Me / R2 = H, b; i-Pr / H, c; ▷ / H, d; t-Bu / H, e; Et / Me

On irradiation through a Pyrex filter (10—15 °C, 4 h), benzophenone reacted with2-trimethylsiloxypropene (**2a**, 1.5 equiv) in benzene to give a mixture of two isomeric oxetanes **3a** and **4a** (94 : 6). Chromatography of the mixture separated the abundant isomer in 73% yield as colorless crystals; the other one was labile and inevitably afforded a hydrolysis product **5a** (4%) on chromatography. The photocycloaddition with other enol ethers **2b**—**e** also occurred regioselectively to yield the corresponding oxetanes **3b**—**e** as the principal product in each case.[3] The results are shown in Table 1. The efficiency for the oxetane formation appears extremely low from **2d** compared to the other enol ethers. This is presumably ascribed to a rapid decay of an intermediate diradical going back to the starting materials, since a cyclization process must be sterically very unfavorable especially when $R^1 = t$-Bu.



The oxetanes **3** except **3d** were readily converted to the corresponding alcohols **6** by treatment with methanol saturated with potassium carbonate (rt, 1 d). **3d** was surprisingly stable under these conditions; however, acidic methanol using *p*-toluenesulfonic acid effected the desilylation.

The oxetanols **6** cleanly underwent a regioselective decomposition on heating (200 °C, 1 h) in the presence of a catalytic amount of carbon tetrachloride to give the corresponding *α,α*-diphenyl ketones **7** in excellent yields.[4] **6c**, for example, gave cyclopropyl diphenylmethyl ketone in 94% yield without cleavage of the cyclopropane ring. The overall reaction therefore corresponds to a transformation of an aliphatic ketone **1** to an arylated ketone **7** *via* a metathesis between benzophenone and an enol silyl ether of **1**.

Thermally, the siloxyoxetane **3a** was stable (240 °C, 4 h) but it rapidly decomposed when treated with boron trifluoride etherate(4 equiv) in dichloromethane to give a rearranged product **8a** in 81% yield after aqueous workup. Two successive reactions both catalyzed by a Lewis acid may account for this rearrangement—regioselective ring cleavage and subsequent recombination of the two fragments, formaldehyde and an enol silyl ether of 1,1-diphenyl-2-propanone. The same rearrangement also occurred smoothly from **3b** and **3c**, but **3d** and **3e** furnished only poor results. **3e** afforded mainly **7e**, although the use of titanium tetrachloride in place of boron trifluoride brought a significant increase in the yield of **8e**, whereas **3d** gave a complicated mixture of products in which neither **7d** nor **8d** was detectable.[5] These results are included in Table 1.

TABLE 1. SYNTHESIS AND REACTIONS OF **3** AND **6**

Et	Me	57	80	92[b]	27[b,d]

a) Isolated yield unless otherwise noted. b) Determined by GLC. c) Based on benzophenone consumed. d) Titanium tetrachloride was used in place of BF_3.

Experimental

NMR spectra were determined in carbon tetrachloride with a Hitachi R-20B spectrometer. Enol trimethylsilyl ethers **2a—e** were prepared by a conventional method.[6]

2,2-Diphenyl-3-trimethylsiloxyoxetanes (3). The following procedure for the preparation of **3a** was representative. A benzene solution (200 ml) of **2a** (3.1 g, 24 mmol) and benzophenone (2.89 g, 16 mmol) was irradiated through a Pyrex filter by a 450 W mercury lamp at 10—15 °C for 4 h under nitrogen. Solvent and excess **2a** were removed on a rotary evaporator. The yellow residue was chromatographed over alumina eluting with hexane–benzene to give **3a** (3.23 g, 73%) and **5a** (245 mg) in order of elution. **3a**: mp 40—41 °C; IR 1260, 985, 850, and 710 cm^{-1}; NMR $\delta=-0.11$ (9H, s), 1.35 3H, s), 4.15 and 4.49 (both 1H, d, $J=5.6$ Hz), and 6.9—7.8 (10H, m). Found: C, 73.24; H, 7.67%. Calcd for $C_{19}H_{24}O_2Si$: C, 73.03; H, 7.74%.

Related Oxetanes: **3b**: Mp 83—84 °C (Found: 73.92; H, 8.21%), **3c**: mp 70—72 °C (Found: 74.39; H, 7.71%), **3d**: Mp 95—96 °C (Found: C, 74.55; H, 8.54%), and **3e** (a mixture of stereoisomers) showed similar spectral data: IR near 1260, 1000, 850, and 710 cm^{-1}; NMR near $\delta=-0.2$ ($SiMe_3$) and the following characteristic signals of the C_4 protons: 4.45 and 4.63 (both 1H, d, $J=7.5$ Hz) for **3b**; 4.20 and 4.60 (both 1H, d, $J=6$ Hz) for **3c**; 4.30 and 4.77 (both 1H, d, $J=7$ Hz) for **3d**; 4.58 (1H, m) for **3e**.

2,2-Diphenyl-3-oxetanols (6). *A*: A solution of **3a** (3.29 g) in methanol saturated by potassium carbonate was stirred for 1 d at room temperature. A crude product obtained after workup was recrystallized from hexane to give **6a** (2.21 g): mp 111—113 °C; IR 3530, 3450, 980, and 715 cm^{-1}; NMR $\delta=1.27$ (3H, s), 2.02 (1H, s), 4.14 and 4.42 (both 1H, d, $J=6.4$ Hz), and 7.1—7.7 (10H, m). Found: C, 79.81; H, 6.68%. Calcd for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71%. Similarly, **3b**, **3c**, and **3e** were respectively converted to **6b**: mp 143—145 °C (Found: C, 80.21; H, 7.46%), **6c**: mp 102—104 °C (Found: C, 81.05; H, 6.80%), and **6e**: mp 132—137 °C. These oxetanes showed IR bands near 3450 and 980 cm^{-1}, and NMR signals characteristic of the C_4 protons: 4.1 and 4.63 (both 1H, d, $J=6.5$ Hz) for **6b**, 4.26 and 4.45 (both 1H, d, $J=6$ Hz) for **6c**, and 4.68 (1H, q, $J=6.5$ Hz) for **6e**.

B: Into a solution of **3d** (650 mg) in carbon tetrachloride (20 ml) was added methanol containing *p*-toluenesulfonic acid (15 mg) and the mixture was allowed to stand for 1 d at room temperature. Workup followed by chromatography gave **6d** (260 mg): mp 150—152 °C; IR 3480 and 985 cm^{-1}; NMR $\delta=0.86$ (9H, s), 4.02 and 4.77 (both 1H, d, $J=7$ Hz), and 7.1—7.8 (10H, m); (Found: C, 80.62; H, 7.80%).

Thermal Decomposition of 6. A mixture of **6** (*ca.* 50 mg), carbon tetrachloride (1 μl), and diphenylmethane (20 mg) was heated at 200 °C for 1 h in a glass ampoule and analyzed directly by GLC. Ketones **7a—e** were characterized by their spectral data.

BF_3-Catalyzed Decomposition of 3. A solution of **3a** (510 mg) in dichloromethane (10 ml) was cooled to −75 °C and boron trifluoride etherate (617 μl) was added. The mixture was stirred for 2 h at −75 °C, then for 1 h at 0 °C and quenched with aq sodium carbonate. A crude oil obtained after workup was chromatographed over alumina to give **8a** (314 mg): IR 3450 and 1705 cm^{-1}; NMR $\delta=2.02$ (3H, s), 2.65 (1H, t), 4.12 (2H, d, $J=7$ Hz), 7.27 (10H, s). Found: C, 79.74; H, 6.70%. Calcd for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71%.

8b: Mp 72—74 °C, **8c**, and **8e** were obtained by the same procedure. **8b**: IR 3490 and 1705 cm^{-1}; NMR $\delta=0.78$ (6H, d, $J=6.6$ Hz), 2.93 (1H, m), 4.18 (2H, broad d, $J=6$ Hz), 7.27 (10H, s); (Found: C, 80.40; H, 7.48%). **8c**: IR 3450 and 1705 cm^{-1}; NMR $\delta=0.5$—2.8 (5H, m), 4.15 (2H, s), 7.27 (10H, s). **8e**: IR 3500 and 1705 cm^{-1}; NMR $\delta=0.85$ (3H, t, $J=7.3$ Hz), 0.90 (3H, d, $J=6.5$ Hz), 2.26 (2H, m), 4.95 (1H, q, $J=6.5$ Hz), 7.28 (10H, s).

Preparation of Aryltributyltin Having Electron-withdrawing Group by Palladium Catalyzed Reaction of Hexabutylditin with Aryl Iodide

Masanori Kosugi, Takao Ohya, and Toshihiko Migita*
Department of Chemistry, Faculty of Technology, Gunma University, Kiryu, Gunma 376
(Received June 27, 1983)

Synopsis. Nitro-, acyl-, and cyanophenyltributyltin can be prepared by the reaction of hexabutylditin with the corresponding aryl iodide in the presence of a catalytic amount of tetrakis(triphenylphosphine)palladium.

Aryltin compounds are generally prepared by the reaction of an aryl organometallic (Grignard or lithium) reagent with organotin halide or by the reaction of organotin lithium with aryl halide.[1] However, aryltin compound in which the aryl groups bear reactive functional substituents (*e.g.* $-NO_2$, $-COR$, $-CN$ *etc.*) cannot be prepared by these methods, because the functional groups are sensitive to the lithium or magnesium reagent. In our previous communication we reported that the palladium-catalyzed reaction of hexabutylditin with aryl bromides is a promising tool to prepare such aryltributyltins, although biaryls are produced as by-products.[2] About the same time, similar trials were also reported by two groups.[3,4] However, optimum reaction conditions for the preparation of nitrophenyltributyltin seem not to be attained.[3] This note describes our results for preparation of these compounds by the method, showing that aryl iodides are better substrates than the bromides.

$$Bu_3SnSnBu_3 + ArX \xrightarrow{Pd(PPh_3)_4} ArSnBu_3 + Bu_3SnX$$

The reaction were carried out by heating a stirred solution of an aryl iodide, 1.5 molar excess of hexabutylditin and a catalytic amount of tetrakis(triphenylphosphine)palladium in toluene at 60 °C for 72 h under argon. After evaporation to remove the solvent, the residue was washed with aqueous potassiun fluoride to remove tributyltin iodide by converting into insoluble tributyltin fluoride. The organic layer was extracted with benzene and dried over sodium sulfate. Purification was performed by column chromatography. The results are presented in Table 1.

Nitro-, cyano-, and acetylphenyltributyltins are obtained in good yields. It is important to note that the usage of mild reaction conditions is necessary to avoid the formation of biaryl, because aryltributyltin formed can react with aryl halide in the presence of the same catalyst, particularly easily at higher temperature.

$$ArSnBu_3 + ArX \xrightarrow{Pd(PPh_3)_4} ArAr + Bu_3SnX$$

The reaction with aryl iodide at 60 °C gave good results enough for the synthetic purpose. In the reaction of *o*-nitrophenyl iodide, no biaryl was obtained, probably due to the steric effect, and yield of aryltin compound was almost quantitative even at higher temperature.

Table 1. Palladium-catalyzed reaction of hexabutylditin with aryl iodide

Y-C_6H_4-I(-Br) Y	Temp/°C	Yield of Y-C_6H_4-$SnBu_3$/%[a] Y

o-NO_2	80	*o*-NO_2	98	(59)
p-Ac	60	*p*-Ac	83	(21)
p-CN	60	*p*-CN	85	(22)

a) Isolated yield based on the iodide. In parenthesis, yield from aryl bromide at 80 °C. b) GLC yield.

Experimental

IR spectra were recorded on a Hitachi EPI-3G spectrophotometer. NMR spectra were recorded on a Varian EM-360 instrument. GLC analyses were carried out with an Ohkura 802 instrument, using column (1.5 m) packed with 10% Silicone SF-96, 10% SE-30, and 10% Carbowax-20M on Celite 545 (AW DMCS).

Materials. Hexabutylditin,[5] $Pd(PPh_3)_4$,[6] *o*-, *m*-, and *p*-iodonitrobenzene,[7] *p*-iodoacetophenone,[8] and *p*-iodobenzonitrile[9] were prepared by the methods described in literatures.

Reaction Procedure. A stirred solution of hexabutylditin (45 mmol), an aryl iodide (30 mmol), and $Pd(PPh_3)_4$ (0.3 mmol) in toluene (60 cm^3) was heated at 60 °C for 72 h under argon. After evaporation to remove the solvent, the residue was washed with aqueous potassium fluoride to remove tributyltin iodide. The organic layer was extracted with benzene and dried over sodium sulfate. Purification was performed by column chromatography (Silica gel: hexane as elutant). The results are shown in Table.

Products. Products were identified by their spectroscopic data and elemental analyses recorded here. *p*-Nitrophenyltributyltin. IR (neat) 1521, 1350 (NO_2), and 870 cm^{-1} (C–C). ^1H NMR (CCl_4) δ=0.45—2.05 (27H, m), and 7.55, 8.12 (4H, ABq, J=8 Hz). Found: C, 52.49; H, 7.85; N, 3.27%. Calcd for $C_{18}H_{31}NO_2Sn$: C, 52.46; H, 7.58; N, 3.40%. *m*-Nitrophenyltributyltin. IR (neat) 1521, 1350 (NO_2), and 870 cm^{-1} (C–N). ^1H NMR (CCl_4) δ=0.45—2.05 (27H, m), and 7.30—8.20 (4H, m). Found: C, 52.54; H, 7.63; N, 2.98%. Calcd for $C_{18}H_{31}NO_2Sn$: C, 52.46; H, 7.58; N, 3.40%. *o*-Nitrophenyltributyltin. IR (neat) 1520, 1340 (NO_2), and 855 cm^{-1} (C–N). ^1H NMR (CCl_4) δ=0.45—2.05 (27H, m), and 7.35—7.85, 8.20—8.55 (4H, m). Found: C, 53.10; H, 7.88; N, 3.45%. Calcd for $C_{18}H_{31}NO_2Sn$: C, 52.46; H, 7.58; N, 3.40%. *p*-Acetylphenyltributyltin. IR (neat) 1690, 1275 cm^{-1} (C=O). ^1H NMR (CCl_4) δ=0.45—2.05 (27H, m), 2.53 (3H, s), and 7.47, 7.71 (4H, ABq, J=6 Hz) Found: C, 58.08; H, 8.38%. Calcd for $C_{20}H_{34}OSn$: C, 58.71; H, 8.38%. *p*-Cyanophenyltributyltin. IR (neat) 2240 cm^{-1} (C≡N). ^1H NMR (CCl_4) δ=0.45—2.05 (27H, m), and 7.17—7.78 (4H, m). Found: C, 57.96; H, 7.98; N, 3.57%. Calcd for $C_{19}H_{31}NSn$: C, 58.19; H, 7.97; N, 3.57%.

Hydrolysis of *p*-Nitrophenyl Esters by Histidine-containing Linear and Cyclic Peptides

Masato KODAKA
National Chemical Laboratory for Industry, Tsukuba 305
(Received July 15, 1983)

Synopsis. Hydrolysis of *p*-nitrophenyl acetate (PNPA) and *p*-nitrophenyl hexanoate (PNPH) catalyzed by several linear and cyclic peptides containing histidine and other amino acid residues was studied. The catalytic activity of the peptides was less than that of imidazole for PNPA and PNPH. On the other hand, in the presence of a cationic surfactant and a hydrophobic peptide the hydrolysis of PNPH was significantly enhanced.

Sheehan *et al.*[1] and Kopple *et al.*[2,3] investigated cyclic hexapeptides containing histidyl and seryl residues or histidyl and tyrosyl residues as hydrolytic enzyme models. In these cases, however, detail study about the conformation of the cyclic peptides was not undertaken. On the other hand, Imanishi *et al.* studied the catalytic behavoir and the conformation of *cyclo*-D-leucyl-L-histidyl and found out that D-leucyl residue was an effective binding site for a hydrophobic substrate.[4,5] Recently they also synthesized the cyclic hexapeptide having L-histidyl-D-leucyl sequences and studied its catalytic activity and conformation in detail, where a substrate seems to be bound to D-leucyl residue by hydrophobic interaction.[6,7] In the previous studies, the author synthesized and investigated the cyclic hexapeptide having D-leucyl-L-histidyl sequences and found out that D-leucyl-L-histidyl sequence brings about β-turn.[8,9] In the present paper, therefore, the author would like to describe the catalytic behavior of the analogous peptides as well as the peptides investigated previously.[8,9] The effect of a cationic micelle on the catalytic activity was studied, too.

Experimental

Linear and cyclic peptides were synthesized in a similar manner as described previously.[8] Other reagents were commercially available. The reaction rate was determined by using the absorbance of *p*-nitrophenolate at 400 nm with a JASCO UVIDEC-1 spectrophotometer. Second-order rate constant (k_2) was estimated from the following equations,

$$\ln\{(OD_\infty - OD_0)/(OD_\infty - OD_t)\} = k_1 t,$$

$$k_2 = (k_1 - k_{spont})/[E],$$

where OD_0, OD_t, and OD_∞ mean the optical density at the time, 0, t, and ∞; k_1 and k_{spont} sinify the pseudo-first-order rate constant in the presence and absence of the catalyst, respectively; [E] designates the catalyst concentration per histidine residue.

Results and Discussion

In Table 1 is shown the second-order rate constant (k_2) of the hydrolytic reaction of *p*-nitrophenyl acetate (PNPA) and *p*-nitrophenyl hexanoate (PNPH) at pH 7.9 (0.1 mol dm^{-3} phosphate buffer) at 25 °C. All the peptides show less activity than imidazole. For PNPA the cyclic peptide **5** has lower activity than the linear peptide **4**. However, **9** has higher activity than **5**, while **8** has similar activity to **4**. There could be seen no significant difference in the behavior of the optical density at 245 nm (*N*-acylimidazole)[10] between **7** and **9**. Therefore it could not be confirmed that acyl group was transferred from the *N*-acylimidazole to the seryl hydroxyl group in **7**.[10] As a whole, the activity for

Table 1. Second-order rate constant (k_2) for the hydrolysis of *p*-nitrophenyl acetate (PNPA) and *p*-nitrophenyl hexanoate (PNPH)[a]

Catalyst	k_2 / mol^{-1} dm^3 min^{-1}

cyclo(-Ala-D-Leu-His-Ala-D-Leu-His-) (**9**)	6.0	4.3

a) 25 °C, pH 7.9 (0.1 mol dm^{-3} phosphate buffer), [PNPA]=[PNPH]=5.0×10^{-5} mol dm^{-3}, [catalyst]=1.0×10^{-3} mol dm^{-3} per histidine residue. 5 v/v % DMF was contained.

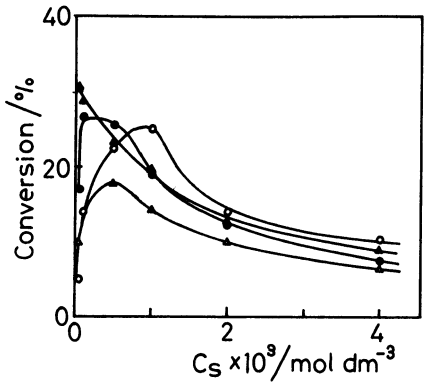

Fig. 1. Relation between the conversion at 20 min and the concentration of the cationic surfactant (C_s): HTAC-**10** (—○—), HTAC-**11** (—●—), BHDAC-**10** (—△—), BHDAC-**11** (—▲—). **10**; Boc-Ser(*O*-Bzl)-D-Leu-His-Ser(*O*-Bzl)-D-Leu-His-OCH_3, **11**; Boc-Ser(*O*-Bzl)-Leu-His-Ser(*O*-Bzl)-Leu-His-OCH_3.

PNPH is lower than that for PNPA. However, in the case of **4** the activity for PNPH is a little higher than that for PNPA. The activation energy of the hydrolysis of PNPA was almost equal to each other, which suggests that the hydrolytic rate is dominated by the frequency factor.

In Fig. 1 is plotted the conversion at 20 min against the concentration of a cationic surfactant. The surfactants used are hexadecyltrimethylammonium chloride (HTAC) and benzylhexadecyldimethylammonium chloride (BHDAC). Maximum of conversion can be seen in Fig. 1. It is considered that the first increasing stage in the lower concentration region may be caused by the formation of the micelle and the subsequent decreasing stage in the higher concentration region may be caused by the dilution of the catalytic sites and the substrate in the micelle. There is some difference in the catalytic property between **10** and **11**. The configurational difference between them is only that of leucyl residue (D and L). Therefore the conformational difference must be responsible for the different catalytic behavior. The rate enhancement by the combination of the peptide and the cationic micelle must be partly due to the formation of the hydrophobic ion pair between the ammonium group of the surfactant and the imidazolate anion which is a potent nucleophile and partly due to the activation of the neutral imidazole itself placed in the hydrophobic environment.[11,12]
