where Z^* is the number of charges on the polymer, γ_p^* is the activity coefficient of the polymer, and m' is the concentration of the salt (mol dm^{-3}) at equilibrium.[37] Since the A_2 is identical for the unimer and the multimer,[38,39] M_p in Eq. 29 can be regarded as M_1. When we assume that the first Donnan term in Eq. 29 mainly contributes to the A_2 value, the number of effective charges on a poly(Glu) unimer can be estimated to be 140—69, 130—61, 100—47, and 80—49, at $R=\infty$($\alpha\cdot=0.94$—0.24), 32 ($\alpha\cdot=0.80$—0 21), 16 ($\alpha\cdot=0.75$—0.15), and 8 ($\alpha\cdot=0.73$—0.15) respectively, where $\alpha\cdot$ is the degree of dissociation of Glu residues unbound by H^+ and Cu^{2+}.[15] The values of Z^* show a tendency to decrease with a lowering of the pH and are parallel with the $\alpha\cdot$. However, the Z^* values are 2 to 5 times smaller than the number of charges on a polymer, which were estimated by the degree of dissociation. This should show qualitatively that the charge-suppression effect by the salt-ion binding is included in the A_2 value and that the decrease in A_2 in Fig. 7(c) with a lowering of the pH and R should be a charge-neutralization effect caused by the binding of the Cu^{2+} and H^+ ions. However, the second term of Eq. 29 could not be determined by this study. Since it has been reported that the activity coefficient of poly(Glu) increases with the polymer concentration (positive second term in Eq. 29),[40] the real values of Z^* should be smaller than the values noted above.

The Equilibrium of the Aggregate Formation of Poly(Glu). With the data shown above, a more detailed discussion of the equilibrium of aggregation and its scheme can be given in combination with the theoretical treatment.

Since the M_w varies depending on the pH, Eq. 13 can be adopted for the analysis of the aggregation equilibrium. Since only two data of M_w at $R=\infty$ were available in the aggregation region, two simultaneous equations according to Eq. 17 were solved to determine the values of m and K''. The data of M_w at pH 4.28 and 4.38 give the number of H^+ ions, *i.e.*, m, to be 18.8 which should take part in the one-step association. With the aid of the value of C_0 ($=1.97\times10^{-6}$ mol of poly(Glu) unimer/dm^3), the log K'' can be estimated to be 87.9. This K'' value may be quite large but still reasonable, because the term of $((\gamma_{H^+}[H^+])^m)^{-1}$ contributes to this value, as may be seen in Eqs. 15 and 16. Since more than 62% of the Glu residues are discharged by H^+ binding at this pH,[15] the number of H^+ unbound Glu residues resting on a helix is less than 269 ($=(1-0.62)\times107000/151.1$). Thus, more than 3.5% ($=(18.8/2/269)\times100$) of the H^+ unbound Glu residues on a helix should be discharged by H^+ for the advance of the one-step association at pH 4.28—4.38. The contribution of Cu^{2+} ions to the aggregation, however, can not be estimated by this analysis, because the competitive binding between H^+ and Cu^{2+} ions to poly(Glu)[15] makes this analysis complicated. The attractive forces for the association of poly(Glu) may be hydrogen bonding between protonized carboxyl groups as in polymethacrylate,[41] intermolecular chelation by Cu(II), and hydrophobic interaction.

Aggregation Scheme, Side-by-side or Head-to-tail. Such an induction of aggregation by H^+ and Cu(II) binding suggests that helices associate in a side-by-side scheme, judging from the binding region of H^+ and Cu(II) on a helix. In order to determine whether the aggregation scheme is side-by-side or head-to-tail, $\langle s^2\rangle_z^{1/2}$ and M_w are correlated and the plots are fitted to the theoretical curves as shown in Fig. 8. Prior to this analysis, $\langle s_1^2\rangle^{1/2}$ should be assumed. The results of the viscosity study showed that the helix of poly(Glu) in 0.15 M NaCl is a slightly fat α-helix, with its long axis 640—1200 Å long (minor axis 10—18 Å),[19] in which the length of the α-helix of 1063 Å is included. In Fig. 8, the plots of $\langle s^2\rangle_z^{1/2}/\langle s_1^2\rangle^{1/2}$ *vs.* M_w/M_1, which were determined by means of the data at a helical content over 90%, are dispersed around the theoretical curves at $\sigma=0.7$—0.8 and $\sigma=0.9$—0.95, depending on the assumed helix types, with long axes of 640 (the upper group of points) and 1200 Å (the lower group of points) respectively, but irrespective of R. This shows that each helix in the multimer overlaps to each other in side-by-side, attached with a 70—95% length of a helix. This means that almost all of the bound Cu(II) is surrounded by helices of poly(Glu) in this case. Thus, it can form the characteristic complex with poly(Glu) ligands, as will be discussed later.

On the other hand, it is difficult to analyze the aggregation scheme in the helix-coil transition region with Eq. 24, because the conformation of the poly(Glu) unimer is not identical; it changes from a helix to not only a rather extended coil, but also to a compact coil, especially in the presence of Cu^{2+} ions, as has been shown above or in an subsequent viscosity study.[19]

However, in the helix-coil region, the increase in M_w is only 2—3 fold at most. Thus, the curve of $\langle s^2\rangle_z^{1/2}/\langle s_1^2\rangle^{1/2}$ *vs.* M_w/M_1 can be regarded as almost linear in the M_w/M_1 range of 1—3 as may be seen in Fig. 3. Since the curves of $\langle s^2\rangle_z^{1/2}/\langle s_1^2\rangle^{1/2}$ *vs.* M_w/M_1 for the aggregation of helices are also linear, as is shown in Fig. 2, the $\langle s^2\rangle_z^{1/2}/n$ value ($n=M_w/M_1$) was obtained; it should be a measure of the extension per poly(Glu) molecule.

The pH Dependence of $\langle s^2\rangle_z^{1/2}/n$ and the Complex Formation. Figure 9(a) shows the pH dependence of $\langle s^2\rangle_z^{1/2}/n$ at various values of R. In the absence of the Cu^{2+} ion and at around pH 5.5, poly(Glu) molecules shrink in the course of transition from a random coil to a helix, and at pH values lower than 4.7, they form the aggregate. Since the aggregate is of the side-by-side form, the $\langle s^2\rangle_z^{1/2}/n$ value does not increase additively with n; thus, $\langle s^2\rangle_z^{1/2}/n$ decreases with the low-

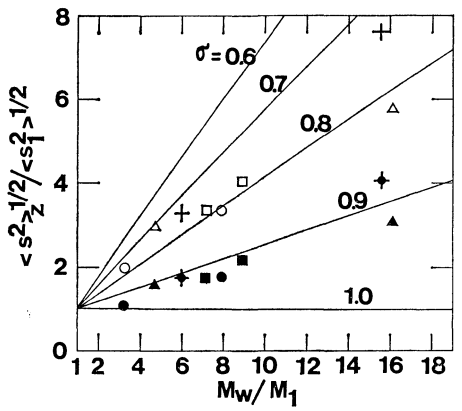

Fig. 8. The dependence of the observed data of $\langle s^2\rangle_z^{1/2}/\langle s_1^2\rangle^{1/2}$ on the values of M_w/M_1 of poly(Glu) at low pH region and at various R(∞ (crosses), 32 (squares), 16 (triangles), and 8 (circles)).
The $\langle s_1^2\rangle^{1/2}$ was assumed to be $640/\sqrt{12}$ Å (open symbols) or $1200/\sqrt{12}$ (filled symbols) Å. The solid lines are theoretical curves which were shown in Fig. 2(b).

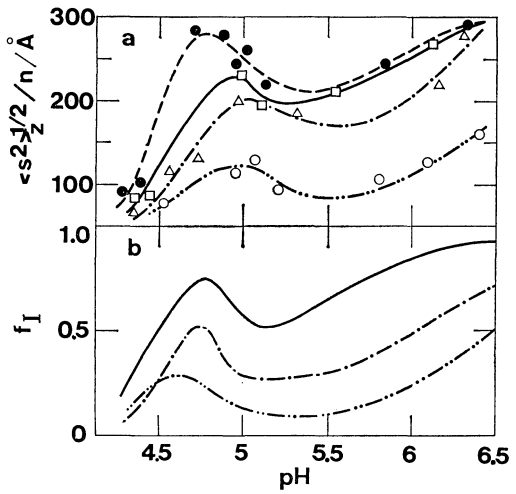

Fig. 9. The comparison of pH dependence of (a) root-mean-square radius of gyration divided by n, $\langle s^2\rangle_z^{1/2}/n$, and (b) the fraction of Complex I, f_I, from the Ref. 15: $R=\infty$ (--, ●), 32 (——, □), 16 (—·, △), and 8 (—··, ○).

ering of the pH because of one-sided increase in n. In the presence of Cu(II), $\langle s^2\rangle_z^{1/2}/n$ further decreases over the entire pH range. It seems that the bound Cu(II) induces the further shrinking of poly(Glu) and/or changes its conformation to a near-spherical type, whose model shows the small slope of the $\langle s^2\rangle_z^{1/2}/\langle s_1^2\rangle^{1/2}$ *vs.* n curve shown in Fig. 3.

It is interesting to compare the pH variation in $\langle s^2\rangle_z^{1/2}/n$ with that in the fraction of one of the three classes of poly(Glu)–Cu(II) complexes, *i.e.*, f_I (the fraction of Complex I in Ref. 15), which was clarified by the spectroscopic method.[15] The curves in both figures are almost parallel to each other. In the region where f_I decreases from 1.0 in Fig. 9(b), Complexes II and III are predominant instead of I in the pH ranges at around 5—5.5 and below 5 respectively.[15] This should show that Complex II appears when the poly(Glu) shrinks in the helix-coil intermediate transition region, while Complex III appears in parallel with the aggregate formation. The Cu(II) which is surrounded by the ligands of poly(Glu) in the intra- and inter-molecular fashions should form the chelates characteristic of its coordination field, *i.e.*, the species, number, and symmetry of the ligand field, like the complexes proposed in Ref. 15. The chelation is different from that of Complex I, in which Cu(II) seems to bind the extended coil or helix of poly(Glu). This interpretation is quite consistent with all our previously reported results.[11,13–15]

Conclusion

It was concluded that, in addition to the helix-coil transition, the conformation of poly(Glu) shrinks in the course of the helix-coil transition and forms an aggregate of helices in the low-pH range. The shrinking and the aggregate formation of poly(Glu) induce the chelation of Cu(II) to poly(Glu) residues in intra- and inter-molecular fashions, and *vice versa*. It is quite consistent that, in Complexes II and III, the Cu(II) binds to the side-chain carboxylate groups which are remote from, and independent of, each other on a single polymer strand or on different ones, as is shown by stoichiometric analysis.[15] Thus, this work further confirms our conclusions that the Cu(II) binds to the nearest-neighbor ligands on the extended coil or the helix portion of the polymer (Complex I), or that it binds to the ligands in the compact coil of poly(Glu)–Cu(II) (Complex II) while, in the low-pH range, Cu(II) binds to the ligands of the helical poly(Glu) in the multistranded aggregate (Complex III).[11,13–15]

The author would like to express his deep gratitude to Associate Professor Kiwamu Yamaoka of Hiroshima University for his helpful discussions and continuous encouragement in the course of this study.

A preliminary work (Light Scattering of Poly(Glu)–Cu(II) Solutions without Equilibrium Dialysis) was presented at the Annual Meeting of the Chemical Society of Japan in the Chugoku and Shikoku Areas (at Ube) in 1979.

Pressure Effect on Transference Numbers for KCl in Ethanol–Water Mixtures at 25 °C

Masakatsu Ueno,* Shōgo I, and Kiyoshi Shimizu

Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602

(Received May 6, 1982)

Cation transference numbers for 0.02 mol dm^{-3} KCl in 0-, 5-, 10-, 15-, 20-, and 30-mol% ethanol–water mixtures were determined by the moving boundary method at 25 °C up to 1500 kg cm^{-2} (1 kg cm^{-2}=0.9807×10^5 Pa). The cation transference number, t_+, initially increases with increasing ethanol content up to 10—15 mol% and then decreases at all the pressures studied. In water and ethanol–water mixtures below 20 mol%, t_+ at the definite solvent decreases with increasing pressure. The decreasing rate becomes smaller as the ethanol content increases, and the tendency is reversed finally at 30 mol%. To account for the variation of t_+ with solvent composition and pressure, specific interactions between the ions and solvent have been taken into consideration.

When we study ionic conductances, transference numbers are required to split electrolyte conductances into the ionic components without any assumptions. There have been several reports on the pressure effect on transference numbers in water,[1–6] but none in alcohol–water mixtures. Ionic conductances in alcohol–water mixtures are needed to elucidate the ionic transport process, in particular in relation to the liquid structure. Numerous properties of alcohol–water mixtures show a extremum in the water-rich region, which may be a reflection of increased solvent structure.[7] The solvent structure is also affected by pressure and temperature as well as by solvent composition.

In the previous paper,[8] conductances of potassium halides in water were measured at high pressure. Here, to provide a basis from which to investigate how the pressure dependence of ionic conductances of K^+, Cl^-, and other ions varies with the ethanol content in ethanol–water mixtures, we carried out the transference number measurements for KCl in the mixed solvents up to 30 mol% ethanol at 25 °C up to 1500 kg cm^{-2}. The results are compared with the Zwanzig dielectric friction theory,[9] which gives one important step to a more quantitative theory.

Experimental

Chemicals and Solutions. Ethanol of guaranteed reagent grade (Nakarai Chemical Co., Ltd.) was dried with Molecular Sieves (3A, Nakarai) and purified by distillation under a nitrogen atmosphere. Fractionally distilled ethanol had a density of 0.7853 g cm^{-3}, and showed a water content of 0.05 wt% in the Karl Fischer test. Its conductivity was less than 3×10^{-7} Ω^{-1} cm^{-1}. Conductivity water was prepared by passing distilled water through a mono-bed ion-exchange resin. Its conductivity was about 1.2×10^{-6} Ω^{-1} cm^{-1}. Potassium chloride salt of high purity was obtained from Merck and dried above 130 °C. Aqueous mixtures up to 30 mol% ethanol were prepared by weighing; the solutions of 0.02 mol dm^{-3} KCl were made by use of measuring flasks. The concentrations of the solutions at high pressure were corrected with the densities of the aqueous mixtures.[10,11]

Apparatus. Cation transference numbers at high pressure were determined by the moving boundary method with an autogenic-type cell equipped with a cadmium anode and a silver–silver chloride cathode, as shown in Fig. 1. The boundary movement was followed by measuring the change in resistance between platinum probe electrodes separated by 3 cm and sealed into 2 mm i.d. hard glass tube. The resistance was measured by a Yanagimoto MY8 type a.c. bridge. A constant current was supplied by a direct current stabilizer (Metronics 691B type), and measured periodically during electrolysis by potentiometric measurement (a Shimadzu digital potentiometer) of a potential drop across a 100-Ω standard resistor, connected in series with the moving boundary cell. The small current of 0.15 mA was used to minimize the effect of heat developed from electrolysis. A stop-watch was used to measure the time during which the current flowed.

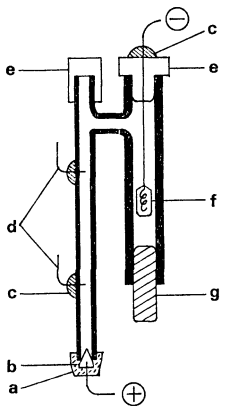

Fig. 1. High pressure autogenic cell for the measurement of the transference number.
a: DeKotinsky, b: cadmium anode, c: Araldite, d: probe electrode, e: Teflon cap, f: silver–silver chloride cathode, g: glass piston.

Conductivities of solvents and solutions were determined by using a syringe-type cell which is described elsewhere.[12]

Pressure generated by means of a hand pump was measured to ±3 kg cm^{-2} by a calibrated Bourdon gauge (Nagano Keiki Seisakusho, Ltd.). The oil pressure in the pressure vessel was transmitted to the solution by a glass piston of the syringe. The temperature of the oil bath in which the pressure vessel was immersed was kept constant at 25± 0.03 °C.

Determination of the Transference Number. The apparent cation transference number, t_+', can be calculated from the equation:[13]

$$t_+' = \frac{\Delta V C F}{i \Delta t}, \quad (1)$$

where ΔV is the volume (cm^3) swept out by the boundary

during time Δt (s) at i (mA) of current, C is the concentration of solution (mol dm^{-3}), and F is the Faraday constant. Considering the change in resistance between probe electrodes $\Delta R(\Omega)$ when the boundary moves upward, Eq. 1 can be transformed to the following equation:[1,5]

$$t_+' = \frac{VCF}{i(R_2-R_1)}\frac{\Delta R}{\Delta t}, \quad (2)$$

where V is the volume (cm^3) between the probe electrodes, and R_1 and R_2 are the resistances (Ω) when the uniform glass tube between the probe electrodes is occupied by KCl solution only and by $CdCl_2$ solution only, respectively. V was determined by calibration runs at 1 atm and 25 °C with 0.02 mol dm^{-3} KCl aqueous solution and by taking Longsworth's value of $t_+=0.4901$.[13] V's at high pressure were corrected with the compressibilities of Pyrex glass.[14] The variation of the resistance between the probe electrodes with time is shown in Fig. 2 for a typical run.

The transference number corrected for the solvent conductivity and volume change at the anode, t_+, is calculated from the following equation:[15]

$$t_+ = (t_+'-C\Delta\overline{V})\left(1+\frac{\kappa^\circ}{\kappa}\right). \quad (3)$$

Here,

$$\Delta\overline{V} = 0.5V^\phi(CdCl_2) - t_+V^\phi(KCl) - 0.5V_m(Cd), \quad (4)$$

and κ° and κ are the solvent and solution conductivities, and V^ϕ and V_m are the apparent molar volume and the molar volume, respectively. The volume correction term is small for dilute solution, so it was neglected.

Estimation of the Experimental Error. From Eq. 2, an estimate can be made of the magnitude of the error. The concentration may be affected through possible contamination with the high pressure system. The volume between probe electrodes, V, was determined within 0.1%. The error for the resistance measurements due to diffusion was about 0.08%. The variation of the current for a given run was within 0.01%. The slope of the resistance *versus* time curve had an error of about 0.05%, when approximately ten points were used for determining the slope. Considering these possible errors in the determined parameters, the transference number given by our measurements should be accurate within 0.3%.

Results and Discussion

Transference numbers obtained are listed in Table 1. The present results at 1 atm are compared with those by other workers.[16–19] As shown in Fig. 3, above 10 mol% our results are higher by 0.8% than those by Erdey-Grúz and Majthényi[16] and lower by 0.8% than those by Fratiello and Kay,[18] and Esteso and Grandoso.[19]

As can be seen in Fig. 4, t_+ has a maximum around 10—15 mol% at all the pressures studied. The solvent composition where t_+ exhibits a maximum slightly shifts to the ethanol-rich region with increasing pressure. In water and aqueous mixtures below 20 mol%, t_+ at the definite solvent decreases with increasing pressure. The decreasing rate becomes smaller as the ethanol content increases, and the tendency is reversed finally at 30 mol%. Since transference numbers for K^+ ion in KCl solutions are close to 0.5, there is very little concentration dependence.[20] In the present discussion, we assume that the variation of t_+ with solvent composition and pressure is equal to that at infinite dilution, t_+°.

To investigate the variation of the transference number with solvent composition, the experimental results are compared with the Zwanzig dielectric friction theory,[9] which is based on a continuum model for solvent. It is expressed by Eq. 5 for the slipping case:

$$\lambda_i^\circ = \frac{eF}{\eta(4\pi r_i + \phi r_i^{-3})}, \tag{5}$$

where,

$$\phi = \frac{3}{4}\left(\frac{e^2\tau}{\eta}\right)\frac{(\varepsilon_o - \varepsilon_\infty)}{\varepsilon_o(2\varepsilon_o + 1)}. \tag{6}$$

Here, λ_i°, r_i, e, η, τ, ε_o, and ε_∞ are the molar conductance of the monovalent ion at infinite dilution, the radius of the ion, the protonic charge, the solvent viscosity, the solvent dielectric relaxation time, the low and the infinite frequency dielectric constants, respectively. From the definition,

$$t_+^\circ = \frac{\lambda^\circ(K^+)}{\lambda^\circ(K^+) + \lambda^\circ(Cl^-)}. \tag{7}$$

Examination of Eqs. 5 and 7 shows that t_+° decreases with increasing ϕ, if r_i is taken to be the crystallographic radius of the ion.[21] By using the values of τ,[22] ε_o,[23] and η[24] at 0-, 20-, and 30-mol% at 1 atm, and with the assumption that ε_∞ is equal to that of water,[25] the calculated value of ϕ in Eq. 6 is shown to increase with increasing ethanol content. That is, t_+° should decrease with increasing ethanol content, which does not agree with the experimental results seen in Fig. 4. Kay *et al.*[26] also pointed out that the initial increase in ionic Walden products with ethanol content can not be explained qualitatively by the Zwanzig theory. Therefore, it is necessary to consider specific interactions between the ions and solvent.

As is reviewed by Franks and Ives,[7] the addition of ethanol to water initially increases the degree of structure of the solvent and then decreases it. From a wide variety of thermodynamic and transport data, both K^+ and Cl^- ions are classified as structure breakers in hydrogen-bonded solvents. If the structure-breaking effect of K^+ ion is larger than that of Cl^- ion, the structural excess mobility of K^+ ion is greater than that of Cl^- ion.[27] The effect is more pronounced in more highly structured solvents. Since the degree of structure of the aqueous mixtures is enhanced in the water-rich region containing up to about 10 mol%, the mobility of K^+ ion becomes progressively faster with respect to Cl^- ion. The initial increase in t_+ obtained with increasing ethanol content would be primarily ascribed to the relative structure-breaking properties of these two ions.

Zwanzig theory can not also account for the pressure dependence of the transference number in water. With the values of ε_o[28] and η,[29] and with the assumption that the pressure dependence of τ at 20 °C[30] is equal to that at 25 °C and ε_∞ is invariant under compression, ϕ in Eq. 6 is shown to decrease with increasing pressure. That is, t_+° in Eq. 7 should increase with increasing pressure, which is in contradiction to the experimental results.

To interpret the pressure dependence of the transference number in water, the effect of pressure to break the water structure may be taken into consideration.[4] As pressure weakens the hydrogen bonds and decreases the degree of structure of water, the structural excess mobility of K^+ ions may decrease relatively more than that of Cl^- ions with increasing pressure. Consequently, the cation transference number may decrease with increasing pressure. In the mixed solvents containing a small amount of ethanol, the decreasing rate of the cation transference number is expected to be larger than in pure water. However, this is not in conformity with the experimental results. Other specific interactions between the ions and solvent must be considered.

The orientation of solvent molecules around the negative ion, Cl^-, may be different from that around the positive ion, K^+. The ion-solvent interaction of K^+ ion is mostly dominated by the ion-dipole interaction, while that of Cl^- ion involves the additional contribution of hydrogen bonds.[31] The hydrogen bonds between water molecules and Cl^- ions may be broken down by pressure, and the degree of the hydration of Cl^- ion may decrease slightly with increasing pressure. The decrease of the cation transference number in water with increasing pressure was ascribed to this pressure effect.[5] Water molecules in alcohol-water mixtures are more basic than in pure water.[32] The contribution of hydrogen bonds between water molecules and Cl^- ion would be smaller in ethanol-water mixtures than in pure water. Therefore, the decreasing tendency of the cation transference number with pressure would become weaker with an increase in ethanol content. At 30 mol%, the specific interaction between water molecules and Cl^- ions would be insignificant.

Further conductivity measurements for KCl and various electrolytes at high pressure will reveal the ion-solvent interactions more thoroughly.

Electronic Structure and Spectra of Organic Dye Anions of Uranine and Eosin Y

Koichi HIRANO

Department of Chemistry, Miyagi University of Education, Aramaki-aoba, Sendai 980

(Received May 14, 1982)

The excited states of the organic dye anions of Uranine and Eosin Y are invesitigated by the semi-empirical SCF-MO-CI calculations. The two-center core integral values of the C–Br bond (−0.20 eV) were determined. Agreement between the calculated and observed spectra was satisfactory. The first intense bands of these dye anions can be assigned to the HOMO→LUMO transition band arising from the local excitation of xanthene ring. The second bands are interpreted as the overlap of the two transition bands for the xanthene ring and for the residual π-systems.

Because of the interest in the metachromatic changes exhibited by many dye ions,[1–5] we have made experimental studies on the solvato-chromic effects of several xanthene dyes.[6] We analyzed the solvent effects on the Eosin Y spectra using the modified McRae's theory,[7] and determined separately the values of the dispersion shift and the hydrogen bond shift.[8] In addition, an attempt was made to estimate the electrostatic shifts for Eosin Y anion by means of Hückel MO perturbation theory.[9] It was concluded that quantitative knowledge about the electronic transitions of the solute dye ions is needed to obtain a deeper understanding of the solvato-chromic effects. For xanthene dyes including Uranine and Eosin Y, however, very little is known about the nature of the electronic transitions.

The main aim of this invesitigation is to gain information about the electronic transitions of Uranine and Eosin Y anions. For this purpose, the lower excited states of the anions of Uranine ($URAN^{2-}$) and Eosin Y ($EOSY^{2-}$) were invesitigated using semi-empirical SCF-MO-CI calculations.

Theoretical

Methods and Models. The Pariser-Parr-pople type of SCF-MO calculations[10,11] with limited D–CI were employed. In these calculations, singly-excited configurations higher than the ground configuration by 10 eV, and doubly-excited configurations higher than the ground configuration by 18—25 eV, were taken into account. The equal charge sharing models (see Fig. 1), in which a formal negative charge is equally shared between the two oxygen atoms O (24) and O(25), were considered for each of the anions. The attached benzene ring with a carboxy group cannot rotate freely around the C(14)–C(15) linkage, because of its steric hindrance.[12] We determined the dihedral angle to be $\theta=73°$ from the sum of the van der Waals radi of C(3) and C(23).[13] The molecular geometry used were assumed as follows: All bond angles equal to 120° and C(14)–C(15)=1.51,[14] C(21)–C(22)=1.24, C(21)–C(23)=1.24,[15] C(5)–O(24)=1.26, C(10)–O(25)=1.26,[16] C(3)–Br(26)=1.89,[17,18] C(6)–O(7)=1.39, and aromatic C–C bond lengths equal to 1.39 Å.

Parametrization. One-center-core and repulsion integrals W's, γ_{rr}'s were evaluated from the valence state ionization potentials and electron affinities. Two-center-core integrals, β_{rs}'s were calculated by the Wolfsberg-Helmholtz's formula.[19] Taking account of the rotation of the benzene ring, the two-center core integral for the C(14)–C(15) bond was formulated by Eq. 1;

$$\beta_{14,15} = \frac{K}{2} S_{14,15}(\theta=0°)\{W_{14}+W_{15}\}\cos\theta, \qquad (1)$$

where, θ is the dihedral angle, $S_{14,15}$ the overlap integral between C(14) and C(15), and K a constant taken to be 0.96 when β_{CC} in benzene is −2.39 eV. For the carbonyl and carboxy oxygen, $W_O^{-1/2}$ is taken as the arithmetic mean of W_O and $W_{O(-)}$; $W_{O(-)}$ is determined by a method identical with that previously reported by Nishimoto and Förster.[20] The two-center-repulsion integrals γ_{rs} were evaluated by the Nishimoto-Mataga's formula.[21] In the present calculations, the Br atom is assumed to participate in the pi-electronic system with a 4p lone electron-pair.

However, we have no available parameters for the atom, so we determined that parameter by following procedure. A one-center-core integral W_{Br} is estimated from the second ionization potential of the free Br atom.[22] The one-center-repulsion integral, γ_{BrBr}, and the effective nuclear charge, Z_{eff}, were evaluated by Morita-Dewer's formula.[23] The two-

Table 1. Parameters

Core	W_{rr}/eV[a]	$\langle rr\|rr\rangle$/eV[b]	Q_r[c]	Z_r^{eff} [d]	A_r/Å[e]
C^+	11.22	10.06	1.00	3.25	1.358
O^+	17.70	15.23	1.00	4.08	0.9453
O^{2+}	33.90	18.93	2.00	5.65	0.7606
$O^{-1/2}$	17.70	15.23	1.00	4.08	0.9453
$O^{(-)}$	17.70	15.23	1.00	4.08	0.9453
Br^{2+}	21.60	13.80	2.00	4.21	1.043

a) W_{rr}: Valence-state ionization potential. b) $\langle rr|rr\rangle$: One-center repulsion integral. c) Q_r: Core charges on atom r. d) Z_r^{eff}: Effective nuclear charge. e) A_r: $A_r=14.398/\langle rr|rr\rangle$ (Å).

center-core integral, β_{CBr}, was regarded as a parameter. Preliminary calculations were made by changing β_{CBr}, from -0.1 to -1.0 eV; an appropriate value of this parameter was determined as $\beta_{CBr}=-0.2$ eV. This value is lower than that estimated for 3-bromophenanthrenquinone molecule by Kuboyama *et al.*[24] A major source of this difference is that in negative ions, the pi-electrons are much more weakly bound and the spatial distribution of the electrons is more diffuse.[25,26]

Subsequently the correct β_{CBr} would be lower in magnitude than that estimated from a Slater type 4p orbital. The parameters finally employed were listed in Table 1.

Experimental

Uranine and Eosin Y obtained commercially were purified in the manner described previouly.[6] Wako Junyaku, Spectro grade, acetonitrile was used without further purification.

Visible and ultraviolet absorption spectra were measured on a Shimadzu UV200-S spectrophotometer. All the measurements were carried out at 25.0 °C.

Results and Discussion

Characteristics of Molecular Orbitals. The SCF-MO energy levels considered in CI calculation are illustrated in Fig. 2. One of interesting features found in the energy-level diagrams is that the HOMO of $URAN^{2-}$ is localized on C=O, whereas that of $EOSY^{2-}$ is localized both on C=O and Br. This indicates that in $EOSY^{2-}$ C=O and Br make dominant contributions to the lower energy excitations arising from the HOMO to the appropriate unoccupied MO's.

Another feature found in the energy diagram for $EOSY^{2-}$ is that the four new levels that originated from the 4p Br orbitals are closely located just below the HOMO level, so that the HOMO level is slightly destabilized. This orbital energy destabilization produces a red shift in the lowest energy absorption band of $EOSY^{2-}$ in comparison with that of $URAN^{2-}$.

Transition Energies and Oscillator Strengths. The calculated and experimental transition energies and oscillator strengths were shown in Table 2, where the calculations without D-CI are also shown for the sake of comparision. Agreement between the calculated and experimental values is satisfactory, excepting the oscillator strength for the lowest transitions of both

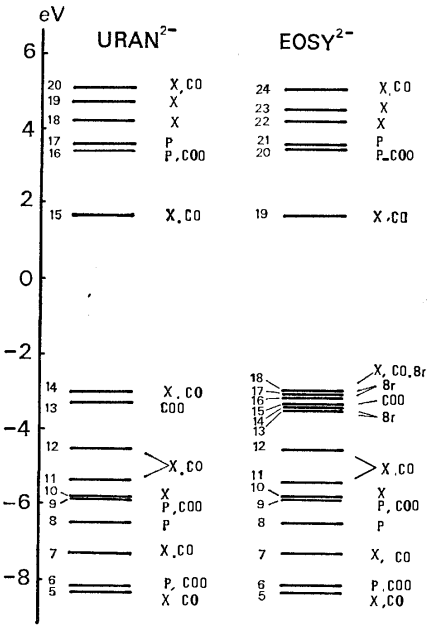

Fig. 2. MO energy-level diagrams for $URAN^{2-}$ and $EOSY^{2-}$, together with the orbital character. Symbol P and X designate the MO of phenyl and xanthene groups, respectively.

dye anions. As is shown in the table, the D-CI procedure does not always reduce the value of oscillator strengths, but it does enhance that value. This unexpected result may be partly ascribable to the fact that in our calculations, the number of doubly-excited configurations is not sufficiently large.

MO Coefficient Diagrams. The ground and excited state functions Ψ_J ($J=0$, $a,b,c,..$) are listed in Table 3. In the table, the configurations whose weight of mixing is larger than 2.0%, are given. On the basis of the main terms of the ground state functions, the MO coefficient diagrams associated with the excitations $\Psi_{t\to m}$'s$\leftarrow\Psi_G$ can be constructed from the one electron molecular orbitals of ϕ_t and ϕ_m as is shown in Figs. 3—4.

Electronic Spectra of $URAN^{2-}$. The calculated and observed spectrum of an acetonitrile solution of $URAN^{2-}$ are shown in Fig. 5. In the absorption spectrum of an acetonitrile solution of $URAN^{2-}$, we can see four π—π^* transition bands at 19.5, 32.5, 37.2, and 43.9×10^3 cm^{-1}. The additional tail at lower energy side ($22—23\times10^3$ cm^{-1}) may be ascribed to the singly ionized species.[27] The first high intensity visible band (1) is assigned to the transition $\Psi_a\leftarrow\Psi_0$, designated by line (a), which is mainly contributed by a HOMO→LUMO transition arising from the local excitation of xanthene ring (Fig. 3). The second weaker band (2), is regarded as the overlap of the two different types of transitions $\Psi_b\leftarrow\Psi_0$ and $\Psi_c\leftarrow\Psi_0$, denoted by (b) and (c): $\Psi_b\leftarrow\Psi_0$ Originates from the excitation of the attached benzene ring with carboxy group, whereas $\Psi_c\leftarrow\Psi_0$ originates from the excitation of the xanthene ring (Fig. 3). The third band (3) may be regarded as the superposition of the two transitions (d) and (e), although this assignment may not be unique. The predicted polarization direc-

tion of transition (*a*) is along the x-axis and those of (*b*) and (*c*) are along the y-axis. This agree well with the prediction based on the fluorescence polarization measurements.[28]

Electronic Spectra of EOSY^{2-}. The absorption spectra of acetonitrile solution of EOSY^{2-} and URAN^{2-} generally resemble (Figs. 5, 6): There are four π—π^* transition bands at 18.9, 31.2, 38.2, and 41.2×10^3 cm^{-1} (Fig. 6). The first intense band (1) shows a small red shift in comparision with the corresponding band of URAN^{2-}. This is interpreted in terms of orbital destabilization due to the substituent effect with bromine. This band is assigned to the transition $\Psi_a\leftarrow\Psi_0$ mainly contributed by a HOMO→LUMO transition, arizing from the local excitation of the xanthene ring. A chracteristic feature of this transition is that on going from Ψ_0 to Ψ_a, a substantial amount of charge transfer from the carbonyl oxygen ($-0.127e$) and from the bromine substituents ($-0.229e$) into the xanthene ring, especially the central carbon atom C(14), the latter being primary (Fig. 4). The second weaker band (2) is regarded as the overlap of the transitions $\Psi_e\leftarrow\Psi_0$ and $\Psi_f\leftarrow\Psi_0$ denoted by (*e*) and (*f*). Transition $\Psi_e\leftarrow\Psi_0$ has almost the same nature as that of $\Psi_b\leftarrow\Psi_0$ for URAN^{2-} which has been already been described. Transition $\Psi_f\leftarrow\Psi_0$, however, is somewhat different in nature from that of $\Psi_c\leftarrow\Psi_0$ for URAN^{2-}: On going from Ψ_0 to Ψ_f, the charge tend to move away from the xanthene ring to the carbonyl oxygen (Fig. 4). The third band (3) may be assigned to the superposition of the transitions (*g*) and (*h*), however, the fourth band (4) cannot be assigned to the calculated transitions.

Neither the transition energies nor the oscillator

The Adsorption of Tetramethylurea at the Mercury/Water Interface

Osamu IKEDA,* Hiroyuki JIMBO, and Hideo TAMURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, 2-1 Yamadaoka, Suita, Osaka 565

(Received June 1, 1982)

The adsorption of tetramethylurea (TMU) at the mercury/water interface was studied by means of differential capacity measurements. TMU was found to take three different orientations, depending on the surface excess and the charge sign of the electrode. These orientations could not be explained simply by the orientation of the TMU dipole in the electric field or by the hydrophobic interaction between the methyl groups of TMU and the electrode, but it was explained on the basis of interactions between TMU and water molecules, and on the basis of the TMU molecules themselves in the adsorption layer and an electronic polarization effect of the nitrogen atoms in TMU. A few water-adsorption models were compared in an attempt to estimate the dipole moment of the TMU molecule at the interface.

It has been shown in a recent paper[1] that tetramethylthiourea (TMTU) at the mercury/aqueous solution interface takes a vertical orientation with the sulfur atom on the electrode, in a manner similar to thiourea.[2] Such an orientation was explained on the basis of the hydrophobicity of the sulfur atom and the high electronic polarizability of the >C=S bond. In order to make these points clearer, it is desirable to study the adsorption behavior of tetramethylurea (TMU), in which the sulfur atom of tetramethylthiourea (TMTU) is displaced by the oxygen atom with a lower electronic polarizability and a higher hydrophilicity, compared to that of the sulfur atom. It is also interesting to see how the dipole moment of TMU, lower than those of other ureas,[3] is reflected in the adsorption behavior.

The adsorption behavior of organic compounds at the mercury/aqueous solution interface[4] is usually elucidated by a determination of the adsorption isotherm and by the change in the potential drop across the inner layer, $\Delta_2^M\phi$, due to adsorption. In the case of organic compounds with a polar group, a somewhat accurate orientation can be estimated from the change in $\Delta_2^M\phi$ due to adsorption. It has seldom been tried, however, to estimate the dipole moment of an adsorbed molecule because of the uncertainty in the potential drop due to adsorbed water dipoles, Δg^w_{dipole}. Parsons and his co-workers[5] first evaluated the dipole moment of an urea molecule at the mercury/water interface after the establishment of the water-adsorption model.[6] Studies along this direction seem to be important for a better understanding of the double-layer structure and property, and of their effects on the electrode kinetics.

The accurate evaluation of the dipole moment of an adsorbed molecule demands an accurate Δg^w_{dipole} as a function of the electric field. Several water-adsorption models[7] have been proposed, along with Δg^w_{dipole} as a function of the surface charge density. Aside from the idea contained in each model, however, the agreement in the values of Δg^w_{dipole} is not so good among models. In this study, the Bockris-Habib (B-H) model,[8] the "experimental" model by Trasatti (T-model),[9] and the Damaskin-Frumkin (D-F) model[10] were taken up and compared in the evaluation of the dipole moment of an adsorbed TMU molecule.

Experimental

An analytical reagent grade of tetramethylurea (TMU) was used, it was vacuum-distilled twice before use. The sodium fluoride was of a high-purity reagent grade (Merck, ultrapure) and was used without further purification. The water and mercury were triply distilled before use. Nitrogen deoxygenated by passing it through copper meshes heated to 400 °C was used for deaeration and then blown over the solution. An aqueous 0.5 M NaF solution (1 M=1 mol dm^{-3}) was used as the supporting electrolyte. Eleven different concentrations of TMU were prepared to cover 2×10^{-3} M and 1×10^{-1} M.

The differential capacity, C, was measured at 25±0.1 °C using a dropping mercury electrode and by a method similar to that of Hills and Payne.[11] The measurement was carried out at 7.2 s after the birth of a mercury drop whose total life was about 13 s in pure 0.5 M NaF and at several frequencies, f, with an amplitude of 5 mV. The equilibrium capacities were obtained by extrapolating the linear relation of C against $f^{1/2}$ at a constant potential to $f=0$. A vertical capillary as the test electrode was prepared by drawing a Pyrex glass tube and was siliconed on the internal wall by passing through a vapor of dimethyldichlorosilane for several seconds. A KCl-saturated calomel electrode (SCE) and a cylindrical platinum plate, with a mercury drop at the center, were used as the reference and the counter electrode respectively. The mercury height from the reservior to the capillary tip was 1.4 m. The flow rate of mercury was determined by weighing mercury recovered during a given time.

The potential of zero charge, E_z was measured using a streaming electrode,[12] while the interfacial tension at the E_z, γ_z was measured by the maximum bubble pressure method following Schiffrin.[13] Most of the parameters essential to the analysis of the adsorption were derived by the double integration of the equilibrium capacity-potential curves using a computer program.

No corrections for the medium effects[14,15] on the activity of the supporting electrolyte or for the activity coefficient of the adsorbate[16] were taken into consideration.

Results and Discussion

Differential Capacity-potential Curves. Figure 1 shows the equilibrium differential capacity-potential curves measured with several concentrations of TMU. Two adsorption-desorption peaks are observed, but the shape of the peak at more negative potentials becomes higher and narrower than that at more positive po-

tentials with an increase in the concentration of TMU. This suggests that the attractive interaction among adsorbed molecules at more negative potentials is stronger than that at more positive potentials.[17]

Data of E_z and γ_z. Table 1 summarizes the data of E_z and γ_z. Positive shift of E_z with an increase in the concentration of TMU, C_{TMU}, was observed, as opposed to the negative shift of E_z in TMTU.[1] The orientation of TMU at E_z is expected to differ from that of TMTU.

Surface Excess. The surface excess, Γ, at a constant charge density, σ, was evaluated by means of the following relation: $\Gamma=-(1/RT)(\partial\xi/\partial\ln C_{TMU})$, where ξ is the Parsons function ($\xi=\gamma+\sigma E$).[18]

Figure 2 shows the variation in Γ at different concentrations of TMU with the surface charge density. The maximum of surface excess, Γ_{max}, was shifted toward a negative charge density with an increase in the concentration.

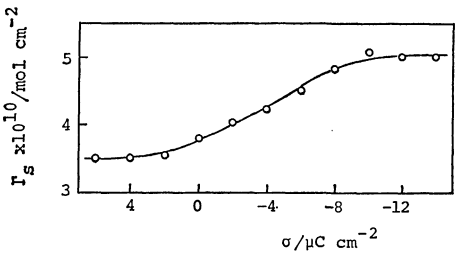

Fig. 3. Variation of Γ_s with surface charge density.

Figure 3 shows the surface excess at saturation, Γ_s, which was obtained by an extrapolation of the plot of $1/\Gamma$ against $1/C_{TMU}$ at a constant charge density to $1/C_{CMU}=0$. We observed two extreme values of Γ_s, namely, 3.5×10^{-10} mol dm^{-2} and 5.0×10^{-10} mol cm^{-2}, at positive and negative extremes of the surface charge density respectively.

Potential Drop across the Inner Layer, $\Delta_2^M\phi$. The value of $\Delta_2^M\phi$ was evaluated using this relation; $\Delta_2^M\phi=E-E_z-\Delta_S^2\phi$, where E and E_z are the potential at a constant charge density and the potential of zero charge for the electrolyte solution without any specific adsorption of ions (−0.432 V *vs.* SCE,[19]) respectively, and where $\Delta_S^2\phi$ is the potential drop across the diffuse layer at a constant charge density, which was calculated using the Gouy-Chapman theory.[20] The $\Delta_2^M\phi$ defined above corresponds to Grahame's rational potential difference.[20]

Figure 4 shows the change in $\Delta_2^M\phi$ due to the adsorption of TMU. The relations between $\Delta_2^M\phi$ and Γ for $\sigma\geqslant2$ μC cm^{-2} were linear, while those for $\sigma<2$ μC cm^{-2} were also linear at a lower surface excess, but were curved at a higher surface excess. When an adsorption isotherm can be described by the two series capacitor (TSC) model,[21] where the free energy

Charge density is indicated by each line.

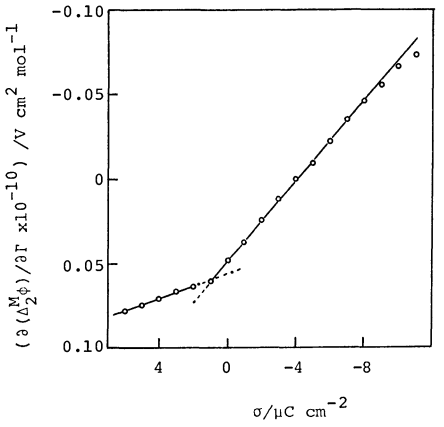

Fig. 5. Relation between $\partial(\Delta_2^M\phi)/\partial\Gamma$ obtained for the region where linear $\Delta_2^M\phi$-Γ relations were observed in Fig. 4 and the surface charge density.

of adsorption is a function of the charge density, a linear relation between $\Delta_2^M\phi$ and Γ should be observed for a constant orientation. In this sense, the linear portion of the $\Delta_2^M\phi-\Gamma$ curves in Fig. 4 can be assumed to result from a constant orientation based on the TSC model.

The magnitude of the positive shift of $\Delta_2^M\phi_{\sigma=0}$ with Γ for TMU is much larger than that of pyrazine[22] or ethylene glycol,[23] which are known as compounds with a small effective normal dipole moment, which means that the normal component of the dipole moment to the electrode surface is small. This suggests that TMU at a higher surface excess is adsorbed through an orientation with the positive end of the dipole toward the electrode surface.

Figure 5 shows the relation between the slope of the linear portion of the $\Delta_2^M\phi-\Gamma$ curves in Fig. 4 and the surface charge density. Two straight lines with different slopes are observed in Fig. 5. This indicates that the adsorption of TMU for $\sigma<2$ μC cm^{-2} and that for $\sigma\geqslant2$ μC cm^{-2} can not be described by the same isotherm. Since the charge of the maximum adsorption, σ_{max}, is defined as σ at $(\partial\Delta_2^M\phi/\partial\Gamma)=0$,[4] the former is the adsorption with $\sigma_{max}=-15$——17 μC cm^{-2}, which was elucidated by an extrapolation, and the slope, $\partial(\partial\Delta_2^M\phi/\partial\Gamma)/\partial\sigma=3.87\times10^{10}$ mV cm^4 μC^{-1} mol^{-1}, while the latter is the adsorption with $\sigma_{max}=-4$ μC cm^{-2} and the slope of 11.83×10^{10} mV cm^4 μC^{-1} mol^{-1}.

Adsorption Isotherm and Free Energy of Adsorption. In order to determine the adsorption isotherm of TMU, various adsorption isotherms were examined using Γ in the region where linear portions were observed on the $\Delta_2^M\phi-\Gamma$ curves in Fig. 4; it was found that the adsorption of TMU could be described by the Frumkin isotherm:

$$\beta x = [\theta/(1-\theta)]\exp(-2\alpha\theta), \quad (1)$$

where β is the adsorption coefficient defined by $\exp(-\Delta\bar{G}^\circ/RT)$ containing the free energy of adsorption at zero coverage, $\Delta\bar{G}^\circ$, x is the molar fraction of the adsorbate, θ is the coverage, and α is the interaction parameter.

The Frumkin isotherm plot in Fig. 6 is drawn with respect to the regions where the linear $\Delta_2^M\phi-\Gamma$ relations were observed in Fig. 4, namely, $\sigma=-10$ μC cm^{-2} and $\sigma\geqslant2$ μC cm^{-2}. The coverage was evaluated using Γ_s in Fig. 3; that is, $\Gamma_s=5.0\times10^{-10}$ mol cm^{-2} for $\sigma=-10$ μC cm^{-2} and $\Gamma_s=3.5\times10^{-10}$ mol cm^{-2} for $\sigma\geqslant2$ μC cm^{-2}. It is thought from Fig. 6 that the adsorption of TMU in $\sigma\geqslant2$ μC cm^{-2} can be described by the Frumkin isotherm with $\Gamma_s=3.5\times10^{-10}$ mol cm^{-2} and $\alpha=-0.25$. The deviation of the points at a lower coverage from a linear relation may be affected by a different adsorption, which will be discussed later. On the other hand, the adsorption of TMU at $\sigma=-10$ μC cm^{-2} could not be described

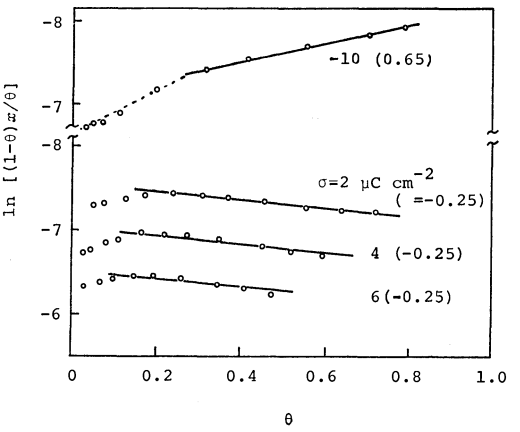

Fig. 6. Test of the Frumkin isotherm with Γ_s varing with surface charge density.
Charge density is indicated by each line, and the values in the parentheses represent the interaction parameter, α.

by a single isotherm throughout the coverage. The linear $\Delta_2^M\phi - \Gamma$ relation at $\sigma = -10$ μC cm^{-2} in Fig. 4 seems to be an incidental result. Probably, a change in the orientation or a mixed adsorption occurs with an increase in the surface excess at this charge density.

At a higher surface excess, the interaction parameter, which is shown in the parentheses of Fig. 6, was negative for $\sigma \geqslant 2$ μC cm^{-2}, but was positive at $\sigma = -10$ μC cm^{-2}. This difference in α at positive and far negative charges is compatible with the explanations given for the adsorption-desorption peaks in Fig. 1.

On the other hand, at a lower coverage in $\sigma < 2$ μC cm^{-2}, the Γ_s seems to be different from the Γ_s shown in Fig. 3, because the latter is obtained by weighing the data at a higher surface excess. In order to estimate the Γ_s for a lower coverage, the following equation was used:[28]

$$\partial(\Delta_2^M\phi)/\partial\Gamma = -RT[\partial \ln \beta/\partial(\sigma - \sigma_{max})], \quad (2)$$

with a previously verified precondition that β is a function of the charge density. If a quadratic dependence of ln β on the charge density is assumed, Eq. 2 can be rearranged to Eq. 3:

$$\partial[\partial(\Delta_2^M\phi)/\partial\Gamma]/\partial(\sigma - \sigma_{max}) = -2RT[\partial \ln \beta/\partial(\sigma - \sigma_{max})^2]. \quad (3)$$

The left-hand side of Eq. 3 has already been estimated as the experimental slope for $\sigma < 2$ μC cm^{-2} in Fig. 5. Therefore, several Γ_s values were chosen and varied step-by-step until the ln β values obtained satisfy Eq. 3. The final value of Γ_s estimated in this way was 3.4—3.5 × 10^{-10} mol cm^{-2}; the average was used in the subsequent analysis. Figures 7 and 8 show the Frumkin isotherm plot using the Γ_s finally estimated and the relation between ln β and $(\sigma - \sigma_{max})^2$ respectively. The satisfactory result with respect to Eq. 3 indicates that the assumption of the quadratic

dependence of ln β on the charge density and the estimated value of Γ_s are generally reasonable. The value of α shown in the parentheses of Fig. 7 were always positive, but changed with the surface charge density. According to the view of Pulidori and his co-workers,[27] the observed lowering of the positive α with an increase in the surface charge density means that the attractive interaction between TMU and water molecules becomes stronger, or that the attractive interaction among TMU molecules themselves becomes weaker with an increase in the surface charge density. So long as a constant orientation is assumed for the adsorption at a lower coverage, the fact that the attractive interaction varies with the charge density on the electrode suggests that adsorbed TMU molecules interact with the neighboring water structure, which also varies with the charge density.

Orientation Models of TMU. The following three fundamental orientations can be considered on the basis of the results presented thus far: (I) Orientation at a lower coverage in the region of $\sigma < 2$ μC cm^{-2}. This orientation takes $\Gamma_s = 3.45 \times 10^{-10}$ mol cm^{-2} and $\sigma_{max} = -4.0$ μC cm^{-2}, which suggests an orientation with a small effective normal dipole moment,[23] and it has positive interaction parameter. This will be a horizontal orientation where the >C=O group is approximately parallel to the electrode surface. (II) Orientation in the region of $\sigma \geqslant 2$ μC cm^{-2}. This orientation takes $\Gamma_s = 3.5 \times 10^{-10}$ mol cm^{-2} and $\sigma_{max} = -15 \sim -17$ μC cm^{-2}, which suggests an orientation with a large positive effective normal dipole moment, and it has negative interaction parameter. This will be a vertical orientation where the >C=O group is approximately vertical to the electrode surface. (III) Orientation at a higher coverage in the region of very negative charges. This orientation takes $\Gamma_s = 5.0 \times 10^{-10}$ mol cm^{-2} and has a positive interaction parameter because of lateral attractive interaction among the TMU dipoles in the adsorption layer.[26] This will also be a horizontal orientation where the >C=O group is nearly parallel to the electrode surface, but the occupied area is different from that of the (I) orientation.

The molecular structure of TMU, unlike that of urea,[27] has been considered to be non-planar because

of a steric repulsion. The single NMR signal of the CH_3 proton of TMU[28] is attributed to an internal rotation of the two $(CH_3)_2N-$ groups, which relieve the steric repulsion. In spite of its similar molecular structure[29] and the internal rotation property,[30] the dipole moment of TMU,[3] 11.6×10^{-30} C m, is greatly different from that of TMTU,[31] 15.7×10^{-30} C m. The dipole moment of TMU is smaller than that of urea,[3] 15.2×10^{-30} C m, but is rather close to that of acetone,[32] 9.7×10^{-30} C m. The lower dipole moment of TMU compared with that of TMTU may be attributable to a slightly deeper pyramidal structure of TMU about N atoms.[29] The most simple and unambiguous explanation, however, is a minor contribution of the conjugate system of $^+N{=}C{-}O^-$ to the dipole moment of TMU.[33] This leads to a consideration that the possibility of the distribution of a positive charge on N atoms is small.

In considering the orientation of TMU on the electrode, three possible extreme molecular conformations[30] were taken into account, and the average was taken for the projected area. Figure 9 shows the models corresponding to the three orientations, (I), (II), and (III). The projected areas of the rectangles enclosing a molecule were (I) 0.481, (II) 0.474, and (III) 0.332 nm^2, while the corresponding Γ_s values were (I) 3.45, (II) 3.5, and (III) 5.0×10^{-10} mol cm^{-2}. The averages of the molecular height, X_1, were estimated to be (I) 0.58, (II) 0.58, and (III) 0.62 nm.

Evaluation of the Dipole Moment of the TMU Molecule at the Interface. From the evaluation of the dipole moment of TMU adsorbed at the interface, we next attempted to confirm the three orientation models and to verify that the variation in the interaction parameter attributable to the charge density with respect to the (I) orientation is caused by the interaction with the neighboring water structure, not by a slight change in the orientation which leads to a change in the lateral attractive interaction among TMU dipoles.

The orientation of organic compounds with a polar group can be determined by the evaluation of the dipole moment of an adsorbed molecule using the following equation, which is similar to that derived by Parsons and his co-workers,[5] and by Damaskin and Frumkin:[34]

$$\Delta(\Delta_2^M\phi) = \theta[(\Gamma_s P_1/\varepsilon_1 - \Gamma_s n P_0/\varepsilon_0) + \sigma(1/K_1^i - 1/K_0^i)], \quad (4)$$

where ε, P, and K^i are the permittivity of the inner layer, the dipole moment of an adsorbed molecule, and the integral inner-layer capacity respectively, where n is the number of water molecules displaced by an adsorbate molecule, and where the subscripts 1 and 0 denote the inner layers saturated with adsorbate and water respectively.

The term $-\Gamma_s n P_0/\varepsilon_0$ in Eq. 4 is equal to the potential drop across the inner layer due to water dipoles, Δg^w_{dipole}. In the evaluation of the dipole moment of TMU, one can use several water-adsorption models[7] in which the value of Δg^w_{dipole} is given as a function of the charge density. The Bockris and Habib model was used in this study for the comparison of the results of TMU with those of TMTU.[1] In addition, the T-model[9] and the D-F model[10] were also applied to Eq. 4; the results will be compared below with those from the B-H model.

The integral inner-layer capacity in Eq. 4 should be $K^{i(ion)}$ as a result of free charges on the electrode; it is free from any contribution by dipoles, $K^{i(dipole)}$.[38] When the B-H model was applied to Eq. 4, $K_0^{i(ion)}$ was evaluated by substituting the K_0^i determined ex-

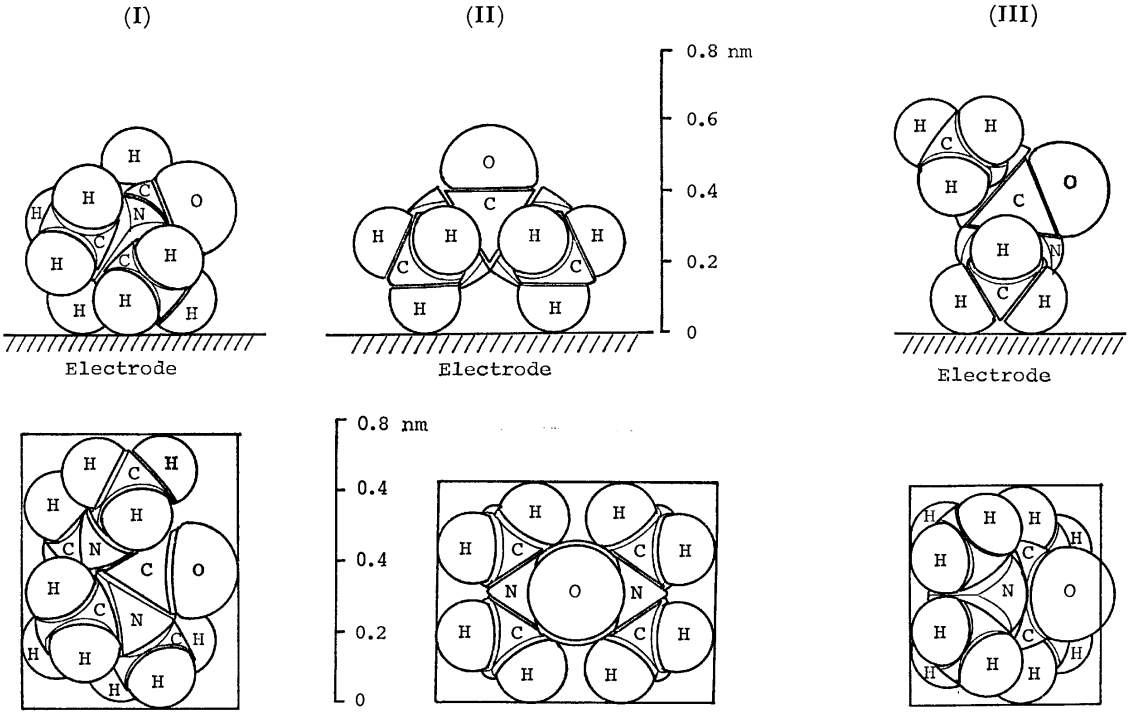

Fig. 9. Scale drawings of an adsorbed TMU molecule through the orientations, (I), (II), and (III). Upper and lower figures show the side and the top views, repectively. Rectangle enclosing a molecule means the projected area.

perimentally and the $1/K_0^{i(\text{dipole})}=8.0\times10^{-3}$ cm^2 μF^{-1} from the B-H model into this relation: $1/K_0^i=1/K_0^{i(\text{ion})}-1/K_0^{i(\text{dipole})}$. When the T and D-F models are applied to Eq. 4, the constant $K_0^{i(\text{ion})}$ values, 17 and 16 μF cm^{-2}, specified by each model were used. On the other hand, $K_1^{i(\text{ion})}$ was assumed to be equal to K_1^i.

For the evaluation of P_1 using Eq. 4, it is further necessary to estimate K_1^i and ε_1 as functions of the charge density. The values of K_1^i were obtained by plotting first the integral inner layer capacity at different surface excesses, K^i, against Γ, and then by extrapolating the plot to each Γ_s, as is shown in Fig. 10. The values of K_1^i for the (I) orientation were, however, obtained by extrapolating a linear relation between $1/K^i$ and Γ at each charge density to $\Gamma_s=3.45\times10^{-10}$ mol cm^{-2}. The values of ε_1 were calculated by substituting K_1^i and the molecular height, X_1, into this relation; $\varepsilon_1=X_1\cdot K_1^i$. Regarding orientations at full coverage in the region of $0\geqslant\sigma\geqslant-10$ μC cm^{-2}, X_1 was estimated by assuming a weighted average between the (II) orientation with $\Gamma_s=3.5\times10^{-10}$ mol cm^{-2} and $X_1=0.58$ nm, and the (III) orientation with $\Gamma_s=5.0\times10^{-10}$ mol cm^{-2} and $X_1=0.62$ nm, for the measured Γ_s in Fig. 3. The above assumption is based on the observation that the Γ_s in Fig. 3 changes from the Γ_s of the (II) orientation to the Γ_s of the (III) orientation with a decrease in the surface charge density.

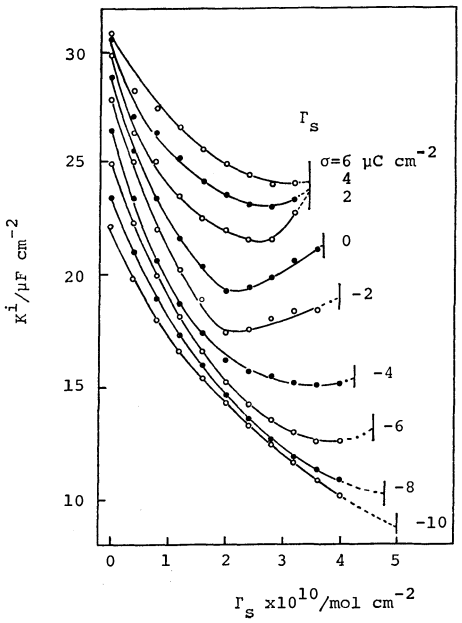

Fig.10. Plot of the integral inner-layer capacity against the surface excess at different surface charge density. Charge density is indicated by each line. Short vertical line represents Γ_s at each surface charge density.

The P_1, ε_1, and K_1^i values finally evaluated are summarized in Table 2, along with K_0^i and $K_0^{i(\text{ion})}$. The result with respect to P_1 indicates that the angles of the C=O bond axis to the electrode surface are about 25°, 90°, and 30° for the (I), (II), and (III) orientations respectively. The models in Fig. 9 were approximately confirmed by the evaluation of the dipole moment of TMU. Since the P_1 for the (I) orientation is almost constant, irrespective of the charge density, it seems most likely that the variation in the interaction parameter with the charge density is not caused by a slight change in the orientation, but by an interaction with neighboring water structure. It was further observed that the P_1 for the (II) orientation was almost the same as that measured on the basis of the polarization phenomena in the bulk of the solution, 11.6×10^{-30} C m.[3]

In summary, the adsorption behavior of TMU can be interpreted as follows. The principal orientation of the TMU adsorbed from lower concentrations is the (I) orientation, which is governed by an interaction with the neighboring water structure. With an increase in the surface excess, however, this orientation changes into the (II) or (III) orientation, depending on the charge sign of the electrode. The orientation at full coverage in the region of $0\geqslant\sigma\geqslant-8$ μC cm^{-2} is a mixture of (II) and (III). The (I) orientation was quite similar to that of urea.[5]

Since the dipole moment of TMU acts along the C^+–O^- bond axis, the observed orientations deviate from those expected from the polarity. For example, the (II) orientation is the most probable orientation at a negative electric field, but it was not observed. Such an deviation from the expectation is often observed,[1,2,36,37] however, and this suggests that the electric field is effective for a short-range interaction, but not for a long-range interaction. The polarity of TMU was not an important factor governing the adsorption behavior. The scarcity of the positive charge on N atoms attributable to a weak conjugation is con-

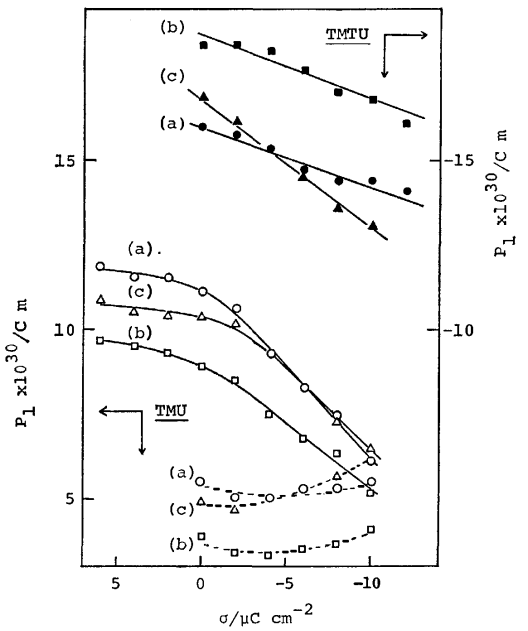

Fig.11. Comparison of P_1 estimated from different water-adsorption models.
(a) B-H model, (b) T-model, and (c) D-F model. Open and closed symbols correspond to TMU and TMTU, respectively.

sidered to be a main cause of the observed adsorption behavior, namely, an attractive interaction between electrons on N atoms and the positive charge on the electrode, and a repulsive interaction at a very negative charge density in addition to the lateral attractive interaction among TMU dipoles in the adsorption layer.

P_1 Evaluated from Different Water-adsorption Models. It is important to use an appropriate Δg^{w}_{dipole} value for the evaluation of P_1 using Eq. 4; it is also important to know the precise orientation state of the adsorbate on the molecular level. Aside from the different ideas contained in the water-adsorption models, as has already been mentioned, the values of Δg^{w}_{dipole} are different among the models. Figure 11 shows the P_1 values of TMU evaluated using the B-H model, the D-F model, and the T model. The results with TMTU[1)] are also plotted in the same figure. A positive (negative) value of P_1 means an orientation with the positive (negative) end of the dipole toward the electrode. In general, the dipole moment of an organic molecule adsorbed around $\sigma=0$ μC cm^{-2} seems to be nearly the same as that measured on the basis of the polarization phenomena in the bulk of the solution. In this sense, the B-H model seems to give reasonable P_1 values for TMU and TMTU.

The difference in P_1 value among the three models was not so large as was expected from the difference in the Δg^{w}_{dipole}, probably because of a compensation action due to $K_0^{1(ion)}$. Strictly speaking, however, the following features are recognized. The way of the variation in P_1 with the charge density between the B-H model and the T model is almost the same, but the values of P_1 are different. On the contrary, the way of the variation in P_1 with the charge density between the B-H model and the D-F model is somewhat different, but the values of P_1 are approximately the same.

The Effect of the Difference in the Oxidation State of the Second Component Added to MoO_3 on the Generation of the Acidic Property

Mamoru Ai

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227

(Received June 11, 1982)

The effect of the difference in the oxidation state of the second component added to MoO_3 on the generation of acidic sites was studied with regard to Sn^{2+}—Sn^{4+}, Fe^{2+}—Fe^{3+}, Cr^{3+}—Cr^{6+}, and Cu^{+}—Cu^{2+}. It was found that a markedly lager amount of acidic sites is generated by the combination of Sn^{2+}, Fe^{2+}, or Cr^{3+} with MoO_3 than by that of Sn^{4+}, Fe^{3+}, or Cr^{6+} respectively. As a general feature of metal-oxide combination, it is proposed that the addition of a metal ion in a lower oxidation state to MoO_3 brings about a markedly more significant acidity generation than that of a metal ion in a higher oxidation state. An explanation to account for the results was attempted in relation to the reducing function of the second component.

It is widely known that a combination of different metal oxides sometimes induces a significant acidity-generation and that this character of metal oxides has actually been applied to the preparation of a catalyst. For understanding the acidity-generation, an explanation has been proposed by Tanabe *et al.* based on the acidity-basicity data for many binary-oxides.[1,2]

However, it still seems difficult to understand the acidity-generation in the case of transition-metal oxides in which the oxidation state is variable. It is, therefore, important to find some general rules effective for predicting the acidity-generation of mixed oxides containing transition-metal oxides, such as MoO_3, V_2O_5, WO_3, and U_3O_8.

It was found in studying Sn–Mo oxides[3] that the acidity-generation is markedly affected by the oxidation state of tin in the starting material as well as by the method of catalyst preparation. This finding led us to a prediction that the acidity-generation is related to the oxidation state of the second component added to a transition-metal oxide.

In the present study, MoO_3 was chosen as the first component, and the effect of the oxidation state of the second component was studied with regard to Sn^{2+}—Sn^{4+}, Fe^{2+}—Fe^{3+}, Cr^{3+}—Cr^{6+}, and Cu^{+}—Cu^{2+}.

Experimental

Catalysts. The catalysts used in this study were nine kinds of MoO_3–X_nO_m with different X/Mo ratios, where X refers to four different metals. They were prepared as follows.

Mo–Sn Oxides: The required quantity of either $SnCl_2$ or $SnCl_4$ was dissolved in water. To this solution, a dilute aqueous ammonia solution was added to precipitate the corresponding hydroxide. After filtering and washing, the paste-like hydroxide was added to an aqueous solution of $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$, and 10 to 20 mesh pumice was mixed with the solution; then the mixture was evaporated with stirring. The amount of pumice was about 500 ml per g atom of metal. The catalyst was calcined under flowing oxygen at 500 °C for 4 to 5 h. The catalysts were denoted as MoO_3–Sn^{2+} and MoO_3–Sn^{4+} respectively.

Mo–Fe Oxides: As the starting materials we used iron(II) oxalate dihydrate, $FeC_2O_4\cdot 2H_2O$, for Fe^{2+} and ammonium tris(oxalato) ferrate(III) trihydrate, $(NH_4)_3Fe(C_2O_4)_3\cdot 3H_2O$, for Fe^{3+}. Aqueous solutions of each compound were mixed with a solution of $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$. Pumice was then added to the solution or slurry thus obtained. The further procedures were the same as those used in the case of Mo–Sn oxides. The catalysts were denoted as MoO_3–Fe^{2+} and MoO_3–Fe^{3+} respectively.

Mo–Cr Oxides: $Cr(NO_3)_3\cdot 9H_2O$ and CrO_3 were used as the starting materials. The further procedures were the same as above. The catalysts were denoted as MoO_3–Cr^{3+} and MoO_3–Cr^{6+}.

Mo–Cu Oxides: As the starting materials we used CuCN and CuCl for Cu^{+} and $Cu(CH_3CO_2)_2\cdot H_2O$ for Cu^{2+}. The catalysts were denoted as MoO_3–CuCN, MoO_3–CuCl, and MoO_3–Cu^{2+} respectively.

Catalytic-activity Measurements. The vapor-phase dehydration of 2-propanol and the oxidation of propylene and methanol were carried out in an ordinary continuous-flow system. The reactor and the experimental procedures were the same as those employed in previous works.[4–7]

Results

Mo–Sn Oxides. The effect of the difference in the oxidation state of tin on the specific surface area was checked by the BET method using nitrogen at −196 °C. As may be seen in Fig. 1, the surface area

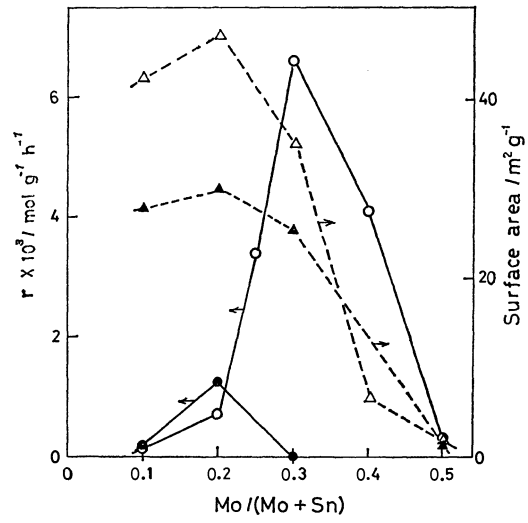

Fig. 1. Surface area and catalytic activity for dehydration of 2-propanol.
r=Rate at 160 °C and 1.7 vol% 2-propanol in air.
○,△: MoO_3–Sn^{2+}, ●,▲: MoO_3–Sn^{4+}.

of both the MoO_3–Sn^{2+} and MoO_3–Sn^{4+} systems are of the same order of magnitude and vary in the same way with an increase in the Mo content; that is, they pass through a maximum at Mo/(Mo+Sn) atomic ratio=0.2 and then sharply decline with the Mo-content at Mo/(Mo+Sn)>0.4.

As a measure of the acidity of a catalyst, the catalytic activity for the dehydration of 2-propanol was chosen for convenience as in the previous studies.[4-6] The initial rate of dehydration was measured at low conversion levels. The rate at 160 °C is plotted as a function of the catalyst composition in Fig. 1. As has been reported earlier,[5] a dramatically high acidity is obtained in the case of the MoO_3–Sn^{2+} catalyst at the Mo/(Mo+Sn) atomic ratio of 0.3, while the generation of acidic sites is much less remarkable in the case of the MoO_3–Sn^{4+} catalysts.

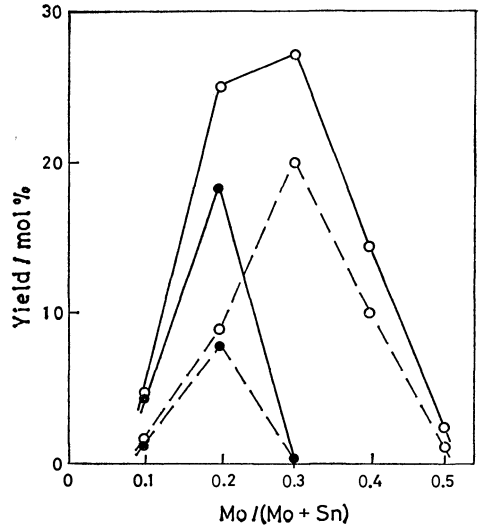

Fig. 2. Yield of acetone in the oxidation of propylene. Feed rates=propylene-20/oxygen-15/nitrogen-24/water vapor-104 ml/min (at 25 °C), catalyst used=20 g, full line=at 240 °C, broken line=at 190 °C, ○: MoO_3–Sn^{2+}, ●: MoO_3–Sn^{4+}.

As another example of an acid-catalyzed reaction, the oxyhydration of propylene to acetone was chosen.[8] The yields of acetone obtained from the MoO_3–Sn^{2+} and MoO_3–Sn^{4+} catalysts are plotted in Fig. 2. The results are well consistent with those shown in Fig. 1, suggesting the validity of these results.

Mo–Fe Oxides. The specific surface areas of the MoO_3–Fe^{2+} and MoO_3–Fe^{3+} systems are compared in Fig. 3. The surface area of the MoO_3–Fe^{3+} system is a little greater than that of the MoO_3–Fe^{2+} system, though the surface areas of both the systems pass through a broad maximum at Mo/(Mo+Fe) atomic ratio=0.2 with an increase in the Mo-content.

As an index of the acidity of the catalyst, the initial rate of 2-propanol dehydration at 200 °C is plotted as a function of the catalyst composition in Fig. 3. The acidity of the MoO_3–Fe^{2+} catalyst is much higher than that of the MoO_3–Fe^{3+} catalysts.

As another example of an acid-catalyzed reaction, the oxidation of methanol to formaldehyde was chosen.[7] The rates of formaldehyde formation at 260 °C obtained from the two series of catalysts are plotted in Fig. 4. The activity for methanol oxidation varies in the same way as that for 2-propanol dehydration, also suggesting the validity of the results.

Mo–Cr Oxides. Figure 5 shows the surface areas of the MoO_3–Cr^{3+} and MoO_3–Cr^{6+} systems. They are of the same order of magnitute, except for the Mo/(Mo+Cr^{3+})=0.9 catalyst.

The initial rate of 2-propanol dehydration at 200 °C is plotted in Fig. 6. The acidity of the MoO_3–Cr^{3+} catalysts is much higher than that of the MoO_3–Cr^{6+} catalysts, though the acidity of the two systems vary in the same way with an increase in the Mo-content. It is interesting to note that the maximum

acidity occurs in Mo-rich regions, unlike the cases of the Mo–Sn and Mo–Fe oxides.

Mo–Cu Oxides. The rate of 2-propanol dehydration was measured at 200 °C for three series of Mo–Cu catalysts, *i.e.*, the MoO_3–CuCN, MoO_3–CuCl, and MoO_3–Cu^{2+} systems. As may be seen in Table 1, the catalytic activity is very low, regardless of the kind and amount of copper compounds. It is concluded that new acidic sites are not generated by the combination of copper with molybdenum. It is, therefore, impossible to ascertain the effect of the difference in the oxidation state of copper.

Discussion

From the experimental findings, it can be deduced as a general feature of metal-oxide combination that the addition of a metal ion in a lower oxidation state to molybdenum oxide brings about a markedly more significant acidity-generation than that of a metal ion in a higher oxidation state, though the surface area is changed only a little with the difference in the oxidation state.

As a possible explanation for this feature of metal-oxide combination, we would like to consider as follows. The combination of a metal ion in a lower oxidation state, which can act as a reductant and so has a special affinity for an oxidant such as the molybdenum ion, induces a reduction of the molybdenum ion, resulting in the generation of an anion vacancy on the molybdenum ion. Possibly, a kind of valence control may take place as a result of the combination, though the situation is much more complex than in the case when oxides of nontransition metals are mixed. On the other hand, it may be hard for the anion vacancy to form with the combination of the metal ion in a higher oxidation state with molybdenum, because the additive metal ion is lacking in the reducing function.

It has already been reported that the reduction of Mo–Al oxide by hydrogen brings about a marked increase in the acidity and that this acidity generation is explained by the formation of an anion vacancy on the molybdenum ion.[9–11)]

This view is also supported by the finding that the combination of other metal ions having no reducing function, such as Al^{3+}, Si^{4+}, and Zn^{2+}, brings about a much lower acidity-generation than that of Sn^{2+}, Fe^{2+}, or Cr^{3+}.[12)]

Actually, the colors of the MoO_3–Sn^{2+} and MoO_3–Fe^{2+} catalysts are darker than the corresponding MoO_3–Sn^{4+} and MoO_3–Fe^{3+} catalysts, even after calcination in an oxygen atmosphere, suggesting the presence of the molybdenum ion in lower oxidation states. It is interesting to note that the reduced molybdenum cannot be reoxidized by the heat treatment in gaseous oxygen.

There may naturally exist other factors deciding the acidity-generation in a combination of transition-metal oxides. For example, the composition showing a max-

imum acidity is different depending on the second components, and the acidity-generation is not observed in the case of the combination of Cu^+ and Cu^{2+} with MoO_3. This study will be followed by a second part in which other factors deciding the acidity-generation will be studied, based on data for various kinds of mixed oxides.

A Conductance Study of 18-Crown-6 and Dibenzo-18-crown-6 Complexes with K^+ in Various Solvents

Yasuyuki TAKEDA

Department of Chemistry, Faculty of Science, Chiba University, Yayoi-chō, Chiba 260

(Received July 7, 1982)

Limiting ionic molar conductivities ($\lambda°$) of 18-crown-6 (18C6) and dibenzo-18-crown-6 (DB18C6) complexes with K^+ in several protic and aprotic solvents have been determined at 25 °C. The crystal ionic radius of 18C6 complex with K^+ is nearly identical with that of tetrabutylammonium ion ($(n\text{-}C_4H_9)_4N^+$). For CH_3OH, the mobility of the 18C6 complex with K^+ is nearly equal to that of $(n\text{-}C_4H_9)_4N^+$. However, for H_2O, the former is much larger than the latter, but the contrary is true for aprotic solvents. Walden products of 18C6 complexes with K^+ for the solvents are nearly equal to each other. For acetonitrile and DMSO, the $\lambda°$ value of the DB18C6 complex with K^+ is smaller than those for the tetrapentylammonium ion ($(n\text{-}C_5H_{11})_4N^+$) and for the tetraisopentylammonium ion ($(i\text{-}C_5H_{11})_4N^+$). For nitrobenzene and propylene carbonate, that of the DB18C6 complex with K^+ is smaller than those of $(n\text{-}C_5H_{11})_4N^+$ and $(i\text{-}C_5H_{11})_4N^+$, respectively. In contrast to the case of the aprotic solvents, the $\lambda°$ value of the DB18C6 complex with K^+ for CH_3OH is nearly equal to those of $(n\text{-}C_5H_{11})_4N^+$ and $(i\text{-}C_5H_{11})_4N^+$. Walden products of the DB18C6 complexes with K^+ for the solvents are nearly equal to each other. From the above data, it appears that a solute which contains a unit of 18C6 in its structure does not enforce a hydrogen-bonded structure for a protic solvent.

Stabilities and selectivities on complexation of 18-crown-6 (18C6) and dibenzo-18-crown-6 (DB18C6) with alkali metal ions in various solvents have been studied in detail.[1–5] However, the behavior of these crown ether complexes in various solvents has scarcely been investigated systematically.

In the present work, limiting ionic molar conductivities of 18C6 and DB18C6 complexes with K^+ in several protic and aprotic solvents have been determined at 25 °C; the limiting ionic molar conductivities of the crown ether complexes have been compared with those of tetraalkylammonium ions in order to investigate the behavior of the crown ether complexes in the solutions.

Experimental

Materials. 18-Crown-6 (Nisso Co., Ltd.) was recrystallized three times from acetonitrile and dried at 70 °C in a vacuum oven before use. DB18C6 (Aldrich Chemical Co., Inc.) was dissolved in chloroform, and filtered while hot. It was then recrystallized four times from benzene and dried at 60 °C in a vacuum oven prior to use. Potassium perchlorate and chloride were obtained from Merck Japan Ltd. The potassium perchlorate was recrystallized twice from water and dried at 150 °C in a vacuum oven prior to use. The potassium chloride was used without further purification. The method of purification of *N,N*-dimethylformamide (DMF),[5] methanol,[6] and propylene carbonate[3] was as has previously been described. Acetonitrile and dimethyl sulfoxide (DMSO) were allowed to stand in contact with molecular sieves for several days. The acetonitrile was then distilled twice and DMSO twice under nitrogen at about 1.8 kPa. In the case of each of these five solvents, the middle 70% of the distillate was used. The water contents of the purified acetonitrile, propylene carbonate, DMF, and DMSO determined by means of the Karl Fischer titration were less than 0.01%, and, in the case of CH_3OH, less than 0.03%. The conductivities of these final products of acetonitrile, propylene carbonate, H_2O, CH_3OH, DMF, and DMSO were less than 2×10^{-7}, 5×10^{-8}, 5×10^{-7}, 2×10^{-7}, 3×10^{-7}, and 8×10^{-8} Ω^{-1} cm^{-1}, respectively.

Apparatus and Procedure. The conductance measurements were made on a Fuso conductivity apparatus, model 362A, in a water bath thermostated at 25±0.005 °C. Three cells were used with cell constants of 0.059707, 0.093936, and 0.20461 cm^{-1}. The experimental procedure to obtain complex-formation constants and limiting ionic molar conductivities of 18C6 and DB18C6 complexes with a potassium ion was described in the previous paper.[3]

Results and Discussion

The procedure for obtaining the complex-formation constants, K_{ML^+}, and limiting ionic molar conductivities, $\lambda°$, of 18C6 and DB18C6 complexes with K^+ was the same as that described in the previous study.[3] M^+ and L denote an alkali metal ion and a crown ether respectively. In this work, it is assumed that the association between a cation and an anion is negligible under these highly dilute experimental conditions and that crown ethers form 1:1 complexes with K^+. Since concentrations of crown ethers were kept low ($<2.0\times10^{-3}$ M; 1 M=1 mol dm^{-3}) during these experiments, corrections for viscosity changes were neglected. The K_{ML^+} and the limiting molar conductivity, $\Lambda°$, values of 18C6 and DB18C6 complexes with potassium salts in various solvents are listed in Table 1.

As can be seen from Table 2, in the cases of K^+, 18C6 and DB18C6 complexes with K^+, the $\lambda°$ value decreases with an increase in the size of the cation for each solvent system. It is interesting to note that the 1,7,10,16-tetraoxa-4,13-diazacyclooctadecane ((2,2)) complex with K^+ is more mobile than the 18C6 complex with K^+ in acetonitrile, although the size and cavity size of (2,2) are nearly the same as those of 18C6. The author cannot explain this phenomenon at present. Both dibenzo-24-crown-8 (DB24C8) and DB18C6 have two benzene rings, and DB24C8 is larger than DB18C6. However, the $\lambda°$ value of DB24C8 complex with K^+ in propylene carbonate is nearly equal to that of DB18C6 complex. Since DB24C8 has a flexible structure and a large cavity, the potassium ion trapped in the cavity is surrounded by DB24C8. Thus, the potassium ion held in the DB24C8

	DB18C6-$KClO_4$	3.3×10^2	32.$_8$

a) Propylene carbonate.

cavity may be effectively screened by DB24C8. On the contrary, since DB18C6 has a rigid structure and an optimum cavity size for K^+, solvent molecules may be able to interact with central K^+ in the DB18C6 cavity in the direction perpendicular to the plane of the DB18C6. This is the reason why the mobilities of the DB24C8 and the DB18C6 complexes with K^+ in propylene carbonate are nearly equal.

The crystal ionic radius of 18C6 complex with K^+ (4.9 Å[3)]) is nearly identical with that of tetrabutylammonium ion, $(n\text{-}C_4H_9)_4N^+$, (4.94 Å[20)]). For CH_3OH, the mobility of the 18C6 complex with K^+ is nearly equal to that of $(n\text{-}C_4H_9)_4N^+$; however, for H_2O, the former is much larger than the latter, contrary to the aprotic solvents (acetonitrile, DMF, DMSO, and propylene carbonate) (Table 2). In the case of $(n\text{-}C_4H_9)_4N^+$, the surface charge of the central nitrogen atom is effectively shielded by four butyl groups, while, for the 18C6 complex with K^+, K^+ trapped in the 18C6 cavity is exposed to solvent molecules on two axial sides of the 18C6 plane. Thus, the interaction between cation and solvent dipole seems to be stronger for 18C6 complex with K^+ than for $(n\text{-}C_4H_9)_4N^+$. Consequently, since the aprotic solvents have no hydrogen-bonded structures, $(n\text{-}C_4H_9)_4N^+$ is more mobile than 18C6 complex with K^+ in these aprotic solvents. In hydrogen-bonding solvents such as H_2O and CH_3OH, enforcement of a hydrogen-bonded structure for hydrophobic butyl groups of $(n\text{-}C_4H_9)_4N^+$ decreases the mobility of $(n\text{-}C_4H_9)_4N^+$. Although the 18C6 complex with K^+ would undergo specific solvation than $(n\text{-}C_4H_9)\ N^+$ much more strongly as is stated above and, moreover, hydrogen bonds between protic solvent molecules and ether oxygen atoms of 18C6 would decrease the mobility of the 18C6 complex with K^+, the 18C6 complex is much more mobile than $(n\text{-}C_4H_9)_4N^+$ in H_2O and is nearly as mobile as $(n\text{-}C_4H_9)_4N^+$ in CH_3OH (Table 2). This indicates that the 18C6 complex with K^+ in H_2O and CH_3OH does not enforce the hydrogen-bonded structure around the complexed ion like $(n\text{-}C_4H_9)_4N^+$ does. This is supported by the data in Table 3. As can be seen from Table 3, Walden products of 18C6 complexes with K^+ for the solvents are nearly equal to each other, while, that of $(n\text{-}C_4H_9)_4N^+$ for H_2O is much smaller than those of $(n\text{-}C_4H_9)_4N^+$ for the other solvents and those of $(n\text{-}C_4H_9)_4N^+$ for the other solvents are nearly identical. Judging from the above observations, the 18C6 complex with K^+ appears to act as a structure breaker in hydrogen-bonding solvents, and the complex shows almost the same behavior for transport phenomena in all the solvents in Table 3. The ratio of λ° value of the 18C6 complex with K^+ to that of $(n\text{-}C_4H_9)_4N^+$ for H_2O (1.3) is much larger than that for CH_3OH (1.0) (Table 2). This may reflect a difference in characteristics of hydrogen bonds for H_2O and CH_3OH. Since H_2O forms three-dimentional structures *via* hydrogen bonding, while, CH_3OH can form only one-dimentional structures *via* hydrogen bonding, the effect of hydrogen-bonded structure enforcement on the mobility of $(n\text{-}C_4H_9)_4N^+$ appears to be much greater for H_2O than for CH_3OH.

As can be seen from Table 2, for acetonitrile and DMSO, the λ° value of DB18C6 complex with K^+ is smaller than those of tetrapentylammonium ion ($(n\text{-}C_5H_{11})_4N^+$) and tetraisopentylammonium ion ($(i\text{-}C_5H_{11})_4N^+$); for nitrobenzene and propylene carbonate, that of DB18C6 complex with K^+ is smaller

than those of $(n\text{-}C_5H_{11})_4N^+$ and $(i\text{-}C_5H_{11})_4N^+$, respectively. In contrast to the cases of aprotic solvents, the λ° value of DB18C6 complex with K^+ for CH_3OH is nearly equal to those of $(n\text{-}C_5H_{11})_4N^+$ and $(i\text{-}C_5H_{11})_4N^+$. For DMSO, the DB18C6 complex with K^+ is not so mobile as tetraheptylammonium ion ($(n\text{-}C_7H_{15})_4N^+$), and contrary holds for C_2H_5OH. The fact that, for every aprotic solvent, the DB18C6 complex with K^+ is less mobile than these tetraalkylammonium ions can be attributed to the fact that the former would undergo specific solvation much more strongly than the latter, as is stated above. The results for protic solvents indicate that the effect of hydrogen-bonded structure enforcement on the mobility is very much larger for these tetraalkylammonium ions than for the DB18C6 complex with K^+. Walden products of DB18C6 complexes with K^+ are nearly equal to each other (Table 3). Thus, it seems that the behavior of the DB18C6 complex with K^+ for transport phenomena is much the same in the various solvents.

From the above discussion, it appears that a solute which contains a unit of 18C6 in its structure does not enforce hydrogen-bonded structure of a protic solvent.

Mechanism of Chlorine Catalytic Oxidation of CO in the Gas Phase

Tomohiro OHTA

Department of Environmental Sciences, Tokyo Metropolitan Research Laboratory of Public Health, Hyakuninchō, Shinjuku-ku, Tokyo 160

(Received July 14, 1982)

The mechanism of the title reaction is determined under steady state conditions by the irradiation of the mixtures of Cl_2, CO, O_2, and N_2 at 300 K with black blue fluorescence lamps using infrared spectroscopy. The pressure dependence of the ratio of the formation rate of carbon dioxide to that of phosgene($COCl_2$) and the other results indicated that the oxidation of CO proceeded *via* intermediates ClCO and $ClC(O)O_2$ as the termolecular process rather than the bimolecular oxidation by ClOO and/or ClO. The ratio of the competitive reactions of chloroformyl radicals, k_8/k_{9a}, was found to be $(6.5\pm0.4)\times10^{-2}$ in the total pressure range from 30 to 755 Torr (1 Torr=133 Pa); $ClCO+Cl_2\rightarrow COCl_2+Cl$ (8), $ClCO+O_2\rightarrow ClC(O)O_2$* (9a). And also, the ratio of the competitive reactions of the vibrationally excited intermediates, k_{9b}/k_{9c}, was $(3.4\pm0.3)\times10^{18}$ molecule/cm^3; $ClC(O)O_2^*\rightarrow ClCO+O_2$ (9b), $ClC(O)O_2^*+M\rightarrow ClC(O)O_2+M$ (9c). The role of this reaction in the stratosphere is discussed and estimated to be unimportant.

Accumulation of CO_2 in the atmosphere has been discussed to affect the temperature of the erath in future.[1] In addition to the direct emission of CO_2 by combustion, breathing, and respiration, the chemical oxidation of CO is believed to occur in the atmosphere. The major pathway is the oxidation by OH radicals.[2] Catalytic oxidation cycle of Cl atoms, which are formed from the ultraviolet photolysis of chlorofluorocarbons in the stratosphere, may contribute to the conversion as another possible path. And any reaction involving Cl atoms is essential to understand chlorine reaction in the atmosphere.

The oxidation of CO by Cl atoms in the presence of O_2 was found as early as 1930's.[3,4] Brenschede,[5] in illuminating mixtures of CO, O_2, and Cl_2, found the ratio of formed CO_2 to formed $COCl_2$ to be given by Eq. 1,

$$\frac{[CO_2]}{[COCl_2]} = A\frac{[O_2]_0}{[Cl_2]_0}, \quad (1)$$

where A increases with total pressure at first rapidly and then slowly. But his interpretation on mechanism involved uncertainty, because he did not analyze the pressure dependence behavior and the value of the proportionality constant in terms of kinetics. A probable mechanism for chlorine catalytic oxidation of CO is Reaction 2 and/or 3 as proposed by Prinn,[6] but very little information is available on the rate constant involving ClO_x. The other is Reaction 4 proposed by Spence *et al.*[7] by observing $ClC(O)OONO_2$ as an oxidation product of the ultraviolet irradiation of Cl_2, NO_2, and CO mixtures in air, though the possibility of Reaction 2 and/or 3 is not excluded from their experiments.

$$ClOO + CO \longrightarrow ClO + CO_2 \quad (2)$$

$$ClO + CO \longrightarrow Cl + CO_2 \quad (3)$$

$$Cl + CO \longrightarrow ClCO \xrightarrow[O_2]{} ClC(O)O_2 \longrightarrow ClCO_2 \longrightarrow Cl + CO_2 \quad (4)$$

In this paper, we try to analyze the relation (1) to get more information on the mechanism of the reaction system by irradiating the mixture of Cl_2, CO, O_2, and N_2 with varying the initial conditions and add some facts that supports the mechanism involving ClCO and $ClC(O)O_2$. And also the role of the reaction in the atmosphere is discussed.

Experimental

Chlorine from a cylider (Fujimoto Sanso) was pumped through a trap immersed in isopentane-liquid nitrogen bath (160 °C). The condensed fraction was used for the experiments. CO, O_2, and N_2 form research grade steel cylinders were used without further purification. Experimental apparatus was described previously.[8] In brief, reactant gases Cl_2, CO, and O_2 and inert gas N_2 were mixed in a 10 cm Pyrex-body infrared absorption cell of 4 cm diameter (window was NaCl). The cell was mounted in the sample beam of the infrared spectrometer. Two 20-W black blue light lamps irradiated into the cell from 7 cm above at 27±1 °C. Concentration-time profile of the products, CO_2 and $COCl_2$, increased lineary within the irradiation time of 50 s. Thus, measurement of the initial rates was made after light exposure of less than 30 s duration. The concentration was determined by measuring the peak intensity. The peak and absorption coefficients used were the same as those in the previous publication except $COCl_2$. $COCl_2$ was measured by the more sensitive absorption at 852 cm^{-1} in this work.

Results and Discussion

It is well confirmed by early works[9] that when mixtures of CO, Cl_2, and O_2 are illuminated with light which is absorbed by Cl_2, part of CO is changed to $COCl_2$ and part to CO_2, and that, at relatively high pressures of O_2, CO_2 formation occurs almost exclusively, whereas at low O_2 pressures $COCl_2$ formation is predominant.

The mechanism of the formation of $COCl_2$ is well established by Burns and Dainton[10] to be the reactions (5) to (8) in this system. In the later work by Jacox and Milligan,[11] the formation of chloroformyl radical, ClCO, from the reaction of Cl with CO was confirmed using an argon matrix by infrared spectroscopy.

$$Cl_2 + h\nu \longrightarrow 2Cl \quad (5)$$

$$Cl + CO + M \rightleftharpoons ClCO + M \quad (6, -6)$$

$$ClCO + Cl \longrightarrow Cl_2 + CO \quad (7)$$

$$ClCO + Cl_2 \longrightarrow COCl_2 + Cl \quad (8)$$

As a first series of experiment, each initial pressure of Cl_2 and O_2 was held constant at 10 Torr (1 Torr=133 Pa) and CO pressure was varied while keeping

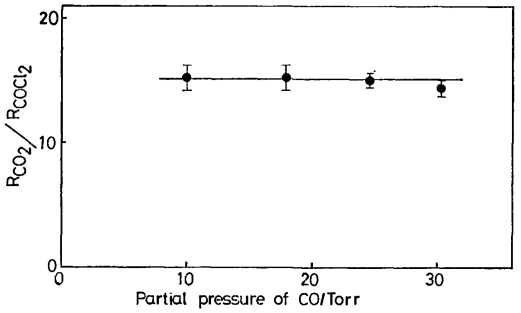

Fig. 1. The function, R_{CO_2}/R_{COCl_2}, *vs.* partial pressure of CO in the photolysis of $Cl_2/CO/O_2/N_2$; $[Cl_2]_0=[O_2]_0=10$ and [total pressure]$_0=755$ Torr.

the total pressure at 755 Torr. The value R_{CO_2}/R_{COCl_2} was plotted against the partial pressure of CO (Fig. 1). The value was independent on the partial pressure of CO as found in the previous work.[5] If the reaction intermediates ClOO and/or ClO were important for the CO oxidation, Cl would have two competitive paths: one is the association with O_2 to form CO_2 *via* Reactions 2 and/or 3 and the other is association with CO to form $COCl_2$ *via* Reactions 6 and 8, R_{CO_2}/R_{COCl_2} would decrease as the initial pressure of CO increases. Thus, the oxidation of CO seems to occur *via* the intermediate ClCO, not *via* ClOO or ClO.

Then, the effect of the total pressure on the ratio of the initial formation rates, R_{CO_2}/R_{COCl_2}, was examined at total pressure ranging from 30 to 755 Torr by changing the amount of added N_2 to a mixture of 10 Torr of Cl_2, 10 Torr of CO, and 10 Torr of O_2. The infrared spectra were taken after filling N_2 up to 755 Torr following the photolysis, since IR intensities of CO and CO_2 depend on the total pressure. The logarithm of R_{CO_2}/R_{COCl_2} is plotted against that of the total pressure (Fig. 2). Typical fall-off behavior is appeared in the figure. Since stripping reaction such as Reaction 8 is not usally pressure dependent, the observed pressure effect is due to the pressure dependence in the CO_2 formation process, and this reaction seems to proceed *via* a stabilized adduct ($ClC(O)O_2$) from a vibrationally excited intermediate ($ClC(O)O_2$*). High pressure limit appears a little above the highest pressure used in our experiment, and it is higher than the limit observed for $C_2H_5+O_2$ by Plumb and Ryan[11] as expected from the consideration of the number of degrees of freedom.

Consequently, let us assume the following reaction mechanism involving ClCO and $ClC(O)O_2$.

$$ClCO + O_2 + M \longrightarrow ClC(O)O_2 + M \quad (9)$$

$$ClC(O)O_2 + ClC(O)O_2 \longrightarrow 2ClCO_2 + O_2 \quad (10)$$

$$ClCO_2 \longrightarrow Cl + CO_2 \quad (11)$$

In order to make some estimation for the fall-off region, the combination reaction 9 is decomposed into the steps 9a to 9c.

$$ClCO + O_2 \longrightarrow ClC(O)O_2^* \quad (9a)$$

$$ClC(O)O_2^* \longrightarrow ClCO + O_2 \quad (9b)$$

$$ClC(O)O_2^* + M \longrightarrow ClC(O)O_2 + M \quad (9c)$$

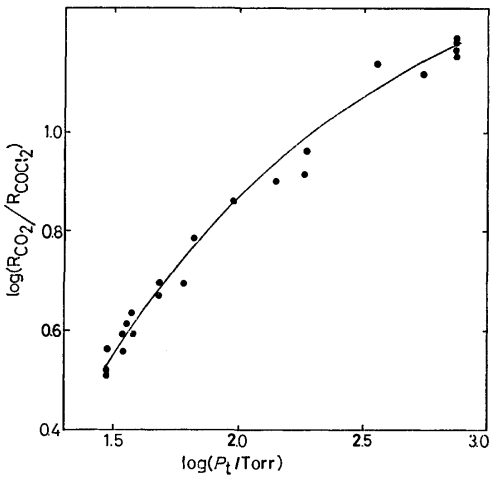

Fig. 2. Total pressure (P_t) dependence of the function, R_{CO_2}/R_{COCl_2} in the photolysis of $Cl_2/CO/O_2/N_2$; $[Cl_2]_0=[O_2]_0=[CO]_0=10$ Torr.

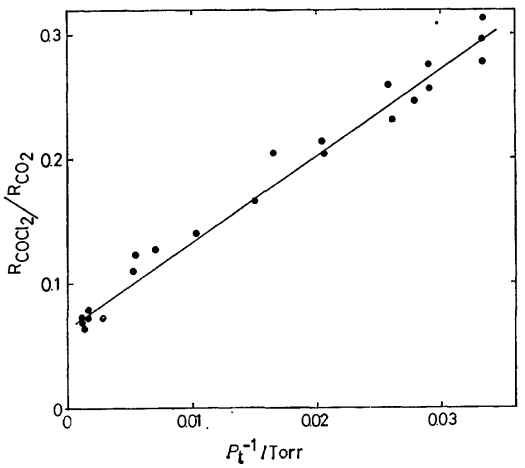

Fig. 3. The function, R_{COCl_2}/R_{CO_2} *vs.* inverse of total pressure (P_t) in the photolysis of $Cl_2/CO/O_2/N_2$; $[Cl_2]_0=[CO]_0=[O_2]_0=10$ Torr.

The steady state treatment with respect to $ClC(O)O_2$* gives,

$$[ClC(O)O_2^*] = \frac{k_{9a}[ClCO][O_2]}{k_{9b}+k_{9c}[M]}. \quad (12)$$

The formation rate of CO_2 is expressed by Eq. 13, if we apply the steady state treatment also to $ClC(O)O_2$ and $ClCO_2$.

$$R_{CO_2} = k_{9c}[ClC(O)O_2^*][M] = \frac{k_{9a}k_{9c}[ClCO][O_2][M]}{k_{9b}+k_{9c}[M]} \quad (13)$$

And,

$$R_{COCl_2} = k_8[ClCO][Cl_2]. \quad (14)$$

Then,

$$\frac{R_{COCl_2}}{R_{CO_2}} = \frac{[Cl_2]}{[O_2]}\left(\frac{k_8}{k_{9a}}+\frac{k_8k_{9b}}{k_{9a}k_{9c}[M]}\right). \quad (15)$$

To correlate Eq. 15 with the pressure dependence, the value, R_{COCl_2}/R_{CO_2}, from the same data used in Fig. 2 is replotted *vs.* inverse of total pressure (Fig. 3). The plots gave a straight line which is fit by

Eq. 15 under our experimental conditions. Assume $[Cl_2]/[O_2]$ is 1 during the course of the irradiation in the experiment of total pressure variation, since the initial concentration of Cl_2 and O_2 were 10 Torr and the photolysis did not exceed 10% of the reactants. We obtained the values of k_8/k_{9a} and $k_8k_{9b}/k_{9a}k_{9c}$ from the intercept and the slope in Fig. 3, respectively.

$$k_8/k_{9a} = (6.45\pm0.41)\times10^{-2}\ \text{Torr} \quad (16)$$

$$k_8k_{9b}/k_{9a}k_{9c} = (6.89\pm0.21)\ \text{Torr}, \quad (17)$$

where error is a standard deviation of the least-squares analysis.

Then,

$$k_{9b}/k_{9c} = (108\pm8)\ \text{Torr} = (3.4\pm0.3)\times10^{18}\ \text{molecule/cm}^3 \quad (18)$$

Eq. 16 and the literature value,[10] $k_8=2.91\times10^{-14}$ cm^3 molecule^{-1} s^{-1} at 300 K, gives $k_{9c}=4.51\times10^{-13}$ cm^3 molecule^{-1} s^{-1}. The k_{9a} value is ten times smaller than the rate constant for a similar recombination $C_2H_5+O_2\rightarrow C_2H_5O_2$* reported by Plumb and Ryan.[12] It is also important to note that $ClCO+O_2$ addition (9a) is faster than the competing reaction of Cl abstraction by ClCO from Cl_2 (8).

To evaluate the obtained value of Eq. 18, 3.4×10^{18} molecule/cm^3, k_{9b} and k_{9c} may be estimated from a quantum RRK theory for unimolecular decomposition of energized molecule. Necessary parameters are assumed as: the proportionality constant is to be 10^{14} s^{-1} from the Arrhenius A factor for the unimolecular decomposition of alkyl-O_2[13]: the bond strength of $ClC(O)$–O_2 is 28 kcal/mol from that of alkyl-O_2[13]: the geometrical mean frequency is guessed at 640 cm^{-1} by assigning 600 Cl–C st. from $ClC(O)CH_3$ in Ref. 14, 1800 for C=O st. from $ClC(O)OONO_2$ in Ref. 7, 1200 for C–O st. in Ref. 15, 880 for O–O st. from HO_2NO_2 in Ref. 16, 400 for O–O–C bend,[15] 420 for O=C–O,[15] 360 for O=C–Cl,[15] and 400 for O–C–Cl,[15] all in units of cm^{-1}. If we choose 9 as the number of effective oscillators, k_{9b} is about 10^8 s^{-1}. By substituting k_{9b} in Eq. 18, k_{9c} becomes 3×10^{-11} cm^{3}molecule^{-1} s^{-1}. Although we do not have enough knowledge what value less than 9 is proper for the number of effective oscillations, the k_{9c} derived from crude calculation is near collision frequency under our experimental conditions. Hence, the value (18) obtained here appears reasonable.

Next, we find k_8/k_9 at 755 Torr from the equations obtained. From Reaction 9,

$$R_{ClC(O)O_2} = k_9[ClCO][O_2][M] = R_{CO_2}. \quad (19)$$

From the comparison of Eq. 19 with 13,

$$k_{9a} = \frac{k_{9a}\,k_{9c}}{k_{9b}+k_{9c}[M]}. \quad (20)$$

From this,

$$\frac{k_8}{k_9} = \frac{k_8}{k_{9a}}\left(\frac{k_{9b}}{k_{9c}}+[M]\right). \quad (21)$$

By substituting the values of $k_8/k_{9a}=6.45\times10^{-2}$ and $k_{9b}/k_{9c}=107$ Torr found before,

$$\frac{k_8}{k_9} = 0.0645(107+[M]). \quad (22)$$

When [M]=755 Torr, k_8/k_9 is calculated to be 55.6 Torr.

Rollefson, in the previous work,[17] assumed Reaction 23 in place of the set of the Reactions 9, 10, and 11. He disregarded the pressure effect on the products distribution and obtained the value 0.2 for k_8/k_{23} by finding that the number of moles of Cl_2 and O_2 reacting to be equal when the Cl_2 pressure was five times that of oxygen.

$$ClCO + O_2 \longrightarrow CO_2 + ClO. \quad (23)$$

The ratio k_8/k_{23} by Rollefson corresponds to $k_8/(k_9[M])$ in our mechanism. Since he did not show the total pressure of each run, we guess mean value for the total pressure [M] as 50 Torr from the list of the partial pressure of three reactants. Then, $k_8/(k_9[M])$ becomes 0.2 that agrees very well with the results shown by Rollefson.

In order to compare the derived value of k_8/k_9 with the value obtained experimentally at constant total pressure, we determined A in Eq. 1 in different initial conditions. First, by keeping the constant total pressure of 755 Torr and the initial concentration of Cl_2 and CO at 10 Torr, the pressure of O_2 was varied. Plot of the values of R_{CO_2}/R_{COCl_2} against the initial pressure of O_2 gave a straight line (Fig. 4). From the relations (14) and (19),

$$\frac{R_{CO_2}}{R_{COCl_2}} = \frac{k_9[M]}{k_8[Cl_2]}[O_2]. \quad (24)$$

The relation (24) fits to the line. The slope is 1.48, which corresponded to $k_9[M]/(k_8[Cl_2])$. Thus,

$$k_8/k_9 = 51.0\ \text{Torr}. \quad (25)$$

Secondly, by keeping the total pressure, initial pressure of CO and O_2 constant, 755, 10, and 10 Torr, respectively, the partial pressure of Cl_2 was varied. The plot of the value of R_{COCl_2}/R_{CO_2} against the partial pressure of Cl_2 gave also a straight line with a slope of 0.00645 (Fig. 5). The slope must be equal to $k_8/(k_9[M][O_2])$. Then,

$$k_8/k_9 = 48.7\ \text{Torr}. \quad (26)$$

In view of the consumption of O_2 and Cl_2 during the irradiation that will cause error, the value 55.6 Torr

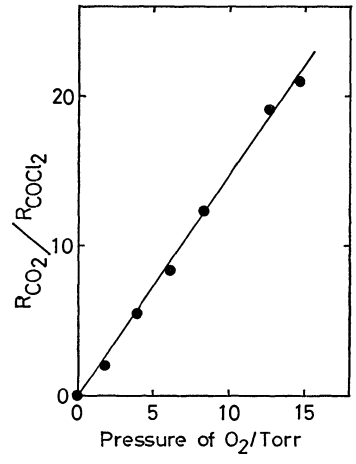

Fig. 4. The function, R_{CO_2}/R_{COCl_2} *vs.* partial pressure of O_2 in the photolysis of $Cl_2/CO/O_2/N_2$; $[Cl_2]_0=[CO]_0=10$ and $[\text{total pressure}]_0=755$ Torr.

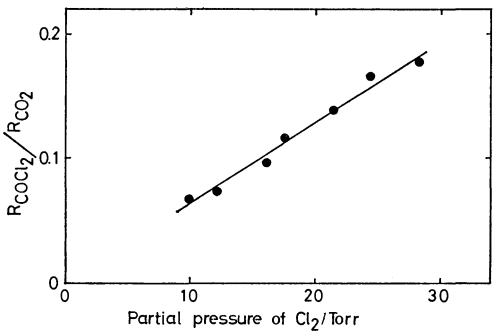

Fig. 5. The function, R_{COCl_2}/R_{CO_2} *vs.* partial pressure of Cl_2 in the photolysis of $Cl_2/CO/O_2/N_2$; $[CO]_0 = [O_2]_0 = 10$ and [total pressure]$_0$ = 755 Torr.

for k_8/k_9 determined from the assumption of termolecular process agrees with the results (25) and (26) obtained from the different experiments.

In consideration of all the points discussed above, the termolecular process via ClCO and $ClC(O)O_2$ is confirmed to be the major pathway for the oxidation of CO by Cl atoms at the pressure range of 30 to 755 Torr.

It is of interset to discuss the role of this termolecular reaction in the atmosphere. The most important reaction of Cl in the stratosphere is beleived to be Reaction 27, whose rate constant is $2.7 \times 10^{-11} \exp(-257/RT)$ cm^3 molecule^{-1} s^{-1}.[18]

$$Cl + O_3 \longrightarrow ClO + O_2 \qquad (27)$$

k_6 was determined to be $10^{14.5}$ cm^6 molecule^{-2} s^{-1} or 8.73×10^{-34} cm^6 molecule^{-2} s^{-1} at 300 K by Clark *et al.*[19] Since the Arrhenius parameters for the rate constant was not given, let us compare k_{27} with $k_6[M]$ at 300 K and 1 atmospheric pressure to get a rough idea on the role of ClCO mechanism in the stratosphere: k_{27} is 10000 times larger than $k_6[M]$. In the upper atmosphere at low pressure, $k_6[M]$ becomes smaller, and moreover, the concentration of ozone is higher than that of CO in the region.[20,21] Thus, Reaction 27 is predominant over Reaction 6. Even when ClCO is formed and becomes adduct, $ClC(O)O_2$*, it dissociates very easily, since the atmospheric density is too low to make three-body reaction effective. Therefore, the oxidation of CO by Cl catalytic cycle is not important in the atmosphere.

The author is grateful to Professor Ikuzo Tanaka, Tokyo Institute of Technology, Professor Okitsugu Kajimoto, The University of Tokyo and Haruo Tsuruta, Yokohama Research Institute for Environmental Protection, for helpful discussions. He also thanks Dr. Isao Mizoguchi for his interest and encouraging.

Conductimetric Study of the Ion Pair Formation in Mixtures of Bivalent Metal Nitrates and Sodium Sulfate in Aqueous Solutions

Shunzo KATAYAMA,* Kazuko TANAKA, and Reita TAMAMUSHI

Inorganic Chemistry Laboratory, The Institute of Physical and Chemical Research, Wako, Saitama 351

(Received September 7, 1982)

The conductance behavior of electrolyte mixtures was investigated for the systems of bivalent metal nitrates and sodium sulfate in aqueous solutions of high ionic strengths ($I \geq 0.3$ mol dm^{-3}) at 25 °C. Significant deviations of the measured conductivities from the additivity were observed in all the systems, which can be attributed to the ion pair formation of the bivalent metal ion with sulfate ion. The conditional formation constants, K_c, were determined by means of computer analysis of the deviation; K_c-values at each ionic strength were found to decrease in the sequence Cd > Mn ≃ Ni ≃ Co ≃ Zn > Mg.

The measurement of electrolytic conductivity of mixtures of two electrolytes provides a valuable method of studying the ionic interaction. The conductance behavior of binary mixtures of 1-1, 2-1, and 2-2 type electrolytes was studied by Rysselberghe *et al.*[1,2] and by Davies.[3,4] Recently, Fisher[5] reported about the ion association in mixtures of 0.005 mol dm^{-3} $MgCl_2$ and 0.005 mol dm^{-3} Na_2SO_4 solutions as a function of pressure.

In our previous works,[6,7] the continuous variation method was applied to the determination of the ion pair formation constants of $[Co(NH_3)_6]^{3+}\cdot SO_4^{2-}$, $[Co(en)_3]^{3+}\cdot SO_4^{2-}$, $[Co(en)_3]^{3+}\cdot(Maleate)^{2-}$, and $[Co(en)_3]^{3+}\cdot(Fumarate)^{2-}$ from the conductivity measurement of mixtures. Good agreement of the results obtained for $[Co(NH_3)_6]^{3+}\cdot SO_4^{2-}$ with those of Jenkins and Monk[8] suggests that the conductivity measurement of mixtures is a useful method for determining formation constants.

The application of the conductimetric continuous variation method to the determination of formation constants appears to have the advantage that the measured quantities can be analysed, in principle, without relying on the quantitative validity of the theoretical equation of conductivity; this advantage is particularly important when the method is applied to systems of higher ionic strengths.[9]

This paper deals with the determination of ion pair formation constants of bivalent metal ions (Mg^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+}, Zn^{2+}, and Cd^{2+}) with sulfate ion at 25 °C in aqueous solutions of apparent ionic strengths 0.3—6 mol dm^{-3} from the conductivity measurements of electrolytic solution mixtures.

Experimental

Materials and Preparation of Solutions. $Mg(NO_3)_2\cdot 6H_2O$, $Mn(NO_3)_2\cdot 6H_2O$, $Co(NO_3)_2\cdot 6H_2O$, $Ni(NO_3)_2\cdot 6H_2O$, $Zn(NO_3)_2\cdot 6H_2O$, $Cd(NO_3)_2\cdot 4H_2O$, and Na_2SO_4 of analytical reagent grade were used without further purification. The purity of the samples was determined by chemical analysis of the components. The analysis gave results which were in good agreement with the theoretical values.

Solutions of different concentrations were prepared by using conductivity water (conductivity $< 2.0\times10^{-7}$ Ω^{-1} cm^{-1} at 25 °C).

Conductivity Measurements. Electrolytic conductivities of mixtures were measured by mixing the solutions of the same ionic strength at various volume fractions. A conductance-linear-bridge, operated at 1000 Hz, was used for conductivity measurements as described in previous papers.[10,11] The resistance readings of the bridge were calibrated by the substitution method with a precision decade resistance box (Dekastat RS-624, Electro Scientific Industries; accuracy ±0.005%). Three conductivity cells designed for solutions of moderate and high conductivities were used. The cell constants were determined to be 11.093 cm^{-1}, 35.422 cm^{-1}, and 97.349 cm^{-1} by using standard potassium chloride solutions. The reproducibility of the conductivity measurements was better than 0.05%. All measurements were carried out in a water–ethylene glycol mixture bath of 25.000± 0.003 °C, which was electrically grounded.

Results and Discussion

Analysis of Conductivity of Electrolyte Mixtures.[6] Let us consider the conductivity of a solution prepared by mixing volume ϕV of a solution of molar concentration, c_1, of MA_2 (M: bivalent metal, A: NO_3) and volume $(1-\phi)V$ of a solution of molar concentration, c_2, of N_2B (N: Na, B: SO_4) to give the solution of total volume V; the concentrations, c_1 and c_2, are adjusted so that the apparent ionic strength of the mixtures is independent of volume fraction, ϕ (in the present study $c_1 = c_2 = c$).

The conductivity, κ_{calcd}, of the mixture calculated by using the additivity rule is given by

$$10^3\kappa_{calcd} = z_M\lambda_M c\phi + z_A\lambda_A 2c\phi + z_N\lambda_N 2c(1-\phi) + z_B\lambda_B c(1-\phi), \quad (1)$$

where z is the charge number of ionic species, and λ the ionic equivalent conductivity at the ionic strength of the mixture. If the following ion pair formation is assumed in the mixture:

$$M^{2+} + B^{2-} \rightleftharpoons M^{2+}\cdot B^{2-},$$

the observed conductivity, κ_{obsd}, of the mixture is given by

$$10^3\kappa_{obsd} = z_M\lambda_M(c\phi - [M^{2+}\cdot B^{2-}]) + z_A\lambda_A 2c\phi + z_N\lambda_N 2c(1-\phi) + z_B\lambda_B(c(1-\phi) - [M^{2+}\cdot B^{2-}]), \quad (2)$$

where $[M^{2+}\cdot B^{2-}]$ is the concentration of ion pairs $M^{2+}\cdot B^{2-}$. The deviation, $\Delta\kappa$, of the observed conductivity from additivity is given by

$$10^3\Delta\kappa = 10^3\kappa_{obsd} - 10^3\kappa_{calcd} = -(z_M\lambda_M + z_B\lambda_B)[M^{2+}\cdot B^{2-}]. \quad (3)$$

The deviation $\Delta\kappa$ is then represented by the equation:[6]

$$10^3\Delta\kappa = \Delta\lambda[c+K_c^{-1} - \sqrt{(c+K_c^{-1})^2-4c^2\phi(1-\phi)}]/2, \quad (4)$$

where

$$\Delta\lambda = -(z_M\lambda_M+z_B\lambda_B), \quad (5)$$

and where K_c is the conditional formation constant of $M^{2+}\cdot B^{2-}$ as given by

$$K_c = \frac{[M^{2+}\cdot B^{2-}]}{[M^{2+}][B^{2-}]}. \quad (6)$$

A set of K_c and $\Delta\lambda$ values giving the best fit between the observed and calculated $\Delta\kappa$ values can be determined by computer calculation.

Conductivities of Mixtures in the Absence of Specific Ionic Interactions. The difficulty involved in the conductimetric continuous variation method consists in the fact that the deviation of the observed conductivity from additivity may be caused not only by specific ionic interactions but also by the non-specific effect of the added ions on the mobility of the ions.[12,13] In the present study, the deviation due to the non-specific effect was examined with mixtures of simple electrolytes, in which no specific individual effects is expected.

The conductivities of ($KCl+KNO_3$) and ($KCl+NaCl$) mixtures at apparent ionic strengths $I_{app}=2$ mol dm^{-3} gave slightly smaller values than those expected from additivity; the deviation reached the maximum value of about 0.7% at the volume fraction $\phi=0.5$, as shown in Fig. 1 (curves (1) and (2)). The conductivity of ($Mg(NO_3)_2+Na_2SO_4$) mixtures of $I_{app}=3$ mol dm^{-3}, however, showed a large deviation from additivity of about 12% at $\phi=0.5$ on account of the ion pair formation between Mg^{2+} and SO_4^{2-} (Fig. 1, curve (3)).

Theoretically, the conductivity of electrolyte mixtures is never strictly additive, because of the effect of added ions on the time of relaxation[13]; in our present systems, however, this effect is shown to be negligibly small in comparison with the specific individual effect as seen from Fig. 1. In the following discussion, therefore, the deviation of the observed conductivities from additivity was attributed entirely to the ion pair formation of bivalent metal ion with sulfate ion, the ion association between the bivalent metal ion and nitrate ion and that between sodium ion and sulfate ion being neglected for the sake of simplicity.

Ion Pair Formation Constants of Bivalent Metal Ions with Sulfate Ion. In mixtures of bivalent metal nitrate and sodium sulfate, a large deviation of the measured conductivity from additivity was observed at each ionic strength, as shown by curve (3) in Fig. 1. The conductivities of the mixtures were always smaller than those expected from additivity and showed an extreme at $\phi=0.5$ in each system. Conductivities, κ, of mixtures and the deviation, $\Delta\kappa$, of the observed conductivities from calculated values are shown in Tables 1—6 as a function of the volume fraction, ϕ, of the bivalent metal nitrate. In our present systems, the volume changes of mixing were smaller than about 0.1% and were neglected in the calculation of $\Delta\kappa$.

The conditional formation constants of ion pair, K_c, were determined by analysing the $\Delta\kappa$ values according to Eq. 4. Table 7 summarizes the values of K_c thus determined for $M^{2+}\cdot SO_4^{2-}$ at various ionic strengths. For the six mixtures studied, the K_c values at 25 °C decrease in the sequence: Cd>Mn≃Ni≃Co≃Zn>Mg.

The conditional formation constants at sufficiently low ionic strengths can be estimated from the knowledge of the thermodynamic association constant K_A[10,14,15] and the activity coefficient $y_\pm$ according to the following equations:

$$K_c = K_A y_\pm, \quad (7)$$

$$\log y_\pm = -A|z_M z_B|I^{1/2}/(1+BaI^{1/2}), \quad (8)$$

where A and B are the Debye-Hückel constants and a is the ion-size parameter. Under the assumption that Eqs. 7 and 8 could be satisfied in solutions of

TABLE 7. CONDITIONAL FORMATION CONSTANTS, K_c/dm^3 mol^{-1}, OF $M^{2+}\cdot SO_4^{2-}$ AT 25 °C IN AQUEOUS SOLUTIONS OF VARIOUS APPARENT IONIC STRENGTHS, I_{app}

Ion pair	I_{app}/mol dm^{-3}			
	0.3	1.5	3.0	6.0
$Mg^{2+}\cdot SO_4^{2-}$	20.6	4.6	2.6	1.7
$Mn^{2+}\cdot SO_4^{2-}$	26.3	6.1	3.5	2.7
$Co^{2+}\cdot SO_4^{2-}$	28.8	6.1	3.2	2.2
$Ni^{2+}\cdot SO_4^{2-}$	28.8	6.1	3.4	2.3
$Zn^{2+}\cdot SO_4^{2-}$	28.1	6.2	3.4	2.2
$Cd^{2+}\cdot SO_4^{2-}$	31.7	7.4	3.8	3.1

higher ionic strengths, the conditional formation constants for ion pair $Mg^{2+}\cdot SO_4^{2-}$ were calculated and are shown in Fig. 2 as a function of ionic strength. The calculation was made at different a-values, the most probable value of a being considered to be about 0.5—0.6 nm.[10] Similar results were obtained for the other systems investigated. It is rather surprising that the experimental values are not very much different from the values estimated by using Eqs. 7 and 8, even at the highest apparent ionic strength (6 mol dm^{-3}).

Hydrates of Organic Compounds. VII. The Effect of Anions on the Formation of Clathrate Hydrates of Tetrabutylammonium Salts

Haruo NAKAYAMA

Department of Chemistry, Faculty of Engineering, Yokohama National University, Tokiwadai, Hodogaya-ku, Yokohama 240

(Received September 13, 1982)

Phase diagrams of the binary mixtures of tetrabutylammonium salt $[(n\text{-}C_4H_9)_4N]_nX$ ($X=NO_2$, NO_3, BrO_3, ClO_3, IO_3, ClO_4, MnO_4, and NCS for $n=1$; $X=CO_3$, SO_4, WO_4, and CrO_4 for $n=2$; and $X=PO_4$ for $n=3$) with water were determined over the temperature range between -10 and $+50$ °C. From these diagrams the following results were obtained: (1) the formation of a clathrate-like hydrate for salts having such anions as NO_2^-, NO_3^-, BrO_3^-, ClO_3^-, IO_3^-, SO_4^{2-}, and PO_4^{3-} was newly confirmed; (2) the melting point of the clathrate hydrate of the salt with monovalent anion was appreciably influenced by the kind of anion; (3) in the hydrates of the salt having either di- or trivalent anions, the melting points were relatively high and were only slightly affected by the kind of anion; (4) the crystal structure of these hydrates was essentially the same as that of the tetrabutylammonium fluoride hydrate, judging from the hydration numbers; (5) the solubilities in water of both permanganate and perchlorate were markedly lower than that of the iodide; and (6) in the thiocyanate system a phase separation into two liquid phases was observed at temperatures higher than $+3.5$ °C. The effect of a monovalent anion on the stability of the clathrate hydrate was discussed in connection with the conventional partial molal volume of the anion.

Such quaternary ammonium salts as tetrabutylammonium halides[1,2-6] and tetraisopentylammonium halides,[1,2,4-6] are now widely known to form a clathrate-like hydrate, similar to so-called "gas hydrates."[7] In these hydrates, each alkyl group of the quaternary ammonium cation is surrounded by a polyhedron constructed by hydrogen-bonded water molecules. In general, the stability of these quaternary ammonium salt hydrates is affected by two factors: (1) the length and the shape of the alkyl group of the quaternary ammonium cation and (2) the kind of anion. Although the effect of an alkyl group has been extensively investigated in previous papers,[4,5] we have no sufficient data to draw any conclusion as to the influence of an anion on the stability of the hydrate, except that tetrabutyl(or tetraisopentyl)ammonium salts having such anions as F^-, Cl^-, Br^-, HCO_3^-, CrO_4^{2-}, WO_4^{2-}, and HPO_4^{2-} were reported to be able to form stable clathrate hydrates.[1] However, even the existence of some of these hydrates is dubious for the reasons described in the following experimental section.

In this paper, from the phase diagrams for thirteen binary systems consisting of tetrabutylammonium salt–water, the effect of anions on the formation of the clathrate hydrates has been examined. The information about what kind of anion can contribute to the formation of the clathrate hydrate and to what extent the melting point of the hydrate is affected by the kind of anion will be of great value for an application of these hydrates, for example, (1) as a heat reservoir utilizing the heat evolved or absorbed when their states change and (2) for highly selective separation of a specific anion from an aqueous solution containing several kinds of anions through the formation of a mixed clathrate hydrate.[8]

Experimental

Materials. Aqueous solutions of the tetrabutylammonium salts, except for perchlorate and permanganate, were prepared by reaction between tetrabutylammonium iodide and the corresponding silver salt in water, followed by filtration of AgI precipitate. Tetrabutylammonium iodide was synthesized by reacting tributylamine with butyl iodide in ethyl acetate and was purified by recrystallization from ethyl acetate–acetone mixture. Such silver salts as $AgNO_3$, $AgClO_3$, $AgIO_3$, Ag_2WO_4, Ag_2SO_4, and Ag_2CrO_4 were purchased from Tokyo Kasei Kogyo Co. Ltd. and were used without further purification. The other silver salts, like $AgNO_2$, AgNCS, $AgBrO_3$, Ag_2CO_3, and Ag_3PO_4, were prepared by mixing an aqueous solution of $AgNO_3$ with the corresponding sodium salt solution. These slightly soluble salts were filtered off, washed with cold water, and used in a wet state.

We attempted and failed to prepare such silver salts as $AgHCO_3$, $AgHSO_4$, AgH_2PO_4, and Ag_2HPO_4. When a sodium hydrogencarbonate solution was mixed with a silver nitrate solution, a yellowish white solid was precipitated with evolution of gas, which was presumably carbon dioxide, indicating that the solid was Ag_2CO_3 rather than $AgHCO_3$. The X-ray diffraction pattern of the solid thus obtained was exactly the same as that of Ag_2CO_3 (ASTM 12-766). The white precipitate obtained from the reaction of a silver nitrate solution and a $NaHSO_4$ solution was also believed to be Ag_2SO_4 instead of $AgHSO_4$, since a supernatant solution became highly acidic, indicating a liberation of hydrogen ion, and the X-ray diffraction pattern of the solid thus obtained gave a similar pattern to that of Ag_2SO_4 (ASTM 7-203) although the diffraction intensities corresponding to $l=3$ were relatively low as compared to those of Ag_2SO_4. Similarly, the yellow solid which was formed by mixing a silver nitrate solution with either a NaH_2PO_4 or a Na_2HPO_4 solution was also concluded to be Ag_3PO_4 from the following reasons: (1) a supernatant solution became highly acidic (pH $\approx$2.5) and the amount of a NaOH solution required to neutralize the supernatant solution agreed very closely with that calculated on the assumption that all the hydrogen, which was initially contained in each phosphate ion, was completely dissociated into hydrogen ion in the supernatant mixture; (2) when an excess amount of $AgNO_3$ solution was reacted with a known amount of each phosphate solution (NaH_2PO_4 or Na_2HPO_4), the silver ion content remaining in the supernatant mixture was reasonably explained by assuming that the precipitate was Ag_3PO_4 in both cases; and (3) their X-ray diffraction patterns were exactly the same as that of Ag_3PO_4 (ASTM 6-505).

Therefore, the existence of hydrates of $(n\text{-}C_4H_9)_4NHCO_3$

and of $[(n\text{-}C_4H_9)_4N]_2HPO_4$, reported by McMullan and Jeffrey,[1] is dubious since they reported that these salts were prepared by a reaction of tetrabutylammonium iodide with the corresponding silver salts.

Tetrabutylammonium perchlorate was prepared by mixing a tetrabutylammonium bromide solution with an aqueous $NaClO_4$ solution, and purified by recrystallization from water. Tetrabutylammonium permanganate was prepared by mixing a tetrabutylammonium chloride solution with a $KMnO_4$ solution, followed by filtration of the mixture and washing it with cold water.

Measurements and Analyses. Phase diagrams for the binary systems of water–tetrabutylammonium salt, except for perchlorate, permanganate and thiocyanate, were determined in the same manner as described in the previous paper[5] (an ampoule method). The concentrations of mother solutions were mostly determined by measuring the water content using the Karl Fischer titration method on a MK-AII apparatus (Kyoto Electronics Manufacturing Co.). For mother solutions containing anions which interfered with the Karl Fischer titration method, the concentrations were determined by one of the following methods: (1) titration by a standard sodium tetraphenylborate solution for the nitrite and iodate solutions; (2) titration by 0.1 mol dm^{-3} hydrochloric acid solution for the carbonate solution; and (3) ordinary iodometry[9] for the chromate solution. The titration method using a sodium tetraphenylborate was carried out in the following way. A sample containing about 1×10^{-4} equivalent was diluted with water to about 15 cm^3. After addition of 0.5 cm^3 of 0.05 wt% Bromophenol Blue solution (indicator), 10 cm^3 of chloroform and 10 cm^3 of 0.1 mol dm^{-3} NaOH solution in this order, the whole mixture was stirred vigorously with a magnetic stirrer for about 15 m. Then the solution was titrated with a 0.02 M $(C_6H_5)_4$-BNa solution, which had been standarized with a known amount of pure $(n\text{-}C_4H_9)_4NI$, until the color in the lower chloroform phase changed from blue to colorless.

The phase diagrams of the systems containing such sparingly soluble salts as perchlorate and permanganate were determined by measuring the solubility of each solid in water at various temperatures.[5] The concentration of perchlorate solution was determined gravimetrically after evaporating a known amount of the solution to dryness at 50 °C under reduced pressure. The concentration of permanganate solution was determined by a standard iodometric method.[9] The phase diagram of the thiocyanate system, in which a liquid-liquid phase separation occurred, was determined by measuring the respective concentrations of the two liquid phases which were in equilibrium with each other at a given temperature. The concentration determination of thiocyanate ion was carried out by a standard KNCS titration method (the Volhard method).[9]

Results and Discussion

(1) Clathrate Hydrate Formation of Tetrabutylammonium Salts Having Monovalent Anions. The solid-liquid phase diagrams for the binary systems, water–$(n\text{-}C_4H_9)_4NX$, where $X=NO_2$, NO_3, ClO_3, BrO_3, and IO_3, are shown in Fig. 1. The logarithm of the concentration expressed in mole fraction (X) is plotted against the reciprocal of the absolute temperature. The temperature expressed in ordinary Celsius units is shown on the upper side of the figure. For comparison, Fig. 1 includes the phase diagram of the tetrabutylammonium fluoride–water system reported earlier.[5]

Table 1. Melting points and hydration numbers of tetrabutylammonium salt clathrate hydrates

Anion	Mp θ_m/°C	Hydration number
F^-	28.3[5,6]	30±1[5,6]
NO_2^-	11.5	29±2
NO_3^-	7.3	30±1
ClO_3^-	−0.9	30±2
BrO_3^-	0.8 (incongruent)	—
IO_3^-	4.9 (incongruent)	—
CO_3^{2-}	18.3	66±2
SO_4^{2-}	12.6	64±2
CrO_4^{2-}	12.7 (13.6[1])	66±2 (65—68[1])
WO_4^{2-}	15.0 (15.1[1])	64±2 (60—63[1])
PO_4^{3-}	17.8	100±4

Figure 1 clearly shows that the three salts with $X=NO_2$, NO_3, and ClO_3 can form clathrate-like hydrates similar to that of the fluoride although their congruent melting points are considerably lower than that of the fluoride hydrate. The congruent compositions of these three hydrates are almost the same as that of the fluoride hydrate. This suggests that these newly found hydrates have the same crystal structure as that of the fluoride hydrate.[3] The melting points and the hydration numbers calculated from their congruent compositions are summarized in Table 1, together with those previously reported.[4-6]

The phase diagrams for the bromate and iodate systems resemble each other and are different from those of the other salts. They show the existence of three types of solid phases other than ice over the

temperature range studied. The incongruent melting points and corresponding compositions are 0.8 °C, X= 0.032 and 14.0 °C, X=0.050 for the bromate and 4.9 °C, X=0.024 and 17.3 °C, X=0.034 for the iodate, respectively. Of these phases, the ones which are stable over a low temperature interval of −2.1—+0.8 °C for the bromate and of −1.5—4.9 °C for the iodate seem to be clathrate hydrates, since not only the temperature dependence of the solubility curves of these two phases but also their morphological appearance is quite similar to those of the other clathrate hydrates. The incongruent melting points of the two hydrates are also given in Table 1. As is obvious from Fig. 1, these incongruent melting points are very close to their hypothetical congruent melting points since the incongruent composition is comparable to that of the hydrate itself ($X \simeq 0.033$).

As pointed out above, the melting points of these hydrates are considerably lower than that of, for example, the fluoride hydrate,[4-6] indicating that the hydrogen-bonded water lattice within the hydrate solid is markedly distorted by the presence of the anion, which is polyatomic and consequently more bulky than a simple anion such as a fluoride ion. Generally, it is hardly possible to evaluate quantitatively the effect of anions on the lattice distortion, because of the lack of any precise knowledge about the behavior of anions within the lattice, for example, about the possibility of hydrogen-bond formation between an oxygen atom of the anion and a hydrogen atom of the water molecule included in the lattice. Here we simply discuss the effect of the geometrical size of an anion on the lattice distortion of the hydrate from the following point of view. Firstly, as an estimation of the effective size of an anion within the hydrate crystal, it would be appropriate to refer to an ionic volume in an aqueous solution rather than its intrinsic (crystallographic) volume, since the anion present in the hydrate solid is undoubtedly surrounded by many water molecules, as if it were in an aqueous solution. Secondly, the ionic volume in an aqueous solution which we can use quantitatively is a conventional partial molal ionic volume at infinite dilution, $\overline{V}^{\circ}_{conv}$, based on the assumption that the partial molar volume of hydrogen ion at infinite dilution is 0 cm^3/mol.[10]

In Fig. 2 the melting point of each hydrate, which may be considered an indication of the stability of the hydrate, is tentatively plotted against the $\overline{V}^{\circ}_{conv}$ of the respective anions at 25 °C including halide and hydroxide hydrates already reported.[11] The melting points of both iodate and bromate hydrates are estimated from the temperature dependence of their solubility curves, which are shown in Fig. 1. It is obvious from this figure that the melting point of the hydrate decreases almost linearly with increasing the $\overline{V}^{\circ}_{conv}$, indicating that the stability of the hydrate is to a considerable extent governed by the distortion effect of the anion. The relationship found in Fig. 2 could also be used to estimate the melting point of the hydrate of tetrabutylammonium salt having a monovalent anion not examined in this study. It is interesting to note that Fig. 2 can reasonably explain the fact that tetrabutylammonium salts having large anions[10] such as I^-

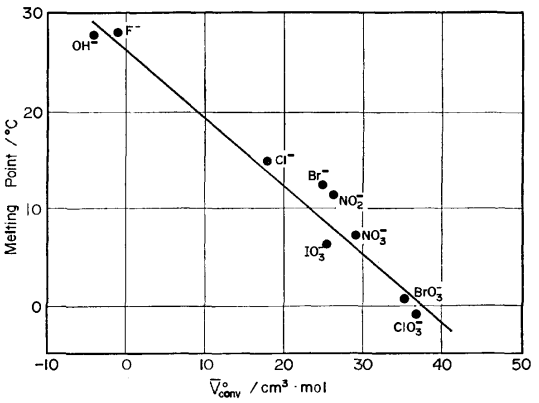

Fig. 2. Relationship between the melting points and the conventional partial molal anionic volumes in the clathrate hydrates of tetrabutylammonium salts with monovalent anions.

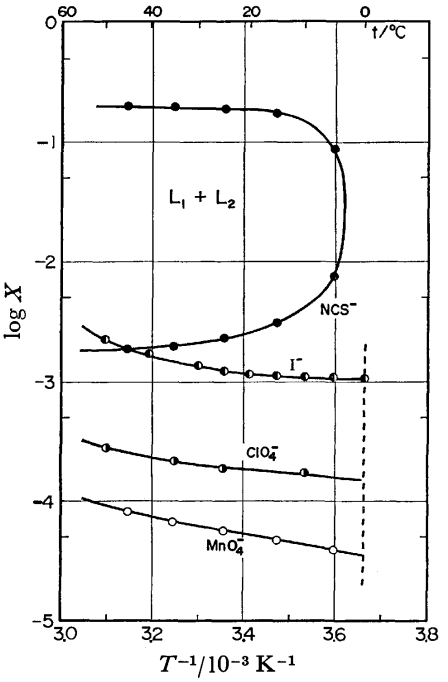

Fig. 3. Solid-liquid and liquid-liquid phase diagrams for the water-(n-$C_4H_9)_4NX$ systems.
◐: X=I, ○: X=MnO_4, ◑: X=ClO_4, ●: X=NCS.

($\overline{V}^{\circ}_{conv}$=36.22 cm^3/mol), NCS^-($\overline{V}^{\circ}_{conv}$=35.7 cm^3/mol), MnO_4^-($\overline{V}^{\circ}_{conv}$=42.5 cm^3/mol) and ClO_4^- ($\overline{V}^{\circ}_{conv}$= 44.12 cm^3/mol) cannot form stable clathrate hydrates.

The phase diagrams for systems which do not form hydrates are shown in Fig. 3 in the same way as in Fig. 1. This figure includes the phase diagram of the water–(n-$C_4H_9)_4NI$ system[5] for comparison. The characteristics of this figure are summarized as follows: (1) the solubilities in water of both permanganate and perchlorate are considerably lower than that of the iodide, which is well known to be a sparingly soluble salt (for example, at 25 °C, the solubilities are 0.112 wt%, 0.345 wt%, and 2.447 wt%[5] for permanganate, perchlorate, and iodide, respectively); and (2) a phase separation into two liquid phases occurs in

the thiocyanate system with lower critical solution temperature of +3.5 °C.

(2) Clathrate Hydrate Formation of Tetrabutylammonium Salts Having Di- and Trivalent Anions. The solid-liquid phase diagrams for the binary systems, water–$[(n\text{-}C_4H_9)_4N]_2Y$, where $Y=CO_3$, SO_4, WO_4, and CrO_4, and water–$[(n\text{-}C_4H_9)_4N]_3PO_4$, are shown in Fig. 4. This figure clearly shows that all the salts studied can form clathrate hydrates which melt congruently. Their melting points and hydration numbers are also listed in Table 1. Of these hydrates, the carbonate, sulfate, and phosphate hydrates are newly confirmed in this study. The data for both chromate and tungstate hydrates are in good agreement with those reported earlier,[1] although some discrepancy in the melting point of the chromate hydrate is seen.

It is interesting to note that these hydrates are fairly stable, as compared with those of the salts with monovalent anion mentioned in the previous section. This fact indicates that the distortion effect of the anion on the water lattice within the hydrate crystal is relatively small. One reason for this will be the fact that the number of anion per one $(n\text{-}C_4H_9)_4N^+$ cation is reduced to either a half or a third of the above mentioned case. An approximately linear relationship between the melting point and the $\overline{V}°_{conv}$ of anion, found for the salts with monovalent anion (Fig. 2), cannot be seen in this series of hydrates, since their melting points vary only over a limited range of temperature (13—18 °C), whereas the $\overline{V}°_{conv}$'s widely vary from −4.3 cm³/mol[10] for CO_3^{2-} ion to 25.7 cm³/mol[10] for WO_4^{2-} ion. This suggests that the distortion on the water lattice due to the introduction of divalent (or trivalent) anion is not the dominant factor which determines the stability of the hydrate. The slight difference in stability of these hydrates seems to be governed by such factors as either geometrical shape of the anion or slight difference in the ability of hydrogen-bond formation of the oxygen atom of the anion with a water molecule.

Judging from the hydration numbers listed in Table 1, the crystallographic structure of these hydrates is believed to be essentially the same as that of the salts with monovalent anion since the numbers of water molecules per one $(n\text{-}C_4H_9)_4N^+$ cation are approximately equal. The fact that the number of water molecules per one $(n\text{-}C_4H_9)_4N^+$ cation in the hydrates of salts with either di- or trivalent anions, around 33, is slightly larger than 30 found in the series of salts with monovalent anion, will be reasonable since the number of water molecules which construct the clathrate lattice must increase in order to fill the vacant space arising from the decrease in the number of anions.

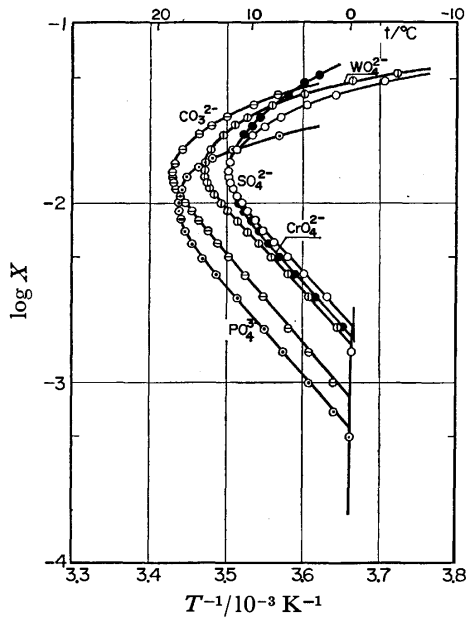

Fig. 4. Solid-liquid phase diagrams for the water–$[(n\text{-}C_4H_9)_4N]_2Y$ and water–$[(n\text{-}C_4H_9)_4N]_3PO_4$ (⊙) systems.

Reactions of the Octahedral Bis(α-diketone dioximato)iron(II) Complexes with Carbon Monoxide and Benzyl Isocyanide

Yoshihiro Sasaki

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received February 5, 1982)

The reactions of bis(α-diketone dioximato)iron(II) coordinated by two nitrogeneous base molecules (X) with carbon monoxide and benzyl isocyanide were studied kinetically in chloroform; here α-diketone dioxime= 2,2′-difurylglyoxime (H_2fr) and dimethylglyoxime (H_2dg). The reactions proceeded reversibly through a dissociative mechanism. For the reaction $Fe(Hfr)_2(X)_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Fe(Hfr)_2(X)+X$, plots of log k_1 *vs.* pK_a (K_a: dissociation constant of conjugate acid of base) for pyridines gave a negative correlation. The log k_1 values of 4-cyanopyridine and 4-acetylpyridine systems were smaller and that of 2,6-dimethylpyridine system larger than predicted by their pK_a values. Imidazole and 1-methylimidazole were more inert than pyridines. For the reaction $Fe(Hfr)_2(X)+CO \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} Fe(Hfr)_2(X)(CO)$, log k_{-2} *vs.* pK_a plots for sterically unhindered pyridines showed a linear relationship, but the basicity of pyridine bases did not affect the CO dissociation processes very much. 2-Methylpyridine, 2,4-dimethylpyridine, and 2,6-dimethylpyridine facilitated the dissociation of CO slightly as compared with pyridine. Imidazole and 1-methylimidazole allowed CO to be more inert and piperidine more labile than pyridines. The dissociation of the base was significantly affected by the change of substituents in α-diketone dioxime, and the dissociation of CO was slightly affected by the change of substituents. The reaction behavior was discussed on the basis of the activation parameters and infrared data.

Many investigations have been reported on axial ligand substitution reactions in six-coordinated iron(II) complexes containing macrocyclic ligands.[1–12] In such complexes the equatorial positions are occupied by four nitrogen atoms of the macrocycles and the axial sites by the ligands taking part in the observed rate processes. All the complexes investigated so far are able to bind carbon monoxide reversibly at the sixth position. The reactions proceed through a dissociative mechanism involving a five-coordinated intermediate which is very reactive. The binding processes of five-coordinated iron(II) porphyrins with bases and CO, which are related to biological functions of hemoproteins, have been studied using flash- or laser-photolysis techniques.[13–16] On the other hand, studies of axial ligand substitution reactions for six-coordinated iron(II) complexes with macrocycles may offer useful information on the dissociative processes of axial ligands such as nitrogeneous bases, CO, and O_2 in iron(II) porphyrins.

Octahedral bis(α-diketone dioximato)iron(II) containing a nitrogeneous base possesses a similar structure to that of iron(II) porphyrins and is able to bind CO reversibly.[17,18] Vaska and Yamaji have studied reactions of bis(diphenylglyoximato)iron(II) with CO; they proposed that the reactions proceed *via* a five-coordinated intermediate.[19] Pang and Stynes have reported the rate parameters for dissociation of base, CO, and benzyl isocyanide in bis(dimethylglyoximato)-iron(II) systems at low and high temperatures.[20] In the reaction systems studied so far, pyridine, 1-methylimidazole, and piperidine have been used as bases.[2,3,5,20] The factors regulating such reactions are not sufficiently understood. The reactivity of iron atom in these complexes is thought to be affected by the properties of the axial ligand as well as by the properties of the equatorial macrocycle. In this study, the reactions of bis(2,2′-difurylglyoximato)iron(II), $Fe(Hfr)_2(X)_2$ (X=base), with CO and benzyl isocyanide have been investigated in order to reveal the basicity effect and the steric effect of axial ligands on the reactions, and the reactions of bis(dimethylglyoximato)iron(II), $Fe(Hdg)_2(X)_2$ (X=pyridine and 1-methylimidazole), with CO have been re-examined in order to compare them with $Fe(Hfr)_2(X)_2$–CO systems.

Experimental

Materials. Pyridine (py), 2-methylpyridine (2-mepy), 4-methylpyridine (4-mepy), 2,6-dimethylpyridine (2,6-me_2py), 2,4-dimethylpyridine (2,4-me_2py), 3,4-dimethylpyridine (3,4-me_2py), 4-acetylpyridine (acpy), 3-chloropyridine (3-clpy), 1-methylimidazole (meim), butylamine (buam), and piperidine (pip) were distilled from KOH solutions prior to use. 4-Cyanopyridine (cnpy) and 4-dimethylaminopyridine (dmnpy) were purified by recrystallization. 2,2′-Difurylglyoxime (H_2fr), dimethylglyoxime (H_2dg), and imidazole (im) of guaranteed grade were used without further purification. 4-Chloropyridine (4-clpy) was prepared from 4-chloropyridine hydrochloride according to Lavalette *et al.*[16] Solutions of 4-clpy in chloroform were stored in a refrigerator. Guaranteed grade chloroform was used as solvent and carbon monoxide was obtained commercially. Benzyl isocyanide (bzlnc) was prepared according to the procedure described by Ugi and Meyer.[21]

Preparation of Complexes. Iron(II) dimethylglyoxime complexes, $Fe(Hdg)_2(X)_2$ (X=py and meim), and some iron(II) 2,2′-difurylglyoxime complexes, $Fe(Hfr)_2(X)_2$ (X= py, meim, 4-mepy, and cnpy), were prepared according to the methods reported previously.[22] $Fe(Hdg)_2(X)(CO)$ and $Fe(Hdg)_2(X)$(bzlnc) (X=py and meim) were prepared according to the procedures described by Pang and Stynes.[20]

$Fe(Hfr)_2$(3-clpy)$_2$: Methanol–water solutions of Mohr's salt (0.4 g) and 2,2′-difurylglyoxime (0.4 g) were mixed together under a nitrogen atmosphere and then 3-chloropyridine (2 ml) was added to the mixture. The pH value of the mixed solution was adjusted to about 7 by adding an aqueous NaOH solution to precipitate reddish brown crystals.

$Fe(Hfr)_2(py)(CO)$: A solution of $Fe(Hfr)_2(py)_2H_2O$ (700 mg) in dichloromethane (200 ml) was stirred for 12 h under a CO atmosphere in the dark and concentrated to about 25 ml by bubbling CO. The brown crystals were precipitated by the addition of petroleum ether (70 ml) to the concentrated solution.

$Fe(Hfr)_2(py)(bzlnc)CH_2Cl_2$: $Fe(Hfr)_2(py)_2H_2O$ (500 mg) was added to 50 ml of dichloromethane containing benzyl isocyanide (350 mg) and pyridine ($\approx 10^{-3}$ mol dm^{-3}). The solution was stirred for 6 h and concentrated to about 20 ml by bubbling N_2. Petroleum ether (70 ml) was added to the solution to precipitate the black crystals.

$Fe(Hfr)_2(acpy)_2$, $Fe(Hfr)_2(3,4\text{-me}_2py)_2$, $Fe(Hfr)_2(dmnpy)_2$, $Fe(Hfr)_2(im)_2$, $Fe(Hfr)_2(meim)(CO)$, $Fe(Hfr)_2(3\text{-clpy})(CO)$, $Fe(Hfr)_2(meim)(bzlnc)$, $Fe(Hfr)_2(3\text{-clpy})(bzlnc)$, and $Fe(Hfr)_2(buam)(bzlnc)$ were prepared by the procedures described above. The analytical results of these new complexes are shown in Table 1.

Physical Measurements. Visible spectra were obtained on a Hitachi 323 automatic recording spectrophotometer, equipped with a thermostated cell-holder and connected with a vacuum line. Infrared spectra were measured in Nujol mull or KBr disk with a Perkin-Elmer 521 spectrophotometer.

$Fe(Hfr)_2(X)_2$, $Fe(Hdg)_2(X)_2$, and Carbonyl Complex Samples. Solutions of $Fe(Hfr)_2(X)_2$ (X=py, 4-mepy, cnpy, 3-clpy, acpy, dmnpy, 3,4-me_2py, im, and meim) ($\approx 3\times10^{-4}$ mol dm^{-3}) and $Fe(Hdg)_2(X)_2$ (X=py and meim) ($\approx 6\times10^{-4}$ mol dm^{-3}) were prepared by dissolving isolated complexes in chloroform containing a large excess of the bases to prevent oxidation of the complexes. Solutions of the other 2,2′-difurylglyoxime complexes (X=buam, 2-mepy, 2,4-me_2py, 2,6-me_2py, 4-clpy, and pip) ($\approx 3\times10^{-4}$ mol dm^{-3}) were prepared by dissolving $Fe(Hfr)_2(3\text{-clpy})_2$ or $Fe(Hfr)_2(py)_2$ in chloroform containing the bases. Carbonyl complexes were prepared by bubbling CO through bis(base) complex solutions for 2—4 h.

Kinetics. For the reactions of Fe(α-diketone dioximato)$_2$(X)$_2$ with CO or bzlnc, a 0.3 ml portion of a bis(base) complex solution was syringed into a serum-capped chloroform solution (2.7 ml) over 1 atm. CO or 10^{-3}—5×10^{-3} mol dm^{-3} bzlnc. The substitution reaction of Fe(α-diketone dioximato)$_2$(X)(CO) with base (X) was carried out by syringing 0.3 ml of a carbonyl complex solution bubbled with N_2 for 2 min into chloroform containing a large excess of base ([X]$>10^{-1}$ mol dm^{-3}) or into base (2.7 ml). The kinetic measurement was made by monitering the absorbance change at a constant temperature (±0.2 °C). The experimental conditions, where the axial ligands were kept in large excess against the complexes ($\approx 3\times10^{-5}$ mol dm^{-3}), gave rise to pseudo-first-order rate constants. The rate constant, k_{obsd}, was evaluated from the $\ln(A-A_\infty)$ *vs.* time plots, which were linear or at least 3-half-lives.

Results and Discussion

$Fe(Hfr)_2(X)_2$ (X=py, 4-mepy, 3-clpy, cnpy, acpy, 3,4-me_2py, dmnpy, im, and meim) and $Fe(Hdg)_2(X)_2$ (X=py and meim) were synthesized in methanol–water (1:1 volume ratio) containing a large excess of the bases. The complexes were oxidized readily in chloroform, but the oxidation was suppressed by the presence of the bases. The H_2fr complexes were more stable than the H_2dg complexes. The other H_2fr complexes (X=pip, 2-mepy, 2,4-me_2py, and 2,6-me_2py) were oxidized immediately in methanol–water containing a large excess of the bases, but the complexes in chloroform were fairly stable in the presence of the bases. The carbonyl and bzlnc complexes in solution displayed photodissociation of CO and bzlnc, respectively. The preparation of $Fe(Hfr)_2(cnpy)(CO)$ and $Fe(Hfr)_2(cnpy)(bzlnc)$ was not successful, since they were very photosensitive. The bzlnc complexes were too stable in the dark to study the dissociation process of bzlnc at 25 °C.

The data of the visible spectra are shown in Table 2. The assignments of the bands for the bis(base) complexes were reported previously.[17,22-25] The bands at longer and shorter wavelengths were assigned to charge transfers from iron to α-diketone dioxime and from iron to pyridine ring, respectively. The bis(base) complexes of meim, im, buam, and pip did not exhibit the second band. The first band shifted to longer wavelengths with increasing basicity of the axial base. The axial ligation of CO and bzlnc, being good π-acceptors, gave rise to a band at short wavelength, and the position was not much affected by trans base. This may mean that the band in the CO and bzlnc complexes can be assigned to charge transfer from iron to CO and to bzlnc, respectively.

The infrared stretching frequencies for the CO and bzlnc complexes are given in Table 3. The CO stretches in the CO complexes occurred at lower wave numbers than that for free CO (ν_{CO}=2143 cm^{-1}). The ν_{CO} for the H_2dg complexes was smaller (by ≈20 cm^{-1}) than that for the H_2fr complexes. If we consider the ν_{CO} for the CO complexes as an indication of the ability of the π back-donation from iron to

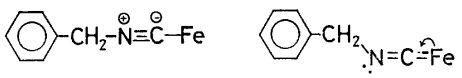
a) X=base.

CO, the H_2dg systems are seen to better than the H_2fr systems. This is expected, based on the greater inductive effect of the methyl group compared with that of the furyl group. The ν_{CO} values of the 3-clpy complexes were larger (by $\approx$15 cm^{-1}) than those of the py and meim complexes, which means that the strength of σ-donor property of trans base also affects significantly the π-bonding between iron and CO. Behavior of the NC stretching frequencies of the bzlnc complexes was more complicated: The ν_{NC} values of the H_2fr complexes were larger and those of the H_2dg complexes smaller than that of free bzlnc (ν_{NC}=2153 cm^{-1}).[26] This seems to be related to the two resonance forms of isocyanides:



a b

In form a, bzlnc acts as a σ-donor ligand; this type of bonding is characterized by a shift of the ν_{NC} to higher frequency upon complex formation. In form b, bzlnc acts as a π-acceptor; this type of bonding occurs preferably with transition metals by making a π back-donation from metal to the ligand.[27] Thus

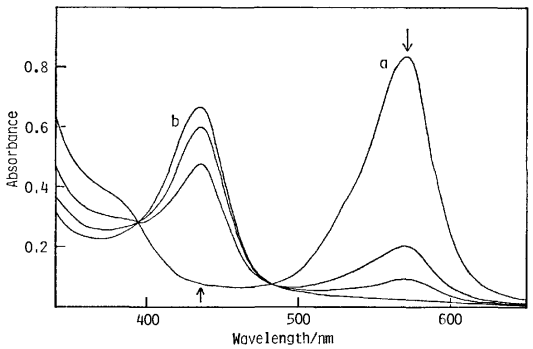


Fig. 1. Time dependence of spectra for Fe(Hfr)$_2$(2,6-me$_2$py)$_2$–CO system in chloroform at 25 °C. [Fe(Hfr)$_2$(2,6-me$_2$py)$_2$]=3.73×10^{-5} mol dm^{-3}, [2,6-me$_2$py]=4.00×10^{-2} mol dm^{-3}, CO: 1 atm. b: after 19 min.

the behavior of ν_{NC} observed in this study shows that form a is dominant in the H_2fr complexes.

The visible spectral change of the CO– and bzlnc–Fe(Hfr)$_2$(X)$_2$ systems with time exhibited two isosbestic points. As a typical example, the spectra of Fe(Hfr)$_2$(2,6-me$_2$py)$_2$–CO and Fe(Hfr)$_2$(2,6-me$_2$py)-(CO)–2,6-me$_2$py systems are shown in Figs. 1 and 2. Two excellent isosbestic points were found at 394 and 481 nm, suggesting that the following reversible reaction takes place without oxidation of the bis(2,6-me$_2$py) complex:

$$\mathrm{Fe(Hfr)_2(X)_2 + L \underset{K}{\rightleftharpoons} Fe(Hfr)_2(X)(L) + X,} \quad (1)$$

where X=base, L=CO or bzlnc, and K is an equilibrium constant. The reaction 1 is to pass through a five-coordinated intermediate (dissociative mechanism), as reported in other systems:

$$\mathrm{Fe(Hfr)_2(X)_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Fe(Hfr)_2(X) + X,} \quad (2)$$

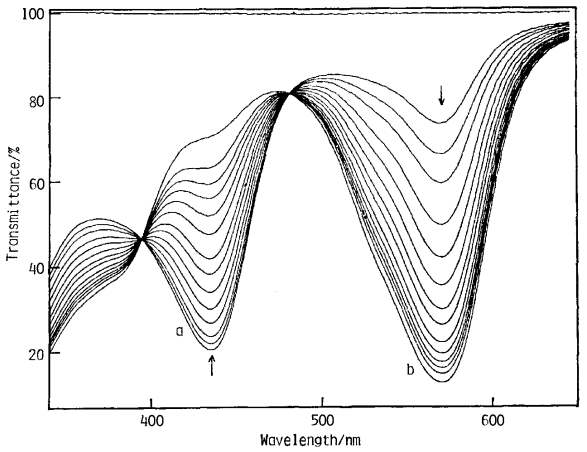

Fig. 2. Time dependence of spectra for $Fe(Hfr)_2(2,6\text{-}me_2py)(CO)$–2,6-$me_2$py system in chloroform at 25 °C. $[Fe(Hfr)_2(2,6\text{-}me_2py)(CO)]=4.03\times10^{-5}$ mol dm^{-3}, $[2,6\text{-}me_2py]=7.25\times10^{-1}$ mol dm^{-3}. b: after 310 min.

$$Fe(Hfr)_2(X) + L \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} Fe(Hfr)_2(X)(L). \quad (3)$$

If we assume a steady-state concentration for the five-coordinated intermediate and neglect k_{-2}, the CO or bzlnc complex-formation rate constant, k_{obsd}, can be represented by:

$$k_{obsd}^{-1} = (1/k_1)(1+(k_{-1}/k_2)([X]/[L])). \quad (4)$$

Plots of k_{obsd}^{-1} *vs.* [X]/[CO] for several $Fe(Hfr)_2(X)_2$–CO systems are shown in Fig. 3. The solubility of CO in chloroform was taken as that in toluene at 25 °C (6.5×10^{-3} mol dm^{-3} atm^{-1}).[5,28] The plots for all the base systems gave good straight lines. The visible spectra of the $Fe(Hdg)_2(X)_2$–CO systems changed with an excellent isosbestic point. The plots of k_{obsd}^{-1} *vs.* [X]/[CO] gave also good straight lines (Fig. 4). The parameters k_1 and k_{-1}/k_2 were determined from the intercepts and the slopes. The intercept of pip in Fig. 3 and that of py in Fig. 4 were too small to allow us to estimate k_1.

The kinetic data were estimated by the least-squares method, and the equilibrium constants were calculated from the kinetic data. Several equilibrium constants were obtained experimentally and consistent with those calculated. The activation parameters were estimated from the kinetic data at 20, 25, and 30 °C.

The rate constants and the activation parameters for the $Fe(Hfr)_2(X)_2$–CO systems are given in Tables 4 and 5, respectively. Figure 5 shows the relationship between the rate constants and pK_a (K_a: dissociation constant of conjugate acid of the base). The $\log k_1$ values of the pyridines increased with decreasing basicity of the bases. But the $\log k_1$ values of cnpy and acpy were smaller and that of 2,6-me_2py was larger than predicted by their pK_a values. The imidazoles were more inert, and buam and pip more labile than predicted by their pK_a values. The sterically unhindered pyridines gave rise to ΔH_1^* values of the same degree in magnitude ($\approx$105 kJ mol^{-1}).[29] The decreased ΔH_1^* valuc of 4-clpy may be due to the polymerizing property of the base.[30] The steric effect on

the dissociation of the pyridines in the $Fe(Hfr)_2$ systems very little. The decreased ΔH_1^* values of the sterically hindered pyridines may support the steric hindrance by the methyl group in α position. The small steric effect is in striking contrast to that on dissociation of imidazoles in iron(II) phthalocyanine system, in which 2-methylimidazole is about 12700 times labile than

imidazole.[2] The dissociation of 1,2-dimethylimidazole in Fe(Hfr)$_2$ system also was too fast to study on a conventional spectrophotometer. Therefore, it seems that the steric effect for both systems may be affected by the difference in rigidity of the macrocycles as well as by some difference in the axial ligation property of pyridine and imidazole. π-Receptive groups such as cyano and acetyl groups in pyridine ring decreased the ΔH_1^* value. If we consider ΔH_1^* as the binding energy between iron and base, the π-receptive groups in pyridine ring are seen to weaken the bond between iron and base. The ΔS_1^* values of cnpy, acpy and the sterically hindered pyridines were rather small, as compared with those of the other pyridines. The increased lability of buam and pip may be attributed to the inability of those bases to undergo dπ-π interaction, in addition to the steric repulsion in the pip system.[31] The imidazoles were more inert and gave rise to larger ΔH_1^* values than the pyridines. This may be explained in terms of π-basicity of the imidazoles,[32] although we could not find good evidence of the dπ-π interaction between iron and imidazole ring in the infrared data of the CO and bzlnc complexes.

The log k_2 values of the sterically unhindered pyridines also increased slightly with decreasing basicity of the bases. The sterically hindered pyridines allowed CO to be a little more labile than predicted by their pK_a values. The small steric effect is in striking contrast to the results for imidazole systems of iron(II) phthalocyanine and chelated hemes, in which 2-methylimidazole allows CO to be about 20 times more labile than imidazole.[2,14] The CO in the imidazole systems was 5 times more inert and the CO in the pip system 10 times more labile than that in the py system. The sterically unhindered pyridines

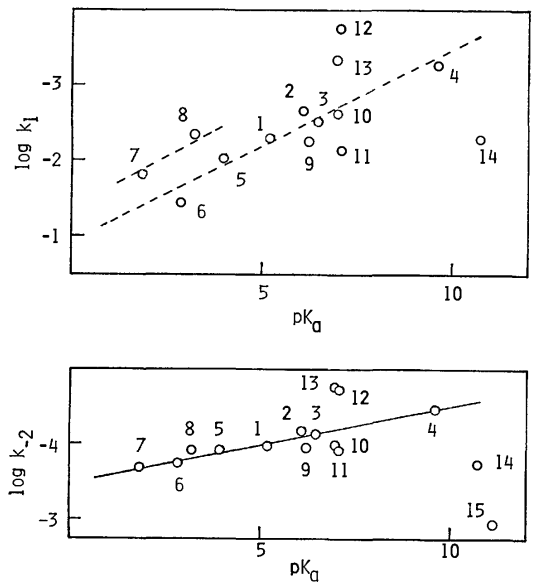

Fig. 5. Plots of $\log k_1$ and $\log k_{-2}$ *vs.* pK_a.
1: py, 2: 4-mepy, 3 3,4-me$_2$py, 4: dmnpy, 5: 4-clpy, 6: 3-clpy, 7: cnpy, 8: acpy, 9: 2-mepy, 10: 2,4-me$_2$py, 11: 2,6-me$_2$py, 12: meim, 13: im, 14: buam, 15: pip.

gave rise to ΔH^*_{-2} values of the same degree in magnitude ($\approx$105 kJ mol^{-1}), which were roughly equal to the ΔH_1^* values. The ΔH^*_{-2} values of the sterically hindered pyridines and those of cnpy and acpy, being π-acceptors, were smaller than 105 kJ mol^{-1}. If factors favoring π back-donation facilitate electron transfer from metal to ligand, π-receptive bases are expected to weaken the dπ-π interaction between iron and CO. This is presumably supported by the small ΔH^*_{-2} values of cnpy and acpy. The ΔH^*_{-2} values of the imidazoles were slightly larger and the ΔH^*_{-2} value of pip smaller than that of py. The ΔS^*_{-2} values were smaller than the corresponding ΔS_1^* values, which results in greater inertness of CO compared with that of the bases. The bases used in this study are strong dipoles (1.2 D for pip—4.3 D for dmnpy), and the five-coordinated intermediate assumed here may have an electric dipole moment (complex dipole moment) along the direction of axial ligand since the iron in the intermediate is found to lie out of the plane of the equatorial ligands. Therefore, it is expected that the activation potential for a dissociative process of base may be contributed to some extent by the long range electrostatic repulsion between the base dipole and the induced complex dipole.[33] On the other hand, the electric dipole moment of CO is very small (0.1 D), suggesting that the activation potential for the dissociation process of CO may be greatly contributed by a short range electron-exchange interaction between iron and CO. If we assume that the Δr ($=r^*-r_0$) value for a dissociation of base is larger than that for the dissociation of CO, where r_0 and r^* are the distances between iron and the leaving ligand in the initial complexes and their transition states, and that the activation entropy is due partially to the Δr values, the dissociation of bases may give rise to larger ΔS^* than that of CO. This rough estimation is consistent with the results obtained in this study.

The dissociation rates of CO in the Fe(Hfr)$_2$ systems did not correlate with the CO stretching frequencies in Table 3, as found in heme systems previously.[34] This suggests that both σ electron donation and π back-donation contribute to the stability of CO complexes, but the CO stretching frequency is sensitive to changes in the π back-donation of CO complexes.

The k_{-1}/k_2 ratios obtained in this study are comparable in magnitude to those for iron(II) phthalocyanine and iron(II) diphenylglyoxime systems.[2,19] On the other hand, the ratio for the sterically hindered pyridine systems was far too small. The steric effect on k_{-1}/k_2 ratio is presumably related to the structure of the five-coordinated intermediate. The result of k_{-1}/k_2 ratio in the pyridine systems is also in striking contrast to that in imidazole systems of iron(II) phthalocyanine, where the ratio of 2-methylimidazole is comparable to that of imidazole.[2] The values of equilibrium constant, K, estimated in this study were roughly equal in magnitude. But the K values of the sterically hindered pyridines were much larger; this resulted from the decreased k_{-1}/k_2 ratio.

The rate constants and the activation parameters for the Fe(Hdg)$_2$(X)$_2$–CO systems are given in Table 6. The Fe(Hdg)$_2$ systems gave rise to k_1 values about 50 times larger than those in the Fe(Hfr)$_2$ systems. The CO in the Fe(Hdg)$_2$ complexes was about twice as inert as that in the Fe(Hfr)$_2$ complexes. The ΔH_1^* value of Fe(Hdg)$_2$(meim)$_2$ was smaller than that of Fe(Hfr)$_2$(meim)$_2$, but the ΔH^*_{-2} and ΔS^*_{-2} values of Fe(Hdg)$_2$(py)(CO) were larger than those of Fe(Hfr)$_2$(py)(CO). The change of the ΔH_1^* values suggests that the bond between iron and axial base (mainly σ bond) in Fe(Hdg)$_2$ complexes is weaker than that in Fe(Hfr)$_2$ complexes, as expected by the greater inductive effect of methyl group than that of furyl group. The result that the dissociation of CO is not much affected by the electronic effect of the substituents is consistent with that reported recently in some chelated hemes.[5] These suggest that stability of CO complexes is determined by both σ electron donation and π back-donation. The increased ΔH^*_{-2} value

4-Cyanopyridine	17±2	1.3
1-Methylimidazole	0.183±0.001	0.8
Imidazole	0.48±0.01	—
Butylamine	5.6±0.2	0.5

of Fe(Hdg)$_2$(py)(CO) is presumably due to better ability of π back-bonding formation of Fe(Hdg)$_2$ complexes, as concluded on the basis of the infrared data.

The rate constants for several Fe(Hfr)$_2$(X)$_2$–bzlnc systems are summarized in Table 7. The k_1 values for the Fe(Hfr)$_2$(X)$_2$–bzlnc systems were in agreement with those for the Fe(Hfr)$_2$(X)$_2$–CO systems; this is good evidence of the dissociative mechanism assumed in this study. The k_{-1}/k_2 ratios for the bzlnc systems were 1/3 in magnitude, compared with those for the corresponding CO systems. This means that the k_2 values of the bzlnc systems are 3 times larger than those of the CO systems. The bzlnc complexes were much more stable than the CO complexes.

The author wishes to thank to Dr. Tadashi Okamoto for helpful discussions.

The Formation of Needle-like Particles of $x CoFe_2O_4 \cdot (1-x)Fe_3O_4$ with $x \leq 0.2$

Masao KIYAMA* and Toshio TAKADA

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received February 12, 1982)

An experimental study was made of the oxidation with air of alkaline suspensions containing needle-like Fe_3O_4 particles and slight amounts of $Co_{1/3}/Fe_{2/3}(OH)_2$ at temperatures between 60 and 90 °C, together with the properties of the resulting oxidation products. It has been found that the H_c (coercivity) values of the products were greatly affected by both the excess NaOH concentration and the oxidation temperature—*i.e.*, the two essential factors in determining the difference in the properties of a cobalt ferrite layer coated on the Fe_3O_4 particles, that these values increased with the heat treatment *in vacuo* of the products within the temperature range of 200 to 450 °C, without decreasing the saturation magnetization values, and that the H_c increment was mainly governed by the Co content.

Needle-like particles of γ-Fe_2O_3, containing a slight amount of Co(II), have been widely used as a ferromagnetic material for high-density recording tapes. The coercivity (coercive force), H_c, of γ-Fe_2O_3 particles has been known to become greater with an increase in the shape anisotropy.[1] The γ-Fe_2O_3 particles become magnetically harder—*i.e.*, the H_c increase, by either the adsorption of Co(II)[2,3] or the epitaxial coating of cobalt ferrite[3-5] on their surfaces, with the participation of the properties of a surface magnetic anisotropy.

The precipitate of $Co_{x/3}Fe_{1-x/3}(OH)_2$, prepared by adding an excess NaOH solution to a mixed solution of Co(II) and Fe(II) salts, can transform itself by oxidation into a ferromagnetic precipitate consisting of cubic $Co_xFe_{3-x}O_4$ particles, whose H_c value is governed by the conditions of oxidation.[6] As has been known, the difference in the lattice constant between Fe_3O_4 and cobalt ferrite is appreciably small relative to that between γ-Fe_2O_3 and cobalt ferrite.

The present authors considered that the use of Fe_3O_4 particles instead of γ-Fe_2O_3 would contribute to the ease of the epitaxial coating of cobalt ferrite, with a consequent attainment of a magnetically harder material. The authors have found that magnetic properties of the products prepared by subjecting aqueous suspensions containing needle-like Fe_3O_4 particles and slight amounts of $Co_{1/3}Fe_{2/3}(OH)_2$ to oxidation were greatly affected by the conditions of oxidation.

This paper is an account of the properties of such products and of the conditions for the formation of $x CoFe_2O_4 \cdot (1-x)Fe_3O_4$ with $0.2 \geq x$, featuring greater H_c values created by coating cobalt ferrite on the surfaces of needle-like Fe_3O_4 particles.

Experimental

A number of α-FeO(OH) samples, each consisting of needle-like particles, were prepared as follows. Alkaline suspensions (each 3 dm^3) of $Fe(OH)_2$, which had been prepared by mixing aqueous solutions of $FeSO_4$ and NaOH (both of an analytical grade), were heated and then oxidized at 40 °C by bubbling CO_2-eliminated air into them at various constant rates until the precipitate of $Fe(OH)_2$ completely disappeared. The oxidation method for these suspensions was the same as that previously reported.[7] The yellowish precipitates of α-FeO(OH) were separated by filtration, washed well with water, treated with acetone, and then dried at 70 °C in air. The mean particle size of the α-FeO(OH) samples was estimated from the BET surface area, S, which had been measured using nitrogen; it could successfully be controlled in the S range between 20 and 45 $m^2 g^{-1}$ by varying the concentrations of Fe(II) and of the excess NaOH in the starting suspension, and the air-flow rate.

The α-FeO(OH) samples were then directly reduced in hydrogen at 330 °C to Fe_3O_4. The Fe_3O_4 sample with the highest H_c value (Fig. 1(b)), which had been prepared from the α-FeO(OH) sample with $S = 30\ m^2 g^{-1}$ (Fig. 1(a)), was selected from the Fe_3O_4 samples and used as the starting ferromagnetic material. The α-FeO(OH) sample (Fig. 1(a)) was prepared by bubbling air at a constant rate of 500 dm^3/h for 20 h into the individual 3-dm^3 suspensions, each containing 0.22 M(1 M = 1 mol dm^{-3}) $Fe(OH)_2$ and 1.25 M excess NaOH; the resulting suspensions were mixed and subjected to further treatment.

The starting suspensions, consisting of the particles of Fe_3O_4 and the hydroxides of Co(II) and Fe(II), were prepared in each 4-dm^3 spherical flask, as will be described. $FeSO_4 \cdot 7H_2O$ and $CoSO_4 \cdot 7H_2O$(both of an analytical grade) in the required amounts were dissolved in the atomic ratio of 1:2 into 1 or 2 dm^3 of water, followed by the dispersion of the Fe_3O_4 sample (60—100 g) in the mixed solution. The Fe(II) and Co(II) in the black suspension were precipitated by adding an excess of NaOH to the acidic suspension. Each alkaline suspension in the flask was diluted with water to 3 dm^3, quickly heated to the desired temperature, and then stirred in air with a mechanical stirrer for 3 to 5 h until the precipitate of $Co_{1/3}Fe_{2/3}(OH)_2$ has been completely transformed by oxidation into $CoFe_2O_4$. The construction

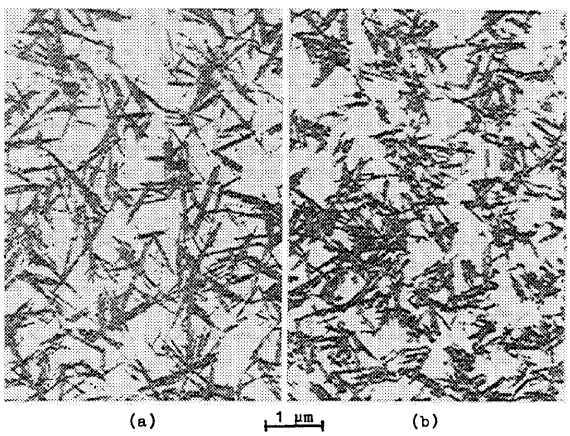

Fig. 1. Fe_3O_4 particles(b) obtained by subjecting α-FeO(OH) particles(a) to direct reduction in H_2 at 330 °C.

Table 1. Properties of some typical $x CoFe_2O_4 \cdot (1-x)Fe_3O_4$ samples prepared at various oxidation temperatures, t, and excess NaOH concentrations

Sample	Excess NaOH (mol dm^{-3})	t/°C	x	S/m^2 g^{-1}	M_s/emu g^{-1}	H_c/Oe
A	1.54	90	0.12	16.3	85	588
B	0.50	90	0.07	17.0	85	521
C	0.02	90	0.12	18.1	83	480
D	1.54	80	0.07	17.5	86	580
E	1.54	60	0.07	18.1	85	536

of the flask for the oxidation was the same as has previously been described, except that the stirrer was inserted in place of an air-introducing tube.[7] The Co-ion contents in the oxidation products were controlled by varying the mixing ratio of the Fe_3O_4 and $Co_{1/3}Fe_{2/3}(OH)_2$. The oxidation products with the $x CoFe_2O_4 \cdot (1-x)Fe_3O_4$ composition were filtered, washed well with water, treated with acetone, and then dried at 50 °C under reduced pressure.

Five kinds of $x CoFe_2O_4 \cdot (1-x)Fe_3O_4$ samples, selected from the numerous samples, were packed into brass cylinders 6 cm in length and 0.6 cm in diameter with packing densities, p (g/cm^3), ranging from 0.1 to 1.2. Some samples with $p<0.5$ had to be immersed in paraffin. After the sample had been magnetized up to 4 kOe (1 Oe$=1000/4\pi$ A m^{-1}) in a solenoid, the demagnetization curve was taken at room temperature with a self-recording permeameter. An inspection of these curves indicated that the H_c values of each sample were independent of the p for $p<0.5$, as could be anticipated from an earlier publication.[8] For $p \geq 0.5$, the H_c values manifested a decrease of $-100p$, regardless of the difference in kind of samples, presumably due to the use of the same starting material.

Exactly the same samples were also packed in brass cylinders 0.6 cm in diameter and 0.2 cm in height in the $0.6 \leq p \leq 0.9$ range. Magnetic measurements with these samples were carried out at room temperature in a magnetic field up to 10 kOe using a vibrating sample magnetometer (VSM). The H_c values for each of these samples were found to be lowered approximately $-50p$ with an increase in the p. In this case, the difference in saturation-magnetization, M_s, values for each sample was within 0.5 emu g^{-1} (1 emu g$^{-1}=4\pi 10^{-4}\rho$ Wb m^{-2}, where ρ=specific gravity in units of 10^3 kg m^{-3}).

As a result of normalizing for $p=0.5$ the H_c values for each sample with $p \geq 0.5$, after these values had been obtained using the previously mentioned two methods, it has been found that the difference between the two sets of normalized H_c values could be held within 15 Oe. Magnetic measurements of the remaining samples were also made using a VSM at room temperature in 10 kOe. The H_c values normalized for $p=0.5$ are presented in the present paper.

The cobalt and iron-ion contents of some samples were determined by atomic absorption after the samples had been dissolved in a HCl solution. The Fe(II) content in the Fe_3O_4 sample was decided by titrating with $KMnO_4$ after it had been dissolved in a mixed solution of H_2SO_4 and H_3PO_4 under a nitrogen atmosphere.

Results and Discussion

The H_c values of the Fe_3O_4 samples prepared from the α-FeO(OH) samples with $S \leq 25$ and $S \geq 35$ m^2 g^{-1} were found to be less than the H_c value of the Fe_3O_4 sample (Fig. 1(b)) prepared from the α-FeO(OH) sample with $S=30$ m^2 g^{-1} (Fig. 1(a)). This was due to the formation of microscopic pores in each needle-like particle (for $S \leq 25$) or the decrease in the shape anisotropy (for $S \geq 35$ m^2 g^{-1}). The starting ferromagnetic material with $S=18.0$ m^2 g^{-1} (Fig. 1(b)) contained 26% Fe(II) of the total iron ions, and its H_c and M_s values were 467 Oe and 87 emu g^{-1} respectively.

The conditions for the formation of five typical samples with the $x CoFe_2O_4 \cdot (1-x)Fe_3O_4$ composition and their magnetic properties at room temperature are given in Table 1, together with the S values. Table 1 demonstrates that, with the increase in the excess NaOH concentration and the elevation of the oxidation temperature, the H_c value increases and the S value decreases.

According to our electron-microscopic observation, no cubic particles could be detected with Samples A and D. This indicates that the $Co_{1/3}Fe_{2/3}(OH)_2$ was almost entirely changed by oxidation to $CoFe_2O_4$ on the surfaces of the needle-like Fe_3O_4 particles. The fact that cubic particles 0.05—0.1 μm in size were intermingled in Samples B, C, and E demonstrates that part or all of the $Co_{1/3}Fe_{2/3}(OH)_2$ was transformed into $CoFe_2O_4$ off the surfaces.

Insoluble oxides suspended in an aqueous solution are known, in general, to be electrically charged by adsorbing H^+ or OH^- ions. At pH values greater than the point of zero charge (PZC), the metal ions that have been combined only with O^{2-} ions are known to be formed in the subsurface of an oxide such as Fe_2O_3[9] or ZnO[10] by the dissociation of surface protons, thus providing the insoluble particles with negatively charged sites, whose number becomes greater with an increase in the pH.

In the present experiments, it is presumed that the metal ions, probably bivalent, in the alkaline-suspension medium tend to be adsorbed at negatively charged sites where the iron ions combined only with O^{2-} ions exist in the subsurfaces of needle-like particles of Fe_3O_4, whose PZC is 6.55 at 25 or 5.4 at 90 °C.[11] It is considered from these results that the surface area coated with the Fe(II) and Co(II) on the needle-like particles becomes wider with an increase in the excess NaOH concentration and that a rise in the oxidation temperature facilitates the formation of $CoFe_2O_4$.

Some samples, each divided into several parts and enclosed in glass tubes under a reduced pressure of 1.33×10^{-3} Pa, were heat-treated at temperatures between 200 and 600 °C for 4 h and then allowed to cool to room temperature. Figure 2 shows a plot of the H_c values of two typical samples A and D, *vs.* the heat-treated temperature to demonstrate that the

Table 2. Properties of some typical samples subjected to heat treatment at 400 °C *in vacuo*

Sample	A	B	C	D	E
$S/m^2\,g^{-1}$	16.0	16.9	14.9	15.8	17.1
H_c/Oe	920	603	687	701	632

H_c values become greater upon heat treatment, even at such low temperatures as 200 °C. It has been found that there was no marked difference in M_s values between samples A and D for heat-treatment temperatures≤450 °C, except that the M_s for 500 °C became less than that for 450 °C due to the formation of α-Fe_2O_3.

As is indicated in Table 2, the S and H_c values of the five samples prepared at 400 °C *in vacuo* become less than and higher than those of the original samples, respectively. As is evident from a comparison of Tables 1 and 2, the increase in H_c is mainly governed by the Co content.

The H_c values were also measured with the original samples, A and D, and their heat-treated samples under the magnetic fields of 10 and 20 kOe within the temperature range from 77 to 350 K. Figure 3 is a plot of [H_c] (ratio of H_c at various measuring temperatures, T, to that at 295 K) against T/K.

The temperature dependence of [H_c] for the other original samples was substantially the same as for the original samples, A and D, regardless of the conditions of oxidation and the Co(II) content. From the gradual variations in [H_c] with the temperature for the original samples, the H_c increase at room temperature may be attributed to the participation of the effect of the magnetic-surface anisotropy caused by the formation of the cobalt ferrite layer on the surface of Fe_3O_4 particles, as has previously been described for γ-Fe_2O_3 ones.[3] The H_c increase at room temperature would be determined by the properties of a ferrite layer coated on the surfaces, notably the percentage of the surface coverage, and the homogeneity and thickness of the ferrite layer, governed by the conditions of oxidation.

The cobalt ferrite layer coated on the surfaces presumably possesses a Co(II) concentration gradient similar to that of the cubic particles of ferrite formed outside the needle-like particles.[6] The reason for the differences in the temperature dependence and in the H_c increase at room temperature among the five kinds of samples prepared by heat treatment *in vacuo* can be attributed to the facts that some of the fine cubic particles of $CoFe_2O_4$ form a ferrite layer on the needle-like particles of Fe_3O_4 and that the participation of the crystal anisotropy effect of Co(II) attributable to the internal diffusion of part of the Co(II) ions into the needle-like particles becomes predominant with the tendency towards the uniform concentration of Co(II) ions in the coated ferrite layer.

The authors wish to thank Messrs. T. Kusuda (this Institute), Y. Enoki (Matsushita Electric Industrial Co., Ltd.), and N. Horiishi (Toda Kogyo Co., Ltd.) for their extensive assistance in conducting a number of experiments.

Synthesis and Characterization of a New Family of Binuclear Nickel(II) Complexes with a Terephthaloyl or Isophthaloyl Bridge

Naohide MATSUMOTO,* Akira HIRANO, and Akira OHYOSHI

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kurokami 2-39-1, Kumamoto 860

(Received June 24, 1982)

A new family of binuclear nickel(II) complexes with a terephthaloyl or isophthaloyl bridge have been prepared by the electrophilic substitution reaction of (11,13-dimethyl-1,4,7,10-tetraaza-10,12-cyclotridecadienato)-nickel(II) ($Ni(Me_2[13]dienatoN_4)]^+$) or (12,14-dimethyl-1,4,8,11-tetraaza-11,13-cyclotetradecadienato)nickel(II) ($[Ni(Me_2[14]dienatoN_4)]^+$) containing a nucleophilic center at the γ-carbon and terephthaloyl chloride or isophthaloyl chloride. The complexes were characterized by elemental analyses, infrared spectra, ^1H NMR spectra, electronic spectra, and conductivity measurements.

Binuclear metal complexes are of much current interest as models for active sites[1-8] in biological systems such as cytchrome oxidase, hemerythrin, hemocyanin, and laccase. In such complexes, two metal ions are positioned in close proximity by the ligand framework to promote substrate binding between them. Recently binuclear complexes with a flexible chain or a bridging moiety such as *p*-xylene or *m*-xylene have been developed to mimic the reactivity to molecular oxygen and carbon monooxide of hemocyanin,[9-11] since it has been reported that hemocyanin consists of a rather flexible binuclear unit.[12] We wish now to report a new family of ligands with a terephthaloyl or isophthaloyl bridge as their nickel(II) complexes, whose possible structure can be described as face-to-face species and has a substrate binding site. In our previous papers,[13,14] we have reported the synthesis, properties, and crystal structure of the substituted mononuclear nickel(II) complexes (**2**), which have been prepared by the electrophilic substitution reaction of $[Ni(Me_2[Z]dienatoN_4)]^+$ (**1**) ($Z=13$, 14) with the *p*-substituted benzoyl chlorides, as shown in Fig. 1. The binuclear nickel(II) complexes reported here have been prepared by a similar reaction procedure for the substituted mononuclear complexes by using terephthaloyl chloride or isophthaloyl chloride, instead of benzoyl chloride (Fig. 1). The complexes were characterized by elemental analyses, infrared spectra, ^1H NMR spectra, electronic spectra, and conductivity measurements. The properties of the binuclear complexes have been compared with those of the mononuclear complexes.

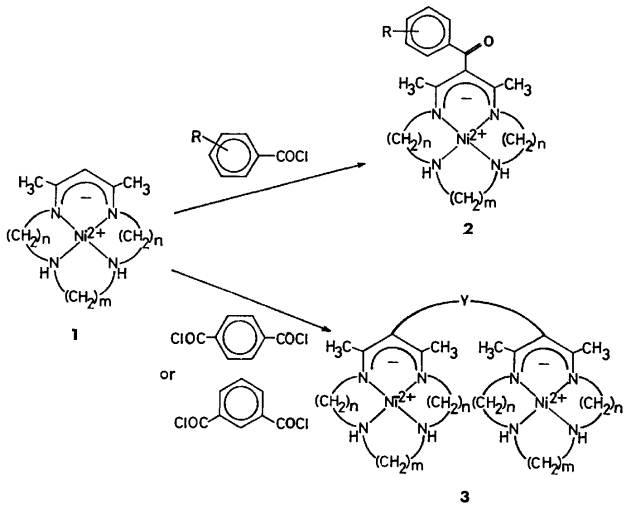

Fig. 1. Reaction scheme from parent complex (**1**) to substituted mononuclear complex (**2**) and binuclear complex (**3**).
1: $[Ni(Me_2[Z]dienatoN_4)]^+$($Z=13$, $n=m=2$, $Z=14$, $n=2$, $m=3$), **2**: $[Ni(Me_2E[Z]dienatoN_4)]^+$(E=benzoyl, *p*-methylbenzoyl, *m*-methylbenzoyl), **3**: $(Ni_2ter[Z])^{2+}$ or $(Ni_2iso[Z])^{2+}$.

Experimental

Physical Measurements. Visible and ultraviolet spectra were obtained with a Hitachi 323 spectrophotometer, while infrared spectra were recorded as KBr disks or Nujol mulls with a Shimadzu IR-410 spectrophotometer. The 100 MHz ^1H NMR spectra were recorded on a JEOL MH 100 spectrometer. The solvent used was CD_3CN and in all cases shift measurements were relative to tetramethylsilane. Elemental analysis was performed at the Technical Service Center of Kumamoto University. The thermogravimetric analysis(TGA) was carried out on a Shimadzu TGC 20 type microthermobalance at the heating rate of 5° min^{-1} using *ca.* 10 mg of the sample for each run, according to a method in the literature.[15] Conductivity measurements were carried out on a Denki Kagaku AOC-10 in methanol.

Syntheses. Parent Nickel(II) Complexes (1): (11,13-Dimethyl-1,4,7,10-tetraaza-10,12-cyclotridecadienato)nickel-(II) bromide hemihydrate, $[Ni(Me_2[13]dienatoN_4)]Br\cdot 0.5H_2O$; (12,14-Dimethyl-1,4,8,11-tetraaza-11,13-cyclotetradecadienato)nickel(II) bromide monohydrate, $[Ni(Me_2[14]dienatoN_4)]Br\cdot H_2O$; (12,14-dimethyl-1,4,8,11-tetraaza-11,13-cyclotetradecadienato)nickel(II) iodide monohydrate, $[Ni(Me_2[14]dienatoN_4)]I\cdot H_2O$: These parent complexes were prepared by the method of S. C. Cummings *et al.*,[16] and identified by elemental analyses.

Substituted Mononuclear Nickel(II) Complexes (2). [11,13-Dimethyl-12-(*p*-methylbenzoyl)-1,4,7,10-tetraaza-10,12-cyclotridecadienato]nickel(II) hexafluorophosphate, $[Ni(Me_2p\text{-}MeBzyl[13]dienatoN_4)]PF_6$; [12,14-dimethyl-13-(*p*-methylbenzoyl)-1,4,8,11-tetraaza-11,13-cyclotetradecadienato]nickel-(II) hexafluorophosphate hemihydrate, $[Ni(Me_2p\text{-}MeBzyl[14]dienatoN_4)]PF_6\cdot 0.5H_2O$: The complexes were prepared by the method described previously,[14] and identified by elemental analyses. [11,13-Dimethyl-12-(*m*-methylbenzoyl)-1,4,7,10-tetraaza-10,12-cyclotridecadienato]nickel(II) iodide, the hexafluorophosphate salt, [12,14-dimethyl-13-(*m*-methylbenzoyl)-1,4,8,11-tetraaza-11,13-cyclotetradecadienato]nickel-(II) tetrafluoroborate and the perchlorate salt were first prepared in this work in a similar manner to $[Ni(Me_2p\text{-}MeBzyl[13]dienatoN_4)]PF_6$[14] in order to compare their properties with those of the binuclear complexes with a isophthaloyl bridge, and abbreviated as $[Ni(Me_2m\text{-}MeBzyl$-

[13]dienatoN$_4$)]I, [Ni(Me$_2$*m*-MeBzyl[13]dienatoN$_4$)]PF$_6$, [Ni(Me$_2$*m*-MeBzyl[14]dienatoN$_4$)BF$_4$, and [Ni(Me$_2$*m*-MeBzyl[14]dienatoN$_4$)]ClO$_4$, respectively.

Binuclear Nickel(II) Complexes with a Terephthaloyl or Isophthaloyl Bridge (3). μ-[12,12′-Terephthaloyl-bis(11,13-dimethyl-1,4,7,10-tetraaza-10,12-cyclotridecadienato)]dinickel(II) hexafluorophosphate (abbreviated as (Ni$_2$ter[13])(PF$_6$)$_2$). To a solution of [Ni(Me$_2$[13]dienatoN$_4$)]Br·0.5H$_2$O (15 mmol) containing 30 mmol of triethylamine in 200 cm^3 of dichloromethane was added dropwise a solution of 7.5 mmol terephthaloyl chloride in 150 cm^3 dichloromethane during 1 h with vigorous stirring at room temperature. After the completion of the addition, the solution was refluxed for 6 h and then evaporated to dryness under reduced pressure. The resultant orange-red viscous oil was dissolved in 50 cm^3 of water and filtered. The pH of the solution was adjusted to 10 with 6 mol dm^{-3} NaOH. The solution was added dropwise to 30 cm^3 of a saturated aqueous solution of ammonium hexafluorophosphate. After standing for several hours in a refrigerator, a deep-red crystalline material precipitated, it was collected and dried *in vacuo* over P_2O_5 overnight.

The other binuclear nickel(II) complexes were prepared according to the procedure described above, by using the corresponding parent complex, terephthaloyl chloride or isophthaloyl chloride and the sodium salt of the counter anion. The binuclear complexes prepared in this study are as follows: (Ni$_2$ter[13])Br$_2$, (Ni$_2$ter[13])(PF$_6$)$_2$, (Ni$_2$iso[13])I$_2$, (Ni$_2$ter[14])Br$_2$, [Ni$_2$ter[14])I$_2$, (Ni$_2$ter[14])(ClO$_4$)$_2$, (Ni$_2$ter[14])I$_2$, (Ni$_2$iso[14])(ClO$_4$)$_2$, (Ni$_2$iso[14])(BF$_4$)$_2$, and (Ni$_2$ter[14])(PF$_6$)$_2$, where (Ni$_2$ter[13])$^{2+}$, (Ni$_2$iso[13])$^{2+}$, (Ni$_2$ter[14])$^{2+}$, and (Ni$_2$iso[14])$^{2+}$ denote μ-[12,12′-terephthaloyl-bis(11,13-dimethyl-1,4,7,10-tetraaza-10,12-cyclotridecadienato)]dinickel(II), μ-[12,12′-isophthaloyl-bis(11,13-dimethyl-1,4,7,10-tetraaza-10,12-cyclotridecadienato)]dinickel(II), μ-[13,13′-terephthaloyl-bis(12,14-dimethyl-1,4,8,11-tetraaza-11,13-cyclotetradecadienato)]dinickel(II), and μ-[13,13′-isophthaloyl-bis(12,14-dimethyl-1,4,8,11-tetraaza-11,13-cyclotetradecadienato)]dinickel(II), respectively.

Results and Discussion

Synthesis. As shown in Fig. 1, the binuclear nickel(II) complexes have been prepared by the electrophilic substitution reaction of the parent complex [Ni(Me$_2$[*Z*]dienatoN$_4$)]$^+$ (*Z*=13, 14) **1** with terephthaloyl chloride or isophthaloyl chloride by the similar reaction procedure for the substituted mononuclear complexes (**2**). The advantages of the present synthetic route for the preparation of bimetallic complex with a bridging group are as follows: (1) Since the complex is derived from the reaction of the parent complex [Ni(Me$_2$[*Z*]dienatoN$_4$)]$^+$ (**1**) containing a coordinated metal center and terephthaloyl chloride or isophthaloyl chloride as a bridging moiety, structural parameters associated with the macrocyclic metal complex and the bridging moiety such as macrocyclic ring size and the orientation of two MN$_4$ planes can be varied independently. (2) Since the parent complex and terephthaloyl chloride or isophthaloyl chloride contain a nucleophilic center and two electrophilic centers, respectively, binuclear species can be obtained easily and selectively without the formation of monomeric and polymeric species.

Elemental analytical data are given in Table 1. As indicated by the elemental analyses, the binuclear nickel(II) complexes tend to crystallize as solvate. The water and dichloromethane as a crystal solvent were detected by thermo-gravimetric analyses (TGA), where the thermal process has a weight change corresponding to the loss of the approximately quantitative molecules of water or dichloromethane estimated by the elemental analyses. The weight loss was observed at 70—100 °C and 40—70 °C for the water and the dichloromethane, respectively.

Infrared Spectra. Some selected infrared frequencies and their assignments are given in Table 1. Infrared spectra of the products differ from those of the

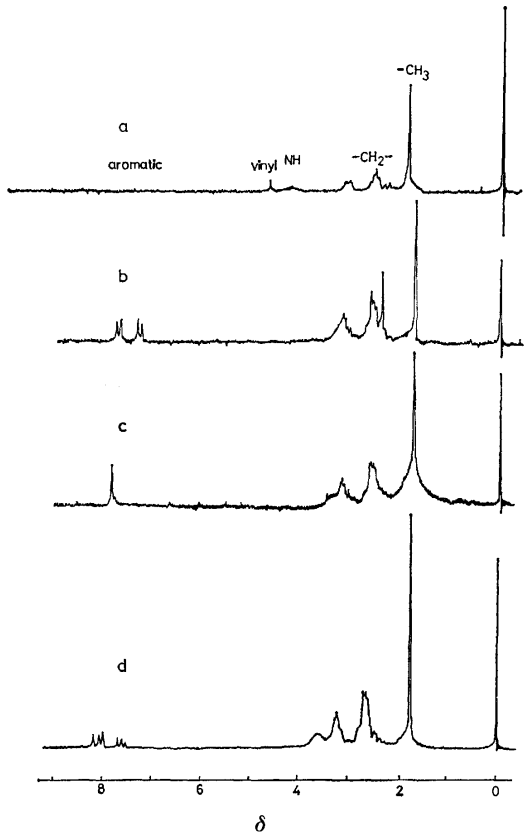

Fig. 2. ^{1}H NMR spectra in CD_3CN of (a) [Ni(Me_2-[14]dienatoN$_4$)]I·H_2O, (b) [Ni(Me_2*p*-MeBzyl[14]dienatoN$_4$)]PF_6, (c) (Ni_2ter[14])$(ClO_4)_2$·0.5CH_2Cl_2, (d) (Ni_2iso[14])$(ClO_4)_2$·CH_2Cl_2.

parent complex [Ni(Me_2[*Z*]dienatoN$_4$)]$^+$, most notably in the appearance of the intense band at *ca.* 1630 cm^{-1} which can be assigned to C=O stretching mode characteristic for the complexes containing a benzoyl group.[13,17,18] Two intense bands of the starting material terephthaloyl chloride (1780, 1724 cm^{-1}) or isophthaloyl chloride (1760, 1730 cm^{-1}) which are assigned to C=O stretching mode are absent in the products. The same feature was also observed for the reactants and the products in the mononuclear system,[13,14] indicating the completion of the substitution reaction and consistent with the formation of the binuclear species.

The NH frequency in a series of the binuclear complexes (Ni_2ter[14])X_2 (X=Br, I, ClO_4, BF_4, PF_6) as well as that of the substituted mononuclear complexes shifts to lower energy in the order of the basicity of the counter anion, Br<I<ClO_4<BF_4<PF_6. As the same phenomenon observed for the parent complexes [Ni(Me_2[*Z*]dienatoN$_4$)]X (X=Br, I, SCN, NO_3, BF_4, PF_6, *Z*=13, 14) was explained due to the hydrogen bond between the secondary amine nitrogen atom and the counter anion[16] and the existence of the hydrogen bond was confirmed by the X-ray analysis of [Ni(Me_2[14]dienatoN$_4$)]Br·H_2O,[13] the shift observed for the binuclear complexes can be also considered due to the hydrogen bond.

^{1}H NMR Spectra. Proton magnetic resonance spectra of the binuclear nickel(II) complexes, along with the substituted mononuclear complexes and the parent complex are shown in Fig. 2. The spectrum consists of four distinct regions with resonances attributable to methyl (singlet), methylene (multiplet), aromatic, and NH (broad) protons. As anticipated, the vinyl proton resonance at the γ-carbon of the parent complex has disappeared in the binuclear and substituted mononuclear complexes, since the electrophilic substitution reaction takes place at the γ-carbon. The methyl proton signal of the binuclear and substituted mononuclear complexes is shifted to a higher magnetic field than that of the parent complex. This can be attributed to the ring current effect of the benzene ring and the shielding effect of the carbonyl group of the substituent, because it has been confirmed for [Ni(Me_2*p*-MeBzyl[13]dienatoN$_4$)]PF_6 by single-crystal X-ray analysis[14] that the substituent is nearly perpendicular to the unsaturated six-membered chelate ring to which the methyl groups are attached.

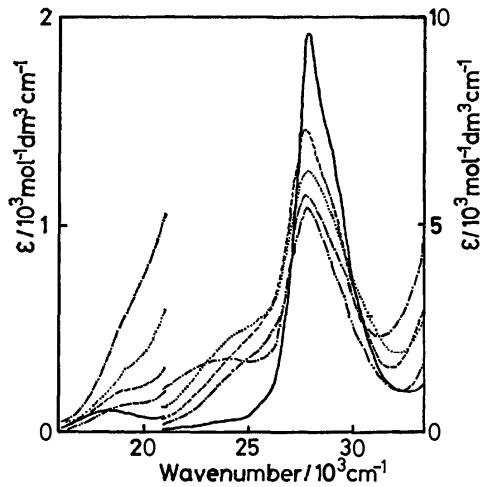

Fig. 3. Absorption spectra in methanol of [Ni(Me_2[14]-dienatoN$_4$)]PF_6·0.5H_2O(——), [Ni(Me_2*p*-MeBzyl[14]-dienatoN$_4$)]I(—··—), [Ni(Me_2*m*-MeBzyl[14]dienato-N$_4$)]BF_4·H_2O(----), (Ni_2ter[14])Br_2·3H_2O(—·—), (Ni_2iso[14])$(BF_4)_2$·H_2O(·····).

Electronic Spectra. Visible and ultraviolet spectra of the complexes were obtained on 10^{-3}—10^{-4} mol dm^{-3} solutions in methanol or acetonitrile. The spectra of the parent complex, the substituted mononuclear complex, and the binuclear complexes are shown in Fig. 3. Electronic spectra of some of the binuclear complexes, especially those of the 13-membered complexes, were not measured due to the sparing solubility. The spectra of the substituted mononuclear complex and the binuclear complex consist of a broad band in the visible region assignable to the d-d transition with an extinction coefficient on the order of *ca.* (100—500)×10^3 mol^{-1} dm^3 cm^{-1} which resembles the d-d transition of other square planar nickel(II) complexes.[19] There are also several peaks in the ultraviolet region assignable to the charge-transfer bands. As shown in Fig. 3, when the substituent of the electron withdrawing group, such as benzoyl group, is replaced at the γ-carbon, the d-d transition band shifts to higher energy and a new band with an extinction coefficient *ca.* (2000—3000)×10^3 mol^{-1} dm^3 cm^{-1} appears at (23—

(a): $[Ni(Me_2[14]dienatoN_4)]I \cdot H_2O$(○), (b): $[Ni(Me_2p\text{-}MeBzyl[13]dienatoN_4)]PF_6$(▲), (c): $(Ni_2iso[14])I_2 \cdot H_2O$(□).

$25) \times 10^3$ cm^{-1}.

Molar Conductivity. The molar conductance was measured in methanol as a function of concentration, and the Onsager plots are shown in Fig. 4. For the parent complex $[Ni(Me_2[14]dienatoN_4)]I \cdot H_2O$ and the substituted mononuclear complex $[Ni(Me_2p\text{-}MeBzyl[13]dienatoN_4)]PF_6$, Onsager plots show the slopes of 351 and 349 S mol^{-1} cm$^{3.5}$ and the Λ_0 values of 114 and 98 S cm^2, respectively, in which their slopes are somewhat higher than the expected value for 1:1 electrolytes.[20,21] On the other hand, Onsager plots of the binuclear complex $(Ni_2iso[14])I_2 \cdot H_2O$ gave a slope of 525 S mol^{-1} cm$^{3.5}$ and the Λ_0 value of 114 S cm^2, which are in the expected range for 2:2 electrolytes.[20,21]

Based on the above described results, it was established that the binuclear complexes are formed, while the detailed structure remains uncertain for the present. The crystal structure determination of $(Ni_2iso[14])I_2 \cdot H_2O$ is in progress in our laboratory.

The authors are grateful to Mrs. K. Wakizaka and T. Hara for their assistance in part of the experiments.

Potentiometric Study of Heteropolyanion Formation from Dimethylarsinate and Molybdate Anions in Acidic Aqueous Solution

Hironobu TAKAHAMA and Yukiyoshi SASAKI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received August 10, 1982)

The equilibria, $p\mathrm{H}^+ + q\mathrm{MoO_4}^{2-} + r(\mathrm{CH_3})_2\mathrm{AsO_2}^- = (\mathrm{H}^+)_p(\mathrm{MoO_4}^{2-})_q[(\mathrm{CH_3})_2\mathrm{AsO_2}^-]_r$ were studied by the use of a glass electrode in 1 M Na(Cl) ionic medium at 25 °C. The data were explained by assuming two heteropolyanions of the compositions, $(p,q,r)=(6,4,1)$ and $(7,4,1)$ with the formation constants $\log \beta_{6,4,1}=39.80\pm0.02$ and $\log \beta_{7,4,1}=46.03\pm0.01$.

Heteropolymolybdates containing organic derivatives of arsenic acid have been investigated by using preparative, X-ray crystallographic and NMR techniques,[1–7] but our knowledge about their solution states and the conditions of their formation is still fairly limited.

In order to clarify the formation equilibria of these compounds in solutions, studies of these compounds in aqueous solutions by the use of potentiometric techniques were planned in this laboratory.

As the first subject of study, the system in the title was chosen because it appeared simpler than others such as a $\mathrm{H^+}$–$\mathrm{MoO_4}^{2-}$–$\mathrm{RAsO_3}^{2-}$ mixture from which at least four different polyanions have been separated as crystals.[1–5]

Heteropolymolybdates containing dimethylarsinate was first studied by Rosenheim in 1913.[6] He reported the preparation of the guanidinium, barium, and potassium salts of the anion $\mathrm{H[As(OH)_2(CH_3)_2(Mo_2O_7)_2]^{2-}}$. These syntheses have recently been reproduced in Georgetown University and in this laboratory and the guanidinium compound was formulated as $(\mathrm{NC_3H_6})_2\cdot[(\mathrm{CH_3})_2\mathrm{AsMo_4O_{14}(OH)}]\cdot\mathrm{H_2O}$. The structure shown in Fig. 1 was determined by the single crystal X-ray diffraction technique.[1,2]

The position of the hydrogen atom shown in Fig. 1 was confirmed by the neutron diffraction work by Pope *et al.*[7] However, the pH titration of this compound by sodium hydroxide showed no evidence of the dissociation of this proton.[2]

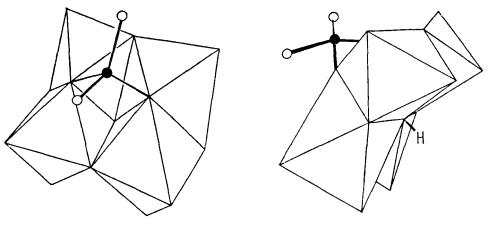

Fig. 1. Polyhedra model of $[(\mathrm{CH_3})_2\mathrm{AsMo_4O_{14}OH}]^{2-}$. ○: $\mathrm{CH_3}$, ●: As.

Symbols and Equations

Symbols. h=free hydrogen ion concentration; H=total analytical hydrogen ion concentration over the zero level $\mathrm{MoO_4}^{2-}$, $(\mathrm{CH_3})_2\mathrm{AsO_2}^-$, and $\mathrm{H_2O}$; B=total molybdenum concentration; b=concentration of free $\mathrm{MoO_4}^{2-}$ ion; C=total arsenic concentration; c=free $(\mathrm{CH_3})_2\mathrm{AsO_2}^-$ ion concentration; (p,q,r)=the composition of the ternary polyanion, $(\mathrm{H}^+)_p(\mathrm{MoO_4}^{2-})_q[(\mathrm{CH_3})_2\mathrm{AsO_2}^-]_r$.

Equations. The equilibria in the solution phase can be written as follows:

$$p\mathrm{H}^+ + q\mathrm{MoO_4}^{2-} + r(\mathrm{CH_3})_2\mathrm{AsO_2}^- = (\mathrm{H}^+)_p(\mathrm{MoO_4}^{2-})_q[(\mathrm{CH_3})_2\mathrm{AsO_2}^-]_r, \quad (1)$$

$$\beta_{pqr} = \frac{\{(\mathrm{H}^+)_p(\mathrm{MoO_4}^{2-})_q[(\mathrm{CH_3})_2\mathrm{AsO_2}^-]_r\}}{(\mathrm{H}^+)^p(\mathrm{MoO_4}^{2-})^q[(\mathrm{CH_3})_2\mathrm{AsO_2}^-]^r}. \quad (2)$$

From the mass action law and the mass balances, we can derive the next relationships in the case of binary complexes.

$$H = h + \sum_1^p \sum_1^q p\beta_{pq}h^p b^q, \quad (3)$$

$$B = b + \sum_1^p \sum_1^q q\beta_{pq}h^p b^q, \quad \text{or} \quad C = c + \sum_1^p \sum_1^r r\beta_{pr}h^p c^r. \quad (4)$$

For ternary systems, we have the equations,

$$H = h + \sum_1^p \sum_1^q \sum_1^r p\beta_{pqr}h^p b^q c^r, \quad (5)$$

$$B = b + \sum_1^p \sum_1^q \sum_1^r q\beta_{pqr}h^p b^q c^r, \quad (6)$$

$$C = c + \sum_1^p \sum_1^q \sum_1^r r\beta_{pqr}h^p b^q c^r. \quad (7)$$

Experimental

Chemicals. Stock solutions were prepared from twice recrystallized $\mathrm{Na_2MoO_4\cdot 2H_2O}$ and $\mathrm{Na(CH_3)_2AsO_2\cdot 2H_2O}$ of the special grade (Wako Chemicals). Sodium chloride of "primary standard" quality (Matsunaga Chemicals) was used after heating at 150 °C.

Apparatus. A glass electrode of TOA Electronics, HGS-2005 type, a Kawai-type half-cell[8] connected with a titration vessel and a Data Precision Digital Multimater were used for the potentiometry. All the titrations were performed by the use of an automated titrator equipped with a pair of Metrohm Multi Dosimat E 415 burettes which was designed and made[9] by the late Dr. Olle Ginstrup.

Potentiometric Titration. All the measurements were carried out at 25±0.1 °C in the ionic medium of 1 M Na(Cl), as potentiometric titrations of sodium molybdate and/or sodium dimethylarsinate with hydrochloric acid. The concentration of the sodium ion was maintained constant at 1 M.

The potentials of the cell electrode was registered four times at each point with intervals of 5 min to ±0.01 mV and the quick attainment of the equilibrium within ±0.1 mV was ascertained. No precipitation was observed during

the series of titrations. The potential in mV of the cell, −Ag,AgCl/1 M NaCl/equilibrium solution/glass electrode+, is expressed as follows:

$$E = E_0 + 59.16 \log h + E_j, \quad (8)$$

where E_0 is an experimental constant and E_j (liquid junction potential)$=j \cdot h$. The values of E_0 and E_j were obtained by an independent titration of 1 M NaCl by HCl in the same medium.

The data were obtained as $H(\log h)_B$ and $H(\log h)_C$. At first, binary systems, H^+-molybdate and H^+-dimethylarsinate were studied to compute the equilibrium constants of these binary complexes which are required for further analyses of the ternary systems.

In the case of dimethylarsinate, 123 points were obtained in four titrations and used in the calculations, the concentration was chosen between 30 and 50 mM and the $-\log h > 1.8$. In the case of the H^+-molybdate system 416 points were obtained from 13 titrations at the $-\log h > 1.6$, the concentrations were between 20 and 50 mM.

In the next step, mixed solutions of molybdate and dimethylarsinate were titrated. The molybdate concentrations were between 40 and 14 mM and the B/C ratios were 1.0, 1.3, 1.5, and 3.0. All the solutions were colorless. About 40 points were obtained from each titration and twelve sets of data containing 459 points in total were collected and used for analyses.

Analysis

The method of analysis and nomenclature proposed by Pettersson were used.[12]

The computer program LETAGROP version ETITR[10,11] was used to find the complexes present and the equilibrium constants which give the best fitting of the experimental data with theoretical titration curves drawn by Eq. 5. In the least squares treatments, the determined values of h are assumed to be always correct and the function to be minimized is $U=\Sigma(H_{calcd}-H)^2$.

Binary System. Table 1 shows the composition and the equilibrium constants together with the minimum value of U and $\sigma(H)=[U_{min}/(m-n)]^{1/2}$, where m and n stand for the number of experimental points, of constants varied, respectively.

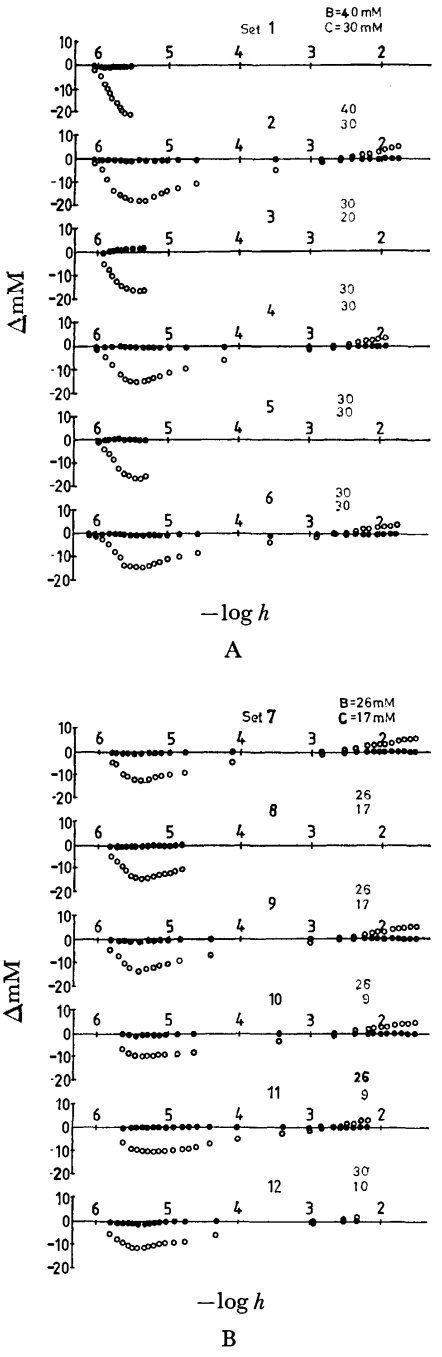

Fig. 2. Residual diagrams of 12 titrations.
○: Only binary species assumed, ●: binary and ternary complexes, (6,4,1) and (7,4,1) are taken into account.

Ternary System. The potentiometric data of the ternary systems are best illustrated as "residual diagrams" shown in Fig. 2. At each $-\log h$ measured, the "residual" defined by $\Delta=(H_{calcd}-H)$ was calculated assuming that only binary complexes are present. The constants given in Table 1 were used. The deviations of unfilled symbols from the abscissa suggest that at least one ternary complex is formed. To spare the computation time, only 96 points (sets 10—12) were used at the beginning to find (p,q,r), the composition of the polyanions formed.

(6,4,1)			40.25±0.06
(7,4,1)	3.94	0.93	44.82±0.06
(10,6,1)			66.13±0.06
(6,4,1)			39.82±0.09
(7,4,1)	3.10	0.63	45.93±0.09
(11,7,1)			72.03±0.09

a) The combinations, (15,8,3) and (10,6,1) giving high values of $U_{min} \times 10^{-2}$ (43.8 and 96.0 respectively) were omitted. b) Assumption of (6,4,1) and (7,4,1) polyanions in equilibrium explains the data most satisfactorily. c) Addition of one more complex (8,4,1) does not improve the agreement. The constants obtained do not make sense either.

As is visualized in Fig. 3, among 91 combinations of p,q and r tested, the species, (7,4,1), (10,6,1), (11,7,1), (11,6,2), (14,8,2), (14,7,3), and (15,8,3) give the U_{min} values lower than 100. In the course of the least squares treatment, preliminary values of the formation constants were also obtained. The final analyses were started from these values of (p,q,r) and $\beta_{p,q,r}$ by using all the points (sets 1—12) and the cases of coexistence

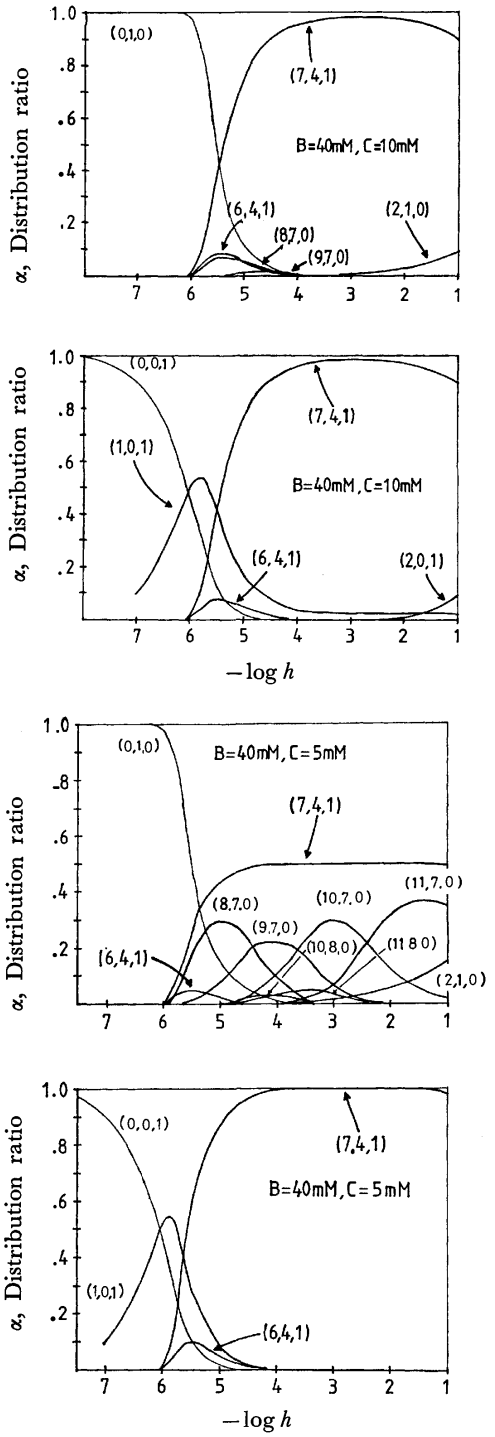

Fig. 4. Distribution diagrams of complexes $\alpha(\log h)$ for B and C, defined as the ratio between molybdenum in complexes and total molybdenum or arsenic in polyanions and total arsenic.

of two or three species were also tested.

Results and Discussion

Table 2 shows that the species, (6,4,1) and (7,4,1) are formed in solutions with the following formation constants, $\log \beta_{6,4,1} = 39.80 \pm 0.02$ and $\log \beta_{7,4,1} = 46.03 \pm 0.01$.

The possibility of the third complex was excluded

since this assumption did not make the $\sigma(H)$ value lower. The filled symbols in Fig. 2 represent the residuals calculated assuming the binary and ternary systems. These correspond to the F_o-F_c table in X-ray crystallography. They deviate very little from 0 in all the $-\log h$ region suggesting that our assumption is correct.

In order to visualize the equilibria in solution, the concentration ratio of the complexes are plotted against $-\log h$ in Fig. 4. The polyanion (7,4,1) predominates in the $-\log h$ range between 1 and 5, when $B=40$ and $C=10$ and this result agrees with the UV spectra.[2]

The possibility that the minor product, (6,4,1) could be a "ghost" derived from an error in E_0 or in stability constants of isopolymolybdates was ruled out. In the concentration range studied, $B/C<3$ and $C>9$ mM isopolymolybdates are always minor species in solutions; their stabilities have very little effect on the computation of heteropoly complexes formed and their equilibrium constants. However, such a condition as simulated in Fig. 4b would be unfavorable for accurate equilibrium studies. The composition of the polyanion, (7,4,1) in solution agrees with that found in crystals as shown in Fig. 1, and very probably the structure may be the same in both phases.

The proton attached to an oxygen atom bridging four molybdenum atoms was acidic with $pK_a=6.23$, but the unprotonated species exists only in a small amount in a narrow $-\log h$ range between 5 and 6, and the acidic form is always predominating. It was thus shown that the binding of a proton to that oxygen atom is an essentially important factor to stabilize the polyanion.

This is understandable from the structural point of view. In general, OH forms longer Mo–O bonds than O and the (6,4,1) anion must be more unstable than (7,4,1), because of the strong repulsion between four molybdenum atoms of short Mo–Mo distances caused by the short Mo–O bonds.

Similar equilibrium studies using methyl- and phenylarsonate are proceeding in this laboratory.

The authors are deeply indebted to Prof. N. Ingri of the University of Umeå, Sweden for his encouragement and supports in many ways to start the solution chemistry work in Tokyo. Thanks are also due to the late Dr. O. Ginstrup for building the automatic titrator and to Dr. L. Lyhamn for his advise in the implementation and use of the program, LETAGROP version ETITR.

Dr. L. Petterson has kindly read through the manuscript and given us many valuable comments.

Mössbauer Studies of Thermal Decomposition of Hexaamminecobalt(III) Hexacyanoferrate(III) and Hexaamminecobalt(III) Hexachloroferrate(III) in Air and in Nitrogen Atmosphere

Ajaib Singh BRAR,*,† Sarvjit BRAR, and Sarjit Singh SANDHU
Chemistry Department, Guru Nanak Dev University, Amritsar-143005, India
(Received January 23, 1981)

Thermal decomposition of hexaamminecobalt(III) hexacyanoferrate(III) (**1**) and hexaamminecobalt(III) hexachloroferrate(III) (**2**) in air as well as in nitrogen atmosphere was studied by using Mössbauer spectroscopy, TGA, DTA, IR spectroscopy, and magnetic susceptibility measurement. **1**, when heated in air, is stable up to 200 °C and then converted into hexacyanoferrate(II) and finally to ferrites; in inert atmosphere iron metal and carbides are formed above 400 °C. **2** in air is reduced to iron(II) species and finally to ferrites; in inert atmosphere ligand exchange takes place forming cobalt(II) chloride. A mechanism is proposed for the decompositions of **1** and **2**.

Mössbauer spectroscopy is a very helpful tool for the investigation of change in the oxidation state of intermediates.[1-3] Sanyal and Dass[4] used DTA and TGA to study thermal decomposition of iron(III) tris(oxalato)-ferrate(III) tetrahydrate. Gallagher and Shurey[5] applied DTA, TGA, and the Mössbauer effect for studying thermal decomposition of europium hexacyanoferrate(III) and ammonium europium hexacyanoferrate(II). Recently, evidence has been given by Gibb[6] from Mössbauer spectroscopy for an orbitally degenerate ground state in hexaamminecobalt(III) hexacyanoferrate(III). Peev and Kurtev[7] reported that solid state decomposition of iron complexes gives ferrites, which are useful because of their semiconducting properties as well as catalytic properties. They reported a change in Mössbauer parameters with catalytic properties of ferrites. The aim of the present paper is to study thermal decomposition of hexaamminecobalt(III) hexacyanoferrate(III) and hexaamminecobalt (III) hexachloroferrate(III) and to disclose effects of ligand on thermal decomposition patterns, by using Mössbauer spectroscopy, TGA, DTA, IR spectra, and magnetic susceptibility measurements.

Experimental

Hexaamminecobalt(III) hexacyanoferrate(III) (**1**) and hexaaminecobalt(III) hexachloroferrate(III) (**2**) were prepared by the methods described in Refs. 6 and 8, respectively. For **2** a solution of hexaamminecobalt(III) trichloride (0.0016 mol) in 3.4 mol dm^{-3} HCl was treated with an aqueous solution of $FeCl_3 \cdot 6H_2O$ (0.005 mol) at 70 °C. The precipitates thus obtained were washed with ethanol and ether and dried in a vacuum desiccator. **1** was obtained as yellow needle-like crystals from a mixed aqueous solution of hexaamminecobalt-(III) trichloride and potassium hexacyanoferrate(III).

IR spectra were recorded on a Mom-2000 spectrophotometer (Hungarian Optical Works) in the range 4000—700 cm^{-1} and magnetic susceptibility was measured by Gouy's method using Hg $[Co(SCN)_4]$ as calibrant. TGA and DTA thermograms were recorded in air at Chemistry Department, I.I.T., Bombay.

For thermal decomposition, **1** or **2** was heated in silica crucibles in a tubular furnace at 100, 200, 300, 400, 500, and 700 °C for 3 h in air or under a flowing nitrogen atmosphere. The nitrogen used for arranging inert atmosphere was purified by passage through copper heated at 300 °C and then through traps of anhydrous calicum chloride and potassium hydroxide. The temperature of the furnace was measured by a small chromel-alumel thermocouple connected to a portable potentiometer (Toshniwal Industries (P), Ltd., India). The sample was heated at a specified temperature for 3 h in air, or under a flowing nitrogen atmosphere. The rate of heating was kept 10 °C/min. The variation in temperature was ±5 °C. The experimental detail of our Mössbauer investigation was described in Refs. 9 and 10. Values for isomer shift were determined with reference to the natural iron.

TABLE 1. MÖSSBAUER PARAMETERS, ISOMER SHIFT (δ) AND QUADRUPOLE SPLITTING (Δ) OF HEXAAMMINECOBALT(III) HEXACYANOFERRATE(III) (**1**), AND HEXAAMMINECOBALT(III) HEXACHLOROFERRATE(III) (**2**) AND THEIR THERMAL DECOMPOSITION PRODUCTS

† Present address: Chemistry Department, Indian Institute of Technology, New Delhi-110016, India.

Results and Discussion

The Mössbauer spectrum of **1** (at 25 °C) indicates an isomer shift value −0.12 mm/s and a quadrupole splitting 0.35 mm/s. The relatively small value of quadrupole doublet is as expected from a distorted trigonal symmetry at the Fe site[6] (Fig. 1a). Infrared frequencies and magnetic measurements confirm the formation of **1** since they are in agreement with the values given in Refs. 11 and 12. The TGA thermogram of the complex in air does not show any weight loss up to 200 °C (Fig. 2), whereas in the DTA thermogram there is an exothermic peak at 175°C and another exothermic peak at 278 °C (Fig. 3). The Mössbauer spectrum of the sample heated at 200 °C for 15 min shows formation of hexacyanoferrate(II) as identified by a single absorption band having an isomer shift value −0.14 mm/s (Fig. 4). There is another doublet due to the parent complex and a six-line pattern associated with magnetic hyperfine splitting. The intensity of magnetic field at the nucleus is 492 kOe (1 Oe=(1000/4π) A m^{-1}), which is only slightly lower than that for normal α-Fe_2O_3. These observations reveal that on heating at this temperature a part of hexacyanoferrate(III) is reduced to hexacyanoferrate-(II), while decomposition to α-Fe_2O_3 occurs concurrently.

1 was heated at 200 °C for 3 h. The Mössbauer spectrum of this sample shows a doublet (Fig. 1b) which has a quadrupole splitting of 0.79 mm/s and an isomer shift of 0.31 mm/s. These values are typical of the tervalent iron of $CoFe_2^{III}O_4$ in the superparamagnetic state. The value of isomer shift shows that the complex has the iron in high spin state. Mössbouer spectra of the samples thermally decomposed at 300, 500, and 700 °C in air are given in Fig. 5. The spectrum of the sample heated at 300 °C shows a six-line pattern due to magnetic hyperfine splitting which has an isomer shift value 0.33 mm/s. It also exhibits a doublet due to superparamagnetism, indicating the formation of $CoFe_2^{III}O_4$. The Mössbauer parameters of α-Fe_2O_3 and

(b) Mössbauer spectrum of hexaamminecobalt(III) hexacyanoferrate(III) heated in air at 500 °C for 3 h. (c) Mössbauer spectrum of hexaamminecobalt(III) hexacyanoferrate(III) heated in air at 700 °C for 3 h.

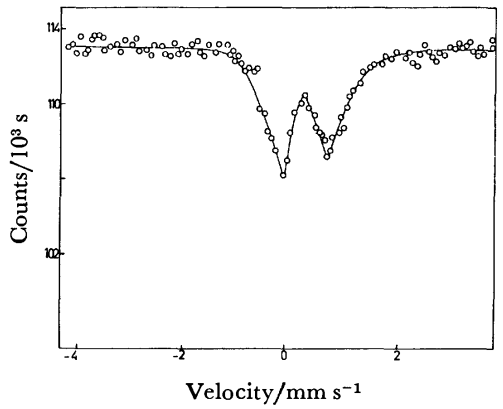

Fig. 6. Mössbauer spectrum of hexaamminecobalt(III) hexacyanoferrate(III) heated under nitrogen at 300 °C for 3 h.

$CoFe_2^{III}O_4$ are almost identical with each other at room temperature and any different sites are not resolved in ferrite, the intensity of magnetic field at the nucleus being about 510 kOe[13-15] in both the compounds. However, we assign the six-line pattern to $CoFe_2^{III}O_4$ since cobalt is available at this stage.

On further heating up to 700 °C, no remarkable change was found in the nature of this sample. The weight loss at 350 °C is 55%, which shows formation of ferrites. The DTA peak at 278 °C is considered to be due to oxidation of the complex (Fig. 3).

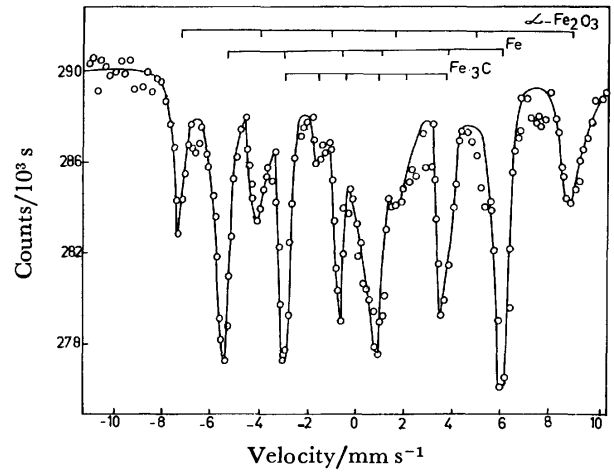

Fig. 7. Mössabauer spectrum of hexaamminecobalt(III) hexacyanoferrate(III) heated heated under nitrogen at 400 °C for 3 h.

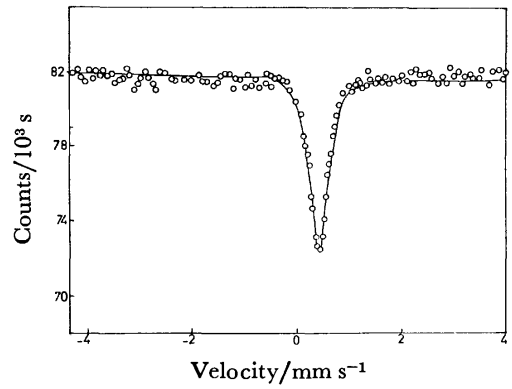

Fig. 8. Mössbauer spectrum of hexaamminecobalt(III) hexachloroferrate(III) at room temperature (25 °C).

1 was heated under a flowing oxygen-free nitrogen atmosphere. No change was found in values for isomer shift and quadrupole splitting up to 200 °C. At 300 °C the sample gives a higher value of isomer shift 0.37 mm/s and a value of quadrupole splitting 0.63 mm/s, which may be due to ligand exchange (Fig. 6). Frequency $\gamma(C\equiv N)$ in the infrared region shows the splitting having absorption bands at 2250 and 2125 cm^{-1}, and the band at 3200 cm^{-1} may be due to NH_3 stretching, in support of the exchange mechanism. On further heating, Mössbauer spectra show formation of iron metal, iron carbide, and a small quantity of ferrite, as shown in Fig. 7. Oxidation takes place only after the sample has been exposed to air to make the strip for recording Mössbauer spectrum. Formation of these products was confirmed also by magnetic measurements.

The Mössbauer spectrum of **2** (at 25 °C) shows a single line absorption band having an isomer shift 0.41 mm/s (with respect to the natural iron) and a line width 0.40 mm/s which indicates a cubic symmetry around the iron atoms, and the electron density is the same in all the d-orbitals of iron(III) (Fig. 8). The value of isomer shift shows that the complex is in a high spin (+3) oxidation state. Infrared frequencies

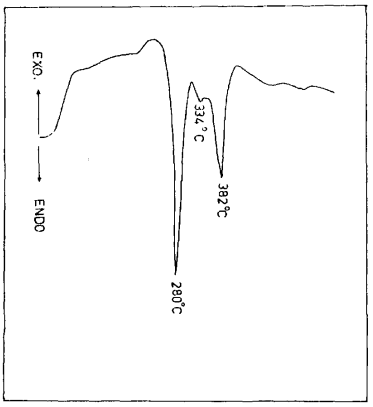

Fig. 9. DTA thermogram of hexaamminecobalt(III) hexachloroferrate(III) in air.

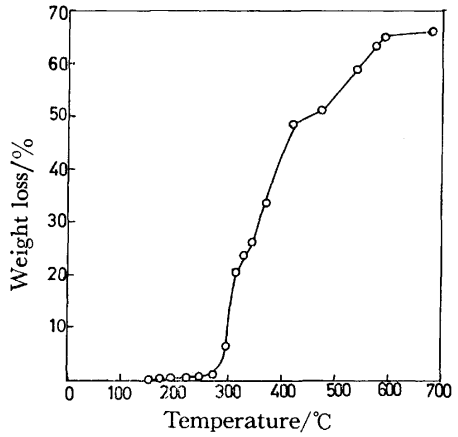

Fig. 10. TGA thermogram of hexaamminecobalt(III) hexachloroferrate(III) in air.

and ω_{eff} show formation of the above complex. The DTA thermogram shows an endothermic peak at 280 °C, very small endothermic peak at 334 °C, and a peak at 382 °C (Fig. 9). The TGA thermogram shows that there is no weight loss up to 270 °C, over which a weight loss occurs, as shown in Fig. 10. It is evident from the DTA and TGA data that this complex is stable up to 270 °C.

2 heated at 300 °C for 15 min gives a Mössbauer spectrum having an absorption band with an isomer shift 0.42 mm/s due to $FeCl_6^{3-}$ moeity and another doublet with an isomer shift 1.27 mm/s and a quadrupole splitting 1.69 mm/s due to Fe^{2+}, along with the magnetic hyperfine splitting of low intensity due to ferrite already mentioned (Fig. 11a). Thus it is clear that iron(III) is reduced to iron(II) and then oxidized to $CoFe_2^{III}O_4$.

The Mössbauer spectrum of the sample heated at 300 °C for 3 h in air shows a six-line pattern having a value of isomer shift 0.21 mm/s, as shown in Fig. 11b. The intensity of the magnetic field is 514 kOe, which agrees well with that of $CoFe_2O_4$. There was no observable change found in the spectra of the samples heated up to 700 °C (Figs. 11b and c). The magnetic moment of the sample at room temperature is 5.9 BM ($\psi_g = 32.7 \times 10^{-6}$). The ψ_g values of the samples at 200 and 300 °C are 37.6×10^{-6} and 51.61×10^{-6} cgs,

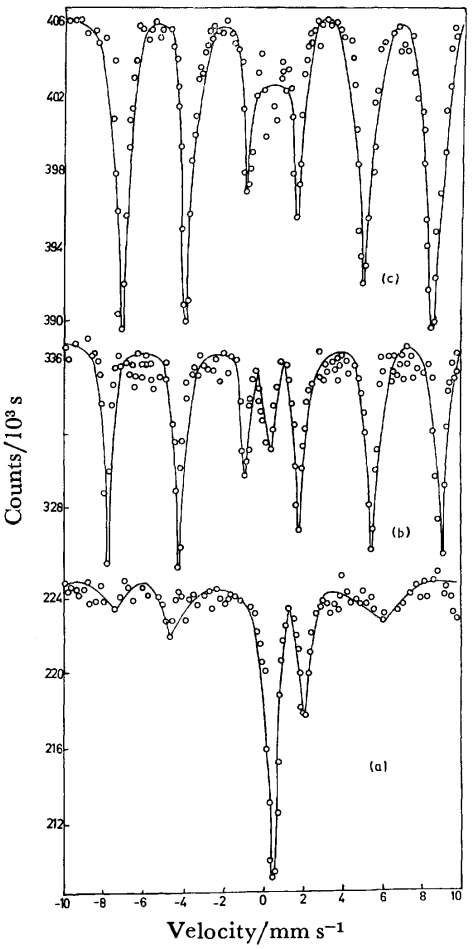

Fig. 11. (a) Mössbauer spectrum of hexaamminecobalt(III) hexachloroferrate(III) heated in air at 300 °C for 15 min. (b) Mössbauer spectrum of hexaamminecobalt(III) hexachloroferrate(III) heated in air at 300 °C for 3 h. (c) Mössbauer spectrum of hexaamminecobalt(III) hexachloroferrate(III) heated in air at 700 °C for 3 h.

respectively. The samples heated at 400, 500, and 700 °C are highly paramagnetic and are attracted towards the magnet. The IR spectrum of the sample heated at 300 °C shows a peak at 3100—3300 cm^{-1} due to ν(N–H), a peak at 1600 cm^{-1} due to δ_{asy}(N–H), and a peak at 1400 cm^{-1} δ_{sym}(N–H), which shows the presence of ammonia at this temperature. Thus it is shown that the parent complex is present in the mixture along with the ferrites. There is, however, no absorption band in the range 4000—700 cm^{-1} with the samples heated at higher temperatures, which shows complete decomposition of the complex into ferrites. This is supported by magnetic susceptibility data. DTA and TGA thermograms also show elimination of ammonia and the chloride group by giving endothermic peaks at 334 and 382 °C. The samples for Mössbauer measurement were first heated at 300 °C and then at a higher constant temperature for 3 h, so that decomposition products were formed at a little lower temperature than expected in DTA and TGA. The weight loss is also in agreement with the formation of ferrites.

In the case of **2** in inert atmosphere, the sample was

found stable up to 300 °C. On further heating, for example, up to 400 °C, ligand exchange takes place. Even with the maximum care to avoid the samples from being exposed to air, they got fully oxidized when taken out of the furnace to make the strip for Mössbauer spectral recording. A chemical analysis of these pinkish products shows presence of cobalt(II) chloride, which is highly hygroscopic, absorbs water from air, and oxidizes the sample quickly. This is why the spectrum of the sample heated at 500 °C in inert atmosphere shows a ferrite pattern (Since we had no arrangement for recording Mössbauer spectra with sample kept in the furnace in nitrogen atmosphere, the experimental information obtainable was limited to what has been given above.).

From the above investigations it is clear that patterns of decomposition and products formed depend on ligands and atmospheres employed, as expected. For both the complexes the temperature of decomposition in air is lower than in inert atmosphere. The temperature of decomposition for **1** is comparable to the temperature of thermal decomposition for alkali metal hexacyanoferrate(III). But the temperature of decomposition for **2** is higher than those for hexacyanoferrate(III) complexes. **1** is reduced to ferrate(II) around 200 °C and on further heating to higher temperatures ferrites are formed in air, whereas iron metal and carbides are formed in inert atmosphere. In the case of **2**, on the other hand, the products formed under inert atmosphere are readily oxidizable and hygroscopic, absorb moisture and oxygen from air, and get oxidized partially to ferrites. In earlier investigations,[16] in a preparation of cobalt oxides from carbonates in vacuum, cobalt oxides prepared at 300 °C were observed to take oxygen from air and to change in color from grey to black. This type of oxidation of cobalt also results in formation of ferrites. Ligand exchange takes place at 300 °C forming cobalt(II) chloride, which was confirmed from its violet pink color and by chemical analysis. The products when exposed to air absorbed water from air, and iron and cobalt are oxidized to ferrites. This may be due to the high surface reactivity of small particles of the powdered iron and cobalt metals (The ferrites and mixed oxides formed by the decomposition of the abovementioned complexes are useful in industry because of their semiconducting as well as catalytic activities.).

Although the mechanism of solid state decomposition is complex, the present information furnished from Mössbauer, infrared, and magnetic measurements, differential thermal analysis, and thermogravimetric analysis, allows us to deduce the following paths of decomposition in air for **1** and **2**:

$$4[Co(NH_3)_6][Fe(CN)_6] \xrightarrow[15\,min]{200\,^\circ C} [Co(NH_3)_6]_4[Fe(CN)_6]_3 + {}^1/_2Fe_2O_3 + 3(CN)_2,$$

$$[Co(NH_3)_6]_4[Fe(CN)_6]_3 + {}^1/_2Fe_2O_3 \xrightarrow[air]{350\,^\circ C} Co_2O_3 + 2CoFe_2^{III}O_4 + 9(CN)_2 + 24NH_3,$$

$$2[Co(NH_3)_6][FeCl_6] \xrightarrow[15\,min]{300\,^\circ C} 2[Co^{II}(NH_3)_6][Fe^{II}Cl_4] + 2Cl_2,$$

$$2[Co(NH_3)_6][Fe^{II}Cl_4] \xrightarrow[air]{400\,^\circ C} CoFe_2^{III}O_4 + {}^1/_2Co_2O_3 + 12NH_3 + 4Cl_2.$$

The percentage weight loss calculated for the decomposition of **1** effected by 15 min heating at 200 °C is 9%, corresponding to 2% weight loss in TGA. The higher value of weight loss is due to the heating time being longer than in TGA. The weight loss for the second step is 57.2% which is in agreement with the TGA value (55%) for decomposition. In the case of **2** the weight loss calculated for the first step is 15% which is higher than the TGA value (10%) due to longer heating time. The weight loss calculated for the second step is 63% which is in agreement with the TGA value (65%) for the thermal decomposition. The temperature of decomposition is higher in the case of **2**, which indicates that the ligand has a great effect on the thermal stability of the complex.

Analytical Extraction of Uranium with TOPO from Sea Water

Sandro Degetto,* Mario Faggin, Anna Moresco, and Livio Baracco
I.C.T.R.-C.N.R., Cso Stati Uniti-35100 Padova, Italy
(Received June 23, 1982)

A distribution study was carried out on the extraction behaviour of uranium in sea water using solutions of TOPO in cyclohexane. The influence of various factors (time, pH, TOPO concn in the organic phase, nitrate or chloride concentration in the aqueous phase and volumetric ratio between the two phases) on the extractability of uranium was investigated. In view of the results obtained, the best conditions for a quantitative recovery were selected. The application of the results to fluorimetric determination of uranium is also reported.

Phosphine oxides are among the most powerful neutral ligands towards uranyl complexes.[1] In particular TOPO (trioctylphosphine oxide) has been widely used in liquid-liquid extraction systems and many application to uranium separation have been reported.[2–8] In the present work a systematic investigation on the extractability of uranium from sea water with TOPO in cyclohexane is reported and selected conditions for a quantitative recovery are recommended.

In view of the results obtained a method for the determination of uranium in sea water by fluorimetric analysis is proposed. The analytical method is simple, rapid and gives reliable and highly reproducible results.

Experimental

Materials. Trioctylphosphine$^-$=(TOPO), Merck product, was used without further purification. Cyclohexane, hydrochloric and nitric acids were C. ERBA analytical grade products.

Instruments. pH measurements were performed with a Metrohom E603 and fluorimetric determinations with a FLUPAD-U fluorimeter equipped with a low current, low noise, selected preamplifier and a very high stability circuit for H. V. power switching supply. In addition, the temperature is controlled in order to avoid drifts in the electronic components response.

Uranium Standard Solutions. Aliquots of a stock solution containing 100 mg of uranium (as uranyl nitrate) per litre of 6 M HNO_3, are diluted with the same acid to give standard solution containing 10100 or 1000 g l^{-1} uranium.

Procedure. Sea water samples were filtered on 0.45 μm Millipore. Sea water collected near the shore at Jesolo (Venice) poured into polyethylene containers was used in most experiments. Uranium content of each stock was accurately determined and the results were always near to an average of 3.0 g l^{-1}. All salinity values of the samples were between 29 and 32 g l^{-1}.

The sea water samples properly acidified with HCl or HNO_3 were thoroughly mixed with solutions of TOPO in cyclohexane at various concentrations and with different volumetric ratios between the two phases (organic phase and aqueous phase). The mixed solutions attain equilibrium rather rapidly. The two phases were allowed to separate (10—20 min) and the uranium content determined in the aqueous or/and in the organic phase by a method described in a previous report[9] and by the present method.

Results and Discussion

Effect of Time. The equilibration time depends on the exchange surface and therefore on the efficiency of mixing of the two phases. In an experiment the extent of uranium extraction from 2 l of sea water 0.5 M in HNO_3 by 80 ml 2.5% TOPO soln in cylohexane was studied. The two phases were allowed to stand carefully separated in a cylindric vessel (internal diameter 9.4 cm) and analysed for uranium from time to time. The rate of equilibration was very low (the equilibrium was attained in more than 15 d) whereas when the two phases were thoroughly mixed by magnetic stirring, equilibrium was rapidly attained (about 10′—20′). In view of these results in all the following experiments an excess time of 1 h was adopted.

Effect of pH. The pH values of sea water show some diurnal and seasonal variation with a mean value 8.3—8.5 at the surface.[10] In these conditions uranium is not extracted by the organic solution of TOPO owing to the very high stability of the uranyl tricarbonate complex ($\log \beta_3 = 21.54$)[11] in which the carbonat anions fully engage the coordination sphere of the oxo cation UO_2^{2+}. On adding an acid (HCl or HNO_3) the $UO_2(CO_3)^{4-}$ complex is progressively destroyed (the maximum stability for this species is at about pH 8.5, whereas it is at 7 for $UO_2(CO_3)_2^{2-}$ and at 6 for neutral species $UO_2(CO_3)$), and the extractant TOPO can more easily enter the coordination sphere of the oxo cation.

In Figs. 1a and 1b the effect of acidification of the sea water solutions with HCl and HNO_3 is reported. It can be seen that up to pH 2.5 the % U extraction is almost independent of the kind of acid used.

The effects observed at lower pH when the molarity of the added acid is increased will be discussed later. The meaning of the maxima presented by curves a and b of Fig. 1 can be interpreted bearing in mind that:

i) The TOPO is capable of capturing uranium from the aqueous phase only when the species are coordinated to neutral donors (in practice water molecules), it cannot compete with anionic species whose coordinating ability is higher by many orders of magnitude.

ii) The nature of the extractant phase makes the extraction of charged species difficult.

Therefore it is likely that at the higher pH side of the "bell" the non extractability of the uranium is due to the presence of almost only one species, the coordinatively saturated $UO_2(CO_3)_3^{4-}$, whereas the low % extraction values obtained at low pH are related to the prevailing presence of the charged solvated UO_2^{2+}.

It is reasonable to suppose that the maximum observed

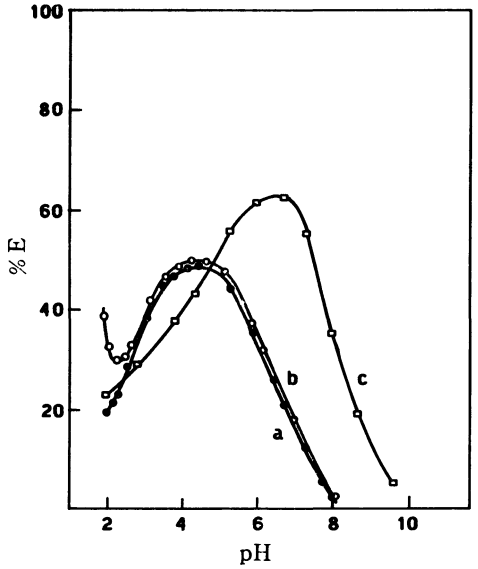

Fig. 1. Effect of pH value on the extraction of uranium.
a: HCl added, b: HNO_3 added, c: carbonates absent. Organic phase/aqueous phase: 0.04, organic phase: 0.5% TOPO soln.

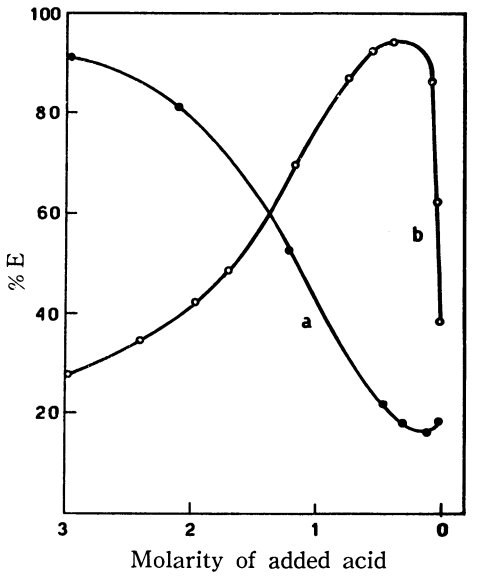

Fig. 2. Effect of increased acid concentration on the extraction of uranium.
a: HCl added, b: HNO_3 added. Organic phase/aqueous phase: 0.04, organic phase: 0.5% TOPO soln.

at about pH 4.5 is due to the presence of neutral uranium complexes containing hydrogen carbonate and hydroxide anions.

The role of carbonates on the extraction ability of TOPO is more evident considering the curve c of Fig. 1 obtained in the absence of carbonate species. In this case also, the maximum (at about pH 6.5) would correspond to the extraction of neutral species (hydroxo or chlorohydroxo complexes) but in this particular case coordinatively unsaturated but charged species, as for instance $(UO_2)_3(OH)_5^+$ and $(UO_2)_4(OH)_7^+$, in which the single charge is widely distributed could contribute to the extractability of uranium.

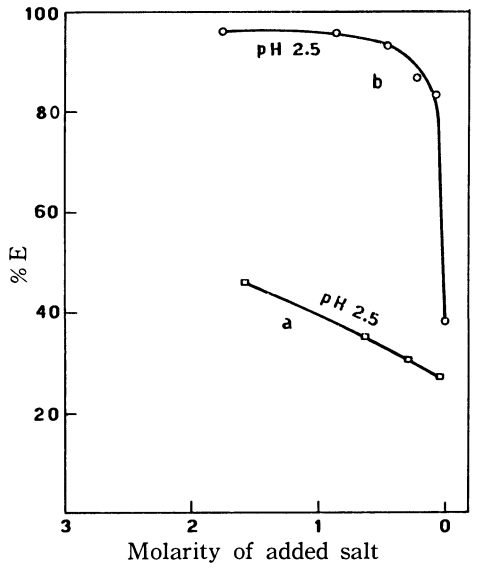

Fig. 3. Effect of added salts on the extraction of uranium at constant pH value.
a: Chloride added, b: nitrate added. Organic phase/aqueous phase: 0.04; organic phase: 0.5% TOPO soln.

The formation constants of the above mentioned hydroxo complexes are in fact very high and compared well with those of carbonato complexes.[12] As far as the extraction mechanism is concerned there exists in this case, (in addition to the usual type of coordination $R_3P{=}O{\rightarrow}U$), the possibility of interaction, through hydrogen bonding of the oxygen of TOPO with the hydrogen atom of a coordinated hydroxyl group.[3,13]

Effect of Chloride and Nitrate Concentration. The extraction curves a and b of Fig. 1 behave differently at pH lower than 2.5 as the molarity of the added acid is increased.

In Fig. 2 the %E of uranium *vs.* the molarity of the HCl or HNO_3 added, up to 3 M, is reported. On adding HCl the extraction yield continuously increases, but HNO_3 presents a second bell shaped curve with a rather sharp maximum at about 0.4 M HNO_3.

The result reported in Fig. 3, the effects of increasing molarity of added Cl^- or NO_3^- at constant pH (2.5), throw some light on this behaviour.

The observed results can be interpreted taking into account:

i) The type of complexes formed by uranyl ion with the anionic species *i.e.* : $UO_2(NO_3)^+$, $UO_2(NO_3)_2$, $UO_2(NO_3)_3^-$ and the analogous series with Cl^- up to $UO_2Cl_4^{2-}$.

ii) The competition of the proton for the oxygen of TOPO

As regards the complex species, the same considerations mentioned above (for carbonate complexes) can be applied. However, up to molarity 2 for NO_3^- and even higher for Cl^- (see Fig. 3). The problem of the competition of TOPO with the anionic species in coordinating the uranyl does not exist.

Comparing curves (b) of Figs. 2 and 3 the importance of the second factor ii) is evident.

The formation of the species TOPO–HNO_3[14] sharply

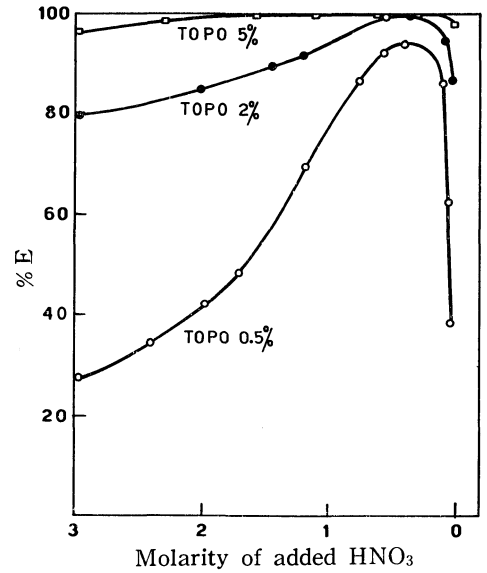

Fig. 4. Effect of TOPO concn in the organic phase on the extraction of uranium at various HNO_3 molarity. Organic phase/aqueous phase: 0.04.

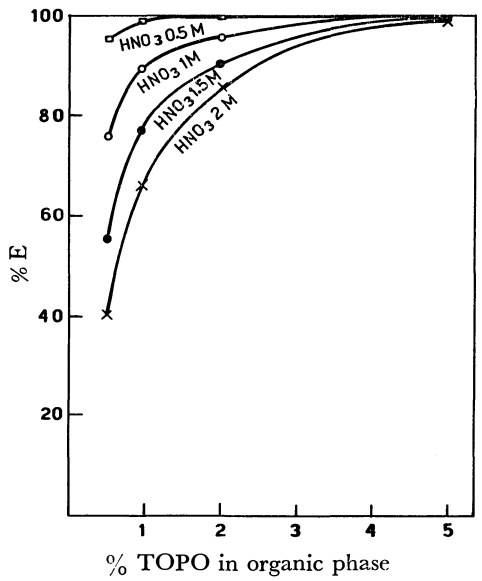

Fig. 5. Effect of TOPO concn in the organic phase on the extraction of uranium. Curves at constant HNO_3 molarity.
Organic phase/aqueous phase: 0.04.

decreases the equilibrium concentration of the free TOPO in the organic layer.

This effect appears to be less important for HCl as the curves a in Figs. 2 and 3 show an increase in % E with both increasing acidity and chloride concentration. Titrations with NaOH of the acids extracted by TOPO into the organic phase indicate that the extraction of HNO_3 is much more favoured compared to HCl.

Effect of TOPO Concentration. In Fig. 4 are reported a series of extraction curves at constant concentration of TOPO in the organic phase and constant volumetric ratio of the two phases. These results show dramatic change in uranium extractability at higher concentrations of HNO_3.

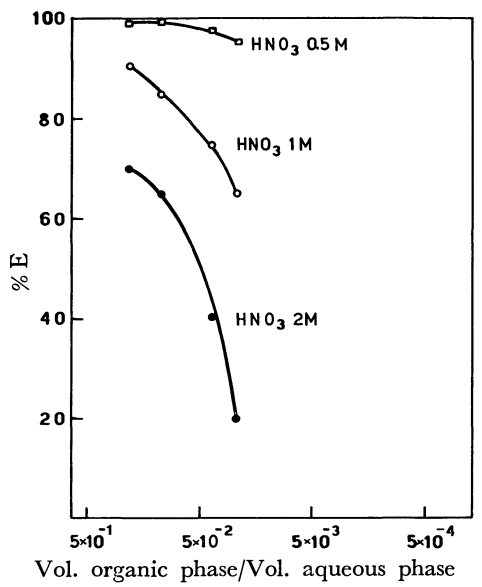

Fig. 6. Effect of the volumetric ratio between the organic and aqueous phases. Curves at constant HNO_3 molarity. Organic phase: 0.5% TOPO soln.

As can be seen from Fig. 4, for organic phase/aqueous phase=0.04, (*i.e.* 4 ml of organic phase per 100 ml of sea water), there is a rather large range of molarity (0.1—1.3 M) for which a 5% TOPO solution gives an extraction yield>99%. The same results can be represented in a different way (see Fig. 5) by curves showing the effects of % TOPO in the organic phase at constant HNO_3 molarity.

Effect of the Volumetric Ratio between the Two Phases. In order to have a complete picture of the situation and to identify the best conditions for quantitative extraction, the final factor considered was the effect of a volumetric ratio change between aqueous and organic phase. These results are reported in Fig. 6 in which the extractant solution is 0.5% TOPO and the organic phase/aqeous phase ratios ranged from 16/100 to 2/100.

The Analytical Method

It is evident from the above results that it is quite simple to reach an essentially complete (>99%) extraction of uranium from sea water in a single-batch contact. As this procedure could be easily applicable for U determination on a routine basis, we examined the possibility of directly measuring the fluorescence of the uranium extracted, (without any supplementary separation), by use of a pellet with a high carbonate flux.

It is well known that in spite of its high sensitivity the fluorimetric method suffers from some disadvantages. First there is the possibility that the uranium fluorescence may be quenched by a number of heavy metals. Secondly there is the need to control carefully the operating conditions. As regards the second point we have already shown[9] that the variability of the results observed in preparing and measuring the pellets from standard uranium samples was from 0.4% for 0.07 μg U up to 2% for 0.007 μg U in easily reproducible conditions.

Thus, high errors are likely to be mainly related to the chemical treatment of the samples.

We have now rechecked these earlier results using a new fluorimeter, of our own design, in which, owing to the very high linearity of instrumental response is possible to obtain a straight line calibration curve for the whole range 0.001—0.1 g U which should satisfy all the needs of environmental or biological samples. The fluorescence signals of the pellets obtained (starting from standard uranium samples) now show a reproducibility better than 1% over the whole range (average of six determinations).

The instrumental response is easily controlled routinely before every series of measurements by a set of quartz buttons containing different appropriate amounts of uranium.

The reliability of such a system tested over two years was excellent.

The procedure recommended for the analysis of uranium entails the following steps:

1°) Filtration of the sea water samples on 0.45 μm Millipore and acidification with concentrated HNO_3 (4 ml per 100 ml sea water).

2°) Addition to the sea water of a 5% TOPO solution in cyclohexane up to a volumetric ratio organic phase/aqueous phase 4×10^{-2}.

3°) Efficient mixing of the two phases (by magnetic stirring) in a tightly closed glass container for about 1 h. (The shape of the container should facilitate the separation of the small organic phase).

4°) At this point an adequate fraction of the organic phase (possibly containing $(1—4)\times10^{-8}$ g of uranium) is transferred onto the platinum dish, brought to dryness by an IR lamp and then heated for a few seconds over a Bunsen burner in order to destroy completely the organic materials. This operation is quite difficult to do without losses as the organic materials tend to lined the rim of the dish. After many attempts we realized that the simplest way to overcome these difficulities is a back extraction of U by a 15% aqueous solution of $(NH_4)_2CO_3$ volume to volume. This step is quantitative within a few minutes of stirring and can be easily performed in a small test-tube.

An aliquot of the carbonate phase is now transferred to the dish by a pipette (without the need to separate the phases) and the sample is treated as reported above.

5°) Preparation of the pellet with a high carbonate flux namely 10% NaF, 40% K_2CO_3, 50% Na_2CO_3. The distance of the head of the Bunsen burner from the platinum dish is adjusted to give a fusion time of about 90″ and the heating is then continued for 30″ more. In such conditions the temperature of the fused salts does not exceed 600—630 °C.

6°) After cooling the dishes the pellets are easily taken off, inserted in a measuring plate and stored for half an hour in a desiccator thermostatted at 25 °C before measurements are made.

None of these steps appears to be "critical," the overall analytical reproducibility for some sea water samples is reported in Table 1.

The reproducibility observed is strictly related, in our opinion, to the almost 100% yield of each step and the use of convenient volume measuring apparatus. As regards the precision of the measurements this is related to the first disadvantage mentioned above for the fluorimetric method, namely the quenching effect.

In the present case such effects are quite small or even absent, owing to the low concentration of any quencher and to the selection resulting from the two extraction steps (see Table 1). As a matter of fact it was difficult to detect (even qualitatively), by X-ray fluorescence analysis, the presence of very low quantities of Fe, Ni, Cu, Zn, and Pb in samples fifty times more concentrated than those normally used for analysis. Anyhow as the quenching effect is known to be proportional to the quantity of quenchers present but independent of the amount of uranium[15] it is possible, even with samples other than sea water, to apply the spiking technique even on a routine basis by adding directly to the platinum dishes different known amounts of uranium.

This simplified procedure can only be applied however when (as in the present case) the procedure warrants an overall extraction yield >99%. In our opinion it is in fact extremely difficult to obtain a good reproducibility of lower extraction yields without any supplementary technique such as, for instance, the isotopic dilution method.

The minimum time interval required between the receipt of a sample and the analytical result (average of

A Kinetic Study on the Oxychlorination of Benzene

Jesus Blanco,* Pedro Avila, and Francisco Vicente Melo
Instituto de Catálisis y Petroleoquimica†, Serrano, 119, Madrid-6, Spain
(Received March 19, 1982)

Gas-phase benzene oxychlorination was carried out over a $CuCl_2$–$CeCl_3/Al_2O_3$ catalyst. A kinetic model is proposed which permits us to obtain a rate equation capable of reproducing experimental results. The presence of cerium in the catalyst increases the reaction rate and maintains the conversion level for a long time. It seems that this element facilitates copper reoxidation by making the total rate independent of the partial pressure of oxygen and stabilizes the active phase of the catalyst.

Oxychlorination is one of the most interesting ways of consuming the HCl surplus produced in conventional hydrocarbon chlorination processes.

A considerable number of kinetic studies on catalytic hydrocarbon oxychlorination are found in the paper by Allen and Clark.[1] The reported data relate mainly to hydrocarbons to be oxychlorinated, reaction temperature, nature of catalyst, and whether reaction takes place in the liquid or gas phase. Most of this information relates, however, to aliphatic hydrocarbons, particularly ethylene, whereas the information about oxychlorination of aromatics in the gas phase is scarce, being restricted to the works of Solomoniv *et al.*[2] on toluene oxychlorination, Shutenkova and Gor'kova,[3] and Blanco *et al.*[4,5] on benzene, and Altuglu and Roberts[6] on chlorobenzene. In the case of chlorobenzene, using a $CuCl_2$–$LiCl/Al_2O_3$ catalyst at 200 °C,[6] the authors claimed that the Deacon reaction should not be included in the overall mechanism, and that the rate limiting step would be the formation of an activated complex compound between the hydrocarbon and adsorbed oxygen: $C_6H_5ClO^*$. Blanco *et al.* have published reports of studies on benzene oxychlorination using $CuCl_2$/alumina[7,8] and $CuCl_2$–KCl/alumina.[4,5] In these studies they have pointed out the existence of an interaction between copper cations and OH groups of the support.

Lately they have developed a series of catalysts containing copper and cerium chlorides on alumina that exhibit greater activity than copper chloride or mixtures of copper and alkali metal chlorides.

In this communication, the behaviour of these $CuCl_2$–$CeCl_3/Al_2O_3$ catalysts has been studied for the oxychlorination of benzene, and the results are compared with kinetic data previously reported.

Experimental

Apparatus. The experiments were carried out at atmospheric pressure in a conventional fixed-bed flow catalytic reactor described elsewhere.[9] The exit gases from the reactor pass through a condenser where the liquid products are collected, and then through a water adsorption column to remove unreacted HCl. The chlorinated products in the organic condensate were analyzed by GLC in a column (6.5 mm × 4.2 m) of SE. 30 Silicone rubber on Chromosorb P (60—80 mesh). Complete balance of C, H_2, and Cl_2 was confirmed for each experiment.

Catalyst. The catalyst used in this work was prepared by impregnation of gamma-Al_2O_3 (EPA, high purity, containing $Fe_2O_3 \leqslant 0.05\%$; $SiO_2 \leqslant 0.5\%$; $Na_2O \leqslant 0.01\%$; $K_2O \leqslant 0.05\%$; LOI = 7.0%) with aqueous solutions of $CuCl_2$–$2H_2O$ (Carlo Erba) and $CeCl_3 \cdot 7H_2O$ (BDH), and drying at 110 °C for 2 h. The alumina support was previously treated at 400 °C in air for 12 h.

The catalyst obtained has surface area 152 m^2/g, pore volume 0.351 cm^3/g, average pore radius 55 Å, and metal contents 0.42×10^{-3} g-atom Cu/g cat. and 0.40×10^{-3} g-atom Ce/g cat., as determined by atomic absorption spectrophotometry, equivalent to about 2.7 wt% Cu and 6.1 wt% Ce. The E.D.A.X. analysis showed that both elements are totally mixed and uniformly distributed throughout the support.

Results and Discussion

Exploratory runs were initially performed in order to define the range of experimental conditions in which the rate is not limited by mass transfer. A test carried out with the reactor packed with support alone gave no detectable conversion.

The effect of reaction temperature and contact time on rate and selectivity was studied with a stoichiometric feed mixture according to the equation

$$C_6H_6 + HCl + \frac{1}{2}O_2 \longrightarrow C_6H_5Cl + H_2O.$$

The operation conditions employed were: reaction temperature, T, 230—300 °C; pressure, P, 700±10 mmHg (1 mmHg = 133.322 Pa); weight of catalyst, W, 1—12 g; catalyst size, 1—2 mm; benzene feed, F_b, $(1.125—2.25) \times 10^{-3}$ mol min^{-1}; feed composition, $C_6H_6 : HCl : O_2 : N_2 = 1 : 1 : 0.5 : 1.9$ molar ratio; and Reynold Number, 20—40.

The catalyst was dispersed over 2—3 mm carborundum particles in order to obtain a bed of 25 cm. In this way the actual reaction temperature was only 1 °C off the desired value over more than 90% of the catalyst bed.

The results obtained are summarized in Table 1, where total benzene conversion (mol of benzene reacted per 100 mol of benzene fed) and product selectivities (mol of each product formed per 100 mol of benzene reacted) are shown.

These results clearly indicate that the maximum benzene conversion to be attained with the stoichiometric feed ratio is about 70%, since part of the starting HCl and O_2 is consumed in the production of higher chlorinated compounds (dichloro- and trichlorobenzene); to avoid this limitation, a series of experiments was carried out at 270 °C with amounts of HCl and O_2

† Formerly called Instituto Rocasolano.

0.930[b]	4064	56.8	—	71.6	24.0	4.4

a) Feed molar ratio is stoichiometric to the formation of dichlorobenzene. Temperature of reaction is 270±1 °C. b) Experiments carried out with C_6H_5Cl in the feed instead of benzene.

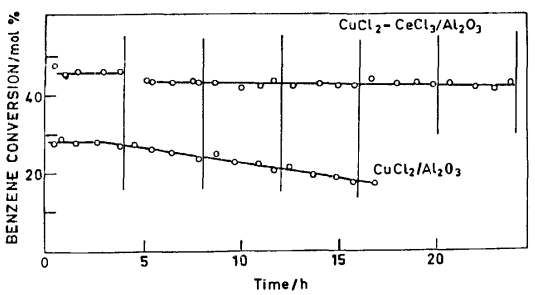

Fig. 1. Accelerated life test carried out at 330±1 °C with W/F_b=444 g min mol^{-1} (benzene) for $CuCl_2$-$CeCl_3$/Al_2O_3 and $CuCl_2/Al_2O_3$ catalysts.

in the feed corresponding to the stoichiometric ratio for the formation of dichlorobenzene. The results are shown in Table 2, together with another series of experiments in which chlorobenzene was the starting material and HCl and O_2 were fed in stoichiometric ratio to produce dichlorobenzene.

Finally, the influence of operation time on catalyst activity was examined by performing an accelerated life test at 330 °C, with the conditions of W/F_b 444 g min (mol benzene)$^{-1}$, atmospheric pressure, and feed molar ratio C_6H_6 : HCl : O_2 : N_2=1 : 1 : 0.5 : 1.9. The system was put in operation for 4 h a day during 6 d. The results of conversion *vs.* time on stream are plotted in Fig. 1. The upper curve corresponds to the catalyst studied in this work while the lower one corresponds to a catalyst containing only $CuCl_2$ on Al_2O_3, which was prepared by substituting the $CeCl_3$ by the equivalent amount of $CuCl_2$.

For the analysis of the experimental results the following reaction scheme is proposed:

$$C_6H_6 + HCl + \frac{1}{2}O_2 \rightleftharpoons C_6H_5Cl + H_2O,$$

$$C_6H_5Cl + HCl + \frac{1}{2}O_2 \rightleftharpoons C_6H_4Cl_2 + H_2O,$$

$$C_6H_4Cl_2 + HCl + \frac{1}{2}O_2 \rightleftharpoons C_6H_3Cl_3 + H_2O,$$

in which no distinction is made between the *o*- and *p*-dichlorobenzene, as far as their rates of formation and urther reaction is concerned. This simplifying assumption can be reasonably introduced on the basis of the experimental data that showed a constant molar ratio of both isomers at all conversion levels of para/ortho= 2.7±0.2.

According to the above scheme, different rate equations were tested by considering several orders of reaction for the various compounds taking part in the process, and different rate controlling steps. A mathematical fitting of the experimental data to the various equations was carried out through analytical integration of the different sets of rate equations by using a 4th order Runge-Kutta method, and the values of the parameters were estimated through nonlinear regression analysis by using also duplicate runs.

The optimized parameter was the variance of correlation defined by

$$\sigma^2 = \frac{\sum_{i=1}^{N}\sum_{j=1}^{N'}(x_{ij}(\text{exp}) - x_{ij}(\text{theor}))^2}{N \times N' - N''},$$

where N is the number of points, N' the number of yields by point, and N'' the number of parameters to be determined.

The experimental error resulting from repeated experiments was estimated by

$$\varepsilon = \frac{\sum_{i=1}^{N}\sum_{j=1}^{N'}\sum_{k=1}^{N''}(x_{ijk}(\text{exp}) - x_{ij}(\text{average}))^2}{N' \times N - N'''} = 0.24 \times 10^{-3},$$

where N''' is the number of average values.

The best fit was obtained with the following set of Langmuir-Hinshelwood type equations:

Benzene disappearance: $$-\frac{dx}{d\left(\frac{W}{F_b}\right)} = \frac{k_1 P_{C_6H_6}}{(1+K_A P_{H_2O})^2},$$

Chlorobenzene formation:

$$\frac{dx_1}{d\left(\frac{W}{F_b}\right)} = \frac{k_1 P_{C_6H_6}}{(1+K_A P_{H_2O})^2} - \frac{k_2 P_{C_6H_6Cl}}{(1+K_A P_{H_2O})^2},$$

Dichlorobenzene formation:

$$\frac{dx_2}{d\left(\frac{W}{F_b}\right)} = \frac{k_2 P_{C_6H_5Cl}}{(1+K_A P_{H_2O})^2} - \frac{k_3 P_{C_6H_4Cl_2}}{(1+K_A P_{H_2O})^2},$$

Trichlorobenzene formation:

$$\frac{dx_3}{d\left(\frac{W}{F_b}\right)} = \frac{k_3 P_{C_6H_4Cl_2}}{(1+K_A P_{H_2O})^2}.$$

Table 3 shows the values of the different kinetic parameters obtained at various temperatures. From these values a similar apparent activation energy is obtained for the oxychlorination of benzene (19.5±0.3 kcal/mol) and chlorobenzene (20.1±0.3 kcal/mol), the small difference being probably due to the "deactivation" of the aromatic ring by the presence of the chlorine atom.

Table 3. Rate constants and variance of the correlation obtained at different temperatures

Temp °C	$k_1\times10^4$	$k_2\times10^4$	$k_3\times10^5$	K_A	σ^2
230	2.753	1.802	—	8.142	2.078×10^{-6}
250	7.028	4.344	—	3.696	2.223×10^{-4}
270	13.97	9.203	9.621	1.422	2.228×10^{-4}
300	30.42	20.87	20.51	0.9466	2.205×10^{-4}

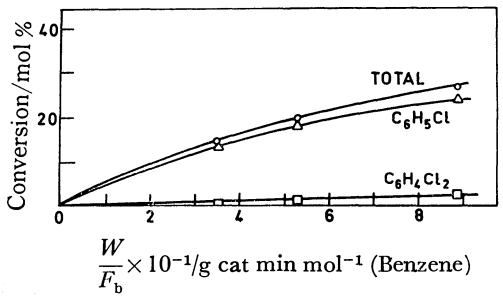

Fig. 2. Experimental results and calculated curves based on the proposed equations at 230±1 °C: △, conversion of benzene; △, C_6H_5Cl formation; □, $C_6H_4Cl_2$ formation.

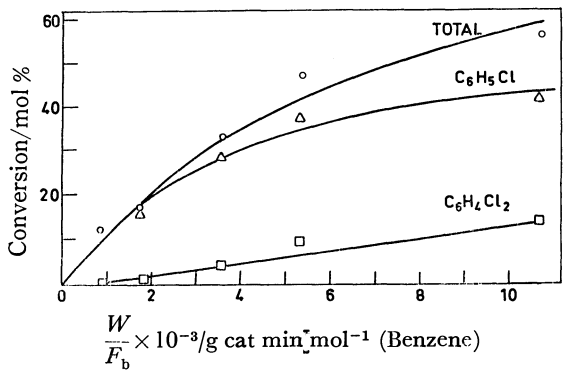

Fig. 3. The same title with Fig. 2 except that the temperature is 250±1 °C.

The variation of K_A with temperature can be related to the heat of adsorption of water on the surface of catalyst, which has a negative effect on the rates, possibly by partially blocking the active sites.

The ratio between the correlation variance and the experimental error was lower than the Fisher parameter[10] $F_{(32,21)}$ for 90%=1.71.

The experimental conversion data obtained as different temperatures are compared in Figs. 2—5 with those calculated by using the proposed equations (continuous lines). These equations reproduce the experimental values satisfactorily the data obtained at 300 °C, where the consumption of HCl and O_2 produced a dramatic decrease in their partial pressures. The dotted line corresponds to the 90% consumption of HCl and O_2. Under these conditions the catalyst may also undergo a change in its active phase composition.

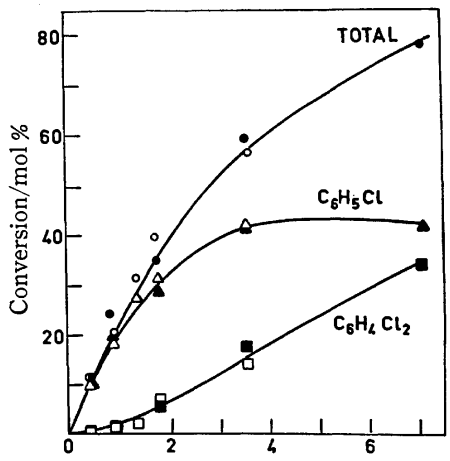

Fig. 4. The same title with Fig. 2 except that the temperature is 270±1 °C. The full points correspond to experiments with a feed molar ratio stoichiometric to the $C_6H_4Cl_2$ formation.

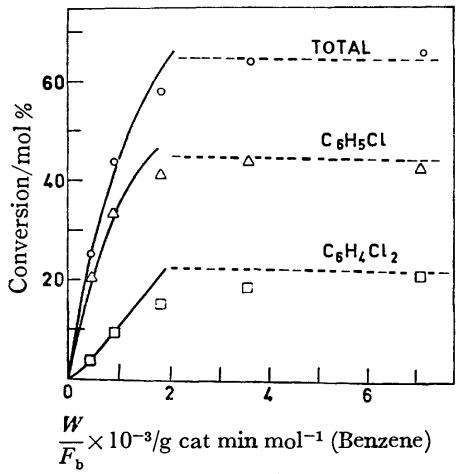

Fig. 5. The same title with Fig. 2 except that the temperature is 300±1 °C. The dotted line corresponds to 90% and O_2 consumption.

The fitness of the experimental data, obtained by replacing benzene will chlorobenzene as feedstock (Table 2), appears in Fig. 6. The use of the parameter values shown in Table 3 gives calculated conversions slightly smaller than the experimental ones. This difference may be due to an effect caused by the benzene adsorption which was neglected in the proposed equations. In any cases, the deviations fell within the experimental error.

According to the proposed equations, the process may be considered independent of the partial pressures of oxygen and hydrogen chloride, the reaction rate being only a function of the partial pressures of the hydrocarbon and water.

In Table 4, the kinetic equations published in previous papers are listed together with the one proposed in this study. As can be seen, when $CuCl_2$ and $CuCl_2$–alkali chloride supported catalysts are used, the reaction rate depends on the partial pressure of oxygen, but in the

6	$CuCl_2$–$LiCl/Al_2O_3$	$r=\frac{k_1P_{HC}\cdot P_{O_2}^{1/2}}{(1+k_2P_{HC}+k_3P_{O_2}^{1/2})^2}$
This study	$CuCl_2$–$CeCl_3/Al_2O_3$	$r=\frac{k_1P_{HC}}{(1+K_AP_{H_2O})^2}$

case of $CuCl_2$–$CeCl_3/Al_2O_3$ this relation is no longer applicable.

The presence of cerium seems to facilitate the copper reoxidation step by making the overall rate higher and also independent of the partial pressure of oxygen. Moreover, the life test results indicate that the cerium in these catalysts not only increases the reaction rate but also maintains the conversion level for a longer time. This effect may be due to the formation of Cu and Ce complex compounds on the alumina surface,[12] which are more stable and therefore less likely to undergo the decomposition to $CuCl_2$, a phenomenon considered to be the main reason for the deactivation of these catalysts.[8]

Barium Manganate. A Versatile Oxidant in Organic Synthesis

Habib FIROUZABADI* and Zohreh MOSTAFAVIPOOR
Chemistry Department, Shiraz University, Shiraz, Iran
(Received July 19, 1982)

Preparation of barium manganate in large-scale is discussed. It is also shown that this reagent is capable of oxidizing organic substrates, converting alcohols to their corresponding carbonyl compounds, aromatic amines to their corresponding azo compounds, hydroquinone to *p*-benzoquinone, benzylamine to benzaldehyde, and triphenylphosphine to its oxide in good yields. Saturated hydrocarbons, unsaturated hydrocarbons, unsaturated ketones, and saturated amines are not affected by this reagent in a reasonable reaction time.

Among many oxides and oxoanions of manganese, only manganese dioxide[1] and potassium permanganate[2] have extensively studied in the oxidation of organic compounds. Recently several permanganates; potassium permanganate "dicyclohexyl-18-crown-6",[3] benzyltriethylammonium permanganate,[4] tetrabutylammonium permanganate,[5,6] bis(pyridine)silver permanganate[7] have been prepared and used in the oxidations of organic substrates in organic solvents. Manganates are also of interest in the oxidation of organic compounds but, very little attention has been paid to their properties in organic oxidation reactions. There have been few reports available in the literature in which potassium manganate is used as an oxidant.[8,9] Very recently basic strontium manganic manganate[10] has also been used in the oxidation of alcohols to their corresponding carbonyl compounds in organic media.

Lately in a communication we introduced barium manganate in heterogeneous system as a good oxidizing agent for the oxidation of alcohols and indicated its advantages over manganese dioxide.[11] Here we discuss the large-scale preparation of this reagent with some modification to our previously reported procedure.[11] We have also extended our studies to the oxidation of different groups of organic compounds.

Results and Discussion

Barium manganate was prepared as following: 1) 2 mol of potassium hydroxide were fused with 1 mol of manganese dioxide at 350 °C to produce dark green potassium manganate.[12] 2) 1 mol of potassium manganate was added while being stirred to a warm solution of 1 mol of barium hydroxide at pH=7. The dark blue crystals of barium manganate[13] were collected and dried at 100 °C for 24 h.

Oxidation with barium manganate, prepared by this method, gives reproducible results without requiring

a) In dichloromethylene.

further activation, while oxidation reaction with manganese dioxide is not reproducible in many aspects.[1] This reagent is indefinitely stable, active, and could be stored for months under dried condition. According to our finding barium manganate is a good reagent in organic synthesis whenever both the rate and the selectivity of the reaction are concerned. To our view this reagent is a good substitute for manganese dioxide in many respects. First, its preparation and isolation is much easier than of active manganese dioxide. Second, the ratio of substrates to manganese dioxide can range from 1 : 5 to 1 : 50.[1] This ratio for barium manganate in our investigation ranged from 1 : 1 to 1 : 10, which makes the isolation of the oxidation product from the solid oxidizing material easier and more practical. Third, the oxidation reactions of organic compounds under investigation with barium manganate were usually faster and resulting higher yields than those obtained from manganese dioxide. The results obtained are summarized in Table 1. Barium manganate reacts very mildly and selectively in dry organic solvents, *e.g.* dichloromethane and benzene, either at room temperature, or under reflux conditions. The rate of reaction under reflux conditions

is much faster.

Benzylic alcohols were converted to the corresponding carbonyl compounds without further oxidation. In the oxidation of diols; (16 and 18) in Table 2 in addition to the isolation of corresponding aldehydes a small amount of the corresponding lactone was also isolated. Allyl alcohols were also very reactive and produced their carbonyl compounds in good yields. 2-Alkyn-1-ols were very reactive and were oxidized very easily to their corresponding carbonyl compounds in good yields. Saturated alcohols were oxidized rather slowly with difficulty. In some cases even after 24 h only fifty percent conversion were observed (Table 2).

Aromatic amines with nitro groups substituted on the aromatic ring and 1-naphthylamine gave none to low yields of their corresponding azo compounds. In these cases manganese dioxide is reported to be quite unreactive.[14] The other aromatic amines were quite reactive and their corresponding azo compounds were produced very easily. Benzylamine was converted to benzaldehyde very rapidly (Table 3).

Triphenylphosphine was converted very easily and rapidly to triphenylphosphine oxide, 2,4-dinitrophenylhydrazine to *m*-dinitrobenzene, and hydroquinone to *p*-benzoquinone. The oxidation of a few hydrocarbons, unsaturated ketones, and saturated amines were also investigated. They were unreactive towards this reagent (Table 4).

Experimental

General. All yields refer to isolated products. Products were characterized by comparison with authentic sample (IR spectrum, thin layer, gas chromatography, melting point, and refractive index). All reactions proceeded in benzene, unless otherwise indicated.

Preparation of Potassium Manganate. Potassium hydroxide (2 mol) were thoroughly mixed with manganese dioxide (1 mol) and left in an oven at 350 °C for 3 h. The fused green potassium manganate was discharged and used for the preparation of barium manganate.

Preparation of Barium Manganate. In a (500 ml) flask, barium hydroxide (7 g, 0.041 mol) was added to distilled water (100 ml) and pH was adjusted to 7 with dilute hydrochloric acid. To the resulting warm solution, 8.6 g (0.043 mol) of potassium manganate was added with stirring. The colour of the reaction mixture immediately changed to dark purple. The reaction mixture was filtered with suction and the dark blue crystals were washed for several times with distilled water. The resulting crystals were put in an oven at 100 °C for 24 h, to produce active barium manganate in 60% yield. Found: Ba, 52.85%. Calcd for $BaMnO_4$: Ba, 53.58%.

General Procedure for the Conversion of Alcohols to Their Aldehydes and Ketones. To a solution of alcohol (0.01 mol) in dry

benzene (30 ml), in a (100 ml) round-bottomed flask, equipped with a condenser and magnetic stirrer, barium manganate (0.05—0.1 mol) was added and refluxed for 1/2-24 h the reaction mixture was filltered with suction and the solid material was washed with dichloromethane for several times. The filterates were added together and evaporated. The resulting material was chromatographed on silica-gel column eluted with benzene. Evaporation of the solvent afforded pure carbonyl compound in 50—100% yield (Table 2).

General Procedure for the Conversion of Aromatic Amines to Their Corresponding Azo Compounds. In a round-bottomed flask (100 ml), equipped with a condenser and magnetic stirrer, amine (0.01 mol) in dry benzene (30 ml) was mixed with barium manganate (0.03—0.05 mol) and refluxed for 0.5 to 4.5 h. The reaction mixture was filtered with suction. The solid material was washed with dichloromethane for several times. The filterates were added together and evaporated. The resulting material was chromatographed on either silica gel or neutral alumina column eluted with benzene. Evaporation of the solvent afforded the azo compound in 0—90% yield (Table 3).

Conversion of 2,4-Dinitrophenylhydrazine to m-*Dinitrobenzene.* In a round-bottomed flask (100 ml) equipped with a condenser and magnetic stirrer, 2,4-dinitrophenylhydrazine (0.01 mol) in dry benzene (30 ml) was mixed with barium manganate (0.05 mol) and refluxed for 1.5 h. The reaction mixture was filtered with suction and the solid material was washed with dichloromethane for several times. The filterates were added together and evaporated. The resulting material was chromatographed on neutral alumina column eluted with benzene. Evaporation of the solvent afforded *m*-dinitrobenzene in 50% yield (Table 4).

Conversion of Benzylamine to Benzaldehyde. In a round-bottomed flask (100 ml) equipped with a condenser and magnetic stirrer, benzylamine (0.01 mol) in dry benzene (30 ml) was mixed with barium manganate (0.02 mol) and refluxed for 1 h. The reaction mixture was filtered with suction. The solid material was washed with dichloromethane for several times. The filterates were added together and evaporated. The resulting material was chromatographed on silica-gel column eluted with benzene. Evaporation of the solvent afforded benzaldehyde in 95% yield (Table 4).

Conversion of Hydroquinone to p-*Benzoquinone.* In a round-bottomed flask (100 ml) equipped with a condenser and magnetic stirrer, hydroquinone (0.01 mol) in dry benzene (30 ml) was mixed with barium manganate (0.02 mol) and refluxed for 20 min. The reaction mixture was filtered with suction. The solid material was washed with dichloromethane for several times. The filterates were added together and evaporated. The resulting material was chromatographed on silica-gel column eluted with benzene. Evaporation of the solvent afforded *p*-benzoquinone in 75% yield (Table 4).

Conversion of Triphenylphosphine to Triphenylphophine Oxide. In a round-bottomed flask (100 ml) equipped with a condenser and magnetic stirrer, triphenylphosphine (0.01 mol) in dry benzene (30 ml) was mixed with barium manganate (0.05 mol) and refluxed for 2 h. The reaction mixture was filtered with suction. The solid material was washed with dichloromethane for several times. The filterates were added together and evaporated. The resulting material was chromatographed on silica-gel column eluted with benzene. Evaporation of the solvent afforded triphenylphosphine oxide in 100% yield (Table 4).

We are thankful to Shiraz University Jehad Council for the Partial support of this work and also Mr. J. Toofan for the elemental analysis.

Catalytic Alkylation, Sulphonation, and Heteroarylation of Some Bicyclic Pyrazolines in Solid-Liquid Two Phase Systems

Ahmed Kamal EL-SHAFEI,* Ahmed Mahmoud EL-SAYED, and Ali Ali KHALAF†

(Received March 29, 1982)

The reaction of some bicyclic pyrazolines with alkyl halides, aryl sulphonyl chlorides as well as with some N–H and S–H containing heterocycles is affected in solid-liquid two phase systems using a catalyst. The catalytic cycle is described, the purity of the obtained products is checked using TLC and their structure is confirmed by a combination of chemical and spectroscopic methods.

It has been recognized recently[1] that numerous N–H acidic compounds can be conveniently alkylated in the presence of concentrated aqueous sodium hydroxide or potassium hydroxide solutions and quaternary ammonium salts as catalysts. The catalytic method has been used for alkylation of aziridine,[2] phenothiazine,[3] pyrrole,[4] indole,[4–7] and its derivatives,[5] diphenylamine,[4] carbazole,[4] some amides,[8] and phenylhydrazones of aldehydes and ketones.[9] These reactions take place in liquid-liquid two phase system in which both phases, aqueous sodium hydroxide and organic reactants (neat or in nonpolar solvent) are mutually immiscible. This catalytc two phase (CTP) system offers numerous advantages over other bases such as NaH, $NaNH_2$, and *t*-BuOK *inter alia* elimination of hazardous and expensive reactants, anhydrous organic solvents, *etc.*

Despite many advantages, the CTP system has some limitations, one of them being the hydrolytic activity of concentrated aqueous alkali. However, it has been reported that many reactions with C–H acidic compounds can be efficiently carried out using anhydrous sodium or potassium carbonate as bases.[9–11] In these cases the reactions proceed in liquid-solid two phase systems, organic reactants neat (if liquids) or in aprotic solvents form the organic phase in which solid sodium or potassium carbonate is suspended. In these systems reactions are catalyzed by tetraalkylammonium salts or crown ethers. The catalysts are unable to transfer carbonate anions (CO_3^{2-}) into the organic phase,[12] thus solid-liquid phase-transfer phenomena are probably not involved here. It is more plausible that the first step, namely proton abstraction, takes place on the surface of the solid carbonate (see Fig. 1). The anions formed then migrate into the organic phase as ion pairs with the catalyst cation. Since several reports indicated the pharmacological importance[13–16] of some bicyclic pyrazolines, we report here the synthesis of some new derivatives of 7-benzylidene-3,3a,4,5,6,7-hexahydro-3-phenyl-2*H*-indazole (**1**) using solid-liquid two phase transfer system. This method offers a convenient synthetic means due to the comparative stability of such compounds.[17] Compound **1** was obtained by refluxing 2,6-dibenzylidenecyclohexanone with hydrazine hydrate in methanol.

was affected in potassium carbonate-acetone using tetrabutylammonium bromide (TBAB) as a catalyst. Time of the reaction at the appropriate temperature was summarized in Table 1. The reactions were monitored by TLC and the identity of the obtained products was based on both microanalytical and NMR data. The starting bicyclic pyrazoline **1** was chloroacetylated by stirring an equimolar mixture of **1** and chloroacetyl chloride in benzene at 18 °C for 1 h. The *N*-chloroacetylpyrazoline derivative **8** was effectively used as an alkylating agent to some N–H and S–H containing heterocycles, namely, morpholine, 2-mercaptopyrimidine, and 2-mercaptobenzothiazole. The reactions were performed in CTP system (K_2CO_3/acetone/TBAB) where the corresponding dehydrochlorinated products **9**, **10**, and **11**, respectively were obtained in fair yields. Figure 1 illustrate the catalytic cycle where Het^- corresponds to cations derived from N–H or S–H containing heterocycles used in CTP reactions, Q^+ to tetrabutylammonium cation and R^+ to

alkyl or *N*-acetylpyrazolinyl cations.

Experimental

Melting points are uncorrected and were determined using a Kopfler bank. ^{1}H-NMR spectra were obtained on a Varian EM 360 A or NV 14 spectrometer at 60 MHz or at 100 MHz using TMS as an internal standard, chemical shifts are expressed in ppm. Qualitative thin layer analyses were carried out using nanoplates (10 cm × 10 cm, HPTLC, 5 μm silica) with nitromethane as eluent.

Catalytic Two Phase Alkylation and Sulphonation of N–H Containing Compound ***1****. General Procedure*: To a mixture of compound **1** (0.05 mol) and potassium carbonate (0.05 mol) in acetone (70 ml) an equimolar amount of alkyl halide or aryl sulphonyl chloride (0.05 mol) was added. The mixture was treated with a catalytic amount of tetrabutylammonium bromide (TBAB) (0.001 mol), and vigorously stirred at the appropriate temperature (see Table 1) over periods of time ranging between 2—6 h. After completion of the reaction (TLC) the mixture was filtered off, dried ($MgSO_4$), evaporated *in vacuo* and the residual solid was crystallized from the appropriate solvent.

Synthesis of N-*Chloroacetyl Bicyclic Pyrazoline Derivative* ***8****.* To a solution of 0.01 mol of compound **1**, 0.015 mol of *N,N*-diethylaniline in 50 ml of benzene, 0.012 mol of chloroacetyl chloride in few ml of benzene was gradually added under efficient stirring, the reaction mixture was stirred at 18 °C for 1 h and was then evaporated *in vacuo*. The obtained solid was washed with water followed by petroleum ether 60—80 °C, dried and crystallized from dioxane.

Reaction of N-*Chloroacetylpyrazoline Derivative* ***8*** *with N–H and S–H Containing Heterocycles Using CTP System. General Procedure*: Compound **8** (0.05 mol) along with 0.05 mol of potassium carbonate in acetone (70 ml) was treated with 0.05 mol of morpholine, 2-mercaptopyrimidine, or 2-mercaptobenzothiazole, in presence of a catalytic amount of TBAB (0.001 mol). The reaction mixture was vigorously stirred at the appropriate temperature for a certain time (see Table 1). After filtration the mixture was dried ($MgSO_4$), evaporated *in vacuo* to give the desired products **9**, **10**, or **11**.

Absorption Intensity of Charge-transfer Transition between Ion Radicals in One-dimensional System of Crystalline Ion Radical Salts

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received August 16, 1982)

Synopsis. The charge-transfer interaction between ion radicals in crystalline ion radical salts was examined with one-dimensional Hubbard model. The intensity of charge-transfer absorption in crystal electronic spectra was estimated with both simple and complex ion radical salts. This approach was then applied to simple cation radical salt of Phenothiazine$^+ \cdot Br^-$ and complex cation radical salt of (Phenothiazine)$_2^+ \cdot Br^-$.

Much attention has been paid to the charge-transfer interaction in one-dimensional system of crystalline ion radical salts.[1-5] In simple ion radical salts where each ion radical carries one unpaired electron, the planar ion radical molecules are known to form, in themselves, a plane-to-plane stacking into one-dimensional column so as to make a large overlap between their half-occupied molecular orbitals. The electronic spectrum of crystalline simple salt differs distinctly from the monomer spectrum of the radical ion, but shows a charge-transfer transition between ion radicals in the low-energy region.[1-4] On the other hand, in crystalline complex ion radical salts, ion-radical and its parent neutral molecules are known to stack together to form regular one-dimensional column, where each molecular site is occupied by less-than-one unpaired electron. The electronic spectrum of complex salt is somewhat different from that of simple salt. Usually, the spectrum of complex salt shows two kinds of charge-transfer absorptions.[1,5] One arises from the electronic transition between ion radical and its parent neutral molecule, and the other, from the electronic transition between ion radicals. Although the latter transition is similar to the charge-transfer transition in simple salt, there may be a marked difference in the absorption intensity. In the present paper, we shall derive the absorption intensity of the charge-transfer transition between ion radicals in simple and complex ion radical salts and apply it to certain ion radical salts.

First, we consider the charge-transfer absorption in simple ion radical salts. In previous papers,[3] we applied the one-dimensional half-occupied Hubbard model to the segregated column of ion radicals. This model is a simplification of the real crystal and is expressed by two parameters I and T. $T(<0)$ is the transfer matrix element which describes hopping of an unpaired electron between adjacent molecular ion radical sites, while $I(>0)$ is the on-site Coulomb repulsion between two electrons with up and down spins on the same molecule. This model can well explain the reason why the absorption due to the charge-transfer transition between ion radicals is observable in simple ion radical salts. The previous paper described that the total intensity of the charge-transfer absorption per unit volume, A, was given by[3]

$$A = \frac{n\pi e^2}{4a} I(at)^2 \left(1 - \frac{3}{8}t^2 + \cdots\right), \quad (1)$$

where n is the number of one-dimensional columns per unit area perpendicular to the column axis, e is the electric charge, a is the lattice separation in one-dimensional column and $t=2T/I$. Hereafter, we only consider the case of $|t|\to 0$ limit and neglect the terms higher than t^4 in Eq. 1. Then, we obtain

$$A = \frac{n\pi e^2}{4a} I(at)^2 = \frac{n\pi e^2 a^2}{a} \cdot \frac{T^2}{I}. \quad (2)$$

Since a is the lattice separation, $(1/a)$ gives the number of sites per unit length in one-dimensional column. Therefore, (n/a) in Eq. 2 gives the number of sites (ion radical molecules) per unit volume in crystalline ion radical salt, being denoted by $N=n/a$. Then, A is expressed by $A=N\pi e^2 a^2 T^2/I$. Note that N is also equal to the number of unpaired electrons, because each ion radical carries one unpaired electron. The magnitude of A is rewritten by $A=N\pi e^2 a^2 J/2$, where $J=2T^2/I$ is an antiferromagnetic spin exchange parameter between adjacent unpaired electrons in one-dimensional column.[4]

It has been experimentally known that the charge-transfer interaction between ion radicals gives an antiferromagnetic Heisenberg chain of ion radical salt and that those ion radical salts which possess large J values show strong charge-transfer absorption intensities.[3] These experimental results can be well understood in terms of $A=N\pi e^2 a^2 J/2$. Here, A is proportional not only to the number of unpaired electrons, N, in the system but also to the magnitude of J. The latter can be explained in the following way. Since the charge-transfer interaction occurs mostly between adjacent ion radicals, the charge-transfer transition can only take place if the unpaired electrons of adjacent ion radicals in the ground state are antiparallel. In this case, the charge-transfer excited state corresponds to occupation of two electrons with up and down spins on the same site of ion radical molecule. If the unpaired electrons of adjacent ion radicals in the ground state are parallel, the charge-transfer transition is forbidden because of Pauli's exclusion principle. Thus, the absorption intensity of charge-transfer transition is closely related to the strength for aligning two unpaired electron spins of adjacent ion radicals antiparallel, and this strength corresponds to the magnitude of J.

On the basis of this discussion, we consider the charge-transfer transition between ion radicals in complex ion radical salts. As was mentioned, we assume a regular one-dimensional column composed of ion radical and its parent neutral molecule. Each mole-

cular site is occupied by less-than-one unpaired electron, the average number of unpaired electron per site being denoted by ρ, $(0 \leq \rho \leq 1)$. Then, we can apply one-dimensional less-than-half occupied Hubbard model to such a column. Here, we again use the parameters of I, T and a, which are common to those used in half-occupied Hubbard model. If we denote N as the total number of molecular sites (ion radicals + parent neutral molecules), the number of unpaired electrons is given by $N\rho$. As for the spin exchange interaction, Shiba and Klein-Seitz have shown that the magnetic susceptibility of a uniform stack of less-than-half occupied molecules ($\rho < 1$) is related to the magnetic susceptibility of a uniform stack of half-occupied molecules ($\rho = 1$) in simple ion radical salts.[6,7] If the value of I is much larger than that of $|T|$, the less-than-half occupied one-dimensional Hubbard model becomes equivalent to an antiferromagnetic Heisenberg chain with exchange interaction,

$$J = \frac{2T^2\rho}{I}\left(1 - \frac{\sin 2\pi\rho}{2\pi\rho}\right). \quad (3)$$

As was mentioned, the absorption intensity of charge-transfer transition between ion radicals is proportional not only to the number of unpaired electrons but also to the magnitude of J. If we apply this approach to the absorption intensity, A, of less-than-half occupied system of complex ion radical salts, we have $A \propto N\rho J = (2NT^2\rho^2/I)(1 - \sin 2\pi\rho/(2\pi\rho))$. As our model requires, if $\rho = 1$, A should become identical with $N\pi e^2a^2T^2/I$ in simple ion radical salts. This condition means that A of complex ion radical salts is given by $A = (N\pi e^2a^2T^2\rho^2/I)(1 - \sin 2\pi\rho/(2\pi\rho))$. In this equation, if $\rho \to 0$, that is, if average unpaired electron density approaches zero, the magnitude of A tends to zero, and we can observe no charge-transfer absorption in such a system. The value of A becomes greatest at $\rho = 1$, so that we obtain maximum intensity of the charge-transfer absorption in simple ion radical salt. On the other hand, if $|T| \to 0$, that is, if no charge-transfer interaction acts between adjacent ion radicals, the magnitude of A also tends to zero, and no charge-transfer absorption appears in such a case.

Let us apply this approach to certain crystalline ion radical salts. For example, we take a simple cation radical salt of Phenothiazine$^{+\cdot}$ Br^- and a complex cation radical salt of (Phenothiazine)$_2^{+\cdot}$ Br^-. The crystal electronic spectrum of the simple salt was measured by the present author,[2] while that of the complex salt, by Doi and Matsunaga.[5] The simple salt shows a strong low-energy band at 12900 cm^{-1}, which was assigned to the charge-transfer transition between phenothiazine cation radicals.[4] The one-dimensional half-occupied Hubbard model was applied to the system of the simple salt, and the parameter values of $I =$ 12900 cm^{-1} and $T = -2500$ cm^{-1} were estimated. On the other hand, the complex salt shows two charge-transfer absorptions at 5200 cm^{-1} and 12600 cm^{-1}.[5] The former was assigned to the transition from neutral phenothiazine to its cation radical, while the latter, to the transition between the cation radicals. We discuss only the latter absorption. Application of regular one-dimensional less-than-half occupied Hubbard model to the complex salt gave values of $I = 12900$ cm^{-1}, $T = -2500$ cm^{-1} and $\rho = 1/2$.[4] We denote the intensities of the charge-transfer absorptions per mol for the simple and complex salts as A(simple) and A(complex), respectively. The molecular sites per mol for the simple and complex salts are $N = N_A$ (Avogadro's number) and $N = 2N_A$, respectively. As for the lattice separation, we have no data on the crystal structures, and assume common value of a for both the salts. By putting those parameter values into the equation of A, the ratio of A(complex)/A(simple) was calculated as 1/2. Therefore, the intensity of the charge-transfer absorption of the complex salt at 12600 cm^{-1} appears to be half of that of the simple salt at 12900 cm^{-1}.

The Quenching of the OH ($^2\Sigma^+$) Produced in the H_2–O_2 Reaction by Collision with Ar

Yoshiaki HIDAKA,* Hiroyuki KAWANO, and Masao SUGA
Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho, Matsuyama 790

(Received November 14, 1981)

Synopsis. H_2–O_2 mixtures highly diluted with Ar were heated to temperatures in the range of 1200—1800 K behind reflected shock waves. The OH*-emission intensity was then measured to determine its quenching-rate constant upon collision with Ar; this constant was found to be about 1/164 of that in the case of H_2O.

The ultraviolet-band system OH ($^2\Sigma^+$—$^2\Pi$) is the most prominent feature in the emission spectra of flames sustained by the oxidation of hydrogenous compounds. A number of studies have been made to clarify the mechanism of OH* ($^2\Sigma^+$) formation in various systems. The collisional quenching of OH* has also been studied by several authors.[1–6] It has been reported that the quenching effect of H_2O is considerably larger than those of other species, while that of Ar is very small. The quenching cross-sections (Q) of Ar reported are very scattered ($Q<0.01$—$Q<2$Å^2),[1,6] even though scarcely cross-sections at high temperatures have been reported. In this report, we will describe OH* emission measurements in the H_2–O_2 reaction, measurements undertaken in order to determine the quenching-rate constant by Ar.

Experimental

The apparatus and procedures are essentially the same as have been described previously.[7–9] Emission was monitored with a Hamamatsu R-306 photomultiplier through an interference filter ($\lambda_{max}=305.5$ nm, half-width=15 nm) located behind a quartz window of the shock tube and through two slits with widths of 0.14 and 0.17 mm, separated by a cylindrical tube.

The computer calculation was carried out based on the Gear-type integration of the set of differential equations describing the chemical kinetics under constant-density conditions for reflected shock waves.

The compositions of the reaction mixtures were:

(A) 0.50% H_2, 0.25% O_2, 99.25% Ar,
(B) 1.00% H_2, 1.00% O_2, 98.00% Ar.

The H_2, O_2, and Ar, specified as 99.9%, 99.9%, and 99.99% pure respectively, were obtained from commercial cylinders and were used without further purification. The initial pressures of the mixtures were about 0.13 atm.

Results and Discussion

Two mixtures, (A) and (B), were heated to temperatures in the range of 1200—1800 K behind reflected shock waves. The typical OH* emission profiles observed with these two mixtures, (A) and (B), are shown in Fig. 1, which also shows the computed [OH*] profiles. Since one volt of the signal corresponds to 4.9×10^{-15} mol cm^{-3} of [OH*] under our experimental conditions,[9] the observed OH* emission intensity can readily be converted into the OH* concentration. In Fig. 2, a plot of $\log I_B/I_A$ *vs.* T is shown, together with the simulation results, where I_A and I_B are the maximum OH* emission intensities measured with Mixtures (A) and (B) respectively.

The OH* formed in the H_2–O_2 reaction may disappear by quenching:

$$OH^* + M = OH + M, \quad (1)$$

and by emission:

$$OH^* = OH + h\nu. \quad (2)$$

The reverse reaction (−1) is the thermal-excitation process, which contributes much less than the chemical excitation pathway at temperatures below 2000 K.[11] The reverse reaction (−2) is the self-absorption process, the extinction coefficient of which is small enough for to be disregarded.[11] Therefore, aside from quenching effects, the OH*-emission intensity observed below 2000 K may be assumed to be proportional to the chemiluminescent OH* concentration. For computations, the value of $k_2=1.4\times10^6$ s^{-1} [12] is used as the rate constant of Reaction (2).

Reaction (3) is adopted as the OH*-formation process attributable to a chemical excitation:[9]

$$H + O + M = OH^* + M, \quad (3)$$

whose rate constant is assumed to have the value of $k_3=1.2\times10^{13}\exp(-6940/RT)$ cm^6 mol^{-2} s^{-1}.[9] The maximum concentration ratios, $\alpha=[OH^*]_B/[OH^*]_A$, calculated for the two mixtures, (A) and (B), are independent of k_3, which is changed by a factor of 10. The value of α is also independent of the mechanism of the OH*-formation reaction (bimolecular or termolecular reaction). Computations are performed by using a mechanism including:

(a) 14 reactions and their rate constants for the H_2–O_2 reaction reported by Olson and Gardiner,[10] and

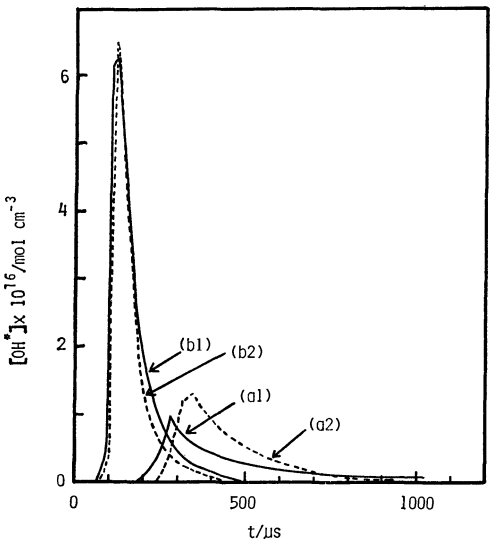

Fig. 1. Comparison of observed OH* emission profiles with [OH*] profiles computed by using $k_1(M=Ar)=5.2\times10^{10}T^{0.5}$ and $k_1(M=H_2O)=8.6\times10^{12}T^{0.5}$.
Profile (a1): observed at 1400 K with Mixture (A),
Profile (a2): computed at 1400 K for Mixture (A),
Profile (b1): observed at 1358 K with Mixture (B),
Profile (b2): computed at 1358 K for Mixture (B).

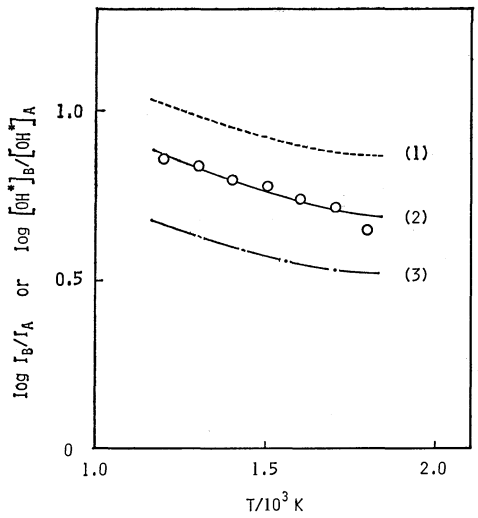

Fig. 2. Temperature dependence of the observed maximum OH* emission intensity ratio (open circle) and of the maximum OH* concentration ratio calculated for Mixtures (A) and (B).
Curve (1): $[OH^*]_B/[OH^*]_A$ calculated by using $k_1(M=Ar)=4.2\times10^{11}T^{0.5}$. Curve (2): $[OH^*]_B/[OH^*]_A$ calculated by using $k_1(M=Ar)=5.2\times10^{10}T^{0.5}$ and $k_1(M=H_2O)=8.6\times10^{12}T^{0.5}$. Curve (3): $[OH^*]_B/[OH^*]_A$ calculated by using $k_1(M=H_2O)=8.6\times10^{12}T^{0.5}$.

(b) 3 reactions (1)—(3) and their rate constants as described above.

In the present system, this relation holds: $I_B/I_A=[OH^*]_B/[OH^*]_A$, where I_A and I_B are the maximum OH*-emission intensities measured with Mixtures (A) and (B) respectively.

Fluorescence measurements (Reaction (1)) in the burnt gases in a lean acetylene-oxygen flame have revealed that the collision cross-sections for quenching by O_2, H_2O, and Ar are 7, 35, and below 2 Å^2 respectively.[1] Of these cross-sections, it is concluded that k_1 $(M=H_2O)=8.6\times10^{12}T^{0.5}$, k_1 $(M=O_2)=1.5\times10^{12}T^{0.5}$, and k_1 $(M=Ar)=4.2\times10^{11}T^{0.5}$ cm^3 mol^{-1} s^{-1} as the rate constants of Reaction (1). Since species such as H_2, O, OH, and H are also present in the reaction system, the quenching by them should also be taken into account. As k_1 $(M=H_2)$ at room temperature, values in the range of 3.6×10^{12}—7.6×10^{13} cm^3 mol^{-1} s^{-1} have been reviewed.[13] Since the quenching data against H, O, and OH as collision partners with OH* have not been reported, it is assumed that H_2, OH, H-atoms, and O-atoms have the same quenching rate as O_2. When we assume that k_1 $(M=Ar)=5.2\times10^{10}T^{0.5}$ cm^3 mol^{-1} s^{-1}, kinetic analysis under our experimental conditions shows that the Ar gas plays a dominant role for the OH* quenching, and that the quenching by O_2, H_2, OH, H, and O is negligible in comparison with those by H_2O and Ar (see Ref. 9). Hence, the quenching reactions by O_2, H_2, OH, H, and O were disregarded in the final computations. When M in Reaction (1) is assumed to be H_2O, the calculated value of α is always smaller than that observed. When M is Ar, on the other hand, the value of α is always larger than that observed, as may be seen in Fig. 2. By trial and error, it has been found that a curve calculated assuming that k_1 $(M=H_2O)/k_1$ $(M=Ar)=164$ fits the experimental data best, as shown in Fig. 2. Consequently, the collision cross-section ratio, $Q(H_2O)/Q(Ar)$, is 140. When the quenching-rate constant of H_2O is assumed to be $8.6\times10^{12}T^{0.5}$ cm^3 mol^{-1} s^{-1} (Q=35 Å^2),[1] that by Ar is $5.2\times10^{10}T^{0.5}$ cm^3 mol^{-1} s^{-1} (Q=0.25 Å^2). In Fig. 1, the typical emission profiles observed in the (A) and (B) mixtures are compared with the [OH*] profiles computed. The maxima of the calculated [OH*] are slightly larger than those observed in both mixtures, while the maxima computed for some runs were found to be slightly smaller than the observed ones. Consequently, the profiles calculated with the expression $k_1=5.2\times10^{10}T^{0.5}$ (M=Ar) are concluded to fit the experimental results best.

Carrington[1] has reported that the quenching cross-section of Ar over the temperature range of 850—1500 K is less than 2 Å^2, which corresponds to k_1 $(M=Ar)<1.2\times10^{13}$ cm^3 mol^{-1} s^{-1}.[13] This upper-limit value is much larger than values at room temperature[13] and is consistent with our observation.

The quenching by inert monoatomic gases is generally accepted to be inefficient compared with that by bi- or triatomic gas molecules. If the smallest value recommended by Schofield[13] is assumed at room temperature, our observation of the larger value at high temperatures must lead to the conclusion that $k_1(M=Ar)$ is strongly dependent on the temperature. Assuming that a large kinetic energy of OH*+Ar collision is required to reach a crossing point of the potential curves of OH*+Ar and OH+Ar, $k_1(M=Ar)$ increases at a higher temperature. However, no significant temperature-dependence of k_1 could be found under our temperature conditions (1200—1800 K). Such independence of $k_1(M=Ar)$ conflicts with the quenching mechanism described above. In order to solve this difficulty, an experiment for the reliable determination of $k_1(M=Ar)$ is desired over a wide temperature range from room temperature to several thousand K.

Hydrogen Evolution from Alkaline Formaldehyde Solution

Hiroshi Okamoto,* Masayuki Katsumoto, and Tetsuichi Kudo
Central Research Laboratory, Hitachi Ltd., 1-280, Higashi-Koigakubo, Kokubunji, Tokyo 185
(Received May 10, 1982)

Synopsis. Hydrogen is evolved from an alkaline solution of formaldehyde in the presence of a tungsten carbide catalyst at room temperature under atmospheric pressure. Neither platinum nor palladium shows any catalytic activity to this reaction. The hydrogen evolution competes with the Cannizzaro reaction.

Much attention has been paid to hydrogen as a fuel of a post-petroleum clean energy system. If hydrogen could be made available in desired quantities without great effort or equipment, this energy system would become more feasible. Formaldehyde in an alkaline solution has been found to yield hydrogen at room temperature under atmospheric pressure when tungsten carbide (WC) is used as a catalyst. This new type of reaction might satisfy some of the above requirements. Moreover, a hydrogen energy system including formaldehyde is related to an efficient utilization of coal since formaldehyde is produced from coal. The present note describes and discusses experimental results of a preliminary investigation on the new reaction.

When WC (0.5 g) was added to a formaldehyde (1 mol dm^{-3}) solution containing 2 mol dm^{-3} NaOH at around room temperature under atmospheric pressure, a gas was evolved after an induction period of about 1 min as shown in Fig. 1. The evolved gas was identified with pure hydrogen gas by gas chromatography (with molecular sieves 5A column and TCD). As Fig. 1 shows, the hydrogen evolution rate decreases with increasing reaction time. This tendency is more predominant at higher reaction temperatures. The hydrogen evolution rate calculated from the amount of hydrogen evolved for 5 min after the beginning of the evolution was greater for the higher temperature. An activation energy estimated was about 36 kJ mol^{-1}.

No change was observed in the X-ray diffraction of WC after the reaction, indicating that it worked as a catalyst.

The relation between the hydrogen evolution rate and the hydroxide ion concentration under conditions where the initial formaldehyde concentration was 2 mol dm^{-3} and the reaction temperature was maintained at 20 °C, is shown in Fig. 2. The evolution rate increased linearly until the concentration was increased to 2 mol dm^{-3}. Above this value, the rate decreased slightly.

The dependence on the formaldehyde concentration of the evolution rate observed at 20 °C with the hydroxide ion concentration of 2 mol dm^{-3}, is shown in Fig. 3. The rate increased when the formaldehyde concentration was increased up to 2 mol md^{-3}. However, further increases in the concentration decreased the rate.

No hydrogen was evolved when benzaldehyde, acetaldehyde, paraldehyde, acetone, methanol, or formic acid was used in place of formaldehyde. No hydrogen evolution was observed either in an acidic formaldehyde solution. Thus, the hydrogen evolution must occur only in an alkaline formaldehyde solution. Therefore, the conceivable reaction is written as

$$HCHO + OH^- = HCOO^- + H_2. \quad (1)$$

The total amount of hydrogen evolved from a solution containing 26 mmol formaldehyde and 26 mmol NaOH was 10 mmol. If only reaction 1 proceeded

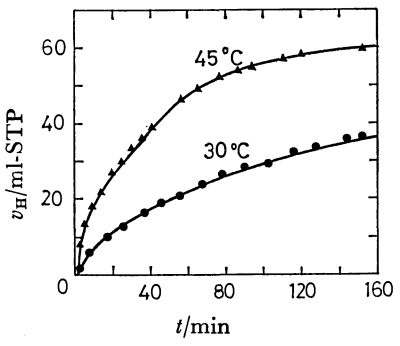

Fig. 1. Hydrogen evolution volume *vs.* time under at mospheric pressure.
v_H: Hydrogen evolution volume in ml-STP, formaldehyde concentration: 1 mol dm^{-3}, hydroxide ion concentration: 2 mol dm^{-3}, WC weight: 0.5 g.

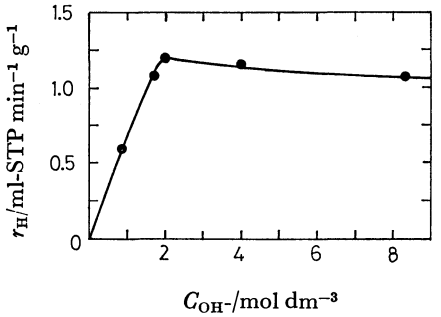

Fig. 2. Dependence of hydrogen evolution rate on hydroxide ion concentration at 20 °C.
r_H: Hydrogen evolution rate measured at 5 min after the beginning of the evolution, formaldehyde concentration: 2 mol dm^{-3}.

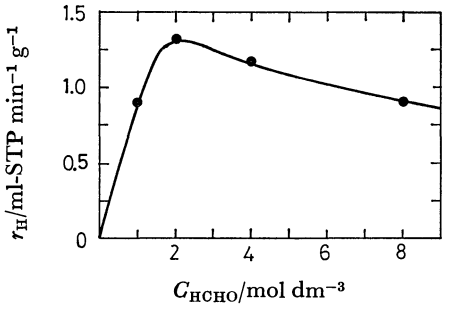

Fig. 3. Dependence of hydrogen evolution rate on formaldehyde concentration at 20 °C.
Hydroxide ion concentration: 2 mol dm^{-3}.

in the reaction solution, the total hydrogen amount must have been 26 mmol. This discrepancy can be explained as follows. In the reaction system, the Cannizzaro reaction

$$2HCHO + OH^- = CH_3OH + HCOO^- \quad (2)$$

must compete with the hydrogen evolution. Thus, the total amount of hydrogen is smaller than that calculated on the basis of only reaction 1.

Sodium formate and methanol were found except for formaldehyde in the reaction solution by Raman spectroscopy. This is consistent with reactions 1 and 2.

The standard Gibbs energy difference of reaction 1 is $-47.7\ kJ\ mol^{-1}$.[1] Therefore, the forward reaction in reaction 1 is thermodynamically easy to proceed. With an acidic formaldehyde or alkaline methanol solution, the standard free energy difference is positive or slightly negative as follows:[1]

$$HCHO + H_2O = HCOOH + H_2$$
$$\Delta G^0 = 10.9\ kJ\ mol^{-1}, \quad (3)$$

$$CH_3OH = HCHO + H_2 \quad \Delta G^0 = 44.9\ kJ\ mol^{-1}, \quad (4)$$

$$CH_3OH + OH^- = HCOO^- + 2H_2$$
$$\Delta G^0 = -0.7\ kJ\ mol^{-1}. \quad (5)$$

Thus, the forward reactions in reactions 3—5 are thermodynamically almost difficult to proceed. By comparing the free energy difference in reaction 1 with that for reaction 3, the motive force for hydrogen evolution is considered to be the heat of neutralization

$$OH^- + HCOOH = HCOO^- + H_2O$$
$$\Delta G^0 = -58.6\ kJ\ mol^{-1}. \quad (6)$$

To find catalysts effective to the hydrogen evolution other than WC, carbides, nitrides, borides, oxides, sulfides, and transition metals of all the groups from III B to VIII B were tested at room temperature with an aqueous solution of 2 mol dm^{-3} formaldehyde concentration and 1.6 mol dm^{-3} hydroxide ion concentration. It was found that Mo_2C, W_2C, (Mo,W)C, Mo_2N, W_2B_5, WB_4, WB_2, Mo, and W were active. It can be pointed out that only the compounds of the VI B group elements have catalytic activities. Among them, WC was most active. It was interesting that platinum black and palladium black were inactive. WC often behaves as a platinum-like catalyst[2,3] due to its similar catalytic activity and electronic structure. However, WC catalyzes the reaction that platinum does not. Since WC is known to be a catalyst for the anodic oxidation of hydrogen,[4] ammonia synthesis,[5] and other reactions,[6] it is a very promising material to replace precious metal catalysts.

Dependence of Electric Polarizability of Rodlike DNA in Aqueous Solutions on Ionic Strength as Studied by Electric Dichroism and Birefringence. A Comparison between Experimental and Theoretical Results

Kiwamu YAMAOKA,* Koichiro MATSUDA, and Kaoru TAKARADA
Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received July 23, 1982)

Synopsis. Orientation of a sonicated DNA fragment in aqueous solutions containing sodium chloride (0.2—4 mmol/dm^3) by an external electric field was discussed in terms of counterion-induced electric moments by using the electric dichroism and birefringence data experimentally determined at limiting low field strengths.

Ample evidence indicates that highly charged DNA in aqueous solutions can be oriented by an external electric field.[1-3] In previous studies of electric dichroism (ED) and electric birefringence (EB), we have shown that the electric field orientation of sonicated DNA fragments (sDNA) obeys the Kerr law in the low field strength region under diverse conditions.[4,5] This result is in good agreement with recent reports by other workers.[6-10] The orientation of sDNA has been attributed to the interaction between the ionized site and counterion and the applied field. Detailed analyses have shown, however, that the polyion behaves as if it possesses both a permanent dipole moment and a covalent polarizability anisotropy.[4-7] Thus, this electric dipole has been termed either the pseudo-[4,5,9] or quasi-permanent dipole[11] or the saturated induced dipole.[12] The electric moment was recently shown to result from the fast polarization of the "bound" counterion.[4,7] For the understanding of the polyelectrolyte property of DNA, its field-orientation mechanism should be fully clarified. Since the counterion-induced dipole is affected by the added simple ions, we examined the dependence of the steady-state ED and EB at limiting low electric field on the ionic strength (thus, saturation of the counterion-induced dipole moment could be avoided). We also present a critical comparison of observed results with recent theoretical developments.[13-15]

Experimental

Materials and Measurements. The sDNA sample is the same as before.[5] In order to adjust the counterion (Na^+) concentration, the sDNA solution was dialyzed at 4 °C for at least 48 hours against distilled water containing sodium chloride at the desired level. Both ED and EB were measured at 7 °C.[5] The observed data were expressed with the parallel (specific) dichroism, $\Delta A_\parallel/A$ at 260 nm, and the specific birefringence, $\Delta n/C$ at 535 nm.[5] At limiting low field strengths, E, the following expression generally holds for charged polyions:

$$\frac{(\Delta A_\parallel/AE^2)_{E^2\to 0}}{(\Delta A_\parallel/A)_s} = \frac{(\Delta n/CE^2)_{E^2\to 0}}{(\Delta n/C)_s} = \frac{1}{15}\left[\left(\frac{\mu_3}{kT}\right)^2 + \frac{\Delta\alpha^t}{kT}\right], \quad (1)$$

where $(\Delta A_\parallel/A)_s$ and $(\Delta n/C)_s$ are the corresponding quantities at limiting high fields, μ_3 is the permanent dipole moment along the symmetry axis, and $\Delta\alpha^t$ is the polarizability anisotropy, which is generally the sum of the covalent (*i.e.*, electronic and atomic) and ionic polarizabilities ($\Delta\alpha^t = \Delta\alpha^c + \Delta\alpha^i$).

Results and Discussion

Dependence of ED and EB on Added Sodium Ions. In the added-salt concentration range of 0.2—4 mM (1 M=1 mol/dm^3), values of $\Delta A_\parallel/A$ and $\Delta n/C$ for the rodlike sDNA sample are proportional to the second power of electric field in the limiting low field region. The results are given in Table 1. The linear portions in the plots of these values against E^2 become narrower and the magnitudes are larger at lower concentrations of added salt (*cf.* Figs. 1 and 2 of Ref. 5). Values of $(\Delta A_\parallel/A)_s$ and $(\Delta n/C)_s$ are nearly independent of the added-salt concentration,[5] *i.e.*, the optical part in Eq. 1 is constant. Therefore, the electric parameter should be responsible for the variation of the observed limiting-low-field quantities with salt concentration. Since the double-helical DNA possesses no permanent dipole moment under ordinary conditions ($\mu_3=0$ in Eq. 1), the variation of $(\Delta A_\parallel/AE^2)_{E^2\to 0}$ and $(\Delta n/CE^2)_{E^2\to 0}$ should result from the change in the electric polarizability $\Delta\alpha^t$, in particular the ionic polarizability $\Delta\alpha^i$. Values of $\Delta\alpha^t$ decrease with the increase in added-salt concentration, and are given in Table 1. Their magnitude is of the order of 10^{-16} cm^3, in good agreement with reported values.[5-7,9,12]

In Fig. 1, values of $(\Delta A_\parallel/AE^2)_{E^2\to 0}$ and $(\Delta n/CE^2)_{E^2\to 0}$ are plotted against the total concentration of sodium ions, $[Na^+]_t$, *i.e.*, the sum of those ions from the added sodium chloride and from the counterions of DNA-phosphates. In Fig. 1, values of $(\Delta A_\parallel/AE^2)_{E^2\to 0}$ at

Table 1. Values of $(\Delta A_\parallel/AE^2)_{E^2\to 0}$ at 260 nm and $(\Delta n/CE^2)_{E^2\to 0}$ at 535 nm of a sonicated DNA sample at various concentrations of added sodium chloride [NaCl] at 7 °C [a]

[NaCl] / mM	$\left(\frac{\Delta A_\parallel}{AE^2}\right)_{E^2\to 0}\times 10^2$ / (kV/cm)$^{-2}$	$\left(\frac{\Delta n}{CE^2}\right)_{E^2\to 0}\times 10^3$ / M^{-1}(kV/cm)$^{-2}$	$\Delta\alpha^t\times 10^{16}$ / cm^3 [b]

4.0	−0.23	—	2.02[d]

a) The concentrations of DNA, C, in nucleotide units are 0.17—0.18 mM. b) 1 cm^3 = 1.113 × 10^{-16} F m^2. c) Values in the parentheses are obtained with the limiting low-field strength birefringence. d) Value of $(\Delta A_\parallel/A)_s$ is −0.593.

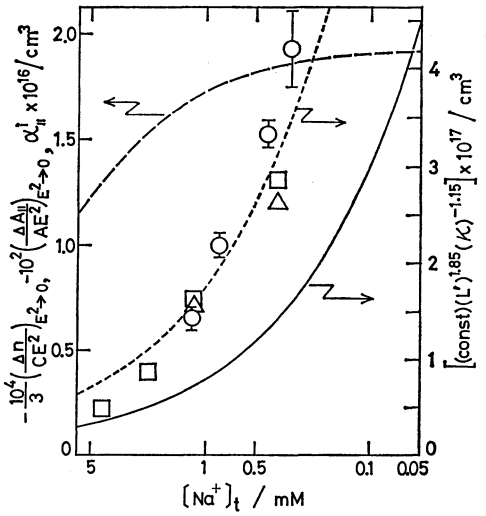

Fig. 1. Dependence of the measured limiting low-field dichroism, birefringence, and the theoretical electric polarizabilities of rodlike sDNA solutions on the total concentration of sodium ions, $[Na^+]_t$. Experimental values: $(\Delta A_\parallel/AE^2)_{E^2\to 0}$ (□) in this work and (○) cited in Ref. 9, and $(\Delta n/CE^2)_{E^2\to 0}$ (△) in (kV/cm)$^{-2}$. Theoretical curves: Fixman's polarizability (——) was calculated from Eq. 2 with the parameters: $q_1 = -q_2 = 1$ and $\gamma^2 = 28.52 \times 10^{12} C_1$, where C_1 (mol/dm^3) is the bulk concentration of Na^+. Rau and Charney's polarizabilities (——), for which the (const) is unity, and (----), for which the (const) is 2.2, were calculated from Eq. 3. Dielectric constant is 80 and temperature is 280 K. The $[Na^+]_t$ includes the concentration of DNA in nucleotide units.

270 nm for a nearly identical sDNA sample are also plotted. They were calculated from published values of $(\Delta A_\parallel/A)$ (*cf.* Fig. 1 of Ref. 9) but they agree well with the present data, which were obtained with an entirely different apparatus.

Comparison between Experimental and Theoretical Results. Recently, Manning derived an expression for the parallel component ionic polarizability $\alpha^1_\parallel$ on the basis of the ion condensation model.[16] The slight dependence of this theoretical $\alpha^1_\parallel$ on ionic strength is, however, in opposition to experimental results.[7,9,13] More recently, Fixman proposed an expression for electric polarizability (with his own notations):[14]

$$\alpha^1_\parallel \equiv \frac{\mu}{E_0} = \frac{2q_1KDL}{(q_1-q_2)\gamma^2}\left[1-\frac{\tanh(\gamma L)}{\gamma L}\right], \qquad (2)$$

where $K=[2\ln(4L/a)-(14/3)]^{-1}$. Approximating the B-DNA form for the present sDNA sample regardless of salt concentrations (a=13 Å, L=319.6 Å),[5] we have calculated the polarizability in Eq. 2 as a function of concentrations of added sodium chloride. The result is shown by a dashed curve in Fig. 1. This curve *decreases* monotonously but in a *convex* fashion with increasing salt concentrations in the range< 6 mM.

Another theoretical advance has been made lately by Rau and Charney.[15] By calculating the electric moment for an electric field-induced polarization of a Debye-Hückel ion atmosphere, they show that the polarizability along a charged rod, $\alpha^1_\parallel$, is approximately proportional to the half length of the rod, L'(=319.6 Å), and to the Debye-Hückel shielding parameter κ (with their own symbolism):[15]

$$\alpha^1_\parallel = (\mathrm{const})(L')^{1.85}(\kappa)^{-1.15}. \qquad (3)$$

As a function of the ionic strength of NaCl, we have calculated the quantity $(L')^{1.85}(\kappa)^{-1.15}$ and plotted it in Fig. 1 (solid curve). This curve, too, *decreases* monotonously and in a *concave* fashion with the increase in the total sodium concentration. The curve is nearly parallel to experimental values of the limiting low-field dichroism and birefringence. To visualize this trend quantitatively, the solid curve was shifted upward by multiplying a factor of 2.2 (shown by the dotted curve); the agreement with the experimental points is good.

In summary, the effect of ionic strength on observed limiting low-field dichroism or birefringence now appears to be explicable reasonably well by the Debye-Hückel ion atmosphere polarization concept. Another test for the Fixman *vs.* the Rau and Charney model may reside on measurements of ED, EB, or dielectric constants as a function of temperature, since the polarizability in Eq. 2 is temperature-independent but that in Eq. 3 is inversely proportional to temperature. A remaining question on the counterion-induced dipole moment is to assess the contribution from the condensed or "bound" counterions.[8,13] This contribution would be most prominent, if it exists, in the DNA solution in which no excessive salt ions are present. Values of, *e.g.*, $(\Delta A_\parallel/AE^2)_{E^2\to 0}$ may show an asymptotic trend in salt-free solutions. Measurements of ED or EB of rodlike sDNA under such conditions are highly desirable.

Intensity Enhancement Caused by Complex Formation between Pyrene and Alcohols

Akira NAKAJIMA

Department of Electronic Engineering, Faculty of Engineering, Saitama Institute of Technology, Okabe, Saitama 369-02

(Received July 31, 1982)

Synopsis. The enhancement of the weak 0-0 band in the absorption spectrum of pyrene has been observed using various mixtures of cyclohexane and alcohols. The relations of the absorption coefficients with the alcohol concentrations have been studied on the assumption of 1:1 complex formation between pyrene and alcohols. The association constants for the hydrogen-bonded complexes have been estimated to be of a reasonable order of magnitude (0.1—0.4 mol^{-1} dm^3).

Growing interest has been shown in the investigations of the microenvironments in micellar and membraneous systems. For spectroscopic studies of the structures and mechanisms in these systems a variety of molecular probes[1] have been employed with appreciable success. It has been demonstrated[2-4] that pyrene (and other related aromatic hydrocarbons) can also be used as such a probe. It may be said however that pyrene has a unique character in that one can utilize not only the overall intensities of its emission and absorption spectra but also the variations of their vibronic structures in various media.

The enhancement of weakly allowed vibronic bands in the absorption and fluorescence spectra of pyrene in polar solvents was first studied by this author[5] and a number of investigations[3,6-9] have so far been undertaken for the purpose of elucidation and application of this phenomenon.

Recently Lianos and Georghiou[10] have studied the systems of pyrene and alcohols in nonpolar solutions by infrared spectroscopy and fluorescence decay analysis and shown that the intensity enhancement arises from the formation of stoichiometric complexes. As reported previously, the present author[11,12] has observed that the weak 0-0 band of pyrene in a nonpolar solvent can gain considerable intensity on addition of a polar solvent and indicated that the large initial increase can be explained by the complex formation between pyrene and polar molecules.

In this work, the enhancement of the 0-0 band has been studied employing various mixtures of nonpolar and polar solvents; cyclohexane was used as a nonpolar component, while 2-methyl-2-propanol, ethanol, and phenol were adopted as polar components. An attempt has been made to interpret the enhancement in terms of 1:1 complex formation between pyrene and the alcohols or phenol and to estimate the association constants.

Experimental

GR grade pyrene obtained from Wako Pure Chemical Industries was recrystallized repeatedly from ethanol. Checking by the absorption spectra indicated no impurity absorption present in the spectral range studied. Spectrograde cyclohexane from Kanto Chemical Co. was used without further purification. Ethanol and 2-methyl-2-propanol were purified by fractional distillations after drying. Phenol was recrystallized many times from the melt.

The solutions were carefully prepared by the volumetric method from various mixtures of cyclohexane and alcohols or phenol with a constant concentration of pyrene (2.99×10^{-3} mol dm^{-3}).

The absorption spectra were recorded at room temperature on a Shimadzu 210A double-beam spectrophotometer, with a slit width for 0.5 nm resolution and at a scan speed of 50 nm/min. In the lowest electronic transition of pyrene the absorption coefficient for the 0-0 band (around 371 nm), which has been found to be most sensitive to the solvent polarity, has been measured by varying the alcohol concentrations. The variation of the band width in different solvents has been observed to be relatively small (less than 3%), of which no account has been taken.

The preparations of the solutions and the measurements were repeated several times, especially at lower alcohol concentrations, followed by averaging the measured values to compensate volumetric and instrumental errors.

Results and Discussion

The observed relations between the absorption coefficients for the 0-0 band (ε) and the concentrations of alcohols or phenol (C_A) are shown in Fig. 1. From the figure it should be noticed that relatively large increases in ε can be observed at lower C_A and changes in the higher C_A region are appreciable. In pure cyclohexane ε is small with a value of 135.0 (mol^{-1} dm^3 cm^{-1}), while its value increases to 226.0 in 2-methyl-2-propanol and 276.3 in ethanol. The general tendency of the increase seems to be explained in terms of the solvent polarity and has been considered on the basis of the bulk properties of solvents.[5] However, recent studies[10-12] have indicated that the formation of complexes occurs considerably. In particular, Lianos and Georghiou[9] have concluded that the enhancement is the result of the reduction of the molecular symmetry caused by the 1:1 complex formation between pyrene and alcohols.

Accordingly, it may be assumed also in this study that the intensity enhancement is primarily induced by the formation of weak 1:1 complexes between pyrene and alcohols or phenol. Thus, an equilibrium is postulated among a pyrene molecule P, an alcohol or phenol molecule A, and a complex PA as follows

$$P + A \overset{K}{\rightleftharpoons} PA.$$

Here the association constant K is given by

$$K = \frac{[PA]}{[P][A]}$$

with the additional conditions:

$$[P] + [PA] = C_P$$
$$[A] + [PA] = C_A$$

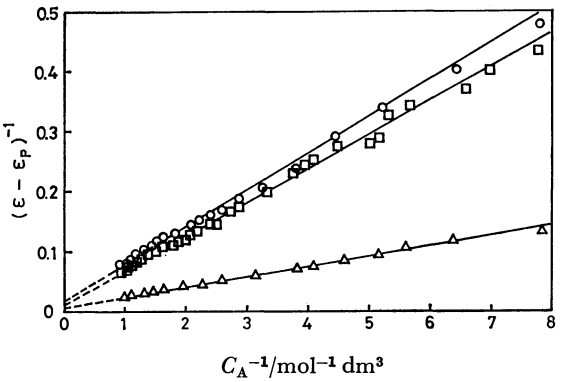

Fig. 2. Plots of $(\varepsilon-\varepsilon_P)^{-1}$ *vs.* C_A^{-1} for 2-methyl-2-propanol–cyclohexane (○), ethanol–cyclohexane (□), and phenol–cyclohexane (△) solutions. ε_P is taken as the absorption coefficient in pure cyclohexane.

where C_P and C_A are the total concentrations of pyrene and alcohol or phenol, respectively.

The absorbance measured at the wavelength for the 0-0 band can be expressed as

$$A = \varepsilon_P l\,[P] + \varepsilon_C l\,[PA],$$

where ε_P and ε_C denote the absorption coefficients for free pyrene and the complex, respectively, and l is the optical path length (1 cm).

Provided that C_A is much larger than C_P ($=2.99\times 10^{-3}$ mol dm^{-3}), [A] is approximated to C_A, and the following relation[12] can be derived between C_A and the apparent absorption coefficient $\varepsilon=A/C_Pl$:

$$\frac{1}{\varepsilon-\varepsilon_P} = \frac{1}{\varepsilon_C-\varepsilon_P} + \frac{1}{(\varepsilon_C-\varepsilon_P)KC_A}.$$

Thus, a plot of $1/(\varepsilon-\varepsilon_P)$ *vs.* $1/C_A$ should give a straight line, from the intercept and slope of which the values of ε_C and K can be determined.

Figure 2 shows such plots for the systems of pyrene in various alcohol- or phenol-cyclohexane mixtures. Because of the condition $C_A \gg C_P$ and much complicated interactions at higher C_A, the concentration range effective for plots should be considerably narrowed (roughly $0.1<C_A<1$). As shown in Fig. 2, fairly good linear relationships have been obtained, a fact which indicates that the stoichiometry corresponds to 1:1 complexation in the lower concentration region. From the values of the slopes and intercepts, the association constants K and the absorption coefficients ε_C have been estimated, as listed in Table 1. The values of K obtained are in good order-of-magnitude agreement with those ($\lesssim 1$ mol^{-1} dm^3) estimated by Lianos and Georghiou,[10] though more accurate determinations are difficult because of unavoidable experimental errors. Similar values have been obtained using aprotic polar solvents.[12]

It can be seen from Table 1 that the K and ε_C values bear no direct relation to the dielectric constants or dipole moments; they seem to be rather correlated with the acidities, which may imply that hydrogen-bonded complexes are formed between pyrene and phenol or alcohols.[10]

Thermodynamic Study on Solvent Extraction of Sodium and Potassium Picrates by Benzo-15-crown-5

Yasuyuki TAKEDA

Department of Chemistry, Faculty of Science, Chiba University, Yayoi-chō, Chiba 260

(Received August 20, 1982)

Synopsis. In order to obtain enthalpy and entropy changes for extraction of sodium and potassium picrates by benzo-15-crown-5 (B15C5) between benzene and water, the overall extraction equilibrium constants for the 1:1:1 complexes of B15C5 with the salts were determined at various temperatures. The enthalpy and entropy changes for both the systems are all large and negative.

For the evaluation of complexing ability of a crown ether for various metal ions, solvent extraction is a facile and useful method. Many overall extraction equilibrium constants for various crown ether–metal ion systems have been reported up to date. In some of these works,[1-4] the role of crown ether in the extraction process has been discussed in detail by analyzing the overall extraction equilibrium constant on the basis of constituent equilibria: the stability and extractability of crown ether–metal ion complex, and the distribution coefficient of crown ether itself. For further investigation on the role of crown ether in the extraction process, it is very important to obtain enthalpy and entropy changes for the extraction reaction of a crown ether with a metal ion. However, there is very little data on enthalpy and entropy changes.[5,6]

In the present study, in order to obtain enthalpy and entropy changes for the extraction of sodium and potassium picrates by benzo-15-crown-5 (B15C5) between benzene and water, the overall extraction equilibrium constants for the 1:1:1 complexes of B15C5 with the salts have been determined at various temperatures.

Experimental

The method of purification of B15C5 (Merck Japan Ltd.) has been described in a previous paper.[7] Concentrations of alkali metal hydroxides and picric acid solutions were determined by means of acid and basic titrations, respectively. Analytical-grade benzene was washed twice with distilled water. A benzene phase of B15C5 (1.9×10^{-4}—3.5×10^{-3} M; 1 M = 1 mol dm^{-3}), and an aqueous phase of the alkali metal hydroxide (4.6×10^{-3}—1.4×10^{-2} M) and picric acid ($(3.2—4.1)\times10^{-3}$ M) in a stoppered glass tube (30 ml) were shaken in a thermostated water bath for 40 min and centrifuged. The initial volume of each phase was 10 ml in all cases. Extractions were conducted at pH 11.1—11.8. The picrate in the benzene phase was back-extracted into 8 ml of 0.01 M NaOH aqueous solution, and the picrate concentration was determined at 356 nm by means of a Shimadzu UV-200 spectrophotometer ($\varepsilon=1.45\times10^{4}$ cm^{-1} M^{-1}). In control experiments, there was no detectable extraction in the absence of B15C5. Extractions for sodium and potassium picrates by B15C5 were conducted at 25, 28, 31, 34, and 37 ± 0.3 °C, and 19, 22, 25, 28, and 31 ± 0.3 °C, respectively.

Results

When an aqueous solution of alkali metal ion (M^+) and picrate ion (A^-) and a benzene solution of crown ether (L) are equilibrated, the equilibrium constants may be defined by

$$K_{ex} = [MLA]_o/[M^+][L]_o[A^-], \quad (1)$$

$$K_{D,L} = [L]_o/[L], \quad (2)$$

$$K_{ML} = [ML^+]/[M^+][L], \quad (3)$$

$$K_{ex'} = [MLA]_o/[ML^+][A^-], \quad (4)$$

where the subscript "o" and the lack of subscript designate the organic and aqueous phases, respectively. Thus, K_{ex} can be written as

$$K_{ex} = K_{ML}K_{ex'}K_{D,L}^{-1}. \quad (5)$$

The distribution ratio of the alkali metal may be represented by

$$D = [MLA]_o/([M^+]+[ML^+]). \quad (6)$$

In the case of $[M^+]\gg[ML^+]$, Eq. 6 becomes

$$D = K_{ex}[L]_o[A^-]. \quad (7)$$

$\mathrm{Log}(D/[A^-])$ *vs.* $\log[L]_o$ plots show a linear relationship with a slope of 1 in every case. This indicates that B15C5 forms a 1:1 complex with the alkali metal ion. The values of $[L]_o$ and $[A^-]$ in Eq. 7 were calculated by

$$[L]_o = [L]_t - [MLA]_o, \quad (8)$$

$$[A^-] = [HA]_t - [MLA]_o, \quad (9)$$

where the subscript "t" denotes the total concentration.

As can be seen from Fig. 1, the $\log K_{ex}$ *vs.* T^{-1} plots for NaA– and KA–B15C5 systems show a linear relationship. The enthalpy change ($\Delta H°$) and the

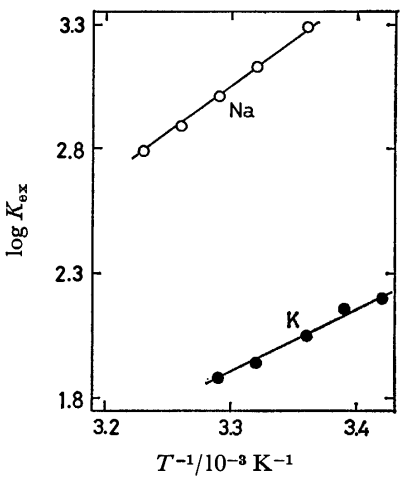

Fig. 1. $\log K_{ex}$ *vs.* T^{-1} plots for sodium picrate- and potassium picrate–B15C5 systems.

Table 1. Thermodynamic quantities

Temp/°C	$\log K_{ex}$	
	Na(B15C5)A	K(B15C5)A
19	—	2.26
22	—	2.16
25	3.29	2.05
28	3.13	1.94
31	3.01	1.88
34	2.89	—
37	2.79	—

	Na(B15C5)A	K(B15C5)A
$\Delta G°$/kJ mol^{-1} (at 25 °C)	−19	−12
$\Delta H°$/kJ mol^{-1}	−74	−50
$T\Delta S°$/kJ mol^{-1} (at 25 °C)	−55	−38

entropy change ($\Delta S°$) were calculated from these data by using the following equations: $\Delta G° = -RT\ln K_{ex}$ and $\Delta G° = \Delta H° - T\Delta S°$ where $\Delta G°$ denotes the free energy change. These thermodynamic quantities are listed in Table 1.

Discussion

It may be seen from Table 1 that overall extraction reactions for B15C5 are all exothermic and the $\Delta S°$ values are all negative. For both Na^+– and K^+–B15C5 systems, the very great $-\Delta H°$ value is canceled by the very large $-T\Delta S°$ value, resulting in the small $-\Delta G°$ value and the relatively low preference of Na^+ over K^+. A similar tendency as mentioned above is found in extractions for sodium and potassium picrates–dibenzo-18-crown-6 systems (benzene/water).[5] It is interesting that the $-\Delta H°$ and $-\Delta S°$ values of Na^+, which fits much more closely into the B15C5 cavity than K^+, are much greater than those of K^+.

The values of enthalpy ($\Delta H°_{ML}$) and entropy changes ($\Delta S°_{ML}$) for the complexation reaction of B15C5 with K^+ in H_2O are −9.75 kJ mol^{-1} and −26 J K^{-1} mol^{-1}, respectively,[8] both the $\Delta H°_{ML}/\Delta H°$ and $\Delta S°_{ML}/\Delta S°$ ratios being only 0.2. Thus, the contributions of $\Delta H°_{ML}$ and $\Delta S°_{ML}$ to $\Delta H°$ and $\Delta S°$ are small, respectively. Since the $K_{D,L}$ value scarcely varies (19—21) in the range 19—37 °C, the contributions of enthalpy and entropy changes of this process to $\Delta H°$ and $\Delta S°$ may be very small, respectively. It thus appears that, for the KA–B15C5 system, the magnitudes of $\Delta H°$ and $\Delta S°$ are determined primarily by those of enthalpy and entropy changes of the process related to Eq. 4, respectively.

The author wishes to thank Professor Shizuo Fujiwara, Chiba University, for his valuable discussion.

Wetting of Coal by Aqueous Surfactant Solutions

Kunio Esumi,* Kenjiro Meguro, and Hidemasa Honda

Department of Applied Chemistry and Institute of Colloid and Interface Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received September 3, 1982)

Synopsis. The rates of wetting of coals of various carbon content by aqueous anionic surfactant solutions were measured. It was found that the rates of wetting increased with increasing concentration of the anionic surfactant in solution and further, the addition of electrolyte significantly promoted the rates of wetting. The presence of the electrolyte on the surface of coal after wetting was confirmed by the zeta potential measurement.

Wettability of coal[1-3] has been investigated to understand mechanisms of coal flotation, coal dust suppression, and coal–oil mixture. Recently, a coal–water mixture has been receiving attention as a fuel source. Thus, extensive studies have been made of the nature of adsorption of surfactants[4] on coal to understand stability of coal–water mixture. Glanville and Wightman[5] have reported that rates of wetting of coal by aqueous surfactant solution are influenced by addition of dipositive metal ions. Acceleration of wettability of coal into aqueous solution is one of the factors necessary to prepare a stable coal–water mixture.

In this note, the wetting behavior of coals of various carbon content by aqueous anionic surfactant solution is discussed by measuring the wetting rates, the zeta potential of the coals and the surface tension of aqueous anionic surfactant solutions.

Experimental

Materials. The coals used in this study were Yallourn, Taiheiyo, Miike, and Hon-gay which were sieved between 60 and 100 mesh. Their pertinent properties have been described elsewhere.[4]

Sodium 1,2-bis(2-ethylhexyloxycarbonyl)ethanesulfonate (Aerosol OT), sodium 1,2-bis(2-methylpentyloxycarbonyl)ethanesulfonate(Aerosol MA), and sodium 1,2-bis[diamyl(mixture of 2-methylbutyl and 3-methylbutyl)oxycarbonyl] ethanesulfonate (Aerosol AY) were obtained from the American Cyanamid Co. They were used without further purification. The metal salts used were obtained as laboratory grade reagents.

The water used was purified by passing through Milli-Q Reagent-Grade Water Systems until its specific conductivity fell below $10^{-7}\,\Omega^{-1}\,cm^{-1}$.

Measurements. To estimate rates of wetting of coal, sink times were measured for 0.30 g of coal gently deposited on the surface of the aqueous surfactant solution. Tests were carried out in a room maintained at 25±2 °C. The time taken for the last trace of unwetted coal particles to break through the surface of the aqueous surfactant solution was measured with a stopwatch. The average value of four or five run was taken as the final sink time. The standard deviation was 15%. The rate of wetting of coal was evaluated as the surface area of coal wetted per second.

The zeta potential of coal particles after exposure to the aqueous surfactant solution was measured using a Pen Kem Laser 500 Zeta Potential. The surface tension of the solution was measured using a Wilhelmy-type tensiometer at 25 °C.

Results and Discussion

Figure 1 shows the rates of wetting of coals of various carbon content by the aqueous surfactant solutions. It is seen that the rates of wetting are increased with the concentration of the surfactant. Furthermore, it is noteworthy that the behavior of rates of wetting of coals of various carbon content by Aerosol OT is different from those by Aerosol MA and Aerosol AY. Although it is known that the rate of wetting is a function of surface tension of the solution,[6] the surface tensions of the three Aerosol surfactant solutions were almost the same at each cmc in this study. Here, each cmc was as follows: Aerosol OT, 2.76; Aerosol MA, 15; Aerosol AY, 34 mmol dm^{-3}. Therefore, the differences among the three surfactants might be explained by diffusion rates and orientation of surfactants at the coal surfaces rather than by a surface tension effect. The surfactants having short-chain hydrophobic groups, such as Aerosol MA and Aerosol AY, are generally[6] believed to have faster rates of diffusion to and orientation at coal surfaces than that with long-chain hydrophobic groups like Aerosol OT. Especially, such a difference in the rates of wetting is apparent on relatively high carbon content coals, such as Miike and Hon-gay.

Since addition of electrolyte to the aqueous surfactant solution would be expected to have a considerable effect on the wetting of coals, the effect of electrolyte on the rate of wetting of coals was examined. The results are depicted in Fig. 2. In Aerosol OT-electrolyte system, the addition of electrolyte to Aerosol OT promoted the rates of wetting of all the coals tried. In particular, the addition of strontium chloride gave the most effective result. Similar results were obtained for systems of Aerosol MA-electrolyte and Aerosol AY-electrolyte. The addition of a tripositive electrolyte, such as lanthanum nitrate, was not so effective on the rate of wetting of coals as that of

(a): Aerosol OT, (b): Aerosol MA, (c) Aerosol AY.

Table 1. The surface tensions of aqueous aerosol surfactant solutions with and without electrolyte

Sample(concn/mmol dm^{-3})	Surface tension / dyn cm^{-1} (at 25 °C)
Aerosol OT(0.69)	39.0
Aerosol OT(0.69)-$SrCl_2$(0.26)	25.5
Aerosol OT(0.69)-$La(NO_3)_3$(0.26)	26.5
Aerosol OT(0.69)-$ZnCl_2$(0.26)	27.6
Aerosol OT(0.69)-$CaCl_2$(0.26)	27.7
Aerosol OT(0.69)-$MgCl_2$(0.26)	28.0
Aerosol MA(7.5)	41.7
Aersol MA(7.5)-$La(NO_3)_3$(0.26)	31.4
Aerosol MA(7.5)-$SrCl_2$(0.26)	37.5
Aerosol AY(34)	32.6
Aerosol AY(34)-$La(NO_3)_3$(0.26)	28.0
Aerosol AY(34)-$SrCl_2$(0.26)	32.3

a dipositive electrolyte. The surface tensions of Aerosol surfactants with and without electrolyte are tabulated in Table 1. The addition of electrolyte, particularly strontium chloride, reduced the surface tension of Aerosol OT surfactant significantly. Thus, the electrolyte that decreased the surface tension of the surfactant solution increased its rate of wetting of coal. In Aerosol MA and Aerosol AY systems, the rates of wetting of coals were promoted by the addition of electrolyte, although the ratio of electrolyte to surfactant is different for each system.

Further, to elucidate the interaction of coal surfaces and the surfactant with and without the electrolyte, the zeta potentials of coal particles after their exposure to the solutions were measured. The results are shown in Fig. 3. The zeta potential of coal particles after the exposure to the Aerosol surfactant solution containing electrolyte was less negative than that in the Aerosol surfactant solution alone. This implies that dipositive or tripositive ions are present on the coal surface. Accordingly, it follows that the adsorption of dipositive or tripositive ions promotes the rate of wetting of coal by Aerosol surfactant solution.

Zeta Potentials of Metal Oxides Coated with Titanate Coupling Agents in Aqueous Solution

Kunio Esumi*, Toshio Suzuki, and Kenjiro Meguro

Department of Applied Chemistry and Institute of Colloid and Interface Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received October 19, 1982)

Synopsis. The zeta potentials of metal oxide surfaces coated with titanate coupling agents were measured as a function of pH in the suspensions. The treatment by titanium(IV) isopropoxide tris(2-methylheptadecanoate) on the metal oxides, such as iron oxide, titanium dioxide, and silica, provided lower zeta potential values over a wide pH range than those of untreated samples. On the other hand, the treatment of the samples by titanium(IV) tris[2-(2-aminoethylamino)ethoxide] isopropoxide rendered the surfaces more cationic. Further, it was found that the titanate coupling layer was almost removed from the surfaces after one day they were immersed in aqueous solution.

Silane coupling agents[1,2] for modifying many fillers have been used to improve the bonding between reinforcements and polymer matrix. Recently, as coupling agents, titanate coupling agents[3] have been attractive for chemical bridges between the interface of an inorganic substrate and the polymer. It is believed that titanate coupling agents form a monomolecular layer on the inorganic substrate providing polymer compatibility and a reduction in the water of hydration and air voids in the inorganic substrate. Accordingly, it seems important to elucidate the interaction between the surface of inorganic substrate treated with titanate coupling agents and aqueous solution.

For this purpose, in this work, the zeta potentials of inorganic substrates treated with titanate coupling agents were measured as a function of pH in aqueous solution.

Experimental

Materials. Two titanate coupling agents, such as titanium(IV) isopropoxide tris(2-methylheptadecanoate) and titanium(IV) tris[2-(2-aminoethylamino)ethoxide] isopropoxide, were kindly supplied by Ajinomoto Co., and were used without further purification. Metal oxides employed were titanium dioxide(rutile type), iron oxide, and silica supplied by Teikoku Chemicals, Titan Chemicals, and Nippon Aerosil Co, respectively.

Procedure. Coating of titanate coupling agents on metal oxide surfaces was carried out with about 3 wt% solution of titanate coupling agents in an organic solvent. For titanium(IV) isopropoxide tris(2-methylheptadecanoate), hexane was used as a solvent and 2-propanol for titanium(IV) tris[2-(2-aminoethylamino) ethoxide] isopropoxide. Then, the metal oxide was added and stirred into the titanate coupling agent solution for 20 min at room temperature. The metal oxide coated with the titanate coupling agent was collected and dried in an oven at 80 °C for 20 min.

Measurements of zeta potential for the metal oxides before and after their titanate coupling agent treatments were made using a Pen Kem Laser 500 Zeta Potential. The pH of the suspension was adjusted with HCl or NaOH.

Results and Discussion

When metal oxides are treated with titanate coupling agents consisting hydrophilic and hydrophobic groups, it is considered that the hydrophilic group of the coupling agent is oriented to the surface of metal oxide and as a result, the treated surface shows hydrophobicity due to exposure of hydrophobic group to outward.

The stability of untreated and titanate coupling agent treated metal oxide suspensions was compared visually in small beakers. The untreated metal oxides were readily dispersible in aqueous solution by gentle shaking, while the treated metal oxides were initially aggregated and floated on the surface of water. However, they dispersed when the suspensions were treated in an ultrasonic cleaning bath.

Figure 1 depicts zeta potentials of untreated and

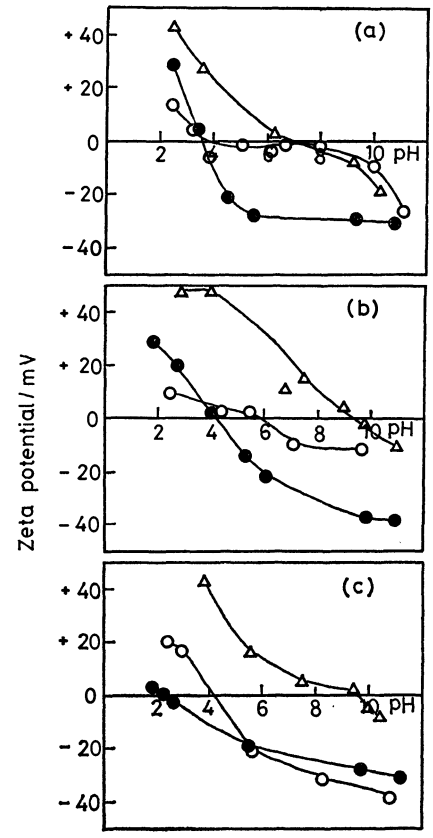

Fig. 1. Zeta potentials of untreated and titanate coupling agents treated metal oxides as a function of pH in suspensions: (a) iron oxide, (b) titanium dioxide (rutile type), (c) silica; (●) untreated, (○) titanium-(IV) isopropoxide tris(2-methylheptadecanoate), (△) titanium(IV) tris[2-(2-aminoethylamino)ethoxide]isopropoxide.

titanate coupling agents treated metal oxides as a function of pH in aqueous suspensions. It can be seen from Fig. 1 that the magnitude of zeta potentials for iron oxide and titanium dioxide treated with titanium-(IV) isopropoxide tris(2-methylheptadecanoate) was smaller in a pH range from 2 to 12 than that of untreated samples. In case of silica, the zeta potential treated with titanium(IV) isopropoxide tris(2-methylheptadecanoate) showed a similar behavior as a function of pH to that of untreated samples. This result may suggest that titanium(IV) isopropoxide tris(2-methylheptadecanoate) does not provide a strong coating on the surface of silica. On the other hand, the zeta potentials of all the samples treated with titanium-(IV) tris[2-(2-aminoethylamino)ethoxide] isopropoxide were much positively over a wide pH range than those of untreated samples. As a result, the zero point of charge (ZPC) of their treated samples shifted to much higher values. Similar behavior has been observed[4] in change of the zeta potential of metal oxides treated with aminosilane coupling agents.

It is also important to study the stability of deposited titanate coupling agent layers on the metal oxides in aqueous solution. For this purpose, the samples treated with two kinds of titanate coupling agents were allowed to stand for one day in aqueous solution at a some pH value and then the zeta potential was measured. The results are given in Fig. 2. The zeta potentials of metal oxides treated with the titanate coupling agents in the suspensions after one day became near the value of the untreated metal oxides as a function of pH in the suspensions. These results indicate that the titanate coupling agent layer was almost removed from the metal oxide surface after one day it was immersed in aqueous solution. Thus, it is suggested that the attachment of titanate coupling agent layer on the surface of metal oxide is not strong in aqueous solution. On the other hand, it has been reported[4] that the zeta potentials of iron oxide, titanium dioxide(rutile type), and silica treated with aminosilane coupling agents were not significantly changed even after one day storage in aqueous solution at a some pH value.

Thus, zeta potential measurement is a useful method to elucidate surface properties of metal oxides treated with titanate coupling agents.

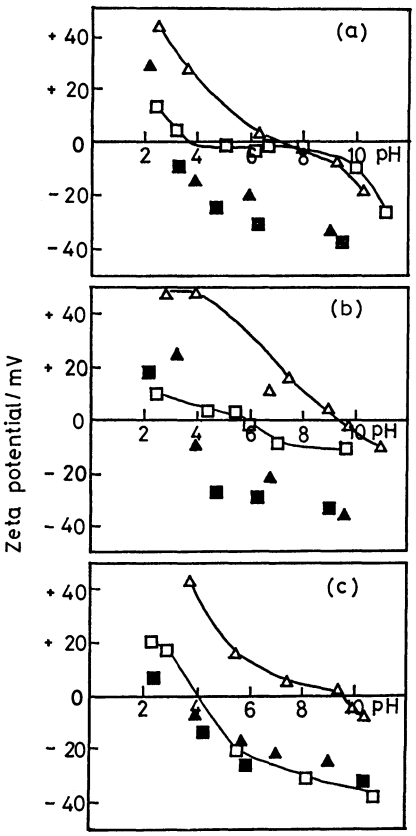

Fig. 2. Effect of storage on zeta potential of metal oxides treated with titanate coupling agents as a function of pH in suspensions: (a) iron oxide, (b) titanium dioxide(rutile type), (c) silica; (□) titanium(IV) isopropoxide tris(2-methylheptadecanoate), (△) titanium(IV) tris[2-(2-aminoethylamino)ethoxide]isopropoxide. Open mark refers to immediate measurement and closed mark to measurement after one day.

Laser Stark Spectroscopy of AsH_3 Using 9.4 and 10.6 μm CO_2 Laser

Kuniaki NAKAGAWA,† Yoshifumi UEDA, and Kozo KUCHITSU*

Department of Chemistry and Department of Physics, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received October 27, 1982)

Synopsis. Perturbation-allowed transitions of the ν_2 and ν_4 bands of AsH_3 were observed. About 100 Stark components were assigned to six $\Delta(k-l)=0$, six $\Delta(k-l)=\pm3$, and three $\Delta(k-l)=\pm6$ transitions. The Stark patterns and hyperfine splittings were used for confirming the assignment.

Since AsH_3 is a nearly spherical top, the rotational energy levels with various k values for a given J value are very close to one another. This near degeneracy increases the importance of various interactions which are usually insignificant, and it enables observation of the transitions that follow the selection rule, $\Delta(k-l)=\pm3n$ $(n=1,2,\cdots)$. The $\Delta(k-l)=\pm3$ transitions have been observed in the rotational spectrum of AsH_3 in the vibrational ground state.[1-3] In the vibrationally excited states, accidental degeneracies of rotation-vibration levels of the same rovibrational symmetry are also caused by the first-order Coriolis effect and possibly by the near degeneracy of vibrational levels. Transitions with $\Delta(k-l)=\pm3$ in the ν_1 and ν_3 bands of AsH_3 have thus been observed by infrared spectroscopy.[4] Recently, Scappini and Oka[5] observed and assigned the $\Delta(k-l)=\pm3$ transitions in the ν_2 and ν_4 bands by infrared-radiofrequency double resonance. The ν_2 and ν_4 bands are much more complicated than the ν_1 and ν_3 bands by the strong Coriolis interaction between them and are difficult to be assigned definitely. However, they assigned the transitions on the basis of the observed hyperfine patterns.

In the present note, laser Stark spectroscopy was used to observe and assign the $\Delta(k-l)=\pm3n$ transitions in the ν_2 and ν_4 bands. The present assignment has been confirmed by well-resolved Stark splitting patterns. The sensitivity of the spectrometer[6] was such that a number of weak forbidden transitions became detectable.

The Stark spectra were observed up to the field strength of 300 esu (90 kV/cm) with 9.4 and 10.6 μm band CO_2 laser following the $\Delta m_J=0$ and ±1 selection rules. About 1000 Stark components were observed, and about 100 components were assigned to those of 15 transitions. The assigned transitions are listed in Table 1.

The Stark shift for a certain level, J, k, m_J, of AsH_3 is mainly caused by the first-order effect. The first-order Stark shift, $\Delta\nu$, of the J', k', $m_J'\leftarrow J''$, k'', m_J'' transition frequency is given by

$$\Delta\nu = -(\varepsilon/h)[\mu' k' m_J'/J'(J'+1) - \mu'' k'' m_J''/J''(J''+1)], \quad (1)$$

where μ is the electric dipole moment and ε is the applied electric field. The relative signs of k', m_J', k'', and m_J'' are especially important for the assignment of the $\Delta(k-l)\neq0$ transitions. For simple designation of their relative signs, quantum numbers K' for $|k'|$, L for $(k'l)/K'$, and K'' for $(k'k'')/K'$ are used in the present note. Assignments of the transitions were confirmed by the following two criteria: First, all the observed patterns of the Stark components, $\Delta m_J=0$ or $\Delta m_J=\pm1$, must be explained consistently. Second, if a splitting is observed, it must agree with that estimated. The hyperfine splittings were calculated by using a formula for the strong-field case[7] with reported eQq values.[5,8]

It was thus possible to confirm the assignment of the $\Delta(k-l)=\pm3$ transitions by taking into account the relative signs of the quantum numbers mentioned above as in the rotational $\Delta k=\pm3$ transitions.[1] All the components, for which the splittings were estimated to exceed their Doppler widths, were actually resolved with splittings consistent with the estimations. Two of the three observed $\Delta(k-l)=\pm6$ transitions, which involve the $|k-l|=3$ levels, need further consideration in regard to the A_1-A_2 splitting of the levels. However, it was possible to explain their Stark patterns approximately by assuming the A_1-A_2 splitting to be zero (*i.e.*, by simply applying Eq. 1). This assumption is valid for the case in which the magnitude of the Stark shift of the levels is considerably larger than that of the A_1-A_2 splitting.

The difference between the Stark shift of the $\Delta(k-l)=\pm6$ transition and that of the normal $\Delta(k-l)=0$ transition is given by Eq. 1 with the relative signs of k', k'', l', and l'' chosen adequately. This equation shows that the magnitude of the Stark shift of the former transition is larger than that of the latter; this facilitates observation of perturbation-allowed transitions by laser Stark spectroscopy.

The Stark shifts of the observed transitions, given in Table 1, were calculated by diagonalization of a matrix, in which Coriolis interaction between ν_2 and ν_4 was taken into account, by use of the molecular constants determined by Olson *et al.*[4] for the ground state and by Sarka *et al.*[9] for the ν_2 and ν_4 states. However, the results were essentially equal to those calculated by the first-order equation (1). The dipole moments for the ν_2 and ν_4 states were assumed to be equal to that for the ground state, $\mu=0.22$ D.[1] Errors in the calculated shifts are mainly caused by the uncertainty in these values. The total uncertainty of the Stark shift is estimated to be less than 10% of the shift itself. As for the zero-field transition frequencies of the two $\Delta(k-l)=\pm6$ transitions mentioned above, neglect of the A_1-A_2 splitting is not adequate, because the magnitude of the splitting can be larger than the uncertainty in the Stark shift. Since the magnitude of the A_1-A_2 splitting is not exactly known, only approximate first-order values derived from the assumption that there is no A_1-A_2 splitting are listed

a) Transitions with $L=0$ and $L=\pm1$ correspond to the ν_2 (A_1) and ν_4 (E) bands, respectively. b) 10: 10.6 μm CO_2 laser, 9: 9.4 μm CO_2 laser. c) A typical $M' \leftarrow M''$ component is listed for each transition. d) Hyperfine splitting is resolved. The listed field values correspond to the centers of the doublets. e) Number in parentheses represents estimated uncertainty in units of 10^{-3} cm^{-1}. f) Estimated from the assumption that there is no A_1-A_2 splitting.

in Table 1.

The obtained zero-field transition frequencies were analyzed in combination with the reported infrared frequencies.[9] The results of a least-squares analysis were essentially the same as that obtained by the infrared data alone. A further analysis of the strong Coriolis interaction between ν_2 and ν_4 and a larger number of accurate spectroscopic data are needed for a more precise determination of the molecular constants. We note that there is no overlapping between the transitions assigned by Scappini and Oka[5] and those assigned in the present study. This is probably because of the difference in the characteristic ranges of applicability of these techniques; radiofrequency-infrared double resonance is more suitable for observing transitions that are relatively close to the laser frequencies, whereas laser Stark patterns can be resolved and assigned more easily for transitions that are separated farther from the laser lines. In this context, laser Stark spectroscopy provides data complementary to RF-IR double resonance spectroscopy.

The authors wish to thank Professor Takeshi Oka for his helpful comments.

Production of Hydrogen by Photochemical Splitting of Water Using Diammonium Tetrathiomolybdate as Photocatalyst

A. Bhattacharya, J. Basu, K. Das, R. G. Bhattacharyya, A. B. Chatterjee, and K. K. Rohatgi-Mukherjee*

Department of Chemistry, Jadavpur University, Calcutta-32, India

(Received December 11, 1981)

Synopsis. Hydrogen gas is generated at the cathode when the anode compartment of a photogalvanic cell anode/$(NH_4)_2MoS_4$(aq, satd.)//5 M HCl (aq)/cathode is illuminated. The photocurrent generated rises slowly with time and reaches a limiting value. A mechanism is suggested involving the conversion of Mo(VI) to Mo(V) and the formation of OH radicals, as evidenced by development of paramagnetism on irradiation. Although the photocatalyst is susceptible to hydrolysis, it can be easily regenerated by passing H_2S.

Transition metal complexes are known to sensitize photodissociation of water to produce hydrogen, a potential fuel. Recently[1] it has been shown that hexakis(alkylammonium)heptamolybdate catalyzes the photochemical splitting of water, but the efficiency of the system is very low since the photocatalyst absorbs in the UV region only. Herein is described the photogalvanic generation of hydrogen gas using diammonium tetrathiomolybdate as the photocatalyst. This compound absorbs in the visible region (λ_{max}=467.3 nm)[2] and, therefore, may be more effective from the standpoint of solar energy utilisation.

Experimental

$(NH_4)_2MoS_4$ was synthesized by following the method available in the literature[3] and was characterized by analytical, as well as spectral data.[2] The IR spectra were measured as KBr pellets using a Perkin Elmer 597 IR spectrophotometer and the UV-visible spectra were measured using a Perkin Elmer Hitachi 200 model instrument. The photocatalyst was preserved in the dark and always a freshly prepared solution was used. The photogalvanic cell consisted of two half-cells connected by a KCl-agar salt bridge. A saturated solution of $(NH_4)_2MoS_4$ was used as the photoactive anolyte and a 5 M HCl solution as the dark catholyte. A Pt-foil or a carbon rod (obtained from a flashlight dry cell) was used as the anode. The cathode was a Pt-wire which was subsequently replaced by platinized Pt and Cu wires. The H_2 gas generated at the dark cathode was collected in an inverted microburette over the cathode wire. The solutions of different pH were prepared from reagent grade NH_4Cl and NH_4OH.

The anode compartment was illuminated by a 1 kW halogen lamp, heating effect being minimised[4] by placing a saturated solution of Na_2SO_4 contained in a 10 cm thick cell, in between the compartment and the light source. The short circuit current was measured by using a Keithley model 616 digital electrometer. A Guoy type magnetic balance was used to measure the paramagnetic susceptibility generated on irradiation of the $(NH_4)_2MoS_4$ solution. A 15% (w/v) aqueous solution of $NiCl_2$, $6H_2O$ was used as the callibrant.

Results and Discussion

The photogalvanic cell can be represented as follows: anode/$(NH_4)_2MoS_4$ (aq, satd.)//5 M HCl/cathode.

On irradiation of the anode compartment hydrogen is generated at the cathode. The amount of hydrogen generation depends on the anode and cathode materials. Effect of changing the cathode material (Table 1) clearly reflects the relative ease of hydrogen evolution on platinized Pt, bright Pt, and Cu as determined by the respective overvoltage. Platinized Pt is known to be a better electrocatalyst than bright Pt for this reaction, whereas Cu is much inferior. However, the increase in the rate of hydrogen production on replacing a Pt-foil by a carbon rod of approximately the same surface area (*ca.* 7.5 sq. cm) can arise due to two different reasons: (i) Difference in the catalytic activities of carbon and Pt for the anode reaction, (ii) the active surface area of carbon may be much greater than the measured 'apparent' surface area due to its somewhat porous nature. This question is sorted out later. The quantum efficiencies of hydrogen production, as given in Table 1, are not monochromatic values and hence, can be considered as the lower limits of actual efficiencies under the given conditions. These values are based on the number of average photons in the visible range received by the anolyte solution which is measured by Reinecke's salt actinometry.[5] The quantum yield of its photoaquation has been assumed to be 0.3 over the entire visible region of the spectrum.[5]

The measurement of the short circuit current, with and without illumination, is more convenient and can provide more quantitative information regarding the mechanism of the overall process. The results are presented in Table 2. Apparently, the greater 'true' surface area of carbon seems to explain the increased efficiency of hydrogen production. Since the ratios of the dark and photo current densities of Pt and carbon are observed to be nearly the same, the effect appears not due to any difference in their catalytic activities. The data in Table 2 are based on apparent surface areas. However, a slow rise of the photocurrent to a limiting

Table 1. Effect of cathode and anode material on the rate of hydrogen generation

Anode	Cathode	Light intensity / E h^{-1}	Volume of H_2 / cm^3 h^{-1}	Quantum efficiency
Pt-foil	Bright Pt	4.8×10^{-4}	0.06	0.011
	Platinized Pt	4.8×10^{-4}	0.1	0.019
Carbon rod	Bright Pt	1.3×10^{-3}	0.25	0.017
	Platinized Pt	1.3×10^{-3}	0.5	0.034
	Copper	1.3×10^{-3}	Negligible	—

Table 2. Short circuit current densities with and without illumination

Anode	Short circuit current density/μA cm^{-2}		
	Dark	Illuminated	Photo
Pt-foil	2.0	12.0	10.0
Carbon rod	16.0	96.0	80.0

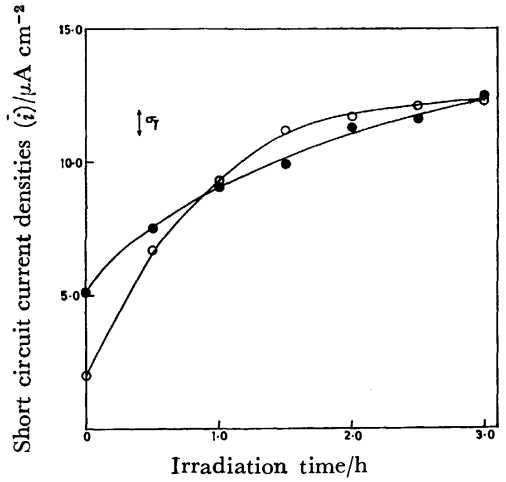

Fig. 1. Rise of short circuit current densities with irradiation time in solutions of pH 8 (○) and pH 10 (●).

value (Fig. 1) seems to indicate a competitive step in the overall reaction mechanism and a consequent slow build up of electroactive material in the anode compartment.

Following Yamase and Ikawa,[1] a sequence of steps, somewhat analogous to those in molybdate system, may be proposed:

$$(1)\ (MoS_4)^{2-} \xrightarrow{h\nu} [(MoS_4)^{2-}]^*$$

$$(2)\ [(MoS_4)^{2-}]^* + H_2O \rightarrow (MoS_3SH)^{2-} + \cdot OH$$

$$(3)\ (MoS_3SH)^{2-} + \cdot OH \rightarrow (MoS_4)^{2-} + H_2O$$

anode $(4)\ (MoS_3SH)^{2-} \rightarrow (MoS_4)^{2-} + H^+ + e$

cathode $(5)\ H^+ + e \rightarrow 1/2\ H_2$.

This sequence assumes the step (3) to be competitive with the anode reaction. Once a steady state concentration of $(MoS_3SH)^{2-}$, in which Mo is in its +5 oxidation state as against +6 state in $(MoS_4)^{2-}$, is reached the photocurrent attains its limiting value. The main water-splitting reaction according to the above mechanism is seen to be

$$H_2O \rightarrow \cdot OH + H^+ + e.$$

Carbon is known to be a better heterogeneous catalyst than Pt[6] for the combination of ·OH radicals leading to the formation of H_2O_2 and O_2 successively as follows:

$$\cdot 2HO \rightarrow H_2O_2 \rightarrow H_2O + 1/2\ O_2.$$

Consumption of ·OH radicals in this way should indirectly favour the anode reaction and thus, may be partly responsible for the observed higher efficiency of carbon than Pt apart from the surface area consideration.

Further evidence in support of the said mechanism is obtained by following the change in the magnetic property of an aqueous solution of $(NH_4)_2MoS_4$ on irradiation. On exposure to light the solution develops paramagnetism as expected if Mo(V) species and OH· radicals are produced, which reaches a limiting value after 1.5 h (Fig. 2). The striking similarity of the rise in photocurrent and growth of paramagnetism with time places the validity of our tentative reaction scheme on a firmer basis. The % conversion of $(MoS_4)^{2-}$ has been calculated from the experimental paramagnetic susceptibility measurements of the irradiated solution and the theoretically computed values for $(NH_4)_2MoS_3SH$ and ·OH taking into consideration the 'spin only' magnetic moments. The decay curves obtained after switching off the light source are also identical in pattern. However, while the photogenerated paramagnetism disappears almost completely within one and a half hour or so, much longer time, even overnight, is necessary for the short circuit current to return to its initial *i.e.*, dark value. Admittedly, at present we are unable to account for this observation quantitatively.

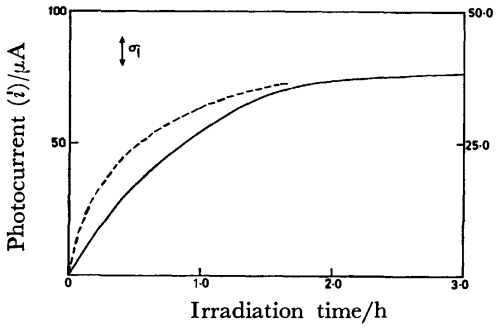

Fig. 2. Rise of photocurrent (solid curve) and growth of paramagnetism (dotted curve) with irradiation time.

All the above experiments were performed in solutions of pH around 8 as the photocatalyst is stable in alkaline solutions only. However, $(NH_4)_2MoS_4$ undergoes a slow hydrolysis in aqueous solution according to the following reaction where stepwise replacement of S atoms by O atoms occurs.

$$(NH_4)_2MoS_4 + nH_2O \rightarrow (NH_4)_2MoO_nS_{4-n} + nH_2S\ [n=1,2,3,4]$$

A part of the resulting H_2S may dissolve and dissociate to give HS^- and S^{2-} ions. Although the dissociation constants are very small in acid solutions (1.1×10^{-7} and 1×10^{-4} respectively) these may increase appreciably with the increase in pH of the solution. Thus, the redox couple H_2S/S may be established at higher pH as S has a tendency to dissolve in alkaline solution, containing excess of S^{2-}, forming polysulphides. The redox potential of the reaction

$$2H^+ + S + 2e \rightarrow H_2S$$

at pH 7 is 0.14 V.[6] We have observed that at pH 10 the dark short circuit currents have appreciably higher values leading to some amount of hydrogen production even in the dark. This seems possible in view of the negative Nernst potential calculated for the couple H_2S/S at these higher pH values. However, the photoeffect remains essentially of the same nature (Fig. 1). Due to this slow hydrolysis, occasional 'reactivations' by passing H_2S has been found to be necessary to use $(NH_4)_2MoS_4$ as a catalyst for photodissociation of water over long periods of time.

Financial support from UGC, New Delhi is gratefully acknowledged

Preparation of Tetraethylammonium Hexamolybdate by the Use of Extraction Method

Katsuo MURATA,* Etsuko YAMAMOTO, and Shigero IKEDA

Department of Chemistry, Faculty of Science, Osaka University 1-1 Machikaneyama-cho, Toyonaka, Osaka 560

(Received April 30, 1982)

Synopsis. It was found that cyclohexanone selectively extracts hexamolybdate from weakly acidic solutions. Tetraethylammonium hexamolybdate was prepared as precipitate in the extracted phase by the addition of alcoholic tetraethylammonium chloride solution. This compound was confirmed to be $[(C_2H_5)_4N]_2Mo_6O_{19}$ by elementary analysis and Raman measurements.

Alkylammonium salt of hexamolybdate was at first prepared from the acidified aqueous molybdate solutions by the use of precipitation and recrystallization.[1] However, it has not been claimed that $Mo_6O_{19}^{2-}$ species is present in the aqueous molybdate solutions.[2] The authors found a small amount of hexamolybdate ion in the acidified molybdate solutions,[3] which was selectively extracted into cyclohexanone. This finding revealed a new extracting procedure for preparation of hexamolybdate salt.

Experimental

Reagent and Apparatus. A molybdenum solution was prepared from sodium molybdate $Na_2MoO_4 \cdot 2H_2O$ of analytical reagent grade and was standardized by gravimetric method of oxinate.[4] Polynuclear molybdate complexes were produced by means of acidification of this molybdate solution.

Extraction procedure is as follows. Ten ml of acidified molybdate solution and equal volume of cyclohexanone were shaken for 20 min. The molybdenum content of the aqueous solutions before and after extraction was determined by atomic absorption spectrometry.[5] Tetraethylammonium hexamolybdate was obtained as precipitate by the addition of alcoholic tetraethylammonium chloride solution to the extracted phase.

Raman spectra were taken with a JASCO Model R750 Raman Spectrophotometer with a triple monochromator by using 514.5 nm line of Ar^+ laser as the excitation source.

Results and Discussion

Heteropolymolybdic acid has been easily extracted by oxygen-containing solvents such as ethers, alcohols, esters, and ketones,[6] but isopolymolybdic acid is not extracted so well by these solvents.[7] The present authors found a good solvent for the extraction of isopolymolybdic acid. Cyclohexanone can efficiently extract yellow polynuclear molybdate from the weakly acidic solutions. The extraction curves for the acidified molybdate solutions of 100, 10, and 1 mM were shown in Fig. 1. The abscissa indicates Z value (the molar ratio of reacted H^+ ion to initially present MoO_4^{2-} ions in the polymerization reaction of molybdate) of molybdate solutions, which exhibits approximately polymerization degree of polynuclear molybdate.[2] It can be seen that each extraction curve

Table 1. Elementary analysis of some extracts and the calculated values

	Found[a] (%)			Calculated (%)	
	(A)	(B)	(C)	$[(C_2H_5)_4N]_2Mo_6O_{19}$	$[(C_2H_5)_4N]_4Mo_8O_{26}$
C	16.67	16.97	17.17	16.86	7.06
H	3.51	3.55	3.57	3.54	5.88
N	2.45	2.50	2.42	2.46	3.95
Mo	49.26	50.23	49.79	50.49	54.18

a) The extracts (A), (B), and (C) were prepared from acidic solutions of pH 2.24(Z=1.58), pH 1.87(Z=1.67), and pH 0.97(Z=2.34), respectively, and then the products were precipitated as tetraethylammonium salt.

$$7\,MoO_4^{2-} + 8\,H^+ \rightleftharpoons Mo_7O_{24}^{6-} + 4\,H_2O \qquad Z = 1.14 \quad (1)$$

$$8\,MoO_4^{2-} + 12\,H^+ \rightleftharpoons Mo_8O_{26}^{4-} + 6\,H_2O \qquad Z = 1.50 \quad (2)$$

$$6\,MoO_4^{2-} + 10\,H^+ \rightleftharpoons Mo_6O_{19}^{2-} + 5\,H_2O \qquad Z = 1.67 \quad (3)$$

shows a similar range of Z value for the optimum extraction as shown in Fig. 1. It is expected from the steep rise of the extractability about Z=1.5 that octamolybdate or hexamolybdate might be concerned with this extraction. The authors could obtain a solid yellow extract as precipitate from the organic phase by the addition of 1% methanol solution of tetraethylammonium chloride. In order to clarify the extracted species, three kinds of extracts were obtained by means of the extraction from different acidic solutions followed by the precipitation as tetraethylammonium salt. Table 1 gives the results of elementary analysis. Three kinds of extracts show similar results. Moreover, these results are close to the calculated value

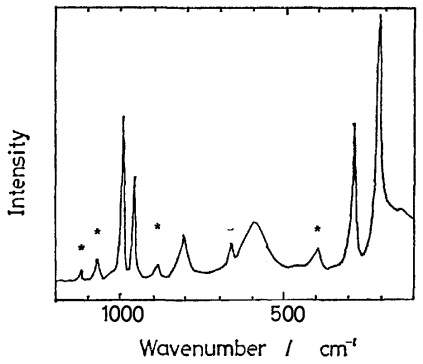

Fig. 2. Raman spectrum of the extract (B), which was obtained by extracting from pH 1.87 ($Z=1.67$) and then precipitating as tetraethylammonium salt in cyclohexanone.
*Raman lines are attributed to tetraethylammonium group.

of hexamolybdate, not octamolybdate. Therefore, these results indicate that the extracted species would be hexamolybdate. Figure 2 shows Raman spectrum of the extract (B). It exhibits four intense Raman lines at 990, 963, 286, and 210 cm^{-1}. Raman lines marked with an asterisk are attributed to tetraethylammonium group. This Raman spectrum resemble closely to that of tetrabutylammonium hexamolybdate $[(C_4H_9)_4N]_2Mo_6O_{19}$, which was previously prepared by means of precipitation from acidified aqueous solution and then recrystallization with acetone.[8] Thus the Raman spectrum also indicates that the extract (B) is hexamolybdate. Raman spectra of acidified molybdate solutions, however, are different from those of solid hexamolybdate. The authors found only small amounts of hexamolybdate ion in the weakly acidic solution ($Z=1.56$—2.05).[3] Consequently, the precipitate obtained from these solutions always contains small amounts of hexamolybdate and large amounts of other molybdate, and recrystallization is necessary to obtain pure hexamolybdate. The yield of hexamolybdate is small. In contrast to this, the extraction method by the use of cyclohexanone results in the production of hexamolybdate with a high yield. The extraction of hexamolybdate is so selective that recrystallization is not required. Since the formation of $Mo_6O_{19}^{2-}$ species is limited to a small extent in the weakly acidic solutions, a longer time of 20 minutes is needed to attain the extraction equilibrium. But this extraction method is better to obtain pure solid hexamolybdate than the previous preparative method by the use of precipitation procedure alone from the weakly acidic solution.

The authors wish to express their thanks to Professor Yukiyoshi Sasaki, the University of Tokyo, for his helpful discussions.

Properties of Alkali-free Magnesium Phosphate Glass Membranes Containing Silver Oxide and Their Application to the Ammonia Selective Electrode

Tsuyoshi NOMURA* and Genkichi NAKAGAWA

Laboratory of Analytical Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466

(Received June 7, 1982)

Synopsis. The properties of magnesium phosphate glass and the potential response of its membrane to ammonia were studied. The most suitable glass composition for the ammonia selective electrode is $5Ag_2O$–$50P_2O_5$–$40MgO$–$5Al_2O_3$. The potential-concentration curve of the electrode exhibits a slope of about 48 mV/decade for the ammonia-concentration range of (10^{-2}—10^{-6}) mol/dm^3.

Various types of alkali silicate glasses containing Al_2O_3 or B_2O_3 have been investigated as materials of the ion selective electrode, and they were used for the measurement of alkali metal ions, Ag^+, Cu^+,[1,2] and the ammonium ion.[3] The ammonia selective electrode consists of a hydrophobic gas-permeable membrane and pH electrode.[4,5] Truesdell and his co-workers[6] found that the glass containing P_2O_5 and Fe_2O_3 as the major constituents can be applied to the ion-selective electrode for alkaline earth cations. According to Eisenman's suggestion,[7] the replacement of aluminium in the sodium-almino-silicate glass by phosphorus would be expected to lead to anion-exchange properties and a response to anionic substances. This paper will describe the composition of alkali-free magnesium phosphate glasses, the durability of glasses against water, and the application of the electrode membrane to ammonia.

Experimental

Preparation of Glass Membrane. Orthophosphoric acid (85%), silver carbonate, tetramagnesium tricarbonate dehydroxide, and aluminium hydroxide were used to prepare the alkali free magnesium phosphate glasses. Mixtures of the chemicals were placed in a quartz evaporating dish and evaporated to dryness. The cake was finely powdered, it was then melted at 1350 °C for 90 min in a platinum crucible, and the melt was poured into a circular hollow of a graphite plate. The final composition of the glass usually deviates from the initial composition because of the loss of phosphoric acid by vaporization during melting.[8] From the determination of P_2O_5 as $Mg_2P_2O_7$ or $AlPO_4$ by the gravimetric method, the volatillization loss of P_2O_5 was found to be about 5 weight % of the initial orthophosphoric acid content from 45 to 55 mol% P_2O_5 glass. Therefore, under all the experimental conditions, the orthophosphoric acid content in the initial materials were established to be about 5 weight % in excess of the calculated amount. To form the electrode, disks (11—12) mm in diameter and (0.4—0.6) mm thick were cut from the glass pellet.

Measurement of the Membrane Potentials. The cell scheme used for the investigation was as follows:

SCE	0.1 mol/dm^3 $NaNO_3$	Glass membrane	Sample soln containing 5×10^{-4} mol/dm^3 NaOH	Agar bridge	0.1 mol/dm^3 $NaNO_3$	SCE
	Ion-selective electrode					

The membrane potentials for ammonia and other anions or compounds were measured in a solution containing 5×10^{-4} mol/dm^3 sodium hydroxide at pH about 10.4 at 20 °C.

TABLE 1. DURABILITY OF GLASSES AGAINST WATER

Glass composition	Solubility in water (mg mm^{-2})	Ratio
$5Ag_2O$–$50P_2O_5$–$45MgO$	3.87×10^{-3}	1.00
$5Ag_2O$–$50P_2O_5$–$40MgO$–$5Al_2O_3$	1.45×10^{-3}	0.37
$25Ag_2O$–$50P_2O_5$–$20MgO$–$5Al_2O_3$	3.11×10^{-3}	0.80
$5Ag_2O$–$50P_2O_5$–$35MgO$–$10Al_2O_3$	1.08×10^{-3}	0.28

From the dissociation constant[9] of the ammonium ion, $K=a_{H^+}\cdot a_{NH_3}/a_{NH_4^+}=10^{-9.25}$, the concentration of the ammonium ion becomes very small at pH values above 10.0. Therefore, the temperature being constant, we can write the glass membrane potential, E, as the following equation:

$$E = \text{Const} - K\log a_{NH_3}, \quad (1)$$

where a_{NH_3} denotes the activity of ammonia and K is the slope of the calibration graph.

The activities of various anions were derived from the concentration by means of the activity coefficients tabulated by kielland.[10]

Durability of Glass against Water. Glass film (about 0.3 g) (surface area, 3×10^2 mm^2) was weighted and placed in a 100-ml portion of distilled water, and then allowed to stand for 60 d at about 30 °C. The durability was measured by the weight loss per unit of area of the glass membrane.

Results and Discussion

Glass-forming Region and Durability of Glass against Water. A glass-forming region in the MgO–P_2O_5 system was found at the composition with a MgO contents of less than 55 mol %. This was in agreement with that found in the previous studies.[11] The same result was observed with the Ag_2O–P_2O_5 system.

Table 1 shows the durability of various glasses against water. With an increase in the amount of Al_2O_3 in the glass composition, the solubility of glass decreased. It can be decided that the durability of glasses is produced by the formation of the –P–O–Al– linkage.[12] However, the melting point for the glass formation becomes very high when the Al_2O_3 content increases to more than about 15 mol %.

Potential Response of the Magnesium Phosphate Glass Membrane Electrode. Figure 1 shows the potential response of the $5Ag_2O$–$50P_2O_5$–$40MgO$–$5Al_2O_3$ glass membrane for various anions or compounds in solutions containing 5×10^{-4} mol/dm^3 sodium hydroxide.

In the case of the alkali silicate glass electrode, cation exchange is the basis for the Nicolsky-Eisenman interpretation.[7] As is shown in Fig. 1, on the contrary, it became clear that this glass shows the properties of the anionic response.

The response for ammonia was linear over the range of (10^{-2}—10^{-5}) mol/dm^3, and had a slope of a 48 mV/decade change in the ammonia concentration at 20

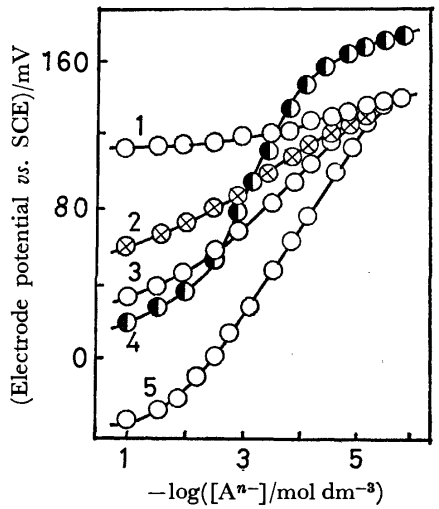

Fig. 1. Potential response of the $5Ag_2O$–$50P_2O_5$–$40MgO$–$5Al_2O_3$ gass electrode.
Here, 5×10^{-4} mol/dm^3 sodium hydroxide was used as the electrolyte solution except for the measurement of hydroxide ion.
1: SO_4^{2-}, 2: Cl^-, 3: NO_3^-, 4: OH^-, 5: NH_3.

°C. Below 10^{-5} mol/dm^3 and above 10^{-2} mol/dm^3, however, the a_{NH_3}-potential graph deviates from linearity.

When the ammonia concentration increases from 10^{-6} to 10^{-2} mol/dm^3, the electrode potential attains a constant value within a minute, but the concentration of ammonia decreases in the same concentration range, the dynamic response time[13] becoming 10 to 20 min.

Response Behavior of Glass Membranes of Various Compositions. The glass electrode containing only MgO and P_2O_5 shows a small response to ammonia. This suggests that no carrier ions which produce the potential response to ammonia, such as the silver ion, are present in the glass composition.

Both the selectivity coefficient of ammonia for other anions and the durability against water decrease with an increase in the Ag_2O content in the glass composition. For the variation in Ag_2O content, the selectivity coefficient of ClO_4^- is found to be $10^{-1.5}$ in Ag_2O content of 15 mol% and $10^{-1.0}$ at 25 mol%, while that of NO_3^- is found to be $10^{-1.5}$ at 15 mol% and $10^{-1.2}$ at 25 mol% respectively.

From these results, it can be concluded that the glass composition of $5Ag_2O$–$50P_2O_5$–$40MgO$–$5Al_2O_3$ is the most suitable for an ammonia selective electrode.

Selectivity Coefficient of Ammonia for the Other Anions or Compounds. The method for the determination of the selectivity coefficients, $K_{NH_3\cdot A}$, is based on the electrode-potential measurements in a mixed solution containing ammonia and the interfering ion, A.[14] The electrode potential of the mixture is expressed by the following equation:

$$E' = \text{Const} - K\log(a_{NH_3}+K_{NH_3\cdot A}\cdot a_A), \quad (2)$$

where $K_{NH_3\cdot A}$ is the selectivity coefficient for A over ammonia and a_A is the activity of an interfering anion or compound A. In the case of $E=E'$, by combining Eqs. 1 and 2 $K_{NH_3\cdot A}$ is obtained by means of the following equation:

$$K_{NH_3\cdot A} = a_{NH_3}/a_A. \quad (3)$$

Therefore, the values of $K_{NH_3\cdot A}$ are obtained by measuring the electrode potential in solutions containing a fixed quantity (10^{-2} mol/dm^3) of the interfering anion or compound and a varied concentration of ammonia.

The selectivity coefficient and the potential slope for each anion or compound obtained using the $5Ag_2O$–$50P_2O_5$–$40MgO$–$5Al_2O_3$ glass electrode are listed in Table 2.

Table 2. Selectivity coefficient for anions or compounds

Anions or compounds	Slope (mV/pC)	Selectivity coefficient
NH_3	48	1
ClO_4^-	37	1.6×10^{-2}
NO_3^-	38	2.1×10^{-2}
OH^-	45	7.4×10^{-2}
Cl^-	32	8.4×10^{-3}
SCN^-	44	8.4×10^{-2}
$CH_3CO_2^-$	30	6.5×10^{-3}
SO_4^{2-}	12	1.4×10^{-3}
$S_2O_3^{2-}$	38	2.1×10^{-2}
Pyridine	33	9.8×10^{-3}
Ethylenediamine	40	5.8×10^{-2}
Triethanolamine	39	5.2×10^{-2}
Urea	14	2.5×10^{-3}

In comparing the pH glass electrode coated by a hydrohobic gas-permeable membrane,[4] the preparation and the operation of the electrode is more simplified, and the effect of interfering species, such as pyridine and urea, is less.

We wish to thank Prof. Yoshihiro Abe for his valuable advice.

(Received August 19, 1982)

Synopsis. The identical chemical state of three gold atoms in trimeric gold(I) azolates and the Au(I)–Au(III) mixed-valence state in their iodine adducts, $Au_3(az)_3I_2$, were confirmed by means of ^{197}Au-Mössbauer spectroscopy.

^{197}Au-Mössbauer spectroscopy is one of the most useful techniques in the structural diagnosis of gold(I) compounds because the Mössbauer parameters are very sensitive to the number and nature of ligands coordinated with the gold atom.

Recently, stable gold(I) derivatives of several azoles have been prepared by Minghetii *et al.*[1] A nine-membered-ring structure containing three gold atoms in a molecule has been suggested in several cases. Some of these trimeric compounds react with iodine to give mixed-valence compounds.

It is our purpose to confirm the trimeric structure and mixed-valence state of gold in several iodine adducts, $Au_3(az)_3I_2$. The present paper will describe the results obtained by ^{197}Au-Mössbauer spectroscopy for monomeric and trimeric gold(I) derivatives of several azoles and their iodine adducts.

Experimental

Materials. The $Au_3(az)_3$ (az=pyrazolato, (pz); 3,5-dimethylpyrazolato, (3,5-Me_2-pz); 3,5-dimethyl-4-iodopyrazolato, (3,5-Me_2-4-I-pz); or benzo-1,2,3-triazolato, (btaz)), $Au_3(3,5\text{-}Me_2\text{-}pz)_3I_2$, $Ph_3PAu(btaz)$, and $Ph_3PAu(3,5\text{-}Me_2\text{-}pz)$ were prepared by following the method described in the literature.[1] The $Au_3(pz)_3I_2$ was prepared by a method similar to that described in Ref. 1. The purity of the samples was checked by elemental analysis.

Measurements. ^{197}Au-Mössbauer spectroscopic measurements were carried out with a source and an absorber, both cooled to 18 K by using a constant acceleration-type spectrometer accompanied with a pure-Ge diode detector. Details of the ^{197}Au-Mössbauer spectroscopy were described in our previous study.[2] All the values of isomer shifts are referred to metallic gold at 18 K. The precision of the Mössbauer parameters obtained is within ±0.04 mm/s.

Results and Discussion

Mössbauer parameters, such as the isomer shift (*IS*), the quadrupole splitting (*QS*), and the half-width (Γ_{exp}), are summarized in Table 1, while some typical spectra are shown in Fig. 1. The values of *IS* and *QS* for $Ph_3PAu(btaz)$ are smaller than those of $Ph_3Au(3,5\text{-}Me_2\text{-}pz)$. This may be ascribed to the reduction of the σ-donating ability of nitrogen by the fused benzene ring. The Mössbauer parameters of monomeric gold(I) azolates are similar to those of the same type of compounds, $[Ph_3PAuL]^+$ (L=C_5H_5N, $C_5H_{10}NH$, or $[N_3]^-$), reported previously.[3,4]

In trimeric gold(I) azolates, the Mössbauer spectra consist of a single doublet, indicating that the three gold atoms in a molecule have an identical chemical state. This means that these compounds have a nine-membered-ring structure. Therefore, in trimeric compounds, the azole acts as an exobidentate *N,N'*-ligand,

Table 1. Mössbauer parameters of gold(I) azolates and their iodine adducts

Compound		*IS* / mm s^{-1}	*QS* / mm s^{-1}	Γ_{exp} / mm s^{-1}

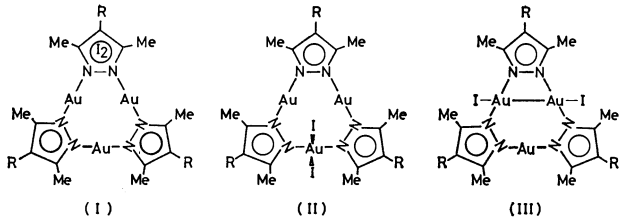

Fig. 2. Possible structures for iodine adducts (from Ref. 1).

forming a cyclic structure. Since the σ-donating ability of the azole ligand is smaller than that of triphenylphosphine, both the *IS* and *QS* values can be expected to decrease for the trimeric compound. A similar trend of the decrease in *IS* and *QS* values is observed on going from $[Ph_3PAuL]^+$ to $[AuL_2]^+$ (L=C_5H_5N, $C_5H_{10}NH$, or $[N_3]^-$).[3,5]

Trimeric gold(I) azolates are stable to air, moisture, and heat and are sparingly soluble in most organic solvents. Those compounds are very stable toward alkalis and acids, but the reaction of trimeric gold(I) azolates with iodine is carried out readily in chloroform and gives only 1:1 adducts, even in the presence of excess iodine. Three kinds of possible structures for these adducts were proposed by Minghetti *et al.* (*cf.* Fig. 2). Based on the results of the visible, IR, and ^{1}H-NMR spectra, they suggested for the adducts the type-II structure. The ^{197}Au-Mössbauer spectra of $Au_3(pz)_3I_2$ and $Au_3(3,5\text{-}Me_2\text{-}pz)_3I_2$ in the present studies show the presence of at least two different sites or oxidation states of gold. A typical spectrum of $Au_3(pz)_3I_2$ is shown in Fig. 2b. The estimated Mössbauer parameters for the adducts are listed in Table 1. One of the sets of parameters is almost the same as that of the original materials. From the Mössbauer parameters, the set is assigned to the Au(I) site which is not attached by iodine. The other set of Mössbauer parameters is very different from the original materials.

In ^{197}Au-Mössbauer spectroscopy, a linear relationship between the observed *IS* and *QS* values has been established for many gold(I) and gold(III) compounds.[6] The average of the literature values is given by:

$$QS = 1.74IS - 2.27 \text{ mm/s for Au(III)}, \quad (1)$$

and:

$$QS = 1.06IS + 3.80 \text{ mm/s for Au(I)}, \quad (2)$$

where the *IS* data are given relative to Au foil.

By using the *IS* data of the new peak components found in $Au_3(pz)_3I_2$ and $Au_3(3,5\text{-}Me_2\text{-}pz)_3I_2$ in Eq. 1, we can estimate the expected values of *QS* as 3.49 and 3.65 mm/s respectively for the adducts. A comparison of these values with the observed values in Table 1 suggests that the Mössbauer parameters of the gold atoms in the other site in the adducts are assigned to gold(III). Furthermore, the area intensity ratio of the absorption line of Au(I) and Au(III) sites is about 2:1. Thus, it may be concluded that the adducts with iodine are Au(I)–Au(III) mixed-valence compounds and have the type-II structure, as has been suggested by Minghetti *et al.*

A part of this work has been carried out under the Visiting Researcher's Program of Kyoto University Research Reactor Institute.

The Solvent Extraction-Spectrophotometric Determination of Perchlorate Ions with Monoethynolog of Malachite Green[1)]

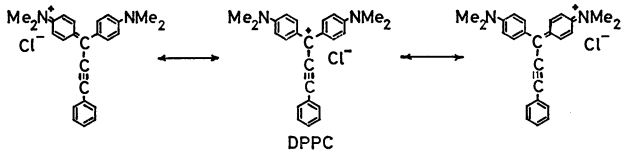
Shuzo AKIYAMA,* Kenichiro NAKASHIMA, Shin'ichi NAKATSUJI, Makiko HAMADA, and Yayoi IZAKI

Faculty of Pharmaceutical Sciences, Nagasaki University, 1-14 Bunkyomachi, Nagasaki 852

(Received September 18, 1982)

Synopsis. By the use of a new reagent, 1,1-bis(*p*-dimethylaminophenyl)-3-phenyl-2-propynylium chloride, *i.e.*, one of the ethynologs of Malachite Green, micro amounts of perchlorate ions could be extracted into chlorobenzene and determined spectrophotometrically. Beer's law holds over the range of 4×10^{-6}—2.5×10^{-5} M (M=1 mol dm^{-3}); $\varepsilon=4.0\times10^{4}$ dm^3 mol^{-1} cm^{-1} at 690 nm.

The study of the synthesis and the properties of the ethynologs of triphenylmethane dyes has been developed and has demonstrated that the introduction of an acetylenic bond into such a classical dye system causes a large bathochromic shift in the longest wavelength.[2)]



For the application of the effect to analytical chemistry, one of the monoethynologs of Malachite Green, *i.e.*, 1,1-bis(*p*-dimethylaminophenyl)-3-phenyl-2-propynylium chloride (DPPC), was newly prepared and examined in order to determine micro amounts of perchlorate ions by means of solvent-extraction spectrophotometry.[3)]

Experimental

Apparatus. The spectrophotometric measurements were made with Shimadzu UV-300 and UV-150 spectrophotometers.

Materials. *Synthesis of DPPC.* Dried hydrogen chloride was bubbled through a solution of 1,1-bis(dimethylaminophenyl)-3-phenyl-2-propyn-1-ol[2)] (0.500 g, 0.0014 M) in toluene (150 ml) for 15 min. The resulting dark green solution was concentrated *in vacuo* to give crude crystals, which were then recrystallized from the same solvent: deep green crystals,[4)] 0.439 g, 81%; mp 85 °C.

Found; C, 67.76; H, 6.72; N, 5.73%. Calcd for $C_{25}H_{25}N_2Cl\cdot3H_2O$; C, 67.80; H, 7.01; N, 6.33%. MS (*m/e*): 353 (M−Cl⁻); UV λ (H_2O) 645 nm (ε=18500).

Buffer (Potassium Phosphate Solution). Various kinds of pH solutions were made by the use of potassium dihydrogenphosphate (1 M), sulfuric acid (0.1 M), and sodium hydroxide (1 M).

Solvents. Chlorobenzene was purified by distillation. All the other reagents were of an analytical grade and were used without further purification.

Procedure. Place an aliquot of the standard potassium perchlorate solution (1×10^{-5}—6.25×10^{-4} M) into a 25-ml calibrated flask. Add 5 ml of a potassium phosphate buffer (1 M, pH 3.5) and 2 ml of a DPPC aqueous solution (1×10^{-3} M). Dilute the solution to the mark with distilled water. Take 10 ml of the above solution, transfer it into a 100-ml separatory funnel, and shake with 10 ml of chlorobenzene for 3 min. Filter the organic layer after 15 min and measure the absorbance at 690 nm in a 1-cm cell against the reagent blank or chlorobenzene as a reference.

Results and Discussion

The absorption spectra of the chlorobenzene extract containing the ion pair obtained by the above procedure are shown in Fig. 1. The wavelength of the maximum absorption occurs at 690 nm.

The effect of the pH value on the absorbance was examined in the range of pH 0.5 to 10. As is shown in Fig. 2, constant absorbances were obtained in the pH region from 2 to 4, from which the buffer solution of pH 3.5 was used.

The concentration of DPPC to 1.6×10^{-5} M of perchlorate was confirmed by using 8×10^{-5} M for the determination.

The effect of the shaking time in the extraction was examined to give a constant absorbance from 2 to 10 min.

The absorbance of the extract of perchlorate did not change at all for 1 h.

Various organic solvents (chlorobenzene, benzene, nitrobenzene, toluene, chloroform, 1,2-dichloroethane, and carbon tetrachloride) were tested for the extrac-

SCN^-	KSCN	1.2×10^{-6}	0.423
SO_4^{2-}	Na_2SO_4	2.4×10^{-5}	0.427

ClO_4^- added: 1.2×10^{-5} M.

tion. Subsequently, chlorobenzene was chosen because it showed a small blank value and the largest absorbance difference at 690 nm between the ion pair and the blank.

On the basis of the above results, a standard procedure was evolved, by which the linear calibration graph was obtained in the range from 4×10^{-6} to 2.5×10^{-5} M of perchlorate. The practical absorptivity was 4.0×10^4 dm^3 mol^{-1} cm^{-1}. The coefficient of variation for the ten replicated experiments was satisfactory (2.20% for 1.6×10^{-5} M of perchlorate).

The interferences due to various ions were also examined, as is shown in Table 1. The periodate, iodide, and thiocyanate caused considerable errors. It is worth noting that the characteristic larger red shift (*ca.* 100 nm) due to the effect of an acetylenic bond larger than Crystal Violet[3] has been observed. The absorptivity was about one-half of that for Crystal Violet; however, the sensitivity and the reproducibility were quite good in this method. DPPC is useful enough as an analytical reagent for perchlorates.[5]

The authors wish to thank Miss Atsuko Yamaguchi for helping with the experiments.

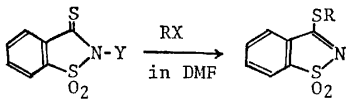
(Received April 30, 1982)

Synopsis. It was found that sodium salt of 1,2-benzisothiazole-3(2*H*)-thione 1,1-dioxide (thiosaccharin) readily reacted with alkyl halide affording 3-(alkylthio)-1,2-benzisothiazole 1,1-dioxide (**3**). Treatment of **3** with piperidine produces the corresponding alkanethiol *in situ* quantitatively and subsequent treatment with various electrophiles gives the corresponding sulfides and thiocarboxylic *S*-esters in good yields.

Recently the herbicidal and fungicidal properties of 3-substituted 1,2-benzisothiazole 1,1-dioxide have been noted,[1,2] and the preparation of such compounds was performed by the reaction of 3-chloro-1,2-benzisothiazole 1,1-dioxide with an alcohol or thiol in the presence of base.[2] Generally, thiols have unpleasant odor, therefore the development of odorless equivalent of thiols would be convenient. We have found that 3-(alkylthio)-1,2-benzisothiazole 1,1-dioxide (**3**), which is prepared from the sodium salt (**2**) of thiosaccharin (**1**) and alkyl halides is an efficient synthetic equivalent of alkanethiols. 3-(Alkylthio)-1,2-benzisothiazole 1,1-dioxide (**3**) was prepared upon treatment of **2** with 1.1 equivalent of halide in excellent yields as shown in Table 1 (Eq. 1). Odorless compounds **3** reacted

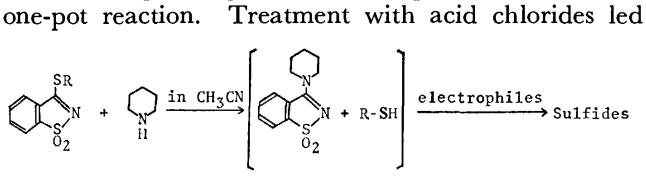


(1)

1 Y=H
2 Y=Na

3(BID-SR)

with secondary amines stoichiometrically. The reaction of **3** with piperidine produces the corresponding alkanethiols smoothly *in situ*. Subsequently treatment with electrophiles gives the corresponding sulfides in one-pot reaction. Treatment with acid chlorides led



3

to the corresponding thiocarboxylic *S*-esters in high yields. In the same manner, the reactions with other electrophiles such as α,β-unsaturated carbonyl compounds, alkyl halides and epoxide also give satisfactory results. As mentioned above, it is clear that readily available **3** is a useful equivalent of the corresponding thiol.

Experimental

*Preparation of 3-(Alkylthio)-1,2-benzisothiazole 1,1-Dioxides (**3a—g**).* Typically, to a solution of **2** (663 mg, 3 mmol) in DMF (2 ml) was added a solution of benzyl bromide (564 mg, 3.3 mmol) in DMF (2 ml) at room temperature under nitrogen. After stirring for 3 h, water was added to the reaction mixture. The precipitate was recrystallized from ethanol and dichloromethane to give 3-(benzylthio)-1,2-benzisothiazole-1,1-dioxide (**3a**) (791 mg, 93%), whose structure was established by comparison with the authentic sample prepared by the reaction of 3-(chloro)-1,2-benzisothiazole 1,1-dioxide with benzenemethanethiol in the presence of triethylamine in CH_3CN (Mp, IR). **3a**: Mp 141.0—142.0 °C; IR (KBr) 1587, 1320, 1163 cm^{-1}; Found: C, 57.82; H, 3.94; N, 4.75%. *Addition of Thiols to α,β-Unsaturated Carbonyl Compounds (**5a—e**).* Typically, to a solution of 3-(cinnamylthio)-1,2-benzisothiazole 1,1-dioxide (**3c**) (154 mg, 0.5 mmol) in CH_3CN (1 ml) was added a CH_3CN solution of piperidine (43 mg, 0.5 mmol) under N_2 at room temperature. After 30 min a solution of methyl vinyl ketone (38 mg, 0.5 mmol) in CH_3CN (1.5 ml) was added dropwise and then after 3 h a drop of triethylamine was added. The reaction mixture was stirred for additional 1.5 h and evaporated *in vacuo*. Purification with preparative TLC (benzene–ethyl acetate=10:1 v/v) gave **5a** (101 mg, 92%). **5a**: Oil; *m/e* 194 (M^+); IR (neat) 1700, 1408, 1353, 693 cm^{-1}; NMR ($CDCl_3$) δ 2.09 (3H, s), 2.62 (4H, s), 3.69 (2H, s), 7.26 (5H, s). **5b**: Oil; *m/e* 208 (M^+); IR (neat) 2920, 1709, 1355, 690 cm^{-1}; NMR ($CDCl_3$) δ 2.12 (3H, s), 2.69 (4H, s), 2.80 (4H, s), 7.17 (5H, s). **5c**: Oil; *m/e* 220 (M^+); IR (neat) 3035, 2933, 1712, 1361, 963 cm^{-1}; NMR ($CDCl_3$) δ 2.08 (3H, s), 2.67 (4H, s), 3.25 (2H, d, J=6.0 Hz), 6.12 (1H, t, d, J=6.0, 15.6 Hz), 6.35 (1H, d, J=15.6 Hz),7.03—7.47 (5H, m).

Compounds (**5d—e**) were not stable to silica gel purification and then characterized as 2,4-dinitrophenylhydrazones, respectively. **5d**: Mp 99.0—99.5 °C (from EtOH); Found: C, 53.24; H, 4.42; N, 15.53%. Calcd for $C_{16}H_{16}N_4O_4S$: C, 53.32; H, 4.48; N, 15.55%. **5e**: Mp 65.0—65.5 °C (from EtOH); Found: C, 54.40; H, 4.69; N, 14.94%. Calcd for $C_{17}H_{18}N_4O_4S$: C, 54.43; H, 4.85; N, 14.96%.

*Preparation of the Sulfides (**5f—i**).* Typically, to a suspension of 3-(benzylthio)-1,2-benzisothiazole 1,1-dioxide (**3a**) (142 mg, 0.5 mmol) in CH_3CN (1 ml) was added a solution of piperidine (43 mg, 0.5 mmol) in CH_3CN (1 ml) under N_2. After stirring for 20 min, a solution of DBU (92 mg, 0.6 mmol) in CH_3CN (1 ml) was added followed by the addition of a solution of benzyl bromide (102 mg, 0.6 mmol) in CH_3CN (1 ml). The reaction mixture was stirred for 5 h and worked up in the usual way. Preparative TLC (hexane–benzene=5:2 v/v) gave pure **5i** (96 mg, 90%). **5f**: Oil; *m/e* 240 (M^+); IR (neat) 3049, 1496, 961 cm^{-1}; NMR ($CDCl_3$) δ 3.21 (2H, d, J=6.4 Hz), 3.62 (2H, s), 6.11 (H, t, d, J=6.4, 15.4 Hz), 6.20 (1H, d, J=15.4 Hz), 6.92—7.74 (10H, m). **5g**: Oil; *m/e* 166 (M^+); IR (neat) 2950, 1484, 1443, 1374, 685 cm^{-1}; NMR ($CDCl_3$) δ 1.23 (6H, d, J=6.6 Hz), 2.68 (1H, q, J=6.6 Hz), 3.67 (2H, s), 7.19 (5H, s). **5h**: Oil; *m/e* 194 (M^+); IR (neat) 2920, 1481, 1443, 685 cm^{-1}; NMR ($CDCl_3$) δ 0.63—1.82 (9H, m), 2.37 (2H, t, J=7.0 Hz), 3.63 (2H, s), 7.18 5H, s). **5i**: Oil; *m/e* 214 (M^+); IR (neat) 3012, 1488, 1445, 685 cm^{-1}; NMR ($CDCl_3$) δ 3.53 (4H, s), 7.20 (10H, s). **5j**: Mp 107—108 °C; IR (KBr) 3390, 1595, 1445, 1046 cm^{-1}; NMR ($CDCl_3$) δ 2.31 (1H, bs), 3.29 (2H, s), 3.80 (1H, d, J=6.4 Hz), 4.85 (1H, d, J=6.4 Hz), 6.71—7.61 (15H, m); Found: C, 78.79; H, 6.26%. Calcd for $C_{21}H_{20}OS$: C, 78.71; H, 6.29%.

Photoinduced Alcoholysis of Trihaloacetyl Group

Yasuji IZAWA, Katsuhiro ISHIGURO, and Hideo TOMIOKA*

Department of Industrial Chemistry, Faculty of Engineering, Mie University, Tsu, Mie 514

(Received June 29, 1982)

Synopsis. Photolysis of trichloroacetamide in non-degassed methanol gave methyl oxanilate (13—44%), along with carbamate (3—20%) and amine (4—12%). Similar irradiation of other trichloroacetyl derivatives of aliphatic ketone, aldehyde, and acetate afforded only radical product. The results are interpreted in terms of the mechanism involving electron transfer of the radical pair.

There has been increasing interest paid recently to photolysis of alkyl and alkenyl halides,[1-4] because, contrary to the earlier belief that only radical intermediates are involved, it becomes clear that cationic, as well as free radical, intermediates play an important role in the solution-phase photochemistry of these halides. During an effort[5-7] to generate α-oxo carbonium ion we found[8,9] that photolysis of α,α,α-trihaloacetophenone in alcohols gave a new photoalcoholysis product, benzoylformate, which was apparently derived from nucleophilic trapping of ionic species. Since thermal (dark) nucleophilic attack of alcohol on trihaloacetyl group is known to occur exclusively at carbonyl function to give benzoate (haloform reaction), the present photoalcoholysis is quite important not only from the standpoint of the reaction mechanism but also from synthetic viewpoints. Thus we have examined the photolysis of other trihaloacetyl compounds in alcohol.

Results and Discussion

Irradiation of a non-degassed solution of trichloroacetoanilide (**1a**) in methanol through a Pyrex filter for 4 h afforded methyl oxanilate (**2a**, 25.9%), along with methyl phenylcarbamate (**3a**, 12.5%) and aniline (**4a**, 12.3%). The similar reactions were found to

$$\underset{\mathbf{1}}{RNHC(=O)CCl_3} \xrightarrow[MeOH]{h\nu} \underset{\mathbf{2}}{RNHC(=O)CO_2Me} + \underset{\mathbf{3}}{RNHCO_2Me} + \underset{\mathbf{4}}{RNH_2} \quad (1)$$

a: R=C_6H_5, **b**: R=*p*-$MeOC_6H_4$, **c**: R=*p*-MeC_6H_4
d: R=*p*-ClC_6H_4, **e**: R=$PhCH_2$, **f**: R=H

occur with other trichloroacetoanilides as summarized in Table 1. The photoalcoholysis was also applicable to trichloroacetamide (**1e**, **f**). This is in marked contrast with that observed for trihalo-ketone where only aromatic ketone derivatives undergo photoalcoholysis to give formate (*vide infra*). Oxanilate **2** and carbamate **3** were apparently formed *via* nucleophilic trapping by methanol of cationic species resulting from C–Cl and C–CO bond fission in heterolytic way, respectively. Amine **4** was derived from radical species since trichloroacetaldehyde was detected in the reaction mixture.

Irradiation of hexachloroacetone (**5a**) in methanol did not result in the formation of expected alcoholysis product, *i.e.*, methyl trichloroacetate or trichloropyruvate. Tribromoacetaldehyde (**5b**) also did not lead to the alcoholysis upon irradiation in methanol. The main product in these photolyses was reduction (radical) product. For example, dibromoacetaldehyde was obtained in more than 90% yield in the photolysis of **5b**. Irradiation of methyl trihaloacetate (**6a**, **d**) in methanol through quartz resulted in the formation of the reduction product *i.e.*, dihaloacetate. GC analysis showed that neither dimethyl oxalate nor carbonate was detected in the reaction mixtures. When aryl ester (**6b**, **c**) was similarly irradiated, phenol was isolated as a main product (70—80%), but no photoalcoholysis product was detected.

Table 1. Photoreaction of **1** in methanol[a]

1	(R)	Irradiation time / h	Yield/%[b] 2	3	4
1a	(C_6H_5)	4	28.9	12.5	12.3
1b	(*p*-$MeOC_6H_4$)	5	43.7	15.8	10.3
1c	(*p*-MeC_6H_4)	4	36.9	13.4	11.9
1d	(*p*-ClC_6H_4)	18	21.1	14.8	10.2
1e	($PhCH_2$)	20	28.5	20.2	3.5
1f	(*c*-C_6H_{11})	20	13.0	3.1	8.2

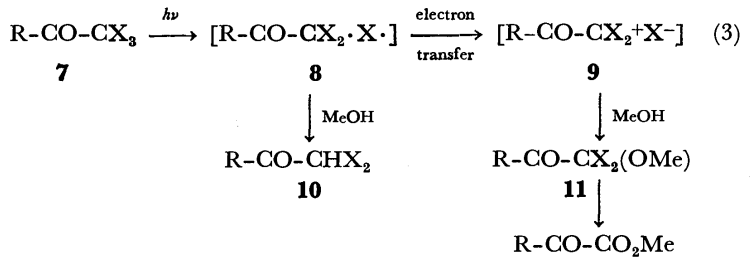
The results indicated that the photoalcoholysis of $COCX_3$ to $COCO_2R$ is applicable to trihaloacetamide group, but not to aliphatic trihalo-ketone, -aldehyde, and trihaloacetate. This is in contrast with that observed for photoalcoholysis of simple halides, where not only arylalkyl halide, *e.g.*, benzyl halide,[1,3] but also more simple alkyl and cycloalkyl halides[2] efficiently undergo photoalcoholysis to give ether and/or olefins along with radical products. In their interesting work on photosolvolysis of alkyl iodide Kropp *et al.*[2] have proposed that ionic intermediates are not produced directly from the photoexcited state, but that the photoexcited state decays by homolysis to a radical pair, which may undergo radical reactions or electron transfer to afford an ion pair as shown in Eq. 2. We

$$R\text{–}X \xrightarrow{h\nu} [R\cdot X\cdot] \xrightarrow[\text{transfer}]{\text{electron}} [R^+X^-] \quad (2)$$

have also suggested[8,9] that photoalcoholysis and photoreduction of trihaloacetophenone (**7**) are coupled

through the common intermediacy of the radical pair (**8**) and that benzoylformate is formed *via* spontaneous (dark) alcoholysis of initial photoalcoholysis product, *i.e.*, α-alkoxy-α,α-dihaloacetophenone (**11**). The ratio of heterolytic products to the radical (reduction) products is then influenced by lifetime of the radical pair **8**, since the radical pair must have a lifetime to permit electron transfer to compete with diffusion of the radical



(3)

components from the caged pair. The present results then suggest that only radical pair generated from trihaloacetophenone and trihaloacetamide has sufficient lifetime for electron transfer to occur, while that derived from aliphatic trihalo derivatives undergoes predominant hydrogen abstraction before electron transfer occurs. Alternatively, an α-oxo dihalo carbonium ion generated from trihaloacetophenone and trihaloamide may be stabilized by non-bonded interaction of phenyl and amide nitrogen. This will facilitate electron transfer process to generate the α-oxo dihalo carbonium ion which may be otherwise very unfavorable.

Experimental

Materials. α,α,α-Trichloroacetamide **1a—f** was prepared by the reaction of hexachloroacetone with amine according to the literature procedure.[10] Tribromoacetaldehyde **5b** was obtained by treatment[11] of paraldehyde with excess bromine. Aryl trichloroacetate **6b**, **6c** was synthesized by the Schotten-Baumann reaction of trichloroacetyl chloride with phenol. Methyl tribromoacetate **6d** was obtained by esterification of the corresponding acid. All other trihalo compounds were obtained from commercial source. Oxanilate **2** and carbamate **3** were prepared by the reaction of amine with dimethyl oxalate[12] and methyl chloroformate,[13] respectively.

Irradiation of Trichloroacetamide in Methanol. In a typical run, a solution of trichloroacetamide (1 mmole) in methanol (200 ml) was placed in a Pyrex tube and irradiated with a high-pressure, 300W, Hg lamp with a water-cooled jacket. The progress of the reaction was monitored by TLC. The irradiated mixtures were concentrated on a rotary evaporator and extracted with ether-water. Acidification of the aqueous layer, followed by ether extraction gave amine. The ethereal solutions were concentrated and chromatographed on 2.0 cm × 30 cm silica gel (Woelm, Activity III) column with $CHCl_3$ as eluant to give oxanilate **2** and carbamate **3**, all of which showed the same NMR spectra and GC retention time as authentic samples.

Irradiation of Other Trihaloacetyl Compounds in Methanol. Irradiations were carried out as outlined above. Identifications of photoproducts were done either by GC comparison with authentic samples or by isolation followed by spectroscopic determination.

Catalytic Activity of $PdCl_2$ Complexes Having Sulfur Compounds as Ligands

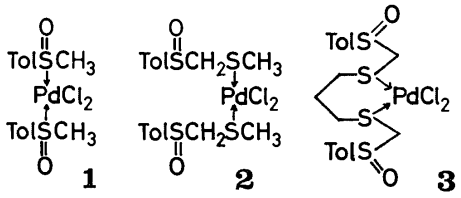
Katsuyuki OGURA,* Teruki AIZAWA, Koichiro UCHIYAMA, and Hirotada IIDA

Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoicho 1-33, Chiba 260

(Received July 8, 1982)

Synopsis. The $PdCl_2$ complexes coordinated with methyl *p*-tolyl sulfoxide (1:2), methylthiomethyl *p*-tolyl sulfoxide (1:2), and 1,3-bis[(*p*-tolylsulfinyl)methylthio]propane (1:1) as ligands were prepared. Among these complexes, bis(methyl *p*-tolyl sulfoxide)palladium dichloride catalyzed effectively cyclotrimerization of diphenylethyne and rearrangement of 3-acetoxy-1-tridecene to 1-acetoxy-2-tridecene.

Sulfur-containing compounds are well known to coordinate strongly to many kinds of metals or metal salts and to poison metallic catalysts, and there are several reports[1] for catalytic reactions using metal complexes with sulfur compounds as ligands. Now we wish to report preparation of three types of $PdCl_2$ complexes (**1**, **2**, and **3**) containing methyl *p*-tolyl sulfoxide (**4**), methylthiomethyl *p*-tolyl sulfoxide (**5**), and 1,3-bis[(*p*-tolylsulfinyl)methylthio]propane (**6**) as ligands, and their catalytic activities for cyclotrimerization of diphenylethyne and rearrangement of 3-acetoxy-1-tridecene.



1 **2** **3**

Complexes **1**, **2**, and **3** were easily obtained by simple stirring of $PdCl_2$ and sulfur compounds **4**, **5**, and **6**, respectively, in CH_2Cl_2 at room temperature. Their structures were assigned by their elemental analyses and IR spectra.[2] The absorption of sulfinyl stretching of **1** appears at a higher frequency (1148 cm^{-1})[5] than that (1030 cm^{-1}) of **4** itself, indicating that the lone-pair electrons of the sulfur atom coordinates to $PdCl_2$. Whereas, **2** and **3** showed their sulfinyl absorptions at 1050 cm^{-1} and 1045 cm^{-1}, respectively, in accord with the assigned structures. We also prepared the $PdCl_2$ complex (**1***) with optically active (*R*)-methyl *p*-tolyl sulfoxide (**4***) as a ligand. The protons of the sulfinyl methyl group of **1*** were observed as a relatively sharp singlet in the NMR spectrum, while those of **1** appeared as a very broad signal as shown in Fig. 1, implying that **1** consisted of two diastereomeric isomers (*dl* and *meso* forms) and underwent fast ligand-exchange in solution.

Next, the catalytic activities of the thus prepared complexes were examined for cyclotrimerization of diphenylethyne (**7**) to form hexaphenylbenzene (**8**).[6] To a solution of **7** in CH_2Cl_2, was added the complex (**1**, **2**, or **3**) (0.03 mol equiv.) and the resulting solution was stirred at 30 °C for 24 h. The yield of **8** based on the used complex was 405% for **1**, 40% for **2**, and 13% for **3**. When insoluble $PdCl_2$ was utilized, **8** was obtained in only 25% yield. These

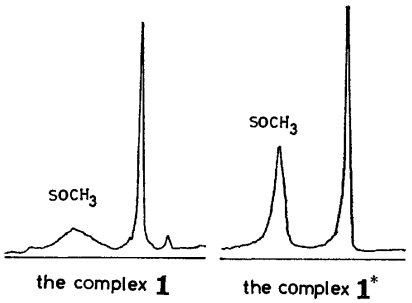


Fig. 1. ^1H NMR signals of methyl protons of complexes **1** and **1***.

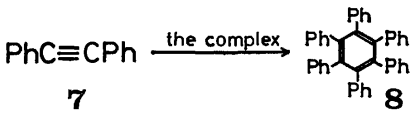
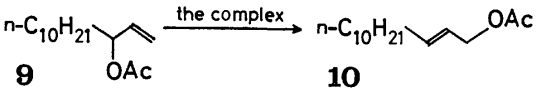
facts indicate that, in the complex **3**, ligand (**6**) coordinates to $PdCl_2$ strongly enough to retard the cyclotrimerization.

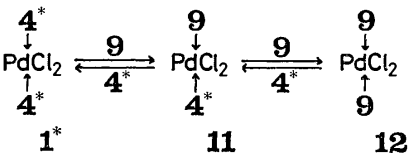


7 **8**

Recently, $(CH_3CN)_2PdCl_2$ was disclosed to promote the rearrangement of 1-alken-3-yl acetates.[7] We also found that **1** catalyzed the conversion of 3-acetoxy-1-tridecene (**9**) to 1-acetoxy-2-tridecene (**10**). When a solution of **9** and **1** (0.03 mol equiv.) in CH_2Cl_2 was stirred at 30 °C for 2 h, a 1:2.1 mixture of **9** and **10** was obtained in a total yield of 92%. Since the ratio remained unchanged even after a prolonged reaction time (16 h), and the similar treatment of **10** afforded a mixture of **9** and **10** in a comparable ratio (1:2.2), it was shown that **9** and **10** were in equilibrium under the present conditions. Although **2** exhibited slight effects on the rearrangement of **9** into **10** (**9**:**10**=10:1 after 149 h), **3** did not promote the rearrangement at all. This tendency seems to be in good relationship with the coordinating strength of the ligand. Furthermore, complex (**1***) with optically active (*R*)-methyl *p*-tolyl sulfoxide was employed in the above rearrangement. Stirring a solution of **9** and **1*** (0.03 mol equiv.) in CH_2Cl_2 gave a mixture of **9** and **10** (1:2.1), but the remained **9** was optically inactive. This phenomenon may be reasonably explained by complete ligand-displacement of **1*** with **9** to produce complex (**12**). For appearance of the optical activity in the remained **9**, complex (**11**) containing both **9** and **4*** must be produced. Hence, we investigated the catalytic rearrangement of **9** in the coexistence of **4***. In the reaction using 0.03 mol equiv. of $PdCl_2$ and



9 **10**



1.0 or 2.0 mol equiv. of **4*** (at room temperature for 8—16 h), no rearrangement took place. When 0.5 mol quiev. of **4*** was used, the rearrangement proceeded slowly and a 10:1 mixture of **9** and **10** was obtained after 16 h. The remained **9** exhibited an optical purity of 2%. This indicates that enantioselectivity in the initial ligand-displacement of **1*** with racemic **9** is approximately 20%.

Thus we have shown that methyl *p*-tolyl sulfoxide (**4**) can coordinate to $PdCl_2$ to make it soluble in CH_2Cl_2, and thus-formed complex (**1**) catalyzes efficiently cyclotrimerization of **7** and rearrangement of **9** to **10** by means of ligand-displacement.

Experimental

The melting points were measured by a Yamagimoto micro melting point apparatus and were uncorrected. The ^1H NMR spectra were taken with a Hitachi R-600 spectrometer, and the IR spectra were recorded on a JASCO A-200 spectrometer. Optical rotations were measured on a JASCO DIP-140 polarimeter.

Bis(methyl p*-tolyl sulfoxide)palladium Dichloride (**1**) and Bis-(methylthiomethyl* p*-tolyl sulfoxide)palladium Dichloride (**2**).* To a solution of **4** (232 mg: 1.50 mmol) in CH_2Cl_2 (10 ml), was added $PdCl_2$ (116 mg: 0.654 mmol), and the resulting mixture was stirred at room temperature for 1 d. Evaporation and recrystallization from benzene-hexane gave **1** as orange crystals (167 mg: 53%): mp 121—122 °C; ^1H NMR ($CDCl_3$): δ 2.42 (6H, s), 3.09 (6H, broad), 7.40 (4H, d, J= 8 Hz), and 7.74 (4H, d, J=8 Hz); IR (KBr): 1148 cm^{-1}. Found: C, 39.60; H, 4.03%. Calcd for $C_{16}H_{20}Cl_2O_2PdS_2$: C, 39.56; H, 4.15%.

In a similar manner, complex **1*** was prepared as orange crystals: mp 75—76 °C (from benzene-hexane).

Complex **2** was analogously obtained in 95% yield: yellow crystals; mp 147—148 °C (from hexane-CH_2Cl_2); ^1H NMR ($CDCl_3$): δ 2.43 (6H, s), 2.67 (6H, s), 4.00 (2H, d, J=13.6 Hz), 4.28 (2H, d, J=13.6 Hz), 7.38 (4H, d, J=8 Hz), and 7.58 (4H, d, J=8 Hz); IR (KBr): 1050 cm^{-1}. Found: C, 37.35; H, 4.17. Calcd for $C_{18}H_{24}Cl_2O_2PdS_4$: C, 37.41; H, 4.19.

*Complex (**3**) of $PdCl_2$ with 1,3-Bis[(*p*-tolylsulfinyl)methylthio]-propane.* To a solution of **6** (300 mg: 0.727 mmol) in CH_2Cl_2 (10 ml), was added $PdCl_2$ (129 mg: 0.728 mmol) and the resulting mixture was stirred at room temperature for 1 d. Evaporation and recrystallization from CH_2Cl_2-hexane afforded **3** as yellow crystals (328 mg: 77%): mp 141—142 °C; ^1H NMR ($CDCl_3$): δ 1.59 (2H, broad s), 2.41 (6H, s), 2.79—3.28 (4H, m), 3.99 (1H, d, J=13 Hz), 4.09 (1H, d, J=13 Hz), 4.67 (1H, d, J=13 Hz), 4.74 (1H, d, J=13 Hz), 7.34 (4H, d, J=8 Hz), and 7.54 (4H, d, J=8 Hz); IR (KBr): 1045 cm^{-1}. Found: C, 38.29; H, 4.05%. Calcd for $C_{19}H_{24}Cl_2O_2PdS_4$: C, 38.68; H, 4.10%.

*Cyclotrimerization of Diphenylethyne (**7**).* To a solution of **7** (200 mg) in CH_2Cl_2 (5 ml), was added **1**, **2**, **3**, or $PdCl_2$ (0.03 mmol equiv. to **7**), and the resulting mixture was stirred at 30 °C for 1 d. Evaporation and chromatography on silica gel [hexane and benzene-CH_2Cl_2 (1:1)] gave **8** as a colorless solid which was identified by comparison of its IR spectrum with that of the authentic sample.[8] The yields of **8** (the recovered **7**) using **1**, **2**, **3**, and $PdCl_2$ were 73.3 mg (127 mg), 7.3 mg (194 mg), 2.4 mg (193 mg), and 4.6 mg (186 mg), respectively. The value in parentheses means the yield of the recovered **7**.

*Rearrangement of 3-Acetoxy-1-tridecene (**9**).* Starting material **9** was prepared by the lit.[9] procedure. Rearrangement product **10** was obtained by the reaction of 1-bromo-2-tridecene (908 mg: 3.48 mmol) with AcOK (425 mg: 4.33 mmol) and KI (8 mg) in AcOH (10 ml) at 80 °C for 11 h, which gave a mixture of **9** and **10** (1:5.05) (617 mg: 74%): a colorless oil; IR (neat): 1742 cm^{-1}. Found: C, 75.07; H, 11.52%. Calcd for $C_{15}H_{28}O_2$: C, 74.95; H, 11.74%. ^1H NMR ($CDCl_3$) of **10** ($CDCl_3$): δ 0.90 (3H, diffused t), 1.31 (18H, broad s), 2.01 (3H, s), 4.51 (2H, d, J=5 Hz), and 5.57 (2H, m).

To a solution of **9** (200 mg) in CH_2Cl_2 (10 ml), was added **1** (12 mg: 0.03 mol equiv.), and the resulting mixture was stirred at 30 °C for 2 h under nitrogen atmosphere. Evaporation and chromatography on silica gel [benzene-hexane (1:1)] gave a mixture (184 mg) of **9** and **10**, the ratio of which was determined to be 1:2.1 by a GLC analysis [Silicone DC 550 column (1 m)/nitrogen gas carrier (1 kg/cm^2)/160 °C].

*Rearrangement of **9** in the Coexistence of **4***.* After $PdCl_2$ (8.8 mg) was added to a solution of **4*** (129 mg) in CH_2Cl_2 (5 ml) and the resulting mixture was stirred at room temperature for 3 h, **9** (400 mg) was added together with CH_2Cl_2 (15 ml). The mixture was further stirred for 16 h at room temperature. Evaporation and chromatography gave a mixture (382 mg) of **9** and **10** (10:1) which showed α_D of 0.022± 0.002 ($CHCl_3$, *c* 15.1), *i.e.* $[\alpha]_D$ of 0.16. The optical purity of the remained **9** was calculated to be 2.0%, from the lit.[9] value ($[\alpha]_D$ +7.28 for (*R*)-**9** of 91.8% e.e.).

The Crystal Structure of the 1-(2-Carboxyethyl)uracil : Phenethylamine (1 : 1) Complex[1]

Toshimasa Ishida,* Keizo Yamamoto, and Masatoshi Inoue
Osaka College of Pharmacy, 2-10-65 Kawai, Mastubara, Osaka 580

(Received August 4, 1982)

Synopsis. The crystal of the title complex is monoclinic, with a space group of Cc, $a=5.678(1)$, $b=33.814(7)$, $c=8.058(2)$ Å, $\beta=103.42(1)°$, and $Z=4$. The two component molecules are linked to each other by hydrogen bonds between the amino and carboxyl groups. No prominent interaction was observed between benzene and uracil rings.

In effort to obtain information bearing on the nature of the interactions between nucleic acid bases and protein side groups, various studies have been done by using the model systems containing these components. As a result, the stacking interaction, as well as hydrogen bonding, with nucleic-acid bases has been found to be essential for the aromatic amino acids.[2-5]

As part of the program aimed at exploring, at atomic resolution, the possible geometrical features of the interaction, we prepared the crystals of the 1:1 complex between 1-(2-carboxyethyl)uracil (CEU) and phenethylamine (PEA) as a model for uracil–phenylalanine interaction. The present paper will report its X-ray crystal structure.

Experimental

CEU, synthesized from uracil and acrylonitrile by the Ueda and Fox method[6] (mp 186—187 °C), was added to a 50% ethanol aqueous solution containing an equimolar amount of PEA.. Transparent platelet crystals were obtained by slow evaporation at room temperature. Although oscillation and Weissenberg photographs showed the space group to be Cc or C2/c, it was assumed to be noncentrosymmetric Cc from the statistical distribution of the normalized structure factors. The crystal data are as follows: $a=5.678(1)$, $b=33.814(7)$, $c=8.058(2)$ Å, $\beta=103.42(1)°$, $Z=4$, $D_m=1.344(1)$, $D_x=1.347$ g cm^{-3}, μ(Cu $K\alpha$)$=8.315$ cm^{-1}, $F(000)=648$. A total of 1297 independent intensity data were collected on a Rigaku four-circle diffractometer with graphite-monochromated Cu $K\alpha$ radiation using the ω-2θ scan technique (sin $\theta/\lambda \leqq 0.588$ Å^{-1}) with a scan speed of 4°/min and a scan width of 1.2°; they were corrected for the Lorentz and polarization factors, but not for the absorption effects (crystal size: $0.4\times0.3\times0.4$ mm^3).

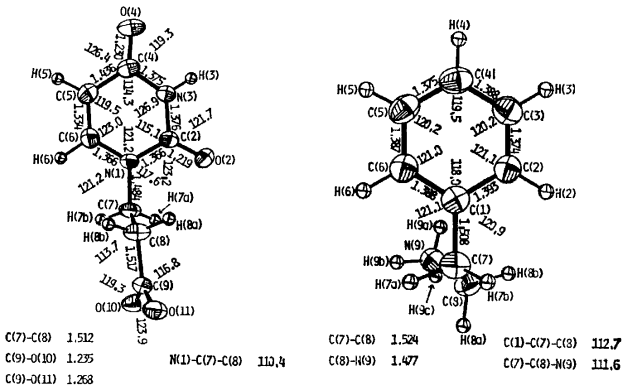

Fig. 1. Atomic numbering of the CEU:PEA complex with the bond lengths (l/Å) and angles (ϕ/°) of non-hydrogen atoms.
E.s.d.'s are 0.003 to 0.004 Å for lengths and 0.2 to 0.3° for angles. This figure also represents the molecular conformations projected onto the uracil and benzene rings.

The structure was solved by the direct method with the MULTAN program.[7] All the non-hydrogen atoms appeared clearly in the E-map, while the hydrogen atoms were found on a difference Fourier map. The R value was finally reduced to 0.029 by the block-diagonal least-squares refinement using the HBLS V program,[8] with anisotropic thermal parameters for non-hydrogen atoms and isotropic ones for hydrogen atoms. The quantity minimized was $\Sigma w(|F_o|-|F_c|)^2$. In the final refinements, the following weighting scheme was used: $w=0.3$ for $F=0.0$, $w=1.0$ for $0.0<F_o\leqq22.0$, and $w=1.0/[1.0+0.464(F_o-22.0)]$ for $F_o>22.0$. All the numerical calculations were carried out on an ACOS-900 computer at the Computation Center of Osaka University. The final positional parameters and equivalent isotropic temperature factors for non-hydrogen atoms are listed in Table 1.[9]

Results and Discussion

The bond lengths and angles for non-hydrogen atoms are given in Fig. 1. The dimensions of the uracil ring are comparable with the published data.[10] The ring is almost planar, with a maximum deviation of 0.014(3) Å at C(4), and the atoms attached to the ring except H(3) lie almost on the plane. The bond sequence of N(1)–C(7)–C(8)–C(9)–O(11) forms a fully

Table 1. Fractional coordinates and isotropic temperature factors of non-hydrogen atoms

The B values are the equivalent isotropic temperature factors calculated from the deposited anisotropic thermal parameters(B_{ij}) using this equation: $B_{eq}=4/3(B_{11}a^2+B_{22}b^2+B_{33}c^2+acB_{13}\cos\beta)$.

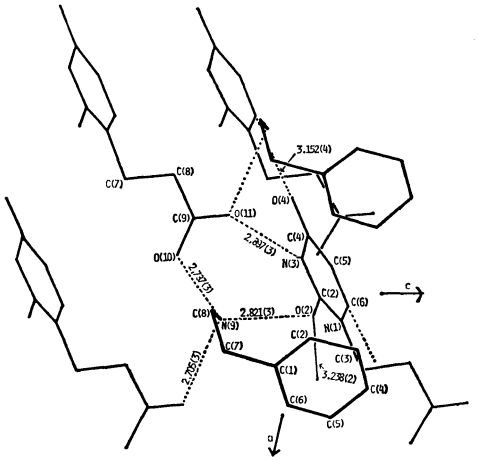

Fig. 2. The molecular arrangement of CEU and PEA in the crystal projected along the b-axis.
The broken lines represent the hydrogen bondings, and the thin line shows the short contact between the O(2) atom of CEU and the benzene ring of PEA.

extended *trans-zigzag* chain, and the torsion angles of C(2)–N(1)–C(7)–C(8), N(1)–C(7)–C(8)–C(9), and C(7)–C(8)–C(9)–O(11) are 84.9(3), −174.8(2), and 172.3(2)° respectively. The carboxyl group makes an angle of 100.6(1)° with the uracil ring. The bond distances and angles of the carboxyl group are in the range of the ionized form.[11]

The bond lengths and angles of PEA are in good agreement with those of phenethylamine[12] and L-phenylalanine.[13] The C–C bond lengths within the benzene ring are in the range of 1.374(4) to 1.393(4) Å (average value of 1.384 Å); this value is slightly shorter than that of the standard aromatic ring (1.395(3) Å).[11] Three hydrogen atoms of H(9a)–H(9c) are tetrahedrally bound to the N(9) atom, indicating the amino group to be in a cationic form. The plane of the aminoethyl group makes an angle of 96.1(1)° with the benzene ring, and the torsion angle of C(1)–C(7)–C(8)–N(9) is −55.3(3)°, in contrast to that of phenethylamine (=−171.1°).

The molecular arrangement projected along the b-axis is shown in Fig. 2. The hydrogen-bond lengths and angles are given in Table 2. In this complex, a salt bridge is formed between the anionic carboxyl group of CEU and the cationic amino group of PEA; the CEU and PEA molecules are linked to each other by three N–H···O hydrogen bonds between the amino nitrogen and carbonyl or carboxyl oxygen atoms [N(9)···O(2), N(9)···O(10) and N(9)···O(11)]. On the other hand, the N(3) of CEU at (x,y,z) is hydrogen-bonded to the O(11) atom of the same molecule translated at $(-1+x, y, -1+z)$, and the O(4) atom is hydrogen-bonded to the C(6) atom translated by the c-glide plane, which forms the *trans-zigzag* connection along the c-axis.

Although the hydrophobic and/or stacking interaction between the aromatic rings was suggested from the solubility study of the phenylalanine–uridine interaction,[14] there was no specific interaction in this crystal; the dihedral angle between the benzene and uracil rings is almost at a right angle [89.1(1)°]. The hydrogen bonds between the acid and amine might be preferable to any specific interaction of the uracil base and the benzene ring.

However, it is of interest to note that the O(2) atom of CEU points to the center of the benzene ring of PEA, with the distance of 3.238(2) Å, and that the angle of the C(2)–O(2) bond to the ring is 74.0°. Even though this distance is slightly longer than the van der Waals separation (3.1 Å), the possibility of interaction between the polarizable π-electron system and the polar carbonyl oxygen atom cannot be disregarded.

Table 2. Hydrogen-bond distances(l/Å) and angles (ϕ/°)

Donor (D)	Acceptor (A)	D----A	H---A	D-H---A

Preparation of Red Organic Pigment with Phenylated Silica Gel as Core

Mituru SUZUKI, Seisirô ITÔ,* and Tosihide KUWAHARA

Department of Applied Chemistry, Faculty of Science and Engineering, Kinki University, Kowakae, Higashiosaka, Osaka 577

(Received August 9, 1982)

Synopsis. The silanols on the surface of silica gel were chlorinated and a phenyl group was introduced onto the silica gel (≡Si–C_6H_5) by phenylating with phenyllithium. The surface group was derived to a structure similar to Sudan I by nitration, reduction, diazotization, and coupling (with 2-naphthol). The prepared pigment showed approximately the same color as Sudan I, and had very good resistance to water.

We have studied the introduction of alkoxyl groups onto silica gel (as model powder), silica, and titanium oxide by treating with aromatic alcohols [C_6H_5–$(CH_2)_n$–OH], and succeeded in the preparation of red or yellow pigments with metal oxides as core, by deriving the surface alkoxyl group to a structure similar to Sudan I (azo dyestuff) or tartrazine (food color).[1-3] But the surface groups of pigments were lost with hydrolysis in boiling water, because the surface groups were alkoxyl groups.

In this paper, silica gel was used as the reaction model; the surface silanols were chlorinated and a phenyl group was introduced onto the surface of silica gel by the reaction with phenyllithium. Pigment with the same color as Sudan I was prepared by deriving the surface phenyl group to a structure similar to Sudan I, by nitration, reduction, diazotization, and coupling with 2-naphthol.

Experimental

Silica gel (Wakogel C-200) was used as in the previous reports.[1,2] Thionyl chloride and benzene (commercial guaranteed reagent grade) were used after purification.[4] Phenyllithium solution (in cyclohexane–diethyl ether) (Aldrich Chemical Company's reagent) and diethyl ether (anhydrous) (Dotite reagent) were used. Chlorination and phenylation were performed according to one of the methods reported by Wartmann and Deuel:[5] 20 g of silica gel dried sufficiently at 110 °C was added to the mixture of 500 g of benzene and 160 ml of thionyl chloride, and was chlorinated by refluxing under stirring for 3 h. Benzene and thionyl chloride were distilled out and then the chloride of the silica gel was dried under 20 Torr (1 Torr=133.322 Pa) at 60 °C for 2 h. And 700 ml of 0.5 mol/l phenyllithium solution (in the mixture of cyclohexane and diethyl ether) was dropped slowly under cooling by ice bath, and the silica gel was phenylated by heating at 40 °C under stirring for 1 h. After the phenylation, the contents were added into about 500 ml of methanol to decompose the excess phenyllithium which did not react, and were filtered, washed (with methanol, water, and acetone) and vacuum dried (50 °C); the resulting sample was called phenylated. Nitration,[1,2] reduction,[2] diazotization,[1,2] and coupling[1,2] methods were the same as the previous reports.[1,2] The samples of each stage were called nitrated sample, reduced sample, and pigmented sample (which was coupled after diazotization).

IR spectrum and ultimate analysis of carbon and nitrogen were measured for the confirmation of the structure of surface group and the investigation of the character of the surface. The methods and conditions of measurements were the same as in the previous report.[2]

Results and Discussion

An IR spectrum of silica gel treated with phenyllithium after chlorination was shown in Fig. 1. Silica gel treated with phenyllithium exhibits 1420 and 700 cm^{-1} bands which are attributed to Si–C_6H_5. The strength of a 950 cm^{-1} band corresponding to the surface silanols of silica gel[6] decreased slightly. So it was confirmed that the surface silanols were phenylated, and the surface phenyl group was bonded directly to silicon atom on silica gel, as reported by Wartmann and Deuel.[5] The number of introduced phenyl groups calculated by carbon content (Table 1) is 2.76×10^{20} g^{-1}.

Then the phenylated sample was nitrated, reduced, diazotized, and coupled with 2-naphthol to prepare the red pigmented sample. The surface groups were separated from the silica gel core at each stage; their

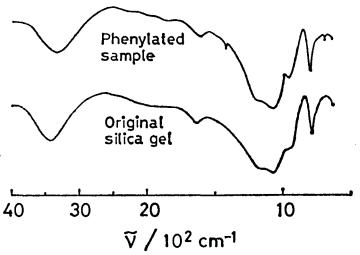

Fig. 1. IR spectra of original and phenylated silica gels.

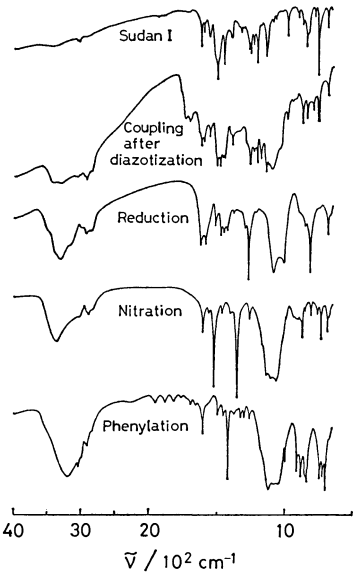

Fig. 2. IR spectra of the surface groups separated from the each sample.

IR spectra are shown in Fig. 2. The core silica gels of samples at each stage were dissolved with hot sodium hydroxide solution and the separated organic surface groups were extracted with ether. The ether extraction from the phenylated sample exhibits absorption bands in the neighborhood of 3000 (weak), 1600 (sharp), 1500 (weak), 1450 (weak), and 700 cm^{-1} (sharp) positions due to aromatic nucleus and also at 1420 (strong), 1120 (strong, shoulder), and 700 cm^{-1} (sharp) due to $Si–C_6H_5$. The bands at 3350 (broad) and 850 cm^{-1} (strong) are due to silanols and those at 1100—1000 cm^{-1} (strong) are due to Si–O–Si. After drying and calcination of the ether extraction part, white ash (SiO_2) remained. These results confirmed that the phenyl group is directly bonded to silicon atom, and that the Si–C bond in $\equiv Si–C_6H_5$ was very stable and did not split even under a severe condition such as in a hot alkali treatment. The ether extraction from the nitrated sample was found to exhibit absorption bands at 1520 (strong) and 1340 cm^{-1} (strong) and 870 cm^{-1} (sharp) positions, the former two bands being due to aromatic nitro group and third one to C–N stretching vibration. This means that the nitro group was introduced on the surface phenyl group. In the extraction from the reduced sample, the bands of the nitro group disappeared and the bands due to aromatic primary amine newly appeared in 3450 (broad), 3350 (broad), 1620 (strong), and 1280 cm^{-1} (strong) positions. The spectrum pattern of pigmented sample which was prepared *via* coupling after diazotization agreed with the pattern of Sudan I. So it was presumed that the surface group was derived to a structure similar to Sudan I by the aforementioned procedure. The strong bands at 1100—1000 cm^{-1} positions, as stated for the phenylated sample, was absorption due to Si–O–Si. The results mean that the red pigment with silica gel as core can be prepared according to the reaction scheme shown in Fig. 3. The pigmented sample showed approximately the same red color as Sudan I, azo dyestuff.

Results of the final analysis for the samples of each stage are shown in Table 1. Values found for the ratio of carbon and nitrogen contents (N/C) almost agreed with calculated values, but were slightly less than the calculated ones. So it was presumed that a small portion of the surface phenyl groups did not react in the further procedure and remained unchanged. The carbon and nitrogen contents of the pigmented sample did not show any decrease after refluxing in water for 5 h. And discoloration also did not occur at all after the refluxing. These results mean that the pigmented samples prepared by this procedure have great resistance to water.

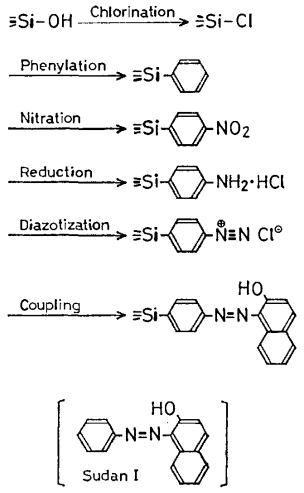

Fig. 3. Postulated reaction scheme.

Table 1. Results of ultimate analysis

Samples	C (%)	N (%)	N/C	
			Found	Calcd
Phenylated sample	3.31	0	—	—
Nitrated sample	3.38	0.55	0.16	0.19
Reduced sample	3.25	0.46	0.14	0.19
Pigmented sample	6.08	0.63	0.10	0.15

The Formation of Vinyl Sulfides by the Cleavage of the Carbon-Sulfur Bond in Dithioacetals with $CuCl_2$

Tatsuo OIDA,* Shigeo TANIMOTO,* Hideyuki IKEHIRA, and Masaya OKANO
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received August 14, 1982)

Synopsis. The elimination of arene- and alkanethiol from diaryl and dialkyl dithioacetals, in the presence of copper(I) or copper(II) salt plus tertiary amine, to produce the corresponding aryl and alkyl vinyl sulfides, respectively, has been studied. The employment of a combination of 2 mol equiv. of $CuCl_2$ and 2 mol equiv. of *N,N*-diisopropylethylamine is most favorable.

Cohen and co-workers have reported that, in the presence of *N,N*-diisopropylethylamine, the benzene complex of copper(I) trifluoromethanesulfonate promotes the removal of benzenethiol from the unsaturated or vinylogous diphenyl dithioacetals to produce 1,3-butadienes substituted with a phenylthio group.[1,2] Prior to this work, Mukaiyama and co-workers have found that, in the presence of 2,6-lutidine, the $CuCl_2$-induced reaction of benzaldehyde diethyl dithioacetal with malononitrile in tetrahydrofuran proceeds smoothly to afford the condensation product, benzylidenemalononitrile.[3] They have also found that $CuCl_2$ together with CuO can convert a wide variety of 1,3-dithiane derivatives into the corresponding carbonyl compounds.[4] Since all of these reactions appear to involve a reaction mechanism in which the alkylthio or arylthio group is liberated from the dithioacetal molecule, it can be concluded that, in the presence or absence of tertiary amine, copper(I) or copper(II) salt effects the cleavage of one or two carbon-sulfur bonds in dithioacetals. With these considerations in mind, we have studied the elimination of arene- and alkanethiol from several diaryl and dialkyl dithioacetals, in the presence of copper(I) or copper(II) salt plus tertiary amine, to produce the corresponding aryl and alkyl vinyl sulfides.

In preliminary experiments, phenylacetaldehyde diphenyl dithioacetal (**1a**) and two molar amounts of *N,N*-diisopropylethylamine in benzene[5] were heated at reflux temperature with stirring for 24 h without any reaction occurring. When copper(I) or copper(II) salt was added to the mixture, the expected reaction took place to afford phenyl styryl sulfide (**2a**) and phenyl disulfide (**3a**).

$$\underset{\mathbf{1}}{(RS)_2CHCHR'R''} \xrightarrow[\text{benzene}]{CuX_n,\ \text{tertiary amine}} \underset{\mathbf{2}}{RSCH{=}CR'R''} + 1/2\ \underset{\mathbf{3}}{RSSR}$$

a: R=R'=C_6H_5, R''=H
b: R=C_6H_5, R'=*n*-C_3H_7, R''=H
c: R=C_6H_5, R'=R''=CH_3
d: R=C_6H_5, R'=CH_2=CH–, R''=H
e: R=C_6H_5, R'=CH_2=C(CH_3)–, R''=H
f: R=$C_6H_5CH_2$, R'=C_6H_5, R''=H
g: R=CH_3, R'=C_6H_5, R''=H
h: R=C_2H_5, R'=C_6H_5, R''=H

Table 1 shows that, among these copper(I) and copper(II) salts, only anhydrous $CuCl_2$ is available for the elimination and that even in the case with $CuCl_2$ the use of an excess or a deficiency of this salt causes a significant decrease in the yield.

We then examined the possibility of substituting the other tertiary amines for the *N,N*-diisopropylethylamine employed in the above experiments. Thus when **1a** and two molar amounts of $CuCl_2$ in benzene were heated at reflux temperature with stirring for 24 h, in the presence of a variety of tertiary amines, **2a** and **3a** were obtained in the yields shown in Table 2, together with unchanged **1a**.

As can be seen from Table 2, the addition of tertiary amine is unessential to promote the formation of **2a**, since the yield of **2a** in the absence of any tertiary amine is nearly equal to that obtained in the cases where 2 mol equiv. of *N,N*-diisopropylethylamine or 2,6-lutidine was used. However, it is noteworthy that

a) Except **2c**, these products seem to be a mixture of *trans*-isomer and *cis*-isomer in small amounts. The isolation of **3**, which was produced together with **2**, was omitted because of its minor importance. The ^{1}H-NMR spectra (60 MHz, δ, in CCl_4) are as follows: **2a**: 6.41(d, 1H, J=17 Hz), 6.68(d, 1H, J=17 Hz), 7.0—7.7(m, 10H). **2b**: 0.96(t, 3H, J=6 Hz), 1.0—1.8(m, 2H), 1.9—2.4(m, 2H), 5.5—6.3(m, 2H), 7.1—7.3(m, 5H). **2c**: 1.86(s, 6H), 5.86(s, 1H), 7.0—7.3(m, 5H). **2d**: 4.7—5.2 (m, 2H), 6.1—6.7(m, 3H), 7.1—7.5(m, 5H). **2e**: 1.83(s, 3H), 5.86(d, 1H, J=1 Hz), 6.35(d, 1H, J=1 Hz), 6.60(d, 1H, J=10 Hz), 7.17(d, 1H, J=10 Hz), 7.0—7.5(m, 5H). **2f**: 3.70(s, 2H), 6.16(d, 1H, J=15 Hz), 6.48(d, 1H, J=15 Hz), 7.0—7.3(m, 10H). **2g**: 2.22(s, 3H), 6.18(d, 1H, J=17 Hz), 6.69(d, 1H, J=17 Hz), 7.1—7.4(m, 5H). **2h**: 1.23(t, 3H, J=7 Hz), 2.4—2.9(m, 2H), 6.18(d, 1H, J=17 Hz), 6.45(d, 1H, J=17 Hz), 7.0—7.5(m, 5H). b) Yield of isolated product based on **1**.

simply by adding 2 mol equiv. of the tertiary amine to the reaction mixture the proportion of recovered **1a** can be increased to 47% from 25%. An advantage of the employment of the tertiary amine lies in that it suppresses the occurrence of undesirable side reaction. Presumably, an obvious difference in yields of **2a** between the former case and the latter case using 2 mol equiv. of the tertiary amine should be observed if the reaction time is extended over 24 h. On the other hand, the use of a large excess of *N,N*-diisopropylethylamine results in a significant decrease in yield of **2a**. The addition of 2 mol equiv. of triethylamine or pyridine also diminished the yield of **2a**, presumably due to the complex formation between the amine and $CuCl_2$. The inactivity of such a complex is easily understandable if we consider the finding that the pre-formed 1:2 complex between $CuCl_2$ and pyridine does not promote the reaction.

This information concerning the elimination of benzenethiol from **1a** in benzene to produce **2a** could help in accomplishing the conversion of the other dithioacetals (**1**) into the corresponding vinyl sulfides (**2**). Thus, when diaryl and dialkyl dithioacetals in benzene were heated at reflex temperature with stirring for 36 h in the presence of 2 mol equiv. of $CuCl_2$ and 2 mol equiv. of *N,N*-diisopropylethylamine, the moderately good yields of the corresponding aryl and alkyl vinyl sulfides were obtained toegther with disulfides (**3**), suggesting that our procedure is fairly general for this type of elimination reaction. Table 3 shows the results obtained with **1b—h**, including **1a**, as the starting substrate.

Experimental

1a, **1b**, **1c**, **1d**, and **1e** were synthesized in yields of 99, 93, 88, 99, and 91%, respectively, by the reaction of lithiated formaldehyde diphenyl dithioacetal in tetrahydrofuran with each of benzyl bromide, butyl bromide, isopropyl bromide, allyl bromide, and 2-methylallyl chloride.[6] **1g** was prepared in yield of 60%, by the same procedure, from lithiated formaldehyde dimethyl dithioacetal and benzyl bromide. **1f** and **1h** were synthesized in yields of 96 and 90%, respectively, by the *p*-toluenesulfonic acid-promoted interchange reaction of phenylacetaldehyde dimethyl acetal in benzene with α-toluenethiol and with ethanethiol.

Reactions Summarized in Table 1. The copper(I) or copper(II) salt used for each run is listed in Table 1. To a suspension of the salt in 20 ml of benzene were added 0.2 mmol of phenylacetaldehyde diphenyl dithioacetal (**1a**) and 0.4 mmol of *N,N*-diisopropylethylamine under nitrogen. The mixture was heated at reflux temperature with stirring for 24 h. Thirty ml of water was added and the organic layer was separated and subjected to GLC.

Reactions Summarized in Table 2. The tertiary amines used were noted in Table 2. To a suspension of 0.4 mmol of $CuCl_2$ in 20 ml of benzene were added 0.2 mmol of phenylacetaldehyde diphenyl dithioacetal (**1a**) and the tertiary amine under nitrogen. The mixture was heated as above, and similarly worked up. The obtained organic layer was subjected to GLC.

Reactions Summarized in Table 3. To a suspension of 0.4 mmol of $CuCl_2$ in 20 ml of benzene were added 0.2 mmol of a dithioacetal (**1**) and 0.4 mmol of *N,N*-diisopropylethylamine under nitrogen. After the addition was complete, the mixture was heated at reflux temperature with stirring for 36 h. Thirty ml of water and 50 ml of saturated aqueous solution of NH_4Cl were added, and the mixture was extracted with several portions of ether. The combined ethereal extracts were dried, filtered, and concentrated *in vacuo* to give a residue. The products were isolated by column chromatography on silica gel, using 20% benzene–hexane or 10% chloroform–hexane as the eluent.

Palladium-catalyzed Reaction of 4′-Iodobenzocrown Ethers with Acetylenes. Convenient Synthesis of Alkyl-substituted Benzocrown Ethers and Bis(benzocrown ether)s *via* Alkynyl-substituted Benzocrown Ethers

Kiyoshi KIKUKAWA,* AkitoABE, Fumio WADA, and Tsutomu MATSUDA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received September 11, 1982)

Synopsis. 4′-Iodobenzo-15-crown-5 and -18-crown-6 were alkynylated by heptyne, propargyl alcohol, 1,7-octadiyne and acetylene in good yields with use of $Pd(PPh_3)_2Cl_2$ and CuI as catalysts. The latter two acetylenes gave bis(crown ether)s in one step. Hydrogenation of the alkynylated benzocrown ethers gave 4′-heptyl, 4′-(3-hydroxypropyl)-benzocrown ethers and bis(benzocrown ether)s connected with ethylene or octamethylene linkage.

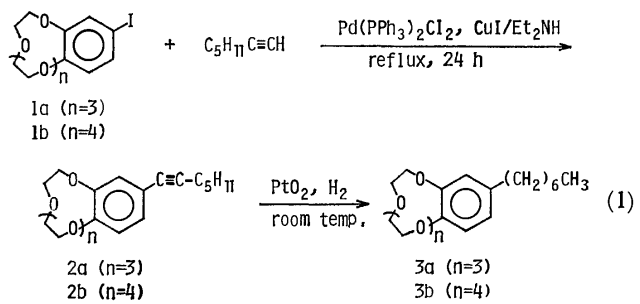
Functionalized benzocrown ethers have received much attention through not only their modified nature of complexation with cations, but also their specialized utility for analytical[1] and pharmaceutical applications,[2] and as potential intermediates for other functionalized crown ethers, such as polymer-bound crown ethers[3] or bis(crown ether)s.[4] Since halogenation and nitration of benzocrown ethers at 4′-position can be carried out with excellent yields, the transformation of halo[5] or nitro group[6] on benzocrown ethers is one of the promising methods to obtain the functionalized benzocrown ethers. Alkenylated benzocrown ethers have been synthesized by palladium-catalyzed reaction of 4′-halobenzocrown ethers with olefins, such as styrene or acrylic acid and its derivatives.[5] The alkenylation of haloarenes with simple olefins such as 1-octene, however, gives a mixture of regioisomers, *i.e.*, 1-aryloctenes and 2-aryloctenes.[7] Whereas there is no ambiguity of the substituted position in the palladium-copper-catalyzed alkynylation of iodoarenes by terminal acetylenes.[8]

Now we wish to report a convenient transformation of 4′-iodobenzocrown ethers to the alkylbenzocrown ethers and bis(benzocrown ether)s *via* the alkynylated benzocrown ethers.

Results and Discussion

*Alkynylation of 4′-Iodobenzocrown Ethers (**1**).* A solution of a 4′-iodobenzocrown ether(**1**), 1-heptyne, $Pd(PPh_3)_2Cl_2$, and CuI in diethylamine was refluxed for 24 h under nitrogen (Eq. 1).

After evaporation of diethylamine from the reaction mixture, the residue was purified by passing it through a short alumina column with chloroform as eluent.



(1)

On being conducted at room temperature as the alkynylation of iodobenzene in the original report,[8] the reaction did not proceed to lead recovery of **1**. Longer reaction time (for 2 d), however, reduced the yield. The use of triethylamine or morpholine instead of diethylamine did not give **2**. Purification of

Table 1. Hydrogenation of alkynylated benzocrown ethers

Products	*n*	Yield[a] %	Mp θ_m/°C	Found (Calcd) (%) C	H

a) Isolated and purified yields based on alkynylated benzocrown ethers.

1 by recrystallization from heptane was found to be essential to obtain good yields, and the present reaction did not proceed when **1** was purified only by column chromatography (alumina–chloroform).

The reaction of **1** with propargyl alcohol and 1,7-octadiyne under the same reaction conditions gave the following compounds, **4** and **5**, respectively. Introduction of acetylene gas to a hot solution of **1**, Pd(PPh_3)$_2Cl_2$, CuI and diethylamine for 3 h gave the bis(benzocrown ether) (**6**). The alkynylated benzocrown ethers in general were obtained in excellent yields, irrespective of the nature of acetylenes.

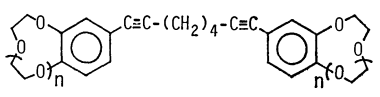
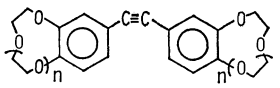
4b (n=4)



5a (n=3)
5b (n=4)



6a (n=3)
6b (n=4)

Hydrogenation of Alkynylated Benzocrown Ethers. The alkynylated benzocrown ethers were effectively hydrogenated by atmospheric hydrogen under PtO_2 catalysis at room temperature (Eq. 1). Typical results are summarized in Table 1.

Since **1** is easily obtained from benzocrown ethers in a good yield, the present method provides a convenient route to prepare functionalized benzocrown ethers, especially a new type of bis(benzocrown ether)s connected with polymethylene linkage.

Experimental

Materials. 1-Heptyne, 1,7-octadiyne, propargyl alcohol, PPh_3, $PdCl_2$, CuI, and PtO_2 were used as received. Diethylamine and methanol were distilled before use. 4′-Iodobenzocrown ethers[9] and Pd(PPh_3)$_2Cl_2$[10] were prepared by the published methods, respectively. 4′-Iodobenzocrown ethers were purified by recrystallization from heptane.

General Procedure. A solution of a **1** (1.0 mmol), an acetylene derivatives (1.2 mmol as ethynyl unit), Pd(PPh_3)$_2Cl_2$ (0.01 mmol), and CuI (0.04 mmol) in diethylamine (10 ml) was refluxed for 24 h under nitrogen. When acetylene was used, acetylene gas was passed through a solution of **1**, Pd(PPh_3)$_2Cl_2$ and CuI in diethylamine under gentle reflux. After removal of diethylamine under reduced pressure, the residue was purified by chromatography (alumina–chloroform) or recrystallization from hexane. In the case of 4′-alkynylated benzo-18-crown-6s which were obtained in *ca.* 61—83% yields, however, small amounts of unknown impurities (2—5%) could not be removed even after purification was repeated several times, although hydrogenation of the crude crown ethers gave easily the corresponding pure hydrogenated products. Therefore the structure of 4′-alkynylated benzo-18-crown-6s was confirmed by both the IR & NMR spectra and elemental analysis of the corresponding hydrogenated crown ethers.

Analytical data of 4′-alkynylbenzo-15-crown-5s are as follows.

*4′-(1-Heptynyl)benzo-15-crown-5(**2a**)*: Yield 87%, oil, NMR ($CDCl_3$) δ=0.93 (–CH_3, t, 3H), 1.15—1.80 (–CH_2–, m, 6H), 2.05—2.55 (–C≡C–CH_2–, t, 2H), 3.50—4.25 (–OCH_2CH_2O–, m, 16H), 6.45—6.91 (aromatic protons, m, 3H), Found: C, 69.06; H, 8.29%. Calcd for $C_{21}H_{30}O_5$: C, 69.59; H, 8.34%.

*4′-(3-Hydroxy-1-propynyl)benzo-15-crown-5(**4a**)*: Yield 73%, mp 118.9—120.3 °C, NMR ($CDCl_3$) δ=2.05 (–OH, s, 1H), 4.4 (–C≡C–CH_2–O–, s, 2H), 3.5—4.3 (–OCH_2CH_2O–, m, 12H), 6.6—7.1 (aromatic protons, m, 3H). Found: C, 63.44; H, 6.93%. Calcd for $C_{17}H_{22}O_6$: C, 63.34; H, 6.88%. **5a**: Yield 88%, mp 108.5—110.7 °C, NMR ($CDCl_3$) δ=1.50—1.95 (–CH_2–, m, 4H), 2.10—2.60 (–C≡C–CH_2–, m, 4H), 3.45—4.15 (–OCH_2CH_2O–, m, 32H), 6.45—6.95 (aromatic protons, m, 6H), Found: C, 67.33; H, 7.37%. Calcd for $C_{36}H_{46}O_{10}$: C, 67.69; H, 7.26%. **6a**: Yield 98%, mp 125.4—127.0 °C, NMR ($CDCl_3$) δ=3.6—4.3 (–OCH_2CH_2O–, m, 32H), 6.6—7.2 (aromatic protons, m, 6H). Found: C, 64.33; H, 6.94%. Calcd for $C_{30}H_{38}O_{10}$: C, 64.50; H, 6.86%. The C≡C stretching of the alkynylated benzocrown ethers was generally not observed, except **4a**(2220 cm^{-1}) and 4′-(3-hydroxy-1-propynyl)benzo-18-crown-6 (2220 cm^{-1}).

Hydrogenation of the alkynylated benzocrown ethers was carried out by atmospheric hydrogen with PtO_2 in methanol at room temperature. After removal of solvent and catalyst, the products were easily purified by chromatography (alumina–chloroform) or recrystallization from hexane, The structure of 4′-alkylbenzocrown ethers was also confirmed by IR, NMR, and elemental analysis.

Primary Structure and Molecular Evolution of Intestinal Calcium-binding Protein

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received September 18, 1982)

Synopsis. The primary structure and the molecular evolution of protein were examined with bovine and porcine intestinal calcium-binding protein (ICaBP). The amino acid sequence of this protein was compared with that of ancestral calmodulin, which had been predicted as the most ancient form in the family of calcium-binding proteins.

Much attention has been paid to the structure and properties of calcium-binding proteins.[1] These proteins interact reversibly with Ca^{2+} to form a protein–Ca^{2+} complex, whose activity is controlled by the cellular flux of Ca^{2+}. They can regulate other enzymatic reactions and cellular processes, thus playing an important role in various biological systems. Of the calcium-binding proteins so far studied, calmodulin (CaM) is the most widely distributed throughout eukaryotes. The highly conserved structure observed in various CaM which had been isolated from phylogenetically diverse species suggests that CaM is probably the most ancient in the family of calcium-binding proteins.[2] In previous papers,[3,4] we examined the primary structure and the molecular evolution of CaM taken from phylogenetically diverse species. One notable feature of the primary structure of CaM is its internal homology. It can be subdivided into four domains having a similar amino acid sequence. This homology implies that the primary structure of CaM should have been elongated by twice events of intragenic duplication. Making use of this internal homology, we could predict, to some extent, the amino acid sequence of ancestral CaM,[3] which is supposed to be the most ancient form of CaM.

On the other hand, another kind of high-affinity calcium-binding proteins has been identified in the intestinal mucosae of a variety of animals, including reptiles, amphibians, birds and mammals.[5,6] These proteins have been shown to exhibit a dependency on vitamin D or its metabolites. Intestinal calcium-binding protein (ICaBP) is an acidic protein with molecular weight of 9000, and appears to bind two Ca^{2+} ions per molecule. Although the molecular role of ICaBP is not known, it is likely that this protein functions analogously to CaM, *i.e.* by conferring calcium sensitivity to another enzymatic reaction.

The amino acid sequence of bovine ICaBP was recently determined by Fullmer *et al.*,[6] while that of porcine ICaBP, by Hofmann *et al.*[5] For the complete amino acid sequences, refer to those references. In the following, we compare the amino acid sequences between ICaBP and the ancestral CaM, and examine the molecular evolution of ICaBP. In connection with this, we also discuss the internal sequence homology of ICaBP itself.

According to our previous analysis,[3] the ancient form of CaM was supposed to be ···HC···HC···, where HC (half-calmodulin) is the amino acid sequence given by Fig. 1, and where HC has two domains of calcium-binding sites. In the sequence of HC, the brackets show amino acid residues which cannot be determined by our analysis. At the birth of CaM, doubling of HC (*i.e.*, ···HC···HC···) occurred through intragenic duplication, resulting in the four calcium-binding sites of CaM. If ICaBP arises from ancestral CaM through evolution, the amino acid sequence of ICaBP will have homology to that of ancestral CaM. Since ICaBP has two calcium-binding sites, we compared the sequences of bovine ICaBP and ···HC··· (former or latter half of ancestral CaM). This result is also shown in Fig. 1, where we found a strong homology between the two sequences. In this figure, solid-line boxes indicate positions for which the amino acid residues of the two sequences are identical, while dashed-line boxes, positions for which the two amino acids are related by functionally conservative replacements. Note that most of the positions of solid-line boxes corresponds to the putative calcium-binding residues as predicted by the Kretsinger model.[7] This fact implies that, in both of ICaBP and CaM, the calcium-binding residues are particularly conservative against evolution. If there occurs significant

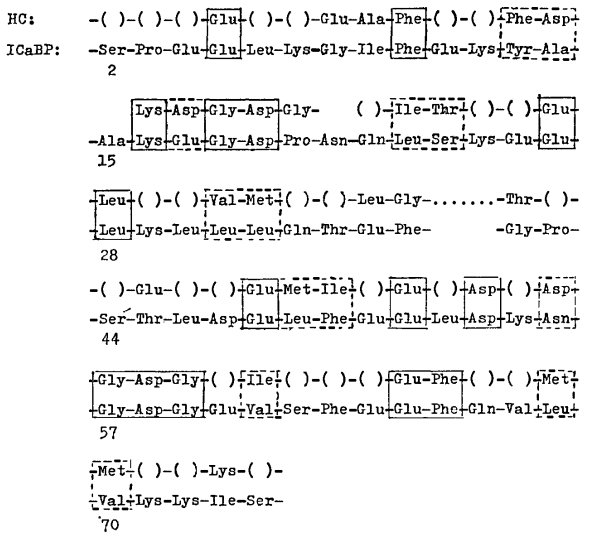

Fig. 1. Comparison of amino acid sequences between ancestral half-calmodulin (HC) and bovine intestinal calcium-binding protein (ICaBP).
Solid-line boxes indicate positions for which the amino acid residues of the two sequences are identical, while dashed-line boxes, positions for which the two amino acids are related by functionally conservative replacements. The sequence of HC was taken from Ref. 3, while that of bovine ICaBP, from Ref. 6. Brackets in HC show amino acids which could not be determined by the analysis described in Ref. 3. Numbers shown in ICaBP indicate positions of amino acid residues as given by Ref. 6.

change of those residues, it will give rise to the loss of calcium-binding function. Thus, the calcium-binding residues have to be highly conservative against evolution.

The strong homology of amino acid sequences between ICaBP and ···HC··· implies that ICaBP should have arisen from ancestral CaM. It was also found that, in order to obtain maximum homology, two amino acid residues of –Ala– and –Asn– should be inserted at positions 15 and 21, respectively, in the sequence of ICaBP, as is shown in Fig. 1. Occurrence of this insertion event in the course of the ICaBP molecular evolution was also supported by examining the internal homology of ICaBP in the following.

As for the homology between ICaBP and ···HC···, a question may arise why the length of the ICaBP sequence is half of that of ancestral CaM. As was mentioned, ICaBP has two domains of calcium-binding sites, while CaM, four domains. If the common ancestor of ICaBP and CaM is the ancient form of ···HC···HC···, the following evolutionary process must have taken place. Since the birth of CaM, CaM has had evolutionary changes and has accumulated accepted point mutations. In the course of evolution, however, several copies of CaM gene have been created by gene duplication, and one of them changed into ICaBP gene at certain time. This change was more drastic than point mutation of amino acid residues. Deletion of former or latter half of the amino acid sequence took place in CaM, and the remaining half of the sequence became ICaBP. The time of such creation of ICaBP may probably be the time when the common ancestor of amphibians, reptiles, birds and mammals appeared, because ICaBP's are found only in the intestines of those animals. After divergence from CaM, ICaBP has received independently accepted point mutations and two amino acid insertions of –Ala– and –Asn– as mentioned above. In Fig. 1, the amino acid sequence of HC is considered as the original one. Then, in ICaBP, those amino acid residues which are no longer identical with those of HC correspond to the residues which have received accepted point mutations. The insertion of two amino acid residues in ICaBP should have taken place after the divergence from CaM, because no such amino acid insertion is detected in CaM. Note that several other copies of CaM gene diverged into various related proteins, such as troponin C, to form the family of calcium-binding proteins.

As for the ancestor of ICaBP, a question may arise if there is any possibility that the ancestor of ICaBP may not be ···HC···HC··· but may be HC itself. However, this possibility can be rejected because of the following reasons. (1) ICaBP is distributed only in the intestines of amphibians, reptiles, birds and mammals. On the other hand, there is an evidence that HC had been living before the birth of ancestral CaM.[3] If the ancestor of ICaBP is not CaM but HC, the descendant protein of HC should be distributed widely in phylogenetically diverse species including fungi and plants. (2) Evolutionary rate of ICaBP is much more rapid than that of CaM. It is very hard to consider that such a rapidly changing protein may be originated from so early living HC. (3) There is another example of calcium-binding protein which has lost long amino acid sequence. Parvalbumin, which also arose from CaM, lost a quarter of the whole sequence.[7]

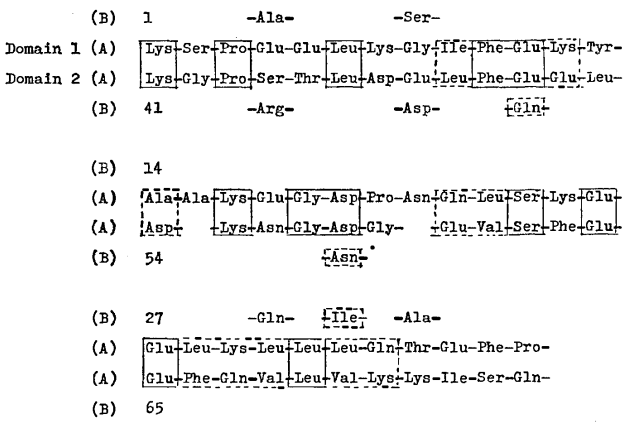

Fig. 2. Internal homology of amino acid sequences of bovine (A) and porcine (B) intestinal calcium-binding proteins (ICaBP).
In each case, the former half (Domain 1) and the latter half (Domain 2) of the sequence are compared. For solid-line boxes, dashed-line boxes and numbers given in the figure, see the caption of Fig. 1. The sequence data were taken from Refs. 5 and 6.

Finally, the amino acid sequence of ICaBP is also found to possess internal homology, that is, the former half of the sequence is very similar to the latter half. This is shown with bovine and porcine ICaBP in Fig. 2. Again, in this case, insertion of two amino acid residues of –Ala– and –Asn– is necessary to obtain maximum homology. The internal homology of ICaBP is well explained if we consider that CaM can be subdivided into four domains with similar amino acid sequences and that ICaBP corresponds to the former or latter half of the CaM sequence.

Benzocyclobutenes Part 8.[1] Geometrical Isomerism of Arylhydrazones of Benzocyclobutene-1,2-dione

Mark Edward CRACKNELL, Michael Charles GOODLAND, and John Frederick William McOMIE*
School of Chemistry, The University, Bristol BS8 1TS, England
(Received June 28, 1982)

Synopsis. Four mono(arylhydrazone)s of benzocyclobutene-1,2-dione (BBD) have been prepared in which the aryl group is 2,4-dinitrophenyl, 4-bromophenyl, phenyl, and 4-nitrophenyl. The first three have been separated into their *E*- and *Z*-isomers whose configurations are assigned on the basis of spectra and R_f values. Improvements in the preparation of BBD from 1,2-dibromo-1,2-dihydrobenzocyclobutene are described.

During studies on reactions of 5,10-diazabenzo-*b*-biphenylene it was found that hydrolysis of this compound with hydrochloric acid in the presence of 2,4-dinitrophenylhydrazine gave the mono(2,4-dinitrophenylhydrazone) of benzocyclobutene-1,2-dione (BBD) (**1**) as a mixture of *E*- and *Z*-isomers.[2] BBD was known to give a bis(2,4-dinitrophenylhydrazone) but attempts to prepare mono-derivatives with hydrazine and tosylhydrazine had given the 1(2*H*)-phthalazinones **2** and **3** respectively.[3] We describe here an improved preparation of BBD and the preparation from it of four monoarylhydrazones also the separation of three of them into their geometrical isomers and the assignment of their configuration.

The monoarylhydrazones were made by treating BBD with one equivalent of the appropriate arylhydrazine. With each reagent a mixture of the *E*- and *Z*-isomers was obtained and those from 2,4-dinitrophenyl-, 4-bromophenyl-, and phenyl-hydrazine were separated by preparative TLC. The mixture of isomers from 4-nitrophenylhydrazine could not be separated. 4-Bromophenylhydrazine gave a variable yield of the 1(2*H*)-phthalazinone **4** (as well as the *E*- and *Z*-hydrazones) depending on the reaction conditions. The structure of the phthalazinone **4** follows from its analysis and its IR spectrum ($\nu_{C=O}$ 1660 and $\nu_{C=N}$ 1595 cm^{-1}; ν_{N-H} was absent) which agrees with that of the 2-tosyl-1(2*H*)-phthalazinone **3** ($\nu_{C=O}$ 1695 and $\nu_{C=N}$ 1600 cm^{-1}). Furthermore the NMR spectrum of compound **4** showed a singlet at δ 8.29 for the azomethine proton and the spectrum did not change when D_2O was added to the solvent, thus confirming the absence of an NH group.

Assignment of Configuration. Our assignments are based on the work of Nashima and co-workers[4] who studied the geometrical isomerism of the 2,4-dinitrophenylhydrazones of four esters of pyruvic acid. They found that in each pair of geometrical isomers the *Z*-isomer (having an intramolecular hydrogen bond between the imino hydrogen and the ester carbonyl group) has the higher R_f value, the longer wavelength of the absorption maximum in the UV/visible spectrum, and the lower C=O and N–H stretching frequencies in the IR spectrum. Our results, shown in the Table 1, are consistent with those of the Japanese workers. Unfortunately most of our compounds were too sparingly soluble in dichloromethane to observe the weak N–H stretching bands. The NMR spectra of each pair of isomers should provide confirmation of the assignments since the hydrogen bonded imine proton should resonate well downfield of the non-hydrogen bonded imine proton. This effect was found by Nashima and co-workers but we were unable to obtain information about the δ_{NH} values, except for compound **9**, because of the low solubility of the arylhydrazones in $CDCl_3$ and CD_3COCD_3. We did not try more polar solvents because they are known to favour interconversion of isomers.[5]

In the above discussion we have tacitly assumed that the *Z*-isomers **5**, **7**, and **9** contain intramolecular N–H···O hydrogen bonds. Scale drawings of these isomers (based on the crystal structure of BBD[6]) show that the relevant N to O distance is about 3.3 Å which is just within the limits for an N–H···O bond (2.6—3.3 Å).[7] However the angle subtended by the atoms N, H, and O can be 134° to 123° depending on the values (from 109° to 120°) chosen for the NNH angle.

TABLE 1. PHYSICAL PROPERTIES OF (*Z*)- AND (*E*)-MONO(ARYLHYDRAZONE)S

Compound	R_f value (CH_2Cl_2/silica gel)	λ_{max}/nm (CH_2Cl_2)	$\nu_{C=O}$/cm^{-1} (CH_2Cl_2)
5	0.35	418	1768
6	0.30	382	1793
7	0.70	434	1760
8	0.50	407	1787
9	0.70	432	1760
10	0.50	408	1782

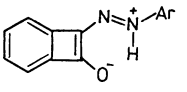
(5) Ar = 2,4-dinitrophenyl (6)
(7) Ar = 4-bromophenyl (8)
(9) Ar = phenyl (10)



(11)

According to Speakman[7] when the angle NHO becomes less than 140° "genuine hydrogen bonding must become minimal." Nevertheless the physical properties of isomers **5**, **7**, and **9**, compared with those of isomers **6**, **8**, **10**, do suggest intramolecular hydrogen bonding. The actual bond angles in these *Z*-isomers may be more favourable than the scale drawings suggest. Furthermore there is the possibility that the canonical form **11** makes a small but significant contribution which would strengthen the hydrogen bond.

Experimental

IR and UV spectra were measured as solutions in dichloromethane. Some of the UV spectra are qualitative because of the sparing solubility of the arylhydrazones in this solvent. The ^{1}H NMR spectra were recorded on a Varian HA-100 spectrometer. Petroleum refers to light petroleum (bp 60—80 °C). TLC was carried out on silica gel M. F. C. (Hopkin and Williams). The product compositions were estimated from the size of spots on TLC and are therefore very approximate.

Improved Preparation of Benzocyclobutene-1,2-dione. 1,2-Dibromo-1,2-dihydrobenzocyclobutene[8] was freed from iodine-containing impurities by keeping a solution of it (100 g) and bromine (20 g) in carbon tetrachloride (600 ml) for 24 h, preferably in sunlight. The solution was then washed with aqueous sodium hydrogensulfite, dried and distilled in vacuo. A solution of the purified dibromide (20 g) in carbon tetrachloride (300 ml) was irradiated by two 200-W tungsten-filament light bulbs placed under the flask: the heat from the bulbs kept the liquid boiling. Bromine (27.2 g) was added dropwise during 2 h and heating/irradiation was continued for 16 h more. The solvent and excess of bromine were removed under reduced pressure. The residual solid (32.5 g) was recrystallized from petroleum and gave 1,1,2,2-tetrabromo-1,2-dihydrobenzocyclobutene (28.9 g, 90%), mp 118—119 °C (lit,[9] mp 117—118 °C, yield 65%). The tetrabromide was hydrolysed to BBD as previously described.[9]

Benzocyclobutenedione Mono(2,4-dinitrophenylhydrazone). BBD (34 mg) was added to a warm solution of 2,4-dinitrophenylhydrazine (50 mg) in 5 M HCl (5 ml) and the mixture was warmed on a water bath at 60—70 °C for 30 min. The mixture was cooled and the mixture of *E*- and *Z*-isomers (70 mg, 89%) was collected, mp 228—240 °C (the previously recorded[2] mp 249—250 °C was an error). TLC using CH_2Cl_2 showed that the mixture contained roughly equal amounts of both isomers which were separated by preparative TLC (CH_2Cl_2–petroleum, 3:2). The band with the higher R_f value gave the (*Z*)-dinitrophenylhydrazone **5** as an orange solid, mp 235—240 °C; IR 1768 and 1713 cm^{-1}; UV λ_{max} (qualitative) 236, 258 sh, 400, and 418 nm. Found: M$^+$, 312.050. Calcd for $C_{14}H_8N_4O_5$: M, 312.049. The band with the lower R_f value gave the (*E*)-dinitrophenylhydrazone **6** as orange crystals, mp 238—239 °C; IR 1793, 1713, 1615, and 1600 cm^{-1}; UV λ_{max} 236 (log ε 3.96), 256 sh (3.86), and 382 (4.08) nm. Found: M$^+$, 312.050.

Benzocyclobutenedione Mono(4-bromophenylhydrazone). BBD (34 mg) was added to a warm solution of 4-bromophenylhydrazine hydrochloride (54 mg) in 4 M HCl (10 ml) and the mixture was warmed on a water bath at 60—70 °C for 30 min. Next day the solid (51 mg) was collected. The mixture was separated into three components by preparative TLC (elution with CH_2Cl_2). The band with the highest R_f value (0.7) gave the (*Z*)-4-bromophenylhydrazone **7** as a yellow-orange solid, mp 205—206 °C; IR 1760, 1595, and 1070 cm^{-1}; UV λ_{max} (qualitative), 259, 295 sh, 315 sh, 339, and 434 nm. Found: M$^+$, 301.985 and 299.988. Calcd for $C_{14}H_9BrN_2O$: M, 301.987 and 299.987. The band with R_f value 0.5 gave the (*E*)-4-bromophenylhydrazone **8** as yellow-orange crystals, mp 219—220 °C (from ethanol) as major product; IR 1787 and 1570 cm^{-1}; UV λ_{max} 258 (log ε 4.26), 342 (4.10), and 407 (4.12) nm. Found: C, 56.1; H, 3.1; N, 9.4%. Calcd for $C_{14}H_9BrN_2O$: C, 55.8; H, 3.0; N, 9.3%. The band with the lowest R_f value (0.3) gave 2-(4-bromophenyl)-1(2*H*)-phthalazinone **4**, mp 168—169 °C; IR (Nujol) 1657 and 1595 cm^{-1}; UV λ_{max} 236 (log ε 4.42), 270 (3.89), and 303 (3.97) nm; NMR ($CDCl_3$) δ 8.50 (m, H-8), 8.29 (s, H-4), 7.83 (m, H-5,6,7), and 7.62 (s, H-2′,3′,5′,6′). Found: C, 55.6; H, 3.1; N, 9.1%. Calcd for $C_{14}H_9BrN_2O$: C, 55.8; H, 3.0; N, 9.3%. The ratio of *E*- to *Z*-isomer was always about 7 : 1 but the yield of phalazinone increased from about 20 to about 40% when the mixture was heated for longer times.

Benzocyclobutenedione Mono(4-nitrophenylhydrazone). This was made in the same way as the mono(2,4-dinitrophenylhydrazone). The crude product (78% yield) was freed from impurities by soxhlet extraction with acetone to give the mono(4-nitrophenylhydrazone) as yellow crystals, mp 265—266 °C; IR (Nujol) 3360, 3080, 1766, and 1747 cm^{-1}. Found: C, 62.9; H, 3.4; N, 15.7%. Calcd for $C_{14}H_9N_3O_3$: C, 62.9; H, 3.4; N, 15.8%. TLC (CH_2Cl_2) showed two yellow spots very close together but it was impossible to separate the *E*- and *Z*-isomers by preparative TLC.

Benzocyclobutenedione Mono(phenylhydrazone). BBD (67 mg) in hot ethanol (1 ml) was added to a solution of phenylhydrazine hydrochloride (73 mg) and sodium acetate (100 mg) in hot water (2 ml), and the mixture warmed on a water bath at 50—60 °C for 2 h. After cooling, the orange-yellow solid (59 mg) was collected. Examination by TLC (CH_2Cl_2) showed one major component (yellow spot, R_f 0.50) with a small component (orange spot, R_f 0.70) in the ratio of about 9 : 1. Recrystallization from ethanol gave the (*E*)-phenylhydrazone **10** as yellow needles, mp 180—183 °C; IR 1782, 1600, and 1042 cm^{-1} (in Nujol N-H stretch at 3310 cm^{-1}); UV λ_{max} 228 (log ε 4.10), 249 (4.09), 290 (3.79), 332 (4.01), and 408 (3.91) nm. Found: C, 75.5; H, 4.3; N, 12.3%. Calcd for $C_{14}H_{10}N_2O$: C, 75.7; H, 4.5; N, 12.6%.

Refluxing a solution of the crude (*E*)-phenylhydrazone (73 mg) in acetic acid (2 ml) increased the amount of orange component (R_f 0.70) in the mixture. Evaporation of the solution followed by preparative TLC (elution with CH_2Cl_2) gave the (*Z*)-phenylhydrazone **9** (20 mg) as red crystals, mp 122—135 °C which recrystallized above 140° to give a mixture of *E*- and *Z*-isomers (confirmed by TLC) as yellow needles, mp 170—178 °C; IR 3350, 3050 (br), 1760, and 1600 cm^{-1}; UV λ_{max} 252 (log ε 4.01), 258 (4.02), 293 (3.88), 334 (4.20), and 432 (4.05) nm; NMR ($CDCl_3$) δ 9.20 (br s, N-H), 7.9—6.7 (m, Ar-H′ s). Found: N, 12.6%. Calcd for $C_{14}H_{10}N_2O$: N, 12.6%.

Reaction of α,α-Bis(trimethylsilyl)phenylthiomethyllithium with (Chloromethyl)oxiranes. Synthesis of 1-Alkyl-3-phenylthio-3-trimethylsilyl-1-trimethylsiloxycyclobutanes

Takeshi TAKEDA,* Satoru NAITO, Kazuo ANDO, and Tooru FUJIWARA

Department of Industrial Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184

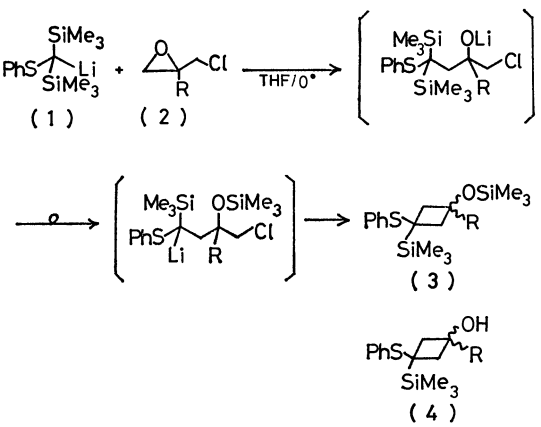
(Received August 31, 1982)

Synopsis. The cyclobutanes of the title are produced in good yields by means of the reaction of the title.

Recently many rearrangement reactions with migration of organosilyl group have been studied and a variety of useful methods for the synthesis of carbonyl compounds and silyl enol ethers have been reported.[1] Although the 1,4-silyl group shift from carbon to oxygen is especially an interesting process and would be utilized for the preparation of various γ-trimethylsiloxy carbanions, only a few examples such as reactions of oxiranes with lithium enolate of *N,N*-dimethyl-2-trimethylsilylacetamide,[2] lithium salt of trimethylsilylacetonitrile,[3] and α-(trimethylsilyl)phenylsulfonylmethyllithium[4] have so far been reported.

In the course of our study on reactions using α-thio carbanions, it was found that the cyclobutane derivatives (**3**) were selectively produced by a reaction of the α,α-bis(trimethylsilyl)carbanion (**1**) with (chloromethyl)oxiranes (**2**)[5] which involves the process of 1,4-silyl group shift.

When α,α-bis(trimethylsilyl)phenylthiomethyllithium (**1**) prepared from the corresponding sulfide with butyllithium at 0 °C was allowed to react with **2** in THF at the same temperature, 1-phenylthio-1-trimethylsilyl-3-trimethylsiloxycyclobutanes (**3**) and 3-phenylthio-3-trimethylsilyl-1-cyclobutanols (**4**) were obtained in good yields (Table 1). This reaction may proceed by the initial addition of the anion (**1**) at the less substituted site to the oxirane (**2**), followed by the 1,4-migration of silicon and cyclization, as shown in the following scheme:



Scheme 1.

Experimental

Reaction of Epichlorohydrin (2) with α,α-Bis(trimethylsilyl)-phenylthiomethyllithium (1). To a THF (6 ml) solution of bis(trimethylsilyl)methyl phenyl sulfide (537 mg, 2 mmol) was added a hexane solution of butyllithium (2.2 mmol) at 0 °C. After stirring for 30 min, THF (2 ml) solution of epichlorohydrin (204 mg, 2.2 mmol) was added to the reaction mixture and stirred for 2 h. The reaction was quenched with a phosphate buffer solution (pH 7) and subjected to extraction with dichloromethane. The extract was dried over Na_2SO_4 and concentrated under reduced pressure. The residue was chromatographed on silica gel (AcOEt–hexane) and trimethylsiloxycyclobutane (**3a**) (238 mg, 37%) and cyclobutanol (**4a**) (205 mg, 41%) were isolated. **3a**: viscous oil; IR (neat) 2950, 1580, 1471, 1248, 1128, 841, 747, and 692 cm^{-1}; ^1H NMR (CCl_4) $\delta=-0.08$ (s, 9H), 0.07 (s, 9H), 1.73—2.65 (m, 5H), 3.57—4.13 (m, 1H), and 7.13—7.66 (m, 5H). **4a**: viscous oil; IR (neat) 3330, 2950, 1580, 1472, 1248, 1117, 840, 748, and 692 cm^{-1}; ^1H NMR (CCl_4) $\delta=0.04$ and 0.08 (2s, 9H), 1.73—2.70 (m, 4H), 2.70—2.93 (br s, 1H), 3.65—4.11 (m, 1H), and 7.09—7.65 (m, 5H). Found: C, 61.91; H, 8.05; S, 12.76%. Calcd for $C_{13}H_{20}OSSi$: C, 61.85; H, 7.99; S, 12.70%.

By a similar procedure, the cyclobutanes (**3b—f** and **4f**) were obtained. **3b**: viscous oil; IR (neat) 2960, 1584, 1474, 1249, 1173, 840, 748, and 693 cm^{-1}; ^1H NMR (CCl_4) $\delta=$ 0.05 (s, 18H), 1.02 (s, 3H), 2.03—2.67 (m, 4H), and 6.97—7.52 (m, 5H). Found: C, 60.38; H, 8.94; S, 9.48%. Calcd for $C_{17}H_{30}OSSi_2$: C, 60.29; H, 8.93; S, 9.47%. **3c**: viscous oil; IR (neat) 2955, 1582, 1437, 1248, 1162, 837, 747, and 692 cm^{-1}; ^1H NMR (CCl_4) $\delta=0.05$ (s, 18H), 0.48—0.84 (m, 3H), 0.96—1.38 (m, 2H), 2.02—2.59 (m, 4H), and 7.02—7.48 (m, 5H). Found: C, 61.37; H, 8.87; S, 8.94%. Importance of Work Terms in the Free Energy Relationship for Electron Transfer

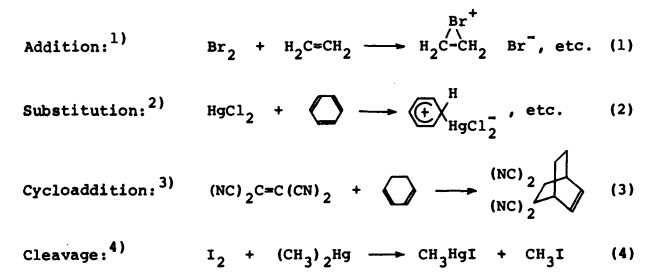
Shunichi Fukuzumi† and Jay K. Kochi*

Department of Chemistry, Indiana University, Bloomington, Indiana 47405, U.S.A.

(Received July 2, 1982)

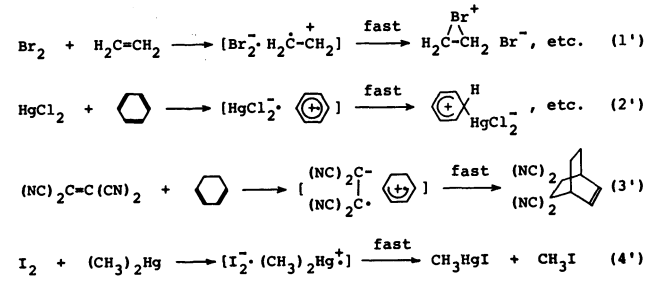
The rates of arene and alkene brominations and mercurations, Diels-Alder cycloaddition as well as alkylmetal cleavages by electrophiles, electron acceptors and free atoms can be quantitatively analyzed in terms of the driving force for electron transfer. The single, unified free energy relationship for all of these rather disparate chemical processes relates the activation free energy to the standard free energy change for electron transfer and the work term for ion-pair formation. The latter is evaluated from charge transfer spectral data of the electron donor-acceptor complexes formed as transient intermediates. The large variations in the apparent Brönsted slopes from unity to even negative values in these systems can be readily attributed to changes in the work terms arising from steric effects in ion-pair formation.

Electron transfer mechanisms are receiving increased attention in a wide variety of reactions previously formulated as more conventional ionic or concerted processes. Let us consider for example such conventional transformations as (1) the addition of halogen to alkenes, (2) aromatic substitution, (3) Diels-Alder reactions, and (4) halogenolysis of organometals. The activation process for each is commonly represented by a single step shown in the following classical examples:



[Note that the activation processes in Eqs. 1 and 2 are subsequently followed by one or more rapid steps to afford the final products.]

The same transformations can be represented by an alternative two-step mechanism in which electron transfer is rate-limiting, *i.e.*,



In this formulation, the followup steps are sufficiently rapid to render the initial electron transfer to be part of an overall irreversible transformation. Such mechanisms have been referred to as SET, or single electron transfer,[5,6] since they derive their driving force from one component (A=Br_2, $HgCl_2$, $(NC)_2C{=}C(CN)_2$, I_2) acting as an one-electron acceptor relative to the other component (D=$H_2C{=}CH_2$, C_6H_6, C_6H_8, $(CH_3)_2Hg$) which is then considered to be the electron donor.[7]

Since electron transfer mechanisms such as these are likely to be considered with increasing frequency in organic and organometallic chemistry, we wish to present in this paper the quantitative relationship between the rate of the reaction and the energetics of the electron transfer process. Such a free energy relationship (FER) would provide a better means to evaluate electron transfer mechanisms and also to facilitate their further analysis.

Mechanistic Formulation of Electron Transfer. Importance of the Work Term

The viability of the electron transfer mechanism is usually evaluated in the light of the standard potentials E^0 for each redox couple, *i.e.*, E^0_{ox} for the oxidation of the donor ($D \rightarrow D^+ + e$) and E^0_{red} for the reduction of the acceptor ($A + e \rightarrow A^-$). Thus the general reaction scheme for an irreversible process is represented by:[8]

$$D + A \overset{K_{DA}}{\rightleftharpoons} [D\ A] \overset{k_{et}}{\longrightarrow} [D^+A^-] \overset{fast}{\longrightarrow} \text{Products}, \quad (5)$$

in which electron transfer in the encounter complex [D A] is rate-limiting. This scheme is particularly applicable to systems which lie in the endergonic region of the driving force [*i.e.*, where the standard free energy change, $\Delta G^0 \gg 0$]. The observed second-order rate constant k_{obsd} is then given by:

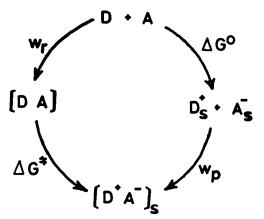
$$k_{obsd} = k_{et}K_{DA}, \quad (6)$$

where K_{DA} is the formation constant of the complex and k_{et} is the intramolecular rate constant for electron transfer. The thermochemical cycle for an irreversible electron transfer in the highly endergonic region[9,10] is schematically illustrated below. In such a highly endergonic region, the activation free energy for electron transfer ΔG^* in the encounter complex is considered to be equal to the free energy change for the ion pair formation, and thus given by Eq. 10 (Scheme 1),[10]

$$\Delta G^* = \Delta G^0 + w_p - w_r, \quad (7)$$

where ΔG^0 corresponds to the standard free energy

† Present address: Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565.



Scheme 1.

change of the redox process: $D+A \rightarrow D^+ + A^-$, and the work terms w_p and w_r represent the energy required to bring together the products and reactants, respectively, to within the mean separation r_{DA} in the ion pair $[D^+ A^-]$. The observed second-order rate constant in Eq. 6 can be expressed in terms of the activation free energy for electron transfer ΔG^* in the encounter complex and the work term w_r as:[11]

$$k_{obsd} = \frac{\kappa T}{h} \exp\left[-\frac{(\Delta G^* + w_r)}{RT}\right]. \quad (8)$$

The combination of Eqs. 7 and 8 affords the free energy relationship for electron transfer as:

$$\log k_{obsd} = -\frac{1}{2.3\,RT}(\Delta G^0 + w_p) + C_1, \quad (9)$$

where $C_1 = \log(\kappa T/h)$ is taken as 12.8 at 298 K. Since the free energy change for electron transfer ΔG^0 is obtained from the standard potentials of the acceptor and donor [*i.e.*, $\Delta G^0(\text{in V}) = E^0_{ox} - E^0_{red}$], the free energy relationship in Eq. 9 may be represented by an equivalent form in Eq. 10,

$$\log k_{obsd} = -\frac{1}{2.3\,RT}(E^0_{ox} + w_p) + \text{Constant}, \quad (10)$$

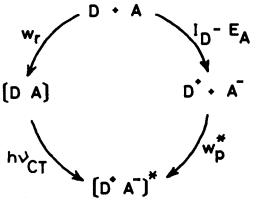
when one is dealing with a series of electron transfer reactions with a fixed acceptor.[12] Thus Eqs. 9 and 10 state that the observed rate constant ($\log k_{obsd}$) for electron transfer can be expressed as the sum of the standard free energy change (ΔG^0) and the work term of the products (w_p). Previous considerations of electron transfer have tended to focus only on the magnitude of ΔG^0, without explicitly taking account the energetics of the ion pair $[D^+ A^-]$ formation, *i.e.*, the work term w_p.[13,16] Such an oversimplication is perhaps understandable if one considers the experimental difficulty of directly evaluating the work terms of ion pairs by the usual procedures. The problem is severely compounded by exceedingly short lifetimes of the transient ion-pairs which must be involved in irreversible electron transfer. We now wish to discuss how the observation of charge-transfer spectra in these systems can be used to evaluate such ion-pairing energies.

Evaluation of the Work Term from Charge-transfer Spectral Data

The intermolecular interaction leading to the precursor complex in Scheme 1 is reminiscent of the electron donor-acceptor or EDA complexes formed between electron donors and acceptors.[18] The latter is characterized by the presence of a new absorption band in the electronic spectrum. According to the Mulliken charge-transfer (CT) theory for weak EDA complexes, the absorption maximum $h\nu_{CT}$ corresponds to the vertical (Franck-Condon) transition from the neutral ground state to the polar excited state.[19,20]

$$[D\ A] \xrightarrow{h\nu_{CT}} [D^+A^-]^* \quad (11)$$

The asterisk identifies an excited ion pair with the same mean separation r_{DA} as that in the precursor or EDA complex. The thermo-chemical cycle for such a charge-transfer transition is schematically illustrated below. The



Scheme 2.

vertical ionization potential of the electron donor is represented by I_D, and the electron affinity of the acceptor by E_A.

The charge-transfer Scheme 2 is akin to the adiabatic electron transfer cycle in Scheme 1. In this case the work term w_p^* required to bring the products D^+ and A^- together to the mean separation r_{DA} in the CT excited state is given by:

$$w_p^* = h\nu_{CT} - I_D + C_2, \quad (12)$$

where $C_2 = E_A + w_r$ and considered to be constant for a fixed acceptor.[21] In the limit of simple ion-pair interactions, the work term is largely coulombic, *i.e.*, $w_p^* \cong -e^2/r_{DA}$.

The charge-transfer spectral data listed in Table 1 relate to the various donors and acceptors pertinent to the various reactions described in Eqs. 1—4. In order to assess these systems quantitatively, we relate the work term w_p^* to that of a reference donor w_p^{0*}, since each series in Table 1 involves a fixed acceptor. This comparative procedure allows the acceptor component in a given series to drop out by cancellation, and it follows from Eq. 12 that:[27]

$$\Delta w_p^* = w_p^* - w_p^{0*} = \Delta h\nu_{CT} - \Delta I_D. \quad (13)$$

In Eq. 13, $\Delta h\nu_{CT}$ refers to the relative CT transition energy with a common acceptor, and ΔI_D is the difference in the ionization potentials of the donor and the chosen reference. Thus by selecting a reference donor, we can express all changes in the ion-pairing energies in the CT excited state (including steric, distortional and other effects in the D/A pair) by a single, composite energy term Δw_p^*.

The values of Δw_p^* for a series of EDA complexes are listed in Table 1, together with the ionization potentials of the donors. The reference donor in each series is appropriately designated.

The relative work term Δw_p^* evaluated from the data in Table 1 and Eq. 13 is plotted in Fig. 1 against the ionization potential of the donor for each series of EDA complexes in Table 1. Several features in Fig. 1 are noteworthy. First, the magnitude and the variation of

a) The reference donor is designated by †. b) From Ref. 26. c) From Ref. 22. d) From Ref. 25. e) From Ref. 24. f) From Ref. 23c. g) From Ref. 23b.

the work term depends strongly on the electron donor as well as the acceptor. Thus w_p^* is rather constant for TCNE when it interacts with various substituted anthracene donors (Fig. 1a), but it decreases significantly as the ionization potential of the organometal donors increases (Fig. 1b). Furthermore, the variation in w_p^* is the largest with organometals, when considered among other donors such as arenes and alkenes. With a particular series of donors, the variation of w_p^* is the largest with the mercury(II) complexes $Hg(OAc)_2$ and $HgCl_2$, among other acceptors such as TCNE and Br_2.

We associate such variations in the work term w_p^* with changes in the mean separation r_{DA} in the EDA complexes. Qualitatively, such changes may be viewed as steric effects which hinder the close approach of the acceptor and the donor.[28] For example, the constancy of w_p^* for the substituted anthracene donors accords with the minor steric perturbation since a substituent is expected to exert on a large π-donor such as a polycyclic aromatic network. By contrast, bulky substituents on alkylmetals can effect large changes in w_p^* owing to the localized nature of the interaction in these σ-donors.[29,30]

Free Energy Relationship for Electron Transfer from the CT Work Terms

Taken all together, the relationships in Fig. 1 graphically underscore the marked variation in the work term w_p^* in the excited ion pair (Scheme 2) as a result of the structural changes in the various donor-acceptor pairs. Moreover the interrelationship between encounter and EDA complexes implies that the work term w_p in the adiabatic ion pair (Scheme 1) can be subject to similar variations arising from structural changes in the donor-acceptor pair. Indeed, we previously showed how the variation of the work terms in the adiabatic ion pairs can parallel those in the excited ion pairs.[17] In order

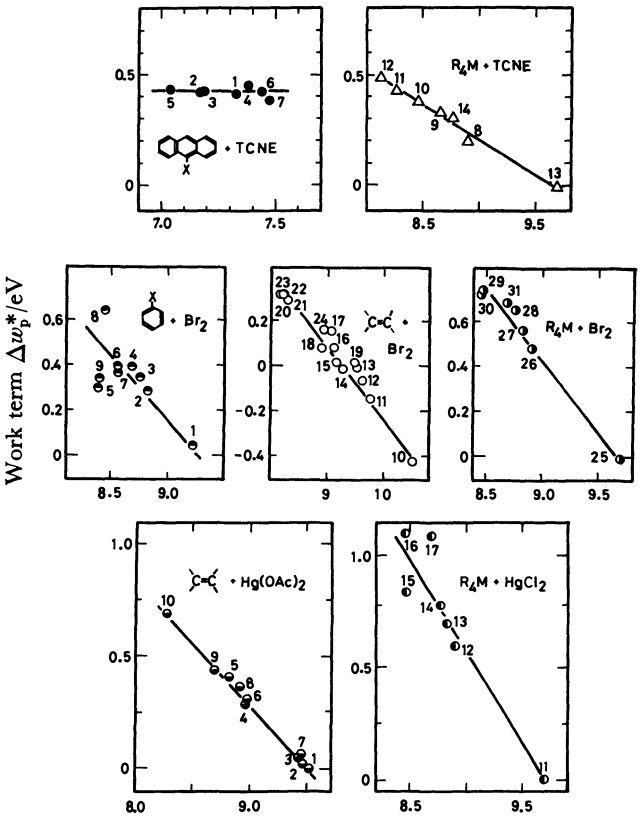

Fig. 1. Variation of the work term w_p* evaluated for the various electron donor-acceptor complexes. The numbers refer to the donors listed in Table 1.

to establish this connection, we initially examined the electron-transfer kinetics of a series of alkylmetal donors R_4M with the inorganic oxidant hexachloroiridate(IV), which is known to effect one-electron transfer, *i.e.*,[31]

$$IrCl_6^{2-} + R_4M \xrightarrow{k} [IrCl_6^{3-}\ R_4M^+]. \quad (14)$$

We next examined the electron transfer kinetics of the same series of alkylmetal donors with the organic electron acceptor tetracyanoethylene, for which the rate-limiting step had been previously established as:[21,32]

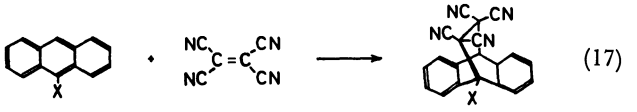
$$TCNE + R_4M \xrightarrow{k} [TCNE^-\ R_4M^+]. \quad (15)$$

In both series of electron transfer processes, the free energy relationship was found to be:

$$\log k = -\frac{1}{2.3\,RT}[E^0_{ox} + \Delta w_p^*] + \text{Constant}, \quad (16)$$

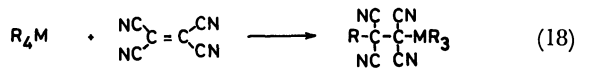
where E^0_{ox} is the standard potential for the alkylmetal donor, and the work term Δw_p^* was evaluated from the charge transfer spectral data of the EDA complex [TCNE R_4M] according to Eq. 13.[17,27,33] Thus the experimental free energy relationship in Eq. 16 is equivalent to that (Eq. 10) obtained from Scheme 1.[34]

The successful derivation of this linear free energy relationship encourages us to now apply it to the series of reactions in Eqs. 1—4 which have been variously described as either an electrophilic or a concerted process. Thus let us first consider anthracene cycloaddition with TCNE,



(17)

in the light of alkylmetal insertion,



(18)

In the following sections, we will also describe how the same treatment applies to diverse reactions of molecular bromine, mercury(II), and atomic iodine with arene, alkene, and alkylmetal donors.

Diels-Alder Cycloaddition of Anthracenes and Organometal Cleavage with Tetracyanoethylene. New, transient absorption bands are observed immediately upon mixing (1) a series of substituted anthracenes or (2) a series of tetraalkyllead and tin compounds with tetracyanoethylene in either 1,2-dichloroethane or chloroform solutions.[26] With both series of donors, the disappearance of the CT bands coincides with the product formation given in Eqs. 17 and 18. Moreover, the rates of reaction in both series follow second-order kinetics overall—first-order in TCNE and first-order in the anthracenes or the alkylmetals. For convenience, the second-order rate constants are relisted in Table 2 together with the standard potentials E^0_{ox} of the anthracenes and the alkylmetals.

In Fig. 2a, we find a direct relationship between the E^0_{ox} of anthracenes and alkylmetals and their reactivity [$\log(k_{obsd}/M^{-1}\,s^{-1})$; 1 M=1 mol dm^{-3}] toward TCNE.

$$\log k_{obsd} = -\frac{1}{2.3RT}(0.96\,E^0_{ox}) + 16. \quad (19)$$

Alkylmetal-TCNE:

$$\log k_{obsd} = -\frac{1}{2.3RT}(0.45\,E^0_{ox}) + 7.6. \quad (20)$$

It is noteworthy that the two different correlations in Fig. 2a emerge as a single correlation when the work term Δw^*_p is included. The result in Fig. 2b is a linear free energy relationship,[35]

$$\log k_{obsd} = -\frac{1}{2.3RT}(E^0_{ox} + \Delta w^*_p) + \text{Constant}, \quad (16)$$

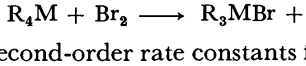
which applies to both anthracene cycloaddition and alkylmetal insertion. Note the line in Fig. 2b is arbitrarily drawn with a slope of $-1/2.3RT$ to emphasize the fit of both sets of data to Eq. 16.[36] Such an unification is remarkable since these processes clearly represen-inherently dissimilar reaction types. Thus the Diels-Alder reaction is usually considered to involve a concerted [2π+4π] cycloaddition,[3] whereas the alkylmetal insertion requires a multistep scission of a σ carbon-metal bond.[22] The applicability of Eq. 16 to such diverse processes as anthracene cycloaddition and alkylmetal insertion derives from a correspondence of the work term variation, *i.e.*, $\Delta w^*_p = \Delta w_p$.[34]

It must be emphasized that the values of w^*_p are obtained from the independent measurements of the ionization potentials and the CT transition energies in Eq. 12. As such, the constancy of Δw^*_p for the anthracenes in Fig. 1a indicates that the relative rates of cycloaddition with TCNE are solely determined by E^0_{ox}. Thus these Diels-Alder reactions can be classified as irreversible electron transfer processes in which the mean separations in the ion pairs are constant. Indeed the apparent Brönsted slope of nearly unity in Eq. 19 accords with an endergonic electron transfer process.[9,37,38]

Bromination of Arenes, Alkenes, and Alkylmetals. Molecular bromine forms transient EDA complexes with a variety of π-donors (arenes and alkenes)[24,25] as well as σ-donors (alkylmetals).[23] The decay of the charge-transfer bands has been shown to coincide with the bromination of the donor molecules, as given by Eqs. 21—23.

(21)[39]

(22)[24]



(23)[23]

The second-order rate constants for the arene and alkene brominations have been reported[40] in acetic acid and are relisted in Table 3, together with the second-order rate constants for alkylmetal brominolysis in carbon tetrachloride.[23c] Since the standard potentials of the donors are not known, we used the general relationship in Eq. 24[43,44] to evaluate E^0_{ox} in these solvents.

$$E^0_{ox} = I_D + \Delta G^s - C \quad (24)$$

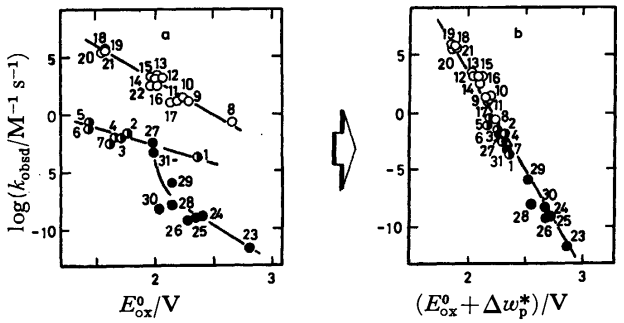

Fig. 3. Brominations. (a) Free energy relationships for arenes (●), alkenes (◑), and alkylmetals (○), as donors identified in Table 3. (b) Unified free energy relationship including the work term as described by Eq. 16.

The free energy change ΔG^s represents the solvation of the donor cation relative to the neutral donor, and are evaluated in Table 6 (see Appendix). C is a constant which includes the potential of the reference electrode on the absolute scale and the junction potential.[44] The relevant values of E^0_{ox} are included in Table 3.

The relationship between the rates of electrophilic bromination ($\log k_{obsd}$) and the standard potentials (E^0_{ox}) of the arene, alkene, and alkylmetal donors is shown in Fig. 3a.[35] Although a rough linear correlation exists for each series,[45] there is no clearcut interrelationship among any of them. However, if the variation of the work term Δw^*_p derived from the CT data in Table 1 is included, the three separate relationships in Fig. 3a become a single correlation. The result in Fig. 3b is the same linear free energy relationship previously expressed in Eq. 16.[46] Indeed the line in Fig. 3b is arbitrarily drawn with a slope of $-1/2.3RT$ to emphasize the correlation of the data with Eq. 16.

Mercuration of Alkenes and Mercurolysis of Alkylmetals. Systems with Large Steric Variations: Transient charge transfer bands are immediately observed when mercury(II) complexes such as mercuric acetate and chloride are mixed with a series of alkene, arene, and alkylmetal donors.[23b,24] The disappearance of the EDA complex of mercury(II) acetate and an alkene is accompanied by the addition reaction in Eq. 25.

$$\text{C=C} + \text{Hg(OAc)}_2 \xrightarrow[\text{MeOH}]{} \text{AcOHg-C-C-OMe} + \text{HOAc} \qquad (25)$$

The rate of this oxymercuration follows overall second-order kinetics in protic solvents such as methanol.[24]

The observed second-order rate constants ($\log k_{obsd}$) for the oxymercuration of various alkenes are collected in Table 4 together with the values of the standard potentials (E^0_{ox}) for the alkene donors in methanol.[47] It is interesting to note that the rates of oxymercuration of electron rich alkenes such as trimethyl- and tetramethylethylene are actually slower than those of normal alkenes such as 1-pentene and 1-octene. Such a trend for $\log k_{obsd}$ to generally decrease with the lowering of E^0_{ox} is in marked contrast to the results in Figs. 2a and 3a. Moreover, the plot of $\log k_{obsd}$ and E^0_{ox} affords the rather random, "buckshot" pattern shown in Fig. 4a. Nonetheless such a nondescript appearance of the data is transformed into the linear correlation shown in Fig. 4b when the work term variation Δw^*_p is included. Although the correlation in Fig. 4b has considerable scatter (owing to the experimental difficulties in the measurement of w^*_p and the limited range of rates), the fit of the data to the line which describes the general free energy relationships of Eq. 16 is unmistakable.[35]

The same relationship applies to the CT interaction of alkylmetals with mercuric chloride leading to the complete scission of a R-M bond,[48] *i.e.*,

TABLE 4. SECOND-ORDER RATE CONSTANTS FOR THE ELECTROPHILIC REACTIONS OF MERCURY(II) COMPLEXES WITH ALKENES AND ALKYLMETALS

a) In methanol at 298 K from Ref. 24. b) In acetonitrile at 298 K from Ref. 48.

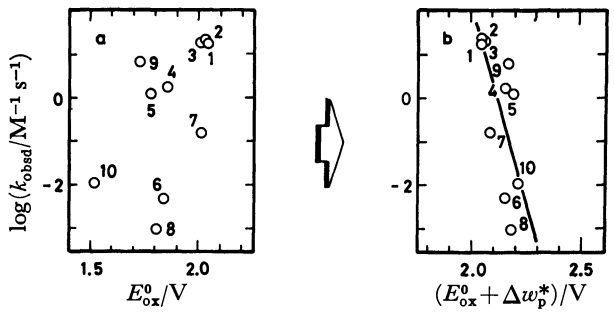

Fig. 4. Oxymercuration of Alkenes. (a) Variation of the rate constant with the standard potentials of the alkene donors identified in Table 4. (b) Unified free energy relationship by inclusion of the work term. The line is arbitrarily drawn with a slope of $-1/2.3RT$ to emphasize the correlation with Eq. 16.

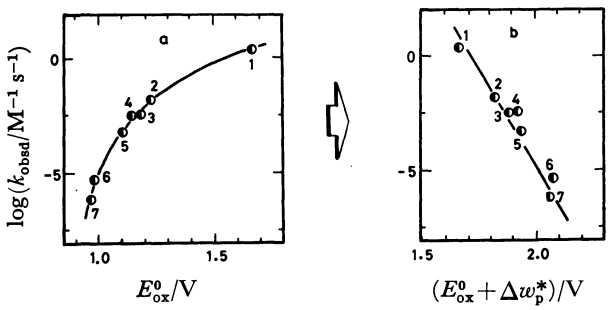

Fig. 5. Alkylmetal Cleavage with $HgCl_2$. (a) Plot of the rate (log k_{obsd}) and the oxidation potentials of the alkylmetal donors identified in Table 4. (b) Unified free energy relationship in which the line is drawn with a slope of $-1/2.3RT$ to emphasize the agreement of the data with Eq. 16.

$$R_4M + HgCl_2 \longrightarrow R_3MCl + RHgCl. \quad (26)$$

Such a cleavage process differs fundamentally from the addition process in Eq. 25, but the rate data listed in Table 4 follows a similar inverse relationship with E^0_{ox}. Thus the apparent Brönsted slope α (which varies with E^0_{ox} in the curved relations shown in Fig. 5a) is clearly negative for these cleavage reactions. Again when the work term Δw^*_p is included with E^0_{ox}, the curved free energy relationship with negative slopes is transformed into the linear correlation in Fig. 5b.

Despite the strong dissimilarity of the addition and the cleavage processes described in Eqs. 25 and 26, they both abide by the same linear free energy relationship described by Eq. 16 when the variation of the work term Δw^*_p is specifically included as a part of the driving force. Moreover, the influence of the work term is sufficiently strong in both of these mercurations to actually invert the negative Brönsted slopes to the unified correlation in Eq. 16. Such an effect underscores the large steric variations extant in these systems. Before commenting on this point further, we wish to describe the application of the free energy relationship to a system in which the CT spectral information is unavailable.

Homolytic Substitution of Alkylmetals by Iodine Atom. The photochemically induced iodinolysis of alkylmetals has been shown to proceed by a radical chain mechanism in which the homolytic S_H2 reaction in Eq. 27 is rate-limiting.[49] The homolytic rate constant (k) for

$$R_4M + I\cdot \xrightarrow{k} R_3MI + R\cdot, \quad (27)$$

the iodinolysis of the various tetraalkyltin compounds in Table 5 have been evaluated relative to tetramethyltin (k_0), and the relative rates (log k/k_0) are plotted in Fig. 6a against E^0_{ox} of the alkylmetal donors.

Table 5. Relative reactivity of alkylmetals in S_H2 cleavage reactions with iodine atom. The stand ardpotentials E^0_{ox} of alkylmetals in carbon tetrachloride[a]

Alkylmetals	E^0_{ox} / V	log (k/k_0)	$E^0_{ox}+\Delta w^*_p$ / eV
1 Me_4Sn	2.36	0	2.36
2 Et_4Sn	1.77	1.71	2.24
3 *n*-Pr_4Sn	1.71	1.69	2.26

6 *s*-Bu_4Sn	1.43	1.68	2.22
7 *i*-Bu_4Sn	1.61	1.01	2.25

a) At 298 K from Ref. 49.

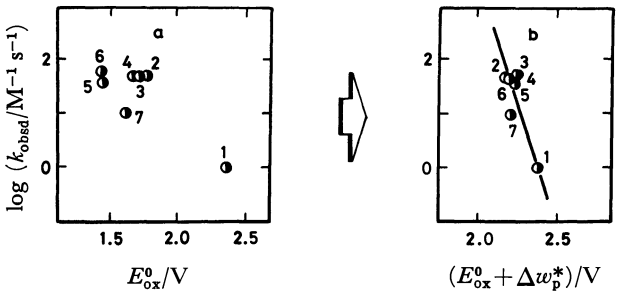

Fig. 6. Homolytic Iodinolysis of Alkylmetals. (a) Variation of the relative rates log (k/k_0) of cleavage of the alkylmetals in Table 5 by iodine atom. (b) Unified free energy relationship with the line arbitrarily drawn with a slope of $-1/2.3RT$ according to Eq. 16.

The charge-transfer spectral data for the EDA complexes in this system are unavailable owing to the transient character of the iodine atom. Thus the values of the work term w^*_p which were previously obtained from the analogous EDA complexes of molecular iodine,[23a] *i.e.*, [R_4M I_2], have been substituted in Table 5. Indeed the resulting free energy correlation shown in Fig. 6b provides a reasonable fit to the general relationship in Eq. 16.[35]

The successful transferal of work terms w^*_p derived from the spectra of *molecular* iodine complexes for use with *atomic* iodine complexes indicates that these acceptors in fact share features in common, despite the substantial difference in the values of their electron affinities (*i.e.*, for I_2, E_A=1.60 eV and for I·, E_A=3.06 eV).[23a] Indeed the steric effects of iodine donors, in both molecular and atomic forms, should be sufficiently similar to render the mean separations in the complexes [R_4M I_2] and [R_4M I·] and therefore the work terms equivalent.[50,51]

The examples in the foregoing sections illustrate how

a knowledge of the standard redox potentials and the ion-pair work terms provides a unified free energy relationship (Eq. 16) for the rates of electron transfer in quite different chemical systems. Since the apparent Brönsted slope α,[52] which measures the dependence of the reaction rate (log k_{obsd}) on the standard free energy change (ΔG^0) for electron transfer, *i.e.*, $\alpha = \partial \Delta G^* / \partial \Delta G^0$, differs from system to system (see Figs. 2a, 3a, 4a, and 5a) we wish to inquire now into the origin of this variation.

Significance of the Brönsted Slope in Electron Transfer

Linear free energy relationships have been extensively studied for electron transfer and related reactions in both inorganic and organic systems.[53,54] For highly endergonic reactions, the Brönsted slope α, is close to unity.[10,55] In many cases, however, the more or less linear plots of ΔG^* (or a related quantity such as the rate constant log k_{obsd}) and ΔG^0 (or some related quantity such as the polarographic $E_{1/2}$ potentials[56]) have been observed with slopes significantly less than unity (*e.g.*, typically $0.1 < \alpha < 0.5$) in systems showing irreversible electron transfer in the endergonic region.[57,58] Such contradictions have led to the explanation that electron transfer is not complete in the transition state. As such, the diminished Brönsted slope would correspond to the fraction of charge transfer in the activated complex.[59] Alternatively, the small Brönsted slopes may be ascribed to large intrinsic barriers ΔG_0^* for electron transfer,[60] since the limit of α will be 0.5 for a sufficiently large value of ΔG_0^*.[8,61] For the latter, α is not related to the fractional charge transfer which is taken to be unity in all cases, but it cannot readily explain those cases with $\alpha < 0.5$.

In this light, our observations of apparent Brönsted slopes which span the limit of $\alpha = 1$ (Fig. 2a) to $\alpha \approx 0$ (Fig. 3a) cannot be easily reconciled with either explanation especially if one includes the examples (Figs. 4a and 5a) in which the apparent Brönsted slopes are actually negative. However, it clearly follows from the electron transfer cycle in Scheme 1 that the work term w_p must be explicitly included in the free energy relationship. Such a FER is expressed by Eq. 7, and the intrinsic Brönsted slope is accordingly evaluated as:[52]

$$\alpha = \frac{\partial \Delta G^*}{\partial \Delta G^0} = 1 + \frac{\partial w_p}{\partial \Delta G^0} \qquad (28)$$

It is important to emphasize that the Brönsted slope is not a meaningful quantity without a knowledge of the variation of w_p from system to system. Indeed the systems shown in Figs. 2a and 3a, for which the apparent Brönsted slopes lie in the range $0 < \alpha < 1$, are those in which variation in the work term is $-1 < (\partial w_p / \partial \Delta G^0) < 0$. Furthermore when the variation of the work term is large enough such that $(\partial w_p / \partial \Delta G^0)$ is less than -1 in Eq. 28, the apparent Brönsted slope will become negative, as observed in Figs. 4a and 5a. In other words the variation of the work term is largely responsible for the magnitudes of the apparent Brönsted slopes in Figs. 2a, 3a, 4a, and 5a.

The right sides of Figs. 2—6 represent the unified free energy relationship in Eq. 16 and uniformly support the use of the CT work term w_p^* in the experimental verification of the thermochemical cycle in Scheme 1 (Eq. 7). Thus the work term w_p^* is sufficient to unify all those systems with small and even negative values of the apparent Brönsted slope into a single general relationship in Eq. 16. At this juncture, we might enquire as to why the work term evaluated from the CT interaction in Scheme 2 serves as such an adequate representation of the adiabatic work term in Scheme 1.

By employing the *variation* of the work term Δw_p^* in Eq. 16, we are actually focussing in large part on the electrostatic interaction in the ion pair, since the other structural factors drop out by cancellation in the comparative procedure used in Eq. 13.[63] Thus the contribution to Δw_p^* consists largely of a coulombic potential (*i.e.*, $-e^2/r_{DA}$) in which the mean separation r_{DA} in the ion pair is the determinant factor. It is then likely that steric effects which mediate the magnitude of r_{DA} in the EDA complex, and thus the CT excited ion-pair state, parallel those in the adiabatic ion pair in Schemes 2 and 1, respectively.

Summary and Conclusions

The varied reactions of the donors and acceptors in Eqs. 1—4 can be quantitatively analyzed by the free energy relationship in Eq. 10, in which the variation of the work term Δw_p in the adiabatic ion pair can be evaluated from the variation of the work term Δw_p^* of the CT excited ion pair. The values of Δw_p^* are readily obtained from the charge-transfer spectra of the transient electron donor-acceptor complexes extant in these systems. The activation processes are governed by the combination of two terms; the standard free energy change E^0 for electron transfer (*i.e.*, $D + A \rightarrow D^+ + A^-$) and the work term of the products w_p (*i.e.*, the interaction energy in the ion pair $[D^+ A^-]$). The importance of the work term lies in the mean separation r_{DA} of the ion pair which is mediated by the steric effects in both donor and the acceptor. The work term variation is experimentally observed in systems showing apparent Brönsted slopes[52] α of substantially less than unity.

For a series of donors reacting with a *fixed acceptor*, the variation in the work term generally increases in the order: anthracenes $\ll$ benzenes $<$ alkenes $<$ alkylmetals. Similarly, for a series of acceptors acting upon a *fixed donor*, the variation in the work term generally increases in the order: TCNE $<$ Br_2 $<$ HgX_2. Thus the interaction of anthracenes with TCNE leading to the Diels-Alder adduct is the least subject to steric effects. Accordingly, the Brönsted slope in the free energy relationship is close to unity, even without specifically taking into account the work term. At the other extreme, the interaction of alkylmetals with HgX_2 is strongly influenced by steric effects. If the work terms are neglected, the apparent Brönsted slope is actually negative. Such variations in α strongly underscore the importance of evaluating work terms in the development of free energy relationships for electron transfer, especially in those systems which

proceed by an inner-sphere pathway.

Appendix

Evaluation of Solvation Energies of Donor Cations in Different Solvents. The solvation energies of arene cations are constant ($\Delta G^s = -2.01$ eV) for the solvents used in this study.[26] The difference in the solvation of $\Delta\Delta G^s$ of alkene and arene cations in acetonitrile was previously obtained from the outer-sphere electron transfer rates of a series of iron(III) oxidants with various alkenes and arenes.[40] The values of $\Delta\Delta G^s$ in other solvents were evaluated relative to those in acetonitrile, with the aid of the modified Born equation,

$$\Delta\Delta G^s = (1-1/\varepsilon)(1-1/\varepsilon_0)^{-1}\,\Delta\Delta G^s_0, \qquad (29)$$

where ε and ε_0 are the dielectric constants of the solvent and acetonitrile, respectively, and $\Delta\Delta G^s_0$ is the value in acetonitrile.

The values of $\Delta\Delta G^s$ for the alkylmetal donors in acetonitrile were reported previously. Those in carbon tetrachloride are evaluated by Eq. 29. The values of $\Delta\Delta G^s$ are listed in Table 6, together with the values of E^0_{ox} evaluated from Eq. 30.

$$E^0_{ox} = I_D + \Delta\Delta G^s - 2.01 - C \qquad (30)$$

6) A wide variety of photochemical processes involving electron transfer in the quenching of excited states is also known. For inorganic examples, see G. L. Geoffroy and M. S. Wrighton, "Organometallic Photochemistry," Academic Press, New York (1979); "Concepts of Inorganic Photochemistry," ed by A. W. Adamson and D. D. Fleischauer, Wiley, New York (1975) for some leading references. For some recent organic systems, see F. D. Lewis, T.-I. Ho, and J. T. Simpson, *J. Am. Chem. Soc.*, **104**, 1924 (1982); J. L. Stavinoha and P. S. Mariano, *ibid.*, **103**, 3136, 3148 (1981); G. B. Schuster, *Acc. Chem. Res.*, **12**, 366 (1979) and related papers.

7) J. K. Kochi, "Organometallic Mechanisms and Catalysis," Academic Press, New York (1978), Part 3.

8) See F. Scandola, V. Balzani, and G. B. Schuster, *J. Am. Chem. Soc.*, **103**, 2519 (1981).

9) In the endergonic limit, the activation barrier for electron transfer corresponds to the energetics of ion pair formation (see Ref. 10). In qualitative terms, this equality is tantamount to a restatement of the Hammond postulate [G. S. Hammond, *J. Am. Chem. Soc.*, **77**, 334 (1955)].

10) R. A. Marcus, *J. Phys. Chem.*, **72**, 891 (1968).

11) The Boltzmann constant is κ and the Planck constant is h.

12) Note that the contribution from the acceptor drops out by cancellation in such a series.

13) For outer-sphere electron transfer mechanisms, it is a common practice to neglect the work term of the product, especially if the ions have like charges (see Ref. 14). However, the importance of w_p has been noted in outer-sphere reactions with ions of opposite charges (see Ref. 15).

14) R. J. Klingler and J. K. Kochi, *J. Am. Chem. Soc.*, **103**, 5839 (1981).

15) A. Haim and N. Sutin, *Inorg. Chem.*, **15**, 476 (1976).

16) In inner-sphere electron transfer for which interaction energies can be large, the neglect of the work term w_p is not justified. For the mechanistic distinction between outer-sphere and inner-sphere electron transfer, see the discussion in Ref. 17.

23) a) S. Fukuzumi and J. K. Kochi, *J. Phys. Chem.*, **84**, 608, 617 (1980); b) S. Fukuzumi and J. K. Kochi, *ibid.*, **85**, 648 (1981); c) S. Fukuzumi and J. K. Kochi, *ibid.*, **84**, 2246, 2254 (1980).
24) S. Fukuzumi and J. K. Kochi, *J. Am. Chem. Soc.*, **103**, 2783 (1981).
25) S. Fukuzumi and J. K. Kochi, *J. Org. Chem.*, **46**, 4116 (1981).
26) S. Fukuzumi and J. K. Kochi, *Tetrahedron*, **38**, 1035 (1982).
27) In previous papers (Refs. 22—26), we used the notation ΔE instead of Δw_p^*. In this paper, we use the notation Δw_p^* to emphasize the relationship to Δw_p in Eqs. 9 and 10. Since the photoexcitation of EDA complexes is a vertical process, the CT transition energies $h\nu_{CT}$ do not include a major change in solvation during the excitation. The minor contribution of the solvent effects on $h\nu_{CT}$ which has been measured in inert solvents (Refs. 22—26) is cancelled out in the relative values of Δw_p^* in Eq. 13.
28) Note that the sign of the work term w_p^* is negative.
29) The HOMO of these alkylmetals is a sigma bonding orbital [T. P. Fehlner, J. Ulman, W. A. Nugent, and J. K. Kochi, *Inorg. Chem.*, **15**, 2544 (1976)].
30) For example, the difference between w_p^* for *s*-Bu_4Sn and that for Me_4Sn in their $HgCl_2$ complexes is as large as 1.10 eV, which corresponds to 106 kJ mol^{-1}. Such a large difference in work terms corresponds to a factor of 3.6×10^{18} in the rates of reaction if Δw_p^* is simply equated to Δw_p in Eq. 9.
31) H. C. Gardner and J. K. Kochi, *J. Am. Chem. Soc.*, **97**, 1855 (1975).
32) H. C. Gardner and J. K. Kochi, *J. Am. Chem. Soc.*, **97**, 5026 (1975).
33) In Ref. 17, values of $(E^0_{ox}+w_p/F)$ were reported. The work term w_p for the electron transfer between $[FeL_3]^{3+}$ and the alkylmetals is neglected here, since the outer-sphere work term w_p with ions of the same charge is negligible (see Ref. 13).
34) Note that the constants in Eqs. 10 and 16 are different, since w_p and Δw_p^* represent absolute and relative work terms, respectively. The equivalency implies that $\Delta w_p = w_p - w_p^0 = \Delta w_p^*$, where w_p^0 is the *absolute* work term of the reference system.
35) Although the error bars are not included in the figures, the correlation and trends are to be conservatively considered to 2 significant digits.
36) When E^0 is given in V (or eV), the Brönsted a corresponds to the slope of -16.9 in the plot between log k_{obsd} and E^0 at 298 K, *i.e.*, $23.04\times10^3/2.3RT=16.9$ (1 V=23.04 kcal mol^{-1}, R=1.987 cal mol^{-1} K^{-1}, T=298 K).
37) Since the reduction potential of TCNE is 0.22 V *vs.* SCE, the standard free energy change for electron transfer ΔG^0 is in the range of 9.9 kcal mol^{-1} for 9,10-Me_2-anthracene and $\approx$33 kcal mol^{-1} for Me_4Sn.
38) By way of contrast, note that the apparent Brönsted slope for the insertion reaction of alkylmetals with TCNE is only 0.45, despite the large positive value (Ref. 17) of ΔG^0. The explanation for the difference is discussed in the last section (*vide infra*). Furthermore, the same Brönsted slope has been reported in Ref. 31 for the more conventional electron transfer reaction of hexachloroiridate(IV) with the same series of alkylmetals (compare Eqs. 14 and 15).

44) a) R. C. Larson, R. T. Iwamoto, and R. N. Adams, *Anal. Chim. Acta*, **25**, 371 (1961); b) The value of C for the Ag/$AgClO_4$ reference in CH_3CN is 4.70 V, which is decreased by 0.30 V relative to the SCE reference electrode.
45) The apparent Brönsted slope in Fig. 3a is 0.37 for alkylmetals, 0.17 for alkenes, and 0.54 for arenes.
46) The unification of the reactions of alkylmetals with Br_2 in CCl_4 and the reactions of olefins and arenes in HOAc in Fig. 3b implies that the solvation term for Br_2^- in CCl_4 is about equal to that in HOAc.
47) See Table 6 in the Appendix.
48) S. Fukuzumi and J. K. Kochi, *J. Am. Chem. Soc.*, **102**, 7290 (1980).
49) S. Fukuzumi and J. K. Kochi, *J. Org. Chem.*, **45**, 2654 (1980).
50) The similarity between I_2 and I· in charge-transfer interactions has been examined with alkyl iodides as donors [R. L. Strong and J. A. Kaye, *J. Am. Chem. Soc.*, **98**, 5460 (1976); R. L. Strong and F. Venditti, Jr., *Chem. Phys. Lett.*, **46**, 546 (1977)].
51) There are other instances in which Δw_p^* determined indirectly has been successfully employed in FERs. For example, the values of Δw_p^* employed in the FER for the inner-sphere oxidation of alkylmetals by hexachloroiridate(IV) in Eq. 14 were obtained from the CT spectral data of [R_4M TCNE] complexes (see Ref. 17).
52) We define the apparent Brönsted slope for an electron transfer process to be the dependence of the rate (log k_{obsd}) on the standard free energy change ΔG^0 of the redox couple. It is to be contrasted with the intrinsic Brönsted slope, which is obtained from a consideration of all contributions to the driving force, including the work terms, as in Eq. 28.

Phase Behavior and Tricritical Phenomena in a Bile Salt System

Hironobu KUNIEDA* and Kōzō SHINODA
Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Tokiwadai 156, Hodogaya-ku, Yokohama 240
(Received July 22, 1982)

A three-phase region consisted of a water (W), a surfactant (D) and an oil (O) phases was found in a sodium taurocholate (NaTC)/brine/co-surfactant (monoglyceride or its model compound)/oil (triglyceride) system. A required concentration of cosurfactant to produce the three-phase region was decreased with increasing salinity. The three-phase region becomes narrower and finally vanishes with decreasing salinity at constant temperature or with the rise in temperature at constant salinity in a NaTC/brine/glycerol mono (2-ethylhexyl) ether/glycerol tris (2-ethylhexanoic) ester system. Since the critical end points of O–D and D–W phases approach and coincide in the system, the three-phase region disappears at a tricritical point at which three coexisting liquid phases become identical. According to the phase rule, there is a line of tricritical points in the space of T and compositions in this five-component system and it moves toward higher temperatures with the increase in salinity. Therefore, the three-phase region exists at temperatures below the tricritical temperature at constant salinity.

In a three-fluid-phase system (a liquid-liquid-gas type or a liquid-liquid-liquid type), two fluid phases become identical in the presence of a third phase at a critical end point.[1-3] There are two kinds of critical end phenomena as is shown schematically in Figs. 1(a) and (b). One is the critical phenomenon between upper (A) and middle (B) phases, and the other is that between middle (B) and lower (C) phases. But, the critical phenomenon between upper and lower phases is not observed in the presence of the middle phase.[4] If these two critical end points coincide each other, three coexisting phases become identical at a high-order critical point, *i.e.*, a tricritical point as is shown in Fig. 1(c).[1-4] This kind of critical phenomenon has been observed in some systems.[5-9]

In a surfactant/water/oil system, three coexisting liquid phases consisted of a water (W), a surfactant (D) and an oil (O) phases appear under certain conditions. For example, a three-phase region is observed at a certain temperature range in a nonionic surfactant/water/oil system and its upper limit corresponds to a critical end temperature of O–D phases, while its lower limit is that of D–W phases.[10-12] The equilibrium of three coexisting phases in a surfactant system at atmospheric pressure is shown schematically in Fig. 2.[10-12] The orientation of X axis corresponds to the oil–water ratio and that of Y axis corresponds to the concentration of surfactant. The Z axis is perpendicular to the plane (X–Y plane) of a three-phase triangle and it corresponds to temperature in a nonionic surfactant system. In Fig. 2(a), K and L are critical curves of D–W and O–D which exist outside the three-phase region and terminate at respective critical end points Kc and Lc. Curves, α, β, γ, are the loci of D, O, and W phases forming a three-phase triangle. The points on α and β curves coincide at Lc point at which O and D phases become identical. The critical mixture of O–D is in

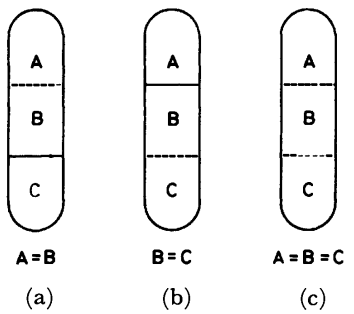

Fig. 1. Schematic figures of critical end points, (a), (b), and a tricritical point, (c).
(a): A and B phases become identical in the presence of C phase, (b): B and C phases become identical in the presence of A phase, (c): A, B, and C phases become identical at a tricritical point.

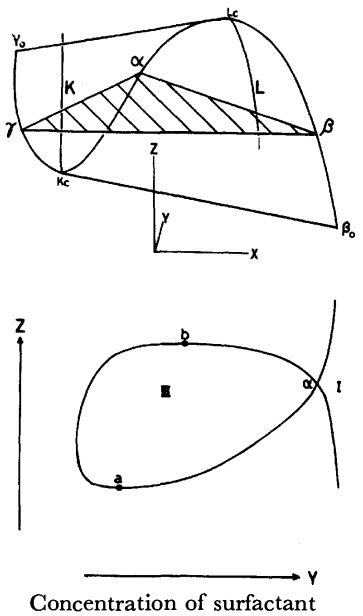

Fig. 2. (a) Schematic diagram of three coexisting phases in a surfactant/water/oil system at constant pressure. Curves α, β, and γ show the loci of compositions of a surfactant(D), and oil(O), and a water(W) phases forming a three-phase region. K and L are the critical curves of D–W and O–D phases. Lc and Kc are the critical end points of D–W and O–D. One of three-phase triangles is shown. (b) Vertical section of Fig. 2(a) at equal amount of water–oil. Points a and b are the intersections of this plane and Kc-β_o, Lc-γ_o lines respectively. The orientation of X axis is vertical to this plane. III is the three-phase region.

equilibrium with W phases (γ_0 point) on the Lc-γ_0 line which is called a critical tie line.[13] Therefore, the critical end phenomenon as is shown in Fig. 1(a) occurs on this line. Similarly the critical end phenomenon occurs on another critical tie line, Kc-β_0 on which the phenomenon in Fig. 1(b) is observed. A three-phase region exists between two critical tie lines.

Vertical section (Z–Y plane) of Fig. 2(a) at a composition of equal amount of water and oil is also shown in Fig. 2(b).[10–12] A three-phase region exists inside a closed loop. Point **a** is the intersection of this plane and a critical tie line Kc-β_0 in Fig. 2(a). Point **b** is that of this plane and Lc-γ_0 line.

If these two critical end points strictly coincide, a tricritical phenomenon as is shown in Fig. 1(c) occurs. But, in a nonionic surfactant systems, it may not appear at atmospheric pressure, because a tricritical point is an invariant point in the space of T, P and compositions in a three-component system.[4,12] On the other hand, similar three-phase region appears in an ionic surfactant/brine/(co-surfactant)/oil system.[10,14–17] In these systems, one or two degrees of freedom increase in comparison with a nonionic surfactant system so that it seems to be easier to find a tricritical phenomenon despite of the difficulty of determining X, Y, Z axes exactly. Although the solution behavior of surfactant in a water–oil system is generally very complicated due to formation of a liquid crystalline phase,[18,19] it is known that there is no liquid crystalline phase in a bile salt system.[19] Therefore, a three-phase region and tricritical phenomenon may appear in a bile salt/brine/co-surfactant(monoglyceride)/oil(triglyceride) system, which can be regarded as a model of biological system.

Experimental

Materials. Sodium taurocholate (NaTC) was obtained from Sibma Chemicals Co. Its purity is above 98%. 3-(2-ethylhexyloxy)-1,2-propanediol (glycerol mono(2-ethylhexyl) ether, MEH) and 3-(*cis*-9-octadecenyloxy)-1,2-propanediol (glycerol monooleyl ether, MO) were obtained from Nikko Chemicals Co. and their purities are above 99%. 1,2,3-propanetriyl tris(2-ethylhexanoate) (glycerol tris(2-ethylhexanoic) ester, TEH) was obtained from Nisshin Seiyu Co. (above 97%) Extra-pure-grade 1,2,3-propanetriyl tris(*cis*-9-octadecenoate) (triolein, TO) was obtained from Nakarai Chemicals Co. Extrapure-grade *cis*-9-octadecenoic acid (oleic acid, OA) and 2,3-dihydroxypropyl dodecanoate (monolaurin, ML) were obtained from Tokyo Kasei Kogyo Co. These reagents were used without further purifications.

Procedures. Various amounts of brine, oil, surfactant and co-surfactant were sealed in ampoules. A series of ampoules kept in a thermostat were well shaken and left at constant temperature from 1 d to one week depending on the stability of solution and the three-phase boundary and the change in volumes of respective phases were determined.

Results and Discussion

Phase Behavior in Sodium Taurocholate (NaTC)/Brine/Co-surfactant/Oil Systems. Figure 3 shows three-phase regions consisted of a water (W), a surfactant (D) and an oil (O) phases in various systems of NaTC/brine/co-surfactant/oil at 35 °C. The concentration of NaTC is 3 wt%/system and (co-surfactant+oil)/brine ratio is unity. The weight percent of co-surfactant, *i.e.*, co-surfactant/(oil+co-surfactant)is plotted vertically and the salinity is plotted horizontally. At constant salinity, D phase is separated from W phase in the presence of O phase with the increase in co-surfactant content and a three-phase region appears. With further increase in co-surfactant content, D and O phases dissolve each other and the three-phase region turns to a two-phase system. The required concentration of co-surfactant to produce a three-phase region becomes low at high salinity. These results completely correspond with that in an ordinary ionic surfactant/brine/co-surfactant/oil system.[16] The change in solution behavior of NaTC from water-soluble to oil-soluble as a function of the concentration of co-surfactant corresponds to that of a nonionic surfactant/water/oil system as a function of temperature.[10,20,21] It is known that solubilization of oil or water in a surfactant solution reaches maximum and ultralow interfacial tensions are attained around a three-phase region due to critical solution phenomena of O–D and D–W phases.[11,21] The solubilization of MEH–TEH mixture in an aqueous NaTC solution has been determined and is shown in Fig. 4. It is clear that the optimum ratio of oil–co-surfactant is very important for large solubilization and the solution behavior of NaTC is highly affected by salinity.

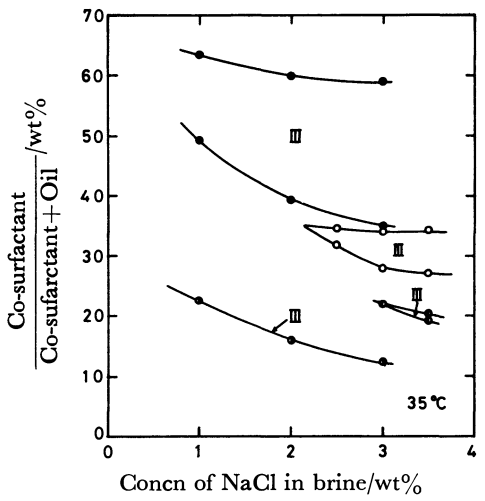

Fig. 3. The effect of salinity on the required concentration of co-surfactant to produce a three-phase region in a NaTC/brine/co-surfactant/oil system at 35 °C. The concentration of NaTC is 3 wt%/system and (oil+co-surfactant)/brine ratio is unity. III, the three-phase region.

	co-surfactant	oil
●	MO	TO
○	MEH	TEH
◐	MEH	OA
◑	ML	OA

The Effect of Salinity and Temperature on the Three-phase Region. Three-phase regions become narrower and finally diminishes with the decrease in salinity in the systems of NaTC/brine/MEH/TEH and NaTC/brine/MEH/OA as is shown in Fig. 3. In order to clarify this

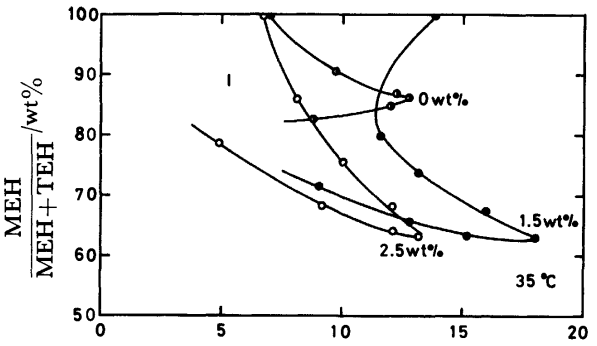

Fig. 4. The effect of NaCl on the solubilization of (TEH +MEH) mixture in brines containing 5 wt% of NaTC at 35 °C. The numerical values indicate concentrations of NaCl in brine.

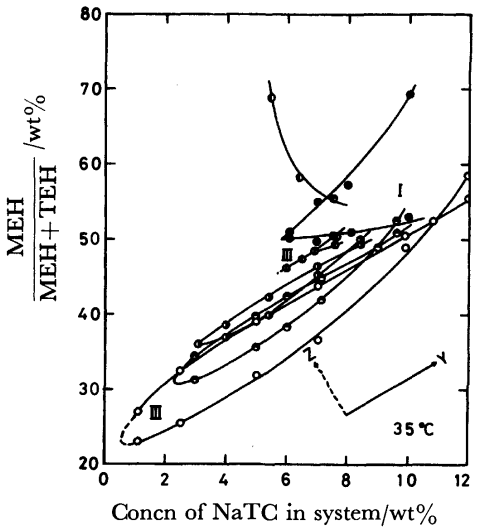

Fig. 5. The effect of NaCl on the three-phase region in NaTC/brine/MEH/TEH system at 35 °C. (MEH+ TEH)/brine ratio is unity. The three-phase region becomes very narrow at 1.5 wt% NaCl.
◐: 0 wt% NaCl, ●: 1 wt% NaCl, ◑: 1.5 wt% NaCl, ◑: 2 wt% NaCl, ◓: 2.5 wt% NaCl, ○: 3.5 wt% NaCl.

phenomenon, the effect of the concentration of NaTC on the three-phase region has been determined at 35 °C in the NaTC/brine/MEH/TEH system and is shown in Fig. 5. The vertical axis is the same as that of Fig. 3 and the concentration of NaTC in system is plotted horizontally. A three-phase region changes to one-phase region with increasing NaTC content, because O and W phases dissolve into D phase. On the other hand, the volume of D phase is decreased and finally, diminishes at the left-hand boundary of the three-phase region. Since inorganic salt is practically soluble only in water, brine can be regarded as a pseudo one component, then a pseudo four-component system of ionic surfactant/ brine/co-surfactant/oil is represented by a tetrahedron at constant temperature and salinity as is shown in Fig. 6. In this pseudo four-component system, degree of freedom of respective regions is the same as that in a nonionic surfactant/water/oil system as is shown in Fig. 2

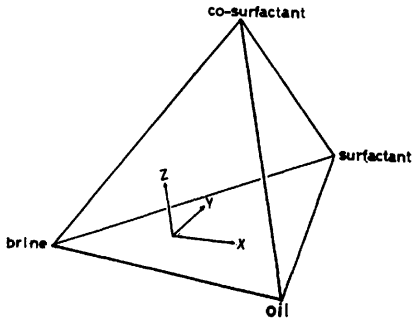

Fig. 6. Composition tetrahedron at constant T and P in a pseudo four-component system.

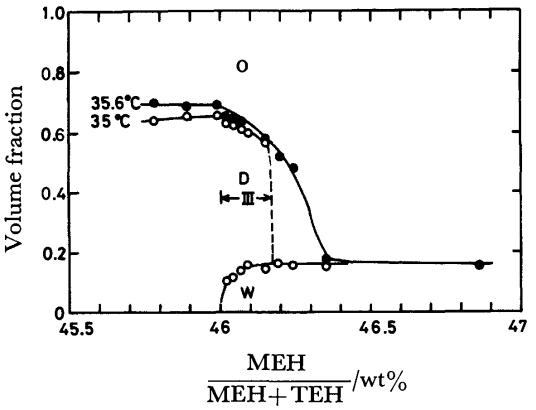

Fig. 7. The effect of $\frac{\text{MEH}}{\text{MEH+TEH}}$ on the volume fractions of respective phases at 1.5 wt% NaCl. The three-phase region diminishes at 35.6 °C. (MEH+TEH)/ brine ratio is unity. The concentration of NaTC is 6 wt%/system.

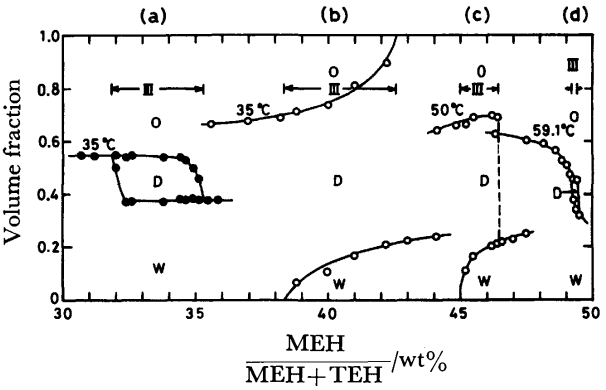

Fig. 8. The effect of temperature and the concentration of co-surfactant on the volume fractions of respective phases at various temperatures in a NaTC/brine(2.5 wt% NaCl)/MEH/TEH system. The concentrations of NaTC are 6 wt%/system (○) and 3 wt%/system (●).

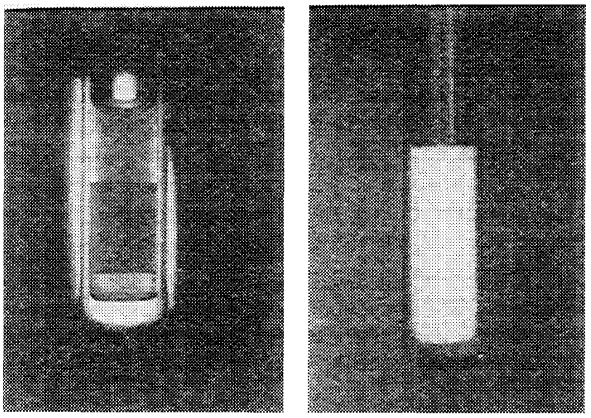
because temperature and salinity are fixed. Therefore, two critical end points are invariant points and two critical tie lines are also fixed in a composition tetrahedron. Accordingly X, Y, Z, coordinate system similar to that in Fig. 2 can be taken in this tetrahedron. The orientation of Y axis in Fig. 5 corresponds to that in Fig. 2, because the volume fraction of D phase is in-



(a) (b)

Fig. 9. The photographs of the three coexisting phases near the tricritical point at 35 °C in transmitted light (a) and in scattered light (b). (NaTC, 6 wt%/system. (MEH+TEH)/brine (1.5 wt% NaCl) is unity. MEH/(MEH+TEH) is 46.05 wt%.)

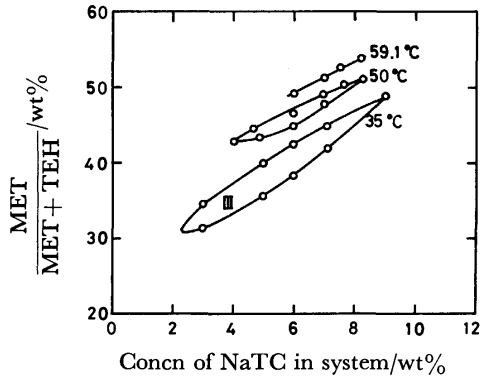


Fig. 10. The effect of temperature on the three-phase region at constant salinity (2.5 wt% NaCl) in a NaTC/brine/MEH/TEH system. The three-phase region vanishes slightly above 59.1 °C. (MEH+TEH)/brine ratio is unity.

creased in this direction. The three-phase region becomes narrower with the decrease in salinity and vanishes slightly below 1.5wt% NaCl. The change in volume fractions of respective phases as a function of co-surfactant content is shown in Figs. 7 and 8(a), (b) at 35 °C. As is shown in Figs. 8(a) and (b), when the concentration of NaTC is low (3 wt%), D phase dissolves into O or W phase and disappers at the right- or left-hand boundaries of the three-phase region. On the other hand, when the concentration of NaTC is high (6 wt%), O or W phase dissolves into D phase and disappears at those boundaries. This means that the critical end phenomena between O–D or D–W phases occur in the presence of a third phase (W or O phase) at a concentration of NaTC between 3—6 wt% on the curve in Fig. 5.[10,11,16] Those points correspond to the intersection between the plane of Fig. 5 and the critical tie lines in a composition tetrahedron (*cf.* points **a** and **b** in Fig. 2). Therefore, Z axis in Fig. 5 corresponds to that in Fig. 2 but is not completely in parallel with the plane of Fig. 5 as described later. Since these two points exist on the closed curve of Fig. 5, the width of a three-phase region at respective salinity represents the relative distance between two critical tie lines and it corresponds to the difference in critical end temperatures in a nonionic surfactant system. As is shown in Fig. 5, that distance shortens with the decrease in salinity and at last becomes zero slightly below 1.5 wt% NaCl at constant temperature (35 °C). In other words, the three-phase region in the composition tetrahedron becomes smaller and smaller with decreasing in salinity. Therefore, a tricritical point exists slightly below 1.5 wt% NaCl. In fact, all three coexisting phases show critical opalescence at 1.5 wt% NaCl as is shown in Fig. 9.

On the other hand, at constant salinity (2.5 wt% NaCl), a three-phase region also becomes narrow and vanishes with the rise in temperature as is shown in Fig. 10. The change in volume fractions of respective phases at 35, 50, and 59.1 °C are also shown in Figs. 8(b), (c), and (d). Hence, it is considered that a tricritical point also exists slightly above 59.1 °C at 2.5 wt% NaCl. From these results, a tricritical point shifts toward higher temperatures with increasing salinity.

Correlation between a Tricritical Phenomenon and the Degree of Freedom.[22] If the number of components are increased, a tricritical phenomenon can be observed more easily. The degree of freedom (f) of pth order critical point is expressed by following relation.[22]

$$f = c - 2p + 3, \quad (1)$$

where p is the number of phases becoming identical, and c is the number of components. Therefore, at a tricritical point, $f=c-4$ at constant pressure. This means that there is a line of tricritical points in the space of T and compositions in a five component system and it becomes an invariant point when temperature or composition of one component is fixed. In other words, a tricritical temperature is invariant at constant salinity, while the salinity at a tricritical point is invariant at constant temperature.

The Shape of a Three-phase Region Near the Tricritical Point. Figure 11 shows the shape of the three-phase region at 1.5 wt% NaCl on the plane almost perpen-

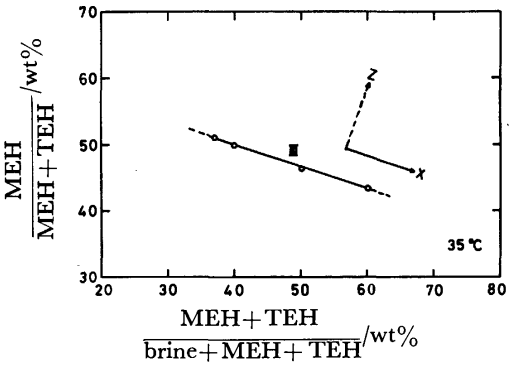

Fig. 11. The effect of (MEH+TEH)/brine ratio on the three-phase region in a NaTC/brine(1.5 wt% NaCl)/MEH/TEH system at 35 °C. The concentration of NaTC in system is 6 wt%. This figure is almost perpendicular to the plane of Fig. 5 in a composition tetrahedron.

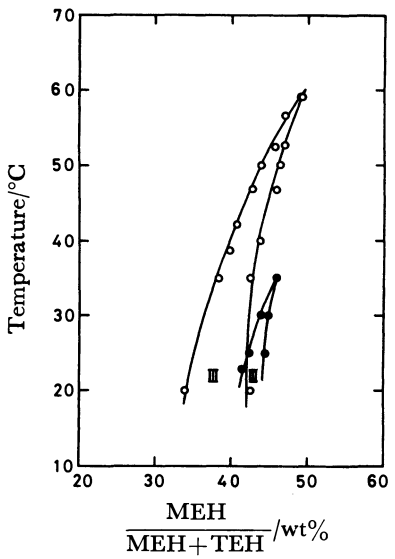

Fig. 12. The effect of temperature on the three-phase region in a NaTC/brine(●, 1.5 wt% NaCl; ○, 2.5 wt% NaCl)/MEH/TEH system. The concentration of NaTC in system is 6 wt%. (MEH+TEH)/brine ratio is unity. The three-phase region vanishes in the vicinity of a tricritical temperature.

dicular to that in Fig. 5 in the composition tetrahedron at 1.5 wt% NaCl. X axis and Y axis are approximately parallel to the respective figures. But Z axis in the figures is the projection of true axis on respective planes judging from Figs. 5 and 11. Although we could not determine the edges of the three-phase region in Fig. 11 because of their narrownesses, it is clear that near the tricritical point, the order of the sizes of the three-phase region in three directions is X>Y>Z. As described before, a three-phase region shrinks to a point, *i.e.*, a tricritical point in a composition tetrahedron with the rise in temperature at constant salinity or with increasing salinity at constant temperature. Griffiths predicted theoretically the shape of a three-phase region as a function of temperature in his coordinate system ξ_1, ξ_2, ξ_3, which is intrinsic to the figure of a three-phase region.[1] Present coordinate system, X, Y, Z, approximately corresponds with his system near a tricritical point.[1,2] According to his theory, the dimensions of the three-phase region vanish at different rates. The size in the ξ_1 direction diminishes proportionally to $(T_{Tcp}-T)^{1/2}$, that in the ξ_2 direction vanishes proportionally to $(T_{Tcp}-T)$ and that in the ξ_3 direction disappears proportionally to $(T_{Tcp}-T)^{3/2}$, where T_{Tcp} is a tricritical temperature.[1,2] Therefore, on approach to the tricritical point the region first becomes flat (the size in the ξ_3 (or Z) direction shrinks), then slender (that in the ξ_2 (or Y) direction shrinks) and finally of vanishing length (that in the ξ_1 (or X) direction shrinks).[1,2] His prediction is qualitatively in correspondence with the NaTC system as is shown in Figs. 5 and 11.

Correlation between a Tricritical Point and a Three-phase Region. As described before, a tricritical point is shifted to higher temperatures with increasing salinity. Accordingly, at fixed salinity, a three-phase region exists at temperatures below the tricritical temperature as is shown in Fig. 12. If the salinity is approached to zero, the tricritical temperature becomes below 0 °C and the three-phase region cannot be observed. This is the reason why it is difficult to obtain a three-phase region in an ionic surfactant/water/co-surfactant/oil system without adding salt.

The authors wish to thank Mr. M. Tanaka for his technical assistance.

Electrochemical Properties of Electrochemically Polymerized Polypyrrole Film in the Dark and under Light Irradiation

Tooru INOUE* and Toshihiro YAMASE
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta-cho, Midori-ku, Yokohama 227
(Received August 2, 1982)

Polypyrrole films prepared on Pt or SnO_2 through electrochemical oxidative polymerization of pyrrole were characterized with respect to electroconductivity by photoelectrochemical measurements. Redox reactions of solution species such as methyl viologen, hydroquinone, oxygen, Cu^{2+}, I^-, and Br^- occur on these electroconductive films. Light excitation of the film with wavelengths shorter than 550 nm results in observable cathodic photocurrent at the potential region more negative than 0.0 V *vs.* Ag. The polypyrrole film is a p-type semiconductor with a bandgap energy of *ca.* 2.2 eV and is stable during redox reactions.

Many works on photoelectrochemical processes have recently been carried out from the standpoint of solar energy conversion to electrical energy and/or chemical energy. There have been intensive studies on semiconductor transducers such as photoelectrodes, composed of TiO_2, CdS, GaP, GaAs, Si, *etc.*, for electrochemical photocells.[1-7]

Thin-layer-coated semiconductor electrodes with dyes,[8,9] metal complexes,[10-12] and organic polymers[13-15] such as Rhodamine B, thiacyanine, chlorophyll, Cu-phthalocyanine, $Ru(bpy)_3^{3+}$, and polypyrrole have been developed as photoelectrodes for electrochemical systems. Fan *et al.*,[13] Simon *et al.*,[14] and Skotheim *et al.*[15] have reported that an Si electrode coated with polypyrrole film is stabilized against photodegradation by the SiO_2 layer formation on Si surface so as to provide an electrochemical photocell capable of supplying stable photocurrent for a long period.

Organic polymers such as polyacetylene $(CH)_x$, poly(sulfur nitride) $(SN)_x$, and polypyrrole $(Pyr)_x$ have been synthesized as promising electrical conductors and their electrical and optical properties have been investigated.[13-21] Diaz *et al.*[17] have reported on electrochemical preparation and behavior of polypyrrole films on a Pt electrode. The polypyrrole films show a metallic conductivity and redox reactions of ferrocene, nitrobenzene, and chloranil occur on the surface of these films.

This paper describes spectral observations during polypyrrole film formation, redox reactions of methyl viologen, hydroquinone, oxygen, Cu^{2+}, I^-, and Br^-, and photocathodic reactions under light irradiation. The polypyrrole film shows an electrical conductivity like a metal or semiconductor electrode. Especially, under light irradiation with wavelengths shorter than 550 nm the polypyrrole film shows cathodic photocurrent under cathodic polarization, so that the film is considered to have a p-type semiconducting property with a bandgap energy of *ca.* 2.2 eV. The polypyrrole film is discussed from the viewpoint of the traditional theory of semiconductors.

Experimental

A Pt electrode and an optically-transparent SnO_2 electrode were employed as substrate electrode for pyrrole polymerization. For the pretreatment of the Pt electrode, the potential of Pt was scanned several times between −0.2 and 1.3 V *vs.* SCE in order to get a clean Pt surface. The SnO_2 electrode was rinsed with a dilute H_2SO_4 aqueous solution and methanol before use.

Polypyrrole film was formed on the electrode by electrochemical oxidation of pyrrole in an electrochemical glass cell with an Ag reference electrode and a Pt counter electrode, a potensiostat system (Hokuto Denko Co. Model HA301) being employed. The solution used for the polymerization was acetonitrile with 0.1 M (1 M = 1 mol dm^{-3}) pyrrole and 0.1 M Bu_4NClO_4. As for the polymerization, the electrode potential was initially polarized at 1.3 V *vs.* Ag in order to produce a cationic radical[17] of pyrrole, $pyrrole^+$. Then to let the $pyrrole^+$ polymerize with other pyrroles, the electrode potential was kept at 1.0 V for several minutes or scanned between −0.5 and 1.0 V *vs.* Ag. For the polypyrrole films in the photoelectrochemical study, the polymerization was carried out *via* oxidation with current charges from 10 to 100 milli coulombs (mC).

For the electrochemical measurement the light source was a 500 W Xe lamp (Ushio Electric Co.) with a glass cut-filter $\lambda(<350$ nm cut-off). Absorption spectra of polypyrrole films in the course of polymerization were measured with an SnO_2 electrode which was attached on the front of a box-type cell settled in the spectrometer. The light intensity dependence of cathodic photocurrents was measured with neutral density filters. Current-potential characteristics were observed by employing a potensiostat with a function generator. Measurements of action spectra of photocurrents were carried out by use of a synchrotrack lock-in amplifier and a light chopper (NF Circuit Design Block Co.). A grating monochromator (Nikon G-250) was employed for the wavelength selection on the light from the 500 W Xe lamp.

Chemicals used in this study were all of reagent grade and used without further purification. Electrolyte solutions were deaerated with a purified nitrogen purge during experiment.

Results and Discussion

Pyrrole was oxidized at the Pt electrode in the acetonitrile solution containing 0.1 M Bu_4ClO_4 (TBAP). Figure 1 shows the current-potential curves obtained in the course of the pyrrole polymerization. At first, the electrode was polarized at 1.2 V *vs.* Ag, where a pyrrole cationic radical was formed. Then the pyrrole was polymerized at the potentials above 1.0 V. In the first cycle of potential under the polarization between −0.5 and 1.0 V, the anodic (I_{pa}) and cathodic peak currents

(I_{pc}) appear at the potentials E_{pc} and E_{pa}, respectively where I_{pa}=411 μA at E_{pa}=0.42 V, I_{pc}=395 μA at E_{pc}=0.3 V, and I_{pc}/I_{pa}=0.96. From these data, the redox reactivity of pyrrole may be considered reversible. This anodic current is due to the oxidation during the polymerization of pyrrole accompanying a ClO_4^- doping into the polypyrrole film matrix.[18] The anodic and cathodic currents decrease with increasing number of potentials cyclings, due to increase in film thickness.

The polymerization reaction under an anodic polarization of an electrode can take place accompanying a doping of ClO_4^- anion, leading to the formation of pyrrole cation radical-ClO_4^- pair, and is controlled by the charge amount of anodic current. That is, the concentration of ClO_4^- as a dopant controls the electrical conductivity of the film from 0.1 to 10 Ω^{-1} cm^{-1}. The polypyrrole film formation is schematically illustrated in Fig. 2.

The thickness of polypyrrole was increased and its blue color deepened with increasing electrolytic charge amount. Absorption spectra of the polypyrrole film on an optically transparent SnO_2 electrode in the course of the polymerization are shown in Fig. 3 as a function of the electrolytic charge amount. The absorbance in

the visible region, especially at wavelengths longer than 600 nm, increases with increase in the oxidation charge amount.

Figure 4 shows current-potential curves which were

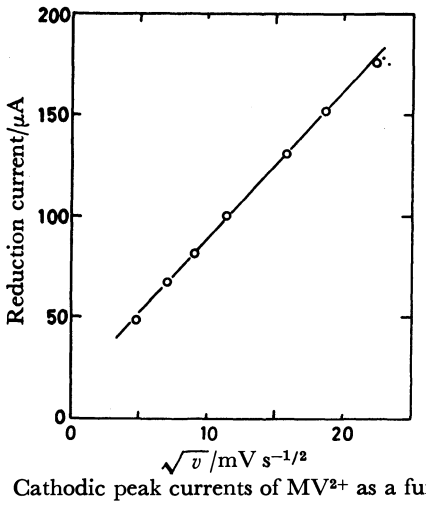

Fig. 5. Cathodic peak currents of MV^{2+} as a function of potential sweeping rate (v).

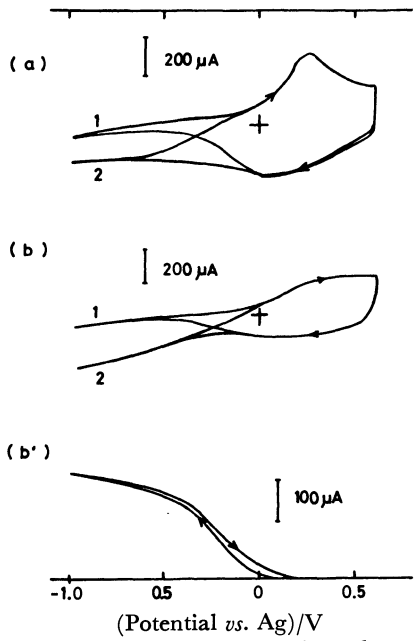

Fig. 6. Current-potential curves at the polypyrrole film in a solution with 0.1 M TBAP in the dark (1) and under light irradiation (2). (a) At the film prepared with the charge of 23.4 mC (1200 Å thickness), (b) at the film prepared with the charge of 30.0 mC (1500 Å thickness), (b') a photocurrent-potential curve at the film (b).

obtained with the Pt electrode with the polypyrrole film in the presence or absence of various redox agents such as methyl viologen (MV^{2+}), hydroquinone (H_2Q), O_2, Cu^{2+}, I^-, and Br^- in solution. The presence of redox agents brings about increase in the anodic and cathodic currents. Especially, the redox agents H_2Q, Cu^{2+}, and I^- can exchange electrons with the polypyrrole electrode surface, resulting in reversible voltammograms. Oxygen can be reduced on this film surface. Therefore, the polypyrrole film doped with ClO_4^- can be considered to have electrical conducting characteristics which are similar to those of metallic electrodes. Diaz *et al.*[17,18] have reported that redox agents such as ferricinium and that redox reactions for these redox agents are reversible on this film electrode.

Figure 5 shows cathodic peak currents as a function of the sweeping rate of potential. The linear relationship of the plot indicates that the charge transfer reaction is controlled by the MV^{2+} diffusion toward the polypyrrole electrode surface. The diffusion constant of MV^{2+} in Fig. 5 is 4.8×10^{-6} cm^2 s^{-1}, a little smaller than the value of 1.38×10^{-5} cm^2 s^{-1} obtained with a Pt electrode in an acetonitrile solution.[22] This discrepancy between the diffusion constants may result from surface constitution of the polypyrrole film.

Figure 6 shows current-potential curves obtained under light irradiation for the polypyrrole films which were prepared by applying charge amounts of (a) 23.4 mC and (b and b$^-$) 30.0 mC for oxidative polymerization with resulting film thicknesses of *ca.* 1200 and 1500 Å, respectively; in these preparations cathodic photocurrents were observed at cathodic potentials more negative than 0.0 V *vs.* Ag. Cathodic photocurrents at the potential of -1.0 V were 120 μA for (a) and 260 μA for (b), reaching a maximum value with the film corresponding to *ca.* 40 mC, as established from variation in the relationship between light absorption and resistance of the film with film thickness. Hysteresis of photocurrent is observed during cyclic potential scanning, as shown in Fig. 6(b'). This may be explained in terms of the concentration of the dopant, that is, the film composition depends on the flow of dopant ClO_4^- which directs from the polypyrrole film into the solution at the cathodic current observed and in the reverse direction at the anodic current.

In the aqueous solution with 0.1 M $NaClO_4$, current-potential characteristics of the redox agents are similar to those in the acetonitrile solution; the non-Faradaic current is a little larger in the former solution than in the latter. The onset potential for cathodic photocurrent is 0.3 V *vs.* SCE.

For interpretation of the electrochemical behavior and photoresponse of polypyrrole film, the following physical properties need to be taken into account: The electrical property of organic polymers such as polyacetylene, polypyrrole, and poly(sulfur nitride) is controlled by the π-electron distribution for polymer, as schematically illustrated in Fig. 7. A polymer film with perfectly localized π-electrons (Fig. 7(1)) has no or a low conducting property because the π-electrons over the polymer are trapped in deep wells of electronic potential in double bonds. According to the traditional semiconductor theory, the energy diagram can be represented as being equal to the one for an intrinsic semiconductor with a large bandgap energy E_g. On the contrary, the polymer film with fully delocalized π-electrons (Fig. 7(2)) has a high conducting property because the π-electrons are distributed over the polymer chain.

For the film involved in the charge transfer doping of an anion (P^-) (Fig. 7(3)), an acceptor is induced to appear removal of one π-electron from one π-bond of the polymer under the requirement of electrical neutrality and causes localized distortion of the π-electrons on the polymer. The nonlinear wave function of the positively-charged localized region is called a soliton.[23,24]

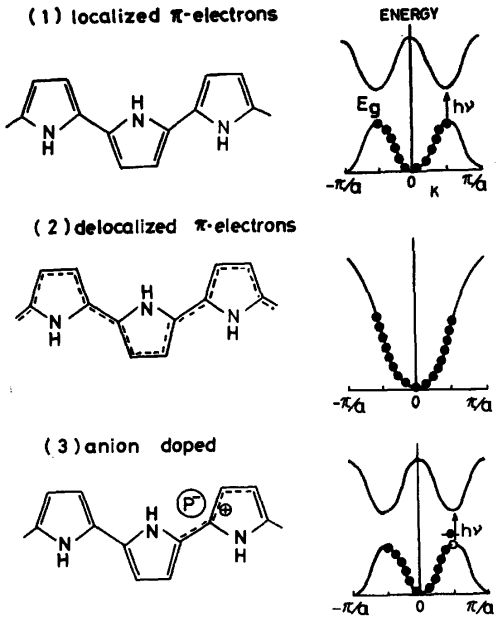

Fig. 7. Schematic diagram of the energy bands of the polypyrrole film where the energy diagram is governed by the electron distribution spreading over the polypyrrole linkage. Electroconductivity of the film with localized π-electrons is quite low because of the large bandgap energy E_g, on the contrary, that of the film with delocalized π-electrons is high because of no bandgap energy. A dopant forms a state within the bandgap resulting in an increase in the conductance.

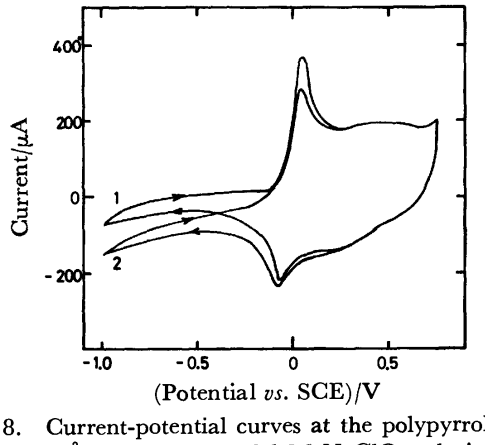

Fig. 8. Current-potential curves at the polypyrrole film of 1000 Å thickness in a 0.1 M $NaClO_4$ solution with 1 mM $CuCl_2$. 1; in the dark, 2; under light irradiation.

The spreading mode of a soliton determines the electrical conductivity of polymer. The soliton density increases with increase in the dopant concentration, enhancing the electrical conductivity of polymer. The polypyrrole film with ClO_4^- anions doped may be considered to be a p-type semiconductor with positive acceptor sites in its bandgap.

The dopant transfer into and out of polymer, allowed to occur by anodic and cathodic polarization, respectively, in the course of potential cycling, can change the acceptor density in the polymer; under cathodic polarization the polymer has a high conductivity. The

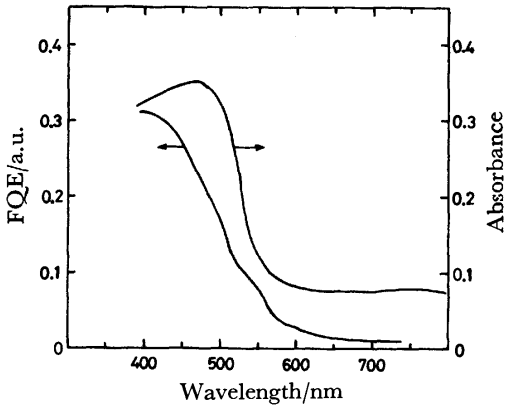

Fig. 9. Actionspectrum of the formal quantum efficiency (FQE) of cathodic photocurrents observed at the polypyrrole film electrode at -1.0 V *vs.* Ag in an acetonitrile solution and the absorption spectrum of the polyrrole film polarized at -1.0 V. FQE denotes the current efficiency against the amount of the incident photons.

hysteresis illustrated in Fig. 6(b') is presumed to be due to a conductivity difference between the anodic and cathodic polarizations.

Figure 8 shows current-potential curves for the polypyrrole electrode in an aqueous solution with 0.001 M $CuCl_2$ and 0.1 M $NaClO_4$ under light irradiation. The current-potential curve in the dark (a) has a couple of anodic and cathodic current peaks around 0.0 V *vs.* SCE, representing an occurrence of the reversible redox reaction of Cu^{2+}/Cu^+

$$Cu^{2+} + e^- \rightleftarrows Cu^+. \quad (1)$$

When the polypyrrole electrode is irradiated with light, cathodic photocurrent appears at negative potentials than 0.3 V. For curve (b) in Fig. 8, the anodic current peak for the oxidation of Cu^+ to Cu^{2+} is larger than the one in the dark (a). The photoinduced increase in anodic current is attributed to the increase in the Cu^+ concentration on the surface due to the reduction by photogenerated conduction band electrons. Because an electron-hole pair produced in a photoexcited polypyrrole film can be separated by the electric field generated by the cathodic polarization, the electron produced reduces the oxidized form (Cu^{2+}) on the film surface. Therefore, it is inferred that the polypyrrole film electrode can act as an active photocathode for the redox reaction of solution species.

The action spectrum of cathodic photocurrents at the potential of -1.0 V *vs.* SCE is shown in Fig. 9, were the action spectrum coincides well with the absorption spectrum of polypyrrole film referring to a photoabsorption due to π-π^* transition at wavelengths shorter than 550 nm. From this result, the bandgap energy of the p-type semiconducting polypyrrole film is estimated to be about 2.2 eV. The action and absorption spectra of the film observed at -1.0 V are different from the absorption spectrum of the film observed at 1.0 V, as seen from Fig. 3. This electrochromic property of the polypyrrole film arises from conformation change of the polymer based on the ClO_4^- doping with electrode

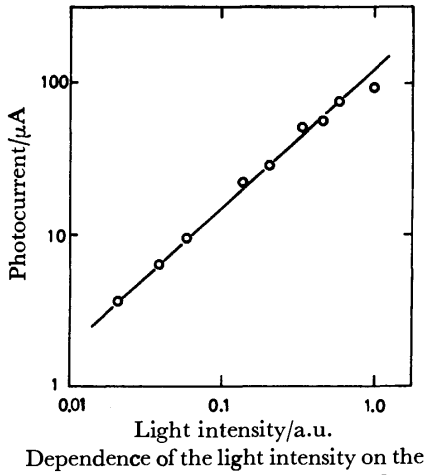

Fig. 10. Dependence of the light intensity on the cathodic photocurrents observed at the polypyrrole film electrode polarized at −1.0 V *vs.* Ag in an acetonitrile solution with 0.1 M TBAP and 2 mM MV^{2+} under light irradiation with wavelengths longer than 430 nm.

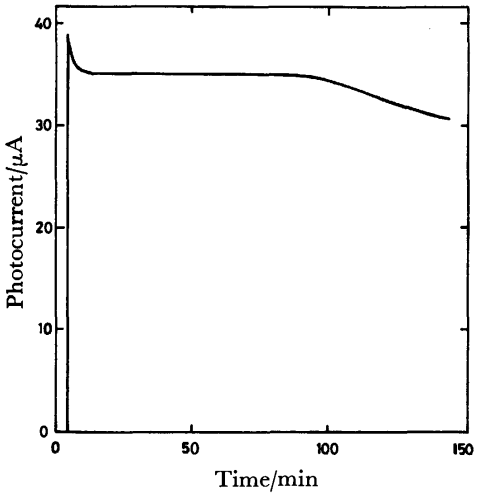

Fig. 11. Time dependence of the cathodic photocurrent observed at the polypyrrole film (500 Å thickness) polarized at −1.0 V *vs.* Ag in an acetonitrile solution with 2 mM MV^{2+}.

polarization.

Figure 10 shows the light intensity dependence of cathodic photocurrent which was observed at −1.0 V *vs.* Ag in an acetonitrile solution. The cathodic photocurrent increases in a linear relationship with a slope of *ca.* 0.9 with increasing light intensity. It follows that the carrier formation is of one photon. The quantum efficiency of the photocurrent is around 0.01.

Figure 11 shows the time dependence of cathodic photocurrent. Photocurrents flow with fair stability but decrease by 15% after a 120 min irradiation. The charge required for the polypyrrole film preparation and the photocurrent charge for 120 min are 10 and 250 mC, respectively. The result suggests that the polypyrrole film works stably under the restriction that the ratio of cathodic photocurrent charge to polymerization charge should be less than 20, although the photocurrent decreases gradually over about 2 h.

Conclusion

The polypyrrole film was formed on Pt and SnO_2 electrodes through an oxidation of pyrrole accompanying a radical linking and an anion doping. The polypyrrole film is capable of electrical conduction based on the solution effect that a doped anion (ClO_4^- in this study) affects the distribution of π-electron densities in the polypyrrole linkage.

Redox reactions of solution species occur on the polypyrrole film electrode. Under visible light irradiaton at $\lambda < 550$ nm, the polypyrrole film electrode shows a p-type semiconducting property, resulting in cathodic photocurrent evolution due to reduction of solution species.

p-Type semiconducting polypyrrole films with high conductance can be developed which are applicable to photoelectrodes in photoelectrochemical cells and to electrochromic devices.[25]

We thank Mr. Koji Asano for the technical assistance in the electrochemical experiments.

A Potential-step Chronoamperometric Study of Ion Transfer at the Water/Nitrobenzene Interface

Tadaaki KAKUTANI, Toshiyuki OSAKAI, and Mitsugi SENDA*

Department of Agricultural Chemistry, Faculty of Agriculture, Kyoto University, Kyoto 606

(Received August 2, 1982)

Potential-step chronoamperometry, cyclic voltammetry, and chronopotentiometry have been applied to the study of the transfer of the tetramethylammonium (TMA^+) ion across the interface between a 0.1 mol dm^{-3} lithium chloride aqueous solution and a 0.1 mol dm^{-3} tetrabutylammonium tetraphenylborate nitrobenzene solution. An analysis of the current-time and current-potential curves obtained by means of potential-step chronoamperometry indicates that the transfer of the TMA^+ ion across the water/nitrobenzene interface is a reversible diffusion-controlled process, which can be explained by the theory of the chronoamperometry of a reversible charge transfer at the electrode surface. The values of the diffusion coefficient of the TMA^+ ion in the aqueous phase and of the reversible half-wave potential of the TMA^+ ion transfer, as determined by means of potential-step chronoamperometry, agreed well with those determined by means of cyclic voltammetry and chronopotentiometry.

Recently there has been growing interest in electrochemical phenomena occurring at the interface between oil and water or two immiscible liquids (for reviews, see Refs. 1, 2, and 3). Electrochemical information on the charge (ion or electron) transfer at the liquid-liquid interface is important for a better understanding of the solvent extraction of ions, of liquid membrane ion-selective electrodes, and of the biological membrane and its model systems. Although several electrochemical techniques have been developed for studying the ion transfer at the interface between two immiscible electrolyte solutions (chronopotentiometry with the stationary interface,[4] cyclic voltammetry with the stationary interface,[5,6] and d.c. polarography with the electrolyte dropping electrode[7-9]), the further development of experimental approaches to the electrochemistry of the ion transfer at the interface seems highly desirable. In this work we have applied potential-step chronoamperometry to the study of the tetramethylammonium (TMA^+) ion transfer at the stationary water/nitrobenzene interface. The electrochemical data obtained by this techniques were then compared with those obtained by cyclic voltammetry and chronopotentiometry.

Experimental

Chemicals. The tetrabutylammonium tetraphenylborate (TBATPB) was prepared by the equimolar addition of an aqueous solution of tetrabutylammonium bromide to an aqueous solution of sodium tetraphenylborate and purified by repeated recrystalizations from acetone. The lithium chloride was a Merck product of the "spurapur" grade. The tetramethylammonium bromide (TMABr) and tetrabutylammonium chloride (TBACl) were analytical reagent-grade products of the Nakarai Chemicals Co. These reagents were used as received. Analytical-grade nitrobenzene was shaken with neutral alumina overnight; after the filtration of the suspension, the filtrate was fractionally distilled under a vacuum. The central 60% fraction of the distillate was collected and washed with triply distilled water. Triply distilled water was also used to prepare the aqueous electrolyte solutions.

Electrochemical Measurements. The transfer of the TMA^+ ion across the interface between a 0.1 mol dm^{-3} TBATPB nitrobenzene solution (Phase II in Cell A) and a 0.1 mol dm^{-3} LiCl aqueous solution containing $(0.5—2)\times 10^{-3}$ mol dm^{-3} TMABr (Phase III in Cell A) was studied. The electrolytic cell assembly is shown in Fig. 1. The test interface, *i.e.*, the water/nitrobenzene interface to be studied for the transfer of the TMA^+ ion, is formed in a glass tube A. A flat and reproducible water/nitrobenzene interface, with an area of 0.159 cm^2, can be formed by treating with dimethyldichlorosilane the inner surface of the tube A that will come in contact with nitrobenzene.[10] The potential difference across the test interface was controlled by a four-electrode potentiostat,[5,10] with two reference electrodes and two counter electrodes. The reference electrode for the nitrobenzene phase, RE2, was an Ag/AgCl/0.1 mol dm^{-3} TBACl (water) electrode which was connected to the nitrobenzene phase by means of a Luggin capillary filled with the 0.1 mol dm^{-3} TBATPB nitrobenzene solution. The reference electrode for the aqueous phase, REl, was an Ag/AgCl electrode immersed in an aqueous phase containing 0.1 mol dm^{-3} LiCl. Accordingly, the cell to be studied can be expressed by:

$$\begin{array}{l}\overset{\text{I}}{\text{(RE2) Ag|AgCl|0.1 mol dm}^{-3}\text{ TBACl(W)}}\\ \overset{\text{II}}{\text{|0.1 mol dm}^{-3}\text{TBATPB(N)}}\\ \left|\begin{array}{l}\overset{\text{III}}{(0.5-2)\times 10^{-3}\text{ mol dm}^{-3}\text{ TMABr}}\\ \qquad\qquad\qquad\qquad\qquad\text{(W)}\\ \qquad+\text{ 0.1 mol dm}^{-3}\text{ LiCl}\end{array}\right.\\ \overset{\text{IV}}{\text{|0.1 mol dm}^{-3}\text{ LiCl(W)|AgCl|Ag(REl).}}\quad\text{(A)}\end{array}$$

As the counter electrodes, Ag/AgCl electrodes with a large surface area (>4 cm^2) were used. One of the counter electrodes, CEl, was immersed in the aqueous phase, while the other, CE2, was immersed in a 0.1 mol dm^{-3} TBACl aqueous solution which was connected to the nitrobenzene phase through sintered glass. The location of the tip of the Luggin capillary of the reference electrode was adjusted by using a manipulator, Narishige BC-4; the distance, d_W, between the tip of the Luggin capillary of REl and the test interface, and the distance, d_N, between the tip of the Luggin capillary of RE2 and the test interface, were accurately measured by means of a travelling microscope, PIKA Seiko Co., Model PRM-2XYZ. Usually d_N and d_W were set at 0.2 mm and 1.0 mm respectively. Then the resistance of the electrolyte-solution column between the tips of the two Luggin capillaries, REl and RE2, r_s, was estimated to be 180 Ω, as calculated from the conductivities of the electrolyte solutions and the area of the test interface. The conductivities of the 0.1 mol dm^{-3} LiCl aqueous solution and the 0.1 mol dm^{-3} TBATPB nitrobenzene solution were

determined to be 9.48×10^{-3} and 1.12×10^{-3} Ω^{-1} cm^{-1} respectively at 25 °C.

For potential-step chronoamperometry and cyclic voltammetry, a four-electrode potentiostat,[10] to which a Yanako Model PE21-TB2S potentiostat was remodelled, and a function generator, Nikko Keisoku Model NFG-3, were used. Figure 2 shows the basic electronic circuit of the four-electrode potentiostat, with the cell system. The current-time curves of the potential-step chronoamperometry were recorded using both a transient memory, Union Giken System 71-02, and an X-Y recorder, Yokogawa 3077. The cyclic voltammograms were recorded with the same X-Y recorder. For chronopotentiometry, the current across the two counter electrodes (CE1 and CE2) of the cell in Fig. 1 was controlled using a conventional, laboratory-made galvanostat,[10,14] and the potential difference across the test interface was measured by means of the two reference electrodes (RE1 and RE2), using a laboratory-made, high-input-impedance differential amplifier and an X-Y recorder, Yokogawa 3077. All the electrochemical measurements were performed at 25±2 °C.

Results

In the following remarks, the potential applied to the cell A, E, is defined as the potential difference between the two reference electrodes, RE1 and RE2, *i.e.*, $E=E_{RE1}-E_{RE2}$. The flow of the positive charge from the aqueous to the nitrobenzene phase is considered as the positive current.

Potential-step Chronoamperometry. In this method, a potential step $\Delta E=E-E_i$, E_i being the initial potential where the current due to the ion transfer is negligible, is applied to the test interface at time $t=0$, and the resulting current, i, is recorded against t. For studying the TMA^+ ion transfer from the aqueous to the nitrobenzene phase, E_i was set at 200 mV. Figure 3 shows an example of the current-time curves of the TMA^+-ion transfer from the aqueous to the nitrobenzene phase. The currents measured at various E's, when corrected for the base current, were inversely proportional to $t^{1/2}$ at $t>0.1$ s, as is shown in Fig. 4. This indicates that the transfer of the TMA^+ ion from the aqueous to the nitrobenzene phase is a diffusion-controlled process at $t>0.1$ s. Figure 5 shows a plot of the current measured at $t=10$ s, $I_{t=10\,s}$, against

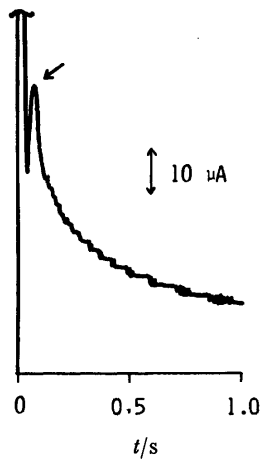

Fig. 3. Chronoamperometric current-time(i-t) curve of TMA^+ ion transfer from the aqueous to the nitrobenzene phase at $E=0.38$ V for 0.5×10^{-3} TMA^+ in 0.1 mol dm^{-3} LiCl aqueous solution. A transient oscillation of the current (as indicated by an arrow) was sometimes observed, depending on the solution resistance and ion transfer impedance at the interface, at the initial part of i-t record.

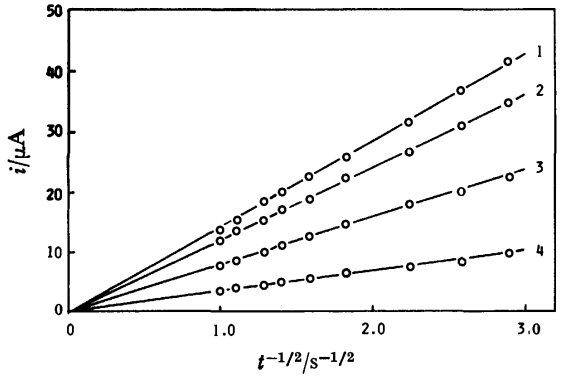

Fig. 4. Plots of i, corrected for the base current, against $t^{-1/2}$ for 0.5×10^{-3} mol dm^{-3} TMA$^+$ ion in 0.1 mol dm^{-3} LiCl aqueous solution. E: (1) 0.38, (2) 0.35, (3) 0.32, (4) 0.29 V.

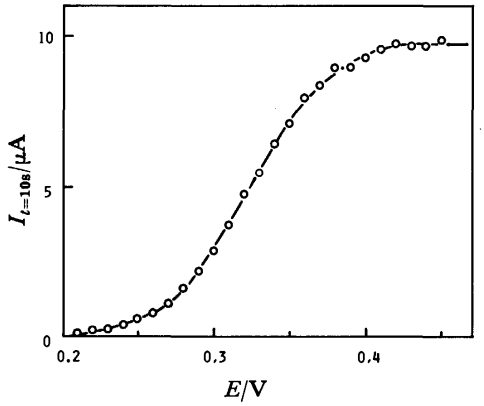

Fig. 5. Plot of $I_{t=10s}$, corrected for the base current, against E for 1×10^{-3} mol dm^{-3} TMA$^+$ ion in 0.1 mol dm^{-3} LiCl aqueous solution.

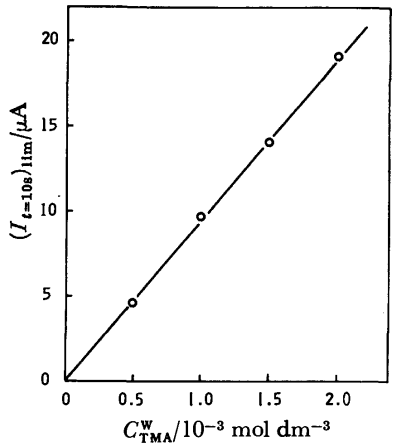

Fig. 6. Dependence of limiting current, $(I_{t=10s})_{lim}$, on the bulk concentration of TMA$^+$ ion, C^W_{TMA}, in 0.1 mol dm^{-3} LiCl aqueous solution.

E for 10^{-3} mol dm^{-3} TMABr in a 0.1 mol dm^{-3} LiCl aqueous solution; it gives a well-defined current-potential ($I_{t=10s}-E$) curve, with the limiting current, $(I_{t=10s})_{lim}$, and the half-wave potential, $E_{1/2}$, for the transfer of the TMA$^+$ ion from the aqueous to the nitrobenzene phase. In the present case (d_N=0.2 mm, d_W=1.0 mm, and t=10 s), the ohmic drop due to r_s was estimated to be always less than 4 mV, even for the 2.0×10^{-3} mol dm^{-3} TMA$^+$ ion in the aqueous phase. Accordingly, no correction for the ohmic drop was made. The limiting current was proportional to the bulk concentration of the TMA$^+$ ion in the aqueous phase, as is shown in Fig. 6. Figure 7 shows a logarithmic analysis of the wave, giving a straight line with the slope of 60 mV. The half-wave potential was 0.32 V, independently of the bulk concentration of the TMA$^+$ ion. These results indicate that the $I_{t=10s}-E$ curve of the TMA$^+$ ion transfer has the same characteristics as a reversible d.c. polarographic wave:

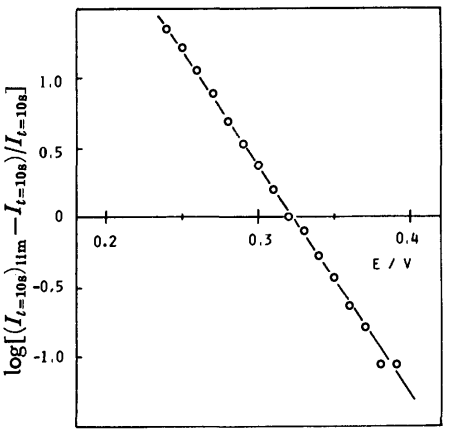

Fig. 7. Logarithmic analysis of the current-potential ($I_{t=10s}-E$) curve shown in Fig. 5.

$$E = E^r_{1/2,j} + (RT/z_jF)\ln[I_{t=t_s}/((I_{t=t_s})_{lim} - I_{t=t_s})], \quad (1)$$

where $E^r_{1/2,j}$ is the reversible half-wave potential of the j ion (here, j=TMA$^+$); z_j the ionic valence of the j ion, and $I_{t=t_s}$, the ion-transfer current at $t=t_s$ (here, t_s=10 s).

The limiting current at $t=t_s$, $(I_{t=t_s})_{lim}$, due to the diffusion-controlled j ion transfer from the aqueous to the nitrobenzene phase should be given by the Cottrell equation:[11]

$$(I_{t=t_s})_{lim} = z_jFA(D^W_j/\pi t_s)^{1/2}C^W_j, \quad (2)$$

where A is the surface area; C^W_j, the bulk concentration, and D^W_j the diffusion coefficient of the j ion in the aqueous phase (W). The application of this equation to the plot in Fig. 6 yielded the diffusion coefficient of the TMA$^+$ ion in the aqueous phase, D^W_{TMA}. The values of $E^r_{1/2,TMA}$ and D^W_{TMA} as determined by means of potential-step chronoamperometry are summarized in Table 1.

Cyclic Voltammetry. Figure 8 shows cyclic voltammograms of the 2×10^{-3} mol dm^{-3} TMA$^+$ ion in the aqueous phase. The positive-current peak on the forward polarization and the negative-current peak on the following backward polarization correspond, respectively, to the transfer of the TMA$^+$ ion from the aqueous to the nitrobenzene phase and its transfer back to the aqueous phase. The voltammograms were influenced by the solution resistance, r_s. The peak potentials of the positive and negative currents, E_{pa} and E_{pc}, varied linearly with d_N, as is shown in Fig. 9.[10] The slopes of

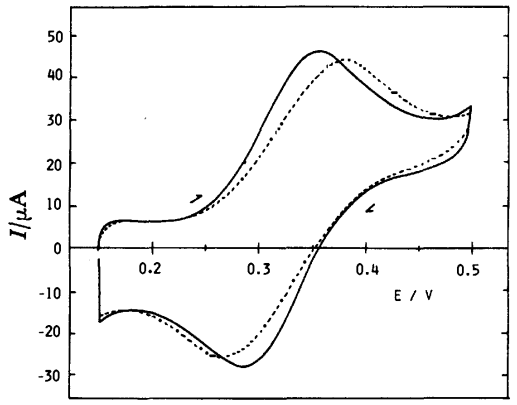

Fig. 8. Cyclic voltammograms for the transfer of 2×10^{-3} mol dm^{-3} TMA^+ ion from 0.1 mol dm^{-3} LiCl aqueous solution to 0.1 mol dm^{-3} TBATPB nitrobenzene solution and back at $v=20$ mV s^{-1}. Solid line: measured at $d_N=0.2$ mm and $d_W=1.0$ mm. Dotted line: measured at $d_N=d_W=1.0$ mm.

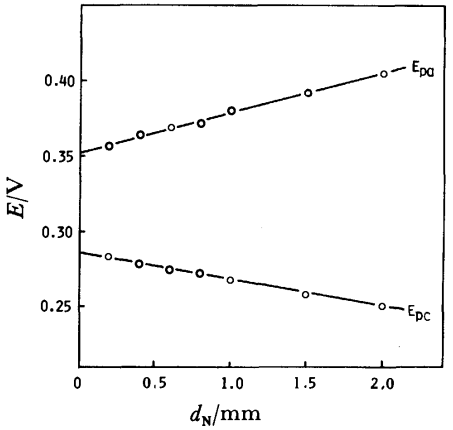

Fig. 9. Plots of the peak potentials of the positive and negative current, E_{pa} and E_{pc}, against d_N for 2×10^{-3} mol dm^{-3} TMA^+ ion in 0.1 mol dm^{-3} LiCl aqueous solution. d_W: 1.0 mm; v: 20 mV s^{-1}.

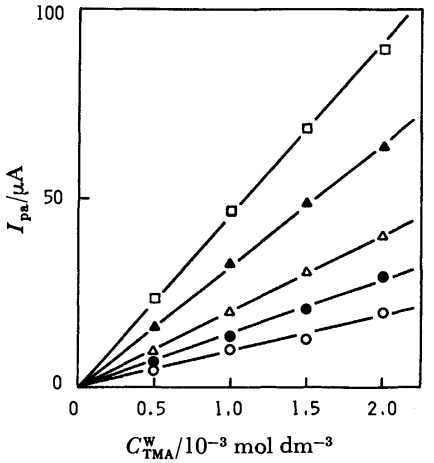

Fig. 10. Dependence of the positive peak current of cyclic voltammogram of TMA^+ ion transfer, I_{pa}, on the bulk concentration of TMA^+ ion, C^W_{TMA}, in 0.1 mol dm^{-3} LiCl aqueous solution. v: (○) 5, (●) 10, (△) 20, (▲) 50, and (□) 100 mV s^{-1}.

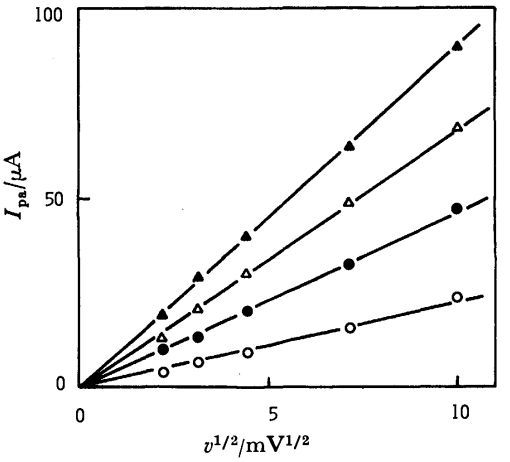

Fig. 11. Dependence of the positive peak current of cyclic voltammogram of TMA^+ ion transfer, I_{pa}, on the voltage scan rate, v. C^W_{TMA}: (○) 0.5×10^{-3}, (●) 1.0×10^{-3}, (△) 1.5×10^{-3}, and (▲) 2.0×10^{-3} mol dm^{-3}.

the linear plots gave 636 Ω mm^{-1} (average of these two plots) for the resistance per mm of the nitrobenzene-solution column; this value agreed well with the calculated value of 563 Ω mm^{-1}. The extrapolation of E_{pa} and E_{pc} to $d_N=0$ should yield the peak potentials corrected for the ohmic drop in the nitrobenzene phase. Correction for the ohmic drop in the nitrobenzene as well as the aqueous phase yielded the corrected peak potentials, $E_{pa,corr}$ and $E_{pc,corr}$, which were independent of both the concentration of the TMA^+ ion in the aqueous phase, C^W_{TMA}, in the range between 0.5×10^{-3} and 2×10^{-3} mol dm^{-3} and the scan rate, v, in the range between 5 and 100 mV s^{-1}. The corrected peak separations, $\Delta E_{p,corr}=E_{pa,corr}-E_{pc,corr}$, were 60 mV over the scan-rate range of 5 to 100 mV s^{-1} for all the concentration of the TMA^+ examined. When $r_s=180$ Ω ($d_N=0.2$ mm and $d_W=1.0$ mm), the positive peak current, I_{pa}, was proportional to the concentration of the TMA^+ ion and to the square root of the voltage-scan rate (see Figs. 10 and 11). Similarly, the negative peak current, I_{pa}, was proportional to the concentration of the TMA^+ ion in the aqueous phase and to the square root of the voltage-scan rate (data are not shown). These results indicated that the transfer of the TMA^+ ion across the water/nitrobenzene interface was a diffusion-controlled process over the scan-rate range from 5 to 100 mV s^{-1}. Accordingly, the theory of the voltammetry of a reversible charge transfer at the electrode surface[11] was used to analyse the cyclic voltammetric data. The reversible half-wave potential (or the midpoint potential between $E_{pa,corr}$ and $E_{pc,corr}$) and the diffusion coefficient of the TMA^+ ion in the aqueous phase, as determined by cyclic voltammetry, are given in Table 1.

Chronopotentiometry. Figure 12 shows chronopotentiometric potential-time ($E-t$) curves with the current reversal at various current densities for the transfer of the TMA^+ ion from the aqueous to the nitrobenzene phase and its transfer back to the aqueous phase. The transition times were inversely proportional to the square of the current density over the range from

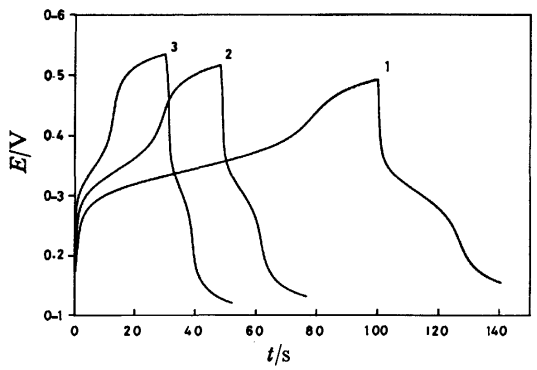

Fig. 12. Chronopotentiometric potential-time curves with current reversal for TMA^+ ion transfer across the water/nireobenzene interface for 1×10^{-3} mol dm^{-3} TMA^+ ion in 0.1 mol dm^{-3} LiCl aqueous solution. The current density: (1) 31.4, (2) 62.9, and (3) 94.3 μA cm^{-2}.

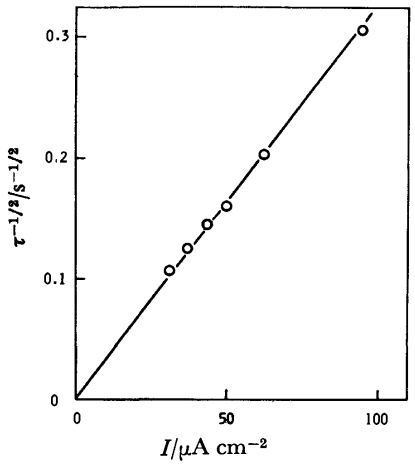

Fig. 13. Dependence of the chronopotentiometric transition time of TMA^+ ion transfer from the aqueous to the nitrobenzene phase, τ, on the current density, I, for the transfer of 1×10^{-3} mol dm^{-3} TMA^+ ion from 0.1 mol dm^{-3} LiCl aqueous solution to 0.1 mol dm^{-3} TBATPB nitrobenzene solution.

Table 1. Half-wave potential for the transfer of TMA^+ ion across water/nitrobenzene interface and diffusion coefficient of TMA^+ ion in the aqueous phase as determined by three electrochemical methods

Method	$E^r_{1/2,TMA}$ / V	D^w_{TMA} / 10^{-5} cm^2 s^{-1}
Potential-step chrononoamperometry	0.32	1.2
Cyclic voltammetry	0.32	1.1
Chronopotentiometry	0.32	1.3

31.4 to 94.3 μA cm^{-2} (Fig. 13). Thus, the chronopotentiometric behavior was interpreted by means of the theory of the chronopotentiometry of a reversible charge transfer at the electrode surface.[11] The reversible half-wave potential and the diffusion coefficient of the TMA^+ ion in the aqueous phase, as determined from the chronopotentiometric data, are given in Table 1.

All three methods yielded the same values of the half-wave potential for the transfer of the TMA^+ ion across the water/nitrobenzene interface and of the diffusion coefficient of the TMA^+ ion in the aqueous phase.

Discussion

We shall define the standard ion-transfer potential of the j ion across the water(W)/nitrobenzene(N) interface, $\Delta^w_N\phi^\ominus_j$, by:

$$\Delta^w_N\phi^\ominus_j = -\Delta G^{\ominus,N\to W}_{tr,j}/z_jF, \quad (3)$$

where $\Delta G^{\ominus,N\to W}_{tr,j}$ is the standard Gibbs free energy of the transfer of the j ion from the nitrobenzene to the aqueous phase. Then, $E^r_{1/2,j}$ is given by:

$$E^r_{1/2,j} = \Delta^w_N\phi_{1/2,j} + \Delta E_{ref}, \quad (4)$$

$$\Delta^w_N\phi_{1/2,j} = \Delta^w_N\phi^\ominus_j + (RT/z_jF)\ln(\gamma^N_j\sqrt{D^w_j}/\gamma^w_j\sqrt{D^N_j}), \quad (5)$$

where ΔE_{ref} is the constant which depends only on the reference electrode system, and where γ^N_j and γ^w_j are the activity coefficients of the j ion in the nitrobenzene and aqueous phases respectively. For the reference electrodes, RE1 and RE2, used here, ΔE_{ref} in Eq. 4 is given by:

$$\Delta E_{ref} = -\Delta\phi_L + E_{Ag/AgCl/0.1\ mol\ dm^{-3}\ LiCl(W)} - E_{Ag/AgCl/0.1 mol\ dm^{-3}\ TBACl(W)}, \quad (6)$$

where $\Delta\phi_L(=\phi^w_I-\phi^N_{II})$ is the potential difference between a 0.1 mol dm^{-3} TBACl aqueous solution(I) and a 0.1 mol dm^{-3} TBATPB nitrobenzene solution(II). Since $\Delta^w_N\phi^\ominus_{TPB}$ is extremely positive compared with $\Delta^w_N\phi^\ominus_{TBA}$, while $\Delta^w_N\phi^\ominus_{Cl}$ is extremely negative compared with $\Delta^w_N\phi^\ominus_{TBA}$, $\Delta\phi_L$ is given in a good approximation by:[10,12]

$$\Delta\phi_L = \Delta^w_N\phi^\ominus_{TBA} + (RT/F)\ln(\gamma^N_{TBA}C^N_{TBA}/\gamma^w_{TBA}C^w_{TBA}), \quad (7)$$

where γ^α_{TBA} and C^α_{TBA} (α=N and W) are the activity coefficient and the concentration of the TBA^+ ion respectively in the nitrobenzene(N) and aqueous(W) phases. The validity of Eq. 7 for the interface between the 0.1 mol dm^{-3} TBACl aqueous solution and the 0.1 mol dm^{-3} TBATPB nitrobenzene solution was proved by measuring the electromotive force, E_{emf}, of the following cell:

$$\begin{array}{l} \overset{I}{Ag|AgCl|0.1\ mol\ dm^{-3}TBACl(W)} \\ \overset{II}{|0.1\ mol\ dm^{-3}\ TBATPB(N)|} \\ \left|\begin{array}{c} \overset{III}{x\ mol\ dm^{-3}\ TBACl} \\ (0.1-x) mol\ dm^{-3}\ LiCl \end{array}\right. (W) \left| AgCl \right| Ag \end{array} \quad (B)$$

for 0.02 mol dm^{-3} $\leq x\leq$ 0.1 mol dm^{-3}; E_{emf} depended linearly on $\ln(C^{III}_{TBA}/C^{I}_{TBA})$, with a slope of 26 mV ($=RT/F$).[10] Upon assuming that $E_{Ag/AgCl/0.1\ mol\ dm^{-3}\ LiCl(W)} - E_{Ag/AgCl/0.1\ mol\ dm^{-3}\ TBACl(W)} \approx 0$, we obtain:

$$\begin{aligned} E^r_{1/2,TBA} &= \Delta^w_N\phi^\ominus_{TMA} + (RT/F)\ln(\gamma^N_{TMA}\sqrt{D^w_{TMA}}/\gamma^w_{TMA}\sqrt{D^N_{TMA}}) \\ &\quad - \Delta^w_N\phi^\ominus_{TBA} - (RT/F)\ln(\gamma^N_{TBA}C^N_{TBA}/\gamma^w_{TBA}C^w_{TBA}) \quad (8) \\ &\approx \Delta^w_N\phi^\ominus_{TMA} - \Delta^w_N\phi^\ominus_{TBA} + (RT/F)\ln(\sqrt{D^w_{TMA}}/\sqrt{D^N_{TMA}}) \end{aligned}$$

since $C^N_{TBA}=C^w_{TBA}=0.1$ mol dm^{-3}, and $\ln(\gamma^N_{TMA}\gamma^w_{TBA}/\gamma^w_{TMA}\gamma^N_{TBA})\approx 0$. The standard ion-transfer potentials of the TMA^+ and TBA^+ ions, as estimated from the ionic distribution coefficient data, are given[13] as $\Delta^w_N\phi^\ominus_{TMA} - \Delta^w_N\phi^\ominus_{TBA} = 0.283$ V, which is 40 mV more negative than

the present result of $E^{\circ}_{1/2,\mathrm{TMA}}=0.32$ V. This difference cannot be explained by the $(RT/F)\ln(\sqrt{D}^{\mathrm{W}}_{\mathrm{TMA}}/\sqrt{D}^{\mathrm{N}}_{\mathrm{TMA}})$ terms. It seems premature to discuss the origin of this discrepancy.

The potential-step chronoamperometry appears a promising technique for the investigation of the charge-transfer processes at the interface between two immiscible electrolyte solutions.

The adsorption behavior of poly(L-lysine) and poly(L-glutamic acid) on negatively and positively charged latices was examined in combination with their stabilizing effects on the latex dispersion. It was realized that the polypeptide adsorption was, to a large extent, determined by the coulombic interaction between the polypeptide and the charged surface, and by the conformational change (helix-coil transition) in the polypeptide in the solution. The flocculation behavior of the dispersion in the presence of polypeptide was also explained reasonably by taking account of the results of electrophoretic measurements of the polypeptide-coated particles.

The stability of a colloid dispersion can be widely modified by adding polymer molecules. Especially, a partially ionic polymer is important as a flocculant in various practical fields.[1] As for the mechanism of destabilization to the dispersion by a polymer, two principal ideas have been proposed. One is the bridging effect,[2] which is built up between the particles containing an adsorbed polymer layer. Under this mechanism, loops and tails in the adsorption layer play an important role. Another mechanism is based on the charge neutralization of the particles by the adsorption of oppositely charged polyelectrolytes.[3] The problem is that these two mechanisms for destabilization are not independent; rather, the colloid stability is practically determined by the combined action of these two effects.[4]

Poly(L-lysine)(PLL) and poly(L-glutamic acid)(PLG) are typical cationic and anionic polypeptides, and the study of molecular conformation, *i.e.*, the helix-coil transition in solution, has been examined extensively. According to Chou *et al.*,[5] the helix-coil transition of PLL is brought about by the change in pH from around pH 11, where the polymer is helix, to pH$<$8, where the helix content is zero and where all the molecules take an extended form. On the other hand, the PLG takes the helical conformation in the pH$<\approx$5.5 range and is changed to a random or a stretched structure in the pH$>$6 range.

In this work, PLL and PLG were used as adsorbates and the adsorption behavior was examined by combining their flocculation effects on the latex dispersion. As the colloidal dispersion, several polystyrene latices of different polarities were used to suppress the effects of electrostatic interaction. The main object in this work is to clarify the following problems:

a) What is the principal mechanism of destabilization (or stabilization) in the present system?

b) How does the helix-coil transition influence the adsorption phenomena?

c) How does the destabilization (or stabilization) appear in the different conformations of the polymers?

Working with well-defined latices of different characters as adsorbents will assist in gaining a better understanding of these ends.

Experimental

Materials. To emphasize the polarity of the substrate, three kinds of polystyrene latices were employed. Latex-A was prepared by the usual Kotera-Furusawa-Takeda method.[6] Latex-B was made by incorporating a small amount of an ionic comonomer, sodium *p*-vinylbenzeulsulfonate, into a polystyrene chain according to Juang *et al.*[7] The charge density of Latex-B is much higher than that of Latex-A. Latex-C consists of amphoteric lat prepared by the method described by Homola *et al.*[8] The characterization data for these samples are shown in Table 1. All the latices were prepared by the use of an emulsifier-free system to reduce the spurious effects of surface-active substance. Also, the use of buffers has been avoided in order to obtain a clean system.

Table 1. Characterization data of polystyrene lattices

Sample	Diameter (2a) / A	Surface charge σ_0 / $\mu C\ cm^{-2}$	ζ-Potential/mV (25 °C, 10^{-3} M KCl) pH 4.5	pH 10
Later-A	5260	3.1	−39	−42
Latex-B	1600	9.0	−67	−70
Latex-C	1950	—	+38	−17

The hydrobromide of PLL was purchased from the Sigma Chemical Co. Ltd. (U. S. A.) and had the reported molecular weights of 4000, 32500, and 57500 respectively. The hydrobromide form was converted to the hydrochloride form by dissolving the PLL in distilled water and by dialyzing them exhaustively against 0.01 M HCl (1 M=1 mol dm^{-3}) and then against distilled water to remove the excess chloride ions.

The sodium salt of PLG was obtained from the Ajinomoto Co., Ltd. (Yokohama, Japan); the molecular weight was determined by the supplier to be 42000 from viscosity measurements.

The other reagents were commercially available and of an analytical grade. All the solutions of these materials were made with deionized and distilled water, using an all-Pyrex apparatus.

Electrophoresis. The electrophoretic mobilities of the bare latex particles were determined at various pH values in an aqueous solution of 1×10^{-3} M KCl at 25 °C. The measurements were performed in a Rank Brothers Microelectrophoresis apparatus (MK-2) using a rectangular glass cell. The ζ-potential was derived following the method of Wiersema *et al.*[9] Polymer-coated particles for electrophoretic measurements were prepared as follows: A dilute latex suspension (*ca.* 0.01 wt%) controlled at a definite pH in 10^{-3} M KCl was mixed immediately with an equal volume of the polypeptide solution (C_p=0.2 mg/dm^{-6}) which gave enough plateau adsorption. After the mixture had been left standing for 2 h at room temperature, the electrophoretic mobilities of the polymer-coated particles were determined by using the same technique with bare particles. The results for Latex-A

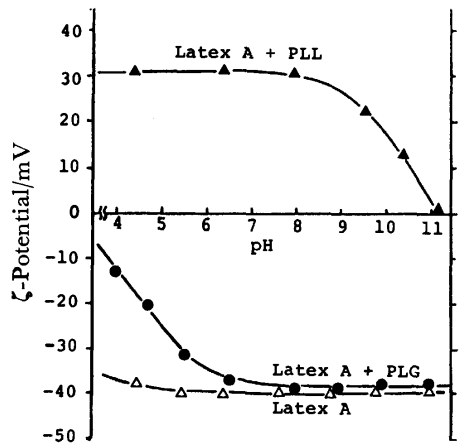

Fig. 1. ζ-Potentials of Latex-A (—△—), PLL-covered Latex-A(—▲—), and PLG-covered Latex-A(—●—) (M_{PLL}=57500, M_{PLG}=42000, 10^{-3} M KCl, 25 °C).

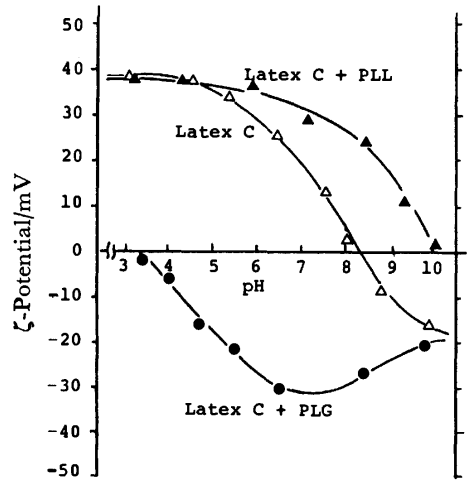

Fig. 2. ζ-Potentials of Latex-C (—△—), PLL-covered Latex-C (—▲—), and PLG-covered Latex-C (—●—) (M_{PLL}=57500, M_{PLG}=42000, 10^{-3} M KCl, 25 °C).

and -C covered by PLL and PLG are shown in Figs. 1 and 2 respectively, along with the data for the respective bare particles.

Adsorption Experiments. In glass-stoppered vials (5 ml), 2 ml of a latex suspension was added to 2 ml of the polypeptide solution. Prior to mixing, both the solutions were brought to the same pH and KCl concentration without using any buffers. The vials were rotated end-over-end for 5 h. The suspension was then centrifuged for 30 min at 25000 g. The concentration of polypeptide in the supernatant as well as in the initial solution was determined by analytical methods, *i.e.*, by the Ninhydrin method for L-lysine and PLL and by the Microbiuret method for PLG. From the difference in the concentrations before and after the adsorption process, the amounts of adsorption per unit of surface area (A_p) was calculated. All the measurements were made at a constant temperature of 25 °C.

Flocculation Experiments. In the flocculation experiments using polyelectrolyte as a flocculant, careful attention must be paid to the method of mixing the polymer solution and the colloid dispersion, because the adsorption of polyelectrolyte on a charged surface is usually very rapid and irreversible.[10] Here, the mixing was performed as follows: Five-ml portions of KCl solutions of various concentrations were added carefully on top of a latex suspension (C_{solid}=0.4 wt%, 2 ml) in such a way that a sharp boundary between the dispersion and the salt solution was formed. Thereafter, on top of these, 2-ml portions of polymer solutions of different contents were added using a pipet. After rotating end-over-end ($10\ min^{-1}$) for 2 h, the system was left to stand for 20 h in order to allow the flocculated particles to settle out. Then, the extinction of supernatant was measured using a Jasco Digital Spectrophotometer (Uvidec-410) at a wavelength of 550 nm. The critical flocculation concentration (CFC) was defined as the salt concentration at which the absorbance of the supernatant was reduced to 50% of the original. The ionic strength was varied using KCl, while all the experiments were carried out at a constant temperature of 25 °C.

Direct Observation of Flocculating States. The flocculating states of latex particles were examined visually by means of a direct-observation technique.[11] The optical microscope used was a lateral-type metallurgical microscope with a magnification of 1500, Type-Mg, Olympus Optical Co., Ltd. (Tokyo, Japan). Some amounts of the latex sample prepared by the same procedure as were used in the flocculation experiments were charged into the observation cell, made of a Pyrex glass tube, 100 mm high and 15 mm in diameter, with a thin glass window at its lower end. The sample was observed through the window by means of the oil-immersion method.

Results and Discussion

Adsorption Behavior. Figure 3 shows the adsorption isotherms of L-lysine on Latex-A, -B, and -C at different pH values in a 10^{-3} M KCl solution. In all the systems, the isotherms have low affinities, with small plateaus. In the acidic medium, Latex-A and -B have electrical signs opposite that of the adsorbate, but Latex-C has the same sign. As may be seen in the figure, the experimental results show the same behavior as would be anticipated from the estimation of the elec-

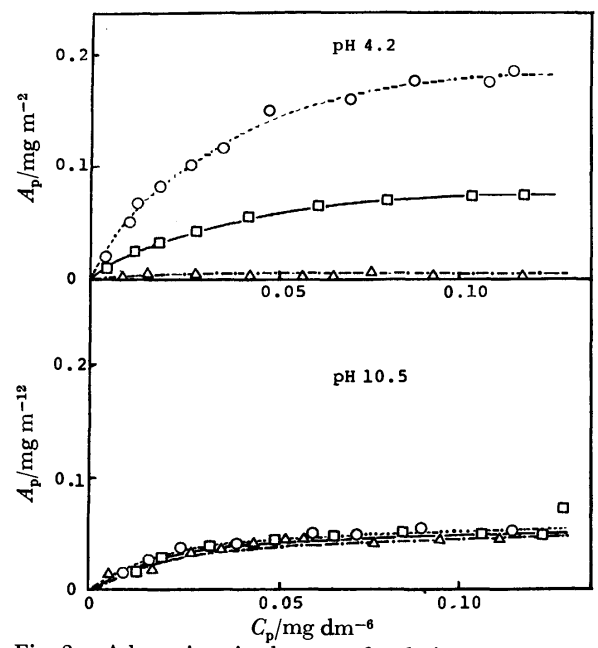

Fig. 3. Adsorption isotherms of L-lysine on Latex-A (—□—), Latex-B (—○—), and Latex-C (—△—) (10^{-3} M KCl, 25 °C).

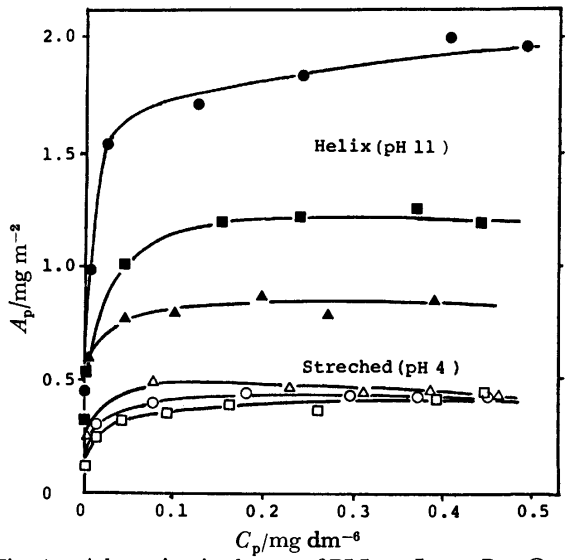

Fig. 4. Adsorption isotherms of PLL on Latex-B. Open symbols; pH 4, filled symbols; pH 11, —○—; M_{PLL}= 57500, —□—; M_{PLL}=32500, —△—; M_{PLL}=4000 (10^{-3} M KCl, 25 °C).

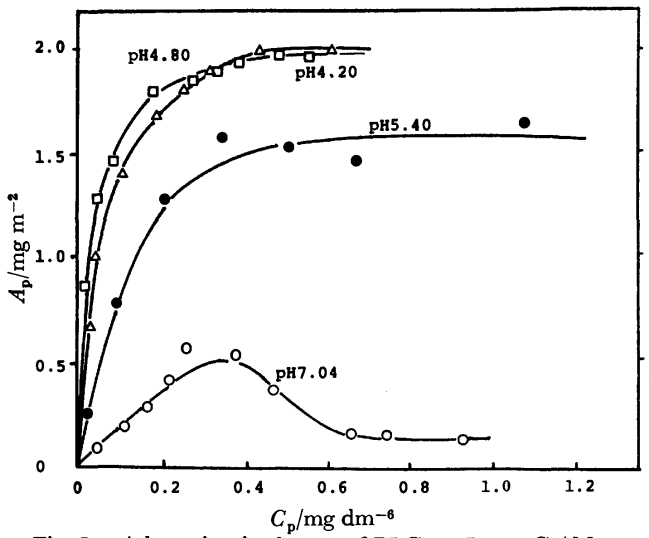

Fig. 5. Adsorption isotherms of PLG on Latex-C (M_{PLG} =42000, 10^{-3} M KCl 25 °C).

trostatic interaction: *i.e.*, Latex-C gives no adsorption, and -A and -B, 0.06_8 mg/m^2 and 0.18 mg/m^2 respectively, values which accord with the calculated values (0.06_4 mg/m^2, 0.18_6 mg/m^2), assuming an equimolar reaction between $-OSO_3^-$ on the latex surface and NH_3^+ in the peptide. In the basic condition (pH 10.5), however, all the latices have a nearly constant plateau (*ca.* 0.05 mg/m^2) which would seem to be based on the deionization of the lysine molecule in the alkaline solution.

As may be seen in Fig. 4, the adsorption isotherms of PLL have a high affinity, with a well-defined plateau. In the acidic solution, the plateau is independent of the molecular weight, which indicates the adsorption in a flat conformation, *i.e.*, with trains only. According to a theoretical study of the molecular model of polypeptide,[12] it may be possible for PLL to take two kinds of conformation in extreme cases: *i.e.*, A fully extended

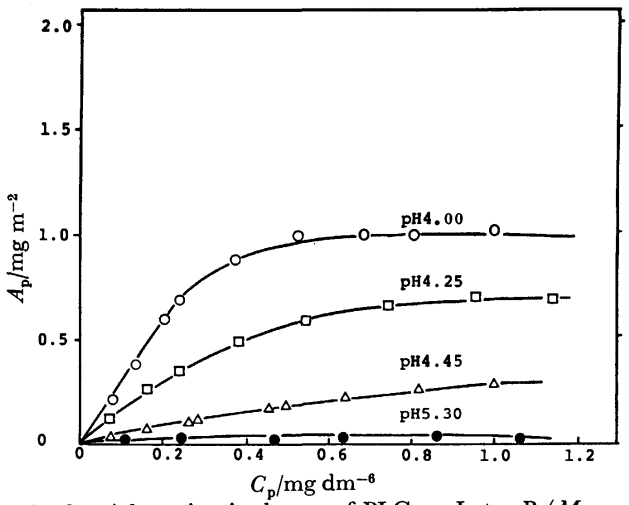

Fig. 6. Adsorption isotherms of PLG on Latex-B (M_{PLG} =42000, 10^{-3} M KCl 25 °C).

conformation, and a compact one. Using these molecular dimensions, the maximum monolayer coverages for these two configurations would amount to 0.41 mg/m^2 and 0.61 mg/m^2 respectively. The plateau value (0.48 mg/m^2) obtained by the present experiments in the acidic medium suggests that PLL molecules would be adsorbed by an intermediate form of these extreme conformations. According to the electrophoretic measurements of the PLL-coated particles (which can be estimated from Fig. 1 for Latex-A), a charge reversal of the original latex particles has occurred at the saturated PLL adsorption (the same result has been reported by Corry[13]). It is indicated that a more positive charge due to PLL than the negative charge on the latices is accumulated on the surface. Though such a superequivalent adsorption, which indicates that the chain effect of the adsorbed polymer overcomes the electrostatic instability, has been observed frequently in polyelectrolyte-colloid systems, the occurrence in the present PLL adsorption with trains only is very interesting as showing a new singularity of polymer adsorption.

The PLL adsorption in the basic medium, however, shows a specific nature. According to the double-layer capacitance measurements on charged silver iodide surfaces in the presence of various oligo- and polypeptide molecules, the helical form in the solution of PLL persists in the adsorbed state.[12] Therefore, the increased plateau values at pH 11 in Fig. 4 may be recognized to be based on the stiff structure of the helical conformation of PLL. When stiff rods of a helical form adsorb on a solid surface, they can either lie flat on the surface or stand on end. The resulting molecular-weight dependence of the plateau adsorption, as may be seen in Fig. 4, suggests that they are adsorbed vertically on the ends of the rods. This is surprising: A detailed analysis of this point will be discussed in the next paper of this series.

Figures 5 and 6 show examples of the adsorption isotherm of PLG on Latex-B and -C. In Fig. 5, in which adsorbate and adsorbent have opposite electric charges at pH values lower than 8.5, the isotherms again exhibit

a high plateau with a steep initial slope, but, as a special feature, an additional reduction of A_p is found at pH 7.04. This reduction is probably due to a partial flocculation of the latex particles: *i.e.*, Under these conditions, the latex particles used as adsorbates become unstable and lose their apparent adsorbable areas. In contradistinction to Fig. 5, the isotherms of Fig. 6 (PLG–Latex-B system) are of a low-affinity type, and the plateaus are much influenced by the pH value. Such behavior may be explained as a consequence of coulombic interaction and the helix-coil transition of PLG. The importance of the coulombic interaction and the helix-coil transition in the polypeptide adsorption can be illustrated by plotting the plateau adsorption (A_{pm}) as a function of the pH value in the medium. Figure 7 shows the A_{pm}(pH) curves for four systems, *i.e.*, PLL–Latex-B, PLL–Latex-C, PLG–Latex-B, and PLG–Latex-C. We can realize that the A_{pm}(pH) curves for PLL–Latex-B and PLG–Latex-C are related symmetrically to the vertical line at pH 7.5. The same trend is also found in the A_{pm}(pH) curves for PLL–Latex-C and PLG–Latex-B. These two trends show that A_{pm} is, to a large extent, determined by the coulombic interaction between the polypeptide and the charged surface. Especially, the first trend indicates that the helical structures of both the polypeptides exert the same influence on the adsorption behavior under the relevant conditions.

Flocculation Behavior. The stability of polymer-coated particles and the conformation of the adsorbed polymer are closely related. By this sense, the study of the stability of polymer-coated particles is instructive with regard to the conformation of the adsorbed polymer. In Fig. 8, the dependence of the critical flocculation concentration (CFC) on the PLL dosage is given for two medium conditions, *i.e.*, the streched-induced conditions (pH 4) and the helix-induced conditions (pH 11). In pH 4, a sharp decrease in the CFC is observed, after which the CFC increases slowly again. Thereafter, the CFC is kept at a constant value (*ca.* 200 mmol/dm^3 of KCl), which is rather lower than

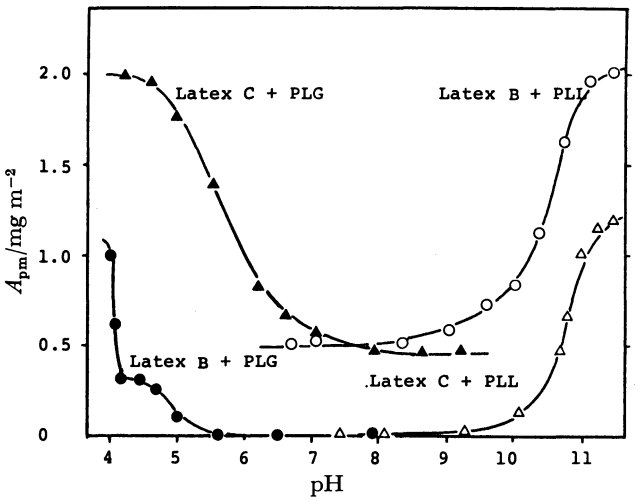

Fig. 7. Relation between the plateau adsorption (A_{pm}) and the medium pH (M_{PLL}=57500, M_{PLG}=42000, 10^{-3} M KCl, 25 °C).

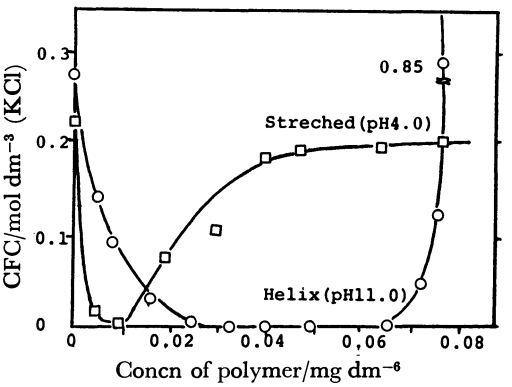

Fig. 8. Dependence of the CFC on the polymer concentration (Polymer; M_{PLL}=57500, Colloid; Latex-B, 25 °C).

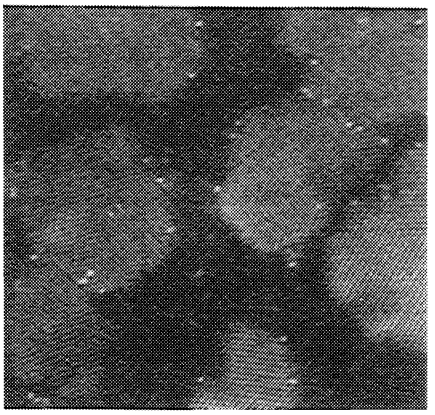

Fig. 9. Microphotograph showing latex aggregates with ordered structure (Polymer; M_{PLL}=57500, Colloid; Latex-A).

the CFC for the bare particles of Latex-B. It is indicative that at pH 4, the adsorption layer of PLL does not confer any steric stabilization on the particles, but brings about the charge reversal in the diffuse double-layer which is shown in Fig. 1. Furthermore, it is known that the narrow flocculation range seen in Fig. 8 does not correspond to the polymer concentration for making an effective interparticle bridging, but does correspond to the charge neutralization performed by the adsorption of PLL with the opposite electrical charge. On the other hand, the CFC in the helix-induced pH stays at a low value for a long period after decreasing slowly from the CFC of bare particles. This phenomena seems to be due to the adsorption of uncharged helix molecules, while the broad range of polymer dosage for flocculation corresponds to the high capacity of polymer adsorption under those conditions (see Fig. 4). Also, the appearance of strong stabilization in the high-polymer dosage may be explained as a result of the thicker adsorption layer. The helical rods of PLL are adsorbed vertically on the latex surface, and their denser (and thicker) adsorption layer throughly resist direct contact with the latex particles.

Formation of Aggregates With an Ordered Structure. Usual latex sediments appear milky white and clusters with an irregular structure are visible under an optical

microscope. Under some conditions, however, especially in concentrated PLL solutions, some latex sediment with a brilliant iridescence is formed. It has been shown that such latex sediments are built up by the large aggregates with an ordered structure.[14] As may be seen in Fig. 9, the particles in the aggregates are arranged in a hexagonal array and seem to be in face-to-face contact. On the formation of such aggregates in the PLL–Latex-A system, the following special features are found:

a) Ordered aggregates are formed only at pH values lower than 8, which are the stretched or random coil-induced conditions for the PLL.

b) In a 10^{-3} M KCl solution, the aggregates were formed in the concentration range of PLL from 0.1—0.6 mg/dm^{-6}. In order to produce the same aggregates in the more concentrated solution of KCl, we must prepare the aggregates in more concentrated PLL solutions.

c) The ordered aggregates were also observed in the system of PLG–Latex-C. In this combination, however, the aggregating capacity was very limitted.

Though, from these results, only a very little can be said about the mechanism of this phenomena, the appearance of such characteristic aggregates suggests that some attractive interaction (perhaps some bridging attraction) is working between the particles covered by the flat adsorption layer of polypeptide.

The authors wish to thank Professor J. Lyklema, Agricultural University, Wageningen, The Netherlands, for his advice and cooperation.

Prediction of Adsorbability of Organic Compounds from Aqueous Solution on Activated Carbon by Means of the Linear Free-energy Relationship

Ikuo ABE,* Katsumi HAYASHI, Mutsuo KITAGAWA,† and Tsuneaki HIRASHIMA
Osaka Municipal Technical Research Institute, Morinomiya, Joto-ku, Osaka 536
†*Society for Activated Carbon Research, Morinomiya, Joto-ku, Osaka 536*
(Received August 16, 1982)

A method is presented for predicting the adsorbability of a wide variety of organic compounds from aqueous solution onto an activated carbon. The method, which is based on the linear free-energy relationship, requires only the solute's molecular refraction and the number of hydrophilic functional groups. The molecular refraction represents the free energy contribution by the solute-adsorbent interaction and the number of hydrophilic functional groups represents that by the solute-solvent interaction.

The ability to predict the adsorbability for a given adsorbent from a knowledge of the physical properties of the adsorbate is an important objective in adsorbent-adsorbate interaction research. In our preceding papers,[1-5] the methods for prediction of the adsorption isotherms of organic compounds from aqueous solution onto activated carbons were discussed. The adsorption isotherms of aliphatic monofunctional compounds,[3] amino acids,[4] and saccharides[5] could be predicted from the molecular refraction alone. The prediction method was applicable to activated carbons with different adsorptive capacities. Manes *et al.* applied the Polanyi adsorption potential theory to adsorption from solution onto activated carbon.[6-8] The Polanyi methods of predicting adsorption isotherms requires the solute's solubility, refractive index, and molar volume. McGuire and Suffet, using the separable formalism of the partial solubility parameters, defined a net adsorption energy for the adsorption of solute from a dilute solution onto adsorbent.[9] The method requires the solute's solubility parameter and molar volume.

Here we describe a method using the linear free-energy relationships which are widely used as tools for investigating chemical similarity.[10]

Experimental

The adsorbent used (Pittsburgh Activated Carbon Co., grade CAL activated carbon) and the experimental techniques were the same as described in a previous paper.[11] All of the adsorbates came from commercial sources (stated minimum assay 99%) and were used without further purification.

Results and Discussion

The adsorption equilibria of 57 organic compounds from aqueous solution onto CAL activated carbon at 25 °C were measured. Table 1 shows the amount adsorbed, k(mg/g), at very low equilibrium concentration, 1 mg/l, including data for 45 compounds from the literatures.

By assuming that the adsorbed molecules behave ideally at the low concentration, the Gibbs free energy change for the adsorption process, ΔG, is calculated experimentally by the following equation:

$$\Delta G = -RT\ln(k/V), \quad (1)$$

where V is the volume of adsorption phase (pore volume).[11-13] This equation indicates that the value

of log k may represent the adsorbability associated with the free energy change.

In the linear free-energy relationship models, the logarithm of activity is expressed as a linear function of physicochemical parameters. The method is based on multiple linear regression analysis. The expression for the free energy change of the adsorption process may be given by the following equation:

$$\Delta G = \Delta G_{js} - \Delta G_{ls} - \Delta G_{jl}, \quad (2)$$

where ΔG is the net free energy change, ΔG_{js} is that associated with the solute-adsorbent interaction, ΔG_{is} the solvent-adsorbent interaction, ΔG_{ji} the solute-solvent interaction, and the subscripts i, j, and s refer to solvent, solute, and adsorbent, respectively. In the case of the adsorption from water, ΔG_{is} is identical for each adsorbate and consequently the following relation may be derived:

$$\Delta G = \Delta G_{js} - \Delta G_{ji} - \text{const.} \quad (3)$$

Each of these terms can be estimated with a knowledge of the physicochemical properties of each species. The ΔG_{js} term is mainly affected by the hydrophobic effect because the surface of activated carbon is hydrophobic. The driving force for the adsorption by hydrophobic effect is the dispersion component of the Van der Waals forces. This adsorptive interaction is strongly dependent on the polarizability of the solute. Since the polarizability of a molecule is proportional to the molecular refraction (Mr), ΔG_{js} can be expressed in terms of molecular refraction. Assuming that the ΔG_{ji} term is identical for each adsorbate, the following equation may be derived:

$$\log k = A_1 Mr + A_0, \quad (4)$$

where A_1 and A_0 are constant. Figure 1 shows a plot of log k *vs.* Mr for 102 organic compounds. A good linear relationship was obtained within each family of compounds with the same number of hydrophilic functional groups (Nf). The correlation coefficient(r) for compounds **1**—**42** with $Nf=1$ was 0.926, $r=0.938$ for compounds **43**—**50** with $Nf=2$, and $r=0.975$ for compounds **51**—**58** with $Nf=3$. The adsorbability of aliphatic compounds decreased with an increase in the number of hydrophilic functional groups in a solute molecule. This indicates that the ΔG_{ji} term in Eq. 3 affects the adsorbability.

The free energy change for the solution process was calculated by Amidon *et al.*.[14] The molecular surface area for 158 aliphatic hydrocarbons, olefins, alcohols, ethers, ketones, aldehydes, esters, and fatty acids were computed and correlated with the aqueous solubilities. The expression was:

$$\log S = \theta_1 \cdot TSA + \theta_2 \cdot IFG + \theta_0, \quad (5)$$

where S is the aqueous solubility, TSA is the total surface area, and IFG is the functional group index (zero for hydrocarbons and unity for a monofunctional compound). From the coefficients for the IFG term, the free energy contribution of functional group to the solution process (ΔG_{sol}) may be calculated. The values of ΔG_{sol} for each functional group are −4090——4310 cal/mol. This suggests that for the functional groups (–OH, –O–, >C=O, –CHO, –COO–, and –COOH) the free energy contributions per one functional group to the ΔG_{ji} term is nearly equal. Therefore, the ΔG_{ji} term may be related to the number of the functional group regardless of the kind. Thus:

$$\log k = A_1 Mr + A_2 Nf + A_0, \quad (6)$$

where A_1, A_2, and A_0 are constant. The data of compounds **1**—**78** were given to a NEC PC-8001 computer to determine the A_1, A_2, and A_0 values by means of multiple regression analysis. The regression equation is:

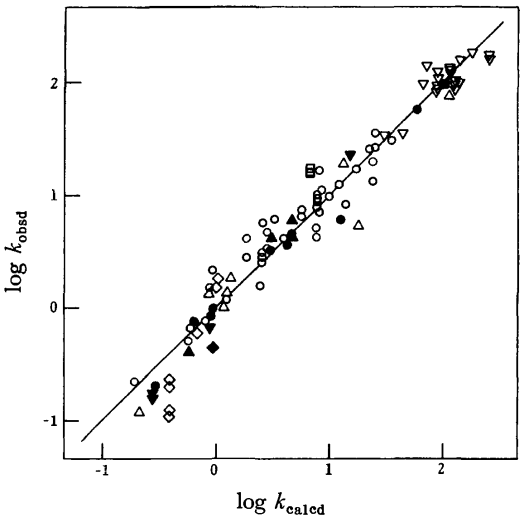

Fig. 2. Relationship between log k observed and log k calculated using Eq. 9.

$$\log k = 0.1089\, Mr - 0.4919\, Nf - 1.520. \quad (7)$$

The correlation coefficient r was 0.9355, the standard deviation s was 0.2596, the F-value representing the over-all goodness of fit was 262.7, and the t-values in the Student test were 22.87*** (for 0.1089) and −21.17*** (for −0.4919). The asterisk, ***, represents that the significant level of the regression coefficient is 0.1%. The results of statistical test indicate that Eq. 7 is statistically significant.

It can be seen from Fig. 1 and Table 1 that the adsorbability of aromatic compounds is higher than the other compounds in spite of the presence of hydrophilic functional groups in a molecule. The phenomena can be explained by the electronic effects and the resonance effects. The solubility of aliphatic compounds increases markedly with an increase in the number of hydrophilic functional groups in a molecule, while the solubility of aromatic compounds does not appreciably increase because of the resonance effects. This suggests that the ΔG_{ji} term can not be related to Nf for aromatics. The high adsorbability of aromatics can be accounted for by the strong interaction with π-electrons in the graphitic structure of an activated carbon. Therefore, ΔG for aromatics must be distinguished from that for aliphatics. Equation 6 has been changed to the following equation:

$$\log k = A_1 \cdot Mr + A_2 \cdot D \cdot Nf + A_0, \quad (8)$$

where D is the dummy variable being zero for aromatics and unity for aliphatics. From the data of 102 compounds in Table 1, a statistical analysis yields the following results:

$$\log k = 0.1044\, Mr - 0.4694 D \cdot Nf - 1.450 \quad (9)$$

($r=0.9642$, $s=0.2409$, $F=654.4$, $t(0.1044)=33.85$***, $t(-0.4694) = -34.29$***).

Figure 2 shows the relationship between log k observed and log k calculated using Eq. 9. These results indicate that the adsorbability of many compounds can be predicted from the molecular refraction and the number of hydrophilic functional group. Since the physical constants Mr and Nf can be easily obtained, the above

method for predicting adsorbability is simpler and more accurate than the other methods.

The Absorption Spectra of Monolayers of Fluorescent Probes and the Orientations of Their Chromophores

Kazunori MATSUKI* and Hideo FUKUTOME
Department of Physics, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606
(Received August 16, 1982)

The UV absorption spectra of monolayers of 12-(9-anthrylcarbonyloxy)octadecanoic acid (12-AS), 2-(9-anthrylcarbonyloxy)hexadecanoic acid (2-AP), and 2-octadecylamino-6-naphthalenesulfonic acid (ONS) were measured at normal incidence and the polarized spectra at 45° incidence. New peaks which were absent in the spectra of their solutions were observed in the polarized spectra at 45° incidence. The orientation of their chromophores in the monolayers were investigated by means of the dichroic ratios obtained from their polarized spectra. These monolayers were found to consist of H-aggregates where chromophores are oriented nearly perpendicularly to the monolayer plane and molecules in a monomer-like state where the chromophores are rather randomly oriented. The molecular axes of 12-AS, 2-AP, and ONS were found to be oriented uniaxially against the normals of their monolayer planes in the ranges 0—7°, 0—21°, and 0—34°, respectively.

Fluorescent probes have been widely used to study the behavior of lipids and proteins in natural and model membranes.[1] Cadenhead *et al.* showed that 12-(9-anthrylcarbonyloxy)octadecanoic acid (12-AS), 2-(9-anthrylcarbonyloxy)hexadecanoic acid (2-AP), and 2-octadecylamino-6-naphthalenesulfonic acid (ONS) form stable and condensed monolayers at the air-water interface.[2,3] Their chromophores will probably interact strongly in these monolayers. Therefore, their monolayer spectra are expected to differ remarkably from their solution spectra. The absorption spectra of these monolayers, however, have not been measured yet and information about the orientation of their chromophores in the monolayers is lacking although Teissie *et al.* studied the fluorescence of 12-AS monolayers.[4]

In this paper the polarized absorption spectra of monolayers of 12-AS, 2-AP, and ONS were measured in order to get information about the interactions and the orientations of their chromophores in monolayers.

Experimental

Materials. 12-AS, mp 79 °C (lit, 78.5 °C[2]) and crystalline dipalmitoyl-L-α-phosphatidylcholine (DPPC) were purchased from Sigma Chemicals Co., stearic acid (standard for elementary analysis) from Merck Co., and 2-AP, mp 96 °C (lit, 91—92 °C[2] and 94 °C[5]) from Molecular Probe Inc. ONS (Nakarai, S.P.-grade) was recrystallized from chloroform–methanol (2 : 1, v/v).[6] The purity of ONS was checked by TLC on precoated plates (Merck, Kieselgel 60 F_{254}) in chloroform–methanol (1 : 1, v/v). It revealed a single spot both under UV light to visualize fluorescent species and in iodine vapor to check nonfluorescent contaminants. All the above chemicals, except stearic acid, were stored in the dark about −20 °C in a desiccator. Hexane, ethanol, methanol, and chloroform were spectroscopic grade (Nakarai). Dichloroacetic acid (Nakarai, E.P.-grade) was distilled under vacuum. These chemicals were used without further purification unless otherwise stated. Twice-distilled water (pH=5.0—5.5) was used in all the experiments. Optically flat quartz plates (50×24×0.8 mm³) were obtained from Kōno Seisakusho (Kyoto).

Methods. The UV absorption spectra of 12-AS, 2-AP, and ONS in organic solvents were recorded on a UV-180 spectrophotometer (Shimadzu Co.). The absorption spectra of their monolayers were measured with a high-sensitivity spectrophotometer using the single-beam and sample in-sample out technique.[7] It was constructed in our laboratory.[8]

In the measurements of the polarized absorption spectra at 45° incidence, a polarizer (a Glan-Thomson prism made of calcite) was set before the plate in such a manner as to make the plane of polarization parallel to the plane of incidence (p-spectrum) or perpendicular to it (s-spectrum).[7]

The Blodgett method[9] was used for preparing spectroscopic samples of monolayers. A monolayer was spread on twice-distilled water at 23±1 °C by dropping a solution(5—10 mg/10 cm³). Spreading solvents were hexane–ethanol (10 : 1, molar ratio)[2] for 12-AS and 2-AP, and chloroform–dichloroacetic acid (9.6 : 0.4, v/v)[3] for ONS. Surface pressure was applied to the monolayer by using oleic acid (30 mN/m), ethyl myristate (20 mN/m), or a mixture of ethyl myristate and liquid paraffin (16 mN/m)[10] as a piston oil. One monolayer was transferred on each side of the lower half of the clean quartz plate.

The details of cleaning the quartz plate were described previously.[8]

Results and Discussion

In the high-sensitivity spectrophotometer with the single-beam and sample in-sample out technique used in this study, the measured absorption includes the apparent absorption due to the difference in reflectivity between the monolayer and the plate and to the inhomogeneousness in the quartz plate as described before.[8] Since 12-AS, 2-AP, and ONS have a stearic acid-like chain, the apparent absorption of their monolayers can be canceled out by subtracting the apparent absorption of a monolayer of stearic acid. In all the spectra shown in this paper this correction for the apparent absorption was made.

The polarized absorption spectra at normal and 45° incidences were measured in order to investigate the anisotropy of the monolayers. In the case of the normal incidence, the spectra of the monolayers were examined with the plane of polarization set at the angles 0°, ±45°, and 90° against the direction of the withdrawal of the plate from the monolayer at the air-water interface. All the monolayers examined showed no significant difference in the polarized spectra at normal incidence. This indicates that no anisotropy exists in the layer plane. In the case of the 45° incidence, however,

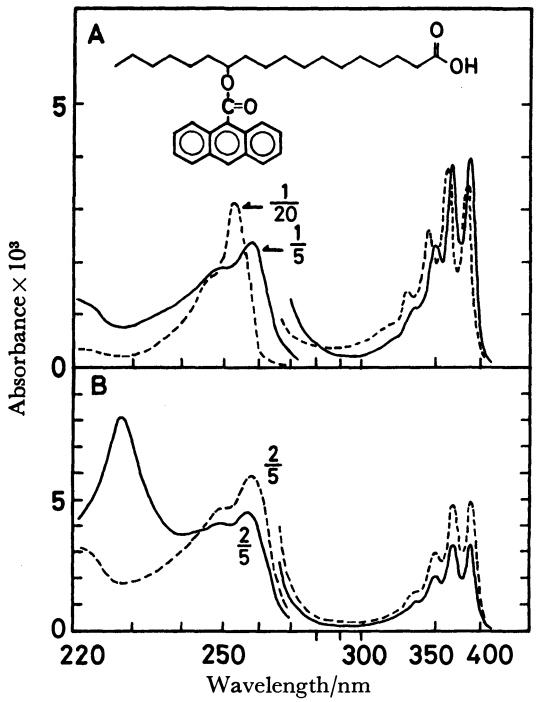

Fig. 1. Absorption spectra of the 12-AS monolayer spread on twice-distilled water and transferred to a quartz plate under the surface pressure of 16 mN/m. The correction for apparent absorptions was made as described in text.

(A) Absorption of the monolayer at normal incidence (n-spectrum) (——) and absorption in solution in an arbitrarily chosen scale (------). (B) Polarized spectra of the monolayer at 45° incidence. The plane of polarization was parallel to the plane of incidence (p-spectrum) (——) or perpendicular to it (s-spectrum) (------).

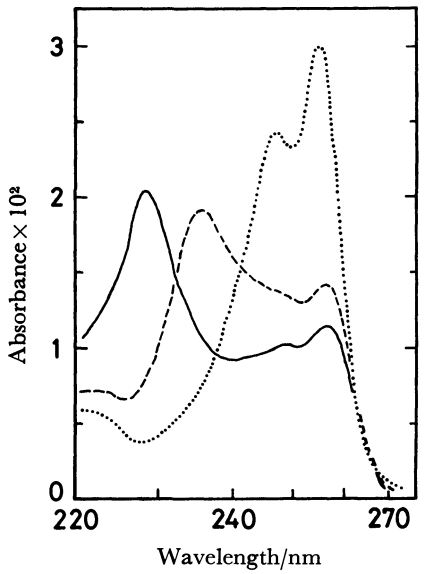

Fig. 2. P-Spectra of the monolayers of 12-AS mixed with DPPC. The monolayers were spread on twice-distilled water and transferred to a quartz plate under the surface pressure of 16 mN/m. The molar ratio of 12-AS to DPPC was 1 : 0 (——), 3 : 2 (------), or 1 : 4 (·····). The absorbances were normalized so as to give the same concentration of 12-AS per area.

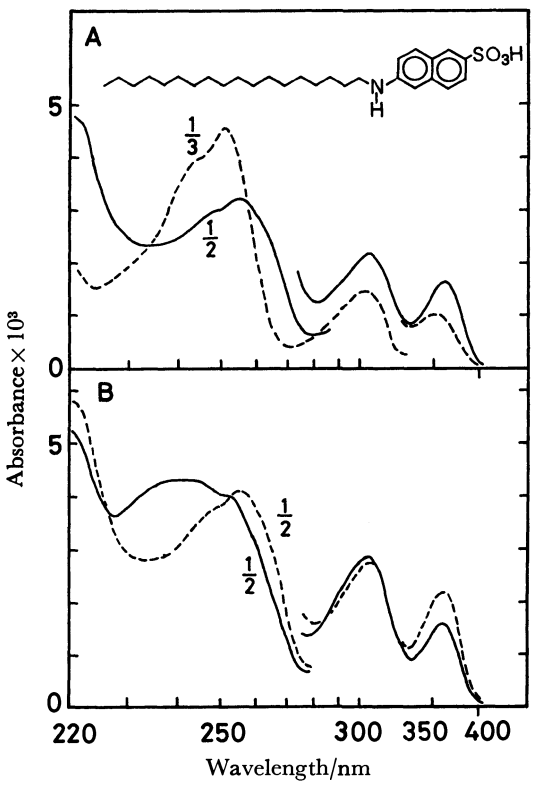

Fig. 4. Absorption spectra of the ONS monolayer spread on twice-distilled water and transferred to a quartz plate under the surface pressure of 30 mN/m. The notations are the same as those in Fig. 1.

remarkable differences between the p- and s-spectra were observed. These indicate that the molecules in all the monolayers are oriented uniaxially. The apparent

dichroic ratio, $R_{app}=A_s/A_p$, was obtained from A_s and A_p, the absorbances of the s- and p-spectra, which were corrected for the apparent absorption as has been described above. The true dichroic ratio, R, corrected for the interference effect[7] was calculated from R_{app} as described before.[8]

Figures 1 to 4 show the observed absorption spectra in solution and those of the monolayers of 12-AS, 2-AP, and ONS which are corrected for the apparent absorption. Table 1 lists the positions of the absorption peaks in the solution and monolayer spectra and the apparent and true dichroic ratios. A new band which was absent in the solution spectra and in the spectra at the normal incidence appeared in all the p-spectra at the 45° incidence. This band seems to arise from the excitonic interaction among chromophores on formation of aggregates in the monolayers as will be discussed in detail later.

The absorption spectra of 12-AS and 2-AP in hexane closely resemble that of anthracene. The longer wavelength bands with fine vibronic structures can be assigned to the ^1L_a transition and the intense bands at shorter wavelength to the ^1B_b transition.[11]

The nonpolarized spectrum at the normal incidence (n-spectrum) of the 12-AS monolayer was similar to its solution spectrum though it was slightly red-shifted (Fig. 1). This shift appears to be due to a solvatochromic effect. In the polarized spectra at the 45° incidence, a new absorption band which was absent in the solution spectra appeared at 229 nm in the p-spectrum. The s-spectrum had no peak corresponding to this new band and showed the same pattern as the n-spectrum. This shows that the transition moment of the new 229 nm band is oriented nearly perpendicularly to the layer plane. The p-spectra of the monolayers of 12-AS mixed with DPPC were measured in order to clarify the origin of the 229 nm band. As can be seen from Fig. 2, the 229 nm band was shifted toward the 257 nm band and its absorption intensity was decreased whereas the intensity of the 257 nm band was increased as 12-AS was diluted with DPPC. The band at 333—386 nm showed no significant changes, and so these spectra are not shown in Fig. 2. The marked concentration dependence of the 229 nm band in the mixed monolayer of 12-AS and DPPC shows that it is a band blue-shifted from the ^1B_b band by the excitonic interaction on formation of aggregates where the chromophores are arranged regularly. The shift of the 229 nm band seen in Fig. 2 can be explained if the size of the aggregates is decreased as 12-AS in the monolayer is diluted.[12] The direction of the transition moment of the ^1B_b band of anthracene is parallel to its long axis according to the data obtained by Inoue *et al.*[13] The p-polarization of the 229 nm band shows that the aggregates formed in the monolayer are H-aggregates.[14] In those H-aggregates, the long axes of the anthracene moieties of 12-AS are oriented parallel to each other and perpendicularly to the layer plane. This explains the blue shift of the ^1B_b band in the H-aggregates.[12]

The 257 nm band in the 12-AS monolayer has the peak position and the band shape similar to the 253 nm band in solution, so it can be obviously assigned to the ^1B_b transition. Its polarization is small as seen from the true dichroic ratio given in Table 1. Its intensity increased as the intensity of the blue-shifted band in the H-aggregates decreased upon dilution of 12-AS. These observations show that the 257 nm band corresponds to the ^1B_b transition in 12-AS molecules with a different state of the chromophores from the H-aggregates. It is most likely that the chromophores in the state are oriented rather randomly. We call this state the monomer-like state. Therefore, the 12-AS monolayer appears to consist of the H-aggregates and the molecules in the monomer-like state. Heesemann reported absorption spectra similar to those in our study in the monolayers of surface-active azo and stilben dyes.[15] The H-aggregates in the 12-AS monolayer seem to correspond to the "microdomains" termed by

Teissie *et al.*[4]

The band at 333—386 nm in the 12-AS monolayer can be assigned to the ^1L_a transition because its peak positions and vibronic structure resemble those of 12-AS in solution. The ^1L_a band of the H-aggregates seems to be almost unchanged and superposed on that of the monomer-like state because no new peaks appeared near this wavelength region. The direction of the transition moment of the ^1L_a band is parallel to the short axis of anthracene and is orthogonal to the transition moment of the ^1B_b band according to Inoue *et al.*[13] This means that the transition moment of the 333—386 nm band is nearly parallel to the monolayer plane in the H-aggregates. The absence of observable excitonic shift in this band might mean that the short axes of the anthracene moieties are not regularly arranged but randomly oriented in the H-aggregates. However, we can not eliminate the possibility of a regular arrangement of the chromophores. The excitonic spectral shift is proportional to the square of the magnitude of the transition moment in the point dipole approximation of excitonic interaction.[16] The spectral shift of the ^1B_b band in the H-aggregates is 28 nm (=257 nm−229 nm). The magnitude of the transition moment of the ^1L_a band is found to be about 1/17 of that of the ^1B_b band from their absorbances in the solution spectrum. The spectral shift of the ^1L_a band in the H-aggregates is estimated from this relative magnitude of the transition moment to be less than 0.3 nm even if the transition moments are completely parallel arranged. Such a small shift can not be detected with our spectrophotometer even if there is no solvatochromic effect. Therefore, we can not discriminate which of the two possibilities is the case that the anthracene moieties in the H-aggregates are stacked or that their short axes are randomly oriented.

The chromophores in the 12-AS monolayer are oriented uniaxially as stated above. The orientation angles of the molecules were calculated by assuming the same model as used in a previous paper.[8] Let γ be the angle between the normal of the layer plane and the principal axis of the molecule and θ be the angle between the transition moment and the principal axis of the molecule. Then, the θ and γ angles to give a fixed value of the true dichroic ratio R make a curve in the θ-γ plane.[8] We show in Fig. 5 the θ-γ curves to give the observed values of R for the absorption peaks in the 12-AS monolayer. In the band at 229 nm, R can be regarded as ≈ 0 because there is no peak corresponding to it in the s-spectrum. The θ and γ angles clearly become $\approx 0°$ in this case, and so its curve is not shown in Fig. 5. The calculation for the peak at 333 nm was not done because it seems unreliable owing to the smallness of the absorbance and the presence of an overlap of the neighboring absorption bands. The dichroic ratio of the 257 nm band belongs only to the monomer-like state. In the 348-, 366-, and 386-nm peaks, it should be noted that their dichroic ratios are the averages of those of the H-aggregates and of the monomer-like state. It is difficult to separate the spectrum of the monomer-like state from that of the H-aggregates because of the overlap of their spectra. The γ angle

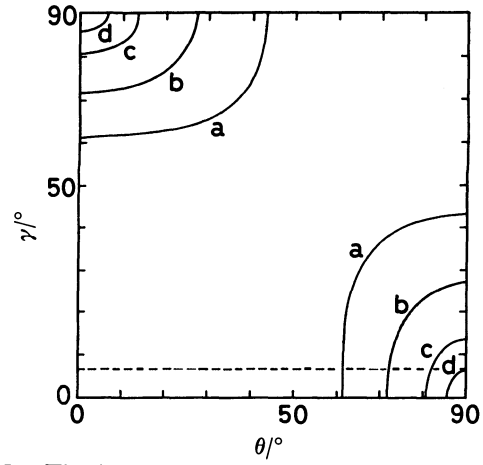

Fig. 5. The θ-γ curves to give the observed values of the true dichroic ratio R in the 12-AS monolayer. Curve a: for the 257 nm band, b: 348 nm band, c: 366 nm band, d: 386 nm band. The broken line indicates the upper limit of γ.

of the monomer-like state was then assumed to be equal to that of the H-aggregates. This means that the 12-AS monolayer is regarded as a homogeneous monolayer as long as fatty acid chains concern though it is a heterogeneous monolayer in chromophore arrangement. Then, the γ angle must have the same value for all the band. Hence, the θ's for each band are obtained from the points where each curve intersects the line of a constant value of γ in Fig. 5. The admissible ranges of γ are determined as 0—7° and 85—90° from the curve d where the permissible range of γ is the narrowest in the four curves. The range, γ=85—90°, is inadequate because it means that the alkyl chains of 12-AS molecules are almost parallel to the water surface. Therefore, we adopt the range, γ=0—7°. This is consistent with the result, $\gamma \approx 0°$, obtained from the polarization of the 229 nm band in the H-aggregates.

The admissible ranges of θ are summarized in Table 1. The ranges of θ for the vibronic peaks in the 348—386 nm band indicate that the direction of the transition moment of this band is roughly parallel to the short axis of the anthracene moiety in agreement with the ^1L_a assignment. Let us assume that the short axes of the anthracene moieties in the monomer-like state are isotropically distributed (R=1) and those in the H-aggregates are fully parallel to the layer plane. Then, the molar ratio of 12-AS molecules in the H-aggregates is estimated to be 98% from the observed R value of 1.295 for the 386 nm band. The dichroic ratio, R, of this band in the H-aggregates is assumed to be 1.299, the theoretical value for γ=0° and θ=90°. This high value of the molar ratio of the H-aggregates is unreasonable because the 257 nm band of the monomer-like state has a considerable absorption intensity. Therefore, the assumption of isotropic distribution of the short axes of the anthracene moieties in the monomer-like state is not valid and they are likely to be oriented much more parallel to the layer plane.

The admissible range of θ is 60—62° for the ^1B_b band at 257 nm. Cadenhead *et al.* suggested that the an-

thracene moiety of 12-AS is parallel to its alkyl chain at the area/molecule about 40 Å².[2] In the H-aggregates, the orientation of the anthracene moiety obtained from the polarized spectra agrees with their suggestion because $\theta \approx 0°$ for the 229 nm band. The θ angle obtained from the 257 nm band, however, indicates that the anthracene moiety fairly twists against the molecular axis in the monomer-like state. This suggests that the anthracene moiety makes an internal rotation around the –CO–C– bond when the molecules in the monomer-like state are transformed into the H-aggregates.

The n-spectrum of the 2-AP monolayer also showed a red-shift compared with its solution spectrum (Fig. 3). This shift may be ascribed to the solvatochromic effect. A new absorption band which was absent in the solution spectrum appeared at 239 nm in the p-spectrum at the 45° incidence but s-spectrum showed no peak corresponding to this band. This indicates that the transition moment of the new band is oriented nearly perpendicularly to the layer plane. The 239 nm band can be assigned to the excitonic band blue-shifted from the ^1B_b band at 258 nm similarly to the 229 nm band of 12-AS. The 2-AP monolayer also appears to consist of the H-aggregates and the molecules in the monomer-like state. The spectral shift of the chromophores in the H-aggregates is smaller than that in the 12-AS monolayer. This may be due to that the excitonic interaction among the chromophores of 2-AP is weaker than that in the 12-AS monolayer because 2-AP makes a more expanded monolayer than 12-AS.[2] The 334—387 nm band may be assigned to the ^1L_a transition. The ^1L_a band of the H-aggregates appears to be almost unchanged and superposed on that of the monomer-like state because no new peaks appeared near this wavelength region. This is the situation also similar to the 12-AS case.

The orientation angles of the molecules in the 2-AP monolayer were calculated by the similar manner to the 12-AS case. In the 239 nm band, R can be regarded as ≈ 0 because there is no peak corresponding to it in the s-spectrum. Hence, γ and θ in this band should be $\approx 0°$. The calculation for the peak at 334 nm was not done for the same reason as the peak at 333 nm in the 12-AS molayer. For the bands at 258-, 350-, 367-, and 387-nm, the admissible ranges or γ and θ were estimated by drawing the θ-γ curves which give the observed values of R. These curves are very similar to those in Fig. 5, and they are not shown. The γ angle of the monomer-like state was also assumed to be equal to that of the H-aggregates. Then, we obtain the admissible ranges of γ as 0—21° and 75—90°. We adopt the former range as the physically reasonable one. The admissible ranges of θ are summarized in Table 1. The ranges of θ for the peaks in the 350—387 nm band indicate that the direction of their transition moments are roughly parallel to the short axis of the anthracene moiety. It should also be noted that the dichroic ratio of a peak in the band is an average of those of the H-aggregates and of the monomer-like state. The assumption of completely random distribution of the transition moments in the monomer-like state again leads to an unreasonably high fraction of the H-aggregates, 86%, from the observed R value of the 387 nm band, 1.256. Hence, the short axes of the anthracene moieties in the monomer-like state are not distributed isotropically but more parallel to the layer plane.

The range of θ is 68—75° for the 258 nm band but $\approx 0°$ for the 239 nm band. This suggests that the anthracene moiety of 2-AP also makes an internal rotation around the –CO–C– bond at the transformation from the monomer-like state to the H-aggregates. The anthracene moiety of 2-AP is very close to its hydrophilic group. The internal rotation of the anthracene moiety is likely to be sterically hindered by the water surface especially when $\theta \approx 0°$. Therefore, formation of H-aggregates seems to be harder in the 2-AP monolayer than in the 12-AS monolayer. The relative intensity of the 239 nm band to the 258 nm band in the 2-AP monolayer is smaller than that of the 229 nm band to the 257 nm band in the 12-AS monolayer (Figs. 1 and 3). This means that the fraction of the H-aggregates in the 2-AP monolayer is smaller than that in the 12-AS monolayer. This observation is consistent with the above mentioned structural feature of the 2-AP molecule.

The absorption spectra of the ONS monolayer are shown in Fig. 4. The solvent for the solution spectra was methanol because ONS was almost insoluble in hexane. A new absorption peak which was absent in the solution spectrum also appeared at 241 nm in the p-spectrum of the ONS monolayer. The transition moment of this band seems to be oriented nearly perpendicularly to the layer plane because its s-spectrum contained no peak corresponding to it. The peak at 241 nm was shifted toward the 255 nm band as the ONS monolayer was diluted with DPPC. Therefore, the 241 nm band is due to the H-aggregates and the ONS monolayer consists of the H-aggregates and the molecules in the monomer-like state similarly to the 12-AS and 2-AP monolayers. The 306- and 360- nm bands are little changed from those of the monomer-like state on formation of the H-aggregates because no new peak appeared near these bands.

The orientation angles of γ and θ in the ONS monolayer were estimated by the similar manner as above. In the 241 nm band, R can be regarded as ≈ 0 because there is no peak corresponding to it in the s-spectrum, and γ and θ in the H-aggregates are $\approx 0°$. The calculation for the 255 nm band was not done because its dichroic ratio could not be reliably measured owing to a large overlap with the 241 nm band in the p-spectrum. The orientation angles were tentatively estimated from the observed R values of the 306- and 360-nm bands. The γ angle in the monomer-like state and that in the H-aggregates were assumed to be the same. The θ-γ curves which give R's of the two bands are shown in Fig. 6. The admissible range of γ is estimated to be 0—34° from the curve b. The ranges of θ for the 306- and 360-nm bands are obtained as 34—45° and 66—90°, respectively. Badley *et al.* estimated θ from comparison of related compounds as 55° (=90°—35°) for the 360 nm band.[17] Their estimation is consistent with ours if the structure of ONS with respect to the bond C–N–C is as shown in Fig. 4. The curves in Fig. 6, however, were obtained from the

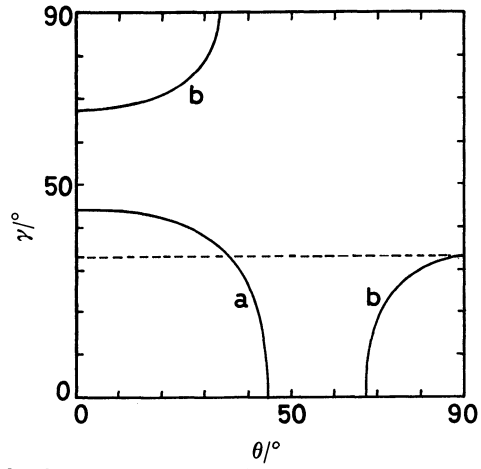

Fig. 6. The θ-γ curves to give the observed values of the true dichroic ratio R in the ONS monolayer. Curve a: for the 306 nm band, b: 360 nm band. The broken line indicates the upper limit of γ.

observed values of R which were the averages for the H-aggregates and the monomer-like state. Since no theoretical and experimental data about the directions of the transition moment of the chromophore of ONS are available, it is difficult to get further information about the orientation of the chromophores in the monomer-like state. By the way, the chromophore of ONS itself is the hydrophilic group at the end of the molecule. Another model for the orientation of ONS molecules is possible where their alkyl chains are randomly oriented independently of the uniaxial arrangement of their chromophores. The ONS monolayer, however, was transferred to the quartz plate under the surface pressure of 30 mN/m where the pressure-area isotherm of the ONS monolayer was steeply rising.[3] It seems unlikely that the alkyl chains in the ONS monolayer are randomly oriented because the surface pressure of the monolayer in such a steeply rising phase of the pressure-area isotherm is mostly produced by solid-like packing of long chains of surface-active molecules. Therefore, the model used by us seems to be plausible.

The pure monolayers of 12-AS, 2-AP, and ONS emitted blue fluorescence when excited by UV light. It was visible even to the naked eye. The fluorescence may provide further information about the H-aggregates and the monomer-like state in these monolayers. Roberts *et al.* reported that Langmuir films of short-chain derivatives of anthracene diplayed interesting electric conduction effects.[18] Electrical properties of 12-AS and 2-AP monolayers may also be worthy of a study.

We would like to thank Dr. Benedikt M. J. Kellner for kindly sending us the data of the isotherms of the 12-AS and 2-AP monolayers when mixed with DPPC at 22—23 °C and for kindly informing us that 2-AP is obtainable from Molecular Probes, Inc.

Selective Adsorption of Alkylbenzenesulfonates on Quaternized Crosslinked Poly(4-vinylpyridine)

Nariyoshi KAWABATA,* Eisuke NATSUHARA, Ichiro HIGUCHI, and Jun-ichi YOSHIDA
Laboratory of Environmental Chemistry, Department of Chemistry, Faculty of Polytechnic Science, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606
(Received August 21, 1982)

Selective ion-exchange adsorption of a series of alkylbenzenesulfonate ions (C_nBS^-) on a series of crosslinked poly(*N*-alkyl-4-vinylpyridinium bromide) (C_mVP) and crosslinked poly(*N*-benzyl-4-vinylpyridinium bromide) (BVP) was investigated based upon the selectivity coefficient of the resins for C_nBS^- relative to Br^- which was expressed as $K_{Br^-}^{C_nBS^-}$. In the adsorption of C_nBS^- of $n<8$, the selectivity coefficient linearly increased with the number of carbon atoms of the alkyl chain, n, of C_nBS^-, which was ascribed to the hydrophobic interaction between the alkyl chain of C_nBS^- and the resin. In the adsorption of C_nBS^- of $n>8$, however, the selectivity coefficient did not increase with n, which was explained in terms of a steric effect. The selectivity coefficient also increased with the number of carbon atoms of the alkyl chain, m, of C_mVP, but saturation was also observed for the adsorption on C_mVP of $m>12$. In the adsorption of C_nBS^- of $n<8$ on BVP, significant influence of the degree of quaternization was not observed. In the adsorption of $C_{12}BS^-$, however, BVP of lower degree of quaternization showed a much larger selectivity than that of BVP of higher degree of quaternization. The observation indicated that steric repulsion between C_nBS^- ions adsorbed on the surface of the resin played a crucial role.

Adsorption of organic materials by polymeric adsorbents is of considerable interest.[1] In a previous paper,[2] crosslinked poly(*N*-benzyl-4-vinylpyridinium bromide) (BVP) was reported to be an excellent polymeric adsorbent for removal of sodium dodecylbenzenesulfonate from aqueous solution. Although the adsorption proceeded by ion-exchange mechanism, the adsorption capacity was scarcely affected by the presence of inorganic anions such as chloride, sulfate, and hydroxide ions. Extremely high selectivity of BVP for alkylbenzenesulfonate ion provided strong motivation for understanding of the nature of such adsorption. In this study, selectivities of BVP and a series of crosslinked poly(*N*-alkyl-4-vinylpyridinium bromide) (C_mVP, here m is the number of carbon atoms of the alkyl group) for a series of alkylbenzenesulfonate ions (C_nBS^-, here n is the number of carbon atoms of the alkyl group) were determined, and an attempt has been made to indicate which factors operate in determining the selectivity.

Experimental

Materials. Sodium dodecylbenzenesulfonate ($C_{12}BS$) of high purity (special grade for the test of synthetic detergent) was supplied from Wako Pure Chemical Industries, Japan. Sodium benzenesulfonate (C_0BS) was supplied from Nakarai Chemicals, Japan. Sodium ethylbenzenesulfonate (C_2BS) was supplied from Tokyo Kasei Kogyo Co., Japan. These sodium alkylbenzenesulfonates (C_nBS) were used without further purification. Sodium butylbenzenesulfonate (C_4BS), sodium hexylbenzenesulfonate (C_6BS), and sodium octylbenzenesulfonate (C_8BS) were prepared according to the literature procedure[3] with minor modifications, and purified by recrystallization from hot methanol before use.

^1H NMR spectra of these C_nBS were obtained with a Varian T-60A spectrometer in dimethyl-d_6 sulfoxide using tetramethylsilane as an internal standard. Aromatic protons showed distinct AB-type quartets. This result indicated that para isomers were predominant and the presence of ortho and meta isomers was not significant. Aliphatic protons showed the presence of only one methyl group in each C_nBS. This result indicated that the normal alkyl groups were predominant and the presence of branched alkyl groups was not significant.

Table 1. Degree of quaternization and ion exchange capacity of resins

Resin	Degree of quaternization/%	Ion exchange capacity/mequiv. g^{-1}
BVP	89	2.85
BVP′	32	1.51
C_4VP	71	2.77
C_8VP	55	2.09
$C_{12}VP$	36	1.44
$C_{16}VP$	20	0.92

Relative amounts of aromatic and aliphatic protons were also consistent with the prescribed structure.

Crosslinked poly(4-vinylpyridine) containing 72 mol% of 4-vinylpyridine was prepared by a copolymerization of 4-vinylpyridine with divinylbenzene followed by grinding and sifting to 60—80 mesh as described previously.[4] Quaternization of the copolymer with benzyl bromide in benzene (60 °C 4 h) yielded crosslinked poly(*N*-benzyl-4-vinylpyridinium bromide) (BVP).[2] Quaternization of the copolymer with a series of alkyl bromides was carried out in a similar fashion (60 °C, 40 h) to yield crosslinked poly(*N*-alkyl-4-vinylpyridinium bromide) (C_mVP). The resins thus obtained were washed with benzene, methanol, and water before the adsorption test. Degree of quaternization and ion exchange capacities of the resins were determined by titration with standard $AgNO_3$ solution using eosin as the indicator, after the reaction with excess aq $NaNO_3$ (Table 1).

Deionized water was used throughout the experiments. Other chemicals were used as obtained commercially.

Equilibrium Adsorption Test. Equilibrium adsorption tests were conducted by placing weighed quantities of the resin and an aqueous solution of sodium alkylbenzenesulfonate and sodium bromide (total concentration 0.1 M) in a 100-cm^3 Erlenmeyer flask equipped with a mechanical stirrer at 30 ± 1 °C. After the mixture reached equilibrium, the concentration of alkylbenzenesulfonate ion was determined based upon the absorptivities at 260 nm using Shimadzu UV-100-02 spectrophotometer. Concentration of bromide ion was determined by titration with standard $AgNO_3$ solution using eosin as the indicator.

Results and Discussion

Selectivities of several quaternized crosslinked poly(4-vinylpyridine) (BVP and C_mVP) for a series of alkylbenzenesulfonate ions (C_nBS^-) were determined by equilibrium adsorption tests. The selectivities were determined relative to bromide ion because of the following reasons. The bromide form of the quaternized crosslinked poly(4-vinylpyridine) can be obtained more easily than the corresponding chloride form since the quaternization with alkyl bromide proceeds more smoothly than that with alkyl chloride. Although the bromide form of the polymer can be transformed into the chloride form or sulfate form by ion-exchange process, it is difficult to confirm the completeness of the transformation. Incomplete transformation might result in a large experimental error in determination of selectivities. The selectivity coefficients, $K_{Br^-}^{C_nBS^-}$, were calculated by use of the following relationship.[5]

$$K_{Br^-}^{C_nBS^-} = \frac{(\text{mmol } C_nBS^- \text{ in resin})}{(\text{mmol } Br^- \text{ in resin})} \times \frac{[Br^-]}{[C_nBS^-]}, \quad (1)$$

where $[Br^-]$ is the molar concentration of bromide ion in the solution and $[C_nBS^-]$ is the molar concentration of alkylbenzenesulfonate ion. The selectivity coefficients somewhat varied with the molar fraction of alkylbenzenesulfonate ion in the resin, x, which was defined as follows:

$$x = \frac{(\text{mmol } C_nBS^- \text{ in resin})}{(\text{mmol } C_nBS^- \text{ in resin}) + (\text{mmol } Br^- \text{ in resin})}. \quad (2)$$

The dependency of $K_{Br^-}^{C_nBS^-}$ on x is illustrated in Fig. 1. Therefore, discussions were made based on the values of $K_{Br^-}^{C_nBS^-}$ at $x=0.5$, which were determined from the plots of log $K_{Br^-}^{C_nBS^-}$ *vs.* x.

Influence of Alkyl Chain Length of Alkylbenzenesulfonates. With increasing alkyl chain length of alkylbenzenesulfonate ions, *i.e.*, when the value of n of C_nBS^- increased, the competition between alkylbenzenesulfonate ion and bromide ion for the ion-exchange sites strongly favored the adsorption of the former. In order to evaluate the influence of alkyl chain length more quantitatively, log $K_{Br^-}^{C_nBS^-}$ of BVP was plotted against the number of carbon atoms, n, of the alkyl chain of C_nBS^-. In the cases where $n<8$, log $K_{Br^-}^{C_nBS^-}$ of BVP increased linearly with n as shown in Fig. 2. It holds widely that the standard free energy change for transfer of hydrocarbon chains from aqueous solution to other phase varied in proportion to the number of carbon atoms. This relationship has been explained in terms of hydrophobic interactions of the hydrocarbon chain.[6] On this basis, it may be reasonably considered that hydrophobic interaction between the resin and the alkyl chain of C_nBS^- is responsible for the increase in selectivity with the length of alkyl chain.

The standard free energy change for the transfer of alkylbenzenesulfonate ion from aqueous solution to the resin phase (ΔG) is correlated to the selectivity coefficient as follows:[7]

$$-RT\delta(\ln K_{Br^-}^{C_nBS^-})/\delta n = \delta\Delta G/\delta n + \Pi\delta V_{C_nBS^-}/\delta n, \quad (3)$$

where Π is the swelling pressure of the resin and $V_{C_nBS^-}$ is partial molar volume of C_nBS^-. The linear part of Fig. 2 gave a value for $RT\delta(\ln K_{Br^-}^{C_nBS^-})/\delta n$ of approximately 2400 J mol^{-1}. Similar values (*ca.* 2200 J mol^{-1}) were reported for the adsorption of aliphatic carboxylate anion on anion exchange resins.[7]

On the other hand, in the cases where $n>8$, log $K_{Br^-}^{C_nBS^-}$ did not increase with n. Steric factor seemed to be responsible for the results, since hydrophobic interaction is expected to increase with further increase in the alkyl chain length. As the alkyl chain length of C_nBS^- increased, steric repulsion between the adsorbed sulfonate ions would increase, which might compensate for the increase in hydrophobic interaction. Steric repulsion between the polymer matrix and the sulfonate ions also seemed to be important.

As has been mentioned above, steric effect seemed to

play an important role in the adsorption. Since steric repulsion between the adsorbed alkylbenzenesulfonate ions was expected to be reduced if the ion exchange sites were separated by enough distances from each other, the influence of degree of quaternization of the resin was examined. Thus, the adsorption tests were carried out with BVP of lower degree of quaternization (32%) and that of higher degree of quaternization (89%). Figure 3 shows the selectivity coefficients obtained for these resins. No significant difference was observed between their selectivities for C_nBS^- of $4<n<8$. In these cases steric repulsion between the adsorbed alkylbenzenesulfonate ions seemed to be insignificant. However, in the case of the adsorption of $C_{12}BS^-$, the selectivity coefficient of BVP of lower degree of quaternization was much higher than that of BVP of higher degree of quaternization. In the latter case, the alkyl chain of $C_{12}BS^-$ was presumably long enough to cause steric repulsion between the adsorbed $C_{12}BS^-$ ions, whereas in the former case such steric repulsion might be reduced by separation of ion exchange sites on the surface of the resin.

Influence of alkyl chain length of alkylbenzenesulfonate ions was also examined in the case of the adsorption on a series of crosslinked poly(*N*-alkyl-4-vinylpyridinium bromide) (C_mVP). In Fig. 4 are shown the plots of log $K_{Br^-}^{C_nBS^-}$ of C_mVP against the number of carbon atoms, n, of C_nBS^-. In the cases where $n<8$, log $K_{Br^-}^{C_nBS^-}$ of each C_mVP also increased linearly with n, which was ascribed to the hydrophobic interaction between the alkyl chain of C_nBS^- and the resin. Although the degree of quaternization of these C_mVP was not equal, Fig. 3 shows that the linearity of the plot of log $K_{Br^-}^{C_nBS^-}$ *vs.* n was not influenced by the degree of the quaternization. The linearity of Fig. 4 gave a value of 2400 J mol^{-1} for $RT\delta(\ln K_{Br^-}^{C_nBS^-})/\delta n$.

Influence of Alkyl Chain Length of Resins. Since hydrophobic interaction between the alkyl chain of the

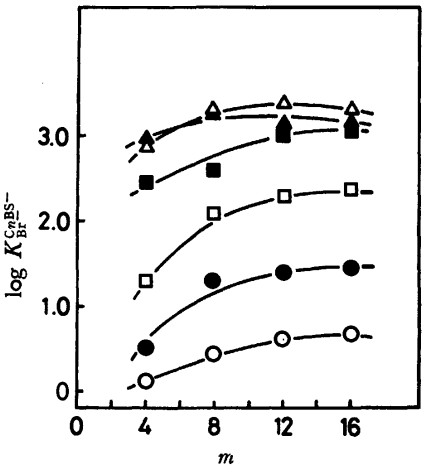

Fig. 5. Variation of selectivity coefficients of C_mVP resins for a series of alkylbenzenesulfonate ions (C_nBS^-) with a number of alkyl carbon atoms of C_mVP.
○: C_0BS^-, ●: C_2BS^-, □: C_4BS^-, ■: C_6BS^-, △: C_8BS^-, ▲: $C_{12}BS^-$.

C_nBS^- ion and the resin was suggested to play an important role in the adsorption, the influence of the hydrophobicity of the resin was then examined. Thus the selectivities of a series of crosslinked poly(*N*-alkyl-4-vinylpyridinium bromide) (C_mVP) were plotted against the number of carbon atoms, m, of the alkyl chain attached to the resin. As can be seen in Fig. 5, log $K_{Br^-}^{C_nBS^-}$ increased with m, which may be attributed to the hydrophobic interaction mentioned above. In the cases where $m>12$, however, saturation of the selectivity coefficients was observed. This may be ascribable to the steric effect as discussed above. It should be noted here that in the case of the adsorption of $C_{12}BS^-$, the selectivity coefficient did not vary appreciably with the value of m. Probably the alkyl chain of $C_{12}BS^-$ was long enough to cause significant steric repulsion even in the case of the resins having a short alkyl chain such as C_4VP and C_8VP.

^{129}I Mössbauer Effect in Several π-σ Charge Transfer Complexes of Iodine

Hiroshi SAKAI,* Tomochika MATSUYAMA, Hitoshi YAMAOKA, and Yutaka MAEDA
Research Reactor Institute, Kyoto University, Kumatori, Sennan-gun, Osaka 590-04

(Received September 6, 1982)

The ^{129}I Mössbauer spectra at 16 K have been measured for the π-σ charge transfer complexes of iodine with benzene, coronene, perylene, and poly(*p*-phenylene). It is suggested that the benzene–iodine complex in benzene prepared by slow cooling consists of alternate benzene and iodine molecules with the six-fold axial symmetry. The Mössbauer spectrum for the coronene–iodine complex (1 : 1) shows only one chemical state of iodine. The acceptor orbital is described by only the σ_u-antibonding molecular orbital of iodine. The extent of charge transfer in the complex is estimated to be $0.06e^-$ in the electronic ground state. In the poly(*p*-phenylene)–iodine complex the iodine exists as almost a free molecule, indicating that the interaction between the phenylene ring and iodine is very weak.

Iodine is a typical electron acceptor and forms charge transfer (CT) complexes with various electron donor molecules.[1-3] In particular, benzene–iodine (Bz–I_2) is one of the most typical π-σ CT complexes and has been extensively treated with many experimental and theoretical investigations. However, the geometrical configuration and the electronic state of the Bz–I_2 complex are not fully understood. Two conflicting models, "resting model" and "axial model," are proposed from various experimental methods such as IR,[4] MCD,[5,6] and ^{129}I Mössbauer[7-9] spectroscopies in addition to the theoretical treatments.[10-14] From the ^{129}I Mössbauer spectroscopic studies, it is found that the iodine in benzene exhibits an anomalously high value of the quadrupole coupling constant (e^2Qq) compared to that of the free iodine molecule.[7,8] Furthermore, the same tendency is found in methylated benzene-iodine complexes.[9,15]

Shibuya[16] determined the crystal and molecular structure of the coronene–iodine (1 : 1) complex by X-ray diffraction. He reported that each iodine molecule was situated between two coronene molecules and that its axis was almost normal to the plane of the coronene molecule, although it was not coincident with the C_{3v} axis of the coronene molecule. This is the only iodine-containing π-σ complex of which the molecular structure is determined. It is therefore worthwhile to compare the ^{129}I Mössbauer spectrum of Bz–I_2 with that of coronene–I_2. Recently Teitelbaum, Ruby, and Marks[17] performed the ^{129}I Mössbauer effect measurement of the perylene–iodine (2 : 3) complex, which is an organic semiconductor with relatively high electrical conductivity ($\approx 10^{-1}$ S/cm).[18,19] They reported from the ^{129}I Mössbauer and the resonance Raman spectra that the perylene–iodine complex was not a well-known molecular complex, such as coronene–iodine, but rather a partially oxidized, mixed-valence compound. We have also studied the ^{129}I Mössbauer effect of the perylene–iodine (2 : 3) complex in order to elucidate the charge state and the configuration of the iodine. A comparison of the Mössbauer results of the coronene–iodine and perylene–iodine complexes will provide some information about the CT bonding formation and the electrical conductivity.

Poly(*p*-phenylene) has attracted much interest because of an increase of the electrical conductivity from about 10^{-12} S/cm of the undoped polymer to 5×10^2 S/cm with the doping of arsenic pentafluoride (AsF_5).[20] It is expected that iodine-doped poly(*p*-phenylene) may also exhibit high electrical conductivity in analogy with the iodine-doped polyacetylene. However, Mainthia *et al.*[21] were unsuccessful in obtaining conductivities higher than 4×10^{-5} S/cm.

In this paper we report ^{129}I Mössbauer effect studies on the aromatic hydrocarbon–iodine (π-σ type) complexes such as benzene–iodine, coronene–iodine (1 : 1), and perylene–iodine (2 : 3) complexes. Furthermore, iodine-doped poly(*p*-phenylene) was also studied in order to elucidate the charge state and the configuration of iodine.

Experimental

All the absorber samples were prepared from Na^{129}I in Na_2SO_3 solution. After oxidizing the iodide with 3 mol dm^{-3} H_2SO_4 and 10% H_2O_2, the resulting molecular iodine ($^{129}I_2$) was extracted with benzene. The benzene solution was washed thoroughly with water and passed through a Teflon filter to eliminate a slight amount of water. The benzene solution of iodine was slowly cooled in a Teflon sample holder and used for the ^{129}I Mössbauer effect measurement as such. The other complexes, coronene–iodine (1 : 1) and perylene–iodine (2 : 3), were prepared by using the procedure of Kommandeur and Hall.[18] In the case of the coronene–iodine complex a large excess of iodine was used for preparation in order to get the brown needle-like crystals in high yields. Since these complexes decompose gradually in air, the products were immediately transferred into Teflon sample holders and kept in liq. N_2 until the Mössbauer measurement.

Poly(*p*-phenylene) was synthesized by polymerization of benzene with the $AlCl_3$–$CuCl_2$ system.[22] Iodine doping was performed by immersing the poly(*p*-phenylene) powder in hexane solution of $^{129}I_2$ at room temperature for 1 d. The content of iodine was estimated to be about 0.01 atoms per the polymer unit, $[(C_6H_4)I_{0.01}]$, from an increase of weight. The molecular iodine was doped very little in this polymer compared with arsenic pentafluoride (AsF_5).[20]

The Mössbauer source in the ^{66}Zn ^{129}Te form was prepared by irradiation of a 150 mg ^{66}Zn ^{128}Te compound at a flux of 2×10^{13} neutrons/cm^2 s for one hour in the Kyoto Univ. Reactor (KUR). The apparatus used for Mössbauer measurements was described in our previous paper.[23]

Results and Discussion

Benzene–Iodine Complex. An ^{129}I Mössbauer spec-

trum of iodine dissolved in benzene at 16 K is shown in Fig. 1. The spectrum was analyzed by the least-square fitting method, as indicated by the solid line. The obtained Mössbauer parameters, such as the quadrupole coupling constant (e^2Qq), the asymmetry parameter (η), the isomer shift (δ), and the line width (2Γ) are given in Table 1 together with the results of Bukshpan *et al.*[8] The e^2Qq value was converted to the ^{127}I nucleus by using the ground state quadrupole moment ratio $^{129}Q/^{127}Q=+0.70121$.[24]

As shown in Table 1, the value of $e^2Qq=-2341\pm13$ MHz is higher and the value of $\delta=0.84\pm0.02$ mm/s is lower than those for the free iodine molecule in inert matrices. Bukshpan *et al.* have observed the same tendency, but their values are slightly different from ours. The slight difference may come from the cooling procedure and the measuring temperature of the sample, that is, Bukshpan *et al.* have prepared the sample by rapid cooling and measured at liq. He temperature, while in our case the sample has been prepared by slow cooling and measured at 16 K. The value $\eta=0$ agrees with that of Bukshpan *et al.*[8] As shown in Fig. 1, only one chemical species of iodine was observed in the benzene-iodine frozen solution. Furthermore, no broadening of the line width was observed in the octet lines compared with the other spectra of crystalline materials. These observations suggest that the Bz–I_2 complex exists as n : n chains of alternate halogen and benzene molecules with the axial configuration in the benzene frozen solution in a similar manner to the

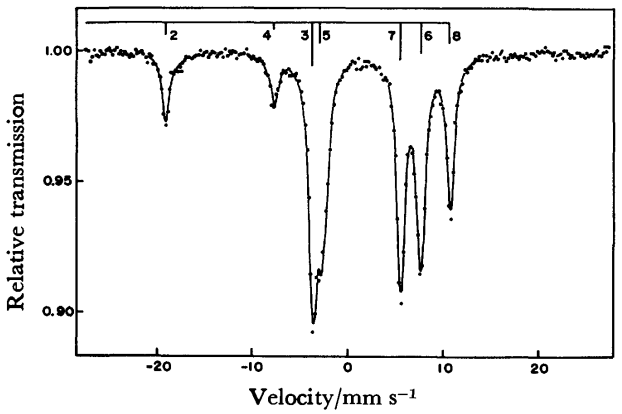

Fig. 1. ^{129}I Mössbauer spectrum of the benzene-iodine complex in the benzene frozen solution at 16 K.

Bz–Br_2 and Bz–Cl_2 crystalline complexes.[25] In contrast, Wynter *et al.*[15] argued from the large value of the asymmetry parameter ($\eta=0.18$) that the *p*- and *o*-xylene-iodine complexes had the resting configuration.

In our previous paper[9] we discussed the electronic state of the Bz–I_2 complex by assuming axial geometry. Comparing the high value of e^2Qq and the low value of δ with those for the free iodine molecule, we found that the CT bonding orbital consisted of an *spd* hybrid orbital of iodine. The contribution of the *5d*-character to the CT bond formation was dependent on the extent of CT. This extent was not directly evaluated from the δ value. From the values of e^2Qq and δ in Table 1, and Eqs. 9 and 10 in Ref. 9, we obtain the *s*- and *d*-characters of the CT bonding orbital to be 0.8% and 8%, respectively, by assuming the extent of CT to be 0.06. This result indicates that the contribution of the *s*- and *d*-characters in the CT bond formation can not be ignored in the case of the Bz–I_2 complex.

Coronene–Iodine Complex. The ^{129}I Mössbauer spectrum of the coronene–iodine (1 : 1) crystalline complex at 16 K is shown in Fig. 2. The Mössbauer parameters obtained by analyzing the spectrum in the same manner as the Bz–I_2 complex are presented in Table 1. The spectrum shows only one chemical species of iodine, as expected from the crystal structure determined by an X-ray diffraction method.[16] The intensities of the absorption peaks are deviated from the ideal ones ($\eta=0$), which are proportional to the square of the Clebsch-Gordan coefficient $|CG|^2$.[26,27] This deviation may be due to: (i) the saturation effect and (ii), the preferred orientation. The first effect depends on the absorber thickness. If the absorber is too thick, the intense peak will be relatively weakened. In our case, the absorber thickness was about 20 mg ^{129}I/cm^2, which seemed to be too thick. Since the coronene–iodine complex is a needle-like crystal, the second possibility is also not ignored.

Both values of e^2Qq and δ for the coronene–iodine complex are lower than those for free iodine molecule. This result suggests that the acceptor orbital of the iodine molecule is only the σ_u-antibonding molecular orbital, as is generally accepted. In this case we can apply the following relationship between δ and *5p* electron populations:[7]

$$\delta(\text{mm/s}) = 1.5\,h_p - 0.54\ (\text{ZnTe source}), \qquad (1)$$

Table 1. The Mössbauer parameters for the π-σ charge transfer complexes of iodine

	e^2Qq[a] / MHz	η	δ / mm s^{-1}	2Γ / mm s^{-1}	U_p[b]	h_p[c]	Ref.

a) The e^2Qq values are converted to ^{127}I. b) $U_p=-e^2Qq_{obsd}/e^2Qq_{at}$, $e^2Qq_{at}=2292.7$ MHz. c) $\delta=1.5\,h_p-0.54$ mm s^{-1}, relative to ZnTe source.

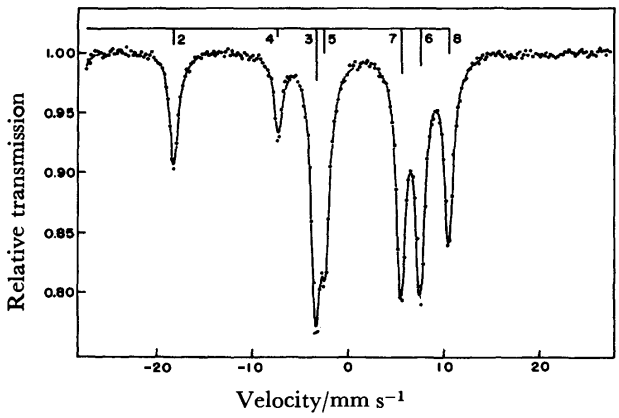

Fig. 2. ^{129}I Mössbauer spectrum of the crystalline coronene–iodine complex at 16 K.

where h_p is the number of p-holes in the $5s^25p^6$ configuration. Substituting the δ value to Eq. 1, we get $h_p=0.97$. It corresponds to the charge transfer of 0.06 electrons from the coronene molecule to the iodine molecule. On the other hand, the charge density localized on each iodine atom is also estimated from the value of e^2Qq according to the Townes and Dailey treatment.[26-28]

$$U_p \equiv -e^2Qq_{obsd}/e^2Qq_{at} \approx 1 - s^2 \pm i - \pi, \quad (2)$$

where U_p is the number of the unbalanced p electrons, s^2 and i are the amount of s-hybridization and the ionic character, respectively, and π is the double bond character and/or the intermolecular bond. The atomic iodine quadrupole coupling constant, e^2Qq_{at}, is equal to 2292.7 MHz. With $e^2Qq=-2216\pm13$ MHz we get $U_p=0.97$. The value obtained is in good agreement with the h_p value. This agreement means that the I–I bond in this complex consists of a pure p_σ bond and the acceptor orbital can be described by only the σ_u-antibonding molecular orbital of the iodine molecule. This is also supported by the small η value.

Although the number of transferred electrons (0.06 e^-) is nearly equal to that for the Bz–I_2 complex, the electronic state of the iodine molecule is appreciably different from that for the Bz–I_2 complex. This result may be attributable to the difference of the geometrical configuration in the two complexes. In the case of the coronene–iodine complex, the axis of the iodine molecule is perpendicular to the coronene molecular plane but is not coincident with the six-fold axis of coronene, as shown in Fig. 3.[16] In the benzene–iodine complex, the iodine molecule is symmetrically situated along the six-fold axis of the benzene molecule.

The values of e^2Qq, δ, and η for the coronene–iodine complex are very close to those for the n-σ type complex of phenazine–iodine[29] which consists of the infinite chains of alternate phenazine and iodine molecules (in Table I). This fact suggests that the mechanism and the bond formation of the charge transfer are not essentially different between the π-σ and n-σ type complexes made up of the infinite alternative chain.

Perylene–Iodine Complex. The ^{129}I Mössbauer spectrum obtained for the perylene–iodine (2 : 3)

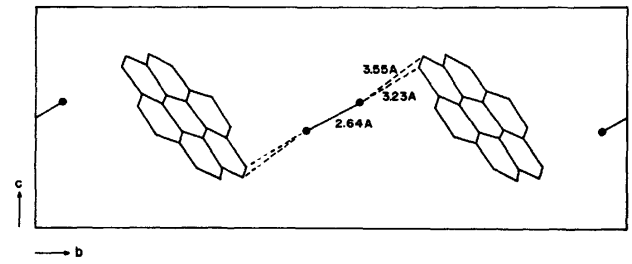

Fig. 3. Molecular structure of the coronene–iodine complex. The black circle represents the iodine atom.

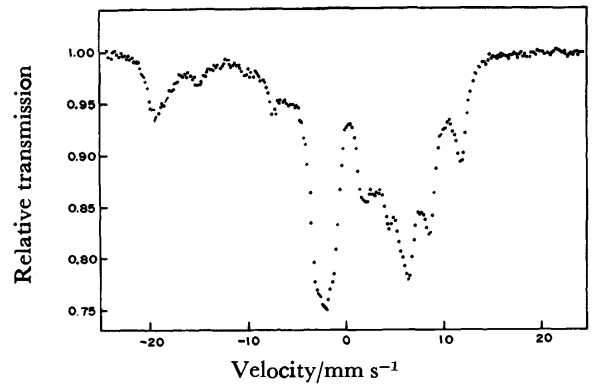

Fig. 4. ^{129}I Mössbauer spectrum of the crystalline perylene–iodine complex at 16 K.

crystalline complex (≈40 mg $^{129}I/cm^2$) at 16 K is presented in Fig. 4. This spectrum has quite complicated features and is clearly different from those of the π-σ charge transfer complexes such as the benzene-iodine and coronene–iodine complexes. It is suggested from the spectrum that the iodine present in the perylene–iodine (2 : 3) complex exists as polyiodides or mixtures of the triiodide ion (I_3^-) and the molecular iodine (I_2). The possibility for the presence of the iodide ion (I^-) is immediately ruled out by finding no single peak at about −0.5 mm/s. The spectrum is very similar to one observed at liq. He temperature by Teitelbaum *et al.*[17] They were successful in analyzing their spectrum into five chemically different iodine sites which consisted of two interacting I_2 units and a distorted I_3^- ion. Their analysis was also supported from the result of the resonance Raman spectra.

There is little doubt that the perylene–iodine complex is not a normal molecular complex but rather an ionic, mixed-valence compound. On the other hand, the coronene–iodine complex is a typical molecular complex which consists of infinite stacks of alternate coronene and iodine molecules (Fig. 3). This difference in the complex formation may first be explained on the basis of the ionization potential of the donor molecules. That is, the ionization potential of perylene (6.85 eV) is much lower than that of coronene (7.50 eV).[30] For many of the solid complexes formed between the donors having lower ionization potential and the acceptors having higher electron affinity, there is a tendency to form ionic, radical salts which show some paramagnetic

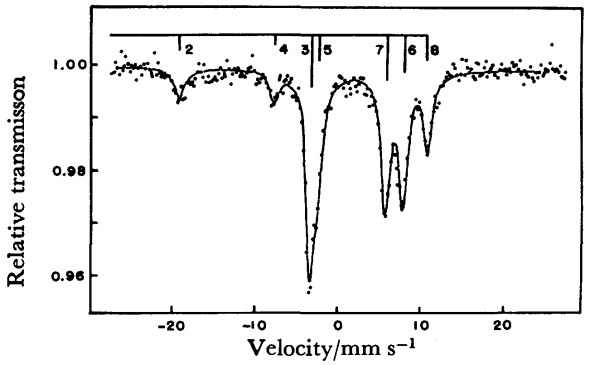

Fig. 5. ^{129}I Mössbauer spectrum of the poly(*p*-phenylene)-iodine complex at 16 K.

behavior and have high electrical conductivities.

Poly(p-phenylene)-Iodine Complex. Figure 5 shows the ^{129}I Mössbauer spectrum for the poly(*p*-phenylene)-iodine complex ($\approx$5 mg ^{129}I/cm^2) at 16 K. The solid line represents the best fitted curve obtained by the least square method. The Mössbauer parameters obtained are given in Table 1. The spectrum shows only one kind of iodine species and the values of e^2Qq and δ are in good agreement with those for the free iodine molecule. Consequently, the iodine doped in poly(*p*-phenylene) exists as almost free iodine molecules. It is then concluded that the iodine molecule interacts little with the phenylene ring. This finding well explains the following experimental results: (i) the electrical conductivity for poly(*p*-phenylene) does not increase with doping of iodine ($\approx 10^{-4}$ S/cm) as much as observed in the case of AsF_5-doping; (ii) the value of the conductivity for the iodine-doped poly(*p*-phenylene) decreases under dynamic vacuum.[20,21] The apparent activation energy for electrical conductivity is also high for Br_2 doping sample ($\approx$0.3 eV).

On the other hand, Matsuyama *et al.*[31] and Kaindl *et al.*[32] found from the ^{129}I Mössbauer spectroscopy that the iodine doped in polyacetylene existed as the chemical forms of I_3^- and/or I_5^- ions. The electrical conductivity for polyacetylene increases drastically with doping of iodine ($\approx 10^2$ S/cm).[33] The activation energy also decreases from 0.3 eV for undoped to $\approx$0.01 eV for iodine-doped polyacetylene. The difference in the doping process between poly(*p*-phenylene) and polyacetylene may be interpreted in terms of the ionization potential of each polymer. For doping of the very strong electron acceptor AsF_5, both polymers indeed exhibit the high electrical conductivity: $\approx 10^2$ S/cm for poly(*p*-phenylene)[20] and $\approx 10^3$ S/cm for polyacetylene.[34]

The authors wish to thank Profs. Takenobu Higashimura and Iwao Shibuya in the Research Reactor Institute, Kyoto University, for their helpful discussions and encouragements. Isotope Effect on the Emission Cross Section and Translational Energy of Excited Hydrogen Atoms Produced in Electron-Hydrogen Chloride Collisions

Morihide HIGO,† Satsuo KAMATA,† and Teiichiro OGAWA*

Department of Molecular Science and Technology, Kyushu University, Kasuga, Fukuoka 816

†*Faculty of Engineering, Kagoshima University, Korimoto, Kagoshima 890*

(Received September 6, 1982)

The Balmer-α, β, γ lines of the excited hydrogen atoms ($n=3$, 4, 5) produced in e-HCl and DCl collisions have been measured in the energy range of 30—300 eV. The average translational energies of H* and D* are 4—5 eV at higher electron energies and 2—2.5 eV at lower electron energies; no appreciable isotope effect is found for the translational energy. The relative emission cross section of D* and H* shows an isotope effect and this effect is larger in the lower electron energy range; σ_D/σ_H's are 0.74 for $n=3$, 0.71 for $n=4$ and 0.78 for $n=5$ at 30 eV. These results show that there are two groups of the excited hydrogen atoms and their relative cross sections vary with the electron energy. The existence of the isotope effect indicates a competing decay process in the repulsive excited states of HCl.

Electron-impact excitation of a hydride molecule leads to the formation of an excited hydrogen atom (H*). The translational energy[1-6] of H* and its distribution[7-16] have clarified the highly excited states and their dissociation mechanism. The Rydberg states converging to the ionic states which produce H^+ play an important role for the formation of H*; comparison of the translational energy distributions of H* with those of H(HR) and H^+ justifies an extension of the core-ion model to the low-Rydberg emissive atoms.[10-14,16] Curve crossing between potential curves is involved in the formation of the excited hydrogen atom.[9-11,13,16]

The translational energy distribution of H*($n=4$) from HCl has two major components; their peaks lie at about 5 eV (the fast component) and 2.5 eV (the slow component).[9] The former is important at higher electron energies, whereas the latter is important at lower electron energies. The production mechanism of the fast component has been assigned to dissociation through Rydberg states converging to the $^2\Pi$ state of HCl^+, and that of the slow component to excitation to Rydberg states converging to the $^4\Pi$, $^4\Sigma^-$ and/or $^2\Sigma^-$ states of HCl^+ followed by curve crossing and succeeding dissociation through those converging to the $^2\Sigma^+$ state.[9]

The investigation of the isotope effect in the emission cross section of H*(D*)[1,15,17-22] is equally important for the elucidation of the molecular dissociation dynamics and for their theoretical interpretation.[23,24] In our previous paper,[20] it has been shown that the isotope effect of H*(D*)($n=4,5,6$) from HCl(DCl) exists even in the repulsive Rydberg states at an electron energy of 300 eV, and principal quantum number dependence has been discussed.

In the present paper, we have observed the Balmer-α,β,γ lines from HCl and DCl at various electron energies, and measured the average translational energy of H*(D*)($n=3,4,5$) and the isotope effect of their emission cross sections in order to discuss the mechanism of dissociative excitation of hydrogen chloride.

Experimental

The apparatus consists of a stainless-steel collision chamber, a 1.26 m monochromator and a photon counting system. The details of the collision chamber have been published previously.[25] The mixture of HCl (99.7%, Tsurumi Souda) and DCl (99%, Merk) gases were jetted into the collision region and collided with electrons. The base pressure was of the order of 10^{-7} Torr (1 Torr≈133.322 Pa) and the operating pressure was of the order of 10^{-4} Torr.

The spectra were measured with a Spex 1269 monochromator equipped with a 1200 grooves/mm grating blazed at 500 nm. Photons were detected with an HTV R585 photomultiplier for the Balmer-β and γ lines or with a cooled HTV R649 photomultiplier for the Balmer-α line, and were counted with an NF PC545A photon counter.

Measurements were carried out where the intensity of the Balmer radiation was proportional to both the gas pressure and the electron-beam current. The energy of the electron was calibrated with the threshold of N_2^+ (3914 Å) at 18.75 eV and its energy resolution was ±1 eV.

Results and Discussion

Average Translational Energy. Collisions between HCl(DCl) and electrons give the excited H*(D*) atoms. The spectra of the Balmer-α,β,γ lines observed at an angle of 90° with respect to the electron beam and at various electron energies are shown in Figs. 1—3, respectively. The line shape depends on the electron energy; it becomes narrower with decreasing the electron energy.

The true width of the Balmer line, $\delta\lambda_t$, was calculated from the observed half-width, $\delta\lambda_{obsd}$, by the following relation:[5]

$$\delta\lambda_{obsd}^2 = \delta\lambda_t^2 + S^2 + a^2, \quad (1)$$

where S is the resolution of the monochromator and a the fine structure splitting.[26] The results are shown in Table 1. The uncertainty is mainly caused by random experimental fluctuation. The true width obtained here agrees well with that observed at higher resolution (0.033 Å) in our previous measurement[9] as shown in parentheses in Table 1.

At lower gas pressures, the spectral line shape of the emissive atom is determined by the Doppler effect[26] and, thus, has information on the velocity. The translational energy distribution can be calculated from the

Table 1. The corrected half-widths ($\delta\lambda_t$/Å) of the Balmer lines of the excited hydrogen and deuterium atoms in electron-hydrogen chloride collisions

Electron energy/eV	Balmer-α		Balmer-β		Balmer-γ	
	H	D	H	D	H	D
300	1.21	0.89	0.96 (0.96) [a)]	0.72	0.88	0.62
200	1.23	0.92	0.98	0.72	0.89	0.61
100	1.23	0.89	0.96 (0.99)	0.70	0.88	0.61
50	1.18	0.89	0.94 (0.92)	0.68	0.83	0.57
40	1.09	0.79	0.84 (0.76)	0.60	0.71	0.49
35	0.97	0.75	0.73	0.50	0.61	0.44
30	0.85	0.67	0.68 (0.72)	0.48	0.55	0.42

a) Calculated from the Balmer-β line taken at a high resolution (0.033 Å).[9)]
The uncertainties are about 5 and 7% for higher electron energies ($\geq$50 eV) and lower electron energies, respectively.

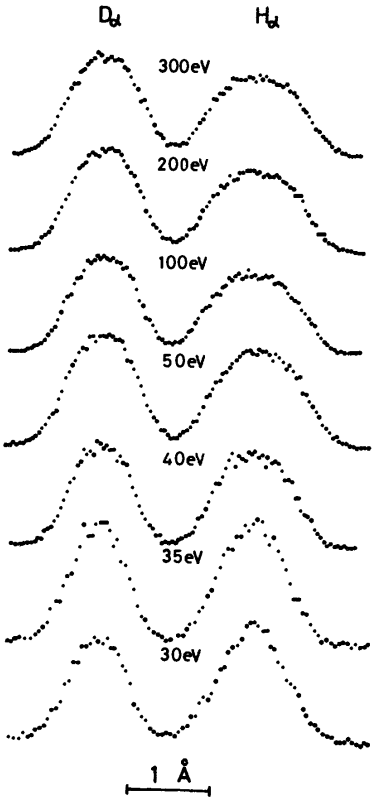

Fig. 1. The spectra of the Balmer-α lines produced in e-HCl and DCl collisions observed at 90° with respect to the electron beam. Spectral resolution: 0.32 Å. Electron-beam current: 220—770 μA. Operating pressure: (1.0—4.0) × 10^{-4} Torr.

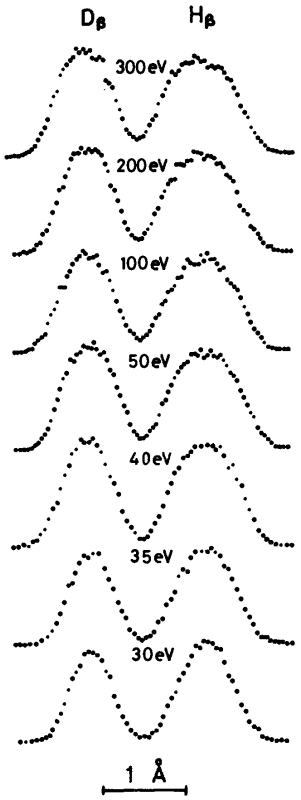

Fig. 2. The Spectra of the Balmer-β lines produced in e-HCl and DCl collisions. Spectral resolution: 0.31 Å. Electron-beam current: 420—740 μA. Operating pressure: (1.5—4.0) × 10^{-4} Torr.

line shape taken at a high optical resolution.[7,9)] Since resolution used here was not good enough to obtain the distribution, we have calculated the average translational energy instead of its distribution.

The average translational energy, E, of H* and D* was calculated by the following equation by assuming the distribution of the velocity to be a delta function:[3-6,15)]

$$E = mc^2/8 \cdot (\delta\lambda_t/\lambda_0)^2, \quad (2)$$

where m is the mass of H*(D*), c the velocity of light and λ_0 the characteristic wavelength of its radiation. The results are shown in Table 2. The electron energy dependence is similar for all of them. The average translational energy of the H*(n=4) is in agreement with the peak of the distribution. Neither the isotope effect nor the dependence on the principal quantum number is clear in the average translational energy of H*(D*) within the experimental uncertainty.

The similarity in both the translational energies of H*(D*) (n=3,4,5) and their electron energy dependence obtained in this measurement indicates that the excited states and their dissociation mechanisms for the formation of H*(n=3,5) and D*(n=3,4,5) are similar

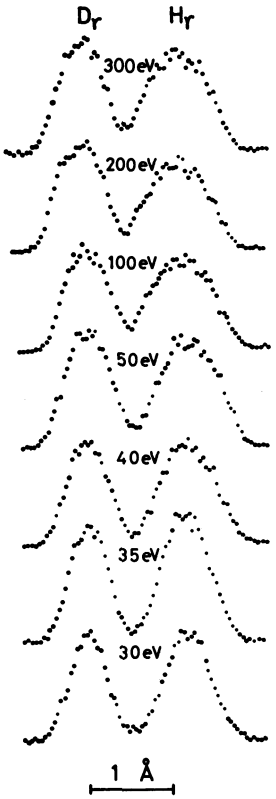

Fig. 3. The spectra of the Balmer-γ lines produced in e-HCl and DCl collisions. Spectral resolution: 0.31 Å. Electron-beam current: 360—820 μA. Operating pressure: $(1.5—4.0)\times10^{-4}$ Torr.

The uncertaintities are about 10 and 15% for higher electron energies (≥50 eV) and lower electron energies, respectively.

to those of H*(n=4).[9] This finding is consistent with the core-ion model.[27] Thus, it is concluded for all of n=3,4,5 of H* and D* that the repulsive Rydberg states converging to the $^2\Pi$ state of $HCl^+(DCl^+)$ produce the fast component and the slightly repulsive Rydberg states which cross the $^2\Sigma^+$ state produce the slow component.

It can generally be concluded that the translational energy for a single component has no isotope effect since the potential curve is common. The traslational energy of H*(D*)(n=3) at higher electron energies, however, is somewhat smaller than those of others. This may suggest that the slow component has a relatively larger

Table 3. Relative emission cross sections (σ_D/σ_H) of the Balmer lines of the excited hydrogen atoms in electron-hydrogen chloride collisions

Electron energy/eV	Balmer-α	Balmer-β	Balmer-γ	Balmer-δ

30	0.74	0.71	0.78	

a) Ref. 20. The uncertainty is estimated to be about 7%.

contribution for the formation of H*(D*)(n=3) even at higher electron energies; singlet Rydberg states converging to the $^2\Sigma^-$ states may be involved in such a process.

Isotope Effect on the Emission Cross Section. The relative emission cross section (σ_D/σ_H) has been obtained by comparing the areas of its spectrum. The results are shown in Table 3, with values measured in our previous paper[20] in parentheses. The main sources of uncertainty are random experimental fluctuation (5%), the sample preparation (4%) and the line overlap between H* and D*(2%). The cascade effect has been neglected; this effect has been estimated to be small for the Balmer-α line and negligible for the other Balmer lines by electron impact on H_2.[17,28]

The relative emission cross section shows an isotope effect ($\sigma_D/\sigma_H<1$), which depends on the electron energy as the translational energy does. Since the isotope effect for a single dissociation process is expected to be independent of the electron energy,[21,22] this dependence shows that two or more processes are involved for the formation of H*(D*) and that their relative cross sections vary with the electron energy. This is consistent with the result obtained in the translational energy.

Rydberg states converging to the $^2\Pi$ state are highly repulsive and produce the fast component. Dissociation and autoionization are main competing decay processes in these repulsive excited states. Since the heavier nuclei of DCl separate more slowly along the repulsive potential curve, more DCl molecules autoionize before they dissociate to neutral atoms (D*+Cl). Such a velocity dependent isotope effect has also been observed in the formation of H*(D*) from $H_2(D_2)$,[11,13] and $CHCl_3(CDCl_3)$[15] by electron impact.

Repulsive Rydberg states which cross the $^2\Sigma^+$ state produce the slow component. Its isotope effect is larger than that of the fast component; however, its n dependence is not clear. The probability for curve crossing depends on the velocity of nuclei[29] and the slower motion of DCl results in a larger probability for curve crossing. In addition to competition with autoionization, the probability difference can induce an isotope effect, which may be dependent on n. An n dependence of the isotope effect for the formation of H*(D*) has been observed in the case of CH_3CN (CD_3CN),[1] $H_2(D_2)$,[21,22] and $CHCl_3(CDCl_3)$.[15]

The authors thank Junichi Kurawaki and Yasuhiro Ueda for their cooperation and Professor Nobuhiko Ishibashi of Kyushu University for his encouragement. The present study was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

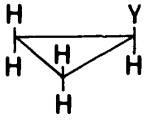
(Received September 7, 1982)

A new method for the synthesis of cyclopropane derivatives is described. It involves treatment of electron-deficient olefins with dibromomethane in the presence of Ni(0) complex/zinc/Lewis acid (or alkali halide) systems. $Ni(PPh_3)_4/Zn/ZnBr_2$ system was effective for the cyclopropanation of methyl acrylate and acrylonitrile, but was ineffective for that of methyl vinyl ketone and acrylaldehyde. $Ni(COD)_2/Zn/NaI$ system was applicable to the cyclopropanation of methyl vinyl ketone as well as to that of methyl acrylate and acrylonitrile. Alternative catalytic systems which were easy to handle were exploited, involving *in situ* generated Ni(0) complexes prepared from $NiBr_2(PPh_3)_2$ and zinc, or nickel bromide, sodium iodide, zinc, and an olefin. Catalytic amounts of nickel compounds are sufficient for the cyclopropanation of methyl acrylate, acrylonitrile, and methyl vinyl ketone, but a 1 : 2 nickel : acrylaldehyde mole ratio results in the best yield. A mechanism is proposed which involves metallacyclobutane as an intermediate.

The Simmons-Smith reaction provides a convenient synthesis of cyclopropane derivatives.[1] Copper has been found to act as an agent for a similar reaction.[2] The metal-carbenoid intermediates of these reactions are electrophilic so that electron-rich olefins are more susceptible to the reactions than electron-deficient ones. Modifications of zinc couples have enabled less reactive *gem*-dihalides and olefins to react: The zinc–copper couple prepared by treating granular zinc with a hot acetic acid solution of copper(II) acetate[3a] and zinc powder prepared by lithium reduction of zinc chloride[3b] can be used in the reactions involving unreactive *gem*-dihalides, and zinc–silver couple can improve yields in the reactions of electron-deficient olefins.[4] However, cyclopropane derivatives of acrylonitrile and acrylaldehyde have been obtained in very low or no yields. We have found a new method for the synthesis of cyclopropane derivatives by the reactions of electron-deficient olefins with dibromomethane by nickel(0) complexes and zinc.[5]

$$CH_2{=}CHY + CH_2X_2 + Zn \xrightarrow[\text{or NaI}]{\text{Ni(0)/Lewis acid}} \quad (1)$$



$+ ZnX_2$

X = Br, I; Y = CO_2CH_3, CN, $COCH_3$, CHO.

Experimental

General. All reactions involving organometallic reagents were carried out under a nitrogen atmosphere. Tetrahydrofuran (THF) was refluxed over sodium, distilled, and stored in a nitrogen atmosphere. Methyl acrylate, acrylonitrile, methyl vinyl ketone, and acrylaldehyde were distilled and stored in N_2 and in a refrigerator. The zinc powder provided by E. Merck was used without further purification. Other chemicals were commercially available and were used without further purification. $Ni(PPh_3)_4$[6] and $Ni(COD)_2$[7] (COD= 1,5-cyclooctadiene) were prepared by literature methods. Analysis and purification of cyclopropanes were run on a Shimadzu 6A gas chromatograph using analytical and preparative columns (PEG, 20% on Celite 545).

Reactions of Olefins with Dibromomethane in the Presence of Ni(0) Complexes and Zinc. In a 100 ml two-necked flask were placed zinc powder (8 mmol) and additives. Tetrahydrofuran (10 ml), an olefin (10 mmol), a Ni(0) complex (0.05—0.90 mmol), and dibromomethane (5 mmol) were added and the reaction mixture was stirred at room temperature for a given period of time.

Reactions of Olefins with Dibromomethane in the Presence of in situ *Generated $Ni(PPh_3)_3$ and Zinc.* In a two-necked flask were placed $NiBr_2(PPh_3)_2$ (0.5 mmol), PPh_3 (0.5 mmol), and zinc (8 mmol). Tetrahydrofuran (10 ml) was added and the mixture was stirred at room temperature. After a few minutes, the color changed from green first to yellow and soon to red-brown. The yellow color is due to the formation of $NiBr(PPh_3)_3$,[8] which is subsequently reduced to red-brown $Ni(PPh_3)_3$.[9] After 30 min, an olefin (10 mmol) and dibromomethane (5 mmol) were added and the mixture was stirred at r.t. for 24 h.

Reactions of Olefins with Dibromomethane in the Presence of in situ *Generated Nickel(0) Complexes and Zinc.* Nickel bromide (0.25—5.0 mmol), alkali halide (0—10 mmol), and zinc powder (8 mmol) were placed in the standard reaction flask. Tetrahydrofuran (10 ml) and an olefin (10 mmol) were added. The mixture was stirred and turned brown in a few minutes. After 20—30 min, dibromomethane (5 mmol) was added and the mixture was stirred at r.t. for a given period of time. If necessary, the flask was thermostated at the desired temperature before dibromomethane was added.

All cyclopropane derivatives were isolated with a Shimadzu 6A preparative gas chromatograph. Their NMR spectra and gas chromatograms agreed well with those of the authentic samples.

Results

Cyclopropanation of Electron-deficient Olefins with Dibromomethane by Ni(0) Complexes and Zinc. Electron-deficient olefins such as methyl acrylate, acrylonitrile, and methyl vinyl ketone (abbreviated as MA, AN, and MVK, respectively) were allowed to react with dibromomethane in the presence of Ni(0) complexes ($Ni(PPh_3)_4$ or $Ni(COD)_2$) to give cyclopropane drivatives.[5] The addition of Lewis acids or sodium iodide is necessary for the reactions. The effects of zinc bromide and sodium iodide on the cyclopropanation of MA, AN, and MVK are shown in Table 1. No cyclopropanation

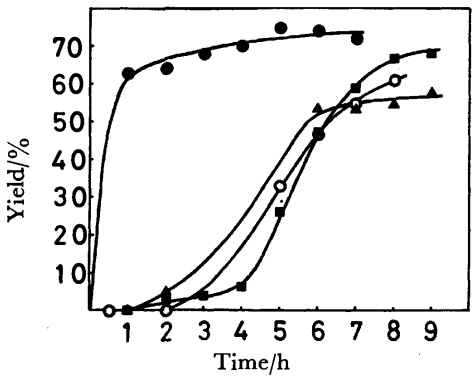

Fig. 1. Time dependence of the yields of methyl cyclopropanecarboxylate in the reaction of MA (10 mmol) with dibromomethane (5 mmol) in THF (10 ml) by the following systems; ○: $Ni(PPh_3)_4$ (0.5)/Zn (8.1)/$ZnBr_2$ (0.56); ▲: $Ni(PPh_3)_4$ (0.3)/Zn (8.1)/$ZnBr_2$ (0.15); ■: $Ni(PPh_3)_4$ (0.1)/Zn (12)/$ZnBr_2$ (0.56); ●: $Ni(COD)_2$ (0.5)/Zn (8.2)/NaI (5.0) where the number in parentheses is given as mmol values.

occurred in the absence of nickel complexes. The yields of methyl cyclopropanecarboxylate slightly increased with an increase in the amount of $Ni(PPh_3)_4$. Although zinc bromide is essential for the reaction, its increase lowers the yield. Lewis acids such as zinc chloride and iodide, and aluminium chloride were also effective,[5] but tin(IV) chloride was ineffective. Sodium iodide played a role similar to that of Lewis acids. In $Ni(PPh_3)_4$/Zn/$ZnBr_2$ or NaI system cyclopropane derivatives from MA, AN, and MVK were obtained in good, moderate, and very low yields, respectively.

The reaction of AN and MVK with dibromomethane gave cyclopropane derivatives in the presence of $Ni(COD)_2$ and NaI.[5] Zinc is required for the cyclopropanation of MA, AN, and MVK by the $Ni(COD)_2$/$ZnBr_2$ system. Sodium iodide is more effective than zinc bromide. An advantage of sodium iodide is the lack of retardation of the reaction by its excess. In $Ni(COD)_2$/Zn/NaI system a further addition of ligands *e.g.* PPh_3, 2,2'-bipyridyl (bpy), 1,10-phenanthroline (phen), lowered the yields of cyclopropanes.

The induction periods were observed in the cyclopropanation of MA by $Ni(PPh_3)_4$/Zn/$ZnBr_2$ system (Fig. 1). The decrease in the amount of $ZnBr_2$ shortens the induction period. It takes about 24 h for the consumption of dibromomethane since the rates after 6 h are very slow. With the elapse of time, zinc bromide is produced (Eq. 1), resulting in a gradual inhibition. On the other hand, the initial rate is very fast in the cyclopropanation of MA by $Ni(COD)_2$/Zn/NaI system. Three-quarters of the total yield is obtained in less than one hour.

Cyclopropanation of Electron-deficient Olefins with Dibromomethane by in situ Generated Ni(0) Complexes and Zinc. When $NiBr_2(PPh_3)_2$ was reduced with zinc in the presence of PPh_3, $Ni(PPh_3)_3$, or $Ni(PPh_3)_4$ was produced *via* $NiBr(PPh_3)_3$.[8b,9] The method serves a double

$$NiBr_2(PPh_3)_2 + PPh_3 \xrightarrow{Zn} NiBr(PPh_3)_3$$
$$\xrightarrow{Zn} Ni(PPh_3)_3 \quad \xrightarrow{PPh_3} Ni(PPh_3)_4 \quad + ZnBr_2 \qquad (2)$$

a) To Ni(0)–olefin complex prepared *in situ* from $NiBr_2$, an olefin (10 mmol), NaI, and Zn (8 mmol) in THF (10 ml) was added dibromomethane (5 mmol); the mixture was stirred for a given period of time. b) Vpc yield based on CH_2Br_2. c) MA (20 mmol), CH_2Br_2 (10 mmol), Zn (15 mmol), and THF (20 ml). d) AC: Acrylaldehyde. e) 1,2-Dimethoxyethane (10 ml) was used as solvent. f) Acetonitrile (10 ml) was used as solvent. g) CH_2I_2 (5 mmol) was used instead of CH_2Br_2.

purpose: The *in situ* generated $Ni(PPh_3)_3$ contaminates the zinc bromide formed, and then catalytic species are completely supplied in Eq. 2 in the presence of excess of zinc.

In the *in situ* generated $Ni(PPh_3)_3$/Zn system, the cyclopropane derivatives from MA was obtained in high yields and that from AN was obtained in moderate yields, but no cyclopropanes from MVK and acrylaldehyde (abbreviated as AC) were produced (Table 2).

Tetrahydrofuran is the most suitable solvent among several examined: The yield decreased in acetonitrile and none was obtained in benzene and diethyl ether.

Dibromomethane gave higher yields than diiodomethane. The yield increased appreciably for reactions with diiodomethane at 0 °C. No reaction occurred with dichlomethane. Zinc could be replaced by manganese, which was a milder reductant, to give a drop in the yield.

We have exploited an alternative catalytic system for $Ni(COD)_2$/Zn/NaI system (Table 3). When the mixture of nickel bromide, sodium iodide, and zinc was stirred in THF in the presence of an electron-deficient olefin, a red-brown solution was obtained after a few minutes. Dibromomethane was added and aliquots were analyzed at various times. A cyclopropane derivative was gradually produced with the elapse of time, in contrast to the case of the $Ni(COD)_2$/Zn/NaI system. This may be due to the slow rate of the formation of a Ni(0)–olefin complex.[10,11] The amount of sodium iodide needed for the reaction is nearly that of the cyclopropane derivative produced. Further addition of sodium iodide brought a slight increase of the yield. Sodium iodide is the most favorable promoter among the alkali halides investigated.

The yields were almost invariable or rather decreased for the cyclopropanation of MA, AN, and MVK with

an increase in the amount of nickel bromide. However the highest yield was obtained at a 1 : 2 nickel : olefin mole ratio for the cyclopropanation of AC. Lower temperatures gave higher yields of cyclopropane derivatives, due to the decrease of the ethylene formation.[12]

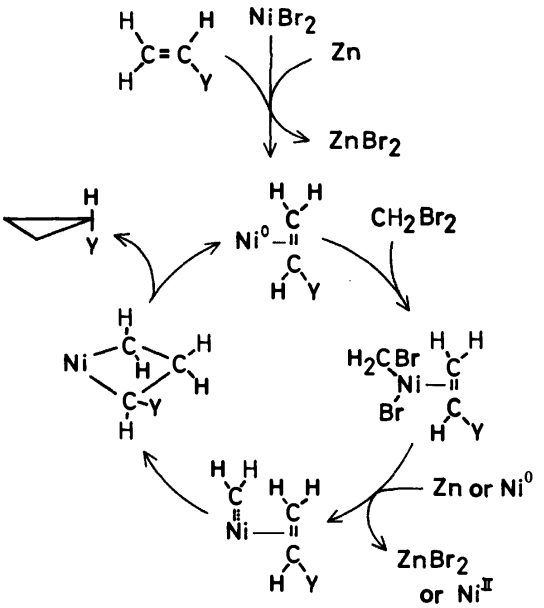
Discussion

The cyclopropanation of electron-deficient olefins with *gem*-dihalides by Ni(0) complex/Zn/Lewis acid systems has some characteristics different from the Simmons-Smith reaction:[1,3,4] (1) Electron-deficient olefins are more susceptible than electron-rich ones; (2) dibromomethane is more suitable than diiodomethane; (3) no cyclopropanation occurs in diethyl ether.

The first requisite for the cyclopropanation of electron-deficient olefins with dibromomethane is the formation of Ni(0)–olefin complexes which are not too much stabilized. Twice as much olefin as dibromomethane was used to complete the reaction of the latter. Ni(0) complexes in the form of $Ni(olefin)_2$ are isolated for olefins with highly electron-deficient groups such as CN, CHO, and $COCH_3$.[10,11] $Ni(MA)_2$ has not been isolated, but its formation in solution may be conceivable on the basis of the results in Tables 1 and 3. The Ni(0) complex of MA is suitably stabilized by further coordination of PPh_3. On the other hand, cyclopropanation of AN, MVK, and AC was inhibited in the presence of PPh_3, bpy, and phen. The inhibition may be caused by the increased stabilization due to their coordination,[13,14] or because olefins are expelled from the sphere of coordination when dibromomethane oxidatively adds to the Ni(0)–olefin complexes.[15] No reaction occurred with electron-rich olefins such as cyclohexene and vinyl acetate because of the absence of nickel–olefin complexes.[14b,17] No cyclopropanation occurred with α- or β-methyl-substituted olefins with polar groups such as methyl crotonate, methyl methacrylate, methacrylonitrile, and 4-methyl-3-penten-2-one due to their weak coordination to nickel complexes.[14b]

The reaction of ethylene with dibromomethane in the presence of Ni(0)–PPh_3 or –bpy complex gives large amounts of propylene and very little cyclopropane.[12] No olefinic products were obtained in the presence of electron-deficient olefins and dibromomethane by Ni(0) complex/Zn/Lewis acid (or sodium iodide) systems.[18] Methylene species formed from dibromethane and Ni(0) complexes[12] or alkylnickel complexes[19] have been thought to be nickel–carbene complexes on the basis of the reactions between metal–carbene complexes and olefins or alkyl groups.[20]

Metallacyclobutane complexes produced from metal–carbene species and olefins are key intermediates for the metathesis of olefins.[21] Metallacyclobutanes undergo metathesis, cyclopropanation, and olefin formation, which are affected by the nature of metals, carbene species, and olefins.[22] The reaction of metal–carbenes and electron-deficient olefins gives reductive elimination products rather than metathesis ones.[20b,c] It seems reasonable to assume that the cyclopropane derivatives from the reactions of electron-deficient



Scheme 1.

olefins and dibromomethane by Ni(0) complex/Zn/Lewis acid (or sodium iodide) systems are produced *via* nickellacyclobutanes. We have not been able to detect any nickel–carbene species.

We propose a mechanism for the cyclopropanation *via* nickellacyclobutane intermediates which are formed from Ni(0)–olefin complexes and dibromomethane. Dibromomethane oxidatively adds to a nickel metal center followed by debromination with a reduced nickel complex or zinc to produce a nickel–methylene complex. The role of Lewis acids or sodium iodide has not been clarified. Lewis acids are necessary cocatalysts in some metathesis reactions.[23] Grubbs *et al.* have found that Me_2AlCl or $AlCl_3$ interacts with titanacyclobutane to facilitate its isomerization and C–C bond cleavage.[24] Lewis acids such as zinc halides and aluminium chloride effectively promoted the cyclopropanation, but their excess hindered the reaction and lengthened the induction period. The basicity of low-valent transition-metal complexes is manifested in many examples.[25] Lewis acids may form adducts involving nickel complexes to saturate coordination sites and/or to deactivate nickel complexes. An excess of sodium iodide, which is the most effective alkali halide, is desirable, but an excess of lithium iodide is not. It is not clear now whether sodium iodide plays the same role as Lewis acids do.

Suitable solvents such as THF may give stabilization to Ni(0)–olefin and/or nickel–carbene and/or nickellacyclobutane complexes by interacting the nickel metal center, and may be easily replaced by olefins. The interaction of Lewis acids with THF may not be neglected completely.[26]

Conformational Changes of the Poly(α-L-glutamic acid)-Cu(II) Macromolecular Complexes in the pH Range 4—7. A Comparative Study by Means of Viscosity and Circular Dichroism[1)]

Tsutomu MASUJIMA,† Kiwamu YAMAOKA,* and Jin-ichiro HORI
Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received September 16, 1982)

Intrinsic viscosity, [η], and far-UV circular dichroism, CD, were measured at 25 °C for poly(α-L-glutamic acid), poly(Glu), solutions in 7.5 mM and 150 mM NaCl in the presence and the absence of copper(II) ions over the pH range 4—7, where poly(Glu) undergoes two conformational transitions. The first is the well-known helix-coil transition and the second, which is followed by completion of the helix, was attributed to the formation of aggregates. The pH dependence of [η] and molar ellipticity was analyzed with the two-state model. The helix-coil transition can not be represented by the all-or-none process. The aggregation mode of helices is predominantly the side-by-side type in 7.5 mM NaCl, but probably a mixture of the side-by-side and the head-to-tail types in 150 mM NaCl. The hydrodynamic shapes of poly(Glu) and its Cu(II)-complexes were calculated with ellipsoid, cylinder, and straight chain element models. The so-called random-coil form is an extended-coil in 7.5 mM NaCl at higher pH. The poly(Glu) helix is probably slightly shortened as compared with the α-helix.

Among the transition metal ions which bind to poly(α-L-glutamic acid), poly(Glu), the copper ion is unique in that it induces the conformational change of poly(Glu).[2-18)] Our recent studies[11-14)] have clarified that three classes of the Cu(II)–Glu residue complexes are present, and that the formation of these complexes is related to the conformational change of the poly(Glu) backbone. A light scattering study has revealed the formation of poly(Glu) aggregates in both the absence and the presence of Cu^{2+} ions in the low pH region.[18)] While the viscosity of poly(Glu) has often been measured,[19-24)] few attempts were made to interpret the conformational changes in terms of the hydrodynamic shape. For example, Go *et al.* have noted, on a qualitative basis, that the variation of the intrinsic viscosity, [η], of poly(Glu) with pH reflects several distinct changes in the backbone conformation.[20,21)] The present viscometric work aims at the quantitative interpretation of the overall conformational changes of poly(Glu) in the absence and the presence of Cu^{2+} ions. For this purpose, the variations of [η] were correlated with changes of the far-UV circular dichroism, CD, under closely paralleled conditions. Thus, the overall hydrodynamic shapes of poly(Glu) in the absence and the presence of Cu^{2+} ions could be compared with optically determined conformational changes. With reference to the previous light scattering results, we present some quantitative discussions on the axial ratio of the rodlike poly(Glu) helix, the possible aggregation mode, and the effects of the concentrations of Cu^{2+} ions and sodium chloride.

Experimental

Materials and Preparations of Sample Solutions. The sodium salt of poly(Glu), hereafter denoted simply as poly(Glu), was described elsewhere.[11)] The degree of polymerization, DP_w, of the sample for viscosity was 708,[18)] and the one for CD was nominally 610.[14)] Other chemicals were of reagent grade and used without further purification. In a given poly(Glu) or poly(Glu)–Cu(II) solution, the final concentration of HCl plus NaCl was kept constant at 7.5 mM (1 M=1 mol dm^{-3}) or 150 mM. The mixing ratio, R, was defined in the same manner as before and adjusted by changing the amount of Cu^{2+}.[11)]

Measurements. A modified Ubbelohde-type viscometer was used at 25±0.01 °C. The flow times were 264.1 and 265.9 s, respectively, for the 7.5 and 150 mM NaCl solutions which were used as solvents. A sample poly(Glu) solution (5 ml, [Glu]=8 mM) was diluted up to twentyfold by the stepwise addition of the NaCl solution to the viscometer. The initial concentration of [Glu] was reduced to 1 mM at pH values lower than 4.6 to avoid precipitation. Since no buffer reagent was used, values of pH of a given polymer solution vary slightly upon dilution. The relation between the shift of pH and the dilution of the poly(Glu) concentration was predetermined outside the viscometer, and utilized to correct the observed values of the reduced viscosity, η_{sp}/c, for an initially set pH, where c is the mass concentration of poly(Glu) in g/100 cm^3. The pH-corrected values of η_{sp}/c were then extrapolated to zero concentration to obtain [η] at the given initial pH as

$$\eta_{sp}/c = [\eta] + k_2c. \quad (1)$$

Linear extrapolations by the least-square method were possible in all cases, except for the poly(Glu) solutions in 7.5 mM NaCl at pH higher than 5, for which the Fouss plot[25)] also produced nonlinear curves. In these cases, the most likely extrapolated values were taken for [η]. The pH of sample solutions was measured on a Hitachi-Horiba N-5 pH meter under the same conditions as used for the viscosity; the measurement of the CD spectra has been described elsewhere.[11)]

Partial Specific Volume. The partial specific volume of the poly(Glu) in the presence and the absence of Cu^{2+} ions, $\bar{v}$, in the 150 mM NaCl solution was calculated with the aid of Eq. 2[26)] by using the value of the refractive index increment, dn/dc, at 436 nm.[18)]

$$\bar{v} = \left(\frac{n_1^2+2}{n_1^2-1}\right)k - \frac{6n_1}{(n_1^2+2)(n_1^2+1)}\left(\frac{dn}{dc}\right), \quad (2)$$

where n_1 is a refractive index increment of the poly(Glu) solution in 150 mM NaCl and k is the specific refraction of the solute prior to mixing with solvent. The value of k was determined to be 0.223 from Eq. 2 with a value of 0.604 for $\bar{v}$ of the poly(Glu) solution in 200 mM NaCl at a pH of 4.42[23)] and with a value of 0.1734 for dn/dc of the poly(Glu) solution

† Present address: Institute of Pharmaceutical Sciences, Hiroshima University School of Medicine, Kasumi 1-2-3, Hiroshima 734.

in 150 mM NaCl at the same pH.[18] The value of k was assumed to be constant at other R and pH values. The dependence of $\bar{v}$ on pH was assumed to be the same for the two poly(Glu) solutions, in 7.5 mM and 150 mM NaCl, for a particular value of R.

Results and Discussion

Dependence of Viscosity on pH. Figure 1 summarizes the intrinsic viscosity and the coefficient k_2 for the poly(Glu) solutions in the presence and the absence of Cu^{2+} ions. When the plot of η_{sp}/c *vs.* c is curved, k_2 was determined from the initial slope of the curved line. Values of $[\eta]$ and k_2 in 7.5 mM NaCl decrease sharply with the decrease in pH. The large value of k_2 indicates that the electrostatic interaction between ionized poly(Glu) ions is poorly suppressed at the low ionic strength; hence, the polyion may be in the highly extended-coil form in the neutral pH range. Qualitatively, the sharp decrease of $[\eta]$ in the pH region between 7 and 5.6 may be ascribed to the change from the extended- to the less extended-coil, mainly because of charge neutralization by added hydrogen ions.[20,21] An apparent plateau region for $[\eta]$ between pH 5.6 and 5.1 may also be attributed to the formation of helix for poly(Glu).[20,21] These views must, however, be verified on a quantitative basis (see below). A further decrease in $[\eta]$ after the completion of the helix (pH 5.1) may reflect the formation of aggregates.[17,18,27-30] The higher contents of Cu^{2+} ions ($R=8$) result in the lower values of $[\eta]$ over the entire pH region. This decrease should be an effect of the bound Cu(II), because almost all Cu^{2+} ions are bound to poly(Glu) at pH higher than 5.[14]

For poly(Glu) solutions in 150 mM NaCl, the behavior of $[\eta]$ is quite different from the above.[20-22] The expansion of the poly(Glu) backbone chain by the charge repulsion of ionized Glu residues is less marked at the higher ionic strength. Values of $[\eta]$ and k_2 are small, k_2 being nearly constant over the entire pH region. Each $[\eta]$ *vs.* pH curve shows a minimum at pH about 5. The curves are similar to each other in the presence and the absence of Cu^{2+} ions, but values of $[\eta]$ decrease with the decrease in R.

Far-UV CD of Poly(Glu) and Its Cu(II)-Complexes. Figure 2 shows typical far-UV CD spectra of poly(Glu) in 150 mM NaCl solutions in the presence and the absence of Cu^{2+} ions. The general characteristics are nearly the same as those in 7.5 mM NaCl solutions.[11] The CD spectra of poly(Glu) show an isoelliptic point at 203.5 nm in the pH range 7.76—4.35; however, they

(a) and (b) at 7.5 mM NaCl and (c) and (d) at 150 mM NaCl. Values of R are ∞ (poly(Glu) only) (——○), 32 (——■), 16 (——▲), and 8 (——●). Dotted curves indicate the helix fraction f_h as given by numerals.

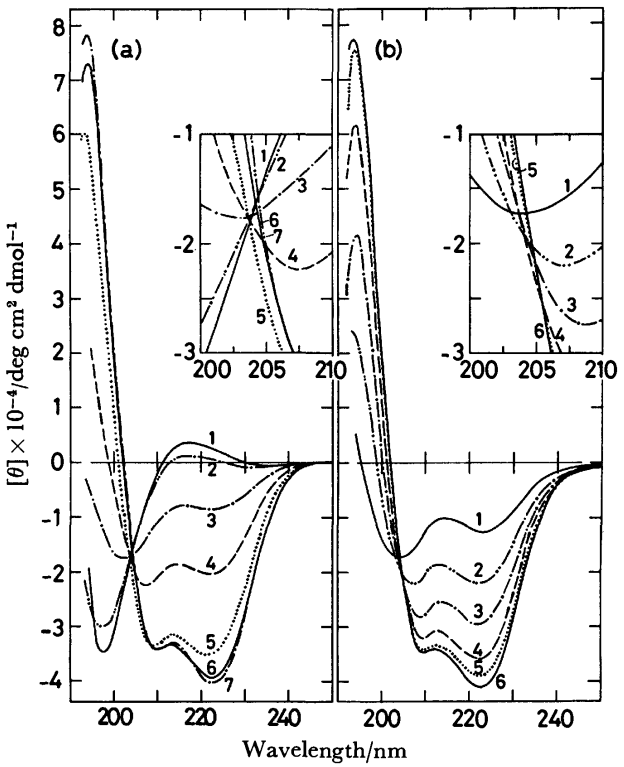

Fig. 2. The far-UV circular dichroism spectra of poly(Glu) at various pH in the absence (a) and the presence ($R=8$) of Cu^{2+} ions (b) at 150 mM NaCl. Values of pH are: (a) 7.76 for 1, 5.68 for 2, 5.21 for 3, 5.07 for 4, 4.57 for 5, 4.28 for 6, and 4.19 for 7; (b) 6.40 for 1, 5.53 for 2, 5.16 for 3, 4.90 for 4, 4.71 for 5, and 4.48 for 6. Inserts are the enlargement of the $[\theta]$ *vs.* wavelength plots in the neighborhood of isoelliptic points.

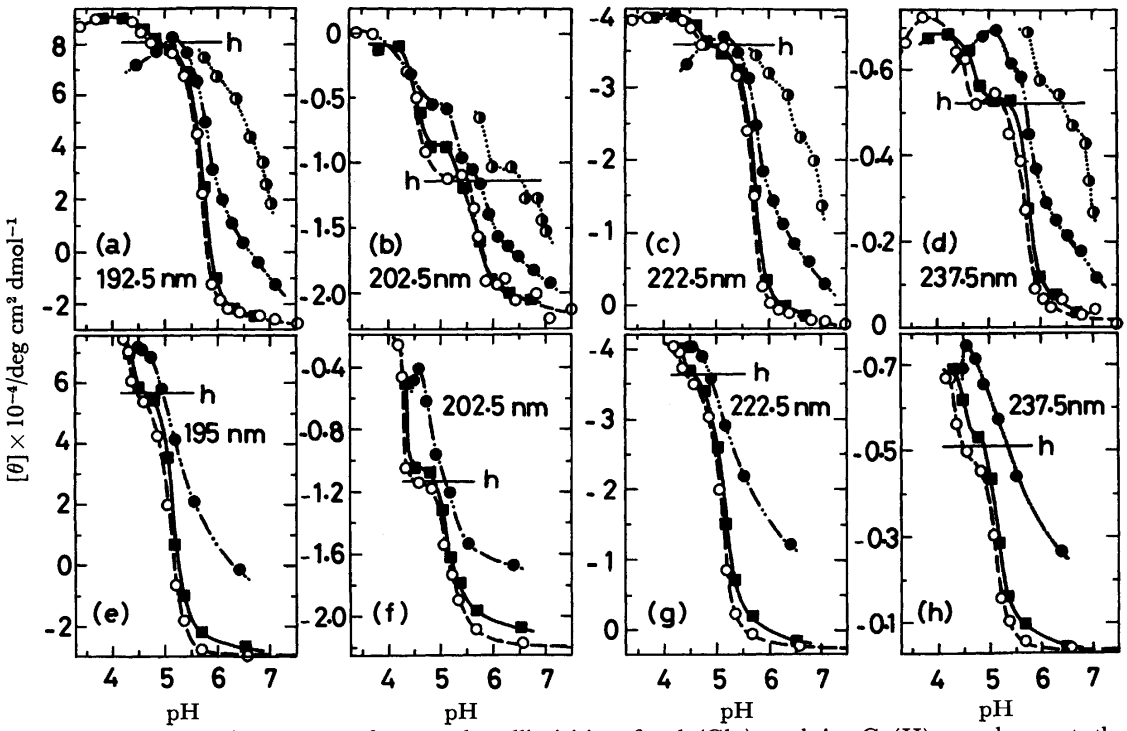

Fig. 3. The pH dependence of the molar ellipticities of poly(Glu) and its Cu(II)-complexes at the selected wavelengths at 7.5 mM ((a)—(d)) and 150 mM ((e)—(h)) NaCl. Values of R are ∞ (— — ○), 32 (——■),8 (—·—●), and 4 (·····◑). The horizontal line in each figure is the value of $[\theta]$ for which $f_h=1$.

deviate from this point at pH's lower than 4.3, showing a larger negative peak at 222.5 nm. The CD spectra of poly(Glu)–Cu(II) complexes show the isoelliptic point only in a limited pH range above 4.5 ($R=32$) or 5.16 ($R=8$). The presence of an isoelliptic point in a family of CD spectra indicates that each observed spectrum can be decomposed into two component-spectra: the helix and the coil spectra in this case.[31] The steady deviation of the isoelliptic point to higher wavelengths indicates that another conformational change is likely to occur at pH lower than 4.28 for poly(Glu) and lower than 5.6 for poly(Glu)–Cu(II). It is now clear that this spectral feature is related to the formation of aggregate helices, as observed by light scattering measurements.[18] The possible contribution of the extrinsic CD band of the bound Cu(II) to the observed molar ellipticity, $[\theta]$, is ruled out, since the CD spectra of poly(Glu) alone show the same kind of deviation.[11]

The dependence of $[\theta]$ on pH was examined at some selected wavelengths to estimate the fraction of helix formed in the poly(Glu) backbone in the presence and the absence of Cu^{2+} ions. Figure 3 shows the plots of $[\theta]$ *vs.* pH for poly(Glu) and its Cu(II)–complexes in 7.5 mM and 150 mM NaCl solutions. A two-step change in $[\theta]$ is clearly observed at each selected wavelength. (The choice of a wavelength often enlarges or conceals the stepwise change.) These two stepwise changes are less overlapped for solutions of lower ionic strength and higher R, but tend to merge to each other, as the amounts of Na^+ and Cu^{2+} ions increase.

The helix fraction, f_h, for poly(Glu) at a given pH may be calculated by the conventional method as[11,14]

$$f_h = \frac{[\theta]^c_\lambda - [\theta]_\lambda}{[\theta]^c_\lambda - [\theta]^h_\lambda}, \tag{3}$$

where $[\theta]^c_\lambda$ and $[\theta]^h_\lambda$ are the molar ellipticities of the pure coil and the pure helix states at the wavelength, λ, and $[\theta]_\lambda$ is the observed molar ellipticity of the poly-(Glu) solution at a given pH. It has been amply documented in the literature that unique assignments of values for $[\theta]^h_\lambda$ and $[\theta]^c_\lambda$ are difficult even for the standard polypeptides, poly(Glu) and poly(L-lysine);[32] however, to retain internal consistency throughout, we selected the molar ellipticity at the onset of the second transition (the one on the lower pH side) for the value of $[\theta]^h_\lambda$ and the molar ellipticity at the highest observed pH 7.76 for $[\theta]^c_\lambda$. Values of $[\theta]^h_\lambda$ are indicated by the horizontal lines in Fig. 3. The helix fraction for the poly(Glu)–Cu(II) complex was also calculated with the above values of $[\theta]^h_\lambda$ and $[\theta]^c_\lambda$. The values of pH, for which $f_h=1$, 0.75, 0.5, 0.25, and 0, were evaluated from the f_h *vs.* pH plots at several wavelengths and averaged for poly(Glu) solutions in 7.5 mM and 150 mM NaCl in the absence and the presence of Cu^{2+} ions.

In order to compare the CD data with the intrinsic viscosity, the f_h *vs.* pH plots must be evaluated at infinitely diluted poly(Glu) concentrations. This was done by making use of a previous report by Nitta *et al.*[33] Their results showed that the f_h *vs.* pH plots shift toward the higher pH side by 0.14 in pH-unit for poly(Glu) in 7.5 mM NaCl, but remain unshifted in 150 mM NaCl. In Fig. 1, the helix fractions thus estimated at infinite dilution (dotted lines) are indicated; hence, comparison

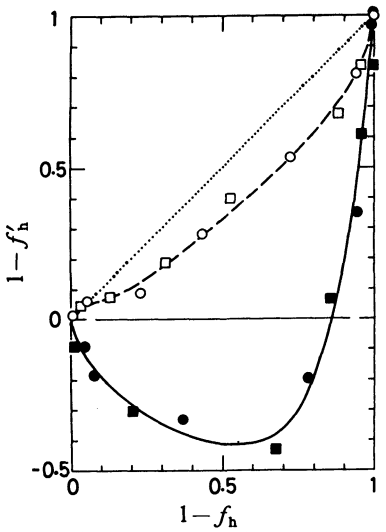

Fig. 4. Comparison of the helix fraction, f'_h, from the intrinsic viscosity with the helix fraction, f_h, from CD for poly(Glu) and poly(Glu)-Cu(II) at $R=\infty$ and 32 and at 7.5 mM (a) and 150 mM NaCl (b). For (a), $[\eta]_h=2.40$ and $[\eta]_c=6.50$ ($R=\infty$, ○) and $[\eta]_h=2.25$ and $[\eta]_c=6.50$ ($R=32$, □). For (b), $[\eta]_h=1.52$ and $[\eta]_c=2.13$ ($R=\infty$, ●) and $[\eta]_h=1.45$ and $[\eta]_c=2.13$ ($R=32$, ■). $[\eta]$'s are in 100 cm^3 g^{-1}.

of the helix fraction with the intrinsic viscosity is now possible for poly(Glu) and poly(Glu)-Cu(II) systems.

Helix Fraction and Hydrodynamic Behavior. (i) Helix-coil Transition and Viscosity: If a poly(Glu) solution contains only pure helix-polyions (the mass concentration of c_h) and pure coil-polyions (c_c), the observed reduced viscosity, $\langle\eta_{sp}\rangle/c$, where $c=c_h+c_c$, and the intrinsic viscosity, $\langle[\eta]\rangle$, may be written as[34]

$$\frac{\langle\eta_{sp}\rangle}{c}=\frac{[\eta]_h c_h+(k_2)_h c_h^2}{c}+\frac{[\eta]_c c_c+(k_2)_c c_c^2}{c}, \tag{4}$$

$$\text{and } \lim_{c\to 0}\frac{\langle\eta_{sp}\rangle}{c}=\langle[\eta]\rangle=f'_h([\eta]_h-[\eta]_c)+[\eta]_c, \tag{5}$$

where $f'_h=c_h/c$, and $[\eta]_h$ and $[\eta]_c$ are the intrinsic viscosities of the unaggregated (single-stranded) helix-polyion and the extended coil-polyion, respectively, while $(k_2)_h$ and $(k_2)_c$ are the corresponding coefficients in Eq. 1. Values of $(1-f'_h)$ were calculated with $[\eta]_h$, $[\eta]_c$, and $\langle[\eta]\rangle$, and are plotted against $(1-f_h)$ in Fig. 4, values of $(1-f_h)$ being calculated from Eq. 3. The values of $(1-f'_h)$ for poly(Glu) and poly(Glu)-Cu(II) do not fit those of $(1-f_h)$ over the entire helix-coil transition region. This result confirms that the helix-coil transition cannot be represented *hydrodynamically* by the all-or-none process of the two-state model. Hence, both partly helical and partly coil portions are contained in each polyion chain in this transition region.

(ii) Viscosity and Aggregation Process of Helices: Light scattering studies have shown that the molecular weight of poly(Glu) and poly(Glu)-Cu(II) increases very rapidly with lowering pH,[18,28] while the viscosity of poly(Glu) tends to increase or decrease in the same pH range depending on ionic strength (Fig. 1). Therefore, it is now beyond doubt that some aggregation process is involved in the pH region where the formation of helix

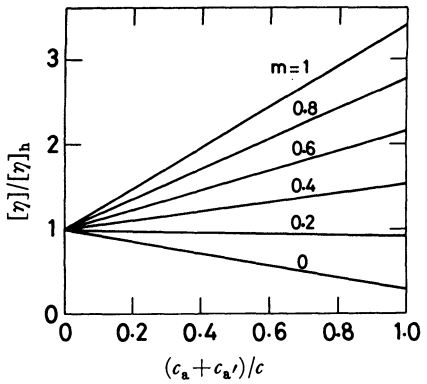

Fig. 5. The theoretical variations of $[\eta]/[\eta]_h$ with the ratio of concentrations of aggregated helices, $c_a+c_{a'}$, to the total concentration of helices, c. The parameter m is $c_{a'}/(c_a+c_{a'})$. For $m=1$ (the head-to-tail type), $L_{a'}=2124$ Å and $2b_{a'}=2b=13$ Å, and for $m=0$ (the side-by-side type), $L_a=1062$ Å and $2b_a=26$ Å, and for unaggregated helix, $L=1062$ Å and $2b=13$ Å being assumed.

is nearly completed. Aggregated helices appear to be quite cohesive against dilution, since extrapolation of scattered light intensity[18] or reduced viscosity to zero concentration of poly(Glu) exhibits no strong tendency of molecular dissociation. The mode of aggregation should be reflected on the pH dependence of $\langle[\eta]\rangle$ or $\langle\eta_{sp}\rangle/c$. Two extreme modes may be represented by the side-by-side and the head-to-tail association schemes. Here, the observed intrinsic viscosity, $\langle[\eta]\rangle$, is given as

$$\frac{\langle[\eta]\rangle}{[\eta]_h}=\frac{c_h}{c}+\frac{c_a}{c}\cdot\frac{[\eta]_a}{[\eta]_h}+\frac{c_{a'}}{c}\cdot\frac{[\eta]_{a'}}{[\eta]_h}, \tag{6}$$

where $[\eta]_a$ and $[\eta]_{a'}$, are the intrinsic viscosities for the aggregated helices of the side-by-side (unprimed) and the head-to-tail (primed) types ($c=c_h+c_a+c_{a'}$). For the rigid rodlike aggregated helix (the n-mer) consisting of n single-stranded helices (monomers), the values of $[\eta]_a$ or $[\eta]_{a'}$ may be calculated with Eq. 7 (see the later sections for detail), together with the appropriate numerical values for the length L and the diameter $2b$.

In order to illustrate the viscometric behavior in the helix-aggregate region (Fig. 1), we utilize Eq. 6 for an assumed simple system of the monomer-dimer equilibrium. Figure 5 shows that the quantity $\langle[\eta]\rangle/[\eta]_h$ decreases with formation of the side-by-side aggregates, but increases with formation of the head-to-tail aggreates. This result is qualitatively in accord with the observed relationship between $[\eta]$ and pH in Fig. 1, indicating that the aggregated poly(Glu) or poly(Glu)-Cu(II) helices are predominantly the side-by-side type in 7.5 mM NaCl, but probably a mixture of both this and the head-to-tail type with a slight chain overlap in 150 mM NaCl. Interchain hydrogen bonds of the acetate dimer type, chelation by Cu(II),[14] and hydrophobic bonds between undissociated side-chain carboxyl groups belonging to different poly(Glu) chains are all attractive forces, favoring formation of the aggregated helices. Indeed, these structures are supported by CPK atomic model building. We are at present unable to specify if the aggregation is the all-or-none process, as

assumed in the present discussion, or if it resumes the open association process, in which aggregated helices elongate lengthwise and become thicker in diameter simultaneously, with lowering of the pH. This is partly because the fractional change of formed aggregates with pH cannot be evaluated by the CD method, in contrast with the result for the helix-coil region (Fig. 4).

Hydrodynamic Shape of Poly(Glu) and Cu(II)-Complexes. Since the two-state model is inadequate for the pH-variation of $[\eta]$, the hydrodynamic shape of poly(Glu) in the presence and the absence of Cu^{2+} ions must be estimated, by use of appropriate models, from values of $[\eta]$ and $\bar{v}$. In the following calculation, the poly(Glu) sample is assumed to be monodisperse as regards the molecular weight.[35]

(i) Undeformable Ellipsoid and Cylindrical Models: As a coarse approximation, the shapes of the poly(Glu) and its Cu(II)-complexes may be assumed by the undeformable prolate ellipsoid of revolution with the axial ratio $p(=a/b)$, where a is the major semi-axis and b is the minor semi-axis. Simha's equation may be employed:[36]

$$[\eta] = \bar{v}\left\{\frac{p^2}{15[\ln(2p)-m]} + \frac{p^2}{5[\ln(2p)-m+1]} + \frac{14}{15}\right\}, \quad (7)$$

where $m=1.5$ for the ellipsoid of revolution, and $m=1.8$ for a long cylinder. Since the results for values of p are almost the same, only the case of ellipsoid is shown in Fig. 6. The apparent axial ratios decrease with the increase in helix fraction. Thus, the hydrodynamic shape of poly(Glu) may be interpreted as being changed from the extended-coil ($p \simeq 160$) to the less extended-coil in the 7.5 mM NaCl solutions and from the less extended- to the shrunk- or compact-coil in 150 mM NaCl solutions, probably because of charge neutralization by added protons and Cu^{2+} ions (especially, at low values of R), and because of charge suppression by added Na^+ ions (in the case of 150 mM NaCl).

If an appropriate value is assigned to b, the length of the cylindrical or ellipsoidal macroion, L, may be estimated. Two extreme values of 10 Å and 16 Å are used for $2b$ in the present calculation. (The distance between the α-carbon and the oxygen of the side chain carboxylate is about 8 Å.) Figure 7 summarizes the results, in which "extended-coil" indicates the upper limit of the length of the polyion in its most extended-form (2560 Å). This limiting value is given by the length of a Glu residue (3.62 Å) multiplied by the weight-average degree of polymerization (708), which was obtained from light scattering.[18] The lengths of the poly(Glu) coil in 7.5 mM NaCl and at neutral pH are in the range of 1500—2400 Å, depending on the hydrodynamic diameter $2b$. This result indicates that the backbone chain is rather elongated in 7.5 mM NaCl, and that the poly(Glu) ions are not in the so-called random-coil state. (This is the reason why we use the term extended-coil). In 150 mM NaCl solution, the

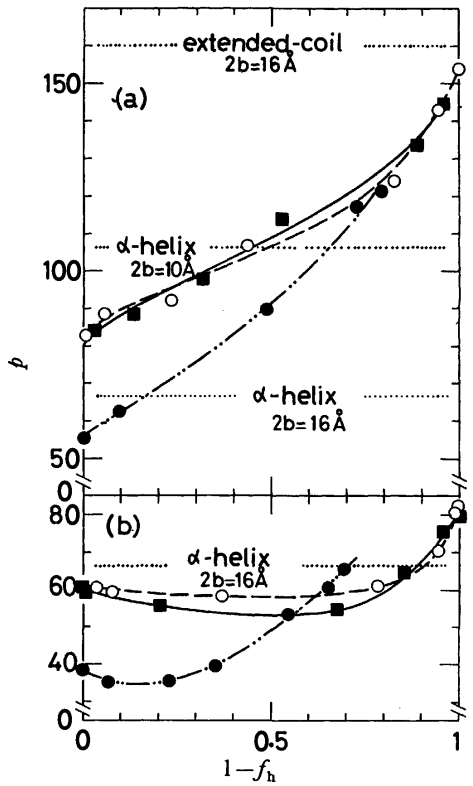

Fig. 6. The dependence of the axial ratio p on the helix fraction f_h of poly(Glu) and poly(Glu)-Cu(II) at 7.5 mM (a) and 150 mM NaCl (b). Values of R are ∞ (——○), 32 (——■), and 8 (——●).

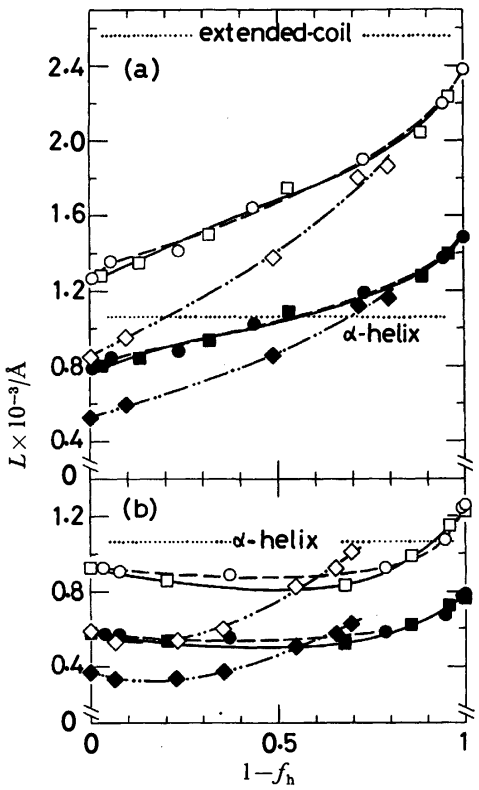

Fig. 7. The dependence of the length of poly(Glu) and poly(Glu)-Cu(II), L, calculated with the cylindrical model on the helix fraction f_h at 7.5 mM (a) and 150 mM NaCl (b). Values of R are ∞ (circles), 32 (squares), and 8 (diamonds). Two extreme values of 10 Å (filled symbols) and 16 Å (open symbols) are assumed for $2b$. The dashed lines indicate the length of α-helix (1062 Å) and that of extended-coil (2560 Å), these lengths being independent of values of $2b$.

poly(Glu) coil is much less extended even at neutral pH.

The possible length for the α-helix is also indicated in Fig. 7 with the horizontal lines, by using a value of 1.5 Å per Glu residue for the axial translation. It is clear that the overall length of the poly(Glu) chain calculated from the viscometric data critically depends on the choice of values of $2b$.[35] If the unhydrated and unaggregated α-helix is assumed for the conformation of poly(Glu), the value of $2b$ would be 13 ± 1 Å in 7.5 mM NaCl, but it would be an unrealistically large value of 20 ± 1 Å in 150 mM NaCl (Fig. 7). On the other hand, the most likely value of $2b$ is probably 11 ± 1 Å, as judged from CPK atomic model building for the unhydrated α-helix. Hence, if poly(Glu) or its Cu(II)-complexes are rigid and rodlike in shape at or near the completion of helix (f_h=0.9—1.0), the helical conformation should not be perfectly α-helical. It should be a slightly shortened helix in the low salt concentration, the length per residue, L/res, being about 1.3 Å instead of 1.5 Å. A more distinct deviation from the α-helix is evident in 150 mM NaCl, the L/res being about 1.0 Å. The effect of bound Cu(II) on the L/res value is also quite large. An alternative interpretation of the results in the helix region (f_h=0.9—1.0) is given as follows: The conformation of poly(Glu) and its Cu(II)-complexes is not perfectly rigid, but is partially broken or semi-flexible even at or near the 100% helix content in aqueous solutions.

(ii) Wormlike Model: As a typical example, Kuhn's straight element model is examined:[37]

$$[\eta] = \frac{A_m d^2 N_A}{M_g} \cdot \frac{0.43\,Z}{-1.6+2.3\log(A_m/d_h)+\sqrt{d/A_m}\sqrt{z}}, \quad (8)$$

where A_m is the length of the straight line chain element, d and M_g are, respectively, the actual length and the molecular weight of the monomeric unit, Z is the degree of polymerization, d_h is the hydrodynamic thickness, and N_A is Avogadro's number. The value of d_h was again assumed to be 10—16 Å under the same consideration as above. The value of d in Å is given by Eq. 9 as a function of helix fraction; the α-helix (at f_h=1) and the most extended chain (at f_h=0) are assumed.

$$d = 1.5f_h + 3.62(1-f_h). \quad (9)$$

The dependence of A_m on f_h is shown in Fig. 8. In the coil region, the length of each straight line chain element is about 200 Å at 7.5 mM NaCl, whereas it is about 80 Å at 150 mM NaCl. The extension of the coil conformation due to the charge repulsion of ionized carboxylate groups is suppressed by the excess salt ions. The smaller value of A_m at R=8 may be explained as being due to the bound Cu(II) folding the backbone chain by the charge suppression and chelation.[11-14] For the $R=\infty$ and 32 solutions, the shortest straight chain elements are 180—190 Å, a value about 15-fold smaller than the contour length, in the region where $0.1<f_h<0.4$, and for the R=8 solution the A_m value is about 150 Å in $0.6<f_h<0.8$ region. Values of A_m depend on the salt conditions greatly. This result should be taken as indicating that the formation of partial helices in the helix-coil region causes a poly(Glu) chain to contract, and that each straight chain element

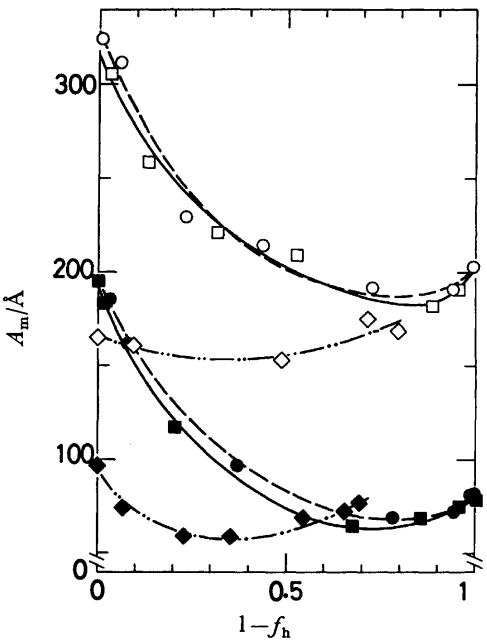

Fig. 8. The dependence of the straight chain element A_m of poly(Glu) chain on pH at 7.5 mM (open symbols) and 150 mM NaCl (filled symbols). Values of R are ∞ (circles), 32 (squares), and 8 (diamonds). The d_h value of 10 Å was used in these calculations.

becomes shorter with more of such elements at a higher salt concentration. As the longer helices are formed at higher f_h, values of A_m increase; however, these values should be only nominal in the high f_h region where this model is unsuitable.

Conclusion

The helix fraction estimated from the far-UV CD data does not correspond linearly to the helix fraction evaluated from viscometric data. Thus the all-or-none conformational transition is unlikely to occur in aqueous added-salt solutions of poly(Glu) and its Cu(II) complexes. At the same helix fraction, the overall conformations of poly(Glu) and poly(Glu)-Cu(II) are not necessarily the same, but depend on pH and the concentrations of Na^+ and Cu^{2+} ions. At a low concentration of salt, the poly(Glu) chain is in an extended-coil in the neutral pH region and the aggregated helices are likely to be of the side-by-side type in the low pH region. At a high salt concentration, the conformation of poly(Glu) seems to be compact in the helix-coil intermediate region. The added Cu^{2+} ions also accelerate the shrinking of poly(Glu) conformation by inducing helix fragments. This shrinking effect should result from intra- and inter-molecular chelations of Cu(II),[14,18] and thus it can be correlated to the appearance of the characteristic absorption band in the helix-coil intermediate region.[11-14]

A Kinetic Study on the Conformational Change of Bovine Serum Albumin Induced by Sodium Dodecyl Sulfate

Kunio TAKEDA

Department of Applied Chemistry, Faculty of Science, Okayama University of Science, 1-1 Ridai-cho, Okayama 700

(Received September 16, 1982)

Stopped-flow measurements were made on the conformational change of bovine serum albumin induced by sodium dodecyl sulfate in a buffer solution containing 3.33 mmol/dm^3 NaH_2PO_4 and 3.56 mmol/dm^3 Na_2HPO_4 (pH 7.0, μ=0.014). The protein adopted a conformation with a smaller helical content than the original native state (helix to coil transition) upon the addition of the surfactant. The rate of transition depended strongly on the surfactant concentration. The results were compared with those of conformational changes of other proteins, in which a helical structure increased in the surfactant solution (coil to helix transition). It is noticeable that the value of the activation entropy is negative in the helix to coil transition, as compared with its positive and large values in the coil to helix transition. It seems that the binding of the surfactant to the protein causes the transition to only a particular conformation of the protein *via* each individual process.

The interactions of surfactants with proteins are interesting *per se*, and so have been extensively investigated.[1,2] However, kinetic studies of the interactions have been neglected. Recently, the kinetic aspects of these interactions have been studied by Wyn-Jones and his coworkers.[3-5] They paid attention to the behavior of the surfactant molecules associated with their binding to macromolecules. Conformational changes of protein polypeptides induced by the binding of surfactants are also interesting. With respect to the conformational changes of proteins, the addition of ionic surfactants such as sodium dodecyl sulfate (SDS) causes either an increase or a decrease of helix content, depending on the nature of the proteins.[6-13] More recently, Takeda and his coworkers have studied the kinetic aspects of the conformational changes of a synthetic homopolypeptide[14,15] and the increase of the helix content of some proteins[16,17] in surfactant solutions. They reported characteristic processes in which the native conformation directly turns to a particular conformation without passing through other conformations.

In this work, a kinetic study was carried out on the conformational change of bovine serum albumin (BSA), which had been reported to adopt a conformation with a smaller helix content than its native state upon the addition of ionic surfactants such as SDS.[9-13]

Experimental

Crystalline BSA and SDS have been described elsewhere.[12] The concentration of the protein was determined spectrophotometrically using $E^{1\%}_{cm}$=6.8 at 280 nm.[18] A sodium phosphate buffer of pH 7.0 was exclusively used (μ=0.014). The final concentrations of NaH_2PO_4 and Na_2HPO_4 in the buffer were 3.33×10^{-3} and 3.56×10^{-3} M (1 M=1 mol/dm^3). The critical micelle concentration of the SDS was determined by the electric conductance method to be 8.3×10^{-3} M in pure water and 5.6×10^{-3} M in the buffer (25 °C).

Static measurements of ultraviolet absorbance were made with a Hitachi double-beam spectrophotometer, Model 220A. The absorbance stopped-flow measurements were carried out with a stopped-flow apparatus, RA-401 of Union Giken Co. equipped with a kinetic data processor, RA-450. The circular dichroism measurements were made with a JASCO J-500A spectropolarimeter equipped with a JASCO DP-501 data processor.[12]

Throughout the measurements, the protein concentration was kept at 1.0×10^{-5} M. The aqueous solution of the protein was used within 6 h of preparation.

Results

Prior to the stopped-flow measurements, the conformational change of the BSA was examined by circular dichroism measurements. Figure 1 shows the circular dichroic spectra of the protein in the absence and the presence of SDS. All of the spectra showed a double negative maximum, which is characteristic of an α-helical structure, although the magnitude of the ellipticity decreased with an increase of SDS. The protein did not lose all of its helical structure[19] and had a constant magnitude of ellipticity above 7.0 mM SDS. However, the predominant loss of the helix content occurs up to 3.5 mM, as seen in Fig. 1. The ultraviolet absorbance change accompanying the conformational change of the protein is shown in Fig. 2. The blue-shift was observed and the difference spectrum had a positive peak around 265 nm and a negative one at 288 nm.

The stopped-flow measurements were carried out at these two wavelengths. Representative time depend-

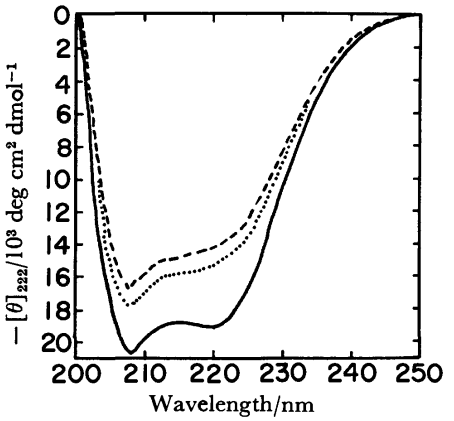

Fig. 1. Typical circular dichroic spectra of BSA in the absence (solid curve) and the presence of 3.5 mM (dotted curve) and 7.0 mM (dashed curve) SDS at 25 °C. These spectra were obtained over 8 repetitions.

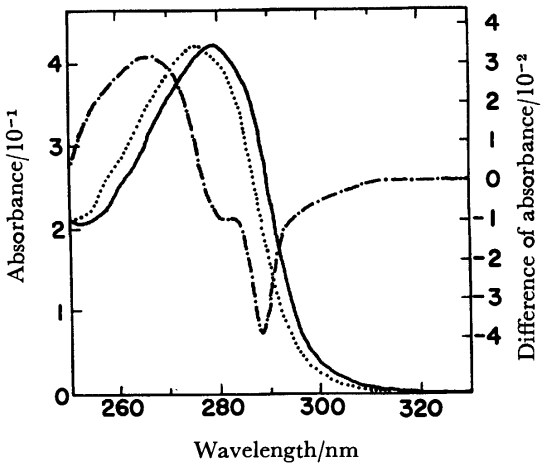

Fig. 2. Typical absorbance spectra of BSA in the absence (solid curve) and the presence of 7.0 mM SDS (dotted curve) and the difference spectrum of them (dot-dashed curve) at 25 °C.

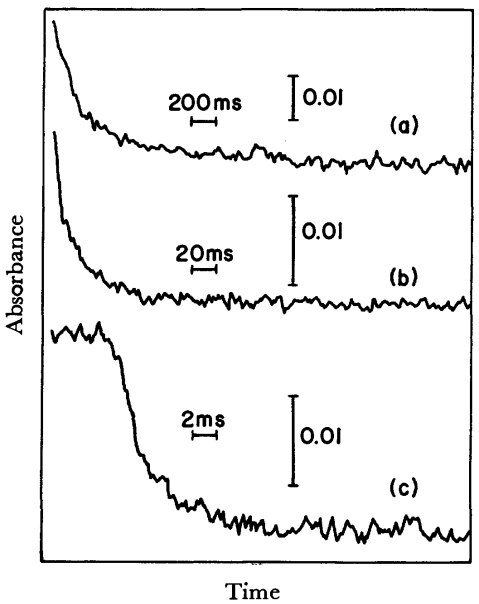

Fig. 3. Representative time courses of absorbance changes at 288 nm. Final concentrations of BSA and SDS were 1.0×10^{-5} M and 3.5 (a), 5.0 (b), and 10.0 mM (c), respectively. The trace (c) is the average of 4 repetitions.

ances of the absorbance changes are shown in Fig. 3. As expected from the absorbance change in Fig. 2, the absorbance decreased with time at 288 nm (as seen in Fig. 3) and increased at 265 nm (not shown here). As clearly recognized in Fig. 3, the rate of the absorbance change became faster with an increase of SDS. Unfortunately, the rate of the conformational change of BSA was too fast to be measured by a circular dichroism stopped-flow method.[14-17] However, it was apparent in previous work[16,17] that the absorbance stopped-flow measurements give identical rates with those obtained by the circular dichroism stopped-flow ones, and the behavior of chromophores such as tryptophan and tyrosine is useful in following the conformational

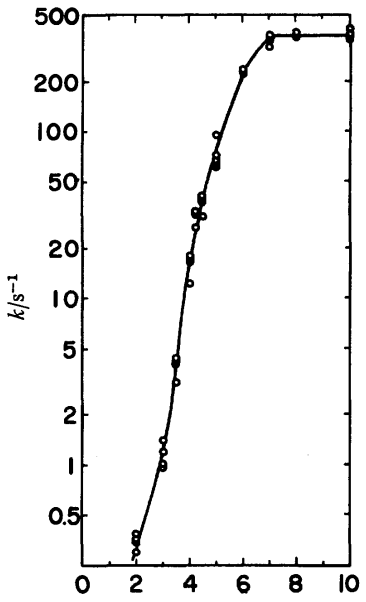

Fig. 4. SDS concentration dependance of rate constant, k, at 25 °C.

TABLE 1. KINETIC PARAMETERS FOR CONFORMATIONAL CHANGES OF PROTEINS IN SDS SOLUTION

	Temperature/°C	Helix to Coil (BSA)	Coil to Helix (δ-Chymotrypsin)
	20	240	0.085
k/s^{-1}	25	370	0.29
	30	470	0.70
ΔH^*/kJ mol^{-1}		48	140
ΔS^*/J K^{-1} mol^{-1}		−34	160

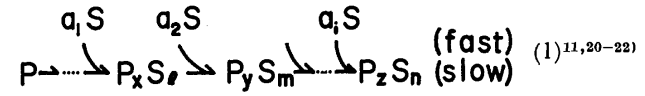
changes of proteins. This is also emphasized when we take account of a similarity of the SDS concentration dependance of the absorption coefficient of the protein at 288 nm to that of the residue ellipticity at 222 nm.[12] Therefore, the absorbance change with time is considered to correspond to the rate of the conformational change of the protein. The first-order rate constant, k, was obtained by the usual treatment.[14] The SDS concentration dependance of k is represented in Fig. 4. The rate constant, k, sharply increased with an increase of the SDS concentration and attained a constant value around 7 mM SDS. The temperature dependance of k was examined at 10 mM SDS in order to evaluate activation parameters of the conformational change. The activation parameters, ΔH^* and ΔS^*, were calculated in the usual manner.[17] Table 1 shows the activation parameters together with those for the conformational change of delta-chymotrypsin.[17]

Discussion

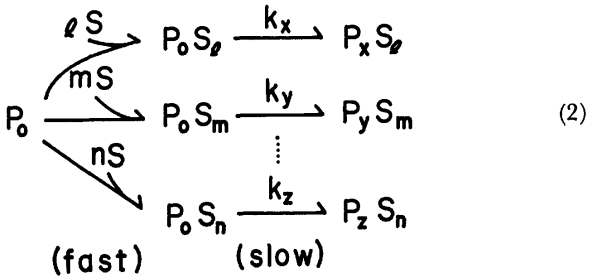
Kinetic studies were made on the conformational change of BSA induced by SDS. The protein loses some parts of the helical conformation (termed the helix to coil transition). This conformational change accompanies the change of the ultraviolet absorbance, as seen

in Fig. 2. The rate constant, k, of the conformational change was obtained by the absorbance changes with time. The value of k strongly depends on the SDS concentration, indicating that the greater the degree of the conformational change, the faster the rate of the conformational change. This tendency also appears in a conformational change of delta-chymotrypsin, in which the helix content increases upon the addition of SDS (termed the coil to helix transition).[17]

The next two processes may be expected for conformational changes of proteins in a solution of surfactant such as SDS,



(1)[11,20-22]



(2)

where P_0: a native protein, S: a surfactant molecule, a_i: a particular number, P_xS_l, P_yS_m,$\cdots$, P_zS_n: complexes (the helix content decreases in the order of x, y, $\cdots$, z in this case), l, m, n: binding numbers of surfactants to a protein, k_x, k_y, k_z: rate constants. In this case, the protein designated by P_0 has the most abundant helical conformation and the complex designated by P_zS_n has the least helix content. If the conformational change proceeds *via* reaction (1) which has been often assumed for the formation of these complexes,[11,20-22] the longest time is required for the transition from P_0 to P_zS_n. However, the transition to P_zS_n with the least helical conformation is faster than those to the intermediate species, as seen in Fig. 4. As discussed before, a protein cannot adopt various different conformations as reaction intermediates in the presence of a ceratin quantity of SDS.[17] This is because the surfactants rapidly bind to a protein,[3-5,23] causing the transition only to a particular conformation of the protein. Reaction (2) indicates that the binding of the surfactant to a protein is completed before the conformational change of the protein,[24] and that the conformation of the protein changes together with the many surfactant molecules bound to it. The bulky hydrophobic groups of the surfactant are obliged to come into maximal contact with the hydrophobic parts of the other surfactants and the protein polypeptide. The saturated binding of SDS would reduce the freedom of choice in adopting a final conformation. On the contrary, the protein with the unsaturated binding of SDS may take much time to choose a final conformation, because this situation necessarily needs more redistribution of the bound surfactants to unoccupied binding sites than in the saturated binding stage. As a result, the rate of the conformational change seems to become faster with an increase of the bound surfactant. It is considered that the conformation of a protein does not change *via* the process expressed by the reaction (1). The reaction (2) appears to be suitable for the understanding of the kinetic aspects of the conformational change of a protein induced by a surfactant such as SDS.

SDS binding to the BSA proceeds in two steps.[12] Under the present condition, the initial binding of about 115 mol of SDS per mole of BSA completes around 4 mM of total SDS and the second binding of a further 90 mol of SDS goes to completion around 7 mM of total SDS (see Fig. 5 in Ref. 12). It is noticeable that the rate constant, k, becomes constant above 7 mM SDS where the binding of SDS saturates (Fig. 4). The stepwise natures of the SDS binding and the conformational change of the protein must be correlated with the fact that the protein has at least two independent domains.[25-29] Jones *et al.* have proposed that the binding initially occurs mainly to the C-terminal section of BSA and then the more stable N-terminal part begins to be bound.[29] In the light of their proposal, it seems that the conformational change occurs only in the C-terminal part of the protein in the initial binding stage (below about 4 mM SDS under the present condition). The rate of the conformational change in the saturated binding stage is faster by two or three orders of magnitude than those in the initial binding stage, as seen in Fig. 4. However, the difference between the rates of conformational changes would not relate to the original stabilities of the C- and N-terminal sections of the protein because of the following reason. Since all of the bindings to both the C- and N-terminal parts occur at the same time in the time scale of the conformational change as mentioned above, the conformations of all of the parts are forced to change together and simultaneously in the sense of reaction (2).

One of the purposes of this work is to make clear distinctions between the helix to coil and the coil to helix transitions. The value of k for the helix to coil transition increases more sharply with an increase of the SDS concentration (Fig. 4), compared with those of k for the other transition.[16,17] In addition, the rate of the helix to coil transition is clearly faster than those of the other one as seen in Table 1, although few kinetic studies have been made on the conformational changes of proteins. The difference between both the transitions is also distinct in their kinetic parameters, as seen in Table 1. The value of ΔH^* for the helix to coil transition is about one-third of that of the other. In particular, it should be noted that the value of ΔS^* is negative in the helix to coil transition, while it is positive and large in the other one. As discussed previously,[17] in the case of the conformational changes induced by the surfactant, the entropic change must reflect not only the folding and unfolding of the protein polypeptide, but also both the rearrangement of the surfactants bound to the polypeptide and the solvent-ordering around the hydrophobic groups of the surfactant exposed to an aqueous environment. Therefore, it seems that the former contribution to the entropic change is

defeated by the latter two of the surfactants, which must be negative, in the activation state of the conformational change of the BSA. It has been considered that a large-scale conformational change of protein-surfactant complex occurs in the coil to helix transition, that is, a part of the polypeptide chain is unfolded, followed by a continuous refolding in the activation state.[17] Compared with this, the helix to coil transition may proceed in a rather simple way.

The kinetic studies of conformational changes of polypeptides made to date[14-17] have strongly suggested that, when a certain number of surfactants bind to a protein, the native conformation of the protein directly transforms into another particular conformation without passing through any intermediate conformation such as may be induced below the binding number mentioned above. This is quite a different feature from the sense of reaction (1) which may be favorable for an interpretation of the gradual growth of complexes.

(Received September 17, 1982)

By considering the charge distribution function around the ion, the effect of the finite size of the solvent molecule can be introduced in the homogeneous dielectric continuum model. A very simple and useful model is presented. The results of this model are compared quantitatively with the experimental Walden products of some simple cations in water, methanol, ethanol, acetone, and acetonitrile solutions, and found to be satisfactory.

There has been a lot of theoretical work on the dielectric friction using the continuum model.[1-5] It has been shown that some of these theories succeed qualitatively.[6-7] Most of the authors of these works regarded the surrounding medium as a dielectric continuum extending up to the surface of the ion. Due to this assumption, dielectric continuum theories do not consider the short range order around the ion correctly. The finite size of the solvent molecule has not yet been properly treated in dielectric continuum theories.

In this article, we will develop a dielectric continuum model without empirical parameters by taking the finite size of the solvent radius into consideration. By introducing the similar treatment of the molecular theory by Wolynes[8] into the dielectric continuum model, we can achieve a very simple and useful model for the dielectric friction theory. We will show that this model is successful for some ion-solvent systems.

Description of the Dielectric Drag Coefficient

We will start from the consideration of the polarization of a volume element at point $\boldsymbol{r}$ due to the electric field originating from the ion. The force exerted on the ion by this induced polarization at point $\boldsymbol{r}$, $\boldsymbol{f}(\boldsymbol{r})$, can be written as[8]

$$\boldsymbol{f}(\boldsymbol{r}) = -2q^2 \frac{\varepsilon_0 - \varepsilon_\infty}{4\pi\varepsilon_0^2} \frac{\boldsymbol{r}}{r^5}, \tag{1}$$

where q is the charge of the ion, ε_0 the static (low frequency) dielectric constant of the solvent, ε_∞ the optical (infinite frequency) dielectric constant of the solvent, and $r=|\boldsymbol{r}|$.

On the other hand, when the ion moves in a potential with relaxation time τ_d, the drag coefficient, $\Delta\zeta$, originating from this electrostatic interaction is expressed by[8]

$$\Delta\zeta = k\tau_d. \tag{2}$$

Here k is the force constant of this potential and the harmonic potential is assumed. This constant, k, can be derived from the differential coefficient of the total electrostatic force, $\boldsymbol{F}$, which acts on the ion, when the ion is displaced a small distance δz from the center of this potential. Namely,

$$k = \left(\frac{\partial \boldsymbol{F}}{\partial z}\right)_{z=0}, \tag{3}$$

where the total force, $\boldsymbol{F}$, is expressed by the sum of the contribution of the polarizations, $\boldsymbol{f}(\boldsymbol{r})$, which are induced on each volume element. When we carry out this summation, we must consider the charge distribution around the ion. For the use of Eq. 1, we will introduce the charge distribution function $\rho(\boldsymbol{r})$ which is normalized in such a way that $\rho(\boldsymbol{r})$ is equal to 1 at large r. Therefore, k can be expressed by the following equation:

$$k = \int \mathrm{d}^3\boldsymbol{r}\rho(\boldsymbol{r})\left(\frac{\partial f(\boldsymbol{r})}{\partial z}\right)_{z=0} = \int_0^\infty \mathrm{d}r \int_\Omega \mathrm{d}\Omega\rho(\boldsymbol{r})\left(\frac{\partial f(\boldsymbol{r})}{\partial z}\right)_{z=0}, \tag{4}$$

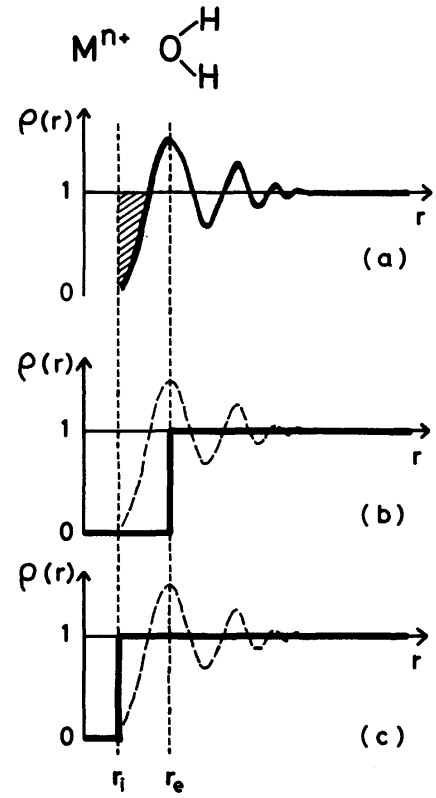

Fig. 1. Schematic charge distribution function around the ion, $\rho(r)$. (a) "Exact" charge distribution. The shaded region indicates the underestimated region of the previous works. (b) Step-wise charge distribution for $r_e=R_{M-O}$. (Eq. 5) (c) Charge distribution for the previous works.

where d^3r is the differential volume element and $d\Omega$ is the angular part of the differential volume element. Considering the effect of the finite size of the solvent radius corresponds to the consideration of the oscillation of $\rho(r)$ (see Fig. 1). In Wolynes' treatment, $\rho(r)$ was calculated by the molecular dynamics method. It can be seen that the distribution function of their model was selected strictly. By introducing a suitable model, we can take the effect of the oscillation of $\rho(r)$ into the continuum theory. For simplicity, we will take the step function for $\rho(r)$ as

$$\rho(r) = \rho(r) \begin{cases} = 0 & \text{for } r < r_e \\ = 1 & \text{for } r \geq r_e, \end{cases} \quad (5)$$

where r_e is the first peak position of the charge distribution function contributing to the induced polarization. This step function, Eq. 5, can take roughly the effect of the first trough of $\rho(r)$ which is shown by the shaded region of Fig. 1-a. The value of $\rho(r)$ at the first peak is larger than 1 and that at the second trough is smaller than 1, *etc.* Therefore, the use of the step function, Eq. 5, possibly underestimates the effect of the first peak and overestimates that of the second trough, *etc.* But these effects partly cancel with each other. So we can use this equation as a first approximation.

By referring to Eq. 5, the drag coefficient, $\Delta\zeta$, is expressed by the following equation:

$$\begin{aligned} \Delta\zeta &= \tau_d \int_0^\infty dr \int_\Omega d\Omega \rho(r) \left(\frac{\partial f(r)}{\partial z}\right)_{z=0} \\ &= \tau_d \int_{r_e}^\infty dr \int_\Omega d\Omega \left(\frac{\partial f(r)}{\partial z}\right)_{z=0} \\ &= \frac{2}{3} q^2 \frac{\varepsilon_0 - \varepsilon_\infty}{{\varepsilon_0}^2} \frac{\tau_d}{{r_e}^3}. \end{aligned} \quad (6)$$

If we replace r_e with the radius of the ion in Eq. 6, this formula will be identical with the results obtained by Zwanzig's theory,[4] which can be regarded as the essence of the dielectric friction theories.

The values of r_e can be obtained from the distance between the center of the ion and the center of the atom that belongs to the first nearest neighbor molecules, *i.e.*, in the case of the aqueous solution, the distance between the ion and the oxygen atom, R_{M-O}. We can take the R_{M-O} data of some of the electrolyte aqueous solutions from X-ray diffraction analyses.[9-14] The R_{M-O} data from the X-ray studies agree well with the sum of the crystalline ion radius and the van der Waals' radius of an oxygen atom.

Results and Discussion

We will examine Eq. 6 with the R_{M-O} values which are used for r_e. R_{M-O} values are taken as the sum of the crystalline ion radius and the van der Waals' radius of the nearest atom of the first nearest neighbor molecule. The other parameters used in the following results are taken from Refs. 15—23. The results of the calculations using the Walden product,[24] $\lambda_0\eta$, are shown in Figs. 2 and 3 in the case of aqueous solutions. Here λ_0 is limiting ionic equivalent conductance: $\lambda_0 = Fq/\zeta$ (F is the Faraday constant) and $\zeta = 4\pi\eta r_i + \Delta\zeta$ (η is the bulk viscosity of the solvent). The results in the case of the solution of some other solvents are also shown in Figs. 4 and 5.

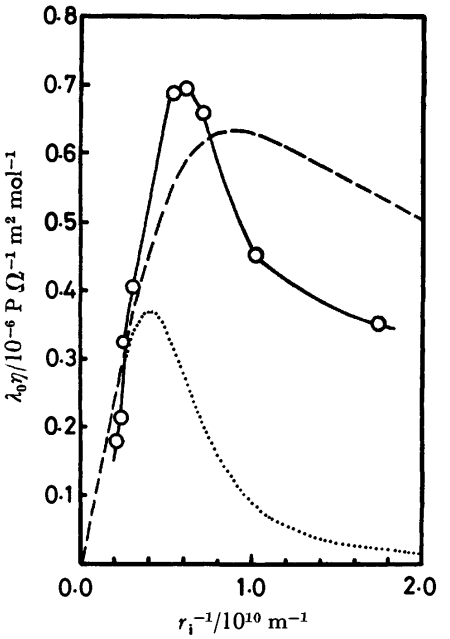

Fig. 2. Experimental (—○—) and calculated (----; $r_e = R_{M-O}$, ·····; $r_e = r_i$) Walden products for the alkali metal and tetraalkylammonium ions in water solutions. The experimental values indicate Li^+, Na^+, K^+, Rb^+, Cs^+, $(CH_3)_4N^+$, $(C_2H_5)_4N^+$, $(C_3H_7)_4N^+$, and $(C_4H_9)_4N^+$, from right side to left side [1 P=0.1 Pa s (in the unit of the vertical axis)].

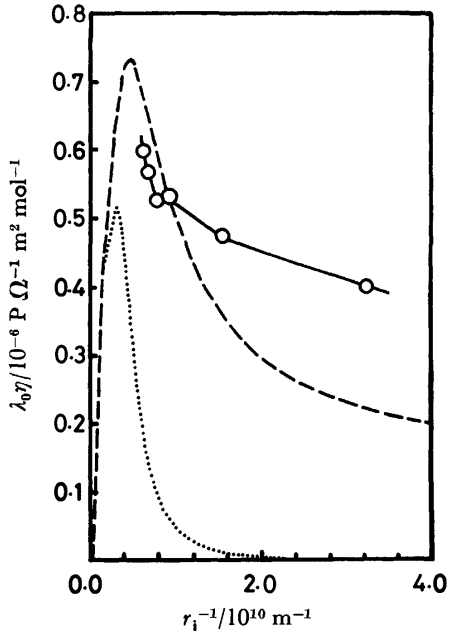

Fig. 3. Experimental (—○—) and calculated (----; $r_e = R_{M-O}$, ·····; $r_e = r_i$) Walden products for the alkaline earth metal ions in water solutions. The experimental values indicate Be^{2+}, Mg^{2+}, Sr^{2+}, Ba^{2+}, and Ra^{2+}, from right side to left side [1 P=0.1 Pa s (in the unit of the vertical axis)].

Figure 2 shows the observed[15,16] and calculated $\lambda_0\eta$

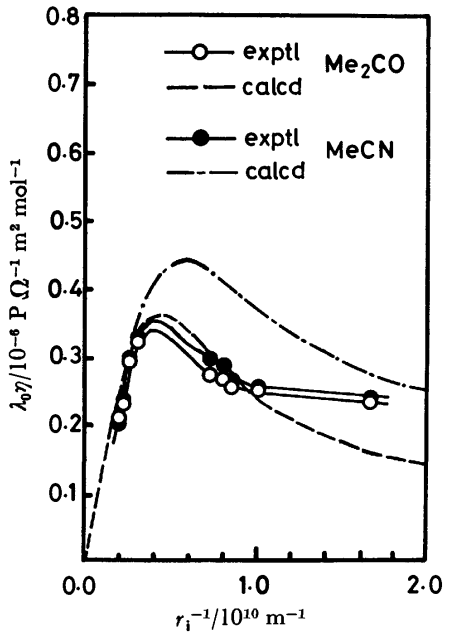

Fig. 4. Experimental and calculated Walden products for the alkali metal and tetraalkylammonium ions in acetone (Me_2CO) and acetonitrile (MeCN) solutions. The experimental values indicate Li^+, Na^+, K^+, Rb^+, Cs^+, $(CH_3)_4N^+$, $(C_2H_5)_4N^+$, $(C_3H_7)_4N^+$, and $(C_4H_9)_4N^+$, from right side to left side [1 P=0.1 Pa s (in the unit of the vertical axis)].

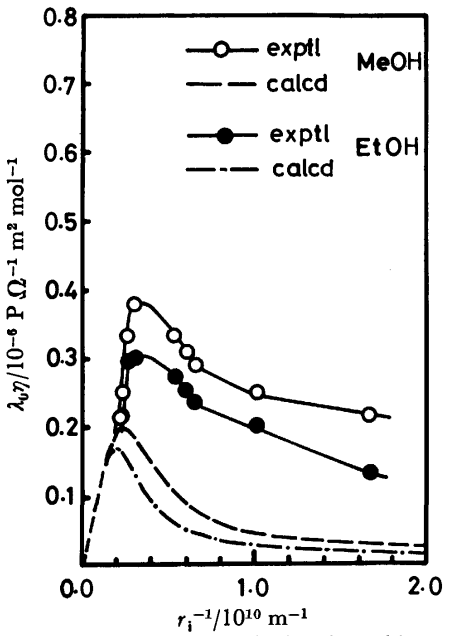

Fig. 5. Experimental and calculated Walden products for the alkali metal and tetraalkylammonium ions in methanol (MeOH) and ethanol (EtOH) solutions. The experimental values indicate Li^+, Na^+, K^+, Rb^+, Cs^+, $(CH_3)_4N^+$, $(C_2H_5)_4N^+$, $(C_3H_7)_4N^+$, and $(C_4H_9)_4N^+$, from right side to left side. The experimental value of $(C_4H_9)_4N^+$ in ethanol solution is lacked [1 P=0.1 Pa s (in the unit of the vertical axis)].

values for the aqueous solutions of some (1+) ions. It can be seen from Fig. 2 that the calculated values agree well with the observed ones. Figure 2 shows also the calculated values using Zwanzig's formula[4] ($r_e=r_i$). Fig. 3 shows the data of the Walden products for the aqueous solutions of some (2+) ions. It shows better agreement than the case of (1+) ions, except for Be^{2+} and Mg^{2+} ions. We can see from this fact that the contribution of the electrostatic interaction will be the main effect for the case where the ion has larger electronic charge than a (1+) ion with the same radius. Figure 4 shows the observed[15,16,18] and calculated Walden products of the (1+) ions dissolved in acetone or acetonitrile. They agree well, as is the case in water. In the case of methanol and ethanol, however, our results do not agree with the observed results,[15,16] as shown in Fig. 5.

Latimer *et al.*[25] and Stokes[26] discussed the problem of the short range order around the ion on the solvation enthalpy. Considering the small region around the ion whose dielectric constant is different from the "bulk" dielectric constant, they have corrected the Born's equation[1] and fitted the calculated solvation enthalpy to the observed one. It is surely important for the ionic mobility problem also that the physical properties around the ion are different from "bulk" ones. But these treatments have some empirical parameters such as the size of the region. Therefore, in this article, we will discuss the ionic mobility problem without such empirical parameters and consider the importance of the charge distribution around the ion.

Wolynes *et al.* gave the results of their molecular theory on the ionic mobility problem.[8] Our results for the case of water and acetonitrile agree well with theirs. It is surprising that a very simple description of the charge distribution function such as Eq. 5 can express the force exerted on the ion well. The advantage of our approach is that it needs only simple parameters.

A theory that regards the surrounding medium as a dielectric continuum extending up to the surface of the ion, like Zwanzig's,[4] is not sufficient. For example, such a theory gives a Walden product of Li^+ ion about 20 times smaller than the one observed in water solution. As compared with this, our treatment of dielectric friction using the very simple charge distribution function agree quite well with observed data quantitatively. This indicates that the short range order around the ion is important for electrostatic interaction. This can be anticipated from the consideration of the r_e dependence of $\Delta\zeta$ in Eq. 6. The same situation occurs in the other dielectric friction theories.[1-3,5,6]

In contrast with the good agreement of the case of water solution *etc.*, our model for the methanol or ethanol solution does not agree with experimental data quantitatively. An effort to make agreement by varying the R_{M-O} value results in physically unreasonable figures. Therefore, some other effect must be involved in these alcohols. The dielectric relaxation times of methanol (69 ps) and ethanol (144 ps) are 1—2 orders larger than that of water (9.3 ps).[16,17] This indicates that some other relaxation time governs the exerted force relaxation, *e.g.*, the translational relaxation time pointed out by Wolynes.[8] The disagreement of our calculation for methanol and ethanol (Fig. 5) may correspond to this possibility.

The calculated Walden products of Be^{2+} and Mg^{2+} of aqueous solution do not agree with observed ones as well as those for the other (2+) ions (Fig. 3). The ionization potential (IP) data[27] suggests the existence of the specific interaction between Be^{2+} or Mg^{2+} and water molecules. The electron affinities of Be^{2+} (18.2 eV) and Mg^{2+} (15.0 eV) are larger than the first IP of water molecule (12.8 eV). Therefore, it is possible that the charge transfer from water molecule to the Be^{2+} or Mg^{2+} ion occurs in the aqueous solutions. This fact suggests that there are two types of cations, *i.e.* Be^{+} or Mg^{+} and H_2O^{+} ion, in these aqueous solutions. The *ab initio* SCF calculation of Mg^{2+}–H_2O system[28] indicates that the charge transfer from H_2O to Mg^{2+} occurs. The atomic population of Mg^{2+} obtained from this calculation is 10.058.

The results shown here indicate that the charge distribution function must be used when we consider the dielectric friction quantitatively. For closer quantitative discussion, the exact (and/or experimental) charge distribution function is necessary. But the simple treatment of the charge distribution like Eq. 5 is sufficient to describe the dielectric friction quantitatively. This fact suggests that the consideration of the electrostatic interaction at the short range order around the ion is important for the macroscopic dielectric friction theories.

The authors would like to thank Prof. P. G. Wolynes of the Univ. of Illinois and Prof. Y. Udagawa of the Institute for Molecular Science for helpful discussions and a critical reading of this manuscript.

Vibration-rotation Spectra of Formamides

Yoko SUGAWARA,† Yoshiaki HAMADA, and Masamichi TSUBOI*
Faculty of Pharmaceutical Sciences, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received October 6, 1982)

Taking advantage of the Fourier transform infrared (FTIR) spectrophotometry in accumulating a very weak available radiation, which comes out from a multiple-reflection-type gas-cell (17 m), we have been able to record the infrared absorption spectrum of formamide ($HCONH_2$ or $DCONH_2$) at room temperature, where its vapor pressure is only 0.1 Torr (1 Torr≈133.322 Pa) in the order of magnitude. From an analysis of the rotational structure (resolution 0.5 cm^{-1}) of the C-H stretching band, a revised set of parameters has been obtained. A Q-branch analysis was made for the $v=2\leftarrow0$ and $v=3\leftarrow1$ bands (resolution 0.24 cm^{-1}) of the amino wagging vibration, where v is its vibrational quantum number. The rotational constants $A-B$ were determined to be 2.0269 cm^{-1} for the $v=2$ state and 1.9990 cm^{-1} for the $v=3$ state, and the transition frequencies 657.7_5 cm^{-1} for $v=2\leftarrow0$ and 769.8_5 cm^{-1} for $v=3\leftarrow1$. On the basis of these new parameter values, a discussion was made of the amino wagging coordinate of this molecule.

The molecular structure of formamide is now precisely known through a microwave study of Hirota *et al.*[1] as well as previous investigations cited by them. The microwave spectrum was observed, not only for the ground-state molecule, but also for a few lower-lying vibrational excited states. It is desirable, however, to observe its vibration-rotation transitions directly by the infrared spectroscopy, to ellucidate intramolecular potential and vibration-rotation interaction in detail. Thanks to the recent FTIR (Fourier transform infrared spectrophotometry) technique, we have succeeded for the first time in observing vibration-rotation spectrum of formamide at room temperature. At room temperature, the vapor pressure of formamide is very low (only 0.1 Torr in the order of magnitude), and an optical path as long as 17 m which is obtained by the use of a multiple-reflection-type gas cell is needed. This causes a very low infrared radiation energy available. By accumulating (1000 times, for example) interferograms of such a weak radiation, however, we could reach a sufficiently good spectrum.

Previous works of the infrared spectrum of formamide vapor were all done at higher temperatures; for example, at 126 °C[2] or 180 °C.[3] At these temperatures, some disturbing emissions, hot-band absorptions, and impurity bands (from decomposition products, *etc.*) may often be generated from the sample system.

Experimental

$HCONH_2$ was purchased from Inumaru Co., Ltd. and $DCONH_2$ from Merck Sharp and Dohme, Canada Ltd. These were used after being dried in vacuum. The sample was placed in a multiple-reflection cell of Wilks Scientific Corporation. Its optical path was set at 17.25 m. Infrared absorption measurement was made with a Nicolet 7199 FT-IR system. The resolution was set at 1.0 cm^{-1} (Figs. 1 and 2), at 0.5 cm^{-1} (Fig. 3), or at 0.24 cm^{-1} (Figs. 4 and 5). For each spectral measurement, the interferometer was scanned 1000 times, and each interferogram was accumulated for Fourier transform.

Results and Interpretations

Whole Vibrational Spectrum. In Figs. 1 and 2, the whole spectra (4000—400 cm^{-1} region) of $HCONH_2$ and $DCONH_2$ are reproduced with a lower dispersion.

For many bands, the fine structures are found to be rather simple. If the band is of A-type or A-B hybrid, the central Q-branch is readily identified. When the Q-branch peaks are sharp enough, the frequencies of such peaks were determined with errors less than ±0.2 cm^{-1}. Therefore, the fundamental frequencies of such bands were determined rather precisely without any detailed analyses (although a slight difference between

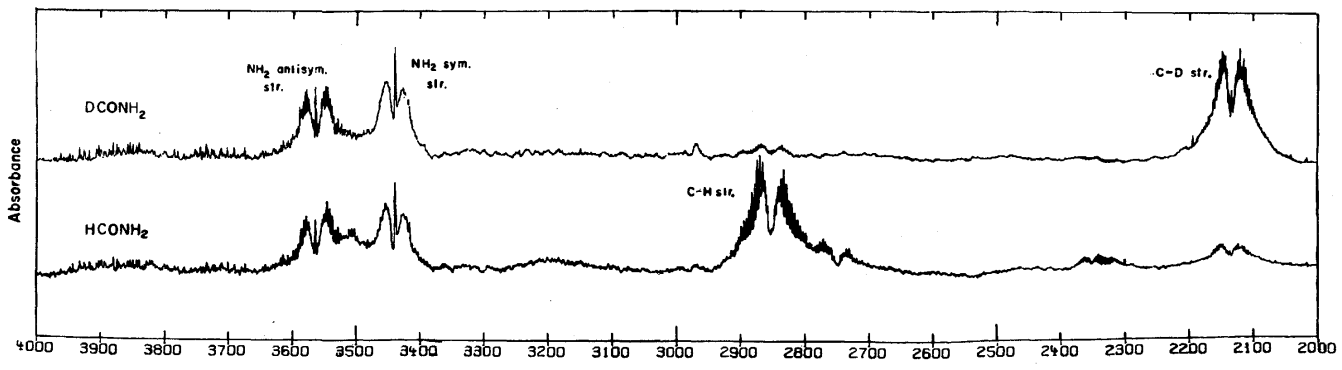

Fig. 1. Infrared absorption spectra (4000—2000 cm^{-1} range) of $HCONH_2$ and $DCONH_2$ in gaseous states. Pressure, vapor pressure at 20 °C. Optical path length, 17.25 m. Resolution, 1.0 cm^{-1}.

† Present address: The Institute of Physical and Chemical Research, Wako, Saitama 351

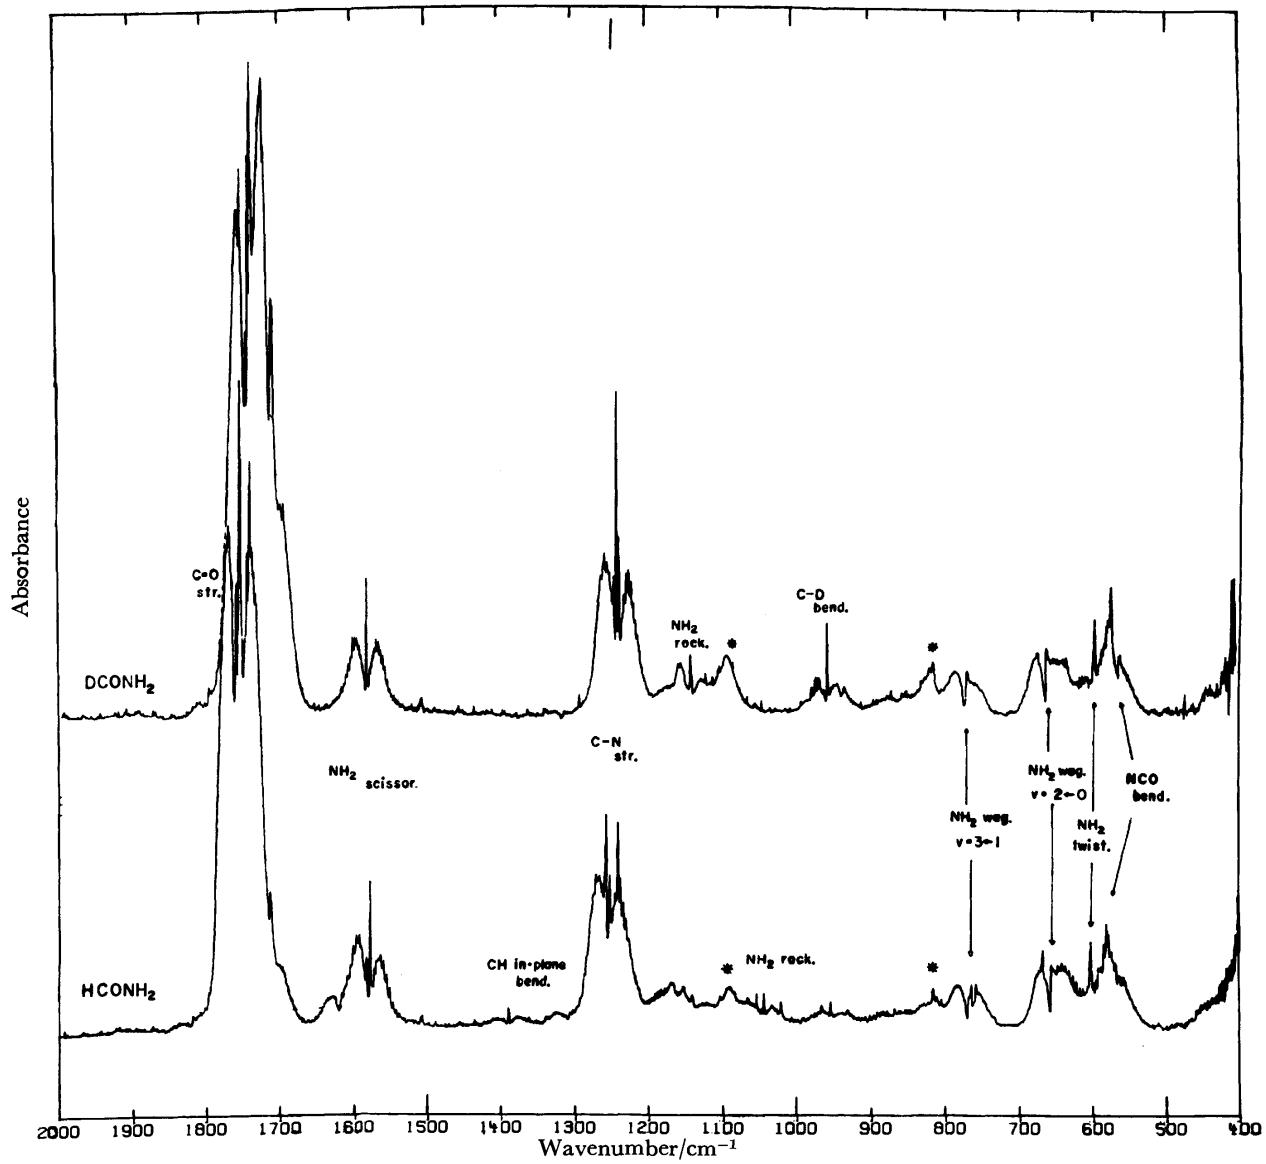

Fig. 2. Infrared absorption spectra (2000—400 cm^{-1} range) of $HCONH_2$ and $DCONH_2$ in gaseous states. Pressure, vapor pressure at 20 °C. Optical path length, 17.25 m. Resolution, 1.0 cm^{-1}. The peaks with* are probably due to impurity.

the Q-peak and band center frequencies must be taken into account). For other bands, however, some ambiguity (given in the footnotes of Table 1) remains in locating the band centers, and therefore in fixing the fundamental frequencies with any greater accuracy than ± 1 cm^{-1}. In Table 1, the fundamental frequencies are listed with these uneven accuracies. The data in the table will be useful in a detailed study of the force field of this molecule in its completely free state.[4]

CH Stretching Band. The band at 2854 cm^{-1}, assignable to the C–H stretching vibration of $HCONH_2$, is an example of what shows relatively simple structure, as shown in Fig. 3. This is a nearly pure B-type band. This is understandable because the C–H bond is directed nearly along the B axis of the molecule. The band consists of a progression of peaks assignable to Q-branch clusters, whose J-structures are not resolved because $\bar{B}'-\bar{B}''$ is small. Evans[2] reported his analysis of this progression with a lower resolution, and we now revise it as follows: Our new K-numbering is given in Fig. 3; this was fixed by forming combination differences for a few trial sets of assignments. As may be seen in the figure, ${}^{R}Q_9$ and ${}^{P}Q_{11}$ peaks are both broader and lower than the neighboring peaks. This probably means that the upper $K'=10$ state has an anomaly. Such a correspondence (of ${}^{R}Q_9$ and ${}^{P}Q_{11}$), on the other hand, may be taken as another support to the assignment. By assuming that the rotational energy is given by $(A-\bar{B})K^2-D_KK^4$, combination relation,

$$({}^{R}Q_K-{}^{P}Q_K)/4K = (A'-\bar{B}') + D_K(2K^2+2) \qquad (1)$$

is derived, where the centrifugal distortion constant D_K is assumed to have an equal value in the upper state to that in the lower state. By the use of this relation, the upper state rotational constant $A'-\bar{B}'$ has been determined to be 2.060 ± 0.003 cm^{-1}, and $D_K=(0.38\pm 0.04)\times 10^{-4}$ cm^{-1}. From a similar combination relation, the lower state rotational constant $A''-\bar{B}''$ came out to be 2.070 ± 0.003 cm^{-1}, which is in agreement with what was determined by the microwave spectroscopy

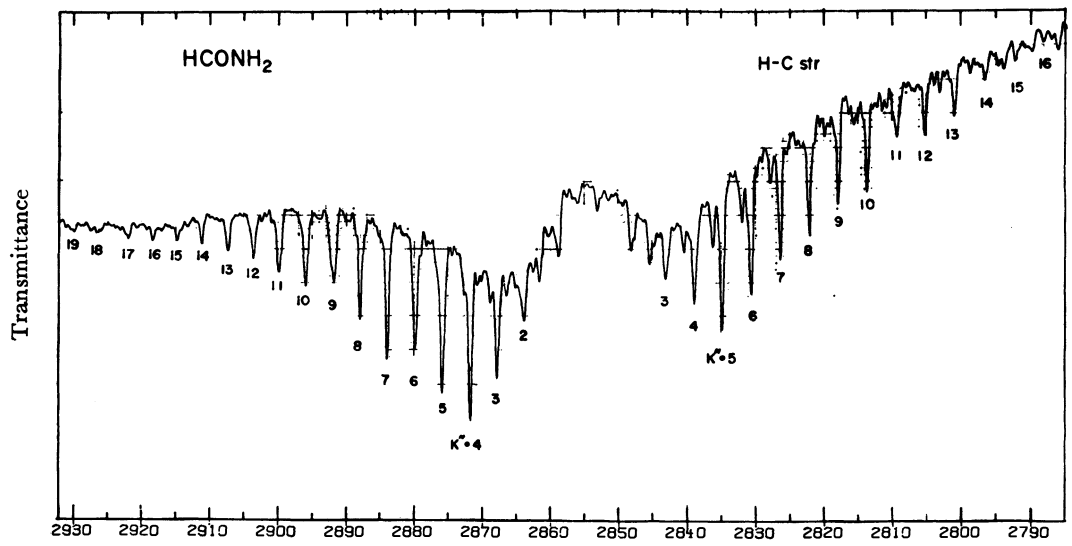

Fig. 3. Fine structure of the absorption band of $HCONH_2$ at 2854 cm^{-1} assignable to the C–H stretching vibration. At the vapor pressure of 20 °C. Optical path length, 17.25 m. Resolution, 0.5 cm^{-1}.

Table 1. Observed frequencies assignable to the fundamental vibrations of $HCONH_2$ and $DCONH_2$

Frequency ν/ cm^{-1}		Assignment[a]
$HCONH_2$	$DCONH_2$	
In-plane modes		
3563.5	3563.2	NH_2 antisym. stretching
3439.3	3437.8	NH_2 sym. stretching
2853.6		CH stretching
	2135.0	CD stretching
1754.1	1739.6	CO stretching
1576.9	1582.4	NH_2 scissoring
1390.2		CH bending
	955.0	CD bending
1258.2	1241.8	CN stretching
1045.6[b]	1142.4	NH_2 rocking
581[c]	563[c]	NCO bending
Out-of-plane modes		
1021.2[d]		CH out-of-plane deformation
	——[e]	CD out-of-plane deformation
602.8[c]	591.4[c]	NH_2 twisting
(288.7)[f]		NH_2 wagging

a) Ref. 4. b) Band shape is anomalous, probably for a Coriolis coupling with the $v=3$ level of NH_2 wagging. c) NCO bending and NH_2 twisting levels are considered to be involved in a Coriolis interaction, and therefore no reliable band center determination is possible for these bands in our present resolution. d) The assignment is not sufficiently supported. e) CD out-of-plane deformation band is considered to be too weak for our present observation or hidden under another band. f) Not observed in the present study. This is what was observed by King[3].

(2.0705 cm^{-1}). Finally, the band center frequency has been determined with a considerable precision: $\nu_0 = 2853.63 \pm 0.10$ cm^{-1}.

Overtone Bands of Amino Wagging Vibration. King[3] observed the far-infrared spectrum of $HCONH_2$ in the 200—450 cm^{-1} region, and found three peaks at 288.7, 368.6, and 401 cm^{-1}. These were assigned by Hirota *et al.*[1] respectively to the $v=1\leftarrow0$, $2\leftarrow1$, and $3\leftarrow2$ transitions of the amino wagging vibration. They also proposed[1] to assign a band at 660 cm^{-1} reported by King[3] to $v=2\leftarrow0$ and that at 770 cm^{-1} to $v=3\leftarrow1$ of the amino wagging vibration. These two bands have been observed in our present study with a higher resolution (0.24 cm^{-1}) and with an expanded wavenumber scale. The results are reproduced in Figs. 4 and 5. It is readily seen that both of these are primarily A-type bands; P and R progressions with apparent average spacings of about 0.7 cm^{-1}, which is nearly equal to $2\bar{B}$, are recognized. It is noticeable that the central Q-branch absorption shows a distinct K-structure in each of these two bands. This fact means that the rotational constant $A-\bar{B}$ is appreciably different in the upper amino wagging state from that in the lower state. The K-numbering given in Figs. 4 and 5 was fixed by calculating simulation spectra with a number of trial sets of rotational constants, and by comparing the calculated intensity distribution among the Q-branch lines with what was observed. The calculation was made with a HITAC M200-H in the Computer Center, University of Tokyo, by the use of programs BC2 and ENVLOP written by Dr. T. Nakagawa, and our own plotter program. The frequency of each of these ${}^{Q}Q_K$ peaks is approximately given by

$$ {}^{Q}Q_K = \nu_0 + [(A'-\bar{B}')-(A''-\bar{B}'')]K^2, \qquad (2) $$

and practically independent of the $\bar{B}'$ and $B'-C'$ values. Because the $A''-\bar{B}''$ values (for $v=0$ and 1) are known,[1] the band center ν_0 and $A'-\bar{B}'$ are readily fixed:

$\nu_0 = 657.7_5$ cm^{-1} for the $v = 2 \leftarrow 0$ band,

$\nu_0 = 769.8_5$ cm^{-1} for the $v = 3 \leftarrow 1$ band,

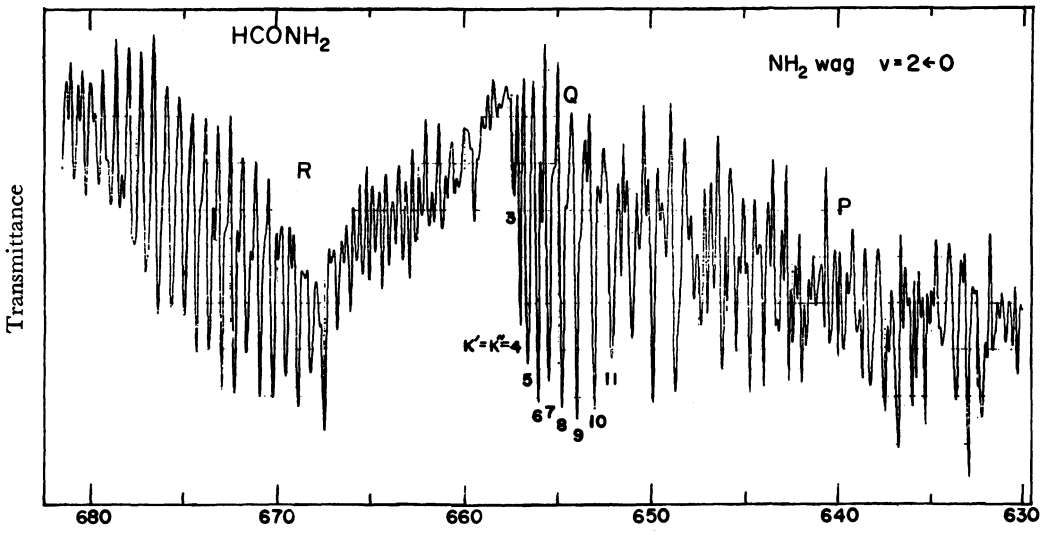

Fig. 4. Fine structure of the absorption band of $HCONH_2$ at 658 cm^{-1} assignable to the $v=2\leftarrow0$ transition of the amino wagging vibration. At the vapor pressure of 20 °C. Optical path length, 17.25 m. Resolution, 0.24 cm^{-1}.

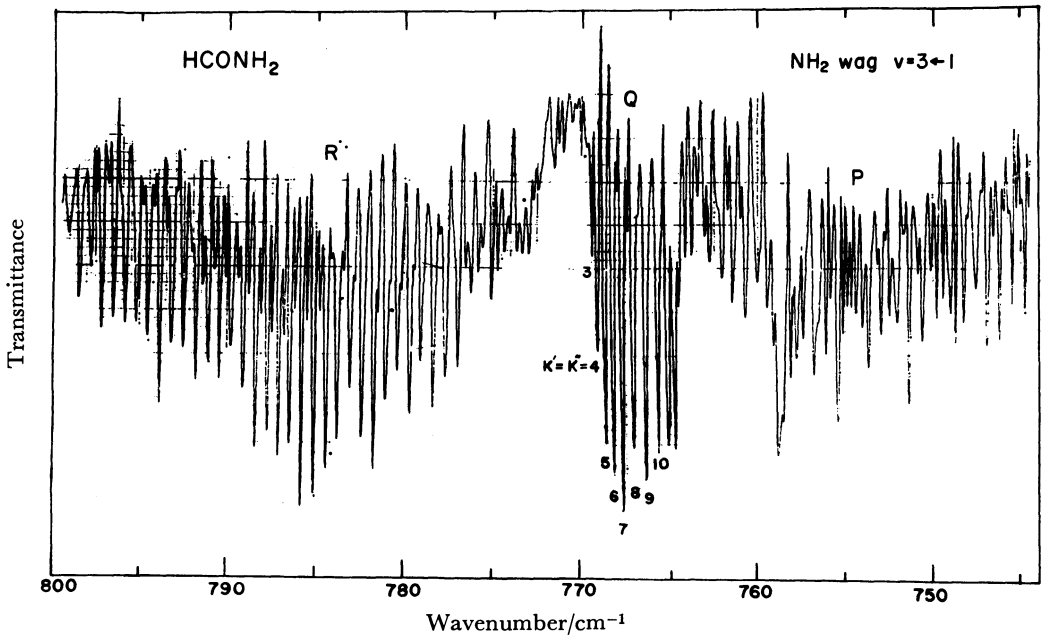

Fig. 5. Fine structure of the absorption band of $HCONH_2$ at 770 cm^{-1} assignable to the $v=3\leftarrow1$ transition of the amino wagging vibration. At the vapor pressure of 20 °C. Optical path length, 17.25 m. Resolution, 0.24 cm^{-1}.

$A - \bar{B} = 2.0269\ cm^{-1}$ for the $v = 2$ state,

and

$A - \bar{B} = 1.9990\ cm^{-1}$ for the $v = 3$ state.

It should be pointed out that an anomaly in the Q-branch progression of the $v=3\leftarrow1$ band is apparent at $K=11$, 12, and a few subsequent K values. Here, the spacings are smaller than they ought to be and intensity distribution is also different from what is expected (see Fig. 5). This is considered to be caused by an A axis ($\Delta K=0$) Coriolis coupling between the $v=3$ level (A'', at 1058 cm^{-1}) of the amino wagging vibration, now in question, and the first excited state (A', at 1045 cm^{-1}) of the amino rocking vibration. If the $A-\bar{B}$ value in the latter state is assumed to be 2.0719 cm^{-1} (equal to the $A-\bar{B}$ value of the ground vibrational state), the accidental coincidence of the unperturbed rotational levels should take place at about $K=14$ of the two vibrational states. The observed band shape of the 1045 cm^{-1} band is also anomalous.

Next an estimation of the $\bar{B}'$ values was made. The $\bar{B}'$ value is reflected in the apparent spacing of the P branch progression. Because of the K-structure of each P branch ($\Delta J=-1$) transition, however, the apparent spacing is not simply correlated to the rotational constants $\bar{B}'$. We have to repeat trial calculation with a

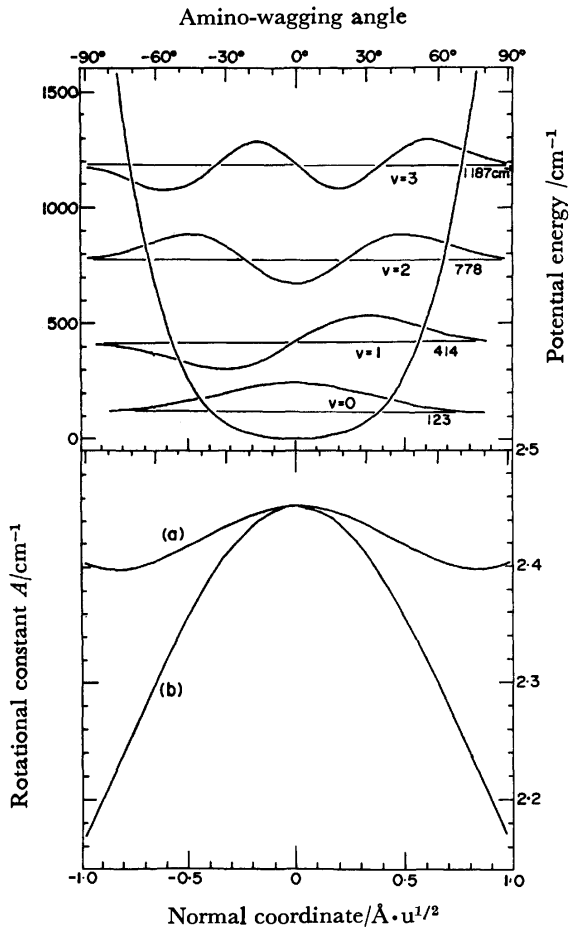

Fig. 6. (Upper) Amino wagging potential function, energy levels, and eigenfunctions of $HCONH_2$. (Lower) Rotational constant A as a function of amino wagging coordinate τ. (a) Calculated on an assumption that, in the "amino wagging motion," only the angle between the OCN plane and the bisector of $\angle$HNH changes, while all the bond lengths and bond angles (except CNH's) are kept unchanged. (b) Calculated by Eq. 5, which was derived to fit the calculated A_v's to the observed (A_v's).

trial $\bar{B}'$ value and with the known $A'-\bar{B}'$ value. Calculation indicates, for example, that in the 670—680 cm^{-1} spectral range 20 main spacings should be involved if $\bar{B}$ (at $v=2$) is assumed to be 0.3505 cm^{-1}, 17 spacings for $\bar{B}$ ($v=2$)=0.3518 cm^{-1}, 15 for $\bar{B}$ ($v=2$)=0.3537 cm^{-1}, and 14 for $\bar{B}$ ($v=2$)=0.3547 cm^{-1}. In the observed spectrum, there are 15 spacings involved in this spectral range (see Fig. 4). In this way we may reach a conclusion that $\bar{B}$ (at $v=2$)=0.3537$\pm$0.0005 cm^{-1}. Likewise, by examining the P branch progression in the 780—790 cm^{-1} spectral range, we know that $\bar{B}$ (at $v=3$)=0.3534$\pm$0.0005 cm^{-1}.

Discussion

One of the interesting problems in the formamide molecule is concerned with the large amplitude motion along the amino wagging coordinate. It has nearly been established that the equilibrium conformation of the molecule is planar.[1] The arrangement of the amino wagging levels (which has now been precisely determined) indicates, however, that the potential function (V) of this out-of-plane motion is severely anharmonic. It involves the fourth power of the amino wagging coordinate (τ) besides the quardratic term, and it is approximately given as,

$$V = V_2\tau^2 + V_4\tau^4. \quad (3)$$

A Hamiltonian with this potential was solved as will be detailed below, and by a least squares fit for the four energy levels ($v=0$, 1, 2, and 3) the coefficients were fixed as $V_2=156$ cm^{-1}/radian^2 and $V_4=410$ cm^{-1}/radian^4. This is close to what Hirota *et al.*[1] gave, but this gives a slightly better fit for the observed levels with $v=2$ and 3. The eigenvalues and eigenfunctions $\phi_v(\tau)$. of the amino wagging Hamiltonian with the potential energy of Eq. 3 are illustrated in the upper half of Fig. 6. In the calculation, the Hamiltonian matrix was represented by the use of proper harmonic oscillator basis functions. If the order of matrix is taken sufficiently large, the eigenvalues and eigenfunctions of lower levels are found independent of the frequency of the basis harmonic oscillator itself. For example, the eigenvalues and eigenfunctions of the lower four levels, shown in Fig. 6, were obtained by diagonalizing a 40×40 Hamiltonian matrix in the representation of the harmonic oscillator with its frequency 156 cm^{-1}. These were found to be exactly equal (over the four significant figures) to those obtained by diagonalizing a 40×40 matrix in the representation of the harmonic oscillator with 300 cm^{-1}.

Let us now proceed with an examination of the amino wagging coordinate, τ. Let us assume, for trial, that τ is equal to the angle between the OCN plane and the bisector of $\angle$HNH. The rotational constant A has been calculated, for trial, at various τ values (0°—90°) by keeping all the bond lengths and bond angles (other than $\angle$CNH's) at the values given by Hirota *et al.*[1] The result is shown in the lower portion of Fig. 6 (curve (a)). On the basis of this $A-\tau$ relation, the average rotational constant at each wagging level can be calculated by

$$A_v = \int_{-\pi}^{\pi} \phi_v(\tau)A(\tau)\phi_v(\tau)d\tau, \quad (4)$$

where $v=0$, 1, 2, and 3. The result is given in the fifth column of Table 2. As may be seen here, the calculated A_v's show desperate disagreement with the observed A_v's. This means that the actual amino wagging motion is greatly different from the mere out-of-plane motion of the NH_2 triangle.

We next inquire: what $A-\tau$ relation can fit the observed A_v values (for $v=0$, 1, 2, and 3)? By expressing A by a power series of τ, a least squares fit resulted in the following expression:

$$A = 2.4520 - 0.1555\tau^2 + 0.01667\tau^4, \quad (5)$$

where A is given in cm^{-1} and τ in radian. This $A-\tau$ relation is shown by curve (b) in Fig. 6. The A_v values obtained by Eq. 4 with this $A-\tau$ relation (Eq. 5) are given in the last column of Table 2. The fit of the calculated A_v values to the observed A_v has certainly been improved. Comparing the curve (a) with (b) in Fig. 6, we now conclude that a large displacement along the amino wagging coordinate causes a great lowering of

TABLE 2. ROTATIONAL CONSTANTS (IN cm^{-1}) OF $HCONH_2$

Vibrational level[a)]	$A-B$ observed	B observed	A observed	A calculated (a)[c)]	A calculated(b)[d)]

a) v is the vibrational quantum number of the amino wagging vibration. b) Determined by Hirota *et al.*[1] by microwave spectroscopy. c) Calculated from the A-τ relation given by the curve (a) of Fig. 6 by Eq. 4. d) Calculated from the A-τ relation given by the curve (b) of Fig. 6 by Eq. 4.

A value (*i.e.*, a great increase of the moment of inertia I_A); the amount of lowering is much greater than that expected for a simple out-of-plane bending of the NH_2 triangle. In other words, this bending motion must be accompanied by appreciable amounts of stretching of some bonds and opening of some angles. Such a coupling of the out-of-plane wagging and in-plane modes may be mainly caused, as Hirota *et al.*[1] pointed out, by anharmonic potential constants. As they also showed, a coupling may partly be caused by a Coriolis force. It should be pointed out, however, that the partner level of an A axis Coriolis coupling should have A'' symmetry for the $v=2$ wagging level (A'), whereas A' symmetry for the $v=3$ wagging level (A'').

This work was partly done in the Institute for Molecular Science, Myodaiji, Okazaki 444, in the period (April 1979—March 1981) in which M. Tsuboi was an Adjunct Professor there. We wish to express our sincere thanks to Professor E. Hirota, late Professor T. Fujiyama, Mr. S. Hyodo, and Mr. S. Sofue for their kind help and valuable discussions. This work was supported by the Joint Studies Program (1980—1981) of the Institute for Molecular Science. Some of our preliminary experiments were made in Faculty of Pharmaceutical Sciences, University of Tokyo, by the use of a Digilab FTS-14 system. In this experiment, we thank Professor S. Tanaka and Dr. T. Matsui (Faculty of Engineering, University of Tokyo) for their kindness in our use of their Wilks multiple reflection cell.

Cobalt(III) Complexes with Quadridentate Ligands. III.[1] The Preparation and Properties of the Salicylato or Dichloro(quadridentate amine)cobalt(III) Complexes

Yoshihisa YAMAMOTO,* Hiroko KUDO, and Eiko TOYOTA

Faculty of Pharmaceutical Sciences, Higashi Nippon Gakuen University, Ishikari-Tobetsu, Hokkaido 061-02

(Received July 20, 1982)

In the ^{1}H and ^{13}C NMR spectra of *trans*- or *cis*-dichloro(quadridentate amine)cobalt(III) chloride hydrates, $[CoCl_2L]Cl \cdot nH_2O$ (L: 2,2,2-tet(trien) (**1a**), 2,3,2-tet (**1b**), 3,2,3-tet (**1c**), and 3,3,3-tet (**1d**)), the signals of their methylene protons and methylene carbons have been assigned to the individual methylene protons and methylene carbon of the coordinated quadridentate amine ligands. The order of ^{1}H and ^{13}C chemical shift of their methylene protons and methylene carbon is as follows:

$$NH_2\underline{CH_2}(CH_2)_n\underline{CH_2}NH\underline{CH_2}- < NH_2\underline{CH_2}(CH_2)_n\underline{CH_2}NH < NH_m\underline{CH_2}\underline{CH_2}\underline{CH_2}NH \quad \begin{pmatrix} m: 1 \text{ or } 2 \\ n: 0 \text{ or } 1 \end{pmatrix}$$

NH-side methylene protons (or carbon); NH_2-side methylene protons (or carbon); Center methylene protons (or carbon)

Thus, the signal of the center methylene protons (or carbon) of the coordinated quadridentate amine ligands appears at higher field than that of the NH-side methylene protons (or carbon). *cis*-β_1-Salicylato(3,7-diazanonane-1,9-diamine)cobalt(III) chloride hydrate, *cis*-β_1-[Co(sal)(2,3,2-tet)]Cl·H_2O (**3b**), and *cis*-β_2-salicylato(quadridentate amine)cobalt(III) chloride hydrates, *cis*-β_2-[Co(sal)L]Cl·nH_2O (L: 2,3,2-tet (**4b**), 3,2,3-tet (**4c**) and 3,3,3-tet (**4d**)) have been isolated from a reaction mixture of sodium salicylate or salicylic acid and **1b—d**. The properties of **3b** and **4b** are similar to those of the previously reported complexes **3a** (L: 2,2,2-tet, β_1-form) and **4a** (L: 2,2,2-tet, β_2-form), respectively. Those of **4c** are similar to those of **4d**. Complex **4d** is the most unstable complex among **4a—d**. This property is attributable to the center methylenes of the coordinated quadridentate amine ligands.

Many investigations of metal complexes with quadridentate amine ligands, *e.g.*, with 2,2,2-tet(trien), 2,3,2-tet, and 3,3,3-tet, have been reported especially in the field of stereochemistry[2-7] and NMR spectra.[7-13] In the NMR spectra, the investigations of methylene protons and methylene carbons of the coordinated quadridentate amine ligands in complexes have received little attention. This is probably because the methylene proton and methylene carbon signals of the coordinated quadridentate amine ligands are close together, and they have not previously assigned separately.

Previous paper[11] has been concerned with the preparation and properties of the *cis*-β_1 and *cis*-β_2-[Co(sal)(2,2,2-tet)]Cl·H_2O. The present paper deals with the assignments of the methylene protons and methylene carbons of the coordinated quadridentate amine ligands of *trans*- or *cis*-$[CoCl_2L]Cl \cdot nH_2O$ (L: 2,2,2-tet, 2,3,2-tet, 3,2,3-tet, and 3,3,3-tet) on their NMR spectra, and deals with the preparation and properties of the *cis*-β_1-[Co(sal)(2,3,2-tet)]Cl·H_2O, and *cis*-β_2-[Co(sal)L]Cl·nH_2O (L: 2,3,2-tet, 3,2,3-tet, and 3,3,3-tet).

Results and Discussion

cis-*α*-*Dichloro(3,6-diazaoctane-1,8-diamine)cobalt(III) Chloride*, *[$CoCl_2$(2,2,2-tet)]Cl (**1a**) and* trans-*Dichloro(quadridentate amine)cobalt(III) Chloride Hydrates*, *[$CoCl_2$-L]Cl·nH_2O L: 2,3,2-tet*, n=*2.5 (**1b**)*; *L: 3,2,3-tet*, n=*1 (**1c**)*; *and L: 3,3,3-tet*, n=*1 (**1d**)*: The ^{1}H NMR spectra of **1a—d** were measured in 0.01 and 1.8 mol dm^{-3} D_2SO_4. The methylene proton signals of the coordinated quadridentate amine ligands in **1a—d** can be divided into three groups at 1.5—2.4, 2.3—3.0, and 2.8—3.8 ppm as shown in Fig. 1 and Table 1. The signals (1.5—2.4 ppm) at highest field of **1b—d** can be assigned to the center methylene protons ($NHCH_2C\underline{H_2}$-$CH_2NH_{1\text{ or }2}$) of the ligands, because the total number of the center methylene protons of **1b**, **1c**, and **1d** is 2, 4, and 6, respectively. The signals at 2.3—3.0 ppm (4H) of **1a**, **1b**, and **1d** can be assigned to the NH_2-side methylene protons ($NHCH_2(CH_2)_nC\underline{H_2}NH_2$ *n*: 0 or 1), and the signals (2.8—3.8 ppm, 8H) at a low field of **1a**, **1b** and **1d** are assigned to the NH-side methylene protons ($-C\underline{H_2}NHC\underline{H_2}(CH_2)_nCH_2NH_2$ *n*: 0 or 1) of the quadridentate ligands. The difference of chemical shifts of the NH_2 and NH-side methylene protons can be attributed to the properties of the terminal NH_2 and secondary NH. Thus, the order of the ^{1}H chemical shifts is given as Scheme 1.

$$NH_2CH_2(CH_2)_n\underline{CH_2}NH\underline{CH_2}- < NH_2\underline{CH_2}(CH_2)_nCH_2NH < NH_m\underline{CH_2}\underline{CH_2}CH_2NH \quad \begin{pmatrix} m: 1 \text{ or } 2 \\ n: 0 \text{ or } 1 \end{pmatrix}$$

NH-side methylene protons; NH_2-side methylene protons; Center methylene protons

Scheme 1.

The ^{1}H NMR spectra of the *trans*-dichloro(2,2,2-tet)-cobalt(III) chloride hydrate hydrochloric acid, *trans*-$[CoCl_2$(2,2,2-tet)]Cl·H_2O·HCl (**2a**), could not be measured in DMSO-d_6, CF_3COOH, 0.01, 0.1 and 1.8 mol dm^{-3} D_2SO_4, because of isomerization to the *cis*-form. The chemical shifts of the terminal NH_2 protons and secondary NH protons of **1a—d** are collected in Table 1.

The ^{13}C NMR spectra of **1b—d** were measured in D_2O. Both the signal at 28.8 ppm of **1b** and that at 23.5 ppm of **1d** can be assigned to the center methylene carbon (C-5) of the quadridentate ligands as shown in

4c		3,2,3-tet	3
4d		3,3,3-tet	1

cis-β_1-*Salicylato(quadridentate amine)cobalt(III) Chloride Hydrate(**3a—d**), and* cis-β_2-*Salicylato(quadridentate amine)-cobalt(III) Chloride Hydrates (**4a—d**)*: Complexes **3b** and **4b—d** have been isolated from a reaction mixture of AgOH, salicylic acid or sodium salicylate and **1b—d**. Salicylato(quadridentate amine)cobalt(III) complexes have three isomeric forms of *cis*-α, *cis*-β_1, and *cis*-β_2 as shown in Fig. 3. The α-form could not be obtained at pH 2—8.[7] The separation of β_1 and β_2-forms was attempted by using ion exchange resin.[11,14] The isolation of **3c** and **3d** from the reaction mixtures was difficult. Complexes **3b** and **4b—d** are soluble in water, acid solvents, DMSO and methanol, but are insoluble in the common organic solvents.

The IR spectra of **3b** and **4b—d** showed 4—5 absorption bands in the 3000—3300 cm^{-1} region and 6 absorption bands in the 990—1100 cm^{-1} region as

TABLE 3. SOME PHYSICAL PROPERTIES OF **3b** AND **4b—d** COMPLEXES

Complex No.	IR spectra $\tilde{\nu}$/cm^{-1} 990—1100 cm^{-1}	Absorption bands λ/nm	ε	Electric conductivity of aqueous solution S cm^2 equiv.$^{-1}$
3b	1005(s), 1017(sh), 1025(vs)	333	2210[1]	106
	1055(vs), 1070(sh), 1087(s)	530	224	
4b	1000(s), 1014(s), 1022(vs)	333	2540[1]	98
	1036(vs), 1060(vs), 1090(vs)	525	241

Solvent: 1) H_2O.

shown in Table 3. This indicates that these complexes assume the β-form.[11,15,16]

The ^{1}H NMR spectra of **3a**, **3b**, and **4a—d** were measured in 1.8 mol dm^{-3} D_2SO_4. The signals of the center methylene protons, NH_2-side methylene protons and NH-side methylene protons of **4a—d** have been assigned by the comparison with those of **1a—d**. In complexes **4b—d**, the intensity ratio of two methylene proton signals at 2.0—2.4 and 2.2—3.2 ppm of the quadridentate ligands is 3 : 9, *i.e.*, one proton in the NH_2-side methylene protons shifts to the region (2.2—3.2 ppm) of the NH-side methylene protons. Those properties are similar to those[11,12] of **4a** (β_2-form). The methylene proton signals (2.2—3.3 ppm) of the coordinated 2,3,2-tet ligand in **3b** are similar to those of **3a** (β_1-form). Thus, the isomeric form of **3b** is *cis*-β_1-form and that of **4b—d** is *cis*-β_2-form. The signals of amine protons and salicylato protons of the coordinated ligands in **3b** and **4b—d** have been assigned by comparison with those of **3a** and **4a** complexes,[11] and are collected in Table 1. These amine proton signals disappeared in heavy water containing NaOH. In the ^{13}C NMR spectra of **4b—d** in D_2O, there have been observed 6—9 signals for the quadridentate ligands and 7 signals for the salicylato ligand. The spectrum of **4c** is similar to that of **4d** as shown in Fig. 2. The chemical shifts of the salicylato ligand in **4b—d** are similar to those of **4a**.[17] The chemical shifts of the quadridentate ligands in **4a—d** are difficult to assign to the individual carbon atoms, but regions of the chemical shifts of center methylene, NH_2-side methylene and NH-side methylene carbons are around 22—27, 37—48, and 45—55 ppm, respectively as shown in Table 2.

The absorption spectra of **4a—d** in H_2O showed two absorption bands at 333 nm (specific absorption band) and at 520—550 nm (first absorption band) as shown in Fig. 4. The ε of both the absorption bands of **4a—d** decreases with the increase of the total number of center methylene carbons of the quadridentate ligands, and their first absorption band shifts from 520 nm (**4a**) to 550 nm (**4d**) as shown in Fig. 4. In the **4a—d** complexes, their colors in the solid state are russet (**4a** and **4b**), pink-violet (**4c**) and dark-brown (**4d**). Their melting points are 240—244 °C (**4a**, **4b**), 231—233 °C (**4c**) and 190—192 °C (**4d**). Their yields of synthesis are 84% for **4a**, 61% for **4b**, 43% for **4c**, and 27% for

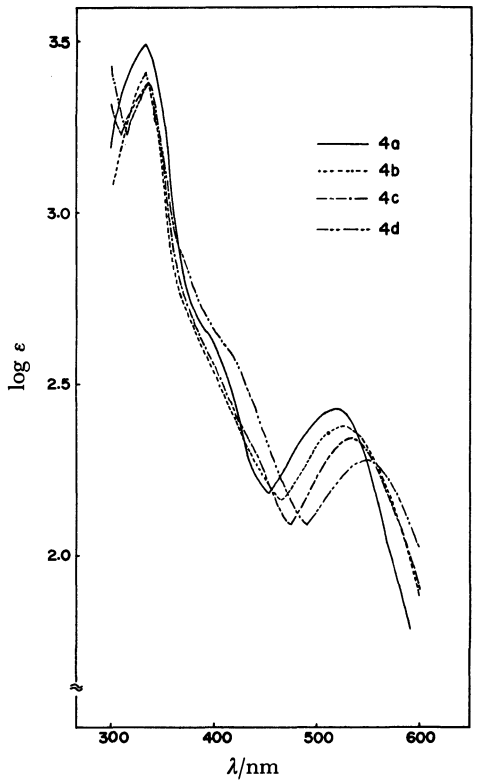

Fig. 4. The absorption spectra of **4a—d** complexes in H_2O. (**4a**): *cis*-β_2-[Co(sal)(2,2,2-tet)]Cl·H_2O. (**4b**): *cis*-β_2[Co(sal)(2,3,2-tet)]Cl·2H_2O. (**4c**): *cis*-β_2-[Co(sal)-(3,2,3-tet)]Cl·3H_2O. (**4d**): *cis*-β_2-[Co(sal)(3,3,3-tet)]-Cl·H_2O.

4d. The *cis*-β_1 complexes of **4a** and **4b** are isolated from the reaction mixtures, but those of **4c** and **4d** could not be isolated. From the above results, the properties of **4b** are seen to be very similar to those of **4a**, though those of **4c** are similar to those of **4d**. Complex **4d** is the most unstable complex among **4a—d**. In the **3b** complex, the color (russet), melting point (≈238 °C) and yield (≈5%) are similar to those of **3a**.[11,12] These properties are attributable to the center methylenes of the quadridentate ligands. All complexes are diamagnetic. The NMR, IR, absorption spectral data and electric conductivity of the aqueous solutions are collected in Table 1—3.

Experimental

Measurements. The NMR spectra were recorded with an FX-60 apparatus (JEOL) for ^{13}C NMR and an R-40 apparatus (Hitachi) for ^{1}H NMR. The visible absorption spectra were recorded with a Shimadzu MPS-5000 recording spectrophotometer. The magnetic susceptibilities were measured by Faraday's method using a magnetic balance (Shimadzu) at room temperature. The pH was measured with a Corning pH-meter M-125. The electric conductivity of an aqueous solution was determined by the use of a conductmetric meter, CM-30 (Shimadzu) at room temperature.

Preparation of Complexes. trans-*Dichloro(3,6-diazaoctane-1,8-diamine(trien))cobalt(III) Chloride Hydrate Hydrochloric Acid (**2a**)* and cis-α-*Dichloro(3,6-diazaoctane-1,8-diamine(trien))cobalt (III) Chloride (**1a**)* were prepared by the Sargeson's method.[10,18]

trans-*Dichloro(3,7-diazanonane-1,9-diamine)cobalt(III) Chloride 2.5 Hydrate (**1b**)* and trans-*Dichloro(4,7-diazadecane-1,10-diamine)cobalt(III) Chloride Hydrate (**1c**)* were prepared by the Bosnich's method.[19,20]

trans-*Dichloro(4,8-diazaundecane-1,11-diamine)cobalt(III) Chloride Hydrate (**1d**)*: Eighteen cubic centimeters of a methanol solution of the tetramine of 3 g (15.9 mmol) were added to 9 cm^3 of an aqueous solution of cobalt(II) chloride hexahydrate of 3.79 g (15.9 mmol). To this solution, was airated 3 h, 4.5 cm^3 of 35% hydrochloric acid was added. The solution was stirred for 1 h and concentrated in a rotary evaporator. The precipitated green complex was filtered. Acetone was added to an aqueous solution of the green complex. Then, precipitated **1c** complex was filtered and dried. Yield: 4.43 g (75.0%). Found: C, 30.06; H, 7.41; N, 15.22; Cl, 28.72%. Calcd for $CoC_9H_{26}N_4OCl_3$ (MW 371.63) C, 29.09; H, 7.05; N, 15.08; Cl, 28.62%. Mp 228—230 °C.

cis-β_1-*Salicyclato(3,7-diazanonane-1,9-diamine)cobalt(III) Chloride Hydrate (**3b**)* and cis-β_2-*Salicylato(3,7-diazanonane-1,9-diamine)cobalt(III) Chloride Dihydrate (**4b**)*: Complex 1b of 5.0 g (13.49 mmol) was added to moistened fresh AgOH, which was made from silver nitrate (4.58 g, 26.96 mmol) and potassium hydroxide (1.52 g, 27.10 mmol). The mixture was stirred in the solid state for several minutes, then 10 cm^3 of water was added to the mixture. The mixture was stirred for about 30 minutes at 60 °C, the precipitated silver chloride filtered off and washed with a small amount of water. To the reddish violet filtrate was added 1.86 g (13.47 mmol) of salicylic acid. The solution was warmed to 50 °C. The reddish brown complex thus precipitated was filtered off, washed with EtOH and acetone, dried in a desiccator over silica gel, and recrystallized from water. Separation of β_1 (**3b**) and β_2 (**4b**) form was carried out by the method described in the previous paper,[11] but the length of the large column of cation-exchange resin (Dowex 50W-X2) was about 18 cm. Yields: 0.26 g (4.7%) for **3b**, 3.5 g (60.8%) for **4b**. Found **3b**: C, 41.22; H, 6.48; N, 13.51; Cl, 9.03%. Calcd for $CoC_{14}H_{26}N_4O_4Cl$ (MW 408.78) C, 41.14; H, 6.41; N, 13.71; Cl, 8.67%. Found **4b**: C, 39.13; H, 6.80; N, 13.47; Cl, 8.41%. Calcd for $CoC_{14}H_{28}N_4O_5Cl$ (MW 426.79) C, 39.40; H, 6.61; N, 13.13; Cl, 8.31%. Mp 237—239 °C for **3b**, 242—244 °C for **4b**.

cis-β_2-*Salicylato(4,7-diazadecane-1,10-diamine)cobalt(III) Chloride Trihydrate (**4c**)*: Complex **1c** (5.0 g, 13.98 mmol) was added to moistened fresh AgOH (3.5 g, 28.0 mmol). The mixture was stirred in the solid state for several minutes, then, 10 cm^3 of water was added to the mixture. The mixture was stirred for about 30 min at 60 °C, the precipitated silver chloride was filtered and washed with a small amount of water. To the reddish violet filtrate, sodium salicylate (2.24 g, 13.99 mmol) was added. The solution was warmed at 50 °C. The precipitated complex was filtered off, washed with EtOH and acetone, dried in a desiccator over silica gel, and recrystallized from water. Yield: 2.75 g (42.9%). Found: C, 39.41; H, 6.88; N, 12.50; Cl, 6.60%. Calcd for $CoC_{15}H_{32}N_4O_6Cl$ (MW 458.83) C, 39.27; H, 7.03; N, 12.21; Cl, 7.73%. Mp 231—233 °C.

cis-β_2-*Salicylato(4,8-diazaundecane-1,11-diamine)cobalt(III) Chloride Hydrate (**4d**)*: The brown complex was prepared from the reaction mixture of **1d** (5.0 g, 13.45 mmol), fresh AgOH (1.68 g, 13.46 mmol), water (about 10 cm^3), and sodium salicylate (2.08 g, 12.99 mmol) according to the preparation method of **4c**. From the brown complex, **4d** was isolated by using column chromatography of alumina. On elution with water, the bands of the complex split into four components. The complex obtained from the first band was rechromatographed with methanol eluent. The methanol solution of the first band was concentrated and dried over silica gel, the **4d** complex was recrystallized from water–acetone, twice. Yield: 1.6 g (27.2%). Found: C, 44.41; H, 7.26; N, 12.62; Cl, 7.10%. Calcd for $CoC_{16}H_{30}N_4O_4Cl$ (MW 436.83) C, 43.99; H, 6.92; N, 12.83; Cl, 8.12%. Mp 190—192 °C.

cis-β_1-*Salicylato(4,7-diazadecane-1,10-diamine)cobalt(III) Chloride (**3c**)* and cis-β_1-*Salicylato(4,8-diazaundecane-1,11-diamine)-cobalt(III) Chloride (**3d**)*: Attempts to isolate the complexes **3c** and **3d** from their reaction mixture were unsuccesful, because the bands of the **3c** and **3d** on the column of ion-exchange resin were very small.

Preparation and ^{119}Sn NMR Spectra of Coordination Compounds of Di-*t*-butyltin(IV) Derivatives

Junzo Otera,* Toru Yano, and Kazunori Kusakabe
Okayama University of Science, Ridai-cho, Okayama 700
(Received September 16, 1982)

Di-*t*-butyltin bis(chelates) were prepared and characterized in comparison with dimethyltin analogs. ^{119}Sn NMR spectra show a six-coordinate configuration for the acetylacetonate, tropolonate, and oxinate; a nonchelating structure is partially involved in the 2-methyloxinate and dialkyldithiocarbamates. Di-*t*-butyltin dichloride gives no isolable adducts with monodentate ligands; however, the Job's continuous variation method using ^{119}Sn NMR spectra has revealed that complexations with 2 : 1 and/or 1 : 1 donor/Sn molar ratios occur in ether. It has been concluded that *t*-butyl group reduces the acceptor property of tin by means of both inductive and steric effects.

Despite extensive preparative and spectroscopic investigations on coordination compounds of dimethyltin(IV) derivatives,[1] rather few studies have been made on the other diorganotin analogs except some diphenyltin(IV) compounds, because IR and NMR spectroscopies are not so powerful means for these compounds. However, X-ray studies have revealed that the configulation was varied in some cases where methyl groups attached to tin were replaced by phenyl groups,[2] and therefore, it seems of interest to investigate other organotin analogs. *t*-Butyl group, possessing increased electron donating ability and bulkiness, seems to be appropriate for evaluating the effect of alkyl group on coordination behavior. Unfortunately, however, only a few coordination compounds of *t*-butyltin(IV) derivatives have been prepared,[3] and no systematic studies on these compounds have been made.

The most popular dimethyl- and diphenyltin(IV) compounds known so far involve diorganotin bis(chelates), $R_2Sn(Ch)_2$ (Ch=chelating ligands), and molecular complexes of diorganotin dihalides with monodentate donors. For $Me_2Sn(Ch)_2$, we have shown the usefulness of ^{119}Sn NMR spectra for elucidating the coordination about tin.[4-7] In this paper, we wish to report the preparation of di-*t*-butyltin bis(chelates), *t*-$Bu_2Sn(Ch)_2$, for which characterization was carried out by means of ^{119}Sn FT NMR spectroscopy. Interaction of *t*-Bu_2SnCl_2 with monodentate ligands in solution will also be described.

Experimental

^{119}Sn and ^{1}H NMR spectra were measured in the FT and CW modes, respectively, as reported previously.[4-7] Chemical shifts are relative to Me_4Sn and Me_4Si for ^{119}Sn and ^{1}H NMR spectra, respectively, and positive signs indicate downfield shifts from the reference. UV spectra were measured with a Hitachi Model 285 spectrophotometer equipped with 1 cm quartz cells. All the solvents were purified by standard methods. *t*-Bu_2SnCl_2 was prepared by a slightly modified Grignard method.[8] The employment of THF in place of ether as solvent resulted in an improvement of yield from 4 to 15%. Abbreviations for ligands are as follows: acac=acetylacetonate, trop=tropolonate, oxin=oxinate (or 8-quinolinolate), meox=2-methyloxinate (or 2-methyl-8-quinolinolate), mdtc and edtc=dimethyl- and diethyldithiocarbamate, DMSO=dimethyl sulfoxide, HMPA=hexamethylphosphoric triamide, DMF=*N*,*N*-dimethylformamide, and Py=pyridine.

Preparation of t-$Bu_2Sn(Ch)_2$. To a methanol solution (10 cm^3) of CH_3ONa (1 mmol) was added Hacac (100 mg, 1 mmol). After stirring for 1 h at room temperature, *t*-Bu_2SnCl_2 (152 mg, 0.5 mmol) in methanol (5 cm^3) was added to this solution. The reaction mixture was stirred for 2 h and subjected to evaporation *in vacuo*. The precipitates thus obtained were extracted with hexane (10 cm^3). After addition of a few drops of Hacac, the hexane solution was concentrated to 2 cm^3. Cooling this concentrated solution in a Dry Ice–methanol bath gave *t*-$Bu_2Sn(acac)_2$ (**1**) as colorless crystals: yield 100 mg (41%). All operations were carried out in an inert atmosphere because **1** decomposes easily in air.

t-$Bu_2Sn(trop)_2$ (**2**), *t*-$Bu_2Sn(oxin)_2$ (**3**), and *t*-$Bu_2Sn(meox)_2$ (**4**) were prepared similarly in 25—55% yields. Recrystallization of these compounds was effected from CH_2Cl_2–hexane in air.

t-$Bu_2Sn(mdtc)_2$ (**5**) and *t*-$Bu_2Sn(edtc)_2$ (**6**) were prepared by mixing mdtcNa (359 mg, 2 mmol) or edctNa (451 mg, 2 mmol) in methanol (10 cm^3) with *t*-Bu_2SnCl_2 (304 mg, 1 mmol) in CH_2Cl_2 (5 cm^3). The pure sample was obtained by recrystallization from CH_2Cl_2–hexane in yields of 308 mg (65%) and 434 mg (82%), respectively. Melting points and analytical data of the compounds thus obtained are summarized in Table 1.

The Job's continuous variation method[9,10] was used under the condition that the total concentration of *t*-Bu_2SnCl_2 and a ligand was 1 M (1 M=1 mol dm^{-3}) in ether. The ligands employed were distilled from CaH_2 before use.

Attempted Isolation of Adducts. *t*-Bu_2SnCl_2 (304 mg, 1 mmol) and DMSO (156 mg, 2mmol) were stirred in ether (3 cm^3) at room temperature for 30 min. After addition of 3 cm^3 hexane, the solution was cooled at −78 °C to give white precipitates, which were filtered out and dried (100 mg). The NMR spectrum of the precipitates in CCl_4 exhibited two methyl proton signals at δ=2.45 (DMSO) and 1.41 (*t*-Bu), but no reproducible results were obtained with respect to their integral ratios, which varied between 12 : 20 and 12 : 28 in

Table 1. Melting points and analytical data of *t*-$Bu_2Sn(Ch)_2$

	Ch	Mp θ_m/°C	Found (Calcd) (%) C	H	N
1	acac	101—103	50.23(50.15)	7.67(7.48)	
2	trop	166—168	55.58(55.62)	5.95(5.94)	
3	oxin	199—202	59.60(59.91)	5.77(5.80)	5.40(5.38)
4	meox	207—208	60.70(61.00)	6.04(6.58)	5.01(5.08)
5	mdtc	174—176	35.56(35.52)	6.37(6.39)	5.98(5.92)
6	edtc	100—102	40.87(40.83)	7.23(7.23)	5.38(5.29)

repeated preparations, indicating coexistence of 2 : 1 and 1 : 1 adducts. Employment of 4 equiv. DMSO also gave similar results. When other monodentate ligands were treated in an analogous manner, no adducts were obtained,only t-Bu_2SnCl_2 being recovered after cooling at −78 °C.

Results and Discussion

t-Bu₂Sn(Ch)₂. All chelates were prepared as analytically pure crystalline compounds from t-Bu_2SnCl_2 and sodium salts of ligand anions, and were fairly stable in air except the acetylacetonato complex, which decomposes easily on exposure to air both in the solid state and in solution. The ^1H and ^{119}Sn NMR spectral parameters of these compounds are summarized in Table 2, in which the deviations in $^3J(^{119}Sn-H)$ and $\delta(^{119}Sn)$ values from those in the corresponding dimethyltin analogs are given as Δ_1 and Δ_2. Evidently, the $^3J(^{119}Sn-H)$ value in t-$Bu_2Sn(Ch)_2$ is constantly increased by 30—40 Hz from the $^2J(^{119}Sn-H)$ value in $Me_2Sn(Ch)_2$, except for the 2-methyloxinato complex **4**

Table 2. ^1H and ^{119}Sn NMR spectral parameters of t-$Bu_2Sn(Ch)_2$ in CCl_4

Compound	$\delta(CH_3-C-Sn)$ ppm	$^3J(^{119}Sn-H)$ Hz	Δ_1[a] Hz	$\delta(^{119}Sn)$ ppm	Δ_2[b] ppm
1	1.01	130.6	31.3	−486	−120
2	1.18	111.4	39.2	−326	−134
3	1.13	107.2	36.0	−338	−105
4	1.03	109.4	20.4	−311	−83
5	1.53	119.3	35.3	−255	+89
6	1.55	119.6	35.6	−262	+76

a) $\Delta_1 = {}^3J(^{119}Sn-H)$ (t-$Bu_2Sn(Ch)_2$) $- {}^2J(^{119}Sn-H)$ ($Me_2Sn(Ch)_2$). b) $\Delta_2 = \delta(^{119}Sn)$ (t-$Bu_2Sn(Ch)_2$) $- \delta(^{119}Sn)$ ($Me_2Sn(Ch)_2$).

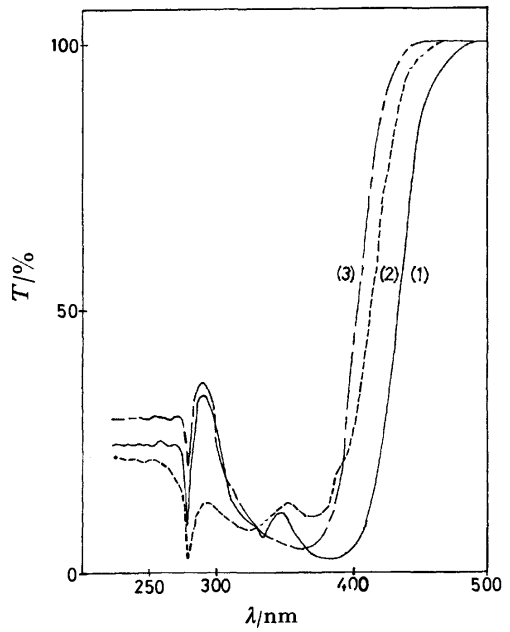

Fig. 1. UV spectra of $R_2Sn(oxin)_2$ and $R_2Sn(meox)_2$ in benzene. (1) t-$Bu_2Sn(oxin)_2$: λ_{max} 386 nm (ε 5200), (2) t-$Bu_2Sn(meox)_2$: λ_{max} 320 nm (ε 3800) and 370 nm (ε 3400), (3) $Me_2Sn(meox)_2$: λ_{max} 365 nm (ε 3900).

(*vide infra*). Since the latter value can be correlated linearly with the C–Sn–C bond angle,[4] it may be said that the $^3J(^{119}Sn-H)$ value in t-$Bu_2Sn(Ch)_2$ also increases with increasing C–Sn–C bond angle. It should be noted, however, that the $^3J(^{119}Sn-H)$ value cannot necessarily be correlated with the coordination mode.[4]

By contrast, a great discrepancy was found for Δ_2. The $\delta(^{119}Sn)$ values in t-$Bu_2Sn(Ch)_2$ shifted upfield by 105—134 ppm from those in corresponding $Me_2Sn(Ch)_2$ for the acetylacetonato **1**, tropolonato **2**, and oxinato **3** complexes. Since the chelation of ligands in these compounds is confirmed on the basis of IR spectra for **1** (ν(C=O) 1590 cm^{-1})[10] and **2** (ν(C=C) 1592 and ν(C=O) 1497 cm^{-1})[12] and UV spectrum for **3** (Fig. 1),[13] the upfield shifts mentioned above has been brought about simply by the replacement of methyl group by t-butyl group. On the other hand, the magnitude of the upfield shift is moderately reduced in the 2-methyloxinato complex **4**. As shown in Fig. 1, the UV spectrum of **4** exhibits two peaks at 320 and 370 nm assignable to nonchelating and chelating structures, respectively, while the dimethyltin counterpart gives rise to a single peak at 365 nm. As a result, the $\delta(^{119}Sn)$ value apparently reflects this coordination behavior. In $Me_2Sn(Ch)_2$, when Ch was changed from oxin to meox, $\delta(^{119}Sn)$ was shifted downfield (from −273 to −228 ppm).[6] Introduction of a methyl group into the α-position of the quinoline ring resulted in expansion of the C–Sn–C bound angle, though a slightly weakened chelation being maintained; that is, a considerable steric repulsion is operative between methyl groups attached to tin and the quinoline ring. Accordingly, a strong steric interaction between t-butyl groups and methyl groups in **4** is reasonably assumed to prevent nitrogen from coordinating to tin.

Quite surprisingly, the $\delta(^{119}Sn)$ values in the dialkyldithiocarbamato complexes **5** and **6** lie downfield relative to those in corresponding dimethyltin compounds. Since we have revealed that the $\delta(^{119}Sn)$ value in organotin chelates is shifted downfield as the coordination number of tin decreases,[7] the above results may be interpreted in terms of coexistence of a nochelating structure with the chelating structure. In general, t-$Bu_2Sn(Ch)_2$ was found to involve a fairly weak chelation as compared with $Me_2Sn(Ch)_2$.

Interactions of t-Bu₂SnCl₂ with Monodentate Ligands. Me_2SnCl_2 forms molecular complexes with various monodentate ligands with 2 : 1 and/or 1 : 1 donor/Sn stoicheometry. For example, DMSO, HMPA, and Py afford quite stable 2 : 1 adducts, while DMF gives

Table 3. ^1H and ^{119}Sn NMR spectral parameters of t-Bu_2SnCl_2 in donor solvents

Solvent	$\delta(CH_3-C-Sn)$ ppm	$^3J(^{119}Sn-H)$ Hz	$\delta(^{119}Sn)$ ppm
CCl_4	1.43	112.8	56
DMSO	1.36	125.0	−147
HMPA	1.42	122.0	−153
DMF	1.38	118.0	−99
Py	1.39	117.0	30

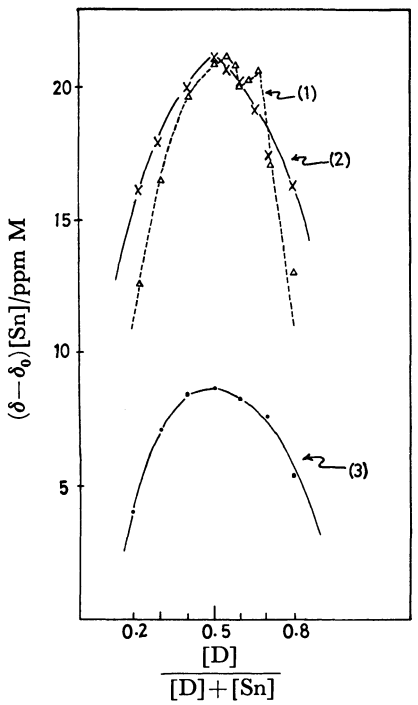

Fig. 2. Job's plots for t-Bu_2SnCl_2–monodentate ligand system in ether at total concentration of 1 M. (1) DMSO (2) HMPA (3) DMF.

both 2 : 1 and 1 : 1 adducts.[1b] Here we have studied the coordinating behavior of these ligands towards t-Bu_2SnCl_2. When t-Bu_2SnCl_2 and a ligand were mixed in hexane in various molar ratios, no adducts were obtained. Treatment of DMSO with t-Bu_2SnCl_2 in molar ratios more than 2 : 1 in ether, followed by addition of hexane and cooling at −78 °C, yielded white precipitates. The ^1H NMR spectrum, however, showed that these precipitates consisted of 2 : 1 and 1 : 1 adducts. Accordingly, we have investigated whether some kind of interaction exists in solution. In Table 3 are listed the $^3J(^{119}Sn–H)$ and $\delta(^{119}Sn)$ values of t-Bu_2SnCl_2 in the donor solvents. The increase in ^3J ($^{119}Sn–H$) values from that in CCl_4 indicates occurrence of donor-acceptor interactions. In line with this, the $\delta(^{119}Sn)$ values in DMSO, HMPA, and DMF shifted 150—200 ppm upfield relative to the one in CCl_4, while a slight shift was observed in Py. This is quite unexpected because Py is classified as the most favorite ligand for Me_2SnCl_2 to afford the 2 : 1 adduct.[1] In the hope of elucidating the stoicheometry of the interaction in solution, the Job's continuous variation method was applied. When hexane was employed as a solvent, $\delta(^{119}Sn)$ shifted only 10 ppm at most, so that a reliable Job's plot could not be drawn. Then, ether was used, which resulted in a shift by more than 50 ppm. Evidently, the shift was not caused by the coordination of ether since $\delta(^{119}Sn)$ of t-Bu_2SnCl_2 in ether (55 ppm) gave no evidence for solvation. Therefore, it can be concluded that the interaction is favored in polar medium. The Job's plots in ether are illustrated in Fig. 2. DMSO gave rise to both 2 : 1 and 1 : 1 complexations but HMPA and DMF only to the 1 : 1 stoicheometry

$$t\text{-}Bu_2SnCl_2 \overset{D}{\rightleftharpoons} t\text{-}Bu_2SnCl_2\cdot D \overset{D}{\rightleftharpoons} t\text{-}Bu_2SnCl_2\cdot 2D. \quad (1)$$

It is apparent from these findings that the acceptor property of tin is considerably reduced in t-Bu_2SnCl_2. Since a consultation with the molecular model showed little steric interaction for t-Bu_2SnCl_2–DMSO and t-Bu_2SnCl_2–DMF systems, the reduction of acceptor property may be attributable to the inductive effect of the t-butyl group. On the other hand, a significant interaction between t-butyl groups and N-methyl groups is induced on coordination of HMPA. Both t-Bu_2SnCl_2–DMSO and t-Bu_2SnCl_2–HMPA systems are comparable in stability constant for the 1 : 1 complexation, judging from the $(\delta-\delta_0)$[Sn] values in the Job's plot which are proportional to stability constants.[9] The $\delta(^{119}Sn)$ values of t-Bu_2SnCl_2 in these systems (Table 3) are consistent with this postulation. Therefore, the absence of the 2 : 1 complexation of HMPA is accounted for by the steric reason.

In summary, di-t-butyltin(IV) compounds showed various differences in coordination behavior from dimethyltin analogs. The reduced acceptor property of tin in the former compounds is primarily caused by the inductive effect of t-butyl groups. However, in some cases where bulky ligands are involved, it was found that the steric factor also is important.

A Nuclear Magnetic Resonance Study of the Kinetics of Ligand Exchange Reactions in Uranyl Complexes. III. Dimethyl Sulfoxide Exchange in Bis(β-diketonato)(dimethyl sulfoxide)dioxouranium(VI)

Yasuhisa IKEDA, Hiroshi TOMIYASU, and Hiroshi FUKUTOMI*

Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received September 30, 1982)

The exchange reactions of dimethyl sulfoxide (DMSO) with $UO_2(acac)_2dmso$ and $UO_2(dbm)_2dmso$ (acac= acetylacetonate, dbm=dibenzoylmethanate) have been studied by the NMR method in CD_3COCD_3 and CD_2Cl_2. In CD_3COCD_3, rates of DMSO exchange for these complexes are independent of the free DMSO concentrations. Rate constants (s^{-1}) at 25 °C and activation parameters ΔH^* (kJ mol^{-1}) and ΔS^* (J K^{-1} mol^{-1}) are 2.36×10^2, 45.8 ± 0.8, -46.6 ± 2.9 for $UO_2(acac)_2dmso$, and 3.92×10^2, 44.5 ± 0.4, -46.2 ± 2.1 for $UO_2(dbm)_2dmso$, respectively. In CD_2Cl_2, the exchange rates are dependent on the free DMSO concentration. For $UO_2(acac)_2dmso$, rate$=(k_d+k_IK_{OS}[DMSO])[UO_2(acac)_2dmso]/(1+K_{OS}[DMSO])$, where $k_d(25\ °C)=1.02\times10^2\ s^{-1}$, $\Delta H^*=47.9\pm5.2$ kJ mol^{-1}, and $\Delta S^*=-46.6\pm11.2$ J K^{-1} mol^{-1}, and $k_I(25\ °C)=1.01\times10^3\ s^{-1}$, $\Delta H^*=35.4\pm12.4$ kJ mol^{-1}, and $\Delta S^*=-69.7\pm20.5$ J K^{-1} mol^{-1}, and $K_{OS}(10\ °C)=4.6\pm2.1\ M^{-1}$ (M=mol dm^{-3}). For $UO_2(dbm)_2dmso$, rate$=(k_1+k_2[DMSO])[UO_2(dbm)_2dmso]$, where $k_1(25\ °C)=1.74\times10^2\ s^{-1}$, $\Delta H^*=29.6\pm2.2$ kJ mol^{-1}, $\Delta S^*=-104\pm9$ J K^{-1} mol^{-1}, and $k_2(25\ °C)=1.62\times10^3\ M^{-1}\ s^{-1}$, $\Delta H^*=34.9\pm0.6$ kJ mol^{-1}, and $\Delta S^*=-67.2\pm2.4$ J K^{-1} mol^{-1}. The D and I mechanisms are proposed for the DMSO exchange in these complexes.

Recently, the kinetics of the ligand exchange reactions for $UO_2L_n^{2+}$, where $n=4$ and L is water[1] or hexamethylphosphoric triamide (hmpa),[2] and $n=5$ and L is *N,N*-dimethylacetamide(dma),[3] trimethyl phosphate(tmp) and triethyl phosphate(tep),[4] dimethyl sulfoxide (dmso),[5] *N,N*-dimethylformamide(dmf),[6] and *N*-methylacetamide(nma),[7] have been studied by NMR. However, only a few studies have been concerned with ligand exchange in uranyl chelate complexes.[8,9] The uranyl β-diketonato complexes, $UO_2(\beta\text{-diketonato})_2L$ (L=adduct ligands), have been of particular interest among these chelate complexes in view of their role in the extraction of uranyl ions.[10-14]

This paper will deal with the kinetics of DMSO exchange in $UO_2(acac)_2dmso$ (acac=acetylacetonate) and $UO_2(dbm)_2dmso$ (dbm=dibenzoylmethanate) by NMR. At the same time the structure of these complexes will be determined, since it has not been reported whether the pentagonal bipyramidal structure which was found by the X-ray study of crystalline $UO_2(acac)_2\text{-}H_2O$[15,16] remains unchanged in solution.

Experimental

Synthesis of Complexes. The $UO_2(acac)_2dmso$ complex was prepared by dissolving $UO_2(acac)_2H_2O$ in warm DMSO. The $UO_2(acac)_2H_2O$ complex was prepared according to the procedure of Comyns *et al.*[17] The $UO_2(acac)_2dmso$ solution was cooled and the resultant orange crystals were filtered and dried *in vacuo* for 1 d. The $UO_2(dbm)_2dmso$ complex was prepared by mixing DMSO with diethyl ether solution of $UO_2(dbm)_2H_2O$ which was synthesized by mixing an aqueous solution of uranyl(VI) acetate dihydrate (1 mol) with an ethanolic solution of dibenzoylmethane (2 mol).[18] The resultant orange crystals were filtered, washed with diethyl ether and dried *in vacuo* for 1 d. The composition of these complexes was determined by elemental analysis. The results are as follows: Calcd for $UO_2(acac)_2dmso$: C, 26.38; H, 3.69%. Found: C, 26.49; H, 3.66%. Calcd for $UO_2(dbm)_2dmso$: C, 48.37; H, 3.55; S, 4.03%. Found: C, 48.32; H, 3.52; S, 4.08%. Elemental analysis of the complexes was carried out in the Institute of Physical and Chemical Research.

Other Materials. Acetone-d_6(CD_3COCD_3, Merck 99.8%) and dichloromethane-d_2 (CD_2Cl_2, Merck 99%), which were used as solvents, were dried over 3A and 4A molecular sieves (Wako Pure Chemical Ind. Ltd.), respectively. Dimethyl sulfoxide (Wako Pure Chemical Ind. Ltd.) was distilled *in vacuo*, followed by distillation with molecular sieves, and stored over 3A molecular sieves. Acetylacetone (Wako Pure Chemical Ind. Ltd.) was used without further purification.

Preparation of Samples. Sample solutions in the appropriate solvent were prepared by weighing sample substances in a 1 cm^3 volumetric flask and some of each solution was placed in an NMR sample tube and sealed. All samples were prepared in a glove box filled with dried nitrogen. Proper precautions were taken to minimize the probability of photochemical redox reactions.

Measurement of NMR and IR Spectra. The measurements of the ^1H NMR spectra were carried out at 100 MHz on a JEOL JNM-MH 100 NMR spectrometer and JEOL JNM-FX 100 FT-NMR spectrometer equipped with a JNM-VT-3B temperature controller. Infrared spectra of the $UO_2(acac)_2\text{-}dmso$ complex in CD_3COCD_3 and CD_2Cl_2 were recorded in the 200—4000 cm^{-1} range by using a JASCO DS-701G IR spectrometer.

Kinetic Analysis. The kinetic parameters were calculated by using a program on the assumption of a two-site exchange process.[19] Input parameters for this program are the chemical shifts and the linewidths at half amplitude of each signal of the coordinated and free sites at −60 °C where no exchange was observed, the site populations, and appropriate life-times (τ-values). The experimental spectra are compared with the calculated spectra and the best-fit τ-values are determined. All computations were carried out with a Hitach M-200 computer.

Results and Discussion

The Structure of $UO_2(acac)_2dmso$ in Solutions. The ^1H NMR spectra in DMSO and CD_3COCD_3 mixtures including $UO_2(acac)_2dmso$ at −25 and 40 °C are shown in Fig. 1. In the spectrum at −25 °C, the signals of (a) and (d) can be assigned to be the methyl protons and 3-H protons of the coordinated acac, respectively. The signals (b) and (c) are the methyl

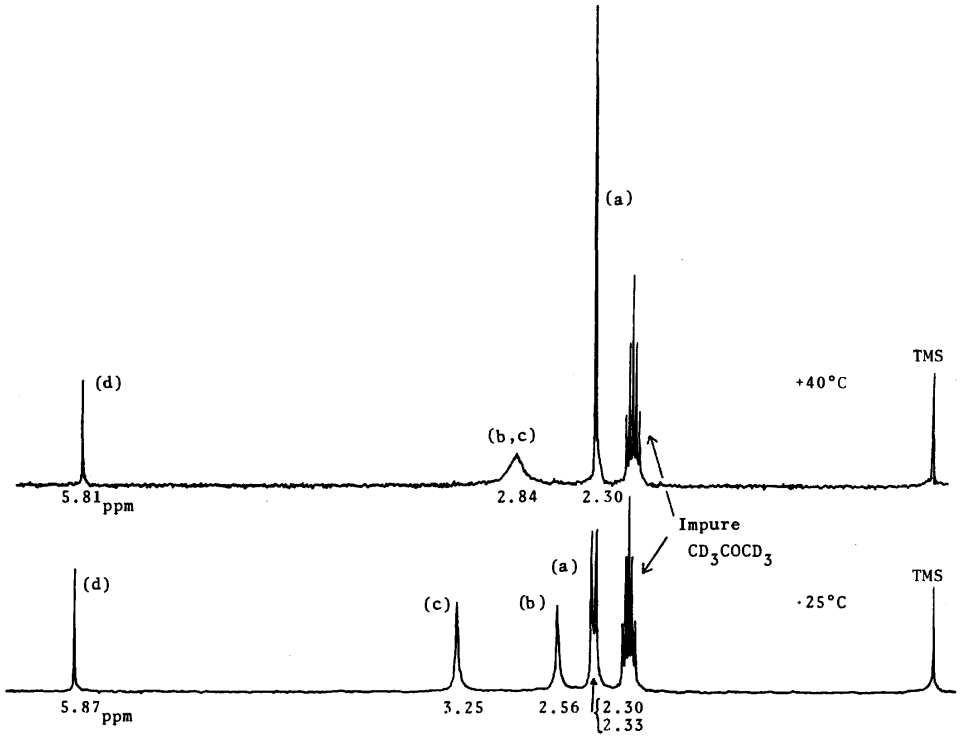

Fig. 1. ^{1}H NMR spectra of a solution consisting of $UO_2(acac)_2$dmso (0.0298 M), DMSO (0.0294 M), and CD_3COCD_3 (13.4 M) at −25 and 40 °C, respectively.

protons of the free and coordinated DMSO, respectively. A comparison of the integrated areas for (b) and (c) indicates that one DMSO molecule is coordinated to each uranyl ion. The area ratio of (a) to (c) to (d) was 6 : 3 : 1, the signal of (d) being used as a standard. The ratio was constant in solutions of various compositions. These facts indicate that two acetylacetonate ions and one DMSO molecule coordinate to uranyl ion. The separation of the methyl protons for coordinated acac means that these methyl groups are not geometrically identical. This may be explained by assuming the structure of this complex to be pentagonal bipyramidal like the crystal structure of the $UO_2(acac)_2H_2O$ complex,[15,16] because in such a structure the methly protons of coordinated acac exist in two different magnetic circumstances, with one near and one distant from the coordinated DMSO. The fact that the 3-H proton of the coordinated acac has a single peak also supports the proposed structure. In CD_2Cl_2, similar phenomena were also obseved in the ^{1}H NMR spectra.

The IR measurements for $UO_2(acac)_2$dmso were made in CD_3COCD_3 and CD_2Cl_2. The results are given in Table 1. The S=O stretch of the uranyl complex in CD_3COCD_3 and CD_2Cl_2 is observed at 1010 cm^{-1}, which is 45 cm^{-1} lower than the 1055 cm^{-1} observed in pure DMSO. Cotton and Francis[20] have shown that the S=O stretching frequency of sulfoxide in complexes decreases when coordination occurs through oxygen. Hence, it is concluded that one DMSO molecule is coordinated through oxygen in this complex. In addition, it was found that the two acetylacetonate ions were coordinated as bidentate ligands, because only one band corresponding to the carbonyl vibration was observed at frequencies less than 1600 cm^{-1}, which is the characteristic frequency of the carbonyl vibration for chelated metal β-diketone complexes.[21]

Table 1. Characteristic IR stretching frequencies for $UO_2(acac)_2$dmso in solution

Solvent	ν_3(O=U=O) cm^{-1}	ν(S=O) cm^{-1}	ν(C–O) cm^{-1}
CD_3COCD_3	905	1010	1517
CD_2Cl_2	908	1010	1570

The Structure of $UO_2(dbm)_2$dmso in Solutions. Figure 2 shows the ^{1}H NMR spectra of $UO_2(dbm)_2$dmso in DMSO and CD_3COCD_3 mixtures at −30 and 30 °C. At −30 °C, the signals (a) and (b) can be assigned to be the methyl protons of the free and coordinated DMSO, respectively. The signals (c) and (d) are the 3-H protons and the protons on benzene rings of the coordinated dbm, respectively. The area ratio of (d) to (c) to (b) was 10 : 1 : 3 and the ratio was constant in solutions of various composition. The signal for the 3-H protons of the coordinated dbm is a single peak as seen in Fig. 2. These ^{1}H NMR spectra in solutions containing $UO_2(dbm)_2$dmso indicate that two dibenzoylmethanate ions and one DMSO molecule coordinate to uranyl ion. Therefore, the structure of $UO_2(dbm)_2$dmso is presumed to be pentagonal bipyramidal which is the same as that of $UO_2(acac)_2$dmso.

DMSO Exchange in $UO_2(acac)_2$dmso. It is noted from Fig. 1 that DMSO exchanges between coordinated and free sites, because the methyl proton signals of the coordinated and free DMSO are observed at −25 °C, while only a single methyl proton signal for DMSO is observed at 40 °C. In addition, coalescence of the methyl proton signal for coordinated acac at 40 °C may

a) Added as DMSO. b) Calculated values from ΔH^* and ΔS^* at 25 °C.

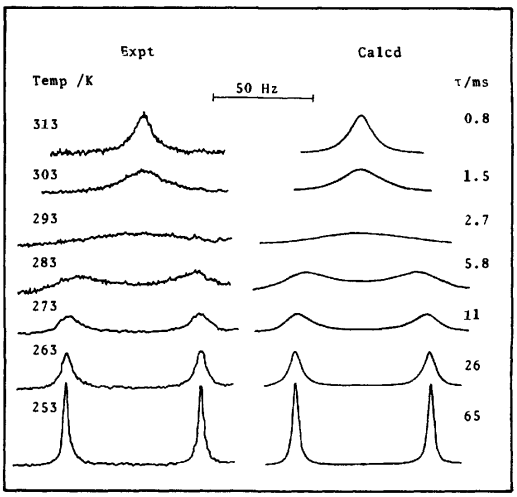

Fig. 3. Experimental (left side) and best-fit calculated lineshapes of a solution consisting of $UO_2(acac)_2dmso$ (0.0298 M), DMSO (0.0294 M), and CD_3COCD_3 (13.4 M). Temperatures and best-fit τ-values are shown at left and right sides of the figure, respectively.

be attributed to intermolecular DMSO exchange or intramolecular exchange for this complex.[22] The ^{1}H NMR measurements for DMSO methyl protons were carried out at various temperatures in order to examine in detail the change in lineshape. Results are shown in Fig. 3. The temperature dependence of the spectra is consistent with the results of previous work dealing with the DMSO exchange in $UO_2(dmso)_5^{2+}$.[5] The best-fit τ-values at each temperature were obtained by the method described in the Experimental Section. The calculated lineshapes are shown in Fig. 3 together with the corresponding best-fit τ-values.

The first-order rate constants, k_{ex}, for the DMSO exchange in $UO_2(\beta$-diketonato$)_2$dmso were calculated from the following equations:

$$\tau = \tau_c P_f = \tau_f P_c \quad (1)$$

$$k_{ex} = 1/\tau_c = \text{rate}/[UO_2(\beta\text{-diketonato})_2dmso] = (kT/h)\exp(-\Delta H^*/RT)\exp(\Delta S^*/R), \quad (2)$$

where the τ_c and τ_f are the mean life-times of the coordinated and free sites, respectively and P_c and P_f refer to the mole fractions of the coordinated and free DMSO, respectively. The rate constants, k_{ex}, were

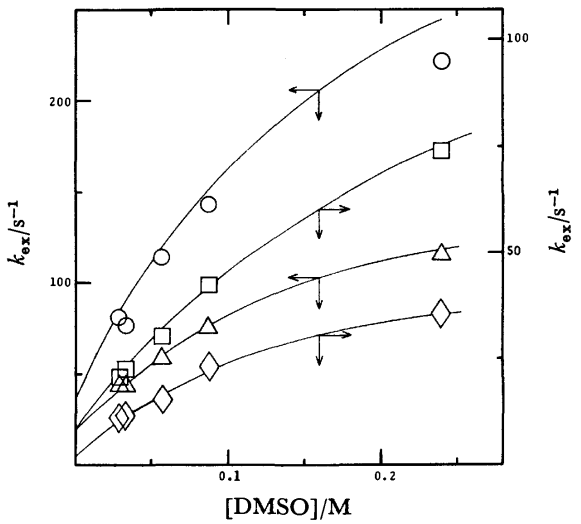

Fig. 5. Plots of k_{ex} *vs.* [DMSO] for the exchange of DMSO in UO_2(acac)$_2$dmso in CD_2Cl_2. ○: 10 °C; △: 0 °C; □: −10 °C; ◇: −20°C.

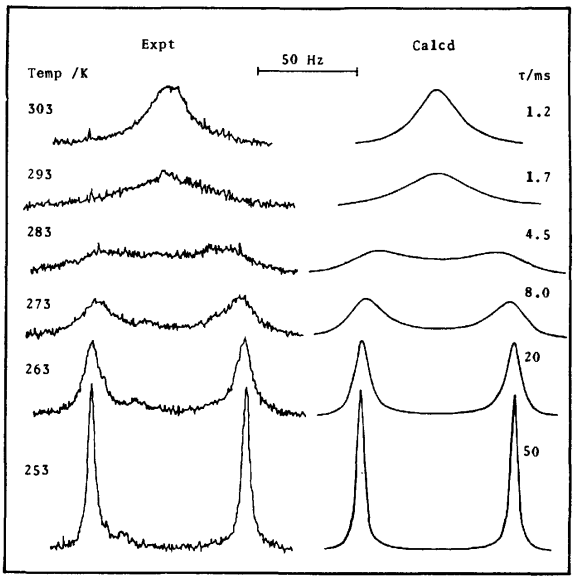

Fig. 6. Experimental (left side) and best-fit calculated lineshapes of a solution consisting of UO_2(dbm)$_2$dmso (0.0117 M), DMSO (0.0115 M), and CD_3COCD_3 (13.5 M). Temperatures and best-fit τ-values are shown at left and right sides of the figure, respectively.

obtained for various solutions listed in Table 2. In Fig. 4, the values of k_{ex} are plotted semilogarithmically against the reciprocal temperature. The activation parameters obtained from Fig. 4 are listed in Table 2. It can be seen from Table 2 and Fig. 4 that the rates of DMSO exchange in CD_3COCD_3 are independent of the free DMSO, while those of the DMSO exchange in CD_2Cl_2 depend on the concentration of free DMSO. The values of k_{ex} in the CD_2Cl_2 system were plotted against the DMSO concentration as shown in Fig. 5. This figure indicates that the rate of DMSO exchange in CD_2Cl_2 does not obey a simple linear relationship with the DMSO concentration.

DMSO Exchange in UO_2(dbm)$_2$dmso. It can be also expected from Fig. 2 that the DMSO exchanges

a) Added as DMSO. b) Calculated values from $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ at 25 °C.

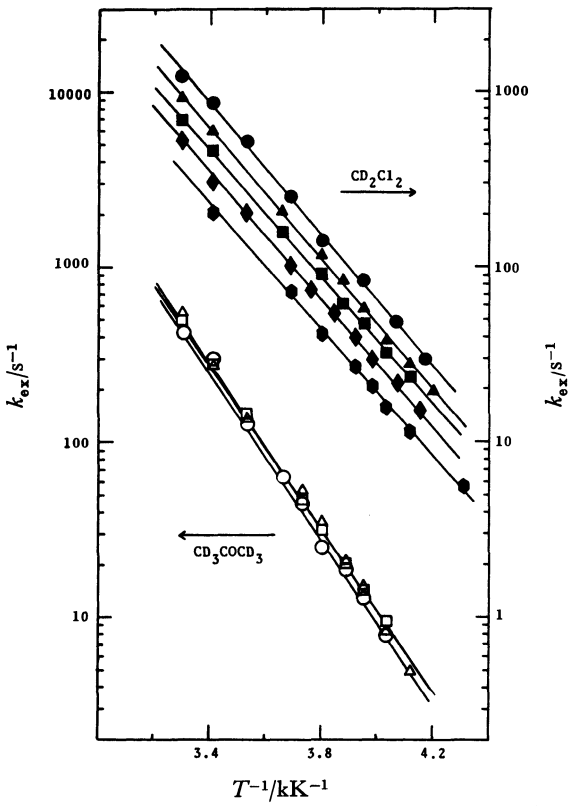

Fig. 7. Semilogarithmic plots of k_{ex} against the reciprocal temperature for the exchange of DMSO in $UO_2(dbm)_2dmso$ in CD_3COCD_3 and CD_2Cl_2. The symbols of ○, △, □, ⧫, ◆, ■, ▲, and ● correspond to i, ii, iii, iv, v, vi, vii, and viii solutions in Table 3.

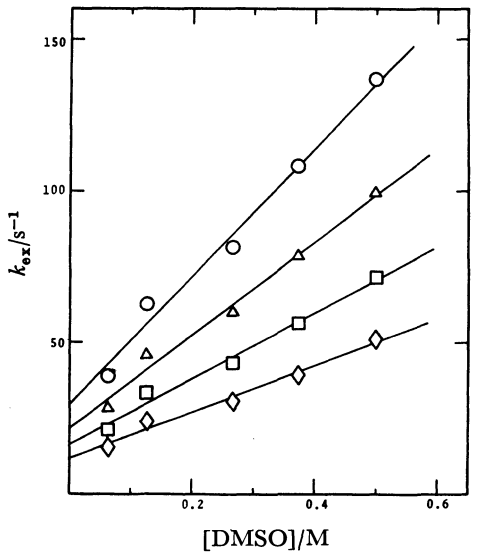

Fig. 8. Plots of k_{ex} *vs.* [DMSO] for the exchange of DMSO in $UO_2(dbm)_2dmso$ in CD_2Cl_2. ○: −10 °C; △: −15 °C; □: −20 °C; ◇: −25 °C.

between the coordinated and free sites with $UO_2(dbm)_2$-dmso in a DMSO and CD_3COCD_3 mixture, because the signal of the DMSO methyl protons changes from two signals at −30 °C to one signal at 30 °C. More detailed spectral changes with temperature are shown in Fig. 6 for the temperature region from −20 to 30 °C.

TABLE 4. THE VALUES OF k_1 AND k_2 AT VARIOUS TEMPERATURES FOR THE EXCHANGE OF DMSO IN $UO_2(dbm)_2dmso$ IN CD_2Cl_2

Temp / °C	k_1 / $10\ s^{-1}$	k_2 / $10^2\ M^{-1}\ s^{-1}$
−10	2.91±0.44	2.12±0.14
−15	2.18±0.33	1.53±0.11
−20	1.62±0.25	1.09±0.08
−25	1.19±0.18	0.76±0.06

The coalescence of the coordinated and free DMSO signals was also observed at high temperature. The best-fit τ-values at each temperature were determined by the same method as mentioned before and the calculated lineshapes are also shown in Fig. 6. The first-order exchange rate constants, k_{ex}, were calculated by Eqs. 1 and 2. The k_{ex} values obtained for the solutions listed in Table 3 were plotted semilogarithmically against the reciprocal temperature (Fig. 7). The activation parameters are given in Table 3. As can be seen in Fig. 7 and Table 3, the rate of DMSO exchange in CD_3COCD_3 is independent of the free DMSO concentration, while the rate in CD_2Cl_2 is dependent on the concentration of free DMSO. A plot of k_{ex} values which were obtained in CD_2Cl_2 against the free DMSO concentration is linear (Fig. 8) and results in the following equation.

$$k_{ex} = k_1 + k_2[\mathrm{DMSO}] \quad (3)$$

The values of k_1 and k_2 were, respectively, obtained from the intercepts and the slopes of the plots from Fig. 8 by means of the least-squares method, and are shown in Table 4. The activation parameters for these paths are given in Table 3.

Possible Mechanism. It was found that the rate of the DMSO exchange reactions in $UO_2(acac)_2dmso$ and $UO_2(dbm)_2dmso$ in CD_3COCD_3 is independent of the free DMSO. This fact suggests that the DMSO exchange process for these complexes in CD_3COCD_3 proceeds through either the D or the I mechanism.[23]

In the D mechanism, the exchange process is expressed as

$$UO_2(\beta\text{-diketonato})_2dmso + DMSO^* \xrightarrow[\text{slow}]{k_d}$$
$$UO_2(\beta\text{-diketonato})_2 + DMSO + DMSO^* \xrightarrow[\text{fast}]{}$$
$$UO_2(\beta\text{-diketonato})_2dmso^* + DMSO. \quad (4)$$

In this mechanism, the rate-determining step is the dissociation of the coordinated DMSO from $UO_2(\beta$-diketonato$)_2dmso$ and an intermediate of reduced coordination number, $UO_2(\beta$-diketonato$)_2$, is formed. Thus, k_{ex} is given as

$$k_{ex} = k_d. \quad (5)$$

In the I mechanism, overall processes are represented as

$$UO_2(\beta\text{-diketonato})_2dmso + DMSO^* \underset{\text{fast}}{\overset{K_{os}}{\rightleftharpoons}}$$
$$UO_2(\beta\text{-diketonato})_2dmso\cdots DMSO^* \xrightarrow[\text{slow}]{k_1}$$

$$UO_2(\beta\text{-diketonato})_2dmso^*\cdots DMSO \xrightarrow[fast]{} UO_2(\beta\text{-diketonato})_2dmso^* + DMSO, \quad (6)$$

where K_{os} is the formation constant of the outer-sphere complex, $UO_2(\beta$-diketonato$)_2$dmso$\cdots$DMSO*, and k_I is the interchange rate constant between DMSO molecules in the first coordination sphere and those in the second coordination sphere. Since the rate-determining step is the k_I path, k_{ex} is given by Eq. 7.

$$k_{ex} = k_I K_{os}[DMSO]/(1+K_{os}[DMSO]) \quad (7)$$

If $K_{os}[DMSO] \gg 1$, Eq. 7 can be simplified as $k_{ex}=k_I$ and the exchange rate of DMSO becomes independent of DMSO. This mechanism also appears to be compatible with the results of the DMSO exchange in $UO_2(acac)_2$dmso and $UO_2(dbm)_2$dmso in CD_3COCD_3.

Although the D or I mechanism can not be distinguished by the form of the rate law, the I mechanism seems to be unlikely for the following reasons. In the I mechanism, the condition $K_{os}[DMSO] \gg 1$ is required and hence $K_{os} \gg 100\ M^{-1}$ should be satisfied over the concentration range in the present experiments. However, such a value of $K_{os}(\gg 100\ M^{-1})$ is too large considering the normal association constant between uncharged molecules. The D mechanism, on the other hand, might be supported by the fact that some uranyl complexes, *e.g.* $UO_2(H_2O)_4^{2+}$ [1,24,25] $UO_2(hmpa)_4^{2+}$ [2,26] exist in solution as a tetragonal bipyramid.

Another mechanism, where the rate-determining step is the ring-opening of one of the coordinated acac groups, might be proposed. However, this mechanism can be ruled out since the rate constant for ring-opening is about 2.04 s^{-1} at 25 °C in o-$C_6H_4Cl_2$ [27] which is much smaller than that observed for the DMSO exchange reaction.

For the DMSO exchange reaction for $UO_2(acac)_2$-dmso in CD_2Cl_2, the observed first-order rate constants, k_{ex}, depend on the free DMSO concentrations but not linearly as shown in Fig. 5. This fact might suggest that the DMSO exchange in this system proceeds through both the D and I mechanisms. From Eqs. 4 and 6, k_{ex} is given by Eq. 8.

$$k_{ex} = \frac{k_d + k_I K_{os}[DMSO]}{1+K_{os}[DMSO]} \quad (8)$$

If $K_{os}[DMSO] \ll 1$, Eq. 8 can be simplified as $k_{ex}=k_d+k_I K_{os}[DMSO]$. This corresponds to the region of low DMSO concentration in Fig. 8, where k_{ex} changes linearly with DMSO concentration. If $K_{os}[DMSO] \gg 1$, k_{ex} is close to k_I. This is consistent with the fact that the k_{ex} values approach the limiting values at high DMSO concentrations. The values of k_d, k_I, and K_{os} were calculated by using the nonlinear least-squares method for Eq. 8 and are listed in Table 5. The experimental data are in close agreement with the calculated best-fit lines, which are shown in Fig. 5 as solid lines. The activation parameters for k_d and k_I were obtained from the data for various temperatures and are shown in Table 2.

Table 5. The values of k_d, k_I, and K_{os} at various temperatures for the exchange of DMSO in $UO_2(acac)_2$ dmso in CD_2Cl_2

Temp / °C	k_d / s^{-1}	k_I / $10^2\ s^{-1}$	K_{os} / M^{-1}
10	35.5±6.1	4.47±1.17	4.6±2.1
0	18.5±0.8	1.86±0.45	5.9±0.4
−10	8.38±0.44	1.65±0.08	3.1±0.2
−20	2.85±0.67	0.57±0.01	6.2±0.5

As can be seen in Fig. 8, the DMSO exchange in $UO_2(dbm)_2$dmso behaves similar to that observed for $UO_2(acac)_2$dmso in CD_2Cl_2 except for the plots being linear even at the high DMSO concentration range. In spite of the linear relationship of k_{ex} against the DMSO concentration, the A mechanism [23] seems to be unlikely, because the size of dbm is much larger than that of acac and the associative attack of the DMSO molecule should be sterically restricted for the dbm complex. If a similar mechanism (combination of the D and I mechanisms) as proposed for $UO_2(acac)_2$dmso In CD_2Cl_2 is assumed, the condition of $K_{os}[DMSO] \ll 1$ should be satisfied over the range of DMSO concentrations from 0.0627 to 0.499 M. This means that K_{os} for $UO_2(dbm)_2$dmso and DMSO is at least fivefold smaller than that between $UO_2(acac)_2$dmso and DMSO. Considering the bulky size of dbm compared with that of acac, such a value of K_{os} might be expected to be reasonable.

The difference in exchange processes which were observed in two different solvents, CD_3COCD_3 and CD_2Cl_2, may primarily be attributed to the difference in affinity of these solvents for uranyl complexes. Acetone has a relatively large basicity compared with dichloromethane on the basis of Gutmann's donor number [28] and tends to solvate the second coordination spheres of uranyl complexes under the present experimental conditions. It may be predicted that in the case of DMSO exchange in CD_3COCD_3, solvation by CD_3COCD_3 assists the dissociation of DMSO from the first coordination sphere, instead of the free DMSO in the bulk solvent being involved in the activated complex. The dielectric constant of acetone (20.7) is larger than that of dichloromethane (8.93), and hence smaller K_{os} values are expected in CD_3COCD_3 than in CD_2Cl_2.

Table 6. Kinetic parameters for the exchange of DMSO in various uranyl complexes in CD_3COCD_3

Complex	Mechanism	ΔH^* / kJ mol^{-1}	ΔS^* / J K^{-1} mol^{-1}	k_{ex}(25 °C) / s^{-1}
$UO_2(dmso)_5^{2+}$	D	53.8±2.4	6.3±14.5	5.53×10^3
	A	39.1±1.7	−28.1± 5.0	$3.22\times10^4/M^{-1}$
$UO_2(acac)_2$ dmso	D	45.8±0.8	−46.6± 2.9	2.36×10^2
$UO_2(dbm)_2$ dmso	D	44.5±0.4	−46.2± 2.1	3.92×10^2

Nevertheless, much larger values of k_{ex} in CD_3COCD_3 may support the above solvent assisted mechanism.

In spite of the DMSO exchange reactions in $UO_2(acac)_2dmso$ and $UO_2(dbm)_2dmso$ proceeding through the D and I mechanisms, large negative activation entropies are observed. This may be due to the solvent effect as suggested by Bennetto and Caldin.[29,30] They suggested that even though the exchange reaction proceeds dissociatively, ΔS^* may have negative values from the contribution of the solvent rearrangement around the metal complexes.

It is interesting to compare the DMSO exchange reactions in $UO_2(dmso)_5^{2+}$, $UO_2(acac)_2dmso$, and $UO_2(dbm)_2dmso$. The kinetic parameters of these DMSO exchange reactions in CD_3COCD_3 are summerized in Table 6. In the case of $UO_2(dmso)_5^{2+}$, the exchange rate is much faster than for the other complexes. This is consistent with general expectation that if the exchange reaction proceeds through an associative process, the reaction rate should be reduced significantly with crowding at the reaction site. It is quite reasonable that the bulky chelating ligands, acac and dbm, may hinder the approach of free DMSO to the first coordination sphere of the uranyl complex. This result may support the notion that the A mechanism is the major process for $UO_2(dmso)_5^{2+}$ in contrast with the D type processes for $UO_2(acac)_2dmso$ and $UO_2(dbm)_2dmso$.

The authors wish to thank Professor Gilbert Gordon of Miami University and Professor Thomas W. Swaddle of the University of Calgary for their helpful discussions.

(Received October 7, 1982)

Green *trans*-dichlorocobalt(III) complexes with a variety of achiral and chiral (2-aminoalkyl)phosphines have been prepared and characterized. The crystal structures of $[CoCl_2\{(2\text{-aminoethyl})diphenylphosphine\}_2]1/2[CoCl_4]$ and $[CoCl_2\{(R)\text{-}(2\text{-aminoethyl})butylphenylphosphine\}_2]ClO_4$ have been determined by X-ray analyses. Both complex cations have a distorted octahedral coordination with two Cl atoms in the *trans* positions and two P (and N) atoms in the *cis* positions. The Co–N distances (2.02—2.05 Å) are 0.05—0.07 Å longer than the usual Co(III)–N distance, and the P–Co–P angles are widened (99.4 and 103.1°) on account of bulky substituents on the phosphorus atoms. The circular dichroism spectra of $[CoCl_2\{(2\text{-aminoethyl})diphenylphosphine\}_2]ClO_4$ (space group $P3_221$) in Nujol mull and the complexes with chiral (aminoalkyl)phosphines in methanol solutions have been recorded and compared with those of related complexes.

In a previous paper,[1] we have reported the preparation, and some spectroscopic and chemical properties of the $[CoCl_2\{NH_2CH_2CH_2P(C_6H_5)_2\}_2]X$ (X=Cl^- or ClO_4^-) complex. The complex has a green color characteristic of the *trans*(Cl,Cl) configuration. However, no clear evidence was obtained for assigning the geometrical configuration of the phosphorus (or nitrogen) donor atoms, *trans*(P,P) or *cis*(P,P). This paper deals with crystal structures of two green complexes, $[CoCl_2\{NH_2CH_2CH_2P(C_6H_5)_2\}_2]1/2[CoCl_4]$ and $[CoCl_2\{(R)\text{-}NH_2CH_2CH_2P(C_4H_9)(C_6H_5)\}_2]ClO_4$, determined by X-ray structure analyses. The latter complex is chiral and shows circular dichroism (CD). The perchlorate salt of the former complex, the structure of which could not be solved because of the twin crystal, crystallizes in the chiral space group $P3_221$ and also exhibits CD in the solid state. This paper includes CD spectra of those and several complexes of the same *trans*-dichloro-type formed with related optically active (aminoalkyl)phosphine ligands.

The ligands used in this study and the abbreviations are as follows; (2-aminoethyl)diphenylphosphine, $NH_2CH_2CH_2P(C_6H_5)_2$=edpp; (2-aminoethyl)dimethylphosphine, $NH_2CH_2CH_2P(CH_3)_2$ = edmp; (*S*)-(2-aminopropyl)diphenylphosphine, (*S*)-$NH_2CH(CH_3)CH_2P(C_6H_5)_2$ = *S*-pdpp; (*R*)-(2-aminoethyl) butylphenylphosphine, (*R*)-$NH_2CH_2CH_2P(C_4H_9)(C_6H_5)$ = *R*-ebpp; (*S*)-2-(diphenylphosphinomethyl)pyrrolidine, (*S*)-$CH_2CH_2CH_2NHCHCH_2P(C_6H_5)_2$=*S*-prdpp; (*S*(C),*R*(P))- and (*S*(C),*S*(P))-2-(butylphenylphosphinomethyl)-pyrrolidine, (*S*(C), *R*(P))- and (*S*(C), *S*(P))-$CH_2CH_2CH_2NHCHCH_2P(C_4H_9)(C_6H_5)$ = *S*(C),*R*(P)- and *S*(C),*S*(P)-prbpp. The notation of the absolute configurations, *R* and *S*, for the chiral phosphorus atom of a free ligand is reversed upon coordination to the cobalt(III) ion.[2] In this paper, however, we use the same notation for a coordinating ligand as that when it is free.

Experimental

Preparations. Free (aminoalkyl)phosphines were prepared according to methods reported and handled under nitrogen atmosphere until they formed air-stable cobalt(III) complexes; edpp,[3] edmp,[4] *S*-pdpp,[5] *R*-ebpp,[6] *S*-prdpp,[7] and *S*(*C*), *R*(P)- and *S*(C), *S*(P)-prbpp.[8]

$[CoCl_2(edpp)_2]ClO_4$ and $[CoCl_2(edpp)_2]1/2[CoCl_4]$. The perchlorate was prepared by the method reported in a previous paper.[1]

The perchlorate (100 mg) was dissolved in methanol (40 cm³), and 5 cm³ of concd hydrochloric acid was added. On standing at room temperature the solution gave green needles of $[CoCl_2(edpp)_2]Cl\cdot HCl\cdot H_2O$ (38 mg). Found: C, 49.86; H, 5.20; N, 4.12%. Calcd for $C_{28}H_{35}N_2OP_2Cl_4Co$: C, 49.58; H, 5.20; N, 4.13%.

The crystals were dissolved again in methanol and $CoCl_2\cdot 6H_2O$ (8 mg) was added. The solution was evaporated slowly by standing at room temperature to give dark green plates of $[CoCl_2(edpp)_2]1/2[CoCl_4]$ which were subjected to X-ray analysis. Found: C, 48.02; H, 4.84; N, 4.09%. Calcd for $C_{28}H_{32}N_2P_2Cl_4Co_{1.5}$: C, 48.82; H, 4.68; N, 4.07%.

$[CoCl_2(edmp)_2]Cl\cdot H_2O$ and $[CoCl_2(edmp)_2]ClO_4\cdot 1/2\ NaClO_4$. The chloride was prepared by two methods. *Method 1*: To a methanol solution (50 cm³) of $CoCl_2\cdot 6H_2O$ (238 mg, 1 mmol) was added edmp (210 mg, 2 mmol) under nitrogen atmosphere, and then the mixture was stirred in the air for 6 h. The resulting brown solution was diluted with water and poured onto an SP-Sephadex column. The product adsorbed was eluted with a 0.01 mol/dm³ NaCl solution, and the eluate was evaporated to dryness under reduced pressure. The residue was extracted with ethanol. The extract was allowed to evaporate slowly at room temperature, giving blue-green crystals of $[CoCl_2(edmp)_2]Cl\cdot H_2O$. Yield: *ca.* 10%.

Method 2: An *N*,*N*-dimethylformamide solution (50 cm³) of *cis*-$[CoCl_2(en)_2]Cl$ (en: ethylenediamine) (285 mg, 1 mmol) was mixed with a methanol solution (10 cm³) of edmp (105 mg, 1 mmol), and the mixture was stirred for 6 h. The resulting solution was diluted and chromatographed by the same method as the above to give the complex. Yield: *ca.* 7%. Found: C, 24.12; H, 6.54; N, 6.95%. Calcd for $C_8H_{26}N_2OP_2Cl_3Co$: C, 24.42; H, 6.66; N, 7.12%. No dichloro complex was

Found for $[CoCl_2(S(C), R(P)\text{-prbpp})_2]ClO_4\cdot 1/2H_2O$: C, 48.45; H, 6.31; N, 4.30%. Calcd for $C_{30}H_{49}N_2O_{4.5}P_2Cl_3Co$: C, 48.89; H, 6.70; N, 3.80%. Found for $[CoCl_2(S(C), S(P)\text{-prbpp})_2]ClO_4\cdot H_2O$: C, 47.68; H, 6.32; N, 4.44%. Calcd for $C_{30}H_{50}N_2O_5P_2Cl_3Co$: C, 48.30; H, 6.76; N, 3.76%.

Spectral Measurements. Absorption and CD spectra were recorded on a Hitachi 323 spectrophotometer and a JASCO J-40CS spectropolarimeter, respectively.

X-Ray Analyses. X-Ray analyses of $[CoCl_2(edpp)_2]1/2[CoCl_4]$ and $[CoCl_2(R\text{-ebpp})_2]ClO_4$ were performed. Space groups and approximate unit-cell dimensions were determined from oscillation and Weissenberg photographs taken with Cu $K\alpha$ radiation. Crystal data and experimental details are given in Table 1.

Intensity data were collected at room temperature on a Philips PW1100 automated diffractometer by the use of graphite-monochromated Mo $K\alpha$ radiation. The intensities of three standard reflections of each compound showed no appreciable decay throughout the data collections. An absorption collection was applied for the ebpp complex, but not for the edpp complex. The maximum and minimum transmission factors are 1.34 and 1.30, respectively. Relative structure factors were calculated by use the program written

TABLE 2. FRACTIONAL COORDINATES AND TEMPERATURE FACTORS FOR *trans*-$[CoCl_2(edpp)_2]1/2[CoCl_4]$

by Hornstra and Stubbe.[9]

The structures were solved by the conventional Patterson and Fourier techniques. The parameters were refined by the block-diagonal least-squares method. The six carbon atoms of the two butyl groups were isotropically refined because they were disordered. The atomic scattering factors of the Co, Cl, P, O, N, and C atoms were taken from the reference.[10] The real part of the anomalous dispersion corrections were applied for the Co, Cl, and P atoms. The absolute configuration of the ebpp complex could not be determined, since the Weissenberg photographs taken with Cu *Ka* radiation showed no appreciable difference in intensities of any Bijvoet pairs.

The atomic coordinates are listed in Tables 2 and 3.

The F_o-F_c tables and anisotropic thermal parameters are preserved by the Chemical Society of Japan (Document No. 8314). The computation were carried out by the FACOM 230-60 computer at Osaka City University and the ACOS 700 computer at the Crystallographic Research Center, Institute for Protein Research, Osaka University. The programs used included local versions of the UNICS[11] and ORTEP II.[12]

Results and Discussion

Crystal Structures of [$CoCl_2$(*edpp*)$_2$]*1/2*[$CoCl_4$] (*A*) *and* [$CoCl_2$(R-*ebpp*)$_2$]ClO_4 (*B*). Figures 1 and 2 show the X-ray structures of the complex cations in **A** and **B**, respectively. Both cations have a distorted octahedral coordination with two Cl atoms in the *trans* positions and two P (and N) atoms in the *cis* positions. The complex cation in **A** has an approximate two-fold axis running through the Co atom and the mid point of the P···P edge. Thus both edpp chelate rings form the same $\delta\delta$ or $\lambda\lambda$ chiral conformation, although the crystal has the achiral space group C2/c, comprising of an equal amount of the $\delta\delta$ and $\lambda\lambda$ conformers. The corresponding perchlorate salt crystallizes in the chiral space group $P3_221$ (or $P3_121$), and all the chelate rings in a crystal should have the same chirality (*vide infra*). Complex **B** contains the optically active ebpp ligand. The absolute configuration of the ligand could not be determined by the X-ray method (Experimental), but has been assigned conclusively to *R* from CD studies of the Pd(II)–dichloro complex of this ligand and the corresponding *S*(C),*S*(P)- and *S*(C),*R*(P)-prbpp complexes.[6] The absolute configuration of the *S*(C),*S*(P)-prbpp complex was determined by the X-ray method.[8] The two *R*-ebpp chelate rings take enantiomeric conformations to each other, δ and λ and the two phenyl (or butyl) groups are disposed in the opposite directions to each other from the plane formed with the two chelate rings. The selected bond distances and angles are given in Tables 4 and 5.

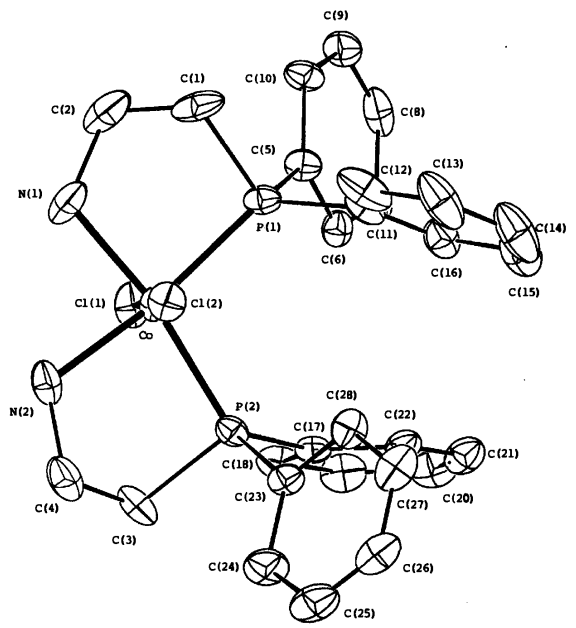

Fig. 1. The *trans*(Cl, Cl), *cis*(P, P)-[$CoCl_2$(edpp)$_2$]$^+$ ion viewed along the Cl–Co–Cl axis. The thermal ellipsoids are drawn at the 30% probability level.

The average Co–P distance in **B** is slightly shorter

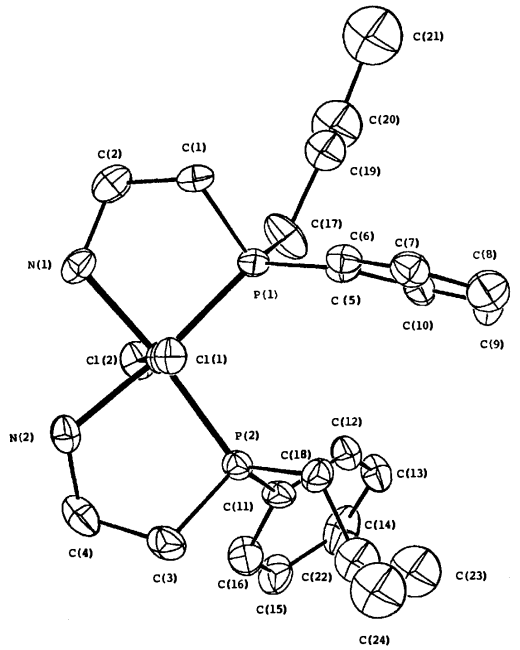

Fig. 2. The *trans*(Cl, Cl), *cis*(P, P)-$[CoCl_2(R\text{-ebpp})_2]^+$ ion viewed along the Cl-Co-Cl axis. The thermal ellipsoids are drawn at the 30% probability level, except for C(24) which is represented by a sphere with arbitrary radius.

than that in **A**, although the difference is not significant in view of the e.s.d.'s. These distances are 0.03—0.10 Å shorter than the Co(III)–P distances found for unidentate phosphine complexes.[13] The Co–N distances range from 2.02 to 2.05 Å which are 0.05—0.07 Å longer than the usual Co(III)–N distance. The lengthening of the Co–N bond has been found in *fac*-$[Co(edmp)_3]Br_3\cdot 3H_2O$ (Co–N=2.04 Å).[4] Such elongation of the Co–N distance is ascribable to the trans influence of phosphine ligands.

The chelate P–Co–N angles in both complexes are less than 90° and similar to the N–Co–N angles in Co(III) complexes of en and its derivatives.[14] In the chelate rings, the average P–C distance of 1.84 Å is *ca.* 0.30 Å longer than the N–C distance. The Co–P–C angle is *ca.* 9—10° smaller than the tetrahedral angle, while the Co–N–C angle is *ca.* 6° greater than the tetrahedral one.

For bis- and tris(aminoalkyl)phosphine complexes, the two phosphino groups tend to prefer the *cis* positions as have been found in the present complexes and *fac*-$[Co(edmp)_3]^{3+}$.[4] No fraction indicative of the *trans*-(P,P) isomer was obtained in column chromatography. The *cis* disposition of the phosphino groups seems to be unfavorable in view of the inter-ligand overcrowding among bulky substituents on the P atoms. However, such overcrowding appears to be alleviated by i) widenning the P–Co–P angle to 103.1° (**A**) and 99.4° (**B**), and ii) varing the Co–P-substituent angle (116°—122°) so as to keep inter-ligand contact distance normal. Such large deviations from the normal angle would cause strain in the ligand. The *cis* preference of the phosphino groups at the expence of the strain of the

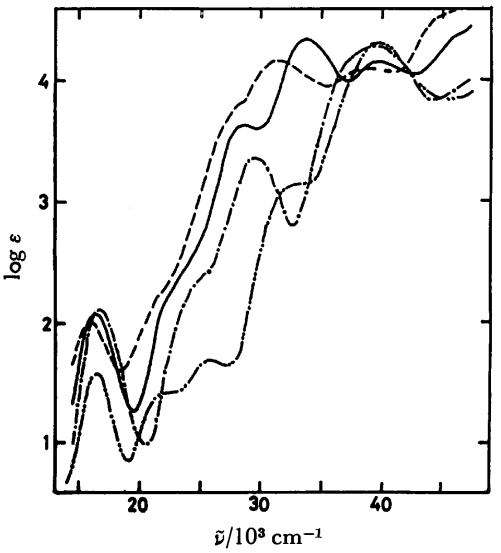

Fig. 3. Absorption spectra of *trans*(Cl, Cl), *cis*(P, P)-[$CoCl_2L_2$]$^+$ in methanol, L: edpp (------), edmp (·–·–), *R*-ebpp (——),-and *trans*-[$CoCl_2$(*S*-pn)$_2$]$^+$ (-·-·-) in methanol.

ligand suggests that the *trans*(P,P) configuration is unfavorable because of the mutual trans influence of P atoms.

The complex ions in **A** and **B** have a very similar coordination geometry, but there is a slight difference between the structural parameters. The P–Co–P angle in **B** is 3.7° smaller than that in **A**. All of the inter-ligand distances among substituents on the P atoms in **B** are longer than 4.0 Å, but some of them in **A** are less than 4.0 Å (*ca.* 3.7 Å). These facts indicate that the

Solvent: methanol. sh: shoulder

–P(C_4H_9)(C_6H_5) group is smaller in bukiness than the –P(C_6H_5)$_2$ group. This is in accord with the cone angle for these groups.[15] On the other hand, the –P(C_4H_9)-(C_6H_5) group should be more basic than the –P(C_6H_5)$_2$ one, since in phenylphosphines, replacement of a phenyl substituent by an alkyl one generally increases basicity of a phosphine.[16] Thus the smaller and more basic –P(C_4H_9)(C_6H_5) group would form a stronger Co–P bond and hence would exert stronger trans influence on a trans ligand than the case of the –P(C_6H_5)$_2$ group. Indeed, the Co–P bonds in **B** are shorter than those in **A**, while the Co–N bonds in **B** are longer than those in **A**, although the differences are less significant on the statistical ground.

Nonbonded distances in both crystals are normal. The shortest hydrogen bond length is 3.01(1) Å [N-(NH_2)···O(ClO_4)] in the *R*-ebpp complex, and 3.37(1) Å [N(NH_2)···Cl($CoCl_4$)] in the edpp complex.

The geometry of green [$CoCl_2$(edmp)$_2$]$^+$ has not yet been determined. However, this complex ion should also have the *cis*(P,P) configuration in view of the small size and strong basicity of the –P(CH_3)$_2$ group. Other aminoalkyl-diphenyl- and -butylphenyl-phosphine complexes prepared in this study can be assigned to the *cis*(P,P) configuration. In fact, all the complexes show absorption spectral patterns very similar to one another (*vide infra*).

Absorption and CD Spectra. Figure 3 shows absorption spectra of the edpp, *R*-ebpp, and edmp complexes together with that of *trans*-[$CoCl_2$(*S*-pn)$_2$]$^+$ (*S*-pn=(*S*)-1,2-propanediamine), and Table 6 lists the spectral data in the region of 15000 to 25000 cm^{-1} (the

d-d transition region). All the (aminoalkyl)phosphine complexes exhibit a medium intensity band at *ca.* 16000 cm^{-1}. This band should correspond to the split component, Ia of the first d-d band of the *S*-pn complex, since the complexes have the *trans*(Cl,Cl), *cis*(P,P) configuration as stated previously, and ligand field strength of these (aminoalkyl)phosphines are similar to or a little stronger than that of *S*-pn.[5] The absorption maxima of these bands are shifted to the high energy side in the order of edpp<*R*-ebpp<edmp complexes. This order is the same as that found for bis(ethylenediamine)complexes of these ligands.[4] The absorption intensities increase in the same order, but it is reverse to that of the bis(ethylenediamine)complexes.

The Ib component and the second d-d bands are observed as shoulders (21000—24000 cm^{-1}) by overlapping of the strong bands (26000—29000 cm^{-1}) which can be assigned to the Co–Cl charge transfer bands.[17] The bands at 31450 and 33600 cm^{-1} of the edpp and *R*-ebpp complexes, respectively, and the shoulder at *ca.* 36500 cm^{-1} of the edmp complex can be assigned to the Co–P charge transfer bands, since the corresponding bis(ethylenediamine) complexes of these phosphine ligands also show similar strong bands at nearly the same wavenumbers. The bands at *ca.* 40000 cm^{-1} can be assigned to another Co–Cl charge transfer band from a comparison with the spectrum of the *S*-pn complex.[17]

As stated previously, the green $[CoCl_2(edpp)_2]ClO_4$ complex crystallizes in the chiral space group. Figure 4a shows the solid CD spectrum of this complex dispersed in Nujol in the d-d transition region. The spectral pattern quite resembles that of *trans*(Cl,Cl)-$[CoCl_2(S\text{-pdpp})_2]^+$ in methanol (Fig. 4b). The *S*-pdpp complex has two sources of optical activity, the chiral carbon atom and the chiral conformation of the chelate ring. However, the similarity in the two CD spectra indicates that the optical activity of both complexes arises mainly from the chiral conformation of the chelate ring. The *S*-pdpp ligand will be stabilized in the δ conformation with the methyl group disposed equatorially. Thus the chelate rings in the edpp complex given in Fig. 4a should be of the δ conformation. In Fig. 4c is given the CD spectrum of *trans*-$[CoCl_2(S\text{-pn})_2]^+$ in methanol for comparison. The *S*-pn chelate ring also forms the same δ conformation. However, the spectrum is different to a large extent from those of the *S*-pdpp and edpp complexes.

Figure 5 compares CD spectra of the *S*-pdpp and *S*-prdpp complexes in methanol. Both CD spectra are similar over the whole region, in particular, in the Ia band region. The *S*-prdpp chelate ring should be fixed in the δ conformation, producing a new chiral source on the nitrogen atom (*S*) stereoselectively.[18] Thus it is presumed that the *S*-pdpp chelate ring is conformationally stable in the δ form, and that the vicinal effect of the chiral nitrogen atom in the *S*-prdpp complex is small.

Figure 6 shows CD spectra of a diastereomeric pair of the *S*(C),*S*(P)- and *S*(C),*R*(P)-prbpp complexes. The nitrogen atoms in these isomers are also chiral to form the *S* configuration. The spectra exhibit the main CD bands with different signs in the Ia band region and are almost enantiomeric to each other in the high energy

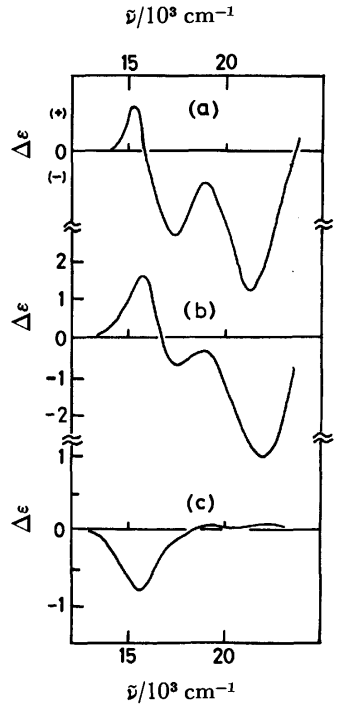

Fig. 4. CD spectra of (a) *trans*(Cl, Cl), *cis*(P, P)-$[CoCl_2(edpp)_2]ClO_4$ in Nujol mull, (b) *trans*(Cl, Cl), *cis*(P, P)-$[CoCl_2(S\text{-pdpp})_2]^+$ in methanol, and (c) *trans*-$[CoCl_2(S\text{-pn})_2]^+$ in methanol.

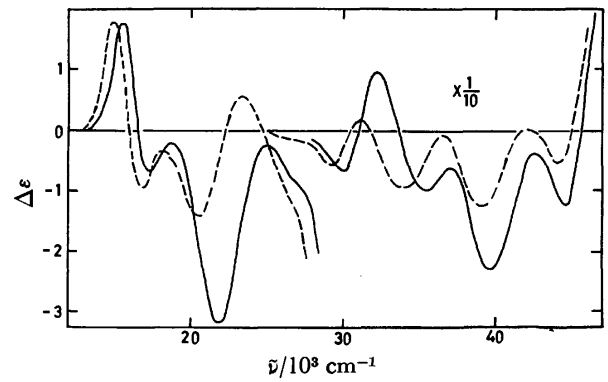

Fig. 5. CD spectra of *trans*(Cl, Cl), *cis*(P, P)-$[CoCl_2L_2]^+$ in methanol, L: *S*-pdpp (——), *S*-prdpp (------).

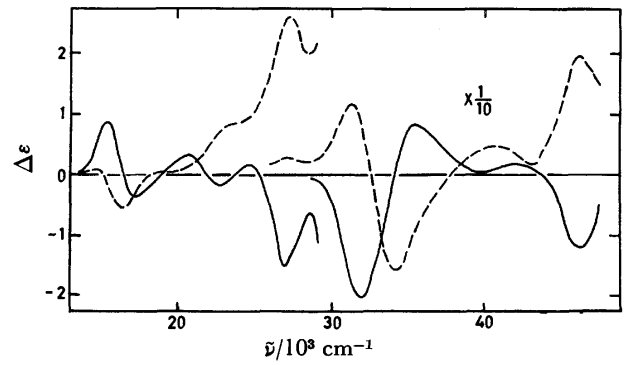

Fig. 6. CD spectra of *trans*(Cl, Cl), *cis*(P, P)-$[CoCl_2L_2]^+$ in methanol, L: *S*(C), *R*(P)-prbpp (——), *S*(C), *S*(P)-prbpp (------).

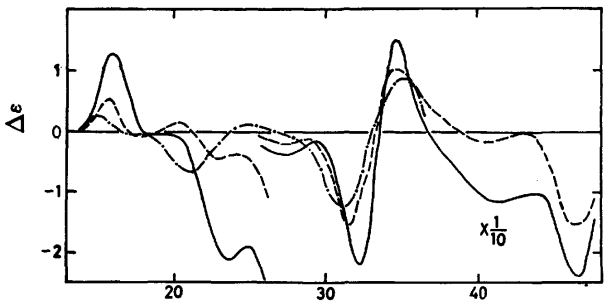

Fig. 7. CD spectra of *trans*(Cl, Cl), *cis*(P, P)-[$CoCl_2$(*R*-ebpp)$_2$]$^+$ (——) and *trans*(Cl, Cl), *trans*(CH_3, CH_3)-[$CoCl_2${(*R*)-*N*-methylethylenediamine}$_2$]$^+$ (·–·–·)[20] in methanol. The vicinal CD curve (------) for the *R*(P)-ligand obtained from CD curves of a pair of diastereomers, *trans*(Cl, Cl)*cis*(P, P) complexes of *S*(C), *R*(P)- and *S*(C), *S*(P)-prbpp (1/2[Δε{*S*(C), *R*(P)-isomer}-Δε{*S*(C), *S*(P)-isomer}]).

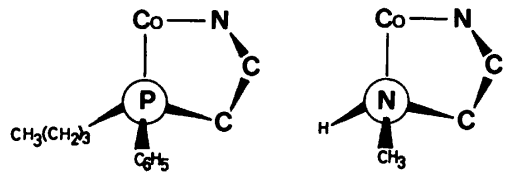

S-configuration *R*-configuration

Fig. 8. Absolute configuration of donating phosphorus and nitrogen atoms.

region. Thus it is suggested that the vicinal effect of the chiral phosphorus atom is considerably large in these complexes. The vicinal effect of the (*R*)-phosphorus atom can be estimated from the observed CD spectra by calculating 1/2[Δε{*S*(C),*R*(P)-isomer}—Δε{*S*(C),*S*-(P)-isomer}]. The result is compared with the CD spectrum of the *R*-ebpp complex, in which the chiral phosphorus atom is the sole source of optical activity (Fig. 7). Both curves are similar, although there is some difference in strength. In Fig. 7 these curves are compared with the CD spectrum of *trans*(Cl,Cl), *trans*-(CH_3, CH_3)-[$CoCl_2${(*R*)-*N*-methylethylenediamine}$_2$]$^+$ in methanol.[19,20] The CD curve calculated for the vicinal effect of the (*R*)-nitrogen atom in *trans*(Cl,Cl), *trans*(C_2H_5,C_2H_5)-[$CoCl_2${(2*S*)-2-amino-4-azahexane}$_2$]$^+$ is also very similar to the CD spectrum of the (*R*)-*N*-methylethylenediamine complex.[21] The absolute configuration of the *R*-ebpp ligand is denoted as *S* upon coordination, as stated previously. Thus the (*S*)-phosphorus and (*R*)-nitrogen donor atoms in the *trans*-dichloro-type complex shown in Fig. 8 induce the vicinal effect of the positive sign in the Ia band region.

For the *R*-ebpp complex, the two chelate rings in crystals are diastereomeric to have *R*(δ) and *R*(λ) chiralities, indicating a small energy difference between the two chiral forms of the ring. In solution the chelate ring would exist in the two forms in a similar amount. Hence the CD spectrum of the *R*-ebpp complex would involve a small vicinal effect of the chiral conformation, δ and λ. This is supported by the fact that the spectrum is similar to the vicinal CD curve of the (*R*)-phosphorus atom obtained from a pair of diastereomeric prbpp complexes.

(Received October 9, 1982)

A simple and convenient analytical method for simultaneous multielement determination of soil and rock samples has been investigated by inductively coupled plasma emission spectrometry. Spectral interferences due to major elements were examined in detail, and the correction coefficients for minor and trace elements were estimated for correction of matrix effects. The determinations of minor and trace elements as well as major elements could be performed without matrix matching of the standard solutions. The present method investigated has been applied to the analysis of various soil and rock samples, and the analytical results have been compared with those obtained by atomic absorption spectrometry.

An inductively coupled plasma (ICP) is an efficient excitation source in emission spectrochemical analysis for major, minor and trace elements in various samples.[1] As has been extensively studied,[2-8] ICP optical emission spectrometry (ICP-OES) provides high sensitivities for a variety of elements, wide linear dynamic ranges of calibration curves, and less chemical and ionization interferences, along with simultaneous multielement detection capability. However, spectral interferences with major elements in samples, which originate from spectral line overlapping, stray light or scattering due to strong emission lines, and continuous emission backgrounds, are severe problems in the determination of trace elements.[9,10] Usually in conventional analyses, the concentrations of major elements in sample solutions and those in standard solutions are matched as closely as possible in order to compensate the matrix effects. This experimental procedure requires the different sets of standard solutions for samples with different matrices, and so it is not easily applicable to or convenient for rapid analysis of a number of samples. The soil or rock samples have been analysed by ICP-OES.[11-16] Since the matrix compositions of soil or rock samples are complicated, spectral interferences mentioned above should be carefully corrected for accurate analyses. In addition, the chemical reagents used for digestion are often prone to contamination and physical interference as well as spectral interference. Generally, acid digestion is preferable to alkali fusion in the viewpoints of contamination from chemicals used and nebulization interference. Hence, acid digestion method has been employed in the present experiment.

Furthermore, we have investigated a conventional method for analysis of digested soil and rock samples without matrix-matching of major elements. The changes of background intensities for trace elements at the monitored wavelengths due to major elements are estimated as the correction coefficients for background correction. The background correction method examined is applied to the analysis of soil and rock samples, and the analytical values are compared with those obtained by atomic absorption spectrometry.

Experimental

Instruments. An ICP emission spectrometer (Mode Plasma Atomcomp Mk II) from Jarrell-Ash Co. was used with a crossflow type nebulizer. The instrumental components and operating parameters for the emission measurements are summarized in Table 1. The solution was fed to the nebulizer through a Teflon capillary tube. The analytical lines employed are shown in Table 2. The calibration curves were made by joining the points for the blank and standard with the straight lines.

Chemicals and Standard Solutions. All the chemicals used were of analytical or spectrochemical reagent grade. Commercially available standard solutions (1000 μg/ml) for atomic absorption spectrometry (Wako Pure Chemicals Co.) were used for the stock solutions except for K, Na, Be, P, Pb, Sc and Y, which were prepared from proper compounds or metals according to the recommended methods.[17] Working standard solutions for calibration curves were simply prepared by mixing and/or diluting the stock solutions in four groups. The combinations of elements for working standard solutions

a) 2nd order.

are summarized in Table 2.

Standard I is composed of major elements in usual soil samples, and these concentrations are similar to the average values of the digested solutions of soil samples. Standards II and III are composed of minor and trace elements. Standard IV for Si was prepared to check the suitability of the digestion procedure, because incomplete digestion resulted in abnormally high concentration of Si in the digested solutions.

In order to minimize the variation of the nebulization efficiency due to the differences of the viscosities of the solutions, the acid contents in each standard solution were adjusted to be 3% $HClO_4$ and HCl so as to match those in the digested sample solutions.

Digestion Procedure. About 0.5 g of powdered soil or rock sample was dried at 110 °C for 4 h, and taken into a Teflon beaker. Ten ml of concd HNO_3 was added in the beaker, and heated to near dryness on a hot plate at 200 °C. Five ml of HF was added into the dried residue, and heated again to dryness. After cooling, 3 ml of HNO_3 and 5 ml of $HClO_4$ were added, and heated for about 3 h until white fume of $HClO_4$ appeared. The digested sample was diluted with 20 ml of distilled water and 3 ml of HCl, and filtered with a 5 A filter paper. Finally, the filtrate was filled up to 100 ml with water.

According to the digestion procedure described above, the final concentration of $HClO_4$ was about 3%, and the content of total salts (major components) was less than 0.5%. As mentioned earlier, the concentrations of $HClO_4$ in the standard solutions were adjusted to be 3%. It was reported that the spectral interferences by major elements were linear in the concentration range of the total salts less than 0.5%.[16] It should be noted that the decomposition of oxide minerals such as chromite and zircon by the digestion method above may not be complete. In general, however, the contents of such minerals in soil samples are not significant.

Results and Discussion

Detection Limits and Recoveries. The detection limits, average contents of minor and trace elements in soils,[18] and the recoveries of elements in the digestion procedure are summarized in Table 3. The detection limits were defined as the analyte concentrations equivalent to twice the standard deviations of the background emission intensities in the presence of major elements at the average concentration levels in the soil samples. The detection limits were obtained under the compromised operating conditions shown in Table 1. The compromised conditions were chosen to make the detection limits as low as possible and to avoid the spectral interferences of major elements as much as possible.

a) The values when each element is aspirated at the concentration given in Table 2. All intensities are shown as the arbitrary unit. b) Relative intensity is expressed as the ratio of net intensities observed without and with major elements.

The detection limits for soil, which were converted as the minimal detectable contents in soil samples from the detection limits for the standard solutions, are also shown in the second column of Table 3. It can be seen from Table 3 that the determinations of elements except for As, Bi, Cd, Mo, Pb, and Sb are possibly made in terms of soil samples.

The recoveries summarized in Table 3 were obtained by digesting about 0.5 g of soil sample with 50 μg of each element added, and measuring the emission intensities simultaneously. The recovery values obtained were good enough to apply the present method to the soil analysis.

Spectral Interferences. The changes of background intensities due to major elements were investigated by observing intensity profiles near analytical lines of minor and trace elements. The profiles were obtained by moving a refractor quartz plate behind the entrance slit. The profile measurements allowed to distinguish the emission signals caused by spectral interferences from those due to impurities. Consequently, the spectral interference due to major elements such as Al, Ca, Fe, K, Mg, Na, and Ti were estimated as correction coefficient expressed as the analyte concentration (ng/ml) equivalent to the background emission intensity which is provided with 1 μg/ml of each major element. The results are summarized in Table 4. For example, the interference with 1000 μg/ml of Al is equivalent to 23.9 μg/ml of As. The largeness of the interference is generally dependent on the operating conditions of the instrument, especially on the RF power. Therefore, the interference data such as those shown in Table 4 should be estimated under each operating condition and also with each instrument.

The effects of major elements on emission intensities of minor and trace elements were observed as the changes of net intensities at various emission lines with and without major elements. The results are shown in Table 5, along with relative intensities. In the experiment, the concentrations of major, minor and trace elements were the same as those shown in Table 2. As can be seen in Table 5, the changes of net intensities caused by major elements are negligibly small at the tested concentrations of minor and trace elements except for Ga, Zr, Cd, Cu, and Y. However, such changes must be carefully examined at the lower concentrations of analytes.

In order to make accurate background correction, the linearity of the spectral interferences with the major element concentration must be investigated at each emission line. The interferences of Ti and K with Cu are, for example, shown in Fig. 1. The interference at Cu I 324.7 nm caused by Ti is proportional to the Ti concentration, while that by K is not. Generally, the interferences were proportional to the concentration of major elements (Al, Ca, Fe, Mg, and Ti) at the level

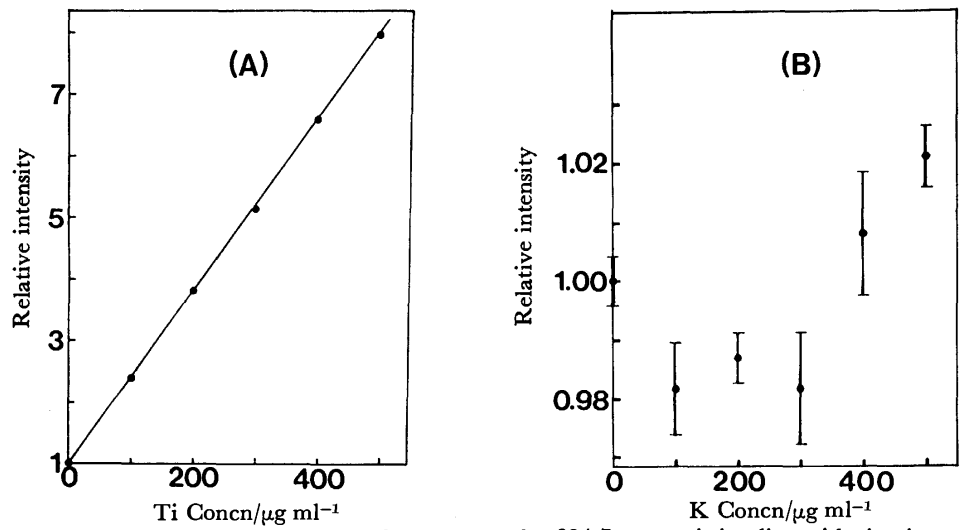

Fig. 1. Spectral interference of copper at the 324.7 nm emission line with titanium and potassium. (A) Interference of titanium, (B) interference of potassium.

less than 500 μg/ml. On the other hand, the linearity of spectral interferences was not found in the case of Na and K, but the interferences due to Na and K were rather small compared to those due to other major elements, or sometimes negative for most minor and trace elements. This result suggests that the interferences due to Na and K are physical ones caused by nebulization changes. In most cases, however, the interferences due to Na and K could be neglected in the background correction except for the case at their high concentration levels.

The additivity of the spectral interferences due to major elements, when the mixed solution of major elements are aspirated, should be also examined for the background correction. In Table 6, the sum of the apparent intensities at the emission lines of Cr, Cu, and La caused by 100 μg/ml of each major element is compared with those caused by the mixed solution which contains all the major elements at the level of 100 μg/ml. As can be seen from Table 6, the interferences due to major elements without Na and K is more similar to the observed interference of the mixed solution than that due to all major elements including Na and K.

Standardization of Analytical Method. The present analytical method was standardized by analysing some standard rock samples of which elemental compositions were known. It is, also, desirable to analyse standard soil samples, but such standard soil samples have not been available yet. The rock samples studied are AGV-1, GSP-1, G-2, and PCC-1 from the United States Geological Survey, and JG-1 from the Geological Survey of Japan.

The correlation between the analytical and recommended values for V in the standard rock samples are shown in Fig. 2, where the observed and corrected

values are indicated as △ and ●, respectively. As can be seen in Fig. 2, most of the corrected values agree well with the recommended values reported in the literature. In the case of PCC-1, the lower value for V was obtained, compared with the recommended value. Since the content of Mg in PCC-1 is relatively high (1200 μg/ml), the over-correction might be made. When the concentrations of some major elements are high like in the case of PCC-1, the over-correction of the spectral interferences is generally made because of the deviation from the linearity of the interference at the high concentration range of major elements.[20]

Analytical results for the standard rock sample G-2 by the present method are shown in Table 7, along with the results obtained by atomic absorption spectrometry (AAS) and the reported values. It can be seen from Table 7 that the present data are almost consistent with those in the literature values for most elements. Thus the present method is well standardized for the rock and soil samples with complicated matrices.

Application to Simultaneous Multielement Determinations of Soil Samples. The present ICP-OES method has been applied to the simultaneous multielement determinations of 40 soil samples from South-East Asian countries. No adjustment of the operating parameters were required during the experimental period for total analysis time of 3 h. The analytical results for some elements were cross-checked with those obtained by AAS. In Fig. 3, the correlations of analytical results obtained for Zn and Co by ICP-OES are shown, respectively.

The extensive data shown in Table 7 and Figs. 2 and 3 suggest that a single set of the calibration standard solutions (see Table 2) suffices for the quantitative determination of the elements at the minor and trace concentration levels in a variety of sample matrices. It should, however, be noted here that the matrix matching of acid contents and the background correction for major elements are strongly recommended for accurate determination of minor and trace elements, when ICP-OES is applied.

The authors express their thanks to Dr. Hideaki Kai in the Kyushu Unive rsity for his providing soil samples This research was supported by Grant-in-Aid for Environmental Science under Grand No. 56030019 from the Ministry of Education, Science and Culture.

A Cation-exchange Study of the Hydrolysis of Tracer Concentrations of Polonium(IV)

Hideo SUGANUMA,* Itsuhachiro HATAYE, and Yoshimasa TAKASHIMA†

(Received October 12, 1982)

A cation-exchange method was used for determining the average cationic charge of polonium species present in hydrolytic equilibrium in solutions. This method is based on measurements of the distribution ratio of polonium at a constant internal hydrogen-ion concentration of the cation-exchanger phase. In 1.0 mol dm^{-3} (H,Na)ClO_4 and 1.0 mol dm^{-3} (H,Na)NO_3 solutions at $-\log[H^+]=1.0$, tracer concentrations of polonium(IV) were found to exist in the mean chemical forms of $Po(OH)_{3.43}^{0.53+}$ and $Po(OH)_{2.83}(NO_3)_{0.60}^{0.57+}$, respectively. The formation of cationic polymerized species was also estimated in region of $4\leqq -\log[H^+]$ in a 1.0 mol dm^{-3} (H,Na)ClO_4 solution.

In polonium compounds, it has been reported that the oxidation numbers of plonium are ± 2, $+3$, $+4$, and $+6$.[1] The quadrivalent state was assigned to a large portion of polonium in every pH region.[2-4] With respect to polonium in solution, the solvent-extraction study of polonium in strongly acidic solutions has been reported by several workers.[5-9] The present authors have investigated the hydrolysis of polonium(IV) ions in the pH region through solvent extraction with dithizone–CCl_4 solutions.[10-12] The dependence of the chemical behavior of polonium on the pH of the solution clearly showed the importance of the hydrolytic processes. Paper chromatography was also used to study the chemical state of polonium in nitrate solutions.[13,14] The results showed appreciable variations in chemical species with the storage time and with the hydrogen-ion concentrations of the polonium solutions. Koch and Schmidt have studied the hydrolysis of polonium in perchlorate solutions by the cation-exchange method.[2] There have been some other reports of ion exchange on polonium,[15-19] but the results, derived from the ion-exchange behavior of polonium, have not indicated the well-defined chemical species for polonium in each solution. In continuation of the preceding work on polonium,[10-12,14] we have now studied the mean chemical species of polonium in 1.0 M (H,Na)ClO_4 (1 M=1 mol dm^{-3}) and 1.0 M (H,Na)NO_3 solutions at $-\log[H^+]=1.0$ with the cation-exchange method.

Experimental

Reagents. The water and reagents used were all purified to the highest degree, especially to overcome the difficulties hitherto experienced as a result of contamination. Bio-Rad AG 50W-X8 was the cation-exchange resin employed in this study. The H-form resin, 100—200 mesh, was washed three times alternatively with 1 M HCl and 1 M NaCl to remove impurities (finally converted to the Na-form), washed with water sufficiently, and dried in air. A part of the polonium (^{210}Po) imported from the Radiochemical Centre, Amersham, England, was used by diluting it to the appropriate concentration with a 1.0 M (H, Na)ClO_4 or 1.0 M (H, Na)NO_3 solution.

Measurements of the Distribution Ratio. Twenty ml (1 ml=1 cm^3) of a 1.0 M (H, Na)ClO_4 or 1.0 M (H, Na)NO_3 solution containing definite amounts of polonium was mixed with 0.3 g of a cation exchanger in a test tube with a stopper and then shaken at room temperature until the partition equilibrium was attained. A 5-ml portion of the aqueous phase was pipetted into a scintillation vial containing 5 ml of a scintillator (Dotite Scintisol 500, Dojindo Lab.), shaken sufficiently, and then subjected to measurements of its α-activity. Because it is difficult to count the activity of the resin phase with the same counting efficiency as the aqueous phase with a liquid scintillation counter, the α-activity of the resin phase ($\bar{A}$) was calculated using $\bar{A}=A_{aq}^{\circ}-A_{aq}$, where A_{aq}° is the initial activity of the aqueous phase before shaking and where A_{aq} is the activity of the aqueous phase after shaking. The distribution ratio of polonium, D, is given as follows:

$D=(\bar{A}$/gram of air-dried resin)/(A_{aq}/ml of aqueous phase).

In each case, the multiple ion-exchange procedures were repeated by using the same test tube on a solution with a definite hydrogen-ion concentration and definite amounts of polonium; the data obtained in the first half were discarded, and only the reproducible data in the other half were taken. As D is influenced by the extent of the dehydration of air-dried resin, a definite water content must be kept in the series of experiments.

Results and Discussion

Adsorption of Polonium onto Test Tube. The inside surfaces of the test tubes used were, in advance, sufficiently and repeatedly equilibrated with respect to the adsorption of polonium with 20 ml of a 1.0 M (H,Na)-ClO_4 solution containing polonium (1.56×10^5 cpm) at $-\log[H^+]=1.2$. After the test tube containing a freshly prepared 1.0 M (H,Na)ClO_4 solution (20 ml, 1.56×10^5

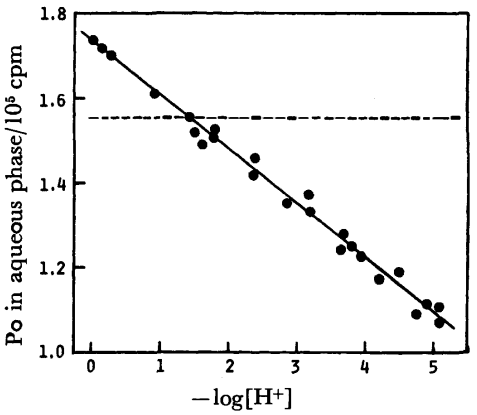

Fig. 1. The adsorption and desorption of polonium onto/from the test tube. The test tubes were in advance equilibrated with 20 ml of ^{210}Po solution (1.56×10^5 cpm, 1.0 M (H, Na)ClO_4) at $-\log[H^+]=1.2$.

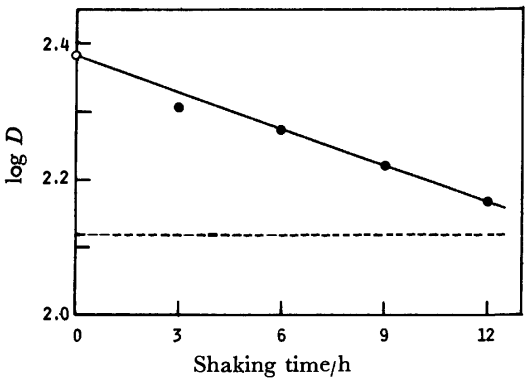

Fig. 3. The time-dependence of desorption from the resin (Bio-Rad AG 50W-X8, 100—200 mesh).
After the partion system (20 ml of ^{210}Po solution of 1.0 M (H, Na)ClO_4 at $-\log[H^+]=3.54$, 0.3 g resin) attained equilibrium, the time-dependence of desorption was measured in the solution whose quarter volume was replaced by the fresh solution free from polonium. (The broken line indicates the D in the equilibrium state.)

cpm), with pH values varying from 0 to 5, had been shaken for 3 h, the activity of the aqueous phase was measured. The results are shown in Fig. 1. Those results indicate that polonium is leached from the glass wall in a higher acidity than $-\log[H^+]=1.2$ and, moreover, adsorbed onto it in a lower acidity. Therefore, the reproducible results of D should be obtained in the cation-exchange study of polonium only when the distribution equilibrium is set up among the resin phase, the glass wall of the test tube, and the aqueous phase in a definite hydrogen-ion concentration.

Time Required for Partition Equilibrium. As is shown in Fig. 2, the sorption of polonium onto Bio-Rad AG 50W-X8 (0.3 g) reaches equilibrium within 3 h in 1.0 M (H,Na)ClO_4 solutions at $-\log[H^+]=0$, 1.95, and 3.95 respectively. Accordingly, the partition system was shaken for more than 3 h in all the experiments in order to attain equilibrium.

Time Dependence of Desorption from the Resin. After the partition system (20 ml of ^{210}Po solution and 0.3 g resin) had attained equilibrium at $-\log[H^+]=3.54$, the time dependence of the desorption was measured in a solution whose quater volume had been replaced by a newly prepared solution containing no polonium. From the results shown in Fig. 3, we can see that the distribution ratio decreases slowly toward equilibrium again in 1.0 M (H,Na)ClO_4 at $-\log[H^+]=3.54$ and that the rate of desorption of polonium from the resin is smaller than that of sorption onto the resin. At any rate, it seems that the sorption reaction of polonium with the resin proceeds reversibly.

Dependence of Selectivity Coefficients of Polonium Species on the Hydrogen-ion Concentration. We have previously reported that polonium was present in the chemical forms of $Po(OH)_3^+$ and $Po(OH)_4$ in a 1.0 M (H,Na)-ClO_4 solution in region of $0 \leq -\log[H^+] \leq 6$.[10] In general, as the ionic strength in the resin phase is higher than in a solution equilibrated with it, the less hydrolyzed species, such as $Po(OH)_2^{2+}$, should be present in the resin, when the hydrolysis reaction on polonium is suppressed. Therefore, the distribution ratio, D, is expressed as follows:

$$D = \frac{[Po^{4+}]_R + [Po(OH)^{3+}]_R + [Po(OH)_2^{2+}]_R + [Po(OH)_3^+]_R + [Po(OH)_4]_R}{([Po(OH)_3^+] + [Po(OH)_4])} \quad (1)$$

$$= K_{H^+}^{Po(OH)_3^+} \times \frac{[H^+]_R}{[H^+]} \times \frac{(K_{-3}[OH^-]_R^{-3} + K_{-2}[OH^-]_R^{-2} + K_{-1}[OH^-]_R^{-1} + 1 + K_1[OH^-]_R)}{(1 + K_1[OH^-])}, \quad (2)$$

where $K_{H^+}^{Po(OH)_3^+}$ (selectivity coefficient) $= \frac{[Po(OH)_3^+]_R[H^+]}{[Po(OH)_3^+][H^+]_R}$ for the reaction, $Po(OH)_3^+ + \overline{H^+} = \overline{Po(OH)_3^+} + H^+$, $K_n = [Po(OH)_{3+n}^{1-n}]/\{[Po(OH)_3^+][OH^-]^n\}$ for the reaction, $Po(OH)_3^+ + nOH^- = Po(OH)_{3+n}^{1-n}$, and $\overline{K_n} = [Po(OH)_{3+n}^{1-n}]_R/\{[Po(OH)_3^+]_R[OH^-]_R^n\}$ for the reaction, $\overline{Po(OH)_3^+} + n\overline{OH^-} = \overline{Po(OH)_{3+n}^{1-n}}$, where species and $[species]_R$ refer to the species in the resin phase and its concentration respectively. It is difficult to determine the selectivity coefficients between hydrogen ions in macro amounts and a definite polonium species in trace amounts. The constancy of its selectivity coefficients was, therefore, examined by replacing that of the selectivity coefficients between Na^+ and H^+, both present in macro amounts in solution. The selectivity coefficient ($K_{Na^+}^{H^+}$) was evaluated from the exchange capacity of the resin (2.581 mequiv./g) and the hydrogen-ion concentration of solutions before/after the ion-exchange reaction. The hydrogen-ion concentration was determined by titration with a standard solution (0.1 M NaOH) for $-\log[H^+]<1.1$ and by measuring with a pH meter for $-\log[H^+]>1.1$. The results are shown in Fig. 4. Taking into account the activity coefficient for the hydrogen-ion concentration in case of the titration,[20] it seems that $K_{Na^+}^{H^+}$ is constant in the region of $0.3<-\log[H^+]<3$.

Dependence of the Distribution Ratio on the Hydrogen-ion Concentration. The distribution ratio of polonium is plotted in Fig. 5 as a function of the hydrogen-ion concentration in a 1.0 M (H,Na)ClO_4 solution. As is shown in the figure, the $\partial \log D/\partial(-\log[H^+])$ slope is negative for $0<-\log[H^+]<3$, naught for $3<-\log[H^+]<4$, and positive for $4<-\log[H^+]<5$. As the condition

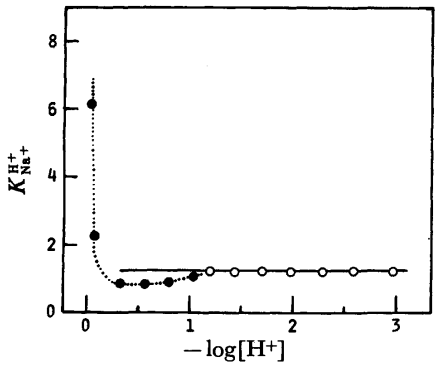

Fig. 4. The dependence of the selectivity coefficient ($K_{Na^+}^{H^+}$) on the hydrogen-ion concentration in 1.0 M (H, Na)ClO_4 solution. The hydrogen-ion concentration was determined by the titration method (●) or with a pH meter (○).

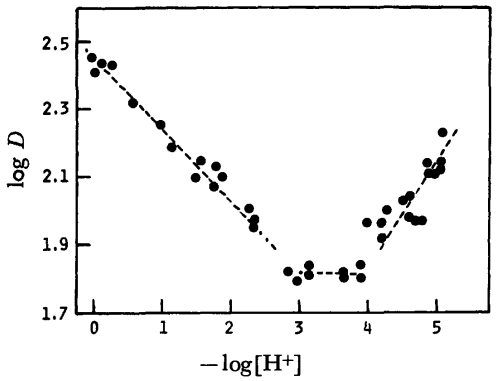

Fig. 5. The dependence of the distribution ratio of polonium on the hydrogen-ion concentration in 1.0 M (H, Na)ClO_4 solution after shaking for 4 h.

of resin in the partition system of cation exchange is changed by varying the hydrogen-ion concentration of the aqueous phase, the variation in log D does not always indicate a change in the chemical species. However, if the selectivity coefficient between polonium species and H^+ is invariant, it can be assumed that the variation in D indicates the change in the chemical species of polonium. The increase in D for $4<-\log[H^+]$ implies the variation in the selectivity coefficient and/or the increase in the cationic polonium species. From the results of the paper chromatography on polonium in nitrate solutions stored for a month or more,[14] it has been indicated that hydrolyzed polynuclear cationic species of polonium might exist for $-\log[H^+]=4.7$—6.6. Consequently, the formation of cationic polymers of polonium after shaking for 4 h can be assumed in the region of $4<-\log[H^+]<5$. On the other hand, the decrease in D for $0.3<-\log[H^+]<3$ indicates a decrease in the cationic polonium species, by analogy with the results of solvent extraction and paper chromatography.[10,14]

The Mean Charge of Polonium Species in 1.0 M (H,Na)-ClO_4 Solutions at $-log[H^+]=1.0$. As the constancy of $K_{H^+}^{Po(OH)_n^{4-n+}}$ in the region of $0.3<-\log[H^+]<3$ has been assumed from $K_{Na^+}^{H^+}$ as is shown in Fig. 4, the distribution ratio, D, was determined under the condition of a constant hydrogen-ion concentration in the resin phase. If the hydrogen-ion concentration in the resin phase is constant, D in Eq. 2 may be simplified as follows:

$$D = \text{constant} \times ([H^+]+K_1Q_W)^{-1}, \quad (3)$$

where $Q_W=[H^+][OH^-]$.

To determine the charge of the polonium species from the distribution ratio at $-\log[H^+]=1.0$ under the condition of a definite ionic strength in (H,Na)ClO_4 solutions, D was, in practice, determined by using the equilibrating solutions shown in Table 1.[21] In Fig. 6, we plot log$D$ as a function of $-\log[H^+]$ in solution. The slope of a tangent line as the mean charge of polonium, that is, the value of -4 plus n_{OH} (number of OH^- ligands combining to a polonium atom), was obtained as -0.45 ± 0.08 at $-\log[H^+]=1.0$. The value of n_{OH} was calculated to be 3.55, slightly larger than 3.43, the value obtained by solvent-extraction study at $-\log[H^+]=1.0$.[10] It is assumed that the true tangential slope at $-\log[H^+]=1.0$ in the cation-exchange method should be larger than the value obtained, for the ionic strength in a higher acidity should be slightly lower than that at $-\log[H^+]=1.0$ (to promote the hydrolysis) and higher in a lower acidity (to depress it). The value of n_{OH}, judging from these facts, may be close to 3.43, result from solvent extraction;[10] hence, the mean chemical form can be estimated to be $Po(OH)_{3.43}^{0.57+}$.

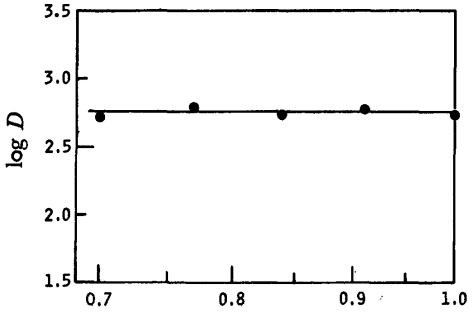

Fig. 7. The effect of the nitrate ion on the distribution ratio of polonium in the cation exchange. The $-\log[H^+]$ of the aqueous phase was kept constant to 1.0.

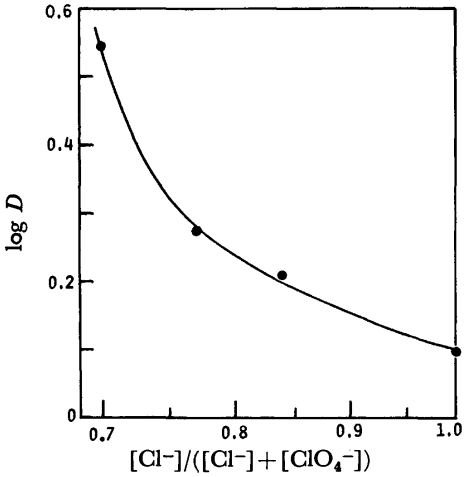

Fig. 8. The effect of the chloride ion on the distribution ratio of polonium in the cation exchange. The $-\log[H^+]$ of the aqueous phase was kept constant to 1.0.

The Mean Charge of Polonium Species in 1.0 M (H,Na)-NO_3 Solutions at $-\log[H^+]=1.0$. In general, the slope of $\log D$ *vs.* $\log\{[NO_3^-]/([NO_3^-]+[ClO_4^-])\}$ in 1.0 M (H,Na)(NO_3,ClO_4) solutions at $-\log[H^+]=1.0$ indicates the difference in the mean charge of the polonium species between 1.0 M (H,Na)NO_3 and 1.0 M (H,Na)ClO_4 solutions at $-\log[H^+]=1.0$. We have determined the slope by varying the mole fractions of the NO_3^- ion, as is shown in Fig. 7. As the slope indicates nearly 0, the mean charge of polonium species in 1.0 M (H,Na)NO_3 at $-\log[H^+]=1.0$ is almost identical with that in 1.0 M (H,Na)ClO_4 at $-\log[H^+]=1.0$. Because it is improbable that the polonium species is polymerized in the shaking period, only the coordination of nitrate ions to polonium should be taken into account. The mean number of NO_3^- combining to a polonium atom being 0.60 at $-\log[H^+]=1.0$,[10,11] the mean chemical form may be $Po(OH)_{2.83}(NO_3)_{0.60}^{0.57+}$ in 1.0 M (H,Na)NO_3 solutions. A similar experiment was carried out with 1.0 M (H,Na)(Cl,ClO_4) solutions at $-\log[H^+]=1.0$. The results are shown in Fig. 8. The distribution ratio of polonium rapidly decreases with an increase in the mole fraction of Cl^- ions, reaching a small value in a 1.0 M (H,Na)Cl solution at $-\log[H^+]=1.0$. This result indicates the formation of negatively charged species and is consistent with the results of solvent extraction.[12] The mean charge of the polonium species in 1.0 M (H,Na)Cl solutions must be further determined by using an anion-exchange method.

The authors are very grateful to Associate Professor Hirohiko Waki of Kyushu University for his valuable suggestions, especially with regard to the ion-exchange method.

Phase Equilibria in the Tm_2O_3-V_2O_3-V_2O_5 System at 1200 °C

Kenzo KITAYAMA* and Takashi KATSURA

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received November 13, 1982)

Phase equilibria in the Tm_2O_3-V_2O_3-V_2O_5 system were established at 1200 °C; the oxygen partial pressure was varied −0.68 (air) to −12.50 atm in terms of log Po_2. In this system, V_nO_{2n-1} (n=2—7), VO_2, Tm_2O_3, $TmVO_3$, $TmVO_4$, $Tm_8V_2O_{17}$ ($4Tm_2O_3 \cdot V_2O_5$), $Tm_7V_3O_{16}$ were stable under the present experimental conditions. The pattern of the phase diagram is different from those of other Ln_2O_3-V_2O_3-V_2O_5 systems (Ln=Sm, Lu, Er, Gd, La, and Nd) that were already established. Compounds $TmVO_3$, $TmVO_4$, $Tm_8V_2O_{17}$, $Tm_7V_3O_{16}$, V_2O_3, and VO_2 have nonstoichiometric compositions. On the basis of the established phase diagram, the Gibbs energies of the reactions,

(1) $2\,Tm_2O_3 + 3\,TmVO_3 + 1/2\,O_2 = Tm_7V_3O_{16}$
(2) $TmVO_3 + 1/2\,O_2 = TmVO_4$
(3) $5/3\,Tm_2O_3 + 2/3\,Tm_7V_3O_{16} + 2/3\,O_2 = Tm_8V_2O_{17}$
(4) $Tm_7V_3O_{16} + O_2 = 5/3\,TmVO_4 + 2/3\,Tm_8V_2O_{17}$

were determined to be −132, −119, −157, and −228 kJ, respectively. The relationship between the ionic radius and ΔG° of the reactions, $LnVO_3 + 1/2\,O_2 = LnVO_4$, is linear, provided that lanthanum and the lanthanoid can be divided into two groups.

Phase equilibria in the Ln_2O_3-V_2O_3-V_2O_5 systems (Ln=Sm, Lu, Er, Gd, La, and Nd) at 1200 °C have been established.[1-6] The oxygen partial pressure was changed from −0.68 to −12.50 or −13.00 atm in terms of log Po_2. We succeeded in obtaining the Gibbs energies of the reactions which appeared in the systems and the crystallographic data of the ternary compounds and the activities of the components in the solid solutions. These established phase diagrams showed the different patterns as a result of the differences of the compounds coexisting under the experimental conditions.

In the present study, Tm_2O_3 was chosen as the Ln_2O_3, because the system might show as interesting a pattern as that of the Lu_2O_3 system.[2] The pyrochlore type compound, $Tm_2V_2O_7$, is well known[7] and its physical properties were studied by many researchers.[7-10]

The Tm_2O_3-V_2O_5 system was studied by Brusset *et al.*[11] in the temperature range from 600 °C to 1500 °C in air. They found two compounds, $4Tm_2O_3 \cdot V_2O_5$ ($Tm_8V_2O_{17}$) and $5Tm_2O_3 \cdot V_2O_5$, besides $TmVO_4$ which is well known. The crystallographic properties of $TmVO_4$ were studied by Brusset *et al.*[11] and Schwarz[12] and those of $Tm_8V_2O_{17}$ by Brusset *et al.*[13] and Ustalova *et al.*[14]

In the Tm_2O_3-V_2O_3 system, only $TmVO_3$ was found; its crystallographic properties were investigated by many researchers.[15-16] But the system has not been completely studied yet on account of the instability of V_2O_3 in air

The objectives of the present study are to (1) make the detailed phase diagram of the Tm_2O_3-V_2O_3-V_2O_5 system at 1200 °C in order to determine the stable compounds under the present experimental conditions, to (2) calculate the Gibbs energies of the reactions found in the established phase diagram, and to (3) ascertain whether or not there is a linear relationship between the Gibbs energies of reactions and the ionic radii of the lanthanoid elements, as found in the Ln-Fe-O system.[17]

Experimental

Analytical grades of Tm_2O_3 (99.9%) and V_2O_5, which was made by heating the guaranteed grade of NH_4VO_3 at 500 °C in air for about 24 h, have been used as the starting materials. Desired Tm_2O_3/V_2O_5 ratios of samples were obtained by mixing the appropriate quantities thoroughly in an agate motar under ethyl alcohol. The mixtures thus obtained were treated by the procedures described in the previous report.[1] The apparatus and procedures for controlling the oxygen partial pressures, keeping a constant temperature, the method of thermogravimetry, the criterion for an equilibrium establishment, the method of the actual oxygen partial pressure measurement, and the method of the chemical analysis are the same as those reported in the previous papers.[1,18-22]

The oxygen partial pressure −12.50 atm in terms of log Po_2 was chosen as the reference oxygen partial pressure; that is, the weight of a samples in the atmosphere of $10^{-12,50}$ atm of oxygen partial pressure was chosen as the reference weight thorough the present experiment.

Results and Discussion

Phase Equilibria. Tm_2O_3 is stable under the present experimental conditions.[23] Eleven samples with Tm_2O_3/V_2O_5 mole ratios 84/16, 8/2, 77/23, 74/26, 7/3, 65/35, 6/4, 1, 3/7, 2/8, and 1/9 were prepared to be used in the thermogravimetric experiment. The thermogravimetric results of the four samples with mole ratios, 84/16, 74/26, 65/35, and 3/7 are shown in Fig. 1 as representative. In Fig. 1, the ordinate is the oxygen partial pressure (atm) in log Po_2 and the abscissa is the composition of the samples represented by Wo_2/W_T, where Wo_2 is the weight gain of the samples from the reference weight at log Po_2=−12.50, and W_T is the total weight gain that the samples would get if V_2O_3 in the samples had changed to V_2O_5. Figure 1 shows the different patterns. That is, Fig. 1a had two sudden weight changes at log Po_2=−8.10 and −9.37, Fig. 1b three at log Po_2=−7.70, −8.10, and −9.37, Fig. 1c also three at −7.70, −8.47, and −9.37. Figure 1d shows the same pattern as those of the previous

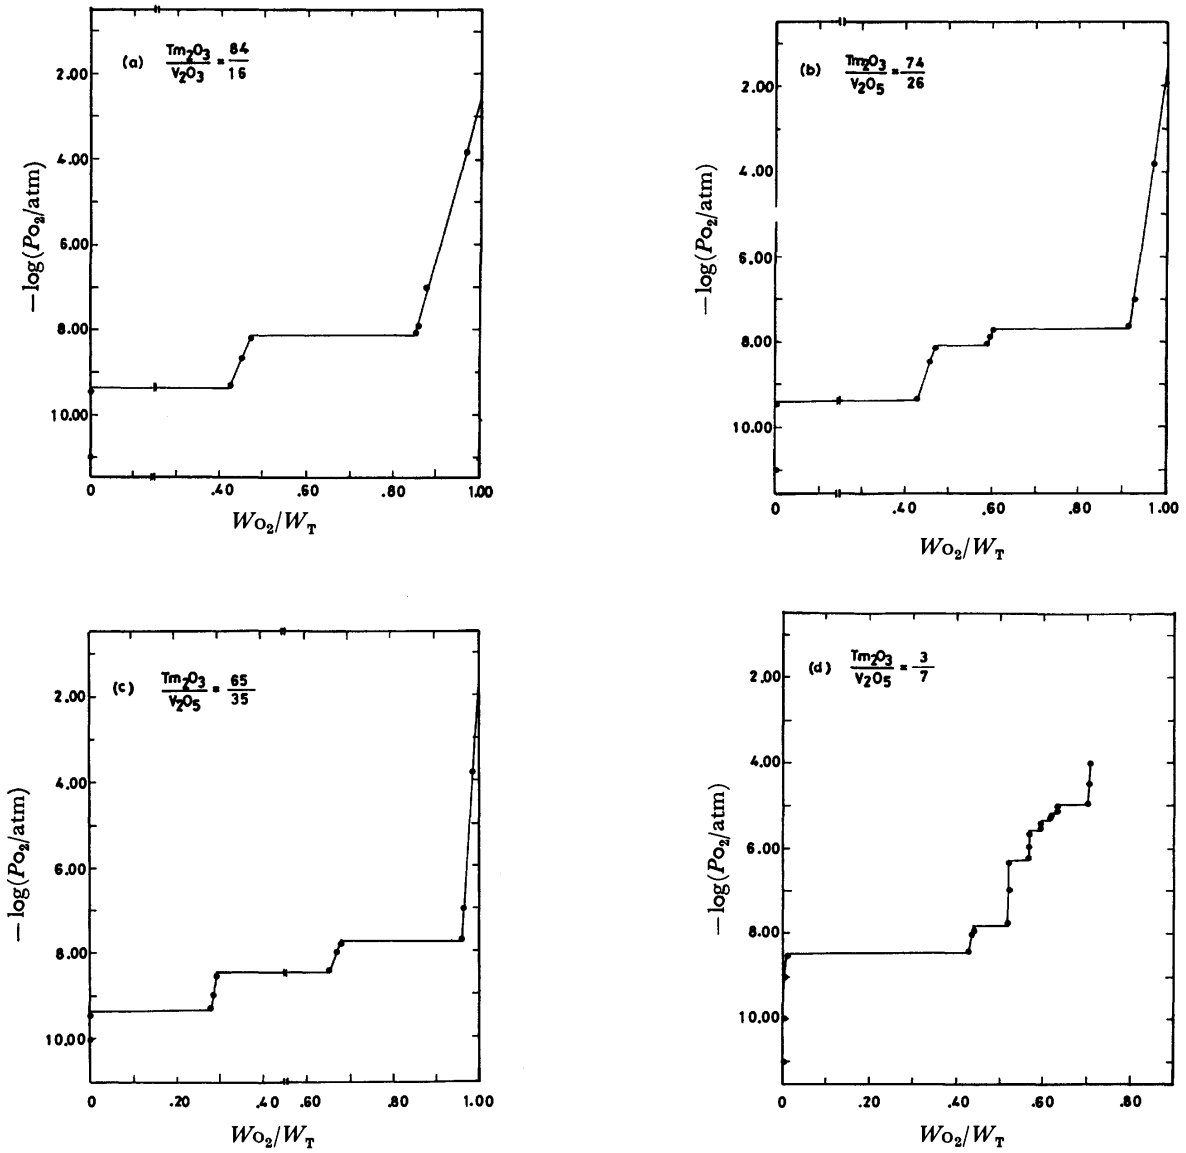

Fig. 1. The relationships between $-\log P_{O_2}$ (atm) and the weight gains, W_{O_2}/W_T, of the samples. (a): $Tm_2O_3/V_2O_5=84/16$, (b): $Tm_2O_3/V_2O_5=74/26$, (c): $Tm_2O_3/V_2O_5=65/35$, (d): $Tm_2O_3/V_2O_5=3/7$.

reports[1,3-6] except one change at the oxygen partial pressure $\log P_{O_2}=-8.47$ that corresponds to the equilibrium oxygen partial pressure of a reaction, $TmVO_3+1/2\ O_2=TmVO_4$. These oxygen partial pressures also correspond to the equilibrium oxygen partial pressures of reactions in the system, as will be shown in Table 5.

In Table 1, the results of the identification of phases are shown. In the first column are shown the compositions of the strating materials in mol%, in the second the experimental conditions of the oxygen partial pressure in terms of $\log P_{O_2}$ (atm), in the third the experimental durations in hours, and in the last the phases that are found in the quenched samples by X-ray powder diffractometer using Cu $K\alpha$ radiation.

Based upon the above thermogravimetric results and the results of the identification of phases, a phase diagram of the system was drawn and is shown in Fig. 2. The following phases are stable under the present experimental conditions, omitting compounds in the V_2O_3–V_2O_5 system and Tm_2O_3 : $TmVO_4$, $TmVO_3$, $4Tm_2O_3\cdot V_2O_5$ ($Tm_8V_2O_{17}$, A), and $Tm_7V_3O_{16}$ (L). The compound $5Tm_2O_3\cdot V_2O_5$, which was reported[11] as a stable compound together with $4Tm_2O_3\cdot V_2O_5$ in air in the Tm_2O_3–V_2O_5 system, and the pyrochlore type $Tm_2V_2O_7$ were not found under the present experimental conditions.

The present phase diagram is different from those of the other systems[1-6] on account of the different coexisting compounds. That is, the Sm_2O_3–V_2O_3–V_2O_5 system has a ternary compound, $5Sm_2O_3\cdot V_2O_5$; the Lu_2O_3–V_2O_3–V_2O_5 system contains $Lu_7V_3O_{16}$, $Lu_2V_2O_7$, and LuV_4O_8; the Er_2O_3–V_2O_3–V_2O_5 system $4Er_2O_3\cdot V_2O_5$; the Gd_2O_3–V_2O_3–V_2O_5 system $0.81Gd_2O_3\cdot 0.19V_2O_5$; the La_2O_3–V_2O_3–V_2O_5 system $0.81La_2O_3\cdot 0.19V_2O_5$, $3La_2O_3\cdot V_2O_5$, and $0.71La_2O_3\cdot 0.19V_2O_5$; and the Nd_2O_3–V_2O_3–V_2O_5 system contains $0.81Nd_2O_3\cdot 0.19V_2O_5$ and $3Nd_2O_3\cdot V_2O_5$.

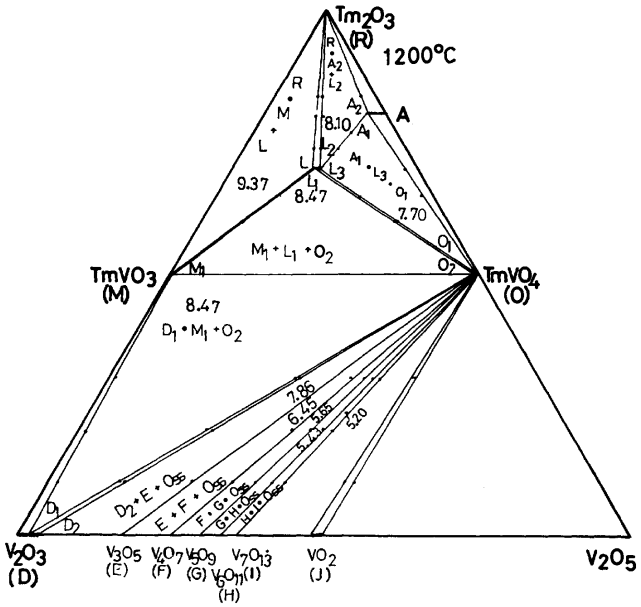

Fig. 2. Phase equilibria in the Tm_2O_3–V_2O_3–V_2O_5 system at 1200 °C. Numerical values in the three solid phases regions are the equilibrium oxygen partial pressure in $-\log P_{O_2}$. Abbreviations are the same as thosein Table 3.

The compound $Tm_7V_3O_{16}$ is a new compound, although the atomic ratio is analogous to the compound $Lu_7V_3O_{16}$ that was found by us thorough the study of the Lu_2O_3–V_2O_3–V_2O_5 system.[2] Both compounds, $Tm_7V_3O_{16}$ and $Lu_7V_3O_{16}$, have a similar powder X-ray diffraction pattern, as shown in Fig. 3, but we could not yet determine the crystallographic system. The spacing and relative intensities which were obtained

Table 5. Gibbs energies of reactions

Reaction	$-\log (Po_2/atm)$	$\frac{-\Delta G°}{kJ}$
(1) $2\,Tm_2O_3 + 3\,TmVO_3 + 1/2\,O_2 = Tm_7V_3O_{16}$	9.37 ± 0.05	132 ± 1
(2) $TmVO_3 + 1/2\,O_2 = TmVO_4$	8.47 ± 0.05	119 ± 1
(3) $5/3\,Tm_2O_3 + 2/3\,Tm_7V_3O_{16} + 2/3\,O_2 = Tm_8V_2O_{17}$	8.10 ± 0.07	157 ± 2
(4) $Tm_7V_3O_{16} + O_2 = 5/3\,TmVO_4 + 2/3\,Tm_8V_2O_{17}$	7.70 ± 0.07	228 ± 2

by the X-ray powder diffractometer are shown in Table 2.

Compounds $Tm_8V_2O_{17}$, $Tm_7V_3O_{16}$, $TmVO_3$, $TmVO_4$, V_2O_3, and VO_2 have nonstoichiometric compositions. The relationship between a composition, N_O/N_Y, and the oxygen partial pressure of the solid solution, Y that means an arbitary component, were determined using the thermogravimetric results. Here, N_O and N_Y are the mole fractions of oxygen and of the component Y. Using the method of the least squares with a linear equation, $N_O/N_Y = a \log Po_2 + b$, the constants a and b for each solid solution were determined as follows: for $Tm_8V_2O_{17}$ 0.10 and 0.49 and for $Tm_7V_3O_{16}$ 0.17 and 0.186. As for the solid solutions $TmVO_4$ and $TmVO_3$, the composition ranges are too narrow to obtain such equations. Especially, the nonstoichiometric ranges of $TmVO_3$ are very small, although the width of ranges is a little exaggerated in Fig. 2. V_2O_3 and VO_2 were already discussed in the previous report.[1]

In Table 3, the compositions of the compounds at various oxygen partial pressures, stability ranges of the compounds in terms of $\log Po_2$, the symbol of the compounds, and the activities of the component in the solid solutions at distinct oxygen partial pressures are tabulated. The activities of the components in the solid solutions were calculated with the Gibbs-Duhem equation using the thermogravimetric results of the N_O/N_Y *vs.* $\log Po_2$ relations described above. A detailed method of the calculation has been discussed in the paper of Kimizuka and Katsura.[21] Since solid solution ranges of $TmVO_4$ and $TmVO_3$ were too small to get the general equations of N_O/N_Y *vs.* $\log Po_2$, we took the activities of components $TmVO_4$ and $TmVO_3$ as unity over the whole range of compositions.

Lattice constants of the compounds $TmVO_4$, $TmVO_3$, and $Tm_8V_2O_{17}$ are tabulated in Table 4. Our values are in good agreement with those quoted in the Table.

Calculation of Gibbs Energies of Reactions. On the basis of the present phase diagram, Gibbs energies of the reactions represented in the system, except those in the partial system V_2O_3-V_2O_5, can be calculated by the equation $\Delta G° = -RT \ln K$, where R is the gas constant, T the absolute temperature, and K the equilibrium constant of each reaction. Chemical reactions, the equilibrium oxygen partial pressure for each reaction, and $\Delta G°$ values calculated are shown in Table 5. Activities of each component of the solid solutions, which are necessary for the calculations, are tabulated in Table 3.

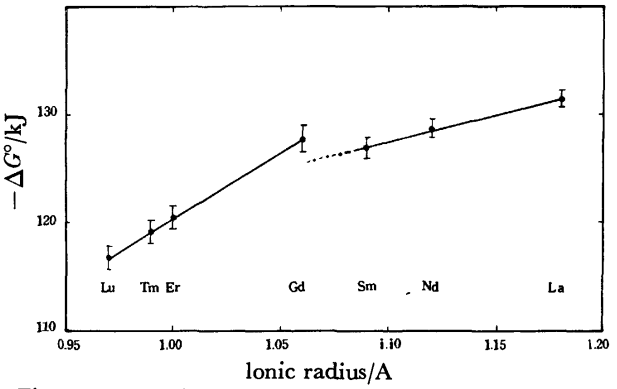

Fig. 4. The relationship between the ionic radius in 8 coordination number and the Gibbs energy of reaction, $LnVO_3 + 1/2\,O_2 = LnVO_4$.

The relationship between $\Delta G°$ and Ionic Radius. In the series of the Ln_2O_3-V_2O_3-V_2O_5 system, the common reaction $LnVO_3 + 1/2\,O_2 = LnVO_4$ appear in all the systems. So it is very interesting to correlate the $\Delta G°$ with some properties of this lanthanoid element. As mentioned above, we reported a linear relation between the $\Delta G°$ values of the formation of perovskite from Ln_2O_3, iron, and oxygen and the tolerance factor. In Fig. 4, is shown the relationship between the ionic radius of the lanthanoid element with coordination number 8[24] of $LnVO_4$ and $\Delta G°$ values. Unlike the case of Ln–Fe–O system, it seems to seperate to two groups:

the so-called heavy lanthanoid series and the so-called light one and they show a linear relationship with a rule that ΔG° values decrease with increasing the atomic radius. This pattern is similar even if the abscissa is changed to the radius of coordination number 12[25] of $LnVO_3$ or to the tolerance factor. As is well known, $LaVO_3$ has a tetragonal crystal system and $LaVO_4$ has a monoclinic system. The linear relation fits well even for La, in spite of the difference of crystal system. This means that the difference of the crystal system does not affect the energies of such a reaction.

Retentive Friedel-Crafts Alkylation of Benzene with Optically Active 2-Chloro-1-phenylpropane and 1-Chloro-2-phenylpropane

Shinji MASUDA,*,† Tadashi NAKAJIMA,†† and Sohei SUGA††

†*Ashikaga Institute of Technology, Ashikaga 356*

††*Department of Industrial Chemistry, Faculty of Technology, Kanazawa University, Kodatsuno, Kanazawa 920*

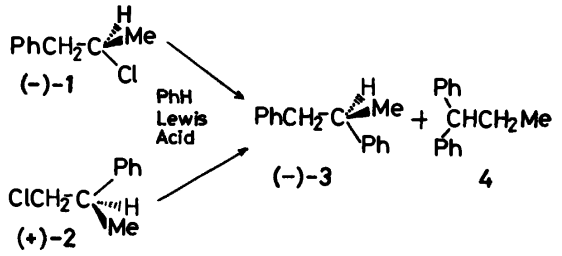
(Received June 15, 1982)

Alkylations of benzene with both (−)-2-chloro-1-phenylpropane (**1**) and (+)-1-chloro-2-phenylpropane (**2**) in the presence of Lewis acid gave the same products: (−)-1,2-diphenylpropane (**3**), 1,1-diphenylpropane, and polymeric materials. In these reactions, (−)-**3** was obtained in 45—100% optical yield and was not racemized under the conditions used. These results reveal that the reaction from **1** to **3** proceeds with retention of configuration and that from **2** to **3** with inversion. The stereochemistry of the alkylation with **1** is elucidated by the mechanism involving a neighboring phenyl π-assisted cation; benzene attacks only the β-carbon of **1** from the side on which the previously attached chloride anion is located. The result of the reaction with **2** can be explained by a process involving the 1,2-shift of phenyl group in the ionization step of **2**, followed by the formation of the same intermediate as in the reaction with **1**. The mechanism of the overall reaction is discussed.

Since the discovery of the Friedel-Crafts reaction with high stereospecific integrity,[1] many reports have been published during the past decade.[2] Most of these stereospecific reactions resulted in the inversion of configuration at the reaction center of the alkylating reagent. Although the Friedel-Crafts reactions have been expected to proceed through a free carbonium ion,[3] the stereospecific examples reported so far indicate that the intermediate cation exists as a tight ion pair with the counterion or as a complex with the Lewis acid used. The validity of such an assumption can be justified by recent stereochemical results on the alkylations of benzene with (+)-2-butanol[4] and (+)-2-chlrobutane;[5] both reactions proceeded with inversion of configuration to give 2-phenylbutane in 27—40% optical yield. Thus, it is expected that the stereospecificity in the Friedel-Crafts reaction using optically active alkylating reagent can be enhanced if the reaction condition was controlled so as not to cause the isomerization of the starting material or the product.

The reaction with inversion of configuration has often been studied. But there have been few studies on the Friedel-Crafts alkylation with retention of configuration. Sprung,[6] Hart,[7] and their co-workers reported that optically active *s*-butyl phenyl ether and α-phenylethyl *p*-tolyl ether rearranged intramolecularly in the presence of a Lewis acid to the corresponding *o*-alkylphenol with retention of configuration. These reactions are in a sence aromatic alkylations with retention. However, when the alkyl phenyl ether was conducted with phenol, the reaction proceeded intermolecularly to give a totally racemic product.[8] Thus, this stereochemical result (retention) of forcing the reaction to be intermolecular has not been reported so far.

In a preliminary account, we demonstrated that the alkylation of benzene with (−)-2-chloro-1-phenylpropane (**1**) by a Lewis acid catalyst proceeded with complete retention of configuration to give (−)-1,2-diphenylpropane (**3**) and that the reaction with (+)-1-chloro-2-phenylpropane (**2**) gave the same product with inversion, as shown in Scheme 1.[2e] The former reaction is the first example of a retentive Friedel-Crafts alkylation which proceeds intermolecularly. In the present paper, we have undertaken a broader investigation of stereochemistry in the Friedel-Crafts alkylation of benzene with (−)-**1** and (+)-**2**, and we discuss the reaction mechanism.



Scheme 1.

Results and Discussion

Both (−)-2-chloro-1-phenylpropane (**1**) and (+)-1-chloro-2-phenylpropane (**2**) reacted with benzene in the presence of 0.1 equivalent of $AlCl_3$ or $FeCl_3$ at −20—40 °C to give the same products: (−)-1,2-diphenylpropane (**3**), 1,1-diphenylpropane (**4**), and polymeric materials. The results under various conditions are summarized in Tables 1 and 2. The structures of **3** and **4** were identified by IR and NMR spectroscopies, and by comparing the retention time of their gas chromatograms with those of authentic samples. The isomer ratio of **3**/**4** was determined by NMR analysis. The optical rotations were taken on the mixture of **3** and **4**, since the two isomers could not be isolated in pure form.[9] The optical yields of the reactions were calculated from the optical purities of the starting materials, the reported rotation of **3**,[4] and the isomer ratio of **3**/**4** in the mixture obtained. The maximum rotation ($[\alpha]_D$) of optically active **1** was evaluated to be +23.9° on the basis of the rotation power of (+)-**1** derived by a series of reaction from optically pure (+)-propylene oxide, as mentioned in the experimental section.[10]

The absolute configurations of (−)-**1**, (+)-**2**, and (−)-**3** have been established to be R,[10] R,[11] and R,[12] respectively. Thus, it is apparent that the reaction from **1** to **3** proceeded with retention of configuration and

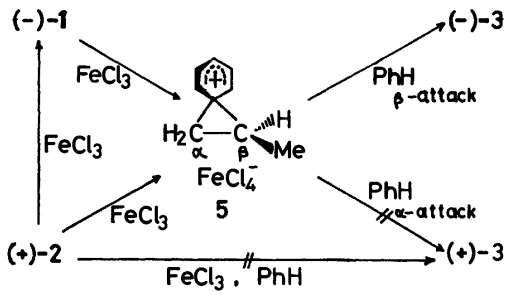
that from 2 to 3 with inversion of configuration at the asymmetric carbon. The $AlCl_3$ catalyzed reaction at 0 °C revealed the highest (complete) stereospecificity. When the reaction was carried out in the presence of $FeCl_3$ or at elevated temperature, considerable racemization of 3 was observed. On the whole, increasing temperature tends to decrease the magnitude of the optical yield of 3 and the isomer ratio of 3/4.

Thus, the stereochemistry (retention) of the alkylation using 1 may be interpreted by a mechanism involving an intermediate (5) of the phenonium ion type, in which benzene attacks only β-carbon of the two bridged carbon atoms from the opposite side of the bulky phenyl ring (the side on which the previously attached chloride anion is located); (Scheme 2).

On the other hand, the stereochemistry of the reaction using 2 indicates that the migration of the phenyl group on C_α to the adjacent carbon takes place simultaneously with the departure of the chlorine atom and then the same phenonium ion (5) as mentioned above was formed prior to the attack of benzene. In connection with this observation, we had found previously that (+)-2 was converted stereospecifically into (−)-1 by trace amounts of Lewis acid.[2e)] If the chlorine atom of 2 was directly replaced with a phenyl group, as suggested by Brown *et al.*,[13)] the alkylation of benzene with (+)-2 should give (+)-3; this does not accord with the result obtained here.



Scheme 2.

The existence of a phenonium ion has recently been recognized on the basis of studies on the rates and products of acetolysis of *threo*-2-aryl-1-methylpropyl brosylate with a number of different substituents,[14)] and has been confirmed spectroscopically to be a stable symmetrically bridged ion in superacid medium,[15)] although there were many controversies over the past two decades.[16)] McMahon *et al.*[17)] also have concluded that the Friedel-Crafts alkylation of toluene with 2-

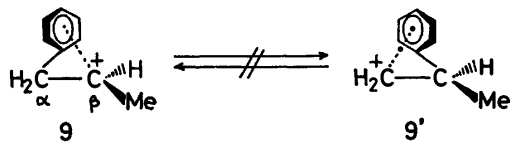
phenylethyl-1-^{14}C chloride proceeded *via* a symmetric phenyl bridged intermediate. In our experiment, if the phenyl ring in the intermediate is equally bonded to both the α and β carbons and if the benzene attacks equally both these carbons, the product (**3**) would not be optically active; such an intermediate must yield a racemic product.

In order to confirm the reaction site in the intermediate, both **1** and **2** were allowed to react with *p*-xylene in the presence of $FeCl_3$. These two reactions gave the same products: 1-phenyl-2-(2,5-dimethylphenyl)propane (**6**) and 1-phenyl-1-(2,5-dimethylphenyl)-propane (**7**), in 80—90% yield. However, no amount of 1-(2,5-dimethylphenyl)-2-phenylpropane (**8**) was detected at all, as shown in Table 3. The process from **2** to **6** involves the 1,2-shift of phenyl group on C_β of **2** to the adjacent carbon, accompanied by the attack of *p*-xylene to the β-carbon. Thus, it is evident that both reactions using **1** and **2** proceed through the same intermediate, in which the β-carbon is attacked exclusively by aromatics.

Accordingly, much of the positive charge in the intermediate resides on the β-carbon, and the participation of phenyl group to that carbon seems to be of the π-bridged type (**9**)[18] (or unsymmetrically bridged type)[19] rather than of symmetrically σ-bridged type (**5**) mentioned above, as shown in Scheme 3. Furthermore, the above result excludes the rapid equilibration between the secondary cation (**9**) and the primary one (**9'**) although such an interconversion between the above two cations is still controversial.[18,19]



Scheme 3.

The stereospecificity of both reactions using **1** and **2** decreased remarkably with a rise in the reaction temperature, as mentioned above (Tables 1 and 2). In order to estimate the net stereospecificity of these reactions, one must know whether the starting chloride or the product is racemized in the course of reaction. Optically

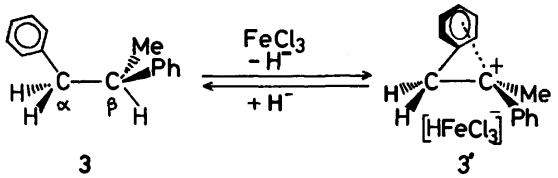
active alkylbenzenes having the asymmetric carbon atom attached to a benzene ring undergo rapid racemization under Friedel-Crafts conditions.[20] The racemization process has been considered to be due to a hydride transfer reaction through a free carbonium ion. In order to ascertain the possibility of such a process, (−)-**3** was treated with $FeCl_3$ in benzene at 30 °C. The result in Table 4 shows that the specific rotation of (−)-**3** remained unchanged before and after the reaction. Furthermore, no rearrangement of **3** to **4** was observed in this treatment. Thus, it turns out that the lesser stereospecificity in the reaction at elevated temperature can not be attributed to the successive racemization of the product. The greater optical stability of **3** than of alkylbenzenes such as 2-phenylbutane[20b] may be interpreted as the following considerations. The first is on the basis of a steric factor for the abstraction of hydrogen of the β-carbon of **3**. If the α-phenyl group of **3** assists the departure of the β-hydrogen as a hydride ion anchimerically, **3** should have the conformation in which two bulky phenyl and methyl groups are next to each other, in the transition state of reaction, as presented in Scheme 4. Such a conformation,



Scheme 4.

however, is unfavorable due to the steric hindrance, and thus the β-hydrogen may not be removed under the condition used. The second involves the formation of π-bridged cation such as **3'** yielded by the removal of the β-hydrogen of **3**. If the hydrogen was abstracted with the aid of $FeCl_3$ or a positive ion (R^+), the phenyl group on C_α would participate with β-carbon to form the π-bridged cation (**3'**), and a reverse attack of hydride ion would take place on the β-carbon from the opposite side of the assisting phenyl group to give (−)-**3** again. Thus, the configuration of (−)-**3** would remains unchanged during the reaction. In this stage, however, it is not clear which explanation is more reasonable.

Next, we examined the possibility of simultaneous racemization of the starting chloride (**1**) by observing

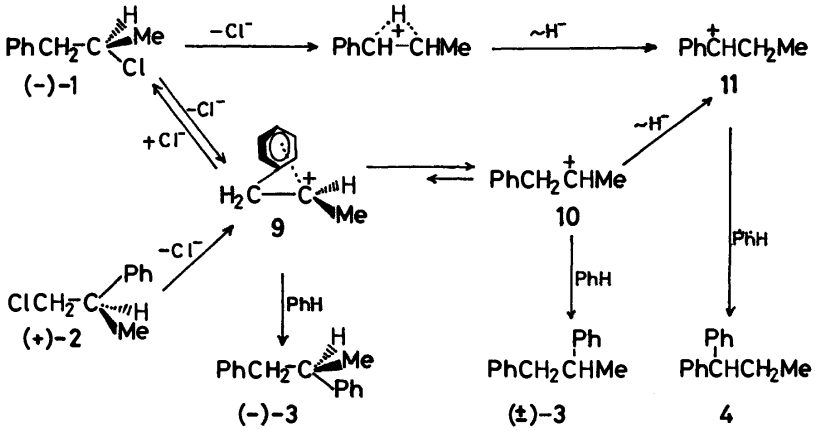

Scheme 5. Lewis acid and its conjugated base are abbreviated for conciseness.

the optical activity of that recovered before the completion of reaction. As can be seen from Table 5, the racemization of (−)-**1** is evident in the reaction catalyzed by $FeCl_3$, especially at elevated temperature. Thus, the lesser stereospecificity at these conditions depends on the simultaneous racemization of the starting chloride. This may be explained in terms of the formation of an open carbonium ion such as 2-phenyl-1-methylethyl-cation (**10**)[21)] followed by an internal return as shown in Scheme 5. Then, the net stereospecificity of reaction was estimated on the basis of the remaining optical activity of **1** and the extent of alkylation observed at the same reaction time according to the method described previously.[2d)] The net stereospecificity of the reaction catalyzed by $FeCl_3$ decreased from 94 to 70% with the rise of temperature from 5 to 30 °C. This result suggests that the alkylation of benzene with **1** involves both intermediates, **9** and **10**, and that the latter plays a rather important role at elevated temperatures.

Consequently, the overall reaction can be illustrated as in Scheme 5. The precursor of 1,1-diarylpropane (**4** or **7**) seems to be 1-phenylpropyl cation (**11**) formed through two distinct pathways; the first path involves the hydride participation in minor competition with the phenyl participation accompanied by ionization of **1**, and the second involves the carbonium ion rearrangement of **10** to **11** (1,2-hydride shift). At the lower reaction temperature, the rate of the reaction (**9**→**10**) is so much slower than those of reactions (**9**→**3**, and **1**→**11**) that the total reaction from **1** to **3** proceeds with high stereospecificity, and the formation of **4** is suppressed. On the contrary, the reversible reaction from **9** to **10** is accelerated by increasing the reaction temperature so that the racemization of **9** takes place easily, which leads to the formation of (±)-**3**. Thus, the stereospecificity in the reaction from **1** to **3** decreases under the high temperature conditions. Furthermore, the formation of **4** is enhanced because of the easy rearrangement of **9** to **10**. The isomer ratio of **6**/**7** in the reaction of *p*-xylene with **1** (or **2**) is lower than that of **3**/**4**. This depends on the higher reactivity (higher basicity) of *p*-xylene toward the intermediate cations than that of benzene.

The Friedel-Crafts alkylation of benzene with **1** in the presence of Lewis acid resembles the solvolysis of 2-phenyl-1-methylethyl tosylate in trifluoroacetic acid with complete retention of configuration.[19)] The solvolysis of all primary and most secondary 2-arylalkyl system has been suggested to proceed through discrete aryl-assisted (retention) and solvent-assisted (inversion) pathways.[14)] However, our Friededl-Crafts alkylation does not involve the latter path in the solvolysis reaction.

Experimental

The optical rotations were taken on a JASCO DIP-SL polarimeter with use of 0.05 and 0.1 dm cells at 25 °C. The NMR spectra were recorded on a JEOL PS-100 spectrometer. The chemical shifts are given in ppm downfield from internal TMS. The IR spectra were determined on a JASCO DS-301 spectrometer. Gas chromatograph analyses (GC) were carried out on a 3 m column of 10% Carbowax 20 M on Diasolid L with Shimadzu DC-6A and GC-3A instruments. All the boiling points are uncorrected.

Benzene was washed with concentrated sulfuric acid and then water, distilled after drying on calcium chloride, and stored over sodium wire. *p*-Xylene was purified by fractional distillation and stored over sodium wire. Other solvents were dried and distilled before use.

Preparation of Optically Active Chlorophenylpropanes. *(+)-2-Chloro-1-phenylpropane (1)*: A solution of (+)-propylene oxide (11.6 g, 0.2 mol, $[\alpha]_D^{25}$ +7.96° (c 5, $CHCl_3$))[2b] in ether (50 ml) was added dropwise into an etheral solution of phenyllithium (0.25 mol). The resulting mixture was stirred at room temperature for 4 h, and then quenched by the slow addition of water. After the organic layer was separated, the aqueous layer was extracted with ether. The combined organic solution was dried over sodium sulfate and concentrated. The resulting yellow oil was distilled under reduced pressure to give a distillate (20.3 g), bp 103—108 °C/17 Torr.* The distillate was subjected to column chromatography on silica gel. Elution with hexane afforded biphenyl (0.7 g) and then that with chloroform gave (−)-1-phenyl-2-propanol in 66% yield (18 g), bp 102—105 °C/19 Torr, $[\alpha]_D^{25}$ −37.57° (*c* 5, $CHCl_3$), [lit,[19] $[\alpha]_D$ +38.69° (*c* 13.4, $CHCl_3$)].

To a stirred solution of the above optically active alcohol (10 g, 74 mmol) in pyridine (10 ml) was added thionyl chloride (9.6 g, 81 mmol) at such a rate that the temperature did not exceed 5 °C. After the addition was complete, the mixture was heated at 65 °C for 6 h, and poured into water. The organic layer was separated and the water layer was extracted with three portions of ether. The combined organic mixture was washed with water, dilute hydrochloric acid, saturated sodium chloride, 6% sodium hydrogencarbonate and water, successively. After drying over sodium sulfate, ether was removed. The residual liquid was distilled under reduced pressure to give (+)-**1** in 68% yield (7.8 g), bp 91 °C/17 Torr, $[\alpha]_D^{25}$ +21.85° (neat), $[\alpha]_D^{25}$ +23.19° (*c* 5, $CHCl_3$). Provided that this chlorination step proceeded with complete inversion, the optical purity of (+)-**1** obtained is evaluated to be 97.1%. Thus the maximum rotation was calculated to be $[\alpha]_D^{25}$ +23.88° [lit,[10] $[\alpha]_{25}^{D}$ −24.9° (neat)]. IR (neat): 1605 (skeltal vibration of phenyl ring), 760 and 700 (δ CH, monosubstituted phenyl), and 610 cm^{-1} (νC–Cl, secondary chloride). NMR ($CDCl_3$, 10%): δ=1.41 (d, *J*=7.6 Hz, 3H, $-CH_3$), 2.92 (m, 2H, $-CH_2-$), 4.10 (m, 1H, -CH=), 7.10 (m, 5H, phenyl). (−)-**1**; The solution of (+)-1-chloro-2-phenylgropane (**2**) (5.0 g, 32 mmol, $[\alpha]_D^{25}$ +14.0°) in dichloroethane (20 ml) was added dropwise to a stirred mixture of anhydrous iron(III) chloride (50 mg, 0.3 mmol) and 1,2-dichloroethane (20 ml) at room temperature. The resulting mixture was stirred at 65 °C for 2 h, and then poured onto a mixture of crushed ice (15 g) and concentrated hydrochloric acid (15 g). The organic layer was separated and the aqueous layer was extracted with two 15 ml portions of 1,2-dichloroethane. The combined organic solution was washed with water, 6% sodium hydrogencarbonate and water, successively, and then dried over sodium sulfate. After removal of the solvent, the residue was distilled under reduced pressure to give (−)-**1** in 70% yield, $[\alpha]_D^{25}$ −20.0° (*c* 5, $CHCl_3$). IR and NMR spectra of (−)-**1** were identical to those of (+)-**1** obtained above.

(+)-1-Chloro-2-phenylpropane (2): The reaction of (+)-2-phenyl-1-propanol (13.6 g, 0.1 mol, $[\alpha]_D^{25}$ +15.7° (neat), 94% optically pure)[2b] with thionyl chloride (9.6 g, 0.1 mol) in pyridine gave (+)-**2** in 80% yield (7.8 g). Bp 94 °C/18 Torr, $[\alpha]_D^{25}$ +14.0° (neat). Thus, the maximum rotation was evaluated to be $[\alpha]_D^{25}$ +14.9° (neat). IR (neat): 1605 (skeltal vibration of phenyl ring), 700 and (δCH, monosubstituted phenyl), and 645 cm^{-1} (νC–Cl, primary chloride). NMR: δ=1.38 (d, *J*=7.4 Hz, 3H, $-CH_3$), 3.20 (m, 1H, -CH=), 3.50 (m, 2H, $-CH_2-$), 7.14 (m, 5H, phenyl).

Reaction Procedures. *Method A*: A slurry of pulverized anhydrous aluminium chloride (60 mg, 0.45 mmol) in dry benzene (12 ml) and carbon disulfide (4 ml) was cooled to 0 °C in a three-necked 100 ml flask equiped with a thermometer, an additional funnel, and a drying tube. To this stirred mixture was added a solution of (−)-**1** or (+)-**2** (0.7 g, 45 mmol) in benzene (3 ml) carefully over a period of 2 min at 0 °C. The resulting mixture was stirred at 0±0.5 °C for 1 h and then poured onto a mixture of crushed ice (5 g) and concentrated hydrochloric acid (5 ml). The benzene layer was separated and the aqueous layer was extracted with two 10 ml portions of benzene. The combined organic solution was washed with dilute hydrochloric acid, water, 6% sodium hydrogencarbonate solution and water, successively, and then dried over anhydrous sodium sulfate. After removal of the solvent, the residue was distilled under reduced pressure to give a distillate (bp 150—155 °C/20 Torr.) and high boiling materials. The distillate was shown to be a mixture of **3** and **4** by NMR analysis. The structure of these products was confirmed by the spectroscopic comparison with their authentic samples (see below). The optical rotations and the isomer ratio of **3**/**4** were determined on this distillate.[9]

The alkylation of *p*-xylene with **1** and **2** were also carried out in the same way as those of benzene and gave a mixture of **6** and **7** in 80—90% yield, bp 158—163 °C/15 Torr.

Details of reaction conditions and results are given in Tables 1, 2, and 3.

Method B: In order to estimate the net stereospecificity of the reaction, the experiment was carried out as follows. To a cooled suspension (below 0 °C) of $FeCl_3$ (0.45 mmol) in benzene (15 ml) was added, all at once, a solution of (+)-**1** (45 mmol) in benzene (3 ml), and the reaction mixture was stirred at the prescribed temperature for the prescribed period (see Table 5). After the reaction was quenched by an addition of water, the resulting benzene solution was subjected to gas chromatography to determine the conversion percent, and then worked up as mentioned above. The unreacted starting chloride and the product were separated by fractional distillation. The results are summarized in Table 5.

Preparation of Authentic Samples. *1,2-Diphenylpropane (3)* was prepared by a series of reactions as follows: 2-Phenylpropionic acid, prepared from 2-phenylpropanol[22] by the silver nitrate oxidation, was converted into 2-phenylpropionyl chloride by the reaction with phosphoryl chloride. The acylation of benzene with the acid chloride obtained above yielded 1,2-diphenyl-1-propanone. The above ketone was reduced according to the method[23] of Clemmensen to give 1,2-diphenylpropane (**3**). Bp 155 °C/20 Torr. IR (neat): 1325 (δCH, $-CH_3$), 700 and 755 cm^{-1} (δCH, monosubstituted phenyl). NMR: δ=1.17 (d, *J*=6.4 Hz, 3H, $-CH_3$), 2.80 (m, 2H, $-CH_2-$), 2.86 (m, 1H, -CH=), 7.10 (m, 10H, 2 phenyl).

1,1-Diphenylpropane (4) was prepared by the alkylation of benzene with 3-phenyl-1-propene in the presence of aluminium chloride at 5 °C, bp 160 °C/18 Torr. IR (neat): 700 and 740 cm^{-1} (δCH, monosubstituted phenyl). NMR: δ=0.88 (t, *J*=8.0 Hz, 3H, $-CH_3$), 2.20 (q, *J*=8.0 Hz, 2H, $-CH_2-$), 3.72 (t, *J*=8.0 Hz, -CH=), 7.11 (s, 10H, 2 phenyl).

1-Phenyl-2-(2,5-dimethylphenyl)propane (6) was prepared by the alkylation of *p*-xylene with **1** in the presence of aluminium chloride at −20 °C. Although the reaction gave a trace amount of **7** as a by-product, the fractional distillation of the mixture gave **6**, bp 169 °C/14 Torr. IR: 810 and 880 (δCH, 1,2,5-trisubstituted phenyl), 700 and 750 cm^{-1} (δCH, monosubstituted phenyl). NMR: δ=1.18 (d, *J*=7.8 Hz, 3H, $-CH_3$), 2.26 (s, 3H, *ortho*-CH_3), 2.37 (s 3H, *meta*-CH_3), 2.86

9) In order to confirm the validity of the optical yield observed, we examined the dependence of the value of $[\alpha]_D$ of **3** on the ratio of **3**/**4**. Some samples having different ratios of **3**/**4** were prepared by adding pure **4** to a mixture of **3** and **4** in the ratio of 83 : 17($[\alpha]_D$ of **3**, −63.0°). The specific rotation of **3** in these samples was calculated to give an almost constant value with an error of about 2.3% as follows: [ratio of **3**/**4**, $[\alpha]_D$ of (**3**+**4**), $[\alpha]_D$ of **3**]; [68 : 32, −41.9°, −62.1°], [58 : 42, −36.9°, −63.6°], [51 : 49, −31.3°, −61.3°], [42 : 58, −26.5°, −63.2°]. Thus the optical yields of **3** listed on the table **1**, **2**, and **4** seem to be accurate.

The Use of Grignard Reagents in Carbohydrate Synthesis.[1] The Synthesis of Branched-chain Deoxy Sugars and Their Anomerizations

Masajiro KAWANA,* Tetsuo KORESAWA, and Hiroyoshi KUZUHARA
The Institute of Physical and Chemical Research, Wako, Saitama 351

(Received June 18, 1982)

The reactions of methyl 5-*O*-benzyl-2-*O*- and -3-*O*-tosyl-β-D-ribofuranosides with methylmagnesium iodide gave, in one-step, 2-deoxy-3-*C*- and 3-deoxy-2-*C*-methyl branched-chain sugars, respectively. These sugars were anomerized with Grignard reagents; the thermodynamically more stable anomers were converted preferentially into the respective less stable anomers.

Recently, one of the authors has reported that methyl 5,6-*O*-cyclohexylidene-3-*O*-mesyl-α- and -β-D-allofuranosides reacted with Grignard reagents to give 3-deoxy or 3-deoxy-2-*C*-methyl-branched-chain sugars in one-step.[2] These reactions proceeded through 2-keto sugars which were formed *via* eliminations of the mesyloxy groups and 1,2-hydride shifts on the furanose rings. In the course of these studies, it has also been found that methyl glycofuranosides were anomerized by the use of the Grignard reagents.[3] The proposed mechanism consisted of the furanose-ring opening-reclosure by the coordination of sugar oxygens to the magnesium atoms of the reagents.

In this paper we would like to report an extention of these deoxygenation reactions to the tosylates of methyl 5-*O*-benzyl-D-ribofuranosides (**1**), and to report the anomerization of the deoxygenated products obtained therefrom.

The starting materials, methyl 5-*O*-benzyl-2-*O*- and -3-*O*-tosyl-D-ribofuranosides (**2** and **3**), were prepared from **1** by two methods **A** and **B**: the former was the conventional way and the latter involved the activation of hydroxyl groups of **1** with dibutyltin oxide.[4] The results are summarized in Scheme 1. Method **B** was superior to **A** in regioselective tosylation of the hydroxyl group at C-2 and in almost avoiding any production of 2,3-di-*O*-tosylates (**4**).

Treatment of **3**β with 3.4 mol equiv. of MeMgI gave methyl 5-*O*-benzyl-3-deoxy-2-*C*-methyl-β-D-*threo*-pentofuranoside (**5**β) and its C-2 epimer (**6**β) in 81 and 6% yields, respectively (Scheme 2). The structure of **5**β was confirmed by chemical conversion to a known compound, 5-*O*-benzyl-1,2-*O*-cyclohexylidene-3-deoxy-2-*C*-methyl-β-D-*threo*-pentofuranose (**10**).[5] The same reaction on **2**β gave methyl 5-*O*-benzyl-2-deoxy-3-*C*-methyl-β-D-*threo*-pentofuranoside (**7**β) and its C-3 epimer (**8**β) in 57 and 2.5% yields, respectively. In addition, an α-anomer (**8**α, 19%) and a small amount of an open-chain product (**9**, 5%) were isolated; these results suggested that 2-deoxy furanosides were easily anomerized under the Grignard reaction conditions. Debenzylation of **7**β afforded methyl 2-deoxy-3-*C*-methyl-β-D-*threo*-pentofuranoside (**11**), which, without further purifications, was converted into a 3,5-*O*-isopropylidene derivative (**12**), thus indicating the 3,5-*cis* structure of the hydroxyl functions of **7**β.

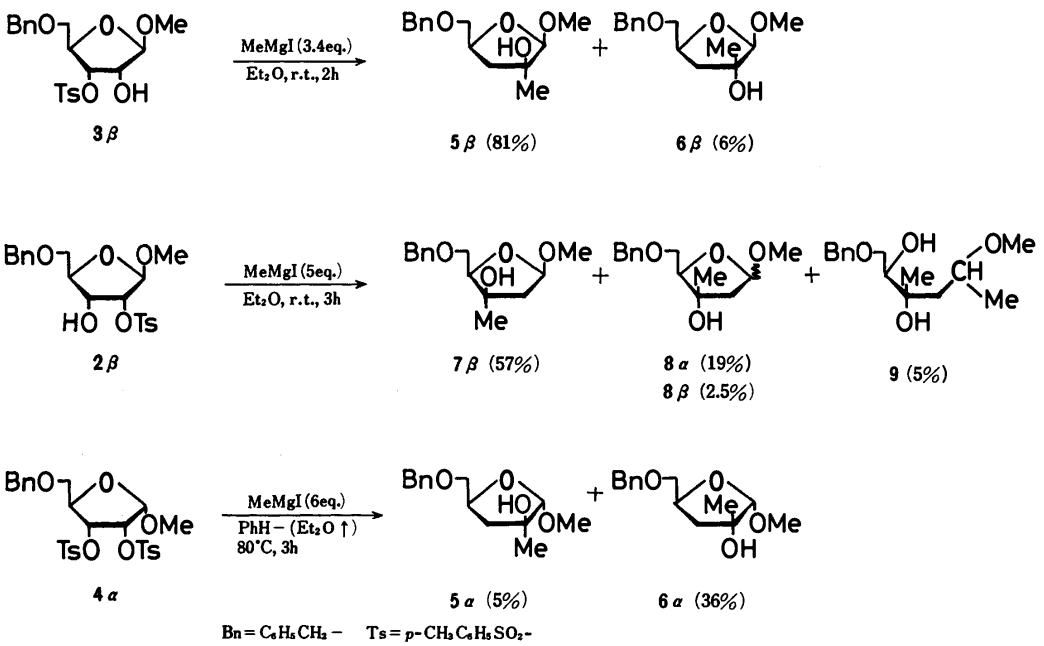
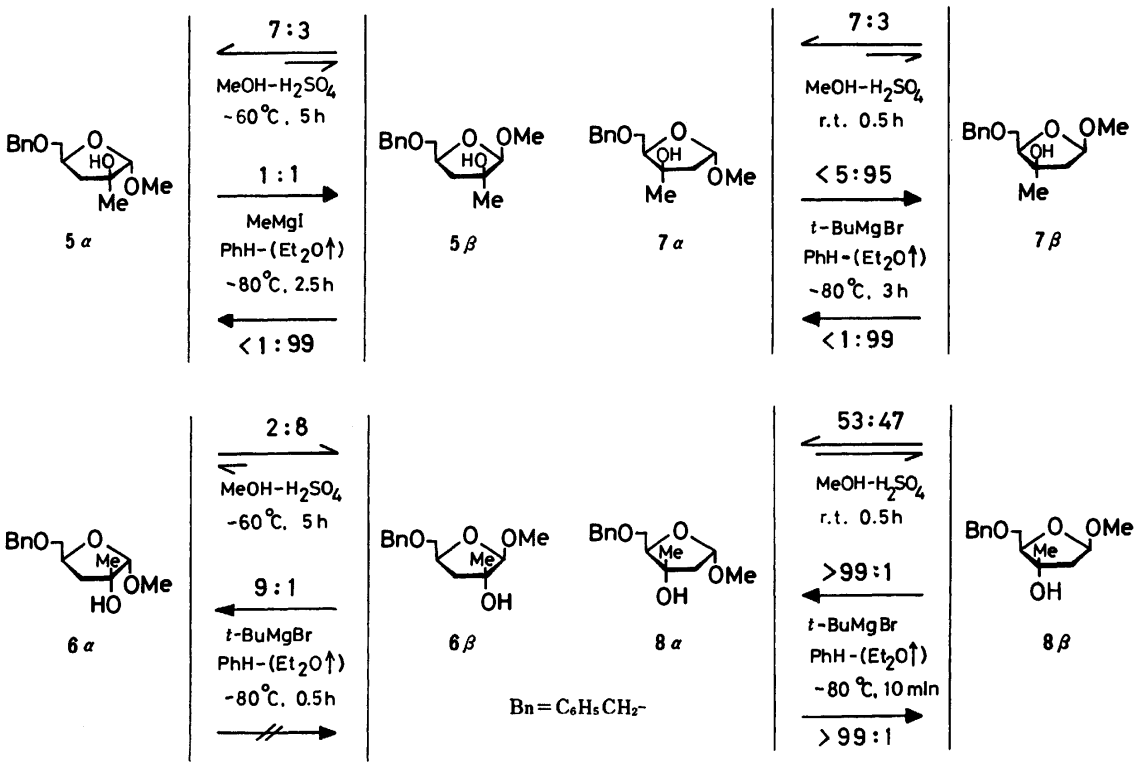
Scheme 1.



Scheme 2.



Scheme 3.

The reaction of **2***α* with MeMgI did not proceed even under refluxing conditions: An insoluble complex was formed when **2***α* was added to the Grignard reagent.

We attempted to use the ditosylate derivatives, **4***α* and **4***β*, in the present reactions, in the hope that one of the tosyl groups would selectively be cleaved to form a monotosylate derivative, which, in turn would react with the Grignard reagent to give the deoxy compounds *via* a keto sugar. A mixture of **4***α* and MeMgI in benzene–ether was treated at *ca.* 80 °C to produce the expected compound, **6***α*, although in low yield. However, starting from **4***β*, we could not isolate any desired products.

The branched-chain deoxy sugars thus obtained were subjected to the anomerization reaction with an acid as well as with the Grignard reagents (Scheme 3). In the acidic anomerization of the 3-deoxy sugars, the anomers which have 1,2-*trans* oxygen functions always predominated over the 1,2-*cis* counterparts under equilibrating conditions because of the repulsion of the

1,2-*cis* oxygen functions. On the other hand, in the case of the 2-deoxy sugars, the anomers having 1,3-*trans* oxygen functions were not always favorable; the equilibrated solution of **8** consisted of a mixture of **8α** and **8β** in a ratio of 53 : 47.

The anomerization of each anomer of the deoxy compounds with the Grignard reagents was carried out using a large excess of *t*-BuMgBr (MeMgI for **5**) in a mixture of benzene–ether. The ether was allowed to distill out from the reaction mixture: under these conditions, a lot of precipitates came out as the ether was lost, so that the reaction mixture became heterogeneous. In the case of **5α**, the anomerization with *t*-BuMgBr was very slow under the conditions used. However, when MeMgI was used instead of *t*-BuMgBr, **5α** was anomerized to give a 1 : 1 anomeric mixture. Starting from **5β**, slight anomerization was observed under the same conditions.

On the other hand, the anomerization of **6β** with *t*-BuMgBr was very fast to give a 9 : 1 mixture of the α- and β-anomers. The reverse reaction (from **6α** to **6β**) did not proceed; thus a one-way anomerization[3] was observed in this case.

It is noted that the 3-deoxy sugars, **5** and **6**, were anomerized predominantly with the Grignard reagents from the thermodynamically more stable 1,2-*trans* anomers to the less stable 1,2-*cis* counterparts. In the case of the 2-deoxy sugars, the anomerization of the 1,3-*trans* anomers, **7α** and **8β**, with *t*-BuMgBr also proceeded smoothly to result in the preferred formation of the 1,3-*cis* anomers, **7β** and **8α**, respectively.

The ^{1}H NMR spectral data of the branched-chain deoxy sugars are summarized in Table 2; these data are consistent with the structures. The methoxyl or methylene (at C-5) protons located next to the branching methyl group in a *cis* manner resonated at higher field than those in a *trans* relation presumably because of the shilding effect of the branching methyl group. These differences in chemical shifts were diagnostic for determining the configuration of the hydroxyl groups at the branching points.

The signs of the specific rotations of the above described deoxy sugars which have the β-D-configuration were negative, whereas the corresponding α-anomers showed positive signs. These phenomena were compatible with those for the methyl pentofuranosides reported earlier.[3,6]

Experimental

The melting points were determined with a Yamato capillary-melting point apparatus and were uncorrected. The ^{1}H NMR spectra were recorded on a JEOL PS-100 NMR spectrometer, with tetramethylsilane as the internal standard The optical rotations were measured on a Perkin-Elmer Model 241MC polarimeter.

Merck silica gel GF_{254} was used for the TLC, and the compounds were detected by heating after spraying them with a methanol–sulfuric acid–*p*-methoxybenzaldehyde (85 : 10 : 5, v/v) mixture. Merck silica gel 60 (0.063—0.29 mm) was utilized for the column chromatography. The elemental analyses were performed by this Institute.

The Grignard reagents, MeMgI and *t*-BuMgBr, were prepared from magnesium and the corresponding alkyl halide in dry ether, and the Grignard reactions were carried out in dry solvents under an atmosphere of dry nitrogen.

The ^{1}H NMR spectral data of the compounds are listed in Table 2, while their physical properties and the results of their elemental analyses are summarized in Table 1.

The Tosylation of Methyl 5-O-Benzyl-α- and -β-D-ribofuranosides (1α and 1β). Some of the results and reaction conditions are described in Scheme 1 and Table 1.

Method A: To a cold (0—5 °C) solution of **1α** (4.32 g, 17.6 mmol)[3] or **1β** (8.94 g, 35.2 mmol)[3] in dry pyridine (60 or

120 ml), there was added tosyl chloride (4.70 g, 24.6 mmol or 9.20 g, 48.3 mmol), respectively. Each mixture was stirred at 0—5 °C for a few hours, and then allowed to stand in a refrigerator at the same temperature overnight. The usual work-up gave a syrupy mixture, which was purified by silica-gel column chromatography with benzene–ethyl acetate (9 : 1) to afford **4α** (3.77 g, 38%), **3α** (0.05 g, 1%), and **2α** (2.96 g, 41%) from **1α**, or to give **4β** (4.14 g, 21%), **2β** (0.69 g, 5%), and **3β** (7.34 g, 52%) from **1β**.

Method B:[4] A mixture of **1α** or **1β** (508 mg, 2 mmol) and dibutyltin oxide (498 mg, 2 mmol) in methanol (7 ml) was heated at 75—80 °C (bath temperature) for 3 h with stirring.

The methanol was removed by co-evaporation with benzene. The residue was dissolved in hot benzene (5 ml) and *N,N*-dimethylformamide (5 ml), and a solution was cooled to 0—5 °C. Pyridine (180 mg) was added, followed by addition of tosyl chloride (382 mg, 2 mmol), and the mixture was stirred at 0—5 °C for 30 min. Aqueous sodium hydrogencarbonate was added, and the mixture was extracted with ether. The usual work-up gave a syrup, which was chromatographed on a silica-gel column with benzene–ethyl acetate (9 : 1) to provide **3***α* (42 mg, 5%) and **2***α* (502 mg, 61%) from **1***α*, or to afford **4***β* (10 mg, 0.9%), **2***β* (310 mg, 38%), and **3***β* (347 mg, 42%) from **1***β*.

*Methyl 5-O-Benzyl-3-deoxy-2-C-methyl-β-*D-threo-*pentofuranoside (5β) and Methyl 5-O-Benzyl-3-deoxy-2-C-methyl-β-*D-erythro-*pentofuranoside (6β).* To a cold solution of MeMgI (11.6 mmol) in ether (30 ml), there was added **3***β* (1.4 g, 3.43 mmol) in benzene (5 ml) over a period of 5 min. The mixture was stirred at room temperature for 2 h. After cooling, aqueous ammonium chloride was added and the mixture was extracted with ether. The extract was washed with water and dried ($MgSO_4$). Evaporation of the solvent gave a syrup, which was chromatographed on a silica-gel column with benzene–ethyl acetate (9 : 1) to give **5***β* (700 mg, 81%) and **6***β* (50 mg, 6%).

*Methyl 5-O-Benzyl-3-deoxy-2-C-methyl-α-*D-erythro-*pentofuranoside (6α).* A solution of **4***α* (819 mg, 1.45 mmol) in benzene (3 ml) was added to a stirred solution of MeMgI (11.6 mmol) in benzene (15 ml) and ether (15 ml) at room temperature. After the mixture in a flask without a refluxing condenser had been heated at 80—85 °C (bath temperature) to remove the ether for 1 h, the flask was fitted with the refluxing condenser and the heating was continued for 45 min. After cooling, aqueous ammonium chloride was added, and the mixture was extracted with ether. The extract was washed with water, dried ($MgSO_4$), and concentrated to give a syrup, which was chromatographed on a silica-gel column with benzene–ethyl acetate (9 : 1) to give the starting material (80 mg, 10%), an unidentified crystalline compound (225 mg), **5***α* (17 mg, 5%), and **6***α* (130 mg, 36%). These compounds (**5***α* and **6***α*) were identical with the samples prepared from the Grignard anomerization of **5***β* and **6***β*, respectively.

*Methyl 5-O-Benzyl-2-deoxy-3-C-methyl-β-*D-threo-*pentofuranoside (7β), Methyl 5-O-Benzyl-2-deoxy-3-C-methyl-α-*D-erythro-*pentofuranoside (8α), and Its β-Anomer (8β), and the Open-chain Product (9).* To a solution of MeMgI (16 mmol) in ether (20 ml), there was added a solution of **2***β* (1.29 g, 3.2 mmol) in benzene (10 ml) at room temperature over a period of 15 min. The mixture was stirred at this temperature for 80 min. The usual work-up gave a syrupy mixture, which was chromatographed on a silica-gel column with benzene–ethyl acetate (9 : 1) to afford **7***β* (455 mg, 57%), **8***α* (150 mg, 19%), **9** (40 mg, 5%), and **8***β* (20 mg, 2.5%).

*5-O-Benzyl-1,2-O-cyclohexylidene-3-deoxy-2-C-methyl-β-*D-threo-*pentofuranose (10).* A mixture of **5***β* (130 mg, 0.52 mmol), cyclohexanone (0.4 ml), and concd sulfuric acid (38 mg) in dry benzene (2 ml) was stirred at room temperature for 30 min. After cooling, aqueous sodium hydrogencarbonate was added under vigorous stirring, and the mixture was extracted with ether. The extract was washed with water and dried ($MgSO_4$). Evaporation of the solvent and an excess of the cyclohexanone by co-evaporation with toluene gave a syrup, which was chromatographed on a silica-gel column with benzene–ethyl acetate (4 : 1) to give **10** (96 mg, 59%). Its physical properties were identical with those of an authentic sample.[5]

*Methyl 2-Deoxy-3,5-O-isopropylidene-3-C-methyl-β-*D-threo-*pentofuranose (12).* A solution of **7***β* (188 mg, 0.75 mmol) in methanol (10 ml) was hydrogenated in the presence of 10%Pd–C (130 mg) under hydrogen atmosphere at ordinary pressure for 3.5 h. The usual work-up gave a syrup, which was chromatographed on a silica-gel column with chloroform–methanol (49 : 1) to afford almost pure methyl 2-deoxy-3-*C*-methyl-*β*-D-*threo*-pentofuranoside (**11**; 119 mg, 98%) as a syrup. This product was used, without further purification, for the isopropylidenation. A mixture of **11** (54 mg, 0.33 mmol), 2,2-dimethoxypropane (0.5 ml), and pyridinium *p*-toluenesulfonate (10 mg)[7] in acetone (1 ml) was stirred at room temperature for 2.5 h. After cooling, aqueous sodium hydrogencarbonate was added, and the mixture was extracted with ether. The extract was washed with water, dried ($MgSO_4$), and concentrated to give a syrup, which was purified by silica-gel column chromatography with benzene–ethyl acetate (1 : 1) to provide **12** (46 mg, 69% from **11**).

The Anomerization of the Branched-chain Deoxy Sugars with an Acid. The ratio of *α*- and *β*-anomers in an equilibrium was determined on the basis of the ^1H NMR spectroscopy; these results are summarized in Scheme 3.

From 5β: A mixture of **5***β* (880 mg, 3.5 mmol) and concd sulfuric acid (250 mg) in methanol (40 ml) was heated at 60—65 °C (bath temperature) for 5 h. An equilibrium was reached within 5 h, judging from TLC and ^1H NMR spectroscopic analyses. After cooling, calcium hydroxide (300 mg) was added and the mixture was stirred vigorously. The undissolved materials were filtered through a Celite pad and washed with methanol. The combined filtrate and washing were concentrated, and the residue (**5***α* : **5***β*=7 : 3) was chromatographed on a silica-gel column with benzene–ethyl acetate (9 : 1) to give **5***α* (568 mg, 65%) and **5***β* (248 mg, 28%).

From 6α: A mixture of **6***α* (32 mg, 0.13 mmol), concd sulfuric acid (80 mg) in methanol (13 ml) was treated under the same conditions as described for the acid anomerization of **5***β* to give a 1 : 4 mixture (29 mg) of **6***α* and **6***β*.

From 7β: A mixture of **7***β* (400 mg, 1.59 mmol) and concd sulfuric acid (120 mg) in methanol (35 ml) was stirred at room temperature for 30 min. Within this time an equilibrium was reached. The mixture was treated in a manner similar to that described for the acid anomerization of **5***β* to give a syrupy mixture (**7***α* : **7***β*=7 : 3), which was chromatographed on a silica-gel column with benzene–ethyl acetate (85 : 15) to afford **7***β* (104 mg, 26%) and **7***α* (250 mg, 63%).

From 8α: A mixture of **8***α* (30 mg, 0.12 mmol), concd sulfuric acid (40 mg) in methanol (12 ml) was treated under the same conditions as described for the acid anomerization of **7***β* to afford a 53 : 47 mixture (28 mg) of **8***α* and **8***β*.

The Anomerization of the Branched-chain Deoxy Sugars with the Grignard Reagents. The ratio of the *α*- and *β*-anomers was determined by means of the ^1H NMR spectroscopy; the results are summarized in Scheme 3.

From 5α: To a solution of MeMgI (2.4 mmol) in ether (5 ml) and benzene (10 ml), there was added a solution of **5***α* (120 mg, 0.48 mmol) in benzene (2 ml), and the mixture was heated at 80—85 °C (bath temperature) to remove the ether for 2.5 h. The usual work-up gave a syrupy mixture (**5***α* : **5***β* =1 : 1; 126 mg), the TLC analyses of which indicated that this contained a small amount of degradation products.

From 5β: To a solution of MeMgI (2.4 mmol) in benzene (10 ml) and ether (5 ml), there was added a solution of **5***β* (128 mg, 0.51 mmol) in benzene (2 ml), and the mixture was treated in a manner similar to that described for the Grignard anomerization of **5***α*. The product (**5***α* : **5***β*=<1 : 99; 126 mg) contained a small amount of decomposed materials.

From 6α: A solution of **6***α* (57 mg, 0.23 mmol) in benzene (2 ml) was added to a stirred solution of *t*-BuMgBr (4.8 mmol) in benzene (10 ml) and ether (5 ml) at room temperature, and the mixture was heated at 80—85 °C (bath temperature) for

30 min with stirring to remove the ether. No anomerization was observed by means of TLC analyses. The usual work-up recovered the starting material (50 mg).

From **6**β: A solution of **6**β (130 mg, 0.52 mmol) in benzene (2 ml) was added to a stirred solution of *t*-BuMgBr (4.8 mmol) in benzene (10 ml) and ether (5 ml), and the mixture was treated under the same conditions as those described for the Grignard anomerization of **6**α. The work-up gave a syrup (**6**α : **6**β=9 : 1), which was chromatographed on a silica-gel column with benzene–ethyl acetate (85 : 15) to give **6**α (93 mg, 72%) and **6**β (8 mg, 6%). The former anomer was identical with a sample prepared from **4**α and MeMgI.

From **7**α: To a stirred solution of *t*-BuMgBr (4.8 mmol) in benzene (10 ml) and ether (5 ml), there was added to solution of **7**α (130 mg, 0.52 mmol) in benzene (2 ml) at room temperature; the mixture was heated at 80—85 °C to remove the ether for 3 h with stirring. The usual work-up gave an anomeric mixture (**7**α : **7**β=$<$5 : 95; 131 mg).

From **7**β: The sugar derivative **7**β (130 mg, 0.52 mmol) was treated under the same conditions as described for the Grignard anomerization of **7**α to provide an anomeric mixture (**7**α : **7**β=$<$1 : 99; 112 mg).

From **8**α: The sugar derivative **8**α (43 mg, 0.17 mmol) was treated with *t*-BuMgBr (4.8 mmol) under the same conditions as described for the Grignard anomerization of **7**α, except that the reaction time was 10 min. The work-up recovered the starting material (43 mg), which contained a trace amount of 8β and of unidentified by-products, judging from TLC analyses.

From **8**β: The sugar derivative **8**β (38 mg, 0.15 mmol) was treated with *t*-BuMgBr (4.8 mmol) under the same conditions as described for the Grignard anomerization of **8**α to give **8**α (39 mg), which contained a trace amount of **8**β and of unidentified by-products.

We wish to thank Dr. Haruo Homma and his staff for the elemental analyses, and Dr. Jun Uzawa and Mrs. Tamiko Chijimatsu for measuring the ^{1}H NMR spectra. We are also grateful to Dr. Hiroshi Ohrui for his valuable discussions.

(Received June 28, 1982)

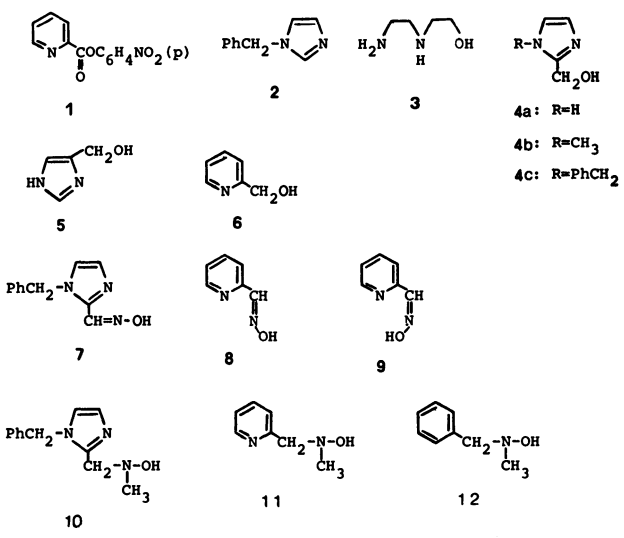
Rate constants for hydrolysis of *p*-nitrophenyl picolinate at 25 °C in the pH range 6.5—8.5 were measured in the absence and presence of divalent metal ions (Ni(II), Zn(II), Co(II), Ca, Mg) and substituted imidazoles or pyridines as ligands having alcoholic hydroxyl groups in their side chains. In the presence of either metal ion or ligand, the rate is slow and the pseudo-first-order rate constant (k_{obsd}) increases linearly in a first-order manner with respect to the concentration of metal ion or ligand until it gives the second-order rate constant, k_M or k_L, respectively. In the presence of both a metal ion (Ni(II) or Zn(II)) and a ligand, rate increase is remarkable for some ligands and the increase in k_{obsd} values constructs saturation curves with respect to increase in either metal ion or ligand concentration. The saturation curves were analyzed based upon rate equations formulated by assuming the formation of 1 : 1 complex of metal ion and ligands as the catalyst, leading to evaluation of the association constant K for complexes and the second-order rate constant k_c for the reaction of complex with substrate. Values of k_{obsd}, k_c, and K are dependent greatly upon the structure of ligands and pH. The ligands complexed with Zn(II) ion appear to be simple but highly active models of hydrolytic metalloenzymes.

Metal ion catalyzed reactions of carboxylic acid derivatives have been extensively investigated in recent years as model reactions of metalloenzymes such as carboxypeptidase A, carbonic anhydrase, and related enzymes.[1-6] It is now well known that a zinc ion is coordinated to two imidazoles and one carboxyl group at the active site of carboxypeptidase A[7-12] and to three imidazole groups at the active site of carbonic anhydrase.[13-16] In these enzymes, the zinc ion is considered to serve as a primary catalytic center for bringing substrate and nucleophile together through formation of a coordination complex, and to activate the substrate carbonyl group toward the action of the nucleophile in carboxypeptidase A or to activate the water molecule in the reversible hydration of carbon dioxide in carbonic anhydrase. In related alkaline phosphatases, the zinc ion appears to activate the serine hydroxyl group.[17,18] Thus it is important for model studies to examine the cooperativity in catalysis between the imidazolyl and hydroxyl groups in the presence of metal ion.

Most of model studies so far conducted are related to intramolecular catalysis, making use of substrates designed to be susceptible to the attack by nucleophile either intramolecularly or intermolecularly through complexation with metal ion.[19] However, there have been known only a few examples of metal ion catalyzed acyl-transfer reactions between coordinated ligands. Breslow *et al.* discovered that the zinc or nickel ion complex of (*E*)-2-pyridinecarbaldehyde oxime, alone[20] or attached to the cyclodextrin moiety,[21] is a remarkably active catalyst for the hydrolysis of esters. Sigman and Jorgensen[22] demonstrated that zinc ion catalyzes the *trans*-esterification between *p*-nitrophenyl picolinate and *N*-(2-hydroxyethyl)ethylenediamine. Very recently, bis(imidazolyl)cyclodextrin[23] and some triimidazolyl derivatives[24] were reported to be effective ligands for the modeling of carbonic anhydrase. However, even in these examples the cocatalysis by imidazolyl and hydroxyl groups has not yet been examined. Furthermore, it should be noted that the catalytic activity of these known complexes is by no means enzymic. Thus complexes more active by several orders should be designed in order to obtain really enzymic artificial enzymes. It has been reported, though with a few examples, that metal-bound imidazolate and hydroxide ions are very reactive nucleophiles.[25]

In our recent communications,[26,27] we reported that *N*-substituted 2-(hydroxymethyl)imidazole-Zn^{2+} ion complexes are much more active catalysts than the above 2-pyridinealdoxime-Zn^{2+} complex for the hydrolysis of *p*-nitrophenyl picolinate. The coexistence of imidazole and hydroxyl groups appears to be essential for the development of catalytic activity, indicating that the system is a simple but good model for the hydrolytic metalloenzymes.

In the present paper, we wish to report a full account of our previous communication[26] as well as results of a further extention including a finding of some more powerful ligands. Activities of ligands **2**—**12** were examined in the presence of divalent metal ions Ni^{2+}, Zn^{2+}, Co^{2+}, Ca^{2+}, and Mg^{2+} for the hydrolysis of *p*-



nitrophenyl picolinate (**1**). These ligands may be classified into two groups: One contains 2-aminomethylamino, imidazolyl, or pyridyl groups as the primary coordination site to bind metal ion, and the other contains alcoholic hydroxyl, aldoxime hydroxyl, or hydroxyamino hydroxyl group as the reacting nucleophile in acyl-transfer reaction.

Results and Discussion

Ligand Hydroxyl Group in Catalysis. Rates of reaction were determined by observing the release of *p*-nitrophenol from the substrate **1** spectrophotometrically. In all cases, under the condition of excess ligand over the substrate, good pseudo-first-order rate constants (k_{obsd}) were obtained up to completion of reaction. Part of the results are shown in Table 1. The table indicates that the uncatalyzed buffer rate constant is $k_0=1.0\times10^{-3}$ min^{-1} at pH 7.05 and 25 °C. In the presence of 1.33×10^{-3} mol dm^{-3} Zn^{2+} ion, the rate increased about 30-fold. This rate increase was little affected by addition of such a ligand as **2** having no hydroxyl group or **12** which is a poor ligand toward Zn^{2+} ion. In the absence of metal ion, the rate enhancement by ligand alone was relatively small, although some of hydroxyl-group bearing ligands showed some enhanced reactivity. At any rate, a large rate enhancement was observed only when ligands with both hydroxyl and neighboring nitrogen groups such as **3**—**11** were used in the presence of either Ni^{2+}, Zn^{2+}, or Co^{2+} ion.

Pseudo-first-order kinetics were also observed under the condition of five molar excess of substrate over the ligand for all the ligands except **3** and **9**, indicating the reaction to occur catalytically. In the case of (*Z*)-2-pyridinecarbaldehyde (**9**), the reaction proceeded in a biphasic manner in which the release of *p*-nitrophenol was initially rapid and then slowed down. Such a biphasic behavior is an evidence for a two-step process involving, in this case, the acylation of the hydroxyl group of catalyst followed by the rate determining deacylation to regenerate the catalyst.[1-3,28] In the case of **3**, as already demonstrated by Sigman and Jorgensen,[22] the second deacylation step was so slow that the reaction ceased in effect at the first acylation step.

The above observation that hydroxyl group is necessary for the enhanced generation and detection of acylated intermediates in **3** and **9**, strongly suggests that catalyses by those ligands with which direct evidence for formation of such acylated intermediates is lacking also occur through the two-step process.

Kinetic Equation. The rates were dependent on both metal ion and ligand concentrations. In the case of *N*-benzylimidazole (**2**) having no hydroxyl group, the k_{obsd} values were found to be given by

$$k_{obsd} = k_o + k_L[L] + k_M[M] + k_{M\cdot L}[L][M], \quad (1)$$

where k_0 is the rate constants due to the buffer, k_L and k_M are the second-order rate constants due to ligand (L) and metal ion (M), respectively, and $k_{M,L}$ is the third-order rate constant for the cocatalysis of metal ion and ligand. The observed values for **2** are $k_L=7.98$ mol^{-1} dm^3 min^{-1}, $k_M=15.3$ mol^{-1} dm^3 min^{-1}, and $k_{M,L}=9.72\times10^3$ mol^{-2} dm^6 min^{-1} at pH 7 and 25 °C.

For other ligands having hydroxyl groups, the rates tended to be saturated with increasing metal ion concentration, as exemplified in Fig. 2 for the case of 1-benzyl-2-(hydroxymethyl)imidazole (**4c**). The figure indicates that in the absence of metal ion, the k_{obsd} values are linear to the ligand concentration with $k_L=1.68$ mol^{-1} dm^3 min^{-1} smaller than the above k_L value for **2**. The saturation curves in Fig. 1 can be analyzed by assuming the formation of 1 : 1 complex of metal ion and ligand according to the kinetic scheme of reactions 2—4 and the set of Eqs. 5—7 for derived rates:

Table 1. Pseudo-first-order rate constants ($k_{obsd}\times10^3$/min^{-1}) for *p*-nitrophenol release from *p*-nitrophenyl picolinate **1** in the presence of metal ion and ligand under the condition of [ligand]$\gg$[1][a]

a) Observed at 25 °C, pH 7.05 (0.1 mol dm^{-3} 2,6-lutidine-HNO_3 buffer), $\mu=0.2$ (KNO_3), [L]=[M]=1.33×10^{-3} mol dm^{-3} mol dm^{-3}, and [1]=1×10^{-4} mol dm^{-3}. b) [L]=1.0×10^{-3} mol dm^{-3} and [M]=1.33×10^{-3} mol dm^{-3}.

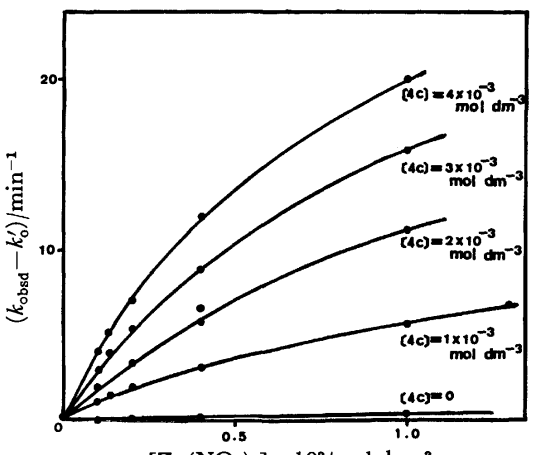

Fig. 1. Plots of pseudo-first-order rate constants for the release of *p*-nitrophenol from **1** as a function of zinc ion concentration; see Table 1 for other reaction conditions.

$$M + L \overset{K}{\rightleftharpoons} \text{complex}, \quad (2)$$

$$S + \text{complex} \xrightarrow{k_c} \text{products}, \quad (3)$$

$$S \xrightarrow{k_o'} \text{products}, \quad (4)$$

$$k_o' = k_o + k_L[L] + k_M[M], \quad (5)$$

$$k_{obsd} = k_o' + \frac{k_c K[L]_T[M]_T}{1+K([L]_T+[M]_T)}, \quad (6)$$

$$\frac{1}{k_{obsd}-k_o'} = \frac{1}{k_c[L]_T} + \frac{1+K[L]_T}{k_c K[L]_T} \cdot \frac{1}{[M]_T}, \quad (7)$$

where L, M, k_o, k_L, and k_M are as defined for Eq. 1, S refers to the substrate, $[L]_T$ and $[M]_T$ are the total concentrations of ligand and metal ion, respectively, K is the association constant between metal ion and ligand and k_C is the catalytic second-order rate constant for the reaction of complex with substrate **1**. A more detailed reaction scheme may involve the complexation between metal ion and substrate, or the formation of ternary complex between the three components (M,L,S). However, such additional complexation equilibria appear to be unimportant, since as mentioned above, the rate was linear to the metal ion concentration in the absence of ligands, indicating that the association constant for the formation of metal ion (Ni^{2+} or Zn^{2+}) and substrate complex is small as compared to that of metal ion and ligand complex.

The above 1 : 1 stoichiometry with the complexation of Eq. 2 was also confirmed for the ligand **4c** by looking at the kinetic version of Job plots shown in Fig. 2. The figure indicates that for both Ni^{2+} and Zn^{2+} ions the plot of k_{obsd} values as a function of mole fraction of **4c** gives a maximum at the mole fraction of 0.5, which corresponds to the 1 : 1 stoichiometry for the kinetically active species.

Saturation curves similar to the one exemplified in Fig. 1 were also obtained for other ligands, although appropriate concentration ranges of metal ion and ligand for kinetics depended on the magnitude of K and k_C values as illustrated in Fig. 3. Based on Eq. 7, three linear plots, *i.e.*, $1/(k_{obsd}-k_o')$ *vs.* $1/[M]_T$, 1/(intercept) *vs.* $[L]_T$, and the slope *vs.* $1/[L]_T$, were obtained for each pair of ligand and metal ion by changing $[M]_T$ and $[L]_T$ and these plots allowed the evaluation of k_C and K. The results of calculation are summarized in Table 2. The table indicates that (*E*)-2-pyridinecarbaldehyde(**8**)-Zn^{2+} ion complex is fairly active in harmony with the activity reported in the literature.[19h,20,21,29] The table also shows that 1-benzyl-2-(*N*-hydroxymethylaminomethyl)imidazole (**10**) and 2-(*N*-hydroxymethylaminomethyl)pyridine (**11**) are more active ligands than **8**. However, for more quantitative comparison, pH dependency of the rate should be examined.

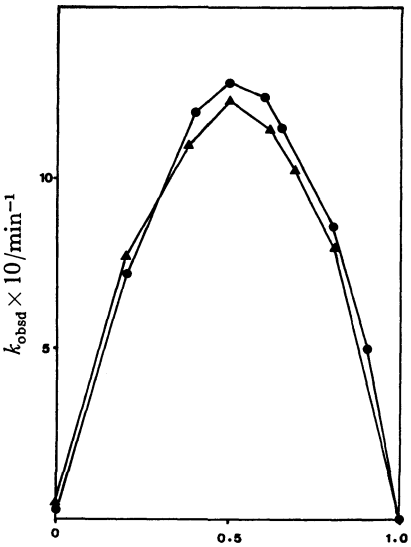

Fig. 2. Job plots for the ligand **4c** and Zn^{2+} and Ni^{2+}. ●: **4c**–Zn^{2+}, $[L]+[M]=2.6\times10^{-3}$ mol dm^{-3}, ▲: **4c**–Ni^{2+}, $[L]+[M]=2\times10^{-3}$ mol dm^{-3}.

pH-Rate Profile. Figure 4 shows plots of log k_{obsd} *vs.* pH for the same reaction conditions as given in Table 1 except for the pH. The figure indicates that both Ni^{2+} and Zn^{2+} ion complexes of **8** yield saturation curves with inflection points at around pH's 6 and 8, respectively. These saturation curves are most likely

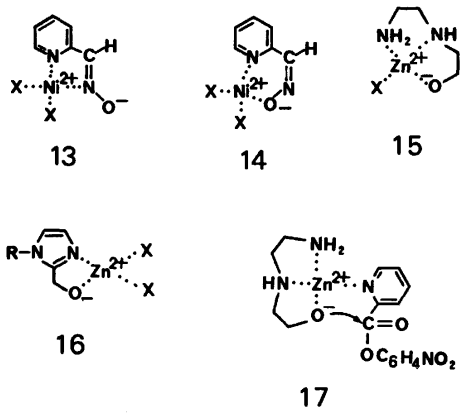
to represent the ionization of hydroxyl group complexed with Ni^{2+} or Zn^{2+} ion. The pK_a 8.6 was assigned to the ionization of hydroxyl group of the latter complex.[20] The lower pH for the ionization of the Ni^{2+} ion complex than that of the Zn^{2+} ion complex suggests that the ligand **8** coordinates to Ni^{2+} ion more tightly than to Zn^{2+} ion, in conformity with the larger K value (1120 mol dm⁻³) for the Ni^{2+} ion complex than that for the Zn^{2+} ion complex (559 mol dm⁻³) at pH 7.05, as shown in Table 2.

All the other five complexes, except for those of **8**, gave linear plots with slopes close to unity in the pH range 6.5—8.5. The ligands **10** and **11** having hydroxyamino hydroxyl group are about tenfold more active than **4c** which has a hydroxymethyl group. These linear plots also seem to represent ionization of hydroxyl groups, although their pK_a values must be higher than 8.5. Unfortunately, it was difficult to use higher pH's due to precipitation of metal hydroxide. For this reason, effects of pH on K and k_c values at higher pH's were not examined further. Nevertheless, the data in Fig. 4 together with others may suffice for qualitative discussion on the relationship among catalytic activity, ligand structure, and nature of metal ion.

Effects of Metal Ion and Ligand Structure on the Mechanism of Catalyses. Table 1 indicates that the activity of metal ions at pH 7 in the absence of ligand is in the order $Ni^{2+}>Zn^{2+}>Co^{2+}>Ca^{2+}>Mg^{2+}$. This order may be reasonable if considered on the basis of the ligand affinity of a pyridine base like **1** toward these metal ions. In the absence of metal ion, the activity of ligands is in the order **8**>**10**>**11**>**3**>**4c**. These activities are enhanced 10^2—10^3 times in the presence of Ni^{2+}, Zn^{2+}, or Co^{2+} ion. Ions Ca^{2+} and Mg^{2+} seem to have no activating effect. It is of interest to note that the activating effect of Ni^{2+} ion is somewhat different from those of Zn^{2+} and Co^{2+} ions, in such a manner that in the presence of Ni^{2+} ion the activity order of ligands is **8**>**4c**>**10**>**11**>**3**, which is changed to **10**>**11**>**4c**>**8**>**3** in the presence of Zn^{2+} or Co^{2+} ion. As is clear from Fig. 5, the reactivity order is also pH-dependent. At higher pH's, the difference in reactivity becomes larger between the complexes of **8** and those of the others.

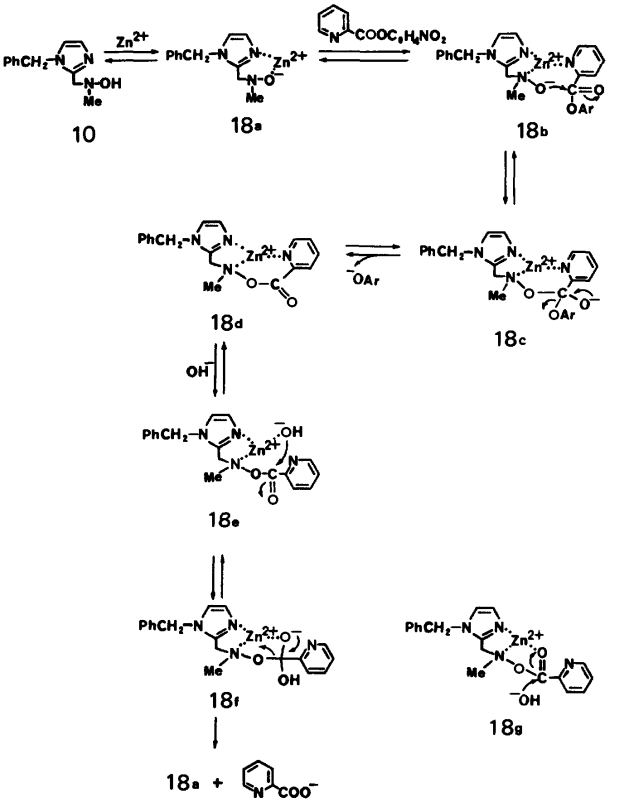
It is most likely that a metal ion activates ligand hydroxyl group by coordination. Comparison of (*E*)- and (*Z*)-oxime **8** and **9** is of interest. The association constants in Table 2 indicate that **8** forms much more stable complexes with Ni^{2+} ion than **9**, presumably because in **8** the two nitrogen atoms are in a coplanar position favorable for chelation with a metal ion, in contrast to **9** (compare the structures **13** and **14**). The activity of complex itself (k_c value), however, is much larger for **9** than for **8**, presumably because the hydroxyl group is bonded to the metal ion much more tightly in **9** (**14**) than in **8** (**13**). Similarly the diamine **3** must form a much stabler complex with Zn^{2+} ion than **4c** (**15** *vs.* **16**), but the resulting activation of hydroxyl group in the former complex is not so large as in the latter complex. Such activation may also be influenced by the nature of nitrogen ligand, such as whether it is aliphatic or aromatic. It is interesting to note with Table 2 that in each pair of **4c**–Zn^{2+} and **6**–Zn^{2+} and **10**–Zn^{2+} and **11**–Zn^{2+}, the imidazole ligands give larger k_c values, whereas the pyridine ligands give larger K values than those of the other. It is also important to note that 2-(hydroxymethyl)imidazole–**4a**–Zn^{2+} ion complex is more active than 4-(hydroxymethyl)-imidazole–**5**–Zn^{2+} ion complex. Moreover, it should be pointed out that the activity of **10**–Zn^{2+} ion complex



is really remarkable as compared to those of known examples in the literature.[20–22]

Sigman and Jorgensen[22] proposed the formation of a reactive ternary complex **17** composed of Zn^{2+} ion, **3** and **1** in the transesterification reaction between **1** and **3**. In this ternary complex the Zn^{2+} ion perturbs the pK_a (estimated to be 8.4) of the hydroxyethyl group of **3** to provide a high concentration of the effective nucleophile, which in turn acts as a template to orient **1** for the intracomplex nucleophilic attack of the ionized hydroxyethyl group on the carbonyl group of **1**. The importance of the formation of the intracomplex for the catalysis was shown by the inability of the **3**–Zn^{2+} ion complex to catalyze the transesterification of *p*-nitrophenyl acetate or *p*-nitrophenyl nicotinate which are unable to form any intracomplex. We also observed a similar substrate specificity in the present systems of **4c**–Zn^{2+} and **10**–Zn^{2+} ion complexes. Thus the formation of the ternary complex **18b**, analogous to **17**, is also conceivable for the catalysis by the **10**–Zn^{2+} ion complex illustrated in Scheme 1. However, as mentioned earlier, such a complex as **18b** should be very low in concentration as compared to the 1 : 1 complex of **18a**. It is rather more reasonable to consider that the Zn^{2+} ion stabilizes the tetrahedral addition intermediate **18c** through which the acylated intermediate **18d** is formed. As already mentioned, the Zn^{2+} ion must also catalyze the deacylation of **18d**. The complex **18e** may explain how the hydroxide ion bound on Zn^{2+} ion facilitates the deacylation through the formation of another tetrahedral intermediate **18f**. Alternatively, the Zn^{2+} ion may act as an electrophile to assist the carbonyl attack by hydroxide ion as illustrated in **18g**, although it is difficult to distinguish between the two mechanisms (**18e** and **18g**) kinetically. Whichever mechanism is true, the breakdown of the tetrahedral intermediate **18f** into products should also be fast for an effective catalysis to occur.

In summary, we have disclosed that the ligands **4c**, **10**, and **11**, when complexed with a metal ion such as Zn^{2+}, Ni^{2+}, or Co^{2+} ion, become highly active toward the hydrolysis of *p*-nitrophenyl picolinate (**1**). The catalysis is most likely to occur through formation of a ternary complex in the transition state or in reactive intermediates. The metal ion in such a complex serves to activate ligand hydroxyl group for nucleophilic attack and to orient the substrate into a favorable position to undergo the reaction. Future interesting subjects are how to incorporate these complexes into more sophisticated systems, such as micellar systems, as active centers of artificial metalloenzymes, although some serious problems still remain to be solved such as how to activate inert substrates.



Scheme 1. Mechanism of hydrolysis of **1** catalyzed by **10**–Zn^{2+} complex.

Experimental

Materials. The water used for kinetic experiments was obtained by distilling deionized water. Buffer reagents, HEPES (2-[4-(2-hydroxyethyl)-1-piperazinyl]ethanesulfonic acid), MES (2-morpholinoethanesulfonic acid), KNO_3, hydrochloric acid, nitric acid, *etc.* were commercial extra pure reagents. Commercially available 2,6-lutidine, *N*-ethylmorpholine, *N*-(2-hydroxyethyl)ethylenediamine (**3**), and 2-(hydroxymethyl)pyridine (**6**) were distilled twice prior to use. Acetonitrile was distilled twice from phosphorus pentaoxide. Commercially available metal salts, $Zn(NO_3)_2 \cdot 6H_2O$, $Ni(NO_3)_2 \cdot 6H_2O$, $Co(NO_3)_2 \cdot 6H_2O$, $Ca(NO_3)_2 \cdot 4H_2O$, and $Mg(NO_3)_2 \cdot 6H_2O$, were used without further purification. *p*-Nitrophenyl picolinate (**1**) was prepared and purified according to the literature procedure.[22] (*E*)-2-Pyridinecarbaldehyde (**8**) was a commercial reagent (Wako Pure Chem.) and was purified by recrystallization from chloroform–hexane. *N*-Benzyl-2-(hydroxymethyl)imidazole (**4c**) was prepared by heating *N*-benzylimidazole and 30% aqueous solution of formaldehyde in an autoclave at 120 °C for 18 h. The resulting mixture was evaporated to dryness and the residue was crystallized after treatment with charcoal from ethyl acetate and white cubes were obtained. These crystals were recrystallized from ethyl acetate and dried: mp 96—97 °C; ^1H NMR ($CDCl_3$) δ=4.60 (2H, s), 4.9 (1H, br s), 5.20 (2H, s), 6.77

(1H, d, J=1.5 Hz), 6.82 (1H, d, J=1.5 Hz), and 7.15—7.30 (5H, m). 1-Benzyl-2-imidazolecarbaldehyde oxime (**7**) was synthesized by slowly adding 1-benzyl-2-imidazolecarbaldehyde and hydroxylamine hydrochloride to a methanol–water (1 : 1 volume ratio) containing sodium carbonate at room temperature. Extraction, drying over magnesium sulfate, concentration *in vacuo*, and column chromatographic separation yielded product **7**: mp 170—171 °C; ^{1}H NMR ($CDCl_3$–$(CD_3)_2SO$) δ=5.55 (2H, s), 7.05 (1H, d, J=1.5 Hz), 7.10 (1H, d, J=1.5 Hz), 7.20—7.35 (5H, m), 8.18 (1H, s), and 11.5 (1H, s). *syn*-Pyridinealdoxime (**9**) was obtained by a photoisomerization of (*E*)-2-pyridinecarbaldehyde oxime (**8**) using a 150 W high-pressure Hg lamp through a Pyrex filter for 30 h. The usual work-up and thin layer chromatographic separation yielded the recovered starting material **8** and (*Z*)-oxime **9**: mp 91—92 °C; ^{1}H NMR ($CDCl_3$) δ=7.3—8.1 (3H, m), 8.68 (1H, s), 8.54—8.65 (1H, m), and 11.25 (1H, br s). 1-Benzyl-2-(*N*-hydroxymethylaminomethyl)imidazole (**10**) was synthesized as follows: *N*-Benzyl-2-chloromethylimidazole hydrochloride, which was obtained by chlorination of **4c** with thionyl chloride, was added to a methanol–water (1 : 5 volume ratio) containing excess amounts of *N*-methylhydroxylamine hydrochloride and sodium carbonate. The usual work-up procedure gave colorless needles of **10**: mp 91—93 °C; ^{1}H NMR ($CDCl_3$) δ=3.30 (1H, s), 4.48 (2H, s), 5.17 (2H, s), 6.88 (1H, d, J=1.5 Hz), and 6.99 (1H, d, J=1.5 Hz). 2-(*N*-Hydroxymethylaminomethyl)pyridine (**11**) was also prepared similarly to **10** and obtained as colorless needles: mp 92—94 °C; ^{1}H NMR δ=2.68 (3H, s), 3.92 (2H, s), 7.00—7.75 (4H, m), 8.0 (1H, br s), and 8.45—8.55 (1H, m). *N*-Hydroxy-*N*-methylbenzylamine (**12**) was obtained by treatment of benzyl chloride with *N*-methylhydroxylamine: mp 41—42 °C; ^{1}H NMR ($CDCl_3$) δ=2.45 (3H, s), 3.66 (2H, s), 7.28 (5H, s), and 8.12 (1H, br s).

Kinetic Measurements. Kinetic runs were generally conducted on a Hitachi 220 spectrophotometer equipped with a thermostated cell compartment. A Hitachi-Horiba pH meter/F-7ss was used for pH determination on buffer and reaction mixtures. The kinetic run was initiated by introducing 10—30 μl of ester stock solution into 3 ml of the buffer solution containing the metal ion and ligand at desired concentrations and maintained at 25 °C. The stock solution contained 1.0—3.0$\times 10^{-2}$ mol dm^{-3} ester in acetonitrile. The ionic strength was maintained at 0.1 mol dm^{-3} with KNO_3. The rate of hydrolysis of *p*-nitrophenyl picolinate (**1**) was obtained by following the appearance of liberated *p*-nitrophenol at 400 nm. The reaction followed a pseudo-first-order kinetics for at least 3 half-lives. Rate constants and derived kinetic parameters were evaluated by a nonlinear least-squars programs.

Synthetic Control by Internal Interaction. The Intramolecular Diels-Alder Reactions of Furan Derivatives and α, β-Unsaturated Amides

Toyonori TAKEBAYASHI, Nobuharu IWASAWA, and Teruaki MUKAIYAMA*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received July 23, 1982)

An efficient method for the acceleration of the intramolecular Diels-Alder reaction was established utilizing the internal interaction——the internal hydrogen bonding and the internal coordination of a magnesium salt. The intramolecular Diels-Alder reaction between nitrofuran derivatives and various acrylic acid derivatives give good yields of the cycloadducts when internal hydrogen bonding is present. When cyclic α,β-unsaturated amides are employed as dienophile, the corresponding cycloadducts are obtained in high yield utilizing internal coordination of a magnesium salt.

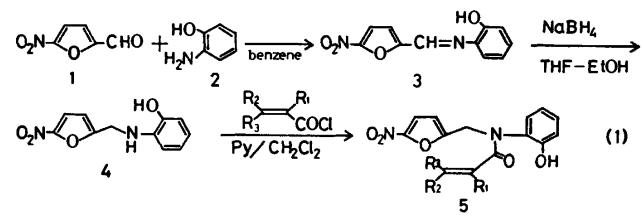
The intramolecular Diels-Alder reaction is one of the most expedient methods for the stereoselective construction of polycyclic systems and is often employed as a key step for the total synthesis of various complex natural products.[1] In general, the intramolecular Diels-Alder reaction profits from entropical factors due to the spatial proximity of the reaction parameters, and many examples are known that verify this feature. However, it is sometimes difficult to obtain the cycloadducts even in the intramolecular Diels-Alder reaction. For example, furan is known as a relatively unreactive diene because of its aromaticity, and only a few examples on the intramolecular Diels-Alder reactions of furan derivatives with reactive dienophiles such as fumaric acid or acrylic acid derivatives have been reported.[2] Then we assumed that even in the unfavorable combination of dienes and dienophiles such as furan moiety and sterically hindered acrylic acid derivatives, it would be possible to obtain the corresponding cycloadducts by manipulating some artificial control on the reaction. Based on these assumptions, we have explored an efficient method for the acceleration of the intramolecular Diels-Alder reaction utilizing the intramolecular interactions —that is, the internal coordination of a magnesium salt and the internal hydrogen bonding.[3,4]

In the present paper, we wish to report this new concept for the acceleration of the intramolecular Diels-Alder reaction between furan derivatives and various sterically hindered α,β-unsaturated amides in detail.

Results and Discussion

It is well known that electron-rich dienes and electron-deficient dienophiles react easily to afford the cycloadducts in good yields. On the other hand, electron-deficient dienes preferentially react with dienophiles substituted with electron-donating groups, that is, the Diels-Alder reaction with "inverse electron demand."[5] Of these reactants, electron-deficient dienes, only a few papers related to dienes substituted with the strongly electron-withdrawing groups such as nitro group have been noted.[6] Notably, there has been only one example of the Diels-Alder reaction of nitrofuran with maleic anhydride reported by Van Campen *et al.*,[7] though they were unable to isolate the corresponding cycloadduct. It seems that, in this case, the cycloaddition reaction is impossible, as both nitrofuran and maleic anhydride are strongly electron-deficient. So the promotion of the reaction of this unfavorable combination of diene and dienophile was undertaken based on the intramolecular interaction taking the intramolecular Diels-Alder reaction between nitrofuran (*i.e.* the electron-deficient diene) and α,β-unsaturated amides (*i.e.* the electron-deficient dienophile), as a model.

In the first place, *N*-(5-nitrofurfuryl)-*N*-(2-hydroxyphenyl)acrylamides (**5**), the Diels-Alder reagents, were prepared from 5-nitrofurfural (**1**) and 2-hydroxyaniline (**2**) as shown in Eq. 1.

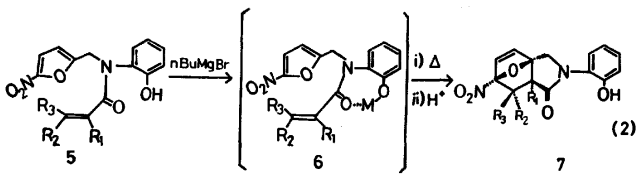


(1)

With the expectation that the formation of internal chelate complex **6** would bring both diene and dienophile groups to come closely to promote the cycloaddition reaction effectively, the reaction of the magnesium salt of amide **5** was examined, and the results are summarized in Table 1.

As shown in Table 1, cycloadducts **7a—c** were obtained only in 44—58% yield,[8] though starting material **5** was consumed completely and several minor products were detected on the thin-layer chromatography. This result indicates that the cycloaddition reaction might be accelerated by the formation of

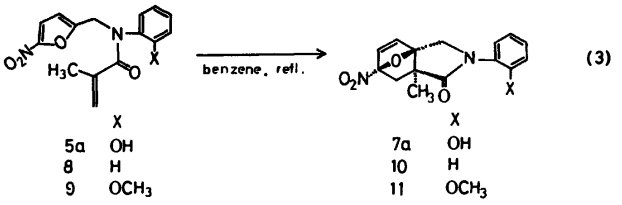
Table 1. The Diels-Alder reaction of **5** with magnesium salt



(2)

Amide	R_1	R_2	R_3	Solvent	Reaction time/h	Yield of **7** %
5a	CH_3	H	H	Benzene	3	46
				Benzene	7	57
5b	H	CH_3	H	Toluene	7	47
				Toluene–THF	9	42
5c	H	CH_3	CH_3	Toluene	7	48
				Toluene–THF	9	44

internal chelate, but some difficulties arose because of side reactions caused by the presence of a nitro group. Then the cycloaddition reaction of amide **5**, without converting to its magnesium salt, was tried on the assumption that the internal hydrogen bonding would be sufficient for the effective promotion of the cycloaddition reaction. Amides **5a**, **8**, and **9** were prepared to compare the reactivity, and to determine the existence and the role of the internal hydrogen bonding, and their reactions were examined under the same conditions (Eq. 3).



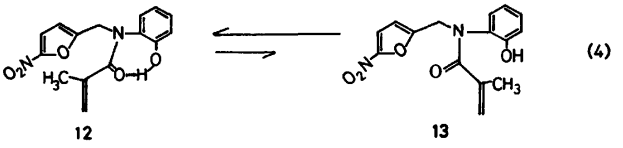
(3)

When a benzene solution of amide **5a** was refluxed for 7 h, adduct **7a** was obtained in 75% yield, but amides **8** and **9**, in which there is no internal hydrogen bonding, gave adducts **10** and **11** in only 30 and 11% yields, respectively, under the same conditions. Further, the existence of the internal hydrogen bonding in amide **5a** was supported by its IR spectra, that is, the absorptions of the carbonyl group of **5a**, **8**, and **9** are at 1600, 1650, and 1650 cm^{-1}, respectively.

These results indicate that the internal hydrogen bonding performs an important part on the acceleration of this cycloaddition reaction as expected.

Among possible conformers of amide **5a**, only conformer **12**, in which the diene and the dienophile approach closely, leads to the cycloaddition reaction.[2)]

In this case, it is apparent that the internal hydrogen bonding of the phenolic hydrogen to the carbonyl oxygen is sufficient to fix the conformation of this molecule to favorable conformer **12** (Eq. 4).



(4)

The yield of adduct **7a** increased to 94% when the reaction was performed in refluxing toluene. Similar reactions with other sterically hindered α,β-unsaturated amide **5** were tried, and adducts **7** were obtained in good yields as shown in Table 2.

The intramolecular cycloaddition reaction between furan moiety and cyclic α,β-unsaturated amide gives the tetracyclic compounds in one step, which are useful for the construction of polycyclic system. Moreover, there is no report on the intramolecular Diels-Alder reaction using the cyclic α,β-unsaturated amide as dienophile, probably because of its high steric hindrance. Then we next tried the cycloaddition reaction between furan derivatives and 1-cyclohexenecarboxamide utilizing the internal interaction—that is, the internal hydrogen bonding or the internal coordination of the metal salt. *N*-Furfuryl-*N*-(2-hydroxyphenyl)-1-cyclohexenecarboxamide (**14**) was prepared from 2-furoyl chloride (**15**) and 2-hydroxyaniline (**2**) as shown in Eq. 6.

TABLE 2. THE DIELS-ALDER REACTION OF **5**

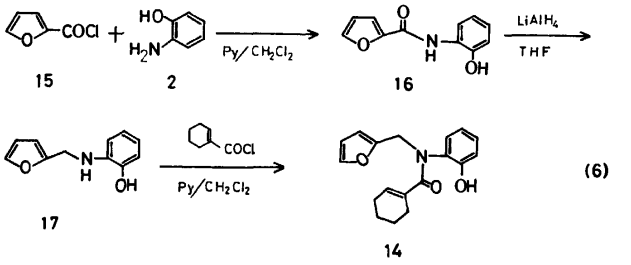
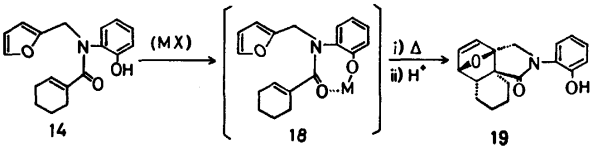
5a		7	94
b		9	93
c		9	73
d		7	96
e		9	30



(6)

With starting material **14** in hand, we then examined the reaction of amide **14** and its magnesium salts based on the same assumption described above (Eq. 7).



(7)

When amide **14** was heated in the refluxing benzene or toluene, only a trace of the cycloadduct was detected. Then, amide **14** was converted to its magnesium salt by the treatment with the Grignard reagent, and the reaction was performed in refluxing toluene. And, in this case, the reaction was effectively accelerated to afford cycloadduct **19** in 38% yield. To increase the yield of **19**, the effect of the solvent was examined. The results are summarized in Table 3. As shown in this Table, remarkable increase in the yield of cycloadduct **19** was not observed. Moreover, the effect of the reaction time was also investigated. When the reaction was continued for 14 h, the yield of cycloadduct **19** increased to 41%. However, longer reaction time decreased the yield of cycloadduct **19**, and only 14% yield of **19** was obtained, when the reaction was run

Table 3. The effect of reaction temperature[a)]

Solvent	Reaction temp/°C	Reaction time/h	Yield of **19** %
Benzene	Reflux	7	Trace
Toluene	Reflux	7	38
Xylene	Reflux	7	18

$-OB(C_2H_5)_2$	10	25
$-OBBr_2$	7	—

a) The reaction was carried out in refluxing toluene.

for 33.5 h. We also found that starting material **14** was recovered in 30% yield, when the magnesium salt of cycloadduct **19** was refluxed in toluene for 7 h. This result indicates that the reaction is an equilibrating one and both cycloaddition reaction and the retro Diels-Alder reaction proceed concurrently at high temperature. And this could partly explain the rather moderate yield of cycloadduct **19** in this reaction.

Finally, we examined other metal salts such as Zn, Al, and B, which are thought to be stronger Lewis acids than Mg. However, as shown in Table 4, the use of these metal salts rather decreased the yield of adduct **19**.

It is well known that the Diels-Alder reaction is accelerated by the Lewis acid,[9)] but, at the same time, side reactions such as polymerization often occur, because both dienes and dienophiles are rather unstable under the acidic conditions.[10)] And in this case magnesium which is regarded as a week Lewis acid, is most favorable, that is, strong enough to accelerate the reaction effectively but not too strong to cause the side reactions. Further, the cycloaddition reaction of other cyclic α,β-unsaturated amides were examined. Molecular models show that in the case of 1-cyclohexenecarboxamide **14**, the axial protons in the cyclohexene ring seem to disturb the approach of the furan ring, and it is assumed that more planar cyclic α,β-unsaturated amides would show higher reactivity in the cycloaddition reaction. Based on this assumption, 1-cyclopentenecarboxamide derivative **20** and 1,5-cyclohexadienecarboxamide derivative **23** were prepared, and their reactivities were examined under the various reaction conditions. The results are summarized in Tables 5 and 6.

As clearly shown in these Tables, these two compounds show higher reactivity than the 1-cyclohexenyl derivative, and the corresponding cycloadducts were obtained in high yields by forming the internal chelate complexes

of magnesium. These results indicate that steric hindrance of the dienophile remarkably affects the reactivity of the intramolecular Diels-Alder reaction, and that by employing coordinating property of magnesium ingeniously, dramatic acceleration of the reaction could be achieved.

In conclusion, it is noted that an efficient and general method is established for the acceleration of the intramolecular Diels-Alder reaction by employing internal hydrogen bonding or the internal coordination of a magnesium salt. By employing this method, various cycloadducts, which cannot be obtained in the previous intramolecular Diels-Alder reaction, have become available in high yields.

Experimental

Measurements. All the melting points were uncorrected. NMR spectra were recorded with a Hitachi R-24B spectrometer. IR spectra were measured with a Hitachi EPI-G2 spectrometer. Mass spectra were measured with a JEOL JMS 01-SG spectrometer.

Materials. All organic solvents used were distilled according to the general methods and stored over sodium metal or molecular sieves as a drying agent.

2-Hydroxy-N-(5-nitrofurfurylidene)aniline (3). 2-Hydro-

xyaniline (2.02 g, 18.5 mmol) was added to the benzene solution (20 ml) of 5-nitrofurfural (2.59 g, 18.4 mmol) at room temperature. A yellow precipitate was formed immediately. After 30 min the precipitate was filtered and recrystallized from benzene to afford **3** as yellow needles (3.73 g, 88%). Mp 158 °C (decomp) (benzene); IR (KBr) 3360, 3160, 1625, 1525, and 1332 cm^{-1}; NMR (DMSO-d_6) δ=6.25—7.53 (6H, m), 8.48 (1H, s), 8.70 (1H, broad); Found: C, 56.91; H, 3.30; N, 11.96%; Calcd for $C_{11}H_8N_2O_4$: C, 56.90; H, 3.47; N, 12.07%.

N-(2-Hydroxyphenyl)-5-nitrofurfurylamine (4). 2-Hydroxy-*N*-(5-nitrofurfurylidene)aniline (**3**) (3.22 g, 13.9 mmol) was dissolved in 165 ml of THF and 66 ml of 95% ethanol. The mixture was cooled to −35—−40 °C. The solution of sodium borohydride (0.79 g, 20.8 mmol) dissolved in 0.8—1.3 ml water and 9 M (1 M=1 mol dm^{-3}) hydrochloric acid were alternately added dropwise to the stirred solution so that pH 6—8 was maintained. During the addition, care was taken to maintain the temperature between −35 and −45 °C. After the addition of the sodium borohydride was complete, the solution was stirred at −35 °C for 1.5 h and hydrolyzed with water. After being acidified with acetic acid–ethanol solution to pH 3—4, the mixture was neutralized with 6 M sodium hydroxide. To the solution dichloromethane was added and the organic layer was washed with water, dried over Na_2SO_4, and the solvent was evaporated *in vacuo*. The residue was purified by silica-gel column chromatography using benzene–ethyl acetate (5 : 1) and amine **4** was obtained (2.72 g, 70%; unstable to light). Mp 85 °C; IR (KBr) 3320, 3130, 1490, and 1350 cm^{-1}; NMR ($CDCl_3$) δ=4.33 (2H, s), 4.63 (2H, broad), 6.30 (1H, d, J=4 Hz), 6.37—6.70 (4H, m), 7.07 (1H, d, J=4 Hz).

N-(5-Nitrofurfuryl)-N-(2-hydroxyphenyl)methacrylamide (5a). To a solution of amine **4** (0.82 g, 3.76 mmol) in 10 ml of dichloromethane and dry pyridine (0.43 g, 5.46 mmol) was added dropwise methacryloyl chloride (0.48 g, 4.55 mmol) in 5 ml of dichloromethane at −20 °C under an argon atmosphere. After the addition was complete, the reaction mixture was stirred at room temperature for 3 h. Then the organic layer was washed with 2 M hydrochloric acid and water. After being dried over Na_2SO_4, the solvent was evaporated *in vacuo* and the residue was purified by silica-gel column chromatography using benzene–ethyl acetate (5 : 1) and amide **5a** was obtained as yellow needles (0.77 g, 71%). Mp 146—147 °C (dichloromethane); IR (KBr) 3250, 1605, 1590, and 1350 cm^{-1}; NMR (DMSO-d_6) δ=1.75 (3H, s), 4.67 (1H, m), 4.90 (3H, m), 6.48 (1H, d, J=4 Hz), 11.10 (1H, broad); Found: *m/e* 302.0943. N-(2-Hydroxyphenyl)-2-furancarboxamide (16). Under an argon atmosphere 2-furoyl chloride (22.9 g, 0.18 mol) was added to the suspension of 2-hydroxyaniline (19.1 g, 0.18 mol) and dry triethylamine 35 ml in 400 ml dichloromethane at 0—5 °C and the mixture was stirred at room temperature for 2 h. After 2 M hydrochloric acid was added to the mixture to afford amide **16** (20.2 g, 57%), a white precipitate formed was filtered. The filtrate was extracted with dichloromethane and the extract was washed with water. The organic layer was dried over Na_2SO_4 and evaporated. The residue was recrystallized from benzene to afford amide **16** (8.76 g, 25%). Mp 165—166 °C (benzene); IR (KBr) 3390, 3100, and 1635 cm^{-1}; NMR ($CDCl_3$) δ=6.37—7.47 (7H, m), 8.00 (1H, m), 8.83 (1H, broad); Found: C, 65.05; H, 4.37; N, 7.01%; Calcd for $C_{11}H_9NO_3$: C, 65.02; H, 4.46; N, 6.89%.

N-(2-Hydroxyphenyl)-2-furfurylamine (17). Under an argon atmosphere, amide **16** (25.0 g, 0.12 mol) in 220 ml THF solution was added dropwise to the suspension of $LiAlH_4$ (6.1 g, 0.16 mol) in 30 ml of THF at −5—0 °C. After the mixture was refluxed for 1 h, saturated sodium sulfate solution was

added cautiously in an ice-cold bath. The precipitate was filtered and washed with ethyl acetate. The filtrate was washed with 2 M hydrochloric acid and neutralized with sodium hydrogencarbonate, and then extracted with ethyl acetate. The organic layer was dried over Na_2SO_4 and the solvent was evaporated *in vacuo*. The residue was distilled and amine **17** was obtained as a colorless oil (2.80 g, 80%). Bp 110 °C/0.2 mmHg (1 mmHg≈133.322 Pa); mp 62 °C; IR (liquid) 3340 and 1610 cm^{-1}; NMR ($CDCl_3$) δ=4.12 (2H, s), 5.25 (2H, s), 6.03 (2H, m), 6.33—6.70 (4H, m), 7.10 (1H, s).

*N-Furfuryl-N-(2-hydroxyphenyl)-1-cyclohexenecarboxamide (**14**).* To a solution of amine **17** (1.42 g, 7.50 mmol) in 20 ml of dichloromethane and dry pyridine (0.89 g, 11.26 mmol) 1-cyclohexenecarbonyl chloride (1.40 g, 7.54 mmol) in 14 ml of dichloromethane was added dropwise at −20 °C under an argon atmosphere. After the addition was complete, the mixture was stirred at room temperature for 3 h. Then the organic layer was washed with 2 M hydrochloric acid and water. After being dried over Na_2SO_4, the solvent was evaporated and the residue was recrystallized from benzene and amide **14** was obtained as white needles (1.85 g, 83%). Mp 171—172 °C (benzene); IR (KBr) 3400 and 1610 cm^{-1}; NMR ($CDCl_3$) δ=1.02—1.67 (4H, m), 1.67—2.33 (4H, m), 4.82 (2H, s), 5.67—6.00 (1H, m), 6.10 (2H, m), 6.60—7.33 (6H, m); Found: C, 72.68; H, 6.41; N, 4.45%; Calcd for $C_{18}H_{19}NO_3$: C, 72.70; H, 6.44; N, 4.71%. By similar procedure amide **20** was prepared. **20**: Mp 114—115 °C (benzene); IR (KBr) 3130 and 1610 cm^{-1}; NMR ($CDCl_3$) δ= 1.28—2.50 (6H, m), 4.78 (2H, s), 5.85 (1H, m), 6.07 (2H, m), 6.52—7.40 (6H, m); Found: C, 72.26; H, 6.07; N, 4.84%; Calcd for $C_{17}H_{17}NO_3$: C, 72.06; H, 6.05; N, 4.94%.

*N-Furfuryl-N-(2-hydroxyphenyl)-1,5-cyclohexadienecarboxamide (**23**).* To 1-methyl-2-chloropyridinium tosylate (1.95 g, 6.5 mmol) in 15 ml of dichloromethane was added a mixture of amine **17** (1.00 g, 5.30 mmol), 1,5-cyclohexadienecarboxylic acid[11] (0.67 g, 5.42 mmol) and triethylamine (0.87 g, 13.11 mmol) in 40 ml of dichloromethane. After being stirred overnight at room temperature under an argon atmosphere, 2 M hydrochloric acid (10 ml) was added to the reaction mixture and the resulting mixture was washed with water (20 ml) three times. The organic layer was dried over Na_2SO_4 and concentrated under the reduced pressure. Amide **23** was isolated after separation by silica-gel column chromatography using benzene–ethyl acetate (5 : 1) (0.48 g, 30%). Mp 139—140 °C (cyclohexane–benzene); IR (KBr) 3150 and 1610 cm^{-1}; NMR ($CDCl_3$) δ=1.92 (4H, m), 4.86 (2H, m), 5.27—6.33 (5H, m), 6.43—7.33 (6H, m); Found: C, 72.97; H, 5.63; N, 4.64%; Calcd for $C_{18}H_{17}NO_3$: C, 73.20; H, 5.80; N, 4.74%.

Intramolecular Diels-Alder Reaction Using Halophenoxy Magnesium Salt.[8] *1,2,3,3a,6,6a,7,8,9,10-Decahydro-(2-hydroxyphenyl)-3a,6-epoxybenz[d]isoindol-1-one (**19**).* To a solution of amide **14** (100.3 mg, 0.337 mmol) in 3 ml of THF was added dropwise butylmagnesium chloride (0.39 ml, 0.86 mol dm^{-3} ether solution) at −78 °C under an argon atmosphere. After the solution being concentrated under the reduced pressure at room temperature, toluene (30 ml) was added and the reaction mixture was refluxed for 14 h under an argon atmosphere. To the solution was added 2 M hydrochloric acid (10 ml), and the organic layer was extracted with dichloromethane. The extract was washed with water and dried over Na_2SO_4. The solution was concentrated under the reduced pressure. Cycloadduct **21** was isolated after separation by the thin-layer chromatography using benzene–ethyl acetate (5 : 1) (44.0 mg, 44%). Mp 138—139 °C (cyclohexane); IR (KBr) 3180 and 1660 cm^{-1}; NMR ($CDCl_3$) δ=0.50—2.10 (8H, m), 2.83 (1H, d, J=5 Hz), 3.58 (1H, d, J=12 Hz), 4.10 (1H, d, J=12 Hz), 4.85 (1H, d, J=5 Hz), 6.37 (2H, s), 6.53—6.97 (4H, m), 7.88 (1H, broad); Found: C, 72.71; H, 6.46; N, 4.77%; Calcd for $C_{18}H_{19}NO_3$: C, 72.70; H, 6.44; N, 4.71%. By similar procedures the intramolecular Diels-Alder reaction of amides **20** and **23** were performed to afford cycloadducts **22** and **25**. **22**: Mp 182—183 °C (benzene); IR (KBr) 3500 and 1670 cm^{-1}; NMR ($CDCl_3$) δ=1.33—2.32 (6H, m), 2.93—3.43 (1H, m), 3.97 (1H, d, J=12 Hz), 4.43 (1H, d, J=12 Hz), 4.87 (1H, d, J=5 Hz), 6.42 (2H, s), 6.63—7.30 (4H, m), 8.18 (1H, s); Found: C, 72.17; H, 6.15; N, 4.90%; Calcd for $C_{17}H_{17}NO_3$: C, 72.06; H, 6.05; N, 4.94%. **25**: Mp 151—152 °C (benzene); IR (KBr) 3450 and 1650 cm^{-1}; NMR ($CDCl_3$) δ=0.90—2.22 (4H, m), 2.67—3.22 (1H, m), 3.87 (1H, d, J=11 Hz), 4.38 (1H, d, J=11 Hz), 4.82 (1H, d, J=4 Hz), 5.43 (1H, d, J=10 Hz), 5.85 (1H, m), 6.20 (2H, s), 6.43—7.20 (4H, m), 7.87 (1H, s); Found: C, 73.18; H, 5.77; N, 4.90%; Calcd for $C_{18}H_{17}NO_3$: C, 73.20; H, 5.80; N, 4.74%.

8) Only one of two stereoisomers was obtained. In this case, based on models and spectral analogy, the exo mode cyclization (trans ring junction) was preferred. The coupling constant between proton Ha and Hb in adducts **19**, **22**, and **25** are 5, 5, and 4 Hz, respectively, suggesting a dihedral angle of 40° or 45° (according to models, the corresponding angle for the alternative structure would be about 90° resulting in no spin-spin coupling) (Fig. 1). These results agree with

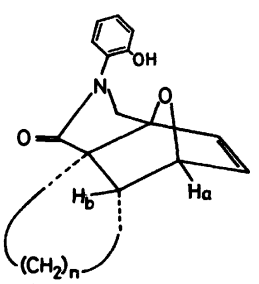

Fig. 1. Stereochemistry of cycloadducts.

spectral data presented by K. A. Parker[2b] for a related set of compounds. In the case of nitrofuran derivatives, we cannot tell the stereochemistry of the formed cycloadduct from the coupling constant becase a nitro group is present in the place of Ha proton. But in the intramolecular Diels-Alder reaction of furan derivatives, it is well known[2,12] that only the exo mode

of cycloadducts are formed, and, in this case also, we assume that only the exo mode of cycloaddition was preferred.

The Reductive Coupling of Organic Halide Using Hydrazine and a Palladium Amalgam Catalyst. II.[1] Homocoupling of Haloarene with Arylhydrazine

Riichiro NAKAJIMA,* Masaji KINOSADA,† Takashi TAMURA, and Tadashi HARA
Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma Imadegawa Kamikyo-ku, Kyoto 602
(Received July 28, 1982)

The function of palladium chloride in the reaction of an arylhydrazine with a haloarene was found to differ from those of other metal salts; palladium chloride was reduced with arylhydrazine, and the palladium metal produced was again oxidized with haloarene to give palladium halide. Thus the reductive coupling of haloarene occurred in the presence of a catalytic amount of palladium chloride. Addition of mercury(II) chloride promoted this reaction. The reaction of *o*-, *m*-, and *p*-bromotoluene with the corresponding tolylhydrazine gave the corresponding bitolyl in 99, 112, and 115% yield, respectively, based on the haloarene.

Monoarylhydrazines are readily oxidized like hydrazine itself by a variety of reagents, the products varying with the oxidant used. For example, when oxidation is effected by either silver(I) oxide, mercury(II) oxide,[2] or lead(IV) acetate[3] in aromatic solvents, an arylhydrazine is converted smoothly into the corresponding biaryl; bromo- or chlorobenzene reacted with phenylhydrazine to give bromo- or chlorobiphenyls without displacement of halogen. On the other hand, Bacon *et al.*[4] have observed catalytic effects of small amounts of phenylhydrazine on the coupling of bromo- or iodonitroarene with copper(I) oxide, but details are not clear. The present study has, therefore, been carried out in order to examine the reaction of haloarene with arylhydrazine in the presence of a palladium catalyst because in the latter case phenylhydrazine is anticipated to play the role of hydrazine in the Busch reaction. The reductive homocoupling of both iodo- and bromoarenes occurs in the presence of a palladium amalgam catalyst and arylhydrazines to give the corresponding halogen-free biaryls in good yield.

Results and Discussion

As Table 1 shows, when halobenzene (25.0 mmol) was treated with phenylhydrazine (10.0 mmol) in the presence of a catalytic amount (2 mol%) of palladium prepared *in situ* from palladium chloride in refluxing methanol for 6 h, the reductive coupling of bromo- or iodobenzene with phenylhydrazine occurred to give biphenyl. In contrast to the behavior of chlorobenzene, no phenylation of bromo- or iodobenzene occurred.

TABLE 1. COUPLING OF HALOBENZENE WITH PHENYLHYDRAZINE BY THE USE OF PALLADIUM METAL OR A PALLADIUM AMALGAM

Halobenzene	Yield of biphenyl/%[a]	
	Pd	Pd-Hg
Chlorobenzene	11.7[b]	7.8[b]
Bromobenzene	61.8	96.6
Iodobenzene	62.2	105.7

a) Based on halobenzene used. b) Traces of chlorobiphenyls were also formed.

† Present address: Toyo Kasei Kogyo Co. Ltd., 2900, Sonecho Takasago 676.

This coupling was promoted by addition of mercury(II) chloride.

It has long been known that the formation of biphenyl arises not only by oxidation of phenylhydrazine with metal oxides, metal acetates, *etc.*, but also by reductive coupling of halobenzenes with metals. To determine the source of the biphenyl, one of the aromatic rings in Eq. 1 was labeled with a substituent to distinguish it from the other.

$$ArX + ArNHNH_2 \xrightarrow{\text{Pd or Pd-Hg}} ArAr, \textit{ etc.} \quad (1)$$

The aryl group in the biaryls was derived mostly from the haloarene, independent of the presence of substituent, as listed in Table 2. When a palladium amalgam catalyst was used, about 75% of *p*-halotoluene was converted to 4,4′-dimethylbiphenyl, the remainder being consumed in the reaction with phenylhydrazine to give 4-methylbiphenyl and toluene. However, the homocoupling of *p*-bromotoluene was scarcely observed in the absence of a palladium catalyst and a large portion of bromotoluene was recovered. These results clearly indicate that the formation of the biaryl occurs mostly by the reductive coupling of haloarene, *i.e.*, Eq. 2.

$$2ArX + Pd \longrightarrow ArAr + PdX_2 \quad (2)$$

Evidently the palladium(II) halide formed *in situ*, as described in Eq. 2, was also reduced with arylhydrazine, because both the palladium(II) salt and the mercury(II) salt used were recovered as the metals. It is known that the oxidation of phenylhydrazine with metal oxide in halobenzene yields benzene, biphenyl, azobenzene, and halobiphenyls, and the formation of these compounds can be explained in terms of a radical mechanism.[3,4] However, in the present system no halobiphenyls were obtained and one of the biphenyls isolated was formed by the displacement of halogen with the aryl group derived from arylhydrazine. These results can be best explained by the mechanism *via* arylhydrazine-palladium halide complex[5] (Eq. 3).

$$2NH_2NHPh + PdX_2 \longrightarrow PdX_2(NH_2NHPh)_2 \xrightarrow{-2HX\ -2H^+} \begin{cases} \longrightarrow 2PhH(\text{and/or } Ph_2+H_2)+2N_2+Pd \\ [Pd(NH{=}NPh)_2] \longrightarrow 2NH{=}NPh + Pd \\ \xrightarrow{+2ArX} 2ArPh + 2HX + 2N_2 + Pd \end{cases} \quad (3)$$

TABLE 2. REACTION OF HALOARENE WITH ARYLHYDRAZINE

ArX (12.5 mmol)	ArNHNH$_2$ (12.5 mmol)	Catalyst (0.5 mmol)	Biaryls(mmol)		
			Ar$_2$	ArAr	Ar$_2$
p-Bromotoluene[a)]	Phenylhydrazine	None	0.10		0.48
p-Bromotoluene	Phenylhydrazine	Pd	1.69	1.11	0.63

2-Bromopyridine	Phenylhydrazine	2,2′Bipyridyl/42[b)] 2-Phenylpyridine/0.6 Biphenyl/1.8
2-Bromothiophene	Phenylhydrazine	2,2′-Bithienyl/41.7 2-Phenylthiophene[c)] Biphenyl/1.4

a) Yield based on organic bromide used except that of biphenyl and determined by GLPC. b) Isolated yield.
c) Not measured.

Consequently, the present reaction is a Busch-type reaction because arylhydrazine acts as a reducing agent and then the reductive homocoupling of haloarene proceeds in the presence of the palladium catalyst.

According to the present method, both iodo- and bromoarenes could be used as the starting materials for the preparation of biaryls. The previous method[1)] gave satisfactory yields of biaryls only when iodoarene was used and, therefore, the utility of the present method was examined in the coupling of bromoarenes (Table 3). Usually traces of arylamine, azoarene, and hydrazoarene, which are well known as the decomposition products of arylhydrazine, were detected, but these compounds were easily separated from the biaryls. Bromotoluenes and bromoxylene reacted with tolyl- and xylylhydrazine, respectively, to give the corresponding biaryls in high yield. 2,2′-Disubstituted biphenyl, which is difficult to prepare by ordinary symmetrical biaryl syntheses with haloarenes except the Ullmann reaction, was also obtained without the formation of 2,3′-isomer.[6)] Although the Busch reaction has been used when the Ullmann reaction is inefficient for the preparation of biaryl, the Busch reaction of bromonaphthalene[7)] and 2-bromopyridine[8)] has been inefficient. Treatment of bromonaphthalene, or bromopyridine with phenylhydrazine gave the corresponding binaphthyl or bipyridyl accompanying of small amounts of phenylnaphthalene or phenylpyridine, and biphenyl, which were easily removed at the isolation/purification stage, and the yield was higher than the previous one.[7,8)] Bithienyl was also prepared by the present method, but the yield is still somewhat modest. These results were always superior to those obtained under the Busch reaction conditions.

Experimental

Materials. The reagents used were commercial reagent grade materials except those noted below. 4-Bromo-*o*-xylene and 3,4-dimethylphenylhydrazine were prepared from 3,4-dimethylaniline according to the method of Bigelow,[9)] and Coleman,[10)] respectively. The following authentic samples were also prepared in accordance with the method given in the literature; 4-methylbiphenyl,[11)] 2,2′-, 3,3′-, and 4,4′-dimethylbiphenyl,[1)] 1,1′-, and 2,2′-binaphthyl,[12)] 2-phenylnaphthalene,[13)] and 2,2′-bithienyl.[14)]

Reductive Coupling of Halobenzene with Phenylhydrazine.

Pd Catalyst: A mixture of halobenzene (25.0 mmol), $PdCl_2$ (0.50 mmol), phenylhydrazine (10.0 mmol), and NaOH (100 mmol) was stirred in refluxing MeOH (12 ml) for 6 h. The resulting mixture was filtered, and the residual metal was washed with benzene, and subsequently water. The organic layer separated from the aqueous layer was concentrated by rotary evaporation under reduced pressure, and analyzed by GLPC and GC–MS. The products exhibited spectral characteristics in accord with those of known samples.

Pd–Hg Catalyst: The reaction was carried out as described above except that both $PdCl_2$ (0.50 mmol), and $HgCl_2$ (0.50 mmol) were used in place of $PdCl_2$.

Reaction of Haloarene with Arylhydrazine. A mixture of haloarene (12.5 mmol), arylhydrazine (12.5 mmol), and NaOH (125 mmol) was refluxed in 16 ml of MeOH in the presence or absence of the catalyst (0.50 mmol of $PdCl_2$, or 0.50 mmol of $PdCl_2$ and 0.50 mmol of $HgCl_2$) for 9 h with stirring. The resulting mixture was worked up as described above.

Synthesis of Biaryls. The following procedure for the synthesis of 2,2′-dimethylbiphenyl is representative. A mixture of *o*-bromotoluene (25.0 mmol), *o*-tolylhydrazine hydrochloride (15.0 mmol), $PdCl_2$ (0.50 mmol), $HgCl_2$ (0.50 mmol), and NaOH (125 mmol) was refluxed in 16 ml of MeOH for 6 h with stirring. The resulting mixture was treated as above,

and after analysis the concentrated organic layer was distilled *in vacuo* using a ball tube distillation apparatus to give 2,2'-dimethylbiphenyl (12.4 mmol, 99%).

2,2'-Bipyridyl: A mixture of 2-bromopyridine (25.0 mmol), phenylhydrazine (15.0 mmol), $PdCl_2$ (0.50 mmol), $HgCl_2$ (0.50 mmol), NaOH (125 mmol), and MeOH (16 ml) was processed as above. The distillate gave bipyridyl together with a small amount of phenylpyridine and biphenyl. This distillate (or the concentrated organic layer) was steam-distilled from iron(II) solution buffered at pH 4.4 to remove biphenyl and phenylpyridine, and the residue was then steam-distilled from a strongly basic medium to give 2,2'-bipyridyl (5.3 mmol, 42%) as crystals, mp 66.5—68.0 °C.

We wish to thank Messrs. M. Aoyama and T. Ikeda for their assistance in the experimental work. The present work was partially supported by the Asahi Glass Foundation For Industrial Technology.

Studies of Bitter Peptides from Casein Hydrolyzate. II.[1] Syntheses of Bitter Peptide Fragments and Analogs of BPIa (Arg-Gly-Pro-Pro-Phe-Ile-Val) from Casein Hydrolyzate[2]

Ken Otagiri, Ichizo Miyake, Norio Ishibashi, Hiroshi Fukui, Hidenori Kanehisa, and Hideo Okai*

Department of Fermentation Technology, Faculty of Engineering, Hiroshima University, Shitami, Saijo-cho, Higashihiroshima 724

(Received August 23, 1982)

In order to investigate the relationship between bitterness and chemical structure of BPIa, eleven kinds of fragments and analogs of BPIa were synthesized. des-Gly^2-BPIa and des-Pro^4-BPIa exhibited extremely bitter taste. However, the pentapeptide (Arg-Gly-Pro-Pro-Phe) of BPIa possessed weak bitterness. The bitterness exhibition of BPIa probably derived from the spatial structure of its molecule.

In the previous paper[1] and the preliminary reports,[3,4] the authors described the synthesis of the bitter peptide BPIa (Arg-Gly-Pro-Pro-Phe-Ile-Val) which was isolated by Minamiura *et al.*[5] and found that the peptide possesses extremely bitter taste, such as quinine and phenylthiourea. They also reported that the bitter taste exhibited by BPIa was associated with its characteristic conformation. In this paper, we describe the synthesis of eleven kinds of peptides as shown in Table 1 to investigate the participation of constituent amino acid residues of BPIa in producing the strong bitter taste.

Table 1. The threshold value for bitter taste of the synthetic peptides

	Compound	T.V.[b] / mM	Rcaf.[c]
(1)	Arg–Gly–Pro–Pro–Phe–Ile	0.025	40.00
(2)	Arg–Gly–Pro–Pro–Phe	2.30	0.43
(3)	Arg–Gly–Pro	13.00	0.08
(4)	Arg–Gly	10.00	0.10
(5)	Ile–Val	12.50	0.08
(6)	Phe–Ile–Val	1.50	0.67
(7)	Pro–Phe–Ile–Val	0.30	3.33

a) BPIa. b) Threshold value. c) The ratio of caffeine.

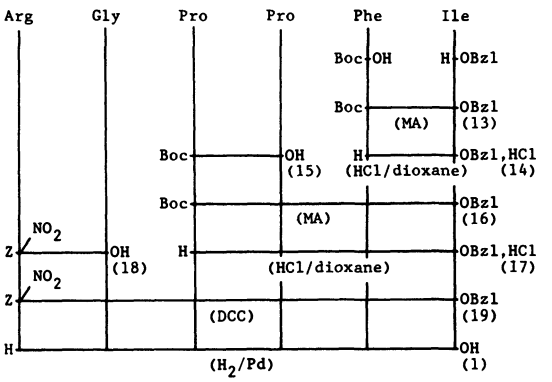

Fig. 1. The synthetic route of Arg–Gly–Pro–Pro–Phe–Ile.

In connection with the syntheses, the BPIa intermediates, as had been reported in the previous paper,[1] were efficiently employed. The synthetic route of the hexapeptide (Arg-Gly-Pro-Pro-Phe-Ile) is shown in Fig. 1. *N*-(*t*-Butoxycarbonyl)phenylalanine was coupled with isoleucine benzyl ester by the mixed anhydride method to yield *N*-(*t*-butoxycarbonyl)phenylalanylisoleucine benzyl ester (**13**). After treatment of the protected dipeptide with hydrogen chloride, the dipeptide benzyl ester hydrochloride (**14**) and *N*-(*t*-butoxycarbonyl)prolylproline (**15**) were coupled by the mixed anhydride method to yield *N*-(*t*-butoxycarbonyl)prolylprolylphenylalanylisoleucine benzyl ester (**16**). The *t*-butoxycarbonyl group was removed from the protected tetrapeptide with hydrogen chloride and the resulting tetrapeptide benzyl ester hydrochloride (**17**) was acylated with N^a-benzyloxycarbonyl-N^G-nitroarginylglycine (**18**) by the dicyclohexylcarbodiimide method to yield N^a-benzyloxycarbonyl-N^G-nitroarginylglycylprolylprolylphenylalanylisoleucine benzyl ester (**19**). The protected hexapeptide was hydrogenated in the presence of palladium black to give the desired hexapeptide (H-Arg-Gly-Pro-Pro-Phe-Ile-OH) (**1**).

The synthetic route to compounds **2**, **3**, and **4**, compounds **6**, **7**, and **11**, and compounds **8**, **9**, and **10** are shown in Fig. 2, 3, and 4 respectively. However, the details of the synthetic route to those peptides is uneventful and is described in the experimental part. The purity of the synthetic peptides and their intermediates was confirmed by thin-layer examinations in two solvent systems and by elemental analyses.

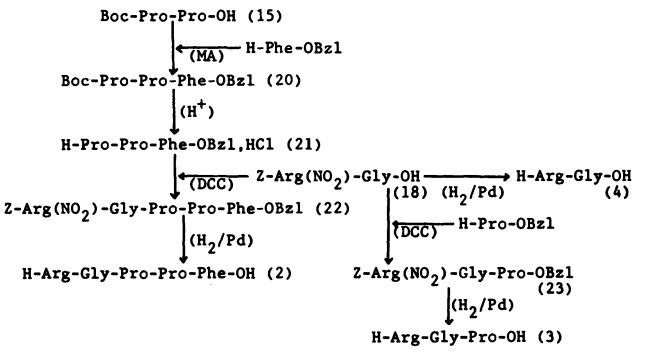

Fig. 2. The synthetic route of compound **2**, **3**, and **4**.

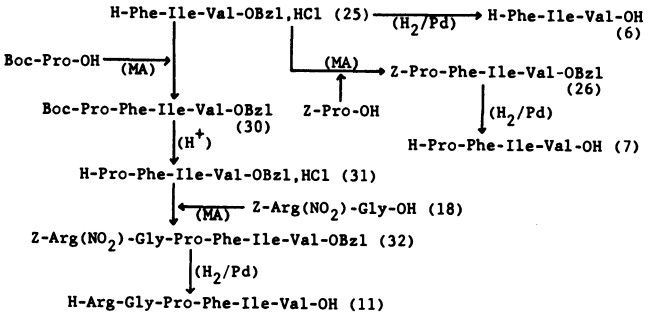

Fig. 3 The synthetic route of compounds **6**, **7**, and **11**.

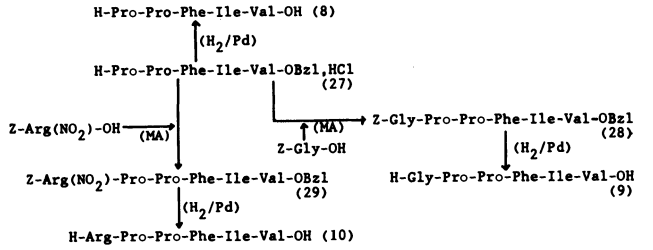

Fig. 4. The synthetic route of compounds **8**, **9**, and **10**.

The bitterness of the synthetic peptides were organoleptically determined by panel evaluation with five people (Table 1). As far as the N-terminal fragments of BPIa, compounds **2**—**4** exibited a weak bitter taste, but the hexapeptide (**1**) exhibited a strong bitter taste of the same level as BPIa. On the other hand, the C-terminal fragments of BPIa **5**—**9** that lack the arginine residue also exhibited a slightly bitter taste. These findings indicated that the L-arginine residue in the N-terminal and at least two hydrophobic amino acid residues in the C-terminal group are necessary for an intense bitter taste exhibition.

In order to confirm the participation of the strong bitter taste exhibition from the glycine residue at the 2-position and the L-proline residue at the 3-position, the bitterness of des-Gly^2-BPIa (**10**) and des-Pro^4-BPIa (**11**) were compared with that of BPIa. Both of these peptides exhibited a strong bitter taste of the same level as BPIa (Table 1). The results indicated that the glycine residue at the 2-position in BPIa is not always necessary, but the L-proline residue at the 3-position is necessary for an intense bitter taste exhibition.

Then, the authors measured circular dichroism (CD) and optical rotatory dispersion (ORD) of the synthetic peptides above mentioned. The CD curves of compounds **1** and **11** afforded a similar shape of BPIa, but those of compound **2** afforded a different shape from that of BPIa as shown in Fig. 5. The ORD curve of compound **10** afforded a similar shape to that of BPIa.[3)]

From the results described above, the strong bitter taste exhibition of BPIa is caused by its characteristic conformation. Furthermore, in this report, we will propose the following requirements for the strong bitter taste exhibition of BPIa; (a) at least six amino acid residues are necessary, (b) the proline residue at the 3-position must have the L-configuration and (c) the number of hydrophobic amino acid residues in the C-terminal is not important.

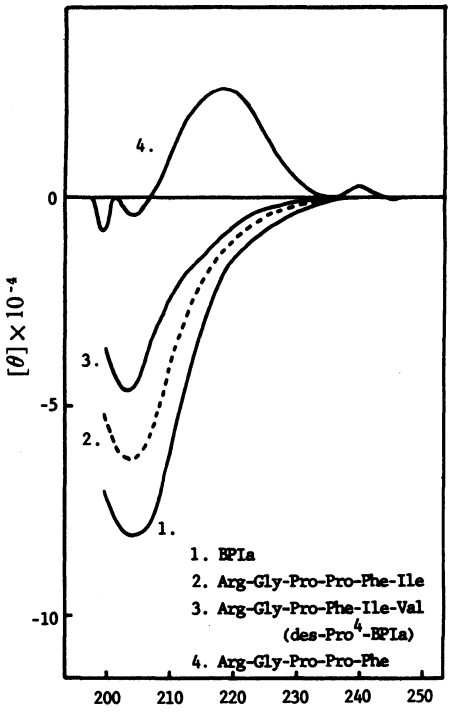

Fig. 5. CD curves of synthetic peptides in water.

Experimental

All the melting points are uncorrected. Thin-layer chromatography was carried out with Merck silica gel 60G. Developing solvents commonly used were (1) 1-butanol–acetic acid–pyridine–water (4 : 1 : 1 : 2, v/v) and (2) chloroform–methanol (5 : 1, v/v). Materials possessing a free amino group on a thin-layer plate were detected by spraying with ninhydrin. Compounds with blocked amino groups were detected by spraying with 25% hydrogen bromide in acetic acid and then with ninhydrin. The optical rotations were measured on an Union PM-101 polarimeter.

Boc–Phe–Ile–OBzl (13). To a solution of Boc–Phe–OH·DCHA[6)] (9.83 g, 22 mmol) in THF (20 ml), ECF (2.0 ml, 20 mmol) and NMM (2.2 ml, 20 mmol) were added at −5 °C. After 10 min, a solution of H–Ile–OBzl·TsOH[7)] (7.87 g, 20 mmol) and NMM(2.2 ml, 20 mmol) in chloroform (20 ml) was added. The reaction mixture was stirred in an ice bath for an hour, then at room temperature overnight. The mixture was evaporated *in vacuo*, and the oily residue was dissolved in ethyl acetate. The solution was washed with water, 4% citric acid, 4% sodium hydrogencarbonate, and water successively, then dried over anhydrous sodium sulfate. Sodium sulfate was removed by filtration, and the filtrate was evaporated *in vacuo*. The oily residue was crystallized with ether–petroleum ether: yield 9.04 g (96%); mp 87—88 °C $[\alpha]_D^{20}$ −18° (*c* 1, MeOH); R_f^1 0.99 and R_f^2 0.54. Found: C, 69.35; H, 7.69; N, 6.01%. Calcd for $C_{27}H_{36}O_5N_2$: C, 69.20; H, 7.74; N, 5.98%.

H–Phe–Ile–OBzl·HCl (14). To a solution of **13** (2.34 g, 5 mmol) in dioxane (10 ml), 4 M HCl(1 M=1 mol dm^{-3})/dioxane (20 ml) was added. The reaction mixture was allowed to stand at room temperature. After 2 h, the solution was evaporated *in vacuo*. The compound was obtained as an oily form: yield 1.86 g (92%); R_f^1 0.81 and R_f^2 0.68.

Boc–Pro–Pro–Phe–Ile–OBzl (16). Boc–Pro–Pro–OH[1)] (**15**) (1.56 g, 5 mmol) and **14** (1.86 g, 4.8 mmol) were coupled

by the same method as has been described for the preparation of **13** This compound was obtained as an oily form: yield 2.89 g (92%); R_f^1 0.97 and R_f^2 0.67.

H-Pro-Pro-Phe-Ile-OBzl·HCl (17). Compound **16** (2.89 g, 4.5 mmol) was treated as has been described in the case of **14**. This compound was obtained as an oily form: yield 2.50 g (88%); R_f^1 0.81 and R_f^2 0.59.

Z-Arg(NO$_2$)-Gly-Pro-Pro-Phe-Ile-OBzl (19). To a solution of Z-Arg(NO$_2$)-Gly-OH[1] (1.64 g, 4 mmol) in DMF (20 ml), DCC (0.81 g, 4 mmol) was added at 0 °C. After 10 min, to the mixture, a solution of **17** (2.50 g, 4 mmol) and NMM (0.44 ml, 4 mmol) in chloroform (20 ml) was added. The mixture was cooled at 0 °C for an hour and allowed to stand overnight at room temperature. The DCUrea was removed by filtration, and the filtrate was evaporated *in vacuo*. The oily residue was dissolved in ethyl acetate and the solution was washed with water, 2% hydrochloric acid, 4% sodium hydrogencarbonate, and water successively. The solution was dried over anhydrous sodium sulfate. Sodium sulfate was removed by filtration, and the filtrate was evaporated *in vacuo*. The residue was crystallized with ether-petroleum ether: yield 2.71 g (74%); mp 111—112 °C; $[\alpha]_D^{20}$ −87° (*c* 1, MeOH); R_f^1 0.91 and R_f^2 0.54. Found: C, 60.51; H, 6.53; N, 14.72%. Calcd for $C_{48}H_{62}O_{11}N_{10}$: C, 60.36; H, 6.56; N, 14.67%.

H-Arg-Gly-Pro-Pro-Phe-Ile-OH (1). A solution of **19** (1.24 g, 1.3 mmol) in methanol (2 ml) and acetic acid (2 ml) was hydrogenated in the presence of palladium black at room temperature for 72 h. The catalyst was removed by filtration, the filtrate was evaporated *in vauco*. The residue was crystallized with acetone: yield 0.72 g (74%) hygroscopic form; R_f^1 0.68 and R_f^2 0.00.

Boc-Pro-Pro-Phe-OBzl (20). Compound **15** (3.12 g, 10 mmol) and H-Phe-OBzl·TsOH[7] (4.28 g, 10 mmol) were coupled by the same method as has been described for the preparation of **13**: yield 5.22 g (95%) oily form; R_f^1 0.98 and R_f^2 0.78.

H-Pro-Pro-Phe-OBzl·HCl (21). Compound **20** (5.22 g, 9.5 mmol) was treated as has been described in the case of **14**: yield 4.25 g (92%); mp 84—86 °C; $[\alpha]_D^{20}$ −115.5° (*c* 1, H_2O); Found: C, 56.35; H, 6.01; N, 16.53%. Calcd for $C_{28}H_{35}O_8N_7$: C, 56.26; H, 5.91; N, 16.41%.

H-Arg-Gly-Pro-OH·HCl (3). Compound **23** (1.50 g, 2.50 mmol) was treated as has been described in the case of **1**: yield 0.43 g (66%) hygroscopic form; R_f^1 0.12.

H-Arg-Gly-OH·2AcOH (4). Z-Arg(NO$_2$)-Gly-OH (**19**) (1.00 g, 2 mmol) was treated as has been described in the case of **1**: yield 0.43 g (76%); $[\alpha]_D^{20}$ +36.7° (*c* 2, H_2O); R_f^1 0.21. Found: C, 42.35; H, 4.50; N, 20.36%. Calcd for $C_{16}H_{11}O_5N_5\cdot 2CH_3COOH$: C, 42.22; H, 4.44; N, 20.52%.

Z-Ile-Val-OH (24). To a solution of Z-Ile-OSu (3.60 g, 10 mmol) in dioxane (10 ml), a solution of H-Val-OH (1.32 g, 11 mmol), Et_3N (2.0 ml, 11 mmol) in water (15 ml) was added at room temperature. After 20 h, the mixture was evaporated *in vacuo*. The oily residue was dissolved in 8% sodium hydrogencarbonate and the solution washed with ether. The aqueous layer was acidified with 10% citric acid. The oily residue was extracted with ethyl acetate. The solution was dried over anhydrous sodium sulfate. Sodium sulfate was removed by filtration, and the filtrate was evaporated *in vacuo*. The oily residue was crystallized with ether: yield 2.86 g (81%); mp 133—134 °C; $[\alpha]_D^{20}$ +7.0° (*c* 1, DMF); R_f^1 0.87. Found: C, 62.36; H, 7.77; N, 7.62%. Calcd for $C_{19}H_{28}O_5N_2$: C, 62.62; H, 7.74; N, 7.69%.

H-Ile-Val-OH (5). Compound **24** (1.77 g, 5 mmol) was treated as has been described in the case of **1**: yield 1.02 g (89%); $[\alpha]_D^{20}$ +12.5° (*c* 1, H_2O); R_f^1 0.81. Found: C, 57.06; H, 9.76; N, 12.08%. Calcd for $C_{11}H_{22}O_3N_2$: C, 57.36; H, 9.63; N, 12.17%.

H-Phe-Ile-Val-OH (6). H-Phe-Ile-Val-OBzl·HCl[1] (**25**) (1.51 g, 3 mmol) was treated as has been described in the case of **1**; yield 0.91 g (80%); $[\alpha]_D^{20}$ +10.5° (*c* 0.5, H_2O); R_f^1 0.77. Found: C, 61.39; H, 8.19; N, 10.74%. Calcd for $C_{20}H_{31}O_4N_3\cdot 2/3\ H_2O$: C, 61.67; H, 8.37; N, 10.79%.

Z-Pro-Phe-Ile-Val-OBzl (26). Z-Pro-OH[10-12] (0.59 g, 2 mmol) and **25** (1.01 g, 2 mmol) were coupled by the same method as has been described for the preparation of **13**: yield 1.15 g (85%); mp 196 °C; $[\alpha]_D^{20}$ −57.1° (*c* 1, $CHCl_3$); R_f^1 0.99. Found: C, 67.97; H, 7.32; N, 7.98%. Calcd for $C_{40}H_{50}O_7N_4\cdot 1/2\ H_2O$: C, 67.87; H, 7.12; N, 7.92%.

H-Pro-Phe-Ile-Val-OH (7). Compound **26** (0.91 g, 1.3 mmol) was treated as has been described in the case of **1**: yield 0.54 g (88%); $[\alpha]_D^{20}$ −51.7° (*c* 0.5, H_2O); R_f^1 0.70. Found: C, 57.41; H, 7.84; N, 10.48%. Calcd for $C_{25}H_{38}O_5N_4\cdot 1/2\ CH_3COOH\cdot 2H_2O$: C, 57.76; H, 8.20; N, 10.36%.

H-Pro-Pro-Phe-Ile-Val-OH (8). H-Pro-Pro-Phe-Ile-Val-OBzl·HCl[1] (0.69 g, 1 mmol) was treated as has been described in the case of **1**: yield 0.47 g (82%); mp 182 °C; $[\alpha]_D^{20}$ −122.0° (*c* 0.7, H_2O); R_f^1 0.61. Found: C, 60.54; H, 7.90; N, 11.14%. Calcd for $C_{30}H_{45}O_6N_5\cdot CH_3COOH$: C, 60.82; H, 7.83; N, 11.09%.

Z-Gly-Pro-Pro-Phe-Ile-Val-OBzl (28). Z-Gly-OH[13-15] (0.32 g, 1.5 mmol) and H-Pro-Pro-Phe-Ile-Val-OBzl·HCl (**27**) (0.90 g, 1.3 mmol) were coupled by the same method as has been described for the preparation of **13**: yield 1.02 g (93%); mp 78—82 °C; $[\alpha]_D^{20}$ −54.0° (*c* 1, DMF); R_f^1 0.93 and R_f^2 0.66. Found: C, 65.55: H, 7.13: N, 9.62%. Calcd for $C_{47}H_{60}O_9N_6\cdot 1/2H_2O$: C, 65.80; H, 7.17; N, 9.80%.

H-Gly-Pro-Pro-Phe-Ile-Val-OH (9). Compound **28** (0.80 g, 0.94 mmol) was treated as has been described in the case of **1**: yield 0.46 g (77%): $[\alpha]_D^{20}$ −133.5° (*c* 1, H_2O); R_f^1 0.75. Found: C, 57.53; H, 7.68; N, 12.31%. Calcd for $C_{32}H_{48}O_7N_6\cdot 2H_2O$: C, 57.81; H, 7.88; N, 12.64%.

Z-Arg(NO$_2$)-Pro-Pro-Phe-Ile-Val-OBzl (29). Z-Arg(NO$_2$)-OH[16,17] (0.54 g, 1.5 mmol) and **27** (1.04 g, 1.5 mmol) were coupled by the same method as has been described for the preparation of **13**: yield 1.06 g (73%); mp 104—107 °C; $[\alpha]_D^{20}$ −60.2° (*c* 0.6, EtOH); R_f^1 0.96. Found: C, 61.00; H, 6.89; N, 13.44%. Calcd for $C_{50}H_{68}O_{10}N_{10}\cdot H_2O$: C, 60.83; H, 7.15; N, 13.19%.

H-Arg-Pro-Pro-Phe-Ile-Val-OH·2AcOH (10). Compound **29** (0.76 g, 0.8 mmol) was treated as has been described in the case of **1**: yield 0.60 g (95%); mp 139—141 °C; $[\alpha]_D^{20}$ −114.0° (*c* 1, H_2O); R_f^1 0.66. Found: C, 54.34; H, 7.48; N, 14.43%. Calcd for $C_{36}H_{57}O_7N_9\cdot 2CH_3COOH\cdot 2H_2O$: C, 54.34; H, 7.87; N, 14.25%.

Boc-Pro-Phe-Ile-Val-OBzl (30). Boc-Pro-OH[19,20] (2.15 g, 10 mmol) and **25** (5.04 g, 10 mmol) were coupled by the same method as has been described for the preparation of **13**: yield 6.06 g (91%); mp 111—112 °C; $[\alpha]_D^{20}$ −83° (*c* 1, MeOH); R_f^1 0.98 and R_f^2 0.88. Found: C, 67.01; H, 7.92; N, 8.39%. Calcd for $C_{37}H_{52}O_7N_4$: C, 66.84; H, 7.88; N, 8.43%.

H-Pro-Phe-Ile-Val-OBzl·HCl (31). Compound **30** (1.99 g, 3 mmol) was treated as has been described in the case of **14**: yield 1.71 g (95%); mp 90 °C (decomp); $[\alpha]_D^{20}$ −66° (*c* 1, MeOH); R_f^1 0.88 and R_f^2 0.61. Found: C, 63.99; H, 7.29; N, 9.36%. Calcd for $C_{32}H_{44}O_5N_4\cdot HCl$: C, 63.93; H, 7.38; N, 9.32%.

Z-Arg(NO$_2$)-Gly-Pro-Phe-Ile-Val-OBzl (32). Z-Arg-(NO$_2$)-Gly-OH (**21**) (0.41 g, 1 mmol) and **31** (0.60 g, 1 mmol) were coupled by the same method as has been described for the preparation of **13**: yield 0.72 g (75%); mp 175—180 °C; $[\alpha]_D^{20}$ −24° (*c* 1, DMF); R_f^1 0.88 and R_f^2 0.74. Found: C,

60.12; H, 6.74; N, 14.52%. Calcd for $C_{48}H_{64}O_{11}N_{10}$: C, 60.23; H, 6.74; N, 14.64%.

H–Arg–Gly–Pro–Phe–Ile–Val–OH (11). Compound **32** (0.50 g, 0.52 mmol) was treated as has been described in the case of 1: yield 0.27 g (69%); $[\alpha]_D^{20}$ −114° (*c* 1, H_2O); R_f^1 0.74 and R_f^2 0.00. Found: C, 55.21; H, 7.95; N, 16.81%. Calcd for $C_{33}H_{53}O_7N_9 \cdot CH_3COOH \cdot 1/2\ H_2O$: C, 55.53; H, 7.72; N, 16.66%.

We would like to acknowledge helpful discussion with Professor Sakuzo Fukui of Hiroshima University. We also wish to thank Associate Professor Michio Kondo of Saga University for the CD measurement and Dr. Shinji Okumura of Ajinomoto Co. Inc., for supplying some amino acids.

Sesquiterpenoid Constituents of the Liverwort *Frullania brotheri* STEPH.

Reiji TAKEDA,* Yoshimoto OHTA, and Yoshio Hirose
Suntory Institute for Bioorganic Research, Wakayama-dai, Shimamoto-cho, Mishima-gun, Osaka 618
(Received August 26, 1982)

Two new sesquiterpene lactones, (+)-β-frullanolide and (+)-brothenolide, have been isolated from the liverwort *Frullania brotheri* STEPH. One of them, (+)-brothenolide, has an allergenic property. The absolute structures of these lactones have been established by spectroscopic analysis and chemical transformation.

It is well-known that a number of sesquiterpene lactones have been isolated from the liverwort belonging to Frullaniacea and that some of them have an allergenic property.[1] In the course of our investigation on terpene constituents of the liverwort, we examined the constituents of *Frullania brotheri* STEPH. collected in Wakayama Prefecture around Mt. Ohto in June 1976 and isolated two new sesquiterpene lactones, (+)-β-frullanolide (**1**) and (+)-brothenolide (**2**), one of which, **2**, had an allergenic property. This paper deals in detail with the structural determination of (+)-β-frullanolide and (+)-brothenolide.[2]

Column chromatographic separation on SiO_2 and $AgNO_3$-SiO_2 of the ether extract of the fresh material gave lactones **1** and **2**. (+)-β-Frullanolide (**1**), mp 165—167 °C, $[\alpha]_D$ +178°, was obtained as colorless needles. The molecular formula $C_{15}H_{20}O_2$ of **1** was determined by the appearence of a molecular ion peak at 232.1453 in the high resolution mass spectrum (HR-MS). The IR spectrum ($CHCl_3$) showed an α,β-unsaturated γ-lactone absorption bands at 1760 and 1670 cm^{-1} and an exocyclic methylene absorption band at 910 cm^{-1}. The ^1H NMR spectrum ($CDCl_3$) indicated the presence of one tertiary methyl group (δ 0.92), four exocyclic methylene protons (δ 4.92, 5.09, 5.52, and 6.07) and one methine proton (δ 4.58) adjacent to oxygen. In the decoupling experiments of **1**, irradiation at δ 5.09 (14-H_B) collapsed the proton of 5-H at δ 2.01 and the allylic methylene protons (3-$H_{A,B}$) at δ 2.1—2.5 to sharp peaks, respectively. Also irradiation of 6-H at δ 4.56 collapsed a doublet of 5-H to a singlet and collapsed a multiplet of 7-H to sharp peaks. Furthermore, irradiation at δ 2.88 (7-H) converted a pair of doublets at δ 5.52 and 6.07 due to exocyclic methylene protons (13-$H_{A,B}$) into a pair of singlets and doublet of doublets at δ 4.58 (6-H) into a doublet. These results indicated that β-frullanolide (**1**) had the partial structure **1a**. When the ^1H NMR spectrum of **1** was compared with those of eudesmanolides,[3] it was similar to them. From these results, we assumed that lactone **1** had an eudesmanolide skeleton, as shown by structure **1**. This assumption was confirmed by a partial synthesis from costunolide (**3**)[4] according to the following pathway (Chart 1).

Costunolide (**3**), isolated from costus root oil, was cyclized with thionyl chloride to give the cyclocostunolide mixture[5] from which β-cyclocostunolide **4** was separated by column chromatography on 10% $AgNO_3$-SiO_2. This compound was identified as β-cyclocostunolide **4** with authentic spectra.[5] Next, this compound was converted to **5** by ethanolysis with Na_2CO_3 in ethanol. The IR spectrum showed hydroxyl and ester

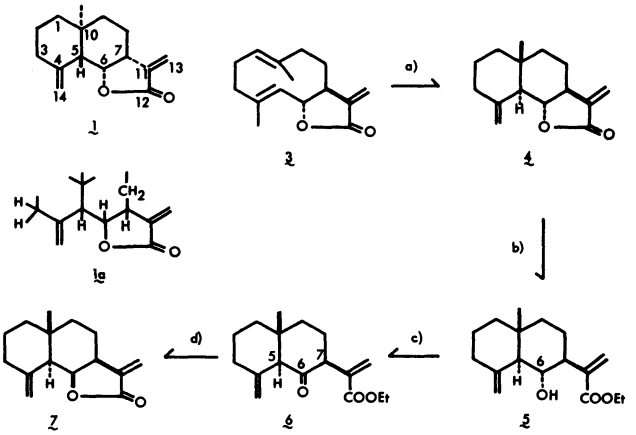

Chart 1. $SOCl_2$/pyridine, b) Na_2CO_3/EtOH, c) Jones reagent, d) $NaBH_4$/MeOH.

absorption bands at 3460 and 1715 cm^{-1}. In the ^1H NMR spectrum, the signals due to an ethyl group as the ester function at δ 1.30 and 4.23 were observed. The alcohol thus obtained was oxidized with Jones reagent to give keto ester **6**. The IR spectrum showed bands at 1718 cm^{-1} due to carbonyl groups and at 910 cm^{-1} due to an exocyclic methylene. In the ^1H NMR spectrum of **6**, the signals of 5-H and 7-H were observed at lower field (5-H: δ 3.08, s; 7-H: 3.67, t, J=10.0 Hz) than those of **5** (5-H: δ 1.90, d, J=11.0 Hz; 7-H: 2.60, dt, J=6.0 and 11.0 Hz). These results and the absence of a hydroxyl absorption in the IR and the signal of 6-H in the ^1H NMR of **6** indicated that hydroxyl group at C-6 was oxidized to keto group. Reduction of keto ester **6** with $NaBH_4$ in methanol gave a *cis* lactone **7**: $[\alpha]_D$ −161.8°.

Compound **7** was identified in every respect with (+)-β-frullanolide except for chiroptical property, CD (MeOH) $\Delta\varepsilon_{254}$+1.5 for **7** *vs.* $\Delta\varepsilon_{254}$−1.5 for **1** (Fig. 1). (+)-β-Frullanolide is fully represented by structure **1**.

(+)-Brothenolide (**2**), mp 113—114 °C, $[\alpha]_D$ +153.0°, CD (MeOH) $\Delta\varepsilon_{255}$−1.6, was obtained as colorless needles. The molecular formula $C_{15}H_{20}O_2$ of **2** was determined by HR-MS together with the ^{13}C and ^1H NMR data. The IR spectrum ($CHCl_3$) showed bands at 3040 cm^{-1} due to a cyclopropane ring, and at 1760 and 1660 cm^{-1} due to an α,β-unsaturated γ-lactone. The ^1H NMR spectrum ($CDCl_3$) showed the signals of two tertiary methyl groups (δ 1.11, s and 1.36, s), one proton on the cyclopropane ring (δ 0.38, t, J=3.6 Hz), two olefinic protons (δ 5.52, d, J=0.6 and 6.09, d, J=0.6 Hz), one allylic methine (δ 2.72, m) and one methine proton (δ 4.76, dd, J=3.0 and 4.8 Hz) adjacent to oxygen. The ^{13}C NMR spectrum ($CDCl_3$)

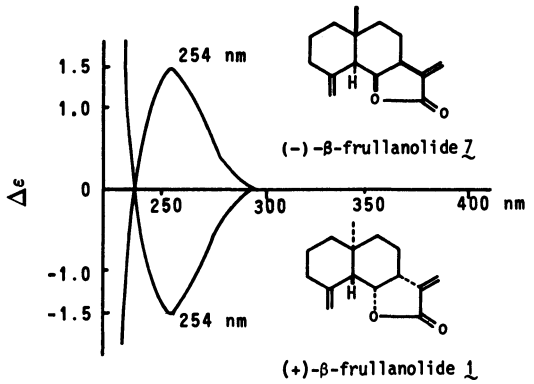

Fig. 1. CD spectra of (+)- and (−)-β-frullanolide.

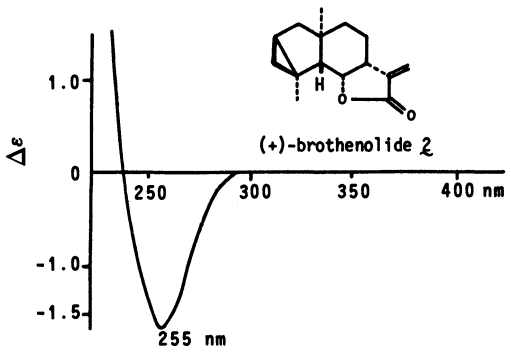

Fig. 2. CD spectrum of (+)-brothenolide.

also indicated the signals of α,β-unsaturated γ-lactone: C=O, δ 171.3; C-, 141.8; $=CH_2$, 119.5 and -O-CH, 77.8.

Hydrogenation of **2** with Pd/C in EtOH yielded a dihydro compound **8** (*m/z* 234). The ^1H NMR spectrum indicated the signal of a secondary methyl group at δ 1.06 instead of the protons of the exocyclic methylene in the spectrum of **2**. This compound was further reduced[6] with PtO_2 in EtOH-AcOH to give a tetrahydro compound **9** (*m/z* 236, $C_{15}H_{24}O_2$). The IR spectrum indicated the absence of a cyclopropane ring absorption and the presence of *gem*-dimethyl absorption bands at 1380 and 1370 cm^{-1}. In the ^1H NMR spectrum, a signal of a tertiary methyl group was observed in place of the protons on the cyclopropane ring. This fact showed that one of the two methyl groups in **2** should be attached to the cyclopropane ring. The presence of the partial structure **2a** was indicated by the above result, and the results of double irradiation experiments in the ^1H NMR spectrum of **2** with the aid of shift reagent. The signal of the proton at 7-H appeared as a multiplet which collapsed to a broad doublet of doublets (J=7.0 and 10.2 Hz) on irradiation of 6-H. In addition, irradiation of the signal of 6-H converted the doublet of 5-H into a singlet. The fact that 7-H is coupled to the 8α- and 8β-H's with J=7.0 and 10.2 Hz indicated that it is axial. Thus the $J_{6,7}$ value of 4.8 Hz shows that 6-H is equatorial. Therefore, the γ-lactone ring must be *cis*-fused at C-6 and C-7. The reduction of **9** with LAH afforded a diol **10**, the IR spectrum of which showed the presence of hydroxyl groups at 3500 and 3430 cm^{-1}. The ^1H NMR spectrum showed the signals of methylene protons adjacent to oxygen as primary alcohol at δ 3.44 and 3.56. The diol **10** was acetylated with acetic anhydride and pyridine at room temperature to give monoacetate **11**, the IR spectrum of which showed bands at 3510 and 1720 cm^{-1} due to the hydroxyl group and the carbonyl group, respectively. The ^1H NMR spectrum showed also the signals of the acetoxymethyl group at δ 2.06 and the $-C\underline{H}_2-OAc$ group at δ 3.94 and 4.24. The monoacetate **11** was oxidized with Jones reagent to yield a corresponding keto compound **12**. The IR spectrum indicated the presence of a 6-membered ring ketone at 1715 cm^{-1}. Furthermore, in the decoupling experiments of **2** using 360 MHz NMR, irradiation of 1-H_A at δ 0.83 collapsed the doublet of doublets of 1-H_B (δ 1.77) to a doublet, and a multiplet of 2-H (δ 1.22) to a sharp peak. In addition, irradiation of 3-H_A (δ 0.38) collapsed the doublet of doublets of 3-H_B (δ 0.93) to a doublet, and 2-H (δ 1.22) to sharp peak. This result indicated that brothenolide (**2**) had a partial structure **2b**. All these data show that the new sesquiterpene lactone **2** is most favorably represented by formula **2**. The fact that the CD Cotton effects of lactones **1** and **2** have the same signs (Figs. 1 and 2) shows that they belong to the same chiroptical series.[7]

Table 1. Chemical shift of the methyl groups (in δ)

	4-CH_3	4-CH_2D	10-CH_3
11-d_2	1.20	1.17	1.03
12-d_2	1.34	1.07	0.91

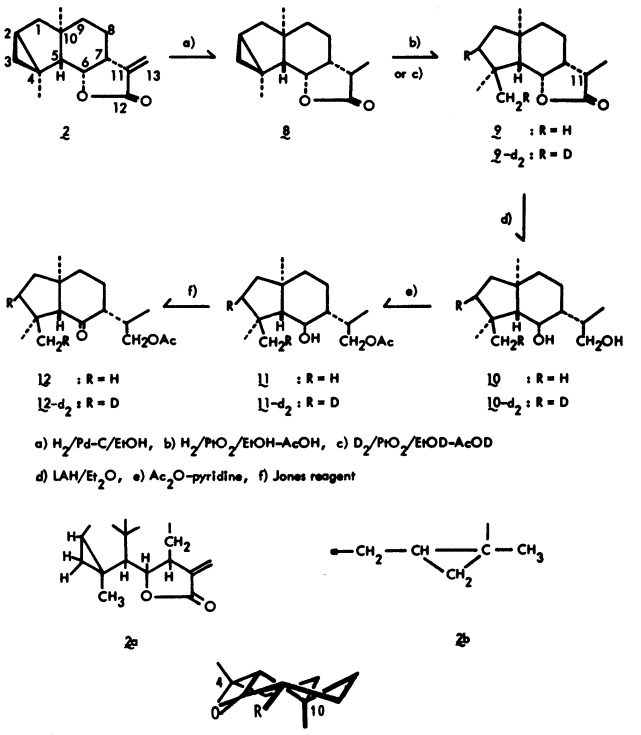

Chart 2.

The β-configuration of the cyclopropane ring was determined as follows. Reduction of dihydrobrothenolide **8** with deuterium instead of hydrogen (see above) in EtOD-AcOD, followed by LAH treatment and acetylation gave **11**-d_2 (the dideuterio derivative of **11**).

The ^1H NMR spectrum of **11** showed three tertiary methyl signals at δ 1.17, 1.20, and 1.03, one of which, at δ 1.17, appeared as a CH_2D signal in **11**-d_2. Oxidation of **11**-d_2 with Jones reagent gave **12**-d_2, the ^1H NMR spectrum of which showed the signals of two tertiary methyl groups at δ 1.34 and 0.91, and a tertiary CH_2D group at δ 1.07. The chemical shifts of CH_3 and CH_2D groups of **11**-d_2 and **12**-d_2 are shown in Table 1. One methyl peak at δ 1.20 in **11**-d_2 underwent a low field shift to δ 1.34 in **12**-d_2 whereas the other methyl peaks at δ 1.17 and 1.03 in **11**-d_2 shifted to δ 1.07 and 0.91 in **12**-d_2. These shifts of methyl peaks were explained by the difference of anisotropic effects between 6α-OH and 6-keto function. The methyl signals at δ 1.17, 1.20, and 1.03 in **11**-d_2 were therefore assigned to 4β-Me, 4α-Me, and 10-Me groups, respectively.

Molecular model **12a** clearly shows that 4-Me group (δ 1.34) should have the α-configuration since it is in-plane in relation to the carbonyl group. The CH_2D group in **11**-d_2 is thus β-oriented, and therefore, the cyclopropane methylene group is also β-oriented in brothenolide (**2**).

Experimental

All melting points are uncorrected. IR spectra were measured with a Hitachi EPI-G2 spectrometer, ^{13}C NMR spectra with a JEOL FX-100 (25.0 Hz) spectrometer, ^1H NMR spectra with a JEOL FX-100 (100 MHz), a Nicolet NT-360 (360 MHz), or a Hitachi R-20B (60 MHz) spectrometer in deuteriochloroform solution containing tetramethylsilane as an internal standard, low resolution mass spectra with a Hitachi RMU-6 mass spectrometer and high resolution mass spectra with a JEOL-JMS 01SG-2, with direct inlet system operating at 70 eV. CD spectra were measured with a JASCO J-20 spectrometer. For column chromatography Kieselgel 60 (E. Merck, Darmstadt) was used. Thin-layer chromatography (TLC) was carried out on Kieselgel GF_{254} (E. Merck, Darmstadt) in 0.25 mm thickness.

Isolation. The fresh material (100 g) of *Frullania brotheri* Steph. collected in Wakayama Prefecture around Mt. Ohto in June 1976 was extracted with ether at room temperature. The ether extract (1.8 g) was chromatographed on SiO_2. Elution with $CHCl_3$ gave a lactone mixture that was subjected to further column chromatography on SiO_2 impregnated with 10% $AgNO_3$. Elution with hexane–Et_2O (20 : 1) yield a fraction of (+)-brothenolide. Next, elution with ether gave crude (+)-β-frullanolide.

(+)-β-Frullanolide (1). The crude material was recrystallized from hexane–EtOAc to yield colorless needles (**1**, 40 mg), mp 165—167 °C, $[\alpha]_D$ +178.0° (*c* 1.17, $CHCl_3$); CD, $\Delta\varepsilon_{254}$ −1.5 (*c* 0.012, MeOH); IR ($CHCl_3$) 1760, 1670, and 910 cm^{-1}; ^1H NMR δ 0.92 (3H, s, 10-CH_3), 4.58(1H, dd, J=4.5 and 3.0 Hz, 6-H), 4.92 (1H, br. s, 14-H_A), 5.09 (1H, br. s, 14-H_B), 5.52 (1H, d, J=0.6 Hz, 13-H_A), and 6.07 (1H, d, J=0.6 Hz, 13-H_B); ^{13}C NMR δ 18.3 (q), 23.0 (t), 24.6 (t), 34.7 (t), 37.5 (t), 38.8 (t), 41.4 (d), 43.0 (t), 50.9 (d), 77.8 (d), 109.7 (t), 119.0 (t), 141.7 (s), 145.7 (s) and 170.8 (s); MS *m/z* (%) 232 (93, M^+), 217 [100, $(M-CH_3)^+$], 176 (35), 171 (34), 91 (46), and 79 (37). Found: *m/z* 232.1453. Calcd for $C_{15}H_{20}O_2$: M, 232.1445.

Isolation of (+)-Brothenolide (2). The crude fraction was recrystallized from hexane–EtOAc to give colorless needles (**2**, 270 mg), mp 113—114 °C, $[\alpha]_D$ +153.0° (*c* 1.14, $CHCl_3$); CD, $\Delta\varepsilon_{255}$ −1.6 (*c* 0.012, MeOH); IR ($CHCl_3$) 3040, 1760, 1660 cm^{-1}; ^1H NMR (360 MHz) δ 0.38 (1H, t, J=3.6 Hz, 3-H_A), 0.83 (1H, br. dd, J=3.6 and 12.5 Hz, 1-H_A), 0.93 (1H, dd, J=3.6 and 8.7 Hz, 3-H_B), 1.06 (1H, d, J=3.0 Hz, 5-H), 1.11 (3H, s, 10-CH_3), 1.22 (1H, m, 2-H), 1.22 (1H, m, 9-H_B), 1.36 (3H, s, 4-CH_3), 1.47 (1H, m, 8-H_A), 1.60 (1H, ddd, J= 3.0, 4.2, and 12.6 Hz, 9-H_B), 1.72 (1H, dd, J=7.5 and 12.5 Hz, 1-H_B), 2.72 (1H, m, 7-H), 4.76 (1H, dd, J=3.0 and 4.8 Hz, 6-H), 5.52 (1H, d, J=0.6 Hz, 13-H_A), and 6.09 (1H, d, J=0.6 Hz, 13-H_B); ^{13}C NMR δ 20.4 (q), 20.9 (q), 25.5 (t), 25.9 (d), 26.6 (s), 34.1 (t), 35.7 (t), 40.5 (d), 46.3 (t), 50.4 (s), 56.5 (d), 77.8 (d), 119.5 (t), 141.8 (s), and 171.3 (s); MS *m/z* (%) 232 (8, M^+), 217 [100, $(M-CH_3)^+$], 199 (39), 171 (44), 145 (31), 119 (45), 91 (41), and 79 (28). Found: *m/z* 232.1472. Calcd for $C_{15}H_{20}O_2$: M, 232.1445.

Isolation of Costunolide (3). Costus root oil (3 g) was chromatographed on SiO_2, and eluted with $CHCl_3$ to give costunolide (**3**, 270 mg), colorless needles, mp 104—105 °C (recrystallized from hexane), $[\alpha]_D$ +127.0° (*c* 1.05, $CHCl_3$). The IR, NMR, and mass spectra, and $[\alpha]_D$ value of **3** were found to be identical with those of known (+)-costunolide.[4]

Cyclization of Costunolide (3). A solution of costunolide (270 mg) in $CHCl_3$ (50 ml) containing $SOCl_2$ (0.1 ml) was kept at room temperature for 1 h. After removal of solvent under vacuum, the resulting residue was chromatographed on 10% $AgNO_3$–SiO_2. Elution with hexane–EtOAc (5 : 1) gave β-cyclocostunolide (160 mg), colorless needles, mp 67—68 °C (recrystallized from EtOH), $[\alpha]_D$ +175.3° (*c* 0.93, $CHCl_3$). The IR, NMR, and mass spectra, and $[\alpha]_D$ value were identical with those of known (+)-β-cyclocostunolide.[5]

Ethanolysis of β-Cyclocostunolide (4). 0.05 M (1 M=1 mol dm^{-3}) Na_2CO_3 aqueous solution (0.2 ml) was added to a solution of β-cyclocostunolide (150 mg) in EtOH (10 ml), and the mixture was kept at room temperature for 2 d. The reaction mixture was diluted with H_2O, evaporated to remove EtOH under reduced pressure and extracted with ether. Ether layer was washed with H_2O and dried over Na_2SO_4. After removal of solvent under reduced pressure, the resulting residue was chromatographed on SiO_2. Elution with $CHCl_3$ gave hydroxy ester **6**, colorless needles, mp 95—96 °C (recrystallized from hexane), $[\alpha]_D^{20}$ +25.2° (*c* 0.92, $CHCl_3$); IR ($CHCl_3$) 3460 and 1715 cm^{-1}; ^1H NMR δ 0.83 (3H, s, 10-CH_3), 1.30 (3H, t, J=8.0 Hz, $OCH_2C\underline{H}_3$), 1.90 (1H, d, J=11.0 Hz, 5-H), 2.60 (1H, dt, J=6.0 and 11.0 Hz, 7-H), 3.92 (1H, t, J= 11.0 Hz, 6-H), 4.23 (2H, q, J=8.0 Hz, $OC\underline{H}_2CH_3$), 4.68 (1H, br. s, 14-H_A), 4.96 (1H, br. s, 14-H_B), 5.69 (1H, br. s, 13-H_A), and 6.27 (1H, br. s, 13-H_B); MS *m/e* (%) 278 (trace, M^+), 232 [53, $(M-EtOH)]^+$], 217 (33), 123 (61), and 81 (100). Found: *m/z* 278.1864. Calcd for $C_{17}H_{26}O_3$: 278.1869.

Oxidation of 5 with Jones Reagent. A few drops of Jones reagent were added slowly to a stirred solution of **5** (80 mg) in acetone (10 ml) at 0 °C, and the mixture was further stirred for 2 d at room temperature. The reaction mixture was treated in the usual way to give a residue which was chromatographed on SiO_2. Elution with $CHCl_3$ gave keto compound **6**, colorless needles, mp 64 °C (recrystallized from hexane), $[\alpha]_D^{22}$ +10.6° (*c* 1.0, $CHCl_3$); IR ($CHCl_3$) 1718, 1640, and 910 cm^{-1}; ^1H NMR δ 0.83 (3H, s, 10-CH_3), 1.27 (3H, t, J=8.0 Hz, $OCH_2C\underline{H}_3$), 3.08 (1H, s, 5-H), 3.63 (1H, t, J=10.0 Hz, 7-H), 4.18 (1H, q, J=8.0 Hz, $OC\underline{H}_2CH_3$), 4.98 (1H, br. s, 14-H_A), 5.54 (1H, br. s, 13-H_A), 5.88 (1H, br. s, 14-H_B), and 6.32 (1H, br. s, 13-H_B); MS *m/z* (%) 276 (55, M^+), 230 [92, $(M-EtOH)^+$], 175 (89), 135 (100), and 107 (97). Found: *m/z* 276.1714. Calcd for $C_{17}H_{24}O_3$: M, 276.1706.

Reduction of 6 with $NaBH_4$. After $NaBH_4$ (4.4 mg) was added to an ice-cooled solution of **6** (26 mg) in MeOH (0.3 ml), the mixture was stirred at room temperature for 2 h. The

reaction mixture was diluted with H_2O and extracted with CH_2Cl_2. The CH_2Cl_2 layer was treated in the usual way to give a residue (20 mg) which was chromatographed on TLC (solvent system; hexane–EtOAc=10 : 1). Colorless needles (**7**, 8 mg) were obtained by recrystallization from hexane–EtOAc, mp 164—165 °C, $[\alpha]_D$ −161.8° (*c* 0.64, $CHCl_3$); CD, $\Delta\varepsilon_{254}$ +1.5 (*c* 0.012, MeOH). Found: *m/z* 232.1449. Calcd for $C_{15}H_{20}O_2$: M, 232.1445. The IR, NMR and mass spectra were found to be identical with those of (+)-β-frullanolide (**1**).

Hydrogenation of Brothenolide (2). Lactone **2** (25 mg) and palladium charcoal (10 mg) in EtOH (2 ml) were stirred under hydrogen atmosphere at room temperature for 3 h. The catalyst was removed by filtration and the solvent was evaporated to give a residue (25 mg), which was purified by recrystallization from hexane (**8**, 18 mg). Colorless needles, mp 105—106 °C; IR ($CHCl_3$) 3040 and 1770 cm^{-1}; ^1H NMR δ 0.32 (1H, t, *J*=3.6 Hz, 3-H_A), 1.06 (3H, d, *J*=7.0 Hz, 11-CH_3), 1.18 (3H, s, 10-CH_3), 1.36 (3H, s, 4-CH_3), and 4.53 (1H, dd, *J*=3.0 and 4.8 Hz, 6-H); MS *m/z* (%) 234 (7, M^+), 219 [100, $(M-CH_3)^+$], 161 (57), 145 (71), and 107 (45). Found: *m/z* 234.1613. Calcd for $C_{15}H_{22}O_2$: M, 234.1608.

Hydrogenation of Dihydro Lactone (8). Dihydro lactone **8** (20 mg) and platinum catalyst (prepared from platinum oxide; 10 mg) in EtOH (1.5 ml) and AcOH) (0.3 ml) were stirred under hydrogen atmosphere at room temperature for 8 h. The reaction mixture was filtered and the filtrate was evaporated under reduced pressure to give a residue (21 mg). Tetrahydro lactone **9** was obtained by recrystallization from hexane, (**9**, 15 mg), colorless needles, mp 138—140°C; IR (CCl_4) 1780, 1380, and 1370 cm^{-1}; ^1H NMR δ 1.04 (3H, s), 1.07 (3H, s), 1.17 (3H, s), 1.20 (3H, d, *J*=6.6 Hz, 11-CH_3), and 4.52 (1H, dd, *J*=3.0 and 4.8 Hz, 6-H); MS *m/z* (%) 236 (1.5, M^+), 221 [16, $(M-CH_3)^+$], 177 (43), 147 (62), 123 (40 , 109 (100), and 107 (69). Found: *m/z* 236.1762. Calcd for $C_{15}H_{24}O_2$: M, 236.1751.

Reduction of Tetrahydro Lactone (9) with Lithium Aluminium Hydride. After a solution of LAH (10 mg) in dry Et_2O (2 ml) was added to an ice-cooled solution of tetrahydro lactone **9** (12 mg) in dry ether (2 ml), the mixture was kept at room temperature for 3 h. The reaction mixture was treated in the usual way to give a residue (15 mg) which was chromatographed on SiO_2. Elution with $CHCl_3$–MeOH (15 : 1) gave a diol compound (**10**, 10 mg), colorless viscous oil, IR (film) 3500, 3430, and 1045 cm^{-1}; ^1H NMR δ 0.98 (3H, d, *J*=7.0 Hz, 11-CH_3), 1.02 (3H, s), 1.19 (6H, s), 3.44 (1H, dd, *J*=5.0 and 12.0 Hz, $\underline{H}_A$CH-OH), 3.56 (1H, dd, *J*=6.5 and 12.0 Hz, HC$\underline{H}_B$-OH), and 4.14 (1H, br. s, 6-H); MS *m/z* (%) 240 (trace, M^+, $C_{15}H_{28}O_2$), 222 [43, $(M-H_2O)^+$], 209 (100).

Acetylation of Diol Compound (10). A solution of diol **10** (10 mg) in dry pyridine (2 ml) and Ac_2O (1 ml) was kept at room temperature for 3 h. The reaction mixture was treated in the usual way to give a residue (13 mg), which was purified by SiO_2 column chromatography using $CHCl_3$ to give monoacetate, (**11**, 8 mg), colorless viscous oil, IR (film) 3510, 1720, and 1370 cm^{-1}; ^1H NMR δ 1.03 (3H, s, 10-CH_3), 1.06 (3H, d, *J*=7.0 Hz, 11-CH_3), 1.17 (3H, s, 4-CH_3), 1.20 (3H, s, 4-CH_3), 2.06 (3H, s, $COCH_3$), 3.94 (1H, dd, *J*=7.5 and 11.0 Hz, 12-H_A), 4.18 (1H, br. s, 6-H), and 4.24 (1H, dd, *J*=2.1 and 11.0 Hz, 12-H_B); MS *m/z* (%) 282 (5, M^+, $C_{17}H_{30}O_3$), 142 (58), 141 (100), and 140 (42).

Oxidation of Acetate (11) with Jones Reagent. A drop of Jones reagent was added to a solution of **11** (10 mg) in acetone (1 ml) at 0 °C, and the mixture was further stirred for 3 h at room temperature. The reaction mixture was treated in the usual way to give a residue (10 mg), which was chromatographed on TLC using $CHCl_3$ to afford keto acetate, (**12**, 6 mg), colorless viscous oil, IR (film) 1735 and 1715 cm^{-1}; ^1H NMR δ 0.91 (3H, s, 10-CH_3), 0.98 (3H, d, *J*=7.0 Hz, 11-CH_3), 1.07 (3H, s, 4-CH_3), 1.34 (3H, s, 4-CH_3), 2.03 (3H, s, $COCH_3$), 2.12 (1H, s, 5-H), 2.24 (1H, m, 7-H), 3.93 (1H, dd, *J*=7.1 and 11.0 Hz, 12-H_A), and 4.09 (1H, dd, *J*=2.1 and 11.0 Hz, 12-H_B); MS *m/z* (%) 280 (17, M^+, $C_{17}H_{28}O_3$), 265 [36, $(M-CH_3)^+$], and 220 [100, $(M-60)^+$].

Preparation of D-Labelled Compounds (9-d_2), (11-d_2), and (12-d_2). Dihydro lactone **8** (10 mg) and platinum catalyst (prepared from platinum oxide; 5 mg) in EtOD (1.5 ml) and AcOD (0.3 ml) were stirred under deuterium atmosphere at room temperature for 8 h. The reaction mixture was filtered and the filtrate was evaporated *in vacuo* to give a residue which was chromatographed on TLC using $CHCl_3$ to give **9**-d_2 (7 mg), MS *m/z* (%) 238 (1, M^+, $C_{15}H_{22}D_2O_2$), and 110 (100); IR (CCl_4) 1780, 1380, and 1370 cm^{-1}; ^1H NMR δ 1.04 (3H, s, 10-CH_3), 1.08 (2H, s, 4-CH_2D), 1.16 (3H, s, 4-CH_3), 1.20 (3H, *J*=6.5 Hz, 11-CH_3), and 4.51 (1H, br. s, 6-H).

Conversion of 9-d_2 into 11-d_2. A mixture of **9**-d_2 (7 mg) and LAH (10 mg) in dry ether (3 ml) was stirred at room temperature for 3 h. The reaction mixture was treated in the usual way. The residue was treated with acetic anhydride (0.5 ml) and pyridine (1 ml) at room temperature for a day and then worked up in the usual way. The resulting residue was chromatographed on TLC using $CHCl_3$ to yield **11**-d_2, (4 mg); MS *m/z* (%) 284 (54, M^+, $C_{17}H_{28}D_2O_3$), 269 [31, $(M-CH_3)^+$] and 209 (100); IR (film) 3500, 1720 and 1380 cm^{-1}; ^1H NMR δ 1.03 (3H, s, 10-CH_3), 1.06 (3H, d, *J*=7.0 Hz, 11-CH_3), 1.17 (2H, s, 4-CH_2D), 1.20 (3H, s, 4-CH_3), 2.06 (3H, s, $COCH_3$), 3.94 (1H, dd, *J*=7.5 and 11.0 Hz, 12-H_A), 4.18 (1H, br. s, 6-H), and 4.24 (1H, dd, *J*=2.1 and 11.0 Hz, 12-H_B).

Oxidation of 11-d_2 with Jones Reagent. To a solution of **11**-d_2 (4 mg) in acetone (1 ml) was added a drop of Jones reagent at 0 °C. The mixture was stirred for a day at room temperature, and then worked up in the usual way. The residue was chromatographed on TLC using $CHCl_3$ to afford **12**-d_2 (2 mg), MS *m/z* (%) 282 (32, M^+, $C_{17}H_{26}D_2O_3$), 267 [28, $(M-CH_3)^+$], and 222 [100, $(M-60)^+$]; IR (film) 1735 and 1715 cm^{-1}; ^1H NMR δ 0.91 (3H, s, 10-CH_3), 0.98 (3H, d, *J*=7.0 Hz, 11-CH_3), 1.07 (2H, s, 4-CH_2D), 1.34 (3H, s, 4-CH_3), 2.03 (3H, s, $COCH_3$), 2.13 (1H, s, 5-H), 2.24 (1H, m, 7-H), 3.93 (1H, dd, *J*=7.1 and 11.0 Hz, 12-H_A), and 4.09 (1H, dd, *J*=2.1 and 11.0 Hz, 12-H_B).

We wish to thank Dr. Tsutomu Kodama of Ottemon Gakuin High School for identification of *Frullania brotheri* Steph., Prof. Tetsuro Fujita of Tokushima Univ. for bioassay of brothenolide, Mr. Hiroshi Nii of Nagaoka Perfumery Co. Ltd., for providing the Costus root oil, and Prof. Yoshinori Asakawa Tokushima-Bunri Univ. for supply of costunolide.

(Received October 25, 1982)

Four sesquiterpenoids, striatene, striatol, β-monocyclonerolidol and ptychanolide, were isolated from the liverwort *Ptychanthus striatus* (LEHM. et LINDENB.)NEES. Their structures have been established by spectroscopic analysis and chemical transformation. Three of them, striatene, striatol and β-monocyclonerolidol, are interesting in terms of the evolution of the liverwort from the algae.

Previously, a number of compounds have been isolated from the liverwort belonging to Jungermanniales.[1] In the course of our investigation on the terpene constituents of the liverwort, we examined the constituents of *Ptychanthus striatus* (LEHM. et LINDENB.) NEES and isolated four new sesquiterpenes, striatene, striatol, β-monocyclonerolidol and ptychanolide together with two known sesquiterpenes, deoxopinguisone[2] and pinguisanene.[3] Three of them, striatene, striatol and β-monocyclonerolidol are interesting in terms of the evolution of the liverwort and the algae. Asakawa *et al.*[3] have reported the identification of mono- and sesquiterpene hydrocarbons, *e.g.* α-pinene, β-pinene, camphene, calamenene, and α-copaene, from the same liverwort. This paper deals in detail with the structural determination of striatene, striatol, β-monocyclonerolidol[4] and ptychanolide.[5]

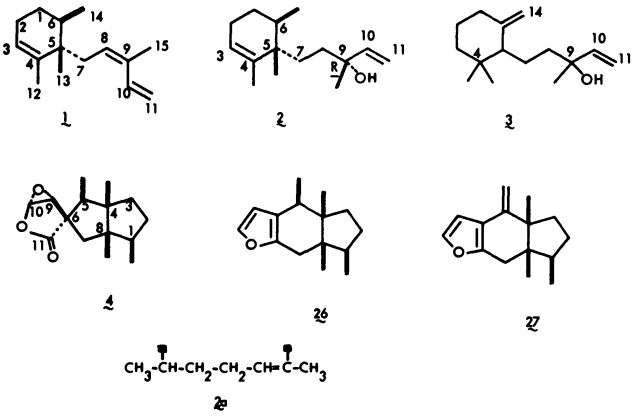

Chart 1.

Striatene (**1**), striatol (**2**), and ptychanolide (**4**) were isolated from the acetone extract of the dry material collected in Tokushima Prefecture in August 1979 by column chromatography on SiO_2 using hexane (F-1) and $CHCl_3$ (F-2 and F-3), while striatene (**1**), β-monocyclonerolidol (**3**), and ptychanolide (**4**) were isolated from the dry material collected in Nara Prefecture in November 1979 by similar procedure.

Striatene (**1**), $[\alpha]_D$ +72.7°, was obtained as a colorless oil by preparative GC of the hydrocarbon fraction. The molecular weight by HR-MS together with the ^1H and ^{13}C NMR data indicated the molecular formula to be $C_{15}H_{24}$. Its IR (1600 cm^{-1}) and UV (λ_{max} 238 nm, ε 24400) spectra showed the presence of conjugated diene system. The IR (1640 and 990 cm^{-1}) and ^1H NMR (δ 5.25, 5.28, and 6.91) spectra also showed characteristic bands and signals due to vinyl groups. Moreover, the ^1H NMR spectrum showed signals due to a tertiary methyl at δ 0.96, a secondary methyl at δ 0.92, two olefinic methyls at δ 1.69 and 1.88, two trisubstituted double bonds at δ 5.34 and 5.56, and an allylic methylene at δ 2.18 and 2.49.

Striatol (**2**), $[\alpha]_D$ +49.5°, was also obtained as a colorless oil by rechromatography on $AgNO_3$-SiO_2 of F-2. The molecular formula $C_{15}H_{26}O$ of **2** was determined by HR-MS together with the ^1H and ^{13}C NMR data. The IR (3400, 1640, 990, and 880 cm^{-1}) spectrum showed bands due to hydroxyl, trisubstituted double bond and vinyl groups. The olefinic functions were further supported by ^1H [δ 5.41 (3-H), 5.09, 5.26 (11-$H_{A,B}$), and 5.92 (10-H)], and ^{13}C NMR (δ 124.0, 145.1, 139.3, and 111.4) spectra. Moreover, ^1H NMR spectrum showed signals due to a secondary methyl at δ 0.87, two tertiary methyls at δ 0.88 and 1.29, and an olefinic methyl at δ 1.59. Treatment of **2** with $POCl_3$ in dry pyridine yielded two trienes, one of which was identified as striatene (**1**) by GLC, IR, and MS. The above spectral data together with this result indicated that striatene and striatol have the same monocyclic carbon skeleton. The presence of the partial structure **2a** was indicated by the results of double irradiation experiments in the ^1H NMR spectrum of **2** using $Eu(fod)_3$. Irradiation of the signal of 6-CH_3 converted a triplet of quartets of 6-H into a triplet (J=6.1 Hz). The fact that 6-H is coupled to 1α- and 1β-H's with J=6.1 Hz indicates it is equatorial. Also, irradiation of 1-H_A collapsed the multiplet of 2-H_A to a sharp peak and a triplet of quartets of 6-H to a doublet of quartets. Further, irradiation of the signal due to 2-H_A collapsed a broad singlet due to 3-H and a multiplet due to 1-H_A to sharp peaks.

Striatene (**1**) was oxidized with *m*-chloroperbenzoic acid (MCPBA) in CH_2Cl_2 at 0 °C to give two monoepoxides **5** and **6**, the UV spectra of which indicated absorption maximum at 238 nm (ε 19500) due to a conjugated diene. The ^1H NMR spectra of epoxides **5** and **6** indicated signals of four olefinic protons (**5**: δ 5.08, 5.21, 5.35, and 6.73; **6**: 5.06, 5.20, 5.67, and 6.82) and a methine proton (**5**: δ 3.01; **6**: 2.77) attached to an epoxy ring. These results indicated that the double

bonds at C_3/C_4 was epoxidized. The stereochemistry of oxirane rings in **5** and **6** were determined by ^1H NMR using shift reagent, *i.e.*, two protons of α-epoxide **6** at C-7 underwent a much larger shift than those of β-epoxide **5**, thus showing that the oxirane ring and side chain in **6** have a *cis* relation, while those of in **5** have a *trans* relation. The presence of the C_6 side chain was suggested by the mass spectra of **1** and **5**, and ^1H NMR of **5**. Namely, the mass spectra contained intense ions at *m/z* 123 (M−81) for **1**, *m/z* 139 for **5** and *m/z* 81 for both compounds originating by cleavage of the C-5/C-7 bond. Furthermore, in the ^1H NMR spectrum of **5**, irradiation at δ 5.21 (8-H) collapsed the allylic methylene at δ 2.15 (7-H_A) and 2.41 (7-H_B) to AB type doublets and the olefinic methyl protons (9-CH_3) at δ=1.86 to a sharp peak. These results indicated that the C_6 side chain in **1** is 3-methyl-1,3-pentadiene. In the ^1H NMR of **2** with the aid of shift reagents [Eu(fod)$_3$], the proton at C-6 together with the CH_3 group at C-4 were observed to have larger shifts than CH_3 groups at C-5 and C-6. In the NOE experiments of benzoate **9** (described below), a 2.7% NOE was observed on the 6-CH_3 group (axial) upon irradiation of 5-CH_3.[6] These results indicated that 6-H and the hydroxyl-containing side chain have a *cis* relation. The geometry of 8-ene in **1** was determined by NOE experiment. An 11% NOE was observed on 8-H upon irradiation of 9-CH_3, *i.e.*, the 8-ene is *Z*. These results lead to structures **1** and **2** for striatene and striatol, respectively.

The absolute configurations of **1** and **2** were determined in the following way. Hydrogenation of monoepoxide **5** with Pd/C gave tetrahydro compound **7**, the IR spectrum of which showed the absence of double bond absorption. The ^1H NMR spectrum indicated signals of two secondary and one primary methyl groups at δ 0.74, 0.84, and 0.88. Compound **7** was treated with diethylamine and *n*-BuLi[7] in dry ether to give **8** which was then reacted with *p*-bromobenzoyl chloride in dry pyridine to yield the corresponding monobenzoate **9**. The IR spectrum exhibited bands at 1718, 1640, and 890 cm^{-1} due to an ester group and an exocyclic methylene group. The ^1H NMR spectrum indicated the presence of a methine proton adjacent to an oxygen (δ 5.57), exocyclic methylene protons (δ 4.76 and 5.08) and protons on an aromatic ring (δ 7.59 and 7.97). The fact that 3-H is coupled to 2-$H_{A,B}$ with J=5.3 and 10.9 Hz indicates that it is axial. The signal of 6-H at δ 1.67 appeared as a triple quartet, (J=4.8 and 6.6 Hz) which collapsed to triplet (J=4.8 Hz) on irradiation of 6-CH_3. This fact indicates that 6-H is equatorial. In the NOE experiments of **9**, an 11% NOE is observed on 12-H_A upon irradiation of 5-CH_3, *i.e.*, 5-CH_3 is equatorial. From these results the conformation of this compound was determined to be as shown by **9a**. Harada *et al.* reported that the absolute configuration of cyclic allylic alcohols can be determined nonempirically by the CD exciton chirality method.[8] Application of this method to benzoate **9**, $\Delta\varepsilon_{241}$+3.1, shows that the exocyclic double bond and the 3-OCOPh group constitute a positive chirality as shown in **9b**. Thus, the absolute configuration of striatene is as shown in structure **1**.

The configuration of the *t*-OH group in **2** was determined by taking (*R*)-(−)-linalool (**10**) as the reference sample. Namely, it was found that the *p*-bromobenzoates of striatol and (*R*)-(−)-linalool both show negative Cotton effects at 252 nm (in MeOH), **2b** $\Delta\varepsilon_{252}$−0.4 and **10a** $\Delta\varepsilon_{252}$−0.5. This establishes the C-9 configuration in **2** to be *R*. Recently, Gonnella *et al.*[9] have shown that the benzoate method described above for cyclic compounds is extensible to acyclic secondary allylic alcohols, namely, that the benzoate of acyclic allylic moiety **11** exhibits a positive CD. The present results including that of linalool show that the method is applicable to *t*-OH system **12** as well (because the methyl group is smaller than other alkyl substituents).

β-Monocyclonerolidol (**3**), $[\alpha]_D$ +3.2°, was obtained as a colorless oil by rechromatography on $AgNO_3$-SiO_2

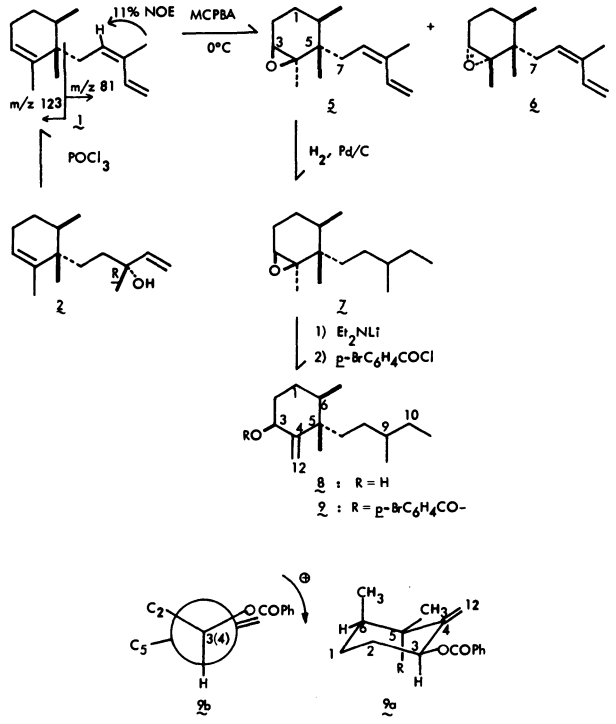

Chart 2.

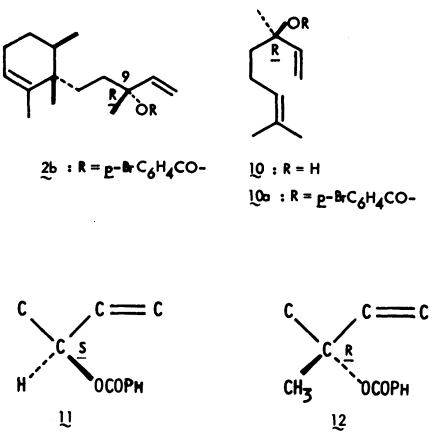

Chart 3.

of F-2′. The molecular formula $C_{15}H_{26}O$ of **3** was determined by HR-MS together with the ^1H and ^{13}C NMR data. The IR spectrum showed the presence of a hydroxyl group at 3400 cm^{-1}, a vinyl group at 1645 and 990 cm^{-1}, and an exocyclic methylene group at 890 cm^{-1}. The ^1H NMR spectrum indicated signals of *gem*-dimethyl groups at δ 0.84 and 0.92, a tertiary methyl group on a carbon bearing hydroxyl at δ 1.27, an exocyclic methylene group at δ 4.53 and 4.75, and vinyl groups at δ 5.02, 5.18, and 5.91. The mass spectrum indicated intense ion peaks at *m/z* 123 (M−18−81) and *m/z* 81 as observed in **1** and **2**. The fact indicates that **3** also has a C_6 side chain. From these results together with biogenetic consideration, we assumed that **3** had a monocyclonerolidol skeleton as shown by structure **3**. This assumption was confirmed by partial synthesis of **3** from α-ionone.

Hydrogenation of commercial (±)-α-ionone **13** with Pd/C in 1.5% KOH-EtOH gave the hydrogenated mixture, from which dihydroionone **14** was separated by column chromatography on SiO_2. Dihydroionone **14** exhibited the molecular ion peak at *m/z* 194 in its mass spectrum. The IR spectrum exhibited bands at 1710 and 810 cm^{-1} due to a carbonyl group and a trisubstituted double bond. The ^1H NMR spectrum indicated the presence of an olefinic methyl group (δ 1.66) and a trisubstituted double bond (δ 5.31). The reaction of **14** with ethylene glycol and TsOH yielded acetal **15**, the ^1H NMR spectrum of which exhibited a signal due to the acetal group at δ 3.90. The IR spectrum showed the absence of a carbonyl group. Next, irradiation of acetal **15** in ether containing 10% phenol with a 450 W-Hg lamp[10] afforded a mixture of **16** and starting material **15**. Then, this mixture was hydrolyzed with TsOH in THF containing H_2O to give a ketone mixture, **16a** and **14**, from which the exocyclic isomer **16a** was separated by column chromatography on $AgNO_3$-SiO_2. The IR spectrum showed exocyclic methylene absorption bands at 1640 and 885 cm^{-1}, and a carbonyl absorption band at 1710 cm^{-1}. The ^1H NMR spectrum also suggested the presence of an exocyclic methylene group at δ 4.49 and 4.74. The exocyclic isomer **16a** was reacted with vinylmagnesium bromide (prepared from vinyl bromide and magnesium in THF) in dry THF to give the racemic alcohol **17**. The NMR, IR, and mass spectra of **17** were identical with those of β-monocyclonerolidol (**3**).

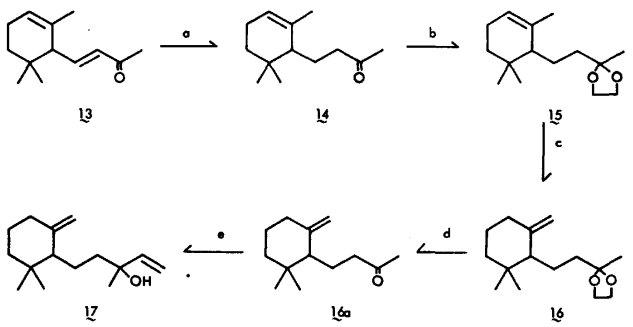

Chart 4.

a) H_2, pd/C, 1.5% KOH-EtOH; b) Ethylene glycol, TsOH c) 10% Penol/ether, *hν*(450 W); d) TsOH, THF THF; e) CH_2=CHMgBr, THF.

On the basis of distribution of terpenoids, Asakawa and co-workers[11] have noted that liverwort are closely related to algae. The fact that the skeletal structures of **1**—**3** are identical with α- and β-snyderol,[12] microcionin,[13] *etc.*[14] which have been found in marine algae and in marine animals feeding on algae, supports the notion that liverworts have evolved from algae.

Ptychanolide (**4**), mp 143—144 °C, $[\alpha]_D$ +23.2° was obtained as a colorless needles by recrystallization of F-2 and 2′. The molecular formula $C_{15}H_{22}O_3$ of **4** was determined by the appearance of a molecular ion peak at 250.1565 in the HR-MS. The IR spectrum showed the presence of a γ-lactone absorption band at 1780 cm^{-1} and the absence of hydroxyl absorptions. The ^1H NMR spectrum indicated signals due to two secondary CH_3 groups at δ 0.84 and 0.98, two tertiary CH_3 groups at δ 0.79 and 0.93, an isolated methylene group at δ 1.39 and 1.99, and two methine protons adjacent to oxygen at δ 3.55 and 5.52. The ^{13}C NMR spectrum also suggested the presence of a γ-lactone group at δ 76.1 and 179.8. Hence the remaining oxygen atom was attributed to an ether linkage. Treatment of the lactone **4** with 10% H_2SO_4 in acetone afforded the diol lactone **18**. The IR spectrum showed bands at 3500 and 1770 cm^{-1} due to hydroxyl and γ-lactone groups. The ^1H NMR spectrum indicated signals of two methine protons adjacent to oxygen at δ 4.13 and 5.62 which were coupled with each other. The formation of an α-glycol from an ether indicates that the diol is derived from an epoxide. The lactone **4** was reduced with LAH in dry ether to triol **19**, the ^1H NMR spectrum of which showed signals of five protons adjacent to oxygen at δ 3.64, 3.72, 3.76, 3.84, and 3.92. In decoupling experiments, irradiation at δ 3.92 collapsed the two double doublets of the $-C\underline{H}_2OH$ group at δ 3.72 and 3.76 to AB type doublets. This result and assignments of *J* values suggested that a hydroxymethyl group at C-11 and 1,2-diol system at C-9 and C-10 are attached to a quaternary carbon. Hence, the γ-lactone must form a spiro linkage at C-6 and the epoxy ring is attached to the γ-lactone ring.

Oxidation of triol **19** with $NaIO_4$ gave aldehyde **20**, M^+ *m/z* 224 ($C_{14}H_{24}O_2$), the IR spectrum of which showed bands at 3560, 3450, and 1715 cm^{-1} due to hydroxyl and formyl group. The ^1H NMR spectrum indicated signals of two protons adjacent to an oxygen as primary alcohol at δ 3.55 and 3.94, and proton of formyl group at δ 9.69 instead of three protons adjacent to oxygen in **19**. Aldehyde **20** was further oxidized with MCPBA in CH_2Cl_2, followed by hydrolysis with Al_2O_3 to yield diol **21** (M^+, *m/z* 212; $C_{13}H_{24}O_2$). Its IR spectrum showed the presence of a hydroxyl absorption band at 3325 cm^{-1} and the absence of carbonyl absorption. The diol **21** was oxidized further with $NaIO_4$ to the corresponding ketone **22** which exhibited a molecular ion peak at 180 ($C_{12}H_{20}O$) in the mass spectrum. The IR spectrum indicated the presence of a five-membered ring ketone (1740 cm^{-1}). These results establish that ptychanolide **4** has a spiro lactone moiety at C-6. Reduction of ketone **22** with LAH in dry ether afforded alcohols **23** and **24**, the ^1H NMR

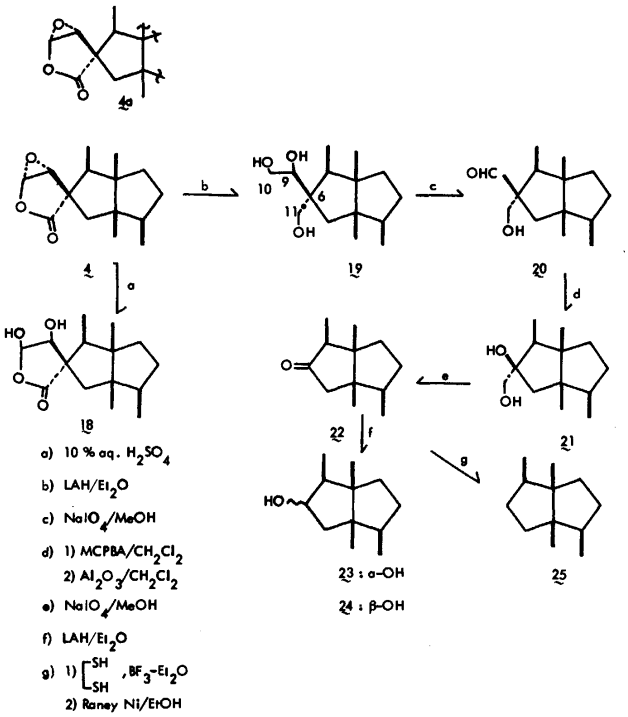

Chart 5.

spectra of which showed signals of protons on carbons bearing hydroxyl groups (**23**: δ 3.77; **24**: 4.20), respectively. In the decoupling experiments of **23**, irradiation of 6-H as a double triplet collapsed a pair of double doublets of 7-CH_2 at δ 1.49 and 1.79 to a pair of doublets and a double quartet of 5-H at δ 1.74 to a quartet. This fact indicated that the OH function was flanked by a methylene group and secondary CH_3 group. Namely, ptychanolide has a partial structure **4a**. Ketone **22** was treated with 1,2-ethanedithiol to give the corresponding thioacetal which was desulfurized with Raney Ni in EtOH to yield the volatile hydrocarbon **25**. Its mass spectrum showed a molecular ion peak at 166 ($C_{12}H_{22}$). However, the ^1H and ^{13}C NMR spectra showed only the signals of two methyl groups and five protons, and those of six carbons, respectively. Therefore, the hydrocarbon **25** has the symmetric bicyclo[3.3.0]octane skeleton. The above results indicate that ptychanolide is represented by formula **4** (planar).

The stereostructure of ptychanolide (**4**) was determined by X-ray analysis. The colorless transparent crystals of **4**, which were recrystallized from hexane-EtOAc, belong to orthorhombic with space group $p2_12_12_1$. The crystal data are as follows: $C_{15}H_{22}O_3$, M_r= 250.16, a=6.514(1), b=19.376(4), c=10.543(3) Å, v= 1330.7(5) Å^3, Z=4, D_m=1.233 (1), D_x=1.249 g cm^{-3}. X-Ray diffraction intensities were measured by Rigaku automatic diffractometer with graphite-monochromated Cu $K\alpha$ radiation using a θ-2θ scan mode and a scan rate of 4°/min. Stationary background counts (5 s each) were taken at both limits of each scan (scan width in 2θ: 1.2+0.15 tanθ). A total of 1344 unique reflections were measured to the limit 2θ=130°. Lorentz and polarization corrections were applied, but no absorption correction was made because of the small size of the used crystal (dimension: 0.3×0.4×0.2 mm^3). The X-ray intensities of four standard reflections monitored at 100 reflection intervals showed no evidence of structural deterioration during the data collection.

Table 1. Atomic coordinates (× 10^4) of nonhydrogen atoms of **4**

Atom	x	y	z
C1	4160 (11)	977 (3)	5420 (6)
C2	3997 (11)	237 (3)	5870 (8)
C3	5405 (11)	162 (4)	7049 (8)
C4	6291 (8)	886 (3)	7297 (6)

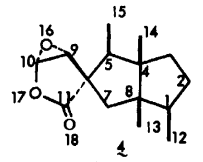

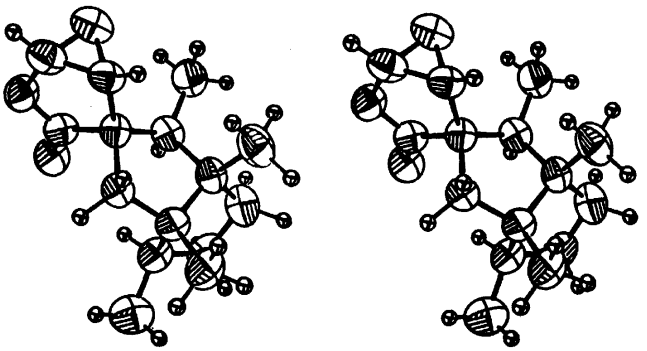

Fig. 1. Perspective drawing of ptychanolide **4**.

The structure was solved by the direct methods with program MULTAN78.[15] An E-map, calculated using 200 reflections ($|E|>1.40$) with the phase set of the highest combined figure of merit (=2.86), revealed the positions of all nonhydrogen atoms. These coordinates were refined by a full-matrix least-squares method with isotropic temperature factors and then by a block-diagonal least-squares method with anisotropic ones. All hydrogen atoms could be located from a difference Fourier map and these were included in a further refinement with isotropic temperature factors. The final R value was 0.078. The final positional parameters with their estimated standard deviations of nonhydrogen atoms are listed in Table 1.

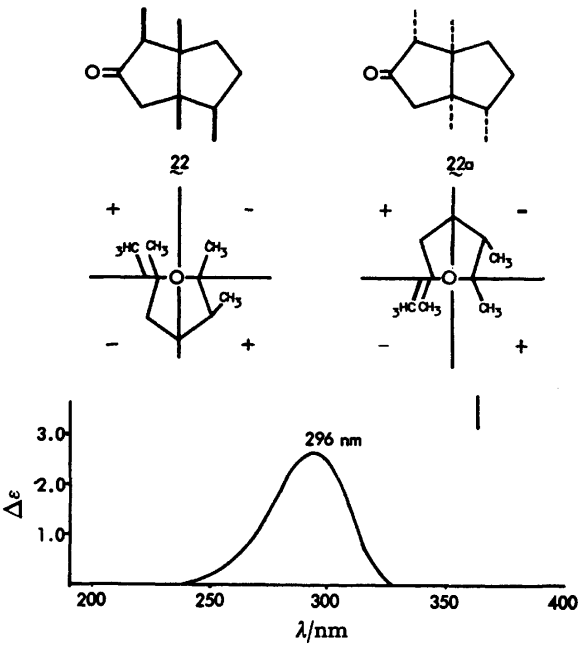

Fig. 2. CD spectrum of **22**.

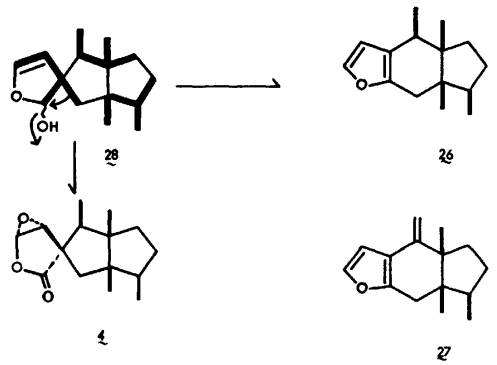

Chart 6.

The atomic scattering factors for all atoms were taken from "International Tables for X-Ray Crystallography."[16] All numerical calculations were carried out on an ACOS-700 computer at the Computation Center of Osaka University using *UNICS* program.[17] The stereostructure of **4** is shown in Fig. 1. The relative stereostructure of ptychanolide (**4**) was thus clarified. Furthermore, the keto compound **22** showed a positive Cotton effect at 295 nm in the CD spectrum (Fig. 2). The positive sign of the Cotton effect can be understood by application of the octant rule[18] to the cyclopentanone system, as visualized in octant projection formula **22** and **22a**. This leads to the absolute configuration shown for **22** which is corroborated by the established configuration of congeners **26**[2,19] and **27**.[3] Thus, the absolute structure of ptychanolide is shown by formula **4**.

The biogenesis of the pinguisone type sesquiterpenoids represented by deoxopinguisone **26** and pinguisanene **27** is as yet not clear. However, the isolation of ptychanolide **4** from the same liverwort suggests that they are derived from an intermediate such as **28**.

Experimental

All melting points are uncorrected. IR spectra were measured with a Hitachi EPI-G2 spectrometer, ^{13}C NMR spectra with a JEOL FX-100 (25.0 MHz) spectrometer, ^1H NMR spectra with a JEOL FX-100 (100 MHz), a Nicolet NT-360 (360 MHz) or a Hitachi R-20B (60 MHz) spectrometer in deuteriochloroform solution containing tetramethylsilane as an internal standard, low resolution mass spectra with a Hitachi RMU-6 mass spectrometer and high resolution mass spectra with a JEOL 01SG-2, with direct inlet system operating at 70 eV. CD spectra were measured with a JASCO J-20 spectrometer. An analytical GC was performed with a Hitachi 163-type apparatus equipped with a Thermon 600T glass capillary column, and preparative GC with Varians model 90 fitted OV-17 on Chromosorb-W, operated at 150°. Kieselgel 60 (E. Merck, Darmstadt) and Silica CC-7 special (Mallinckrodt) were used for column chromatography. Thin-layer chromatography (TLC) was carried out on Kieselgel GF_{254} (E. Merck, Darmstadt) in 0.25 mm thickness.

Extraction and Isolation. The dry material (100 g) of *Ptychanthus striatus* (Lehm. et Lindenb.) Nees collected in Wakayama Prefecture around Kosa-cho in March 1980 was extracted with acetone at room temperature. Acetone was evaporated under vacuum and the concentrate was extracted with $CHCl_3$. The $CHCl_3$ extract (6.6 g) was subjected to column chromatography over SiO_2. The fraction eluted with hexane gave sesquiterpene hydrocarbons (F-1) containing striatene (**1**), deoxopinguisone (**26**), and pinguisanene (**27**). The fraction eluted with $CHCl_3$ yielded crude ptychanolide (**4**) (F-2) and crude striatol (**2**) (F-3). Also, F-1′, F-2′, and F-3′ were isolated from the acetone extract of the dry material (100 g) collected in Nara Prefecture around Ikadaba in November 1979 by a similar procedure.

Striatene (**1**) was isolated from hydrocarbon fractions, F-1 and F-1′, by preparative GC, as a colorless oil (**1**, 200 mg from F-1 and F-1′, respectively), $[\alpha]_D^{22}$ +72.7° (*c* 1.19, $CHCl_3$), IR (film) 1640, 1600, 990, 810 cm^{-1}; UV (cyclohexane) 232 (sh), 238 (ε 24400) and 245 (sh) nm; ^1H NMR δ 0.92 (3H, d, J=6.5 Hz, 6-CH_3), 0.96 (3H, s, 5-CH_3), 1.69 (3H, br.s, 4-CH_3), 1.88 (3H, br.s, 9-CH_3), 2.18 (1H, dd, J=6.0, 16.0 Hz, 7-H_A), 2.49 (1H, dd, J=8.0, 16.0 Hz, 7-H_B), 5.25 (1H, dd, J=1.6, 10.5 Hz, 11-H_A), 5.28 (1H, dd, J=1.6, 17.3 Hz, 11-H_B), 5.34 (1H, m, 8-H), 5.56 (1H, t-like, 3-H), and 6.91 (1H, dd, J=10.5, 17.3 Hz, 10-H); ^{13}C NMR δ 16.0 (q), 19.2 (q), 20.0 (q), 20.7 (q), 25.3 (t), 27.1 (t), 34.2 (t), 34.2 (d), 40.7 (s), 113.2 (t), 124.4 (d), 128.1 (d), 134.0 (d), 133.2 (s), and 139.1 (s); MS *m/z* (%) 204 (7, M^+), 123 [100, $(M-81)^+$] and 81 (25). Found: *m/z* 204.1866. Calcd for $C_{15}H_{24}$: M, 204.1856.

Epoxidation of Striatene (1). The solution of *m*-chloroperbenzoic acid (390 mg) in CH_2Cl_2 (5 ml) was added to an ice-cooled solution of **1** (300 mg) in CH_2Cl_2 (5 ml) and the mixture was stirred for 40 min at 0 °C. The reaction mixture was treated in the usual way to give residue (190 mg), which was chromatographed on 10% $AgNO_3$–SiO_2 (Mallinckrodt, CC-7). Elution with CH_2Cl_2–EtOAc (20 : 1) gave β-epoxide **5** (55 mg) as a colorless oil. Successive elution with the same solvent gave α-epoxide **6** (10 mg) as a colorless oil.

β-Epoxide 5: IR (film) 1640, 1600, 980, 900 cm^{-1}; UV (cyclohexane) 237 nm (ε 19500); ^1H NMR δ 0.75 (3H, d, J=6.5 Hz, 6-CH_3), 0.92 (3H, s, 5-CH_3), 1.26 (3H, s, 4-CH_3), 1.86 (3H, br.s, 9-CH_3), 2.15 (1H, dd, J=5.5, 17.0 Hz, 7-H_A), 2.41 (1H, dd, J=7.5, 17.0 Hz, 7-H_B), 3.01 (1H, br.s, 3-H), 5.08 (1H, dd, J=1.5, 10.5 Hz, 11-H_A), 5.21 (1H, t-like, 8-H), 5.35 (1H, dd, J=1.5, 17.5 Hz, 11-H_B), and 6.73 (1H, dd, J=10.5, 17.5 Hz, 10-H); MS *m/z* (%) 220 (3, M^+, $C_{15}H_{24}O$), 205 [8, $(M-CH_3)^+$], 139 [98, $(M-81)^+$], 109 (92), 95 (100), 81 (99), 43 (98).

α-Epoxide 6: IR (film) 1645, 1605, 980, 900 cm^{-1}; UV

(cyclohexane) 238 nm (ε 18000); ^{1}H NMR δ 0.72 (3H, d, J=6.5 Hz, 6-CH_3), 0.91 (3H, s, 5-CH_3), 1.27 (3H, s, 4-CH_3), 1.86 (3H, br.s, 9-CH_3), 2.36 (2H, br.s, 7-$H_{A,B}$), 2.77 (1H, t, J=1.5 Hz, 3-H), 5.06 (1H, dd, J=1.5, 10.5 Hz, 11-H_A), 5.20 (1H, dd, J=1.5, 17.5 Hz, 11-H_B), 5.67 (1H, br.t, J=4.0 Hz, 8-H), and 6.82 (1H, dd, J=10.5, 17.5 Hz, 10-H); MS m/z (%) 220 (trace, M^+, $C_{15}H_{24}O$), 139 [17, $(M-81)^+$], 95 (30), 81 (20), 43 (100).

Hydrogenation of β-Epoxide ***5***. β-Epoxide **5** (10 mg) and 10% palladium charcoal (10 mg) in EtOH (1 ml) were stirred under hydrogen atmosphere at room temperature for 5 h. The catalyst was removed by filtration and the solvent was evaporated to give a residue (11 mg), which was chromatographed on SiO_2. Elution with $CHCl_3$ yielded tetrahydro epoxide **7** (7 mg), colorless oil, ^{1}H NMR δ 0.74 (3H, d, J=6.5 Hz, s-CH_3), 0.84 (3H, d, J=7.5 Hz, s-CH_3), 0.86 (3H, s, 5-CH_3), 0.88 (3H, t, J=6.6 Hz, 10-CH_3), 1.24 (3H, s, 4-CH_3), and 2.96 (1H, br.s, 3-H); MS m/z (%) 224 (12, M^+, $C_{15}H_{28}O$), 209 [31, $(M-CH_3)^+$], 103 (100), 85 (98), 43 (76).

Conversion of ***7*** *into Benzoate* ***9***. Commercial butyllithium (0.3 ml, 15% solution in hexane) was added to a solution of diethylamine (36.5 mg) in dry ether (1 ml). Tetrahydro epoxide **7** (18 mg) in dry ether (1 ml) was then added and the mixture was refluxed for 3 h. The reaction mixture was poured into NaCl aqueous solution and extracted with ether. The ether layer was treated in the usual way to give residue (14 mg), which was treated with *p*-bromobenzoyl chloride (20 mg) in dry pyridine (2 ml) at room temperature for a day. The reaction mixture was treated in the usual way to give a residue, which was chromatographed on SiO_2. Elution with hexane–EtOAc (20 : 1) gave benzoate **9** (8 mg), colorless viscous oil, IR (film) 1718, 1640, 890 cm^{-1}; UV (MeOH) 205.5, 244 nm (ε 16900, 17500); CD, $\Delta\varepsilon_{241}$ +3.06 (c 0.145, MeOH); ^{1}H NMR δ 0.82 (3H, t, J=6.6 Hz, 10-CH_3), 0.83 (3H, d, J=6.6 Hz, 9-CH_3), 0.90 (3H, d, J=6.7 Hz, 6-CH_3), 1.01 (3H, s, 5-CH_3), 1.67 (1H, tq, J=4.8, 6.6 Hz, 6-H), 4.76 (1H, br.s, 12-H_A), 5.08 (1H, br.s, 12-H_B), 5.57 (1H, dd, J=5.3, 10.9 Hz, 3-H), 7.59 (2H, aromatic protons) and 7.98 (2H, aromatic protons); MS m/z (%) 408, 406 (trace, M^+, $C_{22}H_{31}O_2Br$), 323, 321 [45, 47, $(M-85)^+$], 185, 183 [92, 91, $(p$-$BrC_6H_4CO)^+$], 122 (100), 93 (69).

Benzoylation of (R)-(−)-Linalool ***(10)***. The mixture of (*R*)-(−)-linalool (**10**) (20 mg) isolated from Ho leaf oil and *p*-bromobenzoyl chloride (20 mg) in dry pyridine (1 ml) was kept at room temperature for 2 d. The reaction mixture was treated in the usual way to yield a residue, which was chromatographed on SiO_2. Elution with $CHCl_3$ gave a benzoate **10a** (15 mg), colorless oil, IR (film) 1720, 1645, 910, 830 cm^{-1}; UV (EtOH) 206.5, 244.5 nm (ε 14500, 16400); CD, $\Delta\varepsilon_{252}$ −0.54 (c 2.5, EtOH); ^{1}H NMR δ 1.57, 1.62 (3H each, br.s), 1.68 (3H, s, 6-CH_3), 1.76—2.28 (4H, 4-$H_{A,B}$, 5-$H_{A,B}$), 5.12 (1H, m, 3-H), 5.17 (1H, dd, J=1.2, 10.0 Hz, 8-H_A), 5.23 (1H, dd, J=1.2, 17.5 Hz, 8-H_B), 6.07 (1H, dd, J=10.0, 17.5 Hz, 7-H), 7.52 (2H, aromatic protons) and 7.85 (2H, aromatic protons); MS m/z (%) 185, 183 [100, 98 (p-BrC_6H_4)$^+$], 136 (43).

Isolation of Striatol ***(2)***. Fraction 3 (F-3) was rechromatographed on 10% $AgNO_3$–SiO_2 eluted with hexane–EtOAc (10 : 1) to yield colorless viscous oil (**2**, 70 mg), $[\alpha]_D^{22}$ +49.5° (c 1.2, $CHCl_3$); IR (film) 3400, 1640, 990, 800 cm^{-1}; ^{1}H NMR δ 0.87 (3H, d, J=6.5 Hz, 6-CH_3), 0.88 (3H, s, 5-CH_3), 1.29 (3H, s, 9-CH_3), 1.59 (3H, br.s, 4-CH_3), 5.09 (1H, dd, J=1.6, 10.5 Hz, 11-H_A), 5.26 (1H, dd, J=1.6, 17.5 Hz, 11-H_B), 5.41 (1H, m, 3-H) and 5.92 (1H, dd, J=10.5, 17.5 Hz, 10-H); ^{13}C NMR δ 15.7 (q), 19.0 (q), 21.0 (q), 27.6 (q), 25.4 (t), 27.0 (t), 30.1 (t), 36.5 (t), 33.2 (d), 40.0 (s), 73.1 (s), 111.4 (t), 124.0 (d), 145.1 (d), 139.3 (s); MS m/z (%) 204 [17, $(M-18)^+$], 123 [100, $(M-81)^+$], 81 (44). Found: m/z 222.1994, Calcd for $C_{15}H_{26}O$: M, 222.2004.

Benzoylation of Striatol ***(2)***. A solution of striatol **2** (10 mg) and *p*-bromobenzoyl chloride (10 mg) in dry pyridine (1 ml) was kept at room temperature for 2 d. The reaction mixture was treated in the usual way to give a residue, which was purified by SiO_2 column chromatography using hexane–EtOAc (15 : 1) to afford benzoate **2b** (7 mg), colorless viscous oil, IR (film) 1720, 1645, 980, 800 cm^{-1}; UV (EtOH) 206, 244.5 nm (ε 16000, 18000); CD, $\Delta\varepsilon_{252}$ −0.4 (c 2.7, EtOH), ^{1}H NMR δ 0.81 (3H, d, J=7.0 Hz, 6-CH_3), 0.81 (3H, s, 5-CH_3), 1.59 (3H, br.s, 4-CH_3), 1.69 (3H, s, 9-CH_3), 5.17 (1H, dd, J=1.6, 10.5 Hz, 11-H_A), 5.22 (1H, dd, J=1.6, 17.5 Hz, 11-H_B), 5.40 (1H, m, 3-H), 6.03 (1H, dd, J=10.5, 17.5 Hz, 10-H), 7.53 (2H, aromatic protons) and 7.85 (2H, aromatic protons); MS m/z (%) 185, 183 [100, 98 (p-BrC_6H_4CO)$^+$], 204 (20), 123 (95), 81 (30).

Isolation of β-Monocyclonerolidol ***(3)***. Fraction 3′ (F-3′) was purified by column chromatography on 10% $AgNO_3$–SiO_2 using hexane–EtOAc (10 : 1) to give β-monocyclonerolidol (**3**, 70 mg), colorless viscous oil, $[\alpha]_D^{25}$ +3.2° (c 0.66, $CHCl_3$); IR (film) 3400, 1645, 990, 890 cm^{-1}; ^{1}H NMR δ 0.84, 0.92 (3H each, s, *gem*-dimethyl at C-4), 1.27 (3H, s, 9-CH_3), 4.53 (1H, br.s, 14-H_A), 4.75 (1H, br.s, 14-H_B), 5.02 (1H, dd, J=1.6, 10.5 Hz, 11-H_A), 5.18 (1H, dd, J=1.6, 17.5 Hz, 11−H_B), and 5.91 (1H, dd, J=10.5, 17.5 Hz, 10H); ^{13}C NMR δ 20.4 (q), 26.4 (q), 27.7 (q), 23.7 (t), 28.5 (t), 32.4 (t), 36.2 (t), 41.1 (t), 54.5 (d), 35.0 (s), 73.3 (s), 109.0 (t), 111.4 (t), 145.4 (d), 149.3 (s); MS m/z (%) 204 [25, $(M-H_2O)^+$], 189 (40), 123 [100, $(M-18-81)^+$], 109 (43), 93 (43), 81 (75). Found: m/z 222.1992. Calcd for $C_{15}H_{26}O$: M, 222.2004.

Hydrogenation of α-Ionone ***(13)***. The mixture of α-ionone **13** (500 mg) and Pd/C (50 mg) in EtOH containing 1.5% KOH was stirred under hydrogen atmosphere at room temperature for 4 h. The reaction mixture was filtered and the filtrate was neutralized with 5% aqueous HCl, diluted with H_2O, and extracted with ether. The ether layer was treated in the usual way to give a residue, which was chromatographed on SiO_2. Elution with $CHCl_3$ yielded dihydroionone **14** (190 mg), colorless oil, IR (film) 1710, 810 cm^{-1}; ^{1}H NMR δ 0.88, 0.93 (3H each, s, *gem*-dimethyl), 1.66 (3H, br.s, $=C(CH_3)$), 2.12 (3H, s, $COCH_3$), 5.31 (1H, m, $=CH$); MS m/z (%) 194 (4, M^+, $C_{13}H_{22}O$), 176 [23, $(M-CH_3)^+$], 161 [17, $(M-30)^+$], 136 [80, $(M-15-43)^+$], 121 (100), 43 (84).

Acetalization of Dihydroionone ***14***. A solution of dihydroionone **14** (500 mg) in benzene (40 ml) containing ethylene glycol (6 ml) and TsOH (0.13 g) was stirred at reflux with a Dean-Stark trap for 12 h. The reaction mixture was washed with aqueous $NaHCO_3$ and H_2O, and dried over Na_2SO_4. The solvent was removed *in vacuo* to give a residue (580 mg), which was chromatographed on SiO_2. Elution with $CHCl_3$ gave acetal **15** (400 mg), colorless oil, IR (film) 1650, 1060, 860 cm^{-1}; ^{1}H NMR δ 0.86, 0.92 (3H each, s, *gem*-dimethyl) 1.30 (3H, s,), 1.66 (3H, br. s, $=C(CH_3)$), 3.90 (4H, s), 5.27 (1H, br.s, $H\diagdown=$); MS m/z (%) 238 (1, M^+, $C_{15}H_{26}O_2$), 223 [2, $(M-CH_3)^+$], 136 (25), 87 [100, ], 43 (19).

Irradiation of Acetal ***15***. A solution of acetal **15** (2 g) in ether (270 ml) containing phenol (30 g) was irradiated with 450 W-Hg lamp for 3 h. The reaction mixture was passed an Al_2O_3 column by elution with ether. The ether fraction was evaporated under vacuum to give a residue (1.5 g), which was chromatographed on 10% $AgNO_3$–SiO_2 to yield β-isomer **16** (550 mg) and starting material **15** (600 mg). β-Isomer **16**,

colorless oil, IR (film) 1640, 1070, 890 cm^{-1}; ^1H NMR δ= 0.84, 0.94 (3H each, s, *gem*-dimethyl), 1.31 (3H, s, $\overline{\text{O}}\text{>}$-$CH_3$), 3.92 (4H, s), 4.52, 4.73 (1H each, br.s, $=\langle^{H}_{H}$); MS *m/z* (%) 238 (58, M^+, $C_{15}H_{26}O_2$), 223 [100, $(M-CH_3)^+$], 178 (73), 176 (93), 161 (97), 136 (98), 87 [99, $(CH_3\langle^{O-}_{O-}\rangle)^+$]. 43 (70).

Hydrolysis of Acetal **16**. The mixture of acetal **16** (300 mg) and TsOH (20 mg) in THF (10 ml) and H_2O (1 drop) was kept at room temperature for 2 d. The reaction mixture was diluted with H_2O and extracted with CH_2Cl_2. The CH_2Cl_2 layer was treated in the usual way to afford a residue (250 mg), which was purified by SiO_2 column chromatography using CH_2Cl_2 to yield ketone **16a** (190 mg), colorless oil, IR (film) 1710, 1640, 885 cm^{-1}; ^1H NMR δ 0.94, 0.96 (3H each, s, *gem*-dimethyl), 2.00 (3H, s, $-COCH_3$), 4.49, 4.74 (1H each, br. s, $=\langle^{H}_{H}$); MS *m/z* (%) 194 (2, M^+, $C_{13}H_{22}O$), 176 [25, $(M-CH_3)^+$], 161 (27), 136 (59), 121 (68), 43 (100).

Grignard Reaction of Ketone **16a**. After a solution of ketone **16a** (250 mg) in dry THF (5 ml) was added dropwise to a stirred solution of vinylmagnesium bromide (prepared from 3 g of vinyl bromide and 720 mg of Mg in 10 ml of dry THF) at room temperature, the mixture was heated under reflux for 3 h. The reaction mixture was then decomposed by addition of a saturated solution of NH_4Cl. The water layer was extracted with ether and the ether extract dried over Na_2SO_4. The solvent was evaporated under vacuum to give a residue, which was chromatographed on SiO_2. Elution with $CHCl_3$ yielded alcohol **17** (123 mg).

The IR, NMR, and mass spectra were found to be identical with those of β-monocyclonerolidol (**3**).

Isolation of Ptychanolide (**4**). The crude ptychanolide (F-2 and F-2′) was recrystallized with hexane–EtOAc to yield colorless needles (**4**, 270 mg, 120 mg), mp 143—144 °C, $[\alpha]_D^{24}$ +23.2° (*c* 0.47, $CHCl_3$); IR (KBr) 1780 cm^{-1}; ^1H NMR δ 0.79, 0.93 (3H each, s, 4-CH_3, 8-CH_3), 0.84 (3H, d, J=7.7 Hz, 1-CH_3), 0.98 (3H, d, J=7.7 Hz, 5-CH_3), 1.3—1.4 (2H, m, 2-H_A, 3-H_A), 1.39 (1H, d, J=13.6 Hz, 7-H_A), 1.71 (1H, m, 2-H_B), 1.87 (1H, m, 3-H_B), 1.99 (1H, d, J=13.6 Hz, 7-H_B), 2.38 (1H, m, 1-H), 2.61 (1H, q, J=7.7 Hz), 3.55 (1H, d, J= 2.4 Hz, 9-H and 5.52 (1H, d, J=2.4 Hz, 10-H); ^{13}C NMR δ 10.7 (q), 14.5 (q), 16.7 (q), 18.4 (q), 31.0 (t), 35.5 (t), 44.6 (t), 42.0 (d), 50.0 (d), 54.4 (s), 55.3 (s), 56.3 (s), 57.5 (d), 76.1 (d), 179.8 (s); MS *m/z* (%) 250 (6, M^+), 235 [13, $(M-CH_3)^+$], 205 (24), 109 (100). Found: *m/z* 250.1565. Calcd for $C_{15}H_{22}O_3$: M, 250.1564.

Hydrolysis of Ptychanolide (**4**). After 10% aqueous H_2SO_4 was added to a solution of ptychanolide **4** (20 mg) in acetone (2 ml) at 0 °C, the mixture was kept at room temperature for 3 h. The reaction mixture was diluted with H_2O and extracted with $CHCl_3$. The $CHCl_3$ layer was washed with a saturated solution of $NaHCO_3$ and H_2O, and dried over Na_2SO_4. The solvent was removed under reduced pressure to give residue (24 mg), which was chromatographed on SiO_2. Elution with $CHCl_3$–MeOH (15 : 1) gave diol lactone **18** (17 mg), colorless powder, IR ($CHCl_3$), 3500, 1770 cm^{-1}; ^1H NMR δ 0.84 (3H, d, J=7.5 Hz, 1-CH_3), 0.80, 0.91 (3H each, s, 4-CH_3, 8-CH_3), 1.07 (3H, d, J=7.5 Hz, 5-CH_3), 2.67 (1H, q, J=7.5 Hz, 5-H), 4.13 (1H, d, J=2.0 Hz, 9-H) and 5.62 (1H, d, J=2.0 Hz, 10-H); MS *m/z* (%) 268 (trace, M^+, $C_{15}H_{24}O_4$), 250 [4, $(M-H_2O)^+$], 193 (100), 165 (98), 109 (97), 55 (32).

Reduction of Ptychanolide (**4**) *with Lithium Aluminium Hydride*. A solution of ptychanolide **4** (75 mg) in dry ether (2 ml) was added to an ice-cooled solution of LAH (100 mg) in dry ether (4 ml). After addition, the reaction mixture was stirred at room temperature for 2 h followed by the usual work-up afforded a residue. The residue was chromatographed on SiO_2 using $CHCl_3$–MeOH (15 : 1) to give triol **19** (75 mg). recrystallization of triol **19** from MeOH yielded colorless plates, mp 118—119 °C, $[\alpha]_D^{28}$ −40.0° (*c* 1.04, $CHCl_3$); IR ($CHCl_3$) 3420, 3250 cm^{-1}; ^1H NMR δ 0.69, 0.82 (3H each, s, 4-CH_3, 8-CH_3), 0.81 (3H, d, J=7.7 Hz, 1-CH_3), 1.16 (3H, d, J=7.7 Hz, 5-CH_3), 1.10 (1H, d, J=13.6 Hz, 7-H_A), 1.42 (1H, d, J=13.6 Hz, 7-H_B), 2.15 (1H, q, J=7.7 Hz, 5-H), 2.65, 3.20 (1H each, m, OH), 3.26 (1H, br.s, OH), 3.64, 3.84 (1H each, AB type, J=14.4 Hz, $-C\underline{H}_2OH$), 3.72 (1H, dd, J= 7.2, 14.4 Hz, $-CH-HC\underline{H}-OH$), 3.76 (1H, dd, J=4.0, 14.4 Hz, $-CH-HC\underline{H}-OH$) and 3.92 (1H, dd, J=4.0, 7.2 Hz, $-C\underline{H}-(OH)-CH_2OH$); MS *m/z* (%) 225 [75, $(M-31)^+$], 207 (80), 189 (58), 109 (100). Found: C, 69.98; H, 11.04%. Calcd for $C_{15}H_{28}O_3$: C, 70.27; H, 11.01%.

Oxidation of Triol **19** *with* $NaIO_4$. A solution of $NaIO_4$ (25 mg) in H_2O (1 ml) was added to a solution of triol **19** (20 mg) in MeOH (1 ml) and the mixture was stirred at room temperature for 3 h. The reaction mixture was diluted with H_2O and extracted with ether. The residue after usual treatment was chromatographed on SiO_2 and elution with $CHCl_3$–MeOH (25 : 1) afforded aldehyde **20** (16 mg), colorless oil, $[\alpha]_D^{25}$ −3.3° (*c* 0.42, $CHCl_3$); IR (film) 3560, 3450, 1715 cm^{-1}; ^1H NMR δ 0.81 (6H, s, 4-CH_3, 8-CH_3), 0.89 (3H, d, J=7.5 Hz, 1-CH_3), 0.92 (3H, d, J=7.5 Hz, 5-CH_3), 3.55, 3.94 (1H each, d, J=11.0 Hz, $C\underline{H}_2OH$) and 9.69 (1H, s, CHO); MS *m/z* (%) 224 (2, M^+), 206 [15, $(M-H_2O)^+$], 195 (51), 181 (100), 109 (90). Found: *m/z* 224.1771. Calcd for $C_{14}H_{24}O_2$: M, 224.1768.

Oxidation of Aldehyde (**20**) *with MCPBA*. A solution of aldehyde **20** (16 mg) in CH_2Cl_2 (1 ml) was added to a solution of MCPBA (20 mg) and the mixture stirred at room temperature for a day. Then the reaction mixture was treated with Al_2O_3 for 30 min. Al_2O_3 was removed by filtration and the solvent was evaporated to give a residue, which was purified by column chromatography on SiO_2. Elution with $CHCl_3$–MeOH (15 : 1) gave diol **21** (12 mg), colorless oil, $[\alpha]_D^{23}$ −18.4° (*c* 0.57, $CHCl_3$); IR (film) 3325, 1050 cm^{-1}; ^1H NMR δ 0.88 (3H, d, J=7.5 Hz, 1-CH_3), 0.89, 0.93 (3H each, s, 4-CH_3, 8-CH_3), 0.90 (3H, d, J=7.5 Hz, 5-CH_3), 1.47 (1H, d, J= 13.5 Hz, 7-H_A), 1.92 (1H, d, J=13.5 Hz, 7-H_B), 3.42 (2H, AB q, J=11.0 Hz, $-C\underline{H}_2OH$); MS *m/z* (%) 212 (3, M^+, $C_{13}H_{24}O_2$), 194 [5, $(M-H_2O)^+$], 181 [100, $(M-31)^+$], 163 (62), 137 (53), 109 (97).

Oxidation of Diol **21** *with* $NaIO_4$. A solution of $NaIO_4$ (20 mg) in H_2O (1 ml) was added to a MeOH (1.5 ml) solution of diol **21** (17 mg) and the mixture was stirred at room temperature for a day. The reaction mixture was diluted with H_2O and extracted with hexane. The solvent was removed under vacuum to give a residue (15 mg), which was chromatographed on SiO_2. Elution with CH_2Cl_2 yielded ketone **22** (9 mg), colorless oil, CD, $\Delta\varepsilon_{295}$ +2.6 (*c* 0.0115, MeOH); IR (film) 1740 cm^{-1}; ^1H NMR δ 0.81, 0.87 (3H each, s, 4-CH_3, 8-CH_3), 0.93, 0.95 (3H each, d, J=7.5 Hz, 1-CH_3, 5-CH_3), 1.55 (1H, d, J=13.5 Hz, 7-H_A), 2.32 (1H, d, J=13.5 Hz, 7-H_B) and 2.27 (1H, q, J=7.5 Hz, 5-H); MS *m/z* (%) 180 (82, M^+, $C_{12}H_{20}O$), 165 [33, $(M-CH_3)^+$], 123 (46), 109 (100), 82 (88).

Reduction of Ketone **22** *with Lithium Aluminium Hydride*. A mixture of ketone **22** (9 mg) and LAH (20 mg) in dry ether (3 ml) was stirred at room temperature for 2 h. The reaction mixture was treated in the usual way to give a residue (9 mg), which was purified by column chromatography on SiO_2. Elution with $CHCl_3$ gave a minor alcohol **24** (2 mg), colorless oil, IR (film) 3430 cm^{-1}; ^1H NMR δ 0.84, 0.90 (3H each, s, 4-CH_3, 8-CH_3), 0.84 (3H, d, J=7.7 Hz, 1-CH_3), 0.91 (3H, d,

J=7.7 Hz, 5-CH_3), 1.42 (1H, dd, J=5.4, 13.6 Hz, 7-H_A), 1.95 (1H, dd, J=7.2, 13.6 Hz, 7-H_B), 1.77 (1H, m, 1-H), 1.87 (1H, dq, J=7.2, 7.7 Hz, 5-H) and 4.20 (1H, dt, J=5.4, 7.2 Hz, 6-H). Successive elution with the same solvent gave a major alcohol **23** (5 mg), colorless oil, IR (film) 3450 cm^{-1}; ^1H NMR δ 0.75 (6H, s, 4-CH_3, 8-CH_3), 0.84 (3H, d, J=7.7 Hz, 1-CH_3), 0.91 (3H, d, J=7.7 Hz, 5-CH_3), 1.49 (1H, dd, J=7.7, 13.6 Hz, 7-H_A), 1.74 (1H, dq, J=9.4, 7.7 Hz, 5-H), 1.79 (1H, dd, J=7.7, 13.6 Hz, 7-H_B), 2.01 (1H, tq, J=7.2, 8.1 Hz, 1-H), 3.77 (1H, dt, J=9.4, 7.7 Hz, 6-H); MS m/z (%) 164 [32, $(M-H_2O)^+$], 149 [100, $(M-18-15)^+$].

*Conversion of Ketone **22** into Hydrocarbon **25**.* A mixture of ketone **22** (10 mg) in 1,2-ethanedithiol (0.1 ml) and BF_3–Et_2O (2 drops) was kept at room temperature for 2 h. The reaction mixture was poured into ice-water, and extracted with ether. The ether layer was washed with a saturated solution of $NaHCO_3$ and H_2O, and dried over Na_2SO_4. The solvent was removed under vacuum to give a residue, which was desulfurized with Raney Ni (W-4, 50 mg) in EtOH (1.5 ml) under reflux for 2 h. The reaction mixture was filtered and the filtrate was diluted with H_2O, and extracted with pentane. The solvent was removed with N_2 gas to give a colorless residue, which was subjected to GC separation to yield hydrocarbon **25** (4 mg), colorless oil, ^1H NMR δ 0.73 (6H, s, 4-CH_3, 8-CH_3), 0.83 (6H, d, J=7.7 Hz, 1-CH_3, 5-CH_3), 1.27 (2H, m, 3-H_A, 7-H_A), 1.30 (2H, m, 2-H_A, 6-H_A), 1.50 (2H, m, 3-H_B, 7-H_B), 1.73 (2H, m, 2-H_B, 6-H_B), and 1.85 (2H, m, 1-H, 5-H); ^{13}C NMR δ 15.0, 18.0, 31.7, 37.5, 44.4, 53.7; MS m/z (%) 166 (9, M^+, $C_{12}H_{22}$), 151 [51, $(M-CH_3)^+$], 109 (61), 84 (100).

We wish to thank Dr. Jiro Hasegawa of Kyoto Univ. for identification of *Ptychanthus striatus* (LEHM. et LINDENB.) NEES, to Professor Yoshinori Asakawa of Tokushima Bunri Univ. for supply of deoxopinguisone and Professor Koji Nakanishi of our institute director for many discussions.

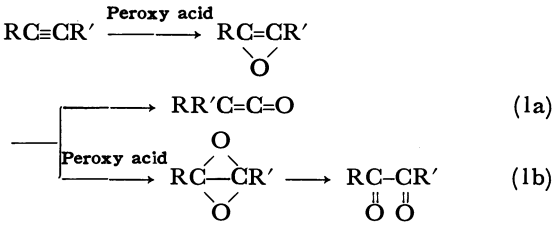
Mechanism for the Oxidative Cleavage of Electron-deficient Acetylenes with Alkaline Hydrogen Peroxide[1]

Yasuhiko SAWAKI,* Hiroshi INOUE, and Yoshiro OGATA
Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464
(Received August 26, 1982)

4-Phenyl-3-butyn-2-one (**1a**) was effectively cleaved by alkaline hydrogen peroxide to afford benzoic and acetic acids. The rate ratio for the addition of HOO^- and HO^- to **1a** resulted in $k_{HOO^-}/k_{HO^-}=1400$, which is comparable to that of benzylideneacetone. The major reaction of the cleavage proceeds *via* benzoylacetone. As a minor pathway, α-keto oxirene intermediate is formed and rearranges only to α-benzoylpropionate in a different way from the corresponding diketo carbene. α-Keto esters are found to be converted by HOO^- to α-alkoxy ketones *via* a novel oxidative substitution of ester group. Methyl phenylpropiolate is oxidized by HOO^- similarly as **1a**. The mechanism is discussed on the basis of oxirene intermediate inconvertible to keto carbene.

The peroxy acid oxidation of acetylenes is understood much less than that of olefins;[2] its mechanism has been discussed in relation to oxirene and keto carbene intermediates.[2,3] The two intermediates are also interested theoretically[4a,b] since oxirenes are anti-aromatic 4π-electron species.[4c] Recently, we have reported that oxirene intermediates produced from phenylacetylenes and peroxy acid are further oxidized or rearrange to ketenes (Eq. 1), but are not convertible to keto carbenes.[5]



Acetylenes are known to be less reactive toward electrophiles but more reactive toward nucleophiles than olefins.[6] Although the epoxidation of α-keto olefins with alkaline hydrogen peroxide is well known,[7] few is known about the nucleophilic oxidation of acetylenes by peroxides. We were interested in the alkaline hydrogen peroxide oxidation of electron-deficient acetylenes,[8] and herein wish to summarize our mechanistic study on the facile C–C cleavage. A study on similar cleavage of acetylenes has appeared,[9] but mechanistic details are still unclear.

Results and Discussion

Oxidative Cleavage of Acetylenes with HOO^-. An attempted oxidation of phenylacetylene with alkaline hydrogen peroxide (HOO^-) was ineffective, but electron-deficient acetylenes are smoothly cleaved by HOO^-. Thus, the oxidation of 0.1 M 4-phenyl-3-butyn-2-one (**1a**) with 1 M H_2O_2 and 0.2 M NaOH in 50% EtOH was complete within 2 h at room temperature (1 M=1 mol dm^{-3}). One molar acetylene consumed

$$\underset{\textbf{1a}}{PhC{\equiv}CCOMe} \xrightarrow{HOO^-} \underset{95\%}{PhCO_2H} + \underset{93\%}{MeCO_2H} + \underset{48\%}{CO_2} \qquad (2)$$

three moles of H_2O_2, affording high yields of benzoic and acetic acids; the yield of CO_2 was not quantitative and formic acid was detectable.

Similar oxidation of methyl phenylpropiolate ($PhC{\equiv}CCO_2Me$, **1b**) with excess HOO^- afforded $PhCO_2H$ (99%) and CO_2 (96%). Here, 96% yield of CO_2 does not mean quantitative one since **1b** possesses two carbons available for decarboxylation. As the excess amount of H_2O_2 was decreased, the hydrolysis of **1b** became a major path and the resulting propiolate ion was quite stable toward HOO^-. 55—70% yields of C–C cleavage has been reported for the case of 4-phenyl-3-butyn-2-ones,[9] but present results indicate that almost quantitative cleavage may be accomplished by using excess H_2O_2 in aqueous alcohols.

Kinetics. The rate of addition of HOO^- to acetylene **1a** was determined in water by following the decrease of **1a** using excess H_2O_2. The rate increased linearly with $[HO^-]$ up to pH 11, reaching a constant value at pH>12 and pK_a of H_2O_2 is 11.37; hence the rate quation satisfies Eq. 3.

$$v = k_2[PhC{\equiv}CCOMe][HOO^-] \qquad (3)$$

The rate constants, $10\,k_2$, for **1a** are 1.04, 1.39, 1.97, 2.50, and 3.47 $M^{-1}\,s^{-1}$ at 15.0, 20.0, 25.0, 30.0, and 35.0 °C, respectively, at pH 11.2 (Na_2CO_3 buffer). For comparison, the epoxidation rate of benzylideneacetone (**2**) was also determined; $10\,k_2$=1.40, 1.76, 2.32, 3.03, and 3.79 $M^{-1}\,s^{-1}$, respectively. The resulting activation parameters are listed in Table 1.

The addition rate of HO^- (0.05—0.28 M) for **1a** to form benzoylacetone was found to be a combination of two- and third-order kinetics (Eq. 4).

$$v = \{k_2[HO^-]+k_3[HO^-]^2\}[PhC{\equiv}CCOMe] \qquad (4)$$

The third-order kinetics suggest a base-catalysis by second HO^- ion, *i.e.*, an attack with $HO^-\cdots HO^-$. Similar third-order kinetics are known for nucleophilic additions[11] such as hydrolysis[12] and aminolysis[13] of esters.

It is generally accepted that acetylenes are more susceptible to nucleophilic attacks than olefins.[6] But acetylene **1a** and olefin **2** have rates of similar magnitude for both additions of HOO^- and HO^-. A small kinetic differences between **1a** and **2** lies in the change in activation parameters; while the activation enthalpy (ΔH^*) for acetylene **1a** is slightly higher than olefin **2**, entropy requirement for **1a** is substantially smaller. The larger entropy loss for olefin **2** is probably due to the rather restricted orientation in the Michael addition

TABLE 1. KINETIC DATA FOR THE ADDITION OF HOO^- AND HO^- TO PhC≡CCOMe (**1a**) AND PhCH=CHCOMe (**2**) IN WATER AT 25.0 °C[a)]

Substrate	Nucleophile	k_2 / $M^{-1}\,s^{-1}$	k_3 / $M^{-2}\,s^{-1}$	ΔH^* / kcal mol^{-1}	ΔS^* / e.u.	α-Effect
1a	HOO^-	1.67×10^{-1}		11.0	−18	1.39×10^3
	HO^-	1.20×10^{-4}	8.5×10^{-3}			
2	HOO^-	2.20×10^{-1}		9.1	−24	1.92×10^3
	HO^-	1.14×10^{-4}	2.2×10^{-4}			

a) The oxidation was conducted with 5×10^{-5} M substrate and 2—10 mM H_2O_2 in an aqueous buffer of 0.1 M Na_2CO_3. The addition reaction of HO^- was carried out with 5×10^{-5} substrate and and 0.05—0.3 M NaOH. The rates were monitored by the decrease of UV absorbance of **1a** or **2**. Notations for k_2 and k_3 are shown in Eqs 3 and 4.

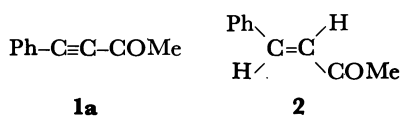
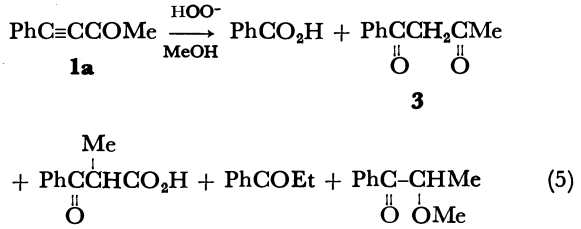
to the planar olefin. On the other hand, the addition to linear acetylenic moiety of **1a** requires smaller restriction on orientation, thus lowering entropy loss in attaining the transition state.



1a **2**

The rate ratio of HOO^- *vs* HO^- is known to exhibits a large α-effect;[14] *e.g.*, the α-effect in the addition to nitriles is in the range of 3000—10000.[15] The ratios k_{HOO^-}/k_{HO^-} for the present reaction are 1400 and 1900 for acetylene **1a** and olefin **2**, respectively (Table 1). A trend has been noted that nucleophilic additions to sp carbon exhibit a larger α-effect than addition to sp^2 carbon.[16] But no significant difference was found between acetylene **1a** (*i.e.*, sp carbon) and olefin **2** (*i.e.*, sp^2 carbon). It seems that there is no single factor to govern the α-effect, although several explanations have been noted on the origin of the effect.[17]

Intermediates. In order to clarify the oxidation mechanism, searches for intermediates were carried out with 1 h reaction in MeOH. GLC, NMR, and GC-MS analyses indicated several intermediates during the oxidation with HOO^- (Table 2). Considerable amounts of adducts with solvent MeOH were produced when **1a** : H_2O_2 was 1 : 1, but became negligible with **1a** : H_2O_2=1 : 5. Products from **1a** and HOO^- are shown in Eq. 5; major intermediates were benzoylacetone **3** and α-benzoylpropionic acid **4**. Minor byproducts were propiophenone **5** and α-methoxypropio-

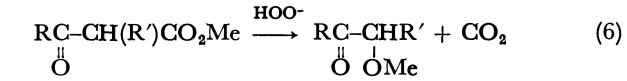


1a **3**

4 **5** **6a** (5)

phenone **6a**, both of which were shown to be produced from methyl α-benzoylpropionate (**7a**) by a control experiment.

The reaction of methyl phenylpropiolate (**1b**) with HOO⁻ afforded, in addition to benzoic and phenylpropiolic acids, methyl benzoate, acetophenone, and α-methoxyacetophenone in MeOH (Table 2). Again, control experiments revealed that the latter two products



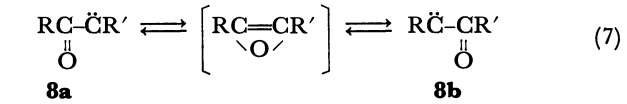
(6)

7 **6**

a, R=Ph, R′=Me
b, R=Ph, R′=H
c, R=Me, R′=Ph

are formed from methyl benzoylacetate (**7b**) and HOO⁻. Thus the formation of α-alkoxy ketones (**6**) from β-keto esters is a novel oxidative substitution of ester group (Eq. 6). The yield of **6** is 33, 19, and 39% from **7a**, **7b**, and **7c**, respectively. For the case of **7b**, its reaction with MeONa alone yielded methyl phenylacetate *via* MeO⁻-catalyzed deacylation.

Decomposition of Diazo Diketone. In the decomposition of α-diazo ketones, ketocarbene-ketocarbene interconversions have been proved experimentally, where oxirenes are often supposed to be an intermediate (Eq. 7).[18] On the other hand, it is reasonable to assume



(7)

8a **8b**

that acetylenes are attacked electrophilically by peroxy acid to form oxirenes in analogy with olefin epoxidation.[3,5] Likewise, a generation of oxirene intermediate is conceivable in the present nucleophilic oxidation of acetylene **1a** or **1b** with HOO⁻.[9] In order to check the intermediacy of oxirene and/or keto carbene, the decomposition of 2-diazo-1-phenyl-1,3-butanedione (**9**) was carried out in alcohols (Table 3). Major products *via* carbene **10** were rearranged esters (**11** and **12**), O–H inserted diketones **13** and **14** (Eq. 8), diketone **14** being formed *via* O–H insertion of isomerized keto carbene from **10**. Benzoylacetone **3**, a hydrogen abstraction

Table 3. Photolysis and thermolysis of diazo ketone (**9**)[a]

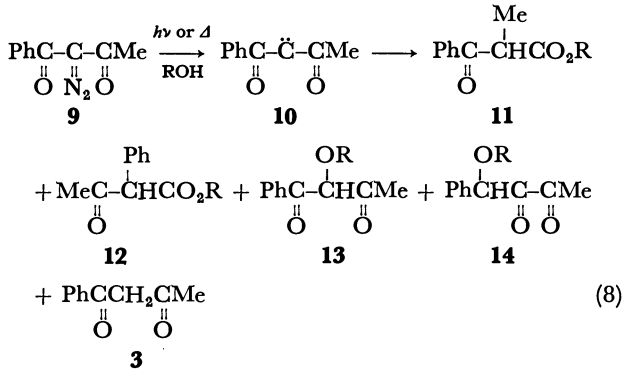
	Δ(95 °C)/4 h	16	27	16	≈12	8

a) A solution of 0.02 M **9** was photolyzed at room temperature or thermolyzed under air unless noted otherwise. b) Products were detemined by NMR, GLC, and GC-MS. The structure of diketone **14** was deduced from its GC-MS spectra although it could not be isolated.

product, was negligible in MeOH (Eq. 8). The product ratios were not changed largely by changing the decomposition conditions, *e.g.*, wavelength of irradiating light,[19] air, or temperature. Somewhat different ratio



(8)

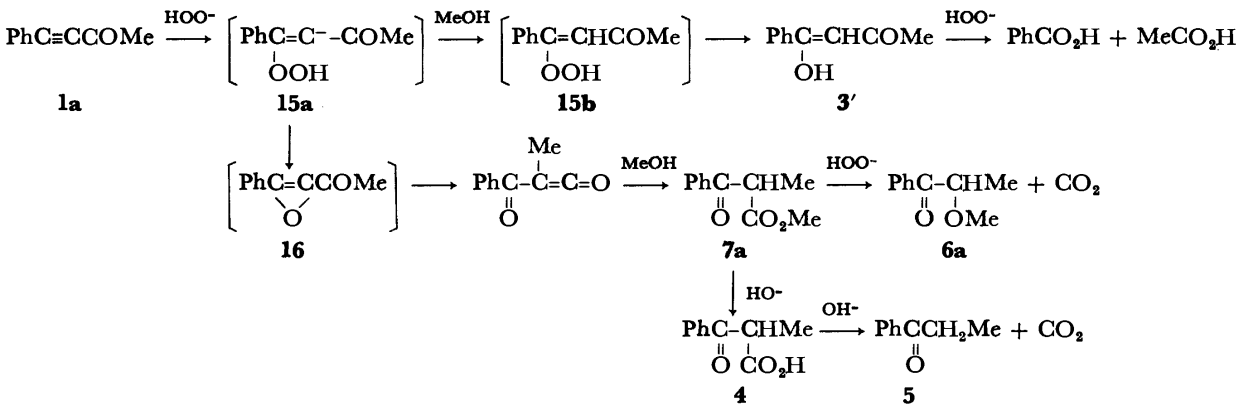
9 **10** **11** **12** **13** **14** **3**

of products has been reported for the photolysis of **9**.[21] The present values are more accurate since the reaction mixture was analyzed directly by NMR and GLC. At any rate, it is apparent that β-diketone **3** is not formed in MeOH and the Wolff rearrangement afforded two products **11** and **12** by methyl and phenyl migration.

Oxidation Mechanism. One of mechanistic points for the HOO⁻ oxidation of electron-deficient acetylenes lies in the intermediacy of oxirene and/or keto carbene. As noted above, acetylbenzoylcarbene **10** affords two products *via* the Wolff rearrangement (*i.e.*, **11** and **12** by Me and Ph migration), but benzoylacetone **3** is not formed in MeOH. In contrast, major primary products for the reaction of **1a** and HOO⁻ are β-diketone **3** and rearranged ester **7a**, which is converted to hydrolyzed acid **4**, propiophenone **5**, and α-methoxypropiophenone (**6a**) (Eq. 5). It is noteworthy that any products (*e.g.*, methyl phenylacetate or α-methoxybenzyl methyl ketone (**6c**)) were not detectable. Therefore, keto carbene (*e.g.*, **10**) is not involved in the HOO⁻ oxidation of **1a**, excluding an equilibrium reaction such as Eq. 7. This is consistent with our recent results not involving ketocarbene in the electrophilic oxidation of phenylacetylenes with peroxy acid.[5] According to calculation by MINDO/3 method oxirene is more stable than keto carbene,[22] but more rigorous ab initio methods leads to a reverse result.[23] Our previous[5] and present studies suggest a rearrangement *via* oxirene itself and a significant energy barrier in isomerization between oxirene and keto carbene.

A reasonable pathway for the nucleophilic oxidation of **1a** would then be formulated as Scheme 1. The addition of HOO⁻ to **1a** produces **15a**, which cyclizes to form α-keto oxirene **16** or is protonated to yield adduct **15b**.[24] For the case of olefinic ketones, the cyclization to epoxides is very facile.[7] But for acetylenic ketones the cyclization to oxirene **16** would be significantly retarded owing to its large strain energy.[25]

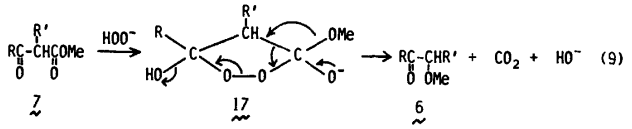
Recently we have reported that the migration aptitude in oxirene rearrangement (*i.e.*, H≫Me>Ph) is in line with that of the Wolff rearrangement of keto carbene.[5] In fact, the rearrangement of ketocarbene **10** afforded two products **11** and **12** by Me and Ph migration, respectively. In contrast, the present oxidation of **1a** with HOO⁻ yielded only **7a** as a rearranged product.



Scheme 1.

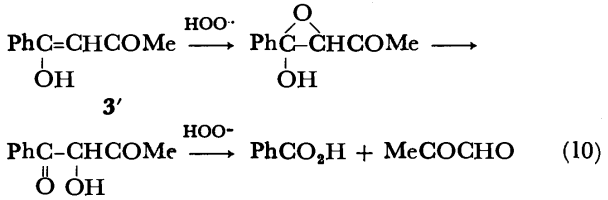
This is comprehensible because oxirene **16** is unsymmetrically substituted and the two groups are attacked to different migration origins, *i.e.*, methyl group to carbonyl and phenyl group to oxirene. Methyl migration in oxirene **16** affords β-benzoyl ester **7a** *via* ketene. Subsequent decarboxylation of β-keto acids is well known.[26]

The novel reaction of β-keto esters with HOO^- to afford α-alkoxy ketones is interesting mechanistically. An appropriate scheme for this oxidative substitution is outlined in Eq. 9, which is somewhat similar to the ring contruction of β-diketones with H_2O_2 (*e.g.*, the synthesis of cyclopentanecarboxylic acid from α-acylcyclohexanone).[27]



(9)

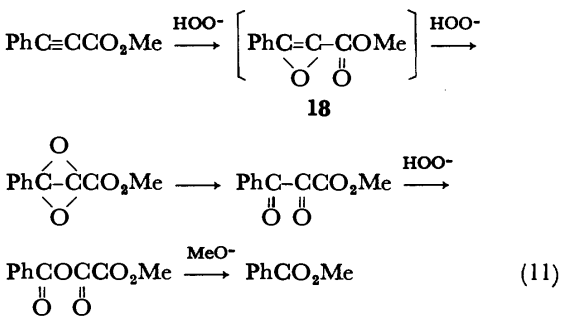
As a major pathway for the HOO^- oxidation of **1a**, carbanion **15a** is protonated to form olefinic hydroperoxide **15b**, which would be promptly decomposed into β-diketone **3** (or its enol **3'**).[28] The diketone **3** could be isolated in *ca.* 30% yield from the reaction mixture at an earlier stage. A possible scheme for the cleavage of **3** is probably *via* an epoxidation of enol **3'** (Eq. 10).[29]



(10)

The facile cleavage of α-hydroxy ketones with HOO^- is reported previously.[30a] The involvement of pyruvaldehyde is in agreement with a fact that CO_2 yields from the aldehyde were in the same range (40—50%) with those from diketone **3'** when treated with a mixture of 1.2 M H_2O_2 and 0.2 M NaOH in 50% EtOH.[30b]

The HOO^- oxidation of **1b** would proceed similarly as Scheme 1. The formation of methyl benzoate seems to suggest a diepoxide pathway (Eq. 11). Since methoxyl group in **18** is probably of very low migratory aptitude, oxirene **18** is further oxidized to diepoxide and then to α-diketone. Ester formation from α-diketone and HOO^-/MeO^- is established.[31]



(11)

In conclusion, acetylenic ketone **1a** is cleaved efficiently by HOO^-, β-diketone **3** being a predominant intermediate. α-Keto oxirene is probably formed even as a minor pathway and affords rearranged products in a different way from the corresponding diazo ketone. β-Keto esters are found to be oxidized by HOO^- to α-alkoxy ketones *via* a novel oxidative substitution of ester group.

Experimental

IR and NMR spectra were recorded on a Parkin-Elmer 337 and a Hitachi R-24 spectrometer, respectively. GLC analysis was carried out by a Yanagimoto G-180 gas chromatograph using biphenyl as an internal standard and three columns: PEG 20M, 10% on Chromosorb WAW, 1 m; Silicon OV-17, 5% on Shimalite W, 1 m; Apiezone GE 15% and 5% H_3PO_4 on Celite 545, 1.5 m. GC-MS spectra were recorded on a JEOL JMS D300 mass spectrometer.

Materials. 4-Phenyl-3-butyn-2-one (**1a**),[32] methyl phenylpropiolate (**1b**),[33] and methyl α-benzoylpropionate (**7a**)[34] were prepared by the literature methods. Methyl α-acetylphenylacetate (**7c**) was prepared from α-phenylacetoacetonitrile.[35] α-Methoxypropiophenone (**6a**) and α-methoxy-α-phenylacetone (**8c**) were obtained by BF_3-catalyzed decomposition[36] of α-diazopropiophenone[37] and 1-diazo-1-phenyl-2-propanone.[38] 2-Diazo-1-phenyl-1,3-butanedione (**9**) was synthesized from benzoylacetone and tosyl azide.[39] Purities of these materials were checked by NMR and/or GLC analysis.

Oxidation of 4-Phenyl-3-butyn-2-one (1a) with HOO^-. In a 50-ml flask were added EtOH (6 ml), 4 M H_2O_2 (12 ml), **1a** in EtOH (1 M×2 ml), water (10 ml), 10^{-2} M EDTA (2 ml), and 1 M NaOH (8 ml). After 10 h at 25 °C, 1 M HCl (10 ml) was added and evolved CO_2 gas was determined by titration with aqueous $Ba(OH)_2$. Then the reaction mixture was

diluted with saturated NaCl and extracted three times with ether. Benzoic and acetic acids were determined by GLC after methylation with diazomethane.

In another run, benzoylacetone **3** could be isolated from 15 min reaction of 0.08 M **1a**, 0.17 M H_2O_2, and 0.17 M NaOH in 50% EtOH at 25 °C. After acidification with HCl, dilution with water, and extraction with ether, 30% of **3** was isolated by column chromatography using Mallinckrodt silica gel (100 mesh, pH 4) and petroleum ether–chloroform (2 : 1). Its NMR and IR spectra were identical with those of authentic sample.

The addition rate of HOO^- was followed by UV absorbance of **1a** at 277 nm in water. The reaction was conducted with 5×10^{-5} M **1a** and 2—10 mM H_2O_2 in buffered aqueous solution. The results are listed in Table 1.

Decomposition of 2-Diazo-1-phenyl-1,3-butanedione (9). Photolysis of **9** was conducted with a low pressure (254 nm) or medium pressure Hg lamp (>290 nm through Pyrex filter). Typically, a solution of 0.02 M **9** in alcohol was photolyzed for 4—8 h at room temperature. Thermolysis was carried out at 80 °C in MeOH or 90 °C in EtOH. The products were identified and determined by NMR, GLC and/or GC-MS analyses.

NMR and GC-MS Data. NMR data for products and authentic sample are as follows (δ, $CDCl_3$). Benzoylacetone (**3**): 2.17 (s, 3H), 6.15 (s, 1H), 7.4—8.0 (m, 5H); minor keto isomer: 2.27 (s, 3H), 4.07 (s, 2H). Methyl α-benzoylpropionate (**7a**): 1.50 (d, J=5.6 Hz, 3H), 3.68 (s, 3H), 4.41 (q, J=5.6 Hz, 1H), 7.4—7.6 (m, 3H), 7.9—8.1 (m, 2H). α-Methoxypropiophenone (**6a**): 1.43 (d, J=6.7 Hz, 3H), 3.29 (s, 3H), 4.42 (q, J=6.7 Hz, 1H), 7.4—7.6 (m, 3H), 7.9—8.2 (m, 2H). Methyl α-benzoylacetate (**7b**); keto isomer: 3.64 (s, 3H), 3.86 (s, 2H); enol isomer: 3.73 (s, 3H), 5.62 (s, 1H), 12.66 (s, 1H); 7.3—8.0 (m, 5H). Methyl α-acetylphenylacetate (**7c**): 2.06 (s, 3H), 3.65 (s, 3H), 4.52 (s, 1H), 7.23 (s, 5H). α-Methoxyacetophenone (**6b**): 3.40 (s, 3H), 4.50 (s, 2H), 7.4—7.6 (m, 3H), 7.85—8.04 (m, 2H). α-Methoxy-α-phenylacetone (**6c**): 2.11 (s, 3H), 3.89 (s, 3H), 4.67 (s, 1H), 7.39 (s, 5H); GC-MS, *m/e* (relative intensity), 43, 121 (100%), 164 (<1%).

2-Methoxy-1-phenyl-1,3-butanedione (**13**, R=Me): 2.24 (s, 3H), 3.30 (s, 3H), 7.2—7.6 (m, 5H), 14.95 (s, 1H); GC-MS, *m/e* (rel intensity), 105 (100), 118 (25), 150 (35), 160 (11), and 192 (3). 1-Methoxy-2-phenyl-1,3-butanedione (**14**, R=Me): 2.36 (s, 3H), 3.54 (s, 3H), 5.10 (s, 1H); GC-MS, *m/e* (rel intensity), 105 (18), 118 (60), 150 (100), 160 (27), and 192 (9). 2-Ethoxy-1-phenyl-1,3-butanedione (**13**, R=Et): 1.18 (t, J=5 Hz, 3H), 2.34 (s, 3H), 3.58 (q, J=5 Hz, 2H), 15.2 (s, 1H); GC-MS, *m/e* (rel intensity), 91 (4), 105 (100), 118 (21), 136 (11), 160 (14), 164 (36), and 206 (4). 1-Ethoxy-2-phenyl-1,3-butanedione (**14**, R=Et): 1.21 (t, J=5 Hz, 3H), 2.29 (s, 3H), 3.70 (q, J=5 Hz, 2H), 5.13 (s, 1H); GC-MS, *m/e* (rel intensity), 91 (9), 105 (17), 118 (49), 136 (30), 160 (34), 164 (100), 165 (11), and 206 (8).

Bitter Limonoids from the Fruit of *Melia azedarach* L. *var. japonica* Makino[1)]

Yoshiyasu FUKUYAMA,† Iwao MIURA,† and Masamitsu OCHI*
Faculty of Science, Kochi University, Akebono-cho, Kochi 780
†*Laboratories of Natural Products Chemistry, Otsuka Pharmaceutical Co. Ltd., Kawauchi-cho, Tokushima 771-01*
(Received August 27, 1982)

Two new bitter limonoids, ohchinolal (**1**) and ohchinin (**2**), have been isolated from the fruit of *Melia azedarach* L. *var. japonica* Makino, and their structures have been established as **1** and **2** by spectroscopic and chemical methods. The complete assignments of the ^1H and ^{13}C NMR data are described.

Recent investigations of the plants of the family Meliaceae have resulted in the isolation of many limonoids of biological interest, such as those with potent cytotoxic activity[2)] and with insect antifeedant and insecticidal properties.[3,4)] Our continuing search for biologically active constituents of *Melia azedarach* L. *var. japonica* Makino has now led to the isolation of two new bitter limonoids, designated as ohchinolal and ohchinin, the latter as the natural precursor of ohchinin acetate (**3**).[5)] The present paper deals with the structural determination of these new compounds.

Ohchinolal (**1**), $C_{34}H_{44}O_{10}$, mp 163—164.5 °C, $[\alpha]_D^{23}$

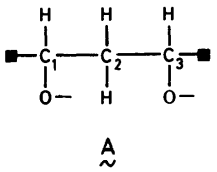
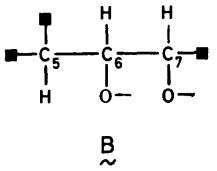
a) The spectra were measured at 100.61 MHz in $CDCl_3$ solutions, and the shifts are given in ppm (δ) relative to the internal TMS. Assignments were made by means of off-resonance and selective proton-noise decoupling techniques.

$+52°$ (c 0.22, EtOH), was isolated from the methanol extract of the fruit as colorless prisms in a 0.013% yield by means of extensive column chromatography. It had IR absorptions attributable to a hydroxyl group (3475 cm^{-1}) and a β-substituted furan ring (3150, 1500, and 875 cm^{-1}). The 400 MHz ^1H NMR spectrum showed signals due to three tertiary methyl groups at $\delta=1.00$, 1.08, and 1.41, one vinylic methyl group at $\delta=1.65$ (d, $J=1.4$ Hz), one acetyl group at $\delta=1.98$, one secondary hydroxyl group at $\delta=2.73$ (d, $J=9.2$ Hz), one ester methyl group at $\delta=3.23$, and one formyl group at $\delta=9.74$ (s). The presence of a tigloyl group was also evident from the ^1H NMR signals at $\delta=1.86$ (3H, dq, $J=7.0$ and 1.1 Hz), 1.94 (3H, dq, $J=1.6$ and 1.1 Hz), and 6.94 (1H, qq, $J=7.0$ and 1.6 Hz), and the MS fragment at m/z 529 [$M^+-CH_3CH=C(CH_3)-C\equiv O^+$]. In addition, extensive ^1H NMDR studies, as summarized in Table 1, revealed the presence of four partial structures (**A**), (**B**), (**C**), and (**D**), the last one showing the following long-range couplings: $J_{H_{15},H_{17}}=1.8$ Hz, $J_{H_{15},H_{18}}=1.4$ Hz, and $J_{H_{17},H_{18}}\approx 0.1$ Hz. The ^{13}C NMR data for **1**, obtained with the assistance of off-resonance and selective proton-noise decoupling techniques, showed the presence of another ester-type carbonyl carbon atom at δ_C 172.6, along with three methylene groups, three methine groups, five oxygen-bearing methine groups, three quaternary carbon atoms, and one tetrasubstituted double bond.

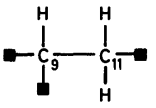
The spectral data and the analogy with the congeners isolated from Melia species[5,6] suggested a close structural relationship between **1** and salannin (**4**).[7] The lack of the ^{13}C NMR signal characteristic for the C_{28} of salannin-type limonoids around δ_C 78 and the paramagnetic shift of the ^1H NMR signal due to H_6 indicate the absence of the C_6–O–C_{28} ether linkage which exists in **4**. The location of the formyl group at C_{28} was revealed by the observation of a nuclear Overhauser effect (NOE) on H_5 (13%) upon the irradiation of the



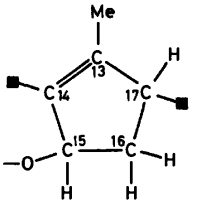
A



B



C



D

formyl proton. The positions of the secondary hydroxyl and tigloyloxyl groups were elucidated as follows. The oxidation of **1** with pyridinium chlorochromate, accompanied by the elimination of tiglic acid, gave an enone (**5**), $C_{29}H_{34}O_8$, as an oil. The ^1H NMR spectrum of **5** contained a typical AB quartet at $\delta=5.99$ and 6.99 ($J=10.3$ Hz, H_2 and H_1 respectively) indicative of an α,β-unsaturated ketone, while the irradiation of the methylene protons at C_{11} under NOE conditions produced a clear enhancement of the intensity of the latter signal (5.2%). This fact suggested the presence of a $-\underset{H}{C_1}=\underset{H}{C_2}-\underset{O}{C_3}-$ grouping in **5** and, hence, the location of the tigloyloxyl group at C_1 and the secondary hydroxyl group at C_3 in **1**. The appearance of the signal of H_6 in **1** at a lower field ($\delta=5.26$) as compared with that of **3** ($\delta=4.05$)[5] revealed the position of the remaining acetoxyl group at C_6.

The ^1H NMDR studies of **1** for the partial structure (**D**) elucidated the chemical shift and the coupling

5

constant values, as summarized in Table 1. From the examination of the J values and the model, it is concluded that H_{15} and H_{17} face opposite sides. The α-configuration for C_{17}-furan is common to all the limonoids;[8] consequently, the C_{15}-ether linkage of **1** must be β-oriented. The α-configuration of the C–O linkages at C_1, C_3, C_6, and C_7 was evident from the J values of their α-protons.[3a,5] From the evidence outlined above, we proposed Structure **1** for ohchinolal.

The second compound (**2**), $C_{36}H_{42}O_8$, mp 184—185 °C, $[\alpha]_D^{23}$ +64° (*c* 0.17, EtOH), was isolated in a 0.020% yield as colorless needles from the more polar fraction; it displayed spectral data similar to those of ohchinin acetate (**3**).[5] The only significant difference in their IR and ^{1}H NMR data was the replacement of the acetoxyl group in **3** by the secondary hydroxyl group [ν_{max} 3450 cm^{-1}; δ=2.46 (d, J=8.9 Hz, OH) and 3.75 (ddd, J=8.9, 3.0, and 3.0 Hz, H_3)] in **2**. This relationship was verified by the acetylation of **2**, which gave the acetate (**3**). Thus, the name "Ohchinin," which we reserved for the natural precursor of **3** in the previous paper,[5] must be assigned to Compound **2**.

Experimental

All the mps were determined on a Mitamura micro-melting-point apparatus and are uncorrected. The IR and UV spectra were recorded on a JASCO model A-202 spectrophotometer and a Hitachi 340 spectrophotometer respectively. The ^{1}H and ^{13}C NMR spectra were taken on a Bruker WH-400 instrument in $CDCl_3$ solutions, with TMS as the internal standard. A JASCO apparatus, model DIP-140, was used for the measurement of the rotations. Column chromatography was performed using neutral alumina (Merck, activity III) and silicic acid (Wakogel C-200).

Isolation. The air-dried and milled fruit (2 kg) of *Melia azedarach* L. *var. japonica* Makino collected in Tokushima City in February, 1980, was extracted with methanol (6 l) at room temperature for two weeks. The methanol extract was then concentrated up to about 0.5 l, water (0.1 l) was added, and it was washed with petroleum ether The aqueous methanol layer was diluted with water (0.5 l) and then extracted with dichloromethane. The dichloromethane layer was washed with water, dried over $MgSO_4$, and evaporated to dryness. Then the residue (50 g) was subjected to chromatography over neutral alumina (1 kg), eluting with benzene–ethyl acetate mixtures, the ethyl acetate increasing from 10 to 70%. Elution with 30% ethyl acetate in benzene gave a fraction (20 g) which was rechromatographed over silicic acid (600 g), using 60% ethyl acetate in hexane as the eluent, to yield ohchinolal (**1**) (380 mg). Subsequent elution with 80% ethyl acetate in hexane afforded ohchinin (**2**) (485 mg).

Ohchinolal (1). The crude material was recrystallized from ether to give colorless prisms (250 mg); mp 163—164.5 °C, $[\alpha]_D^{23}$ +52° (*c* 0.22, EtOH); IR (KBr) 3475, 3150, 1730, 1710, 1690, 1645, 1500, 1250, 1040, 970, and 875 cm^{-1}; UV (EtOH) 215 nm (ε 15000); ^{1}H NMR (see Table 1); ^{13}C NMR (see Table 2); MS (70 eV) *m/z* (rel intensity) 612 (M^+, 22), 584 ($M^+ - CO$, 2), 552 ($M^+ - AcOH$, 6), 529 ($M^+ - C_5H_7O$, 12), 314 (13), 273 (39), 231 (69), 174 (38), 83 ($C_5H_7O^+$, 81), 55 (86), and 43 (100). Found: *m/z* 612.2955. Calcd for $C_{34}H_{44}O_{10}$: M, 612.2934.

Ohchinin (2). The crude substance was recrystallized from methanol to yield colorless needles (400 mg); mp 184—185 °C, $[\alpha]_D^{23}$ +64° (*c* 0.17, EtOH); IR (KBr) 3450, 3140, 1725, 1695, 1625, 1570, 1300, 1264, 1160, 865, 795, and 770 cm^{-1}; UV (EtOH) 215 and 276 nm (ε 22000 and 19000 respectively); ^{1}H NMR (see Table 1); ^{13}C NMR (see Table 2); MS (70 eV) *m/z* (rel intensity) 602 (M^+, 65), 587 ($M^+ - CH_3$, 3), 471 ($M^+ - C_9H_7O$, 12), 283 (73), 259 (20), 230 (16), and 131 ($C_9H_7O^+$, 100). Found: *m/z* 602.2906. Calcd for $C_{36}H_{42}O_8$: M, 602.2933.

The Oxidation of 1 with Pyridinium Chlorochromate. To a suspension of pyridinium chlorochromate (100 mg) in dichloromethane (2 ml) we added a solution of **1** (20 mg) in dichloromethane (0.4 ml). The mixture was stirred for 5 h at room temperature. After dilution with dichloromethane (10 ml), the solution was shaken with a 0.1 M (1 M=1 mol dm^{-3}) aqueous NaOH solution (10 ml) and then separated. The organic layer was washed with water, dried over $MgSO_4$, and evaporated to dryness. The product was chromatographed over silicic acid (3 g), with 50% ethyl acetate in hexane as the eluent, to yield an enone (**5**) as a viscous oil (8 mg); IR ($CHCl_3$) 1730, 1670, 1610, 1490, 1220, 1020, 900, and 865 cm^{-1}; UV (EtOH) 220 nm (ε 9800); ^{1}H NMR ($CDCl_3$) δ= 1.30, 1.31, and 1.42 (3H each, s, 29-, 19-, and 30-H_3), 1.72 (3H, d, J=1.4 Hz, 18-H_3), 1.99 (3H, s, Ac), 2.07 (1H, ddd, J= 12.2, 8.1, and 8.1 Hz, 16β-H), 2.23 (1H, dd, J=12.2 and 6.5 Hz, 16α-H), 2.49 (1H, dd, J=15.7 and 4.9 Hz, 11-H_a), 2.56 (1H, dd, J=4.9 and 4.9 Hz, 9-H), 2.63 (1H, dd, J=15.7 and 4.9 Hz, 11-H_b), 3.57 (3H, s, OCH_3), 3.58 (1H, d, J=12.2 Hz, 5-H), 3.67 (1H, br d, J=8.1 Hz, 17-H), 4.12 (1H, d, J=2.8 Hz, 7-H), 5.27 (1H, dd, J=12.2 and 2.8 Hz, 6-H), 5.49 (1H, m, 15-H), 5.99 (1H, d, J=10.3 Hz, 2-H), 6.99 (1H, d, J=10.3 Hz, 1-H), 6.22, 7.21, and 7.34 (1H each, br s, 22-, 21-, and 23-H), and 9.35 (1H, s, 28-H); MS (70 eV) *m/z* (rel intensity) 510 (M^+, 9), 482 ($M^+ - CO$,9), 422 ($M^+ - CO - AcOH$, 3), 259 (14), 247 (21), 231 (36), and 43 (100). Found: *m/z* 510.2326. Calcd for $C_{29}H_{34}O_8$: M, 510.2254. The combined aqueous solution was acidified with 3 M hydrochloric acid and extracted with ether. The ethereal solution was washed with saturated brine, dried over $MgSO_4$, and evaporated to dryness to give an acidic fraction (4 mg), which was found to contain tiglic acid by means of TLC and MS comparison with an authentic sample [MS (70 eV) *m/z* (rel intensity) 100 (M^+, 96) 85 ($M^+ - CH_3$, 34), 82 ($M^+ - H_2O$, 32), and 55 ($M^+ - COOH$, 100)].

Acetylation of **2**. A solution of **2** (8 mg) in acetic anhydride (0.1 ml) and pyridine (0.4 ml) was allowed to stand at room temperature overnight and then worked up in the usual way. The product was recrystallized from ether–dichloromethane to give an acetate as colorless prisms (7 mg); it was identified by mixed mp, IR, and ^{1}H NMR comparison with ohchinin acetate (**3**) [mp 223—226 °C; IR (KBr) 3160, 3060, 1735, 1695, 1640, 1585, 1500, and 875 cm^{-1}; ^{1}H NMR: see Ref. 5].

The Synthesis and Studies of Several [2.2.2]Ferrocenophane Derivatives[1)]

Akira KASAHARA,* Taeko IZUMI, Iwao SHIMIZU, Tadashi OIKAWA, Hirosni UMEZAWA, and Isao HOSHINO

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992

(Received September 7, 1982)

Several ferrocenophanes, in which the two cyclopentadienyl rings are linked by acetylenic and olefinic bonds and aromatic rings, have been synthesized *via* the titanium-induced reductive coupling of the corresponding formyl compounds. The structures of these ferrocenophane compounds were determined by means of their IR and NMR spectra. The transannular π-electronic interactions between the two chromophores were examined on the basis of the electronic spectra.

Because of the topology and the mostly rigid molecular structure, a large number of layered compounds have been synthesized and their physical and chemical properties studied.[2)] Many ferrocenophanes of [*m*](1,1′)- or [*m.n*](1,1′)-type are known in which one or more intramolecular bridges link heteroannular positions with one or more ferrocene moieties; however, there have been only a few investigations of ferrocenophanes with interactions between the bridging elements. Tanner and Wennerstrom[3)] have recently reported the synthesis of [2.2.2.2]ferrocenophanetetraenes. Moreover, as a part of our studies of metallocenophane chemistry, we ourselves have reported the synthesis of [0]metacyclo-[2]metacyclo[0](1,1′)ferrocenophan-7-ene,[4)] in which substantial repulsive interactions exist between the two aromatic rings. These results have prompted us to study the synthesis of [2.2.2]ferrocenophane derivatives (**1**—**4**), in which the ferrocene moiety is linked by acetylenic and olefinic bonds and aromatic rings.

Results and Discussion

Although a number of synthetic methods have recently been developed for [2.2]cyclophane,[2)] the reductive coupling of carbonyl compounds with low-valent titanium reagents[5)] is still very convenient and advantageous for the synthesis of cyclophane because of the availability of the intermediary compounds.[3,4,6)]

In the present work, we applied the same method for the synthesis of [2.2.2]ferrocenophane derivatives; [2]paracyclo[2]paracyclo[2](1,1′)ferrocenophan-9-ene-1,17-diyne (**1**),[7)] [2]metacyclo[2]metacyclo[2](1,1′)ferrocenophan-9-ene-1,17-diyne (**2**), [2]orthocyclo[2]orthocyclo[2](1,1′)ferrocenophan-9-ene-1,17-diyne (**3**), and [2]paracyclo[2]paracyclo[2](1,1′)ferrocenophane-1,9,17 triene (**4**) were synthesized *via* the titanium-induced coupling of dialdehyde (**5a**—**d**). The syntheses of the intermediate dialdehydes; 1,1′-bis(*p*-formylphenylethynyl)ferrocene (**5a**), 1,1′-bis(*m*-formylphenylethynyl)ferrocene (**5b**), and 1,1′-bis(*o*-formylphenylethynyl)ferrocene (**5c**) were carried out by means of the palladium-catalyzed substitution[8)] of 1,1′-diiodoferrocene (**6**) with acetylenic compounds (**7a**—**c**), whereas another dialdehyde, 1,1′-bis(*p*-formylstyryl)ferrocene (**5d**), was prepared by the palladium-catalyzed substitution[9)] of **6** with *p*-formylstyrene (**7d**).

The reductive coupling reactions of dialdehyde (**5a**—**d**) with low-valent titanium reagents ($TiCl_4$–Zn[5a)] or $TiCl_3$–$LiAlH_4$[5b)]) using a high-dilution method led to the formation of ferrocenophanes (**1**—**4**), accompanied by the formation of the reduction products of **5a**—**d**. The structures of ferrocenophanes (**1**—**4**) were determined on the basis of the IR, NMR, and mass spectra and the elementary analyses.

The IR spectrum of **1** reveals the presence of triple and *cis* olefinic bonds, and the NMR spectrum includes the proposed structure. In the NMR spectrum of **1**, it is noteworthy that the vinylene protons (H_c), which can be easily assigned by means of their relative intensities, appear at a lower field than the aromatic protons, by analogy with the case of [2.2.2](1,3,5)cyclophane-1,9,17-triene (vinylene protons δ=7.37 ppm).[10)] In ferrocene, the distance between the two cyclopentadienyl rings is 3.32 Å.[11)] On the other hand, in **1** the molecule probably exists in the conformation illustrated by Structure 1, with the phenylethynyls approximately parallel to one another and approximately coplanar to the plane of the cyclopentadienyl ring. Thus, in **1**, substantial repulsive interactions must exist between the two phenylethynyl groups, which are bound together by a vinylene bridge at both ends. In the NMR spectrum of **1**, as expected, the aromatic protons (δ=6.47 and 6.82) appear at higher fields than the corresponding protons of the reference compounds, 1,1′-bis(*p*-tolylethynyl)ferrocene (**8a**) (δ=7.10 and 7.38). This phenomenon indicates that the two benzene rings in **1** are held face-to-face in close proximity by the vinylene bridge.

The NMR spectrum of **2** is also consistent with the proposed structure, and the stepped (*anti*) conformation is suggested by the large upfield shift ($\Delta\delta$, 0.59—0.76) for inner aryl protons (H_a) and the downfield shift of the outer aryl protons (H_b, H_c, and H_d) ($-\Delta\delta$, 0.08—0.13), compared with the corresponding signals of the reference compound, 1,1′-bis(*m*-tolylethynyl)ferrocene (**8b**).

On the other hand, in the NMR spectrum of **3**, the aromatic proton signals are observed at nearly the same positions as those of the reference compound, 1,1′-bis(*o*-tolylethynyl)ferrocene (**8c**). This suggests that the two aromatic rings in **3** are not held in a face-to-face conformation and that the *anti*-conformation for **3** is accommodated.

In the IR spectrum, Compound **4** showed the presence of *trans* and *cis* vinylene groups at 950 and 730 cm^{-1} respectively. Moreover, the NMR spectrum of **4** indicated the presence of the signals of two A_2X_2 patterns due to *p*-disubstituted aromatic (J=8 Hz) and

——: **4**, ------: **8d**.

trans vinylene protons (J=16 Hz), in addition to those attributable to 1,1′-disubstituted ferrocene and *cis* vinylene protons. These data are best explained by the parallel stacked configuration (**4**) rather than by the cross-stacked one (**4a**). The protons of aromatic and olefinic groups in **4** are shifted upfield by about 0.5 ppm compared with those of the reference compound, 1,1′-bis(*p*-methylstyryl)ferrocene (**8d**). This phenomenon may be caused by the diamagnetic shielding effect due to an overlapping of the two styryl groups.

The electronic spectra data of the cyclophane (**1**—**4**) and the reference compounds (**8a**—**d**) are summarized in Figs. 1—4. It is well known that the transannular electronic interaction in cyclophane results in the bathochromic and hyperchromic shifts of the absorption bands in its electronic spectrum and that the magnitude of these shifts can simply be utilized as a measure of the interaction.[2] Both phenylacetylene[12] and styrene[13] show no absorption in the long-wavelength region above 300 nm. The electronic spectra of **1**, **2**, and **4** show somewhat bathochromic and hyperchromic shifts and an unambiguous broadening in the range of 230—310 nm, especially as compared with those of the reference compounds, **8a**, **8b**, and **8d** respectively. This may be due to transannular π-electronic interactions between the two chromophores in **1**, **2**, and **4**. On the other hand, Compound **3** exhibits some hyperchromic shift in the 230—310 nm region; however the spectra are practically identical with those of the reference compound, **8c**. This indicates that the interaction between the two chromophores in **3** is relatively weak and that the *anti*-conformation for **3** is also accommodated.

On the other hand, the electronic spectrum of ferrocene has two main absorptions, 325 and 440 nm. In the case of the ring-tilted ferrocenophane, it has been found that the 440-nm band undergoes a bathochromic shift with a marked increase in intensity.[14] In the electronic spectra of **1** and **4**, the 440-nm band undergoes a bathochromic shift and increases in intensity, compared with those of **8a** and **8d** bearing a no-tilt ferrocene ring. This may be caused by a ferrocene ring-tilt distortion due to an interaction between the two phenylethynyl or styryl groups in **1** or **4**.

In Compounds **2** and **3**, the electronic spectra in the

3	6.98—7.28 (m, 8H, Ar-$\underline{H}$)	4.22 (m, 4H, $\underline{H}_\beta$) 4.51 (m, 4H, $\underline{H}_\alpha$)	7.31 (s, 2H, $-C\underline{H}=C\underline{H}-$)
8c	7.01—7.33 (m, 8H, Ar-$\underline{H}$)	4.29 (t, 4H, $\underline{H}_\beta$) 4.49 (t, 4H, $\underline{H}_\alpha$)	2.40 (s, 6H, $-C\underline{H}_3$)
4	6.49 (d, J=8 Hz, 4H, $\underline{H}_e$) 6.71 (d, J=8 Hz, 4H, $\underline{H}_d$)	4.24 (t, 4H, $\underline{H}_\beta$) 4.42 (t, 4H, $\underline{H}_\alpha$)	5.98 (d, J=16 Hz, 2H, $\underline{H}_a$) 6.29 (d, J=16 Hz, 2H, $\underline{H}_b$) 7.17 (s, 2H, $\underline{H}_c$)
8d	7.06 (d, J=8 Hz, 4H, $\underline{H}_d$) 7.18 (d, J=8 Hz, 4H, $\underline{H}_c$)	4.24 (t, 4H, $\underline{H}_\beta$) 4.39 (t, 4H, $\underline{H}_\alpha$)	2.30 (s, 6H, $-C\underline{H}_3$) 6.67 (b-s, 4H, $\underline{H}_a + \underline{H}_b$)

Table 2. IR spectra of the cyclophane and reference compounds

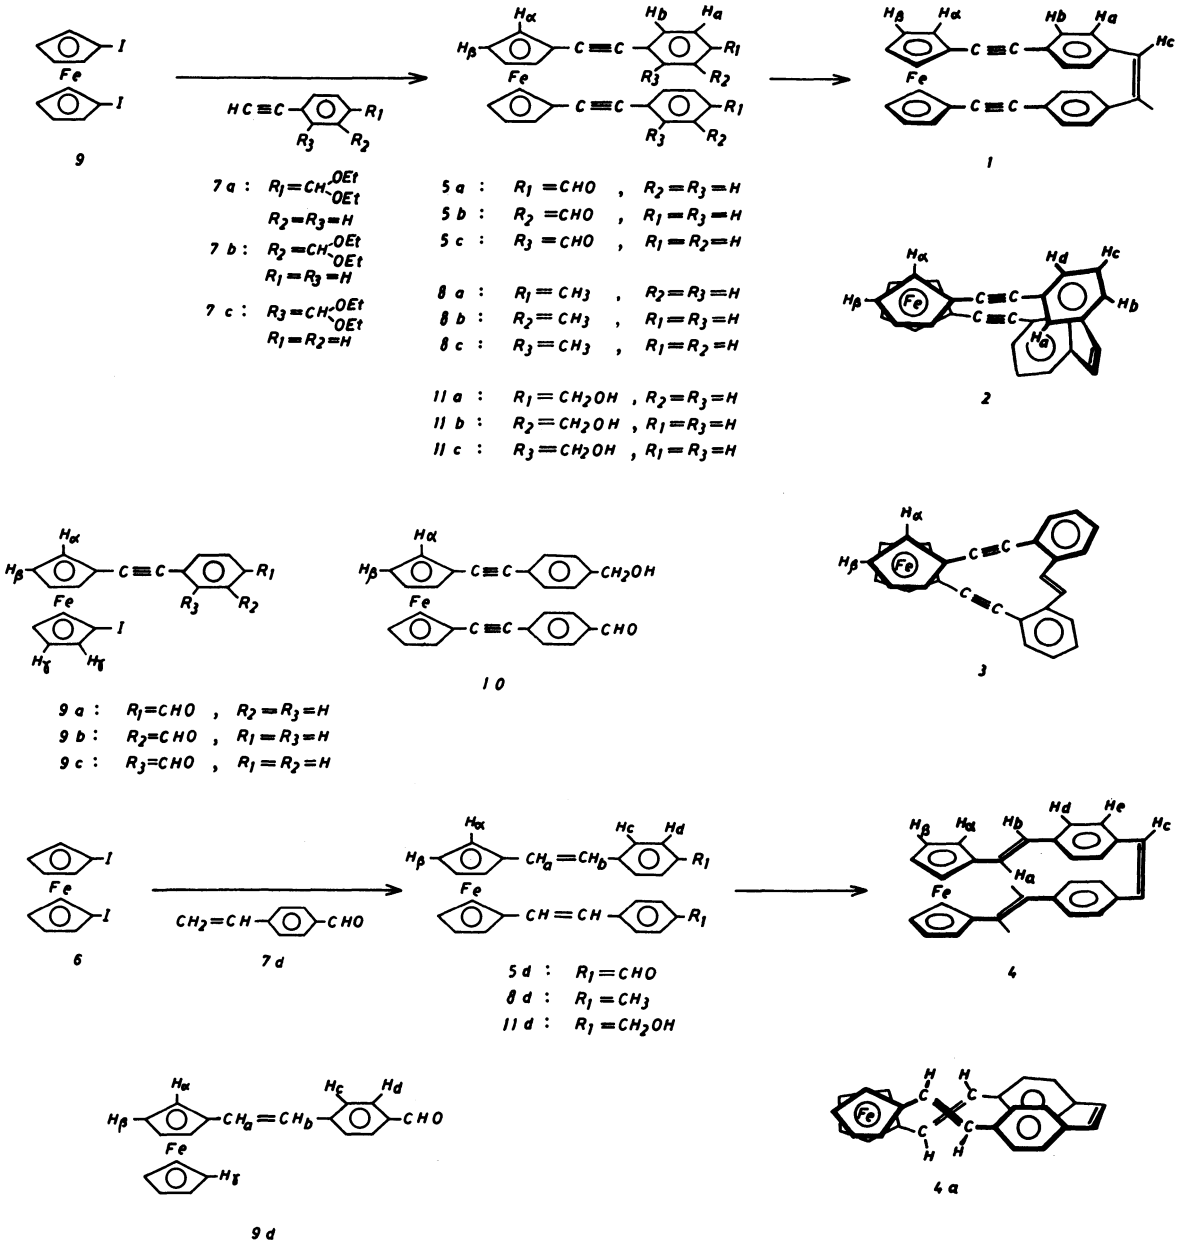
Compound	KBr, $\tilde{\nu}$/cm^{-1}
1	3100, 1400, 810 (1,1′-disubstituted ferrocene ring), 2200 (–C≡C–), 730 (*cis* –CH=CH–), 1600, 1580, 820 (*p*-disubstituted benzene ring), 710, and 690 (distorted benzene ring)
8a	3100, 1410, 805 (1,1′-disubstituted ferrocene ring), 2200 (–C≡C–), 1600, 1580, 1500, and 820 (*p*-disubstituted benzene ring)
2	3100, 1410, 810 (1,1′-disubstituted ferrocene ring), 2200 (–C≡C–), 1630, 720 (*cis* –CH=CH–), 1600, 1580, 1500, 845, and 765 (*m*-disubstituted benzene ring)
8b	3100, 1410, 810 (1,1′-disubstituted ferrocene ring), 2200 (–C≡C–), 1600, 1500, 850, and 770 (*m*-disubstituted benzene ring)
3	3100, 1410, 810 (1,1′-disubstituted ferrocene ring), 2200 (–C≡C–), 1640, 960 (*trans* –CH=CH–), 1600, 1500, and 740 (*o*-disubstituted benzene ring)
8c	3100, 1410, 810 (1,1′-disubstituted ferrocene ring), 2200 (–C≡C–), 1600, 1500, and 740 (*o*-disubstituted benzene ring)
4	3100, 1400, 805 (1,1′-disubstituted ferrocene ring), 1630, 950, (*trans* –CH=CH–), 730 (*cis* –CH=CH–), 1600, 1580, 1500, 820 (*p*-disubstituted benzene ring), 710, and 685 (distorted benzene ring)
8d	3100, 1400, 810 (1,1′disubstituted ferrocene ring), 1640, 960 (*trans* –CH=CH–), 1600, 1580, and 820 (*p*-disubstituted benzene ring)

330—450 nm region are closely similar to those of the reference compounds bearing a no-tilt ferrocene ring, **8b** and **8c**. This indicates that no ferrocene-ring distortion occurs in **2** and **3**.

The IR spectra of [2.2]paracyclophane system are known to reveal obvious features. One is the increase in the intensity of the band in the 1580—1600 cm^{-1} region, which is related to the increased double-bond character due to the distortion of the benzene rings.[15] The other is the appearance of a strong new maximum in the 710-cm^{-1} region. Longone and Warren[15b] reported that the strong maxima at 725 cm^{-1} in [2.2]-paracyclophane and at 710 cm^{-1} in 4,7,12,15-tetramethyl[2.2]paracyclophane might be characteristic bands associated with the distorted benzene ring in the [2.2]-paracyclophane system. Otsubo *et al.*[15c] reported the same phenomenon in the multilayered [2.2]paracyclophane system. Besides the strong peak around 1600 cm^{-1}, the ferrocenophanes, **1** and **4**, exhibit the characteristic strong new band around 710 cm^{-1}, whereas the reference compounds bearing strain-free benzene rings, **8a** and **8d**, exhibit no band in this region. This phenomenon may be due to the distortion of the benzene rings in **1** and **4**. On the other hand, near 710 cm^{-1}, the IR spectra of **2** and **3** are closely similar to those of the open-chain models, **8b** and **8c**. This may be due to the lack of distortion of the benzene rings in **2** and **3**. (see Table 2).

Experimental

Materials and Measurements. All the melting points are uncorrected. The 1,1′-diiodoferrocene (**6**),[16] *p*- (**7a**)[17] and *o*-ethynylbenzaldehyde diethyl acetal (**7c**),[18] and *p*-formylstyrene (**7c**)[19] were prepared as has been described in the literature. The *m*-ethynylbenzaldehyde diethyl acetal (**7b**) was prepared from (*m*-bromophenylethynyl)trimethylsilane[20]



Scheme 1.

by a modification of the method in the literature.[17] The IR, NMR, mass, and electronic spectra were recorded with Hitachi 260-10, Hitachi R-22, Hitachi RMU-6M, and Hitachi 200-10 spectrometers respectively.

1,1'-Bis(p-formylphenylethynyl)ferrocene (5a). A mixture of **6** (4.37 g, 0.01 mol), **7a** (5.71 g, 0.28 mol), copper(I) iodide (0.19 g, 0.001 mol), dichlorobis(triphenylphosphine)palladium (II) (0.70 g, 0.001 mol), and diethylamine (80 cm^3) was heated under nitrogen in an autoclave at 80 °C for 8 h. After the removal of the diethylamine under reduced pressure, chloroform and water were added to the residue. The chloroform layer was separated and washed thoroughly with 10% hydrochloric acid to hydrolyze the acetal to aldehyde. The resulting chloroform layer was washed with a saturated sodium hydrogen carbonate solution and a saturated sodium chloride solution, dried over anhydrous magnesium sulfate, filtered, and concentrated. The residue was purified by silica-gel column chromatography.

The first fraction, eluted with hexane–benzene (1 : 1), gave 1-(*p*-formylphenylethynyl)-1'-iodoferrocene (**9a**) as reddish crystals (mp 139—141 °C) in a 45% yield based on **6** (1.98 g): IR (KBr): 2200 (–C≡C–), 1700 (–CHO), 1600, 1580, 820 (*p*-disubstituted benzene ring), 3100, and 805 cm^{-1} (1,1'-disubstituted ferrocene ring). NMR ($CDCl_3$): δ=4.22 (m, 6H, $\underline{H}_\beta$+$\underline{H}_\gamma$), 4.51 (m, 2H, $\underline{H}_\alpha$), 7.56 (d, J=8 Hz, 2H, Ar–$\underline{H}$), 7.80 (d, J=8 Hz, 2H, Ar–$\underline{H}$), and 9.96 (s, 1H, –C$\underline{H}$O). Found; C, 51.62; H, 2.81%; M^+, 440. Calcd for $C_{19}H_{13}FeIO$: C, 51.85; H, 2.97%; M, 440.

The second fraction, eluted with benzene–chloroform (1 : 1), gave **5a**, as deep red crystals (mp 210 °C (decomp)) in a 27% yield (1.19 g): IR (KBr): 2200 (–C≡C–), 1690 (–CHO), 1600, 1580, 820 (*p*-disubstituted benzene ring), 3100, and 805 cm^{-1} (1,1'-disubstituted ferrocene ring). NMR ($CDCl_3$): δ=4.37 (t, 4H, $\underline{H}_\beta$), 4.59 (t, 4H, $\underline{H}_\alpha$), 7.47 (d, 4H, $\underline{H}_a$), 7.71 (d, 4H, $\underline{H}_b$), and 9.98 (s, 2H, –C$\underline{H}$O). Found: C, 75.85; H, 3.96%; M^+, 442. Calcd for $C_{28}H_{18}FeO_2$: C, 76.03; H, 4.10%; M,

442.

1,1'-Bis(m-formylphenylethynyl)ferrocene (5b). In the presence of $(Ph_3P)_2PdCl_2$ and CuI, the palladium-catalyzed substituted of **6** with **7b** was carried out in the same way as has been described for **5a**; 1-(*m*-formylphenylethynyl)-1'-iodoferrocene (**9b**) (reddish crystals; mp 113—115 °C) and **5b** (reddish crystals; mp 164—165 °C) were thus obtained in 34 and 27% yields respectively.

9b: IR (KBr): 1700 (-CHO), 2200 (-C≡C-), 1600, 1580, 820, 780 (*m*-disubstituted benzene ring), 3100, and 805 cm^{-1} (1,1'-disubstituted ferrocene ring). NMR ($CDCl_3$): δ=4.20 (m, 6H, $\underline{H}_\beta+\underline{H}_\gamma$), 4.49 (m, 2H, $\underline{H}_\alpha$), 7.34—7.89 (m, 4H, Ar-$\underline{H}$), and 9.93 (s, 1H, -C$\underline{H}$O). Found: C, 51.73; H, 2.85%; M^+, 440. Calcd for $C_{19}H_{13}FeIO$: C, 51.85; H, 2.97%; M, 440.

5b: IR (KBr): 1700 (-CHO), 2200 (-C≡C-), 1600, 1580, 850, 770 (*m*-disubstituted benzene ring), 3100, and 805 cm^{-1} (1,1'-disubstituted ferrocene ring). NMR ($CDCl_3$): δ=4.31 (t, 4H, $\underline{H}_\beta$), 4.53 (t, 4H, $\underline{H}_\alpha$), 7.29—7.75 (m, 8H, Ar-$\underline{H}$), and 9.83 (s, 2H, -C$\underline{H}$O). Found: C, 75.78; H, 4.01%; M^+, 442. Calcd for $C_{28}H_{18}FeO_2$: C, 76.03; H, 4.10%; M, 442.

1,1'-Bis(o-formylphenylethynyl)ferrocene (5c). In the presence of $(Ph_3P)_2PdCl_2$ and CuI, the palladium-catalyzed substitution of **6** with **7c** was carried out in the same way as has been described for **5a**; 1-(*o*-formylphenylethynyl)-1'-iodoferrocene (**9c**) (reddish oil) and **5c** (reddish crystals; mp 178—179 °C) were thus obtained in 40 and 14% yields respectively.

9c: IR (neat): 1690 (-CHO), 2200 (-C≡C-), 1600, 1580, 740 (*o*-disubstituted benzene ring), 3100, and 810 cm^{-1} (1,1'-disubstituted ferrocene ring). NMR ($CDCl_3$): δ=4.34 (m, 6H, $\underline{H}_\beta+\underline{H}_\gamma$), 4.55 (m, 2H, $\underline{H}_\alpha$), 7.21—7.74 (m, 4H, Ar-$\underline{H}$), and 10.24 (s, 1H, -C$\underline{H}$O). Found: C, 51.77; H, 2.90%; M^+, 440. Calcd for $C_{19}H_{13}FeIO$: C, 51.85; H, 2.97%; M, 440.

5c: IR (KBr): 1690 (-CHO), 2200 (-C≡C-), 1600, 1580, 1500, 740 (*o*-disubstituted benzene ring), 3100, and 810 cm^{-1} (1,1'-disubstituted ferrocene ring). NMR ($CDCl_3$): δ=4.36 (t, 4H, $\underline{H}_\beta$), 4.58 (t, 4H, $\underline{H}_\alpha$), 7.29—7.74 (m, 8H, Ar-$\underline{H}$), and 10.47 (s, 2H, -C$\underline{H}$O). Found: C, 75.92; H, 3.98%; M^+, 442. Calcd for $C_{28}H_{18}FeO_2$: C, 76.03; H, 4.10%: M, 442.

1,1'-Bis(p-formylstyryl)ferrocene (5d). A mixture of **6** (4.37 g, 0.01 mol), **7a** (3.70 g, 0.28 mol), palladium(II) acetate (0.04 g, 0.002 mol), triphenylphosphine (0.10 g, 0.004 mol), and triethylamine (2.83 g. 0.28 mol) in acetonitrile (60 cm^3) was heated under nitrogen in an autoclave at 90 °C for 10 h. After the removal of the solvent under reduced pressure, the residue was extracted with chloroform. The chloroform extracts were washed with 10% hydrochloric acid, a saturated sodium hydrogencarbonate solution, and a saturated sodium chloride solution, dried over anhydrous magnesium sulfate, filtered, and concentrated. The residue was purified by column chromatography on silica gel.

The first fraction, eluted with benzene, gave (*p*-formylstyryl)-ferrocene (**9d**); yellowish red crystals; mp 145—147 °C, 1.10 g (35% yield based on **6**). IR (KBr): 1690 (-CHO), 1635, 965 (*trans* -CH=CH-), 1600, 1500, 820, (*p*-disubstituted benzene ring), 3100, and 805 (1,1'-disubstituted ferrocene ring). NMR ($CDCl_3$): δ=4.12 (s, 5H, $\underline{H}_\gamma$), 4.32 (t, 2H, $\underline{H}_\beta$), 4.48 (t, 2H, $\underline{H}_\alpha$), 6.67 (d, J=15 Hz, 1H, $\underline{H}_b$), 7.04 (d, J=15 Hz, 1H, $\underline{H}_a$), 7.49 (d, J=8 Hz, 2H, $\underline{H}_c$), 7.78 (d, J=8 Hz, 2H, $\underline{H}_d$), and 9.93 (s, 1H, -C$\underline{H}$O). Found: C, 72.06; H, 4.95%; M^+, 316. Calcd for $C_{19}H_{16}FeO$: C, 72.17; H, 5.10%; M, 316.

The second fraction, eluted with benzene-chloroform (1 : 1), gave **5d** as reddish crystals (mp 218 °C (decomp)) in a 54% yield (2.41 g). IR (KBr): 1695 (-CHO), 1630, 960 (*trans* -CH=CH-), 1600, 1500, 830 (*p*-disubstituted benzene ring), 3100, and 810 (1,1'-disubstituted ferrocene ring). NMR ($CDCl_3$): δ=4.33 (t, 4H, $\underline{H}_\beta$), 4.48 (t, 4H, $\underline{H}_\alpha$), 6.53 (d, J=16 Hz, 2H, $\underline{H}_b$), 6.82 (d, J=16 Hz, 2H, $\underline{H}_a$), 7.28 (d, J=8 Hz, 4H, Ar-$\underline{H}$), 7.63 (d, J=8 Hz, 4H, Ar-$\underline{H}$), and 9.89 (s, 2H, -C$\underline{H}$O). Found: C, 75.19; H, 4.77%; M^+, 446. Calcd for $C_{28}H_{22}FeO_2$: C, 75.35; H, 4.96%; M, 446.

The Reductive Coupling of 5a with $TiCl_4$-Zn. Under a nitrogen atmosphere, Zn dust (5.22 g, 0.08 mol) was added to a solution of $TiCl_4$ (7.58 g, 0.04 mol) in dry THF (150 cm^3) with cooling. The mixture was then refluxed for 1.5 h to give a deep black solution. To the metal complex solution thus obtained we added a solution of **5a** (3.53 g, 0.008 mol) and dry pyridine (0.60 g) in dry THF (550 cm^3) over 11 h under refluxing, followed by an additional 10-h period of reflux. The reaction mixture was then cooled to room temperature and quenched with a 20% aqueous K_2CO_3 solution. After filtration, the filtrate was extracted with chloroform. The chloroform extracts were washed with water and dried over anhydrous magnesium sulfate. After the removal of the solvents, the residue was dissolved in benzene and chromatographed on silica gel.

The first fraction, eluted with benzene, gave **8a** as reddish crystals (mp 193—194 °C) in a 3.5% yield. Compound **8a** is identical in all respects with 1,1'-bis(*p*-tolylethynyl)ferrocene, which was prepared by the palladium-catalyzed substitution of **6** with *p*-tolylacetylene in the same way as has been described for **5a**. Found: C, 81.08; H, 5.29%; M^+, 414. Calcd for $C_{28}H_{22}Fe$: C, 81.16; H, 5.35%; M, 414.

The second fraction, eluted with benzene, gave **1** as deep reddish crystals (mp 260 °C (decomp)) in a 15% yield. Found: C, 81.83; H, 4.31%; M^+, 410. Calcd for $C_{28}H_{18}Fe$: C, 81.96; H, 4.42%; M, 410.

The third fraction, eluted with chloroform, gave 1-(*p*-formylphenylethynyl)-1'-[*p*-(hydroxymethyl)phenylethynyl]-ferrocene (**10**) as reddish orange crystals (mp 190 °C (decomp)) in a 6% yield. IR (KBr): 3300 (-OH), 1700 (-CHO), 2200 (-C≡C-), 1600, 1500, 820 (*p*-disubstituted benzene ring), 3100, and 805 cm^{-1} (1,1'-disubstituted ferrocene ring). NMR (DMSO-d_6): δ=4.36 (t, 4H, $\underline{H}_\beta$), 4.56 (t, 4H, $\underline{H}_\alpha$), 4.72 (s, 2H, -C$\underline{H}_2$-), 5.78 (b-s, 1H, -O$\underline{H}$), 6.91 (d, 2H, Ar-$\underline{H}$), 7.34—7.52 (m, 6$\underline{H}$, Ar-$\underline{H}$) and 9.88 (s, 1H, -C$\underline{H}$O). Found: C, 75.60; H, 4.44%; M^+, 444. Calcd for $C_{28}H_{20}FeO_2$: C, 75.69; H, 4.53%; M, 444.

The fourth fraction, eluted with chloroform–ethanol (10 : 1) gave 1,1'-bis[*p*-hydroxymethyl)phenylethynyl]ferrocene (**11a**) as reddish orange crystals (mp 195 °C (decomp)) in a 3% yield. IR (KBr): 3300 (-OH), 2200 (-C≡C-), 1600, 1500, 840 (*p*-disubstituted benzene ring), 3100, and 815 cm^{-1} (1,1'-disubstituted ferrocene ring). NMR (DMSO-d_6): δ=4.00 (b-s, 2H, -O$\underline{H}$), 4.36 (t, 4H, $\underline{H}_\beta$), 4.56 (t, 4H, $\underline{H}_\alpha$), 4.76 (s, 4H, -C$\underline{H}_2$-), 6.97 (d, 4H, Ar-$\underline{H}$), and 7.33 (d, 4H, Ar-H). Found: C, 75.17; H, 4.85%; M^+, 446. Calcd for $C_{28}H_{22}FeO_2$: C, 75.35; H, 4.96%; M, 446.

The Reductive Coupling of 5b with $TiCl_4$-Zn. The reductive coupling of **5b** was carried out in the same way as has been described for the reaction of **5a** with $TiCl_4$-Zn, and the products were separated by chromatography on silica gel.

The first fraction, eluted with benzene, gave as reddish orange crystals (mp 114—115 °C) in a 7% yield. Compound **8b** was found to be identical with 1,1'-bis(*m*-tolylethynyl)-ferrocene, which has been prepared by the palladium-catalyzed substitution of **6** with *m*-tolylacetylene in the way described for **5a**. Found: C, 81.10; H, 5.28%; M^+, 414. Calcd for $C_{28}H_{22}Fe$: C, 81.16; H, 5.35%; M, 414.

The second fraction, eluted with benzene, gave **2** as reddish crystals (mp 215—216 °C) in a 22% yield. Found: C, 81.88; H, 4.36%; M^+, 410. Calcd for $C_{28}H_{18}Fe$: C, 81.96; H, 4.42%; M, 410.

The third fraction, eluted with chloroform, gave 1,1'-bis[*m*-

(hydroxymethyl)phenylethynyl]ferrocene (**11b**) as reddish orange crystals (mp 245 °C (decomp)) in a 12% yield. IR (KBr): 3300 (-OH), 2200 (-C≡C-), 1600, 1500, 870, 770 (*m*-disubstituted benzene ring), 3100, and 805 cm^{-1} (1,1'-disubstituted ferrocene ring). NMR (acetone-d_6): δ=2.15 (b-s, 2H, -OH), 4.29 (t, 4H, H_β). 4.51 (t, 4H, H_α). 4.72 (s, 4H, $-CH_2-$), and 7.28—7.58 (m, 8H, Ar-H). Found: C, 75.25; H, 4.90%; M^+, 446. Calcd for $C_{28}H_{22}FeO_2$: C, 75.35; H, 4.96%; M, 446.

The Reductive Coupling of 5c with $TiCl_4$-Zn. The reductive coupling for **5c** with $TiCl_4$-Zn was carried out in the same way as has been described for the reaction of **5a** with $TiCl_4$-Zn, and the products were separated by chromatography on silica gel.

The first fraction, eluted with benzene, gave **8c** as reddish orange crystals (mp 97—98 °C) in a 9% yield. Compound **8c** was found to be identical with 1,1'-bis(*o*-tolylethynyl)ferrocene, which has been prepared by the palladium-catalyzed substitution of **6** with *o*-tolylacetylene in the same way as has been described for **5a**. Found: C, 81.03; H, 5.19%; M^+, 414. Calcd for $C_{28}H_{22}Fe$: C, 81.16; H, 5.35%; M, 414.

The second fraction, eluted with benzene, gave **3** as reddish crystals (mp 216—217 °C) in a 26% yield. Found: C, 81.87; H, 4.33%; M^+, 410. Calcd for $C_{28}H_{18}Fe$: C, 81.96; H, 4.42%; M, 410.

The third fraction, eluted with chloroform, gave 1,1'-bis[*o*-(hydroxymethyl)phenylethynyl]ferrocene (**11c**) as reddish orange crystals (mp 201—203 °C) in a 5% yield. IR (KBr): 3400 (-OH), 2200 (-C≡C-), 1600, 1500, 740 (*o*-disubstituted benzene ring), 3100, and 810 cm^{-1} (1,1'-disubstituted ferrocene ring). NMR (acetone-d_6): δ=2.06 (b-s, 2H, -OH), 4.30 (t, 4H, H_β), 4.55 (t, 4H, H_α), 4.75 (s, 4H, $-CH_2-$), and 7.28—7.71 (m, 8H, Ar-H). Found: C, 75.19; H, 4.85%; M^+, 446. Calcd for $C_{28}H_{22}FeO_2$: C, 75.35; H, 4.96%; M, 446.

The Reductive Coupling of 5d with $TiCl_3$-$LiAlH_4$. Under a nitrogen atmosphere, $LiAlH_4$ (0.76 g, 0.02 mol) was added to a stirred slurry of $TiCl_3$ (6.47 g, 0.0042 mol) in dry THF (150 cm^3) at 0 °C. After the resulting black suspension has been stirred for 20 min, a solution of **5d** (3.79 g, 0.0085 mol) in dry THF (100 cm^3) was added drop by drop to this mixture for 6 h under refluxing, followed by an additional 7-h period of reflux. After cooling to room temperature, the reaction was worked up in the way described for **5a**; the crude products were chromatographed on silica gel.

The first fraction, eluted with hexane, gave **8d** as reddish crystals (mp 143—144 °C) in a 1.4% yield. Compound **8d** was found to be identical with 1,1'-bis(*p*-methylstyryl)ferrocene, which has been prepared by the palladium-catalyzed substitution of **6** with *p*-methylstyrene in the same way as has been described for **5d**. Found: C, 80.30; H, 6.14%; M^+, 418. Calcd for $C_{28}H_{26}Fe$: C, 80.38; H, 6.26%; M, 418.

The second fraction, eluted with benzene, gave **4** as reddish crystals (mp 230 °C (decomp)) in a 2.2% yield. Found: C, 81.03; H, 5.35%; M^+, 414. Calcd for $C_{28}H_{22}Fe$: C, 81.16; H, 5.35%; M, 414.

The third fraction, eluted with chloroform–ethanol (10 : 1), gave 1,1'-bis[*p*-(hydroxymethyl)styryl]ferrocene (**8d**) as reddish yellow crystals (mp 152—154 °C) in 3.2% yield. IR (KBr): 3400, (-OH), 1635, 955 (*trans* -CH=CH-), 1600, 1500, 830 (*p*-disubstituted benzene ring), 3100, and 805 cm^{-1} (1,1'-disubstituted ferrocene ring). NMR (DMSO-d_6): δ=2.65 (b-s, 2H, -OH), 4.28 (t, 4H, H_β), 4.49 (t, 4H, H_α), 4.78 (s, 4H, $-CH_2-$), 6.62 (d, J=16 Hz, 2H, -C=CH-Ar), 7.01 (d, J=16 Hz, 2H, -CH=C-Ar-), 7.43 (d, J=8 Hz, 4H, Ar-H), and 7.75 (d, J=8 Hz, 4H, Ar-H). Found: C, 74.56; H, 5.69%; M^+, 450. Calcd for $C_{28}H_{26}FeO_2$: C, 74.67; H, 5.81%; M, 450.

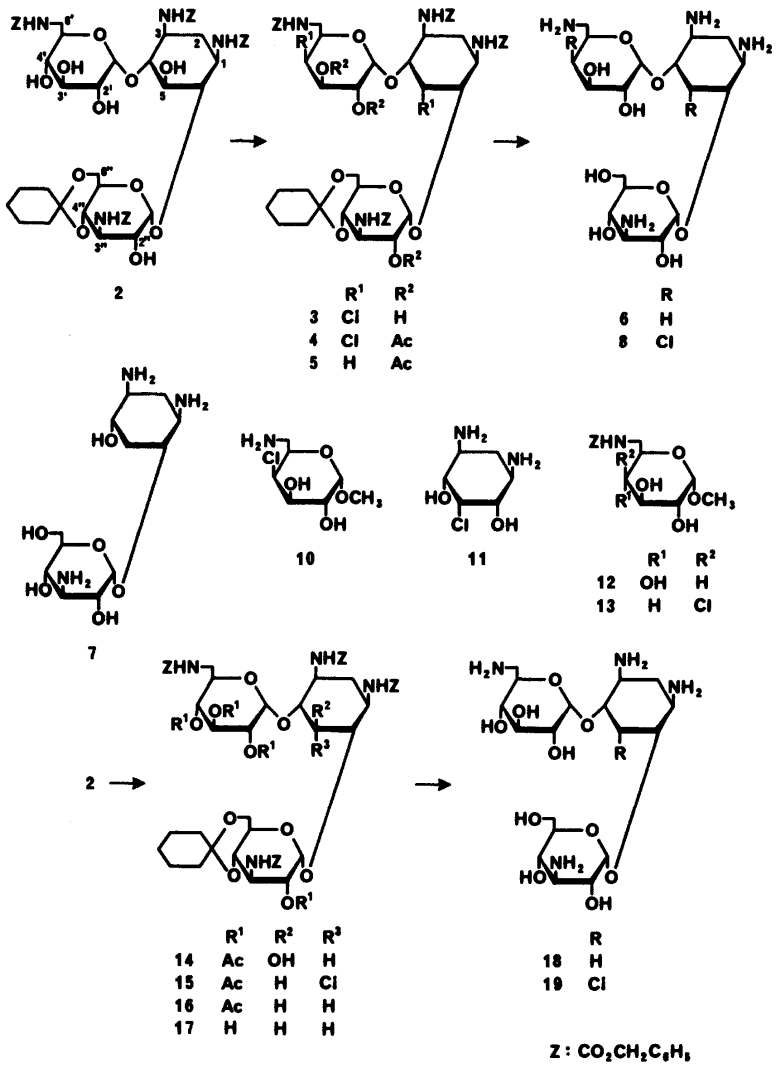
Syntheses of 5-Deoxy-, 5,4′-Dideoxy-, 5-Deoxy-5-epichloro-, and 5,4′-Dideoxy-5,4′-diepichlorokanamycin A

Toshiaki Miyake,* Tsutomu Tsuchiya, Toshiyuki Nishi, and Sumio Umezawa
Institute of Bioorganic Chemistry, 1614 Ida, Nakahara-ku, Kawasaki 211
(Received September 8, 1982)

5,4′-Dideoxy-5,4′-diepichlorokanamycin A has been synthesized from 1,3,6′,3″-tetrakis(*N*-benzyloxycarbonyl)-4″,6″-*O*-cyclohexylidenekanamycin A by treatment with sulfuryl chloride, followed by deblocking. Similar treatment of 2′,3′,4′,2″-tetra-*O*-acetyl-1,3,6′,3″-tetrakis(*N*-benzyloxycarbonyl)-4″,6″-*O*-cyclohexylidenekanamycin A gave 5-deoxy-5-epichlorokanamycin A. 5,4′-Dideoxykanamycin A and 5-deoxykanamycin A were synthesized from the corresponding 5,4′-diepichloro and 5-epichloro derivatives by reductive dechlorination with sodium metal in liquid ammonia or tributylstannane. The structures of these derivatives were confirmed by the ^{1}H- and ^{13}C-NMR spectroscopy.

In previous papers[1,2] we reported the syntheses of 4′-deoxykanamycin A and B, which show activities against some kanamycin-resistant strains including *Pseudomonas aeruginosa*. This paper describes the preparation of some chloro and deoxy derivatives of kanamycin A modified at C-5 and C-4′ utilizing sulfuryl chloride.

Chlorination of sugars by sulfuryl chloride has been extensively studied.[3] In the case of methyl α-D-glucopyranoside (**1**), Helferich *et al.*[4] observed, in the beginning of the 1920's, the formation of 4,6-dichloro-4,6-dideoxy-α-D-hexoside 2,3-cyclic sulfate by treating **1** with sulfuryl chloride, the correct structure of the product being later determined[5] as a 4,6-dichlorogalactoside derivative formed by inversion of the configuration at C-4. This result indicates that chlorination does not occur at the 2- and 3-hydroxyl groups of a α-D-gluco-



Scheme 1.

pyranoside derivative and, after desulfation (or dechlorosulfation[3]), they are regenerated. Regarding kanamycin A, there are four amino and seven hydroxyl groups in the molecule, and, even if the amino and 4″- and 6″-hydroxyl groups are protected, five reactive hydroxyl groups still remain; among them, the 2′-, 3′-, and 2″-hydroxyl groups are expected not to be replaced by chlorine atoms by treatment with sulfuryl chloride from the above point of view.

We were, therefore, interested in the selective chlorination of a kanamycin A derivative, 1,3,6′,3″-tetrakis(*N*-benzyloxycarbonyl)-4″,6″-*O*-cyclohexylidenekanamycin A[2] (**2**) with sulfuryl chloride. Treatment of **2** with the reagent in dichloromethane–pyridine gave the corresponding 5,4′-diepichloro derivative (**3**) in 45% yield. It should be noted that the 5-epichlorination simultaneously occurred in addition to the 4′-epichlorination, which was unexpected from the steric point of view, because the 5-hydroxyl group of kanamycin derivatives are known to be less reactive among the hydroxyl groups against benzoylation and sulfonylation[2,6,7] due to the bulkiness of the adjacent substituents attached at C-4 and 6. Recently, Suami *et al.*[8] also reported the 5-epichlorination of a protected kanamycin B derivative with sulfuryl chloride.

In order to prepare 5,4′-dideoxykanamycin A (**6**), **3** was treated with sodium metal in liquid ammonia, and the desired **6** was obtained in a low yield (19%) after decyclohexylidenation. As already reported,[9] in the case of methyl 3-chloro-4,6-*O*-cyclohexylidene-2,3-dideoxy-2-(*p*-toluenesulfonamido)-α-D-glucopyranoside,[9] reductive dechlorination smoothly occurred by the same treatment. Treatment of the 2′,3′,2″-tri-*O*-acetyl derivative (**4**) of **3** with sodium in liquid ammonia gave **6** in 27% yield together with 6-*O*-(3-amino-3-deoxy-α-D-glucopyranosyl)-2,5-dideoxystreptamine (**7**). The structure of the latter was confirmed by the paper-chromatography of the acidic hydrolyzates of **7**. Occurrence of the high-degree hydrolysis of a glycoside bond of **4** is somewhat surprising.

In order to improve the yield of **6**, **4** was treated in trial, with tributylstannane in the presence of α,α′-azobis(isobutyronitrile)[10] in 1,4-dioxane, affording 4′-deoxy derivative (**5**) in high yield. Successive deblocking of the acetyl, cyclohexylidene, and benzyloxycarbonyl groups of **5** gave **6** in 77% overall yield from **4**.

Next, to prepare a chloro derivative of kanamycin A, the protecting groups of **3** were removed to give 5,4′-dideoxy-5,4′-diepichlorokanamycin A (**8**). Its structure was determined by the ^{1}H-NMR spectra, which gave double doublets with small spacings (δ=5.10, J=4 and 1 Hz, H-4′) and a narrow triplet (δ=5.63, J=3 Hz, H-5) assignable to the protons attached to the carbon bearing chlorine atom; this indicates that both the chloro atoms are axially attached. The structure of **8** was further confirmed by methanolysis in the presence of Amberlite CG120 (H form) resin at a high temperature according to a reported procedure.[11] Methyl 3-amino-3-deoxy-α-D-glucopyranoside (**9**),[12,13] methyl 6-amino-4-chloro-4,6-dideoxy-α-D-galactopyranoside (**10**), and 2,5-dideoxy-5-epichlorostreptamine (**11**) were obtained after chromatography. The compound **10** was identical with that prepared by a different route. Methyl 6-amino-6-deoxy-α-D-glucopyranoside[14] was successively *N*-benzyloxycarbonylated (to give **12**), and 4′-epichlorinated by the method described for **3** (to give **13**), followed by removal of the *N*-protecting group to give **10**. Its ^{1}H-NMR spectrum showed double doublets assignable to equatorial H-4 (δ=4.98, J=3.2 and 1.0 Hz), the splitting pattern being comparable with that of the corresponding resonances of **8**.

5-Deoxy and 5-deoxy-5-epichloro derivatives of kanamycin A were further prepared as follows: The protected kanamycin A (**2**) was acetylated and the resulting 2′,3′,4′,2″-tetra-*O*-acetyl derivative (**14**) having a free hydroxyl group at C-5 was treated with sulfuryl chloride in a similar manner as described above to give the 5-deoxy-5-epichloro derivative (**15**). Treatment of **15** with sodium metal in liquid ammonia in a manner as described for **6** followed by deacetylation and decyclohexylidenation gave 5-deoxykanamycin A (**18**) in good yield (69%). The yield was somewhat surprising because **3** or **4** gave poor yields of **6** by the same treatment. The compound **18** was recently synthesized *via* glycosidation by Kavadias *et al.*,[15] or isolated from the fermentation broths of *S. kanamyceticus*.[16] Reduction of **15** with tributylstannane (to give **16**) followed by deprotection also gave **18**. Deprotection of **15** gave the desired 5-deoxy-5-epichlorokanamycin A (**19**).

The ^{13}C-chemical shifts of the final deoxy compounds (**6**, **8**) and kanamycin A are shown in Table 1. Expected downfield shift (2.3 ppm) based on the shift of kanamycin A[2] caused by the 4′-deoxygenation was observed at C-6′ of **6**, which was not observed in the spectrum of **18**. Upfield shifts (4.8 and 5.4 ppm) caused by the 5-deoxygenation were observed at the C-1′ in both **6** and **18**. Similar upfield shifts were reported for 5-

deoxykanamycin B [4.3 (as the free base, pD 11)[8] and 4.2 ppm (as the sulfate, pD 7)[17]]. In Table 2, the ^{13}C-chemical shifts of the final chloro compounds (**8**, **19**), **10**, methyl 6-amino-6-deoxy-α-D-glucopyranoside, and kanamycin A are compared. Upfield shifts (7.3 and 7.1 ppm) caused by the 4′(or 4)-epichlorination were observed at C-4′ of **8** and C-4 of **10**, but no obvious difference as experienced in the 4′-deoxy derivatives was observed on the shifts of C-6′ (C-6 in the case of **10**) between the chloro compounds (**8**, **19**, **10**) and kanamycin A. Upfield shifts caused by 5-deoxy-5-epichlorination were observed at C-1′ by 5.8 (**8**) and 6.2 ppm (**19**). Recently a similar upfield shift[18] (4.5 ppm) at C-1′ was observed in 5-epikanamycin B compared with kanamycin B.

The antibacterial activities of the compounds **6**, **8**, **18**, **19**, and kanamycin A are shown in Table 3. It was concluded, by the comparison, that the 4′-epichlorination of kanamycin A caused lack of activity. The 5-deoxygenation of kanamycin A caused lowering of activity in accord with the report by Kavadias *et al.*[15]

Experimental

IR spectra were determined in KBr disks with a Hitachi 285 infrared spectrophotometer. ^1H-NMR spectra were recorded at 90 MHz with a Varian EM-390 spectrometer. ^{13}C-NMR spectra were recorded on a Varian XL-100 spectrometer with a Varian 620-L data processing system (25.2 MHz). Tetramethylsilane ($\delta=0$) was used as the internal standard (in organic solvents), or as the external standard (in deuterium oxide). Thin-layer chromatography (TLC) was carried out on E. Merck precoated silica gel 60 plates with the spray of sulfuric acid or 0.5% ninhydrin in pyridine for detection. Paper chromatography (PPC) was carried out on Toyo-Roshi paper No. 50 with 1-butanol–pyridine–water–acetic acid (6 : 4 : 3 : 1), descending for 7—8 d, unless otherwise stated, and spots were visualized by 0.5% ninhydrin in pyridine. For column chromatography, silica gel (Wakogel C-200) was used, unless otherwise stated.

*1,3,6′,3″-Tetrakis(*N*-benzyloxycarbonyl)-5,4′-dideoxy-5,4′-diepichloro-4″,6″-*O*-cyclohexylidenekanamycin A (**3**).* To a solution of **2**[2] (504 mg) in a mixture of dry dichloromethane (9 ml) and dry pyridine (3.5 ml), was added sulfuryl chloride (0.55 ml, 15 mol equivalents for **2**) gradually at −78 °C and the solution was kept at the temperature for 30 min, then at room temperature for 1.5 h. A solution of sodium iodide (750 mg) in aqueous pyridine (1 : 2, 7.5 ml) was added to the reaction mixture. The resulting solution showed, on TLC with chloroform–ethanol (10 : 1), spots at R_f 0.4 (**3**, major), 0.25 (**2**, slight), 0.07 (minor), and others. Concentration of the mixture gave a syrup, which was dissolved in chloroform. The solution was washed with water, dried ($MgSO_4$), and concentrated to give a brown solid (405 mg), which was chromatographed on a silica-gel column with chloroform–ethanol = 15 : 1 to give a colorless solid of **3**, 235 mg (45%), $[\alpha]_D^{25}$ +80° (*c* 0.5, *N*,*N*-dimethylformamide).

Found: C, 58.83; H, 5.80; N, 4.72; Cl, 6.41%. Calcd for $C_{56}H_{66}N_4O_{17}Cl_2$: C, 59.10; H, 5.85; N, 4.92; Cl, 6.23%.

2′,3′,2″-Tri-O-acetyl-1,3,6′,3″-tetrakis(N-benzyloxycarbonyl)-4″,6″-O-cyclohexylidene-5,4′-dideoxykanamycin A (**5**). To a solution of **4** (93.5 mg) in dry 1,4-dioxane (2 ml) were added tributylstannane (0.3 ml) and α,α′-azobis(isobutyronitrile) (10 mg) and the reaction mixture was heated at 80 °C for 2 h under the nitrogen atmosphere. The resulting solution showed, on TLC with chloroform–2-butanone (3 : 1), a single spot at R_f 0.11 (*cf.* **4**, R_f 0.26). The solution was concentrated under reduced pressure to give a solid, which was thoroughly washed with ether and chromatographed on a silica-gel column with chloroform–ethanol=15 : 1 to give a solid of **5**, 78.6 mg (89%), $[\alpha]_D^{25}$ +82° (*c* 0.5, *N,N*-dimethylformamide); ^{1}H-NMR (pyridine-d_5): δ=1.99 (6H) and 2.28 (3H) (each s, $COCH_3$); 1.0—2.8 (25H, C_6H_{10}, $3COCH_3$, CH_2 at C-2,5,4′).

Found: C, 62.07; H, 6.20; N, 4.91%. Calcd for $C_{62}H_{74}N_4O_{20}$: C, 62.30; H, 6.24; N, 4.69%.

5,4′-Dideoxykanamycin A (**6**). *A) From* **5**: To a suspension of **5** (46.2 mg) in dry 1,4-dioxane–methanol (4 : 1, 1 ml) was added 1 M sodium methoxide (1 M=1 mol dm^{-3}) in methanol (0.025 ml), and the mixture was stirred at room temperature for 15 min. The resulting clear solution was neutralized with Dowex 50W×8 resin (H form) pretreated with 1,4-dioxane, filtered, and the filtrate was concentrated to give a solid, 42.0 mg. The deacetyl product was suspended in 80% aqueous acetic acid, and the mixture was stirred at 80 °C for 20 min. The resulting clear solution containing the decyclohexylidenated product was hydrogenated with palladium black under atmospheric pressure of hydrogen for 40 min. The resulting product was purified by chromatography over CM-Sephadex C-25 (NH_4 form, 0→0.3 M aqueous ammonia) to give a solid of **6**, 18.6 mg (86% as the 1.7 carbonate), $[\alpha]_D^{25}$ +130° (*c* 0.5, water); PPC: $R_{f\ \text{kanamycin A}}$ 1.1; TLC (1-butanol–ethanol–chloroform–10 M aqueous ammonia=4 : 7 : 2 : 7): R_f 0.20 (*cf.* kanamycin A, R_f 0.17).

Found: C, 42.42; H, 7.10; N, 10.00%. Calcd for $C_{18}H_{36}N_4O_9\cdot 1.7\,H_2CO_3$: C, 42.41; H, 7.12; N, 10.04%.

Acidic hydrolysis of **6** (6 M HCl, 100 °C, 50 min) gave three products, on PPC (descending for 2 d), corresponding to 3-amino-3-deoxy-D-glucose ($R_{f\ \text{2-deoxystreptamine (DST)}}$ 2.5), 6-amino-4,6-dideoxy-D-*xylo*-hexose ($R_{f\ \text{DST}}$ 2.0) and 2,5-dideoxystreptamine ($R_{f\ \text{DST}}$ 1.6) (*cf.* 6 amino-6-deoxy-D-glucose, $R_{f\ \text{DST}}$ 1.6).

B) From **3**: To a solution of **3** (131 mg) in liquid ammonia (≈35 ml) at −60 °C was added sodium metal (≈260 mg) with stirring, and the resulting deep-blue solution was kept at −50 °C for 2 h. Addition of methanol (5 ml) followed by concentration gave a solid. An aqueous solution of the de(benzyloxycarbonyl)-5,4′-dideoxy intermediate was stirred with Dowex 50W×8 resin (H form, 30 ml), and the resin, after packed in a column and washing it with water, was treated with 1 M aqueous ammonia. The ninhydrin-positive fractions were collected and concentrated. The solid obtained was chromatographed over CM-Sephadex C-25 (NH_4 form, 00.3 M aqueous ammonia) to give a solid of **6**, 12.6 mg (19% as the dicarbonate).

C) From **4**: **4** (60.2 mg) was treated with sodium metal (≈140 mg) in liquid ammonia (≈20 ml) as described for B). Deacetylation of the resulting product was carried out by treating it with 1 M aqueous sodium hydroxide at 50 °C for 30 min. Purification in a manner as described above gave a solid of **6** (6.7 mg, 27% as the 1.2 carbonate) and that of **7** (10.1 mg, 60% as the 0.7 carbonate).

6: Found: C, 43.75; H, 7.18; N, 10.53%. Calcd for $C_{18}H_{36}N_4O_9\cdot 1.2H_2CO_3$: C, 43.76; H, 7.35; N, 10.63%.

7: $[\alpha]_D^{25}$ +72° (*c* 1, water); PPC: $R_{f\ \text{kanamycin A}}$ 2.3; TLC (1-butanol–ethanol–chloroform–10 M aqueous ammonia=4 : 7 : 2 : 7): R_f 0.28; ^{1}H-NMR (D_2O): δ=1.5—2.4 (2H m, H-2ax and 5ax), 2.4—3.2 (2H m, H-2eq and 5eq), 5.53 (1H d, *J* 4 Hz, H-1′).

Found: 43.52; H, 7.55; N, 11.78%. Calcd for $C_{12}H_{25}N_3O_6\cdot 0.7H_2CO_3$: C, 43.49; H, 7.59; N, 11.98%.

PPC of the acidic hydrolyzates of **7** (6 M HCl, 100 °C, 30 min; descending for 2 d): $R_{f\ \text{2-deoxystreptamine (DST)}}$ 2.6 (3-amino-3-deoxy-D-glucose) and 1.6 (2,5-dideoxystreptamine).

5,4′-Dideoxy-5,4′-diepichlorokanamycin A (**8**). A suspension of **3** (161 mg) in 80% aqueous acetic acid was stirred at 90 °C for 45 min. The resulting clear solution was hydrogentated with palladium black under atmospheric pressure of hydrogen at room temperature for 20 min. The crude product was chromatographed over CM-Sephadex C-25 (NH_4 form, 0→0.1 M aqueous ammonia) to give a solid of **8**, 71.5 mg (84% as the monocarbonate monohydrate), $[\alpha]_D^{25}$ +146° (*c* 1, water); PPC: $R_{f\ \text{kanamycin A}}$ 2.5; TLC (1-butanol–ethanol–chloroform–10 M aqueous ammonia=4 : 7 : 2 : 7): R_f 0.32 (*cf.* kanamycin A, R_f 0.18); ^{1}H-NMR (as the HCl salt, in D_2O): δ=5.10 (1H dd, $J_{3',4'}$ 4 Hz, $J_{4',5'}$ 1 Hz, H-4′), 5.63 (1H t, $J_{4,5}=J_{5,6}$ 3 Hz, H-5).

Found: C, 38.21; H, 6.19; N, 9.25; Cl, 12.05%. Calcd for $C_{18}H_{34}N_4O_9Cl_2\cdot H_2CO_3\cdot H_2O$: C, 37.94; H, 6.36; N, 9.32; Cl, 11.79%.

Methanolysis of **8**. To a suspension of **8** (56.8 mg, as the 0.8 carbonate) in dry methanol (4 ml) was added Amberlite CG120 resin (H form, 200—400 mesh, dried *in vacuo* at 60 °C), and the mixture was stirred in a sealed tube at 100 °C for 4.5 h. The mixture was filtered, and the solid was washed with 1 M aqueous ammonia. The filtrate and washings combined were concentrated to give a solid (46.7 mg). The solid showed, on TLC with 1-butanol–ethanol–chloroform–10 M ammonia (4 : 7 : 2 : 7), spots at R_f 0.60 (**10**), 0.58 (minor), 0.55 (**9**), and 0.42 (**11**). The solid was chromatographed over CM-Sephadex C-25 (NH_4 form, 0→0.1 M aqueous ammonia) to give solids of **9** (16.2 mg, 82% as the 0.1 carbonate), **10** (8.0 mg, 38% as the free base), and **11** (10.2 mg, 50% as the 0.3 carbonate) (cited in order of elution).

9: $[\alpha]_D^{25}$ +116° (*c* 1, water) (lit,[12] +144°, lit,[13] +136°); ^{1}H-NMR (20% ND_3 in D_2O): δ=3.93 (3H s, OCH_3), 5.25 (1H d, $J_{1,2}$ 3.8 Hz, H-1).

Found: C, 42.28; H, 7.44; N, 6.81%. Calcd for $C_7H_{15}NO_5\cdot 0.1H_2CO_3$: C, 42.75; H, 7.68; N, 7.06%.

10: $[\alpha]_D^{25}$ +208° (*c* 1, water); ^{1}H-NMR (20% ND_3 in D_2O): δ=4.98 (1H dd, $J_{3,4}$ 3.3 Hz, $J_{4,5}$ 1 Hz, H-4), 5.33 (1H d, $J_{1,2}$ 3.8 Hz, H-1).

Found: C, 39.54; H, 6.50; N, 6.34; Cl, 16.54%. Calcd for $C_7H_{14}NO_4Cl$: C, 39.72; H, 6.67; N, 6.62; Cl, 16.75%.

11: ^{1}H-NMR (20% ND_3 in D_2O): δ=5.03 (1H t, $J_{4,5}=J_{5,6}$ 3.3 Hz, H-5).

Found: C, 37.99; H, 6.63; N, 13.64%. Calcd for $C_6H_{13}N_2O_2Cl\cdot 0.3H_2CO_3$: C, 37.98; H, 6.88; N, 14.06%.

Methyl 6-Amino-4-chloro-4,6-dideoxy-α-D-galactopyranoside (**10**) *Obtained from* **13**. A solution of **13** (55.0 mg) in 1,4-dioxane–

methanol (2 : 1, 1 ml) was hydrogenated with palladium black in the usual manner to give a solid of **10**, 28.9 mg (86% as the base).

Methyl 6-Benzyloxycarbonylamino-6-deoxy-α-D-glucopyranoside (12). A mixture of methyl 6-amino-6-deoxy-α-D-glucopyranoside[14] (530 mg), benzyl chloroformate (0.46 ml) and anhydrous sodium carbonate (293 mg) in aqueous acetone (1 : 1, 10 ml) was stirred at room temperature for 45 min. Usual work-up gave a solid of **12**, 835 mg (93%), $[\alpha]_D^{25}$ +40° (*c* 0.5, chloroform); IR: 1700, 1560 cm^{-1}.

Found: C, 55.14; H, 6.41; N, 4.28%. Calcd for $C_{15}H_{21}NO_7$: C, 55.04; H, 6.47; N, 4.28%.

Methyl 6-Benzyloxycarbonylamino-4-chloro-4,6-dideoxy-α-D-galactopyranoside (13). To a solution of **12** (516 mg) in dry dichloromethane (15.5 ml)–dry pyridine (0.7 ml) was added sulfuryl chloride (0.47 ml, 4 mol equivalents for **12**) at −78 °C. Successive workup as described for **3** gave a syrup, which was recrystallized from ethanol to give needles of **13**, 329 mg (60%), mp 126—128 °C; $[\alpha]_D^{25}$ +129° (*c* 1, chloroform); TLC (chloroform–ethanol, 8 : 1): R_f 0.37 (*cf.* **12**, R_f 0.23); ^{1}H-NMR (pyridine-d_5–D_2O, 20 : 1): δ=4.90 (1H dd, *J* 1 and 3 Hz, H-4).

Found: C, 52.36; H, 5.89; N, 3.85; Cl, 10.34%. Calcd for $C_{15}H_{20}NO_6Cl$: C, 52.10; H, 5.83; N, 4.05; Cl, 10.25%.

2',3',4',2''-Tetra-O-acetyl-1,3,6',3''-tetrakis(N-benzyloxycarbonyl)-4'',6''-O-cyclohexylidenekanamycin A (14). To a solution of **2** (519 mg) in dry pyridine (10 ml) was added acetic anhydride (0.36 ml) and the solution was kept at room temperature overnight, then more acetic anhydride (0.36 ml) was added and the solution was heated at 50 °C for 4 h. The reaction mixture was then worked up as described for **4** to give a solid of **14**, 537 mg (90%), $[\alpha]_D^{25}$ +76° (*c* 0.5, chloroform); IR: 1240 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ=1.87 (3H), 2.02 (6H), and 2.07 (3H) (each s, $COCH_3$).

Found: C, 60.35; H, 5.99; N, 4.40%. Calcd for $C_{64}H_{76}N_4O_{23}$: C, 60.56; H, 6.04; N, 4.41%.

2',3',4',2''-Tetra-O-acetyl-1,3,6',3''-tetrakis(N-benzyloxycarbonyl)-4'',6''-O-cyclohexylidene-5-deoxy-5-epichlorokanamycin A (15). To a solution of **14** (201 mg) in dry dichloromethane (2 ml)–dry pyridine (0.4 ml) was added sulfuryl chloride (0.06 ml, 5 mol equivalents for **14**) at −78 °C, and the solution was kept at the temperature for 30 min, then at room temperature for 1.5 h. The solution showed, on TLC with chloroform–2-butanone (3 : 2), a single spot at R_f 0.45 (*cf.* **14**, R_f 0.31). The reaction mixture was then worked up as described for **3** omitting the treatment with sodium iodide to give a solid of **15**, 170 mg (83%), $[\alpha]_D^{25}$ +74° (*c* 0.5, *N,N*-dimethylformamide).

Found: C, 59.44; H, 5.87; N, 4.30; Cl, 3.01%. Calcd for $C_{64}H_{75}N_4O_{22}Cl$: C, 59.69; H, 5.87; N, 4.35; Cl, 2.75%.

2',3',4',2''-Tetra-O-acetyl-1,3,6',3''-tetrakis(N-benzyloxycarbonyl)-4'',6''-O-cyclohexylidene-5-deoxykanamycin A (16). Compound **15** (112 mg) was treated with tributylstannane similarly as described for **5** to give a solid of **16**, 96.8 mg (89%), $[\alpha]_D^{25}$ +84° (*c* 0.5, chloroform), ^{1}H-NMR ($CDCl_3$): δ=1.83, 2.00, 2.03, 2.13 (each 3H s, $COCH_3$), 1.0—2.4 (26H, C_6H_{10}, 4$COCH_3$, CH_2 at C-2,5).

Found: C, 61.53; H, 6.22; N, 4.52%. Calcd for $C_{64}H_{76}N_4O_{22}$: C, 61.33; H, 6.11; N, 4.47%.

1,3,6',3''-Tetrakis(N-benzyloxycarbonyl)-4'',6''-O-cyclohexylidene-5-deoxykanamycin A (17). Compound **16** (52.1 mg) was deacetylated as described for **6** (A) to give a solid of **17**, 42.2 mg (93%), $[\alpha]_D^{25}$ +66° (*c* 0.5, *N,N*-dimethylformamide).

Found: C, 60.93; H, 6.28; N, 4.93%, Calcd for $C_{56}H_{68}N_4O_{18}\cdot H_2O$: C, 60.97; H, 6.40; N, 5.08%.

5-Deoxykanamycin A (18). *A) From 17*: The protecting groups of **17** (98.5 mg) were removed as described for **6** (A) to give a solid of **18**, 21.5 mg (42% as the 1.5 carbonate), $[\alpha]_D^{25}$ +124° (*c* 0.5, water) [lit,[15] +101.8° (free base)]; PPC: $R_{f\ kanamycin\ A}$ 0.9; TLC (1-butanol–ethanol–chloroform–10 M aqueous ammonia=4 : 7 : 2 : 7): R_f 0.13; ^{1}H-NMR (D_2O): δ=1.6—3.4 (4H, CH_2 at C-2,5); 5.55 (1H d, *J* 4 Hz, H-1' or 1''), 5.65 (1H d, *J* 3 Hz, H-1'' or 1').

Found: C, 41.94; H, 7.03; N, 9.75%. Calcd for $C_{18}H_{36}N_4O_{10}\cdot 1.5H_2CO_3$: C, 41.71; H, 7.00; N, 9.98%.

PPC of the acidic hydrolyzates of **18** (6 M HCl, 100 °C, 50 min; descending for 2 d): $R_{f\ 2\text{-deoxystreptamine}}$ 2.5 (3-amino-3-deoxy-D-glucose) and 1.6 (6-amino-6-deoxy-D-glucose and 2,5-dideoxystreptamine).

B) From 15: **15** (54.6 mg) was treated with sodium metal in liquid ammonia as described for **6** (B) to give a solid of **18**, 16.0 mg (69% as the 1.3 carbonate).

Found: C, 42.22; H, 7.00; N, 10.26%. Calcd for $C_{18}H_{36}N_4O_{10}\cdot 1.3H_2CO_3$: C, 42.21; H, 7.09; N, 10.20%.

5-Deoxy-5-epichlorokanamycin A (19). Compound **15** (252 mg) was treated as described for **6** (A) to give a solid of **19**, 81.4 mg (75% as the 0.8 carbonate), $[\alpha]_D^{25}$ +128° (*c* 1, water); PPC: $R_{f\ kanamycin\ A}$ 1.0; ^{1}H-NMR (20% ND_3 in D_2O) δ=5.6 (3H m, H-5,1', 1'').

Found: C, 41.01; H, 6.96; N, 9.98; Cl, 6.32%. Calcd for $C_{18}H_{35}N_4O_{10}Cl\cdot 0.8H_2CO_3$: C, 40.86; H, 6.68; N, 10.14; Cl, 6.42%.

We are grateful to Professor Hamao Umezawa, Institute of Microbial Chemistry, for his suport and encouragement. We also thank Dr. Hiroshi Naganawa, Institute of Microbial Chemistry, for collaboration on ^{13}C-NMR spectral studies, and Mr. Saburo Nakada, Keio University, for carrying out elemental analyses.

Solution Conformation of Cyclic Dipeptides Having Aliphatic Side Chains

Masao TANIHARA, Tae HIZA, Yukio IMANISHI,* and Toshinobu HIGASHIMURA
Department of Polymer Chemistry, Faculty of Engineering, Kyoto University, Yoshida Honmachi, Sakyo-ku, Kyoto 606
(Received September 8, 1982)

Cyclic dipeptides having aliphatic side chains, *cyclo*(L-Val)$_2$, *cyclo*(L-Val–D-Val), *cyclo*(L-Leu)$_2$, and *cyclo*(L-Leu–D-Leu) were synthesized and their conformation in solution was investigated by circular dichroism (CD) and proton nuclear magnetic resonance (^{1}H NMR) spectroscopy. ^{1}H NMR spectra in $(CD_3)_2SO$ of *cyclo*(L-Val–D-Val) and *cyclo*(L-Leu–D-Leu) indicated that the diketopiperazine ring of these *trans* cyclic dipeptides takes a planar or a chair conformation and the molecules take a center-symmetric conformation. ^{1}H NMR spectra in $(CD_3)_2SO$ and CD spectra in CH_3OH and H_2O of *cyclo*(L-Val)$_2$ and *cyclo*(L-Leu)$_2$ indicated that the conformation of these *cis* cyclic dipeptides is planar-axial and flagpole-boat-type respectively. It is suggested that *cis* cyclic dipeptides having aliphatic side chains take such conformations in polar solvents because of the stabilization by attractive forces between aliphatic side chains.

It is well-known that the secondary structure of enzymes plays an important role in exerting their catalytic activities. Biologically active oligopeptides such as peptide antibiotics involve cyclic peptides containing unusual D-amino acids or *N*-substituted amino acids. These examples also show the importance of the secondary structure determined by these unusual amino acids on the biological activity. In order to investigate the structure/activity relationship of these polypeptides and oligopeptides, the use of synthetic cyclic peptides is very helpful.[1,2] In cyclic peptides side chain functional groups may be fixed in a specific arrangement owing to the rigid conformation of the ring moiety. The reduced freedom of conformation enables a detailed analysis of the conformation in solution to be made. The accumulation of information on the structure/activity relation will make possible the design of a molecule having a specific activity.

With this in mind we have synthesized *cyclo*(D-Leu–L-His) and *cyclo*(D-Val–L-His); these are cyclic dipeptides carrying a hydrophobic and a nucleophilic side chain, and we have investigated their hydrolytic activities toward carboxylic acid *p*-nitrophenyl esters. As consequence, these *trans* cyclic dipeptides proved to be effective catalysts for the hydrolyses of $CH_3(CH_2)_{10}COOC_6H_4NO_2(p\text{-})$ and $CH_3(CH_2)_8COOC_6H_4NO_2(p\text{-})$. On the other hand, the diastereomeric *cis* cyclic dipeptides were nearly inactive in the same reactions.[3,4] The conformation of these cyclic dipeptides in aqueous solution was investigated by nuclear magnetic resonance (NMR) and circular dichroism (CD) spectroscopy.[4,5] It was found that in these cyclic dipeptides the aromatic side chain of the histidine residue stacks over the diketopiperazine ring due to aromatic–amide interaction, and that in *trans* cyclic dipeptides the two side chains are situated on the opposite sides of the nearly planar diketopiperazine ring. Furthermore in *cis* cyclic dipeptides the two side chains compete for the space on the same side of the boat-type diketopiperazine ring. In the case of *cyclo*(L-Leu–L-His) the X-ray structural analysis of a single crystal revealed a conformation very similar to that observed in solution.[6]

In order to get some more general information about the conformational properties of cyclic dipeptides in solution, it is necessary to investigate the solution conformation of cyclic dipeptides having only aliphatic side chains, so that the aromatic–amide interaction is absent. It has been assumed[7] without firm experimental support that side chains of these cyclic dipeptides tend to take a pseudoequatorial position in a bowsprit-boat conformation of the diketopiperazine ring because of steric interactions between the side chains or between side chain and diketopiperazine ring. However, in some papers which have been published on the experimental studies of solution conformation before we started the present investigation, experimental evidence for a flagpole-boat conformation was presented. Hooker, Jr., *et al.*[8] carried out the CD investigation of *cyclo*(L-Ala)$_2$ and observed a flagpole-boat conformation in aqueous solution. Davies and Khaled[9] have measured ^{1}H NMR spectra of a number of *cyclo*(Gly–Xyz) and *cyclo*(Sar–Xyz) in $(CD_3)_2SO$ or D_2O and determined the superposition angle β of the ring from $^3J(H\text{–}C^\alpha\text{–}N\text{–}H)$ and $^5J(H\text{–}C^\alpha\text{–}C'\text{–}N\text{–}C^\alpha\text{–}H)$. They have found a boat-type conformation with many kinds of Xyz except of L-Pro and D-Abu.

We considered that the conformation of cyclic dipeptides consisting only of aliphatic α-amino acids in solution should be investigated in more detail. For this purpose, *cyclo*(L-Leu)$_2$, *cyclo*(L-Leu–D-Leu), *cyclo*(L-Val)$_2$, and *cyclo*(L-Val–D-Val) were synthesized and the relationship between the properties of aliphatic side chains and the solution conformation have been investigated.

Experimental

Cyclic Dipeptides. The *N*-terminal of an α-amino acid was blocked by benzyloxycarbonyl group and the *C*-terminal of the other α-amino acid was blocked by an ethyl ester group. Both were coupled with dicyclohexylcarbodiimide as a condensing agent to yield a linear dipeptide, both terminals of which were blocked. The benzyloxycarbonyl group was removed by catalytic hydrogenation, and the product was refluxed in CH_3OH to yield the cyclic dipeptides. Needle-like crystals were obtained by the recrystallization from CH_3OH/H_2O mixed solvent. The products subjected to thin layer chromatography with effluents $CHCl_3$(95)/CH_3OH(2)/AcOH(3) and *n*-BuOH(15)/AcOH(10)/H_2O(12)/pyridine(13) were ninhydrin-negative and colored with iodine (one spot). *cyclo*(L-Val)$_2$, mp 268 °C. Found: C, 60.33; H, 9.29; N, 13.86%.

Calcd for $C_{10}H_{18}N_2O_2$: C, 60.58; H, 9.15; N, 14.13%. *cyclo*-(L-Val-D-Val), mp 266—268 °C. Found: C, 60.14; H, 9.31; N, 14.12%. *cyclo*(L-Leu)$_2$, mp 276 °C. NMR Spectra. 100 MHz and 270 MHz ^{1}H NMR spectra were measured at room temperature with a Varian HA-100 and a Bruker WH-270 spectrometer, respectively. The solvent was $(CD_3)_2SO$ and the internal standard was $(CH_3)_4Si$. The sample concentration was 20 mg/0.4 cm^3 in 100 MHz measurement and 5 mg/0.4 cm^3 in 270 MHz NMR measurement, The NMR measurement in aqueous solution was impossible because of the extremely low solubility of cyclic dipeptides in water.

The NMR signals were assigned by the spin decoupling method in the 100 MHz or 270 MHz spectrum. The chemical shift and the coupling constant were determined from the 270 MHz NMR spectrum. The signal resolution was about $\pm$0.18 Hz.

CD Spectra. The CD spectra of the cyclic dipeptides in aqueous or methanolic solution were measured at room temperature using a JASCO J-20 spectropolarimeter. The concentration of the cyclic dipeptides was about 4×10^{-4} mol dm^{-3}, and quartz cells having optical path lengths 1 cm and 1 mm were used.

A Gaussian Cotton effect curve was assumed, and the spectra obtained were resolved into each Cotton effect component by a curve-fitting method. The molar elipticity $[\theta]$ was calculated by assuming the maximum wavelength, the half width, and the rotational strength, which were changed by $\pm$0.5, $\pm$0.5, and $\pm$0.1%, respectively. The FACOM M-190 system of Computer Center of Kyoto University was used for the computation. The computation was repeated until the standard deviation, which is the root-mean square of the difference between the calculated $[\theta]$ and the observed $[\theta]$ at each wavelength, became smaller than 10^3 deg cm^2 dmol^{-1}.

Results

NMR Spectra. cyclo*(L-Val)$_2$ and* cyclo*(L-Val-D-Val)*: 270 MHz NMR spectra of $(CD_3)_2SO$ solution of cyclic dipeptides consisting of two valyl residues were measured. Chemical shifts and coupling constants were determined on the basis of the NMR spectra and are shown in Table 1. In the NMR spectra, only one set of signals was observed for the amide protons, $C^\alpha H$, $C^\beta H$ and the $C^\gamma H_3$ for either cyclic dipeptide. This indicates that *cyclo*(L-Val)$_2$ assumes a C_2-symmetric conformation and *cyclo*(L-Leu-D-Leu) assumes a center-symmetric conformation.

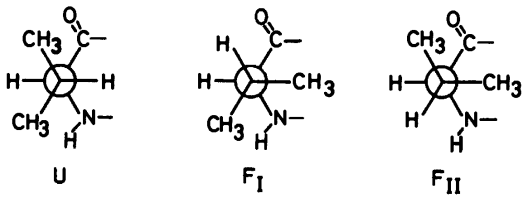

Fig. 1. Rotational isomers around C^α–C^β bond of valyl residue in cyclic dipeptide.

With regard to the side chain conformation of the valyl residues, three kinds of conformational states *U*, F_I, and F_{II} ($U + F_I + F_{II}=1$) corresponding to energy minima of internal rotation around C^α–C^β bond are available; these are illustrated in Fig. 1. The proportions of *U*, F_I, and F_{II} were calculated assuming the coupling constants between a pair of protons which are *gauche* and *trans* with regard to C^α–C^β bond to be 2.60 and 13.56 Hz, respectively.[10] On the above basis, $F_I + F_{II}$ values amount to 94% and 97% for *cyclo*(L-Val)$_2$ and *cyclo*(L-Val-D-Val), respectively. It is somewhat surprising that 94% of the available conformations of *cyclo*(L-Val)$_2$ are folded, because this type of conformation should suffer from steric crowding between side chains.

With regard to the conformation of diketopiperazine ring, information on the rotational angle ϕ of the ring can be obtained from $J_{H\text{-}C^\alpha\text{-}N\text{-}H}$. Since the diketopiperazine ring of the cyclic dipeptides are symmetric and if a planar *cis* peptide bond is assumed, the conformation of diketopiperazine ring is determined by ϕ. Karplus-type equations have been proposed[11-13] for the relationship between the H-C^α-N-H coupling constant and the dihederal angle θ [$\theta=|\phi-60|$]. However, the usual $J_{H\text{-}C^\alpha\text{-}N\text{-}H}$ values (2 Hz) of cyclic dipeptides give only scattered values of θ by the Karplus-type equations, and hence the determination of unequivocal θ value is in general difficult. In the 270 MHz NMR spectra of *cyclo*(L-Val)$_2$ and *cyclo*(L-Val-D-Val) the NH signal is a broad singlet. This makes the determination of $J_{H\text{-}C^\alpha\text{-}N\text{-}H}$ extremely difficult and inaccurate. $J_{H\text{-}C^\alpha\text{-}N\text{-}H}$ is about 1.5 Hz for either cyclic dipeptide as is seen in Table 1. Substitution of this value into the

a) δ in ppm below $(CH_3)_4Si$. b) J in Hz. c) In $(CD_3)_2SO$, $(CH_3)_4Si$ as internal standard.

Ramachandran equation[11] or the Bystrov equation[12] led to $\theta>60°$ ($\phi<0°$), while that into the Cung equation[13] gave $\theta\leq60°$ ($\phi\geq0°$). Therefore, the ring conformations are not very explicit but seem to be nearly planar.

The $C^{\alpha}H$ signals of *cyclo*(L-Val)$_2$ and *cyclo*(L-Val–D-Val) in 270 MHz NMR spectra are a broad doublet. The latter signal does not become much sharper when it is decoupled with NH. This observation as well as the broad singlet NH signals of *cyclo*(L-Val)$_2$ and *cyclo*(L-Val–D-Val) in 270 MHz NMR spectra could be interpreted if the symmetric ring conformations of *cyclo*(L-Val)$_2$ and *cyclo*(L-Val–D-Val) fluctuate around the C^{α}–N bond on the NMR time scale.

cyclo*(L-Leu)$_2$ and* cyclo*(L-Leu–D-Leu)*: 270 MHz NMR spectra of $(CD_3)_2SO$ solution of cyclic dipeptides consisting of two leucyl residues were measured. The chemical shifts and coupling constants were determined on the basis of the NMR spectra, and are shown in Table 2. Similarly to the case of cyclic dipeptides of valine, only one set of signals was observed for each proton. Therefore, it can be concluded that *cyclo*(L-Leu)$_2$ assumes a C_2-symmetric conformation and *cyclo*(L-Leu–D-Leu) assumes a center-symmetric conformation.

With regard to the side chain conformation of the leucyl residues, similarly to the case of the cyclic dipeptides of valine, three kinds of conformational states F, U_{I} and U_{II} ($F+U_{\mathrm{I}}+U_{\mathrm{II}}=1$) corresponding to energy minima of internal rotation around C^{α}–C^{β} bond are available, which are illustrated in Fig. 2. Similarly to the case of cyclic dipeptides of valine, the proportions of each conformer were calculated from $J_{\mathrm{H\text{-}C^{\alpha}\text{-}C^{\beta}\text{-}H}}$ values listed in Table 2 using the theoretical coupling constants of *trans* and *gauche* proton pairs. Consequently, F% were 23.5 and 33.6 for *cyclo*(L-Leu)$_2$ and *cyclo*(L-Leu–D-Leu), respectively. Since the conformation of *cyclo*(L-Leu)$_2$ and *cyclo*(L-Leu–D-Leu) is C_2-symmetric and center-symmetric, respectively, the proportions of F–F conformation are also 23.5 and 33.6%, respectively. When the C^{α} substituent changed from the isopropyl group of valine to the isobutyl group of leucine, the fraction of folded conformation decreased. However, still one quarter of the available conformations of *cyclo*(L-Leu)$_2$ are folded ones. These should be sterically crowded because of the two bulky side chains accommodated in the same side of diketopiperazine ring. Therefore, this observation suggests that in *cyclo*(L-Leu)$_2$ some kind of stabilization must occur between side chains or between a side chain and the diketopiperazine ring.

In the 270 MHz NMR spectra of *cyclo*(L-Leu)$_2$, the NH signal is a relatively sharp doublet, giving $J_{\mathrm{H\text{-}C^{\alpha}\text{-}N\text{-}H}}$ to be 2.4 Hz as seen in Table 2. This value leads to $\theta\leq60°$ ($\phi\geq0°$) through any of the three Karplus-type equations. It was therefore concluded that *cyclo*(L-Leu)$_2$ assumes a flagpole-boat conformation in which side chains occupy pseudoaxial positions. The $C^{\alpha}H$ signal of *cyclo*(L-Leu)$_2$ in 100 MHz NMR spectrum is a broad triplet, and it becomes a sharp quartet when it is decoupled with NH. These observations suggest that the C_2-symmetric conformation of *cyclo*(L-Leu)$_2$ is rigid on the NMR time scale.

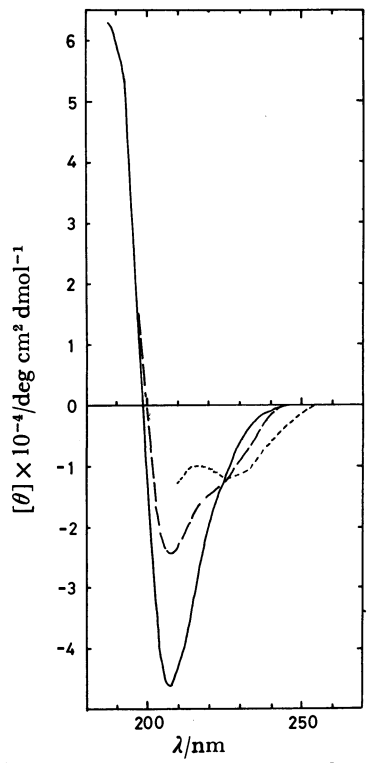

Fig. 3. Circular dichroism spectra of *cyclo*(L-Leu)$_2$. (——), in H_2O: (– – –), in CH_3OH: (------), in dioxane.

On the other hand, the NH signal of *cyclo*(L-Leu–D-Leu) in 270 NHz NMR spectra is a broad singlet, which makes the determination of $J_{\mathrm{H\text{-}C^{\alpha}\text{-}N\text{-}H}}$ extremely difficult and inaccurate. As seen in Table 2, $J_{\mathrm{H\text{-}C^{\alpha}\text{-}N\text{-}H}}$ of *cyclo*(L-Leu–D-Leu) is about 1.5 Hz, which leads to $\theta>60°$ ($\phi<0°$) by the Ramachandran equation[11] and the Bystrov equation[12] and $\theta\leq60°$ ($\phi\geq0°$) by the Cung equation.[13] Therefore, the ring conformation is not explicit but seems to be nearly planar. In 100 MHz NMR spectra of *cyclo*(L-Leu–D-Leu), the $C^{\alpha}H$ signal and the NH signal are a broad triplet and a broad singlet, respectively. The former signal becomes a sharp triplet by the decoupling with NH, and the latter signal becomes a sharp singlet by the decoupling with $C^{\alpha}H$. These observations suggest that the center-symmetric conformation of *cyclo*(L-Leu–D-Leu) is rigid on the NMR time scale.

CD Spectra. With NMR spectroscopy, except in the case of *cyclo*(L-Leu)$_2$, the coupling constant $J_{\mathrm{H\text{-}C^{\alpha}\text{-}N\text{-}H}}$ was not precisely determined and the dihedral angle θ was scattered according to the choice of Karplus-type equations. Consequently, the details of the symmetric

conformations of the diketopiperazine ring are often difficult to clarify. However, CD spectroscopy seems to be helpful to determine the ring conformation of cyclic dipeptides, as we succeeded in the conformational analysis of *cyclo*(L- or D-Leu–L-His).[5] The usefulness of CD spectroscopy is related with a result of computation that the Cotton effect due to the amide π-π^* transition changes the sign at $\theta=60°$.[8,14]

Figure 3 shows CD spectra of *cyclo*(L-Leu)$_2$ in aqueous solution and organic solvents. In aqueous solution, a positive maximum at 190 nm region and a negative minimum at 208 nm region are observed. In CH_3OH solution the negative minimum at 208 nm decreases in intensity and a shoulder appears at 225 nm region. In dioxane, which is less polar, a clear minimum exsists at 227 nm. The shoulder appearing in the 225 nm region has been observed in CD spectra of *cyclo*(L-Ala)$_2$ in CH_3OH and $(EtO)_3PO$ solutions by Hooker, Jr., *et al.*[8] They observed a week positive Cotton effect at 240 nm region in addition to the shoulder at 225 nm region, but they did not discuss the origin of the shoulder. With the present *cyclo*(L-Leu)$_2$ we did not observe any positive Cotton effect at 240 nm region. The same situation as in the case of *cyclo*(L-Leu)$_2$ was met in the CD spectrum of *cyclo*(Gly–L-Leu).[5] Therefore, we ascribe the negative minimum which shifts to the red in nonpolar solvents to the Cotton effect due to the amide π-π^* transition.[8] Furthermore, we ascribed the positive Cotton effect at 190 nm and the negative Cotton effect at 208 nm to a pair of Cotton effects due to the splitting of the amide π-π^* transition. According to this assignment, the CD spectra shown in Fig. 3 were resolved into the component Cotton effects, and are shown in Table 3. A pair of Cotton effects due to an exciton splitting should be opposite in sign and same in the absolute values of the rotational strength. In *cyclo*(L-Leu)$_2$ the couplet of lower wavelength is somewhat stronger than its pair, which should have been caused by the contribution from a Cotton effect at much lower wavelength. Since among two Cotton effects due to the exciton splitting of the amide π-π^* transition

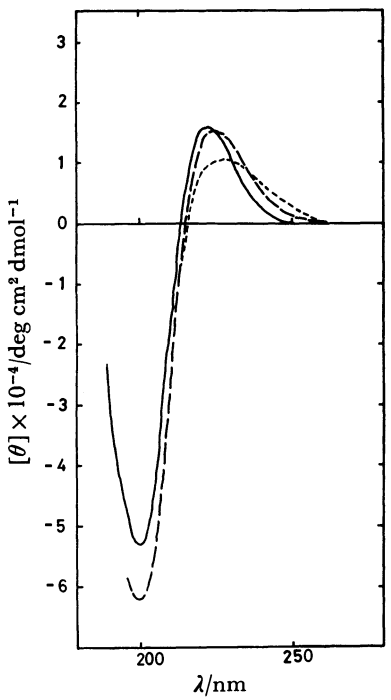

Fig. 4. Circular dichroism spectra of *cyclo*(L-Val)$_2$. (——), in H_2O: (----), in CH_3OH: (------), in dioxane.

the one at the longer wavelength is negative and the other at the shorter wavelength is positive, the rotational angle around N–C$^\alpha$ bond ϕ should be positive. This conclusion is supported by the computation of the CD spectrum of *cyclo*(L-Ala)$_2$ by Hooker, Jr., *et al.*[8] and that of a dipeptide having two substituted *cis* peptide bonds by Bayley, *et al.*[14] It is therefore concluded from CD spectra that the diketopiperazine ring of *cyclo*(L-Leu)$_2$ assumes a flagpole-boat conformation. This conclusion agrees with that obtained from the NMR spectra in $(CD_3)_2SO$ solution. The general conclusion is that *cyclo*(L-Leu)$_2$ assumes a flagpole-boat conformation in aqueous, CH_3OH and $(CD_3)_2SO$ solutions.

Figure 4 shows CD spectra of *cyclo*(L-Val)$_2$ in aqueous

solution and organic solvents. In aqueous solution two distinct Cotton effects were observed, one being negative at 200 nm and the other positive at 222 nm. On change of solvent from H_2O to CH_3OH and further to dioxane, the positive Cotton effect at 222 nm red shifted and a slight hypochromic effect was observed. The positive Cotton effect at 222 nm region is ascribed to the amide n-π^* transition allowing for its wavelength and intensity. On the other hand, the negative Cotton effect at 200 nm region is ascribed to the amide π-π^* transition allowing for its wavelength and intensity. In the present case no evidence for the splitting of the amide π-π^* transition was obtained. This has not been usual with many cyclic dipeptides. In fact, the curve-fitting method using various parameters was unable to realize a pair of Cotton effects having different sign in the 180—210 nm region. Therefore, it was considered that *cyclo*(L-Val)$_2$ shows the only Cotton effect without the splitting of the amide π-π^* transition. The results of spectral resolution by the curve-fitting method and the assignments of spectrum are shown in Table 4.

The methods of computation reported by Hooker, Jr., *et al.*[8] and Bayley, *et al.*,[14] which were applied to *cyclo*(L-Leu)$_2$, cannot be applied in the present case because of the absence of the splitting of the amide π-π^* transition. Taking into account the fact that the splitting of the π-π^* transition occurs with a nonplanar diketopiperazine ring, a planar ring (ϕ=0°) was considered for *cyclo*(L-Val)$_2$. Under such conditions the rotational strength of the amide π-π^* transition due to the exciton splitting is zero, and the observed Cotton effect of the amide π-π^* transition should have appeared due to an unclarified mechanism. No theoretical support can be provided for this explanation and a further investigation is necessary.

With *cyclo*(L-Val–D-Val) and *cyclo*(L-Leu–D-Leu) no optical activity was observed in 190—300 nm region. As was shown by NMR spectra in $(CD_3)_2SO$ solution, these cyclic dipeptides are considered to assume a symmetric conformation in aqueous solution on the time scale of the CD spectrum. In other words, their diketopiperazine ring should assume either a planar or a chair-like conformation rather than a boat-type conformation.

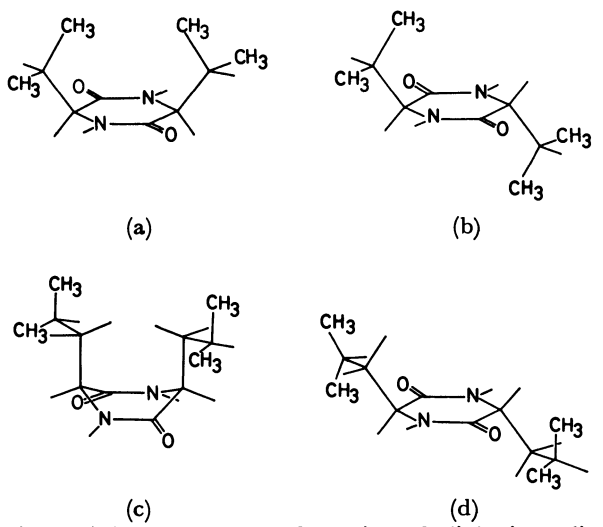

Fig. 5. Most probable conformation of aliphatic cyclic dipeptides in solution. (a), *cyclo*(L-Val)$_2$: (b), *cyclo*(L-Val–D-Val): (c), *cyclo*(L-Leu)$_2$: (d), *cyclo*(L-Leu–D-Leu).

Based on these experimental results, the most probable conformations of the four cyclic dipeptides were considered and are shown in Fig. 5.

Discussion

In the present investigation, conformations of different aliphatic cyclic dipeptides were investigated using ^1H NMR and CD spectroscopy. The same method has been used to determine the solution conformation of *cyclo*(L-Leu–L-His),[5] which was in a good agreement with the crystalline structure investigated by X-ray diffraction analysis.[6] This suggests the validity of the spectroscopy employed in the present investigation to determine the solution conformation of aliphatic cyclic dipeptides.

Vičar, *et al.*[15] investigated the side chain conformation of aliphatic cyclic dipeptide in $(CD_3)_2SO$ by ^{13}C NMR spectroscopy. According to them, *cyclo*(L-Val)$_2$ and *cyclo*(L-Val–D-Val) assume a folded conformation perfectly. On the other hand, the proportions of the folded and the unfolded form of C_2-symmetric *cyclo*(L-Leu)$_2$ were 55 and 45%, respectively. Those of C_2-symmetric *cyclo*(L-Leu–D-Leu) were 50 and 50%, respectively. A folded conformation is in general more important for their results than for the present results. However, both investigations agree in their general aspects.

Exner and Kostelnik[16] investigated the conformation of *cyclo*(L-Leu)$_2$ and *cyclo*(L-Leu–D-Leu) in $(CH_3)_2SO$ or CF_3CO_2H by ^{13}C NMR spectroscopy. They observed that two substituents of *cyclo*(L-Leu)$_2$ were magnetically equivalent and therefore the molecule took a symmetric conformation, which agrees with our conclusion reached by ^1H NMR spectroscopy. While they discussed their experimental results on the assumption that the diketopiperazine ring of *cyclo*(L-Leu)$_2$ takes a bowsprit-boat conformation, they had no experimental evidence to support the assumption. We believe that the conformation of the diketopiperazine ring of *cyclo*(L-Leu)$_2$ is flagpole-boat-type, which is supported by CD spectroscopy. Exner and Kostelnik reported the magnetic nonequivalence of two Leu residues in *cyclo*(L-Leu–D-Leu), which does not agree with our conclusion obtained by ^1H NMR spectroscopy. They synthesized *cyclo*(L-Leu–D-Leu) by the isomerization-cyclodimerization method in which L-leucine was heated at 200 °C in ethylene glycol. Under such drastic conditions, the isomerization of the cyclic dipeptide has been reported.[17,18] Since the isomerization should occur at random, their reaction product might have contained *cyclo*(L-Leu)$_2$ and *cyclo*(D-Leu)$_2$ as well as *cyclo*(L-Leu–D-Leu). This might be a reason for the magnetic nonequivalence observed by Exner and Kostelnik.

According to our experimental results, as shown in Fig. 5, *cyclo*(L-Leu)$_2$ and *cyclo*(L-Val)$_2$ take a flagpole-boat conformation and a planar-axial conformation, respectively. This conclusion differs from previous assumptions that aliphatic cyclic dipeptides in general

take bowsprit-boat conformation.[7] Furthermore, it is somewhat suprising that as far as the side chain conformation is concerned, an attractive force rather than a repulsive force operates between the aliphatic substituents.

The present experimental results can be explained on the basis that the isopropyl groups of *cyclo*(L-Val)$_2$ or the isobutyl groups of *cyclo*(L-Leu)$_2$ solubilized in polar solvents such as water, $(CH_3)_2SO$, and CH_3OH may be stabilized more by solvation of two substituents in a stacked state than by independent solvation of each substituent. In *cyclo*(L-Leu)$_2$ an attractive force between the side chains should be strong enough in polar solvents to confine the solution conformation in that characterized by $\phi > 0°$. This situation has led to a distinct H–C$^{\alpha}$–N–H coupling in NMR spectrum and a distinct splitting of the amide π-π^* transition in the CD spectrum. On the other hand, in *cyclo*(L-Val)$_2$ the conformation of the diketopiperazine ring seems to be planar-axial and to fluctuate around that conformation. This was implied by the facts that the NH signal in 270 MHz spectrum was a broad singlet, and that the splitting of the amide π-π^* transition in the CD spectrum seemed to be absent. However, the attractive force operating between the aliphatic side chains has not been explicitly observed, and a further investigation should be necessary to confirm it.

The present authors are very grateful to Prof. T. Miyazawa of the University of Tokyo for the measurement of 270 MHz NMR spectrum and the discussion of the experimental results.

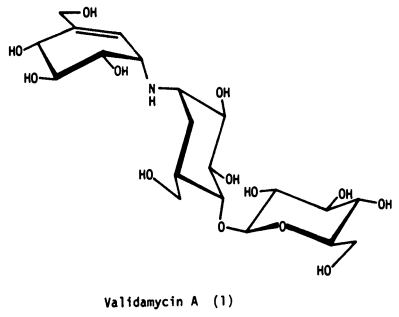
Synthetic Studies on the Validamycins. IV. Synthesis of DL-Valienamine and Related Branched-chain Unsaturated Aminocyclitols[1]

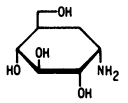
Tatsushi Toyokuni, Seiichiro Ogawa, and Tetsuo Suami*
Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223
(Received September 13, 1982)

The first synthesis has been achieved of the racemates of valienamine and its related, branched-chain unsaturated aminocyclitols. Two synthetic routes for valienamine were developed, one of which is stereoselective and highly efficient. The key transformation is a stereospecific S_N2' attack (apofacial) by an azide ion on the allyl chloride, prepared by regioselective epoxidation of the conjugated diene followed by treatment with hydrochloric acid. Some information is described which is furnished from ^{13}C NMR spectra for the new branched-chain unsaturated aminocyclitols and cyclitols.

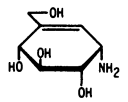
Microbial degradation of validamycin A (**1**)[2] by several soil bracteria such as *Pseudomonas denitrificans*[3] and *Flavobacterium saccharophilium*[4] gave validamine (**2**) and a branched-chain unsaturated aminocyclitol, valienamine (**3**), which is a common cardinal block of the antibiotic validamycins[5] and whose structure has been assigned as 1D-(1,3,6/2)-6-amino-4-hydroxymethyl-4-cyclohexene-1,2,3-triol by ^1H NMR spectroscopy.[3] The valienamine unit serves also as an essential block of several recently-discovered oligosaccharides, highly effective α-glucosidase inhibitors.[6] Furthermore, **3** itself has proved to exhibit an α-glucosidase inhibitory activity as well as an antibiotic activity against *Bacillus* species.[7] The above facts have in recent years stimulated considerable interest in synthetic studies of valienamine and its analogs.[8]



Validamycin A (1)



Validamine (2)



Valienamine (3)

In the present paper, as part of studies directed toward the total synthesis of validamycin A and related substances,[9] the first synthesis of DL-valienamine and related branched-chain unsaturated aminocyclitols is described. In addition, ^{13}C NMR spectra of peracetyl derivatives of aminocyclitols synthesized were measured and part of resonances were assigned by assuming the cyclohexene ring to be in a half-chair conformation.

Results and Discussion

Synthesis of Branched-chain Unsaturated Aminocyclitols Related to Valienamine. It was previously reported[9] that bromination of tri-*O*-acetyl-(1,3/2)-4-methylene-5-cyclohexene-1,2,3-triol (**4**)[10] gave two 1,4-addition products **5** and **6**, from which four monobromo derivatives **7**—**10** of the branched-chain unsaturated cyclitols were prepared. Azidolysis of these bromo compounds and successive reduction readily afforded several branched-chain unsaturated aminocyclitols including DL-valienamine in good yield.

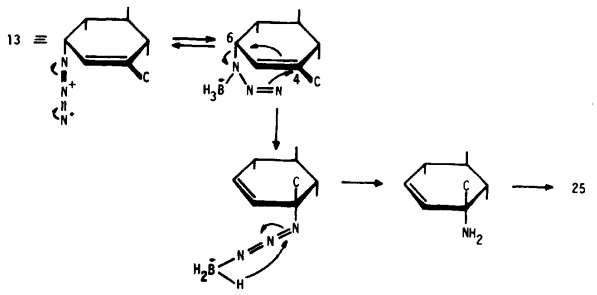
When **5** was treated with sodium azide in *N,N*-dimethylformamide (DMF) at room temperature for 1 h,[11] the crystalline diazide **11** was exclusively obtained in 88% yield. Similar treatment of **6** with an azide ion gave the diazide **13** as a homogeneous syrup in 96% yield. The ^1H NMR spectrum of **13** revealed the olefinic proton (H-5) as a doublet (J=7.5 Hz) at δ=5.94, supporting the pseudoaxial conformation for the C-6 azido group of **13**.[12] However, in the ^1H NMR spectrum of **11**, the H-5 appeared as a poorly resolved multiplet overlapping with H-3. Configurational assignment of C-6 of **11** was, therefore, made by comparing the chemical shift of H-6 in **11** with that of **13**. The signal, observed at δ=4.38 in **13**, was shifted upfield in **11**, indicating that the H-6 is pseudoaxial,[13] that is, **11** is the C-6 epimer of **13**. In both cases, azidolysis proceeded *via* a direct S_N2 mechanism with inversion of the configuration at C-6.

Selective reduction of the azido group of **11** was readily achieved by treatment with hydrogen sulfide[14] in pyridine–water (1 : 1) at room temperature and, after

treatment with acetic anhydride in pyridine, the product was isolated as the crystalline bis(acetamide) **12** in 90% yield. On the other hand, reduction of **13** with sodium boronhydride in 2-propanol at the reflux temperature followed by a similar acetylation gave, after chromatography on silica gel, two crystalline bis(acetamide)s **14** and **25** in 43 and 18% yields, respectively. The structures of **12** and **14** were confirmed by observing the expected singlet at $\delta=5.43$[15] and doublet ($J=4.5$ Hz) at $\delta=5.65$ for the olefinic protons (H-5) of **12** and **14**, respectively. The spectrum of **25** exhibited two olefinic protons as a doublet of doublets ($J=1.5$ and 10.5 Hz) and a broad doublet ($J=10.5$ Hz) at $\delta=5.56$ and 6.21, in support of the proposed structure. The configuration at C-4 was tentatively assigned by assuming that the C-6 azido group would migrate to C-4 during the reduction through a boron-assisted allylic rearrangement (S_N2').[16]



Similarly, the bromides **7** and **8** were converted into the monoazides **15** and **17** in 96 and 80% yields, respectively, which were in turn converted into the corresponding acetamides **16** and **18** in 91 and 87% yields, respectively, by reduction with hydrogen sulfide followed by acetylation.

Synthesis of DL-*Valienamine (22).* The synthesis of DL-valienamine starting from **6** was first worked out. The regioselective displacement reaction[9] at C-7 by an acetoxyl group was fairly improved by use of potassium acetate and 18-crown-6. Treatment of **6** with potassium acetate in DMF in the presence of 18-crown-6 at room temperature produced after 2.5 h a mixture of monobromides **9** and **10**, which, without further isolation, was subjected to azidolysis of the remaining secondary bromine atom, giving, after chromatography on silica gel, two azido compounds **19** (43%) and **21** (26%), together with a syrupy 3 : 1 mixture (9%) of **23** and **24**.[9] The structures of **19** and **21** were assigned, on the basis of a criterion similar to that used for the configurational assignment on C-6 of **11**, by use of the result that the pseudoaxial H-6 proton of **19** resonates at higher field ($\delta=4.12$—4.30) than does the pseudoequatorial H-6 proton of **21** ($\delta=4.41$). Further support was provided by the appearance of the doublet ($J=7.5$ Hz) at $\delta=5.96$ due to the olefinic proton (H-5) of **21**, indicating that the allylic proton (H-6) is pseudoequatorial. Starting from either **5** or **6** gave almost the same distributions of products **19** and **21**.

Reduction of **19** and **21** with hydrogen sulfide followed by acetylation afforded the acetamides **20** and **22** in 69 and 70% yields, respectively. The ^1H NMR spectra of **22** in $CDCl_3$ and in DMSO-d_6 were superimposable on those of an authentic sample of penta-*N*,*O*-acetyl-(+)-valienamine.[17] The structure of **20** was confirmed by an observation of the coupling constant ($J=8.5$ Hz) between H-1 and H-6, indicative of an axial-pseudoaxial relationship between these protons. Compounds **20** and **22** were also obtained by reduction of **19** and **21** with sodium boronhydride in 2-propanol in appropriate yields without any allylic rearrangements of the azido group.

Alternative Stereospecific Synthesis of **22**. Although the synthesis of DL-valienamine had been accomplished, the preparation of large quantities of **21** was very tedious because of nonselectiveness of the reaction. This, coupled with the difficulty of separating **21** from **19** purely, required us to develop an alternative stereoselective route for **21**. For this purpose the spiro epoxide **26** obtainable by regioselective epoxidation of **4**[18] was chosen as the starting material. If S_N2' attack of an azide ion on allylic halides, prepared by halogenation of spiro epoxide with hydrogen halides, would proceed stereospecifically, **19** or **21** could be obtained selectively.

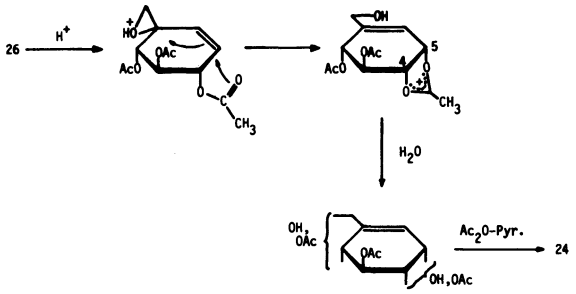
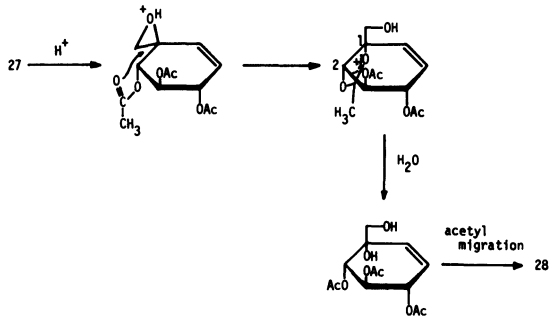
Treatment of **4** with 1.2 molar equiv. of *m*-chloroperoxybenzoic acid in dichloromethane at room temperature yielded two crystalline spiro epoxides **26** (24%) and **27** (8%), together with a branched-chain cyclitol triacetate **28** (13%) and a mixture of slower-moving (on TLC) products from which pentaacetate **24**, after acetylation, was isolated (21% from **4**). TLC analysis indicated that **26** and **27** were both acid-labile and partly changed, under acidic conditions, into **24** and **28**, respectively. Therefore, the yield of **26** and especially of **27** were increased when the oxidation was carried out under buffered conditions (see experimental section).

In the ^1H NMR spectrum of **28**, a triplet ($J=8$ Hz) at $\delta=3.70$ due to H-2 changed to a doublet ($J=8$ Hz) on deuteration. The structure of **28** was finally confirmed by converting it into known **29** and **30**[9] by the usual acetylation. The structures of **26** and **27** were deduced from their behavior under acidic conditions (CH_2Cl_2, TsOH monohydrate, pH *ca.* 3). The pentaacetate **24** derived from **26** was considered to be formed through an S_Ni' mechanism by assistance of the C-4 acetoxyl

group at C-5, leading to the 4,5-cyclic acetoxonium ion that would be opened by a trace of water. On the other hand, the pentaacetate **28** derived from **27** might be formed through an S_N1 mechanism with the participation of C-2 acetoxyl group. For further confirmation, **26** was converted into known methyl ethers **31** and **32**[9] on treatment with methanolic sodium methoxide in methanol followed by acetylation.

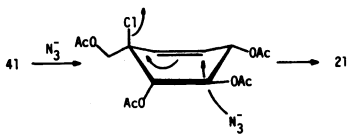




Azidolysis of **26** and **27** with sodium azide in DMF followed by acetylation gave the single azides **33** and **36** in 86 and 81% yields, respectively. They were converted, by reduction with hydrogen sulfide and successive acetylation, into the corresponding acetamides **34** and **35**, and **37** and **38**, respectively. Further acetylation of **34** and **37** yielded **35** and **38** quantitatively. Presumably the formation of **34** and **37** involved the acetyl group migration, during the reduction, from the tertiary hydroxyl to the amino group generated.

Epoxide ring opening of **26** with concd hydrochloric acid in tetrahydrofuran at 0 °C gave a sole crystalline chlorohydrin **39** quantitatively. An attempt to purify **39** with a silica-gel column resulted in the acetyl group migration giving rise to an isomer **40**. Acetylation of **39** and **40** under acidic conditions gave the same tetraacetate **41** in a quantitative yield. The ^{1}H NMR spectrum revealed the C-7 methylene protons as a singlet at δ=4.32, indicative of the presence of an acetoxymethyl group in support of the assigned structure.

Azidolysis of **41** with sodium azide in DMF at 60 °C gave only one azido product stereospecifically in 93% yield, which proved to be identical in all respects with **21**. The reaction seemed to involve an S_N2' mechanism (apofacial)[19] through an initial attack of an azide ion at C-6. When **41** was treated with sodium acetate, a complex mixture of **23**, **24**, **29**, and **30** was formed. The neighboring acetoxyl group participation was likely to predominate when a weak nucleophile was used.



Preparation of Protected Valienamine. In order to prepare the building blocks for the synthesis of validoxylamines and related biologically-important secondary amines, diisopropylidene and benzylidene derivatives of DL-valienamine were synthesized.

De-*O*-acetylation of **21** with methanolic sodium methoxide gave the hydroxy azide **43**, which was successively treated with an excess of 2,2-dimethoxypropane in the presence of *p*-toluenesulfonic acid in DMF, giving the crystalline di-*O*-isopropylidene derivative **47** in 72% yield. Similarly, **44** was directly obtained, along with **47**, from the mixture of **19** and **21** prepared by azidolysis of **9**. In this case, attempted isolation of the hydroxy azides **42** and **43** failed because of their similar chromatographic mobilities.

On the other hand, benzylidenation of the mixture of the hydroxy azides **42** and **43** with 1.2 molar equiv. of α,α-dimethoxytoluene gave, after a silica-gel column chromatography, **51** and **52** in 43 and 18% yields, respectively. Their ^{1}H NMR spectra revealed the vinylic protons as a broad singlet at δ=5.41 for **51** and a doublet (J=5 Hz) at δ=5.69 for **52**, confirming the assigned structures.

Compounds **44** and **47** were reduced with hydrogen sulfide in 1 : 1 pyridine–water to give **45** and **48** in quantitative yields, respectively, which were converted into the corresponding acetamides **46** and **49**. Compound **48** was further converted into the trifluoroacetamide **50** on treatment with trifluoroacetic anhydride in pyridine. Di-*O*-isopropylidene derivative **48** thus obtained is a very versatile building block for the preparation of validoxylamines and related secondary amines. Recently the synthesis of DL-validoxylamine B using **48** was accomplished.[1b]

^{13}C NMR Spectra of Valienamine and Related Compounds. On the basis of the ^{13}C NMR data for 1-methylcyclohexene,[20] the chemical shift assignment on peracetyl derivatives of valienamine (**22**) and related aminocyclitols (**12**, **14**, **16**, **18**, and **20**) and cyclitols (**23** and **24**) could be made by assuming the cyclohexene ring to be in a half-chair conformation. The results are summarized in Table 1.

The chemical shift of the methyl carbon of acetyl group is nearly indifferent to their stereochemical

a) Unless otherwise noted, the ^{13}C NMR spectra were measured in dimethyl-d_6 sulfoxide. b) For convenience, the carbon atoms were numbered as for derivatives of 1-methylcyclohexene. c) Measured in $CDCl_3$. d), e) Assignments may be reversed.

environment. However, it is obvious that the methyl carbon of acetamido (NHAc) group appears at lower field by 1.44—2.17 ppm than that of acetoxyl (OAc) group.

The chemical shift of C-7 is influenced not only by the substituent (OAc, NHAc) attached thereto but also by the orientation of the substituent at C-3. When an OAc group is attached (Z=OAc), the C-7 appears in the range 61.99—62.47 ppm, whereas it appears at upper field (38.80—39.26 ppm) when an NHAc group is attached (Z=NHAc). In addition, a pseudoaxial OAc or NHAc group at C-3 causes a down-field shift of 0.06—0.46 ppm for C-7.

The sp^2 carbons appear in the range 130.39—139.60 ppm for a quarternary sp^2 carbon (C-1) and in the range 120.12—129.61 ppm for a tertiary sp^2 carbon (C-2). It is noteworthy that their chemical shifts depend on substituents (OAc, NAc) at the allylic positions (C-3 or C-7) and also on the configuration at C-3. Thus, the replacement of an OAc group by an NHAc group at each position causes a downfield shift for the β sp^2 carbon by 1.97—3.67 ppm and an upfield shift for the γ sp^2 carbon by 2.56—4.78 ppm. In addition, the pseudoaxial OAc or NHAc group at C-3 (Y=OAc, NHAc) causes an upfield shift of 2.65—3.60 ppm for the β carbon (C-2) and a downfield shift of 2.18—4.20 ppm for the γ carbon (C-1). The latter γ effect on sp^2 carbon[21)] is interesting because in cyclohexane rings the γ effect caused by an axial substituent is generally associated with upfield shifts.[22)] This effect is presumably due to some steric interaction.[23)]

Experimental

General. Melting points were determined on a Büchi 510 capillary melting point apparatus and are uncorrected. Unless otherwise noted, ^1H NMR spectra were taken on a Varian EM-390 (90 MHz) in chloroform-*d* ($CDCl_3$), dimethyl-d_6 sulfoxide (DMSO-d_6), or methanol-d_4 (CD_3OD) with reference to tetramethylsilane as an internal standard. The peak positions are given in terms of δ-values and values given for coupling constants are of first-order. ^{13}C NMR spectra were obtained on a Varian XL-100 spectrometer in $CDCl_3$ or DMSO-d_6 containing a drop of TMS as an internal standard with complete proton-decoupling. TLC was performed on a precoated silica gel 60 F-254 plaques (Merck, Darmstadt; 0.25 mm thickness), and the spots were visualized by heating above 150 °C after spraying with concd sulfuric acid. The silica gel used for a column chromatography was Wakogel C-300 (Wako Pure Chemical Industries, Ltd.). Solutions were dried over anhydrous sodium sulfate and evaporated under reduced pressure at 40—50 °C. Acetylation was conventionally carried out with acetic anhydride in anhydrous pyridine at room temperature overnight and the reaction mixture was evaporated to remove an excess of reagents. Crude syrupy products (acetates) were usually purified preliminarily by rapid passage through a short column of active alumina with chloroform.

DL-*Tri*-O-*acetyl*-(*1,3*/*2,6*)-*6*-*azido*-*4*-*azidomethyl*-*4*-*cyclohexene*-*1,2,3*-*triol* (***11***). A mixture of DL-tri-*O*-acetyl-(1,3,6/2)-6-bromo-4-bromomethyl-4-cyclohexene-1,2,3-triol (**5**)[9)] (0.16 g), sodium azide (0.1 g, 4 molar equiv.), and *N,N*-dimethylformamide (DMF) (6 ml) was stirred at room temperature for 1 h. The mixture was diluted with ethyl acetate (20 ml), and the organic layer was thoroughly washed with cold water (3× 10 ml) and then dried. Evaporation of the solvent left a

syrup which crystallized upon standing in a desiccator overnight. Recrystallization from ethanol gave **11** (0.12 g, 88%): mp 82—83 °C; ^{1}H NMR ($CDCl_3$) δ=2.03 (3H, s), 2.09 (3H, s), and 2.11 (3H, s) (OAc), 3.81 (2H, broad s, C$\underline{H}_2N_3$), 4.14—4.38 (1H, m, H-6), 5.14—5.50 (2H, m, H-1 and H-2), and 5.59—5.98 (2H, m, H-3 and H-5).

Found: C, 44.14; H, 4.60; N, 23.67%. Calcd for $C_{13}H_{16}N_6O_6$: C, 44.32; H, 4.58; N, 23.85%.

DL-*Tri*-O-*acetyl-(1,3,6/2)-6-azido-4-azidomethyl-4-cyclohexene-1,2,3-triol (13)*. A mixture of DL-tri-*O*-acetyl-(1,3/2,6)-6-bromo-4-bromomethyl-4-cyclohexene-1,2,3-triol (**6**)[9] (0.2 g), sodium azide (0.12 g, 4 molar equiv.), and DMF (10 ml) was treated similarly as described in the preparation of **11** for 0.5 h. The crude product was purified by passing through a short column of silica gel with chloroform to give **13** (0.16 g, 96%) as a homogeneous syrup: ^{1}H NMR (60 MHz,[24]) $CDCl_3$) δ= 2.03 (3H, s), 2.07 (3H, s), and 2.11 (3H, s) (OAc), 3.77 (2H, broad s, C$\underline{H}_2N_3$), 4.38 (1H, t, J=7.5 Hz, H-6), 4.95—5.80 (3H, m, H-1, H-2, and H-3), and 5.94 (1H, broad d, J=7.5 Hz, H-5).

Found: C, 44.10; H, 4.63; N, 23.55%. Calcd for $C_{13}H_{16}N_6O_6$: C, 44.32; H, 4.58; N, 23.85%.

DL-*Penta*-N,O-*acetyl-(1,3/2,6)-6-amino-4-aminomethyl-4-cyclohexene-1,2,3-triol (12)*. Into a stirred solution of **11** (94 mg) in 1 : 1 pyridine–water (5 ml) was bubbled hydrogen sulfide at room temperature for 1.5 h, during which insoluble sulfur appeared. The yellowish mixture was evaporated and the residue was acetylated in the usual way. The crude product was transferred to the top of a column of silica gel (3 g) and first eluted with benzene, giving sulfur as colorless needles, and then with 1 : 5 ethanol–benzene, giving colorless crystals. Recrystallization from ethanol gave **12** (92 mg, 90%) as feathers: mp 229.5—230.5 °C (sintering at 228 °C): ^{1}H NMR (DMSO-d_6) δ=1.80 (6H, s), 1.94 (6H, s), and 1.98 (3H, s) (OAc and NAc), 3.45 (1H, dd, J=4 and 16.5 Hz, changing to d with J=16.5 Hz on deuteration) and 3.82 (1H, dd, J=7 and 16.5 Hz, changing to d with J=16.5 Hz on deuteration) (C$\underline{H}_2$NHAc), 4.45—4.80 (1H, m, H-6, changing on deuteration), 4.87—5.33 (2H, m, H-1 and H-2), 5.43 (1H, broad s, H-5), 5.61 (1H, broad d, J=*ca.* 6 Hz, H-3), 7.85 (1H, dd, J= 4 and 7 Hz, C-7-N$\underline{H}$Ac, disappearing on deuteration), and 8.10 (1H, d, J=ɔ Hz, C-6-N$\underline{H}$Ac, disappearing on deuteration).

Found: C, 53.15; H, 6.30; N, 7.20%. Calcd for $C_{17}H_{24}N_2O_8$: C, 53.12; H, 6.29; N, 7.29%.

DL-*Penta*-N,O-*acetyl-(1,3,6/2)-6-amino-4-aminomethyl-4-cyclohexene-1,2,3-triol (14)* and DL-*Penta*-N,O-*acetyl-(1,3,4/2)-4-amino-4*-C-*aminomethyl-5-cyclohexene-1,2,3-triol (25)*. A suspension of **13** (144 mg), sodium boronhydride (93 mg), and 2-propanol (5 ml) was refluxed gently for 1 h. After cooling, the excess of hydride was decomposed by gradual addition of 6 M (1 M=1 mol dm^{-3}) acetic acid (*ca.* 2 ml), and then the mixture was evaporated to dryness. The resulting soild was acetylated in the usual way, and the product was chromatographed on a column of silca gel (5 g). Elution with 1 : 5 ethanol–benzene gave three fractions.

The first fraction gave a small amount of unresolved mixture, which was not further characterized.

The second fraction gave a colorless syrup, which crystallized on standing in a desiccator overnight. Recrystallization from ethanol gave **25** (29 mg, 18%): mp 178.5—181 °C (sintering at 170 °C); ^{1}H NMR ($CDCl_3$) δ=1.94 (3H, s), 1.99 (6H, s), 2.01 (3H, s), and 2.06 (3H, s) (OAc and NAc), 3.28 (1H, dd, J=6 and 13 Hz, changing to d with J=13 Hz on deuteration) and 3.81 (1H, dd, J=6.3 and 13 Hz, changing to d with J=13 Hz on deuteration) (C$\underline{H}_2$NHAc), 5.00 (1H, d, J=10.5 Hz, H-3), 5.15—5.70 (2H, m, H-1 and H-2), 5.56 (1H, dd, J=1.5 and 10.5 Hz, H-6), and 5.92—6.33 (3H, m, H-5 and 2×N$\underline{H}$Ac, changing to broad d with J=10.5 Hz at δ=6.21 on deuteration).

Found: C, 52.91; H, 6.07; N, 7.43%. Calcd for $C_{17}H_{24}N_2O_8$: C, 53.12; H, 6.29; N, 7.29%.

The third fraction gave colorless crystals, which were recrystallized from ethanol, giving **14** (67 mg, 43%) as columns: mp 253—255 °C; ^{1}H NMR (DMSO-d_6) δ=1.77 (3H, s), 1.84 (3H, s), 1.91 (3H, s), and 1.97 (6H, s) (OAc and NAc) 3.46 (1H, dd, J=5 and 15 Hz, changing to d with 15 Hz on deuteration) and (3.92 1H, dd, J=7.5 and 15 Hz, changing to d with J=15 Hz on deuteration) (C$\underline{H}_2$NHAc), 4.74 (1H, ddd, J=4.5, 5, and 9 Hz, H-6, changing to dd with J=4.5 and 5 Hz on deuteration), 4.95 (1H, dd, J=5 and 10.5 Hz, H-1), 5.34 (1H, dd, J=7.5 and 10.5 Hz, H-2), 5.55 (1H, d, J=7.5 Hz, H-3), 5.65 (1H, d, J=4.5 Hz, H-5), 7.84 (1H, dd, J=5 and 7.5 Hz, C-7-N$\underline{H}$Ac, disappearing on deuteration), and 8.11 (1H, d, J=9 Hz, C-6-N$\underline{H}$Ac, disappearing on deuteration).

Found: C, 52.84; H, 6.23; N, 6.99%. Calcd for $C_{17}H_{24}N_2O_8$: C, 53.12; H, 6.29; N, 7.29%.

DL-*Tetra*-O-*acetyl-(1,3/2,4)-5-azidomethyl-5-cyclohexene-1,2,3,-4-tetrol (15)*. A mixture of DL-tetra-*O*-acetyl-(1,3/2,4)-5-bromomethyl-5-cyclohexene-1,2,3,4-tetrol (**7**)[9] (0.15 g), sodium azide (47 mg, 2 molar equiv.), and DMF (6 ml) was stirred at room temperature overnight. The mixture was diluted with ethyl acetate (20 ml) and successively washed with cold water (3×10 ml), and then dried. Evaporation of the solvent gave **15** (0.13 g, 96%) as an analytically pure colorless syrup: ^{1}H NMR ($CDCl_3$) δ=1.98 (6H, s) and 2.02 (6H, s) (OAc), 3.78 (2H, s, C$\underline{H}_2N_3$), 5.21—5.45 (2H, m, H-2 and H-3), 5.45—5.65 (1H, m, H-1), and 5.65—5.88 (2H, broad s, H-4 and H-6).

Found: C, 48.51; H, 5.17; N, 11.12%. Calcd for $C_{15}H_{19}N_3O_8$: C, 48.78; H, 5.19; N, 11.38%.

DL-*Tetra*-O-*acetyl-(1,2,4/3)-5-azidomethyl-5-cyclohexene-1,2,3,-4-tetrol (17)*. A mixture of DL-tetra-*O*-acetyl-(1,2,4/3)-5-bromomethyl-5-cyclohexene-1,2,3,4-tetrol (**8**)[9] (0.15 g), sodium azide (47 mg, 2 molar equiv.), and DMF (5 ml) was treated similarly as described in the preparation of **15**. The crude product was purified by passing through a silica-gel column (5 g) with 1 : 5 2-butanone–toluene as an eluent to give **17** (108 mg, 80%) as a syrup: ^{1}H NMR ($CDCl_3$) δ=2.01 (3H, s), 2.04 (3H, s), and 2.11 (3H, s) (OAc), 3.84 (2H, s, C$\underline{H}_2N_3$), 5.15 (1H, dd, J=4 and 10.5 Hz, H-2), 5.29—5.76 (3H, m, H-1, H-3, and H-4), and 6.00 (1H, broad d, J=6 Hz, H-6).

Found: C, 48.96; H, 5.26; N, 11.25%. Calcd for $C_{15}H_{19}N_3O_8$: C, 48.78; H, 5.19; N, 11.38%.

DL-*Penta*-N,O-*acetyl-5-aminomethyl-5-cyclohexene-1,2,3,4-tetrol (16)*. Hydrogen sulfide was bubbled into a stirred solution of **15** (0.13 g) in 2 : 1 pyridine–water (9 ml) at room temperature for 1.5 h. The mixture was evaporated and the residue was acetylated in the usual way. The product was purified by passing through a short column of silica gel with 1 : 5 ethanol–benzene as an eluent to give colorless crystals. Recrystallization from ethanol gave **16** (0.12 g, 91%): mp 131.5—132.5 °C; ^{1}H NMR ($CDCl_3$) δ=1.98 (3H, s), 2.01 (6H, s), 2.04 (3H, s), and 2.07 (3H, s) (OAc and NAc), 3.71 (1H, dd, J=5 and 15 Hz, changing to d with J=15 Hz on deuteration) and 3.98 (1H, dd, J=7 and 15 Hz, changing to d with J=15 Hz on deuteration) (C$\underline{H}_2$NHAc), 5.15—5.43 (2H, m, H-2 and H-3), and 5.43—6.02 (4H, m, H-1, H-4, H-6, and N$\underline{H}$Ac, changing to relatively narrow m at δ=5.43—5.82 on d uteration).

Found: C, 52.68; H, 5.95; N, 3.52%. Calcd for $C_{17}H_{23}NO_9$: C, 52.98; H, 6.02; N, 3.63%.

DL-*Penta*-N,O-*acetyl-(1,2,4/3)-5-aminomethyl-5-cyclohexene-1,2,-3,4-tetrol (18)*. Reduction of **17** (69 mg) with hydrogen

sulfide in 2 : 1 pyridine–water (5 ml), followed by acetylation, was carried out in the same manner as in the preparation of **16**. The product was purified by passage through a silica-gel column (3 g) with 1 : 10 ethanol–benzene to give **18** (62 mg, 87%): mp 148.5—149.5 °C; ^{1}H NMR ($CDCl_3$) δ=1.97 (3H, s), 2.00 (3H, s), 2.02 (3H, s), and 2.08 (6H, s) (OAc and NAc), 3.75 (1H, dd, J=5.5 and 15 Hz, changing to d with J=15 Hz on deuteration) and 4.00 (1H, dd, J=7 and 15 Hz, changing to d with J=15 Hz on deuteration) ($C\underline{H}_2$NHAc), 5.08 (1H, ddd, J=0.8, 3.5, and 10 Hz, H-2), 5.50 (1H, dd, J=8 and 10 Hz, H-3), 5.52—5.73 (2H, m, H-1 and H-4), and 5.73—5.97 (2H, broad d, J=*ca.* 5 Hz, H-6 and N$\underline{H}$Ac, changing to dd with J=0.8 and 6.5 Hz at δ=5.87 on deuteration).

Found: C, 53.15; H, 5.93; N, 3.69%. Calcd for $C_{17}H_{23}NO_9$: C, 52.98; H, 6.02; N, 3.63%.

DL-*Tetra*-O-*acetyl*-*(1,3/2,6)*- ***(19)*** *and* -*(1,3,6/2)*-*6*-*azido*-*4*-*cyclohexene*-*1,2,3*-*triol* ***(21)***. A mixture of **6** (338 mg), potassium acetate (78 mg, 1 molar equiv.), 18-crown-6 (0.1 g), and DMF (10 ml) was stirred at room temperature for 2.5 h. The sodium azide (105 mg, 2 molar equiv.) was then added to the mixture and the stirring was continued for an additional 1 h. The mixture was then diluted with ethyl acetate (30 ml) and the solution was washed with cold water several times, and dried. TLC indicated the presence of three components, together with a trace of some other products. Evaporation of the solvent and chromatography of the residue on a silica-gel column (10 g) with 1 : 10 2-butanone–toluene as an eluent gave three fractions. The first fraction gave crystals, which were recrystallized from ethanol, giving **19** (125 mg, 43%) as tiny prisms: mp 68—68.5 °C; ^{1}H NMR ($CDCl_3$) δ=2.01 (3H, s), 2.03 (3H, s), 2.05 (3H, s), and 2.08 (3H, s) (OAc), 4.12—4.30 (1H, m, H-6), 4.38 and 4.70 (AB-quartet, J=15 Hz, $C\underline{H}_2$OAc), 5.14—5.43 (2H, m, H-1 and H-2), and 5.67—5.86 (2H, m, H-3 and H-5).

Found: C, 48.68; H, 5.21; N, 11.28%. Calcd for $C_{15}H_{19}N_3O_8$: C, 48.78; H, 5.19; N, 11.38%.

The second fraction gave **21** (76 mg, 26%) as a syrup: ^{1}H NMR ($CDCl_3$) δ=2.03 (3H, s), 2.05 (6H, s), and 2.12 (3H, s) (OAc), 4.41 (1H, dd, J=4.5 and 7.5 Hz, H-6), 4.40 and 4.70 (AB-quartet, J=13 Hz, $C\underline{H}_2$OAc), 5.15 (1H, dd, J=4.5 and 10 Hz, H-1), 5.49 (1H, dd, J=7 and 10 Hz, H-2), 5.68 (1H, broad d, J=7 Hz, H-3), and 5.96 (1H, broad d, J=7.5 Hz, H-5).

Found: C, 48.64; H, 5.19; N, 11.23%. Calcd for $C_{15}H_{19}N_3O_8$: C, 48.78; H, 5.19; N, 11.38%.

The third fraction gave a homogeneous syrupy mixture of DL-penta-*O*-acetyl-(1,3/2,4)- (**23**) and -(1,2,4/3)-5-hydroxymethyl-5-cyclohexene-1,2,3,4-tetrol (**24**), weighing 26 mg (9%). By comparing its ^{1}H NMR spectrum with those of authentic samples[9] the ratio of **23** and **24** was found to be *ca.* 3 : 1.

When **5** was used instead of **6**, a similar result was obtained.

DL-*Penta*-N,O-*acetyl*-*(1,3,6/2)*-*6*-*amino*-*4*-*hydroxymethyl*-*4*-*cyclohexene*-*1,2,3*-*triol (penta*-N,O-*acetyl*-DL-*valienamine)* ***(22)***.

a) Hydrogen sulfide was bubbled into a solution of **21** (57 mg) in 2 : 1 pyridine–water (3 ml) at room temperature for 1 h. The mixture was evaporated and the residue was acetylated in the usual way. Purification of the acetate by passage through a silica-gel column (2 g) with 1 : 10 ethanol–benzene gave crystals, which were recrystallized from ethanol to afford **22** (42 mg, 70%) as tiny prisms: mp 180—181 °C; ^{1}H NMR ($CDCl_3$) δ=2.03 (6H, s) and 2.06 (9H, s) (OAc and NAc), 4.36 and 4.66 (AB-quartet, J=14 Hz, $C\underline{H}_2$OAc), 4.89—5.23 (2H, m, H-1 and H-6), 5.69—6.00 (2H, m, H-5 and N$\underline{H}$Ac, changing to broad d with J=4.5 Hz at δ=5.90; ^{1}H NMR (100 MHz,[25] DMSO-d_6) δ=1.86 (3H, s), 1.93 (3H, s), and 2.20 (9H, s) (OAc and NAc), 4.42 and 4.67 (AB-quartet, J=14 Hz, $C\underline{H}_2$OAc), 4.81 (1H, td, J=4.5 and 9.0 Hz, H-6), 5.03 (1H, dd, J=4.5 and 9.5 Hz, H-1), 5.36 (1H, dd, J=7 and 9.5 Hz, H-2), 5.58 (1H, d, J=7 Hz, H-3), 5.87 (1H, broad d, J=4.5 Hz, H-5), and 8.15 (1H, d, J=9 Hz, N$\underline{H}$Ac, disappearing on deuteration). The spectra were superimposable on those of an authentic optically-active sample.[17]

b) A suspension of **21** (43 mg), sodium boronhydride (13 mg), and 2-propanol (3 ml) was refluxed for 3.5 h. After cooling, the excess of hydride was decomposed by gradual addition of 6 M acetic acid and the mixture was evaporated to dryness. The residue was acetylated in the usual way and the product was chromatographed on a silica-gel column (2 g) with 1 : 1 2-butanone–toluene as an eluent, giving **22** (26 mg, 65%): mp 178—179.5 °C, identical with the compound obtained above.

DL-*Penta*-N,O-*acetyl*-*(1,3/2,6)*-*6*-*amino*-*4*-*hydroxymethyl*-*4*-*cyclohexene*-*1,2,3*-*triol* ***(20)***. *a)* Compound **19** (195 mg) was similarly reduced by hydrogen sulfide to give **20** (140 mg, 69%): mp 120—121 °C; ^{1}H NMR ($CDCl_3$) δ=1.94 (3H, s), 2.00 (3H, s), and 2.03 (9H, s) (OAc and NAc), 4.35 and 4.68 (AB-quartet, J=13 Hz, $C\underline{H}_2$OAc), 4.84 (1H, dd, J=7.7 and 8.5 Hz, H-6, changing to d with J=8.5 Hz on deuteration), 5.10 (1H, dd, J=8.5 and 10.5 Hz, H-1), 5.37 (1H, dd, J=7.8 and 10.5 Hz, H-2), 5.74 (2H, broad s, H-3 and H-5), and 6.06 (1H, broad d, J=*ca.* 7.7 Hz, N$\underline{H}$Ac, disappearing on deuteration).

Found: C, 53.18; H, 6.04; N, 3.55%. Calcd for $C_{17}H_{23}NO_9$: C, 52.98; H, 6.02; N, 3.63%.

b) Compound **19** (134 mg) was treated with sodium boronhydride (41 mg) in a similar manner as in the preparation of **22** to give **20** (84 mg, 65%): mp 119—120 °C, identical with the compound obtained above.

Epoxidation of ***4***: *Synthesis of* DL-*2,3,4*-*Tri*-O-*acetyl*-*1,7*-*anhydro*-*(1,2,4/3)*- ***(26)*** *and* -*(1,3/2,4)*-*1*-C-*hydroxymethyl*-*5*-*cyclohexene*-*1,2,3,4*-*tetrol* ***(27)***. *a)* A mixture of DL-tri-*O*-acetyl-(1,3/2)-4-methylene-5-cyclohexene-1,2,3-triol (**4**)[18] (0.3 g), 70% *m*-chloroperoxybenzoic acid (*m*CPBA) (0.33 g, 1.2 molar equiv.), and dichloromethane (5 ml) was stirred at room temperature for 12 h. The progress of reaction was monitored by TLC (1 : 5 2-butanone–toluene). Two new components (R_f 0.42 and 0.36) appeared and then were gradually converted into slower-moving components before **4** was completely consumed. The reaction mixture was cooled in an ice-bath, and the precipitates (*m*-chlorobenzoic acid) were removed by filtration. The filtrate was washed successively with 10% aqueous sodium sulfite solution, saturated aqueous sodium hydrogencarbonate solution, and water, and then dried. Evaporation of the solvent and chromatography of the residue (0.23 g) on a silica-gel column (7 g) with 1 : 5 2-butanone–toluene gave, as the first fraction, **27** (25.4 mg, 8%) as plates: mp 124.5—125.5 °C; ^{1}H NMR ($CDCl_3$) δ=2.01 (6H, s) and 2.05 (3H, s) (OAc), 2.73 and 3.18 (AB-quartet, J=5 Hz, $C\underline{H}_2O$), 5.32—5.55 (3H, m, H-3, H-4, and H-5), 5.55—5.75 (1H, m, H-2), and 5.84 (1H, dd, J=1.5 and 10 Hz, H-6).

Found: C, 54.73; H, 5.65%. Calcd for $C_{13}H_{16}O_7$: C, 54.93; H, 5.67%.

The second fraction gave crystals, which were recrystallized from ethanol to give **26** (76 mg, 24%) as plates: mp 108.5—109 °C; ^{1}H NMR ($CDCl_3$) δ=2.02 (3H, s) and 2.06 (6H, s) (OAc), 2.88 (2H, s, $C\underline{H}_2O$), 5.29—5.60 (4H, m, H-2, H-3, H-4, and H-5), and 5.96 (1H, dd, J=2 and 10.5 Hz, H-6).

Found: C, 54.73; H, 5.69%. Calcd for $C_{13}H_{16}O_7$: C, 54.93; H, 5.67%.

The third fraction gave crystals, which were recrystallized from ethanol to give DL-3,4,7-tri-*O*-acetyl-(1,2,4/3)-1-*C*-hydroxymethyl-5-cyclohexene-1,2,3,4-tetrol (**28**) (44 mg, 13%): mp 100.5—102 °C; ^{1}H NMR ($CDCl_3$) δ=2.05 (3H, s), 2.07 (3H,

s), and 2.11 (3H, s) (OAc), 2.99 (1H, d, J=8 Hz, C-2-OH, disappearing on deuteration), 3.23 (1H, s, C-1-OH, disappearing on deuteration), 3.70 (1H, t, J=8 Hz, H-2, changing to d with J=8 Hz on deuteration), 4.07 and 4.25 (AB-quartet, J=12 Hz, C$\underline{H}_2$OAc), 5.28 (1H, t, J=8 Hz, H-3), 5.45 (1H, dd, J=1 and 12 Hz), and 5.69 (1H, dd, J=1 and 12 Hz) and 5.85 (1H, dd, J=1 and 12 Hz) (H-5 and H-6).

Further elution of the column gave an unresolved mixture (163 mg). After acetylation in the usual way, followed by fractionation on a silica-gel column (8 g) with 1 : 5 2-butanone–toluene, pentaacetate **24** was obtained in 91 mg (21% from **4**) as a syrup. The ^{1}H NMR spectrum was superimposable on that of an authentic sample.[9]

Acetylation of **28** (29 mg) with acetic anhydride (2 ml) and pyridine (2 ml) at room temperature for 4 d gave, after separation by a silica-gel column (3 g with) 1 : 5 2-butanone–toluene, DL-penta-*O*-acetyl- (**30**) and DL-2,3,4,7-tetra-*O*-acetyl-(1,2,4/3)-1-*C*-hydroxymethyl-5-cyclohexene-1,2,3,4-tetrol (**29**) in 19 mg (52%) and 8 mg (24%) as a syrup, respectively. These compounds were identical with the authentic samples.[9]

b) Compound **4** (0.3 g) was treated with 70% *m*CPBA (0.33 g, 1.2 molar equiv.) in dichloromethane (15 ml), buffered at pH 8 with phosphate buffer solution[26] (20 ml), with vigorous stirring at room temperature. After 20 min, an additional amount of *m*CPBA (0.28 g) was added to the reaction mixture and stirring was continued for further 40 min. The organic layer was then separated and washed similarly as described above. Evaporation of the solvent followed by fractionation of the residual products on a silica-gel column (10 g) gave **26** (124 mg, 31%) and **27** (86 mg, 27%).

c) The above reaction was carried out similarly by using saturated aqueous sodium hydrogencarbonate solution as an acid scavenger, instead of the phosphate buffer solution. Compounds **26** and **27** were obtained in 37 and 29% yields, respectively.

d) A similar epoxidation reaction was carried out in the presence of solid sodium hydrogencarbonate as an acid acceptor. Compounds **26** and **27** were isolated in 39 and 28% yields, respectively.

*Reaction of Spiro Epoxides **26** and **27** under Acidic Conditions.* Spiro epoxides **26** and **27** were each dissolved in dichloromethane containing a trace of *p*-toluenesulfonic acid monohydrate (pH *ca.* 3) and each solution was left at room temperature for 30 min. Examination on TLC revealed that **26** had been converted into slower-moving products, which were convertible into pentaacetate **24** by acetylation, whereas **27** led to triacetate **28**.

*Reaction of **26** with Sodium Methoxide.* To a solution of **26** (0.11 g) in methanol (5 ml) was added 1 M methanolic sodium methoxide (1.3 ml), and the mixture was left at room temperature overnight. After neutralization with Amberlite IR-120 (H^+), the solution was evaporated and the residue was acetylated in the usual way for 5 d. The products were fractionated on a silica-gel column (7 g) with 1 : 5 2-butanone–toluene as an eluent to give DL-tetra-*O*-acetyl-(1,2,4/3)-1-*C*-methoxymethyl-5-cyclohexene-1,2,3,4-tetrol (**32**) (76 mg, 55%), mp 130—131 °C, and the triacetate **31** (11 mg, 9%) as a syrup. They were identical with authentic samples[9] previously obtained from **5**.

DL-*Tetra*-O-*acetyl-(1,2,4/3)-1*-C-*azidomethyl-5-cyclohexene-1,2,-3,4-tetrol (**33**).* A mixture of **26** (125 mg), sodium azide (87 mg), ammonium chloride (24 mg), and DMF (2 ml) was stirred at room temperature for 20 h and then at 60 °C for 3 h. The mixture was evaporated to dryness and the residue was acetylated with acetic anhydride (2 ml) and pyridine (2 ml) at room temperature for 2 d and then at 40 °C overnight. The mixture was evaporated and the residue was purified by passage through a silica-gel column (10 g) with 1 : 8 2-butanone–toluene to give **33** (140 mg, 86%) as a syrup: ^{1}H NMR ($CDCl_3$) δ=2.00 (3H, s), 2.02 (3H, s), and 2.07 (6H, s) (OAc), 3.56 and 3.91 (AB-quartet, J=12.5 Hz, C$\underline{H}_2$N$_3$), 5.20 (1H, dd, J=1.5 and 10.5 Hz, H-2), 5.29—5.64 (2H, m, H-3 and H-4), and 5.73 (1H, dd, J=3 and 11 Hz) and 6.17 (1H, dd, J=1.5 and 11 Hz) (H-5 and H-6).

Found: C, 48.05; H, 5.21; N, 11.26%. Calcd for $C_{15}H_{19}N_3O_8$: C, 47.78; H, 5.19; N, 11.38%.

DL-*Tetra*-O-*acetyl-(1,3/2,4)-1*-C-*azidomethyl-5-cyclohexene-1,2,-3,4-tetrol (**36**).* A mixture of **27** (126 mg), sodium azide (87 mg), ammonium chloride (24 mg), and DMF (2 ml) was treated in a similar manner as in the preparation of **33**. The crude product was subsequently acetylated with acetic anhydride (2 ml) and pyridine (2 ml) at room temperature for 2 d. The mixture was evaporated and the residue was purified by passage through a short column of alumina with ethyl acetate to give crystals, which were recrystallized from ethanol, giving **36** (132 mg, 81%) as particles: mp 99—100 °C; ^{1}H NMR ($CDCl_3$) δ=2.00 (6H, s), 2.03 (3H, s), and 2.08 (3H, s) (OAc), 3.41 and 3.72 (AB-quartet, J=13 Hz, C$\underline{H}_2$N$_3$), 5.27—5.79 (3H, m, H-1, H-2, and H-3), and 5.79—6.03 (2H, m, H-5 and H-6).

Found: C, 47.84; H, 5.22; N, 11.35%. Calcd for $C_{15}H_{19}N_3O_8$: C, 47.78; H, 5.19; N, 11.38%.

DL-*Penta*-N,O-*acetyl-(1,2,4/3)-1*-C-*aminomethyl-5-cyclohexene-1,2,3,4-tetrol (**35**).* Into a stirred solution of **32** (135 mg) in 2 : 1 pyridine–water (3 ml) was bubbled hydrogen sulfide at room temperature for 5 d. The mixture was evaporated to dryness and the residue was acetylated in the usual way for 2 d. The crude products, which were shown to contain two components (R_f 0.27 and 0.39) by TLC analysis (1 : 5 ethanol–benzene), were placed on a column of silica gel (5 g) and first eluted with toluene, giving sulfur, and then with 1 : 5 ethanol-toluene, giving desired products. The fraction having R_f 0.4 yielded **35** (40 mg, 28%) as a syrup: ^{1}H NMR ($CDCl_3$) δ= 1.93 (3H, s), 2.00 (3H, s), 2.02 (3H, s), 2.05 (3H, s), and 2.09 (3H, s) (NAc and OAc), 3.04 (1H, dd, J=6 and 14 Hz, changing to d with J=14 Hz on deuteration) and 4.44 (1H, dd, J=7.5 and 14 Hz, changing to d with J=14 Hz on deuteration) (C$\underline{H}_2$NHAc), 5.08 (1H, d, J=10.5 Hz, H-2), 5.36—5.53 (1H, m, H-4), 5.59 (1H, dd, J=7.5 and 10.5 Hz, H-3), 5.72 (1H, dd, J=3 and 10 Hz, H-5), 6.11 (1H, broad t, J=*ca.* 7 Hz, N$\underline{H}$, disappearing on deuteration), and 6.43 (1H, dd, J=1.5 and 10 Hz, H-6).

Found: C, 53.17; H, 6.03; N, 3.37%. Calcd for $C_{17}H_{23}NO_9$: C, 52.98; H, 6.02; N, 3.63%.

The fraction having R_f 0.3 yielded DL-*N*-acetyl-2,3,4-tri-*O*-acetyl-(1,2,4/3)-1-*C*-aminomethyl-5-cyclohexene-1,2,3,4-tetrol (**34**) (83 mg, 66%) as a syrup: ^{1}H NMR ($CDCl_3$) δ=1.96 (3H, s), 2.00 (3H, s), 2.02 (3H, s), and 2.10 (3H, s) (OAc and NAc), 3.00 (1H, dd, J=6 and 14 Hz, changing to d with J=14 Hz on deuteration) and 3.62 (1H, dd, J=7 and 14 Hz, changing to d with J=14 Hz on deuteration) (C$\underline{H}_2$NHAc), 3.37—3.83 (1H, m, O$\underline{H}$, disappearing on deuteration), 5.01 (1H, d, J=10 Hz, H-2), 5.29—5.62 (2H, m, H-3 and H-4), 5.63 (1H, dd, J=1.5 and 10 Hz, H-5), 5.88 (1H, dd, J=1 and 10 Hz, H-6), and 6.36 (1H, broad t, J=*ca.* 7 Hz, N$\underline{H}$Ac, disappearing on deuteration).

Found: C, 52.72; H, 6.26; N, 3.97%. Calcd for $C_{15}H_{21}NO_8$: C, 52.47; H, 6.17; N, 4.08%.

Further acetylation of **34** at 50 °C for 2 d gave **35** quantitatively.

DL-*Penta*-N,O-*acetyl-(1,3/2,4)-1*-C-*aminomethyl-5-cyclohexene-1,2,3,4-tetrol (**38**).* Reduction of **36** (92 mg) with hydrogen sulfide and successive acetylation, were carried out in a similar way as in the preparation of **35**. Similar fractionation of the

acetylated products gave two fractions (R_f 0.25 and 0.32, 1 : 5 ethanol–benzene). The fraction having R_f 0.32 gave **38** (76 mg, 79%): mp 183—184 °C; ^{1}H NMR ($CDCl_3$) δ=1.97 (3H, s), 2.03 (9H, s), and 2.08 (3H, s) (OAc and NAc), 3.48 (1H, dd, J=5.5 and 14 Hz, changing to d with J=14 Hz on deuteration) and 3.88 (1H, dd, J=5 and 14 Hz, changing to d with J=14 Hz on deuteration) ($C\underline{H}_2NHAc$), 5.36—5.65 (2H, m, H-2 and H-3), and 5.68—6.11 (4H, m, H-4, H-5, H-6, and N$\underline{H}$Ac, changing on deuteration).

Found: C, 53.34; H, 6.14; N, 3.52%. Calcd for $C_{17}H_{23}NO_9$: C, 52.98; H, 6.02; N, 3.63%.

The fraction having R_f 0.25 gave DL-*N*-acetyl-2,3,4-tri-*O*-acetyl-(1,3/2,4)-1-*C*-aminomethyl-5-cyclohexene-1,2,3,4-tetrol (**37**) (11 mg, 13%) as a syrup: ^{1}H NMR ($CDCl_3$) δ=2.02 (9H, s) and 2.10 (3H, s) (OAc and NAc), 3.46 (1H, broad s, O$\underline{H}$, disappearing on deuteration), 3.57 (2H, d, J=6 Hz, $C\underline{H}_2$-NHAc, changing to s on deuteration), 5.13—5.53 (3H, m, H-2, H-3, and H-4), 5.62 (1H, broad d, J=*ca.* 10.5 Hz) and 5.80 (1$\underline{H}$, d, J=10.5 Hz) (H-5 and H-6), and 5.97—6.32 (1H, m, N$\underline{H}$, disappearing on deuteration).

Found: C, 52.86; H, 6.23; N, 3.88%. Calcd for $C_{15}H_{21}NO_8$: C, 52.47; H, 6.17; N, 4.08%.

Further acetylation of **37** at room temperature for 2 d yielded **38** quantitatively.

DL-*Tetra-O-acetyl-(1,3/2,4)-4-chloro-4-C-hydroxymethyl-5-cyclohexene-1,2,3-triol (**41**).* To a cooled, stirred solution of **26** (0.11 g) in tetrahydrofuran (4 ml) was added 12 M hydrochloric acid[27] (0.035 ml), and the mixture was allowed to stand at 0—5 °C for 1 h. The mixture was then neutralized by gradual addition of solid sodium hydrogencarbonate with ice-cooling. After precipitates had been removed by filtration, the filtrate was evaporated to give a syrup, which was crystallized from ethanol–water, affording **39** (124 mg, 100%) as particles: mp 125—126.6 °C; ^{1}H NMR ($CDCl_3$) δ=1.98 (3H, s), 2.02 (3H, s), and 2.10 (3H, s) (OAc), 2.78 (1H, broad s, O$\underline{H}$, disappearing on deuteration), 3.70 and 4.01 (AB-quartet, J=11.5 Hz, $C\underline{H}_2OH$), 5.25—5.67 (3H, m, H-1, H-2, and H-3), and 5.75 (2H, broad s, H-5 and H-6).

Found: C, 48.70; H, 5.40; Cl, 11.06%. Calcd for $C_{13}H_{17}ClO_7$: C, 48.68; H, 5.34; Cl, 11.05%.

Purification of **39** by chromatography on silica gel with 1 : 5 2-butanone–toluene induced an acetyl group migration, which led to partial transformation into syrupy 1,2,7-triacetate **40**: ^{1}H NMR ($CDCl_3$) δ=2.02 (3H, s), 2.08 (3H, s), and 2.10 (3H, s) (OAc), 2.99 (1H, d, J=6 Hz, O$\underline{H}$, disappearing on deuteration), 4.00—4.22 (1H, m, H-3, changing to dd with J=2 and 8 Hz at δ=4.11 on deuteration), 4.39 (2H, s, $C\underline{H}_2OAc$), 5.18—5.70 (2H, m, H-1 and H-2), and 5.57 (1H, d, J=10 Hz) and 5.75 (1H, broad d, J=10 Hz) (H-5 and H-6).

Found: C, 48.73; H, 5.46; Cl, 11.06%. Calcd for $C_{13}H_{17}ClO_7$: C, 48.68; H, 5.34; Cl, 11.05%.

Treatment of **39** and **40** with acetic anhydride containing a trace of sulfuric acid at room temperature overnight gave the tetraacetate **41** in a quantitative yield. Recrystallization from ethanol gave an analytical sample, thin plates: mp 90—91 °C; ^{1}H NMR ($CDCl_3$) δ=1.98 (3H, s), 2.01 (3H, s), 2.08 (3H, s), and 2.11 (3H, s) (OAc), 4.32 (2H, s, $C\underline{H}_2OAc$), 5.37—5.62 (3H, m, H-1, H-2, and H-3), and 5.62 (1H, d, J=10 Hz) and 5.78 (1H, d, J=10 Hz) (H-5 and H-6).

Found: C, 49.58; H, 5.13; Cl, 9.84%. Calcd for $C_{15}H_{19}ClO_8$: C, 49.66; H, 5.28; Cl, 9.77%.

*Azidolysis of **41** with Sodium Azide.* A mixture of **41** (90 mg), sodium azide (32 mg, 2 molar equiv.), and DMF (4 ml) was stirred at 60 °C for 15 h. TLC (1 : 5 2-butanone–toluene) indicated that **4** (R_f 0.47) was converted into a sole azide (R_f 0.41). The mixture was then diluted with ethyl acetate (10 ml) and the solution was washed with cold water thoroughly, and dried. Evaporation of the solvent gave **21** (85 mg, 93%) as a syrup, which was shown to be identical with the authentic sample by ^{1}H NMR analysis.

*Acetolysis of **41** with Sodium Acetate.* A mixture of **41** (53 mg), sodium acetate (48 mg, 4 molar equiv.), and DMF (2 ml) was stirred at 110 °C for 30 h. The mixture was then evaporated and the residue was acetylated in the usual way. TLC and ^{1}H NMR analyses indicated that the acetylated product contained **23**, **24**, **29**, and **30**. Further isolation was not attempted.

DL-*1,2 : 3,7-Di-O-isopropylidene-(1,3,6/2)-6-azido-4-hydroxymethyl-4-cyclohexene-1,2,3-triol (**47**).* To an ice-cooled, stirred solution of **21** (0.16 g) in methanol (3 ml) was added 1 M methanolic sodium methoxide (1 ml), and the mixture was left at 0—5 °C overnight. The reaction mixture was then treated with Amberlite IR-120 (H^+) and evaporated to give a syrup (97 mg). Without further purification, the syrup was dissolved in DMF (3 ml) and to the solution was added 2,2-dimetho ypropane (1 ml) and *p*-toluenesulfonic acid (8 mg). The mixture was stirred at room temperature overnight. After neutralization with solid sodium hydrogencarbonate, the mixture was diluted with ethyl acetate (30 ml), then washed with cold water (3×10 ml), and dried. Evaporation of the solvent left a syrup, which crystallized upon standing in a desiccator. Recrystallization from ethanol gave **47** (88 mg, 72% from **21**): mp 116.5—117.5 °C; ^{1}H NMR ($CDCl_3$) δ=1.40 (3H, s), 1.47 (6H, s), and 1.52 (3H, s) (isopropylidene $C\underline{H}_3$), 3.61 (1H, dd, J=4 and 9.5 Hz, H-1), 3.97 (1H, dd, J=7.5 and 9.5 Hz, H-1), 3.97 (1H, dd, J=7.5 and 9.5 Hz, H-2), 4.15—4.57 (4H, m, H-3, H-6, and $C\underline{H}_2O$), and 5.41 (1H, broad d, J=*ca.* 6 Hz, H-5).

Found: C, 55.37; H, 6.75; N, 14.67%. Calcd for $C_{13}H_{19}N_3O_4$: C, 55.51; H, 6.81; N, 14.94%.

DL-*1,2 : 3,7-Di-O-isopropylidene-(1,3/2,6)-6-azido-4-hydroxymethyl-4-cyclohexene-1,2,3-triol (**44**).* A mixture of DL-tetra-*O*-acetyl-(1,3,6/2)-6-bromo-4-hydroxymethyl-4-cyclohexene-1,2,3-triol (**9**)[9] (0.3 g), sodium azide (72 mg, 1.5 molar equiv.), and DMF (10 ml) was stirred at room temperature for 3 h. TLC showed the formation of two products **19** (major) and **21** (minor). The mixture was diluted with ethyl acetate (40 ml) and the solution was washed with cold water, and then dried. Evaporation of the solvent gave a syrupy mixture of **19** and **21** (0.29 g, 100%).

A 0.16 g portion of the mixture was then treated with 1 M methanolic sodium methoxide (3 ml) in methanol (3 ml) at 0—5 °C overnight. The mixture was neutralized with Amberlite IR-120 (H^+) and evaporated, giving a colorless syrup (68 mg), which was purified by a silica-gel column (3 g) with 1 : 3 2-butanone–toluene to give a syrupy mixture of DL-(1,3/2,6)- (**42**) and (1,3,6/2)-6-azido-4-hydroxymethyl-4-cyclohexene-1,2,3-triol (**43**) (59 mg, 66%). Isolation of **42** and **43** was not achieved, because their chromatographic mobilities on silica gel were identical.

Found: C, 41.97; H, 5.50; N, 20.60%. Calcd for $C_7H_{11}N_3O_4$: C, 41.79; H, 5.51; N, 20.89%.

The syrupy mixture (85 mg) was dissolved in DMF (3 ml) and treated with 2,2-dimethoxypropane (1 ml) in the presence of *p*-toluenesulfonic acid (8 mg) at room temperature for 24 h. After neutralization with solid sodium hydrogencarbonate, the mixture was worked up similarly as described in the preparation of **47**. The crude products were fractionated on a silica-gel column (6 g) with 1 : 15 2-butanone–toluene as an eluent to give two fractions. The first fraction gave **44** (75 mg, 42% from **9**): mp 79—80 °C; ^{1}H NMR ($CDCl_3$) δ=1.40 (3H, s), 1.46 (6H, s), and 1.54 (3H, s) (isopropylidene $C\underline{H}_3$), 3.50 (1H, dd, J=8 and 10 Hz) and 3.69 (1H, dd, J=7 and 10 Hz) (H-1 and H-2), 4.00—4.67 (4H, m, H-3, H-6, and $C\underline{H}_2O$), and

5.28 (1H, s, H-5).

Found: C, 55.37; H, 6.75; N, 14.67%. Calcd for $C_{13}H_{19}N_3O_4$: C, 55.51; H, 6.81; N, 14.94%.

The second fraction gave **47** (17 mg, 9% from **9**): mp 116—117 °C, identical with the compound obtained from **21** described above.

DL-*1,2: 3,7-Di-O-isopropylidene-(1,3,6/2)-6-acetamido-4-hydroxymethyl-4-cyclohexene-1,2,3-triol (49).* Hydrogen sulfide was bubbled into a solution of **47** (80 mg) in 1 : 1 pyridine–water (3 ml) at room temperature for 1 h. The pale yellow mixture with sulfur precipitated was evaporated and the syrup residue was placed on a short column of alumina. The first fraction eluted with toluene gave sulfur as needles and the second fraction, showing a positive test of ninhydrin, eluted with ethanol gave DL-1,2 : 3,7-di-*O*-isopropylidene-(1,3,6/2)-6-amino-4-hydroxymethyl-4-cyclohexene-1,2,3-triol (**48**) (72 mg, 100%) as a syrup.

Acetylation of **48** (30 mg), without further purification, in the usual way gave, after recrystallization from ethanol, **49** (35 mg, 98%) as particles: mp 241—242 °C; ^{1}H NMR ($CDCl_3$–D_2O) δ=1.41 (3H, s), 1.45 (6H, s), and 1.55 (3H, s) (isopropylidene C$\underline{H}_3$), 1.99 (3H, s, NAc), 3.50—3.86 (2H, m, H-1 and H-2), 4.13 and 4.47 (AB-quartet, J=15 Hz, C$\underline{H}_2$O), 4.50 (1H, broad d, J=*ca.* 5 Hz, H-3), 4.66—4.94 (1H, m, H-6), and 5.62 (1H, broad d, J=*ca.* 5 Hz, H-5).

Found: C, 60.85; H, 7.83; N, 4.61%. Calcd for $C_{15}H_{23}NO_5$: C, 60.59; H, 7.80; N, 4.71%.

DL-*1,2 : 3,7-Di-O-isopropylidene-(1,3,6/2)-6-trifluoroacetamido-4-hydroxymethyl-4-cyclohexene-1,2,3-triol (50).* To an ice-cooled solution of **48** (0.26 g) in pyridine (4 ml) was added dropwise trifluoroacetic anhydride (0.45 ml) and the mixture was left at room temperature overnight. Evaporation of the solvent followed by coevaporation with toluene several times gave a colorless syrup, which solidified upon standing in a desiccator to give **50** (0.34 g, 96%). It was analytically pure without further purification: ^{1}H NMR ($CDCl_3$) δ=1.41 (6H, s), 1.46 (3H, s), and 1.54 (3H, s) (isopropylidene C$\underline{H}_3$), 3.56—3.82 (2H, m, H-1 and H-2), 4.11 and 4.41 (AB-quartet, J=15 Hz, C$\underline{H}_2$O), 4.39—4.55 (1H, m, H-6, relatively sharpened on deuteration), and 5.61 (1H, broad d, J=*ca.* 5 Hz, H-5).

Found: C, 51.16; H, 5.77; N, 3.97%. Calcd for $C_{15}H_{20}NF_3O_5$: C, 51.28; H, 5.74; N, 3.99%.

DL-*1,2:3,7-Di-O-isopropylidene-(1,3/2,6)-6-acetamido-4-hydroxymethyl-4-cyclohexene-1,2,3-triol (46).* Compound **44** (190 mg) was reduced in a similar manner as described in the preparation of **48** to give DL-1,2 : 3,7-di-*O*-isopropylidene-(1,3/2,6)-6-amino-4-hydroxymethyl-4-cyclohexene-1,2,3-triol (**45**) (170 mg, quantitative) as a syrup, showing a positive test of ninhydrin.

Acetylation of **45** (30 mg) in the usual way gave **46** (33 mg, 92%) as a pale yellow syrup, which was crystallized from ether by scratching the flask to give **46** (22 mg, 62%): mp 178—179 °C; ^{1}H NMR ($CDCl_3$–D_2O) δ=1.39 (3H, s), 1.43 (6H, s), and 1.52 (3H, s) (isopropylidene C$\underline{H}_3$), 1.96 (3H, s) (NAc), 3.53 (1H, t, J=9 Hz, H-2), 3.78 (1H, dd, J=7.5 Hz, H-1), 4.12 and 4.46 (AB-quartet, J=12.5 Hz, C$\underline{H}_2$O), 4.57—4.81 (2H, m, H-3 and H-6), and 5.38 (1H, broad s, H-5).

Found: C, 60.69; H, 7.64; N, 4.81%. Calcd for $C_{15}H_{23}NO_5$: C, 60.59; H, 7.80; N, 4.71%.

DL-*3,7-O-Benzylidene-(1,3/2,6)- (51) and -(1,3,6/2)-6-azido-4-hydroxymethyl-4-cyclohexene-1,2,3-triol (52).* A syrupy mixture (247 mg) of **42** and **43** was dissolved in DMF (10 ml) and treated with α,α-dimethoxytoluene (0.228 ml, 1.2 molar equiv.) in the presence of *p*-toluenesulfonic acid (12 mg) at 60—65 °C under reduced pressure (22 mmHg) (1 mmHg=133.322 Pa) for 3.5 h. TLC (1 : 2 2-butanone–toluene) indicated the formation of two products (major, R_f 0.4; minor, R_f 0.3). After neutralization with Amberlite IRA-400 (OH^-), the solvent was removed by evaporation and the residue was fractionated on a silica-gel column (5 g) with 1 : 3 2-butanone–toluene as an eluent. The first fraction gave **51** (154 mg, 43%) as needles: mp 149—150 °C; ^{1}H NMR (CD_3OD) δ=3.45 (1H, dd, J=9 and 10.5 Hz, H-2), 3.67 (1H, dd, J=7.5 and 10.5 Hz, H-1), 3.98 (1H, broad d, J=*ca.* 7.5 Hz, H-6), 4.18—4.47 (3H, m, H-3 and C$\underline{H}_2$O), 5.41 (1H, s, H-5), 5.67 (1H, s, benzylic proton), and 7.29—7.64 (5H, m, phenyl).

Found: C, 57.96; H, 5.26; N, 14.48%. Calcd for $C_{14}H_{15}N_3O_4$: C, 58.13; H, 5.23; N, 14.53%.

The second fraction gave **52** (64 mg, 18%) as feathers: decomp at 180.5 °C; ^{1}H NMR (CD_3OD) δ=3.62—4.00 (2H, m, H-1 and H-2), 4.15—4.42 (2H, m, H-3 and H-6), 4.50 (2H, s, C$\underline{H}_2$O), 5.69 (1H, d, J=5 Hz, H-5), 5.70 (1H, s, benzylic proton), and 7.28—7.68 (5H, m, phenyl).

Found: C, 58.06; H, 5.34; N, 14.88%. Calcd for $C_{14}H_{15}N_3O_4$: C, 58.13; H, 5.23; N, 14.53%.

The authors express their sincere thanks to Dr. Shoji Omoto, Meiji Seika Kaisha, Ltd., for the ^{13}C NMR spectra, to Mr. Saburo Nakada for the elementary analyses, and to Mr. Yasuo Abe and Mr. Yoshikazu Iwasawa for assistance in preparative experiments. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 56550617 from the Ministry of Education, Science and Culture.

Ditritylation of Methyl and Benzyl α-D-Gluco-, -Manno-, and -Galactopyranosides and Preparation of Their Partially Benzylated Derivatives[1)]

Shinkiti Koto,* Naohiko Morishima, Toyosaku Yoshida, Masaharu Uchino, and Shonosuke Zen

School of Pharmaceutical Sciences, Kitasato University, Shirokane, Minato-ku, Tokyo 108

(Received September 14, 1982)

The ditritylation of methyl and benzyl α-D-gluco-, -manno-, and -galactopyranosides with trityl chloride in pyridine at 70 °C proceeds in a regioselective manner to give the 2,6-ditrityl ethers of the glucosides, the 3,6-ones of the mannosides, and both 2,6- and 3,6-ones of the galactosides. The rearrangement of the trityl group from *O*-3 to *O*-2 of the mannosides at 100 °C causes the selective formation of the 2,6-ditrityl ethers. From the 2,6- and the 3,6-ditrityl ethers, the 3,4- and 2,4-dibenzyl ethers of the hexopyranosides are prepared.

Trityl group has been used for the selective protection of the primary hydroxyl group of carbohydrates;[2)] tritylation of the secondary one has also often been carried out.[2,3)] The continuing methodological study of oligosaccharide synthesis[4)] needs efficient synthetic routes to various kinds of partially benzylated monosaccharides. This has made us investigate the ditritylation of methyl and benzyl α-D-gluco-, -manno-, and -galactopyranosides in order to protect the primary hydroxyl group and one of the secondary ones temporarily. To our surprise, no practical synthesis of such ditrityl ethers has been reported.† They are useful precursors of partially benzylated sugars, some of which have been synthesized *via* partial stannylation by Ogawa *et al.*[5)]

Results and Discussion

The ditritylation of the methyl hexosides with three molar amounts of trityl chloride (TrCl) in pyridine (Py) proceeded smoothly at 50 and 70 °C (Table 1). The locations of trityl groups in the ditrityl ethers were determined by analyzing the ^{1}H NMR spectra of their acetates (Table 5). The structures of the ditrityl ethers were further confirmed by their conversion into the dibenzyl ethers through benzylation followed by detritylation as described below. The results of the reactions conducted at 50 and 70 °C in Table 1 indicate that the regioselectivity of the reaction depends on the steric disposition of the hydroxyl group involved. The starting materials were always exhausted and the primary hydroxyl group was completely tritylated. The second trityl group was introduced to *O*-2 of the glucoside, *O*-3 of the mannoside, and both *O*-2 and *O*-3 of the galactoside, preferentially. Small amounts of the 4,6-ditrityl ethers of the glucoside and the mannoside were also isolated, but that of the galactoside was not detected.

Table 1. Yields of ditrityl and monotrityl ethers of hexopyranosides

† Ogawa *et al.* have synthesized **7** *via* stannylation (Ref. 5d).

Table 2. Results of reaction of dityrityl ethers with pyridinium chloride

Starting material	Time/h	Yield/%			
		2,6-Dityrityl ether	3,6-Dityrityl ether	4,6-Dityrityl ether	6-Trityl ether
7	18	38	2	1	53
8	18	26	9	1	56
9	18	28	4	2	59
13	18	68	0	0	24
14	18	50	9	0	27
15	18	21	17	2	57
19	6	48	2	0	45
20	6	1	23	0	74

Thus, the orders of reactivity of the secondary hydroxyl group to TrCl in Py at 50 to 70 °C are: OH-2≫OH-3≥OH-4 for the glucoside, OH-3≫OH-4≥OH-2 for the mannoside, and OH-2≈OH-3≥OH-4 for the galactoside; in other words, the equatorial hydroxyl groups vicinal to the axial oxygenous substituent are reactive, whereas the axial ones are not.[2b,6] Highly selective introduction of the trityl group to OH-3 of methyl 6-deoxy-α-L-mannopyranoside and fairly high reactivity of not only OH-2 but OH-3 toward tritylation of methyl 6-deoxy-α-L-galactopyranoside were reported by Otake *et al.*[3b] Benzyl α-D-hexopyranosides also exhibited similar trends of the reactivity of secondary hydroxyl groups in the tritylation at 70 °C.

A remarkable change in the regioselectivity occurred in the tritylation of mannosides **2** and **5** at 100 °C. The formation of the 2,6-dityrityl ether **13** predominated and that of the 3,6-isomer **14** was much lower. The dityritylation of the glucosides and the galactosides also raised the selectivity for the 2,6-dityrityl ethers. The increase in the yield of the monotrityl ether in each case at 100 °C suggests that the trityl group at the secondary hydroxyl group is apt to undergo the reverse reaction with pyridinium chloride (Py·HCl) formed during tritylation in Py (Eq. 1).[7] Since Py·HCl always

$$=CHOH + TrCl + Py \rightleftharpoons =CHOTr + Py\cdot HCl \quad (1)$$

precipitated during the tritylation at 70 °C, while the reaction at 100 °C was homogeneous, greater solubility of the salt in Py at 100 °C may help the reverse reaction in Eq. 1. The time course of the reaction of **2** at 100 °C shows that the second trityl group enters into OH-3 and then rearranges to OH-2 (Fig. 1). It was further found that the 3,6-dityrityl ether **14** was converted into the 2,6-isomer **13** in the presence of Py·HCl in Py at 100 °C

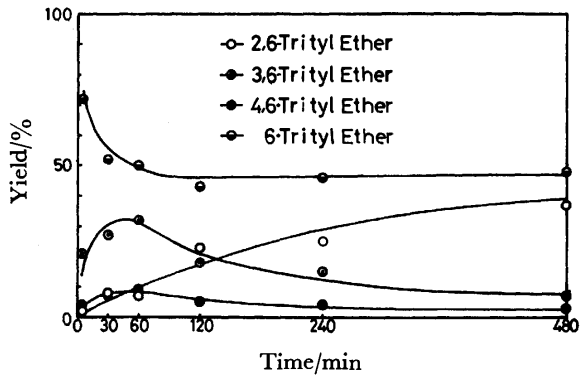

Fig. 1. Time course of tritylation of methyl α-D-mannopyranoside (**2**). Using three molar amount of trityl chloride in pyridine at 100 °C.

(Table 2). The 4,6-isomer **15** behaved in a similar manner. Contrary to these results, the 2,6-isomer **13** did not rearrange. The glucosides exhibited similar trends as shown in Table 2; the 3,6- and the 4,6-dityrityl ethers were converted into the 2,6-isomer but the 2,6-isomer did not change into the 3,6- and the 4,6-isomers. As for the galactosides, although the 3,6-isomer did not rearrange into the 2,6-isomer, the results in Table 2 show that the latter is more resistant to degradation into the monotrityl ether **3t** than the former. Thus, the tritylation of the hexopyranosides with TrCl in Py at 100 °C furnishes a quasi-equilibrium mixture in which the 2,6-dityrityl ether predominates.[8]

The 2,6- and the 3,6-dityrityl ethers thus obtained afforded the 3,4- and the 2,4-dibenzyl ethers, respectively, with ease through benzylation and subsequent

detritylation.[9] The structures of the dibenzyl ethers were readily determined through the examination of the ^1H NMR spectra of their acetates (Table 6) and are consistent with that of the starting ditrityl ethers.

Experimental

General. Methyl α-D-glucopyranoside (**1**, Tokyo Kasei) and methyl α-D-mannopyranoside (**2**, Sigma) were used directly. Methyl α-D-galactopyranoside monohydrate (**3**·H_2O, Pfanstiehl) was dehydrated *in vacuo* over P_2O_5 at 80 °C before use. Benzyl α-D-glucopyranoside (**4**) was prepared as before;[4a] benzyl α-D-manno- and -galactopyranoside (**5** and **6**) were synthesized from the respective hexoses in a similar manner. Trityl chloride (TrCl, Tokyo Kasei) was used directly and pyridinium chloride (Py·HCl, Tokyo Kasei) was dried over P_2O_5 *in vacuo* before use. Pyridine (Py) was distilled from BaO. For other items, see the preceeding reports.[4] Acetylation was carried out with excess acetic anhydride in Py at room temperature; chromatographycally pure acetates were obtained through column chromatography on silica gel (Kanto Kagaku) with the mixture of benzene and 2-butanone (gradient elution).

Procedure for Ditritylation. A mixture of a glycoside (2.0 mmol), TrCl (3.0 equiv.) and Py (5.0 ml/g of glycoside) was heated under anhydrous conditions with good stirring. Py·HCl soon precipitated in the reaction at 70 °C, but did not at 50 and 100 °C. After cooling and quenching with iced water, the mixture was extracted with $CHCl_3$. The organic

a) At 90 MHz in CCl_4 with Me_4Si. b) Underlined values are of H–C–OAc.

layer was washed with H_2O well, dried over Na_2SO_4, evaporated under reduced pressure at ≈50 °C, and chromatographed on silica gel (Kanto Kagaku, No. 37047, >100 mesh) with toluene–2-butanone system (gradient elution, 100 : 1→1 : 1). This gave the results as summarized in Table 1. Physical and analytical data of the dityrityl ethers are summarized in Table 3. The ^1H NMR data of the acetates of the dityrityl ethers are listed in Table 5.

Procedure for Rearrangement of Dityrityl Ethers. A mixture of dityrityl ether (50 mg, 0.074 mmol), Py·HCl (17 mg, 2.0 equiv.), and Py (0.25 ml) was heated at 100 °C under anhydrous conditions. After processing as above, chromatography gave the results in Table 2.

Procedure for Transformation of Dityrityl Ethers into Dibenzyl Ethers. A mixture of dityrityl ether (1.0 mmol), crushed KOH (7 g/g of dityrityl ether), and $PhCH_2Cl$ (20 ml/g of dityrityl ether) was heated at ≈110°C for 18 h under good stirring. After filtration and evaporation under reduced pressure on a boiling water bath, the resulting mixture was heated in a mixture (20 ml/g of dityrityl ether) of CF_3CO_2H, MeOH, and $CHCl_3$ (1 : 3 : 10, v/v/v) for 2—5 h. After neutralization with triethylamine and evaporation, the residue was chromatographed on silica gel using toluene–2-butanone system to give the dibenzyl ethers (60—75% yield). Physical and analytical data of the dibenzyl ethers are summarized in Table 4. The ^1H NMR spectral data of the acetates of the dibenzyl ethers are listed in Table 6.

8) The stability of the 2,6-dityrityl ethers might be, at least in part, attributable to the inductive effect of the anomeric center. The effect may slightly decrease the electronegativity of the oxygen at C-2 to depress effectively its affinity to the proton of the acid PyH^+ in the competing basic medium Py, as in the following equation:

$$\mathrm{ROTr} + \mathrm{PyH^+ \cdot Cl^-} \rightarrow [\overset{\mathrm{H}}{\mathrm{ROTr}}]^+\mathrm{Cl^-} + \mathrm{Py} \rightarrow \mathrm{ROH} + \mathrm{TrCl} + \mathrm{Py}$$

9) In the case of the glucosides, however, the monotrityl ether, **1t** and **4t**, are practically better precursors of the 2,4-dibenzyl ethers, **24** and **26**, respectively, because they are readily prepared through detritylation of methyl and benzyl-2,4-di-*O*-benzyl-6-*O*-trityl-α-D-glucopyranoside (Ref. 4a) prepared directly from **1t** and **4t**.

Synthesis and Enzymatic Carboxylation of a Biotin-containing Peptide Representing the Coenzyme Binding Site of *E. coli* Acetyl-CoA Carboxylase†

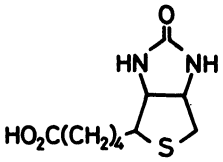
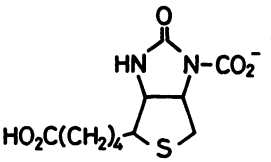
(Received September 16, 1982)

A biotin-containing pentapeptide Boc–Glu–Ala–Met–Bct–Met (**1**) that corresponds to the coenzyme binding site of *E. coli* acetyl–CoA carboxylase has been prepared. Peptide **1** as well as free biotin served as a substrate for the carboxylation reaction catalyzed by the biotin carboxylase subunit dimer of *E. coli* acetyl–CoA carboxylase. The Michaelis constant, K_m, and the maximum velocity, V_{max}, for **1** were 18 mM and 2.8 μM min^{-1} (1 M=1 mol dm^{-3}), respectively. The corresponding values for biotin were 214 mM and 28 μM min^{-1}. Thus, the overall reactivity (V_{max}/K_m) of peptide **1** exceeded that of biotin by 20%.

The biotin (**2**)-dependent carboxylation reaction plays a pivotal role in the synthesis of long-chain fatty acids in biological systems.[1] It is firmly established that the enzymatic carboxylation proceeds *via* the *N*-carboxybiotin intermediate (**3**), which in turn transfers the



2



3

carboxyl group to an acceptor substrate such as acetyl–CoA. By some enzymes biotin itself can be carboxylated, though the Michaelis constant of biotin carboxylation is enormously high compared to that for the natural substrate BCCP, biotin carboxyl carrier protein.[2] It is, hence, clear that the protein attaching to the coenzyme plays an important part in the recognition and binding of biotin to the enzyme active site.[3] In our previous communication we have prepared several biotin-containing peptides such as **4** that corresponds to a local biotin-binding sequence of *E. coli* acetyl–CoA carboxylase BCCP subunit.[4] Unfortunately, however, all

Ac–Met–Bct–Met–Met–OMe

4

these peptides were sparingly soluble in most common solvents and were not feasible for kinetic studies of biotin carboxylation by the enzyme. To improve solubility the peptide sequence was extended towards the *N*-terminus to incorporate glutamic acid.[5] The presence of this extra carboxyl group as well as the *C*-terminal one should increase the solubility of the resulting peptide in neutral aqueous media. This proved to be the case as described below. Furthermore, this peptide (**1**) was found to be carboxylated by the biotin carboxylase subunit of *E. coli* acetyl–CoA carboxylase. The preliminary results on the kinetics of this enzymatic carboxylation are also presented in this article.

† The abbreviations used are: Ala, L-alanine; Glu, L-glutamic acid; Lys, L-lysine; Met, L-methionine; Bct, *N*'-biotinyl-L-lysine; Boc, *t*-butoxycarbonyl; Cbz, benzyloxycarbonyl; CbzCl, benzyloxycarbonyl chloride; DCC, dicyclohexylcarbodiimide; HOBt, 1-hydroxybenzotriazole; NEM, *N*-ethylmorpholine; ATP, adenosine 5'-triphosphate; NADH, nicotinamide adenine dinucleotide, reduced form; DEAE, diethylaminoethyl.

Results

Synthesis. It was envisioned that the liquid phase synthesis of target peptide **1** may be achieved by either one of the following routes. In one route biotin is incorporated at the early stage of peptide synthesis by coupling Boc–Bct and methionine methyl ester.[3] The peptide chain is then elongated step by step up to the *N*-terminal glutamic acid. In the other the biotin-free pentapeptide is prepared first and the coenzyme is incorporated subsequently.[4] The latter strategy was actually adopted in order to be free from possible side reactions on the biotin skeleton and/or interference of the biotin's urea moiety with a coupling reaction.[3] In addition, expensive biotin may be saved in the

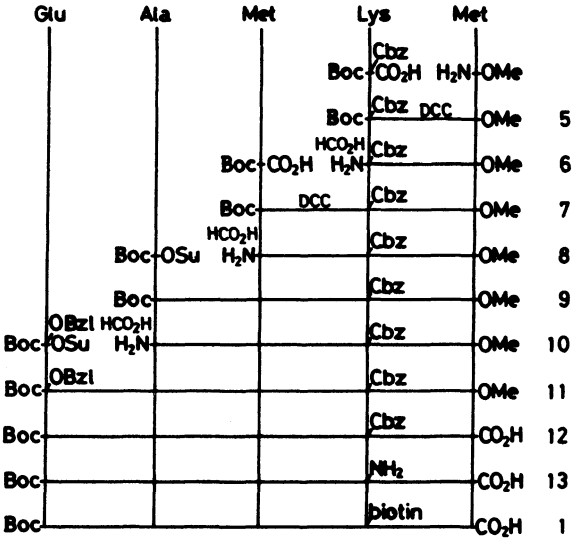


Fig. 1. Synthetic route to peptide **1**.

latter route. Thus, the parent pentapeptide was prepared according to the scheme illustrated in Fig. 1. The DCC coupling method was employed for the synthesis of di- and tripeptide. The third and fourth couplings were accomplished by the active ester method of *N*-hydroxysuccinimide. Each coupling proceeded smoothly and the products obtained were analytically pure (Table 1).

The carboxyl groups of Glu side chain and *C* terminal Met were deprotected by saponification. The final deprotection of the Lys amino moiety with Na/NH_3 was followed by coupling of the resulting peptide with *p*-nitrophenyl biotinate.[4] This led to the incorporation of coenzyme to the peptide, but in low yield (12%). The product was satisfactory by all criteria set forth previously for the purity and identity of biotin-containing peptides; TLC, ^1H NMR and a color test with *p*-dimethylaminocinnamaldehyde.[4] Peptide **1** is soluble considerably in neutral to alkaline aqueous solutions and feasible for kinetic studies on its enzymatic carboxylation.

Enzymatic Carboxylation. The carboxylation of peptide **1** and biotin mediated by the biotin carboxylase subunit dimer of *E. coli* acetyl-CoA carboxylase was carried out at 30 °C (Eq. 1).

$$\text{Biotin} + HCO_3^- + \text{ATP} \longrightarrow \text{Biotin-}CO_2^- + \text{ADP} + \text{Pi} \quad (1)$$

The reaction was followed either by the incorporation of radioactive hydrogencarbonate into biotin or the formation of ADP.[6] Both methods gave virtually identical results. Peptide **1** as well as biotin was carboxylated at a reasonable rate by ≈8 milli-units of enzyme in the presence of 1 mM ATP and 8 mM sodium hydrogencarbonate. The initial rate data obtained by the coupled assay were analyzed in terms of a Lineweaver-Burk plot (Fig. 2). The kinetic parameters are summarized in Table 2. The Michaelis constant K_m for biotin (214 mM) is close to the literature value (170 mM).[2] The corresponding value for peptide **1** (18 mM) indicates that the binding of **1** to the enzyme is about 12 times tighter than that of biotin. On the other hand, the maximum rate, V_{max}, is larger for biotin by a factor of ten than for peptide **1**. This makes the difference in the first-order rate constant (V_{max}/K_m) between the two substrates smaller, only 20% greater in favor of peptide **1**.

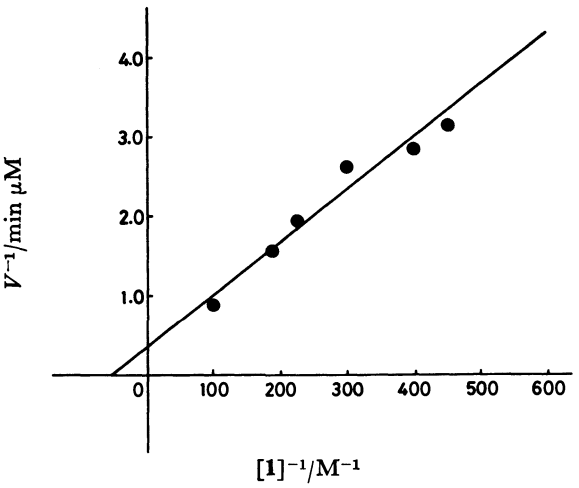

Fig. 2. Lineweaver-Burk plot for the carboxylation of peptide **1** catalyzed by the biotin carboxylase subunit of *E. coli* acetyl-CoA carboxylase in 100 mM triethanolamine buffer, pH 8.0 at 30.0 °C.

Discussion

Part of the primary structure adjacent to the coenzyme-binding site of several biotin-dependent enzymes has been elucidated.[5,7,8] These enzymes share a strikingly similar local sequence in the vicinity of biocytin, suggesting that these enzymes evolved from a common ancestor. An interesting feature of the amino acid sequence, as viewed from a chemical standpoint, is the fact that biocytin is flanked by methionines in all cases. In the case of *E. coli* acetyl-CoA carboxylase another methionine is placed at the *C*-terminal side of the sequence. Thus, the successive four amino acid residues contain a sulfide moiety each in their side chain. It seems likely that this sulfide cluster plays a certain

role in the carboxylation-transcarboxylation cycle of biotin catalysis. For example, the sulfide cluster might be required for the efficient binding of biotin to the enzyme active site during its carboxylation and subsequent carboxyl transfer reactions. In other words, the enzyme recognizes not only the coenzyme but also the neighboring amino acid residues. Also, the peptide sequence adjacent to biocytin could help biotin to assume a specific spatial orientation that may presumably be needed for biotin to bind to the enzyme active site tightly. A further possibility would be the protection by the acyclic sulfides of the biotin's cyclic sulfide from being oxidized. All these hypotheses could be proven only when model peptides representing the biotin binding site become available to test their interaction with the enzyme.[3,4] In this article we have prepared a pentapeptide that represents the coenzyme binding site of *E. coli* acetyl–CoA carboxylase. The synthetic strategy was basically the same as that adopted previously for the synthesis of tetrapeptides.[4] The target peptide (**1**) obtained gave correct analysis but the yield at the final biotinylation step was far from satisfactory (12%). This result is rather strange in veiw of the fact that biotinylation was successfully accomplished even with larger peptides such as glucagon and insulin by the same method.[9,10] In our hands, the active ester method gave the best results, and other coupling methods tested such as the mixed anhydride method with isobutyl chloroformate and the DCC coupling method gave even poorer yields. This poses a serious problem to the synthesis of larger biotin-containing peptides by this method. An alternative route is the incorporation of biotin at the early stage of peptide synthesis by, for example, coupling of Boc–Bct with a growing peptide chain.[3] In addition, the solid phase method may be worth a serious consideration to save time in accomplishing such a synthesis. Our preliminary attempt to prepare biotin-containing peptides by this method appears promising (unpublished results from this laboratory).

The biotin carboxylase subunit of *E. coli* acetyl–CoA carboxylase was capable of carboxylating the biotinyl moiety of peptide **1** as well as free biotin. In conformity with our expectation, peptide **1** was found to bind to the enzyme by one order of magnitude more tightly than biotin. This clearly indicates that the amino acid residues surrounding the coenzyme play an indispensable role in the interaction of biotin with the enzyme active site. All or at least two of the substrates involved in this carboxylation (Eq. 1) must encounter at some moment of the reaction in the enzyme active site. In light of the fact that magnesium(II) ion is the essential component of the reaction and that the metal ion is often found associated with ATP in many biochemical reactions involving ATP,[11] a ternary metal complex composed of magnesium(II), ATP and biotin or HCO_3^- may be the reactive species in this carboxylation reaction. We showed previously that amide groups of peptide **4** have potential to interact with magnesium ion.[4] This could increase the affinity of the biotinyl moiety for the metal ion, and eventually for the enzyme active site.

In contrast to the binding process, the subsequent catalytic process was less favorable for peptide **1** than for free biotin. This unfavorable catalysis offsets a large gain in binding, leading to an enhancement of the overall reactivity of **1** relative to biotin by a small margin (20%). Nevertheless, this figure is significant, since all synthetic derivatives of biotin reported to date such as *d*-biotin methyl ester and biocytin are poorer substrates than biotin for acetyl–CoA carboxylase.[2] The natural substrate of *E. coli* acetyl–CoA carboxylase (BCCP) shows not only tight binding but also high reactivity, but its overall reactivity is governed predominantly by the former term (Table 2).[12,13] In this sense, an improvement of the binding properties of biotin leads automatically to the development of a good substrate for the enzyme. Such a substrate and its analogues are of vital importance in studying and understanding the molecular basis of enzyme-substrate interaction in this carboxylase system. A further synthetic approach to this goal is now in progress in this laboratory.

Experimental

Apparatus. Melting points were determined on a Yanagimoto hot-stage apparatus and are uncorrected. IR spectra were taken on a JASCO A-100 spectrophotometer, while UV spectra were on a Hitachi 200-10 spectrophotometer. ^1H NMR spectra were recorded either on a JEOL JNM-MH-100 or a JEOL JNM-FX-90Q spectrometer. Optical rotations were determined on a Jasco DIP-4. Radioactivity was determined on an Aloka liquid scintillation counter LSC-703.

Materials. Amino acids, *O-t*-butyl *S*-4,6-dimethyl-2-pyrimidinyl thiocarbonate, CbzCl, DCC, and HOBt were obtained from Protein Research Foundation. *d*-Biotin, *p*-dimethylaminocinnamaldehyde, *N*-hydroxysuccinimide, and NEM were the products of Wako Pure Chemical Ind. Co. Scintillation cocktail ACS II and sodium [^{14}C] hydrogencarbonate (0.1 mCi/mmol, 1 Ci$=3.7\times10^{10}$ becquerels) were purchased from Amersham. DEAE-cellulose and phosphocellulose were the products of Brown Company. Lactate dehydrogenase and pyruvate kinase were obtained from Boehringer Mannheim, while bovine serum albumin (BSA), phosphoenol pyruvate (PEP), glutathione, NADH, and ATP were from Seikagaku Kogyo Co.

Enzyme Preparation and Assay. *Escherichia coli* B cells were grown in an enriched medium composed of 1 M potassium phosphate buffer (pH 7.4), yeast extracts and D-glucose. The harvested cells were broken on a French press. The cell-free extracts were subjected to enzyme purification according to the procedures of Guchhait *et al.*[6] Enzyme activity was determined by following either the incorporation of sodium [^{14}C] hydrogencarbonate into biotin or the formation of ADP by the "coupled assay".[6] In the former method, the assay mixture (0.50 ml) consisting of 1 mM ATP, 8 mM $MgCl_2$, 8 mM $NaH^{14}CO_3$ (0.1 mCi/mmol), 50 mM potassium *d*-biotinate, 3 mM glutathione, 0.6 mg/ml BSA, 10% ethanol and the enzyme in 100 mM triethanolamine buffer (pH 8.0) was incubated at 30 °C for a certain period of time. The reaction was initiated by the enzyme and was terminated by the addition of 2 drops of ice-cold 1-octanol. This was followed immediately by an introduction of gaseous carbon dioxide to the reaction mixture at 0 °C for 40 min. An aliquot (0.10 ml) of ice-cold 0.1 M NaOH was added and the resulting solution was transferred to a scintillation vial containing 6 ml of ACS II to determine radioactivity. In the latter method, the formation of ADP was coupled with the oxidation of NADH.

Thus, an assay mixture (1.0 ml) contained the same components as those described above except for unlabeled hydrogencarbonate, instead of radioactive one, plus 0.5 mM PEP, 5 units of lactate dehydrogenase, 3 units of pyruvate kinase and 0.2 mM NADH. The reaction was started by the addition of enzyme at 30 °C and the decrease of NADH absorption was determined at 340 nm. One unit of enzyme activity is defined by the amount of enzyme needed to form 1 μmol of 1-carboxybiotinate per min.

Boc-Lys(Cbz)-Met-OMe (5). To a solution of 21.5 g (55 mmol) of Boc-Lys(Cbz), 11.5 g (55 mmol) of Met-OMe·HCl and 6.3 g (55 mmol) of NEM in 180 ml DMF was added 11.3 g (55 mmol) of DCC at 0 °C. The whole mixture was stirred for 8 h at room temperature. The precipitated DCUrea was filtered off. Evaporation of the solvent left an oil, which was taken up in 180 ml of ethyl acetate. The solution was washed with the following solutions: 4% $NaHCO_3$, saturated NaCl, 10% citric acid, saturated NaCl, H_2O. The organic layer was dried over Na_2SO_4, concentrated to *ca.* 50 ml and kept in a freezer. The product was obtained in 72% yield (21.3 g).

Lys(Cbz)-Met-OMe·HCO_2H (6). A sample of **5** (21.3 g, 41 mmol) was allowed to react with 100 ml of 99% HCO_2H for 5 h at room temperature. Methanol was added and the solvents were evaporated *in vacuo*. The product was crystallized from methanol-ether in 90% yield (19.5 g). Mp 203—204 °C. Complete removal of the Boc group was confirmed by the disappearance of the 1.35 ppm signal.

Boc-Met-Lys(Cbz)-Met-OMe (7). This peptide was synthesized by reaction of **6** (21.1 g, 46 mmol) with Boc-Met (11.5 g, 46 mmol) in the presence of NEM (5.3 g, 46 mmol), HOBt (6.23 g, 46 mmol), and DCC (9.52 g, 46 mmol). The reaction mixture was worked up analogously to that for **5**. The product was recrystallized from ethyl acetate-petroleum ether.

Met-Lys(Cbz)-Met-OMe·HCO_2H (8). Reaction of **7** (10.0 g, 51 mmol) with 100 ml of 99% HCO_2H in the way identical with that described for **6** gave 7.8 g of **8** in 87% yield.

Boc-Ala-Met-Lys(Cbz)-Met-OMe (9). Boc-Ala-OSu (3.23 g, 11 mmol) was allowed to react with **8** in 50 ml of DMF containing 1.27 g (11 mmol) of NEM for 8 h at room temperature. The solvent was removed *in vacuo* and the residue was taken up in 400 ml of ethyl acetate. The organic solution was washed with the solvents used for **5**. After drying over Na_2SO_4, the solution was concentrated to a small volume to provide 5.5 g of the product in 67% yield.

Ala-Met-Lys(Cbz)-Met-OMe·HCO_2H (10). Treatment of 4.6 g (6.3 mmol) of **9** with 100 ml of 99% HCO_2H and the subsequent work-up yielded 4.9 g of the product (94%).

Boc-Glu(OBzl)-Ala-Met-Lys(Cbz)-Met-OMe (11). Reaction of 3.5 g (5.0 mmol) of **10** with 3.38 g (7.5 mmol) of Boc-Glu(OBzl)-OSu in 100 ml of DMF containing 0.60 g (5.0 mmol) of NEM gave 2.7 g of the product.

Boc-Glu-Ala-Met-Lys(Cbz)-Met (12). A sample of **11** (1.04 g, 1.1 mmol) was dissolved in 27 ml of methanol and 14 ml of dioxane. To this was added 2.3 ml of 1 M sodium hydroxide and the whole mixture was stirred for 7 h at room temperature. After adding 11 ml of water, the organic solvents were removed *in vacuo*. The remaining aqueous solution was washed with ether and then brought to pH 3 with 10% citric acid at 0 °C. The product obtained was further purified by recrystallization from methanol-ether. The NMR spectrum of this peptide revealed a complete removal of *O*-Bzl and *O*-Me protecting groups.

Boc-Glu-Ala-Met-Lys-Met (13). A sample of **12** (1.2 g, 1.4 mmol) was dissolved in 80 ml of liquid ammonia. Sodium was added in small portions with stirring. When the blue color of the solution was retained for a few minutes, the reaction was quenched by ammonium chloride. Ammonia was evaporated off. Methanol was added to the residue and the insoluble material was filtered off. The filtrate was concentrated to dryness and the solid left was taken up in 1% acetic acid. The insoluble starting material was removed by filtration. For desalting the filtrate was subjected to column chromatography on a Sephadex G-10 column (3.2×56 cm) with 1% acetic acid as an eluant. The peak fractions were pooled and lyophillized to yield 0.77 g (70%) of the product, mp 221—223 °C. TLC R_f 0.45 (E). Complete removal of the protecting group was ascertained on the basis of the lack of signals for the benzyloxycarbonyl group at 4.98 and 7.28 ppm in the NMR spectrum of this peptide.

Boc-Glu-Ala-Met-Bct-Met (1). A sample of **13** (0.26 g, 0.33 mmol) dissolved in 2 ml of water was mixed with *p*-nitrophenyl biotinate (0.14 g, 0.50 mmol)[14] in 10 ml of DMF containing 0.15 g (1.32 mmol) of NEM. The whole mixture was stirred for a day at room temperature. The solvents were removed *in vacuo* and methanol (40 ml) was added to the residue. The precipitates formed were collected by filtration, 47 mg (12%), mp 199—203 °C. TLC R_f 0.59 (E). This peptide is ninhydrin-negative but develops a pink color upon spraying of *p*-dimethylaminocinnamaldehyde, confirming the presence of a biotinyl moiety.[15] The characteristic ^1H NMR signals for the biotinyl protons are the following: (DMSO-d_6) 2.84 (d, J=14 Hz, 5-exo), 2.56 (d, J=14 Hz, 5-endo), 6.36 (s, NH) and 6.41 (s, NH).

The authors are grateful to Prof. K. Soda of Kyoto University for his kind donation of *E. coli* B cells. Thanks are also due to Professors T. Naito and M. Sugii of Nagasaki University for the use of their French press and scintillation counter, respectively. We are indebted to Professors M. Koida and T. Yoshimoto for helpful discussions. This work was supported by Grants-in-Aid for Special Project Research 521325 and 56109007 from the Ministry of Education, Science and Culture, and in part by the Eighteenth Bank Fund for Community Development and Promotion.

Solution Conformation of *cyclo*(-L-Cys(*S*-Acm)-D-Leu-L-His-L-Cys(*S*-Acm)-D-Leu-L-His-) and Interaction with Cu(II)

Masato KODAKA,*,† Toru SHIMIZU, and Masahiro HATANO
Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Sendai 980
†*National Chemical Laboratory for Industry, Tsukuba 305*
(Received September 17, 1982)

Proton NMR spectra of a cyclic peptide, *cyclo*-(*S*-acetamidomethyl-L-cysteinyl)-D-leucyl-L-histidyl-(*S*-acetamidomethyl-L-cysteinyl)-D-leucyl-L-histidyl, were measured and analyzed in order to investigate its conformation and its interaction with Cu(II). A linear peptide, [*N*-(*t*-butoxycarbonyl)-*S*-acetamidomethyl-L-cysteinyl]-D-leucyl-L-histidyl-(*S*-acetamidomethyl-L-cysteinyl)-D-leucyl-L-histidine methyl ester, was also investigated for comparison. It was strongly suggested that the cyclic hexapeptide forms transannular hydrogen bonds between the cysteine residue peptide bonds and thus two β-turns exist in the D-leucyl-L-histidyl sequences. This finding is particularly noteworthy because the present cyclic peptide has no prolines which are frequently seen in β-turn structures of proteins, naturally occurring peptides or synthetic peptides and because the cyclic peptide we studied is composed of amino acids all bearing the large side chains which seemed likely to prevent β-turn formation due to their steric hindrance. The interactions of the cyclic peptide and the linear peptide with Cu(II) were also studied by observing ^{1}H NMR spectral changes on addition of $CuCl_2$. It was suggested that the imidazolyl groups in the peptides are directly coordinated to Cu(II).

Imidazolyl and carbamoyl groups of histidine and glutamine (or asparagine) residues or main-chain peptide bonds seem to play an important role for the coordination of proteins or naturally occurring peptides to metal cations. It seems particularly interesting to study the interaction of metal cation with the cyclic peptide having both imidazolyl groups and peptide bonds at the side chains. Few studies have been undertaken about the interaction of metal cations with imidazole and amide-containing cyclic peptide. Cyclic peptides are better ligands than linear peptides in the following respects: (i) In naturally occurring antibiotics or other biologically functional peptides, there are many cyclic peptides which have much higher activities than those of the corresponding linear peptides, such as gramicidin S.[1] Therefore, cyclic peptides are important from the biological point of view. (ii) Intramolecular rotations around the main-chain bonds are restricted by cyclization and thus overall conformations are relatively rigid. Contributions of the end groups to the metal ligations can be excluded for cyclic peptides. These features would make the NMR analyses much easier.

D-Leucine is incorporated into the cyclic peptide in order to place the imidazolyl and the acetamido groups on the same side of the cyclic molecular plane. This would make the imidazolyl and acetamido groups liable to coordinate to metal cations.

In this paper, the conformation of the cyclic peptide in the solution has been investigated in detail. We have also studied the effect of Cu(II) on the ^{1}H NMR spectra of the cyclic peptide.

Experimental

Materials. The syntheses of [*N*-(*t*-butoxycarbonyl)-*S*-acetamidomethyl-L-cysteinyl]-D-leucyl-L-histidyl-(*S*-acetamidomethyl-L-cysteinyl)-D-leucyl-L-histidine methyl ester (**1**) (Boc-L-Cys(*S*-Acm)-D-Leu-L-His-L-Cys(*S*-Acm)-D-Leu-L-His-OCH_3) and *cyclo*-(*S*-acetamidomethyl-L-cysteinyl)-D-leucyl-L-histidyl-(*S*-acetamidomethyl-L-cysteinyl)-D-leucyl-L-histidyl (**2**) (*cyclo*(-L-Cys(*S*-Acm)-D-Leu-L-His-L-Cys(*S*-Acm)-D-Leu-L-His-)) used in the present study have been described elsewhere.[2] $CuCl_2 \cdot 2H_2O$ was of reagent grade. D_2O was the product of Commissariat à L'Energie Atomique of France, and dimethyl-d_6 sulfoxide (DMSO-d_6) was obtained from E. Merck, Japan.

Methods. Proton NMR spectra were recorded on a Bruker CXP-300 FT NMR spectrometer operating in the pulsed Fourier transform mode at 300.07 MHz using a spinning 5 mm tube. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) was used as an internal reference (0.00 ppm) in D_2O solution, and partially deuterated dimethyl sulfoxide (2.49 ppm from DSS) was used as a reference in DMSO-d_6 solution. The pD values given are the actual pH meter readings and have not been corrected for the deuterium isotope effect at the glass electrode and pK_a* refers to the pK_a value determined from the chemical shifts of imidazolyl C-2 proton in D_2O. Adjustment of pD was made by adding either NaOD or DCl. Observed NMR signals were assigned to the individual amino acid residue by comparing the chemical shifts of the peptides with those of model compounds and by using the technique of homonuclear spin decoupling.

Results

^{1}H NMR Signals of Acm-Methylene Protons. Proton NMR spectra of the linear and the cyclic peptides in D_2O are shown in Fig. 1. The chemical shift difference between the two protons of the Acm-CH_2 in the cyclic peptide (**2**) (each resonance is further split into two by geminal protons spin-spin coupling) is greater than those in the linear peptide (**1**), indicating that the former methylene protons are located in environments considerably different from each other in D_2O solution. The motional fluctuation of the molecule may apparently reduce the environmental difference of the two protons of the Acm-CH_2 for the linear peptide. In DMSO solution, however, only one resonance split into two by the spin-spin coupling with the amide NH proton (not shown in a figure) was seen for the cyclic peptide, suggesting that the environments of the two protons of the Acm-CH_2 in the cyclic peptide are similar to each other in DMSO solution. For the linear peptide, the two resonances corresponding to the Acm-CH_2 observed

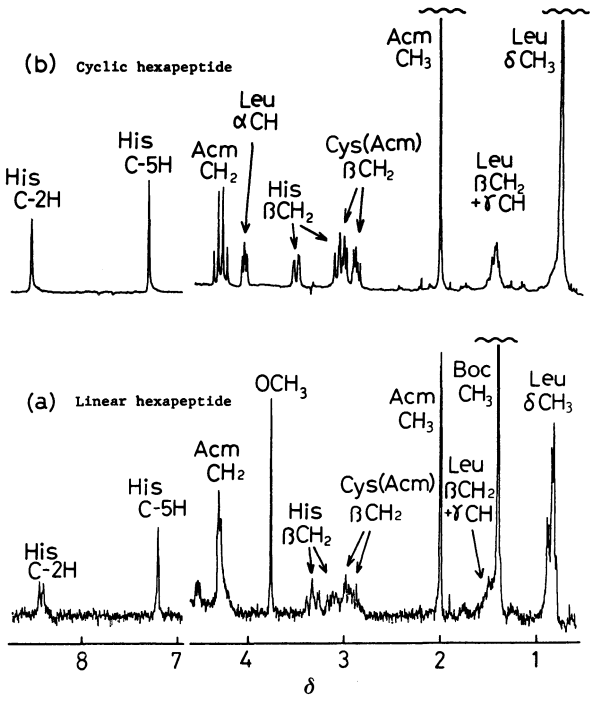

Fig. 1. The 300 MHz proton NMR spectra of linear or cyclic peptides in D_2O solution; peptide concentrations, 1.0×10^{-3} mol dm^{-3}; (a) Boc-L-Cys(*S*-Acm)-D-Leu-L-His-L-Cys(*S*-Acm)-D-Leu-L-His-OCH_3, (b) *cyclo*(-L-Cys(*S*-Acm)-D-Leu-L-His-L-Cys(*S*-Acm)-D-Leu-L-His-).

in D_2O solution do not appear to be split significantly in DMSO solution, too (not shown in a figure).

pK_a* *Values.* The changes of the chemical shifts of the histidyl C-2 and C-5 protons in both the the linear and the cyclic peptides and the change of the chemical shift of one of the histidyl β-CH_2 protons in the cyclic peptide were measured as a function of pD as shown in Figs. 2 and 3. The observed histidyl C-2 proton chemical shifts (δ_{obsd}) were fitted by a nonlinear least-squares method to the equation (1)

$$\delta_{obsd} = \delta_0 + [(\delta_+ - \delta_0)\times 10^{(pK_a^*-pD)}/\{1+10^{(pK_a^*-pD)}\}] \quad (1)$$

in which δ_+ is the chemical shift of the fully protonated histidine and δ_0 that of the neutral histidine. The theoretical curves with the pK_a* values fitted are drawn as shown in Figs. 2 and 3. The pK_a* values of the linear peptide are 6.40 and 6.25, corresponding to those of the two different histidine residues in the molecule, and the pK_a* value of the cyclic peptide is 6.18. The chemical shifts of the histidyl C-5 and β-CH_2 protons were also fitted for comparison. As a whole the values obtained from the C-2 proton chemical shifts agree well with those obtained from the C-5 proton chemical shifts (6.25 and 6.33 for the linear peptide, and 6.19 for the cyclic peptide) and that obtained from the histidyl β-CH_2 chemical shift (6.15 for the cyclic peptide). These values are as a whole a little smaller than those reported.[3)]

Conformation of Histidyl Side Chain in D_2O. The rotamer populations of the histidyl side chain of the cyclic peptide were estimated from the H-C^α-C^β-H protons coupling constant ($J_{\alpha\beta}$) at acidic and basic regions in D_2O solution. In simplified approximation,

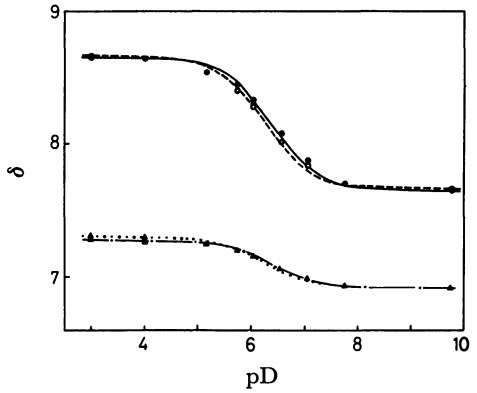

Fig. 2. Effects of pD on the chemical shifts of the histidyl C-2 and C-5 proton resonances of 1.0×10^{-3} mol dm^{-3} Boc-L-Cys(*S*-Acm)-D-Leu-L-His-L-Cys(*S*-Acm)-D-Leu-L-His-OCH_3. The symbols refer to C-2(●, ○) and C-5 (▲, △). The theoretical curves were fitted to the experimental data by a nonlinear least-squares analysis; pK_a*, 6.40 (——), 6.25 (------), 6.33 (·-·-·), 6.25 (·····).

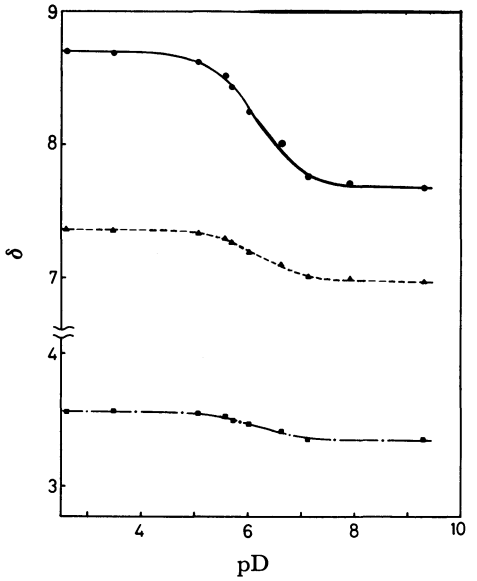

Fig. 3. Effects of pD on the chemical shifts of the histidyl C-2, C-5 and one of the histidyl β-CH_2 protons of 1.0×10^{-3} mol dm^{-3} *cyclo*(-L-Cys(*S*-Acm)-D-Leu-L-His-L-Cys(*S*-Acm)-D-Leu-L-His-). The symbols refer to C-2 (●), C-5 (▲) and low-field resonance of the β-CH_2 (■). The theoretical curves were fitted to the experimental data by a nonlinear least-squares analysis; pK_a*, 6.18 (——), 6.19 (------), 6.15 (-·-·).

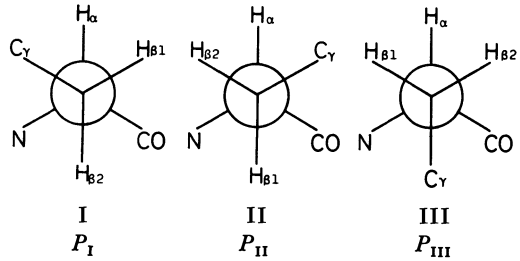

Fig. 4. Examples of rotamers possible for the histidine residue. P_I, P_{II}, and P_{III} denote the rotamer populations.

we have assumed that the $J_{\alpha\beta}$ values are weighted averages of different conformations in fast equilibrium and that a distribution is restricted to the three staggered rotamers in Fig. 4 and the two gauche coupling constants are equal. The $J_{\alpha\beta}$ values of the gauche and the trans rotamers were calculated as 3.2 Hz (J_g) and 12.4 Hz (J_t), respectively, from the Karplus-like equation (2) proposed by Kopple *et al.*,[4]

$$J_{\alpha\beta} = 11.0\cos^2\theta - 1.4\cos\theta + 1.6\sin^2\theta, \quad (2)$$

where θ denotes the dihedral angle of H–C$^\alpha$–C$^\beta$–H planes. Then, the following equations will hold.[5]

$$P_I = (J_{\alpha\beta 2}-J_g)/(J_t-J_g) = (J_{\alpha\beta 2}-3.2)/9.2 \quad (3)$$

$$P_{II} = (J_{\alpha\beta 1}-J_g)/(J_t-J_g) = (J_{\alpha\beta 1}-3.2)/9.2 \quad (4)$$

$$P_{III} = 1 - P_I - P_{II}, \quad (5)$$

where $J_{\alpha\beta 1}$ and $J_{\alpha\beta 2}$ signify the H–C$^\alpha$–C$^\beta$–H$_{\beta 1}$ and the H–C$^\alpha$–C$^\beta$–H$_{\beta 2}$ protons coupling constants, respectively, and P_I, P_{II}, and P_{III} denote the rotamer populations as shown in Fig. 4. P_I, P_{II}, and P_{III} were determined from Eqs. 3—5 by using the experimental values of $J_{\alpha\beta 1}$ and $J_{\alpha\beta 2}$, assuming that the resonance at higher field was that of H$_{\beta 2}$.[6] The observed coupling constants and the estimated rotamer populations are summarized in Table 1.

Temperature Dependence of Chemical Shifts in DMSO-d_6. The temperature coefficients ($-d\delta/dT$) of the main-chain amide and the side-chain Acm amide protons were measured in the temperature range 292—332 K in DMSO-d_6 solution as shown in Table 2, in order to know which protons were shielded from the solvent. One can recognize easily that only the cysteinyl peptide bond proton of the cyclic peptide has the fairly small temperature coefficient (0.0014 ppm deg^{-1}), as compared with the others (0.0028—0.0043 ppm deg^{-1}). In addition, the chemical shift of this proton at 292 K (7.43 ppm) is significantly smaller than that found in an ordinary random-coiled peptide (8.29 ppm for cystine).[7]

Conformation of Cyclic Peptide **2** *in DMSO.* As the cyclic peptide in this study is presumed to take a fairly rigid skeleton conformation, the observed H–N–C$^\alpha$–H protons coupling constant ($J_{HN\alpha}$) would be interpreted in terms of a single conformation. Therefore, the dihedral angle (θ') of H–N–C$^\alpha$–H planes can be estimated from the $J_{HN\alpha}$ value by using the following Karplus-like equation (6) proposed by Ramachandran *et al.*,[8]

$$J_{HN\alpha} = 7.9\cos^2\theta' - 1.5\cos\theta' + 1.3\sin^2\theta'. \quad (6)$$

The conventional ϕ values ($\theta'=|\phi-60°|$ for L-amino acid and $\theta'=|\phi+60°|$ for D-amino acid) can be obtained from the θ' values.[9] In general, two θ' values are possible for a given $J_{HN\alpha}$ value and two ϕ values are possible for a given θ' value, and thus at most four ϕ values are possible. Accordingly, one must estimate the θ' and ϕ values by building a model of the cyclic peptide consistent with the requirement of the Corey-Pauling-Koltun (CPK) molecular model, assuming that all the peptide bonds take the trans conformation ($\omega=+180°$[9]). Thus, the experimentally obtained $J_{HN\alpha}$ values are shown in Table 3.

Effect of Cu(II) on ^1H *NMR Spectra.* In the present study, the effect of Cu(II) addition has been also examined. As Cu(II) has an unpaired electron extremely fast longitudinal and transverse relaxations of the protons situated near Cu(II) will be expected. Accordingly, the signals which are broadened on addition of trace amounts of Cu(II) will be those of the protons located near Cu(II). Of course, the broadenings will be somewhat ascribed to the conformational changes of the molecules caused by the complexation with Cu(II) in the high concentration range of Cu(II). Figure 5 indicates ^{1}H NMR spectral change of the cyclic peptide caused by adding Cu(II) in D_2O solution. There is a tendency that the histidyl C-2, C-5 and β-CH_2 proton signals are markedly broadened on addition of Cu(II) while those of the Acm–CH_2 and Acm–CH_3

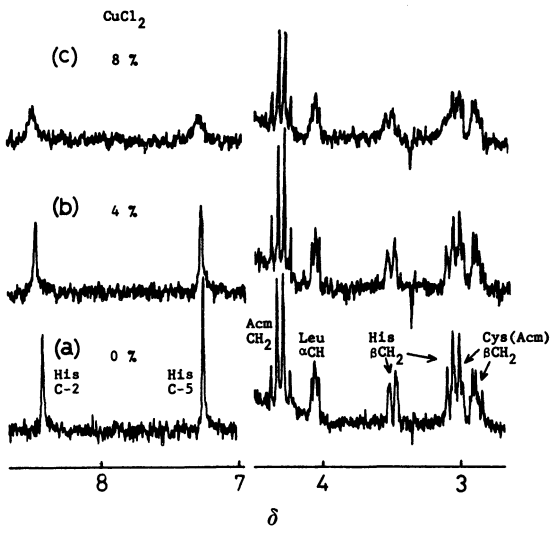

Fig. 5. Effect of $CuCl_2$ addition on the 300 MHz ^1H NMR spectrum of 1.0×10^{-3} mol dm^{-3} *cyclo*(-L-Cys(*S*-Acm)-D-Leu-L-His-L-Cys(*S*-Acm)-D-Leu-L-His-) in D_2O solution at pD 5.70. Contents of $CuCl_2$ (mol%) are (a) 0%, (b) 4%, and (c) 8%.

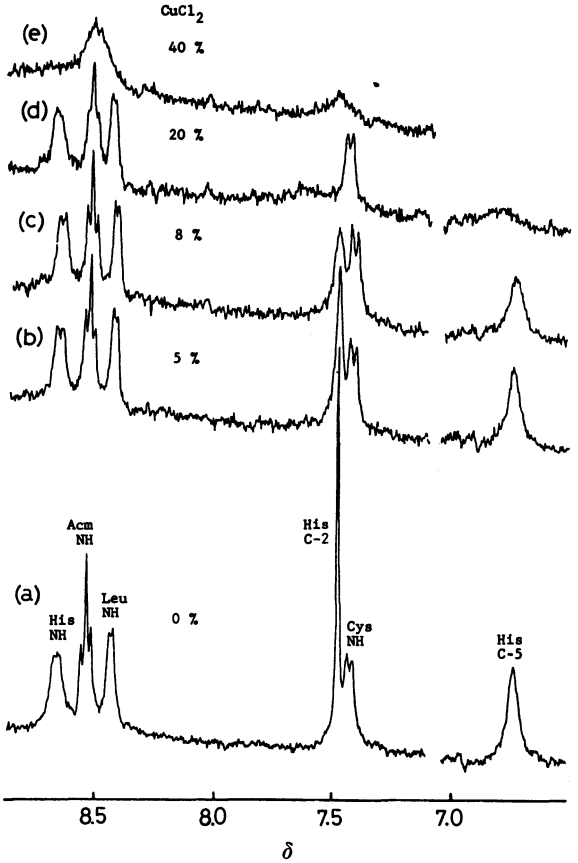

Fig. 6. Effect of $CuCl_2$ addition on the 300 MHz ^1H NMR spectrum of 2.4×10^{-3} mol dm^{-3} *cyclo*(-L-Cys(*S*-Acm)-D-Leu-L-His-L-Cys(*S*-Acm)-D-Leu-L-His-) in DMSO-d_6 solution. Contents of $CuCl_2$ (mol%) are (a) 0%, (b) 5%, (c) 8%, (d) 20%, and (e) 40%.

(not shown in Fig. 5) proton signals are not broadened significantly compared to the histidyl proton signals. Figure 6 shows the change of ^1H NMR spectrum on addition of Cu(II) in DMSO-d_6. The signals of the histidyl C-2 and C-5 protons are broadened or disappear, whereas those of the Acm amide proton and the Acm-CH_2 and the Acm-CH_3 protons (not shown in Fig. 6) are affected much less compared with those of the histidyl protons.

Discussion

The ^1H NMR spectrum of the cyclic hexapeptide (Fig. 1 (b)) clearly indicated that it takes a C_2 symmetric conformation on the NMR time scale, since the same kind of amino acid residues in the molecule shows the same chemical shift. In contrast to this, the spectrum of the linear peptide (Fig. 1 (a)) is more complex, because the two identical amino acid residues are situated in different environments in the molecule. The large difference of the chemical shifts between the two protons of the Acm-CH_2 in the cyclic peptide can be attributed to the environmental difference of these protons probably caused by the particular orientation of the Acm-group in D_2O. This is in striking contrast with the behavior of the Acm-CH_2 protons in DMSO-d_6 solution, where these protons appear to have the same chemical shift (not shown in a figure).

The difference of the pK_a* values of the histidyl imidazolyl groups between the linear (6.25 and 6.40) and the cyclic (6.18) peptides seems to be due to the conformational difference between these two peptides. The two pK_a* values, 6.25 and 6.40, in the linear peptide must reflect the environmental difference between the two histidyl imidazoles, one situated in the C-terminal and the other in the middle of the molecule. In the present study, however, it is impossible to determine which of the histidines corresponds to each of the pK_a* values. On the other hand, the cyclic peptide has only one pK_a* value, 6.18, indicating the identical environment of the two histidine residues.

We have estimated the rotamer populations of the histidyl side chain for the cyclic peptide from the H-C^α-C^β-H protons coupling constant, $J_{\alpha\beta}$. One can see readily from Table 1 that the population of the rotamer I is predominant in both acidic and basic solutions, which indicates that the histidyl imidazole is not folded on the cyclic molecular plane but extended outward. It is generally known that in cyclic dipeptides aromatic side chain is frequently folded but in larger cyclic peptides such folding is rare[10] and that histidyl imidazole has a tendency to orient itself toward the adjacent amide NH group of the peptide backbone.[6] These tendencies are consistent with the results in the present study. It has been also reported that in the case of histidyl side chain the torsion angle χ_2[9] is apt to be around 90°.[6] The CPK molecular model built according to all these results shows that the histidyl imidazolyl plane faces toward the adjacent leucyl side chain, and so the resonances of the leucyl side chain are expected to be shifted to higher field compared with those found in ordinary peptides owing to the imidazole ring current field effect. This inference is supported by the experimental results that the chemical shifts of the leucyl $\beta CH_2+\gamma CH$ (*ca.* 1.47 ppm) and δCH_3 (*ca.* 0.76

ppm) at pD 6.22 of the cyclic peptide are smaller than the chemical shifts (*ca.* 1.6 ppm and *ca.* 0.9 ppm, for the leucyl $\beta CH_2+\gamma CH$ and δCH_3, respectively) of random-coil proteins and peptides reported by McDonald *et al.*[11]

As mentioned in the Results section, the cysteinyl peptide bond proton of the main chain in the cyclic peptide has the temperature coefficient (0.0014 ppm deg^{-1}) strikingly lower than the others (0.0028—0.0043 ppm deg^{-1}) and the chemical shift of this proton (7.43 ppm) is located at the magnetic field much higher than that (8.29 ppm for cystine) of an ordinary peptide.[7] The abnormal chemical shifts of amide protons in a strong hydrogen-bonding solvent such as DMSO may be ascribed to the shielding of the amide protons from the solvent by intramolecular hydrogen bonds or other causes.[10,12-17] Some cyclic hexapeptides form transannular intramolecular hydrogen bonds,[10,12-17] and thus it seems very likely that the cyclic hexapeptide in the present study forms the similar transannular hydrogen bonds between the cysteinyl peptide bonds. This will suggest that two β-turns exist in the D-leucyl-L-histidy sequences. In proteins and naturally occurring or synthetic peptides, proline residues are frequently contributed to β-turn conformations.[18] The cyclic hexapeptide we studied has no proline residues. This finding is thus in contrast of our expectation and noteworthy. The cyclic peptide we studied is composed of the amino acid residues all having the large side chains, which seem to prevent β-turn formation owing to steric hindrance. The orientations of the side chains may happen to be favorable for β-turn formation in the D-leucyl-L-histidyl sequence.

a) Chemical shifts corresponding to all signals observed apparently are described here, except for the tetrapeptide. b) Random coiled tetrapeptide investigated by Bundi *et al.*[7]

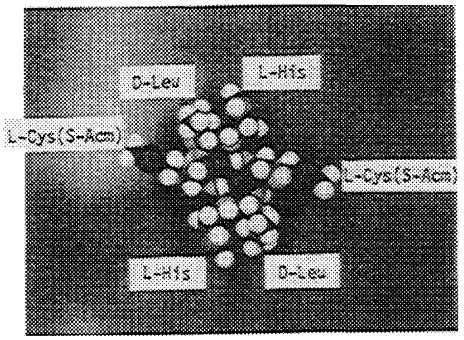

Fig. 7. Corey-Pauling-Koltun (CPK) model of the conformation proposed for *cyclo*(-L-Cys(*S*-Acm)-D-Leu-L-His-L-Cys(*S*-Acm)-D-Leu-L-His-) in DMSO.

The CPK molecular model of the cyclic peptide was built in view of the θ' values derived from the Eq. 6, the transannular hydrogen bonds between the two cysteinyl peptide bonds and the conformational maps proposed by Venkatachalam.[19] We have assumed here that all the peptide bonds take trans conformation ($\omega = +180°$[9]). This assumption seems to be reasonable for the present study, although some deviations from the standard planar trans conformation due to steric hindrance are possible. We have assumed further that the histidyl imidazolyl plane in DMSO solution is apt to be orientated toward the same direction as that in D_2O solution (Table 1). This assumption also seems to be reasonable, since the leucyl δCH_3 proton signals in DMSO-d_6 are shifted to higher field when the leucine residue is situated in D-leucyl-L-histidyl sequence as is shown in Table 4. It is considered that θ' obtained in this way represents an approximate value, since there is some uncertainty in the analysis of $J_{HN\alpha}$. Thus, the error in θ' seems to be about $\pm 10°$.[20,21] The conformation proposed in the present study is shown in Fig. 7, and the estimated θ' and ϕ values are summarized in Table 3.

As is indicated in the Results section, the histidyl imidazoles seem to be mainly coordinated to Cu(II). In order to investigate the complexation quantitatively we have further estimated the dissociation rate constant of the Cu(II)–peptide complex. Figure 8 shows the relation between the reciprocal of the transverse relaxation time ($1/T_{2A}$) of the histidyl C-2 and C-5 protons

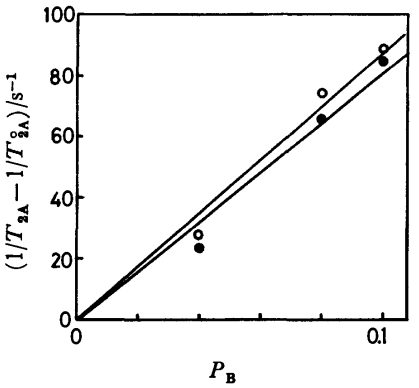

Fig. 8. Paramagnetic effect of Cu(II) on the transverse relaxation rates of the histidyl C-2 (—○—) and C-5 (—●—) proton resonances of *cyclo*(-L-Cys(*S*-Acm)-D-Leu-L-His-L-Cys(*S*-Acm)-D-Leu-L-His-). P_B denotes the mole fraction of the Cu(II)–peptide complex, and T_{2A} and T_{2A}° denote the transverse relaxation times in the presence and absence of Cu(II), respectively.

and the mole fraction of the complex (P_B) in D_2O solution at pD 5.7. $1/T_{2A}$ is obtained experimentally from the following equation (7),

$$1/T_{2A} = \pi\Delta\nu_{1/2}, \quad (7)$$

where $\Delta\nu_{1/2}$ denotes half-band-width of a signal. In the present experimental condition the following equation (8) holds approximately,[22]

$$1/T_{2A} - 1/T_{2A}^{\circ} = P_B/\tau_B, \quad (8)$$

where T_{2A} is the transverse relaxation time of the histidyl C-2 or C-5 proton in the presence of Cu(II), T_{2A}° is that in the absence of Cu(II), and τ_B is the lifetime of the complex. From Fig. 8 we can obtain the dissociation rate constant ($k_d=1/\tau_B$) of the Cu(II)–peptide complex as to be *ca.* 1×10^3 s^{-1}.

In conclusion, the findings we obtained are significantly noteworthy in that D-leucyl-L-histidyl sequence is liable to form β-turn in a cyclic hexapeptide, since this type of peptide sequence in β-turn has never been found. It was also found that Cu(II) interacts with histidyl imidazoles but not with Acm groups, perhaps owing to the conformational rigidity of the cyclic peptide. We are now continuing to investigate other cyclic hexapeptides having sequences such as X-D-leucyl-L-histidyl, X-glycyl-L-histidyl, *etc.* in order to confirm the formation of β-turn by D-leucyl-L-histidyl sequence.

Phosphinyl and Phosphinothioyl Amino Acids and Peptides. VII. The Use of the Dimethylphosphinothioyl Group as a Thiol-protecting Group of Cysteine

Masaaki Ueki* and Kozo Shinozaki

Department of Applied Chemistry, Science University of Tokyo, 1-3 Kagurazaka, Shinjuku-ku, Tokyo 162

(Received September 20, 1982)

The use of the dimethylphosphinothioyl (Mpt) group for the protection of the thiol function in the cysteine side-chain was studied. *N,S*-Bis(Mpt)-L-cysteine was obtained directly by means of a Schotten-Baumann-type reaction of Mpt–Cl with L-cysteine. The *S*–Mpt group was stable under acidic conditions, except for HBr in acetic acid, and it could be removed by treatment with $AgNO_3$ or $Hg(OAc)_2$ in an aqueous medium. Glutathione was synthesized by utilizing the new *S*-protecting group.

The selection of proper protecting groups for various kinds of functional groups of amino acids is very important in peptide synthesis. Some of the common amino acids with side-chain functional groups can be incorporated into a peptide chain without protecting these groups, but the thiol function of cysteine should be protected up to the last stage of the synthesis because of its high nucleophilicity and its lability to air oxidation.

Recently we reported the use of a series of phosphinothioyl groups for the protection of the α-amino functions of amino acids by taking advantage of the well-known acid lability of the P–N bonds.[1-4] These groups could also be utilized for the protection of the phenolic hydroxyl group of tyrosine.[5] Since the P–O bond was stable under the usual acidic conditions encountered during the peptide synthesis, a good orthogonal relationship between the *N*- and *O*-phosphinothioyl groups was established. Since it seems that a similar advantage can be expected for the *S*-phosphinothioyl groups, we tried to use these groups for the protection of the thiol function of cysteine.

In an earlier paper of this series we have already described the preparation and some reactions of *S*-diphenylphosphinothioyl(Ppt) derivatives of L-cysteine and its ester.[2] In these studies it was found that the thiol function was phosphinothioylated preferentially rather than the amino function and that it was regenerated by alkaline hydrolysis. However, *N,S*-Bis(Ppt)-L-cysteine, which would be a key compound to be used in peptide synthesis, could be successfully prepared in only a low yield. We also found that the dimethylphosphinothioyl(Mpt) group was more acid-labile than the Ppt group when used as an amino-protecting group.[3] We have now tried to prepare the Mpt derivatives of L-cysteine.

Results and Discussion

When the L-cysteine methyl ester was treated with dimethylphosphinothioyl chloride (Mpt–Cl)[3] in the presence of *N,N*-diisopropylethylamine (DIEA), the *N,S*-Bis(Mpt)-L-cysteine methyl ester (**1**) was obtained in a 79% yield as a chromatographically homogeneous oil. Because of the high reactivity of the Mpt–Cl, a Schotten-Baumann-type reaction of L-cysteine with the Mpt–Cl could also be performed without difficulty to afford *N,S*-Bis(Mpt)-L-cysteine (**2**) in a 50% yield as its dicyclohexylamine (DCHA) salt. From **1** and **2**, the *N*-Mpt group could be removed selectively by treatment with HCl reagents to give the *S*-Mpt-L-cysteine methyl ester hydrochloride (**3**) and *S*-Mpt-L-cysteine hydrochloride (**4**) in quantitative and 89% yields respectively:

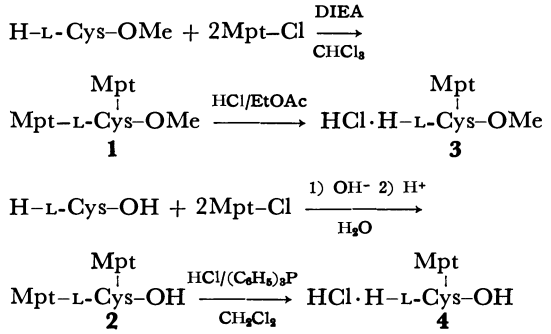

Table 1. Stability of the *S*-Mpt group

Compound	Reagent	Equiv.	Temp °C	Time h	Reaction[a]
Mpt-L-Cys(Mpt)-OMe	2 M† HCl/1 M Ph_3P/CH_2Cl_2	50	RT	24	None
	2 M HCl/EtOAc	50	RT	24	None
	1 M HCl/CH_3OH	50	RT	24	None
	2 M HCl/AcOH	50	RT	24	None
H-L-Cys(Mpt)-OH	1 M HCl/H_2O	100	RT	24	None[b]

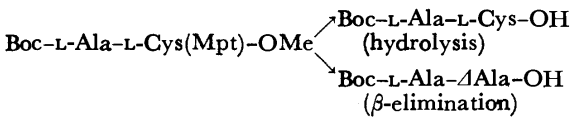
	6 M HCl/H_2O	120	110	20	Complete
	25% HBr/AcOH	100	RT	30 min	Partial
	TFA	100	RT	24	None

a) Detected by TLC. b) Determined by means of an amino-acid-analyzer. † 1 M=1 mol dm^{-3}.

Although these results thus already presented good proof of the acid stability of the *S*-Mpt group, it was further tested under various kinds of acidic conditions; the results are shown in Table 1.

The *S*-Mpt group is stable toward dry hydrogen chloride in organic solvents and trifluoroacetic acid (TFA), although the group is partly cleaved by HBr in acetic acid, probably because of the presence of small amounts of bromine molecules. Under the strongly acidic conditions used for the hydrolysis of peptides prior to amino-acid analysis (6 M HCl, 110 °C 20 h), the P–S bond was also hydrolyzed.

Under the conditions of alkaline hydrolysis, the *S*-Mpt group was removable, while the removal reaction was sometimes accompanied by β-elimination to give dehydroalanine (ΔAla) derivatives. For example, **4** was hydrolyzed completely within 2 h at room temperature by treatment with 4 molar equiv. of a 1 M NaOH solution to regenerate cysteine, but the *t*-butoxycarbonyl-(Boc)-L-alanyl-*S*-Mpt-L-cysteine methyl ester (**6**) gave a 2.5 : 1 mixture of Boc-L-alanyl-L-cysteine and Boc-L-alanyldehydroalanine:



The elimination reaction was found to occur also by means of the action of a tertiary base. If this side reaction is such that it can not be avoided in the presence of any tertiary base, the *S*-Mpt-L-cysteine residue will lose its merit as a synthetic unit. Therefore, the dependence of the ΔAla formation upon the base strength was examined by using **6** as a model compound. The reaction was carried out in a sample tube for NMR spectroscopy measurements, and the yield of the Boc-L-alanyldehydroalanine methyl ester (**7**) produced was obtained from the intensity of the ester methyl signal of **7**. The

$Hg(OAc)_2$	3	1	1	1.02	0	−

a) Internal standard.

results summarized in Fig. 1 show that the *S*-Mpt group is stable enough in the presence of such a bulky base as DIEA to allow the repeated treatments with this base which are necessary to neutralize acid salts of peptide amines containing the *S*-Mpt-L-cysteine residue during synthesis. It may also be noted that the *S*-Mpt-L-cysteine residue can be converted to the ΔAla residue so readily by the action of 1,8-diazabicyclo[5.4.0]-undec-7-ene (DBU) as to make *S*-Mpt-L-cysteine a new and easily available precursor of ΔAla.

The removal of the *S*-Mpt group without any accompanying ΔAla formation was accomplished by utilizing $AgNO_3$ or $Hg(OAc)_2$ as a catalyst for the hydrolysis. The removal conditions were studied by using **4** (neutralized by NH_4OH) as a substrate, since **4** was eluted from the standard amino-acid-analyzer column in the same position with glutamic acid and could be easily monitored. From these reactions it was found that an unexpected intermediate was produced. This intermediate, which could not be isolated, was also hydrolyzed by the use of the metallic reagents in excess, as is shown in Table 2. In order to elucidate the structure of the intermediate, the reaction was attempted by using a dipeptide model, which might produce a more stable intermediate and a dehydroalanine derivative. A starting dipeptide, H-L-Ala-L-Cys(Mpt)-OH (**9**), and the expected products, H-L-Ala-L-Cys-OH (**10**) and H-L-Ala-ΔAla-OH (**11**), were prepared according to the procedures illustrated in Fig. 2.

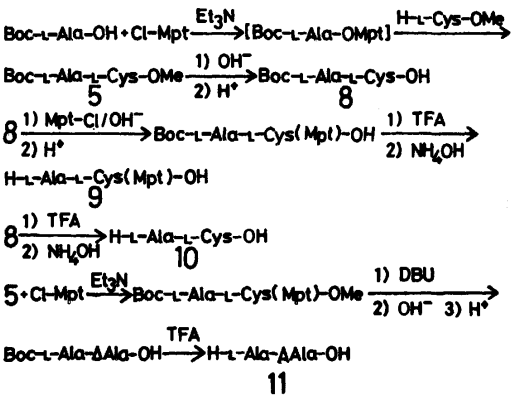

Fig. 2. Synthesis of model peptides.

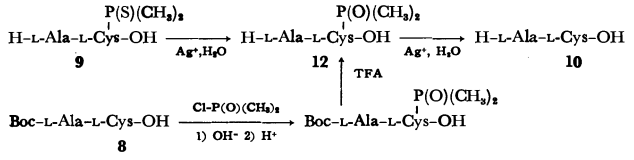
Elution patterns from an amino-acid-analyzer column of a mixture of products from the reaction of **9** with $AgNO_3$ are shown in Fig. 3. Although the starting

material, **9** (elution volume=110 cm³), disappeared within 60 min at 0 °C upon the use of 2 molar equiv. of $AgNO_3$, the reaction was still incomplete, as was shown by the presence of an intermediate. When a 4 molar excess of the reagent was used, complete deprotection occurred to afford **10** (elution volume =115 cm³), without any accompanying dehydroalanine formation (elution volume of **11**=132 cm³). In order to elucidate the structure of the intermediate, it was isolated from a separate reaction mixture by ion-exchange chromatography to give a considerably pure solid material, which showed methyl-proton signals coupled with P, but different from those for the Mpt group. Based on this result, it was speculated that the structure of the compound was the *S*-dimethylphosphinyl (Dmp=$-P(O)(CH_3)_2$) derivative of **10**, H-L-Ala-L-Cys(Dmp)-OH (**12**), produced by the oxidative desulfurization of **9**:



This speculation was confirmed by analyzing a product prepared by the reaction of **8** with dimethylphosphinyl chloride, followed by *N*-deprotection by TFA. As expected, a peak appeared at the same position as the unknown product described above. This result does not necessarily mean that the removal of the *S*-Mpt group by $AgNO_3$ proceeds only through the intermediate formation of the Dmp derivative, but the consumption of $AgNO_3$ being more than the expected amount would be explained by this extra oxidation.

As an application of the Mpt group as a thiol-protecting group, the synthesis of glutathione was attempted according to the scheme illustrated in Fig. 4.

The removal of the *S*-Mpt group was performed either at the final stage (Method A) or before the removal of the other protecting groups (Method B); the latter gave a better yield.

Further applications of the *S*-Mpt-L-cysteine derivatives for the synthesis of cysteine and dehydroalanine containing peptides are now in progress.

Experimental

Thin-layer chromatography (TLC) was performed on silica gel plates (Merck $60F_{254}$) in the following solvent systems: dichloromethane (R_f^1), ether (R_f^2), ethyl acetate (R_f^3), chloroform–methanol–acetic acid (95 : 5 : 3, R_f^4), chloroform–methanol–acetic acid (85 : 25 : 20, R_f^5), chloroform–methanol–acetic acid–water (45 : 30 : 6 : 9, R_f^6), phenol–water (4 : 1 w/v, R_f^7), and 1-butanol–ethyl acetate–acetic acid–water (1 : 1 : 1 : 1, R_f^8). The products were detected on TLC plates using ultraviolet light, iodine vapor, ninhydrin, and the sodium nitroprusside reagent.

N,S-Bis(dimethylphosphinothioyl)-L-cysteine Methyl Ester (Mpt-L-Cys(Mpt)-OMe) (1). A solution of Mpt-Cl[3] (1.29 g, 10 mmol) in 10 cm³ of chloroform was added to a suspension of HCl·H-L-Cys-OMe (0.858 g, 5 mmol) in 10 cm³ of chloroform and 2.1 cm³ (15 mmol) of *N,N*-diisopropylethylamine at 0 °C. After having been stirred for 3 h at 0 °C, the solution was evaporated *in vacuo*. The residue was dissolved in ethyl acetate. The solution was washed successively with water, an ice-cold 5% citric acid solution, water, a 5% sodium hydrogencarbonate solution, water, and a saturated sodium chloride solution, dried over anhydrous sodium sulfate, and evaporated. The oily residue was dissolved in dichloromethane and placed in a silica-gel column (2×10 cm). Subsequent elution with dichloromethane gave **1** as colorless oil; 1.26 g (79%). $[\alpha]_D^{24}$ −13.0° (*c* 1, ethanol); R_f^1 0.60, R_f^2 0.76. Found: C, 29.91; H, 6.30; N, 4.36%. Calcd for $C_8H_{19}NO_2P_2S_3$: C, 30.09; H, 6.00; N, 4.39%.

N,S-Bis(dimethylphosphinothioyl)-L-cysteine Dicyclohexylamine Salt (Mpt-L-Cys(Mpt)-OH·DCHA) (2). L-Cys (2.24 g, 20 mmol) was dissolved in a 1 M sodium hydroxide solution (20 cm³), and then Mpt-Cl (5.65 g, 44 mmol) in ether (40 cm³) was added, drop by drop, at 0 °C. While the mixture was being stirred vigorously, the 1 M sodium hydroxide solution was added carefully, at a rate chosen so as to maintain the pH of the solution between 9.0 and 9.5, until no drop in the pH was observed. Then the solution was extracted twice with ethyl acetate. The aqueous layer was acidified (pH 3—4) with solid citric acid at 0 °C and then extracted with ethyl acetate several times. The organic layer was washed with

water, dried over anhydrous sodium sulfate, and evaporated *in vacuo*. The oily residue was dissolved in ethyl acetate and treated with DCHA (4 cm³, 20 mmol). DCHA salt was collected by filtration, washed with ethyl acetate and ether, and dried. Subsequent recrystallization from ethanol gave **2** as colorless crystals; 5.0 g (50%). mp 150—151 °C; $[\alpha]_D^{24}$ −6.2° (*c* 1, methanol); R_f^4 0.35, R_f^5 0.88. Found: C, 46.34; H, 8.14; N, 5.91; P, 11.97%. Calcd for $C_{19}H_{40}N_2O_2P_2S_3 \cdot 1/2\ H_2O$: C, 46.04, H, 8.34; N, 5.65; P, 12.49%.

S-*Dimethylphosphinothioyl*-L-*cysteine Methyl Ester Hydrochloride (H*–L-*Cys(Mpt)*–*OMe·HCl) (**3**).* Compound **1** (9.65 g, 30 mmol) was stirred with 2.2 M HCl in ethyl acetate at room temperature for 2.5 h. The solvent was then removed *in vacuo*, and the residue was dissolved in methanol. The solution was treated with Amberlyst A-21 resin to neutralize it and to remove a small amount of dimethylphosphinothioic acid (Mpt–OH), and then filtered. The filtrate was treated with an equimolar amount of HCl in methanol and evaporated to give a chromatographically homogeneous oil; 8.19 g (quantitative). R_f^4 0.14, R_f^5 0.58.

S-*Dimethylphosphinothioyl*-L-*cysteine Hydrochloride (H*–L-*Cys-(Mpt)*–*OH·HCl) (**4**).* Compound **2** (4.87 g, 10 mmol) was separated between a 5% citric acid solution and ethyl acetate. The ethyl acetate layer was washed with water, dried, and evaporated. The residue was dissolved in methanol (4 cm³) and dichloromethane (30 cm³), 2 M HCl/1 M Ph_3P/CH_2Cl_2[3] (15 cm³) was added at 0 °C, and the mixture was kept standing at room temperature for 3 h. The crystalline precipitate was then collected by filtration, washed with CH_2Cl_2, and dried over P_2O_5; 2.22 g (89%). An analytical sample was recrystallized from methanol–CH_2Cl_2–ether; mp 157—158 °C (decomp); $[\alpha]_D^{24}$ −18.4° (*c* 1, methanol); R_f^5 0.21. Found: C, 24.13; H, 5.54; N, 5.53; P, 12.61%. Calcd for $C_5H_{13}NO_2PS_2Cl$: C, 24.09; H, 5.26; N, 5.61; P, 12.40%.

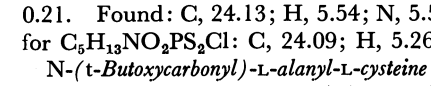
N-(t-*Butoxycarbonyl*)-L-*alanyl*-L-*cysteine Methyl Ester (Boc*–L-*Ala*–L-*Cys*–*OMe) (**5**).* Mpt–Cl (2.57 g, 20 mmol) was added to an ice-cold, stirred solution of Boc–L-Ala–OH (3.78 g, 20 mmol) and triethylamine (2.80 cm³, 20 mmol) in 20 cm³ of chloroform, after which the mixture was stirred for 1 h.[6] To this solution, a mixture of HCl·H–L-Cys–OMe (3.43 g, 20 mmol) and triethylamine (5.6 cm³, 40 mmol) in 80 cm³ of chloroform was added in several portions at 0 °C. After having been kept stirring for 1 h at this temperature, the solution was washed in the usual way, dried, and evaporated *in vacuo*. The solidified residue was washed with ether and recrystallized from ethyl acetate–petroleum ether to give colorless crystals; 3.62 g (59%). mp 110—112 °C; $[\alpha]_D^{26}$ −35.0 °C (*c* 1, ethanol); R_f^2 0.16, R_f^3 0.62. Found: C, 46.74; H, 7.10; N, 9.29%. Calcd for $C_{12}H_{22}N_2O_5S$: C, 47.04; H, 7.24; N, 9.11%.

N-(t-*Butoxycarbonyl*)-L-*alanyl*-S-*dimethylphosphinothioyl*-L-*cysteine Methyl Ester (Boc*–L-*Ala*–L-*Cys(Mpt)*–*OMe) (**6**).* To an ice-cold solution of Boc–L-Ala–L-Cys–OMe (1.53 g, 5 mmol) and *N,N*-diisopropylethylamine (0.871 cm³, 5 mmol) in 5 cm³ of chloroform, Mpt–Cl (0.643 g, 5 mmol) was added, after which the mixture was stirred continuously for 1 h at 0 °C and for 3 h at room temperature. The solution was washed in the usual manner, dried over anhydrous sodium sulfate, and evaporated *in vacuo*. The solid residue was recrystallized from ethyl acetate–petroleum ether to give colorless crystals; 1.69 g (85%). mp 106—108 °C; $[\alpha]_D^{24}$ −28.5° (*c* 1, ethanol); R_f^2 0.38, R_f^3 0.72. Found: C, 42.04; H, 6.81; N, 7.18%. Calcd for $C_{14}H_{27}N_2O_5PS_2$: C, 42.20; H, 6.83; N, 7.03%.

N,S-*Bis(dimethylphosphinothioyl)*-L-*cysteinylglycine* t-*Butyl Ester (Mpt*–L-*Cys(Mpt)*–*Gly*–*OBu^t) (**13**).* Compound **2** (803 mg, 1.65 mmol) was dissolved in 4 cm³ of chloroform and treated with Mpt–Cl (212 mg, 1.65 mmol) at 0 °C. To this solution a solution of the glycine *t*-butyl ester (217 mg, 1.65 mmol) and *N,N*-diisopropylethylamine (0.29 cm³, 1.65 mmol) in 2 cm³ of chloroform was added, after which the solution was stirred for 2 h at 0 °C. After the solvent had been changed to ethyl acetate, the solution was washed with water, an ice-cold 5% citric acid solution, water, a 5% sodium hydrogencarbonate solution, water, and a saturated sodium chloride solution, and dried. After the removal of the solvent *in vacuo*, an oily residue was dissolved in dichloromethane and the solution was placed in a silica-gel column (1.7×20 cm). Subsequent elution by ether gave colorless crystals; 629 mg (91%). An analytical sample was recrystallized from ethyl acetate–petroleum ether; mp 110—112 °C; $[\alpha]_D^{20}$ −24° (*c* 1, methanol); R_f^2 0.17, R_f^3 0.54. Found: C, 37.03; H, 6.84; N, 6.45%. Calcd for $C_{13}H_{28}N_2O_3P_2S_3$: C, 37.31; H, 6.74; N, 6.69%.

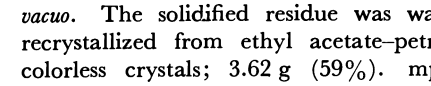
S-*Dimethylphosphinothioyl*-L-*cysteinylglycine* t-*Butyl Ester (H*–L-*Cys(Mpt)*–*Gly*–*OBu^t) (**14**).* Compound **13** (1.88 g, 4.49 mmol) was treated with 2 M HCl in dichloromethane containing 1 M of tributylphosphine (13.45 cm³). After having been stirred at 0 °C for 2.5 h and at room temperature for 6.5 h, the solution was evaporated. The residue was separated between water and ethyl acetate. The aqueous layer was washed with ethyl acetate, the pH was adjusted to 9 by adding solid sodium hydrogencarbonate, and extracted several times with ethyl acetate. The combined extracts were washed with water, dried over anhydrous sodium sulfate, and evaporated. The oily residue was purified by passing its ethyl acetate solution through a short silica-gel column (3×12 cm) to give a chromatographically homogeneous oil; 1.45 g (99%). R_f^4 0.21, R_f^5 0.68.

N-(t-*Butoxycarbonyl*)-L-*γ-glutamyl*-S-*dimethylphosphinothioyl*-L-*cysteinylglycine Di*-t-*butyl Ester*



(**15**). To an ice-cold solution of Boc–L-Glu–OBu^t·DCHA (737 mg, 1.52 mmol) in 3 cm³ of chloroform, Mpt–Cl (195 mg, 1.52 mmol) was added in several portions, after which the solution was stirred at 0 °C for 1 h. To this solution a mixture of Compound **14** (547 mg, 1.68 mmol) and *N,N*-diisopropylethylamine (0.29 cm³, 1.68 mmol) in 10 cm³ of chloroform was added. After having been stirred at 0 °C for 2 h, the solution was washed in the usual manner, dried, and evaporated *in vacuo*. The residue was purified by silica-gel column chromatography. After the elution of a small amount of symmetric dimethylphosphinothioic anhydride (Mpt–O–Mpt), Compound **15** was obtained as an amorphous solid by eluting with CH_2Cl_2 and then with CH_2Cl_2–methanol (9/1, v/v); 840 mg (90%). $[\alpha]_D^{20}$ −40° (*c* 1, methanol); R_f^2 0.25, R_f^3 0.74. Found: C, 48.77; H, 7.70; N, 6.54%. Calcd for $C_{25}H_{46}O_8N_3S_2P \cdot 1/2\ CH_3OH$: C, 48.79; H, 7.71; N, 6.69%.

L-*γ-Glutamyl*-S-*dimethylphosphinothioyl*-L-*cysteinylglycine*



(**16**). Trifluoroacetic acid (16.55 cm³) was added to an ice-cold solution of Compound **15** (1.093 g, 1.79 mmol) in 9 cm³ of CH_2Cl_2 containing anisole (3.57 cm³). After having been kept standing at room temperature overnight, the solution was evaporated. The residue was separated between water and ether, and the organic layer was extracted several times with water. The combined aqueous layer and extracts were evaporated *in vacuo*. Then the solid residue was dissolved in water, and the solution was placed in a column (1.2×51 cm) of Dowex 1-X2 ion-exchange resin (acetate form). The column was eluted with 8% acetic acid. The desired fractions (172—277 cm³) were pooled and evaporated *in vacuo* to give **16** as colorless crystals; 0.629 g (85%). An analytical sample was recrystallized from hot

water; mp 202—203 °C; $[\alpha]_D^{20}$ −23° (*c* 1, H_2O); R_f^6 0.23, R_f^8 0.42. Found: C, 34.89; H, 5.42; N, 10.08%. Calcd for $C_{12}H_{22}O_6N_3PS_2 \cdot 2/3\ H_2O$: C, 35.03; H, 5.72; N, 10.21%.

N,N′-[*Bis*[N-(*t-butoxycarbonyl*)-L-*γ-glutamyl*]-L-*cystinyl*]*bis*-(*glycine*) *Tetra*-t-*butyl Ester*  (**17**). A solution of silver nitrate (340 mg, 2 mmol) in water (5 cm³) was added to a solution of Compound **15** (306 mg, 0.5 mmol) in methanol (10 cm³) containing pyridine (0.16 cm³, 2 mmol) at 0 °C. The mixture was stirred at 0 °C for 1 h. H_2S gas was then bubbled through the solution at 0 °C for 1 h. The precipitate was removed by filtration, and the filtrate was evaporated *in vacuo*. The residue was dissolved in ethyl acetate, and the solution was washed with water, dried and evaporated. The residue was dissolved in CH_2Cl_2, and the solution was placed in a column (0.6×25 cm) of silica gel which was then eluted with ether. The eluates were combined and evaporated *in vacuo* to give a colorless oil; 261 mg (100%). R_f^2 0.31, R_f^3 0.76. This material was dissolved in methanol (5 cm³) containing pyridine (0.09 cm³, 1.1 mmol). To this a 0.1 M I_2–KI solution in 90% ethanol (2.63 cm³) was added at 0 °C. After this solution had been stirred for 1 h, the organic solvents were removed. The residue was dissolved in ethyl acetate, and the solution was washed with water and a sodium thiosulfate solution, dried, and evaporated. The residue was dissolved in CH_2Cl_2, and the solution was placed in a column (0.6×25 cm) of silica gel which was then eluted with CH_2Cl_2, followed by ether. The eluates were combined and evaporated *in vacuo* to give **17** as colorless crystals; 242 mg (93%). mp 102—107 °C; $[\alpha]_D^{20}$ −73° (*c* 1, methanol); R_f^2 0.42, R_f^3 0.84. Found: C, 53.12; H, 7.85; N, 8.05%. Calcd for $C_{46}H_{80}O_{16}N_6S_2$: C, 53.26; H, 7.77; N, 8.10%.

Glutathione (Oxidized Form)  (**18**). *Method A*: To a solution of Compound **16** (749 mg, 1.63 mmol) in water (70 cm³) containing pyridine (0.58 cm³, 7.15 mmol), 7.15 cm³ of 1 M silver nitrate solution was added at 0 °C. The mixture was then stirred at 0 °C for 1 h. H_2S gas was bubbled through the solution at 0 °C for 1 h. The precipitate was removed by filtration, and the filtrate was evaporated *in vacuo*. The residue was dissolved in a small volume of water and methanol, after which the solution was adjusted to pH 7 with pyridine at 0 °C and treated with iodine (232 mg, 1.83 mmol) in methanol (10 cm³). After the removal of the methanol *in vacuo*, the solution was placed in a column (1.2×61 cm) of Dowex 1-X2 ion-exchange resin (acetate form). The column was eluted with water (200 cm³) and then 10 % acetic acid. The desired fractions were colcollected, evaporated *in vacuo*, and dried over P_2O_5 to give **18** as colorless crystals; 270 mg (52%).

Method B: To a solution of Compound **17** (1.017 g, 0.98 mmol) in CH_2Cl_2 (20 cm³) containing anisole (5.11 cm³), trifluoroacetic acid (36.23 cm³) was added at room temperature. After having been kept standing overnight, the solvent was evaporated *in vacuo*; the residue was dissolved in water and placed in a column of Dowex 1-X2 ion-exchange resin (acetate form). Elution as described in Method A gave colorless crystals; 602 mg (97%). An analytical sample was recrystallized from water–ethanol; mp 178—180 °C; $[\alpha]_D^{20}$ −105° (*c* 1, H_2O) (lit,[7] mp 175—195 °C; $[\alpha]_D^{27}$ −92.8° (*c* 1.2, H_2O), lit,[8] $[\alpha]_D$ −94° (*c* 1, H_2O)); R_f^7 0.03, R_f^8 0.13. Found: C, 37.89; H, 5.70; N, 13.03%. Calcd for $C_{20}H_{32}N_6O_{12}S_2 \cdot H_2O$: C, 38.09; H, 5.43; N, 13.33%.

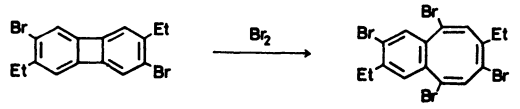
(Received September 25, 1982)

3-Substituted 2-bromobiphenylenes were brominated to give benzocyclooctene or 7(8*H*)-benzocyclooctenone derivatives, but not biphenyl derivatives. The structure of 5,8,10-tribromo-7(8*H*)-benzocyclooctenone was determined by X-ray diffraction analysis.

Biphenylene itself prefers an addition reaction to a substitution reaction on treatment with bromine,[1] probably because biphenylene has a partial anti-aromaticity in the central four-membered ring. On the other hand, biphenylene derivatives having an electron-releasing substituent at the 2-position undergo a predominant bromine-substitution reaction at the 3-position.[1] Further bromination of monobrominated biphenylene derivatives was previously reported to give biphenyl derivatives,[2,3] but the reaction product on bromination of 2-bromo-3-methoxybiphenylene was later corrected by us to be benzocyclooctene derivatives.[4] We now report a reexamination of bromination of 2,6-diethyl-, 2-acetoxy-, and 2-acetamidobiphenylenes.[5]

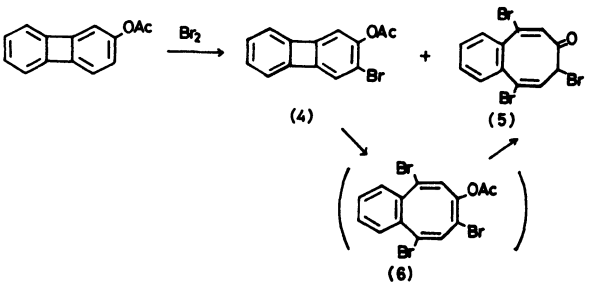
It was reported that the bromination of 2-ethylbiphenylene gave an inseparable mixture of mono- and dibrominated products.[6] On the other hand, 2,6-diethylbiphenylene was brominated in dichloromethane to give 3,7-dibromo-2,6-diethylbiphenylene (**1**) in moderate yield, which was further brominated with an excess of bromine to give 3,5,8,10-tetrabromo-2,7-diethylbenzocyclooctene (**2**) in 70% yield. The structure of **2** was assigned by electronic and ^{1}H-NMR spectral analogy to 5,8,10-tribromo-7-methoxybenzocyclooctene (**3**).[4,5] Thus, **2** showed a ^{1}H-NMR spectrum having two olefinic multiplets at δ=6.58 and 6.74.



(**1**) (**2**)

2-Acetoxybiphenylene was treated with 2 equivalents of bromine at room temperature to give a small amount of the monobrominated product **4** and tribromo ketone **5** in 34% yield. The structure of **4** was assigned to 2-acetoxy-3-bromobiphenylene by its ^{1}H-NMR spectrum: δ=2.32 (s, 3H, $OCOCH_3$), 6.48 (s, 1H, H-1), and 6.5—7.0 (m, 5H, H-4 and Ar–H). Tribromo ketone **5** was the same product with that obtained on bromination of 2-methoxybiphenylene,[4] and was probably formed by the action of a trace of acid on intermediately formed 7-acetoxy-5,8,10-tribromobenzocyclooctene (**6**). The result suggests that bromination of **4** gives **6** easily.

Bromination of 2-acetamidobiphenylene was reported to give 2-acetamido-3-bromobiphenylene (**7**) in 65% yield, which was further brominated to give a biphenyl derivative.[3] We reexamined the reaction of 2-acetamidobiphenylene with an excess of bromine in acetic



acid, and obtained 5,8,10-tribromo-7(8*H*)-benzocyclooctenone (**5**) although in low yield, in addition to a tribromo compound (**A**) (mp 156—157 °C). (**A**) was previously assigned as 3-acetamido-2′,4,6-tribromobiphenyl (**9**) by Baker *et al.*, but the above result suggests that (**A**) is a benzocyclooctene derivative which transforms easily to **5** on acid hydrolysis. (**A**) was alternatively obtained on bromination of **6** in dichloromethane at room temperature in high yield and was converted on treatment with 48% hydrobromic acid in boiling ethanol to **5** in 80% yield. We reprepared (**A**) according to Baker and co-workers' direction,[3] and found it to have a ^{1}H-NMR having two olefinic doublets at δ=6.73 and 6.94 (J=1.3 Hz) and an electronic spectrum closely similar to those of **2** and **3** (Fig. 1), proving that (**A**) is 7-acetamido-5,8,10-tribromobenzocyclooctene (**8**).

We prepared **9** in the following manner. The reaction of *m*-nitrobenzenediazonium tetrafluoroborate with bromobenzene in the presence of 18-crown-6 gave a

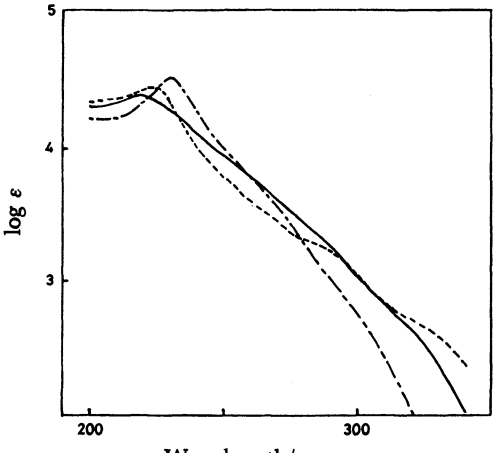


Fig. 1. Electronic spectra of **3** (------), **2** (·–·–·), and **8** (——).

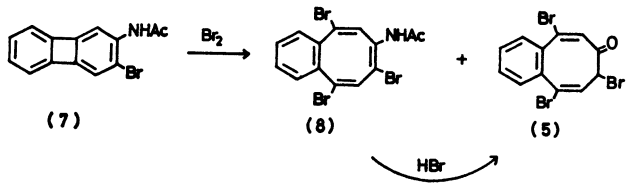

mixture of 2′-bromo- and 4′-bromo-3-nitrobiphenyl in good yield. The former product (separated in 13% yield) was converted by reduction and successive acetylation to 3-acetamido-2′-bromobiphenyl, which was brominated, according to the procedure described by Baker *et al.*, to give **9**, colorless needles, mp 117—118 °C. The ^{1}H-NMR of **9** showed the following signals: δ=2.26 (s, 3H, $COCH_3$), 7.15—7.55 (m, 4H, H-3′—H-6′), 7.70 (broad s, 1H, NH), 7.97 (s, 1H, H-2), and 8.45 (s, 1H, H-5). **9** gave an IR spectrum different from that of **8**. Thus, **8** was unequivocally proved not to be **9**. Ultimately, the structure of **5** was determined by an X-ray crystallographic analysis (see below).

There seems to be a common trend on bromination of biphenylene derivatives having an electron-releasing substituent at the C_2 position. In these derivatives, bromination gives exclusively 3-substituted 2-bromobiphenylenes.[1] Further bromination of the 2-substituted 3-bromobiphenylenes takes place at the C_{4a}-position, forming an intermediate biphenylenium ion, similarly to the bromination of biphenylene itself, because the C_3-position is already occupied by the bromo substituent and the electron-releasing ability of the 2-substituent is cancelled by the electron-withdrawing bromo substituent. Successive addition of a bromide ion on the intermediate biphenylenium ion formed occurs exclusively at the C_{8b}-position, not at the C_{4b}-position. The resulting dibromo adducts undergo a spontaneous ring-opening to give benzocyclooctene derivatives. The bromide ion attack on the biphenylenium ion at the C_{4b}-position and subsequent C_{4a}–C_{4b} bond fission to biphenyl derivatives do not take place. An exceptional example that bromine attacked the unsubstituted benzene ring of 2-substituted biphenylene was presented in bromination of 2-ethylbiphenylene to 3,6- and 3,7-dibromo-2-ethylbiphenylenes.[6]

Crystal and Molecular Structures of 5. The geometrical aspects of the molecule and the atomic numbering are shown in Fig. 2. Bond lengths and angles, and torsion angles are given in Tables 2 and 3, respectively.

The conformation of the eight-membered ring can be described as an approximation to the boat form, although there are some significant deviations. A comparison of the torsion angles found in this study with those calculated for the boat conformation of cyclooctane by Hendrickson,[9] shows that the major difference is at the C(7)–C(6) and C(7)–C(8) bonds attached to the carbonyl group. This may be due to the conjugating effect between the carbonyl group and adjacent double bonds, and these related four atoms, C(5), C(6), C(7), and O(7), are almost planar with a maximum deviation of 0.077 Å at C(6). Thus, the *endo*-cyclic bond angles of the eight-membered ring range from 134.6° (C(4a)–C(5)–C(6)) to 110.3° (C(7)–C(8)–C(9)), corresponding to regular octahedral and tetrahedral angles, respectively. The Br(8) atom is located at the equatrial position of the eight-membered ring.

Experimental

3,7-Dibromo-2,6-diethylbiphenylene (1). To a solution of 2,6-diethylbiphenylene[6] (0.20 g, 0.96 mmol) in dichloromethane (20 ml) was added a solution of bromine (19.7 ml of 0.5% v/v solution, 1.9 mmol) in dichloromethane under ice-cooling. The solution was stirred for 1 h at room temperature, then poured into water and extracted with dichloromethane. After drying over anhyd sodium sulfate the extract was evaporated. The crystalline residue was recrystallized from acetone-hexane. The title compound (128 mg, 36%) was obtained as yellow needles, mp 165—166 °C. Found: C, 52.72; H, 3.91%. Calcd for $C_{16}H_{14}Br_2$: C, 52.49; H, 3.85%. UV (EtOH): 210.2 (log ε 3.91), 252 (4.61), 261 (5.00), and 372 nm (3.82). IR (KBr): 2950, 1555, 1417, and 880 cm^{-1}. ^{1}H-NMR ($CDCl_3$): δ=1.15 (t, 6H, J=7.5 Hz, CH_3), 2.62 (q, 4H, J=8 Hz, CH_2), 6.58 (s, 2H, H-1 and H-5), and 6.84 (s, 2H, H-4 and H-8). MS (70 eV): *m/e* 364 (M^+, 84%), 349 (M^+ +2, 100%).

3,5,8,10-Tetrabromo-2,7-diethylbenzocyclooctene (2). To a solution of **1** (0.12 g, 0.33 mmol) in dry dichloromethane (10 ml) was added a solution of bromine (8.4 ml of 0.5% v/v solution, 0.81 mmol) in dichloromethane. The solution was stirred for 4 h at room temperature. The color of bromine did not disappear. The solution was washed with aq sodium hydrogencarbonate and dried over anhyd sodium sulfate. After evaporation, the crude crystalline residue was recrystallized from acetone-hexane. The title compound (116 mg, 70%) was obtained as pale yellow cubics, mp 133—135 °C. Found: C, 36.29; H, 2.39%. Calcd for $C_{16}H_{11}Br_4$: C, 36.54; H, 2.68%. UV (EtOH): 230 nm (log ε 4.62). IR (KBr): 2950, 1610, 1330, 950, and 640 cm^{-1}. ^{1}H-NMR ($CDCl_3$): δ=0.88 (t, 3H, J=8.0 Hz, CH_3), 1.26 (t, 3H, J=7.0 Hz, CH_3), 1.9—2.5 (m, 2H, CH_2), 2.77 (q, 2H, J=7.3 Hz, CH_2), 6.58 (m, 1H, H-4), 6.74 (m, 1H, H-7), 7.30 (s, 1H, H-6′), and 7.58 (s, 1H, H-3′). ^{13}C-NMR ($CDCl_3$): δ=11.4 (q), 13.7 (q), (29.0 (t), 29.1 (t), 115.5 (s), 119.2 (s), 121.9 (s), 125.1 (s), 129.7 (d), 132.8 (d), 134.8 (d), 135.8 (s), 136.4 (s), 142.4 (s), and 144.2 (s). MS (70 eV): *m/e* 522 (M^+, 0.01%), 442 (M^+ −Br, 5.4%), 362 (M^+ −2Br, 13.5%), and 29 (Et^+, 100%).

Bromination of 2-Acetoxybiphenylene. To a solution of 2-acetoxybiphenylene[7] (0.20 g, 0.95 mmol) in dichloromethane (20 ml) was added a solution of bromine (0.30 mg, 1.9 mmol) in dichloromethane (19.5 ml) under ice-cooling. The solution was stirred for 1.5 h, then washed with aq sodium hydrogencarbonate, and dried over anhyd sodium sulfate. After evaporation, the oily residue was subjected to TLC on silica gel by elution with benzene–ethyl acetate. 5,8,10-Tribromo-7(8*H*)-benzocyclooctenone (**5**) (132 mg, 35%)[4] was obtained, along with an oily mixture. The latter oil was treated three times with methanol to form a small amount of 2-acetoxy-3-bromobiphenylene as yellow needles, mp 125—126 °C. Found: C, 58.39; H, 3.04%. Calcd for $C_{14}H_9BrO_2$: C, 58.15; H. 3.13%. UV (EtOH): 245 (log ε 4.60), 254 (4.97), 345 (3.47), and 365 nm (3.67). IR (KBr): 1765, 1420, 1200, and 745 cm^{-1}. ^{1}H-NMR ($CDCl_3$): δ=2.32 (s, 3H, $COCH_3$), 6.48 (s, 1H, H-1), and 6.5—7.0 (m, 5H). MS (70 eV): *m/e* 288 (M^+, 2.3%), 246 (M^+ −CH_2CO, 34%), 139 (M^+−Br−CH_2CO−CO, 100%) and 138 (M^+ −Br−CH_3CO−CO).

Bromination of 2-Acetamidobiphenylene. To a solution of 2-acetamidobiphenylene[8] (0.33 g, 1.6 mmol) in acetic acid (30 ml) was added a solution of bromine (2 ml of 10% v/v solution, 3.8 mmol) in the same solvent. The solution was stirred for 2 h at 80 °C, then poured into water (150 ml), and extracted three times with ether. The extract was dried over anhyd magnesium sulfate. After evaporation, the residue was chromatographed on silica gel by elution with benzene–ethyl acetate. One of the products obtained was **5** (64 mg, 10%) (mp 138—139 °C).[4] The other was **8** (colorless crystals, mp 155—156 °C) (177 mg, 25%). Found: C, 37.54; H, 2.23; N, 3.03%. Calcd for $C_{14}H_{10}Br_3NO$: C, 37.54; H, 2.25; N, 3.13%. IR (KBr): 1655, 1620, 1292, and 940 cm^{-1}. ^{1}H-NMR ($CDCl_3$): δ=2.03 (s, 3H, $COCH_3$), 6.73 (d, 1H, J=1.3 Hz, H-4), 6.94 (d, 1H, J=1.3 Hz, H-7), 7.3 (broad s, 1H, NH), and 7.44 (s, 4H, Ar-H). ^{13}C-NMR ($CDCl_3$): δ=29.4 (q), 122.2 (s), 125.9 (s), 129.1 (d), 129.5 (d), 129.6 (d), 130.3 (d), 132.3 (d), 133.9 (s), 136.6 (s) 138.3 (s), 139.7 (s), and 145.2 (s), MS (70 eV): *m/e* 445 (M^+, 0.8%), 366 (M^+ −Br, 16%), 323 (M^+−Br−CH_3CO, 38%), and 246 (M^+−2Br−CH_2CO,

100%).

5,8,10-Tribromo-7(8H)-benzocyclooctenone (5). To a solution of 2-acetamido-3-bromobiphenylene (58 mg, 0.2 mmol) in dry dichloromethane (7 ml) was added a solution of bromine (4 ml of 0.5% v/v solution, 0.38 mmol) under ice-cooling. The solution was stirred for 2 h at room temperature. After the usual work-up, the residue obtained was purified by TLC on silica gel by elution with benzene–dichloromethane. The title compound (85 mg, 94%) was obtained.

A solution of **8** (53 mg, 0.12 mmol) in ethanol (2 ml) and 48% hydrobromic acid (0.5 ml) was refluxed for 2 h. After usual work-up, the product obtained was recrystallized from hexane–acetone to give the title compound (35 mg, 80%).

2'-Bromo- and 4'-Bromo-3-nitrobiphenyl. To a suspension of 3-nitrobenzenediazonium tetrafluoroborate, prepared from *m*-nitroaniline (6.7 g, 0.05 mol), in dry bromobenzene, were added 18-crown-6 (0.5 g) and potassium acetate (7.54 g, 0.077 mol). The mixture was stirred for 1.5 h under water-cooling and then filtered. The filtrate was washed with a saturated aq solution of sodium chloride, and dried over anhyd magnesium sulfate. After evaporation, the red oily residue was chromatographed on alumina using benzene–hexane as eluent to give a colorless oil (10.1 g), from which 2'-bromo-3-nitrobiphenyl (1.82 g, 13%) and 4'-bromo-3-nitrobiphenyl (1.1 g, 8%) were obtained by fractional recrystallization from ether. 2'-Bromo-3-nitrobiphenyl, colorless plates, mp 76—78 °C (lit,[3] 77—78 °C). IR (KBr): 1535, 1352, 763, 739, and 687 cm^{-1}. ^{1}H-NMR ($CDCl_3$): δ=7.1—7.6 (m, 3H), 7.6—8.1 (m, 3H), 8.2—8.5 (m, 2H). ^{13}C-NMR ($CDCl_3$): δ=122.1 (s), 122.4 (d), 124.3 (d), 127.6 (d), 128.8 (d), 129.6 (d), 130.9 (d), 133.2 (d), 135.4 (d), 139.9 (s), 142.3 (s), and 147.8 (s). 4'-Bromo-3-nitrobiphenyl, colorless crystals, mp 84—85 °C. IR (KBr): 1535, 1359, 877, 824, 796, 763, 738, and 675 cm^{-1}. ^{1}H-NMR ($CDCl_3$): δ=7.3—8.1 (m, 6H) and 8.15—8.6 (m, 2H).

3-Acetamido-2',6-dibromobiphenyl. According to the direction described by Baker *et al.*,[3] 3-acetamido-2'-bromobiphenyl, prepared by reduction and subsequent acetylation of 2'-bromo-3-nitrobiphenyl, was brominated to give the title compound in 72% yield, but 3-acetamido-2',4,6,-tribromobiphenyl was not isolated.

5-Acetamido-2',4,6-tribromobiphenyl. 2',6-Dibromobiphenyl (365 mg, 1 mmol) and anhydrous sodium acetate (621 mg) were dissolved in boiling acetic acid (9.5 ml) and acetic anhydride (0.8 ml). To the mixture was added a solution of bromine (0.50 g, 3.1 mmol) in acetic acid (5 ml). The solution was refluxed for 1 h and poured into ice-water. The crystals were collected by suction, then washed with water, and dried. The products were chromatographed on silica gel by elution with benzene–ethyl acetate to give a colorless oil (227 mg, 50.6%) and colorless crystals (156 mg, 42.7%). The latter was recovered starting material. Crystallization and recrystallization of the former oil from ether gave the title compound as colorless crystals, mp 117—118 °C.

X-Ray Crystallography of 5. A crystal of dimensions 0.4 $\times$0.4$\times$0.2 mm obtained from hexane–acetone, was used for the intensity measurements. Intensity data were obtained on a Rigaku four-circle automatic diffractometer, equipped with graphite-monochromated Cu *Kα* radiation, and using the θ-2θ scan technique ($2\theta \leq 127°$). 1554 independent reflecions ($F_o \geq 2.5\,\sigma F_o$) were corrected for Lorentz and polarization factors but not for absorption.

Crystal Data. $C_{12}H_7OBr_3$, orthorhombic, Pbca, z=8, a=9.667(2), b=16.261(3), c=15.957(3) Å, D_{calcd}=2.08 g/cm^3. The structure was solved by heavy atom methods. The positional and thermal parameters were refined by block diagonal least-squares methods. The positions of all hydrogen atoms were located from a difference Fourier synthesis. The final discrepancy index R is 0.079. The positional parameters for nonhydrogen atoms are listed in Table 1. Thermal parameters for nonhydrogen atoms, fractional coordinates and isotropic thermal hydrogen atoms, and observed and calculated structure factors are kept at the Chemical Society of Japan (Document No. 8313).

Aryliminodimagnesium Reagents. VI. The Reactions with Conjugated Carbonyl Compounds. The Initial Coordination and the Electron-transfer in the Reactions of Organomagnesium Reagents

Masao Ōkubo,* Masatoshi Yoshida, Kotomi Horinouchi, Hiroshi Nishida, and Yoshinori Fukuyama

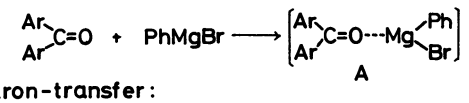
Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjō-machi, Saga 840

(Received October 1, 1982)

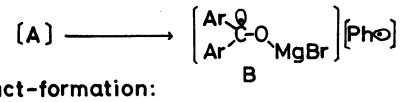
The reactions of aryliminodimagnesium reagents ($ArN(MgBr)_2$) with benzylideneacetophenones, quinones, and benzils were examined. Among the product-distributions in the reactions with the enones and the α-diketones, some examples in which *p*-MeO-substituted substrates gave higher yields of condensation products were obtained. The results are in contrast with the product-distributions in the reaction of ArMgBr with Ar^1COAr^2 and that of $ArN(MgBr)_2$ with Ar^1NO_2: *p*-Cl-Substituted substrates are advantageous for the formation of addition and/or condensation products. These reactions of the two organomagnesium reagents were classified into "coordination controlled" and "electron-transfer controlled" ones on the basis of the combination of electron-donating ability of reagents with the electron-accepting ability of substrates. The classification was illustrated also on the basis of the relative difference of the energy levels of HOMO's and LUMO's of the reactants.

The sequence of the Grignard reaction of benzophenone is formulated as shown in Scheme 1. In

1) coordination:

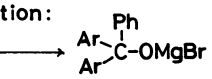


2) electron-transfer:

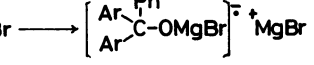


3) product-formation:

i) radical recombination:



ii) radical-anion reaction:



Scheme 1.

general, the initial coordination process is quite rapid and the subsequent electron-transfer process is rate-determining.[1-3] The two types of elementary reactions, i) and ii), are possible for the product-formation process: An evidence for the radical recombination was reported on the basis of product analysis,[4] while another evidence was obtained by ESR on the replacement of electronegative substituents.[2]

The rate-determining electron-transfer process of the reaction of Scheme 1 is accelerated by the electron-attracting *p*-halogeno substituents of the substrate and also by the electron-repelling *p*-methoxyl substituent of the reagent.[2,3] The similar type of the electronic effect of substituents was observed in the product-distribution obtained on the condensation of aryliminodimagnesium reagents ($ArN(MgBr)_2$, aryl-IDMg) with nitroarenes (Scheme 2): A high combined yield of unsymmetrical and symmetrical azoarenes was obtained when Ar^1 had *p*-MeO and Ar^2 had *p*-Cl substituents, while a high yield of azoxyarene was obtained when

$$Ar^1N(MgBr)_2 + Ar^2NO_2 \longrightarrow Ar^1\text{-}N{=}N(O)\text{-}Ar^2 + Ar^1\text{-}N{=}N{=}Ar^2 + Ar^1\text{-}N{=}N\text{-}Ar^1$$

Scheme 2.

the reactants were reversely substituted.[3,5] Though the detailed mechanism of the IDMg reaction remains to be studied, the similar type of the electronic effect of substituents found in the reactions of Schemes 1 and 2 will allow the present authors to compare the reactivities of the two organomagnesium reagents in the common elementary processes, *i.e.*, the initial coordination of the substrate to the Mg atom of the reagent and the subsequent electron-transfer.

A different type of substituent effect was reported previously on the condensation of aryl-IDMg with diaryl ketones (Scheme 3): even the least electron-accepting bis(*p*-dimethylamino)benzophenone gave a sufficient yield of the anil,[6,7] and a higher combined yield of products was obtained in the reaction with 1-methoxy-9-fluorenone than that with 1-halogeno-9-fluorenone.[8]

$$Ar^1N(MgBr)_2 + Ar^2COAr^3 \longrightarrow Ar^1\text{-}N{=}C(Ar^2)(Ar^3)$$

Scheme 3.

In order to find the reason for the apparent contradiction, the reaction of aryl-IDMg with some other types of carbonyl compounds was investigated. In this paper, the product-distribution obtained in the IDMg reaction with benzylideneacetophenones, quinones, and benzils will first be described, and compared with that obtained in the Grignard reaction with the same substrates, respectively. On the basis of the comparison, the role of the initial coordination in the IDMg reaction with carbonyl compounds, including diaryl ketones, will be emphasized. The types of the electronic substituent effects found in the reactions of the two organomagnesium reagents with nitro and carbonyl compounds will be classified and discussed in terms of the electron-accepting and -donating abilities of the reactants.[8]

Results and Discussion

IDMg Reaction with Benzylideneacetophenones. In the Grignard (ArMgBr) reaction of benzylideneaceto-

Table 1. Product-distribution in the IDMg reaction with benzylideneacetophenones (Scheme 4b)

Expt No.	Ar^1	Ar^2	Ar	[IDMg]/[Enone]	Product Type[b]	Product Yield/%
1	2,4,6-$Me_3C_6H_2$	C_6H_5	4-MeC_6H_4	1.2	**4**	42—64

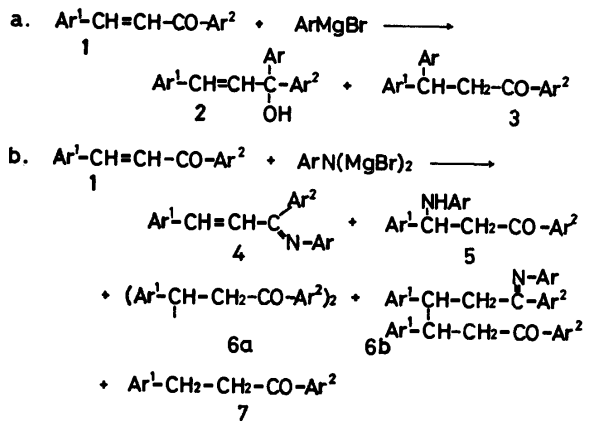
5	4-$MeOC_6H_4$	C_6H_5	4-MeC_6H_4	1.2	**6a** **6b**	37 12
6	4-$MeOC_6H_4$	C_6H_5	4-MeC_6H_4	3.0	**6a**	74
7	4-$MeOC_6H_4$	DMB[a]	4-MeC_6H_4	1.2	**7**	10
8	4-$MeOC_6H_4$	DMB[a]	4-MeC_6H_4	5.0	**7**	59

a) DMB=2,6-Me_2-4-*t*-BuC_6H_2. b) Types of products are given in Scheme 4b.

phenones, **1**, the normal 1,2-addition product, **2**, and the conjugate 1,4-addition product, **3**, are obtained when an excessive molar equivalent of the reagent is used (Scheme 4a): The product **3** is obtained usually in yields higher than 90% almost independently of the electronic effect of substituents of the enones.[9] When a deficient equivalent of the reagent was used, a product due to the radical dimerization at the the β-position of the enone was isolated.[10] The high spin densities on the carbonyl and the β-positions were observed[11,12] and the electron-transfer mechanism for the 1,4-addition and the dimerization was proposed.[2]



Scheme 4.

In contrast, the IDMg reaction with the same substrate gave an appreciably different product-distribution (Scheme 4b and Table 1): The types of products, **4**—**7**, and their yields were specified dramatically by the electronic and steric effect of the benzylidene and benzoyl moieties, Ar^1 and Ar^2, respectively.

The hindered Ar^1 and the unhindered Ar^2 lead to a moderate yield of the normal condensation product **4** (Expts 1 and 2): A low yield of **4** was obtained when both Ar^1 and Ar^2 had the electron-attracting *p*-Cl substituent (Expt 3). A low yield of the 1,4-addition product **5** was obtained only when Ar^1 had *p*-Cl substituent and Ar^2 had *p*-Me substituent (Expt 4). The reductive dimerization product **6a** and the condensation-dimerization product **6b**, both of which were indicative of the existence of the electron-transfer process, were obtained in fair yield when Ar^1 had *p*-MeO substituent (Expts 5 and 6): A high yield of **6a** was obtained when a larger excess of the reagent was used (Expt 6). The reduction product **7** was formed when the enone had hindered Ar^2 (Expts 7 and 8): The comparison of the results of Expts 5 and 6 with those of Expts 7 and 8 shows that the bulkiness of the substrate is in favor of hydrogen abstraction from the solvent molecule by the intermediate radicals but not of their dimerization. No product other than the unreacted enones and the products **4**—**7** were detected in Expts 1—8.

The notably different profiles of the reaction of Scheme 4b from those of Scheme 4a are explained in terms of the moderate reactivity[3,6]—electron-donating ability—of aryl–IDMg compared with that of ArMgBr and also in terms of the initial coordination of substrate to the Mg atom of the reagent. The first factor, the moderate reactivity of aryl–IDMg, is responsible for the unexpectedly enhanced selectivity observed in the reaction of Scheme 4b. The second factor, the effective initial coordination, is responsible for the high yields of the typical radical products in Expts 5—8 in comparison with the low yields of condensation or addition products in Expts 3 and 4: The *p*-MeO substituent of the substrate is advantageous for the coordination and facilitates the subsequent electron-transfer and the product-formation. The attempt to detect the intermediate radicals by ESR at room temperature was unsuccesful: No sufficient accumulation of them is due to the weakly electron-donating ability of the reagent. The role of the initial coordination will be discussed again in the final section.

IDMg Reaction with Quinones. The reaction of PhMgBr with quinones under the ordinary reaction conditions lead to the formation of hydroquinone and biphenyl,[13] their formation indicating the existence of the electron-transfer process. Some products due to radical substitution were also reported,[14] and the detection of the semiquinone radical by ESR was successful only by use of a fully diluted reaction mixture.[15]

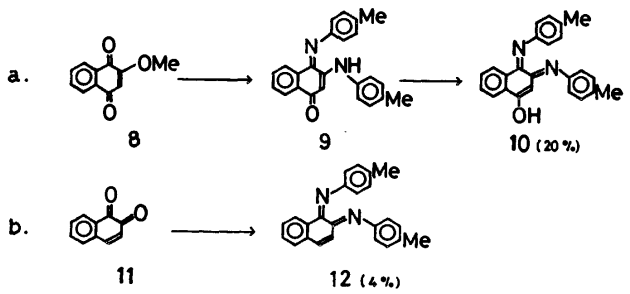
The reactions of aryl–IDMg with 2-methyl- and 2-methoxy-1,4-naphthoquinones were clearly different from that with 9,10-anthraquinone. In the reactions with the naphthoquinones, complex mixtures containing large amounts of quinhydrone-like products and hardly soluble black materials were obtained: The normal

condensation products, quinone imines, were isolated only in low yields (10—20%). In the reaction with anthraquinone, in contrast, good yields of the quinone imines were obtained and no formation of unidentifiable products was observed. The results of the individual reactions will be described first, and a summary discussion will be given in terms of the electron-accepting ability of the quinones.

In the reactions of 2-methyl-1,4-naphthoquinone with 4—6 molar equiv. of *p*-Me– and *p*-MeO–C_6H_4–IDMg, a lower than 10% yield of dark red products—quinone mono- and diimines—was isolated from the complex mixture. The quinone imines show the ^{1}H-NMR spectra having more than two Me- and MeO-proton signals probably due to the geometrical isomerism around the >C=N– groups: The separation of the isomers was unsuccessful.

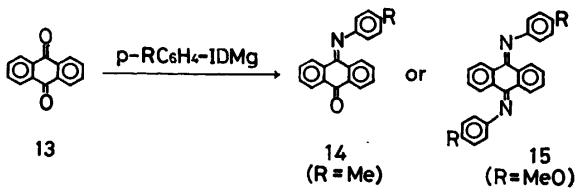
In the reaction of 2-methoxy-1,4-naphthoquinone, **8**, with *p*-Me–C_6H_4–IDMg (4 molar quiv., Scheme 5a), a dark red product which had more than two *p*-Me–C_6H_4 groups but no MeO group was isolated from the complex mixture. The ^{1}H-NMR spectrum has three or four signals at the range of δ=2.3—2.4: The splitt pattern, which indicates that the isolated product is a mixture, changes gradually, during the repeated treatment on silica gel, into another pattern consisting of two signals at δ=2.40 and 2.36. The final product, **10**, shows ν_{OH} absorption band at 3350 cm^{-1} (mp 136 °C). In the reaction with 1,2-naphthoquinone, **11** (Scheme 5b), the quinone diimine, **12** (mp 175 °C), isolated in 4% yield shows two Me-proton signals at δ=2.36 and 2.30: The splitt pattern resembles closely that of **10**. The structure of the primary product in the reaction of **8** is thus assigned to the condensation-replacement product, **9** (yield: 20%), which isomerizes into **10** during the quenching with aqueous NH_4Cl and the subsequent treatment with moist silica gel.

It should be noted here briefly that the formation of the oxidative coupling product, 4,4′-dimethylazobenzene, in the reaction of *p*-Me–C_6H_4–IDMg is associated with the structure of quinones. The azoarene was isolated in 8% yield in the reaction with **11**. The azoarene is the sole identifiable product (yield: 19%) in the reaction with 9,10-phenanthraquinone, which also gave large amounts of unidentifiable black materials and no condensation product. The formation of symmetrical azoarenes is unavoidable in the IDMg reaction with nitroarenes (Scheme 2).[3] The oxidative coupling of the IDMg molecules is thus ascribed to the structural resemblance of the *ortho*-quinones and nitroarenes, those having the similarly oriented two oxygen atoms.



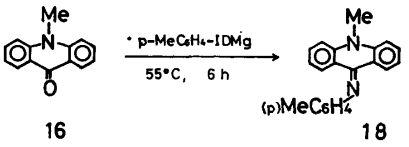
Scheme 5.

In contrast to the poor yields of the condensation products in the reactions of the naphthoquinones and phenanthraquinone, anthraquinone gave good yields of the quinone mono- and diimine depending clearly upon the electron-donating abilities of the reagents, *p*-Me– and *p*-MeO–C_6H_4–IDMg (Scheme 6 and Table 2). The less electron-donating former reagents gave the monoimine, **14** (R=Me), even by use of the reagent in a large excess, whereas the more electron-donating latter reagent gave the diimine, **15** (R=MeO).



Scheme 6.

The inertness of **14** (R=Me) towards *p*-Me–C_6H_4–IDMg is understood by considering the intramolecular charge separation as depicted by the structure, **14a**, which is more favorable for the initial coordination to the reagent's Mg atom but is less favorable for the subsequent electron-transfer. In order to check the electron-repelling resonance effect, *N*-methylacridone, **16**, was treated with the same reagent (Scheme 7): The yield of the corresponding imine, **18**, was 28% by use of 1.2 molar equiv. of the reagent (recovery of **16**: 56%) but the yield was improved to 94% by use of four molar equivalents. The reaction of xanthone, **17**, with aryl–

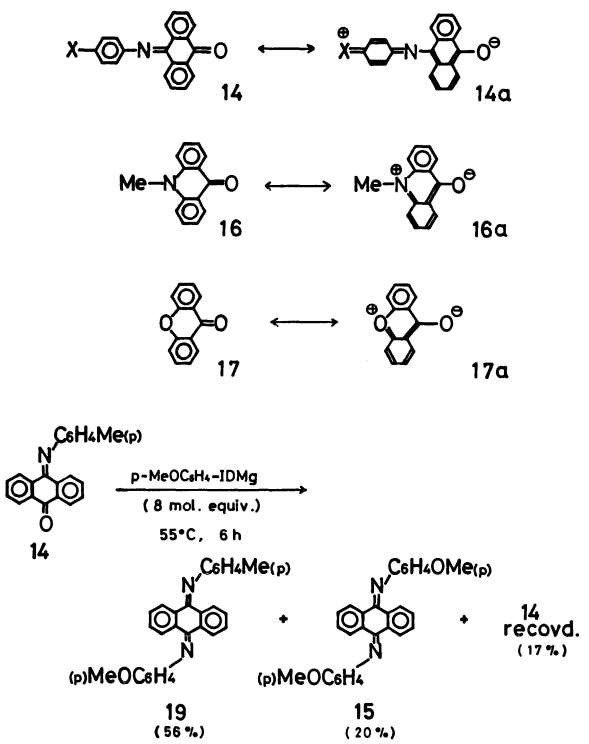


Scheme 7.

Table 2. Product-distribution in the IDMg reaction with anthraquinone (Scheme 6)

Expt No.	[IDMg][a] / [Substrate]	R	Amount of THF/ml	Reaction time at 55 °C / h	Yield/% 14	15	Azo	Recovered
9	4	Me	195	1	16	—	1.8	58
10	8	Me	100	6	68	—	1.3	Yes
11	16	Me	65	48	44	—	2.6	Yes
12	8	MeO	100	6	—	41	2.0	23

a) Sixteen millimols of IDMg reagents were used.

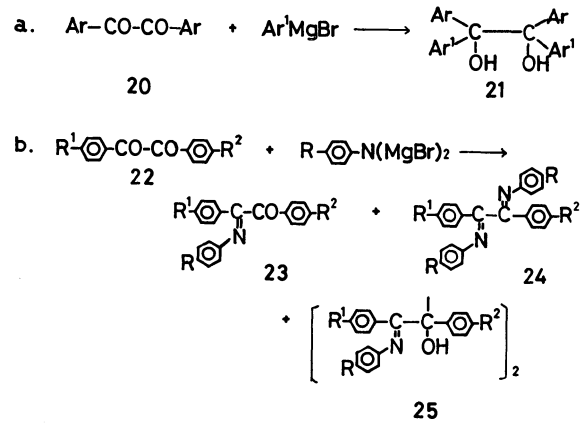


Scheme 8.

IDMg was reported.[5] On the basis of these results, **14** was treated with the more electron-donating *p*-MeO–C_6H_4–IDMg (8 molar equiv.): The expected mixed diimine, **19** and the exchange product, **15** (R=MeO), were obtained (Scheme 8).

The profiles of the IDMg reaction with the quinones described above can be understood by taking their reduction potentials (E_0/V)[16] into account: 1,2-Naphthoquinone (0.58)>1,4-naphthoquinone (0.48)> 9,10-phenanthraquinone (0.46)≫9,10-anthraquinone (0.15). The order of the values seems to be correlated to the following series of the yields of the condensation products: No formation of 9,10-phenanthraquinone imines, the poorest yield 1,2-naphthoquinone diimine (**12**), the 10% yield of 2-methyl-1,4-naphthoquinone imines, the 20% yield of the condensation-replacement product **9**, and the good yields of 9,10-anthraquinone imines (**14** and **15**). The fact that the IDMg reaction with the least electron-accepting (*i.e.*, oxidizing) quinone proceeds most smoothly is indicative of the important role of the combination of electron-donating and -accepting abilities of the reactants.

IDMg Reaction with Benzils. The reaction of benzil and its derivatives, **20**, with excessive amounts of ArMgBr was utilized for preparing substituted benzopinacols, **21**[17] (Scheme 9a): The by-products and the mechanism of the reaction have not been studied extensively, but the ESR evidence for the electron-transfer was reported very recently.[18]



Scheme 9.

The reaction of *p*-substituted benzils with excessive equivalents of aryl–IDMg gave monoimine, **23**, diimine, **24**, and the condensation-dimerization product, **25**, in high combined yields (Scheme 9b and Table 3): The appreciable formation of **25** is reasonable since the higher electron-accepting ability of α-dicarbonyl compound[12] causes a rapid electron-transfer even from the moderately electron-donating reagent.

The distribution of the three types of products was varied but not so dramatically by the reaction conditions (Expts 13—15) and also by the substituents of both substrate and reagent (Expts 14, 16, and 17). The much smaller variation of product-distribution than that of the reaction of Scheme 4b is attributed to the higher electron-accepting ability of benzils: The electronic effect upon the product-distribution is not enhanced but reduced. The intermediate radical derived from 4,4′-dimethylbenzil, **22** (R^1=R^2=Me), observed easily at room temperature, gave the ESR spectrum indicating the symmetrical distribution of the free spin on the two *p*-methylbenzoyl moieties (a^H_{Me}=

Table 3. Product-distribution in the IDMg reaction with benzils (Scheme 9b)

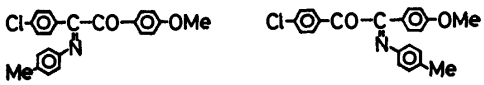
a) Yields obtained after heating at 55 °C for 6 h. b) The addition was carried out in the "reverse" manner. c) For examining the difference between the reactivities of the two carbonyl groups, a small amount of the reagent was added in the "reverse" manner. d) The constitution of the two isomeric 1 : 1-product is given in the text.

1.2 G, a^{H}_{O-H}=2.1 G, 1 G=10^{-4} T).

Though the radical concentration observed in the reaction of 4,4'-dimethoxybenzil, **22** (R^1=R^2=MeO), was remarkably lower than that observed in the reaction of 4,4'-dimethylbenzil, the very similar distribution of the three types of products were obtained (Table 3, Expts 14 and 16). Both the effective electron-transfer from the reagent in Expt 14 and the effective coordination of the substrate to the reagent in Expt 16 are responsible for the closely similar results.

The examination of the reaction with an unsymmetrical benzil, **22** (R^1=Cl, R^2=MeO), gave an explicit evidence for the initial coordination as a governing factor for the product-distribution. In the reaction using one and a half molar equivalents of *p*-Me-C_6H_4-IDMg, a high yield of a mixture of the isomeric monoimines, **23a** and **23b**, was obtained (Expt 18). The



23a **23b**

chromatographic separation of the isomers was incomplete, but the comparison of the ^{1}H-NMR chemical shifts of the Me- and MeO-protons with those of the monoimines obtained in Expts. 16 and 17 showed that the mixture contained **23a** and **23b** in an approximate molar ratio of 1 : 2. Also the relative yields of mono- and diimines in Expts 16 and 17 reflect the advantage of the substrate's *p*-MeO group over the *p*-Cl group for the product-formation.

General Discussion. The significance of the combination of electron-donating ability of reagents with electron-accepting ability of substrates in the reactions of organomagnesium reagents (ArMgBr and ArN-$(MgBr)_2$) was pointed out very recently.[8] Since the new method for preparing unsymmetrical azoxy- and azoarenes by the IDMg reaction with the highly electron-accepting nitroarenes[19,20] owes its success to the moderately electron-donating ability of the reagent,[3,6] it is reasonable to classify the profiles of the reactions of the organomagnesium reagents from the same standpoint. The classification into three types will be given in the following.

The type A represents the "hardly controllable reactions" leading to the formation of large amounts of radical products due to much vigorous electron-transfer. The first example is the reaction of highly electron-donating ArMgBr with highly electron-accepting $PhNO_2$ (A-1). The formation of the three types of products, ArNHPh, ArOH, and Ar–Ar, in comparable yields (50—60%) was reported:[21] The high yield of the biphenyl is the result of efficient oxidative coupling of the reagent molecules. The second example is the reaction of the moderately electron-donating aryl–IDMg with the strongly electron-accepting naphthoquinones (A-2) described above.

The type B represents the "electron-transfer controlled reactions" which involve the moderate electron-transfer followed by efficient formation of normal products due to addition and/or condensation. The reactions of this type are accelerated by the electron-attracting *p*-F and *p*-Cl substituents of substrates and also by the electron-repelling *p*-MeO substituent of reagents. The first example is the well-studied reaction of ArMgBr with the moderately electron-accepting diaryl ketones (B-1; *cf.* Scheme 1). The second example is the IDMg reaction with nitroarenes (B-2; Scheme 2). The reactions B-1 and B-2 involve the rapid coordination followed by the rate-determining electron-transfer[1] and the subsequent product-formation. The more moderate reaction of imino compounds with ArMgBr (B-3) was reported.[8,22]

The type C represents the "coordination controlled reactions," the product-distributions of which are governed by the initial coordination of the substrates to the Mg atom of the reagent: The electron-repelling *p*-MeO substituent of both reactants is favorable for the product-formation. The examples are the IDMg reactions with diaryl ketones (C-1), benzylideneacetophenones (C-2), and benzils (C-3). Though the existence of the electron-transfer process in C-1 and C-2 reactions is indicated by the formation of diarylmethanols[7] and that of **6** respectively, the attempt to detect the ketyl-type radicals by ESR at room temperature is unsuccessful: This fact suggests that the process in these reactions takes place after the initial coordination has been completed. The favorable role of the *p*-MeO-substituted reagent in the type C reactions can be ascribed to the acceleration of the subsequent electron-transfer process. The reaction C-3 involves the most rapid electron-transfer among the three examples: This reaction has the type B character with regard to the substituent effect upon the concentration of radicals (*vide supra*). It is quite reasonable that, as the electron-donating and -accepting abilities of the reactants are lowered, the rate-determining step is shifted to the just initial coordination process (*cf.* Scheme 1).

The electron-accepting ability of substrates should be estimated by comparing the relative values of the reduction potentials:[16,20] The comparison of the published values in detail between the different types of substrates is not always possible at present because the conditions for the measurements have not been generalized.[20] With regard to the electron-donating ability of reagents, the situation is same because any standard method for determining the oxidation poten-

tials of these reagents has not been established.[23] However, the classification of the reaction profiles given above enables us to make qualitative estimates of the reduction potentials of substrates, including nitroarenes and diaryl ketones,[20] and those of the oxidation potentials of the reagents.

Since the oxidation and reduction potentials are correlated to the energy levels of the frontier molecular orbitals of the electron-acceptors and -donors,[24-26] the classification given above can be illustrated in terms of the energy levels of the lowest unoccupied molecular orbitals (LUMO) of substrates and those of the highest occupied ones (HOMO) of reagents as shown in Fig. 1: Only the LUMO's of the typical substrates are designated for simplicity and their levels relative to those of the HOMO's of the reagents are given arbitrarily. The three types of the reaction profiles (A, B, and C) are also designated in the figure.

The discussion and the illustration given above are only qualitative at present, and detailed studies are needed especially for determining the precise mechanisms and the energy levels of the reactants. However, the classification of the reactions into "electron-transfer controlled" and "coordination controlled" ones will provide a clue for understanding the rather complicated profiles of the reactions of organomagnesium reagents.

Experimental

The melting points are uncorrected.

Materials and Procedures. The benzylideneacetophenones were prepared by condensation of the corresponding benzaldehydes and acetophenones in ethanol containing potassium hydroxide. The naphthoquinones, 9,10-anthraquinone, 9,10-phenanthraquinone, and *N*-methylacridone were commercially available. The symmetrical and unsymmetrical benzils were prepared by condensation of benzaldehydes followed by oxidation by copper(II) sulfate in pyridine.[27]

The procedures of the IDMg reaction were reported previously.[3,6,7] The ESR measurements were carried out according to the reported method.[2]

Products. The presence of the quinhydrone-like products in the black mixtures of products obtained in the IDMg reactions with the naphthoquinone and 9,10-phenanthraquinone was suggested from the fact that a part of the starting materials was recovered after the treatment of the mixture with aqueous sodium hydroxide: The black color characteristic to quinhydrones faded to some extent during the treatment.

The melting points, the results of elemental analyses, and the NMR data of the products of IDMg reactions are summarized in Table 4. The products are designated by the numbers given in the reaction schemes (gothic letters) as well as the experiment numbers given in the tables (super-prefixes). The chromatographic separations of the products, ^{17}**24**, ^{17}**25**, ^{18}**23a**, and ^{18}**23b** from the individual reaction mixtures were incomplete, and were not submitted to the elemental analyses: The contents of these products in the mixture (Table 3) were estimated by inspecting the NMR spectra of chromatographic fractions.

The support of this work by research grants from the Ministery of Education, Science and Culture (C-56540308) is gratefully acknowledged.

The Cycloaddition of *N,N*-Diethyl-1,3-butadienylamine with Some Diarylnitrilimines

Tatsuo OIDA,* Shigeo TANIMOTO,* Hideyuki IKEHIRA, and Masaya OKANO
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received October 12, 1982)

The cycloaddition of *N,N*-diethyl-1,3-butadienylamine with some diarylnitrilimines was investigated. 1,3-diaryl-4-vinylpyrazoles, (1,3-diaryl-2-pyrazolin-5-yl)acetaldehydes, 1,3-diaryl-4-(1,3-diaryl-2-pyrazolin-5-yl)-pyrazoles, and 1,3-diarylpyrazoles were obtained.

The presence of conjugated double bonds in conjunction with a amino group makes 1,3-butadienylamines potentially useful intermediates for organic synthesis. For example, recent publications from our laboratory have described the Diels-Alder reactions[1,2] of *N,N*-diethyl-1,3-butadienylamine (**3**) with *trans*-diaroylethylenes and with acetylenecarboxylic acid esters and have illustrated the utility of this diene for the synthesis of 1,3-diarylisobenzofurans and aromatic carboxylic acid esters. In addition to these publications, many reports on the reaction of **3** with various dienophilic reagents such as fulvenes,[3] benzofurazan oxide,[4] and triafulvene,[5] as well as alkyl esters of atropic acid[6] have appeared. Similar experiments using benzonitrile oxide as an enophile were performed in 1970 by Caramella and Bianchessi,[7] who demonstrated that the reaction is applicable to the preparation of 4,5′-diisoxazole ring system. As nitrilimines bear a structural resemblance to nitrile oxides, it would be interesting to utilize the nitrilimines in the cycloaddition with **3**. To our knowledge, there has not been any information published concerning the cycloaddition of **3** with nitrilimines, although the corresponding reaction of 1,3-butadiene (with *C,N*-diphenylnitrilimine) to afford 1,3-diphenyl-5-vinyl-2-pyrazoline has already been elucidated by Huisgen and his co-workers.[8] In this paper we wish to report that the cycloaddition of **3** with several diarylnitrilimines (**2**) proceeds smoothly in benzene to afford the following four kinds of compounds or at least the latter two of them; 1,3-diaryl-4-vinylpyrazoles (**6**), (1,3-diaryl-2-pyrazolin-5-yl)acetaldehydes (**8**), 1,3-diaryl-4-(1,3-diaryl-2-pyrazolin-5-yl)pyrazoles (**9**), and 1,3-diarylpyrazoles (**10**). Among these compounds, only **10** was an unexpected product. In order to explain the formation of **10**, we anticipated that intermediate *trans*-1,3-diaryl-4-(1,3-diaryl-2-pyrazolin-5-yl)-5-diethylamino-2-pyrazolines (**7**) were initially formed; these underwent a deprotonation at the 4′-position (see formula **7**) and the simultaneous bond fission between 4-C and 5′-C, accompanied by a release of the diethylamino group at the 5-position.

Results and Discussion

First, the cycloaddition between **3** and *N*-(*p*-nitrophenyl)-*C*-phenylnitrilimine (**2a**) prepared *in situ* by the dehydrochlorination of *N*-(*p*-nitrophenyl)benzohydrazonoyl chloride (**1a**) was carried out in benzene at room temperature. The products isolated from the reaction mixture were shown to be 1-(*p*-nitrophenyl)-3-phenyl-4-vinylpyrazole (**6a**), [1-(*p*-nitrophenyl)-3-phenyl-2-pyrazolin-5-yl]acetaldehyde (**8a**), 1-(*p*-nitrophenyl)-4-[1-(*p*-nitrophenyl)-3-phenyl-2-pyrazolin-5-yl]-3-phenylpyrazole (**9a**), and 1-(*p*-nitrophenyl)-3-phenylpyrazole (**10a**). When the reaction was conducted at 80 °C, the products isolated from the reaction mixture were the latter two and neither of the former two was found. Similarly, the cycloaddition of **3** with *C,N*-diphenylnitrilimine (**2b**) in benzene at either room temperature or 80 °C gave two products; 1,3-diphenyl-4-(1,3-diphenyl-2-pyrazolin-5-yl)pyrazole (**9b**) and 1,3-diphenylpyrazole (**10b**). In the same manner, the cycloaddition reactions have also been achieved employing diarylnitrilimines derived from *N*-(*p*-chlorophenyl)benzohydrazonoyl chloride (**1c**) and *N*-phenyl-*p*-nitrobenzohydrazonoyl chloride (**1d**).

It is easy to understand the mechanism concerning the formations of **6a** and **8a**. The former should be

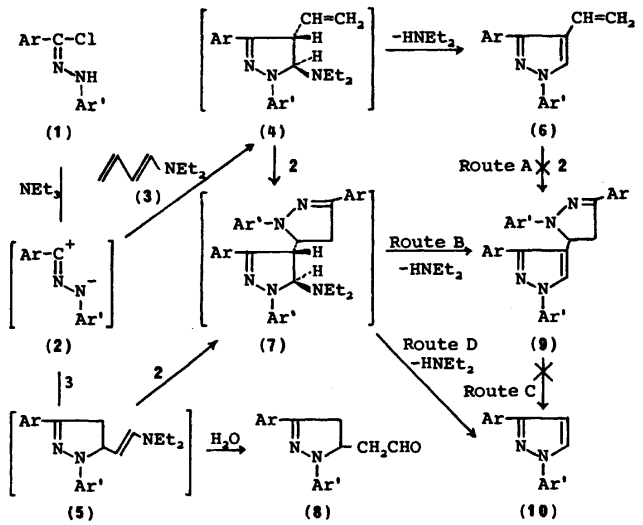
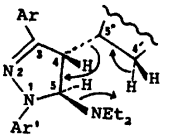
a) The ^{1}H-NMR spectra of **9a**, **9c**, and **9d** were measured in DMSO-d_6 and the other products in $CDCl_3$.



Scheme 1.

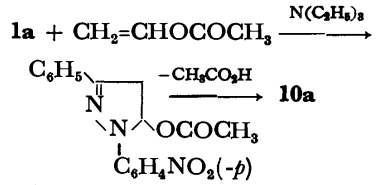
produced *via* a process which involves a regioselective addition of **2a** to the amino-substituted double bond of **3** and a subsequent releasing of the amino group from the intermediate *trans*-5-diethylamino-1-(*p*-nitrophenyl)-3-phenyl-4-vinyl-2-pyrazoline (**4a**). On the other hand, the formation of the latter is believed to be the result of a regioselective addition of **2a** to the terminal double bond of **3** to afford 5-(2-diethylaminovinyl)-1-(*p*-nitrophenyl)-3-phenyl-2-pyrazoline (**5a**), which is further converted to **8a** by hydrolysis. Regarding the formation of **9**, two routes are conceivable; these are represented as routes A and B in Scheme 1. If we assume that route A is operative for the formation of **9**, we are unable to find any substantial explanation of the fact that the cycloaddition of **3** with **2a** in toluene at −10 °C (Run 3 in Table 1) gave only **9a** and **10a**, and no **6a** wa detected. Presumably, **9** were produced by the deamination of the intermediate **7**.

All attempts to decompose **9** to **10** failed. For example, heating of **9** with triethylamine in benzene resulted in the recovery of the starting material together with a small amount of tarry matter, indicating that route C should be ruled out. Thus, we offer a feasible pathway (route D) as mentioned previously in this report. The



presumption that routes B and D are operative as mentioned above is in accord with the observation that the **9a** : **10a** mole ratio in the reaction products of **2a** with **3** was constant under the given reaction conditions and independent of the reaction time (see Experimental).

Because **10a** was an unexpected compound, we synthesized it by the reaction of **1a** with vinyl acetate in the presence of triethylamine, and confirmed that it is identical to that obtained by the cycloaddition of **2a** with **3** (see Experimental).



Experimental

The ^{1}H-NMR and mass spectra were recorded on Varian

EM-360 and JEOL-01SG spectrometers, respectively. The hydrazonoyl chlorides were prepared by the method of Huisgen and his co-workers.[1] Commercial organic materials were used and after distillation or recrystallization. Commercial inorganic materials were used without further purification.

*Reaction of a Hydrazonoyl Chloride (**1**) with* N,N-*Diethyl-1,3-butadienylamine (**3**) in the Presence of Triethylamine. General Procedure*: To a suspension of 0.30 g (2.4 mmol) of **3** and a hydrazonoyl chloride (the mole ratio of the hydrazonoyl chloride to **3** in each run is listed in Table 1) in 50 ml of benzene was added an excess of triethylamine. Exactly twice as much triethylamine as the hydrazonoyl chloride by molar quantity was used. The mixture was stirred under a nitrogen atmosphere in the manner described in Table 1, and poured into 50 ml of aqueous NH_4Cl. After the mixture was stirred thoroughly, the aqueous layer separated. The organic layer was dried ($MgSO_4$), and the volatile solvent was removed under reduced pressure leaving a residue, which was chromatographed (SiO_2, 20% chloroform–benzene).

*Determination of 1-(*p-*Nitrophenyl)-4-[1-(*p-*nitrophenyl)-3-phenyl-2-pyrazolin-5-yl]-3-phenylpyrazole (**9a**) : 1-(*p-*Nitrophenyl)-3-phenylpyrazole (**10a**) Mole Ratio in the Reaction Products of* N-*(p-Nitrophenyl)-*C-*phenylnitrilimine (**2a**) with* N,N-*Diethyl-1,3-butadienylamine (**3**)*. To a suspension of 0.26 g (2.1 mmol) of **3** and 1.5 g (5.4 mmol) of **1a** in 100 ml of benzene was added 1.0 g (10 mmol) of triethylamine. The mixture was heated at reflux temperature under a nitrogen atmosphere. After 2 h, an aliquot was taken of the homogeneous reaction mixture (0.25 ml). Similar aliquots were taken at 4, 8, and 20 h. From each of these aliquots, a mixture of **1a**, **9a**, and **10a** was isolated by preparative TLC (SiO_2, 40% chloroform-benzene as eluent) and **9a** : **10a** mole ratio was determined using a Waters Associates HPLC. The results are summarized in the following table:

Reaction time/h	Mole ratio(**9a**/**10a**)
2	0.33
4	0.34
8	0.33
20	0.35

*Synthesis of 1-(*p-*Nitrophenyl)-3-phenylpyrazole (**10a**) by the Reaction of* N-*(*p-*Nitrophenyl)benzohydrazonoyl Chloride (**1a**) with Vinyl Acetate in the Presence of Triethylamine.* To a mixture of 0.50 g (1.8 mmol) of **1a** and 4.7 g (55 mmol) of vinyl acetate was added 0.54 g (5.3 mmol) of triethylamine. The mixture was heated at reflux temperature for 8 h under a nitrogen atmosphere, after which the mixture was cooled and diluted with *ca.* 20 ml of benzene. The benzene solution was washed repeatedly with aqueous NH_4Cl, dried ($MgSO_4$), and the volatile solvent was removed under reduced pressure leaving a residue, which was slowly filtered through a SiO_2 column. The elution was carried out with 90% benzene–ether. The collected effluent was dried ($MgSO_4$) and evaporated, The resulting precipitate was collected and recrystallized from ethanol to afford 0.23 g of **10a**; mp 169—170 °C (yield, 48% based on **1a**).

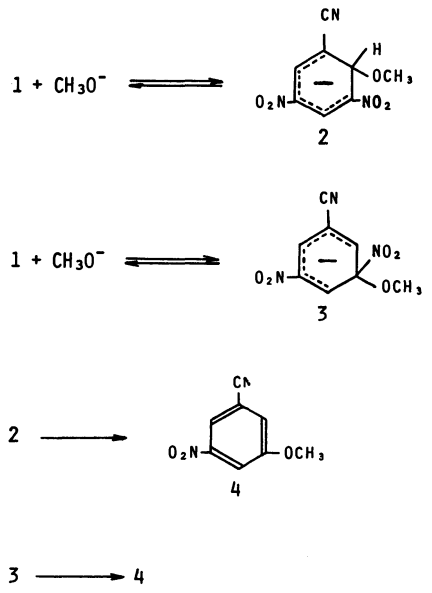
The Mechanism of the Reaction of 3,5-Dinitrobenzonitrile with Sodium Methoxide in Methanol

Takehiro Abe
College of General Education, Tohoku University, Kawauchi, Sendai 980
(Received October 14, 1982)

The reaction of 3,5-dinitrobenzonitrile in a methanolic solution containing a low sodium-methoxide concentration has been reinvestigated. The final product has been found to be methoxy(3,5-dinitrophenyl)methanimine, which is produced by a catalytic reaction. The reaction mechanism has been presented for the formation of the Meisenheimer complexes and the final product in the reaction system. The rate and thermodynamic stabilities for their formation have been discussed on the basis of the LUMO coefficients of 3,5-dinitrobenzonitrile and from the relative potential energies of their formation respectively, considering also the solvent effects.

Previously Fendler *et al.*[1] proposed Scheme 1 for the reaction of 3,5-dinitrobenzonitrile (**1**) with the methoxide ion in methanol. They considered that the product (**4**) was more likely formed through **3**. Moreover, they

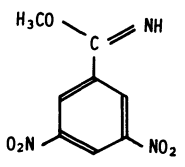


Scheme 1.

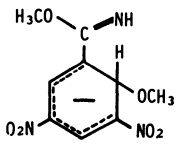
observed the presence of the 3,5-dinitrobenzonitrile anion radical in the reaction system. The present author has been interested in their observation of the radical in connection with our work[2] on anion-radical precursors in nucleophilic substitution. The author has, therefore, reinvestigated the reaction product and, surprisingly, obtained a product different from **4**. In this paper, this product will be reported. Moreover, the reaction mechanism for the formation of the Meisenheimer complexes and product in the reaction system will be qualitatively discussed by simple theoretical treatments, taking the solvent effects into account.

Results and Discussion

The Main Product Formed from 3,5-Dinitrobenzonitrile in a Methanolic Solution Containing a Low Sodium-methoxide Concentration. The addition of a solution of **1** (*ca.* 10^{-5} mol dm^{-3}) in methanol to a methanolic solution of sodium methoxide (10^{-4}—10^{-2} mol dm^{-3}) results in the immediate formation of a red color, which however, rapidly fades.[1] The colored species showing absorption bands at 490 and 390 nm is assigned by Fendler *et al.*[1] to 1-methoxy-2-cyano-4,6-dinitrocyclohexadienide (**2**). Here, the intensity of the 490-nm band is comparable with that of the 390-nm band. These bands could be observed by fast scanning (1200 nm/min) with a usual spectrophotometer at room temperature immediately after the preparation of a methanolic solution of **1** (2.91×10^{-4} mol dm^{-3}) and CH_3ONa (8.12×10^{-3} mol dm^{-3}). These bands completely disappeared within several minutes after the preparation. However, the methanolic solution of **1** (1.95×10^{-4} mol dm^{-3}) and CH_3ONa (0.341 mol dm^{-3}) showed weak but stable absorption bands at 480, 365, and 300 nm within 5 min after the preparation. The intensity of the 480-nm band was considerably weak compared with that of the 365-nm band. The observation of the stable bands suggests the resulting product, which is not **4** but **5** (see Experimental section), further reacts with the methoxide ion to give a Meisenheimer complex like **2**, for the 480- and 365-nm bands are characteristic of 2,4-dinitrocyclohexadienide.[3] Actually, as will be described below, the isolated product (**5**) shows these bands in the presence of CH_3ONa. The pure product (**5**) could be precipitated by allowing **1** to react with a catalytic quantity of CH_3ONa in methanol and by then adding water. The catalytic reaction is quite fast, because the pure product was obtained by adding water (25 cm^3) to a methanolic solution (several cm^3) of **1** (913.4 μmol) and CH_3ONa (51.2 μmol) *ca.* 7 min after the preparation of the solution. The isolated product was identified as **5** (see Experimental section). The methanolic solution of **5** at a relatively high CH_3ONa concentration gave



5



6

absorption bands at 480 and 378 nm, as is shown in Fig. 1. Their absorbances changed somewhat with the time. These bands are due probably to the formation of **6**, judging from their characteristic wavelengths and from the NMR spectrum of dimethyl sulfoxide (DMSO)-

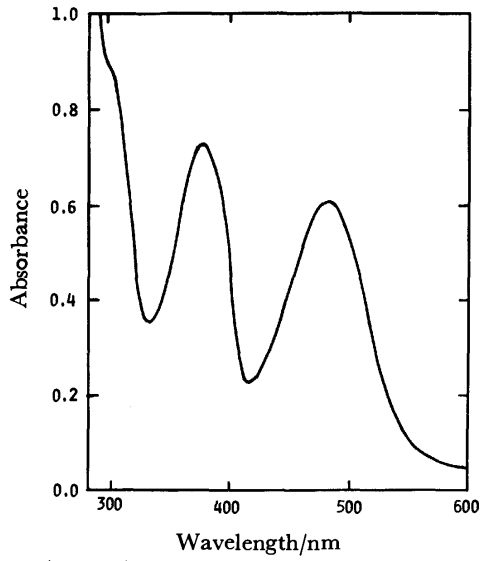


Fig. 1. Absorption spectrum of the methanolic solution of **5** (0.972 mmol dm^{-3}) and CH_3ONa (0.614 mol dm^{-3}).

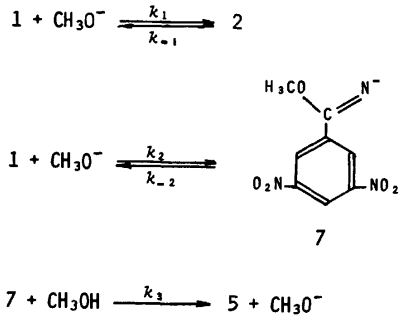
d_6 solution of **5** and CH_3ONa.

The product of **5** is different from that of **4** reported by Fendler *et al.*[1] They poured the NMR sample of the isolated potassium salt of **2** (in methanol or DMSO-d_6) or of *in situ*-generated **2** (in DMSO-d_6) into water, acidified the resulting solution with HCl, and thus obtained the precipitates of **4**. If the solution diluted with water was alkaline enough, the resulting dinitrobenzene derivatives might further react in the solution, because dinitrobenzenes are apt to react in alkaline solutions. In this case, therefore, the acidification with HCl should be done before the dilution with water. In the present experiment, however, the acidification of the reddish-orange methanolic solution of **1** and CH_3ONa before the dilution with water gave a white precipitate of methyl 3,5-dinitrobenzoate. When the methanolic solution of only **5** was treated with HCl, the same precipitate was obtained. It is, therefore, obvious that the product of methyl 3,5-dinitrobenzoate obtained by the acidification of the reddish orange solution was given by the further reaction of the resulting product of **5** with HCl in methanol containing a little water. On the other hand, a similar acidification of the red solution of **1** and CH_3ONa in the DMSO containing a little methanol reproduced **1**. Thus, because of the presence of the protic solvent of methanol, **5** is produced as a stable product from the solution of **1** in the methanol containing a low CH_3ONa concentration.



Scheme 2.

Mechanism of the Reactions of ***1*** *in the Methanol Containing a Low CH_3ONa Concentration.* In view of the experimental finding that the methoxide ion acts as a catalyst in the formation of **5**, Scheme 2 instead of Scheme 1 is poposed for the mechanism of the reactions of **1**. At a high CH_3ONa concentration, **5** further reacts with CH_3O^- to form **6**, as has been described above. The decomposition of the most typical Meisenheimer complex of sodium 1,1-dimethoxy-2,4,6-trinitrocyclohexadienide in methanol is considered to consist not of unimolecular, but of bimolecular reactions with proton and with methanol.[4] In the present alkaline reaction system, the reaction of **2** with H^+ may be neglected. The reverse reaction of **2** should, therefore, be written as $\mathbf{2}+CH_3OH \rightarrow \mathbf{1}+CH_3O^-+CH_3OH$. Therefore, k_{-1} contains the initial concentration of methanol, *i.e.*, $[CH_3OH]_0$, which is kept constant throughout the reaction. Similarly, the unimolecular decomposition of **7** may be written as $\mathbf{7}+CH_3OH \rightarrow \mathbf{1}+CH_3O^-+CH_3OH$, and k_{-2} may also contain $[CH_3OH]_0$.

Fendler *et al.*[1] have found that the formation of **2** in methanol attains equilibrium rapidly and that the observed pseudo-first order rate constant, k_{obsd}, for the subsequent decay of **2** is given by:

$$k_{obsd} = -\frac{d(\ln[\mathbf{2}])}{dt}. \quad (1)$$

Moreover, they have found that k_{obsd} is related to the initial methoxide concentration $[CH_3O^-]_0$ by means of the following equation:

$$k_{obsd} = \frac{\alpha[CH_3O^-]_0}{[CH_3O^-]_0+\beta}, \quad (2)$$

where α and β are constants. Their experimental conditions satisfy the requirements that the initial concentration of **1** (a_0) be much smaller than $[CH_3O^-]_0$ and that $[CH_3O^-]_0$ be much smaller than $[CH_3OH]_0$. Therefore, $[CH_3O^-]_0$ and $[CH_3OH]_0$ are regarded as being kept constant throughout the reaction. They obtained values of $1/\alpha$ and β/α by rearranging Eq. 2 into the expression of $[CH_3O^-]_0/k_{obsd}=\beta/\alpha+(1/\alpha)[CH_3O^-]_0$. Using their data[1] of k_{obsd} *vs.* $[CH_3O^-]_0$ at 25 °C, the present author recalculated and obtained $1/\alpha=(3.07\pm0.09)$ s and $\beta/\alpha=(1.60\pm0.02)$ mol dm^{-3} s, from which $\alpha=0.326\,s^{-1}$ and $\beta=0.521$ mol dm^{-3} were obtained.

Scheme 2 can account for Eq. 2 as follows. According to Fendler *et al.*,[1] let us assume a preliminary equilibrium for the formation of **2**, whose equilibrium constant, K_1, is written as:

$$K_1 = \frac{k_1}{k_{-2}} = \frac{[\mathbf{2}]}{[CH_3O^-]_0[\mathbf{1}]}. \quad (3)$$

At the initial time ($t=0$), therefore, a_0 is written as:

$$a_0 = [\mathbf{1}]_0 + [\mathbf{2}]_0. \quad (4)$$

Scheme 2 gives the following rate equations for the increases in the concentrations of **1** and **7**:

$$\frac{d[\mathbf{1}]}{dt} = -k_2[CH_3O^-]_0[\mathbf{1}] + k_{-2}[\mathbf{7}], \quad (5)$$

$$\frac{d[\mathbf{7}]}{dt} = k_2[CH_3O^-]_0[\mathbf{1}] - (k_{-2}+k_3[CH_3OH]_0)[\mathbf{7}], \quad (6)$$

where t denotes the time. Here let us assume the

following inequality:

$$F = \frac{k_2k_3[CH_3OH]_0[CH_3O^-]_0}{k_2[CH_3O^-]_0+k_{-2}+k_3[CH_3OH]_0} < 1\ s^{-1}. \quad (7)$$

The validity of Eq. 7 will be described below. By solving Eqs. 5 and 6 simultaneously, one finally obtains the following approximate expression for [**1**]:

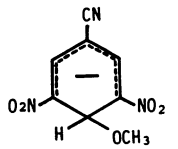
$$[1] = \frac{(k_{-2}+k_3[CH_3OH]_0)[1]_0}{k_2[CH_3O^-]_0+k_{-2}+k_3[CH_3OH]_0} \times \exp\left(-\frac{k_2k_3[CH_3OH]_0[CH_3O^-]_0}{k_2[CH_3O^-]_0+k_{-2}+k_3[CH_3OH]_0} \times t\right). \quad (8)$$

The combination of Eqs. 1, 3, and 8 leads to:

$$k_{obsd} = \frac{k_3[CH_3OH]_0[CH_3O^-]_0}{[CH_3O^-]_0+(k_{-2}+k_3[CH_3OH]_0)/k_2}. \quad (9)$$

Equation 9 is equivalent to Eq. 2. Thus, the experimental relation of Eq. 2 can be accounted for according to Scheme 2. By comparing Eq. 9 with F in Eq. 7, one obtains the relation of $F=k_{obsd}$. The k_{obsd} values measured by Fendler *et al.*[1] are less than 0.16 s^{-1}. Therefore, the assumption of Eq. 7 is reasonable. By comparing the values of α and β with $k_3[CH_3OH]_0$ and $(k_{-2}+k_3[CH_3OH]_0)/k_2$ respectively in Eq. 9, one obtains $k_3=0.326\ s^{-1}/[CH_3OH]_0$ and $k_2=(k_{-2}+0.326\ s^{-1})/0.521$ mol dm^{-3}. From these relations for k_3 and k_2, one obtains $k_3=1.33\times10^{-2}$ mol^{-1} dm^3 s^{-1} at 25.0 °C ($[CH_3OH]_0=24.55$ mol dm^{-3}) and may say that k_2 is larger than either k_{-2} or k_3. If the steady-state treatment is applied to the concentration of **7**, one obtains finally an expression for k_{obsd} in which the denominator of Eq. 9 is replaced by $(k_{-2}+k_3[CH_3OH]_0)/k_2$. In this case, therefore, Eq. 2 cannot be accounted for.

Explanation of the Rates and Thermodynamic Stabilities of the Formations of **2**, **7**, *and* **8** *by Theoretical Treatments Taking the Solvent Effect into Account.* In the case of a DMSO solution containing a little methanol, not only **2**[1,5,6] but **8**[6] is observed by NMR spectroscopy. Crampton and Khan[7] reported that **8** shows an absorption band at 550 nm in the DMSO.



8

Indeed, the longer absorption band characteristic of the Meisenheimer complex,[3] like **8**, was distinctly observed at 560 nm with the usual spectrophotometer when a small quantity of solid CH_3ONa was added to a solution of **1** in DMSO. The formation of **8** is kinetically faster, but thermodynamically less stable, than that of **2** in the DMSO.[6,7] On the other hand, **8** has never been observed in a methanolic solution containing no DMSO. However, the following findings related to the present case seem to suggest the transient formation of **8** in methanol. Terrier *et al.*[3b,6] found that the equilibrium constant for the formation of 1-hydroxy-4-cyano-2,6-dinitrocyclohexadienide from **1** and OH^- in a mixture of water and DMSO decreases with a decrease in the amount of DMSO, while the rate constant for the decomposition of the complex increases reversely. By a temperature-jump method, Bernasconi[8] found that the formation of 1,3-dimethoxy-2,4,6-trinitrocyclohexadienide, corresponding to **8**, proceeds even in methanol, and that the equilibrium constant for the formation of the complex is exceedingly small compared with that for 1,1-dimethoxy-2,4,6-trinitrocyclohexadienide, corresponding to **2**, while the rate constant for the decomposition of the 1,3-dimethoxy complex is exceedingly large compared with that of the 1,1-dimethoxy complex. In view of the above findings, one may consider the transient formation of **8** in methanol on the assumptions that the equilibrium constant for the formation is very small and that the rate constant for the decomposition of **8** is quite large. Moreover, by analogy with the case of the DMSO solution, one may consider that, in methanol, the formation of **8** is kinetically faster and thermodynamically less stable than that of **2**. Thus, one may conclude as follows: The formation of **2** is kinetically slower and thermodynamically more stable than that of **8** in both methanol and DMSO. The formation of **5** is the slowest in methanol and is not produced in the DMSO containing a little methanol.

An attempt will now be made to account for the above conclusions by drawing the potential-energy profiles against a reaction coordinate for the formations of **2**, **7**, and **8** in methanol or DMSO. The rates of these formations may be lower in the order of the increase in the activation energies, because the frequency factors of the rate constants for these formations proceeding in the identical solution of **1** and CH_3O^- may be regarded as approximately the same. According to the frontier orbital theory[9] and the symmetry rules[10] for chemical reactions, CH_3O^- may attack the atomic positions of **1** more easily in the order of their increasing absolute values of the coefficients of the lowest unoccupied molecular orbital (LUMO) for **1** on the assumption that the initial slopes of the potential-energy curves for the formations of **2**, **7**, and **8** are proportional to their activation energies. The theory and the rules have been widely accepted. Accordingly, the rates of the formations of **2**, **7**, and **8** may be lower in the order of the decrease in the coefficients of the LUMO because the activation energies increase in the same order. On the other hand, the thermodynamic stabilities of **2**, **7**, and **8** in the solution increase in the order of their decreasing potential energies and will be discussed by considering their relative potential energies.

Let us consider a neutral solute molecule with a π-electron system and a dipole moment of $\boldsymbol{p}$ (in its free state). By the use of the Onsager reaction field, the rth coefficient (c_{Lr}) of the LUMO for the π-electron system containing n core atoms is given approximately, according to a previous paper,[11] as follows:

$$c_{Lr} = c^\circ_{Lr} + \frac{\varepsilon_r-1}{2\varepsilon_r+1} \times \frac{2e\boldsymbol{p}}{a^3}\sigma_{Lr}, \quad (10)$$

where:

$$\sigma_{Lr} = \sum_{k\neq L}^{all} \frac{\left(\sum_{p=1}^{n} c^\circ_L c^\circ_{kp} \boldsymbol{r}_p\right)}{\varepsilon^\circ_L - \varepsilon^\circ_k} c^\circ_{kr}. \quad (11)$$

Here, e is the charge of the proton, ε_r is a relative permittivity of the solvent, a is a cavity radius, ε°_k is an

energy level of the kth MO for the free solute molecule, c°_{kp} is the pth coefficient of the kth MO, and r_p is a position vector of the pth atom. The letter L denotes the LUMO. Equation 10 is written by neglecting the hydrogen-bonding effect due to a change ($\delta\alpha_p$) in the Coulomb integral of the pth atom, because it is convenient to evaluate the effect of $\delta\alpha_p$ resulting from the hydrogen bonding between the pth atom and the solvent molecule by directly solving a secular equation taking $\delta\alpha_p$ into account using a computer. In the present case, the Onsager reaction field is used for convenience instead of the better Block and Walker reaction field for the neutral molecule,[11] since the reaction field used below for an anion is the Onsager one. As has been described in the previous paper,[11] a dispersion effect is not considered in the above treatment. Consequently, the application of Eq. 10 to a solute molecule with no permanent dipole moment or only a small one is unfavorable. In the present treatment, however, the dispersion effect on all the coefficient of the LUMO is neglected on the assumption that the small dispersion effect of the identical solvent causes no considerable changes in any of the coefficients for the identical solute molecule.

All the molecules of **2**, **7**, and **8** are anions. One considers an anion consisting of N charged particles as a whole. The energy of the ground state, Ψ°_g, of the anion in its free state is denoted by E°_g. The charge and position vector of the jth particle of the N particles are denoted by e_j and r_j respectively. As will be given in the Appendix, the reaction potential (ϕ_R) and field ($\boldsymbol{R}$) of the anion at the center of the cavity are written, respectively, as:

$$\phi_R = \frac{1-\varepsilon_r}{\varepsilon_r} \times \frac{1}{a}\left(\sum_{j=1}^{N} e_j\right), \tag{12}$$

$$\boldsymbol{R} = \frac{\varepsilon_r - 1}{2\varepsilon_r + 1} \times \frac{2\boldsymbol{p}_g}{a^3}, \tag{13}$$

where $\boldsymbol{p}_g$ is the dipole moment of the free anion in its ground state. Here, $\sum e_j$ is $-e$ for the present anion. Both Eqs. 12 and 13 give potential energies twice the corresponding Helmholtz free energies.[12,13] According to the previous paper,[11] the perturbation for the anion in the solution can be written from Eqs. 12 and 13 as:

$$H' = \sum_{j=1}^{N} e_j(\phi_R - \boldsymbol{R}\cdot\boldsymbol{r}_j). \tag{14}$$

From the first-order perturbation theory, therefore, the energy, E_g, of the anion in the solution can easily be obtained as follows:

$$\begin{aligned} E_g &= E^{\circ}_g + (\Psi^{\circ *}_g|H'|\Psi^{\circ}_g) \\ &\quad + \sum_{m\neq g} \frac{(\Psi^{\circ *}_g|H'|\Psi^{\circ}_m)(\Psi^{\circ *}_m|H'|\Psi^{\circ}_g)}{E^{\circ}_g - E^{\circ}_m}, \\ &= E^{\circ}_g - \frac{\varepsilon_r - 1}{\varepsilon_r} \times \frac{e^2}{a} - \boldsymbol{R}\cdot\boldsymbol{p}_g - \frac{R^2\alpha_g}{2}, \end{aligned} \tag{15}$$

where E°_m is an energy of the mth excited state of the free anion and α_g is the isotropic polarizability of the free anion in the ground state. Here, one assumes that the differences among the E°_g values of **2**, **7**, and **8** are mainly due to their π-electronic energies of $2\sum^{occu}\varepsilon^{\circ}_k$, because their σ-bonds are approximately the same except for the bonds of CN, such as C≡N and C=N$^-$. The σ-electronic energy of **7** containing the C=N$^-$ bond is higher by roughly the energy (E_{C-N}) of a C–N bond than those of **2** and **8**, both containing the C≡N bonds. The magnitude of E_{C-N} is considered to be 291.6 kJ mol^{-1} of the C–N bond[14] for the relative potential energy of **7**. In the case of **2** and **8**, the energy (E_{OCH_3}) of the π-electron system of OCH_3 must be considered, because the methoxyl group of **7** participates in the π-electron system. Accordingly, from Eq. 15, the relative potential energy (E_r) being considered for the anion may be approximately written as:

$$\begin{aligned} E_r &= \Delta E + 2\sum_{k=1}^{occu}\varepsilon^{\circ}_k - \frac{\varepsilon_r - 1}{\varepsilon_r} \times \frac{e^2}{a} \\ &\quad - \frac{\varepsilon_r - 1}{2\varepsilon_r + 1} \times \frac{2p_g^2}{a^3} - \left(\frac{\varepsilon_r - 1}{2\varepsilon_r + 1}\right)^2 \times \frac{2p_g^2\alpha_g}{a^6} - \Delta E_H, \end{aligned} \tag{16}$$

Table 1. Atomic coordinates and molecular orbital parameters for π-electron systems of **1**, **2**, **7**, and **8**

Position	Atomic coordinates[a] x/Å	y/Å	Integrals[b]
1	0	1.38	$h_7=h_{10}=2$

where $\Delta E=E_{C-N}+E_{OCH_3}$. Here, ΔE_H is the stabilization energy due to hydrogen bondings between the anion and protic solvent molecules.

The parameters used for the present Hückel MO calculations were taken, for the most part, from Ref. 15: They are shown in Table 1, together with the atomic coordinates based on the X-ray crystal analysis of *m*-dinitrobenzene.[16] The value of $h_{14'}$ is taken to be smaller than that (0.5) for Ṅ by 0.5, because the nitrogen atom of C=N⁻ may decrease its electronegativity compared with that of Ṅ because of the presence of the negative charge on the nitrogen. Here, α_0 and β_0 denote the Coulomb and resonance integrals respectively for the carbon atom bonded to a carbon atom, where $\beta_0=-3.00$ eV (1 eV$=9.648\times10^4$ J mol^{-1}) is assumed. The LUMO coefficients relating to the formations of **2**, **7**, and **8** are shown in the first row of Case 1 in Table 3. The row shows the relation of $c^0_{L4}>|c^0_{L2}|>c^0_{L13}$ in the case of the absence of the solvent. In order to apply Eq. 10 to **1** in methanol, the dipole moment (p) of **1** is necessary, but it can not be found. Therefore, p was estimated to be 0.07 D (1 D$=3.333\times10^{-30}$ C m) in the negative direction of the y axis from the vector sum of the dipole moments of benzonitrile (4.14 D[14]) and nitro groups (4.21 D[14]). The relative permittivities used for methanol and DMSO are 32.70 and 46.68[17] respectively at 25 °C. The relative permittivity of the solution was taken to be approximately equal to that of the solvent. The value of a was tentatively assumed to be the same value of 4.4 Å (1 Å=0.1 nm) as was assumed for a radius of the Meisenheimer complex of 1,3,5-trinitrobenzene with cyanide.[18] The results of calculations according to Eq. 10 are listed in the second row of Case 1 in Table 3. The row shows that the same relation of $c_{L4}>|c_{L2}|>c_{L13}$ holds for the case of the methanolic solution. This relation also holds for the case of DMSO, because the difference in the value of $(\varepsilon_r-1)/(2\varepsilon_r+1)$ between methanol and DMSO is very small. In a methanolic solution, however, the hydrogen bondings can be expected to be formed between **1** and methanol, because the formations of hydrogen bondings are found for the interactions of methanol with nitromethane and with acetonitrile.[19] The hydrogen bonding between methanol and acetonitrile is somewhat stronger than that between methanol and nitromethane.[19] According to the β-scale of the solvent hydrogen-bond acceptor basicities,[20] the hydrogen-acceptor ability of benzonitrile is somewhat stronger than that of nitrobenzene. In view of the above findings, Cases 2—7 in Table 2 have been selected in order to examine the effect of the hydrogen bondings. The most probable case may be either 5 or 7, because the concentration of methanol present as the solvent is extremely high. From the solvent effects on a hyperfine splitting constant in the ESR spectrum of the di-*t*-butyl nitroxide radical,[11] the value of $\delta\alpha_r$ due to the hydrogen bonding was estimated as follows: From the difference in the hyperfine splitting constants between the observed and calculated values for the solvent of methanol, the magnitude of 0.0556 mT was estimated to be due to the hydrogen bonding between methanol and the radical. The combination of the magnitude and the last term of Eq. 20 of Ref. 11 leads to $\delta\alpha_0=0.1\ \beta_0$, where the Hückel MO's used for the π-electron system of N=O were obtained by taking $\alpha_N=\alpha_0+0.5\,\beta_0$, $\alpha_O=\alpha_0+\beta_0$, and $\beta_{NO}=\beta_0$. For convenience, therefore, $\delta\alpha_r=0.1\ \beta_0$ was assumed for all the oxygen and nitrogen atoms of the nitro and cyano groups respectively in **1**, as is indicated in Table 2. The results of the calculations for Cases 2—7 in Table 2 are listed in Table 3. All the cases in Table 3 give the relation of $|c_{L4}|>|c_{L2}|>|c_{L13}|$. Thus, this relation may hold for the methanolic solution of **1**, even if **1** forms hydrogen bonds with the methanol molecules. As has been described above, the relation means that the activation energies of the formations of **2**, **7**, and **8** in

methanol may be higher in the order of **2**, **8**, and **7**.

When Eq. 16 is applied to the anions of **2**, **7**, and **8**, the third term in Eq. 16 is the same for all the anions, because their charges are the same. Here, one assumes that the values of a_g and ΔE_H are approximately the same for all the anions, because their constituent atoms are the same and because, in view of their structures, their abilities to form the hydrogen bonds seem not to differ considerably. Moreover, the fifth term of Eq. 16 is smaller than the fourth one. Accordingly, the difference in the E_r values among the anions are mainly due to the first, second, and fourth terms of Eq. 16. Here, therefore, only these terms are considered as the relative potential energies (E_r). Here, $E_{C-N}=-1.007\ \beta_0$ and $E_{OCH_3}=2\alpha_0+4\beta_0$ are dropped out for **2** and **8** and for **7** respectively. The sums of the first and second terms are shown in the second column of Table 4. The total dipole moments of each anion in the directions of the x and y axes were estimated from the vector sums of two moments; the vector sum of the moments of the constituent bonds and groups and the moment of the negative charge of the anion. The vector sums obtained by using the moments[14] of the bonds and groups are shown in Table 4. The dipole moment of the anion varies with the way of setting the origin of the coordinates; the center of the mass of the anion is usually set as its origin.[18] Therefore, the moments of the negative charges of **2**, **7**, and **8** were calculated by shifting the origins at their centers of masses, shown in Table 4. The negative charge of **7** is located in the nitrogen atom of $C{=}N^-$ and is immediately calculated from the nitrogen coordinates. The negative charges of **2** and **8** are distributed in their π-electron systems, and their moments are equal to the π-moments. The π-moments are given by multiplying the coordinates of the centers of the negative-charge distributions by $-e$. The coordinates of each center of the distribution were calculated by using the Hückel MO's which had been obtained with the use of the parameters and coordinates in Table 1. The moments of the negative charges and the total moments are shown in Table 4. Then, each moment of p_g was obtained from the vector sum of the total x- and y-moments, as is shown in Table 4. Here, 4.4 Å was assumed for all the a values. With the use of the p_g values, the fourth terms of Eq. 16 were calculated to be as shown in Table 4. Accordingly, the relative potential energies, calculated considering only the first, second, and fourth terms of Eq. 1, are shown in the last column of Table 4. The column shows that the relative potential energies of **2**, **7**, and **8** in methanol may be higher in the order of **2**, **8**, and **7**, since $\beta_0<0$.

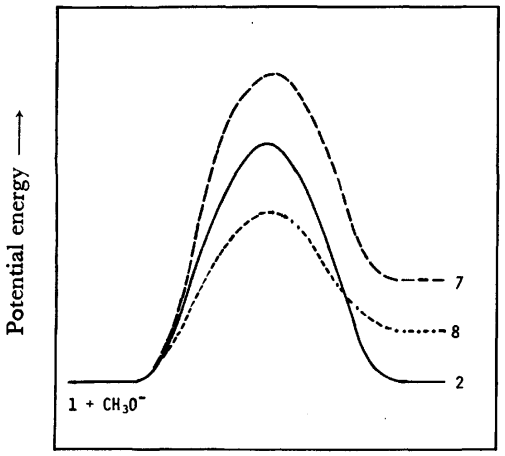

Fig. 2. Profile of potential energy curves for the formations of **2**, **7**, and **8** in methanol.

Thus, from the above discussions of the activation energies and the relative potential energies for the formations of **2**, **7**, and **8**, one may qualitatively draw the potential energy curves *vs.* an arbitrary reaction coordinate as is shown in Fig. 2. The fact that, in methanol, **5** is finally produced from **7** in spite of the activation and potential energies for **7** being highest can be explained by the irreversible reaction of **7** with methanol. Because of these energies for **7** being highest, the concentration of **7** may be small in a methanolic solution, and **5** may be irreversibly produced the most slowly. The relative permittivities of methanol and DMSO are both large. Their contributions to the activation and potential energies for the formations of **2**, **7**, and **8** do not differ considerably in the present treatments, since the contributions of the hydrogen bondings between the methanol molecules and the anions are assumed to be the same and are excluded. The potential energy curves of Fig. 2 can, therefore, probably be applied qualitatively to the case of the DMSO solvent. Thus, Fig. 2 can account for the conclusions that the formation of **2** is kinetically slower and thermodynamically more stable than that of **8**, both in methanol and in DMSO, and that the formation of **5** is the slowest in methanol and is not produced in DMSO. Bernasconi[21] found the enthalpy change of (4.2±6.7) kJ mol^{-1} for the formation of 1-methoxy-2,4,6-trinitrocyclohexadienide from 1,3,5-trinitrobenzene and the methoxide ion in methanol at 25 °C. Since the dipole moment of **1** has been estimated

to be very small, as has been described above, the relationship of the relative potential energies between **2** and the system of **1** and CH_3O^- probably resembles that for the case of 1,3,5-trinitrobenzene. Accordingly, the relative potential energy of **2** is probably near that of **1**+CH_3O^-. In the DMSO solution, a mixture of **2** and **8** (5%) is present at equilibrium.[6] This means that the relative potential energy of **8** is not so high as that of **2**.

Experimental

The melting points were measured by a Yanaco micro-melting apparatus and were uncorrected. The IR spectra were measured as KBr disks by means of a Hitachi grating infrared spectrophotometer 215. The ^{1}H-NMR spectra were measured, with tetramethylsilane as the internal standard, on a Hitachi high-resolution NMR spectrometer, R-22 (90 MHz). The UV spectra were recorded with a Hitachi autorecording spectrophotometer 340 at room temperature.

Material. 3,5-Dinitrobenzonitrile (Aldrich) was checked for purity by means of thin-layer chromatography and was used without further purification.

Reaction of 3,5-Dinitrobenzonitrile With Sodium Methoxide in Methanol. A): When 1.00 cm^3 of a CH_3ONa (1.02 mmol) solution in methanol was added to the solution prepared by dissolving 173.8 mg of **1** (0.900 mmol) in 15 cm^3 of methanol, a reddish-orange solution was immediately produced. This colored solution was acidified with an aqueous HCl solution *ca.* 2 min after the addition of CH_3ONa; a pale-orange solution was thus obtained. When the volume of the pale-orange solution was doubled with water, white crystals were precipitated; they were subsequently separated. The white crystals (mp 106.0—108.1 °C) were found to be pure by means of thin-layer chromatography. The IR spectrum of the white crystals exhibited absorption bands similar to those of the methyl ester (mp 106.0—108.0 °C) obtained by the esterification of 3,5-dinitrobenzoic acid (Kanto, G. R.). The white crystals, therefore, were identified as methyl 3,5-dinitrobenzoate; NMR(DMSO-d_6): δ=3.96 (3H, s), 8.90 (2H, d, J= 2 Hz), and 9.03 ppm (1H, t, J=2 Hz); IR: 1730 and 1305 cm^{-1}.

B): When 50 mm^3 of a CH_3ONa (51.2 μmol) solution in methanol was added to the solution prepared by dissolving 1.0008 g of **1** (5.1823 mmol) in 50 cm^3 of methanol, a reddish-orange solution was immediately formed. When the colored solution was left to stand in the dark at room temperature for two days, a pale yellowish-orange solution was obtained. When the volume of the pale-colored solution was doubled with water, crystals were precipitated. The crystals were filtered off, washed three times with water, and dried. The pale yellow crystals (0.6867 g) thus isolated were found to be pure by means of thin-layer chromatography. The crystals were identified as **5**; mp 109.1 °C; UV(CH_3OH): *ca.* 230 (sh, ε 2.03×10^4), *ca.* 298 (sh, 8.3×10^2), *ca.* 310 (sh, 6.7×10^2) and *ca.* 340 nm (sh, 2.0×10^2); NMR(DMSO-d_6): δ=3.28 (1H, somewhat broad), 3.89 (3H, s), and 8.90—8.95 ppm (3H, dd); IR: 3330 and 1650 cm^{-1}. Found: C, 42.84; H, 2.95; N, 18.73%. Calcd for $C_8H_7N_3O_5$: C, 42.68; H, 3.13; N, 18.66%.

An aqueous HCl solution was added to a solution of **5** in methanol. To the resulting solution water was then added in a large quantity. Then, white crystals were precipitated and subsequently separated. The IR spectrum of the white crystals exhibited absorption bands similar to those of methyl 3,5-dinitrobenzoate.

The NMR sample prepared by adding solid CH_3ONa to a solution of **5** in DMSO-d_6 showed a spectrum characteristic of a Meisenheimer complex, *i.e.*, δ=8.43 (1H, d, J=2 Hz), 7.68 (1H, d, J=2 Hz), and 5.55 ppm (1H, s), although the sample showed a changeable spectrum for several minutes after the addition of CH_3ONa.

C): A solution of CH_3ONa (3.071 mmol) in methanol was added to a solution prepared by dissolving 0.26936 g of **1** (1.3948 mmol) in as little methanol as possible. A red solution was thus immediately formed; it was left to stand overnight in a refrigerator. After the evaporation of some of the solvent by means of a suction at room temperature, crystals precipitated; they were susequently isolated. The IR spectrum of the pale greyish crystals exhibited mainly absorption bands similar to those of **5**, besides a few weak bands due to other substances.

Reproduction of 1 from a Red Solution of 1 and CH_3ONa in the DMSO Containing a Little Methanol. When 1.00 cm^3 of a solution of CH_3ONa (1.024 mmol) in methanol was added to a solution prepared by dissolving 116 mg of **1** (0.601 mmol) in 3.00 cm^3 of DMSO, a red solution was immediately produced. After being shaken, the red solution was left to stand in the dark at room temperature for *ca.* 15 min. Then, two drops of an aqueous dilute solution of HCl were added to the red solution; a yellow solution resulted. When a 25-cm^3 portion of water was added to the yellow solution, white crystals were precipitated. When these crystals were filtered off, washed three times with water, and dried, pale orange crystals (72 mg) were obtained. The IR spectrum of the crystals exhibited absorption bands similar to those of **1**. A similar experiment using DMSO containing 18-crown-6 (Nisso, 1.39 mmol) also gave a reproduction of **1**.

The author wishes to thank Dr. Kuninobu Kabuto of Tohoku University for the NMR measurements.

Appendix

Let us consider a solute molecule contained within a spherical cavity with a radius of a in an isotropic, continuous medium of a solvent with a relative permittivity of ε_r. The permittivity in the cavity is assumed to be unity. Let the origin be the center of the cavity, and let us use the polar coordinates of $\{r, \theta, \phi\}$ to express a position. Let the standard coordinate of θ be the direction of the dipole moment, $\boldsymbol{p}_g$, of the solute. One considers a collection ($\sum_{j=1}^{N} e_j$) of N point charges for the solute molecule, and $\boldsymbol{p}_g$ is written as $\sum_{j=1}^{N} e_j \boldsymbol{r}_j$.

According to Kirkwood's treatment,[12,13] the reaction potential (Φ_R) inside the cavity and the potential (Φ_O) outside the cavity can be written, respectively, as:

$$\Phi_R = \sum_{n=0}^{\infty} \frac{(n+1)(1-\varepsilon_r)}{(n+1)\varepsilon_r+n} \times \frac{1}{a^{2n+1}} \times \sum_{j=1}^{N} e_j r_j^n r^n P_n(\cos\theta_{jr}), \quad \text{(i)}$$

and:

$$\Phi_O = \sum_{n=0}^{\infty} \frac{(2n+1)}{(n+1)\varepsilon_r+n} \times \frac{1}{r^{n+1}} \times \sum_{j=1}^{N} e_j r_j^n P_n(\cos\theta_{jr}), \quad \text{(ii)}$$

where $P_n(\cos\theta_{jr})$ is a simple Legendre polynomial and θ_{jr} is the difference in θ between the positions of $\{r, \theta, \phi\}$ and $\{r_j, \theta_j, \phi_j\}$. Neglecting terms higher than n=1, one reduces Φ_R and Φ_O to:

$$\Phi_R(n=1) = \frac{(1-\varepsilon_r)}{\varepsilon_r} \times \frac{1}{a}\left(\sum_{j=1}^{N} e_j\right) + \frac{2(1-\varepsilon_r)}{2\varepsilon_r+1} \times \frac{1}{a^3}\sum_{j=1}^{N} e_j r_j \cos\theta_{jr}, \quad \text{(iii)}$$

and:

$$\Phi_0(n=1) = \frac{1}{\varepsilon_r} \times \frac{1}{r}\left(\sum_{j=1}^{N} e_j\right) + \frac{3}{2\varepsilon_r+1} \times \frac{1}{r^2}\sum_{j=1}^{N} e_j r_j \cos\theta_{jr}, \quad \text{(iv)}$$

respectively. From Eq. iii, one immediately obtains the reaction potential, $\Phi_R(0)$, at the origin as:

$$\Phi_R(0) = \frac{(1-\varepsilon_r)}{\varepsilon_r} \times \frac{1}{a}\left(\sum_{j=1}^{N} e_j\right). \quad \text{(v)}$$

The electric field, E_r, outside the cavity is obtained by $\boldsymbol{E}_r = -\partial\Phi_0\ (n=1)/\partial r$ in the direction of r. The polarization charge, P_a, induced per unit of area over the cavity is given by putting $r=a$ into the equation of $P_r = \{(\varepsilon_r-1)/4\pi\} \cdot |\boldsymbol{E}_r|$. The charge induced on the infinitesimal area of the cavity surface contained in the solid angle between θ_{jr} and $(\theta_{jr} + \mathrm{d}\theta_{jr})$ is given by $2\pi a^2 P_a \sin\theta_{jr}\,\mathrm{d}\theta_{jr}$, which produces an electric field of $2\pi P_a \sin\theta_{jr}\cos\theta_{jr}\,\mathrm{d}\theta_{jr}$ at the origin in the direction of $\boldsymbol{p}_g$. Then, the reaction field, $\boldsymbol{R}$, parallel to $\boldsymbol{p}_g$ at the point of origin is obtained as follows:

$$\begin{aligned}\boldsymbol{R} &= 2\pi\int_0^{\pi} P_a \sin\theta_{jr}\cos\theta_{jr}\,\mathrm{d}\theta_{jr} \\ &= \frac{(\varepsilon_r-1)}{2\varepsilon_r a^2} \times \left(\sum_{j=1}^{N} e_j\right)\int_0^{\pi} \sin\theta_{jr}\cos\theta_{jr}\,\mathrm{d}\theta_{jr}, \\ &+ \frac{3(\varepsilon_r-1)\boldsymbol{p}_g}{(2\varepsilon_r+1)a^3}\int_0^{\pi} \sin\theta_{jr}\cos^2\theta_{jr}\,\mathrm{d}\theta_{jr}, \\ &= \frac{\varepsilon_r-1}{2\varepsilon_r+1} \times \frac{2\boldsymbol{p}_g}{a^3}. \end{aligned} \quad \text{(vi)}$$

3-Chloro-2-chloromethyl-4-(4-chlorophenoxy)-1-butene as a Functionalized Isoprene Unit. An Electrochemical Preparation and Some Reactions

Kenji UNEYAMA, Nobu HASEGAWA, Hiroyuki KAWAFUCHI, and Sigeru TORII*
Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama 700
(Received October 20, 1982)

3-Chloro-2-chloromethyl-4-(4-chlorophenoxy)-1-butene (**1**) was prepared in 72% yield by electrooxidative double ene-type chlorination of 1-(4-chlorophenoxy)-3-methyl-2-butene. The electrolysis was conducted at room temperature in a two layer solvent system of dichloromethane and water in the presence of acids (HCl, H_2SO_4, H_3PO_4, *etc*). Either 3-chloro-2-methyl-4-(4-chlorophenoxy)-1-butene or **1** was selectively prepared, respectively after 4 or 10 F/mol of electricity were passed using platinum foils as electrodes in an undivided cell. The similar electrolysis of the related 3-methyl-2-butenyl derivatives **2b** and **2c** provided the ene-type products, 3-chloro-2-methyl-4-benzyloxy-1-butene and 4-chloro-1-ethynyl-1,5-dimethyl-5-hexenyl acetate, respectively. In contrast, 3-methyl-2-butenyl derivatives **2d**—**f** and 3-methyl-2-butenoic acid afforded a variety of products such as chlorohydrin, vinyl chloride, and sulfoxide other than ene-type products, suggesting that the functional group of R in **2** affects the reaction course. The elongation at 2-chloromethyl group and the subsequent dechlorophenoxylation convert **1** into 2-(phenylsulfonylmethyl)-1,3-butadiene and 2-(phenylthiomethyl)-1,3-butadiene.

Functionalization and subsequent elongation of isoprene derivatives are one of the effective approaches to the terpene synthesis.[1] Although there have been known various isoprene derivatives as a synthetic building block, 3-chloro-2-chloromethyl-4-(4-chlorophenoxy)-1-butene (**1**) has not been prepared. The compound **1** has two allylic chlorine atoms and can be elongated at the chloromethyl group and subsequently can be converted into a conjugated diene by reductive elimination of the another allylic chlorine atom. This paper describes an electrochemical preparation and some modifications of **1** along with the electrochemical chlorinative functionalization of the related isoprene derivatives **2a**—**g**.

Scheme 1.

Results and Discussion

So far as the allylic chlorination of olefins is concerned, the selenium reagent-mediated NCS chlorination,[2] the action of hypochlorous acid[3] or calcium hypochlorite in dichloromethane[4] and the chlorination with *t*-butyl hypochlorite in the presence of silica gel[5] have been reported. Recently, we communicated an electrochemical chlorinative ene-type reaction of isoprenoids **2h** which offers a simple and highly regio- and chemoselective access to allylic chloride **3h**.[6] The electrolysis is conducted in a two layer solvent system where a chloronium ion or the corresponding active chlorinating reagent is electrooxidatively generated in an aqueous sodium chloride layer and the chlorination occurs subsequently in a dichloromethane layer.[6,7] The electrochemical chlorination, however, did not afford the doubly chlorinated products related to **1** presumably due to the deactivation of the double bond of **3h** by electronegative chlorine atom. On this basis, the acid-promoted activation of the electrochemically generated chlorinating reagent was devised to enable the double ene-type chlorination, and also the electrolysis of isoprene derivatives **2a**—**g** was examined in detail where substituents affect the reaction pathway markedly.

The electrolysis was conducted in a two layer solvent system of CH_2Cl_2–H_2O (2 : 1) using an undivided cell. Platinum electrodes were settled in an aqueous sodium chloride layer and a gentle stirring was preferable to avoid a complete mixing which induced chlorohydrination partially.[8] Upon no stirring the reaction solution, a current efficiency was extremely low. The complete mixing enhances the solubilization of the chlorinating reagent produced in a water layer into the dichloromethane layer to improve the current efficiency, meanwhile it induces chlorohydrination by the increased contact of the water layer with the organic layer. Thus, electrolysis of **2a** in the presence of a large excess amount of sodium chloride and hydrochloric acid in CH_2Cl_2–H_2O at room temperature afforded **3a** in 84% yield after 4 F/mol and **1** in 72% yield after 10 F/mol. Most of mineral acids (HCl, HNO_3, H_2SO_4, H_3PO_4) are effective for the double ene-type chlorination and likewise organic acids affect the reaction highly. However, formic acid is not effective since the current efficiency is unexpectedly low (Table 1). Although formic acid is known to activate *t*-butylhypochlorite for the chemical ene-type chlorination,[9] it is a reducing agent so that it would reduce the electrogenerated

chlorinating reagent. In fact, **1** was obtained in 63% yield by the reaction of **2a** with sodium hypochlorite in CH_2Cl_2–H_2O in the presence of hydrochloric acid. In contrast to this, none of **1** was detected in the presence of formic acid while only 7% of **3a** was isolated and 92% of **2a** was recovered.

The relation of the acid concentration and the yields is shown in Fig. 1. Excess use of hydrochloric acid accelerated dichlorination whereas in the absence of the acid, 57% of the starting substance **2a** was recovered, and 34% of **3a** was obtained but none of **1** was isolated even after 10 F/mol of electricity was passed. In fact, 40 F/mol of electricity was required in order to complete monochlorination of **2a** (89%) in the absence of acid.[10]

The yields of **1** and **3a** are dependent to electricity passed (F/mol) (Fig. 2). In the presence of excess amount of acid, the starting substance **2a** disappeared almost completely at around 4 F/mol where the yield of **3a** reached to an optimum, while the yield of **1** increased steadily in proportion to electricity. This result suggests that **2a** is more reactive toward the chlorinating reagent than **3a**.

The effect of the solvent is also noteworthy. The use of immiscible solvents in water such as dichloromethane, chloroform, 1,2-dichloroethane, and benzene all of which constitute a two-phase system leads to a selective formation of **1** and **3a**. In contrast, the use of miscible solvents such as methanol and acetonitrile induced predominantly chlorohydrination, chloromethoxylation, and chloroacetamidation, respectively. Ethyl acetate is immiscible but slightly soluble in water[11] so that it affected both ene-type chlorination and chlorohydrination. The transition state of the ene-type chlorination where chlorination to double bond and deprotonation from methyl group take place concertedly, is not cation-like,[12] and therefore it would be favored in less polar and water-immiscible solvents.

The mechanism of the acid-catalyzed ene-type chlorination is not clear yet at this stage. However, it is proposed that a protonated chlorinating reagent would be more reactive for the ene-type chlorination.[9] The electrochemically generated chlorinating reagent would be in equilibrium as shown in Eq. 1.[13]

$$2\,HOCl \rightleftharpoons Cl_2O + H_2O \quad (1)$$

Since chlorine monoxide (Cl_2O) is more soluble in

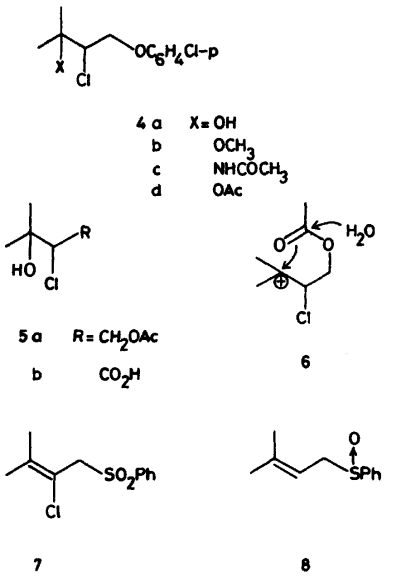
a) CH_2Cl_2 (8 ml)–H_2O (4 ml)–3.2 mol dm^{-3} HCl (1 ml). b) Current density 20 mA/cm^2. c) 1,2-dichloroethane was employed as a solvent. d) Current density 7 mA/cm^2. e) 3.2 mol dm^{-3} (1.5 ml) was used. f) **2f** (7%) was recovered.

organic solvents than in water,[14)] the electrogenerated chlorinating reagent would preferentially migrate as chlorine monoxide into the organic phase where the acid-catalyzed ene-type chlorination proceeds. The fact that the use of organic acids (Table 1) highly facilitates the ene-type reaction suggests the hypothesis.

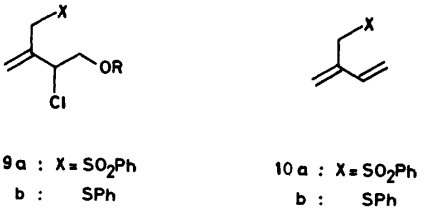
The electrolyses of **2b**—**g** were carried out in similar conditions and the result is shown in Table 3. The result suggests that the reaction pathways of **2** with the electrogenerated chlorinating reagent are extensively affected by the nature of the substituents on the prenyl moiety. The desired chlorination of **2a**, **2b**, and **2c**, proceeds smoothly to give **3a** (84%), **3b** (81%), and **3c** (86%), respectively. However, the electrolyses of **2d**, **2e**, **2f**, and **2g**, are quite dissimilar to the ene-type chlorination. Both **2d** and **2g** provided chlorohydrins **5a** and **5b**. The chlorohydrination of **2d** would proceed *via* intramolecular trapping of the carbocation **6** by acetoxyl group.[15)] Sulfone **2e** gave preferentially a vinyl chloride derivative **7** (68%) along with **3d** (23%). Deprotonation of H-2 would compete with the normal ene-type deprotonation because of the higher acidity



Scheme 2.

of H-2 than H-4 by the electron-withdrawing nature of benzenesulfonyl group. Sulfide **2f** is oxidized at the divalent sulfur atom to give sulfoxide **8**. The exclusive sulfoxidation can be rationalized by the fact that the divalent sulfur atom is more readily oxidized both by electrode process and by chemical reagents like NBS.[16)]

Substitution reaction of **1** with sodium benzenesulfinate in DMF proceeded smoothly at chloromethyl group providing **9a** in 72% yield. Likewise, reaction of **1** with sodium benzene thiolate in DMF at −20 °C yielded **9b** (92%). Dechlorophenoxylation of both **9a** and **9b** were performed in 87 and 74% yields, respectively by reduction with zinc in ethanol.[17)]



Scheme 3.

Experimental

All boiling and melting points are uncorrected. IR spectra were determined with a JASCO IRA-I infrared spectrometer. ^1H NMR spectra were obtained with a Hitachi R-24 (60 MHz) or a JEOL FX-100 (100 MHz) spectrometer and the chemical shifts are expressed in ppm (δ) downfield from TMS as an internal standard.

Electrolysis. Electrolysis was carried out in a beaker (3 cm in diameter and 10 cm in height) fitted with two platinum foil electrodes (1.5×2 cm^2) in 7—10 mm apart. A constant current (20 mA/cm^2) was applied by a regulated DC powder instrument (Metronix 543B). The electrodes were settled in a water layer and the reaction solution was gently stirred by a magnetic stirrer so that the water layer can well contact with the organic layer but drops of the water layer do not disperse into the organic layer.

Electrolysis of 2a; 3-Chloro-2-chloromethyl-4-(4-chlorophenoxy)-1-butene (1) and 3-chloro-2-methyl-4-(4-chlorophenoxy)-1-butene (3a). A mixture of **2a** (50 mg, 0.25 mmol, NaCl (500 mg, 8.5 mmol) and 3.2 mol dm^{-3} HCl (1 ml) in CH_2Cl_2 (8 ml) –H_2O (4 ml) was electrolyzed at room temperature for 27.3 min (4 F/mol). The mixture was neutralized with saturated $NaHCO_3$ and the organic substances were extracted with ether. The organic layer was washed two times with brine, dried (Na_2SO_4), and concentrated under reduced pressure. The residue was chromatographed over silica gel (Wako-gel C-200, *n*-hexane) to give a colorless oil (54 mg) whose HPLC analysis (μ-porasil, hexane–AcOEt=20 : 1) showed purity of **3a** was over 90%. Thus, yield of **3a** was 84%. Other products were **1** (3%), 3-chloro-2-methyl-4-(3,4-dichlorophenoxy)-1-butene (2—3%) and the unidentified product (2—3%) by HPLC analysis: **1**: Bp 118 °C/0.02 mmHg (1 mmHg≈133.322 Pa); IR: 1630, 1595, 1580, 1240 cm^{-1}; ^1H NMR ($CDCl_3$) δ=4.18 (s, 2H, CH_2Cl), 4.21 (d, J=7 Hz, 2H, CH_2), 4.80 (*t*, J=7 Hz, 1H, CHCl), 5.42 (br. s, 2H, CH_2=), 6.7—7.3 (m, 4H, ArH). Found: C, 49.92; H, 4.33%. Calcd for $C_{11}H_{11}Cl_3O$: C, 49.75; H, 4.15%. **3a**: Bp 105 °C/0.33 mmHg; IR: 1650 (C=C), 1595, 1580, 1240 cm^{-1}; ^1H NMR (CCl_4) δ=1.84 (s, 3H, CH_3), 4.08 (d, J=6 Hz, 2H, CH_2), 4.55 (dd, J_1=6 Hz, J_2=5 Hz, 1H, CHCl), 4.9—5.3 (m,

2H, CH_2=), 6.5—7.2 (m, 4H, ArH). Found: C, 57.36; H, 5.11%. Calcd for $C_{11}H_{12}Cl_2O$: C, 57.17; H, 5.20%.

Preparation of New Nitrogen-bridged Heterocycles. 6.[1] First Synthesis of 2-Aroylfuro[2,3-*b*]indolizine Derivatives

Akikazu KAKEHI,* Suketaka ITO, Tsuyoshi OHIZUMI, and Masayoshi ITO
Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380
(Received November 8, 1982)

Alkaline treatment of 2-(aroylmethoxy)-3-(2,2-dicyanovinyl)indolizine derivatives, readily available from the step-by-step reactions of 1-(ethoxycarbonylmethyl)-2-picolinium salts with a base, (ethoxymethylene)malononitrile followed by some phenacyl bromides in ethanol, afforded smoothly the title compounds, 2-aroylfuro[2,3-*b*]-indolizine derivatives, in good yields. These furoindolizines could be also obtained directly from the pyridinium salts without the isolation of intermediate 3-vinylindolizines. Formation mechanisms and some physical properties of these furoindolizines are also discussed.

Recently, we have found a one-pot synthesis of 2-alkoxy- and 2-acyloxy-3-vinylindolizine derivatives using a single Michael addition of various vinylating agents onto 2(3*H*)-indolizinones generated in situ from the corresponding 1-(ethoxycarbonylmethyl)-2-picolinium salts.[1] Since effective functionalization of indolizine derivatives has been scarcely reported except the cyclization of 2-allylidenedihydropyridines[2] and 3-vinylation of 3-unsubstituted indolizines,[3] this route not only has high value from the stand of synthetic methodology, but also polyfunctionalized compounds, thus obtained, should be useful as a synthone for the transformations from them to fused heterocycles and other synthetic intermediates. In this paper we wish to report the syntheses of the indolizine molecules designed as both possessing an active methylene group and a 2,2-dicyanovinyl group as a masked carbonyl one and their successful transformations to furo[2,3-*b*]indolizine derivatives by an alkaline treatment.

Results and Discussion

Preparations of 2-(Aroylmethoxy)- and 2-(Benzyloxy)-3-(2,2-dicyanovinyl)indolizine Derivatives. The reasons for the selection of 2-(aroylmethoxy)-3-(2,2-di cyanovinyl)indolizines as a model compound in this paper are following: a) The molecules have both a nucleophilic reaction center in the 2-substituent and a vinyl moiety which serves as a potential carbonyl group, and b) the subsequent reaction using these functional groups may provide a useful path to furan-fused heterocycles. These 2-(aroylmethoxy)-3-(2,2-dicyanovinyl)-indolizines **9**—**20** were synthesized from the reactions of 1-(ethoxycarbonylmethyl)pyridinium salts **1**—**4** in ethanol with base and (ethoxymethylene)malononitrile **5**, followed by the alkylations with phenacyl bromides **6**—**8** according to the procedure developed by us.[1] On the other hand, 2-benzyloxy derivatives **22** and **23** were also prepared by similar reactions of salts **2** and **4** using benzyl bromide **21** as an alkylating agent in order to compare their reactivities with those of 2-(aroylmethoxy)indolizines **9**—**20** (Scheme 1).

Structural elucidation of these indolizines **9**—**20**, **22**, and **23** were achieved by their elementary analyses and by their spectral comparisons with those of known 1- and 3-vinylindolizine derivatives.[1-3]

Facile Formation of Furo[2,3-b]indolizine Derivatives. When the retro-aldol reaction of the 2,2-dicyanovinyl group in indolizine **9** to a formyl group was examined in ethanol with an aqueous alkali,[4] the direct formation of 2-benzoylfuro[2,3-*b*]indolizine **25**, red prisms, mp 124—127 °C, was observed instead of initially expected 3-formylindolizines such as **24**. Similar treatment of 2-(aroylmethoxy)indolizines **10**—**20** afforded the corresponding 2-aroylfuro[2,3-*b*]indolizine derivatives **26**—**36** as red crystals in comparatively good yields. On the other hand, the reactions of 2-(benzyloxy)indolizines **22** and **23** with an aqueous alkali did not give furoindolizines such as **39** at all, but yielded 2-(benzyloxy)-3-formylindolizines **37** and **38** as colorless oil and crystals in 79 and 75% yields, respectively. Furthermore, our attempts to prepare 2-phenylfuro[2,3-*b*]indolizine derivatives such as **39** from these 3-formylindolizines **37** and **38** under various basic conditions were unsuccessful (Schemes 2 and 3). Next, we examined the possibility of one-pot synthesis from pyridinium salts **1**—**4** to **25**—**36**, since both formation reactions of 3-vinylindolizines **9**—**20** and furoindolizines **25**—**36** took place always in the same solvent such as ethanol. As might be expected, the same products **25**—**36** could be obtained directly in 10—57% yields by the successive reactions of salt **1**—**4** with sodium ethoxide, (ethoxymethylene)malononitrile **5**, bromides **6**—**8**, and aqueous alkali. Similar furoindolizines **41**—**44** were also formed from the reactions of salt **1**—**4** by using *p*-methylphenacyl bromide **40** as an alkylating agent (Scheme 4).

The structures of furoindolizines **25**—**36** and **41**—**44** were mainly determined by the physical and spectral

means and by the mechanistic consideration of the reactions. In particular, the elementary analyses of **25**—**36** and **41**—**44** were in good accord with the proposed compositions but not with those of initially expected 3-formylindolizines **24** at all. This fact was also supported clearly by the molecular ions in the Mass spectra of 2-benzoylfuro[2,3-*b*]indolizine derivatives **25**—**28**. In the NMR spectra of **25**—**36** and **41**—**44**, all of the skeletal proton signals appeared in an aromatic region and any other signals due to the formyl and the methylene protons could not be detected. For example, the NMR spectrum of **25** exhibited proton signals at δ=6.33 (1H, s), 6.62 (1H, dd, J=7.0 and 1.5 Hz), 6.95 (1H, br t, J=9.0 and 7.0 Hz), 7.58 (1H, s), and 7.3—8.2 (7H, m) due to the 9-H, 6-H, 7-H, 3-H, and 5-, 8-, and phenyl-H, respectively. Similar signal patterns and chemical shifts supporting the furoindolizine structure were always observed in the NMR spectra of compounds **26**—**36** and **41**—**44** (See Table 1). Furthermore, the qualitative tests (Ehrlich, Shear, and Liebermann-Burchard reactions) for furan rings were positive in all cases. Interestingly, the carbonyl absorption bands in the IR spectra of these furoindolizines **25**—**36** and **41**—**44** appeared in extremely lowered region (1592—1618 cm^{-1}), suggesting maybe large contribution of delocalized structures **45** and/or **46** as shown in Scheme 5.

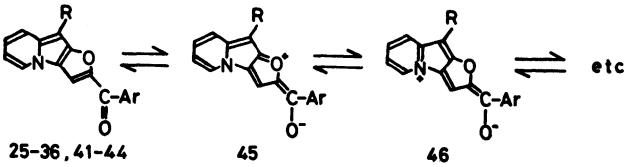
a) The coupling constants of these molecules were as follows; $J_{5,6}=J_{6,7}=7.0$ Hz, $J_{7,8}=9.0$ Hz, $J_{6,8}=1.5$ Hz, and $J_{Et}=7.0$ Hz. b) Overlapped with the phenyl signals. c) The methyl signal of the *p*-methylbenzoyl group.

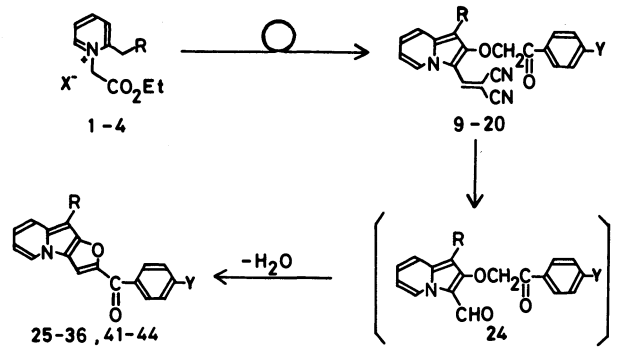


Scheme 5.

On the other hand, compounds **37** and **38** were determined to be 2-benzyloxy-3-formylindolizine derivatives, since their NMR spectra showed the presences of the formyl protons (δ=9.73 (**37**) and 9.79 (**38**)) and the methylene protons (δ=5.22 (**37**) and 4.88 (**38**)), and the elementary analysis of **38** were in accord with the suggested structure.

Mechanistically, the formation reaction of furoindolizines **25**—**36** and **41**—**44** can be explain reasonably by the intermediacy of 2-(aroylmethoxy)-3-formylindolizines such as **24** *via* the retro-aldol reaction of 2-(aroylmethoxy)-3-(2,2-dicyanovinyl)indolizine deriva-

tives and subsequent intramolecular aldol reaction between the 2- and 3-substituents in **24** (Scheme 6). Since 2-(benzyloxy)-3-fromylindolizines **37** and **38** from 3-vinylindolizines **22** and **23** were actually isolated and the utility of the 2,2-dicyanovinyl group as a masked carbonyl is extensively realized,[4] the former hypothesis seems to be undoubtful. The latter reaction is also one of the most important methods for the syntheses of fused furans.[5] The failure to obtain 2-phenylfuro[2,3-*b*]-indolizines such as **39** from 2-(benzyloxy)-3-formylindolizines **22** and **23** must be owing to low acidity of the methylene group of the 2-substituent in contrast with that of the 2-aroylmethoxy group in indolizine derivatives such as **9**—**20**.



Scheme 6.

Experimental

Melting points were measured with a Yanagimoto MP-S3 micromelting point apparatus and are uncorrected. Microanalyses were carried out on a Perkin-Elmer 240 elemental analyzer. NMR spectra were determined with a Varian EM360A NMR spectrometer in deuteriochloroform with tetramethylsilan as an internal standard, chemical shifts expres-

Preparations of 3-(2,2-Dicyanovinyl)indolizine Derivatives ***9—20, 22, and 23.*** *General Method*: To an ethanolic solution (70 ml) of 1-(ethoxycarbonylmethyl)-2-picolinium salt (3 mmol), an ethanolic sodium ethoxide (6 ml, 6 mmol), (ethoxymethylene)malononitrile **5** (3 mmol), and phenancyl bromide (3.5 mmol) were added step-by-step at intervals of 3 min at 60—70 °C. After kept for an hour at this temperature, the reaction mixture was chilled to room temperature. Because of the extremely low solubility of 3-(2,2-dicyanovinyl)indolizines **9—20**, **22**, and **23**,[6] their isolations were carried out by filtrating crude indolizines precipitated from the reaction solution or separated by pouring into water (200 ml). Recrystallizations of the crude compounds from ethanol or chloroform gave pure **9—20**, **22**, and **23** as yellow needles. These results and some properties are given in Table 2.

*Preparations of 2-Aroylfuro[2,3-*b*]indolizine Derivatives* ***25—36 and 41—44.*** *Method A*: To an ethanolic suspension (50 ml) of 2-(aroylmethoxy)-3-(2,2-dicyanovinyl)indolizine (1 mmol), aqueous potassium hydroxide (2 g in 5 ml of water) was added rapidly. After the suspended indolizine was completely disappeared and the resulting solution turned red (about 3—5 min), the reaction mixture was poured into 200 ml of water, neutralized carefully with diluted hydrochloric acid, and extracted twice with chloroform (100 ml). The combined extract was filtered through phase separating filter and the resulting filtrate concentrated at reduced pressure. Recrystallizations of crude products from ethanol or chloroform gave the corresponding 2-aroylfuro[2,3-*b*]indolizines **25—36** as red or dark red crystals. These results and some properties are shown in Tables 1 and 3.

Method B: To the reaction mixture described in the preparations of 3-vinylindolizines **9—20**, aqueous potassium hydroxide (2 g in 5 ml of water) was added and, after 5 min, the resulting reddish solution was poured into 200 ml of water. The aqueous solution was neutralized with diluted hydrochloric acid, extracted twice with chloroform (100 ml), and the combined solution was filtered through phase separating filter and then the filtrate concentrated at reduced pressure. The residue was separated by column chromatography (alumina) using ether and then chloroform as eluents. Recrystallizations from ethanol or chloroform gave the corresponding furoindolizines **25—36**. Similar treatment of the reaction mixtures using *p*-methylphenacyl bromide **40** as an alkylating agent gave furoindolizines **41—44**. These results and some properties are summarized in Tables 1 and 3.

Preparations of 2-(Benzyloxy)-3-formylindolizines ***37*** *and* ***38.*** These 3-formylindolizines were prepared according to the procedure (Method A) described above. Some data of compounds **37** and **38** are as follows: **37**: 79%, colorless oil, ν (Neat) 1620 cm^{-1} (C=O), $\delta(CDCl_3)=2.23$ (3H, s, 1-Me), 5.22 (2H, s, OCH_2), 6.7—7.6 (8H, m 6-, 7-, 8-, and phenyl-H), 9.61 (1H, d, $J=7.0$ Hz, 5-H), and 9.73 (1H, s, CHO). Because of its unstability, pure specimen for its elemental analysis could not be obtained.

38: 75%, colorless prisms, mp 106—107 °C, ν(KBr) 1668 cm^{-1} (C=O), $\delta(CDCl_3)=4.88$ (2H, s, OCH_2), 6.7—7.8 (13H, m, 6-, 7-, 8-, and two phenyl-H), 9.62 (1H, d, $J=7.0$ Hz, 5-H), and 9.79 (1H, s, CHO). Found: C, 80.72; H, 5.40; N, 4.18%. Calcd for $C_{22}H_{17}NO_2$: C, 80.71; H, 5.23; N, 4.28%.

Furthermore, our attempts to obtain 2-phenylfuroindolizines such as **39** from these compounds **37** and **38** under some alkaline conditions (ethanolic sodium ethoxide, potassium *t*-butoxide, and potassium acetate-acetic anhydride) were unsuccessful.

Studies on Salt Hydrate for Latent Heat Storage, II. Eutectic Mixture of Pseudo-binary System $CH_3CO_2Na \cdot 3H_2O$–$CO(NH_2)_2$

Takahiro WADA,* Fumiko KIMURA, and Ryoichi YAMAMOTO

Material Research Laboratory, Matsushita Electric Industrial Co. Ltd., 1006 Kodama, Osaka 571

(Received July 5, 1982)

With a view of developing latent heat storage materials, mixtures of pseudo-binary system, $CH_3CO_2Na \cdot 3H_2O$–$CO(NH_2)_2$ (sodium acetate trihydrate–urea) were subjected to differentital scanning calorimetry, and the partial phase diagram for ternary system CH_3CO_2Na–$CO(NH_2)_2$–H_2O at ambient pressure was constructed. The eutectic mixture, containing 0.6 mass fraction of $CH_3CO_2Na \cdot 3H_2O$ and 0.4 mass fraction of $CO(NH_2)_2$, melts congruently at 31.5 °C with a heat of fusion of 226 J/g, which is larger than the heat of fusion of $CaCl_2 \cdot 6H_2O$, 180 *J/g*. Thus, mixtures of system $CH_3CO_2Na \cdot 3H_2O$–$CO(NH_2)_2$ are promising for solar energy storage.

Recently, some mixtures containing salt hydrate have been studied in order to develop latent heat storage materials. Böer *et al.*[1] used a eutectic mixture of system $Na_2SO_4 \cdot 10H_2O$–NH_4Cl–NaCl as a heat storage material for a solar house "solar one." Yoneda and Takanashi[2] studied on mixtures of system $Mg(NO_3)_2 \cdot 6H_2O$–$MgCl_2 \cdot 6H_2O$ and found that the eutectic mixture of this system melts at 59.1 °C and that its heat of fusion is 144 J/g.

In contrast, no mixtures of salt hydrate and organic compound have yet been studied. In this study, mixtures of pseudo-binary system $CH_3CO_2Na \cdot 3H_2O$–$CO(NH_2)_2$ were subjected to measurements using differential scanning calorimetry (DSC). From these measurements, the partial phase diagram for ternary system CH_3CO_2Na–$CO(NH_2)_2$–H_2O at ambient pressure was constructed and the heat of fusion of the eutectic mixture was determined. The linear velocity of the crystallization from pseudo-binary molten mixtures of system $CH_3CO_2Na \cdot 3H_2O$–$CO(NH_2)_2$ was measured and the microstructure of the mixtures was observed and photographed. From the experimental results, we conclude that the $CH_3CO_2Na \cdot 3H_2O$–$CO(NH_2)_2$ mixture is suitable for solar energy storage.

Experimental

Materials. $CH_3CO_2Na \cdot 3H_2O$, CH_3CO_2Na, $CO(NH_2)_2$, and $Na_4P_2O_7 \cdot 10H_2O$ were obtained commercially. $Na_4P_2O_7 \cdot 10H_2O$ was ground and passed through a 100 mesh sieve before use.

Differential Scanning Calorimetry. Differential scanning calorimetry (DSC) was performed with an SSC 560U DSC (Dainiseikosha Co.), a heat flux DSC. Weighed quantities of $CH_3CO_2Na \cdot 3H_2O$, $CO(NH_2)_2$, *etc.* were heated and mixed to a homogeneous melt. One drop of this melt was placed in a 15 μl silver crucible and was solidified. After the crucible was closed, the sample was heated at the rate of 0.5 °C/min from 10 °C to 90 °C. The melting temperature of the sample was obtained from the endothermic peak on the sample temperature curve. The heat of fusion was obtained from the endothermic peak area. This DSC system was calibrated by using ice (t_m: 0.0 °C; ΔH_m: 335 J/g), sodium sulfate decahydrate (t_m: 32.4 °C), and sodium acetate trihydrate (t_m: 58.4 °C) as standards.

Microscopic and Microphotographic Studies. For microscopic and microphotographic studies, slides were prepared and examined under a microscope. A very small drop of melt was placed on a slide and covered with a cover glass. Nucleation was started from one side.

Linear Velocity of Crystallization. The experimental technique for determining the linear velocity of crystallization was similar to that adopted by Dietz *et al.*[3] Measurement was made in a Pyrex glass tube, 500 mm in length, 1 mm in wall thickness, and 8 mm in inner diameter, provided with two right-angled bends. The tube was placed in a water bath thermostated to ±0.1 °C. The melt was seeded at one end and the time required for the crystal boundary to move a definite distance was measured by a stopwatch. The linear velocity of crystallization was determined for various degrees of supercooling in this manner.

Results and Discussion

The phase diagram for binary system CH_3CO_2Na–H_2O based on Greem's data[4] is shown in Fig. 1. In this figure, W_a shows the mass fraction of CH_3CO_2Na and W_b the mass fraction of H_2O. Therefore, the quantity on the abscissa, $100 \times W_a/(W_a+W_b)$, is the weight per cent of CH_3CO_2Na in the system. We see that $CH_3CO_2Na \cdot 3H_2O$ melts incongruently to an aqueous solution containing 58% CH_3CO_2Na by weight in equilibrium with the balance of CH_3CO_2Na as solid anhydrate, and that the balance of CH_3CO_2Na as solid anhydrate dissolves entirely in its water of crystallization at 78 °C.

DSC curves for some mixtures of pseudo-binary system

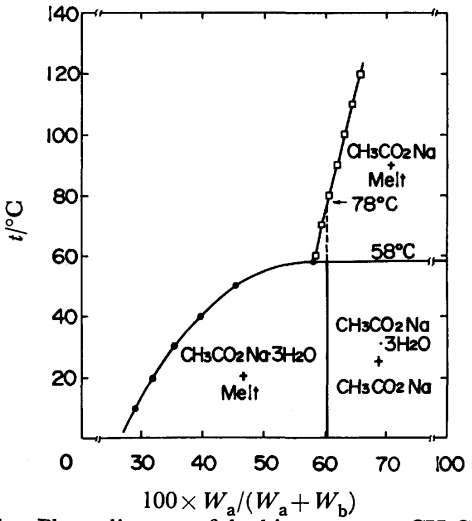

Fig. 1. Phase diagram of the binary system CH_3CO_2Na–H_2O. ●: Melting point of $CH_3CO_2Na \cdot 3H_2O$, □: melting point of CH_3CO_2Na.

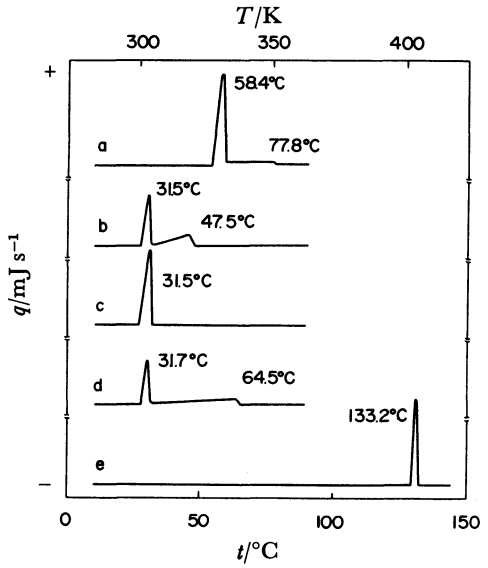

Fig. 2. DSC curves of mixtures of the pseudo-binary system $CH_3CO_2Na \cdot 3H_2O$–$CO(NH_2)_2$. a: $CH_3CO_2Na \cdot 3H_2O$, b: 0.2 mass fraction of $CO(NH_2)_2$, c: 0.4 mass fraction of $CO(NH_2)_2$, d: 0.6 mass fraction of $CO(NH_2)_2$, e: $CO(NH_2)_2$.

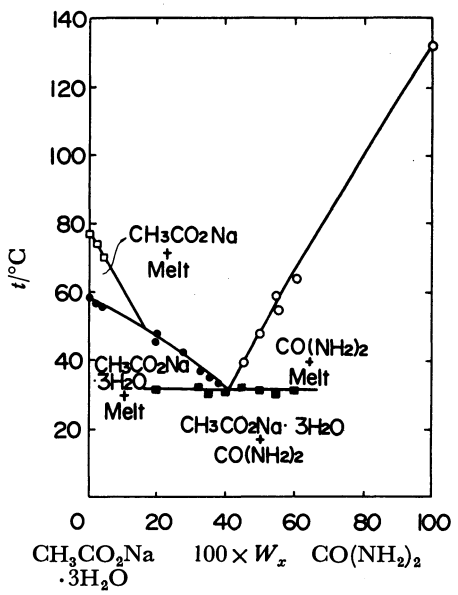

Fig. 3. Pseudo-binary section in a ternary system CH_3CO_2Na–$CO(NH_2)_2$–H_2O at ambient pressure. ●: Melting point of $CH_3CO_2Na \cdot 3H_2O$, ○: melting point of $CO(NH_2)_2$, □: melting point of CH_3CO_2Na, ■: eutectic point.

$CH_3CO_2Na \cdot 3H_2O$–$CO(NH_2)_2$ are illustrated in Fig. 2. Considering the phase diagram of the system $CH_3CO_2Na \cdot H_2O$ shownin Fig. 1, we understand that the peak at 58.4 °C on the DSC curve for $CH_3CO_2Na \cdot 3H_2O$ corresponds to the melting of $CH_3CO_2Na \cdot 3H_2O$ and that the change at 77.8 °C in the DSC curve for $CH_3CO_2Na \cdot 3H_2O$ corresponds to the entire dissolution of the CH_3CO_2Na as solid anhydrate in the water of crystallization.

The pseudo-binary section in ternary system CH_3CO_2Na–$CO(NH_2)_2$–H_2O at ambient pressure which is constructed from such DSC curves is shown in Fig. 3.

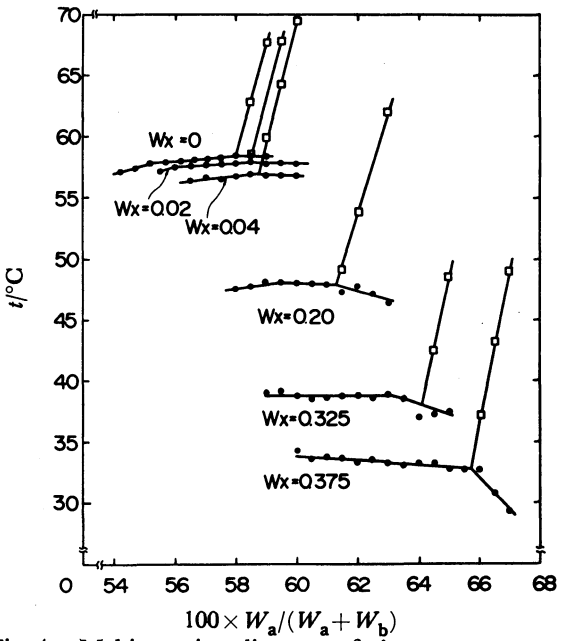

Fig. 4. Melting-point diagram of the ternary system, CH_3CO_2Na–$CO(NH_2)_2$–H_2O, at ambient pressure without $CO(NH_2)_2$ content. ●: Melting point of $CH_3CO_2Na \cdot 3H_2O$, □: melting point of CH_3CO_2Na.

This pseudo-binary section is confirmed by the cooling method adopted by Carlson *et al.*[5] In this figure, W_x shows the mass fraction of $CO(NH_2)_2$, so the quantity on the abscissa $100 \times W_x$ indicates the weight per cent of $CO(NH_2)_2$ in the system. From this figure, it is clear that pseudo-binary system $CH_3CO_2Na \cdot 3H_2O$–$CO(NH_2)_2$ forms a eutectic mixture without forming any new addition compounds. The eutectic mixture of this system, containing 0.6 mass fraction of $CH_3CO_2Na \cdot 3H_2O$ and 0.4 mass fraction of $CO(NH_2)_2$, melts congruently at 31.5 °C.

Melting-point diagrams at ambient pressure for system CH_3CO_2Na–$CO(NH_2)_2$–H_2O, in which the mass fraction of $CO(NH_2)_2$ is kept constant, are plotted in Fig. 4. In this figure, W_a shows the mass fraction of CH_3CO_2Na and W_b the mass fraction of H_2O. Therefore, the quantity on the abscissa, $100 \times W_a/(W_a+W_b)$, is the weight per cent of CH_3CO_2Na in the system with no $CO(NH_2)_2$ content. The melting-point diagram for system $CH_3CO_2Na \cdot H_2O$, which does not contain $CO(NH_2)_2$, is in good agreement with previous data.[4] It is apparent that as the mass fraction of $CO(NH_2)_2$, W_x, increases, the liquidus lines on the $CH_3CO_2Na \cdot 3H_2O$ side shift to lower temperatures and that the liquidus lines on the CH_3CO_2Na side shift to higher concentrations of CH_3CO_2Na.

A partial phase diagram of ternary system CH_3CO_2Na–$CO(NH_2)_2$–H_2O at ambient pressure is constructed by using the results of Figs. 1, 3, and 4 and shown in Fig. 5. From this figure, it is understandable that $CH_3CO_2Na \cdot 3H_2O$ comes to melt congruently when a sufficient quantity of $CO(NH_2)_2$ or H_2O is added to it. Moreover, the liquidus line on the $CH_3CO_2Na \cdot 3H_2O$ side is lowered by addition of $CO(NH_2)_2$ or H_2O. Thus, the effect of addition of

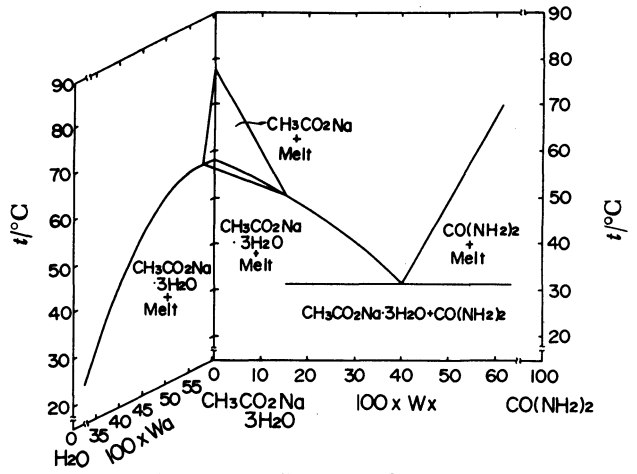

Fig. 5. Partial phase diagram of the ternary system CH_3CO_2Na–$CO(NH_2)_2$–H_2O at ambient pressure.

$CO(NH_2)_2$ to $CH_3CO_2Na \cdot 3H_2O$ is similar to that of addition of H_2O. But, the eutectic point of pseudo-binary system $CH_3CO_2Na \cdot 3H_2O$–$CO(NH_2)_2$ is 31.5 °C, which is suitable for solar energy storage, whereas the eutectic point of system $CH_3CO_2Na \cdot 3H_2O$–H_2O is −18 °C, which is too low. The reason why $CH_3CO_2Na \cdot 3H_2O$ is brought to the point of melting congruently by the addition of a sufficient quantity of $CO(NH_2)_2$ is that $CO(NH_2)_2$ acts not only as a solute in $CH_3CO_2Na \cdot 3H_2O$ melt but also as a solvent for CH_3CO_2Na like H_2O. That is to say, as an aqueous solution of $CO(NH_2)_2$ acts as a mixed solvent for CH_3CO_2Na, the solubility of CH_3CO_2Na for unit mass of H_2O is higher in the mixture of system $CH_3CO_2Na \cdot 3H_2O$–$CO(NH_2)_2$ melt than in the melt of $CH_3CO_2Na \cdot 3H_2O$ without any other substances.

The heat of fusion of the eutectic mixture of this pseudo-binary system is found to be 226 J/g by DSC. This value is larger than the heat of fusion of another latent heat storage material, $CaCl_2 \cdot 6H_2O$ (t_m: 29.5 °C), 180 J/g. The heat of fusion of a binary eutectic mixture ΔH_m^{eu} is calculated from the equation.[6]

$$\Delta H_m^{eu} = T_m^{eu}\left\{W^A\left(\frac{\Delta H_m{}^A}{T_m{}^A}\right) + W^B\left(\frac{\Delta H_m{}^B}{T_m{}^B}\right)\right\}, \quad (1)$$

where W^A and W^B are the mass fractions of components A and B, respectively, T_m^A, T_m^B, and T_m^{eu} are the melting points (in absolute temperature) of component A, component B, and eutectic mixture, respectively, and ΔH_m^A and ΔH_m^B are the heats of fusion of components A and B per unit mass, respectively. This equation is applicable to the eutectic mixture of pseudo-binary system $CH_3CO_2Na \cdot 3H_2O$–$CO(NH_2)_2$, by letting, A and B correspond to $CH_3CO_2Na \cdot 3H_2O$ and $CO(NH_2)_2$, respectively. $CH_3CO_2Na \cdot 3H_2O$ melts incongruently at 58.4 °C with a heat of fusion of 264 J/g,[7] and $CO(NH_2)_2$ melts at 133 °C with a heat of fusion of 251 J/g.[8] Accordingly we take T_m^A=332 K, T_m^B=406 K, T_m^{eu}=305 K, ΔH_m^A=264 J/g, ΔH_m^B=251 J/g, W^A=0.60, and W^B=0.40. Consequently, ΔH_m^{eu} is 221 J/g. This value is in good agreement with the experimental result, 226 J/g.

Microphotographs of mixtures of $CH_3CO_2Na \cdot 3H_2O$ and $CO(NH_2)_2$ are given in Figs. 6—8. The study with a microscope clearly proves that the solid immediately separating out from a eutectic melt is entirely different in appearance from other solids. Large prisms of $CH_3CO_2Na \cdot 3H_2O$ in the eutectic matrix are shown in Fig. 6. White needles of $CO(NH_2)_2$ in the eutectic matrix are shown in Fig. 7. An extremely regular pattern microphotographed for the solid eutectic matrix is shown in Fig. 8.

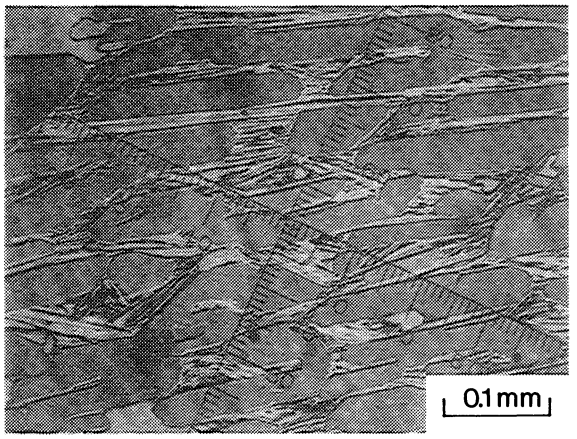

Fig. 6. Microstructure of mixture containing 0.2 mass fraction of $CO(NH_2)_2$.

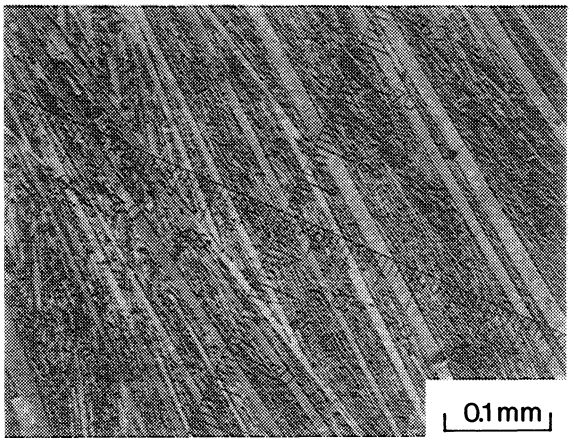

Fig. 7. Microstructure of mixture containing 0.6 mass fraction of $CO(NH_2)_2$.

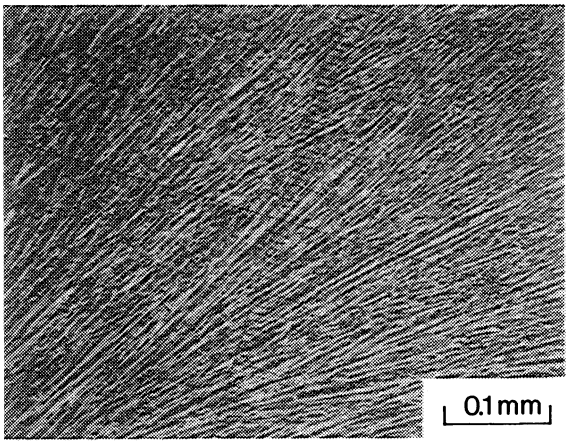

Fig. 8. Microstructure of eutectic mixture containing 0.4 mass fraction of $CO(NH_2)_2$.

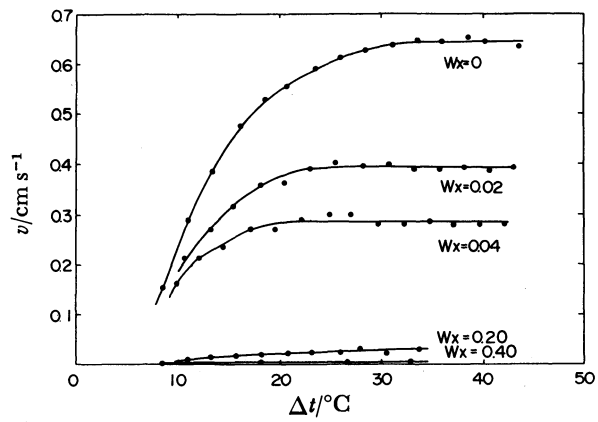

Fig. 9. Linear velocity of crystallization of various melts.

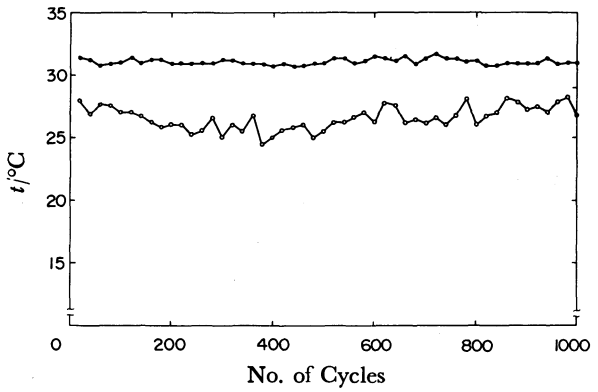

Fig. 10. Changes in melting point t_m and the temperature at which supercooling is broken t_l with cycling.
●: t_m, ○: t_l.

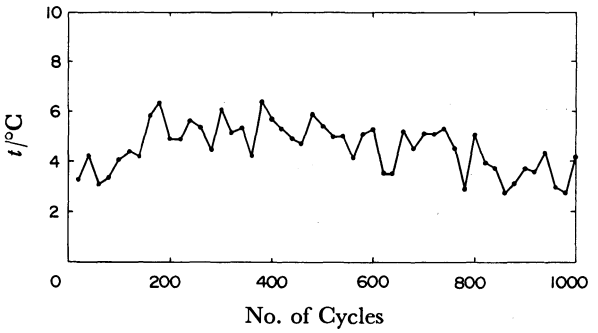

Fig. 11. Changes in supercooling Δt_l with cycling.

Linear velocities of crystallization of various melts are plotted against the supercooling Δt in Fig. 9. The linear velocity of crystallization of $CH_3CO_2Na \cdot 3H_2O$ ($W_x=0$) is in good agreement with the value determined by Dietz *et al.*[3] It is clear that the linear velocity of crystallization of the melt containing 0.04 mass fraction of $CO(NH_2)_2$ at $\Delta t=20$ °C falls to less than half the linear velocity of crystallization of $CH_3CO_2Na \cdot 3HO_2$ at $\Delta t=20$ °C. The linear velocity of crystallization of this eutectic melt at $\Delta t=20$ °C, 0.002 cm/s, is about 1/300 of the linear velocity of crystallization of $CH_3CO_2Na \cdot 3H_2O$ melt at $\Delta t=20$ °C.

To make sure that the mixture of system $CH_3CO_2Na \cdot 3H_2O$–$CO(NH_2)_2$ continuously repeats stable freezing, 30 g of the eutectic mixture of pseudo-binary system $CH_3CO_2Na \cdot 3H_2O$–$CO(NH_2)_2$, in the presence of 0.3 g of $Na_4P_2O_7 \cdot 10H_2O$ as the nucleation catalyst for $CH_3CO_2Na \cdot 3H_2O$, was subjected to cycles of linearly programmed consequtive heating and coolings between 5 and 45 °C in a manner similar to the one adopted previously.[9] Melting points t_m's and temperatures at which the supercooling is broken, t_i's as determined by 1000 continuous heating and cooling cycles, are shown in Fig. 10. The supercooling $\Delta t_i(=t_m-t_i)$ is calculated by using the results in Fig. 10 and plotted in Fig. 11. From these figures, it is apparent that the supercooling of this eutectic mixture Δt_i is almost 6 °C for all the cycles.

$CH_3CO_2Na \cdot 3H_2O$ starts to crystallize from the eutectic melt with the aid of $Na_4P_2O_7 \cdot 10H_2O$ crystals and soon $CO(NH_2)_2$ starts to crystallize. This eutectic mixture was observed not to separate into the components $CH_3CO_2Na \cdot 3H_2O$ and $CO(NH_2)_2$. After 1000 continuous heating and cooling cycles, the heat of fusion of this sample was measured by DSC. The value obtained is 222 J/g, which is in good agreement with the initial heat of fusion of this eutectic mixture, 226 J/g. Consequently, the mixtures of system $CH_3CO_2Na \cdot 3H_2O$–$CO(NH_2)_2$ are promising for solar energy storage.

The authors wish to express their thanks to Dr. Ryoichi Kiriyama for his helpful discussions and to Drs. Eiichi Hirota and Masanari Mikoda for their continuous encouragement. They are also grateful to Dr. Yoshihiro Matsuo for his discussions throughout this work.

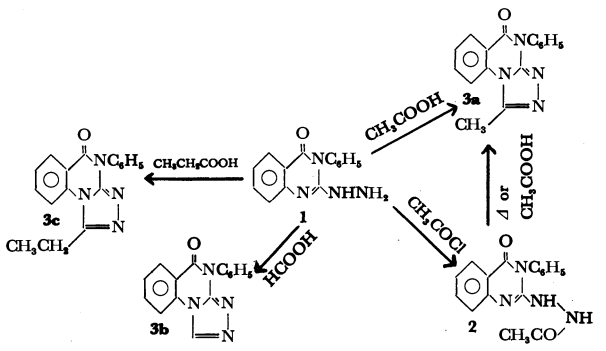
Synthesis of the 1,2,4-Triazolo[4,3-*a*]quinazolin-5-ones and Related Compounds

H. A. El-Sherief,* A. E. Abdel-Rahman, G. M. El-Naggar, and A. M. Mahmoud
Chemistry Department, Faculty of Science, Assiut University, Assiut, Egypt
(Received June 16, 1982)

2-Hydrazino-3-phenyl-4(3*H*)-quinazolinone (**1**) underwent ring closure with aliphatic acid, aldehydes, and carbon disulfide to 1-alkyl-, 1-aryl-, and 1-mercapto-4-phenyl-1,2,4-triazolo[4,3-*a*]quinazolin-5(4*H*)-ones (**7**) for instance. The 1-alkylthio-3-phenyl-1,2,4-triazolo[4,3-*a*]quinazolin-5(4*H*)-ones were readily obtained from **7** and alkyl halides. Reaction of **1** with ethyl acetoacetate gave the corresponding hydrazone which was readily converted into 2-(3-methyl-5-oxo-2-pyrazolin-1-yl)-3-phenyl-4(3*H*)-quinazolinone.

The fusion of quinazoline ring with other biologically active nuclei has aroused considerable interest for synthetic organic chemists because many members of this family exhibit im potant biological activity.[1-3] Some tetrazolo[1,5-*a*]quinazolinones have been prepared,[4] as pesticides, from the corresponding 2-hydrazino-3-aryl-4(3*H*)-quinazolinones and nitrous acid. Tennant[5] first prepared 3-phenyl-1,2,3-triazolo[1,5-*a*]-quinazolin-5-one by condensation of *o*-azidobenzoic acid with phenylacetonitrile.

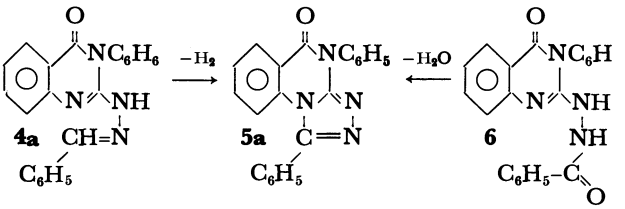
It has been observed in the present study that 2-hydrazino-3-phenyl-4(3*H*)-quinazolinone (**1**) reacted with acetyl chloride in the presence of potassium carbonate in dry chloroform gave 2-(2-acetylhydrazino)-3-phenyl-4(3*H*)-quinazolinone (**2**). Heating of **2** above its melting point for 10 min gave 1-methyl-4-phenyl-1,2,4-triazolo[4,3-*a*]quinazolin-5(4*H*)-one (**3a**), which also can be obtained *via* another route, by refluxing **1** or **2** in acetic acid. In a similar way, reaction of **1** with formic acid and propionic acid gave the corresponding 4-phenyl-1,2,4-triazolo[4,3-*a*]quinazolin-5(4*H*)-one (**3b**) and 1-ethyl-4-phenyl-1,2,4-triazolo-[4,3-*a*]quinazolin-5(4*H*)-one (**3c**) respectively as shown in the following scheme:



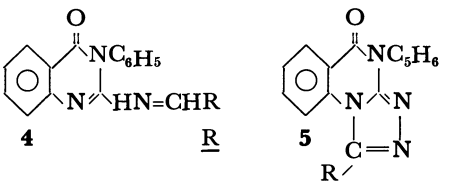
The NMR spectrum of **3a** (in $CDCl_3$) showed a singlet at 2.72 (3H, CH_3), a multiplet at 7.4—7.1 (5H, C_6H_5), and another multiplet at 8.2—7.8 (4H of quinazolinone ring), while the NMR spectrum of **3c** showed a triplet at 1.14 (3H, CH_3), a quartet at 3.23 (2H, CH_2), a multiplet at 7.4—7.0 (5H, C_6H_5) and a multiplet at 8.3—7.8 (4H of quinazolinone ring).

Although the isomerization of 1,2,4-triazolo[4,3-*c*]-quinazolines to 1,2,4-triazolo[1,5-*c*]quinazolines has been reported,[6] no such isomerization has been found in 4-phenyl-1,2,4-triazolo[4,3-*a*]quinazolin-5(4*H*)-one system. When **1** was treated with formic acid under milder conditions[7,8] than those used above, **3b** was obtained.

Fusion of **1** with benzaldehyde, for 3 min, gave benzaldehyde (4-oxo-3-phenyl-3,4-dihydro-2-quinazolinyl)hydrazone (**4a**), which was dehydrogenated to 1,4-diphenyl-1,2,4-triazolo[4,3-*a*]quinazolin-5(4*H*)-one (**5a**) when the reaction was continued for 2 h at 220—225 °C. The same result was also obtained by ring closure of 2-(2-benzoylhydrazino)-3-phenyl-4(3*H*)-quinazolinone (**6**) when heated over its melting point for 10 min. Similarly a series of the hydrazones (**4b—e**)



(Table 1) and 1-aryl-4-phenyl-1,2,4-triazolo[4,3-*a*]-quinazolin-5(4*H*)-ones (**5b—e**) (Table 2) were prepared from **1** and the appropriate aldehydes.

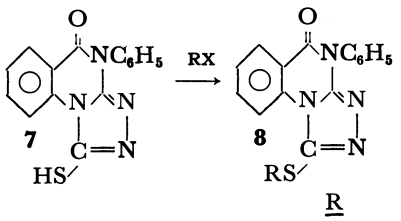


4 and **5a**; C_6H_5
b; C_6H_4Cl-*m*
c; C_6H_4Cl-*p*
d; $C_6H_4CH_3$-*p*
e; $C_6H_4OCH_3$-*p*

The IR spectra of **4a—e** showed bands at 1700—1685 and 3320—3260 cm^{-1} assignable to C=O and NH stretching frequencies, respectively. While the IR spectra of **5a—e** indicated the disappearance of the NH stretching frequency and revealed a characteristic band for C=O at 1690—1680 cm^{-1}.

Further, the reaction of **1** with one equivalent of carbon disulfide resulted in ring closure to 1-mercapto-4-phenyl-1,2,4-triazolo[4,3-*a*]quinazolin-5(4*H*)-one (**7**), which was readily converted into the corresponding alkylthio derivatives **8a—d** with alkyl halides in basic medium.

The NMR spectrum of **8b** (in $CDCl_3$) showed a triplet at 1.63 (3H, CH_3), a quartet at 3.5 (2H, S-CH_2) and a multiplet at 7.6—8.2 (9H, aromatic protons)



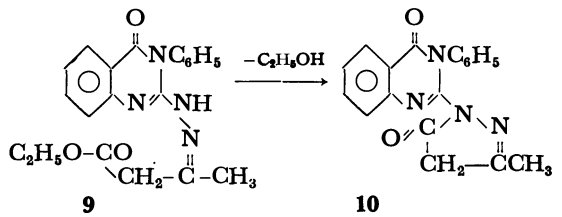
8a; CH_3
8b; C_2H_5
8c; CH_2CH
8d; $CH_2C_6H_5$
8e; $CH_2COOC_2H_5$
8f; CH_2COOH
8g; $CH_2CONHCH_2C_6H_5$

which is in agreement with its structure. Reaction of **7** with ethyl chloroacetate in dry acetone in the presence of potassium carbonate gave 1-ethoxycarbonylmethylthio-4-phenyl-1,2,4-triazolo[4,3-*a*]quinazolin-5(4*H*)-one (**8e**). The IR spectrum of **8e** showed two carbonyl bands one at 1690 cm^{-1} (due to quinazolinone nucleus) and the other at 1740 cm^{-1} (due to the ester group).

However, treatment of **8e** with aq potassium carbonate solution (5%) at 50 °C for 1 h gave 1-carboxymethylthio-4-phenyl-1,2,4-triazolo[4,3-*a*]quinazolin-5(4*H*)-one (**8f**), which was readily obtained by treatment of **7** with chloroacetic acid in the presence of potassium carbonate in dry acetone.

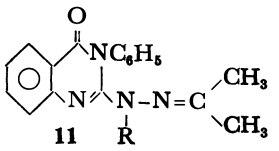
The IR spectrum of **8f** showed two carbonyl bands one at 1685 cm^{-1} (of quinazolinone nucleus) and the other at 1670 cm^{-1} (of the carboxyl group). Synthesis of 1-(benzylcarbamoylmethylthio)-4-phenyl-1,2,4-triazolo[4,3-*a*]quinazolin-5(4*H*)-one (**8g**) was achieved by reaction of **8e** with benzylamine in boiling ethanol. The IR spectrum of **8g** showed bands at 3180 cm^{-1} (NH), 1690 cm^{-1} (C=O of quinazolinone nucleus) and at 1665 cm^{-1} (C=O of amide).

On the other hand, treatment of **1** with ethyl acetoacetate in boiling ethanol produced the corresponding hydrazone **9**. Its IR spectrum exhibited two carbonyl bands one at 1685 cm^{-1} (due to quinazolinone ring) and the other at 1735 cm^{-1} (due to the ester group). When **9** was heated above its melting point for 5 min, the corresponding pyrazolinone **10** was obtained.



The IR spectrum of 2-(3-methyl-5-oxo-2-pyrazolin-1-yl)-3-phenyl-4(3*H*)-quinazolinone (**10**) showed in addition to the carbonyl band of quinazolinone nucleus at 1690 cm^{-1}, the amide band at 1665 cm^{-1}.

Refluxing of **1** with acetone gave the corresponding hydrazone **11a**. According to the literature,[9] attempted formation of **3a** by heating of **11a** at 220—225 °C for 2 h failed. However, **11a** was readily acetylated and sulfonylated using acetic anhydride and benzenesulfonyl chloride in pyridine to give the corresponding derivatives **11b** and **11c** respectively.



11a; H
b; $COCH_3$
c; $SO_2C_6H_5$

The IR spectrum of **11a** showed band at 1690 cm^{-1} (C=O of quinazolinone ring) and at 3320 cm^{-1} (NH group). While, the IR spectra of **11b** and **11c** revealed the disappearance of the NH stretching frequency.

Experimental

Melting points reported are uncorrected. IR spectra were recorded on a Beckman IR-20 spectrophotometer. ^1H NMR spectrum was recorded on a Varian EM-360 60 MHz using TMS as the internal standard.

2-(2-Acetylhydrazino)-3-phenyl-4(3H)-quinazolinone (2). To a solution of **1** (5 g, 0.02 mol) in dry chloroform (100 ml) containing anhyd potassium carbonate (0.5 g), acetyl chloride (0.01 mol) was added slowly. After the addition was complete, the reaction mixture was heated on a water bath for 1 h. The solvent was evaporated and the crude product was collected and crystallized from water as colorless needles, 2.3 g (80%), mp 142 °C. Found: C, 65.46; H, 4.91; N, 19.18%. Calcd for $C_{16}H_{14}N_4O_2$: C, 65.30; H, 4.76; N, 19.05%.

1-Methyl-4-phenyl-1,2,4-triazolo[4,3-a]quinazolin-5(4H)-one (3a). **2** (1 g) was heated above its melting point for 5 min and after cooling, recrystallized from ethanol as colorless needles, 0.6 g (60%), mp 313 °C. The same compound was also obtained by refluxing **2** (1 g) with acetic acid (10 ml) for 20 min. The separated product was crystallized from ethanol 0.7 g (70%), no depression of melting point occurred on admixture with the sample prepared by the above procedure.

3a was also obtained by refluxing **1** (2.5 g; 0.01 mol) with acetic acid for 2 h, as described above in 65% yield. Found: C, 69.67; H, 4.46; N, 20.31%. Calcd for $C_{16}H_{12}N_4O$: C, 69.57; H, 4.35; N, 20.29%.

4-Phenyl-1,2,4-triazolo[4,3-a]quinazolin-5(4H)-one (3b). A mixture of **1** (0.01 mol), 2.5 g and formic (20 ml) was refluxed for 2 h, then the excess acid was evaporated under reduced pressure and the residue was crystallized from ethanol to give colorless needles, 2.1 g (80%), mp 332—334 °C. Found: C, 68.74; H, 3.66; N, 21.45%. Calcd for $C_{15}H_{10}N_4O$: C, 68.70; H, 3.82; N, 21.37%.

The same product was obtained by heating the above mixture at 55 °C for 45 min. The excess acid was evaporated under reduced pressure at 50 °C and the crude product was crystallized from ethanol to give **3b**. There is no melting point depression and the infrared was superimposable with that of **3b** prepared according to above procedure.

1-Ethyl-4-phenyl-1,2,4-triazolo[4,3-a]quinazolin-5(4H)-one (3c). It was prepared by refluxing a mixture of **1** (2.5 g; 0.01 mol) and propionic acid (20 ml) as previously described in **3b**. The crude product was crystallized from ethanol–benzene mixture as colorless needles, 2 g (70%), mp 285—287 °C. Found: C, 70.46; H, 4.70; N, 19.61%. Calcd for $C_{17}H_{14}N_4O$: C, 70.34; H, 4.83; N, 19.31%.

*Reaction of 2-Hydrazino-3-phenyl-4(3H)-quinazolinone (**1**) with Aldehydes.* A mixture of appropriate aldehyde (0.011 mol) and **1** (0.01 mol) was heated for 3 min, and after cooling to room temperature, crystallized from ethanol–benzene mixture as colorless needles. The yield was about 85—90%.

*2-(2-Benzoylhydrazino)-3-phenyl-4(3H)-quinazolinone (**6**).* It was prepared from **1** (0.02 mol) and benzoyl chloride (0.02 mol) in chloroform solution containing potassium carbonate as previously described in **2**. The crude product was crystallized from ethanol as colorless needles, 2.4 g (69%), mp 149—151 °C. IR (KBr), 3340 (NH), 3230 (NH), 1665 (amide CO) cm^{-1}. Found: C, 70.56; H, 4.31; N, 15.62%. Calcd for $C_{21}H_{16}N_4O$: C, 70.79; H, 4.49; N, 15.73%.

*1-Aryl-4-phenyl-1,2,4-triazolo[4,3-a]quinazolin-5(4H)-ones (**5a—e**).* A mixture of appropriate aldehyde (0.015 mol) and **1** (0.01 mol) was heated at 210—225 °C for 2 h. The pyrolysis residue was cooled and triturated with ethanol. The crude product was crystallized from ethanol (charcoal) forming colorless needles of **5a—e**. The yield was about 55—65%. **5a** was also obtained by heating benzaldehyde (4-oxo-3-phenyl-3,4-dihydro-2-quinazolinyl)hydrazone (**4a**) for 1 h at 220—225 °C. The pyrolysis residue, treated as described above gave **5a** in yield 45%.

The same product **5a**, was also obtained in 70% yield by heating **6** (1 g) over its melting point for 10 min as described in **3a**.

*1-Mercapto-4-phenyl-1,2,4-triazolo[4,3-a]quinazolin-5(4H)-one (**7**).* **1** (2 g), methanol (100 ml), potassium hydroxide (0.7 g), and carbon disulfide (6 ml) were refluxed for 4 h. After removal of the methanol, dilute potassium hydroxide was added and the alkaline solution was filtered. After precipitation with dilute hydrochloric acid, the crude product was filtered and recrystallized from ethanol as colorless needles, 1.8 g (77%), mp 342—344 °C. Found: C, 61.41; H, 3.26; N, 19.18; S, 10.76%. Calcd for $C_{15}H_9N_4OS$: C, 61.22; H, 3.40; N, 19.05; S, 10.88%.

*Reaction of **7** with Alkyl Halides.* A solution of **7** (0.5 g; 0.002 mol) and sodium hydroxide (0.1 g) in water (10 ml) was stirred while the appropriate alkyl halide (0.004 mol) was added dropwise. The reaction mixture was stirred for 2 h, then the excess alkyl halide was evaporated and the residue recrystallized from benzene–pet. ether (60—80 °C) mixture, forming colorless needles of the products **8a—d**. The yield was about 65—70%.

*1-Ethoxycarbonylmethylthio-4-phenyl-1,2,4-triazolo[4,3-a]quinazolin-5(4H)-one (**8e**).* To a solution of **7** (1 g) in dry acetone (30 ml) containing anhyd potassium carbonate (0.5 g), ethyl chloroacetate (0.5 ml) was added slowly. The reaction mixture was refluxed on a steam bath for 30 min, then filtered, evaporated and the crude product was collected and crystallized from pet. ether (60—80°C) as colorless needles, 0.9 g (70%), mp 116 °C. Found: C, 60.15; H, 4.32; N, 14.95; S, 8.71%. Calcd for $C_{19}H_{16}N_4O_3S$: C, 60.00; H, 4.21; N, 14.73; S, 8.42%.

*1-Carboxymethylthio-4-phenyl-1,2,4-triazolo[4,3-a]quinazolin-5(4H)-one (**8f**).* A mixture of **8e** (0.5 g) and 20 ml sodium carbonate solution (5%) was stirred for 2 h at 50 °C. The reaction mixture was cooled and acidified, the solid separated was filtered off and crystallized from ethanol as colorless needles to give **8f**, mp 208 °C, 0.3 g (75%). Found: C, 57.81; H, 3.51; N, 15.71; S, 9.26%. Calcd for $C_{17}H_{12}N_4O_3S$: C, 57.95; H, 3.41; N, 15.91; S, 9.09%.

The same product was also obtained by reaction of **7** (0.5 g) and chloroacetic acid in the presence of potassium carbonate in acetone as described before in **8e**. Evaporation of the solvent after acidification gave **8f** in 45% yield.

*1-(Benzylcarbamoylmethylthio)-4-phenyl-1,2,4-triazolo[4,3-a]-quinazolin-5(4H)-one (**8g**).* A mixture of **8e** (0.5 g) and benzylamine (0.3 g) in ethanol (15 ml) was refluxed for 2 h. The reaction mixture was reduced to its half volume and cooled. The separated product was collected and recrystallized from the same solvent as colorless needles, mp 254 °C, (0.3 g; 50%). Found: C, 65.41; H, 4.51; N, 15.90; S, 7.51%. Calcd for $C_{24}H_{19}N_5O_2S$: C, 65.30; H, 4.30; N, 15.87; S, 7.26%.

*2-(3-Methyl-5-oxo-2-pyrazolin-1-yl)-3-phenyl-4(3H)-quinazolinone (**10**).* *a)*: A mixture of **1** (0.002 mol) and ethyl acetoacetate (0.0025 mol) in ethanol (30 ml) was refluxed for 3 h. The reaction mixture was concentrated and cooled. The separated colorless product was crystallized from the same solvent to give the corresponding hydrazone (**9**) mp 142 °C, 5.9 g (82%). Found: C, 65.71; H, 5.58; N, 15.61%. Calcd for $C_{20}H_{20}N_4O_3$: C, 65.93; H, 5.49; N, 15.38%.

b): The hydrazone **9** (0.5 g) was heated over its melting

point for 10 min, the residue was cooled and crystallized from pyridine–methanol mixture as colorless needles (**10**), mp 360 °C, 0.3 g (75%). Found: C, 67.86; H, 4.52; N, 17.81%. Calcd for $C_{18}H_{14}NO_2$: C, 67.79; H, 4.40; N, 17.61%.

*Acetone (4-Oxo-3-phenyl-3,4-dihydro-2-quinazolinyl) hydrazone (**11a**).* A mixture of **1** (1 g) and acetone (15 ml) was refluxed for 2 h. The solvent was evaporated the residue was crystallized from ethanol as colorless needles, mp 185 °C, 0.9 g (81%). Found: C, 69.76; H, 5.58; N, 19.36%. Calcd for $C_{17}H_{16}N_4O$: C, 69.86; H, 5.47; N, 19.17%.

*Acetylation of **11a**.* A mixture of **11a** (0.2 g), acetic anhydride (1 ml) and pyridine (1 ml) was heated on a steam bath for 30 min. The yellow crystalline product was separated, collected and crystallized from ethanol to give **11b**, mp 278 °C, 0.2 g (93%). Found: C, 71.78; H, 5.76; N, 17.80%. Calcd for $C_{19}H_{18}N_4O$: C, 71.69; H, 5.66; N, 17.61%.

*Sulfonylation of **11a**.* A mixture of **11a** (0.2 g), benzenesulfonyl chloride (0.2 ml) and pyridine (2 ml) was heated on a steam bath for 30 min. The reaction mixture was cooled and poured into cold water. The brown solid product was collected and crystallized from methanol to give **11c** as brown crystals, mp 194—195 °C, 0.1 g (45%). Found: C, 63.76; H, 4.51; N, 12.80; S, 7.42%. Calcd for $C_{23}H_{20}N_4O_3S$: C, 63.88; H, 4.62; N, 12.96; S, 7.40%.

The Disproportionation Constants of Mercurry(I) in Dilute Solutions. II[1)]

Isao SANEMASA,* Toyohisa KOBAYASHI, Toshio DEGUCHI, and Hideo NAGAI
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860
(Received August 9, 1982)

Synopsis. The equilibrium constants, K_d, of mercury-(I) disproportionation have been measured by passing air containing mercury(0) vapor through mercury(I) solutions. At 15, 20, 25, 30, and 35 °C, the values of K_d were 1.3, 2.9, 5.2, 8.8, and 11×10^{-9} mol dm^{-3} respectively at $\mu=0.1$ ($NaClO_4$).

In the preceding paper we have reported the equilibrium constants, K_d, for this reaction:[1)]

$$Hg_2^{2+} \rightleftharpoons Hg(aq) + Hg^{2+}. \quad (1)$$

The values of K_d we estimated are, however, considerably larger than those which have more recently been reported.[2)] Our previous method of determining K_d may have caused some uncertainty in the absolute accuracy, so we have decided to reevaluate K_d by a modification of this earlier method.

The disproportionation occurs according to Reaction 1 by letting air flow through a solution containing Hg_2^{2+}, until finally only Hg^{2+} ions remain in the solution. Now, let us consider special conditions where the air introduced into the mercury(I) solution contains vapor of metallic mercury. Under such circumstances, the equilibrium of Reaction 1 will be attained depending on the dissolved Hg(aq) concentration. The K_d can be straightforwardly calculated by means of this equation:

$$K_d = [Hg(aq)][Hg^{2+}]/[Hg_2^{2+}]$$
$$= [Hg(aq)]\{[Hg^{2+}]_0 + [Hg_2^{2+}]_0 - [Hg_2^{2+}]\}/[Hg_2^{2+}], \quad (2)$$

where the subscript 0 denotes the initial concentration.

The apparatus used is shown in Fig. 1. Air flowed by means of an air-pump P at a constant rate of 100 cm^3 min^{-1} through a cylindrical tube A, which was packed with silica gel, and a condenser B. The dried air was introduced into a flask C in which a few drops of metallic mercury had been put, and then bubbled successively into three flasks, D, E, and F. Finally, the air was released out of a cylindrical tube G in which a 1 mol dm^{-3} nitric acid solution had been placed in order to split off the contaminated mercury vapor. The flask C was maintained at a constant temperature below 10 °C by circulating thermostated water through a jacket outside the flask. The flasks, D, E, and F, were

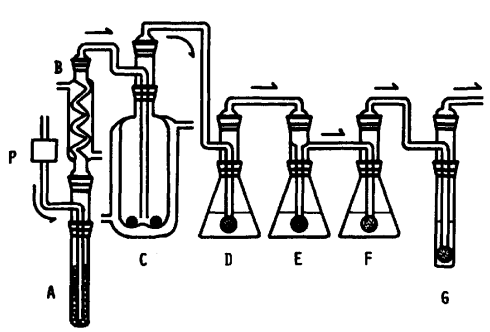

Fig. 1. Apparatus.

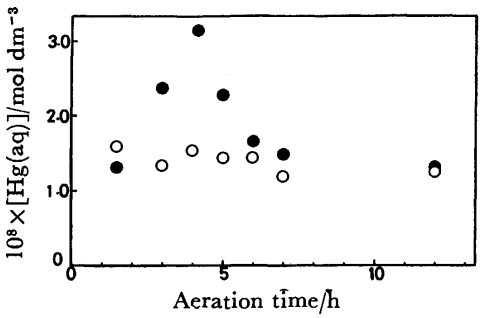

Fig. 2. Concentrations of Hg(aq) dissolved in D and F flasks as a function of aeration time. ○: D Flask, ●: F Flask. Temperature: 25.0 °C.

immersed in another thermostat controlled within 0.05 °C. In the E flask we placed a 100 cm^3 mercury(I) solution in 0.05 mol dm^{-3} perchloric acid, the ionic strength of which had been adjusted to 0.1 with sodium perchlorate. The same volumes of 0.05 mol dm^{-3} $HClO_4$ ($\mu=0.1$, $NaClO_4$) solutions in the absence of mercury(I) were placed in the D and F flasks, which were utilized to estimate the [Hg(aq)] in the E flask. The dissolved Hg(aq) concentrations in the D and F flaks were determined by an atomic-absorption method, and the remaining Hg_2^{2+} concentrations in the E flask were measured spectrophotometrically at 236.5 nm; $[Hg_2^{2+}]_0 = 1.02 \times 10^{-5}$ mol dm^{-3} in all the runs.

As will be seen in Fig. 2, the Hg(aq) concentrations in the D flask were almost constant, irrespective of the aeration time, while those in the F flask increased at first to attain a maximum and then decreased to approach those in the D flask. The initial increase in [Hg(aq)] in the postponed flask is due to the liberation of Hg^0 from mercury(I) in the E flask. We presumed that, when the [Hg(aq)] in the F flask was the same as that in the D flask, the [Hg(aq)] must be the same as in the E flask as well, and that, under such circumstances, the disproportionation equilibrium of mercury-(I) in the E flask should be reached. After a 6-hour aeration, the amount of $[Hg_2^{2+}]$ remaining in the E flask and the mean values of [Hg(aq)] in the D and F flasks were used to calculate K_d by means of Eq. 2. The calculations were made by the successive approximation. That is, $[Hg^{2+}]_0$ was neglected as a first approximation, then, by using the approximate K_d value, $[Hg^{2+}]_0$ was estimated. It corresponded in most cases to *ca.* 10% of $\{[Hg_2^{2+}]_0 - [Hg_2^{2+}]\}$. Next, by using the $[Hg^{2+}]_0$ estimated, the second K_d value was calculated; it was no longer changed by further successive calculations.

The summary of the experimental results and the estimated disproportionation constants are listed in Table 1. The present result, 5.2×10^{-9} mol dm^{-3} at 25 °C, is in good agreement with that of the literature:

a) First approximation by neglecting $[Hg^{2+}]_0$. b) The corrected K_d. c) $[Hg_2^{2+}]_0 = 1.02 \times 10^{-5}$ mol dm^{-3} in all runs.

3.0[2] and 5.3[3] $\times 10^{-9}$ mol dm^{-3} at 25 °C. Our previous results, which are two to four times larger than those obtained in the present work, are considered to be less reliable. In the previous method, we estimated K_d by combining two rate constants determined by separate experiments; one was concerned with Hg^0 transfer from the aqueous to the gaseous phase, and the other, with the disproportionation of mercury(I).[1] The additional errors of the two rate constants may be responsible for the lesser reliability.

In general, the reliability of the method of determining K_d depends on how accurately it can determine the concentration of Hg(aq), which is in equilibrium with Hg_2^{2+} and Hg^{2+} ions. In this respect, several attempts that make use of the characteristic distribution of Hg^0 between aqueous and non-aqueous phases[3] or between aqueous and gaseous phases[2] have been made. We assume in the present method that the solubilities of Hg^0 in aqueous solutions in the presence of Hg_2^{2+} and Hg^{2+} ions are identical with those in their absence under the same vapor pressure of metallic mercury. It should be noticed that the concentration of Hg(aq) in each run is not a saturated solubility, but a so-called steady-state solubility. That is, mercury vapor continuously supplies Hg^0 to an aqueous phase, while the air stream bubbled out of the solution removes the dissolved Hg(aq) at a certain rate.

The total mercury concentrations in the D and F flasks, which can be measured by the atomic-absorption technique by using a tin(II) reductant, did not increase after more than a 10-hour aeration. We concluded, therefore, that the air-oxidation of the dissolved Hg^0 in 0.05 mol dm^{-3} $HClO_4$ solutions did not occur during the aeration. This is why we used air instead of nitrogen gas.

From the temperature dependence of K_d, the ΔH and ΔS values for Reaction 1 were found to be 79 kJ mol^{-1} and 108 J mol^{-1}K^{-1} at 25 °C.

ESR Studies of Unstable Six-coordinated Cobalt(II) Complexes Produced by γ-Radiolysis of Glassy Solutions at 77 K

Mikio HOSHINO,* Shiro KONISHI, Masao NAKAJIMA, and Masashi IMAMURA
The Institute of Physical and Chemical Research, Wako, Saitama 351

(Received August 12, 1982)

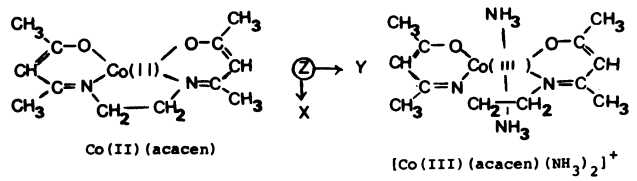
Synopsis. ESR spectra of γ-irradiated glassy solutions of cobalt(II) chelates of *N,N'*-bis(1-methyl-3-oxobutylidene)-ethylenediamine (acacen) having two NH_3 in the axial positions at 77 K show the formation of a metastable cobalt(II) complex in which two NH_3 are forced to be confined in the axial positions.

Fundamental researches on intra- and intermolecular electron transfer mechanisms of metal complexes are of great importance in relation to understanding of the redox reactions occurring in biological systems.[1-4] Numerous kinetics studies for the outer-sphere electron transfer between metal complexes have revealed that the complexes reorganize the ligand molecules with receiving or releasing electrons.[5-7]

Recently, unstable complexes having an anion in the axial position were reported to be formed by the radiation-chemical reduction of the metal complexes in rigid solutions at 77 K.[8-11] These complexes release the anions on warming the solution. In the present paper we wish to report the formation of an unstable six-coordinated complex, Co(II)(acacen)$(NH_3)_2$, having two neutral NH_3 molecules in the axial positions. The complex is considered to be an intermediate in the following reaction,

$$[\text{Co(III)(acacen)}(NH_3)_2]^+ + e^- \longrightarrow \text{Co(II)(acacen)} + 2NH_3, \quad (1)$$

where Co(II)(acacen) and Co(III)(acacen)$(NH_3)_2$ are represented, respectively, as



Experimental

$[Co(III)(acacen)(NH_3)_2]^+[X^-]$ (X=Cl and Br) was prepared according to the method reported by Costa *et al.*[12] Water was purified three times by distillation and ethylene glycol was used as supplied.

Radiolysis was performed with γ-rays from 1.2 kCi ^{60}Co source at 77 K at a dose rate of 57000 rad min^{-1}. ESR spectra were measured on a JEOL JES-FE-3AX X-band spectrometer.

Results and Discussion

When a 1 : 1 mixture of ethylene glycol and water containing 10^{-3} M $[Co(III)(acacen)(NH_3)_2]^+[X^-]$ was irradiated with γ-rays at room temperature, Co(II)-(acacen) was produced. As shown in reaction 1, this result indicates that $[Co(III)(acacen)(NH_3)_2]^+$ is reduced with electrons ejected from solvent molecules (S) upon γ-irradiation

$$S \longrightarrow S^{+\cdot} + e. \quad (2)$$

The use of a mixture of ethylene glycol and water in radiolysis has been applied to the selective formation of one-electron reduced species of solutes.[13]

The ESR spectrum *a* of Fig. 1 was observed for the γ-irradiated solution of $[Co(III)(acacen)(NH_3)_2]^+[Br^-]$ at 77 K. Beside the intense signal from solvent radicals around 3250 gauss, four of the eight hyperfine lines due to the interaction of an unpaired electron and the cobalt nucleus ($I=7/2$) are clearly observed. The spectrum dramatically changed to *b* of Fig. 1 after warming the irradiated solution to room temperature and recooling it to 77 K. Since an authentic Co(II)-(acacen) solution shows an ESR signal identical with *b* of Fig. 1, it is evident that the reduced species giving the spectrum *a* of Fig. 1 produces Co(II)(acacen) at higher temperatures. The most probable structure of the species is Co(II)(acacen)$(NH_3)_2$ in which two NH_3 molecules are forced to be confined in the axial positions owing to the solvent rigidity at 77 K. The γ-radiolysis of a $[Co(III)(acacen)(NH_3)_2]^+[Cl^-]$ solution gives the same ESR spectrum as *a* of Fig. 1. This result indicates that the anions, Cl^- and Br^-, do not exert strong effect to the cobalt atom contrary to the case of constrained complexes.[8-10] Presumably, the anions are located far from the cobalt atom.

For preparing the solution of Co(II)(acacen)$(NH_3)_2$ using the reaction

$$\text{Co(II)(acacen)} + 2NH^3 \longrightarrow \text{Co(II)(acacen)}(NH_3)_2$$

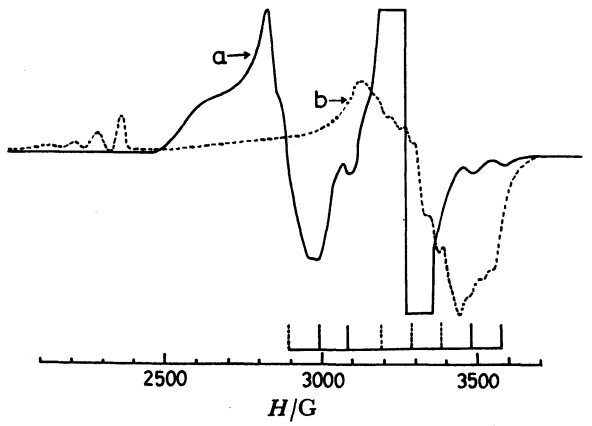


Fig. 1. ESR spectra of Co(II)(acacen) and Co(II)-(acacen)$(NH_3)_2$ in a 1 : 1 mixture of ethylene glycole and water at 77 K. a: ESR spectrum of Co(II)-(acacen)$(NH_3)_2$ obtained with γ-irradiating the solution of $[Co(III)(acacen)(NH_3)_2]^+[Br^-]$ for 45 min at 77 K; b: ESR spectrum observed after warming the irradiated solution to room temperature and recooling it to 77 K.

Table 1. ESR parameters of Co(II)(acacen) and Co(II)(acacen)$(NH_3)_2$ in a 1 : 1 mixture of ethylene glycol and water at 77 K

	g_x [a]	g_y [a]	g_z	A_x^{Co} [b]	A_y^{Co} [b]	A_z^{Co} [b]
Co(II)(acacen)	3.157[c]	1.930[c]	2.006[c]	110±5	36±2	36±2
Co(II)(acacen)$(NH_3)_2$	2.3—2.5[d]	2.3—2.5[d]	2.023[c]	d)	d)	90±4

a) x and y directions are arbitrary. b) Values are in units of 10^{-4} cm^{-1}. c) Experimental errors are 0.002. d) Values were not determined with precision because of poor resolution of the ESR spectrum.

Co(II)(acacen) was dissolved in ethanol saturated with NH_3 gass. However, the decomposition of Co(II)-(acacen) took place by dissolution and no formation of Co(II)(acacen)$(NH_3)_2$ was detected by ESR measurement. It is likely that the formation constant of Co(II)(acacen)$(NH_3)_2$ is very small.

In Table 1 are listed the ESR parameters of Co(II)-(acacen) and Co(II)(acacen)$(NH_3)_2$. The unpaired electron of Co(II)(acacen) has been established to be located in the d_{z^2} orbital of the cobalt atom.[14-16] The **g** tensors are related to the excited state energies, $\Delta E(d_{yz} \rightarrow d_{z^2})$ and $\Delta E(d_{xz} \rightarrow d_{z^2})$, by equations[17]

$$g_x = 2.002 - 6\,k_x^2\lambda/\Delta E(d_{yz} \rightarrow d_{z^2}), \quad \text{(i)}$$

$$g_y = 2.002 - 6\,k_y^2\lambda/\Delta E(d_{xz} \rightarrow d_{z^2}), \quad \text{(ii)}$$

$$g_z = 2.002, \quad \text{(iii)}$$

where λ is the spin-orbit coupling constant and k_x and k_y, the orbital reduction parameters. The large in-plane g anisotropy ($g_x \simeq 3$ and $g_y \simeq g_z \simeq 2$) of Co(II)(acacen) has been interpreted by assuming that the d_{yz} lies closely below the d_{z^2} and d_{xz}, far below.[14]

In contrast to Co(II)(acacen), the ESR spectrum of Co(II)(acacen)$(NH_3)_2$ indicates a nearly axial symmetry about the cobalt atom. The d_{z^2} orbital probably interacts with the nonbonding orbitals of two NH_3 molecules in the axial positions. This interaction increases the d_{z^2} orbital energy, resulting in a substantial decrease in the in-plane g anisotropy as is predicted by equations i and ii. The reduction of out-of-plane puckering due to two NH_3 molecules would also has an effect on the decrease in the anisotropy as suggested in the case of Co(II)(acacen)(Py) (Py : pyridine).[14] Strict theories,[18,19] however, should be applied for complete understanding of the ESR spectrum of Co(II)(acacen)$(NH_3)_2$.

The present study shows that the unstable six-coordinated cobalt(II) complex produced after one-electron reduction undergoes reorganization and ejection of ligand molecules in the axial positions. This kind of unstable complexes should play an important role in the outer-sphere electron transfer of metal complexes as a reaction intermediate.

Growth Morphology of Alumina Whiskers

Takashi HAYASHI,* Masatoshi IWATA, and Hajime SAITO
Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464
(Received September 10, 1982)

Synopsis. Alumina whiskers were grown on a substrate by hydrolysis of aluminium fluoride vapor. The present paper describes some observations concerning the growth and morphology of alumina whiskers. The most frequently observed types in this work were A_2-whiskers and C-whiskers.

The growth of alumina whiskers by vapor phase reaction has been accomplished by several investigators.[1-4] The growth of alumina whiskers occurs with the main crystallographic direction, and the corresponding crystals are sometimes referred to as A_1, A_2, A/C and C-type whiskers. C-whiskers grow in the c direction, [0001], of the hexagonal system, and A_1- and A_2-whiskers grow in the c plane in a [10$\bar{1}$0] direction and in a [11$\bar{2}$0] direction, respectively, and A/C-whiskers grow by approximately equal alteration of the growth direction in the A and C direction.

The size, morphology and crystallographic orientation of whiskers depend strongly on the experimental growth conditions. In the preceding paper,[5] we reported the growth of alumina whiskers by the hydrolysis of aluminium fluoride vapor. The present paper describes some observations concerning the growth and morphology of alumina whiskers.

The apparatus has been previously described in detail.[5] The graphite tube, which was used as a reactor, consisted of a region for vaporization of AlF_3 and a region for growth of Al_2O_3. AlF_3, which was evaporated in a furnace at a given temperature ranging from 710 to 1070 °C, was introduced into the reaction chamber with a carrier gas (Ar gas) and reacted with H_2O vapor, introduced through another inlet with a carrier gas, on a polycrystalline Al_2O_3 substrate. The desired vapor pressure of H_2O was obtained by bubbling the carrier gas through water at 0 °C and diluting the moist carrier gas with the appropriate flow of dry carrier gas. The experimental conditions were as follows: Growth temp: 1400 °C, Growth time: 3 h, AlF_3 vapor pressure: 10^{-4}—10 Torr,† H_2O vapor pressure: 10^{-3}—20 Torr, Ar gas flow rate: 100—200 ml/min. The morphology of the crystals formed was examined by optical microscopy.

Influence of AlF_3 vapor pressure, P_{AlF_3}, and H_2O vapor pressure, P_{H_2O}, on the morphology of the crystals was investigated and the relation between P_{AlF_3} and P_{H_2O} is shown in Fig. 1. Alumina crystals which had various morphology, *viz.* fine powder, bulk crystals, platelet crystals and whiskers, were formed on the substrate, depending on the growth conditions. With the simultaneous decrease of AlF_3 and H_2O vapor pressure, the crystals changed their forms from powder to bulky or platelet crystals and finally to whiskers. Adequate vapor pressures of AlF_3 and H_2O for both needle crystal and whisker growths were found to be below about 5 Torr. Whiskers only were formed under the lower vapor pressures, *i.e.* $P_{AlF_3}<1$ Torr, $P_{H_2O}<1$ Torr. The morphology of the crystals formed depended also on the growth region on the substrate. In the narrow region at which direct impingement of reactant gases occurred, the formation of fine powder or coarse polycrystalline deposits tended to occur, while whiskers tended to grow in the regions which ran along the flow of mixture gases towards the outlet.

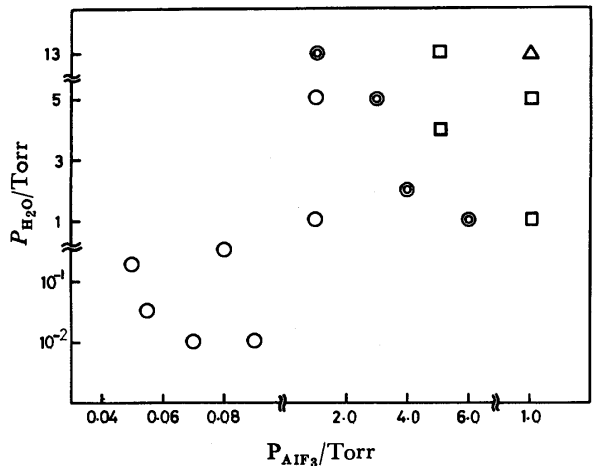

Fig. 1. Influence of P_{AlF_3} and P_{H_2O} on the morphology of grown crystals. Ar(AlF_3): 150 ml/min, Ar(H_2O): 200 ml/min. △: Powdery polycrystal, □: bulk crystal, ◎: needle crystal, ○: whisker.

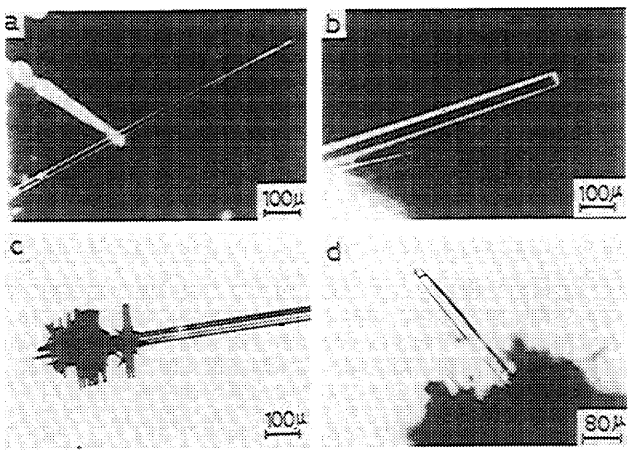

Fig. 2. Optical micrographs of whiskers. (a): Tapered whisker, (b): thin ribbon-like whisker, (c): branched whisker, (d): whisker having a droplet at its tips.

Many whiskers grew straight and grew up to the length of several mm (maximum 7—8 mm) with diameters up to 50 μm. Typical optical micrographs of alumina whiskers are shown in Fig. 2. The most frequently observed types were A_2- and C-whiskers. As expected from its morphology their cross sections showed rectangular and hexagonal shapes, respectively. In the whiskers formed in the present work, both platelet

† 1 Torr=133.322 Pa.

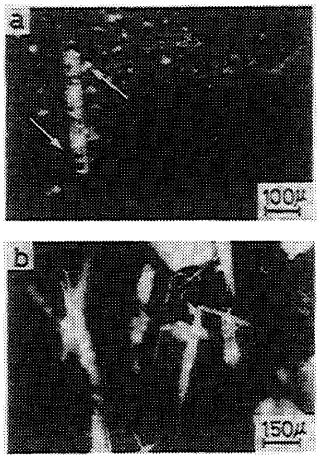

Fig. 3. Optical micrographs of kinked whisker. (a): 90° growth kinks, (b): 60° growth kinks.

and hexagonal forms were observed. Two types exist in the former: pillar and needle-like whiskers. On the other hand, the C-whiskers having many branches on the lateral surfaces near the whisker tip were occasionally observed in the latter. These branched whiskers, inclined at right angles and at about 45° to the crystal axes, were considered to be A-whisker and A/C-whiskers,[6] respectively. These branching tended to occur easily near the whisker tip when the C-whisker reached a certain length. Such secondary whisker growth is similar to the results reported by Sears[6] in which A-type whiskers grow predominantly at the thickened tip of C-whiskers. In some cases, although very rare, a whisker which had a small globule at its tip was observed. It is thought that they grew according to the VLS mechanism in the presence of impurities.

Besides the straight whiskers, kinked whiskers having 60°, 90°, and 120° angles were sometimes observed, as shown in Fig. 3. The possible angle between A_1 growth direction and A_2 growth direction are 30°, 90°, and 150°. It was considered by optical technique that 90° growth kink (Fig. 3,a) occurred by changing the growth direction such as A_1-A_2-A_1 direction or A_2-A_1-A_2 direction, but not such as A-C-A direction. That is, in the case of an A_1 or A_2-whisker which is bounded by both {0001} and {1120} or {1010} types of columnar surfaces two-dimensional nucleation should occur on the {1120} or {1010} surfaces at a lower supersaturation than on the {0001} surfaces, because the surface energy is least for the most closely packed surface {0001}.[6] Also, A-type whiskers would change growth direction by 60°,[6] as shown in Fig. 3,b, because the possible angles between one A growth direction and another A growth direction are 60° and 120°.

Syntheses and Characterization of Lanthanoid(III) Propoxyacetate

Satoshi KONDO,* Kiyofumi NAGAI, and Akira OUCHI
Department of Chemistry, College of General Education, The University of Tokyo, Komaba 3-8-1, Meguro-ku, Tokyo 153

(Received September 30, 1982)

Synopsis. New lanthanoid(III) complexes with the formula of $ML_3 \cdot H_2O$, where M=La, Ce, Pr, Nd, Eu, Dy, or Er, and HL=propoxyacetic acid, have been synthesized; they are isostructural with each other. From the shift direction of the ^{1}H-NMR peaks of L^- in an aqueous solution upon adding Eu(III) or Pr(III) salt, the ligand is likely to be coordinated to the metal by both the ether and carboxyl oxygen atoms.

The interesting structures of some lanthanoid(III) carboxylate complexes in their crystals have already been revealed by the single crystal X-ray diffraction technique.[1-5] The structure of lanthanoid(III) alkylthioacetates has also been elucidated, and it has been found that the ligand is coordinated to the metal only by the carboxylate oxygen atoms, not by the sulfide sulfur atom.[6] On the other hand, in the case of tris-(diglycolato)lanthanoid(III) complexes, the ligand acts as a terdentate where the central metal is coordinated to both the ether and carboxylate oxygen atoms.[7] Therefore, it was thought to be interesting to synthesize the lanthanoid(III) alkoxyacetates and to check whether or not the ether oxygen atom of the ligand in them is coordinated to the metal. The complexes obtained were found to be stable to moisture, even in open air.

Experimental

Synthesis of Lanthanum(III) Propoxyacetate Monohydrate, $La(C_3H_7OCH_2CO_2)_3 \cdot H_2O$. The ligand, propoxyacetic acid, was obtained by Rule's method.[8] Propoxyacetic acid (2.13 g, 18 mmol) and sodium hydrogencarbonate (1.43 g, 17 mmol) were dissolved in about 7 cm^3 of water, and lanthanum(III) chloride heptahydrate (1.86 g, 5 mmol) dissolved in 3 cm^3 of water was added to the former solution. The mixture was then stirred and heated, and the complex was precipitated. It was filtered off, dissolved in about 40 cm^3 of hot water, concentrated by means of a rotary vacuum evaporator to about 10 cm^3, and left standing at room temperature overnight. The crystals thus obtained were filtered off, washed with a little water, and dried in open air. Although the yield of the first crop obtained was only 21%, crystals of almost the same purity were also obtained when the filtrate in a beaker was kept longer in a silica-gel desiccator; the total yield was about 66%.

The propoxyacetates of Ce, Pr, Nd, Eu, and Dy were obtained in almost the same way, and their yields were comparable. In the case of the Er complex, the product appeared as an oily layer when the starting materials were mixed and heated: it gradually turned into a solid precipitate within a few minutes while it was being stirred and cooled.

These complexes have the formula of $M(C_3H_7OCH_2CO_2)_3 \cdot H_2O$. Analyses (Calcd values were obtained from the formula of $C_{15}H_{29}O_{10}M$): M=La, Found: La, 27.16; C, 35.35; H, 5.76%. Calcd: La, 27.33; C, 35.45; H, 5.75%. M=Ce, Found: Ce, 27.61; C, 35.42; H, 5.74%. Calcd: Ce, 27.50; C, 35.36; H, 5.74%. M=Pr, Found: Pr, 27.49; C, 35.25; H, 5.88%. Calcd: Pr, 27.61; C, 35.31; H, 5.73%. M=Nd, Found: Nd, 27.94; C, 35.13; H, 5.71%. Calcd: Nd, 28.08;; C, 35.08; H, 5.69%. M=Eu, Found: Eu, 29.18; C, 34.52 H, 5.74%. Calcd: Eu, 29.15; C, 34.56; H, 5.61%. M=Dy, Found: Dy, 30.58; C, 33.73; H, 5.63%. Calcd: Dy, 30.55; C, 33.87; H, 5.50%. M=Er, Found: Er, 31.14; C, 33.48; H, 5.60%. Calcd: Er, 31.17; C, 33.57; H, 5.45%.

Magnetic Moments, X-Ray, Infrared Spectra, and ^{1}H-NMR Measurements. Their X-ray powder patterns were obtained by the use of a diffractometer, model DX-GO-F JEOL, using Cu $K\alpha$ radiation from 3 to 60° in 2θ.

The infrared spectra of the samples were obtained by means of a JASCO A202 infrared spectrophotometer, using Nujol and hexachloro-1,3-butadiene mull. The ^{1}H-NMR was measured by means of a Varian EM-390 spectrometer, using D_2O as the solvent and sodium 3-(trimethylsilyl)-1-propanesulfonate (DSS) as the internal standard.

The magnetic moments of the complexes at room tempeature were measured by the use of a Gouy balance.

Results and Discussion

From the analyses and from their X-ray powder patterns, all of these seven complexes are isostructural. Their single crystals have a layer structure, consisting of mica-like thin films. As there is a tendency found extreme cleavage, the single-crystal diffraction study has not yet been completed. The magnetic moments of $ML_3 \cdot H_2O$, where HL=propoxyacetic acid are; M=La, diamagnetic; M=Ce, 2.4_9; M=Pr, 3.5_0; M=Nd, 3.5_3; M=Eu, 3.2_8; M=Dy, 10.6_8; M=Er, 9.6_1 BM,** respectively. They mean that no significant metal-metal interaction exists.[9]

Both the ν_{as}(COO) and ν_s(COO) absorptions of the IR spectra split into several peaks. The main ν_{as}(COO) peak of each complex appears between 1596 (La complex) and 1608 (Er complex) cm^{-1}, and the wave number increases depending on the atomic number of the central metal. The wave number of the maximum of the ν_{as}(COO) peak is higher than that of the corresponding lanthanoid(III) alkylthioacetates (about 1590—1580 and 1540 cm^{-1}).[6]

In Fig. 1 are shown the shifts of ^{1}H-NMR peaks of sodium butyrate, propylthioacetate, and propoxyacetate in a D_2O solution upon the addition of europium(III) chloride or of praseodymium(III) chloride. In all cases, the shift direction of the peaks upon the addition of Eu(III) is the opposite of that upon the addition of Pr(III): the ratio of the two shifts is about 1 : 2 for the same proton of the same acid salt. This means that the shifts occur mainly because of the dipole effect.[10] In the case of butyrate, where the central metal atom is coordinated only to the carboxyl oxygen atoms, all the proton peaks shift in the same direction—downfield by Pr(III) and upfield by Eu(III). Also, in the case of propylthioacetate, where the lanthanoid metal atom is coordinated only to the carboxyl oxygen atoms,[6] the shift direction of all the proton signals is the same as

** 1 BM=9.274078(36)·10^{-24} J T^{-1}.

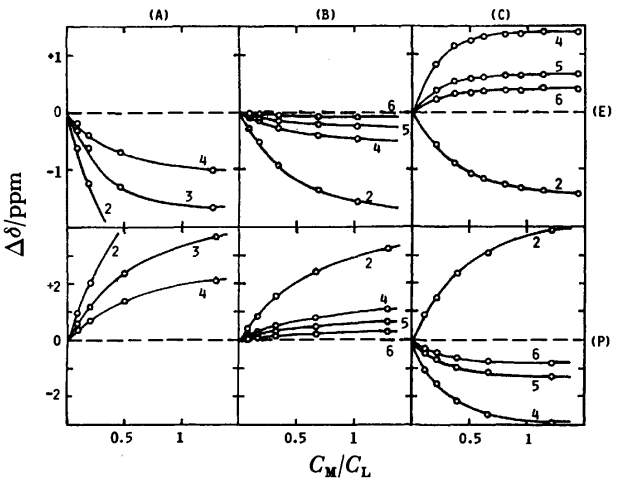

Fig. 1. The shifts of ^{1}H-NMR peaks by the addition of europium(III) chloride (E: the upper ones), or praseodymium(III) chloride (P: the lower ones), in D_2O solution. C_M/C_L=mol/mol. C_M: Concentration of Eu(III) or Pr(III). C_L: Concentration of propoxyacetate. Downfield $\Delta\delta$ was shown positive. Original chemical shifts for (A) CH_3(4)-CH_2(3)-CH_2(2)-CO_2Na, (B) CH_3(6)-CH_2(5)-CH_2(4)-S-CH_2(2)-CO_2Na, (C) CH_3-(6)-CH_2(5)-CH_2(4)-O-CH_2(2)-CO_2Na: (A) (4) 0.87-(t), (3) 1.53(m), (2) 2.15(t); (B) (6) 0.94(t), (5) 1.58(m), (4) 2.52 (t), (2) 3.15(s); (C) (6) 0.88(t), (5) 1.59(m), (4) 3.46(t), (2) 3.88(s) ppm (in δ, DSS=0; s: singlet, t: triplet, and m: multiplet). The concentration of the original sodium salts are, (A) 0.069; (B) 0.068; (C) 0.20 mol dm^{-3} for (E)s, and (A) 0.067; (B) 0.068; (C) 0.19 mol dm^{-3} for (P)s. Used $EuCl_3$ or $PrCl_3$ solutions: (A), (B), 0.13 mol dm^{-3}; (C) 0.37 mol dm^{-3} containing 0.19 mol dm^{-3} of sodium propoxyacetate.

that of butyrate. Thus, all the ligand protons of butyrate or of propylthioacetate can be expected to be out of the axial cone of the central lanthanoid atom.

On the other hand, in the case of propoxyacetate, as is shown in Fig. 1, only the signal of the protons of the methylene group which is next to the carboxyl group shifts in the same direction as those of the butyrate or of propylthioacetate. The signals of propoxyl protons, on the contrary, shift in the opposite direction, and the shift decreases rapidly depending on the increase in the distance between the proton and the ether oxygen atom.[11] This seems to be because the ether oxygen atom moves in the axial direction, while the propoxyl group shifts into the axial cone. Therefore, from this ^{1}H-NMR result, the propoxyacetate ion is found to be coordinated to the lanthanoid(III) metal atom by both carboxyl and ether oxygen atoms.

The authors are greatly obliged to the Shin-Etsu Chemical Co., Ltd., for aiding this study by presenting the highly pure lanthanoid(III) oxides.

The Isotope Effects in the Reactions of Phenylcarbene with Alcoholic Matrices

Hideo Tomioka,* Yasuji Ozaki, and Yasuji Izawa
Department of Industrial Chemistry, Faculty of Engineering, Mie University, Tsu, Mie 514
(Received May 12, 1982)

Synopsis. Product analysis studies on the reaction of phenylcarbene in deuterated alcoholic matrices at 77 K revealed that isotope effect on O–H (D) insertion is very small while substantial isotope effect was observed for C–H (D) insertion.

Recent reports from this[1-4] and other[5-8] laboratories have shown that the reactivity of arylcarbenes dramatically changes in rigid matrix at low temperature. The C–H insertion products increased drastically at lower temperature at the expense of characteristic singlet products (*vide infra*) and are believed to be derived from triplet arylcarbene *via* hydrogen atom abstraction and radical recombination. For example, we have found[1-4] in the reaction of arylcarbene with alcohol that the C–H insertion products increase dramatically at lower temperature at the expense of the OH insertion product. Recent kinetic studies of Platz[9,10] and Gasper[11] have demonstrated that the hydrogen atom abstraction from matrix is not a classical process but quantum mechanical tunneling in nature. There is little doubt that tunneling is often involved in hydrogen atom and proton transfer. It has been indicated[12] in the hydrogen atom abstraction by radicals that one of the characteristic phenomena for tunneling reaction is a very large kinetic isotope effect. For example, Ingold *et al.*[12] have observed k_H/k_D for the intramolecular hydrogen atom tunneling of 2,4,6-tri-*t*-butylphenyl radical is 1.3×10^4 at 123 K, while the maximum possible value for k_H/k_D for the simple rupture of a C–H/C–D bond is estimated to be 260 at 123 K. Similarly, Williams *et al.*[13] have reported that k_H/k_D is larger than 1.3×10^3 for intermolecular hydrogen atom abstraction by $CH_3\cdot$ from matrix at 110 K. Thus in order to obtain more precise insight into the mechanism of carbene reaction in matrix, it is quite important to investigate isotope effect on the product distribution. We wish to report here the product analysis studies on the reaction of phenylcarbene in deuterated alcoholic matrices at 77 K.

Results and Discussion

Degassed solutions of phenyldiazomethane (**1**) in methanol and its deuterated modifications were photolyzed at 77 K until all of **1** was destroyed. The product distributions were determined by GC and reported in Table 1. It is evident that isotope effect on O–H (D) insertion is very small but that there is a substantial isotope effect on C–H (D) insertion.

$$\underset{\mathbf{1}}{PhCH{=}N_2} \xrightarrow[-N_2]{h\nu} \underset{77\ K}{[PhCH{:}]} \xrightarrow[MeOH]{} \underset{\mathbf{3}}{PhCH_2OMe} + \underset{\mathbf{4}}{PhCH_2CH_2OH} \quad (1)$$

Accepting the assumption that the relative yields of products are directly proportional to their relative rates of formation, k_H/k_D for O–H and C–H insertion can be calculated to be 1.2 and 5.6, respectively. A more instructive result is provided in a study of a series of isotopically labelled 2-propanols (see Table 2). Thus,

$$\underset{\mathbf{1}}{} \xrightarrow[-N_2]{77\ K,\ Pr^iOH} PhCH_2OPr^i + \underset{\mathbf{5}}{PhCH_2\text{–}\overset{CH_3}{\overset{|}{C}}\text{–}OH} \quad \underset{\mathbf{6}}{\overset{CH_3}{\overset{|}{C}}H_3} + PhCH_2CH_2\overset{CH_3}{\overset{|}{C}}HOH \quad (2)$$

$$\underset{\mathbf{7}}{}$$

Table 1. Isotope effects in the reaction of phenylcarbene with isotopically labelled methanol at 77 K

Matrix	Yield/%[a]	
	3	**4**
CH_3OH	40.8	26.2
CH_3OD	39.1	31.1
CD_3OD	64.6	9.1

a) Other minor products (≈5%) detected in each run were toluene, bibenzyl, stilbenes, and aldehyde azine. Yield of these minor products was not altered by matrix.

Table 2. Isotope effects in the reaction of phenylcarbene with isotopically labelled 2-propanol at 77 K

Matrix	Yield/%[a]		
	5	**6**	**7**
$(CH_3)_2CHOH$	15.3	52.7	11.9
$(CH_3)_2CDOH$	15.7	17.2	48.7
$(CD_3)_2CHOH$	20.4	50.5	7.3

a) See footnote a in Table 1.

β-C–H insertion product (**7**) increased dramatically in 2-propan-2-*d*-ol matrix while α-C–H insertion (**6**) became dominant in 2-propan-1,1,1,3,3,3-d_6-ol matrix. Thus, k_H/k_D for α-C–H and β-C–H insertion can be similarly calculated to be 3.1 and 2.2, respectively.

The lack of isotope effect on O–H (D) insertion along with the kinetic observation[9,10,17] that retardation of the decay rate of triplet arylcarbene is not significant in alcohol-*hydroxyl-d* matrix indicates that abstraction of hydrogen from an O–H bond of alcohol by triplet carbene hardly occurs in matrix. This is quite reasonable in light of the large O–H bond dissociation energy (103 kcal/mol).[14] Most of ethers are then derived from singlet carbene even in rigid matrix.

Considerable isotope effect on C–H insertion supports the idea that C–H insertion products are arising from

triplet carbene, presumably *via* the abstraction-recombination mechanism. It is somewhat surprising, however, to note that the observed C–H isotope effect is not so large as to prevent the formation of C–D insertion products. In their studies of isotope effect on H atom tunneling, Williams *et al.*[13] have shown that main decay pathways of $CH_3\cdot$ radicals change from H atom abstraction to recombination with other $CH_3\cdot$ radicals in going from CH_3NC to CD_3NC matrix because of large kinetic isotope effect. No appreciable increase in such recombination products as azine and stilbene even in CD_3OD matrix indicates that decay pathways of triplet phenylcarbene are primarily D atom abstraction even in the perdeutrated solvent. The result is consistent with the kinetic observation that isotope effects with arylcarbenes are much more modest (*vide infra*).[9,10] This is partly attributable to a matrix-site problem. The rate of a hydrogen atom tunneling process is dependent upon not only the barrier height but also width: the barrier height is the classical activation energy but the barrier width is the distance that the hydrogen atom must tunnel from matrix molecule to the arylcarbene. The kinetic studies[9–11] show that decay of triplet carbene does not follow the simple pseudo first order kinetics. Such nonexponential decay has been attributed to the effects of different matrix sites offering various degrees of freedom for reaction. The findings[15] that arylcarbene generated in rigid isobutane matrix results in dramatic increase in primary C–H insertion over tertiary have been interpreted in terms of such effects of different matrix sites. In the early stages of the reaction, the reactive sites are quickly depleted while the remaining carbenes are in less reactive sites. The matrix isotope effects are found[9] to vary with matrix sites. Thus, for diphenylcarbene in toluene-d_8, matrix rate constants $k_H/k_D=6.92$ at 77 K, but initial rate constants (10% decay) $k_H/k_D=23$ at 77 K. The bulk chemistry of low temperature samples must reflect sum of those carbenes located in various sites.[16]

Experimental

Materials. Phenyldiazomethane was prepared as described in the literature[17] immediately before use. All deuterated methanols were purchased from E. Merck and used without purification. 2-Propan-2-*d*-ol was prepared by $LiAlD_4$ (E. Merck) reduction of CH_3COCH_3 and 2-propan-1,1,1,3,3,3-d_6-ol was prepared $LiAlH_4$ reduction of CD_3COCD_3 (E. Merck) according to literature procedures.[18] The undeuterated solvents were distilled over anhydrous $CaSO_4$ prior to use. Authentic samples of phenylcarbene adducts with alcohols (**3**—**7**) were synthesized as described in the literature.[19]

Low Temperature Irradiations and Product Analyses. All irradiations were carried out with a Halos 300-W high-pressure mercury lamp with a water-cooled jacket. In a typical procedure, 0.005 mmol of the freshly prepared diazomethane was added to a 2.0 ml of alcohol in Pyrex tubes. Sample tubes were sealed under vacuum after three freezethaw cycles, immersed in a trasparent Dewar filled with liquid nitrogen, and irradiated until all of the diazomethane was destroyed. Product identifications were established by GC or GC-MS comparisons using authentic samples. Product distributions were conveniently determined on 2.0 m 5% OV-17 column at 120 °C.

Reaction Mechanism of 2-(Trimethylsilylmethyl)pyridine with Benzonitrile[1)†]

Takeo KONAKAHARA* and Kenji SATO

Department of Industrial and Engineering Chemistry, Faculty of Science and Technology, Science University of Tokyo, Noda, Chiba 278

(Received July 10, 1982)

Synopsis. The mechanism of the reaction of lithiated 2-(trimethylsilylmethyl)pyridine with benzonitrile is discussed. The reaction proceeds through (*E*)- and (*Z*)-1-phenyl-2-(2-pyridyl)-1-(trimethylsilylamino)ethene, which are quantitatively converted to 2-phenacylpyridine by acidic hydrolysis.

Reaction of a nitrile with a Grignard or organolithium reagent has been extensively investigated by many workers.[2,3)] It is a good synthetic method of ketimines which give ketones by hydrolysis. It is difficult to find a reaction of an α-silyl carbanion with a nitrile, although its reaction with a carbonyl compound has been discussed as the Peterson reaction.[4)] In the course of our investigation of α-silyl carbanion with carbonyl compound or their analogs, we previously reported that *p*-substituted benzonitriles gave the corresponding 2-phenacylpyridine derivatives in high yield when the nitriles were treated with lithiated 2-(trimethylsilylmethyl)pyridine.[1)]

In this paper, we wish to report a mechanism of the reaction of lithiated 2-(trimethylsilylmethyl)pyridine (**1**) with benzonitrile (**2**). The reaction was found to proceed through (*E*)- and (*Z*)-1-phenyl-2-(2-pyridyl)-1-(trimethylsilylamino)ethene, (**4**) and (**5**), which were isolated in good yield, and converted to 2-phenacylpyridine (**3**) quantitatively by acidic hydrolysis.

Results and Discussion

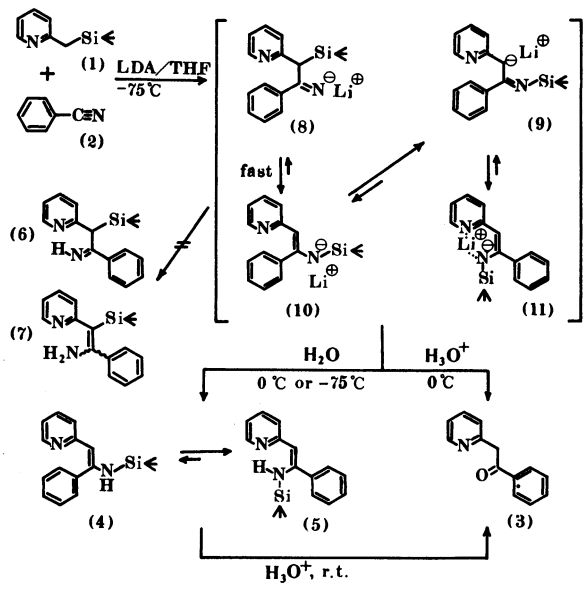
In order to study the behavior of the trimethylsilyl group throughout the reaction, the following three quenching experiments were performed (Table 1). Firstly, the reaction mixture of **1** with **2** was quenched with water at 0 °C (instead of aq ammonium chloride which was used in preparation of **3**[1)]) after stirring for 1 h at −75 °C and for 2 h at room temperature (method A). The organic extract did not contain any **3**, but did contain (*E*)-1-phenyl-2-(2-pyridyl)-1-(trimethylsilylamino)ethene (**4**) and its *Z*-isomer (**5**) (**4** : **5**=10 : 90, by GLC) with a small amount of the unreacted **1** (Scheme 1). A mixture of **4** and **5** was isolated in good yield (74%) by distillation under reduced pressure (**4** : **5**=20 : 80, by GLC; 43 : 57, by ^{1}H-NMR[5)]). Both **4** and **5** were quantitatively converted to **3** by hydrochloric acid, but they did not change to **3** by sodium hydroxide. On the other hand, quenching with *aq.* THF at −75 °C after 5 min (method B) gave a different ratio (**4** : **5**=70 : 30, by GLC under the same conditions as method A). This fact suggests that the formation of **4** is kinetically controlled, while that of **5** is thermodynamically controlled.

The structures of **4** and **5** were determined by their spectroscopic properties. The MS of the distillate obtained by method A, showed a molecular ion (M^+) peak at *m/z* 268 (molecular weight of **4** and **5**: $C_{16}H_{20}N_2Si$=268.43), and the ^{1}H-NMR spectrum of the same

Table 1. Quenching experiment in the reaction of **1** with **2**[a)]

Method	Reaction θ/°C	Reaction t/min	Quenching Quencher	Quenching θ/°C	Ratio of **4**: **5**[b)]
A	−75	60	H_2O	0	10 : 90[c)]
	r.t.	120			(25 : 75)[d)]
B[c)]	−75	5	H_2O/THF	−75	70 : 30
C[c)]	−75	30	AcOH/THF[e)]	−75	100 : ≈0

a) Molar ratio **1** : **2** : LDA = 1 : 1 : 1; spectra were measured after drying, followed by evaporation of the solvent. b) Determined by GLC (10% Silicone GE SE-30, 80 → 200 °C, 8 °C/min, Rt/min=21 and 22.5, respectively). c) Analyzed wtihout purification; includes the unreacted **1**. d) Estimated by GLC and ^{1}H-NMR data of the distillate; **4** : **5**=20 : 80 by GLC, 43 : 57 by ^{1}H-NMR. e) Excess acetic acid was removed *in vacuo*, followed by washing with sodium hydroxide.



Scheme 1.

sample consists of two kinds of trimethylsilyl groups (δ=0.04 for **5** and 0.12 for **4**), two kinds of alkenyl protons (δ=5.23 for **5** and 5.46 for **4** as singlet respectively), and two kinds of N–H protons (δ=9.62 for **5** and 7.85 for **4**), together with the ABCX system for the pyridine protons complicated with multiplet phenyl protons. The IR spectrum suggested the presence of the enamine system (ν_{NH} 3470 cm^{-1} and $\nu_{C=C\text{-}trans}$ 1620 cm^{-1} for **5** and $\nu_{C=C\text{-}cis}$ 1630 cm^{-1} for **4**) together with the trimethylsilyl group (δ_{sCH_3} 1253 cm^{-1} and 840 cm^{-1}). No absorption of C=N bond was observed. The absorption band at 930 cm^{-1} was assigned to $\nu_{asSi\text{-}N}$.[6)] Enamines **4** and **5** easily lost the trimethylsilyl group under acidic medium (Scheme 1), although a trimethylsilyl group attached to a *secondary* carbon is less reactive.[4c)] This does not indicate the presence of the Si–C bond, but the presence of the Si–N bond.[7)] It is

† A preliminary report of this work was presented at the 45th National Meeting of the Chemical Society of Japan, Tokyo, April 1982, Abstr. No. 1G46.

consistent with the result from the IR spectrum; therefore, an imino compound (**6**) and its enamine tautomer (**7**) derived from (**8**) are not stable intermediates. Moreover, *N*-trimethylsilyl imine derived from **9** by C-protonation was not observed.[8]

Finally, the reaction mixture of **2** was quenched with glacial acetic acid in THF at −75 °C after stirring at −75 °C for 30 min (method C). Only **4** was included in the reaction mixture (Table 1 and Experimental).

In conclusion, the lithiated **1** reacts with **2** to give the imino compound **8**, which was immediately converted to the (*E*)-enamide **10** by 1,3-migration of the trimethylsilyl group from C to N (Scheme 1).[7] Through the corresponding imine tautomer **9**, **10** is isomerized to the (*Z*)-enamide **11**, which is thermodynamically more stable. These anions are resonance-stabilized by the electron-attracting 2-pyridyl group and trimethylsilyl group adjacent to the negatively charged nitrogen atom. The anion which would be an intermediate in the reaction of **1** with aldimines[9] would not become stabilized in this way.

Experimental

The melting points and boiling points were uncorrected. The IR spectra were recorded on a Hitachi Model 260-10 spectrophotometer, and the ^{1}H-NMR spectra with a JEOL SNM-FX 100 spectrometer for solutions in $CDCl_3$. The chemical shift are reported in δ (internal TMS). The mass spectra were recorded with a Hitachi RMU-7M double-focusing mass spectrometer at 70 eV. The analytical GLC determination was carried out with a Shimadzu GC-4CPF apparatus equipped with a 10% Silicone GE SE-30 column (4 mm × 2 m) and operated in programmed-temperature mode (80→200 °C, 8 °C/min).

Materials. 2-(Trimethylsilylmethyl)pyridine **1** was prepared by a method reported previously.[1]

Preparation of 2-Phenacylpyridine **3**. A method has been reported in Ref. 1.

Quenching the Reaction of **1** *with* **2**. The reaction was performed in the same way as the preparation of **3**, and the reaction mixture was quenched by the following three methods, before being analyzed by means of IR, GLC, and ^{1}H-NMR (without purification, except for method A). The results are summarized in Table 1.

Method A: A solution of butyllithium (8.6 g, 0.02 mol) in hexane was added to a solution of diisopropylamine (2.0 g, 0.02 mol) in THF (54 ml) at −75 °C with stirring under nitrogen. To the solution, 0.02 mol of **1** was added slowly and stirred for an additional 10 min. The mixture was treated with a THF solution of **2** (0.02 mol), and stirred for 1 h at −75 °C and for 2 h at room temperature. The reaction mixture was quenched with 50 ml of water at 0 °C. The crude product thus obtained was distilled under reduced pressure. Yield, 74% (the mixture of (*E*)-1-phenyl-2-(2-pyridyl)-1-(trimethylsilylamino)ethene **4** and the *Z*-isomer **5**, **4** : **5** = 10 : 80 by GLC and 43 : 57 by ^{1}H-NMR), bp 125.2—130 °C/1.0 mmHg (1 mmHg≈133.322 Pa). An attempt to separate **5** from **4** by column chromatography on Al_2O_3 (neutral) resulted in failure because of hydrolysis of **4** and **5** during the operation. IR (neat) 3470 (ν_{NH}), 1630 ($\nu_{C=C}$ of **4**), 1620 ($\nu_{C=C}$ of **5**), 1253 (δ_{SiCH_3}), and 930 (ν_{Si-N}) cm^{-1}; MS (70 eV) *m/z* (rel intensity) 270 (M+2, 1.0), 269 (M+1, 4.1), 268 (M$^+$, 14.9), 267 (M−1, 8.2), 256 (1.0), 255 (6.2), 254 (24.0), 253 (M−CH_3, 100), 197 (2.3), 196 (15.9), 195 (M−Si$(CH_3)_3$, 35.1), 150 (9.7), 132 (8.4), and 73 (28.1); ^{1}H-NMR δ 0.04 (5.14H, s, Si$(CH_3)_3$ of **5**), 0.12 (3.86H, s, Si$(CH_3)_3$ of **4**), 5.23 (0.57H, s, CH= of **5**), 5.46 (0.43H, s, CH= of **4**), 6.6—8.35 (9H, ABCX system for 2-Py-H and m for Ph-H), 7.85 (0.43H, b, NH of **4**) and 9.62 (0.57H, b, NH of **5**). Found: C, 72.32; H, 7.50; N, 10.45%; *m/z* 268.1385. Calcd for $C_{16}H_{20}N_2Si$: C, 71.59; H, 7.51; N, 10.44%; M$^+$, *m/z* 268.1393.

Method B: The reaction was performed on a smaller scale than in method A (**1**, 3 mmol). After stirring for 5 min at −75 °C, the reaction mixture was quenched with aq THF (H_2O : THF = 1 : 2 v/v, 10 ml) at −75 °C. The crude product contained the unreacted **1** and **2**. IR (neat) 1632 ($\nu_{C=C}$ of **4**), 1620 ($\nu_{C=C}$ of **5**), 1255 (δ_{SiCH_3}), and 930 (ν_{Si-N}) cm^{-1}; ^{1}H-NMR δ 0.14 (s, Si$(CH_3)_3$ of **4**), 5.21 (s, CH= of **5**), and 5.43 (s, CH= of **4**), 6.6—8.4 (ABCX system for 2-Py-H and m for Ph-H), 7.8 (b, NH of **4**), and 9.6 (b, NH of **5**).

Method C: The reaction was performed on the same scale as in method B. After stirring for 30 min at −75 °C, the reaction mixture was quenched with 2 ml of glacial acetic acid in THF (7 ml) and stirred for 1 h at −75 °C. The resultant white precipitate (CH_3COOLi) was removed by filtration under nitrogen atmosphere. The filtrate was concentrated, and excess acetic acid and volatile products were removed under reduced pressure below 40 °C. All these operations were performed under nitrogen atmosphere to prevent the product from undergoing acidic hydrolysis. The residue was washed with 2 M NaOH to remove any trace of acetic acid (it was found that the product **4** did not change during the washing). IR (neat) 1635 ($\nu_{C=C}$ of **4**), 1240 (δ_{SiCH_3}), and 930 (ν_{Si-N}) cm^{-1}; ^{1}H-NMR δ 0.11 (s, Si$(CH_3)_3$ of **4**) and 5.48 (s, CH= of **4**), 6.6—8.4 (ABCX system for 2-Py-H and singlet-like Ph-H), and 7.9 (b, NH of **4**).

Acidic Hydrolysis of **4** *and* **5**. The mixture of **4** and **5** (167 mg) was dissolved in ether (30 ml), and shaken with 2 M HCl (13 ml) for 10 min at room temperature. After washing with ether, the aq. phase was made alkaline (pH 13) with Na_2CO_3, and completely extracted with ether. Both the enamines **4** and **5** were quantitatively converted to **3**.

The present work was partially supported by a Grant-in-Aid for Scientific Research (No. 56750604) from the Ministry of Education, Science and Culture and by the Saneyoshi Foundation.

Selective Oxidation of Sulfides to Sulfoxides by a Polymeric Reagent Electrochemically Generated and Recycled *in Situ*

Jun-ichi Yoshida, Hiroshi Sofuku, and Nariyoshi Kawabata*

Department of Chemistry, Faculty of Polytechnic Science, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606

(Received August 11, 1982)

Synopsis. A polymeric reagent electrochemically generated from crosslinked poly(4-vinylpyridine) hydrobromide was found to oxidize sulfides to give sulfoxides in high yields. The exhausted polymeric reagent was regenerated by continuous electrochemical oxidation *in situ*.

Recently we have reported a facile oxidation of alcohols by a polymeric reagent electrochemically generated from crosslinked poly(4-vinylpyridine) hydrobromide (PVP·HBr).[1,2] Since the exhausted polymeric reagent is regenerated by continuous electrochemical oxidation in situ, the method does not consume any chemical oxidant and does not produce any contaminating reduced product. Based on this methodology, we have begun a program to study the selective oxidation of a variety of functional groups. In this note, we wish to report that the polymeric reagent electrochemically generated from PVP·HBr acts as an effective reagent for the selective oxidation of sulfides to sulfoxides.

$$RSR' + H_2O \xrightarrow[PVP\cdot HBr/CH_3CN]{\text{electric current}} R\overset{O}{\overset{\|}{S}}R' + H_2 \quad (1)$$

In the case of alcohol oxidation, the substrate undergoes a net oxidative dehydrogenation (Eq. 2). The present reaction of sulfides provides another application of the method in which water acts as the primary oxidant in the net sense (Eq. 3).

$$(\text{substrate})H_2 \xrightarrow[PVP\cdot HBr]{\text{electric current}} (\text{substrte}) + H_2 \quad (2)$$

$$(\text{substrate}) + H_2O \xrightarrow[PVP\cdot HBr]{\text{electric current}} (\text{substrate})O + H_2 \quad (3)$$

The sulfide oxidation reaction can be carried out by either the ex-cell method or the in-cell method. In the case of the ex-cell method, the polymeric oxidizing reagent was prepared by passing the electric current (4.5 mF) through PVP·HBr beads (3.00 wet g, containing 5.10 mmol of HBr) in acetonitrile as reported previously.[1] The polymeric reagent was separated by filtration and allowed to react with dibutyl sulfide (2.30 mmol) in acetonitrile at room temperature to afford dibutyl sulfoxide (0.64 mmol).

The in-cell method is more convenient. The electric current was passed through a mixture of a catalytic amount of PVP·HBr, (3.00 wet g) containing 4.94 mmol of HBr, dibutyl sulfide (20.0 mmol) and acetonitrile (3.0 ml) in an undivided cell at 30 °C. After 2.4 F/mol of electricity (based on the sulfide) was passed, GLC analysis of the reaction mixture showed the formation of dibutyl sulfoxide in a quantitative yield. During the course of the reaction hydrogen gas evolved in a quantitative yield, indiacting that water acts as a primary oxidant. The result indicates the efficient electrochemical regeneration of the exhausted polymeric reagent *in situ*. After removal of the resin beads by filtration, the product was isolated by bulb-to-bulb distillation (95% yield). The oxidation of other sulfides also proceeded smoothly under the similar conditions to provide the corresponding sulfoxides in good to excellent yields as

Table 1. Oxidation of sulfides by a polymeric reagent electrochemically generated and recycled *in situ*[a]

Sulfide	Sulfide/Br$^-$ [b]	Electricity F/mol [c]	Product	Yield[d] %

	4.14	2.20		(96)

a) Reactions were carried out with 20.0 mmol of sulfides and 3.00 wet g of PVP·HBr beads in 3.0 ml of acetonitrile at 30°C. b) The molar ratio of sulfide to the bromide ion contained in PVP·HBr. c) Based on the sulfide. d) Isolated yield, based on the sulfide. Yields determined by GLC analysis are given in parentheses. e) The second use of the resin. f) The third use of the resin. g) PVP·HCl was used instead of PVP·HBr. h) Significant amount of dibutyl sulfone was produced as a by-product.

shown in Table 1.

The resin beads are reusable in the electrochemical oxidation. In this case the resin beads were separated from the reaction mixture by filtration, washed with organic solvents, soaked in water, filtered to remove excess water, and used for the electrochemical oxidation of sulfide. The activity of the resin beads did not decrease after the second use.

It is noteworthy that when crosslinked poly(4-vinylpyridine) hydrochloride (PVP·HCl) was used instead of PVP·HBr, the yield of the sulfoxide was lower and significant amount of the sulfone was produced. Thus, the polymeric reagent electrochemically generated from PVP·HCl has higher oxidizing ability than that from PVP·HBr. This is probably due to the higher oxidation potential of the chloride ion than that of the bromide ion.

Although there are several known procedures for the selective oxidation of sulfides to sulfoxides[3] involving either supported reagents[4] or electrochemical methods,[5] the present method is a useful alternative to the conventional methods due to the following features and advantages. (1) The reaction is highly selective and sulfides essentially free from sulfone are obtained in high yields. (2) The procedure is quite simple and the product can be isolated by filtration followed by simple distillation. (3) The resin beads are reusable. (4) Only the electricity and water are consumed during the reaction.

The mechanism of this reaction will be discussed elsewhere.

Experimental

General. A Trio Model PR-653 regulated DC power supply or Kikusui Model PAB-32-0.5 regulated DC power supply was used as a source of electric current. ^{1}H NMR spectra were recorded on a Varian T-60A spectrometer in carbon tetrachloride using tetramethylsilane as an internal standard. IR spectra were recorded on a Hitachi Model 215 grating spectrophotometer. GLC analysis were performed on a Shimadzu GC-4B or GC-4C gas chromatograph.

Materials. Crosslinked poly(4-vinylpyridine) hydrobromide (PVP·HBr) and crosslinked poly(4-vinylpyridine) hydrochloride (PVP·HCl) were prepared as reported previously.[1] Other chemicals were used as obtained commercially.

Electrochemical Oxidation of Sulfides. The reactions were carried out in an undivided cell equipped with two platinum electrodes ($10\times10\times0.5$ mm^3) parallel to each other with about 10 mm of space between them. A sulfide (20 mmol) and PVP·HBr (3.0 g, wet) were allowed to react in 3.0 ml of acetonitrile with a constant electric current (50 mA) at 30 °C under slow stirring. The crude reaction mixture was analyzed by GLC. The mixture was filtered and the filtrate was dried over Na_2SO_4. After evaporation of the solvent, bulb-to-bulb distillation of the residue yielded the products, which were identified by comparison of their IR and ^{1}H NMR spectra with those of authentic materials.

We thank Koei Chemical Co., Ltd, for gifts of 4-vinylpyridine and divinylbenzene. We are also grateful to the Ministry of Education, Science and Culture for a Grant-in-Aid for Scientific Research No. 56750598 for partial support of this work.

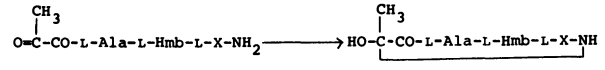
Cyclic Peptides. XV. Synthesis of [4-α-Hydroxyalanine]AM-toxin II

Kosaku NODA,* Junko NAKASHIMA, Sannamu LEE,† and Nobuo IZUMIYA†
Laboratory of Biochemistry, Fukuoka Women's University, Kasumigaoka, Higashi-ku, Fukuoka 813
†*Laboratory of Biochemistry, Faculty of Science, Kyushu University, 33, Hakozaki, Higashi-ku, Fukuoka 812*
(Received August 12, 1982)

Synopsis. An AM-toxin II analog, *cyclo*(–L-Ala[1]–L-Hmb[2]–L-App[3]–Hyala[4]–), with an α-hydroxyalanine (Hyala) residue in place of dehydroalanine in position 4 was synthesized from pyruvoyl–L-Ala–L-Hmb–L-App–amide (Hmb, 2-hydroxy-3-methylbutanoic acid; App, 2-amino-5-phenylpentanoic acid) by intramolecular condensation between the pyruvoyl and carbamoyl groups. The synthetic peptide did not show the toxic activity of AM-toxin II.

The cyclotetradepsipeptide AM-toxins are phytotoxic metabolites of *Alternalia mali* causing necrosis on apple leaves. The structure of AM-toxin II[1] was shown to be *cyclo*(–L-Ala[1]–L-Hmb[2]–L-App[3]–ΔAla[4]–).[2] Previously, we attempted the synthesis of their analogs with L-Phe or L-Tyr residue replacing the uncommon aromatic amino acid in position 3 by the intramolecular condensation of pyruvoyl–L-Ala–L-Hmb–L-Phe–NH_2 (**1b**) or –L-Tyr–NH_2 (**1c**).[3] The product was, however, identified to be cyclotetrapeptide **2b** or **2c** containing a Hyala residue instead of ΔAla expected (Fig. 1), and did not show the activity of AM-toxins. The inactivity of **2b** or **2c** is not attributed to the replacement of ΔAla by Hyala, because [L-Phe[3]]AM-toxin[4] and [L-Tyr-(Me)[3]]AM-toxin[5] were also almost inactive.

In order to examine the influence of substitution of ΔAla by Hyala in position 4 on the activity, we have synthesized [Hyala[4]]AM-toxin II (**2a**). The Hyala residue was expected to contribute toward the toxic activity, because it might be a possible precursor of



1a, X=App **2a**, X=App
1b, X=Phe **2b**, X=Phe
1c, X=Tyr **2c**, X=Tyr

Fig. 1. Intramolecular condensation of pyruvoyl-tripeptide amides.

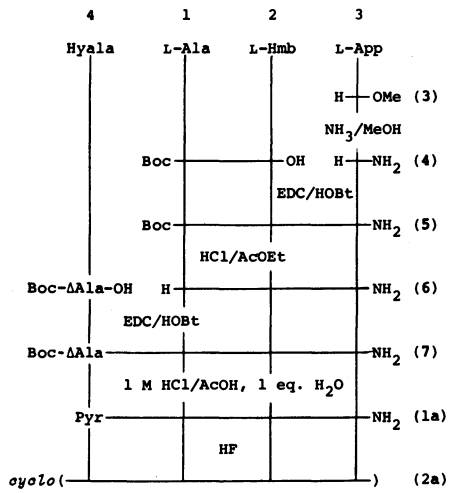


Fig. 2. Synthetic route for [Hyala[4]]AM-toxin II (**1a**).

ΔAla, and an AM-toxin I analog with L-Ser[4], the structural isomer of Hyala, possessed a recognizable activity.[6]

Figure 2 shows the reaction route for the synthesis. The tripeptide, Boc–L-Ala–L-Hmb–L-App–NH_2 (**5**), was prepared by coupling of Boc–L-Ala–L-Hmb–OH and L-App amide (**4**) by the EDC method.[7] Removal of the Boc group of **5** followed by coupling with Boc–ΔAla–OH afforded tetrapeptide amide **7**, which was converted to pyruvoyl-tripeptide amide **1a** by the treatment with HCl in AcOH in the presence of an equivalent amount of water. Treatment of **1a** with HF cyclized the peptide intramolecularly with the formation of Hyala residue to give the desired peptide **2a**. Dimer and polymer formation was not observed in this reaction. After purification by chromatography with silicic acid, the homogeneity and identity of the product were established by thin-layer chromatography, mass spectroscopy and ^{1}H-NMR spectroscopy. The singlet peak assingned for the α-OH of Hyala residue in the NMR data suggests that the Hyala is of a single optical configuration of either L or D.

Bioassay showed that, even at high concentration, **2a** did not show the toxic activity for the induction of necrosis on apple leaves. Thus, replacement of the ΔAla residue by Hyala eliminated the biological activity. The possible conversion of serine residue to ΔAla in the biological system was suggested from the previous results that [L-Ala[4]]AM-toxin I was inactive[4] while [L-Ser[4]]analog was active.[6] The present data indicates that there is no possibility of such a conversion of the Hyala residue to ΔAla in the biological system. The chemical conversion of the Hyala residue to ΔAla is under investigation.

Experimental

Thin layer chromatography was carried out on silica gel G (Merck) with the following solvent systems: R_f^1, $CHCl_3$–MeOH (9 : 1); R_f^2, $CHCl_3$–MeOH–AcOH (85 : 10 : 5); R_f^3, *n*-BuOH–AcOH– pyridine–H_2O (4 : 1 : 1 : 2). Optical rotations were measured with a Union polarimeter PM-201, Mass spectra were taken on a Hitachi RMS-4 mass spectrometer and NMR spectra on a JEOL LNM PS-100 spectrometer.

H–L-App–OMe·HCl (3·HCl). This compound was obtained by the treatment of H–L-App–OH[8] with MeOH and $SOCl_2$ according to the procedure described in the literature;[9] yield, 96%; mp 115 °C;$[\alpha]_D^{25}$ +21.5° (*c* 2, EtOH); R_f^1 0.23; R_f^2 0.54.

Found: C, 59.08; H, 7.39; N, 5.83%. Calcd for $C_{12}H_{18}N_2O_2Cl$: C, 59.13; H, 7.44; N, 5.75%.

H–L-App–NH_2·HCl (4·HCl). This compound was prepared from **3**·HCl by the treatment with saturated NH_3 in MeOH according to the literature;[10] yield, 82%; mp 200 °C; $[\alpha]_D^{25}$ +17.0° (*c* 1, EtOH); R_f^2 0.05; R_f^3 0.67.

Found: C, 57.70; H, 7.55; N, 12.28%. Calcd for $C_{11}H_{17}N_2OCl$: C, 57.76; H, 7.49; N, 12.25%.

Boc-L-Ala-L-Hmb-L-App-NH_2 (5). Boc-L-Ala-L-Hmb-OH[6] (1.45 g, 5 mmol), **4·HCl** (1.14 g, 5 mmol), HOBt (1.35 g, 10 mmol) and NEt_3 (0.70 ml, 5 mmol) was dissolved in DMF (10 ml). To the solution, EDC·HCl (1.15 g, 6 mmol) was added at 0 °C. The mixture was stirred for 1 h at 0 °C and overnight at room temperature, and evaporated *in vacuo*. The residue was treated with a mixture of water and AcOEt. The organic layer was washed with 4% $NaHCO_3$ and 10% citric acid, dried (Na_2SO_4), and evaporated. The product was recrystallized from AcOEt–ether–petroleum ether; yield, 1.67 g (72%); mp 94—95 °C; $[\alpha]_D^{25}$ −40.0° (*c* 1, EtOH); R_f^1 0.40; R_f^2 0.63.

Found: C, 62.33; H, 8.16; N, 9.17%. Calcd for $C_{24}H_{37}N_3O_6$: C, 62.18; H, 8.05; N, 9.07%.

Boc-ΔAla-L-Ala-L-Hmb-L-App-NH_2 (7). Compound **5** (963 mg, 2.1 mmol) was treated with 2 M HCl in AcOEt (25 ml) for 1 h at room temperature, and the mixture was concentrated *in vacuo*, the concentration being repeated twice after addition of AcOEt. The solid residue was washed with ether by means of decantation, and dried in a desiccator. The hydrochloride of H-L-Ala-L-Hmb-L-App-NH_2 (**6·HCl**) was obtained as a powder. To the solution of **6·HCl**, Boc-ΔAla-OH[3] (374 mg, 2 mmol), HOBt (338 mg, 2.5 mmol) and NEt_3 (0.28 ml, 2 mmol) in DMF (10 ml) was added EDC·HCl (383 mg, 2 mmol). The mixture was stirred for 1 h at 0 °C and overnight at room temperature, and evaporated. The residue was treated with a mixture of 20% NaCl and AcOEt. The organic layer was washed with 4% $NaHCO_3$ and saturated NaCl, dried (Na_2SO_4), and evaporated. The product was recrystallized from MeOH–ether–petroleum ether; yield, 643 mg (60%); mp 95—97 °C; $[\alpha]_D^{25}$ −21.0° (*c* 1, EtOH); R_f^1 0.41; R_f^2 0.64.

Found: C, 60.68; H, 7.62; N, 10.47%. Calcd for $C_{27}H_{40}N_4O_7$: C, 60.88; H, 7.57; N, 10.52%.

Pyr-L-Ala-L-Hmb-L-App-NH_2 (1a). Compound **7** (533 mg, 1 mmol) was dissolved in 1 M HCl in AcOH (5 ml) containing an equivalent of water (18 μl). After being kept for 10 min at 60 °C, the solution was evaporated. The residual solid was collected with the aid of ether; yield, 422 mg (96%). This compound was used in the cyclization reaction without further purification.

cyclo(-L-Ala-L-Hmb-L-App-Hyala-) (2a). A solution of **1a** (217 mg, 0.5 mmol) in anhydrous HF (5 ml) was stirred for 1 h at 0 °C. After HF was evaporated, the residual solid was dissolved in $CHCl_3$ and the solution chromatographed on silicic acid (Mallinckrodt, 100 mesh) using a column (1.2 cm × 10 cm) and a solvent system of $CHCl_3$–AcOEt (1 : 1). The main fractions (6—16 ml) were collected and evaporated. The residue was collected with the aid of ether; yield, 160 mg (74%); mp 124—126 °C; $[\alpha]_D^{25}$ −44.0° (*c* 1, DMF); R_f^1 0.39; R_f^2 0.47. NMR (signals arising only from Hyala residue are given) (DMSO-d_6) δ=2.38 (3H, s, HyalaCH$_3$), 7.04 (1H, s, HyalaOH), 7.35 (1H, s, HyalaNH).

Found: C, 60.77; H, 7.31; N, 9.63%; *m/e* 433. Calcd for $C_{22}H_{31}N_3O_6$: C, 60.95; H, 7.21; N, 9.69; M^+, 433.

Biological Assay. Biological assays on apple leaves (susceptible cultivar, Indo) were carried out as described previously.[6] Product **2a** did not show the toxicity at concentration up to 100 μg/ml, whereas synthetic or natural AM-toxin II showed at 0.02 μg/ml.

Synopsis. Cyclohepta[4,5]pyrrolo[2,3-*d*]thiazole and its amino derivatives were obtained in a few steps by starting with 2-amino-1-azaazulene.

1-Azaazulenes(cyclohepta[*b*]pyrroles) are important and interesting compounds not only as non-benzenoid analogues of indoles and isomers of quinolines, but also as azulenoid heterocyclic compounds. Several azulenoid heterocyclic compounds which consist of the 1-aza-azulene ring condensed with heterocyclic aromatics are known.[1] In a previous paper,[2] the preparation of cyclohepta[*b*]thieno[3,2-*d*]pyrrole was reported.

We now wish to report the synthesis of cyclohept[4,5]-pyrrolo[2,3-*d*]thiazole and its amino derivatives. 2-Amino-1-azaazulene (**1**),[3] on treatment with thiocyanogen bromide prepared by adding bromine to a solution of potassium thiocyanate in acetic acid and filtering off the potassium bromide, gave 2-amino-3-thiocyanato-1-azaazulene (**2**). When this compound (**2**) was cyclized by the action of acetic anhydride at the boiling point, 2-acetylaminocyclohepta[4,5]pyrrolo[2,3-*d*]thiazole (**3**) was obtained in a 78% yield. Compound (**3**), when boiled with dilute hydrochloric acid, was converted to 2-aminocyclohepta[4,5]pyrrolo[2,3-*d*]thiazole (**4**). On treatment with acetic anhydride, **4** afforded **3**. On the other hand, in the case of the treatment of **2** with concentrated hydrochloric acid in ethanol, disulfide (**5**) was obtained in an 84% yield. The structure of **5** was established on the basis of the spectral data and the results of elemental analysis (see Experimental). The mass spectrum of **5** is similar to that of 2-amino-1-azaazulene (**1**) in its fragmentation pattern below *m/e* 144. Compound **4** was diazotized with a concentrated aqueous sodium nitrite solution in 85% phosphoric acid, followed by treatment with phosphinic acid to give cyclohepta[4,5]pyrrolo[2,3-*d*]thiazole (**6**) as reddish purple prisms in a 41% yield.

Experimental

All the melting points are uncorrected.

2-Amino-1-azaazulene (1). A solution of 2-chloro-1-azaazulene (6.18 g) in dry ethanol (130 ml) was saturated with ammonia and heated at 170 °C in a sealed tube for 64 h. After cooling, the reaction mixture was concentrated, diluted with water, neutralized with a 10% sodium hydroxide solution, and extracted with chloroform. The extract was dried, the solvent was removed, and the residue was chromatographed on a silica-gel column. From the methanol effluent, **1** was obtained as golden leaves (4.08 g, 75%); mp 177—178 °C (lit. 3 mp 171—172 °C); ^{1}H NMR (100 MHz, in $CDCl_3$) δ=5.54 (2H, bs, NH_2), 6.54 (1H, s, H-3), 7.29—7.74 (3H, m, H-5,6,7), and 7.88—8.12 (2H, m, H-4,8); MS *m/e* 144 (M^+), 117, 89, and 58.5. (Found: C, 75.25; H, 5.72; N, 19.42%).

2-Amino-3-thiocyanato-1-azaazulene (2). To a stirred solution of **1** (1.00 g) in acetic acid (25 ml), thiocyanogen bromide prepared from potassium thiocyanate (1.01 g) and bromine (1.45 g) in acetic acid (35 ml) was added, drop by drop. After stirring for 2.5 h, the reaction mixture was diluted with water and neutralized with a sodium carbonate solution. The resulting precipitate was filtered off and recrystallized from ethanol to give **2** as yellow prisms (1.17 g, 84%); mp 164 °C (decomp); IR (KBr) 3464, 3304, 2162, 1644, 1513, and 1500 cm^{-1}; UV(CH_3OH) 213 (log ε 4.19), 239 (4.07), 285 (4.54), 361 (3.86), and 426 nm (3.58). Found: C, 59.78; H, 3.41; N, 21.07; S, 16.05%. Calcd for $C_{10}H_7N_3S$: C, 59.68; H, 3.51; N, 20.88; S, 15.93%.

*2-Acetylaminocyclohepta[4,5]pyrrolo[2,3-*d*]thiazole (3).* *(a)*: A mixture of **2** (400 mg) and acetic anhydride (2.50 g) was refluxed for 3 h. After cooling, the reaction mixture was poured into water and neutralized with a sodium hydrogencarbonate solution. The resulting precipitate was filtered off, dried, and recrystallized from *N,N*-dimethylformamide to give **3** as purple micro needles (380 mg, 78%); mp 285 °C (decomp); IR (KBr) 3304, 3157, 2912, 1695, 1515, and 1501 cm^{-1}; UV (CH_3OH) 217 (log ε 3.78), 244 (3.64), 303 (4.36), 325 (4.16), 352 (3.60), and 368 nm (3.63). Found: C, 59.48; H, 3.74; N, 17.52; S, 13.26%; M^+, 243. Calcd for $C_{12}H_9ON_3S$: C, 59.24; H, 3.73; N, 17.27; S, 13.18%; M, 243.

(b): A mixture of **4** (100 mg) and acetic anhydride (1.0 ml) was refluxed for 30 min. The reaction mixture was then treated by a method similar to that used for (*a*). Recrystallization from *N,N*-dimethylformamide yielded purple micro needles (80 mg, 66%) of **3** (mp 285 °C), which was identified by a mixed-melting-point determination and by a comparison of its infrared spectrum with that of the sample prepared by means of Method (*a*).

*2-Aminocyclohepta[4,5]pyrrolo[2,3-*d*]thiazole (4).* A mixture of **3** (280 mg) and 6 mol dm^{-3} hydrochloric acid (14 ml) in ethanol was heated at 110 °C for 3 h. After the removal of the solvent, water (50 ml) was added to the residue. When the solution was made slightly basic with a 10% sodium hydroxide aqueous solution, a precipitate separated out. The precipitate was collected by filtration, washed with water, and recrystallized from ethanol to give purple prisms (220 mg, 93%); mp 231 °C (decomp); IR(KBr) 3389, 3272, 3059, 1498, 1469, 1428, and 1407 cm^{-1}; UV(CH_3OH) 216 (log ε 4.63), 237 (4.45), 298 (5.09), 327 (4.98), 361 (4.21), 378 (4.10), and 493 nm (3.85). Found: C, 59.45; H, 3.40; N, 20.73; S, 15.97%. Calcd for $C_{10}H_7N_3S$: C, 59.68; H, 3.51; N, 20.88; S, 15.94%.

2,2'-Diamino-3,3'-dithiodi(1-azaazulene) (5). To a suspension of **2** (260 mg) in ethanol (26 ml), concentrated hydro-

chloric acid (2.6 ml) was added, after which the mixture was refluxed for 10 h. The reaction mixture was evaporated *in vacuo*, and the residue was diluted with water. The solution was then neutralized with a sodium carbonate aqueous solution. The resulting precipitate was filtered off, dried, and recrystallized from *N,N*-dimethylformamide to give red micro needles (190 mg, 84%); mp 255 °C (decomp); IR(KBr) 3457, 3382, 3288, 1640, and 1500 cm^{-1}; UV(CH_3OH) 216 (log ε 4.48), 280 (4.75), and 426 nm (3.92); MS *m/e* 350 M^+, 175, 144, 117, 89, and 58.5. Found: C, 61.55; H, 4.04; N, 15.94; S, 18.16%. Calcd for $C_{18}H_{14}N_4S_2$: C, 61.69; H, 4.03; N, 15.99; S, 18.30%.

*Cyclohepta[4,5]pyrrolo[2,3-d]thiazole (**6**).* A solution of **4** (1.00 g) in 85% phosphoric acid was cooled to −10 °C, after which a concentrated aqueous solution of sodium nitrite (857 mg) was slowly stirred in below the surface at such a rate as to maintain the temperature below −5 °C. To the resulting solution, prechilled (0 °C) 50% phosphinic acid was vigorously stirred in, drop by drop. The reaction mixture was then allowed to warm to room temperature with continued stirring for 1 h and then diluted with water. The resulting solution was made alkaline by adding a potassium carbonate aqueous solution, and extracted with benzene. The benzene layer was dried over anhydrous sodium sulfate and evaporated under reduced pressure. The residue was chromatographed on a silica-gel column with benzene–ethyl acetate (3 : 7). The reddish purple effluent was freed from the solvent to give **6** (374 mg, 41%) as reddish purple prisms; mp 142.5—143.5 °C; IR(KBr) 3050, 1585, 1487, 1463, and 1435 cm^{-1}; UV(cyclohexane 252 (log ε 3.96), 296 (4.80), 312 (4.10), 343 (3.80), 359 (3.86), 525 (2.90), 546 (2.85), 563 (2.84), 588 (2.61), 608 nm (2.58); ^1H NMR (90 MHz, in $CDCl_3$) δ=7.6—8.0 (3H, m, H-6,7,8), 8.64 (1H, dm, J=8.8 Hz, H-9), 8.8—8.9 (1H, m, H-5), and 9.39 (1H, s, H-2); ^{13}C NMR (22.5 MHz, in $CDCl_3$) δ=179.6(C-3a), 163.2(C-2), 161.9(C-4a), 137.9(C-5), 137.7(C-9a), 137.5(C-7), 133.8(C-9), 130.1(C-6), 128.5(C-8), and 115.9(C-9b). Found: C, 64.44; H, 3.25; N, 15.13; S, 17.15%; M^+, 186. Calcd for $C_{10}H_6SN_2$: C, 64.49; H, 3.25; N, 15.05; S, 17.22%; M, 186.

The authors wish to express their thanks to Professor Yasuo Iwanami of Keio University and Dr. Takeshi Inagaki of the Nitto Chemical Industry Co., Ltd., for their measurements and analyses of the mass spectra. We are also grateful to the Sankyo Co., Ltd., for doing the elemental analyses.

(Received August 21, 1982)

Synopsis. *N*-Tosylalkanesulfenamides have been prepared *via* the reactions of alkyl halides with 2-methyl-2-propanethiolate followed by *S*-imination with chloramine T and the thermolysis. This method comprises the use of selective elimination of *t*-butyl group in *S*-alkyl-*S*-*t*-butylsulfilimines.

Sulfenamides are useful compounds as synthetic intermediates, sulfenating agents, and as industrial additives such as accelerators in rubber vulcanization, pesticides, fungicides, and radioprotective agents.

Up to the present various kinds of sulfenamides have been prepared. Among them, only a few examples of alkanesulfenamides[1] have been synthesized because of their instability and unavailability of the corresponding sulfenyl source.

On the other hand, the thermolysis of the sulfilimines which have one or more hydrogens at β-carbon has been known to give an effective, preparative route to olefins[2] and vinyl monomers.[3] Since the thermolysis gives arenesulfenamides in good yields at the same time, it seems to be an effective route to alkanesulfenamides. No active attempt to prepare labile alkanesulfenamides, however, has been made. Thus, to prepare alkanesulfenamides by the thermolysis under mild conditions, the use of *t*-butyl group being liable to eliminate as isobutylene has been undertaken.

For this purpose *S*-alkyl-*S*-*t*-butyl-*N*-tosylsulfilimines were prepared and thermolyzed as follows. First alkyl *t*-butyl sulfides were prepared by the reaction of alkyl halides (**1**) with 2-methyl-2-propanethiol in a phase transfer system. Subsequently sulfides (**2**) were allowed to react with chloramine T (CT) to give *S*-alkyl-*S*-*t*-butyl-*N*-tosylsulfilimines (**3**) in high yields. The structures of sulfilimines **3** were confirmed by IR and NMR spectra and elemental analyses. The results obtained are given in Table 1.

$$\underset{\mathbf{1}}{RX} + t\text{-BuSH} \xrightarrow{NaOH/H_2O\text{-}PTC} \underset{\mathbf{2}}{RS\text{-}t\text{-}Bu} \xrightarrow{CT} \underset{\mathbf{3}}{\overset{R}{\underset{t\text{-}Bu}{\diagdown}}\!\!>S{=}NTs}$$

The thermolysis of **3** was carried out in methanol (at 40 °C or 60 °C), benzene (under refluxing) or without solvent (at 10 °C above mp of **3**). The thermolysis in refluxing benzene gave the best result, affording *N*-tosylalkanesulfenamide (**4**) accompanied with *N*-tosyl-2-methyl-2-propanesulfenamide (**5**) in some cases.

$$\underset{\mathbf{3}}{\overset{R}{\underset{t\text{-}Bu}{\diagdown}}\!\!>S{=}NTs} \xrightarrow{\Delta} \underset{\mathbf{4}}{RS\text{-}NHTs} \text{ or (and) } \underset{\mathbf{5}}{t\text{-}BuS\text{-}NHTs}$$

Thus *S*-*t*-butyl-*S*-ethyl-*N*-tosylsulfilimine (**3a**) was thermolyzed in refluxing benzene for 4 h to give *N*-tosylethanesulfenamide (**4a**) quantitatively. Similarly the other sulfilimines, *S*-*t*-butyl-*S*-propyl-, *S*-butyl-*S*-*t*-butyl-, and *S*-*t*-butyl-*S*-hexyl-*N*-tosylsulfilimines (**3b**, **3c**, and **3d**), were thermolyzed to give the corresponding *N*-tosylalkanesulfenamides, *N*-tosyl-1-propane-, -2-butane-, and -1-hexanesulfenamides (**4b**, **4c**, and **4d**) in quantitative yields, respectively. These sulfenamides were almost pure as shown by their sharp mp's and spectral data without purification. These are so stable as to be stored in sealed bottles at room temperature or preferably at lower temperature in an ice box. With *S*-*t*-butyl-*S*-isopropyl-*N*-tosylsulfilimine (**3e**), two kinds of sulfenamides, *N*-tosyl-2-propane- and 2-methyl-2-propanesulfenamides (**4e** and **5**), were obtained as a mixture with the molar ratio (**4e** to **5**) of about 5, which was determined by NMR and mass spectroscopies. These results are given in Tables 2 and 3. As shown in Table 2, the selectivity of eliminating either *t*-butyl or alkyl group is remarkably exclusive for the former.

The procedure mentioned above may be an effective method, starting from alkyl halides, to prepare alkanesulfenamides *via* alkyl *t*-butyl sulfides and then sulfilimines, in good yields, and further a convenient route to other *N*-substituted alkanesulfenamides by the exchange reaction with amines.[4]

Experimental

Preparation of 3. *General Procedure*: To a stirring solution of chloramine T (11 mmol) in 30 ml of MeOH was added 10 mmol of **2**, which was prepared from the corresponding halide **1**, 2-methyl-2-propanethiol and NaOH in water containing tetrabutylammonium bromide (1%), keeping the temperature below 20 °C (0 °C for **3e**). After 3—4 h stirring the resulting mixture was evaporated to dryness *in vacuo*. The organic part in the residue obtained was dissolved in 30 ml of $CHCl_3$, and the solution was washed with water and dried over anhydrous Na_2SO_4. After the dried solution was evaporated to dryness *in vacuo*, the resulting viscous residue was triturated with ether until the white solid of **3** was deposited. Crude **3** was collected by filtration and purified by reprecipitation from CH_2Cl_2 and ether.

Thermolysis of 3. *General Procedure*: To 20 ml of dried benzene was added 2 mmol of **3**. The resulting mixture was heated under refluxing in a stream of nitrogen. After 4 h the solution obtained was evaporated to dryness under reduced pressure to give white solid of **4**. Sulfenamide **4** obtained in such a manner was almost pure without purification. For the purification of crude **4**, reprecipitation using dried ether and hexane was taken.

A Convenient Synthesis of 2-Phenylbenzo[*b*]thiopyrylium Perchlorates

Hiroyuki NAKAZUMI,* Tamio UEYAMA, Takashi ENDO, and Teijiro KITAO
Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka 591
(Received August 26, 1982)

Synopsis. 2-Phenylbenzo[*b*]thiopyrylium perchlorates were conveniently prepared in good yields by reduction of 2-phenyl-4*H*-benzo[*b*]thiopyran-4-ones (thioflavones) with aluminium hydride, followed by treatment with acid in the presence of 2,3-dichloro-5,6-dicyano-*p*-benzoquinone.

Flavonoid derivatives are well known to be pharmacologically active compounds. It has been reported that 2-phenylbenzo[*b*]pyrylium salts which are an important group of naturally occurring coloring matters, termed anthocyanins,[1] are significantly active in tumour-inhibiting tests.[2] 2-Phenylbenzo[*b*]thiopyrylium salts (**4a—d**) are the interesting thio analogs of anthocyanins, and a new group of pharmacologically active compounds. There are only a few known examples of synthesis of the title compounds.[3,4] For example, compound **4a** has been prepared in low yield by reduction of 2-phenylthiochroman-4-one (**3**) in a several stage process from benzenethiol.[3] In this paper, we report a convenient method for the preparation of the title compounds (**4a—d**) from 2-phenyl-4*H*-benzo-[*b*]thiopyran-4-ones (thioflavones) (**1a—d**) which can be easily prepared from benzenethiols and ethyl benzoylacetates.[5]

1a, 2a, 4a: R=H
1b, 2b, 4b: R=5-OCH_3
1c, 2c, 4c: R=6-OCH_3
1d, 2d, 4d: R=7-OCH_3 Scheme 1.

We investigated the reduction of **1a** with various reagents to prepare the title compound (**4a**). The results are summarized in Table 1. We now found that reduction of **1a** with $LiAlH_4$ and $AlCl_3$ (1/1) gave quantitatively 2-phenyl-4*H*-benzo[*b*]thiopyran **2a** which was identified by means of its NMR spectrum. The use of only $LiAlH_4$ gave compound **2a** in low yield together with other products as 2-phenylthiochroman-4-one **3** (entries 3—5, Table 1). When $NaBH_4$ is used, no reduction product was obtained (entry 6). From these results, it was shown that in the reduction of thioflavone (**1a**) with $LiAlH_4$–$AlCl_3$ a carbonyl group at the 4-position was not converted to a hydroxyl group, but to a methylene group.

Table 1. Reduction of **1** (R=H) at 25 °C

Entry	Reagent	Solvent	Reaction time/min	Yield of **2a**[a] %

a) Isolated Yields. b) **1a** recovered (34%). c) Structures of other products are not assigned (a number of spots on TLC were observed). d) **1a**; 29% and **3**; 22%.

Treatment of a solution of **2a** in glacial acetic acid with 60% perchloric acid for 24 h at room temperature gave 2-phenylbenzo[*b*]thiopyrylium perchlorate **4a** and 2-phenylthiochroman **5** in 45% yield, respectively. In the presence of 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ), compound **4a** could be obtained selectively in 68% yield by treatment of **2a** with the same acid for 1 h at room temperature. In this reaction, it seems likely that compound **4a** is formed by elimination of a hydride ion from compound **2a**. Other new 2-phenylbenzo[*b*]-thiopyrylium salts (**4b—d**) could be obtained in high yield (81—89%) from thioflavones (**1b—d**) by the same reduction (entry 1), followed by treatment with acid in the presence of DDQ. The present method may be extended to the general synthesis of 2-phenylbenzo[*b*]-thiopyrylium perchlorates.

Thioflavones (**1a—d**) and the title compounds (**4a—d**) are currently being tested for antimicrobial activity.

Experimental

All the melting points are uncorrected. Proton NMR spectra were taken on a JEOL JNM-MH-100 spectrometer with tetramethylsilane as an internal standard. Elemental analyses were recorded on a Yanaco CHN recorder MT-2. Mass spectra were recorded on a Hitachi RMU-6E mass spectrometer operating at 80 eV.

2-Phenyl-4H-benzo[b]*thiopyran-4-ones (1a—d).* Compounds **1a** and **1c** were generally prepared by Bossert's method. **1a**: mp 125—127 °C (lit,[5] 124—127 °C), **1c**: mp 155—157 °C (lit,[5] 157 °C). Compounds **1b** (R=5-MeO) and **1d** (R=7-MeO) were obtained as follows; Reaction mixture which was prepared by Bossert's method (starting materials: *m*-methoxybenzenethiol and ethyl benzoylacetate) was chromatographed on silica gel using benzene/acetone (20/1) as an eluent to give **1b** (18%) and **1d** (33%). **1b**: mp 204—205 °C, ^{1}H-NMR($CDCl_3$): δ 3.97 (s, 3H), 6.90 (d, J=8 Hz, 1H), 7.08—7.23 (m, 2H), 7.38—7.68 (m, 6H), *m/e* (rel intensity): 268 (M^+, 100), 267 (37), 240 (29), 222 (52), 210 (26), Found: C, 71.62; H, 4.51%. Calcd for $C_{16}H_{12}O_2S$: C, 71.82; H, 4.34%. **1d**: mp 137—139 °C (lit,[5] 150 °C).

2-Phenyl-4H-benzo[b]*thiopyrans (2a—d).* To a stirred suspension at 25 °C of $LiAlH_4$ (0.19 g, 5 mmol) and $AlCl_3$ (0.66 g, 5 mmol) in THF (30 ml) was added dropwise **1a** (1.2 g, 5 mmol) in THF (15 ml). The reaction mixture was stirred for 100 min at 25 °C, and then water (1.0 ml) and concd H_2SO_4 (2.5 ml) were added. After filtration, the filtrate was extracted with ether to give compound **2a** in 95% yield; mp 61—63 °C (lit,[3] 63—65 °C). Other compounds (**2b—d**) were similarly prepared and recrystallized from methanol. The mp, NMR, mass spectra, and results of elemental analysis of these compounds are summarized in Table 2.

Table 2. 2-Phenyl-4*H*-benzo[*b*]thiopyrans

2-Phenylthiochroman-4-one (3). A solution of $LiAlH_4$ (0.2 g) in dry pyridine (20 ml) was added to a solution of **1a** (1.0 g) in pyridine (15 ml) at 25 °C. The mixture was stirred for 200 min at 25 °C, and then methanol (2.0 ml) and dilute hydrochloric acid (50 ml) were added. After extraction with ether, the extracts were washed with dilute HCl and evaporated. The residue was chromatographed on silica gel using benzene as an eluent to give **3** (22%), **1a** (29%) and **2a** (6%).

2-Phenylbenzo[b]*thiopyrylium Perchlorates (4a—d). Method A*: Compound **2a** (1.1 g) was dissolved in glacial acetic acid (6 ml), and then 60% perchloric acid (3.3 g) was added. After 1 d at room temperature, ether was added, and the resulting solid was separated and recrystallized from glacial acetic acid containing a small amount of perchloric acid to give **4a** (0.72 g). Compound **5** was isolated in 45% yield when the filtrate was extracted with ether, and recrystallized from methanol. **5**: mp 52—54 °C; *m/e* 226 (M^+, 86), 135 (100), 92 (52), 91 (42); ^{1}H-NMR ($CDCl_3$): δ 2.25—2.40 (m, 2H), 2.84—3.04 (m, 2H), 4.46 (d, d, J=9 and 3 Hz, 1H), 7.01—7.54 (m, 9H). Found: C, 79.15; H, 6.09%. Calcd for $C_{15}H_{14}S$: C, 79.60; H, 6.23%.

Method B: A solution of DDQ (1.37 g) in glacial acetic acid (20 ml) was added to a solution of **2a** (1.07 g) in glacial acetic acid (6 ml) under the stirring. After 30 min, 60% perchloric acid (3.3 g) was added, and the mixture was stirred for 30 min. The resulting solid was separated, and ether was added to the filtrate. The resulting solid was again separated. The collected solid was recrystallized from glacial acetic acid to give **4a** (1.0 g) in 65% yield. The other compounds **4b—d** were similarly prepared. The yields, mp's, NMR spectra, and results of elemental analysis of these compounds are summarized in Table 3.

Tosylation Reaction of D-Glucuronolactone

Hiroshi ITOH* and Kiyohiko TAJIMA
The Noguchi Institute, 1-8-1 Kaga, Itabashi-ku, Tokyo 173
(Received September 13, 1982)

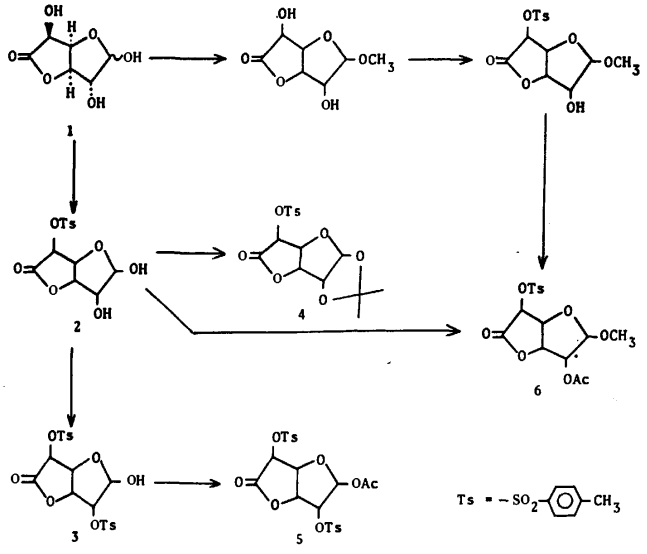
Synopsis. The tosylation reaction of D-glucuronolactone with tosyl chloride in pyridine gave directly 5-*O*-tosyl-D-glucuronolactone and 2,5-di-*O*-tosyl-D-glucuronolactone.

The selective acylation for hydroxyl groups in carbohydrate is important in the synthesis of carbohydrate derivatives. The formation of the quarternary pyridinium salts or chlorination at anomeric carbon take place in the tosylation of carbohydrates having a free glycosidic hydroxyl group with tosyl chloride in pyridine.[1] For example, 2,3,6-tri-*O*-methyl-4-*O*-tosyl-D-glucose or 6-*O*-tosyl-D-glucose was not directly obtained from 2,3,6-tri-*O*-methyl-D-glucose or D-glucose, respectively.[2,3] In continuing the studies about reactions of D-glucuronolactone (**1**), however, 5-*O*-tosyl-D-glucuronolactone (**2**) or 2,5-di-*O*-tosyl-D-glucuronolactone (**3**) was obtained by the direct tosylation of **1** in pyridine with tosyl chloride.

At first, equimolar tosyl chloride was used to afford **2** in 49% yield with a trace of **3**. Compound **2** was also tosylated under the same conditions to give **3** in 39% yield. And then tosylation of **1** with bimolar tosyl chloride gave **2** and **3** in 30 and 31% yields, respectively. The structure of **2** was confirmed by elemental analysis, IR, and ^{1}H-NMR spectra, and by converting it into the isopropylidene derivative, 1,2-*O*-isopropylidene-5-*O*-tosyl-D-glucuronolactone (**4**).[4] The structure of **3** was confirmed by elemental analysis, IR, and ^{1}H-NMR spectra, and by converting it into the acetate, 1-*O*-acetyl-2,5-di-*O*-tosyl-D-glucuronolactone (**5**). The chemical shifts of the ^{1}H-NMR spectra for compounds **1**, **2**, and **3** are listed in the Table. These show the characteristic deshielding effect of the sulfonyl group, the signals of H-2 or H-5 being shifted to lower field. And compound **2** was further methylated and acetylated to give methyl 2-*O*-acetyl-5-*O*-tosyl-D-glucurosiduronolactone (**6**). Compound **6** was also synthesized from methyl D-glucurosiduronolactone by tosylation with equimolar tosyl chloride followed by acetylation. These results indicate a selectivity of the hydroxyl groups in **1** towards tosylation. The order of reactivity HO-5> HO-2 agree well with the result that the degree of hydrogen bonding of HO-5 is higher than that of HO-2.[5]

TABLE 1. CHEMICAL SHIFTS OF ^{1}H-NMR (DMSO-d_6) FOR COMPOUNDS **1**, **2**, AND **3**

Compound	H-1	H-2	H-3	H-4	H-5 (δ)
1	5.17	3.77	← 4.20—4.90 →		
2	5.23	4.03	← 4.50—4.90 →		5.55
3	5.31	4.67	← 4.60—5.06 →		5.56



Experimental

Melting points are uncorrected. The infrared spectra and ^{1}H-NMR spectra were recorded on a JASCO A-102 spectrometer and a JNM-PMX 60 spectrometer, respectively, under standard conditions.

5-O-Tosyl-D-glucuronolactone (2). To a solution of D-glucuronolactone (**1**) (1.8 g) in pyridine (10 ml) was added dropwise a solution of tosyl chloride (1.9 g) in pyridine (10 ml) within 15 min at 0 °C. The mixture was stirred for 16 h at room temperature, after which time pyridine was evaporated under reduced pressure. The residue was extracted with ethyl acetate–5% HCl solution and the ethyl acetate solution was washed with $NaHCO_3$ aq and water. After evaporation of ethyl acetate, the residue was recrystallized from acetone–petroleum ether to give **2** (1.6 g, 49%) as white needles: mp 183—184 °C. ^{1}H-NMR (DMSO-d_6) δ=2.43 (3H, s), 4.03 (1H, s), 4.50—4.90 (2H, m), 5.23 (1H, d, J=3.6 Hz), 5.46—5.80 (2H, m), 6.75 (1H, d, J=3.6 Hz), 7.68 (4H, m). IR (KBr) 3500, 3420, 1780, 1580, 1175 cm^{-1}. Found: C, 47.20; H, 4.09; S, 9.73%. Calcd for $C_{13}H_{14}O_8S$: C, 47.27; H, 4.27; S, 9.71%.

2,5-Di-O-tosyl-D-glucuronolactone (3). Compound **3** was prepared for 64 h in a similar manner to that described above, using 1.8 g of **1** and 3.8 g of tosyl chloride. After evaporation of ethyl acetate, the residue was extracted with benzene. The insoluble material was **2** (1.0 g, 30%). The soluble material was **3**; it was recrystallized from benzene–petroleum ether twice (1.4 g, 31%) and was further recrystallized from acetone–petroleum ether to give **3** as white curdy crystals having a constant mp of 173—175 °C. ^{1}H-NMR (DMSO-d_6) δ=2.43 (6H, s), 4.60—5.06 (3H, s), 5.31 (1H, d, J=3.2 Hz), 5.56 (1H, d, J=6.4 Hz), 7.37—8.06 (9H, m). IR (KBr) 3460, 1800, 1580 cm^{-1}. Found: C, 49.47; H, 4.07; S, 13.21%. Calcd for $C_{20}H_{20}O_{10}S_2$: C, 49.58; H, 4.16; S, 13.24%.

1,2-O-Isopropylidene-5-O-tosyl-D-glucuronolactone (4). The solution of **2** (0.48 g) in acetone (5 ml) and trifluoroacetic acid (0.5 ml) was refluxed for 20 h. After evaporation of the excess reagent under reduced pressure, the residue was recrystallized from benzene–petroleum ether to give **4** (0.48 g, 90%): mp 187—188 °C (lit,[4] 189—194 °C).

1-O-Acetyl-2,5-di-O-tosyl-D-glucuronolactone (5). Compound **3** was acetylated with acetic anhydride–trifluoroacetic acid (55 °C, 15 h). The obtained **5** was a mixture of α and β

anomers (1 : 4.7).

*Methyl 2-O-acetyl-5-O-tosyl-D-glucurosiduronolactone (**6**).* Compound **2** was methylated with methanol–Dowex 50WX2 (R. T. 2 h) and acetylated with acetic anhydride–pyridine (R. T. 2 h) and **6** was recrystallized from acetone–petroleum ether; white needles: mp 121—122.5 °C. ^{1}H-NMR ($CDCl_3$) δ=2.11 (3H, s), 2.48 (3H, s), 3.33 (3H, s), 4.86—5.33 (5H, m), 7.66 (4H, m). IR (KBr) 2920, 1800, 1750, 1590 cm^{-1}.

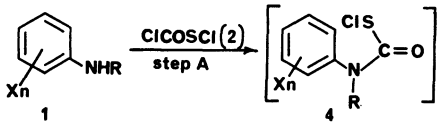
An Improved Method for Preparation of *N*-Alkyl-2(3*H*)-benzothiazolone Analogs

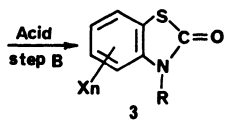
Yoo TANABE,* Takayuki OKABE, Akiko KAKIMIZU, Nobuo OHNO and Hirosuke YOSHIOKA
Pesticide Research Department, Sumitomo Chemical Co. Ltd., 4-2-1 Takatsukasa, Takarazuka, Hyogo 665
(Received September 17, 1982)

Synopsis. A number of *N*-alkyl-2(3*H*)-benzothiazolone analogs could be prepared from *N*-monosubstituted aniline and chlorocarbonylsulfenyl chloride. The new method consists of carbamoylation of aniline and successive Friedel-Crafts type ring closure of an intermediate carbamoylsulfenyl chloride in the presence of suitable Lewis or protic acid catalyst.

N-Alkyl-2(3*H*)-benzothiazolone derivatives (**3**) are well known as useful biologically active substances, *i.e.*, herbicides,[1] fungicides[2] and antiallergic drugs.[3] Therefore, synthesis of 2(3*H*)-benzothiazolone has been studied extensively, and the following two methods[4] which start from aniline are typical ones. According to the first method, *N*-alkyl-2(3*H*)-benzothiazolones (**3**) are prepared by the following series of reactions: 1) Condensation of aniline with thiocyanate ion to give phenylthiourea, 2) oxidative (*e.g.* Br_2 or SO_2Cl_2) cyclization to 2-aminobenzothiazole, 3) transformation of the 2-amino derivative to 2(3*H*)-benzothiazolone by diazotization and subsequent acid hydrolysis of the 2-chlorobenzothiazole, 4) *N*-alkylation to **3**. In the other method, a substituted aniline and carbon disulfide are coupled to give the corresponding 2-mercaptobenzothiazole, which is then converted to **3** by H_2O_2-oxidation followed by alkylation. The former method is general one to prepare *N*-alkyl-2(3*H*)-benzothiazolone, but requires several steps. The latter is of limited applicability, since the coupling reaction often requires drastic reaction conditions (high temperature (up to 150 °C) and pressure (≈3 atm)), and generally give low yields with certain exceptions such as 2-mercaptobenzothiazole.

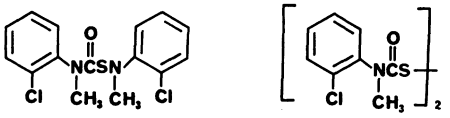


1 **4**



3

Scheme 1.



6 **5**

In contrast, Zumach *et al.* reported[5] a remarkable method for preparation of *N*-methyl-2(3*H*)-benzothiazolone (**3**) by condensation of *N*-methylaniline (**1**) and chlorocarbonylsulfenyl chloride (CCSC) (**2**), an effective "bifunctional" reagent,[7] and they described that the reaction proceeds stepwise as shown in Scheme 1: step A, carbamoylation of *N*-alkylaniline (**1**) with CCSC (**2**) and step B, ring-closure by way of Friedel-Crafts type C–S bond formation. When X_n on **1** is hydrogen atom or an electron donating group, the second step occurs spontaneously. However, when X_n is an electron-withdrawing group, such as halogen or cyano group, step B did not proceed and even a trace amount of benzothiazole (**3**) was not obtained, but the disulfide (**5**, Table 1,(c)) was found. The failure in the cyclization step seems to result from low reactivity of the benzene ring of the aniline (**1**) on the Friedel Crafts cyclization by an electron-withdrawing groups X_n.

In order to overcome the problem, we have extensively attempted a variety of Friedel-Crafts catalysts for the cyclization step B, and found that 1.5 mol of Lewis acid ($AlCl_3$, $FeCl_3$) or a large excess of protic acid (H_2SO_4,[8] CF_3CO_2H) gave *N*-alkyl-2(3*H*)-benzothiazolone (**3**) in

a) 10 mol equiv. *vs.* *N*-alkylaniline (**1**) was used. b) Containing a 10% of 7-chloro-*N*-methyl-2(3*H*)-benzothiazolone originated by the cyclization toward C-2 position of 3-chloroaniline. c) These physical and analitical data are given in experimental tail.

good yield. It is noteworthy that C–S bond formation between the aromatic carbon and the sulfenyl halide was successfully conducted in a protic acid media such as conc H_2SO_4.

Various types of amines were tried as acid scavenger in the step A. For example, in case of *N*-methyl-2-chloroaniline, *N,N*-dialkylaniline gave favorable yield of 4-chloro-*N*-methyl-2(3*H*)-benzothiazolone (**3a**), while pyridine and triethylamine gave poor yield. *N*-Methyl-2-chloro-aniline could also behave as an acid scavenger and gave 53% yield of (**3a**) and *N*-(2-chlorophenyl)-methylcarbamoyl 2-chloro-*N*-methylanilino sulfide (**6**) in 11% yield as a major by-product (Table 1). It was found that the reaction was very sensitive to solvents and bases. It seemed that solvents such as toluene, carbon tetrachloride, and certain tertiary amines such as *N,N*-dimethylaniline are favorable for the step A.

The results were shown in Tables 1 and 2.

Experimental

Materials. CCSC (**2**) was prepared from CCl_3SCl and 95%-H_2SO_4.[6]

Analyses of the Products. Purity of *N*-Alkyl-2(3*H*)-benzothiazolone (**3**) were analyzed by GLC on a 1.5 m×3 mm XE-60 (5 wt%) column at 200 °C.

4-Chloro-N-methyl-2(3H)-benzothiazolone (3a). CCSC (**2**, 5.08 g, 3.83×10^{-2} mol) was added to a solution of 2-chloro-*N*-methylaniline (**1a**, 5.00 g, 3.53×10^{-2} mol) and *N,N*-dimethylaniline (4.73 g, 3.83×10^{-2} mol) in toluene (70 ml) at 0 °C and the solution was stirred at 0 °C for 1 h. After removal of *N,N*-dimethylaniline hydrochloride salt by filtration, the filtrate which contained sulfenyl halide intermediate (**4a**, was added to a suspension of $AlCl_3$ (7.66 g, 5.75×10^{-2} mol) in toluene (50 ml) at room temperature during 30 min, and heated under reflux for 3 h. Then the reaction mixture was poured into water (100 ml) and extracted with toluene. The organic layer was washed with sat. $NaHCO_3$ solution (100 ml) and dried with $MgSO_4$. The solvent was removed *in vacuo*, and the resultant crude crystals were recrystallized from EtOH to give **3a** (4.45 g, 78.2%). (Table 1). In the same manner, the intermediate sulfenyl halide (**4a**, X=2-Cl, R=CH_3) in toluene was added to conc H_2SO_4 (37 g, 0.38 mol) at 0—5 °C, and kept under stirring at room temperature for 5 h. The reaction mixture was worked up with ice (50 g) to give **3a** (4.43 g, 76.1%). (Tables 1 and 2): mp 124—128 °C (lit,[8] mp 130 °C); IR (Nujol) 2950, 1750 (C=O), 1440, 1210, 1160, 1100 and 1060 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=6.08—7.50 (m, 3H, arom.) and 3.80 (s, 3H); ^{13}C-NMR ($CDCl_3$) δ=169.93 (s, C=O), 133.91, 129.09, 124.82, 123.43, 121.15, 117.30 and 33.05 (s, N-$\underline{C}H_3$).

4-Chloro-N-ethyl-2(3H)-benzothiazolone (3b): Mp 97.4 °C (lit,[2] mp 98—99 °C). *4-Chloro-N-(ethoxycarbonylmethyl)-2(3H)-benzothiazolone (3c)*: Mp 78.5 °C (lit,[1] mp 77 °C). *6-Chloro-N-methyl-2(3H)-benzothiazolone (3e)*: Mp 109.5—112.9 °C (lit,[2] mp 109 °C). *4-Bromo-N-methyl-2(3H)-benzothiazolone (3h)*: Mp 141.5 °C (lit,[2] mp 139—140 °C). *5-Chloro-N-methyl-2(3H)-benzothiazolone (3i)*: Mp 102 °C (lit,[9] mp 105—106 °C).

4,6-Dichloro-N-methyl-2(3H)-benzothiazolone (3d): Mp 144—146 °C; ^{1}H-NMR ($CDCl_3$) δ=3.85 (s, 3H) and 7.05—7.55 (m, 2H); Found: C, 41.24; H, 2.11; N, 5.87; S, 13.95 Cl, 30.55%. Calcd for $C_8H_5NOSCl_2$: C, 41.05; H, 2.15; N, 5.99; S, 13.70; Cl, 30.29%.

6-Cyano-N-methyl-2(3H)-benzothiazolone (3f): Mp 141 °C; ^{1}H-NMR ($CDCl_3$) δ=3.80 (s, 3H) and 7.05—7.65 (m, 3H); Found: C, 56.98; H, 3.15; N, 14.55; S, 16.86%. Calcd for $C_9H_6N_2OS$: C, 57.25; H, 3.18; N, 14.73; S, 16.86%.

5,7-Dichloro-N-methyl-2(3H)-benzothiazolone (3g): Mp 97—100 °C; ^{1}H-NMR ($CDCl_3$) δ=3.85 (s, 3H) and 7.20—7.60 (m, 2H); Found C, 41.16; H, 2.16; N, 5.96; S, 13.10; Cl, 30.82%. Calcd for $C_8H_5NOSCl_2$: C, 41.05; H, 2.15, N, 5.99; S, 13.70; Cl, 30.29%.

Bis(N-(2-chlorophenyl)methylcarbamoyl) Sulfide (5): A solution of the sulfenyl halide intermediate (**4a**, X=2-Cl, R=CH_3) in toluene (20 ml) prepared from 2-chloro-*N*-methylaniline (2.00 g, 1.41×10^{-2} mol) in the same manner to those described for **3a**, was heated under reflux for 3 h. Then the solvent was removed in vacuo and the residue was poured into water (40 ml) and extracted with $CHCl_3$ (40 ml×2). The organic layer was washed with aqueous 10% HCl (50 ml×2), sat. $NaHCO_3$ solution (50 ml) and dried with $MgSO_4$. The solvent was removed *in vacuo*, and the resultant product were subjected to column chromatography (silica gel using $CHCl_3$ as an eluent) to give **5** (1.25 g, 30%), mp 172—174 °C; IR (Nujol) 2720, 1680 (C=O), 1465, 1260, 850, and 720 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=6.50—7.80 (m, 8H, arom) and 3.30 (s, 6H); ^{13}C-NMR ($CDCl_3$) δ=164.57 (s, C=O), 137.91, 134.64, 134.52, 131.79, 131.06, 128.32 and 37.90 (s, N-CH_3); Found: C, 47.67; H, 3.50; N, 6.91; S, 15.50; Cl, 17.61%; Calcd for $C_{16}H_{14}Cl_2N_2O_2S_2$: C, 47.89; H, 3.52; N, 6.98; S, 15.98; Cl, 17.67%.

M-(2-Chlorophenyl)methylcarbamoyl (2-Chloro-N-methylanilino Sulfide (6). CCSC (**2**, 5.08 g, 3.83×10^{-2} mol) was added to a solution of 2-chloro-*N*-methylaniline (**1a**, 10.0 g, 7.06×10^{-2} mol) in toluene (70 ml) at 0 °C and the solution was stirred at 0 °C for 1 h. After removal of 2-chloro-*N*-methylaniline hydrochloride by filteration, the filtrate was treated by the same procedure employed in the preparation of **3a**. 6.50 g of crude material was obtained after work up. The crude material was purified by column chromatography (silica gel using $CHCl_3$ as an eluent) to give **3a** (4.16 g, 59%) and **6** (0.66 g, 11%). oil; IR (film) 2920, 1740 (C=O), 1660, 1580, 1480, 1340, 1280 and 1120 cm^{-1}; ^{1}H-NMR ($CDCl_3$), δ=6.55—7.80 (m, 8H, arom.), 3.35 (s, 3H), and 3.17 (s, 3H); MS: (70 ev, DI) *m/e* (rel intensity)=340 (M^+, 40), 168 (100), 140 (68), and 77 (24).

Dimethyl and Diethyl 2-Oxo-1,3-propanedisulfonates as Practical Alkylating Reagents

Fumio OGURA,* Hachiro YAMAGUCHI,† Tetsuo OTSUBO, Takao NAKANO, and Takahiro SAITO

Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Shitami, Saijo, Higashi-Hiroshima 724

(Received October 9, 1982)

Synopsis. The title sulfonates, easily accessible from acetone, were found to be effective and practical alkylating agents.

2-Oxo-1,3-propanedisulfonic acid (**1**), *sym*-disulfonic acid of acetone, was readily prepared by sulfonation with fuming sulfuric acid as a highly hygroscopic crystalline solid.[1,2] The sulfonic acid (**1**) was converted to the dichloride (**2**) with $SOCl_2$ containing a small amount of nitromethane, and **2** was reacted with methanol and ethanol to yield methyl and ethyl esters (**3** and **4**) respectively.

$$CH_3COCH_3 \longrightarrow \underset{\mathbf{1}}{O{=}C(CH_2SO_3H)_2} \xrightarrow{SOCl_2} \underset{\mathbf{2}}{O{=}C(CH_2SO_2Cl)_2} \xrightarrow{ROH} O{=}C(CH_2SO_3R)_2$$

3: R=CH_3, **4**: R=C_2H_5

With the purpose of utilizing these disulfonates as practical alkylating reagents, we studied the alkylation of phenol with them. Thus, phenol was alkylated with **3** or **4** in aq NaOH, and the reaction products were submitted to quantitative gas-chromatographic analysis. For comparison, the alkylation of phenol with conventional reagents was carried out under the same reaction conditions, and the products were analyzed similarly. The combined results are shown in Table 1. From the results obtained, it can be concluded that **3** and **4** react as effectively as dialkyl sulfates in the alkylation.[3] Furthermore, they have several advantages over the sulfates worthy of comment: 1. In **3** and **4** both alkyl groups could be used for the alkylation quite smoothly. 2. No severe toxicity such as that of the dialkyl sulfates was observed. 3. The sulfonates were stable compounds and had a good crystallinity in spite of their low melting points. Therefore, they were easy to handle and showed good reactivities, even in the aq-phase reactions. At present we have not yet tried these sulfonates on many kinds of substrates. However, considering the above results, they seem to be highly promising reagents. For example, sodium *S*-methyl thiosulfate (Bunte salt) was prepared in a good yield by the reaction of sodium thiosulfate on **3**.

Table 1. Comparison of alkylating reagents in the alkylation of phenol

Alkylating agent[a]	Reaction conditions[b] Temp/°C	Time/h	Yield/%
		1	76.0
		2	89.8

C_2H_5Br	30	6	7.5
C_2H_5I	30	6	2.5

a) The molar ratios of alkylating agents to phenol were 1 : 2 for the three disulfonates and 1 : 1 for all the other cases. b) As a base, 12 M aq NaOH was used in 1.5 times and twice the molar quantity of phenol for methylation and ethylaiton respectively. c) Only one alkyl group could be used for the alkylation under these conditions.

Experimental

The melting points were not corrected. The solvents were of a reagent grade. All the known compounds were confirmed by a comparison of the melting points, spectroscopic data, and retention times with those of the authentic samples or the reported data. The ^{1}H-NMR spectra were recorded on a JEOL PMX-60 spectrometer, and the shifts were given in δ units from internal TMS. The gas-chromatographic analysis was performed on a Yanagimoto GCG-550T gas chromatograph equipped with a TCD, using helium as a carrier gas.

2-Oxo-1,3-propanedisulfonyl Dichloride (2): 2-Oxo-1,3-propanedisulfonic acid (**1**, 221.7 g, 1.02 mol)[1] was mixed with $SOCl_2$ (850 g, 7.14 mol) containing nitromethane (31 g, 0.51 mol),[4] and the mixture was refluxed for 6 h to obtain a clear solution. Crystals deposited on cooling were collected by means of suction filtration and washed with cold abs benzene. The chloride (169.3 g, 65%) could be used directly for a further reaction. Recrystallized crystals (from abs benzene) showed a mp of 106—107 °C. ^{1}H-NMR(CD_3COCD_3): 5.17 (s, CH_2). Found: S, 25.30%. Calcd for $C_3H_4O_5Cl_2S_2$: S, 25.10%.

Dimethyl 2-Oxo-1,3-propanedisulfonate (3): To a chilled and stirred methanol (13 g, 0.41 mol), **2** (5.0 g, 0.02 mol) was added, portion by portion, to keep the temperature of the reaction mixture below −10 °C. The mixture was concen-

† Present address: Faculty of Pharmaceutical Sciences, Fukuyama University, Fukuyama 729-02.

trated under reduced pressure immediately after the addition was complete, and ice-cold water was added to the residue. The crystals thus precipitated were collected by means of suction filtration was washed with cold water. Colorless crystals (4.21 g, mp 69—69.5 °C, 87.8%) were thus obtained. ^{1}H-NMR ($CDCl_3$): 2.98 (s, CH_3, 6H), 4.47 (s, CH_2, 4H). Found: C, 24.63; H, 4.15%. Calcd for $C_5H_{10}O_7S_2$: C, 24.39; H, 4.09%.

Diethyl 2-Oxo-1,3-propanedisulfonate (4): By the same procedure, **4** was prepared from **2** and EtOH as colorless crystals (mp 45.5—46.5 °C) in an 80.1% yield. ^{1}H-NMR ($CDCl_3$): 1.43 (t, CH_3, 3H), 4.38 (q, CH_2, 2H), 4.43 (s, CH_2, 2H). Found: C, 30.50; H, 5.10%. Calcd for $C_7H_{10}O_7S_2$: c, 30.65; H, 5.14%.

Alkylation of Phenol and the Quantitative Product Analysis by Gas Chromatography: As an example, the methylation with **3** will be described below. Phenol (0.423 g, 4.49 mmol) was dissolved in 12 M aq NaOH (0.56 ml, 6.72 mmol). To the stirred solution, **3** (0.556 g, 2.25 mmol) and octane (an internal standard, 0.336 g, 2.94 mmol) were added, and the mixture was reacted at 40 °C for a definite time (Table 1). The reaction mixture was then diluted with ice-cold water and extracted with ether. The extract was washed with 1 M aq NaOH, dried, and subjected to gas-chromatographic analysis with the following column: $3\phi \times 200$ mm packed with Apiezon grease L. (15%) on Uniport B (80—100 mesh).[5]

Sodium S-Methyl Thiosulfate: To an aq solution of $Na_2S_2O_3$ (30.50 g, 192.9 mmol in 52 ml H_2O), **3** (15.19 g, 61.75 mmol) was added, and the mixture was stirred at room temp for 17 h. The mixture was then concentrated to dryness under reduced pressure, and the residual solid was extracted with EtOH. Ether was added to the extracts to precipitate the Bunte salt as colorless crystals of monohydrate (15.07 g, 72.63%); mp 156—157 °C (decomp). ^{1}H-NMR (DMSO-d_6): 2.33 (s, CH_3, 3H), 3.33 (s, 2H, H_2O): In D_2O, a singlet methyl peak was observed at a filed 2.57 δ lower from internal DSS. Found: C, 7.14; H, 2.80%. Calcd for $CH_3O_3S_2Na \cdot H_2O$: C, 7.14; H, 3.00%.

Diethyl 1,3-Propanedisulfonate: To a stirred ethanol solution of sodium ethoxide, prepared from sodium (1.91 g, 83 mmol) and ethanol (40 g), 1,3-propanedisulfonyl dichloride[6] (10 g, 41 mmol) was added at −5 °C. After stirring for 1 h at 26 °C, the mixture was concentrated under reduced pressure, poured into cold water, and extracted with ether. Before extraction, the pH of the mixture was adjusted to 4 with HCl. The combined extracts were dried (Na_2SO_4) and concentrated under reduced pressure to yield the sulfonate as a light yellow oil (8.0 g, 74.1%), which solidified in a freezer. ^{1}H-NMR ($CDCl_3$): 1.40 (t, CH_3, 6H), 2.32 (quin, CH_2, 2H), 3.33 (t, CH_2, 4H), 4.30 (q, CH_2, 4H).

Bromination of 4*H*-Cyclopenta[*def*]phenanthrenamines

Masaaki Yoshida, Masahiro Minabe,* Wataru Ookawa,† and Kazuo Suzuki††
Department of Industrial Chemistry, Faculty of Engineering, Utsunomiya University, Ishiicho, Utsunomiya 321
(Received October 18, 1982)

Synopsis. Bromination of 4*H*-cyclopenta[*def*]phenanthren-1-amine, -2-amine, -3-amine, or -8-amine with bromine in chloroform took place at the 2-, 1-, 8-, or 9-position, respectively. The second bromine was introduced at the 8-, 3-, 2-, or 3-position. Similar regioselectivity was observed in the system of bromine in acetic acid–48% hydrobromic acid and of hydrobromic acid in dimethyl sulfoxide. The corresponding acetylamino compound was brominated at the same position as that of the parent amine.

The electrophilic bromination of 4*H*-cyclopenta[*def*]-phenanthrene has been reported to give 1-bromide accompanied by 3- and 8-bromo isomers.[1] When the 1-, 2-, or 3-position of 4*H*-cyclopenta[*def*]phenanthrene was already occupied by an electron-withdrawing group such as a nitro, bromo, or acetyl substituent, the second substituent entered the 5- or 7-position upon nitration or acetylation.[2]

The present paper deals with the bromination of 4*H*-cyclopenta[*def*]phenanthrene having an electron-donating amino group.

a) See Experimental.

Brominations of 4*H*-cyclopenta[*def*]phenanthren-1-amine (**1a**),[3] -2-amine (**2a**), -3-amine (**3a**), and -8-amine (**4a**) were carried out to afford the monobromides (**1b, 2b, 3b, 4b**) and dibromides (**1c, 2c, 3c, 4c**). The substitution with bromine in the acetamides (**5a, 6a, 7a, 8a**) took place at the same position as that of the parent amines to give the monobromides (**5b, 6b, 7b,** and **8b**) (Scheme 1). Table 1 shows the results obtained by gas-chromatographic analyses.

The structural proof of these monobromo amines was established by deamination which gave the known bromo-4*H*-cyclopenta[*def*]phenanthrenes.[1] The configuration of the dibromo amines was estimated by the IR, NMR, and UV spectral data. These physical properties are summarized in Table 2.

In each bromination, no other monobromo isomers were detected by methods of NMR, gas chromatography (Silicone DC-QF 1 or Dexsil 300 GC), and high performance liquid chromatography. The reaction of the amines with bromine in carbon tetrachloride or carbon disulfide gave results similar to those in chloroform. The same regioselectivity was observed in the bromination using a solvent system of acetic acid–48% hydrobromic acid (4 : 1 by volume) in which it had been expected the amines would convert easily to the corresponding conjugated acids.[4] No dibromo amine could be detected by the reaction with hydrobromic acid (48%) in dimethyl sulfoxide, which is similar to the reaction of fluorenamine.[5]

The reaction of **4a** proceeds with regioselectivity analogous to that of 9-phenanthrenamine.[6] The 9-position of **4a** corresponds to the highly reactive 1-position of 2-methoxynaphthalene.[7] A second bromine may be introduced at the 3-position of **4b**, and reactions of **2a** and **3a** can be explained by similar considerations. The bromination of **1a** took place at the 2-position, which corresponds to the reactive 2-position of 1-methoxynaphthalene.[7]

In the acetamide series, the yield of **5b** was only 50% after 60 min of reaction; on the other hand, 98% of **6b** was obtained after 1 min. The low reactivity of **5a** may be interpreted by the fact that the 2-position of the parent hydrocarbon is less reactive than the other positions. The 1-acetylamino group is less electron-donating than the 1-amino group and controls the regioselectivity to be effective at the 2-position, but does not enhance the reactivity significantly.

Experimental

All the melting points are uncorrected. The IR and UV data were recorded with IR-G spectrophotometer (JASCO) as KBr pellets, and using model UV-180 apparatus (Shimadzu) as cyclohexane solutions, respectively. The ^{1}H NMR spectra were obtained with JNM-C-60HL instrument (JEOL) using

$CDCl_3$ (**1**—**4**) or DMSO-d_6 (**5**—**8**) as the solvent. The agreement between the calculated and found values in the elemental analysis of the new compounds is within ±0.3% of variation.

The yield of each bromination is estimated from the average value of three or more runs. The components of the reaction mixtures were separated by gas chromatography (Shimadzu GC-6AM) using a column (1 m) containing 3% Dexsil 300 GC on Chromosorb WAW at 250 °C using FID detector. The amount of each peak was calculated by comparison with octacosane or dotriacontane which has been added as the internal reference to the substrate before the reaction. Retention time of each product is tabulated in Table 2.

The reactants were synthesized by the method similar to that described elsewhere.[3] Chloroform was percolated through an alumina column before use and the other solvents were distilled.

Bromination of 4H-Cyclopenta[def]*phenanthren-1-amine (**1a**).*

Typical Procedure I: Amine **1a** (103.2 mg, 0.5035 mmol) and dotriacontane (21.10 mg) were dissolved in $CHCl_3$ (50 ml), and cooled at 0 °C in the dark. A solution of Br_2 (1.2 mol equivalent to **1a**) in $CHCl_3$ (*ca.* 10 ml) was added all at once to the mixture, and the resulting mixture was stirred for 1 min. Aqueous $NaHSO_3$ (1%, 50 ml) was added to quench the reaction; the organic layer was neutralized by aqueous ammonia (28%) and dried over anhydrous Na_2SO_4, and the solution was submitted to gas chromatography.

Upon evaporation of the solvent, the residue was chromatographed on a silica-gel column (1.8 cm ϕ, 60 cm) with benzene. The lower band of the column was extracted with benzene to give a trace amount of **1c**, mp 164.0—165.0 °C (decomp). The middle band yielded 82 mg (58%) of **1b**, mp 169.0—169.5 °C (decomp) by recrystallization from a mixture of benzene–hexane (*ca.* 1 : 1). The upper band of the column gave a trace amount of **1a**, mp 128—129 °C.

Procedure II: The amine (0.5 mmol) was treated with HBr (48%, 0.6 mmol) in DMSO (60 ml) at 80 °C for 60 min. After addition of aqueous $NaHSO_3$ and neutralization by aqueous ammonia, the mixture was extracted with benzene (50 ml) and analyzed by means of gas chromatography.

The reaction of **3a** gave, in addition to **3b**, a significant amount of dark tar materials from a silica-gel column; these were not studied further.

Procedure III: The acetamide (0.5 mmol) was allowed to react with Br_2 (0.6 mmol) in $CHCl_3$ (85 ml) at 0 °C for 5 min. The resulting solution was treated by a method similar to that described above.

*Deamination of **1b**.* Bromo amine **1b** (134.6 mg, 0.47 mmol) was dissolved in a mixture of THF (2 ml), concd HCl (5 ml), and H_2O (5 ml) and the resulting amine hydrochloride was diazotized with aqueous $NaNO_2$ (5%, 1 ml) at 0—5 °C according to the literature.[8] The reaction mixture was stirred with H_3PO_2 (*ca.* 50%, 3.5 ml) for 17 h at room temperature. The precipitate was extracted with benzene and the benzene solution was chromatographed on a silica gel to yield 2-bromo-4*H*-cyclopenta[*def*]phenanthrene (30.4 mg, 24%), mp 91—92 °C, identical in all respects with an authentic sample.[1]

Also, **2b** afforded the 1-bromide (50% yield, mp 85—86 °C), **3b** gave 8-bromide (42%, mp 94.5—95.5 °C), and **4b** yielded 8-bromide (66%), respectively, by a treatment similar to those described above.

*Acetylation of **1b**.* Bromo amine **1b** (142 mg, 0.50 mmol) was treated with Ac_2O (10 ml) in dry benzene (50 ml) at reflux for 30 min to give **5b** (160 mg, 98%), mp 236—237 °C (decomp), which was identical in all respects with the product obtained by bromination of **5a**.

The Generation of the Ethenethiolate Anion and Its Reaction with Several Chloromethyl Alkyl Ethers and Sulfides

Shigeo TANIMOTO,* Hideyuki IKEHIRA, Tatsuo OIDA, and Toshio KOKUBO
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received October 18, 1982)

Synopsis. 2-Ethoxy-1,3-oxathiolane was deprotonated at the 4-position, followed by the cycloelimination of the resultant anion, leading to ethyl formate and the ethenethiolate anion. The anion was trapped by several chloromethyl alkyl ethers and sulfides to afford alkoxy(vinylthio)methanes and alkylthio(vinylthio)methanes respectively.

In a previous article[1] it was shown that 2-ethoxy-1,3-oxathiolane (**1**) undergoes ring cleavage on treatment with an excess of butyllithium in hexane, giving 5-nonanol together with 5-butyl-5-nonanol. By a similar treatment, 2-ethoxy-1,3-dithiolane (**2**) was also opened to produce 5-nonanethiol, along with 5-butyl-5-nonanethiol. Although the correct mechanism of these reactions is even now in doubt, it may involve three steps. The first step is the deprotonation at the 4-position of **1** or **2**. The second one is the cycloelimination of the resultant anion, leading to ethyl formate or *O*-ethyl thioformate, along with the ethenethiolate anion. The last step is the nucleophilic attack of 2 mol of butyllithium on the intermediate ethyl formate or *O*-ethyl thioformate to afford 5-nonanol or 5-nonanethiol.

Deprotonation at the 4-position of the 1,3-dithiolane ring by a strong base was initially confirmed by Wilson and his co-workers,[2] who reported that the reaction of 2-hexyl-1,3-dithiolane with an excess of butyllithium in ether gives 5-undecanethiol and 5-(butylthio)-undecane. More recently, we ourselves have found[3] that several 2-alkyl-2-aryl- and 2,2-diaryl-1,3-dithiolanes undergo predominant fragmentation by lithium diisopropylamide (LDA) in tetrahydrofuran, a process which is initiated by proton abstraction from C-4. Thus, it is conceivable that the reaction of **2** with butyllithium proceeds by a mechanism involving deprotonation at the 4-position in the first step. On the other hand, no description of deprotonation at the 4-position of the 1,3-oxathiolane ring by any one of the strong bases is available, although it is already well known that a few 1,3-oxathiolane derivatives are capable of proton abstraction from their C-2.[4] In order to verify the deprotonation at C-4 of the 1,3-oxathiolane ring by a strong base, we submitted **1** to a deprotonation-fragmentation sequence using LDA, since a hydrogen at C-4 seems to be more labile than that at C-2 in **1**. When **1** was treated with an excess of LDA in tetrahydrofuran at −78 °C, followed by the addition of an appropriate chloromethyl alkyl ether or sulfide, a series of alkoxy(vinylthio)methanes (**5**) or alkylthio(vinylthio)methanes (**6**) were obtained in moderate yields, suggesting the intermediary presence of the ethenethiolate anion (**4**) in the course of the reaction. The formation of the intermediate **4** is best explained by assuming that the initial deprotonation by LDA occurred not at the 2-position, but at the 4-position of **1**, and that it is followed by the fragmentation. On that occasion, there is no reaction between the less nucleophilic LDA and the ethyl formate which has been produced simultaneously.

The products obtained in this procedure are summarized in Tables 1 and 2, together with their physical properties. Some of these products have been already synthesized by other chemists *via* another route; therefore, our procedure provides an alternative method for the preparation of these acetals.

Experimental

The starting compound **1** was prepared as previously reported.[1] The chloromethyl ethyl ether and chloromethyl methyl sulfide were commercially available and were distilled just before use. The other chloromethyl alkyl ethers and sulfides were made according to one of the published procedures.[7]

*Generation of Ethenethiolate Anion (**4**) from 2-Ethoxy-1,3-oxathiolane (**1**) with LDA and Trapping of **4** by Chloromethyl Alkyl Ethers and Sulfides. General Procedure*: A solution of diisopropylamine (5.0 g, 49.4 mmol) in tetrahydrofuran (40 ml) was cooled to −10—−5 °C under nitrogen, treated with a 1.56 molar solution (31 ml, 48.4 mmol) of butyllithium in hexane, and then stirred at the same temperature for 30 min. The solution of LDA thus prepared was cooled to −78 °C, and a solution of **1** (2.7 g, 20.1 mmol) in tetrahydrofuran (3 ml) was added. After an additional 30 min stirring at −78 °C, 40.8 mmol of a chloromethyl alkyl ether or a sulfide was stirred in. The stirring was continued for 30 min at −78 °C and then for a further 1—2 h at room temperature, after which the mixture was quenched with 60 ml of saturated aqueous NH_4Cl and then extracted with ether (3×50 ml). The combined organic layer was washed repeatedly with a 10% aqueou NaOH solution saturated with Na_2SO_4 and once with saturated aqueous Na_2SO_4. The layer was dried over anhydrous $MgSO_4$, filtered, and concentrated *in vacuo* to give a residue, which was then distilled. The distillate was further chromatographed on silica gel to provide a pure product. Five% ether–hexane was used as the eluent for **5**, and hexane, for **6**.

A Revised Absolute Configuration of 2-Hydroxy-1,1'-binaphthyl

Kuninobu KABUTO,* Fujiko YASUHARA, and Shozo YAMAGUCHI
Department of Chemistry, College of General Education, Tohoku University, Kawauchi, Sendai 980
(Received October 29, 1982)

Synopsis. The absolute configuration of 2-hydroxy-1,1'-binaphthyl (**3**) has been revised to (*R*)-(+) in THF by a reexamination of the previously reported chemical correlation between **3** and 2,2'-diamino-1,1'-binaphthyl. This revised configuration agreed with that obtained from the assignment by means of the MTPA/LSR method.

In the course of the ^{1}H NMR study aimed at determining the absolute configuration of axially chiral biaryls using α-methoxy-α-trifluoromethylphenylacetic acid (MTPA, Mosher's reagent) derivatives (esters and amides) and achiral lanthanoide shift reagents (MTPA/LSR method),[1] we have found that the (*R*)-MTPA esters (amides) of a series of binaphthyls with the configuration indicated in Fig. 1A have larger lanthanoid-induced shifts of the signals due to MeO groups in the MTPA moieties (LIS_{OMe}) than the alternate derivatives of the binaphthyls with the opposite configuration (Fig. 1B). These results can reasonably be interpreted[1] by considering the preferred coordination of the shift reagent to the diastereomeric MTPA derivatives. We faced, however, an exceptional case in correlating the relative magnitudes of LIS_{OMe} to the absolute configurations of the binaphthyls of this type; the regurality described above did not hold for a fundamental binaphthol **3** if the reported configuration of **3** is correct.

There have been two reports on the absolute configuration of **3**. In the first report, (*R*) configuration was tentatively assigned to (+)-isomer in methanol from the result of Prelog's atrolactic acid synthesis.[2] In the second, (−)-**3** was correlated chemically to (−)-2,2'-diamino-1,1'-binaphthyl (**1**), whose configuration had been known to be (*S*), thus establishing the absolute configuration as (*R*)-(−) in THF, as is shown in Scheme 1.[3,4] Although this result seems to contradict that obtained from the Prelog rule, it must be noticed that the optical rotation in each study was taken in a different solvent. We have found that the sign of the optical rotation of **3** in methanol is the opposite of that in THF. The results from these two independent studies, therefore, eventually agree and contradict the result obtained by the use of the MTPA/LSR method. This discrepancy needs to be investigated further, and so we have reexamined the reported chemical correlation between **3** and **1**.

Ref. 3, -95.5°(25°C)	-51.4°, c 1.0	-2.9°, c 1.0

Scheme 1. Configurational correlation between **1** and **3**. a: 1 equiv. Ac_2O, b: HNO_2, c: 48% H_3PO_2, d: concd HCl, e: HNO_2, f: 42% HBF_4, g: 100 °C/AcOH, h: 5% KOH/MeOH.

In the reexamination of the correlation, (*S*)-(−)-**1** was correlated to (−)-**2**, in agreement with the reported result, while (−)-**2** was converted to (+)-**3**, contrary to the previous result. In order to confirm this result, the same correlation was carried out using (*R*)-(+)-**1**, and (−)-**3** was obtained by way of (+)-**2**. In addition, the CD spectra of (−)-**3** and (+)-**2** (Fig. 2) showed the same sign of the Cotton effect, indicating that the configurations of these two were the same.[5] From these new facts, the absolute configurfftion of **3** must be revised to (*R*)-(+) in THF and (*R*)-(−) in methanol.[6] Thus, it is clear that the MTPA/LSR method affords the correct assignment of the configuration of **3**.

Although it has been widely accepted that the Prelog rule can be extended to axially chiral biaryls[7,8] on the basis of Berson's correlation model,[9] it is now clear that the model leads to a wrong configurational assignment for **3**. Therefore, the general applicability of Berson's model must be reconsidered.

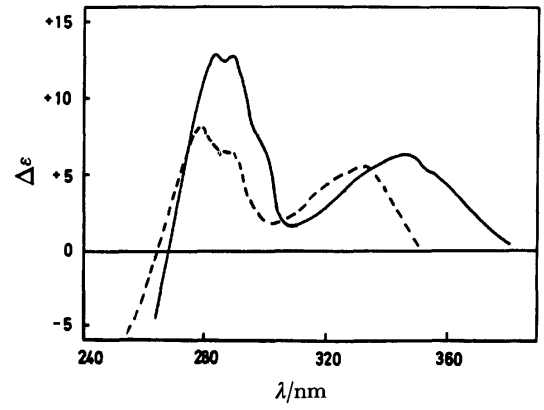

Fig. 2. CD spectra of **2** and **3** in methanol.
——: **2**, ------: **3**; The spectra were determined on the partially active **2** [$[\alpha]_D^{25}$ +24.7° (*c* 0.96, THF), 38% e.e., based on the maximum rotation (+65.2°) estimated by NMR[13]] and **3** [$[\alpha]_D^{20}$ −12.6° (*c* 1.45, THF), 98% e.e.] and corrected for enantiomeric purities.

Experimental

Instruments. The ^{1}H NMR spectra were determined on a Hitachi R-22, 90 MHz spectrometer. The optical rotations were taken on a Perkin-Elmer 241 electronic polarimeter using a 1-dm thermostated microcell. The CD spectra were taken on a JASCO J-20 spectropolarimeter using a 1-cm cell.

(±)-2-Hydroxy-1,1′-binaphthyl (3). A mixture of 2-methoxy-1,1′-binaphthyl (1.42 g, 5 mmol, mp 113—114 °C, lit,[2] 110—111 °C) and lithium iodide (1.34 g, 10 mmol, dried at 300 °C under nitrogen) in collidine (8 ml) was refluxed for 10 h. After cooling, the mixture was poured into ice-water (60 ml) and extracted with benzene. The extract was washed with 2 M HCl, saturated $NaHCO_3$, water, and dried (Na_2SO_4), and then concentrated to give colorless crystals, which were subsequently recrystallized from methanol; 0.97 g (72%), mp 93—95 °C,[10] M$^+$ 270. Found: C, 88.99; H, 5.38%. Calcd for $C_{20}H_{14}O$: C, 88.86; H, 5.22%. ^{1}H NMR ($CDCl_3$) 4.89 (s, OH), 6.9—8.0 (m, aromatic H); IR ($CHCl_3$) 3540, 3050, 3000, 1615, 1595, 1380, 1190 cm^{-1}.

Resolution of 3. The racemic **3** (81 mg, 0.3 mmol) was esterified with acid chloride of (*R*)-MTPA [88 μl, $[\alpha]_D^{24}$ +134.5° (*c* 5.6, CCl_4)] in pyridine (1 ml) in the presence of 4-dimethylaminopyridine (24 mg, 2 mmol) overnight at room temperature. After a usual work-up, the crude product was purified by column chromatography (silica gel, 7% AcOEt in hexane); the resulting diastereomeric mixture of (*R*)-(+)-MTPA esters (105 mg, 72%) was subsequently resolved by HPLC; Lichrospher SI 100 (Merk) 7.8 mm × 30 cm, 3% diisopropyl ether in hexane, Flow rate, 4 ml/min, α=1.15. Less polar (*R*)-MTPA ester; 53 mg, ^{1}H NMR ($CDCl_3$) 2.72 (s, OMe), 6.9—8.0 (m, aromatic H), IR ($CHCl_3$) 1772 cm^{-1}. More polar (*R*)-MTPA ester; 39 mg, ^{1}H NMR ($CDCl_3$) 2.82 (s, OMe), 6.9—8.0 (m, aromatic H), IR ($CHCl_3$) 1772 cm^{-1}.
