A solution of less polar (*R*)-MTPA ester (50 mg) in 5% methanolic KOH (1 ml) was refluxed for 1/2 h. After acidification with 2 M HCl, the mixture was extracted with benzene, and the extract was washed with saturated $NaHCO_3$ and water, and then dried (Na_2SO_4). The solvent was removed, and the residue was purified by TLC (silica gel, 20% AcOEt in hexane) to give 23.5 mg of **3**; mp 160—163 °C (recrystallized from MeOH), $[\alpha]_D^{30}$ +1.9°, $[\alpha]_D^{20}$ +5.6° (*c* 1.0, MeOH), $[\alpha]_D^{20}$ −12.9° (*c* 1.34, THF); M$^+$ 270. Found: C, 88.96; H, 5.26%. Calcd for $C_{20}H_{14}O$: C, 88.86, H, 5.22%.

By the same procedure, the more polar (*R*)-MTPA ester (39 mg) afforded 18.3 mg of **3**; mp 161—164 °C[11] (recrystallized from MeOH); $[\alpha]_D^{30}$ −1.8°,[11] $[\alpha]_D^{20}$ −5.2° (*c* 1.03, MeOH); $[\alpha]_D^{20}$ +13.0°[11] (*c* 1.12, THF).

Configurational Assignment of 3 by the (R)-MTPA/LSR Method. A ^{1}H NMR shift study was conducted on a carbon tetrachloride solution of the diastereomeric mixture of (*R*)-MTPA esters (49 mg) prepared from a partially active **3** ($[\alpha]_D^{20}$ −6.83° (*c* 1.61, THF)) and acid chloride of (*R*)-MTPA. The lanthanoid-induced shifts of the signals due to MeO groups in the MTPA moieties (LIS_{OMe}) were determined by the successive addition of Eu(fod)$_3$ (0.1—0.5 equivalent). The smaller MeO signal initially located at 2.82 ppm showed a larger induced shift (LIS_{OMe}=5.8) than the larger one at 2.72 ppm (LIS_{OMe}=5.1). From the consideration of the preferred coordination of the shift reagent with the diastereomeric MTPA esters,[1] (*R*) configuration was assigned to (+)-isomer in THF.

Chemical Correlation between the Absolute Configurations of 3 and 1. By the previously reported procedure,[3] a partially active (*S*)-(−)-**1**[12] ($[\alpha]_D^{30}$ −87.5° (*c* 1.57, benzene)) was transformed to (*R*)-(−)-**2**; $[\alpha]_D^{25}$ −26.9° (*c* 1.13, THF); M$^+$ 269. Found: C, 89.35; H, 5.78; N, 5.21%. Calcd for $C_{12}H_{15}N$: C, 89.18; H, 5.61; N, 5.20%.

This (−)-**2** (128 mg) was further converted to crude **3** (60 mg, $[\alpha]_D^{25}$ +1.30° (*c* 1.08, THF)) by the procedure previously described in the literature (diazotization, thermal decomposition of diazonium salt in acetic acid, and hydrolysis, successively). The crude **3** was purified by HPLC (Lichrospher SI 100 (Merk) 7.8 mm × 30 cm, 6% AcOEt in hexane) to give colorless crystals; 42.8 mg, M$^+$ 270, $[\alpha]_D^{20}$ +4.77° (*c* 0.86, THF). The IR ($CHCl_3$) and ^{1}H NMR ($CDCl_3$) spectra of this product agreed with those of authentic racemic and optically active **3**.

By the same procedure, (R)-(+)-**1**[12] ($[\alpha]_D^{30}$ +77.6° (*c* 1.64, benzene)) was correlated to (*S*)-(+)-**2** ($[\alpha]_D^{25}$ +24.7° (*c* 0.96, THF)), which was successively correlated to (*S*)-(−)-**3**, M$^+$ 270; $[\alpha]_D^{20}$ −2.43° (*c* 1.48, THF).

We are grateful to Dr. T. M. Suzuki of the Government Industrial Research Institute for the CD measurement.

Sesquiterpenoids in Cultured Cells of Liverwort, *Calypogeia granulata* INOUE

Reiji TAKEDA* and Kenji KATOH

Suntory Institute for Bioorganic Research, Wakayama-dai, Shimamoto-cho, Mishima-gun, Osaka 618

(Received October 30, 1982)

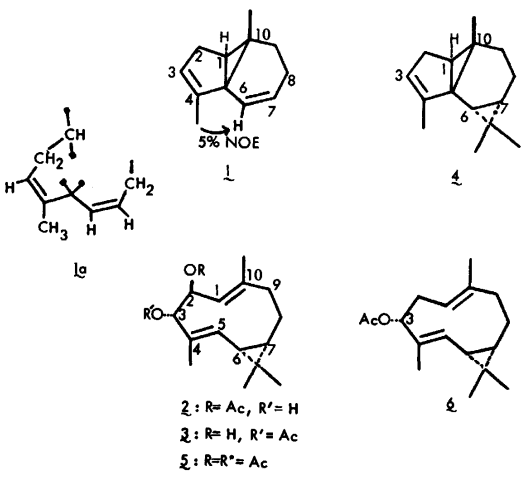
Synopsis. Three new sesquiterpenoids, trinoranastreptene, 2-acetoxy-3-hydroxybicyclogermacrene and 3-acetoxy-2-hydroxybicyclogermacrene, were isolated from cultured cells of *Calypogeia granulata* INOUE. Their structures have been established by spectroscopic analysis.

Recentry, we reported the production of volatile sesquiterpenoids by cultured cells from liverwort of *Calypogeia granulata* INOUE.[1] The result was that the production of essential oil in cultured cells, intact plants and redifferentiated plants was similar. Furthermore, we reported the isolation and structural determination of two new trinor-sesquiterpenoids, 3,10-dihydro-1,4-dimethylazulene and 3,7-dimethylindene-6-carbaldehyde, and biosynthetic studies of trinor-sesquiterpenoids, 1,4-dimethylazulene and 3,7-dimethylindene-6-carbaldehyde, using cultured cells instead of intact plants.[2] The isolation of three new sesquiterpenoids and the identification of eight sesquiterpenoids from the same cultured cells are reported.

The fresh cultured cells for 20 d were steam-distilled to obtain the essential oil (0.3% of fresh weight) as blue oil. The essential oil was subjected to SiO_2 column chromatography using hexane, $CHCl_3$ and Et_2O to give three fractions, I, II, and III. Sesquiterpene hydrocarbons from Fr. I were identified as β-elemene, bicycloelemene, eremophilene, ledene, alloaromadendrene and anastreptene[3] by IR, MS, and GC-retention time of authentic samples. 3-Acetoxy- and 3-hydroxybicyclogermacrene were isolated from Fr. II and identified with authentic data.[4] Three new sesquiterpenoids, trinoranastreptene (**1**), 2-acetoxy-3-hydroxybicyclogermacrene (**2**), and 3-acetoxy-2-hydroxybicyclogermacrene (**3**) were isolated from Fr. I and III, and their structures are described below.

Trinoranastreptene (**1**) was isolated from Fr. I by preparative GC. The molecular formula $C_{12}H_{16}$ of **1** was determined by the appearence of a molecular ion peak at m/z 160 in its mass spectrum. The 360 MHz ^{1}H NMR spectrum indicated signals due to a tertiary methyl at δ 0.93, olefinic methyl at δ 1.73, allylic CH_2 at δ 1.95 and 2.42, and three olefinic protons at δ 5.17, 5.49, and 6.12. In the decoupling experiments of **1**, irradiation of 4-CH_3 collapsed signals of 3-H and 2-H_A to sharp peaks and a multiplet of 2-H_B to a broad double doublet. Also, irradiation of 2-H_B converted two broad doublets of 3-H and 2-H_A into two broad singlets. Further, irradiation of the signal due to 6-H collapsed a double double doublet of 7-H to double doublet. In the NOE experiment of **1**, a 5% NOE was observed on 6-H upon irradiation of 4-CH_3. These results indicate that trinoranastreptene has a partial structure **1a**. The comparison of the 360 MHz NMR of **1** and **4** was quite similar except for the signals of two olefinic protons in **1** and two methyl groups and two protons on the cyclopropane ring in **4**. Also, 1-H of **1** appeared at low field of δ 1.98 relative to 1-H of **4** at δ 1.40. It was represented that 1-H of **4** shifted to high field by anisotropic effect of cyclopropane moiety. These results, together with biogentic consideration showed that the new trinor-sesquiterpene is most favourably represented by formula **1**.

2-Acetoxy-3-hydroxybicyclogermacrene (**2**) and 3-acetoxy-2-hydroxybicyclogermacrene (**3**) were isolated from fraction III by flash chromatography on SiO_2 eluted with hexane–EtOAc (3 : 1). Their molecular weight by high resolution mass spectra indicated the molecular formula to be $C_{17}H_{26}O_3$. Their IR spectra showed a hydroxyl absorption band (**2**: 3450; **3**: 3450 cm^{-1}) an ester absorption band (**2**: 1725; **3**: 1720 cm^{-1}) and a trisubstituted double bond absorption band (**2** and **3**: 1660 and 840 cm^{-1}). The ^{1}H NMR spectra of **2** and **3** indicated signals of two protons on the cyclopropane ring (**2**: δ 0.73 and 1.34; **3**: 0.73 and 1.34), *gem*-dimethyl group (**2**: δ 1.09 and 1.12; **3**: 1.05 and 1.10), two olefinic methyl groups (**2**: δ 1.66 and 1.72; **3**: 1.58 and 1.75), acetoxy methyl group (**2**: δ 2.13; **3**: 2.11) two methine protons (**2**: δ 4.45 and 5.42; **3**: 4.49 and 5.08) adjacent to oxygen and two olefinic protons (**2**: δ 5.10 and 5.23; **3**: 4.90 and 5.08). Acetylation of **2** and **3**, respectively yielded the same diacetate **5** identical in IR and ^{1}H NMR spectra. The ^{1}H NMR spectral signals of **3** closely resembled the corresponding signals in the spectrum of 3-acetoxybicyclogermacrene (**6**) isolated from the same cultured cells, with exception of signal of one proton on a carbon bearing a hydroxyl group at C-2, showing that this compound possessed the same bicyclogermacrene-type sesquiterpene skeleton. The location of acetoxyl and hydroxyl groups in **2** was suggested to be at C-2 and C-3 by spin decoupling experiments. When the proton attached to acetoxyl group at δ 5.42 was irradiated, proton on carbon bearing hydroxyl group (3-H) at δ 4.45 and olefinic proton (1-H) at δ 5.23 collapsed to



broad singlet, respectively. From the above results, the structures of two new sesquiterpenes were established to be **2** and **3**.

The relative stereostructure was determined by the following way. In the NOE experiments of **2**, a 12% NOE was observed on 6-H upon irradiation of 4-CH_3. Also, an 11% NOE was observed on 3-H upon irradiation of 4-CH_3. This result indicates that the hydroxyl group at C-3 and cyclopropane ring have a *cis* relation. The fact that 2-H is coupled to 3-H and 1-H with $J_{2,3}=3.0$ and $J_{1,2}=8.5$ Hz indicates that 2-H and 3-H have a *trans* relation based on inspection of Dreiding models.[5]

Experimental

IR spectra were measured with a Hitachi EPI-G2 spectrometer, ^{1}H NMR spectra with a JEOL FX-100 (100 MHz) or a Nicolet NT-360 (360 MHz) spectrometer in deuteriochloroform solution containing tetramethylsilane as an internal standard, low resolution mass spectra with a Hitachi RMU-6 and high resolution mass spectra with a JEOL 01SG-2, with direct inlet system operating at 70 eV. An analytical GC was performed with a Hitachi 163 type apparatus equipped with a Thermon 600 T glass capillary column, and preparative GC with a Varians model 920 fitted with an aluminum column (10 ft × 3/8 in) packed with 5% Thermon 1000 on Chromosorb W. The gas chromatograph was operated at a bath temperature of 180 °C, He gas was used as the carrier gas. Kieselgel 60 (E. Merck, Darmstadt) was used for column chromatography. Thin-layer chromatography (TLC) was carried out on Kieselgel GF_{254} (E. Merck, Darmstadt) in 0.25 mm thickness.

Isolation. The gametophyte cells developed from spores were cultured for 20 d in twenty 500 ml culture flasks, and the filtered cells (500 g) were steam-distilled to give 1.5 g of a blue oil (2—3.3% of dry weight). The essential oil was subjected to column chromatography on SiO_2. Elution with hexane gave sesquiterpene hydrocarbons (F-I) and 1,4-dimethylazulene. Elution with $CHCl_3$ yielded 3-acetoxybicyclogermacrene and 3-hydroxybicyclogermacrene (F-II). Elution with Et_2O yielded crude 2-acetoxy-3-hydroxybicyclogermacrene and 3-acetoxy-2-hydroxybicyclogermacrene (F-III).

Trinoranastreptene (**1**) was isolated from F-1 by preparative GC, as a colorless oil, ^{1}H NMR δ 0.93 (3H, s, 10-CH_3), 1.73 (3H, br. s, 4-CH_3), 2.00 (1H, br. dd, J=6.4 and 8.5 Hz, 1-H), 1.94 (1H, br. dd, J=6.4 and 17.2 Hz, 2-H_A), 2.42 (1H, m, 2-H_B), 5.16 (1H, br. s, 3-H), 5.49 (1H, ddd, J=2.5, 6.4 and 9.3 Hz, 7-H), and 6.12 (1H, d, J=9.3 Hz, 6-H); MS *m/z* (%) 160 (42, M^+, $C_{12}H_{16}$), 145 [100, $(M-CH_3)^+$], 130 (21).

2-Acetoxy-3-hydroxybicyclogermacrene (2) and 3-Acetoxy-2-hydroxybicyclogermacrene (3). The crude fraction (F-III) was purified by column chromatography on SiO_2. Elution with hexane–EtOAc (3 : 1) gave **2** (60 mg), colorless viscous oil, $[\alpha]_D^{22}$ −10.3° (*c* 0.8, $CHCl_3$); IR (film) 3450, 1725, 1660, and 840 cm^{-1}; ^{1}H NMR δ 0.73 (1H, ddd, J=3.0, 9.0, and 12.5 Hz, 7-H), 1.09 and 1.12 (3H each, s, *gem*-dimethyl), 1.34 (1H, dd, J=8.5 and 12.5Hz, 6-H), 1.66 and 1.72 (3H each, br. s, 4-CH_3 and 10-CH_3), 2.48 (1H, m, 9-H_A), 4.45 (1H, d, J=3.0 Hz, 3-H), 5.10 (1H, br. d, J=8.5 Hz, 5-H), 5.23 (1H, br. d, J=8.5 Hz, 1-H), and 5.42 (1H, dd, J=3.0 and 8.5 Hz, 2-H); MS *m/z* (%) 278 (trace, M^+), 218 [21, $(M-60)^+$], 137 (51), and 109 (100). Found: *m/z* 278.1908. Calcd for $C_{17}H_{26}O_3$: M, 278.1925.

Successive elution with the same solvent yielded **3** (45 mg), as a colorless viscous oil, $[\alpha]_D^{22}$ +63.2° (*c* 1.2, $CHCl_3$); IR (film) 3450, 1720, 1660, and 840 cm^{-1}; ^{1}H NMR δ 0.73 (1H, ddd, J=3.0, 9.0, and 12.5 Hz, 7-H), 1.05 and 1.10 (3H each,s, *gem*-dimethyl), 1.34 (1H, dd, J=8.5 and 12.5 Hz, 6-H), 1.58 and 1.75 (3H each, br. s, 4-CH_3 and 10-CH_3), 2.49 (1H, m, 9-H_A), 4.49 (1H, dd, J=3.0 and 8.5 Hz, 2-H), 4.90 (1H, br. d, J=8.5 Hz, 1-H), 5.08 (1H, br. d, J=8.5 Hz, 5-H), and 5.26 (1H, d, J=3.0 Hz, 3-H); MS *m/z* (%) 278 (trace, M^+), 218 [35, $(M-60)^+$], 152 (100), 109 (95). Found: *m/z* 278.1903. Calcd for $C_{17}H_{26}O_3$: M, 278.1925.

Acetylation of 2-Acetoxy-3-hydroxybicyclogermacrene (2). A solution of **2** (10 mg) in dry pyridine (1 ml) and Ac_2O (0.5 ml) was kept at room temperature for 1 d. The reaction mixture was treated in the usual way to give a residue, which was chromatographed on SiO_2. Elution with hexane–EtOAc (10 : 1) gave diacetate **5** (10 mg).

Acetylation of 3-Acetoxy-2-hydroxybicyclogermacrene (3). This compound (5 mg) was treated with Ac_2O (0.5 ml) and dry pyridine (1 ml) at room temperature for 1 d and then worked up in the usual way. The resulting residue was chromatographed on SiO_2 using hexane–EtOAc (10 : 1) to give diacetate **5** (6 mg), colorless viscous oil, IR (film) 1735, 1645 and 850 cm^{-1}; ^{1}H NMR δ 1.06 and 1.27 (3H each, s, *gem*-dimethyl), 1.66 and 1.77 (3H each, br. s, 4-CH_3 and 10-CH_3), 2.05 and 2.09 (3H each, s, -$COCH_3$), 4.96 (1H, br. d, J=8.5 Hz, 5-H), 5.09 (1H, br. d, J=8.5 Hz, 1-H), 5.39 (1H, d, J=3.0 Hz, 3-H), and 5.52 (1H, dd, J=3.0 and 8.5 Hz, 2-H); MS *m/z* (%) 320 (1, M^+, $C_{19}H_{28}O_4$), 278 [7, $(M-42)^+$], 218 [24, $(M-60)^+$], 152 (57), 109 (50), and 43 (100).

Synthesis of 2,2-Dimethyl-2*H*-pyran-fused Flavonols Using the Modified Algar-Flynn-Oyamada Reaction

A. C. Jain,* S. M. Gupta, and Anita Sharma
Department of Chemistry, University of Delhi, Delhi-110007, India

(Received July 10, 1982)

Synopisis. 6-Acetyl-2,2-dimethylchromenes when separately condensed with *p*-anisaldehyde in the presence of ethanolic NaOH and subsequently oxidized with alkaline hydrogen peroxide without isolating the intermediate chalcones afforded the corresponding 2,2-dimethyl-2*H*-pyran-fused flavonols respectively in good yields. Thus, flavonols having free 3-hydroxyl and fused with 2,2-dimethyl-2*H*-pyran can be synthesized easily.

A number of naturally occurring flavonols possess 2,2-dimethyl-2*H*-pyran ring fused either linearly or angularly with the ring A. For example, sericetin (**1**) was isolated from *Mundulea vericea*[1] in 1960. The synthesis of this natural compound was itself achieved by Jain *et al.*[2] using galangin as the starting flavonol and introducing 2,2-dimethyl-2*H*-pyran ring system later. Similarly, kaempferol derivatives were synthesized by Jain *et al.*[3] An alternative approach for the same synthesis could be to carry out the flavonol synthesis starting from acetophenones having already condensed 2,2-dimethyl-2*H*-pyran ring. Since flavonols are best synthesized[4] by reactions using either Allan-Robinson condensation or Algar-Flynn-Oyamada (AFO) reaction and the former reaction is a high temperature reaction, we attempted preparation of 2,2-dimethyl-2*H*-pyran-fused flavonols by the latter reaction. The normal practice of carrying out the AFO reaction is to subject polyhydroxychalcones, completely protected except for the 2′-hydroxyl group, to oxidation with alkaline hydrogen peroxide.[5] Thus, a large number of flavonols including natural ones have been synthesized by this method.[4] In literature, Ozawa *et al.*[6] have also carried out the above reaction on the reaction mixture of the corresponding ketones and aldehydes without isolating the chalcones. Later, the same modified AFO reaction was also used for the synthesis of a few more flavonols by Smith *et al.*[7] We have now used this modified method for the synthesis of 2,2-dimethyl-2*H*-pyran-fused flavonols.

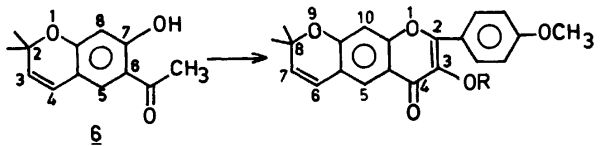
2 **3**. R = H; **4**. R = CH_3; **5**. R = $COCH_3$



6 **7**. R = H; **8**. R = CH_3

As model cases, we have chosen 6-acetyl-2,2-dimethyl-5-hydroxychromene (**2**) and the corresponding 7-hydroxy isomer (**6**) as ketones and *p*-anisaldehyde as an aldehyde. The former chromene when condensed with *p*-anisaldehyde at a room-temperature in the presence of alkali and subsequently treated after 24 h with alkaline H_2O_2 in cold (below 15 °C) without isolating the intermediate chalcone, gave a flavonol derivative. It was identified as 3-hydroxy-2-(4-methoxyphenyl)-8,8-dimethyl-4*H*,8*H*-benzo[1,2-*b* : 5,6-*b*′]-dipyran-4-one (**3**) on the basis of its UV and ^{1}H NMR studies, which ruled out the possibility of alternate formation of the corresponding aurone, aurone hydrate or benzofuran derivatives, which are sometimes reported to form in the AFO reaction.[4] The UV spectrum (see Experimental) was typically of a flavonol derivative and the presence of hydroxyl group was indicated by positive iron(III) chloride reaction and by ^{1}H NMR signal at δ 13.86 and confirmed by the formation of its methyl ether (two methoxyls resonating at δ 3.72 and 3.78) and monoacetate (resonance signal of $-OCOC\underline{H}_3$ at δ 2.26). Further, the ^{1}H NMR spectra of the parent flavonol and its two derivatives showed the resonance signals of all the expected aromatic protons and 2,2-dimethyl-2*H*-pyran ring protons (see Experimental).

A parallel series of experiments with the isomeric chromene (**6**) and *p*-anisaldehyde gave 3-hydroxy-2-(4-methoxyphenyl)-8,8-dimethyl-4*H*,8*H*-benzo[1,2-*b* : 5,4-*b*′]dipyran-4-one (**7**) in very good yields. Again, the structure was established by UV and NMR spectra of the product itself and its methyl ether. From the above results, it appears that the modified AFO reaction can make 2,2-dimethyl-2*H*-pyran-fused flavonols easily accessible. This method has an additional advantage that the pyranoflavonols with a free hydroxyl group in position 3 can be obtained directly.

Experimental

All the mp reported are uncorrected. Unless stated otherwise, UV spectra were recorded on DU-2 spectrophotometer in methanol; the absorption values in parentheses represent log ε values; ^{1}H NMR spectra were recorded on Perkin-Elmer

R-32 (90 MHz) spectrometer in $CDCl_3$; chemical shifts are expressed in ppm downfield from TMS used as an internal reference compound; R_f values recorded refer to TLC plates for which the solvent system was one of the following: (A) chloroform, (B) benzene: petroleum ether (2 : 1) and (C) benzene : petroleum ether (2 : 3); new compounds (**3**, **5**, and **7**) reported showed satisfactory C and H percentages in elemental estimations.

*3-Hydroxy-2-(4-methoxyphenyl)-8,8-dimethyl-4*H,*8*H-*benzo*[*1*,*2*-b : *5*,*6*-b']*dipyran-4-one (3)*. A solution of 6-acetyl-5-hydroxy-2,2-dimethylchloromene[8] (**2**) (0.8 g, 3.68 mmol) and *p*-anisaldehyde (0.45 ml, 3.68 mmol) in ethanol (5 ml) was mixed with vigorous stirring with aq NaOH (0.5 g) at a room-temperature, when a heavy precipitate formed at once, presumably due to the salt formation. The mixture was allowed to stand overnight at a room-temperature and then dissolved in aq NaOH (1.25 g/7.5 ml). After cooling below 15 °C, H_2O_2 (0.42 ml, 30%, 3.68 mmol) was added quickly with stirring. As the oxidation mixture stood, the temperature rose between 38—40 °C. The mixture was cooled after 30 min and solidified with dil sulfuric acid, when the pyranoflavonol and inorganic sulfate precipitated out. The inorganic sulfate was dissolved by pouring the mixture in large amount of water. After standing for some time, the solid was filtered and crystallized from methanol when **3** formed as light yellow needles (600 mg), mp 137—138 °C; light brown color with ethanolic iron (III) chloride; R_f 0.58 (solvent B); Found: C, 71.7; H, 5.4%. Calcd for $C_{21}H_{18}O_5$: C, 72.0; H, 5.1%; UV: λ_{max} 360—368 (4.25), 273—281 (3.87) and 230 nm (4.12); IR: ν_{max} 3470 and 1625 cm^{-1}; ^1H NMR: δ 1.36 (s, 6H, $(C\underline{H}_3)_2C$<), 3.81 (s, 3H, $-OC\underline{H}_3$), 5.51 (d, 1H, J=9 Hz, $\underline{H}_9$), 6.31 (d, 1H, J=9 Hz, $\underline{H}_{10}$), 6.70 (d, 1H, J=10.5 Hz, $\underline{H}_6$), 6.85 (d, 2H, J=9 Hz, $\underline{H}_{3',5'}$), 7.51 (d, 2H, J=9 Hz, $\underline{H}_{2',6'}$), 7.62 (d, 1H, J=10.5 Hz, $\underline{H}_5$) and 13.86 (s, 1H, $-O\underline{H}$ at position 3).

The acetate prepared by the acetic anhydride-pyridine method was obtained as an yellow solid, mp 88—90 °C; R_f 0.32 (solvent B); Found: C, 70.3; H, 5.0%. Calcd for $C_{23}H_{20}O_6$: C, 70.4; H, 5.1%; ^1H NMR: δ 1.42 (s, 6H, $(C\underline{H}_3)_2C$<), 2.26 (s, 3H, $-OCOC\underline{H}_3$), 3.77 (s, 3H, $-OC\underline{H}_3$), 5.64 (d, 1H, J=9.5 Hz, $\underline{H}_9$), 6.34 (d, 1H, J=9.5 Hz, $\underline{H}_{10}$), 6.68 (d, 1H, J=10 Hz, $\underline{H}_6$), 6.82 (d, 2H, J=9 Hz, $\underline{H}_{3',5'}$), 7.47 (d, 2H, J=9 Hz, $\underline{H}_{2',6'}$), and 7.52 (d, 1H, J=10 Hz, $\underline{H}_5$).

*3-Methoxy-2-(4-methoxyphenyl)-8,8-dimethyl-4*H,*8*H-*benzo*[*1*,*2*-b : *3*,*4*-b']*dipyran-4-one (4)*. A solution of the above flavonol (**3**, 100 mg) in dry acetone (5 ml) was refluxed with dimethyl sulfate (0.15 ml) and K_2CO_3 (0.5 g) on water bath for 1 h. The product gave **4** as light yellow oil (80 mg), light red color with ethanolic iron (III) chloride R_f 0.29 (solvent B); ^1H NMR: δ 1.42 (s, 6H, $(C\underline{H}_3)_2C$<), 3.72, 3.78 (2s, 6H, 2-$OC\underline{H}_3$), 5.60 (s, 1H, J=9.5 Hz, $\underline{H}_9$), 6.51 (d, 1H, J=9.5 Hz, $\underline{H}_{10}$), 6.63 (d, 1H, J=10 Hz, $\underline{H}_6$), 6.85 (d, 2H, J=9 Hz, $\underline{H}_{3',5'}$), 7.43 (d, 2H, J=9 Hz, $\underline{H}_{2',6'}$), and 7.48 (d, 1H, J=10 Hz, $\underline{H}_5$).

*3-Hydroxy-2-(4-methoxyphenyl)-8,8-dimethyl-4*H,*8*H-*benzo*[*1*,*2*-b : *5*,*4*-b']dipyran-4-one *(7)*. A solution of 6-acetyl-7-hydroxy-2,2-dimethylchromene[9,10] (**6**) (0.92 mmol, 0.2 g) and an equivalent amount of *p*-anisaldehyde (0.11 ml) in ethanol (2 ml) was mixed with aq NaOH (0.12 g in 2.5 ml water). After 24 h at a room-temperature, the resulting solution was mixed in aq NaOH (0.32 g in 1.5 ml), cooled below 15 °C and treated with hydrogen peroxide (0.1 ml, 30%). The product was worked up and crystallized from methanol when **7** was obtained as light yellow needles (0.15 g), mp 157—158 °C; light brown color with ethanolic iron (III) chloride; R_f 0.74 (solvent C); Found: C, 72.3; H, 5.3%. Calcd for $C_{21}H_{18}O_5$: C, 72.0; H, 5.1%; UV: λ_{max} 366—381 (4.04), 272 (3.99), and 228 nm (4.15); IR: ν_{max} 3475 and 1625 cm^{-1}; ^1H NMR: δ 1.37 (s, 6H, $(C\underline{H}_3)_2C$<), 3.85 (s, 3H, $-OC\underline{H}_3$), 5.52 (d, 1H, J=9 Hz, $\underline{H}_7$), 6.27 (d, 1H, J=9 Hz, $\underline{H}_6$), 6.33 (s, 1H, $\underline{H}_{10}$), 6.85 (d, 2H, J=9 Hz, $\underline{H}_{3',5'}$), 7.43 (d, 2H, J=9 Hz, $\underline{H}_{2',6'}$), 7.62 (s, 1H, $\underline{H}_5$) and 13.54 (s, 1H, $-O\underline{H}$ at position 3).

*3-Methoxy-2-(4-methoxyphenyl)-8,8-dimethyl-4*H,*8*H-*benzo*[*1*,*2*-b : *5*,*4*-b']*dipyran-4-one (8)*. A solution of the above flavonol (**7**, 100 mg) in acetone (5 ml) was refluxed with dimethyl sulfate (0.15 ml) and K_2CO_3 (0.5 g) for 1 h and the reaction mixture was worked up as usual when **8** was obtained as a light yellow oil (70 mg); R_f 0.35 (solvent C); ^1H NMR: δ 1.42 (s, 6H, $(C\underline{H}_3)_2C$<), 3.80, 3.85 (2s, 6H, 2-$OC\underline{H}_3$), 5.46 (d, 1H, J=9.5 Hz, $\underline{H}_7$), 6.26 (d, 1H, J=9.5 Hz, $\underline{H}_6$), 6.36 (s, 1H, H_{10}) 6.85 (d, 2H, J=9 Hz, $\underline{H}_{3',5'}$), 7.40 (s, 1H, $\underline{H}_5$) and 7.49 (d, 2H, J=9 Hz, $\underline{H}_{2',6'}$).

The authors thank the CSIR for awarding SRF and JRF to SMG and AS respectively.

On the Sorption Behaviour of Some Cations on Cobalt Hexacyanoferrate(III) Exchanger. Binary Separations of Rb^+ and Cs^+ on Columns

Ajay K. JAIN,* Rajpal SINGH, and Chand BALA
Department of Chemistry, University of Roorkee, Roorkee 247672, India
(Received March 3, 1982)

Synopsis. Sorption behaviour of Ag, Cs, Rb, Co(II), Zn(II), and Fe(III) ions at low concentration (0.2 mmol) is studied in different concentrations of nitric acid and ammonium nitrate on cobalt hexacyanoferrate(III) exchanger. log K_d *vs.* log concentration plots show that the sorption of these ions is not followed through ion exchange mechanism, only. In case of Rb^+ and Cs^+, a very low K_d is observed at high concentration of nitric acid (>5 mol dm^{-3}) thereby showing the possibility of their elution on columns. For various other ions, such as Ba, Sr, Mn, Hg(II), Mg, Cd, Ca, Pb, Ni, La, and Th, the K_d values are almost zero. Thus the binary separation of Rb^+ and Cs^+ from a number of ions on the columns of this exchanger has been carried out.

During the last two decades a number of inorganic sorbents[1-6] have been prepared and their ion exchange behaviour studied. Although a number of hexacyanoferrates(III)[7-9] are insoluble, they have been little studied, with regard to their sorption behaviour. Recently we have reported on the sorption properties of chromium hexacyanoferrate(III).[10] This sorbent was found to be chemically more stable and showed better selectivity in sorption behaviour as compared to corresponding chromium hexacyanoferrate(II).[11] In view of better stability and selectivity of this hexacyanoferrate(III) exchanger, we have thought it desirable to investigate the exchange properties of other metal hexacyanoferrates(III). In a recent preliminary communication,[12] we have reported on the use of cobalt hexacyanoferrate(III)(CoFic) as Cu(II) selective exchanger. This exchanger is highly stable in salt solution and mineral acids and possesses potentiality for important separations. Further, sorption studies on this exchanger have now been undertaken.

Experimental

Cobalt(II) chloride (B. D. H.) and potassium hexacyanoferrate(III) (Sarabhai merck) both analytical reagent grade were used in the preparation of the exchanger without further purification. All other salts and acids were also of analytical grade. Radioisotopes of ^{134}Cs, ^{86}Rb, ^{110m}Ag, $^{85}Sr+^{89}Sr$, ^{133}Ba, ^{54}Mn, ^{58}Co, ^{65}Zn, ^{203}Hg, and $^{55}Fe+^{59}Fe$ were obtained from Bhabha Atomic Research Centre, Bombay.

Apparatus. pH measurements were made with ELICO pH meter model LI 10. Bausch and Lomb spectronic 20 was used for spectrophotometric determination of ions. Gamma counting of ^{110m}Ag, ^{134}Cs, ^{86}Rb, $^{85+89}Sr$, ^{54}Mn, ^{58}Co, ^{65}Zn, ^{203}Hg, and $^{55}Fe+^{59}Fe$ was done on a Scintillation counter (ECIL, Hyderabad) employing a well type NaI (Tl) crystal.

Preparation of Exchanger. Cobalt(II) potassium hexacyanoferrate(III) ($KCoFe(CN)_6 \cdot 5H_2O$) as reported earlier,[12] was obtained by the gradual addition of cobalt(II) chloride (0.12 mol dm^{-3}) to potassium hexacyanoferrate(III) (0.06 mol dm^{-3}) in a thermostat at 80 °C. The precipitate thus obtained was digested for ≈35 h and finally was washed with distilled water by centrifugation and dried in an oven at 80 °C. The precipitate was equilibrated with 1 mol dm^{-3} HNO_3 for 48 h, the acid being intermittently replaced. All further studies were carried out with exchanger pretreated with HNO_3.

Determination of Ions. Mg, Ca, Ni, Cu(II), Pb, Cd, Al, and Bi were determined by EDTA titrations and radiometric method was used for the determination of radio isotopes.

Determination of Distribution Coefficient. The distribution coefficients were determined by the batch equilibration method by shaking the exchanger (0.1 gm) with 10 cm^3 of 2×10^{-4} mol dm^{-3} metal ion solution in different concentrations of nitric acid or ammonium nitrate.

Determination of Sorption Capacity for Cs^+ and Rb^+ and Column Operation. Studies on the maximum uptake of Cs^+ and Rb^+ on cobalt hexacyanoferrate(III) were carried out by shaking 50 mg of the exchanger with 20 cm^3 solution of Rb^+ or Cs^+ (10^{-6} to 10^{-1} mol dm^{-3}). For column operations, a column of i.d. 0.5 cm containing 0.5 g exchanger was used. Column capacity was determined from breakthrough experiment using Rb^+ or Cs^+ solution (0.1 mol dm^{-3}) at 4 drops (≈0.2 cm^3) per minute and found to be 0.4 mequiv. g^{-1} both for Cs^+ and Rb^+. For separation studies, the column was loaded with a mixture of the metal ions pair to be separated and the elution was started after 15 min at a flow rate of 4 drops (≈0.2 cm^3) per minute.

Results and Discussion

The extent of static sorption of Rb^+ and Cs^+ at different concentrations is given in Table 1. It is seen that in dilute solutions (10^{-4}—10^{-6} mol dm^{-3}) the sorption of Rb^+ and Cs^+ is almost cent percent and it attains a constant value at concentration of 10^{-1} mol dm^{-3} The maximum sorption capacity is found to be 1.68 mequiv. g^{-1} for Cs^+ and 3.4 mequiv. g^{-1} for Rb^+ ions. This high sorption capacity indicates that K^+ is substituted by Rb^+ or Cs^+, the theoretical exchange capacity on the basis of K^+ being liberated is 2.5 mequiv. g^{-1}. The release of K^+ was detected experimentally. The excess sorption capacity of Rb^+ ions may be due to molecular adsorption of Rb^+.

Sorption behaviour of Rb^+, Cs^+, Ag^+, Co^{2+}, Zn^{2+}, and Fe^{3+} For the efficient use of this exchanger in the separation and isolation, it is necessary to have information about their sorption behaviour in presence of acids and salt solutions. Therefore, in order to work out the conditions for the elution of these ions from the column, the variation of their K_d values at 2×10^{-4} mol dm^{-3} concentration was investigated as a function of NH_4NO_3 and HNO_3 concentration. As usual these results in terms of log K_d *vs.* log concentration of NH_4NO_3 and HNO_3 are shown in Figs. 1 and 2, respectively. Perusal of

Concentration of $CsNO_3$ or RbCl mol dm^{-3}	mequiv. of Cs sorbed g^{-1} of the exchanger	mequiv. of Rb sorbed g^{-1} of the exchanger
5×10^{-1}	1.68	3.4
3×10^{-1}	1.68	3.4
1×10^{-1}	1.68	3.4
1×10^{-2}	0.76	1.66
8×10^{-3}	0.62	1.48
5×10^{-3}	0.50	1.41
2×10^{-3}	0.32	0.68
1×10^{-3}	0.31	0.38
1×10^{-4}	0.04	0.04
1×10^{-5}	0.004	0.004
1×10^{-6}	0.0004	0.0004

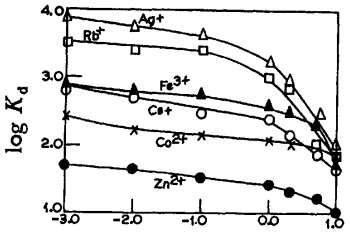

Fig. 1. Variation of log K_d of Cs^+, Rb^+, Ag^+, Co^{2+}, Zn^{2+}, and Fe^{3+} ions with log NH_4NO_3 concentration.

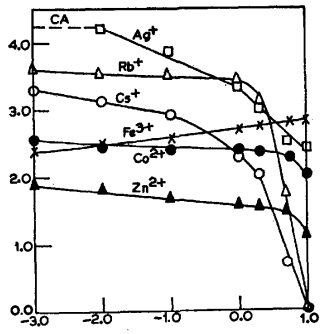

Fig. 2. Variation of log K_d of Cs^+, Rb^+, Ag^+, Co^{2+}, Zn^{2+}, and Fe^{3+} ions with log HNO_3 concentration.

these plots (Fig. 1) shows that the sorption of Ag^+, Rb^+, and Cs^+ ions is little affected upto NH_4NO_3 concentration of 1 mol dm^{-3} and the slope of the plots (−1.3; −1.0, −0.7 for Ag^+, Rb^+, and Cs^+) in the range 1 mol dm^{-3} to 10 mol dm^{-3} approximate to −1 indicating that sorption of these ions may be proceeding through ion exchange mechanism. In the lower concentration range, 10^{-3} to 1 mol dm^{-3}, the exchanger does not get saturated with the NH_4^+ ions and the slope of ≈−1.0 is not thus obtained. The effect of HNO_3 on K_d (Fig. 2) is different in that the K_d of Cs^+ and Rb^+ falls approximately to zero value at 10 mol dm^{-3} HNO_3 and slope of −1 is obtained only for Ag^+ in higher concentration range.

The effect of HNO_3 or NH_4NO_3 concentration on Co^{2+}, Zn^{2+}, and Fe^{3+} is significantly different from that of Cs^+, Rb^+, and Ag^+. The K_d values of these ions remains almost unchanged even in higher concentration of the acid and salt. These ions thus appear to be irreversibly sorbed on the exchanger. This irreversible sorption may be due to the formation of a mixed phase involving the substitution of potassium and cobalt(II) ions. The K_d values of Fe^{3+} surprisingly increases at higher acidity, which possibly indicates the formation of more stable new phase. Similar behaviour was observed for the adsorption of number of bivalent ions on zinc hexacyanoferrate(II) and hexacyanoferrate(III).[7]

Separations of Cs^+ and Rb^+. It is seen from K_d values (Table 2) that the exchanger can be used to separate Cs^+ and Rb^+ from a number of metal ions. 10 mol dm^{-3} HNO_3 was used to elute Cs^+ or Rb^+ from the columns as the K_d of these ions is decreased to appeoximately zero value (Fig. 2) in higher acid concentration. Although, the exchanger has high affinity for Ag^+, but it cannot be used for its recovery because its elution from the columns is very difficult. Further Cs^+ and Rb^+ can also not be separated from Co^{2+}, Zn^{2+}, and Fe^{3+} as they can not be eluted even at high HNO_3 or NH_4NO_3 concentration. The low K_d values (≈0 to 43) of the metal ions, such as Ba(II), Sr(II), Mn(II), Hg(II), Cd(II), Ca(II), Pb(II), Ni(II), Al(III), La(III), Bi(III), and Th(IV), were obtained in their 0.002 mol dm^{-3} solution in 0.01 mol dm^{-3} corresponding acid. Thus the separation of Cs^+ and Rb^+ from these metal ions, which can be eluted with 0.01 mol dm^{-3} HNO_3 is possible and a number of binary separations (Table 2) of analytical importance have been carried out. The recovery of other ions is sharp and quantitative whereas

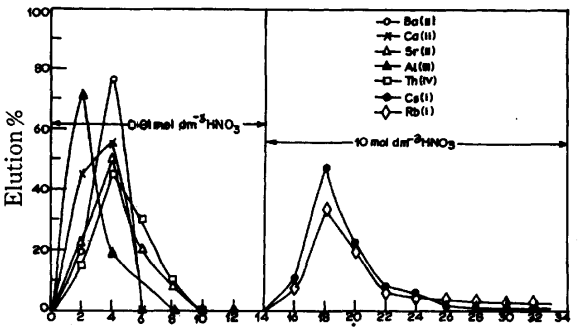

Fig. 3. Separation of Cs^+ or Rb^+ from other cations on cobalt hexacyanoferarte(III)

Table 2. Binary separations of Cs^+ (K_d=200) and Rb^+ (K_d=2401) from various cations on cobalt hexacyanoferrate(III) columns

Sample No.	Other cation	Amount taken/μg				Recovery of Cs^+	Recovery of Rb^+
		K_d a) $cm^3\ g^{-1}$	Cs^+	Rb^+	Other cations	%	%
1	Ba(II)	1	531.64	342	549.44	96.0	90.5
2	Sr(II)	12	531.64	342	350.54	96.2	90.5
3	Mn(II)	4	531.64	342	219.76	95.0	91.0
4	Hg(II)	1	531.64	342	802.44	95.9	91.0
5	Mg(II)	0	531.64	342	97.28	96.0	90.8
6	Cd(II)	0	531.64	342	449.64	95.8	90.6
7	Ca(II)	0	531.64	342	160.32	96.0	90.6
8	Pb(II)	5	531.64	342	828.84	95.2	90.6
9	Ni(II)	0	531.64	342	234.84	95.9	90.5
10	Al(III)	11	531.64	342	107.92	96.0	90.7
11	La(III)	0	531.64	342	555.68	96.0	90.9
12	Bi(III)	43	531.64	342	836.00	95.2	90.2
13	Th(IV)	0	531.64	342	928.40	96.0	90.6

Recovery of all other cations is almost 100%. a) K_d values of Cs^+, Rb^+, and other metal ions are determined at 0.002 mol dm^{-3} concentration of the metal salt solution in 0.01 mol dm^{-3} corresponding acid.

more than 90 percent of Rb^+ and Cs^+ could be eluted with 18 cm^3 of 10 mol dm^{-3} HNO_3. With larger amounts of HNO_3, almost complete recovery of Cs^+ and Rb^+ is possible. Few typical separations are shown in Fig. 3.

Thus this exchanger is useful for many important separation of Cs^+ and Rb^+ from large number of metal ions and is superior to nickel and cobalt hexacyanoferrate(II)[13] exchangers where the elution of Cs^+ from the column is difficult.

One of the authors (Chand Bala) is thankful to CSIR for financial assistance.

Concentration of Organic Pollutants in Water by Evaporation at Reduced Pressure

Kohei URANO,* Seok Ching YAP, and Koji HAYASHI
Department of Safety and Environmental Engineering, Yokohama National University, 156 Tokiwadai, Hodogaya-ku, Yokohama 240
(Received June 18, 1982)

Synopsis. The relative volatilities α of various organic compounds were obtained as a parameter to determine the recovery for the concentration at reduced pressure and room temperature. The evaporation technique is an efficient method for concentrating large molecular weight compounds and ionizing compounds, if ionization is promoted by adjusting the pH of water.

While the research on water pollution and water treatment was conducting, it was sometimes necessary to determine organic pollutants of sub-ppm levels. The authors[1-4] studied various chromatographic methods such as steam carrier gas chromatography (SCGC), gel chromatography (Gel C), and high performance liquid chromatography (HPLC) for direct analyses of organic pollutants in water. However, development of a feasible concentration method is neccesary for these analytical techniques, since direct injection into SCGC, Gel C, or HPLC and analyses by other methods provide only a limited success at ppm levels. In the analysis of drinking water, Cathorne *et al.*[5] used the evaporation technique with a rotary evaporator and the extraction by methanol. These methods are applicable to only small sample sizes and no experiments has been done to ascertain the recovery efficiency. Loy[6] and Kuo *et al.*[7] used the distillation technique to concentrate volatile organics in the distillate. These methods required elevated temperatures, and are considered to be unsuitable for organic compounds that hydrolyse or decompose at elevated temperatures. Cathorne *et al.*[5] obtained large sample sizes by using a freeze-dryer. However, there has been no report on its efficiency for various organic compounds. The purpose of this study is to investigate the recovery efficiency of concentration method at room temperature using the freeze-dryer as a simple and efficient apparatus for concentrating organic pollutants in water for subsequent analytical techniques.

Experimental

The aqueous solutions ranging from 2 to 20 mg/L of organic compounds shown in Table 1 were used in this study. The sample number for each compound as shown in the table is used in Figs. 2 and 3.

The apparatus used in this study consisted of a Yamato freeze-dryer model D-35. It was connected to a vacuum pump, with evacuation rate of 300 L/min, as shown in Fig. 1. The inner container of the freeze-dryer was cooled by a Neslob Cooler to a temperature of −35 to −45 °C. Kjeldahl flasks were filled with 50 mL (V_o) of the sample solutions whose initial concentrations were C_o, cooled in another freezer to form a layer of ice, and then attached to the trap by means of flask joints. The cooling of the samples before evaporation prevented a loss of liquid due to scattering at a sudden decrease in pressure. If the temperature was not controlled during the evaporation, the liquid would freeze, and the concentration process would become time-consuming. Therefore, during the evaporation process, the flasks were partially immersed in a water bath maintained at a temperature of 35 °C so that the solutions in the flasks were kept at a temperature of about

20 °C. At fixed intervals of time, each flask was removed in turn and the weight of the residual solution was measured to obtain the solution volume V. The solution volume V was found to decrease linearly with time at a rate of about 1 mL/min in this method. The concentration C of the residual solution was measured using TOC analyser, TOD analyser, or UV spectrometer. In this way, the volume ratio V_0/V and concentration factor C/C_0 were obtained.

Results and Discussion

If the relative volatility α, which is defined as the ratio of concentration ratio of two components in vapor phase to that in the liquid phase, equals 1.0, no separation takes place. If α is less than 1.0, concentration is possible by the evaporation method. If α is greater than 1.0, concentration is impossible by the evaporation method, but the concentration will be possible by trapping the vapor. The following equations were obtained by considering mass balance; $(C-\mathrm{d}C)\times(V-\mathrm{d}V)=CV-\alpha C\mathrm{d}V$ or $(\alpha-1)C\mathrm{d}V=V\mathrm{d}C-\mathrm{d}C\mathrm{d}V\simeq V\mathrm{d}C$, where $\mathrm{d}V$ is the change in volume of solution and $\mathrm{d}C$ is the change in concentration of solution within a short time. Integrating the above equation between C_0 and C, and V_0 and V, we obtain $(1-\alpha)\log V_0/V=\log C/C_0$. Thus, a plot of $\log C/C_0$ against $\log V_0/V$ will give a straight line with slope $(1-\alpha)$. Therefore, if the value of α for the organic compound in aqueous solution is known, the recovery for the concentration method by evaporation can be predicted from the values of $(1-\alpha)$.

When the sample solution is assumed to be ideal and to obey Raoult's Law, the equilibrium partial pressure p equals the product of its vapor pressure P for pure compound and its mole fraction x in the liquid, and the total pressure P_T is obtained as $P_T=p_{org}+p_{H_2O}=P_{org}x+P_{H_2O}(1-x)$. Thus, the mole fraction of the organic compound in the vapor phase is $y=p_{org}/P_T=P_{org}x/P_T$, and that of water is $1-y=p_{H_2O}/P_T=P_{H_2O}(1-x)/P_T$. Consequently, the value of α can be given as $\alpha=y(1-x)/x(1-y)=P_{org}/P_{H_2O}$ for the ideal solution. However, actual water samples containing organic compounds which require concentration are not necessarily ideal, and the values of α for various organic compounds have not been reported so far.

Examples of the plot of $\log C/C_0$ against $\log V_0/V$ are shown in Fig. 2. For almost all the compounds, the plots could be represented approximately by straight lines, although some volatile compounds in the initial unsteady period deviated from the lines. The values of α for the various organic compounds were computed, and the results are shown in Table 1 together with the values of P_{org}/P_{H_2O} at 20 °C. It was found that the values of α for large molecular weight compounds such as humic acid and polyethylene glycol, sulfonic acids, and dicarboxylic acids were approximately 0, and these compounds could be concentrated with 100% recovery, while the values of α for benzaldehyde and aliphatic esters, alcohols, and ketones were larger than 1, and no concentration was expected. There are many compounds whose values of α were not equal to the calculated values of P_{org}/P_{H_2O}. Furthermore, the values of α for ionizing compounds like acids and amines increased with increasing concentrations, while those of non-ionizing compounds such as propionaldehyde and benzyl alcohol did not show any distinctive change. The experiments were repeated by adjusting the pH of solutions to 7 and 10—12 for acids and amines, and phenolic compounds, respectively. The representative results are shown in Fig. 3. All the tested compounds, except *o*-nitrophenol, can be concentrated with approximately 100% recovery at the pH values where 99% to 99.9% ionization of the compounds were secured, For *o*-nitrophenol, which has a large α value in the unionized form, approximately 100% recovery was obtained at 99.99% ionization.

This concentration method was applied to preconcentrate anionic surfactants in river water and biologically treated sewage before analyses with HPLC. The recovery of nearly 70% by means of TOC was obtained after $V_0/V=10$ was attained. Since anionic surfactants are mainly sulfonates or sulfates, it can be assumed that the recovery of the surfactants was 100%. In the analyses of phenolic compounds and sulfonates in treated wastewater from an oil refinery, preconcentration was necessary, and the recovery of approximately 90% was obtained by means of TOC after V_0/V reached 10.

(Received July 10, 1981)

A simple method has been proposed for estimating the state of mixing in a binary solution directly from the radial distribution function. The method has been applied to the estimation of the size of the cluster or aggregate in a binary solution of methanol and carbon tetrachloride. Pure liquid carbon tetrachloride and a binary solution of pentane and carbon tetrachloride have also been studied as reference systems. The number of methanol molecules which form a cluster in the solution at the volume ratio of 8.5(CCl_4):1.5(CH_3OH) has been estimated to be about 18, which is in good agreement with an estimate by light scattering.

Many X-ray diffraction studies have been carried out to investigate molecular arrangements in liquids. However, the structure analysis for a molecular liquid, even if it is a pure liquid, is rather difficult. A structure cannot be uniquely determined by diffraction methods, since the packing of polyatomic molecules in the liquid is three-dimensional while the information on molecular geometry obtainable from a diffraction pattern is limited to only one dimension. Usually a structure model is constructed by comparing an intensity or radial distribution function calculated for a model with the experimental one. However, it is often difficult to find a model which can sufficiently explain the experimental facts. Even if a model which yields a calculated intensity in good agreement with the experimental one is obtained, there is no assurance that this model is unique. It is often the case that models which are different from one another in the sense of a three-dimensional arrangement give very similar scattering intensities.

For a multi-component organic solution, it becomes still more difficult to make a structure analysis, and very few studies have been carried out. One example is the work by Narten on a CCl_4–$C(CH_3)_4$ system.[1] He observed a radial distribution function only up to 10 Å and interpreted the radial distribution function of the mixture only as a superposition of the radial distribution functions corresponding to the components, CCl_4 and $C(CH_3)_4$. Therefore, his interpretation is only valid for those peaks due to intramolecular interferences or due to intermolecular interferences for the first nearest neighbors concerned. In the case of a mixture of molecular liquids, one should carefully consider the state of mixing, that is, how one component is mixed with the other components, or how molecules of one component are dispersed in molecules of the other components. As will be described in this paper, the information from the radial distribution function up to large distance is important for considering the state of mixing.

In this report we present a simple method by which we estimate the state of mixing in binary mixtures with carbon tetrachloride solvent directly from a radial distribution function. The existence of a long-range correlation in the observed radial distribution function for pure liquid CCl_4 has been well established.

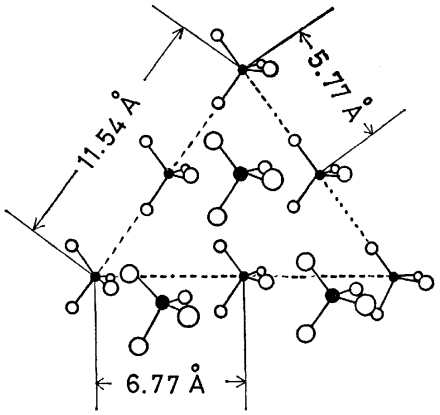

Fig. 1. Packing model for pure liquid CCl_4 (see Ref. 2).
Packing of adjacent molecules is head-tail head-tail with the molecular distance of 5.77 Å. We call this model a "bcc cluster model," because the three-dimensional packing results in a bcc lattice.

The structure of pure liquid CCl_4 has been investigated in detail and a reasonable local structural model has been proposed,[2,3] as shown in Fig. 1. The scattering intensity curve can supply suitable information for the destruction of this long-range structure of liquid CCl_4 by the addition of the other components.

In order to obtain information about the state of mixing, we carried out an X-ray diffraction experiment. Two kinds of carbon tetrachloride solutions, CCl_4–CH_3OH and CCl_4–n-C_5H_{12} systems, were chosen for the samples. In a CCl_4–CH_3OH system, methanol molecules are expected to form clusters through strong hydrogen-bonding. This expectation has been supported by the observed entropy change on mixing,[4] the magnitude of the concentration fluctuation observed by a light scattering experiment, and by theoretical interpretations.[5–7] For a CCl_4–n-C_5H_{12} system, on the other hand, a state of random mixing is believed to be realized.[8,9] It has been reported for the binary solution of methanol and carbon tetrachloride that the fluctuation of concentration has a maximum value at the molar ratio of 7.0(CCl_4):3.0(CH_3OH). It is expected that the aggregate number of methanol molecules becomes maximum at this concentration. Therefore, we observed the diffraction in-

tensity at the corresponding volume ratio of 8.5(CCl_4): 1.5(solute) for the CCl_4–CH_3OH and CCl_4–n-C_5H_{12} systems.

In these systems, it is important that the scattering intensities of the X-rays for the solute molecules, methanol and pentane, are negligibly weak in comparison with that for the solvent molecule, carbon tetrachloride.

Experimental

The scattering intensities of X-rays from liquid samples were measured at 25 °C. An energy-dispersive diffractometer with a vertical goniometer (θ-2θ scanning system) was used.[10] A fine-focus X-ray tube with a tungsten target was used at 45 kV and 20 mA. The scattering intensity was recorded by a multi-channel pulse-height analyzer connected with a Si(Li)-detector. The scattering intensity was measured by the transmission method at scattering angles, 2θ, of 2.5, 4.0, 7.0, 12.0, 20.0, and 35.0°.

The sample holder was the same as that used previously.[11] In the present study, windows of Mylar film (20 μm) were used. The specimens used in this experiment were of commercially available reagent grade. Carbon tetrachloride and pentane were used without further purification. Methanol was further purified by a single distillation.

Data Analysis

The observed scattering intensity was smoothed and was corrected for the scattering from the windows. The scattering intensity curve, thus obtained, was normalized to the energy-distribution curve of the incident beam. The absorption correction was also made by the use of calculated absorption coefficients.[12] The corrected intensity curve was then converted to an absolute scale (in the electron unit) by fitting the experimental intensity to the theoretical one at large s-values. For a pure liquid, the theoretical intensity may be estimated from the intensity calculated for one free molecule. In the case of a binary mixture, the theoretical intensity is a superposition of the scattering intensities from the two components. However, as the scattering intensities from CH_3OH and n-C_5H_{12} are negligibly weak in comparison with that from CCl_4, the theoretical intensity at large s-values may be obtained from the intensity calculated for carbon tetrachloride only. This corresponds to the treatment in which a CCl_4 molecule is fixed as a central molecule and the radial distribution function is regarded as the distribution of other molecules (CCl_4 molecules or solute molecules) around the central molecule. This treatment excludes the case in which a solute molecule occupies the position of the central molecule in the radial distribution function. In the calculation of the scattering intensity for a free CCl_4 molecule, the internuclear distances and the mean-square amplitudes of vabration for CCl_4 obtained by gas electron diffraction[13] were used. The Compton scattering intensity calculated by Cromer was subtracted.[14] The total coherent intensity thus obtained is

$$I_{co}(s) = \sum_n f_n(s)^2 + i_1(s) + i_2(s), \qquad (1)$$

where $f_n(s)$ is the atomic scattering factor, $i_1(s)$ is the coherent intensity from atomic pairs belonging to a

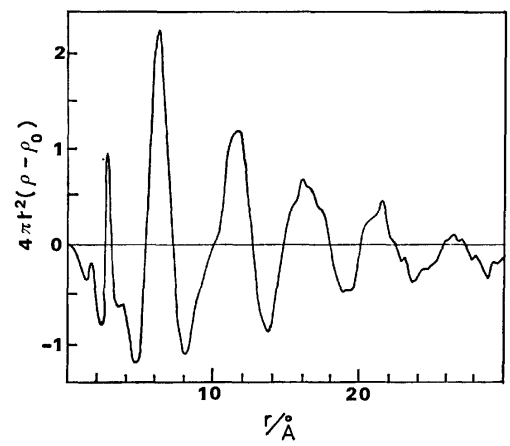

Fig. 2. Radial distribution function observed for liquid CCl_4 at room temperature.

CCl_4 molecule, $i_2(s)$ is the coherent intensity from atomic pairs belonging to different CCl_4 molecules.

The electron radial distribution function from which the bulk density was subtracted, $4\pi r^2(\rho(r)-\rho_0)$, was obtained by the Fourier transformation of $si(s)$ which is defined by $si(s)=s(i_1(s)+i_2(s))$,

$$4\pi r^2(\rho(r)-\rho_0) = \{2r/(\pi \sum_n Z_n^2)\} \sum si(s)\cdot\sin(sr)\Delta s, \qquad (2)$$

where ρ_0 is the bulk liquid density of CCl_4 in the mixture and Z_n is the atomic number of the n-th atom of a CCl_4 molecule.

In the energy-dispersive method, the scattering intensity is scarcely influenced by the fluctuation in the incident beam intensity. Therefore, the accuracy of the observed intensity is mainly limited to the statistical random error, which is estimated to be about 0.5% of the total intensity. The error of scaling due to the neglect of the scattering intensity of the solute molecule is less than 1% in the s-region used for the scaling.

Results and Discussion

The electronic radial distribution functions observed for pure liquid CCl_4,[10] CCl_4–n-C_5H_{12}, and CCl_4–CH_3OH are shown in Figs. 2, 3, and 4, respectively. It can be seen from these figures that, in the case of the CCl_4–CH_3OH system, the peaks occuring at r-values larger than 18 Å are smeared out. On the other hand, there exists clear structure correlation in the mixture of CCl_4–n-C_5H_{12} up to values as large as those observed in the pure liquid CCl_4.

Radial Distribution Function of a Solution with "Vacancies." As described in the introduction, the scattering power of X-rays from solute molecules, methanol or pentane, is negligibly weak in comparison with that from carbon tetrachloride. Therefore, in the first approximation the scattering from these binary systems can be analyzed as though the CCl_4 liquid had "vacancies" whose volumes are equal to those of solute molecules or clusters of the solute molecules. This "vacancy" does not mean that a real void exists in the liquid, but that the scattering power of X-rays by a solute molecule or a cluster can be disregarded.

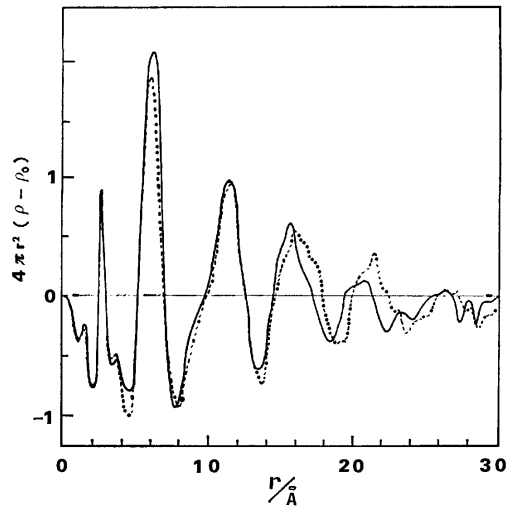

Fig. 3. Radial distribution functions for a binary solution of CCl_4 and n-C_5H_{12}. (——): Observed, (·····): calculated for "ideal mixing."

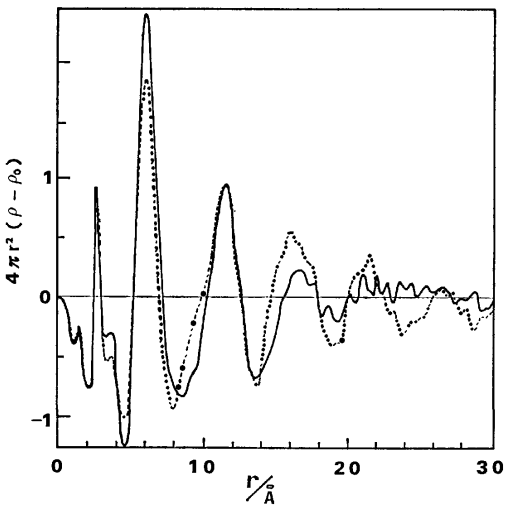

Fig. 4. Radial distribution functions for a binary solution of CCl_4 and CH_3OH. (——): Observed, (·····): calculated for "ideal mixing."

Hereafter in this paper, the term "vacancy" is used in this sense. The analysis of the radial distribution function observed in the binary solutions can be replaced by the analysis of the "vacancy" distribution in liquid CCl_4. In the analysis of the mixing state of such solutions, the following assumptions were made:

(a) It is possible to neglect the scattering intensity of X-rays from solute molecules.

(b) On passing from a pure liquid to the solution, the structure of the solvent is not influenced by the solute molecules.

The error caused by the assumption (a) is estimated to be 5% in the radial distribution function. Namely, the radial distribution functions with "vacancies" in place of the solute molecules are estimated to be 5% smaller in amplitude than the real radial distributions shown by the solid curves in Figs. 3 and 4 containing the contribution of scattering power of solute molecules. This situation, however, does not affect the following discussion. The assumption (b) means that an integral number of sites or CCl_4 molecules is replaced by non-scattering solute molecules ("vacancy") without distortion of the distribution of the sites, namely, the positions which would be occupied by CCl_4 molecules if the system were pure CCl_4 liquid. So the volume of the "vacancy" is assumed to be an integral multiple of the volume of a CCl_4 molecule. Under those assumptions, we will consider the relation between the state of mixing in a binary solution and the radial distribution function.

The radial distribution curve of liquid CCl_4 shows several peaks up to $r \simeq 28$ Å (Fig. 2). By looking at these peaks we may say that a certain number of molecules are located around a representative central molecule at a certain distance from it, if we ignore complications arising from the fact that the molecules are polyatomic and have structure and orientation. In other words, if we sat on the representative central molecule and looked around, we would see several sites that are occupied by other molecules. As is described in the analysis, the data are scaled in such a way that the central molecule is always a CCl_4 molecule and never a "vacancy."

The peak height of the radial distribution curve at a distance r is proportional to the time-averaged number of molecules which occupy the sites at a distance r from the central molecule. Because of the isotropy of the liquid, it is only necessary to consider one representative site instead of all the sites which are located at a given distance from the central molecule.

In the case of the binary solutions discussed in the present paper, the site is not always occupied by another molecule, but is sometimes occupied by a "vacancy." As a result, the peak-height of the radial distribution function decreases in comparison with that of a pure liquid.

If we denote the maximum length between two points within the "vacancy" by $2R$, (which is equal to the diameter in the case of a spherical "vacancy"), it is shown in Appendix that

(i) For $r \geq 2R$, the peak-height decreases to $(1-\alpha)$ times that of the pure liquid where α is the volume fraction of the "vacancies."

(ii) For $r < 2R$, the extent of decrease is less than that for $r \geq 2R$.

Figures 2, 3, and 4 show the quantity $4\pi r^2(\rho(r)-\rho_0)$ instead of the radial distribution function, where ρ_0 is the value of $\rho(r)$ in the limiting case of $r \to \infty$. The term $-\rho_0$ appears because the Fourier transform of the interference term of the coherent intensity is computed without the central scattering (the scattering intensity at $2\theta=0°$).[15] The value of ρ_0 for a binary solution is evidently $(1-\alpha)$ times that of the pure liquid. Thus the above statements (i) and (ii) are valid also for the curve of $4\pi r^2(\rho(r)-\rho_0)$.

Now, let us consider the distribution function of the binary solutions of carbon tetrachloride for two model cases.

1) The case where the size of a "vacancy" is nearly equal to that of CCl_4 molecule.

In this case, the size of the "vacancy" $2R$ is equal to the diameter of a CCl_4 molecule. Therefore, the

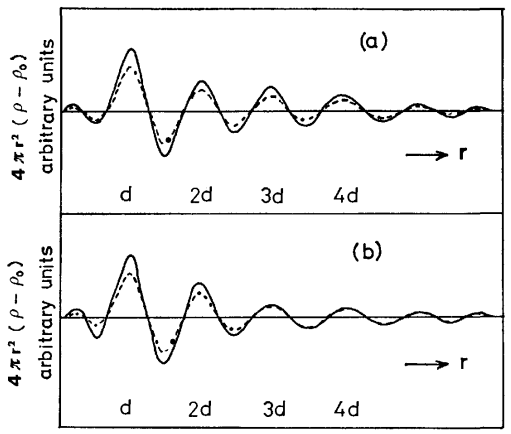

Fig. 5. Radial distribution functions expected for various mixing states for a model case of $\alpha \simeq 0.25$.
(a) The case that the "vacancy" size is equal to that of a CCl_4 molecule. (——): Pure CCl_4, (----): ideal mixing. (b) The case that the "vacancy" size is three times as large as that of CCl_4 molecule. (——): Solution, (----) ideal mixing.

above statements (i) and (ii) predict that the distribution function in this case is reduced by a factor of $(1-\alpha)$ from that of the pure liquid for all the r-values exceeding the diameter of a CCl_4 molecule. In other words, all the peaks beyond that of the first nearest neighbors are reduced to $(1-\alpha)$ times those of the pure liquid. Hereafter, we call this case "ideal mixing." The distribution function in this case is schematically shown in Fig. 5(a), where α is tentatively assumed to be 0.25.

2) The case where the size of the "vacancy" is larger than that of a CCl_4 molecule.

As an example, we consider the case where the "vacancy" size $2R$ is three times as large as the diameter of CCl_4 molecule. The peak-heights of the distribution function, in this case, are considerably stronger than those of the "ideal mixing" case for peaks corresponding to $r<2R$, *i.e.*, the first and second nearest neighbors. For the peaks corresponding to larger r, the distribution function has essentially the same magnitude as that of the "ideal mixing" case, that is, $(1-\alpha)$ times those of the pure liquid. This situation is schematically visualized in Fig. 5(b).

We reach the conclusion that we can estimate the "vacancy" size directly from the observed distribution function. That is to say, the observed radial distribution function becomes equal to that of the "ideal mixing" case at $2R$, which corresponds to the maximum length of the "vacancy." The distribution curve of the "ideal mixing" case can be obtained as $(1-\alpha)$ times that for pure liquid CCl_4.

States of Mixing in CCl_4–n-C_5H_{12} System. The experimental radial distribution function, $4\pi r^2(\rho(r)-\rho_0)$, is shown in Fig. 3 (see the solid curve). A correlation as clear as that for pure liquid CCl_4 (see Fig. 2) is observed up to 27—28 Å. It is also seen that the peak heights of the distribution function are similar to those expected from "ideal mixing," *i.e.*, those obtained by multiplying the distribution function of pure liquid CCl_4 of Fig. 2 by $(1-\alpha)$. The important feature of the distribution curve for CCl_4–n-C_5H_{12} is that the intensity reduction, $(1-\alpha)$, on passing from pure liquid to the solution is nearly equal at any distance r, which corresponds to the situation drawn in Fig. 5(a). This suggests that the state of mixing in the CCl_4–n-C_5H_{12} is "ideal." Since the sizes of the solute and solvent molecules are almost the same, n-C_5H_{12} molecules are randomly dispersed in CCl_4 liquid without forming clusters.

States of Mixing in CCl_4–CH_3OH System. The experimental radial distribution function is shown in Fig. 4 by the solid line, while the distribution function expected for "ideal mixing" is illustrated by a broken line. The magnitude of the former curve is larger than that of the latter at the first peak at 6.3 Å, and these two curves are nearly equal at 12 Å. The peak at 6.3 Å observed for pure liquid CCl_4 has been assigned to the superposition of the first nearest correlations at 5.77 and 6.77 Å (see Fig. 1). The peak at about 12 Å corresponds mainly to the interference at (2×5.77) Å, although it is superimposed on other interferences. On the whole, the behavior of the observed distribution function relative to the "ideal mixing" is similar to that of Fig. 5(b).

The fact that the height of the two curves coincide at 12 Å indicates that the diameter of the methanol cluster is about 12 Å, if the form of the cluster is assumed to be nearly spherical. Since the diameter of a CCl_4 molecule is about 6 Å, the cluster volume is estimated to be about eight times as large as that of a CCl_4 molecule. As the molecular volumes of carbon tetrachloride and methanol at room temperature are 153 and 66.4 Å^3 respectively, the number of methanol molecules which form a cluster is estimated to be $153\times8/66.4\simeq18$. This conclusion is in good agreement with that from the light scattering experiment,[6] which found that the cluster formed in the CCl_4–CH_3OH system at 0.3 mole fraction was composed of about 17 molecules.

In the experimental radial distribution curve shown in Fig. 4, the observed peaks at larger r-values become broader and weaker in comparison with those of "ideal mixing." This deviation of the observed distribution function from that of the "ideal mixing" case at r-values longer than 16 Å may be ascribed to the modification of the long-range structure of liquid CCl_4 caused by the existence of the solute molecules. A detailed analysis of this effect is left for a future problem.

In summary, the distribution functions observed for CCl_4 solutions can be explained by the use of a simple model. This result, in turn, supports the validity and the usefulness of the model for the elucidation of the state of mixing in a binary solution. The present study demonstrates that X-ray diffraction can be used to study the state of mixing in solution without recourse to small-angle-scattering, when the solution contains two kinds of molecules and one component has a much larger scattering power than that of the other component.

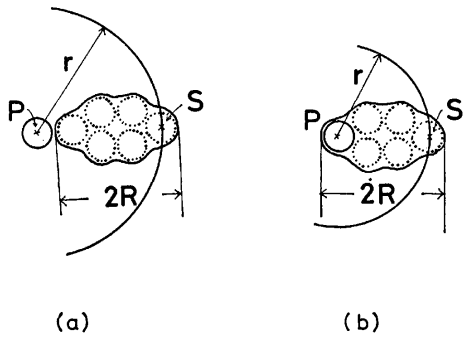

Fig. 6. Particular arrangements of a representative central molecule and a "vacancy". Small circle is a central molecule. The dotted circles are the sites replaced by a "vacancy." (a) The case of $r \geq 2R$ and (b) the case of $r < 2R$. See Appendix for details.

Appendix

Derivation of Statements (i) and (ii) in the Text about the Peak Heights of the Radial Distribution Curve of Binary Solutions.

In the following discussion, it is assumed that an integral number of sites or CCl_4 molecules are replaced by "vacanices" and that the structure or the distribution of the sites are not distorted even if some of the sites are occupied by "vacancies." The radial distribution function shows the time-averaged number of molecules which occupy the site at a distance r from a molecule, which is defined as a representative central molecule. In Fig. 6 are shown a representative central molecule P in a binary solution, a site S located at a distance r from P, and a "vacancy" in a particular orientation. In the treatment of this paper (see Data Analysis), the central site P is always occupied by a CCl_4 molecule.

(A) As long as the distance between S and P is equal to or larger than the effective size of the "vacancy" $2R$, any dotted circle in the vacancy can occupy the site S and all possible orientations of the "vacancy" are permitted. Even if the "vacancy" is orientated in such a way as shown in Fig. 6(a), where the "vacancy" is in contact with the central molecule P, this orientation is still permissible. Therefore, the fraction that the site is occupied by a "vacancy" is simply the volume fraction α, and the time-averaged number of CCl_4 molecules which occupy the site S is $(1-\alpha)$ times that of pure liquid CCl_4. This factor leads to the factor $(1-\alpha)$ for the decreasing factor of the peak height in the case $r \geq 2R$.

(B) If the site S is located at r which is less than $2R$, it happens that some of the orientations of a "vacancy" which occupies the site S should be excluded in counting the fraction that the site is occupied by a "vacancy." In Fig. 6(b), one such orientation is shown. This arrangement should be excluded, because in this orientation the central molecule has also to be replaced by the "vacancy," in contradiction to the initial assumption. Accordingly, the fraction that the site S is occupied by a "vacancy" is less, and the fraction that the site S is occupied by a CCl_4 molecule is more, than that of the case in (A). So the peak height is larger than that of the case in (A).

As is described above, the peak height of the radial distribution curve at a distance r is proportional to the time-averaged number of molecules which occupy the sites at a distance r from a representative central molecule. On the other hand, we may also say that the peak height of the radial distribution curve is proportional to the space-averaged number of molecules which can find a site at a distance r from them occupied by another molecule. This is a space-averaged picture of the problem in contrast to the time-averaged picture mentioned in the preceding. In the following, the statements (i) and (ii) described in the text will be derived on the basis of the space-averaged picture of the problem.

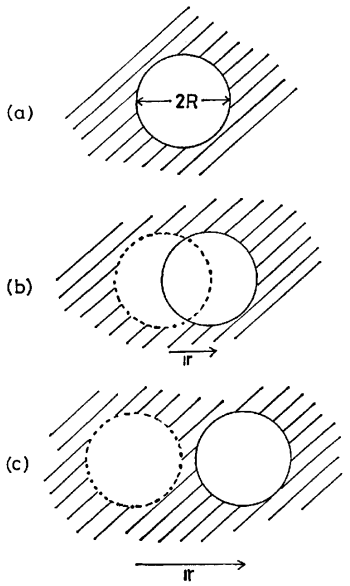

Fig. 7. The space-averaged picture.
(a) A part of the binary solution. A vacant space is a solute molecule or a cluster of them. The diameter of the space is $2R$. (b) The solid circle is the "vacancy." The dotted circle is the "image" obtained by shifting by $\boldsymbol{r}$, in the case of $r < 2R$. (c) In the case of $r \geq 2R$.

According to the assumption of the present work, the radial distribution function is that of pure liquid CCl_4 multiplied by the probability that a site at a distance r from molecule of carbon tetrachloride is found outside the "vacancy," in other words, within the portion of the solution that is occupied by carbon tetrachloride. This probability is given by a characteristic function or a shape function of a figure[16] and can be evaluated as follows.

In Fig. 7(a) is depicted a part of the solution where a vacant space shows a solute molecule and the shaded portion is occupied by solvent molecules. Although there only one vacant space is shown in Fig. 7(a), the figure should extend almost infinitely containing an enormous number of vacant spaces, keeping their volume fraction equal to that of the solute molecules denoted by α.

We then draw an "image" of the figure by shifting the whole figure by a vector $\boldsymbol{r}$ as shown in Fig. 7(b). It is evident that only those molecules that are in the shaded region of Fig. 7(b) can find a site outside the vacant spaces at the position defined by the vector $\boldsymbol{r}$ from themselves. The ratio of the volume of the shaded region of Fig. 7(b) to that of Fig. 7(a) gives the probability that a site at a distance r from a solvent molecule and in a particular direction defined by the vector $\boldsymbol{r}$ is found outside the vacant spaces.

The ratio gradually decreases as r becomes larger, but it remains constant for any orientaion of the "vacancy" if r exceeds $2R$, the maximum length between any two points in the "vacancy" (see Fig. 7(c)). The constant value of the ratio is $(1-2\alpha)/(1-\alpha) \simeq 1-\alpha$.

Because of the isotropy of the liquid, the foregoing argument is valid in any direction of the vector. Thus the probability that a site at a distance r from a solvent molecule is found outside the solute molecules decreases gradually from unity to $(1-\alpha)$ as r increases from 0 to $2R$, and remains constant, $(1-\alpha)$, in the region of r beyond $2R$.

In the present qualitative discussion, such a complication as overlapping of the image of a vacant space with another vacant space is ignored, since this effect should only modify the probability on the order of α^2.

The authors wish to express their thanks to Professor Takao Iijima, Gakushuin University, for his helpful suggestions and discussion.

The Conversion of CH_3OH into Olefins over Al_2O_3–Cr_2O_3 Treated with CF_3Cl

Akito Kurosaki and Susumu Okazaki*

Department of Industrial Chemistry, Faculty of Engineering, Ibaraki University, Hitachi, Ibaraki 316

(Received April 15, 1982)

A mixed oxide of Al and Cr having an atomic ratio(Al/Cr) of around 9 showed catalytic activity for the conversion of CH_3OH into olefins and aromatic compounds after treatment with CF_3Cl at 450 °C. The mixed oxide treated with CF_3Cl adsorbed a considerable amount of NH_3, even at temperatures as high as 500 °C. Analyses of the compositions on the surface layer by using XPS showed that the F component was predominantly bound to Al, not to Cr. Strong acid sites related to the less crystallized AlF_3 seemed to be able to promote the conversion of CH_3OH.

Hydrocarbon production from methanol has become an important process for obtaining materials such as ethylene and propylene from coal, instead of petroleum. The catalytic activity of metal oxides in the conversion of CH_3OH into olefins have, however been little reported on, work having been limited to certain zeolites[1-2] such as ZSM-5 (Mobil Oil Company),[3] heteropolyacids and/or their salts,[4-5] and aluminum dihydrogenphosphate.[6] Sufficiently strong acid sites seem to be essential for the promotion of the reaction.

It has been previously found that Al_2O_3–Cr_2O_3 promotes the disproportionation of CF_3Cl into CF_4 and CF_2Cl_2 at temperatures higher than 400 °C.[7] The scission of the strong C–F bond in the CF_3 group[8] is essential for the disproportionation, and the surface of Al_2O_3–Cr_2O_3 should be first fluorinated when the mixed oxide is used as a disproportionation catalyst. Accordingly, the Al_2O_3–Cr_2O_3 surface treated with CF_3Cl, is considered to have strong acid sites and may be expected to promote the conversion of CH_3OH into olefins. Consequently, the catalytic activities of treated Al_2O_3–Cr_2O_3, with various Al/Cr atomic ratios, were examined and compared to those of unfluorinated Al_2O_3–Cr_2O_3, Al_2O_3, and Cr_2O_3. The effects of CF_3Cl treatment on the surface activation were compared with those of treatment with other chlorofluoromethanes and CCl_4. The surface compositions and properties of treated single and mixed oxides were investigated in connection with the catalytic activities.

Experimental

Materials. Various oxides were prepared from their nitrates through the respective hydroxides. The mixed hydroxides were prepared from aqueous solutions of nitrates by coprecipitation with 28% aqueous ammonia, the final pH being adjusted to 8.0—9.0. The precipitates of the mixed hydroxides were thoroughly washed with deionized water and separated by decantation. After drying at 120 °C for 12 h, the mixed hydroxides were heat-treated in air at 600 °C for 3 h; they were then converted to the mixed oxides. Just before their use as catalysts, the oxides were compressed to 30—40 mesh granules under pressure; they were then submitted to surface treatments with a flow of halogen-substituted methane diluted with He at 450 °C for 30 min in a flow reactor. Although mainly CF_3Cl was used as the surface-treatment agent, other chlorofluoromethanes (CF_2Cl_2 and $CFCl_3$) and CCl_4 were also used for comparison with CF_3Cl. All the chlorofluoromethanes (supplied by the Mitsui Fluorochemical Co.) were of purities higher than 99.9%.

Reaction Procedure. The conversion of CH_3OH was carried out in a pulse reactor connected with a modified gaschromatographic analyzer at 400 °C, using He as the diluent. The pulse size was 1 μl; the weight of the catalyst and the velocity of the diluent were kept constant at 30 mg and 35 ml/min respectively.

The product gas, including CO and CH_4, was first condensed at about −196 °C in a 3-m column packed with Tenax GC. Then the condensed products were allowed to evaporate by removing the liquid nitrogen trap; the column was subsequently heat-treated up to about 150 °C. The evaporated gas flowed through TCD, and the composition of the product was analyzed.

Also, the conversion of the dimethyl ether to olefins was carried out in the same reactor by an operation similar to that described above. In these operations, the low-boiling components, such as CO and CH_4, were almost entirely recovered in a column immersed in the liquid-nitrogen trap. The material balances for the conversions of CH_3OH and CH_3OCH_3 were more than 70% and about 85% respectively.

Determinations of Surface Compositions and Properties. The compositions in the surface layer were determined by XPS using a Shimadzu ESCA-750 apparatus. The spectra were measured with Mg $K\alpha$ radiation. The base pressure of the spectrometer was usually below 10^{-7} Torr (1 Torr ≈133.322 Pa) during the experiments. The compositions were calculated from the area of the peaks (*i.e.*, the maxima in the counting rate) in the spectra on the basis of photoionization cross-sections at 1254 eV in units of the C ls cross-section of 22200 barns.[9] The errors inherent in such a determination are generally 10—30% of the observed value.

The surface areas were determined by applying the BET method to the adsorption isotherm of N_2 at −196 °C. The structures of Al_2O_3 and Al_2O_3–Cr_2O_3 were determined from the powder-diffraction patterns obtained with a Rigaku Denki Gigerflex X-ray diffractometer using filtered Cu $K\alpha$ radiation. The surface acidities were measured by means of the amounts of NH_3 adsorbed at different temperature.

Results and Discussion

Effects of Atomic Ratio (Al/Cr). Table 1 shows the effect of the mixed oxide atomic ratio on the catalytic activity before and after treatment with CF_3Cl. For comparison, SiO_2–Al_2O_3 (N-631, Nikki Chemical Co.), which is a typical strong solid acid, was also used. Except for SiO_2–Al_2O_3, which caused the formation of a slight amount of olefin, none of the single and mixed oxides promoted any olefin formation. On the other hand, except for Cr_2O_3, when the oxides were pretreated with CF_3Cl at 450 °C and then used as catalysts, considerable amounts of ethylene and propene were formed from CH_3OH. The catalytic

a) CO and CH_4 were not observed in the product gases for any of the runs.

activity of Cr_2O_3 for the formations of CO and CO_2 decreased remarkably with the pretreatment, suggesting that the active O atoms on the Cr_2O_3 surface may be removed by the reaction with CF_3Cl.

A maximal conversion of CH_3OH into olefins was obtained with the mixed oxide having the atomic ratio of Al/Cr=9/1. The same atomic ratio also gave a maximum disproportionation for CF_3Cl.[7] Since the disproportionation can be promoted only by the strong acid,[7] the strong acid sites must be formed most abundantly on Al_2O_3-Cr_2O_3 (9/1) after treatment with CF_3Cl.

Comparison of Treatment Using CF_3Cl with Those Using Other Chlorofluoromethanes or CCl_4. The catalytic activities of Al_2O_3-Cr_2O_3 treated with different chlorofluoromethanes or CCl_4 are shown in Table 2 for the CH_3OH conversion. The Al_2O_3-Cr_2O_3 treated with CCl_4 showed the highest activity at the first pulse of the reactant. However, large amount of deposits, which seemed to be aluminum chloride and/or chromium chloride, were formed on the reactor walls and finally clogged the reactor outlet. The deposited amounts decreased with an increase in the number of F atoms in the chlorofluoromethane molecule used for the surface treatment. Thus, when CF_3Cl was used for the treatment, there were hardly any deposits found during the reaction.

When the mixed oxide treated with CCl_4, $CFCl_3$, or CF_2Cl_2 was used as a catalyst, ethylene was obtained as the main olefinic product. On the other hand, a good deal of propene was produced, together with ethylene, when the mixed oxide was treated with CF_3Cl.

Effect of CF_3Cl-treatment Temperature on Catalytic Activity. The effect of the treatment temperature with CF_3Cl on the catalytic activity for the conversion

a) All the oxides were heat-treated at 600 °C for 3 h before the treatment with CF_3Cl or use as a catalyst. b) -F denotes a catalyst treated with CF_3Cl similarly to that shown in Table 1. The treatment conditions with CF_3Cl were the same as for the conversion of CH_3OH.

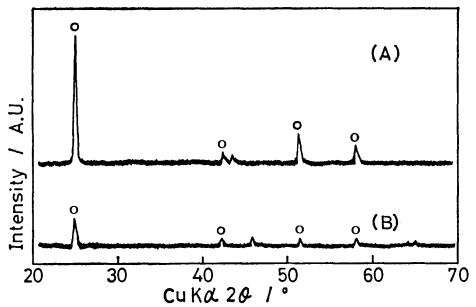

Fig. 1. X-Ray diffraction patterns.
(A): Al_2O_3 treated with CF_3Cl, (B): Al_2O_3–Cr_2O_3 treated with CF_3Cl. (○): Peaks due to α-AlF_3.

of CH_3OH is shown in Table 3. The CF_3Cl treatment was most effectively carried out at 450 °C to give an increase in the catalytic activity for the CH_3OH conversion similar to that for the CF_3Cl disproportionation.

Effect of H_2-treatment before the Treatment with CF_3Cl. To know the effect of reduction on the catalytic activity, Al_2O_3–Cr_2O_3 (9/1) was treated with H_2 at 450 and 600 °C before the treatment with CF_3Cl at 450 °C. The catalytic activity for the formation of olefins was remarkably decreased by the pretreatment with H_2 at 450 °C. Particularly, the formation of propene was not observed when the mixed oxide was pretreated with H_2, although the amount of dimethyl ether formed increased with the pretreatment. The catalytic activity of the mixed oxide treated with CF_3Cl remained for the formation of dimethyl ether, even when the mixed oxide was pretreated at as high a temperature as 650 °C.

Surface Composition and Degree of Crystallization of the Oxide after Treatments. The surface compositions determined by XPS, after treatment with chlorofluoromethanes or CCl_4, are shown in Table 4. In the mixed oxides treated with $CFCl_3$ or CF_2Cl_2, only a small amount of the Cl component was found, together with a much larger amount of the F component. Furthermore, the Cl component was not detected in the mixed oxide treated with CF_3Cl. The F component in the mixed oxide (Al/Cr=9/1) increased with an increase in the number of F atoms in the molecule used for the surface treatment. As is shown in the last line in Table 4, Cr_2O_3 did not bind the F component at all during the treatment with CF_3Cl. In contrast to Cr_2O_3, Al_2O_3 bound a good deal of the F component, as is shown in the seventh line of Table 4. This fact suggests that the F atoms in the mixed oxide may combine with Al, not Cr, atoms.

The X-ray diffraction analysis of Al_2O_3 and Al_2O_3–Cr_2O_3 after treatment with CF_3Cl (Fig. 1) showed that α-AlF_3 formed on both oxides and that the degree of crystallization of the aluminum fluoride on the treated mixed oxide was far less than that on the treated Al_2O_3. The X-ray diffraction patterns ascribable to

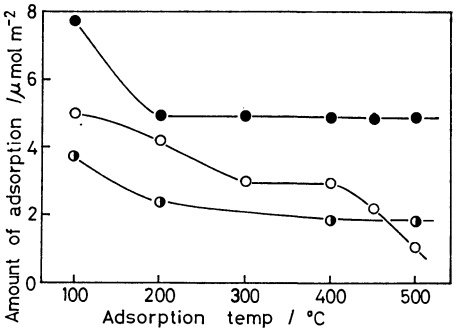

Fig. 2. Adsorption of NH_3 at various temperatures. ◑: SiO_2–Al_2O_3 (N-631), ○: Al_2O_3–Cr_2O_3(9/1), ●: Al_2O_3–Cr_2O_3 treated with CF_3Cl.

metal chlorides and the chromium compound was not observed at all. The absence of the Cl component in the most active oxide, *i.e.*, Al_2O_3–Cr_2O_3 (Al/Cr= 9/1) treated with CF_3Cl, has also been shown by the results obtained by using XPS (Table 4). Thus, the high catalytic activity of the treated mixed oxide may be due not to aluminum chloride, but to the less crystallized, and so active, aluminum fluoride formed on the surface by the treatment.

Conversion of DME over Oxides before and after Treatment with CF_3Cl. As Table 5 shows, Al_2O_3, Cr_2O_3, and Al_2O_3–Cr_2O_3 (Al/Cr=9/1) promote only the conversion of dimethyl ether to CO, CO_2, and CH_4 before treatment with CF_3Cl. After such a treatment, Al_2O_3 and Al_2O_3–Cr_2O_3 showed activities for the conversion of dimethyl ether into olefins. In particular, the Al_2O_3–Cr_2O_3 promoted a formation of propene similar to that observed in the conversion of CH_3OH.

For the conversion of CH_3OH catalyzed by ZSM-5 or other zeolites, it is generally accepted that the formation of hydrocarbons proceeds according to the pathway shown below:[1,5,6]

$$CH_3OH \rightleftharpoons CH_3OCH_3 \longrightarrow C_2H_4,\ C_3H_6,$$
$$\text{and } C_4H_8 \textit{ etc.} \begin{cases} \nearrow \text{Paraffins} \\ \searrow \text{Aromatics.} \end{cases}$$

The fact that dimethyl ether gives a similar or essentially the same product distribution as methanol (shown in Table 1) shows that the pathway described above may be acceptable also for the conversion catalyzed by the treated Al_2O_3–Cr_2O_3 or the treated Al_2O_3. The strong acid sites formed by treatment with CF_3Cl should promote the slowest step in the reaction sequence.

Surface Properties and Formation of Active Sites. The specific surface areas of the mixed oxides before and after treatment with CF_3Cl were almost completely independent of the atomic ratio in the Al/Cr range from 1/0 to 8/2. Hence, the specific surface area does not seemed to be a factor determining the mixed oxide catalytic activity, which is maximal when the atomic ratio of Al/Cr equals 9/1.

As is shown in Fig. 2, the amount of NH_3 adsorbed on treated Al_2O_3–Cr_2O_3 (9/1) at temperatures higher than 450 °C was much more than that on SiO_2–Al_2O_3 or untreated Al_2O_3–Cr_2O_3 (9/1). This fact shows that fair amounts of strong acid sites should be formed

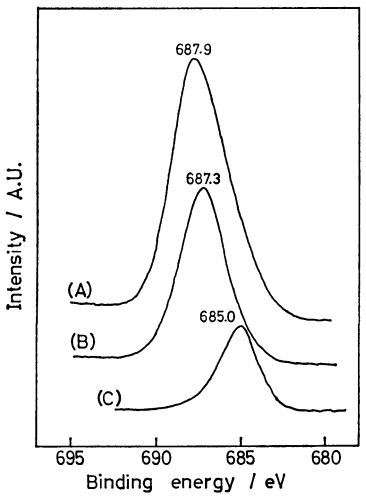

Fig. 3. F 1S peaks in XPS.
(A): Al_2O_3–Cr_2O_3 treated with CF_3Cl, (B): AlF_3, (C): CrF_3.

on the mixed oxides treated with CF_3Cl at 450 °C.

Figure 3 shows that the position of the F is peak (687.9 eV) in the spectrum of Al_2O_3–Cr_2O_3 (9/1) treated with CF_3Cl is close to those of AlF_3 (687.3 eV) or Al_2O_3 treated with CF_3Cl (687.1 eV), while it is far from that of CrF_3. Thus, it is elucidated that the active sites should be related to aluminum fluoride or to Al atoms (or ions) bonded to F atoms (or ions) on the surface.

Because AlF_3 has the highest positive partial charge (0.72) among the typical strong electron-acceptors, such as BF_3 (0.56), $AlCl_3$ (0.57), BCl_3 (0.41), and $GaCl_3$ (0.32),[10] it should be an extremely strong solid acid. However, it tends to form stable crystals due to the very small radius of the F ion and its large electronegativity and, further, the large ion potential, *i.e.*, the ratio of the ionic valence to the ionic radius, of the Al ion. Consequently, it is desirable to prevent the crystallization for aluminum fluoride to fully function as a strong solid-acid catalyst.

By considering also that Cr_2O_3 itself did not catalyze the formation of olefins at all, even after treatment with CF_3Cl (Table 1), and that no F component was found in Cr_2O_3 treated with CF_3Cl (Table 4), the major effect of Cr_2O_3 in the treated mixed oxide seems to be only structural. That is, the crystal structure of Cr_2O_3 is a corundum type in which O atoms are appeared in an approximately hexagonal close-packed arrangement and Al^{3+} ions are situated in two-thirds of the octahedral holes;[11] furthermore, the ionic radius (0.63 Å[12]) is comparatively close to that of Al^{3+} (0.51 Å[12]). Hence, small amounts of Cr^{3+} ions added to Al_2O_3 may be thoroughly mixed with Al^{3+} and may thus suppress the crystallization of AlF_3 by intervening between Al^{3+} ions. However, Cr_2O_3 itself is catalytically far less active for the formation of olefins from CH_3OH, even after treatment with chlorofluoromethanes. Accordingly, the addition of Cr^{3+} in a larger amount was not beneficial for the enhancement of the catalytic activity because an excess Cr_2O_3 component hinders the formation and the function of active aluminum fluoride on the surface. Thus, an optimal

amount of Cr constituent was observed at around 10 atom% in the CF_3Cl-treated mixed oxide.

Catalytic Activity of Sn-Mo Oxides for Propene Oxidation

Takehiko ONO,* Tetsuo IKEHATA, and Yutaka KUBOKAWA*

Department of Applied Chemistry, University of Osaka Prefecture, Sakai, Osaka 591

(Received April 30, 1982)

Sn-Mo oxides were subjected to experimental studies with reference to their catalytic C_3H_6 oxidation and their own reduction by C_3H_6. In the oxidation Sn–Mo oxides are 30—40 times more active than MoO_3 but only 4—5 times than SnO_2. With Sn-Mo oxides as well as SnO_2, the oxidation is zero order in C_3H_6 and about half order in O_2, in contrast to those with MoO_3. It is proposed that the oxidation proceeds via a redox mechanism with the reduction step proceeding very rapidly. ^{18}O tracer experiments show that the mobility of lattice oxygen in Sn-Mo oxides is lower than that in MoO_3 but similar to that in SnO_2. From these results together with those of structural studies, it is concluded that the active phase of Sn-Mo oxides is characterized by the MoO_3 highly dispersed on SnO_2 or Mo ions dissolved in SnO_2, and that their high reducibility possibly originates from the existence of SnO_2 itself in them.

Partial oxidation of alcohols on Sn-Mo oxides has been investigated by several workers, *e.g.*, Niwa *et al.*[1] and Okamoto *et al.*,[2] who investigated the mechanism of the oxidation and the correlation between activity and surface structure for these systems, respectively, by using various techniques such as ESR and XPS. As regards the oxidation of alkenes on Sn–Mo oxides, Morooka *et al.*,[3] Butein,[4] and Ai[5] investigated oxidation at lower temperatures in the presence of water vapor and emphasized the importance of acid-base properties of the oxides in the oxidation. Although the alkene oxidation at higher temperatures has been invesigated by several workers,[6,7] no detailed kinetic studies on the oxidation have been reported. Margolis[6] investigated the propene oxidation by Mössbauer spectroscopy and concluded that adsorbed oxygen plays a significant role in the oxidation. There seems to be no unambiguous evidence supporting their conclusion.

In a previous work we carried out studies on the rate of oxidation of alkenes on V–Sn[8,9] and V–Mo[9] oxides and on their reduction with alkenes, together with ^{18}O tracer studies. These studies, together with structural ones using ESR and X-ray Diffraction, *etc.*, have allowed us to discuss the promoter effect for these systems. In the present work, similar studies have been extended to the oxidation of C_3H_6 on Sn–Mo oxides.

Experimental

Material. Sn–Mo catalysts were prepared as follows. Tin hydroxide precipitates obtained from solutions of tin(II) chloride and ammonia were added to a solution containing a required quantity of ammonium heptamolybdate. The resulting slurry was evaporated with constant stirring, dried, and heated in air at 450 °C. SnO_2 was prepared in a similar manner from a tin hydroxide obtained as described above. MoO_3 was prepared by heating ammonium heptamolybdate in air at 450 °C.

Sn–Mo–M catalysts were prepared by mixing MoO_3 with SnO_2 in a desired ratio and heating the mixture in air at 600 °C for 0.5 h. $^{18}O_2$ (99.1%) was obtained from B.O.C. Limited (U. K.).

Surface areas of catalysts as determined by the BET method were as follows: MoO_3, 1.3—2.0; Sn-Mo(75)(containing Mo in 75 mol%), 18; Sn-Mo(50), 19.5; Sn-Mo(10), 33; SnO_2, 6.8; Sn-Mo(50)-M, 5.1 m^2/g. Prior to measurement, all catalysts were subjected to pretreatment with oxygen at 450 °C.

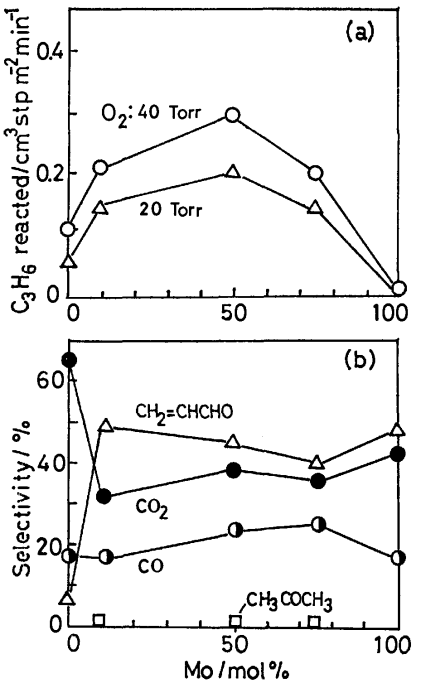

Fig. 1. Rates(a) and product selectivities(b) of C_3H_6 oxidation over Sn–Mo catalysts at 400 °C. $P_{C_3H_6}$= 23 Torr(1 Torr=133.3 N m^{-2}). The product selectivities scarcely changed with oxygen pressure.

Apparatus and Procedure. The catalytic oxidation and the reduction of oxides were carried out in a closed circulation system (320 cm^3). In order to obtain initial rates, conversions were kept below *ca.* 5%. Reaction products such as CH_2=CHCHO, CH_3COCH_3, CO_2, and CO were detected by gas chromatography. The ^{18}O% for a reaction product was determined with a Hitachi RMU-6E mass spectrometer at the following ionization voltages: 80 V for CO and CO_2 and 15 V for CH_2=CHCHO. X-Ray diffraction patterns for catalysts were obtained on a Rigaku-Denki D-3F X-ray diffractometer using Cu $K\alpha$ radiation with a Ni filter. IR spectra of catalysts were recorded on a Hitachi G2 spectrometer, samples being prepared by the KBr pellet technique.

Results and Discussion

C_3H_6 Oxidation over Sn–Mo Oxides and Their Reduction with C_3H_6. Figure 1 shows the rate of oxidation of C_3H_6 and the selectivity for oxidations as a

function of MoO_3 content. The rate of oxidation passes through a maximum, though not pronounced, at Sn–Mo (50). The distribution of products is essentially the same for all the Sn–Mo oxides. The selectivity toward CH_2=CHCHO formation is about 40—50%, the remainder being for CO and CO_2. With SnO_2, the CH_2=CHCHO formation is markedly reduced, while the CO_2 formation is increased. With all the Sn–Mo oxides, formation of CH_3COCH_3 takes place with ratios of CH_3COCH_3 to CH_2=CHCHO less than 0.1 above 400 °C.

Figure 2 shows the dependence of the rate of C_3H_6 oxidation upon O_2 and C_3H_6 pressures, from which reaction orders for the oxidation were determined as shown in Table 1. With MoO_3, the reaction is first order in C_3H_6 and zero order in O_2. It is apparent that the orders for Sn–Mo oxides are similar to those for SnO_2.

Rates of the reduction of Sn–Mo oxides with C_3H_6 were determined in the reaction time range 0.5—3.0 min. Amounts of CO, CO_2, and CH_3COCH_3 formed increase linearly with increasing reaction time, while the CH_2=CHCHO formation takes place practically only in the initial measurement (0.5—1 min), scarcely proceeding any more in later periods. By assuming the initial value to approximate the rate of CH_2=CHCHO formation, yields and distributions were determined as a function of MoO_3 content (Fig. 3). A comparison of the rates of oxidation in the presence and absence of oxygen (Figs. 1 and 3) indicates that there is no marked difference between both the rates of oxidation. Furthermore, essentially the same product distributions are obtained with both the oxidations in the presence and absence of oxygen. This suggests that no adsorbed oxygen plays a significant role in the C_3H_6 oxidation over Sn–Mo oxides. It is therefore concluded that the oxidation proceeds via a redox mechanism, *i.e.*, the repetition of the reduction of oxides with C_3H_6 and their reoxidation with gaseous oxygen. The fact that the oxidation is zero order in C_3H_6 and about half order in O_2, suggests that the reduction of oxides with C_3H_6 is very rapid, the rate-determining step in the oxidation being their reoxidation by gaseous oxygen.

With the Sn–Mo (50) catalyst, initial rates of reduction were determined as a function of C_3H_6 pressure. As shown in Fig. 4, the rate of formation of CH_3COCH_3 increases linearly with increasing pressure of C_3H_6,

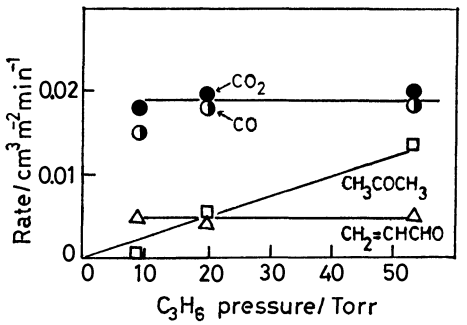

Fig. 4. Variation in the rate of reduction of Sn–Mo(50) with C_3H_6 pressure at 350 °C.

while the rates of formation of CO, CO_2, and CH_2=CHCHO are almost independent of C_3H_6 pressure. These results, together with the fact that the CH_2=CHCHO formation is observed only in the initial measurement, suggest that a very small fraction of the surface is responsible for the reduction, *i.e.*, that the rate for the active part is very large. Such a high rate of reduction is in agreement with the kinetics of the oxidation, *i.e.*, zero order in C_3H_6 and about half order in O_2. Furthermore, it should be noted that essentially the same behavior was observed with the reduction of SnO_2, where reduction products consist of only CO and CO_2.

Structure of Sn–Mo Oxides. According to X-ray diffraction studies, Sn–Mo (10) and Sn–Mo (75) show diffraction lines due only to SnO_2 and MoO_3, respectively. With Sn–Mo (50), lines attributable to SnO_2 as well as MoO_3 appear. No lines indicating any formation of new compounds between SnO_2 and MoO_3 appear, in agreement with results by previous workers.[2,11] The sizes of SnO_2 and MoO_3, as determined from the broadening of diffraction lines,[12] are 15—20 nm and >200 nm, respectively. Intensities of the diffraction lines of MoO_3 in Sn–Mo oxide catalysts were compared with those of mechanical mixtures of MoO_3 and SnO_2. The results indicate that 40—50 mol% of MoO_3 in Sn–Mo (50) and (75) is missing.

In a manner similar to that adopted in a previous work[8] on V–Sn oxides, the intensity of the band due to Mo=O stretching vibration for Sn–Mo oxides was determined as a function of the concentration of Mo ions in KBr pellets. The results are compared with those of similar experiments for MoO_3 (Fig. 5). About 40—50% of MoO_3 in Sn–Mo (50) and (75) exhibits no IR absorption. These results suggest presence of an amorphous material in Sn–Mo (50) and (75) oxides. Although the nature of the amorphous material is unclear, the disappearance of the Mo=O band seems to result from a strong interaction between MoO_3 and SnO_2. No new bands due to the amorphous material are observed to appear. The new bands might be masked by the bands due to SnO_2 or MoO_3. The disappearance of Mo=O band observed with Sn–Mo (10) is attributable to dissolution of Mo ions in SnO_2, as in the case with V–Sn oxides.[8] Okamoto *et al.*[2] have also concluded that the decrease in the crystallinity of MoO_3 in Sn–Mo oxides is attributable to the dissolution of Mo ions in SnO_2 as well as to the

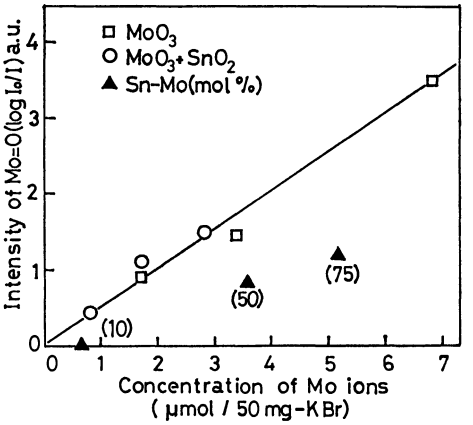

Fig. 5. Estimation of MoO_3 concentration in Sn–Mo oxides.
1 wt% of Sn–Mo oxide in KBr. ○: Mechanical mixture of MoO_3 and SnO_2 at room temperature.

formation of an amorphous material between MoO_3 and SnO_2.

After a heat treatment up to 750 °C the surface area of Sn–Mo (10) decreased from 33 to 25 m^2/g, suggesting a slight increase in the crystal size of SnO_2; no new diffraction lines appeared. With Sn–Mo(50), the intensity of the diffraction lines due to SnO_2 increases by a factor of 1.5, while the MoO_3 crystals grow markedly in the direction perpendicular to the b-axis. Its surface area increases from 19 to 27 m^2/g. In the case of Sn–Mo(75), new diffraction lines due to SnO_2 appear, its surface area increasing from 18 to 29 m^2/g. Such behavior seems explicable in terms of the idea that the amorphous material in Sn–Mo(50) and (75) is decomposed to form SnO_2 and MoO_3, the former crystal being very fine because of its very high melting point. Thus, the presence of amorphous material is confirmed. The lack of any new compounds in Sn–Mo oxides suggests that their promoter effect is attributable to the existence of both Mo ions dissolved in SnO_2 and the amorphous material or of either one.

Catalytic Oxidation of C_3H_6 Using $^{18}O_2$ Tracer. Participation of lattice oxygen in the C_3H_6 oxidation on Sn–Mo oxides was examined by using $^{18}O_2$ as an oxidant instead of ordinary oxygen. No change in the ^{18}O content in oxygen occurred during the reaction, *i.e.*, no formation of $^{18}O^{16}O$ proceeded, which suggests that the exchange of oxygen with the catalyst oxygen is negligible under the present experimental conditions.

As shown in Table 2, with SnO_2 as well as Sn–Mo oxides there is little or no difference between the ^{18}O contents of oxidation products such as CO, CO_2, and CH_2=CHCHO, while with MoO_3 the ^{18}O content of CH_2=CHCHO is larger than those of CO and CO_2. By assuming that the ^{18}O content of H_2O is the average of those of CO, CO_2, and CH_2=CHCHO, for all the oxidation products the ^{18}O content can be determined with each catalyst (Table 2 and Fig. 6).

As previously shown,[9] the feature of the increase in the ^{18}O content of oxidation products with the pro-

gress of reaction provides information on to what extent lattice oxygen participates in the oxidation. The number of sublayers of the oxide participating in the oxidation was calculated (Table 2), as has been done by Keulks *et al.*[13] The extent of participation of lattice oxygen increases in the order SnO_2<Sn–Mo(50)<MoO_3, while the rate of oxidation on Sn–Mo oxides is about 30 times larger than that on MoO_3. Such features are in contrast to those for Bi–Mo oxides, where the extent of participation of lattice oxygen is in parallel with the rate of oxidation.[13] As regards the nature of such different features, it should be noted that the extent of participation of lattice oxygen for the present system is much smaller than those for Bi–Mo[13] and V–Mo oxides.[9] Furthermore, rate-determining steps for the oxidation differ between Sn–Mo oxides and MoO_3 or Bi–Mo oxides, *etc.*, the reoxidation for the former and the reduction for the latter being the rate-determining step. Accordingly, it appears inappropriate to correlate the catalytic activity solely with the extent of participation of lattice oxygen.

Reduction of ^{18}O Substituted Sn–Mo Oxide and Comparison of Sn–Mo(50) with Sn–Mo(50)–M. Studies of reduction of ^{18}O substituted Sn–Mo oxides with C_3H_6 also are expected to give information on to what extent oxide layers are associated with the reduction of oxides and their reoxidation. Sn–Mo(50), Sn–Mo(50)–M, SnO_2, and MoO_3 were reduced with CO at 400—500 °C, 20—40% of the surface lattice oxygen being removed as CO_2. Then, the reduced oxides were reoxidized with $^{18}O_2$ around 300 °C. The period of reoxidation was 10 h for MoO_3, 2 h for SnO_2, and 2—4 h for Sn–Mo oxides. The amounts of ^{18}O incorporated were nearly the same as those removed by the reduction. As shown in Table 3, the ^{18}O content in products for MoO_3 is much smaller than that for SnO_2, the corresponding values for Sn–Mo oxides being similar to those for SnO_2. These facts indicate that the mobility of lattice oxygen in Sn–Mo oxides as well as in SnO_2 is lower than that in MoO_3.

Table 3 also includes results of similar experiments for Sn–Mo(50)–M, where the ^{18}O content in products is larger than the corresponding values for Sn–Mo(50). Furthermore, the IR band due to the Mo=O vibration for Sn–Mo(50)–M decreased in intensity by about 20% in comparison with 40—50% for Sn–Mo(50). Such behavior would be expected from the difference in preparation procedures between both the Sn–Mo(50) oxides. However, there is little or no difference between the distributions of products of C_3H_6 oxidation for both the oxides, although the rate of oxidation for Sn–Mo(50) is about 1.5 times higher than for Sn–Mo(50)–M. Accordingly, it appears that essentially the same active phase as that for Sn–Mo(50) may be formed for Sn–Mo(50)–M, for example by the heat treatment of a mechanical mixture of SnO_2 and MoO_3 at 600 °C.

The Nature of the Active Phase of Sn–Mo Oxides. As described above, the reduction of Sn–Mo oxides with C_3H_6 proceeds very rapidly as compared to their reoxidation. The results obtained in the present work as well as by Seiyama *et al.*[14] suggest that essentially the same situation is expected for SnO_2. Accordingly, it seems likely that such a high reducibility of Sn–Mo oxides arises from the existence of SnO_2 itself in Sn–Mo oxides. As described above, the active phase of

Sn–Mo oxides consist of both or either of Mo ions dissolved in SnO_2 and the amorphous material formed from interaction of molybdenum oxide with tin oxide. The results of the reduction of ^{18}O substituted Sn–Mo(50) oxides show that so far as the features of the reduction are concerned, Sn–Mo oxides resemble SnO_2 rather than MoO_3. This suggests that the amorphous material in Sn–Mo oxides can be approximated to some extent by the MoO_3 highly dispersed on SnO_2, where the crystallinity of MoO_3 disappears.

Although the situation is unclear for Sn–Mo(75) which exhibits no diffraction lines due to SnO_2, it is to be noted that there is no marked difference between the rates of oxidation for all the Sn–Mo oxides. In addition, the selectivity for oxidation is essentially the same for all Sn–Mo oxides. This suggests that for Sn–Mo(75) it seems unnecessary to assume the existence of active phases other than the amorphous material (the MoO_3 highly dispersed on SnO_2). Although the active phase of Sn–Mo(10) consists of Mo ions dissolved in SnO_2, there is no marked difference in the surface structures associated with the oxidation between the Mo ions dissolved in SnO_2 and the MoO_3 highly dispersed on SnO_2, since no special features of the C_3H_6 oxidation are observed with Sn–Mo(10).

Such features are out of accord with results of oxidation of alcohols on Sn–Mo oxides described by Okamoto *et al.*[2] who found that the active phase responsible for the oxidation varies according as the composition becomes rich or poor in Mo. According to the work of Niwa *et al.*,[1] however, the rate of oxidation of alcohol on Sn–Mo oxides is independent of the catalyst composition.

Seiyama *et al.*,[14] have shown that there is little or no doubt that on SnO_2 the oxidative dehydrogenation of C_3H_6 to π-allyl species proceeds very easily, whereas the formation of CH_2=CHCHO from the π-allyl hardly takes place. Accordingly, it appears unlikely that the oxygen necessary for the formation of CH_2=CHCHO on Sn–Mo oxides originates from SnO_2; the source of this oxygen seems to be the MoO_3 adjacent to SnO_2. Such a reaction sequence is essentially the same as the model proposed by Haber,[15] who claimed that the formation of π-allyl from C_3H_6 and that of CH_2=CHCHO from π-allyl occur on SnO_2 and MoO_3, respectively. Of course, in the case of Sn–Mo oxides the reactivity of SnO_2 as well as MoO_3 will be enhanced by their mutual contact. In fact the rate of oxidation of C_3H_6 over Sn–Mo oxides is higher than that over SnO_2 as well as MoO_3. Furthermore, the fact that Sn–Mo oxides are 30—40 times more active than MoO_3 but only 4—5 times than SnO_2, is in agreement with what would be expected from the reaction sequence proposed above.

The authors wish to thank Mr. Masafumi Yoshioka for carrying out part of the experiments.

Fluorescence Spectrum and Its Intensity of Europium Tris(ethyl sulfate) Enneahydrate

Tomoyuki OHOKA and Yoshifumi KATO*

Department of Chemistry, Faculty of Science, Kobe University Nada-ku, Kobe 657

(Received June 24, 1982)

The polarized fluorescence spectrum of the europium tris(ethyl sulfate) enneahydrate crystal was measured at 95 K by using excitation lines of an Ar^+ laser. The multipole character of transitions and the energies and crystal quantum numbers for the crystal field components of the $^7F_J(J=0, 1,\cdots,6)$ and $^5D_{0,1}$ terms were determined from the spectral analysis. It was ascertained that most of the transitions were due to forced electric dipole transitions but some of them due to magnetic dipole transitions, in which nine strong lines appeared as magnetic dipole radiations satisfying the selection rule for ion levels, while three weak lines were magnetic dipole radiations forbidden in ions. The relative intensities of both the forbidden electric dipole transitions and the magnetic dipole transitions were calculated by the crystal field wavefunctions obtained to reproduce the experimental data. From the comparison of the calculated intensities with the observed ones, the ratio of the populations of the $^5D_0$ term to the $^5D_1$ term in fluorescent process was estimated to be about 20, although the $^5D_0$ term was 1750 cm^{-1} lower than the $^5D_1$ term. The result suggested that the configuration mixing due to *g*-orbitals was significant to allow electric dipole transitions.

It has been already well known[1] that the trivalent europium ion of $4f^6$ configuration has a regular ^7F_J multiplet followed by a ^5D_J multiplet and is the only one with a nondegenerate ground state $^7F_0$ among trivalent rare earth metal ions. For the europium tris(ethyl sulfate) enneahydrate, $Eu(C_2H_5SO_4)_3\cdot 9H_2O$ (Eu(ES)), Sayre and Freed[2] determined most of the crystal field components of $^7F_J(J=0,1,\cdots,6)$ terms from the polarized fluorescence spectrum and partially analysed the ultraviolet absorption spectrum. They also pointed out that some of fluorescence lines with $\Delta J=\pm 1$ in the $^5D_{0,1}\rightarrow{}^7F_{0,1,2}$ transitions were due to magnetic dipole (MD) radiation and not due to electric dipole (ED) radiation from the polarization measurements, although the transition probability due to MD transitions is, in general, extremely smaller than that due to ED transitions for parity-allowed transitions (see Appendix A). Similar MD transitions were also observed in the fluorescence spectra of Eu^{3+} and Tb^{3+} in $LaCl_3$ by Dieke *et al.*,[3,4] where only MD transitions satisfying the selection rule for ions ($\Delta J=0, \pm 1$) were observed in the crystals. Hellwege *et al.*[5,6] separately determined the energies and quantum numbers of the crystal field components of the $^7F_{0,1}$, $^5D_{0,1,2}$, and several electronic terms in the ultraviolet region from the absorption spectrum of Eu(ES) and its Zeeman effect.

The present paper deals with a further investigation of the crystal field components of the ^7F_J terms in Eu(ES) from the polarization properties of the laser-excited fluorescence spectrum at the liquid nitrogen temperature. The laser-excited technique is anticipated to give detailed information for the energy levels of a crystal, because of powerful capacity of laser as a light source and the facility of selective excitation to a specific ion level in crystals. Then the fluorescence transition probabilities for both the forbidden ED transitions and the allowed MD transitions are calculated from the wavefunctions which have been determined to reproduce the observed crystal field levels by using the tensor-operator method.[7] Some discussions are presented by comparing calculated relative intensities with observed ones.

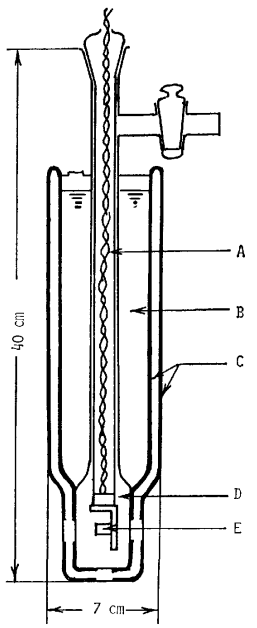

Fig. 1. Glass Dewar vessel for fluorescence measurements at liquid nitrogen temperature. A: Thermocouple, B: liquid nitrogen, C: silver plating, D: nitrogen gas, E: crystal.

Experimental

Preparation of the compound and the crystal growth were described in a previous paper.[8] A crystal was cut into a square rod of $3\times 3\times 8$ mm^3 with the largest side along the principal axis of the crystal. A single crystal was attached to a copper block in a special glass Dewar vessel (Fig. 1), which was filled with nitrogen gas at atomospheric pressure to prevent dehydration of crystalline water under vacuum. Since a crystal was cooled by heat conduction through nitrogen gas, the temperature of the crystal measured by a thermocouple was 95 K under incident Ar^+ laser beam at the liquid nitrogen temperature. The fluorescence spectrum was measured under a 90° scattering geometry by a Spex 14018 double spectrometer equipped with a cooled RCA C31034 photomultiplier and a Coherent Radiation model CR-4 Ar^+ laser. The exciting lines of 457.9 nm (21837

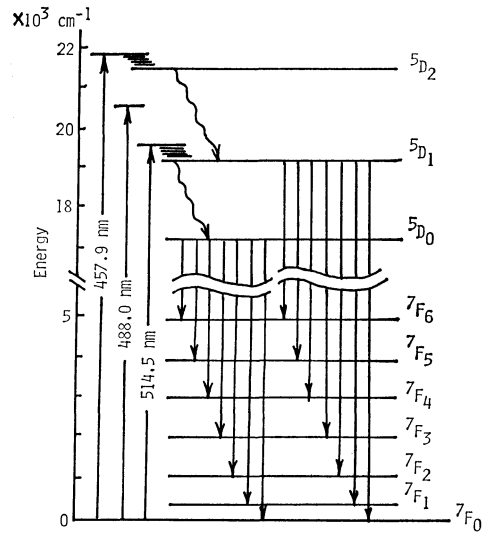

Fig. 2. Energy level diagram and observed fluorescence process of $Eu(C_2H_5SO_4)_3 \cdot 9H_2O$.

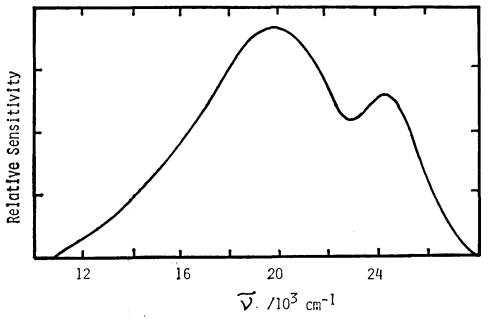

Fig. 3. Intensity response curve of the apparatus. The ordinate is in an arbitrary unit.

cm^{-1}) and 514.5 nm (19435 cm^{-1}) produced fairly intensive fluorescence and the fluorescence by the former was about 100 times as strong as that by the latter, while the exciting line of 488.0 nm (20492 cm^{-1}) scarcely produced fluorescence lines. This fact might easily be seen from the energy level diagram of the Eu^{3+} ion in Fig. 2. Almost all the electrons at 95 K occupy the lowest $^7F_0$ level and not the next $^7F_1$ level being about 380 cm^{-1} higher than the former. Thus, it is possible to produce directly the $^7F_0 \rightarrow {}^5D_2$ and $^7F_0 \rightarrow {}^5D_1$ excitations by the 457.9 and 514.5 nm exciting lines, respectively, and furthermore the former involves an ED transition allowed by the selection rule for crystal field levels, but the latter does not. Since such a condition is not satisfied by the 488.0 nm excitation, the 457.9 nm excitation yields the most intensive fluorescence. The measurement was carried out with the incident laser power of about 200 mW at the position of the crystal and the spectral slit-width was 4—10 cm^{-1} because most of fluorescence lines had intrinsically broad line-width even at 95 K. Wavenumbers were calibrated by already-known lines of neon, krypton, and argon discharge lamps. The accuracy of wavenumbers was within 1 cm^{-1}. The correction of the intensity response for the spectrometer-detector system as a function of wavenumber was performed by the calibration with a standardized tungsten source (Ushio No. 701038). The curve of the intensity response had the maximum at about 20000 cm^{-1} with gradual decrease toward low-wavenumber side and the relative intensity at 12000 cm^{-1} was about one-tenth of that at 20000 cm^{-1} (Fig. 3). The reproducibility of intensities did not vary seriously over all the lines. The average accuracy of intensities was estimated to be within 15% except those for the very weak $^5D_{0,1} \rightarrow {}^7F_{5,6}$ transitions. However, the intensity of very weak transitions was considered to have a fairly large amount of error.

Fluorescence Spectra and Wavefunctions

According to the analysis of the crystal structure of rare earth metal tris(ethyl sulfate) enneahydrates,[9,10] the space group is $P6_3/m$ (C_{6h}^2) and the site symmetry around a rare earth metal ion is C_{3h}. A rare earth metal ion has nine water molecules as nearest neighbors, where the water oxygen atoms are at a distance of about 2.4 A from the metal ion. An ion level $|JM)$ under a crystal field splits into several crystal field levels which are designated by the crystal quantum number μ originally introduced by Hellwege[11] and thereafter partially extended by others.[1] The classification of levels split by C_{3h} symmetry of a given J term is tabulated in Table 1, where the level with double signs is twofold degenerate. The selection rules for ED and MD transitions in C_{3h} symmetry are shown for an even number of electrons in Table 2.[12] The fluorescence spectra of Eu(ES) excited by the 457.9 and 514.5 nm lines of an Ar^+ laser at 95 K are shown in the range from about 19000 to 14000 cm^{-1} in Figs. 4 and 5, where σ- (Fig. 4) and π-polarized (Fig. 5) spectra stand for the radiation emitted in directions perpendicular and parallel to the principal axis of a crystal, respectively. In these figures, all the lines except V, V(O–H), V(C–H), and Vib Raman are due to the fluorescence. The distinction between fluorescence lines and vibrational Raman lines could easily be made when the polarized spectra excited by the 457.9 and 514.5 nm lines are compared with

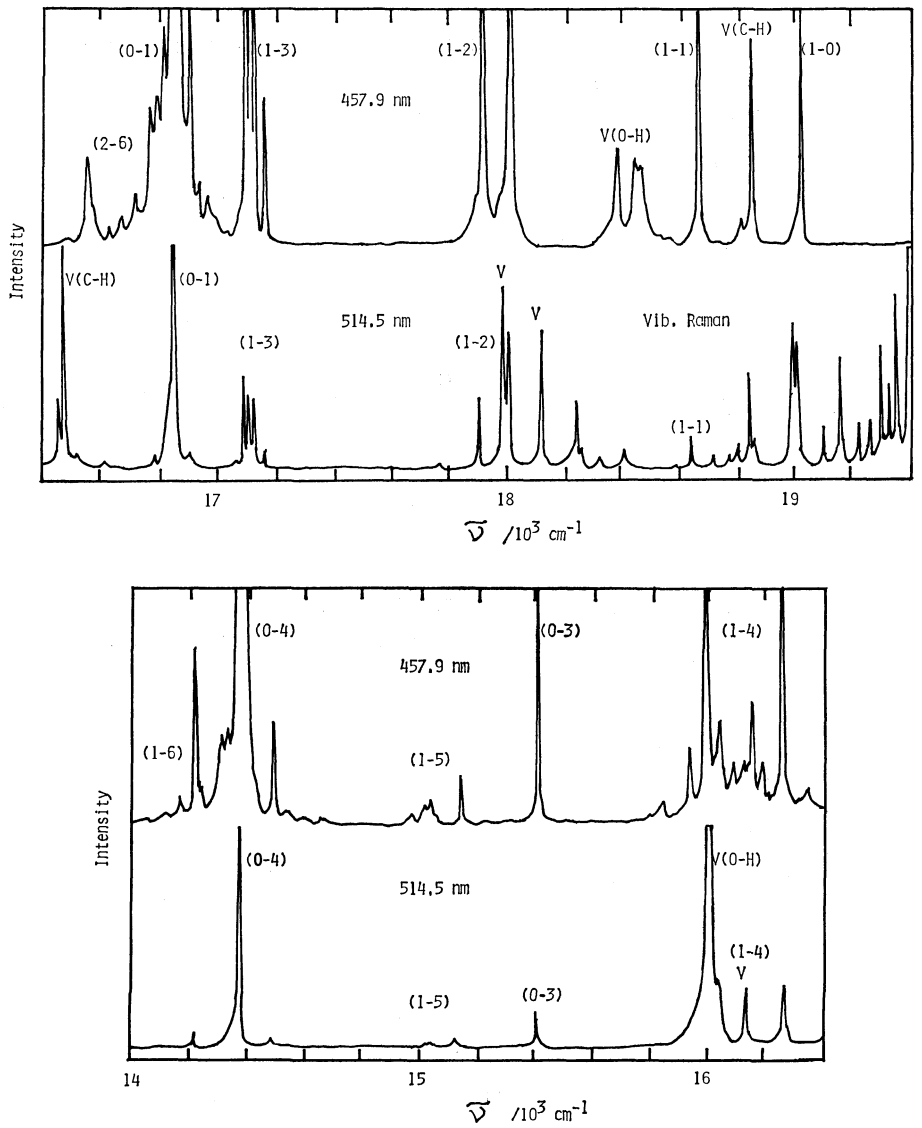

Fig. 4. σ-polarized fluorescence spectra of $Eu(C_2H_5SO_4)_3 \cdot 9H_2O$ at 95 K by the exciting lines of 457.9 nm (21837 cm^{-1}) and 514.5 nm (19435 cm^{-1}) of Ar^+ ion laser. Fluorescence lines between ^5D_J and $^7F_{J'}$ are shown by the notations of (J-J'). Notations of V, V(C–H),V(O–H), and Vib Raman indicate the vibrational Raman lines.

those by the 488.0 nm line or the polarized spectra of La(ES) without f electrons. In the latter spectra there were no fluorescence lines. Observed vibrational frequencies of polarized Raman spectra of Eu(ES) and La(ES) at 95 K are given in Table 3, where ZX- and ZZ-polarizations correspond to σ- and π-polarizations for fluorescences, and also to A_g and E_{1g} irreducible representations for vibrations, respectively. Although the fluorescence lines by the 457.9 nm excitation partially overlap with weak lines from the $^5D_2$ manifold, the latter lines could readily be distinguished from the $^5D_{0,1} \rightarrow {}^7F_J$ lines by comparing with the spectra of the 514.5 nm excitation. Thus the fluorescence lines were reasonably assigned to the transitions between crystal field levels. The nature of radiations was also clarified from the polarization properties following the selection rules and the result of calculated transition probabilities (see later section). The result obtained is given in Table 4, together with observed relative intensities. It can be seen in Table 4 that nine strong MD transitions are observed in the $^5D_{0,1} \rightarrow {}^7F_{0,1,2}$ transitions (the case of $\Delta J = \pm 1$ allowed for ions), and furthermore three very weak MD transitions are also observed in the $^5D_0 \rightarrow {}^7F_{3,4,5}$ transitions (the case of $|\Delta J| > 1$ forbidden for ion), where ΔJ is the difference of J between ion levels regarding a transition. The former MD transitions are those presented already by Sayre and Freed,[2] and the latter MD transitions in case of $|\Delta J| > 1$ have not yet been reported for any rare earth crystals so far as we know. Such transitions should be allowed to occur when there exist considerable interactions between crystal field components belonging to ion levels with different J (J-mixing), in addition to strong spin-orbit interactions (see Appendix A). Since the terms $^5D_{0,1}$ consist of only the crystal field levels with $\mu = 0$ and ± 1, the levels with $\mu = 0$ in the lower terms ^7F_J are able to be determined only by MD

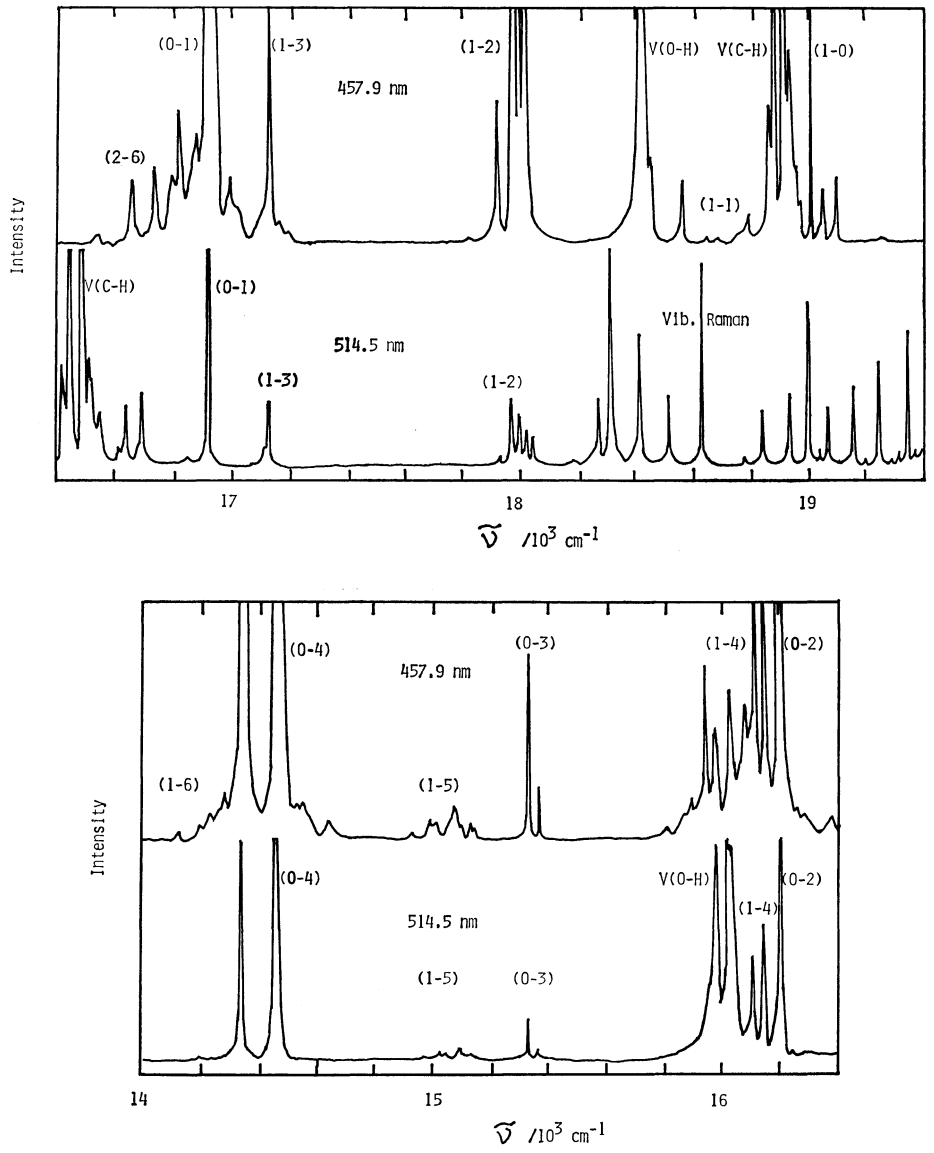

Fig. 5. π-polarized fluorescence spectra of $Eu(C_2H_5SO_4)_3 \cdot 9H_2O$ at 95 K by the exciting lines of 457.9 nm (21837 cm^{-1}) and 514.5 nm (19435 cm^{-1}) of Ar^+ ion laser. Notations are the same as in Fig. 4.

transitions and not by ED transitions as can be seen in the selection rules (Table 2). Observed energies and quantum numbers of crystal field levels are compared with those by Sayre and Freed[2] as given in Table 5. In both the results, there are few discrepancies between them regarding the wavenumbers and the crystal quantum numbers, but the $\mu=0$ levels in the $^7F_{3,4,5}$ terms are first acertained by the present analysis, and the present energy values are more accurate.

Wavefunctions. In order to calculate theoretically the transition probability between crystal field levels, it is necessary to have reliable wavefunctions in a crystal. Under intermediate coupling the wavefunctions of a rare earth metal ion are expressed by

$$|\phi_n) = \sum_n c_n |f^N : qSLJ), \quad (1)$$

where q is additional quantum numbers specifying a state except S, L, and J. When such an ion is placed in a crystal field, crystal field wavefunctions are given as

$$|\phi_a) = \sum_i a_i |f^N : qSLJM). \quad (2)$$

The Hamiltonian in crystals can be written as

$$H = H_{ion} + H_{cry}, \quad (3)$$

where H_{ion} and H_{cry} are the ion and crystal-field parts of interactions, respectively. The H_{ion} part consisting of the Coulomb and spin-orbit interactions can be expressed by a linear combination of the terms with the Slater radial integrals F_n (n=2,4,6) and the spin-orbit coupling constant ζ_{4f}. We further take account of scalar two-body electrostatic interactions arising from the second-order perturbation energies. These contribute to the H_{ion} as the terms with three configuration interaction (CI) parameters α, β, and γ.[14,15] Here we approximate that the site symmetry at a rare earth metal ion is D_{3h} instead of C_{3h} as adopt-

a) vs: Very strong, s: strong, m: medium, w: weak, vw: very weak, sh: shoulder. b) ν: Stretching, δ: bending, ρ_r: rocking, ρ_w: wagging, comb: combination. The assignment is based on the analysis of the internal modes of $La(C_2H_5SO_4)_3 \cdot 9H_2O$ and $La(C_2H_5SO_4)_3 \cdot 9D_2O$ at room temperature in a previous work (see Ref. 13).

ed by most of authors. The adequacy of this assumption has already been discussed by Margolis.[16] In practice, the site symmetry is D_{3h} as far as nine oxygen atoms of the crystalline waters as nearest neighbors are concerned, and the contributions of six ES ions as next nearest neighbors to the crystal field is considered to be very small. Then the crystal field potential of D_{3h} may be expanded by the irreducible tensor $C_n^{(k)}$ [12] as

$$H_{cry}(D_{3h}) = B_0^2 C_0^{(2)} + B_0^4 C_0^{(4)} + B_0^6 C_0^{(6)} + B_6^6 [C_6^{(6)} + C_{-6}^{(6)}], \quad (4)$$

in which B_n^k is the crystal field parameter to be determined from experimental data. The matrix element of the Hamiltonian is reduced by the tensor-operator technique.[12,17] Since we are interested in the crystal field levels of the $^5D_{0,1}$ and ^7F_J terms only, a set of limited electronic terms interacting strongly with these terms is considered, *i.e.*, ^7F, $^5D1$, $^5D2$, $^5D3$, ^5L, $^5G1$, $^5G2$, $^5G3$, $^3P1$, $^3P3$, and $^3P6$ terms, where a final index of terms is an additional index following the table of Nielson-Koster,[18] which corresponds to q in Eq. 1. The procedure of the parameter determination is described in a previous paper.[17] At first, the diagonalization of the H_{ion} part with F_2, F_4, F_6, ζ_{4f}, α, β, and γ as adjustable parameters was performed by fitting calculated values to the centers of gravity of J-manifolds (*i.e.*, the "ion level" in crystals) derived from the experiments. Secondly the crystal field parameters were determined from the deviations of crystal field levels regarding individual "ion level". Finally a minor readjustment of all the parameters was made by the least-squares method by diagonalizing the entire Hamiltonian. Thus the eigenvectors for the "ion levels" (the c_n in Eq. 1) and the crystal field levels (the a_i in Eq. 2) have been determined separately. The final parameters are given in Table 6. The wavefunctions determined are considered to be fairly reliable from the root mean square (rms) deviations evaluated for both ion levels and crystal field levels (Table 6).

Fluorescence Intensity

Judd[19] and Ofelt[20] independently derived the theory for the line strength of induced electric dipole transitions observed between states of rare earth metal ions within the $4f^N$ configuration imbedded in crystalline solids and solutions. Here the basic theory for ED transitions being known as the Judd-Ofelt theory and then the theory for MD transitions are outlined. The fluorescence intensity I in erg per sec of spontaneous emission between ψ_a and ψ_b states is given as

$$I(\psi_a:\psi_b) = g(\psi_a)N(\psi_a)hc\sigma A(\psi_a:\psi_b), \quad (5)$$

where $g(\psi_a)$ and $N(\psi_a)$ are respectively the degeneracy and the number of ions in the initial state ψ_a, σ is the transition frequency in cm^{-1}, and $A(\psi_a:\psi_b)$ is the spontaneous transition probability. The transition probability due to dipole radiations can be written as

$$A(\psi_a:\psi_b) = 64\pi^4\sigma^3[\chi_e|\langle\psi_a|\boldsymbol{D}_e|\psi_b\rangle|^2 + \chi_m|\langle\psi_a|\boldsymbol{D}_m|\psi_b\rangle|^2]/[3h(2J+1)], \quad (6)$$

a) The calculated energy of the $^5D_0(0)$ level is 17256.3 cm^{-1} in vacuum. The observed energies of the $^5D_1(\pm1)$ and $^5D_1(0)$ levels are 19015.0 and 19019.2 cm^{-1} in vacuum, respectively. The lines with asterisk are due to MD transition. b) Wavenumbers in cm^{-1} observed in air. c) Relative intensity in case that the intensity of the $^5D_1(0) \rightarrow {}^7F_0(0)$ transition is taken as 1.00. d) Energies in vacuum. Units in cm^{-1}. e) Values in parentheses are less reliable. f) The sum of the intensities of the $^5D_1(\pm1) \rightarrow {}^7F_4(3)$ and $^5D_1(0) \rightarrow {}^7F_4(\pm2')$ transitions is 5.21.

where $\boldsymbol{D}_e$ and $\boldsymbol{D}_m$ are ED and MD operators, respectively, while χ_e and χ_m are the correction factors of the medium related to the refractive index of the medium. When assumed that the surrounding medium around a rare earth metal ion is optically isotropic, the two correction factors might be taken to be equal approximately.[21] After eliminating the frequency dependence of σ^4 and making the correction of the intensity response for observed intensities, a relative intensity may be written as

$$I_r(\psi_a:\psi_b) = g(\psi_a)N(\psi_a)[|(\psi_a|\boldsymbol{D}_e|\psi_b)|^2 + |(\psi_a|\boldsymbol{D}_m|\psi_b)|^2]/(2J+1). \quad (7)$$

The matrix elements in Eq. 7 can be evaluated theoretically if the crystal-field wavefunctions are available.

Matrix Element of Electric Dipole Operator. ED operator $\boldsymbol{D}_e$ is given as

$$\boldsymbol{D}_e = -e\sum_i \boldsymbol{r}_i(\mathbf{C}_\rho^{(1)})_i = -e\boldsymbol{D}'_e, \quad (8)$$

where $\mathbf{C}_\rho^{(1)}$ is the irreducible tensor of rank 1 and $\rho=0$ gives the z-component corresponding to π-polarized radiation, while $\rho=\pm1$ gives the $(x\pm iy)$-components corresponding to σ-polarized radiation. An ED transition between states within the $4f^N$ configuration is parity-forbidden. According to the Judd-Ofelt theory, we consider that the admixing of $nl^{N-1}n'l'$ configurations of opposite parity to nl^N configuration arises from the addition of a static crystal field with odd parity to the Hamiltonian. Then a perturbed state $\psi_{a'}$ and perturbing odd potential V_{odd} are shown by

$$|\psi_{a'}) = |\psi_a) - \sum_\eta [(nl^{N-1}n'l':\eta|V_{odd}|\psi_a)/\Delta E(\eta)] \times |nl^{N-1}n'l':\eta), \quad (9a)$$

$$\Delta E(\eta) = E(nl^{N-1}n'l':\eta) - E(\psi_a) \simeq \Delta E(n'l'), \quad (9b)$$

where $|nl^{N-1}n'l':\eta)$ is a mixing state and the unperturbed state $|\psi_a)$ is given in Eq. 2. From the perturbation theory, the final expression for the matrix element of $\boldsymbol{D}'_e$ is written in tensor-operator technique as

$$\begin{aligned}(\psi_{a'}|\boldsymbol{D}'_e|\psi_{b'}) = &\sum_{i,j}\sum_{\lambda}\sum_{t,p} a_i^* b_j (-1)^{2J+S+L'+\lambda-M+p+\rho} \\ &\times \delta(S,S')(2\lambda+1)[(2J+1)(2J'+1)]^{1/2} \\ &\times \begin{pmatrix} l & \lambda & t \\ \rho & -p-\rho & p \end{pmatrix}\begin{pmatrix} J & \lambda & J' \\ -M & p+\rho & M' \end{pmatrix} \\ &\times \begin{Bmatrix} J & J' & \lambda \\ L' & L & S \end{Bmatrix} T(t,\lambda)(qSL\|\boldsymbol{U}^{(\lambda)}\|q'SL'),\end{aligned} \tag{11}$$

$$\begin{aligned}T(t,\lambda) = &A_{tp}\sum_{l'}(-1)^{l+l'}2(2l+1)(2l'+1) \\ &\times \begin{pmatrix} l & 1 & l' \\ 0 & 0 & 0 \end{pmatrix}\begin{pmatrix} l & t & l' \\ 0 & 0 & 0 \end{pmatrix}\begin{Bmatrix} 1 & \lambda & t \\ l & l' & l \end{Bmatrix} \\ &\times (R_{nl}|r|R_{n'l'})(R_{n'l'}|r^t|R_{nl})/\Delta E(\eta).\end{aligned} \tag{12}$$

Under the site symmetry of D_{3h}, the odd potential can be written as[20]

$$V_{\text{odd}}(D_{3h}) = \sum_i \sum_t A_{t3} r_i^t (\mathbf{C}_3^{(t)} - \mathbf{C}_{-3}^{(t)})_i. \tag{13}$$

From the triangular condition for the n-j symbols in Eqs. 11 and 12 in case of $l=3$, the following relations can be shown,

$$\lambda = 2, 4, 6, \quad t = \lambda \pm 1, \quad l' = 2, 4. \tag{14}$$

Since the parameters $T(t,\lambda)$ contain perturbing crystal field parameters A_{tp}, and radial integrals and energies regarding mixing states $|nl^{N-1}n'l':\eta)$, it is difficult to estimate the $T(t,\lambda)$ theoretically without introducing several drastic assumptions. In order to study the oscillator strength of a group of lines corresponding to the transitions between the components of a pair of J-manifolds, Judd[19] carried out an ingenious simplification for the basic expression by supposing the energy differences in Eq. 12 as being independent of mixing states and by making the sum over M, M', and ρ. Then the resultant expression with a single set of three adjustable parameters could be directly related to the oscillator strength derived from lanthanide solution spectra and it satisfactorily reproduced the experimental results. However, we have followed an alternate parametrization proposed by Axe,[21] which is appropriate to describe the relative intensity of the transitions between crystal field levels by taking the $T(t,\lambda)$ themselves as adjustable parameters. Following the Judd-Axe treatment, a line strength between J-manifolds $S(\varphi_n J:\varphi_m J')$ defined in crystals is given as

$$\begin{aligned}S(\varphi_n J:\varphi_m J') = &\sum_t \sum_\lambda (2\lambda+1)T(t,\lambda)^2 \\ &\times |(\varphi_n J|\boldsymbol{U}^{(\lambda)}|\varphi_m J')|^2/(2t+1).\end{aligned} \tag{15}$$

The matrix elements of the unit tensor of rank λ can be calculated by the eigenvectors of the "ion levels" given in Eq. 1 as

$$\begin{aligned}(\varphi_n J|\boldsymbol{U}^{(\lambda)}|\varphi_m J') = &\sum_{n,m} c_n^* c_m \delta(S,S')(-1)^{S+L'+J-\lambda} \\ &\times [(2J+1)(2J'+1)]^{1/2}\begin{Bmatrix} J & J' & \lambda \\ L' & L & S \end{Bmatrix} \\ &\times (f^N:qSL\|\boldsymbol{U}^{(\lambda)}\|f^N:q'SL').\end{aligned} \tag{16}$$

Consequently, the parameters $T(t,\lambda)$ may be evaluated

TABLE 7. OBSERVED AND THEORETICAL RELATIVE LINE STRENGTHS IN $Eu(C_2H_5SO_4)_3 \cdot 9H_2O$

$^7F_4$	745.	55.4	$0.0106[T(3,4)^2+T(5,4)^2]$		$0.0121[T(3,4)^2+T(5,4)^2]$	
$^7F_5$	3.13	11.6			$0.00499[T(3,4)^2+T(5,4)^2] + 0.000396[T(5,6)^2+T(7,6)^2]$	
$^7F_6$	12.4	1.89	$0.00167[T(5,6)^2+T(7,6)^2]$		$0.00255[T(5,6)^2+T(7,6)^2]$	

by the line strengths derived from experiments and the calculated values of $(\varphi_n J|U^{(\lambda)}|\varphi_m J')$. Now the number of $T(t,\lambda)$ to be evaluated is five from the restriction in Eq. 14; $T(3,2)$, $T(3,4)$, $T(5,4)$, $T(5,6)$, and $T(7,6)$.

Matrix Element of Magnetic Dipole Operator. MD operator $\boldsymbol{D}_m$ is given as

$$\boldsymbol{D}_m = -\beta(2\boldsymbol{S}+\boldsymbol{L}) = -\beta\boldsymbol{D}'_m, \quad \beta = -eh/(4\pi mc). \tag{17}$$

As MD operator is of even parity, MD transitions are allowed between states within the $4f^N$ configuration. The matrix element of MD transitions in crystals is reduced as

$$(\psi_a|(\boldsymbol{D}'_m)_\rho|\psi_b) = \sum_{i,j} a_i^* b_j (-1)^{J-M} \begin{pmatrix} J & 1 & J' \\ -M & \rho & M' \end{pmatrix} \times (f^N:qSLJ\|\boldsymbol{D}'_m\|f^N:q'S'L'J'), \tag{18}$$

where $\rho=0$ and ±1 correspond respectively to σ- and π-polarized radiations contrary to ED transitions. Following the results of Condon and Shortley,[22] the nonzero matrix elements must be diagonal in the quantum numbers q, S, and L, and furthermore the MD transitions are restricted by the selection rule on J ($\Delta J=0, \pm1$) to the following three cases:

1) $J'=J$,

$$(qSLJ\|\boldsymbol{D}'_m\|qSLJ') = g[J(J+1)(2J+1)]^{1/2}, \tag{19}$$

where

$$g = 1 + [J(J+1)+S(S+1)-L(L+1)]/[2J+1)].$$

2) $J'=J-1$,

$$(qSLJ\|\boldsymbol{D}'_m\|qSLJ') = \left[\frac{(S+L+J+1)(S+L+1-J)(J+S-L)(J+L-S)}{4J}\right]^{1/2}. \tag{20}$$

3) $J'=J+1$,

$$(qSLJ\|\boldsymbol{D}'_m\|qSLJ') = \left[\frac{(S+L+J+2)(S+J+1-L)(L+J+1-S)(S+L-J)}{4(J+1)}\right]^{1/2}. \tag{21}$$

After all, MD transition probability is able to be evaluated straightforwardly by using Eq. 1 for ion levels and Eq. 2 for crystal field levels, respectively.

Comparison of Observed and Calculated Intensities.

Populations of $^5D_{0,1}$ Terms: The observed relative line strengths S_{obsd} and theoretical ones S_{theo} from Eq. 15 for ED transitions and from the ion wavefunctions of Eq. 1 for MD transitions are tabulated in Table 7. Here, nonzero elements involving $T(t,\lambda)$ parameters for ED transitions are restricted by the triangular condition of the 6-j symbol in Eq. 16, whereas those for MD transitions are also limited by the selection rule of ion levels ($\Delta J=0, \pm1$). The S_{obsd} has been derived from the observed intensities by adding appropriate weights regarding the degeneracy of levels concerned and polarization measurements (see Appendix B). For the $^5D_0 \rightarrow {}^7F_{3,5}$ transitions, the S_{obsd} has been obtained from the experiments although these are very small, while there are no corresponding S_{theo} values for both ED and MD transitions. This fact solely results from the approximation adopted in the theory and may be explicable on the basis of the J-mixing effect of the crystal field interactions. The S_{obsd} values are still the quantity involving the populations of initial levels, while the S_{theo} values are independent of such population as be obvious from the definition. Thus, it is possible to estimate the population of initial levels. The fluorescent transitions originate from three crystal field levels; *i.e.*, the $^5D_0(0)$, $^5D_1(\pm1)$, and $^5D_1(0)$ levels. The $^5D_0(0)$ level is about 1750 cm^{-1} below the upper pair of nondegenerate $^5D_1(0)$ and doubly degenerate $^5D_1(\pm1)$ levels, and the two components of the $^5D_1$ term are separated by only 4.2 cm^{-1}. When we assume that three crystal field levels belonging to the $^5D_1$ term are populated identically by electrons, the ratio of the population of the $^5D_0$ to that of the $^5D_1$ is expressed as

$$\frac{N(^5D_0)}{N(^5D_1)} = \frac{S_{obsd}(^5D_0:{}^7F_J)/S_{theo}(^5D_0:{}^7F_J)}{S_{obsd}(^5D_1:{}^7F_{J'})/S_{theo}(^5D_1:{}^7F_{J'})} = R(^5D_0 \rightarrow {}^7F_J:{}^5D_1 \rightarrow {}^7F_{J'}), \tag{22}$$

here $N(^{2S+1}L_J)$ stands for the sum of populations over all the components of a J-manifold. Although the S_{obsd} of the $^5D_1 \rightarrow {}^7F_{1,2}$ transitions can arise from both ED and MD transitions, it will be supposed undoubtedly from the comparison of the order of magnitudes for the S_{obsd} and S_{theo} regarding the $^5D_1 \rightarrow {}^7F_{0,1,2}$ transitions that the $^5D_1 \rightarrow {}^7F_1$ transition is dominantly due to ED transition, while the $^5D_1 \rightarrow {}^7F_2$ transition is

a) Less accurate value for the overlap due to the $^5D_0(0) \rightarrow {}^7F_2(\pm2)$ transition. b) The sum of the relative transition probabililities for the $^5D_1(\pm1) \rightarrow {}^7F_4(3)$ and $^5D_1(0) \rightarrow {}^7F_4(\pm2′)$ transitions is 5.21.

mainly due to MD transition. Then, by substituting the values given in Table 7 into Eq. 22, the population ratios can be evaluated from several possible pairs of transitions as

$$R(^5D_0 \rightarrow {}^7F_1 : {}^5D_1 \rightarrow {}^7F_2) = 17.9 \quad \text{(MD character)} \qquad (23a)$$

$$R(^5D_0 \rightarrow {}^7F_2 : {}^5D_1 \rightarrow {}^7F_1) = 16.9 \quad \text{(ED character)} \qquad (23b)$$

$$R(^5D_0 \rightarrow {}^7F_4 : {}^5D_1 \rightarrow {}^7F_4) = 29.6 \quad \text{(ED character)} \qquad (23c)$$

$$R(^5D_0 \rightarrow {}^7F_6 : {}^5D_1 \rightarrow {}^7F_6) = 16.9 \quad \text{(ED character)}. \qquad (23d)$$

The average value of the ratios becomes 20.3 and agrees well with Axe's estimate[21] (=19) which was estimated from only a set of MD transitions corresponding to Eq. 23a by similar analysis. Since the population ratio of the $^5D_0$ term to one crystal field component of the $^5D_1$ term is only seven, it will be seen that the electron population on upper levels in fluorescent process extremely deviates from the Boltzmann distribution as be expected. Strictly speaking, as the fluorescence intensity must be proportional to the population difference between two levels concerned and not to the population of only the upper level, the population ratio should be estimated from

the intensities of transitions terminating to the same level. Therefore, the fact that the ratios from both Eqs. 23a and 23b are nearly equal to those from Eqs. 23c and 23d may be interpreted as follows: The population of the $^7F_2$ term is almost equal to that of the $^7F_1$ term or small populations of these terms are neglected when compared with large populations on the upper terms $^5D_0$ and $^5D_1$. However, $R(^5D_0\rightarrow{}^7F_1:{}^5D_1\rightarrow{}^7F_0)$ is 47.4 which is over twice as large as the ratio determined. This will probably result from the fact that there exists considerable intensity decrease due to self-absorption for the $^5D_1\rightarrow{}^7F_0$ transition as will be seen later, or the electron population of the lowest ground $^7F_0(0)$ level is not always neglected when compared with the populations of the upper $^5D_0$ and $^5D_1$ terms.

Parameters $T(t,\lambda)$ and Relative Transition Probabilities: When both observed relative intensities I_r and line strengths S_{obsd} for all the transitions from only the $^5D_0$ term are divided by 20.3, resultant observed quantities are independent of the populations of initial levels and correspond to the relative transition probabilities obtained by experiments. Thus, the $T(t,\lambda)^2$ values can be evaluated by a least-squares method from the comparison of the S_{theo} and observed line strengths not involving the population for ED transitions. Furthermore, the determination of the sign of $T(t,\lambda)$ and a minor refinement are made to reproduce the experimental intensities between crystal field levels ascertained as ED transition. The final values of $T(t,\lambda)$ are given as the ratios to $T(3,2)$ in Table 8, together with Axe's estimate. The present values are in good agreement in magnitude with Axe's values, but the sign of $T(5,4)/T(3,2)$ differs from that of Axe. This fact will probably arise from the difference of both cases with respect to the method to reproduce the experimental results. In the present estimate, the final adjustment of the five $T(t,\lambda)$ values is performed for the $^5D_{0,1}\rightarrow{}^7F_J(J=0,1,\cdots6)$ transitions by using the crystal field wavefunctions including complete J-mixing in Eq. 11, while Axe determined three parameters; $T(3,2)$, $T(3,4)$, and $T(5,4)$, for the $^5D_{0,1}\rightarrow{}^7F_J(J=0,1,\cdots4)$ transitions to reproduce both the observed line strengths and the ratio of intensities between the Stark components only within individual J-manifolds by the wavefunctions without J-mixing determined from symmetry consideration alone. The comparison of observed transition probabilities between crystal field levels with calculated ones is given in Table 9, where the values are described as relative values by putting the calculated transition probability of the $^5D_0(0)\rightarrow{}^7F_1(\pm1)$ for ED transitions and that of the $^5D_0(0)\rightarrow{}^7F_2(\pm2)$ for MD transitions to be equal to the corresponding observed values, respectively. The agreement is considered to be satisfactory in view of the approximation used in calculations and the accuracy on experiments. Especially, the nature of radiations from the $^5D_1(\pm1)$ level to degenerate levels $\mu=\pm1$, and $\mu=\pm2$ of the ^7F_J terms, which cannot be distinguished only from polarization measurements as be seen from the selection rules, is determined clearly from the calculated results. In Table 9, the calculated transition probabilities for

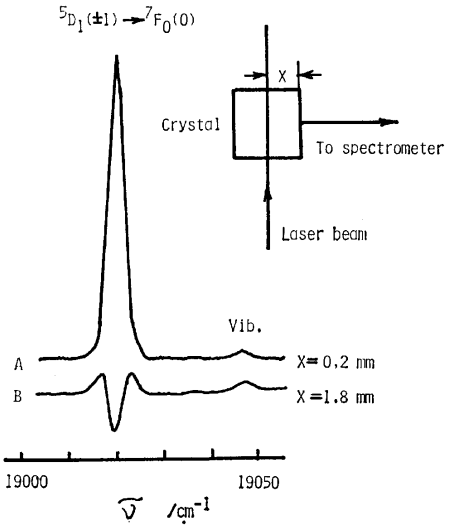

Fig. 6. π-polarized spectrum of the $^5D_1(\pm1)\rightarrow{}^7F_0(0)$ transition of $Eu(C_2H_5SO_4)_3\cdot9H_2O$ at 95 K, showing self-absorption.

two MD transitions from the $^5D_1(0)$ and $^5D_1(\pm1)$ levels to the lowest ground $^7F_0(0)$ level are considerably larger than the corresponding observed values. In practice, these MD transitions only showed heavily self-reserved line-shape in all the observed fluorescence lines when a laser beam passed through the middle of a crystal, as be seen in the case (B) of Fig. 6. Since self-absorption can occur when the absorbers and emitters are specially separated, we always attempted to pass an incident beam as close as possible to the crystal plane facing to a spectrometer (case (A) of Fig. 6). Such a fact that some of fluorescence lines to the lowest ground manifold only exhibit self-absorption at liquid nitrogen temperature has already been reported in other rare earth crystals.[23,24] Thus it does not seem to be an unjustifiable deduction to conclude that there still exists considerable intensity decrease for the above-mentioned MD transitions, although these line-shape did not show typical double humps even in a careful measurement. This phenomenon occurs in a 90° scattering measurement, but should be eliminated by 180° scattering.

Mixing Orbitals for Forbidden ED Transitions: Since the $T(t,\lambda)$ values are related to the radial wavefunctions $R_{n'l'}$ of mixing states, we introduce a parameter Γ following Axe[21] as

$$\Gamma=\sum_{n'}\Omega(n'g)/[\sum_{n'}\Omega(n'g)+\sum_{n'}\Omega(n'd)], \tag{24}$$

where

$$\Omega(n'l')=(R_{4f}|r|R_{n'l'})(R_{n'l'}|r^t|R_{4f})/\Delta E(n'l'). \tag{25}$$

Then the parameter Γ may be considered as a kind of measure on the contribution of admixing orbital $n'l'$ to allow ED transitions: $\Gamma=0$ means the contribution from d orbitals only, while $\Gamma=1$ is the contribution from g orbitals only. Appropriate ratios between $T(t,\lambda)$ values given in Eq. 12 are shown easily as a function of Γ as

$$\frac{T(3,4)}{T(3,2)}=\frac{1.95-1.42\Gamma}{1.0+1.50\Gamma}, \tag{26}$$

$$\frac{T(5,6)}{T(5,4)} = \frac{6.71-6.19\Gamma}{1.0+5.00\Gamma}. \quad (27)$$

Eq. 26 gives a maximum ratio of 1.95 for $\Gamma=0$ (pure d orbitals) and a minimum ratio of 0.212 for $\Gamma=1$ (pure g orbitals), whereas Eq. 27 gives a maximum ratio of 6.71 for $\Gamma=0$ and a minimum ratio of 0.081 for $\Gamma=1$. From the $T(t,\lambda)$ values of Table 8,

$$|T(3,4)/T(3,2)| = 0.0130, \quad |T(5,6)/T(5,4)| = 0.197. \quad (28)$$

Consequently, an unexpected conclusion that $n'g$ orbitals play a predominant role as configuration mixing for ED transitions is derived from both the cases. Dieke *et al.*[25] pointed out that the $4f^{N-1}5d$ configuration gave prominent contribution to emission spectra of the doubly and triply ionized rare earth metal ions. The present result, however, might not be somewhat surprising presumption when recognized that an $n'g$ orbital energy is not so higher than an $n'd$ orbital energy.

Appendix

(A) For an ED allowed transition in ions the oscillator strength f is of the order of magnitude one. An ED transition probability A^{E}_{ion} is related to the oscillator strength as[1]

$$A^{E}_{ion} = \frac{8\pi^2 e^2 \nu^2}{3mc^3} f = 2.68\times 10^9 (\sigma/Ry)^2 f, \quad (A1)$$

where σ is the wavenumber of transition and Ry is the Rydberg constant. Therefore, an ED allowed transition probability for a rare earth metal ion in crystals may be $10^8\ s^{-1}$ with a permissible factor of $10^{\pm 2}$ in the visible or near ultraviolet region. Since the ratio of an allowed MD transition probability, A^{M}_{ion}, to A^{E}_{ion} is expressed by $|[eh/4\pi mc]/e\langle r\rangle|^2$, A^{M}_{ion} becomes $10^2\ s^{-1}$. For the ED transition between the levels of the $4f^N$ configuration, the wavefunction must contain the terms of the configurations with odd parity. Thus the wavefunction is expanded by the perturbation theory as

$$\begin{aligned}|\psi_{a'}) = {} & |4f^N\psi_a : qSL) \\ & - \sum_k [(\varphi_k|H_{SO}|\psi_a)/\Delta E(4f)]\,|4f^N\varphi_k : qSLJ) \\ & - \sum_l [(\varphi_l|V_{even}|\psi_a)/\Delta E(4f)]\,|4f^N\varphi_l : qSLJM) \\ & - \sum_m [(\varphi_m|V_{odd}|\psi_a)/\Delta E(n'l')]\,|4f^{N-1}n'l'\varphi_m : qSLJM),\end{aligned} \quad (A2)$$

where the first term is unperturbed SL basis, and the second, third, and fourth terms are mixing states by the spin-orbit interaction, even- and odd-potential due to the crystal field, respectively. Here, $(\varphi_k|H_{SO}|\psi_a)$, $(\varphi_l|V_{even}|\psi_a)$, $(\varphi_m|V_{odd}|\psi_a)$, $\Delta E(4f)$, $\Delta E(n'l')$ may be the order of 10^2—10^3, 10^2, 10^2, 10^3—10^4, and 10^4—$10^5\ cm^{-1}$, respectively. Thus the transition probability responsible for crystal spectra is able to be expressed in terms of A^{E}_{ion} or A^{M}_{ion} as follows:

(I) for ED transition,

$$A^{E}_{cry} \simeq A^{E}_{ion}[(\varphi_k|H_{SO}|\psi_a)/\Delta E(4f)]^2 \times [(\varphi_m|V_{odd}|\psi_a)/\Delta E(n'l')]^2 = 10\ s^{-1}, \quad (A3)$$

(II) for MD transition ($\Delta J=0,\pm 1$),

$$A^{M}_{cry} \simeq A^{M}_{ion}[(\varphi_k|H_{SO}|\psi_a)/\Delta E(4f)]^2 = 1\ s^{-1}, \quad (A4)$$

(III) for MD transition ($|\Delta J|>1$),

$$A^{M}_{cry} \simeq A^{M}_{ion}[(\varphi_k|H_{SO}|\psi_a)/\Delta E(4f)]^2 \times [(\varphi_l|V_{even}|\psi_a)/\Delta E(4f)]^2 = 10^{-3}\ s^{-1}. \quad (A5)$$

Consequently, for the transitions within the $4f^N$ configuration the MD transition probability can be comparable to the ED forbidden one on some occasions. Especially, the $^5D_J \rightarrow {}^7F_{J'}$ transitions in a crystal are considered to be a further favorable case to yield MD transition, because these transitions also satisfy the selection rules for ion levels: $\Delta S=0,\pm 1$, $\Delta L=0,\pm 1$, and $\Delta J=0,\pm 1$. However, it will be easily found that even in the range of 20000 to 10000 cm^{-1} there are several fluorescence transitions of other triply ionized rare earth ions to satisfy the same conditions as the $^5D_J \rightarrow {}^7F_{J'}$ transitions of Eu^{3+} do; *e.g.*, $Nd^{3+}(^2H_{9/2}\rightarrow {}^4I_{9/2,11/2})$, $Sm^{3+}(^4G_{5/2}\rightarrow {}^6H_{5/2,7/2})$, $Tb^{3+}(^5D_4\rightarrow {}^7F_{3,4,5})$, $Er^{3+}(^2H_{11/2}\rightarrow {}^4I_{11/2,13/2})$, and $Tm^{3+}(^1G_4\rightarrow {}^3H_{4,5})$.

(B) The average intensity scattered from an ion or atom is associated with the intensities by polarization measurements,

$$I = \frac{1}{3}(I_X+I_Y+I_Z) \propto \frac{1}{3}(|\langle \boldsymbol{D}_X\rangle|^2+|\langle \boldsymbol{D}_Y\rangle|^2+|\langle \boldsymbol{D}_Z\rangle|^2), \quad (B1)$$

where I_X, I_Y, and I_Z are polarized intensities along X, Y, and Z axes in the space-fixed Cartesian coordinate, respectively, and $\langle \boldsymbol{D}\rangle$ is the matrix element of either the electric $\boldsymbol{D}_e$ or magnetic dipole moment $\boldsymbol{D}_m$. For an uniaxial crystal as rare earth tris(ethyl sulfate) enneahydrates, I_X must be equal to I_Y. One can estimate $I_X(|\langle(\boldsymbol{D}_e)_X\rangle|^2)$ and $I_Z(|\langle(\boldsymbol{D}_e)_Z\rangle|^2)$ from the intensities corresponding to σ- and π-polarized radiations for ED transitions respectively, whereas $I_X(|\langle(\boldsymbol{D}_m)_X\rangle|^2)$ and $I_Z(|\langle(\boldsymbol{D}_m)_Z\rangle|^2)$ or MD transitions are obtained inversely from π- and σ-polarization measurements. Consequently the average intensities are given as

$$\begin{aligned} I_e &= \frac{1}{3}(I_\pi+2I_\sigma) \quad \text{for ED transition,} \\ I_m &= \frac{1}{3}(I_\sigma+2I_\pi) \quad \text{for MD transition.}\end{aligned} \quad (B2)$$

This fact also may be verified analytically from direct estimate of the matrix elements of dipole moment operators in terms of $|JM)$ basis. In the evaluation of the line strength S_{obsd} (Table 7) from observed polarized intensities (Table 4), S_{obsd} is given as relative value by omitting the coefficient of 1/3 in Eq. B2.

Effect of Adsorption of Potassium Iodide on Catalytic Activity of Plate-type Raney Nickel

Tomio Yoshino* and Tuneyo Abe

Faculty of Pharmaceutical Science, Tokushima University of Arts and Science, Yamashiro-cho, Tokushima 770

(Received June 25, 1982)

An experimental investigation was made of the adsorptive activity of Raney nickel catalyst toward potassium iodide over a wide KI concentration range and of the change with KI adsorption of hydrogenating activity toward unsaturated alcohol and ketone. Adsorbed amounts of K^+ and I^- ions were determined by potentiometry and radioactivity measurement. The adsorptive activity *vs.* I^- concentration relation yields a definitive break at equilibrium concentration 5.5×10^{-5} mol dm^{-3} (surface coverage 26%), the adsorption features in the lower and higher ranges relative to the break point being approximately represented by Freundlich's and BET equations, respectively. Adsorption sites effective for I^- ion in the Freundlich region disappear almost completely when the catalyst is preheated at 600 °C. The surface coverage causing the hydrogenation activity to decrease by 50% is 3% for allyl alcohol and 0.3% for 2-butanone. With allyl alcohol, however, even such a catalyst as has preadsorbed *ca.* 5-monolayer amount of I^- ions possesses a 33% residual activity, though catalyst coverages over 26% result in only a little decrease in activity. These results suggest that the adsorption sites in the Freundlich region may function as strong catalytically active centers for the hydrogenation, which are unstable to heating.

Many reports have dealt with the relation between adsorption of halogen compounds on Raney nickel and catalysis by Raney nickel with preadsorbed halogen compounds. Pattison and Degering[1] reported that the rate of catalytic reduction of styrene was remarkably decreased when the concentration of chloride ion to be preadsorbed exceeded 4.2×10^{-4} mol/g RNi. On reduction of carbonyl groups in unsaturated ketones by Raney nickel, Hoshiai *et al.*[2,3] reported that a complete loss of the hydrogenation activity of catalyst occurred when Raney nickel had preadsorbed more than 4.1×10^{-4} mol of iodide ion per gram of Raney nickel. Sokol'skii and Zakumbaeva[4] reported that catalytic reduction of *p*-nitrophenol and similar compounds was decelerated in the coexistence of alkali halides.

Recent reports[5,6] indicate that preadsorption of NaBr on a modified Raney nickel for asymmetric hydrogenation results in a marked increase in yield owing to enantioface-differentiating hydrogenation and that this increase is caused by selective adsorption of NaBr at active centers involving aluminium compounds[7-9] lacking asymmetric selectivity. Little has yet been clarified of the relation between the adsorption on catalyst surface and the change in catalytic activity.

The present paper deals with the relation between the adsorptive activity of Raney nickel for KI and the catalytic activity of KI-preadsorbed Raney nickel for hydrogenation of unsaturated alcohols or ketones, with particular reference to the nature of surfaces of such catalyst preparations.

Experimental

Materials. Raney alloy was prepared by placing a nickel plate, 0.05 mm thick and 99.96% pure, between aluminium plates, 0.1 mm thick and 99.995% pure, and subjecting the sandwich heated at 630 °C in a nitrogen stream to hot-rolling with a dental roller. A plate-type Raney nickel catalyst,[10,11] suited for the present experiment, was prepared by treating the Raney alloy with a solution of 20 wt% sodium hydroxide at 50 °C for 1 h. The catalyst, thus obtained or further preannealed in a hydrogen atmosphere at 30—600 °C for 1 h, was used to determine the adsorption and hydrogenation activities; the catalyst was divided before use into portions of 16 cm^2 in apparent area (BET specific surface area 4.2×10^2 cm^2/cm^2).

Allyl alcohol, 2-butanone, and mesityl oxide (4-methyl-3-penten-2-one) were of special grade and used without further purification. Solutions of potassium iodide (special grade) were prepared by use of distilled water.

Procedures. The adsorption experiment was carried out by shaking the catalyst, in 100 ml aqueous solution of initial concentration 10^{-7}—10^{-2} mol dm^{-3} of KI labeled with 0.3 μCi of ^{131}I, in an atmosphere of nitrogen at 20—30 °C for 1 h. The catalyst was washed twice with 10 ml ethanol and then twice with 10 ml of a reactant before being used for reduction experiments. Adsorbed and desorbed amounts of iodide ion were determined with a well-type scintillation counter (Fuji Electric Model NHS 2) by measuring radioactivities on 1 ml portions taken from the adsorbate solution and the liquid employed for desorption experiment, respectively. Potentiometric measurement with a microprocessor ionalyzer (Orion Research Model 901) was employed to determine the amount of potassium ion adsorbed from aqueous solution.

The activity of catalysts was determined by use of liquid-phase hydrogenation on 3 ml allyl alcohol, 2-butanone, or mesityl oxide at 1 atm and 70 °C. Products were analyzed with a gas chromatograph (Yanagimoto Model G 180).

Results

Adsorbed Amount and Adsorption Isotherm. Both the time required for saturation adsorption to be reached and the adsorbed amount of I^- ion depend on temperature; with initial concentration 10^{-4} mol dm^{-3}, these values are about 60 min and 4.5×10^{-10} mol/BET cm^2 at 20 °C and about 30 min and 3.1×10^{-10} mol/BET cm^2 at 30 °C. It is noticed that the adsorbed amount may be estimated with a relative error less than about 10% under the same experimental conditions.

Figure 1 illustrates the effect of equilibrium concentration, C, on adsorbed amounts, v, of K^+ and

Table 1. Desorption of iodide ion from the catalyst in ethanol and reactant

Reactant	Initial [KI] mol/dm³	Adsorbed I⁻ mol/BET cm²	Desorbed fraction/% of I⁻			
			Ethanol	Reactant	Reaction	Total
Allyl alcohol	10^{-6}	5.70×10^{-12}	0.82	8.06	1.95	10.83
	10^{-3}	8.14×10^{-10}	1.35	4.63	1.61	7.59
2-Butanone	10^{-6}	5.70×10^{-12}	0.92	3.16	3.20	7.22
	10^{-3}	8.14×10^{-10}	1.19	2.80	0.80	4.79
4-Methyl-3-penten-2-one	10^{-6}	5.70×10^{-12}	0.84	4.27	0.70	5.77
	10^{-3}	8.14×10^{-10}	1.18	2.47	0.53	4.18

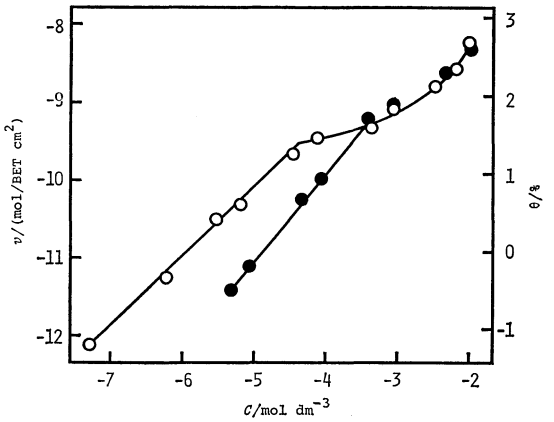

Fig. 1. Adsorption isotherm by the plot of the logarithm of the equilibrium concentration (C) on the logarithm of the adsorbed amount (v) (●: K^+ ion, ○: I^- ion) and surface coverage (θ) of I^- ion at 30 °C.

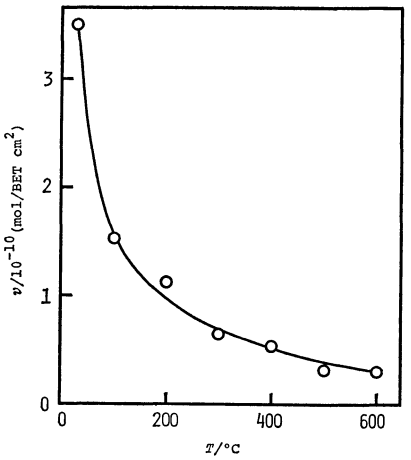

Fig. 2. Variation of I^- adsorptivity at 30 °C of the catalyst preheated for 1 h in H_2. The initial concentration of the adsorbate was 10^{-4} mol dm^{-3}.

I^- ions. Surface coverage, θ, of I^- ion was obtained by a calculation using the value of 2.06 Å as the ionic radius of the ion adsorbed on the surface of Raney nickel. The adsorbed amount of I^- ion, as shown in Fig. 1, yields a break at equilibrium concentration about 5.5×10^{-5} mol dm^{-3} ($v=3.2\times10^{-10}$ mol/BET cm²; $\theta=26\%$). Below the break point, the adsorbed amount is given by Freundlich's equation[12]

$$\log v = a + \frac{1}{n}\log C,$$

where a is a constant, evaluated to be 1.2 from Fig. 1. Beyond the break point, the equilibrium data approximately obey a BET equation, suggesting a multilayer adsorption of I^- ions. In fact, the 100% coverage is obtained at $C=2.1\times10^{-3}$ mol dm^{-3} and $v=1.2\times10^{-9}$ mol/BET cm², and the highest coverage, so far obtained, is 475%.

The isosteric differential heat of adsorption of I^- ion, as obtained by processing the above results according to Clausius-Clapeyron's equation,[13] decreases exponentially with increasing surface coverage of I^- ions in the Freundlich region, and is estimated to be 6.3×10^3 and 3.8×10^3 J/mol at coverages 3 and 25%, respectively.

The adsorbed amount of K^+ ion, as with the adsorption of I^- ion, yields a break at equilibrium concentration about 4.3×10^{-4} mol dm^{-3} (adsorbed amount, 5.4×10^{-10} mol/BET cm²; surface coverage of I^- ion, 43%). Below the break point, the adsorbed amount is much less than that of I^- ion. Beyond the point, however, both the adsorbates, K^+ and I^- ions, give equimolar adsorbed amounts.

Adsorption on Preheated Catalyst. Figure 2 illustrates the variation of the I^- adsorption activity of catalyst caused by application of sintering at 30—600 °C in a hydrogen atmosphere. The adsorptive activity of 3.5×10^{-10} mol/BET cm² ($\theta=28.1\%$) of the catalyst obtained by pretreatment at 30 °C was decreased by a 100 °C sintering to 1.5×10^{-10} mol/BET cm² (12.3%) corresponding to about 56% decrease and by a 600 °C sintering to 0.3×10^{-10} mol/BET cm² (2.4%) corresponding to about 91% decrease. These results suggest that many of the active centers for halogen adsorption are easily caused to disappear even by preheating at low temperature.

Desorption of the Adsorbate. The I^- preadsorbed catalyst was used for the reduction experiment after being successively washed with ethanol and the reactant for the reduction. Table 1 indicates fractions of I^- ions desorbed due to the washing with ethanol (the 4th col.), the washing with the reactant (the 5th col.), and the reduction (the 6th col.), the sum of these fractions being given in the 7th column. The desorption of I^- ion, as seen from Table 1, obviously depends on the initial concentration, giving higher fractions at 10^{-6} mol dm^{-3} than at 10^{-3} mol dm^{-3}; most of the adsorbate is desorbed with allyl alcohol in contrast with 2-butanone and mesityl oxide, the desorptive capacity being in the decreasing order:

Table 2. Change in activity of the preadsorbed catalyst for hydrogenation

Adsorbed I^- mol/BET cm^2	Coverage %	Rate of hydrogenation[a] mmol/h			
		Allyl alcohol	2-Butanone	4-Methyl-3-penten-2-one	
0	—	2.85	0.21	1.12[b]	0.37[c]
7.69×10^{-13}	0.06	2.13	0.17	0.57	0.32
5.70×10^{-12}	0.46	1.93	0.10	0.28	0.24
5.33×10^{-11}	4.28	1.27	0.08	0.22	0.15
3.11×10^{-10}	24.96	1.23	0.06	0.17	0.11
8.14×10^{-10}	65.41	1.21	0.04	—	—
5.92×10^{-9}	475.1	0.93	0.02	—	—

a) In the liquid phase at 1 atm and 70 °C. b) This column refers to product 4-methyl-2-pentanone produced from 4-methyl-3-penten-2-one. c) This column refers to product 4-methyl-2-pentanol.

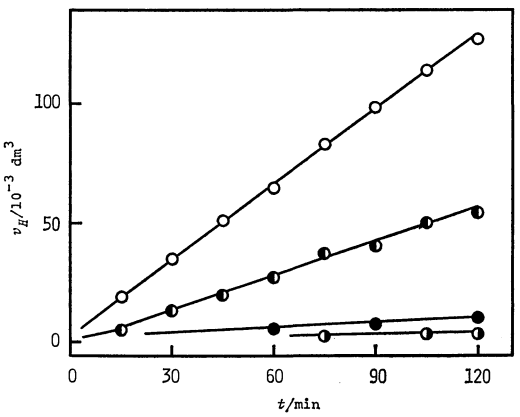

Fig. 3. Time dependences of hydrogen absorption (v_H) by allyl alcohol (○,◐) and by 2-butanone (●,◑) through the catalyst with (◐,◑) or without (○,●) preadsorption of KI. The initial concentration of the adsorbate was 10^{-5} mol dm^{-3}.

allyl alcohol>2-butanone>mesityl oxide.

Hydrogenation Activity of Preadsorbed Catalyst. Figure 3 illustrates the time dependence of the hydrogen adsorption by allyl alcohol or 2-butanone when the substrate is hydrogenated by catalysts with or without preadsorbed potassium iodide (adsorbed amount, 5.3×10^{-11} mol/BET cm^2; coverage, 4.3%). At 70 °C and 1 atm, the hydrogenation activity of catalyst remains constant over a period of 120 min, and is in general higher for the unsaturated alcohol than for the ketone. The hydrogenation activity is lowered by the preadsorption to 42.5% for the alcohol and 38.8% for the ketone.

Table 2 shows rates of hydrogenation of allyl alcohol, 2-butanone, and mesityl oxide on KI preadsorbed catalysts. The hydrogenation of the alcohol or the ketone yielded only 1-propanol or 2-butanol, respectively, but mesityl oxide gave both 4-methyl-2-pentanone and 4-methyl-2-pentanol. As seen from Table 2, the rate of hydrogenation of these compounds is highest for allyl alcohol regardless of the extent of preadsorption, and the rate for the alcohol by such a catalyst as has preadsorbed *ca.* 5-monolayer amount of adsorbate is 33% of that by the catalyst without preadsorption. It turns out that the rate of formation of 4-methyl-2-pentanone and 4-methyl-2-pentanol is remarkably decreased with increasing amount of preadsorbed I^- ions in the low adsorption phase; hydrogenation yields for the catalyst with 4.3% coverage are 71 and 29% for the carbon double bond and carbonyl group of mesityl oxide, respectively.

Discussion

As revealed from Fig. 1, the mode of adsorption of I^- ion is changed according as the adsorbate concentration falls in the lower or higher range relative to the definitive break. In the lower range, the Freundlich region, the isosteric heat of adsorption decreases exponentially with increasing adsorbed amount, and the surface coverage is so low (below 26%) that the surface interaction between adsorbate ions may be neglected and therefore the adsorbate ions may be considered to occupy heterogeneous adsorption sites successively with preference from higher to lower adsorption-activity sites. The number of ionic bonds of the K^+ with I^- ions adsorbed on the catalyst surface, in this region, seems to be smaller for the adsorbed amount than for that of adsorbed I^- ions, because a portion of the I^- ions may be stabilized electrostatically through the specific adsorption or may combine with H^+ instead of K^+ ion.[14]

On the contrary, in the higher concentration range than the break point where the BET equation holds, the change in the mode of adsorption seems to be caused by strong ionic interaction between the adsorbates on the catalyst, as well as by capillary condensation on the porous surface. In addition, multilayer adsorption may be considered to take place at the catalytic surface with equimolar adsorption of counterionic adsorbates to form an ionic double layer at the solid/liquid interface.

As seen from Table 1, the greater portion of the amount of I^- desorbed from the catalyst surface is involved in the course of washing at room temperature, though the absolute fraction desorbed varies with the initial iodide and reactant concentrations and the desorption is made to proceed a little further during the following reduction run at 70 °C. These results suggest that capillary condensation is more important than the Langmuir type adsorption for the understanding of the mechanism of desorption.

As shown in Fig. 2, adsorption sites effective for halogen ions in the Freundlich region are so unstable to heating as to disappear to a considerable extent even at relatively low temperatures and almost completely at 600 °C. In a previous work,[15] it was reported that the catalytic activity of plate-type Raney nickel is decreased by thermal pretreatment, *e.g.*, a catalyst annealed at 600 °C has an activity as low as 16% of that of a 100 °C-annealed one for reduction of acetone and 29% of that of a 150 °C-annealed one for reduction of benzene. These facts indicate that both the adsorption sites and the active sites for hydrogenation are caused easily to disappear by preheating the catalyst.

The hydrogenation activity of catalyst lowers with increasing amount of I^- ions preadsorbed in the Freundlich region, this tendency being more pronounced in the lower adsorption phase, as seen from Table 2. Thus, the surface coverage at the 50% lowering is about 3% for allyl alcohol and about 0.3% for 2-butanone. For the latter compound, the relative catalytic activity lowers to 0.36 at surface coverage 3%; the activity for the reduction of carbonyl group in ketone is remarkably decreased by the preadsorption of I^- ion. Similarly, in the case of mesityl oxide, the hydrogenation of carbon double bond proceeds much more rapidly than that of carbonyl group on catalysts of the same coverage. These results suggest that the preadsorbed I^- ions preferentially occupy many of the strong adsorption sites at or near the active centers effective mainly for the reduction of carbonyl group.

In the case of the adsorption in the range beyond the Freundlich region, the hydrogenation activity of catalyst depends negligibly on surface coverage as seen from Table 2. The residual activity displayed at more than 100% coverage implies wide distribution of preadsorbed I^- ions over the heterogeneous surface of catalyst and partial desorption from the surface of those ions upon attack by the reactant.

The above results agree with previous results,[1-3] though no direct, quantitative comparision can be made for differences in adsorbate properties or adsorption conditions.

Hofer and Hintermann[16] examined properties of the active center of Raney nickel by X-Ray diffraction line broadening analysis and reported that annealed Raney nickel catalysts with much lowered activity had lost many of their surface structural defects. Pearce and Leuis,[17] using the same method, reported that a highly active Raney nickel catalyst was unstable for heating and possessed much more structural defects, microstrains, and stacking faults than an inactive catalyst. As mentioned above, we[15] also reported that active sites of Raney nickel are associated with lattice defects, vacancies and dislocations because the hydrogenation activity of preannealed catalyst was decreased in a temperature range where defects vanish.

It is concluded from the present results that the adsorption sites for I^- ions in the Freundlich region and the greater portion of the active sites for hydrogenation are the same sites on catalyst surface or are located very close to each other, and that they are related to heterogeneous lattice defects.

The authors wish to thank Professor Emeritus Jiro Yasumura (Tokushima University) for his helpful discussion.

Suppression of Electroreductive Dimerization of Benzaldehyde by Addition of α-Cyclodextrin

Tomokazu MATSUE, Chikako TASAKI, Masamichi FUJIHIRA, and Tetsuo OSA*

Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980

(Received July 12, 1982)

The effect of α-cyclodextrin (α-CD) on the electroreduction of benzaldehyde was investigated. The reduction in aqueous system produces benzyl alcohol and 1,2-diphenyl-1,2-ethanediol (hydrobenzoin, dimerization product). The addition of α-CD caused the decrease in the yield of hydrobenzoin. This suppression effect was observed both in the controlled potential and controlled current electrolyses. This is accounted for by the retardation of the dimerization rate between the neutral radicals, since inclusion of substrate provides severe steric hindrance around the reaction site. The addition had only a small influence on the stereochemistry of hydrobenzoin formed by the dimerization.

Electrochemical reduction of carbonyl compounds to the corresponding alcohols is an important subject in organic electrochemistry. However, the reduction accompanies the concurrent formation of dimerization products.[1] In order to suppress the dimerization the following conditions are usually employed;[2] (i) low concentration of starting material, (ii) high current density, (iii) low pH, *etc.* We intend to suppress the dimerization from a quite different standpoint, *i.e.*, steric control at "molecular-level" by addition of cyclodextrin (CD).[3] This compound, constructed from cyclic glucose oligomers, has an ability to include a variety of organic substrates in their hydrophobic interior. Taking advantage of this unique property, we have carried out the selective electrosyntheses; the regioselective chlorination of benzene derivatives[4] and the selective reduction of *o*-nitrophenol in the presence of the *p*-isomer.[5] Recently, Smith and Utley demonstrated that CD acts as a proton source in nonaqueous media.[6] Although complexation is observed in polar aprotic media such as dimethyl sulfoxide and *N,N*-dimethylformamide, the binding ability of CD is much smaller than that in aqueous media.[3] Therefore, aqueous system should be used in order to draw the ability effectively.

We report herein the suppression of electroreductive dimerization of benzaldehyde by addition of α-CD in aqueous solution. The electrochemical reduction of benzaldehyde have been extensively investigated,[1,2] but the reduction mechanism is not clearly identified.[7] The generally accepted mechanism in neutral aqueous media is as follows:[2]

$$\mathrm{ArCHO} + \mathrm{e} \rightleftharpoons \mathrm{ArCHO^{-\cdot}} \quad (1)$$

$$\mathrm{ArCHO^{-\cdot}} + \mathrm{H^+} \longrightarrow \mathrm{ArCHOH\cdot} \quad (2)$$

$$2\mathrm{ArCHOH\cdot} \longrightarrow \mathrm{ArCH(OH)CH(OH)Ar} \quad (3)$$

(1,2-diphenyl-1,2-etnanediol, hydrobenzoin)

$$\mathrm{ArCHOH\cdot} + \mathrm{e} \longrightarrow \mathrm{ArCHOH^-} \quad (4)$$

$$\mathrm{ArCHOH^-} + \mathrm{H^+} \longrightarrow \mathrm{ArCH_2OH} \text{ (benzyl alcohol).} \quad (5)$$

In the above mechanism benzyl alcohol is produced *via* ECEC process. However, it can also be formed *via* regeneration mechanism[8] (or disproportionation mechanism) followed by protonation.

$$\mathrm{ArCHO^{-\cdot}} + \mathrm{ArCHOH\cdot} \rightleftharpoons \mathrm{ArCHO} + \mathrm{ArCHOH^-} \quad (6)$$

With α-CD, complexation of benzaldehyde is anticipated to reduce the dimerization rate since covering by α-CD produces severe steric hindrance around the reaction site, resulting in suppression of formation of 1,2-diphenyl-1,2-ethanediol (hydrobenzoin). If the dimerization between included molecules is permissible, the addition of α-CD may also affect the stereochemistry of hydrobenzoin[9] since inclusion makes the phenyl group more bulky, so that upon dimerization the approaching of each phenyl group would be sterically hindered.

Experimental

All controlled potential and controlled current electrolyses were carried out with a Yanaco VE-8 electrolyzer at room temperature. The cell was a divided H-type with a mercury pool cathode (area 6 cm^2) and a graphite or Pt gauze anode. The catholyte consisted of 25 ml phosphate buffers (pHs 4.6, 7.0, and 9.1) containing 25 mmol dm^{-3} benzaldehyde. In the controlled potential electrolysis, the potentials were referenced to a saturated calomel electrode (SCE) and the cathode potential was set at −1.3 V (at pH 4.6) and at −1.4 V *vs.* SCE (at pHs 7.0 and 9.1).

After the electrolysis, the catholyte was extracted with ether and the extract was analyzed by gas chromatography. Gas chromatographic analysis was carried out using a Shimadzu GC-4CM machine equipped with hydrogen flame ionization detector. The column used in the analyses of benzyl alcohol and unreacted benzaldehyde was 200 mm × 3 mm ϕ SUS packed with 10% Carbowax 20 M on Chromosorb W, and the column temperature was kept at 170 °C. Nitrogen was used as the carrier gas. Hydrobenzoin and its stereochemistry (*dl*/*meso* ratio) were determined by the reported method.[9]

Cyclic voltammetric experiments were carried out using a conventional instruments with a hanging mercury drop electrode (HMDE) in a phosphate buffer and the potentials were measured with respect to an SCE.

The dissociation constant for α-CD-benzaldehyde complex were determined by spectroscopic methods.[10] The analysis showed that the dissociation constant for the complex is $(4.3\pm0.9)\times10^{-3}$ mol dm^{-3}.

Results and Discussion

For mechanistic study, polarography is more appropriate and more accurate,[5,7] but cyclic voltammetry was carried out to see the effect of α-CD on the reduction of benzaldehyde in the present study due to

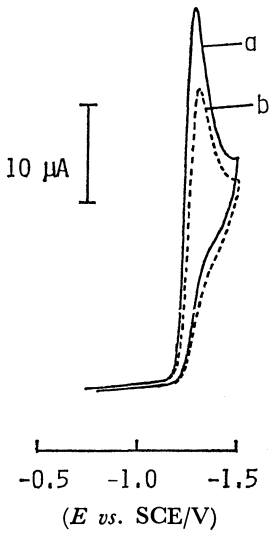

Fig. 1. Cyclic voltammograms of 2.0 mmol dm^{-3} benzaldehyde in the absence (a) and presence (b) of 10 mmol dm^{-3} α-CD at pH 7.0.
Electrode: HMDE, scan rate: 80 mV s^{-1}.

its convenience. Figure 1 shows the cyclic voltammograms of 2 mmol dm^{-3} benzaldehyde in the absence (curve (a)) and presence (curve (b)) of 10 mmol dm^{-3} α-CD in aqueous phosphate buffer (pH 7.0). Curve (a) shows an irreversible reduction peak at −1.30 V *vs.* SCE. As shown in curve (b), upon addition of α-CD to the electrolyte solution, the peak current becomes lower and the peak potential shifts slightly (*ca.* 20 mV) in the cathodic direction. The decrease in peak current is accounted for by the decrease in the effective diffusion coefficient due to the complex formation of benzaldehyde with large α-CD molecule.[5] As described below, the addition of α-CD results in suppression of electroreductive dimerization of benzaldehyde and consequently in the increase in the number of electrons, *n*, consumed for the reduction of one molecule of benzaldehyde. The decrease of the diffusion coefficient is therefore more than that would be expected without change in *n*. The shift in peak potential is probably caused by the "micro-solvent effect"[3] of α-CD; the similar effect has been also observed in the electroreduction of *p*-nitrophenol in the presence of α-CD.[5] In the present conditions concentrations of benzaldehyde and α-CD are 2 and 10 mmol dm^{-3}, respectively), *ca.* 70% of benzaldehyde exists as the complexed form.

Figure 2 depicts the relationship between the ratio of hydrobenzoin to benzyl alcohol, [HB]/[BA], and the conversion of benzaldehyde in the controlled potential electrolysis at −1.3 V *vs.* SCE. The [HB]/[BA] ratio is high at low conversions but decreases with increasing conversion (*i.e.*, decreasing the concentration of unreacted benzaldehyde). This indicates that the hydrobenzoin formation is predominated over the benzyl alcohol formation at beginning of the electrolysis. The tendency is quite consistent with that reported by Aoki and Sekine[7] in which they explained this phenomenon by the concentration effect.

The [HB]/[BA] ratios observed in the presence of

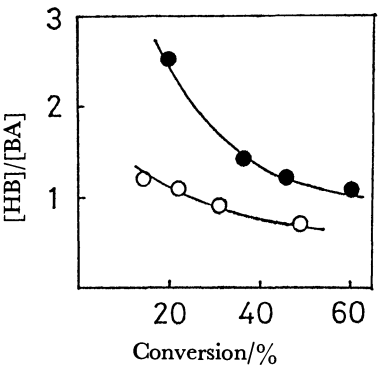

Fig. 2. Relationship between [HB]/[BA] ratio and conversion observed in the controlled potential electrolysis at −1.3 V *vs.* SCE (pH 4.6).

TABLE 1. THE [HB]/[BA] RATIO OBSERVED IN THE CONTROLLED POTENTIAL ELECTROLYSIS UNDER DIFFERENT pH CONDITIONS[a]

pH	Without CD	With α-CD (40 mmol dm^{-3})
4.6	1.2±0.2	0.5±0.2
7.0	2.2±0.4	0.7±0.2
9.1	2.8±0.5	1.0±0.3

a) Cathode potential: −1.3 V *vs.* SCE (at pH 4.6), −1.4 V *vs.* SCE (at pHs 7.0 and 9.1). Initial concentration of benzaldehyde: 25 mmol dm^{-3}. Conversion: 40—60%.

α-CD are lower than those in the absence of α-CD. This clearly suggests that α-CD suppresses the hydrobenzoin formation, *i.e.*, dimerization reaction. Under the initial conditions (concentrations of benzaldehyde and α-CD are 25 and 40 mmol dm^{-3}, respectively), *ca.* 80% of benzaldehyde in the electrolyte solution is included in α-CD's cavity since the dissociation constant for the complex is $(4.3\pm0.9)\times10^{-3}$ mol dm^{-3}. Even if the reduction products, benzyl alcohol and hydrobenzoin, can be trapped strongly by α-CD, the inclusion ratio of benzaldehyde is maintained above 75% through electrolysis. In spite of the fact that such high complex formation is maintained, the suppression effect of α-CD on the dimerization becomes small as the electrolysis proceeds as shown in Fig. 2. At relatively high conversions, benzyl alcohol formation takes precedence over the hydrobenzoin formation, therefore, α-CD cannot exhibit its ability effectively under such conditions.

Table 1 shows the [HB]/[BA] ratios observed in the controlled potential electrolyses under different pH conditions. In all cases the addition of α-CD resulted in decreases in the ratio, indicating that α-CD suppresses the dimerization. From Table 1 it can be seen that the ratio is dependent on the pH of the electrolyte. However, the trend cannot be attributed mainly to the pH effect since the cathode potentials in the present cases are not sufficiently negative with respect to the half-wave potentials.[7] We selected the relatively mild potentials since sufficiently negative potentials (*i.e.*, high current densities) favored

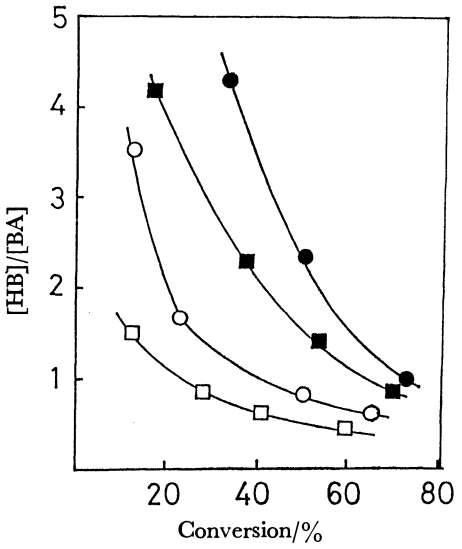

Fig. 3. Relationship between [HB]/[BA] ratio and conversion observed in the controlled current electrolysis at pH 4.6.
●: 0.33 A dm^{-2}, without CD, ○: 0.33 A dm^{-2} with α-CD (40 mmol dm^{-3}), ■: 0.50 A dm^{-2}, without CD, □: 0.50 A dm^{-2}, with α-CD (40 mmol dm^{-3}), initial concentration of benzaldehyde: 25 mmol dm^{-3}.

benzyl alcohol formation;[2] such conditions are not suitable for demonstrating the effect of α-CD.

The current density has a large influence on the product ratio.[2] Then, we carried out the controlled current electrolysis of benzaldehyde in the presence of α-CD. Figure 3 depicts the relationship between the [HB]/[BA] ratio and conversion of benzaldehyde in the controlled current electrolyses at 0.33 and 0.50 A dm^{-2}. Benzyl alcohol formation is favored at high current density in agreement with previous results.[2] In this case, the addition of α-CD also led to decrease in the [HB]/[BA] ratio.

As described above, α-CD can suppress the dimerization reaction both in the controlled potential and in the controlled current electrolyses. It seems possible that the dimerization rate in Eq. 3 is suppressed by the steric hindrance caused by the bulky α-CD molecule since benzaldehyde is included in the interior of α-CD. The anion radical and neutral radical of benzaldehyde must be included in α-CD judging from the results by Smith and Utley;[6] however, the determination of dissociation constants of the inclusion complexes is impossible since these radicals undergo following-up chemical reactions which are complicated. The suppression effect of α-CD may also explained by some influences of α-CD on other elementary reactions. However, the exact mechanism for the electroreduction of benzaldehyde is still unclear,[7] therefore, further discussion is beyound this paper. The current efficiencies of the electrolyses were higher than 70% and the addition of α-CD did not affect the current efficiency.

Finally we investigated the effect of α-CD on the stereochemistry of hydrobenzoin formed by the dimerization reaction. The *dl/meso* ratios[9] of hydrobenzoin are listed in Table 2. The effect of α-CD is quite small, though the addition of α-CD results in a slight increase in the *dl/meso* ratio. This result indicates that dimerization between molecules included in α-CD hardly takes place due to the steric hindrance. The dimerization would occur between free molecules; in the presence of α-CD *ca.* 20% of benzaldehyde exists in the free form at any instance. Therefore, the addition of α-CD cannot largely affect the stereochemistry of hydrobenzoin. The above argument also suggest that α-CD suppresses the dimerization rate (Eq. 3).

Table 2. Diastereomeric ratio (*dl/meso* ratio) of hydrobenzoin formed by the controlled potential electrolysis[a]

pH	Without CD	With α-CD (40 mmol dm^{-3})
7.0	0.96	1.11
9.1	0.85	0.97

a) Cathode potential: −1.4 V *vs.* SCE. Initial concentration of benzaldehyde: 25 mmol dm^{-3}.

In conclusion, the addition of α-CD to the electrolyte solution results in suppression of electroreductive dimerization of benzaldehyde (hydrobenzoin formation). This is probably attained by reducing the dimerization rate between the intermediate radicals, since inclusion of substrate in α-CD provides a severe steric hindrance around reaction sites. The addition has a small influence on the stereochemistry of hydrobenzoin formed in the present electrolysis. This also supports the suppression effect of α-CD on the dimerization rate.

Excimer Fluorescence of 1,2-Di(9-anthryl)ethane, 1,3-Di(9-anthryl)propane, and 9,9′-Bianthryl at High Pressures

Kimihiko HARA,* Yoshikazu KATOU, and Jiro OSUGI

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received July 22, 1982)

Fluorescence spectra of 1,2-di(9-anthryl)ethane (**1**), 1,3-di(9-anthryl)propane (**2**), and 9,9′-bianthryl (**3**) have been studied at high pressures up to 50 kbar both in crystalline state and in PMMA matrix. In the case of **1** and **2** in crystalline state, the excimer emissions appear reversibly at high pressures accompanied by the reversible red shifts. While in PMMA the fluorescence spectra assigned as locally excited state are observed, whose peak shifts are quite analogous to that of anthracene in the same matrix. As for **3**, a new band also appears at high pressure which is similar to the intramolecular charge-transfer band. Possible interpretations of the pressure effects are discussed.

Since the first discovery by Förster and Kasper[1] concerning the complexes between excited and ground state aromatic hydrocarbons which were named "excimer," numerous aromatic hydrocarbons have been found to exhibit excimer fluorescence and the results have been summarized in some reviews.[2] Their prominent feature is the broad and structureless fluorescence band which is shifted 4000—6000 cm^{-1} to lower frequencies relative to the normal molecular fluorescence. This fluorescence has been observed both in fluid solutions and in solid state at atmospheric pressure, if the structure allows a close overlap of molecular planes.

Recently the presence of the so-called "second excimer"[3] with a smaller overlap between the two anthracene moieties as compared with the sandwich arrangement has been suggested for 1,2-di(9-anthryl)-ethane in solution by Hayashi *et al.*[4] Dianthrylalkanes, where a pair of anthracene molecules are linked with methylene groups, have a possibility of the formation of intramolecular excimers.

The primary effect of pressure is to decrease interatomic distances and to increase overlap between adjacent electronic orbitals. Thus, the excimer formation in the solid state is expected to be highly pressure dependent if the crystal structures or molecular conformations are appropriate to allow a sandwich conformation. In the crystals such as anthracene, which has not a dimer structure, the excimer formation has been reported by the application of high pressure,[5] although the crystals with dimer structure such as perylene, pyrene, and 9-methylanthracene are known to exhibit excimer fluorescence at atmospheric pressure.

In this paper we report our studies of the pressure dependence of the excimer formation in 1,2-di(9-anthryl)ethane (**1**), 1,3-di(9-anthryl)propane (**2**), and 9,9′-bianthryl (**3**) [*i.e.*, (anthracene)-$(CH_2)_n$-(anthracene) for n=2, 3, and 0, respectively] up to 50 kbar both in the crystalline state and in the plastic media. Previously we published a preliminary results of **1**.[6] This paper presents the results of a more complete analysis where some points are corrected. In addition, since the high pressure cell, the emission apparatus, and the operation employed for this work have not been previously described, some details are also given here.

Experimental

Materials. The samples of **1**, **2**, and **3** used in this studies were prepared according to the literature procedure.[7-9] **1** was recrystallized from toluene and purified further by sublimation under vacuum. **2** and **3** were purified by successive recrystallizations from benzene and acetic anhydride, respectively. No impurity was detectable in TLC analysis, elementary analysis, and spectroscopic analysis of the purified samples.

The measurements were carried out for the crystals diffused in the NaCl crystal which was used as pressure transmitting medium, and for the poly(methyl methacrylate) (PMMA) film. Methyl methacrylate monomer was purified by the ordinary method[10] and thermally polymerized in bulk. The PMMA was purified by reprecipitations from benzene solution with methanol as precipitant. The compound and the PMMA were dissolved in dichloromethane at a concentration of less than 1%, forming approximately 0.07 mm thick films after evaporating the solvent under nitrogen atmosphere and at reduced pressure. The salt pellet is usually 0.5 mm thick. Two half cylinders of NaCl single crystal are cut to fit the sample hole of the high pressure cell and the pellet or film is inserted in between.

High Pressure Cell. The high pressure cell used for emission measurements is similar to Drickamer's type 1 cell[11] except for some modifications. It has two windows at 90° and uses NaCl as a pressure transmitting fluid, as well as NaCl windows. The outer steel jacket is SNCM hardened to HRC: 45—50. The inner cell is made from maraging steel YAG 300 hardened to HRC: 60. The carboloy pistons are jacketed with SNCM.

The pressure calibration was based on the shift of the R_1 fluorescence line of ruby at 694.2 nm as determined at the NBS (0.75 cm^{-1}/kbar)†. This cell can be used up to 50 kbar with no trouble in pistons as well as in windows.

Emission Apparatus. A block diagram of the emission spectrometer apparatus is shown in Fig. 1. The 27300 cm^{-1} band of a Hanovia 200 W Hg-Xe arc lamp is used as the excitation light source, which is mounted in an LH 150 lamp housing of Schoeffel LPS 271 power supply. The exciting light is dispersed through an ISA Jobin-Yvon H20 monochromator. Quartz lenses focus the excitation light into the high pressure cell. The emitted light is observed by the front surface illumination at 90° to the excitation light. Quartz lenses then collect the emitted light from the sample and focus it onto the entrance slit of the emission monochromator, an ISA Jobin-Yvon HRS 600 mm monochromator with a 1200 grooves/mm grating. For detection

† 1 bar=10^5 Pa.

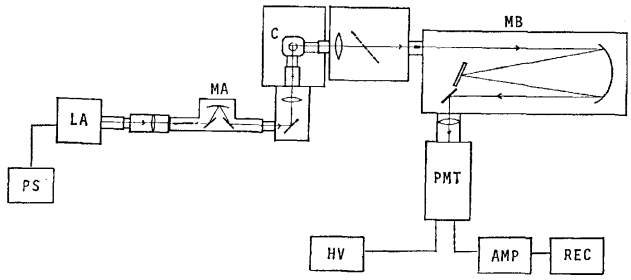

Fig. 1. Schematic diagram of apparatus for measuring the pressure effect on fluorescence.

of the emitted light, the photomultiplier tube used is a Hamamatsu R562 which is operated at a cathode voltage of −1000 V by Fluke 415B, and cooled to −70 °C by a Hamamatsu C659 cooling apparatus. The amplified signal is displayed on a recorder.

The spectrometer can also be employed to measure excitation spectra, where the broad spectrum of a Hanovia 150 W Xe arc lamp and the wavelength drive of the excitation monochromator are required. The spectral corrections were made by quinine sulfate in 0.05 M H_2SO_4 (1 M= 1 mol dm^{-3}) as a reference standard.

Results

Fluorescence Spectra of **1**. Figure 2(a) summarizes the fluorescence spectra of **1** in different matrices at atmospheric pressure, which are normalized at each peak maximum. The spectrum of the crystal exhibits the normal fluorescence, which corresponds to that from ^1L_a state of anthracene. By forming into NaCl pellet with the compression of less than 7 kbar, this band decreases and a new broad structureless band appears at the energy of about 20000 cm^{-1}, although it is relatively weak in intensity. The corresponding change is not observed in the fluorescence excitation spectra. The new band decreases by the thermal annealing and reverts to the original crystalline spectra for 2 h at 100 °C. Thermal annealing removes the irreversible effects.

In PMMA, on the other hand, the main band at around 24000—25000 cm^{-1} are also assigned as the locally excited band, although the vibrational structure disappears. As a reference standard the fluorescence spectra of anthracene at atmospheric pressure in both matrices are shown in Fig. 2(b), where the concentration is about twice of that in **1**. The loss of vibrational structures in **1** may come from some intramolecular interactions accompanied by the substitution at the 9 position of anthracene since the transition moment of ^1L_a state is along the short molecular axis of anthracene. But it has appeared in **2** with larger separation between the two anthracene parts.

Figures 3 and 4 illustrate the effect of pressure on the fluorescence spectra of **1** in crystalline state and in PMMA matrix, respectively. They are normalized

——: Crystals in NaCl pellet, —·—·: crystals, — — —: in PMMA matrix. (They are normalized at the wavenumber corresponding to the maximum intensity.)

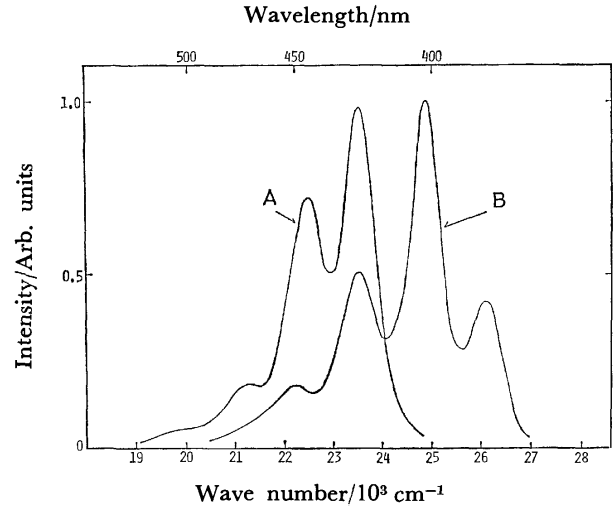

Fig. 2(b). Fluorescence spectra of anthracene.
A: Crystals in NaCl pellet, B: in PMMA

at their peak maxima. In crystals the new broad band grows in intensity at the expence of the normal emission with increasing pressure. These effects are reversible with pressure. The intensity of the normal emission returns to the spectrum obtained before compression, which indicates that no photochemical process is occuring at high pressures.

In PMMA, the band at 20000 cm^{-1} is not observed, but a new shoulder at 22000—23000 cm^{-1} appears as the pressure is applied. It is also reversible with pressure. The fluorescence excitation spectra do not show any new bands at high pressures and the behavior on the spectra are also reversible with pressure.

Fluorescence Spectra of **2**. Figure 5 shows the fluorescence spectra of the crystal at various pressures. A broad structuresless band is observed even at atmospheric pressure as a dominant band. The normal fluorescence appears as a small shoulder which disappears with increasing pressure.

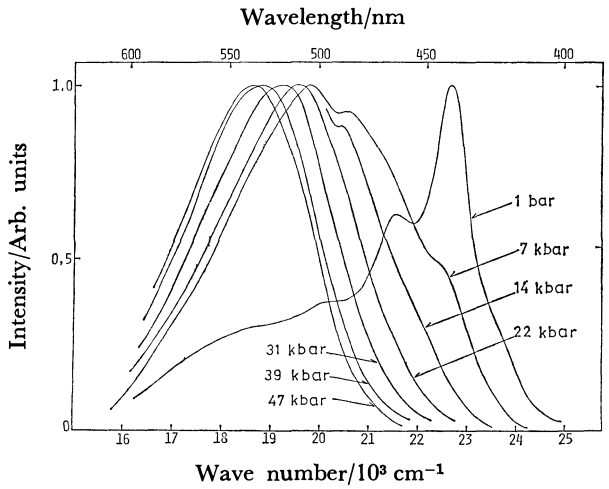

Fig. 3. Fluorescence spectra of **1** in crystals at various pressures.

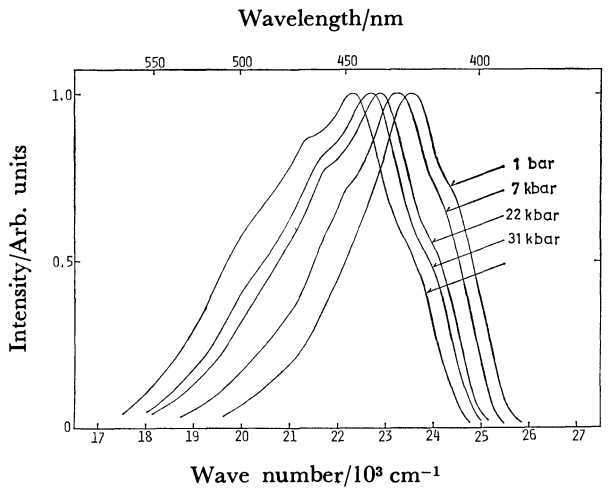

Fig. 4. Fluorescence spectra of **1** in PMMA matrix at various pressures.

Figure 6 shows the fluorescence spectra of **2** in PMMA. The spectrum at atmospheric pressure agrees with that in methanol–ethanol reported by Kobayashi *et al.*[13], except that there exists a shoulder at around 22000 cm^{-1}. It corresponds to that of anthracene monomer. In all cases the fluorescence excitation spectra shows no corresponding change with pressure except for the peak shift.

Fluorescence Spectra of ***3***. Figure 7 illustrates the fluorescence spectra of the crystal at various pressures. The spectrum of **3** at atmospheric pressure exhibits a broad emission at 22200 cm^{-1}. As the pressure is applied, this band decreases relatively with accompanying a red shift and a new band appears at around 20000 cm^{-1} at a pressure of 14 kbar. At the higher pressure the intensity of this peak increases and shifts toward red.

The effect of pressure in PMMA matrix are shown in Fig. 8. The spectrum at atmospheric pressure agrees with that in MCH–IP (1:3) reported by Schneider *et al.*[14] As the pressure is applied, it seems that the broad band of the lower energy grows up relatively, and at the pressure higher than about 14 kbar only

this peak remains. In both cases no change is observed in the fluorescence excitation spectra. These effects are completely reversible with pressure.

Spectral Shifts with Pressure. As expected, there is a red shifts with pressure in all the fluorescence bands. The effects of pressure on the peak locations of **1**, **2**, and **3** both in crystalline state and in PMMA matrices are given in Table 1 and Figs. 9—11. Maxima were carefully read from the corrected curves. The peak shift of anthracene that is measured also

in this work for the sake of comparison is included in Table 1 and in Fig. 9. The amounts of the peak shift of **1** and **2** in PMMA with pressure agree with that of anthracene in the same matrix. The result confirms that the emissions in PMMA for these compounds are originated from the locally excited state in anthracene parts and that these are not the excimer like band with special interactions between the two anthracene chromophores. On the other hand, the excimer emission exhibits a larger shift as compared with that of the locally excited state in PMMA. The lower pressure region of **1** in crystal is the band for the locally excited state.

Careful examination of the results of **3** in crystal indicates that there might be two types of pressure sensitivity. So long as seeing in the peak shift, no nonlinear behavior with pressure is detected in PMMA matrix.

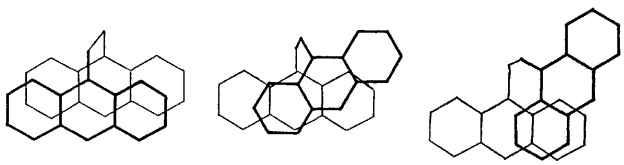
Discussion

The application of high pressure to crystals may create structural defects which are supposed to be crystallographic imperfections with excimer structure and act as a trap to capture singlet excitons. The effect of the creation of such defects is to be observed as irreversible pressure effects.[5] The irreversible behavior for **1** in the formation of sample pellet is likely to be originated from this effect. Thus, all the completely reversible pressure effects at the pressure higher than the residual pressure indicate the intrinsic effects on the excimer conformations. The residual pressure is less than 7 kbar.

The fluorescence spectra of **1** exhibits the vibrational structure from anthracene chromophores at atmospheric pressure. It looks like the type A crystals as classified by Stevens,[15] which fluoresce only normal emissions such as anthracene, naphthalene, and phenanthrene. For the crystal of **1** in NaCl matrix resembling to anthracene, the new broad band which appears at a lower energy region than the normal fluorescence by about 3000 cm^{-1} as the pressure is applied can be assigned as the excimer existing only in the excited state, since no change is observed in the excitation spectra except for the peak shift.

Ferguson *et al.*[16,17] developed an ingenious technique for producing the excimers of **1**. They prepared in single crystals of photocycloadduct of **1** by photocleavage so that a complete parallel conformation for **1** are kept by the constraint in the rigid matrix. By this method they observed three types of excimer emissions for **1**. Based on its energy value, our high-pressure induced excimer emission for **1** with a maximum at 19800 cm^{-1} at 14 kbar seems to correspond to the species B excimer by Ferguson *et al.*[16] with a maximum at 19600 cm^{-1} at 6 K. They proposed to its molecular conformation a partially overlapped sandwich structure with parallel molecular planes. Thus, if the high-pressure induced excimer is intramolecular, it will be the type of species B. If it is intermolecular, it is not a type of completely overlapped sandwich type excimer. The fact that the corresponding band is not observed in PMMA and the analogous behavior to anthracene suggest that this excimer is formed intermolecularly. However, the shoulder appeared in PMMA matrix at around 21000 cm^{-1} under pressure may indicate a formation of intramolecular one, whose peak maximum is close to that observed by Hayashi *et al.*[4] in solution.

The excimer fluorescence observed for **2** in crystals resembles that of type B crystals in which the molecules are arranged pair-wise. The fact that such type B structure is easily achieved suggests that this excimer is formed intramolecularly. This explanation is also based on the results that in PMMA matrix there exists a shoulder band besides the main band of the locally excited state as seen in Fig. 6, and that the relative intensity increases at lower energy region, and this behavior does not change with concentration. Its band maximum lies in the higher wave number as compared with 9-methylanthracene which has a pair-wise structure in the crystal. The amount of the peak shift, however, is similar to that of 9-methylanthracene. This may indicate that the excimer formed has not a complete sandwich arrangement, but has a structure with different mutual orientations such as the species B or C by Ferguson *et al.*, and also the type II by Hayashi *et al.* that have been reported for **1**. The proposed molecular conformations of the excimers for **1** by Ferguson *et al.* are visually shown as follows;



(A) (B) (C)

where (A) is the species A with a complete overlapped sandwich structure, while (B) and (C) are the species B and C, respectively with a smaller overlapped structure. The structure (B) corresponds to type II by Hayashi *et al.*

The excimer peak shifts of **1** and **2** under pressure saturate at the higher pressure region in comparison with that of anthracene. In the case of **2**, it shows only a little change with pressure at higher than 30 kbar, as seen in Fig. 10. While in anthracene it shows a linear pressure dependence of -73 ± 7 cm^{-1}/kbar, which agrees with the reported result[5] within the error limits of the experiments. The difference in peak shifts among these compounds reflects that the more bulky molecule is the more difficult in the molecular motion to stabilize the excimer conformation.

As for **3**, it is impossible to achieve the intramolecular sandwich arrangement. The interesting properties have been reported by Schneider *et al.*[14] that the interaction between the two chromophores shows characteristics of the charge-transfer interactions in the excited state under the influence of solvent perturbations, which accompanies a small conformational change. The fluorescence in polar solvent shows a broad featureless band which is caused by the intramolecular charge transfer resulted from the conformational change in the excited state.

The band maximum of the fluorescence spectra of **3** in crystals at atmospheric pressure is 22200 cm^{-1} as seen in Fig. 7. This cannot be assigned to the charge-transfer band, but to the locally excited fluorescence band from anthracene moiety. In some solvents the corresponding band has been observed at atmospheric pressure, and it has been confirmed that π-electron systems of two anthracene chromophores are scarecely interact with each other, not only by the measurements of absorption and fluorescence spectra,[14] but also by the measurements of polarizability,[18] dipole moment,[18] half reduction potential,[19] molecular refraction,[20] and conbustion energy.[21] Hexane is one of such solvents in which only the locally excited fluorescence band appears. The measurement of pressure effects in hexane up to 6 kbar showed *ca.* -50 cm^{-1}/kbar,[22] which is analogous to that observed in PMMA matrix and in the lower pressure region in the crystal.

On the other hand, the new band observed at the higher pressure than about 15 kbar in crystal can be assigned as the charge-transfer band. It has a peak shift of -77 ± 13 cm^{-1}/kbar. Such a larger peak shift corresponds to that in polar solvents as methanol in which only the charge-transfer band is observed.[22] The high sensitivity with pressure indicates the characteristics of the charge-transfer state. The charge-transfer state shows also a high sensitivity with the solvent polarity change. Thus, the increase in pressure has the same effect as the increase in solvent polarity.

It has been calculated by Schneider *et al.*[23] that the twisted angle between the two anthracene chromophores in **3** is 90° in the ground state, while in the excited state it changes by $\pm12°$. The results of the pressure-induced new band and its larger red shift with pressure are considered to be correlated with the analogous intramolecular conformational change at high pressures. Namely, the change of the twisted angle is to be achieved with increasing pressure, and as the result, the charge transfer state is more stabilized. Further details of the research will be reported in a subsequent paper.

This research was supported in part by a Grant-in-Aid for Scientific Research No. 447007 from the Ministry of Education, Science and Culture, and in part by Grants for Joint Research in Fundamental Chemistry of Japan Society for the Promotion of Science.

Kinetics of the Formation of the Intermediate Complex in the Aromatic Nucleophilic Substitution of Methyl 4-Methoxy-3,5-dinitrobenzoate with Piperidine in Dimethyl Sulfoxide

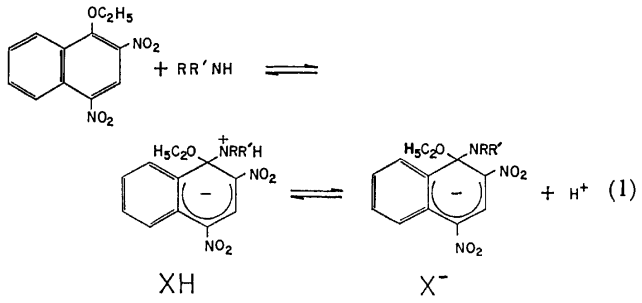
Yoshinori HASEGAWA

College of General Education, Tohoku University, Kawauchi, Sendai 980

(Received August 13, 1982)

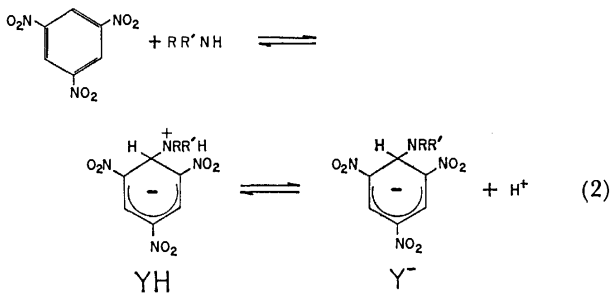
The intermediate complex in the aromatic nucleophilic substitution of methyl 4-methoxy-3,5-dinitrobenzoate with piperidine in dimethyl sulfoxide was confirmed by visible absorption spectroscopy. Kinetics of the formation of the intermediate were studied by a stopped-flow spectrophotometer, and rate and equilibrium constants were determined. The observable intermediate (Z^-) was the conjugate base of the initial zwitterionic complex (ZH). Proton transfer between ZH and Z^- was rate limiting and the intermediate formation was base catalyzed.

Bunnett and coworkers have confirmed the existence of the intermediate complex in the aromatic nucleophilic substitution of 1-ethoxy-2,4-dinitronaphthalene with primary and cyclic secondary amines in dimethyl sulfoxide (DMSO) and presented the mechanism for the formation and decomposition of the intermediate.[1,2] As regard to the formation of the intermediate, proton transfer between XH and X^- is rapid and therefore the formation of the intermediate is not base catalyzed.



XH X^-

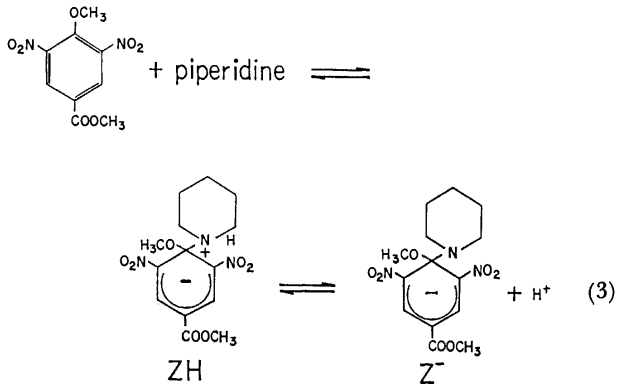
Contrary, kinetic studies on the formation of the anionic σ-complexes[3-5] of trinitrobenzene with primary and secondary amines have shown that proton transfer between YH and Y^- is rate limitting under certain conditions.[5-9]



YH Y^-

Crampton and Gibson have demonstrated from kinetics of the formation of the σ-complex from trinitrobenzene and piperidine in DMSO that proton transfer is rate limiting over the entire range of piperidine concentrations used.[9]

We have observed the visible absorption spectrum of the intermediate complex of methyl 4-methoxy-3,5-dinitrobenzoate (MDNB) with piperidine in DMSO and studied on kinetics of the formation of the intermediate.



ZH Z^-

Experimental

Materials. MDNB was prepared by esterification of 4-chloro-3,5-dinitrobenzoic acid followed by nucleophilic substitution of chlorine by sodium methoxide. The compd was recrystallized from methanol. NMR (DMSO-d_6); δ=8.63 (aromatic protons), 3.99 (OCH_3), 3.92 ($COOCH_3$). Methyl 3,5-dinitro-4-piperidinobenzoate was prepared by substitution of the methyl ester of 4-chloro-3,5-dinitrobenzoic acid with piperidine. The compd was recrystallized from methanol. NMR (DMSO-d_6); δ=8.39 (ring protons), 3.87 ($COOCH_3$), 3.00 (CH_2NCH_2), 1.56 ($CH_2CH_2CH_2$). Piperidine was refluxed over sodium and distilled. Piperidine hydrochloride was prepared from piperidine and concentrated hydrochloric acid in methanol and recrystallized from methanol. S. G. DMSO, tetrapropylammonium iodide, and 1,4-diazabicyclo-[2.2.2]octane (DABCO) were used as supplied.

Measurements. Piperidine (2.8×10^{-4} mol) was injected into a NMR tube containing a DMSO-d_6 solution (0.4 cm^3) of MDNB (2.0×10^{-4} mol) and NMR spectra were recorded on a Hitachi R-22 Spectrometer. Visible absorption spectra were recorded using a Hitachi RSP-2 Rapid Scan Spectrophotometer and a Hitachi 340 Spectrophotometer. Kinetic measurements were carried out using a thermostatted stopped-flow spectrophotometer (Union Giken RA-401).

Results

NMR Spectroscopy. After addition of piperidine to a solution of MDNB, the resonance peaks at δ= 8.63, 3.99, and 3.92 gradually disappeared and completely vanished 1 h after addition at 34 °C. At the expense of the peaks of MDNB, new resonance peaks appeared at δ=8.25, 3.77, 3.06, and 1.58. The new

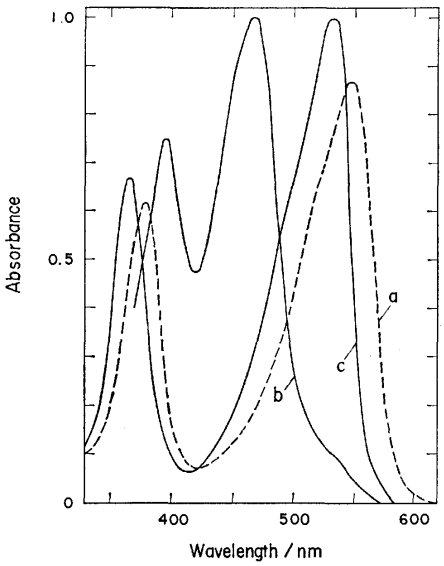


Fig. 1. The visible absorption spectrum observed immediately after mixing of MDNB (4.9×10^{-5} M, 1 M=1 mol dm^{-3}) with piperidine (0.32 M) in DMSO, a; the spectra observed with the DMSO solution containing MDNB (4.9×10^{-5} M), potassium methoxide (8.0×10^{-3} M), and methanol (0.8% by volume); b and c, *ca.* 1/3 s and 5 min after mixing respectively.

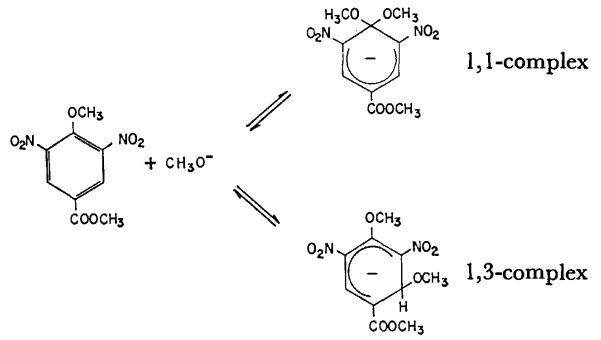
peaks are attributed to methyl 3,5-dinitro-4-piperidinobenzoate; δ=8.25 (aromatic protons), 3.77 ($COOCH_3$), 3.06 (CH_2NCH_2), 1.58 ($CH_2CH_2CH_2$). No evidence for formation of an anionic σ-complex was obtained from NMR spectroscopy.

Visible Absorption Spectroscopy. The spectrum observed immediately after mixing of MDNB with piperidine in DMSO is a in Fig. 1. The absorption bands at 378 and 545 nm slowly decreased in intensity and disappeared several hours after mixing at room temperature.

For comparison, we tried to observe the visible absorption spectra of MDNB with potassium methoxide in DMSO. The spectra observed *ca.* 1/3 s and 5 min after mixing are b and c in Fig. 1, respectively. The absorption bands at 395 and 465 nm appeared at the initial stage are attributed to the 1,3-complex.[10,11] The spectrum c with absorption maxima at 367 and 532 nm is due to the 1,1-complex.[10-12]



The similarity of the spectrum a to c leads to the conclusion that the spectrum c is due to the intermediate complex ZH or/and Z$^-$. The formation of the intermediate is too fast to be measured by conventional means but can be measured by a stopped-flow spectrophotometer.

a) $[MDNB]_0$ 6.0×10^{-5} M; [piperidine hydrochloride] 5.0×10^{-3} M; [tetrapropylammonium iodide] 5.0×10^{-3} M. b) Absorbance at 545 nm. c) In the absence of piperidine hydrochloride and tetrapropylammonium iodide. Conversion of MDNB to Z$^-$ is virtually complete. ε_{545} 19300 M^{-1} cm^{-1}.

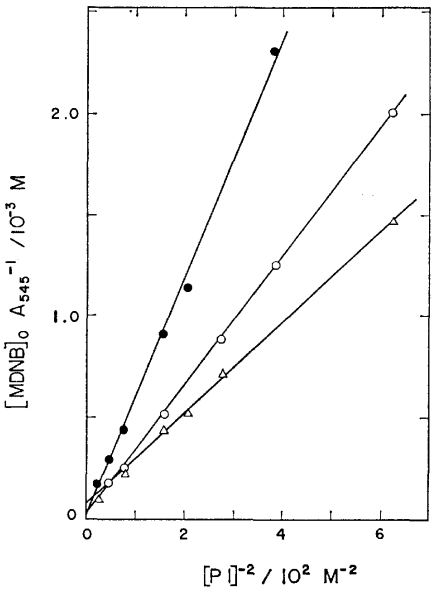

Fig. 2. Plots of $[MDNB]_0$ A_{545}^{-1} *vs.* $[Pi]^{-2}$.

Equilibria. Let us rewrite Eq. 3 as Eq. 4.

$$MDNB \underset{k_{-1}}{\overset{k_1[Pi]}{\rightleftharpoons}} ZH \underset{k_{PiH^+}[PiH^+]}{\overset{k_{Pi}[Pi]}{\rightleftharpoons}} Z^- \quad (4)$$

An equilibrium constant K for the over all conversion of MDNB into Z$^-$ is defined by Eq. 5.

$$K = \frac{[Z^-][PiH^+]}{[MDNB][Pi]^2} \quad (5)$$

And then

$$K = \frac{k_1 k_{Pi}}{k_{-1} k_{PiH^+}}. \quad (6)$$

Assuming that k_{Pi} is much larger than k_{PiH^+},[13] Eq. 5 is rearranged as follows:

$$\frac{[MDNB]_0}{A} = \frac{[PiH^+]}{K\varepsilon[Pi]^2} + \frac{1}{\varepsilon}, \quad (7)$$

Table 2. Rate date in the presence of piperidine in large excess of MDNB at 25 °C[a)]

where $[MDNB]_0$, A and ε are the stoicheiometric MDNB concentration, equilibrium absorbance, and the molar extinction coefficient, respectively.

In the presence of piperidine and piperidine hydrochloride in large excess of MDNB, equilibrium absorbance at 545 nm measured with a stopped-flow spectrophotometer is presented in Table 1. Measurements were carried out at μ 0.01 M using tetrapropylammonium iodide. Plots of $[MDNB]_0 A_{545}^{-1}$ *vs.* $[Pi]^{-2}$ in Fig. 2 give straight lines. K 0.117, 0.083, and 0.045 M^{-1} at 20, 25, and 30 °C respectively were obtained.

Kinetic Analysis. Kinetic runs were carried out in the presence of piperidine in large excess of MDNB and in the absence of piperidine hydrochloride. Under these conditions, we may write as follows:

$$MDNB \underset{k_{r2}}{\overset{k_{f1}}{\rightleftharpoons}} Z^- + AH^+, \tag{8}$$

where AH^+ is the species formed from deprotonatin of ZH by piperidine and is equall in concentration to Z^-, and k_{f1} and k_{r2} are the pseudo-first-order rate constant for the forward reaction and the second-order reverse rate constant, respectively. The solution for Eq. 8 is presented by Eq. 9.[14)]

$$\ln\left(\frac{[MDNB]_0[Z^-]_e+[Z^-]([MDNB]_0-[Z^-]_e)}{[MDNB]_0([Z^-]_e-[Z^-])}\right)= \left(\frac{2[MDNB]_0-[Z^-]_e}{[Z^-]_e}\right)k_{f1}t, \tag{9}$$

where $[Z^-]$ and $[Z^-]_e$ are concentrations of Z^- during the reaction and at equilibrium respectively.

Making use of the steady-state approximation with respect to ZH, k_{f1} is given by Eq. 10. The second-order rate constant k_{f2} for the forward reaction is given by Eq. 11.

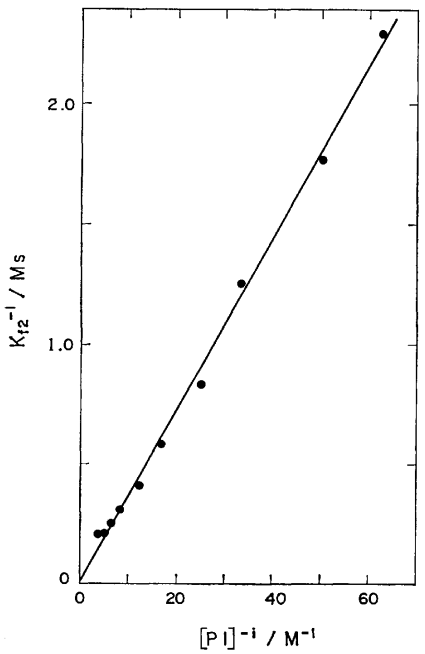

Fig. 3. A plot of k_{f2}^{-1} *vs.* $[Pi]^{-1}$.

$$k_{f1} = \frac{k_1[Pi]k_{PI}[Pi]}{k_{-1}+k_{PI}[Pi]} \tag{10}$$

$$k_{f2} = k_{f1}/[Pi]. \tag{11}$$

Rate date are presented in Table 2. When concentrations of piperidine are smaller than 0.12 M values of $k_{f1}/[Pi]^2$ are substantially constant. This fact implies that k_{-1} is much larger than $k_{PI}[Pi]$ and deprotonation of ZH is rate limiting in the forward direction.

Equation 10 is rearranged as Eq. 12.

$$\frac{1}{k_{f2}} = \frac{1}{k_1} + \frac{k_{-1}}{k_1k_{PI}[Pi]} \tag{12}$$

A plot of k_{f2}^{-1} *vs.* $[Pi]^{-1}$ in Fig. 3 gives straight line. k_1k_{PI}/k_{-1} 28 $s^{-1}M^{-2}$ and k_1 100 $s^{-1}M^{-1}$ were obtained from the inversion of the slope and of the intercept, respectively. And then k_{PI}/k_{-1} 0.28 M^{-1}. From K 0.083 M^{-1}, k_{PIH^+} 340 $s^{-1}M^{-1}$.

Kinetic runs were made with piperidine and DABCO in large excess of MDNB. Under these conditions, k_{f1} is given by Eq. 13.

$$k_{f1} = \frac{k_1[Pi](k_{PI}[Pi]+k_{DABCO}[DABCO])}{k_{-1}+k_{PI}[Pi]+k_{DABCO}[DABCO]}, \tag{13}$$

where k_{DABCO} is the rate constant for deprotonation of ZH by DABCO. As shown in Table 2, k_{f1} increases with DABCO concentration. The intermediate formation is catalyzed by DABCO. At a given concentration of DABCO, k_{DABCO}/k_{-1} can be calculated from Eq. 13 using k_{PI}/k_{-1} 0.28 M^{-1} and k_1 100 $s^{-1}M^{-1}$. The mean value of k_{DABCO}/k_{-1} obtained was 0.067 M^{-1}.

Kinetics were studied in the presence of both piperidine and piperidine hydrochloride in large excess of MDNB. Under these pseudo-first-order conditions, both forward and reverse reactions are pseudo-first-order and so observed rate constant k_{obsd} is the sum

Table 3. Rate date in the presence of piperidine and piperidine hydrochloride in large excess of MDNB at 25 °C[a)]

of the forward and reverse component.

$$MDNB \underset{k_{r1}}{\overset{k_{f1}}{\rightleftharpoons}} Z^{-1} \quad (14)$$

$$k_{obsd} = k_{f1} + k_{r1} \quad (15)$$

Making use of the steady-state approximation with respect to ZH, k_{obsd} is given by Eq. 16.

$$k_{obsd} = \frac{k_1[Pi]k_{Pi}[Pi] + k_{-1}k_{PiH^+}[PiH^+]}{k_{-1} + k_{Pi}[Pi]} \quad (16)$$

Rate date are presented in Table 3. k_{calcd} was calculated from Eq. 16 using k_1 100 $s^{-1}M^{-1}$, k_{PiH^+} 340 $s^{-1}M^{-1}$ and k_{Pi}/k_{-1} 0.28 M^{-1}.

In some cases, kinetic date were obtained in the presence of tetrapropylammonium iodide or water and are presented in Tables 2 and 3.

Rate and equilibrium constants are summarized in Table 4.

Discussion

Intermediate Complex. The similarity of the spectrum a in Fig. 1 to c of the Meisemheimer complex of similar structure affords an evidence for the formation of the intermediate complex.

NMR spectroscopy failed to detect an evidence for intermediate formation. Owing to its insufficient stability (K 0.045 M^{-1} at 30 °C), the intermediate is too small in concentration to be detected by NMR.

Plots of $[MDNB]_0$ A_{545}^{-1} *vs.* $[Pi]^{-2}$ give straight lines. This indicate that the intermediate exists predominantly as its conjugate base rather than the zwitterionic form.

Rate Limiting Proton Transfer. The most striking feature in the formation of the intermediate is that the deprotonation of ZH is rate limiting in the forward direction. The intermediate formation is base catalyzed.

Our results are k_1 100 $s^{-1}M^{-1}$ and k_{Pi}/k_{-1} 0.28 M^{-1}. As the intercept of a plot of k_{f2}^{-1} *vs.* $[Pi]^{-1}$ is small, the value of k_1 obtained from the inversion of the intercept may have high uncertainity. Using our results, under [Pi] 0.06, 0.12, and 0.24 M, $k_{Pi}[Pi]$ are 0.017 k_{-1}, 0.034 k_{-1}, and 0.068 k_{-1}, respectively. These mean that under high piperidine concentrations a process from ZH to Z^- is not negligible. Thus, the depature from constant values of $k_{f1}/[Pi]^2$ under high piperidine concentrations in Table 2 will be appropriately explained by use of our results. As shown in Table 3, k_{calcd} values are in accordance with observed rate constants.

Bunnett *et al.* demonstrated that proton transfer is rapid and so not rate limiting in the formation of the intermediate complex from 1-ethoxy-2,4-dinitronaphthalene and piperidine in DMSO.[2)] The intermediate ZH of MDNB has two nitro groups which will prevent for piperidine to attack on ZH. The steric circumstance of the intermediate of 1-ethoxy-2,4-dinitronaphthalene is different from that of ZH. The difference of the steric circumstance will cause the difference of a rate limiting process.

Effect of Salt and Water. Rates are unaffected by the presence of tetrapropylammonium iodide (0.01 M). Furthermore, rates remain almost constant in the presence of water (0.22 M).

We are grateful to Mrs. H. Yasuhara and Dr. K. Kabuto for obtaining NMR spectra and their helpful discussions.

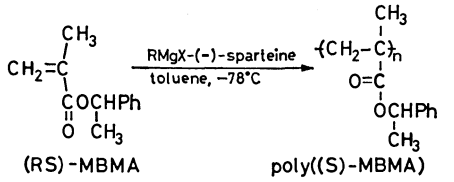
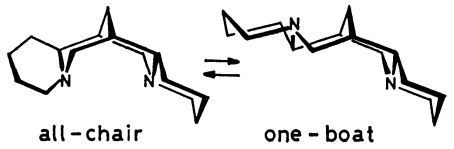
(Received September 18, 1982)

The molecular structure of EtMgBr-(−)-sparteine, which initiates asymmetric (enantiomer) selective polymerization of racemic methacrylates, has been determined by means of X-ray diffraction. The crystal is orthorhombic, space group $P2_12_12_1$, $a=11.278(2)$, $b=14.112(3)$, $c=11.746(2)$ Å, $Z=4$. The structure was established by the heavy atom method and refined by the block-diagonal least-squares procedure: $R=0.100$ for 1272 non-zero reflections. The Mg atom is tetrahedrally coordinated by the Et group, Br and two N atoms of the (−)-sparteine.

Recently, Okamoto, Yuki, and their co-workers have studied the asymmetric-selective (enantiomer selective) polymerization of racemic methacrylates, especially that of the (*RS*)-α-methylbenzyl methacrylate ((*RS*)-MBMA).[1-5]



In this reaction, in toluene at −78 °C, the (*S*)-monomer polymerizes preferentially over the (*R*)-monomer by the presence of a complex between a primary or secondary Grignard reagent and a chiral bidentate ligand, (−)-sparteine†††† or its derivative. The activity and selectivity of the catalysts were discussed[6] on the basis of the molecular structures determined by means of X-ray diffraction. This study deals with the molecular structure of the EtMgBr-(−)-sparteine complex which has a high catalytic activity on the asymmetric-selective polymerization of the MBMA. Interests on the structure and the reactivity of the present complex and also on the conformation of the (−)-sparteine ligand, either one-boat or all-chair form, promoted this study.



Experimental

Crystals used were obtained from a toluene solution. A crystal with approximate dimensions of $0.50\times0.50\times0.38$ mm, sealed in a thin-walled glass capillary tube under nitrogen atmosphere, was mounted on a Rigaku automated, four-circle X-ray diffractometer. The unit-cell dimensions were precisely determined by the least-squares fit using 2θ values of 25 strong reflections.

Crystal Data. $C_{17}H_{31}N_2MgBr$, M 367.7, orthorhombic space group $P2_12_12_1$, $a=11.278(2)$, $b=14.112(3)$, $c=11.746(2)$ Å, $V=1869.5(5)$ Å^3, $D_C=1.306$ g cm^{-3} for $Z=4$, μ(Mo $K\alpha$) = 23.62 cm^{-1}.

Reflection intensities were measured on the diffractometer with Zr-filtered Mo $K\alpha$ radiation by the θ-2θ scan technique ($2\theta\leqq50.5°$). The 2θ scan rate was 4° min^{-1} and the scan width $\Delta2\theta=(2.0+0.7\tan\theta)°$ Backgrounds were counted for 7.5 s at both ends of a scan. Four standard reflections measured after every 27 reflections showed less than 3% intensity fluctuations during the data collection. However the peak profiles of reflections were not so sharp, reflection intensities were rather low, and high order reflections were scarcely observed to have non-zero intensity. Of the 1937 reflections measured only 1272 had non-zero intensities. Usual Lorentz and polarization corrections were applied but absorption and extinction corrections were ignored.

Structure Solution and Refinement

The heavy atom method was applied to solve the structure. The position of the Br atom was determined from the three-dimensional Patterson function. The Mg, N, and C atoms except the C(16) were located by the subsequent Fourier synthesis. The structure was refined isotropically by the block-diagonal least-squares procedure (*HBLS* V).[7] The remaining C(16) atom could be located on the difference Fourier synthesis. Further refinement was carried out anisotropically for non-hydrogen atoms except for the C(10), C(16), and C(17) atoms, because thermal parameters of these atoms could not be refined anisotropically. Hydrogen atoms could not be located on the difference Fourier synthesis. At the final stage of the refinement the anomalous dispersion of the Br and Mg atoms[8] was considered; the R value became 0.100 for non-zero reflections ($R_w=0.103$). The final atomic positional parameters and equivalent[9] (or isotropic) tem-

Results and Discussion

Molecular Structure. A perspective view (*ORTEP II*)[11] of the EtMgBr-(−)-sparteine complex with the numbering scheme of atoms is presented in Fig. 1. Selected bond lengths and bond angles are listed in Fig.2.

The Mg atom is tetrahedrally coordinated by the two N atoms of the (−)-sparteine, the C atom of the Et group, and the Br atom. The N(1)–Mg–N(2) angle [84.0(8)°] is equal to that observed in EtMgBr-(−)-α-isosparteine[12] but is smaller than the corresponding angles in dichloro[(−)-sparteine] cobalt(II) [90.4(3)°],[13] dichloro[(−)-α-isosparteine] cobalt(II) [89.0(2)°],[14] and dichloro[β-isosparteine] copper(II) [90.6(2)°].[15] This can be attributed to the fact that two N atoms of the (−)-sparteine ligand are spatially fixed, and hence the longer the coordination bonds between N atoms and the central metal atom((Mg–N)$_{av}$=2.15††††††, (Co–N)$_{av}$=2.05[13], Co–N=2.07[14], and

†††††† Present study.

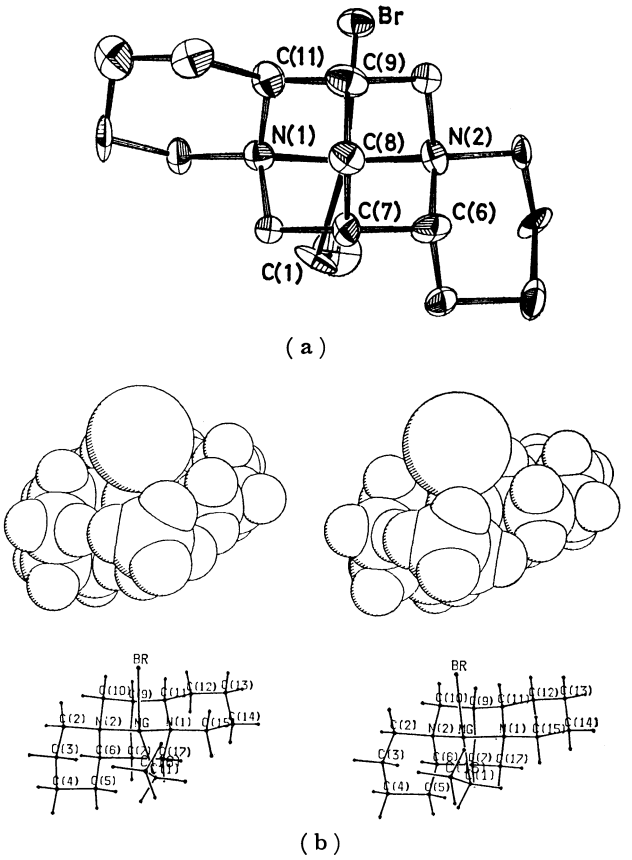

Fig. 3. (a) Molecular structure projected down along the bisector of the N(1)–Mg–N(2) angle. Non-hydrogen atoms are drawn as thermal ellipsoids with 20% probability level.[11] (b) Space-filling model of the molecule viewed up along the bisector.[17]

$(Cu–N)_{av}=1.99$[15]) is the smaller the N–Metal–N angle is expected to be. The C(1)–Mg–Br angle [115.1(8)°] in the present complex is slightly larger than the tetrahedral angle. The N(2)–Mg–C(1) [129.6(10)°] and N(2)–Mg–Br [103.4(7)°] angles largely deviated from the tetrahedral angle, whereas the N(1)–Mg–C(1) [111.4(10)°] and N(1)–Mg–Br [108.3(6)°] angles are similar to it.

Of the two possible conformations, the (−)-sparteine ligand takes the all-chair form. In addition to the bulky Br and ethyl group of the EtMgBr, the coordination of the (−)-sparteine to the Mg atom makes the space small around the N(1) atom but not the neighborhood of the N(2) as can be seen in Fig. 3. This fact may favor the selective coordination of the (*S*)-monomer to the Mg atom of the EtMgBr–(−)-sparteine at the initial stage of polymerization of the methacrylate, which is favorable to the subsequent (*S*)-monomer selection.

Crystal Structure. The packing of EtMgBr–(−)-sparteine molecules in a unit-cell is shown in Fig. 4. The dimeric association of molecules, observed in the crystal structures of Grignard reagents, $[EtMgBr, Et_3N]_2$[17] and $[EtMgBr, (i\text{-}Pr)_2O]_2$[18] is not observed. The closest intermolecular atomic contact is C(17) $(x, y, z)\cdots Br(-x, -1/2+y, 1/2-z)$ (3.62(3) Å).

A part of the cost of this study was defrayed by the Grant-in-Aid (No. 434024) for Scientific Research from the Ministry of Education, Science and Culture.

Polarizability and Electrocapillary Measurements of the Nitrobenzene-Water Interface

Takashi KAKIUCHI and Mitsugi SENDA*

Department of Agricultural Chemistry, Faculty of Agriculture, Kyoto University, Sakyo-ku, Kyoto 606

(Received September 27, 1982)

Electrocapillary curves have been measured of the interface between nitrobenzene solution of tetrabutylammonium tetraphenylborate and aqueous solution of lithium chloride using a dropping electrolyte solution electrode under the precise control of the electrical potential difference and of the ion transfer current across the interface. The nitrobenzene-water interface could be electrically polarized over the voltage span of 300 mV. The residual current was explained as due to both the transfer of tetrabutylammonium ion and tetraphenylborate ion through the interface and the charging current at the interface. The electrocapillary curve was parabolic in shape. The surface charge *vs.* potential curve derived from the electrocapillary curve agreed with that obtained from the differential capacity *vs.* potential curve of the interface. The results indicate that the interface can virtually be treated as an ideal polarized interface over a certain potential range.

This paper describes the measurements of electrocapillary curves at the polarizable interface between aqueous solution of lithium chloride and nitrobenzene solution of tetrabutylammonium tetraphenylborate by the drop time method using a dropping electrolyte solution electrode. Guastalla[1] was the first to show that an electric field across the interface between two immiscible solutions containing ions and ionic surfactants produces changes in the interfacial tension and he called his finding "electroadsorption." Since then, such phenomena have been studied mainly by Blank and Feig,[2] Blank,[3] Watanabe *et al.*,[4,5] Dupeyrat and Michel,[6] Gavach *et al.*,[7-10] Joos,[11,12] and Dupeyrat and Nakache.[13] Watanabe considered it to be electrocapillarity, while Blank and Feig and also Dupeyrat and Nakache made a distinction between electroadsorption and electrocapillarity. In most of these works, except the recent ones by Gavach *et al*,[9,10] however, the electrical potential and the current across the interface were neither controlled nor measured precisely enough to define the electrical state of the interface.

Recently, polarizability of the interface between two immiscible electrolyte solutions has been discussed on the basis of the transfer free energies of ions from one solvent to the other by Koryta *et al.*,[14] who have showed that one can endow the liquid–liquid interface with electrical polarization in a certain range of the potential difference across the interface by choosing suitable ions to be dissolved in the two phases, *e.g.*, lithium chloride in water and tetrabutylammonium tetraphenylborate (TBATPB) in nitrobenzene. Such polarizable interfaces have been extensively used in electrochemical studies[15,16] of ion transfer and electron transfer at the interface.

An interface of two immiscible electrolyte solutions, which behaves practically as an ideal polarized interface, if realized, can be a subject of rigorous thermodynamic theory of an ideal polarized interface and, hence, the electric double layer structure of the interface can be elucidated on the basis of electrocapillary measurements. The purpose of this study is to demonstrate experimentally the existence of such polarized interfaces where there is only negligible ion transfer current through the interface and to establish an experimental method for electrocapillary measurements under the precise control of the potential difference across the interface.

Experimental

A dropping electrolyte solution electrode[14] (DESE) was used to record current-potential curves and to determine electrocapillary curves at a polarized nitrobenzene-water interface. Figure 1 shows the cell configuration used in this study. An aqueous solution, 1, was dropped upward into a nitrobenzene solution, 2, from the tip of a poly(tetrafluoro-

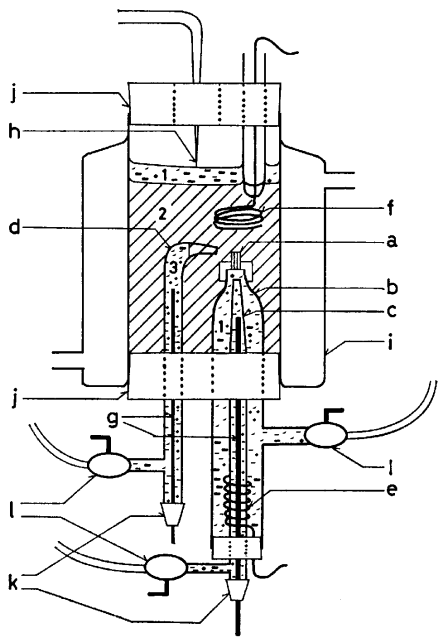

Fig. 1. Electrochemical cell with dropping electrolyte solution electrode for measuring current-potential curves and electrocapillary curves at nitrobenzene-water interface.

ethylene) (PTFE) capillary, a, whose inner diameter and length were 0.5 and 4 mm, respectively. The PTFE capillary was fitted on the top opening of a glass tube, b. By using a PTFE capillary, which neither water nor nitrobenzene wets the surface of, very reproducible drop time was achieved. The cell had four electrodes, *i.e.*, two reference electrodes (c and d) and two auxiliary electrodes(e and f) to meet with a four-electrode potentiostat[17,18] for precise control of the potential drop across the interface. The reference electrodes were Ag/AgCl electrodes, g, immersed in 0.1 mol dm^{-3} LiCl aqueous solution, 1, and in 0.1 mol dm^{-3} tetrabutylammonium chloride (TBACl) aqueous solution, 3. Luggin capillaries sensed the potential of the aqueous and nitrobenzene phases, respectively, in close proximity to the DESE. The auxiliary electrodes were coiled platinum wires. A fine glass capillary, h, was connected to an aspirator to suck off excess aqueous solution flowing out of the DESE, so that the hydrostatic pressure above the tip of the DESE was kept constant during each measurement. The cell assembly was mounted on a heavy molding board which was placed on four cushions made of rubber damper plates and soft rubber balls. This table effectively eliminated most of ambient vibration and resulted in good reproducibility of the drop time of the DESE. The cell was water-jacketed (i in Fig. 1) to maintain the temperature of the cell at 25.00±0.05 °C.

The DESE was connected to an electrolyte solution reservoir of a 200 ml seperatory funnel through a PTFE tubing of 2 mm inner diameter. In the middle of this PTFE tubing a PTFE capillary of 0.25 mm inner diameter and 6 m length was inserted to regulate the flow rate of aqueous electrolyte solution. The flow rate, v, was typically 3×10^{-4} cm^3 s^{-1} when the height of the solution reservoir, H, was 75 cm. The PTFE capillary regulator was immersed in a water bath controlled at 25.00±0.05 °C to regulate precisely the flow resistance, $\alpha=v/H$, of the PTFE capillary regulator. The flow rate was determined to the precision of 0.01×10^{-4} cm^3 s^{-1} using a 1 ml serological pipet and the α-value of the DESE was determined to be 4.63×10^{-6} cm^2 s^{-1} for 0.1 mol dm^{-3} LiCl at 25.00±0.05 °C.

For converting the drop time, t_d, to the interfacial tension, γ, we used the following two equations,[19,20] which have been derived by assuming a spherical drop:

$$\frac{\alpha t_d}{3} = \sigma^3 \ln\left(\frac{x_0(1-x)}{x(1-x_0)}\right) + \sigma^2\left(\frac{1}{x}-\frac{1}{x_0}\right) + \frac{\sigma}{2}\left(\frac{1}{x^2}-\frac{1}{x_0^2}\right) + \frac{1}{3}\left(\frac{1}{x^3}-\frac{1}{x_0^3}\right) \quad (1)$$

$$\Delta\rho g/x^3 = 2\pi r\gamma[1-r(4\pi/3)^{1/3}x] \quad (2)$$

with $\sigma=2\gamma(4\pi/3)^{1/3}/P$, $x=(3/4\pi)^{1/3}/R$ and $x_0=(3/2\pi)^{1/3}/r$, where R is the radius of a drop, r the radius of the orifice of the DESE tip, P the effective hydrostatic pressure, $\Delta\rho$ the difference between the densities of the nitrobenzene and the aqueous solution phases, and g is the accelaration of gravity. By solving these two simultaneous equations numerically, we obtain γ as a function of t_d for given values of α, r, P, and $\Delta\rho$. The density of the aqueous solution and nitrobenzene solution was determined using a Lipkin-Davison pycnometer. The r value was calibrated as 0.240 mm by using mutually saturated nitrobenzene and water at 25.0 °C, the value of 25.1 mN m^{-1} being used for the interfacial tension.[21] The drop time, typically 50 s at $H=75$ cm, was measured to the precision of 0.01 s with an electronic stopwatch. The relative standard deviation of the drop time of the DESE was 0.2% for several consecutive drops.

Since the potential difference across the interface was controlled with respect to the two reference electrodes, the electrochemical cell studied can be represented by

$$\begin{array}{ccccccc} \text{I} & \text{II} & & \text{III} & & & \\ \text{Ag} & \text{AgCl} & \text{0.1 mol dm}^{-3}\ \text{TBACl} & & & & \\ & & \text{(water)} & & & & \\ & & \text{IV} & & & & \\ & & \text{0.1 mol dm}^{-3}\ \text{TBATPB} & & & & \\ & & \text{(nitrobenzene)} & & & & \\ & & \text{V} & & \text{VI} & \text{VII} & \\ & & \text{0.1 mol dm}^{-3}\ \text{LiCl} & & \text{AgCl} & \text{Ag.} & \\ & & \text{(water)} & & & & \end{array} \quad (A)$$

The interface between the phases III and IV is a non-polarizable one and the potential drop across the interface is determined by the activities of TBA^+ ion in the two phases.[18,22,23] Therefore, the left-hand-side half cell, Ag/AgCl/III(W)/IV(NB), virtually functions as a reference electrode reversible to TBA^+ ion in the nitrobenzene phase IV. The interface III/IV was made just inside the Luggin capillary in nitrobenzene phase. The right-hand-side half cell V(W)/AgCl/Ag is reversible to Cl^- ion in the phase V. The potential applied to the cell(A), $E=E^{W-}_{O+}$, is defined by the potential of the right-hand-side reference electrode, E_{right}, with respect to that of the left, E_{left}; $E^{W-}_{O+}=E_{right}-E_{left}$, where the superscript W− and subscript O+ indicate that the reference electrodes in aqueous and nitrobenzene phases are reversible to an anion and a cation, respectively.

When one applies a potential difference across the interface between the phases IV and V by using the four electrode potentiostat, the uncompensated solution resistance between the tips of the two Luggin capillaries mostly resides in the solution thread in the PTFE capillary tip of the DESE, whose resistance was calculated to be 21 kΩ for 0.1 mol dm^{-3} LiCl at 25 °C. Since the residual current flowing through the interface was usually less than 0.2 μA in the polarization potential range (see Fig. 2 below), the iR drop across the uncompensated solution resistance should be less than 4 mV. The error in the potential control due to this iR drop was further minimized to less than 0.1 mV by using the positive feedback circuit equipped in the four-electrode potentiostat.[18]

Lithium chloride monohydrate(a Merk's spurapur grade product) was dissolved into twice distilled water to prepare the stock solution of LiCl. The concentration of LiCl was determined by potentiometric titration with a standard silver nitrate solution. A 0.1 mol dm^{-3} LiCl aqueous solution was prepared from this stock solution. TBATPB was prepared as described previously.[24] TBACl was first recrystallized from aceton–ether mixture. Then, trace impurities of iodide ion were removed from aqueous TBACl solution by metathesis with silver chloride. Nitrobenzene was distilled under reduced pressure and the middle 60% of the distillate was collected and shaken with active alumina overnight. The last treatment was important to reduce the residual current to a low level. After filtration, nitrobenzene was washed and equilibrated with twice distilled water at 25 °C. Nitrobenzene solution of TBATPB was prepared in dark immediately before use.

Results and Discussion

Current-potential Curve. Figure 2 shows a current-potential curve (d.c.polarogram) obtained with the DESE in the dark for the interface between 0.1 mol dm^{-3} LiCl aqueous solution and 0.1 mol dm^{-3} TBATPB

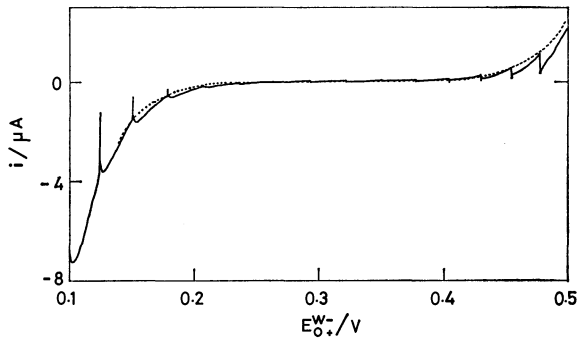

Fig. 2. Current-potential curve for the interface between 0.1 mol dm^{-3} LiCl aqueous solution and 0.1 mol dm^{-3} TBATPB nitrobenzene solution at 25 °C. (——): Experimental. The potential was scanned from 0.1 to 0.5 V with the scan rate of 0.5 mV s^{-1}. (----): calculated by Eq. 3.

nitrobenzene solution. The transfer of a positive charge from the aqueous to the nitrobenzene phase was taken as the positive direction of the current. This polarogram indicates that the current across the interface is negligible except for a trace residual current (less than 0.6 μA cm^{-2}) in the potential range between 0.22 and 0.42 V and that the interface can be polarized over a voltage span of almost 300 mV.

The standard ion transfer potentials of j ion across the water(W)–nitrobenzene(NB) interface, $\Delta^{W}_{NB}\phi^{0}_{j}$, are −0.248, 0.395, 0.372, and −0.324[25,26] for j=TBA$^+$, Li$^+$, TPB$^-$, and Cl$^-$, respectively. Since $\Delta^{W}_{NB}\phi^{0}_{TBA}$ is less negative than $\Delta^{W}_{NB}\phi^{0}_{Cl}$ and $\Delta^{W}_{NB}\phi^{0}_{TPB}$ is less positive than $\Delta^{W}_{NB}\phi^{0}_{Li}$, TBA$^+$ and TPB$^-$ ions are most easily transferable through the interface among the four ions. Accordingly, the "residual" current in the polarization potential range should be attributed to the transfer of TBA$^+$ or TPB$^-$ ion or both. Then the current increase in the positive direction at the positive extreme of the applied potential in Fig. 2 should be mainly due to the transfer of TPB$^-$ ion and the current increase in the negative direction at the negative extreme to that of TBA$^+$ ion from the nitrobenzene to the aqueous phase. The transfer of Li$^+$ and Cl$^-$ ions may be negligible compared with that of TBA$^+$ and TPB$^-$ ions in the potential range considered. It can be shown that the current-potential relationship for the transfer of TBA$^+$ and TPB$^-$ ions from the nitrobenzene to the aqueous phase, where LiCl serves as the supporting electrolyte for the mass transfer of TBA$^+$ and TPB$^-$ ions in the aqueous phase, can be expressed, in analogy to the electrolytic current at a dropping mercury electrode in the absence of supporting electrolyte,[27,28] by

$$i = 4.168Fv^{2/3}t_d^{1/6}c_sA \tag{3}$$

with

$$A = \frac{(D^{W}_{TPB})^{1/2}/q-(D^{W}_{TBA})^{1/2}/p}{1+\frac{(1-t^{NB}_{TBA})}{p}\left(\frac{D^{W}_{TBA}}{D^{NB}_{s}}\right)^{1/2}+\frac{t^{NB}_{TBA}}{q}\left(\frac{D^{W}_{TPB}}{D^{NB}_{s}}\right)^{1/2}},$$

where i is the current, v the flow rate of an aqueous solution, c_s the concentration of TBATPB in the nitrobenzene phase, t_d the drop time, t^{NB}_{TBA} the transport number of TBA$^+$ ion in the nitrobenzene phase, D_j the diffusion coefficient of j ion (j=TBA$^+$ or TPB$^-$) in the aqueous(W) and nitrobenzene(NB) phases, and p, q and D^{NB}_{s} are given by

$$p = \exp\left[\frac{F}{RT}(\Delta\phi-\Delta^{W}_{NB}\phi^{0}_{TBA})\right]$$

$$q = \exp\left[-\frac{F}{RT}(\Delta\phi-\Delta^{W}_{NB}\phi^{0}_{TPB})\right]$$

and

$$D^{NB}_{s} = \frac{2D^{NB}_{TBA}D^{NB}_{TPB}}{D^{NB}_{TBA}+D^{NB}_{TPB}},$$

where F, R, and T are used in the usual meaning. $\Delta\phi$ is the potential difference across the interface and is related to the applied potential by

$$E = E^{W-}_{O+} = \Delta\phi + E_{ref} \tag{4}$$

where E_{ref} is the constant which depends only on the reference electrode system. In deriving Eq. 3 we assumed that the surface concentrations of TBA$^+$ and TPB$^-$ ions in the two phases, $c^{W,0}_{TBA}$, $c^{NB,0}_{TBA}$, $c^{W,0}_{TPB}$, and $c^{NB,0}_{TPB}$ are related by Nernst equations:

$$\Delta\phi = \Delta^{W}_{NB}\phi^{0}_{TBA} + \frac{RT}{F}\ln\frac{c^{NB,0}_{TBA}}{c^{W,0}_{TBA}}$$

and

$$\Delta\phi = -\Delta^{W}_{NB}\phi^{0}_{TPB} - \frac{RT}{F}\ln\frac{c^{NB,0}_{TPB}}{c^{W,0}_{TPB}}$$

and that the transfer of Li$^+$ and Cl$^-$ ions across the interface is negligibly small compared with that of TBA$^+$ and TPB$^-$.

In Fig. 2 the dashed line is a theoretical polarogram which was calculated from Eq. 3 with c_s=0.1 mol dm^{-3}, t_d=50 s, v=0.00036 cm^3 s^{-1}, $D^{W}_{TBA}=D^{W}_{TPB}=5.1\times10^{-6}$ cm^2 s^{-1}, $D^{NB}_{TBA}=D^{NB}_{TPB}=2.6\times10^{-6}$ cm^2 s^{-1},[17] and E_{ref}=0.25 V. For the sake of simplicity, the diffusion potential which may exist in the vicinity of the interface was not taken into account. Agreement between the experimental curve and the theoretical one is good, indicating that the "residual" current in the polarization potential range is largely due to the transfer across the interface of the most easily transferable ions in the two phases.

From Eq. 3 we can expect that the ion transfer current becomes zero at

$$E_{i=0} = \frac{RT}{2F}\ln(D^{W}_{TBA}/D^{W}_{TPB})^{1/2} + \frac{1}{2}(\Delta^{W}_{NB}\phi^{0}_{TBA}+\Delta^{W}_{NB}\phi^{0}_{TPB}) + E_{ref}. \tag{5}$$

In the present case $E_{i=0}$ was calculated to be 0.32 V when E_{ref}=0.25 V. Thus the residual current at and in the vicinity of this potential is due to the charging current of the polarized nitrobenzene–water interface. Figure 3 shows a representative current-time curve at E=0.31 V. The current increases suddenly at the moment of a drop's birth(indicated by an arrow in Fig. 3), then decays subsequently with time. This behavior is quite similar to that of the charging current usually observed at an ideal polarized dropping mercury electrode. Since E=0.31 V is 45 mV more positive than the potential of zero charge of the interface (see below), a positive-going current is observed at

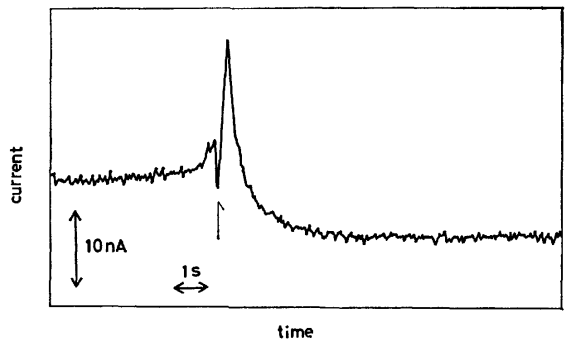

Fig. 3. Current *vs.* time curve at 0.31 V for the interface between 0.1 mol dm^{-3} LiCl aqueous solution and 0.1 mol dm^{-3} TBATPB nitrobenzene solution. The arrow indicates the instant of a drop's birth.

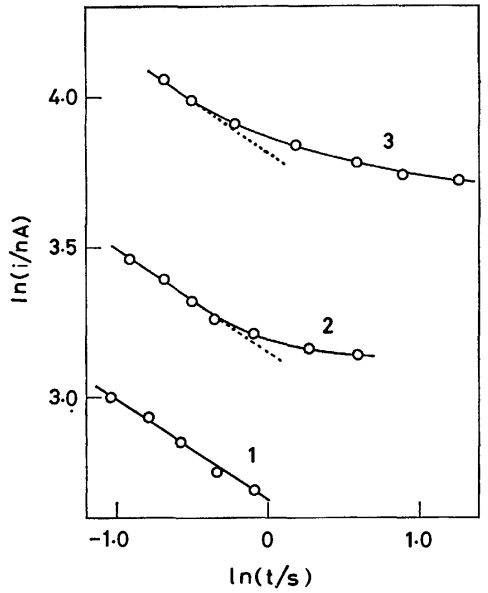

Fig. 4. log i *vs.* log t plot at 0.310(1), 0.330(2), and 0.370 V(3). Dashed lines by the curves are drawn to indicate the slope of $-1/3$.

this potential. As the drop grows and approaches to its maximum stage the residual current increases to an appreciable value, which may be attributable to residual impurities. The decaying part of the current in the current-time curves recorded at three different applied potentials are plotted in logarithmic scales in Fig. 4. At E=0.31 V the plot gives a straight line with the slope of $-1/3$, which is equal to the theoretical value for the charging current.[29] As the applied potential shifts to more positive value the slope of log i *vs.* log t curves deviates from $-1/3$ at large t, indicating that the contribution of ion transfer current (here the transfer of TPB^- ion) becomes appreciable with the increase of the applied potential.

Electrocapillary Curve. Figure 5 shows an electrocapillary curve for the interface between 0.1 mol dm^{-3} TBATPB nitrobenzene solution and 0.1 mol dm^{-3} LiCl aqueous solution. The vertical bars on the curve indicate the standard deviation for the thrice-repeated measurements. The pooled standard deviation was 0.16 mN m^{-1} in the potential range between 0.2 and 0.4 V.

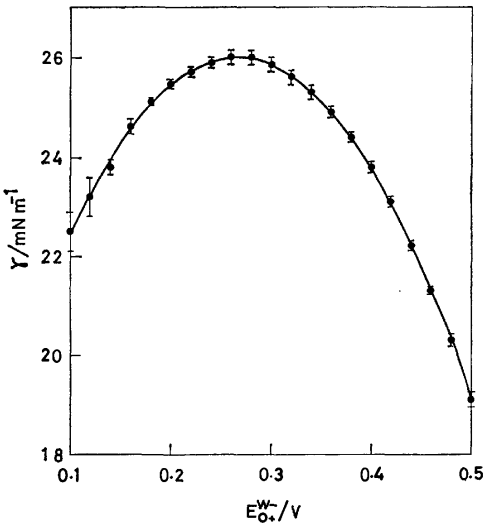

Fig. 5. Electrocapillary curve for the interface between 0.1 mol dm^{-3} LiCl aqueous solution and 0.1 mol dm^{-3} TBATPB nitrobenzene solution at 25 °C. Vertical bars indicate the standard deviation for triplicate measurements.

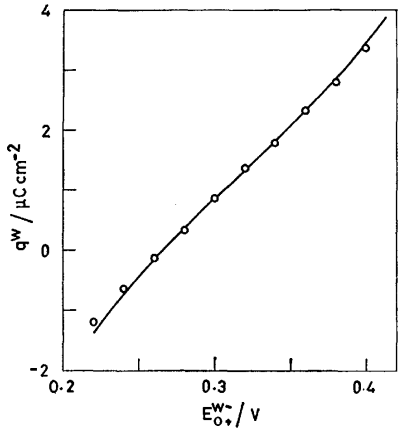

Fig. 6. Comparison of surface charge densities in aqueous solution side obtained from the differentiation of the electrocapillary curve (○) and from the integration of differential capacity curve (—) for the interface between 0.1 mol dm^{-3} LiCl aqueous solution and 0.1 mol dm^{-3} TBATPB nitrobenzene solution.

Thermodynamic theory of ideal polarized interface between two immiscible[30] or partially miscible[31] electrolyte solutions gives

$$-\left(\frac{\partial\gamma}{\partial E^{W-}_{O+}}\right)_{T,P,\mu} = q^W = -q^{NB}$$
$$= F(\Gamma^W_{Li}-\Gamma^W_{Cl}) = F(\Gamma^{NB}_{TPB}-\Gamma^{NB}_{TBA})$$

and

$$-\left(\frac{\partial^2\gamma}{\partial E^{W-2}_{O+}}\right)_{T,P,\mu} = \left(\frac{\partial q^W}{\partial E^{W-}_{O+}}\right)_{T,P,\mu} = C_d,$$

where q^W and q^{NB} are the surface charge densities in the aqueous and the nitrobenzene solution side, respectively, Γ^α_j the surface concentration of j ion in the aqueous(α=W) or the nitrobenzene(α=NB) solution side, C_d the differential capacity of the interface.

The electrocapillary curve was numerically differentiated using the moving quadratic fitting method.[32] The resultant q^{W} *vs.* E^{W}_{O+} curve is shown in Fig. 6, giving the potential of the electrocapillary maximum or the potential of zero charge, $E_{pzc}=0.265$ V. Also plotted in Fig. 6 are the surface charge density data calculated from the differential capacity *vs.* potential curve obtained for the same interface using an a.c. polarographic method.[33] Agreement between the two results is excellent. These results indicate that the interface virtually behaves as an ideal polarized interface.

The present study experimentally demonstrates that the interface between two immiscible electrolyte solutions can be electrically polarized in a certain potential range by choosing suitable electrolytes in the two phases. The residual current can be explained as due to the minute ion transfer across the interface of the most easily transferable ion or ions present in the two phases as well as the charging current of the interface. The present study also shows that the thermodynamic theory of ideal polarized interface can be applied to the interface for elucidating its equilibrium properties in a certain potential range, that is, the potential range where disturbance in the double layer structure caused by the transfer of ion or ions across the interface appears to be not appreciable. Subsequent papers will describe some detailed structure of the electrical double layer at the nitrobenzene–water interface that has been elucidated on the basis of electrocapillarity measurements.

(Received September 27, 1982)

The polarized Raman and infrared spectra of tetramethyl- and 2,6-dimethylpyrazines were studied. Relative intensities of the non-totally symmetric Raman bands for the tetramethylpyrazine crystal were calculated assuming the oriented gas model. Assignments of the fundamental vibrations for tetramethyl- and 2,6-dimethylpyrazines were made through the expected and observed polarization behaviors of the Raman and infrared bands and also through the normal coordinate calculation.

Although the Raman and infrared spectra of pyrazine were studied by many workers,[1-7] only a few investigations were made on the vibrational spectra of methyl-substituted pyrazines. Oertel and Myhre[8] and Bus *et al.*[9] discussed qualitative frequency shifts of the Raman and infrared bands caused by methyl substitution. Watanabe *et al.*[10] studied very recently the normal vibrations of 2-methylpyrazine based on the polarization behaviors of the Raman and infrared bands and on the normal coordinate calculation. Niimori *et al.*,[11] Lim *et al.*,[12] and Hirota *et al.*[13] investigated the natures of the lowest triplet states of tetramethyl- and 2,6-dimethylpyrazines through the kinetic and vibrational analyses of the phosphorescence emissions. They made tentative assignments of the normal vibrations without studies of the vibrational spectra.

In this work, the Raman and infrared spectra of tetramethyl- and 2,6-dimethylpyrazines were investigated and assignments of the normal vibrations were made.

Experimental

Material. The samples, tetramethyl- and 2,6-dimethylpyrazines, obtained from Aldrich Chemical Co. were purified by zone-refining of about 100 passages followed by sublimation under reduced pressure.

Optical Measurement. The polarization behavior of the Raman spectrum was observed in molten and single crystal phases with a JEOL 400 T Laser Raman Spectrophotometer. The sample was excited with the 514.5 nm line from an Ar^+ ion laser. A well-grown single crystal of tetramethylpyrazine obtained by the Bridgman method was cut along the cleavage ab plane, and the a and b crystal axes were determined by observation of the birefringence. Then the crystal was cut along the ac and bc planes and a cubic sample of about $(7\text{ mm})^3$ was obtained. As tetramethylpyrazine sublimates very quickly, Canada balsam was spread over the whole surface of the crystal sample. The method of measurement of the polarized Raman spectrum was exactly the same as that described previously.[14] Since the crystal structure of 2,6-dimethylpyrazine has not been studied yet and the crystal melts by irradiation of the laser beam at room temperature, the polarized Raman spectrum was measured in the following way. The signle crystal grown in a glass tube of about 3 mm in diameter by the Bridgman method was held in a capillary cell system of JEOL Model RS-VTC 41 in such a way that the direction of the crystal growth orients parallel to the polarization direction of the excitation laser beam. The temperature of the cell was kept at 0 °C. The Raman scattering was observed at right angles with the excitation light beam. The Raman spectrum polarized parallel to the crystal growth direction is referred to as // spectrum and the spectrum polarized perpendicular to as $\perp$ spectrum. The polarized Raman spectrum was measured for two crystal orientations. In the first orientation a sharp band at 1534 cm^{-1}, which is strong and depolarized in molten phase, appears strongly in the // spectrum and in the second orientation the 1534 cm^{-1} band appears strongly in the $\perp$ spectrum.

The infrared spectrum was observed in single crystal, liquid, vapor, and CCl_4 or CS_2 solution with a Hitachi Infrared Spectrophotometer Model 345 over the range of 4000 to 200 cm^{-1}. The single crystal was prepared in the following way. The sample was melted on a KRS-5 plate and covered with another hot KRS-5 plate. Then the two plates were put on a heated brass block and allowed to cool gradually. The crystal formed between two plates was held between two sheets of polaroid films whose polarization directions were set at right angles to each other and a single crystal portion was selected. The rest portion of the crystal was masked with a sheet of black paper. The polarized infrared spectrum was measured with the incident lights polarized parallel and perpendicular to the crystal growth direction. The first spectrum is referred to as // and the second to as $\perp$ spectrum.

Normal Coordinate Calculation

A normal coordinate calculation was performed through the standard ***GF*** matrix method with a FACOM M-200 computer at the Computer Center of Kyushu University. The structural parameter of the tetramethylpyrazine molecule was taken from the data given by Braam *et al.*[15] Since the molecular structure of 2,6-dimethylpyrazine has not been studied yet, the structural parameters of the pyrazine ring and methyl group were assumed to be the same as the data given by Wheatley[16] and by Keidel and Bauer,[17] respectively.

The ***F*** matrix elements for the in-plane vibrations were evaluated with the potential field of an improved modification of the Urey-Bradley force field.[14,18] The potential field is given by

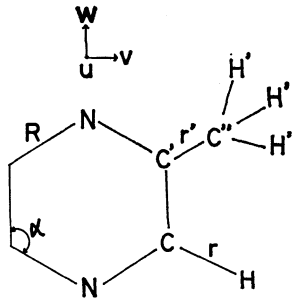

Fig. 1. Symbols for the atoms and internal coordinates.

$$V = V_{UB} + \rho[\overset{6}{\Sigma}(\Delta R,\ \Delta R)_o - \overset{6}{\Sigma}(\Delta R,\ \Delta R)_m + \overset{3}{\Sigma}(\Delta R,\ \Delta R)_p] + \Sigma k^o(\Delta r,\ \Delta r) + \Sigma k^m(\Delta r,\ \Delta r) + \Sigma h^m(\Delta R,\ \Delta\alpha) + \Sigma f^o(\Delta\alpha,\ \Delta\alpha),$$

where the symbols such as V_{UB} are the same as those used in the previous paper.[14,18] The symbols given for atoms and internal coordinates are shown in Fig. 1. For the out-of-plane vibrations the valence force field and ϕ type torsional coordinates were used. The notations of the force constants Q, q, P, p, and t are the same as those given by Whiffen.[19] In the case of the out-of-plane vibration, R and r' refer to the torsional coordinates constructing the ring and side bond, respectively. Procedure of the calculation was exactly the same as described in the previous paper.[14,18]

Calculation of Derived Polarizability Tensors

Tetramethylpyrazine crystallizes in the orthorhombic space group D_{2h}^{15} with four molecules in the unit cell, each molecule being located at the site of symmetry C_i.[15,20] The projection of the crystal structure on the ab plane is shown in Fig. 2. No factor group splitting was observed for the bands due to molecular vibrations and thus, the relationship between the derived polarizability tensors for the free molecule and crystal was derived on the basis of the simple oriented gas model. Evaluation of the matrix elements of the derived polarizability tensors of tetramethylpyrazine was made following the procedure applied for the naphthalene and anthracene crystals by Ito *et al.*[21] The derived polarizability tensor of a free molecule i with respect to the crystal-fixed coordinates is given by

$$\alpha'_{m_i}(Q_\lambda) = \boldsymbol{T}_i\, \alpha'_m(Q_\lambda)\, \tilde{\boldsymbol{T}}_i,$$
$$i = 1,2,3,4,$$

where $\alpha'_m(Q_\lambda)$ is the derived polarizability tensor of a free molecule with respect to a normal vibration Q_λ, and $\boldsymbol{T}$ the transformation matrix between the molecule-fixed u, v, w and crystal-fixed a, b, c coordinates. Using the assumption of the oriented gas model and symmetry coordinates S_{Ag}, S_{B1g}, S_{B2g}, and S_{B3g} appropriate to the four molecule unit cell, the derived polarizability tensors with respect to the unit cell vibrations are given for each symmetry species by

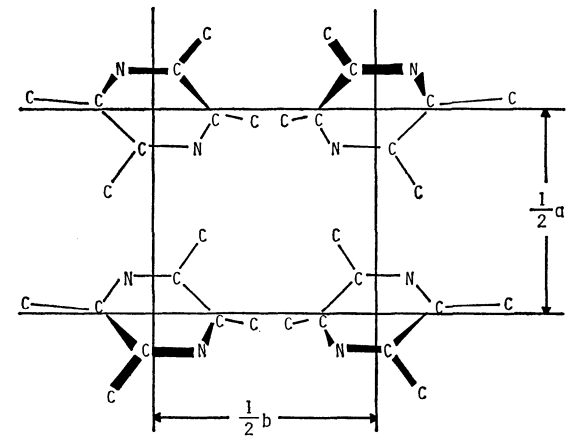

Fig. 2. Projection of the tetramethylpyrazine crystal on the ab plane.

$$\alpha'_u(S_{Ag}) = \begin{vmatrix} A_{aa} & 0 & 0 \\ 0 & A_{bb} & 0 \\ 0 & 0 & A_{cc} \end{vmatrix},$$

$$\alpha'_u(S_{B_{1g}}) = \begin{vmatrix} 0 & A_{ab} & 0 \\ A_{ba} & 0 & 0 \\ 0 & 0 & 0 \end{vmatrix},$$

$$\alpha'_u(S_{B_{2g}}) = \begin{vmatrix} 0 & 0 & A_{ac} \\ 0 & 0 & 0 \\ A_{ca} & 0 & 0 \end{vmatrix},$$

$$\alpha'_u(S_{B_{3g}}) = \begin{vmatrix} 0 & 0 & 0 \\ 0 & 0 & A_{bc} \\ 0 & A_{cb} & 0 \end{vmatrix},$$

where A's are functions of the direction cosines and the elements of the derived polarizability tensors of a free molecule.

According to the character table and selection rules for the D_{2h} molecule, we derived simple analytical expressions of A's for the vibrations belonging to different species of the molecule. These results are given in Table 1.

Results and Discussion

The force constants finally obtained after several iterative calculations for the in-plane and out-of-plane vibrations of tetramethyl- and 2,6-dimethylpyrazines are given in Table 2. The calculated vibrational frequencies and modes are given in Table 3, together with the experimental results. The molecular structures of tetramethyl- and 2,6-dimethylpyrazines were assumed to belong to the point groups D_{2h} and C_{2v}, respectively. The u axis is taken perpendicular to the molecular plane and the v and w axes in the plane with the w axis passing through the nitrogen atoms. The moments of inertia calculated from the molecular structures and the expected rotational envelopes for the infrared bands in vapor phase are given in Table 4. The depolarization measurements of the Raman spectra observed in molten phase and polarized Raman

spectra observed in single crystals of tetramethyl- and 2,6-dimethylpyrazines are shown in Figs. 3, 4, 5, and 6, respectively. The polarized Raman spectrum of tetramethylpyrazine was denoted with two symbols such as ab as used in the previous paper.[14] The first letter refers to the direction of polarization of the excitation light and the second to that of the scattering light.

The polarized Raman spectra of 2,6-dimethylpyrazine observed for the two different orientations of the crystal described in the experimental section are shown in Figs. 6 (A) and (B). We denote type α for the band whose intensity is stronger in the // spectrum than in the $\perp$ spectrum and type β for the band whose intensity is *vice versa*. The polarization behavior of a Raman band is represented by two symbols such as $\alpha\beta$, where the first and second letters refer to the polarization behaviors observed in the first and second crystal orientations and shown in Figs. 6 (A) and (B), respectively. For example, the polarization behavior

a) These polarization behaviors were experimentally determined by comparison with the band envelope in the infrared vapor spectrum.

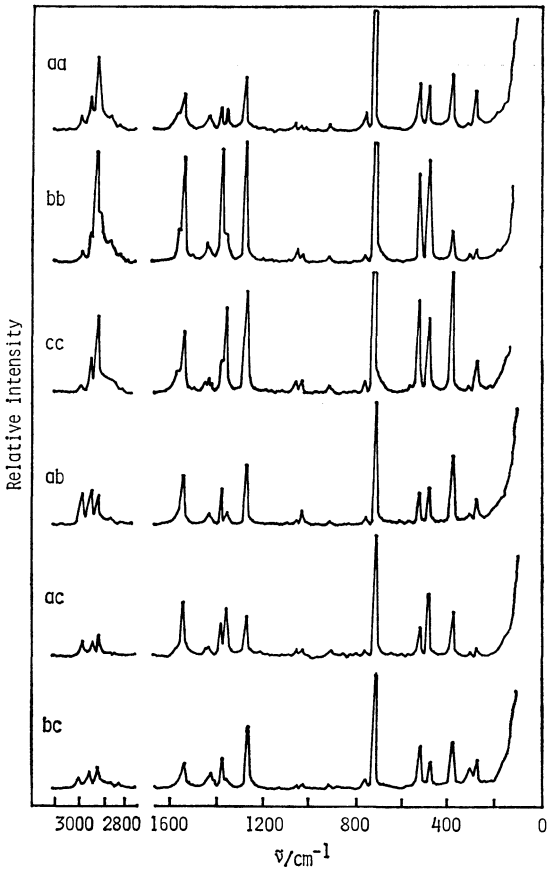

Fig. 5. Polarized Raman spectrum of the tetramethylpyrazine single crystal.

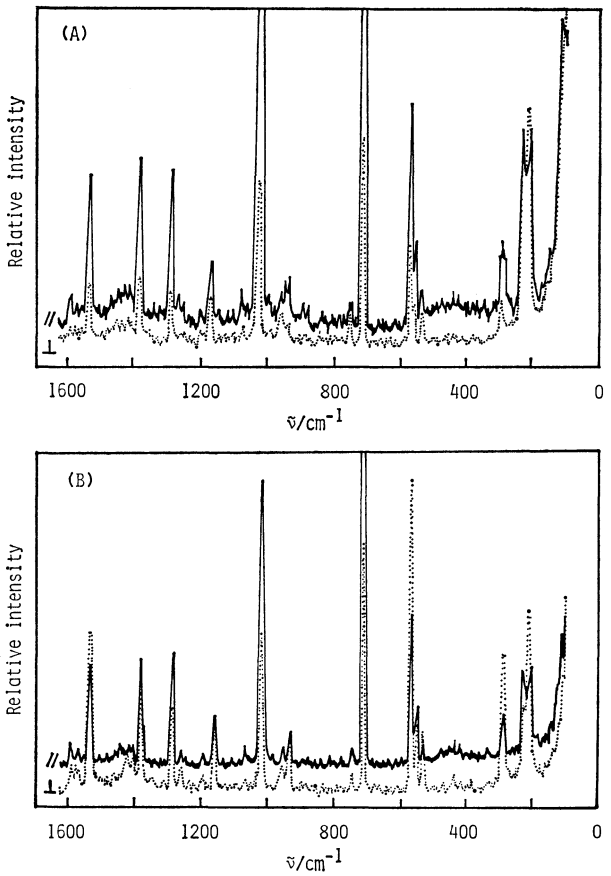

Fig. 6. Polarized Raman spectrum of the 2,6-dimethylpyrazine single crystal. For the polarization behaviors of the (A) and (B), see text.

of the 1534 cm^{-1} band is represented by $\alpha\beta$. The observed polarization behaviors of the non-totally symmetric Raman bands can be classified into three types $\alpha\alpha$, $\beta\beta$, and $\alpha\beta$ through which each Raman band can be experimentally assigned to a certain symmetry species.

The polarized infrared spectra of tetramethyl- and 2,6-dimethylpyrazines are shown in Figs. 7 and 8, respectively. The infrared crystal bands can be classified into three types I, II, and III based on their polarization behaviors. In the first type, the intensities of the // and $\perp$ components of the bands are nearly equal to each other. In the second type, the intensity of the // component is stronger than that of the $\perp$ one, and in the third type, the intensity of the $\perp$ component is much stronger than that of the // one.

Tetramethylpyrazine. The direction cosines between the crystal and molecular axes were calculated using the X-ray diffraction data given by Braam *et al.*[15] and the matrix elements of the derived polarizability tensor listed in Table 1 were evaluated. Squares of the calculated elements of the derived polarizability tensors, which are proportional to the Raman intensities, are given in Table 5 for the non-totally g symmetric vibrations. In this calculation,

Table 5. Squared values of the elements of the derived polarizability tensors for tetramethylpyrazine

	b_{1g}	b_{2g}	b_{3g}
$(A_{aa})^2$	0.19	0.76	0.10
$(A_{bb})^2$	0.08	0.06	0.91
$(A_{cc})^2$	0.53	0.39	0.41
$(A_{ab})^2$	0.40	0.15	0.05
$(A_{ac})^2$	0.10	0.01	0.24
$(A_{bc})^2$	0.10	0.23	0.00

values of the derived polarizability tensors of the free molecule, α'_{uv}, α'_{uw}, and α'_{vw}, are taken to be 1 in order to discuss the relative intensities of the Raman bands belonging to a certain symmetry species. It is expected from Table 5 that the b_{1g} vibrations appear strongly in the cc and ab spectra, the b_{2g} vibrations in the aa and cc spectra and the b_{3g} vibrations in the bb and cc spectra. These expected polarization behaviors of the Raman bands are given in Table 4.

a_g Species: Strongly polarized Raman bands observed at 1547, 1383, 1283, 715, and 530 cm^{-1} in the depolarization measurements were directly ascribed to the a_g vibrations and assigned to the ν_{8a}, ν_{CH_3} symmetric deformation, ν_2(ϕ-CH_3 stretching), ν_1, and ν_{6a} vibrations, respectively based on the calculation. A very broad and almost depolarized Raman band observed around 300 cm^{-1} in liquid phase splits into two bands at 305 and 296 cm^{-1} in the single crystal Raman spectrum. The polarization behavior of the 305 cm^{-1} band corresponds to the b_{3g} vibration, while that of the 296 cm^{-1} band does not correspond to any non-totally symmetric vibrations. Therefore, the 296 cm^{-1} band was assigned to the totally symmetric ν_{9a}(CH_3 bending) vibration.

b_{3g} Species: A Raman band observed at 478 cm^{-1} has strong intensity in the bb spectrum and medium intensity in the cc spectrum. Raman bands observed at 1510 and 1050 cm^{-1} have rather weak intensities in the bb and cc spectra and extremely weak intensities in all other spectra. Table 4 indicates that the polarization behaviors of these bands are consistent with the b_{3g} vibration. Therefore, the 1510, 1050, and 478 cm^{-1} bands were assigned to the ν_{8b}, ν_{7b} (ϕ-CH_3 stretching), and ν_{6b} vibrations of b_{3g} species, respectively. A very weak Raman band at 600 cm^{-1} was observed only in the bb spectrum and thus this band was assigned to the ν_3(CH_3 bending) vibration.

b_{1g} Species: A Raman band observed at 380 cm^{-1} has strong intensity in the cc spectrum and medium intensity in the ab and aa spectra. These polarization behaviors are consistent with the b_{1g} vibration. Thus the 380 cm^{-1} band was assigned to the ν_{10a} (CH_3 wagging) vibration.

b_{2g} Species: A Raman band observed at 275 cm^{-1} has stronger intensity in the aa and cc spectra compared with those in other spectra. A Raman band observed at 750 cm^{-1} decreases its intensity in the order of aa>cc>bc≈ab>bb≈ac spectra. These polarization behaviors definitely indicate that the 275 and 750 cm^{-1} bands have to be assigned to the b_{2g} vibration and hence assigned to the ν_5 (CH_3 wagging) and ν_4 vibrations, respectively.

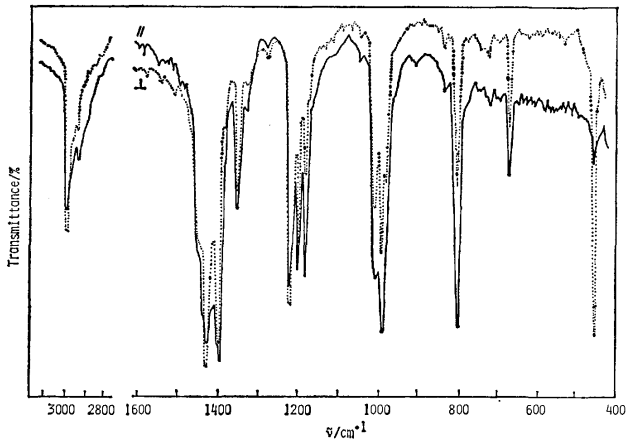

Fig. 7. Polarized infrared spectrum of the tetramethylpyrazine single crystal.

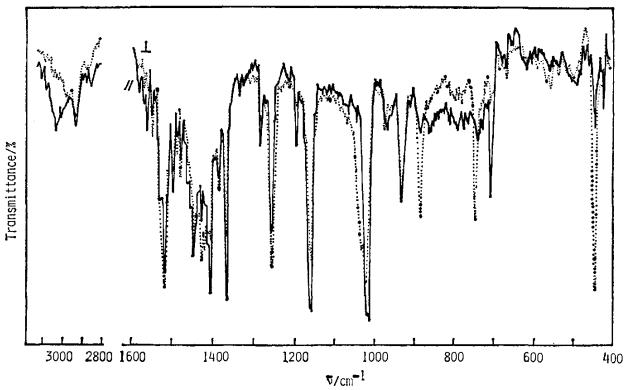

Fig. 8. Polarized infrared spectrum of the 2,6-dimethylpyrazine single crystal.

The assignment of a Raman band observed at 1367 cm^{-1} is rather difficult. This band is depolarized in the molten Raman spectrum, while its polarization behavior in the crystal Raman spectra does not correspond to any non-totally symmetric vibrations. Therefore, this band was tentatively assigned to the superposition of the CH_3 symmetric deformation vibration of b_{3g} species and the overtone vibration of the ν_{13}(ϕ-CH_3 stretching) vibration.

b_{1u} Species: According to Table 4, the infrared b_{1u} band is expected to show the B type band envelope in vapor. Infrared bands observed at 1360 and 1220 cm^{-1} showed the B band type in vapor and the type I polarization behavior in crystal. Since the band envelope and polarization behavior of the infrared band directly depend on the direction of the transition moment, it is expected that the infrared bands showing the type I polarization behavior in crystal should be assigned to the b_{1u} vibration. Strong infrared bands observed at 1440 and 1220 cm^{-1}, a medium intense band at 1360 cm^{-1} and a weak band at 680 cm^{-1} show the type I behavior in crystal and thus these bands were assigned to the ν_{19a}, ν_{12}, ν_{CH_3} symmetric deformation, and ν_{13}(ϕ-CH_3 stretching) vibrations of

a) Observed in crystal phase. b) Observed in liquid phase.

b_{1u} species, respectively. A weak infrared band found at 310 cm^{-1} in liquid was tentatively assigned to the ν_{18a} (CH_3 bending) vibration based on the calculation.

b_{2u} Species: A medium intense infrared band observed at 810 cm^{-1} showed the A band type in vapor. From Table 4, this band was ascribed to the b_{2u} vibration. This band showed the type II polarization behavior in crystal. Therefore, the infrared bands at 1410, 1330, and 810 cm^{-1} showing the type II character in crystal were assigned to the ν_{19b}, ν_{14}, and ν_{20b}

(ϕ-CH_3 stretching) vibrations of b_{2u} species, respectively. A weak band observed at 270 cm^{-1} in liquid was assigned to the ν_{15} (CH_3 bending) vibration based on the calculation.

b_{3u} Species: As a medium intense bands observed at 457 cm^{-1} showed the typical C band type in vapor, this band was definitely ascribed to the b_{3u} vibration and assigned to the ν_{16b} vibration. The CH_3 wagging and ϕ-CH_3 torsional vibrations belonging to b_{3u} species were not detected in the infrared spectrum because of their low frequencies.

a_u Species: Extremely weak infrared and Raman bands observed at 545 and 550 cm^{-1}, respectively, in crystal might be assigned to the ν_{16a} vibration of a_u species. These bands are considered to appear in the spectra by the crystal force distorsion.

2,6-Dimethylpyrazine. *a_1 Species*: Strong and polarized Raman bands observed at 3030, 1587, 1450, 1197, 1159, 1020, 709, and 556 cm^{-1} in molten phase were straightforwardly assigned to the totally symmetric ν_{13}, ν_{8a}, ν_{19a}, ν_2(ϕ-CH_3 stretching), ν_{9a}, ν_{12}, ν_1, and ν_{6a} vibrations, respectively. The corresponding infrared bands showed the type II polarization in crystal and the B band type in vapor. A very weak Raman band at 420 cm^{-1} was assigned to the totally symmetric ν_{18a}(CH_3 bending) vibration based on the calculation.

b_1 Species: A very strong infrared band at 444 cm^{-1} showed the typical C band type in vapor and the type III polarization behavior in crystal. An infrared band at 745 cm^{-1} showed the type III behavior and a depolarized Raman band at 747 cm^{-1} showed the $\beta\beta$ polarization behavior in crystal. According to Table 4, the 444 and 745 cm^{-1} bands should be assigned to the b_1 vibrations and thus assigned to the ν_{16b} and ν_5 vibrations, respectively. A Raman band at 198 cm^{-1} showed the $\beta\beta$ character in crystal and thus this band was assigned to the ν_{11}(CH_3 wagging) vibration of b_1 species. Depolarized Raman band at 675 cm^{-1} was assigned to the ν_4 vibration based on the calculation.

b_2 Species: The infrared bands having the A band envelope in vapor showed the type I polarization behavior in crystal and the corresponding Raman band showed the $\alpha\beta$ polarization character in crystal. According to Table 4, the band showing these polarization behaviors could be assinged to the b_2 vibration. Infrared bands observed at 2965, 1535, 1420, 1255, and 932 cm^{-1} showing the A band type in vapor were assigned to the ν_{7b}, ν_{8b}, ν_{19b}, ν_3, and ν_{20b}(ϕ-CH_3 stretching) vibrations, respectively. Raman bands at 568 and 285 cm^{-1} showed the $\alpha\beta$ polarization character in crystal and assigned to the ν_{6b} and ν_{15}(CH_3 bending) vibrations, respectively. A weak and depolarized Raman band at 1305 cm^{-1} was assigned to the ν_{14} vibration based on the calculation.

a_2 Species: Depolarized Raman bands observed at 955, 220, and 190 cm^{-1} showed the $\alpha\alpha$ polarization character in crystal. These bands were assigned to the ν_{17a}, ν_{10a}(CH_3 wagging), and ϕ-CH_3 torsional vibrations of a_2 species, respectively, because the Raman bands showing the $\beta\beta$ and $\alpha\beta$ polarization behaviors in crystal were already assigned to the b_1 and b_2 vibrations, respectively. A weak and depolarized Raman band at 415 cm^{-1} was assigned to the ν_{16a} vibration based on the calculation.

The characteristic vibrations for CH_3 group of tetramethyl- and 2,6-dimethylpyrazines were determined based on the observed polarization behaviors of the Raman and infrared bands as well as the normal coordinate calculation. Detailed vibrational analyses of the Raman and infrared spectra are given in Tables 6 and 7, and the normal vibrations are summarized in Table 3.

The normal coordinate calculation made for tetramethylpyrazine suggests that the ν_1, ν_{12}, ν_{6b}, ν_{14}, and ν_{16a} vibrations in this molecule couple with the ϕ-CH_3 stretching (ν_2), ϕ-CH_3 stretching (ν_{13}), CH_3 bending (ν_3), ϕ-CH_3 stretching (ν_{20b}), and CH_3 wagging (ν_{17a}) vibrations, respectively. Observed vibrational frequencies of the ν_1 and ν_{6b} vibrations are lower and the frequencies of the ν_{12}, ν_{14}, and ν_{16a} vibrations are higher than those of the corresponding vibrations of pyrazine. These observation are consistent with the calculated results mentioned above. In 2,6-dimethylpyrazine the CH_3 group concerned with the ϕ-CH_3 stretching (ν_{13}), CH_3 bending (ν_3), and CH_3 wagging (ν_{17a}) vibrations is replaced with the H atom and these vibrations do not couple with the ν_{12}, ν_{6b}, and ν_{16a} vibrations, respectively. Therefore, the observed vibrational frequencies of ν_{12}, ν_{6b}, and ν_{16a} vibrations are nearly the same as those of pyrazine, while the frequency of the ν_1 vibration is lower and that of the ν_{14} vibration is higher than those of pyrazine.

We believe that the assignment of the normal vibrations given for tetramethyl- and 2,6-dimethylpyrazines are reliable and quite useful in the reasonable vibrational analyses of the phosphorescence spectra of these molecules.

Temperature Programmed Reduction of Copper–Silica Catalysts Prepared by Ion Exchange Method[1)]

Masahide Shimokawabe,* Nobutsune Takezawa, and Haruo Kobayashi

Department of Chemical Process Engineering, Faculty of Engineering, Hokkaido University, Sapporo 060

(Received September 27, 1982)

Temperature programmed reduction (TPR) has been used to study copper–silica catalysts which were prepared by ion exchange method and the effects of preparation of catalysts upon their reducibilities were elucidated. Three peaks appeared with maxima at 265—300 °C (α), 400 °C (β), and 650—800 °C (γ) over the catalysts calcined at 500 °C. Highly dispersed cupric oxide clusters were reduced to metallic copper, giving α peak. Isolated copper(II) ions which were strongly interacted with silica surface were reduced stepwise to metallic copper through copper(I) ion species, giving α and γ peaks. However, isolated copper(II) ions which were weakly interacted with the support gave α and β peaks. When the catalysts were precalcined above 800 °C, the fourth peak (α') appeared at 330—350 °C and α, β, and γ peaks diminished. This was assigned to the reduction of bulk CuO which was crystallized from species described above. The reducibility of copper–silica catalyst was found to depend strongly upon the conditions of preparation.

Characterization of catalysts is one of the important initial steps for catalyst design.[2)] In our previous work,[3)] copper–silica catalysts prepared by ion exchange method were characterized by means of a variety of analytical methods such as DTA, TG, UV, XPS, AES, and XRD and it was shown that the precursor states of the catalysts depended sensitively upon copper loading and the calcination temperature. The activity and selectivity of methanol steam reforming $CH_3OH+H_2O=CO_2+3H_2$ were found to be strongly influenced by the preparation of the catalysts[4–6)] and metallic copper formed in the course of the reaction was suggested to be active sites for the reaction. The reducibility of the catalyst was also closely associated with the preparation conditions of the catalyst.[7)] Recently, TPR method has been successfully applied for the characterization of supported metal catalysts[8,9)] and TPR peaks obtained are found to reflect sensitively the states of the catalysts such as valence of active species and metal-support interaction. In these connections, the copper-silica catalysts were reduced by hydrogen under temperature programmed conditions and their reducibilities were extensively studied in relation to the states of the precursor species.

Experimental

Catalysts. The catalysts were prepared in a manner similar to that employed in the previous work.[3)] Hydroxyl protons on silica gel (Nihon Chromato. Co., 60—80 mesh in granules) were exchanged at a pH=11—12 overnight with tetrammine copper(II) cations which had been prepared from copper(II) nitrate (Wako Pure Chemicals, extra pure grade) and an aqueous ammonia solution. The ion exchange silica gel was filtered, washed with distilled water and dried at 110 °C for 12 h, and were further calcined in air under various conditions covering temperature range of 500—900 °C and calcination time of 3 min to 3 h. Copper loading in catalyst was estimated from the concentrations of the mother solution and of the filtrate. These were determined by titration with EDTA solution of known concentration by use of PAN as an indicator. Copper loading thus determined varied in the range of 0.5—13.0 wt% copper. As previously stated,[3,5)] no nitrate anion was held on the surface as revealed by XPS of the catalysts and chemical analysis of the solution.

Temperature Programmed Reduction (TPR). A hydrogen–nitrogen mixture (4% hydrogen) was passed over the catalyst at a total flow rate of 50 ml/min. TPR runs were carried out at a heating rate of 10 °C/min with a programming temperature controller (Muto HM 53) and hydrogen consumption was monitored by thermal conductivity cell attached to a gas chromatograph (Ohkura Electric Co. Model 701). The reactor was made of quartz tubing of 12 mm in diameter and the catalyst sample of 0.5—3.0 g was mount ed on loosely packed quartz wool. The temperature was simultaneously recorded with hydrogen concentration on a multipen recorder (Hitachi 056) using a chromel-alumel thermocouple.

Results and Discussion

Copper Loading and TPR Spectra. Figure 1 illustrates TPR spectra obtained over the catalysts which had been prepared by calcination at 500 °C for 3 h in air. Three peaks are seen with maxima at 265—300 °C (referred to as α-peak), 440 °C (β-peak) and 665—800 °C (γ-peak), and these peak areas depend markedly upon copper loading. On the catalysts with high copper loading (10.4 and 13.0 wt% copper), α peak appears predominantly with a small β peak on its shoulder. Three peaks α, β, and γ are seen separately on the catalysts with medium loading (5 wt% copper), while only α and γ peaks are perceptible on the catalyst with copper loading below 2 wt%. The amounts of hydrogen consumed were estimated from the peak area and were plotted against copper loading in Fig. 2. The total amount of hydrogen consumed was found to be practically equal to that of hydrogen required for complete reduction of cupric oxide to metallic copper. α-Peak increases monotonically with the increase of copper loading while β and γ peaks attain to the maximum and decrease as the loading is increased. In Fig. 3, peak area ratio α/γ is plotted against copper loading. It is seen that α/γ decreases and tends to approach unity as the loading is lowered.

In our previous work,[3)] the precursor states of copper–silca catalyst which was prepared by ion exchange method were characterized with the help of a variety of analytical methods and it was shown that when copper(II) ions were held no silica gel support, various states of the precursors appeared. Relative amounts

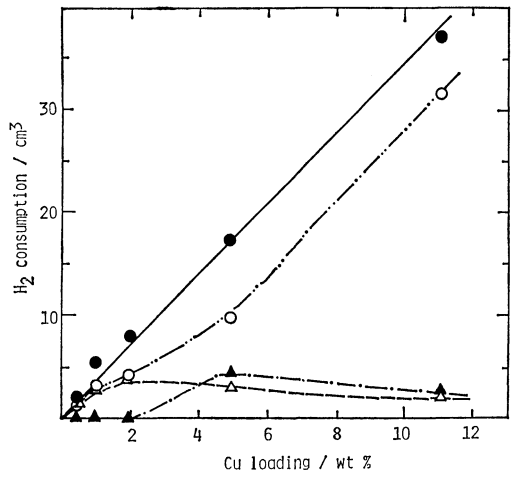

Fig. 2. Cu-loading and the amounts of consumed hydrogen in the course of TPR runs.
(—●—), Total amount of consumed hydrogen. (—○—), Amount of consumed hydrogen which gave α-peak. (—▲—), Amount of consumed hydrogen which gave β-peak. (—△—), Amount of consumed hydrogen which gave γ-peak.

of these species were found to be sensitively affected by copper loading and calcination temperature. On the catalyst with copper loading below 0.5—1 wt%, the precursor which was calcined in the temperature range 300—720 °C existed as isolated copper(II) ions, while with higher copper loadings it existed as small clusters of CuO. When the catalyst was calcined above 720 °C, the latter species were crystallized into bulk CuO, while the former species were partly clustered but in part still remained as isolated copper(II) ions.

In the present work, a variety of TPR peaks were observed. α and β Peaks appeared with the same intensity at lower copper loading (below 2 wt%), while at higher copper loading (10.4 and 13.0 wt%), the

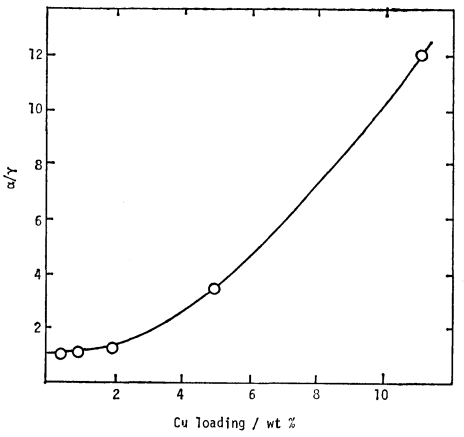

Fig. 3. The ratio of TPR peak areas α/γ against Cu-loading.

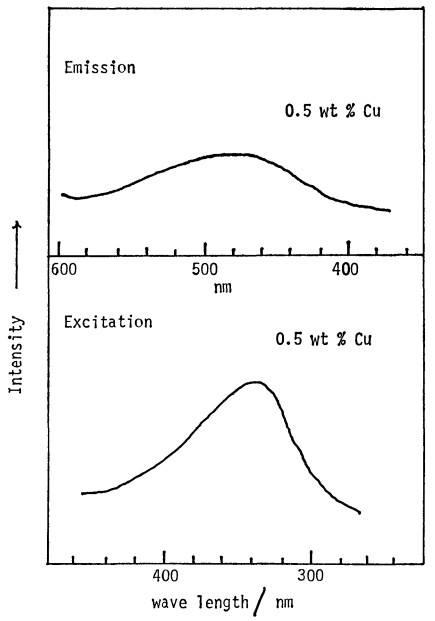

Fig. 4. Phosphorescence spectra of Cu/SiO_2 catalysts which were employed for TPR run to 400 °C.

former peak was exceedingly large compared to other TPR peaks. On the basis of the previous results as to the characterization of the catalyst,[3] it is very likely that α-peak obtained on the catalyst with high copper loading is ascribed to the reduction of small clusters of CuO. These species were transformed to metallic copper as evidenced by the amount of the hydrogen consumption. On the catalyst with 0.5 wt% copper loading the phosphorescence spectra were obtained after a TPR run was carried out to 400 °C where α-peak was completed (Fig. 4). In both the emission and the excitation modes, the peaks due to copper(I) ions are seen at 340 and 490 nm, respectively. α-Peak obtained for the catalysts with low copper loading is, therefore, ascribable to the reduction of isolated copper(II) ions to copper(I) ions. In these respects, γ-peak is ascribed to the reduction of the formed copper(I) ions to metallic copper, so that the ratio of peak area α/γ approaches unity as the loading is lowered. Both isolated copper(II) ions and copper(I)

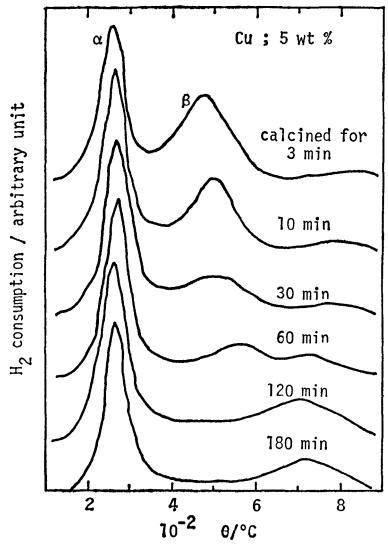

Fig. 5. TPR spectra of Cu/SiO_2 (5.0 wt% copper) catalyst calcined at 500 °C.

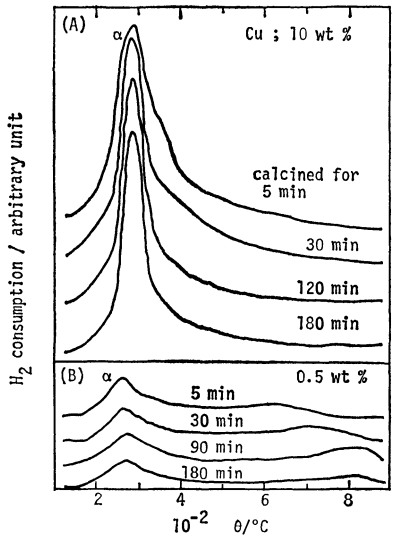

Fig. 6. TPR spectra of Cu/SiO_2 (10.0 wt% and 0.5 wt% copper) catalysts calcined at 500 °C.

ions formed were presumably interacted strongly with silica and stabilized on the support. The copper(II) ions were, therefore, reduced stepwise to metallic copper through the copper(I) ions. On the other hand, the results obtained at medium copper loading appeared to be puzzling in which β-peak was seen. It was tentatively concluded that copper(II) ions which were weakly interacted with silica were also reduced to copper(I) ions, giving α peak, and the formed copper(I) ions were then reduced to metallic copper at the temperature where β peak appeared.

Figure 5 illustrates TPR spectra of Cu/SiO_2 (5.0 wt%) catalysts which were calcined at 500 °C for different length of time. As the calcination time becomes longer, β-peak decreases but γ-peak increases. However, the intensity of α-peak remains practically unchanged. The interaction between copper(II) ions and silica was suggested to be strengthened during the course of calcination. Figure 6 illustrates TPR spectra which were obtained for the catalysts (10 and 0.5 wt% copper) calcined at 500 °C for different length of time. On the catalyst with 10 wt% copper small β-peak on α-peak diminishes with time and only α-peak is observed after 180 min. On the catalyst with 0.5 wt% copper the peaks are initially observed at 260 and 650 °C but γ-peak shifts to higher temperature when the calcination time is increased. This also indicates that the mutual interaction between isolated copper(II) ion and silica support is enhanced with the calcination time.

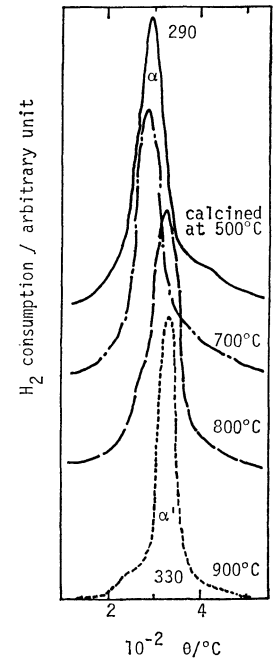

Fig. 7. TPR spectra of Cu/SiO_2 (10.4 wt% copper) catalysts and calcination temperature.

Calcination Temperature and TPR Spectra. Figure 7 illustrates TPR spectra obtained over Cu/SiO_2 catalyst (10 wt%) which was calcined at different temperatures for 3 h in air. α-Peak predominates on the catalyst calcined below 700 °C, but when the catalysts is calcined at 800 or 900 °C, this peak decreases to a considerable extent and a new peak (referred to as α'-peak) appears at 330 °C. As previously examined[3] by XRD, no CuO patterns were observed on the catalyst precalcined below 720 °C, but they grew when the catalyst was precalcined above this temperature. α'-Peak is, therefore, ascribed to the reduction of the bulk CuO. In fact, support-free CuO gave a peak at 340 °C.

Figure 8 shows TPR spectra obtained for the catalysts with lower copper loadings (2.0 and 0.5 wt% copper) which were calcined at various temperatures. The spectra are somewhat complicated compared to those obtained on the catalysts with higher copper loadings. When the cataylsts with 2 wt% copper is calcined at 900 °C, α' peak grows evidently at the expense of α and γ peaks. On the catalyst with 0.5 wt% copper, however, α' peak is also observed while α peak grows slightly but γ peak decreases. This indicates that isolated copper(II) ion precursors transform into CuO clusters and the latter species further transform into

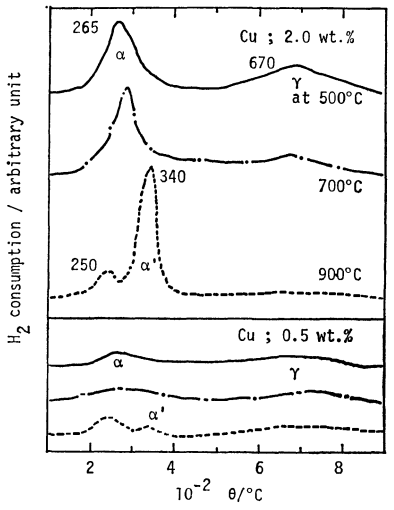

Fig. 8. TPR spectra of Cu/SiO_2 (2.0 and 0.5 wt% copper) catalysts and calcination temperature.

bulk CuO when the catalyst is precalcined at 900 °C. This substantially coincided with the previous results obtained by UV diffuse reflectance spectroscopy in which it was shown that the isolated species became partially clustered but in part still retained its orginal state.

Conclusion

TPR technique has been used to study copper–silica catalysts with varying copper loading and calcination. Four peaks were observed with maxima at 265—300 °C (α), 400 °C (β), 650—800 °C (γ), and 330—350 °C (α'). Relative peak intensities of these peaks depended upon copper loading and calcination temperature. It was concluded that α peak was ascribed to the reduction of highly dispersed CuO clusters and isolated copper(II) ions which were either strongly or weakly held on the support. The CuO clusters were easily reduced to metallic copper, while the isolated species were merely reduced to copper(I) ions when α peak was completed. These isolated copper(II) ions were concluded to be reduced stepwise to metallic copper and consequently β and γ peaks were ascribed to the reduction of intermediate copper(I) ions to metallic copper. When the catalyst was calcined at 900 °C, CuO clusters transformed into bulk CuO to a considerable extent and gave α' peak in TPR runs. On the other hand, the copper ions in the catalyst with lower copper loading are only partly transformed into bulk CuO clusters even after calcination at 900 °C.

The present research has been partially supported by the Grant-in-Aid for Scientific Researches of the Ministry of Education, Science and Culture to which the authors are greatly acknowledged.

Added in Note: After the present work was presented at the Chemical Society of Japan Meeting, April 3, 1981 and at Catalysis Society Meeting, October 15, 1981, Okayama, the TPR work [S. J. Gentry and P. T. Walsh, *J. Chem. Soc., Faraday Trans. 1*, **78**, 1515 (1982)] was recently published for copper catalysts which were prepared by impregnation on silica and alumina. The results shown are practically in accord with those obtained in the present work in which the TPR peaks obtained are reported to be greatly affected by calcination temperature and copper loading.

Pressure Effects on the Hydrolysis of 3-Nitro-4-acyloxybenzoic Acids Catalyzed by Hexadecyltrimethylammonium Bromide Micelle[1)]

Syoichi Makimoto, Keizo Suzuki, and Yoshihiro Taniguchi*

Department of Chemistry, Faculty of Science and Engineering, Ritsumeikan University, Kita-ku, Kyoto 603

(Received October 22, 1982)

The rates of the hydrolysis of 3-nitro-4-acetoxybenzoic acid (NABA), 3-nitro-4-propionyloxybenzoic acid (NPBA), 3-nitro-4-butyryloxybenzoic acid (NBBA), and 3-nitro-4-valeryloxybenzoic acid (NVBA), catalyzed by the hexadecyltrimethylammonium bromide (HTAB) micelle, were measured at pressures up to 2 kbar at 25 °C in Tris buffer solution (0.01 M,† pH 8.7). The ester binding constant K increased and the rate constant of the hydrolysis catalyzed by micelle k_m decreased with longer alkyl chains of esters at 1 bar. The k_m values were separated into the contribution of k_{OH} (hydroxide ion catalyzed hydrolysis) and k_T (Tris catalyzed hydrolysis), which increased monotonically up to 2 kbar. On the other hand, the K values decreased and then inversed with minima at about 1.5 kbar except for that of NABA. From the pressure dependence of log K, the volume changes, ΔV, accompanying the ester binding to the HTAB micelle at 1 bar were estimated to be in the range of 11 ± 2 cm³/mol for NABA to 23 ± 2 cm³/mol for NVBA. The activation volumes for the hydrolysis catalyzed by micelle, were measured as -6 ± 2 cm³/mol for $\Delta V^{\ddagger}_{OH}$ and -16 ± 2 cm³/mol for $\Delta V^{\ddagger}_{T}$ for each ester. The activation volumes for the spontaneous hydrolysis were measured as -5 ± 2 cm³/mol for $\Delta V^{\ddagger}_{OH}$ and -16 ± 2 cm³/mol for $\Delta V^{\ddagger}_{T}$ for each ester. The reaction mechanism was discussed in terms of ΔV and ΔV^{*}.

Hydrolysis of esters catalyzed by micelles as the enzyme-model is recognized to be markedly accelerated above the critical micelle concentration (cmc) and to follow the kinetics of Michaelis-Menten type.[2,3)] Such an accelerating effect is explained by the incorporation of esters into the micellar phase, which is caused by the driving force of the electrostatic and hydrophobic interactions between esters and micelles. In fact, the cooperative effect of electrostatic and hydrophobic interactions on the substrate binding is important for some kinds of protease.

In the previous report,[4)] we have studied about the HTAB micelle-system concerning the hydrophobic interaction as the driving force of the incorporation of neutral esters into the micellar phase. The volume change ΔV accompanying the ester binding to the micellar system at 1 bar was in the range of 0 cm³/mol for *p*-nitrophenyl acetate (PNPA) to 18 cm³/mol for *p*-nitrophenyl hexanoate (PNPH), which means the increment of the positive volume of 2.4 cm³/mol for methyl or methylene group of esters for the transfer of ester molecules from an aqueous environment to the micellar phase. While, ΔV at the formation of the electrostatic interaction (charge neutralization) for 1:1 electrolytes is believed to be around 10 cm³/mol.[5)] So, we can expect that the pressure effects on the electrostatic interactions are larger than hydrophobic effects, especially for an ionic ester molecule containing only a short alkyl chain. The study about the system containing both interactions above as a driving force of the incorporation of ester into the micellar phase is meaningful to clearify the more detail mechanism of protease.

In the present work, the hydrolysis rate of anionic esters of 3-nitro-4-acyloxybenzoic acids catalyzed by a cationic HTAB micelle was measured at the pressures up to 2 kbar at 25 °C to obtain the pressure dependences of the substrate bindings and the micelle-catalyzed hydrolysis. The reaction mechanism is discussed in terms of the volume change for the formation of the micelle–ester complex and the activation volumes for the hydrolysis catalyzed by micelle, being compared with the previous date.[4)]

† 1 M=1 mol dm⁻³.

Experimental

Materials. NABA, NPBA, NBBA, and NVBA synthesized[6)] and HTAB were purified by previous method,[4)] except NABA and NPBA to be recrystallized 5 times from benzene–diisopropyl ether. NABA: mp 156—158 °C (lit,[7)] mp 156—158 °C); MS (75 eV), Found: *m/e* 225.02745. Calcd for $C_9H_7N_1O_6$: M, 225.02734. NPBA: mp 143.5—145.5 °C. Found: *m/e* 239.04252. Calcd for $C_{10}H_9N_1O_6$: M, 239.04300.

Apparatus and Procedure. The measurement of the hydrolysis reaction up to 2 kbar is described in previous report.[4)] The rate was determined by observing the change in the optical density at $\lambda_{max}=410$ nm of 3-nitro-4-hydroxybenzoate anion at pH 8.7 in 0.01 M Tris buffer solution up to 2 kbar at 25 °C±0.5 °C. The cmc of HTAB at pH 8.7 in 0.01 M Tris buffer solution up to 2 kbar was determined by the measurement of the absorption spectra of salicylic acid ($\lambda_{max}=295$ nm) as a probe at 25 °C.

Results and Discussion

The apparent rate constant, k_{app}, of the hydrolysis at 1 bar increases suddenly above cmc of HTAB as shown in Fig. 1. Assuming that one ester molecule is incorporated into a micelle and that the aggregation number, N, of the micelle is independent of ester incorporation, Bunton *et al.*[8)] showed that the scheme of the enzyme-catalyzed reaction in Eq. 1 is applicable to the present kinetic behavior,

$$M + S \overset{K}{\rightleftharpoons} MS \xrightarrow{k_m} M + P, \quad S \xrightarrow{k_s} P. \qquad (1)$$

Here M, S, MS, P, K, k_m, and k_s denote the micelle, esters the micelle–ester complex, products the binding constant between esters and micelles, the rate constants of hydrolysis catalyzed by micelle, and that of the spontaneous hydrolysis, respectively. The concentration of micelle is given by Eq. 2,

$$[M] = (C_D - \text{cmc})/N. \qquad (2)$$

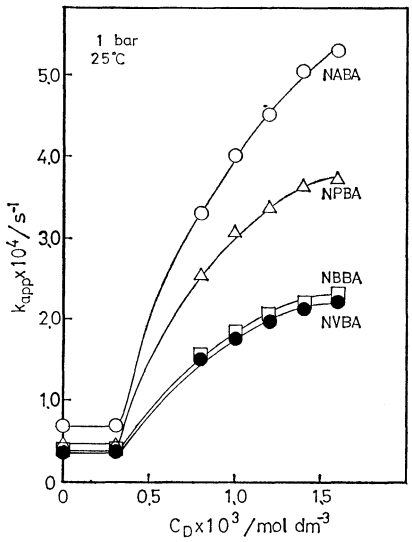

Fig. 1. Hydrolysis of anionic esters in HTAB micelle at 1 bar, pH 8.7 (0.01 M Tris buffer) and 25 °C. Each ester concn is 2.0×10^{-4} M.

$N^{p,a)}$	95	60	52	60	76

a) Ref. 4.

Here C_D is the total concentration of HTAB. The cmc values of HTAB in our experimental conditions at each pressure are shown in Table 1 with values of the aggregation numbers, N, of HTAB micelle. The values of K and k_m determined by Lineweaver-Burk plots[4] in Fig. 2 for anionic esters at 1 bar and Fig. 3 for NBBA up to 2 kbar, are shown in Table 2 with the values of k_s at various pressure.

Ester Binding. From NMR studies[9,10] of benzoate and alkyl phenol (C_nH_{2n+1}-⟨○⟩-OH, n=1, 2, 3) in micellar solutions, benzoate ions exist near the micellar surface, in which the aromatic ring is located between quaternary ammonium head groups of HTAB molecules. Alkyl phenol molecules penetrate more into the micelle with increasing alkyl chains. Therefore, NABA is expected to be incorporated near the micellar surface and the other anionic esters with longer alkyl chains of acyl groups penetrate more into the hydrocarbon core of the micelle. The results mean the difference of the site of solubilization into the micelle between NABA and longer alkyl chains of esters. So that the inversion phenomena at plots of log K *vs.* pressure as shown in Fig. 4 correspond to the appearence of a maximum of the cmc of HTAB at 1 kbar in Table 1. The linear decrease of log K of NABA with increasing pressure was also observed in the systems of PNPA–HTAB[4] and methyl acetate–dodecyl hydrogensulfate micelle.[11] The change of volume ΔV being accompanied by the formation of MS complex at 1 bar in Table 3 is determined from the initial slope of plots of log K *vs.* pressure.

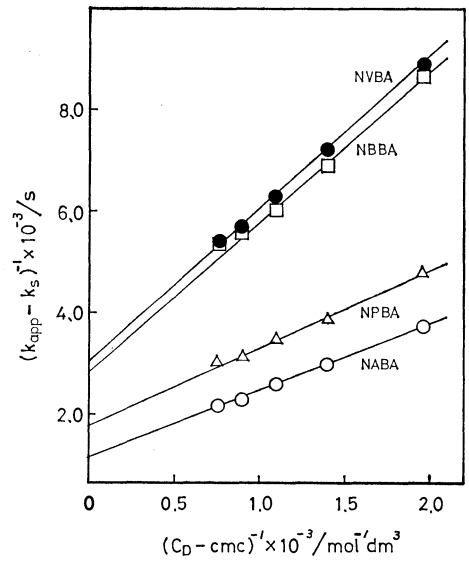

Fig. 2. Lineweaver-Burk plots for anionic esters in HTAB micelle at 1 bar, pH 8.7 (0.01 M Tris buffer) and 25 °C. Each ester concn is 2.0×10^{-4} M.

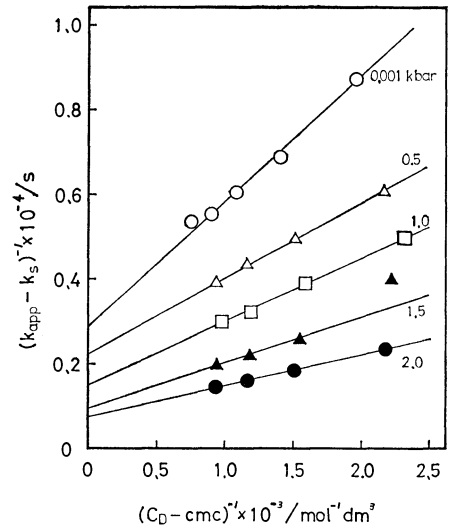

Fig. 3. Lineweaver-Burk plots for NBBA in HTAB micelle under five pressures, pH 8.7 (0.01 M Tris buffer) and 25 °C. Each ester concn is 2.0×10^{-4} M.

The K value increases with increasing alkyl chain of acyl groups of esters, and it is larger than that of neutral ester[4] at 1 bar and 25 °C except NVBA. The fact means that the electrostatic interaction in addition to the hydrophobic interaction plays an important role in the driving force of the incorporation of anionic esters with micelles. If the driving force for the ester incorporation is a sum of the electrostatic and hydrophobic interactions, the volume change ΔV is given by Eq. 3,

$$\Delta V = \Delta V_{ele} + \Delta V_{H\phi}. \quad (3)$$

Here ΔV_{ele} and $\Delta V_{H\phi}$ denote the volume changes of dehydration being accompanied by electrostatic and hydrophobic interactions between a ester molecule and a HTAB micelle, respectively. If an anionic charge of esters is neutralized completely by the electrostatic

interaction on the transfer of esters from the aqueous environment to that of the polycationic micelle, we can estimate about 11 cm³/mol as ΔV_{ele} for the release of the electrostriction around ionic esters as 1:1 electrolyte from the neutralization process such as $CH_3COO^- + H^+ \longrightarrow CH_3COOH$.[12] On the base of $\Delta V_{ele}=11$ cm³/mol, the calculated $\Delta V_{H\phi}$ values for anionic esters are 0 cm³/mol for NABA, 3 cm³/mol for NPBA, 7 cm³/mol for NBBA, and 12 cm³/mol for NVBA. They are in good agreement with $\Delta V_{H\phi}$ values for series of neutral p-nitrophenyl esters[4] with the hydrophobic interaction alone on the incorporation process. Therefore, ΔV values of anionic esters may be explained by the dehydration through both electrostatic and hydrophobic interactions between ester molecules and HTAB micelle.

Hydrolysis in Micelle. The rate constant k_s of spontaneous hydrolysis of anionic esters in Tris buffer solution can separate into the contributions of hydroxide ion and free-amine Tris catalysis as given by Eq. 4,

$$k_s = k_{OH}[OH] + k_T[Tris]. \quad (4)$$

Table 4 shows the k_{OH} and k_T values of NABA, determined by the same method of Neuman *et al.*[13] In the micellar catalyst,[4] the hydroxide ion concentration is higher near the HTAB micellar cations, while the distribution of neutral free-amine Tris would not be influenced by the micelle. Therefore, the pseudo-first-order rate constants for the hydroxide ion catalyst in micelle, $(k_{OH})_{micelle}$, are given by Eq. 5,

$$(k_{OH})_{micelle} = k_{OH}/\langle OH\rangle_{micelle}. \quad (5)$$

Here $\langle OH\rangle_{micelle}$ is the average concentration of the hydroxide ions near the micellar phase determined by using the previous date.[4] The $(k_T)_{micelle}$ values were also determined from Eq. 6 with the known $(k_{OH})_{micelle}$ values. The values of ΔV_{OH}^* and ΔV_T^* of NABA

$$k_m^{\prime} = \sum_i (k_{OH})_{micelle}\langle OH\rangle_{micelle}^{\prime} + \sum_i (k_T)_{micelle}[Tris] \quad (6)$$

for the spontaneous and micellar hydrolysis in Table 3 were obtained by the linear relation of logarithms of k_{OH} and k_T in each system (Figs. 5 and 6).

In nonmicellar systems, the value of ΔV_{OH}^* of -5 cm³/mol for anionic esters is slightly more negative value than that of -3 cm³/mol for nonionic esters. The ΔV_{OH}^* value should be given by a balance between the negative volume change for the bimolecular reaction and the positive volume change for the difference of the solvation effect between reactants and the activation complex. The former is expected to have a negative value of *ca.* -10 cm³/mol for the formation of one covalent bond,[14] for both anionic and nonionic esters. In latter case, it may be expected that there is a difference between anionic and nonionic esters in the solvation effect accompanying the formation of the tetrahedral intermediate. When a ester molecule reacts with a hydroxide ion, the charge dispersion of the activation complex takes place accompanying the formation of the tetrahedral intermediate in the transition state. The partial desolvation effect of hydroxide ions at the initial state with the formation

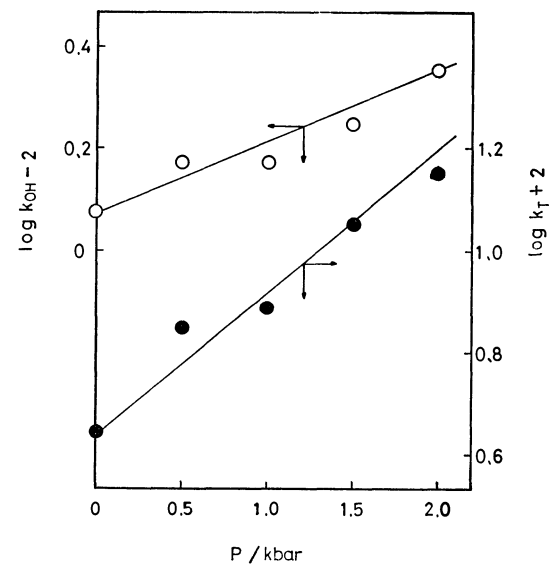

Fig. 6. Log k_{OH} and log k_T *vs.* P for NABA in micellar system at 25 °C.

of the tetrahedral intermediate contributions to the positive volume change. Therefore, the difference of ΔV_{OH}^* between -3 cm³/mol for PNPA and -5 cm³/mol for NABA is correspond to the difference of the desolvation effect on the base hydrolysis between anionic and nonionic esters.

In the micellar system, the solvation effect of water molecules both on the reactants and on the activated complex may be negligible due to the incorporation into the hydrophobic atmosphere and polyions of HTAB micelle. Therefore, the value of $(\Delta V_{OH}^*)_{micelle}$ for NABA is in good agreement with that of PNPA, which has been explained by the only contribution of the formation of one covalent bond without solvation effect.

We are grateful acknowledged to Mr. Hideo Hisatomi and Mr. Syoichi Tanamachi of Ritsumeikan University for the synthesis of esters, and Miss Kayoko Saeki of Kobe Women's College of Pharmacy for the measurement of the purity of the esters by a mass spectrometer.

Study of Ion Transport across Amphoteric Ion Exchange Membrane. II. Transport of Symmetric Tetraalkylammonium Chlorides

Kozue KAIBARA,* Hideaki SONODA, Yoshihiko NAGATA, and Hideo KIMIZUKA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812, Japan

(Received December 6, 1982)

Transport characteristics of NH_4Cl, $(CH_3)_4NCl$ (TMA–Cl), $(C_2H_5)_4NCl$ (TEA–Cl), $(n\text{-}C_3H_7)_4NCl$ (TPA–Cl), and $(n\text{-}C_4H_9)_4NCl$ (TBA–Cl) across homogeneous type amphoteric ion exchange membrane (1.0-PA-29, Kanegafuchi Chem. Ind.) were studied. Membrane potentials and conductances of the concentration cell systems were measured to calculate the membrane permeabilities which represent a measure of ionic permselectivity. Membrane potential changed considerably with cationic species and the membrane tended to behave more anionic selectively with increasing bulkiness of cations. The cationic permeabilities calculated from electrochemical data were $P_{NH_4}>P_{TMA}>P_{TEA}>P_{TPA}>P_{TBA}$. Membrane permeabilities to chloride ions, P_{Cl}, were greater than those to cations in all the systems studied and it was interesting that P_{Cl} values and their dependencies on external electrolyte concentration were almost unchanged irrespective of the difference in cationic species. The present experiment was designed in order to examine the effects of ionic size on the transport processes across homogeneous type amphoteric ion exchange membrane. The obtained results indicated that the hydrated radius of permeant ion is an important factor to control the ionic transport processes and to reveal the potentiometric selectivity in these systems. It was suggested that the ion transport across homogeneous type amphoteric ion exchange membrane is strongly affected by hydrodynamic properties of permeant ion, but scarcely influenced by ionic charges of which effects are well known to be exclusive in the uniform cation and anion exchange membranes.

It has been well known that the charge-mosaic and layered type ion exchange membrane systems exhibit unique transport characteristics unexpected for the uniform ion exchange membrane system, such as piezodialysis, circulating electric current, and rectifying phenomena.[1–4] Including these interesting phenomena, the study of fundamental transport characteristics of homogeneous type amphoteric ion exchange membrane has not been systematically carried out yet.

As reported in the preceding paper, our preliminary experiments illustrated the unique transport characteristics of a 1.0-PA-29 amphoteric ion exchange membrane having a homogeneous structure (Kanegafuchi Chemical Industry Co., Ltd.).[5] A 1.0-PA-29 membrane demonstrated the permselectivity in response to ionic size of permeant electrolyte and, therefore, it seems to be possible that the membrane permselectivity is improved by introducing the amphoteric properties into the polymeric membrane structure. It was also suggested in the preceding paper that electrolyte permeation through the 1.0-PA-29 membrane does not depend upon the coupling flow mechanisms and, accordingly, the charge-mosaic membrane model is not suitable to analyse the transport processes across homogeneous type amphoteric ion exchange membrane.[5,6]

The present experiment was carried out to illustrate more clearly the potentiometric selectivity to ions and to confirm the fact that the ionic size of permeant is a dominant factor controlling the ionic transport processes across homogeneous type amphoteric ion exchange membrane. For this purpose, the transport characteristics of ammonium chloride and of a series of symmetric tetraalkylammonium chlorides, such as tetramethyl-, tetraethyl-, tetrapropyl-, and tetrabutylammonium chlorides, were examined, since a series of tetraalkylammonium ions has similar physicochemical properties except ionic bulkiness. In case of the usual uniform cation exchange membrane (Neosepta CL-25T, Tokuyama Soda Industry Co., Ltd.), membrane potential data for these tetraalkylammonium ions showed the almost ideal Nernstian slope against the logarithmic external electrolyte activity changes irrespectively of the difference in ionic sizes.[7] On the contrary, as shown later the membrane potential data of tetraalkylammonium chloride systems with a 1.0-PA-29 amphoteric ion exchange membrane changed considerably with the hydrated ionic size so as to reveal the potentiometric selectivity. In the present paper, we also discuss to some extent distinctive ion transport characteristics across amphoteric and uniform ion exchange membranes.

Experimental

A 1.0-PA-29 amphoteric ion exchange membrane was kindly supplied by the Central Research Laboratory of Kanegafuchi Chemical Industry Co., Ltd. and the membrane preparation processes were described elsewhere.[6] Ion exchange groups of this membrane are sulfonic acid and trimethylamine types attached to the cross-linked polystyrene skeleton supported by poly(vinyl chloride) network. Basic physicochemical properties are as follows (see also Ref. 5): Cationic and anionic exchange capacity, 1 mequiv./g-wt membrane; cationic/anionic capacity ratio, 1.0 ± 0.2; membrane thickness, 0.1 mm. The closest distance between cationic and anionic exchange sites can be roughly estimated to be *ca.* 0.75 nm when the total ion exchange capacity is 2 mequiv. and the degree of swelling is 0.5; in these situations, it seems to be hard to realize the ion transport mechanisms described with the charge-mosaic model system.[6] Experimental setup and methods were the same as those reported in the previous experiments.[5,8,9]

Electrochemical data, such as the membrane potential and conductance, were measured to estimate the electroconductive membrane permeability. Measurements were carried out on the systems where solution phases I and II were divided by membrane phase; electrolyte concentrations of phase I were varied from 10^{-1} to 10^{-3} mol dm^{-3} and

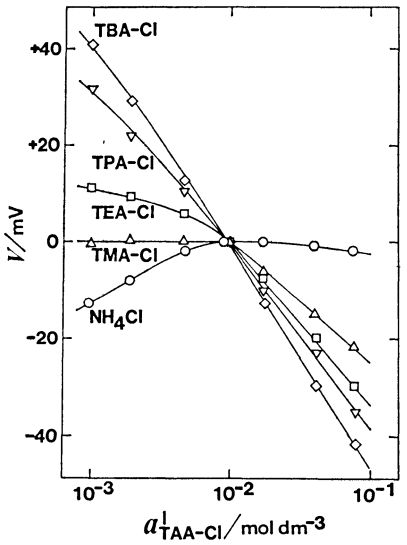

Fig. 1. Membrane potential data as a function of the mean electrolyte activity of phase I.

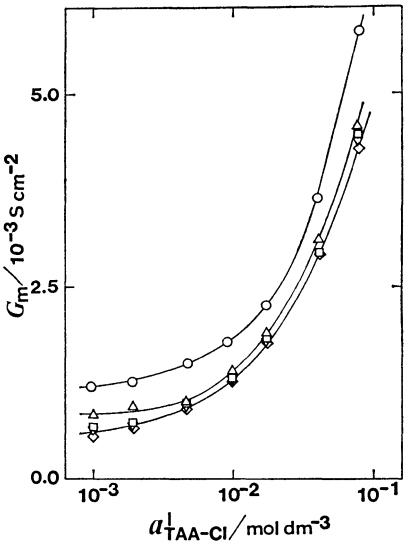

Fig. 2. Membrane conductance data as a function of the mean electrolyte activity of phase I. Symbols are the same as in Fig. 1.

those of phase II were kept constant at 10^{-2} mol dm^{-3}. Electrolyte solutions were prepared from extra pure chemicals (Nakarai Chemicals Ltd.) with conductivity water; ammonium chloride and symmetric tetraalkylammonium chlorides having methyl, ethyl, propyl, and butyl groups were used. All the experiments were carried out under the regulated room temperature, 25±1 °C.

Results and Discussion

Membrane potentials and conductances for the concentration cell systems of NH_4Cl, $(CH_3)_4NCl$ (TMA–Cl), $(C_2H_5)_4NCl$ (TEA–Cl), $(n\text{-}C_3H_7)_4NCl$ (TPA–Cl), and $(n\text{-}C_4H_9)_4NCl$ (TBA–Cl) were measured to estimate the membrane permeabilities. Figures 1 and 2 illustrate the membrane potential and conductance data as a function of mean electrolyte activity of phase I. As can be seen in Fig. 1, each system exhibits different slope of the membrane potential *vs.* logarithmic electrolyte activity plot; the negative slopes indicate that a 1.0-PA-29 amphoteric ion exchange membrane is more permselective to chloride ion than alkylammonium ions in the present situations. Figure 1 also shows that the permeability to chloride ions in general increases under conditions of higher external electrolyte concentrations. These negative slopes of membrane potential plots in Fig. 1 indicating the anionic selectivity decrease with decreasing bulkiness of respective cations from TBA^+ to TMA^+ and, in case of the NH_4Cl system, the potential plots tend to turn positive slope indicating the cationic selectivity of the membrane.

It is the most remarkable feature of the 1.0-PA-29 amphoteric membrane that the potentiometrically selective responses are observed even for ions of the same number of electric charge, as also discussed in the preceding paper.[5] In case of the system with usual uniform cation exchange membranes (*e.g.*, Neosepta CL-25T, Tokuyama Soda Co., Ltd.), similar membrane potential responses indicating the ideal Nernstian characteristics were observed to a series of cations from NH_4^+ to TBA^+; therefore, these membranes developed mainly for the desalination processes are ideally permselective to all the univalent cations and the characteristic potential responses specific to each cation were not observed.[7] Situations are the same in the uniform anion exchange membrane; membrane potential data for bulky surfactant anions were almost the same as those for simple anions.[10,11]

Membrane conductance data are summarized in Fig. 2. Membrane conductance values were not so distinctive to each system as membrane potential values but slightly dependent upon the cationic size. By the way, there is a striking difference between the conductance values of amphoteric ion exchange membrane and those of uniform cation exchange membrane. In case of the usual cation exchange membrane composed of various types of synthetic polymer, such as ACI (Asahi Chemical Industry Co., Ltd.), AMF C-103 (American Machine and Foundry Co., Ltd.), or CL-25T, the membrane conductance values of NH_4Cl amount to over hundred times as those of TBA–Cl system.[6,12]

On the basis of these electrochemical data, electroconductive membrane permeabilities to cation and chloride ion were estimated for each system; electroconductive permeabilities are defined and introduced to describe transport processes related to ionic mobility on the basis of nonequilibrium thermodynamics.[5,9,13] Electrochemical quantities are expressed as a function of membrane permeabilities to tetraalkylammonium ion (or ammonium ion) and chloride ion, P_{TAA} and P_{Cl}:

$$\begin{aligned} V_0 &= t_{TAA}V_{TAA} + t_{Cl}V_{Cl} \\ &= (g_{TAA}/G_m)V_{TAA} + (g_{Cl}/G_m)V_{Cl} \\ &= -(RT/F)\ln[(P_{TAA}a^{II}_{TAA}+P_{Cl}a^{I}_{Cl})/(P_{TAA}a^{I}_{TAA}+P_{Cl}a^{II}_{Cl})] \end{aligned} \quad (1)$$

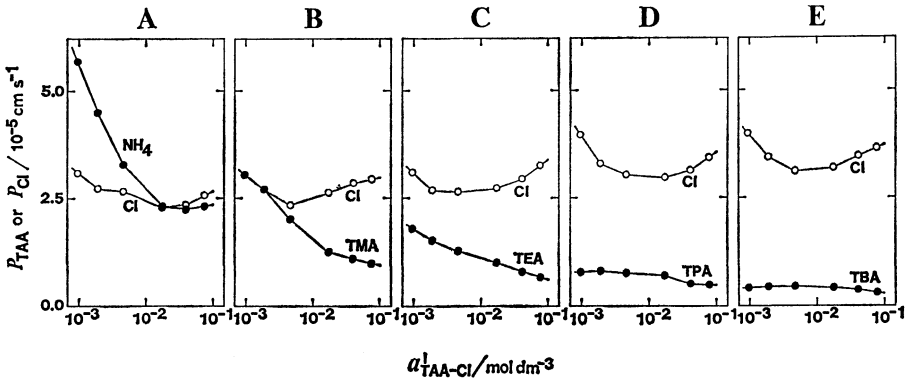

Fig. 3. Electroconductive membrane permeabilities as a function of the mean electrolyte activity of phase I. Closed and open circles indicate membrane permeabilities to cation and chloride ion, P_{TAA} and P_{Cl}, respectively.
A: NH_4Cl, B: TMA–Cl, C: TEA–Cl, D: TPA–Cl, E: TBA–Cl.

$$G_m = g_{TAA} + g_{Cl} = \frac{F^2}{RT}\left\{(a^{I}_{TAA}a^{II}_{TAA})^{1/2}P_{TAA}\frac{\sinh[F(V_0-V_{TAA})/2RT]}{F(V_0-V_{TAA})/2RT} + (a^{I}_{Cl}a^{II}_{Cl})^{1/2}P_{Cl}\frac{\sinh[F(V_0-V_{Cl})/2RT]}{F(V_0-V_{Cl})/2RT}\right\}, \quad (2)$$

where V_0 is the membrane potential in the absence of electric current, G_m is the membrane conductance, a is the activity, t is the transport number, and g is the ionic membrane conductance; V_{TAA} and V_{Cl} are the Nernst equilibrium membrane potentials to tetraalkylammonium ion (or ammonium ion) and chloride ion; F, R, and T indicate usual physical meanings; the subscripts TAA and Cl refer to tetraalkylammonium ion (or ammonium ion) and chloride ion; the superscripts I and II refer to solution phases I and II divided by membrane phase, respectively. Electroconductive membrane permeabilities, P_{TAA} and P_{Cl}, represent the membrane permselectivities to respective ions by indicating the order of electrical migration speed across membrane phase.

Membrane permeability values calculated by Eqs. 1 and 2 with electrochemical data are summarized in Fig. 3. As illustrated in this figure, the values of permeability to chloride ions show only a small change independently of difference in paired cationic species, while those to cations decrease with increasing bulkiness of respective cations as: $P_{NH_4} > P_{TMA} > P_{TEA} > P_{TPA} > P_{TBA}$. It can be also seen that the membrane permeability to smaller cations increases with decreasing external electrolyte concentrations of phase I, but for larger cations, this tendency is reduced and the permeability values are depressed to almost constant low level as shown by P_{TPA} and P_{TBA} values.

The membrane permeability ratios, P_{NH_4}/P_{Cl}, P_{TMA}/P_{Cl}, P_{TEA}/P_{Cl}, P_{TPA}/P_{Cl}, and P_{TBA}/P_{Cl}, are plotted as a function of mean electrolyte activity of phase I in Fig. 4. As expected from the respective permeability values, the permeability ratios decrease with increasing cationic bulkiness. Also in a uniform cation exchange membrane such as a Neosepta CL-25T, P_{TAA} values decrease with increasing cationic bulkiness in the same manner as the present experiment; however, P_{TAA}/P_{Cl} values are more than 100 and constant independently

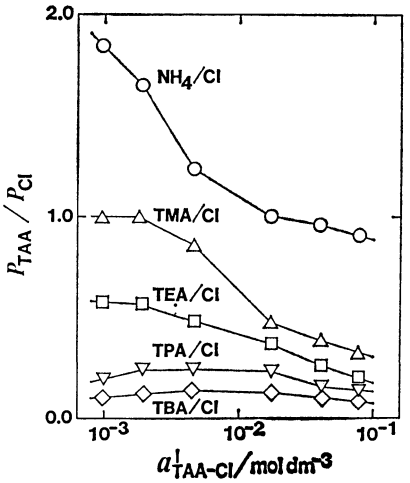

Fig. 4. Membrane permeability ratios as a function of the mean electrolyte activity of phase I.
○: P_{NH_4}/P_{Cl}, △: P_{TMA}/P_{Cl}, □: P_{TEA}/P_{Cl}, ▽: P_{TPA}/P_{Cl}, ◇: P_{TBA}/P_{Cl}.

of cationic bulkiness.[7] These are reasonable results as expected from Eq. 1, since the almost ideal Nernst membrane potentials were observed for the CL-25T membrane system and, accordingly, P_{TAA}/P_{Cl} ratios should be constant and approach to infinitely large values.

The present results suggest that the possible origin of the potentiometric selectivity of 1.0-PA-29 amphoteric ion exchange membrane is a sieve effect on permeant ions as also discussed in the preceding paper.[5] To examine further correlations between the membrane permeability and ionic size, the permeability values and permeability ratios are plotted against the values of hydrated radii of permeant ions, r_H,[14,15] in Figs. 5 and 6, respectively. These figures illustrate the reasonable correlation of hydrated ionic radius to both the permeability and the permeability ratio. The hydrated radii of tetraalkylammonium ions are almost the same as the crystal ionic radii owing to poor hydration. These results suggest that the transport process across amphoteric ion exchange membrane is strongly affected by the hydrated radius of permeant

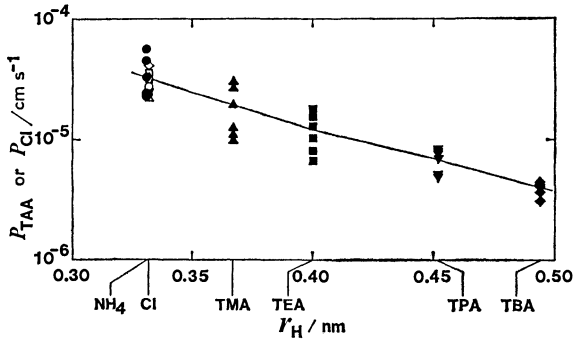

Fig. 5. Electroconductive membrane permeability *vs.* hydrated ionic radius plots.
●: P_{NH_4}, ▲: P_{TMA}, ■: P_{TEA}, ▼: P_{TPA}, ◆: P_{TBA}. P_{Cl}'s are indicated by corresponding open symbols. Solid line traces the average values of respective ions.

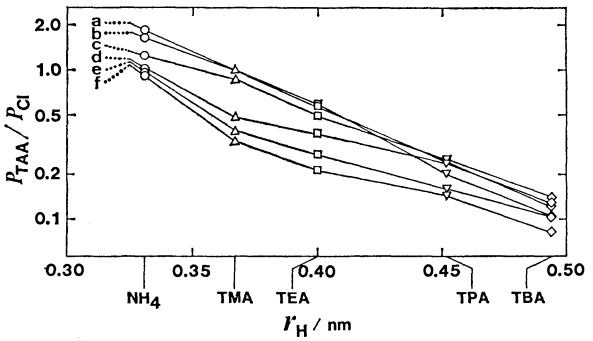

Fig. 6. Membrane permeability ratio *vs.* hydrated ionic radius plots. Symbols are the same as in Fig. 4. a, b, c, d, e, and f refer to the systems in which the electrolyte concentrations of phase I are 1×10^{-3}, 2×10^{-3}, 5×10^{-3}, 2×10^{-2}, 5×10^{-2}, and 1×10^{-1} mol dm^{-3}, respectively.

ion. Since the electroconductive membrane permeability is a function of the ionic mobility within membrane phase,[9,13,16] it is likely that the permeability values are inversely proportional to ionic size, although the mobility of permeant ion within membrane phase is not always the same as that in free solution phase and the ion movement through polymeric substance having charged sites is rather deviated from the movement in free media due to various effects.

As mentioned earlier, differences in electrochemical properties of tetraalkylammonium systems between the usual highly selective ion exchange membrane and the homogeneous type amphoteric ion exchange membrane are as follows: In the former membrane system, the membrane potential responses depend upon strictly the number of ionic charges so as to show the almost ideal Nernst potential for all the systems, but the membrane conductances are spread over wide range of values. In case of the latter membrane system as shown in the present results, the potentiometric selectivity to univalent cations of different ionic sizes is revealed, but the membrane conductances stay at similar values for all the systems. These experimental facts and estimated permeability values suggest some differences in possible ion transport mechanisms of uniform and amphoteric ion exchange membranes. It is generally realized that the ion transport process across uniformly charged membrane is controlled by the co-ion permeation.[16] Only the extremely small electrolyte fluxes are observed in the uniform ion exchange membrane under the steady conditions without membrane electric current, since the co-ion penetrations into membrane phase from external phase are prevented by high electric potential barrier. On the contrary, relatively large salt fluxes were observed in the homogeneous amphoteric membranes irrespectively of the low electrical membrane conductance.[17] It is especially interesting that the membrane permeability to chloride ion is maintained at nearly constant level for all the electrolyte systems having different size of cations as can be seen in Fig. 3. These results suggest that both the cations and anions independently migrate through the membrane phase with the interaction to electric fields built up by positively and negatively charged sites. Three dimensional array of the positive and negative charge, in which each site is adjacent at about 0.75 nm distance to oppositely charged sites, could effectively function rather as a sieve to select the size of permeant ions than as an electrical barrier. Under these situations, the ion transport across homogeneous type amphoteric ion exchange membrane seems to resemble preferably to that in free aqueous electrolyte solution, and consequently the large salt flux is expected.

As a matter of course, the ion permeability of 1.0-PA-29 membrane depends not only upon the hydrated ionic radius but also upon factors such as specific interactions of ions to exchange groups and to matrix polymer of membrane. It is, however, conceivable as shown in the present results that the effects of hydrated ionic size play an important role in the transport process of ions across the amphoteric ion exchange membrane with a homogeneous binary charged structure. On the contrary, the ionic size effects are almost concealed with the ionic charge effects in the uniform ion exchange membrane, and accordingly the potentiometric selectivity to univalent cations is not exposed. The most noticeable property of the 1.0-PA-29 membrane system with ammonium and tetraalkylammonium chlorides is that the slope of membrane potential *vs.* logarithmic electrolyte activity curve is changed stepwise in relation to the cationic hydrated radius as an indication of the appreciable variation in the relative membrane permeability with the constant chloride permeability. The present results suggest that the transport processes of ions across amphoteric ion exchange membrane explicitly reflect the hydrodynamic properties of permeant ions, while the ionic charge effects are dominant in the uniform ion exchange membrane.

We thank members of Central Research Laboratory of Kanegafuchi Chemical Industry Co., Ltd., especially Dr. Tamiyuki Eguchi, for preparing and supplying the amphoteric membrane, 1.0-PA-29, used in this work. This work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

The Precipitation of Human Fibrinogen by Zinc Chloride

Hiroshi MAEDA,* Takaaki KISHI, and Shoichi IKEDA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received December 8, 1982)

The precipitation of human fibrinogen by $ZnCl_2$ was studied by measuring the turbidity and the protein concentration in the supernatant (referred as solubility). Different kinetic patterns, either fast or slow, were observed in both solubility and turbidity depending on whether $ZnCl_2$ concentration (C_M) was larger or smaller than the critical concentration. In the slow pattern, the increase of the turbidity and the decrease of the solubility both occurred slowly and almost linearly with time. In the fast pattern, these changes occurred rapidly and stationary values were reached within 30 min for the turbidity and 2 h for the solubility. These two stationary values were found to be linearly related to each other. The stationary solubility decreased as C_M increased, while it increased with the total amount of the protein. The dissolution of the precipitates was very slow resulting in a practically irreversible precipitation. A gelation model was proposed to account for these characteristic features, according to which fibrinogen molecules were linked to each other through the 'bond' mediated by a zinc atom.

The interaction of zinc ions with human plasma proteins was studied by Cohn *et al.* in relation to their system for the separation of the components of human blood.[1] Complete flocculation of human γ-globulin occurred under the presence of $ZnSO_4$.[2] The binding constant of zinc ions to human serum albumin was shown to be close to that to imidazole.[3] Recently, gelation of bovine fibrinogen was found when various metal ions including Zn^{2+} were added.[4]

Recently, we have also found that the precipitation of human fibrinogen occurs on addition of various divalent metal chlorides.[5] Among them $ZnCl_2$ and $CuCl_2$ were most effective. The interaction of fibrinogen with $ZnCl_2$ or $CuCl_2$ was studied by circular dichroism and fluorescence. However, the mechanism of the precipitation was not clear at all.

In the present study, the precipitation of human fibrinogen by $ZnCl_2$ was examined at a fixed pH of 7.4 in 0.15 M NaCl (1 M=1 mol dm^{-3}), by the measurement of the solubility and by the kinetics of precipitation. The interaction of $CuCl_2$ with tris(hydroxymethyl)aminomethane (Tris) buffer, found previously,[5] prevents us from the measurement of the solubility in the $CuCl_2$–fibrinogen system. Consequently, the present study was carried out on the $ZnCl_2$–fibrinogen system.

The results on the solubility and the kinetics of precipitation obtained in the present study were rather unusual from the standpoint of a phase equilibrium or a coagulation of hydrophobic colloids. Therefore, a considerable amount of efforts is made in the present study to find a reasonable and simple model for a possible mechanism of the present precipitation.

Experimental

Fibrinogen (Kabi, grade L) was dissolved into 0.15 M NaCl and dialyzed against 0.15 M NaCl for 24—36 h and then freeze-dried. Tris and $ZnCl_2$ were purchased from Nakarai chemicals Co. Ltd. (Kyoto). The freeze-dried material was dissolved into the solvent [Tris–HCl 1.0×10^{-2} M (pH 7.4)+NaCl 0.15 M]. Final NaCl concentrations were not larger than 0.17 M even at the highest protein concentration. The protein concentration (g dm^{-3}) was calculated from the absorbance at 280 nm for 1 cm light path, Abs, as Abs/1.60. $ZnCl_2$ concentration (C_M) was expressed in M (mol dm^{-3}).

The protein concentration of the solution phase under phase separation was determined as follows. A given amount (0.01—0.1 cm^3) of $ZnCl_2$ solution was added to a protein solution (4 cm^3, 0.22—0.23 g dm^{-3}) in a glass tube. After a planned incubation period, the glass tube was put into a rotor and centrifuged at ca 1000 g for 20 min. Temperature was kept at 22±2 °C. Then, the absorbance of the supernatant was measured and the concentration was evaluated. The value was assigned to the time when the centrifugation was *started*. Identical results were obtained under different conditions: 500 g for 20 min or 1000 g for 50 min.

In the kinetics of the precipitation, the change of the turbidity was recorded automatically after the complete mixing was established within 1 or 2 s. The details of the mixing procedure will be described in the accompanying paper.[6]

Absorption spectra and turbidity were measured with a Shimadzu UV-200 S spectrophotometer using a cell of 1 cm light path.

Results

The Protein Concentration in Solution Phase. The protein concentration in the solution phase was measured by absorption at 280 nm after centrifugation at 1000 *g* for 20 min. Throughout the present study, the supernatant concentration is conventionally called as 'solubility', though it does not represent a solubility as defined by the phase rule as shown later. The total protein concentration, was 0.22—0.23 g dm^{-3}. The time course of the protein concentration in the solution phase was followed by applying the above procedure at different times after the addition of $ZnCl_2$. Two distinct patterns were found as shown in Fig. 1 depending on the $ZnCl_2$ concentration C_M. At $C_M=1.9\times10^{-5}$ M or lower, the protein concentration decreased slowly with time. This behavior is typical to the slow coagulation phase of hydrophobic colloids. At $C_M=4.5\times10^{-5}$ M or higher, the protein concentration decreased rapidly and reached a stationary value after about 2 h. This behavior also resembles the fast coagulation of hydrophobic colloids. However, the stationary concentrations were different for different 'coagulant' concentration C_M, as shown in Fig. 1, which cannot be properly explained based on the picture of the coagulation of hydrophobic colloids.

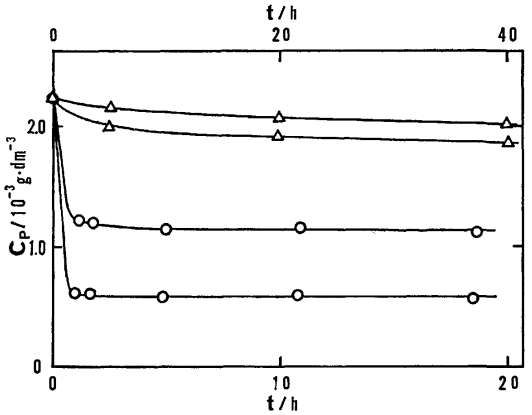

Fig. 1. Time course of the solubility.
$ZnCl_2$ concentrations(mol dm^{-3}) (from top to bottom): 9.02×10^{-6}, 1.80×10^{-5}, 4.49×10^{-5}, and 1.00×10^{-4}. Triangles refer to the upside abscissa.

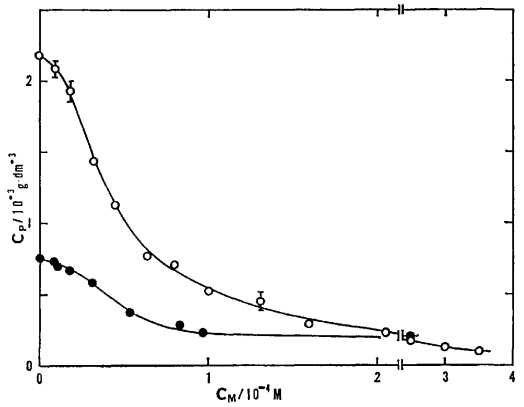

Fig. 2. Dependence of the stationary solubilities on $ZnCl_2$ concentration C_M.
The total protein concentrations (g dm^{-3}): 0.22 (○) and 0.077 (●).

The results in Fig. 1 suggest the presence of a kind of critical concentration in the range $(2—4)\times10^{-5}$ M. The rate of the concentration change of fibrinogen differed markedly depending on whether C_M was larger or smaller than the critical concentration.

In Fig. 2, the stationary values of the 'solubility' are plotted as functions of $ZnCl_2$ concentration C_M for two different total protein concentrations. The values at about 20 h were taken in place of the stationary values in the case of the low total protein concentration, at which the time course of the 'solubility' was not examined. The same approximate procedure was used for small values of C_M at which the protein concentration decreased slowly without exhibiting a stationary state. There are two characteristic features about the present precipitation as clearly shown in Fig. 2. The stationary values depend on $ZnCl_2$ concentration, as already noticed in Fig. 1. This dependence suggests that the chemical potential of $ZnCl_2$ plays an important role in the precipitation. It is likely, therefore, that the interaction of fibrinogen with Zn^{2+} ions leading to the precipitation is rather reversible. The other feature is that the stationary protein concentration depends not only on C_M but

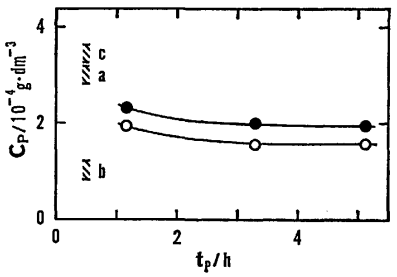

Fig. 3. Dependence of the solubility after dilution on the incubation time for precipitation t_p.
Measuring time of the solubility after dilution: 8 (○) and 20 (●) h. About three levels a, b, and c, see text.

also on the total amount of the protein. A simple phase equilibrium is hence ruled out, while phase equilibria of a multicomponent system can account for this dependence. In a study of bovine fibrinogen, the protein did not behave as a single component as defined by the phase rule.[7]

Irreversible Nature of the Precipitation. The following two kinds of experiments were carried out to examine the reversibility of the precipitation of fibrinogen by the addition of $ZnCl_2$.

Experiment A: A solution of $ZnCl_2$ was added to a protein solution (4 cm^3, 0.22 g dm^{-3}) to give a metal concentration of 1.70×10^{-4} M. Identical solutions were prepared in multiplicate. About one hour after the addition of $ZnCl_2$, one of the members was subject to centrifugation and the 'solubility' was determined as 0.030 g dm^{-3} (level a in Fig. 3), which was consistent with that given in Fig. 2. The other members of the solutions, which were not centrifuged, were diluted with 8 cm^3 of the solvent (containing no $ZnCl_2$) at the time about 70 or 200 or 310 min after the addition of $ZnCl_2$.

The 'solubilities' of these diluted solutions were measured at about 8 and 20 h after the dilution was made. If the precipitation is reversible, the expected 'solubility' can be read from the 'solubility curve' in Fig. 2 corresponding to the low total protein concentration (defined by filled circles) at $C_M=5.66\times10^{-5}$ M, which is about 0.035 g dm^{-3} (level c in Fig. 3). At about 8 h after the dilution (open circles), the 'solubility' was significantly larger than what would be expected for the completely irreversible situation (level b in Fig. 3). Undoubtedly, the precipitates can dissolve, even though slowly. The results as well as these expected values for the completely reversible and irreversible situations are indicated in Fig. 3. At about 20 h after the dilution (filled circles), the 'solubility' increased appreciably from that found at 8 h after the dilution (open circles). The increment of the 'solubility' was nearly independent of the *incubation time for the precipitation*. However, if compared at the same *incubation time for the dissolution*, the 'solubility' is larger if the *incubation time for the precipitation* is shorter. The dependence on the *incubation time for the precipitation* disappeared when it was longer than about 3 h. This dependence is closely related to the time course of the 'solubility' shown in Fig. 1.

In Fig. 3, the 'solubility' never reaches the value expected for the reversible situation (level c) even at 20 h after the dilution. Consequently, the present precipitation is rather irreversible in the sense that the rate of dissolution is very slow.

Experiment B: A small volume of $ZnCl_2$ solution was added to a protein solution (4 cm^3) of a concentration of 0.22 g dm^{-3} to make the metal concentration C_M to be 1.29×10^{-4} M. The 'solubility' was measured at about 5 h after the addition of $ZnCl_2$ to confirm the stationary value. The measured 'solubility' was 0.039 g dm^{-3}, consistent with the results in Fig. 2. Then 2 cm^3 of a protein solution (0.22 g dm^{-3}) containing no $ZnCl_2$ was added and kept for 8 and 20 h. The final metal concentration was the two thirds of the initial value, *i.e.*, 8.57×10^{-5} M. The 'solubilities' measured at 8 and 20 hours were nearly the same and 0.056 g dm^{-3}.

Consider the situation immediately after the above mixing. The protein concentration in the solution phase is 0.1 g dm^{-3} $(0.039\times2/3+0.22\times1/3)$. The 'solubility' expected at $C_M=1.29\times10^{-4}$ M for this total protein concentration is between the two 'solubility' curves in Fig. 2. If the solubility is assumed to be proportional to the total protein concentration, then the 'solubility' is 0.031 g dm^{-3}. On the other hand, the 'solubility' expected for a completely reversible situation is 0.063 g dm^{-3}: the 'solubility' at $C_M=8.57\times10^{-5}$ M for the total protein concentration of 0.22 g cm^{-3}. Since the observed 'solubility' (0.056 g dm^{-3}) was close to 0.063 g dm^{-3} rather than 0.031 g dm^{-3}, it is likely that the precipitation of newly added protein occurred under the control of the amount of the precipitates present in advance to the mixing.

In this experiment, the amount of the precipitates increased after mixing the two solutions. The time dependence of the 'solubility' was not found, therefore, between 8 and 20 h, in contrast to the case shown in Fig. 3, where the dissolution of the precipitates was followed.

A conclusion derived from Experiment A is an extremely slow rate of dissolution of the precipitates. On the other hand, Experiment B suggests that the 'solubility' is controlled by the amount of the precipitates, indicating a microscopic reversibility between the precipitates and the solution phase. The idea of the phase equilibria of a multicomponent system cannot reconcile one of these two results with the other.

Kinetics of Precipitation. The time courses of the turbidity are shown in Figs. 4(A) and (B) for the protein concentration of 0.22—0.23 g dm^{-3}: the same concentration as used in the study of solubility. At $C_M=2.97\times10^{-5}$ M, the turbidity increased linearly but only slightly. However, at $C_M=3.95\times10^{-5}$ M, a sigmoidal increase began to appear. Typical sigmoidal patterns were obtained at $C_M=4.92\times10^{-5}$ M[Fig. 4 (A)], 5.88 and 6.84×10^{-5} M[Fig. 4(B)]. At $C_M\approx(9.7—9.8)\times10^{-4}$ M, a sigmoidal shape could not be recognized any more, probably because the lag time was too short to be detected in the time scale of the present experiment.

The present kinetics can be summarized in the following two points. First, there is a critical $ZnCl_2$ concentration C_M*, below which the turbidity increases linearly but very slowly (slow phase) and above which it increases rapidly in a sigmoidal way (fast phase). The critical concentration was $(3—4)\times10^{-5}$ M for the protein concentration of 0.23 g dm^{-3}. In the second place, the turbidity reaches a stationary value after 25—30 min in the present kinetics as shown by horizontal bars in Fig. 4(A) if $C_M\geq C_M$*. The similar kinetic behavior was recently observed in the gelation of bovine fibrinogen by metal ions, where a stationary turbidity was reached after 2—3 min.[4] This kind of behavior has been rarely observed in the studies on the coagulation of colloids. Since the details of the kinetics of the present precipitation will be described in the following paper,[6] it is sufficient in the present study to point out the close relationship between the 'solubility' and the turbidity as shown below.

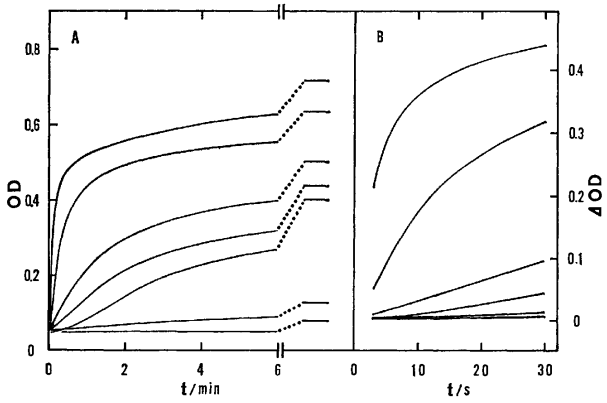

Fig. 4. Time courses of the turbidity at 350 nm. Protein concentration: 0.22—0.23 g dm^{-3}. $ZnCl_2$ concentrations(mol dm^{-3}) (from top to bottom): 1.88×10^{-4}, 9.68×10^{-5}, 6.84×10^{-5}, 5.88×10^{-5}, 4.92×10^{-5}, 3.95×10^{-5}, and 2.97×10^{-5}. In (B) $\Delta OD=OD(t)—OD(t=0)$ is given.

When the kinetic results shown in Figs. 4(A) and (B) are compared with the time course of the 'solubility' in Fig. 1, a good correspondence is found. At first, the critical $ZnCl_2$ concentration found in Fig. 1 lies between 2 and 4×10^{-5} M, which coincides with C_M* ($(3—4)\times10^{-5}$ M) found in the kinetics. When $C_M<C_M$*, both turbidity and 'solubility' change slowly with time in an approximately linear way. When $C_M\geq C_M$*, the turbidity increases and reaches a stationary value, as the 'solubility' decreases and reaches a stationary value. Accordingly, we can conclude that these two kinds of experiments are observing the same process but in terms of different quantities in different time ranges. We can reasonably assume that the change of the protein concentration occurred mostly within about 30 min if $C_M\geq C_M$*, as judged from the kinetic data.

To examine the correlation between the stationary turbidity and the stationary 'solubility', they are plotted against each other in Fig. 5. To construct this plot, the 'solubilities' at the $ZnCl_2$ concentrations where the kinetic measurements were carried out were read from a curve shown in Fig. 2. A good correlation is found between the two quantities as shown in Fig. 5. In other words, the turbidity in the present study

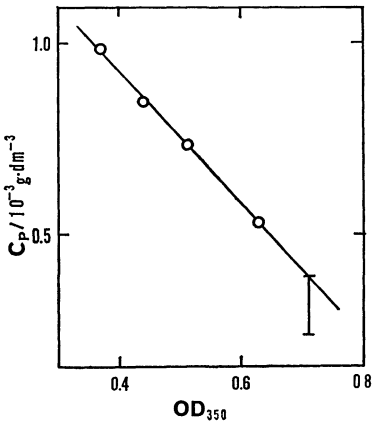

Fig. 5. Correlation between the stationary solubility C_p and the stationary turbidity at 350 nm.
The total protein concentration: 0.22—0.23 g dm^{-3}.

is approximately linearly related to the 'solubility'.

Summary of the Present Results. The 'solubility' behavior examined in the present study is considerably complex. It is pertinent, therefore, to summarize main results concerning a process characterizing the fast kinetic pattern. As to the slow pattern, we cannot make any discussion at present. The main results can be summarized into the four points.

(1) A critical $ZnCl_2$ concentration C_M* exists which defines different time courses of the 'solubility'.

(2) Stationary values of the 'solubility' exist and they decrease as $ZnCl_2$ concentration C_M increases.

(3) The 'solubility' increases with the total amount of the protein.

(4) The precipitates dissolve very slowly, so the precipitation is irreversible to a considerable extent.

The results (1)—(4) cannot be understood consistently by a phase equilibrium even the polydispersity is taken into account, since it fails to explain the irreversible nature. The coagulation of colloids cannot explain the dependence on the 'coagulant' concentration [result (2)], even though it is assumed that a thermodynamically stable fibrinogen solution is converted to a colloidal dispersion of kinetic stability by the addition of $ZnCl_2$.

If we regard the present precipitation as a kind of gelation, on the other hand, these results seem to be understood rather reasonably. The critical concentration is related to the gel point. The dependence of the solubility (proportional to the amount of the sol) on the total amount is consistent with gelation. Irreversible bond formation is also rather frequently encountered in gelation. On the other hand, it is difficult to explain the existence of a finite solubility still after the gelation is completed. However, the 'bond' between fibrinogen molecules is mediated by a zinc atom in the present case. Therefore, there is a room for models describing the coupling between the reversible binding of Zn^{2+} ions and the highly irreversible precipitation. An attempt will be given in the next section.

A Simplified Model. Gelation of Trifunctional Units: We will present a model with some assumptions, which can account for all the results (1)—(4) and for several

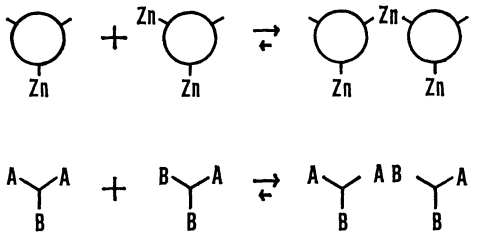

Fig. 6. Schematic representation of the model for gelation.
Free and bound sites on a fibrinogen molecule (represented as a circle) are denoted as A and B, respectively. The bond between two fibrinogen molecules is mediated by a zinc atom. In the model the bond is formed as a reaction between two 'functional groups' A and B.

kinetic results as well, although qualitatively.

Each fibrinogen molecule consists of a pair of three chains, $(A\alpha)_2(B\beta)_2\gamma_2$[8] and presumably carries a number of binding sites for Zn^{2+} ions of different affinities. The number of binding sites should be an even number because of the symmetric structure. However, a simple model of three equivalent binding sites is assumed here, hoping that the essential features of more realistic but more complicated models are fully retained in it (Assumption 1).

The binding equilibrium can be written in terms of free and occupied sites A and B (Assumption 2).

$$A + Zn^{2+} \overset{K}{\rightleftharpoons} B. \quad (1)$$

The association constant K is written in terms of site concentrations [A] and [B].

$$[B]/[A] = KC_M. \quad (2)$$

Here and throughout, free Zn^{2+} ion concentration is approximated to the total metal concentration C_M. At a given protein concentration, relative populations of four possible species A_3, A_2B, AB_2, and B_3 are 1: $2KC_M$: $2(KC_M)^2$: $(KC_M)^3$. As discussed later, values of KC_M in the present study are considered to be much smaller than unity. The contribution from species B_3 is therefore neglected in the following analysis. The binding equilibrium described by Eq. 1 is established instantly compared with the time scale of the present precipitation.

It is assumed that the reaction between site A and site B occurs after the binding equilibrium is established (Assumption 3). An example of the reaction leading to aggregation is schematically depicted in Fig. 6. For species A_2B or AB_2, this kind of association occurs with any other species as well as with themselves, while species A_3 or B_3 cannot associate with themselves. Flory has shown that the self-association of species A_2B or AB_2 cannot produce a gel, though three-dimensional branched polymers are formed.[9] Accordingly, any one of the four species alone cannot produce a gel.

Next, we examine the reactions in binary mixtures of A_3+A_2B or A_2B+AB_2. At low $ZnCl_2$ concentrations, the system can be well approximated to a binary mixture A_3+A_2B. In this mixture, association occurs between A_3 and A_2B as well as between two A_2B mole-

cules. However, gelation does not occur in this mixture. At larger $ZnCl_2$ concentrations where the population of AB_2 is significant, a ternary mixture has to be considered. Since an essential reaction leading to gelation occurs between A_2B and AB_2, we will examine, for simplicity, a binary mixture of A_2B and AB_2. We introduce the extent of reaction p_A (p_B) for a 'functional group' A(B), after the standard theory of gelation.[10] As shown in Appendix, a critical extent of reaction for gelation exists in this mixture. The range of gelation is given as follows.

$$\begin{aligned} &2(2-X_1)/(4+X_1) \ll P_A \ll 1, \text{ for } X_1 \leqq 0.5. \\ &2(1+X_1)/(5-X_1) \ll p_B \ll 1, \text{ for } X_1 \geqq 0.5. \end{aligned} \quad (3)$$

Here X_1 denotes the mole fraction of A_2B. Since $A_2B:AB_2 \simeq 1:KC_M$, and since KC_M is considered to be much smaller than unity, X_1 is supposed to be much larger than 0.5.

In Flory's model, the extent of reaction goes to unity as gelation is completed, since crosslinkings are allowed in gels (but not in soluble aggregates).[10,11] In this extreme case, no free B groups are present any more in gels, while free A groups are still present in gels since p_A is smaller than unity ($p_A=(2-X_1)/(1+X_1)<1$). In this situation, the 'solubility' is expected to be negligibly small.

According to Stockmayer's model, on the other hand, the extent of reaction does not exceed a certain limit, since no crosslinkings are allowed even in gels.[11] A finite solubility can be expected in this case. The limiting value of p_B is calculated in Appendix for the binary mixture A_2B+AB_2 and given as $(2-X_1)^{-1}$. This value is nearly equal to but always smaller than $2(1+X_1)/(5-X_1)$, the critical extent of reaction for $X_1 \geqq 0.5$. Since X_1 is expected to be much larger than 0.5, gelation cannot occur in the binary mixture A_2B+AB_2 if crosslinkings are forbidden in gels.

It is likely that the actual situation lies between these two extreme cases; the limiting value of p_B, $p_B(\infty)$, lies between $(2-X_1)^{-1}$ and unity. Consequently, we can expect that there are not a few free A and B groups in gels even when the gelation is completed ($t \to \infty$). Returning to the original ternary mixture, $A_3+A_2B+AB_2$, we find that a certain amount of soluble substances can exist in equilibrium with these free A and B groups in gels. In soluble fraction, these free A and B groups are present in species A_3, A_2B, and possibly in soluble aggregates. The 'solubility' is hence guaranteed if both free A and B groups are present in gels to a considerable amount even when the gelation is completed. In the above argument, we have to assume that the participation of species A_3 into gelation does not alter the essential features of the gelation of the binary mixture A_2B+AB_2 (Assumption 4).

The suggested 'solubility' is larger when $ZnCl_2$ concentration C_M is lower, if compared at the same protein content, as a consequence of the assumed mass action law:Eq. 2. Since the concentration of species A_3 increases with the total amount of the protein, the 'solubility' also increases with the latter. The critical concentration C_M^* can be identified with the gel point. From these considerations, it is clear that the present model can account for the results (1)—(3). One obvious way to account for result(4), the slow rate of dissolution of the precipitates, is to assume that the rate of dissolution is greatly reduced if crosslinkings occur in gels (Assumption 5). It is to be noted that the validity of the above arguments on the existence of the solubility and its dependence on C_M does not depend on the rate of dissolution of the precipitates.

In this way, the present model can explain the four main results by identifying the present precipitation with a gelation. Also, the time course of the turbidity can be understood based on the present model. Since the turbidity does not develop until the extent of reaction reaches a critical value for the gelation, a lag time will be observed in the kinetics.

Discussion

In the last section, we present a model to account for the present results on the precipitation of human fibrinogen with $ZnCl_2$. It is frequently inferred in deriving various properties of the model that the occupied fraction of binding sites for Zn^{2+} ions is very small. This point is discussed here.

As a rough estimation of the value of the association constant K defined as Eq. 2, we can take $1\times10^3\ M^{-1}$, since the association constant of imidazole with Zn^{2+} ions was about $6\times10^2\ M^{-1}$.[12] The range of KC_M in the present study is then below 0.2 (corresponding to $C_M=2\times10^{-4}$ M) or smaller. When KC_M is 0.1, the fractions of various species are 0.82(A_3), 0.16(A_2B), and 0.016(AB_2) and species B_3 can be safely neglected as assumed. Since X_1 can be roughly equated to the ratio $A_2B/(A_2B+AB_2)$, it is about 0.91. At $C_M=C_M^*$ ($\approx3\times10^{-5}$ M), $KC_M^*\approx3\times10^{-2}$ and $X_1\approx0.97$. Practically, gelation does not occur below C_M^*, for X_1 is nearly unity. It is found that the conditions used in the preceding section, $X_1 \gg 0.5$ and $KC_M \ll 1$, are reasonable.

It has been reported that fibrinogen is a heterogeneous mixture.[7,13-16] However, this point is not taken into account in developing the present model for the sake of simplicity. The introduction of the heterogeneity into the model does not violate its validity, since it only makes the model more versatile.

The most important feature of the present model resides in the respect that it can account for the finite solubility (dependent on $ZnCl_2$ concentration) in the situation that gelation is completed and is highly irreversible. However, the problem is treated only approximately in the present study. Moreover, the treatment is based on the classical theory of gelation, according to which the most probable distribution is considered for an infinitely large system and the mean field approximation is often used. Although the mean field approximation is criticized from the standpoint of the scaling theory,[17] and although the ensemble averages should be used in place of the most probable distribution as was recently carried out by computer simulation,[18,19] it is hoped that the present simple treatment gives an essentially correct picture of the present results.

Appendix

Gelation of a binary mixture of trifunctional units, A_2B and AB_2, is considered here based on the most probable distribution for an infinitely large system.

The mole fractions of A_2B and AB_2 are denoted as X_1 and X_2, respectively: $X_1+X_2=1$.

The extents of reaction of A and B groups are denoted as p_A and p_B. They are related to each other by Eq. A1.

$$p_A(1+X_1) = p_B(1+X_2). \tag{A1}$$

The expected number of units(irrespective of A_2B and AB_2) bound to A_2B is $2p_A+p_B$. Similarly, $2p_B+p_A$ is the expected number of units bound to AB_2. Gelation occurs when the expected numbers of units bound to both kinds of unit are equal to or larger than 2, *i.e.*,

$$2p_A + p_B \geqq 2, \tag{A2}$$

and

$$2p_B + p_A \geqq 2. \tag{A3}$$

Other obvious restrictions on p_A and p_B are

$$p_A \leqq 1 \text{ and } p_B \leqq 1. \tag{A4}$$

When these conditions are rearranged and coupled, we find that gelation occurs if the following conditions are satisfied.

$$\begin{aligned} &2(1+X_1)/(4+X_1) \leqq p_B \leqq (1+X_1)/(2-X_1) \text{ for } X_1 \leqq 0.5. \\ &2(1+X_1)/(5-X_1) \leqq p_B \leqq 1 \text{ for } X_1 \geqq 0.5. \end{aligned} \tag{A5}$$

Inequalities (A5) are given in the text as inequalities (3). For pure species, either $X_1=1$ (pure A_2B) or $X_1=0$ (pure AB_2), gelation occurs only at the end of reaction, either $p_B=1$ or $p_A=1$ ($p_B=0.5$) depending on whether X_1 is larger or smaller than 0.5. This is Flory's result.[9]

Next, the limiting extents of reaction of A and B groups when the gelation is completed are evaluated according to Stockmayer's model, in which no crosslinkings are allowed not only in soluble aggregates (as in most theories) but also in gels (contrary to Flory's model).[10,11] As a first step ($n=1$), only one unit, either A_2B or AB_2, is chosen. The number of unreacted A or B groups, $A_f(1)$ or $B_f(1)$, is given on the average as $A_f(1)=2X_1+X_2$ or $B_f(1)=2X_2+X_1$. The number of reacted groups, $A_b(1)$ or $B_b(1)$, is zero. As the second step ($n=2$), all three groups of a unit chosen in the first step are reacted to make a tetramer [$N(2)=4$]. As the third step ($n=3$), all the unreacted groups on the tetramer are reacted and an aggregate consisting of 10 units [$N(3)=10$] is produced. We define in this way $A_f(n)$, $B_f(n)$, $A_b(n)$, $B_b(n)$, and $N(n)$ as the numbers of A and B groups unreacted, reacted and the total number of units when the n-th step is finished.

The following recurrence formulas are obtained for $A_f(n)$ and $B_f(n)$.

$$\begin{aligned} A_f(n) &= (1+X_1)A_f(n-1) + X_1B_f(n-1), \\ B_f(n) &= (1+X_2)B_f(n-1) + X_2A_f(n-1). \end{aligned} \tag{A6}$$

$A_b(n)$, $B_b(n)$, and $N(n)$ are given as follows.

$$A_b(n) = B_b(n) = \sum_{i=1}^{n-1} [A_f(i)+B_f(i)] = 3(2^{n-1}-1). \tag{A7}$$

$$N(n) = 1 + 3(2^{n-1}-1). \tag{A8}$$

From these results, we obtain

$$\begin{aligned} p_A(n) &= 3(2^{n-1}-1)/[1+X_1+3(1+X_1)(2^{n-1}-1)]. \\ p_B(n) &= 3(2^{n-1}-1)/[1+X_2+3(1+X_2)(2^{n-1}-1)]. \end{aligned} \tag{A9}$$

In the limit that n goes to infinity,

$$p_A(\infty) = (1+X_1)^{-1} \text{ and } p_B(\infty) = (1+X_2)^{-1}. \tag{A10}$$

This result is given in the text.

Kinetics of the Precipitation of Human Fibrinogen by $ZnCl_2$ and $CuCl_2$

Takaaki KISHI, Hiroshi MAEDA,* and Shoichi IKEDA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received December 8, 1982)

Kinetics of the precipitation of human fibrinogen by the addition of $ZnCl_2$ was followed by the turbidity at 350 or 500 nm. Fast or slow precipitation occurred depending on whether the metal concentration (C_M) was higher or lower than its critical value. In fast precipitations, the turbidity reached the stationary value within about 30 min. From the stationary values of the turbidity the critical concentration could be determined. A sigmoidal increase of the turbidity was often observed at low protein concentrations (C_P); the lag time decreased with both C_M and C_P. At the final stage of the precipitation, the turbidity reached the stationary value exponentially; the characteristic time constant was almost independent of both C_M and C_P. These kinetic behaviors were consistent with the gelation model proposed to the present precipitation. When $CuCl_2$ was used in place of $ZnCl_2$, similar kinetic behaviors were obtained in many respects, suggesting the similar mechanism of precipitation for both $ZnCl_2$ and $CuCl_2$. Changes from slow to fast precipitation were observed when ionic strength was lowered.

In the preceding paper,[1] the precipitation of human fibrinogen was examined and the process was shown to be best understood as a kind of gelation where the extent of reaction did not exceed a limit even when gelation was completed. Also an interesting result was obtained in the study that the turbidity was linearly related to the 'solubility' of the protein.[1] Here and throughout the present study, the term solubility does not refer to a thermodynamic phase equilibrium but only represents the protein concentration in the supernatant. The time course of the turbidity can be interpreted as the time course of the solubility in the precipitation of human fibrinogen by $ZnCl_2$. This situation is different from that frequently encountered in the kinetics of coagulation of colloids, where the turbidity is a complex quantity and only its initial changes are used to extract information on the coagulation. In the present study, kinetics of precipitation of human fibrinogen was followed by the turbidity at different protein concentrations and at various $ZnCl_2$ or $CuCl_2$ concentrations.

The interaction of fibrinogen with $CuCl_2$ could not be studied in the previous study,[1] because the measurement of the solubility was hampered by the interaction of $CuCl_2$ with Tris buffer.[2] Since the absorbance at 350 or 500 nm is little affected by the interaction of $CuCl_2$ with Tris buffer, the effect of $CuCl_2$ on the precipitation of human fibrinogen can be studied in the present study by following the time course of the turbidity.

Experimental

Fibrinogen, $ZnCl_2$, $CuCl_2$, and Tris were the same as used in the previous studies.[1,2]

In the kinetics of precipitation, the mixing of $ZnCl_2$ (or $CuCl_2$) solutions was carried out by pushing down a plunger until it reached the bottom of a cell followed by pulling it up. The cell was placed in the light path of a spectrophotometer. In this way, 0.01 to 0.1 cm^3 of metal chloride solution in a basket attached to the end of a plunger could be mixed with a protein solution (3—4 cm^3) contained in a cell. The change of the absorbance (turbidity) was automatically recorded on a recorder (chart speed 0.2 cm/s). It took less than one second for this single down and up manual motion. The extent of uniform mixing was checked using a dye solution. It was found that about 99% of the final absorbance was obtained by a single down-up motion. It took less than 2 s for two successive motions, which gave a practically complete mixing. Absorption spectra and the turbidity were both measured with a Shimadzu UV-200 S spectrophotometer using a cell of 1 cm light path.

The protein concentration (g dm^{-3}) was determined as described in the preceding paper.[1] $ZnCl_2$ or $CuCl_2$ concentration was denoted as C_M and expressed in M (mol dm^{-3}).

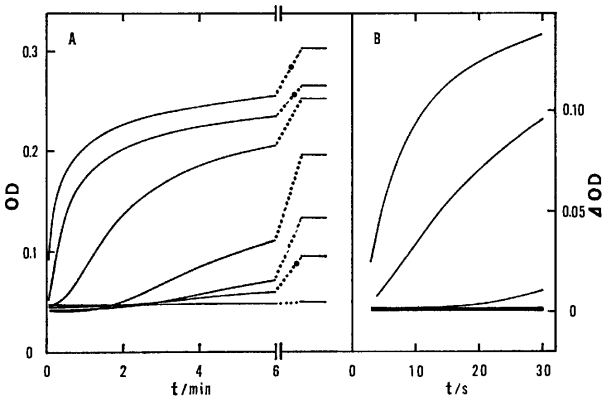

Fig. 1. Time courses of the turbidity at 350 nm at the protein concentration of 0.078 g dm^{-3}. $ZnCl_2$ concentrations (mol dm^{-3}) (from top to bottom): 3.75×10^{-4}, 1.88×10^{-4}, 9.68×10^{-5}, 7.79×10^{-5}, 6.84×10^{-5}, 4.92×10^{-5}, and 2.97×10^{-5}. In (B), ΔOD represents a change from the original level ($t=0$) at each $ZnCl_2$ concentration. Stationary values obtained at 25—30 min are indicated with horizontal bars in (A).

Results

I. $ZnCl_2$. Time Course of the Turbidity: The time course of the turbidity was followed at two protein concentrations, 0.078 and 0.93—0.94 g dm^{-3}. The data obtained at an intermediate concentration (0.23 g dm^{-3}) were given in the preceding paper.[1]

Characteristic time courses were most evident at the lowest protein concentration (0.078 g dm^{-3}) as shown in Figs. 1 (A) and (B). At a $ZnCl_2$ concentration (C_M) of 3.0×10^{-5} M, the turbidity increased slightly and linearly with time. At $C_M=4.9\times10^{-5}$ M, how-

$ZnCl_2$ concentrations (mol dm^{-3}) (from top to bottom): 1.88×10^{-4}, 9.68×10^{-5}, 7.79×10^{-5}, 6.84×10^{-5}, 5.88×10^{-5}, 4.92×10^{-5}, 2.97×10^{-5} and 1.99×10^{-5}. In (B), ΔOD represents a change from the original level ($t=0$) at each $ZnCl_2$ concentration. Stationary values obtained at 25—30 min are indicated with horizontal bars in (A).

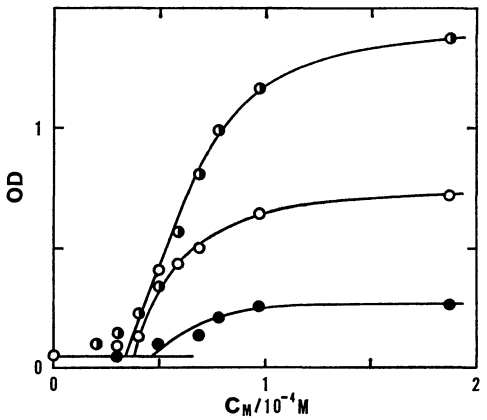

Fig. 3. Stationary turbidities as functions of $ZnCl_2$ concentration C_M.
Protein concentrations (g dm^{-3}): 0.93—0.94 (◑), 0.22—0.23 (○), and 0.078 (●). Wavelength: 350 nm (○,●) and 500 nm (◑).

ever, a sigmoidal shape began to appear; after a lag time the turbidity began to increase and reached a stationary value after 25—30 min.

Typical sigmoidal patterns were clearly observed for a range of $(6.8—9.7)\times10^{-5}$ M. At $ZnCl_2$ concentrations larger than 1.9×10^{-4} M, a sigmoidal shape could not be recognized any more in Fig. 1(A). However, when initial stages were closely examined, as shown in Fig. 1(B), then the presence of a lag time was noticed up to 3.8×10^{-4} M, since initial slopes at these concentrations (1.88 to 3.75×10^{-4} M) could not be extrapolated to zero time. Accordingly, the time course can be characterized by a sigmoidal increase when C_M is larger than about 5×10^{-5} M. In this concentration range, the lag time became shorter and the turbidity in the second phase became larger as C_M increased.

At the intermediate protein concentration (0.23 g dm^{-3}), essentially the same kinetic behavior was observed, which was already reported in the preceding paper.[1]

At the largest protein concentration (0.93—0.94 g dm^{-3}), the turbidity at 500 nm was followed. Sigmoidal changes were not observed except at $C_M=2.97\times10^{-5}$ M, as shown in Figs. 2(A) and (B). However, we assume that the kinetics follow the sigmoidal pattern and that the lag time is only too short to be detected in the time scale of the present experiment. It is to be noted in Fig. 2(A) that the turbidity increases only slightly but rather linearly with time at $C_M=1.99\times10^{-5}$ M. A slow phase was thus present even at this high protein concentration. This clearly indicates that the slow phase is not identical to the first step of the sigmoidal pattern but it is a different process other than the fast phase.

*The Critical $ZnCl_2$ Concentration C_M**: As shown in Figs. 1 and 2 and as suggested in the preceding paper, a critical $ZnCl_2$ concentration C_M* can be defined from kinetics, above which the turbidity increases rapidly but in a sigmoidal shape and reaches a stationary value. To evaluate the critical concentration more accurately, the stationary values of the turbidity are plotted against C_M for three protein concentrations in Fig. 3. The data at the intermediate concentration were taken from the preceding paper.[1] When the stationary turbidities obtained from the fast phase are extrapolated to the original level (protein solution in the absence of $ZnCl_2$), the value of abscissa corresponds to C_M*. The values are $(4—5)\times10^{-5}$ M ($(3—5)\times10^{-5}$ M), $(3.5—4.0)\times10^{-5}$ M ($(3—4)\times10^{-5}$ M), and $(2.5—3.5)\times10^{-5}$ M ($(2—3)\times10^{-5}$ M), for the protein concentrations of 0.078, 0.23 and 0.92—0.94 g dm^{-3}, respectively. The values in parentheses are those estimated from a change of the kinetic patterns (from a slow to a fast pattern).

In a previous study, critical concentrations were determined by turbidimetric titrations.[2] At a protein concentration of about 1.1 g dm^{-3}, C_M* was reported as about 4×10^{-5} M for $ZnCl_2$ at pH 7.4,[2] which approximately coincides with C_M* determined in the present study for the concentration of 0.94 g dm^{-3}. Accordingly, it is shown that the critical concentrations were adequately assessed in the previous study.[2]

Lag Times for the Turbidity: In Fig. 4, lag times obtained at different protein concentrations are shown in a logarithmic scale against $ZnCl_2$ concentration C_M. The kinetic data exhibiting no sigmoidal pattern were interpreted as having lag times smaller than 1 s, and represented on a horizontal line below 1 s in Fig. 4.

At the protein concentration of 0.078 g dm^{-3}, lag times could be determined directly from the kinetic patterns if $C_M<1\times10^{-4}$ M. For $C_M>1\times10^{-4}$ M, the lag times were determined as follows. The kinetic data given in Fig. 1(A) were plotted according to the first-order kinetics. A good linearity resulted between log(amplitude) and the time not only at a later stage of the reaction, which will be discussed in a later section, but also at some initial stage. Here the amplitude of the reaction is defined as [OD(∞)—OD(t)]. However, when the linear relation at the

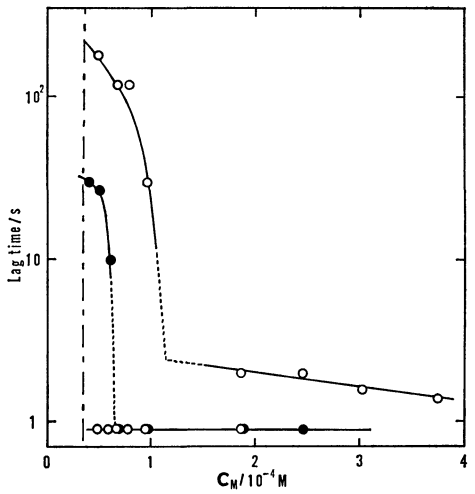

Fig. 4. Dependence of the lag time for the turbidity on $ZnCl_2$ concentration C_M.
Protein concentrations (g dm^{-3}): 0.93—0.94(○, on the lowest horizontal line), 0.22—0.23 (●), 0.078 (○). The points on the lowest horizontal line only represent that lag times are less than 1 second. A vertical chain line indicates the approximate location of the critical $ZnCl_2$ concentration C_M* (for details see text).

initial stage was extrapolated up to the total amplitude [OD(∞)−OD(0)], the time at the intersection was larger than zero and it was taken as the lag time.

The lag time decreases with an increasing C_M at a given protein concentration; fairly sharply at low $ZnCl_2$ concentrations and afterwards it becomes almost independent on C_M. The 'transition range' of C_M undoubtedly decreases as the protein concentration decreases. At a protein concentration of 0.93—0.94 g dm^{-3}, the range is probably lower than the critical concentration C_M*; the precipitation switches from the slow to the fast phase when C_M exceeds C_M*, nevertheless lag times are not observed since they are too short to be measured. The dependence of lag times on C_M will be discussed later, where another interpretation of the dependence will be presented. According to the interpretation, the lag times decrease with C_M rather continuously instead of changing in a sharp 'transition' manner.

Initial Rates of the Precipitation: Generally, initial rates of the coagulation of colloids are plotted against the coagulant concentration in a double logarithmic way to find a critical concentration, at which a slow coagulation changes into a fast one. The same procedure is applied to the present kinetic data. When sigmoidal patterns appeared, initial rates were obtained from the slope of the second step.[3] For the concentrations lower than C_M*, initial rates were evaluated as [OD(t)−OD(0)]/t, where t was taken as 20—30 min.

In Fig. 5, these initial rates are plotted against C_M for three protein concentrations in a double logarithmic way. Unexpectedly, similar results are seen as found in the coagulation of colloids. At each protein concentration, the logarithm of the initial rate linearly increases with log C_M and then reaches a constant level, thus defining a break. It may be argued that the concentration at the break would represent a critical concentration between a slow and a fast coagulation. However, the critical concentration in this sense is given by C_M* in the present case. It is to be noted that there is no break around C_M* in Fig. 5. At the lowest protein concentration (curve c), another break occurs around log $C_M \approx -4$. At the concentration lower than this point, typical patterns were observed as shown in Figs. 1(A) and (B).

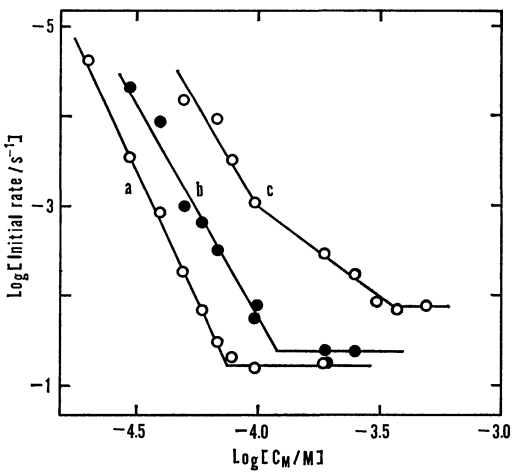

Fig. 5. Log $[dOD/dt]_{t=0}$ against log C_M for the precipitation of fibrinogen with $ZnCl_2$.
Protein concentrations (g dm^{-3}): (a) 0.93—0.94, (b) 0.22—0.23, (c) 0.078. Optical density: 350 nm (b and c) and 500 nm (a).

It is not fully understood, at present, why the initial rates of the present precipitation formally resemble those of the coagulation of colloids. This point will be discussed later.

Final Stage of the Precipitation: It is stressed in the introduction part that the kinetics of the present precipitation is closely related to that of the solubility. Therefore, the whole time course of the turbidity can, potentially, provide useful information of the present precipitation. However, it is too complicated to be analyzed properly, at present. In the preceding two sections, the initial stage of the kinetics is examined; the lag times and the initial rates.

It was found that the final stage of the present kinetics, shown in Figs. 1 and 2, could be described in terms of a single exponential function of time. Therefore, the amplitude $A(t)$, which is equal to [OD(∞)−OD(t)], can be expressed as Eq. 1.

$$A(t) = A_0(t) + A_1 \exp(-t/\tau) \quad (1)$$

The contribution from the term $A_0(t)$ generally becomes negligible about 3—4 and 6—8 min after the addition of $ZnCl_2$, at low and high $ZnCl_2$ concentrations. Consequently, a fraction larger than 3/4 of the entire time region can be described in terms of a single exponential at all C_M (if $C_M > C_M$*) and protein concentrations examined. The relative contribution from the exponential term, A_1/A_t, is shown in Fig. 6(A) as functions of C_M at three protein concentrations. The total amplitude A_t is defined as $A_0(0)+A_1$.

At a low protein concentration of 0.08 g dm^{-3}, the

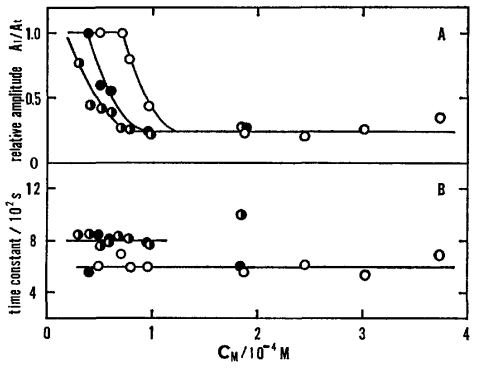

Fig. 6. Relative kinetic amplitude (A_1/A_t) (A) and the characteristic time constant (B) of the final stage of the precipitation as functions of $ZnCl_2$ concentration C_M.
Protein concentrations (g dm^{-3}): 0.93—0.94 (◑), 0.22—0.23 (●), and 0.078 (○).

ratio A_1/A_t is unity if $C_M \lesssim 7\times10^{-5}$ M. Under this condition, the entire time course can be represented by Eq. 2 using a lag time t_o,

$$A(t) = A_1 \exp(-(t-t_o)/\tau) \quad (t \geqq t_o). \tag{2}$$

When C_M becomes larger than 7×10^{-5} M, the relative contribution of the exponential term A_1/A_t becomes smaller than unity and decreases further as C_M increases and reaches as low as 0.2 at large C_M values. In other words, the contribution from other fast processes is dominant for C_M larger than 1×10^{-4} M. As the protein concentration increases, the contribution from the fast processes becomes significant even at lower C_M values as shown in Fig. 6(A).

The time constant τ characterizing the final exponential change is independent of C_M and only slightly dependent on the protein concentration as shown in Fig. 6(B). At the final stage of precipitation, it is likely that the growth of gel occurs as a unimolecular reaction with respect to a monomer protein (P) in solution.

$$\text{P} + \text{gel}(n\text{-mer}) \xrightarrow{k} \text{gel}[(n+1)\text{-mer}]$$
$$\text{d(P)/d}t = -k\text{(P)}, \quad \text{(P)} = \text{(P)}_o \exp(-kt). \tag{3}$$

It is quite reasonable, then, that this rate constant k, which is the reciprocal of τ, is independent of both C_M and protein concentration under the present condition of excess Zn^{2+} ions.

II. $CuCl_2$. The time courses of the turbidity were also measured in the case of $CuCl_2$ at three protein concentrations: about 0.045, 0.23—0.26, and 0.94 g dm^{-3}. Two different kinetic patterns, fast and slow, were also found in the case of $CuCl_2$ depending on whether $CuCl_2$ concentration (C_M) was larger or smaller than the critical value C_M*. Generally, kinetic behavior was similar to that found in the case of $ZnCl_2$. These results suggest that the essential mechanism for the fast precipitation is also common to both cases, $ZnCl_2$ and $CuCl_2$.

The critical concentrations obtained from the kinetic studies were: $(3—3.5)\times10^{-4}$ M ($(3—3.9)\times10^{-4}$ M), $(1.8—2.0)\times10^{-4}$ M ($(1.3—1.8)\times10^{-4}$ M), and $(1—1.5)\times10^{-4}$ M ($(1—2)\times10^{-4}$ M) for the protein concentrations of 0.045, 0.23, and 0.94 g dm^{-3}, respectively. The values in parentheses were estimated from the change of kinetic patterns.

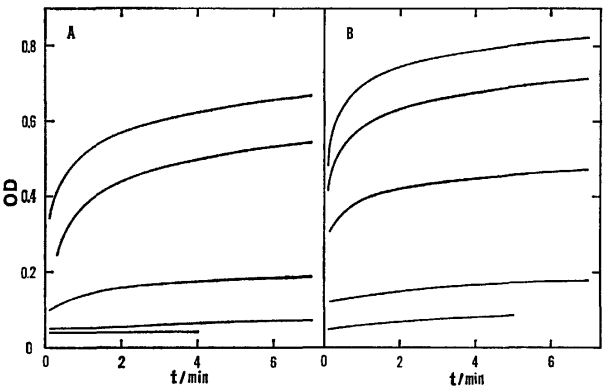

Fig. 7. Effects of ionic strength on the kinetics of precipitation in the case of $CuCl_2$.
NaCl concentrations (mol dm^{-3}): 0.15 (A) and 0.015 (B). Protein concentrations (g dm^{-3}): 0.23 (A) and 0.26 (B). $CuCl_2$ concentrations (mol dm^{-3}) (from top to bottom): (A) 3.87×10^{-4}, 3.78×10^{-4}, 2.76×10^{-4}, 1.82×10^{-4}, and 1.25×10^{-4}. (B) 2.86×10^{-4}, 2.35×10^{-4}, 1.82×10^{-4}, 1.25×10^{-4}, 6.45×10^{-5}.

In the case of $CuCl_2$, the effect of ionic strength was also examined at the protein concentration of about 0.23—0.26 g dm^{-3}.

The kinetic data obtained at 0.15 and 0.015 M NaCl are presented in Figs. 7 (A) and (B), respectively. At 0.015 M NaCl, a fast pattern was already observed even at $C_M = 6.5\times10^{-5}$ M. The critical concentration was thus reduced considerably as ionic strength decreased. This result is consistent with the previous finding[2]. The critical concentration at 0.015 M NaCl was estimated as about $(0.5—1.0)\times10^{-4}$ M from the stationary values of the turbidity.

Discussion

Lag Time for the Turbidity. In the preceding paper, a gelation model was proposed to account for the characteristic features of the present precipitation. The validity of the proposed model is further confirmed in the present kinetic study, since sigmoidal increase of the turbidity is best understood as representing a gelling process. The lag time for the turbidity is no more than the time interval before the extent of reaction reaches the gel point.

According to the classical kinetics of gelation,[4-6] the lag time t_o is given by Eq. 4[4] for the gelation of N units having f identical functional groups ('homogelation').

$$t_o = [f(f-2)Nk]^{-1}. \tag{4}$$

Here k denotes the association rate constant, which is not necessarily identical to the rate constant introduced in Eq. 3.

In the present model, gelation among various species has to be considered, such as A_x, $A_{x-1}B$, $A_{x-2}B_2$, and so on. Here x denotes the total number of binding sites per fibrinogen, which was tentatively assumed as three in the preceding paper.[1] The interconversion

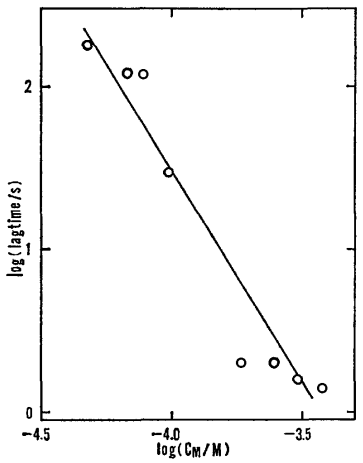

Fig. 8. A double lagarithmic plot of the dependence of the lag time on $ZnCl_2$ concentration C_M. Protein concentration: 0.078 g dm^{-3}.

among these species occurs through the binding equilibria with Zn^{2+} ions. Moreover, the 'bond' is formed only between A and B groups. Therefore, Eq. 4 cannot be applied to the present model in a strict sense. Instead of following the exact kinetic equations relevant to the present model, only a brief discussion is presented here to help understanding the obtained results on the lag time.

The number of units N in Eq. 4 may be approximately equated to the number of various species other than A_x (no zinc ions are bound to it), which is given as

$$N \approx N_p KC_M(1-KC_M)^{-1}. \quad (5)$$

Here N_p denotes the total number of fibrinogen molecules in solution. If species A_x considerably contributes to the aggregation, then we have to set $N \approx N_p$. Generally, we may write $N \approx N_p(KC_M)^{a'}$, where a' varies between 0 and 1. Since KC_M is much smaller than unity as examined in the preceding paper[1], the number of B groups is much smaller than that of A groups. Consequently, the number of 'functional groups' f in Eq. 4 is roughly proportional to KC_M x. Because $KC_M \ll 1$, the term $(f-2)$ in Eq. 4 exhibits a complex dependence on C_M. However, for the moment, we are allowed to write as follows with another parameter a.

$$t_0 \approx N_p^{-1}(KC_M)^{-(2+a)} \quad (0 \leqq a \leqq 1). \quad (6)$$

At a constant protein concentration, *i. e.*, at a constant N_p, Eq. 6 predicts that log(lag time) varies linearly with log C_M with a slope between -2 and -3. The data at the lowest protein concentration (0.08 g dm^{-3}) shown in Fig. 4 are replotted in a double logarithmic way in Fig. 8. An approximately linear relation holds with a slope of about -2.6, consistent with Eq. 6. Unfortunately, the validity of Eq. 6 at higher protein concentrations cannot be examined, since lag times could not be obtained for a wide range of C_M.

Initial Rates of the Precipitation. It is suggested in the preceding paper that the present precipitation is a kind of gelation.[1] Nevertheless, the initial rates of the present precipitation apparently exhibit typical dependence on the 'coagulant' concentration C_M. Although the implication of this unexpected result is not fully understood, the following consideration provides an interpretation of the result.

When Figs. 3 and 5 are compared, it is found that both concentration dependences are very similar. A close relation between the initial rate and the kinetic amplitude (the stationary turbidity) can be shown in the simplest manner, if the turbidity $A(t)$ can be expressed in a single exponential form.

$$A(t) = A_0 \exp(-t/\tau) \quad (7)$$

Then the initial rate $[-(dA/dt)_{t=0}]$ is given as A_0/τ. In this assumed situation, the logarithm of the initial rate is related to log A_0 and log τ. Accordingly, it can happen that the dependence of the initial rates on C_M is totally ascribed to the dependence of the kinetic amplitude A_0 on C_M. Consequently, if the initial stages of the present precipitation can be described by Eq. 7, with a proper τ, then the results shown in Fig. 5 can be understood as essentially identical to those given in Fig. 3.

We thank Professor M. Tagawa, Nara Women's University, for her kind advice in the construction of the mixing device.

The Low Lying Electronic States of Dichloromaleic Anhydride

Yoshimi Ishibashi, Ryoichi Shimada,† and Hiroko Shimada*

Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma, Jonan-ku, Fukuoka 814

† *Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812*

(Received December 18, 1982)

The polarized Raman and infrared spectra of dichloromaleic anhydride were studied and the assignments of the normal vibrations were reinvestigated based on the polarization behaviors of the spectral bands and on the normal coordinate calculation. Using the assignments the vibrational structure of the phosphorescence spectrum was analyzed and the phosphorescence lifetime was also measured. These results indicate that the lowest triplet state of this molecule is a $^3(\pi, \pi^*)$ state perturbed by closely located $^3(n, \pi^*)$ states. The near ultraviolet absorption and phosphorescence excitation spectra were measured and four absorption bands due to $^3(n, \pi^*)\leftarrow {}^1A_1$, $^1A_2(n, \pi^*)\leftarrow {}^1A_1$, $^1B_1(n, \pi^*)\leftarrow {}^1A_1$, and $^1A_1(\pi, \pi^*)\leftarrow {}^1A_1$ transitions were found. The polarization experiment made on the $^1A_2(n, \pi^*)\leftarrow {}^1A_1$ absorption suggests that this transition borrows the intensity from the $^1A_1(\pi, \pi^*)\leftarrow {}^1A_1$ transition.

The assignments of the normal vibrations of dichloromaleic anhydride were first made by Rogstad *et al.*[1] based on the infrared vapor contours, the depolarization measurement of the Raman bands and the normal coordinate calculation. Their assignments given for the non-totally symmetric vibrations seem to be unreliable because the assignments were not made based on the enough experimental evidences and the reasonable vibrational analysis of the phosphorescence spectrum could not be made using their assignments.

The near ultraviolet absorption spectra and phosphorescence lifetimes of maleic anhydride and its halo derivatives were first studied by Scharf and Leismann.[2] They suggested that the lowest singlet and triplet states of dichloromaleic anhydride are to be a $^1(n, \pi^*)$ and a mixed state of $^3(n, \pi^*)$ and $^3(\pi, \pi^*)$ configurations, respectively. Detailed studies for the electronic states of these molecules have not been made yet.

In this work, the assignments of the normal vibrations of dichloromaleic anhydride are reexamined on the basis of the polarization behaviors of the Raman and infrared spectra and the assignments given for several bands by previous workers are corrected. The low lying excited singlet and triplet states of this molecule are studied in detail through the vibrational analyses of the phosphorescence and phosphorescence excitation spectra and also the polarized near ultraviolet absorption spectrum.

Experimental

Material. Dichloromaleic anhydride obtained from Aldrich Company was purified by zone-refining of about 100 passages followed by sublimation under reduced pressure. Cyclohexane of Dotite Spectrosol grade was purified by passing through the activated silica gel and alumina columns.

Optical Measurement. The Raman spectrum was observed in the liquid and single crystal phases with a JEOL 400 T Laser Raman Spectrophotometer. The sample was excited with the 514.5 nm beam from an Ar^+ ion laser. The single crystal was obtained in the following way. The sample was sealed in a evacuated closed glass tube. Temperature of one side of the tube, where the sample was placed, was kept a little higher than the other side. Crystals grown in the tube were collected. The well grown and approximately rectangular shaped single crystal was selected with a polarization microscope and used for the observation of the polarized Raman spectrum. Although the crystal structure of dichloromaleic anhydride was not determined yet, the directions of the crystal growth and the two-fold symmetry axis of the crystal were found to be the crystal axes by observation of the birefringence under the polarization microscope. These axes were tentatively taken to be the c and b axes, respectively. The a axis was taken to be perpendicular to both the b and c axes. The method of the measurement of the polarized Raman spectrum was exactly the same as that described previously.[3]

The infrared spectrum was observed with a Hitachi Infrared Spectrophotometer Model 345 over the range of 4000—250 cm^{-1} in the vapor and single crystal phases. The vapor spectrum was observed at 50 °C with a gas cell of 10 cm in optical path. The polarized infrared spectrum of a single crystal grown between two KRS-5 plates was measured with an AgBr wire-grid polarizer by the method described in the previous paper.[4] The infrared spectrum of the thin film obtained by sublimation was also observed.

The phosphorescence lifetime and the time resolved phosphorescence spectrum were measured in cyclohexane at 1.4 K using the optical setup described in the previous paper.[5] The short lifetime phosphorescence was observed in the following way. The sample was excited for 40 ms and the excitation was cut off. 1 ms after ceasing the excitation, the phosphorescence was sampled for 40 ms. The longer lifetime phosphorescence was observed with the exciting, waiting and sampling times of 120, 360, and 120 ms, respectively.

The excitation spectrum was observed in cyclohexane at 77 K monitoring the intensity of the phosphorescence 0-0 band with the excitation light source of a 500 W Xenon arc lamp of Ushio UXL-500D. The near ultraviolet absorption spectrum was observed in cyclohexane and in the thin film at room temperature and at 77 K with a Hitachi Ultraviolet Spectrophotometer Model 323 over the range of 500—210 nm. The polarized ultraviolet absorption spectrum was also measured with the single crystal grown between two quartz plates over the range of 350—315 nm.

Normal Coordinate Calculation

A normal coordinate calculation was performed through the standard GF matrix method with FACOM M-200 computer at the computer center of Kyushu University. Hilderbrandt *et al.*[6] showed that the mo-

Force constants are given in aJ/rad² (=mdyn Å/rad²) units.

lecular structure of maleic anhydride belongs to the point group C_{2v} and gave the geometric parameters for the molecular structure. We assumed that the molecular geometry of dichloromaleic anhydride was the same as that of maleic anhydride except for the C–Cl bond, whose distance was assumed to be 0.177 nm.

The F matrix elements for the in-plane and out-of-plane vibrations were evaluated with the potential fields of an improved modification of the Urey-Bradley force field and the valence force field, respectively, as used for the calculation made on maleic anhydride.[3]

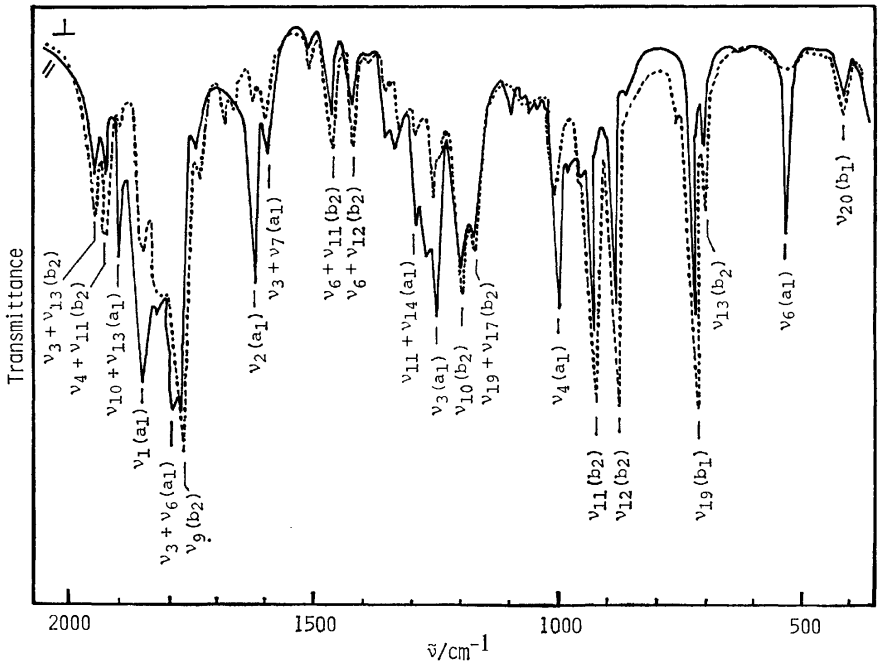

Fig. 2. Polarized infrared spectrum of the dichloromaleic anhydride single crystal.

The notations of the force constants are exactly the same as those given in the previous calculation.[3]

Results and Discussion

Normal Vibration. The force constants finally obtained after several iterative normal coordinate calculations for the in-plane and out-of-plane vibrations are given in Tables 1 and 2, respectively. The calculated frequencies and vibrational modes are given in Table 3, together with the experimentally assigned vibrational frequencies.

The polarized Raman spectrum is shown in Fig. 1. The spectrum was denoted by two symbols such as ab. The first letter refers to the direction of the polarization of the excitation light and the second to that of the scattering light. The non-totally symmetric Raman bands were divided into three types of polarization behavior according to the relative intensities of the bands in the polarized spectrum. The intensities of the bands belonging to the first type are much stronger in the ab and bc spectra than those in other spectra. The intensities of the second type bands are much stronger in the aa and cc spectra than those in other spectra, and the third type bands can be observed only in the bc spectrum with appreciable intensity.

The polarized infrared spectrum observed in the single crystal is shown in Fig. 2. The spectra measured with the incident lights polarized parallel and perpendicular to the crystal growth direction are referred to as // and ⊥ spectra and drawn with the solid and dotted lines, respectively. The polarized infrared bands can be divided into two types according to their polarization behaviors. The bands belonging to the first type appear strongly in the // spectrum and extremely weakly in the ⊥ spectrum. The bands belonging to the second type appear strongly in the ⊥ spectrum and weakly in the // spectrum. These two types of the bands are denoted as types I and II, respectively. Rogstad *et al.*[1] indicated that the infrared vapor bands belonging to the a_1, b_1, and b_2 symmetry species show the B, C, and A band envelopes, respectively, from the calculated values of the moments of inertia, where the z axis was taken to be along the C_2 symmetry axis and the x axis to be perpendicular to the molecular plane.

The assignments of the normal vibrations belonging to each symmetry species were made based on the following observations.

a_1 Species: The polarized bands in the depolarization measurement of the Raman spectrum can be definitely assigned to the a_1 vibrations. The infrared crystal bands showing the type I polarization behavior are also to be assigned to the a_1 bands, since the corresponding infrared vapor bands showed the B band envelope and the frequencies coincide with those of the Raman a_1 bands.

b_2 Species: The b_2 bands showing the A band envelope in the infrared vapor spectrum showed the type II polarization behavior in the infrared crystal spectrum. The corresponding Raman bands were observed strongly in the ab and bc polarized Raman spectra.

b_1 Species: The b_1 bands showing the C band envelope in the infrared vapor spectrum showed the type II polarization behavior in the infrared crystal spectrum. The corresponding Raman bands were observed only in the bc polarized Raman spectrum with appreciable intensity.

a_2 Species: The crystal Raman bands showing the aa and cc polarization behavior should be assigned to the a_2 vibration, because other two polarization behaviors of the Raman bands were already ascribed

to the b_2 and b_1 vibrations, and no corresponding bands were observed in the infrared spectrum.

The normal vibration thus determined are given in Table 3 and also shown in Figs. 1 and 2. The assignments for the a_1 vibrations given in this work exactly agree with those given by Rogstad *et al.*[1] This is quite natural because the a_1 vibrations were straightforwardly determined based on the depolarization measurement of the Raman bands. On the other hand, our assignments given for the non-totally symmetric vibrations were somewhat different from those given by them as can be seen in Table 3. Rogstad *et al.*[1] gave the assignments based on the band envelope in the infrared vapor spectrum, where only four band envelopes could be observed. In our work, the assignments were made based on the polarization behaviors of the Raman and infrared bands and also on the band envelope in the infrared vapor spectrum, where eleven band envelopes were observed. Therefore, we believe that our assignments are to be more reliable than those given by Rogstad *et al.*

Phosphorescence Spectrum. Dichloromaleic anhydride emits a weak yellow phosphorescence in cyclohexane matrix. Scharf and Leismann[2] measured the phosphorescence lifetime in mixed solvents of methylcyclohexane and isopentane, and of ethanol and isopentane at 77 K and got the lifetimes of 13.9 and 75 ms, respectively. We analyzed the phosphorescence decays observed in cyclohexane at 1.4 K with changing the exciting, waiting and sampling times of the phosphorescence and obtained the lifetimes of 62 and about 300 ms. The third lifetime component could not be precisely measured due to its extremely weak intensity. The decay analysis showed that the third lifetime is longer than 1500 ms. These values of the lifetime would be reasonable because the lifetime observed in cyclohexane at 77 K was 150 ms. We also traced the measurement made by Scharf and Leismann, but we could not reproduce their results.

The time resolved phosphorescence spectrum is shown in Fig. 3. The vibrational analysis of the short lifetime phosphorescence spectrum will be discussed first. The strongest and shortest wavelength band observed at 477.88 nm was taken as the 0-0 band. Very strong bands separated by 639 and 1621 cm^{-1} from the 0-0 band were assigned to the ring deformation (ν_5) and C=C stretching (ν_2) vibrations, respectively. These bands constitute the main progressions. Medium intense bands separated by 180, 1008, 1245, and 1881 cm^{-1} from the 0-0 band were assigned to the Cl bending (ν_8), C–C stretching (ν_4), and C–O stretching (ν_3), and C=O stretching (ν_1) vibrations, respectively. These bands belong to the totally symmetric species. A medium intense band separated by 420 cm^{-1} from the 0-0 band was assigned to the C=O wagging (ν_{20}) vibration of the b_1 symmetry species. Medium intense bands separated by 453 and 585 cm^{-1} were assigned to the C=O wagging (ν_{17}) and ring deformation (ν_{16}) vibrations of the a_2 species, respectively. Detailed vibrational analysis is given in Fig. 3.

The middle lifetime phosphorescence spectrum could not be successfully measured because of its very weak intensity. The intensity ratio of the 0-0 bands of the middle and short lifetime phosphorescence spectra was

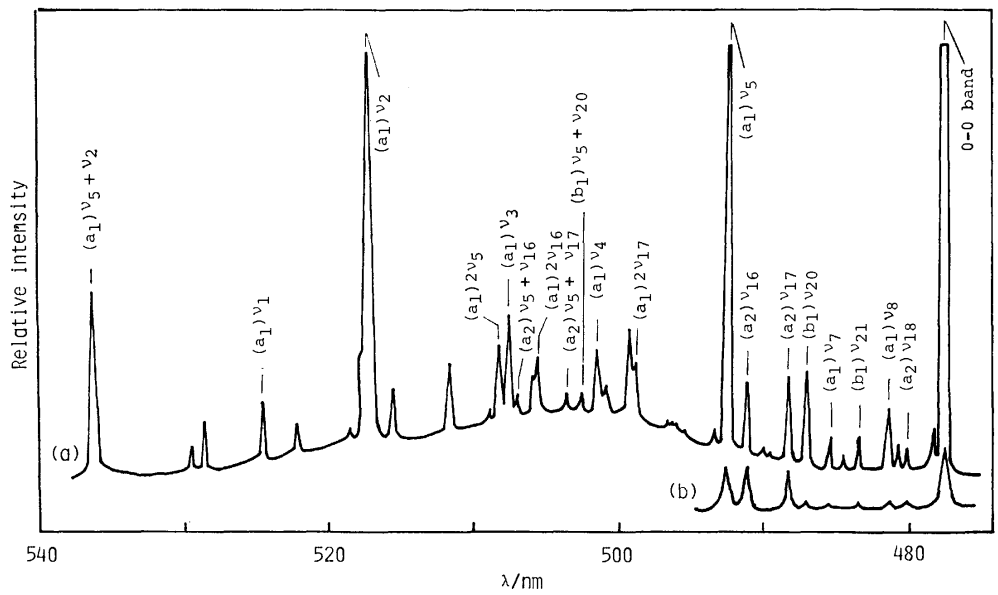

Fig. 3. Phosphorescence spectrum of dichloromaleic anhydride in cyclohexane at 1.4 K. The exciting, waiting, and sampling times of the phosphorescence are (a): 40, 1, 40 ms, (b): 120, 360, and 120 ms, respectively.

measured to be less than 1/100. The most characteristic spectral feature of the middle lifetime phosphorescence is that the relative intensities of the bands assigned to the Cl wagging (ν_{18}), C=O wagging (ν_{17}), and ring deformation (ν_{16}) vibrations of the a_2 species to the intensity of the 0-0 band remarkably increased compared with those of the short lifetime phosphorescence.

A weak phosphorescence excitation spectrum was observed in the 450 nm region in cyclohexane at 77 K, but no spectrum could be observed in the 470 nm region. A extremely weak absorption spectrum was also observed in the 450 nm region with the f-value of about 1×10^{-7} in cyclohexane at room temperature as shown in Fig. 4. The observed band is separated by about 1000 cm^{-1} from the 0-0 band of the phosphorescence spectrum. These observations suggest that the lowest triplet state of this molecule is a $^3(\pi, \pi^*)$ state and a $^3(n, \pi^*)$ state is located about 1000 cm^{-1} above the phosphorescent $^3(\pi, \pi^*)$ state. These assignments of the states are consistent with the relatively short $\pi\leftarrow\pi^*$ phosphorescence lifetime and the complicated vibronic structure of the phosphorescence spectrum. The strong intensities of the 0-0 and totally symmetric ν_5 and ν_2 bands in the short lifetime phosphorescence spectrum indicate that the lowest $^3(\pi, \pi^*)$ state is strongly coupled with the $^1B_1(n, \pi^*)$ state through the first order spin-orbit interaction. This means that the short lifetime phosphorescence arises from the B_1 triplet sublevel. Observations of the out-of-plane b_1 and a_2 bands with medium intensity in the short lifetime phosphorescence and the remarkable intensification of the a_2 vibronic bands relative to the intensity of the 0-0 band in the middle lifetime phosphorescence indicate that the phosphorescent $^3(\pi, \pi^*)$ state is vibronically coupled with the closely located $^3(n, \pi^*)$ states as suggested by Scharf and Leismann.[2]

Near Ultraviolet Absorption Spectrum. The near ultraviolet absorption spectra observed in cyclohexane and the thin film prepared by sublimation at room temperature and 77 K, respectively, are shown in Fig. 4. The absorption observed in the 290—230 nm region with $\varepsilon\approx7000$ in cyclohexane looses the intensity in the thin film spectrum. We observed the infrared spectrum of the thin film sample with the unpolarized light. The b_2 and b_1 vibrational bands were observed with strong intensity, while the a_1 band with very weak intensity. This observation clearly indicates that the 290—230 nm absorption should be ascribed to the $^1A_1(\pi, \pi^*)\leftarrow{}^1A_1$ transition.

The absorption observed in the 350—300 nm region with $\varepsilon\approx25$ in cyclohexane, which was ascribed to the $n\rightarrow\pi^*$ transition by Scharf and Leismann,[2] shifts toward the blue side in the thin film. Generally the absorption observed in the solid at low temperature shows the red shift and hence two absorption systems are expected to locate in this region. We observed the polarized near ultraviolet absorption spectrum of the single crystal grown between two quartz plates and the result is shown in Fig. 4. The notations of the // and $\perp$ spectra are the same as those given in the polarized infrared spectrum of the single crystal grown between two KRS-5 plates. The observation indicates that the polarization of the 350—325 nm absorption is clearly different from that of the 325—300 nm absorption. By analogy with the polarization behaviors of the infrared bands, the former absorption could be ascribed to the forbidden $^1A_2(n, \pi^*)\leftarrow{}^1A_1$ transition perturbed by the $^1A_1(\pi, \pi^*)\leftarrow{}^1A_1$ transition and the latter to the $^1B_1(n, \pi^*)\leftarrow{}^1A_1$ transition.

The phosphorescence excitation spectrum observed in cyclohexane at 77 K gives well resolved vibrational structure as shown in Fig. 4. The longest wavelength and very weak band at 355.0 nm was taken as the 0-0 band of the $^1A_2(n, \pi^*)\leftarrow{}^1A_1$ absorption, which may appears in the spectrum by the crystal field dis-

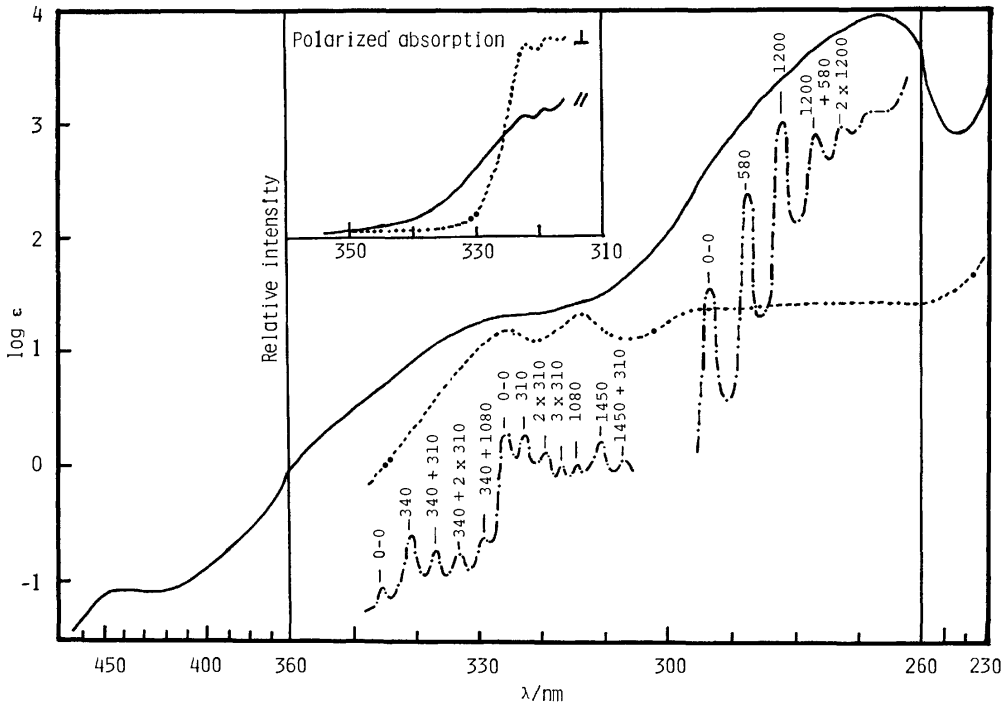

Fig. 4. Near ultraviolet absorption and phosphorescence excitation spectra of dichloromaleic anhydride. ——: Absorption spectrum in cyclohexane at room temperature, ----: absorption spectrum in the thin film at 77 K, -·-·-: phosphorescence excitation spectrum in cyclohexane at 77 K. Polarization behavior of the 350—315 nm absorption region is shown in the upper part of the figure. The absorption spectrum in cyclohexane was plotted against log ε, while the other spectra were against relative intensity.

tortion. A strong band separated by 340 cm^{-1} from the 0-0 band was ascribed to the perturbing vibration of the a_2 species. The frequency of 340 cm^{-1} was assigned to the upper state frequency of the C=O wagging (ν_{17}) vibration. This assignment would be reasonable because the C=O wagging vibration could be expected to be most effective for the vibronic coupling between the (n, π^*) and (π, π^*) states. Band intervals of 310 and 1080 cm^{-1} were observed and these were assigned to the upper state frequencies of the C=O bending (ν_7) and C–O stretching (ν_3) vibrations of the a_1 species, respectively.

A strong band at 325.7 nm was taken as the 0-0 band of the $^1B_1(n, \pi^*) \leftarrow {}^1A_1$ absorption. The upper state frequencies of the ν_7 and ν_3 vibrations were also observed in this absorption. A strong band separated by 1450 cm^{-1} from the 0-0 band was ascribed to the upper state C=O stretching (ν_1) vibration of the a_1 species.

A strong band at 293.2 nm was taken as the 0-0 band of the $^1A_1(\pi, \pi^*) \leftarrow {}^1A_1$ absorption. Band separations of 580 and 1200 cm^{-1} were observed and these were assigned to the upper state frequencies of the ring deformation (ν_5) and C=C stretching (ν_2) vibrations of the a_1 species, respectively. These vibrations were observed quite strongly in the $^3(\pi, \pi^*) \rightarrow {}^1A_1$ phosphorescence spectrum as described above.

The CNDO-MO calculation suggests that the two n orbitals on the O atoms of the C=O bonds couple with each other through the C–O bonds and hence the $n \rightarrow \pi^*$ transition gives rise to changes of the C=O and also C–O bond characters. Therefore, the observations of the C=O bending, C–O stretching, and C=O stretching vibrations in the $^1A_2(n, \pi^*) \leftarrow {}^1A_1$ and $^1B_1(n, \pi^*) \leftarrow {}^1A_1$ excitation spectra could be reasonably understood.

Mono-complex Formation Kinetics of 2-Thenoyltrifluoroacetone with Nickel(II) and Copper(II) Ions in Aqueous Solution

Isao Ando,* Kiyomi Yoshizumi, Kazuhisa Ito, Kikujiro Ujimoto, and Hirondo Kurihara

Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma, Jonan-ku, Fukuoka 814-01

(Received July 29, 1982)

The mono-complex formation of 2-thenoyltrifluoroacetone (HTTA) with nickel(II) and copper(II) ions was studied in aqueous solution at 25.0 °C and an ionic strength of 0.20 mol dm^{-3} by means of a stopped-flow method. The rate-[H$^+$] profiles for the formation of these mono-complexes revealed that the rate-determining step of the complex formation interchanges depending upon hydrogen-ion concentration, as in the case of the Ni(II)–bpy complex. The rate constants of the mono-complex formation with TTA$^-$, k_f, and that with HTTA, k_{fh}, were determined from the rate-[H$^+$] profile in the region of the high hydrogen-ion concentration, where the pseudo-equilibrium of acid dissociation of the ligand was maintained during the complex formation; $k_f=(9.2\pm3.0)\times10^2$, $k_{fh}=(1.3\pm0.3)\times10^{-1}$ mol^{-1} dm^3 s^{-1} for the Ni(II)–TTA complex and $k_f=(2.0\pm1.2)\times10^3$, $k_{fh}=(5.0\pm0.9)\times10^{-1}$ mol^{-1} dm^3 s^{-1} for the Cu(II)–TTA complex. The deprotonation-rate constants of HTTA could be evaluated from the apparent rate constants of the complex formation in low hydrogen-ion concentration. The values thus obtained agreed well with that determined independently by a pH jump method.

Many complex formations with the ligands which have both acidic and basic conjugated forms in aqueous solution have been investigated kinetically for various metal ions, especially nickel(II) ion.[1-6] In those studies the concentration ratio at protolytic equilibrium (the pseudo-equilibrium of acid dissociation) of the ligand has been taken as constant throughout the course of the complex formation. However, the pseudo-equilibrium may fail in a complex formation with the ligand undergoing a slow proton-transfer reaction. Recently we found the first such example, so far as we know, in the mono-complex formation of Ni(II)–bpy at low hydrogen-ion concentration.[7] The kinetic measurements under such conditions lead to erroneous rate constants because of the failure of the pseudo-equilibrium of the ligand. It is, therefore, essential in the kinetic study of the complex formation with such a ligand to make sure the maintenance of the acid-base pseudo-equilibrium of the ligand during the complex formation.

β-Diketones undergo a slow proton-transfer reaction[8-11] and also form the complexes with various metal ions.[10-16] Hence, further results are expected to prove that the proton-transfer process of β-diketones is the rate-determining step of the complex formation in some experimental conditions, especially in low hydrogen-ion concentration. In this study we investigated fully the rate-[H$^+$] profiles for the complex formation of nickel(II) and copper(II) ions with 2-thenoyltrifluoroacetone (HTTA) as an available β-diketone. The results showed that the deprotonation process of HTTA could be the rate-determining step of these complex formations under some given conditions.

This phenomenon provided a new method of the estimation of the deprotonation-rate constant of the ligand, by measuring the complex-formation rate.

Experimental

Materials and Sample Solutions. Nickel(II) and copper(II) sulfates were purchased from Wako Pure Chemical Industries and were purified by recrystalization from water before use. 2-Thenoyltrifluoroacetone (Dotite TTA) was purchased from Dojindo Laboratories and used without further purification. All other chemicals were of guaranteed reagent grade and used without further purification, unless otherwise noted.

The stock solution of nickel(II) or copper(II) ion was prepared by dissolving the corresponding sulfate in water acidified faintly with sulfuric acid, and the metal-ion concentration of the solution was determined by edta titration. The stock solution of HTTA was prepared by dissolving a desired amount of it in water. Deionized-distilled water was used for all preparations of the solution.

These stock solutions were appropriately diluted for kinetic measurements. The ionic strength of the resulting solution was adjusted to 0.20 mol dm^{-3} with sodium sulfate, and the sample solution contained no buffer.

For the measurement of the acid dissociation constant of HTTA, the ionic strength of the sample solutions was adjusted to 0.20 mol dm^{-3} with sodium chloride, and the pH of them was adjusted with the following buffers: acetate buffer at pH 4—6.5, phosphate buffer at pH 5.5—8. Each buffer was added at the concentration smaller than 0.05 mol dm^{-3}.

Kinetic Measurement of Proton Transfer. The rates of proton-transfer of the ligand were measured at 25.0 °C by the pH jump technique[17,18] according to the following procedure. The solution of HTTA in dilute sulfuric acid (pH 4—4.5) was rapidly mixed with a dilute sodium hydroxide solution at the same ionic strength in a Union RA-1300 stopped-flow spectrophotometer. The increase of TTA$^-$ concentration caused by pH jumping was followed as the increase in absorbance at 339 nm, the wavelength of maximum absorption of TTA$^-$. The apparent first-order rate constant for the deprotonation of HTTA at reaction time zero, k_{dpo}, was evaluated according to a previous method.[17,18] Each k_{dpo} value was obtained from fifteen kinetic runs.

Kinetic Measurement of Complex Formation. The complex formation was followed at 349 nm and 25.0 °C by means of a Union RA-1300 stopped-flow spectrophotometer, as reported previously.[7] The concentration of metal ion was always kept in large excess (400 or more times that of HTTA) in order to ensure only the mono-complex formation. The complex formation obeyed first-order kinetics within the 50% conversion. Each pseudo first-order rate constant, k_{obsd}, was obtained from ten kinetic runs.

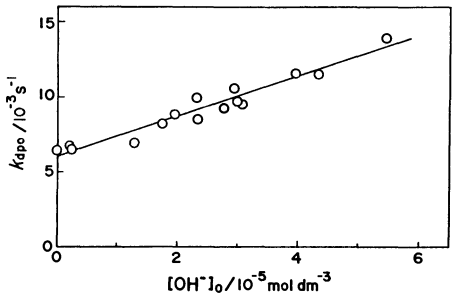

Fig. 1. Plot of k_{dpo} against $[OH^-]_0$ for 2-thenoyltrifluoroacetone.
The solid line is the linear regression line for the plot.

Measurement of Acid Dissociation Constant. Absorption spectra of HTTA in aqueous solution were recorded on a Hitachi 323 recording spectrophotometer. The acid dissociation constant, K_a, of HTTA was measured by the spectrophotometric titration at 339 nm and 25.0 °C by means of a JASCO Uvidec-2 digital spectrophotometer equipped with a thermostated cell holder.

Results and Discussion

Deprotonation Reaction of HTTA. The absorbance of HTTA at 339 nm remarkably increases with increasing pH. A spectrophotometric titration over the pH range of 2 to 8 at this wavelength yielded the number of transferred protons of 1.03±0.01 and the pK_a value of 6.35±0.01, indicating that the spectral change should be ascribed to the acid dissociation of HTTA to TTA^-. This pK_a value is in good agreement with the literature value.[19] The same spectral change was also observed on the heels of a pH jump in the stopped-flow apparatus by a rapid scanning technique. Consequently the apparent first-order rate constants for the deprotonation reaction of HTTA, k_{dpo}, can be determined by the stopped-flow pH jump technique.

The proton transfer of HTTA presumably proceeds through the following two simultaneous reaction paths, as in the cases of phen, pyridine and its derivatives:[17,18]

$$HTTA \underset{k_p}{\overset{k_{dp}}{\rightleftharpoons}} TTA^- + H^+, \quad (1)$$

$$HTTA + OH^- \underset{k_{H_2O}}{\overset{k_{OH}}{\rightleftharpoons}} TTA^- + H_2O, \quad (2)$$

where k_{dp}, k_p, k_{OH}, and k_{H_2O} are the rate constants in Reactions 1 and 2, respectively. Since the decreasing rate of HTTA concentration is expressed by

$$-d[HTTA]/dt = (k_{dp}+k_{OH}[OH^-])[HTTA] - (k_p+k_{H_2O}[H_2O]/[H^+])[TTA^-][H^+], \quad (3)$$

at reaction time zero k_{dpo} can be expressed as a function of hydroxide-ion concentration at reaction time zero, $[OH^-]_0$;

$$k_{dpo} = k_{dp} + k_{OH}[OH^-]_0. \quad (4)$$

The plot of k_{dpo} against $[OH^-]_0$ gave a straight line, as shown in Fig. 1. The values of k_{dp} and k_{OH} given in Table 1 were obtained from the intercept and the slope of the linear regression line in Fig. 1. The k_{dp} value was in good agreement with the rate constant of the enolation of keto tautomer of HTTA, $(8.4\pm0.3)\times10^{-3}$ s^{-1} obtained by the bromination method.[11] According to Jaffe and co-workers,[11] the concentration ratio of enol to keto tautomer in aqueous HTTA solution is 4.4×10^{-3} and the rate-determining step of the enolation is the deprotonation of keto tautomer. Therefore, k_{dp} in this study corresponds to the enolation-rate constant of keto form. This k_{dp} value is also comparable to that of other β-diketones.[20]

Table 1. Rate constants for the mono-complex formation and the proton-transfer reaction of 2-thenoyltrifluoroacetone at 25.0 °C and 0.20 mol dm^{-3} ionic strength

Rate constant	Ni-TTA	Cu-TTA
k_f/mol^{-1} dm^3 s^{-1}	$(9.2\pm3.0)\times10^2$	$(2.0\pm1.2)\times10^3$

k_{dp}/s^{-1}	$(7.2\pm1.1)\times10^{-3}$ a)	$(2.8\pm1.0)\times10^{-3}$ a)
	$(6.0\pm0.6)\times10^{-3}$ b)	
k_{OH}/mol^{-1} dm^3 s^{-1}	$(1.3\pm0.2)\times10^2$ b)	

a) The values were obtained from the data of the complex formation rates. b) The value was obtained by the pH jump method.

Complex Formation Kinetics. The mono-complex formation of nickel(II) and copper(II) ions with HTTA is thought to proceed through the following two concurrent reaction paths:

$$M^{2+} + TTA^- \xrightarrow{k_f} MTTA^+, \quad (5)$$

$$M^{2+} + HTTA \xrightarrow{k_{fh}} MTTA^+ + H^+, \quad (6)$$

where k_f and k_{fh} are the second-order rate constants in Reactions 5 and 6, respectively. As long as the pseudo-equilibrium of the acid dissociation of HTTA holds throughout the complex formation, the rate of the complex formation is expressed by

$$d[MTTA^+]/dt = (k_f[TTA^-] + k_{fh}[HTTA])[M^{2+}] = \{(k_f+k_{fh}[H^+]/K_a)/(1+[H^+]/K_a)\} \times [M^{2+}][TTA'], \quad (7)$$

where [TTA′] denotes the analytical concentration of HTTA, in the early stage of the complex formation, in which the dissociation of the complex can be ignored. Therefore, the pseudo first-order rate constant, k_{obsd}, is correlated with k_f and k_{fh} by

$$k_{obsd}(1+[H^+]/K_a)/[M^{2+}] = k_f + k_{fh}[H^+]/K_a. \quad (8)$$

Figure 2 shows the plots of k_{obsd} values against $[H^+]$ according to Eq. 8 for the formation of the mono-complexes of Ni(II)- and Cu(II)-TTA. In both cases, the plots in the $[H^+]$-region higher than around 2×10^{-3} mol dm^{-3} yield linear relationships, while the data at lower $[H^+]$ deviate below the straight lines extrapolated from the high $[H^+]$-region. This suggests that the pseudo-equilibrium of the acid dissociation of HTTA holds only in the high $[H^+]$-region, on the analogy of the mono-complex formation of Ni(II)-bpy.[7] Hence, the k_f and k_{fh} values given in Table 1 were obtained from the intercept and the slope of the straight lines in the high $[H^+]$-region where the pseudo-equilibrium seems to hold.

In order to verify the establishment of the pseudo-

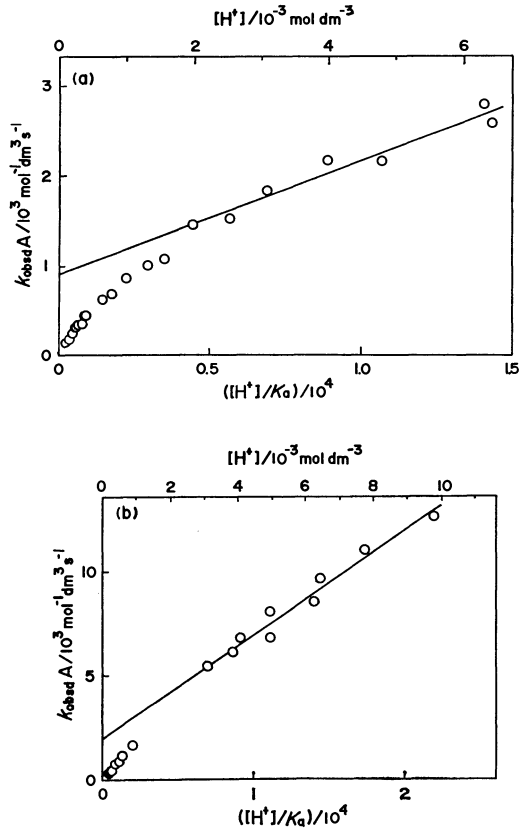

Fig. 2. Plots of $k_{obsd}A$ against $[H^+]/K_a$.
$A=(1+[H^+]/K_a)/[M^{2+}]$. (a) Ni(II)–TTA complex; $[Ni^{2+}]=2.00\times10^{-2}$ mol dm^{-3}, $[HTTA]=5.00\times10^{-5}$ mol dm^{-3}. (b) Cu(II)–TTA complex; $[Cu^{2+}]=1.02\times10^{-2}$ mol dm^{-3}, $[HTTA]=1.04\times10^{-5}$ mol dm^{-3}.

equilibrium of the acid dissociation of HTTA in the $[H^+]$-region where the k_f and k_{fh} values evaluated, the initial rates of the processes concerned were compared with each other. Figure 3 illustrates the initial rates for the Ni(II)–TTA system as a function of pH, where (rate f), (rate fh), (rate dp), and (rate p) are the rates of the complex formation in Reactions 5 and 6, and those of the deprotonation of HTTA and the protonation of TTA^- through Reaction 1, respectively. The subscript 0 denotes the values at reaction time zero. The deprotonation rate in Reaction 2 was ignored because of its negligible contribution to (rate dp) in acidic solution. These initial rates were calculated using the k_f, k_{fh}, and k_{dp} values obtained and the initial concentrations of the species participating in the reactions. As the equilibrium of the acid dissociation of HTTA holds at reaction time zero, $(\text{rate p})_0$ must be equal to $(\text{rate dp})_0$. As can be seen in Fig. 3, with the Ni(II)–TTA system the pseudo-equilibrium mentioned above proved to hold over the pH range where the k_f and k_{fh} values were evaluated, because at pH below 3 $(\text{rate dp})_0$ is larger than $(\text{rate f})_0$, and $(\text{rate p})_0$ is larger than $(\text{rate fh})_0$. With Cu(II)–TTA system, the establishment of the pseudo-equilibrium was also confirmed in the high $[H^+]$-region.

In order to establish the mechanism assumed in this study, the k_{dp} value of HTTA was evaluated from

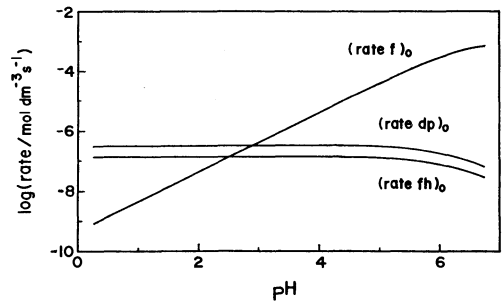

Fig. 3. Relationship between initial rates and pH for the Ni(II)–TTA complex at 25.0 °C.

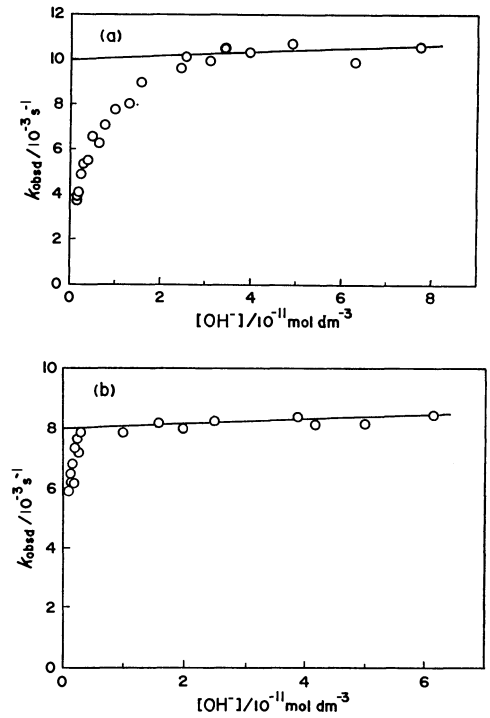

Fig. 4. Plots of k_{obsd} against $[OH^-]$ for (a) Ni(II)–TTA and (b) Cu(II)–TTA complex.
Data were taken from Fig. 2.

the data of the complex formation in the pH range where the rate was controlled by the deprotonation rate, and was compared to that obtained by the pH jump method. At the pH beyond 3, $(\text{rate dp})_0$ is less than $(\text{rate f})_0$ and comparable to $(\text{rate fh})_0$, as shown in Fig. 3. Therefore, the rate of the complex formation should be controlled by (rate dp) and (rate fh), after having been stationary with respect to $[TTA^-]$. Under such conditions, the rate of the complex formation is expressed by

$$d[MTTA^+]/dt = (k_{dp}+k_{OH}[OH^-]+k_{fh}[M^{2+}])[HTTA]. \quad (9)$$

Accordingly,

$$k_{obsd} = k_{OH}[OH^-] + (k_{dp}+k_{fh}[M^{2+}]). \quad (10)$$

Figure 4 shows the plots of k_{obsd} against $[OH^-]$ for the Ni(II)- and Cu(II)–TTA systems. The k_{obsd} values were evaluated from the absorbance change after the reaction became stationary. The k_{dp} values of HTTA in both systems were evaluated from the

intercepts of these straight lines at relatively high [OH^-], using [M^{2+}] and k_{fh} values. Although the k_{OH} values were also evaluated from their slopes, no significant value was obtained because of the experimental error due to the extremely low hydroxide-ion concentration. The k_{dp} values are summarized in Table 1 together with the k_{dp} and k_{OH} values obtained by the pH jump method. The average value of k_{dp} obtained by the complex-formation experiments is in excellent agreement with that by the pH jump method. This fact strongly supports the conclusion that the proton-transfer reaction of the ligand can be the rate-determining step of the complex formation depending upon the hydrogen-ion concentration. Additionally, it should be noted that the k_{dp} value of the ligand could be evaluated from the data of the complex-formation kinetics.

Jaffe and co-workers studied the same systems on the assumption that keto form of HTTA does not react directly with metal ion.[11] According to their description, the present k_f corresponds to the complex-formation rate constant of enolate ion, k_{fh} to the complex-formation rate constant of enol tautomer or to the enolation-rate constant of keto tautomer, and k_{dp} to the enolation-rate constant. Our values of k_f and k_{fh} for the Ni(II)–TTA system differ from their corresponding values, 1.0×10^4 and 2.3 $mol^{-1}\,dm^3\,s^{-1}$, respectively. For the Cu(II)–TTA system, the k_f value in this study is remarkably different from their's, $\geqq 3\times10^6$ $mol^{-1}\,dm^3\,s^{-1}$. Since k_{fh} is the overall rate constant, irrespective of keto or enol form of HTTA, the small value of k_{fh} may be partly ascribed to the unreactivity of the keto form. M. R. Jaffe *et al.* assumed that the equilibrium between enol tautomer and enolate ion of HTTA is always maintained throughout the reaction. This assumption seems to be reasonable only just after the reaction occurred. However, the direct deprotonation and/or the deprotonation *via* enol from keto form of HTTA become significant during the progress of the reaction. Comparing the initial rates of the complex-formation processes and the proton-transfer process, (rate f) and/or (rate fh) are larger than (rate dp) in both Ni(II)– and Cu(II)–TTA systems under their experimental conditions. This suggests that the pseudo-equilibrium for the acid dissociation or the enolation of the ligand failed in the course of the complex formation. This presumably explains the discrepancies of the rate constants between Jaffe's and our study. The fact that the rate constants in this study are not characteristic for metal ions should support the conclusion that in the complex formation forming the six-membered chelate ring the closure of the chelate ring is the rate-determining step.[15]

In conclusion, we obtained further evidence that the proton-transfer reaction of the ligand became the rate-determining step of the complex formation depending on the hydrogen-ion concentration, as in the case of the Ni(II)–bpy complex. Under such conditions, the deprotonation-rate constant of the ligand could be determined from the complex-formation rate, as well as by the pH jump method.

The authors wish to thank Professor S. Kida and Professor T. Taketatsu of Kyushu University for valuable discussions and encouragement. The present work was partially supported by a grant from the Central Research Institute of Fukuoka University.

(Received September 17, 1982)

The reaction of sodium *cyclo*-triphosphate (P_{3m}) with ethylenediamine (en) was studied with special attention paid to the kinds and amounts of products under various conditions and to its reaction mechanism. 1) The reaction of P_{3m} with ethylenediamine in the pH range of 8—12 gave six new compounds; three of them were identified as *N,N*-bis(2-aminoethyl)phosphorodiamidate (P_1-en_2), *N*-(2-aminoethyl)amidodiphosphate (P_2-en), and *N*-(2-aminoethyl)-*P*-amidotriphosphate (P_3-en). 2) The formation of P_3-en and P_2-en was most favored at a pH near 10(about 32 and 9% respectively), while that of P_1-en_2 proceeded extensively at pH 10—12(about 12%). 3) The amounts of products varied greatly depending on the mixing ratio of P_{3m} and ethylenediamine. P_1-en_2 was the predominant product at $en/P_{3m} > 1$, while P_3-en was at $en/P_{3m} \leqq 1$. 4) At a pH value below 10, tetra-(P_4) and pentaphosphate (P_5) were formed in addition to the above products. The reaction between P_{3m} and ethylenediamine scarcely proceeded under acidic conditions. 5) Ortho-(P_1), pyro-(P_2), and triphosphate (P_3) did not react with ethylenediamine at all. 6) The reaction mechanism between P_{3m} and ethylenediamine was discussed.

Linear condensed phosphates have found wide practical applications as food and drug additives, detergents, and fertilizers,[1–3] but little is known about the applications of cyclic condensed phosphates.[4] It was first reported by Quimby and Flautt[5] in 1959 that cyclo-triphosphate (P_{3m}), a six-membered cyclic phosphate, readily undergoes a ring-opening reaction in the presence of ammonia to give amidotriphosphate. After that, it was reported that P_{3m} reacts with amines, such as alkylamine,[6,7] 1,6-hexandiamine[8] and amino acids,[9–12] to yield new compounds with a P–N bond in their molecules. Recently, it was found that P_{3m} also reacts with other organic compounds, such as alcohols,[13] sugar,[13] and nucleoside,[14–19] and that it is effective for the stabilization of vitamin C.[20] As a result, extensive attention has been paid to the potential commercial applications of P_{3m}. However, the details of the reaction of P_{3m} with these organic compounds still remain unclear. In the present study, therefore, P_{3m} was allowed to react with ethylenediamine, the simplest member of the diamine family, under various conditions, and the kinds and amounts of the products as well as the reaction mechanism were investigated by using anion-exchange chromatography, chemical analysis for phosphorus and ethylenediamine, and IR spectroscopy.

Experimental

Chemicals. The sodium *cyclo*-triphosphate, $Na_3P_3O_9 \cdot 6H_2O$, was prepared by the procedure described in a previous paper[21] and recrystallized five times from an aqueous solution. Unless otherwise stated, guaranteed reagents from Wako Chemical Industries, Ltd., were used without further purification.

Reaction between cyclo-*Triphosphate and Ethylenediamine.* A 0.5 mol dm^{-3} portion of the sodium *cyclo*-triphosphate (P_{3m}) solution was mixed with a 0.5 or 5 mol dm^{-3} ethylenediamine (en) solution (molar ratio; P_{3m}:en=1:1 and 1:10), the mixed solution was controlled to the prescribed pH by adding a 6 mol dm^{-3} hydrochloric acid or sodium hydroxide solution(pH:12, 10, and uncontrolled), and the reaction was allowed to proceed at room temperature. Since the pH of the mixed solutions lowered as the reaction progresses, it was held at the prescribed pH, when required, by adding a sodium hydroxide solution.

Anion-exchange chromatography, the determination of phosphorus, and IR spectroscopy were carried out by the methods described in a previous paper.[21]

A Yanagimoto Micro Elemental Analyzer, MT-2 type, was used for the determination of ethylenediamine in the reaction products.

Results and Discussion

Reaction of cyclo-*Triphosphate with Ethylenediamine.* The initial pH of the mixed solution of P_{3m} and ethylenediamine at a molar ratio of 1:1 was above 14, but it was lowered sharply with the progress of the reaction, reaching about 12 after 2 h and going down to about 8.7 after 3 d. This indicates that P_{3m} reacted with water or ethylenediamine to afford chain-phosphates or their derivatives. To prove this, we attempted to separate and determine the reaction products by means of anion-exchange chromatography. An example of the results obtained is given in Fig. 1, which shows the elution patterns for the reaction products after 1 and 7 d. Then, the pH values of the solution were about 9.2 and 8.3 respectively. As can be seen, elution peaks of P_1, P_2, and P_3 appeared after 1 d. In addition, a large peak of an unknown compound(designated as Compound D) was observed between the peaks of P_1 and P_2, and two other peaks of unknown compounds(Compounds A and B) were noticed before the peak of P_1. Furthermore, peaks of tetra-(P_4) and pentaphosphate(P_5) were also observed after 39 d, though they are not shown in Fig. 1.

Figure 2 shows the changes in the amounts of P_1, P_2, P_3, P_4, and P_5, as well as in Compounds A, B, and

D, with the passage of time or with the decrease in the pH. It is apparent from the figure that Compound D began to be formed immediately after the reaction, and that its amount reached a maximum level of 32.4% after 3 d, followed by a gradual decrease with the reaction time or with a decrease in the pH. A similar tendency was observed in Compound A. Compound B, on the other hand, was first observed after 3 d, and its amount increased with the time, reaching about 8.7% after 114 d. The amounts of P_1 and P_2 also showed a gradual increase with the time, reaching about 13.8 and 48.2% respectively after 114 d. The formation of P_2 was particularly marked. These results indicate that the formation of Compounds A and D is favored by a high pH. To provide further evidence for this, the reaction of P_{3m} with ethylenediamine was carried out at the controlled pH values of 12 and 10 at a mixing ratio of 1:1.

Figure 3 shows the elution patterns for the reaction

mixture after 1 and 17 d at pH 12. In this experiment, the gradient elution technique with a 0.12—0.32 mol dm^{-3} sodium chloride solution was used for the eluant up to 1600 cm^3, while the step-wise elution method with 0.4 and 1.5 mol dm^{-3} sodium chloride solutions was used for the elution of an unknown compound F and P_{3m}, respectively. Compared with the reaction of P_{3m} with ethylenediamine at an uncontrolled pH, we observed remarkable differences in the kinds and amounts of products at pH 12. That is, a small peak of an unknown compound(Compound C) was observed between the elution peaks of P_1 and Compound B. In addition, a peak of an unknown compound(Compound E) was also found at an eluant of 1250 cm^3, and another one of an unknown compound (Compound F) when the mixture was eluted with a 0.4 mol dm^{-3} sodium chloride solution. In short, six unknown compounds(Compounds A, B, C, D, E, and F) were formed by the reaction of P_{3m} with ethylenediamine at pH 12. Sodium pyrophosphate decahydrate, $Na_4P_2O_7 \cdot 10H_2O$, began to precipitate after 3 d, and its amount increased with the time. P_4 was formed in significant quantities(about 9.8%) in the initial stage of the reaction(up to 5 d), but its amount decreased after that with the lapse of time. Figure 4 shows the changes in the amounts of P_1, P_2, P_3, and P_4, as well as in Compounds A through F, with the time. As can be seen from Fig. 3, the elution peaks of Compounds B and C were too close together to be determined. Also, all attempts to separate Compounds B and C by changing the elution conditions failed. The sum of the amounts of Compounds B and C is, therefore, shown in Fig. 4. A comparison of Fig. 4 with Fig. 2 indicates a marked difference between the reactions carried out at pH 12 and those carried out with no control of the pH. Particularly, when the pH of the solution was not controlled, the formation of Compound D was apparently favored under mildly

alkaline conditions(pH 10—8.5). Compound A, on the contrary, was produced more readily in highly alkaline regions(pH 12). Compounds C, E, and F were also formed in high pH regions, but their amounts were rather small. Compound E was produced in significant quantities in the initial stage of the reaction (up to 3 d), but disappeared completely after 6 d. In addition, the precipitation of $Na_4P_2O_7 \cdot 10H_2O$ was observed after 3 d at pH 12. The same phenomenon has been experienced by the present authors in the reaction of P_{3m} with L-valine[21] or glycine.[22]

In contrast, the products obtained by the reaction of P_{3m} with ethylenediamine at pH 10 were very similar to those in the reaction at an uncontrolled pH; the products obtained at pH 10 were Compounds A, B, D, and E, but Compounds C and F were not formed at all. The only difference between the two reactions was that Compound E was produced at pH 10, while

—◆—: A, —·—●—·—: D —■—: P_{3m}.

P_5 was produced at an uncontrolled pH.

Figure 5 shows the changes in the amounts of products (Compounds A, B, D, and E), as well as P_1, P_2, P_3, P_4, and P_{3m}, with the lapse of time at pH 10. It is apparent from Fig. 5 that Compound D was formed in considerable quantities in the initial stage, its amount reaching a maximum level of about 28.6% after 1 d and then decreasing with time. The amount of Compound A, on the other hand, gradually increased for the first week and after that was almost constant(about 11.5%).

Figures 2, 4, and 5 show that Compound A is stable at a pH of 10 or higher. The amounts of P_4 and Compound E were very small, about 1.5% for both.

The formation of the products(Compounds A, B, C, D, E, and F) in the reaction between P_{3m} and ethylenediamine at a molar ratio of 1:1 under various pH conditions may be summarized as follows: 1) Compound D was rapidly formed in the initial stage of the reaction(1—3 d) at pH 10—8.5, its amount reaching about 32%. 2) Compound A was formed in significant quantities at pH 10—12, its amount reaching about 12%. This compound was stable within this pH region for a long time(30 d). 3) Compound B was formed at pH 10 over a long period(30 d), its amount reaching about 9.2%. However, it was found only in minute quantities at pH 12, and the rate of its formation was also very low at a pH of 8.5 or lower. 4) Compound C was produced only in a high pH region(12 or higher) and in small quantities(about 2%). 5) Compound E was formed in the initial stage of the reaction (1—3 d) at a pH of 10 or higher, but it was decomposed almost completely after two weeks. Its amount was about 4.5% at pH 12. 6) Compound F was formed at a pH of 12 or higher, but its amount was as small as about 1.7%. Besides these compounds, the formation of P_4 and P_5 was also observed at a pH of 10 or lower; their amounts tended to increase slightly as the pH was lowered to near neutral. The mechanism of the formation of P_4 and P_5 will be presented in detail later.

No reaction of P_{3m} with ethylenediamine took place under acidic conditions. This is probably ascribable to the formation of inactive $H_3N^+CH_2CH_2NH_2$ or $H_3N^+CH_2CH_2N^+H_3$.

Next, the effect of the mixing ratio of P_{3m} and ethyl-

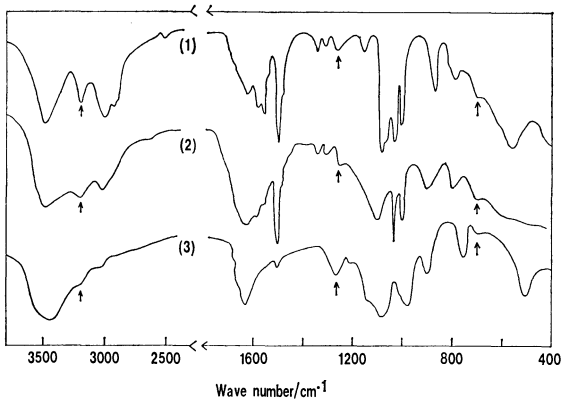

Fig. 7. IR spectra of the compounds A, B, and D. (1): Compound A, (2): B, (3): D. Arrow(↑): absorption due to the P–N bond.

enediamine on the kinds and amounts of reaction products was studied. Figure 6 shows the changes in the amounts of various phosphates with the time at a molar ratio of P_{3m}:en=1:10. As can be seen, the reaction proceeded at a higher rate in the presence of a large excess of ethylenediamine. The products obtained in the reaction were P_1, P_2, P_3, and Compounds A, D, and E. However, the date for P_3 and Compound E are omitted in Fig. 6, because their amounts are very small. In response to the consumption of P_{3m}, Compound D began to be formed immediately after the reaction, its amount reaching about 47% after 5 h; thereafter, it decreased rapidly. On the contrary, Compound A began to be formed after 5 h, its amount reaching about 37% after 1 d. P_2 was also formed concurrently with the formation of Compound A, its amount reaching about 64%. Precipitates of $Na_4P_2O_7 \cdot 10H_2O$ were observed about 3 h after the reaction. As may be apparent from Fig. 6, the reaction of P_{3m} with ethylenediamine at a molar ratio of 1:10 afforded Compound A and P_2 as the main products; the amount of the former(about 32% as phosphorus concentration) is just half that of the latter (about 64%). This suggests that Compound A is an orthophosphate derivative of ethylenediamine.

The results obtained by the reactions in the mixing-ratio range from P_{3m}:en=1:0.1 to 1:10 may be summarized as follows: the formation of Compound A was predominant at $P_{3m}/en<1$, and that of Compound D, at $P_{3m}/en \geqq 1$.

Molecular Structures of the Three Unknown Compounds, A, B, and D. Compounds A, B, and D were isolated by anion-exchange chromatography according to the method described in the previous paper;[21] the structure of each compound was then investigated by means of chemical analysis for phosphorus and ethylenediamine and by means of IR spectroscopy, as well as by means of its structural change with the pH.

Chemical analysis revealed that the P/en ratios are 1:2, 2:1, and 3:1 for Compounds A, B, and D respectively. This indicates that Compound A may be a P_1-derivative of ethylenediamine containing P_1 and ethylenediamine in the molar ratio of 1:2, Compound B, a P_2-derivative of ethylenediamine(P_2:en=1:1), and Compound D, a P_3-derivative of ethylenediamine(P_3:en=1:1).

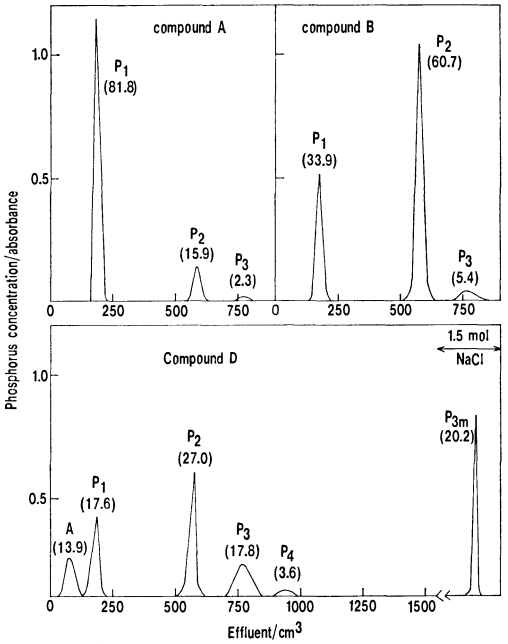

Fig. 8. Decomposition of the compounds A, B, and D at pH 3.

Figure 7 shows the IR spectra of Compounds A, B, and D as measured by means of a KBr tablet. For Compound A, characteristic absorptions due to the P–N bond were observed at about 3330—3150, 1270, 875, and 700 cm^{-1},[23-25] while those attributable to the P–O bond were noticed at about 1160 and 970—1050 cm^{-1}.[26,27] Absorptions that can be assigned to the $-CH_2-$ group were also observed at 2925, 2850, and 1470 cm^{-1},[28] while characteristic absorptions due to the $-NH_2$ were present at about 3500 and 1065 cm^{-1}.[28] For Compound B, absorptions ascribable to the P–N bond were noticed at about 3330—3150, 1260, and 700 cm^{-1}, but the absorption due to the P–N bond near 875 cm^{-1} was uncertain because of overlapping with the strong absorption due to the P–O–P bond near 900 cm^{-1}. A peak that can be assigned to the P–O bond was also observed at 970—1050 cm^{-1}.

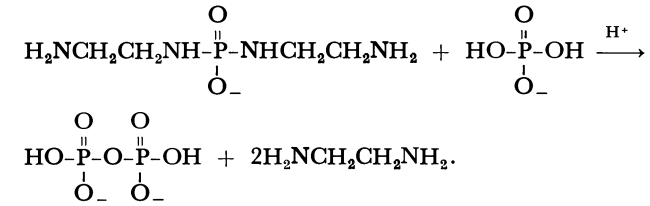
Compound D, as in the case of Compound B, showed characteristic absorptions due to the P–N, P–O–P, and P–O bonds. Also, there were characteristic bands[29] of the vibrations of the triphosphate anion at about 1230(ν_{as} PO_2), 1160(ν_{as} PO_3), 1000(ν_s PO_3), 735($\delta_s PO_2$), and 510 cm^{-1} in Compound D.

These results of chemical analysis and IR spectroscopy indicate that Compounds A, B, and D are phosphate derivatives of ethylenediamine containing the P–N bond in their molecules. Compounds B and D, which showed absorption due to both the P–N and P–O–P bonds, can be considered as pyro- and triphosphates derivatives of ethylenediamine. Compound A, on the other hand, has no P–O–P bond in the molecule, and so it may be regarded as an orthophosphate derivative of ethylenediamine.

To provide further evidence for the above, Compounds A, B, and D were dissolved in distilled water,

allowed to stand for 15 min. at a pH controlled to 3 by adding dilute hydrochloric acid, and then analyzed by anion-exchange chromatography. The results are shown in Fig. 8, the numerals in which are the amounts of products represented in P%. It is apparent from Fig. 8 that Compound A, upon acidification (to pH 3), was decomposed to give P_1 in about an 80% yield. P_2 and P_3 were also formed at the same time, though in small amounts. This clearly indicates that Compound A is a P_1-derivative of ethylenediamine(P_1-en_2), in which two molecules of ethylenediamine are combined with P_1. On the other hand, Quimby[5] and also Feldmann and Thilo[6] reported that, when amidophosphates having the P–N bond were acidified, the condensation of phosphate took place and amidotriphosphate was recyclized to P_{3m}.

The formation of P_2 and P_3 by the hydrolysis of P_1-en_2 under the acidic conditions in the present study may be explained by the mechanism described by Quimby[5] and by Feldmann and Thilo:[6]



That is, the P_1 formed by the hydrolysis of P_1-en_2 reacts with undecomposed P_1-en_2 or partially hydrolyzed $H_2NCH_2CH_2NH\text{-}\overset{\overset{O}{\|}}{P}\text{-}OH$ (P_1-en) to form P_2, which in turn reacts with P_1-en_2 or P_1-en to give P_3.

Compound B, when acidified, affords about 61% in P_2, 34% in P_1, and 5% in P_3. This indicates that this compound is $^{-}O\text{-}\overset{\overset{O}{\|}}{P}\text{-}O\text{-}\overset{\overset{O}{\|}}{P}\text{-}NHCH_2CH_2NH_2$ (P_2-en), in which one molecule of ethylenediamine is attached to P_2. The large amount of P_1 observed may be ascribed to the hydrolysis of the P_2 once formed.

It is apparent from Fig. 8 that, under acidic conditions, Compound D is changed into P_1, P_2, P_3, P_4, and Compound A, and that about 20% of it is recyclized to P_{3m}. This shows clearly that Compound D is a triphosphate derivative of ethylenediamine.

It was demonstrated that Compound A is *N,N'*-bis(2-aminoethyl)phosphorodiamidate $H_2NCH_2CH_2\text{-}\overset{\overset{O}{\|}}{P}\text{-}NHCH_2CH_2NH_2$, Compound B, *N*-(2-aminoethyl)amidodiphosphate $^{-}O\text{-}\overset{\overset{O}{\|}}{P}\text{-}O\text{-}\overset{\overset{O}{\|}}{P}\text{-}NHCH_2CH_2NH_2$, and Compound D, *N*-(2-aminoethyl)-*P*-amidotriphosphate $^{-}O\text{-}\overset{\overset{O}{\|}}{P}\text{-}O\text{-}\overset{\overset{O}{\|}}{P}\text{-}O\text{-}\overset{\overset{O}{\|}}{P}\text{-}NHCH_2CH_2NH_2$, from the results of the chemical analysis for phosphorus and ethylenediamine and from the results of IR spectroscopy, as well as from the results of the hydrolysis of these compounds under acidic conditions.

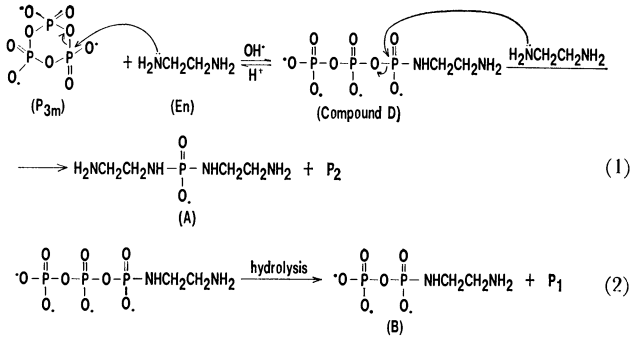


Fig. 9. Mechanism of the reaction of P_{3m} with en.

The structures of Compounds C, E, and F have not yet been characterized because they were formed in only minute amounts and could not be isolated in a pure form.

Reaction of Short-chain Phosphates with Ethylenediamine. A solution of trisodium orthophosphate (P_1), tetrasodium pyrophosphate (P_2), or pentasodium triphosphate (P_3) was mixed with an ethylenediamine solution in a molar ratio of 1:1, and then the mixed solution was adjusted with a hydrochloric acid or sodium hydroxide solution to pH 12 and allowed to react at room temperature. No reaction products were observed at all in the reaction of ethylenediamine with P_1, P_2, or P_3.

Reaction Mechanism of P_{3m} and Ethylenediamine. The mechanism of the reaction between P_{3m} and ethylenediamine at pH 10—12 is summarized in Fig. 9. Probably, the first step of the reaction is the nucleophilic attack of the lone pair of the nitrogen atom in ethylenediamine on the phosphorus atom in P_{3m} to cause a ring opening of *cyclo*-triphosphate, forming P_3-en. The P_3-en once formed is then attacked by free ethylenediamine or undergoes hydrolysis to give P_1-en_2 or P_2-en.

This reaction mechanism can reasonably explain the fact that P_3-en, formed predominantly in the initial stage of the reaction at pH 10—12, was gradually converted into P_1-en_2, P_2-en, and other phosphates with the passage of time. In the presence of a large excess of ethylenediamine(P_{3m}:en=1:5—1:10), it was found that P_3-en, which was formed in large quantities immediately after the reaction, completely disappeared after 1 d, leaving only P_1-en_2 and P_2. This fact also supports the above mechanism in which the reaction of P_3-en with free ethylenediamine affords P_1-en_2.

Pyrolytic Sulfurization Gas Chromatography. XIV. Simultaneous Determination of the Absolute Contents of C, H, O, and N in an Organic Compound by Means of a Calibration Method

Tadashi HARA* and Fujio OKUI

Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602

(Received September 17, 1982)

The absolute content of C, H, O, and N in an organic compund including a metal organic chelate was satisfactorily determined on the basis of pyrolytic sulfurization gas chromatography. A 1.0—1.3 mg sample was weighed on a microbalance, and was subjected to pyrolytic sulfurization. The gases evolved by the reaction were estimated by gas-chromatography. By using both the analytical result of each product and its calibration factor previously obtained by analyzing cyanoguanidine, 8-quinolinol, and sucrose as standard samples, the absolute content of C, H, O, and N was calculated satisfactorily for each substance.

Pyrolytic sulfurization gas chromatography (PSGC) was originated[1] and has been reported[2-13] by the authors for the purpose of establishing a new method of elemental analysis by which several elements in an organic compound can be simultaneously determined. By using PSGC, the atomic ratio between C, H, O, and N in a usual organic compound,[1] a metal organic chelate compound,[3,13] a polymer,[5] and an organic halogen compound[7,9] have been successfully and simultaneously determined.

In PSGC, a 0.3—0.5 mg sample is subjected to pyrolytic sulfurization with 5 mg of high purity sulfur[4] in a sealed quartz tube. The gaseous products from this reaction, carbon dioxide (CO_2), carbonyl sulfide (COS), carbon disulfide (CS_2), hydrogen sulfide (H_2S), and nitrogen molecule(N_2), are estimated by gas-chromatography, followed by the calculation of the atomic ratio between C, H, O, and N. Organic elemental analysis by PSGC is mainly characterized by the followings: 1) The atomic ratio between C, H, O, and N can be simultaneously determined within an absolute error of about $\pm 0.2\%$;[12] 2) no weighing is necessary for sampling and thus a microbalance is not necessary; 3) no additional combustion is required for a less combustible compound; 4) this method is applicable to various compounds such as metal organic chelates, thermosetting polymers, and organic halogen compounds; 5) the atomic ratio between C, H, O, N, Cl, Br, and I in an organic halogen compound can be determined[9] in a single analysis; and 6) the measurement is inexpensive because with a slight modification commercial apparatus is available. However, PSGC is not yet as satisfactory as conventional organic elemental analysis based on an oxygen combustion technique in the following respects; 1) the absolute amount of each element in a sample cannot be determined; as in PSGC only the atomic ratio between C, H, O, and N in a sample is calculated from the analytical data of the gaseous products. 2) Compounds which contain elements additional to C, H, O, and N cannot be analyzed. These problems must be solved by further improvement of PSGC, to establish a method by which each absolute content of C, H, O, and N in a sample can be determined. Therefore, the present study has been carried out with this objective in mind. Since the reaction products obtained by pyrolytic sulfurization of a common organic compound sample is restricted to CO_2, COS, CS_2, H_2S, and N_2, calibration curves of these products were easily obtained by analyzing three standard samples which were previously weighed. By using such calibration curves, various samples could be analyzed and the absolute content of C, H, O, and N in a sample was successfully and simultaneously determined.

Experimental

Apparatus and Reagents. The apparatus used in this study was the same as that previously reported.[11] A definite amount of sample was measured on a Shimadzu microbalance MDP-5.

The organic compounds used as analytical samples were of reagent grade for elemental analysis except for cyanoguanidine, which was of reagent grade for melting-point standard.

Procedure. A sample in the range of 1.0 to 1.3 mg was weighed exactly in a quartz tube, which was closed at one end, and about 10 mg of S was also added. The air inside the quartz tube containing the sample and S was next displaced with He for 10 min, after which the other end of the tube was sealed. The ampule was next heated for 1 min in a high-frequency induction furnace as described in the previous study.[10] The gaseous products evolved in the reaction between a sample and S were analyzed by gas-chromatography under the same conditions as those previously reported.[11] From the analytical data, the absolute contents of C, H, O, and N in a sample were separately calculated by use of calibration curves of the products which had been previously obtained by analyzing three standard samples, such as cyanoguanidine, 8-quinolinol, and sucrose.

Results and Discussion

Sample Amount. According to the conventional PSGC, 0.3—0.5 mg of sample has been subjected to pyrolytic sulfurization. Since a sample had to be weighed, in the present study, to four significant figures with the microbalance which could weigh to a precision of 1 μg, a sample more than 1 mg was used for an analysis. Therefore, the following examinations were undertaken to confirm whether PSGC could be applied or not to the analysis using about 1 mg of sample. 1) Approximately 0.5—1.3 mg of alanine as a standard sample and 10 mg of S (5 mg of S was

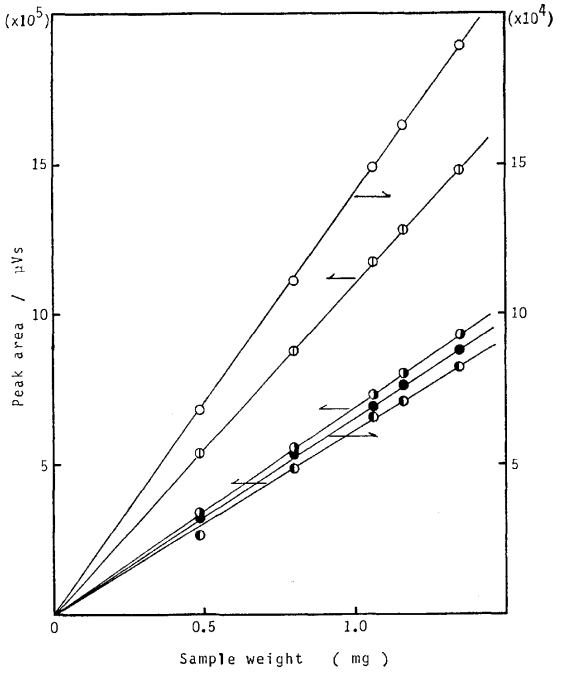

Fig. 1. Relationship between sample weight and peak area of each product. ○: N_2, ●: CO_2, ⦶: H_2S, ◑: COS, and ◐: CS_2.

used in the conventional PSGC) were subjected to PSGC analysis, and the relationship between the sample weight and the peak area of each product was determined. Figure 1 shows that a plot of peak area of each product *vs.* sample weight gives a straight line. 2) In order to examine the reproducibility of the analytical value under the present conditions, the present PSGC analysis was repeated 10 times using 1 mg of alanine and 10 mg of S. The same procedure was repeated 10 times with 0.5 mg of alanine and 5 mg of S. By using these analytical data, the analytical values under the present conditions were compared with those under the previous ones by estimating the coefficient of variation (CV) of the peak area ratio of each product to their sum (Table 1). These examinations indicate that PSGC analysis is also feasible for use with 1 mg samples though the reproducibility of the analytical values under the present conditions is slightly inferior to those under the conventional ones, as is inferred from Table 1.

Calculation Method of C, H, O, and N Content. The individual absolute content of C, H, O, and N in a sample can be calculated theoretically by the following equations.

$$\mathrm{C(wt\%)} = \frac{W_A(\mathrm{C})[f_C(\mathrm{CO_2})N(\mathrm{CO_2}) + f_C(\mathrm{COS})N(\mathrm{COS}) + f_C(\mathrm{CS_2})N(\mathrm{CS_2})]}{w} \times 100 \quad (1)$$

$$\mathrm{H(wt\%)} = \frac{W_A(\mathrm{H})f_H(\mathrm{H_2S})N(\mathrm{H_2S})}{w} \times 100 \quad (2)$$

$$\mathrm{O(wt\%)} = \frac{W_A(\mathrm{O})[f_O(\mathrm{CO_2})N(\mathrm{CO_2}) + f_O(\mathrm{COS})N(\mathrm{COS})]}{w} \times 100, \quad (3)$$

Table 1. Reproducibility of the peak area ratio of each procuct to their sum

Sample weight (mg)	CV/%[a]				
	N_2	CO_2	H_2S	COS	CS_2
1	0.850	1.84	0.385	0.508	1.29
0.5	0.451	0.942	0.230	0.484	1.06

a) Calculated from 10 runs for alanine.

Table 2. Products from each standard sample

Standard sample	Products
Cyanoguanidine	N_2, H_2S, CS_2
8-Quinolinol	N_2, H_2S, COS, CS_2
Sucrose	CO_2, H_2S, COS, CS_2

$$\mathrm{N(wt\%)} = \frac{W_A(\mathrm{N})f_N(\mathrm{N_2})N(\mathrm{N_2})}{w} \times 100, \quad (4)$$

where $W_A(\alpha)$ is the atomic weight of α(α=C, H, O, and N), $N(\beta)$ is the mole number(mol) of β(β=CO_2, COS, CS_2, H_2S, and N_2), w is the sample weight(mg), and $f_\alpha(\beta)$ is the number of element α in a reaction product β. Then the following equation is defined in the case of gas-chromatographic analysis.

$$A(\beta) = F(\beta)N(\beta), \quad (5)$$

where $A(\beta)$: peak area(μV s) of β and $F(\beta)$: proportional constant (μV s/mol), which is called calibration factor. Moreover, $f_\alpha(\beta)$ are offered by the following values.

$$f_C(\mathrm{CO_2}) = f_C(\mathrm{COS}) = f_C(\mathrm{CS_2}) = f_O(\mathrm{COS}) = 1 \quad (6)$$

$$f_H(\mathrm{H_2S}) = f_O(\mathrm{CO_2}) = f_N(\mathrm{N_2}) = 2 \quad (7)$$

Therefore, by introducing Eqs. 5—7 into Eqs. 1—4, Eqs. 1—4 are rewritten as follows.

$$\mathrm{C(wt\%)} = W_A(\mathrm{C})\left[\frac{A(\mathrm{CO_2})}{F(\mathrm{CO_2})} + \frac{A(\mathrm{COS})}{F(\mathrm{COS})} + \frac{A(\mathrm{CS_2})}{F(\mathrm{CS_2})}\right] \times \frac{1}{w} \times 100 \quad (8)$$

$$\mathrm{H(wt\%)} = W_A(\mathrm{H}) \times \frac{2A(\mathrm{H_2S})}{F(\mathrm{H_2S})} \times \frac{1}{w} \times 100 \quad (9)$$

$$\mathrm{O(wt\%)} = W_A(\mathrm{O}) \times \left[\frac{2A(\mathrm{CO_2})}{F(\mathrm{CO_2})} + \frac{A(\mathrm{COS})}{F(\mathrm{COS})}\right] \times \frac{1}{w} \times 100 \quad (10)$$

$$\mathrm{N(wt\%)} = W_A(\mathrm{N}) \times \frac{2A(\mathrm{N_2})}{F(\mathrm{N_2})} \times \frac{1}{w} \times 100 \quad (11)$$

Each absolute content of C, H, O, and N in a sample can be calculated by use of Eqs. 8—11 from the analytical data of a sample if the values of $F(\beta)$ have been determined by Eqs. 8—11 from the analytical data of standard samples.

Determination of Calibration Factors. According to the PSGC method, the carbon in a sample is converted to CO_2(its amount is negligibly small when the value of C/O exceeds about 8), COS, and CS_2, hydrogen is converted to H_2S, oxygen to CO_2 and COS, and nitrogen to N_2 by the pyrolytic sulfurization. Therefore, in order to determine $F(\beta)$ of the products, the

TABLE 3. CALIBRATION FACTOR

compounds which satisfy the following requirements must be selected as the standard samples; 1) N-containing compound, 2) H-containing compound, 3) C-containing and O-free compound, 4) C-containing and O-rich compound from which CO_2 is produced, and 5) C-containing and O-poor compound from which CO_2 is produced in small amounts. In the present study, cyanoguanidine will satisfy the requirements of 1), 2), and 3), sucrose will satisfy that of 4), and 8-quinolinol will satisfy that of 5). Accordingly there substances were selected as the standard samples for the determination of $F(\beta)$. The reaction products from each standard sample on pyrolytic sulfurization are shown in Table 2. As can be seen from Table 2, $F(N_2)$ can be calculated by Eq. 11 from the analytical results for cyanoguanidine and 8-quinolinol; $F(H_2S)$ by Eq. 9 from that of cyanoguanidine, 8-quinolinol, and sucrose; $F(COS)$ by Eq. 10 from that of 8-quinolinol; and $F(CS_2)$ by Eq. 8 from that of cyanoguanidine. $F(CO_2)$ can also be calculated by Eq. 10 from both $F(COS)$ and the analytical result of sucrose. The calibration factor of each product was shown in Table 3. All of the calibration factors (Table 3) were used for the calibration of each absolute content of C, H, O, and N in a sample.

Analysis of Various Organic Compounds. Various organic compounds including metal organic chelates were analyzed by the present procedure; the results are shown in Table 4. Table 4 indicates that each absolute content of C, H, O, and N in an organic compound can be successfully and simultaneously determined by the present method.

Comparison of the Present Method with the Conventional PSGC. The present method was compared with the conventional PSGC in the following manner. An analysis using about 1 mg of sample is repeated 10 times by use of alanine as a standard sample, and both the absolute content of C, H, O, and N in alanine and the atomic ratio between C, H, O, and N were calculated by the present method and by the conventional PSGC, respectively. Moreover, fluctuation of analytical data by the present method and the conventional PSGC, respectively, was also calculated and the value of CV for each value of C, H, O, and N was compared (Table 5). Table 5 indicates that the present method is superior to the conventional PSGC with regard to the value of H but inferior for C and O.

Table 5. Comparison of the present method with the conventional PSGC

Method	CV/%[a]			
	C	H	O	N
Present	0.820	0.217	0.562	0.646
Conventional PSGC	0.351	0.685	0.357	0.654

a) Calculated from 10 runs for alanine.

From the results obtained by the present study, it can be concluded that the absolute content of C, H, O, and N in an organic compound can also be determined, if necessary, by PSGC. This makes possible the simultaneous determination of the atomic ratio between C, H, O, and N in an organic compound without weighing a sample. This will make PSGC a more valuable method in organic elemental analysis.

Determination of a Small Amount of Biological Constituent by Use of Chemiluminescence. I. The Flow-injection Analysis of Protein

Tadashi HARA,* Motohiro TORIYAMA, and Kazuhiko TSUKAGOSHI

Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602

(Received October 14, 1982)

A new method in which luminol-hydrogen peroxide luminescent system is used has been proposed for the determination of the presence of protein. Since the catalytic activity of copper(II) for the chemiluminescent reaction between luminol and hydrogen peroxide decreased when copper(II) interacted with polypeptide linkage, this phenomenon was applied to the determination of protein. Determination of protein was carried out by a flow-injection method. The effects of reagent concentration, flow-rate, and reaction time on the analytical value were examined and the conditions for the determination of protein were established. Similar calibration curves were obtained for human serum albumin, bovine serum albumin, bovine serum α-globulin, and bovine serum γ-globulin. According to the present flow-injection method using chemiluminescent reaction, a small amount of protein could be conveniently and economically determined over a wide range of concentration, 7×10^{-4}—7×10^{-2} g dm^{-3}, with the detection limit of 0.2 μg and at the rate of about 30 samples per hour. The present method was applicable to the determination of protein in serum.

It is well known that the chemiluminescence (CL) emitted by 5-amino-2,3-dihydro-1,4-phthalazinedione (luminol) in the presence of hydrogen peroxide(H_2O_2) is remarkably enhanced by a catalyst such as Co(II), Co(III), Cr(III), Cu(II), Fe(II), Fe(III), Hg(II), Mn(II), Ni(II), Os(IV), Os(VIII), and their complex compounds.[1] This has been used for the determination of a small amount of H_2O_2 or metal ion.[2-4] Since the catalytic activity of copper(II) for the CL reaction between luminol and H_2O_2 was found to decrease with the amount of coexisting protein, a new method for the determination of protein based on this phenomenon was examined. Judging from the facts that the catalytic activity of a copper(II) complex is maximum when two of the four coordination sites are occupied by a ligand, while it is not observed when all four coordination sites are occupied by a ligand,[5] and that copper(II) in the biuret reaction reacts with four nitrogen atoms of a polypeptide chain to form a violet complex,[6] the decrease of the catalytic activity of a copper(II) complex in the present study seems to be attributed to the formation of a copper(II)–polypeptide complex, that is, the occupation of four coordination sites by a protein molecule.

Various methods such as a Kjeldahl method, a biuret method, a UV method, a Lowry method, a dyestuff combination method, and a fluorometric(thiamine) method have been reported for the determination of protein.[7] Though both a Kjeldahl method and a biuret method are known as standard methods, the former is difficult to operate and the latter is less sensitive. A UV method and a Lowry method are sensitive but they are unsuitable for the determination of protein in a unknown sample because the analytical values obtained by them vary by the kind of protein. A dyestuff combination method is also unsuitable for the determination of protein having different origins because the reaction between dyestuff and protein is too complicated. These methods can estimate protein amounts more than 1 μg, whereas a thiamine method based on fluorescence can estimate 0.1—1.0 μg protein.[8] However the fluorometric method requires a complicated procedure and has to be applied under rigid conditions. The CL method for the determination of protein is characterized by the following: 1) Highly sensitive, 2) determinable over a wide range of protein concentration, 3) easy to operate, 4) inexpensive apparatus and reagent, and 5) it is easy to set up the flow-injection system. This will make the CL method available for the determination of a trace amount of protein in various samples.

Experimental

Reagent. A luminol solution was prepared as 1.0×10^{-3} mol dm^{-3} by dissolving luminol in the buffer solution (pH 10.15) containing 0.1 mol of potassium hydroxide and of boric acid in 1 dm^{-3}. A H_2O_2 solution was prepared (2.5×10^{-3} mol dm^{-3}) by diluting a 0.3 wt% H_2O_2 solution with water.

A copper(II) solution was prepared as a 2.0×10^{-2} mol dm^{-3} concentration by dissolving copper(II) sulfate pentahydrate 5.0 g, potassium sodium tartrate 45.0 g, sodium hydroxide 8.0 g, and potassium iodide 5.0 g in that order and by bringing the mixture to 1 dm^{-3} with water.[9] Each catalyst solution, which contained copper(II), hematin(ICN Pharmaceuticals, Inc.), hexacyanoferrate(III), or osmium(VIII) oxide, was prepared by diluting with the above-mentioned buffer solution. The reagents used were of commercially available special grade. Human serum albumin and bovine serum α-globulin from ICN Pharmaceuticals, Inc., and bovine serum albumin(BSA) and bovine serum γ-globulin from SIGMA CHEMICAL Co., and control serum(Q-PAK-Chemistry Control Serum II) from HYLAND were used.

Ion exchange water was distilled for use.

Apparatus and Procedure. Both a luminol solution which had been left standing overnight in a dark place and a buffer solution were degassed by stirring under reduced pressure and were then used. The schematic diagram of the apparatus which was set up for flow-injection analysis is shown in Fig. 1. A Teflon tube(1 mm i.d.) and a connector were used. A buffer solution(a), a H_2O_2 solution(b), and a luminol solution(c) were delivered at the flow rate of 2.5 cm^3 min^{-1} with the corresponding pumps: (p_1), (p_2), (p_3)-(PERISTA MINI PUMP SJ-1211). A buffer solution and

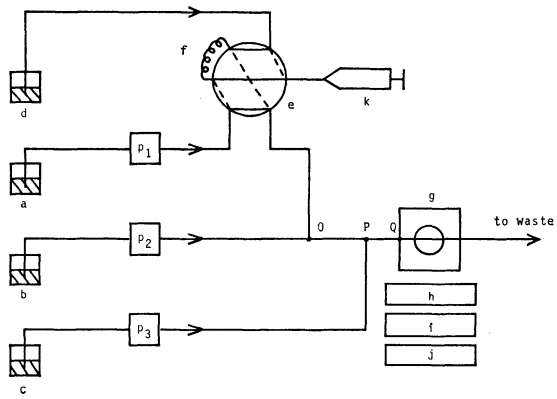

Fig. 1. Flow-injection system.

a H_2O_2 solution were first mixed and the resulting mixture was combined with a luminol solution; the distances between P and O or Q were 35 and 10 cm, respectively. A sample solution containing protein was diluted with a buffer solution and to it a copper(II) solution was added so as to become 5.0×10^{-6} mol dm^{-3}; it was held at 30 °C for 50 min. A definite amount(0.4 cm^3) of the sample solution thus obtained was injected into the line of a buffer solution. If the catalytic activity of a metal salt catalyst had to be examined, the catalyst solution alone was injected into the line of a buffer solution instead of the above-mentioned sample solution. A poly(vinyl chloride) tube(45 cm$\times$0.8 mm i.d.) was spirally wound and was then used as the cell (g). The CL intensity of the solution passing through the cell was measured by a photomultiplier(h) (Hamamatsu TV Co. Ltd., R928), amplified with a amplifier(i)(Horiba Ltd., OPE-402), and recorded on a recorder(j)(Yokogawa Electric Works, Ltd., 3046). The net CL intensity of a sample solution was obtained by subtracting the background (the CL intensity of the solution containing no sample) from the observed intensity. The ratio of CL intensity of a protein sample solution to that of a 5.0×10^{-6} mol dm^{-3} copper(II) solution was used for the presentation of data. According to the present apparatus, measurement could be done at the rate of about 30 samples per hour.

Results and Discussion

Determination of Analysis Conditions. The effect of H_2O_2 concentration and of luminol concentration on the CL intensity are shown in Figs. 2 and 3, respectively. As can be seen from Fig. 2, the CL intensity increased with an increasing concentration of H_2O_2 and was accompanied by increasing noise. The CL intensity in Fig. 3 was found to be maximum when the luminol concentration was the same (1.0×10^{-3} mol dm^{-3}) as the H_2O_2 concentration. Therefore 1.0×10^{-3} mol dm^{-3} luminol and 2.5×10^{-3} mol dm^{-3} H_2O_2 were chosen as their optimum concentrations in the following experiment.

Though the CL intensity increased with an increasing flow rate, all the flow rates were set at 2.5 cm^3 min^{-1} because of the capacity of the pumps. The high sensitivity was attained by adding a H_2O_2 solution to a buffer solution, followed by mixing the mixed solution with a luminol solution.

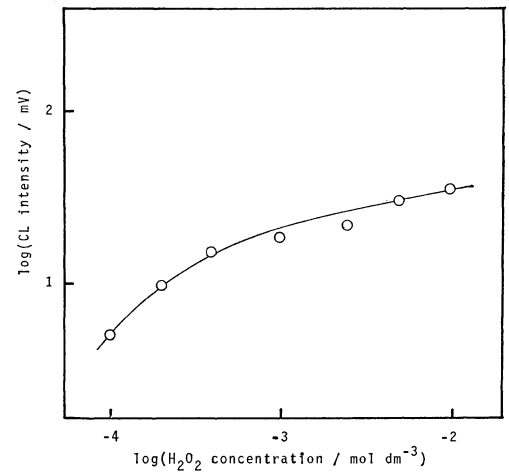

Fig. 2. Effect of H_2O_2 concentration on CL intensity. Conditions: 1.0×10^{-4} mol dm^{-3} luminol and 1.0×10^{-5} mol dm^{-3} $K_3[Fe(CN)_6]$.

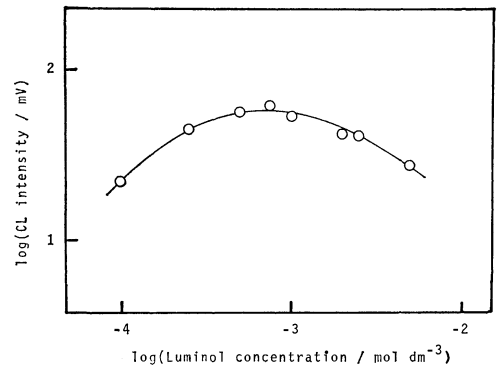

Fig. 3. Effect of luminol concentration on CL intensity. Conditions: 1.0×10^{-3} mol dm^{-3} H_2O_2 and 1.0×10^{-5} mol dm^{-3} $K_3[Fe(CN)_6]$.

Selection of Chemiluminescent Catalyst. We examined the catalytic activity of copper(II) sulfate, and of osmium(VIII) oxide and hematin, which are compounds of Os and Fe belonging to the eighth group transition elements in the periodic table and had been known to show high catalytic activity for the CL reaction.[10] The relationship between catalyst concentration and CL intensity was obtained by means of the apparatus shown in Fig. 1 (Fig. 4). Chemiluminescent response was observed for 1×10^{-7}—5×10^{-5} mol dm^{-3} copper(II) sulfate, 2×10^{-9}—2×10^{-6} mol dm^{-3} osmium(VIII) oxide, and 5×10^{-10}—5×10^{-6} mol dm^{-3} hematin, respectively.

By using a definite amount of 5.0×10^{-6} mol dm^{-3} copper(II) sulfate, 7.9×10^{-7} mol dm^{-3} osmium(VIII) oxide, and 4.0×10^{-7} mol dm^{-3} hematin solutions, which were slightly higher concentrations than those at each middle point in the above-mentioned catalyst concentrations, three calibration curves were obtained for BSA (Fig. 5). When a hematin solution or copper(II) sulfate solution was added to a protein solution, their catalytic activities or CL intensity decreased with time and finally stabilized after 2 h at room tem-

perature. In a similar experiment using osmium(VIII) oxide, the catalytic activity or CL intensity did not stabilize until after about 24 h. Judging from the detection limit of protein, concentration range suitable for the determination of protein, lowering of CL intensity by a definite amount of protein, and time necessary for the stabilization of CL intensity, copper(II) sulfate was most recommendable as a chemiluminescent catalyst for the present study.

The CL intensities in the presence of copper(II) sulfate alone or of copper(II) sulfate-tartaric acid are shown in Fig. 6. The catalytic activity of the former was a little smaller than that of the latter and its difference was remarkable at high concentration of copper(II), 1×10^{-5}—5×10^{-5} mol dm^{-3}, where the formation of copper(II) hydroxide was observed after allowing the copper(II) solution to stand alone for several hours. Therefore, the above difference seems to be related to the formation of copper(II) hydroxide. The catalytic activity of copper(II) solution was ob-

○: 1.4×10^{-3} g dm^{-3}-, ●: 3.5×10^{-3} g dm^{-3}-, ◑: 7.0×10^{-3} g dm^{-3}-, ◐: 1.4×10^{-2} g dm^{-3}-, ⓘ: 3.5×10^{-2} g dm^{-3}- BSA, and (○): BSA free. Conditions: 1.0×10^{-3} mol dm^{-3} luminol and 2.5×10^{-3} mol dm^{-3} H_2O_2.

tained with good reproducibility in the presence of tartaric acid without producing the copper(II) hydroxide. A small amount of potassium iodide was also added to the copper(II) solution to prevent it from undergoing autoreduction.[11] The calibration curve for copper(II) sulfate-tartaric acid was not linear but sigmoidal. The reason for this remains unclear.

Determination of Protein. The relationship between CL intensity and elapsed time after mixing of copper(II) with each BSA solution of 1.4×10^{-3}, 3.5×10^{-3}, 7.0×10^{-3}, 1.4×10^{-2}, and 3.5×10^{-2} g dm^{-3} was examined at 30 °C; the result was shown in Fig. 7. CL intensity decreased with time after mixing, but no lowing of CL intensity was observed in 50 min—24 h after mixing. It was, therefore, necessary for the determination of protein to hold the mixed solution

Conditions: 1.0×10^{-3} mol dm^{-3} luminol and 2.5×10^{-3} mol dm^{-3} H_2O_2.

of copper(II) and protein at 30 °C for 50 min.

Figure 8 showed calibration curves of BSA which were obtained by use of 1.0×10^{-6}, 5.0×10^{-6}, 1.0×10^{-5}, and 5.0×10^{-5} mol dm^{-3} of copper(II) sulfate. The detection limit of protein concentration and the decrease of CL intensity for a definite amount of protein suggested that a 5.0×10^{-6} mol dm^{-3} copper(II) sulfate solution be used in the present study.

The calibration curve for BSA was obtained under the same conditions as specified above (Fig. 9), and it was usable for the determination of protein in the concentration range of 7×10^{-4}—7×10^{-2} g dm^{-3}. The decrease of CL intensity in the presence of protein is attributed to the lowing of the catalytic activity of copper(II) based on the formation of a copper(II)–polypeptide complex. This is understandable from the following facts: 1) The catalytic activity of a copper-(II) complex is maximum when two of the four coordination sites are occupied by a ligand, while it is

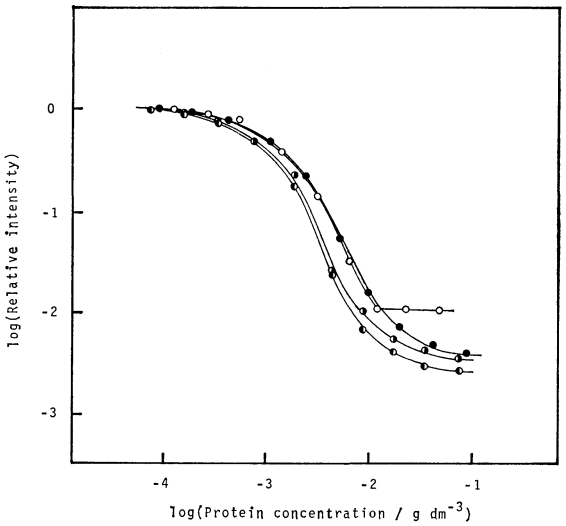

Fig. 10. Calibration curves of various proteins.
○: Bovine serum α-globulin, ●: human serum albumin, ◑: bovine serum albumin, and ◑: bovine serum γ-globulin.
Conditions: 1.0×10^{-3} mol dm^{-3} luminol and 2.5×10^{-3} mol dm^{-3} H_2O_2.

not observed when all four coordination sites are occupied by a ligand,[5] 2) copper(II) in the biuret reaction reacts with four nitrogen atoms of a polypeptide chain to form a violet complex.[6] The present method makes use of the formation of copper(II)–polypeptide complex and estimates the amount of protein indirectly by measuring the catalytic activity of copper(II) for CL; it will be suitable for the determination of protein in a biological fluid sample in which no constituent except protein shows biuret reaction.[12]

The calibration curves for human serum albumin, bovine serum α-globulin, and bovine serum γ-globulin were prepared in a way similar to that for BSA; they are compared in Fig. 10. The constant CL intensity in the concentration range of 1.2×10^{-2}—6.0×10^{-2} g dm^{-3} bovine serum α-globulin may be attributed to insolubility of protein because suspended substances were observed at protein concentrations above 1.0×10^{-1} g dm^{-3}. Furthermore there were some differences between CL intensities of individual proteins. Assuming that the decrease of CL intensity is based on the decrease of catalytic activity by the formation of copper(II)–polypeptide complex, the differences between CL intensities of individual proteins will markedly depend on the total amount of the peptide linkage in a definite weight of protein.

According to the present method, 7×10^{-4}—7×10^{-2} g dm^{-3} protein could be determined with a detection limit of 0.2 μg. The present method is shown in Table 1 together with some typical conventional methods and with their determinable amounts of protein. The present method was 10—100 times as sensitive as in the conventional methods, except for a thiamine(fluorometric) method, and was applicable to the determination of a wide concentration range of protein. Furthermore the present method is characterized by easy operation based on a flow-injection system and by

TABLE 1. RANGE OF PROTEIN DETERMINABLE BY VARIOUS METHODS

Method	Determinable range (μg)	Ref.
Present	0.2—20	
Micro biuret	26—530	13
Kjeldahl	30—100	14
UV	20—100	15
Lowry	5—100	16
Dyestuff combination	1—10	17
Thiamine	0.1—1.0	8

TABLE 2. REPRODUCIBILITY OF THE PRESENT METHOD

BSA concentration/g dm^{-3}	CV value/%
0	7.7
7.0×10^{-4}	7.9
7.0×10^{-3}	6.5
7.0×10^{-2}	3.7

inexpensive reagent and apparatus. According to a thiamine(fluorometric) method, 0.1—1.0 μg of protein can be determined but it requires a complicated procedure and has to be applied under rigid conditions.

As can be seen from Fig. 10, the difference in analytical data based on the difference of CL intensity was about 50% for the two kinds of protein in which the difference was maximum. This value seems reasonable if we take the corresponding values of a dyestuff combination method(about 200%) and of a Lowry method(about 20%) into consideration.

The coefficient of variation (CV) of the present method for the determination of protein is shown in Table 2. The CV values increased with a decreasing concentration of protein. Since the fluctuating flow offered by a pump seriously affected the precision of the present determination, an improvement of the apparatus was still necessary for the minimization of this CV value.

Application to Serum Analysis. In order to determine the amount of protein in serum by the present method, a serum sample is diluted to 10^3—10^5 times its volume. The effect of iron salt, chloride, and urea contained in the serum on the CL intensity was examined by use of iron(III) chloride hexahydrate, potassium chloride, and urea. Fe(III) 2.0×10^{-8} mol dm^{-3}, Cl^- 1.0×10^{-4} mol dm^{-3}, and $(NH_2)_2CO$ 1.0×10^{-5} mol dm^{-3} corresponding to the concentration at 10^3 times' dilution of a serum sample did not influence the CL intensity at all.

Then different amounts of BSA were added to a definite amount of control serum(final concentration 1.2×10^{-3} g dm^{-3}), and the total amount of protein was estimated by use of the calibration curve of BSA (Fig. 11). The analytical value of the ordinate indicated the protein content in a sample solution, which was expressed as BSA. The difference between straight lines I and II just corresponded to the added amount of control serum. This result showed that the present method was applicable to the determination of protein in a serum sample without being interfered with by

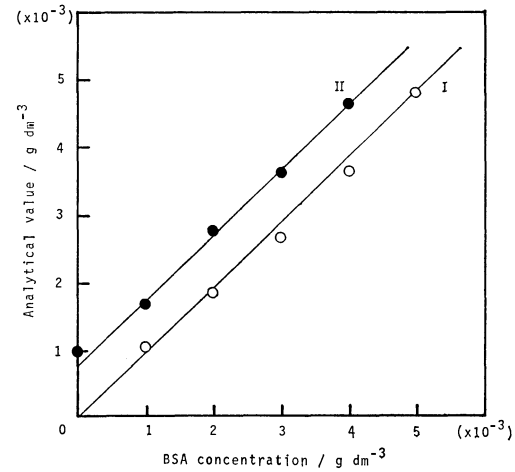

Fig. 11. Relationship between BSA concentration and analytical value.
○: BSA and ●: BSA+control serum.
Conditions: 1.2×10^{-3} g dm^{-3} control serum, 1.0×10^{-3} mol dm^{-3} luminol, and 2.5×10^{-3} mol dm^{-3} H_2O_2.

coexisting constituents. Here 0.01 μl of control serum was diluted to 10^5 times volume and analyzed.

On the basis of the above-mentioned investigation, a method for the determination of a small amount of protein was newly established. The present method by means of a flow-injection system is characterized by the following: 1) Protein amounts are determinable in the protein concentration range of 7×10^{-4}—7×10^{-2} g dm^{-3} with detection limit of 0.2 μg; 2) the method is 10—100 times more sensitive than the conventional methods except the fluorometric one; 3) it is easy to operate; 4) it is inexpensive in the apparatus and the reagent; 5) about 30 samples per hour can be measured. The present method is applicable to the determination of protein in a serum sample and is expected to promote the field of highly sensitive detection of protein amounts.

The authors wish to thank Mr. Masakatsu Imaki (Horiba Ltd.,) for providing the apparatus necessary for the present study.

(Received September 24, 1982)

Alkoxo-bridged polynuclear copper(II) complexes with condensation products of 3-ethoxymethylene-2,4-pentanedione and each of three amino alcohols, 2-aminoethanol, 3-amino-1-propanol, and 1-amino-2-propanol, were prepared and characterized by elemental analyses, infrared spectra, electronic spectra, molecular weight measurements, magnetic susceptibility measurements, and crystal structure analysis, the complexes being abbreviated as Cu(L-2), Cu(L-3), and Cu(L-2m), respectively. Cu(L-3) is a dimer, but Cu(L-2m) and Cu(L-2) are tetramers. The magnetic susceptibility of violet Cu(L-3), whose electronic spectrum exhibits a d-d band maximum at 17.7×10^3 cm^{-1}, is in conformity to the Bleaney-Bowers equation with exchange integral $-2J=$ 920 cm^{-1}. Cu(L-3) consists of alkoxo-bridged centrosymmetric binuclear units, where the geometries around the copper ion and bridged oxygen atom are planar and the angle of Cu–O–Cu is 103.6(1)°. The magnetisms of blue complexes Cu(L-2) and Cu(L-2m) exhibiting a d-d band maximum at 15.7×10^3 cm^{-1} obey the Curie-Weiss law with positive Weiss constants 17 and 20 K, respectively, and are in accord with the Heisenberg model based on a tetranuclear cubane-like structure.

A great number of hydroxo- or alkoxo-bridged polynuclear copper(II) complexes have been studied in order to clarify the mechanism of magnetic interactions operating between copper(II) ions.[1-4] Hatfield *et al.*[1,2] found that the $2J$ value representing the copper(II)–copper(II) magnetic interaction correlates linearly with the angle of Cu–O–Cu, and emphasized the importance of the angle for the spin-exchange interaction. Kida and coworkers[3-9] investigated extensively the polynuclear copper(II) complexes with linear aliphatic amino alcohols such as $R_2N(CH_2)_nOH$, $R_2N(CH_2)_mX(CH_2)_nOH$, and $RS(CH_2)_mNH(CH_2)_nOH$ (R=alkyl; m,n=2 or 3; X=S, NH). Their conclusion with respect to the relationship between structure and magnetic property can be summarized as follows: (1) The planarity around the bridging oxygen atom is essentially important for the spin-exchange interaction rather than the angle of Cu–O–Cu; (2) the axial coordination accompanies deviation from the planarity around the oxygen atom and decreases the magnetic interaction; (3) the ring size of the chelate ring consisting of amino alcohol and copper ion is important in determining not only the planarity around the bridging oxygen atom, *i.e.*, the magnetic interaction, but also which the complex prefers to be, dimeric, trimeric, or tetrameric species. Two copper(II) complexes with each of ligands derived from 2,4-pentanedione and 2-aminoethanol or 3-amino-1-propanol (to be abbreviated as Cu(eia) and Cu(pia), respectively), may supply a set of typical examples for this point, since the complex Cu(pia) is a dimer with 0.41 BM. at room temperature, while the complex Cu(eia) is a cubane-like tetramer with 1.87 BM. at room temperature.[10]

In this study, polynuclear copper(II) complexes with Schiff base ligands derived from 3-ethoxymethylene-2,4-pentanedione and each of three amino alcohols, 2-aminoethanol, 3-amino-1-propanol, and 1-amino-2-propanol, have been prepared in order to examine their conclusion, (these complexes to be abbreviated as Cu(L-2), Cu(L-3), and Cu(L-2m), respectively). The complexes were characterized by elemental analyses, molecular weights, infrared spectra, electronic spectra, magnetic susceptibility measurements, and single-crystal X-ray analysis. Properties have been discussed in relation to the size of the chelate ring involving the amino alcohol and copper ion.

Experimental

Syntheses. 3-Ethoxymethylene-2,4-pentanedione was prepared from 2,4-pentanedione, acetic anhydride, and triethyl orthoformate according to the procedure of Riley and Busch.[11]

H_2L-2: To 50 cm^3 of 98% ethanolic solution of 0.05 mol of freshly prepared 3-ethoxymethylene-2,4-pentanedione was slowly added 0.05 mol of 2-aminoethanol in 30 cm^3 of ethanol at room temperature. After the reaction mixture had been allowed to stand for several hours in a refrigerator, white crystals which precipitated were collected and dried *in vacuo*. Found: C, 50.63; H, 8.02; N, 7.62%. Calcd for $C_8H_{13}NO_3\cdot H_2O$: C, 50.79; H, 7.93; N, 7.40%. IR: 3260 (ν_{OH}) and 1613 ($\nu_{C=N}$) cm^{-1}.

Cu(L-2): Ligand (H_2L-2), copper(II) acetate monohydrate, and sodium hydroxide in a mole ratio of 1:1:2 were mixed in ethanol and the mixture was refluxed for 1 h. The ethanol was removed by evaporation to dryness and dichloromethane was added. The resultant slurry was filtered and during the volume reduction of solution, crystalline Cu(L-2) was precipitated. It was recrystallized from a mixture of dichloromethane and methanol as dark blue crystals. Found: C, 40.97; H, 4.87; N, 6.01%. Calcd for $C_8H_{11}NO_3$-Cu: C, 41.28; H, 4.76; N, 6.01%.

Cu(L-2m) and Cu(L-3): Copper(II) complexes Cu(L-2m) and Cu(L-3) were prepared by mixing copper(II) acetate monohydrate, 3-ethoxymethylene-2,4-pentanedione, the corresponding amino alcohol, and sodium hydroxide in a mole ratio of 1:1:1:2 in ethanol. The mixture was refluxed

for 1 h and the ethanol was removed to dryness by evaporation. The resultant solid was dissolved in dichloromethane and the solution was filtered, and during the volume reduction of solution, crystalline materials were precipitated. Complexes Cu(L-2m) and Cu(L-3) were recrystallized from a mixture of dichloromethane and methanol as dark blue rhombic and violet plate crystals, respectively. Found for Cu(L-2m): C, 43.39; H, 5.49; N, 5.25%. Calcd for $C_9H_{13}NO_3Cu$: C, 43.81; H, 5.31; N, 5.68%. Found for Cu(L-3): C, 43.68; H, 5.43; N, 5.69%. Calcd for $C_9H_{13}NO_3Cu$: C, 43.81; H, 5.31; N, 5.68%.

Physical Measurements. Infrared spectra were measured with Nujol mulls on a Shimadzu IR-410 spectrophotometer. Electronic spectra were recorded on a Hitachi 323 spectrophotometer in dichloromethane. Molecular weights were determined in benzene at 40 °C on a Corona vapor pressure osmometer Model 117. Magnetic susceptibilities were measured by the Faraday method in the temperature range from the liquid nitrogen temperature to room temperature. The apparatus was calibrated by use of $[Ni(en)_3]S_2O_3$.[12] The susceptibility was corrected for the diamagnetism of component atoms by use of Pascal's constants.[13] Effective magnetic moment was calculated from the equation $\mu_{eff}=2.828\sqrt{(\chi_A-N\alpha)T}$, where χ_A is the magnetic susceptibility per copper atom and $N\alpha$ is the temperature independent paramagnetism.

X-Ray Analysis of Cu(L-3). Violet plate-like crystals of Cu(L-3) were obtained by slow precipitation from a dichloromethane and methanol solution at room temperature. A crystal with approximate dimensions of $0.4\times0.5\times0.5$ mm^3 was cut out from a large crystal and used for X-ray diffraction study. Unit-cell parameter and intensity data were obtained on a Rigaku Denki AFC-5 automated four-circle diffractometer with a monochromatized Mo $K\alpha$ radiation ($\lambda=0.71069$ Å) at 24 ± 1 °C. Unit-cell parameters were determined by the least-squares refinement based on 20 reflections in the range $15°<2\theta<41°$. Crystal data: $C_{18}H_{26}N_2O_6Cu_2$, F.W.=493.5, monoclinic, space group=$P2_1/c$, $a=5.700(1)$, $b=8.654(3)$, $c=20.270(5)$ Å, $\beta=95.05(2)°$, $V=996.1(5)$ Å^3, $D_x=1.645$ ($Z=2$), $D_m=1.61$ g cm^{-3} (by the flotation method in aqueous KI solution), μ(Mo $K\alpha$)=13.4 cm^{-1}.

Intensity data were collected by the θ-2θ scan technique with a scan rate of 8° min^{-1} in 2θ. For weak reflections the peak scan was repeated two or three times depending on their intensities. Three standard reflections were monitored every 100 reflections throughout the set to confirm no occurrence of decay in intensity. A total of 1756 reflections with $2.5°<2\theta<50°$ were collected, of which independent 1514 reflections with $|F_o|>3\sigma(|F_o|)$ were considered as "observed" and used for structural analysis. Intensity data were corrected for the Lorentz and polarization effects but not for absorption because of the small crystal size and low absorption coefficient.

The structure was solved by the conventional heavy-atom method and refined by the block-diagonal least-squares method. In the least-squares calculation, the function minimized was $\sum w(|F_o|-k|F_c|)^2$ where $w=1/\sigma(|F_o|)^2$. The neutral atomic scattering factors for H, C_{cov}, N, O, and Cu were taken from International Tables for X-Ray Crystallography, Vol. IV.[14] Anomalous dispersion corrections $\Delta f'$ and $\Delta f''$ for all the component atoms were also taken from the literature.[14] All calculations were carried out on a FACOM M-200 computer at the Computer Center of Kyushu University by use of the UNICS II Crystallographic Computing System.[15,16] The coordinates of the copper atom were easily obtained by an interpretation of Harker's peaks on the Patterson map. A Fourier synthesis based on the copper position revealed all the nonhydrogen atoms. Least-squares refinement with isotropic thermal parameters and then with anisotropic ones reduced the disagreement factors $R=\sum(|F_o|-|F_c|)/\sum|F_o|$ and $R_w=[\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2]^{1/2}$ to 6.00 and 7.55%, respectively. At this stage, a difference Fourier synthesis was calculated and located all the hydrogen atoms at chemically reasonable positions. Further refinement with anisotropic thermal parameters for nonhydrogen atoms and isotropic temperature factors for hydrogen atoms gave final values of 4.20 and 4.39% for R and R_w, respectively. The final difference Fourier synthesis showed no significant features.

Final positional parameters with estimated standard deviations are given in Table 1. Lists of structure factors (F_o and F_c) and anisotropic thermal parameters have been deposited as the supplementary data at the Chemical Society of Japan as Document No. 8312.

a) Atomic coordinates for nonhydrogen and hydrogen atoms have been multiplied by 10^4 and 10^3, respectively. The hydrogen atoms are labeled for identification by reference to the atoms to which they are attached.

Results and Discussion

Infrared Spectra. The OH stretching vibration at 3260 cm^{-1} observed for the free ligand H_2L-2 is

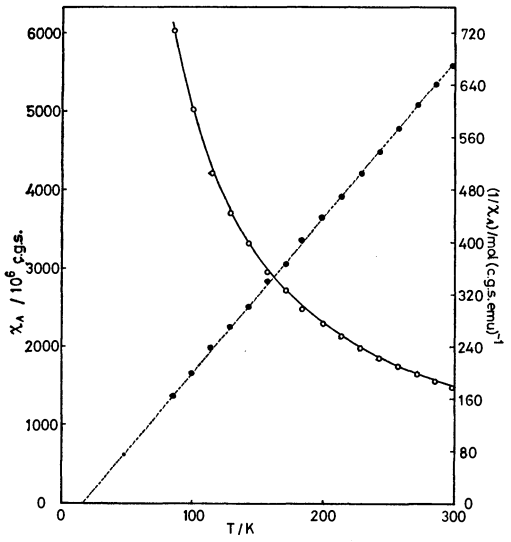

Fig. 1. Temperature dependence of magnetic susceptibility of Cu(L-2). Solid line of magnetic susceptibility represents the theoretical curve based on the equation (2) with the parameters of $J=40\ \mathrm{cm^{-1}}$, $J'=4\ \mathrm{cm^{-1}}$, $g=2.05$, $N\alpha=60\times10^{-6}$ c.g.s. emu/mol.

absent in complex Cu(L-2), indicating that alcoholic proton is lost upon the complexation.

Electronic Spectra. Visible and ultraviolet spectra of the complexes were obtained in dichloromethane and the band maxima are given in Table 2. Electronic spectra of the complexes consist of a broad band in the visible region assignable to the d-d transition with an extinction coefficient of the order of *ca.* 150 $\mathrm{mol^{-1}\,dm^{3}\,cm^{-1}}$ and several bands in the ultraviolet region assignable to charge-transfer bands. The spectrum of complex Cu(L-3) exhibits a d-d transition band maximum at $17.7\times10^{3}\ \mathrm{cm^{-1}}$, while the spectra of complexes Cu(L-2) and Cu(L-2m) exhibit a band maximum at $15.5\times10^{3}\ \mathrm{cm^{-1}}$. This indicates that the coordination environment might be different between the two groups. The bands at *ca.* $(27\text{—}28)\times10^{3}\ \mathrm{cm^{-1}}$ is characteristic of alkoxo-bridged copper(II) complexes and is assignable to the $p_{\pi}(O)\rightarrow d(Cu)$ charge-transfer transition.[3]

Molecular Weights. Molecular weights were estimated by vapor pressure osmometry. The results were as follows: Found for Cu(L-3): 440; calcd for $C_{18}H_{26}N_2O_6Cu_2$ as dimer:496. Found for Cu(L-2): 920; calcd for $C_{32}H_{44}N_4O_{12}Cu_4$ as tetramer: 931. Found for Cu(L-2m): 925; calcd for $C_{36}H_{52}N_4O_{12}Cu_4$ as tetramer: 987. It is apparent that complexes Cu (L-2) and Cu(L-2m) with a five-membered chelate ring involving an amino alcohol and copper ion are tetramer, whereas complex Cu(L-3) with a six-membered chelate ring is dimer.

Magnetic Properties. The magnetic moment of complex Cu(L-3) is 0.35 BM. at room temperature, indicating the operation of a strong antiferromagnetic spin-exchange interaction between the copper(II) ions. The temperature dependence of the magnetic susceptibilities can be interpreted in terms of the following Bleaney-Bowers equation[17] with a paramagnetic impurity term[18] for the isotropic exchange interaction

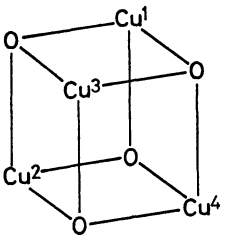

Fig. 2. Structure of tetranuclear cubane-like copper-(II) complex.

TABLE 2. ELECTRONIC SPECTRAL DATA MEASURED IN DICHLOROMETHANE

Complex	Band maxima $\tilde{\nu}/10^{3}\ \mathrm{cm^{-1}}$ (log ε)[a]			
Cu(L-3)	17.7(2.18)	27.7(3.85)	32.2(4.15)	37.3(4.45)
Cu(L-2)	15.7(2.16)	27.0(2.72)*	32.4(4.14)*	36.7(4.45)
Cn(L-m)	15.7(2.21)	27.3(2.72)	32.8(3.96)*	36.4(4.06)*

a) Symbol * means shoulder.

in a copper(II) dimer:

$$\chi_A=\frac{Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp(-2J/kT)\right]^{-1}(1-p)+\frac{0.45p}{T}+N\alpha, \quad (1)$$

where χ_A is the magnetic susceptibility per copper ion, p is the ratio of mononuclear copper(II) ions to total copper(II) ions, and N, g, J, β, and $N\alpha$ have the usual meanings. The experimental data fit Eq. 1 with magnetic parameters $-2J=920\ \mathrm{cm^{-1}}$, $g=2.10$, $p=0.01$, and $N\alpha=60\times10^{-6}$ c.g.s. emu/mol.

The magnetic moments of complexes Cu(L-2) and Cu(L-2m) are 1.88 and 1.86 BM. at room temperature, respectively. As shown in Fig. 1, the magnetisms of complexes Cu(L-2) and Cu(L-2m) obey the Curie-Weiss law with positive Weiss constants 17 and 20 K, respectively, indicating that a ferromagnetic interaction is operative in these complexes. For complexes with this kind of magnetic properties, the tetranuclear cubane-like structure shown in Fig. 2 has been assumed and the temperature dependence of their magnetic properties has been interpreted on the basis of the Heisenberg model.[6,15] The Hamiltonian for the spin-exchange interaction of a tetranuclear structure may be written as $H=-2J_{12}S_1S_2-2J_{13}S_1S_3-2J_{14}S_1S_4-2J_{23}S_2S_3-2J_{24}S_2S_4-2J_{34}S_3S_4$, where the numbering of copper ions are given in Fig. 2. On assuming $J=J_{13}=J_{24}$ and $J'=J_{12}=J_{23}=J_{34}=J_{14}$, magnetic susceptibilities are given by

$$\begin{aligned}\chi_A=3g^2\{&10\exp[(J+2J')/kT]+4\exp(-J/kT)\\&+2\exp[(J-2J')/kT\}/32T\{4\exp[(J+2J')/kT]\\&+5\exp(-J/kT)+\exp(-Q(11)/kT)\\&+\exp(-Q(22)/kT)+\exp(-Q(33)/kT)\\&+\exp(-Q(44)/kT)+3\exp[(J-2J')/kT]\}+N\alpha, \quad (2)\end{aligned}$$

where $Q(11)$, $Q(22)$, $Q(33)$, and $Q(44)$ have the same meanings as those used by Hatfield and Inman.[19] The exchange integral (J, J'), g, and $N\alpha$ were evaluated from the best-fit of experimental data to Eq. 2. The evaluated values for Cu(L-2) are $J=40\ \mathrm{cm^{-1}}$,

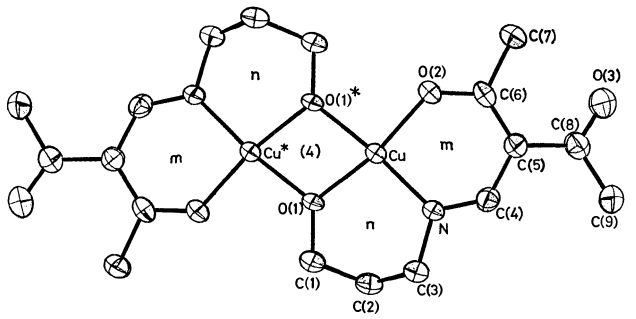

Fig. 3. Molecular structure of Cu(L-3) with the atom numbering scheme.

$J'=4$ cm^{-1}, $g=2.05$, and $N\alpha=60\times10^{-6}$ c.g.s. emu/mol, and those for Cu(L-2m) are $J=40$ cm^{-1}, $J'=5$ cm^{-1}, $g=2.10$, and $N\alpha=60\times10^{-6}$ c.g.s. emu/mol. It is found that the magnetic behavior of complexes Cu(L-2) and Cu(L-2m) can be interpreted in terms of Eq. 2 formulated on the basis of the tetranuclear cubane-like structure and the assumption that both J and J' are positive.

Molecular Structure of Cu(L-3). The molecular structure of complex Cu(L-3) consists of discrete alkoxo-bridged centrosymmetric binuclear units, as deduced on the molecular weight measurement and magnetic behavior. An ORTEP plot of the perspective molecule is shown in Fig. 3, with the atom numbering scheme. Bond lengths and angles with estimated standard deviations are given in Table 3.

The coordination geometry around the copper ion is a square planar within ±0.01 Å for deviations of the component atoms. The geometries of Cu(O)(O)Cu and around the bridging oxygen atom are perfectly planar. Such a structural feature is similar with the related copper(II) complex Cu(pia) containing the ligand derived from 2,4-pentanedione and 3-amino-1-propanol,[10] and has been observed for binuclear copper(II) complexes associated with strong antiferromagnetic interaction.[4] The Cu–O–Cu angle 103.6(1)° is smaller than that of Cu(pia) (106°).[10] The saturated six-membered chelate ring containing amino alcohol has a chair conformation, and atoms Cu and C(2) are displaced by −0.13 and 0.70 Å, respectively, from the plane through O(1), C(1), C(3), and N. The acetyl group is tilted to the unsaturated six-membered chelate ring by 12.5° due to the steric hindrance between the acetyl and methyl groups attached to the unsaturated chelate ring. This steric hindrance is also found in the deviations of O(3) and C(7) by 0.21 and −0.16 Å, respectively, from the plane through atoms C(5), C(6), and C(8).

Based on the above-described results, it has been established that complexes Cu(L-2) and Cu(L-2m) with a five-membered chelate ring consisting of amino alcohol and copper ion are of tetranuclear cubane-like structure associated with ferromagnetic interaction, whereas complex Cu(L-3) with a six-membered chelete ring is a dimer associated with strong antiferromagnetic interaction. Mikuriya *et al.*[20] examined a number of molecular structures of alkoxo-bridged polynuclear copper(II) complexes and pointed out that for the formation of binuclear copper(II) complexes the favorable chelate ring system is the 6-6-(4)-6-6 and 5-6-(4)-6-5 fused chelate ring systems, and that the 6-5-(4)-5-6 system often forms a stable tetranuclear species, where the fused chelate ring system is represented by m-n-(4)-n-m according to their notation (Fig. 3). The complexes prepared in this study supply good examples to support their suggestions. The planarity around the bridging oxygen atom should be mainly attributable to the conformation of the chelate ring involving amino alcohol and copper ion. It can be considered that in the case of complex Cu(L-3) the chair conformation of the six-membered chelate ring allows a planar geometry around the bridging oxygen atom and that the complex prefers to be a dimer associated with strong antiferromagnetic interaction. On the other hand, for complexes Cu(L-2) and Cu(L-2m) with a five-membered chelate ring, it can be considered that the deviation from the planar geometry around the bridging oxygen atom should occur and that the oxygen atom can coordinate to another copper ion to form a tetranuclear copper(II) complex, since a five-membered chelate ring takes a gauche or envelope conformation.

Table 3. Bond distances and angles with estimated standard deviations in parentheses, for Cu(L-3)[a]

Mixed-ligand Palladium(II) Complexes Containing *O,O'*-Chelated β-Diketonate and η^3-Carbon-bonded Ethyl 3-Oxobutanoate Anions. Preparation and Reactions with Some Lewis Bases**

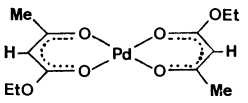
Kurumi YAMADA, Shigeru BABA,† Yukio NAKAMURA,* and Shinichi KAWAGUCHI

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

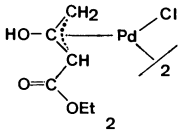
(Received October 20, 1982)

Novel palladium(II) complexes [Pd(β-dik)(η^3-etac)] (**5**), in which anions of a β-diketone and ethyl 3-oxobutanoate coordinate to the central metal atom by the *O,O'*-chelation and the η^3 carbon bonding, respectively, were prepared by the reactions of a dinuclear complex [PdCl(η^3-etac)]$_2$ with thallium(I) β-diketonates in benzene or acetone at room temperature. Reactions of **5** with Lewis bases (L) such as triphenylphosphine, diethylamine, propylamine and benzylamine were investigated. In almost all reactions, only the η^3-carbon-bonded ester ligand in **5** was converted into a terminal-carbon-bonded one to afford complexes [Pd(β-dik)(etac-C^4)L]. The bonding modes for the ligands in these products as well as in **5** were determined by means of IR and ^{1}H and ^{13}C NMR spectroscopy.

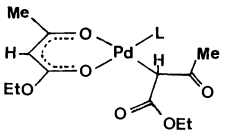
Four kinds of coordination modes for the monoanion of ethyl 3-oxobutanoate have been observed so far in palladium(II) complexes: *O,O'*-chelation (**1**, **3**),[1] η^3 carbon bonding (**2**),[2] central carbon bonding (**3**),[1] and terminal carbon bonding (**4**).[3]



1



2



3

4

Of these complexes, **3** and **4** were derived from **1** and **2** by the reactions with Lewis bases, respectively. Similarly, all these bonding modes described above[4–6] as well as *O*-unidentate bonding[7,8a,b] have also been established for 2,4-pentanedione and other β-diketones in palladium(II) and platinum(II) complexes. Comprehensive studies on the interconversion among these bonding modes of β-diketonate anions have recently been performed.[8]

As the continuation of this line of studies, we intended to prepare novel complexes of palladium(II) which involve two kinds of coordination modes for β-diketonate monoanions and to examine relative stability of each bonding mode. In this paper, preparation and characterization of complexes **5a**—**c** and their reactions with some Lewis bases to show which bonding mode is less stable are described.

Results and Discussion

Preparation and Characterization of Complexes **5**. The η^3 complex of ethyl 3-oxobutanoate anion with palladium(II), [PdCl(η^3-etac)]$_2$ (**2**), which was first prepared by Tezuka *et al.*,[2a] was used as a starting material for preparation of complexes **5**. The bridge-splitting and concurrent chloride-abstracting reactions of **2** with twice molar amounts of thallium(I) β-diketonates yielded mononuclear complexes **5a**, **5b**, and **5c** in high yields, whose analytical data are given in Table 1.

The ^{1}H NMR data for complexes **5** in $CDCl_3$ are listed in Table 2 and compared with those for **2** which were previously reported[9] and reasonably interpreted on the basis of the η^3 structure confirmed by X-ray analysis.[2b] Complex **5c** shows five signals due to the etac ligand, together with a singlet at 6.12 ppm attributable to the methine proton of the *O,O'*-chelated hfac ligand.[4] These five signals from etac appear as a singlet at 3.74 ppm, two doublets at 2.80 and 3.87 ppm, a triplet at 1.36 ppm and a multiplet centered at 4.3 ppm, with relative intensities of 1:1:1:3:2. The first three signals can be assigned to the H^a, H^b, and H^c protons of the allylic moiety and the others to methyl and methylene protons of the ethyl groups by comparison with those of **2**. The spectral pattern similar to that of the starting complex **2** confirms that the η^3 structure of the etac ligand in **2** is maintained intact in the reaction product **5c**, although the H^d signal observed for **2** can not be detected for **5c**. This conclusion is firmly supported by the ^{13}C NMR for **5c** and **2** listed in Table 3. Both spectral data are in fairly good agreement with each other, although three additional signals from hfac appear in the spectrum of **5c**. The three signals resonate at 90.1, 175.4, and 117.8 ppm from internal Me_4Si and each couples to ^{19}F nuclei appearing as a multiplet, a quartet and a quartet, respectively, the coupling constants increasing in this order. These signal frequencies and

** In this paper β-dik represents a monoanion of β-diketones such as 2,4-pentanedione (acacH), 1,1,1-trifluoro-2,4-pentanedione (tfacH), and 1,1,1,5,5,5-hexafluoro-2,4-pentanedione (hfacH), etac denoting that of ethyl 3-oxobutanoate.

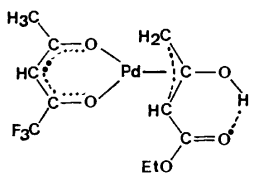
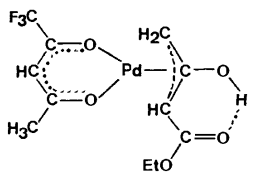
coupling constants are compatible with those for the *O,O'*-chelate of hfac.[4)]

As is seen in Table 2, the similarity of the ^{1}H NMR data for **5b** to those for **5c**, except the additional methyl signal from tfac in **5b**, shows that the coordination structures of the β-dik and etac ligands around palladium are the same in these complexes. Owing to the unsymmetrical nature of tfac, two geometrical isomers, *cis*(CH_3,CH_2) and *trans*(CH_3,CH_2), coexist in the case of **5b**.



cis(CH_3,CH_2)



trans(CH_3CH_2)

Although the very slight splitting is recognized in the methyl signals from the tfac and ester ligands, other signals do not discriminate these two isomers. On the other hand, the ^{13}C NMR spectrum (Table 3) of **5b** clearly exhibits the presence of *cis*(CH_3,CH_2) and *trans*(CH_3,CH_2) isomers in $CDCl_3$, two sets of signals attributable to the trifluoromethyl-substituted carbonyl carbon and the methyl and methylene carbons of ethyl group appearing at 167.8, 14.0, 62.0 and at 168.3, 14.5, 62.2 ppm, respectively. Each set of signals can be assigned only arbitrarily to the cis or trans isomer.

Complexes **5** including the acac complex **5a** are soluble in most organic solvents such as haloalkanes, ketones, ethers, aromatic hydrocarbons, and even in hexane. Although **5b** and **5c** are stable in these organic solvents, **5a** is rather unstable and a less soluble substance precipitates from its solution in chloroform on addition of hexane, which is not isolated in a pure form (see Experimental section). The ^{1}H NMR spectrum of **5a** in $CDCl_3$, therefore, includes some signals other than those assignable to [Pd(acac)-(η^3-etac)], even immediately after dissolution. Only the latter signals are listed in Table 2. In this case, two methyl signals from acac are observed at 1.94 and 1.98 ppm and such different environments of the

methyl hydrogens are caused by unsymmetric coordination of the ester ligand in **5a**.

Table 4 lists the characteristic IR bands of complexes **5** and products of their reactions with Lewis bases. The bonding modes of the β-dik and etac ligands are easily diagnosed on the basis of the spectral pattern in the 1500—1700-cm^{-1} region. Two or four bands observed in the 1520—1627-cm^{-1} region for **5** are assigned to the $\nu(C{\cdots}O)+\nu(C{\cdots}C)$ vibrations of the *O,O'*-chelates of β-dik,[4] while a band in the 1670—1675-cm^{-1} region is assigned to the $\nu(C{=}O)$(ester) of the η^3-carbon-bonded etac ligand.[2a] Weak bands around 545 and 3200 cm^{-1} are attributed to the δ(CCC) and ν(OH) vibrations, respectively, characteristic of the η^3 carbon bonding of etac by reference to the data for complex **2**.[2a]

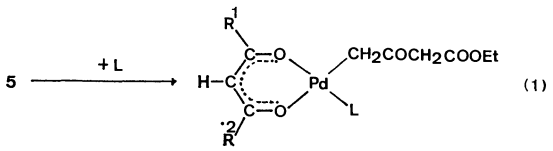
a) Same as footnote a) for Table 2. Figures in braces give $^3J(^{31}P\text{-}H)$ in Hz. b) Data for the low-temperature limitting spectrum at −29 °C are given. c) Chemical shifts for L. Et: 2.7 m, 1.42 t (for **6d**). *n*-Pr: 2.7 m, 1.7 m, 0.99 t (for **6e**). CH_2: 3.49 (for **7**).

Reactions of **5** *with Lewis Bases Producing Terminal-carbon-bonded Complexes of etac.* Although the reactions of complexes **5** with triphenylphosphine and a variety of nitrogen bases such as propylamine, diethylamine, *t*-butylamine, benzylamine, pyridine, and piperidine were tried, only five complexes of the type **6** and complex **7** listed in Table 1 could be isolated as reaction products in pure forms. Quite high solubilities of these products in most organic solvents described earlier make those isolation difficult. When complexes **5** were allowed to react with an equimolar amount of triphenylphosphine in benzene or chloroform, the η^3 carbon bonding of the etac ligand in **5** was converted into the terminal carbon bonding to afford neutral complexes **6a**, **6b**, and **6c**.



(1)

	R^1	R^2	L
6a	CH_3	CH_3	PPh_3
6b	CH_3(CF_3)	CF_3(CH_3)	PPh_3
6c	CF_3	CF_3	PPh_3
6d	CH_3	CH_3	Et_2NH
6e	CH_3(CF_3)	CF_3(CH_3)	*n*-$PrNH_2$

Similarly, diethylamine and propylamine reacted with **5a** and **5b** to produce **6d** and **6e**, respectively. In contrast with these bases, benzylamine reacted with **5c** to give solely the cationic complex **7**, irrespective of the reactant mole ratio, which has hfac as a counter anion in the outer sphere.

$$\mathbf{5c} \xrightarrow{+3L} [Pd(CH_2COCH_2COOEt)L_3](CF_3COCHCOCF_3) \quad \mathbf{7}\ (L=PhCH_2NH_2) \qquad (2)$$

The analytical and molecular weight data for these complexes isolated are also included in Table 1.

The ^{1}H NMR data for complexes **6** and **7** are collected in Table 5. The H^a, H^b, and H^c signals observed for **5** are lost in **6a**—**c** and instead two signals appeared at 3.54—3.64 and 2.26—2.59 ppm as a singlet and a doublet with relative intensity of 1:1, each signal corresponding to 2H protons. Such a spectral change indicates that the η^3-carbon-bonded etac ligand in **5** was converted into the terminal-carbon-bonded one in **6a**—**c** as shown by Eq. 1. Thus, the singlet and the doublet are assigned to protons of the central methylene and the terminal methylene coordinated to palladium, respectively, by reference to the spectral data of **4** (L=py or 1/2·bipy).[3a] The latter methylene protons couple to ^{31}P cis to them to give a doublet with $^3J(P\text{-}H)=2\text{—}4$ Hz.

As Fig. 1a shows, the ^{1}H NMR spectrum of **6a** in the methyl and methylene proton regions exhibits two methyl signals from acac at 1.58 and 2.00 ppm. The lower-field signal is assigned to the methyl protons trans to P, while the higher-field one to the methyl cis to P because such an appreciable upfield shift is caused by the anisotropic shielding effect of triphenylphosphine at the cis position.[6a]

Figure 1b shows the variable-temperature ^{1}H NMR spectra of **6b** in the same regions as in Fig. 1a. The spectrum at room temperature (33 °C) is composed of a broad singlet (3.56 ppm), a broad doublet (2.37 ppm), and two collapsed signals (*ca.* 1.7 and 2.2 ppm). With increasing temperature, the first two signals sharpen, while the other two give a coalesced signal. On the other hand, as the temperature is lowered, the first two signals become broader and split, and then sharpen to give two sets of signals each composed of a singlet and a doublet at −29 °C. Similarly, other two signals gradually sharpen with decreasing temperature finally giving two sharp singlets at 1.74 and 2.18 ppm, which correspond to resonances of the meth-

Table 6. ^{13}C NMR data for complex **6c** in $CDCl_3$[a)]

a) Same as footnote for Table 3. Figures in parentheses and brackets give $J(^{19}F\text{-}C)$ and $J(^{31}P\text{-}C)$, respectively. Chemical shifts for PPh_3: C^1, 127.6 d[55.7]; C^2, 134.4 d[11.1]; C^3, 128.6 d[11.1]; C^4, 131.3 d[2.6].

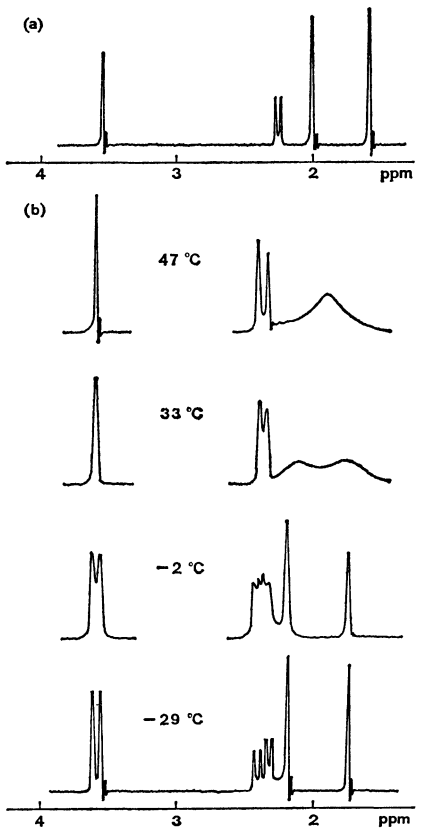

Fig. 1. ^1H NMR spectra at 100 MHz of (a) [Pd(acac)(etac-C^4)(PPh_3)], **6a** ($CDCl_3$; 33 °C) and (b) [Pd(tfac)(etac-C^4)(PPh_3)], **6b** ($CDCl_3$; −29, −2, 33, and 47 °C) in the methyl and methylene proton regions.

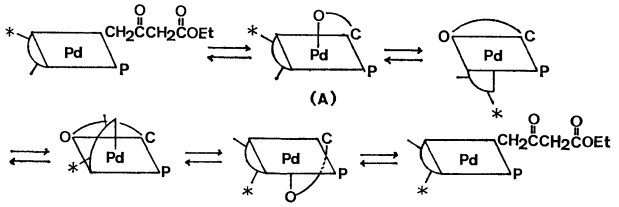
yl groups cis and trans to P (compare Figs. 1a and 1b). These results imply that complex **6b** exists as a mixture of two geometrical isomers, *cis*(CH_3, P) and *trans*(CH_3, P) (in the mole ratio of 1:1.3), in $CDCl_3$ at −29 °C and these isomers are readily interconvertible at 33 °C and above. In Table 5, the low-temperature limitting spectral data for these isomers are given.

Table 6 denotes the ^{13}C NMR data for **6c** as a representative of **6** which gives the most simple spectrum. Two trifluoromethyl signals appear at 117.4 and 117.7 ppm as quartets with $^1J(C\text{–}F)=285$ Hz, thus reflecting the slight difference in environments caused by the trans ligands, etac and triphenylphosphine and also showing stereochemical rigidity of this complex in $CDCl_3$ at room temperature.

Much attention has recently been given to the mechanisms of geometrical isomerization of the square-planar metal complexes.[10)] In the case of the present complex **6b**, coupling of the terminal methylene protons of etac to ^{31}P is maintained during the isomerization (see Fig. 1b), showing inapplicability of the dissociative mechanism involving the Pd–P bond rupture. Thus the transformation, as depicted below, of a five-coordinate intermediate **A**, in which the fifth coordination site of palladium is occupied by the ester carbonyl oxygen atom, may be the most probable mechanism to be proposed:



The *C,O*-chelation of tfac as in **A** has been found as a stable bonding mode for the tfac dianion in a series of [Pd(tfac(2-)-*C,O*)LL']-type complexes[11)] and the Pt(II) analogues.[12)] An intermolecularly associated complex, in which the metal atom of a reacting species is coordinated by the ester carbonyl oxygen of a neighboring molecule, is also conceivable as an alternative intermediate for the coordination-site exchange. Such an example that another molecule of the same species acts as a catalyst was found for the σ-pyridyl complex, [Pd(acac)(σ-pyridyl)PPh_3], and the effect was termed "self catalysis" by Tanaka *et al.*[13)] Similar phenomenon was also observed for [Pd(acac)(CH_2CN)PPh_3].[14)] As described above, complexes **6a** and **6c** are stereochemically rigid in $CDCl_3$ at room temperature, while **6b** shows fluxional motion under the same conditions. However, it is not rationalized why only complex **6b** having the unsymmetric tfac ligand brings about the coordination-site exchange.

As is seen in Table 5, reaction products with nitrogen bases, both **6d** and **6e**, show only a single methyl

signal from β-dik in their ^{1}H NMR spectra. Two possibilities are conceivable: 1) Accidental coincidence of the two methyl signals; 2) coalescence to a single peak by coordination-site exchange of the β-dik ligand. In the present case, the second possibility to occur will probably be excluded because the acac complex **6a** does not cause such a reaction and **6e** shows two methine and CH_2–Pd proton signals corresponding to the *cis*(CH_3,N) and *trans*(CH_3,N) isomers.

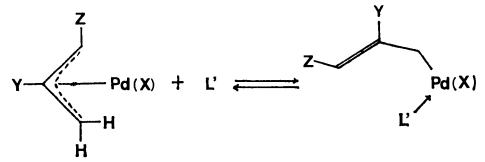
The product complex, **7**, from the reaction of **5c** with benzylamine gave satisfactory analysis as Pd(etac)(hfac)$(PhCH_2NH_2)_3$ which differs from other products, **6**, in composition. However, the coordination mode of etac to palladium is the same as that in **6** on the basis of the similarity of ^{1}H NMR data (Table 5). On the other hand, the methine proton from hfac in **7** resonates at higher field (5.62 ppm) than that (6.30 ppm) in **6c**. Such an upfield shift of the methine proton signal is generally observed for the outer-sphere complexes of the type $[PdL_4](hfac)_2$ compared with the *O,O'*-chelate because of the higher charge density on noncoordinating anion: the methine protons of $[Pd(hfac)_2]$,[4] $[Pd(n\text{-}PrNH_2)_4](hfac)_2$,[8a] $[Pd(py)_4](hfac)_2$,[8b] and $[Pd(PMe_2Ph)_4](hfac)_2$[8b] resonate at 6.42, 5.92, 6.00, and 5.67 ppm in $CDCl_3$, respectively.

When the IR spectral data (Table 4) of **5** and **6** are compared with each other, a considerable difference is noticed only in the absorption bands characteristic of the etac ligand. Thus complexes **5** have the ν(OH) and ν(C=O)(ester) bands at around 3200 and 1670 cm^{-1}, respectively, while complexes **6** show no absorption bands around 3200 cm^{-1}, but exhibits two strong ν(C=O) vibrations in the 1725—1745 and 1630—1670-cm^{-1} regions. This confirms the above-mentioned conclusion that the η^3-carbon-bonded enolate anion of 3-oxobutanoate was converted into the terminal-carbon-bonding of the keto tautomer. These carbonyl bands assignable to the ν(C=O)(ester) and ν(C=O)(keto) vibrations are also found for complexes of the type **4** as follows: [PdCl(etac-*C*^{4})$(py)_2$] 1740vs, 1650vs; [PdCl(etac-*C*^{4})(bipy)] 1730vs, 1640vs.[3a]

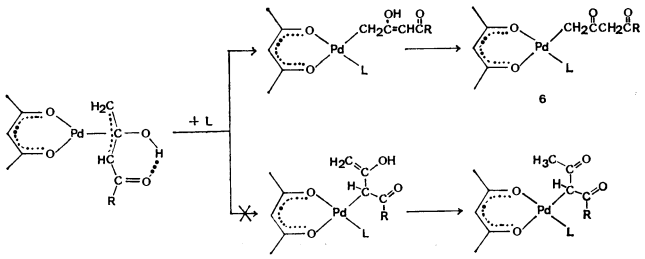
The IR spectrum of complex **7** has four bands of strong to medium intensities in the 1600—1700-cm^{-1} region. Of these, a medium band observed at 1619 cm^{-1} is assigned to the $\delta(NH_2)$ vibration of the coordinated benzylamine and hence omitted in Table 4. Although two strong bands at 1698 and 1645 cm^{-1} are slightly closer mutually than those for **6**, they can be assigned to the ν(C=O) vibrations of the terminal-carbon-bonded etac ligand. On the other hand, no band shows in the region attributable to the ν(C≡O) + ν(C≡C) vibrations of the *O,O'*-chelated β-dik ligand, but instead a strong band appears at 1661 cm^{-1}. The frequency of this band is close to that for potassium 1,1,1,5,5,5-hexafluoro-2,4-pentanedionate, thus conforming to the cationic formulation [Pd(etac-*C*^{4})$(PhCH_2NH_2)_3$](hfac) which was deduced from the ^{1}H NMR spectral data.

Consideration on Bonding Nature of the β-dik and etac Ligands in **5**. As described before, complexes **5b** and **5c** are stable in solution, but **5a** is rather unstable in most organic solvents and decomposes to give an uncharacterized crude substance. The stability difference among these complexes may be brought about by the substituent effect for the methyl groups of acac. The more basic acac ligand can coordinate more tightly to palladium than tfac and hfac do and destabilize the η^3-carbon-bonding of etac to the metal as a result. The conversion of the η^3-carbon-bonded etac ligand in **5a** into the terminal-carbon-bonded one without any free ligand in solution could produce a less soluble substance in which presumably the vacant site of palladium is coordinated by a free carbonyl oxygen of another molecule.

In all the reactions of **5** with Lewis bases except that of **5c** with benzylamine, it was found that the O,O'-chelate of the β-dik ligand in **5** is more stable than the η^3 carbon bonding of etac and the latter was converted into the terminal-carbon-bonding. Powell *et al.* have studied insertion reactions of olefins,[15] 1,2-dienes,[16] and 1,3-dienes[17] (L') into the allylic palladium bonds of the η^3-allylic complexes (η^3-allyl)Pd(X) (X=hfac, acac, or chloride). In either case of the bidentate ligands (hfac and acac), the η^1-allylic complex (η^1-allyl)(L')Pd(X) was conceivable as



an intermediate on the basis of *syn-anti* proton exchange on the NMR time scale, whereupon the less substituted terminal carbon of the allylic moiety invariably linked with the metal atom. These results are also in accord with the present case to give **6** but not the central-carbon-bonded etac complexes as follows:



However, similar palladium(II) complexes, **3**, containing the central-carbon-bonded etac ligand have been prepared so far by the reactions of bis-*O,O'*-chelate, **1**, with L (L=a variety of nitrogen bases).[1]

Experimental

Preparation of Complexes **5**. The starting dinuclear η^3 complex, $[PdCl(\eta^3\text{-etac})]_2$ (**2**) was prepared according to the Yanase's modification[9] of the method originally proposed by Tezuka.[2a]

[Pd(acac)(η³-etac)] (**5a**): Complex **2** (225 mg, 0.415 mmol) was dissolved in benzene (30 cm^3) on heating and then the solution was cooled to room temperature. Thallium(I) 2,4-pentanedionate (277 mg, 0.913 mmol) was added to the solution and the mixture was stirred for 2 h at room temperature. After standing for further 2—3 h, the mixture was filtered to remove thallium(I) chloride precipitated

and the filtrate was concentrated to 5 cm³ under reduced pressure. On addition of hexane, a crude decomposition product was deposited and again removed by filtration. The filtrate was evaporated to dryness to obtain a yellow solid (214 mg) in a 71% yield.

The crude substance shows no IR band at 3200 cm^{-1}, which is assigned to the ν(OH) vibration of the η^3-carbon-bonded etac, but instead shows a new strong IR absorption at 1620 cm^{-1}. The substance has not been further characterized because of its poor solubility in most organic solvents.

[Pd(tfac)(η³-etac)] (5b): Thallium(I) 1,1,1-trifluoro-2,4-pentanedionate (326 mg, 0.913 mmol) was added to a suspension of **2** (225 mg, 0.415 mmol) in acetone (20 cm³). After being stirred for 30 min at room temperature, the mixture was allowed to stand for further 2—3 h to precipitate thallium(I) chloride, which was filtered and the filtrate was then concentrated to 2—3 cm³ under reduced pressure. On addition of hexane to the concentrate, a pale yellow solid (246 mg) was obtained in a 76% yield.

[Pd(hfac)(η³-etac)] (5c): To a suspension of **2** (225 mg, 0.415 mmol) in acetone (20 cm³) was added thallium(I) 1,1,1,5,5,5-hexafluoro-2,4-pentanedionate (376 mg, 0.913 mmol). After being stirred for 30 min at room temperature, the mixture was allowed to stand for additional 2—3 h and then filtered to give a transparent solution, which was evaporated to dryness under reduced pressure. The residue was redissolved in hexane and filtered again to remove a small amount of insoluble substance. The filtrate was evaporated to dryness under reduced pressure, affording a pale yellow solid (302 mg) in an 82% yield.

Reactions of [Pd(β-dik)(η³-etac)] (5) with Lewis Bases. 5a with Triphenylphosphine: Triphenylphosphine (156 mg, 0.598 mmol) was added to a benzene (15 cm³) solution of **5a** (200 mg, 0.598 mmol) and the mixture was stirred for 20 min at room temperature. The solvent was then evaporated to 2—3 cm³ under reduced pressure before adding hexane to deposit a yellow powder of [Pd(acac)(etac-C^4)(PPh_3)] (**6a**). Scratching the flask was necessary to deposit **6a** effectively. Recrystallization from benzene–hexane gave a yellow crystalline solid (303 mg) in an 85% yield.

5b with Triphenylphosphine: Complex **5b** (100 mg, 0.257 mmol) was also allowed to react with triphenylphosphine (68 mg, 0.26 mmol) in benzene (10 cm³) at room temperature. After being stirred for 30 min, the solution was concentrated to 2—3 cm³ under reduced pressure and hexane was added to the concentrate. A yellow crystalline solid of [Pd(tfac)(etac-C^4)(PPh_3)] (**6b**), deposited from the solution on standing at room temperature. The yield was 139 mg (81%).

5c with Triphenylphosphine: Chloroform (10 cm³) was used as a solvent for the reaction of **5c** (100 mg, 0.226 mmol) with triphenylphosphine (59 mg, 0.23 mmol). When the reaction mixture was stirred for 20 min at room temperature and then concentrated under reduced pressure, an oily substance was obtained, which was extracted with petroleum ether and the extract was left at −20 °C to give an orange crystalline solid of [Pd(hfac)(etac-C^4)(PPh_3)] (**6c**). The yield was 76 mg (48%).

5a with Diethylamine: Diethylamine (0.07 cm³, 0.677 mmol) was added to a benzene (15 cm³) solution of **5a** (200 mg, 0.598 mmol) and the mixture was stirred for 1 h at room temperature before the solvent was evaporated to 2—3 cm³ under reduced pressure. A pale yellow powder of [Pd(acac)(etac-C^4)(Et_2NH)] (**6d**), was deposited by scratching the flask after the addition of hexane. Recrystallization from benzene–hexane gave a crystalline solid in a 53% yield (132 mg).

5b with Propylamine: Propylamine (0.03 cm³, 0.364 mmol) was added to a benzene (10 cm³) solution of **5b** (140 mg, 0.360 mmol) and the mixture was stirred for 20 min at room temperature. Evaporation of the solvent under reduced pressure left an oily residue, which was extracted with hexane. A yellow powder of [Pd(tfac)(etac-C^4)(*n*-$PrNH_2$)] (**6e**), precipitated from the extract on standing overnight at −20 °C. The yield was 103 mg (60%).

5c with Benzylamine: A three times molar amount of benzylamine (0.10 cm³, 0.914 mmol) was allowed to react with **5c** (130 mg, 0.294 mg) in benzene (10 cm³) for 30 min with stirring at room temperature. Evaporation of the solvent under reduced pressure left an oily substance. The substance was redissolved in a small amount of acetone, hexane was added to the solution, and then the solution was kept for a week at −20 °C, from which a pale yellow powder of [Pd(etac-C^4)($PhCH_2NH_2$)$_3$](hfac) (**7**), was precipitated. The yield was 130 mg (59%). Even when an equimolar amount of benzylamine was used, the same complex **7** was produced in a low yield.

Measurements. Infrared spectra were obtained in Nujol mull with a JASCO DS 701G infrared spectrophotometer. NMR spectra were recorded on JNM-MH100 (in the case of ^1H) and FX60Q (for ^{13}C) instruments. Molecular weight was determined in dichloromethane at 28 °C with a vapor pressure osmometer manufactured by Knauer, West Berlin, West Germany.

Solvent Effects on the Extraction of Gallium(III) with Decanoic Acid

Hiromichi YAMADA,* Shozo IMAI, and Eiichi TAKEUCHI
Faculty of Engineering, Gifu University, 1-1, Yanagido, Gifu 501-11

(Received November 5, 1982)

Extraction of gallium(III) with decanoic acid (HA) in several solvents was carried out at 25 °C and at an aqueous ionic strength of 0.1 mol/dm³($NaClO_4$). Organic solvents used are toluene, chlorobenzene, 1,2-dichloroethane, and 1-octanol. Extracted species differs from solvent to solvent: $Ga_6A_{18}(H_2O)_w$ for toluene, Ga_3A_9 for chlorobenzene, GaA_3 and Ga_3A_9 for 1,2-dichloroethane and $GaA_2(OH)$, $Ga_2A_4(OH)_2$ and Ga_2A_6 for 1-octanol. The less polar the solvent, the more extensive is the polymerization of the extracted species.

Polymeric metal carboxylates are known to be extracted into the organic phase with carboxylic acids. In particular, aluminium(III),[1] gallium(III),[2] indium(III),[3] and scandium(III)[4] are characterized to be extracted into benzene as hexameric species.

In the previous paper,[5] it has been shown that copper(II) is extracted with decanoic acid in various inert solvents as dimeric copper(II) decanoate, $Cu_2A_4(HA)_2$, and that the solvent effect on the extraction constants was interpreted in terms of the regular solution theory.

The present paper describes the results on the extraction of gallium(III) with decanoic acid in several organic solvents. The more polar the solvent, the less polymerized are the extracted decanoates.

Experimental

Reagents. *Gallium(III) Perchlorate Solution*: Metallic gallium (99.99%) was dissolved in a small excess of concentrated perchloric acid. The solution was diluted as required and standardized complexiметrically with the Cu–EDTA–TAR system as an indicator.[6] 8-Quinolinol was used for the determination of lower concentration of gallium in the organic phase.

Sodium Perchlorate: The reagent grade sodium perchlorate was recrystallized from distilled water after removal of the impurities (heavy metal ions) as hydroxides at pH≃8.

Decanoic Acid: Chemically pure grade decanoic acid was purified by distillation.

Solvents: Toluene and chlorobenzene of reagent grade were washed successively with concentrated sulfuric acid, with dilute sodium hydroxide solution and then with distilled water. Reagent grade 1,2-dichloroethane was washed with dilute potassium hydroxide solution and then with distilled water. Reagent grade 1-octanol was washed successively with dilute potassium hydroxide solution, with dilute perchloric acid solution and with distilled water.

All other reagents were reagent grade and used as purchased.

Procedure. Partition was carried out in a thermostat at 25±0.2 °C using a 50 cm³ centrifuge tube in which 15 cm³ each of the aqueous and organic phases were contacted. Shaking for overnight was found sufficient for complete equilibration in each solvent system used. Ionic strength in the aqueous phase was adjusted to 0.1 mol/dm³ with sodium perchlorate. Total concentration of gallium was 5×10^{-3} mol/dm³. Hydrogen ion concentration in the aqueous phase was measured without any phase separation with 1.00×10^{-2} mol/dm³ perchloric acid solution (ionic strength 0.1 mol/dm³) as a standard. Then the measured pH values were corrected for the apparent liquid junction potential.[3]

Apparatus. For mechanical shaking in a thermostat, TAIYO incubator, M-1 (Taiyokagaku-Kogyo Co., Tokyo) was used. The pH measurements were carried out with a Beckman research pH Meter Model 101900 (Beckman Instruments, Inc., Fullerton, California, U.S.A.) and Orion research microprocessor Ionalyzer 901 (Orion Research Inc., U.S.A.). The temperature of a sample solution was kept constant in a Coolnics Circulator Model CTE-1B (Komatsu Solidate Co., Komatsu, Japan). Colorimetric determination of gallium in the organic phase was carried out on a Shimadzu double-beam type UV-210A spectrophotometer (Shimadzu Seisakusho Ltd., Kyoto, Japan).

Results and Discussion

When a j-merized gallium(III) decanoate of the composition $Ga_jA_aH_h$ ($3j=a-h$) is responsible for the extraction of gallium ion with decanoic acid, the extraction equilibria for toluene, chlorobenzene and 1,2-dichloroethane are written as:

$$jGa^{3+} + \frac{a}{2}(HA)_{2,o} \overset{K_{ex(jah)}}{\rightleftharpoons} (Ga_jA_aH_h)_o + 3jH^+$$

$$\text{with} \quad K_{ex(jah)} = \frac{[Ga_jA_aH_h]_o[H^+]^{3j}}{[Ga^{3+}]^j[(HA)_2]_o^{a/2}}, \tag{1}$$

where the subscript o refers to the organic phase and $(HA)_{2,o}$ denotes the dimeric decanoic acid in the organic phase.

On the other hand, the dimerization of decanoic acid does not occur to any appreciable extent in 1-octanol. The extraction equilibrium for 1-octanol is then expressed as follows:

$$jGa^{3+} + a(HA)_o \overset{K_{ex(jah)}}{\rightleftharpoons} (Ga_jA_aH_h)_o + 3jH^+$$

with the extraction constant:

$$K_{ex(jah)} = \frac{[Ga_jA_aH_h]_o[H^+]^{3j}}{[Ga^{3+}]^j[HA]_o^a}. \tag{2}$$

Total concentration of gallium in the organic phase, $C_{Ga,o}$ is given by the following equations corresponding to Eqs. 1 and 2, respectively:

$$C_{Ga,o} = \sum_j\sum_a j[Ga_jA_aH_h]_o$$

$$= \sum_j\sum_a jK_{ex(jah)}([Ga^{3+}][H^+]^{-3})^j[(HA)_2]_o^{a/2} \tag{3}$$

and

$$C_{Ga,o} = \sum_j\sum_a jK_{ex(jah)}([Ga^{3+}][H^+]^{-3})^j[HA]_o^a. \tag{4}$$

Under the present experimental conditions, the hydrolysis and complexation of gallium ion not being appreciable in the aqueous phase, the total concentration of gallium in the aqueous phase, $C_{Ga,w}$ may be regarded as $[Ga^{3+}]$.

Suppose that only $Ga_jA_aH_h$ is responsible for the

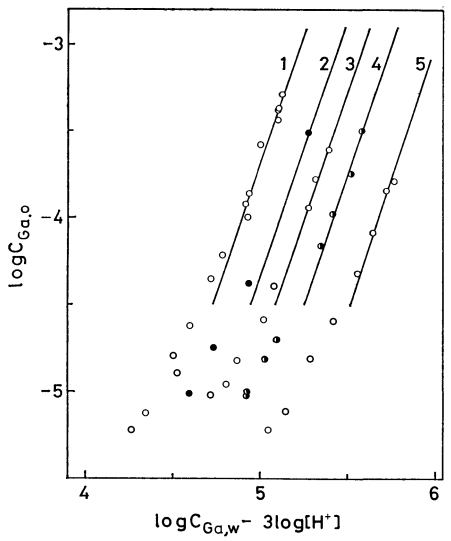

Fig. 1. Determination of the degree of polymerization of Ga(III) decanoate in 1,2-dichloroethane.
Solid lines are the straight lines with a slope of 3.0. C_{HA}; No. 1: 2.0, No. 2: 1.5, No. 3: 1.25, No. 4: 1.0, No. 5: 0.7 mol/dm^3.

extraction. Equations 5 and 6 can then be derived from Eqs. 3 and 4, respectively:

$$C_{Ga,o} = jK_{ex(jah)}(C_{Ga,w}[H^+]^{-3})^j[(HA)_2]_o^{a/2} \quad (5)$$

and

$$C_{Ga,o} = jK_{ex(jah)}(C_{Ga,w}[H^+]^{-3})^j[HA]_o^a \quad (6)$$

which are rewritten as a logarithmic form:

$$\log C_{Ga,o} = j(\log C_{Ga,w} - 3\log[H^+]) + \frac{a}{2}\log[(HA)_2]_o + \log j + \log K_{ex(jah)} \quad (7)$$

and

$$\log C_{Ga,o} = j(\log C_{Ga,w} - 3\log[H^+]) + a\log[HA]_o + \log j + \log K_{ex(jah)}. \quad (8)$$

These expressions provide a basis for the determination of the degree of polymerization of Ga(III) decanoates and the number of decanoic acid molecules involved in the extracted species. The degree of polymerization of the extracted species can be determined from the slope of the plot of $\log C_{Ga,o}$ against $(\log C_{Ga,w} - 3\log[H^+])$ at constant $[(HA)_2]_o$ (or $[HA]_o$ in the case of 1-octanol). The plot for toluene fitting well the straight line with a slope of six, the hexameric Ga(III) decanoate is extracted into toluene. And in the lower concentration of gallium in the organic phase the plot deviates slightly upward from the straight line with a slope of 6.0. This suggests that there would be at least another extracted species less polymerized than the main hexameric species. The plot for chlorobenzene fitting well the straight line with a slope of 3.0, the trimeric Ga(III) decanoate is responsible for the extraction. In the case of 1,2-dichloroethane, as evident from Fig. 1, the degree of polymerization of extracted species depends on the concentration of gallium in the organic phase. The plot deviates upward from the straight line with a slope of three with decreasing concentration of gallium in the 1,2-dichloroethane phase. Therefore, another extracted species less polymerized than 3.0 is responsible for the extraction together with the main trimeric species. If the other extracted species is $Ga_{j'}A_{a'}H_{h'}$, the concentration of gallium in the organic phase is written as follows:

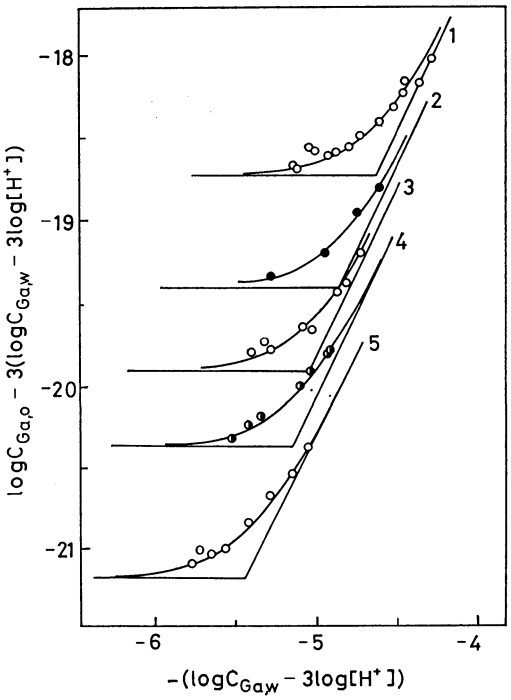

Fig. 2. Determination of the degree of polymerization of Ga(III) decanoate in 1,2-dichloroethane by the curve fitting method.
Solid curves are the normalized curves, $\log(1+X^2)$ *vs.* $\log X$. Solid lines are the asymptotes of the normalized curves. Numbers are the same as in Fig. 1.

$$C_{Ga,o} = 3[Ga_3A_aH_h]_0 + j'[Ga_{j'}A_{a'}H_{h'}]_o, \quad (9)$$

where $j'<3$. And we have the following expression from Eq. 9:

$$\frac{C_{Ga,o}}{(C_{Ga,w}[H^+]^{-3})^3} = 3K_{ex(3ah)}[(HA)_2]_o^{a/2} \times \left\{1 + \frac{j'K_{ex(j'a'h')}}{3K_{ex(3ah)}}[(HA)_2]_o^{(a'-a)/2} \times (C_{Ga,w}[H^+]^{-3})^{(j'-3)}\right\}, \quad (10)$$

where $K_{ex(3ah)}$ and $K_{ex(j'a'h')}$ represent the extraction constants of the trimer, $Ga_3A_aH_h$ and j'-mer, $Ga_{j'}A_{a'}H_{h'}$, respectively. According to Eq. 10, comparing the plot of $\{\log C_{Ga,o} - 3(\log C_{Ga,w} - 3\log[H^+])\}$ against $-(\log C_{Ga,w} - 3\log[H^+])$ at constant $[(HA)_2]_o$ with the normalized curves, $\log(1+X^n)$ *vs.* $\log X$, we find the degree of polymerization of the other extracted species, $Ga_{j'}A_{a'}H_{h'}$. The results are shown in Fig. 2. The plot fits well the normalized curve with $n=2$, that is, $-(j'-3)=2$ or $j'=1$.

Figure 3 depicts the results for 1-octanol. As shown in Fig. 3, the slope of the plot according to Eq. 8 is close to two at higher concentration of gallium in the organic phase. The plot, however, deviates grad-

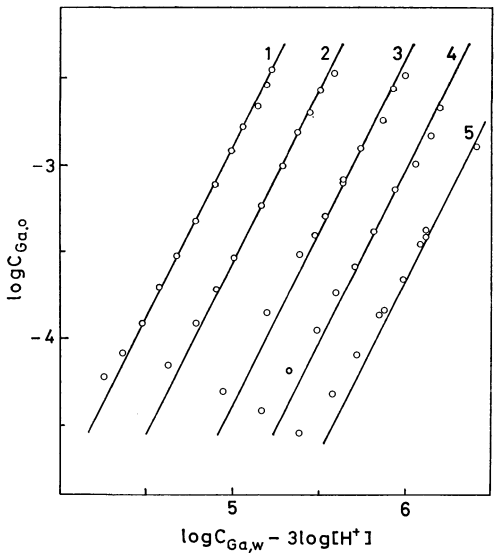

Fig. 3. Determination of the degree of polymerization of Ga(III) decanoate in 1-octanol.
Solid lines are the straight lines with a slope of 2.0. C_{HA}; No. 1: 2.0, No. 2: 1.5, No. 3: 1.0, No. 4: 0.7, No. 5: 0.5 mol/dm^3.

ually upward from the straight line with a slope of two with decreasing gallium concentration in the organic phase. Therefore, the monomer and dimer may be involved in the extraction for 1-octanol. Now suppose a monomer GaA_aH_h and a dimer $Ga_2A_{a'}H_{h'}$ are responsible for the extraction, the following expression can be derived from Eq. 4:

$$\log C_{Ga,o} - (\log C_{Ga,w} - 3\log[H^+]) = \log K_{ex(1ah)} + a\log[HA]_o$$
$$\log\left\{1+\frac{2K_{ex(2a'h')}}{K_{ex(1ah)}}[HA]_o^{(a'-a)}C_{Ga,w}[H^+]\right\}, \quad (11)$$

where $K_{ex(1ah)}$ and $K_{ex(2a'h')}$ represent the extraction constants of the monomer GaA_aH_h and the dimer $Ga_2A_{a'}H_{h'}$, respectively. According to Eq. 11, fitting the plot of $\{\log C_{Ga,o} - (\log C_{Ga,w} - 3\log[H^+])\}$ against $(\log C_{Ga,w} - 3\log[H^+])$ at constant $[HA]_o$ with the normalized curve, $\log(1+X)$ *vs.* $\log X$, we can confirm the degree of polymerization of the extracted species. The results are depicted in Fig. 4. The obtained curves fitting well the normalized curve, $\log(1+X)$ *vs.* $\log X$, the monomeric and dimeric gallium decanoates are involved in the extraction in 1-octanol.

Thus, the degree of polymerization of the extracted species is determined as follows: Hexamer for toluene, trimer for chlorobenzene, monomer and trimer for 1,2-dichloroethane and monomer and dimer for 1-octanol.

Subsequently, the number of decanoic acid molecules involved in the extracted species was determined. In the region where the j-mer prevails, the following equation is derived from Eq. 3:

$$\frac{1}{j}\log C_{Ga,o} - (\log C_{Ga,w} - 3\log[H^+]) = \frac{1}{j}\log\sum_a (K_{ex(jah)}[(HA)_2]_o^{a/2}) + \frac{1}{j}\log j. \quad (12)$$

Solid curves are the normalized curves, $\log(1+X)$ *vs.* $\log X$. Solid lines are the asymptotes of the normalized curves. Numbers are the same as in Fig. 3.

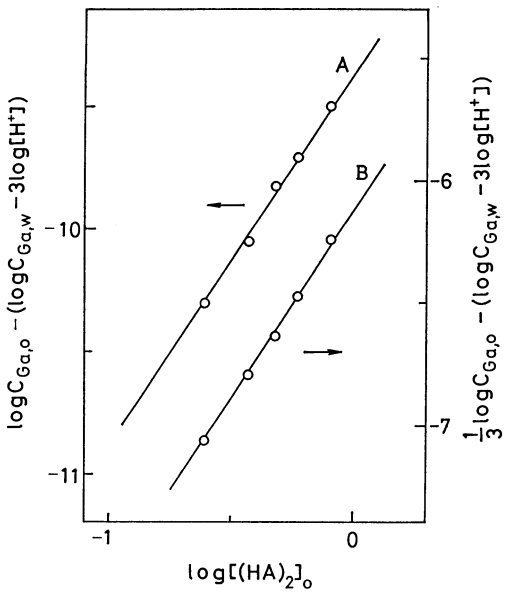

Fig. 5. Determination of the number of decanoic acid involved in Ga(III) decanoates in 1,2-dichloroethane. Solid lines are the straight lines with a slope of 1.5. A: Monomeric Ga(III) decanoate. B: Trimeric Ga(III) decanoate.

This is corresponding to toluene, chlorobenzene and 1,2-dichloroethane. On the basis of Eq. 12, the total number of decanoic acid molecules involved in the j-mer can be determined from the slope of the plot of $\{(1/j)\log C_{Ga,o} - (\log C_{Ga,w} - 3\log[H^+])\}$ against $\log[(HA)_2]_o$. Both plots for toluene and chlorobenzene fit the straight line with a slope of 1.5, that is, $a=18$ and $a=9$, respectively. In addition, by the coulometric titration using the Karl-Fischer reagent, it was proved that more than one water molecule per atom of gallium was involved in the hexameric Ga(III) decanoate in the toluene phase. Consequently, we conclude that the extracted species involved in the

TABLE 1. EXTRACTED SPECIES AND EXTRACTION CONSTANTS

Solvent	ε[a)]	δ[b)]	Extracted species	Extraction constants $\log K_{ex(jah)}$
Benzene[2)]	2.3	9.15	$Ga_6A_{12}(OH)_6$	-35.8 ± 0.1

a) Dielectric constant. b) Solubility parameter.

toluene phase are $Ga_6A_{18}(H_2O)_w(w>6)$ and $Ga_jA_aH_h$ ($j<6$). While, only Ga_3A_9 is extracted into the chlorobenzene phase. Figure 5 shows the number of decanoic acid involved in the monomeric and trimeric Ga(III) decanoates which are extracted into the 1,2-dichloroethane solution. The straight lines with a slope of 1.5 are obtained in both the monomer and trimer, that is, $a/2=1.5$ and $a/6=1.5$, respectively. Thus, the monomer GaA_3 and trimer Ga_3A_9 are responsible for the extraction with decanoic acid in 1,2-dichloroethane.

And further, from the intercepts of the plots of the left hand side of Eq. 12 against $\log[(HA)_2]_o$, we can determine the extraction constants for each extracted species. The results obtained for each extracted species are summarized in Table 1.

On the other hand, for 1-octanol the following relation is set up in place of Eq. 12:

$$\frac{1}{j}\log C_{Ga,o} - (\log C_{Ga,w} - 3\log[H^+]) = \frac{1}{j}\log\sum_a (K_{ex(jah)}[HA]_o^a) + \frac{1}{j}\log j. \quad (13)$$

The plot of the left hand side of Eq. 13 against $\log[HA]_o$ (Fig. 6) illustrates the number of decanoic acid molecules involved in the monomer and dimer which are extracted into 1-octanol. As evident from Fig. 6, the number of molecules of decanoic acid involved in the monomer is equal to 2 and then h is equal to -1. Therefore, from the electroneutrality of the extracted species, one hydroxide ion should be involved in the extracted monomer, since no perchlorate ion was found in the extracted species. The extraction constant $K_{ex(12-1)}$ for $GaA_2(OH)$ was determined from the intercept of the plot in Fig. 6. Decanoic acid molecules involved in the dimer depends on the concentration of decanoic acid in the organic phase. At lower concentration of decanoic acid in the organic phase, the plot falls on the straight line with a slope of 4.0, that is, $a=4$, and then $h=-2$. In analogy with the monomer described above, two hydroxide ions should be involved in the dimeric extracted species. But at higher concentration of $[HA]_o$, the slope tends to be steeper. This result suggests the presence of another dimeric species in which is involved more than four

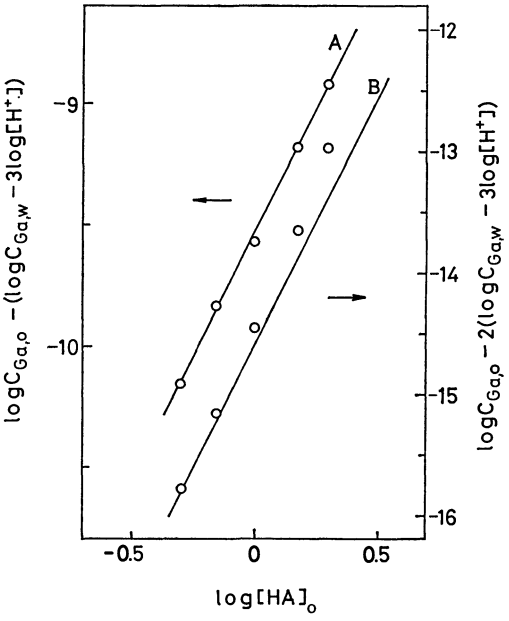

Fig. 6. Determination of the number of decanoic acid involved in Ga(III) decanoates in 1-octanol. Solid lines, A and B are the straight lines with a slope of 2.0 and 4.0, respectively. A: Monomeric Ga(III) decanoate. B: Dimeric Ga(III) decanoate.

decanoic acid molecules. Now, suppose the two dimeric species $Ga_2A_4(OH)_2$ and $Ga_2A_aH_h(a>4)$ are both responsible for the extraction. In this case, the total concentration of gallium in the organic phase can be expressed as follows:

$$C_{Ga,o} = 2[Ga_2A_4(OH)_2]_o + 2[Ga_2A_aH_h]_o. \quad (14)$$

And with the aid of the extraction constants $K_{ex(24-2)}$ and $K_{ex(2ah)}$, Eq. 14 can be rewritten as:

$$\log C_{Ga,o} - 2(\log C_{Ga,w} - 3\log[H^+]) - 4\log[HA]_o = \log\left\{1+\frac{K_{ex(2ah)}}{K_{ex(24-2)}}[HA]_o^{(a-4)}\right\} + \log 2 + \log K_{ex(24-2)}. \quad (15)$$

Then the values of $\{\log C_{Ga,o} - 2(\log C_{Ga,w} - 3\log[H^+]) - 4\log[HA]_o\}$ are plotted against $\log[HA]_o$. According to the curve-fitting method, in which the plot is compared with the normalized curves, $\log(1+X^n)$

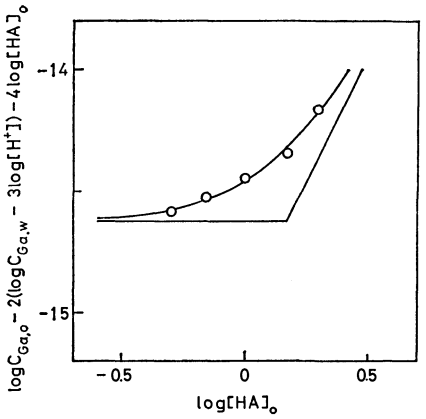

Fig. 7. Determination of the number of decanoic acid involved in dimeric Ga(III) decanoates in 1-octanol by the curve fitting method.
Solid curve is the normalized curve, $\log(1+X^2)$ *vs.* $\log X$. Solid lines are the asymptotes of the normalized curve.

vs. $\log X$, the number of decanoic acid molecules in another dimeric species can be determined together with the extraction constants of the two dimeric Ga(III) decanoates. The results are shown in Fig. 7. As shown in Fig. 7, the plot fits well with the normalized curve, $\log(1+X^2)$ *vs.* $\log X$, that is, $n=a-4=2$, or $a=6$. The extraction constants $K_{ex(24-2)}$ and $K_{ex(260)}$ determined by the curve-fitting method are given in Table 1. Consequently, $GaA_2(OH)$, $Ga_2A_4(OH)_2$, and Ga_2A_6 are extracted in the 1-octanol phase.

Then, the extraction equilibria for different solvents are described as follows:
toluene:

$$6Ga^{3+} + 9(HA)_{2,o} + wH_2O \overset{K_{ex(6180)}}{\rightleftharpoons} (Ga_6A_{18}(H_2O)_w)_o + 18H^+$$

chlorobenzene:

$$3Ga^{3+} + \frac{9}{2}(HA)_{2,o} \overset{K_{ex(390)}}{\rightleftharpoons} (Ga_3A_9)_o + 9H^+$$

1,2-dichloroethane:

$$Ga^{3+} + \frac{3}{2}(HA)_{2,o} \overset{K_{ex(130)}}{\rightleftharpoons} (GaA_3)_o + 3H^+$$

$$3Ga^{3+} + \frac{9}{2}(HA)_{2,o} \overset{K_{ex(390)}}{\rightleftharpoons} (Ga_3A_9)_o + 9H^+$$

1-octanol:

$$Ga^{3+} + 2(HA)_o + H_2O \overset{K_{ex(12-1)}}{\rightleftharpoons} (GaA_2(OH))_o + 3H^+$$

$$2Ga^{3+} + 4(HA)_o + 2H_2O \overset{K_{ex(24-2)}}{\rightleftharpoons} (Ga_2A_4(OH)_2)_o + 6H^+$$

$$2Ga^{3+} + 6(HA)_o \overset{K_{ex(260)}}{\rightleftharpoons} (Ga_2A_6)_o + 6H^+.$$

In the 1,2-dichloroethane and 1-octanol phases, the trimerization and dimerization of Ga(III) decanoates are written as follows, respectively:
1,2-dichloroethane phase:

$$3GaA_3 \overset{K_{trim}}{\rightleftharpoons} Ga_3A_9$$

1-octanol phase:

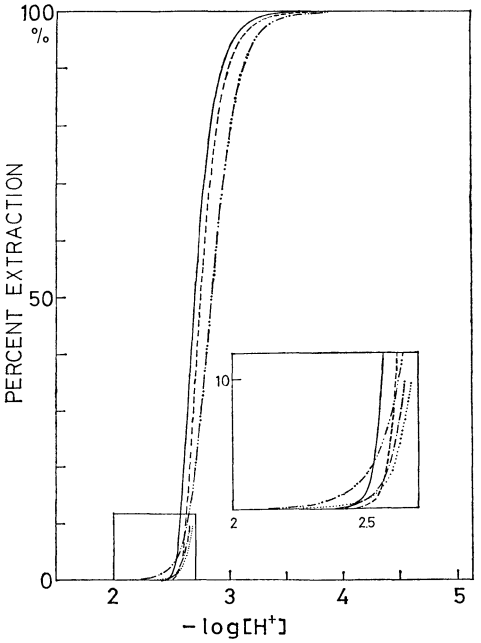

Fig. 8. The calculated extraction curves based on the results obtained in this study.
——: Toluene, ---: benzene, —·—: 1-octanol, ···: 1,2-dichloroethane, —·—: chlorobenzene. $C_{Ga,tot}=5\times10^{-3}$ mol/dm^3, $C_{HA}=1.0$ mol/dm^3.

$$2GA_2(OH) \overset{K_{dim-1}}{\rightleftharpoons} Ga_2A_4(OH)_2.$$

$$2GaA_2(OH) + 2HA \overset{K_{dim-2}}{\rightleftharpoons} Ga_2A_6 + 2H_2O$$

with the following trimerization and dimerization constants calculated from the respective extraction constants: $\log K_{trim}=9.4\pm0.2$, $\log K_{dim-1}=4.16\pm0.06$ and $\log K_{dim-2}=3.82\pm0.06$ (where the deviation of each polymerization constant originates in the uncertainties in the respective extraction constants).

Figure 8 shows the calculated extraction curves based on the results obtained in this investigation. The extracted species and the extraction constants are summarized in Table 1 together with the dielectric constants and the solubility parameters of solvents. The uncertainties in the respective extraction constants represent the probable deviations of the experimental data from the best fit curve or straight line. The previous results for benzene are also included in Fig. 8 and Table 1 for comparison.

The extraction of Ga(III) differs from that of copper(II): We observe the same extracted species with the similar extraction constant for the extraction of copper(II) decanoate in different inert solvents(hexane, cyclohexane, carbon tetrachloride, toluene, benzene, chlorobenzene and 1,2-dichloroethane).[5] The main extracted species are the hexameric Ga(III) decanoate for benzene and toluene, the trimer for chlorobenzene and the monomer and trimer for 1,2-dichloroethane, respectively. The less polar the solvent, the more extensive is the polymerization of the extracted species. In chlorobenzene and 1,2-dichloroethane the emulsion was observed in the region where the percent extraction of gallium exceeds 10%. This low extractability of gallium in these nonsolvating polar solvents

results from the formation of some hydrated less polymerized species.

As was expected from the similarity of the physical properties of the two solvents, the same hexameric species with the similar extraction constant is extracted for both benzene and toluene, and the same trimer with the similar extraction constant is found for both chlorobenzene and 1,2-dichloroethane.

On the other hand, it was found that the quite different species from those in nonsolvating solvents were extracted into 1-octanol. As we have already reported, also in the extraction of copper(II) there was a remarkable difference in the extracted species between 1-octanol[7] and nonsolvating solvents.[5] Though the less polymerized species are responsible for the extraction of gallium(III) with decanoic acid in 1-octanol, no emulsion appeared, which was the feature different from chlorobenzene and 1,2-dichloroethane. Then, the formation of some solvated, less polymerized species would contribute to a good extractability. Therefore, it can be assumed that Ga(III) decanoate in 1-octanol is polymerized through a mechanism different from that in nonsolvating solvents such as benzene and toluene *etc.*

Consequently, the results obtained in this paper suggest that the solvent used plays an important part in the extraction of metals with carboxylic acids.

The authors wish to thank Professor Motoharu Tanaka of Nagoya University for his valuable discussions and Dr. Yukio Fujii of Gifu University for his interest in this work. Inversion of the Retention Volume Order of Enantiomers Caused by the Concentration of Eluent[1)]

Ushio SAKAGUCHI, Ippei YAMAMOTO, Shinji IZUMOTO, and Hayami YONEDA*

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received November 12, 1982)

The retention volumes of enantiomers of several complex anions on the IEX 220 anion-exchange resin, when eluted by an aqueous solution of Δ-$[Co(en)_3]^{3+}$, Δ-$[Co(sep)]^{3+}$, or Δ-$[Co(l\text{-chxn})_3]^{3+}$, have been measured as a function of the eluent concentration, where en=ethylenediamine, sep=1,3,6,8,10,13,16,19-octaazabicyclo-[6.6.6]eicosane, and *l*-chxn=(−)-*trans*-1,2-cyclohexanediamine. The order of retention volumes of enantiomers of some complex anions has been found to be inverted by the concentration of the eluents. The mechanism of the inversion has been discussed.

Optical resolution of metal complex ions has been effected frequently by ion-exchange chromatography.[2)] Usually, the complex ion is adsorbed on an achiral ion-exchange resin and eluted by an aqueous solution of some optically active substance (resolving agent). In this type of experiment, it would appear rather reasonable to assume that the faster-eluted enantiomer should be the one which forms the favorable diastereomeric pair with the resolving agent in the eluent. Though such is often the case indeed, such an assumption does not necessarily hold true because of the two fundamental processes involved in the chromatographic separation; adsorption of complex ions to the resin in the stationary phase and ion-pairing of complex ions with the resolving agent in the mobile phase. Thus, critical examination is needed to establish which of these two processes governs the chromatographic optical resolution.

In this work, we have measured the retention volumes of enantiomers of several complex anions when eluted by an aqueous solution of Δ-$[Co(en)_3]^{3+}$, Δ-$[Co(sep)]^{3+}$, or Δ-$[Co(l\text{-chxn})_3]^{3+}$, as a function of the eluent concentration, where en=ethylenediamine, sep=1,3,6,8,10,13,16,19-octaazabicyclo[6.6.6]eicosane, and *l*-chxn=(−)-*trans*-1,2-cyclohexanediamine. It has been found that the order of retention volumes of enantiomers of some complex anions is inverted by the concentration of the eluents. The implications of this result have been discussed from the viewpoints of the above two processes and the mode of chiral discrimination between complex ions.

Experimental

All the metal complexes used in this work were available from previous works.[3,4)]

The resin used was the IEX 220 (Toyo Soda Manufacturing Co., Ltd.), which is based on a styrene-divinylbenzene copolymer and carries the tetraalkylammonium group as the functional group. A column (50×4 mm) of the IEX 220 anion-exchange resin was equilibrated with an eluent, which was an aqueous solution of an optically active cationic complex. An aqueous solution containing one enantiomer of an anionic complex and bis(glycinato)copper(II), which was used as a marker for void volume measurement, was injected by a syringe on top of the column and eluted at an elution rate of 0.3 cm³/min. The concentration of the cationic complex in eluents was varied from 4×10^{-3} to 60×10^{-3} mol dm^{-3}. The adjusted retention volumes were obtained from the elution curves as in the previous studies.[3,4)] The retention volumes were found to be reproducible to within 0.05%.

Results

In this work, one enantiomer of an anionic complex was adsorbed on an anion-exchange resin and eluted by an aqueous solution containing a Δ complex cation. The adjusted retention volumes obtained in this way are summarized in Table 1. The most noteworthy feature in Table 1 is the inversion of the order of retention volumes of some enantiomers caused by the concentration of the eluents. For example, in the combination of Δ-$[Co(sep)]Cl_3$···$[Co(mal)_2(en)]^-$ (mal=malonate dianion), the faster-eluted enantiomer at lower eluent concentrations is Λ, whereas it is Δ at an eluent concentration higher than 15×10^{-3} mol dm^{-3}. Likewise, Δ-$[Co(edta)]^-$ (edta=ethylenediaminetetraacetate) is eluted faster by the 4×10^{-3} mol dm^{-3} solution of Δ-$[Co(sep)]Cl_3$, while Λ-$[Co(edta)]^-$ is eluted faster by the eluent of higher concentrations or by an eluent containing Δ-$[Co(sep)]Br_3$. A similar inversion takes place for other combinations. Further, the bromide salts are more effective in inverting the retention volume orders than the chloride salts, in that lower concentrations of bromides yielded similar results obtained for higher concentrations of chlorides.

Discussion

Recently, we have studied the mode of chiral discrimination between optically active complex ions in solution.[3)] It was proposed there that (i) chiral discrimination is effected along the C_2 axis of Δ-$[Co(en)_3]^{3+}$ and Δ-$[Co(sep)]^{3+}$, while it is effected along the C_3 axis of Δ-$[Co(l\text{-chxn})_3]^{3+}$, (ii) the chirality of $[Co(edta)]^-$ or $[Co(tdta)]^-$ (tdta=1,4-butanediamine-*N*,*N*,*N*′,*N*′-tetraacetate) is recognized by a complex cation along their pseudo C_3 axes, whereas the chirality of $[Co(mal)_2(en)]^-$ or $[Co(ox)_2(en)]^-$ (ox=oxalate) is recognized along their C_2 axes, and (iii) favorable ion pairs are formed in the combinations for which the handedness of chelate rings of both ions, when oriented along the above axes, is the same.[3)] The handedness of a Δ complex ion can be specified as either P(C_3) (right-handed propeller) when viewed along the C_3 axis, or M(C_2) (left-handed propeller) when viewed along the C_2 axis.[5)] For example, the

a) The eluent concentration is in 10^{-3} mol dm^{-3}.

favorable pair is M(C_2)–M(pseudo C_3) for Δ-[Co(sep)]$^{3+}$···Λ-[Co(edta)]$^-$, where the former chirality notation refers to the cation and the latter one to the anion. Likewise, the favorable pairs are P(C_3)–P(pseudo C_3) for Δ-[Co(*l*-chxn)$_3$]$^{3+}$···Λ-[Co(edta)]$^-$, M(C_2)–M(C_2) for Δ-[Co(sep)]$^{3+}$···Λ-[Co(ox)$_2$(en)]$^-$, and P(C_3)–P(C_2) for Δ-[Co(*l*-chxn)$_3$]$^{3+}$···Λ-[Co(ox)$_2$(en)]$^-$. The ions [Co(en)$_3$]$^{3+}$, [Co(tdta)]$^-$, and [Co(mal)$_2$(en)]$^-$ can be considered in the same way as for [Co(sep)]$^{3+}$, [Co(edta)]$^-$, and [Co(ox)$_2$(en)]$^-$, respectively.

The inversion of the retention volume order of enantiomers obtained in this work may be explained by combining the above ideas with the two fundamental processes in ion-exchange chromatographic experiments. The origin of the inversion of the combination Δ-[Co(sep)]$^{3+}$···[Co(mal)$_2$(en)]$^-$ will be considered as an example. In this work, one enantiomer of an anionic complex was adsorbed on the anion-exchange resin and eluted by an aqueous solution containing a Δ complex cation. The [Co(mal)$_2$(en)]$^-$ ion will be adsorbed to the resin functional group along its C_2 axis *via* two oxygen atoms of coordinated malonates. At higher eluent concentrations, the elution is governed by ion-pairing in the mobile phase rather than in the stationary phase. This is because the chloride or bromide ions in the eluent replace the [Co(mal)$_2$(en)]$^-$ ions adsorbed on the resin and the concentration of [Co(mal)$_2$(en)]$^-$ in the mobile phase is thus enhanced. As a result, the enantiomer that associates more favorably with Δ-[Co(sep)]$^{3+}$ in the mobile phase is eluted faster and shows a smaller retention volume than its enantiomorph. The favorable combination is therefore Δ–Δ or M(C_2)–M(C_2), as stated previously, and this situation is illustrated in Fig. 1(a).

At lower eluent concentrations, the elution is governed by adsorption of a complex anion to the resin functional group, which means that chiral discrimination is effected through ion-pairing of the Δ cation with the [Co(mal)$_2$(en)]$^-$ ion adsorbed to the resin, *i.e.*, chiral discrimination is effected in the stationary phase. Recall that the [Co(mal)$_2$(en)]$^-$ anion is bound to the resin along its C_2 axis, leaving only the pseudo C_3 axis for the ion-pairing direction for the Δ cation. Thus, the Δ-[Co(sep)]$^{3+}$ cation will be forced to associate with [Co(mal)$_2$(en)]$^-$ along the anion's pseudo C_3 axis. This situation is illustrated in Fig. 1(b). It should be noted here that the handedness of chelate rings of the complex anion is inverted depending upon the direction of watching the anion;[5] Δ-[Co(mal)$_2$(en)]$^-$ is left-handed or M(pseudo C_3) when watched along the pseudo C_3 axis, while it is right-handed or P(C_2) when watched along the C_2 axis. Since Δ-[Co(sep)]$^{3+}$ has the M(C_2) chirality and is discriminated along its C_2 axis, and since the enan-

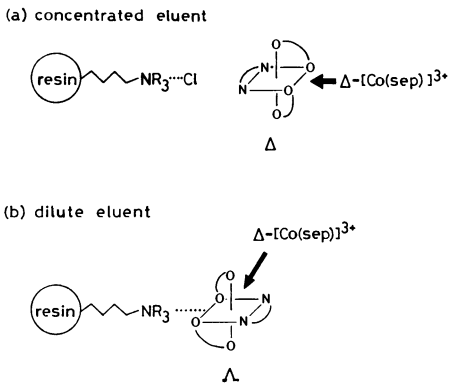

Fig. 1. An illustration of the ion-pairing equilibrium in stationary and mobile phases. The enantiomer depicted for [Co(mal)$_2$(en)]$^-$ is the one which forms the favorable pair with Δ-[Co(sep)]$^{3+}$. The cation discriminates the chirality of the anion along (a) the anion's C_2 axis and (b) the anion's pseudo C_3 axis.

tiomer of the anion that associates more favorably with the M(C_2) cation should have the same M chirality, the preferred enantiomer is either M(C_2) or M(pseudo C_3). As depicted in Fig. 1(b), the [Co(mal)$_2$(en)]$^-$ anion is now assumed to be discriminated along its pseudo C_3 axis. Thus, the M(pseudo C_3) enantiomer (the Λ enantiomer) is preferred and the favorable pair at lower eluent concentration is Δ-[Co(sep)]$^{3+}$···Λ-[Co(mal)$_2$(en)]$^-$. Namely, at higher eluent concentrations, the anion is discriminated along its C_2 axis in the mobile phase, whereas at lower eluent concentrations, the anion has to be discriminated along its pseudo C_3 axis in the stationary phase. This may be responsible for the observed inversion. The results for the other combinations may be explained similarly.

The above reasoning seems to gain some support from the results obtained by using the bromide salts instead of the chloride salts. The bromide anion is known to be adsorbed to anion-exchange resins more strongly or selectively than the chloride ion.[6] Thus, compared with the chloride ion, the bromide ion will enhance the effective concentration of a complex anion in the mobile phase, which will in turn enhance the ion-pairing with a Δ cation in the mobile phase. This will make the situation similar to that depicted in Fig. 1(a). Namely, the bromide ion is more effective in driving the dynamic equilibrium to the side of elution-governing. This may be the reason for the bromides being more effective in inverting the retention volume orders.

In Table 1, it is also noted that [Co(mal)$_2$(en)]$^-$ shows much smaller retention volumes than the other anions for all the eluents. This suggests either that this complex anion associates very strongly with the Δ cations in the mobile phase, or that [Co(mal)$_2$(en)]$^-$ is adsorbed very weakly to the resin. But the former possibility seems to be unlikely, because even at lower Δ-[Co(sep)]Cl$_3$ concentrations, where the elution is adsorption-governed as explained above, this anion exhibits much smaller retention volumes than the other complex anions. Thus, [Co(mal)$_2$(en)]$^-$ may be adsorbed to the resin more weakly than [Co(edta)]$^-$, [Co(tdta)]$^-$, and [Co(ox)$_2$(en)]$^-$ owing possibly to greater hydration of [Co(mal)$_2$(en)]$^-$. An indication that [Co(mal)$_2$(en)]$^-$ is hydrated to a greater extent than [Co(edta)]$^-$ has been obtained recently by conductance measurements.[7]

Conclusion

The inversion of the retention volume orders of enantiomers reflects that ion-pairing is highly directional both in mobile and stationary phases and a cation recognizes an inverted chirality of an anion when the cation approaches the anion along different directions.

(Received November 19, 1982)

A Schiff base, 4-[2-(methylthio)anilino]-3-penten-2-one (Hmtap), prepared from acetylacetone and 2-(methylthio)aniline, reacted with $Na_2[PdCl_4]$ in the presence of sodium ethoxide to give [PdCl(mtap-*O,N,S*)] (**1**). Complex **1** was treated with carbanions formed from dimethyl malonate, methyl cyanoacetate, and malononitrile in the presence of sodium methoxide to afford the corresponding (disubstituted methyl)palladium(II) complexes, [Pd(CHYY')(mtap-*O,N,S*)] (Y,Y'=COOMe and/or CN). On the other hand, **1** reacted with Tl(acac) to yield an *O,O'*-chelating complex, [Pd(mtap-*N,O*)(acac)], in which the mtap moiety served as a bidentate ligand. Moreover, **1** reacted with 2,2'-bipyridine (bpy) and 4-(dimethylamino)pyridine (dmapy) in the presence of $NaClO_4 \cdot H_2O$ to give [Pd(mtap-*N,O*)(bpy)]ClO_4 and [Pd(mtap-*O,N,S*)(dmapy)]ClO_4, respectively. These complexes are characterized by means of elemental analysis and IR and NMR spectroscopy.

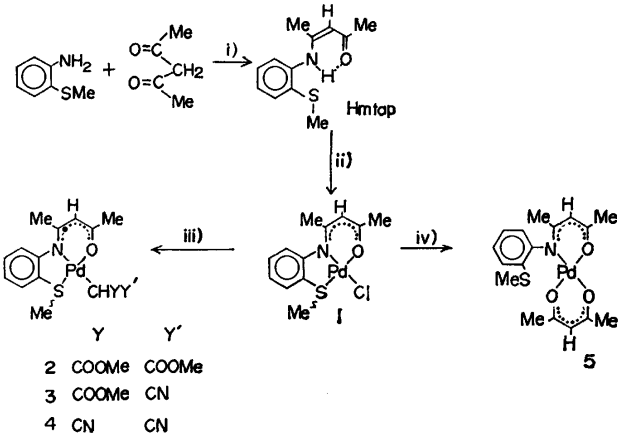
The previous papers from our laboratory revealed that Schiff bases, 4-(α-picolylamino)- and 4-[2-(diphenylphosphino)ethylamino]-3-penten-2-ones (Hpap and Hdpeap, respectively) reacted with $Na_2[PdCl_4]$ in the presence of base to yield [PdCl(pap-*N,N,O*)][1] and [PdCl(dpeap-*O,N,P*)],[2] respectively. In these square planar palladium(II) complexes, the Schiff bases served as a monoanionic tridentate ligand. Carbanions formed from active methylene compounds displaced the remaining chloro ligand at the fourth coordination site in the complexes to give (disubstituted methyl) palladium(II) complexes retaining the NNO- or ONP-typed tridentate chelate.[1,2]

It is interesting to investigate both the coordinating ability of sulfur atom in an ONS-typed chelate and the stabilizing effect of the chelate for the carbon-palladium σ-bond. In this paper, we present some palladium(II) complexes derived from reactions of chloro[4-[2-(methylthio)anilino]-3-penten-2-onato-*O,N,S*]palladium(II) [PdCl(mtap-*O,N,S*)] [mtap=4-[2-(methylthio)anilino]-3-penten-2-onato] with the carbanions or a few pyridine derivatives. Furthermore, the coordination ability of the sulfur atom in the mtap chelate and the stabilizing effect of the chelate for the C–Pd σ-bond were compared with the respective ones of the pap and dpeap chelates.

Results and Discussion

*Preparation of Hmtap and [PdCl(mtap-*O,N,S*)].* A mixture of 2-(methylthio)aniline and an excess amount of acetylacetone was refluxed to give colorless crystals of Hmtap in 84% yield. The spectroscopic data of Hmtap were quite consistent with its structure. Furthermore, it was possibly associated with the hydrogen-bonded keto-enamine form, by analogy with the cases of Hpap[1] and other related Schiff bases.[3]

After treating an ethanol solution of $Na_2[PdCl_4]$ with Hmtap in the presence of an equimolar amount of sodium ethoxide, the resulting red microcrystals were collected and assignable to [PdCl(mtap-*O,N,S*)] (**1**) (*vide infra*). In the ^{1}H-NMR spectrum of **1** in $CDCl_3$, methyl group on sulfur showed a downfield shift by 0.42 ppm due to the coordination to palladium.



Scheme 1. i) Reflux, ii) $Na_2[PdCl_4]+NaOC_2H_5$, iii) $CH_2YY'+NaOCH_3$, iv) Tl(acac).

Mass spectrum of **1** exhibited a parent-ion pattern centered at *m/e* 362, corresponding to [^{106}Pd^{35}Cl(mtap-*O,N,S*)]. In the far-infrared spectrum, there were two bands at 325 and 338 cm^{-1} for ν(Pd–^{37}Cl) and ν(Pd–^{35}Cl), respectively.

*Reactions of **1** with Carbanions Derived from Active Methylene Compounds.* Reactions of **1** with carbanions, formed from dimethyl malonate, methyl cyanoacetate, and malononitrile, were carried out in THF at room temperature to yield complexes, [Pd{$CH(CO_2CH_3)_2$}(mtap-*O,N,S*)] (**2**), [Pd{$CHCN(CO_2CH_3)$}(mtap-*O,N,S*)] (**3**), and [Pd{$CH(CN)_2$}(mtap-*O,N,S*)] (**4**), respectively, as shown in Scheme 1. No reaction occurred between **1** and a carbanion formed from ethyl nitroacetate, in analogy with the case of [PdCl(pap)] system.[1] The complexes obtained in this study are considerably stable in the solid state in air. Yields, microanalytical data, and spectroscopic properties are summarized in Tables 1—3.

The IR spectra of **1**—**4**, as well as **5**—**8**,[4] showed three bands near 1560, 1515, and 1380 cm^{-1}, characteristic of 4-amino-3-penten-2-onato-*N,O* moiety. The ^{1}H-NMR spectra of **1**—**8** exhibited three singlets in the range of δ 1.35—2.9, ascribable to 1-, 5-, and sulfur-bonded methyl groups of the mtap moiety (Table

2). Among them, two resonances at the highest and an intermediate fields were assigned to 5- and 1-methyl protons of the 3-penten-2-onato-*N*,*O* moiety, respectively, on the basis of both analogy with the data for [Pd(CHYY′)(pap)] (Y,Y′ = CO_2CH_3 and/or CN)[1] and the difference of electronegativities of the nearly-located coordinating atoms, nitrogen and oxygen. This assignment was also supported by the {^{1}H}-^{13}C-NMR data of C⋯N and C⋯O groups (Table 3). The remaining resonance at the lowest field was unambiguously associated with the sulfur-bonded methyl group.

The ^{1}H-NMR spectra of **2**—**4** exhibited a singlet in the range of δ 2.8—3.7, assignable to a palladium-bonded methine proton (Table 2). As for **2**, there was a singlet at δ 3.65 for two esteric methyl groups with a satisfactory intensity implying their spectroscopic equivalence. In addition, its IR spectrum in chloroform showed only one ν(C=O) band at 1718 cm^{-1}, and the wave number was indicative of retention of esteric carbonyl groups without bonding of oxygen to hydrogen or palladium in an enol fashion. The IR spectrum of **4** exhibited a strong ν_{as}(C≡N) band at 2222 cm^{-1} together with a very weak ν_s(C≡N) one at 2170 cm^{-1}, attributable to a *C*-bonded dicyanomethyl group, Pd–CH(CN)$_2$ rather than an *N*-bonded 2-cyanoetheniminato one, Pd–N=C=CH–CN.[5] On the

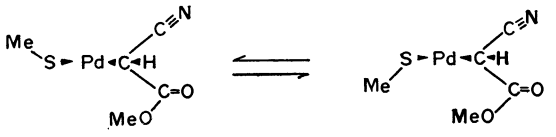

Fig. 1. Two configurational isomers of **3**. The 4-anilino-3-penten-2-onato-*O,N* moiety is deleted for simplification.

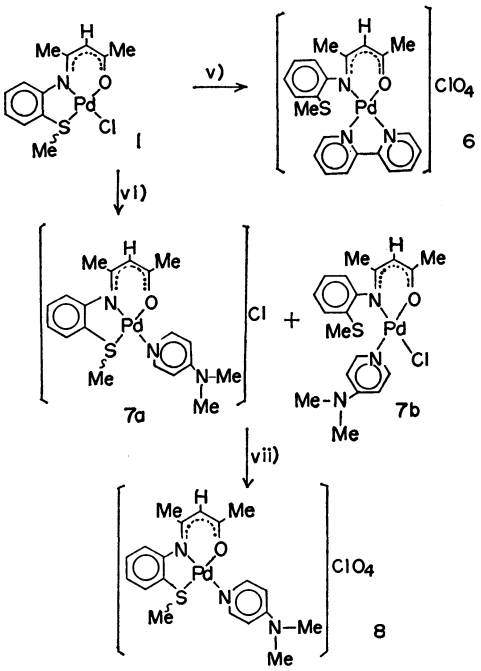
basis of these facts, **2**—**4** were concluded to have the structure with the carbon-palladium σ-bond, as shown in Scheme 1. The ^{1}H-decoupled ^{13}C-NMR data are fully consistent with the *C*-bonded structure (Table 3). The methine carbons bonded to palladium appeared as a singlet at δ 32.3 for **2**, at δ 12.2 for **3**, and at δ −10.6 for **4**. It is noteworthy that the higher-field resonances of the methine carbons in **3** and **4** are reasonably correlated to the smaller deshielding effect of the cyano group as compared with that of ester group,[6] together with the shielding effect by palladium through the σ-bond. A similar high-field shift was observed in the case of [Pd{CH(CO$_2$R)Z}-(pap)] (Z=CO$_2$C$_2$H$_5$ or CN).[1] As for three methyl carbon resonances in the range of δ 24—28, two singlets near δ 24.5 and 25.8 were attributable to 5- and 1-methyl carbons of the 3-penten-2-onato-*N,O* moiety on the analogy of their chemical shifts to the coorresponding data of [Pd{CH(CO$_2$R)Z}(pap)].[1] Especially, the singlet near δ 25.8 was associated with the 1-methyl carbon on the basis of both the actual coincidence of the chemical shift with the corresponding value for [Pd{CH(CO$_2$R)Z}(pap)][1] and the difference of the electronegativities of the nearly-located coordinating atoms (*vide ante*). The third singlet near δ 27.8 was ascribed to sulfur-bonded methyl carbon.

The configuration of **3** is diastereotopic leading to two configurational isomers, because of the sp^3 sulfur atom and the asymmetric carbon bonded to palladium. It is notable that **3** showed temperature-dependent ^{1}H-NMR spectra. At 27 °C, **3** showed two slightly broad signals at δ 2.81 (3H, SC$\underline{H}_3$) and 3.30 (1H, Pd–C$\underline{H}$) and a sharp singlet at δ 2.08 (3H, 5-C$\underline{H}_3$), as seen in Table 2. Each of these three signals separated into two considerably sharp singlets at −5 °C; SC$\underline{H}_3$ at δ 2.85 (2.4 H) and 2.68 (0.6H); Pd–C$\underline{H}$ at δ 3.32 (0.8H) and 3.22 (0.2H); and 5-C$\underline{H}_3$ at δ 2.09 (2.4H) and 2.07 (0.6H).[7] These data indicate that inversion of the sulfur-bonded methyl group in **3** took place rapidly on the NMR time scale above room temperature and that the two configurational isomers, as shown in Fig. 1, were fixed in the population ratio of about 4:1 at −5 °C, owing to the quenching of the inversion. Similar configurational change at sulfur atom has been observed as regards (dialkyl sulfide)-palladium(II) complexes.[8-10]

In sharp contrast to the cases of carbanions derived from dimethyl malonate, methyl cyanoacetate and malononitrile, **1** reacted with Tl(acac) to give an *O,O'*-chelated acetylacetonato complex, **5**. This structure was confirmed by the lack of ν(C=O) band of free carbonyl groups and by a singlet resonance at δ 5.09 characteristic of the methine proton of the *O,O'*-chelated acetylacetonato moiety. Dissociation of sulfur



Scheme 2. v) 2,2'-Bipyridine+NaClO$_4$, vi) dmapy, vii) NaClO$_4$·H$_2$O.

donor in the mtap moiety from palladium by the incoming acac chelate was shown by the upfield shift of the *S*-methyl proton resonance by *ca.* 0.4 ppm. In addition, 5-methyl protons of **5** resonated at a higher field by *ca.* 0.6 ppm than those of **1**—**4**. This upfield shift was attributed to the anisotropic effect due to the phenylene ring, lying actually perpendicular to the coordination plane. The dpeap complex, [PdCl-(dpeap-*O,N,P*)] reacted easily with Tl(acac) in CH$_2$Cl$_2$ at room temperature to yield a (diacetylmethyl)palladium(II) complex involving a palladium-carbon σ-bond stabilized by the phosphine.[2] It has been reported that triphenylphosphine and pyridine also stabilized the diacetylmethyl-palladium(II) bond.[11,12] On the other hand, our present mtap system could not furnish a stabilizing field enough to produce the (diacetylmethyl)palladium(II) complex, and labile coordination property of the sulfur donor helped the formation of the *O,O'*-chelated structure. In our previous research,[1] Tl(acac) did not react with [PdCl-(pap)] under THF reflux, owing to rigid coordinate bonds to palladium.

Reactions of **1** *with Pyridine Derivatives.* Dissociation of the *S*-donor from palladium in **5** led us to undergo the reactions of **1** with some pyridine derivatives in order to elucidate the coordination behavior of the *S*-donor to palladium. When **1** was treated with excess 4-picoline in THF at room temperature, no 4-picoline adduct to **1** was isolated. On the other hand, the ^{1}H-NMR spectrum of a mixture of **1** and 2,2'-bipyridine (bpy) (1:1) exhibited signals corresponding to two species of [PdCl(mtap-*O,N,S*)] and [Pd(mtap-*N,O*)(bpy)]Cl in a ratio of 73:27, indicating the following equilibrium.

$$[PdCl(mtap\text{-}ON,S)] + bpy \rightleftharpoons [Pd(mtap\text{-}N,O)(bpy)]Cl$$

Preference of 2,2'-bipyridine to bidentate coordination brought about the equilibrium leading to [Pd(mtap-

N,O)(bpy)]Cl with the dissociation of the *S*-donor. The dissociation of the *S*-donor in [Pd(mtap-*N,O*)-(bpy)]Cl was determined easily by the chemical shift of the *S*-methyl proton resonance. The mixture of the two species was converted quantitatively to [Pd(mtap-*N,O*)(bpy)]ClO_4 (**6**) by treatment with $NaClO_4 \cdot H_2O$ in THF at room temperature (Scheme 2).

Complex **1** was also treated with a slight excess of 4-(dimethylamino)pyridine (dmapy), a well-known strong base, in THF at room temperature to give a pale yellow powder (**7**), which was suggested as a 1:1 adduct of **1** with dmapy by its elemental analysis. Moreover, the ^{1}H-NMR spectrum of **7** in $CDCl_3$ revealed the coexistence of two isomers, which are [Pd(mtap-*O,N,S*)(dmapy)]Cl (**7a**) and [PdCl(mtap-*N,O*)(dmapy)] (**7b**) in a ratio of 55:45. *S*-Methyl proton resonances unambiguously indicated the retention of the *S*-donor coordination to palladium in **7a** and dissociation of the *S*-donor in **7b**. An ionic complex, [Pd(mtap-*O,N,S*)(dmapy)]ClO_4 (**8**), was obtained quantitatively from the mixture of **7a** and **7b** and $NaClO_4 \cdot H_2O$. Transformation of **7b** to **8** proceeded reasonably through **7a**. These results indicate that the *S*-donor in **1** is relatively labile and can be displaced by the strong nucleophile or the multidentate ligand. In the case of 4-picoline, nucleophilicity is not enough, together with its non-chelate structure.

Experimental

Materials and General Proceduces. 2-(Methylthio)aniline[13] and thallium(I) acetylacetonate[14] were prepared by the respective literature methods. Solvents were dried by the standard methods and distilled. Preparative operations were performed under nitrogen. ^{13}C-NMR spectra were recorded on JEOL FX-90-Q, using tetramethylsilane as an internal standard. Mass spectra were obtained with a Nichiden-Varian TE-600 gas chromatograph-mass spectrometer. IR and ^{1}H-NMR spectra, melting points, and molar conductivities were measured according to the methods described in the previous paper.[1] The temperature of the NMR samples was determined with methanol or 1,3-propanediol.

Preparation of 4-[2-(Methylthio)anilino]-3-penten-2-one (Hmtap). A mixture of 2-(methylthio)aniline (0.13 mol) and acetylacetone (0.33 mol) was refluxed for 3 h with removal of liberated water. Unreacted starting materials were removed under *ca.* 0.5 mmHg (1 mmHg≈133.322 Pa) at *ca.* 100 °C, and the residue was recrystallized from dichloromethane and hexane to yield colorless crystals of Hmtap: Found: C, 65.18; H, 6.96; N, 6.33%; M^+, 221. Calcd for $C_{12}H_{15}NOS$: C, 65.12; H, 6.83; N, 6.33%; M, 221.32. Mp 58 °C: IR ($CHCl_3$) 3375 (NH), 1616, 1566, and 1518 cm^{-1} (α,β-unsaturated β-amino ketone); ^{1}H-NMR ($CDCl_3$) δ= 1.85 (3H, s, CH_3), 2.10 (3H, s, CH_3), 2.38 (3H, s, SCH_3), 5.22 (1H, s, CH), 7.0—7.4 (4H, m, aromatic CH), and 12.20 (1H, broad, NH).

Preparation of [PdCl(mtap-O,N,S)] 1. An ethanol solution of sodium ethoxide (6.1 mmol) was added slowly to a mixture of $Na_2[PdCl_4]$ (6.1 mmol) and Hmtap (6.8 mmol) in ethanol (150 ml). After stirring at room temperature for 16 h, the solvent was removed under vacuum. Recrystallization of the residue from dichloromethane and hexane gave red microcrystals of **1**.

Reactions of 1 with Carbanions Formed from Active Methylene Compounds. Dimethyl malonate (0.80 mmol) in THF was treated with sodium methoxide (0.96 mmol), followed by slow addition of **1** (0.80 mmol) in THF. The mixture was stirred for 27 h at room temperature, and the solvent was removed under vacuum. The residue was recrystallized from dichloromethane and hexane to yield brown microcrystals of [Pd{$CH(COOCH_3)_2$}(mtap-*O,N,S*)] (**2**). Complex **1** reacted similarly with methyl cyanoacetate and malononitrile to afford reddish orange microcrystals of [Pd{$CHCN(CO_2CH_3)$}(mtap-*O,N,S*)] (**3**) and orange ones of [Pd{$CH(CN)_2$}(mtap-*O,N,S*)] (**4**), respectively.

Reaction of 1 with Thallium Acetylacetonate. Thallium(I) acetylacetonate (1.0 mmol) was added in portions to a dichloromethane solution (10 ml) of **1** (0.8 mmol) and the mixture was stirred for 30 h under reflux. After the solvent was evaporated *in vacuo*, the residue was recrystallized from benzene and hexane, yielding light-brown microcrystals of [Pd(mtap-*N,O*)(acac)] (**5**).

Reaction of 1 with 2,2′-Bipyridine. Sodium perchlorate–water(1/1) (0.69 mmol) was added to a THF suspension of **1** (0.69 mmol) and 2,2′-bipyridine (0.89 mmol), and the mixture was stirred for 20 h at room temperature. The solvent was removed under vacuum, and the recrystallization of the residue from dichloromethane and hexane gave a pale yellow powder of [Pd(mtap-*N,O*)(bpy)]ClO_4 (**6**).

Reaction of 1 with 4-(Dimethylamino)pyridine. 4-(Dimethylamino)pyridine (1 mmol) was added to a THF (20 ml) suspension of **1** (0.83 mmol) and the color turned into orange-yellow. After stirring for 20 h at room temperature, a pale yellow precipitate was collected and washed with diethyl ether and hexane to give PdCl(mtap)(dmapy) (**7**).

A THF (20 ml) suspension of **7** was treated with sodium perchlorate–water(1/1) in a molar ratio of 1:1.2, followed by stirring at room temperature for several hours. After filtration and removal of the solvent from the filtrate, the residue was recrystallized from dichloromethane and diethyl ether, and [Pd(mtap-*O,N,S*)(dmapy)]ClO_4 (**8**) was isolated as red microcrystals.

The authors thank Mrs. Hisako Mazume and Miss Yumi Kojima, Nagasaki University, for their technical assistance.

Stereochemical Investigation on Asymmetrically Modified Raney Nickel Catalyst. Mode of Interaction between Modifying Reagent and Substrate in the Enantioface-differentiating Process

Akira TAI,* Tadao HARADA, Yuji HIRAKI, and Sigeki MURAKAMI
Institute for Protein Research, Osaka University, Yamada-oka, Suita, Osaka 565

(Received May 27, 1982)

The mode of enantioface-differentiating hydrogenation with asymmetrically modified Raney nickel (MRNi) was investigated by using various sorts of modifying reagents and substrates. The optical yields (O.Y.) of the hydrogenation of methyl acetoacetate over MRNi for different modifying reagents occured in the following order: $HO_2CCH(OH)CH(OH)CO_2H$ (O.Y. 85%) > $HO_2CCH(OX)CH(OH)CO_2H$, (X = CH_3–, and PhCO–) ≈ $HO_2CCH_2CH(OH)CO_2H$ (O.Y. 61—65%) ≫ $HO_2CCH(OX)CH(OX)CO_2H$ (X = CH_3–, and PhCO) ≈ $CH_3CH(OH)CH(OH)CO_2H$ (O.Y. 1—8%). The hydrogenation of various substrates of the structure, R–C(Y)–CH_2–C(=O)–R′, over tartaric acid-modified Raney nickel (TA-MRNi), gave high optical yields only when the substituent –Y functioned as a good hydrogen bond acceptor like a carbonyl group, and two pairs of hydrogen bondings between substrate and two hydroxyl groups of tartaric acid were available. As for the stereochemistry of the reaction in such a case, (*R,R*)-TA-MRNi always gave (*R*)-product in excess. Based on the stereochemistry of the reaction and the role of hydrogen bonds between modifying reagent and substrate, a stereochemical model is proposed to elucidate the mode of enantioface-differentiating hydrogenation of prochiral ketones over TA-MRNi.

It has been reported that the asymmetric modification of Raney nickel (RNi) with an aqueous solution of tartaric acid (TA) and NaBr gave an excellent catalyst (TA–NaBr–MRNi) for the enantioface-differentiating hydrogenation. The hydrogenation of methyl acetoacetate (MAA) over this catalyst gave methyl 3-hydroxybutyrate (MHB) in a quantitative chemical yield and almost 90% of optical yield. Studies on the development of the above-mentioned catalyst have made it clear that the enantioface-differentiating ability of the catalyst is governed by two major factors. The first one is the proportion of the number of enantioface-differentiating reaction sites (where the enantioface-differentiating hydrogenation of substrate takes place by the aid of modifying reagent) to the number of non-enantioface-differentiating sites (where the racemic product is produced because of the absence of the modifying reagent on the catalyst). Our recent study has shown that NaBr on the catalyst is specifically adsorbed on the non-enantioface-differentiating reaction sites, inhibiting the hydrogenation activity of these sites.[1] Thus, the hydrogenation of MAA over TA–NaBr–MRNi proceeded overwhelmingly at the enantioface-differentiating reaction sites in giving the product with a high optical purity. The second factor is the degree of the intrinsic enantioface-differentiating ability of the modifying reagent, which depends not only on the structural features but also on the mode of adsorption on the catalyst surface. Arguing from the structural features of TA and MAA, and the stereochemistry of the hydrogenation product, we have proposed a mode of interaction between TA and MAA at the enantioface-differentiating step of the hydrogenation.[2] In this paper, we wish to report the details on the mode of enantioface-differentiation process and the validity of the proposed stereochemical model, based on the following two series of investigations: 1) The hydrogenation of MAA over RNi modified with NaBr and the compound whose structure is analogous to TA, and 2) the hydrogenation of various prochiral ketones over TA–NaBr–MRNi.

Results

Hydrogenations of MAA over Various Sorts of MRNi. Several analogs of TA were prepared and their enantioface-differentiating abilities (e.d.a.) were evaluated from the optical yield of the hydrogenation of MAA over the MRNi prepared from TA-analogs and NaBr. The results are summarized in Table 1.

Among the compounds examined, only TA and 2-methyl-TA gave rise to more than 70% of e.d.a. (Entries 1 and 2). When one of the hydroxyl groups of TA was replaced by H–, benzoyloxyl or methoxyl group, appreciable decreases of e.d.a. were observed (Entries 3, 4, and 5). The e.d.a.'s of this type of compounds were around 65%. The replacement of one of the carboxyl groups of TA by a methyl group resulted in a complete loss of e.d.a. (Entry 6), even if vicinal hydroxyl groups existed. A drastic decrease in e.d.a. was also observed when both hydroxyl groups of TA were acylated or alkylated (Entries 7 and 8). These results clearly show that two hydroxyl groups and two carboxyl groups in TA were absolutely necessary functional groups for the effective enantioface-differentiation of MAA.

Hydrogenations of Prochiral Ketones over TA–NaBr–MRNi. In Table 2, the results of the hydrogenation of various prochiral ketones over TA-NaBr–MRNi are summarized.

In the series of the hydrogenations of methyl esters of α-, β-, γ-, and δ-keto acids (**1a**—**4a**) over TA–NaBr–MRNi, the excellent optical yield was obtained only with β-keto ester (Entry 2). Furthermore, the hydrogenation rate of **2a** was much faster than those of **1a**, **3a**, and **4a**. Although γ-keto ester (**3a**) was

a) MAA(100 mmol) in methyl propionate(23 ml) and acetic acid(0.2 ml) was subjected to hydrogenation over MRNi prepared from 1.6 g of Raney alloy at initial hydrogen pressure of 100 kg/cm^2 at 100 °C. b) Degree of e.d.a. was evaluated by the optical yield(%) of the reaction of MAA to MHB.

hydrogenated to **3b** in 40% optical yield, the hydrogenations of α- and δ-keto ester gave only racemic **1b** and **4b**, respectively (Entries 1 and 4).

It is interesting that the hydrogenations of simple ketone (**5a**) and γ-keto ester (**3a**) proceeded with almost the same optical yields but in opposite directions of enantioface-differentiation; that is, **3a** gave (*R*)-**3b** in excess, while **5a** gave (*S*)-**5b** in excess (Entries 3 and 5).

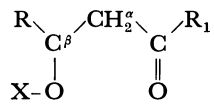
In the preceding paper, which dealt with the hydrogenation of **1a**—**4a** with various amino acid–MRNi's it was shown that the geometrical fitness of functional groups in the modifying reagent and substrate was an essential factor for giving high optical yield.[3)] It is thus expected that **2a** can enter a well-fitting interaction with TA, whereas other substrates (**1a**, **3a**, **4a**, and **5a**) cannot.

Two types of homologues of **2a**, that is, alkyl acetoacetates (**6a**—**9a**) and methyl alkanoylacetates (**10a**—**12a**) were found to be smoothly hydrogenated over TA–NaBr–MRNi in uniformly excellent optical yields (Entries 6—12).

Acetylacetone (**13a**), in which one of the carbonyl groups takes the place of the ester carbonyl group of **2a**, was also found to be a good substrate.[4)] In this case, TA–NaBr–MRNi differentiates not only the enantioface of carbonyl group but also the one out of two carbonyl groups in **13a**. When the hydrogenation of **13a** is discontinued at 1.1 molar equivalent of hydrogen uptake, a mixture of **13b** and 2,4-pentanediol in a ratio of 91 to 9 was obtained. The optical yield of **13b** was 74%. (Entry 13). The complete hydrogenation of **13a** gave (*2R,4R*)-2,4-pentanediol of high optical purity.[5)]

The compounds, in which the ester group of **2a** was substituted with some other polar functional group such as $-SO_2CH_3$ (**14a**, **15a**),[6)] $-CH_2OH$ (**16a**),[7)] and $-CH_2OCH_3$ (**17a**) were found to be favorable substrates for the enantioface-differentiating hydrogenation with TA–NaBr–MRNi. As shown in Table 2 (Entries 14—17), the hydrogenation of these substrates over (*R,R*)-TA–NaBr–MRNi proceeded in reasonable optical yields in giving (*R*)-isomer in excess.

From the results mentioned above, it becomes evident that the essential factor for a good substrate is the presence of an oxygen atom bound to the β-carbon from the prochiral carbonyl group (to be hydrogenated as shown below).



Discussion

The rigorous enantioface-differentiating reaction over MRNi should be attained when the preadsorbed modifying reagent is well settled on the nickel surface and offers uniform chiral binding sites for the prochiral substrate approaching the nickel surface. The adsorbed substrates are uniformly orientated on the nickel surface with one side of enantiofaces by the aid of the well-fitting interaction between binding sites of modifying reagent and substrate.

According to the physicochemical studies[8)] on the mode of adsorption of modifying reagent on the nickel surface, a 2-hydroxyl carboxylic acid is coordinated to a surface nickel atom only through its carboxyl group dissociated as a carboxylate ion, while its hydroxyl group is essentially free from the surface metal.

In order to implant a modifying reagent and make it stationary on the surface of a catalyst, interactions may be required between modifying reagent and catalyst surface at more than two points. Thus, the presence of two carboxyl groups is expected to be one of the necessary conditions for a good modifying reagent. This consideration is compatible with the experimental results that the modifying reagent of high e.d.a. are limited to α-hydroxyl and α,β-dihydroxyl dicarboxylic acid.

The poor e.d.a.'s of *O,O'*-dibenzoyl- and *O,O'*-dimethyl-TA indicate that no effective interactions leading to the efficient enantioface-differentiation take place between modifying reagent and MAA, as a result of the absence of free hydroxyl groups in the modifying reagent. Although α-hydroxyl dicarboxylic acids (malic acid, *O*-benzoyl-TA, and *O*-methyl-TA) gave moderate e.d.a.'s, high e.d.a.'s (more than 70%) were exhibited only by using α,β-dihydroxyl dicarboxylic acid. Thus it is evident that two hydroxyl groups in a modi-

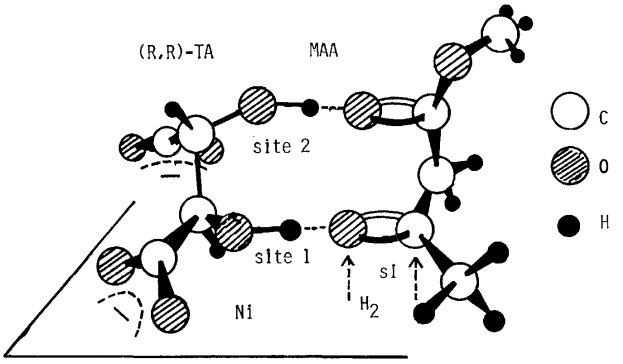

Fig. 1. Schematic representation of the interaction between (*R*,*R*)-TA and MAA on the MRNi.

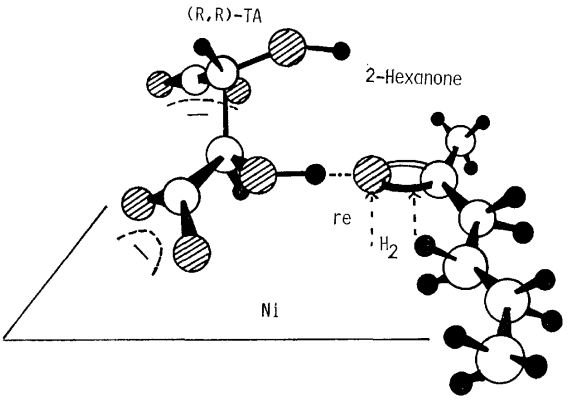

Fig. 2. Schematic representation of the interaction between (*R*,*R*)-TA and 2-hexanone on the MRNi.

fying reagent play an indispensable role in the enantioface-differentiation of MAA and analogs. Based on the hydrogen-bonding capacity between two hydroxyl groups in TA and two carbonyl groups in MAA, we have proposed the modes of co-adsorbed MAA and TA on the catalyst (Fig. 1).[5] When the mode of interaction is examined by a CPK model, it is expected that one of the hydroxyl groups of TA will come close to the catalyst surface (site 1), whereas the second hydroxyl group is somewhat remote from the surface (site 2).

If the adsorption of MAA takes place as shown in Fig. 1, the carbonyl group of MAA to be hydrogenated is fixed with site 1 and comes close to the surface of catalyst with its *si*-face facing to the catalyst. The MAA thus adsorbed is ready to be hydrogenated by the supply of activated hydrogen from the surface (*si*-face attack).

Thus, the hydrogenation of MAA over (*R*,*R*)-TA–NaBr–MRNi was expected to proceed predominantly by *si*-face attack.

As may be found in Fig. 1, the two hydroxyl groups of TA are arranged at a separation of around 2.5 Å and function as donors of the hydrogen bondings. Thus, it is predicted that not only MAA but also the compounds having two hydrogen bond acceptors arranged at a distance of around 2.5 Å, should be hydrogenated over TA–NaBr–MRNi in high optical yields. The good predictability of our stereochemical model is proved by the results summarized in Table 2. That is, all compounds satisfying the structural requirement shown in Fig. 1 were hydrogenated in high optical yields.

α-Keto ester (**1a**), which mostly exists in anti conformation, cannot make the interaction with TA through two hydrogen bonds. Even when it takes syn conformation its structure does not easily allow a well-fitting interaction with TA. Thus, the hydrogenation of **1a** was slow and gave an extremely poor optical yield.

In the case of γ-keto ester (**3a**), the distance between two carbonyl groups is a little longer than that between hydroxyl groups in TA. Therefore, a well fitting interaction leading to a high optical yield is not expected. However, the flexible nature enables the substrate to make some two-point interactions with TA. Thus, the hydrogenation of **3a** over (*R*,*R*)-TA–NaBr–MRNi gave (*R*)-**3b** in excess with a moderate optical yield.

A flexible $CH_3OCCH_2CH_2CH_2-$ group in δ-keto
O
ester (**4a**) behaves either as an acceptor of hydrogen bonding with its ester carbonyl, or as a simple hydrophobic alkyl chain. The almost negligible optical yield in the reaction of **4a** would be caused by the exsistence of the two opposite modes of adsorptions. One is the same adsorption mode as in **2a** or **3a** and gives the product of *si*-face attack. The other mode is caused by the repulsion of hydrophobic chain with the hydroxyl group of TA, as will be discussed shortly.

In the case of simple ketone (**5a**), the adsorption mode is determined only by the hydrophobic alkyl group. The proximity of the hydroxyl groups of TA on the catalyst is expected to form a highly hydrophilic region. When the carbonyl group of **5a** interacts with one of the hydroxy groups of TA (site 1), the other hydroxyl group of TA (site 2) should expel the large hydrophobic hydrocarbon residue of the substrate to the other side. Consequently, the mode of adsorption shown in Fig. 2, leading to the *re*-face attack in giving (*S*)-isomer in excess, is expected to be preferable for **5a**. Since this sort of differentiation originates from the repulsive force and the only one-point interaction between substrate and modifying reagent, the reaction rate and optical yield are expected to be less than those of β-keto ester. Thus, the stereochemistry and the slow rate of hydrogenation of **5a** were explained by the partial modification of the above-mentioned stereochemical model.

The data listed in Table 2 show that the substrate being hydrogenated at the higher rate gives always the higher optical yield. The result clearly shows that the some attractive force between modifying reagent and substrate leading to the rigorous stereocontrol also functions to increase the concentration of the substrate at the reaction site. That is, the enhancements of both optical yield and rate in the hydrogenation of β-keto esters over TA–MRNi must originate from the hydrogen bondings between the modifying reagent and the substrate on the catalyst surface.

Experimental

The ^{1}H-NMR and IR spectra were taken with a JEOL-FX-100 spectrometer and a Shimadzu IR 27G spectrometer, respectively.

The optical rotation was measured with a Perkin Elmer 241 polarimeter. The GLC was carried out with a Shimadzu 6A-PF Gas Chromatography, using 3 m—5 mm o.d. glass column packed with 2% Silicone OV-17 on Chromosorb W. (OV-17), 5% Tween 80 on Shimalite W (TW 80), or 5% neopentyl glycol succinate on Chromosorb W (NPGS), at the stated temperature.

All chemicals except those described below were obtained from commercial sources and were used without further purification.

Modifying Reagent. All modifying reagents employed in this study were synthesized by the reported methods. The physical and analytical data are listed in Table 3.

Substrate. Methyl pyruvate (**1a**):[3] bp 61—63 °C/13 mmHg (1 mmHg≈133.322 Pa), methyl 4-oxopentanoate (**3a**):[3] bp 76—78 °C/12 mmHg, methyl 5-oxohexanoate (**4a**):[3] bp 95—97 °C/15 mmHg, isopropyl acetoacetate (**7a**):[15] bp 82—84 °C/13 mmHg, isobutyl acetoacetate (**8a**):[15] bp 88—90 °C/19 mmHg, hexyl acetoacetate (**9a**):[15] bp 133—134 °C/24 mmHg, methyl 3-oxopentanoate (**10a**):[16] bp 68—71 °C/13 mmHg, methyl 4-methyl-3-oxopentanoate (**11a**):[16] bp 85—87 °C/22 mmHg, methyl 3-oxotetradecanoate (**12a**):[17] mp 30 °C, methyl 2-oxobutylsulfone (**14a**):[18] mp 44.0—44.5 °C, methyl 2-oxoheptylsulfone (**15a**):[18] mp 37—38 °C, 4-hydroxy-2-butanone (**16a**):[7] bp 56—58 °C, and 4-methoxy-2-butanone (**17a**):[19] bp 48—49 °C/20 mmHg were prepared by the reported methods.

MRNi. The modifying solution was prepared by dissolving 0.67 mol equivalent of modifying reagent and 10 g of NaBr in 100 ml of deionized water.

The solution was adjusted to pH 3.2 with 1 mol dm^{-3} NaOH. The Raney nickel prepared from 1.9 g of alloy (Kawaken Fine Chemical Co. Ni/Al=42/58) was subjected to modification at 100 °C by the method reported before.[1]

Hydrogenation. The hydrogenation was carried out in a 100 ml autoclave under 90—120 kg/cm^2 of initial hydrogen pressure at the conditions specified in Table 1 or 2 in the text.

Data listed in Entries 12, 13, 14, 15, and 16 in Table 2 are taken from our published papers. The details of isolation and determination of optical purity of each reaction product are described in the paper cited in Table 2.

The hydrogenation products of **1a**, **2a**, **5a** to **11a**, and **17a** in Table 2 were purified by fractional distillation. The hydrogenation products of **3a** and **4a**, mixture of ester of hydroxy acid and lactone, were converted to the corresponding lactone by refluxing in benzene with Amberlyst 15 for 3 h.[3] The resulting lactone was purified by fractional distillation.

The isolated hydrogenation products are listed in Table 4.

The optical purity of the reaction products was determined by three different methods, referred to as A, B, and C in Table 4.

(A) The optical purity was directly determined by polarimetry based on the published value of $[\alpha]_D^{20}$ for optically pure material.

(B) The optical purity of the hydrogenation product was evaluated from the optical purity of MHB derived from the hydrogenation product via saponification and the following esterification with CH_2N_2.

(C) The optical purity was determined by ^{1}H-NMR in the presence of Eu(hfmc)$_3$. In the case of **10b**, and **11b**, the difference of chemical shift for methyl proton of $-\overset{\overset{O}{\|}}{C}-O-CH_3$ (singlet) of (*S*) and (*R*)-isomers was 5.5 Hz when the spectra were measured with solution of **10b** or **11b** (10 mg) and Eu(hfmc)$_3$ (25 mg) in 400 μl of $CDCl_3$.

In the case of **17b**, the difference for methyl proton of (*R*) and (*S*)-isomer was 8 Hz in the spectra taken with a solution of **17b** (10 mg) and Eu(hfmc)$_3$ (5 mg) in 400 μl of $CDCl_3$.

The results are listed in Table 2.

The authors wish to express their thanks to Professor Yoshiharu Izumi and Dr. Hiroshi Ozaki, Institute for Protein Research, Osaka University, for helpful suggestions.

Aryl Rearrangement on the Photolysis of 2-Aryl-2-ethoxy-2-phenylethyl Cobaloxime

Masaru TADA,* Kunimi INOUE, and Masami OKABE

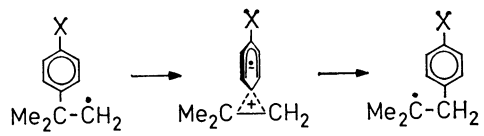
Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160

(Received June 7, 1982)

The photolysis of 2-aryl-2-ethoxy-2-phenylethyl cobaloxime followed by hydrolysis gave two kinds of substituted 1,2-diphenylethanones arising *via* phenyl or substituted-phenyl migration. The substituent effect on the aryl rearrangement is similar to that on the reported neophyl rearrangement, and the rearrangement takes place by a radical mechanism without the deep involvement of cobaloxime(II).

Organo-bis(dimethylglyoximato)(pyridine)cobalt(III), hereafter organo-cobaloxime(III) or R–(Co), has been often used as a model compound of coenzyme B_{12}, organo-cobalamin(III).[1] The photolysis of the Co–C bond of an organo-cobaloxime(III) gives organic radical and cobaloxime(II), (Co^{II}), pair[2] which reasonably mimics the substrate radical and cobalamin(II) in an enzymatic system.[3] In studies on the photolyses of β-acylalkyl cobaloximes, we have demonstrated that the migration of the β-acyl group takes place in a radical state.[1b] However, we have not ruled out the possibility that the rearrangement takes place under the influence of the paramagnetic cobaloxime(II). Some interactions between cobaloxime(II) and the organic radical can be envisaged; one is a charge transfer, and another is a orbital interaction.

It has been established that the neophyl rearrangement has a slightly polar character as depicted in Eq. 1 in an exaggerated manner.[4] These situations

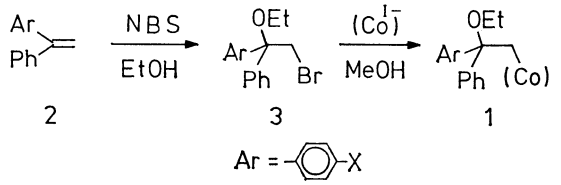


(1)

prompted us to investigate the substituent effect in the aryl rearrangement on the photolysis of 2-aryl-2-ethoxy-2-phenylethyl cobaloxime(III) (**1**). The same substituent effect as the reported neophyl rearrangement should be observed if the rearrangement is not influenced by cobaloxime(II).

Results

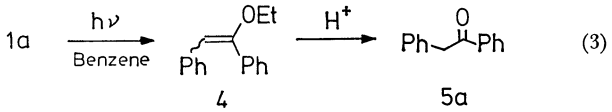
Preparation of 2-Aryl-2-ethoxy-2-phenylethyl Cobaloxime (1). The route of synthesizing the organo-cobaloxime is shown in Eq. 2. 1-Aryl-1-phenylethene



(2)

(**2**) was obtained by the reaction of (*p*-substituted phenyl)magnesium bromide with acetophenone or the reaction of phenylmagnesium bromide with *p*-substituted acetophenone followed by dehydration. The olefin **2** was then treated with *N*-bromosuccinimide in ethanol to give 2-aryl-2-ethoxy-2-phenylethyl bromide (**3**). The organo-cobaloxime **1** was prepared by the reaction of the bromide **3** with cobaloxime(I) anion.[5] The structure of the organo-cobaloxime **1** was ascertained by elemental analysis and spectral data (see the Experimental part).

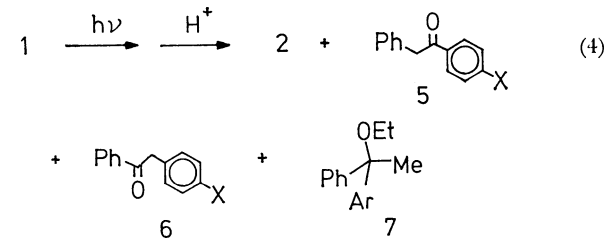
Photolysis of Organo-cobaloxime 1 in Benzene. Anaerobic photolysis followed by acid treatment of 2,2-diphenyl-2-ethoxyethyl cobaloxime (**1a**) gave 1,2-diphenylethanone (**5a**), which formed by the hydrolysis of the primary products, *cis*- and *trans*-enol ethers **4**[6] (Eq. 3). The photolyses of the organo-cobaloximes



(3)

1b—e followed by hydrolyses gave two kinds of substituted 1,2-diphenylethanones arising *via* phenyl group migration (**5b—d**) or *via* substituted phenyl group migration (**6b—e**) (Table 1). The residual organo-cobaloximes decomposed into olefins **2** on chromatography of the products on Florisil in the workup step. This property is common to 2-alkoxy-2,2-diarylethyl cobaloximes.[7] The material balance before and after the reaction is well maintained in all photolyses.

When the *p*-substituent X was an electron-withdrawing group, the substituted phenyl group migrated in preference to the phenyl group. When the substituent was cyano group (X=CN), no migration of phenyl group was observed. When the substituent was an electron-releasing group (X=Me), the phenyl group migrated preferentially.



(4)

Photolysis of Organo-cobaloxime 1 in Chloroform or Acetonitrile. The anaerobic photolysis of **1** in chloroform gave the ketones **5** and **6** together with 1-aryl-1-ethoxy-1-phenylethane (**7**) (Table 2).[8] The latter product is expected to be generated by the hydrogen abstraction of the radical intermediate from chloroform. The photolysis in chloroform is faster than in benzene and no starting material was left under similar

Table 1. Photolysis of organo-cobaloxime 1 in benzene

Substrate	Substituent X	Product composition (%) 5	6	Ratio 6/5	k_{rel}[a]	Total yield/% 5+6
1a	H	50[b]	50[b]	1.00	1.00	62
1b	Me	60	40	0.67	0.72	73
1c	Cl	24	76	3.17	1.76	78
1d	Br	21	79	3.76	1.91	93
1e	CN	0	100	—	35.0	75

a) Relative rate of the migration of *p*-substituted phenyl group to that of the phenyl group; the values were determined by the thermal decomposition of the ester of 3-aryl-3-methylperoxybutanoic acid (C. Rüchardt and R. Hecht).[4] b) In the case of **1a** the product was divided equally been **5** and **6**.

Table 2. Photolysis of organo-cobaloxime 1 in chloroform or acetonitrile

Substrate	Substituent X	Solvent	Product composition (%) 5	6	7	Product ratio 6/5	7/5	Total yield/% 5+6+7
1a	H	$CHCl_3$	27[a]	27[a]	46	1.00	1.69	82
1b	Me	$CHCl_3$	28	16	56	0.57	2.00	70
1c	Cl	$CHCl_3$	17	50	33	2.94	1.92	82
1e	CN	$CHCl_3$	0	100	0	—	—	72

1c	Cl	MeCN	21	79	0	3.76	0	80
1e	CN	MeCN	0	100	0	—	—	73

a) In the case of **1a** the migrated product was divided equally between **5** and **6**.

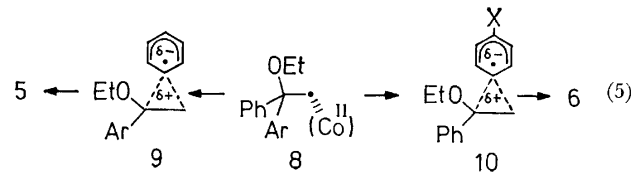
conditions to the photolysis in benzene. The photolyses of the cobaloxime in chloroform or chloroform itself is expected to produce hydrogen chloride in trace amount, and the acid hydrolysis of the enol ethers seem to take place under the photolysing conditions.

The ratios of **6/5** in chloroform are similar to those in benzene. The ratio of hydrogen abstraction to phenyl rearrangement (**7/5**) does not vary much with the substituent X on the non-rearranged aryl group.

The photolysis of organo-cobaloxime **1** in acetonitrile, a polar solvent, gave similar results as in benzene except for the formation of **7b** in trace amount from **1b** (Table 2).

Discussion

In the present study we found that the order of the aryl groups in migration-ability is similar to the order in the neophyl rearrangement by a radical mechanism.[4] This finding indicates that the aryl migration on the photolysis of organo-cobaloxime **1** involves a radical mechanism. The substituent effect observed in the present study and the reported neophyl rearrangement is interpreted in terms of the slightly polar transition state (**9** or **10**). The polarization can be ascribed to the electron-releasing character of the



cyclopropane ring.[9] When the substituent X is an electron-withdrawing group, the transition state **10** is more stabilized and the migration of the *p*-substituted phenyl group becomes more favorable (Eq. 5).

The ratio of **6/5** is not much affected by the polarity of the solvent; this indicates that the charge transfer or electron transfer between (Co^{II}) and the radical species is not an important factor in driving the rearrangement. Furthermore the charge separation in the transition states (**9** and **10**) is not so extensive that the stabilization of the transition states does not depend strongly on the polarity of the solvent. From the limitation of the present study we can not discuss the absolute formation rate of **5** and **6**, and the discussion must be limited to the relative rate of phenyl or aryl migration. The present findings are explained by the assumption that both transition states **9** and **10** are stabilized to a similar extent by a polar solvent. The solvent dependence of the formation of **7** can be understood as a consequence of the hydrogen donating ability of the solvent.[10] It can be assumed that the rates of hydrogen abstraction and phenyl migration are independent of the substituent X on the non-rearranged aryl group. Therefore the variation in the formation of **5** and **7** depending on X in chloroform can be explained in terms of the difference in the rate of the migration of the substituted phenyl group.

The organo-cobaloxime **1e** (X=CN) did not give the hydrogen-abstracted product **7** even in chloroform, a strong hydrogen donor. On the other hand, the decomposition of the ester of 3-(*p*-cyanophenyl)-3-methylperoxybutanoic acid gives a small amount of the hydrogen-abstracted product even in tetralin,[4] which is a weaker hydrogen donor than chloroform.[10] It

is considered that cobaloxime(II) in the radical pair **8** may promote the rearrangement by weak orbital interaction.

In conclusion the photolysis of organo-cobaloxime **1** causes the homolytic cleavage of Co–C bond, and the resulting radical pair does not cause the charge transfer or electron transfer between cobaloxime(II) and the organic radical. The intervention of ionic species in the rearrangement is thus ruled out, though the weak orbital interaction in the radical pair may promote the rearrangement. The explanation of the insensitivity of the formation ratio **6**/**5** to solvent polarity must await more ellaborate studies.

Experimental

Preparation of 1-Aryl-1-phenylethene (2). The preparations of 1,1-diphenylethene (**2a**),[11] 1-(*p*-methylphenyl)-1-phenylethene (**2b**),[12] 1-(*p*-chlorophenyl)-1-phenylethene (**2c**),[13] and 1-(*p*-bromophenyl)-1-phenylethene (**2d**),[14] are described in the literature. 1-(*p*-Cyanophenyl)-1-phenylethene (**2e**) is prepared as described below.

To a solution of *p*-cyanoacetophenone (7.25 g, 50 mmol) in dry ether (100 cm^3) a solution of phenylmagnesium bromide (50 mmol) in dry ether (20 cm^3) was added dropwise at 0 °C. After stirring for 30 min at room temperature, saturated ammonium chloride solution (10 cm^3) was added dropwise at 0 °C. The ethereal solution was decanted and evaporated to give crude 1-(*p*-cyanophenyl)-1-phenylethanol. A mixture of the crude material and powdered potassium hydrogensulfate (8 g) in toluene (50 cm^3) was refluxed for 10 h. After the addition of water (50 cm^3), the mixture was extracted with ether (2×50 cm^3). The combined ethereal extracts were dried over anhydrous sodium sulfate. Distillation gave 5.06 g (49%) of pure **2e**, bp 116 °C/93 Pa. Found: C, 87.52; H, 5.58; N, 6.49%. Calcd for $C_{15}H_{11}N$: C, 87.77; H, 5.40; N, 6.82%. IR (CCl_4) 2225, 901, and 698 cm^{-1}; NMR (CCl_4) δ=5.51 (d, 1H, J=1 Hz), 5.57 (d, 1H, J=1 Hz), 7.22—7.45 (m, 5H), 7.47 (d, 2H, J=8 Hz), and 7.63 (d, 2H, J=8 Hz).

Preparation of 2-Aryl-2-ethoxy-2-phenylethyl Bromide (3). 2,2-Diphenyl-2-ethoxyethyl bromide (**3a**) was prepared from **2a** by the reported method.[15] The general procedure for the preparations of 2-ethoxy-2-(*p*-methylphenyl)-2-phenylethyl bromide (**3b**), 2-(*p*-chlorophenyl)-2-ethoxy-2-phenylethyl bromide (**3c**), 2-(*p*-bromophenyl)-2-ethoxy-2-phenylethyl bromide (**3d**), and 2-(*p*-cyanophenyl)-2-ethoxy-2-phenylethyl bromide (**3e**) is described below.

To a suspension of *N*-bromosuccinimide (2 g, 11.2 mmol) in dry ethanol (20 cm^3) a solution of **2** (10 mmol) in dry ethanol (10 cm^3) was added dropwise at −10 °C. After stirring for 2 h at −10 °C and for 4 h at room temperature, the resulting succinimide was filtered off and the filtrate was evaporated. The residue was placed on a silica gel column and eluted with benzene to give the bromide **3** (53—77%). **3b**—**e** were converted directly to the organo-cobaloximes **1b**—**e** without further purification.

3b, oil; NMR (CCl_4) δ=1.18 (t, 3H, J=7 Hz), 2.25 (s, 3H), 3.23 (q, 2H, J=7 Hz), 4.13 (s, 2H), and 6.95—7.48 (m, 9H).

3c, oil; NMR (CCl_4) δ=1.23 (t, 3H, J=7 Hz), 3.23 (q, 1H, J=7 Hz), 3.27 (q, 1H, J=7 Hz), 4.05 (d, 1H, J=12 Hz), 4.13 (d, 1H, J=12 Hz), and 7.08—7.43 (m, 9H).

3d, oil; NMR (CCl_4) δ=1.20 (t, 3H, J=7 Hz), 3.18 (q, 1H, J=7 Hz), 3.23 (q, 1H, J=7 Hz), 4.07 (d, 1H, J=12 Hz), 4.13 (d, 1H, J=12 Hz), and 7.06—7.58 (m, 9H).

3e, mp 97—99 °C; IR (CCl_4) 2225 and 697 cm^{-1}; NMR (CCl_4) δ=1.20 (t, 3H, J=7 Hz), 3.18 (q, 1H, J=7 Hz), 3.31 (q, 1H, J=7 Hz), 4.12 (d, 1H, J=10 Hz), 4.23 (d, 1H, J=10 Hz), 7.12—7.40 (m, 5H), and 7.45 (bs, 4H).

Preparation of 2-Aryl-2-ethoxy-2-phenylethyl Cobaloxime (1). The organo-cobaloxime **1** was prepared from the bromide **3** (5 mmol) and cobaloxime(I) (6 mmol) in methanol (15 cm^3) in the conventional manner.[7] Chromatography on aluminum oxide containing 10% (w/w) of water using benzene–chloroform as an eluent and recrystallization from acetonitrile yielded pure **1** (44—65%).

The strong infrared absorption bands due to the cobaloxime(III) moiety are common to all **1**: 1560, 1450, 1240—1200, and 1100—960 cm^{-1}.

1a, mp 142 °C (decomp). Found: C, 58.29; H, 5.96; N, 11.99%. Calcd for $C_{29}H_{36}N_5O_5Co$: C, 58.68; H, 6.11; N, 11.80%. NMR ($CDCl_3$) δ=1.22 (t, 3H, J=7 Hz), 1.83 (s, 12H), 2.56 (s, 2H), 3.00 (q, 2H, J=7 Hz), 6.85—7.30 (m, 12H), 7.45—7.63 (m, 1H), and 8.35—8.47 (m, 2H).

NMR ($CDCl_3$) δ=1.24 (t, 3H, J=7 Hz), 1.85 (s, 12H), 2.35 (d, 1H, J=10 Hz), 2.64 (d, 1H, J=10 Hz), 2.97 (q, 1H, J=7 Hz), 3.03 (q, 1H, J=7 Hz), 6.94—7.38 (m, 11H), 7.51—7.71 (m, 1H), and 8.46—8.56 (m, 2H).

1e, mp 154 °C (decomp). Found: C, 58.03; H, 5.78; N, 13.80%. Calcd for $C_{30}H_{35}N_6O_5Co$: C, 58.25; H, 5.70; N, 13.59%. NMR ($CDCl_3$) δ=1.22 (t, 3H, J=7 Hz), 1.87 (s, 6H), 1.91 (s, 6H), 2.43 (d, 1H, J=10 Hz), 2.63 (d, 1H, J=10 Hz), 3.03 (q, 1H, J=7 Hz), 3.10 (q, 1H, J=7 Hz), 6.98—7.87 (m, 12H), and 8.43—8.62 (m, 2H). IR ($CHCl_3$) 2230 cm^{-1}.

Photolysis of Organo-cobaloxime 1. A Typical Procedure for 1a in Benzene: A solution of the organo-cobaloxime **1a** (1.25×10^{-3} mol dm^{-3}) in benzene (15 cm^3) was placed in a Pyrex tube, dipped in an ultrasonic bath, and bubbled with argon from a syringe needle for 30 min. The solution was irradiated externally for 12 h with a 450-W high-pressure Hg lamp mounted in a rotary irradiation apparatus (Rikosha RH-400), the distance between the lamp and the reaction tube being *ca.* 5 cm. The reaction solution was evaporated *in vacuo* and the residue was chromatographed on Florisil, using chloroform as an eluent, to give the mixture of *cis*- and *trans*-enol ethers **4**[16] containing a small amount of **2a**. A solution of the enol ethers **4** in ether/ methanol/ aqueous hydrogen chloride (6 mol dm^{-3}) (5:3:1) was stirred overnight. After the addition of saturated aqueous sodium hydrogencarbonate, the mixture was extracted several times with ether. The combined ethereal extracts were washed with water and dried over anhydrous sodium sulfate. Evaporation of the solvent gave 1,2-diphenylethanone (**5a**) and **2a**.

Photolyses of ***1b—e*** *in Benzene*: The photolyses of **1b—e** were carried out by the procedure described above. A similar workup gave the mixture of olefin **2** and enol ethers containing a small amount of hydrolysis products **5** and **6**. Acid treatment of the mixture gave the products **2**, **5**, and **6**, which were identified by comparison with authentic samples synthesized by reported methods.[16-22] The results are summarized in Table 1. The physical data of the products are as follows.

5b,[16] mp 106—108 °C. IR ($CHCl_3$) 1677 cm^{-1}; NMR ($CDCl_3$) δ=2.38 (s, 3H), 4.23 (s, 2H), 7.03—7.43 (m, 7H), and 7.91 (d, 2H, J=8 Hz).

6b,[17] mp 92—94 °C. IR ($CHCl_3$) 1675 cm^{-1}; NMR ($CDCl_3$) δ=2.28 (s, 3H), 4.22 (s, 2H), 7.14 (s, 4H), 7.37—7.60 (m, 3H), and 7.87—8.17 (m, 2H).

5c,[18] mp 106—108 °C. IR ($CHCl_3$) 1680 cm^{-1}; NMR ($CDCl_3$) δ=4.22 (s, 2H), 7.22 (bs, 5H), 7.34 (d, 2H, J=8 Hz), and 7.90 (d, 2H, J=8 Hz).

6c,[19] mp 132—133 °C. IR ($CHCl_3$) 1681 cm^{-1}; NMR ($CDCl_3$) δ=4.22 (s, 2H), 7.03—7.62 (m, 7H), and 7.82—8.07 (m, 2H).

5d,[20] mp 110—111 °C. IR ($CHCl_3$) 1680 cm^{-1}; NMR ($CDCl_3$) δ=4.18 (s, 2H), 7.20 (bs, 5H), 7.48 (d, 2H, J=9 Hz), and 7.76 (d, 2H, J=9 Hz).

6d,[21] mp 145—147 °C. IR ($CHCl_3$) 1681 cm^{-1}; NMR ($CDCl_3$) δ=4.20 (s, 2H), 7.08 (d, 2H, J=9 Hz), 7.30—7.64 (m, 5H), and 7.88—8.01 (m, 2H).

6e,[22] mp 112—114 °C. IR ($CHCl_3$) 2240 and 1686 cm^{-1}; NMR ($CDCl_3$) δ=4.33 (s, 2H), 7.20—7.69 (m, 7H), and 7.84—8.12 (m, 2H).

Photolysis of ***1a*** *in Chloroform*: The same procedure for the photolysis in benzene was employed but the acid treatment was not required. The products thus obtained are **5a** and 1,1-diphenyl-1-ethoxyethane (**7a**) (see Table 2).

7a, oil. IR (CCl_4) 702 cm^{-1}; NMR (CCl_4) δ=1.27 (t, 3H, J=7 Hz), 1.78 (s, 3H), 3.20 (q, 2H, J=7 Hz), and 6.90—7.38 (m, 10H). The structure of **7a** was determined by an unequivocal synthesis from 1,1-diphenylethanol,[11] diethyl sulfate, and sodium hydride in THF.

Photolyses of ***1b***, ***1c***, *and* ***1e*** *in Chloroform*: The photolyses of **1b**, **1c**, and **1e** were carried out by using the same procedure as for the photolysis of **1a** in chloroform, and the results are summarized in Table 2.

7b, oil. IR (CCl_4) 701 cm^{-1}; NMR (CCl_4) δ=1.15 (t, 3H, J=7 Hz), 1.74 (s, 3H), 2.23 (s, 3H), 3.18 (q, 2H, J=7 Hz), and 6.79—7.28 (m, 9H). The structure of **7b** was determined by an unequivocal synthesis from 1-(*p*-methylphenyl)-1-phenylethanol,[12] diethyl sulfate, and sodium hydride in THF.

7c, oil. IR (CCl_4) 701 cm^{-1}; NMR (CCl_4) δ=1.16 (t, 3H, J=7 Hz), 1.74 (s, 3H), 3.18 (q, 2H, J=7 Hz), and 6.97—7.29 (m, 9H). The structure of **7c** was determined by an unequivocal synthesis from 1-(*p*-chlorophenyl)-1-phenylethanol,[13] diethyl sulfate, and sodium hydride in THF.

Photolyses of ***1b***, ***1c***, *and* ***1e*** *in Acetonitrile*: The same procedure described for the photolysis of **1a** in benzene was employed and the results are summarized in Table 2.

A Convenient Method for the Synthesis of Adenylyl-(2′—5′)-adenylyl-(2′—5′)-adenosine Using 3′-*O*-Benzoyladenosine Derivatives

Hiroshi TAKAKU* and Souichi UEDA

Laboratory of Organic Chemistry, Chiba Institute of Technology, Tsudanuma, Narashino, Chiba 275

(Received July 5, 1982)

N^6,3′-*O*-Dibenzoyladenosine was prepared by treating 2′,3′-*O*-(dibutylstannylene)-N^6-benzoyladenosine with benzoyl chloride in methanol. The trimeric adenylyl-(2′—5′)-adenylyl-(2′—5′)-adenosine was synthesized in a good yield using N^6,3′-*O*-dibenzoyladenosine as the starting material *via* the phosphotriester approach.

It has recently been reported[1] that 5′-*O*-triphosphoryl-adenylyl-(2′—5′)-adenylyl-(2′—5′)-adenosine (pppA$^{2'}$p$^{5'}$A$^{2'}$p$^{5'}$A) is isolated from interferon-treated cells and is acting as an inhibitor of cell-free protein synthesis. The pppA$^{2'}$p$^{5'}$A$^{2'}$p$^{5'}$A is synthesized from rabbit reticulocytes with double-stranded RNA and ATP. The core A$^{2'}$p$^{5'}$A$^{2'}$p$^{5'}$A has also been found to be an inhibitor of Concanavalin A-stimulated DNA synthesis.[2] Consequently, several groups have recently described the chemical synthesis of various structurally modified 2′—5′ linked triadenylates.[3]

In this paper, we report a convenient method for the synthesis of adenylyl-(2′—5′)-adenylyl-(2′—5′)-adenosine (2—5 core) by using N^6,3′-*O*-dibenzoyladenosine as the starting material.

Preparation of N^6,3′-O-*Dibenzoyladenosine.* Moffatt and his co-workers have recently reported[4] that when 2′,3′-*O*-stannylene nucleosides were treated with benzoyl chloride and triethylamine in dry methanol, 3′-*O*-benzoylnucleoside derivatives were obtained in good yields. This method may serve for the preparation of 3′-*O*-protected adenosine derivative as a key intermediate for the synthesis of 2′—5′ adenylate trimers.

We examined the preparation of N^6,3′-*O*-dibenzoyladenosione **3** by a modification of the procedure of Moffatt and his co-workers[4]. 2′,3′-*O*-(Dibutylstannylene)-N^6-benzoyladenosine (**2**) was easily obtained as a crystalline product in 56% yield by the reaction of N^6-benzoyladenosine (**1**) with dibutyltin oxide in dry methanol, and by subsequent crystallization of the product from ethanol–acetone. In this reaction, a very small ammount of debenzoylated product can be detected on TLC. However, the by-product could be separated from **2** since it was removed by crystallization from ethanol–acetone.

Nucleoside derivative **2** thus obtained (1.0 molar equiv.) was treated with benzoyl chloride (5.0 molar equiv.) in the presence of triethylamine (5.0 molar equiv.) in dry methanol at room temperature. After 15 min, the reaction mixture was worked up and purified to give N^6,3′-*O*-dibenzoyladenosine (**3**) in 48% yield. Product **3** was characterized by elemental analysis and NMR spectroscopy. ^{1}H-NMR spectra of **3** showed the characteristic downfield of the H-1′ and H-3′ signals, and the presence of signals due to the $C_{2'}$–OH and $C_{5'}$–OH groups. For H-1′ of **3**, the data were consistent with the rules developed by Reese and his co-workers;[5] namely 3′-substituted compounds had larger $J_{1',2'}$ coupling constants, and their H-1′ signal showed high field shifts compared to that of the 2′-isomar.

The reaction of **3** with dimethoxytrityl chloride in dry pyridine gave corresponding 5′-*O*-dimethoxytrityl-N^6-dibenzoyladenosine (**4**) in 86% yield.

When **3** was treated with methanolic ammonia for 16 h at 25 °C, the corresponding adenosine was obtained in 97% yield.

Synthesis of Adenylyl-(2′—5′)-adenylyl-(2′—5′)-adenosine (Core). The synthesis of 2′—5′ linked triadenylates (2—5 core) **8** by using **4** is as follows: The nucleoside derivative **4** was phosphorylated with 5-chloro-8-quinolyl phosphate[6] in the presence of 8-quinolylsulfonyl chloride (QS)[7] in dry pyridine for 2 h to give correspondong phosphodiester **5** in almost quantitative yield. The ^{31}P NMR spectrum of **5** (pyridine) consists of one resonance signal at δ +4.68.

Phosphodiester intermediate **5** thus obtained (1.5 molar equiv.) was now allowed to react together with N^6, 2′,3′-*O*-tribenzoyladenosine (1.0 molar equiv.) and 1-(8-quinolylsulfonyl)-1*H*-tetrazole (QS-te)[8] After 1 h, no starting material, N^6,2′,3′-*O*-tribenzoyladenosine

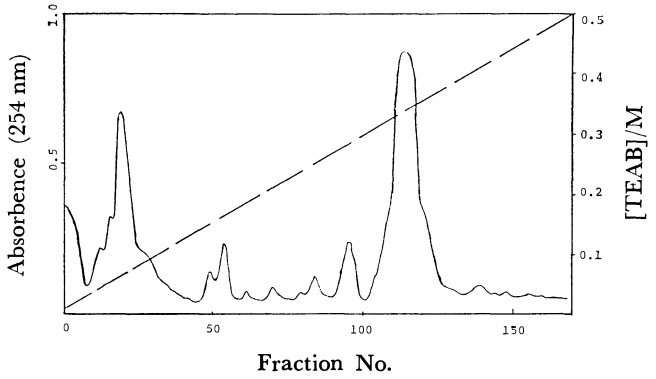

Fig. 1. Chromatography of the trinucleotide on a column (1.0×55 cm) of DEAE cellulose DE-52 equilibrated with 0.01 M TEAB. Elution was performed with a linear gradient of TEAB (0.01—0.5 M, total 550 ml). Fractions of 3 ml were collected every 10 min. The main peak contained the product $A^{2'}p^{5'}A^{2'}p^{5'}A$.

can be detected on TLC in the reaction mixture. Work-up and purification by short silica-gel column chromatography afforded the required dinucleotide **6** in 92% yield. Fully protected dinucleotide **6** was treated with 2% *p*-toluenesulfonic acid solution in a mixture of dichloromethan and methanol (7:3 v/v) for 15 min at 0 °C.[6] The reaction mixture was neutralized with phosphate buffer (pH 8) solution and the mixture was worked up and precipitated with hexane and ether (95:5 v/v) to give partially protected dinucleotide **7** in 92% yield. Compound **7** was used for the next coupling reaction without further purification. Phosphodiester intermediate **5** (1.5 molar equiv.) was condensed with **7** (1.0 molar equiv.) in the presence of QS-te (4.5 molar equiv.) in dry pyridine. After 1 h, the reaction was nearly completed as judged by TLC, and the reaction mixture was worked up and chromatograph to give the fully protected trinucleotide ($A^{2'}p^{5'}A^{2}p^{5'}A$) (core) **8** in 93% yield.

In the above reaction, 1-(8-quinolylsulfonyl)-1*H*-tetrazole (QS-te) can be effectively used as the coupling agent for the synthesis of internucleotidic bonds.

The protecting groups of **8** was removed in the following order to obtain **9**. Treatment of **9** with zinc chloride (25 parts) in aqueous pyridine for 24 h at room temperature removed completely 5-chloro-8-quinolyl protective groups. The resulting compound which contains soley phosphodiester bonds was then treated with concentrated aqueous ammonia for 5 h at 50 °C to cleave the benzoyl groups. Finally, the treatment with 80% acetic acid solution for 5 min removed the dimethoxytrityl group. $A^{2'}p^{5'}A^{2'}p^{5'}A$ (core) **9** thus obtained was then purified through a DEAE cellulose DE-52 column with a linear gradient of 0.01—0.5 M† triethylammonium hydrogencarbonate (TEAB, pH 7.5) (Fig. 1), and the yield was *ca.* 73%.

The purity of **9** was checked by TLC, paper chromatography, and paper electrophoresis. The presence of only 2′—5′ internucleotidic bonds in the completely deblocked product thus obtained was established by complete digestion of **9** with snake venom phosphodiesterase to the expected products in the correct ratio, and it was insensitive to nuclease P1 which cleaves only 3′—5′ linkage.

Experimental

UV absorption spectra were measured with a Shimadzu Model UV-200 spectrophotometer. Proton nuclear magnetic resonance spectra at 100 MHz were taken with JEOL JNMPS 100 spectrometer; the shifts are given in ppm (δ) relative to tetramethylsilane as an internal standard. Merck silica gel $60F_{254}$ plates were usually developed in solvents A [CH_2Cl_2–MeOH (9:1 v/v)], and B [C_6H_6–$(CH_3)_2CO$ (1:1 v/v)]. DC-Alufolien cellulose F sheets were used for TLC. Paper chromatography was performed by using the descending technique on Toyo Roshi No. 51A. The solvent systems employed were the following: solvent C [2-propanol–concentrated aqueous ammonia–water (7:1:2 v/v)], solvent D [1-propanol–concentrated aqueous ammonia–water (55:35:10 v/v)], and solvent E [1-butanol–acetic acid–water (5:2:3 v/v)]. Paper electrophoresis was carried out on Toyo Roshi No. 51A paper in 0.05 M triethylammonium hydrogencarbonate (pH 7.5) at 1100 V/40 cm. Kanto Chemical silica gel was used for short column chromatography. Anion exchange chromatography on DEAE cellulose DE-52 was carried out with a linear gradient of triethylammonium hydrogencarbonate (pH 7.5). Compounds containing the dimethoxytrityl group were detected on TLC by spraying the samples with 10% sulfonic acid solution and drying them in a stream of warm air.

8-Quinolylsulfonyl chloride and tetrazole were purchased from the Dojin Chemical Co.

Enzymatic hydrolyses were done as described previously.[8,9]

2′,3′-O-(Dibutylstannylene)-N⁶-benzoyladenosine (2). A suspension of N^6-benzoyladenosine[10] **1** (4.58 g, 12.3 mmol) and dibutyltin oxide (3.07 g, 12.3 mmol) in dry methanol (300 ml) was heated under reflux. After 30 min the solution was evaporated to dryness and the residue was crystallized from ethanol–acetone (1:1 v/v), giving 4.15 g (56%) of **2**: Mp 167—169 °C; UV (MeOH) λ_{max} 278 nm, λ_{min} 247 nm; R_f 0.1 (solvent A); Calcd for $C_{25}H_{21}N_5O_5$: C, 51.94; H, 6.97; N, 12.11%. Found: C, 51.81; H, 7.06; N, 12.17%.

N⁶,3′-O-Dibenzoyladenosine (3). Nucleoside derivative **2** (7.50 g, 12.45 mmol) was co-evaporated with dry methanol (2×15 ml) and dissolved in dry methanol (156 ml). To the solution was added benzoyl chloride (7.7 ml, 62.30 mmol) and triethylamine (8.7 ml, 62.30 mmol). After being kept at room temperature for 15 min, the solution was concentrated and the residue was triturated with ether (3×

† 1 M=1 mol dm^{-3}.

150 ml) and water (3×150 ml), and then dried *in vacuo*. The residue was recrystallized from ethanol to give 2.89 g (48%) of **3**: Mp 195—198 °C; R_f 0.50 (solvent A); UV (MeOH) λ_{max} 278, 228 nm, λ_{min} 248 nm; NMR (DMSO-d_6) δ=3.91 (brs, 2H, H-5′), 4.50 (brd, 1H, $J_{3',4'}$=2 Hz, H-4′), 5.22 (dd, 1H, $J_{1',2'}$=7.5 Hz, $J_{2',3'}$=5.5 Hz, H-2′), 5.59 (t, 1H, C_5'-OH), 5.73 (d, 1H, H-3′), 6.18 (d, 1H, C_2'-OH), 6.30 (d, 1H, $J_{1',2'}$=7.5 Hz, H-1′), 7.65 and 8.12 (m, total 10H, Ar), 8.91 (s, 2H, C_2-H and C_8-H), (The signals at δ=5.59 and 6.18 disappeared on addition of D_2O); Calcd for $C_{24}H_{21}N_5O_6$: C, 60.63; H, 4.45; N, 14.73%. Found: C, 60.40; H, 4.59; N, 14.81%.

5′-O-Dimethoxytrityl-N⁶-3′-O-dibenzoyladenosine (4). N^6-3′-*O*-Dibenzoyladenosine (**3**) (1.35 g, 2.83 mmol) was co-evaporated with dry pyridine and treated with dimethoxytrityl chloride (1.05 g, 3.10 mmol) in dry pyridine (14 ml) at room temperature. After 3 h, an aliquot was analyzed by TLC to confirm the starting material [R_f 0.50 (solvent A)] tritylated [R_f 0.55 (solvent A)]. The mixture was poured into ice-water (30 ml), extracted with CH_2Cl_2 (3× 30 ml), and the extract was washed with water (3 times). The solution was evaporated after being dried over Na_2SO_4 and the residue was co-evaporated with toluene (3 times). The residue was redissolved in CH_2Cl_2 (10 ml) and the solution was poured into hexane (500 ml). The precipitate was collected and dried in a dessicator over P_2O_5 to give **4** (1.67 g, 76%): UV (MeOH) λ_{max} 278, 231 nm, λ_{min} 256 nm; R_f 0.55 (solvent A); NMR ($CDCl_3$) δ=3.79 (s, 6H, OCH_3), 6.27 (d, 1H, $J_{1',2'}$=6.5 Hz, H-1′), 6.65—8.11 (m, 23H, Ar).

5′-O-Dimethoxytrityl-N⁶-3′-O-dibenzoyladenosine 3′-(5-Chloro-8-quinolyl) Phosphate (5). Nucleoside **4** (2.40 g, 3.09 mmol) and 5-chloro-8-quinolyl phosphate (1.20 g, 4.65 mmol) were co-evaporated with dry pyridine, and then treated with 8-quinolinesulfonyl chloride (QS) (2.13 g, 9.27 mmol) in dry pyridine (30 ml) for 2 h at room temperature. The phosphodiester product was detected by TLC [R_f 0.05 (solvent A)] and the mixture was quenched with ice-water. The product was extracted with CH_2Cl_2 (3×30 ml), and the extract was washed with 0.1 M triethylammonium hydrog ncarbonate (pH 7.5) (3×30 ml), then with water (3× 30 ml), and dried over Na_2SO_4. The CH_2Cl_2 layer was concentrated to 15 ml, and poured into hexane–ether (9:1 v/v) (400 ml). The precipitate was collected and dried in a dessicator over P_2O_5 *in vacuo* to give the triethylammonium salt of **5** (3.17 g, 98%); UV (MeOH) λ_{max} 280, 236 nm, λ_{min} 256 nm; R_f 0.05 (solvent A); ^{31}P NMR (pyridine, 85% H_3PO_4) δ+4.68.

Preparation of Fully Protected Dinucleotide (6). Phosphodiester **6** (1.08 g, 1.03 mmol) and N^6,2′,3′-*O*-tribenzoyladenosine (0.39 g, 0.68 mmol) were co-evaporated with dry pyridine, and then treated with 1-(8-quinolylsulfonyl)-1*H*-tetrazole (QS-te) (0.68 g, 2.60 mmol) in dry pyridine (5 ml) for 1 h at room temperature. The reaction mixture was quenched with ice-water, and then extracted with CH_2Cl_2 (3×15 ml). The combined organic extracts were washed with 0.1 M triethylammonium hydrogencarbonate (pH 7.5) (2×20 ml), then with water (2×20 ml), and was dried over Na_2SO_4 and concentrated. The residue was co-evaporated with toluene (3 times), dissolved in CH_2Cl_2, and the solution was applied on a short column of silica gel. Elution was performed with a stepwise gradient of methanol (0—5%) in CH_2Cl_2, and the product was precipitated with hexane–ether (95:5 v/v) (150 ml). The precipitate was collected and dried in a dessicator over P_2O_5 *in vacuo* to give fully protected dinucleotide **6** (1.02 g, 92%): *R* 0.53 (solvent A), 0.81 (solvent B); UV (MeOH) λ_{max} 278, 230 nm, λ_{min} 255 nm.

Detritylation of Fully Protected Dinucleotide (6). Fully protected dinucleotide **6** (0.79 g, 0.49 mmol) was dissolved in CH_2Cl_2–MeOH (7:3 v/v) (17 ml) containing 2% *p*-toluenesulfonic acid and the solution was kept for 15 min at 0 °C. The detritylated product was detected by TLC [R_f 0.48 (solvent A)] and the reaction mixture was washed with phosphate buffer (pH 8), and then with water (3× 20 ml). The CH_2Cl_2 layer was dried over Na_2SO_4 and evaporated *in vacuo*. The residue was dissolved in CH_2Cl_2 and the solution was poured into hexane–ether (95:5 v/v) (80 ml). The precipitate was collected and dried in a dessicator over P_2O_5 *in vacuo* to give the 5′-hydroxyl dinucleotide **7** (0.59 g, 92%): R_f 0.48 (solvent A), R_f 0.62 (solvent B); UV (MeOH) λ_{max} 278, 232 nm, λ_{min} 255 nm.

Preparation of Fully Protected Trinucleotide (8). Phosphodiester derivative **5** (0.76 g, 0.72 mmol) and 5′-hydroxyl dinucleotide **7** (0.60 g, 0.40 mmol) were co-evaporated with dry pyridine, and then treated with QS-te (0.47 g, 1.80 mmol) in dry pyridine (4 ml) for 1 h at room temperature. After usual work-up as described in the preparation of **6**, the product was applied on a short column of silica gel. Elution was performed with a stepwise gradient of methanol (0—5%) in CH_2Cl_2 and the desired fully protected trinucleotide was precipitated with hexane–ether (95:5 v/v) (50 ml). The precipitate was collected and dried in a dessicator over P_2O_5 *in vacuo* to give fully protected trinucleotide **8** (0.99 g, 93%): R_f 0.50 (solvent A), R_f 0.75 (solvent B); UV (MeOH) λ_{max} 278, 230 nm, λ_{min} 256 nm.

Unblocking of Fully Protected Trinucleotide (8). A solution of fully protected trinucleotide **8** (23 mg, 0.01 mmol) and $ZnCl_2$ (1.02 g, 5.0 mmol) in aqueous pyridine (10%) (20 ml) was stirred at room temperature. After 24 h the reaction mixture was treated with Dowex 50W-X2 (pyridinium form), filtered, and the filtrate was concentrated to gum. The gum was redissolved in concentrated aqueous ammonia (20 ml) at 50 °C. After 5 h the solution was evaporated under reduced pressure. The residue was treated with 80% acetic acid (15 ml) for 15 min. The acetic acid was removed by repeated co-evaporation with 1-butanol. The residue was dissolved in 0.01 M triethylammonium hydrogencarbonate (pH 7.5) (50 ml) and the solution was washed with CH_2Cl_2 (2×20 ml). The solution was applied on a column of DEAE cellulose DE-52 (hydrogencarbonate form). The elution profile and conditions are shown in Fig. 1. The appropriate fractions were combined and lyophilized to give the corresponding trinucleotide **9** (252 OD, 73%). The purity of **9** was checked by TLC, paper chromatography, and paper electrophoresis as well as complete hydrolysis by snake venom phosphodiesterase to adenosine (A_{260}=8.44) and adenosine 5′-phosphate (A_{260}=16.80). Ratio of adenosine and adenosine 5′-phosphate was 1.00: 1.94. On the other hand, when it was incubated with nuclease Pl, $A^{2'}p^{5'}A^{2'}p^{5'}A$, **9** was recovered in 99.2% yield: R_f 0.21 (solvent D), $R_{f_{pA}}$ 0.71 (solvent D); $R_{f_{pA}}$ 0.78 (0.05 M triethylammonium hydrogencarbonate, pH 7.5); UV (H_2O, pH 7.0) λ_{max} 257 nm.

We thank Professor Tsujiaki Hata of Tokyo Institute of Technology for discussion throughout the investigation.

Oxygen Promoted Addition of 1,3-Dioxolane to Electron-deficient Alkenes

Yoshihisa WATANABE,* Yasushi TSUJI, and Ryo TAKEUCHI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received July 27, 1982)

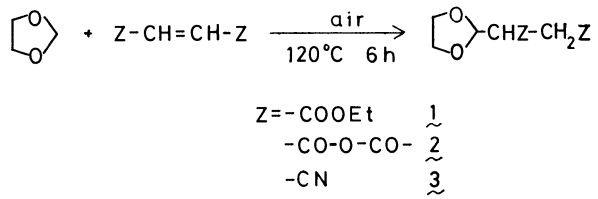
1,3-Dioxolane reacted with electron-deficient alkenes, such as diethyl maleate, maleic anhydride, diethyl fumarate and fumaronitrile, under an oxygen atmosphere or in air to give 1:1 adducts in good to excellent yields. The presence of oxygen promoted the reaction. The reaction appears to be characteristic of 1,3-dioxolane. Methylal and ethylal did not react with diethyl maleate under the same conditions.

Recently, great attention has been paid to C_1 chemistry, in which carbon monoxide and methanol are key materials as starting C_1 compounds.[1] However, only a little attention has been paid to the chemistry of other C_1 compounds, such as formic acid and formaldehyde. We have recently shown that formic acid, a C_1 derivative from carbon monoxide, could be used as a hydrogen source for catalytic reduction of ketones and aldehydes.[2]

On the other hand, 1,3-dioxolane, formaldehyde ethylene acetal, is known to react with several alkenes by UV irradiation, or in the presence of radical initiators.[3] The reactions have been considered to proceed in radical mechanisms. The present work describes the reaction of 1,3-dioxolane with electron-deficient alkenes under an air or an oxygen atmosphere to give 1:1 adducts. The reaction is simple and convenient, since the reaction is carried out without irradiation or radical initiators.

Results and Discussion

1,3-Dioxolane reacted with such electron-deficient alkenes as diethyl maleate, maleic anhydride, diethyl fumarate, and fumaronitrile in air at 120 °C for 6 h to give 1:1 adducts (Scheme 1). The results are listed in Table 1. These alkenes reacted with 1,3-dioxolane only at the 2-position. On the other hand, simple alkenes such as 1-octene reacted at the 4-position as well as at the 2-position of 1,3-dioxolane to give 1:1 adducts in low yields by initiators.[4] In the present study, diethyl maleate reacted with 1,3-dioxolane in air or under oxygen atmosphere to give 1:1 adducts in 73 and 83% yields, respectively (Runs 1 and 2).



Scheme 1.

The higher yield under the latter conditions suggests that the oxygen atmosphere may be more favorable than air for the formation of the 1:1 adducts. No 1:1 adduct was obtained under an argon atmosphere. These results showed that the presence of oxygen was essential for the reaction. Conversion of diethyl maleate and yield of the 1:1 adduct decreased at a lower reaction temperature (80 °C) and a shorter reaction time (3 h) (Runs 3 and 4). Radical initiators such as di-*t*-butyl peroxide (DTBP) or azobisisobutyronitrile (AIBN) could also initiate the reaction under an inert atmosphere (Runs 5 and 6). As a radical initiator, DTBP was more effective than AIBN. The decomposition of DTBP has a half-life of about 20 h at 120 °C and of about 1 h at 150 °C, whereas AIBN decomposes into 1-cyano-1-methylethyl radicals under mild conditions (40 °C). AIBN is useful as a initiator in the range from 40 °C to 80 °C.[5] The radical species from AIBN would not work efficiently at such a high reaction temperature (120 °C). Oxygen atmosphere appears to be more favorable to the reaction than the addition of initiators.

The effect of molar ratio, 1,3-dioxolane/alkene, on the product yield was examined in detail by employing diethyl maleate. The results are shown in Table 2.

TABLE 1. THE 1:1 ADDITION OF 1,3-DIOXOLANE TO ALKENES[a]

Run	Alkene	Conversion[b] %	Atmosphere	Product	Yield[b] %
1	Diethyl maleate	93	Air	**1**	73
2	Diethyl maleate	100	Oxygen	**1**	83
3[c]	Diethyl maleate	39	Air	**1**	16
4[d]	Diethyl maleate	50	Air	**1**	24
5[e]	Diethyl maleate	100	Argon	**1**	69
6[f]	Diethyl maleate	40	Argon	**1**	18
7	Maleic anhydride	98	Air	**2**	89
8	Diethyl fumarate	100	Air	**1**	38
9	Fumaronitrile	54	Air	**3**	23

a) A mixture of 1,3-dioxolane (60 mmol) and alkene (6.0 mmol) was stirred at 120 °C for 6 h. b) Determined by GLC based on the amount of alkene used. c) Reaction temperature: 80 °C for 6 h. d) Reaction time: 3 h at 120 °C. e) DTBP was used as a radical initiator. f) AIBN was used as a radical initiator.

Table 2. The 1:1 addition of 1,3-dioxolane to diethyl maleate: effect of molar ratio

Run	Molar ratio[b]	Conversion/%[c]	Product yield/%[c]
10	1:1	57	4
11	5:1	85	52
12	10:1	93	73
13	20:1	100	88

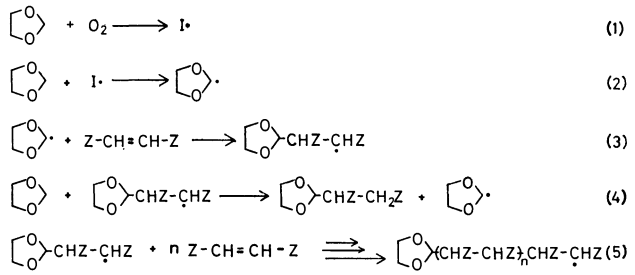
a) At 120 °C, for 6 h, under air. b) 1,3-Dioxolane/Maleate. c) Product **1**: Determined by GLC based on the amount of diethyl maleate.

The yield of 1:1 adduct decreased dramatically with a decrease in the molar ratio. In runs 10 and 11, the product mixture contained a considerable amount of oligomers, whose molecular weights were less than 800 according to gel-permeation chromatography.

With maleic anhydride, the 1:1 adduct was obtained in excellent yield (Run 7). However, the alkenes with (*E*)-configuration gave the product in poor yields. Diethyl fumarate and fumaronitrile gave the 1:1 adducts in 38 and 23% yields respectively (Runs 8 and 9).

For this reaction, only the alkene having two electron-withdrawing groups appears to react with 1,3-dioxolane under the conditions used. Methyl acrylate and acrylonitrile gave no 1:1 adducts even at a more elevated temperature, 180 °C. 1-Hexene was also inactive for the present reaction.

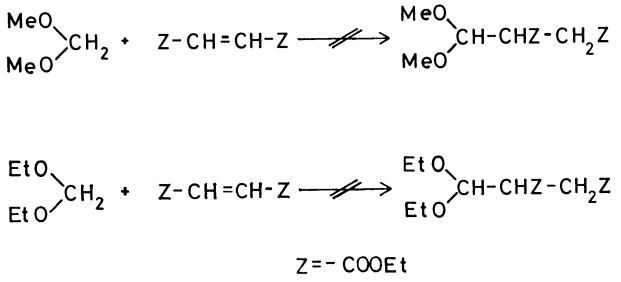
The reactions is considered to proceed in radical mechanisms (Scheme 2), since the 1:1 adduct was



Scheme 2.

obtained with radical initiators (Runs 5 and 6) and the reaction was inhibited completely with a radical scavenger such as 2,6-di-*t*-butyl-4-methylphenol. A peroxide species is generated by the reaction of 1,3-dioxolane with oxygen (Step 1), and this presumably initiates the chain reaction leading to the 1:1 adducts (Step 2—4). In the reaction between 2-phenyl-1,3-dioxolane and oxygen, a peroxide species has been isolated.[6] In runs 10 and 11, the yields of 1:1 adduct drastically decreased. In these runs, step 5 would predominate and many oligomers of the alkene were produced.

The present reaction is characteristic of 1,3-dioxolane. Methylal and ethylal, formaldehyde dimethyl acetal and diethyl acetal, did not react with diethyl maleate under the same reaction coditions as run 1 (Scheme 3). This difference occurs because peroxide species are liable to be generated with the more strained cyclic ether.[7]



Scheme 3.

The present reaction is considered to be a modified hydroformylation reaction since the ethylene acetal moiety is easily hydrolyzed into carbonyl groups. Hydroformylation of internal conjugated alkenes such as diethyl maleate and maleic anhydride is known to be rather difficult and requires severe conditions.[8] Therefore, the present reaction offers an alternative route to the hydroformylation of these alkenes with a simple precedure under rather mild conditions.

Experimental

1,3-Dixolane and other reagents were carefully purified by distillation over suitable drying reagents before use. The boiling points are uncorrected. IR spectra were measured on a Hitachi model 215 grating spectrophotometer. ^{1}H-NMR spectra (300 MHz) were recorded on a Nicolet NTC-300 spectrometer equipped with 1180E computer system. ^{13}C-NMR spectra (25.05 MHz) were obtained using a JEOL JNM FX-100 pulsed Fourier Transform spectrometer. The chemical shift values were expressed in ppm relative to Me_4Si as an internal standard. Gel-permeation chromatograms were recorded on a Waters ALC/GPC 244 equipped with four columns ($10^5+10^4+10^3+500$ Å). The molecular weight was estimated according to calibration curves obtained with standard polystyrenes.

General Reaction Procedure. A 50 ml stainless steel autoclave equipped with a glass liner was charged with an alkene (6 mmol, 1.0 ml) and 1,3-dioxolane (60 mmol, 4.2 ml) under an air or an oxygen atmosphere. The autoclave was set in an oil bath and the temperature was raised to 120 °C in 20 min. The mixture was stirred magnetically at 120 °C for 6 h. The products were isolated by distillation under reduced pressures and submitted to analysis (IR, NMR, and MS). The GLC analysis of the reaction products was made using a column (3 mmϕ × 3 m) packed with Silicone OV-17 on Uniport HP 60—80 mesh. The yields of products were determined by GLC.

The Reaction of Diethyl Maleate or Fumarate with 1,3-Dioxolane gave ***1***. **1**: Colorless oil, bp 116—119 °C/0.9 Torr (1 Torr≈133.322 Pa). ^{13}C-NMR ($CDCl_3$): δ=14.1 (q, $-COOCH_2\underline{C}H_3$), 30.4(t, $-CH-\underline{C}H_2-$), 45.9 (d, $-\underline{C}H-CH_2-$), 60.7(t, $-C\underline{O}OCH_2CH_3$), 61.6(t, $-COO\underline{C}H_2CH_3$), 65.3(t, $-\underline{C}H_2CH_2-$), 102.9 (d, $-O-\underline{C}H-O-$), 170.8 (s, C=O), and 171.8 (s, C=O). ^{1}H-NMR ($CDCl_3$): δ=1.25 (3H, t, J=6.9 Hz, $-COOCH_2C\underline{H}_3$), 1.27 (3H, t, J=6.9 Hz $-COOCH_2C\underline{H}_3$), 2.59(1H, d of d, J=16.8, 4.6 Hz, $-CH-CH_2-$), 2.76(1H, d of d, J=16.8, 9.2 Hz, $-CH-C\underline{H}_2-$), 3.20(1H, d of d of d, J=9.2, 4.6, 4.6 Hz, $-C\underline{H}-CH_2-$), 3.84—4.01(4H, m, $-O-C\underline{H}_2-C\underline{H}_2-O-$), 4.13(2H, q, J=6.9 Hz, $-COOC\underline{H}_2CH_3$), 4.19(2H, q, J=6.9 Hz, $-COOC\underline{H}_2-CH_3$), and 4.19 (1H, d, J=4.6 Hz, $-O-C\underline{H}-O-$). IR (neat): 1735 cm^{-1} (ν C=O) and 1030 cm^{-1} (ν C-O-C). MS(*m/e*): 246(M^+), and 201 (M^+-OEt). Found: C, 53.95;

H, 7.60; O 38.74%. Calcd for $C_{11}H_{18}O_6$: C, 53.65; H, 7.37; O, 38.98%.

The Reaction of Maleic Anhydride with 1,3-Dioxolane Gave **2**. **2**: Colorless oil, bp 128—138 °C/1.2 Torr. ^{13}C-NMR ($CDCl_3$): δ=28.5 (t, -CH-$\underline{C}H_2$-), 44.8(d, -$\underline{C}$H-CH_2-), 65.7(t, -O-$\underline{C}H_2$-$\underline{C}H_2$-O-), 100.7(d, -O-$\underline{C}$H-O-), and 169.6 (s, C=O). ^{1}H-NMR ($CDCl_3$): δ=2.958 (1H, d, J=8.4 Hz, -CH-C$\underline{H}_2$-), 2.961(1H, d, J=6.6 Hz, -CH-C$\underline{H}_2$-), 3.54(1H, d of d of d, J=8.4, 6.6, 2.4 Hz, -C$\underline{H}$-CH_2-), 3.84—4.17(4H, m, -C$\underline{H}_2$-C$\underline{H}_2$-), and 5.29 (1H, d, J=2.4 Hz, -O-C$\underline{H}$-O-). IR (neat): 1785 cm^{-1} (ν C=O), and 1860 cm^{-1} (ν C=O).

The Reaction of Fumaronitrile with 1,3-Dioxolane Gave **3**. **3**: Colorless oil, bp 111—114 °C/4 Torr. The ^{13}C-NMR spectra of the isolated product gave a similar pattern to those of **1** and **2**. ^{13}C-NMR ($CDCl_3$): δ=16.3 (t, -CH-C$\underline{H}_2$-), 33.9 (d, -$\underline{C}$H-CH_2-), 66.1 (t, -O-$\underline{C}H_2$-$\underline{C}H_2$-O-), 100.6 (d, -O-$\underline{C}$H-O-), 115.5 (s, -CN), and 119.1 (s, -CN).

The 1:1 Addition in the Presence of Radical Initiator. The 50 ml autoclave was charged with diethyl maleate (6.0 mmol, 1.0 ml), 1,3-dioxolane (60 mmol, 4.2 ml), and a radical initiator, DTBP (0.6 mmol, 87.7 mg) or AIBN (0.6 mmol, 81.7 mg), and then the mixture was stirred at 120 °C for 6 h under an argon atmosphere.

The Reaction in the Presence of Radical Scavenger. The 50 ml autoclave was charged with diethyl maleate (6.0 mmol, 1.0 ml), 1,3-dioxolane (60 mmol, 4.2 ml), and 2,6-di-*t*-butyl-4-methylphenol (15 mmol, 3.31 g) under air. The mixture was stirred at 120 °C for 6 h.

Synthetic Studies on Methyl α-Trioxacarcinoside B

Tetsuo SUAMI,* Katsumi NAKAMURA, and Tamio HARA

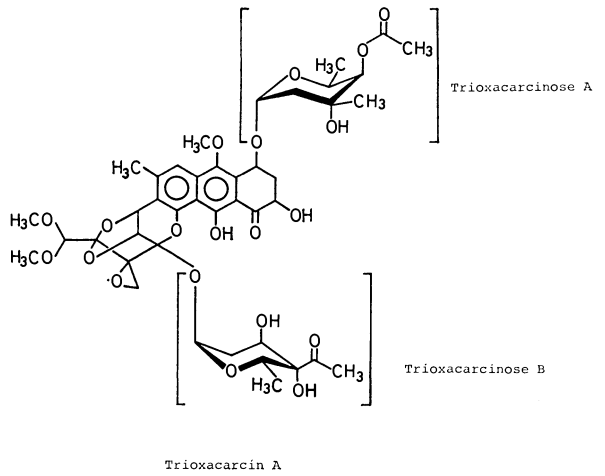
Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama, 223

(Received August 14, 1982)

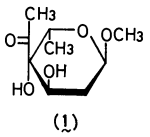
Trioxacarcinose B is a unique carbohydrate which has been discovered in antibiotic trioxacarcin A as a component. As a step of total synthesis of the antibiotic, methyl α-trioxacarcinoside B has been synthesized from methyl 2,3-anhydro-6-deoxy-α-L-*allo*-hexopyranoside by a 7 steps reaction in a yield of 4.3%. The product has been identified by comparison with the authentic sample which was prepared by methanolysis of the antibiotic.

Trioxacarcinose A and B are unique carbohydrates which are components of antitumor antibiotic trioxacarcin A produced by *Streptomyces ochraceus*.[1,2,3]

Methanolysis of the antibiotic afforded a mixture of two methyl glycosides: methyl trioxacarcinoside A and B.



Trioxacarcin A



(1)

Trioxacarcinose A is a known sugar and its de-*O*-acetyl derivative is named axenose, which has been synthesized by Garegg and Norberg.[4] Trioxacarcinose B has been known as a component of naturally occurring isoquinocycline B[5] but its synthesis has never been described; a closely related compound, methyl 2,6-dideoxy-4-*C*-(L-glycero-4[1]-hydroxyethyl)-α-L-*xylo*-hexopyranoside, was synthesized by Paulsen and Sinnwell.[6]

We have attempted to synthesize methyl α-trioxacarcinoside B (**1**) from the readily accessible methyl 2,3-anhydro-6-deoxy-α-L-*ribo*-hexopyranosid-4-ulose (**2**).[6]

Treatment of **2** with 2-methyl-1,3-dithiane[7] in the presence of butyllithium in tetrahydrofuran (THF) yielded two products: methyl 2,3-anhydro-6-deoxy-4-*C*-(2-methyl-1,3-dithiolan-2-yl)-α-L-*allo*-hexopyranoside (**3**) and the corresponding L-*galacto* derivative (**4**) in 26 and 7% yields, respectively.

Reduction of **3** with $LiAlH_4$ in THF afforded methyl 2,6-dideoxy-4-*C*-(2-methyl-1,3-dithiolan-2-yl)-α-L-*ribo*-hexopyranoside (**5**) in a quantitative yield.

Scheme 2.

Deprotection of **5** with mercury(II) chloride and mercury(II) oxide in aq methanol gave crystalline methyl 4-*C*-acetyl-2,6-dideoxy-α-L-*ribo*-hexopyranoside (**6**) in 38% yield, which was found to be the 4-epimer of **1** by ^1H NMR spectroscopy.

To avoid the formation of **4**, an alternative route has been attempted. Protection of the hydroxyl group on C-4 of methyl 2,3-anhydro-6-deoxy-α-L-*allo*-hexo-

pyranoside[6] (**7**) with 3,4-dihydro-2*H*-pyran and successive hydrogenation of the 2,3-oxirane ring with $LiAlH_4$ afforded two products: the 2-deoxy derivative (**9**) and the 3-deoxy derivative (**10**) in 80 and 19% yields, respectively.

Protection of another hydroxyl group on C-3 in **9** with a 2-methoxyethoxymethyl group (MEM) gave the fully protected compound (**11**) as a syrup. Selective deprotection of the tetrahydropyranyl group in **11** with pyridinium *p*-toluenesulfonate in methanol[8] gave the anomers (**12**) and (**13**) in 71 and 23% yields, respectively.

Oxidation of **12** with ruthenium tetraoxide gave methyl 2,6-dideoxy-3-*O*-(2-methoxyethoxymethyl)-α-L-*erythro*-hexopyranosid-4-ulose (**14**) in a yield of 86%. When **14** reacted with 2-methyl-1,3-dithiane[7] in the presence of butyllithium, methyl 2,6-dideoxy-3-*O*-(2-methoxyethoxymethyl)-4-*C*-(2-methyl-1,3-dithiolan-2-yl)-α-L-*xylo*-hexopyranoside (**15**) was obtained in 54% yield, together with a small amount of the corresponding 4-epimer (**16**). Deprotection of **15** in methanolic hydrogen chloride gave **1** in 23% yield.

In this reaction process (**11**→**12**→**14**→**15**→**1**), another protective group, *t*-butyldimethylsilyl group (TBDMS), was used analogously to result in the process (**17**→**18**→**21**→**22**→**1**).

Experimental

General Methods. Melting points were determined on a Büchi 510 capillary melting point apparatus and are uncorrected. Solutions were concentrated under reduced pressure below 50 °C. Optical rotation was measured on a Japan Spectroscopic Co. DIPL-SL polarimeter. ^1H NMR spectra were taken on a Varian EM-390 (90 MHz) spectrometer in deuteriochloroform with reference to tetramethylsilane as an internal standard. Chemical shifts are given in δ-values, and the *J*-values given are of first-order. TLC was performed on precoated Wakogel B-5F plates (Wako Pure Chemical Co., Ltd.), and silica gel (Wakogel C-200) was employed for column chromatography.

*Methyl 2,3-Anhydro-6-deoxy-4-C-(2-methyl-1,3-dithiolan-2-yl)-α-L-allo-hexopyranoside (**3**) and Methyl 3,4-Anhydro-6-deoxy-4-C-(2-methyl-1,3-dithiolan-2-yl)-α-L-galacto-hexopyranoside (**4**).* To a stirred solution of 2-methyl-1,3-dithiane (342 mg, 2.5 mmol) in THF (3.0 ml), a 1.8 ml portion of 1.6 M (1 M = 1 mol dm^{-3}) butyllithium hexane solution (2.9 mmol) was added with acetone–Dry Ice cooling (−30 °C) in an argon atmosphere. After 1.5 h, the mixture was cooled at −70 °C and a solution of methyl 2,3-anhydro-6-deoxy-α-L-*ribo*-hexopyranosid-4-ulose (**2**, 400 mg, 2.5 mmol) in THF (3.0 ml) was added to the mixture. After stirring for 10 min, a 0.6 ml portion of acetic acid was added to the reaction mixture. The mixture was concentrated and the residue was dissolved in chloroform. The chloroform solution was washed with H_2O, dried over anhydrous Na_2SO_4 and concentrated. The residue was recrystallized from ethyl acetate–hexane to give 189 mg (26%) of **3**: mp 140—141 °C; $[\alpha]_D^{23}$ −65.5° (*c* 0.84, $CHCl_3$). The ^1H NMR spectrum of **3** was superimposable on that of the corresponding D-diastereomer.[7]

Found: C, 49.17; H, 6.69; S, 21.75%. Calcd for $C_{12}H_{20}S_2O_4$: C, 49.29; H, 6.81; S, 21.93%.

The mother liquor was concentrated and the residue was purified on a silica-gel column with 1:8 (v/v) ethyl acetate–toluene as an eluant. Fractions homogeneous on TLC (R_f 0.59) in 1:1 (v/v) ethyl acetate–toluene were combined and concentrated. The residue was recrystallized from ether to give 54 mg (7%) of **4**: mp 127—128 °C; $[\alpha]_D^{23}$ −115.9° (*c* 2.67, CH_3OH). The ^1H NMR spectrum of **4** was superimposable on that of the corresponding D-diastereomer.[7]

Found: C, 49.46; H, 6.81; S, 21.72%. Calcd for $C_{12}H_{20}S_2O_4$: C, 49.29; H, 6.81; S, 21.93%.

*Methyl 2,6-Dideoxy-4-C-(2-methyl-1,3-dithiolan-2-yl)-α-L-ribo-hexopyranoside (**5**).* To a suspension of $LiAlH_4$ (83 mg, 2.2 mmol) in THF (8.0 ml), a solution of **3** (245 mg, 0.8 mmol) in THF (8.0 ml) was added. After refluxing for 1 h, the reaction mixture was quenched in ice-cooled water (10 ml). The precipitates were filtered off and the filtrate was concentrated. The residue was purified on a silica-gel column with 1:9 (v/v) ethyl acetate–toluene. Fractions homogeneous on TLC (R_f 0.48) in 1:3 (v/v) ethyl acetate–toluene were combined and concentrated to give 239 mg (97%) of **5** as a syrup: $[\alpha]_D^{23}$ −67.1° (*c* 2.16, CH_3OH). The ^1H NMR spectrum of **5** was identical with that of the corresponding D-diastereomer.[7]

Found: C, 48.73; H, 7.43; S, 21.52%. Calcd for $C_{12}H_{22}S_2O_4$: C, 48.95; H, 7.53; S, 21.78%.

*Methyl 4-C-Acetyl-2,6-dideoxy-α-L-ribo-hexopyranoside (**6**).* To a stirred solution of **5** (207 mg, 0.7 mmol) in 80% aq methanol (16.0 ml), mercury(II) chloride (344 mg, 1.3 mmol), and mercury(II) oxide (365 mg, 1.7 mmol) were added. After 1 h, the mixture was filtered and the filtrate was concentrated. The residue was dissolved in chloroform and the solution was washed with 1 M KI solution and cold water, dried over anhydrous Na_2SO_4 and concentrated. The residue was purified on a silica-gel column with 5:1 (v/v) cyclohexane–ethyl acetate. Fractions homogeneous on TLC (R_f 0.50) in 30:1 (v/v) chloroform–methanol were combined and concentrated to give 55 mg (38%) of **6**: mp 35—39 °C; $[\alpha]_D^{23}$ −183.2° (*c* 0.61, $CHCl_3$); ^1H NMR δ = 1.18 (3H, d, $J_{5,6}$ = 7.0 Hz, H-6), 2.01 (1H, ddd, $J_{1,2ax.}$ = 3.0 Hz, $J_{2ax.,2eq.}$ = 15.0 Hz, $J_{2ax.,3}$ = 4.5 Hz, H-2ax.), 2.30 (3H, s, CH_3), 2.44 (1H, ddd, $J_{1,2eq.}$ = 4.0 Hz, $J_{2eq.,2ax.}$ = 15.0 Hz, $J_{2eq.,3}$ = 3.5 Hz, H-2eq.), 3.38 (3H, s, OCH_3), 3.85 (1H, q, $J_{5,6}$ = 7.0 Hz, H-5) and 4.84 (1H, dd, $J_{1,2ax.}$ = 3.0 Hz, $J_{1,2eq.}$ = 3.5 Hz, H-1).

Found: C, 52.12; H, 7.54%. Calcd for $C_9H_{16}O_5$: C, 52.93; H, 7.90%.

*Methyl 2,6-Anhydro-6-deoxy-4-O-tetrahydropyranyl-α-L-allo-hexopyranoside (**8**).* To a stirred mixture of 3,4-dihydro-2*H*-pyran (896 mg, 10.6 mmol) and pyridinium *p*-toluenesulfonate (234 mg, 0.9 mmol) in CH_2Cl_2 (60.0 ml), methyl 2,3-anhydro-6-deoxy-α-L-*allo*-hexopyranoside[6] (**7**, 1.50 g, 9.4 mmol) was added. After 22 h, the reaction mixture was diluted with CH_2Cl_2, washed with cold water, dried over anhydrous Na_2SO_4 and concentrated. The residue was purified on a silica-gel column with 1:12 (v/v) ethyl acetate–toluene. Fractions homogeneous on TLC (R_f 0.29) in 1:3 (v/v) ethyl acetate–toluene were combined and concentrated to give 2.19 g (96%) of **8** as a syrup: ^1H NMR δ = 1.17 (d, $J_{5,6}$ = 6.5 Hz) and 1.25 (d, $J_{5,6}$ = 6.5 Hz) (3H, H-6), 3.41 (3H, s, OCH_3), 4.77 (3/2 H, d, *J* = 3.0 Hz, H-1 and THP's H-1) and 5.00 (1/2 H, bs, THP's H-1).

Found: C, 59.29; H, 8.14%. Calcd for $C_{12}H_{20}O_5$: C, 59.00: H, 8.25%.

*Methyl 2,6-Dideoxy-4-O-tetrahydropyranyl-α-L-ribo-hexopyranoside (**9**) and Methyl 3,6-Dideoxy-4-O-tetrahydropyranyl-α-L-ribo-hexopyranoside (**10**).* To a mixture of $LiAlH_4$ (0.4 g, 10.5 mmol) and THF (50 ml), a solution of **8** (2.36 g, 9.7 mmol) in THF (10 ml) was added. After the mixture was heated under reflux for 1 h, water (60 ml) was added to the mixture. The mixture was filtered and the filtrate

was concentrated. The residue was purified on a silica-gel column with 1:12 (v/v) acetone–hexane. Fractions homogeneous (R_f 0.40) on TLC in 1:3 (v/v) acetone–hexane were combined and concentrated to give 1.91 g (80%) of **9** as a syrup.

Found: C, 58.75; H, 8.80%. Calcd for $C_{12}H_{22}O_5$: C, 58.52; H, 9.00%.

Fractions homogeneous (R_f 0.30) on TLC in the same solvent system were combined and concentrated to give 0.45 g (19%) of **10** as a syrup.

Found: C, 58.59; H, 8.76%. Calcd for $C_{12}H_{22}O_5$: C, 58.52; H, 9.00%.

*Methyl 2,6-Dideoxy-3-*O*-(2-methoxyethoxymethyl)-4-*O*-tetrahydropyranyl-α-*L*-ribo-hexopyranoside (**11**).* To a stirred solution of **9** (0.68 g, 2.8 mmol) in CH_2Cl_2 (4.0 ml), 2-methoxyethoxymethyl chloride (0.68 g, 2.8 mmol) and *N,N*-diisopropylethylamine (0.72 g, 5.5 mmol) were added. After 1 h, the mixture was diluted with CH_2Cl_2, washed with water, dried over anhydrous Na_2SO_4 and concentrated. The residue was purified on a silica-gel column with 1:8 (v/v) ethyl acetate–toluene. Fractions homogeneous (R_f 0.22) on TLC in 1:1 (v/v) ethyl acetate–toluene were combined and concentrated to give 0.68 g (74%) of **11** as a syrup: ^{1}H NMR δ=1.19 (d, $J_{5,6}$=6.5 Hz) and 1.28 (d, $J_{5,6}$=6.5 Hz) (3H, H-6), 3.30 (3H, s, OCH_3), 3.36 (3H, s, OCH_3) and 4.57—4.95 (4H, m, H-1, THP's H-1 and $-OCH_2O-$ of MEM).

Found: C, 57.57; H, 8.83%. Calcd for $C_{16}H_{30}O_7$: C, 57.47; H, 9.04%.

*Methyl 2,6-Dideoxy-3-*O*-(2-methoxyethoxymethyl)-α-*L*-ribo-hexopyranoside (**12**) and Methyl 2,6-Dideoxy-3-*O*-(2-methoxyethoxymethyl)-β-*L*-ribo-hexopyranoside (**13**).* A mixture of **11** (0.68 g, 2.0 mmol) and pyridinium *p*-toluenesulfonate (51 mg, 0.2 mmol) in methanol (30 ml) was heated at 50 °C for 1 h. The mixture was concentrated and the residue was purified on a silica-gel column with 1:1 (v/v) ethyl acetate–toluene. Fractions homogeneous (R_f 0.10) on TLC in the same solvent were combined and concentrated to give 0.36 g (71%) of **12** as a syrup: $[\alpha]_D^{23}$ −184.4° (*c* 1.28, $CHCl_3$); ^{1}H NMR δ=1.25 (3H, d, $J_{5,6}$=6.5 Hz, H-6), 1.84 (1H, ddd, $J_{1,2ax.}$=4.5 Hz, $J_{2ax.,2eq.}$=15.0 Hz, $J_{2ax.,3}$=3.5 Hz, H-2eq.), 3.32 (3H, s, OCH_3), 4.64 (1H, dd, $J_{1,2ax.}$=4.5 Hz, $J_{1,2eq.}$=1.5 Hz, H-1) and 4.80 (2H, s, $-OCH_2O-$ of MEM).

Found: C, 53.02; H, 8.60%. Calcd for $C_{11}H_{22}O_6$: C, 52.79; H, 8.86%.

Fractions homogeneous (R_f 0.16) on TLC were concentrated to give 0.12 g (23%) of **13** as a syrup: $[\alpha]_D^{24}$ −36.5° (*c* 1.24, $CHCl_3$); ^{1}H NMR δ=1.28 (3H, d, $J_{5,6}$=6.5 Hz, H-6), 1.61 (1H, ddd, $J_{1,2ax.}$=9.5 Hz, $J_{2ax.,2eq.}$=14.0 Hz, $J_{2ax.,3}$=3.0 Hz, H-2ax.), 2.11 (1H, ddd, $J_{1,2eq.}$=2.5 Hz, $J_{2ax.,2eq.}$=14.0 Hz, $J_{2,3}$=4.0 Hz, H-2eq.), 3.35 (3H, s, OCH_3), 3.44 (3H, s, OCH_3), 4.60 (1H, dd, $J_{1,2ax.}$=9.5 Hz, $J_{1,2eq.}$=2.5 Hz, H-1) and 4.77 (2H, s, $-OCH_2O-$ of MEM).

Found: C, 53.04; H, 8.68%. Calcd for $C_{11}H_{22}O_6$: H, 52.79; H, 8.86%.

*Methyl 2,6-Dideoxy-3-*O*-(2-methoxyethoxymethyl)-α-*L*-erythro-hexopyranosid-4-ulose (**14**).* To a stirred mixture of **12** (0.34 g, 1.3 mmol), K_2CO_3 (56 mg, 0.5 mmol), RuO_2 (8.9 mg), and chloroform (4 ml), a solution of $NaIO_4$ (0.48 g, 2.3 mmol) in water (5 ml) was added. After 5 h, 2-propanol was added to the reaction mixture. The mixture was filtered, and the filtrate was diluted with chloroform, washed with water, dried over anhydrous Na_2SO_4 and concentrated. The residue was purified on a silica-gel column with 1:2 (v/v) ethyl acetate–toluene. Fractions homogeneous (R_f 0.36) on TLC in 1:1 (v/v) ethyl acetate–toluene were combined and concentrated to give 0.29 g (86%) of **14** as a syrup: $[\alpha]_D^{22}$ −127.7° (*c* 5.68, $CHCl_3$); ^{1}H NMR δ=1.29 (3H, d, $J_{5,6}$=6.5 Hz, H-6), 1.86 (1H, ddd, $J_{1,2}$=6.0 Hz, $J_{2,2'}$=13.5 Hz, $J_{2,3}$=13.0 Hz, H-2), 2.63 (1H, dt, $J_{1,2'}$=7.0 Hz, $J_{2,2'}$=13.5 Hz, $J_{2',3}$=7.0 Hz, H-2'), 3.36 (3H, s, OCH_3), 3.37 (3H, s, OCH_3), 4.31 (1H, q, $J_{5,6}$=6.5 Hz, H-5), 4.51 (1H, dd, $J_{2,3}$=13.0 Hz, $J_{2',3}$=7.0 Hz, H-3), 4.80 (2H, s, $-CH_2O-$ of MEM) and 4.97 (1H, dd, $J_{1,2}$=6.0 Hz, $J_{1,2'}$=7.0 Hz, H-1).

Found: C, 53.40; H, 8.05%. Calcd for $C_{11}H_{20}O_6$: C, 53.22; H, 8.12%.

*Methyl 2,6-Dideoxy-3-*O*-(2-methoxyethoxymethyl)-4-*C*-(2-methyl-1,3-dithiolan-2-yl)-α-*L*-xylo-hexopyranoside (**15**) and Methyl 2,6-Dideoxy-3-*O*-(2-methoxyethoxymethyl)-4-*C*-(2-methyl-1,3-dithiolan-2-yl)-α-*L*-ribo-hexopyranoside (**16**).* A mixture of 2-methyl-1,3-dithiane (0.16 g, 1.2 mmol), 1.6 M hexane solution of butyllithium (0.82 ml, 1.3 mmol), and THF (2.0 ml) was stirred for 1.5 h at −30 °C in an argon atmosphere. To the mixture, a solution of **14** (0.29 g, 1.2 mmol) in THF (2.0 ml) was added at −70 °C. After 20 min, the reaction mixture was mixed with acetic acid (0.3 ml) and concentrated. The residue was dissolved in chloroform and the solution was washed with water, dried over anhydrous Na_2SO_4 and concentrated. The residue was purified on the column with 1:5 (v/v) ethyl acetate–toluene. Fractions homogeneous (R_f 0.49) on TLC in the same solvent were combined and concentrated to give 0.24 g (54%) of **15** as a syrup: $[\alpha]_D^{24}$ −82.8° (*c* 1.69, $CHCl_3$); ^{1}H NMR δ=1.35 (3H, d, $J_{5,6}$=6.5 Hz, H-6), 1.75 (3H, s, CH_3), 2.92 (1H, s, OH), 3.31 (3H, s, OCH_3), 3.36 (3H, s, OCH_3), 4.30 (1H, t, J=3.0 Hz, H-3), 4.36 (1H, q, $J_{5,6}$=6.5 Hz, H-5), 4.64 (1H, t, J=2.5 Hz, H-1), 4.84 (1H, d, J=13.5 Hz, $-OCH(H')O-$ of MEM) and 4.92 (1H, d, J=13.5 Hz, $-OCH(H')O-$ of MEM).

Found: C, 50.49; H, 7.71; S, 16.52%. Calcd for $C_{16}H_{30}S_2O_6$: C, 50.24; H, 7.90; S, 16.76%.

Fractions homogeneous (R_f 0.36) gave 94 mg (22%) of **16** as a syrup. The structure of **16** was established by converting **5** into **16** as follows.

To a stirred solution of **5** (56 mg, 0.2 mmol) in CH_2Cl_2 (2 ml), 2-methoxyethoxymethyl chloride (47 mg, 0.4 mmol), and *N,N*-diisopropylethylamine (49 mg, 0.4 mmol) were added. The mixture was worked up as described in the preparation of **16** to give 20 mg (28%) of **16**.

*Methyl 3-*O*-(t-Butyldimethylsilyl)-2,6-dideoxy-4-*O*-tetrahydropyranyl-α-*L*-ribo-hexopyranoside (**17**).* To a stirred solution of **9** (1.86 g, 7.6 mmol) in DMF (5.0 ml), imidazole (1.28 g, 18.8 mmol) and *t*-butyldimethylsilyl chloride (1.59 g, 10.6 mmol) were added. After 20 h, the mixture was concentrated and the residue was purified on a column with 1:20 (v/v) ethyl acetate–hexane were concentrated to give 2.67 g (97%) of **17** as a syrup: ^{1}H NMR δ=0.87 and 0.89 (9H, s×2, $-SiC(CH_3)_3$), 1.17 (d, $J_{5,6}$=6.5 Hz) and 1.26 (d, $J_{5,6}$=6.5 Hz) (3H, H-6), 3.25 and 3.27 (3H, s×2, OCH_3), 4.56—4.68 (3/2 H, m, H-1 and THP's H-1) and 4.80 (1/2 H, bs, THP's H-1).

Found: C, 59.68; H, 9.75%. Calcd for $C_{18}H_{36}O_5Si$: C, 59.96; H, 10.06%.

*Methyl 3-*O*-(t-Butyldimethylsilyl)-2,6-dideoxy-α-*L*-ribo-hexopyranoside (**18**), Methyl 3-*O*-(t-Butyldimethylsilyl)-2,6-dideoxy-β-*L*-ribo-hexopyranoside (**19**), and Methyl 2,6-Dideoxy-α-*L*-ribo-hexopyranoside (**20**).* To a stirred solution of **17** (0.53 g, 1.5 mmol) in methanol (20 ml), pyridinium *p*-toluenesulfonate (37 mg) was added at 40 °C. After 1.5 h, the mixture was concentrated and the residue was purified on a column with 1:20 (v/v) ethyl acetate–hexane. Fractions homogeneous (R_f 0.58) on TLC in the same solvent were concen-

trated to give 0.16 g (40%) of **18** as a syrup: $[\alpha]_D^{22}$ −134.5° (*c* 1.12, $CHCl_3$); ^1H NMR δ=0.09 (3H, s, -SiC$(CH_3)_3$), 0.11 (3H, s, -SiCH_3), 0.91 (9H, s, -SiC$(CH_3)_3$), 1.25 (3H, d, $J_{5,6}$=6.5 Hz, H-6), 1.77 (1H, dt, $J_{1,2ax.}$=4.0 Hz, $J_{2ax.,2eq.}$=15.0 Hz, $J_{2ax.,3}$=4.0 Hz, H-2ax.), 2.00 (1H, ddd, $J_{1,2eq}$=2.0 Hz, $J_{2ax.,2eq.}$=15.0 Hz, $J_{2eq.,3}$=4.0 Hz, H-2eq.), 2.18 (1H, d, $J_{4,4-OH}$=10.0 Hz, 4-OH), 3.25 (3H, s, OCH_3), 3.83 (1H, dq, $J_{4,5}$=9.0 Hz, $J_{5,6}$=6.5 Hz, H-5), 4.03 (1H, q, $J_{2ax.,3}$=4.0 Hz, $J_{2eq.,3}$=4.0 Hz, $J_{3,4}$=4.0 Hz, H-3) and 4.63 (1H, dd, $J_{1,2ax.}$=4.0 Hz, $J_{1,2eq.}$=2.0 Hz, H-1).

Found: C, 56.84; H, 9.79%. Calcd for $C_{13}H_{28}O_4Si$: C, 56.48; H, 10.21%.

Fractions homogeneous (R_f 0.44) on TLC gave 0.10 g (25%) of **19** as a syrup: $[\alpha]_D^{22}$ −11.6° (*c* 1.22, $CHCl_3$); ^1H NMR δ=0.12 (6H, s, -Si$(CH_3)_2$), 0.94 (9H, s, -SiC$(CH_3)_3$), 1.28 (3H, d, $J_{5,6}$=6.0 Hz, H-6), 1.57 (1H, ddd, $J_{1,2ax.}$=9.0 Hz, $J_{2ax.,2eq.}$=13.5 Hz, $J_{2ax.,3}$=3.0 Hz, H-2ax.), 1.84 (1H, d, $J_{4,4-OH}$=10.0 Hz, 4-OH), 1.97 (1H, ddd, $J_{1,2eq.}$=2.5 Hz, $J_{2ax.,eq.}$=13.5 Hz, $J_{2eq.,3}$=3.5 Hz, H-2eq.), 3.13 (1H, ddd, $J_{3,4}$=3.5 Hz, $J_{4,4-OH}$=10.0 Hz, $J_{4,5}$=9.0 Hz, H-4), 3.55 (3H, s, OCH_3), 3.71 (1H, dq, $J_{4,5}$=9.0 Hz, $J_{5,6}$=6.0 Hz, H-5), 4.11 (1H, dt, $J_{3,4}$=3.5 Hz, $J_{2ax.,3}$=3.0 Hz, $J_{2eq.,3}$=3.5 Hz, H-3) and 4.62 (1H, dd, $J_{1,2ax.}$=9.0 Hz, $J_{1,2eq.}$=2.5 Hz, H-1).

Found: C, 56.66; H, 9.93%. Calcd for $C_{13}H_{28}O_4Si$: C, 56.48; H, 10.21%.

Fractions homogeneous (R_f 0.05) on TLC gave 44 mg (12%) of **20** as a syrup: $[\alpha]_D^{23}$ −165.4° (*c* 1.08, $CHCl_3$); ^1H NMR δ=1.31 (3H, d, $J_{5,6}$=6.0 Hz, H-6), 1.87 (1H, dt, $J_{1,2ax.}$=3.5 Hz, $J_{ax.,2eq.}$=15.0 Hz, $J_{2eq.,3}$=3.0 Hz, H-2eq.), 3.10 (1H, dd, $J_{3,4}$=3.0 Hz, $J_{4,5}$=10.0 Hz, H-4), 3.36 (3H, s, OCH_3), 3.70 (1H, dq, $J_{4,5}$=10.0 Hz, $J_{5,6}$=6.0 Hz, H-5) and 4.76 (1H, dd, $J_{1,2ax.}$=3.5 Hz, $J_{1,2eq.}$=1.5 Hz, H-1).

Found: C, 51.79; H, 8.55%. Calcd for $C_7H_{14}O_4$: C, 51.84; H, 8.70%.

*Methyl 3-O-(t-Butyldimethylsilyl)-2,6-dideoxy-α-*L*-erythro-hexopyranosid-4-ulose (21).* Compound **18** (0.16 g, 0.6 mmol) was oxidized with ruthenium tetraoxide in a chloroform solution and the reaction mixture was worked up analogously as described in the preparation of **14** to give 82 mg (52%) of **21** as a homogeneous syrup: R_f 0.76 on TLC in 1:4 (v/v) ethyl acetate-hexane; $[\alpha]_D^{22}$ −173.9° (*c* 3.86, $CHCl_3$); ^1H NMR δ=0.05 (3H, s, SiCH_3), 0.13 (3H, s, SiCH_3), 0.90 (9H, s, SiC$(CH_3)_3$), 1.30 (3H, d, $J_{5,6}$=6.5 Hz, H-6), 1.89 (1H, ddd, $J_{1,2}$=7.0 Hz, $J_{2,2'}$=14.0 Hz, $J_{2,3}$=13.0 Hz, H-2), 2.55 (1H, dt, $J_{1,2'}$=7.0 Hz, $J_{2,2'}$=14.0 Hz, $J_{2',3}$=7.0 Hz, H-2'), 3.39 (3H, s, OCH_3), 4.29 (1H, q, $J_{5,6}$=7.0 Hz, H-5), 4.46 (1H, dd, $J_{2,3}$=13.0 Hz, $J_{2',3}$=7.0 Hz, H-3), 4.91 (1H, t, $J_{1,2}$=7.0 Hz, $J_{1,2'}$=7.0 Hz, H-1).

Found: C, 57.16; H, 9.28%. Calcd for $C_{13}H_{26}O_4Si$: C, 56.90; H, 9.55%.

*Methyl 3-O-(t-Butyldimethylsilyl)-2,6-dideoxy-4-C-(2-methyl-1,3-dithiolan-2-yl)-α-*L*-xylo-hexopyranoside (22) and Methyl 3-O-(t-Butyldimethylsilyl)-2,6-dideoxy-4-C-(2-methyl-1,3-dithiolan-2-yl)-α-*L*-ribo-hexopyranoside (23).* Compound **21** (0.13 g, 0.5 mmol) was treated with 2-methyl-1,3-dithiane in THF as described in the preparation of **15** to give 87 mg (44%) of **22** as a syrup: R_f 0.63 on TLC in 1:4 (v/v) ethyl acetate-hexane; $[\alpha]_D^{22}$ −121.6° (*c* 1.96, $CHCl_3$); ^1H NMR δ=0.11 (3H, s, SiCH_3), 0.13 (3H, s, SiCH_3), 0.91 (9H, s, SiC$(CH_3)_3$), 1.37 (3H, d, $J_{5,6}$=6.5 Hz, H-6), 1.79 (3H, s, CH_3), 3.29 (3H, s, OCH_3), 4.42 (1H, q, $J_{5,6}$=6.5 Hz, H-5) and 4.65 (1H, d, J=4.5 Hz, H-1).

Found: C, 52.00; H, 8.40; S, 15.15%. Calcd for $C_{18}H_{36}S_2O_4Si$: C, 52.90; H, 8.88; S, 15.69%.

Fractions (R_f 0.72 on TLC in the same solvent) gave 6.1 mg (3%) of **23** as a syrup: ^1H NMR δ=0.17 (6H, s, Si$(CH_3)_2$), 0.91 (9H, s, SiC$(CH_3)_3$), 1.55 (3H, d, $J_{5,6}$=7.0 Hz, H-6), 1.96 (3H, s, CH_3), 2.26 (1H, dt, $J_{1,2eq.}$=5.0 Hz, $J_{2ax.,2eq.}$=14.5 Hz, $J_{2eq.,3}$=5.0 Hz, H-2eq.), 3.30 (3H, s, OCH_3), 3.57 (1H, s, 4-OH), 4.11 (1H, q, $J_{5,6}$=7.0 Hz, H-5), 4.55 (1H, dd, $J_{2ax.,3}$=8.0 Hz, $J_{2eq.,3}$=5.0 Hz, H-3) and 4.65 (1H, t, $J_{1,2ax}$=5.0 Hz, $J_{1,2eq.}$=5.0 Hz, H-1).

The structure of **23** was elucidated by converting **5** to **23** as follows. To a stirred solution of **5** (33 mg, 0.1 mmol) in DMF (0.5 ml), imidazole (19 mg, 0.3 mmol) and *t*-butyldimethylsilyl chloride (20 mg, 0.1 mmol) were added. The mixture was worked up as described in the preparation of **17** to give 26 mg (57%) of **23**.

Methyl α-Trioxacarcinoside B (1). *(a)*: To a stirred solution of **15** (0.12 g, 0.6 mmol) in methanol (2.0 ml), methanol (2.0 ml) containing 20% HCl was added. After 20 h, the mixture was concentrated and the residue was purified on a silica-gel column with 1:7 (v/v) ethyl acetate-toluene. Fractions homogeneous (R_f 0.70) on TLC in 30:1 (v/v) chloroform-methanol were combined and concentrated. The residue was recrystallized from isopropyl ether to give 15 mg (23%) of **1**: mp 111—112 °C; $[\alpha]_D^{24}$ −154.2° (*c* 0.34, $CHCl_3$). The product was identical with an authentic sample[3,5] in all respects.

(b): An 87 mg portion of **22** was treated with methanolic HCl analogously as described in *(a)* above to give 3.5 mg (8%) of **1**.

The authors wish to express their thanks to Dr. Kunikatsu Shirahata for his helpful advice and to Kyowa Hakko Co. for providing an authentic sample of **1**. Also, they thank Mr. Saburo Nakada for his elemental analysis.

Synthesis of Potential Antineoplastic Anthracenedione Derivatives. I. Sugar Derivatives

Katsumi NAKAMURA, Tomoyuki ASAI, Tamio HARA, Naoki MINORIKAWA, and Tetsuo SUAMI*

Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama, 223

(Received November 22, 1982)

Seven 1-*O*-glycosyl derivatives of 4-[2-(2-hydroxyethylamino)ethylamino]-9,10-anthracenedione have been prepared as potential antineoplastic agents.

Doxorubicin (adriamycin)[1] and daunorubicin (daunomycin)[2] are well known as the clinically useful, antineoplastic agents and members of anthracycline antibiotics, together with carminomycin,[3] dihydrodaunomycin,[4] rhodomycin B,[5] pyrromycin,[6] and cinerubin.[7] Their cytotoxic effects are primarily due to their ability to intercalate their molecules between the base pairs of the DNA double helix.

The utilization of doxorubicin and daunorubicin is, however, limited by undesirable side effects, such as irreversible cardiotoxicity. To avoid the side effect and to improve antineoplastic activity, a series of anthracenedione derivatives having one or two aminoalkyl side chains, as model compounds of intercalating agents, have been studied by Double and Brown.[8]

Among these model compounds, bis(substituted aminoalkylamino)anthracenediones[9] and 1-hydroxy-4-[2-(2-hydroxyethylamino)ethylamino]-9,10-anthracenedione[10] (**1**) have exhibited good antineoplastic activities.[11]

Also, it has been well known that significant cytotoxic activity is always associated with aminoglycosides of the parent nucleus of anthracycline antibiotics.[12] This seems to be due to an electrostatic interaction between the phosphate group of the DNA molecules and the amino groups of a sugar moiety in the antibiotics.

While, in a series of anthracenedione derivatives, it has never been established that whether a glycosidation of the nucleus does improve its cytotoxic activity or not. To clarify this interesting problem, seven glycosides of **1** have been prepared, and their preliminary antineoplastic activity has been determined against leukemia L1210 in mice.

Results and Discussion

Preferential mono-*N*-acetylation of **1** with acetic anhydride in methanol gave 4-[2-(*N*-acetyl-2-hydroxyethylamino)ethylamino]-1-hydroxy-9,10-anthracenedione (**2**) in 74% yield. Protection of the primary hydroxyl group of **2** with trityl chloride in pyridine afforded the compound (**3**) in 90% yield. Successive acetylation of **3** with acetic anhydride in pyridine gave the two compound (**4**) and (**5**) in 59 and 33% yield, respectively. Selective *O*-deacetylation of **4** gave the aglycon (**6**) in 94% yield.

Condensation of **6** with acetobromoglucose in the presence of silver carbonate and quinoline afforded the product (**7**) in 84% yield. Detritylation of **7** with aqueous acetic acid and successive *O*-deacetylation in methanolic ammonia gave the compound (**9**). An attempt was made to remove *N*-acetyl groups on the side chain by alkaline hydrolysis, but it was failed, owing to a cleavage of the glycosidic linkage.[13]

An alternative protective group was used, instead of the acetyl group, to cleave *N*-acetyl bond under more mild conditions. Treatment of **1** with di-*t*-butyl dicarbonate resulted in a formation of 4-[2-(*N*-*t*-butoxycarbonyl-2-hydroxyethylamino) ethylamino]-1-hydroxy-9,10-anthracenedione (**10**) in 80% yield.

Tritylation of **10** gave the compound (**11**) in 77% yield. Acetylation of **11** in an appropriate conditions yielded preferentially *O*-acetyl derivative (**12**) in 95% yield. Treatment of **12** with trifluoroacetic anhydride in pyridine gave the compound (**13**) in 68% yield by causing a scission of the *O*-acetyl bond.

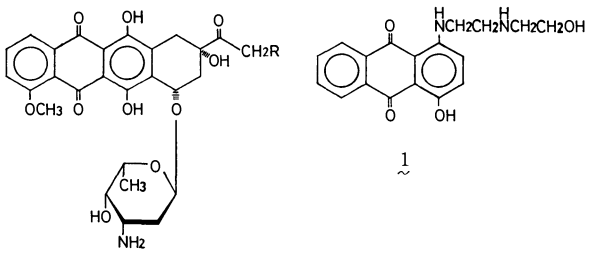
Direct *N*-acylation of **11** with trifluoroacetic anhydride in pyridine yielded a complex mixture which could not be able to isolate **13** in a good yield.

Condensation of **13** with acetobromoglucose in the presence of silver carbonate and quinoline afforded the product (**14**) in 80% yield.

Complete deprotection of **14** gave the aimed 1-(β-D-glucopyranosyloxy)-4-[2-(2-hydroxyethylamino)-ethylamino]-9,10-anthracenedione (**16**) in 48% yield. The structure of **16** was confirmed by converting **16** into hepta-*N*,*O*-acetyl derivative (**17**) which was determined by ^{1}H NMR spectroscopy.

Using the same aglycon **13** and the analogous condensation procedure, six 1-*O*-glycosyl analogs have been synthesized. The sugar moieties used are β-D-galactopyranosyl, 6-deoxy-β-D-glucopyranosyl, α-L-rhamnopyranosyl, 2-acetamido-2-deoxy-β-D-glucopyranosyl, 3-acetamido-3-deoxy-β-D-glucopyranosyl and β-cellobiosyl residues.

The preliminary determination of antineoplastic activity against leukemia L1210 in mice revealed that the glycosidation of the 1-*O*-hydroxyl group in **1** was



Doxorubicin R=OH
Daunorubicin R=H

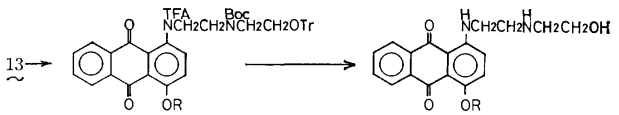
not hopeful in the production of large increase of life span in the leukemia L1210 transplanted mice. Details of the determination of antineoplastic activity will be reported elsewhere.

Experimental

General Methods. Melting points were determined on a Büchi 510 capillary melting point apparatus and are uncorrected. Solutions were concentrated under reduced pressure below 50 °C. The optical rotation were measured on a Japan Spectroscopic DIPL-SL polarimeter. The IR spectra were recorded with a Hitachi 225 spectrophotometer and expressed in reciprocal centimeters. The UV spectra were measured with a Japan Spectroscopic UVIDEC-1



14	2,3,4,6-tetra-*O*-acetyl-*β*-D-glucopyranosyl	**16**	*β*-D-glucopyranosyl

spectrophotometer. ^{1}H NMR spectra were taken on a Varian EM-390 (90 MHz) spectrometer in chloroform-*d* with reference to tetramethylsilane as an internal standard. The chemical shifts are given in *δ*-values and *J*-values given are of first-order. TLC was performed on precoated silica gel 60 F-254 plaques (Merk, Darmstadt; 0.25 mm thickness). The silica gel used for a column chromatography was Wakogel C-200 (Wako Pure Chemical Co. Ltd.).

4-[2-(N-Acetyl-2-hydroxyethylamino)ethylamino]-1-hydroxy-9,10-anthracenedione (2). To a stirred solution of **1** (100 mg) in methanol (6 ml), acetic anhydride (0.3 ml) was added at room temperature. After 45 min, the solution was stand at 0—5 °C overnight. The products were collected by filtration and recrystallized from ethanol to give 84 mg (74%) of **2**, mp 149—150 °C; UV ($CHCl_3$) 253 (log *ε*, 4.56), 287 (3.89), 555 (4.09), 593 nm (4.04). ^{1}H NMR (pyridine-d_5): *δ*=2.27 (3H, s, NAc), 7.21 (1H, s, H-3), 7.32 (1H, s, H-2), 7.53—7.78 (2H, m, H-6 and 7), 8.18—8.43 (2H, m, H-5 and 8), 10.45 (1H, bs, aromatic NH).

Found: C, 63.92; H, 5.44; N, 7.15%. Calcd for $C_{20}H_{20}N_2O_5 \cdot 1/2\,H_2O$: C, 63.65; H, 5.61; N, 7.42%.

4-[2-[N-Acetyl-2-(trityloxy)ethylamino]ethylamino]-1-hydroxy-9,10-anthracenedione (3). To a stirred solution of **2** (1.00 g) in pyridine (90 ml), trityl chloride (4.53 g) was added at 50 °C. After 65 h, the mixture was concentrated, and the residue was dissolved in chloroform. The chloroform solution was washed with water, dried over anhydrous Na_2SO_4 and concentrated. The residue was purified on a column using 1:3 (v/v) ethyl acetate–toluene. Fractions homogeneous (R_f 0.36) on TLC in the same solvent were combined and concentrated. The residue was recrystallized from chloroform–petroleum ether to give 1.49 g (90%) of **3**, mp 238—240 °C; UV ($CHCl_3$) 556 (log *ε*, 4.24), 594 nm (4.21). ^{1}H NMR: *δ*=2.13 (3H, s, NAc), 3.20—3.73 (8H, m, CH_2 of side chain), 7.13—7.43 (17H, m, H-2,3 and $C(C_6\underline{H}_5)_3$), 7.65—7.83 (2H, m, H-6 and 7), 8.23—8.40 (2H, m, H-5 and 8), 10.28 (1H, bs, aromatic NH), 13.68 (1H, s, 1-OH).

Found: C, 74.83; H, 5.66; N, 4.42%. Calcd for $C_{39}H_{34}N_2O_5 \cdot H_2O$: C, 74.50, H, 5.77; N, 4.46%.

1-Acetoxy-4-[N-acetyl-2-[N-acetyl-2-(trityloxy)ethylamino]ethylamino]-9,10-anthracenedione (4) and 1-Acetoxy-4-[2-[N-acetyl-2-(trityloxy)ethylamino]ethylamino]-9,10-anthracenedione (5). To a solution of **3** (300 mg) in pyridine (10 ml), acetic anhy-

dride (8 ml) was added. After 24 h at 100 °C, the mixture was concentrated, and the residue was dissolved in ethyl acetate. The solution was washed with sat. $NaHCO_3$ solution, H_2O dried over anhydrous Na_2SO_4 and concentrated. The residue was purified on the column using 15:1 (v/v) benzene–ethyl acetate. Fractions homogeneous (R_f 0.22) on TLC in 3:1 (v/v) benzene–ethyl acetate were concentrated and recrystallized from methanol to give 203 mg (59%) of **4**, mp 168—170 °C; UV ($CHCl_3$) 320 (log ε, 3.97), 348 (4.04), 408 nm (3.73); IR (KBr) 1765 (phenolic Ac), 1710 (aromatic NAc), 1655 (quinone), 1625 cm^{-1} (NAc). ^1H NMR; δ=2.20 (3H, s, NAc), 2.48 (3H, s, phenolic Ac), 2.62 (3H, s, aromatic NAc), 3.22—3.67 (6H, m, NAc-$CH_2C\underline{H}_2NAcC\underline{H}_2C\underline{H}_2OTr$), 4.25—4.55 (2H, m, NAc-$C\underline{H}_2CH_2NAc$), 7.09—7.48 (16H, m, aromatic protonand $C(C_6\underline{H}_5)_3$), 7.53—7.73 (2H, m, aromatic protons), 7.82—8.00 (1H, m, aromatic proton), 8.23—8.48 (2H, m, H-5 and 8).

Found: C, 74.06; H, 5.34; N, 3.78%. Calcd for $C_{43}H_{38}N_2O_7$: C, 74.34; H, 5.51; N, 4.03%.

Fractions homogeneous (R_f 0.38) on TLC in 3:1 (v/v) benzene–ethyl acetate were concentrated and the residue was recrystallized from methanol to give 106 mg (33%) of **5**, mp 146—148 °C; UV ($CHCl_3$) 249 (log ε, 4.52), 277 (3.99), 321 (3.77), 508 nm (3.83); IR (KBr) 1775 (phenolic Ac), 1670 (quinone), 1635 cm^{-1} (quinone and NAc). ^1H NMR: δ=2.12 (3H, s, NAc), 2.39 (3H, s, phenolic Ac), 3.18—3.52 (8H, CH_2 of side chain), 7.09—7.42 (17H, m, H-2,3 and $C(C_6\underline{H}_5)_3$), 7.52—7.73 (2H, m, H-6 and 7), 8.00—8.22 (2H, m, H-5 and 8), 9.95 (1H, bs, aromatic NH).

Found: C, 73.79; H, 5.79; N, 4.04%. Calcd for $C_{41}H_{36}N_2O_6\cdot H_2O$: C, 73.42; H, 5.71; N, 4.18%.

4-[N-Acetyl-2-[N-acetyl-2-(trityloxy)ethylamino]ethylamino]-1-hydroxy-9,10-anthracenedione (6). To a stirred solution of **4** (150 mg) in ethanol (10 ml), 1 M NaOH (1 M=1 mol dm^{-3}) solution (8 ml) was added. After 24 h, 1 M HCl solution (8 ml) was added to the mixture. Pecipitated solids were collected, washed with water, and dissolved in chloroform. After drying over anhydrous Na_2SO_4, the solution was concentrated, and the residue was purified on a column using 10:1 (v/v) benzene–ethyl acetate. Fractions homogeneous (R_f 0.20) in 3:1 (v/v) benzene–ethyl acetate were combined and concentrated. The residue was recrystallized from ethanol to give 132 mg (94%) of **6**, mp 257—258 °C; UV ($CHCl_3$) 313 (log ε, 4.36), 348 (4.42), 503 nm (4.23); IR (KBr) 1710 cm^{-1} (aromatic NAc), 1650 (quinone), 1625 (quinone and NAc). ^1H NMR: δ=2.18 (3H, s, NAc), 2.70 (3H, s, aromatic NAc), 3.20—3.67 (6H, m, $NAcCH_2C\underline{H}_2$-$NAcC\underline{H}_2CH_2OTr$), 4.27—4.53 (2H, m, $NAcC\underline{H}_2CH_2NAc$), 7.10—7.47 (16H, m, aromatic proton and $C(C_6H_5)_3$), 7.57—7.77 (2H, m, aromatic protons), 7.92—8.07 (1H, m, aromatic proton), 8.30—8.57 (2H, m, H-5 and 8).

Found: C, 75.57; H, 5.62; N, 4.04%. Calcd for $C_{41}H_{36}N_2O_6$: C, 75.44; H, 5.56; N, 4.29%.

1-(2,3,4,6-Tetra-O-acetyl-β-D-glucopyranosyloxy)-4-[N-acetyl-2-[N-acetyl-2-(trityloxy)ethylamino]ethylamino]-9,10-anthracenedione (7). To a solution of **6** (100 mg) in quinoline (3 ml) and benzene (3 ml), acetobromoglucose (202 mg) and silver carbonate (218 mg) were added in the dark. The mixture was stirred for 47 h at room temperature, the insoluble materials were removed by filtration, and then the filtrate was diluted with benzene. The solution was washed with 5% H_2SO_4, sat. $NaHCO_3$ solution and water. After drying over anhydrous Na_2SO_4, the solution was concentrated, and the residue was purified on a column using 3:1 (v/v) benzene–ethyl acetate. Fractions homogeneous (R_f 0.28) on TLC in 1:1 (v/v) benzene–ethyl acetate were concentrated and the residue was resolidified with benzene–hexane to give 127 mg (84%) of **7**, mp 123—129 °C; $[\alpha]_D^{22}$ −17.1° (*c* 0.55, $CHCl_3$); UV (EtOH) 325 (log ε, 4.24), 348 (4.28), 430 nm (4.04). ^1H NMR: δ=2.03 (6H, s, Ac×2), 2.08 (3H, s, Ac), 2.18 (6H, s, Ac×2), 2.62 (3H, s, aromatic NAc), 3.19—3.63 (6H, m, $NAcCH_2C\underline{H}_2NAcC\underline{H}_2C\underline{H}_2$-OTr), 3.83 (1H, m, H-5′), 4.13—4.47 (4H, m, $NAcC\underline{H}_2$-CH_2NAc and H-6′), 5.03—5.47 (4H, m, H-1′, 2′, 3′, and 4′), 7.06—7.40 (16H, m, aromatic proton and $C(C_6\underline{H}_5)_3$), 7.50—7.70 (2H, m, aromatic protons), 7.77—7.90 (1H, m, aromatic proton), 8.30—8.43 (2H, m, H-5 and 8).

Found: C, 66.94; H, 5.60; N, 2.67%. Calcd for $C_{55}H_{54}N_2O_{15}$: C, 67.20; H, 5.54; N, 2.85%.

1-(2,3,4,6-Tetra-O-acetyl-β-D-glucopyranosyloxy)-4-[N-acetyl-2-(N-acetyl-2-hydroxyethylamino)ethylamino]-9,10-anthracenedione (8). A solution of **7** (600 mg) in 80% aqueous acetic acid (10 ml) was heated for 40 min at 100 °C. The solution was concentrated and the residue was purified on a column using 1:10 (v/v) ethanol–toluene. Fractions homogeneous (R_f 0.20) on TLC in 1:5 (v/v) ethanol–toluene were combined and concentrated. The residue was resolidified with benzene–hexane to give 367 mg (81%) of **8**. ^1H NMR: δ=2.03 (6H, s, Ac×2), 2.10 (3H, s, Ac), 2.15 (3H, s, Ac), 2.18 (3H, s, Ac), 2.58 (3H, s, aromatic NAc), 3.42—3.95 (7H, m, H-5′ and $NAcCH_2C\underline{H}_2NAcC\underline{H}_2C\underline{H}_2OTr$), 4.12—4.60 (4H, m, H-6′ and $NAcC\underline{H}_2CH_2NAc$), 5.00—5.47 (4H, m, H-1′, 2′, 3′, and 4′), 7.47—7.90 (4H, m, H-2,3,6, and 7), 8.17—8.38 (2H, m, H-5 and 8).

4-[N-Acetyl-2-(N-acetyl-2-hydroxyethylamino)ethylamino]-1-(β-D-glucopyranosyloxy)-9,10-anthracenedione (9). A solution of **8** (300 mg) in methanolic ammonia (5 ml) was stirred for 24 h at 0—5 °C. The solution was concentrated and the residue was washed with hot methanol to give 203 mg (88%) of **9** as yellow solid, mp 218—220 °C; UV (H_2O) 225 (log ε, 4.65), 314 (4.01), 352 (4.07), 427 nm (3.88). ^1H NMR (pyridine-d_5): δ=2.20 (3H, s, NAc), 2.77 (3H, s, aromatic NAc), 5.33 (1H, d, J=7.5 Hz, H-1′), 7.40—7.55 (2H, m, H-2 and 3), 7.87—8.05 (2H, m, H-6 and 7), 8.22—8.43 (2H, m, H-5 and 8).

Found: C, 58.88; H, 5.45; N, 4.64%. Calcd for $C_{28}H_{32}N_2O_{11}$: C, 58.74; H, 5.63; N, 4.89%.

4-[2-[N-(t-Butoxycarbonyl)-2-hydroxyethylamino]ethylamino]-1-hydroxy-9,10-anthracenedione (10). To a stirred solution of **1** (1.00 g) in 1 M NaOH solution (8 ml) and dioxane (12 ml), di-*t*-butyl dicarbonate (2.00 g) was added. After 1 h, 1 M HCl solution (8 ml) was added to the mixture and the solution was extracted with ethyl acetate. The Organic layer was washed with water, dried over anhydrous Na_2SO_4, and concentrated. The residue was purified on a column using 2:1 (v/v) benzene–ethyl acetate. Fractions homogeneous (R_f 0.26) on TLC in 1:1 (v/v) benzene–ethyl acetate were concentrated to give 1.04 g (80%) of **10** as amorphous solid; UV ($CHCl_3$) 253 (log ε, 4.58), 291 (3.88), 558 (4.11), 608 nm (4.07). ^1H NMR: δ=1.47 (9H, s, Boc), 2.57 (1H, bs, $CH_2CH_2O\underline{H}$), 3.28—3.55 (6H, m, $NHC\underline{H}_2$-$C\underline{H}_2N(Boc)C\underline{H}_2CH_2OH$), 3.73 (2H, t, J=4.5 Hz, $CH_2C\underline{H}_2$-OH), 7.10 (2H, d, J=3.0 Hz, H-2 and 3), 7.52—7.72 (2H, m, H-6 and 7), 8.05—8.22 (2H, m, H-5 and 8), 10.13 (1H, bs, aromatic NH), 13.47 (1H, s, 1-OH).

Found: C, 64.93; H, 6.13; N, 6.32%. Calcd for $C_{23}H_{26}N_2O_6$: C, 64.93; H, 5.92; N, 6.58%.

4-[2-[N-(t-Butoxycarbonyl)-2-(trityloxy)ethylamino]ethylamino]-1-hydroxy-9,10-anthracenedione (11). To a stirred solution of **10** (966 mg) in pyridine (30 ml), trityl chloride (1.89 g) was added. After 24 h at 50 °C, the mixture was poured into ice-cooled water, and the precipitates were collected. The product was purified on a column using 1:3 (v/v) ethyl

acetate–hexane. Fractions homogeneous (R_f 0.56) on TLC in the same solvent were concentrated, and the residue was recrystallized from hexane to give 1.16 g (77%) of **11**, mp 151—152 °C; UV ($CHCl_3$) 254 (log ε, 4.45), 294 (3.65), 559 (3.68), 601 nm (3.64). ^1H NMR: δ=1.30—1.56 (9H, m, Boc), 3.03—3.56 (8H, m, CH_2 of side chain), 7.00—7.40 (17H, m, H-2,3 and $C(C_6\underline{H}_5)_3$), 7.50—7.70 (2H, m, H-6 and 7), 8.10—8.27 (2H, m, H-5 and 8), 10.18 (1H, bs, aromatic NH), 13.47 (1H, s, 1-OH).

Found: C, 75.40; H, 6.32; N, 4.13%. Calcd for $C_{42}H_{40}N_2O_6$: C, 75.42; H, 6.03; N, 4.19%.

1-Acetoxy-4-[2-[N-(t-butoxycarbonyl)-2-(trityloxy)ethylamino]-ethylamino]-9,10-anthracenedione (12). Compound **11** (100 mg) was acetylated with acetic anhydride (3 ml) and pyridine (6 ml) for 20 h. The mixture was concentrated and the residue was purified on a column using 1:3 (v/v) ethyl acetate–hexane. Fractions homogeneous (R_f 0.25) on TLC in the same solvent were concentrated and the residue was recrystallized from hexane to give 101 mg (95%) of **12**, mp 85—88 °C; UV ($CHCl_3$) 250 (log ε, 4.66), 278 (4.19), 319 (4.03), 511 nm (4.01); IR (KBr) 1765 cm^{-1} (phenolic Ac), 1690 (NBoc), 1655 (quinone), 1630 (quinone). ^1H NMR: δ=1.27—1.48 (9H, m, Boc), 2.40 (3H, s, phenolic Ac), 3.03—3.63 (8H, m, CH_2 of side chain), 7.00—7.47 (17H, m, H-2,3 and $C(C_6\underline{H}_5)_3$), 7.52—7.77 (2H, m, H-6 and 7), 8.00—8.28 (2H, m, H-5 and 8), 10.00 (1H, bs, aromatic NH).

Found: C, 74.34; H, 6.22; N, 3.84%. Calcd for $C_{44}H_{42}N_2O_7$: C, 74.35; H, 5.96; N, 3.94%.

4-[2-[N-(t-Butoxycarbonyl)-2-(trityloxy)ethylamino]-N-(trifluoroacetyl)ethylamino]-1-hydroxy-9,10-anthracenedione (13). To a ice-cooled solution of **12** (300 mg) in pyridine (10 ml), trifluoroacetic anhydride (0.6 ml) was added with stirring, and the mixture was stirred for 21 h at room temperature. The mixture was poured into ice cold water, and the precipitates were filtered off. The product was purified on a column using 1:8 (v/v) ethyl acetate–hexane. Fractions homogeneous (R_f 0.45) on TLC in 1:3 (v/v) ethyl acetate–hexane were concentrated and solidified with hexane to give 276 mg (86%) of **13** as amorphous solid; UV ($CHCl_3$) 257 (log ε, 4.59), 338 (3.60), 402 nm (3.82); IR (KBr) 1700 (C=O, broad), 1640 (quinone). ^1H NMR: δ=1.30 (9H, s, Boc), 7.03—7.52 (17H, m, H-2,3 and $C(C_6\underline{H}_5)_3$), 7.63—7.83 (2H, m, H-6 and 7), 8.07—8.30 (2H, m, H-5 and 8), 13.10 (1H, s, 1-OH).

Found: C, 68.83; H, 5.42; N, 3.44%. Calcd for $C_{44}H_{39}N_2F_3O_7$: C, 69.10; H, 5.14; N, 3.66%.

1-(2,3,4,6-Tetra-O-acetyl-β-D-glucopyranosyloxy)-4-[2-[N-(t-butoxycarbonyl)-2-(trityloxy)ethylamino]-N-(trifluoroacetyl)ethylamino]-9,10-anthracenedione (14). To a stirred solution of **13** (1.35 g) in quinoline (5 ml) and benzene (5 ml), acetobromoglucose (2.18 g) and silver carbonate (916 mg) were added. After 54 h in the dark, the reaction mixture was filtered and the filtrate was diluted with benzene. The solution was washed with 5% H_2SO_4 solution, H_2O, sat. $NaHCO_3$ solution, H_2O, dried over anhydrous Na_2SO_4, and concentrated. The residue was purified on the column using 7:1 (v/v) benzene–ethyl acetate and 1:3 (v/v) ethyl acetate–hexane. Fractions homogeneous (R_f 0.52) on TLC in 1:1 (v/v) ethyl acetate–hexane were concentrated and recrystallized from cyclohexane to give 1.55 g (80%) of **14**, mp 113—118 °C; $[\alpha]_D^{22}$ −28.7° (*c* 0.53, $CHCl_3$); UV (EtOH) 255 (log ε, 4.55), 347 nm (3.68). ^1H NMR: δ=1.30 (9H, s, Boc), 2.02 (9H, s, Ac×3), 2.15 (3H, s, Ac), 4.98 (4H, m, H-1′2′,3′, and 4′), 7.07—7.43 (17H, m, H-2,3 and $C(C_6\underline{H}_5)_3$), 7.56—7.73 (2H, m, H-6 and 7), 7.93—8.12 (2H, m, H-5 and 8).

Found: C, 63.85; H, 5.45; N, 2.38%. Calcd for $C_{58}H_{57}N_2F_3O_{16}$: C, 63.61; H, 5.25; N, 2.56%.

1-(β-D-Glucopyranosyloxy)-4-[2-(2-hydroxyethylamino)ethylamino]-9,10-anthracenedione (16). Compound **14** (241 mg) was dissolved in trifluoroacetic acid (1 ml) under ice cooling and stirred at room temperature. The mixture was concentrated and the residue was purified on a column using 5:1 (v/v) benzene–ethanol. Fractions homogeneous (R_f 0.34) on TLC in 1:3 (v/v) benzene–ethanol were concentrated to give 116 mg of **15** as amorphous solid. The solid was dissolved in methanolic ammonia (5 ml) and the solution was stirred overnight at 0—5 °C. Precipitated solids were collected and washed with ethyl acetate–methanol to give 52 mg (48% from **14**) of **16**, mp 211—218 °C; UV (MeOH) 248 (log ε, 4.56), 280 (3.93), 526 nm (3.87); IR (KBr) 1640 cm^{-1}, 1630 (quinone).

Found: C, 58.42; H, 5.78; N, 5.52%. Calcd for $C_{24}H_{28}N_2O_9 \cdot 1/4\,H_2O$: C, 58.47; H, 5.83; N, 5.68%.

2-(2,3,4,6-Tetra-O-acetyl-β-D-glucopyranosyloxy)-4-[N-acetyl-2-(N-acetyl-2-aceloxyethylamino)ethylamino]-9,10-anthracenedione (17). Compound **16** (10 mg) was acetylated with acetic anhydride (1.5 ml) and pyridine (1.5 ml) at 100 °C. The mixture was diluted with ethyl acetate, washed with water, dried over anhydrous Na_2SO_4, and concentrated. The residue was solidified with benzene–hexane to give 13 mg (81%) of **17**, mp 102—112 °C; $[\alpha]_D^{23}$ −19.0° (*c* 0.62, $CHCl_3$); UV (EtOH) 208 (log ε, 4.91), 230 (4.92), 311 (4.31), 346 (4.34), 421 nm (4.12). ^1H NMR: δ=2.03 (3H, s, Ac), 2.05 (6H, s, Ac×2), 2.10 (3H, s, Ac), 2.17 (6H, s, Ac×2), 2.63 (3H, s, aromatic NAc), 3.45—3.91 (5H, m, $NAcCH_2C\underline{H}_2$-$NAcC\underline{H}_2CH_2OAc$ and H-5′), 4.10—4.66 (6H, m, $NHAc$-$C\underline{H}_2CH_2NAcCH_2C\underline{H}_2OAc$ and H-6′), 5.01—5.44 (4H, m, H-1′,2′,3′, and 4′), 7.49—7.93 (4H, m, H-2,3,6, and 7), 8.20—8.43 (2H, m, H-5 and 8).

Found: C, 58.44; H, 5.18; N, 3.27%. Calcd for $C_{38}H_{42}N_2O_{16}$: C, 58.31; H, 5.41; N, 3.85%.

Condensation of 13 with Halogen Sugars. Halogen sugars of galactose,[14] 6-deoxyglucose,[15] L-rhamnose,[16] cellobiose,[17] 2-acetamido-2-deoxyglucose,[18] 3-acetamido-3-deoxyglucose,[19] were prepared according to the authentic methods. The reaction procedure was analogous as described in the preparation of **14**.

1-(2,3,4,6-Tetra-O-acetyl-β-D-galactopyranosyloxy)-4-[2-[N-(t-butoxycarbonyl)-2-(trityloxy)ethylamino]-N-(trifluoroacetyl)ethylamino]-9,10-anthracenedione (18). Compound **18** was obtaine in 93% yield from **13** and showed a spot at R_f 0.45 on TLC in 1:1 (v/v) ethyl acetate–hexane; mp 118—125 °C; $[\alpha]_D^{20}$ −5.9° (*c* 1.05, $CHCl_3$); UV (EtOH) 225 (log ε, 4.83), 258 (4.75), 350 nm (3.80). ^1H NMR: δ=1.31 (9H, s, Boc), 2.02 (6H, s, Ac×2), 2.17 (6H, s, Ac×2), 7.07—7.43 (17H, m, H-2,3 and $C(C_6\underline{H}_5)_3$), 7.48—7.75 (2H, m, H-6 and 7), 7.83—8.20 (2H, m, H-5 and 8).

Found: C, 63.57; H, 5.43; N, 2.41%. Calcd for $C_{58}H_{57}N_2F_3O_{16}$: C, 63.61; H, 5.25; N, 2.56%.

1-(2,3,4-Tri-O-acetyl-6-deoxy-β-D-glucopyranosyloxy)-4-[2-[N-(t-butoxycarbonyl)-2-(trityloxy)ethylamino]-N-(trifluoroacetyl)-ethylamino]-9,10-anthracenedione (19). Compound **19** was obtained in 91% yield from **13** and showed a spot at R_f 0.42 on TLC in 1:3 (v/v) ethyl acetate–toluene; mp 146—148 °C; $[\alpha]_D^{24}$ −24.8° (*c* 1.16, $CHCl_3$); UV ($CHCl_3$) 256 (log ε, 4.62), 350 nm (3.71). ^1H NMR: δ=1.30 (12H, bs, Boc and H-6′), 2.00 (6H, s, Ac×2), 2.10 (3H, s, Ac), 4.67—5.47 (4H, m, H-1′,2′,3′, and 4′), 6.90—7.80 (19H, m, H-2,3,6,7 and $C(C_6\underline{H}_5)_3$), 7.80—8.23 (2H, m, H-5 and 8).

Found: C, 65.05; H, 5.54; N, 2.53%. Calcd for $C_{56}H_{55}N_2F_3O_{14}$: C, 64.86; H, 5.35; N, 2.70%.

1-(2,3,4-Tri-O-acetyl-α-L-rhamnopyranosyloxy)-4-[2-[N-(t-

butoxycarbonyl)-2-(trityloxy)ethylamino]-N-(trifluoroacetyl)ethylamino]-9,10-anthracenedione (20). Compound **20** was obtained in 42% yield from **13** and showed a spot at R_f 0.47 on TLC in 1:3 (v/v) ethyl acetate–toluene; mp 115—119 °C; $[\alpha]_D^{24}$ −24.6° (*c* 1.00, $CHCl_3$); UV ($CHCl_3$) 256 (log ε, 4.67), 354 nm (3.75). ^{1}H NMR δ=1.21 (3H, d, $J_{5',6'}$= 6.0 Hz, H-6'), 1.31 (9H, s, Boc), 2.03 (6H, (6H, s, Ac×2), 2.16 (3H, s, Ac), 6.97—7.77 (19H, m, H-2,3,6,7, and C(C$_6$H$_5$)$_3$), 7.80—8.27 (2H, m, H-5 and 8).

Found: C, 64.68; H, 5.35; N, 2.76%. Calcd for $C_{56}H_{55}N_2F_3O_{14}$: C, 64.86; H, 5.35; N, 2.70%.

1-(2,2',3,3',4',6,6'-Hepta-O-acetyl-β-cellobiosyloxy)-4-[2-[N-(t-butoxycarbonyl)-2-(trityloxy)ethylamino]-N-(trifluoroacetyl)-ethylamino]-9,10-anthracenedione (21). Compound **21** was obtained in 66% yield from **13** and showed a spot at R_f 0.45 on TLC in 1:3 (v/v) ethyl acetate–toluene; mp 131—139 °C; $[\alpha]_D^{27}$ −31.1° (*c* 0.52, $CHCl_3$); UV (EtOH) 214 (log ε, 4.61), 254 (4.51), 341 nm (3.70). ^{1}H NMR: δ= 1.30 (9H, s, Boc), 1.93 (3H, s, Ac), 1.97 (3H, s, Ac), 2.00 (3H, s, Ac), 2.07 (9H, s, Ac×3), 2.13 (3H, s, Ac), 6.91—7.43 (17H, m, H-2,3 and C(C$_6$H$_5$)$_3$), 7.53—7.79 (2H, m, H-6 and 7), 7.87—8.13 (2H, m, H-5 and 8).

Found: C, 60.51; H, 5.45; N, 1.95%. Calcd for $C_{70}H_{73}N_2F_3O_{24}$: C, 60.78; H, 5.31; N, 2.03%.

1-(2-Acetamido-3,4,6-tri-O-acetyl-2-deoxy-β-D-glucopyranosyloxy)-4-[2-[N-(t-butoxycarbonyl)-2-(trityloxy)ethylamino]-N-(trifluoroacetyl)ethylamino]-9,10-anthracenedione (22). Compound **22** was obtaine in 82% yield from **13** and showed a spot at R_f 0.32 on TLC in 1:3 (v/v) ethyl acetate–chloroform; mp 148—150 °C; $[\alpha]_D^{21}$ +29.2° (*c* 1.06, $CHCl_3$); UV ($CHCl_3$) 256 (log ε, 4.64), 345 nm (3.71). ^{1}H NMR: δ= 1.32 (9H, s, Boc), 2.00 (3H, s, Ac), 2.03 (6H, s, Ac×2), 2.07 (3H, s, Ac), 6.43 (1H, d, *J*=9.0 Hz, NHAc), 7.07—7.47 (17H, m, H-2,3 and C(C$_6$H$_5$)$_3$), 7.50—7.85 (2H, m, H-6 and 7), 7.90—8.20 (2H, m, H-5 and 8).

Found: C, 63.44; H, 5.44; N, 3.85%. Calcd for $C_{58}H_{58}N_3F_3O_{15}$: C, 63.67; H, 5.34; N, 3.84%.

1-(3-Acetamido-2,4,6-tri-O-acetyl-3-deoxy-β-D-glucopyranosyloxy)-4-[2-[N-(t-butoxycarbonyl)-2-(trityloxy)ethylamino]-N-(trifluoroacetyl)ethylamino]-9,10-anthracenedione (23). Compound **23** was obtained in 62% yield from **13** and showed a spot at R_f 0.24 on TLC in 1:1 (v/v) ethyl acetate–chloroform; mp 182—186 °C; $[\alpha]_D^{21}$ +10.8° (*c* 1.01, $CHCl_3$); UV (EtOH) 211 (log ε, 4.61), 254 (4.52), 346 nm (3.63). ^{1}H NMR: δ=1.34 (9H, s, Boc), 1.85 (3H, s, Ac), 2.07 (3H, s, Ac), 2.19 (6H, s, Ac×2), 7.10—7.52 (17H, m, H-2,3 and C(C$_6$H$_5$)$_3$), 7.56—7.96 (2H, m, H-6 and 7), 8.01—8.32 (2H, m, H-5 and 8).

Found: C, 63.75; H, 5.50; N, 3.72%. Calcd for $C_{58}H_{58}N_3F_3O_{15}$: C, 63.67; H, 5.34; N, 3.84%.

Deprotection of **18**, **19**, **20**, **21**, **22**, *and* **23**. Deprotection was worked up with trifluoroacetic acid and methanolic ammonia analogously as described in the preparation of **16**.

1-(β-D-Galactopyranosyloxy)-4-[2-(2-hydroxyethylamino)ethylamino]-9,10-anthracenedione (24). Compound **24** was obtained in 52% yield from **18**; mp 202—205 °C; IR (KBr) 1655 cm^{-1} and 1630 (quinone).

Found: C, 58.02; H, 5.73; N, 5.44%. Calcd for $C_{24}H_{28}N_2O_9\cdot 1/2\,H_2O$: C, 57.94; H, 5.88; N, 5.63%.

1-(6-Deoxy-β-D-glucopyranosyloxy)-4-[2-(2-hydroxyethylamino)-ethylamino]-9,10-anthracenedione (25). Compound **25** was obtained in 26% yield from 19; mp 175—180 °C; IR (KBr) 1655 cm^{-1} and 1630 (quinone).

Found: C, 58.50; H, 5.84; N, 5.38%. Calcd for $C_{24}H_{28}N_2O_8\cdot H_2O$: C, 58.76; H, 6.17; N, 5.71%.

4-[2-(2-Hydroxyethylamino)ethylamino]-1-(α-L-rhamnopyranosyloxy)-9,10-anthracenedione (26). Compound **26** was obtained in 39% yield from 20; mp 162—164 °C; IR (KBr) 1655 cm^{-1} and 1630 (quinone).

Found: C, 58.69; H, 5.94; N, 5.79%. Calcd for $C_{24}H_{28}N_2O_8\cdot H_2O$: C, 58.76; H, 6.17; N, 5.71%.

4-[2-(2-Hydroxyethylamino)ethylamino]-1-(β-cellobiosyloxy)-9,10-anthracenedione (27). Compound **27** was obtained in 43% yield from **21**; mp 198—206 °C; IR (KBr) 1645 cm^{-1} and 1620 (quinone).

Found: C, 53.79; H, 5.80; N, 4.26%. Calcd for $C_{30}H_{38}N_2O_{14}\cdot H_2O$: C, 53.88; H, 6.03; N, 4.19%.

1-(2-Acetamido-2-deoxy-β-D-glucopyranosyloxy)-4-[2-(2-hydroxyethylamino)ethylamino]-9,10-anthracenedione (28). Compound **28** was obtained in 53% yield from **22**; mp 186—189 °C; IR (KBr) 1650 cm^{-1} and 1625 (quinone).

Found: C, 57.24; H, 5.83; N, 7.31%. Calcd for $C_{26}H_{31}N_3O_9\cdot H_2O$: C, 57.03; H, 6.08; N, 7.67%.

1-(3-Acetamido-3-deoxy-β-D-glucopyranosyloxy)-4-[2-(2-hydroxyethylamino)ethylamino]-9,10-anthracenedione (29). Compound **29** was obtained in 40% yield from **23**; mp 118—121 °C; IR (KBr) 1650 cm^{-1} and 1625 (quinone).

Found: C, 58.18; H, 5.88; N, 7.30%. Calcd for $C_{26}H_{31}N_3O_9\cdot 1/2\,H_2O$: C, 57.99; H, 5.99; N, 7.80%.

Acetylation of **24**, **25**, **26**, **27**, **28**, *and* **29**. Acetylation was worked up with acetic anhydride and pyridine at room temperature.

1-(2,3,4,6-Tetra-O-acetyl-β-D-galactopyranosyloxy)-4-[2-(N-acetyl-2-acetoxyethylamino)ethylamino]-9,10-anthracenedione (30). Compound **30** was obtained in 81% yield from **24** and showed a spot at R_f 0.54 on TLC in 1:1 (v/v) acetone–toluene; mp 85—98 °C; UV (EtOH) 206 (log ε, 4.43), 247 (4.61), 316 (3.74), 511 nm (3.89). ^{1}H NMR: δ=1.99 (6H, s, Ac× 2), 2.01 (3H, s, Ac), 2.15 (3H, s, Ac), 2.19 (3H, s, Ac), 7.09—7.29 (2H, m, H-2 and 3), 7.37—7.74 (2H, m, H-6 and 7), 7.94—8.23 (2H, m, H-5 and 8).

Found: C, 58.05; H, 5.53; N, 3.62%. Calcd for $C_{36}H_{40}N_2O_{15}$: C, 58.38; H, 5.44; N, 3.62%.

1-(2,3,4-Tri-O-acetyl-6-deoxy-β-D-glucopyranosyloxy)-4-[2-(N-acetyl-2-acetoxyethylamino)ethylamino]-9,10-anthracenedione (31). Compound **31** was obtained in 66% yield from **25** and showed a spot at R_f 0.53 on TLC in 1:5 (v/v) ethanol–toluene; mp 101—103 °C; UV ($CHCl_3$) 250 (log ε, 4.53), 276 (4.00), 320 (3.72), 516 nm (3.85). ^{1}H NMR: δ=1.22 (3H, d, $J_{5',6'}$=3.0 Hz, H-6'), 2.00 (6H, s, Ac×2), 2.02 (3H, s, Ac), 2.10 (3H, s, Ac), 2.15 (3H, s, Ac), 4.70—5.37 (4H, m, H-1',2',3', and 4'), 7.30 (1H, d, *J*=9.0 Hz, aromatic proton), 7.52 (1H, d, *J*=9.0 Hz, aromatic proton), 7.60—7.83 (2H, m, H-6 and 7), 7.97—8.30 (2H, m, H-5 and 8), 10.11 (1H, bs, aromatic NH).

Found: C, 60.07; H, 5.62; N, 3.89%. Calcd for $C_{34}H_{38}N_2O_{13}$: C, 59.82; H, 5.61; N, 4.10%.

1-(2,3,4-Tri-O-acetyl-α-L-rhamnopyranosyloxy)-4-[2-(N-acetyl-2-acetoxyethylamino)ethylamino]-9,10-anthracenedione (32). Compound **32** was obtained in 97% yield from **26** and showed a spot at R_f 0.49 on TLC in 1:5 (v/v) ethanol–toluene; mp 192—194 °C; UV ($CHCl_3$) 249 (log ε, 4.71), 276 (4.18), 320 (3.88), 514 nm (4.04). ^{1}H NMR: δ=1.20 (3H, d, $J_{5',6'}$=6.0 Hz, H-6'), 2.03 (3H, s, Ac), 2.06 (6H, s, Ac× 2), 2.12 (3H, s, Ac), 2.18 (3H, s, Ac), 4.93—6.00 (4H, m, H-1',2',3', and 4'), 7.13—7.50 (2H, m, H-2 and 3), 7.56—7.98 (2H, m, H-6 and 7), 8.03—8.43 (2H, m, H-5 and 8), 10.10 (1H, bs, aromatic NH).

Found: C, 59.81; H, 5.66; N, 3.87%. Calcd for $C_{34}H_{38}N_2O_{13}$: C, 59.82; H, 5.61; N, 4.10%.

1-(2,2',3,3',4',6,6'-Hepta-O-acetyl-β-cellobiosyloxy)-4-[2-(N-acetyl-2-acetoxyethylamino)ethylamino]-9,10-anthracenedione (33). Compound **33** was obtained in 86% yield from **27** and showed

a spot at R_f 0.53 on TLC in 1:3 (v/v) ethanol–toluene; mp 162—164 °C; UV (EtOH) 247 (log ε, 4.64), 271 (3.99), 316 (3.72), 509 nm (3.95). ^{1}H NMR: δ=1.97 (3H, s, Ac), 1.98 (3H, s, Ac), 1.99 (3H, s, Ac), 2.01 (3H, s, Ac), 2.07 (3H, s, Ac), 2.08 (3H, s, Ac), 2.09 (3H, s, Ac), 2.14 (3H, s, Ac), 2.17 (3H, s, Ac), 7.30 (1H, d, J=6.5 Hz, aromatic proton), 7.50 (1H, d, J=6.5 Hz, aromatic proton), 7.60—7.78 (2H, m, H-6 and 7), 8.13—8.33 (2H, m, H-5 and 8), 10.11 (1H, bs, aromatic NH).

Found: C, 55.94; H, 5.58; N, 2.58%. Calcd for $C_{48}H_{56}N_2O_{23}$: C, 56.03; H, 5.49; N, 2.72%.

*1-(2-Acetamido-3,4,6-tri-O-acetyl-2-deoxy-β-D-glucopyranosyloxy)-4-[2-(N-acetyl-2-acetoxyethylamino)ethylamino]-9,10-anthracenedione (**34**).* Compound **34** was obtained in 70% yield from **28** and showed a spot at R_f 0.26 on TLC in 1:2 (v/v) acetone–chloroform; mp 179—182 °C; UV ($CHCl_3$) 250 (log ε, 4.70), 280 (4.17), 319 (3.96), 514 nm (4.00). ^{1}H NMR: δ=1.99 (3H, s, Ac), 2.03 (3H, s, Ac), 2.05 (9H, s, Ac×3), 2.13 (3H, s, Ac), 3.33—3.80 (6H, m, NHC$\underline{H}_2$-C$\underline{H}_2$N(Ac)C$\underline{H}_2$CH_2OAc), 3.87—4.47 (6H, m, H-2′,5′,6′, and CH_2C$\underline{H}_2$OAc), 4.87—5.33 (3H, m, H-1′,3′,4′), 7.03 (1H, bd, J=6.0 Hz, N$\underline{H}$Ac), 7.22 (1H, d, J=9.0 Hz, aromatic proton), 7.41 (1H, d, J=9.0 Hz, aromatic proton), 7.53—7.83 (2H, m, H-6 and 7), 7.90—8.30 (2H, m, H-5 and 8), 9.93—10.20 (1H, bs, aromatic NH).

Found: C, 58.25; H, 5.60; N, 5.49%. Calcd for $C_{36}H_{41}N_3O_{14}$: C, 58.45; H, 5.59; N, 5.68%.

*1-(3-Acetamido-2,4,6-tri-O-acetyl-3-deoxy-β-D-glucopyranosyloxy)-4-[2-(N-acetyl-2-acetoxyethylamino)ethylamino]-9,10-anthracenedione (**35**).* Compound **35** was obtained in 93% yield from **29** and showed a spot at R_f 0.52 on TLC in 1:3 (v/v) ethanol–toluene; mp 96—106 °C; UV (EtOH) 205 (log ε, 4.51), 247 (4.61), 514 nm (3.91). ^{1}H NMR: δ=1.81 (3H, s, Ac), 2.05 (6H, s, Ac×2), 2.15 (3H, s, Ac), 2.18 (6H, s, Ac×2), 3.43—3.76 (6H, m, NHC$\underline{H}_2$C$\underline{H}_2$N(Ac)-CH_2CH_2OAc), 4.01—4.69 (6H, m, H-3′,5′,6′ and CH_2C$\underline{H}_2$-OAc), 5.06—5.60 (3H, m, H-1′,2′, and 4′), 7.37—7.82 (3H, m, aromatic protons), 8.00—8.32 (3H, m, aromatic protons), 10.06 (1H, bs, aromatic NH).

Found: C, 58.30; H, 5.68; N, 5.80%. Calcd for $C_{36}H_{41}N_3O_{14}$: C, 58.45; H, 5.59; N, 5.68%.

The authors wish to express their thanks to Dr. Iwao Umezawa for his evaluation of the antineoplastic activity and to Mr. Saburo Nakada for his elementary analysis.

Pseudo-sugars. VIII. Synthesis of DL-1-Epivalidamine and Related Compounds[1,2]

Seiichiro OGAWA, Masayuki OYA, Tatsushi TOYOKUNI, Noritaka CHIDA, and Tetsuo SUAMI*

Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223

(Received November 11, 1982)

DL-1-Epivalidamine has been synthesized starting from the dianhydro compound derived from DL-1,2,3-tri-*O*-acetyl-(1,3/2,4,6)-4-bromo-6-bromomethyl-1,2,3-cyclohexanetriol. DL-7-Amino-7-deoxy-1-epivalidamine, which is considered to be a homolog of 2-deoxystreptamine, has also been prepared.

In connection with the previous paper of this series,[3] the 1-epimer of validamine and its derivatives have been synthesized regioselectively from the dianhydro derivative of (hydroxymethyl)cyclohexanetetrol.

It was described that the nucleophilic substitution reaction of DL-1,2,3-tri-*O*-acetyl-(1,3/2,4,6)-4-bromo-6-bromomethyl-1,2,3-cyclohexanetriol (**1**)[3] with an azide ion proceeded specifically through an S_N2 mechanism to give the diazido compound with an inversion of the configuration at C-4.[3] On the other hand, attempted introduction of an azido function at C-4 with retention of the configuration have been made *via* an intermediate cyclic 3,4-acetoxonium ion or a 3,4-epoxide,[4] but all failed probably due to a steric hindrance of a bulky substituent at C-6 and/or a ready anchimeric assistance of the C-2 acetoxyl group at C-3. Therefore, in order to control the course of a nucleophilic attack at the oxirane ring, the 2,7-anhydro ring was introduced to protect the C-2 hydroxyl group and to restrict a conformational flexibility. Thus, treatment of **1** with an excess of methanolic sodium methoxide at reflux for 2 h gave selectively the dianhydro compound **2** in 65% yield. The structure of **2** was confirmed on the basis of analytical data and ^{1}H NMR spectroscopy. In the ^{1}H NMR spectrum, the signal due to the C-7 endo proton appeared as a doublet (J_{gem}=9 Hz) at δ 3.75, which would correspond to the dihedral angle $\Phi_{5,7endo}$ (90°) ($J_{5,7endo}$= *ca.* 0 Hz) derived from a Dreiding model.

A nucleophilic substitution reaction of **2** with a methoxide ion or azide ion occurred regiospecifically at C-1 to give, after successive acetylation, the methyl ether **3** (87%) or the azide **4** (81%). An attack of an anion at C-2 seemed to be hindered by the ring oxygen atom. The structures were established by the ^{1}H NMR spectra. In the spectrum of **3**, the signal for the C-7 endo proton was remarkably deshielded (*ca.* 0.25 ppm) by a close proximity of the endo methoxyl group. Compound **4** was hydrogenated in ethanol in the presence of Raney nickel followed by acetylation to give the amine acetate **5** in 40% yield, which was alternatively prepared in 74% yield by ammonolysis of **2** in methanol followed by acetylation. *O*-Deacetylation of **5** with methanolic sodium methoxide followed by the conventional tosylation gave the ditosylate **6** in 45% overall yield. Opening of the anhydro ring of **3** was effected by heating in acetic acid–acetic anhydride (1:1) in a sealed tube at 85 °C for 20 h to give DL-2,3,4-tri-*O*-acetyl-1-*O*-methyl-(1,3,5/2,4)-5-acetoxymethyl-1,2,3,4-cyclohexanetetrol (**7**) in 39% yield.

Scheme 2.

The anhydro ring of **5** was cleaved readily by the influence of 30% hydrobromic acid in acetic acid in a sealed tube at 75 °C for 23 h to give DL-1,2,3-tri-*O*-acetyl-(1,3/2,4,6)-4-acetamido-6-bromomethyl-1,2,3-cyclohexanetriol (**8**, 67%). Similarly, the corresponding bromo ditosylate **12** was obtained from **6** in 45% yield. The ^{1}H NMR spectrum of **12** was in fully accord with the assigned structure, establishing the ring structure of **4**.

The C-7 bromine atom of **8** was easily displaced by an acetate ion or an azide ion in the usual way to produce a peracetyl 1-epivalidamine (**9**, 61%) or the azido compound (**10**, 90%). Compound **10** was reduced with Raney nickel and successively acetylated to give the diamine diacetate **11** in 92% yield. Acid hydrolysis of **9** and **11** with 6 M hydrochloric acid

(1 M=1 mol dm^{-3}) at reflux for 2 h gave the hydrochloride **13** and the dihydrochloride **14** in quantitatively yields, respectively.

Compound **13** was pseudo-β-DL-glucopyranosylamine, and **14** was considered to be a homolog of 2-deoxystreptamine, a common constituent of clinically important aminocyclitol containing antibiotics.[5] Therefore, biological activities of antibiotics being replaced the 2-deoxystreptamine moiety with this homolog may be of considerable interest.

Interest in a reactivity of the stereoisomer **21** of **2** stimulated us to prepare it from (bromomethyl)cyclohexenediol diacetate **15**.[1] Treatment of **15** with bromine in aqueous acetic acid at room temperature afforded, after chromatography on silica gel, three dibromides **16** (34%), **19** (1.4%), and **20** (16%), and one tribromide **18** (0.7%). The ^{1}H NMR spectrum of triacetate **17** derived from **16** was interpreted by a first-order method, confirming the assigned structure. Mechanistically, an intermediate α-bromonium ion was opened by the adjacent trans acetoxyl group followed by acetyl group migration to give **16**, whereas, a β-bromonium ion was attacked from the rear side by nucleophiles present.[6] A similar treatment of **16** with an excess of methanolic sodium methoxide gave **21** in 84% yield. The ^{1}H NMR spectrum of **21** showed the signal for the C-7 endo proton as a doublet (J_{gem}=9.3 Hz) at δ 3.87 somewhat higher-field as compared with that of the *exo*-epoxide **2**.

In contrast with the case of **2**, a nucleophilic substitution reaction of **21** with an azide ion was shown to be very slow and give a complex mixture of products after a prolonged reaction time. The C-4 endo acetoxyl group seemed to interfere the attack of a nucleophile at C-1 or C-2. Therefore, the epoxide **22** was prepared by treatment of **15** with *m*-chloroperoxybenzoic acid in 1,2-dichloroethane in 23% yield.[7] Reaction of **22** with sodium azide and ammonium chloride in aqueous *N*,*N*-dimethylformamide gave selectively the diazide **24** in 65% yield. When the similar reaction was carried out in the absence of ammonium chloride, the monoazide **23** was obtained in 25% yield, together with **24** (48%). The epoxide ring seemed to be first opened by an azide ion and then the C-3 hydroxyl group, formed by an acetyl group migration under the basic conditions, competed with an azide ion to attack the C-6 bromomethyl group. Compound **24** was similarly converted into the diamine diacetate **25** in 41% yield. The ^{1}H NMR spectra of **24** and **25** supported their assigned structures.

Experimental[8]

DL-*4*-O-*Acetyl-1,2*:*3,7*-dianhydro-*(1,2,4/3,5)-5-hydroxymethyl-1,2,3,4-cyclohexanetetrol* (syn-*9-Acetoxy*-trans-*3,8-dioxatricyclo*[*4.2.1.0*^{2,4}]*nonane) (2).* A mixture of DL-tri-*O*-acetyl-(1,3/2,4,6)-4-bromo-6-bromomethyl-1,2,3-cyclohexanetriol (**1**)[3] (10 g) in methanol (140 ml) containing sodium (2.33 g) was refluxed for 2 h. After having been cooled, the reaction mixture was treated with 1 M hydrochloric acid for neutralization and then evaporated to dryness. The residue was treated with acetic anhydride (20 ml) and pyridine (30 ml) at room temperature overnight. The reaction mixture was concentrated and the residue was dissolved in ethyl acetate and the solution was passed through a short column of alumina. The filtrate was evaporated and the residue was recrystallized from ligroin to give 2.8 g (65%) of **2** as needles: mp 64.5—65.5 °C. ^{1}H NMR ($CDCl_3$) δ=2.03 (3H, s, OAc), 3.03—3.20 (2H, br s, H-1 and H-2), 3.75 (1H, d, J_{gem}=9 Hz, H-7endo), 4.10 (1H, ddd, $J_{5,7exo}$=7.5 Hz, $J_{6exo,7exo}$=2 Hz, H-7exo), 4.78—4.83 (2H, m, H-3 and H-4).

Found: C, 58.68; H, 6.57%. Calcd for $C_9H_{12}O_4$: C, 58.38; H, 6.57%.

DL-*2,4-Di*-O-*acetyl-3,7-anhydro-1*-O-*methyl-(1,3,5/2,4)-5-hydroxymethyl-1,2,3,4-cyclohexanetetrol (3).* A mixture of **2** (0.20 g) and 5 M methanolic sodium methoxide (8 ml) was refluxed for 1 h. The reaction mixture was processed similarly as described for the preparation of **2** and the product was acetylated in the usual way to give, after crystallization from ethanol, 0.24 g (87%) of **3** as plates: mp 75—76.5 °C. ^{1}H NMR ($CDCl_3$) δ=2.00 (3H, s) and 2.08 (3H, s) (OAc), 3.35 (3H, s, OMe), 3.81 (1H, ddd, $J_{5,7exo}$=4.5 Hz, $J_{6exo,7exo}$=1.5 Hz, J_{gem}=7.5 Hz, H-7exo), 4.00 (1H, d, H-7endo), 4.26 (1H, t, $J_{2,3}$=$J_{3,4}$=4.5 Hz, H-3), 4.85 (2H, t, $J_{1,2}$=$J_{4,5}$=4.5 Hz, H-2 and H-4).

Found: C, 55.76; H, 6.92%. Calcd for $C_{12}H_{18}O_6$: C, 55.80; H, 7.04%.

DL-*1,3-Di*-O-*acetyl-2,7-anhydro-(1,3/2,4,6)-4-azido-6-hydroxymethyl-1,2,3-cyclohexanetriol (4).* A mixture of **2** (0.30 g), sodium azide (0.37 g), and 90% aqueous 2-methoxy-

ethanol (6 ml) was heated at 110 °C for 1 h. The reaction mixture was evaporated to dryness and the residue was treated with acetic anhydride and pyridine at 60 °C for 2 h. The product was crystallized from ethanol–ether to give 0.36 g (81%) of **4** as prisms: mp 62.5—63.5 °C. ^{1}H NMR ($CDCl_3$) δ=2.00 (3H, s) and 2.08 (3H, s) (OAc), 3.67—4.07 (2H, m, H-7 and H-7′), 4.25 (1H, dd, $J_{1,2}$=3 Hz, $J_{2,3}$=5 Hz, H-2), 4.76—5.03 (2H, m, H-1 and H-3).

Found: C, 49.14; H, 5.73; N, 15.59%. Calcd for $C_{11}H_{16}N_3O_5$: C, 48.88; H, 5.98; N, 15.55%.

DL-*1,3-Di*-O-*acetyl-2,7-anhydro-(1,3/2,4,6)*-4-*acetamido*-6-*hydroxymethyl-1,2,3-cyclohexanetetrol (5)*. *a)*: A solution of **4** (0.20 g) in ethanol (10 ml) was hydrogenated in the presence of Raney nickel T-4[9] (one spatula) at room temperature overnight. The catalyst was removed by filtration and the filtrate was evaporated to dryness. The residue was treated with acetic anhydride and pyridine in the usual way. The product was crystallized from ethanol–ether to give 85 mg (40%) of **5** as needles: mp 108.5—109.5 °C. ^{1}H NMR ($CDCl_3$) δ=1.95 (3H, s), 2.00 (3H, s), and 2.14 (3H, s) (NAc and OAc), 3.88 (2H, br s, H-7 and H-7′), 4.00—4.27 (1H, m, H-4), 4.14 (1H, dd, $J_{1,2}$=6 Hz, $J_{2,3}$=3 Hz, H-2), 4.74 (1H, t, $J_{3,4}$=3 Hz, H-3), 4.90 (1H, t, $J_{1,6}$=6 Hz, H-1), 6.19 (1H, br d, J=9 Hz, NH).

Found: C, 54.98; H, 6.67; N, 5.16%. Calcd for $C_{13}H_{19}NO_6$: C, 54.72; H, 6.73; N, 4.91%.

b): A mixture of **2** (2.8 g) and methanolic ammonia (150 ml, saturated at 5 °C) was heated in a sealed tube at 105 °C for 30 h. After having been cooled, the reaction mixture was concentrated and the residue was treated with acetic anhydride and pyridine in the usual way. The product was recrystallized from ethanol–ether to give 3.2 g (74%) of **5**, identical with the compound obtained from **4**.

DL-*2,7-Anhydro-1,3-di*-O-p-*tolylsulfonyl*-*(1,3/2,4,6)*-*4*-*acetamido*-*6*-*hydroxymethyl*-*1,2,3*-*cyclohexanetriol (6)*. Compound **5** (0.26 g) was dissolved in 1 M methanolic sodium methoxide (5 ml) and the mixture was allowed to stand at room temperature overnight. The reaction mixture was neutralized with Amberlite IR-120 (H^+) and concentrated to an oil, which was treated with *p*-toluenesulfonyl chloride (1.1 g) in pyridine (7 ml) at room temperature for 2 d. The reaction mixture was poured into ice-water and extracted with chloroform (10 ml×3). The extracts were washed with aqueous sodium hydrogencarbonate and water, and dried. Evaporation of the solvent gave an oil (0.38 g), which was crystallized from ethanol to give 0.21 g (45%) of **6** as prisms: mp 156—157 °C. ^{1}H NMR ($CDCl_3$) δ=1.77 (3H, s, NAc), 2.40 (6H, s, tosyl methyl), 3.68—4.10 (4H, m, H-2 ,H-4, H-7, and H-7′), 4.41 (1H, dd, $J_{2,3}$=4.5 Hz, $J_{3,4}$=3 Hz, H-3), 4.72 (1H, t, $J_{1,2}$=$J_{1,6}$=4.5 Hz, H-1), 5.83 (1H, br d, J=7.5 Hz, NH), 7.23 (2H, d) and 7.67 (2H, d) and 7.26 (2H, d), and 7.76 (2H, d) (J=9 Hz, phenyl).

Found: C, 53.93; H, 5.32; N, 2.62; S. 12.31%. Calcd for $C_{23}H_{27}NO_8S_2$: C, 54.21; H, 5.35; N, 2.75; S, 12.58%.

DL-*2,3,4-Tri*-O-*acetyl-1*-O-*methyl-(1,3,5/2,4)*-*5*-*acetoxymethyl-1,2,3,4-cyclohexanetetrol (7)*. A mixture of **3** (0.2 g), acetic acid (2 ml), and acetic anhydride (2 ml) was heated in a sealed tube at 85 °C for 20 h. After having been cooled, the mixture was poured into ice water (20 ml) and then neutralized with sodium hydrogencarbonate and extracted with ethyl acetate (20 ml). The extract was washed with aqueous sodium hydrogencarbonate and water, dried, and concentrated to dryness. The product was crystallized from ethanol–ether to give 0.11 g (39%) of **7** as needles: mp 74.5—75.5 °C. ^{1}H NMR ($CDCl_3$) δ=1.97 (3H, s), 2.00 (3H, s), and 2.03 (6H, s) (OAc), 3.33 (3H, s, OCH_3), 3.16—3.57 (1H, m, H-1), 3.90—4.17 (2H, m, H-7 and H-7′), 4.73—5.37 (3H, m, H-2, H-3, and H-4).

Found C, 53.56; H, 6.66%. Calcd for $C_{16}H_{24}O_9$: C, 53.32; H, 6.73%.

DL-*1,2,3-Tri*-O-*acetyl-(1,3/2,4,6)*-*4*-*acetamido*-*6*-*bromomethyl-1,2,3-cyclohexanetriol (8)*. A mixture of **5** (2.0 g) and 30% hydrogen bromide–acetic acid (4 ml) was heated in a sealed tube at 75 °C for 23 h. After having been cooled, the mixture was poured into ice-water and the solution was processed similarly as described for preparation of **7**. The product was crystallized from ethanol to give 1.9 g (67%) of **8** as prisms: mp 184—184.5 °C. ^{1}H NMR ($CDCl_3$) δ=1.92 (3H, s), 1.98 (3H, s), and 2.03 (6H, s) (NAc and OAc), 3.34 (2H, br d, $J_{6,7}$=$J_{6,7'}$=3 Hz, H-7 and H-7′). 3.83—4.37 (1H, m, H-4), 4.83 (1H, t) and 5.11 (1H, t) ($J_{1,2}$=$J_{2,3}$=9 Hz, H-2 and H-3), 4.91 (1H, t, $J_{1,6}$=9 Hz, H-1), 5.82 (1H, br d, J=7.5 Hz, NH).

Found: C, 44.06; H, 5.29; N, 3.55; Br, 19.31%. Calcd for $C_{15}H_{22}O_7BrN$: C, 44.12; H, 5.44; N, 3.43; Br, 19.57%

DL-*2*-O-*Acetyl-1,3-di*-O-p-*tolylsulfonyl-(1,3/2,4,6)*-*4*-*acetamido*-*6*-*bromomethyl-1,2,3-cyclohexanetriol (12)*. A mixture of **6** (0.15 g) and 15% hydrogen bromide in acetic acid (2 ml) was heated in a sealed tube at 85 °C for 22 h. The reaction mixture was poured into ice-water (30 ml) and, after, neutralization with sodium hydrogencarbonate, extracted with chloroform (45 ml). The extract was processed similarly as described for preparation of **7**. The product was crystallized from acetone to give 0.17 g (45%) of **12** as prisms: mp 207—209 °C. ^{1}H NMR (DMSO-d_6) δ=1.49 (3H, s) and 1.73 (3H, s) (NAc and OAc), 2.88—3.62 (2H, m, H-7 and H-7′), 3.80—4.30 (1H, m, H-4), 4.56 (1H, dd) and 4.67 (1H, dd) ($J_{1,2}$=$J_{2,3}$=10.5 Hz, $J_{1,6}$=$J_{3,4}$=7.5 Hz, H-1 and H-3), 5.19 (1H, t, H-2), 7.33 (2H, d) and 7.59 (2H, d), and 7.38 (2H, d) and 7.68 (2H, d) (J=9 Hz, phenyl).

Found: C, 47.28; H, 4.77; N, 2.08%. Calcd for $C_{25}H_{30}O_9BrNS_2$: C, 47.46; H, 4.79; N, 2.21%.

DL-*1,2,3-Tri*-O-*acetyl-(1,3/2,4,6)*-*4*-*acetamido*-*6*-*acetoxymethyl-1,2,3-cyclohexanetriol (9)*. A mixture of **8** (0.2 g), anhydrous sodium acetate (0.24 g), and 90% aqueous 2-methoxyethanol (5 ml) was heated at 85 °C for 23 h. The reaction mixture was evaporated and the residue was acetylated in the usual way. The product was recrystallized from ethanol–ether to give 0.12 g (61%) of **9** as prisms: mp 109—110 °C. ^{1}H NMR δ=1.89 (3H, s), 1.96 (3H, s), 1.98 (3H, s), and 2.00 (6H, s) (NAc and OAc), 3.82—4.27 (3H, m, H-4, H-7, and H-7′), 4.78 (1H, t) and 5.08 (1H, t) ($J_{1,2}$=$J_{2,3}$=$J_{3,4}$=9 Hz, H-2 and H-3), 4.96 (1H, t, $J_{1,6}$=9 Hz, H-1), 5.73 (1H, br d, J=7.5 Hz, NH).

Found: C, 52.61; H, 6.38; N, 3.59%. Calcd for $C_{17}H_{25}NO_9$: C, 52.70; H, 6.52; N, 3.62%.

DL-*1,2,3-Tri*-O-*acetyl-(1,3/2,4,6)*-*4*-*acetamido*-*6*-*azidomethyl-1,2,3-cyclohexanetriol (10)*. A mixture of **8** (0.20 g), sodium azide (0.1 g), and 90% aqueous 2-methoxyethanol (4 ml) was heated at 85 °C for 3 h. The reaction mixture was evaporated and the residue was acetylated in the usual way. The product was recrystallized from ethanol to give 0.16 g (90%) of **10** as prisms: mp 152.5—154 °C. ^{1}H NMR ($CDCl_3$) δ=1.91 (3H, s), 1.97 (3H, s), 2.02 (3H, s), and 2.03 (3H, s) (NAc and OAc), 3.18 (1H, dd, $J_{6,7}$=4.5 Hz, J_{gem}=12 Hz, H-7), 3.36 (1H, dd, $J_{6,7'}$=4.5 Hz, H-7′), 3.87—4.27 (1H, m, H-4), 4.79 (1H, t) and 5.08 (1H, t) ($J_{1,2}$=$J_{2,3}$=$J_{3,4}$=9 Hz, H-2 and H-3), 4.84 (1H, t, $J_{1,6}$=9 Hz, H-1), 5.85 (1H, br d, J=7.5 Hz, NH).

Found: C, 48.78; H, 5.97; N, 14.84%. Calcd for $C_{15}H_{22}N_4O_7$: C, 48.63; H, 6.00; N, 15.13%.

DL-*1,2,3-Tri*-O-*acetyl*-*(1,3/2,4,6)*-*4*-*acetamido*-*6*-*acetamido*-

*methyl-1,2,3-cyclohexanetriol (**11**).* A mixture of **10** (0.10 g) in ethanol (10 ml) was hydrogenated in the presence of Raney nickel T-4 (one spatula) in a Parr shaker apparatus at room temperature overnight. The mixture was processed as described for the preparation of **5**. The product was crystallized from ethanol to give 0.10 g (92%) of **11**: mp 56—57.5 °C. ^{1}H NMR ($CDCl_3$) δ=1.87 (3H, s), 1.97 (6H, s), 2.00 (3H, s), and 2.05 (3H, s) (NAc and OAc), 2.83 (1H, dd, $J_{6,7}$=5 Hz, J_{gem}=7.5 Hz, H-7), 3.55 (1H, dd, $J_{6,7'}$=3 Hz, H-7'), 3.90—4.28 (1H, m, H-4), 4.71 (1H, dd) and 4.74 (1H, dd) ($J_{1,2}=J_{2,3}$=9 Hz, $J_{1,6}$=10 Hz, $J_{3,4}$=10.5 Hz, H-1 and H-3), 5.09 (1H, t, H-2), 5.75 (1H, br d, J=5 Hz, 4-NH), 6.01 (1H, m, 7-NH).

Found: C, 52.98; H, 6.73; N, 6.91%. Calcd for $C_{17}H_{26}N_2O_8$: C, 52.82; H, 6.79; N, 7.25%.

DL-*(1,3/2,4,6)-4-Amino-6-hydroxymethyl-1,2,3-cyclohexanetriol Hydrochloride (**13**).* A mixture of **9** (0.20 g) and 6 M hydrochloric acid (10 ml) was refluxed for 90 min, and then evaporated to dryness. The residue was crystallized from ethanol–water to give 0.11 g (100%) of **13** as prisms: mp 195—196 °C. TLC (cellulose): R_f 0.37, 1-butanol–ethanol–water–17% aqueous ammonia (4:5:2:4).[10]

Found: C, 39.59; H, 7.63; N, 6.31; Cl, 16.80%. Calcd for $C_7H_{16}NO_4Cl$: C, 39.34; H, 7.56; N, 6.56; Cl, 16.59%.

DL-*(1,3/2,4,6)-4-Amino-6-aminomethyl-1,2,3-cyclohexanetriol Dihydrochloride (**14**).* A mixture of **11** (0.61 g) and 6 M hydrochloric acid (25 ml) was refluxed for 2 h, and then evaporated to dryness. The residue was crystallized from ethanol–water to give 0.39 g (100%) of **14** as prisms: mp 194 °C, decomposed at 200—228 °C. TLC (cellulose): R_f 0.22, 1-butanol–ethanol–water–17% aqueous ammonia (4:5:2:4).[10]

Found: C, 33.54; H, 7.04; N, 11.00; Cl, 28.59%. Calcd for $C_7H_{18}N_2O_3Cl_2$: C, 33.74; H, 7.30; N, 11.25; Cl, 28.45%.

Bromination of DL-*1,2-Di-O-acetyl-(1,3/2)-3-bromomethyl-5-cyclohexene-1,2-diol (**15**).*[11] Compound **15**[1] (2.0 g) was dissolved in acetic acid (30 ml) and then water (15 ml) was added. To the stirred solution was added bromine water (40 ml) containing 0.67 ml of bromine dropwise during 20 min at room temperature. After the reaction mixture was allowed to stand in a refrigerator overnight, the precipitates were collected by filtration and washed thoroughly with water to give a crystalline mixture (1.65 g) of products, which contained one major (R_f 0.20) together with two minor components [R_f 0.33 and 0.75 in 2-butanone–toluene (1:6)]. Recrystallization of the mixture from ethanol gave DL-1,3-di-*O*-acetyl-(1,4/2,3,6)-4-bromo-6-bromomethyl-1,2,3-cyclohexanetriol (**16**, 0.92 g, 34%) as needles: mp 176—178 °C. ^{1}H NMR ($CDCl_3$) δ=2.11 (6H, s, OAc), 3.36 (2H, d, J=4.5 Hz, H-7 and H-7'), 4.12 (1H, br dd, $J_{1,2}$=9.5 Hz, $J_{2,3}$=3 Hz, H-2, on deuteration), 4.20—4.35 (1H, m, H-4), 4.90 (1H, t, $J_{1,6}$=9.5 Hz, H-1), 5.12 (1H, br t, $J_{3,4}$=3 Hz, H-3).

Found: C, 34.14; H, 4.17; Br, 40.96%. Calcd for $C_{11}H_{16}O_5Br_2$: C, 34.05; H, 4.16; Br, 41.18%.

Compound **16** (0.82 g) was acetylated with acetic anhydride in pyridine in the usual way and the product was recrystallized from ethanol to give 0.41 g (45%) of the triacetate **17** as prisms: mp 96.5—97 °C. ^{1}H NMR ($CDCl_3$, 60 MHz) δ=2.00 (3H, s), 2.09 (3H, s), and 2.17 (3H, s) (OAc), 3.34 (2H, d, J=4.5 Hz, H-7 and H-7'), 4.33 (1H, q, $J_{3,4}=J_{4,5ax}=J_{4,5eq}$=3 Hz, H-4), 5.29 (1H, t, $J_{1,2}=J_{1,6}$=9.5 Hz, H-1), 5.63 (1H, dd, $J_{2,3}$=3 Hz, H-2).

Found: C, 36.40; H, 4.22; Br, 37.35%. Calcd for $C_{13}H_{18}O_6Br_2$: C, 36.30; H, 4.42; Br, 37.16%.

The mother liquor of the crystalline mixture was neutralized with sodium hydrogencarbonate and extracted with ethyl acetate (150 ml). The extracts were concentrated and the residual oil was chromatographed on a silica gel column (50 g) with 2-butanone–toluene (1:15) as an eluent. The first fraction gave DL-1,2-di-*O*-acetyl-(1,4/2,3,6)-3,4-dibromo-6-bromomethyl-1,2-cyclohexanediol (**18**, 22 mg, 0.7%) as prisms: mp 94—95 °C. ^{1}H NMR ($CDCl_3$) δ=1.99 (6H, s, OAc), 3.19—3.35 (2H, m, H-7 and H-7'), 5.12—5.34 (2H, m, H-1 and H-2).

Found: C, 29.55; H, 3.51; Br, 52.95%. Calcd for $C_9H_{10}O_4Br_3$: C, 29.30; H, 3.35; Br, 53.16%.

The second fraction gave (R_f 0.54) gave DL-1,3,4-tri-*O*-acetyl-(1,4/2,3,5)-2-bromo-5-bromomethyl-1,3,4-cyclohexanetriol (**19**, 40 mg, 1.4%) as an oil. ^{1}H NMR ($CDCl_3$) δ=2.00 (6H, s) and 2.04 (3H, s) (OAc), 3.10—3.42 (2H, m, H-7 and H-7'), 4.29 (1H, dd, $J_{1,2}$=3 Hz, $J_{2,3}$=3.5 Hz, H-2), 4.90 (1H, dd, $J_{3,4}$=9 Hz, H-3), 5.02—5.32 (2H, m, H-1 and H-4).

Found: C, 36.64; H, 4.20; Br, 37.17%. Calcd for $C_{13}H_{18}O_6Br_2$: C, 36.30; H, 4.23; Br, 37.15%.

The third fraction (R_f 0.33) gave DL-3,4-di-*O*-acetyl-(1,4/2,3,5)-2-bromo-5-bromomethyl-1,3,4-cyclohexanetriol (**20**, 0.44 g, 16%) as prisms: mp 109—110 °C. ^{1}H NMR ($CDCl_3$) δ=2.00 (6H, s, OAc), 3.12—3.46 (2H, m, H-7 and H-7'), 4.06—4.25 (1H, m, H-1), 4.25—4.40 (1H, m, H-2), 4.95—5.30 (2H, m, H-3 and H-4).

Found: C, 34.27; H, 4.29; Br, 40.97%. Calcd for $C_{11}H_{16}O_5Br_2$: C, 34.05; H, 4.16; Br, 41.18%.

The fourth fraction gave an additional amount of **16** (37 mg, total yield, 35.5%).

DL-*4-O-Acetyl-1,2:3,7-dianhydro-(1,2,3,5/4)-5-hydroxymethyl-1,2,3,4-cyclohexanetetrol (**21**).* A mixture of **16** (0.40 g) and 1 M methanolic sodium methoxide (6.4 ml) was heated at 60 °C for 3.5 h. TLC [2-butanone–toluene (1:2)] indicated that **16** (R_f 0.44) disappeared immediately with a formation of an intermediate compound (R_f 0.08) which was then converted into a single compound (R_f 0.31). The reaction mixture was neutralized with 1 M hydrochloric acid and concentrated. The residue was treated with acetic anhydride and pyridine at room temperature overnight. The product was purified by chromatography on silica gel with 2 butanone–toluene (1:5) as an eluent to give 0.16 g (84%) of **21** as an oil. TLC: R_f 0.38 [2-butanone–toluene (1:4)]. ^{1}H NMR ($CDCl_3$) δ=2.14 (3H, s, OAc), 2.47—2.82 (1H, m, H-5), 3.87 (1H, d, J_{gem}=9.3 Hz, H-7endo), 4.08 (1H, dd, $J_{5,7exo}$=4.7 Hz, H-7exo), 4.22—4.47 (1H, m, H-1 or H-2), 4.47—4.69 (2H, m, H-3 and H-1 or H-2), 5.13 (1H, t, $J_{3,4}=J_{4,5}$=4.8 Hz, H-4).

Found: C, 58.40; H, 6.50%. Calcd for $C_9H_{12}O_4$: C, 58.69; H, 6.57%.

DL-*3,4-Di-O-acetyl-1,2-anhydro-(1,2,3,5/4)-5-bromomethyl-1,2,3,4-cyclohexanetetrol (**22**).* A mixture of **15** (1.5 g), *m*-chloroperoxybenzoic acid (1.52 g, *ca.* purity 70%), and dry 1,2-dichloroethane (40 ml) was refluxed for 3 h. The reaction mixture was washed with successively with 10% aqueous sodium sulfite (40 ml×3), saturated aqueous sodium hydrogencarbonate (40 ml×3), and water (40 ml×2), and dried over anhydrous sodium sulfate. Evaporation of the solvent gave an oil, which was crystallized from ethanol. Recrystallization from ethanol–ether gave 0.44 g (23%) of **22**: mp 112.5—114 °C. ^{1}H NMR ($CDCl_3$) δ=2.02 (3H, s) and 2.05 (3H, s) (OAc), 3.08—3.45 (4H, H-1, H-2, H-7, and H-7'), 5.01 (1H, dd, $J_{3,4}$=8.5 Hz, $J_{4,5}$=9.5 Hz, H-4), 5.19 (1H, dd, $J_{2,3}$=1.5 Hz, H-3).

Found: C, 43.10; H, 4.85; Br, 25.76%. Calcd for $C_{11}H_{15}O_5Br$: C, 43.01; H, 4.92; Br, 26.02%.

*Reaction of **22** with Sodium Azide.* *a) In the Presence of Ammonium Chloride*: A mixture of **22** (63 mg), sodium

azide (67 mg, 5 molar equiv.), ammonium chloride (110 mg, 10 molar equiv.), and 90% aqueous *N,N*-dimethylformamide (DMF) (5 ml) was stirred at 80—85 °C for 3 h. The mixture was concentrated and the residue was treated with acetic anhydride (5 ml) and pyridine (5 ml) at room temperature overnight. Evaporation of the excess reagent gave a crude product which was purified by chromatography on silica gel (3 g) with 2-butanone–toluene (1:10) as an eluent to give 48 mg (67%) of DL-1,2,3-tri-*O*-acetyl-(1,4/2,3,6)-4-azido-6-azidomethyl-1,2,3-cyclohexanetriol (**24**) as an oil. TLC: R_f 0.52 [2-butanone–toluene (1:5)]. ^{1}H NMR ($CDCl_3$) δ=1.98 (3H, s), 2.04 (3H, s), and 2.11 (3H, s) (OAc), 3.24 (1H, dd, $J_{6,7}$=6 Hz, J_{gem}=12 Hz, H-7), 3.41 (1H, dd, $J_{6,7'}$=4 Hz, H-7'), 3.87 (1H, br q, J=*ca.* 4 Hz, H-4), 5.01—5.32 (3H, m, H-1, H-2, and H-3).

Found: C, 44.34; H, 5.36; N, 23.48%. Calcd for $C_{13}H_{18}N_6O_6$: C, 44.07; H, 5.12; N, 23.72%.

b) In the Absence of Ammonium Chloride: A mixture of **22** (0.10 g), sodium azide (0.11 g, 5 molar equiv.), and 90% aqueous DMF (5 ml) was stirred at 80—85 °C for 3 h. The mixture was concentrated and the residue was treated with acetic anhydride and pyridine in the usual way. TLC indicated the formation of two major products [R_f 0.52 and 0.45, 2-butanone–toluene (1:5)]. Evaporation of the excess reagent and the products were fractionated by a silica-gel column (5 g) with 2-butanone–toluene (1:10) as an eluent. The first fraction (R_f 0.52) gave 55 mg (48%) of **24** as an oil. The second fraction (R_f 0.45) gave DL-1,3-di-*O*-acetyl-2,7-anhydro-(1,4/2,3,6)-4-azido-6-hydroxymethyl-1,2,3-cyclohexanetriol (**23**, 22 mg, 25%) as an oil. ^{1}H NMR ($CDCl_3$) δ=2.12 (3H, s) and 2.15 (3H, s) (OAc), 2.65 (1H, quintet, J=3.3 Hz, H-6), 3.65—4.12 (3H, m, H-4 and CH_2O), 4.19 (1H, br d, J=*ca.* 6 Hz, H-2), 4.90—5.19 (2H, m, H-1 and H-3).

Found: C, 48.89; H, 5.54; N, 15.92%. Calcd for $C_{11}H_{15}N_3O_5$: C, 49.07; H, 5.62; N, 15.61%.

*DL-1,2,3-Tri-O-acetyl-(1,4/2,3,6)-4-acetamido-6-acetamidomethyl-1,2,3-cyclohexanetriol (**25**).* A solution of **24** (0.54 g) in ethanol (10 ml) containing acetic anhydride (0.9 ml) was hydrogenated in the presence of Raney nickel T-4 for 28 h. The reaction mixture was filtered and the filtrate was concentrated. The residue was taken up in chloroform (50 ml) and passed through a short column of alumina. The filtrate was concentrated and the residue was crystallized from ethanol to give 0.24 g (41%) of **25** as prisms: mp 197—199 °C. ^{1}H NMR ($CDCl_3$, 60 MHz) δ=2.00 (9H, s), 2.07 (3H, s), and 2.11 (3H, s) (NAc and OAc), 3.30—4.30 (2H, br m, H-7 and H-7'), 4.90—5.45 (4H, m, H-1, H-2, H-3, and H-4), 6.30 (1H, br t, J=6 Hz, C_7–NHAc), 6.70 (1H, br d, J=7 Hz, C_4–NHAc).

Found: C, 52.98; H, 6.78; N, 7.12%. Calcd for $C_{17}H_{26}N_2O_8$: C, 52.84; H, 6.78; N, 7.25%.

The authors express their sincere thanks to Mr. Saburo Nakada for the elementary analyses.

Regio-controlled Prenylation and Geranylation of 3-Furylmethylmagnesium Bromide. Selective Syntheses of 3-Substituted Furanoid and 2-Substituted 3-Methylfuranoid Terpenes

Shuki Araki and Yasuo Butsugan*

Department of Synthetic Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466

(Received October 27, 1982)

Coupling reactions of 3-furylmethylmagnesium bromide with prenyl and geranyl diethyl phosphates gave 2-substituted 3-methylfurans, rosefuran and sesquirosefuran, as the main products. When the reactions were carried out in the presence of a catalytic amount of copper(I) iodide, normal coupling occurred and 3-substituted furans, perillene and dendrolasin, were formed in good yields. The related naturally occurring 3-substituted thiophene, 3-(4-methyl-3-pentenyl)thiophene, was also synthesized from 3-thienylmethylmagnesium bromide and prenyl diethy phosphate.

3-Substituted furans and 2-substituted 3-methylfurans are widely distributed in nature.[1] Dendrolasin (**1**)[2] and sesquirosefuran (**2**),[3] and their monoterpene homologs, perillene (**3**)[4] and rosefuran (**4**),[5] are examples of such furanoid terpenes. We have previously described[6] that **1** and **2** were selectively synthesized by the regio-controlled geranylation of 3-furylmethylmagnesium bromide (**7**) with geranyl diethyl phosphate (**8**) using copper(I) iodide as a catalyst. In this article, full experimental details of the above reactions as well as the selective syntheses of **3** and **4** by the same methodology are described. A convenient synthesis of the thiophene analog (**5**), a constituent of the essential oil of hop,[7] is also reported.

Results and Discussion

Reaction of 3-Furylmethylmagnesium Bromide with Geranyl Diethyl Phosphate. The Grignard reagent, 3-furylmethylmagnesium bromide (**7**), was prepared in the conventional manner from the known 3-furylmethyl bromide[8] in tetrahydrofuran. Geranyl diethyl phosphate (**8**) was added to a solution of the Grignard reagent **7** at −78 °C and the mixture was left overnight at room temperature. Workup followed by vacuum distillation gave a colorless oil. GLPC analysis revealed that the oil consisted of three components (**A**, **B**, and **C**) in the ratio of 7:77:16. They were separated by preparative GLPC and the structures were assigned on the basis of the spectroscopic data. Compound **A**, having the shortest retention time, showed characteristic signals of a terminal vinyl group in addition to a methylene singlet adjacent to the furan ring in its ^1H NMR spectrum. This compound was assigned as 3-(2,6-dimethyl-2-vinyl-5-heptenyl)furan (**9**). IR and ^1H NMR data of the main product **B** and the third component **C** were in good agreement with the literature values of sesquirosefuran (**2**) and dendrolasin (**1**), respectively.

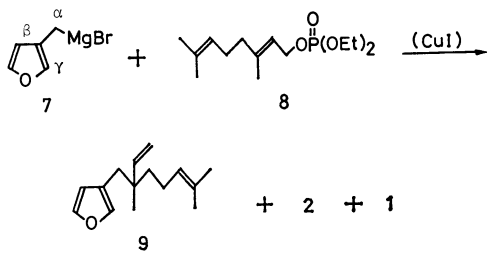

Table 1. Grignard reaction of **7** with geranyl phosphate **8** and geranyl bromide

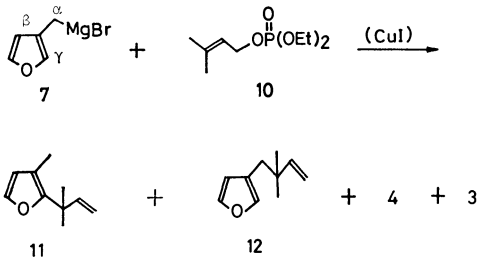
Geranyl compound	CuI	Product ratio **9** : **2** : **1**	Total yield %
Phosphate **8**	Absence	7 : 77 : 16	83
	Presence	21 : 0 : 79	81
Bromide	Absence	32 : 45 : 22	82
	Presence	25 : 6 : 68	83

The results show that the Grignard reagent **7** was electrophilically attacked mainly at the γ-position (C-2 ring carbon) by the geranyl phosphate **8**. This observation is consistent with the facts that 3-furylmethylmagnesium chloride reacts at the γ-position with hard electrophiles such as carbon dioxide and formaldehyde leading to 3-methyl-2-furoic acid and 3-methylfurfuryl alcohol, respectively.[9] When geranyl bromide, a softer electrophile than the phosphate **8**, was employed as a geranylation reagent, the γ-regioselectivity decreased from 77% to 45% (Table 1).

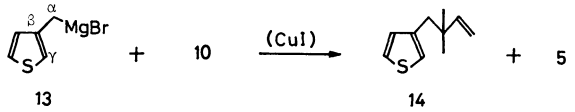
When the reaction of **7** and **8** was conducted in the presence of a catalytic amount (10 mol% of **7**) of copper(I) iodide, normal coupling at the α-position exclusively took place;[10] dendrolasin(**1**) was formed in 79% selectivity accompanied by 21% of the regioisomer **9**. In this case, reaction at the γ-position (formation of **2**) was negligible. Preference for the α-coupling was also observed in the copper(I)-catalyzed reaction of **7** with geranyl bromide, though the selectivity was lower.[11] Results are summarized in Table 1.

Reaction of 3-Furylmethylmagnesium Bromide with Prenyl Diethyl Phosphate. When prenyl diethyl phosphate (**10**) was employed in place of **8**, a mixture of prenylated 3-methylfurans was obtained in 78% combined yield. GLPC of the mixture showed four peaks (**D**,

E, **F**, and **G**) in the ratio of 2:7:72:19. Although compound **D** could not be isolated because of its small quantity, the remaining three components were isolated by preparative GLPC, and characterized. Peak **E** was a new compound and the structure was deduced to be 3-(2,2-dimethyl-3-butenyl)furan (**12**), by means of MS and ^{1}H NMR spectra. Peaks **F** and **G** were found to be identical with rosefuran **4** and perillene **3**, respectively, on the basis of IR, Mass, and ^{1}H NMR spectral comparisons with those in literatures.[4,5] Peak **D** could be, therefore, tentatively assigned as 2-(1,1-dimethyl-2-propenyl)-3-methylfuran (**11**). As expected, the copper(I)-catalyzed reaction of **7** with **10** gave **12** and **3** in the ratio of 2:98 in 83% yield. Again, in this catalytic reaction the coupling at the γ-position was not observed.



Reaction of 3-Thienylmethylmagnesium Bromide with Prenyl Diethyl Phosphate. As described, geranyl (**8**) and prenyl diethyl phosphates(**10**) attacked prefentially the harder γ-position (adjacent position to the hard oxygen atom) of 3-furylmethylmagnesium bromide **7** rather than the α-position. The γ-position of 3-thienylmethylmagnesium bromide (**13**), in which the oxygen atom of **7** is replaced by soft sulfur atom, must be softer than the α-position and therefore the phosphates should attack the α-position. This proved to be the case. The reaction of **13** with **10** gave 3-(4-methyl-3-pentenyl)thiophene (**5**) in 71% yield accompanied with a trace amount (1%) of 3-(2,2-dimethyl-3-butenyl)-thiophene (**14**). No trace of γ-substituted products such as **6** was observed in this reaction. The thiophene derivative **5** is a constituent of a hop oil,[7] and although synthesized by the photo-induced reaction between myrcene and elemental sulfur in a trace yield,[12] this is the first practical synthesis so far reported. By the addition of copper(I) iodide, the product ratio (**14**:**5**) changed from 1:99 to 18:82. γ-Substitution was not observed in this catalytic reaction.



Experimental

General. Infrared spectra were recorded on a JASCO IRA-1 spectrometer. ^{1}H NMR spectra were determined with a Hitachi R-24A (60 MHz) spectrometer, or with a JEOL JNM-FX-100 (100 MHz) spectrometer in CCl_4 or in $CDCl_3$. Chemical shifts (δ) are recorded in ppm downfield from Me_4Si. Mass spectra were measured on a Hitachi M-52 mass spectrometer, operating with an ionization energy of 20 eV. GLPC analyses and preparative GLPC were performed on a Yanaco G1800 gas chromatograph, equipped with columns (1 m, 2 m, or 3 m × 3 mm) packed with Apiezon grease L on Uniport B (15%). Elemental analyses were performed at the Elemental Analysis Center of Kyoto University. For Kugelrohr distillation, a Shibata GTO-250R glass tube oven was used.

Material. Geranyl (**8**) and prenyl diethyl phosphates (**10**) were prepared according to the method for the corresponding diphenyl phosphates.[13] 3-Furylmethyl bromide[8] and 3-thienylmethyl bromide[14] were prepared by the methods described in the literatures. Copper(I) iodide, obtained from Nakarai Chemicals, LTD., was used as received.

Reaction of 3-Furylmethylmagnesium Bromide (7) with Geranyl Diethyl Phosphate (8). (a) In the Absence of Copper(I) Iodide: 3-Furylmethyl bromide (403 mg, 2.5 mmol) in THF (4 ml) was added dropwise to magnesium turnings (120 mg, 5 mmol) in THF (1 ml) cooled in an ice-salt bath. After the addition was complete, the mixture was gradually warmed to room temperature and further stirred at that temperature for 1 h. To remove the excess magnesium, the resulting Grignard solution was transferred by a syringe to the second flask and cooled to −78 °C. To this was added a solution of geranyl diethyl phosphate (**8**) (435 mg, 1.5 mmol) in THF (3 ml), the mixture was gradually warmed to room temperature and left overnight. Saturated aqueous ammonium chloride was added and the products were extracted with ether. The extracts were washed with brine, dried over anhydrous sodium sulfate and concentrated. The residue was distilled (bp 130 °C/3 Torr, 1 Torr ≈133.322 Pa) to give a colorless oil (272 mg, 83% yield). GLPC analysis using the 1 m column (temperature 160 °C, He 90 ml/min) showed three peaks of **9** (t_R=12 min), **2** (14.5), and **1** (16.5) in the ratio of 7:77:16. They were isolated by preparative GLPC.

3-(2,6-Dimethyl-2-vinyl-5-hepenyl)furan (9): IR (neat) 2930, 1640, 1520, 1454, 1416, 1376, 1168, 1069, 1028, 1002, 912, 872, 786, and 732 cm^{-1}; ^{1}H NMR (CCl_4) δ=7.20 (m, 1H, furan), 7.08 (s, 1H, furan), 6.13 (m, 1H, furan), 5.73 (dd, J=17, 11 Hz, 1H, CH_2=C<u>H</u>–), 5.2—4.5 (m, 3H, olefin), 2.31 (s, 2H, CH_2), 2.2—1.0 (m, 4H, CH_2), 1.60 (s, 3H, CH_3), 1.51 (s, 3H, CH_3), 0.91 (s, 3H, CH_3); MS *m/z* (rel intensity) 218 (M^+; 22), 137 (22), 123 (36), 95 (59), 81 (86), and 69 (100); Found: C, 82.71; H, 10.00%. Calcd for $C_{15}H_{22}O$: C, 82.51; H, 10.16%.

Sesquirosefuran (2): IR (neat) 2930, 1665, 1514, 1448, 1380, 1150, 1085, 890, and 724 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=7.21 (d, J=1.6 Hz, 1H, furan), 6.15 (d, J=1.6 Hz, 1H, furan), 5.26 (t, J=7 Hz, 1H, olefin), 5.08 (br, 1H, olefin), 3.28 (d, J=7 Hz, 2H, CH_2), 2.02 (m, 4H, CH_2), 1.96 (s, 3H, ring-CH_3), 1.70 (s, 3H, CH_3), 1.67 (s, 3H, CH_3), 1.59 (s, 3H, CH_3); MS *m/z* (rel intensity) 218 (M^+; 68), 175 (45), 149 (43), 131 (43), 123 (100), 95 (45), and 69 (67).

Dendrolasin (1): IR (neat) 2930, 1670, 1562, 1505, 1444, 1382, 1164, 1064, 1025, 874, and 778 cm^{-1}; ^{1}H NMR (CCl_4) 7.19 (m, 1H, furan), 7.08 (m, 1H, furan), 6.13 (m, 1H, furan), 5.05 (m, 2H, olefin), 2.31 (m, 4H, CH_2), 1.96 (m, 4H, CH_2), 1.63 (s, 3H, CH_3), 1.55 (s, 6H, CH_3); MS *m/z* (rel intensity) 218 (M^+; 7), 203 (17), 175 (18), 136 (17), 123 (10), 95 (12), 82 (17), 81 (56), and 69 (100).

(b) In the Presence of Copper(I) Iodide: The Grignard reagent **7** prepared as above was added to a suspension of copper(I) iodide (47 mg, 0.25 mmol) in THF (1 ml) at −5 °C and stirred for 15 min. To this mixture was added the phosphate **8** (435 mg, 1.5 mmol) in THF (3 ml) at −78 °C. The mixture was treated as described. Distillation (bp 130 °C/3 Torr) gave a mixture of **9** and **1** (265 mg, 81%

yield) in the ratio of 21:79 (by GLPC).

The reactions of **7** with geranyl bromide were carried out in the same procedure. The results are summarized in Table 1.

Reaction of 3-Furylmethylmagnesium Bromide (7) with Prenyl Diethyl Phosphate (10). (a) In the Absence of Copper(I) Iodide: To the Grignard solution **7**, prepared from magnesium (240 mg, 10 mmol) and the bromide (805 mg, 5 mmol) in THF (10 ml), was added a solution of prenyl diethyl phosphate (**10**) (666 mg, 3 mmol) in THF (5 ml) at −78 °C. The mixture was treated as described. Distillation (bp 115 °C/35 Torr) afforded a colorless oil (350 mg, 78% yield). GLPC analysis using the 3 m column (temperature 135 °C, He 32 ml/min) showed four peaks of **11** (t_R=16 min), **12** (18), **4** (27), and **3** (29) in the ratio of 2:7:72:19. Products **12**, **4**, and **3** could be isolated by preparative GLPC.

3-(2,2-Dimethyl-3-butenyl)furan (12): ^{1}H NMR ($CDCl_3$) δ=7.31 (m, 1H, furan), 7.18 (m, 1H, furan), 6.24 (m, 1H, furan), 5.86 (dd, J=18, 10 Hz, 1H, CH_2=C<u>H</u>–), 5.0—4.7 (m, 2H, C<u>H$_2$</u>=CH–), 2.38 (s, 2H, CH_2), 1.00 (s, 6H, CH_3); MS *m/z* (rel intensity) 150 (M^+; 62), 135 (27), 82 (59), 81 (47), 69 (100), and 41 (24). IR and elemental analysis could not be performed because of the small quantity of this sample.

Rosefuran (4): IR (neat) 2950, 1680, 1514, 1448, 1376, 1150, 1082, 1024, 892, and 726 cm^{-1}; ^{1}H NMR (CCl_4) δ=7.03 (d, J=1.6 Hz, 1H, furan), 5.95 (d, J=1.6 Hz, 1H, furan), 5.15 (t, J=7 Hz, 1H, olefin), 3.10 (d, J=7 Hz, 2H, CH_2), 1.83 (s, 3H, ring-CH_3), 1.63 (s, 6H, CH_3); MS *m/z* (rel intensity) 150 (M^+; 100), 135 (43), 111 (46), 95 (27), 71 (33), and 69 (54).

Perillene (3). IR (neat) 2950, 1680, 1508, 1446, 1380, 1168, 1068, 1030, 878, and 782 cm^{-1}; ^{1}H NMR (CCl_4) δ=7.20 (m, 1H, furan), 7.09 (m, 1H, furan), 6.13 (m, 1H, furan), 5.04 (t, J=7 Hz, 1H, olefin), 2.30 (m, 4H, CH_2), 1.63 (s, 3H, CH_3), 1.53 (s, 3H, CH_3); MS *m/z* (rel intensity) 150 (M^+; 83), 135 (27), 82 (30), 81 (47), 69 (100), and 41 (33).

(b) In the Presence of Copper(I) Iodide: The Grignard reagent **7**, prepared from magnesium (120 mg, 5 mmol) and the bromide (403 mg, 2.5 mmol) in THF (5 ml), was added to a suspension of copper(I) iodide (47 mg, 0.25 mmol) in THF (1 ml) at −5 °C and stirred for 20 min. To this mixture was added the phosphate **10** (333 mg, 1.5 mmol) in THF (3 ml) at −78 °C. The mixture was treated as described. Distillation (bp 110 °C/25 Torr) gave a mixture of **12** and **3** (187 mg, 83% yield) in the ratio of 2:98 (by GLPC).

Reaction of 3-Thienylmethylmagnesium Bromide (13) with Prenyl Diethyl Phosphate (10). (a) In the Absence of Copper(I) Iodide: 3-Thienylmethyl bromide (885 mg, 5 mmol) in THF (8 ml) was added dropwise to magnesium turnings (240 mg, 10 mmol) in THF (2 ml) cooled in an ice-salt bath. After the addition was complete, the mixture was gradually warmed to room temperature and stirred at that temperature for 1 h. The solution of the Grignard reagent thus prepared was transferred by the aid of a syringe into the second flask and cooled to −78 °C. To this was added a solution of prenyl diethyl phosphate (**10**) (666 mg, 3 mmol) in THF (5 ml) and the mixture was left overnight at room temperature. Workup followed by distillation (bp 155 °C/37 Torr) gave a colorless oil (352 mg, 71% yield). GLPC analysis using the 2 m column (tempetature 170 °C, He 76 ml/min) showed two peaks of **14** (t_R=11 min) and **5** (16) in the ratio of 1:99. They were isolated by preparative GLPC.

3-(2,2-Dimethyl-3-butenyl)thiophene (14): IR (neat) 3100, 2980, 2940, 1642, 1466, 1416, 1380, 1362, 1004, 914, 854, 836, and 784 cm^{-1}; ^{1}H NMR (CCl_4) δ=7.05 (m, 1H, thiophene), 6.77 (m, 2H, thiophene), 5.80 (dd, J=17, 8 Hz, 1H, CH_2=C<u>H</u>–), 5.05—4.65 (m, 2H, C<u>H$_2$</u>=CH–), 2.55 (s, 2H, CH_2), 0.95 (s, 6H, CH_3); MS *m/z* (rel intensity) 166 (M^+; 38), 110 (22), 98 (41), 97 (100), and 69 (75); Found: C, 72.02; H, 8.78%. Calcd for $C_{10}H_{14}S$: C, 72.23; H, 8.49%.

3-(4-Methyl-3-pentenyl)thiophene (5): IR (neat) 3110, 2980, 2935, 2860, 1675, 1442, 1378, 1240, 1104, 1079, 839, and 775 cm^{-1}; ^{1}H NMR (CCl_4) δ=7.10 (m, 1H, thiophene), 6.80 (m, 2H, thiophene), 5.05 (t, J=7 Hz, 1H, olefin), 2.85—2.15 (m, 4H, CH_2), 1.62 (s, 3H, CH_3), 1.50 (s, 3H, CH_3); MS *m/z* (rel intensity) 166 (M^+; 56), 151 (16), 110 (65). 98 (38), 97 (100), and 69 (60); Found: C, 71.97; H, 8.57%. Calcd for $C_{10}H_{14}S$: C, 72.23; H, 8.49%.

(b) In the Presence of Copper(I) Iodide: The Grignard reagent **13** prepared from magnesium (240 mg, 10 mmol) and the bromide (885 mg, 5 mmol) in THF (10 ml) was added to a suspension of copper(I) iodide (94 mg, 0.5 mmol) in THF (2 ml) at −5 °C and stirred for 15 min. To the mixture was added the phosphate **10** (666 mg, 3 mmol) in THF (5 ml) and the whole was treated as described above. Distillation (bp 160 °C/40 Torr) gave an oil (387 mg, 78% yield). GLPC showed that the oil was a mixture of **14** and **5** in the ratio of 18:82.

We wish to thank the Instrumental Center, the Institute for Molecular Science, for assistance in obtaining the ^{1}H NMR spectra (100 MHz).

The Identification of 3-Amino-9*H*-pyrido[3,4-*b*]indole Derivatives in L-Tryptophan Pyrolysates

Masao TADA,* Hisaaki SAEKI, and Atsushi OIKAWA

Research Institute for Tuberculosis and Cancer, Tohoku University, Seiryomachi 4-1, Sendai 980

(Received August 16, 1982)

The compounds, 3-amino-9*H*-pyrido[3,4-*b*]indole and 3-amino-1-methyl-9*H*-pyrido[3,4-*b*]indole, which are effectors in induction of sister chromatid exchanges in human cells, were isolated from pyrolysis products of L-tryptophan and characterized by HPLC and UV techniques.

A number of heterocyclic amines in pyrolysates of amino acids, proteins, and proteinaceous foods were found to be highly mutagenic to *Salmonella typhimurium*.[1] Sugimura *et al.*[2,3] reported that the main mutagenic components of pyrolysates of L-tryptophan were 3-amino-1,4-dimethyl- (**1**) and 3-amino-1-methyl-5*H*-pyrido[4,3-*b*]indole (**2**). Compounds **1** and **2** have been synthesized from 2-indolecarboxylic acid and 2,5-lutidine, respectively.[4] The isolation of 2-amino- (**3**) and 2-amino-3-methyl-9*H*-pyrido[2,3-*b*]indole (**4**) as mutagens from the pyrolysis product of tryptophan was also reported.[5] 9*H*-Pyrido[3,4-*b*]indole (**5**, norharman) and its 1-methyl derivative (**6**, harman) were also found in the pyrolysates.[3] Compounds **1** and **2** are carcinogenic to rodents[6] and active in inducing sister chromatid exchanges (SCEs) in human cells.[7]

In a previous paper,[8] we reported that 3-amino-9*H*-pyrido[3,4-*b*]indole (**7**) and 3-amino-1-methyl compound (**8**) were relatively weak SCE inducers, and inhibited SCE induction by other stronger SCE inducers. Thus, it is quite interesting to examine whether those compounds **7** and **8** are present in pyrolysates of amino acids and proteins or not. This paper describes the identification of **7** and **8** in L-tryptophan pyrolysates.

Results and Discussion

Pyrolysis of L-*Tryptophan and Analyses of Products.* A one hundred gram sample of L-tryptophan was pyrolyzed and dry-distilled by a direct flame at 400 to 500 °C for 1 h to give a tar (61 g). The tar was separated into acidic, basic, and neutral fractions by the ordinary method to afford 22 g of basic mixture. The mixture was fractionated by a silica-gel column using dichloromethane and a mixture of dichloromethane and ethanol as elution solvents. The fraction expected to contain the title derivatives was further fractionated on a column of silica gel into four subfractions by eluting with a mixture of dichloromethane and ethanol. The material at each step of purification was checked by thin-layer chromatography. Each of the resulting subfractions was subjected to preparative thin-layer chromatography on a silica-gel plate with an appropriate solvent system. The bands corresponding to **2**, **3**, **5**—**8**, and 1-amino-9*H*-pyrido[3,4-*b*]indole (**9**) were made visible under UV light, scraped off, and extracted with methanol. This isolation protocol is summarized in Fig. 1. Each of the methanol extracts was then applied to high performance liquid chromatography (HPLC) to analyze the target compounds, **2**, **3**, **5**—**8**, and **9**, qualitatively and quantitatively.

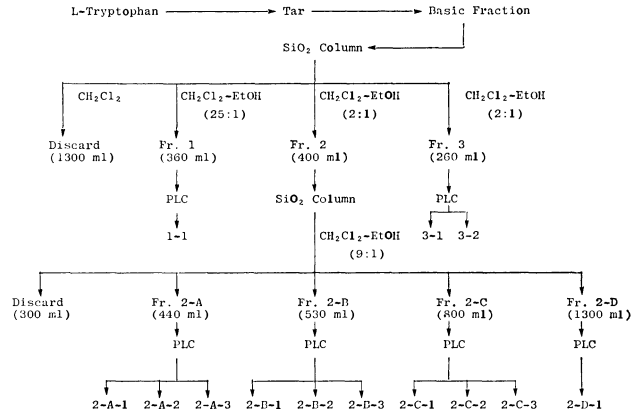

Fig. 1. Protocol for isolation of the target compounds from the pyrolysate.

Typical examples of analytical HPLC of fractions containing the target compounds are shown in Fig. 2. Satisfactory coincidence of retention times of the target bases with those of the authentic specimens was observed. The retention times of the title compounds, **7** and **8**, under various chromatographic conditions were in agreement with the bases of the pyrolysates (Table 1).

Analytical HPLC of Fraction 2-C-2 under the chromatographic condition No. 2 (Table 1) is shown in Fig. 3. Retention times of Peaks I and II coincided with those of **7** and **8**, respectively. Peaks I and II fractions were pooled separately from several identical runs of HPLC. As shown in Fig. 4, the absorption curves in UV of these two peak substances were completely identical to those of synthetic **7** and **8**, respectively. These facts confirm that peaks I and II are

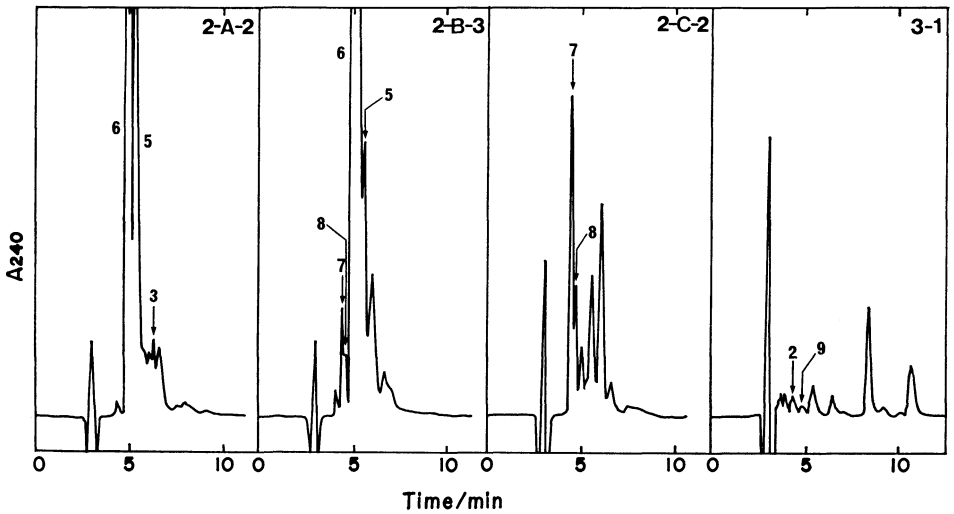

Fig. 2. Analytical HPLC of typical fractions containing the target compounds. The chromatographic conditions are shown as No. 1 in Table 1.

of **7** and **8**, respectively. Both **7** and **8** were also detected in fr. 2-B-2. Analyses of other bases of the pyrolysates were worked up in a similar manner to that given above. Compounds **3**, **5**, and **6** were mainly detected in both fr. 2-A-1 and fr. 2-A-2. Compounds **2** and **9** were found in fr. 2-D-1, fr. 3-1, and fr. 3-2. The contents of the target compounds were estimated from HPLC data, ignoring their decomposition and loss during separation, and are shown in Table 2.

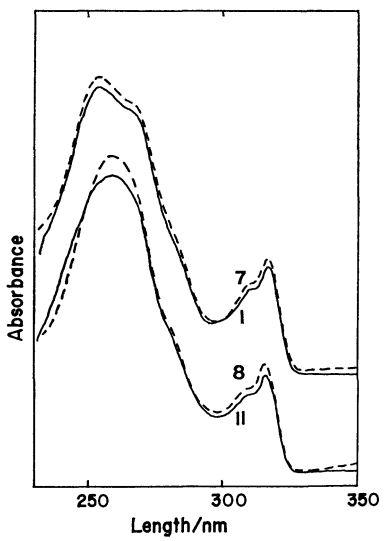

Fig. 4. UV spectra of Peaks I and II (——) and compounds **7** and **8** (----).

Compounds **7** and **8**, in methanol solution were stable at room temperature in the dark, but were considerably photosensitive. At a distance of 20 cm

TABLE 2. PYROLYSATES OF L-TRYPTOPHAN (100 g)

Compound	Content/mg
6	1140—1040
5	852—846

7	12.7—11.9
8	4.7—3.1
9	4.9—0.11
2	2.6—0.28

from a 20 W-fluorescent tube the half-life times of **7** and **8** were *ca.* 25 h and *ca.* 12.5 h in methanol, respectively (Fig. 5). From these facts it seems that the original contents of **7** and **8** in the fresh pyrolysates did not differ so much from each other as those seen in Table 2. Compound **2** was stable under these conditions.

The present work shows that the combined use of column and preparative thin-layer chromatography, HPLC, and UV is highly effective for analysis of pyrolysis products.

The identification of the title derivatives in pyrolysates of natural substances are currently under investigation.

Synthesis of 9H-Pyrido[3,4-b]indole Derivatives. 1,2,3,4-Tetrahydro-9*H*-pyrido[3,4-*b*]indole-3-carboxylic acid (**10**)[9] was treated with methanol and ethanol to afford methyl and ethyl esters (**11** and **12**), respectively. The methyl ester (**11**) was dehydrogened with sulfur to give methyl 9*H*-pyrido[3,4-*b*]indole-3-carboxylate (**13**). Treatment of the ethyl ester (**12**) under similar conditions resulted in dehydrogenation to afford ethyl carboxylate (**14**). When lead(IV) acetate was used, compounds **11** and **12** were also converted into **13** and **14**, respectively, but the yields were poor. Treatment of **13** and **14** with acid yielded the carboxylic acid (**15**) in a quantitative yield. The acid (**15**) was treated with methanol and ethanol in the presence of acid to afford the esters **13** and **14** in quantitative yields, respectively.

The carboxylic acid (**15**) was submitted to Curtius rearrangement by the diphenylphosphinic azide method[10] to yield the desired 3-amino derivative (**7**), which was confirmed to be exactly identical with the product obtained by the modified Snyder's method.[11] In this method, either **13** or **14** was converted to the hydrazide (**16**), which was then treated with nitrous acid to afford the corresponding azide (**17**). The treatment of the azide (**17**) with benzyl alcohol in toluene gave the benzyl carbamate (**18**), which was further submitted to the acidic or alkaline hydrolysis to yield the amino compound (**7**). In comparison with the overall yields of **7** from **13**, this modified method was better than the diphenylphosphinic azide method. Recently, Agarwal *et al.*[12] reported that **7** could be synthesized starting from methyl DL-1,2,3,4-tetrahydro-9*H*-pyrido-[3,4-*b*]indole-3-carboxylate *via* a Curtius reaction. Their method is essentially the same as our modified method.

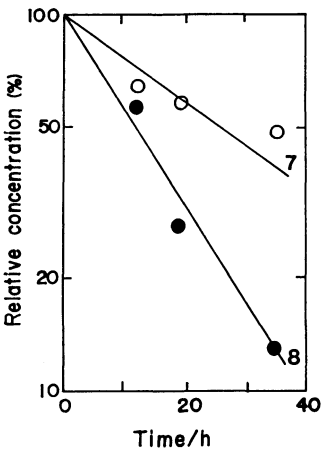

Fig. 5. Time course of degradation of **7** and **8**.

Experimental

Column chromatography was carried out over silica gel (Merck, Kieselgel 60). Merck pre-coated silica gel 60 F-254 TLC plates (5×20 cm²) and PLC plates (20×20 cm²) were used for the TLC and preparative TLC, respectively. Unless otherwise noted, the developing solvent system was a CH_2Cl_2–ethanol (9:1, v/v) mixture, and visualization was effected by the use of a Pan UV lamp. The homogeneity of each compound was always checked by TLC on silica gel. HPLC was made with a Toyo Soda Model HLC-803A equipped with an appropriate analytical column. Retention times of HPLC under various conditions are shown in Table 1. Absorption spectra were recorded with a Hitachi Model EPI-S_2 IR spectrophotometer and a Hitachi Model 124 spectrophotometer. Mass spectra were run with a Shimadzu LKB-9000 spectrometer, operating at an electron beam energy of 70 eV and with direct inlet. All melting points were taken on a hot-stage apparatus and are uncorrected.

Pyrolysis of L-Tryptophan. A hundred grams of L-tryptophan dried with P_2O_5 was pyrolyzed and dry-distilled by a direct flame at 400—500 °C for 1 h to give a tar (61 g). The tar was dissolved in ether (1 L) and the solution was extracted with 20% HCl (400 ml×5). The extracts were combined, cooled, and made alkaline with NaOH. The alkaline mixture was then extracted with ether (250 ml×6). The ethereal extract was washed (H_2O), dried (Na_2SO_4), and concentrated, giving 22.6 g of basic substances. The substances were dissolved in CH_2Cl_2 and fractionated by a silica-gel column (3×20 cm) using CH_2Cl_2 and CH_2Cl_2–EtOH (25:1 and 2:1, v/v) mixtures as elution solvents, giving three fractions (lst fr., 0.49 g; 2nd fr., 3.72 g; 3rd fr., 1.36 g). The second fraction was expected to contain 3-amino compounds, **7** and **8**, and was further fractionated on a column (5×20 cm) of silica gel into four subfractions by a CH_2Cl_2–EtOH (9:1, v/v) mixture to afford fractions, 2-

A-2-D. These procedures of fractionations are shown in Fig. 1. Each fraction was then subjected to preparative TLC to develop multiple times. In the cases of the lst fraction, fraction 2-C, and 3rd fraction, the number of times of development was three, and in the cases of fractions 2-A and 2-B it was two. In the case of 3rd fraction, the developing solvent system was a CH_2Cl_2–EtOH (4:1, v/v) mixture. A plate charged with fraction 2-D was developed six times.

The bands corresponding to **2**, **3**, **5**—**8**, and **9** were visualized under UV light. As shown in Fig. 1, band 1—1 was obtained from fr. 1, bands 3—1 and 3—2 from fr. 3, and band 2-D-1 from fr. D, respectively. Fractions 2-A, 2-B, and 2-C were each divided by similar chromatography into three bands. Each band was then scraped off, added to methanol, and mixed well. Each methanol mixture was centrifugalized and the resulting supernatant was then applied to HPLC to analyze the contents of the target compounds. These results are shown in Table 2.

*3-Amino-1-methyl-5*H*-pyrido[4,3-*b*]indole (**2**).* Compound **2** was supplied under the Research Resources Program (No. 57010022) for Cancer Research, the Ministry of Education, Science, and Culture: TLC R_f 0.01; UV (MeOH) 241 (log ε 4.61), 263 (4.87), 303 (4.00), and 315 nm (4.00).

*2-Amino-9*H*-pyrido[2,3-*b*]indole (**3**).* Compound **3** was also supplied under the same program as described above: TLC R_f 0.47; UV (MeOH) 231 (log ε 4.10), 260 (3.66), and 337 nm (3.76).

*9*H*-Pyrido[3,4-*b*]indole (**5**).* Compound **5** was prepared by a procedure similar to that reported[13] and purified with column chromatography, giving needles (from dil MeOH): mp 199—200 °C; TLC R_f 0.30; UV (MeOH) 233 (log ε 4.61), 248 (sh, 4.37), 281 (sh, 4.09), 288 (4.29), 366 (3.67), and 349 nm (3.68); IR (KBr) 3260 and 1630 cm^{-1}.

*1-Methyl-9*H*-pyrido[3,4-*b*]indole (**6**).* Compound **6** was prepared as reported[14] and purified with the chromatography, giving needles (from dil MeOH): mp 229—230 °C; TLC R_f 0.22; UV (MeOH) 234 (log ε 4.63), 238 (sh, 4.62), 248 (4.43), 281 (sh, 4.07), 287 (4.29), 333 (3.75), and 347 nm (3.76); IR (KBr) 3210 and 1622 cm^{-1}.

*Compounds **11** and **12**.* To a suspension of **10** (8.8 g) in MeOH (200 ml), conc. H_2SO_4 (10 ml) was added. The mixture was refluxed for 8 h, concentrated, poured into ice, and made neutral with K_2CO_3. The resulting mixture was extracted with CH_2Cl_2 and the extract was then washed (H_2O), dried ($MgSO_4$), and concentrated, giving 7.6 g (81%) of the methyl ester (**11**): TLC R_f 0.69.

A mixture of **10** (13 g) in EtOH (200 ml) and conc. H_2SO_4 (12 ml) was treated as above to afford 7.78 g (54%) of the ethyl ester (**12**): TLC R_f 0.76.

*The Esters **13** and **14**.* *i) With Sulfur*: A suspension of **11** (2.6 g) and powdered sulfur (1 g) in xylene (40 ml) was refluxed for 6 h and cooled. The crystals which then formed were purified by column chromatography to yield 2.05 g (80%) of **13**. Recrystallization from EtOH gave needles: mp 255—257 °C (decomp); TLC R_f 0.48; UV (MeOH) 216, 232, 269, 301 sh, 330, 345 nm; IR (KBr) 3250, 1723, and 1710 cm^{-1}.

Found: C, 68.78; H, 4.35; N, 12.10%. Calcd for $C_{13}H_{10}N_2O_2$: C, 69.01; H, 4.46; N, 12.38%.

The ethyl ester (**14**) was prepared from **12** in a 68% yield under similar conditions to those described above: Needles (from C_6H_6–EtOH); mp 207—208 °C; TLC R_f 0.53; IR (KBr) 3250 and 1725 cm^{-1}.

Found: N, 11.35%. Calcd for $C_{14}H_{12}N_2O_2$: N, 11.66%.

The esters **13** and **14** were obtained in quantitative yield by the treatment of the acid (**15**) with MeOH and EtOH in the presence of H_2SO_4, respectively.

ii) With Lead(IV) Acetate: To a solution of **11** (2.3 g) in acetic acid (35 ml), lead(IV) acetate (9.3 g) freshly prepared from Pb_3O_4 was added, and the mixture was allowed to stand at room temperature for 30 min. After addition of ethylene glycol (1 ml), the mixture was poured into ice-water and made alkaline with dil. aqueous ammonia to yield 565 mg (25%) of **13**.

The ester **14** was obtained in a 28% yield by the same treatment of **12** with lead(IV) acetate.

*The Carboxylic Acid (**15**).* *i) From **13***: A suspension of **13** (1.0 g) in 5% aq NaOH solution (20 ml) was heated on a water bath for 8 h to give a clear solution. Acetic acid was added to the solution to make it acidic. The precipitate thereby formed was collected, washed (MeOH), and dried, giving the carboxylic acid (**15**) in a quantitative yield: mp 318—320 °C (decomp).

*ii) From **14***: Treatment of **14** under similar conditions gave **15** in a quantitative yield.

*3-Amino-9*H*-pyrido[3,4-*b*]indole (**7**).* *i) By Modified Snyder's Method*: To a suspension of methyl ester **13** (5 g) in 1-pentanol (50 ml) and ethanol (15 ml), 100% hydrazine hydrate (20 ml) was added. The mixture was refluxed for 5 h, cooled, and filtered, giving 4.92 g (98%) of the hydrazide (**16**): TLC R_f 0.06; IR (KBr) 3320, 3240 (broad), and 1650 cm^{-1}. To a solution of **16** (2.26 g, 10 mmol) in conc. HCl (1.5 ml) and water (100 ml), a solution of $NaNO_2$ (828 mg, 12 mmol) in water (5 ml) was added under cooling with ice-water. The resulting mixture was allowed to stand in the cold with stirring for 30 min and then neutralized with saturated $NaHCO_3$ solution to give 2.27 g (96%) of the azide (**17**): TLC R_f 0.55. A mixture of **17** (2.27 g) in xylene (25 ml; dried with "Dry Soda") and benzyl alcohol (2.2 ml; dried with molecular sieve 3A) was heated at 110—120 °C for 20 min and then allowed to stand in a refrigerator overnight to afford 2.81 g (92%) of the benzyl carbamate (**18**): mp 208—212 °C (decomp), TLC R_f 0.53. To a suspension of **18** (2.8 g) in ethylene glycol (30 ml) and water (3 ml), KOH (3 g) was added. The mixture was stirred and heated at 150—160 °C for 30 min to yield 1.40 g (86%) of the amine (**7**). The overall yield of **7** from **13** is 74%: Bright yellow scales (from aq DMF); mp 286—288 °C (blacken) and 290—291 °C (decomp); TLC R_f 0.11, R_f 0.14 with CH_2Cl_2–EtOH (4:1, v/v); UV (MeOH) 236 (log ε 4.53), 248 (sh, 4.49), 292 (sh, 4.00), and 299 nm (4.10); IR (KBr) 3460, 3420, 3300, and 1625 cm^{-1}.

Found: C, 72.05; H, 4.90; N, 22.71%; M^+ 183. Calcd for $C_{11}H_9N_3$: C, 72.11; H, 4.95; N, 22.94%; M 183.

The acidic hydrolysis of the carbamate (**18**) was made as follows: A suspension of **18** (159 mg, 5 mmol) in 10% HCl (10 ml) was refluxed for 5 h and then made alkaline with diluted KOH aq solution, giving 64 mg (70%) of **7**.

The ethyl ester **14** was converted into the hydrazide **16** in an 85% yield under similar conditions.

ii) By Diphenylphosphinic Azide Method: To a mixture of **15** (850 mg) in triethylamine (1 ml), diphenylphosphinic azide (1.20 g) was added. The resulting mixture was heated at 80 °C for 1 h. Benzyl alcohol (1 ml) was added to the mixture, which was further heated at 120 °C for 10 h. After purification with column chromatography, 150 mg (12%) of the carbamate **18** was obtained and the alkaline hydrolysis of **18** gave **7**. The overall yield of **7** from **15** is 10%.

*3-Amino-1-methyl-9*H*-pyrido[3,4-*b*]indole (**8**).* Compound **8** was prepared from the methyl ester by a procedure

of the method of Snyder *et al.*,[11] giving needles (from MeOH) (Found: C, 73.01; H, 5.59; N, 21.45%): mp 228—229 °C; TLC R_f 0.11; R_f 0.15 with CH_2Cl_2–EtOH (4:1, v/v); UV (MeOH) 240 (log ε 4.56), 291 (sh, 4.00), and 297 nm (4.09); IR (KBr) 3380, 3170 (broad), and 1632 cm^{-1}. MS M^+ 197.

*1-Amino-9H-pyrido[3,4-b]indole (**9**).* According to the method reported by Snyder *et al.*,[15] **9** was prepared by the reaction of **5** and $NaNH_2$ in liquid NH_3, giving needles (from dil EtOH) in a 95% yield: mp 203—204 °C (decomp), TLC R_f 0.03; R_f 0.19 with CH_2Cl_2–EtOH (4:1, v/v); UV (MeOH) 240 (log ε 4.70), 278 (3.90), 288 (4.00), 299 (3.47), 326 (3.73), 337 (3.85), and 350 nm (3.78); IR (KBr) 3420, 3370, 3310, and 1632 cm^{-1}.

We thank Professor Kyozo Ogura, Tohoku University, for his helpful discussion. The present work was partially supported by Grants-in Aid for Cancer Research No. 57010079 from the Ministry of Education, Science and Culture, No. 55-04 from the Ministry of Health and Welfare, and from the Association for the Advancement of Cancer Research of Japan.

Syntheses of Acyclic Polyethers Containing a Ferrocene Nucleus and Its Extraction Ability

Sadatoshi Akabori,* Michiko Ohtomi, Masaru Sato,† and Seiji Ebine††

Department of Chemistry, Toho University, Funabashi, Chiba 274

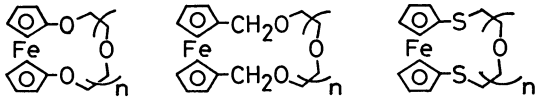
† *Chemical Analysis Center, Saitama University, Urawa, Saitama 338*

†† *Department of Chemistry, Faculty of Science, Saitama University, Urawa, Saitama 338*

(Received September 13, 1982)

Acyclic polyethers (**7**) (containing a ferrocene nucleus in both terminal sites) were synthesized by a one-pot reaction of 1,1′-diacetoxyferrocene with halide. Also, ferrocene derivatives (**11**) having polyethylene glycols were synthesized by the reaction of potassium salt of hydroxyferrocene with dihalide in DMF. On the addition of alkali metal thiocyanate in methanol, a hypsochromic shift and an increasing intensity of the absorption band at 438 nm were observed in ferrocene-containing polyethers **7**, suggesting the complexing of **7** with cations. However, a similar spectral change could not be observed in **11**. **7a** extracts silver and thallium ions most effectively, the extraction efficiency of several metal cations being in this order: $Ag^+ > Tl^+ > Cs^+ > K^+ > Li^+ > Na^+$.

While the investigations of macrocyclic polyether complexes[1] have been steadily gaining popularity during the past several years, it seems that most attention has so far been focused on the syntheses of new types of ligands. During the course of our investigation of polyoxa[*n*]ferrocenophanes **1**, **2**, and **3**,[2-4] we observed



1 2 3

1a n=4 n=2~4 n=1~4
1b n=3

that the incorporation of a ferrocene nucleus into the framework of a crown-ether ring increases the extraction efficiency toward a transition-metal cation. For example, **1** showed a high extraction percentage with the thallium cation, although it showed little or no extractability with alkali-metal cations. Furthermore, **2** similarly showed a high complexing ability with thallium and silver cations, although **1** decomposed rapidly when the silver cation was present. Those results suggest that the distance between the iron atom of the ferrocene nucleus and the incorporated silver cation controls the oxidation of the ferrocene nucleus.[3] In this connection, we wish now to report the syntheses of acyclic polyethers (**7**)(containing a ferrocene nucleus in both terminal sites) and ferrocene derivatives (**11**) having polyethylene glycols and the complexing ability of **7** and **11** with alkali and transition metal cations.

Syntheses. The syntheses of **7a—d** were carried out by the following method. The hydrolysis of 1,1′-diacetoxyferrocene (**4**) was carried out under an atmosphere of nitrogen by the usual method. To the resulting alkali solution of the potassium salt of 1,1′-dihydroxyferrocene (**5**) we added at once a solution of halide (**6**) in 60% ethanol at the reflux temperature. Then the mixture was refluxed for 3.5 h. After a usual work-up, the products were chromatographed on silica gel. From the main fraction, pure **7a—d** were obtained in moderate to good yields. It is noteworthy that this one-pot preparation of **7** starting directly from **4** avoids the isolation of very air-sensitive 1,1′-dihydroxyferrocene.[5] Compounds **11a—c** (containing a ferrocene nucleus in both terminal sites) were prepared by the reaction of hydroxyferrocene (**9**), which had itself been obtained by the hydrolysis of acetoxyferrocene (**8**), with appropriate dihalide (**10**) in DMF in the presence of potassium hydroxide. The molecular formula of **7a** was deduced to be $C_{24}H_{38}O_8Fe$ by means of mass spectroscopy (M^+, *m/e* 510) and the elemental analysis. In the ^{1}H-NMR spectrum of **7a**, the resonance for the α- and β-ring protons of the ferrocene nucleus appeared as the A_2B_2 pattern at δ=4.10 (4H, t, J=2.0 Hz) and 3.84 (4H, t, J=2.0 Hz) respectively, in addition to the signal of methylene protons as a multiplet at δ=3.45—3.90 (m, 24H) and the signal of the methyl group as a singlet at

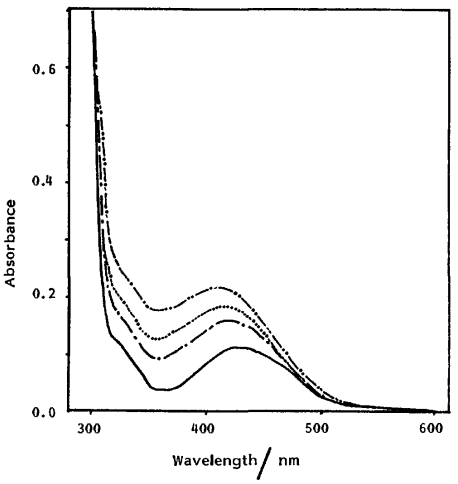

Fig. 1. Spectral change of **7a** by the addition of KSCN. Time: —— 0, ——— 1 h, ---- 2 h, —··— 3 h. Concentration: [**7a**]=1×10^{-3} M, [KSCN]=2.0×10^{-2} M.

δ=3.35 (s, 6H). The IR spectrum of **7a** showed ferrocene ring C–H absorption and ether-linkage absorption near 1480 and 1125 cm^{-1} respectively, but no absorption attributable to hydroxyl and carbonyl groups. The molecular formula of **11a** was deduced to be $C_{30}H_{38}O_6Fe_2$ by means of mass spectroscopy (M^+, *m/e* 608) and elemental analysis. The ^{1}H-NMR spectrum of **11a** showed the signal of unsubstituted ferrocene-ring protons as a singlet at δ=4.14 and the substituted ring protons as the A_2B_2 pattern at δ=4.06 (t, J=2.0 Hz, 4H, H_α) and 3.80 (t, J=2.0 Hz, 4H, H_β), in addition to the signal of the methylene protons at δ=3.72—3.94 (m, 8H) and 3.64 (s, 12H). The IR spectrum of **11** displayed absorptions of the ferrocene ring and ether linkage at 1470 and 1100 cm^{-1} respectively, but the absence of any bands arising from the hydroxyl group. The electronic spectra of **7** and **11** (λ_{max} 434 nm in MeOH) suggest the presence of a ferrocene nucleus. The structures of other new compounds were also determined by a method similar to that described above.

Additive Effect of Metal Salt. At first we examined the electronic spectral change in the ferrocenyl derivatives upon the addition of metal thiocyanate in order to determine the cation complexing ability qualitatively. It is well known[6] that the spectral shapes in the curves for the complexing polyethers are altered by the addition of complexable salts. A typical spectral change in **7a** on the addition of potassium thiocyanate in methanol is shown in Fig. 1. All compounds containing a ferrocene nucleus in the middle of the polyethylene glycol chain show a characteristic absorption maximum at 434 nm in methanol. Upon the addition of potassium thiocyanate, the curve of **7a** shows a remarkable change. Its hypsochromic shift and increase in absorbance suggest the complex formation between **7a** and potassium thiocyanate. These results are listed in Table 1. On the other hand, Compounds **11a—c**, which contain a ferrocene nucleus in both terminals, showed no spectral change upon the addition of any given alkali metal salt. In these compounds, no conformational change imposed on complexing with the metal cation takes place, probably because of the steric repulsion between the two ferrocenyl groups. Therefore, **11** could have no complexing ability with the metal cation.

Table 1. Electronic absorption spectral data and their metal complexes in methanol[a]

Compound	Additive salt λ/nm (ε)			
	None	LiSCN	NaSCN	KSCN

a) Measured in the presence of about a 50-fold molar excess of alkali metal thiocyanate at 20 °C.

Extractability. The extraction efficiency of **7** with alkali, alkaline earth, and transition-metal cations was measured according to Pedersen's method;[7] the results are listed in Table 2, together with those for **1a** and **1b**, which were synthesized previously.[2] It was observed that **7** showed only a little complexing ability with alkali and alkaline earth-metal cations, although they showed a relatively high complexing ability with transition metal cations. For the silver cation, Compounds **7a—d** have an excellently high complexing ability, as shown in Table 2. When the concentration of **7** was 7×10^{-4} M (1 M=1 mol dm^{-3}), the extractability could not be obtained because a rapid oxidative decomposition of the ferrocene nucleus by the complxed silver cation took place. However, this interaction may be weaker than that of polyoxa-[*n*]ferrocenophanes (**1**) with a closed oxyethylene chain, because, according to a consideration of its molecular model, the complexed silver ion in **7** is situated in a position apart from the iron atom of ferrocene because

a) Solvents: Water and dichloromethane (equal volumes). b) Ferrocenyl ether=7.0×10^{-4} M. Picric acid=7.0×10^{-5} M. Metal nitrate=0.1 M. c) Ferrocenyl ether=7.0×10^{-5} M.

of the flexibility of the polyether chain. The extractability of the metal cations by **7a** was in this order: $Na^+ < Li^+ < K^+ < Cs^+ < Tl^+ < Ag^+$.

These phenomena can be explained by the HSAB rule;[8] that is, the incorporation of the iron atom of ferrocene (a soft acid) into the framework of acyclic polyethers decreases the affinity to a hard cation (alkali and alkaline-earth metal ions) and increases the affinity to a soft transition-metal cation. Furthermore, the extraction efficiency of **7** for the several alkali metal cations examined here was in this order: **7a**>**7b**>**7c**≈**7d**. These results suggest that the extraction efficiency of these cations is dependent on the length of the oxyethylene unit of acyclic polyethers (**7**). The above results suggest that there is an appreciable interaction between the incorporated metal ion and the iron atom of the ferrocene nucleus. It is also surprising that **7a** and **7b**, containing many oxygen atoms, showed some extraction efficiency with the lithium ion, although **1a** and **1b** showed no extraction efficiency with the lithium ion. According to a consideration of their molecular models, this was probably because of the nonfitness between the guest ion and the hole size of the host molecule. The extraction efficiency of the lithium ion with **7a** and **7b** suggests that the lithium ion becomes incorporated into the cavity formed by one of the two acyclic polyether arms, while the uptake of the lithium ion into the cavity made by the two side oxyethylene arms seems to be unfavorable because the ion radius of the lithium cation is too small for fitting with the hole size of the host molecule. It is also interesting to note that **7a** and **7b** showed only a little extraction efficiency with alkaline earth-metal ions, although alkaline earth metal ions were not extracted by any of the compounds **1**.

Experimental

The melting points are uncorrected. The mass spectra were taken by using a JEOL-OlSG-2 spectrometer. The ^{1}H-NMR spectra were obtained on a Hitachi R-90 spectrometer, TMS being chosen as the internal standard. The optical spectra were obtained on a Hitachi Model 200-10 spectrometer.

Materials. 1,1′-Diacetoxyferrocene (**4**)[2,5] and acetoxyferrocene (**8**)[5,9] were prepared according to the previously reported method. The other reagents employed were commercial materials or were prepared by the usual methods.

Syntheses of 7a—d. *General Procedure*: **4** (2.14 mmol) was added to a 20% aq potassium hydroxide solution (17 ml) under nitrogen, and the mixture was stirred at 100 °C. After 30 min, a solution of halide (**6**) (4 ml) in ethanol was added all at once, and then the mixture was stirred for 3.5 h at 120 °C. After the solution had been cooled to room temperature, 30 ml of water was added to the reaction mixture. The ether extracts were combined, washed with water, dried over anhydrous magnesium sulfate, and concentrated to give a residue. The residual oil was chromatographed on a silica-gel column, using acetone as the solvent. The crude **7** thus obtained was rechromatographed on a column of silica gel. Elution with chloroform gave pure **7** as a yellow oil.

1,1′-Bis(1,4,7,10-tetraoxaundecyl)ferrocene (7a). Yellow oil, 53% yield. Found: C, 56.20; H, 7.58%. Calcd for $C_{24}H_{38}O_8Fe$: C, 56.47; H, 7.45%. MS (75 eV): *m/e* 510 (M^+, 81.7%) and 218 ($Fc(OH)_2$, 7.2%). ^{1}H-NMR ($CDCl_3$): δ=4.10 (t, 4H, J=2.0 Hz, H_α), 3.84 (t, 4H, J=2.0 Hz, H_β), 3.45—3.90 (m, 24H, OCH_2CH_2O), 3.35 (s, 6H, OCH_3).

1,1′-Bis(1,4,7-trioxaoctyl)ferrocene (7b). Yellow oil, 67% yield. Found: C, 57.13; H, 7.29%. Calcd for $C_{20}H_{30}O_6Fe$. C, 56.87; H, 7.11%. MS (75 eV): *m/e* 422 (M^+, 100%) and 218 ($Fc(OH)_2$). ^{1}H-NMR ($CDCl_3$): δ=4.16 (t, 4H, J=2.0 Hz, H_α), 3.93 (t, 4H, J=2.0 Hz, H_β), 3.60—4.01 (m, 16H, OCH_2CH_2O), and 3.43 (s, 6H, OCH_3).

1,1′-Bis(1,4-dioxapentyl)ferrocene (7c). Yellow oil, 85% yield. Found: C, 57.70; H, 6.87%. Calcd for $C_{16}H_{22}O_4Fe$: C, 57.49; H, 6.59%. MS (75 eV): *m/e* 334 (M^+, 100%) and 218 ($Fc(OH)_2$). ^{1}H-NMR ($CDCl_3$): δ=4.17 (t, 4H, J=2.0 Hz, H_α), 3.92 (t, 4H, J=2.0 Hz, H_β), 3.60—3.90 (m, 8H, OCH_2CH_2O), and 3.40 (s, 6H, OCH_3).

1,1′-Dimethoxyferrocene. Orange crystals, mp 36—37 °C (lit,[5] 35—36 °C), 78% yield. Found: C, 58.32; H, 5.81%. Calcd for $C_{12}H_{14}O_2Fe$: C, 58.54; H, 5.69%. MS (75 eV): *m/e* 246 (M^+, 100%) and 218 ($Fc(OH)_2$, 72.8%). ^{1}H-NMR ($CDCl_3$): δ=4.12 (t, 4H, J=2.0 Hz, H_α), 3.91 (t, 4H, J=2.0 Hz, H_β), and 3.58 (s, 6H, OCH_3).

Syntheses of 11a—c. *General Procedure*: **8** (3.2 mmol) was added to ethanol (16 ml) containing 10% aq potassium hydroxide. The mixture was stirred for 1 h at 100 °C under nitrogen and then evaporated in a vacuum. After the residue had been cooled to room temperature, dilute sulfuric acid (10 ml) was added to the residue, and the resulting yellow precipitates were collected by filtration. The yellow solid was dissolved in *N,N*-dimethylformamide (50 ml). To the solution was added potassium hydroxide (1.0 g), and the resulting solution was stirred at room temperature. After 20 min, dibromide (**10**) (0.98 mmol) was added all at once, and the mixture was stirred for 7 h at 80—100 °C. After the solution had been cooled to room temperature, water (200 ml) was added to the reaction mixture. The solution was extracted with four 100 ml-portions of ether. The ether extracts were combined, washed with water, dried, and concentrated to give dark yellow oil. The residue was chromatographed on a silica-gel column. Elution with chloroform gave yellow crystals except for **11a**.

Pentaethylene Glycol Diferrocenyl Ether (11a). Yellow oil, 68% yield. Found: C, 59.15; H, 6.48%. Calcd for $C_{30}H_{38}O_6Fe$: C, 59.41; H, 6.27%. MS (75 eV): *m/e* 608 (M^+, 87.8%) and 202 (FcOH, 100%), and 121 ($C_5H_5Fe^+$, 65.4%). ^{1}H-NMR ($CDCl_3$): δ=4.15 (s, 10H, Fc–H), 4.06 (t, 4H, J=2.0 Hz, H_α), 3.80 (t, 4H, J=2.0 Hz, H_β), 3.72—3.94 (m, 8H, OCH_2CH_2O), 3.64 (s, 12H, OCH_2CH_2O).

Tetraethylene Glycol Diferrocenyl Ether (11b). Yellow crystals, mp 49—51 °C, 86% yield. Found: C, 59.60; H, 6.30%. Calcd for $C_{28}H_{34}O_5Fe$: C, 59.79; H, 6.05%. MS (75 eV): *m/e* 562 (M^+, 100%), 202 (FcOH, 78.2%), and 121 ($C_5H_5Fe^+$, 60.9%). ^{1}H-NMR ($CDCl_3$): δ=4.14 (s, 10H, Fc–H), 4.05 (t, 4H, J=2.0 Hz, H_α), 3.78 (t, 4H, J=2.0 Hz, H_β), 3.72—3.92 (m, 8H, OCH_2CH_2O), and 3.67 (s, 8H, OCH_2CH_2O).

Triethylene Glycol Diferrocenyl Ether (11c). Yellow crystals, mp 87—89 °C, 68% yield. Found: C, 60.35; H, 5.98%. Calcd for $C_{26}H_{30}O_4Fe$: C, 60.28; H, 5.79%. MS (75 eV): *m/e* 518 (M^+, 100%), 202 (FcOH, 46.9%), 121 ($C_5H_5Fe^+$, 57.7%). ^{1}H-NMR ($CDCl_3$): δ=4.16 (s, 10H, Fc–H), 4.06 (t, 4H, J=2.0 Hz, H_α), 3.80 (t, 4H, J=2.0 Hz, H_β), 3.72—3.95 (m, 8H, OCH_2CH_2), and 3.61 (s, 4H, OCH_2CH_2).

Method of Solvent Extraction. Solvent extraction was carried out by the method described by Pedersen.[7] Equal volumes (5 ml) of dichloromethane containing 7×10^{-4} (or 7×10^{-5}) M of **7** and an aq solution containing 1×10^{-1} M MNO_3 (M: metal cations) and 7×10^{-5} M picric acid were agitated throughly at 25 °C. The solution was then

equilibrated at 25 °C, the aliquot of the upper aq solution was withdrawn, and its electronic spectrum was recorded. A similar extraction was performed with pure dichloromethane. The extractability was determined by means of the difference between two absorbances of picrate in the aq solution and by calculating using by the following equation:

$$\text{Extractability} = \frac{A_0 - A}{A_0} \times 100.$$

A_0 is the absorbance in the absence of MNO_3. A is the absorbance in the presence of MNO_3.

The authors wish to acknowledge the assistance given in the experimental work by Mr. Yoichi Habata and Miss Hiroko Ohteki in the experimental work.

(Received November 10, 1982)

Mononuclear polyoxathia[*n*]ferrocenophanes (**8a—d**) and binuclear polyoxadithia[*n,n*]ferrocenophanes were synthesized by the reaction of 1,1′-bis(ω-chloropolyethyleneoxy)ferrocene with sodium sulfide in *N,N*-dimethylformamide and the complexing ability of **8a—d** with alkali and transition metal cations was measured by an extraction method. Compound **8d** extracts a thallium ion specifically, the extraction efficiency of several ions being in the order: $Tl^+ \gg Rb^+ > K^+ > Cs^+ > Na^+ > Li^+$.

During the past decade, several papers[1] have described the remarkable interactions between alkali metal ions and crown ethers containing oxygen and heteroatoms. However papers concerned with the complexing ability of transition metal ions by crown ethers are rare.[2] Recently the syntheses of highly functionalized crown ethers have been reported, and in this connection several research groups[3-6] have described the preparation of new-type crown ethers containing a ferrocene unit as a ring member, in which the iron atom may play a role of coordinatable heteroatom. We have previously reported that polyoxa[*n*]ferrocenophanes (**1** and **2**)[7,8] and polyoxathia-[*n*]ferrocenophanes (**3**)[9] exhibit considerably enhanced transition metal cation binding, compared with the corresponding ring-membered crown ethers. In this paper we discuss the syntheses of polyoxathia[*n*]ferrocenophanes (**8**) and polyoxadithia[*n,n*]ferrocenophanes (**9**) and the complexing behavior of **8a—d** with alkali and transition metal picrates.

Syntheses of 8 and 9. It has been reported[7] that the potassium salt of 1,1′-dihydroxyferrocene (**5**), which is obtained from 1,1′-diacetoxyferrocene (**4**), reacts with the dihalide of polyethylene glycol (**6**) to give polyoxa[*n*]ferrocenophane (**1**). This method has been applied to the syntheses of **7**. We first attempted the reaction of ten molar equivalent of **6** with **5** which was obtained by the hydrolysis of **4**. The product, however, was an intractable mixture of unwanted materials and the yield of the desired **7** was very low. Subsequently, we examined the reaction of **4** with **6** in the presence of 18-crown-6 as phase transfer catalyst[10] (Scheme 1) and obtained the corresponding **7** in 26—54% yields together with small amounts of **1** which was formed by the reaction of an equivalent molar quantity of **6** with **4**. The structures of **1a—d** were also determined by the spectral data and admixture with authentic samples.[7] The molecular formula of **7a** was, for example, deduced to be $C_{14}H_{16}Cl_2O_2Fe$ by mass spectroscopy (M^+, *m/e* 342, 344) and elemental analysis. In the ^{1}H-NMR spectrum of **8a**, the resonances for the α- and β-ring protons of ferrocene nucleus appeared as an A_2B_2 pattern at δ=4.05 (t, J=2.0 Hz), and 3.65 (t, J=2.0 Hz), respectively, in addition to the signal of the methylene protons as a multiplet at δ=3.65—4.05 (m, 8H). The IR spectrum of **7** showed ferrocene ring C–H absorption and ether linkage absorption near 1470 and 1110 cm^{-1}, respectively, but no absorption attributable to hydroxy and carbonyl groups. A new series of polyoxathia[*n*]ferrocenophanes (**8**) and polyoxadithia[*n,n*]ferrocenophanes (**9**) were synthesized by the reaction of an equimolar amount of sodium sulfide with dichloride (**7**) in several solvents. Best results were achieved when *N,N*-dimethylformamide (DMF) was used as solvent at refluxing temperature. For example, the reaction of **7b** with sodium sulfide in DMF gave a mixture of mononuclear 1,4,10,13-tetraoxa-7-thia[13]ferrocenophane (**8b**) and binuclear 1,4,10,13,24,27,33,36-octaoxa-7,30-dithia[13,13]ferrocenophane (**9b**) in 22% and less than 1% yields, respectively. However, from the reactions of **7a** and **7d** with sodium sulfide the binuclear **9a** and **9d** could not be isolated. Furthermore, the yields of the products were very low when *t*-butyl alcohol or *t*-butyl alcohol–water (1:1) was used as solvent, although the products were similar. The structures of the products **8a—d**, **9b**, and **9c** were established by their spectral data and elemental analyses. The structures of **8b** and **9b** were confirmed as follows. The molecular formula of **8b** was deduced to be $C_{18}H_{24}O_4SFe$ by elemental analysis and mass spectroscopy (M^+, *m/e* 392). In the ^{1}H-NMR spectrum of **8b**, the resonance for the methylene protons attached to the sulfur atom appeared as a triplet (4H, J=10 Hz) at δ=2.85, in addition to a multiplet (12H, $-CH_2CH_2OCH_2CH_2S-$) at δ=3.65—4.00 and a pair of triplets (each 4H, J=2.0 Hz, Fc–H_α, Fc–H_β) at δ=4.10 and 3.82. The molecular formula of **9b** was also deduced to be $C_{36}H_{48}O_8S_2Fe$ by mass spectroscopy (M^+, *m/e* 748) and elemental analysis. In the ^{1}H-NMR spectrum of **9b**, the resonance for methylene protons attached

a) Solvents: Water and dichloromethane (equal volumes). b) Ferrocenophane $=7.0\times10^{-4}$ M (1 M = 1 mol dm^{-3}). Picric acid $=7.0\times10^{-5}$ M. Metal nitrate = 0.1 M.

to the sulfur atom appeared as triplet (4H, $J=11$ Hz) at $\delta=2.80$, in addition to a multiplet (24H, $-OCH_2CH_2OCH_2CH_2S-$) at $\delta=3.61$—4.00, a pair of triplets (each 8H, $J=2.0$ Hz, Fc–H_α, Fc–H_β) at $\delta=$ 4.09 and 3.84. The structures of the other new compounds were also determined by similar methods.

Extraction Efficiency of 8a—d. Compounds **8a—d** were tested for extractability with metal ions by the Pedersen method.[11] The data are summarized in Table 1, along with those of **1a** and benzo-15-crown-5. Compounds **8** (except **8d**) showed poor extraction efficiency with alkali metal ions. Furthermore, **8b** showed less extraction efficiency than those of the corresponding ring membered polyoxaferrocenophane (**1a**) with all alkali metal cations except lithium. This is not surprising for the ferrocenophanes since Pedersen[12] has shown that the complexing power of crown ethers for alkali metal ions is largely destroyed by substituting –S– for –O– in the macrocyclic polyether ring. From the HSAB rule[13] it is expected that the incorporation of a sulfur atom (a soft atom) into the macrocycle has a strong influence on the complexing ability with transition metal ions (a soft atom). Indeed, the extraction efficiency of **8** toward thallium ion was remarkably higher than those toward alkali metal ions, although the benzo-crown ether showed a similar extraction efficiency toward any of the cations described above. However, it was shown that the extraction efficiency of **8b** with thallium ion is weaker than that of **1a** which has the same ring member. For silver cation, the extraction efficiency of **8**, especially **8d**, could not be measured because of a rapid decomposition in which the iron atom of ferrocene nucleus might be oxidized by the incorporated silver cation. These results are similar to those of the extraction efficiency of **1** with silver ion.[7] Finally, it is noteworthy that **8d** showed high preference toward transition metal ions and the relationship between the hole size of the host molecule and the size of the guest ions was the second factor. The results seem to be reasonable when considering that the macrocyclic polyethers complex with cations within their very larger rings by wrapping themselves completely arround the cation. These results are similar to those of the complexing ability of macrocyclic antibiotics such as nonactin with metal cations.[14]

Experimental

All melting points are not corrected. ^{1}H-NMR spectra were determined in the indicated solvent on a Hitachi R-90 spectrometer. Chemical shifts are expressed in parts par million downfield from an internal tetramethylsilane. Mass spectra were recorded on a JEOL-OlSG-2 spectrometer and Hitachi M-80 spectrometer at 75 and 70 eV, respectively. Optical spectra were obtained on an Hitachi Model 100-10 spectrometer.

Materials. All solvents and reagents were used as purchased unless otherwise specified. 1,1′-diacetoxyferrocene (**4**) was prepared according to the previously reported method. 1,11-dichloro-3,6,9-trioxaundecane (**6c**) and 1,14-dichloro-3,6,9,12-tetraoxatetradecane (**6d**) were prepared according to the usual method. Silica gel for thin layer chromatography utilized Wakogel B-5F.

1,1′-Bis(3-chloro-1-oxapropyl)ferrocene (7a). 1,1′-Diacetoxyferrocene (**4**) (0.8 g, 2.6 mmol) was added to 10% aq potassium hydroxide solution (10 ml) containing 18-crown-6 (0.2 g, 0.075 mmol) under nitrogen and the mixture was stirred under refluxing. After 20 min a large excess of 1,2-dichloroethane (12 g, 80 mmol) was added at once and the mixture was stirred for 6 h at 80 °C. After the solution was cooled to room temperature, the mixture was extracted with three 20 ml portions of ether. The extracts were combined, washed with water, and concentrated *in vacuo*. The residual oil was chromatographed on a silica gel TLC (acetone–hexane 1:9 as eluent). The first band was extracted with acetone at room temperature, followed by filtration and evaporation of the solvent, to give a yellow oil which solidified on standing. The crude material was recrystallized from hexane to give 1,4-dioxa[4]ferrocenophane (**1a**) in 9% yield; mp 129—131 °C (lit,[7] 129—131 °C). The second band was extracted with acetone at room temperature, followed by filtration and evaporation of the solvent, to give yellow crystals. Recrystallization of the crude material from hexane gave **7a**, mp 58—59.5 °C, in 54% yield. ^{1}H-NMR ($CDCl_3$): $\delta=4.05$ (t, $J=2.0$ Hz, 4H, Fc–H_α), 3.65 (t, $J=2.0$ Hz, 4H, Fc–H_β), 3.65—4.05 (m, 8H, $-OCH_2-CH_2Cl$). MS (75 eV): *m/e* 342 and 344 (M^+). Found: C, 48.98; H, 4.66%. Calcd for $C_{14}H_{16}Cl_2O_2Fe$: C, 49.27; H, 4.66%.

1,1′-Bis(7-chloro-1,4-dioxahexyl)ferrocene (7b). Reaction of **4** (0.8 g, 2.6 mmol) with **6b** (12 g, 75 mmol) by the method described above gave **1b** (2%) and **7b** (53%). **1b**, mp 120—121 °C (lit,[7] 120—121 °C). **7b**, oil, ^{1}H-NMR ($CDCl_3$): $\delta=4.20$ (t, $J=2.0$ Hz, 4H, Fc–H_α), 3.80 (t, $J=$ 2.0 Hz, 4H, Fc–H_β), 3.65—4.07 (m, 16H, $-OCH_2CH_2-OCH_2CH_2Cl$). MS (75 eV): *m/e* 430 and 432 (M^+). Found: C, 49.93; H, 5.89%. Calcd for $C_{18}H_{24}Cl_2O_4Fe$: C, 50.15; H, 5.61%.

1,1′-Bis(9-chloro-1,4,7-trioxanonyl)ferrocene (7c). Reaction of **4** (0.8 g, 2.6 mmol) with **6c** (12 g, 60 mmol) gave **1c** (0.5%) and **7c** (26%). **1c**, mp 58—59 °C. **7c**, oil, ^{1}H-NMR ($CDCl_3$): $\delta=4.12$ (t, $J=2.0$ Hz, 4H, Fc–H_α), 3.89 (t, $J=2.0$, 4H, Fc–H_β), 3.76 (s, 12H, $-OCH_2CH_2O-$), 3.70—3.98 (m, 12H, $-OCH_2CH_2OCH_2CH_2Cl$). MS (75

eV): *m/e* 518 and 520 (M^+). Found: C, 50.63; H, 6.41%. Calcd for $C_{22}H_{32}Cl_2O_6Fe$: C, 50.89; H, 6.21%.

*1,1'-Bis(12-chloro-1,4,7,10-tetraoxadodecyl)ferrocene (**7d**).* Reaction of **4** (0.8 g, 2.0 mmol) with **6d** (12 g, 49 mmol) gave **1d** (0.7%) and **7d** (26%). **1d**, mp 60—61 °C (lit,[7] 60—61 °C). **7d**, oil, ^{1}H-NMR ($CDCl_3$): δ=4.13 (t, J=2.0 Hz, 4H, Fc-H_α), 3.87 (t, J=2.0 Hz, 4H, Fc-H_β), 3.75 (s, 16H, $-OCH_2CH_2O-$), 3.71—4.00 (m, 16H, $-OCH_2CH_2OCH_2CH_2Cl$). MS (75 eV): *m/e* 606 and 608 (M^+). Found: C, 51.57; H, 6.70%. Calcd for $C_{26}H_{40}Cl_2O_8Fe$: C, 51.42; H, 6.64%.

*Reaction of **7a** with Sodium Sulfide in DMF.* To a solution of $Na_2S\cdot 9H_2O$ (0.864 g, 3.6 mmol) in 200 ml of DMF at refluxing temperature was added a solution of **7a** (1.03 g, 3.00 mmol) in 40 ml of DMF under nitrogen. Stirring was continued at refluxing temperature for 20 h, and the reaction mixture was then cooled to room temperature. After evaporation of the solvent, the residue was diluted with water and extracted three times with ether. The combined extracts were washed with water, dried over anhydrous magnesium sulfate, and concentrated. The residual oil was chromatographed on silica gel TLC (dichloromethane: tetrachloromethane 4:1 as eluent). The first band was extracted with acetone at room temperature, followed by filtration and evaporation of the solvent, to give a yellow oil which solidified on standing. The crude material was recrystallized from hexane to give **8a**, mp 104—106 °C, in 66% yield. ^{1}H-NMR ($CDCl_3$): δ=4.20 (t, J=2.0 Hz, 4H, Fc-H_α), 4.14 (t, J=10.0 Hz, 4H, $-SCH_2CH_2O-$), 3.79 (t, J=2.0 Hz, 4H, Fc-H_β), 2.92 (t, J=10 Hz, $-OCH_2CH_2S-$). MS (75 eV): *m/e* 304 (M^+). Found: C, 55.61; H, 5.65%. Calcd for $C_{14}H_{16}O_2SFe$: C, 55.28; H, 5.31%. The second band was extracted with acetone at room temperature, followed by filtration and evaporation of the solvent, to give yellow crystals. Recrystallization of the crude material from hexane gave the starting material, mp 58.5—59.5 °C.

*Reaction of **7b** with Sodium Sulfide in DMF.* Reaction of **7b** (1.29 g, 3.00 mmol) with $Na_2S\cdot 9H_2O$ (0.864 g, 3.60 mmol) in 240 ml of DMF gave a mixture of **1b**, the starting material, and **9b**. After usual work-up, the reaction mixture was chromatographed on silica gel TLC (hexane: acetone 4:1). The first fraction was extracted with acetone, followed by filtration and evaporation of the solvent, to give yellow crystals. Recrystallization of the crude material from hexane gave **8b** as yellow crystals, mp 93—95 °C, in 21% yields. ^{1}H-NMR ($CDCl_3$): δ=4.10 (t, J=2.0 Hz, 4H, Fc-H_α), 3.82 (t, J=2.0 Hz, 4H, Fc-H_β), 3.65—4.00 (m, 12H, $-OCH_2CH_2O-$), and 2.85 (t, J=11 Hz, $-CH_2SCH_2-$, 4H). MS (75 eV): *m/e* 392 (M^+). Found: C, 55.13; H, 6.36%. Calcd for $C_{18}H_{24}O_4SFe$: C, 55.11; H, 6.17%. The second band gave the starting material, oil (8%). The third fraction was extracted with acetone. Evaporation of the solvent gave yellow oil. Crystallization of the crude material from hexane give pure **9b**, mp 108—109 °C, in 0.8% yield. ^{1}H-NMR ($CDCl_3$): δ=4.09 (t, J=2.0 Hz, 8H, Fc-H_α), 3.84 (t, J=2.0 Hz, 8H, Fc-H_β), 3.61—4.00 (m, 24H, $-OCH_2CH_2O-$), 2.80 (t, J=11 Hz, 8H, $-SCH_2CH_2O-$). MS (75 eV): *m/e* 784 (M^+). Found: C, 55.35; H, 6.24%. Calcd for $C_{36}H_{48}O_8S_2Fe$: C, 55.11; H, 6.17%.

*Reaction of **7c** with Sodium Sulfide in DMF.* Reaction of **7c** (1.55 g, 3.00 mmol) with $Na_2S\cdot 9H_2O$ (0.864 g, 3.60 mmol) in 240 ml of DMF gave a mixture of **8c**, **9c**, and the starting material. **8c**, mp 52—53.5 °C, in 30% yield, ^{1}H-NMR ($CDCl_3$): δ=4.09(t, J=2.0 Hz, 4H, Fc-H_α), 3.82 (t, J=2.0 Hz, 4H, Fc-H_β), 3.66 (s, 8H, $-OCH_2CH_2O-$), 3.60—3.95 (m, 12H, $-OCH_2CH_2OCH_2CH_2O-$), 2.79 (t, J=11 Hz, 4H, $-SCH_2CH_2O-$). MS(75 eV): *m/e* 480 (M^+). Found: C, 55.28; H, 6.93%. Calcd for $C_{22}H_{32}O_6SFe$: C, 55.00; H, 6.71%. **9c**, oil, a trace yield, ^{1}H-NMR ($CDCl_3$): δ=4.01 (t, J=2.0 Hz, 8H, Fc-H_α), 3.80 (t, J=2.0 Hz, 8H, Fc-H_β), 3.58 (s, 16H, $-OCH_2CH_2O-$), 3.47—3.80 (m, 24H, $-OCH_2CH_2OCH_2CH_2Cl$), 2.67 (t, J=11 Hz, 8H, $-SCH_2CH_2O-$). MS (75 eV): *m/e* 961 (M^+). Found: C, 55.26; H, 6.90%. Calcd for $C_{44}H_{64}O_{12}S_2Fe$: C, 55.00, H, 6.71%.

*Reaction of **7d** with Sodium Sulfide in DMF.* Reaction of **7d** (1.82 g, 3.00 mmol) with $Na_2S\cdot 9H_2O$ (0.864 g, 3.60 mmol) in 240 ml of DMF gave a mixture of **8d** and the starting material. **8d**, mp 47—48 °C, 38% yield, ^{1}H-NMR ($CDCl_3$): δ=4.10 (t, J=2.0 Hz, 4H, Fc-H_α), 3.83 (t, J=2.0 Hz, 4H, Fc-H_β), 3.69 (s, 16H, $-OCH_2CH_2O-$), 3.56—4.05 (m, 12H, $-OCH_2CH_2O-$), and 2.67 (t, J=11 Hz, 4H, $-SCH_2CH_2O-$). MS (75 eV): *m/e* 568 (M^+). Found: C, 55.23; H, 7.01%. Calcd for $C_{26}H_{40}O_8SFe$: C, 54.94; H, 7.09%.

Extraction Ability. Extraction ability of **8** with metal cations was examined by the method described in the previous paper.[7]

The authors wish to acknowlege the assistance given by Mr. Ribun Turuoka and Sumio Shibahara in the experimental work.

Hydroxymethylation and Alkoxymethylation of Methacryloguanamine

Toshihiro SEO,* Kenji ABE, and Toshio KAKURAI

Department of High Polymer Technology, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

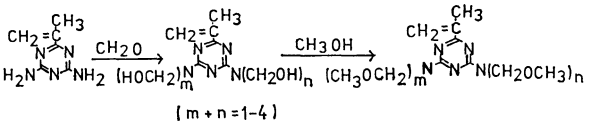
(Received October 7, 1982)

The reaction of 2-amino-4-(substituted amino)-6-isopropenyl-1,3,5-triazines (methacryloguanamine) with formaldehyde gave several new monomers having hydroxymethyl groups in satisfactory yields. These monomers were easily converted into the corresponding alkyl ethers with methanol. Their melting points and solubilities were affected considerably by the species and the number of substituted groups. Especially, tetrakis(hydroxymethyl)methacryloguanamine and its methoxymethyl derivative were readily soluble in water and nonpolar solvents, respectively. The former was polymerized and crosslinked smoothly to yield a insoluble polymer. Copolymerization of the latter with methyl methacrylate, however, gave soluble polymers, formed flexible and tough films. Similarly, the reactive polymers were prepared from polymers containing guanamine structure by hydroxymethylation followed by etherification.

Poymers containing amino-1,3,5-triazinyl groups have been investigated as industrial materials and heat-stable polymers. Furthermore, the polymers with aminotriazine units in the side or main chain are expected to have a variety of other properties, such as rigidity, intermolecular interaction, thermal stability and basicity.[1-3]

Recently, 2-amino-4-(substituted amino)-6-isopropenyl-1,3,5-triazines (methacryloguanamine) were readily prepared from methacrylic active esters and biguanides.[4] The syntheses and properties of copolymers of these monomers with styrene, unsaturated carboxylic acid, and their alkyl esters have been studied previously:[1,5] Softening and glass transition temperature rose, specific gravity increased, and solubilities markedly changed with the content of triazine units; copolymers with methacrylic acid were ampholytes.

This paper describes the syntheses of new reactive monomers with hydroxymethyl and methoxymethyl groups, starting from *N*-substituted methacryloguanamines by hydroxymethylation followed by etherification as given below; their polymerization and some properties of both the monomers and the polymers further were investigated. Similarly, the preparation of polymers having pendant highly reactive groups by polymer side reaction will be reported.



Experimental

Materials. Biguanides were prepared by the method of Kono and Odo[6] or Cohn[7] from dicyanodiamide and the corresponding amines. Formalin (*ca.* 37 wt%), paraformaldehyde, benzoyl peroxide, and DMSO-d_6 were commercial materials. All other reagents and solvents were commercially available and were used after purification if necessary. 2,4-Diamino-(AIPT), 2-amino-4-dimethylamino-(DMAIPT)-, and 2-amino-4-anilino-6-isopropenyl-1,3,5-triazine (AAIPT) were prepared from phenyl methacrylate and biguanides by the procedure described previously.[4]

Procedure. Hydroxymethylation and etherification of *N*-substituted methacryloguanamine were as described below.

2,4-Bis[bis(hydroxymethyl)amino]-6-isopropenyl-1,3,5-triazine (4F-AIPT): A mixture of 2.79 g (18.5 mmol) of AIPT and 12 cm³ of formalin which was adjusted to pH 9.0 with aqueous sodium hydroxide solution, was stirred at 50 °C. This mixture became homogeneous after 2 h and was stirred for another hour. The solution was allowed to stand at room temperature, and concentrated at 5—10 °C using evaporator. To the resulting solution was added 100 cm³ of ether, and colorless crystals (mp 122—124 °C) was obtained in 67.8% yield.

Found: C, 44.07; H, 6.29; N, 26.08%. Calcd for $C_{10}H_{17}N_5O_4$: C, 44.28; H, 6.27; N, 25.83%.

2,4-Bis[bis(methoxymethyl)amino]-6-isopropenyl-1,3,5-triazine (4M-AIPT): A mixture of 2.57 g of 4F-AIPT and 1 cm³ of concd HCl (*ca.* 35 wt%) in 30 cm³ of methanol was stirred at room temperature for 30 min and became clear. After the solution had been neutralized with a methanol solution of potassium hydroxide, and it was concentrated under reduced pressure at 10—20 °C. To the remaining product was added 75 cm³ of water, and the crude product obtained were recrystallized from ether to afford collorless needles (mp 46—47 °C) in 80.0% yield.

Found: C, 50.93; H, 7.89; N, 21.75%. Calcd for $C_{14}H_{25}O_4$: C, 51.38; H, 7.65; N, 21.41%.

Polymerization was carried out in vacuum-sealed ampoules. Methanol or methanol-water solution was used as a precipitant. The composition of compounds were evaluated from the carbon and nitrogen contents.

Measurement. IR, UV, and ^{1}H-NMR spectra were recorded on a Hitachi 285 spectrometer, a Hitachi 139 spectrometer, and a Hitachi R-24B (60 MHz) spectrometer, respectively. DTA experiments were carried out on a Shimadzu thermal analyzer DT-20. Softening temperature was measured with a Shimadzu MM-2 micro-softening apparatus.

Results and Discussion

Hydroxymethylation and Alkoxymethylation of Methacryloguanamines. As shown in Table 1, the reaction of 2,4-diamino-6-isopropenyl-1,3,5-triazine(AIPT) with formaldehyde was carried out at 50 °C for 3 h in the presence of basic catalyst. The observed molar ratio of hydroxymethyl group to AIPT increased with increasing initial molar ratio. Especially, for the molar ratio of 3.0 and 8.0, di- and tetrakis(hydroxymethyl) derivatives were obtained in adequate purity and satisfactory yield, respectively. Moreover, these monomers were easily converted into the corresponding derivatives with a large excess of methanol at room

a) Conditions; AIPT: 2.79 g (18.5 mmol), at pH 9.0, at 50 °C, for 3 h, F: formaldehyde or hydroxymethyl group. b) Conditions; 2F-AIPT or 4F-AIPT: 9.5 mmol, concd HCl: 1.0 cm^3, at room temp, for 30 min, M: methoxymethyl group. c) Calculated from the carbon and the nitrogen content. d) Calcd % of N are for pure bis- and tetrakis(hydroymethyl), and its methoxy derivatives.

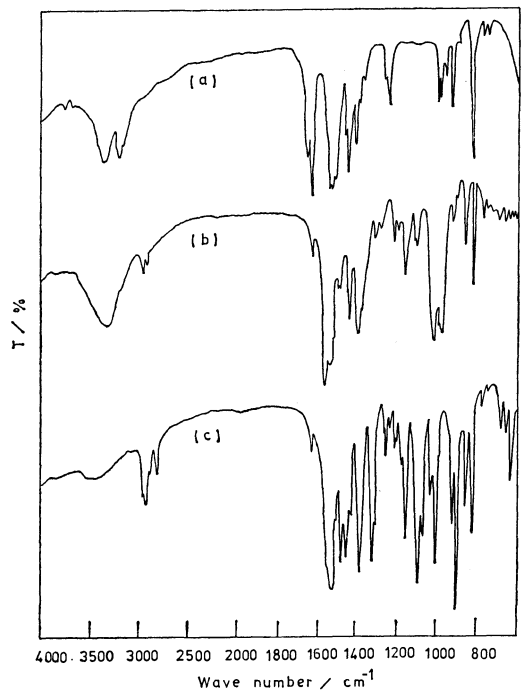

Fig. 1. IR spectra of (a) 2,4-diamino-6-isopropenyl-1,3,5-triazine (AIPT), (b) the tetrakis(hydroxymethyl) derivative (4F-AIPT), and (c) the tetrakis(methoxymethyl) derivative (4F-AIPT).

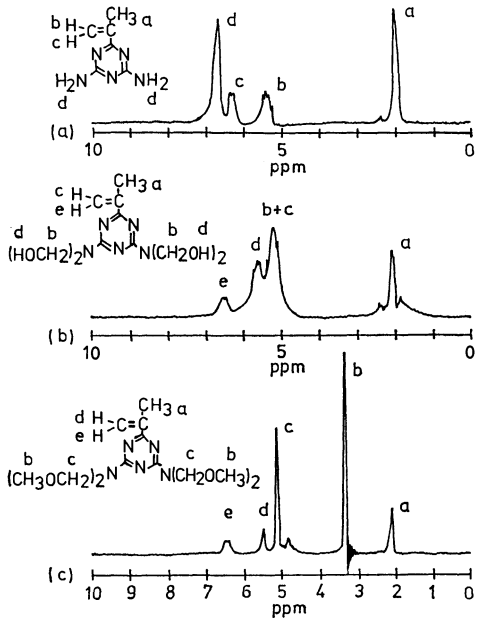

Fig. 2. ^{1}H-NMR spectra of (a) 2,4-diamino-6-isopropenyl-1,3,5-triazine (AIPT) in DMSO-d_6, and (b) the tetrakis(hydroxymethyl) derivative (4F-AIPT) in DMSO-d_6, and (c) the tetrakis(methoxymethyl) derivative (4M-AIPT) in CCl_4.

temperature in the presence of acid catalyst.

The new monomers were identified by elemental analyses, IR, ^{1}H-NMR, and UV spectra. For example, the IR spectra of tetrakis(hydroxymethyl) and tetramethoxy derivatives are shown in Fig. 1. The characteristic bands of isopropenyl-1,3,5-triazine were observed at 830 (the triazine ring), 1640 (the C=C stretching), and 930 cm^{-1} (the C–H bending), whereas the absorption near 1640—1660 cm^{-1} due to the N–H scissoring was rarely detected. In Fig. 1(b) the absorption at 1000 cm^{-1} due to C–O stretching indicates the presence of hydroxymethyl group;[8] the strong absorptions near 2950 and 1110 cm^{-1} are assigned to the C–H stretching and the C–O–C stretching of methoxymethyl group, respectively.

In the NMR spectrum given in Fig. 2(b), the signal at 6.68 ppm due to the protons of NH_2 group is rarely observed, and the appearance of the absorption in the region of 5.1 to 5.5 ppm may be attributed to the methylene protons and the hydroxyl group protons on $N(CH_2OH)_2$; in Fig. 2(c) the singlet signals at 3.35 and 5.16 ppm are due to the absorptions for the methoxyl and methylene protons on $N(CH_2OCH_3)_2$,[8] and the characteristic signals of isopropenyl group are also found at 2.11(CH_3), 5.49 and 6.49 ppm (CH_2=C). The ratio of the absorption intensities of the signals is recognized to be in agreement with the calculated one for pure hydroxymethyl or methoxymethyl derivative.

Table 2 shows that the solubilities of the reactive monomers obtained increased generally with the reduction of melting point (T_m). T_m of the hydroxymethyl derivatives rose 90 to 124 °C with the number of substituents, but became much lower than that of

a) Substituent; DMAIPT: 4-dimethylamino, AAIPT: 4-anilino. b) Conditions; DMAIPT or AAIPT: 15.0 mmol, at pH 9.0, at 50 °C, for 8 h, F: formaldehyde or hydroxymethyl group. c) Conditions; F-DMAIPT or F-AAIPT: 12.0 mmol, concd HCl: 1.0 cm^3, at room temp, for 30 min, M: methoxymethyl group. d) Calculated from the carbon and the nitrogen content. e) Calcd % of N are for pure mono(hydroxymethyl) and mono(methoxymethyl) derivatives.

AIPT (248 °C). Then, these derivatives became more soluble in MEK, alcohols and water compared to AIPT; these properties could be related to not only the decrease of intermolecular interaction between aminotriazine rings, but also the increase of intra- and intermolecular hydrogen bonding of hydroxymethyl group to nitrogen atom on the triazine ring.

On the other hand, upon introducing methoxyl groups into the bis(hydroxymethyl) derivative, T_m rose markedly and the solubilities decreased; this may be due to the increase of modelately strong interaction between triazine rings with NH groups.

The tetramethoxy derivative, however, showed noticeable properties: This monomer melts at a very low temperature (47 °C), soluble not only in alchols and water, but also readily soluble in nonpolar solvents such as hexane, benzene, and carbon tetrachloride; this suggests that introduction of four methoxyl groups to AIPT reduces the rigidity of the triazine ring, decreases extremely its intra- and intermolecular interaction,[5] and increases the hydrophobicity as well as the hydrophilicity.

In addition, in the UV spectra, the electron-releasing effect of hydroxymethyl and methoxymethyl groups resulted in a bathochromic shift compared with AIPT; ε values also increased.

Subsequently, as shown Table 3, the reaction of *N*-dimethylamino- (DMAIPT) or *N*-phenylmethacryloguanamine (AAIPT) with excess formaldehyde was performed at 50 °C for 8 h; the molar number of the combined formaldehyde to guanamine, however, was 1.0 and 1.4, respectively. Then, the almost complete conversion of these monomers to their methoxy derivatives occurred during a rapid lapse of time.

Table 4 shows that the reduction of T_m occurred remarkably with hydroxymethylation, and T_m rises significantly again with etherification. The mono(hydroxymethyl) derivative of DMAIPT as well as the tetramethoxy derivative of AIPT exhibited high solubilities in water and nonpolar solvents, in which the corresponding methoxy derivative was insoluble. The hydroxymethyl derivative of AAIPT was more readily soluble in benzene and alcohols than the methoxy derivative, but insoluble in water.

As a result, new reactive monomers were readily prepared from *N*-substituted methacryloguanamine, by hydroxymethylation followed by methoxymethylation; then these monomers differ in the melting points and the solubilities, which are affected markedly by the species and the number of substituents attached to triazine ring.[4]

a) Conditions; [4M-AIPT]+[MMA]=0.40 mol dm^{-3}, [*N*,*N*-dimethylaniline]=[BPO]=2×10^{-3} mol dm^{-3}, in dioxane at 30 °C, for 24 h. b) AIPT: 2,4-Diamino-6-isopropenyl-1,3,5-triazine. c) C=0.30 g/dl, in benzene at 30 °C. d) C=0.30 g/dl, in DMSO at 30 °C. e) ++: Readily soluble, +: soluble, ±: soluble at heating, −: insoluble, IPA: isopropyl alcohol, MCS: Methyl cellosolve, DMSO: dimethyl sulfoxide, δ: solubility parameter.

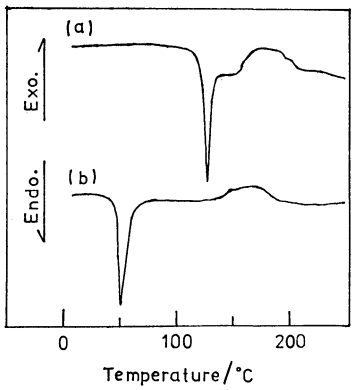

Fig. 3. DTA curves of (a) the tetrakis(hydroxymethyl) derivative (4F-AIPT) and (b) the tetrakis(methoxymethyl) derivative (4M-AIPT), derived from 2,4-diamino-6-isopropenyl-1,3,5-triazine (AIPT) at heating rate of 10 °C/min.

Preparation of Polymers Containing Hydroxymethylguanamines and/or Their Alkyl Ethers. As given in Fig. 3, the tetrakis(hydroxymethyl) derivative (4F-AIPT) melts at 125 °C and exhibited a broad peak near 130—180 °C, which probably corresponds to reaction (condensation and polymerization). Thus, by hot melt at 80—100 °C in aqueous solution, 4F-AIPT was polymerized and crosslinked smoothly to yield an insoluble polymer, having softening temperature (T_s) of over 300 °C; similarly, copolymerizations of 4F-AIPT with methyl methacrylate (MMA), using redox initiator at 30 °C, formed insoluble polymer films, which did not softened up to 300 °C.

On the other hand, the tetramethoxy derivative (4M-AIPT) was relatively stable below 100 °C, but polymerized at 140—160 °C to give a benzene-soluble polymer which softened at 150—155 °C. Moreover, as shown in Table 5, the redox copolymerizations of 4M-AIPT with MMA gave polymers having much lower softening temperature (90—120 °C) than both T_s of the polymer containing AIPT (over 250 °C) and T_s of poly(MMA) (145—155 °C); these polymers showed fair solubilities in not only benzene and dioxane, but also in alcohols and DMSO, and gave a more flexible, tough, and transparent film, compared with the polymer containing AIPT.

Finally, as shown in Table 6, AIPT–MMA copolymer (AIPT content 10.2 mol%) reacted with paraformaldehyde in DMF at 80 °C over basic catalyst to give a crosslinked insoluble polymer with hydroxymethyl groups, having T_s of over 300 °C. Subsequently, hydroxymethylation was carried out at pH 9 using a large excess of paraformaldehyde and butanol at 60 °C, followed by hydroxymethylation at pH 3 with maleic anhydride as acid catalyst. Then, the IR spectra of the product shows the strong absorptions

1.80	1.90	50/40	60/9/18[b] 60/3/18[c]	2.05	1000, m 1100, m	105—110	Soluble: DMSO, Acetic acid

a) AIPT-MMA copolymer (triazine content 10.2 mol%); softening temperature: 177—187 °C, soluble: DOX, MCS, DMSO, Acetic acid, Insoluble: IPA, Bz, MEK. b) Hydroxymethylation. c) Butoxymethylation using maleic anhydride as acid catalyst. d) s: Strong intensity, m: medium intensity.

near 1110 cm^{-1} (CH_2OBu) and 1000 cm^{-1} (CH_2OH), and the C(%)/N(%) value (10.4) became much larger than that of starting polymer (8.6); the polymer probably contains 10 mol% of triazine rings having two butoxymethyl groups and one hydroxymethyl group as pendants. The properties of this polymer, therefore, are very similar to that of the above-mentioned copolymers containing more than 25 mol% of triazine rings with four methoxyl groups; the polymer obtained, which softened at 108—113 °C, dissolved freely in 2-propanol, benzene, and MEK, whereas the starting polymer, having T_s of 177—187 °C, was insoluble in these solvents. A longer reaction period gave a flexible polymer, film, soluble only in DMSO or organic acid, maybe due to the intramolecular crosslinking reaction.

In conclusion, the reactive polymers containing hydroxymethyl and/or alkoxymethylguanamines were readily prepared both by polymerization of the suitable monomers and by polymer side reaction. Their properties were greatly affected by the species of substituents and the composition of the polymer;[5] these effects can be based upon not only the rigidity of triazine rings and the flexibility of substituents, but also their intra- and/or intermolecular interactions and reactivities.

In addition, these polymers are thermally crosslinkable with or without acid catalyst. Therefore, the above monomers and polymers having highly reactive groups may be utilized as a crosslinking agent for thermosetting resin or an adhesive as well as a modifier for improved properties of various polymers.

The authors wish to thank Mr. T. Saito of Tokyo Institute of Technology for his elementary analysis.

The Synthesis of Tetrakisdehydrotetraazaannulenes. Tetramethyl[36]-, -[48]annulene, and Their Benzoannelated Derivatives

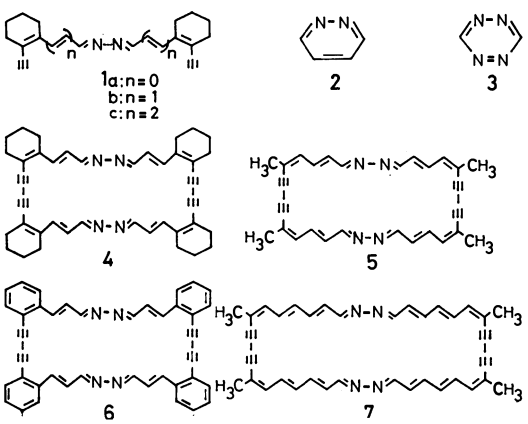
Jūro Ojima,* Mitsuru Kirita, Yoshiko Murosawa, and Tetsuya Nakada

Department of Chemistry, Faculty of Science, Toyama University, Gofuku, Toyama 930

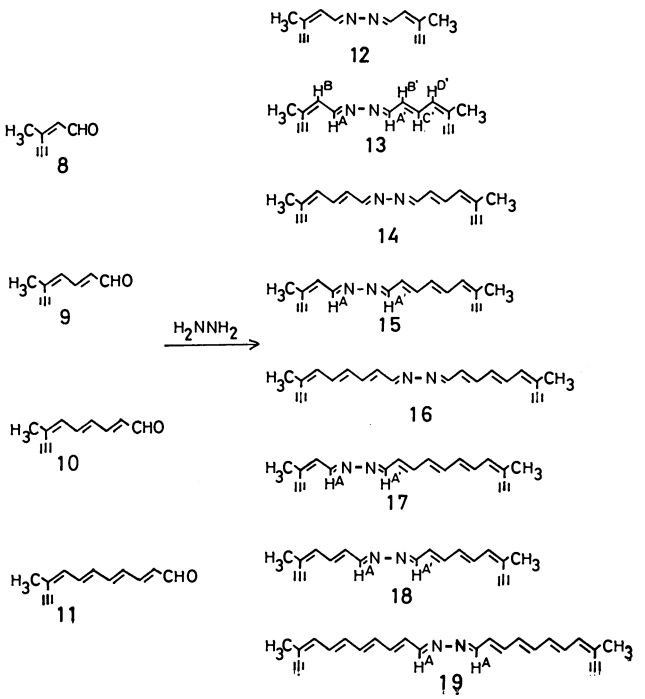
(Received October 13, 1982)

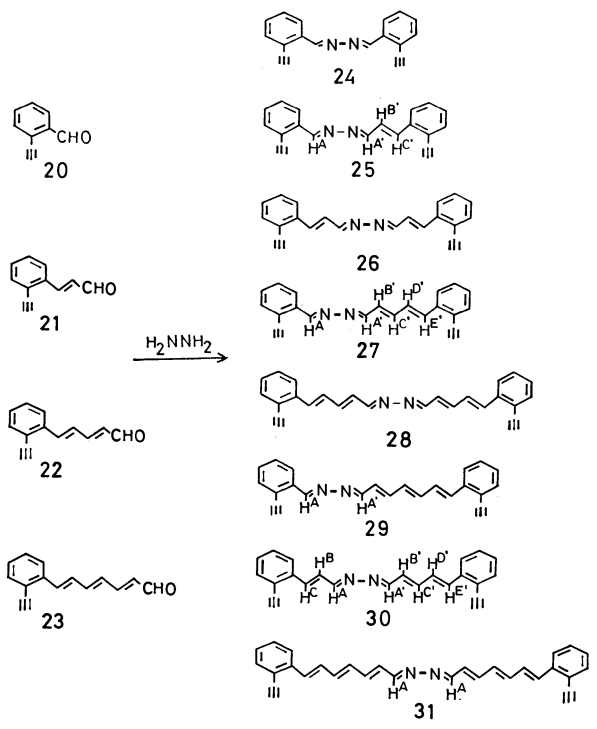
The conjugated mono-, di-, tri-, and tetraene, containing a terminal acetylene group were converted into a variety of symmetrical and unsymmetrical conjugated azines on treatment with aqueous hydrazine in ethanol. Oxidative couplings of these azines were attempted using anhydrous copper(II) acetate in pyridine and ether. Each of unsymmetrical azines, 3,16-dimethyl-8,9-diaza-3,5,7,9,11,13,15-octadecaheptaene-1,17-diyne and 1,10-bis(*o*-ethynylphenyl)-4,5-diaza-1,3,5,7,9-decapentaene, gave the corresponding two isomeric cyclic dimers: The former gave 7,12,25,30-tetramethyl-8,10,26,28-tetrakisdehydro-1,2,17,18-tetraaza[36]annulene and 7,12,25,30-tetramethyl-8,10,26,28-tetrakisdehydro-1,2,19,20-tetraaza[36]annulene, and the latter gave 6,7:12,13:24,25:30,31-tetrabenzo-8,10,26,28-tetrakisdehydro-1,2,17,18-tetraaza[36]annulene and 6,7:12,13:24,25:30,31-tetrabenzo-8,10,26,28-tetrakisdehydro-1,2,19,20-tetraaza[36]annulene, although only in poor yields. Coupling of symmetrical azines, 3,22-dimethyl-12,13-diaza-3,5,7,9,11,13,15,17,19,21-tetraeicosadecaene-1,23-diyne and 1,16-bis(*o*-ethynylphenyl)-8,9-diaza-1,3,5,7,9,11,13,15-hexadecaoctaene, furnished cyclic dimers, 11,16,35,40-tetramethyl-12,14,36,38-tetrakisdehydro-1,2,25,26-tetraaza[48]annulene and 10,11:16,17:34,35:40,41-tetrabenzo-12,14,36,38-tetrakisdehydro-1,2,25,26-tetraaza[48]annulene, respectively, in moderate yields. Examination of ^{1}H NMR spectra indicates that these tetraazaannulenes are atropic.

In 1974, Yamamoto and Sondheimer attempted oxidative couplings of conjugated azines **1a—c** using copper(II) acetate monohydrate in pyridine and ether under relatively dilute conditions in order to obtain the corresponding monomeric and/or dimeric cyclic compounds, which are macrocyclic analogs of pyridazine (**2**) and 1,2,4,5-tetrazine (**3**), respectively.[1] They obtained cyclic dimer **4**, a higher analog of **3**, only from azine **1b**. Subsequently, Darby *et al.* found that oxidative coupling of terminal diacetylenes to macrocyclic 1,3-diacetylenes usually proceeds in good yield when anhydrous copper(II) acetate instead of the monohydrate is employed.[2] We used advantageously the conditions for oxidative couplings of symmetrical conjugated, methylated azines **12**, **14**, **16** and their benzoannelated azines **24**, **26**, **28**. In practice, cyclic dimers **5** and **6** were obtained from azines **14** and **26**, respectively, as similarly as **4** formed from azine **1b**, and further we could also obtain cyclic dimer **7** from azine **16**.[3] However, we could not obtain monomeric cyclic compounds corresponding to higher analogs of pyridazine (**2**) from these azines even under the conditions reported by Darby *et al.*,[2] as well as under several different conditions. Thus, the failure of attempts to obtain monomeric compounds from these azines led us to consider the following.



Firstly, oxidative couplings should be attempted under high dilution conditions in order to obtain monomers from azines. Secondly, if symmetrical azines would be converted into the corresponding monomers, preparation of unsymmetrical azines available from aldehydes **8—11** and **20—23** is worthwhile, since we had it in mind that the unsymmetrical azines (**13**, **17**, **18**, **25**, **29**, **30**) make formally a potentially aromatic $(4n+2)\pi$-electron system on their intramolecular cyclization, in contrast that the symmetrical azines (**12**, **14**, **16**, **19**, **24**, **26**, **28**, **31**) do a nonaromatic $4n\pi$-system. This paper is concerned with synthesis and properties of title compounds together with attempts of oxidative couplings of symmetrical and unsymmetrical azines **12—19** and **24—31**, prepared from aldehydes **8—11** and **20—23**.





Results and Discussion

For preparation of azines **12**—**19**, a large amount of aldehydes **8**—**11** were required. Therefore, reported procedures[3,4] of preparation of aldehydes **9** and **10** were reexamined, since yields were variable (20—80% in different experiments on **8** and 15—55% in those on **9**). The starting material was (*Z*)-3-methyl-2-penten-4-ynal (**8**), which was prepared by acid treatment of 1-chloro-3-methyl-1-penten-4-yn-3-ol.[5] A homologation of **8** to (2*E*,4*Z*)-5-methyl-2,4-heptadien-6-ynal (**9**)[4] as well as a further homologation of **9** to (2*E*,4*E*,6*Z*)-7-methyl-2,4,6-nonatrien-8-ynal (**10**)[3] was modified, according to the procedure of that of (*Z*)-3-*t*-butyl-2-penten-4-ynal reported by Iyoda *et al.*[6] Isolation of diethyl acetal of **8**, condensation of the acetal with ethyl vinyl ether in the presence of boron trifluoride etherate, and then hydrolysis of the condensate with aqueous acetic acid containing sodium acetate gave the dienyne aldehyde **9** in 64% yield. The aldehyde **9** was then homologated to the trienyne aldehyde **10** in 70% yield in a similar manner to that of **8** to **9**, except without isolation of diethyl acetal of **9** (Experimental). Thus, modification of a reported procedure could be adapted to preparation of a large amount of aldehydes **9** and **10**.

For preparation of benzoannelated azines **24**—**31**, the starting material was *o*-ethynylbenzaldehyde (**20**), which was prepared as reported.[8] A homologation of **20** to **21**,[9] and subsequent homologations of **21**[10] to **22**[11] were carried out by Wittig condensation with [(1,3-dioxolan-2-yl)methyl]triphenylphosphonium bromide and lithium ethoxide, followed by hydrolysis, as reported previously.

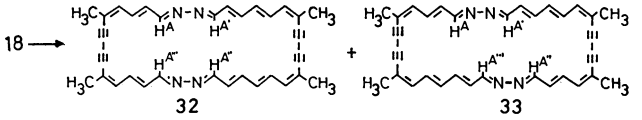
Treatment of aldehydes **8**—**11** and **20**—**23** in ethanol with aqueous hydrazine yielded the corresponding symmetrical azines **12**, **14**, **16**, **19**, **24**, **26**, **28**, **31**, respectively, as described previously.[3] Similarly, combination of two different aldehydes in each group of **8**—**11** and **20**—**23** in place of only one yielded a variety of unsymmetrical azines **13**, **15**, **17**, **18**, **25**, **27**, **29**, **30**. As expected in formation of unsymmetrical azines, the product was admixed with two different symmetrical azines: For formation of **13**, **12**, and **14** were also formed. Careful chromatography on alumina resulted in an almost complete separation of three azines. The yields and melting points of these unsymmetrical azines are summarized in Table 1, altogether with those of symmetrical azines **19** and **31**.

Table 1. Yields and melting points of azines

Compd	Yield %	Mp θ_m/°C
13	23	137—138 (decomp)
15	19	132—133 (decomp)
17	22	100—101 (decomp)
18	46	172—173 (decomp)
19	39	238—240 (decomp)
25	41	136—137
27	30	141—142
29	43	143—144
30	23	136—137
31	54	278—279 (decomp)

Oxidative couplings of these azines were attempted. At first, in order to obtain monomeric cyclic compounds from symmetrical azines **12**, **14**, **16**, an attempt was made under high dilution conditions. Thus, very slow addition of **12** was done to a stirred solution of anhydrous copper(II) acetate in a large volume of pyridine, ether, and methanol (*ca.* 2000 ml, 500 ml, 500 ml). After careful work up of the reaction mixture, the product was chromatographed on alumina. However, no monomeric and dimeric compounds were obtained. Oxidative couplings of azines **14** and **16** under high dilution conditions were carried out similarly to that of azine **12**. Neither azines **14** nor **16** gave monomers, but the respective dimers **5** and **7** in lower yields than in those under the conditions reported previously.[3]

These results led us to consider it impossible to obtain monomeric cyclic compounds from the other azines even if high dilution conditions would be used. Therefore, we turned out to investigate thereafter oxidation of azines, summarized in Table 1, using anhydrous copper(II) acetate in pyridine and ether at 50 °C under relatively dilute conditions as reported by Darby *et al.*[2]



Among the unsymmetrical methylated azines, none of **13**, **15**, and **17** gave monomeric and dimeric cyclic compounds in attempted oxidative couplings. On the other hand, an oxidative coupling of azine **18** resulted in a mixture of cyclic dimers in a yield of 3.5%, which,

upon chromatography on alumina, yielded a high melting isomer and a low melting isomer in a ratio of *ca.* 3:1. As the isomerism can reasonably be attributed to positional isomers due to two azine groups in tetrakisdehydro[36]annulene system, we tentatively assigned a high melting isomer to 7,12,25,30-tetramethyl-8,10,26,28-tetrakisdehydro-1,2,17,18-tetraaza-[36]annulene (**32**) and a low melting isomer to 7,12,25,30-tetramethyl-8,10,26,28-tetrakisdehydro-1,2,19,20-tetraaza[36]annulene (**33**). Both **32** and **33** were obtained as microcrystalline purple powders, and decomposed on exposure to diffused light and air within 1—2 d, and did at 144 °C and 112 °C, respectively, on attempted melting point determination. The gross structure of **32** and **33** was supported by mass spectra, which showed molecular ion peaks at *m/e* 520. The infrared spectra of **32** and **33** exhibited maxima at 2180 and 2190 (–C≡C–), 1615 and 1620 (C=N), respectively, and 995 cm^{-1} (*trans* C=C), but no maxima at −3300 cm^{-1} due to a terminal acetylene. The electronic spectra of both **32** and **33** in tetrahydrofuran, illustrated in Fig. 1, altogether with those of tetramethyl[32]- **5** and -[40]annulene **7**, showed main maxima at the same wavelength, 367 nm, which is middle

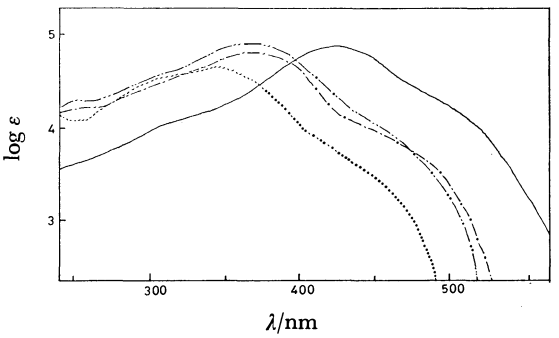


Fig. 1. Electronic spectra of tetraazatetrakisdehydroannulenes **5** (----), **32** (————), **33** (————————), and **7** (——) in THF.

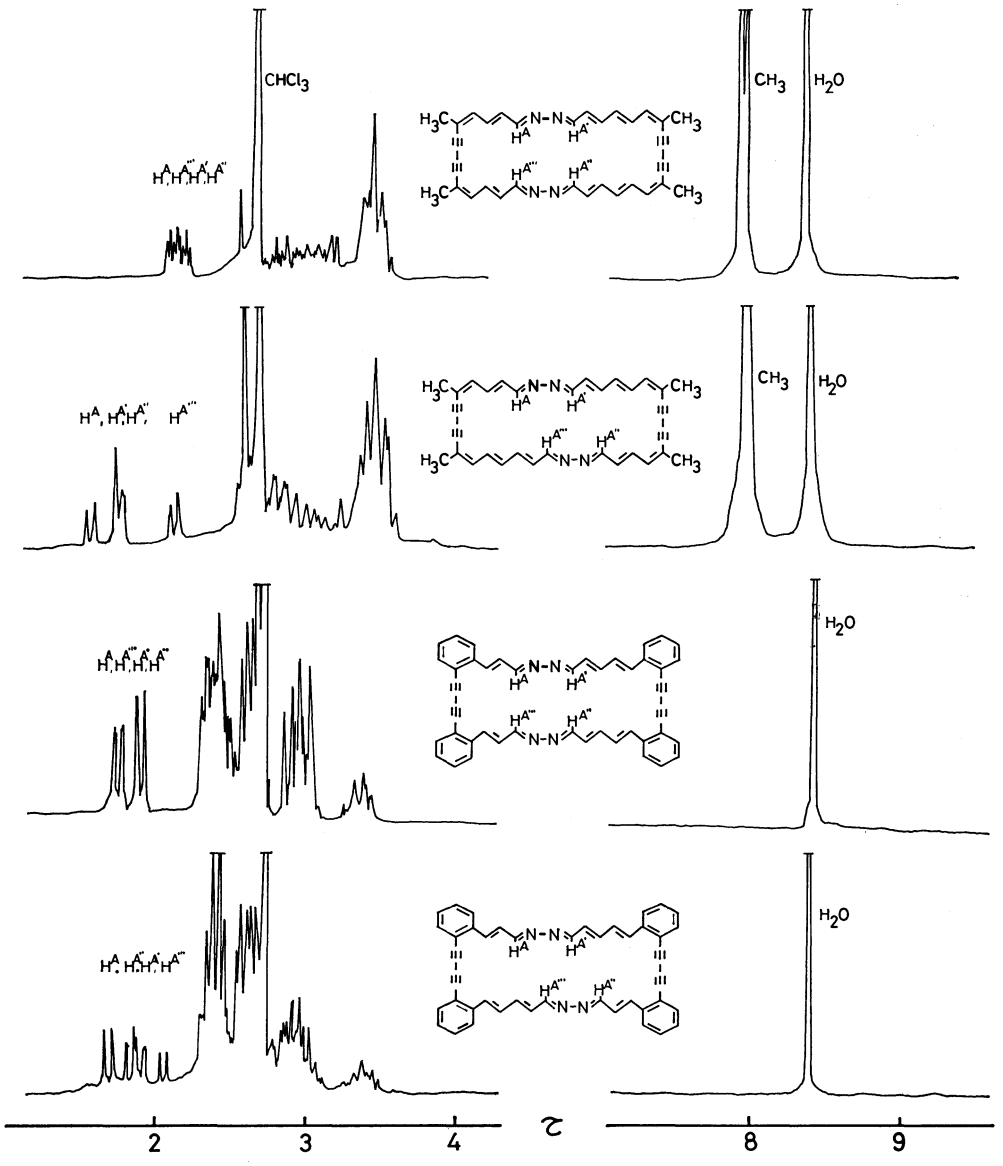

Fig. 2. The ^1H NMR FT spectra of **32**, **33**, **38**, and **39** in $CDCl_3$ at 200 MHz (internal standard, TMS).

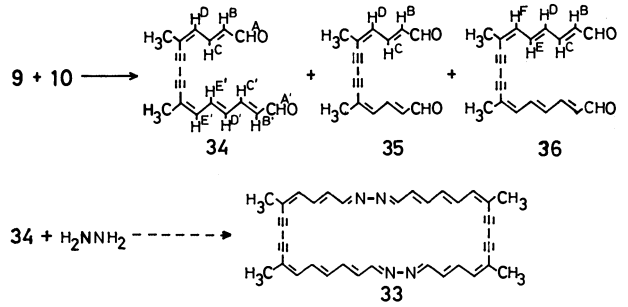
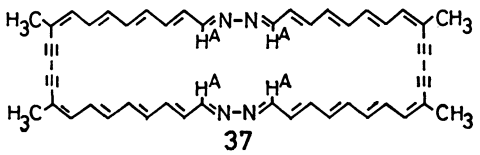
one of the main maxima observed in **5** (339 nm) and **7** (381 nm), reflecting the number of double bonds in the cyclic conjugated system.

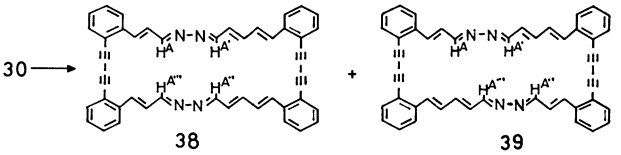
The ^{1}H NMR spectra were taken in $CDCl_3$ at 200 MHz, and are reproduced in Fig. 2. In these ^{1}H NMR spectra of cyclic tetraazaannulene system, it has been found that only protons adjacent to nitrogen atom resonate at relatively low field among olefinic protons. In annulenes **5** and **7** the protons (H^A) resonate at τ 2.30 and 2.03, respectively.[3] The spectrum of **32** consists of signals of τ 2.14 (1H, d, J=9 Hz, H^A), 2.16 (1H, d, J=9.5 Hz, $H^{A'''}$), 2.23 (1H, d, J=9.5 Hz, $H^{A'}$), 2.26 (1H, d, J=9 Hz, $H^{A''}$), *ca.* 2.6—3.6 (m, olefinic H), 7.98 (6H, s, Me), and 8.01 (6H, s, Me). On the other hand, the spectrum of **33** showed signals at τ 1.59 (1H, d, J=9.5 Hz, H^A), 1.77 (1H, d, J=9.5 Hz, $H^{A''}$), 1.78 (1H, d, J=10 Hz, $H^{A'}$), 2.14 (1H, d, J=10 Hz, $H^{A'''}$), *ca.* 2.6—3.6 (m, olefinic H), 8.00 (3H, s, Me), and 8.03 (3H, s, Me). Thus, the spectrum of **32** exhibits four doublets due to olefinic protons adjacent to nitrogen in narrow region and in high field as compared with those of the corresponding protons of **33**, although we have no explanation for these observations.



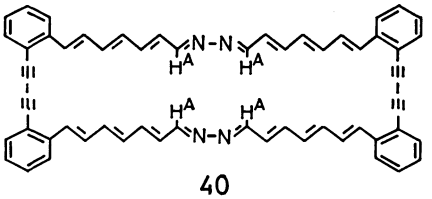
We attempted the following chemical means to determine which isomer should be assigned to the structure **33**. If the reaction similar to that of preparation of azines, between hydrazine and dialdehyde **34** would occur, an expected cyclic product have the structure **33** which is identical to that of one of the two isomers from azine **18**, eliminating the structure **32**. For this aim we prepared the pentaenediynedial **34**. The dialdehyde **34** was obtained in 25% yield from **9** and **10** by oxidative coupling, admixed with tetraenediynedial **35** and hexaenediynedial **36**. The dialdehyde **34** thus obtained was subjected to a reaction with aqueous hydrazine in ethanol. However, no evidence for the presence of the same product as that obtained from azine **18** was detected. Thus, although we could not elucidate the exact structual assignment between **32** and **33**, we believe that the isomer which shows four doublets at very narrow region (τ 2.14—2.26) in its ^{1}H NMR spectrum, has the structure of **32** as described above, from comparison with ^{1}H NMR spectra of annulenes **5** and **7**.



The azine **19** gave cyclic dimer, 11,16,35,40-tetramethyl-12,14,36,38-tetrakisdehydro-1,2,25,26-tetraaza-[40]annulene (**37**), on oxidation in 20% yield. The dimeric structure **37** was established by mass spectrum. The mass spectral measurement of **37** using direct inlet system was not satisfactory owing to decomposition during measurement. However, the spectrum by a field desorption technique was satisfactory one, revealing a molecular ion peak at *m/e* 676 (mol wt, 676). The electronic spectrum of **37** showed main maximum at 420 nm, exhibiting a bathochromic shift by 39 nm as compared with that of [40]annulene **7**. The ^{1}H NMR spectrum of **37** showed only one doublet at τ 1.98 due to olefinic protons (H^A) adjacent to nitrogen, revealing a symmetrical structure of **37**, a multiplet at τ 2.2—3.5 due to other olefinic protons, and a singlet at τ 8.04 due to methyl protons.



We carried out oxidative couplings of benzoannelated unsymmetrical azines **25**, **27**, **29**, **30** and symmetrical azine **31** under the same conditions as those for methylated azines. When these were done, we expected a stabilizing effect due to fused benzene rings on products of these reactions. However, we could not also obtain cyclic dimers from azines **25**, **27**, **29**, similarly to the cases of the corresponding methylated azines **13**, **15**, **17**. On the other hand, as in the case of the corresponding methylated azine **18**, azine **30** gave two cyclic dimers **38** and **39** in better yield (17%) than in that of **32** and **33** from azine **18**. The molecular weight of both **38** and **39** could not be determined by mass spectra owing to their low volatility. The structual assignment of **38** and **39** follows from examination of their IR, ^{1}H NMR, and electronic spectra, given in Experimental section. Both **38** and **39** showed main maxima at the same wavelength (355 nm) in tetrahydrofuran, as similarly to those observed in both **32** and **33**. The ^{1}H NMR spectra of **38** and **39**, illustrated in Fig. 2, resembled those of **32** and **33**, and the chemical shifts of H^A, $H^{A'}$, $H^{A''}$, $H^{A'''}$ protons are closer between **38** and **39** than between **32** and **33**.



Azine **31** afforded cyclic dimer **40**. The very low solubility and involatility of compound **40** prevented a complete characterization, but UV and ^{1}H NMR spectral data supported the structure **40**.

The chemical shifts of olefinic and methyl protons of the annulenes **32**, **33**, **37**, **38**, **39**, **40** indicates that these annulenes are atropic molecules.

In conclusion, oxidative couplings of conjugated azines **12**—**19** and **24**—**31** did not furnish cyclic monomers, but cyclic dimers in some cases. It was found that a possibility to obtain cyclic dimers is high from symmetrical azines than from unsymmetrical ones.

Experimental

All boiling and melting points are uncorrected. IR spectra were measured on Hitachi 260-50 spectrophotometer as KBr disk unless otherwise stated; only significant maxima are reported. Electronic spectra on Hitachi 124 or Hitachi 220 A spectrophotometer were recorded in nm, in tetrahydrofuran solution. The ε-values are given in parentheses, the shoulder being denoted by sh. Mass spectra were measured with JEOL JMS-200 spectrometer at 75 eV using a direct inlet system or JMS-D spectrometer equipped with field desorption system. ^{1}H NMR spectra were taken on Varian EM-390 (90 MHz) or Varian XL-200 (200 MHz) spectrometer, and refer to solution in $CDCl_3$, in τ-values with TMS as an internal standard. The coupling constants (J) are given in Hz. The individual assignments are made on the basis of multiplicities and coupling constants. Alumina (II—III) was used for column chromatography. Progress of most reactions was followed by TLC using Merck precoated alumina. Preparative TLC was carried out on 20×20 cm alumina plates (Merck, 0.5 or 2 mm thick). Evaporation of solvents was performed at water aspirator pressure, and sodium sulfate was used as drying agent unless otherwise specified.

Diethyl Acetal of (2Z)-3-Methyl-2-penten-4-ynal (8). This compound was prepared by a slight modification of the reported procedure.[5b] A mixture of 3-methyl-2-penten-4-ynal (**8**)[5] (37.8 g, 0.40 mol), ammonium nitrate (3.0 g), and triethyl orthoformate (50.0 g, 0.38 mol) in abs ethanol (105 ml) was heated under reflux for 2 min. Then the mixture was poured onto dilute aq ammonia and extracted with benzene. The extracts were washed with dilute aq ammonia, and passed through Hyflo Super-Cel. The filtrate was concentrated to one-fourth its original volume and the concentrate was mixed with saturated aq sodium hydrogensulfite soln (440 ml). The mixture was stirred for 30 min at room temp. Then the mixture was passed through Hyflo Super-Cel and the precipitates formed were washed with benzene. The filtrate was washed with aq sodium chloride soln and dried over potassium carbonate. After removal of solvent, the residual dark red liquid was distilled, giving diethyl acetal of **8** (42.9 g, 69%) as a colorless liquid; bp 81 °C/19 mmHg** (lit,[5b] 59%, 77 °C/12 mmHg), MS *m/e* 168 (M^+, 37%) and 123 (100); mol wt 168.2; IR (neat) 3300 (-C≡CH), 2100 (-C≡C-), 1135, and 1060 cm^{-1} (C-O-C); ^{1}H NMR (90 MHz) τ=4.18 (d, 8, 1H, olefinic H), 4.70 (d, 8, 1H, $-C\underline{H}(OCH_2CH_3)_2$), *ca.* 6.2—6.5 (m, 4H, $-C\underline{H}_2CH_3$), 6.80 (-C≡CH), 8.07 (s, 3H, CH_3), and 8.78 (t, 7, 6H, $-CH_2C\underline{H}_3$).

(2E,4Z)-5-Methyl-2,4-heptadien-6-ynal (9). This compound was prepared with a modification of the previously described method.[4] To a soln of diethyl acetal of **8** (33.1 g, 0.20 mol) in dry benzene (244 ml) was added a soln of boron trifluoride etherate (243 mg) in dry benzene (12 ml) at 37 °C with stirring, and then a soln of ethyl vinyl ether (17.2 g, 0.24 mol) in dry benzene (63 ml) was added slowly dropwise during 1.5 h at 38—40 °C with stirring. After the mixture had been stirred at the same temp for 2 h, finely powdered potassium carbonate (22.5 g) was added. The inorganic material was removed by filtration and washed with ether. Then the filtrate was added to a mixture of sodium acetate trihydrate (104 g), water (66 ml), and acetic acid (1420 ml), and the soln was stirred under reflux for 3 h. After cooling, the reaction mixture was poured onto water and extracted with benzene. The combined extracts were washed with water, aq sodium hydrogencarbonate, and aq sodium chloride soln successively, and dried. After removal of solvent, the residual red liquid was chromatographed on alumina (200 g). The fractions eluted with hexane gave the aldehyde **9** (21.7 g, 92%, 64% based on **8**) as a red liquid. For spectral properties of **9**, see Ref. 4.

(2E,4E,6Z)-7-Methyl-2,4,6-nonatrien-8-ynal (10). This compound was prepared with a modification of the previously described method.[3] To a mixture of the dienyne aldehyde **9** (10.0 g, 83.2 mmol) and triethyl orthoformate (150 g, 0.91 mol) was added a soln of *p*-toluenesulfonic acid monohydrate (2.0 g) in abs ethanol (20 ml). After being stirred at room temp overnight, the reaction mixture was poured onto aq sodium hydrogencarbonate soln, and extracted with benzene. The extracts were washed with aq sodium hydrogencarbonate and sodium chloride soln, and dried over potassium carbonate. Evaporation of solvent yielded a crude diethyl acetal of **9** as a red liquid. The liquid was dissolved in dry benzene (100 ml) and warmed to 35 °C in a flask equipped with a dropping funnel, a condenser, and a magnetic stirrer. A soln of boron trifluoride etherate (238 mg) in dry benzene (7.5 ml) was added, and then a soln of ethyl vinyl ether (7.0 g, 97 mmol) in dry benzene (25 ml) was added during 3 h with stirring at 35—37 °C. After the mixture had been stirred for a further 1.5 h at the same temp, finely powdered potassium carbonate (22.0 g) was added. The inorganic material was removed by filtration and washed with ether. Then a mixture of the filtrate, sodium acetate trihydrate (33.0 g), acetic acid (493 ml), and water (23 ml) was heated under reflux with stirring at 79—80 °C for 3 h, and then allowed to cool to room temp. The mixture was poured onto aq sodium chloride soln and extracted with benzene. The extracts were washed successively with aq sodium hydrogencarbonate and aq sodium chloride soln, and dried. The residue obtained on evaporation of solvent was chromatographed on alumina (120 g). The fractions eluted with 10% ether in hexane yielded the trienyne aldehyde **10** (8.50 g, 70%, lit,[3] 50%) as an unstable red solid. For spectral and physical properties, see Ref. 3.

(2E,4E,6E,8Z)-9-Methyl-2,4,6,8-undecatetraen-10-ynal (11). This compound was prepared from **10** by Wittig condensation with [(1,3-dioxolan-2-yl)methyl]triphenylphosphonium bromide and lithium ethoxide, followed by hydrolysis with dilute hydrochloric acid, as reported previously.[7]

3,12-Dimethyl-6,7-diaza-3,5,7,9,11-tetradecapentaene-1,13-diyne (13). A soln of **8** (3.1 g, 33 mmol) and **9** (4.0 g, 33 mmol) in ethanol (98 ml) was added dropwise during 1.5 h to a stirred soln of hydrazine sulfate (5.0 g), sodium carbonate (6.1 g), and water (105 ml) at 12—19 °C. The mixture was stirred for a further 40 min at 17—18 °C. Then the mixture was poured onto aq sodium hydrogencarbonate soln and extracted with benzene. The extracts were washed with aq sodium hydrogencarbonate soln and dried over potassium carbonate. The residual dark red liquid, after solvent removal, was chromatographed on alumina (150 g). The early fractions eluted with hexane–ether (4:1—3:2) gave azine **12**[3] (1.58 g, 26%). The following fractions eluted with hexane–ether (2:3) gave azine **13** (1.59 g, 23%) as a solid. Recrystallization from hexane–benzene afforded yellow leaflets: mp 137—138 °C (decomp); MS *m/e* 210 (M^+, 80%) and 195 (100); mol wt 210.3; IR 3200 (-C≡CH),

**1 mm Hg≈133.322 Pa.

The later fractions eluted with hexane–ether (1:1) gave azine **14**[3] (937 mg, 12%).

*3,14-Dimethyl-6,7-diaza-3,5,7,9,11,13-hexadecahexaene-1,15-diyne (**15**).* A soln of **8** (1.60 g, 17 mmol) and **10** (2.50 g, 17 mmol) in ethanol (50 ml) was added dropwise during 1.5 h to a stirred soln of hydrazine sulfate (2.6 g), sodium carbonate (3.1 g), and water (54 ml) at 17—21 °C. The mixture was stirred for a further 30 min at 20—21 °C. Then the mixture was worked up as in the preparation of **13**. The residual red liquid, after solvent removal, was chromatographed on alumina (200 g). The early fractions eluted with hexane–ether (2:3) gave azine **14** (887 mg, 29%). The following fractions eluted with hexane–ether (2:3—1:4) gave azine **15** (748 mg, 19%) as a solid. Recrystallization from chloroform–ethanol afforded orange needles: mp 132—133 °C (decomp); MS *m/e* 236 (M^+, 40%) and 39 (100); mol wt 236.3; IR 3200 (-C≡CH), 2100 (-C≡C-), 1620 (C=N), 1595 (C=C), and 990 cm^{-1} (*trans* C=C); UV_{max} 233 (13500), 277 (8410), 289 (8870), 342 sh (46100), 359 (64400), 377 (69400), and 395 nm (50300); ^1H NMR (90 MHz) τ=1.33 (d, 10, 1H, H^A), 1.75 (d, 10, 1H, $H^{A'}$), 2.88—3.70 (m, 6H, olefinic H), 6.52 (s, 1H, -C≡CH), 6.57 (s, 1H, -C≡CH), 7.87 (s, 3H, CH_3), and 7.97 (s, 3H, CH_3).

Found: C, 81.21; H, 6.87; N, 11.74%. Calcd for $C_{16}H_{16}N_2$: C, 81.32; H, 6.83; N, 11.86%.

The later fractions eluted with ether gave azine **16**[3] (440 mg, 8.9%).

*3,16-Dimethyl-6,7-diaza-3,5,7,9,11,13,15-octadecaheptaene-1,17-diyne (**17**).* A soln of **8** (1.70 g, 18 mmol) and **11** (3.10 g, 18 mmol) in ethanol (53 ml) was added dropwise during 1 h to a stirred soln of hydrazine sulfate (2.70 g), sodium carbonate (3.30 g), and water (57 ml) at 23 °C. The mixture was stirred for a further 2 h at the same temp. After the mixture was worked up as in the preparation of **13**, the residual brown liquid was chromatographed on alumina (17×4 cm). The early fractions eluted with hexane–ether (3:7) gave azine **12**[3] (1.71 g, 52%). The following fractions eluted with hexane–ether (2:3) gave azine **17** (1.04 g, 22%) as a solid. Recrystallization from hexane–benzene afforded brown needles: mp 100—101 °C (decomp); MS *m/e* 262 (M^+, 35%) and 78 (100); mol wt 262.3; IR 3200 (-C≡CH), 2100 (-C≡C-), 1620 (C=N), 1570 (C=C), and 1000 cm^{-1} (*trans* C=C); UV_{max} 248 (11000), 293 (6940), 305 (7770), 359 sh (38300), 381 sh (58300), 397 (66400), and 417 nm sh (51500); ^1H NMR (90 MHz) τ=1.33 (d, 10, 1H, H^A), 1.75 (d, 10, 1H, $H^{A'}$), *ca.* 2.9—3.8 (m, 8H, olefinic H), 6.52 (s, 1H, -C≡CH), 6.58 (s, 1H, -C≡CH), 7.88 (s, 3H, CH_3), and 7.98 (s, 3H, CH_3).

The later fractions eluted with ether gave azine **28** (4.2 g, 35%).

1,16-Bis(o-ethynylphenyl)-8,9-diaza-1,3,5,7,9,11,13,15-hexadecaoctaene (31). A soln of **23** (0.50 g, 2.4 mmol) in ethanol (5.7 ml) was added dropwise during 30 min to a stirred soln of hydrazine sulfate (0.31 g), sodium carbonate (0.37 g), and water (3.1 ml) at 15 °C. The mixture was stirred for a further 2 h at the same temp. Then the mixture was worked up as in the preparation of **29**, the residual red solid was chromatographed on alumina (3×10 cm). The fractions eluted with chloroform gave azine **31** (268 mg, 54%) as a solid. Recrystallization from chloroform–ethanol afforded red needles: mp 278—279 °C (decomp); MS *m/e* 412 (M^+, 25%) and 178 (100); mol wt 412.5; IR 3280 (–C≡CH), 2100 (–C≡C–), 1620 (C=N), 1600, 1580 (C=C), and 1005 cm^{-1} (*trans* C=C); UV_{max} 230 (16700), 268 (11700), 295 sh (9110), 357 sh (17700), 418 (62600), 437 (62300), and 459 nm sh (41700); ^1H NMR (200 MHz) τ=1.73 (d, 10, 2H, H^A), 2.34—2.80 (m, 8H, benzenoid H), 2.95—3.49 (m, 12H, olefinic H), and 6.62 (s, 2H, –C≡CH).

Found: C, 87.34; H, 5.79; N, 6.85%. Calcd for $C_{30}H_{24}N_2$: C, 87.34; H, 5.87; N, 6.79%.

Oxidative Coupling of 18 to Two Isomeric Tetramethyl[36]annulenes 32 and 33. A soln of azine **18** (2.68 g, 10.2 mmol) in pyridine (160 ml) and dry ether (53 ml) was added dropwise during 4 h to a stirred soln of anhyd copper(II) acetate (13.0 g) in pyridine (355 ml) and dry ether (120 ml) kept at 50 °C; the mixture was stirred for a further 1 h at the same temp. Then the mixture was chilled and filtered through Hyflo Super-Cel. After the precipitates formed were washed with benzene, the filtrate was poured onto water. The organic layer combined with the benzene extracts from aq layer was washed with water fifteen times to remove pyridine, and dried over potassium carbonate. The residual dark red liquid, after solvent removal, was passed through a short column of alumina. The red liquid thus obtained was chromatographed on alumina (4×10 cm). The fractions eluted with hexane–ether (3:7–2:3) gave a slightly crude **32** (132 mg, 2.5%) as a crystalline liquid. Repeated thin layer chromatography gave a solid. Recrystallization from chloroform–ethanol afforded purple microcrystals: mp 144 °C (decomp); MS *m/e* 520 (M^+, 25%) and 115 (100); mol wt 520.6; IR 2190 (–C≡C–), 1620 (C=N), and 1000 cm^{-1} (*trans* C=C); UV_{max} 252 (17200) and 367 nm (62800), and see Fig. 1; ^1H NMR (200 MHz) τ=2.14 (d, 9, 1H, H^A), 2.16 (d, 9.5, 1H, $H^{A'''}$), 2.23 (d, 9.5, 1H, $H^{A'}$), 2.26 (d, 9, 1H, $H^{A''}$), *ca.* 2.6—3.6 (m, 16H, olefinic H), 7.98 (s, 6H, CH_3), and 8.01 (s, 6H, CH_3), and see Fig. 2. Compound **32** formed crystals containing 1 mol of chloroform.

Found: C, 69.59; H, 5.39; N, 8.89%. Calcd for $C_{36}H_{32}N_2 \cdot CHCl_3$: C, 69.43; H, 5.21; N, 8.76%.

The following fractions eluted with hexane–ether (2:3) gave a slightly crude **33** (50 mg, 0.90%) as a partly crystallized liquid. Thin layer chromatography gave a solid. Recrystallization from chloroform–ethanol afforded purple microcrystals: mp 112 °C (decomp); MS *m/e* 520 (M^+, 7%) and 18 (100); mol wt 520.6; IR 2180 (–C≡C–), 1615 (C=N),

and 1000 cm^{-1} (*trans* C=C); UV_{max} 251 (16000) and 367 nm (58400), and see Fig. 1; ^1H NMR (200 MHz) τ=1.59 (d, 9.5 1H, H^A), 1.77 (d, 9, 1H, $H^{A''}$), 1.78 (d, 10, 1H, $H^{A'}$), 2.14 (d, 10, 1H, $H^{A''}$), *ca.* 2.6—3.6 (m, 16H, olefinic H), 8.00 (s, 6H, CH_3), and 8.03 (s, 6H, CH_3), and see Fig. 2.

*5,10-Dimethyl-2,4,10,12,14-hexadecapentaene-6,8-diynedial (**34**).* A soln of **9** (3.30 g, 27.5 mmol) and **10** (4.00 g, 27.4 mmol) in pyridine (74 ml) and methanol (74 ml) was added dropwise during 1 h to a stirred soln of copper(II) acetate monohydrate (37.0 g) in pyridine (298 ml) and methanol (298 ml) at 20 °C. After being stirred at room temp overnight, the reaction mixture was poured onto aq sodium chloride soln and extracted with benzene. The extracts were washed with 3 M† hydrochloric acid until it turned acidic, and then with aq sodium hydrogencarbonate soln, and dried. The residual red liquid, after solvent removal, was chromatographed on alumina (4×10 cm). The early fractions eluted with hexane–ether (3:2) gave the tetraenediynedial **35** (840 mg, 13%) (*vide infra*). The following fractions eluted with hexane–ether (1:1) gave the desired pentaenediynedial **34** (1.79 g, 25%) as a solid. Recrystallization from benzene afforded orange needles: mp 48—49 °C; MS *m/e* 264 (M^+, 10%) and 78 (100); mol wt 264.3; IR 2190 (–C≡C–), 1670 (CHO), 1610 (C=C), 1010, 990, and 980 cm^{-1} (*trans* C=C); UV_{max} 257 sh (10100), 268 (10800), 318 (23800), 340 sh (23800), 375 (27400), and 405 nm sh (19800); ^1H NMR (90 MHz) τ=0.27 (d, 8, 1H, CH^AO), 0.33 (d, 8, 1H, $CH^{A'}O$), 2.42 (dd, 16, 11, 1H, H^C), 2.60 (s, 6H, benzene), 2.74 (dd, 16, 12, 1H, $H^{E'}$), 2.83 (dd, 16, 11, 1H, $H^{C'}$), 3.33 (d, 12, 1H, H^D), 3.43 (d, 12, 1H, $H^{F'}$), 3.45 (dd, 16, 12, $H^{D'}$), 3.78 (dd, 16, 8, 2H, H^B and $H^{B'}$), 7.90 (s, 3H, CH_3), and 7.95 (s, 3H, CH_3).

Found: C, 83.92; H, 6.39%. Calcd for $C_{18}H_{16}O_2 \cdot C_6H_6$: C, 84.17; H, 6.47%.

Compound **34** formed crystals containing 1 mol of benzene.

The later fractions eluted with hexane–ether (3:2) gave the hexaenediynedial **36** (607 mg, 7.6%) (*vide infra*).

The teraenediynedial **35** and the hexaenediynedial **36** were also prepared from **9** and **10**, respectively, in higher yields than in those described above.

*5,10-Dimethyl-2,4,10,12-tetradecatetraene-6,8-diynedial (**35**).* A soln of **9** (3.00 g, 25 mmol) in pyridine (35 ml) and methanol (35 ml) was added dropwise during 30 min to a stirred soln of copper(II) acetate monohydrate (18.0 g) in pyridine (138 ml) and methanol (138 ml) at 20 °C. After being stirred at room temp overnight, the reaction mixture was worked up as in the preparation of **34**. The residual red liquid obtained after solvent removal was chromatographed on alumina (4×10 cm). The fraction eluted with hexane–ether (3:2) gave the teraenediynedial **35** (1.65 g, 54%) as a crystalline liquid. Crystallization from hexane–benzene afforded yellow needles: mp 160—161 °C; MS *m/e* 238 (M^+, 4%) and 165 (100); mol wt 238.2; IR 2200 (–C≡C–), 1675 (CHO), 1610 (C=C), 1000, and 980 cm^{-1} (*trans* C=C); UV_{max} 245 sh (13200), 254 (17200), 293 (23900), 339 (25700), 62 (25200), and 387 nm (20600); ^1H NMR (90 MHz) τ=0.25 (d, 8, 2H, CHO), 2.43 (dd, 15, 12, 2H, H^C), 3.31 d, 12, 2H, H^D), 3.78 (dd, 15, 11, 2H, H^B), and 7.87 (s, H, CH_3).

Found: C, 80.94; H, 5.99%. Calcd for $C_{16}H_{14}O_2$: C, 0.64; H, 5.92%.

*7,12-Dimethyl-2,4,6,12,14,16-octadecahexaene-8,10-diynedial (**36**).* A soln of the aldehyde **10** (6.00 g, 43 mmol) in pyridine (59 ml) and methanol (59 ml) was added dropwise during 1 h to a stirred soln of copper(II) acetate monohydrate (30.0 g) in pyridine (235 ml) and methanol (235 ml) at 19 °C. After being stirred at room temp overnight, the reaction mixture was worked up as in the preparation of **34**. The residual red liquid obtained after solvent removal was chromatographed on alumina (4×15 cm). The hexaenediynedial **36** (2.50 g, 40%) was obtained from the fractions eluted with hexane–ether (2:3). Recrystallization from hexane–benzene afforded orange needles: mp 130—131 °C; MS *m/e* 290 (M^+, 18%) and 203 (100); mol wt 290.3; IR 2200 (–C≡C–), 1680 (CHO), 1610, 1590 (C=C), 1010, and 985 cm^{-1} (*trans* C=C); UV_{max} 239 (18300), 283 (17600), 321 sh (31600), 334 (35400), 377 (32500), 391 sh (31300), and 423 nm (21900); ^1H NMR (90 MHz) τ=0.32 (d, 8, 2H, CHO), 2.72 (dd, 15, 12, 2H, H^E), 2.85 (dd, 15, 12, 2H, H^C), 3.43 (dd, 16, 12, 2H, H^D), 3.45 (d, 12, 2H, H^F), 3.76 (dd, 15, 8, 2H, H^B), and 7.93 (s, 6H, CH_3).

Found: C, 82.70; H, 6.32%. Calcd for $C_{20}H_{18}O_2$: C, 82.73; H, 6.25%.

*The Reaction of **34** with Hydrazine Sulfate.* A soln of pentaenediynedial **34** (1.15 g, 4.36 mmol) in ethanol (26 ml) was added dropwise during 1.5 h to a stirred soln of hydrazine sulfate (0.66 g) and sodium carbonate (0.80 g) in water (19 ml) at room temp. The mixture was stirred for a further 1 h at the same temp. Then the mixture was worked up as in the preparation of **13**. The residual red liquid obtained after solvent removal was chromatographed on alumina. However, we could not detect the fractions containing cyclic products corresponding to **33**.

*Oxidative Coupling of **19** to Tetramethyl[48]annulene **37**.* A soln of **19** (3.30 g, 9.69 mmol) in pyridine (152 ml) and dry ether (51 ml) was added dropwise during 1 h to a stirred soln of anhyd copper(II) acetate (12.0 g) in pyridine (337 ml) and dry ether (113 ml) kept at 45 °C; the mixture was stirred for a further 30 min at the same temp. Then the mixture was chilled and filtered through Hyflo Super-Cel. The precipitates formed were washed with chloroform, and the filtrate was poured onto water. The organic layer combined with the chloroform extracts from aq layer was washed with water ten times to remove pyridine and dried. The residual brown liquid obtained after solvent removal was chromatographed on alumina (4×12 cm). The early fractions contained pyridine. The following fractions eluted with chloroform contained the desired **37**. The dark red liquid obtained was again chromatographed on alumina (4×9 cm). The fractions eluted with benzene–chloroform (1:1) gave **37** (618 mg, 19%) as a crystalline liquid. Although crystallization was unsuccessful in our hands due to low solubility of **37**, thin layer chromatography (0.5 mm thick) afforded purple microcrystals: mp 175—176 °C (decomp); MS (field desorption method) *m/e* 676 (M^+); mol wt 676.8; IR 2180 (–C≡C–), 1620 (C=N), 1595 (C=C), and 1000 cm^{-1} (*trans* C=C); UV_{max} 300 sh (10300) and 420 nm (73200); ^1H NMR (200 MHz) τ=1.98 (d, 10, 1H, H^A), *ca.* 2.4—3.5 (m, 20H, olefinic H), and 8.04 (s, 12H, CH_3).

*Oxidative Coupling of **30** to Two Isomeric Tetrabenzo[36]annulenes **38** and **39**.* A soln of azine **30** (1.2 g, 36 mmol) in pyridine (66 ml) and dry ether (22 ml) was added dropwise during 2.5 h to a stirred soln of anhyd copper(II) acetate (4.5 g) in pyridine (125 ml) and dry ether (42 ml) kept at 50 °C; the mixture was stirred for a further 2 h at the same temp and chilled. After work up as in the preparation of **37**, the residual red liquid obtained by solvent removal was chromatographed on alumina (3×8 cm). The fractions eluted with ether–benzene (1:4) gave a mixture of **38** and **39** as a brown liquid. The liquid was again chromatographed on alumina (4×15 cm). The early fractions eluted

† 1 M=1 mol dm^{-3}.

with benzene–chloroform gave **38** (118 mg, 9.8%) as a solid. Recrystallization from chloroform–ethanol afforded yellow microcrystals: mp 182 °C (decomp); IR 2200, 2150 (–C≡C–), 1620 (C=N), 1605, 1600 (C=C), 1000, and 980 cm^{-1} (*trans* C=C); UV_{max} 238 (68100), 263 (52200), 307 sh (59000), and 355 nm (95100); ^1H NMR (200 MHz) τ= 1.76 (d, 9.5, 1H, H^A), 1.77 (d, 9.5, 1H, $H^{A'''}$), 1.90 (d, 10, 1H, $H^{A'}$), 1.91 (d, 10, 1H, $H^{A''}$), and *ca.* 2.3—3.8 (m, 28H, olefinic and benzenoid H), and see Fig. 2. The following fractions eluted with benzene–chloroform gave **39** (86 mg, 7.0%) as a solid. Recrystallization from chloroform–ethanol afforded yellow microcrystals: mp 234 °C (decomp); IR 2220, 2150 (–C≡C–), 1630 (C=N), 1610, 1600 (C=C), 1000, and 980 cm^{-1} (*trans* C=C); UV_{max} 267 sh (39200), 282 (50400), 355 (90700), 410 sh (31100), and 435 nm sh (17100); ^1H NMR (200 MHz) τ=1.70 (d, 9.5, 1H, H^A), 1.85 (d, 9.5, 1H, $H^{A''}$), 1.89 (d, 9.5, 1H, $H^{A'}$), 2.06 (d, 9.5, 1H, $H^{A'''}$), and *ca.* 2.3—3.7 (m, 37H, olefinic and benzenoid H), and see Fig. 2.

*Oxidative Coupling of **31** to Tetrabenzo*[48]*annulene **40**.* A soln of azine **31** (2.80 g, 6.79 mmol) in pyridine (124 ml) and dry ether (41 ml) was added dropwise during 1 h to a stirred soln of anhyd copper(II) acetate (8.50 g) in pyridine (236 ml) and dry ether (79 ml) kept at 50 °C; the mixture was stirred for a further 30 min at the same temp. After work up as in the preparation of **37**, the residual dark red liquid obtained by solvent removal was chromatographed on alumina (4×10 cm). The early fractions contained pyridine. The later fractions eluted with chloroform gave **40** (414 mg, 15%) as a dark red gum, which resisted attempted crystallization and did not run from the base line on preparative layer chromatography. Precipitates formed from chloroform solution afforded purple powders: mp 235—240 °C (decomp ; IR 2200, 2140 (–C≡C– , 1620 (C=N), 1590, 1580 (C=C), and 1000 cm^{-1} (*trans* C=C); UV_{max} 290 (27300), 416 (92200), and 470 nm sh (44700); ^1H NMR τ=1.99 (d, 9, 4H, H^A), and *ca.* 2.3—3.6 (m, 40H, olefinic and benzenoid H).

*Oxidative Couplings of Azines **13**, **15**, **17**, **25**, **27**, **29**.* These oxidative couplings were carried out under almost the same conditions as those described for azines **18** and **30**. However, in attempted runs, no monomeric and dimeric cyclic compounds were obtained.

*Oxidative Coupling of **14** to Tetramethyl*[32]*annulene **5**[3] under High Dilution Conditions.* A soln of azine **14** (2.1 g, 8.9 mmol) in ether (77 ml), methanol (77 ml), and pyridine (309 ml) was added dropwise during 8 h to a stirred soln of anhyd copper(II) acetate (16.2 g) in pyridine (2100 ml), ether (525 ml), and methanol (525 ml) kept at 68—70 °C. After being refluxed for a further 2 h at the same temp, the mixture was allowed to stand overnight at room temp. Then the mixture was concentrated to 150 ml *in vacuo* on a water bath kept below 45 °C. The concentrate was chilled, diluted with benzene (200 ml), and filtered through Hyflo Super-Cel. The precipitates formed were washed with benzene, and the filtrate was poured onto water. The organic layer combined with benzene extracts from aq layer was washed with water ten times to remove pyridine and dried over potassium carbonate. After removal of solvent, the residual red liquid was chromatographed on alumina (150 g). The fractions eluted with ether–benzene (7:3) gave the corresponding cyclic dimer **5** (116 mg, 2.8%). No monomeric product could be obtained.

*Oxidative Coupling of **16** to Tetramethyl*[40]*annulene **7**[3] under High Dilution Conditions.* A soln of azine **16** (3.40 g, 11.8 mmol) in ether (102 ml), methanol (102 ml), and pyridine (410 ml) was added dropwise during 7 h to a stirred and refluxing soln of anhyd copper(II) acetate (18.0 g) in pyridine (2141 ml), ether (410 ml), and methanol (410 ml) kept at 72—74 °C. After being stirred for a further 1.5 h, the mixture was worked up as in the isolation of **5**, as described above. The residual red liquid obtained after solvent removal was chromatographed on alumina (180 g). The fractions eluted with benzene–chloroform gave the corresponding cyclic dimer **7** (330 mg, 9.8%).

*Oxidative Coupling of Azine **12**.* This was carried out in almost the same scale as that for azine **14** described above. However, no desired cyclic products could be obtained.

The present work was partially supported by a Grant-in-Aid from the Itō Science Foundation.

Persistent Nitrogen-centered Free Radicals, *N*-(Arylthio)-3,5-di-*t*-butylphenylaminyls. The Reactions with Phenols[1)]

Yozo MIURA,* Akifumi YAMAMOTO, and Masayoshi KINOSHITA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received October 23, 1982)

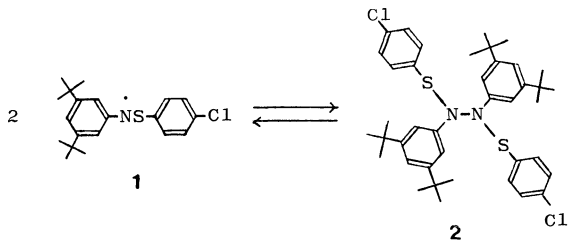
The reactions of *N*-(4-chlorophenylthio)-3,5-di-*t*-butylphenylaminyl (**1**) with phenols were examined. The reaction with 2,6-dimethyl- and di-*t*-butylphenols gave 2,6-dimethyl- and di-*t*-butyl-*p*-benzoquinone 3,5-di-*t*-butylphenylimines, respectively, in excellent yields. In the reaction with unsubstituted phenol, 2,6-bis[*N*-(4-chlorophenylthio)-3,5-di-*t*-butylphenylamino]-*p*-benzoquinone 3,5-di-*t*-butylphenylimine was obtained in 32—56% yields. On the other hand, the reactions with *p*-substituted phenols such as *p*-cresol, *p*-*t*-butylphenol, and 2,4-di-*t*-butylphenol, gave phenols which were substituted by **1** at the *ortho*-positions to the OH group. Furthermore, the reactions with *o*-cresol, 2,6-di-*t*-butyl-*p*-cresol, and 1-naphthol were examined. On the basis of these results, plausible mechanisms for the reactions are presented.

Reactions of phenols with nitroxide radicals have been widely studied from the synthetic viewpoint. For example, the reaction of potassium nitrosodisulfonate (Fremy's salt) with phenols, well-known as the Teuber reaction,[2)] gave a variety of quinones, usually in excellent yields. Similarly, the reactions using organic nitroxides afforded quinones in relatively good yields.[3,4)]

In contrast to the widely studied reactions of nitroxide radicals with phenols, the reactions with nitrogencentered free radicals have rarely been investigated. Rieker *et al.* reported that phenylamino radicals reacted with phenols to give quinone imines in 5—40% yields.[5)] On the other hand, the reactions reported by Barton *et al.* of bis(arylthio)aminyl radical with phenols gave quinone *N*-thioimines in fair to good yields.[6)]

In a continuous study on *N*-thioaminyl radicals ($R_1\dot{N}SR_2$),[1)] we have found that *N*-(arylthio)-3,5-di-*t*-butylphenylaminyls persist in solution, even in the presence of oxygen and can be isolated as crystalline dimers which dissociate, upon dissolution, into the original radicals with relatively large equilibrium constants.[7)]

In order to examine the properties of this new class of nitrogen-centered free radicals, we carried out the reactions of *N*-(4-chlorophenylthio)-3,5-di-*t*-butylphenylaminyl (**1**) with a variety of phenols. In this paper we wish to report the results.



Results and Discussion

The reactions of **1** with phenols were carried out at room temperature under a nitrogen atmosphere. The completion of the reactions was indicated by discharge of the dark blue color attributable to **1**. The results of the reactions are summarized in Table 1.

Table 1. Results of the reactions of **1** with phenols[a)]

Phenol	Molar ratio of **1**/Phenol	Products (Yield/%)[b)]
2,6-Me_2	3.0	**3**(96)
2,6-*t*-Bu_2	3.0	**7**(92)

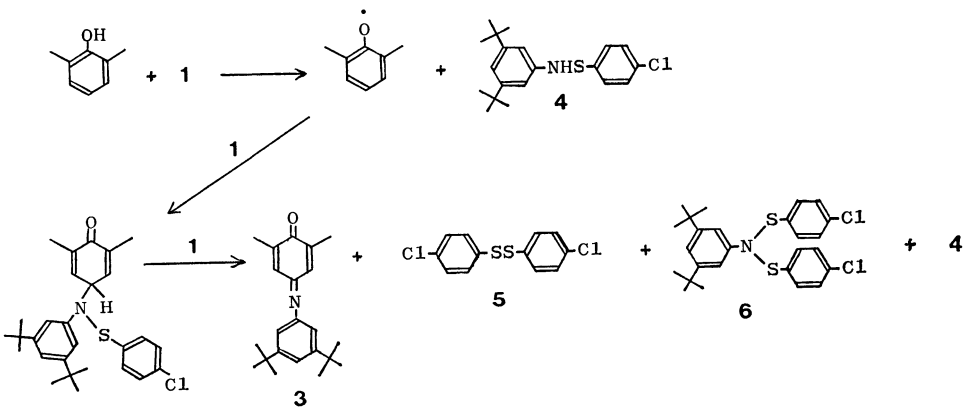
a) In benzene at room temperature. b) Iolated yields based on starting phenol. c) Based on the isolated yield (86%) of **21**.

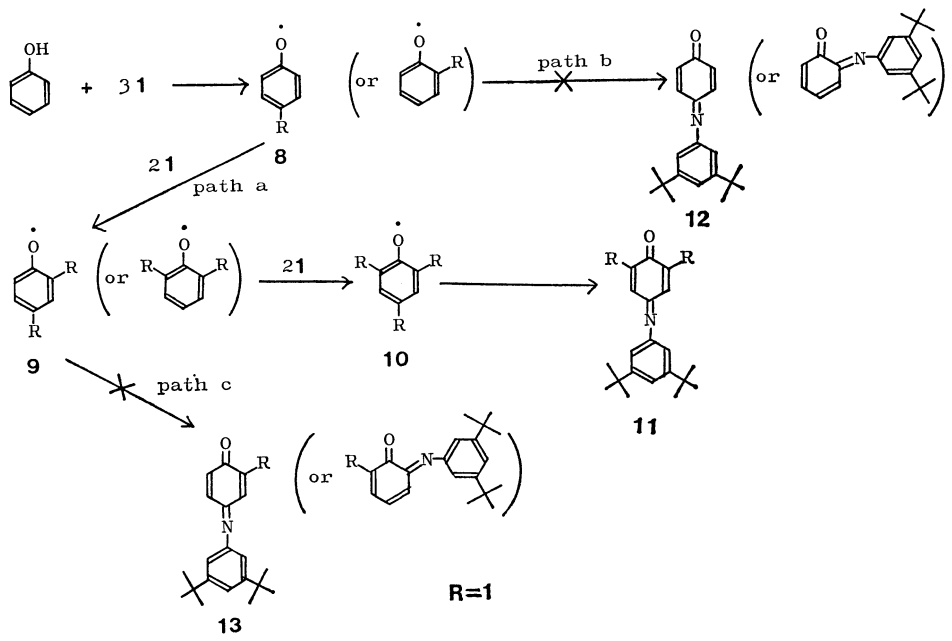
The reaction of 2,6-dimethylphenol with 3 equiv. (1.5 equiv. of **2**) of **1** was complete in 1 min on addition of the phenol, and the resulting orange-red reaction mixture gave 2,6-dimethyl-*p*-benzoquinone 3,5-di-*t*-butylphenylimine (**3**) almost quantitatively. The other products from the reaction were *N*-(4-chlorophenylthio)-3,5-di-*t*-butylaniline (**4**), and small amounts of bis(p-chlorophenyl) disulfide (**5**) and *N*,*N*-bis(4-chlorophenylthio)-3,5-di-*t*-butylaniline (**6**). Based on these products, this reaction mechanism can be reasonably described as in Scheme 1.

Similarly, 2,6-di-*t*-butylphenol reacted rapidly with 3 equiv. of **1** to give 2,6-di-*t*-butyl-*p*-benzoquinone 3,5-di-*t*-butylphenylimine (**7**) in 92%. This imine is probably produced by the same mechanism as above.

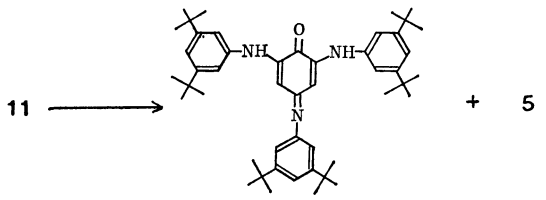
The reaction of unsubstituted phenol with 5.4 equiv. of **1** gave only **11** as quinone imine in 56% yield, and other quinone imines such as **12** and **13** were not found among the products. Quinone imine **11** was relatively unstable, being decomposed slowly in hydrocarbon solvents, and rapidly in methanol to **14** and bis(*p*-chlorophenyl) disulfide (Scheme 3). A plausible mechanism for the formation of **11** is represented



Scheme 1.



Scheme 2.



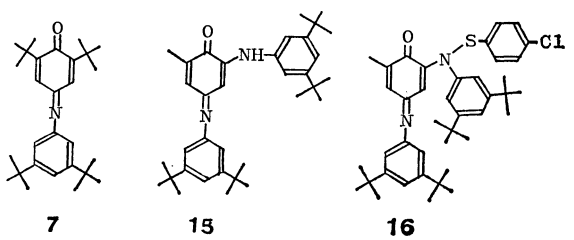
Scheme 3.

in Scheme 2. This reaction requires 7 equiv. of **1**, provided that the phenol is converted exclusively into **11**. However, even when the ratio of **1** to the phenol was 3, the quinone imine formed was only **11**. This interesting observation suggests that addition (path a) of **1** to the intermediate phenoxyl radicals **8** and **9**, giving **11** as the final product, is much faster than elimination (paths b and c) of a *p*-chlorophenylthiyl radical from the phenoxyl radicals, giving **12** and **13**.

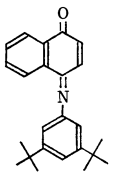
In the previously reported reactions of phenols with free radicals,[2-6] unsubstituted phenol was converted into the unsubstituted quinone or quinone imine, and monosubstituted phenols were usually converted into the monosubstituted quinones or quinone imines. Thus, the formation of the polysubstituted quinone imine such as **11** in the reaction with unsubstituted phenol is different from the previous results.

The reaction of *o*-cresol with 1—3 equiv. of **1** gave similarly only one quinone imine (**15**) in 13—57% yields. This quinone imine seems to be produced *via* **16**, by assumption of the above reaction.

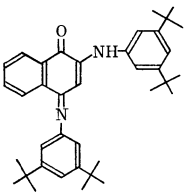
In contrast to the above reactions, the reactions of 1-naphthol with **1** gave two kinds of quinone imines (**17** and **18**). For example, a 1:3 equimolar mixture



of 1-naphthol and **1** afforded **17** and **18** in 39 and 22% yields, respectively. However, a 1:1 mixture of the naphthol and **1** gave only **17** in 26% yield (**18** was shown to be present in trace amounts by TLC inspection of the reaction mixture). In order to examine whether **18** was produced *via* **17** or not, a 1:2 equimolar mixture of **17** and **1** was stirred in benzene at room temperature for 2 h. TLC inspection showed no reaction occurred.

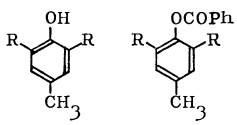


17



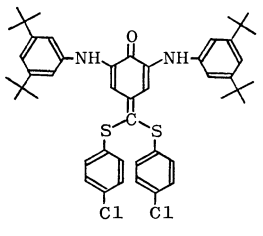
18

The reactions of **1** with *p*-substituted phenols such as *p*-cresol, *p*-*t*-butylphenol, and 2,4-di-*t*-butylphenol gave *ortho*-substituted phenols and no quinone imine was found among the products. For example, the reaction of *p*-cresol with 4 equiv. of **1** gave phenol **19** in good yield (≧86%). This phenol was not stable enough to be isolated. In order to confirm its structure, **19** was converted into a thermally stable benzoic ester **20** by treatment with benzoyl chloride. The phenol was decomposed slowly in benzene solution at room temperature (1 d for complete decomposition), and rapidly on reflux (30 min) to give dark yellow-blue crystals of **21** in 27% yield. The structure of this unexpected product was confirmed by IR, and ^{1}H and ^{13}C NMR spectroscopy, and the molecular weight (determined by vapor pressure osmometry).[5] The IR spectrum showed absorptions of NH at 3350 cm^{-1} and C=O at 1620 cm^{-1}, and in the ^{13}C NMR spectrum eight singlet peaks due to the aromatic, quinonoid, and carbonyl carbons and five doublet peaks due to the aromatic and quinonoid carbons were found. The observed molecular weight (807) was in good agreement with that calculated (798). Furthermore, the ^{1}H NMR spectrum and elemental analysis gave satisfactory results. On the basis of these instrumental analyses, we identified the crystal as **21**.



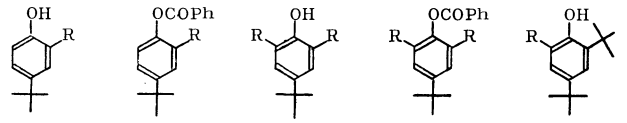
19 20

R=1



21

In the case of 4-*t*-butylphenol, 1:1 and 1:2 equimolar mixtures of the phenol and **1** gave two kinds of phenols, **22** and **24**, in 22—29 and 9.8—30%, respectively. However, a 1 3.8 equimolar mixture of the phenol and **1** afforded only **24** in 82% yield. On the other hand, the reaction of 2,4-di-*t*-butylphenol with 2 equiv. of **1** gave phenol **26** in 90% yield. These phenols, as well as **19**, were very unstable and could not be obtained as pure crystals. To confirm their structures, **22** and **24** were converted into the benzoic esters **23** and **25** by the same procedure as for **19**. In the case of **26**, however, the corresponding benzoic ester could not be obtained in the same manner, probably because of steric hindrance due to the bulky *o*-*t*-butyl group in **26**.



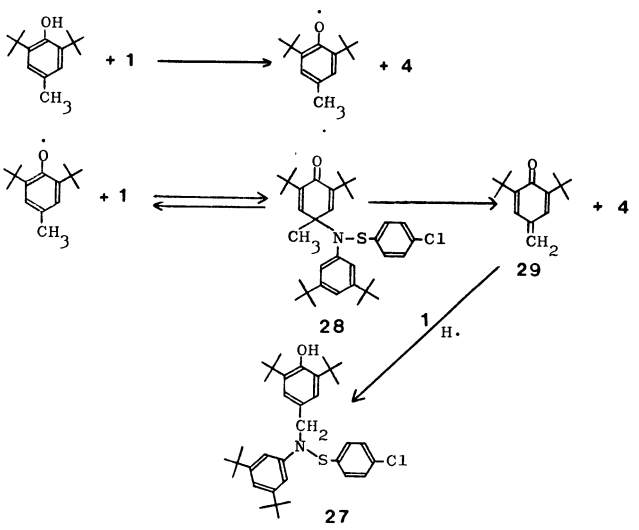
22 23 24 25 26

R=1

The previously reported reactions of *p*-substituted phenols with nitroxide or bis(phenylthio)aminyl radicals gave *o*-quinones or *o*-quinone imines.[2-6] On the other hand, the reactions of **1** with *p*-substituted phenols afforded polysubstituted phenols such as **19** and **22**, but never *o*-quinone imines. This unusual result is worthy of note.

The reaction of 2,6-di-*t*-butyl-*p*-cresol with 2 equiv. of **1** yielded **27** in 61% yield. However, the careful TLC inspection of the reaction mixture revealed that **27** was not the product formed at the completion of the reaction. When the reaction mixture, which was light blue at the completion of the reaction, was allowed to stand at room temperature for 1 d, the color of the reaction mixture changed from light blue to light orange; TLC inspection revealed the complete decomposition of the initially formed product and the appearance of **27**. It seems that the initially formed product is **28**, which is a coupling product of **1** and 2,6-di-*t*-butyl-*p*-methylphenoxyl radical, and that **27** was produced through the coupling of **1** and quinone methide **29**. A similar reaction occured between 2,4,6-trimethylphenol and benzoyl *t*-butyl nitroxide radical.[4] An attempt to isolate **28** was unsuccessful.

Finally, the reaction of **1** with 2,4,6-tri-*t*-butylphenol



Scheme 4.

was examined. However, the mixture of **1** and the phenol gave no coupling product.

Experimental

All melting points were taken on a Yanaco micro melting-point apparatus and are uncorrected. IR spectra were run on a JASCO Model IR-G spectrometer, and UV and visible spectra were recorded with a Hitachi 220 spectrophotometer. Mass spectra were taken with a Hitachi M-52 spectrometer. ^{1}H NMR spectra were recorded with a Hitachi Perkin Elmer R-20 (60 MHz) or JEOL PS-100 (100 MHz) spectrometer with tetramethylsilane as internal standard, and ^{13}C NMR spectra were taken on a JEOL FX-100 (25 MHz) spectrometer.

The phenols were commercially available and were purified by distillation or recrystallization from the appropriate solvents. Dimer **2** was prepared by our previous method.[7]

General Procedure for the Reactions of 2 with Phenols. Dimer **2** in benzene (30 ml) was stirred at room temperature until the dimer was completely dissolved in the solution (*ca.* 1 h). After nitrogen was bubbled through the stirred dimer solution for 30 min, a benzene solution (2 ml) of the phenol was added in one portion to the dimer solution, and the resulting reaction mixture was stirred for 10—120 min with continuous bubbling of nitrogen. After the solvent was removed by either evaporation or freeze-drying, the residue was chromatographed on alumina (Merck Art 1097; column size 3×40 cm) or silica gel (Wako gel C-200; column size 3×40 cm) with the appropriate solvents. The results are shown in Table 1.

Reaction with 2,6-Dimethylphenol. To a benzene solution of **2** (400 mg, 0.577 mmol) a benzene solution of 2,6-dimethylphenol (47 mg, 0.39 mmol) was added and the resulting red reaction mixture was stirred for 10 min, evaporated, and the residue chromatographed on alumina. Elution with benzene–hexane (1:5) gave a mixture of bis(*p*-chlorophenyl) disulfide (**5**) and *N*,*N*-bis(4-chlorophenylthio)-3,5-di-*t*-butylaniline (**6**); subsequent elution with benzene–hexane (1:2) gave *N*-(4-chlorophenylthio)-3,5-di-*t*-butylaniline (**4**) (227 mg, 0.653 mmol) and 2,6-dimethyl-*p*-benzoquinone 3,5-di-*t*-butylphenylimine (**3**) (120 mg, 0.371 mmol). The quinone imine was recrystallized from methanol to give red needles; mp 118—120 °C; IR (KBr): 1640 cm^{-1} (C=O); UV and vis (hexane): 451 (ε 3600), 291 (16500), and 270 (19800) nm; MS (70 eV): *m/e* (rel intensity), 325 (M^++2, 29), 324 (M^++1, 32), 323 (M^+, 100), 309 (23), 308 (74), 252 (32), 91 (21), and 57 (64); ^{1}H NMR (CCl_4): δ=1.33 (s, *t*-Bu, 18H), 1.86 and 2.02 (d, J=1.6 Hz, *syn*- and *anti*-CH_3, 6H), and 6.42—7.02 (m, aromatic and quinonoid, 5H). Found: C, 81.40; H, 9.04; N, 4.38%. Calcd for $C_{22}H_{29}NO$: C, 81.69; H, 9.04; N, 4.33%.

The mixture of **5** and **6** was treated on a preparative silica-gel TLC (Merck, Art 7730; 20×20 cm, 30 g) with benzene–hexane (1:20) as eluant to give 33 mg (0.12 mmol) of **5** and 28 mg (0.057 mmol) of **6**. The products **4**, **5**, and **6** were identified by comparison (mps and IR spectra) with authentic samples.[7,9]

Reaction with 2,6-Di-t-butylphenol. To a benzene solution of **2** (350 mg, 0.505 mmol) a benzene solution of 2,6-di-*t*-butylphenol (69 mg, 0.33 mmol) was added. The resulting red reaction mixture was stirred for 10 min, evaporated, and the residue chromatographed on alumina with benzene–hexane (1:5) to give 125 mg (0.307 mmol) of **7** which was recrystallized from methanol to afford red prisms; mp 75—77 °C; IR (KBr): 1640 cm^{-1} (C=O); UV and vis (hexane): 445 (ε 4040), 295 (16800), and 272 (17200) nm; MS (70 eV): *m/e* (rel intensity), 409 (M^++2, 19), 408 (M^++1, 31), 407 (M^+, 100), 392 (18), and 57 (45); ^{1}H NMR (CCl_4): δ=1.19 and 1.32 (s, *syn*- and *anti*-*t*-Bu, 18H), 1.32 (s, *t*-Bu, 18H), and 6.54—7.09 (m, aromatic and quinonoid, 5H). Found: C, 82.30; H, 10.22; N, 3.51%. Calcd for $C_{28}H_{41}NO$: C, 82.50; H, 10.14; N, 3.44%.

Reaction with Phenol. To a benzene solution of **2** (400 mg, 0.577 mmol) a benzene solution of phenol (36 mg, 0.38 mmol) was added and the resulting red reaction mixture was stirred for 10 min. The solvent was removed by freeze-drying and the resultant red powdery residue was chromatographed on silica gel with benzene–hexane (3:1), using a column cooled by circulating ice-water. The fractions of the red zone were collected and concentrated to *ca.* 30 ml below 10 °C under reduced pressure. The residual solvent (benzene) was then removed by freeze-drying to give red powdery crystals of **11** (120 mg, 0.122 mmol) (TLC one spot). Since this product was thermally unstable, recrystallization was unsuccessful. The results of instrumental and elemental analyses for the powdery **11** are as follows: IR (KBr): 1660 cm^{-1} (C=O); ^{1}H NMR (CCl_4)[10]: δ=1.18 (s, *t*-Bu, 18H), 1.25 (s, *t*-Bu, 36H), and 6.52—7.15 (m, aromatic and quinonoid, 19H). Found: C, 73.57; H, 7.59; N, 3.86%. Calcd for $C_{60}H_{73}Cl_2N_3OS_2$: C, 72.99; H, 7.45; N, 4.26%.

Similarly, the reaction of 400 mg (0.577 mmol) of **2** with 20 mg (0.21 mmol) of phenol gave 118 mg (0.120 mmol) of **11**.

Conversion of 11 into 14. Quinone imine **11** (95 mg, 0.096 mmol) in 20 ml of methanol was stirred for 20 min at room temperature. After complete removal of the solvent in vacuum, the residue was chromatographed on alumina (column size 3×20 cm) with benzene–hexane (1:1) as eluant, giving 23 mg (0.080 mmol, 83%) of bis(*p*-chlorophenyl) disulfide and 62 mg (0.088 mmol, 92%) of quinone imine **14**. This quinone imine was recrystallized from methanol to give dark red prisms; mp 133—136 °C; IR (KBr): 3370 (NH) and 1630 cm^{-1} (C=O); UV and vis (hexane): 495 ε 8300), 414 (7300), and 271 (36800) nm; MS (70 eV): *m/e* (rel intensity), 703 (M^++2, 27), 702 (M^++1, 55), 701 (M^+, 100), and 57 (50); ^{1}H NMR (CCl_4): δ=1.12 (s, *t*-Bu, 18H), 1.19 (s, *t*-Bu, 18H), 1.36 (s, *t*-Bu, 18H), 6.46—7.01 (m, aromatic and quinonoid, 11H), and 6.82 (s, NH, 2H, exchanged by D_2O). Found: C, 81.80; H, 9.73; N, 5.84%. Calcd for $C_{48}H_{67}N_3O$: C, 82.12; H, 9.62; N, 5.98%.

The bis(*p*-chlorophenyl) disulfide isolated was identified by its IR spectrum.

Direct Preparation of 14. 1) A reaction mixture, obtained from 400 mg (0.577 mmol) of **2** and 36 mg (0.38 mmol) of phenol, was evaporated and the residue was dissolved in 20 ml of methanol. The solution was stirred for 20 min at room temperature and the solvent was completely removed in vacuum, the residue was chromatographed on alumina. Elution with benzene–hexane (1:2) gave bis(*p*-chlorophenyl) disulfide and **4**, and subsequent elution with benzene–hexane (2:1) gave 95 mg (0.14 mmol, 37%) of **14**. 2) The reaction mixture, obtained from 400 mg (0.577 mmol) of **2** and 36 mg (0.38 mmol) of phenol, was refluxed in benzene for 30 min and evaporated. The resulting residue was chromatographed on alumina in the same manner as described above to give 90 mg (0.13 mmol, 33%) of **14**.

Reaction with o-*Cresol.* To a benzene solution of **2** (400 mg, 0.577 mmol) was added a benzene solution of *o*-cresol (41 mg, 0.38 mmol) and the resulting red reaction mixture was stirred for 10 min. The mixture was evaporated and the residue chromatographed on alumina, using a column

cooled by circulating ice-water. Elution with benzene–hexane (1:1) gave bis(*p*-chlorophenyl) disulfide, **4**, and **6**, and subsequent elution with benzene–hexane (2:1) gave 112 mg (0.22 mmol) of **15**. This quinone imine was dissolved in a small amount (2 ml) of benzene, 10 ml of hexane was added to the solution and cooled to 5 °C, giving dark red needles (this quinone imine was immediately decomposed in methanol and slowly in benzene and hexane at reflux); mp 175—176 °C; IR (KBr): 3330 (NH) and 1640 cm^{-1} (C=O); UV and vis (hexane): 486 (ε 6050) and 275 (22600) nm; MS (70 eV): *m/e* (rel intensity), 514 (M^++2, 48), 513 (M^++1, 93), 512 (M^+, 100), 455 (15), and 57 (74); ^1H NMR (CCl_4)[11]: δ=1.10, 1.18, 1.32, and 1.34 (s, *t*-Bu, 36H), 1.96 and 2.08 (d, J=1.4 Hz, *syn*- and *anti*-CH_3, 3H), and 6.24—6.88 (m, aromatic, quinonoid, and NH, 9H). Found: C, 81.59; H, 9.84; N, 5.15%. Calcd for $C_{35}H_{48}N_2O$: C, 81.98; H, 9.44; N, 5.46%.

Similarly, the reaction of 130 mg (0.188 mmol) of **2** with 41 mg (0.38 mmol) of *o*-cresol gave 26 mg (0.051 mmol) of **15**.

Reaction with 1-Naphthol. To a benzene solution of **2** (409 mg, 0.590 mmol) a benzene solution of 1-naphthol (56 mg, 0.39 mmol) was added. The resulting red reaction mixture was stirred for 120 min, evaporated, and the residue chromatographed on alumina with benzene–hexane (2:3). The fractions of the red zone (mixture of quinone imines **17** and **18**) were collected, concentrated, and the residue was run on a preparative alumina TLC (Merck, Art 1064; 20×40 cm, 80 g) to afford 52 mg (0.15 mmol) of **17** and 46 mg (0.084 mmol) of **18**. The quinone imines were recrystallized from methanol; **17**: red prisms; mp 148—150 °C; IR (KBr): 1650 cm^{-1} (C=O); UV and vis (hexane): 454 (ε 3460), 435 (sh, 3120), and 255 (22000) nm; MS (70 eV): *m/e* (rel intensity), 346 (M^++1, 47), 345 (M^+, 100), 330 (35), 274 (22), 140 (21), and 57 (52); ^1H NMR (CCl_4): δ=1.37 (s, *t*-Bu, 18H) and 6.56—8.52 (m, aromatic and quinonoid, 9H). Found: C, 83.03; H, 7.97; N, 4.02%. Calcd for $C_{24}H_{27}NO$: C, 83.44; H, 7.88; N, 4.05%.

Quinone imine **18**: red prisms; mp 200—202 °C; IR (KBr): 3350 (NH) and 1650 cm^{-1} (C=O); UV and vis (hexane): 468 (ε 6770), 277 (25500), 248 (sh, 21000), and 235 (sh, 23200) nm; MS (70 eV): *m/e* (rel intensity), 550 (M^++2, 20), 549(M^++1, 57), 548 (M^+, 100), and 57 (28); ^1H NMR (CCl_4): δ=1.17 (s, *t*-Bu, 18H), 1.24 (s, *t*-Bu, 18H), 7.26 (s, NH, 1H, exchanged by D_2O), and 6.56—8.60 (m, aromatic and quinonoid, 11H). Found: C, 82.85; H, 8.96; N, 5.33%. Calcd for $C_{38}H_{48}N_2O$: C, 83.16; H, 8.82; N, 5.11%.

On the other hand, the reaction of 136 mg (0.196 mmol) of **2** with 56 mg (0.39 mmol) of 1-naphthol gave only 35 mg (0.10 mmol) of **17** (**18**: trace amounts from TLC inspection of the reaction mixture).

Reaction with p-*Cresol.* To a benzene solution of **2** (400 mg, 0.577 mmol) a benzene solution of *p*-cresol (31 mg, 0.29 mmol) was added and the resulting mixture stirred for 15 min, turning light greenish yellow. After the solvent was removed by freeze-drying, the residue was dissolved in 20 ml of dry benzene and cooled to 5 °C in an ice-water bath. To the solution was added 0.58 g (5.7 mmol) of triethylamine and 0.48 g (3.4 mmol) of benzoyl chloride with stirring, and the mixture was stirred for 20 min at 5 °C and for 3 h at room temperature. The mixture was washed with K_2CO_3 aq solution, then with water, and dried over anhyd $MgSO_4$. After filtration and concentration, the residue was chromatographed on alumina (Merck, Art 1097) with benzene–hexane (1:2) to give 218 mg (0.250 mmol, 86%) of **20**, which was recrystallized from methanol–benzene; colorless prisms; mp 167—168.5 °C; IR (KBr): 1745 cm^{-1} (C=O); ^1H NMR (CCl_4): δ=1.12 (s, *t*-Bu, 36H), 2.29 (s, CH_3, 3H), and 6.76—7.25 (m, aromatic, 21H). Found: C, 74.15; H, 6.70; N, 3.05%. Calcd for $C_{54}H_{60}Cl_2N_2O_2S_2$: C, 74.37; H, 6.94; N, 3.21%.

The reaction mixture, obtained from 400 mg (0.577 mmol) of **2** and 31 mg (0.29 mmol) of *p*-cresol, was refluxed for 30 min, turning dark red. After the mixture was evaporated, the residue was chromatographed on alumina. Elution with benzene–hexane (2:3) gave a mixture of **4** and **5**. Subsequent elution with benzene gave 63 mg (0.079 mmol, 27%) of **21**, which was recrystallized from methanol; dark yellow-blue needles; mp 138—140 °C; IR (KBr): 3350 (NH) and 1620 cm^{-1}; ^1H NMR (CCl_4): δ=1.29 (s, *t*-Bu, 36H) and 6.91—7.68 (m, aromatic, quinonoid, and NH, 18H). ^{13}C NMR ($CDCl_3$): δ=177.5 (s), 152.2 (s), 139.7 (s), 138.9 (s), 138.7 (s), 136.0 (s), 134.0 (s), 132.9 (d), 132.7 (s), 129.0 (d), 117.0 (d), 114.6 (d), 103.2 (d), 35.2 (s), and 31.6 (q); molecular weight determined by vapor pressure osmometry (Knauer; benzene, 45 °C): 807 (calcd: 798). Found: C, 70.46; H, 6.94; N, 3.38%. Calcd for $C_{47}H_{54}Cl_2OS_2$: C, 70.74; H, 6.82; N, 3.51%.

Reaction with p-t-*Butylphenol.* To a benzene solution of **2** (400 mg, 0.577 mmol) a benzene solution of *p-t*-butylphenol (87 mg, 0.58 mmol) was added and the reaction mixture stirred for 30 min, turning colorless or wine-red. The solvent was removed by freeze-drying and the residue was chromatographed on silica gel, using a column cooled by circulating ice-water. Elution with benzene–hexane (2:3) gave 177 mg (0.509 mmol) of **4** and 145 mg (0.172 mmol) of **24**, and subsequent elution with benzene–hexane (2:1) gave 84 mg (0.17 mmol) of **22**. Isolation of **22** and **24** was performed by the same procedure as for **11**. Since these isolated phenols contained small amounts of impurities, they were recrystallized. However, this caused further decomposition of the phenols. In order to confirm their structures, the phenols were converted into stable benzoic esters **23** and **25** by treating them with benzoyl chloride. Phenol **22**: IR (KBr): 3420 cm^{-1} (OH); ^1H NMR (benzene-d_6): δ=1.07 (s, *t*-Bu, 9H), 1.23 (s, *t*-Bu, 18H), 5.06 (s, OH, 1H), and 6.70—7.28 (m, aromatic, 10H).

Phenol **24**: IR (KBr): 3480 cm^{-1} (OH); ^1H NMR (benzene-d_6): δ=1.00 (s, *t*-Bu, 9H), 1.26 (s, *t*-Bu, 36H), 5.36 (s, OH, 1H), and 6.77—7.30 (m, aromatic, 16H).

The reaction of 400 mg (0.577 mmol) of **2** with 175 mg (1.17 mmol) of *p-t*-butylphenol gave 126 mg (0.254 mmol) of **22** and 96 mg (0.11 mmol) of **24**. On the other hand, the reaction of 400 mg (0.577 mmol) of **2** with 46 mg (0.31 mmol) of the phenol gave only 211 mg (0.251 mmol) of **24** (**22**: trace amounts from TLC inspection).

Conversion of 22 into Benzoic Ester 23. To a stirred solution of **22** (142 mg, 0.286 mmol) and triethylamine (0.58 g, 5.7 mmol) in dry benzene (10 ml), 0.24 g (1.7 mmol) of benzoyl chloride was added at 5 °C. After being stirred for 2 h at room temperature, the reaction mixture was passed through a short column (4×10 cm) packed with alumina (Merck, Art 1097; eluant benzene) to remove unreacted benzoyl chloride. After concentration of the eluate, methanol–water was added to the residue to give 168 mg (0.280 mmol, 98%) of a light yellow powder (TLC one spot), which was recrystallized from methanol–water: colorless prisms; mp 134—136 °C; 141 mg (0.235 mmol, 82%); IR (KBr): 1745 cm^{-1} (C=O); ^1H NMR (CCl_4): δ=1.15 (s, *t*-Bu, 18H), 1.32 (s, *t*-Bu, 9H), and 6.78—7.68 (m, aromatic, 15H). Found: C, 73.72; H, 6.94; N, 2.28%. Calcd for $C_{37}H_{42}ClNO_2S$: C, 74.04; H, 7.05; N, 2.33%.

Conversion of 24 into Benzoic Ester 25. The conversion

was carried out by the same procedure as that for **22**. To a stirred solution of **24**(125 mg, 0.148 mmol) and triethylamine (0.58 g, 5.7 mmol) in dry benzene (10 ml) was added 0.24 g (1.7 mmol) of benzoyl chloride at 5 °C. The reaction mixture was stirred for 2 h at room temperature and passed through a short column packed with alumina. After concentration of the eluate, methanol–water was added to the residue to give 132 mg (0.140 mmol, 95%) of colorless crystals (TLC one spot), which were recrystallized from methanol–benzene: colorless needles; mp 176—177 °C; 111 mg (0.117 mmol, 79%); IR (KBr): 1750 cm^{-1} (C=O); ^1H NMR (CCl_4): δ=1.16 (s, *t*-Bu, 36H), 1.24 (s, *t*-Bu, 9H), and 6.79—7.35 (m, aromatic, 21H). Found: C, 72.36; H, 7.01; N, 2.85%. Calcd for $C_{57}H_{66}Cl_2N_2O_2S_2$: C, 72.36; H, 7.03; N, 2.96%.

*Reaction with 2,4-Di-*t*-butylphenol.* To a benzene solution of **2** (200 mg, 0.289 mmol) a benzene solution of 2,4-di-*t*-butylphenol (60 mg, 0.29 mmol) was added and the resulting reaction mixture was stirred for 20 min, turning colorless or wine-red. The solvent was removed by freeze-drying and the residue was chromatographed on silica gel, using a column cooled by circulating ice-water. Elution with benzene–hexane (1:3) gave 143 mg (0.259 mmol) of powdery **26**, which was isolated from the eluate by the same procedure as for **11**. Since the phenol isolated was contaminated with trace amounts of bis(*p*-chlorophenyl) disulfide, it was recrystallized. However, this resulted in further decomposition of the phenol. IR (KBr): 3500 cm^{-1} (OH); ^1H NMR (benzene-d_6): δ=1.14 (s, *t*-Bu, 9H), 1.24 (s, *t*-Bu, 18H), 1.53 (s, *t*-Bu, 9H), 5.53 (s, OH, 1H), and 6.70—7.35(m, aromatic, 9H).

*Reaction with 2,6-Di-*t*-butyl-*p*-cresol.* To a benzene solution of **2** (400 mg, 0.577 mmol) a benzene solution of 2,6-di-*t*-butyl-*p*-cresol (125 mg, 0.567 mmol) was added and the reaction mixture was stirred for 10 min, turning light blue. After standing for 1 d at room temperature, the resulting yellow reaction mixture was evaporated and the residue chromatographed on alumina with benzene–hexane (1:2) to give 196 mg (0.346 mmol) of **27** as a yellow oil, which was recrystallized from methanol–water (20:1): light orange prisms: mp 130—131 °C; IR (KBr): 3580 cm^{-1} (OH); MS (70 eV): *m/e* (rel intensity), 565 (M^+, 4), 422 (16), 346 (83), 219 (100), 204 (30), and 57 (44); ^1H NMR (CCl_4): δ= 1.22 (s, *t*-Bu, 18H), 1.35 (s, *t*-Bu, 18H), 4.73 (s, CH_2, 2H), 4.92 (s, OH, 1H), and 6.76—7.17 (m, aromatic, 9H). Found: C, 74.50; H, 8.51; N, 2.22%. Calcd for $C_{35}H_{48}ClNOS$: C, 74.24; H, 8.54; N, 2.47%.

A New Synthesis of Triphenodithiazines and Triphenodithiazinequinoes

Hisao Nishi,* Yuichi Hatada, and Kiyoshi Kitahara
Department of Applied Chemistry, Faculty of Engineering, Saitama University, Shimo-Okubo, Urawa 338
(Received November 4, 1982)

A new class of 6,13-bis(arylamino)triphenodithiazines has been synthesized by condensing chloranil with arylamines followed by the reaction of the resulting 2,5-bis(arylamino)-3,6-dichloro-1,4-benzoquinones with zinc 2-aminobenzenthiolates (**4**) in the presence of a base in Methyl Cellosolve. On the other hand, the reaction of 2,5-dianilino-3,6-dichloro-1,4-benzoquinone (**3a**) with **4** in DMF proceeded unexpectedly to give 7,14-dihydro-6,13-triphenodithiazinequinones by eliminating the anilino groups of **3a**.

Few triphenodithiazine ([1,4]benzothiazino[2,3-*b*]-phenothiazine) derivatives have been studied in comparison with triphenodioxazine derivatives, which are useful dyes and pigments.[1] Recently, however, Mital and Jain *et al.* have reported[2,3] the synthesis of 6,13-dichlorotriphenodithiazine and its derivatives. In a previous paper, we ourselves studied[4,5] the dechlorination of some 6,13-dichlorotriphenodithiazine (**Ia**) and -dioxazine (**Ib**) with tin powder in polyphosphoric acid (PPA), as is shown in Scheme 1. Then, it was

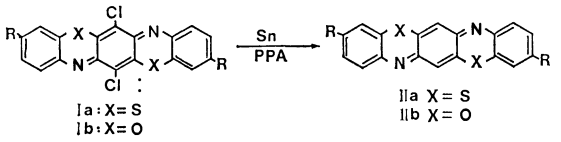
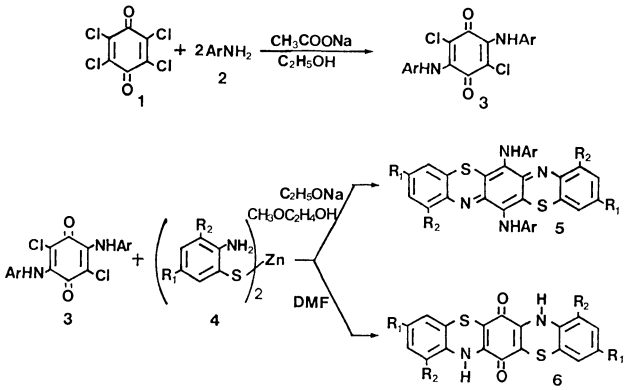
clarified that the replacement of two chlorine atoms at the 6 and 13 positions by hydrogen atoms brought about a decrease in the melting point and a strong hypsochromic shift in the electronic spectrum.



Scheme 1.

Furthermore, it will be interesting to ascertain the effects on the physical properties of the introduced bulky substituents at these positions. We wish here to report the synthesis and several properties of the new triphenodithiazines (**5**) and 7,14-dihydro-6,13-triphenodithiazinequinones (**6**). We have established these novel synthetic routes to be as is shown in Scheme 2. These compounds may be suited for new organic pigments.



Scheme 2.

Results and Discussion

The condensation of chloranil **1** (1:2 molar ratio) with amines **2** in ethanol containing sodium acetates gave 2,5-bis(arylamino)-3,6-dichloro-1,4-benzoquinones (**3**) in good yields by using Mital's method.[2] These findings are summarized in Table 1.

Zinc 2-aminobenzenethiolate (**4a**) was prepared from commercial 2-aminobenzenethiol by Nodiff's method.[6] Zinc 2-aminobenzenethiolate derivatives **4b—h** were synthesized by improving Mital's method.[2] The basic hydrolysis of substituted 2-aminobenzothiazoles with 50% aqueous potassium hydroxide afforded the corresponding potassium 2-aminobenzenethiolates in the solution. These salts were converted to zinc 2-aminobenzenethiolates **4b—h** by the following treatment. That is, the potassium-salt solution was adjusted with acetic acid to pH 8 and filtered; then, methanol and zinc chloride in a 15% acetic acid solution were added to this filtrate. Some examples of these results are summarized in Table 2. The use of Compound **4** was necessary to cause the following reaction to proceed smoothly without forming a tarry product.

In the presence of sodium ethoxide, Compound **3** reacted with Compound **4** in 2-methoxyethanol (Methyl Cellosolve) to give 6,13-bis(arylamino)triphenodithiazine derivatives **5** as a new class of heterocycles. The

a) These results were obtained by DTA.

synthetic results of Compound **5** are listed in Table 3. When the molar ratio of sodium ethoxide: Compound **3a** (Ar=phenyl) were equal to 1, 2, 4, and 8, Compound **5a** was obtained in yields of 26, 40, 42, and 29% respectively. The best yield of Compound **5a** was afforded by using a 1.5-fold excess of **4a** in relation to the **3a** in Methyl Cellosolve.

The decomposition point of Compound **5**, as examined by DTA, was observed to be as high as the other triphenodithiazines previously reported by us.[4,5] Especially, the replacement of two chlorine atoms at the 6 and 13 positions in Compound **Ia** to phenyl groups caused a rise in the decomposition point. Compound **5** was easily soluble in organic solvents. However, by the introduction of *p*-(benzamido)anilino groups at the 6 and 13 positions Compound **5** became sparingly soluble as compared with that of other arylamino groups.

The UV and visible absorption spectra showed 320—358 nm in H_2SO_4 and 555—621 nm in dioxane respectively. When the R_1 and R_2 substituents were hydrogen atoms, the UV and visible spectra of Compound **5** were found in the narrow regions of 320—328 nm and 555—560 nm respectively. These values were nearly the same as those of 6,13-dichlorotriphenodithazine[5] (**Ia**) (UV: λ_{max} 332 nm, visible: λ_{max} 560 nm) and triphenodithiazine[5] (**IIa**) (UV:λ_{max}(H_2SO_4) 321 nm, visible: λ_{max}(dioxane) 560 nm). It was suggested that the spectral change caused by conjugation effect was very little, for 6,13-disubstituted arylamino groups could not be coplanar with the triphenodithiazine ring.

The bathochromic effect was observed by introducing the substituents, R_1 and/or R_2. Especially, the annelation compound **5n** showed a remarkable shift in both UV and visible spectra. The streak colors of

a) These results were obtained by DTA. b) In H_2SO_4.

Compound **5** were from purple to blue.

The IR absorption spectra in KBr showed the N–H stretching band (around 3300 cm^{-1}) and the disappearance of the C=O stretching band (around 1660 cm^{-1}) of Compound **3**.

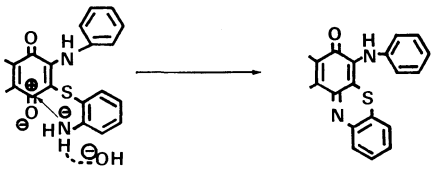
On the other hand, the reaction of Compound **3a** (Ar=phenyl) with Compound **4** in *N*,*N*-dimethyformamide (DMF), in the absence of a base, afforded 7,14-dihydro-6,13-triphenodithiazinequinone derivatives **6** by eliminating the anilino groups of Compound **3a**.[7] The synthetic results of Compound **6** are listed in Table 4. Some of the triphenodithiazinequinones have already been synthesized by another synthetic route.[8] A good yield of Compound **6a** (unsubstituted) was obtained only when the molar ratio of **3a**:**4a** was 1:2 in DMF. This reaction was tested in various solvents: chlorobenzene, nitrobenzene, anisole, acetic acid, cyclohexanol, Methyl Cellosolve, DMF, *etc.* Consequently, DMF was found to be the best solvent for dissolving **3** together with **4**.

Several **3** compounds as well as **3a** reacted with **4a** to give the same compound, **6a**, in 60—68% yields. When **3k** (R=cyclohexyl) or **3l** (R=butyl) was used as the starting material, however, Compound **6a** was obtained in a low yield.

The **6** compounds decomposed at 342—420 °C, and the streak colors were from blue to green. Because the **6** compounds were sparingly soluble in the usual solvents, then UV and visible absorption spectra were measured as 331—362 nm and 723—860 nm respectively in H_2SO_4. Accordingly, the visible spectra were actually observed in the near-infrared region. The bathochromic effect of Compound **6** was observed as well as that of Compound **5**.

The IR absorption spectra in KBr showed a N–H stretching band (around 3250 cm^{-1}) and a C=O stretching band (around 1630 cm^{-1}).

It may be assumed that the reaction mechanisms are based on Pearson's HSAB (Hard and Soft Acids and Bases) principle[9], as is shown in Schemes 3a and 3b. The mechanisms in the residual side of the intermediate can also be similarly.



Scheme 3a. Hard acid and hard base type.

Scheme 3b. Soft acid and soft base type.

Experimental

The melting points are uncorrected. The DTA was measured on Rigaku Denki YGHD. The IR spectra were taken with a JASCO IRA-2 apparatus. The UV and visible spectra were recorded with a Hitachi EPS-3T apparatus.

Condensation of Chloranil ***1*** *with Amines* ***2***. To a stirred

suspension of **1** (0.025 mol) and sodium acetate (0.061 mol in ethanol (50 ml), we added arylamine **2** (0.10 mol). The mixture was then heated under reflux for 3—5 h and filtered while still hot. The residue was washed with ethanol, hot water, and water, and dried. Recrystallization from the appropriate solvents gave 2,5-bis(arylamino)-3,6-dichloro-1,4-benzoquinones (**3**) in a good yield. The yield and properties of **3** are listed in Table 1.

Preparation of 6,13-Dianilino-type ***5***. A mixture of **3** (0.0025 mol), zinc salt of substituted 2-aminobenzenethiol **4** (0.0025 mol), and sodium ethoxide (0.0075 mol) was refluxed for 6—8 h in Methyl Cellosolve (150 ml) and then cooled overnight. The precipitated solid was collected, washed with Methyl Cellosolve, ethanol, hot 3 M HCl (1 M=1 mol dm^{-3}), and water, and dried. Recrystallization from *o*-dichlorobenzene produced 6,13-bis(arylamino)triphenodithiazines (**5**). The yield and properties of **5** are listed in Table 3.

Preparation of 6,13-Quinone-type ***6***. A mixture of **3** (0.0025 mol) and **4** (0.0050 mol) in DMF (50 ml) was refluxed for 12 h and filtered while still hot. The residue was washed with hot DMF until the filtrate was almost colorless, washed with ethanol, and dried. Further, the solid was washed with hot 3 M HCl for a long time and then with water, and dried. Sublimation *in vacuo* gave 7,14-dihydro-6,13-triphenodithiazinequinones (**6**). The yield and properties of **6** are listed in Table 4.

(Received November 5, 1982)

Conformational preference and rotational barriers of 1′,1′,2,2-tetrachloro-3′-formyl-1′a,7′b-dihydrospiro-[cyclopropane-1,2′(3′*H*)-cyclopropa[*c*]quinolines] (**1**) and related *N*-formyl heterocyclic compounds were determined by ^{1}H- and ^{13}C-NMR spectroscopy. The *sp*-conformer is usually more preferable in **1** and their rotational barriers about amide C–N bond are within a relatively narrow range from 70.7 to 72.8 kJ mol^{-1}. Infrared carbonyl absorptions of these compounds also support the preferred conformation from the NMR data. The results were discussed from the view point of N–C=O conjugation.

In the course of investigations on mono- and diazanaphthalenes and related heterocycles, a new synthesis of cyclopropa[*c*]quinolines,[1] 2,2-dichloro-1′-formylspiro-[cyclopropane-1,2′(1′*H*)-quinoline] and related heterocyclic amides[2,3] have been reported by the present authors. Steric effect on the conformations and dynamic behaviors of these amides are very interesting, since they have sterically hindered *N*-formyl groups. The rotational barriers of amides have been studied very extensively, and a great deal of investigations have been reported.[4] One of the present authors has also studied the effect of intramolecular hydrogen bonding on the rotational barrier of *N*,*N*-dimethylbenzamide.[5] In this connection, the conformational preference and rotational barriers of 1′,1′,2,2-tetrachloro-3′-formyl-1′a,7′b-dihydrospiro[cyclopropane-1,2′(3*H*)-cyclopropa[*c*]quinolines] (**1**), 2,2-dichloro-5′-formylspiro[cyclopropane-1,6′(5′*H*)-phenanthridine] (**2**), and related compounds were determined and discussed from the view of the ring-conformation and steric hindrance on the amide group in this paper.

2

a: Unsubstituted
b: 3-CH_3

Experimental

Preparation and identification of the materials were reported previously.[1-3,6] Commercially available spectro grade solvents were used without further purification. Temperature-dependent ^{1}H-NMR spectra were recorded on a JEOL JNM C-60H spectrometer. The exchange rates between the two sites (usually unequivalent) were evaluated by use of total line shape analysis program. NOE measurements were carried out with a JEOL JMN FX-90Q spectrometer. Infrared spectra were measured on carbon tetrachloride solutions using a Hitachi 225 infrared spectrophotometer.

Results and Discussion

Rotational Barriers about the C–N Bonds of N-*Formyl Groups and Conformational Preference.* In order to examine steric and electronic effects on the rotational barrier of **1**, ^{1}H dynamic NMR measurements were carried out on the following compounds in addition to **1** and **2**.

a) ΔG^{*} values are always given with respect to the more stable conformer (at 298.2 K). b) In DMSO-d_6. c) Synperiplanar to ethoxyl group. d) With reference to vicinal CH_3 group. e) A sharp singlet at −60 °C.

The DNMR data including free energies of activation of these *N*-formyl azaheterocycles are given in Table 1, together with the chemical shift and intensity data at the temperatures below coalescence temperatures (T_c). Coalescence of the two formyl signals usually occurs near room temperature.

Since amide group has a tendency to take a planar conformation, the two different planar (or nearly planar) conformers ((A) and (B) in Fig. 1) are possible in these heterocyclic amide, each of which giving a separate formyl proton signal below T_c. With the compounds **1**—**6**, the signal at the lower field was assigned to the formyl proton *syn* to aromatic ring and the one at the higher field to the *anti* formyl proton. The assignment was ascertained by the nuclear Overhauser enhancement of *anti*-formyl proton by irradiation of 3-hydrogen atom (H_a) on the spirocyclopropane ring in some typical instances. Two formyl signals in **6** were assigned unambiguously by NOE

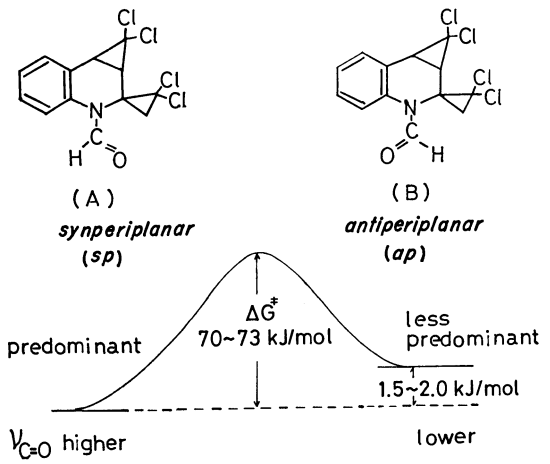

Fig. 1.

experiments irradiating both cyclopropyl methylene (H_a) and vicinal methyl groups (Chemical shifts given by bold letters in Table 1 were assigned by NOE.). The compound **1a** is expected to have a nearly planar and rather rigid tetrahydropyridine ring, because it has a fused cyclopropane ring on the 3 and 4 positions (1′a and 7′a positions of the new ring system). Thus the spirocyclopropane ring lies nearly perpendicular to the heterocyclic ring and facing to the formyl group. The *sp*-conformation is generally more stable than the *ap*-conformation in **1a**—**d**, the free energy difference between the two conformers being 1.5—2.0 kJ mol^{-1}. Since several evidence concerning the steric hindrance of *peri*(8)-hydrogen atom towards the planarity of 1-carbonyl group on the naphthalene nucleus have been reported,[8] the destabilizing effect due to *peri*-hydrogen might be the reason for the preference of *sp*-conformer in **1a**—**d**. Introduction of electron-donating substituent *para* to the formamide moiety on the aromatic ring is expected to lessen the resonance contribution by the aromatic ring and to increase the rotational barrier of the C–N bond. . However, the ΔG^{*} values of **1b**—**d** agree with that of **1a**, showing no indication of substituent effect. Methyl substituent on 7′a-position in **1e** again does not affect the rotational barrier considerably. The ΔG^{*} and the conformational ratios of **2** are also very close to those of **1**. This can be another evidence for the nearly planar ring conformation of **1**.

^{13}C-NMR data of **1** and **2** are given in Table 2. These compounds have two separate signals in the carbonyl region. Since the formyl carbon atom is not expected to be displaced considerably by rotating the formyl group around the C–N bond, through-space field and anisotropy effect is assumed to be nearly identical on the carbonyl carbon atoms of the both conformers. Therefore, the difference in chemi-

Table 2. ^{13}C-Chemical shifts

Orientation of C=O group	*sp*-Conformer Towards dichloro-cyclopropropyl	*ap*-Conformer Towards aromatic ring
1b	164.5	160.9
1c	164.5	160.9
1e	164.9	160.9

2b	162.4	160.4
3a	163.5	160.9
9	167.7	—

cal shifts should arise from the change in conjugation effect through C–N bond. This can be another evidence for the steric hindrance in different degrees to the planarity of conformers of **1** and **2**.

The rotational barriers of **3a**, **5**, and **6** (68.2, 69.2, and 70.7 kJ mol^{-1}, respectively) are almost similar to those of **1** and **2**, suggesting the similarity in conformations around the formyl groups of these compounds. Dispiro[cyclopropane-1,2′(1′*H*)-pyridine-4′,(3′*H*) 1″-cyclopropane] (**6**) is void of fused aromatic ring. However, it is reasonable that its ΔG^* value is almost identical with those of **1**, since the steric effect by *ortho*-methyl group is nearly equivalent to that of *peri*-hydrogen atom as evidenced by other experiments of the authors.[9] *N*-(2,2-Dichloro-1-methylcyclopropyl)formanilide also supposed to take a nearly planar conformation to keep the cross-conjugated amide system including cyclopropyl moiety. 1′-Formyl-3′,3′-dimethylspiro[cyclopropane-1,2′-indoline] (**7**) has a considerably low rotational barrier about the amide C–N bond. It is quite unexpected since the steric hindrance to the planarity seems less in this five-membered analog **7**. The rotational barrier about the similar bond of *N*-formylindoline has however been reported to be 64.8 kJ mol^{-1},[10] which is very close to the ΔG^* of **7**.

As a model for a formanilide in which aryl–nitrogen conjugation is forbidden perfectly by steric hindrance, the rotational barrier of *N*,2′,6′-trimethylformanilide (**10**) was determined to be 77.0 kJ mol^{-1}. The barrier is considerably high. This fact can be interpreted that the steric inhibition of Ar–N conjugation enhances the effect of N–C=O conjugation, resulting higher $C_{carbonyl}$–N bond order. The barriers of **1** and **2** are considerably lower than that of **10**. This implies the persistence of conjugative effect by aromatic system in **1** and other compounds of similar ΔG^* values, in spite of considerable deviation from the planarity and cross-conjugative effect by the carbonyl group.

The Infrared Carbonyl Frequency and Conjugative Effect. Frequencies (in cm^{-1}) of the carbonyl stretching absorption bands of **1**—**9** are given in Table 1. Carbonyl stretching frequency of amide is affected most remarkably by the amount of resonance contribution of mesomeric structure D. The contribution of D is suppressed both by the loss of the planarity of N–C=O system and the neighbor electronegative group repelling the negative charge on the carbonyl oxygen atom. In the case of the heterocyclic amide carrying spiro(dichlorocyclopropane)moiety (**1**, **3**, **5**, and **6**), the carbonyl group *syn* to the cyclopropane moiety absorbs at 1707—1709 cm^{-1}, considerably higher frequency than normal formanilide (for example, 1686 cm^{-1} for $C_6H_5NMeCHO$ (**11**)). The high frequency shift can be attributed to the neighbor electronegative group effect, in a through space manner, by the dichlorocyclopropane moiety. The carbonyl group opposing to *peri*-hydrogen atom generally absorbs at 1700—1701 cm^{-1}. The frequency is also considerably higher than that of **11**, suggesting the deviation from the planarity in this conformer. Intensities of the two carbonyl bands (in Table 1) agree qualitatively with the abundances of the two conformers which are estimated from the intensities of their ^{1}H signals at low temperatures (Table 1). Both carbonyl bands of the phenanthridine derivatives **2** shifts to *ca.* 5 cm^{-1} lower frequencies than the corresponding bands of **1**. Low frequency shifts are also observed with the carbonyl bands of **4** which is void of dichlorocyclopropane moiety. *N*-Formyltetrahydro-1,8-naphthyridine derivative **8** shows a single formyl signal at a very low field (9.05 ppm) in ^{1}H-NMR and also a symmetrical carbonyl band at 1712 cm^{-1}. This behavior is best explained by assuming that the *sp*-conformer is extremely stable, probably because of the electrostatic repulsive force between the lone pair electrons on heteroaromatic nitrogen and on carbonyl oxygen. Weak hydrogen bond-like attractive interaction between formyl hydrogen and lone pair electrons on heteroaromatic nitrogen is also possible.

The authors are grateful to Dr. Kazuhisa Abe for his kind advice and assistance throughout this work. This research was supported in part by the Grant-in-Aid for Special Project Research from the Ministry of Education, Science and Culture.

Photoinduced Alcoholysis of α,α,α-Tribromoacetophenone to Benzoylformate

Yasuji IZAWA, Katsuhiro ISHIGURO, and Hideo TOMIOKA*

Department of Industrial Chemistry, Faculty of Engineering, Mie University, Tsu, Mie 514

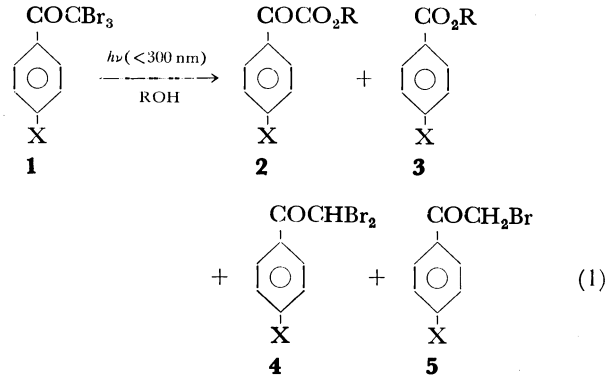
(Received November 8, 1982)

Irradiation of *p*-substituted α,α,α-tribromoacetophenones (**1**) in O_2-saturated alcohols (MeOH, prim. and sec. alcohols) afforded a new alcoholysis product, benzoylformate (**2**), in good yield (75—85%) along with benzoate and radical (reduction) products. Sensitization experiments showed that **2** was derived from the triplet excited **1**. Formation of **2** as well as the decomposition rate of **1** were greatly accelerated by oxygen, presumably as a result of the involvement of the normally forbidden $S_0 \rightarrow T_1$ transition of **1** due to the oxygen-**1** charge transfer complex. Independent synthesis and reaction of possible intermediates in the photoalcoholysis of **1** leading to **2** suggested that **2** was formed from spontaneous (dark) reactions of initial photoalcoholysis product, α,α-dibromo-α-alkoxyacetophenone.

Since photoinduced solvolysis reactions of nitrophenyl phosphates were first discovered by Havinga *et al.*,[1] related reactions were found to occur with other aromatic esters, ethers, halides, *etc.*, reacting with a variety of nucleophiles.[2] Interest has increased in this new domain of chemistry, not only from the stand-point of the reaction mechanism but also from a synthetic viewpoint. These reactions often proceed to a high degree of conversion—resulting in good yields of products which are sometimes difficult to prepare by other reactions. Although the investigations in this field had been mainly focussed on the aromatic photosubstitutions, since the report[3] by Zimmerman and Sandel on the photosolvolysis of benzyl acetate in aqueous dioxane to form benzyl alcohol, a considerable amount of work has been reported[4-9] on the photochemistry of benzyl compounds, mainly benzyl halides, in nucleophilic solvents. It has been reported that products resulting from both heterolysis and homolysis of the benzyl-heteroatom are formed either upon direct irradiation or upon photosensitization. Apart from work with benzyl halides there has been increasing interest paid recently to photolysis of alkyl and cycloalkyl halides.[10,11] Contrary to the earlier belief that only radical intermediates are involved, it becomes clear that cationic, as well as free radical, intermediates may also play an important role in the solution-phase photochemistry of simple alkyl halides. Competing ionic and radical photobehavior has also been observed[12-14] for haloalkenes. However, there are only a few reports on the study of photochemical behavior of α-halo carbonyl compounds. Although the intervention of an α-keto carbonium ion has been suggested in the photoelimination[15] and photorearrangement[16] of some α-halo ketones, few attempts have been made to trap α-keto carbonium ions intermolecularly with nucleophiles. We have already shown that the intermediate generated photolytically from α-halo esters can be trapped by phosphite[17] and electron-rich aromatic nuclei.[18] As an extension of this study, we examined the photolysis of α,α,α-trichloroacetophenone in alcohols and found[19] that a new photoalcoholysis product benzoylformate was formed, albeit in low yield (≈10%), along with other radical products. The formate clearly arose from nucleophilic trapping of ionic species. Since thermal (dark) nucleophilic attack of alcohol on trihaloacetophenone is known to occur exclusively at the carbonyl function to give benzoate (haloform reaction), the formation of formate in the present photoalcoholysis reaction is quite significant and in sharp contrast with the other photosolvolysis reactions in which the type of photoproducts is mostly similar to that obtained in the dark reaction. Thus, it is of obvious interest to get deeper insight into the nature of this novel photoalcoholysis. We wish to report here that tribromoacetophenone undergoes the photoalcoholysis much more efficiently than the trichloro analog, forming benzoylformate in much higher yield (75—85%). The present study also reveals the important role of oxygen, the excited state intermediates leading to photoalcoholysis, and the chemical intermediates leading to benzoylformate.

Results and Discussion

Irradiation of an oxygen-saturated solution of α,α,α-tribromoacetophenone (**1a**) in MeOH for 2 h resulted in the formation of methyl benzoylformate (**2a**, R=Me, 76%) as the main product along with small amounts of methyl benzoate (**3**, R=Me, ≈1%), di- (**4**), and monobromoacetophenones (**5**) (<5%). The identity of these products was confirmed by comparison with authentic samples. Control experiments showed that there was no reaction under identical conditions in the absence of light. Plots of the product yields determined by GC as a function of irradiation time in MeOH (Fig. 1) suggest that esters (**2** and **3**) and the dibromide (**4**) are the primary photoproducts of tribromoacetophenone, but that monobromide (**5**) is apparently derived from **4**. Control experiments also showed that irradiation of **4** in MeOH gave **5**



(1)

a: X=H, **b**: X=MeO, **c**: X=Br, **d**: X=CN.

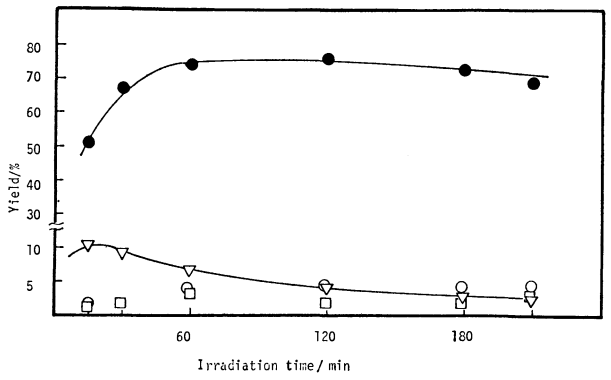


Fig. 1. Yields of **2a** (●), **3a** (□), **4a** (▽), and **5a** (○) during irradiation of **1a** in non-degassed methanol.

along with small amounts of the esters (**2** and **3**). The latter two acetophenones apparently arise at least principally *via* radicals. On the other hand, the major photoproduct **2** clearly arises from nucleophilic trapping of ionic species. This alcoholysis is applicable to a wide variety of alcohols as summarized in Table 1. Yields of formate **2** were generally good (75—85%) for MeOH and the primary and secondary alcohols, but decreased rather sharply with tertiary alcohol-concomitant with formation of several by-products, *e.g.*, benzaldehyde. This is in a marked contrast with the similar photolysis[19] of trichloroacetophenone in an alcohol, where the yields of formate are generally low (≈10%) and the main products are radical products, *e.g.*, dichloroacetophenone. Photolysis of trifluoroacetophenone in alcohol gave neither the alcoholysis product nor radical products.

Effects of Oxygen. Since oxygen has been shown[10] to have a marked effect on some photosolvolytic processes, we next examined the effect of oxygen on the present photoalcoholysis reaction. The results summarized in Table 2 indicate that oxygen has a marked effect on the product ratio. When the solution was purged with oxygen for 30 min before irradiation, the formation of the formate (**2**) as well as the rate of decomposition of **1** were substantially increased. But when the solution was deoxygenated by bubbling argon, both the formation of **2** and the decomposition rate were suppressed, concomitant with appreciable increase in the dibromide (**4**). In connection with the acceleration of the reaction by oxygen, we have examined the UV absorption spectra of **1** in the presence and absence of oxygen. Oxygen-saturated tribromoacetophenone shows a contact charge transfer spectrum with oxygen at around 363 nm, which disappears on bubbling with argon (Fig. 2). The involvement of the charge-transfer (CT) complex in the photoalcoholysis reaction was shown by irradiating the CT band selectively with monochromatic light. Thus, when the irradiation of the monochromatic light of 363 nm was carried out in the presence of oxygen, the yield of the formate was about three

Cyclohexene[d]	35.7	<1	16.9	4.2
Hydroquinone[d]	32.5	<1	15·8	5.2

a) Irradiations were preformed on a 40 mM solution of **1a** in oxygen-saturated MeOH in Pyrex tubes at 10 °C for 15 min. b) Determined by GC. c) About 5-fold excess of Ph_2CO was added as a triplet sensitizer. Irradiated with monochromatic light of 366 nm. d) 0.5 mM.

times that obtained in the similar irradiation in the absence of oxygen. The yield of **2** was not appreciably altered by oxygen when the absorption maximum of **1** (265 nm) was irradiated. It should be noted that the product distributions exhibited a wavelength dependence. That is, the yield of radical products was higher at 265 nm than at 363 nm.

Sensitization and Quenching Studies. When the irradiation was carried out in the presence of benzophenone as a triplet sensitizer with monochromatic light of 366 nm, where >98% of the incident light was absorbed by the sensitizer, the yield of **2** was essentially unaltered with its rate of formation being accelerated (Table 3). This indicates that **2** is essentially derived from the triplet excited state of **1**. Addition of 1,3-pentadiene as a triplet quencher in the reaction caused a marked decrease in the formate formation (Table 3). However, the examination of the product distributions as a function of the concentration of 1,3-pentadiene showed that the formation of dibromide, as well as the decomposition rate of **1**, increased as the concentration of the quencher was increased. The data are presented graphically in Fig. 3 in the usual form of a Stern-Volmer plot. A possible explanation is that 1,3-pentadiene is not acting as a triplet quencher, but as a hydrogen-atom donor. This was easily confirmed by the findings that the Stern-

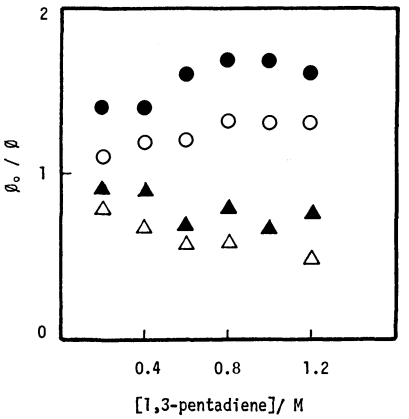

Fig. 3. Effect of 1,3-pentadiene on the quantum yield for formation of **2a** (●), **3a** (○), and **4a** (▲) from **1a** (△) in methanol.

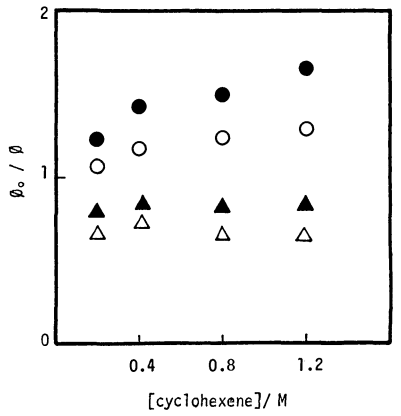

Fig. 4. Effect of cyclohexene on the quantum yield.

Volmer plot using cyclohexene, a good hydrogen donor, also resulted in similar dependence of product distributions (Fig. 4). These results can be interpreted as indicating that there is a delicate balance between ionic (photoalcoholysis) and radical (photoreduction) pathways.

Effects of Solvent. The present photoalcoholysis can be similarly carried out in a mixture of MeOH and solvent (1:10 v/v), instead of absolute MeOH. As summarized in Table 4, however, the product

Table 4. Effect of solvent on photoreaction of **1a** in MeOH[a)]

Solvent	Yield/%[b)]			
	2a	**3a**	**4a**	**5a**

CCl_4	64.1	1.0	<1	<1
None[c)]	51.0	2.0	10.4	1.2

a) Irradiations were performed on a 40 mM solution of **1a** in oxygen-saturated mixtures of MeOH and solvent (1:10 v/v) in Pyrex tubes for 15 min. b) Determined by GC. c) Absolute MeOH was used as solvent.

distributions were somewhat sensitive to the nature of solvent employed. Notably, the significant increase in the yield of **2** was observed in CCl_4 and benzene, while the yield was decreased concomitant with the appreciable increase in **4** and **5** in other solvents. Apparently, the difference reflects in part the hydrogen donor ability of solvents. A good hydrogen donor like ether favors the radical pathway by trapping radicals to give **4** and **5** in competition with ionic process leading to **2** and **3**. The heavy-atom effect in the case of CCl_4 facilitates the intersystem crossing of the excited singlet state to the triplet. CCl_4 is therefore the best co-solvent for the photoalcoholysis.

Effects of Substituents. A number of *p*-substituted tribromoacetophenones were irradiated in an attempt to learn whether there might be any effect of ring substituents on the photoalcoholysis. The results summarized in Table 1 indicate that, just as with tribromoacetophenone itself, the principal products of the substituted tribromoacetophenones were the corresponding benzoylformates, with small amounts of benzoates and dibromoacetophenones also being formed. Thus, neither strong electron-donating nor -withdrawing substituents caused much change in the yield of **2**. This is to be noted in connection with the facts that many photosolvolytic reactions of aryl compounds have been shown[2,20)] to be dramatically affected by ring substituents. For example, Grinter *et al.*[21)] have shown in the photohydrolysis of monosubstituted benzylidyne trifluorides that *m*-chlorobenzylidyne trifluoride shows hardly any reactivity under the conditions where the *m*-hydroxy derivative undergoes photohydrolysis. Such a marked sensitivity to ring substituents often limits the photosolvolytic method as a general synthetic procedure, although its mechanistic implications are very important. The fact that the present photoalcoholysis can be applicable, regardless of the aryl substituents, opens a route to the benzoylformates from the readily available tribromoacetophenones.

Reaction Mechanism. From the above results it is seen that tribromoacetophenones afford new photosolvolytic products, benzoylformates, which are most easily rationalized as resulting from nucleophilic trapping of a cationic intermediate. The corresponding free radical (reduction) products are also observed in lower yield. These results pose two main questions as to the reaction mechanism. (1) Are the excited state intermediates leading to photoalcoholysis the same as those leading to homolysis? That is, where does branching occur in the photoreaction scheme? (2) What are the possible chemical intermediates in the formation of benzoylformate **2**?

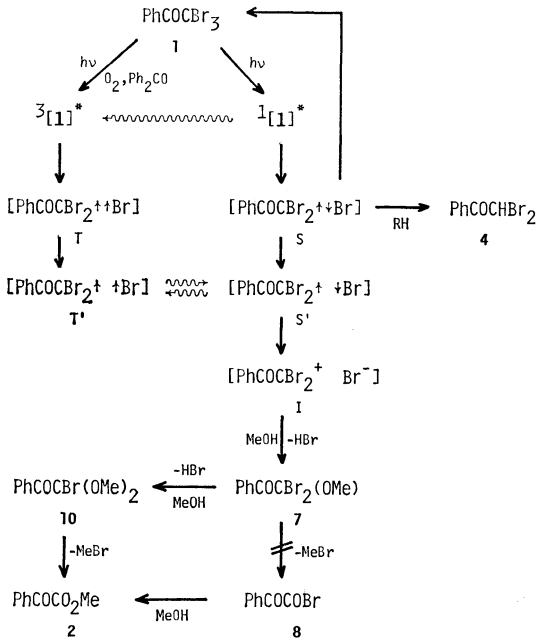
(1) Previous works in this field have examined the effect of sensitizer on the competing ionic and radical photobehavior of halides. It has been indicated[9)] in the photolysis of benzyl halides in nucleophilic solvents that, in general, the triplet states produced by sensitization favor heterolysis, whereas the excited states produced as a result of direct light absorption disfavor heterolysis compared with homolysis. The present results (effects of benzophenone photosensitizer and solvent) also indicate that the benzoylformate comes from a triplet excited state of **1**. In their interesting work on photosolvolysis of alkyl iodide, Kropp and his coworkers have proposed[10)] that ionic intermediates are not produced directly from the photoexcited state, but that the photoexcited state decays by homolysis to a radical pair, which may undergo radical reactions or may undergo electron transfer to afford an ion pair, which would then undergo carbocation reactions.

$$R\text{-}X \xrightarrow{h\nu} [R\cdot X\cdot] \xrightarrow[\text{transfer}]{\text{electron}} [R^+X^-] \qquad (2)$$

This is mainly based on the observation that irradiation of alkyl halide in an alcohol saturated with oxygen resulted in simultaneous quenching of the formation of the free radical product and the ionic product, suggesting trapping of the radical by oxygen in competition with the electron transfer process. The reductive work-up of the resulting mixture affords alcohol arising from peroxide. In the present photoalcoholysis, presence of oxygen also caused quenching of the formation of the radical product (**4**, **5**), but it increased the formation of alcoholysis product. Similar marked acceleration of photoalcoholysis by oxygen has been observed[22)] in the irradiation of α,α,α-trichlorotoluene in alcohol and explained in terms of the involvement of the normally forbidden $S_0 \rightarrow T_1$ transition of trichlorotoluene due to the trichlorotoluene–oxygen charge-transfer (CT) complex. Moreover, such complexes of organic compounds with oxygen have been frequently observed[23)] and are responsible for some photochemical reactions[24)] in the presence of oxygen. Since the present photoalcoholysis product is derived from the triplet excited state of **1**, the effect of oxygen is attributable to the CT complex which facilitates the intersystem crossing. However, we cannot eliminate the possibility that some of the formate may arise from the reaction of oxygen with an initially formed radical *via* homolytic C–Br cleavage. A possible test of this, involving an $^{18}O_2$ tracer experiment, is in progress and will be reported later. The effects of hydrogen donor on the product distributions are more intriguing in this respect. Thus, the addition of a hydrogen donor, *e.g.*, 1,3-pentadiene, cyclohexene, and hydroquinone, always resulted in a marked in-

crease in the reduction product at the expense of the formate. This is most conveniently explained in terms of the idea that radical and ionic photoproducts from **1** are coupled, as shown in Eq. 2, through the common intermediacy of the radical pair. Appreciable increase in the apparent decomposition rate of **1** in the presence of a hydrogen donor suggests that there is substantial recombination within the radical pair to regenerate the starting bromide **1**. The origin of the solvent effect, in which the use of poor hydrogen donor solvent affords increased yields of ionic product, is also thought to be at least in part due to decreased opportunity for the common radical pair to abstract hydrogen from the solvent. The markedly increased ionic behavior of bromides as compared with their chloro analog also reflects that chlorine atoms abstract hydrogen from the solvent cage (in competition with the electron transfer process) more readily than bromine atoms do.

The mechanism of a route from triplet substrates to solvolysis products is very important. Recently, McKenna and his coworkers have studied the photosolvolysis of benzyl halides and suggested[6] that the formation of photosolvolysis product from triplet substrates must include interconversion of loose singlet and triplet radical pairs, followed by electron transfer in the singlet pair to give a solvent-separated ion pair (see Scheme 1). The present results can be



Scheme 1.

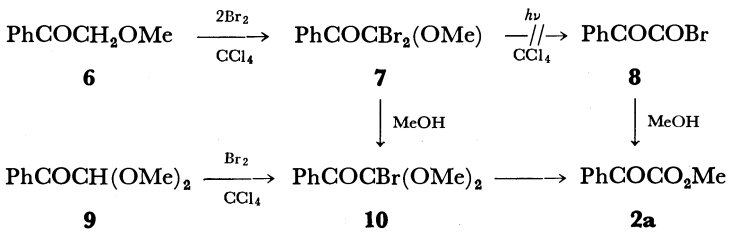
equally well explained by this suggestion. Presumably, singlet radical pairs (S) are very reactive and might either undergo recombination to **1** or abstract hydrogen from the solvent to give dibromoacetophenone (**4**), before they form loose radical pairs (S'). Triplet radical pairs (T), on the other hand, are less reactive and have enough lifetime to shift to loose radical pairs (T') where the partners are already adequately separated to form a solvent-separated ion pair (I).

(2) There are *a priori* several intermediates for the formation of **2** from the photoalcoholysis of **1**. In the photohydrolysis of monosubstituted benzylidyne trifluoride, Grinter and his coworkers[21] have isolated benzoyl fluoride as an intermediate. Sugimori and his coworkers[22] have also suggested that ethyl chloride and intermediary benzoyl chloride are generated from α-ethoxy-α,α-dichlorotoluene in the photoethanolysis of α,α,α-trichlorotoluene. α-Methoxy-α,α-dibromoacetophenone (**7**), a possible initial photoalcoholysis product, was easily prepared by bromination of α-methoxyacetophenone (**6**) in CCl_4. **7** was, however, stable in non-hydroxylic solvent either upon standing in dark or upon prolonged irradiation. When dissolved in MeOH at room temperature, **7** reacted instantaneously to give methyl benzoylformate (**2**) almost quantitatively. More conveniently, when bromination of **6** was carried out in MeOH, **2** was obtained in quantitative yield. Bromination of α,α-dimethoxyacetophenone (**9**) in CCl_4 resulted in a 1:1 mixture of α-bromo-α,α-dimethoxyacetophenone (**10**) and methyl benzoylformate. The former was gradually changed to the formate upon standing at room temperature. These facts indicate that benzoylformyl bromide (**8**) is not generated in the present photoalcoholysis and that the initial photoalcoholysis product **7** reacted spontaneously with MeOH to give **2** probably *via* dimethoxybromoacetophenone (**10**).

Experimental

Instrumentation. UV spectra were recorded on a Hitachi 220-S spectrophotometer. IR spectra were measured on a JASCO IR-G recording spectrometer, and ^1H NMR spectra were determined with a JEOL JNM-MH-100 NMR spectrometer in $CDCl_3$ with Me_4Si as an internal reference. GC analyses were performed on a Yanagimoto Model G-180 instrument with flame ionization detector using a 2.0 m×4.0 mm column packed with (A) 5% PEG 6000 and (B) 5% OV-17 on 60—80 mesh Diasolid L.

Materials. Mono- (**5a—d**),[25] di- (**4a—d**),[26] and tribromoacetophenones (**1a—d**)[26] were prepared by bromination of corresponding acetophenones. Trifluoroacetophenone was prepared[27] by the Friedel-Crafts reaction.



Scheme 2.

Authentic benzoylformates (**2a**—**d**) were prepared[28] from the corresponding dichloroacetophenone followed by esterification. All alcohols were dried and distilled before use.

Irradiation for Product Isolation. In a typical run, a solution of tribromoacetophenone (300 mg) in MeOH (30 ml) was placed in a Pyrex tube. The solution was purged with oxygen at 0 °C for 20—30 min before irradiation. The tube was then septum-sealed and irradiated with a high-pressure, 300W, Hg lamp with a water-cooled jacket. The progress of the reaction was monitored by GC. After irradiation for 2 h, the mixtures were concentrated on a rotary evaporator and chromatographed on 2.0×30 cm^2 silica gel (Woelm, activity III) column with $CHCl_3$ as eluent to give methyl benzoate ($\approx$2 mg, $\approx$1%), methyl benzoylformate (110 mg, 80%), and a mixture of mono- and dibromoacetophenone, all of which showed the same NMR spectra and GC retention times as authentic samples.

Irradiation for Analytical Purposes. Irradiations outlined in Tables 1—4 were carried out on 40 mM solution of **1** in alcohol in a Pyrex tube of 5.0 ml capacity. The progress of the reaction was monitored by GC analysis of aliquots removed periodically from the irradiation mixture in order to obtain time-conversion curves for each product. The identity of the products was confirmed either by GC comparison with authentic samples prepared as above or by separation of each of the components by column chromatography, followed by spectroscopic identification. A purge of the samples with the gas (O_2 or Ar) was carried out at 0 °C with vigorous stirring by a magnetic stirring bar.

Sensitized irradiations were conducted by using a Ritsu MC-20 radiating monochromator (250-W Xenon arc lamp) so as to assure absorption of most of incident light by the photosensitizer; when sensitized irradiation was carried out in Pyrex tubes containing 131 mM benzophenone ($\varepsilon\approx70$ at 366 nm) and 25 mM **1a** ($\varepsilon\approx1.0$ at 366 nm) with light of 366 nm wavelength from the monochromator, more than 98% of the incident light was absorbed by the sensitizer.

For quenching studies, a stock solution of **1** in MeOH was prepared, and 3 ml portions were added to Pyrex tubes containing varying amounts of quenchers. The tubes were then septumsealed and placed in the "merry-go-round" for irradiation. The irradiation was generally interrupted at about 30% completion in order to minimize error associated with product decomposition.

Bromination of α-Methoxyacetophenone. *(A) In CCl_4*: To a stirred solution of α-methoxyacetophenone[29] **6** (0.45 g, 3.0 mmol) in CCl_4 (20 ml) was added dropwise a solution of Br_2 (0.49 g, 3.0 mmol) in the same solvent (2.0 ml) at room temperature, and the mixture was further stirred for an additional 1 h. Evaporation of the solvent *in vacuo* gave crude α-methoxy-α-bromoacetophenone as a yellow oil: 0.63 g, 92%; ^{1}H NMR 3.62 (s, 3H), 6.37 (s, 1H), 7.20—8.10 (m, 5H).

To a refluxing solution of crude α-methoxy-α-bromoacetophenone (0.63 g, 2.7 mmol) in CCl_4 (20 ml) was added dropwise a solution of Br_2 (0.46 g, 2.8 mmol) in the same solvent, and the mixture was refluxed for an additional 1 h. Evaporation of the solvent *in vacuo* gave crude α-methoxy-α,α-dibromoacetophenone **7** as a yellow oil: 0.67 g, 80%; ^{1}H NMR 3.79 (s, 3H), 7.00—8.10 (m, 5H).

7 (0.67 g, 2.2 mmol) was dissolved in MeOH 10 ml) and left for 30 min at room temperature. Evaporation of the solvent gave methyl benzoylformate (**2a**) almost quantitatively.

(B) In MeOH: A solution of Br_2 (1.0 g, 6.3 mmol) in MeOH (4 ml) was added dropwise to a refluxing solution of **6** (0.46 g, 3.1 mmol) in the same solvent (20 ml), and the mixture was further boiled for an additional 1 h. Evaporation of the solvent *in vacuo* gave crude **2a** (0.47 g, 92%).

Bromination of α,α-Dimethoxyacetophenone (9). When **9**[30] was reacted with equivalent bromine in refluxing CCl_4, the crude product after evaporation of the solvent was shown to be 1:1 mixture of **10** and **2a** by NMR analysis, which also revealed that **2a** was increased at the expense of **10** upon standing at room temperature and that **2a** was the exclusive product after standing overnight.

Preparation and Characterization of Poly(thienylene)s

Takakazu YAMAMOTO,* Ken-ichi SANECHIKA, and Akio YAMAMOTO
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227

(Received November 20, 1982)

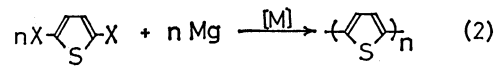
Nickel compounds ($NiCl_2$ and $NiCl_2$(2,2′-bipyridine)) catalyze polycondensation of dihalothiophenes (2,5-dihalothiophenes, 2,4-dibromothiophene, and 3-methyl-2,5-dibromothiophene) by dehalogenation with magnesium to give the corresponding poly(thienylene) type polymers (poly(2,5-thienylene), poly(2,4-thienylene), and poly(3-methyl-2,5-thienylene)). Copolymerization of 2,5-dibromothiophene and 2,4-dibromothiophene affords copolymers formulated as $\{2,5\text{-}C_4H_2S\}_m\{2,4\text{-}C_4H_2S\}_n$. About 15 wt% of poly(2,5-thienylene) prepared in THF at 66 °C is soluble in $CHCl_3$ at room temperature and the $CHCl_3$-soluble fraction has a molecular weight of 1370. The remaining fraction is considered to have a higher molecular weight as judged from its physical properties. IR and ^{1}H-NMR spectra of the polymers are consistent with the structures described above. The electronic spectra of poly(2,5-thienylene) and poly(3-methyl-2,5-thienylene) show large bathochromic shifts of the π-π^* absorption bands from those of thiophene and 3-methylthiophene, respectively, indicating that π-electrons in these polymers are extensively delocalized along the polymer chains. In contrast to the electronic spectra of these polymers, that of poly(2,4-thienylene) shows only a minor shift of the π-π^* absorption band from that of thiophene reflecting the less extensive π-electron delocalization along the polymer chain in the poly(2,4-thienylene). All the polymers are nonsensitive to air and have high thermal stabilities.

Preparation of polymers having π-conjugation systems along the polymer chains is a subject of recent interest in connection with their potential utility as polymer conductors or semiconductors.[1] A previous paper[2] from our group revealed that the transition metal catalyzed C–C coupling reaction between RMgX and R′X[3] was applicable to the preparation of poly(phenylene) type polymers from dihaloaromatic compounds, X–Ar–X,

$$n\,X\text{-}Ar\text{-}X + n\,Mg \longrightarrow [X\text{-}Ar\text{-}MgX] \xrightarrow{[M]} \{Ar\}_n \quad (1)$$

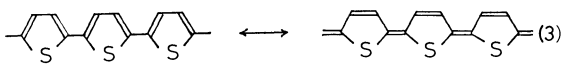
M = Ni, Pd, etc.

We have applied this transition metal-catalyzed dehalogenative polycondensation to the preparation of poly(2,5-thienylene) from 2,5-dihalothiophene,



(2)

The polymer has a π-conjugation system similar to that of poly(acetylene) which shows high electric conductivities when doped with electron acceptors such as I_2 and AsF_5 or electron donors such as Li and Na,[1]

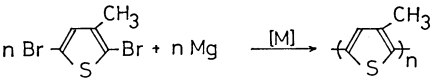


(3)

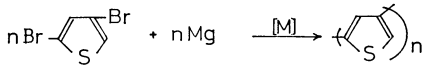
(4)

This paper deals with the preparation and characterization of poly(2,5-thienylene) and its related polymers including its methylated analogue (poly(3-methyl-2,5-thienylene)), its isomer (poly(2,4-thienylene)), and copolymers of 2,5-dibromothiophene and 2,4-dibromothiophene,

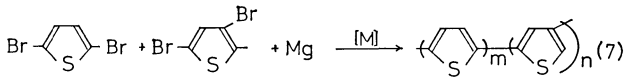
Part of the results were briefly reported in communication form.[4] After publication of our first communication, Lin and Dudek[5] also reported preparation of



(5)



(6)



(7)

poly(2,5-thienylene) using a similar technique, and more recently preparation of polymers having similar π-conjugation systems to that of poly(2,5-thienylene), poly(2,5-pyrrolylene) derivatives[6] and poly(2,5-selenienylene),[7] by using the dehalogenative polycondensation technique has been reported. Electrochemical polymerization of thiophene in an $[N(Et)_4][BF_4]$ solution was also reported.[8]

Results and Discussion

Preparation of Polymers. Poly(2,5-thienylene): Table 1 shows results of the dehalogenative polycondensation of dihalothiophenes. As shown in Table 1, 2,5-dibromothiophene and 2,5-dichlorothiophene are polymerized at reflux temperature of THF (66 °C) to give poly(2,5-thienylene) according to Eq. 2. 2,5-Dibromothiophene and 2,5-dichlorothiophene seem to have almost the same reactivities in the polymerization.

Gas chromatographic analysis of compounds obtained by hydrolysis of the reaction product of 2,5-dibromothiophene and magnesium (1:1) before addition of the catalyst revealed that the 1:1 reaction of 2,5-dibromothiophene and magnesium afforded a mixture containing 2,5-C_4H_2S(MgBr)Br and 2,5-$C_4H_2S(MgBr)_2$ as well as intact 2,5-dibromothiophene in about 2:1:1 ratio. Thus, the polymerization is considered to proceed through the C–C coupling between these compounds,

TABLE 1. PREPARATION OF POLY(THIENYLENE)S

Expt	Monomer[a]	Catalyst[b]	Solvent[c]	Temp °C	Time h	Yield %	$CHCl_3$-extractable[d] fraction / $CHCl_3$-unextractable fraction
1	2,5-$C_4H_2SBr_2$	None	THF	66	5	0	
2	2,5-$C_4H_2SBr_2$	$NiCl_2$(bpy)	THF	66	3	61	22/78
3	2,5-$C_4H_2SBr_2$	$NiCl_2$(bpy)	THF	66	5	78	Not measured
4	2,5-$C_4H_2SBr_2$	$NiCl_2$(bpy)	THF	25	21	7	37/63

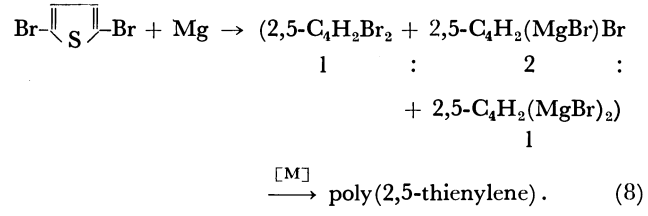
9	2,5-$C_4H_2SBr_2$	$PdCl_2$(bpy)	THF	66	5	0	
10	2,5-$C_4H_2SBr_2$	$FeCl_3$	THF	66	5	14	Not measured
11	2,5-$C_4H_2SBr_2$	Fe(acac)$_3$	THF	66	5	12	Not measured
12	2,5-$C_4H_2SBr_2$	$CoCl_2$	THF	66	5	5	Not measured
13	2,5-$C_4H_2SCl_2$	$NiCl_2$(bpy)	THF	66	4	40	27/73
14	2,4-$C_4H_2SBr_2$	$NiCl_2$(bpy)	THF	66	5	17	69/31
15	2,4-$C_4H_2SBr_2$	$NiCl_2$(bpy)	THF+n-Bu_2O	110	5	58	29/71
16	3-Me-2,5-C_4HSBr_2	$NiCl_2$(bpy)	THF	66	3	55	83/17
17	3-Me-2,5-C_4HSBr_2	$NiCl_2$(bpy)	THF+n-Br_2O	110	3	40	95/5

a) $C_4H_2SX_2$=Dihalothiophene. 3-Me-C_4HSBr_2=3-Methyl-2,5-dibromothiophene. b) bpy=2,2′-Bipyridine. dppp=1,3-Bis(diphenylphosphino)propane. 0.003 mol% of the catalyst per monomer was added. c) THF+n-Bu_2O=1:4 mixture of THF and dibutyl ether. d) See text.



$$\text{Br-(2,5-thienylene)-Br} + \text{Mg} \rightarrow (\underset{1}{\text{2,5-}C_4H_2Br_2} + \underset{2}{\text{2,5-}C_4H_2(MgBr)Br} + \underset{1}{\text{2,5-}C_4H_2(MgBr)_2}) \xrightarrow{[M]} \text{poly(2,5-thienylene)}. \quad (8)$$

It is seen in Table 1 that nickel catalysts are effective for the polymerization, whereas $PdCl_2$(bpy), which has high activities in the preparation of the poly(phenylene) type polymers, is not. $FeCl_3$, Fe(2,4-pentanedionato)$_3$, and $CoCl_2$ showed feeble catalytic activities. When the polymerization was carried out at lower temperatures (Expts 4 and 7), the yield of the polymer as well as the proportion of the $CHCl_3$-unextractable fraction (*vide infra*) decreased. The polymerization at 110 °C by using a 1:4 mixture of THF and dibutyl ether (Expt 6) proceeded smoothly and most of the polymer obtained was not extractable by hot $CHCl_3$.

When the ratio of Mg to 2,5-dibromothiophene deviates from unity, yield of the polymer and the proportion of the $CHCl_3$-unextractable fraction considerably decrease in accord with the theory of polycondensation. Addition of a monofunctional compound, 2-bromothiophene, also causes decrease in the yield and the proportion of the $CHCl_3$-unextractable fraction.

Poly(2,4-thienylene) and Poly(3-methyl-2,5-thienylene): Polymerization of 2,4-dibromothiophene and 3-methyl-2,5-dibromothiophene can be carried out analogously. However, as for the polymerization of 2,4-dibromothiophene, polymerization at the reflux temperature of THF did not give a satisfactory yield and the polymerization at higher temperature by using a 1:4 mixture of THF and dibutyl ether (Expt 15) was required to get a reasonably high yield.

Copolymers: Table 2 summarizes results of copolymerization of 2,5-dibromothiophene and 2,4-dibromothiophene according to Eq. 7. In Table 2 the ratio of the 2,5- and 2,4-thienylene units in the polymer was calculated from relative intensities of absorption bands in IR spectra characteristic of 2,5-thienylene and 2,4-thienylene units (*vide infra*). The calibration line for the calculation was obtained by taking IR spectra of samples containing pure poly(2,5-thienylene) and poly(2,4-thienylene) in various ratios.

It is seen from Table 2 that the ratio between 2,5- and 2,4-thienylene units in the copolymers is almost the same as the ratio of the two monomers employed for the copolymerization (Runs 4 and 5). This indicates that both monomers have almost the same reactivities in the copolymerization (2,4-dibromothiophene seems to have a slightly higher reactivity), and consequently the polymer is considered to have a random sequence with respect to the two thienylene units. The compositions of the copolymers obtained in Runs 2 and 3 could not be determined from their IR spectra, since the proportions of 2,4-thienylene units were too small. The data obtained in Runs 4 and 5, however, suggest that the copolymers obtained in Runs 2 and 3 contain *ca.* 6 and 13% of 2,4-thienylene units, respectively.

Properties of Polymers: Poly(2,5-thienylene) prepared in Expt 2 in Table 1 was fractionated into two parts by extraction with hot $CHCl_3$. The brown $CHCl_3$-extract (22 wt%) softens at 116 °C. About 2/3 of the $CHCl_3$-extract (about 14 wt% of the crude polymer) was soluble in $CHCl_3$ at room temperature and had number-average molecular weight of 1370 as de-

Table 2. Copolymerization of 2,5-dibromothiophene and 2,4-dibromothiophene[a)]

Run	Monomer ratio		Time	Yield[b)]	Ratio of monomer unit in the polymer

a) Catalyst: $NiCl_2$(bpy) (0.003 mol/monomer). Solvent: THF for Runs 1 and 2, and an 1:4 mixture of THF and $(n\text{-Bu})_2O$ for Runs 3—6. b) Calculated from the weight and carbon content of the crude polymer. c) Data from Ref. 2a using commercially available (from Merck Co. Ltd.) 2,5-dibromothiophene without purification. d) The proportion of 2,4-thienylene is too small to be determined from IR.

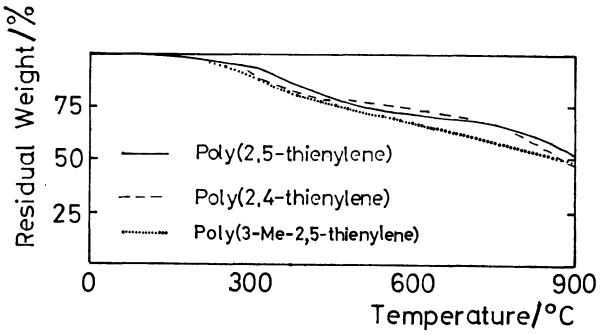

Fig. 1. Thermogravimetric analyses of poly(thienylene)s.

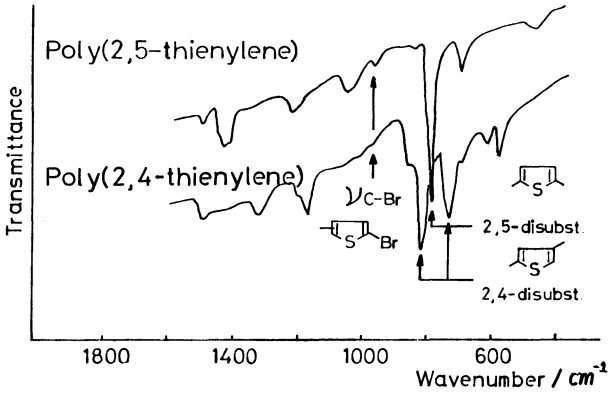

Fig. 2. IR spectrum of poly(2,5-thienylene) and poly(2,4-thienylene).

termined by VPO. The molecular weight corresponds to a formula of $Br\{C_4H_2S\}_{14.8}Br$ and analytical data roughly agrees with the formulation (Found: C, 51.6; H, 2.8. Calcd: C, 51.7; H, 2.8). The remaining $CHCl_3$-unextractable polymer (78 wt%) is insoluble in most organic solvents and seems to have a higher molecular weight than the $CHCl_3$-soluble fraction as judged from its higher thermal stability, lower solubility, and analytical data which show higher carbon content (C, 53.7; H, 2.7).[9)]

Thermogravimetric analyses of poly(2,5-thienylene) and related polymers are shown in Fig. 1. Poly(2,5-thienylene)s prepared in experiments other than Expt 2 were also separated into the $CHCl_3$-extractable and -unextractable fractions and the fractions were found to have similar properties described above.

Poly(2,4-thienylene) and the copolymers of 2,5- and 2,4-dibromothiophenes have similar thermal stabilities to that of poly(2,5-thienylene), but there is a trend that both the proportion and molecular weight of the $CHCl_3$-soluble fraction extracted at room temperature increase with increase in the proportion of the 2,4-thienylene unit in the polymer chain. In the case of pure poly(2,4-thienylene) 23 wt% of the crude polymer was soluble in $CHCl_3$ at room temperature, and the $CHCl_3$-soluble fraction had a number average molecular weight of 2100, which corresponds to a formula of $Br\{C_4H_2S\}_{23.7}Br$.

A larger part of poly(3-methyl-2,5-thienylene) is extractable by hot $CHCl_3$ and a fraction soluble in $CHCl_3$ at room temperature had a higher molecular weight (M_w=2300) than poly(2,5-thienylene) prepared under similar conditions, indicating that solubility of poly(2,5-thienylene) is enhanced by substitution of the 3-hydrogen of the thienylene ring with the CH_3 group. Poly(3-methyl-2,5-thienylene) has similar thermal stability to that of poly(2,5-thienylene) as shown in Fig. 1. Poly(2,5-thienylene), poly(2,4-thienylene), and the copolymers have apparent specific gravities of 1.3—1.4 as measured by weighing pellets of the polymers obtained by pressing them at 600 kg/cm^2. Poly(3-methyl-2,5-thienylene) had a somewhat smaller apparent specific gravity, 1.2.

IR and NMR Spectra. The IR spectra of the polymers are consistent with the structures of the polymers shown in Eqs. 2, 5, 6, and 7. Figure 2 shows the IR spectra of poly(2,5-thienylene) and poly(2,4-thienylene). The IR spectrum of poly(2,5-thienylene) shows one sharp out-of-plane δ(C–H) vibration band characteristic of 2,5-disubstituted thienylene[10)] at 788 cm^{-1}, whereas that of poly(2,4-thienylene) shows two out-of-plane δ(C–H) vibration bands at 730 and 820 cm^{-1}. The out-of-plane δ(C–H) vibration band of poly(3-methyl-2,5-thienylene) appears at 810 cm^{-1}. The IR spectra of the copolymers show both bands assignable to the 2,5-thienylene and 2,4-thienylene units and the composition of the copolymers were determined from their relative intensities as described before.

ν(C–Br) and ν(C–Cl) bands of the terminal halo-

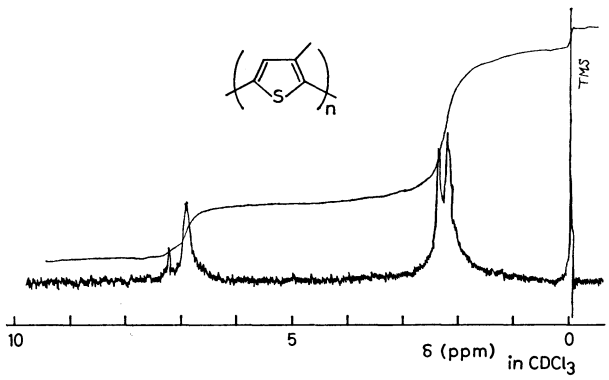

Fig. 3. ^{1}H-NMR spectrum of Poly(3-methyl-2,5-thienylene) in $CDCl_3$. 100 MHz.

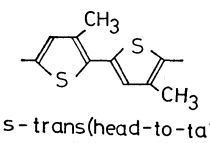
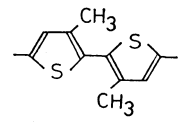
thienyl groups are sometimes observable at 980 and 1000 cm^{-1}, respectively, but the intensities of the bands were very weak.

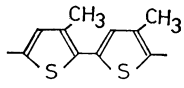
The ^{1}H-NMR spectra of the $CHCl_3$-soluble poly(2,5-thienylene) and poly(2,4-thienylene) show complex bands in a range of δ 6.5—7.5 assignable to hydrogens of the thienylene unit, whereas that of the $CHCl_3$-soluble poly(3-methyl-2,5-thienylene) (Figure 3) shows two absorption bands at δ 2.0—2.5 and δ 6.5—7.1 in an intensity ratio of 3:1, the former being assignable to the CH_3 protons and the latter to hydrogen directly attached to the thienylene ring. The separation of the CH_3 band into two peaks seems to be due to the presence of both *s-trans* and *s-cis* configuration and/or head-to-tail and head-to-head units in the polymer chain,



s-trans(head-to-tail)



s-trans(head-to-head)



s-cis(head-to-tail)

It is known[11] that 2,2′-bithiophene derivatives exist as mixtures of *s-trans* and *s-cis* isomers in solution.

Optical Properties. The extent of π-conjugation in the polythienylenes is reflected in their colors and electronic spectra. Poly(2,5-thienylene) and poly(3-methyl-2,5-thienylene) are dark reddish brown, whereas poly(2,4-thienylene) is light brown. The electronic spectrum of the $CHCl_3$-soluble poly(2,5-thienylene) shows a large bathochromic shift of the π-π^* absorption band from the λ_{max} of thiophene at 230 nm to 418 nm (Fig. 4), but that of the $CHCl_3$-soluble poly(2,4-thienylene) shows only a small shift. When exposed to UV-light (365 or 253.7 nm) poly(2,5-thienylene) fluorecses a light green color, whereas poly(2,4-thienylene) does not show the fluorescence. These results indicate that the π-electrons in poly(2,5-thienylene) are extensively delocalized along the polymer chain

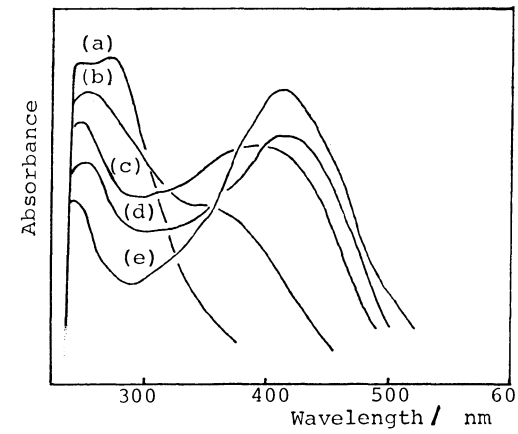


Fig. 4. Electronic spectra of $CHCl_3$-soluble (a) poly(2,4-thienylene) (M_w=2100), (b) copolymer obtained in Run 5 in Table 2, (c) copolymer obtained in Run 4 in Table 2, (d) copolymer obtained in Run 3 in Table 2, and (e) poly(2,5-thienylene) (M_w=1370). $\varepsilon_{max}/C_4H_2S$=about 5000 for all polymers.

(Eq. 3), whereas those in poly(2,4-thienylene) are not.

If a simplified molecular orbital theory proposed by Hückel[12] for conjugated polyens can be applied to other π-conjugated polymers $H\{A\}_nH$ (A=π-electron-system containing unit such as *p*-phenylene and 2,5-thienylene), the energies of the orbitals of the polymer are given by the following equation,

$$E_i = \alpha + 2\beta \cos\frac{i\pi}{n+1} \quad (i=1,2,\cdots, n), \tag{9}$$

where α and β represent energy of an orbital of isolated unit, A, and exchange integral between the two orbitals in the adjacent two A's, respectively. Application of this equation to HOMO of A gives the following energies of the polymer $H\{A\}_nH$

$$E_i(\text{occupied}) = \alpha_1 + 2\beta_1 \cos\frac{i\pi}{n+1} \quad (i=1,2,\cdots, n), \tag{10}$$

where α_1 and β_1 represent the energy of HOMO of A and exchange integral between the HOMO's in the adjacent two A's, respectively. Application to LUMO gives an analogous equation,

$$E_i(\text{unoccupied}) = \alpha_2 + 2\beta_2 \cos\frac{i\pi}{n+1} \quad (i=1,2,\cdots, n), \tag{11}$$

E_i(occupied) and E_i(unoccupied) given by Eqs. 10 and 11 are depicted in Fig. 5.

Equations 10 and 11 afford the following highest occupied energy ε_1 and the lowest π-π^* transition energy $\Delta\varepsilon$

$$\varepsilon_1 = \alpha_1 - 2\beta_1 \cos\frac{\pi}{n+1} \tag{12}$$

$$\Delta\varepsilon = (\alpha_2-\alpha_1) + 2(\beta_1+\beta_2) \cos\frac{\pi}{n+1} \tag{13}$$

and cosequently a plot of ε_1 against $\Delta\varepsilon$ is expected to give a linear line with a slope of $-2\beta_1/2(\beta_1+\beta_2)$. By using data of peak anode potential which corresponds to $-\varepsilon_1$ and the lowest π-π^* transition energy which

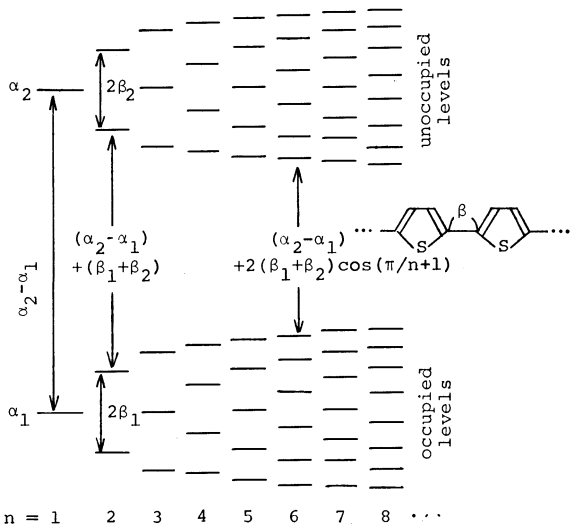

Fig. 5. Energy levels in $H\{A\}_nH$.

corresponds to $\Delta\varepsilon$, Diaz and his coworkers showed[1g] that the plot of $-\varepsilon_1$ against $\Delta\varepsilon$ actually gives straight lines with a slope of *ca.* 0.5 for oligo(*p*-phenylene), oligo(2,5-thienylene), and oligo(2,5-pyrrolylene). The value of the slope indicates that β_1 and β_2 equal to each other in these oligomers. The β_1 (or β_2 estimated using the data of Diaz is -0.63 eV for oligo(2,5-thienylene) and -0.58 eV for oligo(*p*-penylene).

Since poly(*p*-phenylene) is known to be converted into a good electric conductor with an electric conductivity of 10^4 S cm^{-1} when doped with AsF_5,[1c] the present result that the absolute value of β in oligo(2,5-thienylene) is larger than that in oligo(*p*-phenylene) implies a possibility that poly(2,5-thienylene) can be converted into similar or better electric conductors when doped with suitable acceptors. The observed values of $\Delta\varepsilon$ of oligo- or poly(2,5-thienylene), $H\{2,5\text{-}C_4H_2S\}_n$ (n=3, 4, ∞), agree well with values calculated by using Eq. 13 and the $(\alpha_2-\alpha_1)$ and $(\beta_1+\beta_2)$ values estimated from the λ_{max}'s of thiophene and 2,2'-bithiophene.

Figure 4 indicates the electronic spectra of the copolymers. It is seen that the λ_{max} shifts to longer wavelength with increase in the content of the 2,5-thienylene unit reaching 418 nm where the pure poly-(2,5-thienylene) shows the absorption peak. This indicates that the π-electrons in the sequence composed of 2,5-thienylene units are delocalized along the polymer chain, whereas the delocalization is broken by intervention of the 2,4-thienylene unit. These results clearly indicate that the polymer obtained in the copolymerization is not a mixture of the two homopolymers but it contains both the 2,5- and 2,4-thienylene units in a polymer chain.

The electronic spectrum of poly(3-methyl-2,5-thienylene) also shows a large bathochromic shift of the π-π^* absorption band from λ_{max} of 3-methylthiophene at 230 nm to 420 nm, the magnitude of the bathochromic shift (190 nm) being almost the same as that observed for nonsubstituted poly(2,5-thienylene). This indicates that π-electrons in poly(3-methyl-2,5-thienylene) are also extensively delocalized along the polymer chain, similarly to those in poly(2,5-thienylene). It is reported[13] that optical properties of substituted poly(acetylene)s, $\{CH{=}CR\}_n$, are much different from $\{CH{=}CH\}_n$ because of difficulties in forming a planar π-electron-conjugated polymer chain due to the steric repulsion between R and H or two R's. The finding obtained with poly(3-methyl-2,5-thienylene) is in contrast to the finding obtained with $\{CH{=}CR\}_n$, and the examination with the CPK molecular model indicates that there exists no special steric repulsion in forming a planar, conjugated polymer chain in the case of poly(3-methyl-2,5-thienylene) composed of recurring 5-membered rings.

As revealed by the electronic spectra of the polymers, the degree of delocalization of π-electrons along the polymer chain is affected by the mode of joining the thienylene units as well as by the composition of the two kinds of thienylene units in the copolymer. The degree of delocalization of π-electrons determines reactivities and electric conducting properties of the polymers as will be reported in the succeeding paper.

Stability in Air. All the poly(thienylene)s described above have high stabilitities in air in contrast to the sensitivity of poly(acetylene) against oxygen in air. The IR spectra of poly(thienylene)s showed no change after exposure of the polymer to air more than 1 year. Their high stabilities in air provide a great advantage in using them in various possible application.

Comparison with Electrochemically Prepared Poly(thiophene). Recently it has been reported that electrochemical oxidation of thiophene gives an electric conducting polymer film[8] and it has been proposed that the polymer has a structure similar to above-mentioned poly(2,5-thienylene).[8b] However, the IR spectrum of the electrochemically prepared polymer[8b] is somewhat different from that of poly(2,5-thienylene) prepared in the present study. Particularly notable in the IR spectrum of the polymer prepared by the electrochemical method is that the characteristic band of the 2,5-thienylene unit around 788 cm^{-1} due to the δ(C–H) absorption is considerably weaker in the IR spectrum.[18] It may be argued that the electrochemically prepared polymer of thiophene has a structure somewhat different from that of poly(2,5-thienylene).

Experimental

Materials. Commercially available 2,5-dibromothiophene was recrystallized from hexane. 2,4-Dibromothiophene,[14] 3-methyl-2,5-dibromothiophene,[15] $NiCl_2$(bpy),[16] and $NiCl_2$(dppp)[17] were prepared according to methods in literature. Solvents for polymerization were dried over Na, distilled under dry N_2, and stored under dry N_2. Granular magnesium was activated by stirring under N_2 for 1 d.

Preparation of Polymers. Expt 2 in Table 1: 2,5-Dibomothiophene (22.7 g, 94.0 mmol) was added dropwisely into a vessel containing 2.29 g (94.0 mmol) of Mg and dry THF (60 ml). After consumption of all magnesium (1—2 h) at room temperature a small amount of the solution taken by a micro syringe was hydrolyzed with water, and gas chromatography indicated the hydrolyzed product contained thiophene, 2-bromothiophene, and 2,5-dibromo-

thiophene in a 1:2:1 ratio. When $NiCl_2$(bpy) (90 mg, 3.1×10^{-1} mmol) was added to the remaining THF solution of the product of the reaction of 2,5-dibromothiophene and magnesium, a smooth polymerization started. After carrying out the reaction for 5 h under reflux, the polymerization solution was poured into an HCl-acidic methanol mixture to obtain a dark brown precipitate. From the methanol solution a yellow solid (0.10 g, low-molecular weight poly(2,5-thienylene)) was recovered. The dark brown precipitate was collected over a glass filter, washed with methanol repeatedly, and dried in vacuum to yield 7.0 g (78%) of crude poly(2,5-thienylene), which was fractionated into $CHCl_3$-extractable (78 wt%) and $CHCl_3$-unextractable (22 wt%) fractions by extracting it with $CHCl_3$ by using a Soxhlet extractor. About 2/3 of the $CHCl_3$-extract was soluble in $CHCl_3$ at room temperature. The other polymerization in THF or diethyl ether was carried out analogously.

Expt 6 in Table 1: A similar reaction between 2,5-dibromothiophene and magnesium (1:1) was carried out in dry THF (10 cm^3). After completion of the reaction, dibutyl ether (40 cm^3) and $NiCl_2$(bpy) were added. After carrying out the polymerization for 1 h under reflux (100 °C), the reaction mixture was poured into the HCl-acidic methanol and polymer obtained was treated as in the case of Expt 2 described above. The other polymerizations in the mixture of THF and dibutyl ether were carried out analogously.

Analysis and Measurements. Microanalysis of C and H was performed by Mr. T. Saito of our laboratory by using Yanagimoto CHN Autocorder Type MT-2. IR and ^{1}H-NMR spectra were recorded on a Hitachi Model 295 spectrometer and a Japan Electron Optics Laboratory PS-100 NMR spectrometer, respectively. Thermogravimetric analysis was performed with a Shimadzu thermoanalyzer TGA-30. Glc analysis was carried out with a Shimadzu GC-6A or GC-3BT gas chromatograph. Molecular weight was determined by a Corona 117 vapor pressure osmometer.

9) Although the $CHCl_3$-extractable fraction did not contain magnesium, the $CHCl_3$-unextractable fraction contained magnesium (2.5—3.0 wt%) as proved by macroanalysis. $MgBr_2$ captured by poly(2,5-thienylene) through coordination to sulfur may be the origin of the magnesium component. For this reason, the true carbon content of the $CHCl_3$-unextractable poly(2,5-thienylene) is regarded to be higher than the found value. It was difficult to remove magnesium from the $CHCl_3$-unextractable fraction.

Aizawa, private communication).

Formation of Adducts of Poly(thienylene)s with Electron Acceptors and Electric Conductivities of the Adducts

Takakazu YAMAMOTO,* Ken-ichi SANECHIKA, and Akio YAMAMOTO

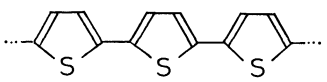
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227

(Received November 20, 1982)

Affinities of poly(thienylene) type polymers toward electron acceptors (iodine and SO_3) and electric conductivities of the polymer-electron acceptor adducts have been investigated. π-Conjugated poly(2,5-thienylene) has a high affinity toward iodine to absorb 60 wt% of iodine per the polymer. Poly(3-methyl-2,5-thienylene) has a higher affinity toward iodine and absorbs 136 wt% of iodine per the polymer. In the case of copolymer composed of 2,5- and 2,4-thienylene units the affinity against iodine increases with increase in the proportion of the 2,5-thienylene unit in the copolymer. The poly(2,5-thienylene)–iodine and poly(3-methyl-2,5-thienylene)–iodine adducts show electric conductivities of 5×10^{-2} S cm^{-1} and 4×10^{-1} S cm^{-1}, respectively, at room temperature. The activation energies of the electric conduction are 10 kJ/mol and 7.6 kJ/mol for the poly(2,5-thienylene)–iodine adduct (wt% of iodine=60) and poly(3-methyl-2,5-thienylene)–iodine adduct (wt% of iodine=136), respectively. The electric conductivity of the copolymer–iodine adduct sharply decreases on introduction of the 2,4-thienylene unit into the copolymer. The electric conductivity of the iodine adduct of the copolymer containing only 6% of 2,4-thienylene unit drops to *ca.* 1/100 of that of the iodine adduct of pure poly-(2,5-thienylene). The activation energy of the electric conduction of the polymer-iodine adducts decreases with increase in the content of the 2,5-thienylene unit as well as with the increase in the amount of iodine absorbed. Every poly(thienylene) type polymer has a high affinity toward SO_3, a stronger electron acceptor than iodine, to absorb about 70 wt% of SO_3 per the polymer. The SO_3–polymer adducts have electric conductivities of *ca.* 10^{-4} S cm^{-1}.

Synthesizing electric conducting π-conjugated polymers and revealing the mechanism of the electric conduction are subjects of recent interest. Several polymers including poly(acetylene),[1] poly(*p*-phenylene),[2] poly(pyrrolylene),[3] and poly(phenylene sulfide)[4] have been found to have high electric conductivities when they form adducts with electron acceptors or electron donors.

In the preceding paper[5] we reported preparation of poly(2,5-thienylene) having conjugated thiophene



rings and compared its properties with those of poly-(2,4-thienylene). It was revealed that the π-electrons in poly(2,5-thienylene) are extensively delocalized whereas the conjugation in poly(2,4-thienylene) is very limited. The difference in the electron delocalization is expected to be reflected in the chemical reactivities of these polymers toward electron acceptors and hence in their development of electric conductivities. In the present paper we wish to report on the reactions of these polymers with electron acceptors such as iodine and SO_3 and on the enhancement of electric conductivities on their adduct formation. Since the polymers employed in the present study are structurally better defined than electrochemically prepared polymers having similar π-conjugation systems (poly(pyrrole),[3] poly(thiophene),[6] and poly(furan)[6]), one can investigate effects of the structure of the polymers (*e.g.*, effect of the bonding between the thienylene units in the polymer chain, effect of the CH_3-substituent, and effect of the composition of the copolymer) on the affinity toward electron acceptors and electric conductivities of the adducts. This is taken as one of advantages of the present study.

Results and Discussion

Formation of Adducts with Electron Acceptors. As described in the preceding paper, poly(2,5-thienylene) is colored dark reddish brown with its λ_{max} in $CHCl_3$ at 418 nm. When exposed to the vapor of I_2, the color of poly(2,5-thienylene) changes from deep brown to black, indicating the formation of an adduct between the polymer and iodine. Figure 1 shows time course of the absorption of iodine by $CHCl_3$-unextractable poly(2,5-thienylene), and copolymers composed of 2,5- and 2,4-thienylene units on exposure to the vapor of I_2 at room temperature (29—31 °C). Pure poly(2,5-thienylene) has a high affinity toward iodine and it absorbs about 60 wt% of iodine on its prolonged exposure to the iodine vapor. Most of the iodine once absorbed by poly(2,5-thienylene) are not removed by evacuation at room temperature. A copolymer composed of 94% of 2,5-thienylene and 6% of 2,4-thienylene units has almost the same affinity toward iodine as the 2,5-thienylene homopolymer, whereas further increase in the fraction of 2,4-thienylene unit in the copolymer strongly decreases the affinity toward iodine. Thus, the final amount of iodine absorbed by a copolymer containing 13% of 2,4-thienylene unit ((3) in Fig. 1) decreases to about 30 wt%.

The delocalization of π-electrons along the recurring 2,5-thienylene units is expected to raise the energy level of HOMO as shown in Fig. 5 of our preceding paper[5] and this makes poly(2,5-thienylene) strongly interact with an electron acceptor, iodine in this case. On the other hand such delocalization is absent in poly(2,4-thienylene) as we observed in the electronic spectra. Thus, intervention of the 2,4-thienylene unit into the 2,5-thienylene polymer will break the delocalization and the interaction between the polymer and iodine then decreases in accord with the data

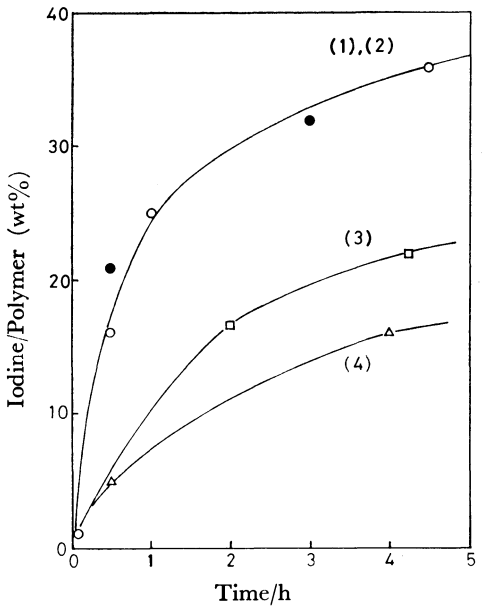


Fig. 1. Time course of absorption of iodine by poly-(2,5-thienylene) and copolymers composed of 2,5- and 2,4-thienylene units. Exposed to vapor of I_2 in a vacuum line at room temperature. 2,5-Thienylene: 2,4-thienylene=100:0 (○, (1)); 94:6 (●, (2)); 87:13 (□, (3)); 62:38 (△, (4)). In Figs. 1, 3, 4, and 5 the number attached to a curve or line corresponds to the number of Run in Table 2 of our preceding paper.[5]

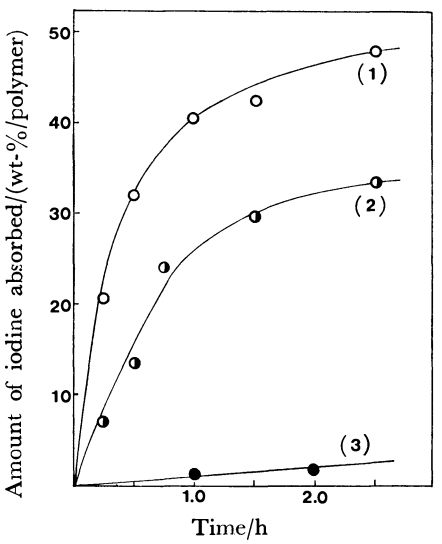

Fig. 2. Time course of absorption of iodine by poly-(2,5-thienylene). ○: $CHCl_3$-unextractable fraction, ◑: $CHCl_3$-soluble fraction (M_w=1370), ●: CH_3OH-soluble fraction (M_w=600).

shown in Fig. 1.

Although the $CHCl_3$-unextractable poly(2,5-thienylene) has a strong affinity toward iodine, $CHCl_3$-soluble (M_w=1370) and methanol-soluble (M_w=600) fractions have considerably weaker affinities (especially in the case of the methanol-soluble fraction) toward iodine (Fig. 2), indicating that the extent of delocalization in the polymers is not sufficient to lend the polymer strong affinity toward iodine.

The methyl-substituted polymer, poly(3-methyl-2,5-thienylene), has a higher affinity toward iodine than poly(2,5-thienylene). Thus, $CHCl_3$-soluble and $CHCl_3$-unextractable poly(3-methyl-2,5-thienylene) absorb 116 and 136 wt% of iodine, respectively, after exposure to the vapor of iodine for 10 h, the amounts being more than twice of the amounts of iodine absorbed by the $CHCl_3$-soluble and $CHCl_3$-unextractable unsubstituted poly(2,5-thienylene), respectively. Enhancement of electron-donating ability of poly(2,5-thienylene) by the methyl substitution accounts for the higher affinity of poly(3-methyl-2,5-thienylene) toward iodine. The iodine adducts of the poly(thienylene) type polymers have high stabilities in air, which provide an advantage in using the iodine adducts as semiconductors or positive electrodes in galvanic cells.[7]

In IR spectra of the polymers, the absorption bands are generally broadened on the complex formation with iodine. The IR spectra of the adducts generally show four major peaks in a region of 1000—1400 cm^{-1} which are assignable to skeletal deformation vibration of the thienylene group. The poly(2,5-thienylene)–iodine adduct has an apparent specific gravity of 2.2. An ESR spectrum of the adduct shows an absorption signal at g=2.008.

When the polymers are exposed to a vapor of SO_3, a stronger electron acceptor, every poly(thienylene) type polymer absorbs about 50—60 wt% of SO_3. Since thiophene itself has donor properties, such a strong acceptor as SO_3 seems to be able to interact even with nonconjugated poly(2,4-thienylene). The $CHCl_3$-soluble poly(2,5-thienylene) is soluble in concd H_2SO_4 and the fluorescing blue solution gives rise to an absorption band at 850 nm ($\varepsilon_{max}=6\times10^3$) which may be assigned to a CT band.

In contrast to the facile formation of adducts with iodine and SO_3, poly(2,5-thienylene) and its related polymer did not form adducts with tetracyanoquinodimethan, a typical organic electron acceptor. Since it is known that tetracyanoquinodimethan forms a stable 1:1 adduct with thiophene,[8] the low affinity of the polymers against tetracyanoquinodimethan seems to be due to difficulty in entry of the electron acceptor into microcrystals of the polymers or due to sterical non-fitting of tetracyanoquinodimethan with the polymers. Kossmehl and Chatzitheodorou reported formation of adducts of poly(2,5-thienylene) prepared by our method with AsF_5, one of the strongest electron acceptors, and electric conductivity of the adducts.[9]

When poly(2,5-thienylene) was dipped into a THF solution of potassium naphthalenide, color of the polymer changed from deep reddish brown to black, suggesting formation of an adduct of the polymer with potassium similar to the reported adduct of poly(acetylene) with alkali metals.[1,10] However, characterization of the adduct was not feasible due to the high air-sensitivity of the adduct (explosive in air).

Electric Conductivity. Iodine Adduct: All the poly(thienylene) type polymers are insulators having electric conductivity of 10^{-14}—10^{-11} S cm^{-1}. The electric conductivity, however, increases markedly on the ad-

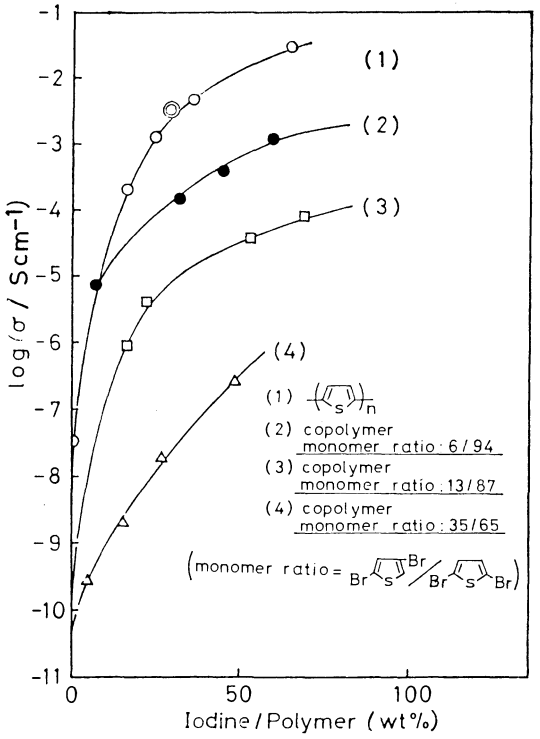

Fig. 3. Electric conductivities of the iodine adducts of poly(2,5-thienylene) and the copolymers *vs.* amount of iodine absorbed. The numbering of the curve corresponds to that in Fig. 1.

duct formation with the electron acceptors as observed in the other π-conjugated polymers such as poly(acetylene)[1] and poly(*p*-phenylene).[2] Figure 3 shows the increase of the electric conductivities of poly(2,5-thienylene) and the copolymers on interaction with iodine.

The following observations are made from experiments related to Fig. 3.

(1) The electric conductivity, σ, increases with increase in the amount of iodine absorbed. The electric conductivity of the poly(2,5-thienylene)–iodine adduct is comparable to those of commercially used inorganic semiconductors such as doped Si and Ge ($\sigma = 10^{-4}$—10^{1} S cm^{-1}).

(2) The composition of the copolymer strongly influences the electric conductivity, incorporation of only 6% of 2,4-thienylene unit causes decrease in the electric conductivity by a factor of 10^2 ((2) in Fig. 3), although the incorporation of only 6% of 2,4-thienylene unit does not affect the electronic spectrum[5] and the affinity of the polymer toward iodine. The steep decrease in the electric conductivity by the contamination with only a small amount of 2,4-thienylene unit indicates that the electric conductivity is strongly influenced by the extent of the delocalization of π-electrons along the polymer chain. However, it is inferred from these results that the random incorporation of considerable proportion of insulating 2,4-thienylene unit, roughly one part per two parts of the 2,5-thienylene units, still leaves appreciable conductivity in the polymer ((4) in Fig. 3).

(3) A 1:1 mixture of poly(2,5-thienylene) and poly(2,4-thienylene) on treatment with iodine shows much

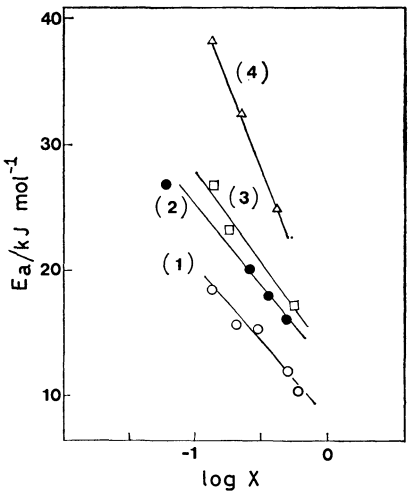

Fig. 4. Activation energy of the electric conduction of the iodine adducts of poly(2,5-thienylene) and copolymers *vs.* logarism of the amount of iodine absorbed (X= mass of iodine/mass of polymer). For numbering of the line, see a caption of Fig. 1.

higher electric conductivity (see a double circle in Fig. 3) than the copolymer containing 2,5- and 2,4-thienylene units in about 1:1 ratio. Although the electronic spectral data reported in our preceding paper have afforded evidence that the polymer obtained by the dehalogenative polycondensation of a mixture of 2,5- and 2,4-dibromothiophene is not a mixture of two homopolymers, the present result renders additional evidence for the formation of the copolymer. In the absorption of iodine by the 1:1 mixture of pure poly(2,5-thienylene) and poly(2,4-thienylene), iodine is absorbed only by poly(2,5-thienylene). Therefore, the 1:1:0.27 mixture of poly(2,5-thienylene), poly(2,4-thienylene), and iodine shown by the double circle in Fig. 3 is considered to be a mixture of poly(2,5-thienylene) absorbing 54 wt% of iodine and pure poly(2,4-thienylene). On this basis it may be concluded that electric conductivity of 2×10^{-2} S cm^{-1} of poly(2,5-thienylene) containing 54 wt% of iodine has decreased to 4×10^{-3} S cm^{-1} (datum shown by the double circle) by mixing with the insulating poly(2,4-thienylene).

Poly(3-methyl-2,5-thienylene)–iodine adducts show somewhat higher electric conductivities than the poly(2,5-thienylene)–iodine adducts: for example, poly(3-methyl-2,5-thienylene) absorbing 136 wt% of iodine has an electric conductivity of 4×10^{-1} S cm^{-1}.

The electric conductivities, σ, of the iodine-adducts varies with temperature according to the following equation,

$$\sigma = \sigma_0 \exp(-E_a/RT). \quad (1)$$

Figure 4 shows plots of the activation energy, E_a, of the electric conduction against logarithm of the amount iodine absorbed, log X. As shown in Fig. 4 a linear correlation holds between E_a and log X for each polymer. A similar linear correlation between E_a and log X has been observed concerning the electric conduction of poly(acetylene) absorbing moderate amounts of iodine (3—30 wt% per poly(acetylene)). This de-

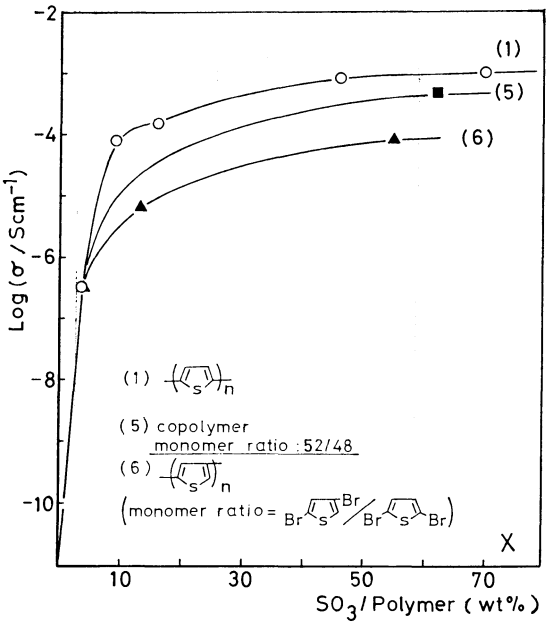

Fig. 5. Electric conductivities of the SO_3 adducts of poly(2,5-thienylene) (1), poly(2,4-thienylene) (6), and a copolymer composed of 52% of 2,5-thienylene and 48% of 2,4-thienylene units (5).

crease in E_a with the increase in the amount of iodine absorbed by poly(acetylene) is called "semiconductor-metal transition" since further increase in the amount of iodine absorbed gives the poly(acetylene)–iodine adduct a metallic conductivity ($\sigma > 10^3$ S cm^{-1}) with small E_a.[1b,d] However, in cases of poly(2,5-thienylene) and the copolymers the iodine adducts still show appreciable activation energies even at a high concentration of iodine and metal-like conductivity has not been attained, although a recent paper reported that electrochemically prepared poly(thienylene-0.25BF_4) have electric conductivity of 10^1—10^2 S cm^{-1}.[6b]

E_a increases with increase in the proportion of 2,4-thienylene unit in the copolymer. The iodine adduct of the $CHCl_3$-unextractable poly(3-methyl-2,5-thienylene) (iodine=136 wt%) shows somewhat lower activation energy of the electric conduction (E_a=7.6 kJ/mol) than the iodine adduct of poly(2,5-thienylene).

SO_3 Adduct: Figure 5 shows the electric conductivities of the SO_3 adducts of poly(2,5-thienylene), poly(2,4-thienylene), and a copolymer containing 2,5- and 2,4-thienylene units in about 1:1 ratio. Although π-conjugated poly(2,5-thienylene), among the polymers, shows the highest electric conductivity on the adduct formation with SO_3, the structure of the polymer affects the electric conductivity to a much less extent, compared with the iodine adducts of the polymers. The activation energy for the electric conduction of the SO_3 adducts decreases with increase in the amount of SO_3 absorbed (Fig. 6), but such a linear correlation observed for the iodine adducts (Fig. 5) is not observed for the SO_3 adducts. An ESR spectrum of the SO_3–poly(2,5-thienylene) shows an absorption signal at g=1.962.

Mechanism of the Electric Conduction. It is known

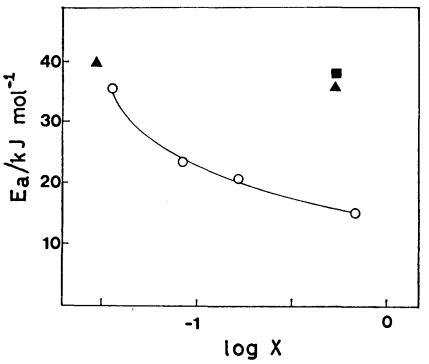

Fig. 6. Activation energy of the electric conduction of the SO_3 adducts of poly(2,5-thienylene) (○), poly(2,4-thienylene) (▲), and a copolymer composed of 52% of 2,5-thienylene and 48% of 2,4-thienylene units (■). X=mass of SO_3/mass of polymer.

that a part of iodine absorbed by poly(acetylene) exists in the form of I_3^- and it is generally accepted that the counter cation (hole) formed in poly(acetylene) participates in the electric conduction.[1b-c] Since poly(thiophene) reportedly has ionization potential of 0.7 V[6c] comparable to that of poly(acetylene) (0.7 V), it will be reasonable to assume that iodine can abstract an electron from poly(2,5-thienylene) to form an ion pair and the electron conduction originates from the migration of the cation center along the π-conjugated chain.[11] If the 2,4-thienylene unit is incorporated into the polymer chain, the migration of the cation center will stop at the 2,4-thienylene unit and thus the electric conduction will be hindered in accord with the results described above.

The electric conductivity of the SO_3–poly(2,4-thienylene) adduct, however, is not explained by such a simple mechanism and thinking of special mechanisms of the electric conduction (for example, SO_3^- assisted migration of the cationic center or tunnel effect) seems to be necessary.

Experimental

Materials. Poly(thienylene) type polymers were prepared according to methods described in our preceding paper.[5] Commercially available I_2 and SO_3 were used without purification. Tetracyanoquinodimethan was purified by recrystallization before use. The THF solution of potassium naphthalenide was prepared by a reaction of naphthalene (2.0 g, 16 mmol) and potassium metal (1.5 g, 38 mmol) in THF (15 cm^3) for 21 h at room temperature. Remaining potassium was filtered off.

Absorption of Electron Acceptors. Powdery poly(thienylene) type polymer placed in a glass vessel was exposed to vapor of iodine at room temperature by using a vacuum line. The amount of iodine absorbed was measured by weighing the polymer-iodine adduct and halogen analysis of the adduct. Both data coincided within an experimental error. The reactions of the polymers with SO_3 (vapor) were carried out analogously. When a pellet prepared by pressing the powdery polymer at 600 kg/cm^2 was used, the rate of absorption of iodine was considerably slower.

Measurement of the Electric Conductivity. The powdery polymer-electron acceptor adduct was molded into a pellet

(diameter = 1.3 cm) by pressing it at 600 kg/cm². From the pellet a bar was obtained by cutting off other parts of the pellet, and the electric conductivity was measured with the bar using the four-point method. A Takeda Riken TR-8651 electrometer was used to measure the electric conductivity.

Measurement of Spectra. Electronic and IR spectra were recorded on Hitachi model 200-20 and Hitachi model 295 spectrometers, respectively.

11) This explains chemical concept of the electric conduction. Physical treatment of the electric conduction of poly(acetylene)-acceptor (or donor) adducts have revealed that positive (or negative) solitons play important roles in the electric conduction (Refs. 1c and 1d as well as H. Takayama, Y. R. Lin-Lin, and K. Maki, *Phys. Rev. B*, **21**, 21 (1980)).

Alkylation of the Sulfur- and Nitrogen-containing Compounds Analogous to Thiazoline Systems

Yoshio OHARA, Kin-ya AKIBA,† and Naoki INAMOTO*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received November 26, 1982)

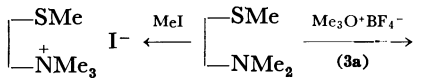
N,N-Dimethyl-2-(alkylthio)ethylamines and 3-methylthiazolidines underwent *N*-methylation both with trimethyloxonium tetrafluoroborate (**3a**) and with methyl iodide. In the methylation of *N,N*-dimethyl-*o*-(methylthio)aniline, the main reaction was *S*-methylation. On the other hand, in the *o*-ethylthio derivative, *S*-methylated product was major with methyl iodide, while *N*-methylated product was major with **3a**. In the *N*-ethyl or *N*-benzyl derivative, only *S*-methylation occurred with both reagents. 3-Methyl-2, 2-diphenyl-2,3-dihydrobenzothiazole gave *S*-methylated product with **3a**, suggesting that *S*-methylation becomes major when the 2-substituent is bulkier. 4-Methyl-3,4-dihydro-2*H*-benzo[*b*][1,4]thiazine was methylated on the nitrogen with **3a**, while it gave *S*-methylated product with methyl iodide. Phenothiazines and 1-dialkylamino-8-(methylthio)-naphthalenes gave only *S*-methylated products. The selective *S*-methylation in the case of *N*-methylation was carried out through protonation on the nitrogen atom followed by methylation with **3a**. Possibility of intramolecular interaction between sulfonio and amino groups has been discussed based on their NMR data.

In the alkylation of a compound containing both sulfur and nitrogen atoms, the position of alkylation depends on the structure of the compound and the kind of alkylating reagent.[1] We previously reported that 3-alkyl-2,3-dihydrobenzothiazoles were selectively alkylated on the nitrogen with Meerwein reagents.[1]

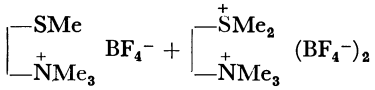
Therefore, our work on alkylation was extended to the compounds containing both sulfur and nitrogen atoms analogous to thiazoline systems, in order to obtain an information on the relation between the structure of the compound and the alkylated position.

Results and Discussion

Methylation of N,N-*Dimethyl-2-(alkylthio)ethylamines (**1**) and 3-Methylthiazolidines (**7**).* *N,N*-Dimethyl-2-(methylthio)ethylamine (**1a**) reacted with methyl iodide to give trimethyl(2-methylthioethyl)ammonium iodide (**2a**(I^-)), while with trimethyloxonium tetrafluoroborate (**3a**) it gave a mixture of *N*-methylated (**2a**(BF_4^-)) and *N,S*-dimethylated salts (**4a**). These structures could be assigned by NMR.



2a(I^-) **1a**

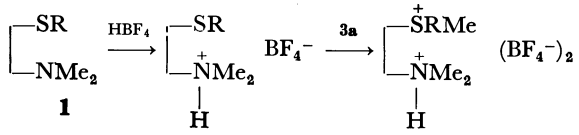


2a(BF_4^-) **4a**

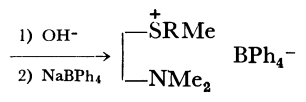
Accordingly, **1a** is methylated on nitrogen to give **2a** both with methyl iodide and with **3a**, but with a stronger alkylating reagent such as **3a**, **2a** is further methylated on the sulfur to give **4a**.

Based on the above result, we succeeded in preparation of the sulfonium salt (**6**) from **1**. The nitrogen atom in **1** was first protonated with tetrafluoroboric acid and then the ammonium salt was methylated with **3a** to give [2-(dialkylsulfonio)ethyl]dimethylammonium salt (**5**) which was deprotonated to give **6**.

† Present address: Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730.



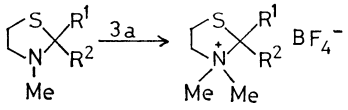
1 **5**



6

a: R=Me
b: R=Et

3-Methylthiazolidines (**7**) were methylated with **3a** to give cyclic ammonium salts (**8**) analogously to that of **1**. The NMR spectra of **8** were analogous to those of 3,3-dimethylbenzothiazolinium salts,[1] confirming the structure (**8**).

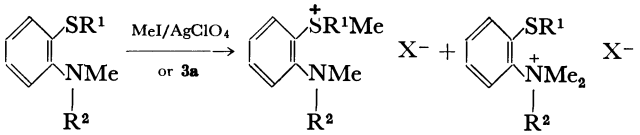


7 **8**

a: R^1=Ph, R^2=H
b: R^1=R^2=Me

Thus it is concluded that aliphatic or alicyclic compounds containing sulfur and nitrogen atoms are selectively alkylated on nitrogen both with methyl iodide and with **3a**.

Methylation of o-*(Alkylthio)aniline Derivatives (**9**).* Methylation of *N,N*-dimethyl-*o*-(methylthio)aniline (**9a**) with methyl iodide–silver perchlorate system gave a mixture of the sulfonium (**10a**(ClO_4^-)) and the ammonium salts (**11a**(ClO_4^-)) in a ratio of *ca.* 4:1 (by NMR), while methylation with **3a** gave a mixture of **10a**(BF_4^-) and **11a**(BF_4^-) in a ratio of *ca.* 1.5:1. The salts **10a** and **11a** were isolated in pure form by repeated recrystallization from ethanol.



9 **10**(X^-) **11**(X^-)

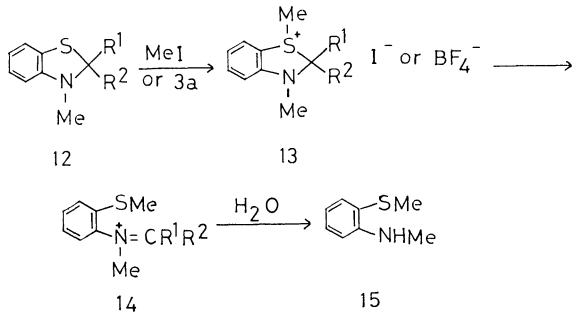
a: R^1=R^2=Me; **b**: R^1=Et, R^2=Me: **c**: R^1=Me, R^2=Et; **d**: R^1=Me, R^2=$PhCH_2$. X=ClO_4, BF_4.

The results are consistent with that methyl iodide is regarded as a soft reagent possessing a considerable affinity to sulfur atom and **3a** as a hard one possessing a considerable affinity to nitrogen.

Methylation of **9b** with methyl iodide–silver perchlorate gave a mixture of **10b**(ClO_4^-) and **11b**(ClO_4^-) in a ratio of 2:1, while that with **3a** gave a mixture of **10b** (BF_4^-) and **11b**(BF_4^-) in a ratio of 1:2, indicating to be more selective than in the case of **9a**. In the former, the ratio did not change after single recrystallization, but in the latter, only **11b** was isolated after single recrystallization. Both **9c** and **9d** gave only *S*-methylated products (**10c** and **10d**) with both reagents.

These results are attributed to the considerable decrease of the nucleophilicity of nitrogen atom due to conjugation with benzene ring as compared with that of sulfur atom, and suggest that a congestion around sulfur atom moderately decreases the *S*-methylation, while a congestion around the nitrogen drastically decreases *N*-methylation with **3a**.

*Methylation of 3-Methyl-2,2-diphenyl-2,3-dihydrobenzothiazole (**12c**) and 4-Methyl-3,4-dihydro-2H-benzo[b][1,4]-thiazine (**16**).*



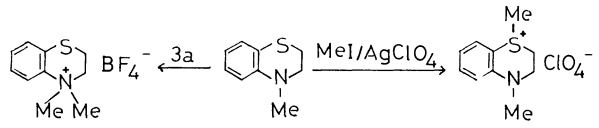
a: $R^1=R^2=Me$; **b**: $R^1=H$, $R^2=Ph$; **c**: $R^1=R^2=Ph$; **d**: $R^1=H$, $R^2=t$-Bu.

3-Methyl-2,3-dihydrobenzothiazoles (**12**) are methylated on the nitrogen atom.[1] However, considering the above results, it is expected that **12** would be methylated rather on the sulfur atom, if a bulky group exists at the 2-position, because of steric congestion around the nitrogen due to shorter C–N bond than C–S bond.

In fact, Hori *et al.*[2] have reported that methylation of 2,2,3-trimethyl-2,3-dihydrobenzothiazole (**12a**) with methyl iodide gave ring-opening immonium salt (**14a**) *via* *S*-methylated compound (**13a**). We also found that methylation of 3-methyl-2-phenyl-2,3-dihydrobenzothiazole (**12b**) with **3a** gave *N*-methyl-*o*-(methylthio)aniline (**15**) as by-product,[1] which is decomposition product of *S*-methylated product (**13b**).[2]

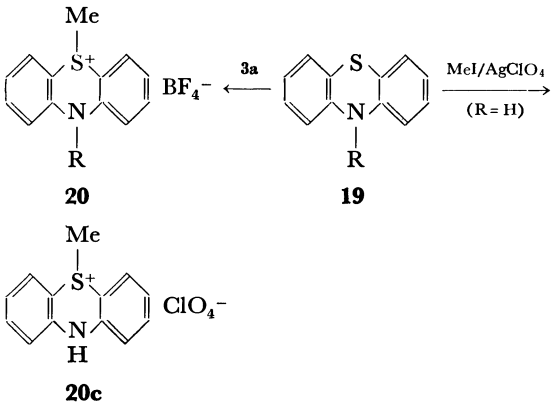
Therefore, **12c** was methylated with **3a** to expect *S*-methylation. Actually, the reaction gave *S*-methylated **13c** in 31% yield. Very recently, Hori *et al.*[3] have reported that methylation of **12d** with **3a** gave **15** through unstable **13d**.

On the other hand, methylation of **16** with **3a** selectively gave ammonium salt (**17**), while methylation with methyl iodide–silver perchlorate gave sulfonium salt (**18**).

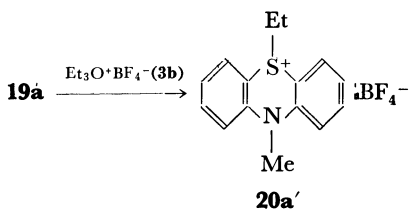


The difference in **12** and **16** may be ascribable to an effect of five-membered ring fused with benzene ring in **12**. Namely, it is considered that thiazoline ring makes the delocalization of the lone pair electrons of nitrogen conformationally unfavorable, while sulfur atom can resonate with benzene ring under such circumstances.[4] Thus the reactivity towards **3a** becomes larger on nitrogen than on sulfur analogously to the aliphatic systems.

*Alkylation of Phenothiazines (**19**).* 10-Methylphenothiazine (**19a**) was methylated on sulfur even with **3a** to give sulfonium salt (**20a**). The ethylated salt (**20a'**) from **19a** with triethyloxonium tetrafluoroborate (**3b**) was different from the methylated salt (**20b**) from **19b** with **3a**, indicating that these salts were sulfonium salts. Phenothiazine (**19c**) was also methylated on sulfur with methyl iodide–silver perchlorate to give sulfonium salt (**20c**).



a: R=Me; **b**: R=Et; **c**: R=H



These facts indicate that the reactivity on the nitrogen atom extremely decreases because of the large delocalization of lone pair electrons over two benzene rings. It may also be attributed to not only the steric hindrance due to two benzene rings but also the steric hindrance due to two *peri*-hydrogen atoms.

*Methylation of 1-Dialkylamino-8-(methylthio)naphthalenes (**24**).* 1-Dialkylamino-8-(methylthio)naphthalenes (**24**) were prepared from the reported hexachlorostannate (**21**)[5] as Scheme 1.

Methylation of **24** with methyl iodide–silver perchlorate gave sulfonium salt (**25**), while with **3a** it gave a mixture of *S*-methylated **25a** and ammonium tetrafluoroborate (**26a**) from **24a** and only **26b** from **24b**.

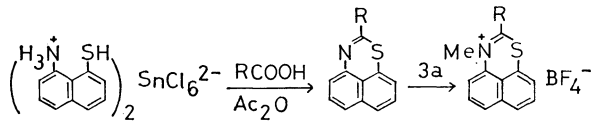
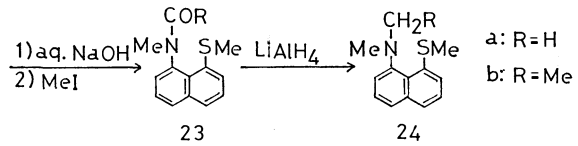
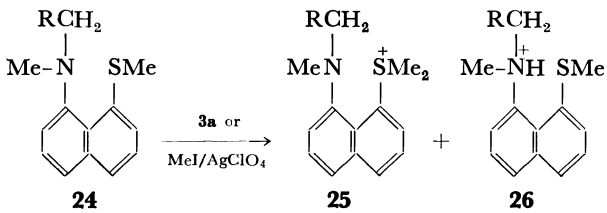
a) Accuracy is within ±0.02 ppm. b) Values in parenthesis are those in CF_3COOH. c) Naph denotes naphthalene ring.





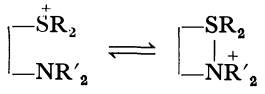
Scheme 1.



a: R=H; **b**: R=Me

Apparently **26** is derived from the protonation of **24** in the course of the decomposition of **3a** by ethanol. Methylation on the nitrogen atom did not take place even with Meerwein reagent, because of an extremely large steric congestion around the nitrogen atom.

Possibility of Intramolecular Interaction Between Sulfonio and Amino Groups. It would be expected that the sulfonium salts (**27**) containing amino group such as **6**, **10**, and **25** may be in an equilibrium with ammonio-sulfuranes (**28**) or exist in the form of **28**, which have both an ammonium part and a σ-sulfurane part (hypervalent I-type[6]).



27 **28**

Although many stable σ-sulfuranes have recently been synthesized by Martin *et al.*,[7] there is no example of the σ-sulfurane such as **28**, which has alkyl groups on sulfur atom. Therefore, it is quite interesting to examine whether there is any possibility of contribution of **28** in **27**.

In order to characterize the structures of **6**, **10**, and **25**, several reference compounds and their methylated compounds were prepared. In Table 1 were shown chemical shifts of methyl protons in both parent and their methylated compounds. The accuracy for these data was estimated to be ±0.01 ppm for the solvent effect (checked by changing the ratio of DMSO-d_6 to $CDCl_3$), −0.02 ppm for S^+-Me, +0.02 ppm for *N*-Me in methanol-d_4 *vs.* DMSO-d_6, and the concentration effect was essentially negligible.

The *N*-methyl protons in **6** (δ 2.15) are in rather higher field than those in parent compound (**1**) (δ

2.28), probably because of anisotropy effect due to tetraphenylborate anion (*cf.* **10d**(BPh_4^-): δ 2.61 (NMe), 2.91 (SMe) *vs.* **10d**(BF_4^-): δ 2.63 (NMe), 3.12 (SMe)).

Both in **10** and **25**, the *N*-methyl protons are in lower field than those in parent compounds (**9** and **24**). The *S*-methyl protons in **10** and **25** are not so low as for those of reference compounds (**30** and **36**). This may be attributed to **28**. It is considered that **28** is decomposed by protonation in trifluoroacetic acid, so that the *S*-methyl chemical shifts in **10** and **25** are in lower field by the release of lone pair electrons on nitrogen. However, these phenomena can be interpreted as the inductive effect due to additional cationic center by protonation of the amino group.

In **34**, the methyl protons of dimethylamino group are in rather higher field than those in parent **33**, while that in **10** is rather lower than that in parent **9**. This phenomenon may be interpreted by the contribution of **28**. However, the inductive effect by the sulfonio group is slightly stronger than that by the ammonio group.[8] Therefore, the above fact can also be attributed to the difference of inductive effect.

From the above discussion based on NMR, no definite conclusion to support the structure **28** could be obtained. However, since the amino and sulfonio groups in **25a** are fixed closely (0.22—0.25 nm) in the peri position, there may be a possibility of strong interaction between nitrogen and sulfur atoms. The related works are in progress.

Experimental

All the boiling and melting points are not corrected. ^{1}H NMR spectra were measured with Hitachi R-24B and R-20B spectrometers using TMS as an internal standard.

Materials. *N,N*-Dimethyl-2-(methylthio)ethylamine (**1a**),[9,10] 3-methyl-2,2-diphenyl-2,3-dihydrobenzothiazole (**12c**),[11] 4-methyl-3,4-dihydro-2*H*-benzo[*b*][1,4]thiazine (**16**),[12] *N*-methyl- (**19a**) and *N*-ethylphenothiazines (**19b**),[13] and *N,N,N',N'*-tetramethyl-*o*-phenylenediamine (**33**)[14] were prepared by the reported methods. *N,N*-Dimethyl-2-(ethylthio)ethylamine (**1b**) was prepared by a similar method to that of **1a**, bp 90 °C/60 mmHg (1 mmHg≈133.322 Pa) (lit,[15] 61 °C/16 mmHg). 3-Methyl-2-phenyl- (**7a**)[16] and 2,2,3-trimethylthiazolidines (**7b**)[16] were prepared by the reported method.[17]

N,N-*Dimethyl-o-(methylthio)aniline (9a).* *o*-(Methylthio)aniline (5.05 g, 36.3 mmol) was methylated with Me_2SO_4 (8.9 ml, 94 mmol) and K_2CO_3 (7 g) in C_6H_6 (20 ml) to give **9a** (4.18 g, 69%), bp 92 °C/0.2 mmHg (lit,[18] 130 °C/20 mmHg).

N,N-*Dimethyl-o-(ethylthio)aniline (9b).* This compd was prepared by a similar methylation of *o*-(ethylthio)-aniline in 56% yield, bp 95 °C/0.3 mmHg; ^{1}H NMR ($CDCl_3$): δ=1.32 (t, J=7 Hz, 3H), 2.72 (s, 6H), 2.90 (q, J=7 Hz, 2H), and 7.0—7.2 (br s, 4H). Found: C, 66.02; H, 8.49; N, 7.95%. Calcd for $C_{10}H_{15}NS$: C, 66.25; H, 8.34; N, 7.73%.

N-*Ethyl*-N-*methyl*-o-*(methylthio)aniline (9c).* Bis[*o*-(ethylamino)phenyl] disulfide,[19] prepared from 3-ethylbenzothiazolium iodide (9.62 g, 33.0 mmol), was methylated with **3a** (3.16 g, 21.4 mmol) in CH_2Cl_2 (20 ml) and then treated with aq NaOH. After dry column chromatography (DCC) (SiO_2, CCl_4) the methylated product was reduced with sodium (0.5 g, 22 mmol) in liq NH_3 (50 ml) and ether (20 ml). To the residue, after evaporation, were added EtOH (20 ml) and MeI (1.5 ml). Extraction with ether after addition of water and distillation gave **9c** (1.19 g, 20%), bp 80 °C/0.3 mmHg; ^{1}H NMR ($CDCl_3$): δ=1.10 (t, J=7 Hz, 3H), 2.39 (s, 3H), 2.70 (s, 3H), 2.97 (q, J=7 Hz, 2H), and 7.04 (br s, 4H). Found: C, 66.05; H, 8.51; N, 7.56%. Calcd for $C_{10}H_{15}NS$: C, 66.25; H, 8.34; N, 7.73%.

N-*Benzyl*-N-*methyl*-o-*(methylthio)aniline (9d).* To a mixture of *o*-(methylthio)aniline (17.3 g, 124 mmol), benzaldehyde (60 g, 590 mmol), NaOAc (20 g, 240 mmol), and AcOH (100 ml) in EtOH (250 ml) was added $NaBH_4$ (25 g, 660 mmol) portionwise. After stirring for 4 h and usual work-up, distillation gave *N*-benzyl-*o*-(methylthio)aniline (21.4 g, 75%), bp 142 °C/0.25 mmHg. The aniline (16.1 g, 70 mmol) was treated with the Me_2SO_4 (8.0 ml, 85 mmol) and Na_2CO_3 (8 g, 76 mmol) in C_6H_6 (60 ml) to give **9d** (6.44 g, 38%), bp 142 °C/0.2 mmHg; ^{1}H NMR ($CDCl_3$): δ=2.41 (s, 3H), 2.60 (s, 3H), 4.07 (s, 2H), and 7.0—7.6 (m, 9H). Found: C, 74.00; H, 7.15; N, 5.89%. Calcd for $C_{15}H_{17}NS$: C, 74.03; H, 7.04; N, 5.76%.

Preparation of 24. *1) 24a*: Naphtho[1,8-*de*][1,3]-thiazine (**22a**) was prepared by a modified method of preparation of **22b**.[5b] To anhyd NaOAc (19 g) in boiling HCOOH (160 ml) were added tin (8.0 g, 68 mmol) and **21** (18.9 g, 30.5 mmol) under nitrogen. To this soln was added Ac_2O (26 ml) portionwise, and the mixture was neutralized with aq NH_3. From the ethereal extract of the resulting ppt, **22a** was isolated by DCC (SiO_2, CH_2Cl_2–CCl_4 (1:2)), 4.73 (42%), mp 95—110 °C; ^{1}H NMR ($CDCl_3$): δ=6.6—7.4 (m, 6H) and 7.97 (s, 1H). Found: C, 71.61; H, 3.63; N, 7.60; S, 17.20%. Calcd for $C_{17}H_7NS$: C, 71.32; H, 3.81; N, 7.56; S, 17.31%.

22a (2.16 g, 11.7 mmol) was methylated with **3a** (3.09 g, 20.9 mmol) in refluxing CH_2Cl_2 (70 ml) for 1.5 h. After addition of ether, the resulting ppt was suspended in EtOH (60 ml), aq NaOH (6 g, 70 ml H_2O) was added under nitrogen, and refluxing was kept for 1 h. MeI (3.5 ml, 56 mmol) was added, and the mixture was heated for 0.5 h. After usual work-up, DCC (Al_2O_3, CH_2Cl_2) gave **23a** (1.29 g, 48%), bp 165 °C/0.5 mmHg; ^{1}H NMR ($CDCl_3$): δ=2.40 (s, 3H), 3.23 (s, 3H), 6.9—7.8 (m, 6H), and 8.00 (s, 1H). Found: C, 67.35; H, 5.60; N, 5.92%. Calcd for $C_{13}H_{13}NOS$: C, 67.50; H, 5.66; N, 6.06%.

To **23a** (1.29 g, 5.6 mmol) in ether (30 ml) at 0 °C was added dropwise $LiAlH_4$ (450 mg, 12 mmol) in ether (40 ml), and the mixture was stirred for 1 h. After usual work-up, distillation gave **24a** (1.03 g, 85%), bp 110 °C/0.15 mmHg; ^{1}H NMR ($CDCl_3$): δ=2.40 (s, 3H), 2.69 (s, 6H), and 7.0—7.7 (m, 6H). Found: C, 71.61; H, 7.09; N, 6.57; S, 14.27%. Calcd for $C_{13}H_{15}NS$: C, 71.84; H, 6.96; N, 6.44; S, 14.75%.

2) 24b: **23b** was prepared in the same manner as that of **23a** from **22b**[5b] in 52% yield; ^{1}H NMR ($CDCl_3$): δ= 1.71 (s, 3H), 2.45 (s, 3H), 3.19 (s, 3H), and 6.9—7.9 (m, 6H).

24b was prepared in the same manner as that of **24a** in 57% yield, bp 125 °C/0.25 mmHg; ^{1}H NMR ($CDCl_3$): δ=1.07 (t, J=7 Hz, 3H), 2.40 (s, 3H), 2.67 (s, 3H), 3.04 (dq, J=7 Hz and 2 Hz, 2H), and 7.0—7.8 (m, 6H). Found: C, 72.44; H, 7.42; N, 5.97; S, 13.51%. Calcd for $C_{14}H_{17}NS$: C, 72.68; H, 7.41; N, 6.05; S, 13.86%.

Methyl 1-Naphthyl Sulfide (35). 1-Naphthalenethiol was prepared from 1-naphthalenesulfonyl chloride (6.05 g, 26.7 mmol) and zinc (12.2 g, 186 mmol) in concd H_2SO_4 (13 ml) by a similar method to Org. Synth.,[20] and methylated with MeI (3 ml) and NaOH (2 g) in EtOH (30 ml). Usual work-up gave **35** (1.20 g, 26%), bp 90 °C/0.25

mmHg (lit,[21] 104 °C/1 mmHg).

N-Ethyl-N-methyl-1-naphthylamine (37). 1-Naphthylamine (6.83 g, 47.7 mmol) was treated with triethyl orthoformate (10.6 g, 71.2 mmol) and concd H_2SO_4 (0.3 g) by a similar method to Org. Synth.[22] to give *N*-ethyl-*N*-naphthylformamide (71.4 g, 78%), bp 153 °C/0.1 mmHg. This amide (4.19 g, 21.0 mmol) was reduced with $LiAlH_4$ (600 mg, 16 mmol) in ether (90 ml). After usual work-up, DCC (Al_2O_3, hexane) gave **37** (2.85 g, 73%), bp 90 °C/0.3 mmHg; ^1H NMR ($CDCl_3$): $\delta=1.19$ (t, $J=7$ Hz, 3H), 2.83 (s. 3H), 3.13 (q, $J=7$ Hz, 2H), and 6.9—8.4 (m, 7H). Found: C, 84.43; H, 8.21; N, 7.43%. Calcd for $C_{13}H_{15}N$: C, 84.28; H, 8.16; N, 7.56%.

General Procedure of Alkylation. *1) With 3 (Method I):* A mixture of a compd (5 mmol) and **3a** or **3b** (5.5—7 mmol) in CH_2Cl_2 (10—15 ml) was stirred at room temp for several hours. The soln was evaporated to a few ml, to which abs ether was added. The resulting ppt was washed with ether followed by addition of a few ml of EtOH to decompose **3**, washed with ether, and dried *in vacuo*. NMR spectrum of a portion of the crude ppt in DMSO-d_6 was measured to determine the ratio of sulfonium and ammonium salts. The yield was determined after recrystallization.

2) With Methyl Iodide in the Presence of Silver Perchlorate (Method II): To a compd (5 mmol) and MeI (5.5—7.5 mmol) in CH_2Cl_2 (10—20 ml) was added $AgClO_4$ (5 mmol) with $MeNO_2$ (5 ml). The mixture was stirred at room temp for several hours. The filtrate was treated by the same method as in Method I.

2a(I^-): 94% yield (Method II but without $AgClO_4$), mp 226—227.5 °C (decomp) (from EtOH); ^1H NMR: $\delta=2.17$ (s, 3H), 2.6—2.9 (m, 4H), and 3.22 (s, 9H).

2a(BF_4^-): 28% yield from filtrate by Method I, mp 166—170 °C (from MeOH-Et_2O): ^1H NMR: $\delta=2.18$ (s, 3H), 2.6—3.8 (m, 4H), and 3.14 (s, 9H). Found: C, 32.76; H, 7.38; N, 6.45%. Calcd for $C_6H_{15}BF_4NS$: C, 32.60; H, 7.30; N, 6.34%.

4a: 25% yield from ppt by Method I, mp 239—242 °C (from MeOH-MeCN); ^1H NMR: $\delta=2.99$ (s, 6H), 3.17 (s, 9H), and 3.81 (br s, 4H). Found: C, 25.76; H, 5.72; N, 4.20%. Calcd for $C_7H_{19}B_2F_8NS$: C, 26.04; H, 5.93; N, 4.34%.

8a(BF_4^-): not crystallize; 60% yield (Method I); ^1H NMR: $\delta=2.93$ (s, 3H), 3.21 (s, 3H), 3.3—4.5 (m, 4H), 6.20 (s, 1H), and 7.4—8.0 (m, 5H). Found: C, 47.13; H, 5.62; N, 4.79%. Calcd for $C_{11}H_{16}BF_4NS$: C, 47.00; H, 5.74; N, 4.98%.

8b(BF_4^-): 50% yield (Method I), mp 190—192 °C (decomp) (from EtOH-Et_2O); ^1H NMR: $\delta=1.80$ (s, 6H), 3.21 (s, 6H), 3.25 (br t, $J=6$ Hz, 2H), and 4.08 (br t, $J=6$ Hz, 2H). Found: C, 35.78; H, 7.15; N, 5.75%. Calcd for $C_7H_{16}BF_4NS$: C, 36.07; H, 6.92; N, 6.01%.

10a(ClO_4^-): 65% yield (Method II), mp 143—145 °C (from EtOH); ^1H NMR: $\delta=2.79$ (s, 6H), 3.21 (s, 6H), and 7.3—8.1 (m, 4H). Found: C, 42.78; H, 5.86; N, 5.04%. Calcd for $C_{10}H_{16}ClNO_4S$: C, 42.63; H, 5.72; N, 4.97%. The ^1H NMR spectrum of the crude salt showed methyl peaks of **11a**(ClO_4^-) at $\delta=2.69$ (SMe) and 3.87 (Me_3N^+), indicating formation of a mixture of **10a** and **11a** in a ratio of *ca.* 4:1.

Mixture of **10a**(BF_4^-) and **11a**(BF_4^-): *ca.* 1.5:1 in crude (Method I); 81% yield after recrystd from EtOH. **10a** (BF_4^-): from soluble part to CH_2Cl_2; mp 127—128 °C (from EtOH-Et_2O); ^1H NMR: $\delta=2.81$ (s, 6H), 3.21 (s, 6H), and 7.3—8.0 (m, 4H). Found: C, 44.62; H, 6.22; N, 5.22%. Calcd for $C_{10}H_{16}BF_4NS$: C, 44.63; H, 5.99; N, 5.20%. **11a**(BF_4^-): from the insoluble part; mp 186—186.5 °C (from EtOH); ^1H NMR: $\delta=2.67$ (s, 3H), 3.83 (s, 9H), and 7.2—8.0 (m, 4H). Found: C, 44.49; H, 6.03; N, 5.20%. Calcd for $C_{10}H_{16}BF_4NS$: C, 44.63; H, 5.99; N, 5.20%.

Crude mixture of **10b**(ClO_4^-) and **11b**(ClO_4^-): *ca.* 2:1 (Method II); 99% yield. Recrystallization from EtOH gave the mixture of the same ratio, 69% yield, mp 100—101 °C. **10b**(ClO_4^-): ^1H NMR: $\delta=1.30$ (t, $J=7$ Hz, 3H), 2.80 (s, 6H), 3.23 (s, 3H), *ca.* 3.6 (q, $J=7$ Hz, 2H), and 7.1—7.9 (m, 4H). **11b**(ClO_4^-): ^1H NMR: $\delta=1.38$ (t, $J=7$ Hz, 3H), *ca.* 3.2 (q, $J=7$ Hz, 2H), 3.89 (s, 9H), and 7.1—7.9 (m, 4H). Found (mixture): C, 44.59; H, 6.27; N, 5.03%. Calcd for $C_{11}H_{18}ClNO_4S$: C, 44.67; H, 6.13; N, 4.74%.

Crude mixture of **10b**(BF_4^-) and **11b**(BF_4^-): *ca.* 1:2 (Method I), 96% yield. Pure **11b**(BF_4^-): 46% yield; ^1H NMR: $\delta=1.32$ (t, $J=7$ Hz, 3H), 3.16 (q, $J=7$ Hz, 2H), 3.81 (s, 9H), and 7.2—7.9 (m, 4H). **10b**(BF_4^-): ^1H NMR: $\delta=1.21$ (t, $J=7$ Hz, 3H), 2.78 (s, 3H), 3.19 (s, 3H), *ca.* 3.6 (t, $J=7$ Hz, 2H), and 7.2—7.9 (m, 4H).

Crude mixture of **10c**(ClO_4^-) and **11c**(ClO_4^-) ($\delta=3.69$, *N*-Me): >10:1 (Method II), 89% yield. Pure **10c**(ClO_4^-): 33% yield, mp 107—108 °C (from EtOH); ^1H NMR: $\delta=1.14$ (t, $J=7$ Hz, 3H), 2.77 (s, 3H), 3.06 (q, $J=7$ Hz, 2H), 3.21 (s, 6H), and 7.3—8.0 (m, 4H). Found: C, 44.59; H, 6.08; N, 4.85%. Calcd for $C_{11}H_{18}ClNO_4S$: C, 44.67; H, 6.13; N, 4.74%.

Crude mixture of **10c**(BF_4^-) and **11c**(BF_4^-): >10:1 (Method I), *ca.* 100% yield. Pure **10c**(BF_4^-): 42% yield, mp 95—96 °C (from EtOH); ^1H NMR: $\delta=1.11$ (t, $J=7$ Hz, 3H), 2.73 (s, 3H), 3.03 (q, $J=7$ Hz, 2H), 3.17 (s, 6H), and 7.3—8.0 (m, 4H). Found: C, 46.71; H, 6.50; N, 4.82%. Calcd for $C_{11}H_{18}BF_4NS$: C, 46.66; H, 6.41; N, 4.95%.

10d(ClO_4^-): 99% yield (Method II), mp 104—105 °C (from EtOH-Et_2O); ^1H NMR: $\delta=2.67$ (s, 3H), 3.19 (s, 6H), 4.16 (s, 2H), and 7.3—8.1 (m, 9H). Found: C, 53.40; H, 5.73; N, 3.86%. Calcd for $C_{16}H_{20}ClNO_4S$: C, 53.70; H, 5.63; N, 3.91%.

10d(BF_4^-): by Method I; ^1H NMR: $\delta=2.63$ (s, 3H), 3.12 (s, 6H), 4.09 (s, 2H), and 7.0—8.0 (m, 9H). Because of difficulty of purification, BF_4^- was exchanged with Ph_4B^- to give **10d**(BPh_4^-): 37% yield, mp 135—136.5 °C; ^1H-NMR: $\delta=2.61$ (s, 3H), 2.91 (s, 6H), 4.05 (s, 2H), and 6.6—7.8 (m, 29H). Found: C, 83.33; H, 6.77; N, 2.36%. Calcd for $C_{40}H_{40}BNS$: C, 83.17; H, 6.98; N, 2.42%.

13c(BF_4^-): 31% yield (Method I), mp 178.5—179.5 °C (from EtOH); ^1H NMR: $\delta=2.36$ (s, 3H), 2.88 (s, 3H), and 6.6—7.9 (m, 14H). Found: C, 62.10; H, 5.05; N, 3.60%. Calcd for $C_{21}H_{20}BF_4NS$: C, 62.24; H, 4.97; N, 3.46%.

17: 38% yield (Method I), mp 90—93 °C (from EtOH-Et_2O); ^1H NMR: $\delta=3.60$ (s, 6H), 3.3—3.8 (m, 2H), 4.0—4.3 (m, 2H), and 6.5—8.0 (m, 4H). Found: C, 45.06; H, 5.49; N, 5.34%. Calcd for $C_{10}H_{14}BF_4NS$: C, 44.97; H, 5.28; N, 5.24%.

18(BPh_4^-): 43% yield by Method II followed by anion exchange, mp 226—227.5 °C (decomp); ^1H NMR: $\delta=2.96$ (s, 3H), 3.49 (s, 3H), 3.62 (br s, 4H), and 6.5—7.5 (m, 24H). Found: C, 81.90; H, 7.05; N, 2.89%. Calcd for $C_{34}H_{34}BNS$: C, 81.75; H, 6.86; N, 2.80%.

20a: 79% yield (Method I), mp 264.5—265.5 °C (decomp) (from EtOH); ^1H NMR: $\delta=2.92$ (s, 3H), 3.72 (s, 3H), and 7.1—8.0 (m, 8H). Found: C, 53.15; H, 4.52; N, 4.73%. Calcd for $C_{14}H_{14}BF_4NS$: C, 53.36; H, 4.48; N, 4.44.

20a': 82% yield (Method I), mp 158.5—160 °C (from EtOH); ^{1}H NMR: δ=1.08 (t, J=7 Hz, 3H), 3.33 (q, J=7 Hz, 2H), 3.69 (s, 3H), and 7.1—8.0 (m, 8H). Found: C, 54.67; H, 5.04; N, 4.56%. Calcd for $C_{15}H_{16}BF_4NS$: C, 54.73; H, 4.90; N, 4.26%.

20b: 81% yield (Method I), mp 241—242.5 °C (decomp) (from EtOH); ^{1}H NMR: δ=1.47 (t, J=7 Hz, 3H), 2.89 (s, 3H), 4.33 (q, J=7 Hz, 2H), and 7.1—8.1 (m, 8H). Found: C, 54.59; H, 4.86; N, 4.31%. Calcd for $C_{15}H_{16}BF_4NS$: C, 54.73; H, 4.90; N, 4.26%.

20c: 59% yield (Method II), mp 184.5—187 °C (decomp) (from EtOH); ^{1}H NMR: δ=2.88 (s, 3H), 7.0—8.0 (m, 8H), and 11.1 (br s, 1H); IR (KBr): 3300 cm^{-1} (NH). Found: C, 49.96; H, 3.98; N, 4.70%. Calcd for $C_{13}H_{12}ClNO_4S$: C, 49.77; H, 3.86; N, 4.46%.

25a(ClO_4^-): 85% yield (Method II), mp 196—197.5 °C (from EtOH); ^{1}H NMR: δ=2.82 (s, 6H), 3.23 (s, 6H), and 7.5—8.4 (m, 6H). Found: C, 50.80; H, 5.38; N, 4.46%. Calcd for $C_{14}H_{18}ClNO_4S$: C, 50.68; H, 5.47; N, 4.22%.

Crude mixture of **25a**(BF_4^-) and **26a**(BF_4^-): 2:3 (Method I); 93% yield; ^{1}H NMR: **25a**, δ=2.79 (s, 6H) and 3.19 (s, 6H); **26a**, δ=2.48 (s, 3H) and 2.98 (s, 6H).

25b(ClO_4^-): 36% yield (Method II), mp 107.5—109 °C; ^{1}H NMR: δ=1.17 (t, J=7 Hz, 3H), 2.84 (s, 3H), 3.24 (d, J=3.6 Hz, 6H), 3.3—3.8 (m, 2H), and 7.6—8.4 (m, 6H). Found: C, 52.21; H, 5.92; N, 3.81%. Calcd for $C_{15}H_{20}ClNO_4S$: C, 52.09; H, 5.83; N, 4.05%.

26b(BF_4^-): 87% yield (Method I), mp 148—150 °C (from EtOH); ^{1}H NMR: δ=1.09 (t, J=7 Hz, 3H), 2.50 (s, 3H), 3.00 (br s, 6H), 3.40 (br q, J=7 Hz, 2H), and 7.3—8.1 (m, 6H). Found: C, 53.20; H, 5.84; N, 5.04%. Calcd for $C_{14}H_{18}BF_4NS$: C, 52.68; H, 5.68; N, 4.39%.

30: 57% yield (Method II), mp 162—163 °C (from EtOH); ^{1}H NMR: δ=3.33 (s, 6H) and 7.6—8.2 (m, 5H).

32: 93% yield (Method II), mp 183—186 °C (from EtOH); ^{1}H NMR: δ=3.69 (s, 9H) and 7.5—8.1 (m, 5H).

34: 78% yield (Method I), mp 142—143 °C (from EtOH); ^{1}H NMR: δ=2.72 (s, 6H), 3.82 (s, 9H), and 7.3—8.0 (m, 4H).

36: 97% yield (Method II), mp 157—158 °C (from EtOH); ^{1}H NMR: δ=3.43 (s, 6H) and 7.7—8.6 (m, 7H).

38: 48% yield (Method I), mp 165—166 °C (from EtOH); ^{1}H NMR: δ=0.99 (t, J=7 Hz, 3H), 3.91 (s, 6H), 4.45 (q, J=7 Hz, 2H), and 7.5—8.7 (m, 7H).

Preparation of ***6***. *1)* ***6a***: **1a** (222 mg, 1.87 mmol) was protonated with 42% aq HBF_4 (2 ml) in CH_2Cl_2 (8 ml). The resulting material was dissolved in CH_2Cl_2 (10 ml), to which was added **3a** (431 mg, 2.91 mmol). After usual work-up, recrystallization from EtOH-MeCN gave **5a** (487 mg, 85%). A suspension of **5a** (342 mg, 1.11 mmol) in CH_2Cl_2 (15 ml) was deprotonated with aq NaOH and the aqueous layer was separated, to which was added aq $NaBPh_4$. The resulting ppt was recrystd from EtOH-MeCN to give colorless crystals of **6a**, 297 mg (59% yield based on **5a**), mp 160 °C (decomp); ^{1}H NMR (DMSO-d_6): δ=2.16 (s, 6H), 2.48 (s, 6H), 2.3—2.6 (br t, J=6 Hz, 2H), 3.16 (br t, J=6 Hz, 2H), and 6.6—7.5 (m, 20H). Found: C, 79.72; H, 8.25; N, 3.09%. Calcd for $C_{30}H_{36}BNS$: C, 79.46; H, 8.00; N, 3.09%.

2) ***6b***: **5b** was prepared from **1b** by the same method as that of **5a**, *ca.* 100% yield; ^{1}H NMR (DMSO-d_6): δ=1.39 (t, J=7 Hz, 3H), 2.86 (s, 6H), 2.93 (s, 3H), 3.40 (q, J=7 Hz, 2H), and 3.58 (br s, 4H). Similarly **6b** was obtained in 64% yield, mp 143—147 °C (decomp) (from EtOH-Me_2CO); ^{1}H NMR (DMSO-d_6): δ=1.12 (t, J=7 Hz, 3H), 2.15 (s, 6H), 2.31 (s, 3H), 2.4—3.2 (m, 6H), and 6.7—7.6 (m, 20H). Found: C, 79.81; H, 8.44; N, 3.25%. Calcd for $C_{31}H_{38}BNS$: C, 79.64; H, 8.19; N, 3.00%.

The Reaction of Benzonitrile Oxides with *S,S*-Dimethyl-*N*-(2,4,6-trihalophenyl)sulfimides. The Formation of Benzoxazole Derivatives

Shinsaku SHIRAISHI,* Tohru HAYAKAWA, and Tadashi SHIGEMOTO

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received November 27, 1982)

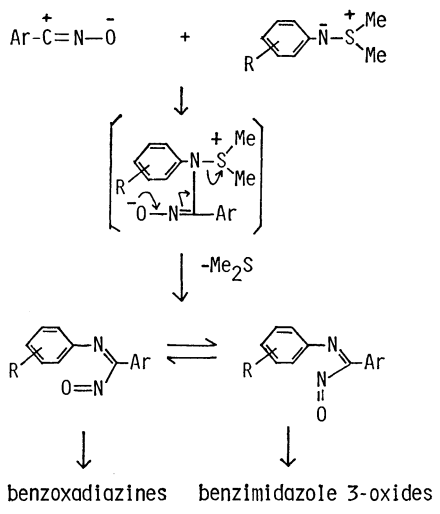
The reactions of nitrile oxides with *S,S*-dimethyl-*N*-(2,4,6-trihalophenyl)sulfimides gave unusual products, which structure was determined to be 2-aryl-4,6-dihalobenzoxazoles from their elementary analyses and spectral data. While the reactions with *S,S*-dimethyl-*N*-(2-bromophenyl)- or *S,S*-dimethyl-*N*-(2,4-dibromophenyl)-sulfimide gave 1,2,4-benzoxadiazine derivatives. A plausible reaction mechanism for the unusual formation of benzoxazoles was proposed.

Nitrile oxides are typical 1,3-dipoles and are known to react with various unsaturated bonds, not only with carbon-carbon unsaturated bonds but also with hetero unsaturated ones. Many studies have also been reported on the reaction with ylides.[1,2] We reported before that benzimidazole 3-oxides and/or benzoxadiazines were obtained in the reactions of aromatic nitrile oxides with *N*-aryl-*S,S*-dialkylsulfimides, and suggested that the reaction proceed *via* nitroso intermediacy as shown in Scheme 1.[3] Gilchrist *et al.* reported the formation of 1,2,4-benzoxadiazines in the reaction of nitrile oxides with *N*-aryl-*S,S*-dimethylsulfimides.[4] As a support of nitroso intermadiacy, though it is in an indirect manner, dibenzyl sulfide was isolated in the reaction with *N*-aryl-*S,S*-dibenzylsulfimides.[5]

During the course of the study, we attempted the reactions of nitrile oxides with *S,S*-dimethyl-*N*-(2,4,6-trihalophenyl)sulfimides, in expectation to isolate or detect the nitroso intermediate. In the reactions, however, unusual reaction products were isolated against the expectation, as reported in the previous communication.[6] We describe here the result of the further investigation of the reactions with *S,S*-dimethyl-*N*-(2,4,6-trihalophenyl)sulfimides together with the reactions with *S,S*-dimethyl-*N*-(2-halophenyl)sulfimides.

Results and Discussion

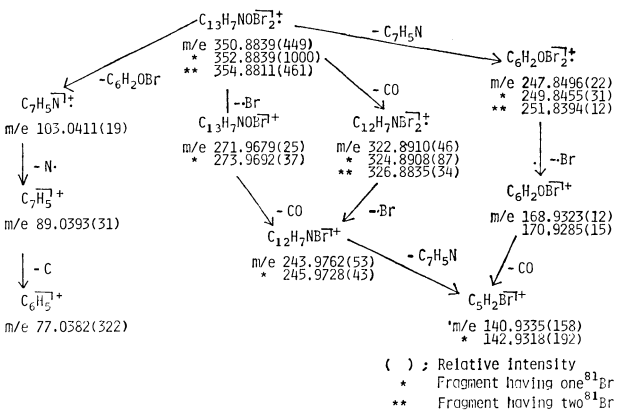
We tried the reactions of benzonitrile oxide (**1a**) and *p*-chloro- (**1b**) and *p*-bromobenzonitrile oxide (**1c**) with *S,S*-dimethyl-*N*-(2,4,6-tribromophenyl) sulfimide (**2a**) and *S,S*-dimethyl-*N*-(2,4,6-trichlorophenyl)sulfimide (**2b**). The results of the reactions and the analytical data of the reaction products are shown in Table 1. High resolution mass spectra of the products gave the molecular formulae of $C_{13}H_6NOXY_2$ (X= H,Cl,Br; Y=Br,Cl), which were consistent with the analytical data. The molecular formulae shows the loss of dimethyl sulfide, one halogen and one nitrogen atoms from the sum of the two starting components.



Scheme 1.

Mass fragmentation pattern of the product **3a** is shown in Scheme 2. Elimination of CO and benzonitrile from the molecular ion is observed to occur independently. The fragmentation pattern is common to the other reaction products and is very similar to those of benzoxazole and 1,2-benzisoxazole derivatives.[7] The unusual reaction products are suggested to have benzoxazole or 1,2-benzisoxazole structure.

In order to determine the structure of the product, we compared the UV and ^{13}C NMR spectra of them with those of 2-phenylbenzoxazole (**4**) and 3-phenyl-1,2-benzisoxazole (**5**), which were synthesized by methods of Somayajulu[8] and of Minisci,[9] respectively. UV spectra of the products **3a**—**f** and the reference compounds **4** and **5** are listed in Table 2. Absorption maxima of **3a**—**f** are at 305—316 nm with ε_{max} of $(2.6—3.8)\times10^4$. The spectral pattern of the products resembles to that of **4** more closely than that of **5**. ^{13}C NMR spectral data are listed in Table 3. The signals due to C-2, C-3a and C-7a of 2-phenylbenzoxazole (**4**) are at 162.1, 141.5, and 150.1 ppm.[10] On the other hand, the signals due to C-3, C-3a, and C-7a of 3-phenyl-1,2-benzisoxazole (**5**) are at 157.2, 120.4, and 163.8 ppm. The signals at 162—164 ppm of the reaction products **3a**—**f** can be assigned to be C-2



Scheme 2. Mass fragmentation of **3a**.

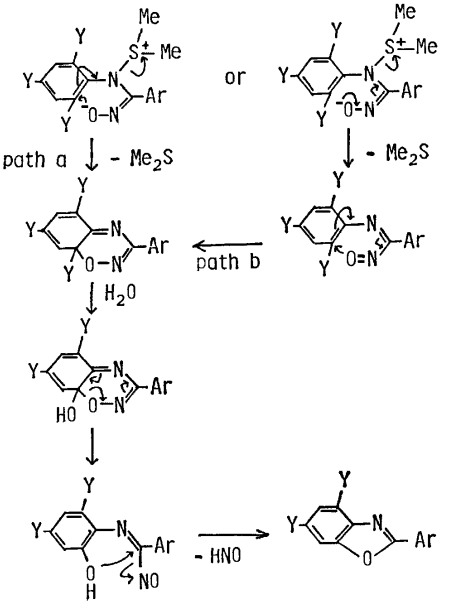
carbon atom of benzoxazole structure. Assignment of the other signals is shown in the Table.

^{1}H NMR spectral data are shown in Table 4. The signals due to H-5 and H-7 of **3a—c** happened to appear at the same chemical shift in $CDCl_3$, but became separated in D_2SO_4. For example, the signals of **3a** at 7.64 ppm in $CDCl_3$ comes to appear at 8.58 and 8.50 separetedly in D_2SO_4. The recovered samples from the D_2SO_4 solutions were confirmed to be unchanged from the orginal ones. In the case of **3d—f**, the signals due to H-5 and H-7 were observed at different positions even in $CDCl_3$. The data are well consistent with the proposed 2-arylbenzoxazole structure.

The data mentioned above, however, cannot definitely rule out the isomeric structure of 2-aryl-5,7-dihalobenzoxazoles. But the melting point of **3a** is 148—149 °C (See Table 1) and much different from that of 5,7-dibromo-2-phenylbenzoxazole which was reported to melt at 175—176 °C.[11]



Scheme 3. Reaction route to the 2-arylbenzoxazole.

Thus the structure of the reaction products was determined to be 2-aryl-4,6-dihalobenzoxazole.

This structure determination was further confirmed by an independent synthesis of the authentic sample of 2-phenyl-4,6-dichlorobenzoxazole by the condensation of benzaldehyde with 3,5-dichloro-2-aminophenol. Infrared, ^{1}H NMR, and mass spectra of the authentic sample were the same as those of the compound **3d**. Also the melting point and R_f-value of thin layer chromatography were the same.

Table 3. ^{13}C NMR Spectra of 2-aryl-4,6-dihalobenzoxazoles (**3a**—**f**), 2-phenylbenzoxazole (**4**), and 3-phenyl-1,2-benzisoxazole (**5**)

* ppm from external TMS.

In order to see the scope and limitation of this unusual formation of 2-arylbenzoxazole derivatives, we tried the reaction of nitrile oxide (**1a**—**c**) with only one ortho-substituted *N*-arylsulfmides, such as *S,S*-dimethyl-*N*-(2-bromophenyl)sulfmide (**2c**) and *S,S*-dimethyl-*N*-(2,4-dibromophenyl)sulfimide (**2d**). The reaction products in the reactions were benzoxadiazine derivatives and no benzoxazole derivatives nor benzimidazole 3-oxide were formed. The yields of the 1,2,4-benzoxadiazines were very high as seen in Table 5. The result that no benzimidazole 3-oxide was formed is consistent with the mechanistic consideration previously reported.[3]

The reaction mechanism leading to benzoxazole formation is not obvious yet, but may be considered to be the same as that for the 1,2,4-benzoxadiazine formation at the initial stage of the reaction. The subsequent stages may be such as illustrated in Scheme 3. In this reaction, the intervention of a nitroso intermediate can neither be regarded nor disregarded at present, but by taking its intervention into consideration, the reactions of nitrile oxides with *N*-phenyl-

sulfimide, *N*-(2,6-dihalophenyl)sulfmides, and *N*-(2-azaaryl)sulfimides can be interpreted in terms of the same type of the intermediacy. The reaction of *N*-(2-pyridyl)sulfimide with a nitrile oxide, for example, have been reported to give a 1,2,4-triazolo[1,5-*a*]pyridine derivative *via* nitroso intermediate.[12] In the reaction forming benzoxazole derivatives presented here, the cyclized intermediate from the nitroso intermediate has a halogen substituent at the angular carbon atom which is linked with oxygen atom. This type of C–Cl bond is considered to be highly susceptible to hydrolysis. Therefore, the intermediate hydrolyzed with moisture in the reaction mixture, then once ring opened and recyclized to the benzoxazole with loss of the nitroso group. This mechanistic speculation is based on an assumption of the participation of water in the reaction. A further investigation as to the effect of some nucleophiles as well as water is now under progress and will be presented elsewhere.

Experimental

Melting points were measured using a micro-melting-point measuring apparatus (Yazawa Co., Ltd.) and are uncorrected. IR spectra were recorded with a JASCO IRA-1 spectrophotometer. Mass spectra were recorded with a Hitachi RMU-7L high-resolution mass spectrometer. UV spectra were recorded with a JASCO UVIDEC-505 spectrophotometer. ^{1}H NMR and ^{13}C NMR spectra were measured in $CDCl_3$ with JEOL JMN-MH 100 and FX-60 spectrometers respectively, and chemical shifts were reported in ppm from internal tetramethylsilane, unless otherwise cited. Column chromatography was conducted on silica gel (Wakogel C-200) with chloroform as an eluent.

Materials. Benzonitrile oxide and *p*-substituted benzonitrile oxides were generated at low temperature from the corresponding benzhydroxamoyl chlorides, which were synthesized by the usual methods.[13] *N*-aryl-*S*,*S*-dimethylsulfimides were prepared from dimethyl sulfoxide, substituted anilines, and trifluoroacetic anhydride.[14]

Reaction of Sulfimides with Nitrile Oxides. A General Procedure: A solution of hydroxamoyl chloride (1 mmol) in 10 ml of tetrahydrofuran (THF) was cooled below −10 °C. An equimolar amount of triethylamine was added to the solution through microsyringe. The solution became turbid due to the precipitation of triethylammonium chloride. Then an equimolar amount of sulfmide in 10 ml of THF was added dropwise to the mixture, during which the reaction mixture was kept below −10 °C. After the mixture was allowed to stand at ambient temperature overnight, triethylammonium chloride was separeted by filtration and the solvent was removed by evaporation under reduced pressure. The residue was worked up with column chromatography on silica gel (Wakogel C-200) with chloroform as an eluent to give a 2-arylbenzoxazole, which was recrystallized from methanol. Some typical examples follow.

*Reaction of Benzonitrile Oxide (**1a**) with* S,S-*Dimethyl*-N-*(2,4,6-tribromophenyl)sulfimide (**2a**)*: Into a cooled solution of 0.65 g (1 mmol) of benzhydroxamoyl chloride in 10 ml of THF was added 140 µl (1 mmol) of triethylamine at a temperature below −10 °C. A white precipitate of triethylammonium chloride deposited. Then 0.391 g (1 mmol) of **2a** in 5 ml of THF was added dropwise to the mixture kept below −10 °C, through a dropping funnel, which was washed with 5 ml of THF. The mixture was allowed to stand at ambient temperature overnight. Triethylammonium chloride was separeted by filtration and the filtrate was evaporated. The residue was worked up with column chromatography. 2-Phenyl-4,6-dibromobenzoxazole (**3a**) was isolated and weighed 0.13 g (37%). It was purified

by recrystallization from methanol.

Reaction of p-*Bromobenzonitrile Oxide (**1c**) with* S,S-*Dimethyl*-N-*(2-bromophenyl)sulfimide (**2c**)*: A solution of 0.236 g (1 mmol) of *p*-bromobenzhydroxamoyl chloride in 10 ml of THF was cooled below −10 °C by an ice-salt bath. Triethylamine 140 μl (1 mmol) was added into the solution through microsyringe, depositing a white precipitate of triethylammonium chloride. Then 0.235 g (1 mmol) of **2c** in 5 ml of THF solution was added dropwise through a dropping funnel to the mixture, during which the reaction mixture was kept below −10 °C. The dropping funnel was washed with 5 ml of THF. The solution was allowed to stand at ambient temperature overnight. Triethylammonium chloride was removed by filtration and the solvent was evaporated. The residue was worked up with column chromatography. 3-(*p*-Bromophenyl)-5-bromo-4*H*-1,2,4-benzoxadiazine (**6c**) 0.310 g (85%) was isolated and recrystallized from ether–petroleum ether.

Independent Synthesis of 2-Phenyl-4,6-dichlorobenzoxazole: 3,6-Dichloro-2-aminophenol was synthesized by method of Hodgson and Wignall.[15] The condensation reaction was carried out according to the method of Osman and Bassiouni[16] with a slight modification. A mixture of the 2-aminophenol 1.6 g (9 mmol) and benzaldehyde 3.8 g (36 mmol) was heated to reflux for 10 h. The reaction mixture was then cooled to room temperature and poured into methanol to give a precipitate, which was collected by filtration and dried. 2-Phenyl-4,6-dichlorobenzoxazole 1.4 g (60%) was isolated and recrystallized from methanol.

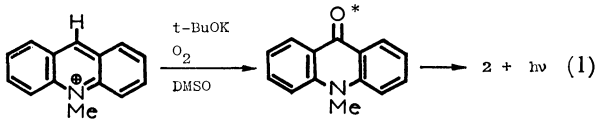
Base-induced Oxygenation and Chemiluminescence of 10-Methylacridinium and 1-Methylquinolinium Salts in Dimethyl Sulfoxide[1]

Nobutaka Suzuki,* Yoshihiko Kazui, Toshio Tsukamoto,
Masahiro Kato, and Yasuji Izawa
Department of Industrial Chemistry, Faculty of Engineering, Mie University, Tsu, Mie 514
(Received December 9, 1982)

10-Methylacridinium methyl sulfate and the 1-methylquinolinium salt gave strong light emission, when oxidized with ground state oxygen in the presence of *t*-BuOK in DMSO, owing to the fluorescence of 10-methyl-9(10*H*)-acridinone and 1-methyl-1(4*H*)-quinolinone excited to their S_1 state.

Lucigenin[2] is one of the most powerful chemiluminescent compound (quantum yield of CL: Φ_{CL} 3.0×10^{-3})[3] and has the most complex mechanism known so far, for the chemiluminescence reactions.[4]

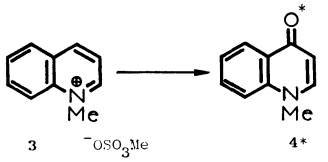
In the course of the studies on chemiluminescence (CL) of 9,10-substituted acridine compounds,[5] a new chemiluminescent reaction of 10-methylacridinium salts (**1**), which resembles to lucigenin apparently, was found when oxidized by molecular oxygen under basic conditions. We describe here the bright blue chemiluminescent reactions of 10-methylacridinium methyl sulfate (**1a**) owing to the fluorescence of 10-methyl-9(10*H*)-acridinone (**2**) excited to the S_1 state, when oxidized with ground state oxygen in the presence of t-BuOK in dimethyl sulfoxide (DMSO) (scheme 1). The similar CL reaction of 1-quinolinum methyl sulfate (**3**) is also described. Happ *et al.* reported a weak CL of a similar chemiluminescent system, 10-methylacridinium chloride (**1b**) *via* addition of $^-$CN anion to 9-carbon, catal zed by excess KCN, instead of *t*-BuOK, in DMSO/H_2O (9:1).[6] Under the similar conditions, **1a** yielded reduced amounts of CL (less than 1/3 of that by *t*-BuOK).



(1)

1a: X=OSO_3Me
1b: X=Cl

2*



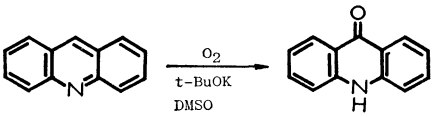
(2)

3 $^-OSO_3Me$ **4***

CL spectrum of **1** was identical with the fluorescence (FL) spectrum of **2** (420 and 435 nm) under the similar basic conditions (*t*-BuOK/DMSO/O_2 or KCN/DMSO–H_2O/O_2). These results suggest that the emitter in the CL reactions is the ketone **2** generated during the reactions quantitatively. When treated first by the base *in vacuo* (freeze-thaw cycle: 10^{-4} mmHg** $\times$3 times)[7] and then by oxygen, **1a** also gave CL. The compound **3** showed the similar behavior under the similar conditions above.

The behavior of **1a** in the present reactions shows that the reaction pathway is different both from that of the Happ's[6] and also that for the 9-substituted compounds shown by Kamiya and Sugimoto.[8]

Contamination of **1** with acridine (**5**) or its *N*-protonated salt was suspected to be responsible for the strong CL emission. In fact, acridine itself showed CL, although it was very weak, to give 9(10*H*)-acridinone under the similar conditions (scheme 3).



(3)

5 **6**

Rosenthal and Bercovici[9] found that the final product, **2**, gave CL in DMSO when treated with KO_2. The CL spectrum exhibits a broad emission band with three peaks, maxima at 470, 494, and 532 nm of the relative intensities 3:5:2, respectively, owing to the fluorescence of radical anion of **2**. The comparison of CL spectra shows that the present CL reactions do not result from the Rosenthal's mechanism (scheme 4).

$$2 + O_2^{\cdot-} \longrightarrow (2^{\cdot-})^* + O_2$$
$$(2^{\cdot-})^* \longrightarrow 2^{\cdot-} + h\nu \qquad (4)^{9)}$$

The degradation energy of 67.3 kcal/mol***, at least, is required for exciting **2** to the lowest singlet excited state.[5] (i) If one O_2 molecule oxidizes one molecule of **1** to give one molecule of **2** and 1/2 molecule of H_2O_2,[6,10] the balance of the heat of reaction (ΔH) would be $\Delta H = +5.6$ kcal/mol (scheme 5), which is not sufficient to excite **2**. (ii) If one O_2 molecule oxidizes two molecules of **1** to give two molecules of **2** and H–OR, ΔH would be -113.5 kcal/mol, which is sufficient for exciting **2** to its S_1 state (scheme 6) (Table 2). Thus, we prefer the latter mechanism (scheme 6) for the explanation of the present effective chemiluminescent reaction of **1a**.

Kamiya and Sugimoto[8] have investigated the similar chemiluminescent systems, 9-alkyl- and 9-benzyl-10-methyl-acridinium methyl sulfates (**7**) in the presence of *t*-BuOK and O_2 in DMSO solution (Φ_{CL} 10^{-2}—10^{-4}) and suggested the reaction mechanism initiating from a deprotonation reaction of the alkyl side chain of **7**. The emitter is probably the anhydrobase excited by the ketones **2*** produced primarily as the excited state(s). After mixing with *t*-BuOK in the

absence of O_2, the solution of **7** did not give CL on exposure to O_2 gas. The mechanism seems to be similar to the CL of lucigenin.[3]

Experimental

Instrumentation. All mps were uncorrected. Following spectrophotometers were used for spectral measurements: IR: JASCO IR-G and A-100; UV: Hitachi 220S Spectrophotometer; NMR: JEOL JNM-MH-100 (100 MHz) and FX-100 (99 MHz for ^1H and 25.05 MHz for ^{13}C); MS: JEOL JMS-D-100; Fluorescence: Hitachi MPF-2A. The spectral data are presented as follovs: IR in cm^{-1}; UV: λ_{max} in nm (ε given in parentheses); NMR: δ in ppm from int. TMS and J in Hz (accuracy±0.5 Hz); MS in m/z; fluorescence; λ_{max} in nm. GLC were carried out by Yanagimoto Yanaco G-1800F. GLC Conditions: Yanagimoto Yanaco G-1800F (FID); 10% Silicone GE-SE-30 on Diasolid L in 0.93×ϕ 4 mm stainless steel column; col. temperature 240 °C, inj. temperature 280 °C, carrier gas (N_2) 42.0 ml/min. TLC Conditions: Silica gel 60 PF_{254}-gipshaltig (Merck, #7749), thickness: 0.25 mm, $CHCl_3$.

Photometric determinations were made by measuring the output of R106 photomultiplier-photometers (Hitachi MPF-2A Fluorescence/Phosphorescence Photometer) exposed to the reacting solution. The values obtained were corrected for phototube spectral response. Quantum yields (Φ_{CL}) are relative to luminol.[11]

Materials. Acridine, quinoline, and 9(10*H*)-acridinone (**6**) were purchased. 10-Methylacridinium chloride (**1b**),[12] 10-methyl-9(10*H*)-acridinone (**2**),[13] and 1-methyl-1(4*H*)-quinolinone (**4**)[14] were prepared according to literatures.

1b: mp 180—187 °C (decomp) [lit,[12] mp 183 °C (decomp)]; ν_{max} (KBr) 1620, 1230, 1010, 730 cm^{-1}; δ (DMSO-d_6) 3.40 (4H, br), 4.80 (3H, s), 7.9—8.9 (8H, m), 10.30 (1H, s).

2: mp 207—209 °C (lit,[13] 203.5 °C); ν_{max} (KBr) 1630, 1590, 1490, 1180 cm^{-1}; δ ($CDCl_3$) 3.82 (3H, s), 7.46 (6H, m), 8.52 (2H, d).

4: mp 143—151 °C (lit,[14] 152 °C); ν_{max} (KBr) 1620 cm^{-1}; δ ($CDCl_3$) 3.80 (3H, s), 6.20 (1H, m), 7.50 (4H, m), 8.40 (1H, m).

*10-Methylacridinium Methyl Sulfate (**1a**)*: A solution of acridine (Nakarai Chem. Co) (5 g; 27.9 mmol) and dimethyl sulfate (bp 189 °C) (2.9 ml; 30.5 mmol) in benzene (50 ml) was stirred at 30—40 °C overnight with excluding moisture. Resulted precipitates were filtered and washed with ether. Into the mother liquor was added 1 ml of dimethyl sulfate. After strring, resulted ppt was collected with filtration. Yellow granules, mp >300 °C. Yields 7.14 g (23.4 mmol; 83%). Found C, 59.28; H, 5.15%. Calcd for $C_{15}H_{15}NO_4S$: C, 59.00; H, 4.952%; m/z 194 (cation part) ν_{max}

(KBr) 3000, 1390, 1220, 1170 cm^{-1}; δ (DMSO-d_6) 3.40 (3H, s), 4.88 (3H, s), 8.04 (2H, m), 8.60 (4H, m), 10.20 (1H, br, s).

1-Methylquinolinium Methyl Sulfate (3): A solution of quinoline (TCI) (3.0 ml: 3.27 g; 25.3 mmol) and dimethyl sulfate (10 ml: 13.3 g; 105 mmol) in benzene (30 ml) was stirred at 30—40 °C for 20 h and, then, cooled in an ice bath. Resulted precipitate was filtered and crystallized from acetone. Colorless needles, mp 98.0—99.0 °C (lit,[15] 100 °C), yields 5.04 g (19.7 mmol; 77.9%); ν_{max} (KBr) 1620, 1210, 1020, 760 cm^{-1}; δ (DMSO-d_6) 3.40 (3H, s), 4.64 (3H, s), 8.42 (2H, m), 9.35 (2H, m).

Chemiluminescent Reaction of 1 and 3: Each solution (2 ml) of **1a**, **1b**,[15] and **3** (1 mmol/l) in DMSO (dried over and distilled from CaH_2 and saturated by O_2 before use) was treated with DMSO solution (2 ml) of *t*-BuOK (Merck, 10 mmol/l) or KCN (Wako, 10 mmol/l) at room temperature. The mixture was flushed by O_2 gas for 10 min before and during the oxygenation reaction. Fast light emission was observed.[11] After neutralization of the resulted mixture with Dry Ice, solvents were evaporated *in vacuo* and the residue was extracted with ether, from which the final product **2**[13] and **4** were characterized by IR, NMR, and mp and identified on GLC and TLC with the authentic samples. The results are shown in Table 1. CL spectra were recorded and compared with their fluorescence spectra measured under the similar conditions.

Base Catalyzed Oxygenation of 5. The CL reactions of **5** (1.00 mmol/l) were observed under the similar conditions and the spectra and products were analysed as described above (Table 1). Products were also determined by UV spectra.

We thank Dr. T. Kondo and Professor T. Goto, Nagoya University, for taking MS; Professor I. Kamiya and Dr. T. Sugimoto for valued discussions, and the Ministry of Education, Science and Culture of Japan for the financial support (Grant-in-Aid).

Synthesis of 5″-Deoxy-5″-fluorolividomycin B

Takahiro Torii, Tsutomu Tsuchiya,* Sumio Umezawa, and Hamao Umezawa†

Institute of Bioorganic Chemistry, 1614 Nakahara-ku, Kawasaki 211

† *Institute of Microbial Chemistry, Kamiosaki, Shinagawa-ku, Tokyo 141*

(Received December 13, 1982)

A masked lividomycin B derivative in which only the C-5″ hydroxyl group remains free has been prepared and treated with diethylaminosulfur trifluoride as the key step to give the title compound. A macrocyclic compound, that is, 2′,5″-carbamate was also obtained by the above reaction, and the structure was determined chemically and by the NMR-spectrum of its deblocked derivative.

Lividomycin B[1] is an amino glycoside antibiotic produced by *Streptomyces lividus* nov. sp. This antibiotic has strong activity[2] in inhibiting the growth of resistant strains producing 3′-phosphotransferase II which transfers the phosphate of ATP to the 3′-hydroxyl group of paromomycin I (which is synonymous with 3′-hydroxylividomycin B). However, lividomycin B is inactivated[2] by the other resistant strains producing 3′-phosphotransferase I, which transfers the phosphate to the 5″-hydroxyl group.[3] To overcome the inactivation by this enzyme, 5″-deoxylividomycin B[2] had been prepared; however, the derivative had only weak antibacterial activity, suggesting the importance of the role of the 5″-hydroxyl group in the antibacterial action. Recently we prepared several fluoro derivatives[4] of amino glycoside antibiotics in the purpose of developing useful antibacterial amino glycosides. This paper describes the preparation of 5″-deoxy-5″-fluorolividomycin B, to investigate the effect of strongly electronegative fluorine atom instead of the electronegative 5″-hydroxyl group.

First attempts to fluorinate the *N*,*O*-protected 5″-*O*-tosyl derivative[2] (**10**) with cesium fluoride or tetrabutylammonium fluoride, both of which are commonly used for fluorination, were unsuccessful, to give several unidentified products. Therefore, direct fluorination of a 5″-hydroxyl derivative (**6**) with diethylaminosulfur trifluoride[5] (DAST reagent) was attempted. Pentakis (*N*-benzyloxycarbonyl)lividomycin B[2] (**1**) reported earlier was treated with chlorotriphenylmethane in the presence of 2 molar equivalents of phenylboronic acid. Then, 5″-*O*- (**2**, 72%) and 6′-*O*-triphenylmethyl (**3**, 2%) derivatives were produced together with 6′,5″-bis(*O*-triphenylmethyl) derivative (**4**, 8%). Reaction without addition of phenylboronic acid gave **3** as the major product, suggesting that, in the presence of phenylboronic acid, a phenylboronic ester was tentatively formed between the 4′- and 6′-hydroxyl groups.[6] This facilitated the selective 5″-*O*-triphenylmethylation. Acetylation of **2** (to give **5**) followed by acidic hydrolysis of the triphenylmethyl group gave **6** carrying the free 5″-hydroxyl group. The structure of **6** was confirmed by the fact that tosylation of **6** gave the product identical with the derivative (**12**) obtained by debenzylidenation (to give **11**) of an authentic **10**[2] followed by acetylation.

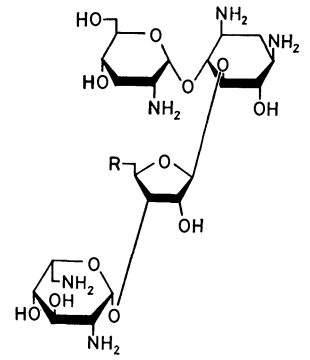
Reaction of **6** with diethylaminosulfur trifluoride proceeded smoothly to give two products, the minor one being the desired 5″-deoxy-5″-fluoro derivative (**7**, 28%) and the major, 2′-*N*:5″-*O*-carbonyl macrocyclic compound (**8**, 61%). Deacetylation of **7** followed by catalytic debenzyloxycarbonylation gave the desired 5″-deoxy-5″-fluorolividomycin B (**9**).

The structure of **9** is evident from the synthetic pathway, but further confirmed by NMR spectral study. In ^{1}H-NMR spectrum, presence of $-CH_2F$ was clarified from the splitting pattern having large $^2J_{H,F}$ (47 Hz) values (see Experimental section). In (proton decoupled) ^{13}C-NMR spectrum, signals of C-5″,-4″, and -3″ appeared as a doublet with a spacing of 168.5 ($=^1J_{C,F}$), 17.7 ($=^2J_{C,F}$), and 6.7 Hz ($=^3J_{C,F}$), respectively (see Table 1), supporting the presence of above fragment.

As a reference compound, 5″-chloro-5″-deoxylividomycin B (**15**) was prepared. A *N*-protected 4′,6′-*O*-benzylidene-5″-chloro-5″-deoxy derivative (**13**) was prepared from **10**[2] according to the method of Watanabe,[7] and it was led to **15** by debenzylidenation (to give **14**) followed by catalytic debenzyloxycarbonylation. One-step deblocking of **13** by the catalytic hydrogenolysis required long reaction-period giving 5″-deoxylividomycin B[2] (**21**). The 5″-chloro structure of **15** was confirmed by the resonance of C-5″ appeared

at high-field (45.8 ppm) in ^{13}C-NMR spectrum, the value being typical for that of the terminal chloromethyl carbon of carbohydrates reported.[8]



Lividomycin B	R=OH
9	R=F
15	R=Cl
21	R=H

The structure of 2′-*N*:5″-*O*-carbonyl compound (**8**) was determined as follows: Deacetylation of **8** with methanolic aqueous ammonia (to give **16**) followed by catalytic hydrogenolysis gave the 2′-*N*:5″-*O*-carbonyl compound (**17**). The presence of one carbonyl carbon was evidenced by the resonance at down-field (157.8 ppm) in ^{13}C-NMR spectrum. Bridging the 2′-amino and 5″-hydroxyl groups with a carbonyl was verified by the ^{1}H-NMR spectral study. The HC(2′)NH– proton resonances, which should appear at rather down-field ($\delta \approx 3.6$, see Experimental section), were not in the usual methine region (δ=2.5—3.1) of HCNH$_2$ (measured in 20% ND_3 in D_2O as the free base). Furthermore, one of the proton resonances of C(5″)H_AH_BO–, which appeared separately at δ= 4.10 and 5.15, lay beyond the usual region of methylene protons carrying a hydroxyl group. These results led to the conclusion that bridging the 2′-amino and 5″-hydroxyl groups with a carbonyl group occurred to give **8**.

A similar kind of cyclic carbamate formation as that of **8** was also observed[9] on fluorination of tetrakis-(*N*-benzyloxycarbonyl)sporaricin B with the DAST reagent. The tendency to form the carbamates in these cases will be ascribed[9] to the basic nature of fluoride ion liberated during the reactions.

Furthermore, the above conclusion was chemically confirmed. A *N*-protected derivative (**16**, *loc. cit.*) of **17** was treated with 1,1-dimethoxycyclohexane in a usual manner[10] to give the 4′,6′-*O*-cyclohexylidene derivative (**18**), which could not be triphenylmethylated by reaction with chlorotriphenylmethane (in pyridine, 50 °C, 2 d). On the other hand, 4′,6′-*O*-cyclohexylidene derivative (**19**) of **1** gave a mono-*O*-triphenylmethyl (5″-*O*-triphenylmethyl) derivative (**20**) by the same treatment. This result clearly shows that the 5″-hydroxyl group of **17** is blocked. Another structural confirmation was given from the alkaline hydrolysis (2 M aqueous NaOH,** 80 °C, 2 h) of **17**, when lividomycin B was obtained almost quantitatively.

** 1 M=1 mol dm^{-3}.

a) In ppm downfield from TMS calculated as $\delta^{TMS}=\delta^{dioxane}+67.4$ ppm. b) Assignments were made based on the data of lividomycin B reported,[6] and also on selective proton decoupling on the following cases (H-4, δ=3.44; H-5: 3.6—3.7, H-6: 3.23, H-1′: 5.21, H-1″: 5.33, H-3″: 4.40, H-1‴: 4.93, H-3‴: 4.00, H-5‴: $\approx$3.85). c,d) Figures indicated by the same character may be interconvertible.

Antibacterial spectra of **9** and **15** were shown in Table 2 in comparison with those of lividomycin B and 5″-deoxylividomycin B[2] (**21**). The substitutions of the 5″-hydroxyl group with halogens were shown to diminish the antibacterial activity as in the case of 5″-deoxygenation, although the fluoro compound (**9**) showed the best activity among them (**9**, **15**, **21**). The macrocyclic compound **17** was devoid of antibacterial action.

Experimental

General. ^{1}H-NMR spectra were recorded at 250 MHz at 30 °C (unless otherwise stated) in the FT mode with a Bruker WM 250 spectrometer. ^{13}C-NMR spectra were recorded at 30 °C (unless otherwise stated) in the FT mode with a Bruker WM 250 spectrometer operating at 62.5 MHz. Mass spectrum (field desorption) was recorded with a Hitachi M-80H spectrometer. Thin-layer chromatography (TLC) was performed on precoated Kieselgel 60, Merck. For column chromatography, silica-gel (Wakogel C-200) was used.

*1,3,2′,2‴,6‴-Pentakis(*N*-benzyloxycarbonyl)-5″-O-triphenylmethyllividomycin B (2).* A mixture of **1**[2] (5.0 g) and phenylboronic acid (0.94 g, 2 mol equiv. for **1**) in dry pyridine

(50 ml) was kept for 2 h at room temperature. Chlorotriphenylmethane (5.5 g) was added, and after standing the solution overnight at room temperature, another chlorotriphenylmethane (5.5 g) was added, and the solution was kept overnight at 37 °C. Addition of methanol (15 ml) and 1,3-propanediol (1 ml) followed by concentration gave a residue, which was extracted with chloroform. The chloroform-soluble products were separated by silica-gel column chromatography with chloroform-methanol (30: 1→25: 1→20: 1→10: 1, gradually changed) to give a solid each of **4**, 548 mg (8%), **3**, 136 mg (2%), **2**, 4.30 g (72%), and the starting material (**1**) recovered, 293 mg (6%).

Compound **2**: $[\alpha]_D^{20}+37°$ (*c* 1, chloroform); Found: C, 64.91; H, 5.87; N, 4.48%. Calcd for $C_{82}H_{89}N_5O_{23}$: C, 65.11; H, 5.93; N, 4.63%.

Compound **3**: $[\alpha]_D^{20}+23°$ (*c* 1, chloroform); Found: C, 64.89; H, 5.97; N, 4.63%. Calcd for $C_{82}H_{89}N_5O_{23}$: C, 65.11; H, 5.93; N, 4.63%.

Compound **4**: $[\alpha]_D^{20}+15°$ (*c* 1, chloroform); Found: C, 69.34; H, 5.92; N, 3.87%. Calcd for $C_{101}H_{103}N_5O_{23}$: C, 69.12; H, 5.92; N, 3.99%.

*6,4′,6′,2″,3‴,4‴-Hexa-*O*-acetyl-1,3,2′,2‴,6‴-pentakis(*N*-benzyloxycarbonyl)-5″-*O*-triphenylmethyllividomycin B (**5**).* A mixture of **2** (3.9 g), acetic anhydride (20 ml) and pyridine (40 ml) was kept at room temperature overnight. Another acetic anhydride (10 ml) was added and the mixture was kept further overnight. Concentraction gave a syrup, which was dissolved in chloroform. The organic solution was washed with 0.4 M aqueous potassium hydrogensulfate solution, then aqueous sodium hydrogencarbonate solution (saturated), dried over sodium sulfate, and concentrated. The residue was reprecipitated from hexane-chloroform to give a solid of **5**, 4.22 g (93%), $[\alpha]_D^{20}+31°$ (*c* 1, chloroform); ^{1}H-NMR ($CDCl_3$): $\delta=1.83$, 1.97, 2.00, 2.07, 2.08, and 2.17 (each 3H s, Ac).

Found: C, 63.72; H, 5.86; N, 3.88%. Calcd for $C_{94}H_{101}N_5O_{29}$: C, 63.97; H, 5.77; N, 3.97%.

*6,4′,6′,2″,3‴,4‴-Hexa-*O*-acetyl-1,3,2′,2‴,6‴-pentakis(*N*-benzyloxycarbonyl) lividomycin B(**6**).* A solution of **5** (4.22 g) in a mixture of acetic acid-acetone-water (2: 1: 1, 120 ml) was heated at 60 °C for 6 h. Concentration gave a syrup, which was dissolved in chloroform, and the organic solution was washed with aqueous sodium hydrogencarbonate (saturated). The product obtained by concentration was purified by silica-gel column chromatography with benzene-ethyl acetate (1: 1→2: 3) to give a solid of **6**, 3.52 g (97%), $[\alpha]_D^{20}+25°$ (*c* 1, chloroform); ^{1}H-NMR ($CDCl_3$): $\delta=1.93$ (3H), 2.00(6H), 2.05(3H), 2.08(3H), and 2.16(3H) (each s, Ac).

Found: C, 59.30; H, 5.75; N, 4.50%. Calcd for $C_{75}H_{87}N_5O_{29}$: C, 59.17; H, 5.76; N, 4.60%.

*6,4′,6′,2″,3‴,4‴′-Hexa-*O*-acetyl-1,3,2′,2‴,6‴-pentakis(*N*-benzyloxycarbonyl)-5″-deoxy-5″-fluorolividomycin B (**7**) and 6,4′,-6′,2″,3‴,4‴-Hexa-*O*-acetyl-1,3,2‴,6‴-tetrakis(*N*-benzyloxycarbonyl)-2′-*N*: 5′-*O*-carbonyllividomycin B (**8**).* To a cold (−15 °C) solution of **6** (300 mg) in dichloromethane (3.5 ml), was added diethylaminosulfur trifluoride (0.1 ml) and the solution was kept at the temperature for 15 min, then at room temperature for 30 min. After addition of water (0.1 ml) followed by standing for 30 min, chloroform (30 ml) was added, and the solution was washed with aqueous sodium hydrogencarbonate (saturated) and water, dried (sodium sulfate), and concentrated to give a syrup. On checking by TLC with benzene-ethyl acetate(1: 1), the syrup showed two spots at R_f 0.2 (**8**) and 0.5 (**7**) (*cf.* **6**: R_f 0.3). Separation of the products by silica-gel column chromatography with benzene-ethyl acetate (3: 2→2: 3) gave a solid each of **7**, 83 mg (28%) and **8**, 171 mg (61%).

Compound **7**: $[\alpha]_D^{20}+28°$ (*c* 1, chloroform); ^{1}H-NMR ($CDCl_3$): $\delta=1.77$, 1.92, 2.00, 2.06, 2.09, and 2.18 (each 3H s, Ac), 7.35 (25H s, $NHCO_2CH_2C_6\underline{H}_5$); Found: C, 58.87; H, 5.91; N, 4.49; F, 1.39%. Calcd for $C_{75}H_{86}FN_5O_{28}$: C, 59.09; H, 5.67; N, 4.59; F, 1.25%.

Compound **8**: $[\alpha]_D^{20}+43°$ (*c* 1, chloroform); ^{1}H-NMR ($CDCl_3$): $\delta=1.88$ (3H), 1.97 (6H), 2.06 (6H), and 2.13 (3H) (each s, Ac), 7.35 (20H s, $NHCO_2CH_2C_6\underline{H}_5$); Found: C, 57.46; H, 5.62; N, 4.87%. Calcd for $C_{68}H_{79}N_5O_{28}$: C, 57.74; H, 5.63; N, 4.95%.

*5″-Deoxy-5″-fluorolividomycin B (**9**).* A solution of **7** (80 mg) in a mixture of methanol (8 ml) and 28% aqueous ammonia (9 ml) was kept at room temperature overnight. Concentration gave a syrup (de-*O*-acetyl product), which was dissolved in 0.2 M methanolic hydrochloric acid (4 ml), and the solution was hydrogenated under atmospheric pressure of hydrogen in the presence of palladium catalyst for 2 h. The resulting crude product was purified by chromatography first on a column of Dowex 50 W (NH_4^+ form) (the charged column was washed with water, then 1 M aqueous ammonia was used as the developer), and then on a column of CM-Sephadex C-25 (0→0.1→0.3 M aqueous ammonia was used as the developer) to give pure **9** as the carbonate, 29 mg (83%), $[\alpha]_D^{20}+48°$ (*c* 1, water); ^{1}H-NMR (20% ND_3 in D_2O): $\delta=1.18$ (1H q, $J=12.5$ Hz H-2ax), 1.59 (1H q, $J=11.5$ Hz, H-3′ ax), 1.95 (1H dt, $J=12.5$, ≈4.5, ≈4.5 Hz, H-2eq), 2.01 (1H dt, $J=11.5$, ≈4.5 ≈4.5 Hz, H-3′eq) 4.95 (1H d, $J_{1''',2'''}\approx1.3$ Hz, H-1‴), 5.22 (1H d, $J_{1',2'}=3.5$ Hz, H-1′), 5.34 (1H d, $J_{1'',2''}\approx1.7$ Hz, H-1″). The signals for the AB part of an ABX system (A,B=H-5″a, −5″b; X=H-4″) were divided into two groups (each octet) centered at $\delta=4.62$ and 4.81, respectively. The upper quartet of each group was constituted from couplings of 11.5 ($=J_{5''a,5''b}$) and 4 Hz ($=J_{5''a,4''}$), and the lower quartet, from couplings of 11.5 and 2.5 Hz ($=J_{5''b,4''}$) (each 1H in total). These two groups were separated by 47 Hz ($=J_{5''a,F}=J_{5''b,F}$).

Found: C, 43.93; H, 7.17; N, 10.89; F, 2.58%. Calcd for $C_{23}H_{44}FN_5O_{12}\cdot H_2CO_3$: C, 43.43; H, 6.99; N, 10.55; F,

2.87%.

6,4′,6′,2″,3‴,4‴-Hexa-O-acetyl-1,3,2′,2‴,6‴-pentakis(N-benzyloxycarbonyl)-5″-O-tosylliuidomycin B (12). *From* **10**[2]: A solution of **10** (282 mg) in a mixture of acetic acid–acetone–water (2: 1: 1, 6 ml) was heated for 3 h at 60 °C. Concentration gave a syrup, which was dissolved in chloroform and the solution was washed with aqueous sodium hydrogencarbonate (saturated). Silica-gel column chromatography of the crude product with chloroform, then with chloroform–methanol (10: 1) gave a solid of **11**, 242 mg (91%), $[\alpha]_D^{20}+29°$ (*c* 1, chloroform); ^{1}H-NMR ($CDCl_3$): $\delta=2.32$ (3H s, Ts).

A mixture of **11** (136 mg) and acetic anhydride (2 ml) in dry pyridine (4 ml) was kept overnight at room temperature. Concentration gave a syrup, which was purified by silica-gel column chromatography with benzene–ethyl acetate (3: 1) to give a solid of **12**, 144 mg (90%), $[\alpha]_D^{20}+27°$ (*c* 1, chloroform); ^{1}H-NMR ($CDCl_3$): $\delta=1.80$, 1.87, 2.00, 2.06, 2.08, 2.21 (each 3H s, Ac); 2.42 (3H s, CH_3 of Ts).

Found; C, 58.45; H, 5.56; N, 4.13; S, 1.87%. Cacld for $C_{82}H_{93}N_5O_{31}S$: C, 58.74; H, 559; N, 4.18; S, 1.91%.

From **6**: A mixture of **6** (72 mg) and *p*-toluenesulfonyl chloride (105 mg) in pyridine (3.5 ml) was kept overnight at 37 °C. Concentration gave a syrup, which was purified as described above for **12** to give a solid of **12**, 72 mg (91%).

4′,6′-O-Benzylidene-1,3,2′,2‴,6‴-pentakis(N-benzyloxycarbonyl)-5″-chloro-5″-deoxylividomycin B (13). Prepared from **10**[2] (500 mg) with lithium chloride (580 mg) in *N,N*-dimethylformamide (95 °C, overnight) in the presence of calcium sulfate (Drierite), according to Watanabe[6]; a solid, 422 mg (93%), $[\alpha]_D^{20}+59°$ (*c* 1, chlornform).

1,3,2′,2‴,6‴-Pentakis(N-benzyloxycarbonyl)-5″-chloro-5″-deoxylividomycin B (14). A solution of **13** (300 mg) in a mixture of acetone–water–acetic acid (1: 1: 2, 6 ml) was heated at 60 °C for 3 h. Concentration gave a syrup, which was purified by silica-gel column chromatography first with chloroform, then with chloroform–methanol (10: 1) as the developers to give a solid of **14**, 261 mg (92%), $[\alpha]_D^{20}+35°$ (*c* 1, chloroform).

Found: C, 57.74; H, 5.76; N, 5.15; Cl, 2.95%. Calcd for $C_{63}H_{74}ClN_5O_{22}\cdot H_2O$: C, 57.90; H, 5.71; N, 5.36; Cl, 2.71%.

5″-Chloro-5″-deoxylividomycin B (15). A solution of **14** (monohydrate, 102 mg) in 0.2 M methanolic hydrochloric acid (10 ml) was hydrogenated in the presence of palladium black under atmospheric pressure of hydrogen for 2 h and the product was purified as described for **9** to give a solid of **15** as the carbonate, 48 mg (88%), $[\alpha]_D^{20}+51°$ (*c* 1, water); ^{1}H-NMR (20% ND_3 in D_2O): $\delta=1.18$ (1H q, $J=12.5$ Hz, H-2ax), 1.59 (1H q, $J=11.5$ Hz, H-3′ax), 1.94 (1H dt, $J=12.5$, ≈4.5, ≈4.5 Hz, H-2eq), 2.00 (1H dt, $J=11.5$, ≈4.5, ≈4.5 Hz, H-3′eq), 4.93 (1H d, $J_{1'',2''}\approx2$ Hz, H-1‴), 5.25 (1H d, $J_{1',2'}=3.5$ Hz, H-1′), 5.32 (1H d, $J_{1'',2''}\approx2$ Hz, H-1″).

Found: C, 41.69; H, 6.77; N, 9.79; Cl, 5.35%. Calcd for $C_{23}H_{44}ClN_5O_{12}\cdot H_2CO_3\cdot H_2O$: C, 41.29; H, 6.93; N, 10.03; Cl 5.07%.

1,3,2‴,6‴-Tetrakis(N-benzyloxycarbonyl)-2′-N:5″-O-carbonyllividomycin B (16). A solution of **8** (103 mg) in a mixture of methanol–28% aqueous ammonia (1: 1, 10 ml) was kept at room temperature overnight. The solid precipitated was filtered, washed with aqueous methanol (1: 1), and dired to give a solid of **16**, 78 mg (92%), $[\alpha]_D^{20}+41°$ (*c* 1, dimethyl sulfoxide).

Found: C, 57.57; H, 5.73; N, 5.85%. Calcd for $C_{56}H_{67}N_5O_{22}$: C, 57.87; H, 5.81; N, 6.03%.

2′-N:5″-O-Carbonyllividomycin B (17). A suspended mixture of **16** (70 mg) in 70% aqueous oxolane (10 ml) containing 0.1 ml of 2 M aqueous hydrochloric acid was hydrogenated in the presence of palladium black under atmospheric pressure of hydrogen at room temperature for 3 h with occasional additions of 0.1 M aqueous hydrochloric acid (2 ml×2). Filtration of the reaction mixture followed by concentration of the filtrate gave a residue, which was chromatographed on CM-Sephadex C-25 column with water, then with 0.3 M aqueous ammonia to give a ninhydrin-positive solid of **17**, 33 mg (71%), $[\alpha]_D^{20}+86°$ (*c* 1, water); ν_{max}^{KBr} 1700 cm^{-1}; *m/z* 626 (M^+), 600, 466 ($M^+-C_6H_{12}N_2O_3$), 440 ($600^+-C_6H_{12}N_2O_3$). ^{1}H-NMR (20% ND_3 in D_2O measured at 4 °C): $\delta=1.19$ (1H q, H-2a), 1.74 (1H q, H-3′a), 1.95 (1H apparent dt, H-2e), 2.09 (1H m, H-3′e), 2.6—3.05 (5H, H-1, 3, 2‴, 6‴a, 6‴b), 3.29 (1H t, H-6), 3.47 (1H t, H-4), 4.01 (1H t, H-3‴), 4.10 (1H d, H-5″a), 4.14 (1H dd, H-4″), 4.31 (1H d, H-2″), 4.51 (1H dd, H-3″; broad HOD signal at $\delta=4.2$—4.6 was suppressed by homogated decoupling), 4.97 (1H apparent s, H-1‴), 5.15 (1H dd, with small splittings, H-5″b), 5.96 (1H s, H-1″), 6.08 (1H d, H-1′); $J_{1,2a}=J_{2a,2e}=J_{2a,3}\approx12$, $J_{1,2e}=J_{2e,3}\approx4$, $J_{3,4}=J_{4,5}=J_{5,6}=J_{6,1}\approx9.5$, $J_{1'2'}=3.5$, $J_{2',3'a}=J_{3'a,3'e}=J_{3'a,4'}\approx12$, $J_{1'',2''}=0$, $J_{2'',3''}=4$, $J_{3'',4''}=9$, $J_{4'',5''a}=0$, $J_{4'',5''b}\approx4$, $J_{5''a,5''b}=13$, $J_{1'',2''}\approx1$, $J_{2'',3''}=J_{3'',4''}\approx3$ Hz. Irradiation of H-3″ caused H-2″ d to s, and H-4″ dd to a narrow-space d; irr. of H-5″ b caused H-4″ dd→a large-space d, and H-5″ a d →s; irr. at $\delta=2.7$ (H-3) caused H-2a q→t, H-2e dt→dd, and H-4 t→d; irr. at $\delta=2.87$ (H-1) caused H-2a q→t, H-2e dt→dd, and H-6 t→d; irr. at $\delta=2.95$ (H-2‴) caused H-3‴ t→d; irr. at $\delta=3.63$ (H-2′, 4′, 4‴) caused H-3‴ t→d, H-1′ d→s, H-3′a q→d, and H-3′e q→d, the latter two doublets forming an AB quartet.

^{13}C-NMR (20% ND_3 in D_2O, measured at 4 °C): 31.7 (C-3′), 36.1 (C-2), 42.2 (C-6‴), 50.3, 50.6, 51.3, 53.6 (C-2‴), 60.2, 61.4 (C-6′), 64.7, 69.1 (C-4‴), 71.4 (C-3‴), 72.8, 73.6, 74.5, 76.4, 77.0 (C-5‴), 78.1, 80.3, 81.4, 92.8, 98.9, 107.2, 157.8 (C=0) ppm.

Found: C, 40.42; H, 6.56; N, 9.21%. Calcd for $C_{24}H_{43}N_5O_{14}\cdot 2H_2CO_3\cdot H_2O$: C, 40.68; H, 6.43; N, 9.12%.

1,3,2‴,6‴-Tetrakis(N-benzyloxycarbonyl)-2′-N:5″-O-carbonyl-4′,6′-O-cyclohexylidenelividomycin B (18). To a solution of **16** (50 mg) in *N,N*-dimethylformamide (10 ml) were added 1,1-dimethoxycyclohexane (0.5 ml) and anhydrous *p*-toluenesulfonic acid (10 mg) and the mixture was heated at 30 °C under reduced pressure (10—15 Torr, 1 Torr≈133.322 Pa) for 6 h. Addition of aqueous sodium hydrogencarbonate (saturated, 0.5 ml) followed by evaporation gave a residue, which was washed with water. The water-insoluble product was washed with ether to give a solid, 51 mg (94%), $[\alpha]_D^{20}+38°$ (*c* 1, dimethyl sulfoxide).

Found: C. 59.33; H, 6.03; N, 5.12%. Calcd for $C_{62}H_{75}N_5O_{22}\cdot H_2O$: C, 59.08; H, 6.16; N, 5.56%.

1,3,2′,2‴,6‴-Pentakis(N-benzyloxycarbonyl)-4′,6′-O-cyclohexylidenelividomycin B (19). Compound **1** was treated with 1,1-dimethoxycyclohexane as described for **18** to give a solid of **19** in 90% yield, $[\alpha]_D^{20}+46°$ (*c* 1, chloroform).

Found: C, 60.96; H, 6.12; N, 5.01%. Calcd for $C_{69}H_{83}N_5O_{23}\cdot 1/2\,H_2O$: C, 60.96; H, 6.23; N, 5.15%.

1,3,2′,2‴,6‴-Pentakis(N-benzyloxycarbonyl)-4′,6′-O-cyclohexylidene-5″-O-triphenylmethyllividomycin B (20). Compound **19** (202 mg) was treated with chlorotriphenylmehtane (200 mg) in pyridine (4 ml) at 50 °C for 2 d. After usual work-up, the product was chromatographed on a silica-gel column with chloroform–methanol (30: 1) to give a solid of **20**, 158 mg (66%), $[\alpha]_D^{20}+28°$ (*c* 1, chloroform).

Found: C, 65.93; H, 6.20; N, 4.09%. Cacld for $C_{88}H_{97}N_5O_{23}\cdot H_2O$: C, 65.62; H, 6.20; N, 4.35%.

The authors wish to thank Mr. Saburo Nakada of Keio University for the microanalysis, Dr. Hiroshi Naganawa of Institute of Microbial Chemistry for measurement of a mass spectrum, and Miss Yukiko Suzuki of our Institute for measurements of NMR spectra. Thanks are also due Miss Junko Yamamoto of our Institute for preparation of the manuscript.

Studies on the β-Turn of Peptides. II.[1] Syntheses and Conformational Properties of *N*-(2,4-Dinitrophenyl)tetrapeptide *p*-Nitroanilides Related to the β-Turn Part of Gramicidin S

Kazuki SATO,* Masao KAWAI, and Ukon NAGAI

Mitsubishi-Kasei Institute of Life Sciences, 11 Minamiooya, Machida, Tokyo 194

(Received December 24, 1982)

N-(2,4-Dinitrophenyl)tetrapeptide *p*-nitroanilides related to the β-turn part of gramicidin S were synthesized and subjected to CD measurements. The β-turn preference of the tetrapeptide derivatives had correlation with the antibiotic activities of the gramicidin S analogs containing similar tetrapeptide sequences at their β-turn part. So, conformational preference of partial sequences of gramicidin S analogs seem to play a significant role for determining their biological activities.

Gramicidin S (GS) is a cyclic decapeptide antibiotic with the primary structure *cyclo*(–L-Val[1]–L-Orn[2]–L-Leu[3]–D-Phe[4]–L-Pro[5]–L-Val[1']–L-Orn[2']–L-Leu[3']–D-Phe[4']–L-Pro[5']–). Conformation of GS consists of the intramolecular antiparallel β-form with four hydrogen bonds between L-Val and L-Leu residues and two β-turns (type II') around the D-Phe–L-Pro sequences (Fig. 1).[2] The characteristic feature of the conformation is the orientation of side chains in which the charged L-Orn side chains are on one side and the hydrophobic L-Val and L-Leu side chains on the other side of the molecule. The conformation of GS is considered to be stabilized not only by the four intramolecular hydrogen bonds but also by the stable β-turn formed by D-Phe–L-Pro sequence. Izumiya *et al.* summarized the antibacterial activities of many GS analogs.[3] The activities of GS analogs were correlated to their conformations.[4] For example, the activity and the population of GS-type β-sheet conformer were in the order of GS≈[D-Ala[4,4']]-GS> [Gly[4,4']]-GS≫[L-Ala[4,4']]-GS≈0.[5] It is of interest to study β-turn preference of the amino acid sequences at the corner positions of GS analogs.

In the previous paper, we gave an outline of a new method to study the β-turn conformation of linear tetrapeptides.[1] *N*-(2,4-Dinitrophenyl)tetrapeptide *p*-nitroanilides (Dnp–tetrapeptide–pNA's)[6] exhibited characteristic CD spectra above 300 nm when they took β-turn conformations (Fig. 2). The Cotton effects were considered to be due to the interaction of the two terminal chromophores and the magnitude of the Cotton effects were shown to reflect the β-turn preference of the peptides.

This paper deals with the details of synthesis and conformational properties of Dnp–tetrapeptide–pNA's related to the β-turn part of GS and with the relation between the activity of GS analogs and the β-turn preference of their partial peptide sequences.

To study the effect of amino acid residues at 4,4'- and 5,5'-positions of GS on β-turn preference, we synthesized tetrapeptide derivatives having a general structure of Dnp–L-Leu–X–Y–L-Val–pNA (**7a—o**) for all the combinations of X=D-Ala, Gly, or L-Ala and Y=L-Pro, L-Leu, Gly, Sar, or D-Leu (Fig. 3). Boc–L-Pro–L-Val–pNA (**1a**) was prepared by EDC coupling of Boc–L-Pro–OH and H–L-Val–pNA, and deprotected with hydrogen chloride in formic acid, to afford H–L-Pro–L-Val–pNA·HCl (**2a**·HCl). Mixed anhydride coupling of Boc–L-Leu–OH and H–D-Ala–OEt afforded Boc–L-Leu–D-Ala–OEt (**3a**), which was converted into Boc–L-Leu–D-Ala–N_2H_3 (**4a**) with hydrazine hydrate. Compounds **2a** and **4a** were coupled by azide method to afford Boc–L-Leu–D-Ala–L-Pro–L-Val–pNA (**5a**), which was converted into the Dnp derivative, Dnp–L-Leu–D-Ala–L-Pro–L-Val–pNA (**7a**), by deprotection and subsequent treatment with 1-fluoro-2,4-dinitrobenzene. Homogeneities of the synthetic peptides were confirmed by thin-layer chromatography and elemental

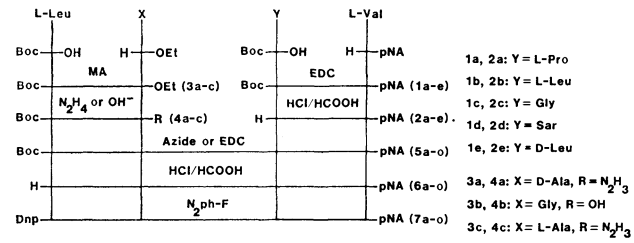

Fig. 3. Syntheses of Dnp–tetrapeptide–pNA's (**7a—o**).

analysis. Compounds **7b—o** were prepared by a similar manner as described for the synthesis of **7a** except for the steps of saponification of **3b** to **4b** and EDC coupling of **4b** and **2a—e** to afford **5f—j**.

Figures 4, 5, and 6 show CD spectra of synthetic peptides with a general structure of Dnp-L-Leu-D-Ala-Y-L-Val-pNA (**7a—e**), Dnp-L-Leu-Gly-Y-L-Val-pNA (**7f—j**), and Dnp-L-Leu-L-Ala-Y-L-Val-pNA (**7k—o**), respectively. From these figures it can be seen that the highest Cotton effects were observed

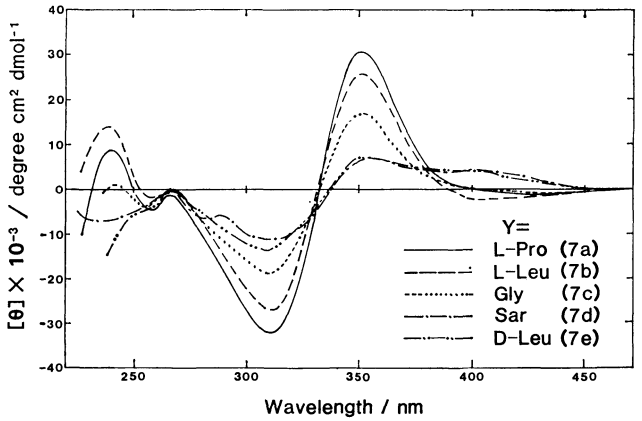

Fig. 4. CD spectra of Dnp-L-Leu-D-Ala-Y-L-Val-pNA's (**7a—e**) in MeOH.

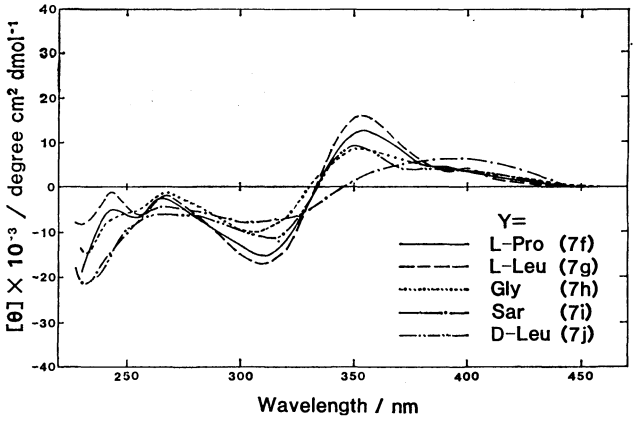

Fig. 5. CD spectra of Dnp-L-Leu-Gly-Y-L-Val-pNA's (**7f—j**) in MeOH.

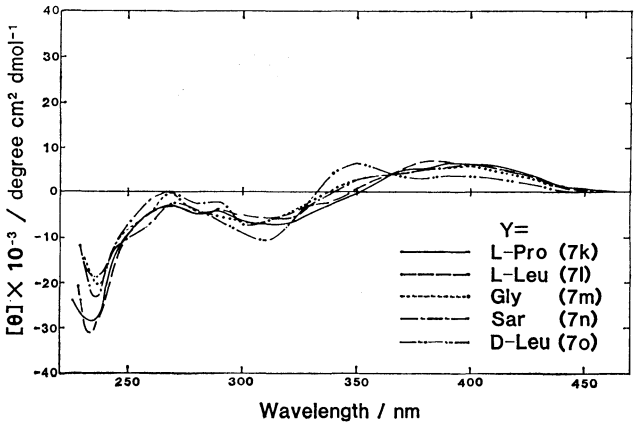

Fig. 6. CD spectra of Dnp-L-Leu-L-Ala-Y-L-Val-pNA's (**7k—o**) in MeOH.

in the case of X-Y=D-Ala-L-Pro or D-Ala-L-Leu. When Y is fixed to L-Pro or L-Leu, D-Ala at X position gives the highest CD band indicating strong β-turn preference of the sequence, Gly at X position gives weaker bands, and L-Ala gives negligibly small $[\theta]_{350}$-values suggesting their random conformations. The tendency is also kept though at a lower level when Y is fixed to Gly. Antibiotic activities of the GS analogs containing the tetrapeptide sequences with L-Pro at the Y position have good correlation with their β-turn preference described above. Though the synthesis of [D-Ala$^{4,4'}$, L-Leu$^{5,5'}$]-, [Gly$^{4,4'}$, L-Leu$^{5,5'}$]-, and [L-Ala$^{4,4'}$, L-Leu$^{5,5'}$]-GS have not been reported, we can predict that they would have the similar tendency of their conformations and antibiotic activities to that of [D-Ala$^{4,4'}$]-, [Gly$^{4,4'}$]-, and [L-Ala$^{4,4'}$]-GS.[5]

In the series of compounds with D-Ala at X position, both **7b** and **7c** with D-Ala-L-Leu and D-Ala-Gly sequences, respectively, also showed large Cotton effects as well as **7a**, but **7d** and **7e** showed very weak Cotton effects (Fig. 4). The L-Pro residue at 5,5'-positions of GS can be replaced by a variety of amino acids (Gly, L-Leu, L-Phe, Sar) without loss of activity.[3] So, high activities of [L-Leu$^{5,5'}$]-GS[7] and [Gly$^{5,5'}$]-GS[8] can be explained by the β-turn preference of their amino acid sequences at the corner positions. When Sar was at Y position, an exception was observed. Compounds **7d** with D-Ala-Sar sequence showed weak Cotton effects, though [Sar$^{5,5'}$]-GS was as active as GS.[9] The β-turn conformer in linear tetrapeptide **7d** would be decreased because of *cis-trans* isomerism of D-Ala-Sar bond. There has been no report about GS analogs having D-amino acid at 5,5'-positions, but D-D sequences at 4-5- and 4'-5'-positions are considered not to prefer the β-turn conformation and the analogs not to show any antibiotic activity since weak Cotton effects were observed in **7e** with D-Ala-D-Leu sequence. When the second residue X was L-Ala, all the derivatives (**7k—o**) showed weak Cotton effects (Fig. 6). This afford the reason why L-amino acid is not suitable for 4,4'-positions of GS, regardless of the configurations of the amino acid residues at 5,5'-positions. All the compounds with Gly at X position (**7f—j**) showed intermediate Cotton effects between the corresponding D-Ala (**7a—e**) and L-Ala (**7k—o**) compounds, respectively (Fig. 5), and the similar effect of substitution at the Y position on the CD spectra was observed.

Next, in order to study the contribution of L-Val$^{1,1'}$ and L-Leu$^{3,3'}$ residues of GS to the β-turn conformation, we synthesized Dnp-Gly-D-Ala-L-Pro-Gly-pNA (**12**), in which both of L-Leu and L-Val residues of **7a** were replaced with Gly residues. Figures 7 and 8 show the synthetic scheme and CD spectrum of **12**, respectively. Cotton effect of **12** was as strong as that of **7a**, indicating that **12** took the β-turn conformation to a high extent. The result agreed well with the fact that both L-Leu and L-Val residues had no significant role for stabilizing the conformation of GS but contributed to the activity of GS with the hidrophobic side chains.[3] For example, [L-Ala$^{1,1',3,3'}$]-GS had similar conformation to that of

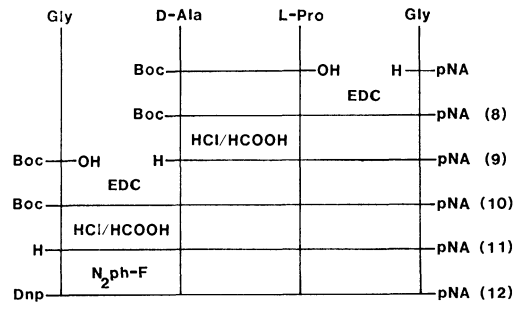

Fig. 7. Synthesis of Dnp–Gly–D-Ala–L-Pro–Gly–pNA (**12**).

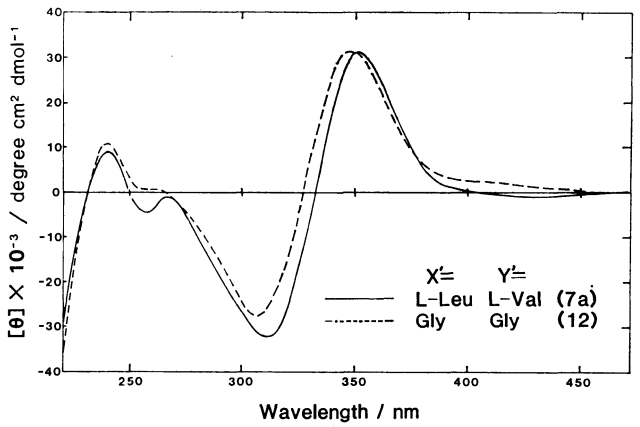

Fig. 8. CD spectra of Dnp–X'–D-Ala–L-Pro–Y'–pNA's (**7a** and **12**) in MeOH.

GS but had no antibiotic activity.[10]

Conformational properties of a number of tetrapeptides related to the corner position sequence of GS analogs were analyzed by means of CD spectra of their Dnp-pNA derivatives. From the results, following conclusion can be drawn: (i) D-Amino acids are suitable choice for the 4,4'-position residues. They can be replaced by Gly, but L-amino acids are not allowed for β-turn conformation at the corner. (ii) L-Pro seems the best choice of the 5,5'-residues for β-turn. It can be replaced by other L-amino acid, but D-amino acids are not allowed. (iii) The terminal L-Leu and L-Val residues of the tetrapeptide sequence seem to have no significant effect for stabilizing β-turn in the series of compounds. As a whole, structure-activity relationship of GS analogs concerning the 4,4'- and 5,5'-positions can be explained largely on the basis of β-turn preference of the tetrapeptide sequences at the corner positions.

Experimental

Synthesis of Peptides. All the melting points were measured on a Yanagimoto micro melting point apparatus and uncorrected. TLC's were carried out on Merck silica gel 60 F_{254} plates with the following solvent systems: R_f^1, $CHCl_3$-MeOH (5:1, v/v); R_f^2, $CHCl_3$-MeOH-AcOH (95:5:1, v/v); R_f^3, *n*-BuOH-AcOH-pyridine-H_2O (4:1:1:2, v/v). Optical rotations were measured on an Union automatic polarimeter PM-201. Yields, physical constants, and the results of elemental analyses of the synthetic peptides are summarized in Table 1.

*Boc-L-Pro-L-Val-pNA (**1a**).* To a chilled solution of Boc-L-Pro-OH (1.08 g, 5 mmol) and H-L-Val-pNA (1.19 g, 5 mmol) in DMF (20 ml) was added EDC·HCl (0.96 g, 5 mmol) at 0 °C. The mixture was stirred at 0 °C for 1 h and at room temperature overnight, evaporated *in vacuo*, and the residue was dissolved in EtOAc. The solution was washed successively with 10% citric acid, 4% $NaHCO_3$, and water, dried (Na_2SO_4), and evaporated. The residue was solidified by addition of ether and petroleum ether, and the product was recrystallized from EtOH-ether-petroleum ether; yield, 1.76 g (81%).

Compounds **1b**—**e** were prepared by a similar manner to that described for **1a**.

*H-L-Pro-L-Val-pNA·HCl (**2a**·HCl).* Compound **1a** (434 mg, 1 mmol) was dissolved in 0.1 M (1 M = 1 mol dm^{-3}) hydrogen chloride in formic acid (15 ml). The solution was allowed to stand at room temperature for 30 min and evaporated *in vacuo* to leave an oil which was crystallized by addition of ether; yield, 345 mg (93%).

Compounds **2b**—**e** were prepared by a similar manner to that described for **2a**.

*Boc-L-Leu-D-Ala-OEt (**3a**).* To a chilled solution of Boc-L-Leu-OH (2.31 g, 10 mmol) and TEA (1.4 ml, 10 mmol) in THF (20 ml) was added isobutyl chloroformate (1.31 ml, 10 mmol) at −15 °C. After 10 min, a chilled solution of H-D-Ala-OEt·HCl (1.54 g, 10 mmol) and TEA (1.4 ml, 10 mmol) in $CHCl_3$ (20 ml) was added. The reaction mixture was treated by a similar manner to that described for the preparation of **1a**; yield, 2.58 g (78%).

Boc-L-Leu-Gly-OEt (**3b**)[11] and Boc-L-Leu-L-Ala-OEt (**3c**)[11] were prepared as described for **3a**; yield, 85 and 81%, respectively.

*Boc-L-Leu-D-Ala-N_2H_3 (**4a**).* A solution of **3a** (1.65 g, 5 mmol) and hydrazine hydrate (4.85 ml, 100 mmol) in DMF (10 ml) was allowed to stand at room temperature for 3 d. The solution was evaporated and the residue was dissolved in $CHCl_3$ (100 ml). The solution was washed with water, dried (Na_2SO_4), and evaporated. The residue was solidified by addition of ether, and recrystallized from MeOH-ether; yield, 1.33 g (84%).

*Boc-L-Leu-Gly-OH (**4b**).* A solution of **3b** (1.58 g, 5 mmol) in a mixture of MeOH (20 ml) and 1 M NaOH (6 ml) was allowed to stand at room temperature for 1 h. After the addition of water (50 ml), the solution was concentrated at low temperature and acidified with 10% citric acid. The oily product was extracted with EtOAc and the solution was washed with H_2O, dried (Na_2SO_4), and evaporated. The residue was solidified by addition of ether and petroleum ether, and recrystallized from MeOH-ether-petroleum ether; yield, 1.38 g (96%).

Compound **4c** was prepared as described for **4a**.

*Boc-L-Leu-D-Ala-L-Pro-L-Val-pNA (**5a**).* To a solution of **4a** (158 mg, 0.5 mmol) in DMF (2 ml) were added 2 M hydrogen chloride in EtOAc (0.75 ml) and isopentyl nitrite (0.071 ml, 0.5 mmol) at −60 °C. After being left to stand at −20 °C for 20 min, the solution was cooled again to −60 °C and neutralized with TEA (0.21 ml, 1.5 mmol). To the mixture was added a chilled solution of **2a**·HCl (196 mg, 0.5 mmol) and TEA (0.07 ml, 0.5 mmol) in DMF (2 ml). The reaction mixture was stirred at 0 °C for 4 d and then evaporated. The residue was dissolved in EtOAc and the solution was washed successively with 10% citric acid, 4% $NaHCO_3$, and water, dried (Na_2SO_4), and evaporated. The residue was solidified by addition of ether and petroleum ether. The crude product (287 mg, 93%) dissolved in MeOH (2 ml) was applied to a column (3×170 cm) of Sephadex LH-20 and eluted with MeOH.

a) *c* 1, MeOH, unless otherwise stated. b) ½ H_2O. c) ¼ H_2O. d) H_2O. e) *c* 1, DMF.

The fractions with the desired product detected by UV absorption and TLC were collected and evaporated, and the oily residue was solidified by addition of ether and petroleum ether and recrystallized from MeOH-ether-petrolum ether; yield, 248 mg (80%).

Compounds **5b**—**e** and **5k**—**o** were prepared as described for **5a**.

Boc-L-*Leu*-*Gly*-L-*Pro*-L-*Val*-*pNA* (**5f**). This compound was prepared from **4b** (144 mg, 0.5 mmol) and **2a** (167 mg, 0.5 mmol) as described for **1a**; yield, 202 mg

(67%).

Compounds **5g**—**j** were prepared as described for **5f**.

H-L-Leu-D-Ala-L-Pro-L-Val-pNA·HCl (6a·HCl). Compound **5a** (118 mg, 0.2 mmol) was dissolved in 0.1 M hydrogen chloride in formic acid (3 ml). The solution was allowed to stand at room temperature for 30 min and evaporated to leave an oil. The product was used for the next reaction without further treatment; yield was quantitative.

Compounds **6b**—**o** were prepared as described for **6a**.

Dnp-L-Leu-D-Ala-L-Pro-L-Val-pNA (7a). To a solution of **6a**·HCl (106 mg, 0.2 mmol) and TEA (0.084 ml, 0.6 mmol) in DMF (2 ml) was added N_2ph-F (74 mg, 0.4 mmol). The reaction mixture was stirred at room temperature for 3 h and evaporated *in vacuo*. The residue dissolved in $CHCl_3$ (5 ml) was applied to a column (1.8×20 cm) of silica gel 60 (Merck) and the column was washed with $CHCl_3$. The desired product was eluted with a mixture of $CHCl_3$ and MeOH (5: 1, v/v). The fractions containing the desired product were evaporated to leave an oil, which was crystallized by addition of ether and recrystallized from MeOH-ether; yield, 91 mg (67%).

Compounds **7b**—**o** were prepared as described for **7a**.

Boc-D-Ala-L-Pro-Gly-pNA (8). This was prepared from Boc-D-Ala-L-Pro-OH[5] (573 mg, 2 mmol) and H-Gly-pNA (390 mg, 2 mmol) as described for **1a**; yield, 713 mg (77%).

H-D-Ala-L-Pro-Gly-pNA·HCl (9·HCl). This was prepared from **8** (463 mg, 1 mmol) as described for **2a**; yield, 292 mg (73%).

Boc-Gly-D-Ala-L-Pro-Gly-pNA (10). This was prepared from Boc-Gly-OH (88 mg, 0.5 mmol) and **9**·HCl (200 mg, 0.5 mmol) as described for **1a**; yield, 174 mg (67%).

H-Gly-D-Ala-L-Pro-Gly-pNA·HCl (11·HCl). This was prepared from **10** (104 mg, 0.2 mmol) as described for **6a**·HCl; yield was quantitative; R_f^1 0.12, R_f^3 0.68.

Dnp-Gly-D-Ala-L-Pro-Gly-pNA (12). This was prepared from **11**·HCl (91 mg, 0.2 mmol) as described for **7a**; yield, 84 mg (72%).

CD Measurements. CD spectra were recorded on a JASCO spectropolarimeter model J-20 or J-40 in a 0.5 mM MeOH solution at room temperature (23±2 °C) unless otherwise stated.

The authors wish to express their thanks to Professor Tatsuo Miyazawa and to Dr. Tsutomu Higashijima of The University of Tokyo for helpful discussion. Thanks are also due to the members of Analytical Department of System Engineering Laboratory, Mitsubishi-Kasei Industries Ltd., for elemental analyses.

Kinetics of Ion-exchange on Sodium-, Calcium-, and Magnesium Saturated Kaolinites

Om Prakash BANSAL

Chemical Laboratories, Dharam Samaj College, Aligarh-202001, India

(Received December 1, 1981)

The kinetics of Na^+, Ca^{2+}, Mg^{2+}, and Ni^{2+} ion-exchange reactions on kaolinite have been studied at four temperatures 16, 26, 36, and 46 °C. The mechanism of ion-exchange is a film diffusion as shown by interruption and ϕ tests. Kinetics parameters *e.g.* diffusion coefficients, half time of exchange, energies of activation have also been calculated and were used to predict the theoretical behaviour (mechanism) of Ni^{2+} exchange on the kaolinite surface.

The replacement of cations is one of the most important phenomenon which controls the storage capacity of a soil for plant nutrient elements. Thermodynamics is a powerful tool to study conditions at equilibrium but kinetics have an important role in the study of the mechanism of ion-exchange. A relatively little consideration has been given to the kinetics of ion-exchange. Various studies of the kinetics of ion-exchange on zeolites,[1] synthetic ion-exchangers[2-6] have been reported. Information in regard to kinetics of exchange in clays and soils is meagre.[7,8]

Nickel is an important trace element in plant nutrition and its formulation as $NiCl_2$ are often used as fungicide in soils. Kaolinite mineral is a 1:1 layer silicate, and occurs commonly in soils. It is a dioctahedral mineral with triclinic symmetry. The structure of the mineral involves hydrogen bonding between adjacent layers, which prevents the expansion of kaolinite beyond its basal spacing. Clay minerals constitute the most important reactive surface of soil providing reactive sites at the edges, corners, interlayer, and interlattice positions.[9-11] In the present report I have summarized my studies on the kinetics of exchange between Ni(II) and Na-, Ca-, Mg-kaolinites.

Experimental

Kaolinite used in these studies was a monomineralic standard from Bath, South Carolina. Less than 2 μm clay fraction was purified by sedimentation and centrifugation. It was converted into chloride free Na-kaolinite and then into Ca- and Mg-saturated kaolinites by ion exchange technique. The concentration of the mineral suspension ranged from 11.0 to 12.2 g dm^{-3}. The base exchange capacity (BEC) of the Na-kaolinite was 135 μequiv. g^{-1} clay, determined by Ganguli's method.[12] For the determination of the BEC of Ca- and Mg-kaolinite[13] a known volume of suspension was treated with a mixture consisting of 1 mol dm^{-3} $NiCl_2$ in 0.0001 mol dm^{-3} HCl (keeping in contact for 24 h) and the amount of calcium and magnesium released was estimated by titration with EDTA, giving the value 110 and 118 μequiv. g^{-1} clay respectively.

The ion-exchange reaction between Na-, Ca-, and Mg-kaolinites and Ni^{2+} can be represented as

$$2\overline{Na}^{+} + Ni^{2+} \rightleftharpoons \overline{Ni}^{2+} + 2Na^{+}, \quad (1)$$

$$\overline{M}^{2+} + Ni^{2+} \rightleftharpoons \overline{Ni}^{2+} + M^{2+}, \quad (2)$$

(where $M^{2+}=Ca^{2+}$ or Mg^{2+}).

Kinetic Measurement. Rates of exchange were measured by limited bath technique, for it, 10 cm^3 of appropriate clay suspensions were treated with 15 cm^3 of 0.002 mol dm^{-3} nickel solution. The solutions were kept in contact for appropriate time intervals (2—60 min) of time. The contents were then centrifuged and the concentration changes in the suspensions were determined by EDTA titrations in case of Ni^{2+}, Ca^{2+}, and Mg^{2+} ions and flame photometry in Na^+. The values of fractional attainment of equilibrium (F) at 16, 26, 36, and 46 °C were calculated using the expression:

$$F = \frac{\text{The amount of } Ni^{2+} \text{ exchange at time } t}{\text{The amount of exchange at infinite time (equilibrium)}}. \quad (3)$$

To perform the interruption test above procedure was applied for another set at two concentrations of Ni^{2+} and after a specified time intervals (10 and 30 min) the clay particles were removed and quickly separated from adhering solution by centrifugation. After 5 min they were re-immersed in their solutions and the experiment continued (Fig. 1). The concentration of Ni^{2+} at different time intervals at 16, 26, 36, and 46 °C was estimated before and after interruption.

The nature of the rate determining step was confirmed by calculating the value of function ϕ[14] as the values of are $\gg 1$ for film diffusion control and $\ll 1$ for particle diffusion. The values of ϕ are given by the following relation

$$\phi = \frac{X\bar{D}\delta}{CDr_o}(5+2\alpha_B^A), \quad (4)$$

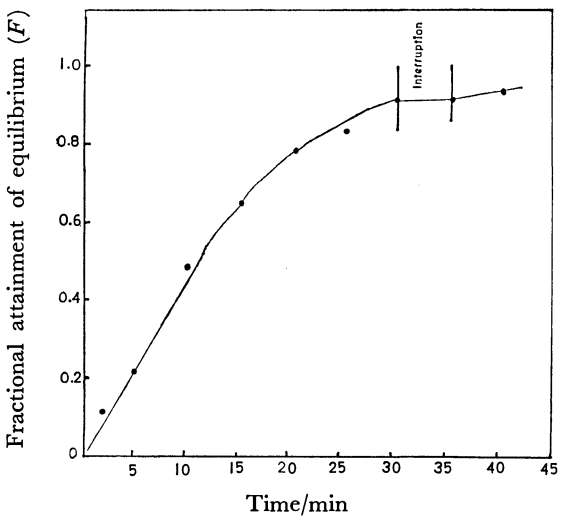

Fig. 1. The effect of interruption test on the rate of Ni^{2+} ion-exchange on Na-kaolinite at 16 °C after 30 min.

where X=concentration of fixed ionic groups taken as equivalent to a maximum exchange, C=concentration of counter ions in solution mequiv. cm^{-3}, $\overline{D}$=interdiffusion coefficient in the ion-exchanger, D=interdiffusion coefficient in the film, r_0=radius of clay particle (10^{-4} cm), δ=film thickness (10^{-2} cm in unstirred solution) and α_B^A the separation factor.

The separation factor α_B^A was calculated from the equivalent ionic fractions, using the equation

$$\alpha_{Na}^{Ni^{2+}} = \overline{X}_{Ni}(X_{Na})^2/X_{Ni}(\overline{X}_{Na})^2, \quad (5)$$

$$\alpha_{M^{2+}}^{Ni^{2+}} = \overline{X}_{Ni}X_M/\overline{X}_M X_{Ni}, \quad (6)$$

where $\overline{X}$=equivalent ionic fraction in clay phase and X= mole fraction in solution phase.

The values of $\overline{D}_i$ (effective diffusion coefficient in the clay phase) were calculated from the relationship:

$$\overline{D}_i = Br_0^2/\pi^2. \quad (7)$$

The value of B was obtained from the plots of Bt *vs.* t (Fig. 2), the Bt values have been obtained from the suitable values of 'F' as tabulated by Reichenberg.[15] The values of D_i were calculated by Wheeler's[16] relation $\overline{D}_i = D_{i_\varepsilon}/2$ which has a resemblance (within $\pm 15\%$ error) with the values obtained by Mackie and Meares[17] relation $\overline{D}_i = D_i[\varepsilon/(2-\varepsilon)]^2$, where ε is pore volume of clay. The fractional pore volume of Na-, Ca-, and Mg-kaolinites were determined from bulk and particle densities.

The half time of exchanges ($t_{1/2}$) were calculated from the expression

$$t_{1/2} = 0.23\delta r_0 X/DC. \quad (8)$$

Since temperature effect has been very useful in providing an insight into the theory of all rate processes, the energetics of Ni^{2+} ion-exchange on clay were examined by temperature studies. The diffusion coefficient (D_i) can be related to temperature by the following expression[18]

$$D_i = D_0 \exp(-E_a/RT). \quad (9)$$

The activation energy (E_a) was calculated by the linear relationships of $\log D_i$ *vs.* $1/T$ and D_0 by extrapolation (Fig. 3). The values are given in Table 2.

The enthalpy (ΔH_a), entropy (ΔS_a) and free energy (ΔG_a) of activation were calculated using the expressions[19]

$$\Delta H_a = E_a - RT, \quad (10)$$

$$D_0 = 2.72d^2kT/h \exp(\Delta S_a/R), \quad (11)$$

$$\Delta G_a = \Delta H_a - T\Delta S_a,$$

where d=ionic jump distance (5×10^{-8} cm), k=Boltzmann constant, h=Planck constant, R=gas constant and T=ab-

solute temperature. The values obtained are recorded in Table 2.

Results and Discussion

To study the mechanism of ion-exchange both experimental and theoretical approach were used. The interruption test was applied as an experimental test to decide whether the kinetics are controlled by film diffusion or particle diffusion.[20] The results are presented in Fig. 1. These results showed no change in rate of exchange after 5 min interruption, indicate that the rate determining step is governed by film diffusion at all four temperatures studied. This is because that no concentration gradient was found to exist in the clay and the rate depended on the concentration differences across the film.

The values of ϕ calculated for the Na–Ni, Ca–Ni, and Mg–Ni exchanges at all four experimental temperatures were more than unity indicating that rate is controlled by film diffusion ($\phi \gg 1$) in all the case studied.[14] Table 1 also showed that order of exchange is Na->Ca->Mg-kaolinites as of ϕ values.

A plot of F (fractional attainment) *vs.* t (see Fig. 4) showed that Ni^{2+} exchange on Na-, Ca-, and Mg-kaolinites was characterized by a rapid initial exchange followed by subsequent falling in the rate as the concentration gradient diminished in the film. Rate of exchange also increases with rise in temperature from 16 to 46 °C, which may be due to the fact that mobility of Ni^{2+} increased with increase in temperature.

The values of half time of exchange ($t_{1/2}$) (Table 1) are in the order Mg>Ca>Na, and decreased with increase in time of contact, indicating that the rates of exchange as characterized by half time increased with time of contact (as half time decreases rate of exchange increases). With rise in temperature the $t_{1/2}$ values decreased, confirming the earlier inference.

An observation of Table 1 revealed that the rate of diffusion in the aqueous phase was much faster than in the clay phase at the all four temperatures in all the three exchanges studied and the order was Na->Ca->Mg-kaolinites. The diffusion coefficients increased with rise in temperature as well as with passage of time *i.e.* the rate of exchange of Ni^{2+} ion on Na-, Ca-, and Mg-kaolinites increased with time

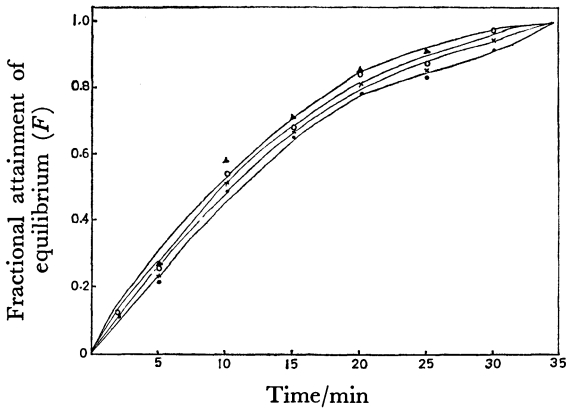

Fig. 4. A plot of fractional attainment of equilibrium (F) *vs.* t for Ni^{2+} ion-exchange on Na-kaolinite at 16 (●), 26 (×), 36 (○), and 46 °C (▲).

and temperature and the order of exchange was Na->Ca->Mg-kaolinite.

An examination of Table 2 showed an E_a range from 7.66 to 13.40 kJ/mol, and were in order Mg>Ca->Na-kaolinites. The magnitude of E_a showed that Ni^{2+} exchange is a film diffusion controlled process without steric hindrance.[21,22] The values of activation energies also confirm that order of exchange is Na->Ca->Mg-kaolinites. The low values of ΔH_a, support the physical type of adsorption involving ion-exchange process. The values of ΔH_a (see Table 2) decreased with rise in temperature or the rate of exchange of the Ni^{2+} increases as temperature of reaction went up, an inference in accordance with earlier conclusions. The negative values of ΔS_a (Table 2) pointed to a greater order produced during the activation process.[6,23] It may be due to formation of activated complex between Ni^{2+}, and Na-, Ca-, or Mg-kaolinites, resulting in a more orderly structure of Ni^{2+} ions on clay surface due to association or fixation and immobilisation of Ni^{2+} ions with consequent loss in the degrees of freedom of the system during the process. The free energy of activation (ΔG_a) (Table 2) for the exchange reaction had a tendency to increase with rise in temperature and were in order Na-<Ca-<Mg-kaolinites, indicating that the activated complexes of Ni^{2+} ions with Na-, Ca-, or Mg-kaolinites

were not very stable and probability of formation of activated complex further decreased with rise in temperature.[24] The increase in rate of exchange of Ni^{2+} with rise in temperature was due to large number of ions passing into an activated state with a less stable configuration.[23]

The author is thankful to Dr. S. S. Gupta, Principal, D. S. College, Aligarh (India) for necessary facilities and encouragement and to U. G. C., New Delhi for financial assistance.

Studies on Synthetic Inorganic Ion Exchangers. VI. Synthesis and Characterization of Iron(III) Molybdate as an Ion Exchanger

Pritam Singh THIND,* Harbans SINGH, and (Miss) PARVEEN
Department of Chemistry, Guru Nanak Dev University, Amritsar(Pb.), India

(Received September 16, 1981)

Six preparations of iron(III) molybdate were obtained at various pH values under different conditions. They all possess cation exchange properties. The preparation, obtained by reaction of iron(III) nitrate with ammonium molybdate at pH 1 with 24 h refluxing, is the stablest and has an ion exchange capacity of 1.39 mequiv. g^{-1}. The mole ratio of Fe: Mo is 1: 3. Distribution coefficients for many metal ions were determined on this preparation. On the basis of pH titrations, chemical and thermal analyses, and infrared and Mössbauer spectra, a tentative structure of iron(III) molybdate is proposed.

Since the classical work of Amphlett[1] numerous inorganic ion exchangers have been prepared and used for several possible applications.[2-5] Recently, some studies on iron-based exchangers have been reported.[6-8] A search of literature showed that no studies have so far been reported on iron(III) molybdate. In the present report we summarize synthesis and ion-exchange and physicochemical properties of iron(III) molybdate as a new ion exchanger.

Experimental

Reagents. Iron(III) nitrate (B. D. H.) and ammonium molybdate (Reanal, Hungary) were used for the synthesis. All other materials used were of analytical grade.

Apparatus. A thermostated oven, digital pH meter, TGA instrument (Fertilizer Corp. of India, Sindhri), Spectrochem 2000 (Hungary), Specol Spectrophotometer, MBS-35 (ECIL) Mössbauer apparatus were used for drying samples, pH measurements, thermal analysis, infrared and visible spectrophotometric measurements, and Mössbauer studies, respectively.

Synthesis. Six samples of iron(III) molybdate were prepared by mixing 0.05 mol dm^{-3} solution of iron(III) nitrate with 0.05 mol dm^{-3} solution of ammonium molybdate under the conditions given in Table 1. The pH of the mixed solution was adjusted by adding either acid or alkali solution. The precipitate obtained was filtered and washed with demineralized water. The gel was dried at 40 °C. The dried product broke down into granules when immersed in water. The material was converted into the hydrogen form by treating with 0.1 mol dm^{-3} nitric acid for 24 h with occasional shaking and intermittent supply of the acid. The material was then washed free of acid with demineralized water and was finally dried at 40 °C.

Ion-exchange Capacity. The ion-exchange capacity of a sample of iron(III) molybdate was determined by taking 1.0 g of the H-form exchanger in a glass column having a glass wool support. The column after being washed with demineralized water was eluted with 1.0 mol dm^{-3} sodium nitrate solution. A 400 cm^3 portion of the effluent was collected at a rate of 15—20 drops/min. The H^+ concentration of the effluent was determined by titration with a standard sodium hydroxide solution.

Ion-exchange capacity for some uni- and bivalent cations on sample 6 (Table 1) was also determined.

Chemical Analysis. One-half gram of sample was treated with 5 cm^3 of each of nitric and hydrochloric acids until it was dissolved, and diluted with water. Iron(III) was precipitated as iron(III) hydroxide and estimated. The molybdenum in the filtrate was precipitated by 8-quinolinol and determined as $MoO_2(C_9H_6ON)_2$.

Chemical Stability. Exchanger samples (0.2 g) were kept separately for 24 h in 20 cm^3 of each of various solvents, such as nitric, oxalic, hydrochloric, and acetic acids, dimethylformamide, and dioxane, and then filtered. The iron and molybdenum in the filtrate were determined spectrophotometrically by the 1,10-phenanthroline and thiocyanate methods, respectively.

pH Titration. pH titration on 0.2 g of iron(III) molybdate was performed by using 0.1 mol dm^{-3} standard solutions of lithium, sodium, and potassium hydroxides, aqueous ammonia, and their respective salts according to the method of Topp and Pepper.[9] The volume ratio of alkali to its salt solution was selected in such a way that the total volume of 20 cm^3 was to be maintained in each conical flask.

Sorption Studies. Distribution Coefficients of nineteen metal ions were determined on iron(III) molybdate in 50% ethanol. The loading of metal ions for the system was less than 3% of the working ion-exchange capacity of sample after 24 h of equilibrating period. The equation used for the calculation is,

TABLE 1. CONDITIONS OF PREPARATION AND PROPERTIES OF IRON(III) MOLYBDATES

Sample	Conditions of synthesis				Properties					
	Molarity of reagents mixed		Mixing ratio	pH	Refluxing time/h	Color in H-form	Ion exchange capacity for Na^+/mequiv. g^{-1}	Composition	Solubility in water/μg in 20 cm^{-3}

4	0.05	0.05	2:1	1.0	8	Yellow	1.55	1:3.2	220	720
5	0.05	0.05	2:1	1.0	12	Yellow	1.52	1:3.1	240	520
6	0.05	0.05	2:1	1.0	24	Yellow	1.39	1:3.0	150	360

Table 2. Ion exchange capacity of iron(III) molybdate sample 6

Metal ion	Salt used	Solution	Hydrated radii/Å	pH	Ion exchange capacity/mequiv. g^{-1}
Li^+	$LiNO_3$	(1.0 mol dm^{-3})	3.40	6.05	1.34
Na^+	NaCl	(1.0 mol dm^{-3})	2.76	5.50	1.39
K^+	KNO_3	(1.0 mol dm^{-3})	2.32	6.90	1.47
Mg^{2+}	$Mg(NO_3)_2$	(0.5 mol dm^{-3})	7.00	6.00	1.80
Ca^{2+}	$Ca(NO_3)_2$	(0.5 mol dm^{-3})	6.30	6.40	1.86
Sr^{2+}	$Sr(NO_3)_2$	(0.5 mol dm^{-3})	—	6.50	1.92

$$K_d/cm^3\,g^{-1} = \frac{I-F}{F} \times \frac{20}{0.2},$$

where I and F are the volumes of the 0.025 mol dm^{-3} EDTA solutions required for titration before and after the equilibration, respectively. The total volume of the equilibrating solution was 20 cm^3 and the amount of exchanger taken was 0.2 g.

Structural Studies. Infrared absorption spectra of iron(III) molybdate in an H-form exchanger dried at 40, 100, 200, 600, or 700 °C were obtained in KBr media.

Thermogravimetric analysis of iron(III) molybdate in H-form exchanger was performed at a heating rate of 10 °C min^{-1}.

Mössbauer spectra of iron(III) molybdate in H-form exchanger dried at 40, 200, or 500 °C were obtained by using a ^{57}Co source at a constant acceleration. Sodium pentacyanonitrosyl ferrate(III) was used as the reference for the value of isomer shift to be reported.

Results and Discussion

Ion-exchange capacities of various samples prepared by refluxing are comparatively low. This is associated with the fact that stabler materials were obtained by refluxing the mother liquor. In order to investigate the working capacity of the exchanger, capacities for some uni- and bivalent cations were determined (Table 2). In general, exchange capacities for uni- and bivalent ions are found to be in the orders: $K^+ > Na^+ > Li^+$ and $Sr^{2+} > Ca^{2+} > Mg^{2+}$. These results show that ion exchange capacity depends upon hydrated radii of metal ions of the same group. We used the equilibrium in the solution phase where hydrated radii play an important role, so that the ion exchange capacity in the same group is found to decrease as the (hydrated) radii of ingoing cations increase.

A Chemical analysis of various samples (Table 1) revealed that Fe:Mo is 1:3. The results in Table 1 show that sample 6 is the stablest among the six samples. Its solubility in most of the common solvents is quite low as seen from Table 3. It is also observed that the chemical stability increases with increasing refluxing time. The pH titrations performed (Fig. 1) show that iron(III) molybdate behaves as a weak bifunctional cation exchanger.

Results of Mössbauer studies are given in Table 4. Originally, it was thought that one of the fundamental requirements of the Mössbauer effect expected to become actually applicable would be that Mössbauer atoms should be bound in a crystal lattice. It was, however, shown in an earlier paper[10] that there is a high possibility of observing the effect in amorphous substances (or in solid solution).

Table 3. Solubility of ion(III) molybdate sample 6 in various solvents

Solvent		Solubility/μg in 20 cm^3	
		Fe	Mo
HNO_3	(1.0 mol dm^{-3})	460	288
$H_2C_2O_4$	(1.0 mol dm^{-3})	1540	1220

Fig. 1. pH titrations of iron (III) molybdate by added salt method.

Table 4. Isomer shift and quardrupole splitting of various inorganic iron compounds

Compound	Drying temp/°C	δ/mm s^{-1}	ε/mm s^{-1}
Iron(III) molybdate	R.T.[a)]	0.68	0.48
Iron(III) molybdate	200	0.61	0.59
Iron(III) molybdate	500	0.64	0.00
α-FeOOH	R.T.	0.53	0.00
β-FeOOH	R.T.	0.43	0.62
γ-FeOOH	R.T.	0.48	0.54
δ-FeOOH	R.T.	0.45	0.00

a) R.T.: Room temperature.

The Mössbauer spectrum of iron(III) molybdate in the H-form exchanger dried at 40 °C consists of a sharp and well defined doublet with δ=0.68 mm/s and

$\varepsilon=0.48$ mm/s at room temperature. These parameters characterize an iron atom in the "high spin tetravalent" state incorporated in the distorted octahedral site in the gel structure. The room temperature spectrum of the iron(III) molybdate dried at 200 °C shows a doublet which indicates a more covalent bonding and less distorted sites. Further, raising the drying temperature to 500 °C gives an unresolved single broad peak indicating a motional narrowing magnetic spectrum at room temperature. Further heat treatment results in growth of small particles in large crystallites as indicated by the isomer shift.

The results given in Table 4 allow a comparison of Mössbauer parameters of iron(III) molybdate dried at 40 °C with those of α,β,γ, and δ-FeOOH, which rules out the existence of α- and δ-FeOOH in the condensed phase with molybdate on the basis of quadrupole splitting. The value of quadrupole splitting for iron(III) molybdate which is close to that for γ-FeOOH, indicates the presence of the latter in the former. The product dried at 200 °C contains β-FeOOH, whereas the product dried at 500 °C contains iron in the form of α-Fe_2O_3.

The infrared spectra of the samples dried at 100, 200, 600, and 700 °C show that, as the drying temperature is raised, intensities of the bands at 3300 and 1625 cm^{-1} are decreased and ultimately caused to disappear at 600 °C due to complete removal of the water and OH groups present in the ion exchanger. Hence the product dried at 700 °C is simply a mixed oxide of iron and molybdenum, as confirmed by a single infrared band at 850 cm^{-1} due to the metal-oxygen bond.

In the light of the above discussion, chemical analysis, pH titrations, thermal analysis, Mössbauer spectra, and infrared absorption studies, a tentative structure of iron(III) molybdate can be worked out.

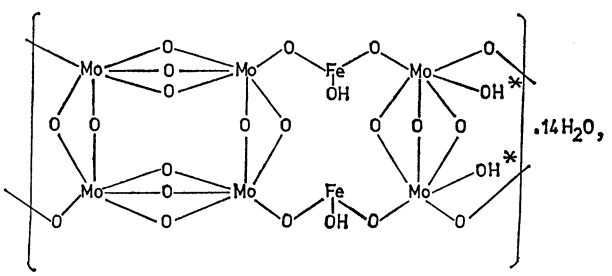
Results of the chemical analysis show that the ratio Fe:Mo in sample 6 iron(III) molybdate is 1:3. The thermogravimetric analysis shows that the loss in weight due to water molecules amounts to an extent of 20%. Since on heating oxides of iron and molybdenum are formed in the same ratio, the empirical formula for the mixed oxide should be $Fe_2O_3 \cdot 6MoO_3$ with a formula weight 1023.

If n is the number of moles of water per mole of mixed oxide, then

$$\frac{1800n}{(1023+18n)} = 20 \text{ or } n=24,$$

and the formula weight is 1275.

Thus, the structure of iron(III) molybdate may be



where the asterisked hydrogens are exchangeable protons.

Table 5. Distribution coefficients (K_d) for cations on iron(III) molybdate

Cation	K_d/cm^3 g^{-1}	Cation	K_d/cm^3 g^{-1}
Mg^{2+}	21	Ni^{2+}	17
Zn^{2+}	21	Cd^{2+}	20
Ba^{2+}	50	Bi^{3+}	400
Sr^{2+}	316	Al^{3+}	45
Ca^{2+}	80	La^{3+}	12
Pb^{2+}	650	Nd^{3+}	29
Cu^{2+}	15	Th^{4+}	80
Mn^{2+}	9	V^{5+}	121
Hg^{2+}	155	Ce^{4+}	54
Co^{2+}	239		

Table 6. Separation factors of some pairs of cations on iron-based synthetic inorganic ion exchanges

Separaction factor	Iron(III) molybdate	Iron(III) antimonate	Iron(III) phosphate
α_{Pb}^{Zn}	30.4	8.2	10.5
α_{Pb}^{Ba}	13.0	2.0	6.3
α_{Pb}^{La}	56.6	0.0	—
α_{Pb}^{Cu}	42.2	0.0	7.8
α_{Pb}^{Ni}	36.9	1.2	5.7
α_{Sr}^{Hg}	15.3	1.4	—
α_{Sr}^{Mn}	33.6	2.9	1.9
α_{Sr}^{Cd}	15.8	0.6	—

Iron(III) molybdate acts selectively for Pb^{2+}, Co^{2+}, Sr^{2+}, Hg^{2+}, and Bi^{3+}. For many other cations K_d values are quite low, as shown in Table 5. This makes it possible to separate the above cations from a number of other cations.

The order of selectivity for various cations is found to be: $Pb^{2+}>Bi^{3+}>Sr^{2+}>Co^{2+}>Hg^{2+}>V^{5+}>Th^{4+}=Ca^{2+}>Ce^{4+}>Ba^{2+}>Al^{3+}>Nd^{3+}>Zn^{2+}=Mg^{2+}=Cd^{2+}>Ni^{2+}>Cu^{2+}=La^{3+}>Mn^{2+}$.

On the basis of the selectivity sequence, separation factors were calculated (Table 6), and in all the cases separation factors on iron(III) molybdate are found to be greater than the other iron-based ion exchangers.

Thanks are due to Professor Harjit Singh and Dr. Ajaib Singh Brar for providing the research facilities and performing Mössbauer studies, respectively.

The Catalytic Isomerization of Butenes over a Sulfuric Acid-Graphite Intercalation Compound

Susumu Tsuchiya,* Masao Hara, and Hayao Imamura

Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Ube, Yamaguchi 755

(Received August 23, 1982)

Synopsis. The relative rate constants and the activation energies of the isomerization of butenes over sulfuric acid-graphite intercalation compound have been measured. *cis*-2-Butene is more reactive than 1-butene. The reaction profile shown on the triangular graph is of the *trans*-convex type.

Much attention has been paid to all the characteristic properties of graphite intercalation compounds, and the catalytic properties of the compounds have been extensively investigated in various reaction systems.[1-2] In this study, the interest has centered on the catalytic characteristics of the sulfuric acid–graphite intercalation compound (H_2SO_4–GIC), the isomerization of butenes being employed as a model reaction.

Experimental

A usual flow-type system with a by-pass at atmospheric pressure was employed to follow the reaction, nitrogen being used as the diluent. The H_2SO_4-GIC, the catalyst, prepared beforehand in a vacuum system similar to that described previously,[3] was fixed in the system.

The nitrogen stream with butene as a reactant was flowing only through the by-pass in the meantime; then it was diverted to flow through the reactor. The flowing rate of the nitrogen was *ca.* 40 cm³/min, the amount of catalyst used being 0.10 g for each run. The reaction mixtures were analyzed by means of gas chromatography with a column packing of 2,4-dimethylsulfolane on Uniport C.

The butenes were obtained from the Tokyo Kasei Kogyo Co., Ltd.; their purity was confirmed by gas chromatography to be more than 99%. Before each run, the catalyst was treated with a nitrogen stream at 373 K for 2 h, and the experimental results were well reproducible.

Results and Discussion

The double-bond migration and the *cis-trans* isomerization of butenes took place over H_2SO_4–GIC. The graphite does not show any catalytic activity for the reaction under the same experimental conditions. The skeletal isomerization could not be observed, as was reported previously.[3] No gaseous hydrocarbon other than butenes could be detected in the reaction mixtures under the present experimental conditions.

The rate of the isomerization of butenes was almost proportional to the pressure of the reactant. From the rates of reaction and the selectivity ratios, all six of the relative rate constants and the activation energies of reaction were determined in a manner similar to that described previously.[4] The results are shown in Fig. 1. It is of much interest that *cis*-2-butene is more reactive than 1-butene.

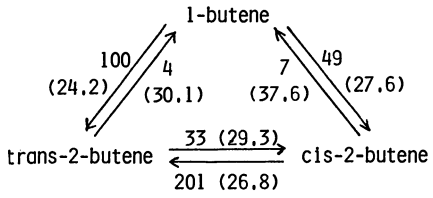

Fig. 1. Relative rate constants at 300 K and activation energies (kJ/mol) bracketed.

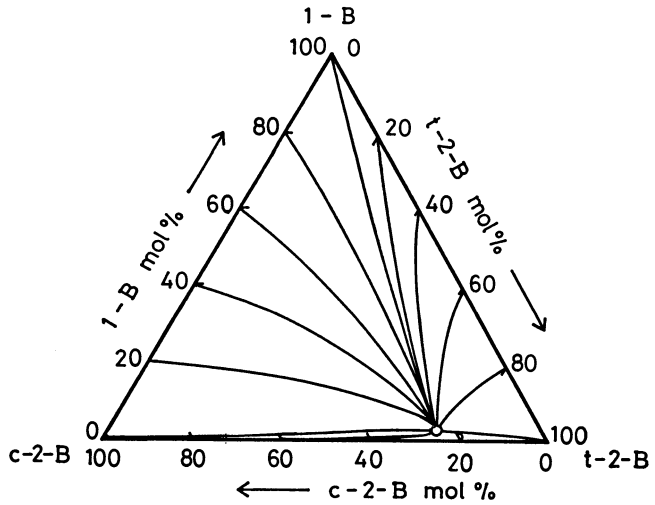

Fig. 2. Reaction profile of isomerization of butenes over H_2SO_4-GIC at 300 K.

Figure 2 shows the reaction paths calculated at 300 K. The triangular graph thus represents one of the catalytic characteristics of H_2SO_4–GIC for the isomerization of butenes. Since the rate equations employed are expressed on the basis of the sum of the forwards and backwards reactions, and since the time variable, t, is eliminated in the graph, the compositions of butenes can be shown from the initial to the equilibrium state. The curves, which originate from the left side of the triangle, bend convexly to the right. The profile may be named the "*trans*-convex type," which is entirely different from that obtained in the isomerization over KC_8.[4]

The following mechanisms for the isomerization of butenes have been proposed for different catalytic systems.[5] (1) A hydride-addition mechanism for metals, (2) a carbenium-ion mechanism for acid catalysts, and (3) an allylic mechanism for basic catalysts. When the isomerization takes place with a carbenium-ion mechanism, the selectivity ratio, *cis*/*trans*, is about unity, while 1/*cis* and 1/*trans* are less than 3.0,

usually less than 1.0. The selectivity ratios obtained in the present may be in agreement with a carbenium-ion mechanism.

The observed order of the relative rate constants of isomerization, *cis*-2-butene>1-butene>*trans*-2-butene, however, does not agree with what would be expected from a carbenium-ion mechanism. Accordingly, it can not necessarily be concluded that the active sites of H_2SO_4–GIC have same kind of acidic properties as hitherto reported.[6] The further discussion on the points will have to await new results, which may clarify the reaction mechanism.

This work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture for which the authors' thanks are due.

The Crystal and Molecular Structure of 3,4-Dichloronitrobenzene

Shigekazu KUMAKURA* and Yoshinobu KUROISHI

Department of Chemistry, Saitama University, 255 Shimo-okubo, Urawa 338

(Received October 5, 1982)

Synopsis. $C_6H_3Cl_2NO_2$, F. W. = 192.0, tetragonal, $I4_1/a$, $a=28.094(12)$, $c=3.838(6)$ Å, $V=3030$ Å^3, $Z=16$, $D_x=1.68$ Mg m^{-3}, μ(Mo $K\alpha$) = 0.8 mm^{-1}. Refinement with 1093 diffractometer data gave a final R value of 0.07. The molecule is practically planar except for the nitro group, the plane of which is inclined at 8.8° to the benzene plane. The two C–Cl bond distances are approximately equal to each other. The intermolecular Cl(2)···O(2^{11}) contact of 3.095 Å is remarkably short.

Our previous NQR study showed the equivalent character of the two C–Cl bonds in the title compound (abbreviated hereafter as DCNB), which are not equivalent with respect to the nitro substituent.[1] The crystal-structure analysis and a CNDO/2 calculation of DCNB have been carried out in order to clarify the C–Cl bond character in this compound.

Experimental

Commercial material was purified by recrystallization from a benzene solution. The crystals of DCNB are colorless needles. A crystal with dimensions of $0.3\times0.3\times0.4$ mm^3, obtained by cutting off a part of the specimen used for the NQR measurement and sealed in a Lindemann glass capillary, was used for the intensity measurement. The intensities of 1183 independent reflections were measured on a Rigaku automated four-circle diffractometer in $\omega/2\theta$ scan mode, using Mo $K\alpha$ radiation monochromated by a graphite crystal. Three standard reflections, monitored every 50 reflections, showed a steady decline in intensity; at the end of the data collection, the maximum reduction reached 13%. The intensity data were then put on a common scale with reference to the standard reflections. 1093 reflections with $|F_o|\geq3\sigma(|F_o|)$ were used for the analysis. No correction was made for absorption or extinction.

The positions of the Cl atoms were located from a sharpened Patterson map, and the remaining non-H atoms, by Fourier methods. A block-diagonal least-squares refinement using anisotropic temperature factors reduced the R value to 0.09. At this stage, a difference synthesis revealed all the hydrogen atoms in plausible positions. Further refinement was carried out including the isotropic H atoms. The final R value was 0.07 for 1093 observed reflections. A weighting scheme of $w=1$ if $|F_o|\geq5.5$ and $w=0.3$ otherwise was employed. The final atomic parameters and their standard deviations are listed in Table 1.[2] The atomic scattering factors were taken from the *International Tables for X-Ray Crystallography*.[3] The calculations were carried out on HITAC 5020E and 8800/8700 computers at the Computer Center of the University of Tokyo and on TOSBAC 3400 and HITAC 8250 computers at Saitama University.

C(6)	1976(2)	1292(2)	2234(18)	4.17

Results and Discussion

The bond lengths and angles of DCNB are shown in Fig. 1, together with the atomic numbering scheme. All the atoms of DCNB are practically coplanar except for those of the nitro group, the plane of which is inclined at 8.8° to the benzene plane. The geometry of the nitro group in DCNB seems to be normal as compared with those of unhindered nitro groups in other aromatic nitro compounds.[4–6] The C(2)–C(1)–C(6) bond angle is 124.1(5)°. Such an increase in the internal angle at the nitro-substituted carbon is commonly observed for other aromatic nitro compounds.[5,6] The C–C bond distances in the benzene ring vary from 1.358 Å to 1.390 Å. The C–Cl bond distances are 1.728(6) Å and 1.739(6) Å. A CNDO/2 calculation based upon the molecular geometry observed was carried out in order to gain a better understanding of the ground-state electronic distribution of the π orbitals.[7] The π characters of the C–C bonds in the benzene ring are essentially equivalent; those of the two C–Cl bonds are also equivalent (4%). These results reveal that the nitro group in DCNB exerts no influence on the electronic distribution of the π orbitals of the C–Cl bonds and are consistent with the conclusion derived from the NQR data.

The crystal structure viewed along the c axis is

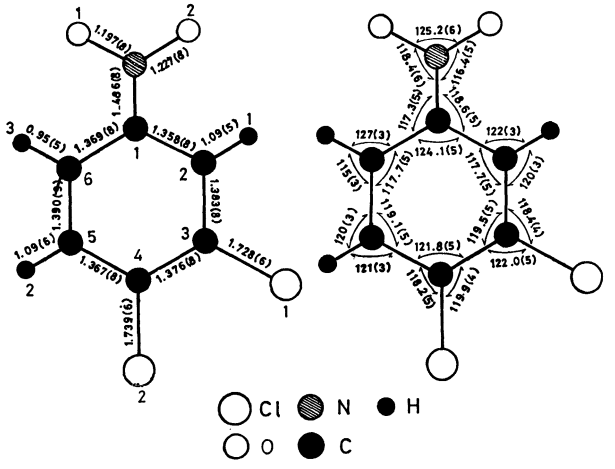

Fig. 1. Bond lengths (l/Å) and angles (ϕ/°) with their e.s.d.'s in parentheses.

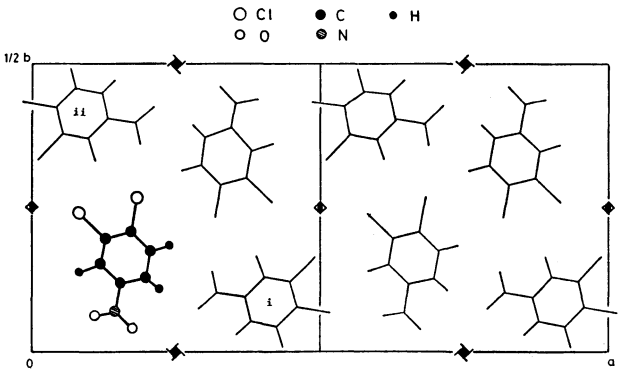

Fig. 2. A projection of the crystal structure along the c axis.

Table 2. Short C-Cl···O intermolecular distances

	C-Cl···O angle ϕ/°	Cl···O distance l/Å
2,5-Dichloro-1,4-benzoquinone	164	3.10
2,3-Dichloro-1,4-benzoquinone	164	3.01
2,3-Dichloro-1,4-naphthoquinone	164	3.10
3,4-Dichloronitrobenzene	164.8	3.095

presented in Fig. 2. The DCNB molecules are stacked in infinite columns along the c axis, with the mean interplanar distance of 3.601 Å. The intermolecular contacts between molecular stacks are normal except for Cl(2)···O(2^{ii}) (3.095 Å) and H(2)···O(2^{i}) (2.43 Å), which are shorter than the usually quoted van der Waals distances. The C(4)–Cl(2)···O(2^{ii}) angle is 164.8°. Similar short intermolecular contacts were observed in the crystals of some benzoquinone and naphthoquinone derivatives, which are listed in Table 2.[8] Gaultier, Hauw, and Schvoerer observed a red shift of the absorption maxima of the C=O stretching bands of these compounds in their crystalline and solution states, and proposed that the unusual contacts are attributable to charge-transfer interaction between the Cl atom and the carbonyl oxygen.[8] The absorption maxima of the symmetric and antisymmetric NO_2 stretching bands in the crystalline DCNB were observed at 1347.7 cm^{-1} and 1538.2 cm^{-1} respectively, and those in a CCl_4 solution, at 1345.2 cm^{-1} and 1534.6 cm^{-1}. Seemingly, these deviations are too small to be significant.

The authors are grateful to Professor Yoshihiko Saito for the use of the Rigaku four-circle diffractometer at the Institute of Solid State Physics, the University of Tokyo. Thanks are also due to Professor Takashi Shimozawa, Saitama University, for his keen interest and valuable discussion.

Structure of a Potent Antithyroid Drug, 6-Propyl-2-thiouracil

Nobuo OKABE,* Takaji FUJIWARA, Yuriko YAMAGATA, and Ken-ici TOMITA

Faculty of Pharmaceutical Sciences, Osaka University, Yamadaoka 1-6, Suita, Osaka 565

(Received October 8, 1982)

Synopsis. The crystal strure of 6-propyl-2-thiouracil (PTU), an antithyroid drug, has been determined as a 2:1 complex with 1,4-dioxane [$(C_7H_{10}N_2OS)_2(C_4H_8O_2)$]. The crystals are monoclinic, space group $P2_1/a$, with $a=8.983(5)$, $b=23.706(12)$, $c=4.942(2)$ Å, $\beta=95.79(3)°$, $V=1047.1(9)$ Å^3, $Z=4$, $D_x=1.36$ Mg m^{-3}, $D_m=1.35$ Mg m^{-3}, MW=214.29, λ(Cu $K\alpha$)=1.5418 Å. Final $R=0.098$ for 1575 reflexions.

6-Propyl-2-thiouracil (PTU) is a potent antithyroid drug as well as 2-thiouracil (TU) and 6-methyl-2-thiouracil (MTU). These compounds inhibit the biosynthesis of thyroid hormones and have been used for the treatment of hypothyroidism.[1-3] PTU is also known as a strong inhibitor of monoiodination of thyroid hormones in some tissues, such as liver, kidney or brain.[4,5] Although it appears that PTU inhibits the thyroid peroxidase in the thyroid gland or the deiodinase in some tissues, little is known about the actual mechanisms of these inhibitory effects. In this study, the molecular conformation of PTU is determined by X-ray analysis as a first step for elucidation of these inhibitory mechanisms.

Experimental

PTU and 1,4-dioxane were purchased from Nakarai Chemicals Ltd. Kyoto, Japan. PTU was crystallized from 2%(v/v) 1,4-dioxane aqueous solution by slow evaporation of the solvent at room temperature, and it was found that PTU crystallized as a 2:1 complex with 1,4-dioxane. A brittle needle crystal with the dimensions $0.30\times0.30\times0.15$ mm^3 was sealed in a capillary with mother liquor for X-ray analysis. Intensity data were collected on a Rigaku four-circle diffractometer AFC-5 with graphite-monochromated Cu $K\alpha$ radiation (45 kV, 25 mA) yielding 1809 independent reflexions with $2\theta\leq125°$. The intensities were corrected for Lorenz and polarization factors, but not for absorption. The structure was solved by MULTAN.[6] The positions of 14 non-hydrogen atoms were correctly determined and 14H atoms were located from a difference Fourier map. Refinement was performed by a block-diagonal least squares method up to $R=0.098$. The atomic scattering factors for C, N, O, and S were taken from International Tables for X-Ray Crystallography.[7]

Results and Discussion

The molecular shape of PTU complex with dioxane (2:1) is illustrated in Fig. 1. The final atomic parameters are listed in Table 1. The bond lengths and angles of PTU and dioxane are summarized in Table 2. These values are in good agreement with those of uracil[8] and its related derivatives, 2-thiouracil,[9] 1-methyluracil,[10] 1-ethyl-5-bromouracil,[11] and the dioxane complexes with oxalyl dichloride and oxalyl dibromide,[12] with iodoform[13] and with 1,7-diacetoxy-2,4,6-trinitro-2,4,6-triazaheptane,[14] except C(2)–S bond length of PTU, 1.647(5) Å, which is somewhat shorter than that of TU, 1.67 Å.[9] The propyl group attached to C(6) position forms an extended planar trans conformation. The uracil plane is nearly coplanar with the propyl one and the dihedral angle between the planes is 10.4(5)°. Bond lengths of the propyl group, C(6)–C(7), 1.500(8) Å, C(7)–C(8), 1.516 (8) Å, and C(8)–C(9), 1.532(8) Å are a little shorter in this order than that of the ideal C–C single bond

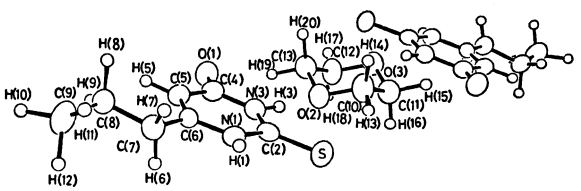

Fig. 1. A view of PTU complex with dioxane and the atomic numbering.

known as 1.54 Å. The shortening of the C–C bonds occurs markedly close to the pyrimidine ring. This suggests the resonance effect between the pyrimidine ring and the propyl group, which may explain the extended planar conformation of the propyl group. No disordering of the propyl group was observed. This indicates that the observed trans conformation of the propyl group might be a most stable one in the crystal. The dioxane molecule takes a chair conformation which has been found in the crystals as a stable form.[12-14] The molecular packing of PTU and dioxane in the crystal is shown in Fig. 2. Two PTU and one dioxane molecules are joined together in pairs by the hydrogen bond formation, N(3)–H(3)···O(2) (or O(3)), 2.929(6) Å. A PTU molecule is also connected with adjacent molecules to form endless chains by the hydrogen bond, N(1)–H(1)··· O(1), 2.952(5) Å. The sulfur atom at C(2) position does not participate in the hydrogen bond network, while in the crystals structure of TU, the N–H···S hydrogen bond with the length of 3.32 Å was formed.[9] This may explain the reason why the bond length, C(2)–S of PTU is a little shorter than that of TU. No stacking interaction between uracil bases was observed.

The relative antithyroid activity of PTU is 75 and that of MTU is 100 assuming TU as 100.[1] Supposing that the extended planar trans conformation of PTU found in the crystal is dominant as the antithyroid active form, lower antithyroid activity of PTU as compared with MTU or TU may be interpreted by the conformational feature of PTU. The planarity of PTU with the extended planar propyl group may have some negative effects for binding ability of it at the active center of the enzyme by steric hindrance. When thyroid hormones bind to carrier proteins, the 4'-OH group of these participates in a hydrogen bond

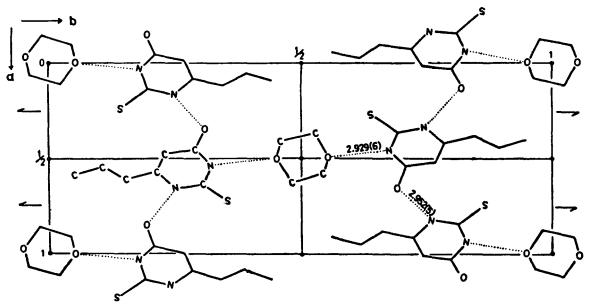

Fig. 2. Packing of the molecules viewed down c. The H atoms are excluded for clarity. The dotted lines represent the hydrogen bonds. Distances are in Å.

formation.[15] The hydrogen bond between PTU and dioxane may be concerned with the role of the 4'-OH group of the thyroid hormones at the active center of the enzyme. The three hydrogen bonds found in this crystal may be indispensable for fixing PTU on the binding site of the enzyme and for the following inhibitory action against the function of peroxidase or deiodinase resulted in the sulfur atom at C(2) position. Unfortunately, no physicochemical data on the interaction between PTU and relative enzymes is available. For this result, systematic studies concerning the effects of PTU on the endocrinal homeostasis may also be desirable.

(Received October 26, 1982)

Synopsis. The crystal structure of the title compound was determined by the X-ray method. The space group is $P\bar{1}$, with $a=8.537(1)$, $b=5.223(3)$, $c=9.505(1)$ Å, $\alpha=91.04(2)$, $\beta=80.58(1)$, $\gamma=99.16(3)°$, and $Z=2$. The hydroxyl group of the oxime takes the *anti* conformation to the amino group in the solid state. The molecules, linked together by NH···Cl and OH···Cl hydrogen bridges, form columns in the crystal.

2-Aminocyclohexanone oxime is easily converted into α-amino-ε-caprolactam by means of the Beckmann rearrangement reaction, which is well-known to be highly stereospecific in that the group *anti* to the hydroxyl group migrates in an acid-catalyst solution. In the solid state, however, it is anticipated that, because of the steric hindrance, the hydroxyl group of the oxime can not take the *syn* conformation to the amino group. In order to elucidate the stable conformation in the crystalline state, an X-ray structural analysis of two salts, hydrochloride and sulfate, was undertaken; the results show that hydroxyl groups take the *anti* conformation in both molecules, as might be expected.

The crystal data for both molecules are summarized in Table 1. The sulfate recrystallized from aqueous and ethanol solutions showed a disordered structure, with the sulfate ion disordered statistically about the two-fold crystallographic axis of the space group C2 and with several improbable bond dimensions being observed. Therefore, in this paper we will report only on the crystal structure of hydrochloride.

Experimental

The title compound was recrystallized from an aqueous solution as colorless plates elongated in the b direction. The unit-cell parameters were refined by the least-squares fit of 14 reflections as measured on a Hilger & Watts automatic four-circle diffractometer. The density was measured by flotation in a carbon tetrachloride-hexane mixture. A crystal with dimensions of $0.25\times0.35\times0.5$ mm³ was used for the data collection. The intensities of 1074 reflections with $2\theta\leq114°$ were measured by the $2\theta-\omega$ step-scan technique with Ni-filtered Cu $K\alpha$ radiation. No significant changes were observed in the intensities of the standard reflections measured periodically throughout the data collection. The measured intensities were corrected for Lorentz-polarization factors, but no absorption correction was applied. 895 reflections with $F\geq2\sigma(F)$ were used in the refinement of the structure.

Structure Determination and Refinement

The structure was solved by the usual Patterson and Fourier methods and refined by the block-diagonal least-squares procedure, using the HBLS VI program[1] with anisotropic temperature factors for all the non-hydrogen atoms and isotropic ones for the hydrogen atoms. In the refinement, the function minimized was $\Sigma w(|F_o|-|F_c|)^2$, with the weighting scheme of $w=[\sigma^2(F_o)+a|F_o|+b|F_o|^2]^{-1}$, where $\sigma(F_o)$ is the standard deviation based on the counting statistics. The final refinement ($a=0.0652$, $b=-0.0006$) led to the R value of 0.070. All the scattering factors were taken from the International Tables for X-Ray Crystallography.[2] The final atomic parameters are shown in Table 2.[3]

Results and Discussion

The bond lengths and angles of the atoms, excluding the hydrogen atoms, are shown in Fig. 1, together with the atomic numbering system. The estimated standard deviations of the bond lengths are 0.005—0.010 Å, while those of the bond angles are 0.4—0.5°. X-Ray structural analysis shows that the hydroxyl group of the oxime takes the *anti* conformation to the amino group in the crystalline state. The cyclohexane ring takes a chair form, and the ring C-C bond lengths and angles are in essential agreement with the values obtained in 3,3,5,5-tetramethylcyclohexanone oxime,[4] 3,3,5-trimethyl-5-phenylcyclohexanone oxime,[5] and 1,4-cyclohexane-dihydroxyimine.[6] The distance of the C(1)–N(1) bond (1.294 Å) suggests its double-bond character; the coplanarity of the C(1), C(2), C(6), N(1), and O atoms is due to this double-bond character(Table 3). The N(1)–O bond distance (1.404 Å) is also within the expected range of values.[7]

Contribution of Quadruply Degenerate π-Electron Orbitals to London Susceptibility

Tsuyoshi HORIKAWA and Jun-ichi AIHARA*

Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422

(Received November 24, 1982)

Synopsis. A graph-theoretical formula was derived to evaluate the contribution of quadruply degenerate π-electron orbitals to London diamagnetism. This formula enables us to calculate London susceptibilities of such compounds as *p*-terphenyl and perylene without factorization of their secular determinants.

In 1952 Berthier *et al.*[1] elaborately derived analytical formulas for London (or ring-currents) susceptibility[2,3] of a polycyclic conjugated system with nondegenerate and/or doubly and/or triply degenerate π-electron orbitals. However, there have been no such formulas for systems with quadruply degenerate orbitals. Secular equations of *p*-terphenyl (**1**) and perylene (**2**) were factored into algebraic equations of lower degree,[1] because they have quadruply degenerate orbitals. We have been developing graph theory of cyclic conjugated systems to elucidate their magnetic properties.[4-9] In this note we present a graph-theoretical formula of London susceptibility applicable to quadruply degenerate orbitals of a cyclic conjugated system.

Let a polycyclic conjugated system G be placed perpendicularly to the external magnetic field H, and its characteristic polynomial is denoted by $P_G(X,H)$. If there are quadruply degenerate π-electron orbitals in G, $P_G(X,0)$ can be written as

$$P_G(X, 0) = (X-X_0)^4 U(X), \tag{1}$$

where X_0 is the energy of quadruply degenerate orbitals.[10] $P_G(X,H)$ is expressible in the form:[5]

$$P_G(X, H) = P_G(X, 0) + H^2 \sum_i^G P_{G-r_i}(X, 0)\theta_i^2 + H^4 A(X) + \cdots. \tag{2}$$

Here, r_i is the ith π-electron ring in G;[11] G-r_i is a subsystem of G, obtained by deleting from G the ith π-electron ring and all π bonds incident to it; i runs over all π-electron rings in G, defined in Sachs' sense;[11] $\theta_i = eS_i/c\hbar$, where S_i is an area of the ith π-electron ring, and e, c, and $\hbar$ are the standard constants with these symbols; and $A(X)$ is a term proportional to H^4, which is not specified here.

Since the magnetic field can be treated as a small perturbation, field-dependent energies of the four orbitals which are degenerate in energy at $H=0$ are given by solving the following equation:[5]

$$P_G(X, H) = P_G(X, 0) + H^2 \sum_i^G P_{G-r_i}(X, 0)\theta_i^2 + H^4 A(X) = 0. \tag{3}$$

This equation is written as

$$(X-X_0)^4 = -H^2 S(X) - H^4 T(X), \tag{4}$$

where

$$S(X) = \frac{1}{U(X)} \sum_i^G P_{G-r_i}(X, 0)\theta_i^2 \tag{5}$$

and

$$T(X) = \frac{A(X)}{U(X)}. \tag{6}$$

Since $|X-X_0| \ll 1$ for the four orbitals, Eq. 4 can be expanded into

$$(X-X_0)^4 = -H^2\left\{S(X_0) + S^{(1)}(X_0)(X-X_0) + \frac{1}{2}S^{(2)}(X_0)(X-X_0)^2 + \frac{1}{6}S^{(3)}(X_0)(X-X_0)^3\right\} - H^4\{T(X_0) + T^{(1)}(X_0)(X-X_0)\}, \tag{7}$$

where

$$S^{(k)}(X_0) = \left[\frac{d^k}{dX^k}S(X)\right]_{X=X_0}, \tag{8}$$

and

$$T^{(1)}(X_0) = \left[\frac{d}{dX}T(X)\right]_{X=X_0}. \tag{9}$$

Higher-order terms missing on the right-hand side of Eq. 7 are obviously negligible.

Since Eq. 4 is an eigen-equation derived from an Hermitian matrix, all roots of Eq. 7 must be real for an arbitrary small value of H. Necessary conditions for the existence of four real roots are

$$S(X_0) = 0, \tag{10}$$

$$S^{(1)}(X_0) = 0, \tag{11}$$

and

$$S^{(2)}(X_0) < 0. \tag{12}$$

Otherwise, Eq. 7 would not always have four real roots. This can easily be proved by drawing graphs of the following two functions found in Eq. 7:

$$Y = (X-X_0)^4, \tag{13}$$

and

$$Y = -H^2\left\{S(X_0) + S^{(1)}(X_0)(X-X_0) + \frac{1}{2}S^{(2)}(X_0)(X-X_0)^2 + \frac{1}{6}S^{(3)}(X_0)(X-X_0)^3\right\}. \tag{14}$$

For an arbitrary small H value, Eqs. 10—12 are necessary for the two graphs to intersect fully with each other. In fact, secular equations of **1** and **2** satisfy these conditions. Then, Eq. 7 becomes

$$(X-X_0)^4 + \frac{H^2}{6}S^{(3)}(X_0)(X-X_0)^3 + \frac{H^2}{2}S^{(2)}(X_0)(X-X_0)^2 + H^4 T^{(1)}(X_0)(X-X_0) + H^4 T(X_0) = 0. \tag{15}$$

This is an algebraic equation in $(X-X_0)$ of degree 4.

Let the degenerate orbital energy X_0 split into X_1, X_2, X_3, and X_4, and the following expression is deduced straightforwardly from the coefficient of $(X-X_0)^3$ in Eq. 15:

$$\sum_{j=1}^{4}(X_j - X_0) = -\frac{H^2}{6}S^{(3)}(X_0). \quad (16)$$

Consequently, the sum of the energies of eight π electrons in these four orbitals is

$$\varepsilon(H) = 2\sum_{j=1}^{4}X_j = 8X_0 - \frac{H^2}{3}S^{(3)}(X_0). \quad (17)$$

It is to be noted that $\varepsilon(H)$ is independent of $T(X)$. More explicitly, $\varepsilon(H)$ is expressed as

$$\varepsilon(H) = 8X_0 + \frac{3U^{(1)}(X_0)V^{(2)}(X_0) - U(X_0)V^{(3)}(X_0)}{3U(X_0)^2}H^2, \quad (18)$$

where

$$U^{(1)}(X_0) = \left[\frac{d}{dX}U(X)\right]_{X=X_0} \quad (19)$$

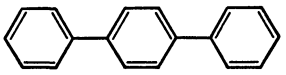
and

$$V^{(k)}(X_0) = \left[\frac{d^k}{dX^k}P_{G-r_i}(X, 0)\theta_i^2\right]_{X=X_0}. \quad (20)$$

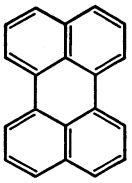
Finally, we obtain the following formula for a susceptibility contribution from eight π electrons in quadruply degenerate orbitals:

$$\Delta\chi_G = \left[\frac{d^2}{dH^2}\varepsilon(H)\right]_{H=0} = \frac{2}{3}\frac{3U^{(1)}(X_0)V^{(2)}(X_0) - U(X_0)V^{(3)}(X_0)}{U(X_0)^2}. \quad (21)$$

Susceptibility contributions from nondegenerate and doubly degenerate orbitals can be estimated using formulas published by Berthier *et al.*[1] or by us.[5] London susceptibilities of compounds **1** and **2** can now be calculated easily without factorization of their field-dependent secular determinants. They are 2.730 χ_0 and 4.120χ_0 for **1** and **2**, respectively, where χ_0 is London susceptibility of the benzene conjugated system. These values are identical with those reported by Berthier *et al.*[1,3]



1



2

The following relationships are derived from Eqs. 10 and 11:

$$V(X_0) = \sum_{i}^{G}P_{G-r_i}(X_0, 0)\theta_i^2 = 0, \quad (22)$$

and

$$V^{(1)}(X_0) = \left[\frac{d}{dX}\sum_{i}^{G}P_{G-r_i}(X_0, 0)\theta_i^2\right]_{X=X_0} = 0. \quad (23)$$

These characterize quadruply degenerate orbitals.

A susceptibility contribution from six π electrons in triply degenerate orbitals can be formulated graph-theoretically in a similar way. It is given as

$$\Delta\chi_G = \frac{4U^{(1)}(X_0)V^{(1)}(X_0) - 2U(X_0)V^{(2)}(X_0)}{U(X_0)^2}, \quad (24)$$

where $U(X)$ is defined by

$$P_G(X, 0) = (X - X_0)^3U(X). \quad (25)$$

This is mathematically identical with the formula derived by Berthier *et al.*[1]

Dimeric Copper(II) Acetate Complexes of Thiazoles and Oxazoles

Tadashi Tokii and Yoneichiro Muto*

Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840

(Received October 18, 1982)

Synopsis. Copper(II) acetate monoadducts, $Cu(CH_3COO)_2 \cdot L$ (L=thiazole, benzothiazole, benzoxazole, 2-methylbenzothiazole, 2-methylbenzoxazole, 2,4-dimethylthiazole, or 2,4,5-trimethylthiazole) were prepared, and they all show antiferromangnetism ($-2J=318$—$344\ cm^{-1}$) of copper(II) dimer type. The variation in magnetic interaction with the steric nature of the ligand, L, is discussed.

The recent X-ray studies on dimeric copper(II) carboxylate adducts with pyridine analogues have demonstrated that ortho-substituents in the pyridine ring of the ligands make copper atoms displace out of the plane of the four carboxylate-oxygen atoms toward the nitrogen atom by the mutual repulsion between the substituents and the oxygen atoms.[1,2] Under such conditions the steric effect is expected to enhance the metal–metal distance; in fact, the Cu–Cu distance in dimeric copper(II) acetate adducts with pyridine (py), quinoline (quin), and 2-picoline (2-pic) increases in the order, py (2.630 Å)[3]<quin (2.652 Å)[1]<2-pic (2.671 Å),[4] as expected from the effectiveness of the steric effect. However, no significant correlation has been observed between the Cu–Cu distance and the magnitude of the singlet-triplet separation ($-2J$) in these adducts. In this work we prepared seven copper(II) acetate adducts, $Cu(CH_3COO)_2 \cdot L$, where L= thiazole (tz), benzothiazole (btz), benzoxazole (boz), 2-methylbenzothiazole (2-mbtz), 2-methylbenzoxazole (2-mboz), 2,4-dimethylthiazole (2,4-dmtz) or 2,4,5-trimethyloxazole (2,4,5-tmoz), and measured their magnetic susceptibilities as a function of temperature in order to obtain information on the effect of the ortho-substituents in L upon the magnetic interaction.

Experimental

Synthesis. A typical synthetic method is as follows. A solution of the ligand L (5 mmol) in ethanol (5 ml) was added to a solution of $Cu(CH_3COO)_2 \cdot H_2O$ (5 mmol) in ethanol (30 ml). After keeping the solution overnight at *ca.* 5 °C in a freezer, the separated green crystals were collected, washed with ethanol and dried at *ca.* 60 °C. **1.** $Cu(CH_3COO)_2 \cdot (tz)$. Found: C, 31.66; H, 3.57; N, 5.05; Cu, 23.69%. Calcd for $C_7H_9NO_4SCu$: C, 31.52; H, 3.40; N, 5.25; Cu, 23.82%. **2.** $Cu(CH_3COO)_2 \cdot (btz)$. Found: C, 41.66; H, 3.70; N, 4.34; Cu, 20.01%. the corrected molar magnetic susceptibility (χ_A) *vs.* the temperature (T).

Results and Discussion

Complexes **1**—**7** were readily isolated by the reaction of $Cu(CH_3COO)_2\cdot H_2O$ with the ligand in ethanol. However, under the similar conditions no adduct formation was observed between copper(II) acetate and benzo[*b*]thiophene or benzofuran. This finding indicates that the nitrogen atom in the ligand L is most probably the donor atom.

The variable-temperature magnetic susceptibility data were analyzed by the Bleaney-Bowers equation,

$$\chi_A = \frac{Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp\left(\frac{-2J}{kT}\right)\right]^{-1} + N\alpha. \quad (1)$$

where each symbol has the usual meaning. As can be seen in Figs. 1 and 2, the thermal magnetic data are well represented by Eq. 1. The g and $-2J$ values listed in Table 1 were evaluated from the best-fit of the experimental data to Eq. 1, assuming $N\alpha=60\times 10^{-6}$ cgs emu mol^{-1} (1 cgs emu mol$^{-1}=4\pi\times 10^{-6}$ m^3 mol^{-1}). On the basis of the magnetic behavior, a dimeric structure similar to that found in copper(II) acetate monohydrate can be assigned for the present acetate complexes.

Coordination of thiazole, benzothiazole or benzoxazole to the dimeric copper(II) acetate units will cause an increase in antiferromagnetic interaction as is seen in the $-2J$ value of the adducts, 344 cm^{-1}, a value somewhat larger than those reported for the well-characterized dimeric copper(II) acetate adducts (284—325 cm^{-1}).[6] It is also noted that the $-2J$ value of complex **2** is just the same as that of complex **1**; this suggests that the steric nature of the adjacent benzo group in benzothiazole does not exert any appreciable effect upon the magnitude of $-2J$. This observation is in accord with the fact that the $-2J$ of 320 cm^{-1} determined for $[Cu(CH_3COO)_2\cdot quin]_2$ is practically identical with that of 325 cm^{-1} found for $[Cu(CH_3COO)_2\cdot py]_2$.[6] On the other hand, the $-2J$ values for complexes **4**—**7** were found to fall in a rather low range of 318—327 cm^{-1}. For the mechanism of the magnetic interaction in dimeric copper(II) carboxylates, two models have been proposed: Cu–Cu direct exchange interaction, and superexchange interaction through the bridging carboxylato groups. The predominance of the latter mechanism has been recognized by some experimental evidence,[6-9] but it has also been suggested that the effect of the former interaction is not entirely negligible.[10] The direct interaction would be expected to decrease with increasing Cu–Cu separation, whereas the superexchange interaction may be affected by such structural features as the distances and angles within the Cu–O–C–O–Cu bridge and the geometry around the metal atom. In the present adducts, $Cu(CH_3COO)_2\cdot L$, the presence of methyl group at the 2-position of thiazole- or oxazole-ring will make the Cu–Cu distance increase with the displacement of the copper atom from its basal coordination plane toward the nitrogen atom in L, and will reduce both the direct and superexchange interactions. Thus, this steric effect seems to be the main factor for the decrease in the $-2J$ values of complexes **4**—**7** by 17—26 cm^{-1} as compared with those of complexes **1**—**3**.

Finally, it should be noted that the $-2J$ of complex **1** (344 cm^{-1}) is higher than that of $[Cu(CH_3COO)_2\cdot py]_2$ (325 cm^{-1}).[6] The pK_a of the terminal ligand of the former complex (2.44)[11] is lower than that of the latter (5.32).[12] We have also evaluated the $-2J$ of 341 cm^{-1} for dimeric copper(II) acetate adduct with 3,5-dichloropyridine (pK_a=0.67).[13] These facts are not in accord with the observation that, in the pyridine and picoline adducts of copper(II) propionate, the value of $-2J$ decreases as the pK_a of the terminal ligand decreases.[14] Thus, these magnetic data suggest that the $-2J$ in dimeric copper(II) carboxylate adducts is not a simple function of the base strength of the terminal ligand.

(Received November 27, 1982)

Synopsis. The reaction of *trans*-[$CoCl_2$(2,3,2-tet)]$^+$ (2,3,2-tet: 3,7-diazanonane-1,9-diamine) with (2-aminoethyl)-dimethylphosphine (edmp) afforded only one geometrical isomer of [Co(edmp)(2,3,2-tet)]$^{3+}$, the structure of which was determined by X-ray analysis to have the *cis*-β,*trans*-(*sec*-*N*,*P*) configuration.

Formation of cobalt(III)–phosphine complexes is often specific or selective concerning geometrical isomerism.[1,2] This note reports preparation and X-ray structure analysis of [Co(edmp)(2,3,2-tet)]$^{3+}$ (edmp: (2-aminoethyl)dimethylphosphine, 2,3,2-tet: 3,7-diazanonane-1,9-diamine) which is only one geometrical isomer formed by the reaction of *trans*-[$CoCl_2$(2,3,2-tet)]$^+$ with edmp.

Experimental

Preparation of the Complex. To an oxygen-free dimethyl sulfoxide solution (100 cm^3) of *trans*-[$CoCl_2$(2,3,2-tet)]-ClO_4[3] (340 mg, 0.84 mmol) was added an oxygen-free methanol solution (5 cm^3) of edmp[1] (91 mg, 0.87 mmol) with stirring under nitrogen atmosphere. After stirring for 2 h, the resulting orange solution was mixed with water (400 cm^3) and diethyl ether (100 cm^3) to extract unreacted edmp. The orange aqueous-dimethyl sulfoxide solution was diluted to 1 dm^3 with water and poured on a column (ϕ2.5×150 cm^2) of SP-Sephadex C-25. The product adsorbed was eluted with 0.2 mol dm^{-3} NaCl, giving two bands. The first yellow eluate was *fac*-[Co(edmp)$_3$]$^{3+}$.[1] The second orange eluate was evaporated to dryness under reduced pressure. The residue was extracted with methanol (200 cm^3). The extract was diluted with water (1 dm^3) and the solution was poured on a column (ϕ2.5×15 cm^2) of SP-Sephadex C-25. The complex adsorbed was eluted with 1 mol dm^{-3} KBr. The eluate was concentrated in a vacuum desiccator over P_4O_{10} to yield red-orange crystals, which were recrystallized from water and dried in air. Yield: *ca.* 50%. Found: C, 22.39; H, 5.93; N, 12.11%. Calcd for [Co(edmp)(2,3,2-tet)]$Br_3\cdot 2H_2O = C_{11}H_{36}N_5Br_3CoO_2P$: C, 22.02; H, 6.05; N, 11.67%. The complex in aqueous solution shows two d-d absorption bands at 21980 cm^{-1} (log ε=2.37) and 28740 cm^{-1} (log ε=2.41).

X-Ray Analysis. Crystal data: monoclinic, $P2_1/a$, a=17.719(2), b=8.776(1), c=14.966(1) Å, β=108.01(1)°, V=2213.2(4) Å^3, Z=4, D_m=1.803, D_x=1.801 g cm^{-1}, μ(Mo $K\alpha$)=6.63 mm^{-1}. A specimen with dimensions 0.32×0.34×0.37 mm^3 was used for the X-ray work. Diffraction data were collected on a Rigaku AFC-5 diffractometer with graphite monochromatized Mo $K\alpha$ radiation. Within the range $2\theta<60°$, 3687 independent reflections with $F_o>3\sigma(F_o)$ were obtained. Intensities were corrected for Lorentz and polarization factors, and for absorption.

The structure was solved by the direct method (MULTAN). The method used in the solution and refinement of the structure were standard and have been described previously.[4] Hydrogen atoms except for those bonded to one of water molecules of crystallization were located by the difference syntheses, and were included in the final refinement with the isotropic temperature factors. The final R indices were R=0.044 and R_w=0.043. Table 1 lists the atomic parameters.[5] The F_o-F_c data, final thermal parameters, and hydrogen atomic coordinates are preserved by the Chemical Society of Japan (Document No. 8322).

Results and Discussion

Figure 1 shows a perspective view of the complex ion. The 2,3,2-tet ligand coordinates to the cobalt(III) ion with the four nitrogen atoms to form *cis*-β

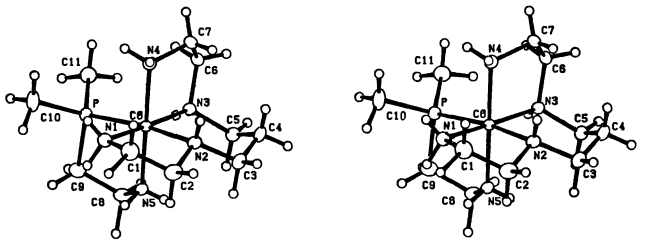

Fig. 1. A stereo view of $[Co(edmp)(2,3,2\text{-tet})]^{3+}$.

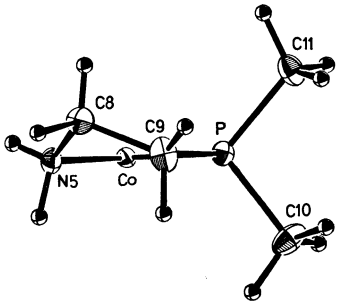

Fig. 2. Conformation of the edmp chelate ring.

configuration, and the phosphorus atom of edmp takes the position *trans* to the secondary amine (N2) of 2,3,2-tet. The bond distances and angles are listed in Table 2. The Co–N(2) distance of 2.029(4) Å is the longest among those reported for analogous 2,3,2-tet complexes, $(+)_{470}$-*Λ-cis-β*-$[Co(NO_2)_2\{(R)\text{-}NH_2CH_2CH_2NHCH(CH_3)CH_2CH_2NHCH_2CH_2NH_2\}]Br$ (2.004(4) Å)[6] and $(-)_{546}$-*Λ-cis-β*-$[Co(C_2O_4)\{(R,R)\text{-}NH_2CH_2CH_2NHCH(CH_3)CH_2CH(CH_3)NHCH_2CH_2NH_2\}]ClO_4$ (1.99(1) Å).[7] The elongation of the Co–N(2) bond can be attributed to trans influence of the phosphorus atom of edmp. Similar elongations of Co–N bonds have been observed in $(+)_{589}$-*Λ-fac*-$[Co(edmp)_3]Br_3\cdot 3H_2O$ (2.041 Å)[1] and $(+)_{589}$-*Λ*-$[Co(en)_2\{(CH_3)_2PCH_2CH_2P(CH_3)_2\}]Br_3\cdot 1.5H_2O$ (2.032 Å).[8] The Co–P distance of 2.243 Å is similar to 2.237(5)[1] and 2.256(3) Å[8] in the complexes given above.

The chelate rings of 2,3,2-tet and edmp in the *Λ*-complex adopt (*δ*-gauche)(chair)(*δ*-gauche) and pseudo *δ*-gauche conformations, respectively (Figs. 1 and 2). Bond angles around the phosphorus atom deviate argely from the normal tetrahedral angle; Co–P–C(11):120.9(2)°, Co–P–C(10):116.6(2)°, Co–P–C(9):101.6(2)°, and C(10)–P–C(11):103.3(3)°. These deviations seem to come from a crowded structure around the phosphorus atom.

The other *cis-β,cis(sec-N,P)* isomer was not formed. Molecular models indicate that this isomer has big steric hindrance among one methyl group and axial hydrogen atoms on C(3) and C(5). Attempts to prepare $[Co\{(CH_3)_2PCH_2CH_2P(CH_3)_2\}(2,3,2\text{-tet})]^{3+}$, which has the $-P(CH_3)_2$ group at the *cis(sec-N,P)* position, were unsuccessful, no reaction taking place between *trans*-$[CoCl_2(2,3,2\text{-tet})]^+$ and the diphosphine ligand. No *cis-α* isomer of a 2,3,2-tet complex has been reported probably because of strong preference of the chair conformation of the six-membered chelate ring. Thus the $[Co(edmp)(2,3,2\text{-tet})]^{3+}$ complex forms only one geometrical isomer of the *cis-β,trans(sec-N,P)* configuration.

Preparation and Characterization of Cobalt(III)–Phosphine Complexes of the Type [Co(CN)$_2$(acetylacetonate)(L)] (L: Tertiary 2-Aminoethylphosphines, and 1,2- and 1,3-Diphosphines)

Tomoji Ohishi, Kazuo Kashiwabara, and Junnosuke Fujita*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received November 29, 1982)

Synopsis. Four new cobalt(III)-phosphine complexes of the type [Co(CN)$_2$(acetylacetonate)(L)] (L= $NH_2CH_2CH_2P(C_6H_5)_2$, $NH_2CH_2CH_2P(CH_3)_2$, $(C_6H_5)_2PCH{=}CHP(C_6H_5)_2$, and $(C_6H_5)_2PCH_2CH_2CH_2P(C_6H_5)_2$) were prepared. The geometrical structures of the 2-aminoethylphosphine, and 1,2- and 1,3-diphosphine complexes were assigned to have *trans(C,N)* and *cis* configurations, respectively on the basis of the ^{1}H and ^{13}C NMR spectra.

In previous papers,[1,2] we reported usefulness of ^{1}H and ^{13}C NMR spectra for assigning geometrical structures of mixed cobalt(III)–phosphine complexes. In order to extent such studies, we have prepared mixed cobalt(III)–phosphine complexes of the type [Co(CN)$_2$(acac)(L)], where acac denotes an acetylacetonate ion, and L is $NH_2CH_2CH_2P(C_6H_5)_2$(edpp), $NH_2CH_2CH_2P(CH_3)_2$(edmp), $(C_6H_5)_2PCH{=}CHP(C_6H_5)_2$(dpee), $(C_6H_5)_2PCH_2CH_2P(C_6H_5)_2$(dppe), or $(C_6H_5)_2PCH_2CH_2CH_2P(C_6H_5)_2$(dppp), and assigned their geometrical structures by means of ^{1}H and ^{13}C NMR techniques.

Experimental

The edpp[2] and edmp[3] ligands were prepared by the methods reported and handled under nitrogen atmosphere until they formed the cobalt(III) complexes. The dpee, dppe, and dppp ligands were purchased from Strem Chemicals Inc. Absorption, and ^{1}H and ^{13}C NMR spectra were recorded on a Hitachi 323 spectrophotometer, and JEOL JNM-PMX 60 and JNM-FX 100 spectrometers, respectively.

[Co(CN)$_2$(acac)(edpp)]·H$_2$O. A solution of K[Co(CN)$_2$(acac)$_2$][4] (638 mg, 1.8 mmol) and edpp (282 mg, 1.2 mmol) in oxygen-free methanol (100 cm^3) was stirred for 4 h at 50 °C. Water (400 cm^3) and diethyl ether (100 cm^3) were added to the solution to extract the unreacted edpp. The aqueous solution was passed through columns of SP-Sephadex C-25 and DEAE Sephadex A-25 ion exchangers successively to remove charged species. The effluent was evaporated to dryness under reduced pressure, and the residue was extracted with a small amount of methanol. The extract was chromatographed with an alumina column (ϕ1 cm×30 cm) and an eluent of benzene-ethanol (10:1), giving three orange bands. The complexes in the first and last bands were too small in the amount and not isolated. The eluate of the main second band was concentrated under reduced pressure to yield orange crystals of the complex. Yield: *ca.* 10%. Found: C, 54.69; H, 5.31; N, 8.98%. Calcd for $C_{21}H_{25}N_3CoO_3P$: C, 55.15; H, 5.51; N, 9.19%. The complex is hardly soluble in water, but soluble in common organic solvents.

[Co(CN)$_2$(acac)(edmp)]·1/2 H$_2$O. A solution of K[Co(CN)$_2$(acac)$_2$] (656 mg 1.9 mmol) and edmp (198 mg, 0.86 mmol) in oxygen-free methanol (80 cm^3) was stirred for 10 h at room temperature. The unreacted edmp and charged species in the resulting solution were removed by the procedures described above. The methanol extract containing only noncharged species was chromatographed with a column (ϕ2 cm×40 cm) of LH-20 Sephadex and an eluent of benzene-ethanol (10:1), yielding only one yellow-orange band. The complex was very soluble in water and common organic solvents, so that it was obtained as powder by evaporating the eluate to dryness. Yield: *ca.* 10%. Found: C, 40.89; H, 6.62; N, 12.54%. Calcd for $C_{11}H_{20}N_3CoO_{2.5}P$: C, 40.75; H, 6.22; N, 12.96%.

In the preparation of these edpp and edmp complexes, use of an equimolar amount of the aminoalkylphosphine ligand decreases the yield of the desired complex, affording dicyanobis(aminoalkylphosphine) complexes. No such reactions take place between [Co(CN)$_2$(acac)$_2$]$^-$ and diphosphine ligands as described below.

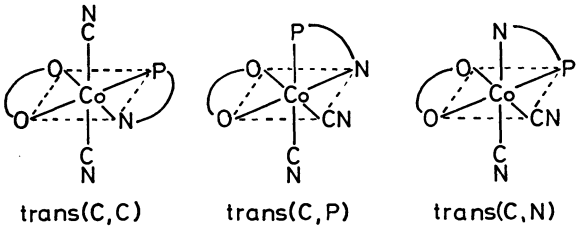

Fig. 1. Geometrical isomers of [Co(CN)$_2$(acac)(edpp or edmp)].

[Co(CN)$_2$(acac)(dpee)]·CHCl$_3$. This complex was prepared by a method similar to that for [Co(CN)$_2$(acac)(dppe)],[1] using K[Co(CN)$_2$(acac)$_2$] (348 mg, 1 mmol) and dpee (396 mg, 1 mmol), and recrystallized from chloroform. Yield: *ca.* 40%. Found: C, 56.31; H, 3.63; N, 3.58%. Calcd for $C_{34}H_{30}N_2CoCl_3O_2P_2$: C, 56.26; H, 4.16; N, 3.68%. The complex is insoluble in water but soluble in common organic solvents.

[Co(CN)$_2$(acac)(dppp)]·C$_6$H$_6$. A mixture of K[Co(CN)$_2$(acac)$_2$] (303 mg, 0.87 mmol), dppp (359 mg, 0.87 mmol), and a small amount of active charcoal in oxygen-free methanol (100 cm^3) was stirred for 10 h at 50 °C, and filtered. The filtrate was evaporated to dryness under reduced pressure. The residue was extracted with hot benzene (50 cm^3). On standing at room temperature the extract gave orange crystals of the complex. Yield: *ca.* 10%. Found: C, 68.10; H, 5.34; N, 3.98%. Calcd for $C_{40}H_{39}N_2CoO_2P_2$: C, 68.57; H, 5.61; N, 4.00%. The complex is insoluble in water but soluble in common organic solvents.

[Co(CN)$_2$(acac)(dppe)] was prepared by the method reported.[1]

Results and Discussion

The [Co(CN)$_2$(acac)(edpp or edmp)] complex can have three geometrical isomers (Fig. 1). In this study, each of the edpp and edmp complexes formed only one isomer. The isomers were resolved partially by the chromatographic method of Norden[5] using an alumina–(+)-lactose column. In the ^{13}C NMR spectra, the edpp and edmp complexes show signals due to two kinds of the phenyl and methyl (on P) groups, respectively, the two substituents on the phosphorus atom being diastereomeric. Thus both isomers are chiral and have either the *trans(C,P)* or the *trans(C,N)* structure. Of these two structures, the edpp complex

can be assigned to the *trans(C,N)* isomer from the ^{1}H NMR spectrum (Table 1). The methine proton of acac in this complex is observed at a fairly lower field than those of the corresponding diphosphine complexes and one methine proton of $[Co(acac)_2(edpp)]^+$ (4.93 ppm).[2)] One phenyl group of edpp in $[Co(acac)_2(edpp)]^+$ is disposed over one acac ring and its methine proton is shielded by this phenyl group to resonate at a high field. Thus $[Co(CN)_2(acac)(edpp)]$ has no phenyl group over the acac ring, and is assigned to the *trans(C,N)* isomer. This assignment is supported by the ^{13}C NMR spectrum. Each one of the two carbonyl and two methyl carbons of acac in this complex shows a doublet signal due to the three-bond and four-bond ^{13}C-^{31}P couplings, respectively (Fig. 2(a)). Such couplings have been observed only when C and P atoms are situated in *trans* positions to each other through central Co(III).[2)] The edmp complex shows similar patterns in the carbonyl and methyl regions of acac. Thus it is concluded that both edpp and edmp complexes have the *trans(C,N)* structure in which the phosphino group takes the position *trans* to one of the oxygen donor atoms of acac.

The structures of the diphosphine complexes can be assigned in a similar manner to *cis* configuration from the ^{1}H and ^{13}C NMR spectra. The ^{13}C NMR spectra of the complexes show two kinds of signal due to the methyl group and doublet signals due to one carbonyl and one methyl carbons. Furthermore, the methylene and methine carbons bonded to the P atom become a quartet, the two P atoms of the diphosphine ligand being non-equivalent. All these features support conclusively *cis* configuration for the diphosphine complexes.

The data for the first absorption bands of the complexes are as follows (cm^{-1} (log ε)); edpp: 23250(2.65), edmp: 24170(2.80), dpee: 23420(3.07), dppe: 23360 (3.12), dppp:23250(3.03). Thus the spectrochemical series of the ligands is edpp, dppp<dppe<dpee< edmp.

Catalytic Hydrogenolysis of 1,1-Difluoro-2-phenyl- and 1,1-Difluoro-3-methyl-2-phenylcyclopropane

Koji Isogai,* Naomi Nishizawa, Tetsuji Saito, and Jun-ichi Sakai

(Received August 19, 1982)

Synopsis. The title compounds were hydrogenolyzd over PdO or Raney nickel. The C_2–C_3 bond of the cyclopropane ring underwent cleavage exclusively over the both catalysts. The contribution of the fluorine substituent to the lengthening and weakening the C_2–C_3 bond of the cyclopropane ring seems to become a dominant factor in the regioselectivity.

In a previous paper[1] we reported that the palladium oxide (PdO)-catalyzed hydrogenolysis of 1,1-dichloro-3-methyl-2-phenylcyclopropane caused exclusive cleavage of the C_2–C_3 bond, whereas both the C_1–C_2 and C_2–C_3 bonds were cleaved competitively using Raney nickel (R-Ni) as a catalyst.

In this paper, we wish to report that the regioselective cyclopropane ring cleavage occurs in the catalytic hydrogenolysis of 1,1-difluoro-2-phenylcyclopropane(**1**) and its 3-methyl derivative(**2**) by the use of PdO and R-Ni. The products arising from the C_2–C_3 bond cleavage of the cyclopropane ring were obtained exclusively.

The results are given in Tables 1 and 2. PdO-catalyzed hydrogenolysis of **1** gave propylbenzene(**1a**), 2-fluoro-1-phenylpropane(**1b**), and 2,2-difluoro-1-phenylpropane(**1c**). The addition of a large amount of potassium hydroxide reduced the rate of hydrogenolysis of **1** and gave a substantial amount of (*Z*)-2-fluoro-1-phenylpropene(**1d**). **1d** was hydrogenated readily to give **1a** and **1b** in the absence of the additive. Hence **1d** seems to be a precursor of **1a** and **1b**. Using R-Ni as a catalyst, **1** gave mainly **1a** accompanied by **1b** and **1c** in the absence and the presence of a base such as triethylamine (TEA). The addition of ethylenediamine (EDA), however, inhibited effectively the hydrogenolysis of **1**.

The catalytic hydrogenolysis of **2** was slower than that of **1** and gave butylbenzene(**2a**), 2-fluoro-1-phenylbutane(**2b**), (*Z*)-2-fluoro-1-phenyl-1-butene(**2d**), and (*Z*)-2-fluoro-1-phenyl-2-butene(**2e**). 2,2-Difluoro-1-phenylbutane(**2c**) was detected only in the case of the PdO-catalyzed hydrogenolysis in the absence of the additive, although **2c** was identified only by use of GC-MS (H^+=170) because of the difficulty to isolate **2c** by VPC preparatively. The products show more clearly that the cyclopropane ring cleavage occurs selectively at the C_2–C_3 bond, and the olefins are the important intermediates as the precursors of the final products.

Table 1. Hydrogenolysis of **1**

Catalyst		Additive	Time	Composition of products(%)				
	(mg)	(mmol)	min	**1**	**1a**	**1b**	**1c**	**1d**

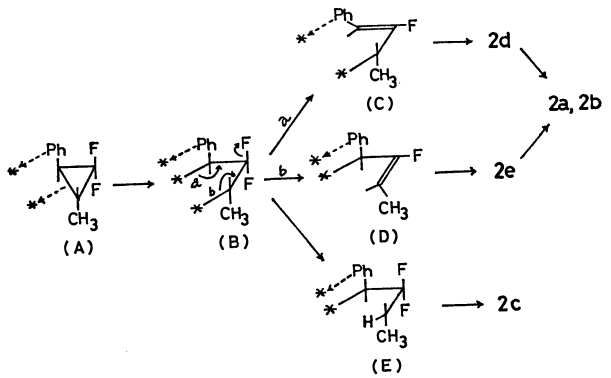
R-Ni	15	EDA 0.6	60	100	—	—	—	—

168 mg (1 mmol) of **2** was used for each PdO-catalyzed hydrogenolysis. 34 mg (0.2 mmol) of **2** was used for each R-Ni-catalyzed hydrogenolysis.

According to Hoffmann's proposal,[2] using the Walsh model as a basis, the π-electron donating groups raise the electron density of antibonding LUMO to cause weakening of ring bonds together with an increase in their length. The available data of ring bond lengths (Å) for C_1–C_2 and C_2–$C_{2'}$ bonds in cyclopropane,[3] dichloro-,[4] fluoro-,[5] and difluorocyclopropanes[6] are reported, respectively, as follows; 1.514, 1.514; 1.532, 1.534; 1.494, 1.527; 1.464, 1.553. Analogous deformation of the cyclopropane ring is expected for **1** and **2**. Therefore, the affinity of fluorine to the catalysts seems to become a minor factor even when R-Ni is used, and the cleavage of the cyclopropane ring of **1** and **2** occurs at the weakened C_2–C_3 bond exclusively.

A plausible pathway of hydrogenolysis of **2** is shown in Scheme 1. From species (B), the elimination of fluoride ion (or fluorine atom) is caused by the electron transfer from C_2– or C_3–metal bond to give (C) and (D). In competition with the elimination, unlike dichloro derivatives, the combination of *s*-type adsorbed hydrogen[7] at the C_2– and C_3–metal bonds occurs to give **2c** *via* (E). As the adsorption of EDA to the nickel catalyst is more stronger than that of monoamines, the adsorption by C_1–C_2 or C_2–C_3 bond of cyclopropane ring seems to be not strong enough to promote the hydrogenolysis.



Scheme 1.

Experimental

*1,1-Difluoro-2-phenylcyclopropane (**1**).* **1** was prepared according to the method described in the literature.[8] The fraction, bp 55—65 °C/25 mmHg (1 mmHg=133.322 Pa) was purified preparatively by VPC. MS *m/e*: 154(M^+) ^{1}H NMR(CCl_4): δ=1.70 (2H, m, C(H)—C(H)—H), 2.67 (1H, m, C_6H_5-C(H)—C), 7.17 (5H, s, C_6H_5-). Found: C, 70.17; H, 5.31%. Calcd for $C_9H_8F_2$: C, 70.12; H, 5.23%.

*1,1-Difluoro-3-methyl-2-phenylcyclopropane (**2**).* **2** was prepared in a similar manner as **1** and the fraction, bp 45—50 °C/19 mmHg, was purified preparatively by VPC. MS *m/e*: 168(M^+), ^{1}H NMR(CCl_4): δ=1.36 (3H, m, CH_3-), 1.76 (1H, m, C(H)—C-CH_3), 2.16 (1H, m, C_6H_5-C(H)—C), 7.16 (5H, s, C_6H_5-). Found: C, 71.54; H, 6.05%. Calcd for $C_{10}H_{10}F_2$: C, 71.42; H, 5.99%.

General Procedure of Catalytic Hydrogenolysis. Substrates were hydrogenated over prescribed amount of PdO (Nippon Engelhard Co.) or R-Ni (alloy NDH, Kawaken Fine Chemical Co., was treated according to the W-5 method[9] and washed with water until free from the alkaline solution) catalyst in the presence or absence of additives, such as potassium hydroxide or amines, in methanol at room temperature under atmospheric pressure. The composition of products was determined by VPC (DOS, 2 m, 100 and 130 °C) at appropreate time intervals.

Identification of Products. After the hydrogenolysis proceeded appropriately, the reaction mixture was subjected to measurement of GC-MS. For measurement of NMR and elementary analysis, each component of the products was separated preparatively by VPC.

*Propylbenzene (**1a**)*: MS *m/e*: 120(M^+), which was identical with that of an authentic sample.

*2-Fluoro-1-phenylpropane (**1b**)*: MS *m/e*: 138(M^+), ^{1}H NMR (CCl_4): δ=1.24 (3H, dd, -CH_3, $J(CH_3$-H)=6.0 Hz, $J(CH_3$-F)=23 Hz), 2.65 (1H, dd, C_6H_5-C(H_a)—C(H_c)-, H_b, F, $J(H_a$-H_c)=6.0 Hz, $J(H_a$-F)=6.0 Hz), 2.98 (1H, dd, C_6H_5-C(H_b)—C(H_c)-, F, $J(H_b$-H_c)=6.0 Hz, $J(H_b$-F)=2.5 Hz), 4.73 (1H, mm, H_c-C(F)-CH_3, $J(H_c$-F)=48 Hz), 7.15 (5H, s, C_6H_5). Found: C, 77.68; H, 7.98%. Calcd for $C_9H_{11}F$: C, 78.23; H, 8.02%.

*2,2-Difluoro-1-phenylpropane (**1c**)*: MS *m/e*: 156(M^+), ^{1}H NMR(CCl_4): δ=1.46 (3H, t, -CF_2-CH_3, $J(CH_3$-F)=18 Hz), 3.08 (2H, t, C_6H_5-CH_2-CF_2-, $J(CH_2$-F)=15 Hz), 7.20 (5H, s, C_6H_5). Found: C, 69.12; H, 6.57%. Calcd for $C_9H_{10}F_2$: C, 69.21; H, 6.45%.

(Z)-*2-Fluoro-1-phenylpropene (**1d**)*: MS *m/e*: 136(M^+), ^{1}H NMR(CCl_4): δ=2.05 (3H, d, C(F)=C(H_3)-, $J(CH_3$-F)=15 Hz), 5.35 (1H, d, C_6H_5-C(F)=C(H)-, J(H-F)=36.5 Hz), 7.24 (5H, m, C_6H_5), IR(CCl_4): 1695 cm^{-1} (C=C). Found: C, 79.27; H, 6.98%. Calcd for C_9H_9F: C, 79.38; H, 6.66%.

*Butylbenzene (**2a**)*: MS *m/e*: 134(M^+), which was identical with that of an authentic sample.

*2-Fluoro-1-phenylbutane (**2b**)*: MS *m/e*: 152(M^+), ^{1}H NMR (CCl_4): δ=0.97 (3H, t, -CH_3), 1.15—1.94 (2H, m, -CHF-CH_2-CH_3), 2.67 (1H, dd, C_6H_5-C(H_a)—C(H_c)-, H_b, F, $J(H_a$-H_c)=6.0 Hz, $J(H_a$-F)=3.0 Hz), 3.01 (1H, ss, C_6H_5-C(H_a)—C(H_c)-, H_b, F, $J(H_b$-H_c)=6.0 Hz, $J(H_b$-F)=0 Hz), 4.50 (1H, mm, H_c-C(F)-F, $J(H_c$-F)=52 Hz), 7.15 (5H, s, C_6H_5). Found: C, 78.30; H, 8.49%. Calcd for $C_{10}H_{13}F$: C, 78.91; H, 8.61%.

(Z)-*2-Fluoro-1-phenyl-1-butene (**2d**)*: MS *m/e*: 150(M^+), ^{1}H NMR(CCl_4): δ=1.15 (3H, t, -CH_2-CH_3), 2.28 (2H, m, C=CF-CH_2-, J(H-F)=14 Hz), 5.30 (1H, ss, C_6H_5-C(H)=C-, F, J(H-F)=37 Hz), 7.27 (5H, m, C_6H_5), IR(CCl_4): 1685 cm^{-1} (C=C). Found: C, 79.86; H, 7.48%. Calcd for $C_{10}H_{11}F$: C, 79.79; H, 7.38%.

(Z)-*2-Fluoro-1-phenyl-2-butene (**2e**)*: MS *m/e*: 150(M^+), ^{1}H NMR(CCl_4): δ=1.60 (3H, mm, -CF=CH-CH_3, $J(CH_3$-H)=7.0 Hz), 3.42 (2H, ss, C_6H_5-CH_2-CF=C, H, J(H-F)=15 Hz), 4.48 (1H, mm, -C(F)=C(H)-CH_3, J(H-F)=35 Hz), 7.18 (1H, s, C_6H_5), IR(CCl_4): 1700 cm^{-1} (C=C). Found: C, 79.82; H, 7.47%. Calcd for $C_{10}H_{11}F$: C, 79.97; H, 7.38%.

Kinetic Study of Aqueous Decompositions of *N*-(2-Haloethyl)-*N'*-cyclohexyl-*N*-nitrosoureas. Effect of Haloethyl Group on the Preference in Decomposition Pathways

Kitaro YOSHIDA* and Kazuyuki YANO

Department of Chemistry, Saitama Medical School, 981 Kawakado, Moroyama, Iruma-gun, Saitama 350-04

(Received September 20, 1982)

Synopsis. The aqueous decompositions of the title nitrosoureas under various pH conditions were studied kinetically to generalize their hydrolytic mechanisms. The relative decomposition rates of these analogs were in order of the leaving ability of the halogen moiety, which also affected on the preference in their reaction pathways.

Extensive studies[1] on the mechanism of action of antitumor agent *N*-(2-chloroethyl)-*N'*-cyclohexyl-*N*-nitrosourea (CCNU, **1-Cl**) under chemical hydrolytic conditions have established at least three competitive reaction pathways (A, B, and C, Scheme 1). Pathway A provides cyclohexyl isocyanate and 1-chloro-(2-hydroxyazo)-ethane **3** (X=Cl) with the latter intermediate becoming 2-chloroethyl cation which attacks certain nucleotides *in vivo*. Pathway B proceeds *via* an unstable nitrosooxazolidine **4** which breaks down to give acetaldehyde as a volatile product. Both processes are necessarily attended with proton elimination from N' as an initial step and are kinetically indistinguishable. The third pathway C, however, takes place by nucleophilic attack to C-2 by nitroso oxygen to liberate the chloride ion and affords oxadiazoline intermediate **5**. Although relative contributions of each competing pathways are varied depending on pH, solvent polarity, and nature of buffering medium, the propensity of **1-Cl** to provide a significant quantity of 2-chloroethyl cation through pathway A is a mainstay of its antitumor activity. Incidentally, little has been investigated for the chemical reactivities of other halogenated analogs, **1-F** and **1-Br**.[2] This note describes and compares a few kinetic results of aqueous decompositions of **1** in various buffer solutions.

Results and Discussion

The decomposition rates were measured by following the decrease of UV absorption of the substrates (230 nm). For each nitrosourea pseudo-first-order rate constant (k/s^{-1}) was observed and the kinetic data under various pH conditions are drawn in Fig. 1. As shown in Fig. 1, the rate of hydrolysis of **1-F** becomes larger with increasing hydroxide ion concentrations and is clearly dependent on pH over the whole range studied. A similar kinetic result was also observed for **1-Cl** within the range of pH 7—8. The decomposition rate of **1-Cl** is reduced at lower pH's, but the extent of the rate reduction becomes rather small. This trend is still more obvious in the case of bromine analog, **1-Br**. It is apparently shown that the reactivity of **1-Br** is higher than those of **1-F** and **1-Cl**. It decomposes at a rate 6 times faster than does **1-Cl** and is about 10 times more reactive than **1-F** at pH 7.1. Moreover, there is a broad pH range over which the decomposition rate is irrespective of acid or base.

Degradation study appears to be agreed with the above observations. When **1-Cl** was decomposed at pH 7.2, 2-chloroethanol was produced in 28% yield based on parent nitrosourea (Table 1), which must imply the occurence of elimination pathway A. Similarly, **1-Br** could afford the corresponding 2-haloethanol. Thus it would appear that the hydroxide ion catalyses are valid under the neutral conditions. However, as the pH is lowered, the contribution of the

a) Acetate. b) Phosphate.

catalysis tends to decrease. At pH 4.3, the amount of 2-chloroethanol from **1-Cl** reduced to 13% yield. Most obviously, none of the formation of 2-bromoethanol from **1-Br** was looked under the same conditions.

The results suggest that at higher pH values, the abstraction of the ureido proton is substantial, while as the pH is decreased, the nitroso oxygen assisted mechanism (pathway C) becomes increasingly more important. In the case of **1-F**, a poor leaving group attached to C-2 may resist to such an intramolecular process.[3] Further consistent evidence with the favored formation of the oxadiazoline intermediate from **1-Br** was also available. We synthesized the next higher homolog with three methylene units **2**, since it has already been reported that an introducing of the third methylene group into methyl-(2-tosyloxyethyl)-*N*-nitrosamine [$CH_3N(NO)CH_2CH_2OTs$] causes to prohibit its intramolecular process in such a way as to retard its decomposition rate.[4] As would be expected, **2** was quite modest under the present conditions. It is less reactive than **1-Br** by a factor of 15 at pH 7.1. Also, the kinetic feature of **2** is distinctly separated from that of **1-Br** and is closely parallel to **1-F**. The remarkable difference between two reactivities of **1-Br** and **2** must be due to a conformational restriction whereby the cyclic oxadiazoline from **2** with six membered ring is much less favorable than that from **1-Br** with five membered one. Probably, **2** decomposes by ordinary mechanisms (A or B).

The present study shows that an alteration of haloethyl moiety of the title nitrosoureas causes significant influences not only on their relative decomposition rates but on the preference in particular reaction pathways. Such the variations are related to the leaving properties of the C-2 substituent.

Experimental

Materials. *N*-(2-Haloethyl)-*N'*-cyclohexyl-*N*-nitrosoureas (**1**) were prepared by the method of Johnston.[2] *N*-(3-Bromopropyl)-*N'*-cyclohexyl-*N*-nitrosourea (**2**) was prepared from condensation of 3-bromopropylamine with cyclohexyl isocyanate, followed by nitrosation by sodium nitrite (63% overall yield): mp 42—44 °C; IR (KBr) 3280 (NH), 1690 (C=O), 1520 (C-NH), and 1470 cm^{-1} (N=O); ^1H NMR ($CDCl_3$) δ=0.91—2.26 (12H, m), 3.28 (2H, t, J=6 Hz, $CH_2CH_2C\underline{H}_2Br$), 3.94 (2H, t, J=6 Hz, $C\underline{H}_2CH_2CH_2Br$), 3.96 (1H, m, methine), and 6.81 (1H, m, NH). Found: C, 40.86; H, 6.16; N, 14.35; Br, 27.03%. Calcd for $C_{10}H_{18}N_3O_2Br$: C, 41.11; H, 6.21; N, 14.38; Br, 27.35%.

Kinetics were performed with a Shimadzu UV 200 spectrophotometer according to our previous method.[5] The pH of the buffer solution was measured with a Toa-denpa pH meter (HM-5A).

Product Analysis. Nitrosourea **1-Cl** (70 mg) in acetonitrile (3 ml) was added to 300 ml of 0.1 M (1 M=1 mol dm^{-3}) phosphate buffer solution (pH 7.2, μ=0.5). After the solution was stirred at 36.9 °C for 23 h, 2-bromoethanol (18 mg) was added as an internal standard. The cooled solution was saturated by sodium chloride, extracted with three portions of ether (450 ml), dried and evaporated. The GLPC analysis of the crude product showed the formation of 2-chloroethanol in 28% yield. The yield of 2-bromoethanol from **1-Br** was also determined by using 2-chloroethanol as an internal standard. The results are summarized in Table 1. Control experiments indicated that both of the 2-haloethanols did not hydrolyzed at pH 7.2. Owing to its insolubility in ether, attempts to trap ethylene glycol were unsuccessful.

This paper is dedicated to Professor Kazuo Nagamatsu in our laboratory on the 60th anniversary of his birth.

An Improved Synthesis of *threo*-3-Methyl-D-cysteine

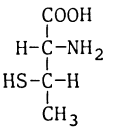
Tateaki WAKAMIYA, Koichi FUKASE, Kuniaki SHIMBO, and Tetsuo SHIBA*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

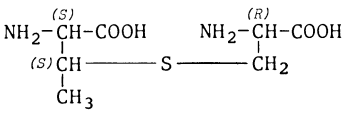
(Received October 18, 1982)

Synopsis. Synthesis of *threo*-3-methyl-D-cysteine, a moiety of β-methyllanthionine as a component of the peptide antibiotics nisin and subtilin, was achieved *via* (2*R*,3*R*)-1-*t*-butoxycarbonyl-3-methyl-2-aziridinecarboxamide derived from D-threonine. An addition of thioacetic acid or thiobenzoic acid to the aziridinecarboxamide gave *S*-acyl-β-mercapto-α-amino acid amide derivatives which were hydrolyzed directly or after the preformation of disulfide bond to afford the desired amino acid.

In our previous paper,[1] we reported the preparation of *threo*-3-methyl-D-cysteine (**1**), *i.e.*, (2*S*,3*S*)-2-amino-3-mercaptobutanoic acid[2] which corresponds to a moiety of β-methyllanthionine (**2**)[3] in the peptide antibiotics



1

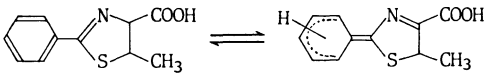


2

nisin[4] and subtilin,[5] *via* (2*R*,3*R*)-1-benzyloxycarbonyl-3-methyl-2-aziridinecarboxylic acid methyl ester (Z-3-MeAzyOMe) derived from D-threonine.[1] According to this procedure, the addition of thiobenzoic acid to the aziridinecarboxylic ester in the presence of $BF_3 \cdot Et_2O$ gave *threo*-*S*-benzoyl-*N*-benzyloxycarbonyl-3-methyl-D-cysteine methyl ester in less than 60% yield, which was caused by the formation of *N*-benzyloxycarbonyl-*O*-thiobenzoyl-D-threonine methyl ester as a by-product. Certainly, an equilibrium between thiobenzoic *S*-acid (C_6H_5COSH) and *O*-acid (C_6H_5CSOH) resulted in such undesirable side reaction. On the other hand, it was found that the reaction of thiobenzoic acid with 3-methyl-2-aziridinylcarbonyl peptides produced solely *S*-benzoyl-3-methylcysteinyl peptides without the addition of Lewis acid which seemed to enhance the reactivity of *O*-acid relatively.

Based on the above observation and consideration, we attempted to improve the synthetic procedure of **1** by use of aziridinecarboxamide in place of the ester derivative. Furthermore, *t*-butoxycarbonyl (Boc) group was adopted as *N*-protecting group rather than benzyloxycarbonyl (Z) group to prevent an attack of benzyl cation formed during acid hydrolysis to free mercapto group. Thus, (2*R*,3*R*)-1-*t*-butoxycarbonyl-3-methyl-2-aziridinecarboxamide [(2*R*,3*R*)-Boc-3-MeAzyNH$_2$] (**4**) was prepared in the usual way. The addition of thiobenzoic acid to **4** took place smoothly with the sole formation of *S*-benzoyl-*N*-Boc-*threo*-3-methyl-D-cysteinamide (**5a**) as we expected. An overall yield in the introduction of mercapto moiety was now considerably increased, even though the modified procedure required an extra step for the amidation. In addition, the easy precipitation of the product from the reaction mixture made the procedure so simple that we could avoid the tedious extraction step to separate the product from ill-smelling thiocarboxylic acid and also the column chromatographic purification as in the case of ester derivative.

However, although the introduction of mercapto moiety was able to be achieved successfully, acid hydrolysis of **5a** resulted in the unexpected formation of quite stable 5-methyl-2-phenyl-2-thiazoline-4-carboxylic acid (**6**)[6] which gave racemic amino acid conceivably through a tautomerism between **6** and **6′**



6 **6′**

under prolonged heating. Therefore, in order to avoid such an undesirable formation of thiazoline compound, *S*-benzoyl group was first removed to afford a disulfide derivative **7** which was then satisfactorily hydrolyzed to an optically pure *threo*-3,3′-dimethyl-D-cystine (**8**).[7]

Another or even better solution of the problem was arisen from the following consideration. Since the formation of stable thiazoline ring may be due to the stabilization of the molecule by phenyl group, suitable choice of the *S*-acyl moiety seemed to make the hydrolysis easy. Based on such an assumption, use of *S*-acetyl-*N*-Boc-*threo*-3-methyl-D-cysteinamide (**5b**) for this reaction was attempted. The compound **5b** was prepared in a similar manner as in the preparation of **5a**. Indeed, the acid hydrolysis of **5b** under the usual conditions proceeded readily *via* a labile thiazoline **9** as a plausible intermediate to produce an optically pure *threo*-3-methyl-D-cysteine (**1**) in a satisfactory yield. Thus, we succeeded to establish an improved preparative method of **1** which can be utilized as an important component for the syntheses of rings B, C, D, and E in nisin.

Experimental

(2R,3R)-3-Methyl-2-aziridinecarboxamide [(2R,3R)-3-MeAzyNH$_2$] (3). A solution of (2*R*,3*R*)-3-MeAzyOMe prepared from (2*R*,3*R*)-trityl-3-MeAzyOMe (2.80 g, 7.84 mmol) according to the usual manner[8] in 45 ml of methanol was saturated with liquid ammonia under cooling in an ice-salt bath. The reaction mixture was kept in a pressure bottle at 25 °C for 4 d. Evaporation of the solvent and excess ammonia gave crystalline product in a yield of 740 mg (94%). A crop of the product was recrystallized from methanol and ether: mp 132—133.5 °C; $[\alpha]_D^{18}$ +103° (*c* 0.900, DMF).

Found: C, 48.00; H, 8.01; N, 27.54%. Calcd for $C_4H_8ON_2$: C, 47.99; H, 8.05; N, 27.98%.

(2R,3R)-Boc-3-MeAzyNH$_2$ (4). To a solution of (2*R*,3*R*)-3-MeAzyNH$_2$ (**3**) (7.20 g, 72.0 mmol) in 100 ml of methanol was added di-*t*-butyl dicarbonate (17.3 g, 79.0 mmol). The reaction mixture was concentrated *in vacuo* to afford crystalline product which was recrystallized from ethyl acetate and hexane: yield 12.3 g (85.3%); mp 118—119 °C; $[\alpha]_D^{18}$ +116° (*c* 1.06, $CHCl_3$).

Found: C, 53.96; H, 8.05; N, 13.89%. Calcd for $C_9H_{16}O_3N_2$: C, 53.99; H, 8.05; N, 13.99%.

S-*Benzoyl*-N-t-*butoxycarbonyl*-threo-*3-methyl*-D-*cysteinamide (5a).* Thiobenzoic acid (8.28 g, 60.0 mmol) was added to a solution of **4** (6.00 g, 30.0 mmol) in 60 ml of dichloromethane. A part of the crystalline product precipitated after stirring at room temperature overnight and hexane was added to complete the precipitation, yield 9.62 g (94.8%). An analytical sample was obtained by recrystallization from ethanol and hexane: mp 165.5—167 °C; $[\alpha]_D^{18}$ −41.7° (*c* 0.700, MeOH).

Found: C, 57.01; H, 6.64; N, 8.13; S, 9.37%. Calcd for $C_{16}H_{22}N_2O_4S$: C, 56.79; H, 6.55; N, 8.28; S, 9.47%.

S-*Acetyl*-N-t-*butoxycarbonyl*-threo-*3-methyl*-D-*cysteinamide (5b).* The reaction of thioacetic acid (6.36 g, 84.0 mmol) and **4** (6.00 g, 30.0 mmol) in dichloromethane (60 ml) was carried out in a similar manner as the preparation of **5a** and crystalline product **5b** was obtained in a yield of 7.86 g (94.9%). An analytical sample was prepared by recrystallization from ethyl acetate and hexane: mp 104—104.5 °C; $[\alpha]_D^{30}$ −35.5° (*c* 1.17, MeOH).

Found: C, 48.00; H, 7.29; N, 10.15; S, 11.68%. Calcd for $C_{11}H_{20}N_2O_4S$: C, 47.81; H, 7.29; N, 10.14; S, 11.60%.

N,N′-*Bis (t-butoxycarbonyl)*-threo-*3,3′-dimethyl*-D-*cystinediamide (7).* To a solution of **5a** (7.00 g, 20.7 mmol) in 200 ml of methanol was added dropwise 1 M† methylamine in methanol (20.7 ml, 20.7 mmol) for 8 h. After stirring overnight, 0.5 M iodine in methanol was added until the completion of the oxidation. The reaction mixture neutralized with methylamine was concentrated *in vacuo* to about 100 ml. The residue was cooled in an ice bath and the precipitate was filtered. The product was washed with hexane, suspended in water, and again filtered to afford pure material: yield 3.71 g (77.0%); mp 224—226 °C; $[\alpha]_D^{18}$ +82.1° (*c* 0.610, DMF).

Found: C, 46.22; H, 7.32; N, 11.91; S, 13.81%. Calcd for $C_{18}H_{34}N_4O_6S_2$: C, 46.33; H, 7.34; N, 12.01; S, 13.74%.

threo-*3,3′-Dimethyl*-D-*cystine (8).* A suspension of **7** (3.60 g, 7.72 mol) in 70 ml of 6 M HCl was refluxed for 10 h at 110 °C. The hydrolyzate concentrated *in vacuo* was suspended in 80 ml of ethanol to remove insoluble NH_4Cl and the filtrate was concentrated again. A solution of the residue in 25 ml of water and 30 ml of ethanol was neutralized with pyridine and then kept in refrigerator overnight. Crystalline precipitate was filtered, washed with ethanol, and recrystallized from water and ethanol: yield 1.96 g (94.7%); mp 190—196 °C (decomp); $[\alpha]_D^{27}$ −419° (*c* 0.540, 1 M HCl) [lit,[2d]) $[\alpha]_D^{19}$ −414° (*c* 1, 1 M HCl)].

Found: C, 34.65; H, 6.12; N, 10.06; S, 23.51%. Calcd for $C_8H_{16}O_4N_2S_2 \cdot 0.4H_2O$; C, 34.87; H. 6.15; N, 10.17; S, 23.27.

threo-*3-Methyl*-D-*cysteine (1).* A suspension of **5b** (1.00 g, 3.62 mmol) in 20 ml of 6 M HCl was refluxed for 10 h at 110 °C under argon atmosphere. The same work-up as mentioned for the preparation of **8** gave colorless crystalline product: yield 0.40 g (82%); mp 199.5—200 °C; $[\alpha]_D^{23}$ +16.9° (*c* 1.24, 1 M HCl) [lit,[2c]) $[\alpha]_D^{25}$ +17.5° (*c* 1, 1 M HCl)].

Found: C, 35.41; H, 6.82; N, 10.28; S, 23.03%. Calcd for $C_4H_9O_2NS \cdot 0.1H_2O$; C, 35.05; H, 6.77; N, 10.23; S, 23.41%.

† 1 M = 1 mol dm^{-3}.

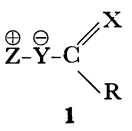
Pyridinium-1-thioacylaminides

Hiroshi YOSHIDA,* Kiyomi URUSHIBATA, and Tsuyoshi OGATA
Department of Applied Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu 432
(Received November 1, 1982)

Synopsis. Pyridinium-, 2-methylpyridinium-, and 2,6-dimethylpyridinium-1-thioacylaminides (**5**—**7**) were prepared from the corresponding unsubstituted pyridinium-1-aminides and methyl dithiocarboxylates in fairly good yields. The alkylation reaction of **5**—**7** took place exclusively on the thiocarbonyl sulfur, yielding pyridinium salts in quantitative yields. The NMR spectroscopic studies indicated that *E* and *Z* forms existed for these pyridinium salts. The thermal decomposition of **5**—**7** yielded the corresponding pyridine, nitrile, and sulfur in good yields.

Recently a number of heterocyclic aminides have been prepared, and their physical and chemical properties have been clarified.[1-4] In a continuation of our previous studies of the *P*- and *S*-ylides and aminides[5] with C=S or C=N groups as substituents such as **1**, we have become interested in the chemistry of pyridinium-1-thioacylaminides **5**, **6**, and **7**:



1

Z=Ph_3P, Ph_2S, Me_2S, Me_2SO
Y=CH, N
X=NR′, S
R=Ar, R′O,

Some pyridinium-1-aminides with thioacyl groups as substituents have been previously prepared. 2,4,6-Triphenylpyridinium perchlorate reacts with thioacylhydrazine to give the rather unstable 1-thioamidotriphenylpyridinium perchlorate, which then decomposes on attempted deprotonation.[2] Isothiocyanate reacts with free pyridinium-1-aminides **2**—**4** to yield thiourea derivatives.[3] 2-Methylpyridinium-1-[(methylthio)-thiocarbonylaminide](**6c**) has been prepared from free aminide **3**, carbon disulfide, and an alkylating reagent in a 59% yield.[4]

The action of methyl dithiocarboxylates to **2**, **3**, or **4**, generated from the corresponding 1-aminopyridinium mesitylene-sulfonates[6] and potassium carbonate in ethanol, yielded the expected pyridinium-1-thioacylaminides **5**, **6**, or **7** in good yields, as are listed in Table 1. The structure of the products was elucidated on the basis of their elemental analyses, ^{1}H-NMR spectra, alkylation reaction, and thermal-decomposition reaction.

The alkylation of the oxygen analogues of **5**, **6**, or **7** takes place on the aminide nitrogen, not on the acyl oxygen.[1b] In contrast, the alkylation of **5**, **6**, and **7** with various alkylating reagents (R′X) takes place exclusively on the sulfur, very easily at room temperature, to give the corresponding pyridinium salts **5**, **6**, and **7**(R′X) in fairly good yields.

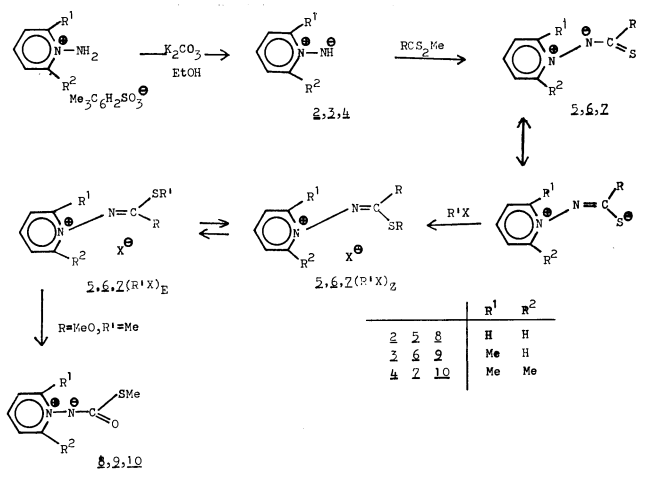
Pyridinium 1-methoxythiocarbonylaminides **5d**, **6b**, and **7b** reacted with methyl iodide to give the corresponding (methylthio)carbonylaminides **8**, **9**, and **10** as final products in quantitative yields. The reaction with methyl benzenesulfonate yielded the expected salts **5d**, **6b**, and **7b**($MeOSO_2Ph$).

The stereochemistry of the salts was assigned on the basis of the fact that the R′ groups cis to the pyridine ring are shielded by the ring and that they appear at the higher field than the R′ trans to the ring.[7]

Alkylation and isomerization reaction of **5**—**7** were studied by means of NMR spectroscopy. On heating at 70 °C for 2 h in $CDCl_3$ **5**$(R'X)_Z$ and **6**$(R'X)_Z$ were easily isomerized to give equilibrium mixtures; in contrast, **7**$(R'X)_Z$ showed no isomerization on heating for 10—20 h, indicating the retardation of rotation around the C=N bond due to the steric hindrance.

The stereochemistry of the C=N bond with alkyl, aryl, alkoxy, alkylthio, or amino groups as substituents has been widely studied.[8] A number of factors seem to govern the *E*—*Z* equilibrium ratios for this system.[8] Table 2 seems to indicate that *E*-forms are furnished for the **5**(R′X) and **6**(R′X) salts, in this order with respect to the substituent R′:phenyl, alkylthio, and alkoxy. The steric effect seems to be a dominant factor for the salts with alkylthio groups as substituents **5f**(EtI, $PhCH_2Br$, $PhCOCH_2Br$), while interorbital repulsion[9] seems to control the stereochemistry of the salts with alkoxyl groups [**5d**, **5e**, and **7b**($MeOSO_2Ph$)].

The conformations of the initial alkylation products **5**, **6**, and **7**$(R'X)_Z$ seem to show that the starting aminides **5**—**7** were of the *Z*-form, indicating the importance of the delocalization of the aminide electrons through the thiocarbonyl groups of **5**—**7**, as is shown in Scheme 1.



Scheme 1.

Although **5**—**7** were stable in a refrigerator, on heating at 80—120 °C in a solvent(benzene or toluene) a smooth decomposition was observed, yielding nitrile, pyridine, and sulfur in good yields.

Trapping experiments to find an intermediate, nitrile sulfide,[5b] for the thermolysis of **5**—**7** failed. On heating, a mixture of **5**, **6**, or **7** and dimethyl acetylenedicarboxylate in tarry mass, from which no crystalline compound was isolated.

Experimental

Preparation of 5—7. A mixture of 1-amino-, 1-amino-2-methyl-, or 1-amino-2,6-dimethylpyridinium mesitylenesulfonate[6] (1.1 mmol), potassium carbonate (3 mmol), and methyl dithiocarboxylate (1 mmol) in ethanol (25 cm³) was stirred for 2.5 h at room temperature. The solvent was then removed *in vacuo* at room temperature; the subsequent separation of the chloroform-soluble product yielded crystalline pyridinium-1-thioacylaminides **5—7**. The physical properties are collected in Table 1.

Alkylation of 5—7. To a solution of **5**, **6**, or **7** in benzene we added a 2-fold excess amount of an alkylation reagent (R'X) at room temperature. The reaction was checked by TLC (silica gel) until the starting material was reacted completely. The precipitated salt **5**, **6**, or **7**(R'X) was washed with dry benzene and dried *in vacuo* (Table 2). The isomerization and the determination of the equilibrium ratios in $CDCl_3$ were studied by means of NMR spectroscopy.

The Reaction of 5d, 6b, and 7b with Methyl Iodide. To a solution of **5d**, **6b**, or **7b**(1 mmol) in chloroform (5 cm³) we added methyl iodide (2 mmol) in one portion. The solution was then kept standing at room temperature for 12 h. The evaporation of the solvent and recrystallization from benzene gave **8**, **9**, or **10** in a quantitative yield. The NMR spectroscopic studies in $CDCl_3$ indicated that the initially formed salts showed the same spectra as those from the reaction with methyl benzenesulfonate. **8**: mp 131—132 °C; NMR($CDCl_3$) δ=2.33(SMe) and 7.6—8.8 (m, Ar). Found: C, 49.88; H, 4.73; N, 16.59%. Calcd for $C_7H_8N_2OS$: C, 49.98; H, 4.79; N, 16.65%. **9**: mp 116 °C; NMR($CDCl_3$) δ=2.35 (SMe), 2.71 (2-Me), and 7.6—8.8 (m, Ar). Found: C, 52.41; H, 5.64; N, 15.11%. Calcd for $C_8H_{10}N_2OS$: C, 52.73; H, 5.53; N, 15.37%. **10**: mp 142—143 °C; NMR($CDCl_3$) δ=2.34 (SMe), 2.67 (2,6-Me), and 7.7—8.8 (m, Ar). Found: C, 55.43; H, 6.02; N, 14.13%. Calcd for $C_9H_{12}N_2OS$: C, 55.08; H, 6.16; N, 14.27%.

Thermal Decomposition of 5—7. A solution of **5**, **6**, or **7** in benzene or toluene (100 mg in 3 cm³) was heated until the starting material had reacted completely. The prducts were confirmed by comparisons of their NMR spectra or VPC with those of authentic samples.

Table 1. The preparation of pyridinium-1-aminides, **5—7**

Pseudo-sugars. IX. Synthesis of Three (Hydroxymethyl)-cyclohexanepentols[1)]

Seiichiro OGAWA, Toshinobu NAKAMURA, Noritaka CHIDA, and Tetsuo SUAMI*

Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223

(Received November 11, 1982)

Synopsis. Three new DL-(hydroxymethyl)cyclohexanepentols, of which configurations are related to biologically important *chiro*- and *myo*-inositols, have been synthesized as hexaacetates from DL-tri-*O*-acetyl-(1,3/2,4)-4-benzoyloxymethyl-5-cyclohexene-1,2,3-triol by osmium tetraoxide-oxidation or peroxy acid-oxidation followed by acid hydrolysis, and their structures have been established by ^{1}H NMR spectroscopy.

During the course of synthetic studies of hydroxyvalidamine and valienamine,[2)] three new (hydroxymethyl)cyclohexanepentols have been prepared and characterized as hexaacetates. These branched-chain cyclitols are useful not only as reference compounds for structural elucidation of new cyclitols by ^{1}H NMR spectroscopy, but also as biologically interesting inositol analogs with *chiro*- and *myo*-configurations.

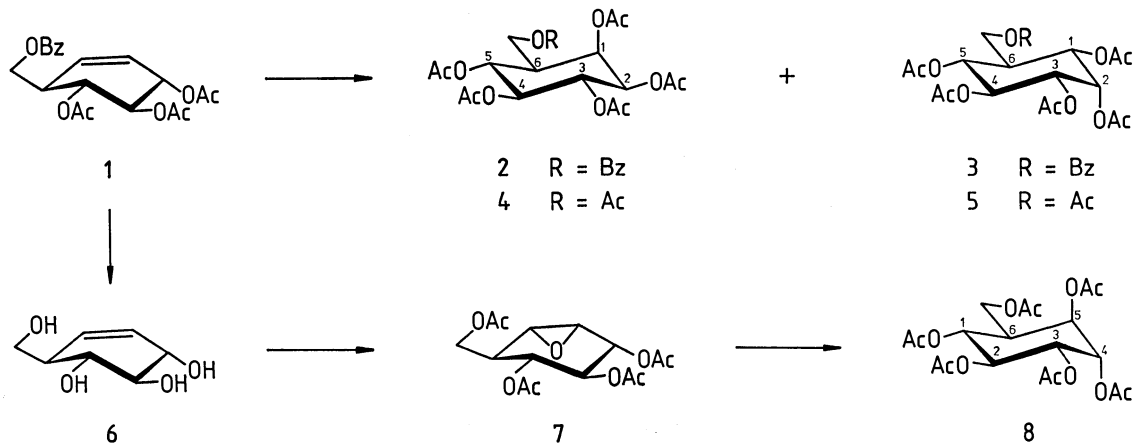
Treatment of DL-tri-*O*-acetyl-(1,3/2,4)-4-benzoyloxymethyl-5-cyclohexene-1,2,3-triol (**1**)[2)] with osmium tetraoxide in aqueous *t*-butyl alcohol containing 3% hydrogen peroxide at 40 °C for 120 h, followed by conventional acetylation, gave, after chromatography on silica gel, two peracyl (hydroxymethyl)cyclohexanepentols **2** and **3** in 24 and 24% yields, respectively. The assigned structures were established on the basis of their ^{1}H NMR spectra. Thus, in the spectrum of **2**, the signals for H-1, H-2, H-3, H-4, and H-5 appear as a triplet (δ=5.67, J=3 Hz), a doublet of doublets (δ=4.95, J=3 and 10.2 Hz), a triplet (δ=5.43, J=10.2 Hz), a doublet of doublets (δ=5.22, J=9 and 10.2 Hz), and a doublet of doublets (δ=5.34, J=10.2 and 10.5 Hz), respectively, indicating equatorial-axial-axial-axial-axial conformations for H-1, H-2, H-3, H-4, and H-5. The spectrum of **3** exhibits the signal for H-4 as a triplet (J=10 Hz) at δ=5.42, which seems deshielded by 0.2 ppm relative to that of **2** by the C-2 acetoxyl group in the 1,3-diaxial disposition. *O*-Deacylation of **2** and **3** with methanolic sodium methoxide in methanol followed by acetylation gave crystalline hexaacetates **4** and **5** in 43 and 59% yields, respectively.

On the other hand, the epoxide **7** prepared specifically by peroxy acid-oxidation of the tetrahydroxy compound **6** derived from **1**[2)] was hydrolyzed by refluxing in aqueous 2-methoxyethanol containing 0.7% sulfuric acid for 2 h. The product was successively acetylated to give a single crystalline hexol hexaacetate **8** in 70% yield. The structure was assigned as shown in the scheme by ^{1}H NMR spectroscopy. The spectrum indicated the signals for two acetoxyl groups to be as a 6-proton singlet in the regions characteristic of axial groups (δ=2.13),[3)] supporting that the reaction involves trans-diaxial opening of the oxirane ring.

Experimental

Melting points were determined on a Mitamura Riken micro hot stage and are uncorrected. ^{1}H NMR spectra were taken on a Varian EM-390 (90 MHz) spectrometer in chloroform-*d* with reference to tetramethylsilane as an internal standard. TLC was performed on precoated silica gel 60 F-254 plates (Merck, Darmstadt; 0.25 mm thickness). The silica gel used for column chromatography was Wakogel C-300 (Wako Pure Chemical Industries, Ltd.).

Oxidation of DL-*Tri*-O-*acetyl-(1,3/2,4)-4-benzoyloxymethyl-5-cyclohexene-1,2,3-triol (1) with Osmium Tetraoxide.* To a solution of **1** (0.20 g) in aqueous *t*-butyl alcohol (3 ml) containing 3% hydrogen peroxide was added osmium tetraoxide (5 mg) in *t*-butyl alcohol (1 ml), and the mixture was stirred at 40 °C for 120 h. The reaction mixture was concentrated and the residue was treated with acetic anhydride (1 ml) and pyridine (1 ml) at room temperature overnight. Evaporation of the excess reagent gave crude



Scheme 1.

products, which were fractionated on a silica-gel column (8.5 g) with 2-butanone–toluene (1: 12) as an eluent. The first fraction [R_f 0.45, 2-butanone–toluene (1: 5)] gave an oil (61 mg, 24%), which was crystallized from ethanol to give 15 mg of DL-1,2,3,4,5-penta-*O*-acetyl-7-*O*-benzoyl-(1,2,4,6/3,5)-6-hydroxymethyl-1,2,3,4,5-cyclohexanepentol (**2**) as prisms: mp 156—158 °C; ^{1}H NMR ($CDCl_3$) δ=1.95 (3H, s), 1.99 (6H, s), 2.01 (3H, s), and 2.10 (3H, s) (OAc), 2.45 (1H, m, H-6), 4.08 (1H, dd, $J_{6,7}$=9 Hz, J_{gem}=11 Hz) and 4.35 (1H, dd, $J_{6,7'}$=4.5 Hz) ($C\underline{H}_2OBz$), and 7.33—8.03 (5H, m, phenyl).

Found: C, 56.85; H, 5.30%. Calcd for $C_{24}H_{28}O_{12}$: C, 56.69; H, 5.55%.

Compound **2** (160 mg) was treated with 0.3 M (1 M= 1 mol dm^{-3}) methanolic sodium methoxide (3 ml) at room temperature for 1 h, and the reaction mixture was neutralized by 1 M hydrochloric acid and concentrated. The residual product was acetylated in the usual way and the product was crystallized from ethanol to give 68 mg (43%) of the hexaacetate **4** as prisms: mp 158—159 °C; ^{1}H NMR ($CDCl_3$) δ=1.96 (3H, s), 1.98 (3H, s), 2.00 (6H, s), 2.01 (3H, s), and 2.12 (3H, s) (OAc), 3.85 (1H, dd, $J_{6,7}$=4.5 Hz, J_{gem}=10.8 Hz) and 4.04 (1H, dd, $J_{6,7'}$=9 Hz) ($C\underline{H}_2OAc$), 4.87 (1H, dd, $J_{1,2}$=3 Hz, $J_{2,3}$=10.2 Hz, H-2), and 5.51 (1H, dd, $J_{1,6}$=2.3 Hz, H-1).

Found: C, 51.11; H, 5.80%. Calcd for $C_{19}H_{26}O_{12}$: C, 51.12; H, 5.87%.

The second fraction (R_f 0.40) gave an oil (63 mg, 24%), which was crystallized from ethanol to give 18 mg of DL-1,2,3,4,5-penta-*O*-acetyl-7-*O*-benzoyl-(1,2,3,5/4,6)-6-hydroxymethyl-1,2,3,4,5-cyclohexanepentol (**3**) as prisms: mp 146—148 °C; ^{1}H NMR ($CDCl_3$) δ=1.97 (6H, s), 2.01 (3H, s), 2.06 (3H, s), and 2.16 (3H, s) (OAc), 2.60 (1H, br t, $J_{1,6}$ =$J_{5,6}$=10 Hz, H-6), 4.28 (2H, br s, $C\underline{H}_2OBz$), 5.18 (1H, t, $J_{4,5}$=10 Hz, H-5), 5.42 (1H, t, $J_{3,4}$=10 Hz, H-4), 5.57 (1H, t, $J_{1,2}$=$J_{2,3}$=2.5 Hz, H-2), and 7.25—8.07 (5H, m, phenyl).

Found: C, 56.56; H, 5.57%. Calcd for $C_{24}H_{28}O_{12}$: C, 56.69; H, 5.55%.

Compound **3** (230 mg) was *O*-deacylated similarly as described above and acetylated to give a crystalline product, which was recrystallized from ethanol to give 135 mg (59%) of the hexaacetate **5** as prisms: mp 180—182 °C; ^{1}H NMR ($CDCl_3$) δ=1.99 (6H, s), 2.01 (3H, s), 2.04 (6H, s), and 2.16 (3H, s) (OAc), 4.00 (2H, br d, J=2 Hz, $C\underline{H}_2OBz$), 5.37 (1H, t, $J_{3,4}$=$J_{4,5}$=10.5 Hz, H-4), and 5.87 (1H, t, $J_{1,2}$=$J_{2,3}$=3 Hz, H-2).

Found: C, 51.10; H, 5.78%. Calcd for $C_{19}H_{26}O_{12}$: C, 51.12; H, 5.87%.

DL-*Hexa-O-acetyl-(1,3,4/2,5,6)-6-hydroxymethyl-1,2,3,4,5-cyclohexanepentol (**8**).* A mixture of DL-tetra-*O*-acetyl-1,2-anhydro-(1,2,3,5/4,6)-6-hydroxymethyl-1,2,3,4,5-cyclohexanepentol (**7**)[2] (83 mg) in 2-methoxyethanol (2 ml) and 1% sulfuric acid (5 ml) was refluxed for 1.5 h. The reaction mixture was neutralized with sodium hydrogencarbonate and concentrated. The residue was acetylated and the product was purified by passage through a short column of alumina with chloroform. The crystalline product was recrystallized from ethyl acetate–hexane to give 75 mg (70%) of **8** as prisms: mp 102—105 °C; ^{1}H NMR ($CDCl_3$) δ=1.96 (3H, s), 2.00 (3H, s), 2.01 (3H, s), and 2.13 (6H, s) (OAc), 2.52 (1H, m, H-6), 3.93 (1H, dd, $J_{6,7}$=4.5 Hz, J_{gem}=11.3 Hz) and 4.19 (1H, dd, $J_{6,7'}$=8.3 Hz) ($C\underline{H}_2OAc$), 5.16 (1H, dd, $J_{2,3}$=9 Hz, $J_{3,4}$=3.2 Hz, H-3), 5.28 (1H, t, $J_{1,2}$=$J_{1,6}$=9 Hz, H-1), 5.38 (1H, t, $J_{4,5}$=3.2 Hz, H-4), and 5.41 (1H, t, H-2).

Found: C, 51.35; H, 5.88%. Calcd for $C_{19}H_{26}O_{12}$: C, 51.12; H, 5.88%.

The authors wish to express their thanks to Mr. Saburo Nakada for elemental analyses.

Studies on 2-Aziridinecarboxylic Acid. X.[1] Simple Stereospecific Synthesis of Optically Active Cystine and *threo*-3,3'-Dimethylcystine

Kiichiro NAKAJIMA* and Kenji OKAWA

Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Nishinomiya 662

(Received November 20, 1982)

Synopsis. The reaction of (2*S*)-Z-Azy-OBzl, (2*S*, 3*S*)-Z-3-MeAzy-OBzl, and their enantiomers with H_2S gave the optically active cysteine and *threo*-3-methylcysteine derivatives *via* the stereospecific ring-opening reaction of aziridine, and subsequent oxidation and deblocking procedure gave the titled compounds in good yields.

Photaki[2] have reported the preparation of DL-*S*-tritylcysteine from L-serine *via* the β-elimination reaction of its *O*-tosylated derivative. Carter *et al.*[3] and Hoogmartens *et al.*[4] prepared 3-methylcystine *via* addition of thiol to 2-phenyl-4-ethylidene-5(4*H*)-oxazoline. Morell *et al.*[5] have reported that the displacement reaction of the *O*-tosyl-*allo*-threonine derivative with potassium thioacetate gave the *threo*-*S*-acetyl-3-methylcysteine, which was converted into *threo*-3,3'-dimethylcystine by hydrolysis and oxidation procedure. But these methods involved some technical trouble in obtaining the optically pure cystine or 3,3'-dimethylcystine, that is, the Carter-Hoogmartens's procedure requires a complex optical resolution procedure to get the optically pure product, and the Morell's procedure requires *allo*-threonine as a starting material to prepare *threo*-3-methylcysteine. More recently, Wakamiya *et al.*[6] reported the synthesis of *threo*-3,3'-dimethylcystine *via* ring-opening reaction of aziridine with thiobenzoic acid, this reaction still remained the problem concerning to the product, that is, two products of *S*-benzoyl and *O*-thiobenzoyl derivatives were prepared by this reaction procedure, due to the possible equilibrium in thiobenzoic acid, *e.g.* $C_6H_5COSH \rightleftharpoons C_6H_5CSOH$.

In this study, we employed a more simple stereospecific synthesis of optically active cystine and *threo*-3,3'-dimethylcystine. The synthetic route is shown in Scheme 1.

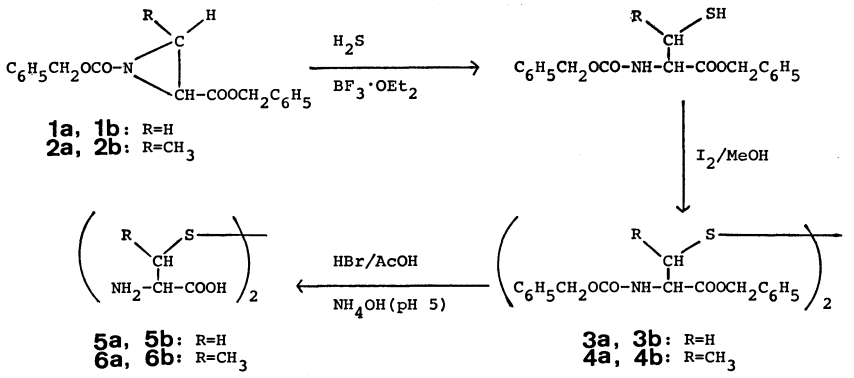
The aziridine derivatives used were benzyl (2*S*)-1-benzyloxycarbonyl-2-aziridinecarboxylate [(2*S*)-Z-Azy-OBzl] (**1a**), benzyl (2*S*,3*S*)-1-benzyloxycarbonyl-3-methyl-2-aziridinecarboxylate [(2*S*,3*S*)-Z-3-MeAzy-OBzl] (**2a**), and their enantiomers(**1b** and **2b**), which were prepared by *N*-benzyloxycarbonylation of (2*S*)-H-Azy-OBzl, (2*S*,3*S*)-H-3-MeAzy-OBzl, and their enantiomers with benzyloxycarbonyl chloride as described in our previous paper.[1] The ring-opening reaction of **1a**, **1b**, **2a**, and **2b** were carried out in dichloromethane saturated with H_2S in the presence of boron trifluoride etherate at room temperature for 3 h, and the corresponding cysteine derivatives obtained were oxidized with iodine in methanol solution to give the cystine(**3a**, **3b**) and 3,3'-dimethylcystine(**4a**, **4b**) derivatives. The deblocking procedure of benzyloxycarbonyl and benzyl ester was carried out in acetic acid saturated with HBr for 12 h at room temperature, and the crude cystine(**5a**, **5b**) and 3,3'-dimethylcystine (**6a**, **6b**) were purified by isoelectric point precipitation at pH 5 and recrystallized from hot water or water–ethanol to give the optically pure **5a**, **5b**, **6a**, and **6b**.

The above results show that, compared with conventional methods, synthesis of cysteine and 3-methylcysteine by the stereospecific ring-opening reaction of aziridine with H_2S is very convenient for transforming the serine or threonine into optically pure cystine or *threo*-3,3'-dimethylcystine.

Experimental

Uncorrected melting points are reported. The homogeneity of the products was checked by thin-layer chromatography on silica-gel plates. The optical rotations were determined at the D line on a Perkin-Elmer 141 polarimeter. The NMR spectra were obtained with Hitachi R 20 B high-resolution NMR spectrometer, the chemical shifts being obtained using TMS as the internal reference.

N,N'-*Bis*(*benzyloxycarbonyl*)-L-*cystine Dibenzyl Ester* (**3a**). Dry H_2S gas was bubbled through a solution of (2*S*-Z-Azy-OBzl (**1a**, 320 mg, 1.03 mmol) in dry CH_2Cl_2 (30 ml) until saturation at room temperature and $BF_3 \cdot OEt_2$ (5 drops) was added. Then H_2S gas was bubbled for additional 15 min. After the reaction mixture was stood at room temperature for 3 h, the solvent was removed *in vacuo*. The residual syrup was dissorved in MeOH (30 ml) at 0 °C and



Scheme 1.

a 0.2 M (1 M=1 mol dm^{-1}) solution of I_2 in MeOH (13 ml) was added dropwise for 45 min with stirring, and additionaly stirred for 45 min at room temperature. And then, 10% sodium thiosulfate was added until the brown color has disappeared. After the reaction mixture was concentrated *in vacuo* to 10 ml, the product was extracted by ethyl acetate and the extract was washed with water, dried over Na_2SO_4, and concentrated *in vacuo*. The crude product was purified by silica-gel column chromatography($CHCl_3$). Crystallization from MeOH-ether-hexane gave **3a** (250 mg, 70%) 85.5—87.0 °C, $[\alpha]_D^{23}$ +38.0° (*c* 1.0, $CHCl_3$). NMR ($CDCl_3$) δ: 3.01 (4H d, CH_2), 5.08, 5.16 (8H 2s, CH_2), 4.62 (2H m, CH), 5.70 (2H bd, NH), 7.31 (20H s, C_6H_5).

Found: C, 62.68; H, 5.31; N, 4.12; S, 9.26%. Calcd for $C_{36}H_{36}N_2O_8S_2$: C, 62.77; H, 5.27; N, 4.07; S, 9.31%.

N,N′-*Bis(benzyloxycarbonyl)*-D-*cystine Dibenzyl Ester* (**3b**). The reaction of (2*R*-Z-Azy-OBzl (**1b**, 320 mg, 1.03 mmol) with H_2S was carried out as described above to give **3b** (285 mg, 80.3%) after recrystallization from MeOH-ether-hexane, mp 86—87 °C, $[\alpha]_D^{23}$ −39.8° (*c* 1.1, $CHCl_3$). NMR ($CDCl_3$) δ: 3.04 (4H d, CH_2), 4.63 (2H m, CH), 5.05, 5.10 (8H 2s, CH_2), 5.79 (2H bd, NH), 7.36 (20H s, C_6H_5).

Found: C, 62.72; H, 5.43; N, 4.22; S, 9.37%. Calcd for $C_{36}H_{36}N_2O_8S_2$: C, 62.77; H, 5.27; N, 4.07; S, 9.31%.

N,N′-*Bis(benzyloxycarbonyl)*-threo-3,3′-*dimethyl*-L-*cystine Dibenzyl Ester* (**4a**). The reaction of (2*S*,3*S*)-Z-3-MeAzy-OBzl (**2a**, 340 mg, 1.05 mmol) with H_2S was carried out as described above to give **4a** (280 mg, 74%) as a syrup, $[\alpha]_D^{23}$ +42.3° (*c* 1.0, MeOH). NMR ($CDCl_3$) δ: 1.02 (6H d, CH_3), 3.43 (2H dd, CH), 4.60 (2H dd, CH), 5.05, 5.10 (8H 2s, CH_2), 5.80 (2H bd, NH), 7.25 (20H s, C_6H_5).

Found: C, 63.71; H, 5.65; N, 4.10; S, 9.01%. Calcd for $C_{38}H_{40}N_2O_8S_2$: C, 63.68; H, 5.62; N, 3.91; S, 8.94%.

N,N′-*Bis(benzyloxycarbonyl)*-threo-3,3′-*dimethyl*-D-*systine Dibenzyl Ester* (**4b**). The reaction of (2*R*,3*R*)-Z-3-MeAzy-OBzl (**2b**, 340 mg, 1.05 mmol) with H_2S was carried out as described above to give **4b** (295 mg, 78%) as a syrup, $[\alpha]_D^{23}$ −42.5° (*c* 1.0, MeOH). NMR ($CDCl_3$) δ: 1.23 (6H d, CH_3), 3.44 (2H dd, CH), 4.60 (2H dd, CH), 5.07, 5.11 (8H 2s, CH_2), 5.68 (2H bd, NH), 7.28 (20H s, C_6H_5).

Found: C, 63.75; H, 5.73; N, 4.12; S, 9.11%. Calcd for $C_{38}H_{40}N_2O_8S_2$: C, 63.68; H, 5.62; N, 3.91; S, 8.94%.

L-*Cystine* (**5a**). **3a** (200 mg) was dissolved in acetic acid saturated with HBr (5 ml) at room temperature. After 12 h, the reaction mixture was concentrated *in vacuo*. The residue was triturated with anhydrous ether and was dissolved in small amount of water, and was adjusted to pH 5 with 5 M NH_4OH and ethanol was added. The precipitates were filtered off and recrystallized from hot water to give **5a** (57.8 mg, 78%), mp 204 °C (decomp), $[\alpha]_D^{23}$ −213° (*c* 1.1, 1 M HCl).

Found: C, 30.16; H, 4.92; N, 11.98; S, 26.42%. Calcd for $C_6H_{12}N_2O_4S_2$: C, 29.99; H, 5.03; N, 11.66; S, 26.68%.

D-*Cystine* (**5b**). **3b** (200 mg) was dissolved in acetic acid saturated with HBr (5 ml) at room temperature. After 12 h, the reaction mixture was worked up as described above to give **5b** (55.8 mg, 75.3%), which recrystallized from hot water, mp 206 °C (decomp), $[\alpha]_D^{23}$ +213° (*c* 1.0, 1 M HCl).

Found: C, 30.22; H, 5.12; N, 11.75; S, 26.58%. Calcd for $C_6H_{12}N_2O_4S_2$: C, 29.99; H, 5.03; N, 11.66; S, 26.68%.

L-threo-3,3′-*Dimethylcystine* (**6a**). **4a** (117 mg) was dissolved in acetic acid saturated with HBr (5 ml) at room temperature. After 12 h, the reaction mixture was worked up as described above to give **6a** (55 mg, 83%), was recrystallized from water-ethanol, mp 177.5—178 C (decomp), $[\alpha]_D^{23}$ +412.9° (*c* 0.6, 1 M HCl).

Found: C, 34.63; H, 6.22; N, 10.09; S, 23.32%. Calcd for $C_8H_{16}N_2O_4S_2 \cdot 1/2\,H_2O$: C, 34.64; H, 6.18; N, 10.10; S, 23.12%.

D-threo-3,3′-*Dimethylcystine* (**6b**). **4b** (141 mg) was dissolved in acetic acid saturated with HBr (5 ml) at temperature. After 12 h, the reaction mixture was worked up as described above to give **6b** (40 mg, 75.8%), which was recrystallized from water-ethanol, mp 175 °C (decom), $[\alpha]_D^{23}$ −414° (*c* 1.0, 1 M HCl). [lit,[6] $[\alpha]_D^{19}$ −416° (*c* 0.50, 1 M HCl), lit,[5] $[\alpha]_D^{13}$ −414° (*c* 1.0, 1 M HCl)].

Found: C, 34.65; H, 6.20; N, 10.12; S, 23.25%. Calcd for $C_8H_{16}N_2O_4S_2 \cdot 1/2\,H_2O$: C, 34.64; H, 6.18; N, 10.10; S, 23.12%.

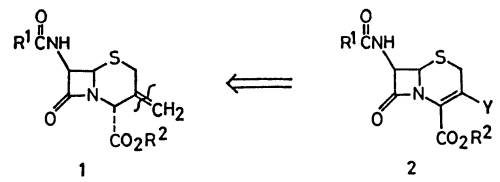
(Received December 2, 1982)

Synopsis. Efficient conversion of 2-(7-oxo-2,6-diaza-4-thiabicyclo[3.2.0]hept-2-en-6-yl)-3-chloromethyl-3-butenoates (**4**), derived from natural penicillins, into 3-methylenecephams (**1**) has been performed by a simple two-step operation, which comprises replacement of the allylic chlorine atom of **4** with iodine and subsequent acid-catalyzed hydrolysis, leading to **1** in 70—54% overall yields. In the latter step, the ring opening of the thiazoline moiety and the intramolecular substitution of the iodide with the thiol group proceed simultaneously.

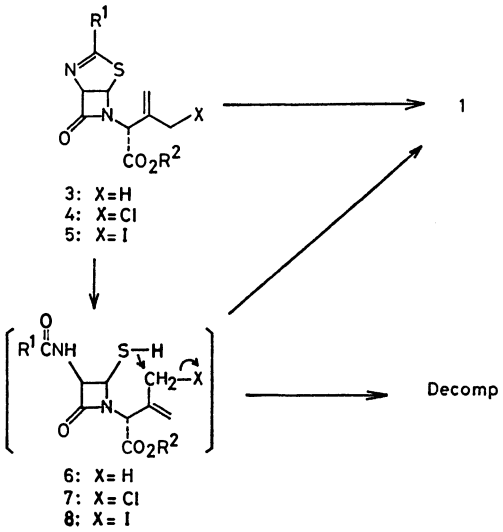
3-Methylenecephams **1** are important intermediates for the synthesis of useful cephalosporin antibiotics **2**, bearing an electronegative substituent, *e.g.*, halogen atom and methoxyl group, directly attached to the C-3 position.[1] These have been prepared by either reductive elimination of the acetoxyl group of 3-acetoxymethylcephalosporins[2] or chemical conversion of penicillins.[3] In connection with the current interest in the penicillin-cephalosporin conversion,[4] considerable efforts have been made to develop a significant route to **1** from natural penicillins.

In the preceding communication,[5] we disclosed electrolytic ene-type chlorination of thiazoline-azetidinones **3** derived from penicillins, providing 2-(7-oxo-2,6-diaza-4-thiabicyclo[3.2.0]hept-2-en-6-yl)-3-chloromethyl-3-butenoates **4**, which can be expected to be a good precursor of the 3-methylenecephams **1**. In fact, the conversion of **4** to **1** has been carried out by treatment with $AgClO_4$ in dioxane,[3a] although the yields are not satisfactory.[6] The insufficient yields in a practical sense and use of a stoichiometric amount of the expensive silver salt prompted us to find out a new and more efficient method for this purpose. We now report a convenient two-step conversion of **4** to **1** which comprises replacement of chlorine atom of **4** with iodine and subsequent acid-catalyzed hydrolysis of the thiazoline ring of **5**, leading to the desired 3-methylenecephams **1** via the intermediate **8** (Scheme 2).

It has been demonstrated that the hydrolysis of the thiazoline ring of **3** in aqueous acidic media affords thiol **6** in high yields.[7] Thus, the hydrolysis of **4** to the thiol **7** followed by the ring closure by the intramolecular nucleophilic substitution of the allylic chlorine atom with the mercapto group seemed to be a straightforward route to **1**. At first, we investigated this possibility since no such conversion has yet been realized. Hydrolysis of **4a** ($R^1=PhCH_2$; $R^2=CH_3$) in aqueous 30% $HClO_4$–acetone–CH_2Cl_2 (0.2:1:1) proceeded smoothly to afford the thiol **7a** ($R^1=PhCH_2$; $R^2=CH_3$). The ring closure of **7a** was attempted with base, *e.g.*, NaH, Na_2CO_3, pyridine, and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) under various conditions. But all attempts brought about a complex mixture of the decomposition products of **7a** and



Scheme 1.



Scheme 2.

failed in obtaining the desired product **1**.

These failure made us believe that the allylic chloride is not reactive enough for this cyclization. Consequently, we tried to use iodide **5** in place of chloride **4**. The iodide **5a** ($R^1=PhCH_2$; $R^2=CH_3$) was readily prepared from **4a** by heating with NaI in acetone. Then, hydrolysis of **5a** in methanol–CH_2Cl_2 (3/1) containing aqueous 5% HCl at room temperature afforded the desired 3-methylenecepham **1a** (70% yield). Although thiol **8a** ($R^1=PhCH_2$; $R^2=CH_3$) could not be detected in the reaction mixture, the ring closure would proceed via **8a** at room temperature without using any base due to the high reactivity of the iodide **8a**. With regard to the acid hydrolysis (**5a**→**1a**), an aqueous 5% HCl–methanol–CH_2Cl_2 system was found to be most effective among the following systems (yields of **1a**): aqueous 5% HCl–methanol (60%); aqueous 30% $HClO_4$–methanol (43%), aqueous 10% H_2SO_4–methanol (43%); aqueous 5% HCl–acetone (39%).

The conversion of **4** to **1** could be also performed by one-pot reaction without isolation of the intermediates **5**. Thus, after iodization of **4** with NaI in refluxing acetone, the reaction mixture was concentrated and the residue was treated with aqueous 5% HCl–methanol–CH_2Cl_2, affording **1** in 57—70% yields.

Experimental

IR spectra were determined on a JASCO IRA-I grating infrared spectrometer. ^{1}H NMR spectra were recorded at 60 M Hz with a Hitachi R-24 spectrometer and chemical shifts are reported in parts per million (δ) relative to $(CH_3)_4Si$ ($\delta=0.0$ ppm) as an internal standard. 2-(7-oxo-2,6-diaza-4-thiabicyclo[3.2.0]hept-2-en-6-yl)-3-chloromethyl-3-butenoates **4** were prepared by the electrolytic ene-type chlorination[5] of thiazoline-azetidinones **3**. Authentic samples of 3-methylenecephams **1** were obtained by the reported procedure.[3]

Hydrolysis of ***4a*** *($R^1=PhCH_2$; $R^2=CH_3$)* A mixture of **4a** (59 mg, 0.16 mmol) in acetone (1 ml) and CH_2Cl_2 (1 ml) containing aqueous 30% $HClO_4$ (0.2 ml) was stirred at room temperature for 1 h. The mixture was diluted with CH_2Cl_2 washed with brine, dried (Na_2SO_4), and concentrated *in vacuo*, affording forms **7a** ($R^1=PhCH_2$; $R^2=CH_3$, 61 mg),[8] essentially homogeneous on TLC analysis: $R_f=0.05$ (SiO_2; benzene/AcOEt, 4/1). Without further purification,[9] the crude products were treated with DBU (5 μl) in *N,N*-dimethylformamide (1 ml) at -30 °C for 5 h. Usual work-up gave a complex mixture and any detectable amount of 3-methylenecepham **1a** ($R^1=PhCH_2$; $R^2=CH_3$) could not be observed on TLC analysis.

Conversion of ***4*** *to* ***1****.* *Procedure A*: A mixture of **4a** ($R^1=PhCH_2$; $R^2=CH_3$, 376 mg, 1.03 mmol) and NaI (230 mg, 1.53 mmol) in acetone (10 ml) was heated to reflux for 3 h. The mixture was diluted with water (5 ml) and extracted with AcOEt. Usual work-up followed by column chromatography (SiO_2, hexane/AcOEt, 4/1) afforded iodide **5a** ($R^1=PhCH_2$; $R^2=CH_3$, 425 mg, 90%): ^{1}H NMR ($CDCl_3$) δ 3.62 (2H, s, CH_2I), 3.74 (3H, s, CH_3O), 3.87 (2H, s, CH_2Ph), 5.04 (1H, s), 5.45 (1H, s), 5.91 (2H, br s), 7.27 (5H, s). Immediately after isolation of the product,[10] **5a** (59 mg, 0.13 mmol) was dissolved in methanol (0.5 ml) and CH_2Cl_2 (0.5 ml) containing aqueous 5% HCl (0.2 ml). After stirring for 15 h, usual work-up followed by column chromatography (SiO_2), benzene/AcOEt, 5/1) gave **1a** ($R=PhCH_2$; $R^2=CH_3$, 31 mg, 70%), which was identical in all respects with the authentic sample;[3c] IR ($CHCl_3$) 3385, 1770, 1744, 1678, 1506 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 3.17, 3.61, (2H, AB q, $J=14$ Hz, CH_2S), 3.60 (2H, s, CH_2CO), 3.74 (3H, s, CH_3O), 5.05 (1H, s), 5.18 (2H, br s), 5.35 (1H, d, $J=4$ Hz, CH(6)), 5.62 (1H, dd, $J=4$ and 10 Hz, CH(7)), 6.43 (1H, d, $J=10$ Hz, NH), 7.28 (5H, s).

Procedure B: A mixture of **4a** (82 mg, 0.22 mmol) and NaI (39 mg, 0.26 mmol) in acetone (1 ml) was heated to reflux for 3 h. After removal of the solvent *in vacuo*, the residue was dissolved in methanol (1.5 ml) and CH_2Cl_2 (0.5 ml) containing aqueous 5% HCl (0.4 ml). After being stirred at room temperature for 8 h, usual work-up gave **1a** ($R^1=PhCH_2$; $R^2=CH_3$, 55 mg) in 70% yield after column chromatography (SiO_2, benzene/AcOEt, 5/1). The IR and ^{1}H NMR spectra were fully identical with those of the sample **1a** prepared above.

In a similar manner as described above, benzyl 7-phenoxyacetamido-3-methylenecepham-4-carboxylate (**1b**) ($R^1=PhOCH_2$; $R^2=PhCH_2$) was obtained from **4b** ($R^1=PhOCH_2$; $R^2=PhCH_2$) in 57% overall yield, which was identical in all respects with the authentic sample; IR ($CHCl_3$) 3385, 1770, 1738, 1689, 1596 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 3.18, 3.58 (2H, AB q, $J=14$ Hz, CH_2S), 4.50 (2H, s, OCH_2CO), 5.15 (4H, br s), 5.23 (1H, s), 5.39 (1H, d, $J=4.5$ Hz, HC(6)), 5.70 (1H, dd, $J=4.5$ Hz and 9.5 Hz, HC(7)), 6.7 $-$7.5 (6H, m), 7.31 (5H, s).

9) Upon chromatography on a SiO_2 column, **7a** was decomposed even on a neutral SiO_2 (Mallinckrodt CC-7).

10) Iodide **5a** was unstable and gradually decomposed under standing in atmosphere.

Lewis Acid Mediated Reaction of Trimethylstyrylsilanes with Thioacetal Derivatives

Toshikazu HIRAO,* Shuichiro KOHNO, Yoshiki OHSHIRO, and Toshio AGAWA

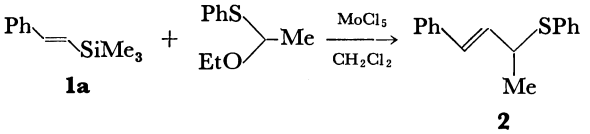
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-oka, Suita, Osaka 565

(Received December 6, 1982)

Synopsis. Treatment of trimethylstyrylsilanes with 1-ethoxy-1-(phenylthio)ethane or 2-ethoxy-1,3-dithiolane in the presence of Lewis acid gives the corresponding (*E*)-allyl sulfide or (*E*)-2-styryl-1,3-dithiolane, respectively. In both cases, a carbon-oxygen bond of thioacetal derivatives is cleaved selectively.

Electrophilic substitution reaction of vinylsilanes provides a versatile method for stereospecific and regioselective carbon–carbon bond formation.[1] However, electrophiles are limited to acid chloride,[2,3a] and α-chloro ether.[3] We previously found that acetal acts as an electrophile in the presence of Lewis acid, especially $MoCl_5$.[4] This methodology was used in the intramolecular reaction by Tius[5] and dithioacetal has been shown to be an electrophile in the cyclization reaction.[6] Now, we wish to report the Lewis acid mediated reaction of trimethylstyrylsilanes with monothioacetal.

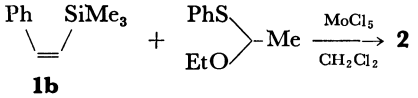
Treatment of (*E*)-trimethylstyrylsilane (**1a**) with 1-ethoxy-1-(phenylthio)ethane in the presence of $MoCl_5$ at up to −20 °C gave the 1:1 adduct, (*E*)-1-phenyl-3-phenylthio-1-butene (**2**), in 42% yield exclusively.



1a **2**

The reaction at −78 °C decreased the yield of **2**, as shown in Table 1. $TiCl_4$ was less effective than $MoCl_5$, as observed in the reaction with acetal.[4] A fission of a carbon-oxygen bond occurred selectively, and the product derived from the attack of $EtOC^+HMe$ was not detected. This finding exhibits a contrast to the reaction of trimethylstyrylsilanes with benzaldehyde diethyl acetal. In the latter case, both ethoxyl groups participate in the reaction to produce the 1,4-pentadiene derivatives selectively.

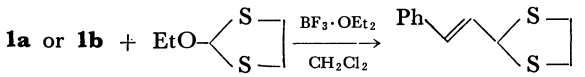
(*Z*)-Trimethylstyrylsilane (**1b**) was also allowed to react with 1-ethoxy-1-(phenylthio)ethane in the presence of $MoCl_5$ to yield the same allyl sulfide **2** (53%)



1b

exclusively. The stereochemistry of **1b** is not retained, which might be due to the Lewis acid catalyzed isomerization of the (*Z*)-allyl sulfide into the stable *E*-isomer as reported in the reaction of dichloromethyl methyl ether.[3d] This result strikingly contrasts with the stereospecific reaction of trimethylstyrylsilanes with acetal.

2-Ethoxy-1,3-dithiolane was subjected to the substitution reaction with trimethylstyrylsilanes in the presence of $BF_3 \cdot OEt_2$ to give the 1:1 adduct, (*E*)-2-styryl-1,3-dithiolane (**3**), though the yield was not high. Lewis acid such as $MoCl_5$ or $TiCl_4$ appeared to decompose 2-ethoxy-1,3-dithiolane giving none of the adduct. A carbon-oxygen bond of 2-ethoxy-1,3-dithiolane was cleaved selectively and the *E* product **3** was



3, 20% from **1a**
22% from **1b**

formed regardless the configuration of the starting vinylsilanes **1**, as mentioned in the reaction with monothioacetal.

We showed a new carbon–carbon bond formation with trimethylstyrylsilanes, but it is disappointing to find that the other vinylsilanes such as 1-trimethylsilyl-1-hexene and -cyclohexene were not so reactive as trimethylstyrylsilanes.

Table 1. Reaction of (*E*)-trimethylstyrylsilane (**1a**) with 1-ethoxy-1-(phenylthio)ethane[a]

Lewis acid	Reaction temp/°C	Isolated yield/% of **2**
$MoCl_5$	−78	28
	−78→−20	42
$TiCl_4$	−78	10
	−78→−20	24

a) Reaction time, 4 h.

Experimental

^1H NMR and ^{13}C NMR spectra were obtained on a JEOL JNM-PMX 60 or JNM-FX 90Q with tetramethylsilane as an internal standard, respectively. IR spectra were recorded with a JASCO IRA-I spectrometer. The mass spectra were taken with a Hitachi RMU-6E spectrometer. Commercially available reagents were used unless otherwise noted. (*Z*)- and (*E*)-Trimethylstyrylsilanes,[7] 1-ethoxy-1-(phenylthio)ethane,[8] and 2-ethoxy-1,3-dithiolane[9] were prepared by the reported methods.

Reaction of 1a with 1-Ethoxy-1-(phenylthio)ethane. To a suspension of $MoCl_5$ (0.273 g, 1.0 mmol) in dichloromethane (4 ml) was added (*E*)-trimethylstyrylsilane (**1a**; 0.176 g, 1.0 mmol) and 1-ethoxy-1-(phenylthio)ethane (0.182 g, 1.0 mmol) in dichloromethane (4 ml) at −78 °C under nitrogen. The mixture was stirred at −78 °C for 2.5 h, and then warmed to −20 °C. At this temperature, the mixture was stirred for 1.5 h, and quenched with 50% aqueous methanol. The resultant mixture was warmed to 0 °C, and poured into saturated aqueous Na_2CO_3 solution (5 ml), which was extracted with ether (3×10 ml). The combined organic layers were dried over $MgSO_4$ and concentrated *in vacuo*. The residue was chromatographed on

a silica-gel column to give 0.101 g (42%) of (*E*)-1-phenyl-3-phenylthio-1-butene (**2**) and 0.0541 g of 1,1-bis(phenylthio)ethane. **2**: ^{1}H NMR ($CDCl_3$) δ 1.44 (d, 3H, J=7.1 Hz), 3.85 (qdd, 1H, J=7.1, 6.6, 0.2 Hz), 6.11 (dd, 1H, J=15.7, 6.6 Hz), 6.17 (dd, 1H, J=15.7, 0.2 Hz), 6.8—7.6 (m, 10H); ^{13}C NMR ($CDCl_3$) δ 20.7, 46.4, 126.3, 127.2, 127.3, 128.4, 128.6, 129.9, 131.6, 133.2, 134.7, 136.9; IR (neat) 1575, 960 cm^{-1}; MS *m/e* 240 (M^+).

Reaction of ***1b*** *with 1-Ethoxy-1-(phenylthio)ethane.* The reaction was carried out in the same way as mentioned above. The allyl sulfide **2** was produced in 53% yield.

Reaction of ***1a*** *with 2-Ethoxy-1,3-dithiolane.* To a solution of $BF_3 \cdot OEt_2$ (0.13 ml, 1.0 mmol) in dichloromethane (2 ml) was added (*E*)-trimethylstyrylsilane (**1a**; 0.176 g, 1.0 mmol) in dichloromethane (1 ml) at 0 °C under nitrogen. Then, 2-ethoxy-1,3-dithiolane (0.150 g, 1.0 mmol) in dichloromethane (2 ml) was added dropwise to the mixture at 0 °C for 30 min. The resultant solution was stirred at room temperature for 5 h. Saturated aqueous Na_2CO_3 solution (5 ml) was added to the mixture, which was extracted with ether (3×10 ml). The combined organic layers were dried over $MgSO_4$ and concentrated *in vacuo*. The residue was chromatographed on a silica-gel column to give 0.0416 g (20%) of (*E*)-2-styryl-1,3-dithiolane (**3**). Mp 67 °C (uncorrected); ^{1}H NMR ($CDCl_3$) δ 3.25 (broad s, 4H), 5.18 (d, 1H, J=7.6 Hz), 6.12 (dd, 1H, J=15.4, 7.6 Hz), 6.50 (d, 1H, J=15.4 Hz), 7.1—7.5 (m, 5H); IR ($CHCl_3$) 950 cm^{-1}; MS *m/e* 208 (M^+).

Reaction of ***1b*** *with 2-Ethoxy-1,3-dithiolane.* The reaction was carried out in the same way as mentioned above. (*E*)-2-Styryl-1,3-dithiolane (**3**) was produced in 22% yield.

The Reaction of Organoboranes with Lithium Salts of Trisylhydrazones of Cycloalkanones Followed by Treatment with Iodine

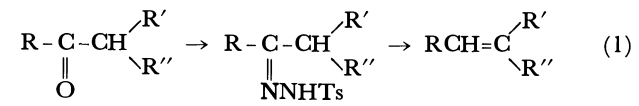
Tsutomu BABA, Kamlakar AVASTHI, and Akira SUZUKI*

Department of Applied Chemistry, Faculty of Engineering, Hokkaido University, Sapporo 060

(Received December 15, 1982)

Synopsis. The titled reaction proceeds smoothly under mild conditions to give corresponding 1-alkylcycloalkenes in excellent yields. The overall reaction provides a convenient synthetic procedure of cycloalkenes for cycloalkanones, with various alkyl substituents readily available by means of hydrobortation.

Recently, organoborates have been recognized as important intermediates in the formation of carbon–carbon bonds.[1] On the other hand, there are various methods to convert ketones to alkenes,[2] one of which is the conversion through their tosylhydrazones (Bamford-Stevens reaction and the related reactions, Eq. 1).[3] Although such methods are established as

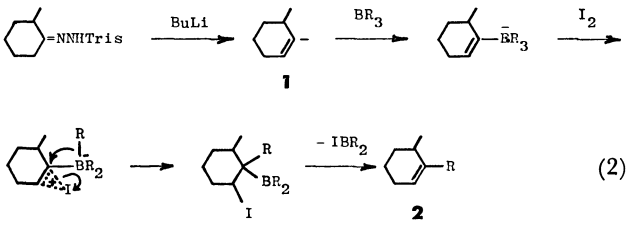


(1)

useful synthetic routes to alkenes with a wide variety of structures, they have unavoidable limitation that only alkenes with the skeltons of the parent ketones are obtained as shown in Eq. 1. Previously, we reported that the reaction of iodine with 1-alkenyltrialkylborates derived from trialkylboranes and 2,4,6-triisopropylphenylsulfonylhydrazones (trisylhydrazones) of methyl ketones provides a novel synthesis of 1,1-dialkylethylenes.[4] However, that procedure did not give satisfactory results for trisylhydrazones of cycloalkanones.

In this paper, we wish to report that the modified procedure by using THF as a solvent gives excellent results for cycloalkanone derivatives. Representative results are summarized in Table 1.

The reaction is considered to proceed through the vinylic anion[5] derived from a trisylhydrazone as reported previously.[4] More interesting examples involve unsymmetrical ketones, which can give rise to geometrically isomeric vinyllithium reagents. As an example of such a type, the derivative (**1**) formed from 2-methylcyclohexanone gives good yields of 1-alkyl-6-methylcyclohexenes (**2**).

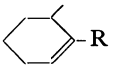


(2)

Experimental

Materials. Commercial alkenes and butyllithium were used. THF was purified by distillation from $LiAlH_4$ before use. Trialkylboranes were prepared by the hydroboration of corresponding alkenes with borane in THF.[6] Trisylhydrazones of cycloalkanones were prepared by the reported method[5] from ketones and 2,4,6-triisopropylphenylsulfonylhydrazide.[7]

Table 1. Synthesis of 1-alkylcycloalkenes from cycloalkanones

Cycloalkanone (Mp θ_m/°C of trisylhydrazone)	Organoborane R_3B, R =	Yield/%[a] of product[b]
(124 decomp)	Propyl	82
	Butyl	77
	s-Butyl	96
	Isobutyl	67
	Cyclopentyl	79
		
(109 decomp)	Propyl	93
	Butyl	92
	s-Butyl	94
	Isobutyl	96
	Cyclopentyl	87
	Hexyl	92
		


(134 decomp)	Butyl	95
	s-Butyl	93
	Isobutyl	90
	Cyclopentyl	98
	Hexyl	96

a) Based on the organoborane used. b) Satisfactory spectral data and elemental analyses were obtained for all products.

The IR and NMR spectra were taken on a Hitachi-Perkin Elmer Model 125 spectrophotometer and a Hitach R-22 spectrometer at 90 MHz using tetramethylsilane as an internal standard, respectively.

General Procedure. The following procedure for the preparation of 1-propyl-6-methylcyclohexene is representative. A dry 50 ml-flask equipped with a magnetic stirring bar, a septum inlet, and a reflux condenser was flushed with dry nitrogen. The flask was charged under nitrogen with 0.784 g (2.04 mmol) of 2-methylcyclohexanone trisylhydrazone, mp 109 °C (decomp) and 10 ml of a 10% TMEDA solution in THF under stirring. The mixture was cooled to −78 °C, and 2.59 ml (5.03 mmol) of a 1.97 M (1 M = 1 mol dm^{-3}) solution of butyllithium in ether was added dropwise. The solution was stirred at the temperature for 30 min, and then allowed to warm to 0 °C. The flask was held at the temperature for additional 15 min to ensure the completion of nitrogen evolution. To the mixture again cooled to −78 °C, 0.65 ml (1.43 mmol) of a 2.2 M solution of tripropylborane in THF was added carefully. The mixture was stirred at −78 °C for 60 min followed by 60 min stirring at room temperature. The flask was again cooled to −60 °C and 0.40 g (1.57 mmol) of iodine in 4 ml of THF was added dropwise. The reaction mixture was stirred around −60 °C for 30 min followed by 60 min stirring at room temperature, and a few drops of aqueous sodium thiosulfate solution was added to remove an excess

of iodine. After the usual alkaline hydrogen peroxide oxidation, the solution was saturated with potasium carbonate. The VPC analysis of the separated organic layer indicated formation of 1-propyl-6-methylcyclohexene in a 93% yield.

Identification of the Products. In all cases analytically pure samples were obtained by preparative VPC with Varian autoprep Model-2800 and characterized by NMR, IR, and mass spectra, and elemental analyses.

Cyclohexanone Trisylhydrazone: Mp 125 °C (decomp). Found: C, 66.66; H, 9.04; N, 7.38; S, 8.42%. Calcd for $C_{21}H_{34}O_2N_2S$: C, 66.75; H, 9.01; N, 7.42; S, 8.49%. ^{1}H-NMR (CCl_4): δ 1.20 (d, 18H), 1.56 (s, 6H), 2.28 (s, 4H), 2.90 (m, 1H), 4.25 (m, 2H), 7.15 (s, 3H).

2-Methylcyclohexanone Trisylhydrazone: Mp 108 °C (decomp). Found: C, 67.49; H, 9.25; N, 7.01; S, 7.99%, Calcd for $C_{22}H_{36}O_2N_2S$: C, 67.48; H, 9.20; N, 7.15; S, 8.19%. ^{1}H-NMR (CCl_4): δ 0.94 (d, 3H), 1.22 (d, 18H), 1.60—2.15 (m, 10H), 2.85 (m, 1H), 4.25 (m, 2H), 7.06 (s, 2H).

Cyclopentanone Trisylhydrazone: Mp 133—134 °C (decomp). Found: C, 65.85; H, 8.85; N, 7.68; S, 8.80%. Calcd for $C_{20}H_{32}O_2N_2S$: C, 65.91: H, 8.92; N, 7.63; S, 8.60%. ^{1}H-NMR (CCl_4): δ 1.25 (d, 18H), 1.80 (s, 4H), 2.32 (d, 4H), 2.95 (m, 1H), 4.30 (m, 3H), 7.10 (s, 2H).

1-Propylcyclohexene: Found: C, 86.98; H, 13.02%. Calcd for C_9H_{16}: C, 87.02; H, 12.98%. Mass: $m/e=124$ (M+). IR (neat): 820, 1665 cm^{-1}. ^{1}H-NMR (CCl_4): δ 0.90 (t, 3H), 1.62 (m, 2H), 1.72—2.10 (m, 8H), 3.65 (t, 2H), 5.34 (s, H).

1-Butylcyclohexene: Found: C, 86.90; H, 13.10%. Calcd for $C_{10}H_{18}$: C, 86.88; H, 13.12%. Mass: $m/e=138$ (M+). IR (neat): 820, 1665 cm^{-1}. ^{1}H-NMR (CCl_4): δ 0.90 (t, 3H), 1.32 (m, 2H), 1.58 (m, 2H), 1.75—2.05 (m, 8H), 3.64 (t, 2H), 5.35 (s, H).

1-(s-Butyl)cyclohexene: Found: C, 86.80; H, 13.23%. Calcd for $C_{10}H_{18}$: C, 86.88; H, 13.12%. Mass: *m/e* 138 (M+). IR (neat): 810, 1660 cm^{-1}. ^{1}H-NMR (CCl_4): δ 0.84 (t, 3H), 0.95 (d, 3H), 1.62 (m, 2H). 1.72—2.05 (m, 8H). 3.68 (t, H), 5.40 (s, H).

1-Isobutylcyclohexene: Found: C, 86.72; H, 13.01%. Calcd for $C_{10}H_{18}$: C, 86.88; H, 13.12%. Mass; $m/e=138$ (M+). IR (neat): 820, 1660 cm^{-1}. ^{1}H-NMR (CCl_4): δ 0.86 (d, 6H), 1.54—2.05 (m, 9H), 3.68 (t, 2H), 5.35 (s, H).

1-Cyclopentylcyclohexene: Found: C, 87.89; H, 12.11%. Calcd for $C_{11}H_{18}$: C, 87.92; H, 12.08%. Mass: $m/e=150$ (M+). IR (neat): 820, 1665 cm^{-1}. ^{1}H-NMR (CCl_4): δ 1.50—2.30 (m, 17H), 5.40 (m,H).

1-Propyl-6-methylcyclohexene: Found: C, 86.66; H, 12.95%. Calcd for $C_{10}H_{18}$: C 86.88; H, 13.12%. Mass: $m/e=138$ (M+). IR (neat): 805, 1670 cm^{-1}. ^{1}H-NMR (CCl_4): δ 0.89 (t, 3H), 1.02 (d, 3H), 1.20—1.66 (m, 7H), 1.90—2.05 (m, 4H), 5.33 (s, H).

1-Butyl-6-methylcyclohexene: Found: C, 86.36; H, 13.01%. Calcd for $C_{11}H_{20}$: C, 86.76; H, 13.24%. Mass: $m/e=152$ (M+). IR (neat): 810, 1670 cm^{-1}. ^{1}H-NMR (CCl_4): δ 0.89 (t, 3H), 0.96 (d, 3H), 1.15—1.55 (m, 7H), 1.76—2.10 (m, 6H), 5.30 (s, H).

1-(s-Butyl)-6-methylcyclohexene: Found: C, 86.65; H, 13.35%. Calcd for $C_{11}H_{20}$: C, 86.76; H, 13.24%. Mass: $m/e=152$ (M+). IR (neat): 800, 1660 cm^{-1}. ^{1}H-NMR (CCl_4): δ 0.86 (d, 6H), 1.00 (d, 3H), 1.30—1.66 (m, 6H), 1.80—2.15 (m, 4H), 5.33 (s, H).

1-Isobuty-6-methylcyclohexene: Found: C, 86.80; H, 13.19%. Calcd for $C_{11}H_{20}$: C, 86.76; H, 13.24%. Mass: $m/e=152$ (M+). IR (neat): 790, 1660 cm^{-1}. ^{1}H-NMR (CCl_4): δ 0.88 (t, 6H), 1.02 (d, 3H), 1.18—1.30 (m, 4H), 1.45—1.65 (m, 4H), 1.95 (m, 2H), 5.32 (s, H).

1-Cyclopentyl-6-methylcyclohexene: Found: C, 87.69; C, 12.23%. Calcd for $C_{12}H_{20}$: C, 87.73; H. 12.27%. Mass: $m/e=164$ (M+). IR (neat): 800, 1650 cm^{-1}. ^{1}H-MNR (CCl_4): δ 1.02 (d, 3H), 1.20—2.00 (m, 15H), 2.20 (m, H), 5.38 (s, H).

1-Hexyl-6-methylcyclohexene: Found: C, 86.50; H, 13.38%. Calcd for $C_{13}H_{24}$: C, 86.58; H, 13.42%. Mass: $m/e=180$ (M+). IR (neat): 810, 1660 cm^{-1}. ^{1}H-NMR (CCl_3): δ 0.88 (t, 3H), 0.98 (d, 3H), 1.15—1.58 (m, 11H), 1.75—2.05 (m, 6H), 5.32 (s, H).

1-Butylcyclopentene: Found: C, 86.98: H, 12.89%. Calcd for C_9H_{16}: C, 87.02; H, 12.98%. Mass: $m/e=124$ (M+). IR (neat): 810, 1650 cm^{-1}. ^{1}H-NMR (CCl_4): δ 0.92 (t, 3H), 1.40 (m, 4H), 1.75—2.30 (m, 8H), 5.29 (s, H).

1-(s-Butyl)cyclopentene: Found: C, 87.21; H, 12.85%. Calcd for C_9H_{16}: C, 87.02; H, 12.98%. Mass; $m/e=124$ (M+). IR (neat): 790, 1660 cm^{-1}. ^{1}H-NMR (CCl_4): δ 0.88 (t, 3H), 0.92 (d, 3H), 1.48—2.22 (m, 9H), 5.28 (s, H).

1-Isobutylcyclopentene: Found: C, 86.94; H, 12.93%. Calcd for C_9H_{16}: C, 87.02; H, 12.98%. Mass: $m/e=124$ (M+). IR (neat): 800, 1660 cm^{-1}. ^{1}H-NMR (CCl_4): δ 0.90 (t, 6H), 1.50—2.25 (m, 9H), 5.30 (s, H).

1-Cyclopentylcyclopentene: Found: C, 88.12; H, 11.82%. Calcd for $C_{10}H_{16}$: C, 88.16; H, 11.84%. Mass: $m/e=136$ (M+). IR (neat): 800, 1650 cm^{-1}. ^{1}H-MNR (CCl_4): δ 1.30—1.93 (m, 9H), 2.05—2.35 (m, 6H), 5.30 (s, H).

1-Hexylcyclopentene: Found: C, 86.75; H, 13.24%. Calcd for $C_{11}H_{20}$: C, 86.76; H, 13.04%. Mass: $m/e=152$ (M+). IR (neat): 810, 1650 cm^{-1}. ^{1}H-NMR (CCl_4): δ 0.88 (t, 3H), 1.28 (m, 10H), 1.75—2.30 (m, 6H), 5.28 (s, H).

A New Glycoside, Kusaginin Isolated from *Clerodendron trichotomum*

Atsushi SAKURAI* and Takahiko KATO†

Department of Chemistry, Faculty of Science, Shizuoka University, Ohya, Shizuoka 422

(Received December 22, 1982)

Synopsis. A new glycoside, kusaginin was isolated from *Clerodendron trichotomum* Thunb. and 2-(3,4-dihydroxyphenyl)ethyl 3-*O*-α-L-rhamnopyranosyl-4-*O*-(3,4-dihydroxycinnamoyl)-β-D-glucopyranoside was assigned to this substance from studies on the hydrolysis products and from analyses of the ^{1}H NMR and ^{13}C NMR spectra.

From the leaves of *Clerodendron trichotomum* Thunb. (Kusagi in Japanese) a flavonoid glycoside, acacetin 7-*O*-2-β-D-glucopyranuronosyl-β-D-glucopyranuronoside[1] and a bitter principle, clerodendrin A,[2] and from the fruits of the plant two blue pigments, trichotomin and trichotomin G_1,[3] have been isolated.

During our studies on the constituents of this plant we isolated a new glycoside and named it kusaginin (**1**). In this paper we wish to report the isolation and structure of **1**.

The methanol extract of the fresh leaves of the plant was triturated with water and ethyl acetate and the aqueous layer was subjected to chromatography on a column of Sephadex LH-20 eluting with methanol. The last effluent gave **1** as colorless crystals, mp 154—156 °C in 0.3% yield from wet plant. Compound **1** is optically active, $[\alpha]_D$ −104° and from its elemental analyses was suggested the formula $C_{29}H_{36}O_{15}$. The IR spectrum of **1** shows absorption bands indicative of the existence of a conjugated ester group at 1716 and 1278 cm^{-1} and the UV spectrum of **1** in ethanol shows absorption maxima characteristic of an ester of 3-(3,4-dihydroxyphenyl)-2-propenoic acid[4] at 202, 219, 245, 290, and 332 nm. From the IR spectrum coupled with ^{1}H NMR spectrum of **1** which has complex signals corresponding to the protons on oxygenated carbon atoms at δ 3.0—4.0, it is considered that **1** has sugar portions.

The ^{1}H NMR spectrum of **1** in DMSO-d_6 shows the signals attributed to the protons attached to two 1,3,4-trisubstituted benzene rings at δ 6.58 (1H, dd, J=1.5 and 8 Hz), 6.69 (1H, d, J=8 Hz), 6.71 (1H, d, J=1.5 Hz), 6.80 (1H, d, J=7.5 Hz), 6.95 (1H, dd, J=2 and 7.5 Hz), and 7.07 (1H, d, J=2 Hz), two *trans* olefinic protons at δ 6.28 (1H, d, J=16 Hz) and 7.58 (1H, d, J=16 Hz), two anomeric protons of sugar portions at δ 4.35 (1H, d, J=8 Hz) and 5.00 (1H, d, J=2 Hz), a proton attached to a carbon atom bearing an ester group at δ 4.67 (1H, t, J=9 Hz), methylene protons of a benzyl group at δ 2.67 (2H, t, J=7.5 Hz), and methyl protons at δ 0.98 (3H, d, J=6 Hz), besides them.

Acetylation of **1** with acetic anhydride and pyridine gave a nonaacetate of **1** as colorless crystals, mp 92—96 °C and its ^{1}H NMR spectrum shows the signals ascribed to the methyl protons of acetoxyl groups at δ 1.89 (3H, s), 1.97 (3H, s), 2.02 (3H, s), 2.08 (3H, s), 2.10 (3H, s), 2.26 (3H, s, aromatic acetoxyl), 2.28 (3H, s, aromatic acetoxyl), and 2.29 (6H, s, aromatic acetoxyl).

† Present address: Kuramoto Sangyo Co. Ltd., 1-4-1 Minamidai, Kawagoe, Saitama 350.

Treatment of **1** with 10% hydrogen chloride in methanol gave 2-(3,4-dihydroxyphenyl)ethanol (**2**),[5] methyl caffeate (**3**),[4] a substance **4**, methyl α-L-rhamnoside (**5**), methyl α-D-glucoside (**6**), and small amounts of methyl β-L-rhamnoside (**7**) and methyl β-D-glucoside (**8**). Since **4** gives **2**, **6**, and **8** by further treatment with hydrogen chloride in methanol and the ^{1}H NMR spectrum of **4** in CD_3OD shows a sharp doublet of 1′-proton of the D-glucose at δ 4.27 (J=7.5 Hz, axial/axial coupling indicative of β-D-glucoside), D-glucose and **2** should be linked by a β-glycoside bond. In the ^{13}C NMR spectra of **2**, **4**, methyl α-D-glucopyranoside (**6**), and methyl β-D-glucopyranoside (**8**) as shown in Table 1, the 8-carbon in **4** appears at a field lower by 7.5 ppm than that of **2** and the 7-carbon in **4** also appears at a field higher by 3.1 ppm than that of **2**. These results[6] indicate that the D-glucose in **4** might be linked by a β-glycoside bond to the C-8 of **2**.

Hydrolysis of **1** with sodium hydroxide in aqueous methanol gave caffeic acid (**9**)[5b,7] and a substance **10**. Since **10** gives **2**, **4**, **5**, and **6** by further treatment with hydrogen chloride in methanol and the ^{1}H NMR spectrum of **10** in CD_3OD shows a sharp doublet of 1″-proton of the L-rhamnose at δ 5.13 (J=1.8 Hz, equatorial/equatorial coupling indicative of α-L-rhamnoside), L-rhamnose and **4** should be linked by an α-glycoside bond. In the ^{13}C NMR spectra of **4**, methyl α-L-rhamnopyranoside (**5**), methyl β-L-rhamnopyranoside (**7**), and **10** as shown in Table 1, the 3′-carbon of the glucose in **10** appears at a field lower by 6.3 ppm than that of **4** and the 4′-carbon of the glucose in **10** also appears at a field higher by 1.5 ppm than that of **4**. These results indicate that the L-rhamnose in **10** might be linked by an α-glycoside bond to the C-3′ of **4**.

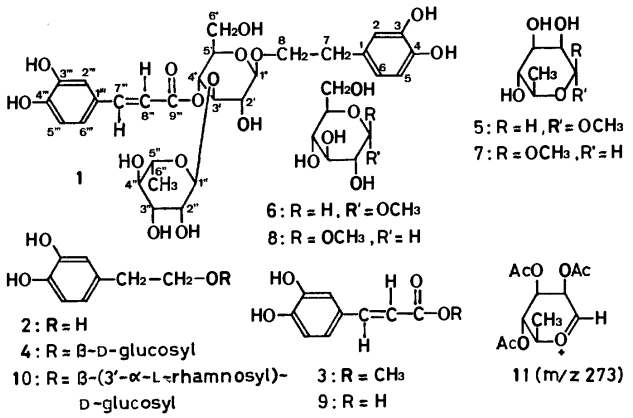
In parts per million downfield from tetramethylsilane. Asterisks indicate that assignments are unambigous.

Methanolysis and base catalyzed hydrolysis of **1** gave methyl caffeate (**3**) and caffeic acid (**9**) respectively as described above, which indicates that caffeic acid and **10** might be linked by an ester bond. In the in-beam electron impact mass spectrum[8,9] of an acetate of **1** could not be observed the molecular ion peak, however the spectrum exhibits a fragment ion peak corresponding to the ion structure **11** shown in Figure at m/z 273 as base peak, which indicates that caffeic acid should not be linked to the L-rhamnose in **1**. In the ^{1}H NMR spectrum of **1** irradiation of the proton on a carbon atom bearing the ester group at δ 4.67 shows no change in the spectral pattern of the anomeric proton of glucose at δ 4.35 and *vice versa*, which indicates that caffeic acid should not be linked to the 2-position of glucose in **1**.

In the ^{13}C NMR spectra of **1**, **3**, and **10**, the 9'''-carbonyl carbon in **1** appears at a field higher by 1.4 ppm than that of **3** and both 3'- and 5'-carbons in **1** also appear at fields higher by 2.6 and 1.6 ppm respectively than those of **10**. This fact is the consequence of steric compression[10] between the C-9 of caffeic acid and the C-3 or C-5 of D-glucose. These results indicate that caffeic acid might be linked by an ester bond to the C-4' of **10**.

These ^{1}H NMR and ^{13}C NMR spectroscopic data and all experimental results described above support the structure of kusaginin (**1**) to be 2-(3,4-dihydroxyphenyl)ethyl 3-*O*-α-L-rhamnopyranosyl-4-*O*-(3,4-dihydroxycinnamoyl)-β-D-glucopyranoside.



Experimental

All melting points are uncorrected. The ^{1}H NMR spectra were measured with a Varian EM-390 90 MHz NMR spectrometer. The ^{13}C NMR spectra were measured with a JEOL JNM-PFT-60 NMR spectrometer at 15.04 MHz. Chemical shifts were obtained by δ value (ppm) from tetramethylsilane as internal standard.

Isolation of Kusaginin (1). The fresh leaves of the plant (1.5 kg)[11] were extracted with methanol. The extract was condensed to a syrup under reduced pressure and the syrup was triturated with water (300 cm^3) and ethyl acetate (500 cm^3). The aqueous layer was condensed to a syrup under reduced pressure and the syrup was dissolved in methanol (150 cm^3). Each 50 cm^3 of the methanol solution was subjected to chromatography on a column of Sephadex LH-20 (3.5 × 120 cm) eluting with methanol. The last effluents gave **1** as colorless crystals after recrystallization from a mixture of methanol and chloroform: mp 154—156 °C; yield, 4.5 g (0.3% from wet plant); $[\alpha]_D^{20}$ −104° (*c* 1.0, MeOH); UV (EtOH) 202 (ε 41000), 219 (19300), 237 (sh 12500), 245 (11200), 290 (13200), 300 (sh 13600), and 332 nm (13600); IR (KBr) 3535, 3400—3100, 1716, 1640, 1606, 1598, 1523, 1445, 1390, 1310, and 1278 cm^{-1}. Found: C, 55.38; H, 5.79%. Calcd for $C_{29}H_{36}O_{15}$: C, 55.77; H, 5.81%.

Acetylation of **1** with acetic anhydride and pyridine at room temperature gave a nonaacetate of **1** as colorless crystals: mp 92—96 °C. Found: C, 56.23; H, 5.40%. Calcd for $C_{47}H_{54}O_{24}$: C, 56.29; H, 5.43%.

Methanolysis of 1. Compound **1** (500 mg) was dissolved in dry methanol containing 10 wt% of hydrogen chloride (30 cm^3), which was allowed to stand at room temperature for 20 h under nitrogen atmosphere. The mixture was concentrated to dryness under reduced pressure. The residue was subjected to chromatography on a column of Sephadex LH-20 in the same manner as described above and gave **2** (colorless crystals, mp 80—82 °C; yield, 85 mg), **3** (colorless crystals, mp 151—152 °C; yield, 135 mg), **4** (colorless oil; yield, 120 mg), and a mixture of sugars.

Acetylation of **4** with acetic anhydride and pyridine gave a hexaacetate of **4** as colorless crystals: mp 40.5—42 °C. Found: C, 54.82; H, 5.71%. Calcd for $C_{26}H_{32}O_{14}$: C, 54.93; H, 5.67%.

The sugar fraction was subjected to thin layer chromatography and the sugars were proved to be identical with authentic **5**, **6**, **7**, and **8**.

Hydrolysis of 1 with Sodium Hydroxide. Compound **1** (325 mg) was dissolved in a mixture of methanol (4 cm^3) and 1 M (1 M = 1 mol dm^{-3}) aqueous sodium hydroxide (4 cm^3), which was allowed to stand at room temperature for 4 h under nitrogen atmosphere. After being acidified with hydrochloric acid, the mixture was concentrated to dryness under reduced pressure. The residue was subjected to chromatography on a column of Sephadex LH-20 and gave **9** (colorless crystals, mp 207—208 °C; yield, 51 mg) and **10** (colorless oil; yield, 195 mg).

Acetylation of **10** with acetic anhydride and pyridine gave an octaacetate of **10** as colorless crystals: mp 71—73 °C. Found: C, 54.04; H, 5.64%. Calcd for $C_{36}H_{46}O_{20}$: C, 54.13; H, 5.80%.

Studies on Salt Hydrate for Latent Heat Storage. III. Pseudo-binary System, $CH_3CO_2Na \cdot 3H_2O$–$HCONH_2$

Takahiro WADA,* Fumiko KIMURA, and Ryoichi YAMAMOTO

Material Research Laboratory, Matsushita Electric Industrial Co. Ltd., Kadoma, Osaka 571

(Received July 29, 1982)

Synopsis. A pseudo-binary system $CH_3CO_2Na \cdot 3H_2O$–$HCONH_2$ has been studied by differential scanning calorimetry. In this system, a one to one addition compound $CH_3CO_2Na \cdot HCONH_2 \cdot 3H_2O$ is formed. This addition compound melts congruently at 40.5 °C and its heat of fusion is 255 J/g. So, it is hopeful for solar energy storage.

Salt hydrates have received attention recently, because of their large heat of fusion.[1] A few salt hydrates were used for solar energy storage.[2,3] Materials with melting points within the range 40—45 °C are suitable for solar energy storage.

In order to develop a latent heat storage material with melting point within the range 40—45 °C, the pseudo-binary system $CH_3CO_2Na \cdot 3H_2O$–$HCONH_2$ was studied by differential scanning calorimetry (DSC). From this measurement, the partial phase-diagram of the ternary system CH_3CO_2Na–$HCONH_2$–H_2O at ambient pressure was constructed. In this system, a one to one addition compound of the two components, $CH_3CO_2Na \cdot 3H_2O$ and $HCONH_2$ was formed. The heat of fusion of this addition compound was determined.

Experimental

$CH_3CO_2Na \cdot 3H_2O$, CH_3CO_2Na, and $HCONH_2$ were of guaranteed grade reagent supplied from Wako Pure Chemical Industries Ltd.

Differential scanning calorimetry (DSC) was performed using SSC 56OU DSC (DAINISEIKOSHA CO. Ltd.), which was heat-flux DSC. Weighed quantities of $CH_3CO_2Na \cdot 3H_2O$, $HCONH_2$, and other chemicals were heated and mixed to form a homogeneous melt. One drop of this melt was placed in a 15 μl silver crucible and was solidified. After the crucible was closed, the sample was heated at the rate of 0.5 °C/min from 10 °C to 90 °C. The melting temperature of the sample was obtained from the sample temperature curve at time corresponding to endothermal peak. This DSC system was calibrated by using ice (t_m: 0.0 °C, ΔH_m: 335 J/g), sodium sulfate decahydrate (t_m: 32.4 °C) and sodium acetate trihydrate (t_m: 58.4 °C) as standards.

Results and Discussion

The phase diagram of the binary system CH_3CO_2Na–H_2O based on W. F. Greem's data[4] is shown in Fig. 1. In this figure, W_a shows mass fraction of CH_3CO_2Na and W_b shows mass fraction of H_2O. We see that $CH_3CO_2Na \cdot 3H_2O$ melts incongruently to an aqueous solution containing 58 percent CH_3CO_2Na by weight in equilibrium with the balance of CH_3CO_2Na and that the balance of CH_3CO_2Na dissolves entirely in its water of crystallization at 78 °C.

The DSC curves of some mixtures of the pseudo-binary system $CH_3CO_2Na \cdot 3H_2O$–$HCONH_2$ are illus-

●: Melting point of $CH_3CO_2Na \cdot 3H_2O$, ○: melting point of $CH_3CO_2Na \cdot HCONH_2 \cdot 3H_2O$, △: melting point of CH_3CO_2Na, □: eutectic point.

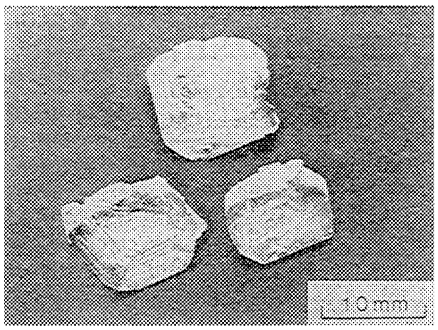

Fig. 4. Photograph of crystals of the addition compound, $CH_3CO_2Na \cdot HCONH_2 \cdot 3H_2O$.

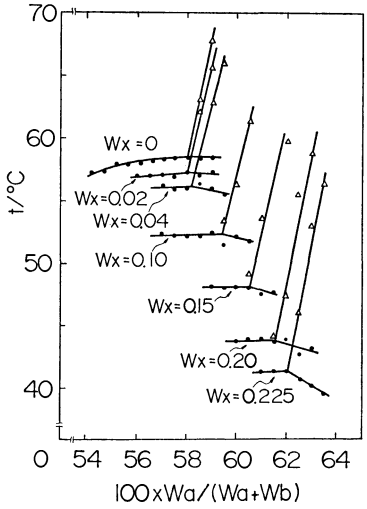

Fig. 5. Melting-point diagram of the ternary system CH_3CO_2Na–$HCONH_2$–H_2O, at ambient pressure in which the mass fraction of $HCONH_2$ is kept constant in each system. ●: Melting point of $CH_3CO_2Na \cdot 3H_2O$, △: melting point of CH_3CO_2Na.

trated in Fig. 2. In this figure, the numbers on the ordinate, q indicates heat flux. The heat absorption accompanying the dissolving of CH_3CO_2Na in its water of crystallization is much smaller than that accompanying the melting of $CH_3CO_2Na \cdot 3H_2O$ but it is illustrated in magnified scale. Considering the phase diagram of the system CH_3CO_2Na–H_2O shown in Fig. 1, we understand that the peak at 58.4 °C of DSC curve of $CH_3CO_2Na \cdot 3H_2O$ corresponds to the melting of $CH_3CO_2Na \cdot 3H_2O$ and the change at 77.8 °C corresponds to the entire dissolution of CH_3CO_2Na in its water of crystallization.

The pseudo-binary section in a ternary system CH_3CO_2Na–$HCONH_2$–H_2O at ambient pressure, which is constructed from such DSC curves, is shown in Fig. 3. In this figure, W_x shows mass fraction of $HCONH_2$, while Y_x shows mole fraction of $HCONH_2$. From this figure, it is clear that in the pseudo-binary system $CH_3CO_2Na \cdot 3H_2O$–$HCONH_2$, a one to one addition compound of the two components forms, and this addition compound $CH_3CO_2Na \cdot HCONH_2 \cdot 3H_2O$ melts congruently at 40.5 °C. The photograph of crystals of this addition compound is shown in Fig. 4. These crystals are colorless and transparent. The specific gravity of this crystal at room temperature is

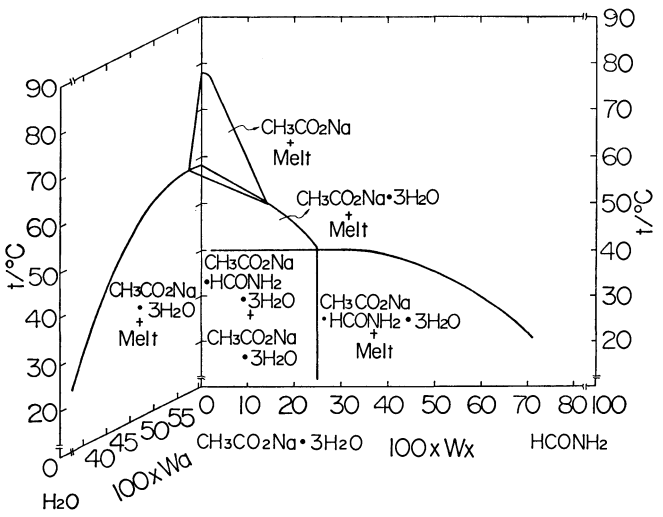

Fig. 6. Partial phase diagram of the ternary system CH_3CO_2Na–$HCONH_2$–H_2O at ambient pressure.

1.404 g/cm³.

The melting-point diagrams for the system CH_3CO_2Na–$HCONH_2$–H_2O at ambient pressure, in which the mass fraction of $HCONH_2$ is kept constant in each system are plotted in Fig. 5 by using DSC caves such as the curve (c) in Fig. 2. In this figure, the numbers on the abscissa, $100 \times W_a/(W_a+W_b)$ is weight percent of CH_3CO_2Na in the system without $HCONH_2$ content. The melting-point diagram for the system CH_3CO_2Na–H_2O which does not contain $HCONH_2$ is in good agreement with reported data.[4] It is apparent that as mass fraction of $HCONH_2$, W_x increases, the liquidus line on $CH_3CO_2Na \cdot 3H_2O$ side shifts to lower temperature and the liquidus line on CH_3CO_2Na side shifts to higher concentration of CH_3CO_2Na.

The partial phase diagram of the ternary system CH_3CO_2Na–$HCONH_2$–H_2O at ambient pressure is constructed by using the results of Figs. 1, 3, 5, and it is shown in Fig. 6.

The heat of fusion of the addition compound $CH_3CO_2Na \cdot HCONH_2 \cdot 3H_2O$ is found to be 255 J/g by DSC. This value is much larger than the heat of fusion of $Ca(NO_3)_2 \cdot 4H_2O$ (t_m: 43 °C), 142 J/g.

The melting point of this addition compound, 40.5 °C is suitable for solar energy storage and its heat of fusion is very large. So, this addition compound $CH_3CO_2Na \cdot HCONH_2 \cdot 3H_2O$ is, hopeful for solar energy storate use.

The authors wish to express their thanks to Dr. Ryoichi Kiriyama for his many helpful discussions and to Dr. Eiichi Hirota and Dr. Masanari Mikoda for their continuous encouragement. They are also grateful to Dr. Yoshihiro Matsuo for his discussions throughout this work.

(Received March 13, 1982)

The title compound, $C_{15}H_{16}O_9 \cdot 2H_2O$, crystallizes in orthorhombic space group $P2_12_12_1$ with $a=7.082(2)$, $b=34.789(5)$, $c=6.867(2)$ Å, and $Z=4$. The structure was solved by direct method and refined by least-squares to a final R of 0.038 based on 1841 observed reflections measured on a four-circle diffractometer. The coumarin ring is approximately planar and the torsion angle around the glucosidic C–O bond is 13.5°; this is much smaller than the corresponding value in 8-glucosyloxy-7-hydroxycoumarin, and causes considerable intramolecular repulsion around the glucosidic linkage. The valence angle of the oxygen atom linking the coumarin and glucose moieties is quite large, 118.5°. The glucopyranose portion is in a C_1 chair conformation. Glucosidation at the 7-hydroxyl group brings about considerable decrease of the resonance system of the 7-hydroxylated coumarin moiety. Such an effect seems to play an important role in the transglucosidation of dihydroxycoumarin glucosides.

In the course of investigation on the biosyntheses of hydroxylated coumarins and their glucosides, some characteristic transglucosidases were isolated from *Daphne odora* and *Cicholium intybus*.[1] In *D. odora*, it is considered that 7-(β-D-glucosyloxy)-8-hydroxycoumarin (or daphnetin 7-glucoside: **D7G**) is formed from *p*-glucosyloxycinnamic acid and that this is changed into 8-(β-D-glucosyloxy)-7-hydroxycoumarin (or daphnetin 8-glucoside: **D8G**) by the action of transglucosidase. This reaction proceeds *via* two steps: *i.e.*, hydrolysis of **D7G** to 7,8-dihydroxycoumarin (or daphnetin: **D**) and glucose, and glucosidation of **D**, as shown in Fig. 1.[2] The back reaction, the formation of **D7G** from **D8G**, could not be detected. In order to elucidate the structural significance of these substrates for the interconversion reactions, the crystal structures of **D**[3] and **D8G**[4] have been determined. In **D8G** the glucosidation at 8-hydroxyl group of **D** caused little effect on the coumarin structure and the glucosyl moiety takes a conformation so as to minimize the intramolecular repulsion. This paper deals with the crystal structure of **D7G** to determine the effect of glucosidation at 7-hydroxyl group of **D**.

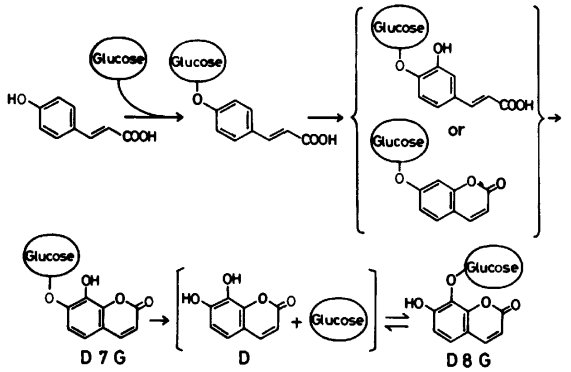

Fig. 1. Biosynthesis of **D7G** and conversion into **D8G**.

Experimental

Single crystals were prepared by slow evapolation from aqueous ethanol solution. They are colorless prisms elongated along the c axis. The space group was determined to be $P2_12_12_1$ from photographs. The density was measured by flotation method in a mixture of carbon tetrachloride and hexane. The lattice constants and intensity data were obtained on a Rigaku four-circle diffractometer with graphite monochromated Cu $K\alpha$ radiation. Of 1940 independent reflections measured within $2\theta<153°$, 1842 had intensities greater than 3σ ($|F_o|$) and these were used for the structure analysis. No correction was made for absorption. The crystallographic data are: $C_{15}H_{16}O_9 \cdot 2H_2O$, F.W.=376.3. Orthorhombic $P2_12_12_1$, $a=7.082(2)$, $b=34.789(5)$, $c=6.867(2)$ Å, $Z=4$, $D_x=1.48$ g cm^{-3}, $D_m=1.48$ g cm^{-3}, μ(Cu $K\alpha$)=12.7 cm^{-1}.

Structure Determination

The structure was solved by the direct method[5] and the structural parameters were refined by block-diagonal least-squares method. All the hydrogen atoms were located on a difference electron density map and their positional and isotropic thermal parameters were included in the refinement. In the later stage of refinement the 012 reflection seemed to be extinct and was given zero weight. The weighting scheme for the other reflections was $w=(10.0/|F_o|)$ if $|F_o|\geq 10.0$, $w=1.0$ if $10.0\geq|F_o|>3.0$, and $w=(|F_o|/3.0)$ if $|F_o|<3.0$. The final R value was 0.038 for 1841 observed reflections. Atomic scattering factors were taken from Ref. 6. The final atomic parameters are shown in Table 1 with equivalent isotropic temperature factors.[7]

Results

Bond Lengths and Angles. The perspective drawing of the molecule with the numbering system is shown in Fig. 2. The daphnetin moiety is nearly planar.[7] The bond lengths and angles are given in Fig. 3. The bond length of carbonyl C=O, 1.226 Å, is larger than those values in coumarin (1.203 Å),[8] gnidicoumarin (1.204 Å),[9] amyrolin (1.210 Å),[10] and xanthotoxin (1.198 Å),[11] and this is close to those of 7-hydroxylated coumarins such as **D** (1.219 Å), **D8G** (1.222 Å), and esculetin (1.227 Å).[12] In the benzene ring, the C(5)–C(6) and C(8)–C(9) bonds are somewhat shorter than the other four C–C bonds. In the 7-hydroxylated

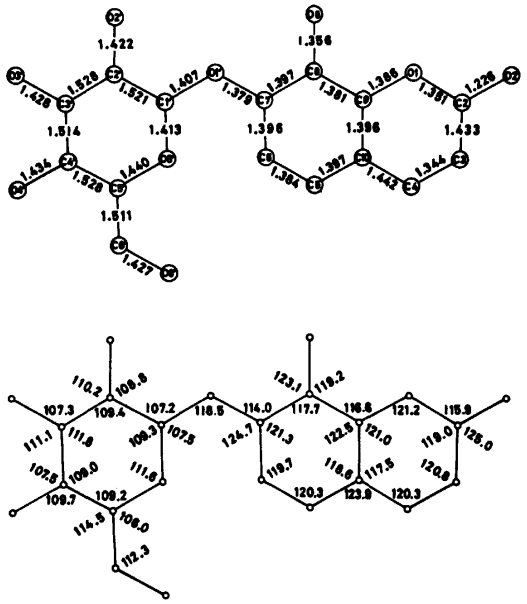

Fig. 3. Bond lengths (l/Å) and angles (ϕ/°). The e.s.d.s are 0.003—0.004 Å for lengths and 0.2—0.3° for angles.

coumarins so far determined by X-rays, the differences in length between C(5)–C(6) and C(6)–C(7) are significantly large. They are 0.024, 0.036, 0.039, and 0.032 Å for **D**, **D8G**, esculetin, and 4-methylumbelliferone,[13] respectively. However, the difference in this molecule, 0.012 Å, is rather small.

The glucopyranose ring is in the usual C_1 chair conformation; the endo- and exocyclic torsion angles are similar to those of **D8G** (Table 2). The anomeric effect in the bond lengths of the sequence C(5′)–O(5′)–C(1′)–O(1′) is unusual: C(5′)–O(5′)>O(5′)–C(1′)≃C(1′)–O(1′), which is similar to the case in **D8G**, whereas in usual β-glucosides C(5′)–O(5′)≃O(5′)–C(1′)>C(1′)–O(1′).[14]

Conformation of the Glucosyl Linkage. The anomeric C(1′)–O(1′) bond is twisted only by 13.8° against the daphnetin plane with the valence angle at O(1′) of 118.5°. The corresponding values in **D8G** are 101.8° and 114.4°, respectively, as shown in Fig. 4. While the glucosyl moiety in **D8G** takes the conformation so as to minimize intramolecular repulsion, the small torsion angle of glucosidic bond in **D7G** results in unusually short intramolecular distances between C(1′)···C(6) (2.863 Å) and C(1′)···H(C6) (2.59 Å). A great difference between the bond angles of C(6)–C(7)–O(1′) and C(8)–C(7)–O(1′), 10.7°, also indicates steric hindrance, while the corresponding values in **D** and **D8G** are only 6.0° and 6.3°, respectively. The angle at the glucosyl oxygen in **D7G** is definitely larger than that in **D8G** and is approximately the same as the value of the sp^2 angle. The geometries of the glycosyl linkage in the aromatic β-glycopyranosides so far determined are listed in Table 3. All of them, except for **D8G**, are similar to the

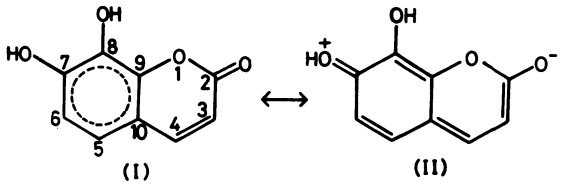
structure in **D7G**. It is thus plausible that the glycosyl bond of aromatic β-glycopyranoside usually takes a conformation with small torsion angle of θ. π Electrons of the oxygen atom of glycosyl linkage may take part in the resonance of the aromatic ring and stabilize the molecular structure in spite of the large intramolecular repulsion; this will be explained in the discussion.

Crystal Structure. Figure 5 shows the crystal structure viewed along the a axis. The coumarin moieties are stacked along the c axis and a three-dimensional network of hydrogen bonding connects the molecules. The hydrogen bonds O(3′)–H···O(W1)–H···O(4′) form infinite arrays along the c axis and O(4′)–H···O(3′) connects the glucose moieties related by 2_1 axis along the a axis. The remaining six hydrogen bonds link the three molecules at i, v, and vii. The hydrogen bond parameters are listed in Table 4.

Discussion

It has been found that the structure of **D** can be well explained by the following resonance:



The contribution from the limiting structure(II) is also apparent in the related structures: esculetin, which has a hydroxyl group at the 6 position instead of 8, and 4-methylumbelliferone, which contains a methyl group bonded to C(4) instead of the 8-hydroxyl group. Such a conjugation effect has been postulated to account for the characteristic nature of the spectral[15] and chemical[16] properties in 7-hydroxylated coumarins.

The structure of **D8G** reveals that the glucosidation at 8-hydroxyl group of **D** causes little effect on the resonance of daphnetin moiety. The C(5)–C(6) bond is significantly shorter than C(6)–C(7) and the C(2)–O(2) bond is longer than the corresponding one of coumarin.

In the present **D7G** molecule, however, the contribution from the structure(II) is expected to be less as a result of the glucosidation at the 7-hydroxyl group. The difference between C(5)–C(6) and C(6)–C(7) is significantly smaller than that in **D8G**. Although a slight contribution from the structure(II) is observed for **D7G**, most of the resonance energy may be compensated by the intramolecular repulsion between the coumarin ring and the glucose moiety. These results clearly indicate that **D8G** is more stable energetically than **D7G**.

Action of transglucosidase for dihydroxycoumarin glucosides has already been shown in Fig. 1. Although the structure of the active site of the enzyme is still unknown, the structures of substrate and product can explain the reaction mechanism. At the intermediate stationary state of the enzymatic reaction, both **D7G** and **D8G** may be formed from **D** and glucose; however the formation of **D8G** is considered to be far more favorable in terms of the stability of the molecule, so

that glucose is transferred from **D7G** to **D8G**.

The authors are grateful to Professor Yoshio Sasada and Dr. Yuji Ohashi of Tokyo Institute of Technology for their valuable discussions and encouragement.

Dispersibility of Magnetic and Nonmagnetic Iron(III) Oxides in 2-Butanone

Kazuhiko KANDORI,* Ayao KITAHARA, and Kijiro KON-NO
Department of Industrial Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received June 25, 1982)

The dispersion stability of needlelike and octahedral iron(III) oxides of magnetic or nonmagnetic particles in 2-butanone was studied. Two kinds of copolymers of poly(vinyl acetate-vinyl chloride-maleic acid) (VAVCCOOH) and poly(vinyl acetate-vinyl chloride-vinyl alcohol) (VAVCOH) were used as dispersants. The sedimentation of dispersions, the adsorption of copolymer dispersants on the particles and zeta potentials were measured. By polymer adsorption, the dispersion of nonmagnetic needlelike iron(III) oxide was stabilized and the dispersions of magnetic needlelike iron(III) oxides were somewhat stabilized, but the dispersions of magnetic octahedral iron(III) oxides were only slightly stabilized. This characteristic behavior of the sedimentation experiment was discussed in relation to the amount of polymer adsorption and zeta potential and was correlated with the observations by an electron microscope. The magnetic attractive force operating between the two magnetic particles was calculated to illustrate the dispersibility of magnetic oxides. It was suggested from the calculation that the strength of the magnetization and the volume of a particle are the main factors affecting the flocculation of the magnetic particles.

The dispersions of the magnetic particles in polar organic media have been used as a paint for magnetic tapes. Good dispersibility is necessary to improve the properties of the magnetic tapes. However, the fundamental studies on dispersibility are very few, though some rheological studies have been done.[1-3]

Many data on the stability of colloidal dispersions in nonpolar organic media as well as in water have been accumulated. The stability of colloidal dispersions in water has been discussed by the well-known DLVO theory,[4] and this theory has been extended to that in nonpolar organic media.[5-9] Recently, synthetic polymers have drawn attention as dispersants and the effect of adsorbed polymer layers on the stability of pigment dispersions has been reported.[10-16] The double layer interaction between the particles indicated by the DLVO theory and the steric stabilization by the adsorbed polymers must both be considered in order to illustrate the stabilization of pigment dispersions in nonpolar organic media.[17]

However, few studies on the stability in polar organic media such as alcohols and ketones have been done.[18]

In this paper, as fundamental study of magnetic paints, the dispersions of needlelike and octahedral iron(III) oxides of the magnetic or nonmagnetic particles were prepared in 2-butanone. The sedimentation of dispersed particles, the adsorption of copolymer dispersants on the particles and zeta potentials were measured. The characteristic behavior of the sedimentation experiment is compared with the observation by an electron microscope.

Experimental

Material. Five kinds of iron(III) oxides were prepared according to the references.[19-21] Each property of these iron(III) oxides is shown in Table 1. They were washed with 2-butanone in a Soxhlet apparatus for 16 h and then with hot distilled water in order to remove inorganic salts. This procedure was followed by drying in vacuum for 16 h at 100 °C; the materials were stored in a desiccator before use.

Two kinds of copolymers of poly(vinyl acetate-vinyl chloride-maleic acid) (abbreviated as VAVCCOOH) and poly (vinyl acetate-vinyl chloride-vinyl alcohol) (VAVCOH) were prepared[22-24] and used as dispersants. Their molecular weights and chemical compositions, determined by the gel permeation chromatographic method (GPC), are shown in Table 2. These copolymers were extracted with methanol in a Soxhlet apparatus for 16 h and dried in vacuum for 16 h at 60 °C.

The 2-butanone used as a solvent was purified as follows: It was shaken four times with saturated potassium carbonate solutions and kept over potassium carbonate anhydride for a day. It was then distilled and dried with Molecular Sieve 4A to remove any trace of water.

Preparation of Dispersions. The dispersion of the particle content of 0.2 wt% and fixed concentration of a dispersant** (VAVCCOOH or VAVCOH) was prepared by mixing the particles and the solution under irradiation with an ultrasonic apparatus (Kaijo Denki Co. Model TA-4015, Power Supply 150 W, 20 kHz) for 5 mins. No precipitation was observed

TABLE 1. PROPERTIES OF IRON (III) OXIDES

VAVCOH	3.29	6.95	2.11	VA : VC : OH=3 : 91.5 : 5.5

a) Apparatus: Water associates GPC-244, column: TSK-GEL, solvent: THF 2.0 ml/min 25 °C, sample: 0.5 w/v% 500 μl. Molecular weights were computed from the polystyrene calibration curve.

immediately after this procedure.

Estimation of Dispersion Stability. The stability of dispersion was estimated by the sedimentation experiment. The dispersion prepared by the above method was again shaken in a flask for 16 h at 30 °C and then transferred in a sedimentation tube. The dispersion had a height of 30 cm in each tube. The movement of the sharp boundary between supernatant and sediment was recorded with time after the material was introduced the tube and shaken at 30±0.1 °C.

A state of flocs of particles which formed in the medium after 24 h was directly observed by an electron microscope (JEM-100B). The sample was prepared as follows: Collodion solution was evaporated to obtain cellulose trinitrate. A small quantity of this cellulose trinitrate was dissolved (1.5 wt%) in the dispersion used for the sedimentation experiment. A small amount of the dispersion was dropped on the water (30 °C) and the film formed was stretched on the mesh used for an electron microscope.

The electron microscope observation showed that the states of flocs of particles were similar in all of the meshes for the same dispersion. No effect of collodion addition on the dispersibility was observed.

Adsorption and Zeta Potential Measurement. The amount of the polymer adsorbed on iron(III) oxides was determined as follows: The polymer solution of the known concentration involving a fixed amount of an iron(III) oxide (4 wt%) was shaken for a given period of time at 30±0.1 °C until adsorption equilibrium was reached. The adsorption equilibrium was reached after about 16 h for each system. The iron(III) oxides was then separated by centrifugation and a known amount of the supernatant was taken to determine the equilibrium polymer concentration. The quantity of polymer adsorbed was determined by direct weighting of the polymer which had been dried up by evacuated evaporation of the solvent from the supernatant.

Electrophoretic mobility was measured by microelectrophoresis with Laser Zee TM Model 500 (PEN KEM CO.) to which was attached externally a constant voltage power supply (BIO SCIENCE MODEL PS-30); here a rectangular quartz cell was used to prevent the leakage of electric current along the wall. Particles were illuminated by He-Ne laser (2 mW, 6328 Å). Zeta potential was calculated with use of the Hückel equation. The dispersion used for the microelectrophoresis was about 0.01 wt% diluent of the supernatant in the sedimentation experiment.

Results and Discussion

Effect of Polymer Concentration. All of the particles, especially the needlelike ones, were stabilized by the addition of polymer, as exemplified in Fig. 1. In order to examine the effect of the polymer concentration on the dispersibility and zeta potential, the sedimentation experiment and zeta potential measurement were carried out for the nonmagnetic needlelike particle (No. 2). The dependence of the height of the boundary in the sedimentation tube at 24 h after the shaking and zeta potential on the polymer concentration is indicated

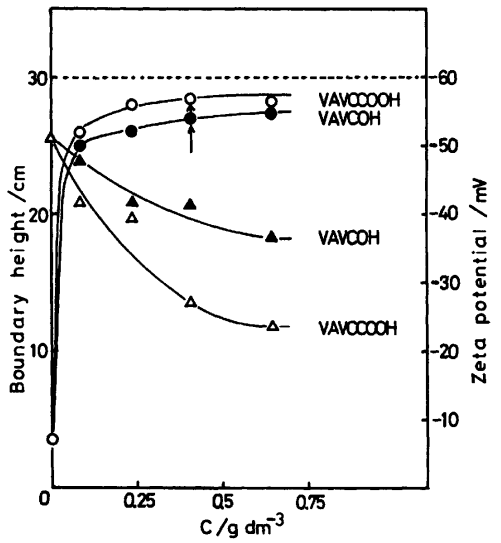

Fig. 1. Relation of the boundary height and ζ-potential with polymer concentration for No. 2 sample. Particle concentration=0.2 wt%. ○, ●: Boundary height, △, ▲: zeta potential.

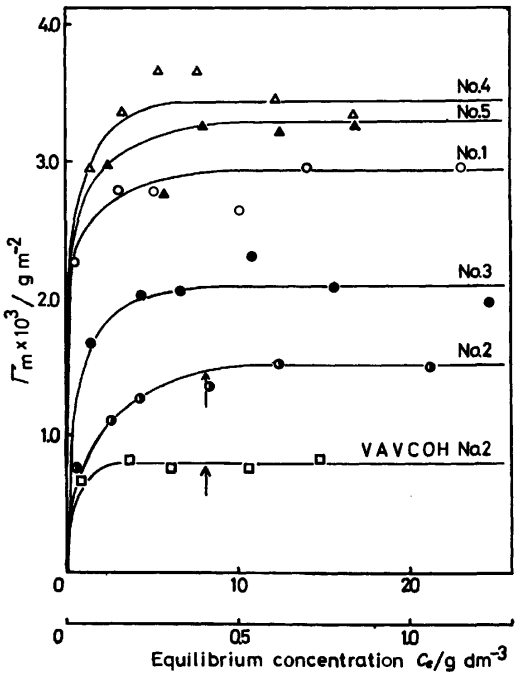

Fig. 2. Adsorption Isotherms. Particle concentration=4 wt%. The lower scale correspond to the particle concentration of 0.2 wt%. Arrows correspond with the arrows in Fig. 1.

in Fig. 1. The dispersion stability was markedly improved by addition of a small amount of both kinds of polymers and the zeta potential decreased gradually

Table 3. Results of each measurement for VAVCCOOH and VAVCOH systems

Particle No.	VAVCCOOH			VAVCOH	
	Initial velocity / mm min^{-1}	ζ-Potential / mV	$\Gamma_m \times 10^3$ / g m^{-2}	ζ-Potential / mV	$\Gamma_m \times 10^3$ / g m^{-2}
1	0.65	−46.9	2.95	−32.4	1.54
2	0.014	−29.2	1.57	−41.4	0.84
3	0.017	−32.2	2.00	−35.4	0.86
4	10	−24.9	3.40	−24.9	1.59
5	7.5	−23.8	3.37	−48.7	0.85

with increase of the polymer concentration. The decrease would be due to the shift of the slipping plane from the particle surface caused by the polymer adsorption.[15] The fact that the zeta potential of the VAVCOH system is higher than that of the VAVCCOOH system results from the difference of the adsorbed amount of polymer; this assertion will be depicted in Fig. 2.

The measurement of polymer adsorption was done in order to investigate the effect of polymer. The adsorption isotherms of VAVCCOOH for five kinds of iron(III) oxides (4 wt%) in 2-butanone are shown in Fig. 2. All isotherms were of the Langmuir type. Their Langmuir plots, $C/\Gamma \approx C$ curves, were linear in all cases. This same relationship was also obtained for the VAVCOH systems. One of them (No. 2) is shown in Fig. 2. The saturation values of adsorption (Γ_m) for the VAVCCOOH and VAVCOH were obtained from these Langmuir plots. The results are listed in Table 3. The saturation values of the adsorption for the VAVCCOOH system are larger than that for the VAVCOH system, as seen in Table 3. Such results would be due to the effect of functional groups in the interaction of the polymers with iron(III) oxides. It is known that carboxyl group interacts more strongly with oxide surfaces than does the hydroxyl group.[25-27]

The dispersibility was improved by addition of polymer, as pointed out in Fig. 1 of the sedimentation experiment. The polymer concentration shown by the arrow in Fig. 2, where the adsorption reaches approximately the saturation, coincides roughly with the concentration of the attainment of the stabilization shown by the arrows in Fig. 1. The effect of adsorbed polymer on the dispersibility of the nonmagnetic No. 2 sample can be illustrated from this correspondence.

Comparison of the Dispersibility of Five Kinds of Iron(III) Oxides. The sedimentation experiment was carried out for each sample to compare the dispersibilities of five kinds of iron(III) oxides. The change of the boundary height in the tube is shown as a function of time for five samples in Fig. 3. Here VAVCCOOH of 25 wt% per particles was used as a dispersant and the particle concentration was 0.2 wt%. The effect of the polymer on the stabilization of dispersions was marked in the system of the needlelike nonmagnetic iron(III) oxide (No. 2), as shown in Figs. 1 and 3. The dispersibility of No. 3, the needlelike magnetic iron(III) oxides, was considerably improved by the addition of the polymer, as shown in Fig. 3, though that of No. 1, needlelike and highly magnetic iron(III) oxide, was not much improved compared with Nos. 2 and 3. On the other hand, the dispersibility of the octahedral magnetic iron(III) oxides (Nos. 4 and 5) was scarcely improved at all. The improvement of the dispersibility of the five samples by VAVCOH was similar to that in the VAVCCOOH systems.

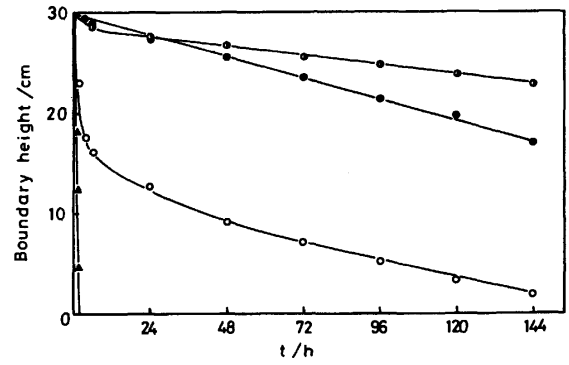

Fig. 3. Plots of boundary height *vs.* time.
○: No. 1, ●: No. 2, ◑: No. 3, ▲: No. 4, 5. [VAVCCOOH]=25 wt% per particles constant.

The initial velocity of the sedimentation curves, that is, the initial slope of the curves in Fig. 2, is listed in Table 3 to allow us to estimate the dispersibility. Table 3 shows that the order of the magnitude of sedimentation velocity is as follows:

$$\text{No. 4} \gtrsim \text{No. 5} \gg \text{No. 1} > \text{No. 3} > \text{No. 2.} \quad \text{(A)}$$

The electron microscope photographs of typical states of the flocs for each particle are shown in Fig. 4. These electron microscope observations show that the state of the flocs of particles is similar in all of the meshes for each particle. Figure 4 shows that the order of the size of the flocs is approximately as follows:

$$\text{No. 4} > \text{No. 1} > \text{No. 5} > \text{No. 3} > \text{No. 2.} \quad \text{(B)}$$

The particles of No. 2 do not form the flocs. The result of (B) agrees with the result of (A) except for the ordering between Nos. 1 and 5. The difference in (A) and (B) appearing between Nos. 1 and 5 can probably be ascribed to the difference in the density of the flocs.

Table 3 shows that there are no great differences among the zeta potentials of each particle, and the values do not agree with the flocs' size or with the sedimentation velocity. Moreover, the order of the saturation amount of adsorbed polymer (Γ_m) does not agree with that of the flocs' size.

The electric repulsion and the steric repulsion of the adsorbed polymer layer, therefore, are not the determinative factors of the formation of the flocs and the

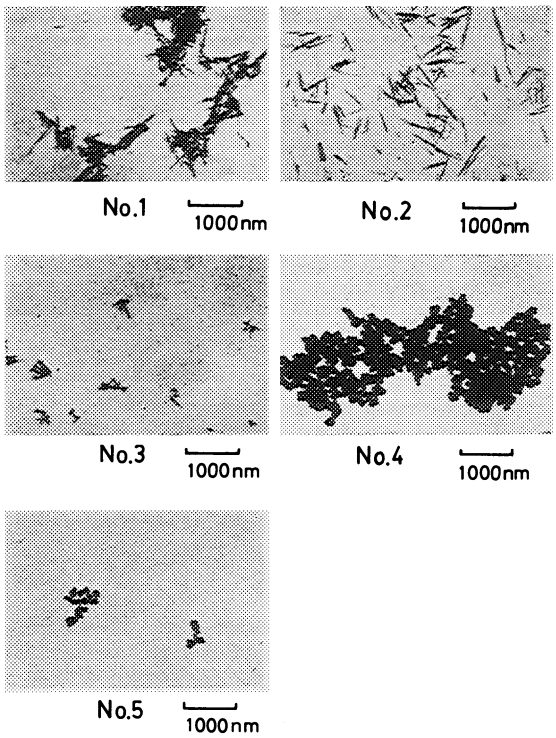

Fig. 4. Photographs of the electron microscope for each particle. Magnification: ×15000.

dispersibility of the five kinds of particles.

Here the magnetic attractive force has to be considered. The magnetic potential energy between two magnetic particles is expressed as follows:[28]

$$V_A^M = -K\left(\frac{M}{4\pi}\right)^2 \frac{V^2}{r^3},$$

where M is the strength of the saturation magnetization (Gauss), V is the volume of a particle, r is the distance between two particles and K is a constant ($K=2$ for the octahedral particles and head-tail interaction of the needlelike particles and $K=1$ for parallel interaction of the needlelike particles). The calculated values of V_A^M, at a constant distance r using the values of M in Table 1, are listed in Table 4. The order of the magnitudes of V_A^M agreed qualitatively with the results of (A) and (B).

Table 4. MAGNETIC ATTRACTIVE FORCE OF EACH PARTICLE

Particle No.	V_A^M/J
1	-8.0×10^{19}k[a]
2	-8.9×10^{15}k
3	-2.3×10^{19}k
4	-7.7×10^{23}k
5	-1.8×10^{23}k

a, $k=K/r^3$ (unit : m^{-3}).

The strength of the magnetization and the volume of a particle are, therefore, the main factors which control flocculation of the magnetic particles and the size of the flocs.

The Temperature Dependence of the Ultrasonic Relaxation Process Due to Interaction between Water and Allyl Cellosolve

Sadakatsu NISHIKAWA* and Tatsuro YAMAGUCHI
Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840
(Received July 1, 1982)

Ultrasonic absorption and velocity measurements have been performed in aqueous solutions of Allyl Cellosolve (ethylene glycol monoallyl ether) as functions of the concentration and the temperature. Only a single relaxational absorption has been observed in the frequency range from 15 to 220 MHz and, it has been attributed to the perturbation of the equilibrium expressed as $AB \rightleftarrows A+B$, where A and B are the solute and the solvent molecule respectively. The rate constants at various temperatures have been determined from the concentration dependence of the relaxation frequency, and the thermodynamic parameters associated with the reaction have been calculated. The enthalpy change has also been estimated from the concentration dependence of the maximum excess absorption per wavelength. From these results, it has been concluded that Allyl Cellosolve molecules act as water structure promoters and that the interaction between the solute and the solvent is due to hydrogen bonding. Furthermore, the rate and the thermodynamic properties obtained are compared with those for aqueous solutions of other ethers.

It has been recognized that the interaction between water and biological compounds play important roles in living systems. However, the dynamical properties of the interactions have not been well interpreted because the rates are too fast and the complex reactions proceed at the same time. The ultrasonic absorption method has been used to investigate the dynamical properties in solutions. The present authors have also reported some ultrasonic results for aqueous solutions of alcohols and ethers.[1-5] In these solutions, we have found that the excess absorption associated with the interaction between the solute and the solvent is observed in the MHz frequency range, and have predicted from the concentration dependence of the absorption that the interaction may be due to hydrogen bonding. In order to confirm the origin of the interaction, an investigation of the temperature dependence of the absorption is required; it may provide useful information about the rate and the thermodynamic properties. For this purpose, Allyl Cellosolve (ethylene glycol monoallyl ether) has been chosen as a solute; in this report the results are compared with those of other ethers.

This kind of fundamental informations seems to be very important for the understanding of more complex interactions.

Experimental

The Allyl Cellosolve was purchased from the Tokyo Kasei Co., Ltd. and was distilled once under reduced pressure. The purity was confirmed to be more than 99.8% by means of the gas-chromatographic method. The sample solutions were prepared using doubly distilled water by weighing.

The ultrasonic absorption coefficients, α, were measured by a pulse method. The 5 MHz x-cut crystal was used in the frequency range from 15 to 95 MHz and the 20 MHz crystal, in the range from 60 to 220 MHz. An ultrasonic interferometer was used to measure the sound velocity, c, at 2.5 MHz. All the measurement cells were immersed in a water bath which was maintained within ± 0.005 °C. The measurements were carried out at 20, 25, and 30 °C.

Results and Discussion

Figure 1 shows an illustrative example of the ultrasonic absorption spectra for aqueous solutions of Allyl Cellosolve at 25 °C. They are all characteristic of a single relaxation process and are well described by the following equation.

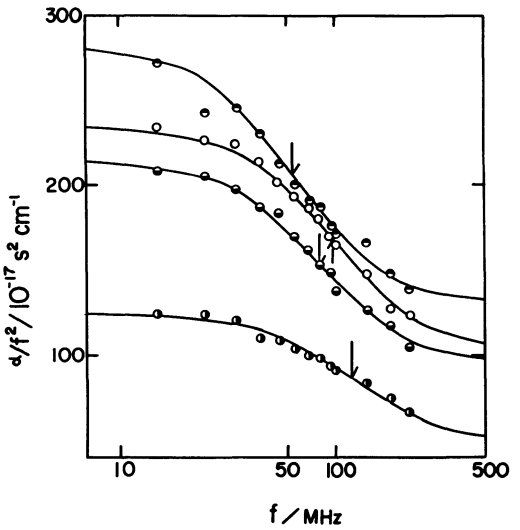

Fig. 1. Ultrasonic absorption spectra in aqueous solution of Allyl Cellosolve at 25 °C. Arrows show the positions of the relaxation frequency. ◑; 3.01 M, ◒; 3.50 M, ◓; 4.00 M, and ○; 4.50 M.

$$\alpha/f^2 = A/[1+(f/f_r)^2] + B, \quad (1)$$

where f is the frequency; f_r the relaxation frequency, and A and B, constants. These ultrasonic parameters, f_r, A, and B, were determined so as to obtain the best fit of the experimental data to Eq. 1, using a nonlinear least-meansquare method.[3] They are listed in Table 1 as a function of the analytical concentration of Allyl Cellosolve, C_e. The sound velocity shows a maximum at 2.5 M, 1 M=1 mol dm^{-3}, above which the excess absorption appears. The value of A which is the relaxation amplitude also shows a maximum at around 4.0 M though it is dependent on the temperature. These concentration dependences of ultrasonic properties are characteristic of aqueous solutions of nonelectrolytes, and we predict that the same mechanism as that proposed previously[1-5] is associated with the excess absorption in the aqueous solution of Allyl Cellosolve.

Table 1. Ultrasonic parameters for aqueous solution of Allyl Cellosolve at 25 °C

C_e / M[a]	f_r / MHz	A	B	r.m.s.[b]	c	ρ
		10^{-17} s^2 cm^{-1}			m s^{-1}	g cm^{-3}

4.23	88.9	140	116	3.55	1566	0.9950
4.51	96.7	130	103	2.78	1564	0.9942
4.77	102	115	105	3.25	1557	0.9937

a) 1 M=1 mol dm^{-3}. b) *r.m.s.* is defined as $\sum[[(\alpha/f^2)_{\text{calcd } i}-(\alpha/f^2)_{\text{exptl } i}]^2/N]^{1/2}$; the details of the procedure of the analysis are described in Ref. 3.

The model is as follosw:

$$\mathrm{AB} \underset{k_b}{\overset{k_f}{\rightleftharpoons}} \mathrm{A}+\mathrm{B}, \qquad (2)$$

$$C_1 \qquad C_2 \quad C_3$$

where AB stands for the complex; A, the Allyl Cellosolve and B, the water which has ability of hydrogen-bonding. The C_i's indicate the equilibrium concentrations of the individual components. It is assumed that the liquid water consists of two states, that is, the hydrogen-bonded water and the nonhydrogen-bonded water, and that the rates between these states are too fast to be observed in our frequency range. Only nonhydrogen-bonded water may participate in the reaction considered here. The relation between the relaxation frequency and the concentrations is derived as follows:

$$2\pi f_r = k_b[(C_e-\beta C_w+K)^2+4\beta C_w K]^{1/2}, \qquad (3)$$

where β is the mole fraction of the nonhydrogen-bonded water and C_w the analytical concentration of water, and where K is defined as $K=k_f/k_b$. The parameters, k_b, β, and K in Eq. 3 could be determined so as to get a reasonable curve which satisfied the experimental data to the relaxation frequency. The detail of the method for the determination have been shown elsewhere.[4] Similar experiments and calculations were performed at 20 and 30 °C. Figure 2 shows the concentration dependence of the relaxation frequency at various temperatures. The solid lines were calculated using the obtained parameters. The minimum position of the relaxation frequency shifts to a higher concentration with an increase in the temperature. This means that the fraction of the nonhydrogen-bonded water increases with the temperature. This is also clear from the temperature dependence of the β value. The obtained rate and the thermodynamic constants are listed in Table 2.

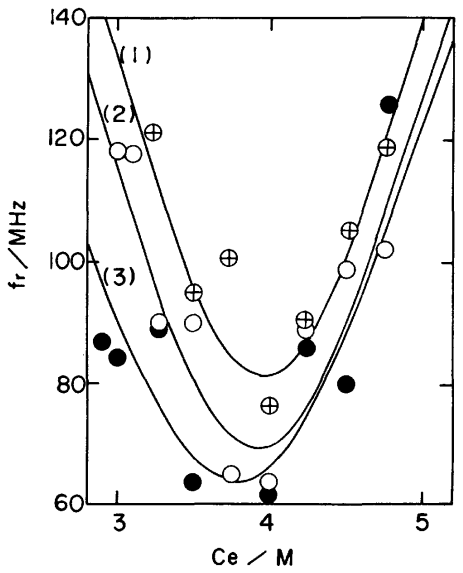

Fig. 2. Concentration dependence of the relaxation frequencies at various temperature. ⊕; 30 °C, ○; 25 °C, and ●; 20 °C.

Table 2. Rate and thermodynamic constants for interaction between water and Allyl Cellosolve

T / °C	β	$10^{-}k_b$ / M^{-1} s^{-1}	10^2K / M
20	0.113±0.002	3.3±0.3	8.9±0.8
25	0.121±0.001	3.7±0.2	9.0±0.7
30	0.123±0.002	4.0±0.2	10.0±0.6

Now, it is possible to estimate the activation enthalpy for the backward reaction, $\Delta H_b^{\ddagger}$, from the plots of $\ln(k_b)$ *vs.* $1/T$, and the enthalpy change of the reaction, ΔH, from those of $\ln(K)$ *vs.* $1/T$. Using the most probable values of the rate and equilibrium constants, they are calculated to be $\Delta H_b^{\ddagger}=14\pm3$ kJ mol^{-1} and $\Delta H=8\pm2$ kJ mol^{-1}. The forward rate constants in Table 3 are obtained from the relation of $K=k_f/k_b$. The forward activation enthalpy, $\Delta H_f^{\ddagger}$ is found to be 22 ± 4 kJ mol^{-1} from the relation of $\Delta H=\Delta H_f^{\ddagger}-\Delta H_b^{\ddagger}$. The entropy change of the reaction, ΔS, is also estimated to be approximately 13 J mol^{-1} deg^{-1} from $\Delta G=\Delta H-T\Delta S$, where ΔG is defined as $-\Delta G=RT\ln(K)$.

Another parameter which is obtained from the ultrasonic experiments is the maximum excess absorption per wave length, $\mu_{\max}$, which is expressed by this equation:

$$\mu_{\max} = Af_r c/2 = (\pi c^2\rho\Gamma/2RT)(\Delta V-\Delta H\alpha_p/\rho C_p)^2, \qquad (4)$$

where ρ is the solution density; ΔV, the volume change of the reaction; C_p, the specific heat, and α_p the thermal expansion coefficient. The term Γ is derived as $\Gamma=[1/C_1+1/C_2+1/C_3-1/(C_1+C_2+C_3)]^{-1}$ for the reaction considered here.[1] In order to determine accurately the enthalpy and volume changes of the reaction from Eq. 4, the values of α_p and C_p as the each concentration are necessary. Many thermodynamic parameters, including α_p and C_p in aqueous solutions of nonelectrolytes may show anomalous characters at around or less than the concentration where the sound velocity exhibits the maximum. The concentration range where the sound excess absorption appears is more than that concentration and so we may expect that these thermodynamic parameters change gradually with the concentration. Therefore, it is assumed that the α_p and C_p for the Allyl Cellosolve solution are expressed as linear functions of the mole fraction of the solute, n, in our

Table 3. Comparison of the rate and thermodynamic constants for three ethers at 25 °C

Solute	β	$10^{-7}k_f$ / s^{-1}	10^2K / M	Reference
Allyl Cellosolve	0.121	3.0	9.0	This work
Propyl Cellosolve	0.100	9.6	74	4
Butyl Cellosolve	0.029	4.2	25	3

limited concentration range. The values of α_p and C_p for Propyl Cellosolve are used for the estimation because the data for Allyl Cellosolve are unfortunately not available. They are $C_{p,\mathrm{soln}}=1.7n+4.2(1-n)$ [J g^{-1}] and $\alpha_{p,\mathrm{soln}}=1.1\times10^{-3}n+2.6\times10^{-4}(1-n)$ [deg^{-1}]. The obtained enthalpy and volume change are $\Delta H=8\pm4$ kJ mol^{-1} and $\Delta V=0.6\pm0.4$ cm^3 mol^{-1}. It should be noticed that a serious error may be contained in both the determinations of the enthalpy change of the reaction; these two values seem to be almost the same in the experimental error also because of the uncorrect values of the thermal expansion coefficient and the specific heat for Allyl Cellosolve. The obtained enthalpy change is still quite small; this might be because the reaction sites are surrounded by extremely polar water molecules.[6]

From these results in the present study, the following conclusions are derived. First, there are some aspects estimating the effects of solutes on the water structure.[7-10] The β parameter is also useful for the estimation because it is the fraction of nonhydrogen-bonded water molecule. As may be seen in Table 3, Allyl Cellosolve acts as a water structure promoter when the β value is compared with that in pure water.[10] However, its activity is not so much as that of the ether with a larger hydrophobic group. This dependence of the β parameter on the solute structure may reflect the effect of the hydrophobic group of the solute molecules or the hydrophobicity. With increasing the hydrophobicity, the fraction of the nonhydrogen-bonded water decreases.

Second, there might be various interactions between the solute and the solvent. The hydrogen bonding of water with the allyloxy group might also be possible. However, a similar concentration dependence of the ultrasonic absorption has been observed in alcohol solutions,[1,2,11] and even if such interaction exists, the time range may be different from ours. It might be considered in quite low frequency range because the water molecules around the alkyl group may be tightly bound by themselves.

Finally, other reaction mechanisms, for example, the association reactions between ethers by hydrogen-bonding, are possible causes of the excess absorption. However, the concentration dependence of the relaxation frequency can not be interpreted in terms of such reaction mechanisms. The background absorption, B, is still high than those expected from the classical aboorptions. Other relaxational absorptions may also exist in the higher frequency range. Therefore, we may confirm that the excess absorption solution is due to the interaction between water and the hydroxyl group of the ether.

General Relations between Bond Orders and Imaginary Bond-Bond Polarizabilities

Noriyuki MIZOGUCHI
Department of Physics, Meiji College of Pharmacy, Nozawa, Setagaya-ku, Tokyo 154
(Received August 3, 1982)

The imaginary bond-bond polarizability has been studied. Several general relations exist between the bond order and the imaginary bond-bond polarizability and between imaginary bond-bond polarizabilities.

Benzenoid hydrocarbons are known to have large magnetic anisotropies. A semiclassical theory by Pauling[1] showed that this arises from the Larmor precession of pi-electrons around the carbocyclic framework (ring current). In 1937 London[2,3] formulated this picture in simple quantum-mechanical terms. His method involves the use of gauge invariant atomic orbitals as a basis for the LCAO scheme. McWeeny[4,5] modified London's theory and represented the energy change due to the effect of the external magnetic field in terms of the imaginary bond-bond polarizability. When applied to a series of aromatic hydrocarbons, McWeeny's method gives a good agreement with experimental values of the ratio $\Delta\chi/\Delta\chi$ (benzene) and of NMR chemical shifts.[6-10] Here $\Delta\chi$ stands for the magnetic anisotropy of a conjugated system.

On the basis of McWeeny's method and with Gayoso-Boucekkine's unitary transformation,[11] Mallion[12] gave an explicit expression for the ring current in individual rings of polycyclic hydrocarbons. He emphasized, from the graph theoretical view point, that the concepts of "spanning tree"[13] and "circuit"[13] play impotant roles in the theory of the ring current. And many authers have discussed the concept of the ring current from the view point of the aromatic character of conjugated compounds.[14-19]

Imaginary bond-bond polarizability has been widely used to calculate the ring currents of conjugated systems. Nevertheless, the properties of the imaginary bond-bond polarizability have never been discussed. Only in Haddon's paper[20] is found a relation between the bond order and the imaginary bond-bond polarizability. But this is a special case of relations given in this paper.

Here the property of the imaginary bond-bond polarizability in a conjugated molecule will be discussed. And it will be shown that several general relations exist between bond orders and imaginary bond-bond polarizabilities.

The Imaginary Bond-Bond Polarizability

In order to understand the meaning of the imaginary bond-bond polarizability, the London-McWeeny theory, which is an extension of the simple HMO method, will be briefly outlined in this section. And each term of the expression for the magnetic susceptibility will be evaluated.

With London's approximations,[2] the resonance integrals in the presence of an external, uniform, magnetic field H normal to the plane of the molecule are given as[4-5]

$$\beta_{rs} = \beta \exp[2\pi i(e/hc)S_{rs}H] = \beta \exp(i\,\theta_{rs}),$$

where e, h, and c are the usual fundamental constants, S_{rs} the signed area of the triangle formed by an arbitrary origin and the bond r-s, counted positive if r-s is right-handed about the normal to the plane of the molecule, and β is the resonance integral in the absence of the magnetic field, which is assumed to be equal for all bonds.

With respect to the zero-field atomic orbital AO, the matrix elements of the perturbation due to the field are

$$\Delta_{rs} = \beta_{rs} - \beta = \beta\left(i\theta_{rs} - \frac{1}{2}\theta_{rs}^2 + \cdots\right).$$

The usual perturbation method gives the first- and second energy changes in the J-th molecular orbital MO (which is supposed to be nondegenerate):

$$\delta E_J^{(1)} = \sum_{rs} P_{J,sr}\Delta_{rs},$$

and

$$\delta E_J^{(2)} = \sum_{rs}\sum_{tu} \pi_{J,rs,tu}\Delta_{rs}\Delta_{tu}.$$

Here $P_{J,rs}$ is the partial bond order of the bond r-s[21] and is given by

$$P_{J,rs} = C_{rJ}C_{sJ},$$

and

$$\pi_{J,rs,tu} = \sum_{K(\neq J)} \frac{C_{rJ}C_{sK}C_{tK}C_{uJ}}{E_J - E_K},$$

where C_{rJ} and E_J are the coefficients of the r-th AO and the orbital energy of the J-th MO in the absence of the magnetic field. In this article, for simplicity, all the coefficients of AO are supposed to be real, since the wave function can always be written in real form in the absence of the magnetic field.

If we keep the first two terms in the series expansion of the perterbation and let X_{rs} and Y_{rs} be the real and imaginary parts of Δ_{rs} respectively, then

$$X_{rs} = -\frac{\beta}{2}\theta_{rs}^2 = X_{sr},$$

and

$$Y_{rs} = \beta\,\theta_{rs} = -Y_{sr}.$$

Considering the above equations, the first- and second energy changes in the J-th MO can be written as follows:

$$\delta E_J^{(1)} = 2\sum_{(rs)} P_{J,rs}X_{rs},$$

and

$$\delta E_J^{(2)} = -\sum_{(rs)}\sum_{(tu)} \bar{\pi}_{J,(rs)(tu)} Y_{rs} Y_{tu},$$

where (rs) indicates a sum over bonds, not a double sum over atomic centers and we have written

$$\bar{\pi}_{J,(rs)(tu)} = \pi_{J,rs,tu} - \pi_{J,rs,ut} + \pi_{J,sr,ut} - \pi_{J,sr,tu}$$
$$= \sum_{K(\neq J)} \frac{(C_{rJ}C_{sK} - C_{sJ}C_{rK})(C_{tK}C_{uJ} - C_{uK}C_{tJ})}{E_J - E_K}. \quad (1)$$

Term $\bar{\pi}_{J,(rs)(tu)}$ is the partial imaginary bond-bond poplarizability between bonds r-s and t-u.[22]

Thus the energy change in the J-th MO is

$$\delta E_J = -\beta\left(\frac{2\pi e}{hc}\right)^2 \{\sum_{(rs)} P_{J,rs} S_{rs}^2 + \sum_{(rs)}\sum_{(tu)} \beta\bar{\pi}_{J,(rs)(tu)} S_{rs} S_{tu}\} H^2.$$

Moreover the total pi-electron energy change of a conjugated molecule is given by

$$\delta E = \sum_J \lambda_J \delta E_J = -\beta\left(\frac{2\pi e}{hc}\right)^2 \{\sum_{(rs)} P_{rs} S_{rs}^2 + \sum_{(rs)}\sum_{(tu)} \beta\,\bar{\pi}_{(rs)(tu)} S_{rs} S_{tu}\} H^2, \quad (2)$$

where λ_J is the occupation number of the J-th MO,

$$P_{rs} = \sum_J \lambda_J P_{J,rs},$$

and

$$\bar{\pi}_{(rs)(tu)} = \sum_J \lambda_J \bar{\pi}_{J,(rs)(tu)}$$
$$= \sum_J \lambda_J \sum_{K(\neq J)} \frac{(C_{rJ}C_{sK} - C_{sJ}C_{rK})(C_{tK}C_{uJ} - C_{uK}C_{tJ})}{E_J - E_K}. \quad (3)$$

Term P_{rs} is the Coulson bond order of bond r-s,[23] and the term $\bar{\pi}_{(rs)(tu)}$ is what McWeeny defined as the imaginary bond-bond polarizability between bonds r-s and t-u.[4-5] The magnetic susceptibility of a conjugated molecule is defined as the second derivative of the total pi-electron energy with respect to H, *i.e.*,

$$\chi = -\frac{\partial^2}{\partial H^2}[(E^0 + \delta E)]_{H=0}$$
$$= 2\beta\left(\frac{2\pi e}{hc}\right)^2 \{\sum_{(rs)} P_{rs} S_{rs}^2 + \sum_{(rs)}\sum_{(tu)} \beta\bar{\pi}_{(rs)(tu)} S_{rs} S_{tu}\}$$
$$= \sum_J \lambda_J \chi_J, \quad (4)$$

where E^0 is the zero-field total pi-electron energy of a conjugated molecule and χ_J is the partial magnetic susceptibility for the J-th MO, as defined in the last equation.[22]

From Eq. 3 it can easily be shown that the mutual imaginary bond-bound polarizability $\bar{\pi}_{(rs)(tu)}$ is antisymmetric with respect to rs and tu, *i.e.*,

$$\bar{\pi}_{(rs)(tu)} = -\bar{\pi}_{(rs)(ut)} = -\bar{\pi}_{(sr)(tu)}.$$

Since the sum in Eq. 3 is antisymmetric in J and K, for molecules in which all the pi-electrons are paired, the imaginary bond-bond polarizability can be written as follows:

$$\bar{\pi}_{(rs)(tu)} = 2\sum_J^{\text{occ}}\sum_K^{\text{unocc}} \frac{(C_{rJ}C_{sK} - C_{sJ}C_{rK})(C_{tK}C_{uJ} - C_{uK}C_{tJ})}{(x_J - x_K)\beta}, \quad (5)$$

where $\sum^{\text{occ}}$ and $\sum^{\text{unocc}}$ run over occupied and unoccupied MO's respectively, and, as in the usual HMO method, it has been assumed that the orbital energy E_J can be written as follows:

$$E_J = \alpha + \beta x_J.$$

Here α is the coulomb integral.

From Eq. 5, it can be shown that the self imaginary bond-bond polarizabilities of any bonds are positive, *i.e.*,

$$\bar{\pi}_{(rs)(rs)} > 0, \quad (6)$$

where β is assumed to be negative.

From Eq. 6 we can say that the terms associated with the self imaginary bond-bond polarizability in Eq. 4 correspond to the paramagnetic terms of the magnetic susceptibility. Since the bond order P_{rs} of the bond r-s is positive,[24] the first terms in Eq. 4 correspond to the diamagnetic terms of the magnetic susceptibility. But the other terms associated with the mutual imaginary bond-bond polarizabilities do not have definite effects on the magnetic susceptibility because these polarizabilities do not have a definite sign.

General Relations between Bond Orders and Imaginary Bond-Bond Polarizabilities

The property of the imaginary bond-bond polarizability in a conjugated molecule will be dependent on the topological nature of the carbon skeleton, *i.e.*, the mode of branching. But the degree of vertices (atoms) in the Hückel molecular graph does not exceed 3.[25] It is therefore enough to consider only two subgraphs G1 and G2 as shown in Figs. 1 and 2.

Let first consider subgraph G1. This is a sequence of vertices a_j $(j=1,2,\cdots,n)$ whose degrees are all two. Then we have the following equalities for these edges (bonds):

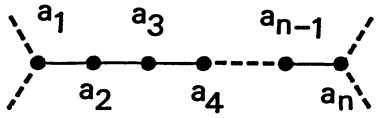

Fig. 1. Subgraph G1.

$$\bar{\pi}_{J,(rs)(a_i a_{i+1})} = \bar{\pi}_{J,(rs)(a_j a_{j+1})}, \quad (A')$$
$$\bar{\pi}_{(rs)(a_i a_{i+1})} = \bar{\pi}_{(rs)(a_j a_{j+1})}, \quad (A)$$
$$P_{J,a_i a_{i+1}} + \beta\bar{\pi}_{J,(a_i a_{i+1})(a_i a_{i+1})} = P_{J,a_j a_{j+1}} + \beta\bar{\pi}_{J,(a_j a_{j+1})(a_j a_{j+1})}, \quad (B')$$
$$P_{a_i a_{i+1}} + \beta\bar{\pi}_{(a_i a_{i+1})(a_i a_{i+1})} = P_{a_j a_{j+1}} + \beta\bar{\pi}_{(a_j a_{j+1})(a_j a_{j+1})}, \quad (B)$$
$$P_{J,a_i a_{i+1}} = \beta\bar{\pi}_{J,(a_i a_{i+1})(a_j a_{j+1})} - \beta\bar{\pi}_{J,(a_i a_{i+1})(a_i a_{i+1})}, \quad (C')$$
$$P_{a_i a_{i+1}} = \beta\bar{\pi}_{(a_i a_{i+1})(a_j a_{j+1})} - \beta\bar{\pi}_{(a_i a_{i+1})(a_i a_{i+1})}, \quad (C)$$

where $i, j = 1,2,\cdots,n$ and $i \neq j$.

Relations A' and A hold as far as a given edge r-s is not equal to edges a_i-a_{i+1} or a_j-a_{j+1}, *i.e.*, as far as the imaginary bond-bond polarizabilities under consideration are mutual ones. Relations B', B, C', and C hold even when the vertex a_1 is jointed to the vertex a_n, *i.e.*, even when the sequence of a_j $(j=1,2,\cdots,n)$ forms a ring.

Proof of Relations A' and A. We first consider Relation A' for $i=i$ and $j=i+1$. By substituting Eq. 1 into Relation A' and with some manipulations, the following equation is derived:

$$\beta(\bar{\pi}_{J,(rs)(a_ia_{i+1})} - \bar{\pi}_{J,(rs)(a_{i+1}a_{i+2})}) = \sum_{K(\neq J)} \frac{1}{x_J - x_K}(C_{rJ}C_{sK} - C_{sJ}C_{rK}) \times \{C_{a_{i+1}J}(C_{a_iK} + C_{a_{i+2}K}) - C_{a_{i+1}K}(C_{a_iJ} + C_{a_{i+2}J})\}. \quad (7)$$

Making use of the variational constraint for the vertex a_{i+1}

$$-x_JC_{a_{i+1}J} + C_{a_iJ} + C_{a_{i+2}J} = 0, \quad (8)$$

and with some manipulations, Eq. 7 can now be written as follows:

$$\beta(\bar{\pi}_{J,(rs)(a_ia_{i+1})} - \bar{\pi}_{J,(rs)(a_{i+1}a_{i+2})}) = \sum_K C_{a_{i+1}J}C_{a_{i+1}K}(C_{rJ}C_{sK} - C_{sJ}C_{rK}), \quad (9)$$

where the sum $\sum_{K(\neq J)}$ in Eq. 7 is changed to the sum $\sum_K$ since this change has no effect. Since, from the orthonormal property of the molecular orbitals, we have

$$\sum_J C_{rJ}C_{sJ} = \begin{cases} 1 & \text{if } r = s \\ 0 & \text{otherwise,} \end{cases} \quad (10)$$

it can be seen that the right hand side of Eq. 7 is equal to zero. Therefore it follows that

$$\bar{\pi}_{J,(rs)(a_ia_{i+1})} = \bar{\pi}_{J,(rs)(a_{i+1}a_{i+2})}. \quad (11)$$

After the repeated use of Eq. 11 for other edges Relation A′ is finally obtained. And Relation A can be obtained from Eq. 3 and Relation A′.

Proof of Relations B′ and B. After some manipulations similar to those in the proof of Relation A, the following equation can be derived:

$$\beta(\bar{\pi}_{J,(a_ia_{i+1})(a_ia_{i+1})} - \bar{\pi}_{J,(a_{i+1}a_{i+2})(a_{i+1}a_{i+2})}) = \sum_K C_{a_{i+1}J}C_{a_{i+1}K}\{C_{a_{i+1}J}(C_{a_iK} - C_{a_{i+2}K}) - C_{a_{i+1}K}(C_{a_iJ} - C_{a_{i+2}J})\}. \quad (12)$$

Because of Eq. 10, both the first and second terms of the right hand side of Eq. 12 are equal to zero. The third term of Eq. 12 is $-P_{J,a_ia_{i+1}}$ and the fourth term is equal to $P_{J,a_{i+1}a_{i+2}}$. Therefore we have

$$P_{J,a_ia_{i+1}} + \beta\bar{\pi}_{J,(a_ia_{i+1})(a_ia_{i+1})} = P_{J,a_{i+1}a_{i+2}} + \beta\bar{\pi}_{J,(a_{i+1}a_{i+2})(a_{i+1}a_{i+2})}. \quad (13)$$

After the repeated use of Eq. 13 for other edges we can obtain Relation B′ and thus Relation B.

Proof of Relations C′ and C. Making use of Eq. 8 for the vertex a_{i+1} and with some manipulations, we can obtain the following equation:

$$\beta\bar{\pi}_{J,(a_ia_{i+1})(a_{i+1}a_{i+2})} = \sum_K C_{a_{i+1}J}C_{a_{i+1}K}(C_{a_iJ}C_{a_{i+1}K} - C_{a_iK}C_{a_{i+1}J}) + \sum_{K(\neq J)}(C_{a_iJ}C_{a_{i+1}K} - C_{a_{i+1}J}C_{a_iK}) \times (C_{a_{i+1}J}C_{a_iK} - C_{a_{i+1}K}C_{a_iJ})\frac{1}{x_J - x_K}. \quad (14)$$

Since Eq. 10 holds, the first and second terms in the first sum of the right hand side of Eq. 14 are equal to $P_{J,a_ia_{i+1}}$ and to zero, respectively. The second sum is equal to $\beta\bar{\pi}_{J,(a_ia_{i+1})(a_ia_{i+1})}$. Therefore, the following equation is obtained:

$$\beta\bar{\pi}_{J,(a_ia_{i+1})(a_{i+1}a_{i+2})} = P_{J,a_ia_{i+1}} + \beta\bar{\pi}_{J,(a_ia_{i+1})(a_ia_{i+1})}. \quad (15)$$

After the repeated use of Eq. 15 for other edges, we can obtain Relation C′ and thus Relation C.

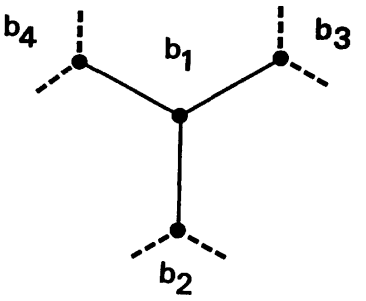

Fig. 2. Subgraph G2.

Next we consider subgraph G2 as shown in Fig. 2, in which the degrees of vertices b_2—b_4 are arbitrary and the vertex b_1 is jointed to vertices b_2—b_4. Then we have

$$\bar{\pi}_{J,(rs)(b_2b_1)} = \bar{\pi}_{J,(rs)(b_1b_3)} + \bar{\pi}_{J,(rs)(b_1b_4)}, \quad (D′)$$

$$\bar{\pi}_{(rs)(b_2b_1)} = \bar{\pi}_{(rs)(b_1b_3)} + \bar{\pi}_{(rs)(b_1b_4)}, \quad (D)$$

$$P_{J,b_1b_2} = \beta\bar{\pi}_{J,(b_1b_2)(b_3b_1)} + \beta\bar{\pi}_{J,(b_1b_2)(b_4b_1)} - \beta\bar{\pi}_{J,(b_1b_2)(b_1b_2)}, \quad (E′)$$

$$P_{b_1b_2} = \beta\bar{\pi}_{(b_1b_2)(b_3b_1)} + \beta\bar{\pi}_{(b_1b_2)(b_4b_1)} - \beta\bar{\pi}_{(b_1b_2)(b_1b_2)}. \quad (E)$$

Relations D′ and D hold even when a given edge r-s may be jointed to vertices b_2—b_4.

Proof of Relations D′ and D. Making use of the variational constraint for the vertex b_1,

$$-x_JC_{b_1J} + C_{b_2J} + C_{b_3J} + C_{b_4J} = 0,$$

and with some manipulations similar to those in the proof of Relation A, the following equation is derived:

$$\beta(\bar{\pi}_{J,(rs)(b_2b_1)} - \bar{\pi}_{J,(rs)(b_1b_3)}) = \sum_K C_{b_1J}C_{b_1K}(C_{sJ}C_{rK} - C_{rJ}C_{sK}) + \sum_{(K\neq J)}\frac{1}{x_J - x_K}(C_{rJ}C_{sK} - C_{sJ}C_{rK}) \times (C_{b_4J}C_{b_1K} - C_{b_1J}C_{b_4K}). \quad (16)$$

Note that in the first term of the right hand side of Eq. 16 the sum $\sum_{K(\neq J)}$ changes to the sum $\sum_K$. The first term of Eq. 16 is equal to zero since Eq. 10 holds. The second term of Eq. 16 is equal to $\beta\bar{\pi}_{J,(rs)(b_1b_4)}$. Therefore Relation D′ is obtained. Thus Relation D can be obtained from Eq. 3 and Relation D′.

Since the proofs of Relations E′ and E can be performed by the same way, they are omitted.

Discussion

The degeneracy of energy levels has not yet been considered. The derived relations between the partial bond order and the partial imaginary bond-bond polarizability, *i.e.*, Relations A′—E′, do not hold for degenerate energy levels. A slight modification is necessary for these energy levels. But it can be readily shown that Relations A—E hold also for molecules with degenerate energy levels as far as degenerate levels are not singly occupied. In such case we must, however, use the imaginary bond-bond polarizability in the form of Eq. 5.

Here $(4n+2)$-annulenes will be considered as examples. These molecules consist only of segments such as Subgraph G1. Therefore we consider only Relations A—C. Since these molecules have degenerate energy levels, we must, as dicussed above, use the imaginary

bond-bond polarizability in the form of Eq. 5. For annulenes, analylitical solutions of the secular equation have been reported. Therefore the sum in Eq. 5 can be performed and the following equations can be obtained:[20]

$$\bar{\pi}_{(rs)(tu)} = \frac{2}{N^2 \beta \sin(\pi/N)}, \quad (17)$$

$$\bar{\pi}_{(rs)(rs)} = \frac{2(1-N)}{N^2 \beta \sin(\pi/N)}, \quad (18)$$

$$P_{rs} = \frac{2}{N \sin(\pi/N)}, \quad (19)$$

where $N=4n+2$, and r-s and t-u are arbitrary two edges (bonds) in the annulene under consideration. Equation 17 is just Relation A for $(4n+2)$-annulenes. It should be noticed that Relation B can be obtained from their symmetry alone. Moreover from Eqs. 17 and 19 it follows that

$$\bar{\pi}_{(rs)(tu)} = \frac{P_{rs}}{N\beta}.$$

The above equation shows that all the mutual imaginary bond-bond polarizabilities in $(4n+2)$-annulenes are directly related to the bond order P_{rs} and equal to $P_{rs}/\beta N$. From Eqs. 17—19 we can obtain

$$P_{rs} + \beta\bar{\pi}_{(rs)(rs)} = \beta\bar{\pi}_{(rs)(tu)},$$

which is Relation C for $(4n+2)$-annulenes.

By use of a suitable unitary transformation[11-12] McWeeny[4] has shown that the sums in Eqs. 2 and 4, which runs over all bonds in a molecule, can be reduced to sums over one bond in each closed ring. We can show that the result of McWeeny's unitary transformation can be obtained by virtue of Relations A—E.[26] Moreover it is noteworthy that Relations A and D are very similar to Kirchhoff's law in the electro-magnetic theory. By virtue of Relations A—E, it can be shown that in the London-McWeeny theory the ring currents[12] are conserved.[26] The applications of Relations A—E to other problems will be discussed elsewhere.

We wish to thank Professor Haruo Hosoya, Ochanomizu University, and Professor Chuya Inoue, Meiji College of Pharmacy, for their helpful discussions.

24) Strictly speaking, this is not correct. Certainly in conjugated molecules, the bond orders of almost bonds are positive. But a bond whose bond order is equal to zero is found, for example, in butalene. Moreover in a very unstable system there exists a bond whose bond order is negative. This subject will be discussed in detail elsewhere.

Cyclopropanation of Dimethyl Fumarate and Maleate with *gem*-Dihalides Catalyzed by Co(0)- or Ni(0)-Complex and Zinc

Hiroyoshi KANAI,* Yoshimasa NISHIGUCHI, and Hideki MATSUDA
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received September 22, 1982)

The reaction of bis(acetonitrile)bis(diethyl fumarate)cobalt(0) with dibromomethane gave diethyl *trans*-1,2-cyclopropanedicarboxylate in a 67% yield based on the cobalt complex. Dimethyl *cis*-1,2-cyclopropanedicarboxylate was obtained in a 52% yield from the reaction of dimethyl maleate with dibromomethane in the presence of acetonitrilebis(dimethyl maleate)nickel(0) accompanied by the formation of the *trans*-isomer in a 14% yield. The addition of zinc gave cyclopropanes in over 100% yields based on cobalt or nickel. 3-Methyl- and 3,3-dimethyl-1,2-cyclopropanedicarboxylic acid esters were produced by the reaction of dimethyl fumarate or maleate with 1,1-dibromoethane and 2,2-dibromopropane. The yield in the cobalt catalyst system decreases with an increase of substituents of *gem*-dibromides, while that in the nickel catalyst system does not vary appreciably. A small amount of dimethyl isopropenylsuccinate was formed as a by-product in the reaction of 2,2-dibromopropane. A mechanism is briefly discussed which involves metallacyclobutane as an intermediate.

In the previous paper,[1] we reported the cyclopropane synthesis in which electron-deficient olefins were allowed to react with dibromomethane by the catalysis of Ni(0)-complexes and zinc. We have found that the best catalytic species are those coordinated by olefin and solvent molecules without additional ligands. Their candidates are bis(acetonitrile)bis(dialkyl fumarate)-cobalt(0) and acetonitrilebis(dialkyl maleate)nickel-(0). The treatment of the complexes with dibromomethane gave cyclopropane derivatives in the absence of Lewis acids or sodium iodide.[1b]

1,2-Cyclopropanedicarboxylic acid esters are produced from base-catalyzed reactions of α-substituted acrylic esters with α-halo esters,[2] or from reactions of α-halo esters with acrylic esters or of polyhalo compounds with α,β-unsaturated diesters by copper–isonitrile complexes.[3] The cyclopropanation of dialkyl fumarate and maleate with *gem*-dihalides in the presence of Co(0)- or Ni(0)-complex and zinc serves as a method of the synthesis of 3-alkyl-1,2-cyclopropanedicarboxylic acid esters. We have studied the effects of several variables on the yield and on the stereochemistry.

Results and Discussion

Cyclopropanation of Dimethyl Fumarate with Dihalomethanes Catalyzed by Bis(acetonitrile)bis(dimethyl fumarate)cobalt(0) (1) and Zinc. The stoichiometric reaction of bis-(acetonitrile)bis(diethyl fumarate)cobalt(0) with dibromomethane in acetonitrile gave diethyl *trans*-1,2-cyclopropanedicarboxylate in a 67% yield based on cobalt (Eq. 1). The cyclopropanation needs neither Lewis

$$Co(E\text{-}H_5C_2O_2CCH{=}CHCO_2C_2H_5)_2(CH_3CN)_2 + CH_2Br_2 \longrightarrow \begin{matrix} H_5C_2O_2C & & H \\ & \diagdown\diagup & \\ H & & CO_2C_2H_5 \end{matrix} + CoBr_2 \quad (1)$$

acids nor sodium iodide nor zinc, differing from that of monosubstituted olefins with electron-withdrawing groups.[1] As the data in Table 1 indicate, the addition of zinc increases the yield based on cobalt to over 100%. Zinc reduces cobalt bromide formed in Eq. 1 to regenerate a catalytic species in the presence of dimethyl fumarate (Eq. 2). A small amount of reduction product

$$CoBr_2 + \begin{matrix} H & & CO_2CH_3 \\ \diagdown & & \diagup \\ & C{=}C & \\ \diagup & & \diagdown \\ H_3CO_2C & & H \end{matrix} + Zn \xrightarrow{CH_3CN} Co(E\text{-}H_3CO_2CCH{=}CHCO_2CH_3)_2(CH_3CN)_2 + ZnBr_2 \quad (2)$$

1

was formed by the zinc bromide–zinc system.[4] The reduction is suppressed by the addition of sodium iodide which does not affect the yield of cyclopropane.

The cyclopropanation proceeded slowly as shown in Fig. 1. An increase in the amount of zinc results in an increase in the yield and reduction in the reaction time. Excess cobalt compound rather decreased the yield. When cobalt halides with water of crystallization were used, the yield decreased due to the production of a considerable amounts of succinate. Manganese can be substituted for zinc as a reductant although it takes a long time to prepare Co(0)-complex.

The best yield based on dibromomethane is obtained when a 1:1 fumarate:dibromomethane mole ratio is used. A slight excess of dibromethane is necessary for the reaction of fumarate to proceed to completion. The

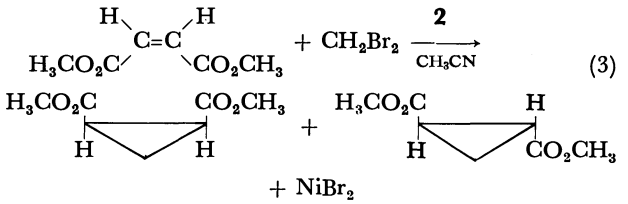
a) To the Co(0)-fumarate complex prepared *in situ* from CoX_2, dimethyl fumarate (5 mmol), NaI, and zinc in CH_3CN (10 ml) was added dibromomethane and the mixture was stirred at room temperature for a given period of time. b) Conversion of dimethyl fumarate. c) Yield based on dimethyl fumarate. d) Dimethyl *trans*-1,2-cyclopropanedicarboxylate. e) $CoBr_2 \cdot 6H_2O$. f) $CoI_2 \cdot 4H_2O$. g) THF(10 ml) was used as solvent. h) Dimethyl maleate (5 mmol) was used in the place of fumarate. i) Total yield of dimethyl *cis*- and *trans*-1,2-cyclopropanedicarboxylate. The number in parenthesis is the ratio of *cis* to *trans*. j) Conversion of chloroiodomethane.

yield in the reaction of dimethyl fumarate with dihalomethanes is in the order: $CH_2BrCl > CH_2Br_2 > CH_2I_2 > CH_2ClI \gg CH_2Cl_2$. This contrasts with the observation that some modifications are needed to use dibromomethane as a reactant in the Simmons-Smith reaction.[5)]

Lithium and potassium iodides are less effective than sodium iodide and bring about a decrease in the yield. Acetonitrile is superior to THF as a solvent because the former causes stabilization of the cobalt(0)-complex.

When dimethyl maleate was allowed to react with cobalt chloride in the presence of zinc, a red-brown solution was obtained in the same manner as for dimethyl fumarate. The treatment of the solution with dibromomethane gave a large amount of dimethyl *trans*-1,2-cyclopropanedicarboxylate and very little of the *cis*-isomer. The red-brown solution containing Co(0)-complex was decomposed in air and analysis of the residual substrate gave almost pure dimethyl fumarate. The isomerization of dimethyl maleate occurred neither in the presence of **1** nor in the zinc bromide–zinc system. It may be assumed that the active catalyst for the isomerization of maleate is a cobalt(I) species which is formed in the course of the reduction.

*Cyclopropanation of Dimethyl Maleate with Dihalomethanes Catalyzed by Acetonitrilebis(dimethyl maleate)nickel(0) (**2**) and Zinc.* Three-coordinate acetonitrilebis(olefin)-nickel(0) (olefin=dimethyl maleate and fumarate) is prepared from nickel bromide, an olefin, and zinc in acetonitrile.[6)] Maleate is not isomerized during the preparation of the Ni(0)-complex in contrast to the case of the cobalt complex. The reaction of dimethyl maleate with dibromomethane in the presence of **2** gave dimethyl *cis*-1,2-cyclopropanedicarboxylate in a 52% yield based



(3)

on nickel and the *trans*-isomer in a 14% yield (Eq. 3). Analysis of residual olefins shows a 90:10 dimethyl maleate: fumarate mole ratio. The addition of zinc increased the yield based on nickel in the same manner as in the cyclopropanation of the cobalt catalyst system (Table 2). Total yields of cyclopropane derivatives increased with an increase in the amounts of zinc and

nickel compounds. In the presence of a small amount of zinc, cyclopropanation started under the catalysis of Ni(0)-complex prepared beforehand, followed by a slow reaction step, until the fast reaction set in (Fig. 1). A large excess of zinc suppressed the slow step to make the whole reaction proceed smoothly.

Selectivity for the *cis*-isomer formation decreases slightly with an increase in the amount of zinc. Appreciable retention of stereochemistry in the maleate can be explained if isomerization of maleate rarely occurs and no isomerization of dimethyl *cis*-1,2-cyclopropanedicarboxylate takes place, unlike cyclopropanation by the copper–isonitrile system.[3b)] No isomerization of dimethyl maleate occurred in the presence of **2**. It may be assumed, as in the reaction with cobalt catalyst system, that the isomerization catalyst is a nickel(I) species. Bromo(dimethyl maleate)nickel(I) is inert to the isomerization.[7)] Nickel(I) species responsible for the isomerization of maleate are presumed to be bromobis(dimethyl maleate)nickel(I) and bis(dimethylmaleate)-nickel(I) tribromozincate on the assumption that dimerization of terminal olefins is catalyzed by (π-C_3H_5)-NiBr and (π-C_3H_5)Ni($AlCl_4$).[8)]

A concomitant formation of the *trans*-isomer is originated from the cyclopropanation of fumarate. The initial rate for the formation of dimethyl *cis*-1,2-cyclopropanedicarboxylate from **2** and dibromomethane was 2.8×10^{-3} mol^{-1} min^{-1}, while that for the formation of the *trans*-isomer from acetonitrilebis(dimethyl fumarate)-nickel(0) (**3**) and dibromomethane was 1.4×10^{-4} mol l^{-1} min^{-1}. However, the cyclopropanation of the mixture of equal moles of maleate and fumarate gave the *trans*-isomer in a six-fold ratio to the *cis*-isomer, indicating that the coordinating strength of fumarate is greater than that of maleate. Dimethyl fumarate which is once formed inhibits the cyclopropanation of dimethyl maleate.

Manganese can be substituted for zinc as a reductant. The order of effectiveness of dihalomethanes is the same as that in the cyclopropanation of dimethyl fumarate by the cobalt catalyst system.

The cyclopropanation of dimethyl fumarate gave the corresponding cyclopropane derivative in yields similar to those in the reaction of dimethyl maleate. The cobalt catalyst system for the cyclopropanation of dimethyl fumarate is superior to the nickel one although it takes a longer reaction time.

Cyclopropanation of Dimethyl Fumarate and Maleate with gem-Dihalides. The cyclopropanation of dimethyl fumarate and maleate with *gem*-dihaloalkanes gave

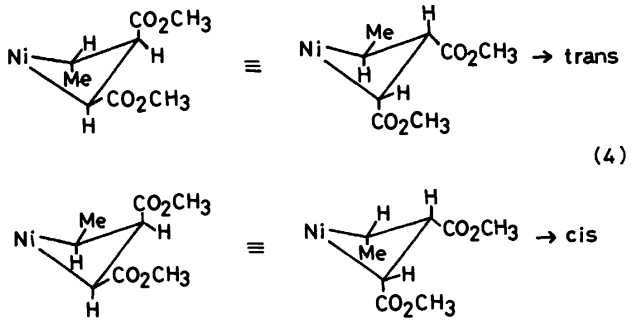
a) To the Co(0)- or Ni(0)-complex prepared *in situ* from $CoCl_2$ or $NiBr_2$, an olefin (5 mmol), NaI (5 mmol), and zinc (8 mmol) in CH_3CN (10 ml) was added *gem*-dihalide and the mixture was stirred at room temperature for a given period of time. b) Yield based on olefin. Y=CO_2CH_3. The numbers in parentheses are yields of dimethyl succinate and isopropenyl succinate. c) NaI (2.5 mmol). d) Zn (15 mmol). e) H_2O (0.1 ml) was added.

dimethyl 3-substituted *trans*- and *cis*-1,2-cyclopropanedicarboxylates under the catalysis of Co(0)- or Ni(0)-complex–zinc system (Table 3). The yield decreases with an increase of substituents of *gem*-dihaloalkanes in the cobalt system. A 1 : 1 cobalt : dimethyl fumarate mole ratio gave the best yield in the cyclopropanation with 2,2-dibromopropane. There is little difference in yields between the reactions of 2,2-dichloro- and 2,2-dibromopropane.

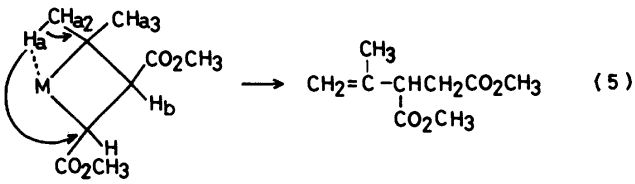
The reaction of dimethyl maleate with 1,1-dibromoethane catalyzed by the nickel catalyst system gave cyclopropane derivatives in a 70% yield: the ratio of *cis*-dicarboxylate to the *trans*-isomer is 67: 33 which is somewhat less than that produced in the reaction with dibromomethane. The ratio of the *cis*-methyl isomer to the *trans*-isomer in *cis*-dicarboxylates is 15: 85. It has been proposed that cyclopropanation proceeds *via* metallacyclobutane as an intermediate.[1] If the reductive elimination of a nickelacyclobutane intermediate takes place with retention of configuration, the configuration of the nickelacyclobutane would be that in which the methyl group is predominantly *trans* to both methoxy carbonyl groups by 1,2- and 1,3-steric repulsion. This leads to the *trans*-isomer (Eq. 4). In the reaction of



(4)

dimethyl maleate with 2,2-dibromopropane, dimethyl 3,3-dimethyl-1,2-cyclopropanedicarboxylate (*cis* : *trans*= 87 : 13) was obtained in a 39% yield.

Dimethyl isopropenylsuccinate was concomitantly produced in the reaction of dimethyl fumarate and maleate with 2,2-dibromopropane in both cobalt and nickel systems. Two mechanisms have been proposed for the olefin formation from platinacyclobutanes which involves splitting of α-C–H bond[9] and that of β-C–H bond.[10] The postulated intermediate has seven hydrogen atoms bonded to β-carbons and one hydrogen atom bonded to α-carbons (Eq. 5). If dimethyl isopropenylsuccinate is produced from metallacyclobutane,[11] its formation must be originated from splitting of β-C–H_a bond in methyl groups not of β-C–H_b bond in the methine group. The hydrogen of a methyl group is more easily split off than that of the methine group in platinacyclobutane.[9a,b] The addition of water promotes



(5)

the olefin production in the reaction of dimethyl fumarate with 2,2-dibromopropane catalyzed by the cobalt catalyst system. Photolysis of platinacyclobutane gives mainly propylene in solvents of low dielectric constant (*e.g.* CH_2Cl_2), but mainly cyclopropane in solvents of high dielectric constant (*e.g.* CH_3CN, Me_2SO):[12] ionization of the platinacyclobutane precedes the formation of cyclopropane. Water, which has a high dielectric constant, should favor the formation of the ionized species. However, the effect of the solvent on the reaction of fumarate with 2,2-dibromopropane is opposite to that on the reaction of platinacyclobutane.

Mechanism. We have proposed a mechanism which involves metallacyclobutane as an intermediate. The cyclopropanation of electron-deficient monosubstituted olefins needs Lewis acids or sodium iodide and zinc as promotors in most cases.[1] Both components are not necessary for the cyclopropanation of dimethyl fumarate and maleate with *gem*-dihalides catalyzed by cobalt(0)- or Ni(0)-complex. Only the cyclopropane derivative of dimethyl fumarate was obtained in the competitive reaction between dimethyl fumarate and methyl acrylate, indicating that the coordinating strength of the former is greater than that of the latter. It may be concluded that the cyclopropanation of olefins coordinated strongly to the metal center does not need promotors such as Lewis acids nor sodium iodide. We added sodium iodide to prevent reduction of olefins by the zinc bromide–zinc system.[4]

Acetonitrile is the most suitable solvent among several examined. It is required for stabilization of Co(0)- and Ni(0)-olefin complexes. Tetrahydrofuran is preferable to acetonitrile for the cyclopropanation of monosubstituted olefins[1] in which Lewis acids or sodium iodide in combination with tetrahydrofuran may promote the catalysis of the nickel complex catalyst.

Metal–carbene complexes are generated by the reaction of Co(0)- or Ni(0)-complex with *gem*-dihalides.[13] Cobalta- and nickelacyclobutanes are produced from the reaction of metal–carbene complexes with olefins in a similar manner as titana- and tungstenacyclobutanes.[14] Reductive elimination of metallacyclobutanes gives exclusively cyclopropane derivatives unless R=R′=CH_3. It is not known at present whether too many hydrogens bonded to β-carbons facilitate their splitting, or whether the metallacyclobutane is distorted due to the bulkiness of two alkyl groups to accelerate access of hydrogens of β-carbons to the active center.

Experimental

All operations were done under an atmosphere of nitrogen. Chloroiodomethane was prepared by treating dichloromethane with sodium iodide in *N,N*-dimethylformamide.[15] Other chemicals were analytical grade commercial materials and used without further purification. Bis(acetonitrile)bis(diethyl fumarate)cobalt(0) was prepared from the reaction of cobalt chloride with diethyl fumarate in the presence of zinc in acetonitrile according to the method of Agnes *et al.*[16] Acetonitrilebis(dimethyl maleate)nickel(0) (**2**) was prepared according to the literature method.[6] ^{1}H NMR spectra were measured on a JEOL PM-60 spectrometer and ^{13}C NMR spectra on a JEOL FX-100 spectrometer. GLC analysis and preparative purification were performed on a Shimadzu GC-6A gas chromatograph equipped with FID and 3 mm×4 m (PEG 20M 20% on Celite 545) and 5 mm×3 m (silicon SE-30 20% on Celite 545) columns were used.

Reaction of Bis(acetonitrile)bis(diethyl fumarate)cobalt(0) with Dibromomethane. To a solution of bis(acetonitrile)bis(diethyl fumarate)cobalt(0) (1 mmol) in acetonitrile (5 ml) was added dibromomethane (2 mmol) and the reaction mixture was stirred for 7 h. Diethyl *trans*-1,2-cyclopropanedicarboxylate was obtained in a 67% yield based on cobalt.

*Reaction of **2** with Dibromomethane.* To a solution of **2** (1 mmol) in acetonitrile (10 ml) were added dimethyl maleate (3 mmol) and dibromomethane (5 mmol) and the reaction mixture was stirred for 24 h. Dimethyl *cis*-1,2-cyclopropanedicarboxylate and the *trans*-isomer were obtained in 52 and 14% yields based on nickel, respectively.

General Procedures for the Reaction of Dimethyl Fumarate or Maleate with gem*-Dihalides Catalyzed by* in Situ *Prepared Co(0)- or Ni(0)-complex and Zinc.* A 100-ml two-necked flask was charged with anhydrous cobalt chloride (1 mmol) or nickel bromide (1 mmol), sodium iodide, and zinc powder (8 mmol). Acetonitrile (10 ml) was introduced and the mixture was stirred magnetically for 20—30 min at room temperature to form the red-brown catalyst solution. *gem*-Dihalide (5 mmol) was then added and reacted at room temperature for the specified time.

The reactions between dimethyl fumarate or maleate and *gem*-dihalides are summarized in Tables 1, 2, and 3. Spectral and elemental analyses of some cyclopropane derivatives are given below.

Dimethyl c-*3-Methyl*-r-*1*, t-*2-Cyclopropanedicarboxylate*: ^{1}H NMR ($CDCl_3$) δ=1.24 (d, 3H), 1.6—2.5 (m, 3H), 3.68 (s, 6H). ^{13}C NMR ($CDCl_3$) δ=11.2 (HC–$\underline{C}H_3$), 23.8 (H$\underline{C}$–CH_3), 27.9 (*r*-1-$\underline{C}HCO_2CH_3$), 28.3 (*t*-2-$\underline{C}HCO_2CH_3$), 51.8 (*r*-1-$CO_2\underline{C}H_3$), 52.0 (*t*-2-$CO_2\underline{C}H_3$), 170.4 (*r*-1-$\underline{C}O_2CH_3$), 172.3 (*t*-2-$\underline{C}O_2CH_3$). Found: C, 55.94; H, 7.27%. Calcd for $C_8H_{12}O_4$: C, 55.80, H, 7.02%.

Association of Chlorophyll with Amides on Plasticized Polyethylene Particles. II. The Isomeric *N*-Pyridylmyristamides

Yoshihumi Kusumoto,*,† Gilbert R. Seely, and Velu Senthilathipan
Charles F. Kettering Research Laboratory, Yellow Springs, Ohio 45387 U.S.A.
(Received October 12, 1982)

When chlorophyll, together with certain other amphiphilic substances, is adsorbed to particles of polyethylene plasticized by incorporation of tetradecane, it is maintained in monomeric or oligomeric forms with characteristic absorption and fluorescence spectra. The present work describes the properties of chlorophyll a on such particles in the presence of the three isomeric *N*-pyridylmyristamides, and of the similarly shaped but not basic compound myristanilide, in an effort to ascertain the structural factors governing associations of these species. Absorption and fluorescence spectra at room temperature are resolved into minimal sets of Gaussian components, and relations between the component sets are proposed. The positions of the component bands and their relative abundance are characteristic of the amide used. The 3- and 4-pyridyl isomers bind more strongly to chlorophyll, probably by ligation of the pyridine nitrogen to Mg of the pigment. The 2-pyridyl isomer and myristanilide bind more weakly, probably through the amide carbonyl group. The association of chlorophyll into species with characteristic absorption and fluorescence bands is promoted more strongly by the 3- and 4-isomers than by the 2-isomer and myristanilide, and probably involves hydrogen bonding to chlorophyll carbonyl groups. A possible manner of association of chlorophyll in the presence of *N,N*-dimethylmyristamide is also presented. By way of comparison, chlorophyll adsorbed with *N*-dodecylpyridinium bromide, which lacks a nucleophilic function, is mainly in the microcrystalline hydrate form absorbing near 740 nm.

Preliminary accounts of this subject have reported the association of chlorophyll a with a number of amphiphilic amides when both are adsorbed to polyethylene particles swollen by absorption of a hydrocarbon diluent such as undecane.[1] The previous paper in this series (I) presented in some detail the evidence for interaction of chlorophyll with *N,N*-dimethylmyristamide (DMMA) adsorbed to swollen polyethylene.[2a] In the presence of sufficient DMMA, chlorophyll is maintained in monomeric and associated species with characteristic absorption and fluorescence spectral bands. The associated as well as the monomeric species were apparently capable of strong fluorescence even at chlorophyll densities corresponding to monolayer coverage, and photochemical activity was demonstrated.

We have also examined the interaction of chlorophyll with the closely related amphiphile *N*-methylmyristamide, and found quite different sorts of chlorophyll association.[2b] In this paper we report the association of chlorophyll with certain other *N*-monosubstituted amphiphilic amides, specifically the three isomeric *N*-pyridylmyristamides (NPMA's). These substances were chosen principally for two reasons. First, since the pyridine nitrogen function, like the amide carbonyl, is known to bind to the Mg of chlorophyll, we might find evidence for association of chlorophyll through either or both functions, depending on the isomer. Second, the pyridine chromophore provides a convenient means of accurately estimating the amphiphile concentration in the particle preparations, which is lacking for entirely aliphatic amides. We further include for comparison preparations with myristanilide (MAn), which resembles the NPMA's in shape but lacks pyridine nitrogen, and with *N*-dodecylpyridinium bromide (DPB), a surfactant made from pyridine which has no Lewis base function capable of binding to chlorophyll.

† Present address: Chemical Institute, College of Liberal Arts, Kagoshima University, Korimoto, Kagoshima 890.

Experimental

Materials. The isomeric *N*-pyridylmyristamides were prepared by reaction of the corresponding aminopyridines with myristoyl chloride in acetone or *N,N*-dimethylformamide, similarly to the procedure of Deady and Stillman,[3] and were purified by reprecipitation from methanol–aqueous ammonia. Myristanilide was prepared by reaction of myristoyl chloride with aniline in toluene containing triethylamine, and recrystallized finally from ethanol. *N*-Dodecylpyridinium bromide was prepared by refluxing pyridine with 1-bromododecane in toluene.

N-*(2-Pyridyl)myristamide*: IR (KBr): 3355 (N–H), 1698 (amide I), 1538 (amide II), 1590, 1447, and 778 cm^{-1} (pyridyl). UV_{max} (1-propanol): 276 (ε, 5670) and 236 nm (10360). Found: C, 74.70; H, 10.93; N, 8.84%. Calcd for $C_{19}H_{32}N_2O$: C, 74.95; H, 10.59; N, 9.20%.

N-*(3-Pyridyl)myristamide*: Mp 80.5—82 °C. IR (KBr): 3331, 1676, 1543, 1597, 1423, 802, and 707 cm^{-1}. UV_{max} (1-propanol): 279 (4400) and 241 nm (16450). Found: C, 75.48; H, 11.40; N, 9.07%.

N-*(4-Pyridyl)myristamide*: Mp 75—77 °C. IR (KBr): 3428, 1686, 1534, 1615, 1427, and 834 cm^{-1}. UV_{max} (1-propanol): 246.5 nm (17790). Found: C, 73.28; H, 10.79; N, 8.62%.

Myristanilide: Mp 84.5—85 °C. IR: 3312, 1670, 1549 (amide), and 1612, 1454, 759, 696 (phenyl). UV_{max} (1-propanol): 243 nm (16310).

N-*Dodecylpyridinium Bromide*: IR: 1650, 1497, 782, and 691 cm^{-1} (pyridinium). UV_{max}: 260 nm (4660).

Methods. The polyethylene particles swollen with tetradecane were prepared as described.[2] Tetradecane was used as diluent instead of undecane, as in (I), primarily because of its lower solubility in aqueous methanol. The swollen particles contained about 75% tetradecane. The adsorption of chlorophyll and amide from aqueous methanol was performed as described in (I), but because of their low solubility in 60% methanol, the amides were present only in the initial 90% methanol solution, along with chlorophyll. Chlorophyll and amphiphile contents of the recovered particles were estimated spectrophotometrically on a 1-propanol extract of a sample of particles. The uptake of amide by the particles is linear

with concentration at low values thereof, and their concentrations on the particles, $[NPMA]_p$, are related to their concentrations in 75% methanol solution ([NPMA]) by Eqs. 1—4.

$$[4\text{-NPMA}]_p/\mu\text{mol g}^{-1} = 0.84([4\text{-NPMA}]/\text{mM}),^{\dagger\dagger} \quad (1)$$

$$[3\text{-NPMA}]_p = 0.93[3\text{-NPMA}], \quad (2)$$

$$[2\text{-NPMA}]_p = 11.9[2\text{-NPMA}], \quad (3)$$

$$[\text{MAn}]_p = 48[\text{MAn}]. \quad (4)$$

Above 2.5 mM [3-NPMA] and about 1.5 mM [2-NPMA] or [MAn], the amount of amide bound to the particles exceeded that predicted by the equations, because of precipitation out of 75% methanol or multilayer adsorption. The proportionality constants suggest that 3-NPMA and 4-NPMA are adsorbed only to the particle surface, while MAn and 2-NPMA are dissolved in the particles to some extent. The solubility of 2-NPMA is perhaps owing to the formation of a cylic dimer, like that of 2-aminopyridine in CCl_4 solution.[4]

Absorption Spectroscopy. Absorption spectra were recorded on a Perkin-Elmer Hitachi 557 spectrophotometer, of mixtures not exceeding 2% (wt) of green particles with a densely scattering white paste. At these concentrations, the absorbance is proportional to the relative absorptivity, and the expected optical path enhancement by multiple scattering is observed.[5]

The pastes usually consist of three components: (1) a fluid, normally a non-solvent for chlorophyll such as water or glycerol; (2) a thickener, often a polysaccharide, to keep the particles in suspension; (3) an inert scattering material such as cellulose (Sigmacell, 20 μm particles). Two pastes that have proved useful in absorption spectroscopy are water (43.3%), Ficoll 400 (Pharmacia) (28.9%), cellulose (27.8%), and water (25.8%), sucrose (51.7%), cellulose (22.5%). For fluorescence spectroscopy a paste (CGW) of Carbowax PEG-1000 : glycerol : water (10 : 11 : 1 in wt/v/v) was used, so that the sample could be cooled to 77 K. A paste (OCC) which extracts chlorophyll from the particles was compounded out of 1-octanol (42.4%), Carbowax PEG 1500 (18.3%) and cellulose (39.3%). For recording spectra, the pastes were spread in an even layer 0.10 cm deep in a demountable silica cell. Second derivative absorption spectra were also recorded.

Fluorescence Spectroscopy. Most fluorescence spectra discussed here were recorded from the front surface of a thin layer of particles mixed with CGW paste, first at room temperature then after quickly cooling with liquid nitrogen.

Exciting light was provided by a Sylvania 250-W Q/CL/DC tungsten-halogen lamp and dispersed by a Beckman DU monochromator. It was focused on the sample surface at an angle of about 15° to the normal. The fluorescence was dispersed by a Spex 0.5 m Czerny-Turner monochromator, with 64×64 mm grating, 1200 grooves/mm, blazed for 750nm, and turned by a Minidrive stepping motor. The rated dispersion was 1.6 nm/mm, and it was usually operated with 1 mm slits.

The fluorescence was detected with a Hamamatsu R666 GaAs photomultiplier at 1000 V; the signal was amplified by a Keithley 610 B Electrometer and recorded on a Kipp and Zonen BD 12 Intergrating Recorder. The apparatus was calibrated for variation of sensitivity with wavelength by means of a tungsten lamp operated at different color temperatures.

Analysis of Spectra. Absorption spectra, and fluorescence spectra corrected for variation of sensitivity with wavelength, were resolved into Gaussian component bands with the aid of an IBM 5100 portable computer. Two programs were used. For absorption spectra, where the band positions (λ) are close together and there was little direct evidence for the value of the component bandwidths (B) at half peak height, all trial bandwidths were assumed to have the same value. This program found the trial band heights and the value of B which simultaneously fitted the spectrum at the N band positions, and minimized the sum of deviations at $N+1$ other points on the spectrum. The calculated spectrum was compared with the observed at about 30 points spaced 2 nm apart, and trial band positions were adjusted to remove any systematic deviations. If no further adjustment could return a satisfactory fit, one more band was added and the process was repeated.

For all fluorescence spectra and some absorption spectra the assumption of identical B was plainly invalid. The program in these cases assumed trial values of λ and B for each band, and calculated band heights to match the observed spectrum at the N band positions. Band positions and widths were varied individually, and bands added if necessary, until acceptable fit was obtained to the observed spectrum.

So far as possible, only bands identified as peaks or shoulders in the absorbance or fluorescence spectrum, or as troughs or shoulders in the second derivative spectrum, were included as trial bands in the analysis. A minimal number of other components were introduced only when resolution based on identified bands was unsatisfactory. Furthermore, the bandwidth of components located at $\lambda<720$ nm was not allowed to exceed 24 nm, approximately the maximum value observed under any circumstances for monomeric chlorophyll.[6]

An inherent limit to the precision of spectral reconstruction is the non-Gaussian shape of the chlorophyll band itself. However, the absorption spectrum of chlorophyll in acetone could be fitted by one Gaussian ($\lambda=661.7$ nm, $B=20.6$ nm) within 1% of peak height from 652 to 680 nm, and within 2% to 710 nm. Similar precision was accepted as evidence of satisfactory fit for the particle sample spectra. As a further test of acceptability, a single set of bands (λ, B within ±1 nm) should fit the spectra of all particles prepared with chlorophyll and a given surfactant. To a surprising extent these criteria have been met in the systems under discussion. In practice, the reconstructed spectrum proved sensitive to variations of $\pm(0.5—1)$nm in component band position and width, so that we have reasonable confidence in our representations.

Results

Chl in OCC. When green particles are mixed with this paste, chlorophyll is dissolved from them by the 1-octanol component. Absorption and fluorescence spectra (Fig. 1) are therefore of monomeric chlorophyll in a highly scattering solution and serve as a standard for comparison with chlorophyll adsorbed to particles in a highly scattering suspension. The absorption band can be represented well enough by one Gaussian component at 665.8 nm, with bandwidth $B=24$ nm. The fluorescence at room temperature is well represented by three components, at 680 nm ($B=23$ nm) 57.3%, 702 nm (20 nm) 9.0%, and 732 nm (40 nm) 33.8%, where the percentages represent the fraction of the integrated fluorescence intensity contributed by the component. The last two components are separated from the first by 450 and 1040 cm^{-1}, which perhaps correspond to pyrrole ring deformation and pulsation frequencies. At 77 K the same three components are present, with slightly altered contributions: 680(20)

†† 1 M=1 mol dm^{-3} and 1 mM=1×10^{-3} mol dm^{-3} in this paper.

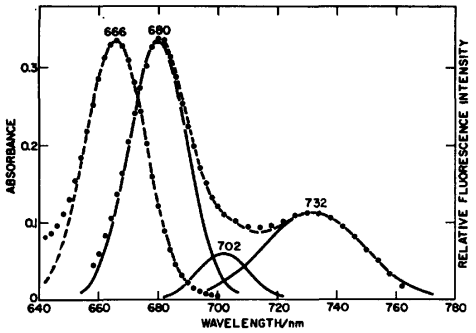

Fig. 1. Absorption and fluorescence spectra (the latter normalized at the 680-nm peak to match the absorption band) of chlorophyll-containing particles ($[Chl]_p$= 1.046 μmol g^{-1}) suspended in a paste of 1-octanol (42.4%), Carbowax 1500 (18.3%), and cellulose (39.3%) (OCC), in which chlorophyll is soluble. The particles were prepared with a concentration of 3-NPMA so low (0.625×10^{-3} M) that most of the chlorophyll was in the form of the microcrystalline hydrate absorbing around 740 nm (see Fig. 2). The disappearance of that band shows that the chlorophyll has dissolved in the OCC paste. For the absorption spectrum, 0.0109 g of green particles was blended with 0.721 g of OCC paste; for the fluorescence spectrum, 0.1235 g of particles with 0.300 g OCC paste. The red band of the absorption spectrum is represented adequately by one Gaussian component (dashed curve), the fluorescence spectrum by three. The fluorescence components are shown as solid traces, their sum as a dashed trace. Observed absorption and fluorescence intensities, the latter corrected for variation of instrumental sensitivity with wavelength, are plotted as open circles.

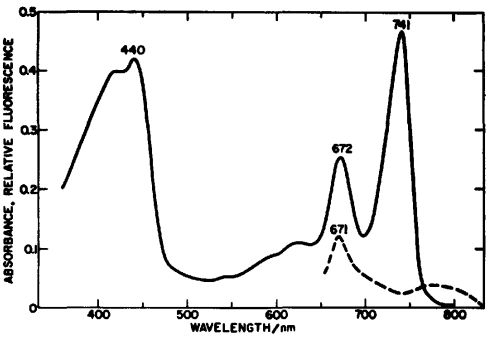

Fig. 2. Visible absorption and fluorescence spectra of particles containing chlorophyll (1.36 μmol g^{-1}) and DPB (2.66 μmol g^{-1}), the latter adsorbed from a 5 mM solution, initial concentration. For absorption spectral measurement, 0.0141 g of yellow-green particles was mixed with 0.578 g of a paste of Ficoll (39%), cellulose (Sigmacell, 15%), and water (46%). The paste scattering background has been subtracted. For fluorescence (dashed trace), 0.0585 g of particles was mixed with 0.255 g of the paste, and excited at 616 nm. There is indication of reabsorption by the strong 741 nm absorption band. The weak fluorescence was not corrected for variation of apparatus sensitivity to wavelength, because of uncertainty in the location of the baseline.

48.1%, 702(20) 9.4%, and 734(40) 42.6%.

Although there is little reason to doubt that chlorophyll is monomeric in this system, the Stokes shift (14 nm), and the 732 nm fluorescence vibronic component, are large in comparison with those of other spectra we have recorded, *i.e.*, chlorophyll in acetone, or in undecane solution with DMMA.[2] The absorption bandwidth (24 nm) is larger than twice the half-bandwidths in any of the solvents reported previously by Seely and Jensen.[6] The broadening and red-shifting are perhaps consequences of strong hydrogen-bonding between octanol and chlorophyll carbonyls in the ground and excited states.[7] The mirror-image relation between absorption and fluorescence bands is obvious, which incidentally demonstrates that reabsorption of fluorescence is not a domineering phenomenon in our systems.

N-*Dodecylpyridinium Bromide.* This surfactant is not basic and therefore does not bind to functional groups of chlorophyll. In sharp contrast to the foregoing spectra, the spectrum of chlorophyll (1.359 μmol g^{-1}) with DPB (2.66 μmol g^{-1}, from 5 mM DPB in solution initially) in Fig. 2 show mainly the microcrystalline hydrate form of the pigment (741 nm). The same form appears when chlorophyll is adsorbed to the particles in the absence of an amphiphile[2] and in many other systems where water is present.[8] The fluorescence is weak; the most prominent band in its spectrum (671 nm) probably corresponds to a small amount of monomeric chlorophyll absorbing around 662 nm. No attempt was made to resolve these spectra into components.

The presence of DPB does not prevent chlorophyll from associating with 3-NPMA on the same particle. Particles prepared with [DPB] and [3-NPMA], both 10 mM initially, and having the composition $[Chl]_p$= 1.212, $[DPB]_p$=1.55, and $[3\text{-NPMA}]_p$=5.32 μmol g^{-1}, had the same absorption and fluorescence spectra as chlorophyll in the presence of 3-NPMA alone (see below).

N-*(2-Pyridyl)myristamide.* As increasing amounts of an amphiphile such as 2-NPMA are present in solution to be adsorbed along with chlorophyll, the amount of chlorophyll in the 741 nm hydrated form decreases, and the amount in forms absorbing at shorter wavelengths increases. At sufficiently high amphiphile concentration, the 741 nm form of chlorophyll disappears altogether from the green particles. In Figs. 3—5, spectra of adsorbed chlorophyll with the three isomeric NPMA's are compared at $[Chl]_p$ around 1 μmol g^{-1}, and at a high enough NPMA concentration to eliminate the 741 nm species. In the absorption spectra, only the longest-wave, "red" band is shown and analysed; the remainder of the visible spectrum superficially resembles that of normal monomeric chlorophyll in a non-hydroxylic solvent. Differences seen at other chlorophyll and NPMA concentrations will be noted. Second derivative spectra generally show a sharper and more complex band system throughout the visible than is seen in the spectrum of chlorophyll in acetone, for example.

Spectra with 2-NPMA appear the easiest to interpret. At high amphiphile concentration the red absorption

band is resolved into two components, both relatively broad (Fig. 3a). The major one (666 nm) falls in the wavelength range expected for a monomeric chlorophyll species, but the minor one (684 nm) must represent some associated species, probably dimeric in chlorophyll. The fluorescence spectrum (Fig. 3b) is resolved into five components. Comparison with Fig. 1 suggests that the 693 nm component represents fluorescence from the 684 nm species in the absorption spectrum; the 1132 cm^{-1} interval between the 693 and 752 nm components, and their relative strength, suggest that the 752 nm component is a vibrational satellite of the other. Apart from these two bands, the fluorescence spectrum resembles that of monomeric chlorophyll in Fig. 1 (with a $\approx$6 nm blue shift), but the 726.5 nm component is distinctly stronger in the 2-NPMA spectrum.

At lower chlorophyll concentration ($[Chl]_p$=0.23 μmol g^{-1}), the spectra were quite similar to the foregoing,

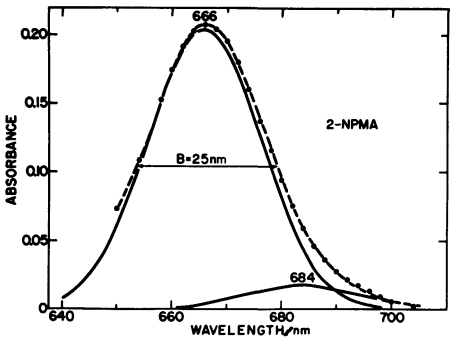

Fig. 3a. Absorption spectrum of particles containing chlorophyll (1.029 μmol g^{-1}) and 2-NPMA (68 μmol g^{-1}) in Ficoll–cellulose paste (0.0063 g green particles mixed with 0.603 g paste). The red band is most simply represented as the sum of two Gaussian components (solid traces), both 24 nm in bandwidth. Observed absorbances are plotted as open circles.

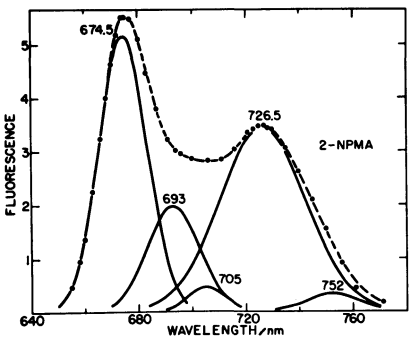

Fig. 3b. Fluorescence spectrum at room temperature of particles of Fig. 3a., 0.0794 g mixed with 0.191 g of CGW paste, under excitation at 600 nm. The spectrum is resolved into five components (solid traces): 674.5 nm (B=21 nm) 36.1%, 693(23) 15.2%, 705(16) 2.4%, 726.5(38) 43.7%, and 752(24) 2.5%. The sum of these is represented as a dashed trace, and observed fluorescence intensities are plotted as open circles. Compared to Fig. 1, there is more evidence of emission in longer-wavelength bands, indicating the presence of associated chlorophyll species.

but the monomer (674.5 nm) fluorescence component was greater (47.4%), and the 693 and 726 nm component contributions were smaller.

At 2-NPMA concentrations of 28 μmol g^{-1} or less, some of the chlorophyll remains in the 741 nm form. Now, a third component at 673.5 nm must be included to resolve the red band; *e.g.*, for $[Chl]_p$=1.10 and $[2\text{-NPMA}]_p$=28 μmol g^{-1}, the band was resolved into components at 666 nm (B=24 nm) 68.5%, 673.5(22) 29.2%, and 684(20) 2.3%. The fluorescence spectrum was not much different from that of Fig. 3b, and contained no component clearly corresponding to the 673.5 nm absorption component. This component may therefore represent the same species as the 672 nm band in Fig. 2. At 77 K the monomer fluorescence band at 674 nm was suppressed and replaced by a band in the 683—687 nm region. This band may reflect the 673.5 nm absorption component, or it may arise from a species formed on cooling the particles.

Myristanilide. This amphiphile resembles the NPMA's in shape but lacks the pyridine base function. Even more than 2-NPMA, it is soluble in the plasticized polyethylene particles and a fairly high concentration is needed to suppress the 741 nm chlorophyll species. Not many preparations have been examined with this amphiphile, but those that have show relatively simple absorption and fluorescence spectra, resembling those with 2-NPMA. The red absorption band of a preparation with $[Chl]_p$=0.974 and $[MAn]_p$=66.6 μmol g^{-1} in Ficoll–glycerol–cellulose paste is simple, but too broad (29 nm) to be represented by one Gaussian with $\leq$24 nm bandwidth. It was resolved satisfactorily into three components, at 658 nm (19.6%), 671 (64.7%), and 680.5 (15.7%), all with B=24 nm. However, the band is rather smooth and there are few clues to guide the selection of trial component wavelengths. The shape of the second derivative suggests that there may be four components in the red band region, and resolution into 655 nm (11.5%), 665 (34.8%), 674 (37.5%), and 682.5 (16.2%), all with B=20 nm, was also satisfactory. The fluorescence spectrum of the same preparation in CGW paste was resolved into four components, at 676 nm (B=24 nm) 52.1%, 697.5(20) 9.4%, 723.5(40) 33.3%, and 765(32) 5.2%. Except for the last component, the spectrum closely resembles that of monomeric chlorophyll in OCC, but displaced a few nm to the blue. At 77 K, the leading fluorescence band appears at 685 nm.

N-*(4-Pyridyl)myristamide.* The absorption spectrum resembles that with 2-NPMA but the red band, now at 668 nm, is broader. Two of three preparations showed a distinct shoulder in the second derivative spectrum around 684 nm, identifying a component there. The red band could not be resolved into two or even three bands of acceptable bandwidth as was done with the 2-NPMA preparations; a satisfactory resolution into four principal bands and a fifth, small band at 697.5 nm is presented in Fig. 4a. It was necessary to include a component (656 nm) at a shorter wavelength than the presumed monomer component band (666 nm), to represent the broadened short-wave side of the absorption band. The spectrum of a preparation with $[Chl]_p$=

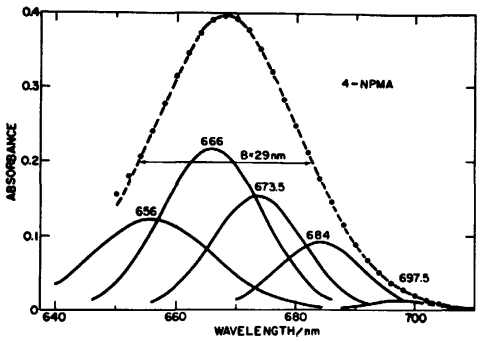

Fig. 4a. Absorption of particles containing chlorophyll (1.142 μmol g^{-1}) and 4-NPMA (4.18 μmol g^{-1}), 0.0082 g of green particles mixed with 0.608 g of Ficoll-cellulose paste. The broad red band is resolved into five components (solid traces): 656 nm (B=24 nm) 24.8%, 666(20) 37.0%, 673.5(18) 23.6%, 684(17) 13.2%, and 697.5(13) 1.4%. Their sum is shown as a dashed line, and observed absorbances are plotted as open circles.

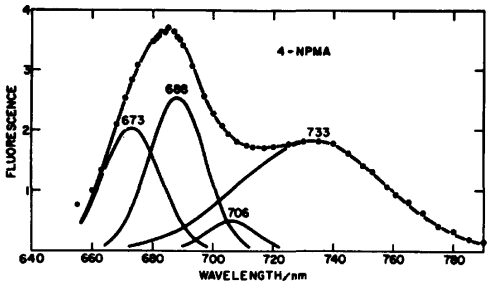

Fig. 4b. Fluorescence spectrum at room temperature of the particles of Fig. 4a, 0.0504 g mixed with 0.203 g of CGW paste, and excited at 600 nm. The fluorescence is resolved into four components (solid traces): 673 nm (B=23 nm) 21.4%, 688(22) 25.7%, 706(20) 4.6%, and 733(58) 48.3%. Their sum is shown as a dashed trace, and observed intensities as open circles. On cooling to 77 K, the strongest band is at 688 nm.

2.40 μmol g^{-1} and $[4\text{-NPMA}]_p$=3.50 μmol g^{-1} was similarly resolved, but the composition (656 nm (24 nm) 32.4%, 665.5(20) 24.2%, 673.5(18) 25.8%, 685(17) 15.3%, 697.5(13) 2.4%) indicates less monomeric component and more of all the others.

The fluorescence spectra of these preparations are markedly broadened and red-shifted, even at room temperature, compared to those with 2-NPMA (Fig. 3b). A resolution into four bands is presented in Fig. 4b. In

a) The columns list the chlorophyll and 3-NPMA contents of the particles, the ratio of these quantities, and data for the component bands into which each spectrum was analyzed. These data are the peak wavelength (λ) and bandwidth (B) at half peak height, and the percent of the total integrated absorption or fluorescence occupied by the component band. Sometimes a small component at 741nm was present in the absorption spectrum; this was omitted from the analysis. b) A small component around 760 nm was omitted from the calculation because of excessively noisy trace in this region.

the red region, the component at 688 nm is stronger than the presumed monomer component at 673 nm. The broad band centered at 733 nm is probably complex, and contains vibrational satellites of the 673 and 688 nm bands, but appears too strong to be accounted for entirely this way.

On cooling the sample of Fig. 4b to 77 K, the 673 nm fluorescence is suppressed and the 688 nm component remains as the leading band in the spectrum. In the more concentrated sample with $[Chl]_p=2.40$ μmol g^{-1}, the leading band peak at 77 K is at 691 nm.

N-*(3-Pyridyl)myristamide.* Spectra with this isomer were the most complex of the three. A total of 15 preparations were examined ranging in chlorophyll content from $[Chl]_p=0.146$ to 2.38 μmol g^{-1}, and in initial 3-NPMA concentration (in 90% methanol) from 0.625 to 20 mM. Above 10 mM initial concentration the solubility limit of 3-NPMA in 75% methanol was exceeded, and crystals of the amide were to some extent collected with the particles, a circumstance that seems to have had no effect whatever on the visible spectrum of adsorbed chlorophyll. The red band is broadened, as it is in spectra with 4-NPMA, and the peak position varies with $[Chl]_p$ in the range 665—670 nm. The second derivative spectra were rather complex. Especially in relatively concentrated suspensions most preparations showed a trough or shoulder near 684 nm; several of these, particularly those with a low $[3\text{-NPMA}]_p/[Chl]_p$ ratio, also showed a sharp trough near 692 nm. Only when the initial 3-NPMA concentration was less than 2.5 mM, or $[3\text{-NPMA}]_p/[Chl]_p<2$, was there a significant amount of the 741 nm chlorophyll species in the particles.

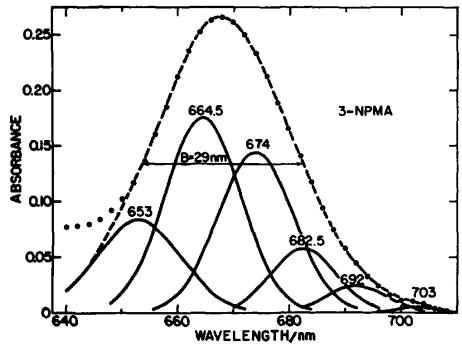

Fig. 5a. Absorption spectrum of particles containing chlorophyll (0.875 μmol g^{-1}) and at least 8 μmol g^{-1} 3-NPMA (see Table 1), 0.0085 g mixed with 0.577 g sucrose–cellulose paste. The broad red band is resolved into six components: 653 nm ($B=18$ nm) 19.3%, 664.5 (16) 36.0%, 674(16) 29.7%, 682.5(14) 10.4%, 692(13) 4.0%, and 703(8) 0.6%. The last three components are identified in numerous second derivative spectra, but the small 703 nm component may belong to the paste background. The sum of the components is shown as a dashed trace, and observed absorbances as open circles.

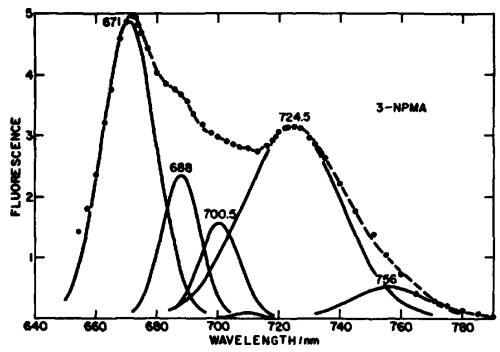

Fig. 5b. Fluorescence spectrum at room temperature of the particles of Fig. 5a, mixed with CGW paste, and excited at 600 nm. The spectrum is resolved into six components (solid traces): 671 nm ($B=21$ nm) 34.3%, 688(15) 11.9%, 700.5(16) 8.4%, 710(10) 0.3%, 724.5 (38) 39.0%, and 756(30) 5.2%. Their sum is shown as a dashed trace, and observed intensities as open circles. For fluorescence resolutions at other chlorophyll and 3-NPMA concentrations, see Table 1.

Acceptable resolution of absorption spectra was obtained with six components of almost invariable position and bandwidth at 653, 664.5, 674, 682.5, 692, and 703 nm. The 682.5 and 692 nm components were located approximately by second derivative spectroscopy, as just mentioned. The first three components were required to represent the broadening of the main part of the red band, as in the resolution of spectra with 4-NPMA. The 703 nm component is always small and may belong to the paste background. Results for several of the samples are compiled in Table 1, and one of the resolutions is illustrated in Fig. 5a. The resolution is really rather similar over the concentration ranges covered. However, the 682.5 and 692 nm component contributions increase by a factor of about 2 as $[Chl]_p$ increases, largely at the expense of the presumed monomeric component at 664.5 nm.

Fluorescence spectra were consistently resolved into six bands, near 671, 688, 700, 710, and 724 nm, and one in the range 748—766 nm. The 710 nm component is insignificant. Some resolutions are compiled in Table 1, and the one corresponding to the absorption spectrum of Fig. 5a is shown in Fig. 5b. The strongest fluorescence component at low $[Chl]_p$ is the 671 nm band, which evidently belongs to monomeric chlorophyll. The 688 nm component, which appears as a shoulder in Fig. 5b, appears as a peak in the $[Chl]_p=2.245$ μmol g^{-1} preparation, higher than the 671 nm peak and clearly set apart from it. The 700 and 724 nm bands also tend to increase somewhat with $[Chl]_p$, at the expense of monomer fluorescence.

On quickly cooling the preparation with smallest $[Chl]_p$ to 77 K, the main fluorescence band peak appeared at 685 nm; in the other preparations, the band appeared in the range 693—700 nm, generally near 695 nm.

Discussion

It has thus been possible to resolve both the absorption and fluorescence spectra of adsorbed chlorophyll into minimal, consistent sets of Gaussian components characteristic of the amphiphile adsorbed with it. The next step in comparison of amphiphiles is to determine, if possible, correspondences between absorption and fluorescence components (Table 2). This process is

TABLE 2. CORRELATION OF ABSORPTION AND FLUORESCENCE SPECTRA OF CHLOROPHYLL a ADSORBED TO POLYETHYLENE–TETRADECANE PARTICLES WITH VARIOUS AMIDE-CONTAINING AMPHIPHILES

a) Abbreviations: OCC: Chlorophyll particles mixed with 1-octanol–Carbowax–cellulose paste; MAn: myristanilide; NPMA: *N*-pyridylmyristamide; DMMA: *N*,*N*-dimethylmyristamide. b) Absorption spectra of Figs. 1, 3a—5a and of MAn in a paste of 6 : 10 : 3 Ficoll : glycerol : cellulose. All fluorescence spectra were recorded on samples in CGW paste. The composition of the paste has little effect on the spectral properties of the particles. Components marked (77K) have been identified with certainty only at a low temperature usually as the leading band of the fluorescence spectra. c) Calculated from the Stepanov theory of spectral band shape.[9,10] Dashed lines connect calculated band positions with most probably corresponding observed positions. d) Percentages given for typical spectra of Figs. 1, 3—5 or as noted; $[Chl]_p$ *ca.* 1 μmol g^{-1} and 741 nm species absent. e) An alternative analysis gave: 656 nm (17.2%), 665.5 (53.9%), 674.5 (24.3%), 690 (4.6%), all with B=20 nm. This analysis accommodates the presence of a 673.5 nm band at low $[2\text{-NPMA}]_p$ and perhaps the strength of the fluorescence band at 726.5 nm (see Discussion). f) A resolution into three bands: 658 nm (19.6%), 671 (64.7%), and 680.5 (15.7%) all with B=24 nm gave an acceptable fit but does not correlate well with the fluorescence spectrum. g) Spectra recorded and analyzed as reported in (I); a slightly better resolution might have been achieved with an additional band near 653 nm. The 683 nm absorption component is sensitive to the value of B chosen and is not present with certainty within the accuracy of the analysis. The 705 nm component in fluorescence, and at 77 K, which is strong only in preparations with low $[DMMA]_p/[Chl]_p$ is unique to this amphiphile.

assisted by a relation derived from Stepanov theory between the frequencies ν_M^{abs} and ν_M^{flu} of corresponding absorption and fluorescence band maxima, Eq. 5,[9]

$$\nu_M^{abs} - \nu_M^{flu} = B^2/8(\ln 2)kT, \quad (5)$$

which has been shown to be valid for chlorophyll in solution.[10] The relation will be accurate unless there is substantial rearrangement in the excited state before emission, or variations in the molecular environment

which give rise to heterogeneous band broadening are preserved during the lifetime of the excited state. Fluorescence band positions were calculated for several of the absorption band components by Eq. 5 and are liested next to them in Table 2. These predicted positions are connected by dashed lines to observed bands to which they most likely correspond.

The absorption and fluorescence components belonging to monomeric chlorophyll bound to the NPMA's and MAn are located in the ranges 664.5—666 nm and 671—676 nm; agreement between positions predicted by Eq. 5 and assigned fluorescence bands is satisfactory. The three NPMA isomers also have absorption band components at 682.5 nm (3-NPMA) or 684 nm (2- and 4-NPMA) which are evidently related to fluorescence components at 688 nm (3- and 4-NPMA) or 693 nm (2-NPMA). The agreement between predicted and observed positions is again quite good. An analogous pair of bands for MAn was not obvious.

Acceptable resolution of absorption spectra of 3- and 4-NPMA, probably of MAn, and perhaps of 2-NPMA, required a pair of components on either side of the monomer component, *e.g.*, at 656 and 673.5 nm for 4-NPMA. Their positions suggest that they could be the result of exciton interaction in dimers similar to that of the cofacial covalently-linked pyrochlorophyllide dimer described by Bucks and Boxer.[11] Alternatively, they might represent heterogeneous broadening of the monomeric chlorophyll band, but if so, the broadening is not reflected in the fluorescence spectrum. We could not identify a fluorescence component, with the aid of Eq. 5, corresponding to either of these absorption components at room temperature in spectra with any of these four amphiphiles.

On the other hand, the fluorescence spectra with the NPMA's all contain a broad farred component at 726.5 nm (2-NPMA), 724.5 nm (3-NPMA), and 733 nm (4-NPMA) which is stronger than can be accounted for as vibrational satellites of shorter-wave fluorescence components, as assumed for chlorophyll in OCC. Indeed, chlorophyll in many other model systems shows a fluorescence band in this region.[2] Fluorescence in this region is usually ascribed to an absorption band in the 695—700 nm region, as in the example described by Hindman *et al.*[12] In none of our spectra have we been able to resolve an absorption band in this region broad enough to account for the farred emission. As was discussed in the case of DMMA, where a 725 nm emission band is prominent, a very weak but broad absorption band could escape detection, but it is also conceivable that the farred fluorescence is a kind of excimer emission, associated with absorption bands at much shorter wavelengths. It is tempting to associate the farred emission bands, which have no observed corresponding absorption bands, with the above-mentioned pair of absorption bands (*e.g.*, 656 and 673.5 nm), which have no corresponding fluorescence. The validity of such an assignment must be established by further experimentation.

Data for the DMMA system[2] are also transcribed in Table 2; it is evident that there is very good agreement between observed fluorescence band positions and those calculated from the absorption bands by Eq. 5.

However desirable it may be to assign structures to the associated chlorophyll species detected in these studies, it is rarely possible to do so on the basis of electronic spectra alone. Nevertheless, the nature of the system imposes some limitations on the kinds of association that can be imagined to exist. A discussion of structures reasonably proceeds from the following assumptions. (1) The chlorophyll molecules tend to float at or near the particle surface, with the phytyl groups directed toward the particle interior, and the porphyrin planes making an angle of about 50° to the surface, as they have been found to do in lecithin layers.[13] (2) The amphiphile will be similarly oriented at the particle surface, and will therefore bind primarily to the Mg from the underside of the porphyrin plane. (3) The *N*-substituent of the monosubstituted amides will be directed mainly *trans* to the myristoyl group.[14] (4) Because water is present in abundance during adsorption, the Mg and C(9) or ring carbonyl of chlorophyll will be bound to water (or possibly methanol) unless it is displaced by a stronger nucleophile or H-bond donor respectively.[7,15] (5) Established structures of chlorophyll hydrate species[16] and anhydrous chlorophyll oligomers[17] are valid models for chlorophyll association and its spectral manifestations.

It is clear, through earlier work with DMMA and other amphiphilic amides, that these compounds act as nucleophiles toward the Mg of chlorophyll, and thus keep most of the pigment in a monomeric state.[1,2] The amphiphiles used in the present work (except DPB) are also potentially capable of ligating Mg through their amide carbonyl groups. The monosubstituted amides (but not DMMA) can also form hydrogen bonds with carbonyl groups of chlorophyll. The NPMA's, but not MAn, are potentially able to bind to Mg through the pyridine function as well as through the carbonyl. Finally, since all of these functional groups are normally bound to water in aqueous systems, water may serve as an intermediate link in any of these connections.

The results of Table 2, taken as a whole, suggest that MAn and 2-NPMA behave somewhat differently from 3- and 4-NPMA. In spite of their greater solubility in the particles (or perhaps because of it), MAn and 2-NPMA interact rather weakly with chlorophyll, give absorption spectra which are somewhat broadened but not clearly structured, and show fluorescence in which monomer emission predominates. In contrast, 3- and 4-NPMA appear confined to the particle surface, where they interact strongly with chlorophyll, produce absorption bands which are distinctly structured and broadened, especially on the long-wavelength side, and show fluorescence spectra with important contributions from associated species. Models of these amides suggest that direct ligation of the carbonyl group to Mg of chlorophyll is somewhat hindered by the aromatic substituent, except perhaps in 3-NPMA. However, direct ligation of the pyridine nitrogen to Mg is unhindered in 3- and 4-NPMA, whereas it is almost impossible in 2-NPMA. It therefore seems likely that 3- and 4-NPMA are bound to the underside of the porphyrin plane through pyridine nitrogen, whereas 2-

NPMA and MAn are bound through the amide carbonyl, directly or perhaps through water. The binding of amide carbonyl in DMMA to Mg does not appear to be hindered.

According to Table 2, the three NPMA's and perhaps MAn give absorption spectral components in the range 682.5—684 nm, which are associated with fluorescence components in the range 688—693 nm. Particles with DMMA lack these components, within the sensitivity of the analysis. Since only the monosubstituted amides could form hydrogen bonds directly to chlorophyll carbonyls, it is possible that the associated species responsible for these bands are linked by ligation of the amide carbonyl or pyridine group to the Mg of one chlorophyll, and by a hydrogen bond from the amide nitrogen to the ring carbonyl of another. The monosubstituted amide thus acts as a bifunctional linking agent between two chlorophylls, much as simpler compounds such as alcohols do in solution at low temperature.[7] 3- and 4-NPMA form the strongest associations of this type. In this sort of association, the angle between the chlorophyll porphyrin planes is not well defined but tends to be rather large.

When a molecule of DMMA is bound through the amide carbonyl to the underside of one chlorophyll molecule, there is no functionality remaining by which it can link to another. However, chlorophyll adsorbed at high density to particles with DMMA does show bands of definite associated species at 674 and 689 nm. Construction of models, subject to the considerations outlined above, shows that the most likely way to link two chlorophyll molecules together is through a third DMMA molecule, bound to hydrated Mg on the upper side of one chlorophyll molecule and to the hydrated ring carbonyl group of the other. In this structure, the amide carbonyl is hydrogen-bonded to two waters at once, which is plausible because in the presence of water, amide carbonyls tend to be bound to two water molecules anyway.[18] The chlorophyll planes tend to be intermediate between parallel and perpendicular in this construction. If two chlorophyll molecules so connected produce the 674 nm absorption band component, three or more connected in series might give rise to the 689 nm component.

The four monosubstituted amides could link chlorophylls together in the same way, with one change: the amides could form hydrogen bonds directly from NH to chlorophyll carbonyl. The inequivalence of the linked chlorophyll molecules could be conductive to charge separation, as proposed by Yuen *et al.*,[19] and thus account for the farred band of fluorescence for which a charge-transfer excimer nature has been suggested.

The structures described above must be considered tentative until they can be supported by evidence bearing more directly on the nature of the linkages, such as resonance Raman spectroscopy. More important than the exact structures is that in these systems with closely related amphiphiles, the nature of chlorophyll association is conditioned by the structure of the amphiphile, and that the associated species are for the most part fluorescent.

This work was supported in part by Grant No. DE-FG01-80 ER10563 from the U. S. Department of Energy. We thank Dr. John W. McDonald for the C-H-N analyses, and Mr. Elwood R. Shaw for the synthesis of myristanilide. This is Contribution No. 802 from the Charles F. Kettering Research Laboratory.

Penetration of Lysine Hydrochloride into Lecithin Monolayers from Underlying Aqueous Solutions

Masayuki NAKAGAKI and Emiko OKAMURA*

Faculty of Pharmaceutical Sciences, Kyoto University, Yoshida-Shimoadachicho, Sakyo-ku, Kyoto 606

(Received October 23, 1982)

The surface pressure of the monolayers of dimyristoyl phosphatidylcholine (DMPC) on lysine mono- and dihydrochloride solutions was measured and the amount of positively charged lysine which had penetrated into a DMPC monolayer was calculated by successive approximation. The amount of penetration was smaller for lysine monohydrochloride than for the dihydrochloride. Moreover, both were smaller than that of uncharged lysine because mono- and dihydrochloride are more hydrophilic than uncharged lysine. The average area per molecule in the monolayer consisting of lysine and DMPC, A_{23}, was obtained. In the case of charged lysine, A_{23} increased with the mole fraction of lysine in a monolayer, X_2, in contrast it decreased with X_2 in the case of uncharged lysine. The partial molecular area of positively charged lysine was considerably larger than that of uncharged lysine. This indicates that the remarkable expansion of a monolayer is caused by the penetration of positively charged lysine because of electrostatic repulsion in the monolayer. The effect of sodium chloride on the adsorption of lysine was also investigated, but the amount adsorbed was independent of the presence of 0.5 mol dm^{-3} sodium chloride.

It has been widely accepted, according to the fluid mosaic model of Singer and Nicolson,[1] that biomembranes consist essentially of bimolecular lipid layers in which some proteins are dissolved. Many investigations of the interaction between lipids and proteins at the interfaces, have been made in order to elucidate the structure and the functions of the biomembranes.[2-7] From this point of view, the interaction between lecithin monolayers as a model of lipid membranes and lysine,[8] leucine and norleucine[9] as the components of proteins at the air/water interface was discussed in our previous papers.

Three typical patterns of the effects of different proteins on the properties of lipid bilayers and monolayers have been proposed by Papahadjopoulos *et al.*[10] 1) Simple adsorption, 2) adsorption and deformation, and 3) penetration. Which of the above three patterns is preferable depends on the kind of lipids or proteins that interact with each other, but, even for the same substances, the pattern or the intensity of interaction depends on the state and conditions of their existence. In the case of a basic amino acid, such as lysine, which was used in our previous work, the interaction with a lecithin monolayer should change with the pH of the solution, since the dissociation states of the amino and carboxyl groups of the amino acid changes. For lysine the pK values are: pK_1(COOH)=2.18, pK_2(α-NH_3^+)=8.95, and pK_3(ε-NH_3^+)=10.53,[11] and the possible charged forms of lysine, *i.e.*, free base (Lys), lysine monohydrochloride (Lys·HCl), and lysine dihydrochloride (Lys·2HCl) are (a), (b), and (c), in Fig. 1, respectively. The net charge is 0, +1, +2, in order of (a), (b), (c). Some appreciable changes in the interaction with lipids are expected to be caused by the difference between the charged forms. In this paper, Lys·HCl and Lys·2HCl were used, the amounts adsorbed onto lecithin monolayers were obtained, and discussed in comparison with the case of Lys.[8] Moreover, sodium chloride (NaCl) was used as an added electrolyte, and the effect of chloride ion (Cl^-) and that of the ionic strength were also investigated.

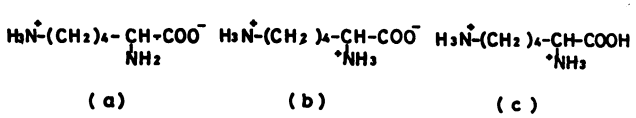

Fig. 1. Three forms of uncharged and charged lysine. (a) L-Lysine(free base) [Lys], (b) L-lysine monohydrochloride [Lys·HCl], and (c) L-lysine dihydrochloride [Lys·2HCl].

Experimental

Materials. Lys·HCl and Lys·2HCl, purchased from Wako Chemical Industries, Ltd, were dissolved in redistilled water. L-α-Dimyristoyl phosphatidylcholine (DMPC) from Sigma Company was used as lecithin, dissolved in distilled chloroform and preserved in a refrigerator until use. The stock solution was prepared every few days in order to avoid disintegration. NaCl from Merck and Co., Inc. was used without further purification.

Surface-tension Measurement. The surface tension of lysine hydrochloride solution, γ_{lys}, was measured by the capillary-height method, and the surface pressure of lysine hydrochloride, F_{lys}, was obtained by Eq. 1:

$$F_{lys} = \gamma_0 - \gamma_{lys}, \quad (1)$$

where γ_0 is the surface tension of pure water. The solution temperature was kept at 25±0.5 °C.

Surface-pressure Measurement. The surface pressure of the DMPC monolayer was measured by Wilhelmy's plate method. The details of this method were the same as described before.[8] The experimental error of the measurement was within ±0.1 mN m^{-1}. The temperature of the solution was kept at 25±0.5 °C.

Results

Surface Tension of Lysine Hydrochloride Solution. Figure 2 shows the surface tension of Lys·HCl or Lys·2HCl solution. The surface tension of Lys solution as already reported in Fig. 1 of Ref. 8 is also shown by open circles(○) in Fig. 2. It is seen that the surface tension decreases slightly with the increase in the concentration of solution, C_2, and the extent of the decrease is almost independent of the charged forms of the lysine.

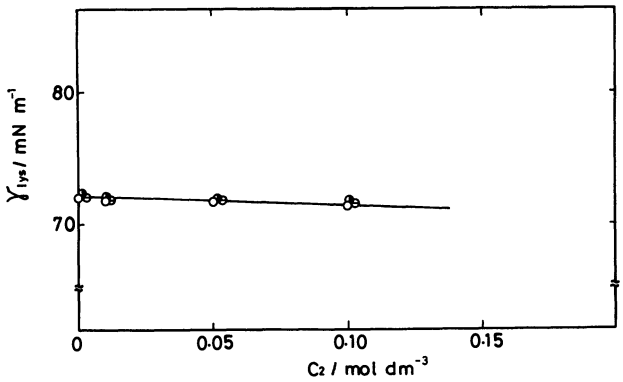

Fig. 2. The relation of surface tension, γ_{lys}, and the concentration of solution, C_2. ◑ Lys·HCl, ⊖Lys·2HCl. Symbols (○) designate the values in the case of Lys.

Surface Pressure-Area Curves of the DMPC Monolayers. The surface pressure-area curves of the DMPC monolayers spread on Lys·HCl and Lys·2HCl solutions are shown in Figs. 3(a) and (b), respectively. Although the curve shifted to the higher surface pressure region with the increase in concentration of lysine, C_2, in both cases, the extent of the shifts was larger in the case of Lys·2HCl than that of Lys·HCl.

The Amount Adsorbed onto a DMPC Monolayer. The relation between the surface pressure, F, and the concentration, C_2, at various constant areas per molecule of lecithin, A_3, was obtained from Figs. 3(a) and (b) and the amount of lysine adsorbed onto a DMPC monolayer was calculated, as described before,[8] by the following equation:

$$\Gamma_2 = \frac{1}{iRT}\left(1-\frac{\bar{A}_3}{A_3}\right)\left(\frac{\partial F}{\partial \ln C_2}\right)_{A_3}, \qquad (2)$$

where Γ_2 is the adsorbed amount of solute, R is the gas constant, T is the absolute temperature, and $\bar{A}_3$ is the partial molecular area of DMPC. $\bar{A}_3$ was approximated by the molecular area of DMPC on pure water, $A_3°$, by Pethica.[12] Hereafter, this will be called the first approximation. The values of the coefficient, i, to be discussed later in detail, are $i=2$ and 3 for Lys·HCl and Lys·2HCl, respectively, since no added electrolytes coexist in this case. Values of Γ_2 thus calculated in the first approximation are shown in Fig. 4. The values of Γ_2 in the case of Lys[8] are also shown in this figure. Besides the fact that the amount adsorbed Γ_2 increases with the concentration, C_2, it is seen from Fig. 4 that the value of Γ_2 is smaller for Lys·HCl(b) and Lys·2HCl(c) than for Lys(a). This indicates that the positively charged lysine(Lys·HCl or Lys·2HCl) is less adsorbed onto an interface than the uncharged lysine (Lys) because the hydrophobicity of the former two is stronger than that of the latter.

The Effect of Added Electrolytes. As an electrolyte, 0.5 mol dm^{-3} NaCl was added into the lysine solution and the effect of the ionic strength on the adsorption of lysine was investigated. The $\gamma_{lys}-C_2$ curves for Lys·HCl and Lys·2HCl are shown in Figs. 5(a) and (b), respectively. It was found that, in both cases, the surface tension decreased slightly with the increase in C_2, irrespective of whether or not a NaCl was added. The surface pressure-area curves of the DMPC monolayers spread on Lys·HCl and Lys·2HCl solutions with 0.5 mol dm^{-3} NaCl are shown in Figs. 6(a) and (b), respectively. The calculation of the amount of lysine adsorbed in the presence of added electrolytes is discussed later in detail.

Discussion

may be considered that at an interface, a mixed monolayer of DMPC and lysine is formed as the result of the penetration of lysine into a DMPC monolayer. The mole fraction of lysine, in this mixed monolayer, X_2, and the average area per molecule of the monolayer, A_{23}, are given by:

$$X_2 = \frac{\Gamma_2}{\Gamma_2+\Gamma_3}, \tag{4}$$

and

$$A_{23} = \frac{1}{(\Gamma_2+\Gamma_3)N_A}, \tag{5}$$

respectively, where Γ_3 is the moles of DMPC per unit area ($=1/(A_3 \cdot N_A)$), and N_A is the Avogadro number. The relation between X_2 and A_{23} at a given surface pressure is shown in Figs. 7(a) and (b) in the cases of Lys·HCl and Lys·2HCl, respectively. It was found that, in each case, the value of A_{23} increased with the increase in the mole fraction of lysine, X_2. Because of the relatively small amount of penetration, the value of X_2 was smaller than 0.1 or 0.15 in the case of Lys·HCl or Lys·2HCl, respectively, even at a low pressure region, in spite of that the concentration of lysine solution, C_2, was as high as 0.1 mol dm^{-3}.

It can be seen in Fig. 7 that the partial molecular area of DMPC on the solution, $\bar{A}_3$, is almost constant in the region other than at very small X_2-value, but the value of $\bar{A}_3$ is not equal to that on pure water ($X_2=0$), $A_3°$. The amount of lysine hydrochloride adsorbed onto a DMPC monolayer, Γ_2, was therefore, recalculated by substituting in Eq. 2 the value of $\bar{A}_3$ obtained from Fig. 7, instead of $A_3°$, as described in the previous paper.[8] This will be called the second approximation. The successive approximation was allowed to proceeded three times by which the value of Γ_2 had converged to a defined value. The values, thus obtained, are shown in

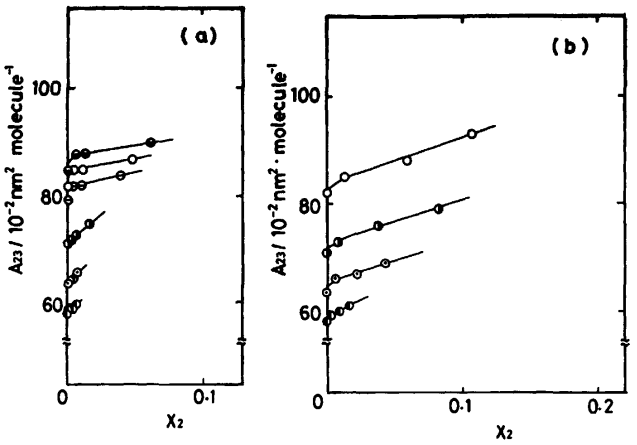

Fig. 7. The relation of the average area per molecule of a lysine-DMPC mixed monolayer, A_{23}, and the mole fraction of lysine, X_2. (a) Lys·HCl, (b) Lys·2HCl. F/mN m^{-1}: ◒ 4, ○ 5, ⊖ 6, ◑ 10, ⊙ 15, ○ 20.

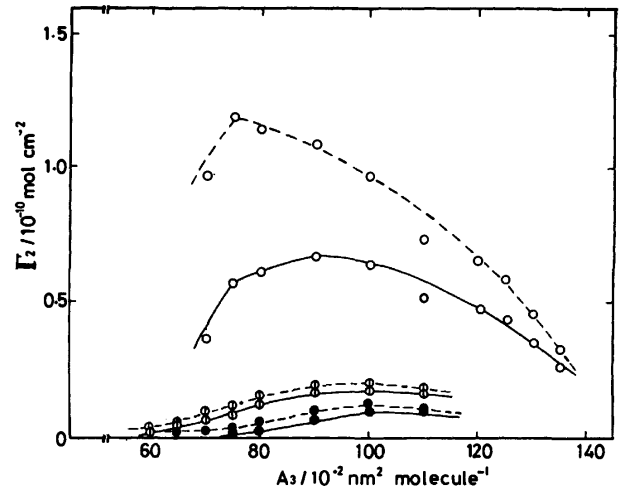

Fig. 8. The converged values of the amount of lysine adsorbed onto DMPC monolayer, when the concentration of solution, C_2, is 0.10 mol dm^{-3}. ● Lys·HCl, ⓘ Lys·2HCl. Broken lines show the values obtained on the assumption that $\bar{A}_3=A_3°$. Symbols (○) designate the values in the case of Lys.[8]

Fig. 8 by solid lines for example where the concentration of each lysine solution, C_2, is 0.10 mol dm^{-3}. Broken lines show the values calculated on the assumption that $\bar{A}_3=A_3°$. The data of lysine (free base)[8] is also shown in open circles(○). Although the converged values are smaller than the values obtained on the assumption that $\bar{A}_3=A_3°$, the sequence of the larger adsorbed amount was not changed, *i.e.*, it was Lys>Lys·2HCl> Lys·HCl, in each approximation, and this sequence was independent of the value of C_2. This order also coincided with the extent of shifts in surface pressure-area curves (Fig. 3). The result that Lys$^+$ has three units of electric charge (two + and one −) and is more hydrophilic than Lys^{2+} which has only two units of electric charges. Positive and negative charges in Lys$^+$ can interact with water molecules separately, in contrast to the case of macromolecules, such as proteins at the isoelectric point. In the latter case, the effect of the positive and negative

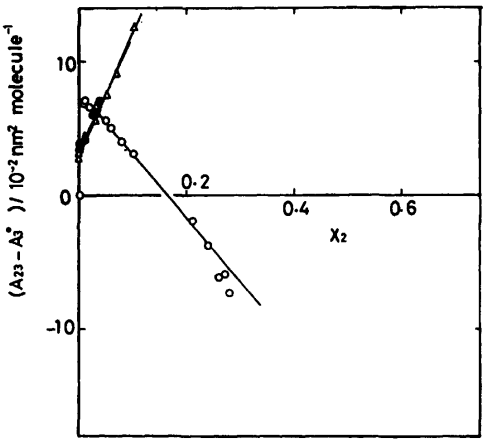

Fig. 10. $(A_{23}-A_3°)$ *vs.* X_2, obtained by the last approximation. ● Lys·HCl, △ Lys·2HCl. Symbols (○) designate the values in the case of Lys.[8]

electric charges would fairly compensate with each other since the distance to the water molecule at the surface of the macromolecule may be larger than the distance between the positive and negative charges.

The Effect of Added Electrolytes. The adsorbed amount of lysine, Γ_2, in the presence of electrolytes was calculated from Figs. 6(a) and (b), by using Eq. 2. When lysine hydrochloride $[(Lys^{+z+})(Cl^-)_{\nu_-}]$ (its concentration, C_2) and NaCl(C_3) are contained in the solution, the coefficient, i, in Eq. 2 is given by

$$i = 1 + \nu_- \frac{\nu_- C_2}{\nu_- C_2 + C_3}. \quad (3)$$

In this experiment, ν_- is equal to 1 or 2 in the case of Lys·HCl or Lys·2HCl, respectively, C_2 is 0—0.1 mol dm^{-3}, and C_3 is 0.5 mol dm^{-3}. Figure 9 shows the results thus obtained in the case of Lys·2HCl. The converged Γ_2-values are shown in this figure. It is seen that the values of Γ_2 in the presence of 0.5 mol dm^{-3} NaCl did not differ much from those in the absence of NaCl shown in Fig. 8. The same was also seen for Lys·HCl, though it is not shown in the figure. These facts indicate that the adsorption of lysine is not appreciably affected by the added NaCl electrolyte.

The Interaction between Charged Lysine and DMPC. The relation between the mole fraction of lysine, X_2, and the average area per molecule of the mixed monolayer, A_{23}, was obtained again, by using recalculated

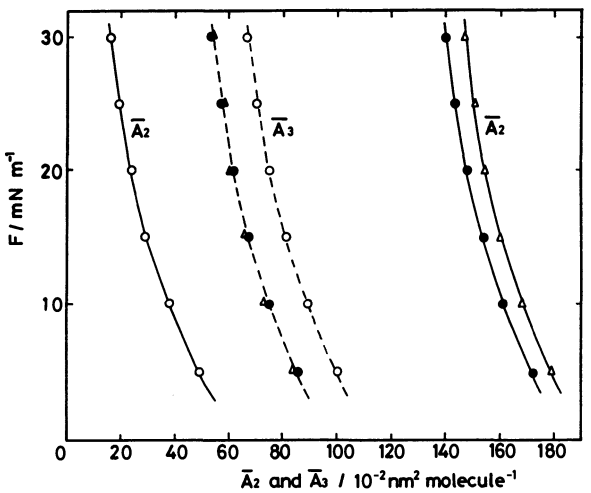

Fig. 11. The relation of the surface pressure, F, and the partial molecular areas of lysine, $\bar{A}_2$, and DMPC, $\bar{A}_3$. Solid lines show the values of $\bar{A}_2$, and broken lines show those of $\bar{A}_3$. ● Lys·HCl, △ Lys·2HCl. Symbols (○) designate the values in the case of Lys.[8]

values of Γ_2, in the case of lysine hydrochloride, and the values of $(A_{23}-A_3^\circ)$ were plotted against X_2 in Fig. 10. The open circles designate in the case of Lys. As the result of subtracting A_0^3 from A_{23}, the values of $(A_{23}-A_3^\circ)$ came on to one curve, independent of the surface pressure, F. It has also been found that $(A_{23}-A_3^\circ)$ increased with X_2 in the case of Lys·HCl of Lys·2HCl, on the contrary to the decrease in the case of Lys. This indicates that the positively charged lysine molecule which had penetrated into a DMPC monolayer occupied a larger area than lecithin. From Fig. 10, the relation between X_2 and A_{23} was obtained by the least-square method, and described in the cases of Lys·HCl and Lys·2HCl as follows:

$$A_{23} = A_3^\circ + 3.4 + 86.3X_2 \quad \text{(for Lys·HCl)} \tag{6}$$

$$A_{23} = A_3^\circ + 3.2 + 93.6X_2 \quad \text{(for Lys·2HCl),} \tag{7}$$

where Eq. 6 is, for the X_2 value smaller than 0.1, and Eq. 7 is for X_2 smaller than 0.15. The experimental errors of the constant in Eqs. 6 and 7 are 3.4 ± 0.5, 86.3 ∓ 3.5, 3.2 ± 0.5, and 93.6 ∓ 3.0, respectively. From these equations, the partial molecular area of lysine, $\bar{A}_2$, and that of DMPC, $\bar{A}_3$, are calculated respectively as follows:

$$\begin{cases} \bar{A}_2 = A_3^\circ + 89.7(\pm3.0) \\ \bar{A}_3 = A_3^\circ + 3.4(\mp0.5) \end{cases} \quad \text{(for Lys HCl)} \tag{6a}$$

$$\begin{cases} \bar{A}_2 = A_3^\circ + 96.8(\pm2.5) \\ \bar{A}_3 = A_3^\circ + 3.2(\mp0.5) \end{cases} \quad \text{(for Lys·2HCl)} \tag{7a}$$

These are shown in Fig. 11. The values of A_2 and $\bar{A}_3$ in the case of Lys are also shown with open circles. Solid lines and broken lines show the values of $\bar{A}_2$ and $\bar{A}_3$, respectively. The partial molecular area of DMPC, $\bar{A}_3$, was almost the same for both Lys·HCl and Lys·2HCl, although it was a little smaller than for Lys. On the other hand, the partial molecular area of lysine, $\bar{A}_2$, for Lys·HCl and Lys·2HCl, was remarkably larger than that for Lys, and the value of Lys·2HCl, which has Lys^{2+}, was a little larger than that of Lys·HCl, which has Lys^+. From this experiment on lysine hydrochloride, the following conclusions were deduced: 1) the amount of positively charged lysine adsorbed onto a DMPC monolayer is small because of its stronger hydrophilicity, and 2) the remarkable expansion of a monolayer is caused by electrostatic repulsion in the monolayer, at the time as the penetration of the charged lysine.

NMR Studies of Picolyl-type Carbanions. VI.[1,2] Anions Produced by Reactions of Methyl-substituted Quinolines and Isoquinolines with Butyllithium

Kazuyori KONISHI* and Kensuke TAKAHASHI†

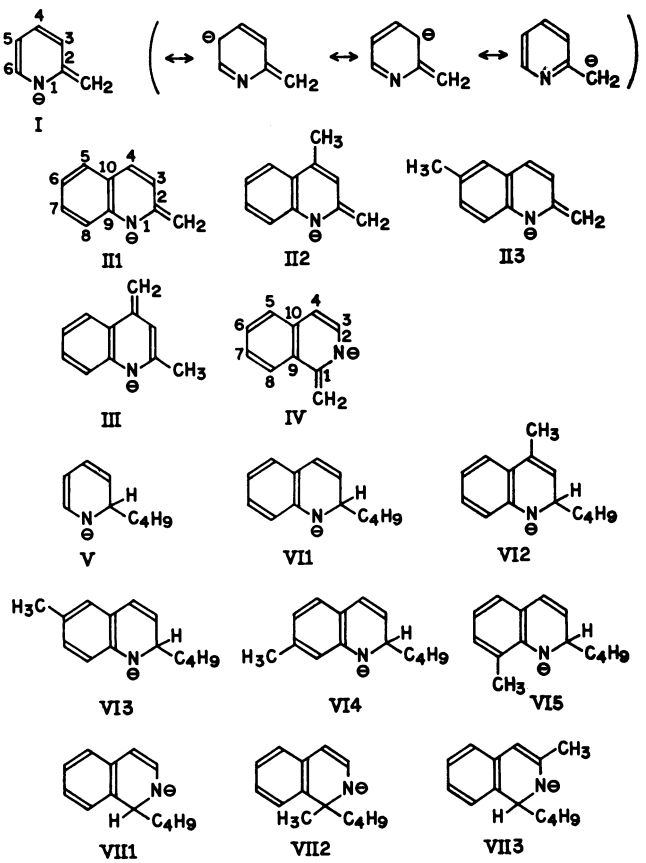
The Industrial Technology Center of Mie Prefecture, Takajayakomori-cho, Tsu 514

†*Department of Industrial Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466*

(Received October 29, 1982)

The ^{13}C and ^{1}H NMR spectra have been observed for the title anions with lithium as a counter ion in polar solvents. Two kinds of anions are formed by lithium-proton exchange and addition of butyllithium. The charge distributions in the anions are discussed in terms of the σ-included ω-HMO method. The former anions can be regarded as picolyl-type carbanions, but the latter ones are ionic species having two of three basic characteristics on picolyl-type carbanions.

In our previous papers, the ^{1}H, ^{7}Li, and ^{13}C NMR spectra were observed for charge-delocalized anions, I and II1 (shown below).[1,3,4] The studies have now been extended to the anions produced by reactions of methyl-substituted quinolines and isoquinolines with butyllithium. The present paper deals with charge distributions in the anions in terms of their ^{13}C chemical shifts and total ($\sigma+\pi$) electron densities. The anions prepared are numbered as follows:



Experimental

The method of preparation of the anions is similar to that described previously.[3]

The ^{13}C spectra were measured at 22.6 and 25.0 MHz on a Hitachi R-42FT and a JEOL JNM-FX100 spectrometers respectively. The chemical shifts were evaluated with the solvent peaks used as an internal reference and then converted to δ_c values from TMS by taking 26.4 and 37.0 ppm for tetrahydrofuran (THF) and hexamethylphosphoric triamide (HMPA) respectively.

Theoretical Calculation

The total electron densities on the atoms were calculated for the anions by the σ-included ω-HMO method.[5] In this study, the fourth and the fifth terms in Eq. 1 (shown below), called through space effects, were introduced into the calculation of the π-electron density. The Coulomb integral associated with the π-AO of the λ-th atom, α_λ^π, is, therefore, given by

$$\alpha_\lambda^\pi = \alpha + \delta_\lambda^\pi\beta + \omega^\pi\Delta Q_\lambda^T\beta + \sum_\mu \omega'^\pi \Delta q_\mu^\pi \beta + \sum_\nu \omega''^\pi \Delta q_\nu^\pi \beta, \quad (1)$$

where

$$\Delta Q_\lambda^T = \Delta Q_\lambda^\sigma + \Delta q_\lambda^\pi, \quad (2)$$

ΔQ_λ^T, ΔQ_λ^σ, and Δq_λ^π are the net total, σ-, and π-electron densities on the atom λ respectively. The atom μ is adjacent to the atom λ and, further, the ν is adjacent to the μ. The values of ω'^π and ω''^π are assumed to be $\omega^\pi/1.5$ and $\omega^\pi/6.0$ respectively.[6] The resonance integral for the $\lambda-\mu$ bond, $\beta_{\lambda\mu}^\pi$, is given by

$$\beta_{\lambda\mu}^\pi = k_{\lambda\mu}^\pi\beta. \quad (3)$$

The parameters associated with π- and σ-AO's, used in the calculation, δ_λ^π, $k_{\lambda\mu}^\pi$, ω^π, δ_λ^σ, $k_{\lambda\mu}^\sigma$, and ω^σ, were taken from the paper of Miyajima *et al.*[5] This MO calculation was carried out using the Okitac-4300C computer system.

Results and Discussion

Typical spectra of the anions are shown in Figs. 1 and 2. The ^{1}H and ^{13}C chemical-shift data are given in Tables 1 and 2 respectively.

Reactions of Methyl-substituted Quinolines and Isoquinolines with Butyllithium. In methyl-substituted quinolines, 2-methyl-, 2,4-, and 2,6-dimethylquinolines, having a 2-methyl group, underwent metal-proton exchange to give charge-delocalized anions, II(III—III3),[4] but 4-, 6-, 7-, and 8-methylquinolines, having no 2-methyl group, did addition of butyllithium to give anionic σ-complexes, VI2—VI5. In the case of 2,4-dimethylquinoline, as well as 2,4-dimethyl- and 2,4,6-trimethyl-

a) Errors are estimated to be within ± 0.3 ppm. b) From the data in Table 2 of Ref. 1.

pyridines,[3)] the exchange reaction occurred at the 2-methyl group, and the anion formed, II2, isomerized to III. Similar isomerizations were reported previously.[3)] Next, 1-methylisoquinoline underwent both exchange and addition to give IV and VII2 simultaneously, but 3-methylisoquinoline did only addition at the 1-position to give VII3. These reaction sites were confirmed by ^1H and ^{13}C chemical-shift considerations.

As can be seen from these results, two kinds of anionic species are formed by exchange and addition. In the case of quinoline and isoquinoline, having no methyl group, the addition reaction can be expected to occur at a specific position. In fact, quinoline, isoquinoline, and, furthermore, pyridine react with butyllithium to give anionic σ-complexes, VI1, VIII, and V.

Charge Distributions and Characteristics on the Anions. Typical ^1H NMR spectra of III and VI1 are shown in Figs. 1(a) and 1(b). The signals in the region of aromatic protons of both anions are present in higher fields than those of their starting materials. This upfield shift is ascribed to the excess-charge delocalization into the aromatic ring.[7)] Further, the 4-, 5-, and 7-proton signals of both anions appear at comparable fields, but the 3-, 6-, and 8-signals of VI1 do at a higher field than those of III respectively. This may arise from an increase of the negative charge in the aromatic ring except for the 2-position. The same tendencies are observed in the spectra of II2 and VI2, and II3 and VI3. Next, a typical spectrum of a mixture of IV and VII2 formed simultaneously is shown in Fig. 1(c). The signals, appearing as doublets, at δ 4.49 and 5.01 are attributable to the 4-protons of VII2 and IV respectively. The ratio of the two peak areas is about 1 : 1, indicating that IV and VII2 are present in this ratio. The signals at δ 3.28 and 3.68 are attributable to each of the methylene protons of IV. In III, the signals at δ 3.36 and 3.76 are also attributable to the methylene protons. The two protons of each anion, as well as those of II,[4)] show magnetic nonequivalence at room temperature. This nonequivalence is explained by the inhibited rotation around the bond between the ring and the methylene carbon, caused by the resonance stabilization in a molecular plane. Therefore, the methylene carbons of III—IV, as well as I—II, are virtually sp^2-hybridized.

The charge distributions in I, III, IV, V, VI1, and VIII are discussed on the basis of the relationship between the carbon(^{13}C) chemical shifts and the total electron densities. In Fig. 3, the total electron densities calculated by the method described before are plotted

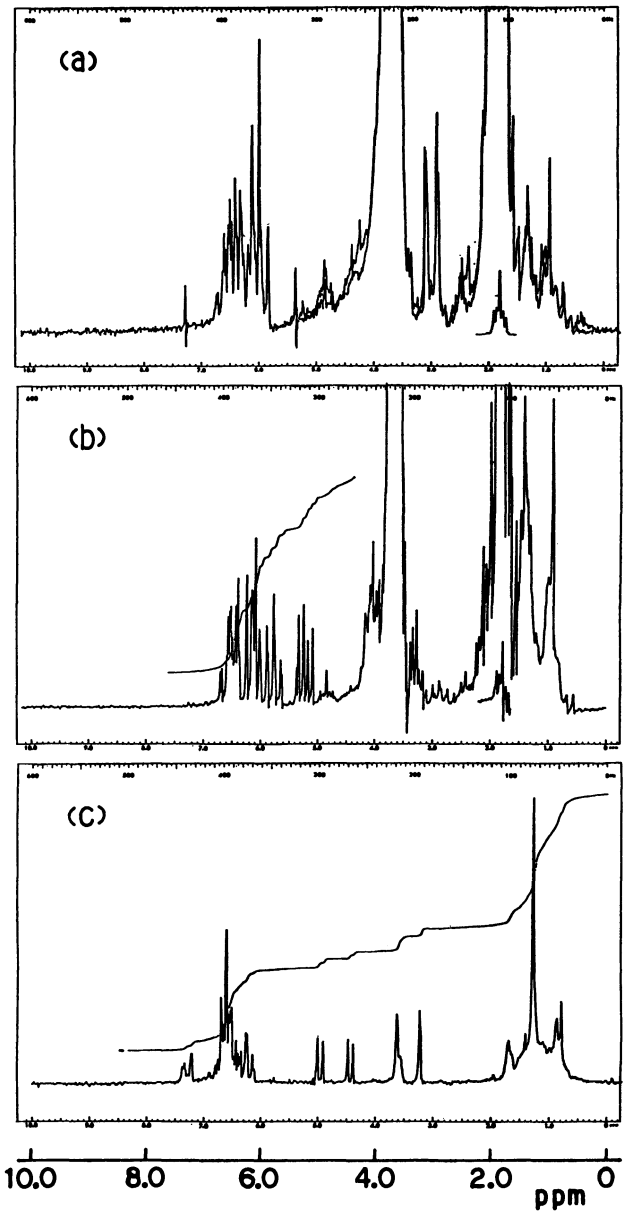

Fig. 1. ^{1}H spectra of the anions in THF at 60 MHz; (a) III, (b) VII, and (c) IV and VII2.

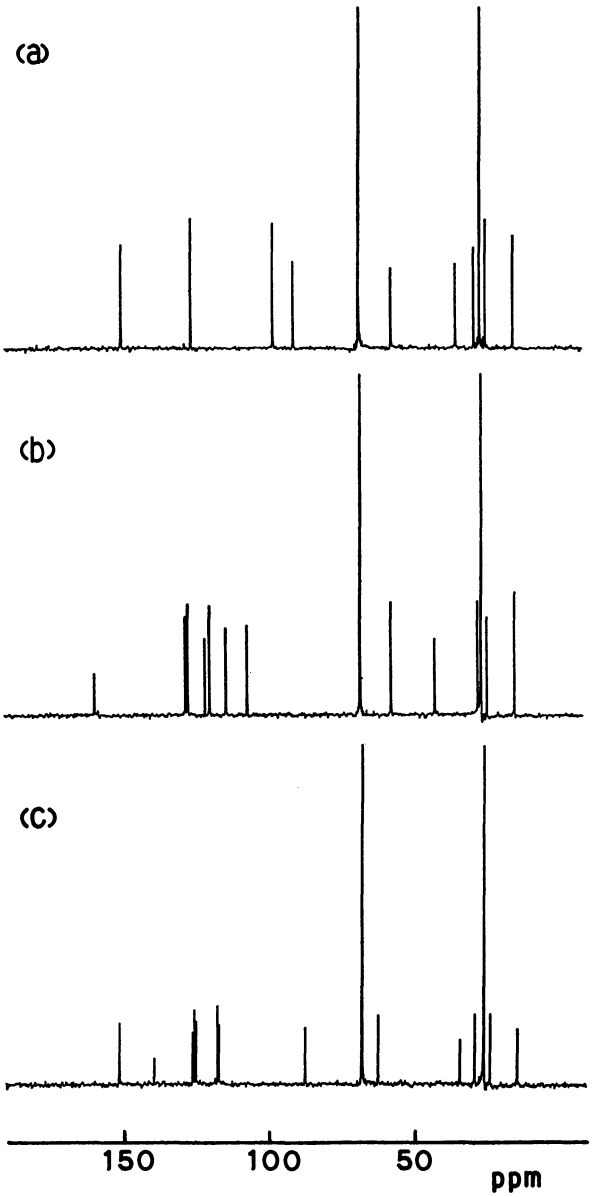

Fig. 2. ^{13}C spectra of the anions in THF at 25 MHz; (a) V, (b) VII, and (c) VIII.

against the carbon chemical shifts, except for the 2-carbons of V and VII, the 1-carbon of VIII, and the butyl carbons, having no π-electron. A good correlation exists between them, with a correlation coefficient of -0.981. Thus, these chemical shifts are linearly related to the total electron densities at the carbons in question, with a slope of -149 ppm electron^{-1}. This relationship implies that the total electron densities on the carbons of six different anions can be estimated from the observed carbon chemical shifts with an identical scale. The δ_c values of the aromatic carbons of I and V increase in the order 5-, 3-, 4-, and 6-carbons, showing that the total electron densities decrease in the same order. The δ_c values for III and VII, and for IV and VIII also increase in almost the same order respectively. In the aromatic rings of two kinds of anions, I, III, and IV, and the corresponding V, VII, and VIII, the

charge-distribution patterns are clearly analogous respectively.

The carbon chemical shifts of I, III, V, VII, and VIII3 in THF and HMPA are given in Table 2. In the aromatic carbon shifts, the effect of a change in solvent from THF to HMPA, that is, the upfield shift induced by a change to a more polar solvent, is large on the 5-carbons of I and V, the 6-carbons of III and VII, and the 4-carbon of VIII3. The variation in the shift of V is similar to that of I, and those of VII and VIII3 are larger than and similar to that of III respectively. In addition, the ^{7}Li resonances for V, VII, and VIII3 in THF and HMPA are found in a range (0—$\pm$0.5 ppm) similar to those for I and III.[1] Therefore, two kinds of anions with lithium as a counter ion have essentially the same ion-pair structure, that is, V—VII, as well as I—II,[1] are present in THF as tight ion pairs in which the anion-cation interaction takes place mainly at the ring nitrogen and so are III—IV. In the case of V—VII, it is reasonable to regard the ring nitrogen as the site where the anion-cation interaction takes place mainly in view of the process of formation.

In conclusion, a series of anions, termed picolyl-type carbanions, with lithium as a counter ion in THF have basically three characteristics as follows: (1) This ionic species is formed by metal-proton exchange at a specific methyl group of the starting material and its methylene carbon is virtually sp^2-hybridized; (2) this ionic species is a charge-delocalized one and the total electron densities on the carbons can be estimated from the ^{13}C chemical shifts, that is, the observed chemical shifts are linearly related to the calculated electron densities; and (3) this ionic species is present as a tight ion pair in which the anion-cation interaction takes place mainly at the ring nitrogen. In view of these characteristics, I—IV can be regarded as picolyl-type carbanions, but V—VII are ionic species having the second and the third terms of the characteristics on picolyl-type carbanions.

The authors wish to thank Professor Y. Sasaki (Osaka University, Suita) for his kindness in giving opportunities to use the NMR facilities, and Mr. A. Yoshino (Nagoya Institute of Technology, Nagoya) for his help in measuring the 25 MHz spectra.

Mössbauer Spectroscopic Study of $FeCl_3$-doped Polyacetylene

Hiroshi SAKAI,* Yutaka MAEDA, Taka-aki KOBAYASHI†, and Hideki SHIRAKAWA†

Research Reactor Institute, Kyoto University, Kumatori-cho, Sennan-gun, Osaka 590-04

†*Institute of Materials Science, University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 305*

(Received November 1, 1982)

Mössbauer spectra of $FeCl_3$-doped polyacetylenes $[CH(FeCl_3)_y]_x$ (y=0.074, 0.087, and 0.13), which exhibit high electrical conductivities of ≈800, ≈800, and ≈100 S/cm at room temperature, have been measured at the temperatures of 290, 196, 78, and 5 K, respectively. The spectra consist of a superposition of two quadrupole-split doublets, described as doublet (A) and doublet (B), at 290, 196, and 78 K. At 5 K the doublet (A) splits into six lines arising from the magnetic hyperfine interaction, whereas the doublet (B) still remains paramagnetic. The doublet (B) increases remarkably in the Mössbauer absorption with decreasing temperature and is predominant. The values of the isomer shift, the quadrupole splitting, and the internal magnetic field, indicate that the iron compounds corresponding to the doublet (A) and (B) are $FeCl_2 \cdot nH_2O$ (n=1 and/or 2) and $FeCl_4^-$, respectively. These results established that the mechanism of the $FeCl_3$-doping process in polyacetylene is as follows:

$$2FeCl_3 + e^- \longrightarrow FeCl_4^- + FeCl_2,$$
$$FeCl_2 + nH_2O \longrightarrow FeCl_2 \cdot nH_2O (n=1 \text{ and/or } 2).$$

Polyacetylene, $(CH)_x$, has attracted much interest in recent years because this polymer exhibits dramatic increases in electrical conductivity on doping with electron acceptor molecules such as AsF_5, SbF_5, Br_2, and I_2, or electron donors such as Na and K metals. From analogy with graphite intercalation compounds, it is expected that metal halides can also be doped and act as acceptor dopants in polyacetylene. Recently Proń *et al.*[1] have found that $FeCl_3$-doped polyacetylene, $[CH(FeCl_3)_{0.10}]_x$, exhibits very high electrical conductivity of 780 S/cm at room temperature. This value is comparable to those of AsF_5- and I_2-doped polyacetylenes.[2] From the ^{57}Fe Mössbauer spectra at room temperature, they concluded that an Fe(II) compound formed by reduction of $FeCl_3$ existed as the dopant anion in the polymer. However, they carried out no Mössbauer effect measurement at any low temperature. In these circumstances, one might overlook the other iron compounds having the lower Debye temperatures.

We have investigated in more detail $FeCl_3$-doped polyacetylenes, $[CH(FeCl_3)_{0.074}]_x$, $[CH(FeCl_3)_{0.087}]_x$, and $[CH(FeCl_3)_{0.13}]_x$, by ^{57}Fe Mössbauer spectroscopy at 290, 196, 78, and 5 K, respectively, in order to reveal the chemical form of the active iron compound and the nature of the doping process. We find from the low temperature Mössbauer spectra that two distinct iron species, *i.e.*, $FeCl_4^-$ and $FeCl_2 \cdot nH_2O$ (n=1 and/or 2), exist in the polymers. In this paper we report the mechanism of the $FeCl_3$-doping process in polyacetylene from ^{57}Fe Mössbauer effect measurements at low temperatures.

Experimental

cis-Polyacetylene films were synthesized using the method described previously.[3] The $FeCl_3$-doping was carried out by immersing the *cis*-$(CH)_x$ film in a saturated solution of $FeCl_3$ in dry nitromethane. After doping the film was washed with dry nitromethane and vacuum-dried. The dopant content was controlled by the immersion time and determined by elemental analysis. The average Fe : Cl ratio was found to be 1 : 3.9, which was larger than that of the sample of Pron *et al.* (1 : 3.65).[1]

The d.c. electrical conductivity was measured at room temperature in an inert atmosphere by the standard four-probe technique. The Mössbauer effect measurements were made with the absorbers at temperatures of 290, 196, 78, and 5 K, respectively. The thicknesses of the absorber samples were about 20 mg natural iron/cm^2. The spectra obtained were analyzed by the least square method and the velocity scale was calibrated with the magnetic hyperfine six lines of an α-Fe metallic foil, so that values of the isomer shift are given with respect to α-Fe.

Results and Discussion

The Mössbauer spectra of the $[CH(FeCl_3)_{0.087}]_x$ sample at temperatures of 290, 196, 78 K are shown in Fig. 1. This sample exhibits a room temperature conductivity (σ_{RT}) of 800 S/cm. The spectra of the other systems, $[CH(FeCl_3)_{0.074}]_x$ (σ_{RT}≈800 S/cm) and $[CH(FeCl_3)_{0.13}]_x$ (σ_{RT}≈100 S/cm), are similar to those of the $[CH(FeCl_3)_{0.087}]_x$ system. In this temperature range, the spectra consist of a superposition of two quadrupole-split doublets ((A) and (B)), as indicated by the dashed lines. The Mössbauer spectrum at 5 K of the $[CH(FeCl_3)_{0.074}]_x$ system, which has the lowest dopant content of our specimens, is shown in Fig. 2. At 5 K the doublet (A) splits into six well-resolved lines arising from the magnetic hyperfine interaction, whereas the doublet (B) still remains paramagnetic with the small quadrupole splitting. The solid lines in Figs. 1 and 2 represent the best superimposed Lorentzian curves fitted by the least square method. The Mössbauer data obtained for the $[CH(FeCl_3)_{0.087}]_x$ sample are summarized in Table 1 together with the result of Proń *et al.*[1] The data for the other systems were in good agreement with those for this system within the experimental error.

From the values of the quadrupole splitting (ΔE_Q) and the isomer shift (δ), the species possessing the large quadrupole doublet (A) is identified as a typical high spin (S=2) Fe(II) compound whereas that of the small doublet (B) is a high spin (S=5/2) Fe(III) compound. The Mössbauer absorption of the doublet (B) increases remarkably with lowering of the temperature from 290 to 5 K. This phenomenon is characteristic of compounds having a low Debye temperature. The values of ΔE_Q

and δ for the doublet (A) at room temperature are in good agreement with the result of Proń *et al.*[1]

Fe(II) Species Present in Polyacetylene. The high spin Fe(II) compound of the doublet (A) may be formed by reduction of the doped $FeCl_3$, that is, electron transfer from polyacetylene to $FeCl_3$. Then the Fe(II) species should be either $FeCl_4^{2-}$, anhydrous $FeCl_2$, or hydrated $FeCl_2$. Edwards *et al.*[4] measured the Mössbauer effect of tetrahedrally coordinated $FeCl_4^{2-}$ ions in the temperature range 1.5—363 K. The ΔE_Q value at 78 K for the Fe(II) compound observed in polyacetylene is close to the mean value for the $FeCl_4^{2-}$ ions (ΔE_Q=2.76 mm/s at 77 K), whereas the δ value

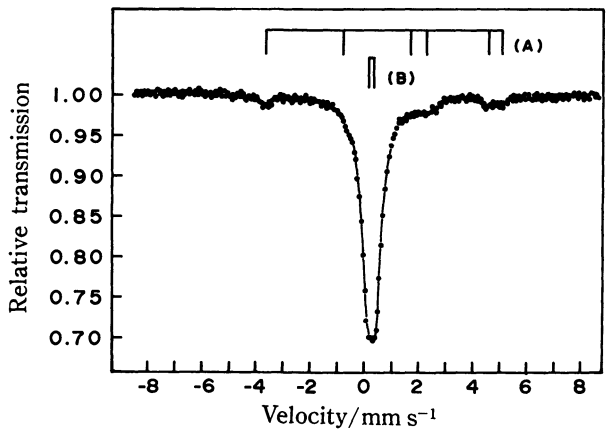

Fig. 2. Mössbauer spectrum of the $[CH(FeCl_3)_{0.074}]_x$ system at 5 K.

for the former is considerably larger than those for the tetrahedral $FeCl_4^{2-}$ ions (δ=0.86 mm/s at 77 K) and is rather close to those in the octahedral Fe(II) compounds. The possibility of anhydrous $FeCl_2$ is immediately ruled out from the Mössbauer spectrum at 5 K, showing six absorption lines due to the internal magnetic field (H_{int}) of 250 kOe (1 Oe=1000/4π A m^{-1}). The Mössbauer spectrum of the anhydrous $FeCl_2$ compound does not show six absorption lines due to the magnetic hyperfine interaction even below the Néel temperature of 24 K.[5,6] Hydrated $FeCl_2$ compounds, $FeCl_2 \cdot H_2O$, $FeCl_2 \cdot 2H_2O$, and $FeCl_3 \cdot 4H_2O$, have been well studied by Mössbauer spectroscopy.[7] $FeCl_2 \cdot 4H_2O$, in which the Fe^{2+} ion is octahedrally surrounded by two chlorine atoms in *trans* configuration with $4H_2O$, is paramagnetic even at 5 K and becomes antiferromagnetic below the Néel temperature of 1.1 K.[8] Therefore, it is clear that the Fe(II) species in polyacetylene is different from $FeCl_2 \cdot 4H_2O$.

The Mössbauer spectra of the dihydrated compound, $FeCl_2 \cdot 2H_2O$, which consists of edge-sharing octahedral chains, are very similar to those of the Fe(II) species present in polyacetylene over the temperature range between 300 and 5 K.[9] $FeCl \cdot 2H_2O_2$ becomes antiferromagnetic below the Néel temperature of 23 K and its Mössbauer spectrum at 4.2 K shows the unsymmetrical six lines due to the internal magnetic field of 255±6 kOe and the quadrupole splitting of +2.48 mm/s with $|\eta|$=0.2.[9] These values of H_{int} and ΔE_Q for $FeCl_2 \cdot 2H_2O$ are in good agreement with those at 5 K for the Fe(II) compound observed in polyacetylene (Table 1).

In the paramagnetic phase, for example at room temperature, the values of ΔE_Q(=2.32 mm/s) and δ(=1.16 mm/s) for $FeCl_2 \cdot 2H_2O$[10] are also very close to those for our Fe(II) species. $FeCl_2 \cdot H_2O$ is also antiferromagnetic below the same temperature of 23 K and the saturation value of the internal magnetic field ($T \rightarrow 0$ K) is about 252 kOe.[11] The value of ΔE_Q at $T=0$ K is evaluated to be +2.50 mm/s. These values of H_{int} and ΔE_Q for $FeCl_2 \cdot H_2O$ in the antiferromagnetic region are in good agreement with those for $FeCl_2 \cdot 2H_2O$. Furthermore, the values of ΔE_Q and δ in the paramagnetic region are also close to those for $FeCl_2 \cdot 2H_2O$. Therefore, the Fe(II) species, formed by reduction of $FeCl_3$ doped in polyacetylene, is determined to be either $FeCl_2 \cdot 2H_2O$ or $FeCl_2 \cdot H_2O$, or their mixture. The Fe(II) compound may exist as clusters in the polyacetylene film because it has the same values of δ, ΔE_Q, and H_{int} at corresponding temperatures as those for the crystalline $FeCl_2 \cdot 2H_2O$ or $FeCl_2 \cdot H_2O$.

Fe(III) Species Present in Polyacetylene. From the doping process of $FeCl_3$, it is expected that one of the $FeCl_4^-$ and $FeCl_6^{3-}$ ions, and anhydrous $FeCl_3$ and $FeCl_3 \cdot 6H_2O$ compounds corresponds to the high spin Fe(III) species of the small quadrupole doublet (B) in the doped polyacetylene. A detailed comparison of our Mössbauer spectra of the doublet (B) with those for the expected compounds is pertinent. The possibility of two neutral compounds, anhydrous $FeCl_3$ and $FeCl_3 \cdot 6H_2O$, is ruled out for the following reasons: (i) the former anhydrous compound becomes antiferromagnetic below the Néel temperature of 15 K and the extrapolated value ($T \rightarrow 0$ K) of the internal magnetic field is about 487 kOe,[12] (ii) the δ value (=0.55 mm/s at 78 K) for the former is also larger than that of the doublet (B), and (iii) the both values of ΔE_Q(=0.91 mm/s at 78 K) and δ(=0.60 mm/s at 78 K) for the latter hydrated compound[13] are considerably larger than those for the Fe(III) species of the doublet (B). Therefore, the Fe(III) species present in polyacetylene is different from the anhydrous $FeCl_3$ and $FeCl_3 \cdot 6H_2O$. It is confirmed that an octahedral $FeCl_6^{3-}$ ion exists in certain solid complexes in association with a smaller, univalent cation. The Mössbauer parameters for the $FeCl_6^{3-}$ ions were reported as δ=0.48—0.52 mm/s and ΔE_Q=0 mm/s at 78 K, respectively.[14] The δ values for the octahedrally coordinated $FeCl_6^{3-}$ ions are slightly larger.

The δ value for the Fe(III) species in polyacetylene suggests that this species is a tetrahedrally coordinated substance. It is well known that the covalency is greater in tetrahedral FeX_4^- ions than in the corresponding octahedral FeX_6^{3-} ions. The tetrahedral $FeCl_4^-$ ion is stable and found in many chemical compounds. The Mössbauer spectra of the typical compounds R_4NFeCl_4 (R=Me, Et, and Ph) were measured in the temperature range 293—1.1 K by Edwards and Johnson.[15] They found that these compounds at 4.2 K showed single absorption peak and still remained paramagnetic. The δ values were found to be about 0.30 mm/s at 77 K. For the compounds containing the small cations, Me_4N^+ and Et_4N^+, the ΔE_Q values are equal to zero, whereas the value is 0.2 mm/s for Ph_4NFeCl_4, indicating that the tetrahedral $FeCl_4^-$ ion is distorted. These values of δ and ΔE_Q for the tetrahedrally coordinated $FeCl_4^-$ ions are in good agreement with those for the Fe(III) species of the doublet (B) over the temperature range 290—5 K. Thus it is concluded that the Fe(III) species present in the doped polyacetylene is a distorted tetrahedral $FeCl_4^-$ ion.

Mechanism of the $FeCl_3$-doping Process. As mentioned above, it was found that two chemical species of $FeCl_2 \cdot nH_2O$ (n=1 and/or 2) and $FeCl_4^-$ existed in the $FeCl_3$-doped polyacetylene. This experimental fact suggests strongly that following reactions occur between the doped $FeCl_3$ molecule and polyacetylene:

$$FeCl_3 + e^- \longrightarrow FeCl_2 + Cl^-,$$

$$FeCl_3 + Cl^- \longrightarrow FeCl_4^-,$$

$$FeCl_2 + nH_2O \longrightarrow FeCl_2 \cdot nH_2O \ (n=1 \text{ and/or } 2).$$

In these reactions there are two kinds of $FeCl_3$ dopants which have individual roles in polyacetylene; one acts as an electron acceptor and the other as a stabilizer for Cl^- produced by reduction of $FeCl_3$. This behavior is similar to that of I_2 dopant in polyacetylene. In the latter system the presence of the triiodide ion (I_3^-), formed by the combination of the I_2 molecule and the resulting I^- ion, has been confirmed by Raman spectroscopy,[16,17] XPS,[16,18,19] and the ^{129}I Mössbauer effect.[20,21]

The finding of no anhydrous $FeCl_2$ in the Mössbauer spectra suggests that the neutral species is removed from the system together with the unreacted $FeCl_3$ dopant by washing with dry nitromethane. In the presence of a small amount of water in the solvent and the doped salt, the hydrated compound, $FeCl_2 \cdot nH_2O$ (n=1 and/or 2), may be formed and no longer removed by washing. Therefore, the content of the hydrated species in the polymer film may be dependent on the water content of the solution. This expectation well interprets the Mössbauer spectra especially at low temperature, indicating that the absorption area of the doublet (B) is much larger than that of the doublet (A) even at 78 K. The Mössbauer absorption area is approximately proportional to the content of each resonant nucleus at a sufficiently low temperature compared with each Debye temperature and in a sufficiently low concentration of each resonant nucleus. Furthermore, the Fe : Cl ratio obtained by the elemental analysis was found to be 1 : 3.9, which also supported strongly the validity of the expectation. If only two chemical species, $FeCl_4^-$ and $FeCl_2 \cdot nH_2O$, exist in the polymer film (no contaminant), the ratio 1 : 3.9 indicates that the content of the $FeCl_4^-$ ion is 19 times greater than that of the hydrated $FeCl_2$ species. This seems reasonable for the absorption area ratio of the Fe(III) to Fe(II) species in the Mössbauer spectrum at 5 K (Fig. 2).

The mechanism of the $FeCl_3$-doping process in polyacetylene differs from that in graphite. In the $FeCl_3$-graphite intercalation compound, the doped $FeCl_3$ is not reduced and its values of δ and ΔE_Q are nearly equal to those for pure anhydrous $FeCl_3$.[22] Many $FeCl_3$ molecules can nevertheless be doped in graphite. In the $FeCl_3$-doped polyacetylene the neutral $FeCl_3$ is completely converted to $FeCl_2$ and $FeCl_4^-$ and the

latter is the dominant dopant species.

This work at University of Tsukuba was supported partly by a Grant-in-Aid for Scientific Research No. 56470083 from the Ministry of Education, Science and Culture.

Studies on Aqueous Solutions of Saccharides. I. Activity Coefficients of Monosaccharides in Aqueous Solutions at 25 °C

Koichiro MIYAJIMA,* Masahiro SAWADA, and Masayuki NAKAGAKI
Faculty of Pharmaceutical Sciences, Kyoto University, Yoshida Shimoadachi-cho, Sakyo-ku, Kyoto 606
(Received November 13, 1982)

Activity coefficients of isomeric monosaccharides, D-glucose, D-mannose, and D-galactose were determined by isopiestic comparison method at 25 °C. Excess partial molar entropy of water ($\bar{S}_w^{ex}$) of each monosaccharide solution was negative and the absolute value increased with concentration of solute. From the magnitudes of negative $\bar{S}_w^{ex}$, it was concluded that the structure making ability among three isomers lies in the order D-glucose> D-mannose>D-galactose.

Many papers have been published on the properties of aqueous solutions of monosaccharides, because they are not only biologically important compounds but also the typical hydrophilic nonelectrolytes in the field of solution chemistry.

On the hydration of monosaccharides, Kabayama and Patterson[1] postulated that the spacing of oxygen atoms of equatorial hydroxyl groups of hexopyranose in chair conformations, which are predominant in aqueous solution, are compatible to the spacing of oxygen atoms in tridymite-like structure of water. This model is a so called "specific hydration model."[4] To investigate the validity of the hypothesis, various kinds of experiments, such as partial molar volume,[2,3] compressibility,[2,3] ^{1}H- and ^{17}O-NMR[4-7] and dielectric relaxation[4,8] were carried out. However their conclusions are still in controversy.

From the similar viewpoint, we determined the activity coefficients of three isomeric monosaccharides, *i.e.* D-glucose, D-mannose, and D-galactose in aqueous solution at 25°C and calculated the excess partial molar entropy of water ($\bar{S}_w^{ex}$) from the excess free energy combining the excess enthalpy data[9,10] and investigated the correlation between $\bar{S}_w^{ex}$ and the structure making ability predicted by the special hydration model.

Experimental

Materials. Reagent grade D-glucose, D-mannose, and D-galactose obtained from Wako Chemical Co. Ltd., were dried over P_2O_5 *in vacuo* at room temperature for several days. Reagent grade $CaCl_2 \cdot 2H_2O$ was used without further purification. These compounds were dissolved in purified water by distillation and deionization.

Method. Osmotic coefficients were determined at 25±0.02 °C by isopiestic comparison method described elsewhere.[11] From the osmotic coefficient (ϕ), activity coefficient (γ) was calculated by

$$\ln \gamma = (\phi - 1) + \int_0^m \frac{\phi - 1}{m} dm, \quad (1)$$

where m is the molality of solute. Buoyancy correction was made for monosaccharides assuming that the densities of the solutes in solid states were unity. Experimental determination of isopiestic concentration was precise to ±0.2%. The molalities of isopiestic solution are shown in Table 1. The concentration of $CaCl_2$ used as a reference solute was determined by gravimetric analysis with silver nitrate.

Results and Discussion

Osmotic and activity coefficients of D-monnose and D-galactose are shown in Table 2 together with those of D-glucose. The values of ϕ and γ of D-glucose obtained from this experiment are in a fair agreement with those of Taylor and Rowlinson,[12] but are larger than those of Bonner and Breazeale.[13] The values of γ for three monosaccharides lie in the order D-glucose>D-galactose>D-mannose.

The standard states are taken asymmetrically; taking the infinite dilution and the pure solvent as the standard states of the solute and solvent, respectively, the total excess Gibbs free energy of solution containing a kilogram of solvent is calculated from ϕ and γ by Eq. 2.[14]

$$G^{ex} = mRT(1 - \phi + \ln \gamma). \quad (2)$$

From the heat of dilution of monosaccharides, excess enthalpy of solution (H^{ex}) is expressed in the following form,[9]

$$H^{ex} = h_{xx}m^2 + h_{xxx}m^3, \quad (3)$$

where h_{xx} and h_{xxx} are the interaction parameters. Excess entropy of solution (S^{ex}) is calculated by Eq. 4.

$$S^{ex} = (H^{ex} - G^{ex})/T. \quad (4)$$

Excess quantities *vs.* concentration curves for three monosaccharides are shown in Figs. 1, 2, and 3. The small value of positive excess free energy comes from the difference between largely positive enthalpy and entropy term, that is, the entropy-enthalpy compensation takes place in each system. The predominance of enthalpy term over entropy term characterizes hydrophilic solute in water,[15] in contrast with the hydrophobic solute in aqueous solution, where the entropy term is superior to enthalpy term.[16] The values of TS^{ex} among three isomers decrease in the order D-glucose, D-mannose, and D-galactose.

To investigate the structural change of solvent water, excess partial molar quantities of water were calculated by the following equations.

$$\bar{G}_w^{ex} = mRT(1 - \phi)\frac{M_w}{1000}, \quad (5)$$

$$\bar{H}_w^{ex} = -(h_{xx}m^2 + 2h_{xxx}m^3)\frac{M_w}{1000}, \quad (6)$$

$$\bar{S}_w^{ex} = (\bar{H}_w^{ex} - \bar{G}_w^{ex})/T, \quad (7)$$

where $\bar{G}_w^{ex}$, $\bar{H}_w^{ex}$, and $\bar{S}_w^{ex}$ are the excess partial molar free energy, enthalpy, and entropy of water, respectively.

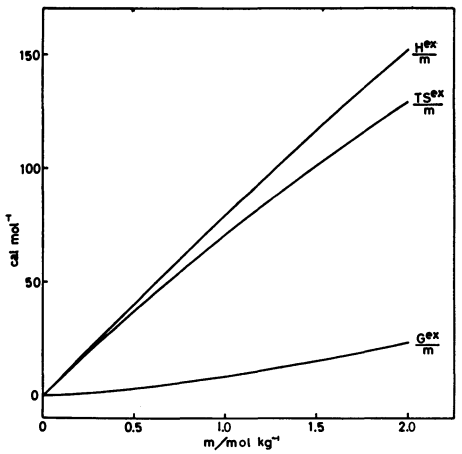

Fig. 1. Excess thermodynamic quantities for aqueous D-glucose solutions at 25 °C.

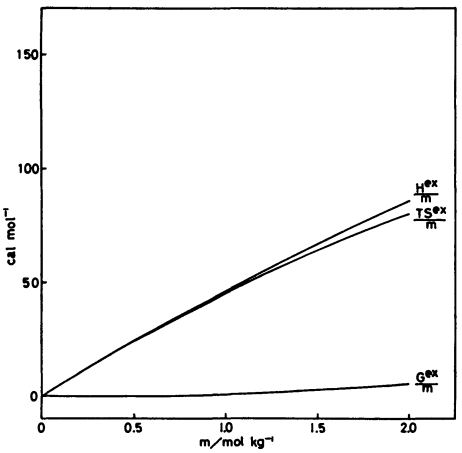

Fig. 2. Excess thermodynamic quantities for aqueous D-mannose solutions at 25 °C.

As shown in Fig. 4, the values of $\bar{S}_w^{ex}$ for D-glucose, D-mannose, and D-galactose are negative and the absolute values increase with concentration of monosaccharide, indicating the ordering of water molecule by the dissolution of these monosaccharides. As shown in Fig. 5, the predominance of enthalpy term over entropy term gives the negative value of $\bar{G}_w^{ex}$. The negative $\bar{S}_w^{ex}$ values which mean the increase of water structure lie in the order D-glucose>D-mannose>D-galactose. Tait[4] calculated the percentage of equatorial

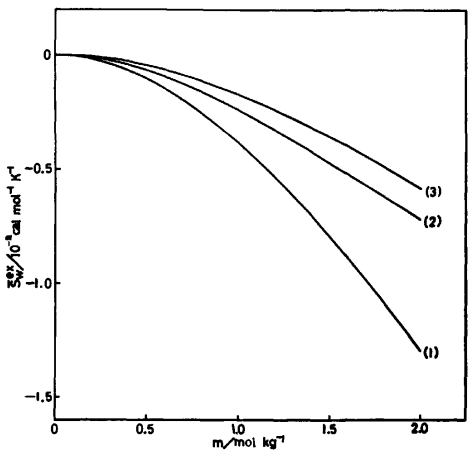

Fig. 4. Excess partial molar entropy of water ($\bar{S}_w^{ex}$) in aqueous D-glucose (1), D-mannose (2), and D-galactose (3) solutions at 25 °C.

OH groups of isomeric monosaccharides assuming that these monosaccharides take chair conformations and are the equilibrium mixtures of α- and β-anomers. Using his results, we calculated the equatorial OH content of D-galactose and D-mannose relative to D-glucose, resulting in 0.78 and 0.71 for D-galactose and D-mannose, respectively. Therefore the structure making ability must be in the order D-glucose>D-galactose>D-mannose. From the ^{17}O-NMR study,[4] Tait could not distinguish the hydration properties of three isomers and concluded that "at least three equatorial hydroxyl groups are required for the monosaccharide to be an effective substitute for the water within structured cluster of water molecules." Judging from the $\bar{S}_w^{ex}$ values of three isomers obtained from this work, the structure making ability lies in the order D-glucose>D-mannose>D-galactose. We cannot explain the discrepancy of structure making ability observed between our result and special hydration model at the present stage. A possible explanation is that the nature of structure promotion of these monosaccharides is affected not only by the number of equatorial hydroxyl groups but also by the relative position of equatorial hydroxyl groups,

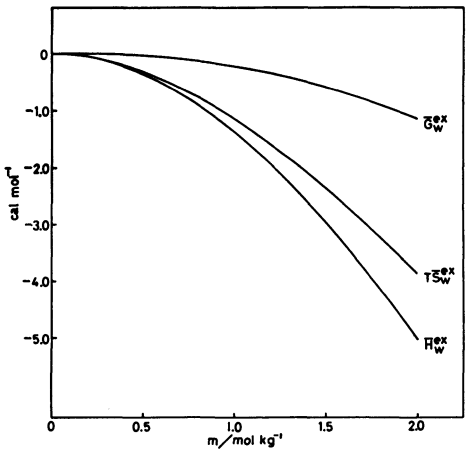

Fig. 5. Excess partial molar free energy, enthalpy, and entropy of water in aqueous D-glucose solutions at 25 °C.

on the assumption that the special hydration model is correct.

Gravimetric Determination of Copper(II) Using N^1-Hydroxy-N^1-(*m*-tolyl)-N^2-(*o*-chlorophenyl)-*p*-toluamidine Hydrochloride

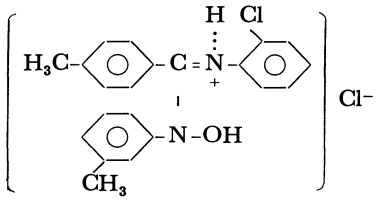
Hemlata Mohabey, Pramod Kumar Sharma,* and Rajendra Kumar Mishra

Department of Chemistry, Ravishankar University, Raipur, 492 010, India

(Received August 13, 1982)

A simple, rapid, and accurate method has been developed for the gravimetric determination of Copper(II) using a new reagent N^1-hydroxy-N^1-(*m*-tolyl)-N^2-(*o*-chlorophenyl)-*p*-toluamidine hydrochloride (HTCPTH). The proposed reagent reacts quantitatively with copper at 3.3—11.0 pH giving a buff coloured precipitate. The precipitated complex can be easily filtered, dried and directly weighed as $(C_{21}H_{18}N_2OCl)_2Cu$. The complex is thermally stable as is evident from DTA and TGA studies up to 210 °C and insoluble in many organic solvents. Most of the common ions including Ni(II), Co(II), Cr(III), Mn(II), *etc.* do not interfere. The interference due to iron(III) can be eliminated by masking it with tartaric acid. The method has been successfully applied for the determination of copper in some British Chemical Standards alloys.

N^1-Hydroxy-N^1,N^2-diarylbenzamidines have been found to be potential analytical reagents for the determination of various transition elements.[1-3] This communication describes the use of a new *N*-hydroxyamidine, N^1-hydroxy-N^1-(*m*-tolyl)-N^2-(*o*-chlorophenyl)-*p*-toluamidine hydrochloride(I) for the gravimetric determination of copper(II).



1

The reagent reacts with copper(II) giving a buff coloured precipitate at 2.2—11.5 pH but the reaction is quantitative only at pH 3.3—11.0. The complex is stable towards heat and dilute mineral acids and no weight loss is observed upto 210 °C. The coprecipitated reagent can be completely removed by washing with hot 50% aqueous ethanol as the complex is insoluble in it. The conversion factor (metal/metal complex is very small (0.0833) and therefore small quantities of copper can be accurately determined. The method is free from interference of many foreign ions and is comparable to established methods.[4-9]

Experimental

Reagents and Chemicals. All the chemicals used were of A. R. grade.

Copper stock solution was prepared by dissolving the British Drug House, AnalaR copper metal in dilute nitric acid and the solution boiled to expel nitrogen oxides. The solution was standardized gravimetrically using salicylaldehyde oxime.[10]

The reagent, HTCPTH was prepared by condensing *N*-(*o*-chlorophenyl)-*p*-toluimidoyl chloride and *N*-(*m*-tolyl) hydroxylamine in equimolar amounts in ether as mentioned earlier.[1] A 1% solution of the reagent in ethanol was used for precipitation purposes. The pH of the solution was adjusted to 3.3 to 11.0 with acetic acid and ammonia.

Apparatus. A single pan semimicrobalance SAHM-68 (VEB-Analytic DDR) was used for weighing. The pH of the solution was measured with a Systronic pH meter type −322.

Recommended Procedure. An aliquot of copper solution containing 10—15 mg of copper was diluted to 150 ml. The pH of the solution was adjusted to 3.3 to 11.0 and heated to about 60 °C. To this added 1% reagent solution (20—30 ml per 12.8 mg copper) dropwise with constant stirring. The buff coloured precipitate was digested on water bath for 20 min and filtered through a preweighed G-3 sintered crucible. The complex was washed with hot water followed by 60% ethanol till the washings gave no red-purple colour with iron(III) chloride. It was dried at 120 °C to constant weight and weighed as $Cu(C_{21}H_{18}N_2OCl)_2$ (Found: C, 65.98; H, 4.66; N, 7.28; Cu, 8.30%. Calcd for: C, 66.09; H, 4.72; N, 7.34; Cu, 8.33%).

Properties of the Complex: The copper complex is insoluble in water and sparingly soluble in ethanol, acetone, carbon tetrachloride, chloroform and many other organic solvents. The complex can be dried to constant weight at 110—180 °C with out decomposition. The melting point of the complex is 208 °C and it blackens at this temperature. Though there was change in colour at the melting point of the complex, weight loss was observed only at 220 °C during thermogravimetric studies of the complex.

Precision. The standard deviation of ten independent determinations with 12.8 mg copper is 0.0066 while the relative standard deviation is 0.051%.

Effect of Foreign Ions. Following the procedure described above a known amount of copper (12.8 mg) was accurately determined at pH 3.5—5.5 in presence of many foreign ions. Vanadium(V), iron(II), and iron(III) form coloured complexes with the proposed reagent under the recommended procedure. These ions could be masked with tartaric acid (2 g) and thus the interference due to these ions was eliminated. It is evident from Table 1 that copper can be separated from almost all common ions like Pb(II), Co(II), Ni(II), Bi(III), Sn(IV), V(V), Fe(III), *etc.* and hence the method is suitable for analysis of copper alloys.

Determination of Copper in Alloys. An accurately weighed amount of alloy containing 10—15 mg of copper in 25 ml aliquot of the final solution was dissolved in 40% nitric acid. The solution was evaporated to near dryness to remove the oxides of nitrogen. It was diluted to 100 ml and the precipitated tin and antimony oxides were filtered and washed with hot dilute acetic acid and the solution diluted to 250 ml. Copper was determined by the recommended procedure. It is evident from the results summarised in Table 2, that the amount of copper in its alloys could be determined accurately and precisely.

Thermal Analysis of Copper Complex. Thermogravimetric and differential thermal analysis were carried out to evaluate the thermal stability of the copper complex of HTCPTH. The TGA and DTA curves were obtained using

a) BCS: British Chemical Standards.

an automatic unit HOM-BUDAPEST Devitograph (Type-OD-102). The TGA curve (Fig. 1) shows that there is no weight loss upto 220 °C thereby indicating that the chelate is nonhydrated in nature. At 220 °C the complex starts to decompose and 5% weight loss is observed between 220 to 240 °C. Accelerated weight loss takes place in the region 240—760 °C. At about 760 °C nearly 90% weight loss is observed. Here oxide level beings giving a horizontal straight line. It is evident from thermogravimetric analysis that the thermal stability 220 °C of copper-HTCPTH complex is higher than copper-salicylaldehyde oxime[11] *i.e.* 140 °C.

The DTA curve of the complex consists of a pronounced

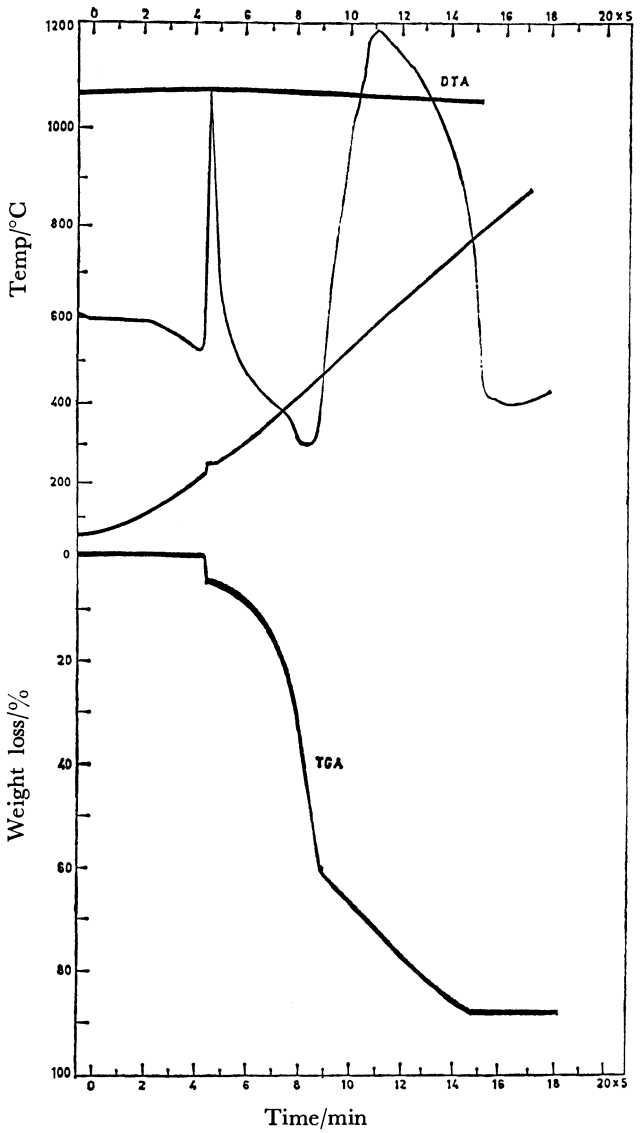

Fig. 1. DTA and TGA curves of copper complex of N^1-hydroxy-N^1-(*m*-tolyl)-N^2-(*o*-chlorophenyl)-*p*-toluamidine hydrochloride.

exothermic peak at about 210 °C which may be due to possible phase transition from solid to liquid (melting). Melting may be accompanied by the loss of organic part of the compound as nearly 5% weight loss takes place at 220 °C (melting with decomposition). The other broad and prominent exothermic peak at about 550 °C may be due to another phase transition in the complex due to loss of ligand molecules as accelerated weight loss is observed in the range 240—760 °C. A small but noticiable endothermic peak is noticed at about 400 °C. There must be some new decomposition products at this temperature as is obvious from weight loss curve. Metal 8-quinolinolates[12] and 2-quinolinecarboxylates[13] also show endothermic decomposition peaks.

Hence the direct weight of copper complex after drying at 110—180 °C for gravimetric determination is justified.

Infrared Spectra. The ligand molecule consists of a broad band at 2550 cm^{-1} confirming the presence of protonated azomethine nitrogen in *N*-hydroxyamidine hydrochloride.[14] The absence of any band in the region 2500—2730 cm^{-1} due to $\overset{+}{N}$–H stretching mode in the spectra of copper

complex suggests that deprotonation of azomethine nitrogen occurs when copper complex is formed. The band due to $C{=}N^+$ stretching (1610 cm^{-1})[15,16] is displaced to lower frequency (1570 cm^{-1}) on complex formation. This indicates the formation of C=N·····Cu coordinate linkage. The N–O stretching mode appears at 930 cm^{-1} in the free ligand.[17,18] Replacement of proton of N–OH group by copper leads to displacement of N–O stretching mode to higher frequency and appears at 950 cm^{-1} in the copper complex.

The authors are thankful to Head, Department of Chemistry, Ravishankar University, Raipur for providing Research facilities and to the Council of Scientific and Industrial Research, New Delhi for the award of a Fellowship to one of them (P.K.S.).

Thermal Properties of Solid Bis(2,3-alkanedione dioximato)nickel(II). Crystal Structure Transformation

Mikiya I, Hisanobu WAKITA,* and Isao MASUDA

Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma, Jonan-ku, Fukuoka 814-02

(Received July 23, 1982)

The thermal behavior in the solid state of the title complexes was investigated. Here 2,3-alkanedione dioximato is CH_3-C(=NOH)-C(=NO)-R; R includes C_2H_5 (**1**), n-C_3H_7 (**2**), n-C_4H_9 (**3**), n-C_5H_{11} (**4**), n-C_6H_{13} (**5**), and n-C_8H_{17} (**6**) groups. The complexes, **1**, **2**, **5**, and **6**, underwent thermal crystal structure transformation; the transformation was irreversible for **1** and **5**, and reversible for **2** and **6**. The ΔH_t values, heats of transformation, were found to fall in the 5.3—32.6 kJ mol^{-1} range. The ΔH_m values, heats of melting, were determined for the complexes, **2**—**6**. On the basis of these data, the thermal characteristics for these complex crystals are discussed in relation to the nature of the R groups.

The nickel(II) complexes of 2,3-alkanedione dioximes have been extensively studied in the fields of analytical and coordination chemistries.[1] The current interest has been concentrated rather on the interpretation of the properties and structures in the solid state of the complexes connected with their solubilities: these solubilities closely relate to the function of these dioximes as a specific precipitant for Ni^{2+} and Pd^{2+} ions and also to the proposed presence of a novel, intermetallic interaction[2] in the crystals of these metal-dioximato complexes.

In the crystal of bis(dimethylglyoximato)nickel(II), $Ni(dmgH)_2$,[3] planar complex molecules are stacked face to face along the c_o axis and are rotated alternately by 90° around the c_o axis;[4] this is referred to as the cross-form. The Ni atoms array along the c_o axis apart by 3.5 Å, posing as if there is an intermetallic Ni–Ni interaction.[2] For the $Ni(emgH)_2$ complex, two different forms of crystal are known. In one form, planar complex molecules array like the slats of a venetian blind inclined with an angle of 44°, when the cord of the blind is likened to the a_o axis of the crystal;[5] this is referred to here as the blind-form. In the other form, molecular packing is considered to be like the above mentioned cross-form of $Ni(dmgH)_2$ according to the analysis of the X-ray powder diffractions.[6] Anex and Krist have reported that the slow evaporation of the complex solution gives rise to the precipitation of the blind-form, whereas the hasty evaporation yields the cross-form.[7]

These facts are thought to imply that a crystal structure transformation occurred in the solid of these complexes. However, there has so far been no report which proved the existence of such a thermal crystal structure transformation.[8] In the present paper, the thermal properties of a series of the bis(2,3-alkanedione dioximato)[3] complexes have been investigated by thermal and X-ray powder diffraction analyses. The crystal structure transformation has been found to occur for the complexes whose dioximato ligand is emgH, prmgH, hxmgH, or omgH,[3] and the thermodynamic data have been determined.

Experimental

Preparation of Ligands. Following the general procedure given in the literature,[9] 2,3-alkanedione dioximes were prepared by the condensation reaction of 3-hydroxyimino-2-alkanone and hydroxylamine; the hydroxyimino derivatives were prepared by the isonitrosation of the corresponding 2-alkanones with ethyl nitrite. The dioximes thus obtained were purified by recrystaliization from methanol–chloroform (3 : 7), and were identified by elemental analysis, melting point, and ^{13}C-NMR spectrum.

Preparation of Complexes. The precipitates of the complexes were obtained in the following general manner: an aqueous solution saturated with nickel acetate was added to a hot methanol solution of the dioximes, and then the precipitate produced was collected on a filter. The recrystallization of the complexes was carried out as follows: the complex was added into the boiling solvent indicated in Table 1 for each complex, and then the saturated solution was filtered while it was hot. If the crystals were separated during the filtration, the crystals were dissolved again by heating the filtrate. Then the filtrate was cooled by allowing it to stand at room temperature. The crystals were separated by filtration, and then dried *in vacuo*.

The X-ray diffractions of crystalline $Ni(emgH)_2$ obtained in the above manner indicated it to be the blind-form.[5] The cross-form of $Ni(emgH)_2$ was prepared by the literature method.[6b]

Measurements. The differential thermal analysis (DTA) and differential scanning calorimetry (DSC) were carried out by use of a Rigaku Denki thermal analyzer, Model 8002; the particle size of samples was under 200 mesh. Heats of transformation and of melting were measured by DTA method for $Ni(prmgH)_2$, and by the DSC method for the other complexes; potassium nitrate (transformation temperature, 127.9 °C; heat of transformation, ΔH_t, 5.4 kJ mol^{-1})[10] was employed as the standard compound.

The X-ray powder diffractograms were recorded on a Rigaku Denki Geigerflex diffractometer using Co *Kα* radiation. The sample was heated in a furnace constructed in our laboratory: a sample placed in a holder equipped with a thermocouple was heated in a porcelain, cylindrical skeleton wrapped with a nichrome wire; the temperature was controlled by a PID action thermal controller constructed in our laboratory.

The reflectance spectra were recorded on a Shimadzu UV-300 spectrophotometer, by means of an opal glass method.[11]

Results

The complexes subjected to the investigation are listed in Table 1 along with their thermal character. The ^{13}C-NMR measurements suggested the trans-coordination of the two 2,3-alkanedione dioximato ligands in these complexes, like that in the $Ni(emgH)_2$ complex.[5] The complexes remained diamagnetic on raising temperature until their decomposition initiated.

(b) Ni(prmgH)$_2$: 1, form-II; 2, crystal obtained by heating original form-II at 50—100 °C; 3, sample obtained by heating form-II until melting. (c) Ni(hxmgH)$_2$: 1, form-II; 2, form-I obtained by heating form-II at *ca.* 100 °C; 3, sample obtained by heating form-II until melting. (d) Ni(omgH)$_2$: 1, form-II; 2, form-I obtained by heating form-II at *ca.* 100 °C; 3, sample obtained by heating form-II until melting.

Ni(emgH)$_2$. The DTA curve shown in Fig. 1 indicates that the cross-form crystal of Ni(emgH)$_2$ decomposes exothermally at an initial temperature of 251 °C. The blind-form crystal shows an endothermic DTA peak with a maximum at 213 °C, accompanied by no weight-loss, and then it begins to decompose at 250 °C. The crystal obtained after having heated the blind-form crystal at *ca.* 200 °C no longer shows any DTA peak around 213 °C, and it only shows decomposition initiated at 251 °C, like the authentic cross-form. Moreover, its powder X-ray diffractogram closely corresponded to that of the cross-form.[6b)] These facts indicate that the blind-form is irreversibly transformed into the cross-form in the solid state at *ca.* 200 °C, and the DTA peak at 213 °C is due to this transformation. The thermal analysis showed that the cross-form thus

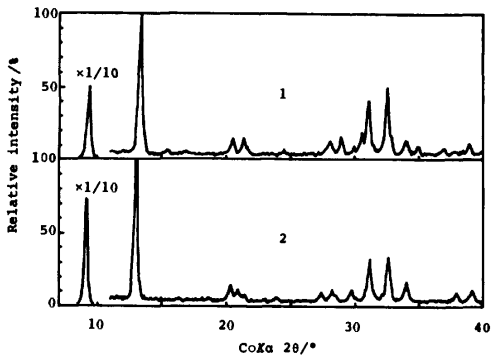

Fig. 2. X-Ray powder diffractograms of Ni(prmgH)$_2$. 1, Form-II; 2, form-I, recorded for form-II at 40 °C.

obtained through the transformation could be reformed as the blind-form by the recrystallization from nitrobenzene solution.

Ni(prmgH)$_2$. As seen in Fig. 1, the crystal of the complex isolated from acetone solution, noted here as form-II, undergoes two endothermic changes, showing DTA peaks with the maxima at 38 and 156 °C; these changes are accompanied by no weight-loss. The peak at 156 °C is due to melting. The crystal initiate decomposition at 210 °C. The crystal obtainable after keeping the form-II crystal at 50—100 °C, still reproduces a DTA curve which corresponds closely to that shown by the original form-II; this is observed to occur repeatedly. Thus, the form-II obviously undergoes reversible transformation to the form-I at 38 °C. As Fig. 2 shows, there is only a little difference in the X-ray diffractograms between form-II and form-I. However, the sample obtained by heating the form-I to melting shows no DTA peak at 38 °C and only shows one due to the melting at 129 °C, lower than that of the original form-I at 156 °C. And its X-ray diffractogram is quite different from those of the form-II and/or -I; this is in line with the above results obtained by DTA.

Ni(hxmgH)$_2$. The DTA curve given in Fig. 1 shows that the crystal obtained from methanol solution, noted as form-II, undergoes two endothermic changes, showing DTA peaks with the maxima at 80 and 148 °C; both changes cause no weight-loss. The peak at 148 °C is due to melting. Its decomposition initiates at 174 °C. The crystal obtained by heating the form-II at 100 °C, denoted as form-I, does not show any DTA

t, Transformation; m, melting; d, decomposition. →, Irreversible; and ⇄, reversible changes. ——, Solid; ……, liquid states. Temperature/°C indicates DTA peak maximum temperature for transformation and melting, and initial temperature for decomposition. ΔH values are given in kJ mol^{-1}; and ΔS, in J K^{-1} mol^{-1}.

peak around 80 °C but shows one at 148 °C. Thus, the transformation from form-II to form-I occurs irreversibly at 80 °C. The comparison of the X-ray diffractograms shown in Fig. 3 implies that the above transformation brought about a marked change in the crystal structure. The sample obtained by heating the form-I to melting at 148 °C undergoes melting at 80 °C, lower than the melting point of the form-I at 148 °C.

Ni(omgH)$_2$. As seen in Fig. 1, the thermal character of the crystal obtained from methanol solution, denoted as form-II, resembles those of the form-II crystals of Ni(prmgH)$_2$ and Ni(hxmgH)$_2$; it transforms into its form-I at 78 °C and then melts at 119 °C. For the crystal obtained after having kept the form-II at 100 °C, the DTA peak due to the transformation is not observed at 78 °C. And for the crystal obtained after having heated the form-II until the melting occurred, no DTA peak due either to transformation or to melting is observed. The change in the X-ray diffractogram caused by the transformation at 78 °C is shown in Fig. 3. It is noticed in this case that, on keeping the form-I crystal at room temperature for two or three days, it comes to show the color and X-ray diffractogram characteristic of the form-II, indicating that the transformation of form-I to form-II takes place slowly.

The form-I crystals of Ni(hxmgH)$_2$ and of Ni(omgH)$_2$ yielded by the transformation are rather poorly shaped crystal, as compared with the form-I crystal of Ni(prmgH)$_2$ or with the cross-form crystal of Ni(emgH)$_2$, yielded by the similar transformation. The transformation in the former two cases tends to be accompanied by the formation of an amorphous complex under the conditions employed. The ΔH_t values, heats of transformation, given in Table 1 for the former two cases may partly include the heat needed for a partial crystal-to-amorphous change.

The crystals of Ni(bmgH)$_2$ and Ni(pnmgH)$_2$ were only observed to melt and then to decompose.

The thermal properties for the complexes which undergo the crystal structure transformation are illustrated in Fig. 4.

Discussion

Crystal Structure Transformation. The structure of

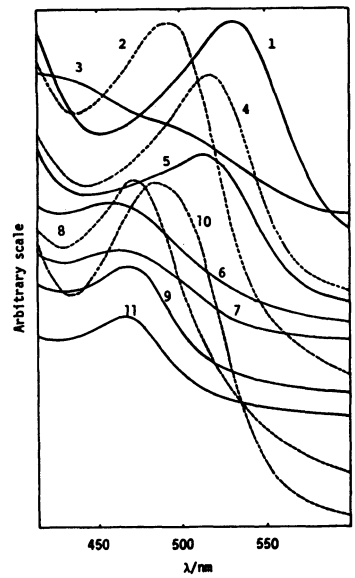

Fig. 5. Reflectance spectra.
1, Ni(dmgH)$_2$; 2, cross-form Ni(emgH)$_2$; 3, blind-form Ni(emgH)$_2$; 4, form-I Ni(prmgH)$_2$; 5, form-II Ni(prmgH)$_2$; 6, Ni(bmgH)$_2$; 7, Ni(pnmgH$_2$); 8, form-I Ni(hxmgH)$_2$; 9, form-II Ni(hxmgH)$_2$; 10, form-I Ni(omgH)$_2$; 11, form-II Ni(omgH)$_2$.

the cross-form crystal of Ni(emgH)$_2$ is similar to that of the cross-form crystal of Ni(dmgH)$_2$; the neighboring Ni atoms in the crystals are 3.44 Å apart for the former and 3.23 Å for the latter.[6b] As seen in Fig. 5, the cross-form Ni(emgH)$_2$ shows the reflectance spectrum with a distinct peak-maximum at 490 nm that may arise from the same origin as the peak at 530 nm observed for Ni(dmgH)$_2$.[12] In the blind-form of Ni(emgH)$_2$, the neighboring Ni atoms in the crystal are separated by a distance of 4.74 Å.[5] This longer Ni–Ni distance, along with the molecular packing in the crystal can hardly indicate the presence of intermetallic Ni–Ni interaction in the blind-form crystal. As Fig. 5 shows, its spectrum

has no clear peak in the visible region.[6b])

It is important that the blind- to cross-form transformation is endothermic with a change of enthalpy $\Delta H_t = 9.1$ kJ mol^{-1}, indicating that thermally the cross-form crystals are less stable than the blind-form crystals. The ΔH_t value is considered to be a measure for the difference in the lattice energy between these two forms; it is found to fall, in fact, in the hydrogen-bond energy range, 4—33 kJ mol^{-1}. Assuming the change in free energy of the transformation to be $\Delta G_t \leqq 0$, change in entropy is calculated to be $\Delta S_t = S_{cross} - S_{blind} \geqq 18.7$ J K^{-1} mol^{-1}. Judging from only the symmetry of the crystal system, the orthorhombic cross-form seems to have less entropy than the monoclinic blind-form. The observed increment in the entropy value caused by the blind- to cross-form transformation could be explained in terms of the change in the density of the crystal, that is, as the transformation progresses, the density 1.58 g cm^{-3} of the blind-form[5] decreases to 1.46 g cm^{-3} of the cross-form crystals.[6]

While the crystal structure of Ni(prmgH)$_2$ has so far not been elucidated,[15] the reflectance spectra of both its form-II and form-I crystals show a peak whose position is close to that of Ni(dmgH)$_2$, as seen in Fig. 5. By comparison of the X-ray data for Ni(prmgH)$_2$ with the ones reported for Ni(dmgH)$_2$,[4] the X-ray diffractions with strong intensity of these form-II and -I crystals could be indexed as those of the orthorhombic system. These suggest that the crystal structure of both forms is similar to that of the cross-form Ni(dmgH)$_2$. This is not inconsistent with the fact that the transformation between the form-II and form-I of Ni(prmgH)$_2$ reversibly took place at the low temperature of 38 °C, with a ΔH_t value as small as 5.3 kJ mol^{-1}. The transformation may include a change not like a molecular displacement but like a small conformational displacement of the propyl groups. Since $\Delta G_t = 0$ in this transformation, the ΔS_t value is calculated to be 17.0 J K^{-1} mol^{-1}, which is smaller than that for Ni(emgH)$_2$.

For Ni(hxmgH)$_2$ and Ni(omgH)$_2$, the ΔH_t values of the form-II to -I transformation are, respectively, 24.4 and 32.6 kJ mol^{-1}, as shown in Table 1 and Fig. 4; these are larger than those for the transformations of Ni(emgH)$_2$ and Ni(prmgH)$_2$. And the ΔH_t value for Ni(hxmgH)$_2$ is as large as its ΔH_m value (heat of melting) and that for Ni(omgH)$_2$ is larger than its ΔH_m value. These ΔH_t values may partly include the heat of the crystal-to-amorphous change. As Fig. 5 shows, the above transformation caused no remarkable change in the position of the visible absorption peaks.

Heat of Fusion. Few investigations have dealt with the characterization of the transition metal complexes by such a value as heat of fusion. The stability of the crystal lattice is considered to be reflected on the heat of fusion, which may be represented by the ΔH_m values obtained here.[14] In the cases of the crystals of Ni(hxmgH)$_2$ and Ni(omgH)$_2$ the form-II to -I transformation occurred with the concomitant crystal-to-amorphous change, which brought about inaccuracy in the ΔH_m values measured with their form-II crystals. In addition, the form-II type crystals in the present series of the complexes were obtainable under the conventional preparative conditions. Therefore, the $\Delta H_t + \Delta H_m$ values of the form-II type crystals will be considered here. As seen in Table 1, the $\Delta H_t + \Delta H_m$ value is the smallest for Ni(bmgH)$_2$. For the complexes with alkyl chains shorter than that of Ni(bmgH)$_2$, the $\Delta H_t + \Delta H_m$ values tend to increase. For Ni(prmgH)$_2$ which has an alkyl chain shorter than that of Ni(bmgH)$_2$, the $\Delta H_t + \Delta H_m$ value is observed to increase again.

Table 1 shows that the crystal having the larger $\Delta H_t + \Delta H_m$ value shows a peak maximum at a higher energy site. From the preliminary result of the X-ray crystallographic investigation on the Ni(prmgH)$_2$ (form-II crystal),[15] the crystal structure may be expected to be similar to that of Ni(dmgH)$_2$ (cross-form),[4] wherein the complex molecules are stacked face to face. This similarity in the molecular array of the crystal is thought to be reflected in the appearance of the peak in the visible reflectance spectrum, as shown in Fig. 2 and Table 1. In fact, the blind-form crystal of Ni(emgH)$_2$ shows no peak.

Studies of Inorganic Ion Exchangers. VI.[1] The Formation Region and Dehydration Behavior of Various Titanium(IV) Bis(hydrogenorthophosphate) Hydrates

Etsuro KOBAYASHI and Shinsuke YAMAZAKI
National Chemical Laboratory for Industry, Yatabemachi, Tsukuba-gun, Ibaraki 305
(Received August 13, 1982)

The formation region, dehydration behavior, and lattice constants of various types of titanium(IV) bis(hydrogenorthophosphate) hydrates were investigated. α-$Ti(HPO_4)_2 \cdot H_2O$ was formed by refluxing an amorphous titanium phosphate (ATP) with H_3PO_4 at 110—165 °C or by treating it with H_3PO_4 (up to 11.5 mol dm^{-3}) under hydrothermal conditions at temperatures up to 250 °C. (β-γ)-$Ti(HPO_4)_2 \cdot xH_2O$ was obtained by refluxing ATP with H_3PO_4 (15—16 mol dm^{-3}) above 165 °C. γ-$Ti(HPO_4)_2 \cdot 2H_2O$ was formed by a hydrothermal reaction of ATP and H_3PO_4 (10—16 mol dm^{-3}) at 200—300 °C. In the thermal analysis of $Ti(HPO_4)_2$, no difference in weight loss was found at temperatures up to 920 °C of α-form irrespective of the drying conditions of the samples. The (β-γ)-form dried under reduced pressure over P_2O_5 had a composition corresponding to that of a 1/2 hydrate. The γ-form dried at a relative humidity of 75% had a composition identical to that of the dihydrate. In view of the X-ray diffraction, it seemed that the (β-γ)-form (11.6 and 9.2 Å) was changed by drying under reduced pressure over P_2O_5 to the β-form (9.2 Å) as anhydride. The γ-form (11.6 Å) was dehydrated to the β-form by heating. The change in the inter-layer distance upon dehydration was also confirmed by means of a that of the electron diffraction. Thus, it was considered that the (β-γ)-form was a mixture as a quasi stable form.

Various types of titanium(IV) bis(hydrogenorthophosphate) hydrates have been synthesized by refluxing amorophous titanium phosphate with phosphoric acid, and their peculiar ion-exchangeability has been investigated.[1-5] α-$Ti(HPO_4)_2 \cdot H_2O$[6] was formed at phos phoric acid concentrations of 13—62%, while $Ti(HPO_4)_2 \cdot 0$—1/2 H_2O was obtained at 64% or higher.[2,3] Alluli *et al.*[7] synthesized $Ti(HPO_4)_2 \cdot 2H_2O$ by heating amorphous titanium phosphate with 10 mol dm^{-3} of phosphoric acid at temperatures of 200 °C or higher in a sealed tube. They suggested that the crystal structure of this compound was not identical with that of α-$Ti(HPO_4)_2 \cdot H_2O$, but similar to that of γ-$Zr(HPO_4)_2 \cdot 2H_2O$.

In the present study, crystalline titanium phosphates are synthesized by refluxing and by hydrothermal reactions, and the formation regions of the individual modifications are determined.

Experimental

Preparation of Crystalline Titanium(IV) Bis(hydrogenorthophosphate). Refluxing Method: The preparation of $Ti(HPO_4)_2 \cdot xH_2O$ by refluxing phosphoric acid with amorphous titanium phosphate was carried out by the method previously reported.[2,3] The products were dried by storing them in a desiccator charged with a saturated aqueous solution of urea (75—78% in relative humidity at room temperature).

Hydrothermal Reaction Method: One gram of amorphous titanium phosphate was sealed with 10 cm^3 of phosphoric acid (10—16 mol dm^{-3}) in a 20-cm^3 hard glass tube, after the tube was placed in a 200-cm^3 stainless steel autoclave with 80 cm^3 of water to prevent its rupture. The autoclave was then heated at 140—300 °C. The products in the tubes were separated from the mother liquors, washed with water, and then dried at a relative humidity of 75—78%.

Analyses: The chemical analyses of the product were carried out by the method previously reported.[2] The X-ray diffraction was performed with Ni-filtered Cu *Ka* radiation (30 kV P, 20 mA). The thermal analysis was carried out with a microthermal analyzer at a heating rate of 10 °C/min.

Electron Diffraction: The electron diffraction was performed with the aid of a Hitachi HU-12A electron microscope equipped with a standard cooling holder, HC-4. Selected area diffraction patterns were measured at 100 kV.

Results and Discussion

Formation of Various Titanium(IV) Bis(hydrogenorthophosphate). The conditions for the synthesis of $Ti(HPO_4)_2 \cdot xH_2O$ by the reaction of amorphous titanium phosphate with phosphoric acid and the analytical data of the products are shown in Table 1.

Chemical Analysis and X-Ray Diffraction: In No. 1 of Table 1, α-titanium(IV) bis(hydrogenorthophosphate) monohydrate was produced by refluxing amorphous titanium phosphate with phosphoric acid at 140°C. This product was already known to have an interlayer distance of 7.6 Å[7] (Å=10^{-10} m). In Nos. 2—4, the drying conditions for the products obtained by refluxing amorphous titanium phosphate with phosphoric acid of high concentrations were different from that established hitherto, so the products gave analytical data corresponding to those of the 1/2—1 hydrate. In the X-ray diffraction diagram, the products are shown to have interlayer distances of 11.6 and 9.2 Å. When we prepared this product for the first time, we gave it the chemical formulas of $Ti(HPO_4)_2 \cdot 1/2\,H_2O$[2] and also $Ti(HPO_4)_2 \cdot 0$—$1/2H_2O$.[3] In the present study, however, this product gave, as has been described above, values of 1/2—1 hydrate. Accordingly, we will now designate as (β-γ)-$Ti(HPO_4)_2 \cdot xH_2O$ the product shown in the past as $Ti(HPO_4)_2 \cdot 0$—$1/2H_2O$.

In Nos. 5—7, hydrothermal reactions between amorphous titanium phosphate and phosphoric acid having various concentrations were carried out at 175 °C. α-$Ti(HPO_4)_2 \cdot H_2O$ was formed at H_3PO_4 concentrations of 10 and 14.4 mol dm^{-3}. However, a mixture of the α- and γ-forms was formed at a H_3PO_4 concentration of 16 mol dm^{-3}.

In Nos. 8—10, when the hydrothermal reaction was

a) ATP: Amorphous titanium phosphate. b) REF: Refluxing method, HTR: hydrothermal reaction method.
c) The products are stored for one week in a desiccator with a relative humidity of 75% and then analyzed.

carried out at 200 °C, the product was gradually converted from the α-form to the γ-form *via* a mixture of the α- and γ-forms due to the increasing concentration of H_3PO_4. In Nos. 11—13, the hydrothermal reaction was carried out at 250 °C. The α-form was formed at a H_3PO_4 concentration of 10 mol dm^{-3}, but the γ-form was formed at 14.4 mol dm^{-3}. The hydrothermal reaction was carried out at 280 °C in No. 14 and at 300 °C in Nos. 15—17. At such an elevated temperature, γ-$Ti(HPO_4)_2 \cdot 2H_2O$ was formed at a H_3PO_4 concentration of 10 mol dm^{-3} or higher.

The Formation Regions of Various Titanium(IV) Bis-(hydrogenorthophosphate) Hydrates: The formation regions of various titanium(IV) bis(hydrogenorthophosphate) are shown in Fig. 1.

The curve AB shows the relation between the temperature of phosphoric acid and its concentration. The solid phase formed under the reaction conditions on the curve AB was α-$Ti(HPO_4)_2 \cdot H_2O$. At higher phosphoric acid concentrations, $(\beta\text{-}\gamma)$-$Ti(HPO_4)_2 \cdot xH_2O$ was formed as the solid phase at a refluxing temperature of 165 °C or higher. The conditions for forming this product are shown by a dotted line (BC) as an extension of the solid line (AB). The regions of the formation of the α- and γ-forms by the hydrothermal reaction are separated by a curve MN. A mixture of the α- and γ-forms was formed in the vicinity of the curve.

Water of Crystallization of Various Titanium(IV) Bis-(hydrogenorthophosphate) Hydrates: Table 1 shows the percentages of H_2O calculated from the weight loss at 700 °C of the reaction product stored in a desiccator at a relative humidity of 75—78%. As the water content varies according to the degree of drying, the DTA and TG of α-, $(\beta\text{-}\gamma)$-, and γ-titanium(IV) bis-(hydrogenorthophosphate) differed in drying conditions,

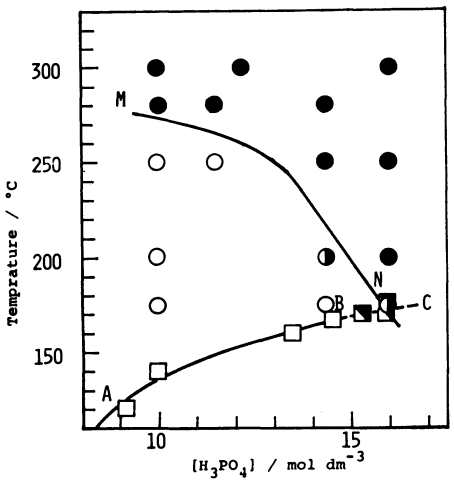

Fig. 1. Formation region of titanium(IV) bis(hydrogenorthorhosphate).
○, ◥: α-$Ti(HPO_4)_2 \cdot H_2O$, □ $(\beta\text{-}\gamma)$ $Ti(HPO_4)_2 \cdot xH_2O$, ◑: $\alpha+\gamma$-$Ti(HPO_4)_2 \cdot 1$—$2\,H_2O$, ●: γ-$Ti(HPO_4)_2 \cdot 2H_2O$. Reflux is indicated with square signs. Hydrothermal reaction is indicated with circular signs.

as Figs. 2, 3, and 4 show.

α-$Ti(HPO_4)_2 \cdot H_2O$: In the DTA curve of Fig. 2, the broad endothermic peak appearing at temperatures below 100 °C is caused by the dehydration of free water attached to the sample. The endothermic peaks at 260 and 510 °C are due to the liberation of the water of crystallization and condensation. The weight losses at 200 °C of the samples dried at relative humidities of 100 and 75% and under reduced pressure over P_2O_5 were as small as 2.0, 0.9, and 0.8% respectively, thus

permitting the assumption that the water of crystallization of α-$Ti(HPO_4)_2 \cdot H_2O$ is strongly combined with the salt. The weight losses of the individual samples by heating up to 900 °C were 15.0, 14.2, and 13.3% respectively. These values approximately equal a theoretical value of 13.9 (%) ($2H_2O/\alpha$-$Ti(HPO_4)_2 \cdot H_2O \times 100$).

(β-γ)-$Ti(HPO_4)_2 \cdot xH_2O$: In the DTA curve of Fig. 3, a big endothermic peak resulting from dehydration appears at about 100 °C. Two small endothermic peaks resulting from condensation appear at 370 and 464 °C. In the TG curve of Fig. 3, the weight losses at 200 °C of the samples dried at relative humidities of 100 and 75% and under reduced pressure over P_2O_5 were 8.5, 7.0, and 3.0% respectively. These values were extremely large as compared with those of the above described α-$Ti(HPO_4)_2 \cdot H_2O$. In the case of (β-γ)-$Ti(HPO_4)_2 \cdot xH_2O$, the interlayer distance was so great that the water contained therein was easily eliminated by heating at a relatively low temperature. The weight losses at 920 °C of (β-γ)-$Ti(HPO_4)_2 \cdot xH_2O$ dried at relative humidities of 100 and 75% and under reduced pressure over P_2O_5 were 15.5, 12.5, and 10.4% respectively. Only the weight loss of the sample which had been dried under reduced pressure over P_2O_5 agreed with the calculated value of 10.86 (%) ($1.5\ H_2O/Ti(HPO_4)_2 \cdot 1/2\ H_2O \times 100$).

γ-$Ti(HPO_4)_2 \cdot 2H_2O$: Allulli *et al.*[7] measured the TG of titanium(IV) bis(hydrogenorthophosphate), which was regarded identical with the γ-form, and gave this compound the chemical formula of $Ti(HPO_4)_2 \cdot 2H_2O$. In the DTA curve of Fig. 4, a slightly branched endothermic peak by dehydration appears at about 100 °C, while endothermic peaks by condensation appear at 390 and 498 °C, in a tendency similar to that of the DTA curve of the (β-γ)-form. In the TG curve of Fig. 4, the weight losses at 200 °C of the samples dried at relative humidities of 100 and 75% and under reduced pressure over P_2O_5 were 13.6, 12.0, and 2.4% respectively. A substantial part of the water of crystallization in each sample was released up to the above temperature. The weight loss at 920 °C of only the sample dried at a relative humidity of 75% was in agreement with the calculated value of 19.6 (%) ($3H_2O/Ti(HPO_4)_2 \cdot 2H_2O \times 100$).

Change in the Interlayer Distance of (β-γ)- and γ-Titanium-(IV) Bis(hydrogenorthophosphate). Clearfield *et al.*,[8] who first synthesized γ-$Zr(HPO_4)_2 \cdot 2H_2O$ with an interlayer distance of 12.2 Å, obtained β-$Zr(HPO_4)_2$ with an interlayer distance of 9.4 Å by drying the γ-form under reduced pressure over anhydrous calcium sulfate for several weeks at room temperature. In the present studies, we have confirmed whether or not the interlayer distance of titanium(IV) bis(hydrogenorthophosphate) is also changed by drying.

In the case of α-$Ti(HPO_4)_2 \cdot H_2O$, the interlayer distance (7.6 Å) of the samples was not changed by the drying conditions.

(β-γ)-$Ti(HPO_4)_2 \cdot xH_2O$ synthesized by the refluxing method had a composition of approximately 0.7 hydrate at a relative humidity of 75%, and it showed X-ray diffraction peaks at 11.6 and 9.2 Å. The occurrence

of these two peaks is suggestive of the coexistence of the γ-form with an interlayer distance of 11.6 Å and the β-form with that of 9.2 Å. It is of interest that, when this sample was dried under reduced pressure over P_2O_5, the diffraction peak of the γ-form entirely disappeared, while the diffraction peak of the β-form alone appeaed. This compound can be converted reversible into, the γ-form by the absorption of water and into the β-form by releasing the water.

γ-$Ti(HPO_4)_2 \cdot 2H_2O$ synthesized by the hydrothermal reaction method had a composition corresponding exactly to that of the dihydrate at a relative humidity of 75%, and it showed an intensive diffraction peak at 11.6 Å. When the sample was dried under reduced pressure over P_2O_5, this peak was reduced in intensity, but a diffraction peak at 9.2 Å which characterized the β-form as anhydrous salt did not appear. When the water of crystallization was entirely eliminated from the sample by drying it further under heating (120 °C), the γ-form was converted into the β-form; the latter, however, tended to be converted reversibly into the γ-form by absorption of moisture in the air.

Lattice Constants. *α-$Ti(HPO_4)_2 \cdot H_2O$*: The indices of each lattice of α-$Ti(HPO_4) \cdot {}_2H_2O$ and the calculated values of the corresponding spacing are shown in (1) and (3) of Table 2. The patterns of this crystal may be indexed by assuming an monoclinic unit cell with dimensions of a=8.95 Å, b=5.24 Å, c=15.97

Å, and $\beta=107.45°$. The calculated spacings, "d_{calcd}" were almost entirely consistent with those measured by the selected-area electron diffraction. The results of the calculation are shown in Table 2.

γ-Ti(HPO$_4$)$_2$·2H$_2$O: When the crystals of γ-Ti(HPO$_4$)$_2$·2H$_2$O under cooling below -150 °C with liquid nitrogen, were subjected to selected-area electron diffraction, interlayer water was not released; the crystal structure of the γ-form was also retained.

The values of spacing obtained from the electron-diffraction patterns are shown in Table 2(9). The index of the crystal face and the spacing of γ-Ti(HPO$_4$)$_2$·2H$_2$O were calculated using the lattice constants estimated from the peak values in powder X-ray diffraction and from electron-diffraction net patterns. The values of the spacing are shown in Table 2(10). These values (10) are in agreement with the values (9) obtained from the electron-diffraction patterns, if the axes *a*, *b*, and *c* are 5.29, 6.44, and 23.94 Å, and if the angle β is 103.9°.

β-Ti(HPO$_4$)$_2$: When γ-Ti(HPO$_4$)$_2$·2H$_2$O was irradiated with an electron beam under a high vacuum in the column of an electron microscope, the water of crystallization between the layers was released; the γ-form (dihydrate) was, therefore, converted into the β-form (anhydrate). The values of the lattice constant and of the face index, as determined by the electron-diffraction net patterns are shown in Table 2.

In comparing the lattice constants of β-Ti(HPO$_4$)$_2$ with these of γ-Ti(HPO$_4$)$_2$·2H$_2$O, the a and b axes were found to be almost equal in length in the two forms, while the c axis was 23.9 Å in the γ-form, but as short as 18.7 Å in the β-form. In view of this fact, the β-form was converted from the γ-form when the interlayer water of the γ-form was eliminated from the crystal.

Electron Diffraction of (β-γ)-Ti(HPO$_4$)$_2$·xH$_2$O: To confirm (β-γ)-Ti(HPO$_4$)$_2$·xH$_2$O as a mixture of the β- and γ-form in a quasi-stable form, we observed the electron-diffraction patterns of this compound when the water of crystallization had been eliminated by elevating the temperature by means of irradiation with an electron beam. Table 2(8) shows the measured values of the spacing obtained from the electron-diffraction patterns of the (β-γ)-from. These values were in good agreement with the values of the electron diffraction of the β-form alone, as is shown in Table 2(5). This result apparently shows that a mixture of β-Ti(HPO$_4$)$_2$ and γ-Ti(HPO$_4$)$_2$·2H$_2$O crystals was dehydrated and converted to the β-form.

The Crystal Structure of Bis(2,2′-bipyridine)-*catena*-μ-tetrafluoroborato-copper(II) Tetrafluoroborate

Hisayoshi Nakai

Department of Chemistry, Hyogo College of Medicine, Mukogawa-cho, Nishinomiya, Hyogo 663

(Received September 13, 1982)

The crystal structure of the title compound was determined by means of the X-ray diffraction technique. The crystal is triclinic, space group $P\bar{1}$, $a=11.288(8)$, $b=15.186(17)$, $c=7.368(4)$ Å, $\alpha=74.93(3)$, $\beta=78.23(3)$, $\gamma=65.92(3)°$, and $Z=2$. The structure was solved by the heavy-atom method and refined by the least-squares method to $R=0.068$ for 3678 non-zero reflections. The crystal is composed of BF_4^- ions and polymeric chains of $[Cu(BF_4)(bpy)_2^+]$ in which a tetrafluoroborate ion bridges two adjacent copper atoms through its two fluorine atoms. The coordination polyhedron around the copper atom is a tetragonally distorted octahedron; the four nitrogen atoms of bipyridine molecules in the equatorial plane are arranged in a flattened tetrahedral manner (average Cu–N = 1.99 Å) and the two axial Cu–F distances are 2.566(6) and 2.662(4) Å. In both bipyridine molecules, the two pyridine rings are twisted slightly from each other; the interplanar angle is 3.1° in one bipyridine ligand and 10.2° in the other.

Since the crystal structure of $[CuI(bpy)_2]I$ was reported in 1963,[1] bis(bipyridine)copper(II) complexes have attracted much attention because of the diversity of their stereochemistry. They have been shown to take various stereochemistries such as distorted trigonal bipyramid,[1-3] distorted square pyramid,[4-6] and *cis*- and *trans*-distorted octahedra.[7-10,22] Recently, some attempts to understand such changes in coordination geometry have been made.[4-5]

In this paper, as a part of our structural study on bis(bipyridine)copper(II) complexes, the crystal structure of $[Cu(BF_4)(bpy)_2]BF_4$ will be reported and the structures of some bis(bipyridine)copper(II) complexes will be discussed in terms of the sense of distortion illustrated in Fig. 3.

Experimental

Blue crystals of $[Cu(BF_4)(bpy)_2]BF_4$ were prepared by adding a methanol solution of 2,2′-bipyridine (20 mmol in 30 cm^3 of the solvent) to an aqueous solution of copper(II) tetrafluoroborate (10 mmol in 30 cm^3 of water), and were recrystallized from a water–methanol mixture. Found: C, 43.53; H, 2.99; N, 10.19%. Calcd for $Cu(bpy)_2(BF_4)_2$: C, 43.72; H, 2.93; N, 10.20%.

Preliminary X-ray photographs taken with Cu $K\alpha$ radiation showed $\bar{1}$ Laue symmetry, indicating a triclinic space group. No systematic absences were observed. The space group $P\bar{1}$ was confirmed by a successful refinement of the structure.

A crystal was shaped into a sphere 0.30 mm in diameter and used for data collection. The lattice constants were determined by a least-squares fit using 45 independent θ-values measured accurately on a diffractometer. Crystal data: $[Cu(BF_4)(bpy)_2]BF_4$, $M.W.=549.5$, triclinic, space group $P\bar{1}$, $a=11.288(8)$, $b=15.186(17)$, $c=7.368(4)$ Å, $\alpha=74.93(3)$, $\beta=78.23(3)$, $\gamma=65.92(3)°$, $U=1106.5$ Å^3, $Z=2$, $D_c=1.65$, $D_m=1.65$ g cm^{-3} (by flotation in a benzene–bromoform mixture), Mo $K\alpha$ radiation ($\lambda=0.71069$ Å), μ(Mo $K\alpha$) = 10.7 cm^{-1}.

Intensity data with $2\theta \leqq 55°$ were collected at room temperature by means of the ω-2θ scan techniques on a Philips PW1100 four-circle diffractometer using graphite-monochromated Mo $K\alpha$ radiation. The scan speed and scan width were 0.033° s^{-1} and $(1.00+0.20\tan\theta)°$ respectively. Background counts were measured for scantime/2 at each side of the scan range. A total of 5125 reflections having $I_t - 2\sqrt{I_t} > I_b$ were collected; I_t is the intensity (counts/s) measured at the top of the peak, while I_b is the mean background measurement for 5 s at each side of the peak, but 3678 reflections for which $F_o^2 > 2\sigma(F_o^2)$ were used in the structure analysis. Intensity data were corrected for the Lp factor[11] but not for absorption.

Structure Determination

The structure was solved by the heavy-atom method. The positions of the copper atoms were determined from a three-dimensional Patterson map; all the other non-hydrogen atoms were successively located by means of Fourier syntheses. The positional and thermal parameters were refined by the use of the block-diagonal least-squares method. The minimized function was $\sum w(F_o - |F_c|)^2$. A weighting scheme of the type suggested by Hughes[12] was applied using $w=1.0$ for $F_o \leqq 120.0$ and $w=(120.0/F_o)^2$ for $F_o > 120.0$. The atomic scattering factors were taken from Ref. 13. The positions of hydrogen atoms were obtained from a difference Fourier synthesis. These hydrogen atoms were included in the final refinement with isotropic thermal parameter of 4.0 Å^2. In the final cycle of the refinement, all the parameter shifts were less than one-third of the corresponding standard deviations. The final R value was 0.068 for 3678 non-zero reflections. The final atomic parameters are summarized in Tables 1 and 2 with averaged isotropic temperature factors. The anisotropic thermal parameters for non-hydrogen atoms and complete lists of the F_o and $|F_c|$ values have been preserved by the Chemical Society of Japan (Document No. 8320). All computations were carried out on an ACOS 700S computer at the Crystallographic Research Center, Institute for Protein Research, Osaka University. The computer programs used in the calculation were as follows: HBLS-V[14] (least-squares calculation), RSSFR-5[15] (Fourier synthesis), and DAPH[14] (interatomic distances and coordinates of the H atoms).

Results and Discussion

The crystal structure of $[Cu(BF_4)(bpy)_2]BF_4$ consists of tetrafluoroborate ions and polymeric chains of $[Cu(BF_4)(bpy)_2^+]$ approximately parallel to the c axis, in which $Cu(bpy)_2$-moieties are bridged by tetrafluoro-

borate ligands through the F atoms, as shown in Figs. 1 and 2. The bond lengths and angles with their estimated standard deviations are given in Table 3.

In the complex cation, the coordination polyhedron around the copper atom is a distorted *trans*-octahedron, in which four N atoms of the two bpy chelates form an equatorial plane (mean Cu–N=1.99 Å) and two F atoms of bridging BF_4^- ions occupy the axial positions (Cu–F(1)=2.566(6) Å and Cu–F(2)=2.662(4) Å). Although the four N atoms are arranged around the copper atom in a flattened tetrahedral manner, the copper atom lies almost on the least-squares plane defined by these nitrogen atoms (Table 5). Such a tetrahedral distortion of planar $Cu(bpy)_2$-moiety is now well-known to be due to the steric repulsions between the hydrogen atoms on 6- and 6′-carbon atoms of the bpy chelates. The dihedral angle between the (N(1)–Cu–N(2)) and (N(3)–Cu–N(4)) planes is 36.1°. Analogous stereochemistries have been found in $[Cu(ClO_4)(bpy)_2]ClO_4$[8]

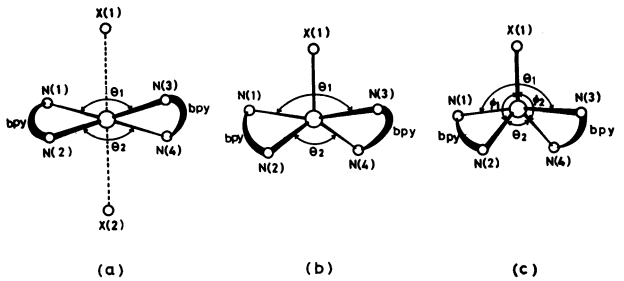

Fig. 3. Structures of bis(bipyridine)copper(II) complexes and their numbering schemes. (a): Distorted *trans*-octahedral structure ((1)—(4) complexes in Table 4), (b): five-coordinate structure with $\theta_1<180°$ ((5)—(8) complexes in Table 4), (c): five-coordinate structure with $\theta_1>180°$ ((9)—(15) complexes in Table 4).

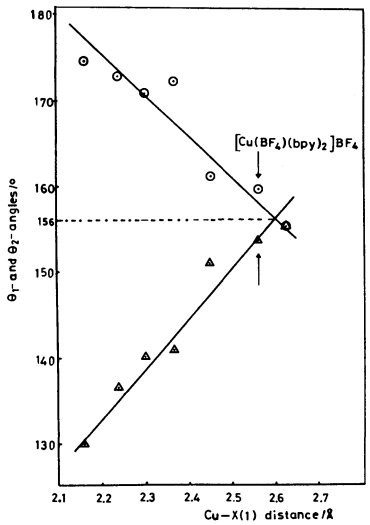

Fig. 4. Correlation between the Cu–X(1) distances (X= O or F) and the angles of θ_1 (⊙) and θ_2 (△) in the (2)—(8) complexes of Table 4. The values denoted by ⊙ and △ line up from right to left in numerical order respectively.

and $[CuX(bpy)_2]$ (X=S_3O_6[9] and S_4O_6[10]).

For comparison, the main bond lengths and angles around the copper atom are given in Table 4; those for $[Cu(S_3O_6)(bpy)_2]$ have not yet been reported in detail. In three *trans*-octahedral complexes (except $[Cu(S_3O_6)(bpy)_2]$), it is very interesting that as the axial Cu–X(1) distances (X=O or F) decrease from 2.627(6) Å in $[Cu(S_4O_6)(bpy)_2]$[10] to 2.566(6) Å in the present complex and to 2.45(2) Å in $[Cu(ClO_4)(bpy)_2]ClO_4$,[8] the θ_1-angles increase from 155.2° to 161.1(8)° and the θ_2-angles decrease from 155.2° to 151.0(7)° systematically. On the other hand, the distances between the X(1) and the N(1) (or N(3)) atoms in those complexes are 2.91, 2.949(8), and 2.79(3) Å respectively; these values are approximately equal to the sum of the van der Waals radii of O(or F) and N atoms. These prove that the enlargement of the θ_1-value with the decrease of the Cu–X(1) distance is due to the steric interference between the X(1) atom and the atoms of N(1) and N(3) in the flattened tetrahedral $Cu(bpy)_2$-moiety. Similar correlations between the Cu–O(1) distances and the

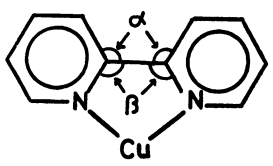
angles of θ_1 and θ_2 have also been found in $[CuN_4O]$-chromophores of bis(bipyridine)copper(II) complexes, having θ_1-values<180° (Table 4). The plots of the θ_1- and θ_2-angles against the Cu–X(1) distances (X=O or F) in the complexes mentioned above are shown in Fig. 4 and have been found to be linear. As a result, the θ_1-angle is expected to become 180° when the Cu–X-(1) distance is about 2.1 Å; on the other hand, in the complexes of (9)—(15) of Table 4 with Cu–X(1) distances(X=N or O)<2.1 Å and θ_1-angles>180°, a great lengthening has been observed in the Cu–N(4) distance from 2.1 Å to 2.2 Å, and, as has been suggested by Hathaway,[2,6] the angle of X(1)–Cu–N(2) (=ϕ_1 in Fig. 3), which is opposite the Cu–N(4) bond, is considered to play an important role in the decision of their stereochemistries.

The bipyridine ligands are not planar, but the pyridine rings are planar within ±0.023 Å. The pyridine rings of the bipyridine molecule are slightly twisted from each other about the 2,2′-carbon bond; the twist angle is 3.1° for the molecule comprising N(1) and N(2) and 10.2° for the other, values of which are in the range of 0.1—13° reported previously.[5,8] Furthermore, the bond angle of α is larger than that of β by 7.9—9.2°. A



similar difference in these angles (5—10°) has also been observed in the crystal structure of the 2,2′-bipyridine molecule[18] and its copper(II) complexes.[8] Bond lengths and angles in bipyridine ligands are in good agreement with the previously reported ones.[4]

The B–F bond lengths and F–B–F angles of bridging BF_4^- ions are in the range of 1.359(9)—1.394(9) Å and 108.1(6)—110.8(6)° respectively, while those of the uncoordinating BF_4^- anions are less accurate and can not be discussed in detail because of the distorted arrangement in the crystal. The closest approach of the uncoordinating BF_4^- ion to the bipyridine ligand is 3.23(2) Å, between the F(22) and C(3)[$1-x$, $1-y$, $1-z$] positions.

The author is very grateful to Professor Yukinao Noda for his kind advice and encouragement throughout the present work. The author is also grateful to Professor Emeritus Hisao Kuroya and Professor Shun'ichiro Ooi of Osaka City University for their valuable discussions, and to Dr. Keiji Matsumoto, Osaka City University, for the use of a Philips PW1100 diffractometer.

Noncovalent Interactions in Metal Complexes. VI.[1] Bonding Interaction between Chelate π-System and Menthyl Group in Copper(II), Nickel(II), and Palladium(II) Complexes of 1-*l*-Menthyloxy-3-benzoylacetone

Michio NAKAMURA, Hisashi ŌKAWA,* and Sigeo KIDA
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812
(Received December 6, 1982)

Metal complexes, M(*l*-moba)$_2$(H$_2$O)$_n$ (M=Cu(II), n=0; Ni(II), n=2; Pd(II), n=0) and M(bpy)(*l*-moba)ClO$_4$ (M=Cu(II), Pd(II)), where H(*l*-moba) denotes 1-*l*-menthyloxy-3-benzoylacetone, have been synthesized and characterized by means of elemental analyses, NMR spectra, electronic spectra, and circular dichroism spectra. In the NMR spectra of H(*l*-moba), Pd(*l*-moba)$_2$, and Pd(bpy)(*l*-moba)ClO$_4$, the methylene protons adjacent to the *l*-menthyloxy group were observed as AB quartet. The chloroform solutions of Cu(*l*-moba)$_2$ and Cu(bpy)(*l*-moba)ClO$_4$ showed a positive CD band at 15500 and 16200 cm^{-1}, respectively. The chloroform solution of Ni(*l*-moba)$_2$(H$_2$O)$_2$ also showed a weak, positive CD band near 16000 cm^{-1}. When pyridine or *t*-butylamine was added to the chloroform solution of Cu(*l*-moba)$_2$, a negative CD appeared around 17000 cm^{-1} attributable to the five-coordinate species Cu(*l*-moba)$_2$B. On the other hand, with adding an amine to the chloroform solution of Ni(*l*-moba)$_2$(H$_2$O)$_2$, the 16000 cm^{-1} CD band decreased its intensity and finally disappeared. Similar trend was observed when alcohol, DMSO, or DMF was added to the chloroform solution of Ni(*l*-moba)$_2$(H$_2$O)$_2$. NMR and CD spectral results have been rationalized by assuming that the *l*-menthyl group interacts with the chelate ring of *l*-moba$^-$ and this interaction gives rise to a chirality around the metal ion.

Inter-ligand, noncovalent interactions which cause stereoselectivity and stereospecificity in metal complexes are of current interest, because of their importance in biological processes involving metal ion.[2-6] Recently we reported[2] that tris(1-*l*-menthyloxy-3-benzoylacetonato)M(III) complexes, M(*l*-moba)$_3$ (M=Co, Cr, and Mn), prefer the *cis*-Δ-configuration, and this was attributed to an inter-ligand CH/π-interaction between the *l*-menthyl group of the ligand and the phenyl group of the neighbouring ligand in the molecule; on the other hand, no CD induction was observed in the cases of Cu(*l*-moba)$_2$, Ni(*l*-moba)$_2$(H$_2$O)$_2$, Co(*l*-moba)$_2$(H$_2$O)$_2$, and Mn(*l*-moba)$_2$(H$_2$O)$_2$.

In this study, the CD spectra of Cu(*l*-moba)$_2$ and Ni(*l*-moba)$_2$(H$_2$O)$_2$ were reexamined in a highly concentrated chloroform solution, and it was noticed that these complexes show a weak CD band in the d-d band region. It is known that Cu(*l*-moba)$_2$ and Ni(*l*-moba)$_2$(H$_2$O)$_2$ take a square planar and a *trans*-octahedral configuration, respectively.[2] In these configurations, the phenyl group of the ligand is considerably separated from the *l*-menthyl group of the other ligand,and hence it is unlikely that there operates an inter-ligand, CH/π-interaction between these two groups. In this study, new metal complexes, Pd(*l*-moba)$_2$ and M(bpy)(*l*-moba)ClO$_4$ (M=Cu(II), Pd(II)), were prepared and the configurations of the complexes including Cu(*l*-moba)$_2$ and Ni(*l*-moba)$_2$(H$_2$O)$_2$ were examined by means of NMR, electronic absorption, and circular dichroism spectra, in a hope to clarify the mechanism how the *l*-menthyl group of the ligand invokes a chirality around the central metal ion.

Experimental

Preparations. Synthetic methods of H(*l*-moba) and its nickel(II) and copper(II) complexes, Ni(*l*-moba)$_2$(H$_2$O)$_2$ and Cu(*l*-moba)$_2$, are described in the preceding paper.[2] Benzyl *l*-menthyloxyacetate was synthesized by the reaction of *l*-menthyloxyacetyl chloride[7] and benzyl alcohol, in a similar way to that for ethyl *l*-menthyloxyacetate.

1-Ethoxy-3-benzoylacetone (Heoba). This was prepared from ethyl ethoxyacetate and acetophenone by a method similar to that for H(*l*-moba). It was isolated and purified as nickel(II) complex Ni(eoba)$_2$(CH$_3$OH)$_2$.

Found: C, 58.55; H, 6.47%. Calcd for C$_{26}$H$_{34}$O$_8$Ni: C, 58.56; H, 6.43%.

The free ligand was obtained as follows. The nickel complex (2 g) was dissolved in ether (100 cm^3). To this was added 20% sulfuric acid (100 cm^3) and the mixture was vigorously shaken. The ether layer was separated, shaken twice with saturated sodium hydrogencarbonate solution and then twice with water, and dried over sodium sulfate. Evaporation of the solvent left Heoba as a colorless liquid.

Pd(l-moba)$_2$. Palladium chloride (0.2 g, 1.12 mmol) and ammonium chloride (0.12 g, 2.24 mmol) were added to methanol (30 cm^3), and the mixture was vigorously stirred for 2 h to give a brown solution. To this was added dropwise a methanol solution of H(*l*-moba) (0.71 g, 2.24 mmol) and KOH (0.13 g, 2.24 mmol). A cream yellow precipitate thus obtained was collected and recrystallized from methanol.

Found: C, 64.92; H, 7.35%. Calcd for C$_{40}$H$_{54}$O$_6$Pd: C, 65.17; H, 7.38%.

Cu(bpy)(l-moba)ClO$_4$·2H$_2$O. A solution of Cu(bpy)$_2$(ClO$_4$)$_2$ (0.08 g, 0.14 mmol) and Cu(*l*-moba)$_2$ (0.1 g, 0.14 mmol) in methanol (100 cm^3) was heated for an hour. The reaction mixture was concentrated to 20 cm^3 and water was added drop by drop to this mixture to give a green precipitate. It was collected and recrystallized from methanol–water as green crystals. The product appeared to be pure crystals under a microscope observation.

Found: C, 53.17; H, 5.90; N, 4.02%. Calcd for C$_{30}$H$_{39}$N$_2$O$_9$ClCu: C, 53.72; H, 5.86; N, 4.18%.

Pd(bpy)(l-moba)ClO$_4$. To a suspension of Pd(bpy)$_2$Cl$_2$[8] (0.3 g, 1.7 mmol) in methanol (30 cm^3) was added a solution of H(*l*-moba) (0.29 g, 0.9 mmol) and KOH (0.05 g, 0.9 mmol) in methanol (10 cm^3), and the mixture was stirred for 1 h. To this reaction mixture was added a solution of AgClO$_4$ (0.38 g) in methanol to yield a precipitate of AgCl, which was separated by filtration. The filtrate was further

stirred for additional 2 h and was filtered. The filtrate was concentrated to 10 cm^3. When water was added drop by drop to the solution, a yellow precipitate was separated. It was collected and dried *in vacuo* over diphosphorus pentaoxide.

Found: C, 52.36; H, 5.13; N, 4.03%. Calcd for $C_{30}H_{35}N_2O_8ClPd$: C, 52.00; H, 5.09; N, 4.04%.

Measurements. NMR spectra were measured on a Hitachi NMR Spectrometer Model R-20-B in carbon tetrachloride and JEOL Fourier Transform NMR Spectrometer FX90Q in $CDCl_3$, tetramethylsilane being used as an internal standard. Circular dichroism spectra were measured on a JASCO ORD/CD optical dispersion recorder. Electronic absorption spectra were measured on a Shimadzu Multipurpose Spectrophotometer Model MSP-5000. The elemental analyses were carried out at the Service Center of Elemental Analysis, Kyushu University.

Results and Discussion

The proton NMR spectra of H(*l*-moba), Pd(*l*-moba)$_2$, and pd(bpy)(*l*-moba)ClO_4 are given in Fig. 2. The most characteristic feature in these spectra is the AB quartet around 4 ppm attributable to the methylene protons adjacent to the *l*-menthyloxy group. One of the possible origins of the AB quartet of the methylene protons is the effect of the chirality of the neighbouring *l*-menthyl group. In order to examine this, we measured the NMR spectra of benzyl *l*-methyloxyacetate and ethyl *l*-menthyloxyacetate (Fig. 1(b) and (c)) and found that the methylene protons adjacent to the *l*-menthyloxy group of these esters appeared as singlet. Therefore, the AB quartet of the methylene protons of H(*l*-moba), Pd(*l*-moba)$_2$, and Pd(bpy)(*l*-moba)ClO_4 should be attributed to a particular configuration of *l*-moba$^-$. We showed in the previous paper[2] that the ligand assumes the enol form in the metal-free state as well as in the metal complexes. However, benzyl *l*-menthyloxyacetate and ethyl *l*-menthyloxyacetate can not form such an intramolecular hydrogen bonding. Therefore, we assume that an intramolecular interaction is operating between the *l*-menthyl group and the metal chelate ring of the *l*-moba complexes or the hydrogen-bonded ring of H(*l*-moba). This interaction would hinder the free rotation around the methylene group and hence bring about the inequivalence of the methylene protons. In the NMR spectrum of 1-ethoxy-3-benzoylacetone (Fig. 1(d)), the methylene protons appeared as singlet at 4.0 ppm. The Dreiding model consideration has indicated that the ethyl group can not approach so close to the hydrogen-bonded ring as to cause an appreciable interaction with the benzene ring.

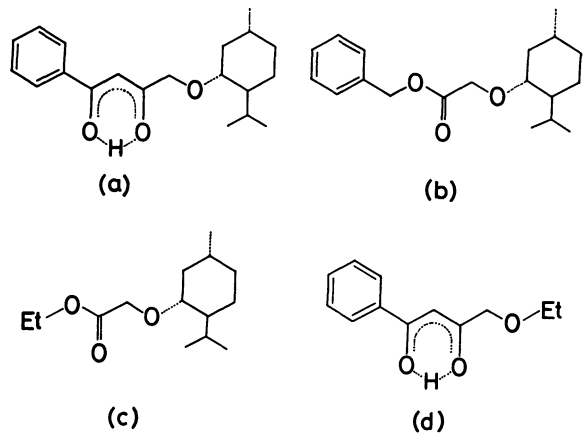

Fig. 1. Chemical structure of (a) 1-*l*-menthyloxy-3-benzoylacetone (H(*l*-moba)), (b) benzyl *l*-menthyloxyacetate, (c) ethyl *l*-menthyloxyacetate, and (d) 1-ethoxy-3-benzoylacetone (Heoba).

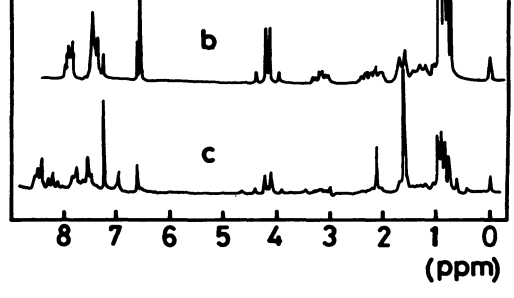

Fig. 2. NMR spectra of (a) H(*l*-moba), (b) Pd(*l*-moba)$_2$, and (c) Pd(bpy)(*l*-moba)ClO_4.

The NMR spectra have revealed that the coupling constants of the methylene protons of Pd(*l*-moba)$_2$ and Pd(bpy)(*l*-moba)ClO_4 are larger than that of H(*l*-moba). This implies that the interaction between the *l*-menthyl group and the ring is enhanced when H(*l*-moba) coordinates to palladium(II) ion. There is little difference between Pd(*l*-moba)$_2$ and Pd(bpy)(*l*-moba)ClO_4 in chemical shift and the coupling constant of the methylene protons. This suggests that in Pd(bpy)(*l*-moba)ClO_4 the *l*-menthyl group does not interact with the π-system of bpy but with the chelate ring of *l*-moba$^-$. This interaction differs from the intramolecular CH/π-interaction observed for the ternary complexes composed of 2,2'-bipyridyl (or 1,10-phenanthroline) and a carboxylic acid,[5] 2,2'-bipyridyl and a sulfonic acid,[5] and 2,2'-bipyridyl and an amino acid.[6] Based on the Dreiding model consideration, no interaction seems to operate between the *l*-menthyl group and the bpy molecule, so long as bpy and *l*-moba$^-$ are planarly coordinated to palladium(II) ion.

Another characteristics in the NMR spectrum of Pd(*l*-moba)$_2$ is two singlets at 6.60 and 6.62 ppm which can be assigned to the methine proton on the chelate ring. This may be reasonably explained by assuming that the sample of Pd(*l*-moba)$_2$ is the mixture of the *cis*- and *trans*-isomers.

In order to investigate further an interaction operating between the *l*-menthyl group and the chelate ring of *l*-moba$^-$, we examined the CD spectra of Cu(*l*-moba)$_2$, Cu(bpy)(*l*-moba)ClO_4, and Ni(*l*-moba)$_2$(H_2O)$_2$. The absorption and CD spectra of Cu(*l*-moba)$_2$ and Cu(bpy)(*l*-moba)ClO_4 in chloroform are shown in Figs. 3 and 4, respectively. The absorption spectrum of Cu(*l*-moba)$_2$ showed three d-d bands at 15200, 17700, and 18900 cm^{-1}; this spectrum resembles that of Cu-

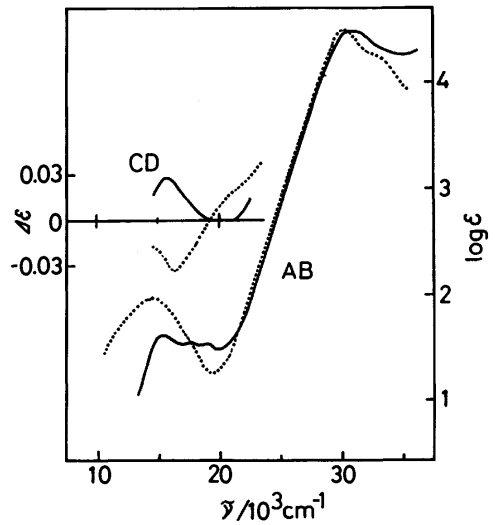

Fig. 3. Absorption and CD spectra of Cu(*l*-moba)$_2$ in $CHCl_3$ (——) and in pyridine (------).

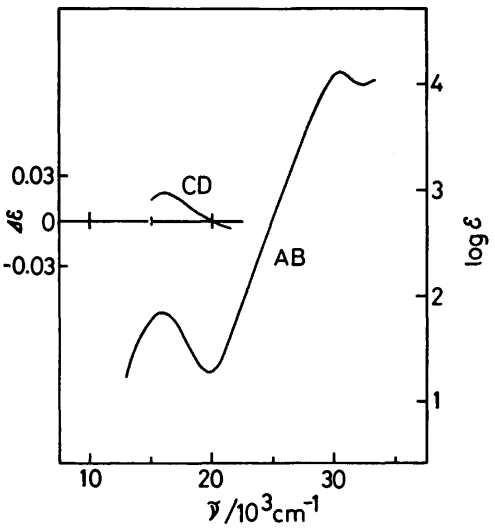

Fig. 4. Absorption and CD spectra of Cu(bpy) (*l*-moba)-ClO_4 in $CHCl_3$.

(acac)$_2$.[9,10] The chloroform solution of Cu(*l*-moba)$_2$ showed a weak, positive CD around 15500 cm^{-1}. On adding excess pyridine or *t*-butylamine to this solution, the CD spectral pattern changed dramatically and a weak, negative CD appeared around 17000 cm^{-1}. In the presence of excess pyridine or *t*-butylamine, Cu(*l*-moba)$_2$ will take a square-pyramidal configuration with the base(B) at the axial site. Because the sixth coordination site is still vacant, one of the *l*-menthyl groups can approach the vacant site of the coordination plane to cause the menthyl/chelate-interaction. The chloroform solution of Cu(bpy)(*l*-moba)ClO_4 showed a d-d band at 16000 cm^{-1} and a weak, positive CD at 16200 cm^{-1}. The marked resemblance in CD spectra between Cu(*l*-moba)$_2$ and Cu(bpy)(*l*-moba)ClO_4 indicates that the *l*-menthyl group of the latter complex does not interact with the π-system of 2,2′-bipyridyl but with the chelate ring of *l*-moba$^-$, similarly to the case of the Pd analogue.

The absorption spectrum of Ni(*l*-moba)$_2$(H_2O)$_2$ in chloroform showed d-d bands at 8800 and 15600 cm^{-1}

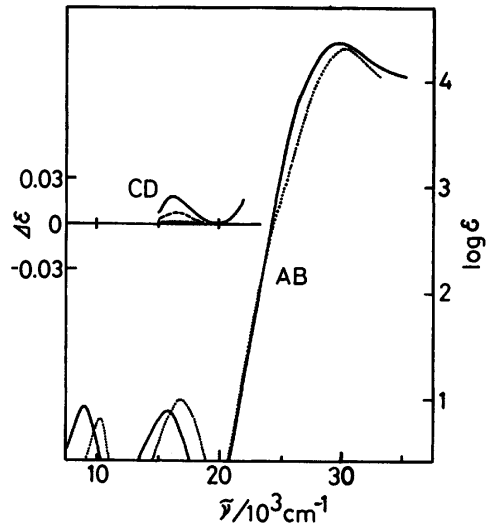

Fig. 5. Absorption and CD spectra of Ni(*l*-moba)$_2$-(H_2O)$_2$ in $CHCl_3$ in the absence and in the presence of propylamine: [propylamine]/[Ni(*l*-moba)$_2$(H_2O)$_2$]=0 (——), 1.5 (------), and 15 (·····).

(Fig. 5), indicating a nearly octahedral symmetry around the metal ion.[11,12] This solution showed a positive CD band near 16000 cm^{-1}. It is likely that the water molecules coordinated at the apical positions do not sterically hinder the interaction between the *l*-menthyl group and the chelate ring. Then, we have examined the CD spectra of Ni(*l*-moba)$_2$(H_2O)$_2$ in the presence of an amine or an alcohol. The CD spectral change for Ni(*l*-moba)$_2$(H_2O)$_2$ on adding propylamine is shown in Fig. 5 as an example. The positive CD at 16000 cm^{-1} gradually decreased its intensity on increasing the amine ratio and finally disappeared. The absorption spectrum of Ni(*l*-moba)$_2$(H_2O)$_2$ in the presence of a large excess of propylamine showed d-d bands at 10000 and 16700 cm^{-1}, implying that the species in the solution is Ni(*l*-moba)$_2$(*n*-prNH_2)$_2$. Thus, the CD spectral change mentioned above can be rationalized by assuming that propylamine coordinated at the apical position sterically hinders the intramolecular interaction between the *l*-menthyl group and the chelate ring of the *l*-moba$^-$ molecule. Similar CD spectral behaviors were also observed when other amines (pyridine, piperidine, *t*-butylamine, and dipropylamine), alcohols (methanol, ethanol, 1-propanol, 1-butanol, 2-methyl-1-propanol, 2-butanol, and 2-methyl-2-propanol), DMF and DMSO were added. In all cases, the interaction between the *l*-menthyl group and the chelate ring must be inhibited due to the steric effect of the molecules coordinated at the apical positions. When triethylamine was added to the chloroform solution of Ni(*l*-moba)$_2$(H_2O)$_2$, no absorption and CD spectral change occured. It is likely that triethylamine can not coordinate to the nickel(II) ion because of the F-strain of the amine.

In the case of addition of excess pyridine, piperidine, *t*-butylamine, 2-methyl-1-propanol, or 2-butanol to the chloroform solution of Ni(*l*-moba)$_2$(H_2O)$_2$, a weak, negative CD peak appeared around 16500 cm^{-1} ($\Delta\varepsilon \approx -0.005$). The origin of this CD is unclear at present, but some intra- or inter-ligand interactions other than

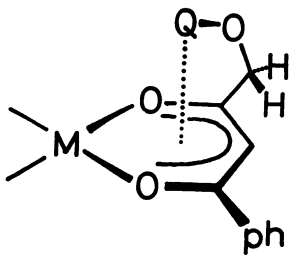

Fig. 6. Schemati· representation of the intramolecular menthyl/chelate-interaction.

the *l*-menthyl/chelate-interaction, such as the interaction between the *l*-menthyl group and the hydrophobic moiety of an amine or an alcohol, might contribute to the weak CD induction.

Based on these facts we conclude that in the *l*-moba metal complexes an intramolecular interaction occurs between the *l*-menthyl group and the chelate ring, and this interaction causes an chirality around the metal ion. It is most likely that the *l*-menthyl group bondingly interacts with the π-system of the chelate ring (Fig. 6). Such a new-type interaction resembles the inter-ligand π/π-interaction suggested for mixed-chelate cobalt(III) complexes containing acetylacetonate ion and (2-aminoethyl)methylphenylphosphine.[13]

Stereochemical Aspects of the Optical Resolution of *cis*(N)-$[Co(N)_2(O)_4]^-$ Complexes by Reversed-phase Ion-pair Chromatography with Cinchona Alkaloid Cations as the Ion-pairing Reagents[1)]

Shinji Izumoto, Ushio Sakaguchi, and Hayami Yoneda*
Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730
(Received December 24, 1982)

The reversed-phase ion-pair chromatography with cinchona alkaloid cations as the ion-pairing reagents has been used to resolve optically several anionic complexes of the type *cis*(N)-$[Co(N)_2(O)_4]^-$. Complete optical resolution has been achieved for $[Co(edta)]^-$, *cis*-$[Co(ida)_2]^-$, $[Co(cydta)]^-$, $[Co(ox)_2(en)]^-$, and *cis*-*α*-$[Co(ox)(edda)]^-$ by quinine, quinidine, and cinchonidine but not by cinchonine, where edta=ethylenediaminetetraacetate, ida=iminodiacetate, cydta=*trans*-1,2-cyclohexanediaminetetraacetate, ox=oxalate, en=ethylenediamine, and edda=*N*,*N*′-ethylenediaminediacetate. The adjusted retention volumes have been measured for the enantiomers. From comparison of the retention volumes and separation factors obtained for the alkaloids and their derivatives, the mode of chiral discrimination has been proposed.

Cinchona alkaloids, *e.g.*, cinchonine, quinine, quinidine, and cinchonidine, are well-known resolving agents for the optical resolution of anionic metal complexes. The cations of these alkaloids are soluble in water, yet bear a hydrophobic character, which suggests these cations to be likely candidates for good ion-pairing reagents in the reversed-phase ion-pair chromatography.[2)] Recently, Yamazaki[3)] has exploited this technique for the optical resolution of several anionic complexes. Using the cation of quinine as the ion-pairing reagent, complete optical resolution has been achieved for $[Co(edta)]^-$, *cis*-$[Co(ida)_2]^-$, $[Co(ox)_2(en)]^{-1}$, and *cis*-*α*-$[Co(Cl)_2(edda)]^-$, where edta=ethylenediaminetetraacetate, ida=iminodiacetate, ox=oxalate, en=ethylenediamine, and edda=*N*,*N*′-ethylenediaminediacetate. The mechanism of optical resolution has been explained by assuming that both dynamic ion-exchange and ion-pairing are important. The stereochemical aspects has not, however, been considered.

In this work, we have applied the reversed-phase ion-pair chromatography with several cinchona alkaloids as the ion-pairing reagents to the optical resolution of anionic complexes of the type *cis*(N)-$[Co(N)_2(O)_4]^-$. Figure 1 shows the schematic illustration of the structure of the complexes examined in this work. The structure of the cinchona alkaloids used here is depicted in Fig. 2, where the atom numbering scheme is also indicated. The adjusted retention volume has been measured for each enantiomer over a range of pH values. From comparison of these retention volumes obtained for these alkaloids and their derivatives, the stereochemical aspects of the mechanism of optical resolution have been discussed.

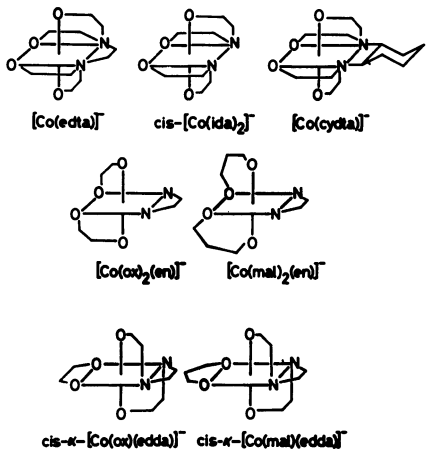

Fig. 1. The structure of the complexes investigated in this work. The figure is drawn for the *Λ* absolute configuration.

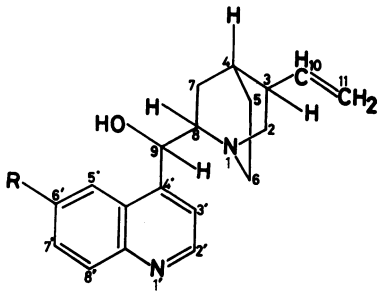

Fig. 2. The structure of the alkaloids used in this work. Cinchonine ((8*R*, 9*S*), R=H); cinchonidine ((8*S*, 9*R*), R=H); quinine ((8*S*, 9*R*), R=OCH_3); quinidine ((8*R*, 9*S*), R=OCH_3). 1-Methylquininium chloride and 9-acetoxyquinine were also employed.

Experimental

Materials. The anionic complexes used in this work were K[Co(edta)],[4)] *cis*-K[Co(ida)$_2$],[5)] K[Co(cydta)](cydta=*trans*-1,2-cyclohexanediaminetetraacetate),[6)] Na[Co(ox)$_2$(en)],[7)] Na[Co(mal)$_2$(en)] (mal=malonate),[8)] *cis*-*α*-K[Co(ox)(edda)],[9)] *cis*-*α*-K[Co(mal)(edda)].[10)] All these complexes were prepared by the literature methods. The absolute configurations of the enantiomers of these complexes were assigned previously.

The following cinchona alkaloids were used as the ion-pairing reagents; (+)-(8*R*, 9*S*)-cinchonine, (−)-(8*S*, 9*R*)-cinchonidine, (−)-(8*S*, 9*R*)-quinine, (+)-(8*R*, 9*S*)-quinidine, 1-methylquininium chloride, and 9-acetoxyquinine. The last two alkaloids were prepared by the literature methods[11,12)] and identified by ^{1}H NMR and chemical analysis. The other alkaloids were obtained from Wako Pure Chemical Industries, Ltd. and used without further purification.

The column packing used in this work was LS-410.ODS.SIL. (Toyo Soda Manufacturing Co., Ltd.), which carries linear

long-chain alkyl groups (octadecyl groups) covalently bonded to the surface of silica gel.

Chromatographic Experiments. A column (4×300 mm) packed with LS-410.ODS.SIL. was equilibrated with an eluent, which was a 0.2 mol dm^{-3} sodium acetate/acetic acid buffered solution containing 0.01 mol dm^{-3} ion-pairing reagent. An aqueous solution of a racemic complex (0.1 mol dm^{-3}) and bis(ethylenediamine)copper(II) chloride (0.1 mol dm^{-3}), which was used as a marker for void volume measurements, was injected by a syringe on top of the column and eluted at an elution rate of 0.50 cm^3/min. The eluate containing an optically resolved anionic complex was fractionally collected and the circular dichroism (CD) spectra were measured to assign the absolute configuration of the resolved complex anion. Interference in the CD spectra due to chiral ion-pairing reagents, an effect called induced CD,[13] was not observed. The pH of the buffered solution was changed from 4.28 to 6.12.

The chromatographic apparatus used here was the same as in previous studies.[3,14] The CD spectra were obtained on a JASCO J-40CS recording spectropolarimeter.

Results and Discussion

Figure 3 shows the elution curves of $[Co(edta)]^-$, $[Co(ox)_2(en)]^-$, and *cis*-α-[Co(ox)(edda)]$^-$, all obtained with quinine at pH 4.28. The $[Co(edta)]^-$ and $[Co(ox)_2(en)]^-$ ions are completely resolved with separation factors of 1.14 and 1.10, respectively. As a rough measure of complete resolution, we may use the separation factor greater than about 1.07 in our experiments. Tables 1 to 4 summarize the results obtained for quinine, quinidine, cinchonidine, and cinchonine, respectively, in terms of the later-eluted enantiomers, their retention volumes, and the separation factors. From these tables, the following points are noted. (i) $[Co(edta)]^-$, *cis*-$[Co(ida)_2]^-$, $[Co(cydta)]^-$, and $[Co(ox)_2(en)]^-$ are completely resolved by any one of quinine, quinidine, and cinchonidine. (ii) $[Co(mal)_2(en)]^-$ and *cis*-α-[Co(mal)(edda)]$^-$ can not be resolved completely by any alkaloids. (iii) *cis*-α-[Co(ox)(edda)]$^-$ can be resolved completely only by quinidine or cinchonidine. (iv) Cinchonine is ineffective in resolving all the complexes and the retention volumes with this alkaloid are much smaller than those with the other alkaloids for all the complexes.

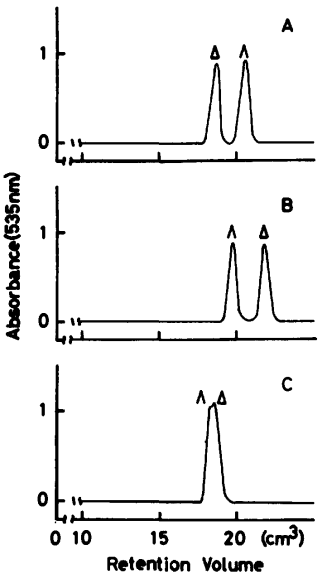

Fig. 3. The elution curves of (A) $[Co(edta)]^-$, (B)$[Co(ox)_2(en)]^-$, and (C) *cis*-α-[Co(ox)(edda)]$^-$, obtained with quinine at pH 4.28.

1. Analysis of Data. In the reversed-phase ion-pair chromatography, the enantiomer that associates more favorably with the ion-pairing reagent is better adsorbed to the hydrophobic stationary phase and eluted later.[2,3] Since protonation of all the alkaloids except 1-methylquininium chloride has been reported[15] to take place at pH 9.70 to 10.03 on the quinuclidine N(1) nitrogen and at pH 5.07 to 5.85 on the quinoline N(1′) nitrogen, the ion-pairing reagents exist as monopositive or dipositive cations in the pH range studied (pH 4.3 to 6.1). Thus, the ion association of the anionic complex ions with the alkaloid cations will take place mainly *via* electrostatic forces. This reasoning has been substantiated clearly by examining the pH dependence of the retention volumes.

(*a*) *Effect of pH*: For all the complex/alkaloid combinations, the retention volume increases substantially as the pH of the eluent solution is lowered beyond the point where the quinoline N(1′) protonation occurs. This is due to an increase in the concentration of alkaloid dications rather than monocations and hence to an increase in the concentration of ion-pairs. The effect of solution pH on the separation factor is, however, rather small, which indicates that the association of metal complex ions to the protonated N(1) nitrogen is effective in chiral discrimination but that to the quinoline N(1′) nitrogen is not. The only mode of association that is effective for chiral discrimination is, therefore, at the protonated N(1) nitrogen. One peculiar result may be noted in Table 4 for the combinations cinchonine/$[Co(edta)]^-$ and cinchonine/$[Co(mal)_2(en)]^-$. For these two combinations, the elution order of enantiomers is inverted by the pH of the eluent. Since these combinations gave only single elution curves and the degree of resolution was very low at any pH, no further investigation on this point was attempted.

(*b*) *Effect of C(8) and C(9) Configurations*: From Tables 1 to 4, it can be seen that the enantiomer eluted faster by the (8*R*,9*S*) alkaloids (cinchonine and quinidine) is eluted later by the (8*S*,9*R*) alkaloids (cinchonidine and quinine). Note here that the latter alkaloids are not the mirror images of the former ones owing to the presence of four asymmetric centers, C(3), C(4), C(8), and C(9).[16] Further, the C(8) and C(9) centers are close to the N(1) nitrogen spatially (see below), this result is considered to be consistent with the inference that the association of complex anions with the protonated N(1) nitrogen is essential in chiral discrimination. Broadly speaking, the (8*S*,9*R*) alkaloids yielded larger separation factors than the (8*R*,9*S*) alkaloids but the reason for this trend is not clear as yet.

(*c*) *Effect of C(6′) Methoxyl Group*: Another point to be noted in Tables 1 to 4 is that the alkaloids with the C(6′) methoxyl group, quinine and quinidine, gave rise to greater retention volumes and separation factors than the alkaloids without the methoxyl group, cinchoni-

a) Single elution curve.

dine and cinchonine (see also Fig. 2). This result indicates that the association with complex anions and also the chiral discrimination are enhanced by the presence of the methoxyl group, which is in turn consistent with the postulated N(1) association, because the C(6′) methoxyl group is spatially in rather close proximity to the N(1) center (see below).

(d) Effect of N(1)-Methylation of Quinine: Now that the association to the protonated N(1) center is seen to play a key role in chiral discrimination, it would be expected that the methylation at this nitrogen reduces the degree of ion association and also the degree of chiral discrimination. Thus, 1-methylquininium cation was employed to measure the retention volumes and separation factors. The results are given in Table 5. The separation factors for all but *cis*-α-$[Co(ox)(edda)]^-$ are in fact reduced greatly compared with those obtained with quinine, as expected. The exceptional behavior of *cis*-α-$[Co(ox)(edda)]^-$ has not been properly explained.

(e) Effect of C(9)-OH Acetylation: The C(9)-OH group is spatially close to the N(1) center (see below), and might be thought to take part in chiral discrimination through, *e.g.*, hydrogen bonding to an oxygen atom of complex anions. This possibility may be tested by measuring retention volumes or separation factors using an acetylated (at C(9)-OH) alkaloid. Thus, 9-*O*-acetylquinine was prepared and measurements were made similarly. The results are given in Table 5. The separation factors with 9-*O*-acetylquinine will be seen to be better somewhat than those with quinine itself. Though this result does not support nor deny that the postulated hydrogen bond with C(9)-OH group takes part in chiral discrimination, this result suggests that the C(9)-OH group is indeed involved in chiral discrimination in some ways.

2. Mode of Chiral Discrimination. Taken all the above experimental results together, we may envisage the mode of association which is effective for chiral discrimination. Before the presentation of the association model, it will be pertinent to see the structure of the alkaloids. The structures of quinidine,[17] quinidinium monocation,[18] cinchonine,[19] and cinchoninium dication[20] have been determined previously by three-

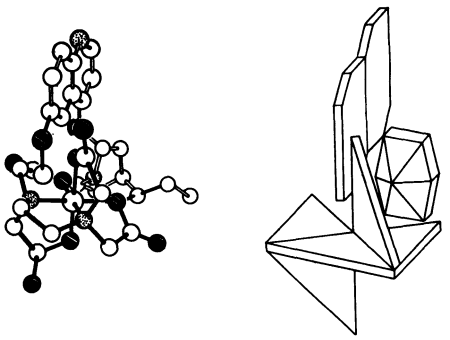

Fig. 4. (a) Proposed mode of chiral discrimination between the quininium cation and Λ-$[Co(edta)]^-$. The dotted and hatched circles represent nitrogen and oxygen atoms, respectively. (b) Simplified version of (a).

dimensional X-ray analysis. Except for the quinidinium salt of (−)-1′,3-dimethyl-1-ferrocenecarboxylic acid, where the conformation about the C(8)–C(9) bond is constrained severely by strong hydrogen bonds between the two carboxyl oxygens and N(1) and C(9)–OH hydrogens,[18] the conformations about C(8)–C(9) and C(9)–C(16) assume surprisingly the same ones (to within $\pm 3.5°$) in all these crystals. This result, as well as considerations using molecular models, suggests strongly that the conformation about these bonds in solution should be rather similar to that in the solid state. Thus, we assume that all the alkaloid cations used in this work have the same conformation in solution (but, of course, not the same absolute configuration); the dihedral angles defined by C(4′)–C(9)–C(8)–N(1) and O–C(9)–C(4′)–C(3′) bonds are about 163° and 22°, respectively.

(a) $[Co(edta)]^-$, cis-$[Co(ida)_2]^-$, and $[Co(cydta)]^-$: The mode of chiral discrimination between the quininium cation and Λ-$[Co(edta)]^-$, as inferred from the results described above, is shown in Fig. 4(a), where hydrogen atoms are omitted for clarity. In Fig. 4(b) is illustrated the mode of fitting of both ions in a very simplified form. It will be seen that the Λ-$[Co(edta)]^-$ ion can fit very nicely with the cation. The Δ-$[Co(edta)]^-$ ion can not fit nicely because the sense of handedness of two R rings is now reversed to that depicted in Fig. 4 and severe steric hindrance with the quinoline ring (including the C(6′) methoxyl group) is anticipated. Thus, in the combination of the quininium cation/$[Co(edta)]^-$, one R ring may be considered as serving as a chiral discriminator. In Fig. 4, the C(6′) methoxyl group may be seen to be useful in chiral discrimination. This mode of association is consistent with the observation that the complexes $[Co(edta)]^-$, *cis*-$[Co(ida)_2]^-$, and $[Co(cydta)]^-$ exhibited the same elution order of enantiomers with similar separation factors, because in this model the substituents ($-CH_2-CH_2-$, H–, and cyclohexane ring) at coordinated nitrogen atoms of complexes are farthest apart from the alkaloid cation.

In the combination with the (8*R*,9*S*) epimers (quinidine and cinchonine) instead of the (8*S*,9*R*) epimers like equinine and cinchonidine, the Δ enantiomers of $[Co(edta)]^-$, *cis*-$[Co(ida)_2]^-$, and $[Co(cydta)]^-$ are

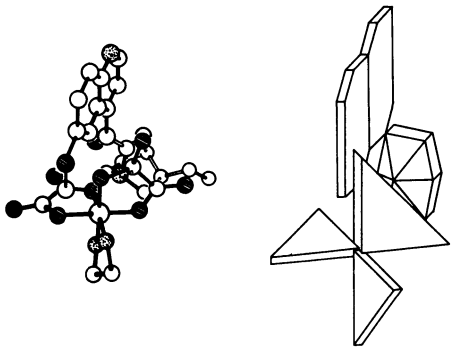

Fig. 5. (a) Proposed mode of chiral discrimination between the quininium cation and Δ-[Co(ox)$_2$(en)]$^-$. The dotted and hatched circles represent nitrogen and oxygen atoms, respectively. (b) Simplified version of (a).

preferred, as opposed to the Λ enantiomer depicted in Fig. 4. If we note that the immediate environment about the N(1) center of these (8*R*,9*S*) epimers is rather similar to the mirror image of the respective (8*S*,9*R*) epimers, this preference is easily understood.

(b) [*Co(ox)$_2$(en)*]$^-$ *and* [*Co(mal)$_2$(en)*]$^-$: Figure 5 illustrates the proposed mode of chiral discrimination between the quininium cation and Λ-[Co(ox)$_2$(en)]$^-$ which is preferred by the cation. The N(1) positive center of the alkaloid cation approaches the complex anion from the side of three anionic oxygen atoms. It will be seen that both ions fit very well from both electrostatic and spatial points of view. If the opposite enantiomer is combined with the cation, a severe steric repulsion is clearly expected. Thus, in the combination of quininium cation/[Co(ox)$_2$(en)]$^-$, the interleaving chelate ring appears to play the role of chiral discriminator.

The [Co(mal)$_2$(en)]$^-$ ion could be resolved very little by any ion-pairing reagents, which makes a sharp contrast to the case of [Co(ox)$_2$(en)]$^-$, where complete optical resolution was attained for all the alkaloids except cinchonine. (Cinchonine was ineffective in the optical resolution of all the complexes investigated, as noted above). Further, the elution order of enantiomers of [Co(mal)$_2$(en)]$^-$ is opposite to that of [Co(ox)$_2$(en)]$^-$ for any alkaloids and at any pH (see, Tables 1 to 5). Two possibilities could be considered as the reason for [Co(mal)$_2$(en)]$^-$ being not resolved. One is that since the malonate chelate ring is more bulky than the oxalate ring and flexible to such an extent that the chelate ring is interconverting rapidly among several conformers,[21] [Co(mal)$_2$(en)]$^-$ can not make a so close contact or can not make a so compact fit to the alkaloids as [Co(ox)$_2$(en)]$^-$ does. The other possibility is that the [Co(mal)$_2$(en)]$^-$ ion is hydrated to a greater degree than [Co(ox)$_2$(en)]$^-$ and its association with hydrophobic alkaloid cations is proportionately weaker. The latter possibility gains some support from the the fact that the retention volume of [Co(mal)$_2$(en)]$^-$ is substantially smaller than that of [Co(ox)$_2$(en)]$^-$ at any pH and for all the alkaloids. A result pointing to greater hydration of [Co(mal)$_2$(en)]$^-$ than [Co(ox)$_2$(en)]$^-$ has been found recently in ion-exchange chromatographic experiments.[14] Further, *cis*-*α*-[Co(ox)(edda)]$^-$ and *cis*-*α*-[Co(mal)(edda)]$^-$ exhibited a similar trend in retention volumes (see Tables 1 to 5), which seems to favor the view that the cobalt(III)-malonate ring is more hydrophilic and hydrated more extensively than the cobalt(III)-oxalate counterpart.

(c) cis-*α*-[*Co(ox)(edda)*]$^-$ *and* cis-*α*-[*Co(mal)(edda)*]$^-$: The *cis*-*α*-[Co(ox)(edda)]$^-$ ion could be resolved completely by quinidine and to a lesser extent by cinchonidine but not by quinine and cinchonine. The separation factors of this ion are generally smaller than those of [Co(edta)]$^-$, *cis*-[Co(ida)$_2$]$^-$, [Co(cydta)]$^-$, and [Co(ox)$_2$(en)]$^-$ for any alkaloids and at any pH. This lower degree of chiral discrimination of *cis*-*α*-[Co(ox)(edda)]$^-$ seems to preclude the proposal of any plausible mode of chiral discrimination for this ion. The distinctive behavior between *cis*-*α*-[Co(ox)(edda)]$^-$ and *cis*-*α*-[Co(mal)(edda)]$^-$ is noted above. As for [Co(ox)$_2$(en)]$^-$ and [Co(mal)$_2$(en)]$^-$, *cis*-*α*-[Co(ox)(edda)]$^-$ and *cis*-*α*-[Co(mal)(edda)]$^-$ appear to show opposite elution orders of enantiomers.

Finally, it will be interesting to compare the present results with the results of the Pfeiffer effect observed[22] for [Cr(ox)$_3$]$^{3-}$, [Cr(ox)$_2$(phen)]$^-$, and [Cr(ox)$_2$(bpy)]$^-$ with the monocations of the cinchona alkaloids as the environment substances, where phen=1,10-phenanthroline and bpy=2,2′-bipyridine. As for the present complexes, the [Cr(ox)$_3$]$^{3-}$ ion was assumed to approach the N(1) positive center of the alkaloids *via* electrostatic forces. For [Cr(ox)$_2$(phen)]$^-$, both electristatic forces (between the oxalate ligands and the N(1) center) and hydrophobic attractive forces (between the phen ligand and the quinolyl ring) were invoked. The mode of chiral discrimination of [Cr(ox)$_2$(phen)]$^-$ was thus utterly different from any of the chiral discrimination modes proposed here.[23]

23) Additionally, we found that the *cis*-*a*-$[Co(NO_2)_2(edda)]^-$ ion can be resolved completely by cinchonidine and partially by quinine and quinidine but not by cinchonine. Since this ion does not belong to the *cis*(N)-$[Co(N)_2(O)_4]^-$ type, the data for this ion were not included in this paper.

Kinetics of Valinomycin- and Tetranactin-mediated Cation Transport through Liposomal Membrane

Masaharu UENO,* Tomomi YASUI, and Isamu HORIKOSHI
Department of Hospital Pharmacy, Toyama Medical and Pharmaceutical University, 2630 Sugitani, Toyama 930-01
(Received May 28, 1982)

Kinetics of valinomycin- and tetranactin-mediated cation transport were studied. An equation was derived which describes the kinetics of ionophore induced cation leakage from liposomes. The theoretically predicted ion-selectivity of the ionophore-mediated cation transport agreed well with that given by experiments. This supports the assumptions used in the derivation and is consistent with the following characteristics of the ionophores: (1) Ionophore-mediated cation transport is carried out by stoichiometrically forming a ternary complex between ionophore, cation and lipophilic anion. (2) The ion-selectivity of the ionophore is determined primarily by the formation constant of the ionophore cation complex in water. (3) A relative value of the complex formation constant in water can be calculated from both the complex formation constant in methanol, which is estimated more easily than that in water, and the difference between desolvation energy of the cation in water and methanol.

Neutral ionophores, such as valinomycin and tetranactin function as mobile carriers of specific ions through biomembranes or model membranes. Block *et al.* studied the kinetics of valinomycin-induced K^+ leakage from liposomes and determined a partition constant of valinomycin between membrane phase and aqueous phase, and a turnover rate of potassium transport across liposomal membrane.[1] Yamaguchi and Anraku studied the mechanism of SF6847-mediated proton uptake in liposomes and showed that the proton uptake was compensated by valinomycin-induced potassium efflux.[2] Results showed that potassium ion leakage or the exchange transport between proton and potassium ion was induced by ternary complex formation between valinomycin, potassium ion and thiocyanate ion or between valinomycin, potassium ion and SF6847. But in their reports, the ion-selectivity was not discussed.

In the present report, we studied the ion-selective permeation induced by ionophore through liposomal membranes. First, we derived an equation which described the ion selective transport of ionophore through the liposomal membrane. Secondly, we showed experimentally that the equation adequately predicted the ion selectivity of the ionophore. The derivation required two assumptions: (1) It is assumed that ionophore distributes uniformly throughout liposomal membrane. This contrasts with the assumption made by Block *et al.*[1] that ionophore should be localized on the inside and outside membrane surfaces. (2) The association constant for ionophore-cation complexation in water may be expressed in terms of the association constant obtained in methanol and the difference between the desolvation energy of the cation in methanol and water.

Theoretical

In the specific liposomal system under investigation, only the transport of ion through the outer bilayer of the multilamellar liposomes contributes directly to the observed leakage. A model for ionophore-mediated ion transport through membrane is proposed as shown in Fig. 1. In this model it is assumed that only ternary complex (IMX) of ionophore (I), cation (M) and anion (X) can carry ions through membrane, and ionophore is distributed uniformly throughout the membrane phase.

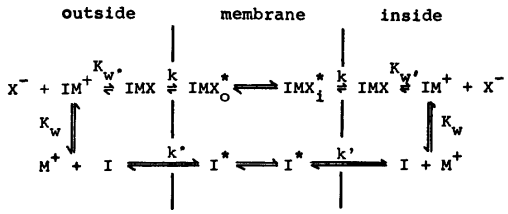

Fig. 1. Model for ionophore-mediated cation leakage from liposomes containing MSCN.

In the water phase inside the bilayer, ionophore (I) and cation (M) form complex (IM) *i.e.* $I+M \overset{K_w}{\rightleftharpoons} IM$. The complex formation constant K_w is expressed by Eq. 1,

$$K_w = \frac{C_{IM}}{C_{IM}C_M}. \quad (1)$$

Complex IM and anion X form ternary complex IMX, $IM+X \overset{K'_w}{\rightleftharpoons} IMX$. K'_w can be expressed by Eq. 2,

$$K'_w = \frac{C_{IM}}{C_{IM}C_X}. \quad (2)$$

Ternary complex IMX is distributed into membrane, $IMX \overset{k}{\rightleftharpoons} IMX^*$, where asterisk (*) indicates the membrane phase. The distribution constant k of the ternary complex is expressed by Eq. 3,

$$k = \frac{C^*_{IMX}}{C_{IMX}}. \quad (3)$$

The distribution constant of ionophore k' is expressed by Eq. 4,

$$k' = \frac{C^*_I}{C_I}. \quad (4)$$

The ternary complex IMX* diffuses through membrane from inside to outside. The flux J of the ternary complex is assumed to be proportional to the concentration gradient of the ternary complex in membrane. We get following equation,

$$J = D\frac{C^*_{IMXi} - C^*_{IMXo}}{d}, \quad (5)$$

where D is the diffusion constant of the ternary complex in methanol and d is the thickness of the membrane.

Subscripts i and o denote inside and outside surfaces of the membrane, respectively. When the distribution equiliblium of IMX between aqueous and membrane phases is achieved quickly, that is, the transmembrane diffusion of the ternary complex is the rate-limiting process of ion transport, $C^*_{MIXo} \ll C_{IMX_i}$ in the initial stage after addition of ionophore, since $C_{IMXo}=0$ in the initial stage. Then the leakage L $(=JS)$ is expressed by Eq. 6,

$$L = JS = D\frac{S}{d}C^*_{IMX_i} = D\frac{S}{d}kC_{IMX}, \tag{6}$$

where S is the surface area of the membrane. From Eqs. 1, 2, 3, and 6, we get

$$L = D\frac{S}{d}kK'_wK_wC_IC_MC_X. \tag{7}$$

If we define b and m as the liposomal volumes of water and membrane phases, and assume the concentration of cation M in extra liposomal water can be regarded as zero in the initial stage after the addition of ionophore, then the total amount of cation a_{MT} and anion a_{XT} are represented by Eqs. 8 and 9.

$$a_{MT} = b(C_M+C_{IM}+C_{IMX}) + m(C^*_M+C^*_{IM}+C^*_{IMX}) \tag{8}$$

$$a_{XT} = b(C_X+C_{IMX}) + m(C^*_X+C^*_{IMX}) \tag{9}$$

In the present case, $C_M \gg C_I$, Eqs. 8 and 9 can be reduced to Eqs. 8′ and 9′,

$$a_{MT} = bC_M, \tag{8'}$$

$$a_{XT} = bC_X. \tag{9'}$$

For uni-valent electrolyte

$$a_T = a_{MT} = a_{XT} = bC_M = bC_X, \tag{10}$$

where a_T is the amount of the salt contained in liposomes before addition of ionophore. When w is the total volume of water (*i.e.* in and out of liposomes), total amount of ionophore a_T is represented as follows;

$$a_T = w(C_I+C_{IM}+C_{IMX})+m(C^*_I+C^*_{IM}+C^*_{IMX}). \tag{11}$$

Since K'_w can be regarded as far less than K_w[1] and ion concentration within the membrane regarded as negligible. Eq. 11 is reduced to Eq. 11′,

$$a_I = w(C_I+C_{IM})+mC^*_I. \tag{11'}$$

From Eqs. 1, 4, and 11′, we get following equation.

$$a_I = w\left(C_I+K_wC_I\cdot\frac{a_T}{b}\right)+mk'C_I \tag{12}$$

From Eqs. 7, 10, and 12, we get following equation.

$$L = D\frac{S}{d}kK'_wK_w\frac{a_I}{w+mk'+\dfrac{wa_T}{b}K_w}\left(\frac{a_T}{b}\right)^2 \tag{13}$$

S, d, m, w, and k' are invariant with cation species. k, D, and K'_w can be regarded as invariant with cation species, because in ionophore-univalent cation complexes cations are enveloped by ionophore and the complexes are similar in shape and size with each other.[3-6] Therefore setting $D\frac{S}{d}kK'_w=A$=constant and $w=mK'=B$=constant, we get

$$L = AK_w\frac{a_I}{B+K_ww\cdot\dfrac{a_T}{b}}\left(\frac{a_T}{b}\right)^2. \tag{14}$$

When the amount of lipid is constant, C_{IT} can be defined as the total amount of ionophore per mg of lipid, and C_T as the concentration of metal thiocyanate in water phase in liposome before addition of ionophore, that is $C_T=\frac{a_T}{b}$, Eq. 14 can be represented as Eq. 15 where A' is A per amount of lipid.

$$L = A'K_w\frac{C_{IT}C_T^2}{B+K_wwC_T} \tag{15}$$

The relation between leakage L and association constant K_w, under the condition where the concentration of ionophore and metal thiocyanate are constant, as defined by Eq. 15, is shown in Fig. 2. When $K_w \ll \frac{B}{wC_T}=\frac{w+mk'}{wC_T}$, Eq. 15 can be reduced to Eq. 16.

$$L = \frac{A'}{B}K_wC_{IT}C_T^2 \tag{16}$$

In this case, leakage L is proportional to K_w, C_{IT}, and C_T^2. According to Eq. 16, the leakage of ion from liposome is proportional to the complex formation constant between ionophore and the cation in water which agrees with the electrical study of Eisenman *et al.*[7-10] When $K \gg \frac{B}{wC_T}=\frac{w+mk'}{wC_T}$, Eq. 15 can be reduced to Eq. 17.

$$L = \frac{A'}{w}C_{IT}C_T \tag{17}$$

In this case, L is proportional to the concentrations of ionophore and metal thiocyanate and has no relation to the association constant.

The ion-selectivity of the ionophore can be evaluated indirectly. It is difficult to estimate the complex formation constant in water (K_w) directly by experimental measurement, because of very low solubility of ionophore in water and small K_w. However, it is only necessary to estimate relative value of K_w in evaluating ion-selectivity and not the absolute value. As discussed in the preceding study,[18] the free energy of complex formation, ΔG^0, is defined as a sum of the conformational energy difference of ionophore between complex form and uncomplex form (ΔU), the desolvation energy of cation with complex formation (ΔG^0_M), and the other factor (I), which includes the solvation effect and the change in entropy of the ionophore upon complex formation and can be regarded as independent of ion

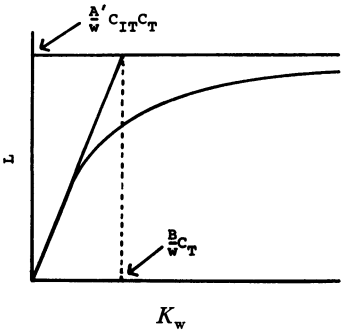

Fig. 2. Scheme of L(leakage) and K_w (complex formation constant) relation under the condition of constant concentration of ionophore and ion.

species.

Then in water,

$$-RT\ln K_w = \Delta G_w^\circ = \Delta U + \Delta G_{Mw}^\circ + I_w \quad (18)$$

and in methanol,

$$-RT\ln K_m = \Delta G_m^\circ = \Delta U + \Delta G_{Mm}^\circ + I_m. \quad (19)$$

By Eqs. 18 and 19, we get

$$K_w = K_m \exp\frac{\Delta G_{Mm}^\circ - \Delta C_{Mw}^\circ}{RT} \exp\frac{I_m - I_w}{RT}. \quad (20)$$

From Eqs. 16 and 20, we get

$$L = \frac{A'}{B} C_{IT} C_T^2 \exp\frac{I_m - I_w}{RT} \cdot K_m \exp\frac{\Delta G_{Mm} - \Delta G_{Mw}}{RT}. \quad (21)$$

Since the $\exp\frac{I_m - I_w}{RT}$ can be regarded as independent of ion species, in the case of C_{IT}=constant and C_T= constant, Eq. 21 is reduced to Eq. 22 with $\frac{A}{B} C_{IT} C_T^2 \exp\frac{I_m - I_w}{RT} = \text{constant} = E$.

$$L = EK_m \exp\frac{\Delta G_{Mm}^\circ - \Delta C_{Mw}^\circ}{RT}. \quad (22)$$

The complex formation constant between ionophore and cation in methanol (K_m) and desolvation energy of cation in methanol (ΔG_{Mm}^0) and in water (ΔG_{Mw}^0) has already been determined.[12-14]

Experimental

Materials. Valinomycin was obtained from Calbiochem Co. Ltd. Tetranactin was gifted from Chugai Pharmaceutical Co. Ltd. Egg lecithin was a purified substance given by Asahi Kasei Co. Ltd. Phosphatidic acid was obtained from Sigma Co. Ltd. The other reagents were special grade of Wako Pure Chemical Industries Ltd.

Methods. Multilayer liposomes were prepared as follows: The inner surface of a 50 ml round-bottomed flask was coated with 10 mg of egg lecithin containing 2% of phosphatidic acid by evaporation of solvent. Then, 5 ml of a 150 mM KSCN/10 mM Tris solution which was adjusted to pH 7.0 by adding H_2SO_4 was poured into the lecithin coated flask and gently shaken until all lipid was removed from the flask. The liposome suspension was centrifuged for 20 min at 40000 g at 4 °C. The liposome preparation was washed with isotonic 150 mM $MgSO_4$/10 mM Tris/H_2SO_4 solution followed by centrifugation at 40000 g for 20 min at 4 °C. The obtained liposome pellet was dispersed in 10 ml of isotonic 150 mM $MgSO_4$/10 mM Tris/H_2SO_4 solution (pH 7.0). Ionophore, dissolved in methanol, was added with a microsyringe (20 μl) to the liposome-dispersed solution. The ion leakage was measured by an ion-meter (Orion Research) with appropriate ion-selective electrodes.

Results and Discussion

When valinomycin was added to the liposomes containing KSCN, the K^+ leakage as well as the SCN^- leakage increased maximally immediately following the addition of the ionophore (Figs. 3-a, b), but when valinomycin was added to the liposomes containing KCL, the increase in K^+ leakage was far smaller than those containing KSCN (Fig. 3-c). These observations suggest that the permeation of K^+ from the liposomes induced by valinomycin is facilitated by lipophilic

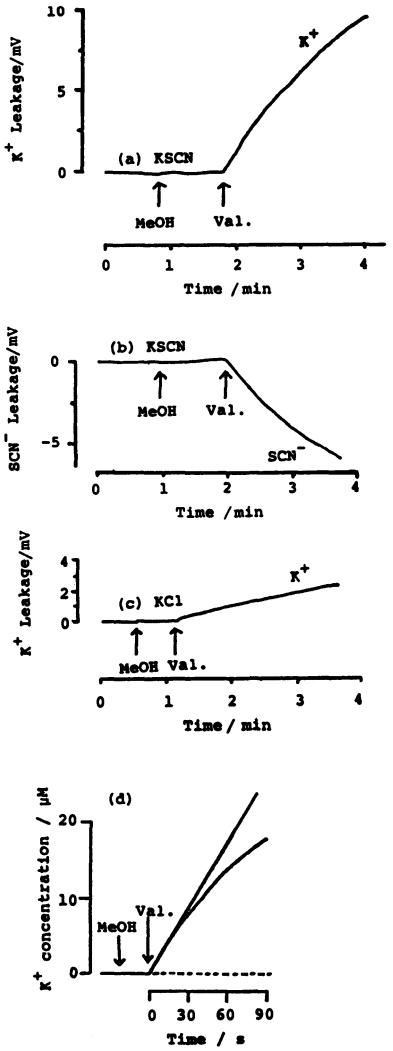

Fig. 3. Recorder trace of the valinomycin-induced ion leakage and the time course of K^+ concentration in medium.
(a) and (b) show K^+ and SCN^- leakages from liposomes containing 150 mM of KSCN. (c) shows K^+ leakage from liposomes containing 150 mM of KCl. (d) shows the time course of K^+ concentration in medium dispersing liposomes containing 150 mM of KSCN.

anions, such as SCN^-. Equation 16 suggests that cation leakage is proportional to the concentration of ionophore, C_{IT}, when C_T and K_w are constant or to the square of the concentration of metal thiocyanate in the liposomes, C_T^2, when C_{IT} and K_w are constant. In Fig. 4, the initial rate of K^+ leakage was plotted against the concentration of valinomycin at constant KSCN concentration. The plot showed a good linear relation. In the Fig. 5, the initial rate of K^+ leakage was plotted against the logarithm of the KSCN concentration at constant valinomycin. The plot showed a linear relation with a slope of near 2. From these observations, Eq. 16 has been found primarily to hold in our experimental condition. Accordingly the assumption, $K_w \ll B/wC_t$, is practically satisfied. In addition, the fact that the slope of the line in Fig. 5 was near 2 supports

the assumption that valinomycin functions only as a mobile carrier by forming stoichiometrically a ternary complex with K^+ and SCN^-, as described originally by Block *et al.*[1] That the above slope was slightly smaller than 2 may be attributed the <1 activity coefficient of KSCN at 150 mM.

Equation 22 suggests that cation leakage induced by ionophore is proportional to the product of the association constant between the cation and the ionophore in methanol and the exponent of the desolvation energy difference between methanol and water at constant ionophore concentration and constant metal thiocyanate concentration. The association constant in methanol, K_m, and desolvation energy difference, $\Delta G^0_{Mm}-\Delta G^0_{Mw}$, have been reported.[12-14] In Table 1, K_m and $K_m\frac{\Delta G^0_{Mm}-\Delta G^0_{Mw}}{RT}(=L/E)$ were summerized. The experimental values of initial rates of several cations and the calculated values, $K_m\frac{\Delta G^0_{Mm}-\Delta G^0_{Mw}}{RT}$, were plotted against the ionic radii of the cation in Fig. 6 for valinomycin as ionophore and in Fig. 7 for tetranactin. The ion-selectivity of the ionophores given from direct

experimental measurements agreed well with those predicted from Eq. 22. The term, $\Delta G^0_{Mm} - \Delta G^0_{Mw}$, in Eq. 22 ensures the effects of solvation energy of ions on the ion selectivity of the ionophores. The fact that the permeation of Cs^+ or Rb^+ was relatively large as compared with that predicted from the K_m alone shows that the contribution energy of the cation to ion-selectivity of the ionophore is different in methanol and in water. Thus the experimental results justified the validity of application of Eq. 22 to the elucidation of ion selectivity of ionophore-mediated ion transport through liposomal membrane.

Studies on the β-Turn of Peptides. III[1]. Syntheses and Conformational Properties of *N*-(2,4-Dinitrophenyl)tetrapeptide *p*-Nitroanilides Related to β-Turn Preferring Sequences in Proteins

Kazuki Sato,* Ukon Nagai, and Tsutomu Higashijima†

Mitsubishi-Kasei Institute of Life Sciences, Minamiooya, Machida, Tokyo 194

†*Department of Biophysics and Biochemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113*

(Received September 1, 1982)

To confirm the general applicability of CD spectra of *N*-(2,4-dinitrophenyl(Dnp))tetrapeptide *p*-nitroanilides (pNA's) to the analysis of β-turn preference of the tetrapeptide sequences, Dnp-pNA derivatives of some tetrapeptides related to β-turn preferring sequences in proteins were synthesized and subjected to CD and ^{1}H NMR measurements. CD spectra of Dnp–Gly–L-Pro–L-Asn–Gly–pNA (**5a**) were just the mirror image of those of gramicidin S-model peptide, Dnp–Gly–D-Ala–L-Pro–Gly–pNA (**6**). This suggested that **5a** strongly preferred the β-turn and the type of turn was different from that of **6**. The relative intensities of Cotton effects of the tetrapeptide with the general structure Dnp–Gly–L-Pro–Y–Gly–pNA (Y=L-Asn, Gly, L-Ala, or L-Gln) roughly agreed with the bend potentials of the amino acid residues at the third position of β-turns in proteins reported by Chou and Fasman. The effects of changing the amino acid residues at the second position of β-turn were also examined.

In the previous paper, we gave an outline of a new method to study the β-turn conformation of linear tetrapeptides.[2] *N*-(2,4-Dinitrophenyl)tetrapeptide *p*-nitroanilides (Dnp–tetrapeptide–pNA's)[3] exhibited characteristic CD spectra above 300 nm when they took β-turn conformations (Fig. 1). The Cotton effects were considered to be due to the interaction of the two terminal chromophores, namely, the exciton coupling of the transition moments in the two terminal chromophores, and the magnitude of the Cotton effects were shown to reflect the β-turn preference of the peptides. β-Turn preferences of the tetrapeptide derivatives has strong correlation with antibiotic activities of the gramicidin S (GS) analogs containing similar tetrapeptide sequences at their β-turn part.[1] This paper deals with the details of syntheses and conformational properties of Dnp-pNA derivatives of some tetrapeptides related to the β-turn preferring sequences in proteins to confirm the general applicability of the CD spectra of the tetrapeptide derivatives to the analysis of their β-turn conformation.

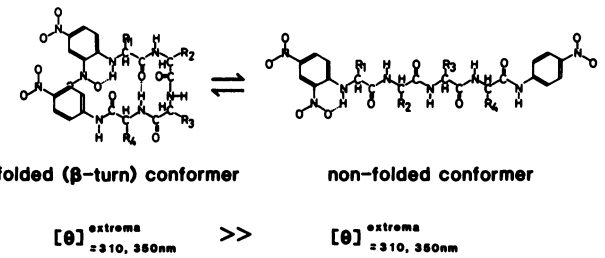

Fig. 1. Models of folded (β-turn) and non-folded conformers of a Dnp–tetrapeptide–pNA.

The first compound synthesized was Dnp–Gly–L-Pro–L-Asn–Gly–pNA (**5a**). The sequence was expected to take the β-turn to a high degree because of the high bend potential of each component amino acid residue at the respective position in the table proposed by Chou and Fasman on the basis of statistical analysis of the X-ray crystallographic data of 29 globular proteins.[4] Kopple and Go,[5] and Fermandjian *et al.*[6] reported that Z–Gly–L-Pro–L-Asn–Gly–NHNH–Boc and H–Gly–L-Pro–L-Asn–Gly–OH, respectively, formed type-I β-turn by NMR analysis. Synthesis of **5a** is outlined in Fig. 2. Boc–L-Asn–Gly–pNA (**1a**) was prepared by coupling of Boc–L-Asn–ONp and H–Gly–pNA, and was deprotected with hydrogen chloride in formic acid to afford H–L-Asn–Gly–pNA·HCl (**2a**·HCl). Coupling of Boc–Gly–L-Pro–OH[7] and **2a** by EDC–HOBt method

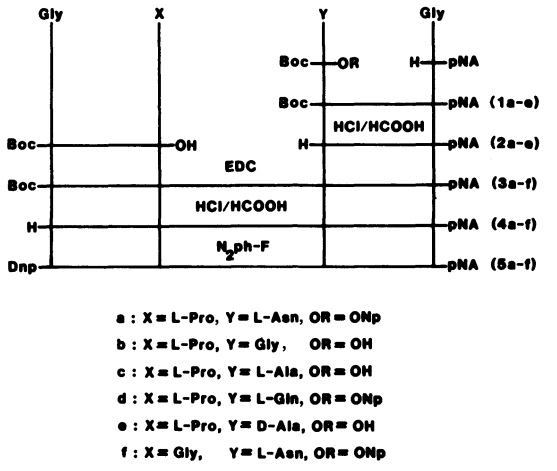

Fig. 2. Syntheses of Dnp–tetrapeptide–pNA's (**5a**—**f**).

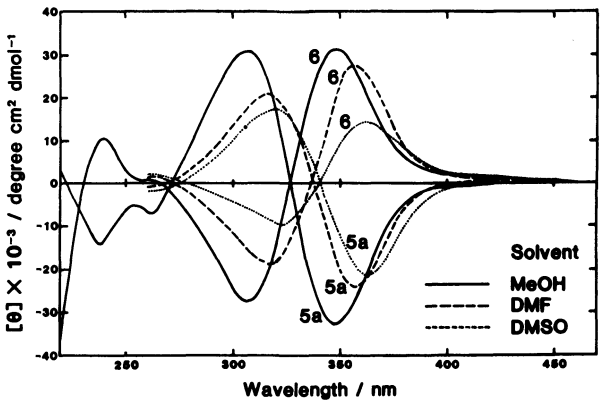

Fig. 3. CD spectra of Dnp–Gly–L-Pro–L-Asn–Gly–pNA (**5a**) and Dnp–Gly–D-Ala–L-Pro–Gly–pNA (**6**).

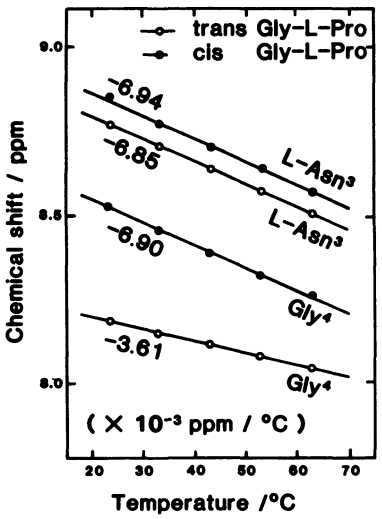

Fig. 4. Temperature dependences of the chemical shifts of the α-amide protons of **5a** in DMSO-d_6 solution.

afforded Boc–Gly–L-Pro–L-Asn–Gly–pNA (**3a**), which was converted into the Dnp derivative, Dnp–Gly–L-Pro–L-Asn–Gly–pNA (**5a**), by deprotection and subsequent treatment with 1-fluoro-2,4-dinitrobenzene. Homogeneities of the synthetic peptides were confirmed by thin-layer chromatography and elemental analysis.

The CD spectra of **5a** were just the mirror image of those of GS-model peptide Dnp–Gly–D-Ala–L-Pro–Gly–pNA (**6**)[1] (Fig. 3). The result indicates that **5a** strongly prefers the β-turn, and the type of the turn would be different from that of the GS model peptide. Certainly, GS is known to take a type II′ β-turn, however **5a** cannot take a type II′ β-turn because of five-membered ring structure of L-Pro residue at the second position. Though it is difficult to discriminate exactly the type of the turn, type II β-turn seems probable for **5a** because of enantiomeric feature of the CD spectra. The ^{1}H NMR spectrum of **5a** in DMSO-d_6 showed two sets of resonances for most of the protons due to *cis-trans* isomerism for the Gly–L-Pro bond. The *cis-trans* ratio was estimated to be 3 : 7 according to the relative peak area of the same proton. Chemical shifts of aromatic protons on the Dnp chromophore of the *trans* isomer (H-3, 8.78 ppm; H-5, 8.25 ppm; H-6, 7.09 ppm) were shifted to higher field compared with those of the *cis* isomer (H-3, 8.78 ppm; H-5, 8.27 ppm; H-6, 7.15 ppm), suggesting the approach of the two terminal chromophores in the *trans* isomer. The Gly^4–NH proton of the *trans* isomer showed smaller temperature dependence than the other NH protons, indicating the presence of 4→1 hydrogen bond essential for β-turn conformation (Fig. 4).[8] Most of the protons other than CO–NH protons show little temperature dependences, suggesting that the conformation of **5a** did not change significantly in the range of this experiment (23—63 °C).

To study the sequence-conformation relationship, a series of compounds having a general structure Dnp–Gly–L-Pro–Y–Gly–pNA (**5b**, Y=Gly; **5c**, Y=L-Ala; **5d**, Y=L-Gln; **5e**, Y=D-Ala) were examined. Syntheses of **5b**—**e** were carried out by a similar manner to that described for the synthesis of **5a** except that EDC coupling was used for the preparation of **1b**, **c**, and **e** (Fig. 2). The CD spectra of **5a**—**e** in DMSO are shown in Fig. 5. They all showed a pair of strong Cotton effects near 310 and 350 nm, and their intensities decreased in the order, L-Asn (**5a**)>Gly (**5b**)>L-Ala (**5c**)>L-Gln (**5d**), which corresponds roughly to that of decreasing bend potentials at the third position in the table of Chou and Fasman.[4] The results suggest that the bend potentials in proteins may be valid also for oligopeptides. When Y was D-Ala (**5e**), the highest ellipticities were observed suggesting that the presence of an D-amino acid at the third position is favorable for the β-turn conformation. Certainly, ^{1}H NMR study of **5e** also indicated that **5e** had higher population of β-turn conformer than **5a**. The ^{1}H NMR spectrum of **5e** in DMSO-d_6 showed two sets of resonances and the *cis-trans* ratio for the Gly–L-Pro bond was about 3 : 7, which is similar to that of **5a**. However, in the *trans* isomer of **5e**, aromatic protons on the Dnp-chromophore showed chemical shifts at higher field (H-3, 8.77 ppm; H-5, 8.20 ppm; H-6, 7.02 ppm) than those of **5a**, and the Gly^4–NH proton showed smaller temperature dependence (-3.27×10^{-3} ppm °C^{-1}) than that of **5a**. This means that CD spectra of Dnp-pNA derivatives are good measures of β-turn preference of tetrapeptide sequences besides GS-model peptides.

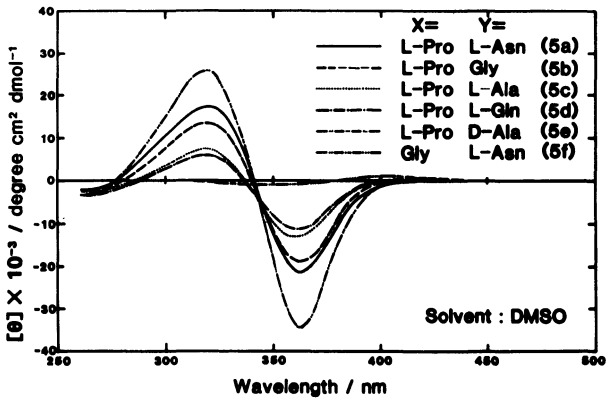

Fig. 5. CD spectra of Dnp–Gly–X–Y–Gly–pNA's (**5a**—**f**) in DMSO.

To examine the contribution of L-Pro at the second position of a tetrapeptide to the β-turn formation, Dnp–Gly–Gly–L-Asn–Gly–pNA (**5f**) was synthesized similarly (Fig. 2). The CD spectrum of **5f** measured in DMSO was compared with those of **5a** and **5b** (Fig. 5). High β-turn preference of the Gly–L-Pro–L-Asn–Gly sequence was not affected so much by replacement of L-Asn^3 with Gly but decreased significantly by replacement of L-Pro^2 with Gly. The results emphasized the importance of L-Pro residue at the second position for the β-turn formation as expected from remarkably high bend potential of the residue at the second position.[4]

It is interesting to note that the β-turn preference of amino acid residues in tetrapeptides well reflects that in proteins. The fact suggests that such a small fragment conformation of a protein is largely governed by short-range interactions of the amino acid residues involved.

Experimental

Synthesis of Peptides. All the melting points were measured on a Yanagimoto micro melting point apparatus and uncorrected. TLC's were carried out on Merck silica gel 60 F_{254} plates with the following solvent systems: R_f^1, $CHCl_3$–MeOH (5 : 1, v/v); R_f^2, $CHCl_3$–MeOH–AcOH (95 : 5 : 1, v/v); R_f^3, *n*-BuOH–AcOH–pyridine–H_2O (4 : 1 : 1 : 2, v/v). Optical rotations were measured on an Union automatic polarimeter PM-201. Yields, physical constants, and the results of elemental analyses of the synthetic peptides are summarized in Table 1.

*Boc-L-Asn-Gly-pNA (**1a**).* To a solution of H–Gly–pNA (351 mg, 1.8 mmol) in DMF (8 ml) was added Boc–L-Asn–ONp (636 mg, 1.8 mmol). The reaction mixture was stirred overnight at room temperature, evaporated *in vacuo*, and the residue was dissolved in EtOAc. The solution was washed successively with 10% citric acid, 4% $NaHCO_3$, and water, dried (Na_2SO_4), and evaporated to leave crystals, which was recrystallized from EtOH; yield, 601 mg (82%).

Compound **1d** was prepared by a similar manner to that described for the preparation of **1a**.

*Boc-L-Ala-Gly-pNA (**1c**).* To a chilled solution of Boc–L-Ala–OH (378mg, 2 mmol) and H–Gly–pNA (390 mg, 2 mmol) in DMF (8 ml) was added EDC·HCl (383 mg, 2 mmol), and the mixture was stirred at 0 °C for 1 h and at room temperature overnight. The reaction mixture was treated as described for **1a**; yield, 542 mg (74%).

Compounds **1b** and **1e** were prepared by a similar manner to that described for **1c**.

*H-L-Asn-Gly-pNA·HCl (**2a**·HCl).* Compound **1a** (409 mg, 1 mmol) was dissolved in 0.1 M (1 M=1 mol dm^{-3}) hydrogen chloride in formic acid (12 ml). The solution was allowed to stand at room temperature for 30 min and evaporated *in vacuo*. The residue was crystallized by addition of ether; yield, 323 mg (93%).

Compounds **2b—e** were prepared as described for **2a**.

*Boc–Gly–L-Pro–L-Asn–Gly–pNA (**3a**).* To a chilled solution of Boc–Gly–L-Pro–OH[7] (54 mg, 0.2 mmol), **2a**·HCl (69 mg, 0.2 mmol), and TEA (0.028 ml, 0.2 mmol) in DMF (2 ml) were added HOBt (54 mg, 0.4 mmol) and EDC·HCl (38 mg, 0.2 mmol). The reaction mixture was stirred at 0 °C for 1 h and at room temperature overnight and evaporated. After the addition of water, the solid was collected by filtration, washed successively with 10% citric acid, 4% $NaHCO_3$, and water, and dried *in vacuo* over P_2O_5. The crude product dissolved in MeOH (2 ml) was applied to a column (3×170 cm) of Sephadex LH-20 and eluted with MeOH. The fractions with the desired product detected by UV absorption and TLC were collected and evaporated, and the residue was solidified by addition of ether and recrystallized from MeOH–ether; yield, 71 mg (63%).

Compounds **3b—e** were prepared as described for **3a**.

*Boc–Gly–Gly–L-Asn–Gly–pNA (**3f**).* Boc–Gly–Gly–OH[9] (46 mg, 0.2 mmol) and **2a**·HCl (69 mg, 0.2 mmol) were coupled as described for **3a**. The crude product obtained by filtration and subsequent washing, was recrystallized from EtOH; yield, 55 mg (53%).

*H–Gly–L-Pro–L-Asn–Gly–pNA·HCl (**4a**·HCl).* Compound **3a** (56 mg, 0.1 mmol) was dissolved in 0.1 M hydrogen chloride in formic acid (1.2 ml). The solution was allowed to stand at room temperature for 30 min and evaporated to leave an oil. The product was used for the next reaction without further treatment; yield was quantitative.

Compounds **4b—f** were prepared as described for **4a**.

*Dnp–Gly–L-Pro–L-Asn–Gly–pNA (**5a**).* To a solution of **4a**·HCl (50 mg, 0.1 mmol) and TEA (0.042 ml, 0.3 mmol) in DMF (2 ml) was added N_2ph–F (37 mg, 0.2 mmol). The reaction mixture was stirred at room temperature for 3 h and evaporated *in vacuo*. The residue was dissolved in $CHCl_3$ (5 ml) and applied to a column (1.8×20 cm) of silica gel 60

(Merck), and the column was washed with $CHCl_3$. The desired product was eluted with a mixture of $CHCl_3$ and MeOH (5 : 1, v/v). The fractions containing the desired product were collected and evaporated to leave a solid, which was recrystallized from MeOH–ether; yield, 31 mg (98%).

Compounds **5b**—**e** were prepared as described for **5a**.

Dnp–Gly–Gly–L-Asn–Gly–pNA (5f). To a solution of **4f**·HCl (46 mg, 0.1 mmol) and TEA (0.042 ml, 0.3 mmol) in DMF (2 ml) was added N_2ph–F (37 mg, 0.2 mmol). The reaction mixture was stirred at room temperature for 3 h and evaporated *in vacuo*. After the addition of water, the precipitate was collected by filtration, washed successively with 10% citric acid, 4% $NaHCO_3$, and water, and dried *in vacuo* over P_2O_5. The crude product was recrystallized from DMF–ether; yield, 55 mg (93%).

CD Measurements. CD spectra were recorded on a JASCO spectropolarimeter model J-20 or J-40 in a 0.1 mM solution at room temperature (23±2 °C). Concentrations of peptide solutions were corrected by UV absorbances based on the fact that all the peptides showed the same molar absorptivity in the same solvent irrespective of the structures: UV_{max}; 326 nm (MeOH), 337 nm (DMF), 343 nm (DMSO).

^1H NMR Measurements. ^1H NMR spectra were recorded on a Bruker WH-270 spectrometer equipped with a Nicolet-1180 computer and with a Bruker B-ST-100/700 temperature control unit. The spectra were measured at 23±0.5 °C if not mentioned otherwise. Chemical shifts were measured from the internal standard of DSS.[3] The spectra were assigned by spin-decoupling, H–D exchange, and saturation transfer methods.

The authors wish to express their thanks to Professor Tatsuo Miyazawa of The University of Tokyo for helpful discussion. Thanks are also due to the members of Analitical Department of System Engineering Laboratory, Mitsubishi-Kasei Industries Ltd., for elemental analyses.

Studies on Long-range Couplings between ^{77}Se and ^{13}C in Some Aryl Selenides, Dichlorides, and Selenoxides. The Inverse Effect on Couplings in the Selenoxide Formation

Warō Nakanishi* and Yoshitsugu Ikeda

Department of Chemistry, Faculty of Education, Wakayama University, Masagocho, Wakayama 640

(Received September 20, 1983)

Long-range coupling constants between ^{77}Se and ^{13}C in selenoanisole, diphenyl selenide, diphenyl diselenide, and their 2-mono- and 2,2′-disubstituted derivatives, selenoxanthone, selenanthrene, dichlorides, and selenoxides were measured to disclose predominant factors governing the magnitude of the coupling. Extraordinary large values for two- and three-bond couplings are found in selenoxanthone. Three factors are operative: the orientational effect, the coordination number, and the effect of ring formation. The last factor accompanies a stronger inverse effect on the coupling of selenoxides than on that of selenides.

Since selenium has a magnetic isotope ^{77}Se with nuclear spin 1/2 and natural abundance 7.6%, one can study the structure and reactions of organoselenium compounds directly by NMR spectroscopy.[1-4] Chemical shifts have been shown to be correlated with the oxidation state of selenium atom.[1,2] Coupling constants appear to reflect the stereochemistry of organoselenium compounds.[1,2,4] Reich and Trend,[4] for example, have shown a stereochemical dependence of geminal ^{77}Se–^{13}C spin coupling constants in sterically fixed three-coordinated selenium compounds, *i.e.*, a selenonium salt, a selenoxide, and an ylide. In each case, one methyl carbon atom *cis* to the lone pair is substantially more strongly coupled than the other two.

We wish to report here long-range couplings in some aromatic organoselenium compounds which show interesting structural correlations.

Results and Discussion

Orientational Effect of the Lone Pair(s). The two- and three-bond coupling constants between ^{77}Se and ^{13}C (^2J(Se–C) and ^3J(Se–C), respectively) of selenoanisole (**1**), diphenyl selenide (**2**), diphenyl diselenide (**3**), their 2-mono- and 2,2′-disubstituted derivatives, selenoxanthone (**4**), and selenanthrene (**5**) were measured[5] and the results are shown in Tables 1 and 2.

The ^2J(Se–C(2,6)) values of **1**, **2**, and **3** are all about 11 Hz. The ^2J(Se–C(2′,6′)) values of 2-(phenylseleno)-benzoic acid and 2-(hydroxymethyl)phenyl phenyl selenide are 11.1±0.7 Hz, but the ^2J(Se–C(6)) values of these compounds are 6.0±0.5 Hz. Then the ^2J(Se–C) values between selenium and *ortho*-carbon of the benzene ring which has no additional substituent are about 11 Hz, and those associated with substituent attachment

at the other *ortho*-position are about 6 Hz in these five compounds. These results suggest that ^2J(Se–C) values are small when the steric repulsion between the substituent at the *ortho*-position of a benzene ring and the group attached to the selenium increases the population of the group at the selenium in the neighborhood of the carbon of benzene ring carrying the substituent at the other *ortho*-position, *i.e.*, they are small when the lone pair of electrons is on the average far from the carbon under consideration.

This is further confirmed by an examination on ^2J(Se–C) in 2,2′-disubstituted diphenyl selenides and diphenyl diselenides. The ^2J(Se–C(6,6′)) values of 2,2′-diselenodibenzoic acid, di-2-tolyl and bis(2-methoxyphenyl) diselenides are 3.4—4.6 Hz and not affected by electronic properties of the substituents. Those for 2,2′-selenodibenzoic acid and its dimethyl ester are too small to measure. The ^2J(Se–C(2,2′)) values of di-2-tolyl and bis(2-methoxyphenyl) diselenides are 12.8 and 13.7 Hz, respectively, and are larger than that of diphenyl selenide.

When the selenium atom retains at least one lone pair of electrons, the 4s-atomic orbital of selenium to be used for bonding is expected to be low.[6] Namely, most of the s-character of selenium in organoselenium compounds is attributable to its lone pair(s). Since indirect nuclear-nuclear spin couplings are mainly governed by the Fermi contact term[7] and therefore by the s-overlap integral of the bonds under consideration, the orientation of the lone pair of electrons on the selenium atom is important.

Examination of the ^2J(Se–C) values of **4** and **5** is necessary to clarify the effect of the orientation of lone pair of electrons because the ^2J(Se–C(6,6′)) values of **4** and **5**[8] are expected to be larger since the lone pairs of these compounds should spread over carbons C(6) and C(6′). Table 2 shows NMR data for **4** and **5**. Actually, very large ^2J(Se–C) values have been obtained for **4** and **5**, which are 34.0 and 24.0 Hz, respectively. Especially, the ^2J(Se–C) value of **4** is the largest that has ever been obtained for selenides to the best of our knowledge, which is almost the same as that reported for certain ylides.[4] These results provide support for the importance of the orientation of lone pairs for ^2J(Se–C). Three-bond couplings, ^3J(Se–C), were also found in **4** and **5**. The value of ^3J(Se–C(5,5′)) is larger than that of ^3J(Se–C(3,3′)) in **4** and the former is also larger than that of ^3J(Se–C(5,5′ or 4,4′)) of **5**.

The large couplings of selenium with C(6) and C(5) in **4** indicate effective spread of lone pairs over these carbons. The carbonyl group has a smaller covalent radius than selenium, which renders a favorable space

	X	Y
4	None	C=O
5	None	Se
11	O	C=O
12	O	Se=O

to the lone pair of electrons to interact with these carbons, and since the group is likely to arrange the two benzene rings coplanar due to its sp^2 hybridization state, the selenium can interact with the carbons advantageously. That the value of ^3J(Se–C(3,3′)) is smaller than that of ^3J(Se–C(5,5′)) may also indicate the orientational effect of lone pairs.

The large ^2J(Se–C) and ^3J(Se–C) values in **5** may also be explained in terms of the effective spread of lone pairs over these carbons.

After all, these couplings may be well understood on the basis of the orientation of the lone pair of electrons on the selenium.

Effect of the Coordination Number. As ^2J(Se–C) is essentially related to the s-character of selenium and carbon atoms in the bonds,[7] it is expected to vary with change in the coordination number of the selenium atom. Table 3 shows ^{13}C NMR chemical shifts and coupling constants, ^2J(Se–C) and ^3J(Se–C), of **1**, **2**, dichlorides **6** and **7**, selenoxides **8** and **9**, and diphenyl selenone (**10**). The values of ^2J(Se–C) become larger in the order: selenides, dichlorides, and selenoxides. The chemical shift of the C(2) carbons of these organoselenium compounds as well as some aromatic organosulfur compounds[9] moves to higher field if the substituent is electronegative; that is, the ^2J(Se–C) values should be related to the electron-withdrawing ability of the selenium atom and therefore are related to the ^{13}C chemical shift of the C(2) carbons. As shown in Fig. 1, the plots of ^2J(Se–C) value *vs.* ^{13}C chemical shift show a trend in which the slope for the selenoanisoles is more

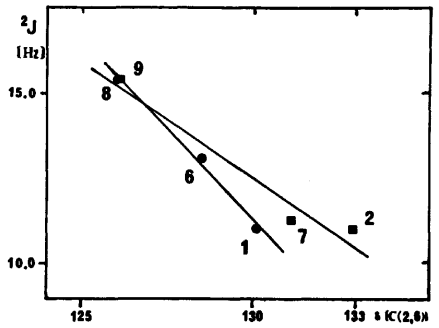

Fig. 1. Plots of ^2J(Se–C(2, 6)) *vs.* δ(C(2, 6)) for selenoanisoles (●) and diphenyl selenides (■).

Table 3. ^{13}C NMR chemical shifts and coupling constants of selenoanisoles and diphenyl selenides

Compound	Chemical shift[a]					Coupling constant[b]	
	C(1)	C(2,6)	C(3,5)	C(4)	C(Me)	^2J(Se–C(2,6))	^3J(Se–C(3,5))
PhSeMe (**1**)	131.7	130.2	128.8	125.9	7.2	11.0

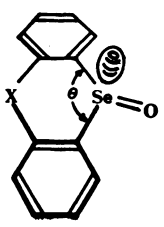
a) In ppm from TMS in $CDCl_3$. b) In Hz.

negative than that for the diphenyl selenides. Since the sign of ^2J(Se–C) is expected to be positive except **10** with which a negative sign is expected,[6] **10** should be put aside from the plots.

An unexpectedly large ^3J(Se–C) value (14.6 Hz) was found for **10**. This may be due to the increased s-character of the bonds caused by the lack of lone pair of electrons which carry otherwise most of the s-character of the selenium atom.[6]

Effect of the Ring Formation—The Inverse Effect on the Long-range Couplings. The ^{13}C NMR chemical shifts and the long-range coupling constants, ^2J(Se–C) and ^3J(Se–C), of selenoxanthone 10-oxide (**11**) and selenanthrene 9,10-dioxide (**12**) are collected in Table 2. Although the selenoxide formation from **1** and **2** to **8** and **9** increases the ^2J(Se–C) values of these compounds, the values for **11** and **12** are 22.9 and 19.0 Hz, respectively, which are smaller than those for **4** and **5**. The decrease in the long-range couplings between selenium and carbon with the formation of selenoxides relative to that of selenides (the inverse effect) is also found in the three-bond couplings, ^3J(Se–C), of **11** and **12** relative to those of **4** and **5**. The inverse effect may be attributed to the cyclic structure of **11** and **12**. Since ^2J(Se–C) values of **11** and **12** are still larger than those of **8** and **9**, the oxygens in **11** and **12** are supposed to operate in a way to increase the coupling constant but they could not overcome the disadvantageous steric factor. In other words, the s-orbital of the selenium atoms of **11** and **12** could not interact with that of the carbons in the benzene rings so effectively as in **4** and **5**. As mentioned above, the ^2J(Se–C) value of **4** is extraordinary large, which is three times as large as that of **2**, and the value of **5** is twice as large as that of **2**. Then the inverse effect on the long-range coupling in these compounds may be caused by the extraordinary large values resulting from the cyclic structure of these compounds. If the main factor for determining the large coupling constants is the sp^2-character of the selenium atoms in **4** and **5**, the factor should be smaller in **11** and **12** because the formation of selenoxides is expected to increase the sp^3-character of selenium atom. The increased sp^3-character may also decrease the values of ^3J(Se–C) of **11** and **12**. The increase in sp^2-character in **4** and **5** must be due to the cyclic structure with selenium atom(s) in the ring where the steric strain results in change in bond angle.



Experimental

^{13}C NMR spectra were obtained on a JEOL FX-60Q spectrometer operating at 15 MHz using chloroform as the solvent and tetramethylsilane as the internal standard. Spectral widths of 600, 1000, 3000, and 3500 Hz with 8 K data points and 30° or smaller pulses were employed. ^{77}Se–^{13}C coupling constants were obtained by observing the ^{77}Se satellites in ^{13}C spectra. A selective decoupling mode was also applied to assignment of ^{13}C chemical shifts if conditions were favorable.

Materials. The following compounds were prepared as described in the literature: 2-(methylseleno)benzoic acid,[10] 2-(phenylseleno)benzoic acid,[11] 2,2′-selenodibenzoic acid[12] and its dimethyl ester,[13] 2,2′-diselenodibenzoic acid,[10] selenoxanthone (**4**)[12] and its 10-oxide (**11**),[12] and selenanthrene 9,10-dioxide (**12**).[14] Physical properties agreed well with those in the literature.

Bis(2-methoxyphenyl) Diselenide. 2-Methoxyselenophenol, which had been prepared from 2-methoxyphenylmagnesium bromide and selenium in ether,[15] was oxidized in hexane with air. Recrystallization from hexane gave the diselenide in good yield, yellow needles, mp 85—87 °C. Found: C, 45.19; H, 3.72%. Calcd for $C_{14}H_{14}O_2Se_2$: C, 45.16; H, 3.76%.

Di-2-tolyl Diselenide. This compound was prepared as above in a red oil. Found: C, 49.82; H, 4.38%. Calcd for $C_{14}H_{14}Se_2$: C, 49.43; H, 4.15%.

Selenanthrene (5). To an ethanol solution (150 ml) of sodium diselenide, which had been prepared from selenium (12 g), sodium borohydride (3.2 g), and sodium hydroxide (3.0 g) according to the methods of Klayman and Griffin[16] and Bogert and Stull,[17] was added a solution of 2-chloronitrobenzene (19.5 g) in 50 ml of ethanol and refluxed for 3 h. After work-up, crystallization from acetic acid gave 2,2′-dinitrodiphenyl diselenide, yellow needles, 10.7 g (43%), mp 209—210 °C (lit,[17] 209 °C).

The diselenide (10.7 g) was dissolved in 30% aqueous dioxane (150 ml) and treated with hydrochloric acid and zinc until the solution became colorless. Then the solution was filtered and the filtrate was diazotized with 3.6 g of sodium nitrite in 50 ml of water at low temperature. The end of the diazotization was monitored with a potassium iodide-starch paper. After 0.5 h at 0 °C, the solution was extracted with ether. The residue obtained after evaporation of the solvent

was dissolved in 10 ml of acetic acid and refluxed for 5 h. After evaporation of the solvent, the product was chromatographed on silica gel to give pale brown needles, 1.7 g (21%), mp 183—184 °C (lit,[18] 181 °C).

2-(Hydroxymethyl)phenyl Phenyl Selenide. This compound was prepared through reduction of 2-(phenylseleno)benzoic acid with lithium aluminium hydride. The details will be described elsewhere.

The authors thank Professor Hiizu Iwamura of IMS for his helpful discussion.

The Claisen Rearrangement of the Lithium Enolate of 1-(2-Thienyl)alkyl Alkanoate and the Birch Reduction of the Resulting 2-(3-Thienyl)alkanoic Acid

Mitsuo Sado, Hideaki Abe, Nobuki Inuzuka, Kozo Shirai, and Takanobu Kumamoto*
Department of Chemistry, Faculty of Science, Tokai University, Kitakaname, Hiratsuka, Kanagawa 259-12
(Received October 7, 1982)

It was found that the Claisen rearrangement of the lithium enolate of 1-(2-thienyl)alkyl alkanoate in refluxing THF resulted in the formation of 2-(3-thienyl)alkanoic acid (**2**). Similarly, when the lithium enolate of 4-(2-thienyl)-4-butanolide was stirred at room temperature in the presence of hexamethylphosphoric triamide, 5,6-dihydro-4*H*-cyclopenta[*b*]thiophene-4-carboxylic acid was obtained. Further, it was found that the Birch reduction of **2** and subsequent alkylation with benzyl bromide gave a regioselective ring-opening product, 4-benzylthio-3-ethyl-3-alkenoic acid, in a good yield. The Birch reduction of 2-thienylacetic acid, followed by alkylation with benzyl bromide, also gave (*Z*)-3-benzylthio-3-hexenoic acid as the main product.

The Claisen rearrangement is an important and useful synthetic reaction, however, there has been few report,[1] of successfully obtaining 3-substituted thiophene derivatives starting from 1-(2-thienyl)-1-alkanol derivatives by the use of the Claisen rearrangement because of the formation of [1,3] sigmatropic rearrangement products.[2]

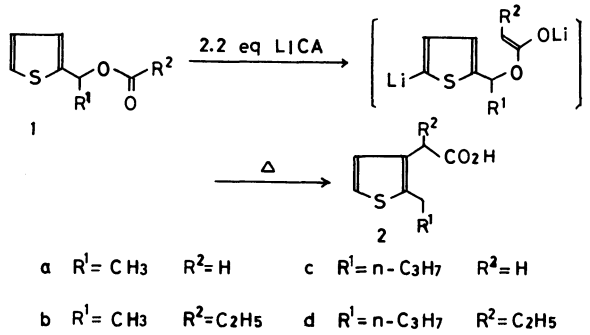
During the course of our investigation of the synthetic methodology which utilized thiophene derivatives as the key substances,[3] we needed a convenient method for the preparation of 3-substituted thiophenes. In this investigation, it was found that the Claisen rearrangement of the lithium enolate[4] of 1-(2-thienyl)alkyl alkanoate (**1**) successfully gave 2-(3-thienyl)alkanoic acid (**2**). Further, regioselective ring-opening products, 4-benzylthio-3-ethyl-3-alkenoic acids, were obtained by the Birch reduction of **2** and subsequent alkylation with benzyl bromide.

Results and Discussion

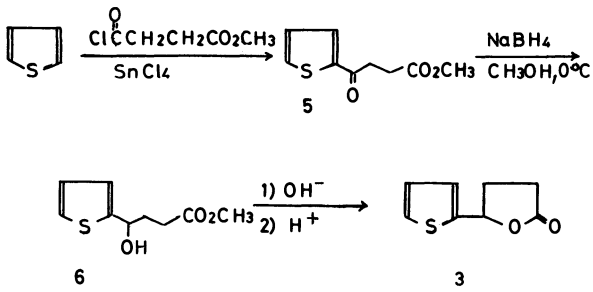
The Claisen Rearrangement of 1. It was found that, when **1a—d** were treated with 2.2 equivalents of lithium *N*-isopropylcyclohexylamide (LICA) at −70 °C in THF under nitrogen and the resulting lithium enolates were subsequently refluxed in THF, **2a—d** were obtained. (See Table 1).

As in shown in Table 1, the reaction of an equimolar amount of LICA with **1a** did not give the rearrangement product because of the formation of lithium salt at the 5-position of the thiophene nuclei (Run 1). Further, when butyryl derivatives, **1b, d**, were used as starting materials, rearrangement products, **2b, d**, were obtained in rather better yields than in the rearrangement of acetyl derivatives, **1a, c**.

Next, we investigated the rearrangement of 4-(2-thienyl)-4-butanolide (**3**) to form the corresponding cyclopentanecarboxylic acid derivative (**4**).



The preparation of **3** was carried out as in the following Scheme, the yields of **5**, **6**, and **3** were 91, 96, and 85% respectively.



Scheme 1.

As in shown in Table 2, when **3** was treated with LICA under reaction conditions similar to these in the rearrangement of **1**, the expected rearrangement product, **4**, was not obtained, but **3** was recovered

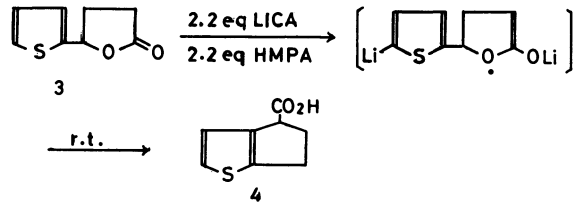
Table 1. Claisen rearrangement of the lithium enolate of 1-(2-thienyl)alkyl alkanoate (**1**)

Run	R^1	R^2	Reaction conditions: LICA(eq)	Reaction conditions: Temp/°C (Time/h)	Yield/% of **2**
1	CH_3	H	1.2	−78(1)→50(5)	—
2	CH_3	H	2.2	−78(1)→66(3)	38
3	CH_3	C_2H_5	2.2	−78(1)→66(5)	82
4	*n*-C_3H_7	H	2.2	−78(1)→66(3)	30
5	*n*-C_3H_7	C_2H_5	2.2	−78(1)→66(3)	81

Table 2. Claisen rearrangement of the lithium enolate of 4-(2-thienyl)-4-butanolide (3)

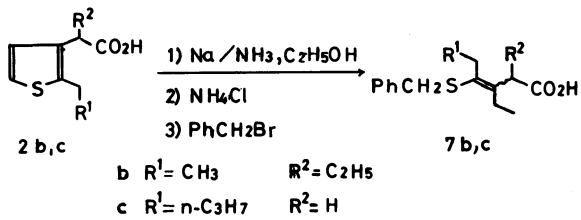
Run	Reaction conditions				Yield/% of 4
	Solvent	HMPA(eq)	Temp	Time/h	
1	THF	—	Reflux	3	—
2	THF	2.2	Reflux	3	42
3	THF	2.2	rt	18	44
4	THF/HMPA 9 : 1		rt	12	22

completely. However, it was found that the reaction of **3** with 2.2 equivalents of LICA in the presence of 2.2 equivalents of hexamethylphosphoric triamide (HMPA) at −70 °C in THF, and subsequent stirring at room temperature for 18 h, resulted in the formation of **4** in a 44% yield.



The Birch Reduction of 2. It is well known that the Birch reduction of thiophene derivatives results in the formation of many products. For example, the Birch reduction of thiophene gives 2,5- and 2,3-dihydrothiophenes and a mixture of ring-opening products, butenethiols.[5] However, in recent investigations, it has been reported that the Birch reduction of 2-acyl-[6] or 2-carboxythiophene[7] formed 2,5-dihydrothiophenes selectively. It has been also reported from our laboratory[3] that the selective formation of 2-acyl-2-alkyl-2,5-dihydrothiophene derivatives has been established by the Birch reduction of 2-acylthiophene and subsequent alkylation with alkyl halides. In the present investigation, it was found that a regioselective ring-opening reaction occurred by means of the Birch reduction of **2**.

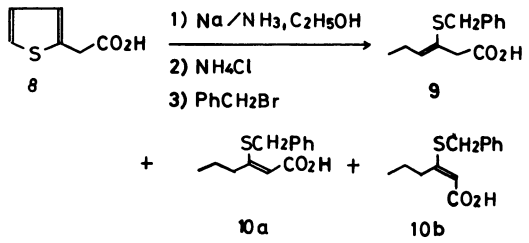
When **2b** was allowed to react with 5 equivalents of sodium in liquid ammonia in the presence of ethanol, and to the reaction mixture then were subsequently added 3 equivalents of ammonium chloride and benzyl bromide, 4-benzylthio-2,3-diethyl-3-hexenoic acid (**7b**) was obtained in a 72% yield. In a similar manner, the Birch reduction of **2c** and subsequent alkylation with benzyl bromide gave 4-benzylthio-3-ethyl-3-octenoic acid (**7c**) in an 82% yield.



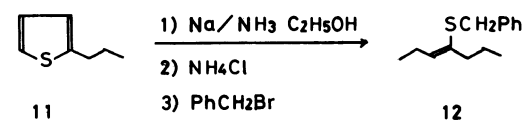
A regioselective ring-opening Birch reduction has been disclosed by Joullié *et al.*[7] It was reported there that the Birch reduction of 2-thiophenecarboxylic acid by 3 equivalents of lithium gave 2,5-dihydro-2-thiophenecarboxylic acid, while that by 5 equivalents of lithium gave (*Z*)-5-mercapto-3-pentenoic acid, which was formed regioselectively by reductive cleavage between the sulfur atom and the carbon atom at the 1-position of the thiophene ring. However, in our reaction, the reductive cleavage of the thiophene ring occurred between the sulfur atom and the carbon atom at the 5-position of thiophene ring regioselectively, while the double bond of the thiophene ring remained at the 1-position. Further, the reaction of **2b** with 3 equivalents of sodium and the subsequent addition of benzyl bromide resulted in the formation of **7b** in a 52% yield while the starting material, **2b**, was recovered in a 32% yield without any formation of dihydrothiophene derivatives. These results show that the regioselective ring-opening reaction occurred predominantly.

Next, the Birch reduction of 2-thienylacetic acid (**8**) was investigated under the assumption that the unusual ring-opening reaction would occurred as the effect of the carboxymethyl group.

When **8** was allowed to react with 5 equivalents of sodium in liquid ammonia, and to this mixture then were subsequently added 3 equivalents of ammonium chloride and benzyl bromide, similar type ring-opening product was obtained in an 84% yield. On the other hand, this product contained (*Z*)-3-benzylthio-3-hexenoic acid (**9**) and the double bond isomerized products, (*Z*)- and (*E*)-3-benzylthio-2-hexenoic acid (**10a, b**), in the ratio of 84 : 12 : 4.



Further, it was found that the Birch reduction of 2-propylthiophene (**11**), which did not contain the carboxyl group, with 4 equivalents of sodium and subsequent alkylation with benzyl bromide also gave a regioselective ring-opening product, (*Z*)-4-benzylthio-3-heptene (**12**), in a 72% yield.



From these results, we could not make clear the reason for the specificity of reductive ring-opening reaction of thiophene derivatives, but we are continuing our investigation of the Birch reduction of many types of thiophene derivatives.

Experimental

Preparation of 1-(2-Thienyl)ethyl Acetate (1a). Into a solution of 1-(2-thienyl)ethanol (3.89 g, 30 mmol) in 20 ml of

dry dichloromethane and 20 ml of dry pyridine, acetyl chloride (2.2 ml, 31 mmol) was added at 0 °C with stirring. The stirring was continued for 2 h at 0 °C and then for additional 22 h at room temperature. The reaction mixture was acidified by 10% hydrochloric acid and extracted with dichloromethane. The dichloromethane layer was dried over sodium sulfate. After the removal of the solvent, the residue was chromatographed on silica gel, **1a** was obtained by the elution of benzene [5.05 g (98%)]. The **1a** was further purified by distillation; bp 93 °C (10 mmHg, 1 mmHg=133.32 Pa). IR (NaCl): 1735 cm^{-1} (C=O), 1230 cm^{-1} (-O-); NMR($CDCl_3$): δ=1.67 (3H, d), 2.08 (3H, s), 6.31 (1H, q), 7.03—7.22 (2H, m), 7.35—7.47 (1H, m); MS: *m/e* 170 (M^+).

Similarly, 1-(2-thienyl)ethyl butyrate (**1b**), 1-(2-thienyl)-butyl acetate (**1c**), and 1-(2-thienyl)butyl butyrate (**1d**) were prepared from the corresponding alcohols and acid chlorides. The spectral and analytical data of **1b**, **1c**, and **1d** are as follows:

1b: Yield 92%, bp 82—85 °C (2.5 mmHg); IR(NaCl): 1730 cm^{-1} (C=O), 1165 cm^{-1} (-O-); NMR($CDCl_3$): δ=0.95 (3H, t), 1.42—2.00 (5H, m), 2.35 (2H, t), 6.35 (1H, q), 7.03—7.25 (2H, m), 7.36—7.47 (1H, m); MS: *m/e* 198 (M^+). Found: C, 60.51; H, 7.18%. Calcd for $C_{10}H_{14}O_2S$: C, 60.56; H, 7.23%.

1c: Yield, 98%, bp 74—75 °C (2 mmHg); IR(NaCl): 1730 cm^{-1} (C=O), 1220 cm^{-1} (-O-); NMR($CDCl_3$): δ=0.95 (3H, t), 1.22—2.03 (4H, m), 2.02 (3H, s), 6.16 (1H, t), 6.95—7.18 (2H, m), 7.27—7.38 (1H, m); MS: *m/e* 198 (M^+). Found: C, 60.56; H, 7.23%. Calcd for $C_{10}H_{14}O_2S$: C, 60.59; H, 7.12%.

1d: Yield, 94%. The **1d** was used for the next reaction without distillation. An oily product; IR(NaCl): 1735 cm^{-1} (C=O), 1170 cm^{-1}, 1095 cm^{-1} (-O-); NMR($CDCl_3$): δ=0.78—1.03 (6H, m), 1.17—2.03 (6H, m), 2.28 (2H, t), 6.05 (1H, t), 6.82—7.30 (3H, m); MS: *m/e* 226 (M^+). Found: C, 63.45; H, 7.95%. Calcd for $C_{12}H_{18}O_2S$: C, 63.70; H, 8.02%.

The Claisen Rearrangement of Lithium Enolate of 1a. To a solution of lithium *N*-isopropylcyclohexylamide, prepared from *N*-isopropylcyclohexylamine (1.56 g, 11 mmol) and butyllithium (11 mmol) in THF (13 ml), a solution of **1a** (0.850 g, 5 mmol) in THF (13 ml) was added at −78 °C under nitrogen. The reaction mixture was stirred at −78 °C for 1 h and then refluxed for 3 h with stirring. After the addition of a 5% potassium hydroxide solution, the mixture was extracted with diethyl ether. The water layer was acidified with concentrated hydrochloric acid and extracted with dichloromethane. The dichloromethane layer was dried over sodium sulfate, and the solvent was removed under reduced pressure. After the residue has been chromatographed on silica gel, (2-ethyl-3-thienyl)acetic acid (**2a**) was obtained as an oily product from the elution of benzene–diethyl ether (4 : 1) [0.329 g (38%)]. IR(NaCl): 3200—2560 cm^{-1} (CO_2H), 1705 cm^{-1} (C=O); NMR($CDCl_3$): δ=1.28 (3H, t), 2.82 (2H, q), 3.62 (2H, s), 6.97—7.30 (2H, m), 12.15 (1H, s); MS: *m/e* 170 (M^+). Found: C, 56.34; H, 5.77%. Calcd for $C_8H_{10}O_2S$: C, 56.46; H, 5.92%.

Further, the structure of the **2a** was established by reductive desulfurization with Raney nickel.[8] The reaction of **2a** (0.319 g, 2 mmol) with Raney nickel, prepared from 20 g of the nickel–aluminum alloy, in refluxing 95% ethanol (100 ml) for 12 h gave a known carboxylic acid,[9] 3-ethylhexanoic acid [0.103 g (38%)]. IR(NaCl): 3400—2300 cm^{-1} (CO_2H), 1705 cm^{-1} (C=O); NMR($CDCl_3$): δ=0.80—1.13 (6H, m), 1.33—1.56 (7H, m), 2.30 (2H, t), 11.06 (1H, s); MS: *m/e* 144 (M^+).

In a similar procedure, the rearrangement of **1b**, **1c**, and **1d** was performed, 2-(2-ethyl-3-thienyl)butyric acid (**2b**), 2-(2-butyl-3-thienyl)acetic acid (**2c**), and 2-(2-butyl-3-thienyl)-butyric acid (**2d**) respectively were thus obtained. The spectral and analytical data are as follows: **2b**: Bp 139—140 °C (4 mmHg); IR(NaCl): 3200—2550 cm^{-1} (CO_2H), 1700 cm^{-1} (C=O); NMR($CDCl_3$): δ=0.90 (3H, t), 1.29 (3H, t), 1.65—2.28 (2H, m), 2.88 (2H, q), 3.67 (1H, t), 7.15 (2H, m), 11.92 (1H, s); MS: *m/e* 198 (M^+). Found: C, 60.78; H, 6.84%. Calcd for $C_{10}H_{14}O_2S$: C, 60.59; H, 7.12%.

2c: An oily product; IR(NaCl): 3200—2550 cm^{-1} (CO_2H), 1700 cm^{-1} (C=O); NMR($CDCl_3$): δ=0.95 (3H, t), 1.25—1.80 (4H, m), 2.63—2.93 (2H, m), 3.63 (2H, s), 6.98—7.25 (2H, m), 12.08 (1H, s); MS: *m/e* 198 (M^+). Found: C, 60.50; H, 7.16%. Calcd for $C_{10}H_{14}O_2S$: C, 60.95; H, 7.12%.

2d: An oily product; IR(NaCl): 3100—2530 cm^{-1} (CO_2H), 1700 cm^{-1} (C=O); NMR($CDCl_3$): δ=0.78—1.03 (6H, m), 1.23—2.27 (6H, m), 2.87 (2H, t), 3.67 (1H, t), 7.07—7.28 (2H, m), 12.11 (1H, s); MS: *m/e* 226 (M^+). Found: C, 63.70; H, 7.83%. Calcd for $C_{12}H_{18}O_2S$: C, 63.70; H, 8.02%.

Preparation of 4-(2-Thienyl)-4-butanolide (3). Methyl 4-oxo-4-(2-thienyl)butyrate (**5**) was prepared from thiophene (8.44 g, 0.1 mol) and methyl 3-(chloroformyl)propionate (15.07 g, 0.1 mol) by the use of the Friedel-Crafts reaction[10] [18.03 g (91%), bp 125—127 °C (2 mmHg)]; IR(NaCl): 1730 cm^{-1}, 1660 cm^{-1} (C=O), 1215 cm^{-1}, 1160 cm^{-1} (-O-); NMR ($CDCl_3$): δ=2.72 (2H, t), 3.24 (2H, t), 3.63 (3H, s), 6.97—7.10 (1H, m), 7.50—7.73 (2H, m); MS: *m/e* 198 (M^+). Found: C, 54.81; H, 5.05%. Calcd for $C_9H_{10}O_3S$: C, 54.54; H. 5.09%.

To a solution of **5** (4.02 g, 20 mmol) in 30 ml of methanol, sodium borohydride (0.391 g, 10 mmol) was added in small portions at 0 °C. After stirring for 1 h at 0 °C, to the reaction mixture we added 1.4 ml of acetic acid and 100 ml of water. The mixture was then extracted with diethyl ether, and the ether layer was washed with a saturated solution of sodium hydrogencarbonate and dried over sodium sulfate. After the removal of the solvent, the residue was chromatographed on silica gel and methyl 4-hydroxy-4-(2-thienyl)butyrate (**6**) was obtained from the elution of benzene and diethyl ether (1 : 1) [3.88 g (96%), an oily product]. IR(NaCl): 3440 cm^{-1} (OH), 1720 cm^{-1} (C=O); NMR($CDCl_3$): δ=1.87—2.60 (4H, m), 3.47 (1H, brs), 3.60 (3H, s), 4.92 (1H, q), 6.77—7.00 (1H, m), 7.12—7.30 (1H, m); MS: *m/e* 200 (M^+). Found: C, 54.00; H, 6.05%. Calcd for $C_9H_{12}O_3S$: C, 53.99; H, 6.04%.

A mixture of **6** (2.02 g, 10 mmol) and sodium hydroxide (0.49 g, 12 mmol) in 10 ml of water and 5 ml of methanol was stirred at room temperature for 0.5 h. The methanol was then removed under reduced pressure and concentrated hydrochloric acid (3 ml) was added to the residue. After the the mixture has been stirred for 2 h at room temperature, 20 ml of water was added and the mixture was extracted with diethyl ether. The ether layer was dried over sodium sulfate. The solvent was removed by distillation, and the residue was chromatographed on silica gel. From the elution of benzene and diethyl ether (3 : 1), 4-(2-thienyl)-4-butanolide (**3**) was obtained as an oily product [1.44 g (85%)]. The **3** was further purified by distillation under reduced pressure [bp 153 °C (5 mmHg)]; IR(NaCl): 1770 cm^{-1} (C=O), 1200 cm^{-1}, 1120 cm^{-1} (-O-); NMR($CDCl_3$): δ=2.30—2.87 (4H, m), 5.68 (1H, t), 6.85—7.03 (2H, m), 7.19—7.32 (1H, m); MS: *m/e* 168 (M^+). Found: C, 57.18; H, 4.78%. Calcd for $C_8H_8O_2S$: C, 57.14; H, 4.80%.

The Claisen Rearrangement of the Lithium Enolate of 3. Into a solution of lithium *N*-isopropylcyclohexylamide, prepared from *N*-isopropylcyclohexylamine (1.555 g, 11 mmol) and butyllithium (11 mmol), and hexamethylphosphoric triamide (1.978 g, 11 mmol) in 25 ml of THF, a solution of **3** (0.843 g, 5 mmol) in 8 ml of THF was added at −78 °C with stirring

under nitrogen. After the temperature has then been elevated to room temperature, the reaction mixture was stirred for 18 h. After the addition of 10% hydrochloric acid, the mixture was extracted with diethyl ether. The ether layer was dried over sodium sulfate and the solvent was removed under reduced pressure. When the residue was chromatographed on silica gel, 5,6-dihydro-4*H*-cyclopenta[*b*]thiophene-4-carboxylic acid (**4**) was obtained as a solid product by the elution of dichloromethane [0.368 g (44%)]; mp 52—53 °C; IR(KBr): 3100—2550 cm^{-1} (CO_2H), 1690 cm^{-1} (C=O); NMR($CDCl_3$): δ= 1.20—2.10 (4H, m), 2.63—2.95 (1H, m), 6.80—7.18 (2H, m), 11.65 (1H, s); MS: *m/e* 168 (M^+). Found: C, 57.05; H, 4.90%. Calcd for $C_8H_8O_2S$: C, 57.14; H, 4.80%.

The Birch Reduction of ***2b****, Followed by Benzylation.* To a mixture of **2b** (0.834 g, 4.2 mmol), 1.5 ml of dry diethyl ether, 1.5 ml of absolute ethanol, and 25 ml of liquid ammonia, small pieces of sodium (0.519 g, 22.6 mmol) were added over the period of 1 h under reflux. After the mixture then been stirred for 1 h in refluxing liquid ammonia, a solid of ammonium chloride (0.721 g, 13.5 mmol) was added and the mixture was stirred for 0.5 h. Next, benzyl bromide (0.6 ml, 5 mmol) was added to the mixture, and the mixture was stirred for 20 min. Further, additional benzyl bromide (0.6 ml, 5 mmol) was added into the mixture, and the mixture was stirred for 1 h with refluxing. The ammonia was then evaporated, and the residue we added 10 ml of 10% hydrochloric acid and 10 ml of chloroform. The mixture was stirred for 1 h, and then the chloroform layer was separated. The chloroform layer was washed with water and dried over sodium sulfate. After the removal of the solvent, the residue was chromatographed on silica gel. From the elution of benzene–diethyl ether (10 : 1), 4-benzylthio-2,3-diethyl-3-hexenoic acid (**7b**) was obtained as an oily product [0.888 g (72%)]. IR(NaCl): 3080—2600 cm^{-1} (CO_2H), 1700 cm^{-1} (C=O); NMR($CDCl_3$): δ=0.68—2.57 (15H, m), 3.43 (1H, t), 3.80 (2H, s), 7.25 (5H, s), 11.32. (1H, s); MS: *m/e* 292 (M^+). Found: C, 69.78; H, 8.29% Calcd for $C_{17}H_{24}O_2S$: C, 69.83; H, 8.27%.

In a similar procedure, the Birch reduction and subsequent benzylation of **2c** and 2-thienylacetic acid (**8**) were performed. The yield and spectral data of products are as follows: 4-Benzylthio-3-ethyl-3-octenoic acid (**7c**): Yield, 82%; an oily product; IR(NaCl): 3050—2550 cm^{-1} (CO_2H), 1700 cm^{-1} (C=O); NMR($CDCl_3$): δ=0.73—1.13 (6H, m), 1.27—1.82 (4H, m), 2.23—2.62 (4H, m), 3.25 (2H, s), 3.92 (2H, s), 7.43 (5H, s), 12.08 (1H, s); MS: *m/e* 292 (M^+). Found: C, 70.08; H, 8.32%. Calcd for $C_{17}H_{24}O_2S$: C, 69.83; H, 8.27%.

(E)-3-Benzylthio-3-hexenoic acid (**9**): Yield, 71%; mp 92.5—94 °C (from petroleum ether); IR(KBr): 3100—2550 cm^{-1} (CO_2H), 1710 cm^{-1} (C=O); NMR($CDCl_3$): δ=0.87 (3H, t), 2.23 (2H, quen), 3.27 (2H, s), 3.89 (2H, s), 5.90 (1H, t), 7.32 (5H, m), 11.45 (1H, s); MS: *m/e* 236 (M^+). Found: C, 66.37; H, 6.78%. Calcd for $C_{13}H_{16}O_2S$: C, 66.08; H, 6.83%.

(Z)-3-Benzylthio-2-hexenoic acid (**10a**): Yield, 9%; mp 117.5—118.5 °C (from petroleum ether); IR(KBr): 3075—2550 cm^{-1} (CO_2H), 1680 cm^{-1} (C=O), 1580 cm^{-1} (C=C); NMR($CDCl_3$): δ=0.98 (3H, t), 1.30—1.87 (2H, m), 2.83 (2H, t), 4.03 (2H, s), 7.36 (5H, s), 11.55 (1H, s); MS: *m/e* 236 (M^+). Found: C, 65.71; H, 6.76%. Calcd for $C_{13}H_{16}O_2S$: C, 66.08; H, 6.83%.

(E)-3-Benzylthio-2-hexenoic acid (**10b**): Yield, 3%; mp 145—146 °C (from petroleum ether); IR(KBr): 3050—2500 cm^{-1} (CO_2H), 1655 cm^{-1} (C=O), 1555 cm^{-1} (C=C); NMR ($CDCl_3$): δ=1.00 (3H, t), 1.30—1.85 (2H, m), 2.53 (2H, t), 4.17 (2H, s), 5.93 (1H, s), 7.50 (5H, s); MS: *m/e* 236 (M^+). Found: C, 66.02; H, 6.83%. Calcd for $C_{13}H_{16}O_2S$: C, 66.08; H, 6.83%.

*The Birch Reduction of 2-Propylthiophene (****11****), Followed by Benzylation.* To a liquid ammonia solution (50 ml) of absolute ethanol (2.5 ml) and **11** (1.269 g, 10 mmol) dissolved in diethyl ether (2.5 ml) we added small pieces of sodium (0.926 g, 40 mmol) over a period of 1.5 h. After refluxing for 1 h, ammonium chloride (1.641 g, 31 mmol) was added to the mixture, and the mixture was stirred for 0.5 h. Next, benzyl bromide (1.5 ml, 12.5 mmol) was added to the mixture, and the mixture was stirred for 20 min. Further, additional benzyl bromide (1.5 ml, 12.5 mmol) was added to the mixture. The reaction mixture was then refluxed for 1 h. The ammonia was subsequently removed, and 10% hydrochloric acid was added to the residue. The mixture was extracted with diethyl ether, and the ether layer was dried over sodium sulfate. After the removal of the solvent, the residue was chromatographed on silica gel and (*Z*)-4-benzylthio-3-heptene (**12**) was obtained as an oily product from the elution of petroleum ether [1.646 g (74%)]. IR(NaCl): 1605 cm^{-1}, 1500 cm^{-1}, 1460 cm^{-1} (Ph); NMR($CDCl_3$): δ=0.73—0.99 (6H, m), 1.28—1.87 (2H, m), 2.28—2.43 (4H, m), 3.82 (2H, s), 5.68 (1H, t), 7.36 (5H, s); MS: *m/e* 220 (M^+). Found: C, 76.72; H, 9.06%. Calcd for $C_{14}H_{20}S$: C, 76.32; H, 9.15%.

(Received October 9, 1982)

The intramolecular Diels-Alder reactions between acyclic dienes and α,β-unsaturated amides utilizing the internal coordination of the metal salts have been studied in detail. When the magnesium salts of *N*-(*trans*, *trans*-2,4-alkadienyl)-*N*-(2-hydroxyphenyl)acrylamide derivatives are employed, the intramolecular Diels-Alder reactions are remarkably accelerated and the corresponding cycloadducts are obtained in high yields with isomeric ratios (*exo*-adducts: *endo*-adducts) of about 3 : 2. And the same reactions of *N*-(*trans*, *trans*-2,4-alkadienyl)-*N*-(2-hydroxyphenyl)-1-cyclopentenecarboxamide afford predominantly (60 : 40 to 85 : 15 selectivity) *trans*-fused cycloadducts (*exo*-adducts) in good yields.

The intramolecular Diels-Alder reaction has become one of the most powerful methods for the construction of a variety of interesting ring systems, and has been applied to the syntheses of various natural products.[1]

Though the efficiency of this reaction, derived from the entropical factor, is well established, it sometimes needs high temperature to perform the reaction, and, in some cases, the desired cycloadducts cannot be obtained at all even by the intramolecular Diels-Alder reaction. Moreover, the stereochemical features must be well-defined for this reaction to become widely accepted as a synthetic method.

As for the former problems, we recently reported an efficient method for the acceleration of the intramolecular Diels-Alder reaction between furan derivatives and α,β-unsaturated amide derivatives employing the internal coordination of magnesium salt or internal hydrogen bonding.[2] As for the stereochemical problems, a large amount of work has recently been reported by Roush,[3] Boeckmann,[4] White,[5] and so on. They, in most cases, have dealt with terminally activated trienoate systems, and made it clear that when acyclic diene is employed, two stereoisomers (*endo* and *exo* adducts) are produced, and that non-bonded interaction plays more important role in the stereoselection of this reaction than the secondary orbital control.

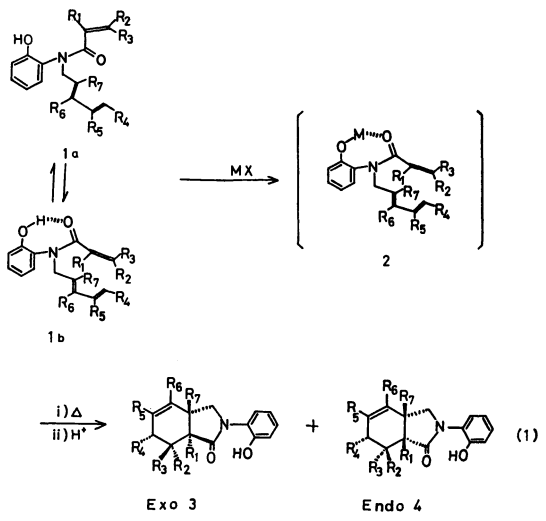
In this paper, we would like to describe our recent results about the reaction rate and stereoselection of the intramolecular Diels-Alder reaction between acyclic diene and α,β-unsaturated carbonyl unit connected by the amide bond, with the assumption that the formation of internal chelate complex not only accelerates the reaction but also alters the stereochemical course of this reaction.

Results and Discussion

Only a few examples have been known about the intramolecular Diels-Alder reaction of an acyclic diene and a dienophile linked by the amide bond,[6] and only one report was published on the stereoselection of these compounds by Gschwend *et al.*[7]

Our recent results on the intramolecular Diels-Alder reaction between furan derivatives and α,β-unsaturated amides, utilizing the internal coordination of the magnesium salt and the internal hydrogen bonding, prompted us to examine the reactivity and stereoselection of the reaction between acyclic dienes and α,β-unsaturated carboxyl compounds linked by the amide bond.

Among various conformers of *o*-aminophenol derivative **1**, only conformer **1b** in which diene and dienophile groups are located nearby would contribute to the cycloaddition reaction, and it is assumed that by the employment of the internal interaction (the internal hydrogen bonding or the internal coordination of the metal salt of compound **1**), the conformation of amide **1** would be fixed to **1b** and, combined with the Lewis acid character of the metal salt, the cycloaddition reaction would be accelerated efficiently. Moreover, it is expected that the formation of this rigid internal chelate complex **2** would result in the more efficient stereoregulation by the nonbonding steric repulsion combined with the enhanced secondary orbital control caused by the Lewis acid character of the metal salts (Eq. 1).



(1)

Based on these assumptions, various *N*-(*trans*,*trans*-2,4-alkadienyl)-*N*-(2-hydroxyphenyl)acrylamide derivatives **9** were prepared as shown in Eq. 2.

In the first place, the intramolecular Diels-Alder reaction of acrylamide derivative **9a** and its magnesium

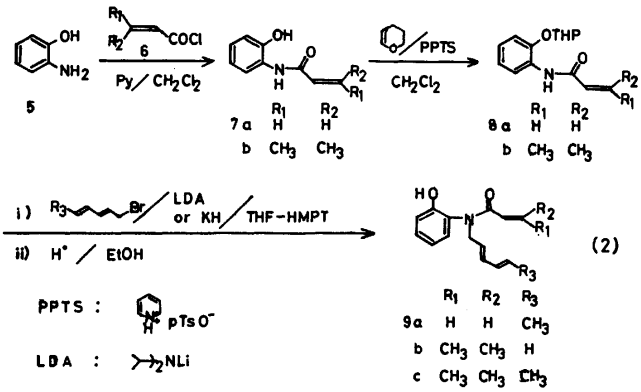
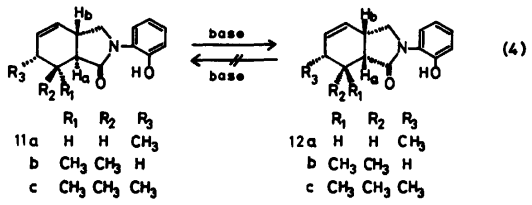
-OMgBr	Dichloromethane	36	21	52 : 48
-OMgCl	Toluene	16	77	58 : 42

a) The reaction was performed in refluxing solvent under an argon atmosphere.



salt was examined and the results were summarized in Table 1.

As shown in this Table, when the toluene solution of amide **9a** was refluxed for 20 h, nearly equal amounts of two cycloadducts (that is, *trans*-fused **11a** and *cis*-fused **12a**) were obtained in only 16% yield along with substantial amount of polymerized product. These two isomers were separated by silica-gel thin-layer chromatography (hexane–ethyl acetate, 3 : 2) and the structures were determined by ^{1}H-NMR (270 MHz).



The proton H_a in **11a** appears at δ 2.42 as a doublet-triplet splitting. Coupling constants are $J_{H_a-H_b}=J_{H_a-R_2}=13$ Hz, and $J_{H_a-R_1}=3$ Hz, indicating the trans ring fusion of this compound. On the other hand, the proton H_a in **12a** appears at δ 2.82 as a doublet-doublet-doublet splitting. Coupling constants are $J_{H_a-H_b}=8$ Hz, $J_{H_a-R_1}=5$ Hz, $J_{H_a-R_2}=13$ Hz, indicating the cis ring fusion of this compound. Further, the examination of Dreiding models of **11a** and **12a** suggested the *trans*-fused product is more strained than the *cis*-fused one. In accordance with this, it is observed that trans **11a** was completely isomerized to cis **12a** by the treatment of 0.1 equivalent of sodium methoxide in refluxing methanol. On the other hand, treatment of cis **12a** under the same conditions resulted in the complete recovery of **12a** (Eq. 4).

The IR spectrum of amide **9a** indicates that the internal hydrogen bonding exists in this molecule (carboxyl absorption appears at 1610 cm^{-1}). However, above result indicates that the fixation of the conformation of **9a** by the hydrogen bonding is not enough to promote the cycloaddition reaction effectively.

Next, with the expectation that the formation of internal chelate complex not only accelerate the reaction, but also alter the stereoselection, amide **9a** was converted to its bromomagnesium salt and heated for 9 h in refluxing toluene. As expected, the yield of cycloadducts **11a** and **12a** increased up to 72%, and the ratio of **11a** and **12a** also changed from 45 : 55 to 59 : 41. However, further examination of reaction temperature did not alter the stereoselectivity dramatically.

Next, we examined various metal salts such as Al, Sn, Zn, and B, based on the consideration that stronger Lewis acid than Mg would enhance the secondary orbital control and *endo*-mode of cyclizations would be preferred. And the results are summarized in Table 2.

–OAl(Et)Cl	Xylene	tBC	14	54	59 : 41
$-OSn(Bu)_2Cl$	Xylene	tBC	14	55	62 : 38

a) The reaction was performed in refluxing solvent under an argon atmosphere. b) The catalitic amount of 4-*t*-butylcatechol (tBC) was added. c) Two stereoisomers of the cycloadduct were separated by silica-gel thin-layer chromatography.

Though the acceleration of the reaction is rather modest compared to the magnesium salt (one serious problem is the polymerization of starting material caused by the existence of Lewis acid), the preferred formation of *endo*-cycloadduct **12a** should be noted and when phenyldichloroborane is added to the solution of sodium salt of amide **9a**, up to 86 : 14 stereoselection could be achieved.

Next, we examined the reaction of more sterically hindered 3-methyl-2-butenamide derivatives **9b** and **9c** using various metal salts. And the results are summarized in Tables 3 and 4.

As shown in these Tables, the reaction proceeded rather slowly in refluxing toluene even when the magnesium salt was employed. However, the xylene solutions of the magnesium salts of **9b** and **9c** were refluxed with catalytic amount of 4-*t*-butylcatechol as a radical scavenger, high yields of the corresponding cycloadducts were realized. However, remarkable change in the stereoselection of the two cycloadducts was not observed in these cases.

The structures of these stereoisomers were determined by ^{1}H-NMR. The proton H_a in **11b** appears at δ 2.21 as a doublet with a coupling constant of 12 Hz, indicating the trans ring fusion of this compound. On the other hand, the proton H_a in **12b** appears at δ 2.56 as a doublet with a coupling constant of 8 Hz, indicating the cis ring fusion of this compound (Eq. 4). Treatment of **11b** with 0.1 equivalent of sodium methoxide in refluxing methanol completely isomerized **11b** to **12b**. On the other hand, treatment of **12b** under the same conditions resulted in the complete recovery of **12b**. The structures of **11c** and **12c** were assigned similarly. That is, ^{1}H-NMR analysis indicates that coupling constants of proton H_a in **11c** and **12c** are 12 Hz and 8 Hz, respectively, and isomerization of **11c** proceeded smoothly by the treatment of **11c** with NaH in refluxing THF, but when **12c** was treated in the same manner,

a) The reaction were carried out in refluxing toluene. b) GC analysis were performed on 2 m, 2% OV-17 Chromosorb W column at 200 °C. c) In separable by TLC or GC. Product ratio were determined by ^{1}H-NMR.

complete recovery of **12c** was observed.

Finally, we examined the reaction of cyclic α,β-unsaturated amide compounds to construct polycyclic systems in a single step.

Amides **14** were prepared by the same procedure described in Eq. 1, and the results are shown in Table 5.

As shown in Table 5, when the toluene solution of amide **14a** was refluxed for 17 h, equal amounts of two stereoisomeric adducts **16a** and **17a** were obtained in 46% yield. On the other hand, when toluene solution of the chloromagnesium salt of amide **14a** was refluxed for 10 h, adduct **16a** and **17a** were obtained in 80% yield and the isomeric ratio of the products came up to 85 : 15. The ratio of these two stereoisomers was determined by gas chromatography and the configuration of the predominantly formed adduct was defined from X-ray analysis to be *trans*-fused (*i.e.* **16a**). Similar reactions of the magnesium salts of amides **14b—d** showed that the reaction is surely accelerated by the formation of internal chelate complex and that, in these cases, the *exo*-cycloadducts are predominantly formed.[8)] Recently, Roush[3c)] has reported the Lewis acid catalyzed intramolecular Diels-Alder reaction of terminally activated trienoates, and, in his case, the *endo*-cycloadducts were preferentially obtained, probably because of the enhanced secondary orbital control by the Lewis acid. But in our cases, the *exo*-cycloadducts were predominantly formed by the employment of magnesium salt. This result is interpreted as that, in our magnesium salt mediated intramolecular Diels-Alder reaction, steric control is more important than the secondary orbital control in the stereoselection of the products.

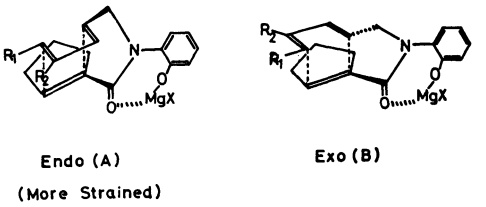

Fig. 1. Transition states of cycloaddition reaction.

When the reaction is carried out without converting to the metal salt, there is little energy difference between

endo-mode and *exo*-mode in the transition state. However, when amide **14** is converted to its magnesium salt, the coordination of the Mg to the carbonyl oxygen should make the conformation of the molecule more rigid and the *endo*-mode of cyclization (A) would become more strained compared with the *exo*-mode of cyclization (B), because of the planarity of the amide group (Fig. 1). When the stronger Lewis acid such as

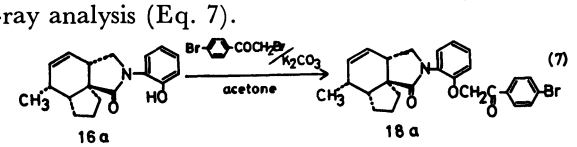
Al or Sn were employed, there would be some delicate balance between steric control and enhanced secondary orbital control, and two cycloadducts were obtained in almost the same ratio with the noncatalyzed reaction.

Thus, magnesium salt is the most effective both for the acceleration of the reaction and for the stereoselective formation of the cycloadducts.

X-Ray analysis revealed the relative configuration of the predominantly afforded cycloadduct to be the *exo*-mode cycloadduct (trans ring junction; **16a**). The analysis was carried out as follows. The preferentially formed cycloadduct was obtained by the recrystallization of the mixture of two stereoisomers from cyclohexane. This isomer was converted to its *p*-bromobenzoylmethyl ether **18a** to get a good single crystal for X-ray analysis (Eq. 7).



(7)

16a 18a

The crystal data for this compounds are: $a=11.611(4)$ Å, $b=17.874(5)$ Å, $c=11.480(5)$ Å, $\beta=110.50(3)°$, space group $P2_1/c$, $D_c=1.43$ g/cm^3. Intensities of 1896 independent reflection within the limited sphere $2\theta=110°$ were collected on a fully automated diffractometer with graphic-monochromated Cu-$K\alpha$ radiation using ω-2θ scan technique. The structure was solved by the heavy atom method. All non-hydrogen atoms were found in the E-map and subsequent Fourier syntheses. A three dimentional difference Fourier map showed the positions of all H atoms. Block-diagnoal least-squares refinement reduced final R-value and R_w-value to 0.082 and 0.087, respectively. The function minimized was $(\sum w||F_o|-|F_c||^2)$, where the weights w are $1/\sigma(F)$. The atomic parameters with their estimated standard deviations are listed in Tables 6, 7, 8, and 9.[9] The numbering system and a stereoscopic view of the molecule are shown in Figs. 2 and 3, respectively. The bond distances and angles are given in Tables 10 and 11, respectively.

As shown in Fig. 3, the ring junction between the ring A and the ring B is *trans*-configuration and the ring B links to the ring C with *cis*-configuration. The ring B is boat conformation, the atom C(5) and C(8) being displaced by 0.57 and 0.65 Å, respectively, form the plane of the other four atoms in this ring. The five-membered ring A and C both take an envelop conformation where the atoms C(8) and C(29) lie 0.63 and 0.59 Å, respectively, out of the plane composed of the other atoms. The atomic configuration of N(1) atom is estimated to be sp^2 hybrid orbital, since this atom is displaced by 0.06 Å from the plane consisted of three attached carbon atoms.

In conclusion, it is noted that an efficient and general method is established for the stereoselective intramolecular Diels-Alder reaction by employing internal coordination of the magnesium salt. By employing this

method, various cycloadducts, which cannot be prepared in the previous intramolecular Diels-Alder reaction, have become obtainable stereoselectively and in good yield.

Experimental

Measurements. All the melting points were uncorrected. ^{1}H-NMR spectra were recorded on a Bruker WH-270 (270 MHz) or a JEOL FX-90Q (90 MHz)or a Varian Model T-60 (60 MHz). IR spectra were taken on a Hitachi 260-50 spectrometer. Mass spectra were measured with JEOL JMS 01-SG. The intensity of crystal were collected on a Rigaku AFC-5 four-circle diffractomer. GC analyses were done on a Hitachi 163.

Materials. N-*(2-Hydroxyphenyl)acrylamide (7a)*: Under an argon atmosphere acryloyl chloride (9.06 g, 0.1 mol) was added to the suspension of 2-aminophenol **5** (10.91 g, 0.1 mol) and dry pyridine (8.1 ml) in dichloromethane (40 ml) at 0—5 °C and stirred at room temperature for 2 h. To the reaction mixture 2 M hydrochloric acid (5 ml)†† was added and the organic layer was washed with water (15 ml×3). After being dried over Na_2SO_4, the solution was evaporated *in vacuo*. The residue was recrystallized from benzene to afford amide **7a** (13.06 g, 80%). Mp 114.5—115.5 °C (benzene); IR (KBr) 3405, 3092 and 1685 cm^{-1}; NMR ($CDCl_3$) δ=5.50—5.97 (1H, m), 6.17—6.50 (2H, m), 6.70—7.27 (4H, m), 7.50—8.00 (1H, broad), 8.73 (1H, s); Found: C, 66.21; H, 5.49; N, 8.43%. Calcd for $C_9H_9NO_2$: C, 66.24; H, 5.56; N, 8.58%. By similar procedure amide **7b** was prepared. **7b**: Mp 147.0—148.5 °C (benzene); IR (KBr) 3291 and 1627 cm^{-1}; NMR ($CDCl_3$) δ=1.87 (3H, s), 2.17 (3H, s), 5.83 (1H, m), 6.50—6.97 (3H, m), 7.30—7.60 (1H, m), 8.98 (1H, s), 9.33—9.87 (1H, broad); Found: C, 69.03; H, 6.84; N, 7.48%. Calcd for $C_{11}H_{13}NO_2$: C, 69.09; H, 6.85; N, 7.33%.

N-[*2-(Tetrahydropyranyloxy)phenyl*]*acrylamide (8a)*. To the solution of amide **7a** (5.23 g, 32.0 mmol) and pyridinium *p*-toluenesulfonate (0.81 g, 3.2 mmol) in dichloromethane (150 ml), 3,4-dihydro-2*H*-pyran (5.11 g, 60.5 mmol) was added dropwise. After being stirred for 2 h at room temperature, 2 M sodium hydroxide (30 ml) was added to the mixture. The organic layer was washed with water (3×30 ml) and dried over Na_2SO_4. After the solvent was evaporated *in vacuo*,

†† 1 M=1 mol dm^{-3}.

residual oil was crystallized from petroleum ether to afford amide **8a** as white needles (6.42 g, 81%). Mp 81.0—82.0 °C (hexane); IR (KBr) 3408 and 1680 cm^{-1}; NMR ($CDCl_3$) δ= 1.50—2.20 (6H, m), 3.30—4.17 (2H, m), 5.20 (1H, m), 5.47—5.73 (1H, m), 6.03—6.33 (2H, m), 6.70—7.13 (3H, m), 7.73—8.00 (1H, broad), 8.03—8.37 (1H, m); Found: C, 67.92; H, 7.08; N, 5.55%. Calcd for $C_{14}H_{17}NO_3$: C, 67.99; H, 6.93; N, 5.66%. By similar procedure amide **8b** was prepared. **8b**: Mp 88.5—89.5 °C (hexane); IR (KBr) 3354 and 1667 cm^{-1}; NMR ($CDCl_3$) δ=1.40—2.07 (6H, m), 1.90 (3H, s), 2.20 (3H, s), 3.37—4.00 (2H, m), 5.30 (1H, m), 5.33 (1H, m), 6.80—7.23 (3H, m), 7.57—7.97 (1H, broad), 8.07—8.50 (1H, m); Found: C, 69.50; H, 7.83; N, 4.98%. Calcd for $C_{16}H_{21}NO_3$: C, 69.79; H, 7.69; N, 5.09%.

N-(trans, trans-2,4-Hexadienyl)-N-(2-hydroxyphenyl)acrylamide (9a). Under an argon atmosphere, amide **8a** (3.93 g, 15.9 mmol) in dry THF (15 ml) was added slowly at 0 °C to the suspension of potassium hydride (0.64 g, 15.9 mmol) in dry THF (15 ml) and the mixture was further stirred at room temperature for 15 min. To the mixture *trans,trans*-2,4-hexadienyl bromide (2.55 g, 15.9 mmol) was added dropwise at −76 °C over 10 min. After being stirred at room temperature overnight, the reaction mixture was quenched with water (10 ml) and extracted with ethyl acetate (3×20 ml). The extracts were dried over Na_2SO_4 and evaporated *in vacuo*. The residual oil was purified by the silica-gel column chromatography using hexane–ether (2 : 1). Then, the product was dissolved in ethanol (15 ml) and 2 M hydrochloric acid (2 ml). After being heated at 50—55 °C for 2 h, the reaction mixture was neutralized with 5% sodium hydrogencarbonate and extracted with dichloromethane (2×15 ml). The organic layer was washed with water and dried over Na_2SO_4. The solvent was evaporated *in vacuo* and the residual oil was purified by the silica-gel column chromatography using dichloromethane to afford amide **9a** (2.68 g, 70%). Oil; IR (liquid) 3150, 1630, and 1610 cm^{-1}; NMR ($CDCl_3$) δ=1.67 (3H, d, J=6 Hz), 3.87 (1H, dd, J=5 and 14 Hz), 4.70 (1H, dd, J=5 and 14 Hz), 5.13—6.33 (6H, m), 6.70—7.40 (5H, m), 8.60 (1H, s).

N-(trans, trans-2,4-Pentadienyl)-N-(2-hydroxyphenyl)-3-methyl-2-butenamide (9b). Under an argon atmosphere, amide **8b** (5.51 g, 0.02 mol) in dry THF (15 ml) was added dropwise at 0 °C to the solution (THF 50 ml–HMPT 10 ml) of lithium diisopropylamide (0.02 mol) and the mixture was further stirred at room temperature for 30 min. Then *trans,trans*-2,4-pentadienyl bromide (2.96 g, 0.02 mol) was added dropwise to the reaction mixture at −76 °C. After being stirred at room temperature for 2 h, the reaction mixture was quenched with 2 M hydrochloric acid (20 ml) and water (30 ml), and extracted with dichloromethane (3×30 ml). The extracts were washed with water (3×30 ml), dried over Na_2SO_4 and evaporated *in vacuo*. The residual oil was purified by the silica-gel column chromatography using hexane–ether (2 : 1). The product was hydrolyzed with 2 M hydrochloric acid in ethanol in the same way with the preparation of amide **9a** to afford amide **9b** (3.86 g, 75%). Mp 140.5—142.0 °C (hexane); IR (KBr) 3170, 1642, and 1604 cm^{-1}; NMR ($CDCl_3$) δ=1.65 (3H, s), 2.08 (3H, s), 3.58—4.10 (1H, m), 4.28—4.57 (1H, m), 4.83—5.55 (3H, m), 5.62—6.47 (3H, m), 6.67—7.28 (4H, m), 7.42 (1H, s); Found: C, 74.77; H, 7.31; N, 5.72%. Calcd for $C_{16}H_{19}NO_2$: C, 74.68; H, 7.44; N, 5.44%. By similar procedure amides **9c** and **14a—d** were prepared. **9c**: Mp 69.0—70.0 °C (hexane–cyclohexane); IR (KBr) 3220, 1644, and 1608 cm^{-1}; NMR ($CDCl_3$) δ=1.63 (3H, s), 1.70 (3H, d, J=6 Hz), 2.07 (3H, s), 3.50—4.07 (1H, m), 4.20—4.83 (1H, m), 5.10—6.17 (5H, m), 6.53—7.27 (4H, m), 7.67 (1H, s); Found: C, 75.19; H, 7.57; N, 5.25%. *Isomerization of Cycloadducts **11a** to **12a**.* A solution of adduct **11a** (99.5 mg, 0.39 mmol) and 28% sodium methoxide (0.15 ml, commercially available in methanol solution) was refluxed for 20 h. The mixture was neutralized with 2 M hydrochloric acid and extracted with dichloromethane. The organic layer was washed with water and dried over Na_2SO_4. The needles obtained by the evaporation of the solvent *in vacuo* was identical in all respects with adduct **12a** (99.0 mg, 99%). By similar procedure adduct **11b** was isomerized to adduct **12b**, but, in the case of adduct **11c**, sodium hydride was used as base instead of sodium methoxide.

*2,3,3a,6,6a,7,8,9-Octahydro-2-[2-(4-bromobenzoylmethoxy)phenyl]-1H-cyclopent[d]isoindol-1-one (**18a**).* To the suspension of adduct **16a** (413.2 mg, 1.46 mmol) and potassium carbonate (111.9 mg, 0.81 mmol) in aceton (20 ml) 4-bromophenacyl bromide (446.6 mg, 1.61 mmol) was added. After the mixture was refluxed for 2 h, water (10 ml) was added. After the extraction with dichloromethane (2×20 ml) the organic layer was dried over $MgSO_4$ and evaporated *in vacuo*. The residue was purified by silica-gel column chromatography using ether–hexane (1 : 1) to afford **18a** (547.1 mg, 80%). Mp: 188.0—189.0 °C (methanol); IR (KBr) 1702, 1681, and 1588 cm^{-1}; NMR ($CDCl_3$) $\delta=1.11$ (3H, d, $J=7$ Hz), 1.21—1.78 (6H, m), 2.20 (1H, m), 2.40—2.80 (2H, m), 3.78 (2H, m), 5.20 (2H, s), 5.76 (1H, m), 5.91 (1H, m), 6.84—7.44 (4H, m), 7.62 (2H, d, $J=8$ Hz), 7.84 (2H, d, $J=8$ Hz).

Studies of Bitter Peptides from Casein Hydrolyzate. III.[1] Bitter Taste of Synthetic Analogs of BPIa (Arg-Gly-Pro-Pro-Phe-Ile-Val) Containing D-Proline or Glycine in Place of L-Proline[2]

Ichizo MIYAKE, Katsushige KOUGE, Hidenori KANEHISA, and Hideo OKAI*

(Received October 22, 1982)

In order to elucidate the relationship between chemical structure and bitter taste of BPIa, the analogs containing D-proline or glycine in place of the L-proline in the 3- or 4-positions were synthesized. The bitter taste of [D-Pro^{3,4}]-BPIa (**1D-D**), [D-Pro^3]-des-Pro^3-BPIa (**2D**), and [Gly^3]-des-Pro^3-BPIa lacking the L-proline residue was much weaker than that of the peptides containing the L-proline, BPIa (**1L-L**), **1L-D**, **1D-L**, and **2L**. The CD curves of these analogs and BPIa were measured in water. The results suggested that the bitter taste of BPIa is caused by the spatial structure attributed to the L-proline residue.

BPIa is an extremely bitter peptide isolated by Minamiura *et al.* from cow milk casein hydrolyzate by alkaline proteinase of *Bacillus subtilis*. Its amino acid sequence has been determined to be H–Arg–Gly–Pro–Pro–Phe–Ile–Val–OH (**1L-L**).[3] This peptide has been synthesized by the authors and the threshold value of its bitter taste measured.[4] BPIa was found to be one of the most bitter compounds, which include phenylthiourea and quinine; the threshold value of BPIa was 0.05 mM. To study the relationship between chemical structure and bitter taste of BPIa, we prepared a number of fragments and analogs of it, and compared their taste and CD curves with those of BPIa in the previous paper.[1] The report shows that the spatial structure of BPIa might contribute to its bitter taste.

It is of interest to examine the taste variation of BPIa analogs caused by alteration of the spatial structure of BPIa. Among the constituent amino acids of BPIa, the L-proline residue in the 3- or 4-position seems to be very important in the structure. Therefore, we prepared the analogs containing D-proline or glycine residues in place of L-proline residue. The present paper deals with the syntheses and taste of the BPIa diastereomers (**1L-D**, **1D-L**, and **1D-D**), in which L-prolyl-L-proline in the 3- and 4-positions was replaced by L-prolyl-D-proline, D-prolyl-L-proline, and D-prolyl-D-proline respectively. Further, this paper deals with Des-Pro^3-BPIa (**2L**) in which an L-proline residue of BPIa was missing, and with two analogs of BPIa, in which the remaining L-proline residue of **2L** is replaced by D-proline or glycine residues; these are indicated by **2D** and [Gly^3]-des-Pro^3-BPIa(**3**).

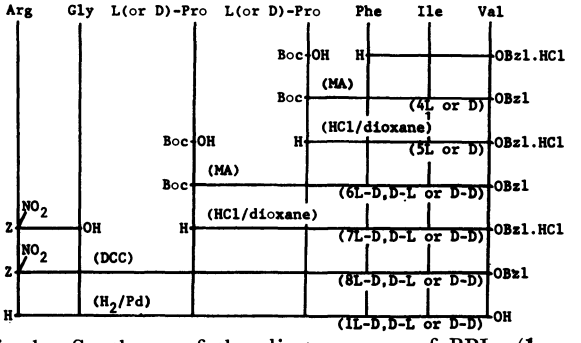

Fig. 1. Syntheses of the diastereomers of BPIa (**1L-D**, **1D-L**, and **1D-D**).

The synthesis of **1L-D** is outlined in Fig. 1. Condensation of Boc–D-Pro–OH with H–Phe–Ile–Val–OBzl·HCl by the mixed anhydride (MA) method gave acyltetrapeptide ester (**4D**). The removal of the Boc group from **4D** with hydrogen chloride in dioxane afforded the corresponding tetrapeptide ester hydrochloride (**5D**). **5D** was coupled with Boc–L-Pro–OH by the MA method to yield acylpentapeptide ester (**6L-D**). It was converted to the corresponding pentapeptide ester hydrochloride (**7L-D**) by the action of hydrogen chloride in dioxane. The protected heptapeptide (**8L-D**) derived from Z–Arg(NO$_2$)–Gly–OH and **7L-D** was hydrogenated in the presence of palladium black to yield the desired product (**1L-D**). A similar procedure was employed for the preparation of **1D-L** and **1D-D**. Des-Pro^3-BPIa (**2L**) and its diastereomer, H–Arg–Gly–D-Pro–Phe–Ile–Val–OH (**2D**), were obtained by hydrogenation of Z–Arg(NO$_2$)–Gly–L(or D)–Pro–Phe–Ile–Val–OBzl (**9L** or **D**) derived from Z–Arg(NO$_2$)–Gly–OH and **5L** or **5D**.

The synthetic procedure of **3** is as follows: Condensation of Boc–Gly–Gly–OH (**10**) with H–Phe–Ile–Val–OBzl·HCl by the MA method gave Boc–Gly–Gly–Phe–Ile–Val–OBzl (**11**). It was converted to the corresponding pentapeptide ester hydrochloride (**12**) by the action of hydrogen chloride in dioxane. Z–Arg(NO$_2$)–OH and **12** were condensed by the MA method to yield the protected hexapeptide, Z–Arg(NO$_2$)–Gly–Gly–Phe–Ile–Val–OBzl (**13**). Hydrogenation of **13** gave H–Arg–Gly–Gly–Phe–Ile–Val–OH (**3**). The homogeneity of the final products was confirmed by paper electrophoresis, amino acid analysis, and elemental

Table 1. The threshold values for bitter taste of BPIa and its analogs

Compounds	Threshold value for bitter taste/mM
Arg–Gly–L-Pro–L-Pro–Phe–Ile–Val(**1L-L**, BPIa)	0.05
Arg–Gly–L-Pro–D-Pro–Phe–Ile–Val (**1L-D**)	0.08
Arg–Gly–D-Pro–L-Pro–Phe–Ile–Val (**1D-L**)	0.11
Arg–Gly–D-Pro–D-Pro–Phe–Ile–Val (**1D-D**)	0.20
Arg–Gly–L-Pro–Phe–Ile–Val (**2L**)	0.05
Arg–Gly–D-Pro–Phe–Ile–Val (**2D**)	0.32
Arg–Gly–Gly–Phe–Ile–Val(**3**)	0.80

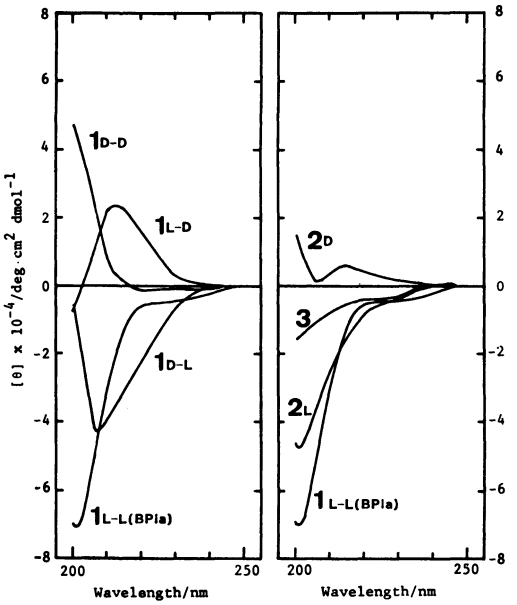

Fig. 2. CD curves of BPIa and its analogs.

analysis.

The taste of the BPIa analogs was organoleptically determined by panel evaluation employing several persons.

The results are listed in the Table. All the synthesized BPIa analogs possessed a bitter taste. The threshold value of BPIa diastereomers shows that the L-proline residue in the 3 position is more necessary for the bitter taste of BPIa than that in the 4-position. The value of **2L** is equal to that of BPIa. However, the bitter taste of **1D-D**, **2D**, and **3** lacking L-proline residue appreciably decreased, compared to that of the peptides containing L-proline residue. This means that L-proline residue is indispensable for the extremely bitter taste of BPIa.

The CD curves of these peptides in water as well as BPIa are shown in Fig. 2. The troughs of **1L-L** and **1D-L** show opposite signs to those of **1D-D** and **1L-D**. **2L** which exhibits the same bitterness as BPIa, has a curve with a negative trough at 202 nm; BPIa possesses a similarly shaped curve. **2D** and **3**, which have much weaker bitterness than BPIa, give different curves. The results of both taste and CD measurements prove that the bitter taste of BPIa is caused by the spatial structure of the molecule attributed to the L-proline residue.

Experimental

All the melting points are uncorrected. The thin layer chromatography was carried out on Merck silica gel G with the solvent systems: R_f^1, 1-butanol–acetic acid–pyridine–water (4 : 1 : 1 : 2, v/v); R_f^2, chloroform–methanol (5 : 1, v/v). Spots of materials possessing a free amino group on a thin layer plate were detected by spraying ninhydrin, and those of amino group blocked materials by spraying 25% hydrogen bromide in acetic acid and then ninhydrin. The optical rotations were measured on a Union PM-101 polarimeter. Amino acid analyses in acid hydrolyzate with 6 M hydrochloric acid (1 M = 1 mol dm^{-3}) at 110 °C for 72 h were performed with a Hitachi amino acid analyzer, KLA-5 type. Molar ratios of amino acids were based on the isoleucine value. Prior to analyses, the compounds were dried over phosphorus pentoxide at 66 °C and 2 mmHg (1 mmHg≈133.322 Pa) for 2 h, except in the case of the peptide ester hydrochlorides.

*Boc-L-Pro-Phe-Ile-Val-OBzl (**4L**).* To a solution of Boc-L-Pro-OH (2.15 g, 10 mmol) and NMM (1.1 ml, 10 mmol) in THF (20 ml), ECF (1.0 ml, 10 mmol) was added at −5 °C with stirring. After 10 min, a solution of H-Phe-Ile-Val-OBzl·HCl[4] (5.04 g, 10 mmol) and NMM (1.1 ml, 10 mmol) in DMF (20 ml) was added to it. The reaction mixture was stored in an ice bath for 1 h and then at room temperature overnight. The mixture was evaporated *in vacuo* and dissolved in ethyl acetate. The solution was washed with 4% sodium hydrogencarbonate, 4% citric acid and water successively, and then dried over anhydrous sodium sulfate. The filtrate was evaporated *in vacuo* and the oily residue was crystallized with ether–petroleum ether: yield 6.06 g (91%); mp 111—112 °C; $[\alpha]_D^{20}$ −83° (*c* 1, methanol); R_f^1 0.98 and R_f^2 0.88.

Found: C, 66.54; H, 8.06; N, 8.37%. Calcd for $C_{37}H_{52}O_7N_4$: C, 66.84; H, 7.88; N, 8.43%.

*Boc-D-Pro-Phe-Ile-Val-OBzl (**4D**).* This was prepared from Boc-D-Pro-OH (2.15 g, 10 mmol) and H-Phe-Ile-Val-OBzl·HCl[4] (5.04 g, 10 mmol) as described above: yield 6.02 g (91%); mp 145—148 °C; $[\alpha]_D^{20}$ −32° (*c* 1, methanol); R_f^1 0.96 and R_f^2 0.78.

Found: C, 66.71; H, 8.11; N, 8.55%. Calcd for $C_{37}H_{52}O_7N_4$: C, 66.84; H, 7.88; N, 8.43%.

*H-L-Pro-Phe-Ile-Val-OBzl·HCl (**5L**).* Compound **4L** (3.32 g, 5 mmol) was dissolved in 4.1 M hydrogen chloride in dioxane (25 ml). The solution was allowed to stand for 1.5 h at room temperature and then evaporated *in vacuo*. The oily residue was solidified by the aid of ether: yield 2.86 g (95%); mp 90 °C (decomp); $[\alpha]_D^{20}$ −66° (*c* 1, methanol); R_f^1 0.88 and R_f^2 0.61.

Found: C, 63.32; H, 7.83; N, 9.11%. Calcd for $C_{32}H_{45}O_5N_4Cl\cdot 1/2\,H_2O$: C, 62.99; H, 7.60; N, 9.18%.

*H-D-Pro-Phe-Ile-Val-OBzl·HCl (**5D**).* This was prepared from **4D** (3.22 g, 5 mmol) as described above: yield 2.67 g (89%); mp 92 °C (decomp); $[\alpha]_D^{20}$ −31° (*c* 1, methanol); R_f^1 0.88 and R_f^2 0.59.

Found: C, 62.72; H, 7.74; N, 8.98%. Calcd for $C_{32}H_{45}O_5N_4Cl\cdot 1/2\,H_2O$: C, 62.99; H, 7.60; N, 9.18%.

*Boc-L-Pro-D-Pro-Phe-Ile-Val-OBzl (**6L-D**).* Boc-L-Pro-OH (0.65 g, 3 mmol) and **5D** (1.80 g, 3 mmol) were coupled by the same method as described for the preparation of **4L**: yield 2.07 g (91%); mp 107 °C; $[\alpha]_D^{20}$ +2° (*c* 1, methanol); R_f^1 0.97 and R_f^2 0.70.

Found: C, 65.92; H, 8.10; N, 9.01%. Calcd for $C_{42}H_{59}O_8N_5$: C, 66.20; H, 7.81; N, 9.19%.

*Boc-D-Pro-L-Pro-Phe-Ile-Val-OBzl (**6D-L**).* Boc-D-Pro-OH (0.65 g, 3 mmol) and **5L** (1.80 g, 3 mmol) were coupled by the same method as described for the preparation of **4L**: yield 1.82 g (80%); mp 68 °C; $[\alpha]_D^{20}$ −50° (*c* 1, methanol); R_f^1 0.94 and R_f^2 0.76.

Found: C, 66.06; H, 8.03; N, 8.98%. Calcd for $C_{45}H_{59}O_8N_5$: C, 66.20; H, 7.81; N, 9.19%.

*Boc-D-Pro-D-Pro-Phe-Ile-Val-OBzl (**6D-D**).* Boc-D-Pro-OH (0.65 g, 3 mmol) and **5D** (1.80 g, 3 mmol) were coupled by the same method as described for the preparation of **4L**: yield 1.60 g (73%); mp 82—84 °C; $[\alpha]_D^{20}$ +10° (*c* 1, methanol); R_f^1 0.97 and R_f^2 0.77.

Found: C, 66.40; H, 7.98; N, 8.83%. Calcd for $C_{42}H_{59}O_8N_5$: C, 66.20; H, 7.81; N, 9.19%.

*H-L-Pro-D-Pro-Phe-Ile-Val-OBzl·HCl (**7L-D**).* Compound **6L-D** (1.52 g, 2 mmol) was treated with hydrogen chloride as described for **5L**: yield 1.33 g (95%); mp 103 °C (decomp); $[\alpha]_D^{20}$ −85° (*c* 1, methanol); R_f^1 0.80 and R_f^2 0.45.

Found: C, 62.74; H, 7.75; N, 9.72%. Calcd for $C_{37}H_{52}O_6N_5Cl \cdot 1/2\ H_2O$: C, 62.82; H, 7.55; N, 9.90%.

*H-D-Pro-L-Pro-Phe-Ile-Val-OBzl·HCl (**7D-L**).* Compound **6D-L** (1.52 g, 2 mmol) was treated with hydrogen chloride as described for **5L**: yield 1.16 g (83%); mp 98 °C (decomp); $[\alpha]_D^{20}$ −73° (*c* 1, methanol); R_f^1 0.81 and R_f^2 0.59.

Found: C, 62.40; H, 7.55; N, 9.51%. Calcd for $C_{37}H_{52}O_6N_5Cl \cdot H_2O$: C, 62.04; H, 7.60; N, 9.78%.

*H-D-Pro-D-Pro-Phe-Ile-Val-OBzl·HCl (**7D-D**).* Compound **6D-D** (1.52 g, 2 mmol) was treated with hydrogen chloride as described for **5L**: yield 1.34 g (96%); mp 115 °C (decomp); $[\alpha]_D^{20}$ −35° (*c* 1, methanol); R_f^1 0.82 and R_f^2 0.62.

Found: C, 62.42; H, 7.60; N, 9.42%. Calcd for $C_{37}H_{52}O_6N_5Cl \cdot H_2O$: C, 62.04; H, 7.60; N, 9.78%.

*Z-Arg(NO2)-Gly-L-Pro-D-Pro-Phe-Ile-Val-OBzl (**8L-D**).* To a solution of Z-Arg(NO_2)-Gly-OH[4] (0.62 g, 1.5 mmol), **7L-D** (1.05 g, 1.5 mmol), and NMM (0.17 ml, 1.5 mmol) in DMF (6 ml), DCC (0.34 g, 1.65 mmol) was added at 0 °C with stirring. The reaction mixture was stirred for 3 h at 0 °C and then at room temperature overnight. DCUrea was filtered off and the filtrate was diluted with ethyl acetate. The solution was washed with 4% sodium hydrogencarbonate, 0.5 M hydrochloric acid, and water successively and then dried over anhydrous sodium sulfate. The filtrate was evaporated *in vacuo* and the residue was collected by the aid of ether. It was recrystallized from methanol–ether: yield 1.22 g (77%); mp 108 °C (decomp); $[\alpha]_D^{20}$ −35° (*c* 1, methanol); R_f^1 0.84 and R_f^2 0.68.

Found: C, 60.17; H, 6.84; N, 14.40%. Calcd for $C_{53}H_{71}O_{12}N_{11}$: C, 60.38; H, 6.79; N, 14.62%.

*Z-Arg(NO2)-Gly-D-Pro-L-Pro-Phe-Ile-Val-OBzl (**8D-L**).* This was prepared from Z-Arg(NO_2)-Gly-OH[4] (0.41 g, 1 mmol) and **7D-L** (0.70 g, 1 mmol) as described above: yield 0.72 g (68%); mp 118 °C (decomp); $[\alpha]_D^{20}$ −62° (*c* 1, methanol), R_f^1 0.87 and R_f^2 0.69.

Found: C, 60.08; H, 6.81; N, 14.48%. Calcd for $C_{53}H_{71}O_{12}N_{11}$: C, 60.38; H, 6.79; N, 14.62%.

*Z-Arg(NO2)-Gly-D-Pro-D-Pro-Phe-Ile-Val-OBzl (**8D-D**).* This was prepared from Z-Arg(NO_2)-Gly-OH[4] (0.62 g, 1.5 mmol) and **7D-D** (1.05 g, 1.5 mmol) as described above: yield 1.10 g (70%); mp 118 °C (decomp); $[\alpha]_D^{20}$ +16° (*c* 1, methanol); R_f^1 0.86 and R_f^2 0.64.

Found: C, 60.09; H, 6.79; N, 14.34%. Calcd for $C_{53}H_{71}O_{12}N_{11}$: C, 60.38; H, 6.79; N, 14.62%.

*H-Arg-Gly-L-Pro-D-Pro-Phe-Ile-Val-OH·AcOH (**1L-D**).* Compound **8L-D** (0.32 g, 0.3 mmol) was dissolved in a mixture of methanol (3 ml) and acetic acid (3 ml) and hydrogenated in the presence of palladium black for 24 h at room temperature. The filtrate from catalyst was evaporated *in vacuo* and the residual oil was solidified by the aid of acetone. The product was recrystallized from methanol–ether: yield 0.20 g (79%); $[\alpha]_D^{20}$ −16° (*c* 1, H_2O); R_f^1 0.68 and R_f^2 0.00. Amino acid ratios in acid hydrolyzate: Arg 0.96, Gly 1.00, Pro 2.06, Phe 1.03, Ile 1.00, Val 0.99.

Found: C, 56.35; H, 7.79; N, 16.13%. Calcd for $C_{38}H_{60}O_8N_{10} \cdot CH_3COOH \cdot 1/2\ H_2O$: C, 56.25; H, 7.75; N, 16.40%.

*H-Arg-Gly-D-Pro-L-Pro-Phe-Ile-Val-OH·AcOH (**1D-L**).* Compound **8D-L** (0.32 g, 0.3 mmol) was hydrogenated as described above: yield 0.19 g (73%); $[\alpha]_D^{20}$ −24° (*c* 1, H_2O); R_f^1 0.69 and R_f^2 0.00. Amino acid ratios in acid hydrolyzate: Arg 1.02, Gly 1.16, Pro 2.31, Phe 1.21 Ile 1.00, Val 0.98.

Found: C, 55.17; H, 7.70; N, 15.96%. Calcd for $C_{38}H_{60}O_8N_{10} \cdot CH_3COOH \cdot 3/2\ H_2O$: C, 55.09; H, 7.74; N, 16.06%.

*H-Arg-Gly-D-Pro-L-Pro-Phe-Ile-Val-OH·AcOH (**1D-D**).* Compound **8D-D** (0.32 g, 0.3 mmol) was hydrogenated as described above: yield 0.16 g (62%); $[\alpha]_D^{20}$ +78° (*c* 1, H_2O); R_f^1 0.62 and R_f^2 0.00. Amino acid ratios in acid hydrolyzate: Arg 0.86, Gly 1.09, Pro 2.18, Phe 1.20, Ile 1.00, Val 0.97.

Found: C, 55.80; H, 7.74; N, 15.90%. Calcd for $C_{38}H_{60}O_8N_{10} \cdot CH_3COOH \cdot H_2O$: C, 55.67; H, 7.71; N, 16.23%.

*Z-Arg(NO2)-Gly-L-Pro-Phe-Ile-Val-OBzl (**9L**).* To a solution of Z-Arg(NO_2)-Gly-OH[4] (0.41 g, 1 mmol) and NMM (0.11 ml, 1 mmol) in THF (2 ml), ECF (0.1 ml, 1 mmol) was added at −5 °C with stirring. After 10 min, a solution of **5L** (0.60 g, 1 mmol) and NMM (0.11 ml, 1 mmol) in THF (2 ml) was added to it. The reaction mixture was stored in an ice bath for 1 h and then at room temperature overnight. The mixture was evaporated *in vacuo* and the residue was solidified with water. It was filtered, washed with 4% sodium hydrogencarbonate, 0.5 M hydrochloric acid, and water successively, and dried. The product was dissolved in methanol and collected by the aid of ethyl acetate: yield 0.72 g (75%); mp 175—180 °C; $[\alpha]_D^{20}$ −24° (*c* 1, DMF); R_f^1 0.88 and R_f^2 0.74.

Found: C, 60.12; H, 6.74; N, 14.52%. Calcd for $C_{48}H_{64}O_{11}N_{10}$: C, 60.23; H, 6.74; N, 14.64%.

*Z-Arg(NO2)-Gly-D-Pro-Phe-Ile-Val-OBzl (**9D**).* This was prepared from Z-Arg(NO_2)-Gly-OH[4] (0.62 g, 1.5 mmol) and **5D** (0.90 g, 1.5 mmol) as described for **8L-D**: yield 1.10 g (77%); mp 175 °C (decomp); $[\alpha]_D^{20}$ +3° (*c* 1, DMF); R_f^1 0.96 and R_f^2 0.78.
