(Received January 14, 1982)

The polarization characteristics of poly(tetrafluoroethylene)-bonded Raney nickel hydrogen- and silver oxygen-electrodes have been measured as a function of the thickness of the catalyst layer, and the polarization curves of these electrodes have been analyzed on the basis of the electrolyte film model. The observed polarization curves were divided into several segments and a linear polarization-current equation, derived from the model, has been applied to each segment. The performance of the electrodes approaches asymptotically to an upper limit with the thickening of the catalyst layers. The profiles of the faradayic current density across the electrode wall have been estimated for both electrodes. In contrast with the almost flat profiles of the Raney nickel electrodes, the current densities for the silver electrodes are localized on the liquid side of the electrodes; a thin area of the catalyst layer ranging from the electrode-face/electrolyte interface to 5.3×10^{-3} cm distance sustains most of the load current at a polarization of 220 mV. The catalytic activities of both the silver and Raney nickel catalysts are enhanced with progression of the polarization while the resistivities of the electrolyte film maintained essentially constant. A slight surface oxidation for the Raney nickel and a surface reduction for the silver catalysts have been suggested as probable explanations for the enhanced catalytic activities observed.

The performance of Raney nickel hydrogen-electrodes is markedly improved with increasing catalyst loading[1,2] while that of silver oxygen-electrodes is not so sensitive to the change of the loading as the hydrogen-electrodes.[3,4] The present study involves an attempt to explain this difference on the basis of the electrolyte film model.

The feature of this model is the thin electrolyte film covering the catalyst surface.[1,5,6] Owing to the ionic conductivity of the film the electrode reaction takes place not only on the electrode-face/electrolyte interface but also on the portion of the catalyst located at a distance from the interface. The load current is sustained by the electrode reaction occurring in this zonal area so that the performance of the electrode depends upon the thickness of the catalyst layer as well as on the geometrical working area of the electrode. If the reaction zone extends toward the gas side in a long range, a good performance can be expected when a thick electrode is used. If it is short range, a thin electrode suffices to yield the performance of the upper limit for the catalyst used.

The polarization characteristics and the thickness of the reaction zone are determined by the catalytic activity and the film resistivity. Mund and his coworkers have calculated these parameter values from the polarization data, assuming a linear polarization-faradayic current relation.[1,5] The formula derived from this assumption however cannot be applied to curved polarization characteristics as is observed in the present study. The more rigorous formula that is applicable to curves, is derived from the assumption that the faradayic current is an exponential function of the polarization, but complicated mathematical calculations are required for the derivation of the potential-current relation.[7,8] In the present study, to apply a linear function to curves, the polarization curves observed are divided into several segments that can be regarded as straight lines, and a linear potential-current relation is applied to each segment.

This analytical method for the polarization data is applied to the foregoing hydrogen and oxygen electrodes to estimate the catalytic activities and the film resistivities. These parameter values should explain why the Raney nickel electrodes differ from the silver electrodes in the performance-catalyst loading relationship. Setting desired parameter values that are not yet realized in the experiment, one can calculate polarization curves for unreal electrodes. This may provide us with some hints and orientations for improving the electrode performance.

Experimental

Preparation of the Raney Nickel Catalyst. An ingot containing 40% Ni (99.95% purity) and 60% Al (99.99% purity) was prepared by using an induction furnace. The ingot obtained was crushed and powdered to a particle size of less than 37 μm. The aluminium was leached with a 6 M KOH solution (1 M=1 mol dm^{-3}) at 80 °C for 5 h. The Raney nickel thus obtained was washed with water and methyl alcohol.

Preparation of the Silver Catalyst. Ten grams of silver nitrate (guaranteed reagent, Yoneyama Chemical Co., Ltd.) was dissolved into 5 ml of water with 2.5 ml of formaline (guaranteed reagent, Kanto Chemical Co., Inc.). The solution obtained was added dropwise into 200 ml of 0.6 M KOH solution at 10 °C with stirring. The silver powder thus obtained was washed with water and dried in an oven at 120 °C.

Preparation of the Electrodes. The electrodes were prepared with the same method as in the previous work.[2] Poly(tetrafluoroethylene)(PTFE) (D-1, Daikin Industrial Company) was added to the catalyst powder in an amount proportional to 10% of the weight of the catalyst. The mixture was milled and dried to become a paste. The paste was calender-rolled by hand into sheets. They were used as catalyst layers.

The gas-side layers for the hydrogen-electrodes were prepared by binding nickel black powder with PTFE and by calender-rolling it into sheets.

Those for the oxygen-electrodes were prepared by using a mixture of graphite powder and activated carbon powder

† Present address: Fuji Electric Co., Ltd., Nagasaka, Yokosuka 240-01.

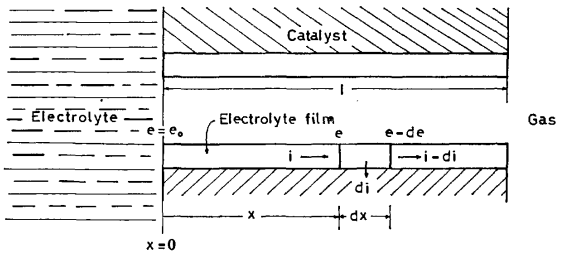

Fig. 1. Schematic cross section of an electrode pore.

instead of nickel black. After the sheets were reinforced with stainless steel screens (60—100 mesh), they were heated at 380 °C for 15 min in a nitrogen atmosphere. The gas-side layers thus obtained were attached to the catalyst layers by pressing at a pressure of 420 kg/cm². The double-layered electrodes obtained were heated in a hydrogen atmosphere at 150 °C for the hydrogen-electrodes and at 380 °C for the oxygen-electrodes.

Measurement of the Polarization. The geometrical working area of the electrodes was 7 cm². The electrolyte was a 6M KOH solution and was circulated at a rate of 5 ml/min. The electrolyte temperature was 60±0.5 °C. The IR voltage drop was eliminated by the current-interruption method.[9]

Theoretical

When the PTFE-bonded electrodes contact with the electrolyte solution, the inner face of the electrode pore is covered with a thin electrolyte film while the electrolyte penetration into the central area of the pore is hindered by the repellency of PTFE. Thus the supplied gas can permeate the porous space to react with the electrolyte on the catalyst surface. This feature can be modeled as a cylindrical electrode pore as shown in Fig. 1. For the potential in the electrolyte film, e, Ohm's law holds:

$$\frac{de}{dx} + i\rho = 0, \tag{1}$$

where x is the distance from the electrode-face/electrolyte interface, i the ionic current density and ρ the resistivity of the electrolyte film. A linear function is assumed for the faradayic current density, di/dx:

$$\frac{di}{dx} + \frac{e}{k} = 0, \tag{2}$$

where k is the impedance for the inner-face/electrolyte interface per unit length of the pore. If ρ and k are independent of both x and e, and the edge effect of the pore can be neglected, Eqs. 1 and 2 can be integrated under the boundary conditions, $e=e_0$ at $x=0$ and $i=0$ at $x=l$:

$$e = e_0 \cdot \frac{\cosh\sqrt{\rho/k}(l-x)}{\cosh\sqrt{\rho/k}\,l} \tag{3}$$

$$i = \frac{e_0}{\sqrt{\rho k}} \cdot \frac{\sinh\sqrt{\rho/k}(l-x)}{\cosh\sqrt{\rho/k}\,l}, \tag{4}$$

where l is the length of the pore. Substituting $x=0$ into Eq. 4 one can obtain a potential-current relation to compare with experimental data:

$$i = \frac{e_0}{\sqrt{\rho k}} \cdot \tanh\sqrt{\rho/k}\,l. \tag{5}$$

Regarding e_0 as the polarization corrected for IR voltage drop, i as the current density per unit working area of the electrode, l as the thickness of the catalyst layer, ρ as the resistivity of the electrolyte film per unit working area of the electrode whose catalyst layer has unit thickness, and k as the impedance per unit thickness of the catalyst layer, one can apply Eq. 5 to the calculation of the polarization curves.

The polarization resistance, ω, is defined as

$$\omega \equiv \left(\frac{e}{i}\right)_{x=0} = \sqrt{\rho k}\coth\sqrt{\rho/k}\,l. \tag{6}$$

The polarization resistance is the slope of the polarization curves and its application is limited to linear polarization characteristics. For application to the curves, they are divided into several segments with polarization values at intervals of 10—20 mV and Eq. 6 is then applied to each segment, regarding it as a straight line. From the polarization curves observed for various catalyst loadings, the reciprocal polarization resistance ω^{-1} can be calculated as a function of the thickness of the catalyst layer l for each of the polarization regions. Thus ρ and k are obtained as values that make curves for Eq. 6 best fit the observed ω^{-1} *vs.* l plots.

The faradayic current density, i_F, can be obtained as a function of x by substituting Eq. 3 into Eq. 2:

$$i_F \equiv \left|\frac{di}{dx}\right| = \frac{e_0}{k} \cdot \frac{\cosh\sqrt{\rho/k}(l-x)}{\cosh\sqrt{\rho/k}\,l}. \tag{7}$$

The ratio of i_F at $x=x$ to that at $x=0$, i_F/i_F°, is given by

$$\frac{i_F}{i_F^\circ} = \frac{\cosh\sqrt{\rho/k}(l-x)}{\cosh\sqrt{\rho/k}\,l}. \tag{8}$$

The above equation gives the profile of the faradayic current density across the electrode wall.

Results

Figure 2 shows plots of the polarization, η, against current density, I, measured for Raney nickel hydrogen-electrodes with variation of the catalyst loading. The ω^{-1} *vs.* l plots obtained from the data above are represented in Fig. 3, where the catalyst loading is given as the scale of the thickness of the catalyst layer; the conversion factor was obtained by measuring the thickness of the catalyst layers with a micrometer as 0.01 cm thickness=30 mg/cm² loading. The solid lines in the figure are the calculated curves of the best fit. The ρ and k values yielding the best fitting curves are shown in Table 1. The solid lines in Fig. 2 are polarization curves calculated from these parameter values using Eq. 5. The agreement with the observed plots is good.

As seen in Fig. 3, the ω^{-1} values reaches 90% of their upper limits when $l=4\times10^{-2}$ cm. Hence one centimeter was used as an l value that gives the upper limit of ω^{-1}. Line 1 in Fig. 2 is a polarization curve calculated for $l=1$ cm holding ρ and k to the values in Table 1. This is the best performance that can be theoretically expected using the Raney nickel catalyst prepared in the present study. If the catalytic activity is improved to yield $k=1.7\times10^{-3}\ \Omega\ \mathrm{cm}^3$, which

of Table 2 and $l=1$ cm. It is very close to the open triangles in Fig. 4 (data for the thickest catalyst layer used in this study). Thus no marked improvement in the performance can be expected from thicker electrodes when the same catalyst is used. If the ρ value can be lowered to 10 Ω cm and $k=0.1$ Ω cm^3, Line 2 can be expected as the best performance. If the k value is lowered to 10^{-2} Ω cm^3 in addition to the above lowering in the ρ value, the best performance attainable is given by Line 3.

Discussion

When the polarization curves are divided into segments, there is a choice of sectionalizing with respect either to polarization or current density. When polarization was chosen, it was assumed implicitly that ρ and k depend upon polarization rather than current density. This assumption was open, but the good agreement found between the calculated and observed plots suggests the validity of the assumption employed.

As seen in Tables 1 and 2, the k values of both the hydrogen- and oxygen-electrodes decrease with progression of the polarization. This is due to an enhancement of the catalytic activity which is probably brought about by polarizing the electrode catalyst. As the hydrogen-electrode is polarized to a noble potential as a result of loading current, the Raney nickel catalyst is apt to accept oxygen onto the surface so that the concentration of the oxygen atom on the surface increases.

It has been recently suggested that the precipitates of oxides or hydroxides dispersed on the metal catalysts not only prevent the catalysts from diminishing the reactive area, but also accelerate the catalytic reaction through unknown metal-oxide interactions.[10-15] Also, in the Raney nickel studied, a slight oxidation of the surface that does not reach the formation of non-conductive oxide film may enhance the catalytic activity for the electrode reaction. Attributing these polarization-induced activating effect for the Raney nickel catalyst to the activating effect of the oxide precipitates, we may identify the decrease in the k values due to polarization with the slightly oxidized surface state as described above. The plots deviate upward from the calculated curves in highly polarized regions, suggesting however that too much oxidation is harmful to the catalytic action.

The silver catalyst is also activated with progression of the polarization (Table 2). Contrary to the case of the hydrogen electrodes, this may be ascribed to surface reduction since the decrease in the k value results from polarizing to a less noble potential. No signs of loss of catalytic activity are observed in the region of high polarization.

In the silver oxygen-electrode studied, a total polarization required to sustain a load of 600 mA/cm^2 is 220 mV, but more than 120 mV out of the total value is expended for an initial 10 mA/cm^2 load. To improve the performance of this electrode, therefore, the reduction of the polarization, particularly in the low load current, is necessary. As expected from Eq. 5, the upper limit of ω^{-1} decreases with increasing ρ for a given k value. The ρ value of the oxygen-electrode studied is as high as 150 Ω cm in the polarization region 0—120 mV (Table 2). This very large value limits ω^{-1} to a very low value and results in only a poor electrode performance. Hence an enhancement in the conductivity of the electrolyte film is needed to improve the polarization characteristics.

Höhne has prepared oxygen-electrodes catalyzed with silver powder coprecipitated with metal hydroxides.[16] His electrode is less polarized than the electrode prepared in the present study: The polarization of his electrode is 60 mV at a load of 40 mA/cm^2 while that of the present electrode is 130 mV at the same load. The same analytical method was applied to his polarization data to estimate the ρ and k values with assuming the same weight of the catalyst layer per 1 cm^3. The parameter values obtained by the analysis are $\rho=15$ Ω cm and $k=4.3\times10^{-3}$ Ω cm^3 in a low load current. These are smaller than the values ob-

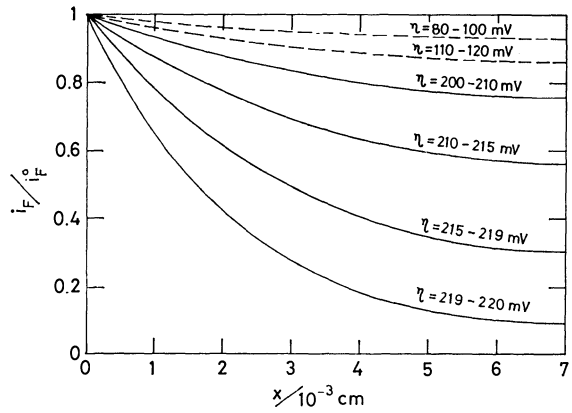

Fig. 7. Profiles of the faradayic current density across the electrode face.
Solid lines: Silver oxygen-electrodes, broken lines: Raney nickel hydrogen-electrodes, $l=7\times10^{-3}$ cm and the ρ and k values in Table 2 used for the calculation.

tained in the present study for the same load current. Höhne's electrodes were dried at 100 °C and no further heat treatment was applied, while the present electrodes were heated at 380 °C to remove the surfactant which had been originally introduced in the PTFE dispersion. The heat treatment at high temperatures deprives the catalyst of wettability and the reactive surface areas. In addition, the co-precipitated hydroxides may enhance the reactive surface area and the wettability of the catalyst. These two factors lower both the ρ and k values, but the lowering in the ρ value is the more important reason for bringing about the better performance.

The profiles for the faradayic current density across the electrode face were calculated for the parameter values in Tables 1 and 2 using Eq. 8. The results are given in Fig. 7. In contrast to the almost flat profiles for the hydrogen electrodes, the current densities for the silver electrodes are localized to the electrode-face/electrolyte interface as the electrodes are polarized; at $\eta=220$ mV, such a thin area of 5.3×10^{-3} cm thickness sustains 90% of the total load. If electrodes thicker than the above value are employed, the portion of the catalyst layer exceeding this thickness makes hardly any contribution to the improvement of the performance. Since the electrode preparation has usually been performed in the thicker region than the above value, the performance of the silver electrodes appears to be less dependent upon the catalyst loading than that of the Raney nickel electrodes. If thinner electrodes can be prepared and their polarizations measured, the dependence of the catalyst loading will be obtained more effectively.

This marked current localization is ascribed to the small k values of silver catalyst (Table 2), as is expected from Eq. 8. The large k values for Raney nickel catalyst, on the other hand, yield almost flat profiles, leading to long-ranging reaction zones. Thus the performance continues to enhance over the long distance in the coordinate of the electrode thickness (Fig. 3). Consequently, in the case of Raney nickel catalyst, thick electrodes yield good performance.

Excited-state Reactions of Coumarins in Aqueous Solutions. I. The Phototautomerization of 7-Hydroxycoumarin and Its Derivative

Tetsuo MORIYA

Electrotechnical Laboratory, 1-1-4 Umezono, Sakura-mura, Niihari-gun, Ibaraki, 305

(Received April 12, 1982)

The kinetics and mechanism of the reaction in the photo-excited state of 7-hydroxycoumarin and its derivative have been studied in aqueous solutions by means of measuring the fluorescence spectra and the fluorescence lifetime. The four fluorescence bands have been identified as emissions from the neutral, anionic, tautomeric, and cationic forms of 7-hydroxycoumarins. The quantitative analysis was performed by using the rate equation which included the term for the direct conversion of the excited neutral molecule to its tautomer in addition to the usual reaction term of dissociation. The rate constants of the tautomerization and dissociation were discussed in detail, and it was revealed that the tautomerization in aqueous solutions was mainly caused by the transfer of a proton between two active sites in the molecule. Such an intramolecular proton-transfer of the coumarins, found first in this paper, is considered to be promoted by water molecules with a hydrogen bond surrounding the excited molecule.

In recent years there have appeared many experimental works on the fluorescence behavior of solutions in which there had been dissolved various coumarin derivatives, which are used practically as fluorescennt indicators, and as laser-dye solutions.[1-3] The greater part of the experiments have been performed only on the solutions under particular conditions, and most investigators have used rather qualitative methods for the analysis of fluorescence phenomena. In regard to coumarins with a 7-hydroxyl group as a substituent, complex fluorescence spectra have been observed in a variety of organic solvents and in acidic, neutral, and basic aqueous solutions. It has been revealed that, typically, four fluorescent species exist in the photo-excited state according to the solvent conditions; they have been tentatively identified as neutral, anionic, tautomeric, and protonated species of the excited molecule.

Concerning this 7-hydroxy compound, several authors have studied the reaction kinetics of these molecular species using quantitative or semiquantitative methods;[4-7] they have derived some reaction-rate constants from the fluorescence spectra and the fluorescence lifetime. Although the results obtained by the former workers may be valid under restricted solvent conditions, it will be shown later in this article that an important point is missing in their conclusions and that the total fluorescence data cannot be explained without including a new mechanism in the reaction process to generate a phototautomer. Therefore, we wish to report here the detailed fluorescence data which enabled one to analyze quantitatively the reaction mechanism of the photo-excited 7-hydroxycoumarins in an aqueous solution, and to show a generalized method to treat the reaction kinetics over a very wide range of hydrogen-ion concentrations in solution. The way of analysis performed below should also be applicable to various 7-hydroxycoumarin derivatives and essentially to other types of hydroxy- and amino-substituted coumarins.

Experimental

The 7-hydroxycoumarin (**1**) was obtained from Wako Pure Chemical Ind., and the 7-hydroxy-4-methylcoumarin (**2**), from Tokyo Kasei; they were both recrystallized from ethanol and then washed with diethyl ether. The purity was checked by means of differential thermal analysis (DTA), which could rigorously monitor the melting point of the reagents: **1**, mp 233.5 °C; **2**, mp 186.3 °C. Solutions for the measurement of the absorption and fluorescence spectra were prepared by diluting an aqueous solution of a known concentration with distilled water; their pH (or H_0[8]) value was controlled over wide ranges by the use of $HClO_4$ for the pH (or H_0) —4.3—5 and by utilizing the following buffer solutions for the pH 5—11: pH 5—5.8, succinic acid–borax; pH 5.8—9.2, KH_2PO_4–borax; pH 9.2—11, Na_2CO_3–borax. All the chemicals used for the pH control were analytical or spectrograde reagents. The ionic strength of the buffer solutions was suppressed as much as possible within the limit of effective buffer action in order to avoid the influence of various ions on the excited-state reactions of the molecular species being observed. The absorption spectra were obtained on a Hitachi 323 spectrophotometer, and the fluorescence spectra, on a Hitachi MPF 4 fluorescence spectrophotometer with an S-5 type photomultiplier tube. Usually the output response was not corrected for instrumentaf response, since the correction did not affect the analysis ol the reaction kinetics. The lifetimes of the photo-excited state of each molecular species were measured by using a time-correlated single-photon-counting fluorometer similar to the one described in Ref. 9. When a repetitive short-pulsed light at 337 nm from an air-flash lamp was used as the excitation source, a fluorescence lifetime as short as 1 ns could be measured. In order to observe the steady-state fluorescence, the excitation was effected at the isosbestic point of the absorption spectra, *i.e.*, at 337 nm for 7-hydroxycoumarin and at 334 nm for 7-hydroxy-4-methylcoumarin. The concentrations of the fluorescent molecules in the solution were $\approx 6.1 \times 10^{-5}$ mol dm^{-3} for 7-hydroxycoumarin and $\approx 6.3 \times 10^{-5}$ mol dm^{-3} for 7-hydroxy-4-methylcoumarin; these values are most appropriate for the reliable and stable recording of the fluorescence spectra.[10] The pH value of solutions was measured directly with a Radiometer PHM 64 pH meter equipped with a G2401C combined glass electrode. Much care was taken for each measurement run to set the quartz cell containing the sample solution at exactly the same position, thus ensuring the reproducibility of the recorded fluorescence intensity. The temperature of the solution could be controlled by a cell holder with water circulation. Usual spectral measurements were performed at 20 °C otherwise mentioned.

Results and Discussion

pH Dependence of Absorption and Fluorescence Spectra.

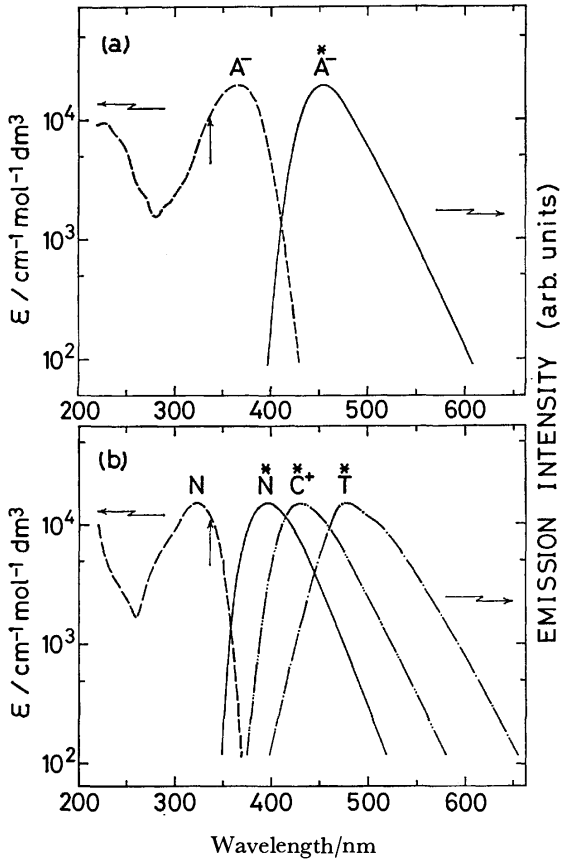

Fig. 1. Absorption and fluorescence spectra of 7-hydroxycoumarin (**1**) in aqueous solutions with various pH values. (a) Spectra at pH$\geqslant$11; (b) spectra at pH$\leqslant$5. A^- and N indicate the absorption spectra, and $\overset{*}{A}^-$, $\overset{*}{N}$, $\overset{*}{T}$, and $\overset{*}{C}^+$ the fluorescence spectra. The fluorescence bands are separated each other by the procedure described in the text and normalized to the same peak intensity. In (b) the fluorescence spectrum of $\overset{*}{A}^-$ is omitted since this is the same as in (a). The little arrow in the figure shows the isosbestic point.

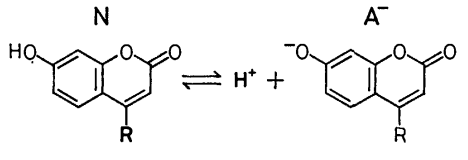
In the electronic ground-state of 7-hydroxycoumarins in aqueous solutions, only two molecular species are spectroscopically detectable. One is a neutral molecule (N), and the other is an ionized molecule (A^-), in which the 7-hydroxyl group is ionized as is shown below:



1 : R=H , 2 : R=CH_3

Figures 1 and 2 show the absorption spectra of 7-hydroxycoumarin (**1**) and 7-hydroxy-4-methylcoumarin (**2**) respectively. The absorption maxima of the neutral and anionic forms of **1** and **2** are 324 nm and 366 nm, and 321 nm and 361 nm, respectively. The pK values of the 7-hydroxyl substituent were 7.75 (**1**) and 7.84 (**2**). From these values, it is readily shown that, in the ground state, almost all molecules

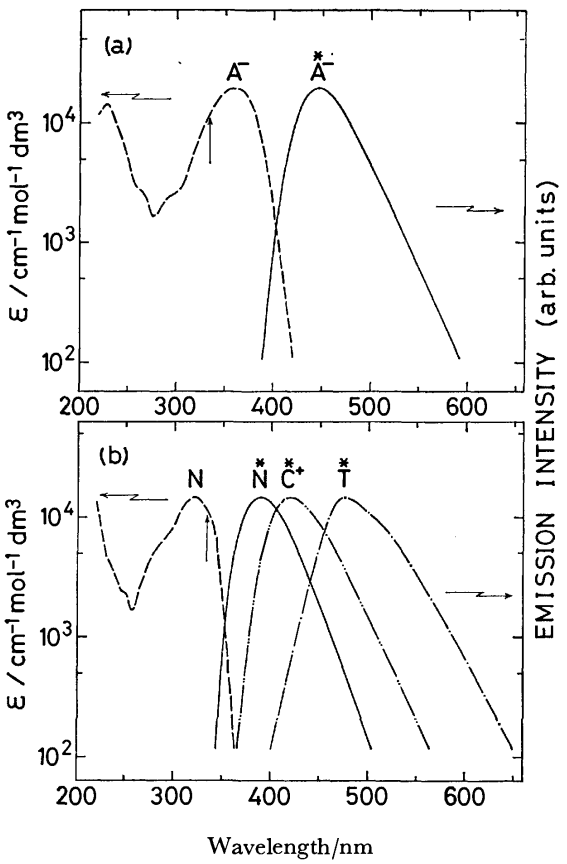


Fig. 2. Absorption and fluorescence spectra of 7-hydroxy-4-methylcoumarin (**2**) in aqueous solutions with various pH values. (a) Spectra at pH$\geqslant$11; (b) spectra at pH$\leqslant$5. The notations are the same as in Fig. 1.

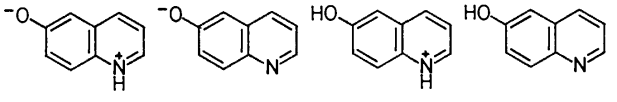
exist as anions at pH$\geqslant$10 and as neutral molecules at pH$\leqslant$6. The isosbestic points of the absorption spectra were 337 nm (**1**) and 334 nm (**2**).

When only the anion was excited at a high pH, the observed fluorescence band was due simply to the anionic form with emission peaks at 453 nm (**1**) and 447 nm (**2**). The interrelation between the corresponding absorption and emission spectra may be read from Figs. 1(a) and 2(a). In contrast to this, when the neutral molecule was excited at a low pH, three kinds of fluorescence bands with emission peaks at about 397 nm, 478 nm, and 431 nm for **1**, and at about 390 nm, 475 nm, and 419 nm for **2**, were observed in addition to the emission from the anion. In many cases, these fluorescence bands overlapped each other to a greater or lesser extent; therefore, we must make an effort to separate each spectral band from the others. In the course of this separation procedure, it is very convenient to plot the emission intensity of the fluorescence spectrum with a logarithmic scale, as is shown in Figs. 1 and 2, because the spectral shape of each band can readily be recognized by shifting the plotted spectral band upward or downward in the graph. At first, each band was roughly separated by the inspection of the graphs obtained for solutions with a variety of pH values; then, the band spectrum was improved by a numerical treat-

ment until a self-consistent relation became realized between every fluorescence band. The emission-band spectra thus separated are shown in Figs. 1 and 2.

From the energy positions of the absorption and emission bands, the fluorescence designated by $\overset{*}{A}^-$ may naturally be thought to originate from an anionic form, and $\overset{*}{N}$, from a neutral form, of the photo-excited molecule. This is supported by the fact that the spectrum of the long-wavelength absorption band of the neutral molecule (N) and the anionic molecule (A^-) coincides very well with a mirror image of their corresponding emission bands, $\overset{*}{N}$ and $\overset{*}{A}^-$, which can easily be read from Figs. 1 and 2. The fluorescence measurement in various solvents also supported this conclusion.[11] When organic solvents without a hydroxyl group, *e.g.*, dioxane, chloroform and acetonitrile, were used, simply an emission band which corresponded to $\overset{*}{N}$ in Figs. 1(b) and 2(b) was observed in the neutral solution; apparently, this originated from the neutral molecule. Further, the luminescence experiment using the method of Beens *et al.*[12] revealed that, on the addition of alkylamines to the solution, a contact ion-pair between –OH and NR_3 as well as an ionized anionic species could exist in the photo-excited state for the solvent without a hydroxyl group, while in basic alcoholic and aqueous solutions only an ionized anionic species was detected because of the higher ionizing ability of such solvents as possessed a hydroxyl group. Therefore, the formerly proposed model of Zinsli,[4] which assumed the existence of a bound ion-pair of the excited molecule in ethanol–water mixtures, is highly improbable.

As for the determination of the origin of the remaining two emission bands, *i.e.*, $\overset{*}{T}$ and $\overset{*}{C}^+$, the case of quinolinols and its analog offers a very similar example which was fully discussed in Refs. 13 and 14. It has been shown that the long-wavelength absorption and fluorescence maxima of quinolinols generally lie at wavelengths, dependent on the ionic species, in the order of: tautomer ($\overset{*}{T}$)>anion ($\overset{*}{A}^-$)>cation ($\overset{*}{C}^+$)>



neutral molecule ($\overset{*}{N}$).[14] This conclusion is derived essentially by the use of the general concept that, in MO calculations, the Coulomb integral and the electronegativity of the conjugated atom are roughly proportional to one another, and that the electronegativity is ordered: oxygen>nitrogen>carbon, and positively charged atom>neutral atom>negatively charged atom. By coupling these facts with the one-electron charge densities in the highest-occupied and lowest-unoccupied π-orbitals of the molecule, we are able to account qualitatively for the relative positions of the absorption and emission maxima of the various ionic species formed in the solution. From the similarity of the fluorescent behavior of the 7-hydroxy-

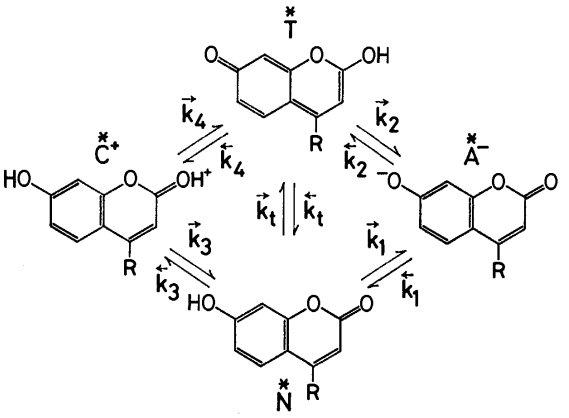


Fig. 3. Reaction scheme of the photo-excited states of 7-hydroxycoumarins. $\overset{*}{N}$, $\overset{*}{A}^-$, $\overset{*}{T}$, and $\overset{*}{C}^+$ represent the excited states of the neutral, anionic, tautomeric and cationic molecular forms, respectively. $\vec{k}$'s and $\overleftarrow{k}$'s are the reaction rate constants between them.

coumarins with that of quinolinols, and also from the MO calculations of the tautomeric form of the molecules,[15,16] $\overset{*}{N}$, $\overset{*}{A}^-$, $\overset{*}{C}^+$, and $\overset{*}{T}$, in Figs. 1 and 2 may naturally be identified as fluorescence from the neutral, anionic, cationic, and tautomeric forms of 7-hydroxycoumarins respectively.

In the most basic solution (pH$\geqslant$11), the anionic form ($\overset{*}{A}^-$) is the only existing species, while in the most acidic solution ($H_0\leqslant -4$), the cationic form ($\overset{*}{C}^+$), probably protonated on the carbonyl oxygen in the molecule, is also generated. For the intermediate pH range, three of the emission bands, *i.e.*, $\overset{*}{N}$, $\overset{*}{A}^-$, and $\overset{*}{T}$, appear simultaneously, and the role of the emission band $\overset{*}{T}$ becomes very important in the reaction kinetics of the excited species, as will be discussed fully below. We concentrated our attention especially on this pH range and took the luminescence data as carefully as possible, because the former workers[4-7] did not notice the coexistence of the $\overset{*}{T}$ band with the $\overset{*}{N}$ and $\overset{*}{A}^-$ bands, which caused much confusion in the interpretation of the phenomenon.

Rate-equation Analysis of Reactions in the Excited State. We have shown in Fig. 3 a generalized total scheme for the excited-state reactions which is different from the previously proposed model in the point that there exist the terms $\vec{k}_t$ and $\overleftarrow{k}_t$ representing a reaction pathway that does not involve a step-by-step protonation or deprotonation process, *i.e.*, a "nondissociative" reaction pathway. $\vec{k}_1$ and $\overleftarrow{k}_1$ are the usual forward and backward reaction rates of the $\overset{*}{N}\rightleftharpoons\overset{*}{A}^-+H^+$ dissociative process respectively; k_2—k_4 have the same meaning. As for the region of pH$\leqslant$6, only the neutral molecule exists in the electronic ground-state, as has been mentioned before, so only the neutral molecule can be excited by light absorption in the first instance. Therefore, this excited molecule in the solution is converted in its lifetime into the anionic or cationic species,

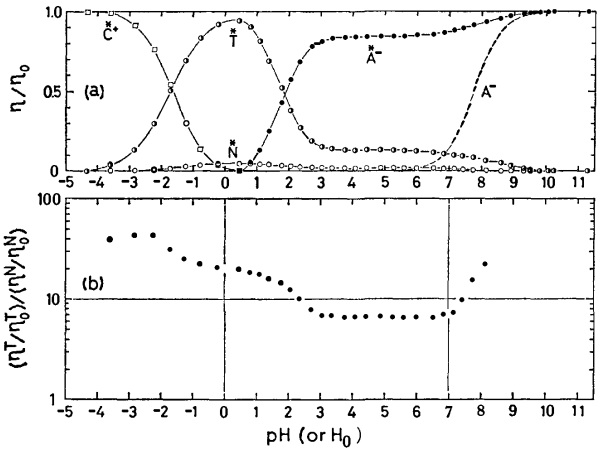

Fig. 4. Relative fluorescence efficiency of the excited species of 7-hydroxycoumarin (**1**) in aqueous solution (6.1×10^{-5} M); $\lambda_{ex}\approx337$ nm; 20 °C. (a) Dependence of the relative efficiency η/η_0 on pH: (○) $\overset{*}{N}$, (●) $\overset{*}{A}^-$, (◑) $\overset{*}{T}$, (□) $\overset{*}{C}^+$. The ground-state equilibration between N and A^- is also indicated by a dashed curve. (b) Dependence of $\overset{*}{K}_t=(\eta^T/\eta_0^T)/(\eta^N/\eta_0^N)$ on pH.

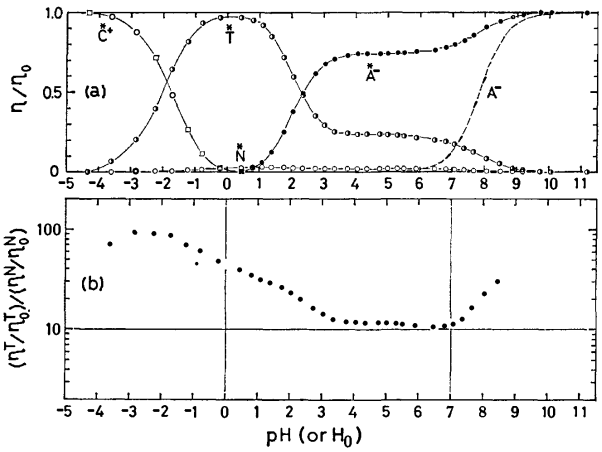

Fig. 5. Relative fluorescence efficiency of the excited species of 7-hydroxy-4-methylcoumarin (**2**) in aqueous solution (6.3×10^{-5} M); $\lambda_{ex}\approx334$ nm; 20 °C. (a) Dependence of the relative efficiency η/η_0 on pH: (○) $\overset{*}{N}$, (●) $\overset{*}{A}^-$, (◑) $\overset{*}{T}$, (□) $\overset{*}{C}^+$. The ground-state equilibration between N and A^- is also indicated by a dashed curve. (b) Dependence of $\overset{*}{K}_t=(\eta^T/\eta_0^T)/(\eta^N/\eta_0^N)$ on pH.

which are the base and acid common to both the neutral molecule and the tautomer. Because of the low concentration of the substrate and the hydroxide ion, and the weak contribution of water as a proton-donating acid, it is inferred, by considering the mechanism of general acid-base catalytic reactions,[17] that, typically, two reaction pathways, *i.e.*, $\overset{*}{N}\rightleftharpoons\overset{*}{A}^-+H^+\rightleftharpoons\overset{*}{T}$ and $\overset{*}{N}+H^+\rightleftharpoons\overset{*}{C}^+\rightleftharpoons\overset{*}{T}+H^+$, are effective for the tautomerization. In the former reaction process, water participates in practice as a proton-accepting base. In addition to the two above-mentioned processes, we have now proposed a direct nondissociative tautomerization process such as $\overset{*}{N}\rightleftharpoons\overset{*}{T}$. Here, the k_t's represent the rate constants for such a nondissociative intramolecular hopping of a hydrogen ion. The mechanism and structural requirements for this type of proton transfer have been studied by Bensaude *et al.*[17] Although their investigation was performed on phenomena in the ground state of molecules, the situation is very similar to our case; the importance of such terms as $\vec{k}_t$ and $\overleftarrow{k}_t$ can be clearly seen by using a rate-equation analysis as will be shown below.

In order to study the reaction kinetics between the ionic species formed in aqueous solutions with various hydrogen-ion concentrations, it was essential to control precisely the pH value over very wide ranges. Each spectrum measured with a given pH value was separated into the respective emission bands, $\overset{*}{N}$, $\overset{*}{A}^-$, $\overset{*}{C}^+$, and $\overset{*}{T}$; then their emission intensity was represented by the relative emission efficiency, η/η_0, in Figs. 4 and 5 rather than by the emission intensity itself, where η is the quantum efficiency of light emission under a given condition and where η_0 is the efficiency when all the molecules are hypothetically of the same species. This relative efficiency is obtainable directly from the ratio of the actual emission intensity, I, and the maximum emission intensity, I_0, the latter being the fluorescence intensity when all the excited molecules are in the single corresponding species. Assuming that the natural lifetime, τ, of the excited molecule and the maximum efficiency, η_0, are independent of the pH value of the solution, the following equation is satisfied under steady-state excitation over the whole pH range:

$$\frac{\eta^N}{\eta_0^N}+\frac{\eta^A}{\eta_0^A}+\frac{\eta^T}{\eta_0^T}+\frac{\eta^C}{\eta_0^C}=1, \qquad (1)$$

where the superscript of η indicates the respective molecular species. Equation 1 is indispensable for the determination of η^N/η_0^N and η^T/η_0^T, because the $\overset{*}{N}$ and $\overset{*}{T}$ bands do not have a pH range in which only the emission from either $\overset{*}{N}$ or $\overset{*}{T}$ is observed, and therefore I_0^N and I_0^T cannot be known directly. The absolute values of η^N/η_0^N and η^T/η_0^T must, then, be consistently determined so as to satisfy Eq. 1 over the whole pH range. The relative emission efficiencies, η/η_0, for the emissimon bands, $\overset{*}{N}$, $\overset{*}{A}^-$, $\overset{*}{T}$, and $\overset{*}{C}^+$, of **1** and **2** are plotted in Figs. 4(a) and 5(a). Excitation was effected at the isosbestic points of **1** and **2**, which are indicated in Figs. 1 and 2 by small arrows. Consequently, the generation rate of the excited molecule was always the same, regardless of species being excited by light absorption, and of course only the neutral molecule could be photo-excited when pH$\leqslant$6. From an inspection of Figs. 4(a) and 5(a), it may be noticed that between pH$\approx$3 and pH$\approx$6 each η/η_0 value is constant. Further, the $\overset{*}{A}^-$ band vanishes if pH$\leqslant$0; instead, the $\overset{*}{C}^+$ band begins to increase, along with the decrease in the pH value. The contribution of the $\overset{*}{T}$ emission to the relative efficiency is larger than that of the $\overset{*}{N}$ emission in the whole pH range. This was first

found by us because we plotted the data not in terms of the emission intensity, but in terms of the relative efficiency. It is noted that the large contribution to the relative efficiency does not always mean a high emission intensity because of the difference in the quantum efficiency of each molecular species.

After all, the fate of the photo-excited 7-hydroxycoumarins can be thoroughly described by the generalized scheme of Fig. 3. In the case of pH$\leqslant$6, where our main concern resides, illuminating light is absorbed solely by neutral molecules, so the generation rates of the molecular species, $\overset{*}{\mathrm{N}}$, $\overset{*}{\mathrm{A}}^-$, $\overset{*}{\mathrm{T}}$, and $\overset{*}{\mathrm{C}}^+$, in the singlet excited-state are expressed as:

$$\frac{\mathrm{d}[\overset{*}{\mathrm{N}}]}{\mathrm{d}t} = G - (n_1+\vec{k}_1+\overleftarrow{k}_3[\mathrm{H}^+]+\vec{k}_t)[\overset{*}{\mathrm{N}}] + \overleftarrow{k}_1[\mathrm{H}^+][\overset{*}{\mathrm{A}}^-] + \vec{k}_3[\overset{*}{\mathrm{C}}^+] + \overleftarrow{k}_t[\overset{*}{\mathrm{T}}], \quad (2)$$

$$\frac{\mathrm{d}[\overset{*}{\mathrm{A}}^-]}{\mathrm{d}t} = -(n_2+\overleftarrow{k}_1[\mathrm{H}^+]+\overleftarrow{k}_2[\mathrm{H}^+])[\overset{*}{\mathrm{A}}^-]+\vec{k}_1[\overset{*}{\mathrm{N}}]+\vec{k}_2[\overset{*}{\mathrm{T}}], \quad (3)$$

$$\frac{\mathrm{d}[\overset{*}{\mathrm{T}}]}{\mathrm{d}t} = -(n_3+\vec{k}_2+\overleftarrow{k}_4[\mathrm{H}^+]+\overleftarrow{k}_t)[\overset{*}{\mathrm{T}}] + \overleftarrow{k}_2[\mathrm{H}^+][\overset{*}{\mathrm{A}}^-] + \vec{k}_4[\overset{*}{\mathrm{C}}^+] + \vec{k}_t[\overset{*}{\mathrm{N}}], \quad (4)$$

$$\frac{\mathrm{d}[\overset{*}{\mathrm{C}}^+]}{\mathrm{d}t} = -(n_4+\vec{k}_3+\vec{k}_4)[\overset{*}{\mathrm{C}}^+]+\overleftarrow{k}_3[\mathrm{H}^+][\overset{*}{\mathrm{N}}]+\overleftarrow{k}_4[\mathrm{H}^+][\overset{*}{\mathrm{T}}], \quad (5)$$

where G is the conversion rate of the neutral molecule to its excited state by the light absorption, and where n_1—n_4, the rates of the deactivation of the excited molecule, are the reciprocals of the lifetimes of $\overset{*}{\mathrm{N}}$, $\overset{*}{\mathrm{A}}^-$, $\overset{*}{\mathrm{T}}$, and $\overset{*}{\mathrm{C}}^+$ respectively. If the steady-state condition is satisfied, we can get the densities of the excited molecules by letting the left-hand side of Eqs. 2—5 be zero, and the relative emission efficiencies are given as:

$$\frac{\eta^{\mathrm{N}}}{\eta_0^{\mathrm{N}}} = \frac{n_1[\overset{*}{\mathrm{N}}]}{G}, \quad \frac{\eta^{\mathrm{A}}}{\eta_0^{\mathrm{A}}} = \frac{n_2[\overset{*}{\mathrm{A}}^-]}{G}, \quad \frac{\eta^{\mathrm{T}}}{\eta_0^{\mathrm{T}}} = \frac{n_3[\overset{*}{\mathrm{T}}]}{G}, \quad \frac{\eta^{\mathrm{C}}}{\eta_0^{\mathrm{C}}} = \frac{n_4[\overset{*}{\mathrm{C}}^+]}{G}. \quad (6)$$

The dependence of η/η_0 on pH predicted by Eq. 6 can be shown to explain extremely well the results in Figs. 4(a) and 5(a). In the relatively high pH region, *i.e.*, pH 4—6, all terms containing $[\mathrm{H}^+]$ become negligible compared with those that do not. This situation can readily be understood by the following consideration. The values of n_1—n_4 are of the order of $10^8\ \mathrm{s}^{-1}$, judging from the fluorescence lifetimes of the excited molecules, which will be discussed later. When the hydrogen-ion concentration $[\mathrm{H}^+]$ is as low as 10^{-4} mol dm^{-3} or less, the terms of $\overleftarrow{k}_{1-4}[\mathrm{H}^+]$ become negligibly small compared with n_{1-4}, because the values of $\overleftarrow{k}_{1-4}$ never exceed the order of the rate constants estimated from diffusion-controlled processes, which are about 10^9—$10^{10}\ \mathrm{mol}^{-1}\ \mathrm{dm}^3\ \mathrm{s}^{-1}$.[18] The appearance of a flat region in the η/η_0 *vs.* pH curves around pH 5 can be consistently explained by these facts. Now, formally letting $[\mathrm{H}^+]\to 0$ in Eqs. 2—5, the limits of the relative efficiencies in the higher pH region are given as:

$$\frac{\eta^{\mathrm{N}}}{\eta_0^{\mathrm{N}}} \to \frac{n_1(n_3+\overleftarrow{k}_t+\vec{k}_2)}{(n_1+\vec{k}_1)(n_3+\overleftarrow{k}_t+\vec{k}_2)+(n_3+\vec{k}_2)\vec{k}_t}, \quad (7)$$

$$\frac{\eta^{\mathrm{A}}}{\eta_0^{\mathrm{A}}} \to \frac{\vec{k}_1(n_3+\overleftarrow{k}_t+\vec{k}_2)+\vec{k}_2\vec{k}_t}{(n_1+\vec{k}_1)(n_3+\overleftarrow{k}_t+\vec{k}_2)+(n_3+\vec{k}_2)\vec{k}_t}, \quad (8)$$

$$\frac{\eta^{\mathrm{T}}}{\eta_0^{\mathrm{T}}} \to \frac{n_3\vec{k}_t}{(n_1+\vec{k}_1)(n_3+\overleftarrow{k}_t+\vec{k}_2)+(n_3+\vec{k}_2)\vec{k}_t}, \quad (9)$$

$$\frac{\eta^{\mathrm{C}}}{\eta_0^{\mathrm{C}}} \to 0. \quad (10)$$

The experimental values obtained from Figs. 4(a) and 5(a), which correspond to Eqs. 7—9 were, at pH 3.5—5.5, $\eta^{\mathrm{N}}/\eta_0^{\mathrm{N}}$:0.020, $\eta^{\mathrm{A}}/\eta_0^{\mathrm{A}}$:0.847, $\eta^{\mathrm{T}}/\eta_0^{\mathrm{T}}$:0.136 for **1**, and $\eta^{\mathrm{N}}/\eta_0^{\mathrm{N}}$:0.021, $\eta^{\mathrm{A}}/\eta_0^{\mathrm{A}}$:0.742, $\eta^{\mathrm{T}}/\eta_0^{\mathrm{T}}$:0.240 for **2**.

It is convenient here to define $\overset{*}{K}_t$ by:

$$\overset{*}{K}_t = \frac{\eta^{\mathrm{T}}/\eta_0^{\mathrm{T}}}{\eta^{\mathrm{N}}/\eta_0^{\mathrm{N}}} = \frac{n_3[\overset{*}{\mathrm{T}}]}{n_1[\overset{*}{\mathrm{N}}]}, \quad (11)$$

which is proportional to the ratio of the concentration of $\overset{*}{\mathrm{T}}$ to the concentration of $\overset{*}{\mathrm{N}}$. Figures 4(b) and 5(b) show the dependence of $\overset{*}{K}_t$ on the pH value. The theoretical expression obtained from Eq. 11 can elucidate fairly well the behavior of $\overset{*}{K}_t$ over a wide pH range. If the hydrogen-ion concentration is so small that the terms containing $[\mathrm{H}^+]$ are negligible in the expression, as before, then Eqs. 7 and 9 give:

$$\overset{*}{K}_t \to \frac{n_3}{n_1}\frac{\vec{k}_t}{n_3+\overleftarrow{k}_t+\vec{k}_2}. \quad (12)$$

The corresponding values of **1** and **2** were, at pH 3.5—5.5, 6 7, and 11.7 respectively.

In the excited state, the protonated carbonyl group of the cation shown in Fig. 3 is a very strong acid comparable with the oxonium ion, $\mathrm{H_3O^+}$ ($\mathrm{p}K_{\mathrm{H_3O^+}} \approx -1.7$), while, in spite of the drastic decrease in the pK of the hydroxyl substituent of the neutral molecule, $\overset{*}{\mathrm{N}}$, with excitation, $\mathrm{p}\overset{*}{K}_{\mathrm{N}}$ remains positive, as will be mentioned later; therefore, the $\mathrm{p}\overset{*}{K}_{\mathrm{C}^+} < \mathrm{p}\overset{*}{K}_{\mathrm{N}}$ relation is satisfied. Combining this inference with the fact that the rate constants for the reaction between charged species with an attractive force, such as $\overleftarrow{k}_1$ and $\overleftarrow{k}_2$, are larger than those without an attractive force, such as $\overleftarrow{k}_3$ and $\overleftarrow{k}_4$,[10] it is naturally assumed that $\overleftarrow{k}_1$ and $\overleftarrow{k}_2$ are much larger than $\overleftarrow{k}_3$ and $\overleftarrow{k}_4$. In the case of Compounds **1** and **2**, as the pH was decreased toward zero, there occurred a pH region around pH 0 where the terms of $\overleftarrow{k}_1[\mathrm{H}^+]$ and $\overleftarrow{k}_2[\mathrm{H}^+]$ become very large, but the terms of $\overleftarrow{k}_3[\mathrm{H}^+]$ and $\overleftarrow{k}_4[\mathrm{H}^+]$ are still negligible compared with the other rate constants. The limiting value of $\overset{*}{K}_t$ calculated from Eq. 11 is written:

$$\overset{*}{K}_t \approx \frac{n_3}{n_1}\frac{\vec{k}_t+\vec{k}_1\overleftarrow{k}_2/(\overleftarrow{k}_1+\overleftarrow{k}_2)}{n_3+\overleftarrow{k}_t+\vec{k}_2\overleftarrow{k}_1/(\overleftarrow{k}_1+\overleftarrow{k}_2)}. \quad (13)$$

The experimental values of $\overset{*}{K}_t$ around pH 0 were $\approx$20 for **1** and $\approx$40 for **2**.

When the solution becomes most acidic, such as when $H_0 \leqslant -3$, the effective concentration of the hydrogen-ion [H^+] is formally taken to be more than 10^3 mol dm^{-3},[8] so the terms of $\overleftarrow{k}_{1-4}[H^+]$ dominate all the other rate constants. Therefore, within such a limit, we have:

$$\overset{*}{K}_t \to \frac{n_3}{n_1}\frac{\overleftarrow{k}_3}{n_4+\vec{k}_3}\frac{\vec{k}_4}{\overleftarrow{k}_4}. \quad (14)$$

The experimental values of **1** and **2** corresponding to this condition were, for $H_0 \leqslant -3$, $\approx$43, and $\approx$92 respectively.

If the reaction pathway represented by $\vec{k}_t$ and $\overleftarrow{k}_t$ does not exist, the limiting value of $\overset{*}{K}_t$ in the high pH region apparently becomes zero, as $\vec{k}_t \to 0$ in Eq. 12. This contradicts the experimental fact that there is in reality no pH region having a zero value of $\overset{*}{K}_t$ as may be seen in Figs. 4(b) and 5(b). Therefore, we must admit the existence of a tautomerization mechanism unrelated to the general acid-base catalyzed scheme. Further, it may be noted that, by comparing Eq. 12 with Eq. 13, the limiting value of $\overset{*}{K}_t$ in the lower pH region can be predicted theoretically to be larger than that in the higher pH region, as is again clearly shown in the results (Figs. 4(b) and 5(b)) between pH 0 and 6. Corresponding to this change in $\overset{*}{K}_t$, η^T/η^T_0 as a function pH has its maximum at about pH 0 and a flat region between pH 3 and 6. Around pH 0, the contribution from η^A/η^A_0, like as that from η^C/η^C_0, becomes nearly zero; on the contrary, the contribution from η^T/η^T_0 becomes nearly unity, although that from η^N/η^N_0 still small. Toward the highest-concentration region of the hydrogen-ion, η^C/η^C_0 increases and reaches unity at the end, since the terms of $\overleftarrow{k}_3[H^+]$ and $\overleftarrow{k}_4[H^+]$ overcome all other terms. Parallel with the change in η^C/η^C_0, $\overset{*}{K}_t$ increases when pH (or H_0) decreases from 0 to -3. This increase is rather accidental, as there is no relation in magnitude between the values of Eqs. 13 and 14. In contrast to these results, the rise in $\overset{*}{K}_t$ and the approach of η^A/η^A_0 to unity toward a pH higher than 6 is caused by another situation, because the amount of the anionic molecule in the ground state becomes large at pH>6; therefore, the assumption used above—that only the neutral molecule is excited from the ground state—must be changed. Although this modification is simple and straightforward, we would not here be concerned with this matter further.

Mechanism for Tautomerization. In earlier studies[4-7] only the dissociative processes such as $\overset{*}{N} \rightleftarrows \overset{*}{A}^- + H^+ \rightleftarrows \overset{*}{T}$ were emphasized for the tautomeric interconversion of the excited molecule; however, this led to erroneous conclusions about the reaction mechanism in the case of 7-hydroxycoumarins. From a careful consideration of $\overset{*}{K}_t$ as a function of the pH, we have come to the conclusion that the direct conversion between the neutral molecule and the tautomeric molecule which proceeds without generating dissociated ionic species as an intermediate, *i.e.*, $\overset{*}{N} \rightleftarrows \overset{*}{T}$, is most essential in the tautomerization reaction. In view of the results of the investigation of Bensaude *et al.*,[17] the most probable model for the origin of the nondissociative process represented by the $\vec{k}_t$ and $\overleftarrow{k}_t$ terms is a concerted bifunctional proton-transfer through water molecules, as is described schematically in Fig. 6. The existence of such a tautomerization process is strongly supported by the following discussion. In general, substituents to aromatic and heteroaromatic compounds can be classified in two types of groups.[18] One is composed of substituents that become more acidic in the excited state than in the ground state, such as hydroxyl and amino groups. The other is composed of substituents that become more basic in the excited state, such as carbonyl and carboxyl groups. In the case of 7-hydroxycoumarins, this tendency makes the transfer of a proton from the hydroxyl group to the carbonyl group very easy in their electronic excited-state. Because of the ability of water to form chains of hydrogen bonds and the Grotthus-type migration of the proton (or proton-hole) along the chain,[19] the proton transfer between the two active sites in a molecule can be promoted cooperatively and the interconversion of the neutral form to the tautomeric form can occur without liberating any proton or ionic species to an outside region of the molecule which is hydrated by participating water molecules. Because this type of proton jump in the molecule is considered to proceed at an extremely high velocity in comparison with other reaction rates, no intermediate species can appear in the rate-equation formulation; instead, the rate constants which represent the direct conversion between the neutral molecule and the tautomeric molecule, *i.e.*, $\vec{k}_t$ and $\overleftarrow{k}_t$, appear.

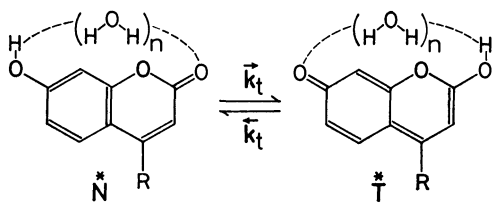

Fig. 6. Concerted mechanism for the tautomerization of 7-hydroxycoumarins in the excited state.

Such a mechanism of tautomerization is also expected for lower alcohols, but the effect will be weaker in that case because the hydrogen bond is much weaker than that of water and the motion of the proton is highly restricted. It has been pointed out by several authors[1-5,7] that the addition of a small amount of water to alcoholic solutions of 7-hydroxycoumarins induced a very large effect on the fluorescent behavior of the excited molecule. As it has become clear that the tautomerization of 7-hydroxycoumarins proceeds through the proton transfer between two sites in the molecule and is accelerated by the participation of water molecules, the reported increase in the ratio of the emission intensity of $\overset{*}{T}$ to that of $\overset{*}{N}$ with an

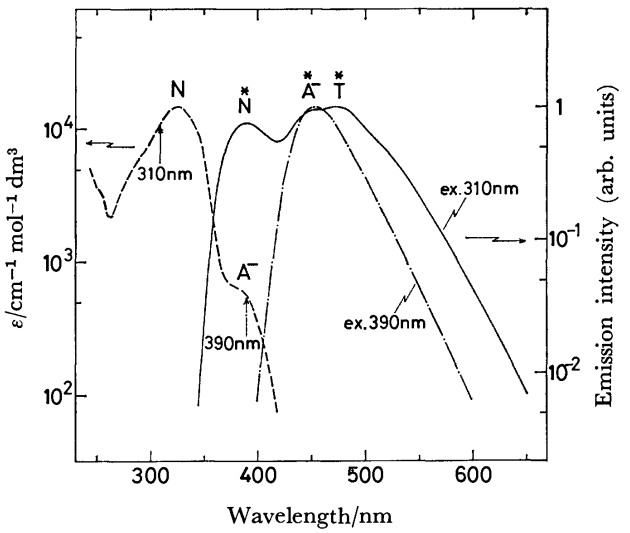

Fig. 7. Absorption and fluorescence spectra of 7-hydroxycoumarin (**1**) in ethanol–water solution (90:10 vol%).
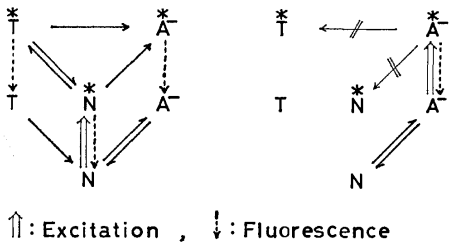
The fluorescence spectra are obtained by using the excitation wavelength at 310 nm (——) and 390 nm (—·—).

increased water content[4,7] is considered to arise from the increase in the value of $\vec{k}_t$, not from the increased rate of the $\overset{*}{N} \rightleftharpoons \overset{*}{A}^- + H \rightleftharpoons \overset{*}{T}$ reaction. This prediction is distinctly proved by the result shown in Fig. 7. From the absorption spectrum of 7-hydroxycoumarin (**1**) it was found, in neutral solutions of ethanol–water mixtures, that both the neutral and the anionic molecule existed in the ground state, as may be seen from Fig. 7. By choosing an appropriate excitation wavelength, it was possible to excite separately either the neutral or the anionic molecule. If the neutral molecule alone was excited by using the wavelength of 310 nm, three of the fluorescence bands, *i.e.*, $\overset{*}{N}$, $\overset{*}{A}^-$, and $\overset{*}{T}$, were obtained simultaneously. On the other hand, only the fluorescence band of $\overset{*}{A}^-$ was detectable if the anionic molecule was excited by using the wavelength of 390 nm. The results are summarized in the following scheme:



As may easily be recognized from this scheme, the reaction pathway $\overset{*}{N} \rightarrow \overset{*}{A}^- + H^+ \rightarrow \overset{*}{T}$ cannot exist in the ethanol–water solution because the $\overset{*}{A}^- + H^+ \rightarrow \overset{*}{T}$ reaction is forbidden in reality and the $\overset{*}{N} \rightarrow \overset{*}{T}$ pathway alone can generate the tautomeric form of the molecule. The same conclusion was obtained for 7-hydroxy-4-methylcoumarin (**2**).

If the dependence of the rate constants on the water concentration in alcohol–water solutions is approximately written:

$$\vec{k}_t = \vec{k}_t'[H_2O], \quad \overleftarrow{k}_t = \overleftarrow{k}_t'[H_2O],$$
$$\vec{k}_1 = \vec{k}_1'[H_2O], \quad \vec{k}_2 = \vec{k}_2'[H_2O], \tag{15}$$

then, at a low hydrogen-ion concentration (pH 3—6), the ratios of $[\overset{*}{A}^-]$ and $[\overset{*}{T}]$ to $[\overset{*}{N}]$ are given by Eqs. 7—9 as:

$$\frac{n_2[\overset{*}{A}^-]}{n_1[\overset{*}{N}]} \propto \frac{\vec{k}_t'[H_2O](n_3+\overleftarrow{k}_t'[H_2O]+\vec{k}_2'[H_2O])+\vec{k}_2'[H_2O]\vec{k}_t'[H_2O]}{n_1(n_3+\overleftarrow{k}_t'[H_2O]+\vec{k}_2'[H_2O])}, \tag{16}$$

$$\overset{*}{K}_t = \frac{n_3[\overset{*}{T}]}{n_1[\overset{*}{N}]} \propto \frac{n_3\vec{k}_t'[H_2O]}{n_1(n_3+\overleftarrow{k}_t'[H_2O]+\vec{k}_2'[H_2O])}. \tag{17}$$

In the low-concentration region of the water content where $n_3 \gg \overleftarrow{k}_t'[H_2O]$, $\vec{k}_2'[H_2O]$, $[\overset{*}{T}]/[\overset{*}{N}]$ varies linearly with the water concentration, while $[\overset{*}{A}^-]/[\overset{*}{N}]$ increases superlinearly with the increase in the water component, since the numerator of Eq. 16 has a quadratic term of $[H_2O]$. These predictions explain reasonably well the fluorescence behavior of **1** and **2** in alcohol–water solutions, including the results in Refs. 4 and 7. In this manner, the dependence of η/η_0 and $\overset{*}{K}_t$ on the pH was completely described by the formulation of Eqs. 2—5. Above all, it was impossible to explain the behavior of $\overset{*}{K}_t$ if the terms of $\vec{k}_t$ and $\overleftarrow{k}_t$ were not introduced. Further, the dependence of the relative intensity of $\overset{*}{N}$, $\overset{*}{A}^-$, and $\overset{*}{T}$ in aqueous alcoholic solutions on the water content can be understood in terms of Eqs. 16 and 17 if we admit the assumption of Eq. 15.

Fluorescence Lifetimes and Energy-level Considerations. In order to argue about the rate constants that appear in Eqs. 7—14, it is necessary to know the lifetime, τ, which is the reciprocal of the deactivation rate of the excited molecule, n. Table 1 shows the values of the lifetime measured under various solvent conditions at the wavelength of the emission peak of each molecular species. In the case of the anionic and cationic molecular forms, the lifetime measurement was performed when the luminescence from a single molecular species was observable, and so the measured lifetimes τ_A and τ_C naturally correspond to the true lifetimes of the excited state of the anionic and cationic molecular species. On the other hand, $\bar{\tau}_{TN}$ and $\bar{\tau}_{NT}$ indicate the apparent decay times of the fluorescence from $\overset{*}{T}$ and $\overset{*}{N}$ respectively when they coexist at around pH 0. $\bar{\tau}_{NAT}$ is also the apparent decay time of the excited neutral molecule when it coexists with the anionic and tautomeric forms at around pH 4. In the first-order approximation, they are written:

$$\frac{1}{\bar{\tau}_{NT}} = n_1 + \vec{k}_t, \tag{18}$$

Table 1. Lifetimes of the fluorescent molecular species

Substance	τ_C/ns	τ_A/ns	$\bar{\tau}_{TN}$/ns[a]	$\bar{\tau}_{NT}$/ns[a]	$\bar{\tau}_{NAT}$/ns[a]
1	5.8	5.4	4.6	4.5	1.7
2	5.9	5.5	4.9	3.2	1.6

a) The meanings of $\bar{\tau}_{TN}$, $\bar{\tau}_{NT}$, and $\bar{\tau}_{NAT}$ are described in the text.

Table 2. Separations of the energy levels and changes in the thermodynamical functions

Substance	ΔE_N [a] / kcal mol^{-1}	ΔE_A [a] / kcal mol^{-1}	ΔE_T [b] / kcal mol^{-1}	ΔE_C [b] / kcal mol^{-1}	ΔH_{NA} / kcal mol^{-1}	ΔS_{NA} / cal mol^{-1} K^{-1}
1	80.11	70.60	67.61	74.13	4.29	-21.0_4
2	81.17	71.56	67.93	75.97	4.16	-21.8_1

a) Obtained from the absorption and fluorescence data, and accurate within ± 0.1 kcal mol^{-1}. b) Inferred from the fluorescence data, and accurate within ± 0.5 kcal mol^{-1}.

$$\frac{1}{\bar{\tau}_{TN}} = n_3 + \overleftarrow{k}_t, \tag{19}$$

$$\frac{1}{\bar{\tau}_{NAT}} = n_1 + \vec{k}_t + \vec{k}_1. \tag{20}$$

By the use of Eqs. 18 and 20 and the values in Table 1, it can readily be known that $\vec{k}_1$ is 3.7×10^8 s^{-1} for **1** and 3.1×10^8 s^{-1} for **2**. The dissociation constant, $p\overset{*}{K}_{NA}$, corresponding formally to the excited-state equilibrium between $\overset{*}{N}$ and $\overset{*}{A}^-$ can be calculated by the method outlined by Weller as:[18]

$$p\overset{*}{K}_{NA} = pK_{NA} - \frac{\Delta E_N - \Delta E_A}{2.303RT}, \tag{21}$$

where ΔE_N and ΔE_A are the energy-level separations between the singlet ground-state and the singlet excited-state of the neutral and anionic species and are obtainable as the mean of the energies at the absorption-band and emission-band maxima.[20] These values are listed in Table 2, together with ΔE_T and ΔE_C, the energy-level separations for the tautomeric and cationic species, which in this case are inferred from only the emission-band maximum assuming that the Stokes shift is the same for all molecular species. Using the values of ΔE_N and ΔE_A in Table 2, and also pK_{NA}, $p\overset{*}{K}_{NA}$ is calculated to be 0.66 for **1** and 0.68 for **2** at 20 °C. Since the equilibrium constant in the excited state is defined by $\overset{*}{K}_{NA}=\vec{k}_1/\overleftarrow{k}_1$, we get $\overleftarrow{k}_1$ of **1** and **2** as 1.7×10^9 s^{-1} mol^{-1} dm^3 and 1.5×10^9 s^{-1} mol^{-1} dm^3 respectively.

ΔH_{NA} and ΔS_{NA} in Table 2 are the enthalpy and entropy changes in the $N\rightleftharpoons A^-+H^+$ reaction; they were obtained by the measurement of the temperature dependence of pK_{NA} with the aid of the thermodynamical relation: $K=\exp[-(\Delta H-T\Delta S)/RT]$. If we can neglect the change in the PV term of the relation, $H=E+PV$, the enthalpy change, ΔH, is equated to the energy change, ΔE. Considering these facts and the values in Table 2, the energy-level scheme of the reacting molecular species of 7-hydroxycoumarins around pH 3—5 can roughly be drawn as Fig. 8. Since $\Delta E_N+\Delta\overset{*}{H}_{NA}=\Delta E_A+\Delta H_{NA}$, the values of $\Delta\overset{*}{H}_{NA}$ for the $\overset{*}{N}\rightleftharpoons\overset{*}{A}^-+H^+$ reaction are -5.22 kcal mol^{-1} for **1** and -5.45 kcal mol^{-1} for **2**. Putting together

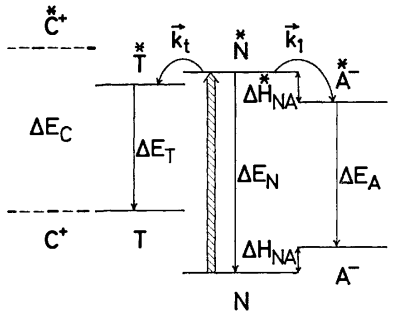


Fig. 8. Energy level diagram of 7-hydroxycoumarins in the weakly acidic solution (pH 3—5). The hatched arrow shows the photo-excitation of N into $\overset{*}{N}$. The levels of C^+ indicated by dashed lines do not take part in the reaction in this pH range.

all the results discussed so far, the interrelation of the energy levels between the neutral and anionic molecules was firmly determined, as is shown in Fig. 8. Although the energy position of the tautomer and the cation relative to that of the neutral molecule could not determined strictly, the energy levels are presumably ordered as $N<A^-\ll C^+$, T in the ground state and as $\overset{*}{A}^-<\overset{*}{T}<\overset{*}{N}<\overset{*}{C}^+$ in the excited state.

Unfortunately, several rate constants defined in Fig. 3 have left unknown because of a lack of information about the reaction process. The main reason for this uncertainty must be sought in the impossibility of transforming the neutral molecule into the tautomeric form in the ground state under any condition of solvents different from the case of the 7-hydroxyquinolines. Therefore, we cannot know about the ground-state equilibration between the neutral and tautomeric molecules, and the direct excitation of the tautomer by light absorption is never possible. In spite of this unfavorable situation, though we are now trying to analyze the decay properties of the excited species over the whole pH range which is controllable. This procedure, which will be described thoroughly in a forthcoming paper, would provide more detailed information about the rate constant and the reaction mechanism.

I wish to thank Dr. Hiroyuki Anzai of this laboratory for his helpful advice and stimulating discussions during the course of this work.

Cathodic Reduction of Ubiquinone-10 Dissolved in Carbon-paste Electrode

Tatsuo ERABI* and Masaya TANAKA

Department of Industrial Chemistry, Faculty of Engineering, Tottori University, Koyama, Tottori 680

(Received April 19, 1982)

Carbon-paste electrodes were prepared with use of ubiquinone-10 dissolved in organic liquids, 1-chloronaphthalene, 1-bromonaphthalene, 1-methylnaphthalene and undecane. Ubiquinone-10 shows a well-defined, pH-dependent cathodic reduction wave in each liquid system and its reduction seems to proceed with two electrons and a proton transfer around neutral pH. The experimental results indicate the wave to be diffusion-controlled, and the apparent diffusion coefficient was additionally calculated in each liquid system.

It is generally accepted[1] that ubiquinones and the reduction products take part in the formation of pH gradient across chromatophore membrane, that is indispensable for ATP production, in addition to the role as an electron pool in the photosynthetic electron transport system. Moreover, it has become apparent[2-7] that ubiquinones also function as primary or secondary electron acceptors in the photosynthetic reaction centers. The majority of ubiquinones bound to chromatophores are reduced with two electrons and two protons transfer[8] around neutral pH, but in the case of primary or secondary acceptor, it was suggested that they were reduced with an electron transfer to form corresponding semiquinones,[7,9] similar to a cathodic reduction in an aprotic nonaqueous solvent.[10] Although most of these studies have been carried out by means of analyzing their absorbance[8,9] and/or EPR spectrum,[7] disadvantages of these methods may be that its absorbance and difference spectra are not so distinctive, and the measurements should be carried out at temperature as low as liquid nitrogen in order to sharpen the spectra. On the other hand, electrochemistry provides essentially the knowledge on oxidation-reduction properties of a material of interest. On this viewpoint, we studied electrochemically the reduction of ubiquinone-10 in an aqueous ethanol[11,12] and in a SDS micelle[12] as a model of chromatophore membrane, and all of these reductions seemed to proceed with two electrons transfer. A cyclic voltammetric study of ubiquinone-10 bound to chromatophores was also carried out,[11] but the reaction mechanism is not clear yet because of the difficulty of mass transfer in the suspension. Usually, use of a carbon-paste electrode has been limited to aqueous solutions because of flowing the paste. But, this limitation, as applied to water-insoluble, electroactive organic compounds, can be circumvented by dissolving these organics in electrode itself.[13] In addition, a carbon-paste electrode dissolving ubiquinone-10 is supposed to mimic chromatophore membrane, most of ubiquinones being present at membrane-water interface.[11] So, we report a cathodic behavior of ubiquinone-10 dissolved in a carbon-paste electrode, prior to elucidating the reactivities of ubiquinone-10 bound to chromatophores.

Experimental

Ubiquinone-10 was extracted and purified by the usual method.[14,15] The exactly weighed ubiquinone-10 was dissolved in 1 cm^3 of an organic solvent (1-chloronaphthalene, 1-bromonaphthalene, 1-methylnaphthalene or undecane), 1.7 g of graphite was then added and mixed until the carbon appeared uniformly wetted. The paste was stored in water for a few days at 4 °C. A working electrode was prepared by packing the Teflon cavity (ϕ 2.56 mm × 0.24 mm depth) with the paste, smoothing the surface with a filter paper and removing excess paste from the edge surface of the Teflon with tissue paper. After each measurement, it was necessary to remove all of the paste in which the concentration of ubiquinone-10 had been changed by electrolysis, and the cavity was washed with petroleum ether. Commercially obtained ferrocene was further purified chromatographically on an alumina column with spectroscopic-quality hexane as eluent, and then recrystallized from redistilled methanol. Ferrocene thus purified was used for preparation of a carbon-paste electrode in a similar manner as above, and a peak current for ferrocene oxidation was measured for comparison of specific limiting currents.[16]

A conventional H-type cell was used with the working electrode and a saturated calomel reference electrode located in the main compartment. A platinum disk electrode was served as auxiliary electrode in the other compartment. Buffer solutions of various pH values were prepared with 0.6 mol/dm^3 GTA–HCl or GTA–NaOH.[12] Dissolved oxygen in this solution was removed by bubbling nitrogen for 30 min before electrolysis, and the electrolysis was carried out at 25 °C. A current-potential curve was recorded using a potentiostat PS-1000, a linear potential scanning unit LS-1D (Hokuto Denko Ltd.) and a Hitachi Model 056 recorder. Potential sweep rate was 250 mV/min unless otherwise noted. A coulometric measurement was carried out at a peak potential for ubiquinone-10 reduction controlled by a Hokuto Model HA-104 potentiostat using a working electrode packed with a known weight of carbon-paste containing ubiquinone-10 until the electrolytic current decreased to 1—2% of the initial current. Usually, 100 min of the electrolytic time was required, and the quantity of electricity was measured using a coulometer HF-201 (Hokuto Denko Ltd.).

Results and Discussion

Current-potential curves of ubiquinone-10 dissolved in carbon-paste electrodes always showed typical well-defined, pH-dependent reduction waves. Table 1 shows a comparison of specific limiting currents[16] for ferrocene oxidation and ubiquinone-10 reduction dissolved in 1-chloronaphthalene at pH 7.0. Since the oxidation of ferrocene is known to proceed with one electron transfer,[13] the total number of electrons transferred in ubiquinone-10 reduction can be determined by comparing the both specific limiting currents. The results suggest that the reduction proceeds with two electrons transfer. This presumption is supported by a coulometric measurement summa-

TABLE 1. COMPARISON OF SPECIFIC LIMITING CURRENTS FOR FERROCENE OXIDATION AND UBIQUINONE-10 REDUCTION AT pH 7.0

Exptl No.	$I_{SL}/\mu A\ mmol^{-1}\ dm^3\ cm^{-2}$ a)		Ratio
	Ferrocence oxidation b)	Ubiquinone-10 reduction b)	
1	2.67	−5.34	
2	2.31	−5.58	
3	2.31	−5.44	
	av. 2.43	av. −5.45	2.24

a) I_{SL} is specific limiting current. b) The both concentrations in 1-chloronaphthalene were kept constant at 4.0×10^{-2} mol/dm^3, and potential sweep rate was 250 mV/min. Similar results were obtained in the other liquids.

TABLE 2. COULOMETRIC DATA FOR UBIQUINONE-10 REDUCTION IN 1-CHLORONAPHTHALENE

Exptl No.	Weight of carbon-paste/mg a)	Q/mC		
		Calculated as $n=1$	Measured	Ratio
1	3.8	4.94	8.85	1.79
2	3.6	4.68	7.35	1.57
3	3.3	4.29	6.94	1.62

a) The ubiquinone-10 concentration was kept constant at 4.0×10^{-2} mol/dm^3. Controlled potential electrolyses were carried out for 100 min at −260 mV *vs.* NHE. Similar results were obtained in the other liquids.

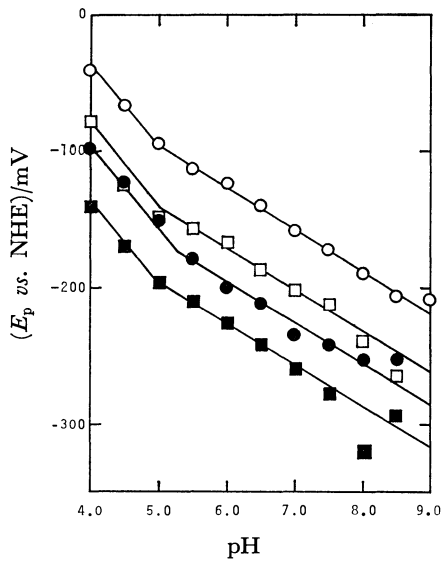

Fig. 1. Plots showing the pH dependence of the peak potentials for ubiquinone-10 reduction.
Symbols in this figure represent the data in each organic liquid as follows: ■; 1-chloronaphthalene, ●; 1-bromonaphthalene, □: 1-methylnaphthalene, or ○; undecane. Potential sweep rate was 250 mV/min. Ubiquinone-10 concentration was 4×10^{-2} mol/dm^3 in each liquid.

rized in Table 2 in which the ratio of measured quantity of electricity to calculated one assuming the number of electrons transferred was 1, could be shown to be about 2. When the plots showing the pH dependence of the peak potentials for ubiquinone-10 reduction were made with each pasting liquid; 1-chloronaphthalene, 1-bromonaphthalene, 1-methylnaphthalene or undecane (Fig. 1), the slope of the straight lines was −60 mV/pH in the more acidic than about pH 5.0 and −30 mV/pH in the more basic region. Therefore, the number of protons transferred is estimated to be 2 in the more acidic than about pH 5.0 and to be 1 in the more basic region because the number of electrons transferred from the electrode is presumed to be 2 from the comparison of the specific limiting currents and the coulometric data. By titrating with mixture of succinate and fumarate, and determining the redox state of ubiquinone-10 spectrophotometrically, Kakuno *et al.*[8] measured a midpoint potential of +23 mV for the endogenous ubiquinone-10 of chromatophore membrane. The reduction was two electrons process, coupled to the uptake of one proton per electron around neutral pH. Our present data indicate the reduction occurs in two electrons transfer, and as expected, ubiquinone-10 dissolved in the carbon-paste seems to be in the similar environment to most of those bound to chromatophore membrane rather than that in an aprotic nonaqueous solvent.[10] However, its reduction potential is quite different from that bound to chromatophores. The peak potentials of ubiquinone-10 reduction at pH 7.0 were −260 mV with 1-chloronaphthalene, −240 mV with 1-bromonaphthalene, −205 mV with 1-methylnaphthalene and −160 mV with undecane, respectively. These potentials in the organic liquids are fairly lower than that in chromatophores even considering that the reaction is totally irreversible electron transfer process, because the transfer coefficient was calculated to be 0.2—0.3 from the slope of Tafel plots. Since Loach[17] reported that the redox potential of ubiquinones became more negative in the more hydrophobic medium, it seems possible that the microenvironment around ubiquinone-10 molecule in chromatophore membrane is more hydrophilic than that in the organic liquids. In any event, the reduction of ubiquinone-10, though that is the reaction in a model system, was first characterized electrochemically in the present study to the best of our knowledge except those in acetonitrile[10] and ethanolic solution.[11,12,18] Studies of the redox properties of the components in photosynthetic and other biological electron transport systems, such as those in nitrogen fixation and oxidative phosphorylation, are very important to the understanding of the reaction mechanism.[19] Especially, the knowledge of the redox potential levels and the number of electrons and protons transferred of the electron carriers in the photosynthetic electron transport system has greatly aided in the assessment of their physiological functions. That is, for instance, determining the phosphorylation sites along the photosynthetic electron transport system because the energy necessary for ATP synthesis must come from the free energy derived from the potential difference and the proton concentration gradient across the biological membrane.[20] So, the development of

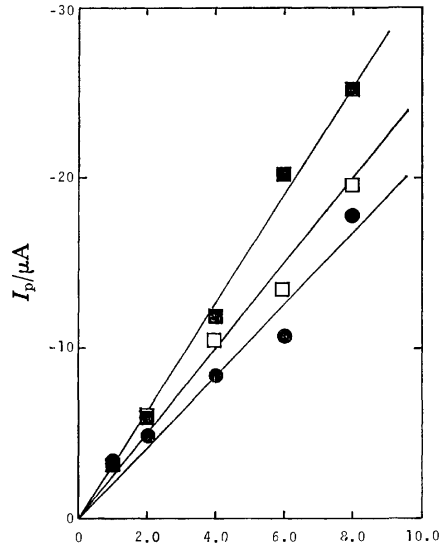

Fig. 2. Relationship of peak current to ubiquinone-10 concentration.
Symbols and experimental conditions are the same as those in Fig. 1, except that ubiquinone-10 concentration is varied and the solution pH is kept constant at 7.0.

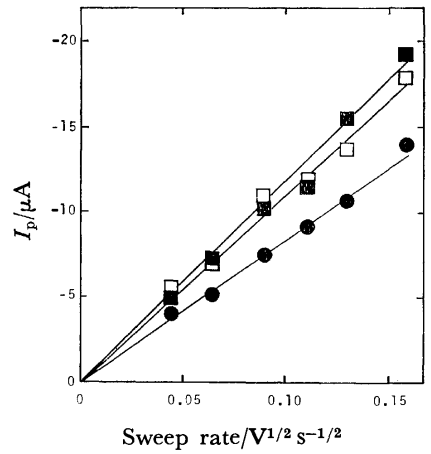

Fig. 3. Relationship of peak current to the square root of potential sweep rate.
Symbols and experimental conditions are the same as those in Fig. 1, except that the potential sweep rate is varied and the solution pH is at 7.0.

other new better model system of chromatophore membrane is still necessary to elucidate clearly the role of ubiquinone-10 in the photosynthetic electron transport system.

In addition, the reduction mechanism of ubiquinone-10 in the organic liquids was briefly examined. The linear relationship of peak current to varying concentration of ubiquinone-10 was observed with each pasting liquid (Fig. 2), and the peak current was proportional to the square root of the potential sweep rate (Fig. 3). It is evident from these results that the observed wave is due to the reduction of ubiquinone-10 itself, and the mass transfer rate is governed by diffusion from the paste. If mass transfer rate is

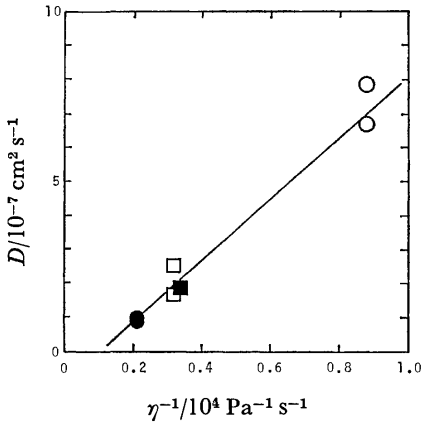

Fig. 4. Relationship of diffusion coefficient to the viscosity of pasting liquids.
Symbols are the same as those in Fig. 1, and values of viscosity are cited from the literture.[13]

governed by diffusion, the viscosity of the pasting liquid should affect this rate and consequently peak current. The Stokes-Einstein relation predicts a linear relationship between the diffusion coefficient and the reciprocal of viscosity. The diffusion coefficient was calculated by an ordinary method,[21,22] and the plots of D *vs.* $1/\eta$, as shown in Fig. 4, are linear but cannot extrapolate to the origin. Since the actual, effective concentration in the pasting liquid is not known, the calculated values of the diffusion coefficient must be considered as apparent values.

This series of studies has been supported by Grants-in-Aid for Scientific Research (No. 511609 and 56112009) from the Ministry of Education, Science and Culture.

Arrhenius Parameters for the Reactions of Hydrogen and Deuterium Atoms with Four Butenes

Takeshi KYOGOKU, Toshifumi WATANABE, Shigeru TSUNASHIMA, and Shin SATO*,†

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

† *Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152*

(Received April 27, 1982)

The absolute rate constants of the H and D atom addition to 1-butene, *cis*- and *trans*-2-butenes, and isobutene have been measured over the temperature range 200—500 K at the total pressure of about 600 Torr (1 Torr= 133.3 Pa). The rate constants obtained were well expressed by the Arrhenius equations: $k(\mathrm{H}+1\text{-butene})=(2.48\pm0.43)\exp[-(1492\pm94)/RT]$, $k(\mathrm{H}+cis\text{-2-butene})=(2.67\pm0.39)\exp[-(1918\pm83)/RT]$, $k(\mathrm{H}+trans\text{-2-butene})=(3.96\pm0.27)\exp[-(2096\pm37)/RT]$, $k(\mathrm{H}+\text{isobutene})=(2.08\pm0.16)\exp[-(860\pm49)/RT]$, $k(\mathrm{D}+1\text{-butene})=(2.42\pm0.72)\exp[-(1642\pm169)/RT]$, $k(\mathrm{D}+cis\text{-2-butene})=(2.25\pm0.19)\exp[-(2082\pm48)/RT]$, $k(\mathrm{D}+trans\text{-2-butene})=(2.33\pm0.23)\exp[-(2036\pm55)/RT]$, and $k(\mathrm{D}+\text{isobutene})=(1.54\pm0.19)\exp[-(879\pm81)/RT]$ in units of 10^{-11} cm^3 molecule^{-1} s^{-1}. The isotope effects due to the difference between H and D atoms can simply be explained by the difference in collision frequency. The difference between *cis*- and *trans*-2-butenes in reactivity may be explained in terms of the pre-exponential factors.

The reactions of hydrogen atoms with olefins have long been a subject for chemical kinetics. Twenty years ago, the relative rate constants of addition of hydrogen atoms to a number of simple olefins at room temperature were measured by Jennings and Cvetanović, who used a photochemical competitive technique.[1] Since then, several different experimental approaches were devised for the determination of these relative rate constants, and some disparities in the rate constants were reported.[2,3]

In the last decade, new techniques such as flash photolysis,[4] pulse radiolysis,[5] and a phase shift method[6] were introduced for the determination of the absolute rate constants of simple reactions. Consequently, the absolute rate constants as well as their temperature dependence for a number of simple reactions have been accumulated and are awaiting theoretical analysis. Absolute rate constants of hydrogen atom addition to olefins have also been measured.[7] A few years ago, our laboratory used the pulse radiolysis-resonance absorption technique for the determination of the rate constants of these reactions[8] and confirmed that the relative rate constants reported by Jennings and Cvetanović are the most reliable among earlier measurements.

The temperature dependence for these rate constants, however, has not been reported except for the reaction $\mathrm{H}+\mathrm{C_2H_4}\rightarrow\mathrm{C_2H_5}$. In the preceding paper,[9] we reported the temperature dependence for the reaction $\mathrm{H}+\mathrm{C_3H_6}\rightarrow\mathrm{C_3H_7}$; therefore, we have extended our measurement to the reactions with four butenes: 1-butene, *cis*- and *trans*-2-butenes, and isobutene.

It is well known that among simple mono-olefins at room temperature isobutene is the most reactive to hydrogen atoms. This is probably because the activation energy for this reaction is the smallest; however, the absolute value has not been reported. On the other hand, in many free radical addition reactions, *trans*-2-butene is often found to be about 10% more reactive than *cis*-2-butene;[10] therefore, it may be worthwhile to know whether this difference in the hydrogen atom addition reaction comes from its activation energy or from the pre-exponential factor.

Experimental

The experimental procedure is the same as described in a previous paper.[11] The mixture of about 600 Torr hydrogen or deuterium and a small amount of an olefin (0.01—0.1 Torr) was pulse-irradiated with high energy electrons from a Febetron 706 (Hewlett Packard) and the decay of the concentration of hydrogen or deuterium atoms was followed by the absorption of the Lyman-α radiation.

1-Butene, *cis*- and *trans*-2-butenes, and isobutene were purchased from the Takachiho Shoji Co. and used as supplied. Gas-chromatographic analysis using a 5 m long column packed with dimethyl sulpholane on celite showed that impurities in each butene are less than 1%.

Results

Table 1 summarizes the rate constants obtained at various temperatures. Each rate constant was estimated as the average of four to five measurements. Figure 1 shows the Arrhenius plots. For comparison, the rate constants obtained with ethylene and propylene are also plotted. All data are well expressed by the Arrhenius equations. The Arrhenius parameters calculated by the least squares method[12] are summarized in Table 2.

Discussion

Isotope Effects Due to the Difference between H and D Atoms and the Tunneling Effect. Figure 1 clearly shows that Arrhenius plots for H and D atom reactions with the same olefin are always parallel and the interval is nearly constant irrespective of the kind of reactant olefin. This fact can simply be explained by the difference in collision frequency as follows:[13]

$$k_H/k_D \approx \left[\frac{m_D m_{olefin}}{m_D + m_{olefin}}\right]^{1/2} \Big/ \left[\frac{m_H m_{olefin}}{m_H + m_{olefin}}\right]^{1/2} \cong \sqrt{2}.$$

Here k_H and k_D are the rate constants of the H and D atom reactions. m_H, m_D, and m_{olefin} are the masses

Table 3. Relative values of pre-exponential factors

Olefin	H-Atom addition	D-Atom addition
Ethylene	(2.0)	(2.0)
Ethylene-d_4	1.94	2.11
cis-2-Butene	1.14	1.34
trans-2-Butene	1.69	1.39
Propylene	1.28	1.18
Propylene-d_6	1.09	1.31
1-Butene	1.05	1.44
Isobutene	0.89	0.92

of H and D atoms and olefin molecules, respectively.

In the hydrogen atom-molecule reaction, $H+H_2 \rightarrow H_2+H$, the Arrhenius plots deviated from linearity at temperatures lower than 300 K and the deviation showed a strong H/D isotope effect.[14] This result has been attributed to the tunneling effect. In the present reaction systems, however, no such deviation from linearity could be observed within experimental error. Although a slightly concave curve can be realized in the Arrhenius plot for the reaction of $H+C_2H_4 \rightarrow C_2H_5$, this is also found in the reaction of $D+C_2D_4 \rightarrow C_2D_5$; therefore, this curvature cannot be attributed to the isotope effect.

The Number of Reaction Site and the Difference in Reactivity between cis- *and* trans-*2-Butenes.* It is now well known that in the reactions of unsymmetric olefins such as propylene, 1-butene, and isobutene, a hydrogen atom adds to the less substituted carbon atom of the double bond. In other words, there is only one reaction site. On the other hand, symmetric olefins such as ethylene and 2-butenes have two identical reaction sites. In the simple collision theory, the difference in the number of reaction sites should appear in the pre-exponential factors. Table 3 compares the relative values for the pre-exponential factors. Although the exact ratio between symmetric and unsymmetric olefins is not clearly determined, the expected trend can be observed.

Another noticeable point in Table 3 is the difference between *cis*- and *trans*-2-butenes. Although the experimental errors prevent us from estimating the quantitative ratio, the difference in reactivity between *cis*- and *trans*-2-butenes may be attributed to the difference in the pre-exponential factors. If methyl radical substitution restricts the reaction zone for an attacking hydrogen atom, unrestricted spaces on two carbons at both sides of the double bond may overlap with each other in the case of *cis*-2-butene, but not in the case of *trans*-2-butene. This difference probably corresponds to the difference in the pre-exponential factors.

Atom Localization Energies. When Jennings and Cvetanović measured the relative rate constants of H atom addition to a series of simple olefins, they compared the logarithms of the rate constants with the atom localization energies of the olefins, which were calculated by the simple Hückel method on the assumption of hyperconjugation, and obtained a linearity.[1] However, it is obvious that the atom localization energies should be compared with the activation energies. Figure 2 shows this comparison. A linear relation has been obtained as expected.

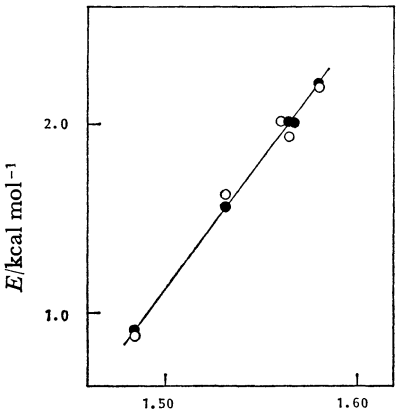

Fig. 2. Correlation between activation energies (○ for H atom reactions and ● for D atom reactions) and atom localization energies of olefins.

The atom localization energy is a very rough concept. A more sophisticated treatment is highly desirable.

The Corrosion Inhibition of SS 41 Steel by Shoyu Oil

Isao SEKINE* and Masahiro ASAZUMA

Faculty of Science and Technology, Science University of Tokyo, Yamazaki, Noda, Chiba 278

(Received May 6, 1982)

The addition of shoyu (soy sauce) oil to an NaCl solution for use as a corrosion inhibitor of SS 41 steel was investigated by measuring the corrosion weight loss, the polarization curve, the polarization resistance, and the impedance of the metal-solution interface. The value of the weight loss and the double-layer capacitance, C_{dl}, decreased as the shoyu oil was added to NaCl solutions of various concentrations. The value of the corrosion current density, I_{corr}, as calculated from the weight loss, the polarization curve, and the impedance measurement, decreased with an increase in the concentration of shoyu oil. An efficient inhibition of the corrosion of SS 41 steel was observed above an additive concentration of about 0.3%. Thus, the shoyu oil was found to be useful as a corrosion inhibitor of an economical and anti-pollution type. From the results of the IR analysis, the inhibition of the shoyu oil was considered to be caused by the adsorption of fatty acids, especially unsaturated fatty acids involved in the shoyu oil.

It has been reported by Markina and Misler that the sodium soaps of synthetic fatty acids of C_5—C_6, C_{10}—C_{16}, and C_{17}—C_{20} are effective as corrosion inhibitors of 12Khl MF steel, which is a material used for boilers.[1] The corrosion-inhibition effect by the adsorption of amine salts of oleic acid on iron in 0.5 M H_2SO_4 (1 M=1 mol dm^{-3}) has been discussed by Szauer and Brandt.[2,3] According to some articles,[4-6] fatty acid with C_{16}–C_{18} atoms has been considered as exerting the most effective inhibition. Such a corrosion-protection effect is caused by the adsorption of the anion of fatty acid or the cation of amine. The adsorption in this case is known to obey the Frumkin or Temkin isotherm. Further, the adsorption of fatty acid shows a tendency to increase with an increase in the length of the aliphatic chain, while the inhibition effect shows a tendency to decrease with an increase in the number of the double bond of fatty acid.[2,3]

In the present work, we examined the use of shoyu oil added to an NaCl solution as a corrosion inhibitor of metal, for example, SS 41 steel. Since this oil is a by-product of shoyu production and a mixture of five kinds of natural fatty acids with C_{16}—C_{18} atoms, it was expected to be useful and economical as a corrosion inhibitor of an anti-pollution type. Thus, the inhibition effect of the shoyu oil was investigated by measuring the weight loss, the polarization curve, the interfacial impedance, and the polarization resistance in a neutral NaCl solution. From the results obtained, it was found that the shoyu oil inhibits the corrosion of SS 41 steel sufficiently and can be used satisfactorily as an inhibitor of corrosion by cooling water and industrial water. The corrosion inhibition of shoyu oil was considered, from the results of the IR reflection spectrum, to be caused by the adsorption of the anion of fatty acid.

Experimental

Materials. The shoyu oil used as a corrosion inhibitor was from intact soybeans and defatted soybeans. Since these shoyu oils are insoluble in water, soluble sodium salts of them were prepared according to the procedure shown in Fig. 1. The sodium salt of shoyu oil from intact soybeans is abbreviated as SSOI, and the sodium salt of shoyu oil from defatted soybeans, as SSOD. The compositions of these SSOI and SSOD are shown in Table 1. This table shows that the shoyu oils consist of about 80% unsaturated fatty acids and of about 20% saturated fatty acids. The concentrations of the NaCl solutions used as blank solutions were 0.003, 0.03, 0.3, and 3%. The concentrations of these inhibitors were 0.1, 0.3, 0.5, and 1.0% respectively. Before each run, all the solutions were sufficiently aerated and adjusted to pH 7. The specimen used was SS 41 steel.

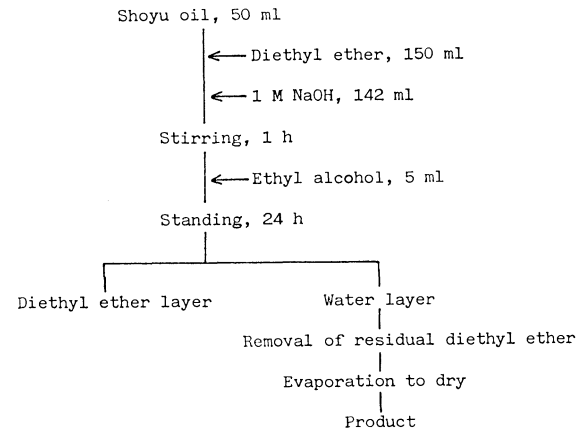

Fig. 1. Preparation of sodium salt of shoyu oil.

TABLE 1. COMPOSITIONS OF SSOI AND SSOD

Sodium salt of fatty acid	SSOI(%)	SSOD(%)
$C_{15}H_{31}COONa$	10.7	16.7
$C_{17}H_{35}COONa$	9.2	6.1
$C_{17}H_{33}COONa$	17.6	27.8
$C_{17}H_{31}COONa$	55.2	45.7
$C_{17}H_{29}COONa$	7.4	3.7

Weight-loss Measurement. The specimen sheet of 25×60×0.5 mm was immersed in the test solution for five weeks at room temperature. Before use, the specimen was abraded with emery papers from No. 240 to No. 1200, and successively washed with distilled water, methanol, and acetone. In the corrosion weight-loss test at high temperature, the weight loss of the specimen was measured after the specimen had been immersed in a test solution maintained at 95 °C for 3 d. The boiling point of the test solution was 95 °C.

Polarization Measurement. A specimen wire 1 mm in diameter was covered with a mixture of paraffin wax and pine resin, and only the cross-section of the specimen was used. The counter electrode was a platinum wire, while the potential was measured with reference to a saturated calomel electrode (SCE). The polarization potentials were scanned from the cathodic region to the anodic region.

Impedance Measurement. The specimen used was the same as that used in the polarization measurement. The corrosion potential, E_{corr}, of the test electrode was stabilized 1—2 h after immersion. Thus, the measurements of the impedance were started when the E_{corr} value was stabilized. In the frequency range of 2 kHz—1 Hz, a lock-in amplifier (NF Circuit Design Block; model LI-574) was used, while in the frequency range of 1 Hz—0.006 Hz, Lissajou's method was used.

Polarization-resistance Measurement. A specimen rod 4 mm in diameter was covered with pine resin except for the bottom 30 mm. The measurement was made by using a corrosion-rate meter (Hokuto Denko; model HK-103). The frequency and time of measurement were 0.1 Hz and 110 h respectively.

IR Analysis. Before the IR analysis, the specimen sheet taken out from the test solution to measure its corrosion weight loss was vacuum-dried for about 30 min. The angle of incidence was 12°, and the number of reflections was one.

Results and Discussion

The weight loss against the concentration of SSOI is shown in Fig. 2. As may be seen in this figure, the value of the weight loss was lowered with an increase in the concentration of SSOI and held constant in concentrations more than 0.3%. Such a tendency was also seen for SSOD. In any concentration of NaCl solution used, the surface of test pieces in the blank solution became dark brown, and then a reddish-brown precipitate in the solution was observed. However, the test pieces immersed in solutions with concentration over 0.3% of SSOI and 0.5% of SSOD kept the same silvery metallic luster as before immersion. Such a surface state may be seen in Photo 1.

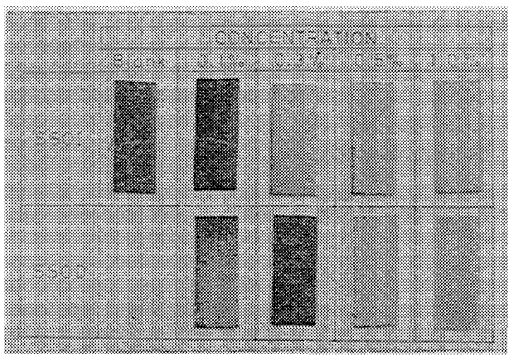

Photo 1. Surface state of specimen after corrosion weight loss for various concentrations of SSOI and SSOD in 3% NaCl solution at room temperature.

Figure 3 shows a comparison between the shoyu oil and other inhibitors. Sodium benzoate (SB) and sodium *p-t*-butylbenzoate (SBB) have been used as corrosion inhibitors for a long time. As can be seen from this figure, the outstanding inhibitive effectiveness at a concentration over 0.3% of SSOI added to a 0.003% NaCl solution was comparable to that of SB and SBB.

Table 2 shows the results of the weight-loss test at 95 °C from the viewpoint of practical utilization. In general, when an inhibitor is used, the adjustment

of the pH is very troublesome. Consequently, all runs at 95 °C were carried out without adjusting the pH. This table further compares the natural shoyu oil as a by-product, the synthetic shoyu oil prepared by mixing all the components of Table 1, sodium salt of five fatty acids containing the components of shoyu oil, and the fatty acids with C_5–C_6 atoms reported by Markina *et al.*[1] As can be seen in this table, among all the inhibitors under investigation, natural SSOI is the most efficient. The natural SSOD is less effective than SSOI, as can be seen from Photo 1. However, it seems that both SSOI and SSOD are efficient corrosion inhibitors in view of the utilization of by-products.

The polarization curves for SS 41 steel in a 0.003% NaCl solution containing SSOD are shown in Fig. 4. The current density of the cathodic process decreases with an increase in the concentration of SSOD, and the E_{corr} shifts to the direction of the cathodic

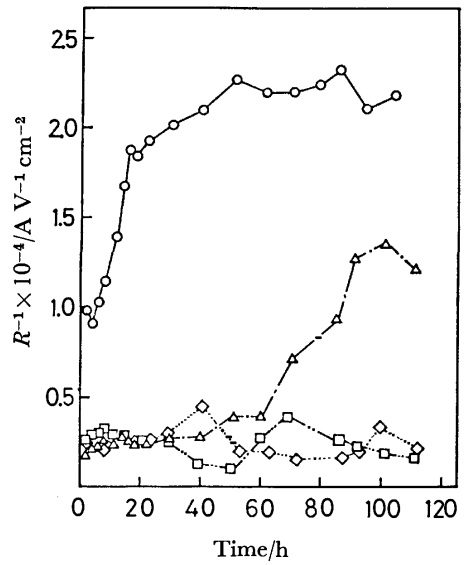

Fig. 6. $1/R$ *vs.* time curves in 0.003% NaCl solution.
—○—: Blank, -·-△-·-: 0.1% SSOI, -·-□-·-: 0.3%, --◇--: 1.0%.

region. In general, when oxygen is dissolved in a neutral solution, the corrosion rate is determined by the limiting current density due to oxygen reduction. The decrease in the cathodic current density with an increase in the concentration of inhibitors indicates a lowering of the corrosion rate.

The relationship between the I_{corr} value and the concentration of SSOD is shown in Fig. 5. At each concentration of NaCl solutions, the I_{corr} value can be seen to decrease with an increase in the concentration of SSOD. Consequently, the SSOD is regarded as a good corrosion inhibitor. However, the I_{corr} value shows something of a tendency to increase at the concentration of 0.3% of SSOD. Since the determination of I_{corr} from the polarization curves is arbitrary, such a tendency may be attributed to the method of drawing the line.

Figure 6 shows the time dependence of $1/R$, which is the quantity corresponding to the corrosion rate ($I_{corr}=K/R$). The value of $1/R$ decreases with an increase in the concentration of SSOI. Especially at a concentration over 0.3% of SSOI, it is seen to be lowered for a long time. A similar result was also obtained for SSOD. From these results, it is considered that both SSOI and SSOD are fairly sufficient inhibitors.

Some typical results of impedance measurements at E_{corr} are shown in Fig. 7. In a high-frequency region, the loci of the circular arcs are seen to be a part of a semicircle whose center is shifted under the real axis. On the other hand, straight lines with a slope of about 45° are obtained in the low-frequency region. The charge-transfer resistance, R_{ct}, obtained by the extraporation of a part of the semicircle to the real axis was about 850 Ω at the blank solution and about 1 kΩ at the solution with 0.3% SSOD added. The straight lines in the low-frequency region seem to be based on the diffusion of oxygen, because all the solutions used are aerated before each run. Consequent-

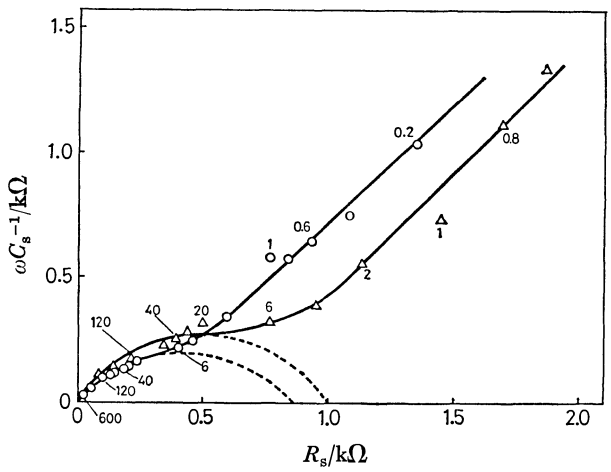

Fig. 7. Complex impedance plane plot at E_{corr} in 3% NaCl solution.
—○—: Blank, —△—: 0.3% SSOD.

Table 3. Comparison of the results obtained in a 3% NaCl solution

SSOD %	Impedance measurement R_{ct} Ω	Impedance measurement C_{dl} μF cm^{-2}	Impedance measurement I_{corr} μA cm^{-2}	Weight loss I_{corr} μA cm^{-2}	$i-E$ curve I_{corr} μA cm^{-2}
0	850	3980	1290	106.0	35
0.1	950	2130	1160	29.1	19
0.3	1000	1010	1100	18.9	26
0.5	1080	470	1020	17.4	17

ly, the diffusion process of oxygen is the rate-determining step. The value of C_{dl} calculated from Fig. 7 was about 4000 μF/cm^2 at the blank solution and about 1000 μF/cm^2 at 0.3% SSOD.

Table 3 shows the values of R_{ct}, C_{dl}, and I_{corr} against each concentration of SSOD. It can be seen that the R_{ct} value increases with an increase in the concentration of SSOD, while the C_{dl} value decreases. When the R_{ct} values, that is, the reaction resistance of corrosion, becomes greater, the SSOD seems to be the better inhibitor. On the other hand, the decrease in C_{dl} can be seen to be based on a reduction of the surface area of the specimen by a corrosion inhibitor. This can be explained by means of a Helmholtz parallel-plate condenser model:[7]

$$C_{dl} = C_H = \varepsilon(S/d),$$

where C_H is the Helmholtz capacity; S, the area of the condenser plates opposite to each other; d, the distance between the condenser plates, and ε, the dielectric constant. These results seem to be evident, for the SSOD leads to an efficient inhibition with an increase in the concentration of SSOD. Further, the values of I_{corr}, as calculated from the polarization curve, correspond very well with those calculated from the weight loss. However, these I_{corr} values differ very much from those calculated from the impedance measurement. This discrepancy can be ascribed to the fact that the determination of R_{ct} is very difficult, because the center of the semicircle obtained is shifted under the real axis. Therefore, the I_{corr} value with respect to R_{ct} may be considered to admit of further argument.

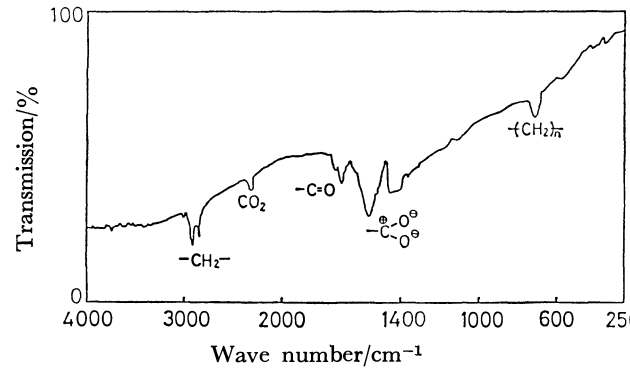

Fig. 8. Result of reflection type IR spectrum in 0.3% NaCl solution with 0.3% SSOD.

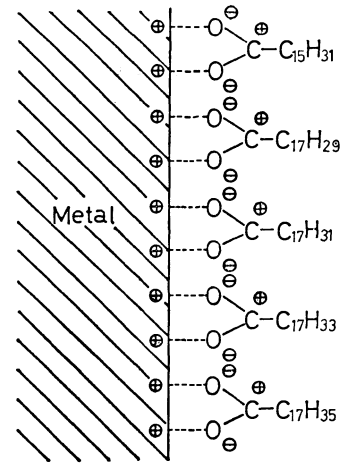

Fig. 9. Adsorption model of SSOI and SSOD.

The inhibition mechanism of SSOI was examined by means of infrared analysis. An example of the spectrum of the IR reflection type is shown in Fig. 8. It shows the spectrum of a specimen immersed for 3 d in a 0.3% NaCl solution containing 0.3% SSOI. In the IR spectrum, the two peaks at 2850 and 2900 cm^{-1} represent the stretching vibration of -C-H of the methylene group; the peak at 1700 cm^{-1}, that of aliphatic carboxylic acid; the two peaks from 1400 to 1600 cm^{-1}, that of the carboxylate ion, and the peak at 700 cm^{-1}, the rocking vibration of the polymethylene chain. Consequently, the adsorption model of SSOI and SSOD is roughly represented in Fig. 9. According to Szauer and Brandt,[2] when the unsaturated fatty acids of C_{18} were used as corrosion inhibitors, the effect of corrosion inhibition is related to the number of the double bond of fatty acid, and the inhibition effect decreases with an increase in the number of the double bond in the order of oleic acid> linoleic acid>linolenic acid. This is considered to be caused by the influence of π electrons in the double bond. In the present study, the adsorption seems to occur in two steps.[8] At first, the hydrophilic carboxylate ions adsorb on the metal surface. Subsequently, the hydrophobic alkyl groups are vertically oriented to the metal surface toward the bulk solution. How-

ever, when the double bond is involved in fatty acid, the alkyl groups are bent to the metal surface by the influence of π electrons in the double bond, and then corrosive chemical species (Cl^-, O_2, H_2O, *etc.*) come near to the metal surface. Therefore, it is considered that the inhibition effect decreases with an increase in the number of double bonds. As may be seen in Table 2, linolenic acid exerts the most efficient inhibition compared with the other unsaturated fatty acids. These results differ from those described by Szauer and Brandt.[2] Hence, in order to clarify such a discrepancy, further work would be required from the standpoint of the influence of the double bond.

According to Wolstenholme and Schulman,[9] fatty acid does not simply adsorb on the metal surface, as is represented in Fig. 9, but makes a complex with the iron ion which grows relatively thick. However, the adsorption model in Fig. 9 may be supposed to show not only unsaturated fatty acids, but also saturated ones such as stearic acid, because it is impossible to discriminate the carboxylate ions of both fatty acids by IR analysis. As can be seen from Table 1, since the shoyu oil consists of about 80% unsaturated fatty acids, the adsorption of SSOI and SSOD would be caused chiefly by unsaturated fatty acids. Hence, the adsorption model of shoyu oil shown roughly in Fig. 9 may be considered to be reasonable.

It is generally known that the adsorption of fatty acids on iron obeys Frumkin-Temkin's isotherm. In the present work, the adsorption of shoyu oil is also assumed to obey Frumkin-Temkin's isotherm. Thus, we investigated whether the adsorption is chemisorption or physical adsorption. According to Reshetnikov,[10] when the inhibition takes place by means of physical adsorption, Eq. 1 is valid without chemisorption, and the inhibition by chemisorption satisfies Eq. 2:

$$\ln \gamma = m\theta \tag{1}$$

$$Z = 1 - \frac{1}{\gamma} = \theta, \tag{2}$$

where γ is the inhibition coefficient which is defined by the relation $\gamma = k/k_{inh}$; k and k_{inh}, the rates of iron dissolution in the absence and presence of the inhibitor respectively; Z, the inhibition efficiency; θ, the surface coverage calculated on the basis of the capacitance measurement, and m, the constant. In the present study γ and Z were calculated from I_{corr}, which has itself been obtained from the measurements of the impedance and the weight loss, and θ is the value of C_{dl} at E_{corr} obtained from the impedance measurement.

Figures 10 and 11 show the results plotted for SSOD according to Eqs. 1 and 2. In Fig. 10 the linearity of ln γ *vs.* θ can not be seen, but the plots of Z *vs.* θ in Fig. 11 give a straight line. Consequently, the adsorption in the case of SSOD is regarded as chemisorption.

In order to elucidate more clearly the adsorption state of these inhibitors, there seems to be no alternative but to wait for future work *in situ* by means of optical methods.

The authors are very grateful to Professor Zenjiro Sugizaki of our university for his useful suggestions and to the Kikkoman Co. for the gift of a shoyu oil sample. The authors also wish to thank Messrs. Toshiki Mitsuka, Hiroyuki Mizoguchi, and Hideaki Sako for carrying out a part of the experiments.

A Solid State Electrochemical Study on the 5,6 : 11,12-Bis(epidithio)-naphthacene–Iodine and Bromine Complexes

Eiji CHINO, Yoshio MATSUNAGA,* and Noboru TANABE
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received May 8, 1982)

Electromotive force (emf) measurements were made on solid-state galvanic cells, Ag|AgI|TTT-I_n, where TTT-I_n is the 5,6:11,12-bis(epidithio)naphthacene–iodine complex, as functions of the composition, n, and also of the temperature. A continuous increase in the emf at 25 °C from 491 to 593 mV was observed in the range from $n=1.0$ to 1.5, suggesting the occurrence of a nonstoichiometric phase. The upper limit of the existence region agrees with the composition of the well-known metallic phase. The emf changes again continuously up to 628 mV in the range from $n=2.7$ to 2.9, which corresponds with the composition of another highly-conducting complex. Similar measurements were carried out for the cells Ag|AgBr|TTT-Br_n. Distinct phases were found at the following compositions: $n=0.5$—0.8, about 1, about 1.2, about 1.5, and about 2. The Gibbs energy, enthalpy, and entropy of cell reactions as well as complex formation reactions were estimated.

Mixed-valence 5,6:11,12-bis(epidithio)naphthacene–iodine complexes, TTT–I_n,[1] have attracted the interest of many research groups. The complex TTT–$I_{1.5}$ is among the extensively studied organic metals. In addition to this particular complex, Buravov *et al.* have reported the isolation of a complex with $n\simeq 1$ and Kamaras *et al.* have found a complex with the composition range from $n=2.6$ to 2.9.[2,3] Moreover, the preparation of the complex TTT–$I_{0.72}$ has been described by Kathirgamanathan and Rosseinsky.[4] We examined earlier the electrical resistivity and thermoelectric power of TTT–I_n as functions of n using polycrystalline compactions.[5] Our resistivity-composition isotherm at 25 °C showed a minimum of 0.3 Ω cm at the composition of the metallic phase, TTT–$I_{1.5}$, and a shoulder as large as 200 Ω cm at the other phase, TTT–$I_{2.7}$. The presence of the latter phase was also manifested by a drastic increase in the thermoelectric power near $n=2.7$. No singularity due to the other complexes, TTT–$I_{0.72}$ and TTT–I, could be detected by these techniques, however.

The same techniques were employed for the elucidation of the TTT–Br_n complexes.[6] A minimum of about 7 Ω cm found near $n=0.5$ in the resistivity-composition isotherm at 25 °C indicated the formation of a mixed-valence complex, $(TTT)_2{}^+Br^-$. The resistivity increases monotonously up to $n=1.4$ and then abruptly by a factor of forty between $n=1.4$ and 1.5. This change implies the formation of another mixed-valence complex having the ideal composition of $(TTT)_2{}^{3+}(Br^-)_3$. The latter anomaly is accompanied by an increase of the activation energy for semiconduction by a factor of almost two and also by the change of sign in the variation of the thermoelectric power with the temperature from positive to negative. Here again, no indication of a well-established monobromide TTT^+Br^- was found by these techniques.

As our experiments on solid-state galvanic cells involving reactions between silver and the halogen in electronically-conducting thiazine–iodine complexes had provided a powerful tool for elucidating the constitution,[7] we decided to extend the work to the TTT–I_n and TTT–Br_n complexes. The electromotive force (emf) depends on n quite differently from the electrical resistivity and the thermoelectric power studied before. Two-phase mixtures should be identified by a constant emf, a stoichiometric complex by a discontinuous increase and a nonstoichiometric single-phase region by a continuous increase in emf with n.

Experimental

Materials. TTT was synthesized following the method reported by Marschalk and Stumm and recrystallized at least three times from 1,2,4-trichlorobenzene.[8] TTT–I_n samples were prepared by grinding the weighed TTT and iodine in an agate mortar in the presence of a small amount of benzene. The iodine contents were determined by elemental analysis. An additional sample prepared by the reaction between TTT and iodine in boiling nitrobenzene has a composition of $n=1.53$.

$TTT^{2+}(Br^-)_2$ was prepared by the oxidation of powdered TTT suspended in 1,2,4-trichlorobenzene with bromine, as described by Marschalk and Niederhauser.[9] The samples with n values less than two were obtained by grinding the weighed dibromide and TTT. The exact compositions were determined by microanalysis.

Measurements. The galvanic cell, Ag|AgI|TTT-I_n, was assembled. It was found to be necessary to mix intimately the electrolyte and TTT-I_n and to thermostat the cell at 80 °C for several days to attain an initial constant emf. The measurements were carried out in the range from room temperature to 80 °C, only for increasing temperatures. The cell was kept at each temperature for about one hour. The emf was read by means of a high-impedance universal digital meter, Yokogawa 2502. The work on the Ag|AgBr|TTT-Br_n cells was found to be more difficult. Reproducible emf values could be obtained only above 50 °C and only when the cell was kept for several days at each temperature.

Results and Discussion

TTT–I_n Complexes. The compositional variation of the emf at 25 °C is presented in Fig. 1. Below $n=1$, the cell maintains an emf of 491 mV. The samples in this composition range are supposed to be mixtures of the parent organic compound TTT and its iodine complex, TTT–I. The present work failed to provide any evidence supporting the existence of the TTT–$I_{0.72}$ reported by Kathirgamanathan and Rosseinsky. The emf increases continuously between $n=1$ and 1.5, suggesting the formation of a nonstoi-

TABLE 1. THERMODYNAMIC DATA FOR THE COMPLEX FORMATION REACTION, $TTT+n/2\ I_2 \longrightarrow TTT\text{-}I_n$

1	−18.8	−21.1±1.1	−7.6±3.7	−18.8
1.5	−26.7	−27.7±1.3	−3.2±4.3	−17.8
2.7	−37.4	−35.8±2.5	5.3±5.2	−13.9
2.9	−38.8	−37.1±3.3	5.7±7.8	−13.6

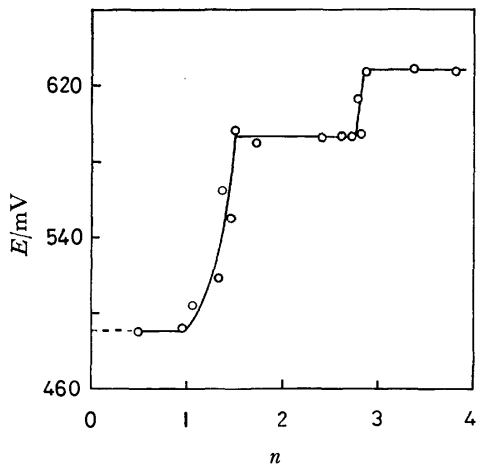

Fig. 1. Electromotive force of the solid-state cell, Ag|AgI|TTT-I_n *versus* n at 25 °C.

chiometric complex covering this range. In addition to the work by Buravov *et al.* mentioned above, Kamaras *et al.* have noted that TTT–I can be produced occasionally together with TTT and TTT-$I_{1.5}$. The compositions of these two complexes are identified as the lower and upper limits of a nonstoichiometric phase. Kaminskii *et al.* have reported that the iodine content in the complex TTT-$I_{1.5}$ may be varied from 1.5 to 1.55.[10] Apparently, the existence region of this nonstoichiometric phase is not limited to such a narrow range.

A plateau indicative of a two-phase region appears between n=1.5 and 2.7, giving an emf of 593 mV. The continuous increase observed between n=2.7 and 2.9 implies that the complex is again homogeneous over this range. In other words, a nonstoichiometric complex is formed. These results are in fair agreement with the observation made by Kamaras *et al.*, namely, the composition of recrystallized samples ranges from n=2.6 to 2.9 and the resistivity value along the needle axis is scattered by a factor of 16.[3] The occurrence of this phase was already confirmed by our resistivity and thermoelectric power measurements. The emf is 628 mV above n=2.9. The upper limit of this two-phase region could not be determined.

Since the current in AgI is exclusively carried by Ag^+ ions, the emf values observed in the two-phase regions below n=1 and between n=1.5 and 2.7 yield the Gibbs energies of the following cell reactions:

$$Ag(s) + TTT\text{-}I(s) \longrightarrow AgI(s) + TTT(s) \quad \text{and}$$

$$Ag(s) + 1/1.2\ TTT\text{-}I_{2.7}(s) \rightarrow AgI(s) + 1/1.2\ TTT\text{-}I_{1.5}(s).$$

Two more cell reactions covering the single phase regions are conceivable. It is convenient to consider the Gibbs energies in terms of the reactions:

$$Ag(s) + TTT\text{-}I(s) \longrightarrow AgI(s) + TTT(s) \quad (1)$$

$$0.5\,Ag(s) + TTT\text{-}I_{1.5}(s) \longrightarrow 0.5\,AgI(s) + TTT\text{-}I(s) \quad (2)$$

$$1.2\,Ag(s) + TTT\text{-}I_{2.7}(s) \longrightarrow 1.2\,AgI(s) + TTT\text{-}I_{1.5}(s) \quad (3)$$

and

$$0.2\,Ag(s) + TTT\text{-}I_{2.9}(s) \longrightarrow 0.2\,AgI(s) + TTT\text{-}I_{2.7}(s). \quad (4)$$

The energies associated with the reactions (1) and (3) are easily calculated to be −47.4 and −68.7 kJ mol^{-1}. As is evident from Fig. 1, these values represent the area under the emf-composition relation between the upper and lower n values defined in each cell reaction. Therefore, the Gibbs energies associated with the reactions (2) and (4), in which the nonstoichiometric complexes participate, may be estimated by a graphic integration to be −25.2 and −11.7 kJ mol^{-1} respectively.

Combining with $\Delta G^\circ_f(AgI) = -66.2$ kJ mol^{-1},[11] the Gibbs energies in terms of the following complex formation reactions:

$$TTT(s) + 1/2\ I_2(s) \longrightarrow TTT\text{-}I(s)$$

$$TTT(s) + 1.5/2\ I_2(s) \longrightarrow TTT\text{-}I_{1.5}(s)$$

$$TTT(s) + 2.7/2\ I_2(s) \longrightarrow TTT\text{-}I_{2.7}(s)$$

$$TTT(s) + 2.9/2\ I_2(s) \longrightarrow TTT\text{-}I_{2.9}(s)$$

are determined as presented in Table 1. The emf of the cell was a linear function of the temperature for all the samples studied. The entropy changes for the cell reactions (1)—(4) are estimated to be 18.5±2.4, 5.6±0.6, 6.8±0.4, and 14.5±1.1 J K^{-1} mol^{-1} on the basis of the temperature coefficients. The application of Gibbs-Helmholtz equation yields enthalpies of −42.0±0.7, −23.5±0.2, −66.7±0.1, and −7.4±0.3 kJ mol^{-1} for these cell reactions. With the aid of $\Delta S^\circ_f(AgI) = 14.6$ J K^{-1} mol^{-1},[11] the entropy changes in terms of the complex formation reactions can be computed, and then with $\Delta H^\circ_f(AgI) = -61.8$ kJ mol^{-1},[11] the enthalpy changes can be estimated. The results are summarized in Table 1. It may be noted that the entropy change is positive above n=2.7, while it is negative below this composition.

The Gibbs energy divided by the number of iodine atoms is in the range from −13.6 to −18.8 kJ mol^{-1}. These values show that the affinity of TTT for iodine is undoubtedly larger than that of the thiazines estimated earlier: *e.g.*, −6.9 kJ mol^{-1} at n=2.8 in the phenothiazine complex and −11.8 kJ mol^{-1} at n=2.7 in the benzo[*a*]phenothiazine complex. The diffusion of iodine in the present complexes appears to be appreciably hindered by strong binding to TTT. As the passage of current results in quick mass-transfer

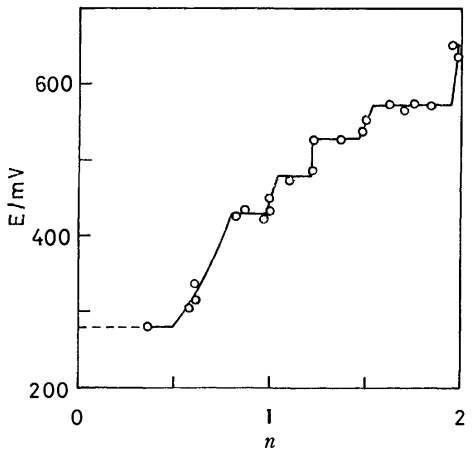

Fig. 2. Electromotive force of the solid-state cell, Ag|AgBr|TTT-Br_n *versus* n at 25 °C.

polarization, the application of a solid-state coulometric titration to the TTT-I_n complexes was found to be impracticable even if AgI is replaced with a highly-conducting AgI-based solid electrolyte.

We concluded that, on the basis of thermoelectric power, the TTT molecule in the iodine complex does not attain a unit positive charge even at n=4.5.[5] By contrast, both TTT^+ and TTT^{2+} bromides have been known by the work of Marschalk and Niederhauser.[9] The existence of these two has been fully supported by the significant differences in their electronic and vibrational spectra.[6,12] Consequently, one might foresee the appearance of many phases in the TTT–Br system in spite of the limitation of the study to the range n<2.

TTT-Br_n Complexes. In Fig. 2, the emf of the TTT-Br_n complexes extrapolated to 25 °C is plotted against n. When n<0.5, the cell exhibits an emf of 281 mV. An increase of the emf seems to be continuous between n=0.5 and 0.8. The lower limit coincides with the composition of the minimum resistivity found in the TTT–Br system. The emf remains at 429 mV until n reaches a little below one, and then increases continuously up to 480 mV in a relatively narrow range. Thus, the monobromide appears to be nonstoichiometric but only to the extent of 0.06. An abrupt increase in the emf at about n=1.2 from 480 to 528 mV suggests that this phase is stoichiometric or nearly so. The third single phase region appearing around n=1.5 corresponds to the mixed-valence compound $(TTT)_2^{3+}(Br^-)_3$ established by the resistivity-composition isotherm approach. The existence region is located from n=1.48 to 1.54; these values are a little higher than those reported before.[6] Then the two-phase region exhibiting an emf of 572 mV appears. Its upper limit is rather arbitrarily located at n=1.96.

The Gibbs energies, enthalpies, and entropies computed for the cell reactions, Δn Ag(s) + TTT-Br_n(s) → Δn AgBr(s) + TTT-$Br_{n-\Delta n}$(s), are summarized in Table 2. With the aid of ΔG_f°(AgBr) = −96.9 kJ mol^{-1}, ΔH_f°(AgBr) = −100.4 kJ mol^{-1}, and ΔS_f°(AgBr) = −11.7 J K^{-1} mol^{-1},[11] the thermodynamic data for the complex formation reactions, TTT(s) + n/2 Br_2(l) → TTT-Br_n(s) were estimated as given in Table 3. The Gibbs energy divided by the number of bromine atoms is in the range from −55.0 to −69.7 kJ mol^{-1}, indicating that bromine forms TTT complexes of greater stability than iodine does. The entropy changes are always negative. The order of magnitude is comparable with that known for the thiazine-iodine complexes. In conclusion, it must be emphasized that not only most of the complexes reported in earlier works but also some new phases have been established for both the iodine and bromine complexes by the present solid-state electrochemical study. The phases

were found to be more or less nonstoichiometric.

This work was partly supported by Grant-in-Aid for Scientific Research No. 434023 from the Ministry of Education, Science and Culture.

Phase Diagrams and Association Structures of Combined Surfactants-Water Systems

Hiromichi SAGITANI† and Stig E. FRIBERG*

Chemistry Department, University of Missouri-Rolla, Rolla, MO., 65401, U.S.A.

(Received May 8, 1982)

Phase regions were determined in systems with water and sodium dodecyl sulfate combined with a series of nonionic surfactants of the structure di-, tetra-, hexa-, and octaoxyethylene dodecyl ethers. The results showed the more hydrophobic members to act as cosurfactants, stabilizing the lamellar structure at high water contents. The more hydrophilic members of the nonionic series acted in a manner similar to ionic surfactants with a slight tendency to stabilization of the lamellar phase for 1:1 combinations of the surfactants.

Modern formulations for use in the laundry process use a combination of nonionic and anionic surfactants, a necessity in order to obtain optimum removal of soil from different kinds of fabric.

The nonionic/ionic surfactant combinations are also of importance for emulsion stability; the well known combination of a long-chain alcohol plus a long-chain ionic surfactant has been extensively discussed.[1-4] Similar surfactant combinations using medium-chain alcohols are well known for their use in microemulsion systems; the literature in that field is as rich as it is varied.[5-11]

These investigations have been confined to essential but limited parts of the total systems, and we found an investigation of the systematic changes in the general features of surfactant combination systems to be desirable in order better to understand their behavior.

The combination chosen was water and sodium dodecyl sulfate with a series of polyoxyethylene dodecyl ethers. The latter were varied from the most hydrophobic one, the alcohol, to a member with distinctly hydrophilic properties, the octaoxyethylene homologue.

Experimental

Materials. Sodium dodecyl sulfate ($C_{12}SO_4Na$), specially pure grade, BDH Chemicals, Ltd., was recrystallized twice from ethanol. Di-, tetra-, hexa-, and octaoxyethylene dodecyl ether ($C_{12}(EO)_n$) were 98% from Nikko Chemical Co.; 1-decanol ($C_{10}H_{21}OH$) was practical grade from Eastman Kodak Co.

Phase Diagrams. The solubility regions were determined by titration of water to a mixture of the other components. The liquid crystalline and crystalline regions were analyzed by visual observation between polarized films and in a microscope with polarized light. The measurements and determinations were made at 30±0.1 °C.

Light Scattering Measurements. The light scattering measurements were done on a Sofica Photo Gonio Diffusometer, Model 42000, at 30 °C and 546 nm. The reported $I_{90°}$ values were scaled to the value of pure benzene, put a 100. The cells were immersed in a chromosulfuric acid solution for 15 h and rinsed several times with twice distilled water. The benzene and the distilled water were filtered through a Millipore filter, 0.22 μm prior to use. Dust particles were finally removed from the solutions by centrifugation at 25000 g for 3 h immediately before the determinations.

X-Ray Measurements. The interlayer spacings of lamellar phases were determined by low angle diffraction X-ray (Siemens Crystalloflex 4) with an X-ray detector (Tennelec, PSD-100) and a multichannel analyzer (Packard, Model 901). The measurements were done at 40 KV, 30 mA, and room temperature (24 °C).

Results

The results have a bearing on both the extension of the phase regions and the structure of the associations. They will be reported in order.

Phase Regions. The combination with 1-decanol, Fig. 1, has the expected phase regions: two isotropic liquid phases, A and B in the figure. A emanating from the pure water corner is an aqueous micellar solution solubilized 1-decanol. B emanating from the 1-decanol is an alcoholic solution solubilized water. This alcoholic solution of water and surfactant will contain inverse micelles.[12] In addition, 2 liquid crystals are found. One has a structure of close-packed cylinders with the amphiphiles radially packed (C), while the other is the well known lamellar structure (D).[13] Observation under polarized light confirmed

the structures of C and D phase; the pattern of "Oily streaks" and "Angular texture" for the lamellar and the hexagonal liquid crystals, respectively.[14] The structure and extension of these phases is exactly what would be expected, considering earlier material in this area.[12]

The replacement of 1-decanol with dioxyethylene dodecyl ether led to a series of modifications (Fig. 2). The solubilization of the ether in the aqueous micellar solution was increased, and the lamellar liquid crystalline required a higher content of the nonionic surfactant. The upper limit with a 10:1 weight ratio of the nonionic to anionic surfactant gave a lamellar liquid crystal with a pronounced stability with high contents of water. Its phase region actually reached to 98% water. The third liquid crystalline phase showed a cubic structure (E). The nonionic surfactant solution did not show the typical water solubilization maximum found for alcohols.[12]

With the tetraoxyethylene dodecyl ether (Fig. 3), the cloud point is still below 30 °C, and its lamellar liquid crystal is in equilibrium with pure water. The

changes in the region of the water and continuous phases are a direct continuation and further extension of those found at the shift from 1-decanol to the dioxyethylene ether. The solubilization of the ether in the aqueous micellar solution was very much enchanced, reaching an ether/sulfate weight ratio of 10:1. The extension of the lamellar phase toward the aqueous corner disappeared.

The hexa- and octaoxyethylene ethers both have cloud points in excess of 30 °C, and the diagrams contain only minor details of interest (Figs. 4 and 5). For both compounds the liquid crystal with a hexagonal arrangement showed higher maximum water content for mixtures than for the individual surfactant.[3] Combinations with the octaoxyethylene ether formed an isotropic liquid crystalline between the region of the lamellar and the hexagonal structure.

X-Ray Diffraction Patterns. The X-ray data is plotted in the usual manner as interlayer distance *versus* amphiphilic weight fraction in Fig. 6. The data, with few exceptions, were suited for extrapolation to water content equal to zero. The results show a reduction of interlayer distance with increased content of the ionic surfactant. This is true also for the extrapolated values, although the difference in this case was smaller. The extrapolated value is increased with increased polar chain length of the nonionic surfactant.

Light Scattering. The light scattering of samples in the isotropic liquid of the sample, dioxyethylene dodecyl ether, showed small values (Fig. 7). The values are given as fractions of the scale value for a pure liquid, benzene. The values are approximately unity, showing the scattering to be similar to that from a pure liquid.

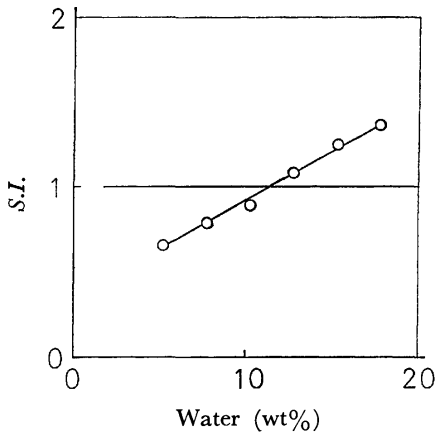

Fig. 7. Light scattering intensity for the dioxyethylene dodecyl ether ($C_{12}(EO)_2$) solution of water and sodium sulfate ($C_{12}SO_4Na$).
$C_{12}(EO)_2/C_{12}SO_4Na$ weight ratio=9:1. The scattering intensity (*S.I.*) is given relative to the value for pure benzene ($S.I._{benzene}=1$).

Discussion

The experiments gave general trends for the phase behavior of the mixed surfactants; the lower homologues performed as hydrophobic cosurfactants enhancing the stability of the liquid crystalline phases. This is most remarkable for the case of the dioxyethylene ether. Its combination gave a liquid crystalline phase with extremely high tolerance toward water. This behavior should indicate this combination to be good as emulsion stabilizers.[15] Subsequent experiments[16] have confirmed this assumption.

The liquid crystalline region C and D in Figs. 4 and 5 do not remarkably change with the ratio of sodium dodecyl sulfate/cosurfactant. This is interpreted that nonionics with long polar chain lengths (hexa- and octaoxyethylene ethers) have hydrophilic properties and behave in a similar manner as the ionic surfactant.

A minimum amount of water was necessary in order to bring the ionic surfactant into solution, which is shown by the right hand solubility limit in Figs. 1—5. The amount of water was identical for all the nonionic surfactants, from the most hydrophilic to the most hydrophobic one. A calculation shows a need of eight water molecules in order to dissolve one molecule of soap. It appears evident that the ether groups do not partake in the polar interactions[17] that lead to the ionic surfactant being dissolved. The ether bridge of the polyoxyethylene compounds obviously do not form sufficiently strong ligands with the metal ion to solubilize the surfactant.

The results also gave information about the structure of the liquid crystalline phase and indirectly about the order of the polar chain of the nonionic surfactant. The extrapolated values (Fig. 6) show a value of 26 Å for the 1-decanol/surfactant combination. A comparison with the corresponding values for the ethers (Fig. 6) shows all values to be larger. The slope of interlayer spacing/(C_w/C_a) for the 1-decanol/surfactant combination is steeper than that for the others. Fur-

thermore, a tendency of lower values with enhanced content of ionic compound is also found. We interpret these results in the form of the following model. The nonionic surfactant allows water to penetrate between the polar layers in accordance with results from NMR spectroscopy.[18,19] The addition of the ionic surfactant causes two changes: the presence of the polar group allows more water to penetrate between the polar chains of the nonionic surfactant and causes an enhanced disorder of its polar part.

This interpretation also accommodates itself to the values for variation of interlayer spacing with water content. The increase of spacing with water content was less for samples which contained also the ionic surfactant, an indication of enhanced disorder and increased water penetration between the molecules.

It is interesting to observe the extremely small values for the light scattering from solutions in the dioxyethylene dodecyl ether solution of water and surfactant. The scattering is similar to the one from a pure liquid. A reasonable interpretation is absence of colloidal aggregates.

Infrared ATR Measurements at Low Temperatures. An Apparatus and the Absorption Intensities of Crystalline Benzene and Carbon Disulfide

Haruka YAMADA* and Masao SAHEKI

Department of Chemistry, Kwansei Gakuin University, Nishinomiya 662

(Received May 17, 1982)

An infrared ATR apparatus for use at low temperatures was constructed for the determination of the optical constants and absorption intensities of crystalline samples. The ATR spectra of benzene and carbon disulfide polycrystals were measured with two different incident angles. The optical constants and then the absorption intensities were accurately obtained for the fundamental bands from these ATR spectra. Experiments for transmission spectra were also carried out with an improved absorption cell at low temperatures, confirming the present ATR results. A comparison of the intensities in different phases was made for the ν_{18}, ν_{19}, ν_{20}, and ν_{11} fundamental bands of benzene and the ν_3 band of carbon disulfide.

Studies of infrared intensities have recently attracted revived interest from both theoretical and experimental points of view.[1-4] Infrared intensities on solids had been studied considerably in the 1960s by measuring the absorption spectra of polycrystalline molecular crystals at low temperatures and by comparing their intensities with those of free molecules. They were discussed in connection with the intermolecular interactions and the field effects.[5-13] However, the observed intensities included considerable errors caused by ambiguity in the determination of the sample thickness, because the thicknesses were determined by measuring the interference fringes observed when the samples were sublimed from the gases onto a cold window.

We first applied the ATR method to a naphthalene single crystal[14] in 1971 and succeeded in obtaining the absolute absorption intensities of the fundamental bands. On the basis of the results thus obtained we discussed the deviation from the oriented gas model. Fortunately, naphthalene was a crystal at room temperature and was so soft that good optical contact between naphthalene and an ATR element might be easily made. By the ATR method we could also obtain the infrared intensities for the charge-transfer complexes in a solid.[15] However, molecular crystals consisting of small molecules, which are convenient for theoretical analysis, are usually liquid or gas at room temperature. If the ATR method can be applied at low temperatures, accurate absorption intensities can be obtained for such crystals. In the present study we have tried to construct an ATR apparatus at low temperatures. With the apparatus, the ATR spectra of polycrystalline benzene and carbon disulfide have been measured.

ATR Experiments

Apparatus. *ATR Cell*: A low-temperature cell, with a hemicylinder (ATR element) of KRS-5 (10 mm radius and 30 mm in height), is shown in Fig. 1. A photograph of the sample part is given in Fig. 1-b. It is made of Pyrex glass (except for the sample part A) and consists of two parts: a cooling part for the ATR element and a sample-spraying part. The outer vessel has two windows, attached with Q wax, whose faces make a right angle. The hemicylinder, H, is supported by a copper holder A and can be cooled down to the temperature of the coolant in E through the connection of Kovar and copper. To make good thermal

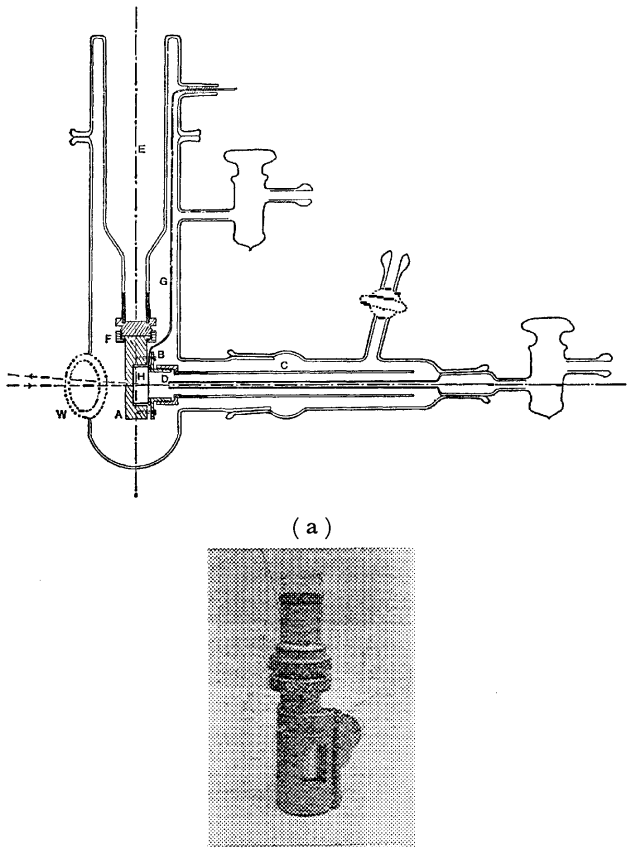

Fig. 1. ATR cell at low temperatures.

contact between A and H, an indium spacer was used. When E was filled with liquid N_2, the center of H (at the reflecting surface) was cooled to *ca.* 100 K. Sample vapor is directly sublimed onto the reflective surface of H (right side) through the nozzle, D, so that good contact between the ATR element and the sample may be attained. The nozzle is covered with a long glass tube (150 mm) to avoid the condensation of the sample on the back side, that is, on the cylindrical surface of H. The connection B is also made of copper and is equipped with screws. The incident light irradiates H (through the hole of A) and reflects at the interface between H and the deposited sample. By connecting the cell to a vacuum line, it can be evacuated to 10^{-4}—10^{-6} Torr (1 Torr = 133.322 Pa).

Optical System: The optical system for the low-temperature ATR apparatus is shown in Fig. 2. A light source

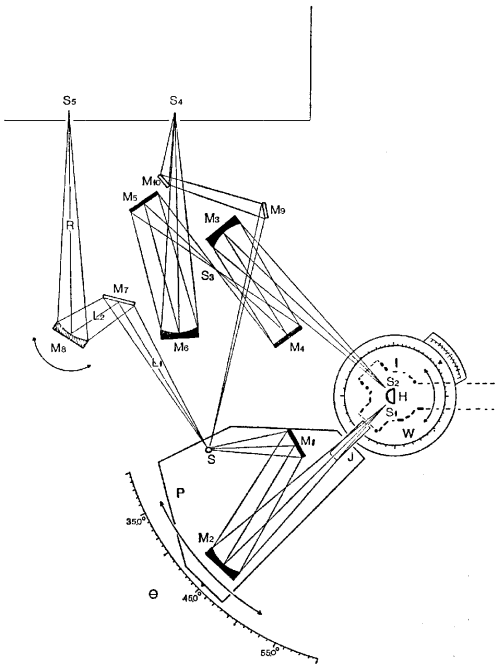

Fig. 2. Optical system.

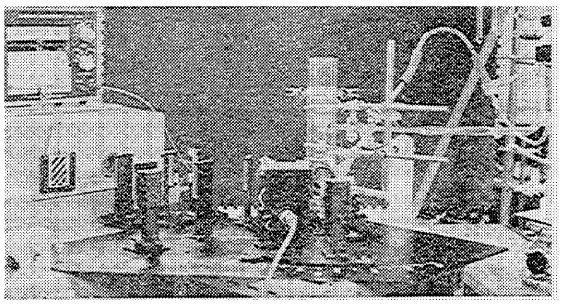

Fig. 3. Uncovered ATR apparatus constructed.

S, a plane mirror M_1, and a concave mirror M_2 ($R=340$ mm) are fixed on a plate P, which can move around the ATR cell as it rotates. The ATR cell described above is fixed by clamps on a circular table, W, so that the rotating axis of W may coincide with the cylindrical axis of H. By rotating the circular table, the ATR cell can be rotated around the vertical axis, that is, the cylindrical axis. Connecting P and W with a bar J, P, and W move simultaneously around the same axis. W has an angle graduation marked in degrees with a vernier, so that the incident angle can be known to an accuracy of one minute. The light beam is first focussed on S_1 in front of the cylindrical surface of H, passes through the hemicylinder H as a parallel beam, and is then refocussed on S_2. Afterwards the light beam is focussed on S_3 and S_4 (the entrance of a monochromator) by concave mirrors, M_3($R=340$ mm) and M_6($R=340$ mm). The mirrors (M_3, M_4, M_5, and M_6) in Fig. 3 are all fixed.

The reference beam from the light source S is focussed on S_5 by M_8 ($R=340$ mm), where $L_1+L_2=R$ (340 mm). A concave mirror M_8 is fixed on its position and can be rotated around the vertical axis; M_7 is approximately placed so as to satisfy: $L_1+L_2=R$ (340 mm).

Two plane mirrors are used for the correction of the zero line (reflectivity zero) so as to introduce extra light (from S) on S_4. M_9 and M_{10} can move and rotate. The angle of incidence can be chosen in the region of 33—59°, making

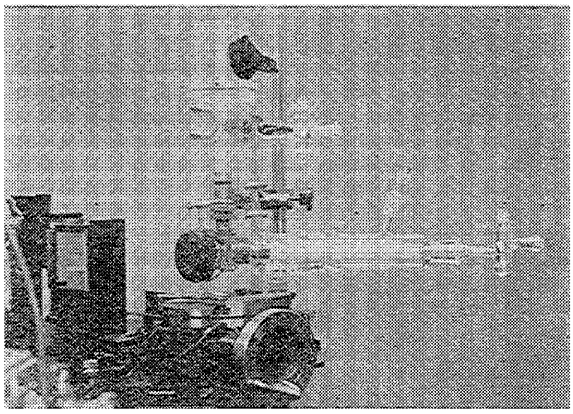

Fig. 4. The ATR cell on the circular table.

a right angle with the cylindrical surface of H.

For the ATR measurements, the optical system can be covered by using plastic sheets and plates; it is blown by dried air to eliminate atmospheric H_2O and CO_2.

Measurements of ATR Spectra. The uncovered apparatus constructed is shown in Fig. 3. It is connected to a JASCO 402-G spectrophotometer by replacing its source and sample parts, while the cell is connected to a vacuum line.

Figure 4 shows the side view of the low-temperature ATR cell on the circular table. The cell can rotate when the handle is operated.

We first set the angle of incidence at 45°, as is shown in Fig. 2; that is, by connecting W with P the cell direction is set so that the mark (incident angle) on P points to 45° on the base. For any other incident angle, we rotate W with P until the mark on P points to the desired angle θ; then we fix P on the base and disconnect P from W. Next, we rotate the cell, only W, in the opposite direction as much as a half of the angle just moved, $|(\theta-45°)|/2$, and then fix the cell at that position.

Sampling. After the apparatus is set as has been described above, the ATR cell is evacuated to 10^{-4}—10^{-6} Torr, and then H is cooled by filling E with a coolant. Sample vapor is sprayed from the nozzle D onto the reflecting surface of H through a needle valve. A uniform film (more than 20 μm in thickness) can be prepared by controlling the speed of sublimation and the vapor pressure. Samples which are solid at room temperature can also be measured with the apparatus when the samples make optical contact with the ATR element, as in the cases of naphthalene[14] and iodoform.[16]

R_s Measurements. The polarized ATR spectra of the samples at about 100 K are measured with an AgCl polarizer placed in front of the thermocouple detector. The reflectivity, R_s(electric vector perpendicular to the incident plane), is measured with two different incident angles, θ_1 and θ_2. The monochromator and the ATR attachment were blown out by dried air passed through molecular sieves.

Background and Zero Line. The background is determined by recording R_s for each incident angle without a sample at that temperature. The zero line of R_s (reflectivity zero) can be recorded when a shutter is placed in front of the ATR cell with the sample. The true zero curve lowers in the region where the sample absorbs.[21] To record such a fluctuation, the level of the sample beam has to be kept a little higher than that of the reference by introducing additive energy using M_9 and M_{10}.

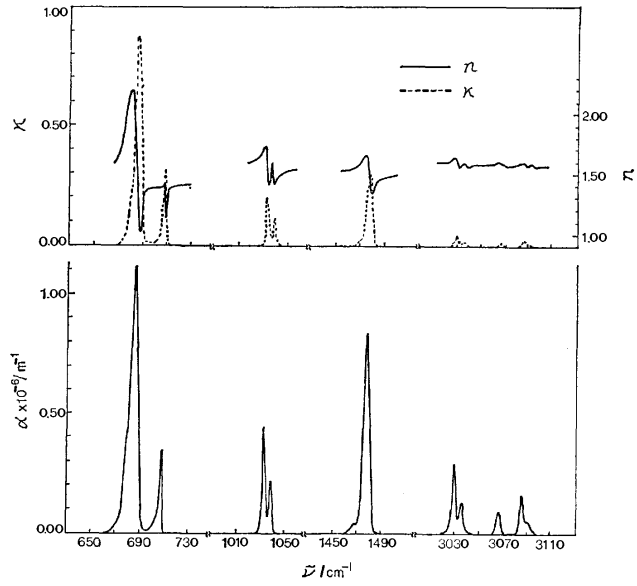

Fig. 7. Optical constants (n, k) and absorption coefficient (α) for polycrystalline benzene at 88 K.

Determination of Optical Constants and Absorption Intensities

The optical constants, refractive index n, and attenuation index k can be obtained from the observed ATR spectra. n and k are calculated from the reflectivities, (R_s)'s measured at two different incident angles, θ_1 and θ_2, by the use of polarized light whose electric vectors vibrate perpendicularly to the incident plane. The method used is essentially the same as that previously reported,[14] namely, the method by Fahrenfort and Visser,[17] with some modifications suggested by Hansen.[18]

The computations were performed on a FACOM 270-38 computer. The refractive indices of KRS-5 at 100 K were obtained by correcting the values[19] for the temperature coefficient. The calculated n, k, and Lambert's $\alpha=4\pi nk/\lambda$ values were plotted *vs.* the wave number with a X-Y plotter.

The absorption intensity, A, is given by:

$$B = \frac{1}{\rho}\int_{\text{band}} \alpha d\tilde{\nu},$$

$$A = \lim_{\Delta s_{1/2}\to 0} B,$$

where ρ is the density of the sample crystal and $\Delta s_{1/2}$, the spectral slit width. The integration was taken over a region three times as wide as the half-width of the band.

Benzene Crystal

ATR Measurements. Crystalline benzene films were prepared at 88 K by subliming the vapor onto the reflecting surface of the ATR element by a technique similar to that used for transmission measurements.[5,7] To obtain uniform films, the vapor was deposited as slowly as possible through a needle valve (Edwards High Vacuum), and the junction part (connection of the ATR cell with the spraying tube) was warmed from the outside to prevent vapor deposition in the vicinity of the top of the nozzle. The ATR spectra were measured for the four fundamental bands of benzene, ν_{18}, ν_{19}, ν_{20}, and ν_{11}.

Figure 5 shows the apparent R_s curves for ν_{20} obtained from the ATR measurements with the background and zero lines. For the four fundamentals bands, R_s curves were obtained as in Fig. 6. The n, k, and α curves calculated are shown in Fig. 7, which were reproducible for several samples. The average refractive index, $\bar{n}$, in the infrared ragion is obtained as 1.57, which agrees well with the value observed from the polycrystalline benzene at 77 K.[5] The α curves obtained coincide well with the transmission curves observed for the stable polycrystalline benzene.[5]

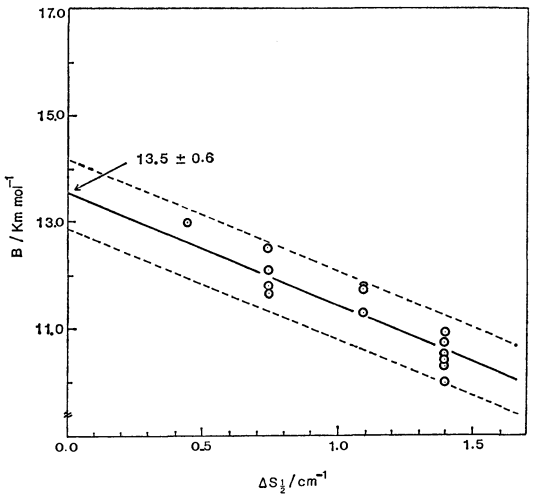

Fig. 8. Plots of B *vs.* spectral slit width for the ν_{20} band of polycrystalline benzene.

TABLE 1. ABSORPTION INTENSITIES OF BENZENE FUNDAMENTALS IN POLYCRYSTALS

$\nu_{11}(a_{2u})$	685	81.5±6.0	92.0(80.0)[b]

a) J. L. Hollenberg and D. A. Dows, *J. Chem. Phys.*, **37**, 1300 (1962). b) D. E. Glover and J. L. Hollenberg, *J. Phys. Chem.*, **73**, 889 (1969).

(R_s)'s could be measured with an error of less than 0.5% for ν_{18}, ν_{19}, ν_{20}, and ν_{11}, resulting in accuracies of ±2% for n, ±(4—13)% for k, and ±(4—12)% for α at the peaks.

The integrated absorption intensities, B, for the four fundamental bands can be obtained from the α curves, using ρ(density) = 1.42×10^4 mol m^{-3}. Since the spectral slit widths, $\Delta S_{1/2}$, used were not so small as the half-widths, $\Delta\tilde{\nu}_{1/2}$, of the respective bands, corrections for a finite spectral slit-width were needed. For ν_{18} and ν_{19}, the condition (1/3) $\Delta\tilde{\nu}_{1/2} > \Delta S_{1/2}$ is satisfied, so $\Delta\tilde{\nu}_{1/2}$ and B are almost constant over the spectral slit-widths used, 1.3—1.8 cm^{-1}; therefore $B \approx A$. On the other hand, the above condition did not hold for ν_{20} and ν_{11}. The absolute absorption intensities for ν_{20} and ν_{11} were then obtained by extrapolating B's to $\Delta S_{1/2} \to 0$. The plots of B *vs.* $\Delta S_{1/2}$ are shown for ν_{20} in Fig. 8.

In Table 1 the absolute absorption intensities, A, obtained from the ATR measurements are given for the fundamental bands, together with the values reported from the transmission measurements. The present ATR values are all smaller than those reported from the transmission measurements. The ratios of the values between ATR and transmission differ from band to band in the 77—95% region. The smaller the intensity value, the smaller the ratio. The values obtained from the ATR measurements are independent of the sample thickness and are certainly more accurate than those reported from the transmission measurements.

Intensity Changes in Different Phases. Now that we have obtained reliable intensities in solid benzene, we can proceed to compare the values in different phases. Going from gas to a solid, the intensity of the ν_{18} band decreases to about 1/3 of the gaseous value, while that of the ν_{19} band increases by three times. The ν_{20} band also increases in intensity a little going from gas to a solid. The intensity changes observed, thus, vary with the bands in both direction and amount, and do not depend on the symmetry species to which the vibrational mode belongs. For the ν_{11} band, the value in the liquid phase is still uncertain, so at present no appropriate comparison can be made for the ν_{11} band.

Transmission Measurements. We have succeeded in obtaining the absorption intensities for the benzene polycrystal from the ATR measurements. The present values are smaller by 5—23% than the intensities reported from the transmission measurements. The inaccuracy in obtaining A from the transmission measurements is mainly caused by the determination of the thickness of the film used. However, it seemes probable to improve the transmission experiments, for during the ATR measurements we noticed that the samples were sublimed easily on the cylindrical (back) surface of the ATR element unless quite a long shielding tube was used. Judging from the structure of the cold cell used previously for the transmission measurements, it is supposed that the samples were sublimed onto both sides of the substrate. Therefore, we tried to modify the old cell in the way shown in Fig. 9.

TABLE 2. COMPARISON OF ABSORPTION INTENSITIES OF FUNDAMENTAL BANDS OF BENZENE IN THREE PHASES (km mol^{-1})

Irons and H. W. Thompson, *Proc. R. Soc. London, Ser. A*, **298**, 160 (1967). d) I. C. Hisatsune and E. S. Jayadevappa, *J. Chem. Phys.*, **32**, 565 (1960).

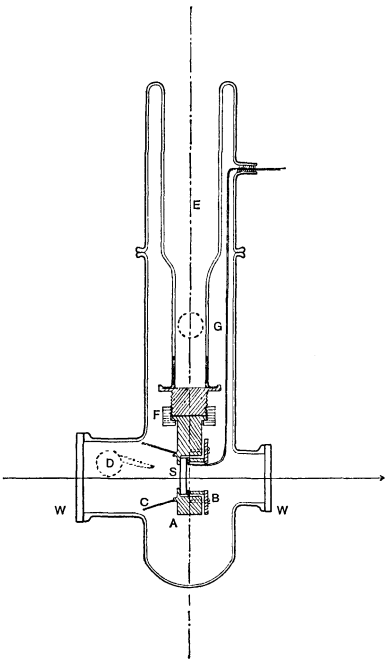

Fig. 9. Improved transmission cell at low temperatures.

A shielding cover, C, made of a thin copper sheet was attached to the copper block, A, with solder around the substrate (KRS-5, 20×10 mm). The top of the nozzle, D, had to be inserted into C, and the separation of D from the substrate surface should be 20 mm, so that the sample vapor can be sublimed uniformly onto the front side (and not onto the back surface) of the substrate.

The transmission spectra of polycrystalline thin films of benzene were measured with a modified cold cell attached to the JASCO DS-402G infrared spectrophotometer. The sampling and spectral measurements were the same as those described earlier.[13,14] The thickness of the sample was estimated by counting the interference fringes which were observed by the Hollenberg-Dows method,[5] when the sample vapor was subliming onto the substrate.

The integrated absorption intensity was calculated by means of:

$$B = \frac{1}{\rho l}\int_{\text{band}} \ln(I_0/I)\mathrm{d}\tilde{\nu},$$

where ρ is the density and l, the thickness of the sample crystal. The intensities, A, corrected for a finite spectral slit width are 16.3 ± 1.0 for ν_{18}, 31.7 for ν_{19}, 14.2 ± 0.6 for ν_{20}, and 74.5 ± 3.5 for ν_{11} in km mol^{-1} units; these are rather close to the values obtained from the ATR measurements and seem to justify the present ATR results.

Carbon Disulfide Crystal

Polycrystalline carbon disulfide was also measured by the ATR method. Because of the high vapor pressure and the low melting point of CS_2, especially careful sublimation was carried out in order to obtain uniform and stable polycrystals. If the holder B was colder than the reflecting surface of H, the CS_2 vapor

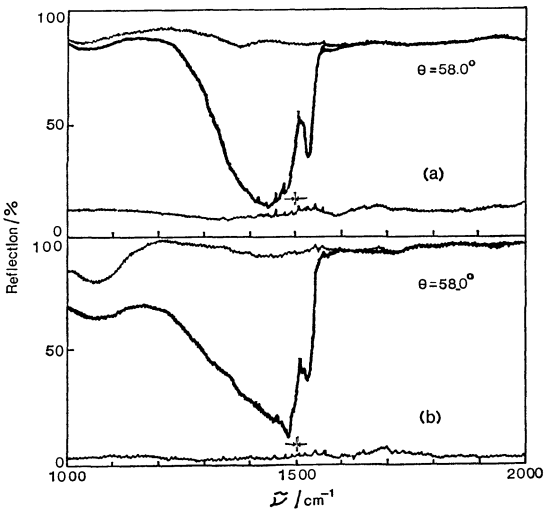

Fig. 10. Apparent R_s curves for sprayed carbon disulfide at 109 K.
(a): Slowly deposited sample, (b): rapidly deposited sample.

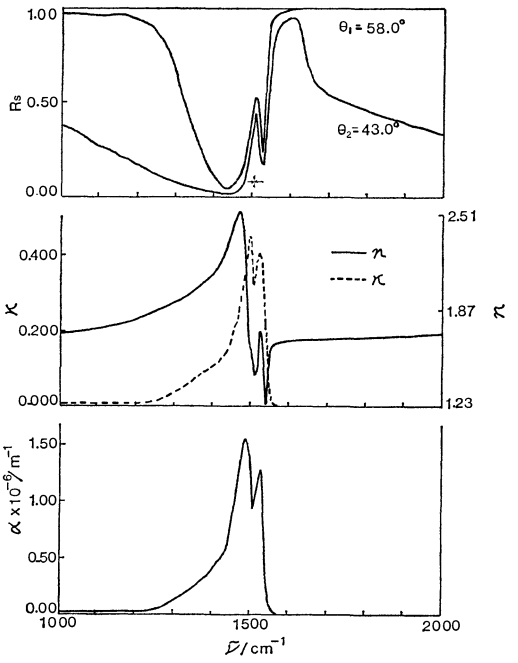

Fig. 11. R_s, n, k, and α curves for polycrystalline carbon disulfide at 109 K.

was first condensed onto B, not on H. We inserted, therefore, a Teflon spacer between B and H, so that the temperature of H was kept higher by 20—30 K than that of H.

The ATR spectra were measured for a fundamental band, ν_3. When the CS_2 vapor was sprayed onto H, two kinds of spectra were observed, depending on the spraying speed. The spectra observed with $\theta=58°$ and at 109 K are shown in Fig. 10; (a) was obtained with the speed of 4.6×10^{-4} mol h^{-1} and (b) with that of 2.8×10^{-2} mol h^{-1}. The (a) spectrum is sharper than the (b) spectrum. Comparing these spectra with those observed for the transmission measurements,[7] the (a) spectrum is, seen to be quite similar to the trans-

TABLE 3. ABSORPTION INTENSITIES OF THE ν_3 BAND OF CS_2 IN THREE PHASES (km mol^{-1})

$\tilde{\nu}$/cm^{-1}	Gas[a)]	Liquid[a)]	Solid	
			ATR	Transmission[a)]
$\approx$1500	567±10	752±20	725±110	800±140

a) H. Yamada and W. B. Person, *J. Chem. Phys.*, **40**, 309 (1964).

mission spectrum observed for the stable thin polycrystalline CS_2, except for a small peak at 1457 cm^{-1} observed for the transmission. The small peak at 1457 cm^{-1}, assigned to the isotopic molecule, $^{13}CS_2$, was also observed during the sample sublimation for the thin film, but was obscured for the present thick sample. The peaks at 1530 and 1485 cm^{-1} are components of ν_3 split by the correlation-field effect.[7)] The (b) or a similar spectrum was observed for a worse (not uniform) or unstable crystal.

The optical constants and absorption intensity were determined for the samples which showed the (a) spectrum. The R_s, n, k, and α curves are shown in Fig. 11. The mean refractive index, $\bar{n}$, is obtained as 1.80, which is close to the value, 1.82±0.05, obtained for the polycrystalline CS_2 at *ca.* 80 K.

The absorption intensity, A, was calculated, to be 725 km mol^{-1}, using $\rho = 2.13 \times 10^4$ mol m^{-3} (109 K), estimated from the X-ray structure;[20)] this value is a little smaller than the value obtained from the transmission measurements.[7)] The ν_3 band is so broad that the correction for the finite spectral slit width is negligible. The A values are tabulated with the values reported from the transmission measurements. The difference in values between ATR and transmission is rather small for the ν_3 band of CS_2. This might be explained as follows: Because of the strength of ν_3, extremely thin films were prepared for the transmission measurements. The sublimation time, therefore, was so short that the back-side deposition of CS_2 might not be so serious as for the benzene crystal. Consequently, it seems that the error included in A was not so serious for the transmission band of ν_3. For the CS_2 crystal, the previous results[7)] are confirmed by the present ATR measurements.

A Rate Equation System Having a Mnemonic Function

Kazutoshi IWAMOTO, Shun-ichi MITOMO, and Manabu SENŌ*
Institute of Industrial Science, The University of Tokyo,
7-22-1 Roppongi, Minato-ku, Tokyo 106
(Received May 31, 1982)

A chemical system having a mnemonic function is constructed and its behavior is analyzed. The system consists of a subsystem having seven steady states and, under suitable conditions, it stays in a stable steady state or in an oscillating state depending on the initial state. Moreover, the system can show an additional oscillating state around the oscillating state and transitions between two different oscillating states occur by a little change in a certain parameter value(input), which is the characteristic point in this system. Therefore, a response behavior of the system to an input differs drastically depending on the states, *i.e.*, oscillating or stationary. This property could be related to appearance of a mnemonic function. Moreover, it is demonstrated that the system could be linked with an excitable subsystem to show more clearly the mnemonic function proposed here.

It has been demonstrated that a chemical system far from an equilibrium state occasionally shows some peculiar behaviors like chemical oscillations,[1,2] periodic pattern formation,[3-5] excitation, [6-8] wave propagation,[9-11] etc. One of the most important points in this field is that these peculiar behaviors are very often observed in a living system,[2] and many articles discussed the behaviors with relation to the activities of the living system.[2,12,13] The chemical oscillation is also criticized in relation to the circadian rhythm,[14] beating of heart,[15] excitation of nerve membrane,[16] and the problem of pattern formation was first discussed in relation to morphogenesis in the living system by Turing.[17]

As one of the various activities of the living system, the functions of the living brain have been treated in various aspects. McCulloch and Pitts[18] analyzed the unidirectional travel of a signal from the output of a neuron to the input of the neurons connected to it. Caianiello developed their model and proposed a mnemonic equation in addition to the neuronic equation which includes absolutely and relatively refractory periods of each neuron.[19] He proposed an idea to treat mathematically the memory function of the brain; that is, the memory gained through experiences is stored in the coupling coefficients a_{ij} by the mechanism that the coupling coefficient a_{ij} increases as increasing number of pulses from neuron j to neuron i, and he led a mnemonic equation describing his idea. He developed his idea for thought-processes and thinking machines.

According to the Caianiello equation, the propagation of signal along the nerve of a living brain was studied by a computer simulation method, and the coexistence of a stably oscillating state and a stationary state was confirmed. Some investigators consider that the oscillating state is of the brain recalling a certain matter.[20] According to this explanation, any system that shows coexistence of a stably oscillating and a stationary states may be a candidate for the system having a mnemonic function. There are some model systems relating to this behavior.[21,22]

In this paper, we intend to analyze the mnemonic function in a chemical system with a different standpoint of views. We refer to the system with a mnemonic function as the system-M and consider that it should respond in quite different ways for an input dependently whether the system-M is storing a memory of not. We consider that there should be another external system-E, which utilize the memory stored in the system-M to attain its own specific purpose. The external system-E changes a given parameter value of the system-M to observe its response in order to draw an information from the system-M.

The essential point of the proposed equations is that there coexist one stable steady state and one stable oscillating state, around which another oscillating state appears by a little change in parameter values, and the system is stationary or oscillating dependently on its career it has experienced. Under this situation, we can say that the system remembers the past events. The phase diagram satisfying the steady state conditions is essential in this treatment and there is not a special meaning in the corresponding model reaction processes. Therefore, our main object in this article is not to construct a model system but to show a possibility of mnemonic function in a chemical reaction system.

In the following sections, the differential equations exhibiting a mnemonic function are proposed and the system behaviors are analyzed, and a little more functional system that an excitable system is linked with the original system is developed. In this system, the response caused by an input is more drastic and our idea about the mnemonic function is clearly shown.

Rate Equations Related to a Mnemonic Function

Let us consider the following rate equations without showing corresponding chemical reaction processes,

$$\frac{dE}{dt} = \alpha(b_1 - b_2EX - b_3X), \tag{1}$$

$$\frac{dX}{dt} = \beta(a_1X^9 - a_2X^8 + a_3X^7 - a_4X^6 - a_5X^5 + a_6X^4 - a_7X^3 + a_8X^2 - a_9X + a_{10} + E), \tag{2}$$

where E and X represent the concentrations of two intermediates E and X. The ninth order equation seems to be essential to display an expected mnemonic function, but it is not necessarily the simplest and the most realizable equation for the mnemonic function. It is considered that the system giving such rate equations is not difficult to be realized as being dis-

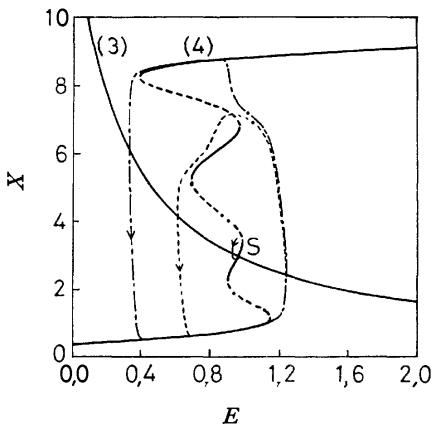

Fig. 1. Relationships between X and E determined by Eqs. 3 and 4.
The numbers in the figure correspond to the equation numbers. The crossing point S of the two curves (3) and (4) is a stable steady state. A thin solid line represents the route into the stable steady state, and a dotted line and a dot and rod line represent the routes of oscillating states of the system-M. Parameter values used for calculations are: $a_1=8.609\times 10^{-6}$, $a_2=3.267\times 10^{-4}$, $a_3=4.609\times 10^{-3}$, $a_4=2.635\times 10^{-2}$, $a_5=7.552\times 10^{-3}$, $a_6=0.8573$, $a_7=4.3985$, $a_8=9.898$, $a_9=10.16$, $a_{10}=2.696$, $b_1=3.65$, $b_2=1.0$, $b_3=0.27$, $\alpha=0.25$, and $\beta=70.0$ for the dotted line and 75.0 for the dot and rod line.

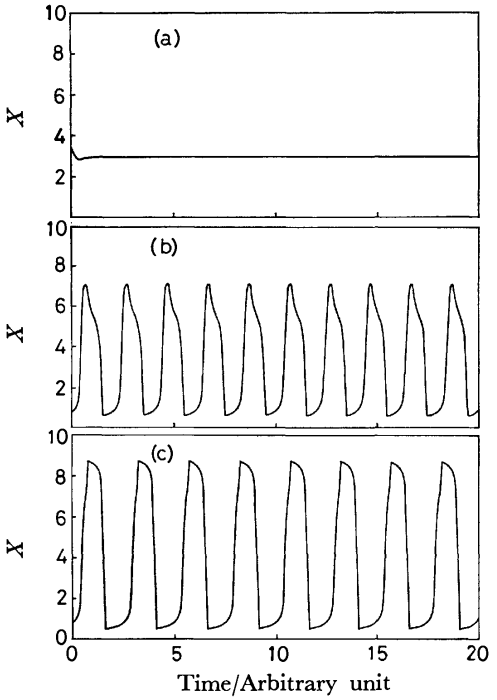

Fig. 2. System behaviors under various conditions.
(a), (b), and (c) show the responses corresponding to the behaviors as shown by solid, dotted, and dot and rod lines, respectively, in Fig. 1.

cussed later. Although the behaviors of the chemical system-M obeying Eqs. 1 and 2 can be determined by direct calculations of these equations with a digital computer, we first discuss the stability of the steady states in order to predict its behaviors. From the steady state conditions, $dE/dt=0$ and $dX/dt=0$, we have

$$b_1 - b_2EX - b_3X = 0, \tag{3}$$

$$a_1X^9 - a_2X^8 + a_3X^7 - a_4X^6 - a_5X^5 + a_6X^4 - a_7X^3 + a_8X^2 - a_9X + a_{10} + E = 0. \tag{4}$$

Equations 3 and 4 determine two relations between X and E at the steady state, which are displayed on the X-E phase plane in Fig. 1. The parameter values used for the calculations are as follows;

$a_1=8.609\times 10^{-6}$, $a_2=3.267\times 10^{-4}$, $a_3=4.609\times 10^{-3}$,
$a_4=2.635\times 10^{-2}$, $a_5=7.552\times 10^{-3}$, $a_6=0.8573$,
$a_7=4.3985$, $a_8=9.898$, $a_9=10.16$, $a_{10}=2.696$,
$b_1=3.65$, $b_2=1.0$, and $b_3=0.27$.

These parameter values are arbitrarily chosen to produce an expected behavior. Of course, this selection is not unique for this purpose. The curve defined by Eq. 4 has six marginal points where dE/dX is equal to zero. The states along the dotted lines are unstable; that is, when the rate equation 2 is solved for an initial state which is deviated a little from the dotted line at a fixed value of E, the value of X develops to another stable state apart from the dotted line.

The steady state is determined by the crossing point of the two curves defined by Eqs. 3 and 4. It is proved from the result by the standard stability analysis[1] that the steady state is stable when the two curves intersect on the solid part of the line (4) in Fig. 1. The present system has a stable steady state S at $E=0.9561$ and $X=2.9770$. In this case, the system, which lies initially in the vicinity of the steady state, goes into and remains stable at this steady state. This behavior is shown with a thin solid line falling into the crossing point S from the initial state, $E=0.95$ and $X=3.5$, in Fig. 1. The values of $\alpha=0.25$ and $\beta=70.0$ are used for calculation. The arrow on the line represents the direction of the temporal change of the system. On the other hand, when the initial state of the system is far from the stable steady state S, say $E=1.0$ and $X=0.8$, the oscillating state shown by a closed cycle with a thin dotted line is realized as a final state for the parameter values, $\alpha=0.25$ and $\beta=70.0$. For the system having the parameter values, $\alpha=0.25$ and $\beta=75.0$, the oscillating state represented by a dot and rod line is realized as a final stable state.

These behaviors discussed above are shown as temporal changes of X in Fig. 2. (a) and (b) are of the steady state and the oscillating state, respectively, for $\alpha=0.25$ and $\beta=70.0$, and (c) is of the oscillating state solved for $\alpha=0.25$ and $\beta=75.0$.

Here, let us investigate how the system behaviors are affected by a change in β value. Initially the value of β is 70.0. Then, the system is stationary or oscillating. When the system lies in the oscillating state shown by a dotted line in Fig. 1, the oscillatory trajectory transfers to the cycle represented by a dot and rod line for an increasing value of β to 75.0. When β is brought back to the original value, the oscillating state regresses reversely to the original state of smaller amplitude. On the contrary, when the system is in

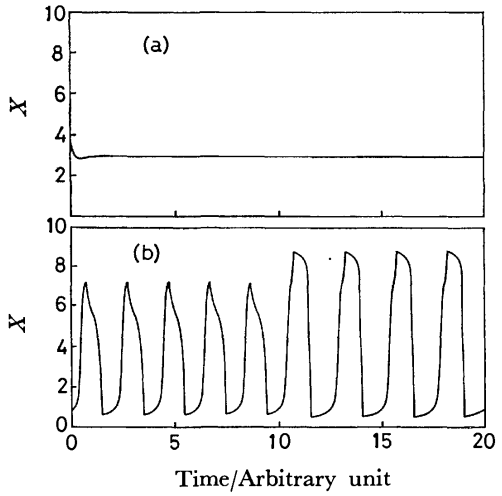

Fig. 3. Response behaviors of the system-M to change in β value.
In both (a) and (b), the value of β is changed from 70.0 to 75.0 at time 10. (a) shows a response of the system-M which is initially in the stable steady state and there is no detectable change. (b) is a response of the system which is initially in the stable oscillatory state and the behavior is suddenly changed in amplitude at time 10. All the parameter values are the same with those of Fig. 1.

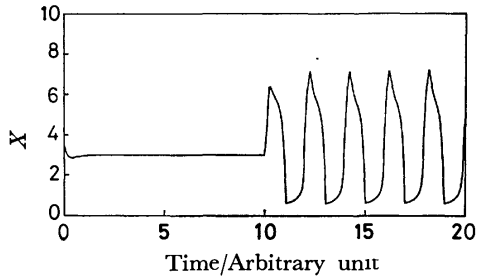

Fig. 4. Response of the system-M initially in the stable steady state to change in E value.
At time 10, the E value is changed into 1.1. The steady state is located at $X=2.9770$ and $E=0.9561$ and other parameter values are the same with those of Fig. 1.

the stable steady state, any changes can not be observed by this change in β value. These responses are demonstrated in Fig. 3. Initially, the system is in the steady state (case a) or in the oscillating state (case b). In both cases (a) and (b), the value of β is changed from 70.0 to 75.0 at time 10. Only the case (b) shows a noticeable response to the change in β value. This is the point on which we have an interest.

Now, let us examine the behavior of the system which is initially in the steady state, being subject to a certain deviation of E value as a result of external stimulus. As an example, when E increases beyond over a threshold value of 1.035, the system falls into the stably oscillating state as shown in Fig. 4. In this example, the E value is increased to 1.1 at time 10, and after that time, the system is in the oscillating state, storing with the memory of this stimulus.

Now, let us introduce another external system-E,

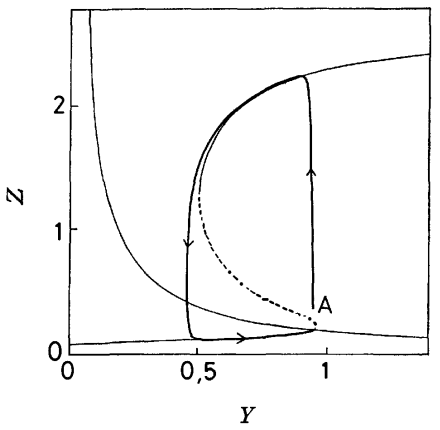

Fig. 5. System behaviors falling into the stable steady state from an initial state A.
Parameter values used for calculations are: $c_1=0.9$, $c_2=4.76$, $d_1=1.332\times10^3$, $d_2=4.864\times10^2$, $d_3=5.02\times10^2$, and $d_4=53.5$.

which may utilize the stored memory in the system-M in order to attain its own specific purpose. In order to draw the memory from the system-M, it should respond to a certain input depending on whether the system-M is storing with a memory or not, because the external system-E can not draw the memory without examining its response to an input. In this meaning, the system-M proposed here can be said that it has a mnemonic function as revealed by the system behaviors shown in Figs. 3 and 4.

System Linked with an Excitable System (System-M')

In the preceding section, we have shown a series of differential equations related to the mnemonic function. Here, we develop a model by combining an excitable subsystem with the system-M in order to demonstrate more drastically the mnemonic function. The newly introduced system is referred hereafter as system-M'.

Let us introduce the following equations[7]

$$\frac{dY}{dt} = c_1 - c_2YZ, \tag{5}$$

$$\frac{dZ}{dt} = d_1YZ^2 - d_2YZ^3 - d_3Z + d_4. \tag{6}$$

For the parameters we choose the following values;
$c_1=0.9$, $c_2=4.76$, $d_1=1.332\times10^3$, $d_2=4.864\times10^2$, $d_3=5.02\times10^2$, and $d_4=53.5$.

As is clear from Fig. 5, the system shows an excitation behavior when the Z value is increased beyond over the critical value on the dotted line.[7] Now, let us construct a system which a large value of X causes an increase in Z. With this device, we could construct a mechanism which generates one pulse by each of the large amplitude oscillation (Fig. 2c) but no pulse by the small amplitude oscillation (Fig. 2b). To this end, Eq. 6 is modified as follows;

$$\frac{dZ}{dt} = d_1YZ^2 - d_2YZ^3 - d_3Z + d_4 + d_5X, \tag{7}$$

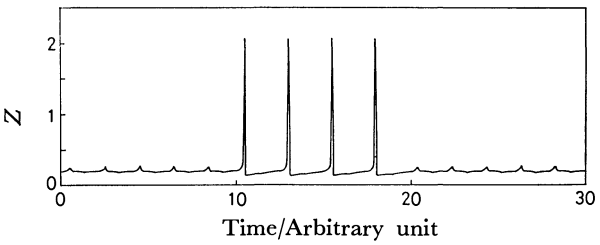

Fig. 6. Effect of change in β value on the behavior of the system-M′.
At time 10, the β value is changed from 70.0 to 75.0, and at time 20, the value is regressed to 70.0. The value of $d_5=0.39$ is used for calculations.

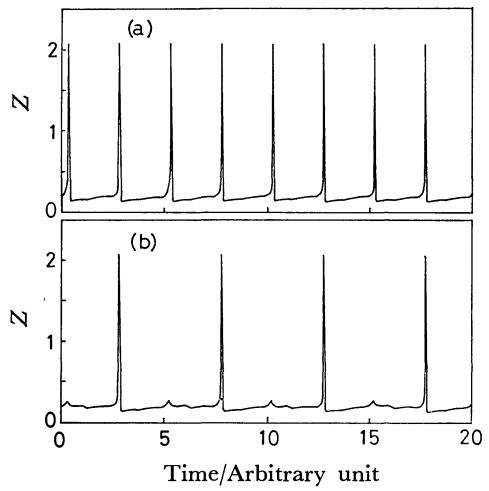

Fig. 7. Behaviors of the system-M′ for the two values of d_5.
(a) $d_5=0.39$ and (b) $d_5=0.38$.

where the last term represents a linkage between the two systems and insures an increase in the Z value owing to an increasing X value.

The behavior of the system-M′ thus constructed is determined by solving Eqs. 1, 2, 5, and 7 with a digital computer. Figure 6 is of an example of the calculated results and shows the response of the system-M′ due to an increase in the parameter β from 70.0 to 75.0 at time 10 and an decrease to its original value at time 20. The input given by the change in β gives large amplitude pulse-like oscillations when the system-M′ stores the memory of the past deviations. Reversely, when the system-M′ does not have any memories, it does not generate any pulses by an input. In this case, the coupling parameter d_5 is assumed to be 0.39

When the value of d_5 is shifted to 0.38, the system-M′ shows a peculiar behavior. Figure 7 shows the behaviors of the system having the d_5 values of 0.39(a) and 0.38(b). In the case of $d_5=0.39$, the excitable subsystem generates pulse-like oscillations as a response to every oscillation of the system-M. On the other hand, in the case of $d_5=0.38$, the excitable subsystem does not respond to every oscillation but responds to every second oscillation. This is because the excitable subsystem has a refractory period after an excitation. In such a situation, a skip of excitation occurs; when a succeeding oscillation of the system-M comes during the refractory period, the excitable subsystem can not respond to this stimulus.

Reaction Processes

In this article, we proposed an artificial rate equation system to show a mnemonic function in a chemical reaction system far from an equilibrium state. The rate equation (2) contains unnatural terms of higher orders than second order. In this section, we show a series of reaction processes to show appearance of a higher order polynomial by a proper selection of bimolecular reaction processes.

For example, let us presume the following consecutive reactions

$$X + X \rightleftharpoons X_2, \quad \text{(R1)}$$

$$X_2 + X \rightleftharpoons X_3, \quad \text{(R2)}$$

$$\cdots\cdots\cdots\cdots$$

$$X_{i-1} + X \rightleftharpoons X_i, \quad \text{(R3)}$$

$$A + X_i \xrightarrow{k} P, \quad \text{(R4)}$$

where we presume that the rate constants of (R1)—(R3) are much larger than k of (R4) and the processes (R1)—(R3) attain nearly equilibria. Then, we get

$$X_i = K \cdot X^i, \quad (8)$$

where K is an overall equilibrium constant which is a product of equilibrium constants of the respective steps (R1)—(R3). Then, the decreasing rate of X in the reaction processes (R1)—(R4) is given by

$$\frac{dX}{dt} = -ikAX_i = -ikKAX^i, \quad (9)$$

this is the i-th order polynomial equation. With a similar procedure, we can deduce the rate equation (2) from a series of bimolecular elementary processes. But the scheme thus constructed is no more than one of the possible schemes and has no essential meaning in this work.

CIDEP Study of Durosemiquinone Radical in Various Solvents

Akihiko KANEMOTO, Sigeya NIIZUMA,† Siro KONISHI,†† and Hiroshi KOKUBUN*
Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980
(Received June 4, 1982)

F-pair polarization and triplet mechanism (TM) polarization of durosemiquinone radical produced by light irradiation of duroquinone–phenol systems were discriminated at 260 K in a simple way based on the analysis of the enhancement factors in the steady-state method with intermittent light irradiation. Both polarizations are not so sensitive to viscosity or polarity of solvents. TM enhancement factor is nearly constant (−0.8) in wide range of viscosity (2.5—25 cP, 1 cP = 0.001 Pa s). F-pair polarization is suppressed in some extent by halogenated solvents while TM polarization is not affected by such solvents.

Semiquinone radicals produced by light irradiation of quinones in the presence of reducing agents show Chemically Induced Dynamic Electron Polarization (CIDEP) arising from both the triplet mechanism (TM) and the radical pair mechanism (RPM).[1,2] The elementary descriptions of these mechanisms are as follows: The TM polarization arises from the anisotropic intersystem crossing from the lowest excited singlet state (S_1) to each spin sublevel of the triplet state (T_n) in a photoexcited molecule, and the RPM polarization comes from the magnetic interaction in radical pairs, which are formed from initial reactions of excited molecules or from random encounters among the radicals in the later stage. Then some fundamental questions arise. Is the magnitude of TM polarization varied by interaction with the external heavy atom because of the change in the anisotropy of the $S_1 \rightarrow T_n$ intersystem crossing as is observed in phosphorescence in solid phase at very low temperatures[3]? And, is the magnitude of RPM polarization influenced by the solvent viscosity, which the interacting period for two radicals is likely to depend upon?

In order to answer such questions, we chose duroquinone–phenol (DQ–PhOH) systems, because durosemiquinone radical produced by light irradiation shows polarizations caused by both mechanisms. Some halogenated solvents were used to see the external heavy atom effect and also used a variety of mixed solvents to change viscosity and polarity.

Experimental

All chemicals were GR grade and used without further purification except 1-bromo-2-propanol, which was distilled under reduced pressure to remove the coloured component. But it remained containing 2-bromo-1-propanol (20%). No effect was observed for the experimental results by the addition of a small amount of water to *i*-PrOH dried over molecular sieves.

In ESR observations, DQ and PhOH concentrations were fixed to 0.1 mol dm^{-3} and 2.2 mol dm^{-3}, respectively, and the temperature was kept at 260 K.

The CIDEP observation system is illustrated in Fig. 1. A JEOL PE-1X type ESR spectrometer using 100 KHz field modulation was improved to have sufficient short responce time (150 μs) to observe the rise and decay of neutral durosemiquinone radical (DQH·). The sample solution was

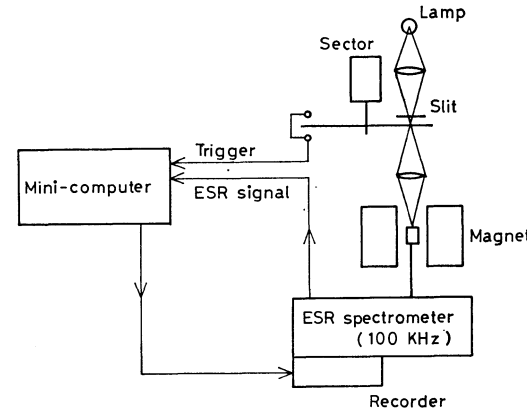

Fig. 1. Block diagram of CIDEP observation.

irradiated intermittently by the sector whose light-ON and light-OFF periods were 13.3 and 26.7 ms, respectively. The light source was a 1 kW Ushio USH-1005D super-high-pressure mercury lamp. The temperature rise of about 1 K during irradiation was observed.

ESR signal was sampled at every 60 μs over 36 ms at a fixed magnetic field corresponding to one of the first derivative peak positions of DQH· spectrum. The time profile of the signal obtained in this way were accumulated 6000—20000 times with a JEOL EC-6 minicomputer (Fig. 2). The time required for accumulation was 5—16 min. Irradiation of this rather long time gave no change in the UV absorption spectra of the samples. The absorption spectra were recorded on a Hitachi EPS-3T spectrophotometer.

Analysis of the Time Profile

The steady-state enhancement factor V_{ss} is defined as:

$$V_{ss} = \frac{I_{ss} - I_{ss.0}}{I_{ss.0}}, \quad (1)$$

where I_{ss} is the intensity of the ESR signal in the presence of CIDEP and $I_{ss.0}$ that in the absence of CIDEP.

It has been known that DQH· produced by light irradiation of DQ–PhOH systems show TM and F-pair polarization.[1,2] The latter is one type of RPM polarization caused by random encounters among DQH· radicals. It is possible that initial (or geminate) pair polarization occurs in the radical pair $\overline{\text{DQH·}\ \text{PhO·}}$ formed by the initial reaction

$$^3\text{DQ}^* + \text{PhOH} \longrightarrow \overline{\text{DQH·, PhO·}}, \quad (\text{I})$$

where ^{3}DQ* is the excited triplet state of DQ and

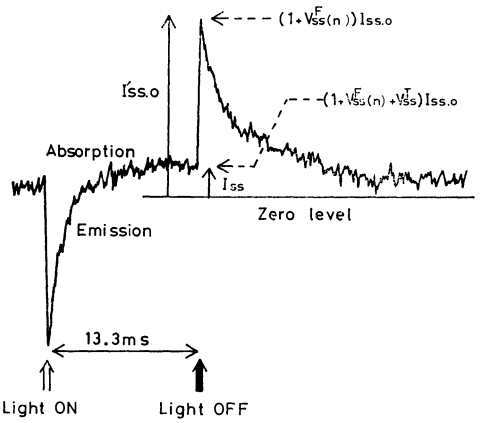

Fig. 2. Time profile of ESR signal intensity.

PhO· phenoxyl radical. As far as photochemically produced geminate radical pairs are concerned, there are few reports about initial pair polarization.[4,5] It is assumed that initial polarization observed in our experiment is due to TM only. We denote the enhancement factor for initial polarization as V_{ss}^{T}, which has no hyperfine dependence. The magnitude of F-pair polarization depends upon the nuclear spin state in DQH·. We denote the enhancement factor of F-pair polarization observed at the nth peak in ESR spectrum as $V_{ss}^{F}(n)$.

In the time profile shown in Fig. 2, the concentration of DQH· immediately after the light-OFF point is equal to the steady-state concentration reached in the light-ON period because of the slow decay of DQH· radical. Therefore the upward spike can be attributed to the rapid disappearance of TM polarization. From the definition (Eq. 1),

$$I_{ss} = (1+V_{ss})I_{ss.0} \tag{2}$$

Signal intensities immediately before and after the light-OFF point (I_{ss} and $I'_{ss.0}$, respectively) can be written as follows:

$$I_{ss} = (1+V_{ss}^{F}(n)+V_{ss}^{T})I_{ss.0} \tag{3}$$

$$I'_{ss.0} = (1+V_{ss}^{F}(n))I_{ss.0}. \tag{4}$$

With our CIDEP observation system, absolute signal intensity can not be measured. Instead, the following dimensionless quantity, which is slightly different from the enhancement factor, is measured.

$$V'(n) = \frac{I_{ss}-I'_{ss.0}}{I'_{ss.0}} \tag{5}$$

From Eqs. 3 and 4, we obtain

$$V'(n) = \frac{V_{ss}^{T}}{1+V_{ss}^{F}(n)}. \tag{6}$$

Since the signal intensity at the center of the ESR spectrum is unaffected by F-pair polarization,[6] there exists the following relation.

$$V'(n)_{center} = V_{ss}^{T} \tag{7}$$

$V_{ss}^{F}(n)$ can be obtained from Eqs. 6 and 7.

Time dependence of signal intensity is written as Eq. 8 following Fessenden's treatment.[7]

$$I(t) = \left(\frac{V_{ss}^{F}(n)}{1+t/t_{1/2}}+1\right)\cdot\frac{I'_{ss.0}}{1+t/t_{1/2}}, \tag{8}$$

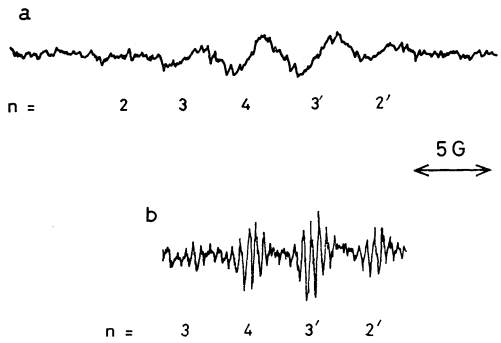

Fig. 3. ESR spectra of durosemiquinone radical DQH· in *i*-PrOH at 260 K.
Concentrations of DQ and PhOH are 0.1 and 2.2 mol dm^{-3}. Modulation width are 2.0 G (a) and 0.2 G (b).

where $t_{1/2}$ is the half-life of a radical. At the center line ($V_{ss}^{F}(n)=0$) Eq. 8 becomes simple second order decay. Signal zero level was so determined that the decay analysis in the light-OFF period gave the best fit to the second order kinetic. Decays of other lines were also well approximated by hyperbolas.

Results and Discussion

On the TM Enhancement Factor. The ESR spectrum of DQH· is shown in Fig. 3. Only neutral radical was detected and durosemiquinone anion radical (DQ^{-}) was not observed. Hyperfine splitting constants of DQH· were 4.8 G (1 G=10^{-4} T, 6H) and 0.6 G (6H). A modulation width of 2.0 G was used to make the spectrum large septet lines.

Light intensity dependence of V_{ss}^{T} was studied to examine the reliability of our apparatus and to find whether the following relation, which had been given for $V_{ss}^{F}(n)$ by Fessenden,[7] could be applied to V_{ss}^{T}.

$$V_{Int} = \frac{V_{ss}t_{1/2}}{T_1}, \tag{9}$$

where V_{int} is the intrinsic enhancement factor independent of the radical concentration, and T_1 is the longitudinal relaxation time. T_1 of DQH· could not be measured because of the long responce time of the spectrometer. It is likely to be constant regardless of the light intensity. If that is the case, $V_{ss}t_{1/2}$ should be independent of the radical concentration, which depends on light intensity. A plot of $V_{ss}^{T}t_{1/2}$ *vs.* the square root of light intensity is shown in Fig. 4. Values of V_{ss}^{T} were measured at the higher and the lower field peaks of the central resonance line (n= 4). The numbering of the septet line is illustrated in Fig. 3. The average of four measurements at each line is taken and listed in Fig. 4.

$V_{ss}^{T}t_{1/2}$ is independent of the light intensity as expected. Therefore the Eq. 9 is valid for V_{ss}^{T} as well as $V_{ss}^{F}(n)$. Fig. 4 also shows the square root dependence of V_{ss}^{T} on the light intensity. This can be attributed to the disproportional radical decay:

$$DQH\cdot + DQH\cdot \longrightarrow DQ + DQH_2. \tag{II}$$

In the neat solvents except *i*-PrOH, DQH· was

a) The light intensity was kept constant. b) Added solvents to *i*-PrOH and their content in molar fraction. c) Dielectric constants were calculated from volume ratio of added solvent and PhOH. d) Light intensity change was corrected using the relation (9).

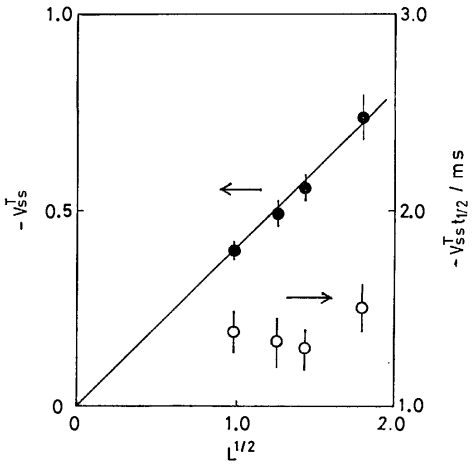

Fig. 4. Light intensity dependence of V_{ss}^{T} and $V_{ss}^{T}t_{1/2}$. L denotes the relative light intensity.

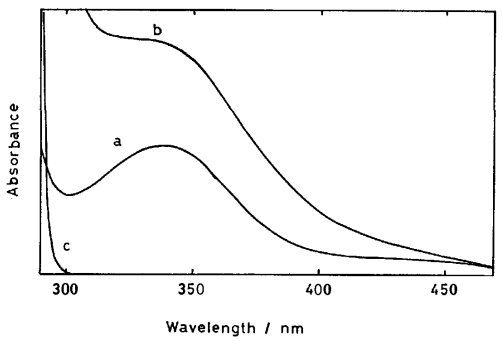

Fig. 5. Absorption spectra of a: DQ (0.07 mol dm^{-3}), b: DQ and PhOH (0.07 and 1.7 mol dm^{-3}) and c: PhOH (1.7 mol dm^{-3}) in *i*-PrOH at room temperature.

not detected. Thus, V_{ss}^{T} was measured in the mixed solvents with *i*-PrOH. Results are listed in Table 1. The light intensity was kept constant.

Only a small change in V_{ss}^{T} was observed with the change of dielectric constants of solvents from 11 to 23. Any simple correlation between V_{ss}^{T} and ε could not be found. Hence $S_1 \rightarrow T_n$ intersystem crossing in DQ* is thought to be unaffected by solvent polarity in spite of the near location of both (n,π^*) and (π,π^*) states with the lowest triplet state.[8)]

It must be noted that the addition of PhOH to the DQ solution gave an obvious change in absorption spectra (Fig. 5). This was referred previously by Elliot and Wan,[1)] and attributed to the change in hydrogen bonding characteristics as the addition of PhOH. However, similar spectral change was observed by the addition of other aromatic compounds such as benzene or toluene, but not with aliphatic additives such as cyclohexane or acetonitrile. Thus, the change of optical spectra is explained in terms of the interaction between aromatic rings of DQ and PhOH rather than the hydrogen bond.

Table 1 also indicates that V_{ss}^{T} is not sensitive to solvent viscosity. V_{int}^{T} was described by Wan and Elliot[1,2)] as follows:

$$\frac{1}{V_{int}^{T}} = \frac{1}{V_{\infty}^{T}}\left(1+\frac{1}{{}^3T_1 \times k_q[\mathrm{PhOH}]}\right), \tag{10}$$

where ${}^3T_1$ is the longitudinal relaxation time of ^{3}DQ*, k_q is the second order rate constant of the reaction (I), and V_{∞}^{T} is the limitting value of V_{int}^{T} at infinite concentration of PhOH. V_{ss}^{T} was expected to be sensitive to solvent viscosity because of the viscosity dependences of T_1, ${}^3T_1$, and k_q. But noticeable dependence of V_{ss}^{T} on solvent viscosity was not observed.

There is a correlation between $V_{ss}^{T}t_{1/2}$ and the viscosity. To discuss this, Eqs. 9 and 10 are combined to give

$$V_{ss}^{T}t_{1/2} = \frac{1}{{}^3T_1^{-1}\cdot k_q^{-1}\times[\mathrm{PhOH}]^{-1}+1}\cdot V_{\infty}^{T}\cdot T_1 \tag{11}$$

If cancellation occures between the effect of ${}^3T_1$ and k_q, the denominator of the right hand side of Eq. 11 is insensitive to the viscosity. This seems to be the case found in the report on $DQ^{\cdot-}$, which was given by Atkins as shown in Table 2.[9)] Values of $k_q \cdot {}^3T_1$ are nearly constant except in methanol. From the same reason, $k_q \cdot {}^3T_1$ is likely to be insensitive to viscosity variation in our systems. Then, if we assume that V_{∞}^{T} is independent of solvent viscosity, from Eq. 11 viscosity dependence of $V_{ss}^{T}t_{1/2}$ is attributed to that of T_1, and from the values of $V_{ss}^{T}t_{1/2}$ it turns out that T_1 increases about twice as the viscosity

Table 2. Rate constant k_q of the reaction $^3DQ^* + (C_2H_5)_3N \rightarrow DQ^{\cdot-} + (C_2H_5)_3N^{+}$ and longitudinal relaxation times in some solvents, by Atkins, *et al.*[9]

changes from 2.5 to 24.7 cP, and V_{int}^{T} is independent of viscosity.

The above assumption that V_{∞}^{T} is not influenced by solvent viscosity can be rationalized as follows. The enhancement factor V_{int}^{T} can be written as Eq. 12 using the theoretical equation for the magnetization $\langle S_z\rangle$ of a radical polarized due to TM given by Atkins and Evans (Ref. 10, Eq. 5—3).

$$V_{int}^{T} = \frac{\langle S_z\rangle - \langle S_{z.e}\rangle}{\langle S_{z.e}\rangle} \simeq \frac{\langle S_z\rangle}{\langle S_{z.e}\rangle} = \frac{(DK+3EI)}{1+k_T^{-1}\cdot{}^3T_1^{-1}} \cdot \frac{2}{15}\left(\frac{4\omega_0\tau_2^2}{1+4\omega_0^2\tau_2^2} + \frac{\omega_0\tau_2^2}{1+\omega_0^2\tau_2^2}\right) \cdot \frac{1}{\langle S_{z.e}\rangle} \tag{12}$$

where $\langle S_{z.e}\rangle$ is the thermal magnetization of the radical, k_T is the triplet quenching rate which can be substituted by $k_q\cdot$[PhOH] in our case, D and E are zero-field splitting constants, K and I are parameters showing anisotropy of $S_1 \rightarrow T_n$ intersystem crossing rate, ω_0 is angular frequency of the microwave, and τ_2 is the rotational correlation time. In the derivation of $\langle S_z\rangle$, isotropic rotational diffusion and the unity yield of intersystem crossing are assumed. The latter condition is valid for DQ.[11] Then we get Eq. 13 from Eq. 10.

$$V_{\infty}^{T} = \frac{2}{15}\left(\frac{4\omega_0\tau_2^2}{1+4\omega_0^2\tau_2^2} + \frac{\omega_0\tau_2^2}{1+\omega_0^2\tau_2^2}\right)\cdot\frac{DK+3EI}{\langle S_{z.e}\rangle} \tag{13}$$

If we adopt the Debye's relation $\tau = 4\pi\eta r^3/3kT$ for τ_2 (assuming r=4 A), Eq. 13 reduces to Eq. 14 because $\omega_0\tau_2 \gg 1$.

$$V_{\infty}^{T} = \frac{4}{15}\cdot\frac{DK+3EI}{\langle S_{z.e}\rangle}\cdot\frac{1}{\omega_0} \tag{14}$$

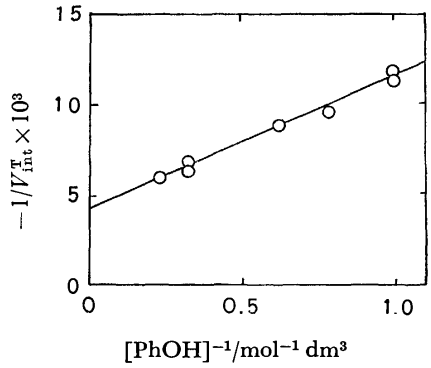

Fig. 6. Effect of phenol concentration on V_{int}^{T} of DQH· in *i*-PrOH at 260 K.

Consequently V_{∞}^{T} does not depend on viscosity.

The value of V_{∞}^{T} can be obtained by extrapolating the plot of $(V_{int}^{T})^{-1}$ *vs.* [PhOH]$^{-1}$ according to Eq. 10 and the value $(DK+3EI)$ of $^3DQ^*$ in liquid phase is calculable from V_{∞}^{T}. This plot was carried out for the PhOH concentration range from 1 to 4 mol dm^{-3} using T_1 values of $DQ^{\cdot-}$ in ethanol reported by Rengan *et al.*[12] The plot was linear and V_{∞}^{T} was obtained to be −240, as shown in Fig. 6. By using Eq. 14, we obtain $(DK+3EI) = -0.1$ cm^{-1}. This is a reasonable value for an aromatic compound. Also $^3T_1$ of $^3DQ^*$ was estimated to be 2.6 ns from the slope of the plot using the value of $k_q = 2\times10^8$ mol^{-1} dm^3 s^{-1}.[1]

With aromatic carbonyls in solid phase, D, E and the rate of intersystem crossing are remarkably influenced by the nature of host and the external heavy atom.[3] On the other hand in liquid phase, the addition of nonpolar or viscous solvents to the $DQ^{\cdot-}$

PhOH system does not affect the TM enhancement factor as discussed above. The addition of halogenated solvents to the system also gives little change in V_{ss}^{T} (see Table 1).

On the RPM Enhancement Factor. In various solvents, $V_{ss}^{F}(3)$ and $V_{ss}^{F}(3')$, together with V_{ss}^{T} were measured. Table 3 lists the ratios of $V_{ss}^{F}(n)/V_{ss}^{T}$ which are intrinsic value independent of the light intensity:

$$V_{ss}^{F}(n)/V_{ss}^{T} = \frac{V_{ss}^{F}(n)t_{1/2}}{T_1} \Big/ \frac{V_{ss}^{T}t_{1/2}}{T_1} = V_{int}^{F}(n)/V_{int}^{T}. \quad (15)$$

This ratio can be regarded as the reflection of the solvent dependence of V_{int}^{F}, because V_{ss}^{T} or V_{int}^{T} is nearly independent of solvents as discussed. The sign of $V_{ss}^{F}(3)$ is negative (emission) and the one of $V_{ss}^{F}(3')$ positive (enhanced absorption). Absolute values of $V_{ss}^{F}(3)$ and $V_{ss}^{F}(3')$ of each sample were equal, which is consistent with the theory of RPM.[6] This fact gives a support to the validity of the simple method of the analysis we adopted.

In the first five lines in Table 3, results on samples without heavy atoms are listed. In spite of the wide change in viscosity ranging from 2.9 to 24.7 cp, the deviation of the ratio is within 25%. As mentioned previously, the change in viscosity is expected to vary the period of magnetic interaction between radicals within the radical pair $\overline{\text{DQH}\cdot\ \text{DQH}\cdot}$, so that the enhancement factor of RPM is likely to be sensitive to solvent viscosity. The result is contrary to this expectation. The value of $V_{ss}^{F}(n)/V_{ss}^{T}$ decreases slightly with increasing viscosity.

$V_{ss}^{F}(n)/V_{ss}^{T}$ is remarkably small when the sample contains 1-bromo-2-propanol, as shown in the lower part of Table 3. Other halogenated solvents have the similar effect to 1-bromo-2-propanol, however the magnitude is small. Two possible causes for this effect are considered. (1) The yield or the rate of the reaction (II), which is the origin of F-pair polarization, decreases for the participation of such solvents. (2) There is the external heavy atom effect on the F-pair polarization, *i.e.*, the reduction of the singlet-triplet mixing in the radical pair $\overline{\text{DQH}\cdot\ \text{DQH}\cdot}$. A possible mechanism for (1) is that a considerable amount of DQH· decays through a process other than (II). This mechanism, however, fails to explain that the half-life of DQH· is unaffected by halogenated solvents. Although the cause (2) cannot explain quantitatively the difference in magnitude of the effect among halogenated solvents, it is likely to exist. A probable mechanism of cause (2) is a suppression of the interaction between radicals by another interaction between radicals and halogenated solvents.

Enthalpies of Combustion of Organic Compounds. IV. Acetanilide and Nicotinic Acid**

Tomoko SATO-TOSHIMA, Akeji KAMAGUCHI, Keiichi NISHIYAMA, Minoru SAKIYAMA,* and Syûzô SEKI†

Chemical Thermodynamics Laboratory and Department of Chemistry, Faculty of Science, Osaka University, Toyonaka 560

(Received June 24, 1982)

Standard energies of combustion at 298.15 K have been determined for crystalline acetanilide and nicotinic acid by static oxygen bomb calorimetry. Derived standard enthalpies of combustion and of formation are $-(4224.8\pm1.0)$ and $-(209.5\pm1.5)$ kJ mol^{-1} for acetanilide, and $-(2730.83\pm0.48)$ and $-(344.81\pm0.92)$ kJ mol^{-1} for nicotinic acid, respectively. Nicotinic acid pellets of 1.2 g in mass showed remarkable tendency to spatter when partially burnt. Factors governing the completeness of combustion of the material have been explored through 28 test combustion experiments.

The role and desired properties of test substances in combustion calorimetry were discussed in detail by Armstrong and Johnson[1] and by Cox.[2] A recommendation was issued from IUPAC on reference materials for enthalpy measurements including combustion calorimetry.[3] Urea,[1-3] acetanilide,[2-4] hippuric acid,[3] and tris(hydroxymethyl)aminomethane[3] were recommended or proposed as test substances and nicotinic acid[1] as a candidate, for oxygen bomb combustion calorimetry of organic compounds containing carbon, hydrogen, oxygen and nitrogen.

For acetanilide and nicotinic acid, Johnson determined standard enthalpies of combustion.[1,4,5] Johnson's value for acetanilide[4] is in good agreement with the value deduced from Wadsö's reaction calorimetric results.[6] However, no other combustion calorimetric results have been reported so far for these compounds.

In this paper, results of combustion calorimetric studies on these compounds are reported. In the course of this study, remarkable tendency of spattering during burning was found for nicotinic acid, so twenty-eight test combustion experiments were carried out on this compound in order to disclose requirements to realize complete combustion. The results of these test experiments are also reported.

Experimental

Materials. Acetanilide used in this study was a commercial standard material for organic microanalysis (Kishida, SMA-SP-1) prepared under the certification of a subcommission of the Japan Society for Analytical Chemistry. The sample as received was pressed into pellets and used in the experiments. The purity was found to be higher than 99.9 mole per cent by the analysis of DSC heating curves in the melting region. Nicotinic acid was a commercial reagent (Nakarai, G. R.), which was purified by recrystallization from aqueous solution and then from ethanol solution, followed by fractional sublimation *in vacuo* and recrystallization from aqueous solution. The last-mentioned step was additionally carried out, since DSC heating curves in the melting region for the sublimed sample gave an indication that it was in a metastable crystalline state. The recrystallized sample was dried *in vacuo* (about 1 Pa) and then subjected to pellet-drying[7-9] to remove a trace of occluded water. Pellets were produced again and stored on anhydrous magnesium perchlorate for one week. The purity of the purified nicotinic acid was found to be higher than 99.9 mole per cent by the method mentioned above. In the test combustion experiments on nicotinic acid, the untreated reagent as well as the purified material was employed. No significant difference was observed between these samples in the tendency of spattering.

Combustion Calorimetry. A constant temperature jacket type rotating bomb calorimeter with a platinum-lined bomb, described elsewhere,[10,11] was used without rotating the bomb. The samples were burnt at 3.04 MPa of oxygen pressure in the presence of 1 g of water. An ordinary platinum crucible with no lid(denoted by **a**; Parr, 43A5, 2.4 cm in diameter, 1.2 cm in depth, and 11 g in mass) was used for acetanilide. For nicotinic acid, a platinum crucible with a small lid[12] (denoted by **b**; 2.4 cm in diameter, 2.5 cm in depth, and 29.5 g in mass) was used to prevent the incomplete combustion. The calorimeter was calibrated by burning thermochemical standard benzoic acid (U.S. National Bureau of Standards, SRM 39i) under certificate conditions. Mean and standard deviation of the mean for the energy equivalent of the empty calorimetric system were (15158.53 ± 0.58) and (15166.91 ± 0.33) J K^{-1} for acetanilide and nicotinic acid experiments, respectively.

Nitric acid was determined by titration with aqueous sodium hydroxide. Carbon monoxide was barely detected in the present combustion calorimetric experiments.

Relative atomic masses were taken from the recommendation of IUPAC Commission on Atomic Weights (1977). Densities, specific heat capacities, and $(\partial U/\partial p)_T$ values at 298.15 K were taken from Refs. 4 and 5. Specific standard enthalpy of combustion at 298.15 K for cotton fuse ($CH_{1.86}O_{0.93}$) was -16507 J g^{-1} and the internal volume of the bomb was 0.3458 dm^3. Uncertainties in this paper are uncertainty intervals defined by Rossini,[13] unless otherwise stated.

Test Combustion Experiments on Nicotinic Acid. Measured amounts of nicotinic acid were pressed into pellets and they were ignited in the same way as in the combustion calorimetric experiments. After every test experiment, the internal surface and the internal fittings of the bomb were visually examined.

Results and Discussion

Combustion Tests on Nicotinic Acid. As was mentioned above briefly, nicotinic acid showed remarkable tendency of spattering to cause incomplete combustion,

TABLE 1. SUMMARY OF RESULTS OF TEST COMBUSTION ON NICOTINIC ACID

Series	$\frac{m(\text{sample})}{\text{g}}$	Pellet preparation method[a)]	Crucible[b)]	Number of experiments in which combustion was:	
				Complete	Incomplete
I	1.2	A	**a**	1	7
II	1.2	B	**a**	3	3
III	1.2	A	**b**	8	1
IV	0.3	A	**a**	0	2
V	0.3	B	**a**	0	3

a) A: The use of a hand pellet press, B: the use of a high pressure and an evacuable die. b) **a**: An ordinary platinum crucible with no lid, **b**: a deep platinum crucible with a small lid.

when a sample pellet weighing 1.2 g was ignited in an open crucible at 3 MPa of oxygen pressure. Nicotinic acid of 1.2 g mass gives rise to an adiabatic temperature rise of about 1.8 K for our calorimeter, which is of similar magnitude to that for the calibration experiments. In order to evaluate the degree of difficulty of combustion of this material, twenty-eight test combustion experiments were undertaken. If combustion is complete, carbon dioxide, water, nitrogen, and a small amount of nitric acid alone will be produced. The presence of the unburnt material, the carbonized material, or soot, in the bomb after the combustion, is taken to be the evidence of incomplete combustion in this context.

Two methods of pellet preparation were tested. One is the use of a commercial hand pellet press (Parr, 2811), which has been used in most of combustion calorimetric works in this laboratory(method A). The other is the use of a high pressure press with an evacuable die, which has been used for preparing KBr discs for infrared spectrometry (method B). The die, which was charged with powdered nicotinic acid, was evacuated, and then the powder was pressed at 700 MPa to produce a pellet. The die for method A cannot be evacuated. Two kinds of crucibles were examined: crucibles **a** and **b**, described in the experimental section. Pellets of two masses were tested: 1.2 and 0.3 g. Results of the test combustion experiments are given in Table 1.

In series I, pellets weighing 1.2 g were prepared by method A and ignited in crucible **a**. Combustion was complete in one of eight experiments. In the other seven experiments, unburnt nicotinic acid lumps, covered with the carbonized material, were found spattered on the internal bomb wall. This suggests that the fragmentation of the pellets occured in the course of combustion, and the extinction of fire resulted by the collision of the burning fragments with the cold bomb wall.

In series II, pellets weighing 1.2 g were produced by method B, and ignited in crucible **a**. Of six experiments, combustion was complete in three. In the other experiments, the deposition of a small amount of soot was observed on the internal bomb wall, but the spattering of unburnt sample was not experienced. The adoption of the high pressure and the evacuation of the die, both of which would serve to prepare rigid pellets, were considerably effective in suppressing the fragmentation. However, the method used in this series was not sufficient to produce complete combustion.

In series III, pellets weighing 1.2 g were prepared by method A and ignited in crucible **b**. Although spattering was observed in one of nine experiments, combustion was complete in the other eight experiments. The small lid would act as baffle for spattering fragments and at the same time it would serve to form a hot zone in the crucible to prevent the soot formation. This series was the most successful one and the method of this series was adopted in the combustion calorimetric experiments, as described in the experimental section.

In Johnson's experiments,[2)] in which pellets weighing 0.3 g were ignited in a crucible with no baffle plate at 3 MPa of oxygen pressure, incomplete combustion was not experienced.[16)] In order to study the effect of mass decrease on the completeness of combustion, experiments of series IV and V were conducted. Pellets weighing 0.3 g were produced by method A(series IV) or B(series V) and ignited in crucible **a**. In series IV, a small amount of soot was found only in the crucible. In these series, spattering was not experienced. Thus, the decrease of mass was confirmed to be effective in preventing the spattering. The soot formation in these series would probably be caused by insufficient temperature rise around the crucible during combustion, owing to the decrease of mass of the material.

To summarize, the methods other than the use of a crucible with a small lid are more or less insufficient to get complete combustion of a nicotinic acid pellet of the present size. This is the conclusion of the present study on the difficulty of complete combustion of nicotinic acid. The characteristics, disclosed in this study, should be taken into consideration properly, when the material is scrutinized as a candidate test substance.

Standard Enthalpies of Combustion. Each of six combustion calorimetric experiments was carried out for both compounds. Standard energies and enthalpies of combustion reported in this paper refer to the following idealized combustion reactions at 298.15 K:

$$C_aH_bO_cN_d(c) + [(4a+b-2c)/4]O_2(g) = aCO_2(g) + (b/2)H_2O(l) + (d/2)N_2(g), \quad (1)$$

where $a=8$, $b=9$, $c=1$, and $d=1$ for acetanilide and

a=6, b=5, c=2, and d=1 for nicotinic acid. Combustion calorimetric results on these compounds are presented in Tables 2 and 3. Symbols in these tables are essentially similar to those used by Hubbard *et al.*[14] except for ΔU_{Σ}, the sum of contributions from items 81—85, 87—91, and 93—94 as defined by Hubbard *et al.*[14] Mean and standard deviation of mean of the standard energies of combustion, $\{\Delta U_c^{\circ}/M\}$, are $-(31.2337\pm0.0037)$ and $-(22.1821\pm0.0017)$ kJ g^{-1} for acetanilide and nicotinic acid, respectively.

Derived molar standard thermodynamic quantities are presented and compared with literature values in Table 4. The following CODATA key values for thermodynamics[15] were used to calculate standard enthalpies of formation of both compounds: $\Delta H_f^{\circ}(CO_2, g) = -(393.51 \pm 0.13)$ and $\Delta H_f^{\circ}(H_2O, l) = -(285.830\pm0.042)$ kJ mol^{-1}, where uncertainties are those at the 95 per cent confidence level.

Uncertainties attached to the values of ΔU_c°(c) and ΔH_f°(c) are the uncertainty intervals, defined by Rossini.[13] Uncertainties for the values of ΔH_f°(c) are the square roots of the sum of the squares of weighted uncertainties of ΔH_f°(c), $\Delta H_f^{\circ}(CO_2, g)$, and $\Delta H_f^{\circ}(H_2O, l)$. The weight for ΔH_f°(c) is 1, and those for $\Delta H_f^{\circ}(CO_2, g)$ and $\Delta H_f^{\circ}(H_2O, l)$ are a and $(b/2)$, given in Eq. 1, respectively. Uncertainties of Johnson's standard enthalpies of combustion and of formation[4,5] were recalculated so as to be in accord with the present assignment. The standard enthalpy of formation from Wadsö's experiments on acetanilide was quoted from Ref. 2.

Table 4. Standard thermodynamic quantities at 298.15 K of acetanilide and nicotinic acid and comparison with literature values

	$-\Delta U_c^{\circ}$(c) / kJ mol^{-1}	$-\Delta H_c^{\circ}$(c) / kJ mol^{-1}	$-\Delta H_f^{\circ}$(c) / kJ mol^{-1}

This work	4221.7 ±1.0	4224.8 ±1.0	209.5 ±1.5
Nicotinic acid			
Johnson[5]	2731.29±0.38	2730.67±0.38	344.97±0.87
This work	2731.45±0.48	2730.83±0.48	344.81±0.92

The standard enthalpies of combustion for both compounds, obtained in this study, agree with those of Johnson[4,5] within the assigned uncertainties. The present standard enthalpy of formation for acetanilide is in agreement with Wadsö's reaction calorimetric value[6] within the assigned uncertainties. Thus, standard enthalpies of combustion for these compounds have been determined more confirmatively.

Film Dichroism. VI.[1] Linearly-polarized Absorption Spectra of Neutral and Divalent 3,6-Diaminoacridine Dyes in the Stretched Poly(vinyl alcohol) Film

Kiwamu YAMAOKA* and Mitsuaki SHIMADZU

Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730

(Received April 16, 1982)

The linear dichroic spectra of the neutral (uncharged) and divalent (doubly charged) Acridine Orange, Acridine Yellow, and Proflavine were measured at 25 °C in the visible and UV wavelength regions by the film dichroism method. These 3,6-disubstituted symmetric acridine dyes were molecularly dispersed in the heat-treated poly(vinyl alcohol) film by the staining method. The neutral and divalent dye species were prepared by adding a sufficient amount of sodium hydroxide or sulfuric acid to the staining dye solutions. The wavelength dependence of the reduced dichroism, $\Delta A/A$, of the neutral species at a given stretch ratio was very similar to that of the monovalent species previously reported [*Bull. Chem. Soc. Jpn.*, **52**, 3163 (1979)]. Values of $\Delta A/A$ for the divalent species were nearly constant over the entire wavelength region 550—220 nm. The long-axis and short-axis polarized component (A_z and A_y) spectra were computed for the neutral dye species from the observed parallel- and perpendicular-polarized dichroic spectra by using a reduction procedure. The broad, principal band of each dye species in the visible region was deduced to be a composite of two orthogonal (a strong A_z and a weak A_y) electronic transitions.

In previous papers in this series,[2,3] we have shown that the monovalent, symmetrically-substituted acridine dyes can be oriented unidirectionally in the stretched poly(vinyl alcohol) (PVA) film and that the linearly polarized spectra of these dyes can be analyzed into the long-axis and short-axis (A_z and A_y) components whose transition moments are polarized in the molecular plane. For 3,6-disubstituted acridine dyes, such as Acridine Orange and Proflavine, the broad, long-wavelength absorption band in the visible region was resolved, without exception, into composite of a strong A_z-component and a very weak A_y-component.[2,3] Since these dyes are known to bind to various kinds of biopolymers, and since the binding has been studied mostly by the spectrophotometric methods, the optical properties of the individual dyes must be clarified thoroughly to facilitate the correct interpretation of the spectroscopic behavior of the dye–polymer complexes.

The monovalent 3,6-disubstituted acridine dyes are susceptible to deprotonation or further protonation, becoming neutral (uncharged) in alkaline solutions or divalent (doubly charged) in acid solutions. The visible absorption spectra of these neutral and divalent dye species are very different from those of the corresponding monovalent (singly charged) species,[4] but, interestingly, often resemble the metachromatic spectra of the monovalent species in the presence of various kinds of polyelectrolytes.[5] Therefore, the film dichroism study of the neutral and divalent acridine dyes is highly desirable for identifying the electronic transition moments responsible for the visible absorption bands, and, if possible, for confirming the systematic changes of these bands in terms of two overlapping (A_y and A_z) component spectra. For this purpose, painstaking efforts were made in the preparation of the neutral and divalent dye species molecularly dispersed in the PVA film, and in the measurements of the dichroic spectra of the stretched films.

Experimental

Materials. Monovalent dyes in the hydrochloride form have been described elsewhere.[2] Abbreviations used in this work are as follows: Acridine Orange, 3,6-bis(dimethylamino)acridinium chloride (AO); Acridine Yellow, 3,6-diamino-2,7-dimethylacridinium chloride (AY); Proflavine, 3,6-diaminoacridinium chloride (PF). Each of these dyes in the neutral form is denoted as AO°, AY°, and PF°, and the monovalent cations as AO^+, AY^+, and PF^+, whenever so needed. The divalent cations are denoted as AO^{2+}, AY^{2+}, and PF^{2+}. Poly(vinyl alcohol) with a nominal degree of polymerization of 2000 was purchased from Nakarai Chemicals, Ltd. (Kyoto). Other chemicals were of reagent grade.

Preparations of Dye–PVA Films. A stock PVA solution was prepared by dissolving the powdered PVA sample (10 g) in redistilled water (100 ml) under gentle stirring at 80—90 °C. The clear solution was filtered through a G-1 sintered glass filter, cooled to ambient temperature, and then spread onto a glass plate to prepare a clear film (10 cm × 10 cm).[2,6] The well-dried PVA film was cut to rectangular pieces; each piece was subjected to heat-treatment at 80 °C for four hours. The preparation of the dye-containing PVA film from a dye–PVA solution by the standard method[2,6] was unsuccessful because of the following reasons. To retain the respective dye species in the purely neutral or divalent form without being contaminated by the stable monovalent form, a sufficient amount of sodium hydroxide or sulfuric acid must be added to the aqueous dye–PVA solution. Attempts to cast a good-quality film from this mixture failed; the mixture either remained translucent for the neutral dye–PVA system or jellified for the divalent dye–PVA system.

After many trials-and-errors, film-staining was found to be the best method. Two heat-treated PVA films (one for the sample, the other for the reference) were immersed into the aqueous sulfuric acid solution (*ca.* 1.8 M, 1 M = 1 mol dm^{-3}). (If the concentration of the acid is too high, the film tends to dissolve. If it is too low, the film contains both the mono- and divalent dye species.) After sufficient time for swelling, the sample film was stained by the acid dye solution. The reference film was kept immersed in the dye-free acid solution for the same period of time. Both films were then dried on a glass plate. (When hydrochloric acid was used for sulfuric acid, the divalent dye species in the sample film was partly converted back to the monovalent form, probably because of the evaporation of hydrogen chloride from the film.)

The sample and the reference films for the neutral dye species were similarly prepared by immersing two heat-treated PVA films in the aqueous sodium hydroxide solution (*ca.* 2.5 M). The swollen sample film was transferred to the alkaline dye solution which contains ethanol enough for the uncharged dye not to precipitate. On being dried on a glass plate, both sample and reference films formed the white powder of carbonate on the surface. The carbonate was washed off with distilled water and then with ethanol. The transparent films were kept in a desiccator.

Measurements. A large number of dye–PVA films were prepared and the spectra of the nonstretched sample films were carefully compared with the solution spectra of the respective dye species, in order to select the films which were not contaminated by the monovalent species and were suitable for the dichroism measurement. The linear dichroic spectra, which are polarized parallel ($A_\parallel$) and perpendicular ($A_\perp$) to the direction of the film stretch, and the isotropic nonstretched spectrum (A) of the dye–PVA film[6] were measured, together with the visible spectra of dye solutions, at 25 °C as described previously.[2,3] Because of the difficulty in the multiple stretching of a given film, each film was stretched only once to a predetermined macroscopic stretch ratio S, as defined previously.[2,3,6]

Analytical Procedure. The dichroic data were expressed with the reduced dichroism $\Delta A/A$:

$$\frac{\Delta A}{A} = \frac{(A_\parallel - A_\perp)}{1/3(A_\parallel + 2A_\perp)}. \tag{1}$$

For symmetric 3,6-diaminoacridine dyes which belong to the C_{2v} point symmetry group, the reduction procedure[7,8] may be utilized for evaluating the A_y- and A_z-spectra (the short-axis and the long-axis polarized component spectra, respectively) from the observed dichroic $A_\parallel$- and $A_\perp$-spectra as before:[2]

$$\left.\begin{aligned} A_\perp - d_\perp A_\parallel &= \frac{K_z - K_y}{2K_z} A_y \\ A_\parallel - d_\parallel A_\perp &= \frac{K_z - K_y}{1 - k_y} A_z, \end{aligned}\right\} \tag{2}$$

where $d_\parallel$ and $d_\perp$ are the reduction factors, and K_y and K_z are the orientation factors.

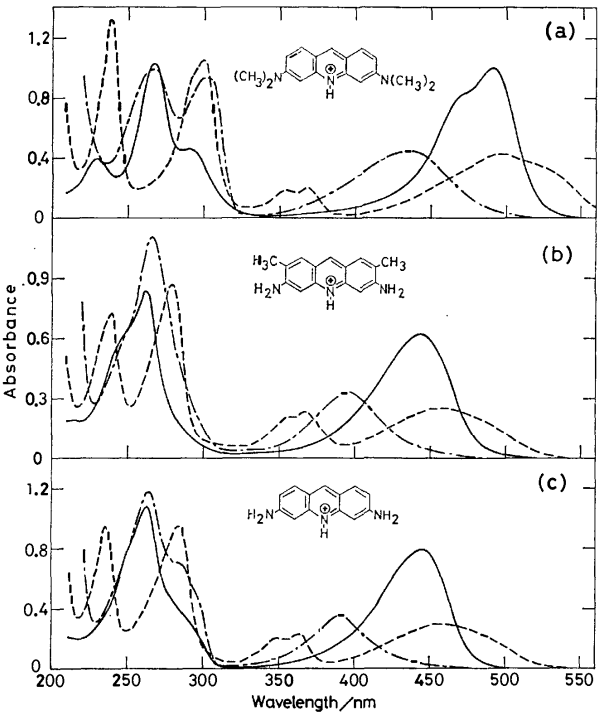

Fig. 1. Absorption spectra of three diaminoacridine dyes in solution at three representative pH regions. The neutral (uncharged) forms in alkaline solution (—·—), the divalent (doubly charged) forms in acid solution (----), and the monovalent (singly charged) forms in aqueous solution (——) for which the structural formulas are given. Conditions are: (a) Acridine Orange, AO° (21 μM) in 0.17 M NaOH solution, AO^+ (25 μM) at a neutral pH, and AO^{2+} (16 μM) in 2.3 M HCl; (b) Acridine Yellow, AY° (16 μM) in 0.17 M NaOH, AY^+ (19 μM) at a neutral pH, and AY^{2+} (14 μM) in 1.7 M HCl; (c) Proflavine, PF° (19 μM) in 0.17 M NaOH, PF^+ (22 μM) at a neutral pH, and PF^{2+} (14 μM) in 2.3 M HCl. The absorption of each solution was measured in a 1-cm cuvette cell.

Results and Discussion

Solution Spectra. Figure 1 shows the solution spectra of three diaminoacridine dyes in the acid, neutral, and alkaline pH regions. In all cases, the neutral (uncharged) dye species give rise to the visible spectra which are hypochromic and hypsochromic relative to those of the monovalent dye cations. The visible spectra of divalent dye cations reveal some remarkable features; the principal band shifts toward the long wavelength and a new twin-peaked band appears in the wavelength region 370—340 nm, where the monovalent and neutral species show only monotonically-decreasing absorption profile. It should be noted that this twin-peaked band, which was earlier observed for AO^{2+} by Zanker,[4] is in fact a feature common to the divalent 3,6-diaminoacridine cations. The purely divalent Trypaflavine, the quaternized homolog of PF^{2+}, was found to show the twin-peaked band at 365—350 nm.[9] It was also confirmed in this work that the divalent cations of the 10-methyl derivatives of AO and AY[3] give rise to the absorption spectra with the twin peak very much similar to those in Fig. 1. Therefore, no further details will be given on the dichroic behavior of the divalent species of those quaternary 3,6-diaminoacridine dyes.

Dichroic Spectra and Reduced Dichroism. Figures 2—4 show the dichroic spectra, *i.e.*, the $A_\parallel$- and $A_\perp$-spectra, and the wavelength dependence of the reduced dichroism $\Delta A/A$ (hereafter denoted as the RD-spectrum) for the neutral species (upper half) and for the divalent species (lower half). The results may be summarized as follows. (1) Regardless of the dye species examined, the $A_\parallel$-spectra are more intense than the $A_\perp$-spectra at a given stretch ratio; hence, the sign of the RD-spectra (filled circles) remains positive throughout the wavelength region. (2) The RD-spectra of the neutral species (AO°, AY°, and PF°) are not constant but decrease on the long and short wavelength sides of the principal band (the error is large for PF° due to the background scattering). This behavior is very similar to that of the corresponding monovalent dye species,[2] immediately indicating that the broad and featureless band of each

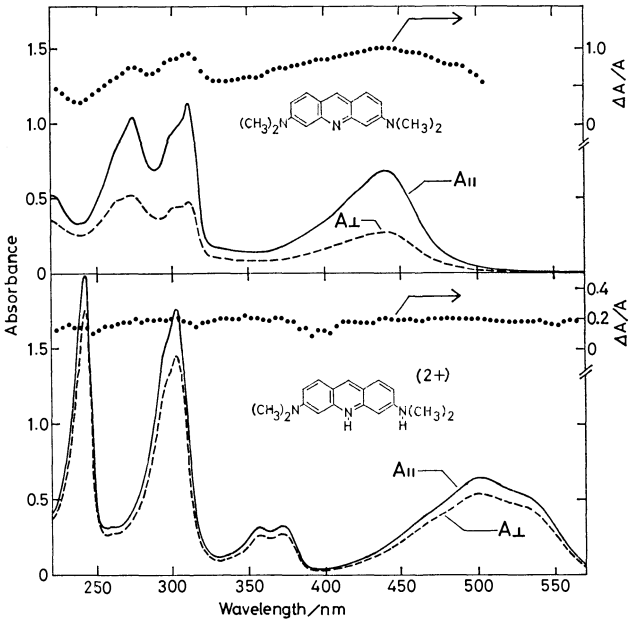

Fig. 2. The dichroic spectra polarized parallel ($A\parallel$) and perpendicular ($A\perp$) to the direction of stretch and the reduced dichroism ($\Delta A/A$) of Acridine Orange in the stretched PVA film. Upper: the neutral form. Lower; the divalent ionic form. The nominal stretch ratio S of the PVA film is 3.8,[2,6] which corresponds to the rotation of the mechanical stretcher of 15 turns.[6] This, in turn, corresponds to the threefold elongation of the PVA sample film along the stretching direction.

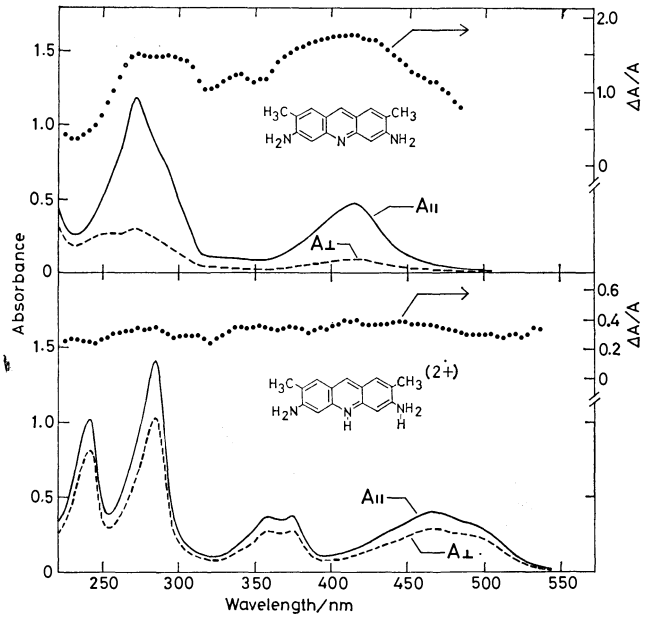

Fig. 3. The dichroic spectra ($A\parallel$ and $A\perp$) and the reduced dichroism ($\Delta A/A$) of Acridine Yellow in the stretched PVA film. The symbols and conditions are the same as in Fig. 2.

neutral species in the visible region (Fig. 1) is only apparent and contains at least two electronic transition moments.[2,3] The close similarity between the monovalent and neutral species may be accounted

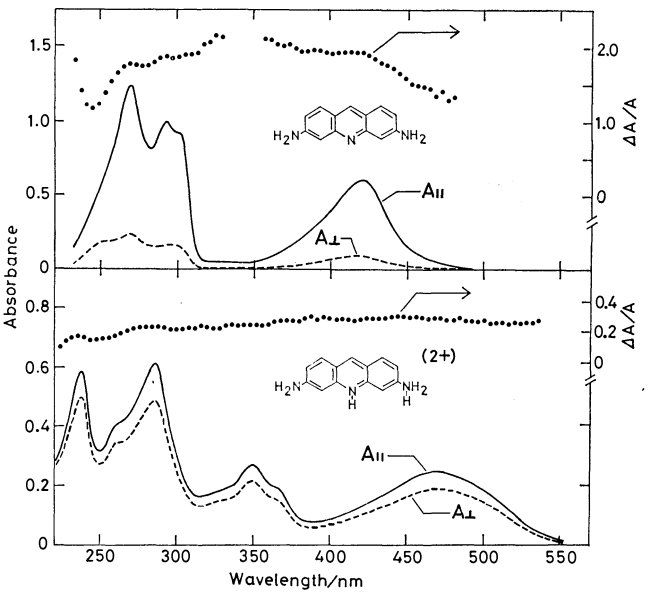

Fig. 4. The dichroic spectra ($A\parallel$ and $A\perp$) and the reduced dichroism ($\Delta A/A$) of Proflavine in the stretched PVA film. The symbols and conditions are the same as in Fig. 2.

for by considering their molecular symmetry and chemical structure: one class is deprotonated and the other is protonated at the ring nitrogen. (3) The RD-spectra of the divalent dye cations (AO^{2+}, AY^{2+}, and PF^{2+}) are nearly constant throughout the visible and UV regions; both the principal band near 450—500 nm and the new twin peak behave similarly on stretching. This is a remarkable contrast with the cases of the neutral and monovalent dye species. (4) The divalent dye cations are less orientable than the uncharged counterparts, *i.e.*, values of $\Delta A/A$ are smaller by a factor of 10—5, at a given stretch ratio; a feasible explanation is that the H_2SO_4-containing PVA film matrix is less rigid than the NaOH-containing one.

Reduction Procedure. Because of the additives (H_2SO_4 and NaOH) in the dye-PVA films, the dichroic measurements for each film could be carried out only at a single stretch. It was not possible to determine the dependence of $\Delta A/A$ on stretch ratio at some selected wavelengths as in previous studies;[2,6,10] hence, the intrinsic value of the dichroism at infinitely high stretch ratio could not be estimated. Nor could the orientational behavior inside the "orientation triangle"[2,10] be established. Since the reduction procedure does not require the exact degree of orientation of the guest molecules,[7,8] this technique will be employed to estimate the short-axis polarized (A_y) and the long-axis polarized (A_z) component spectra. Figure 5 shows an example of the reduction procedure applied to AO°. Both ($A\parallel - d\parallel A\perp$) and ($A\perp - d\perp A\parallel$) were searched for A_y and A_z with a HITAC M-180 computer. While the factor $d\perp$ (hence, the value K_z and an unnormalized A_y-spectrum) could be determined (Fig. 5b), the other factor $d\parallel$ (hence, the value K_y) could not, because none of the trial spectra ($A\parallel - d\parallel A\perp$) falls on (or crosses over) the zero absorbance line. Thus, the normalized A_y- and A_z-spectra are undeterminable. In order to circumvent this prob-

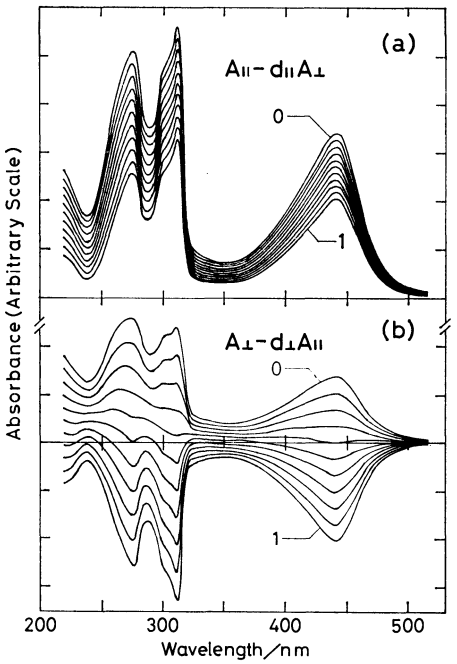

Fig. 5. The reduction procedure applied to the dichroic spectra of Acridine Orange in the neutral form. The $A_{\parallel}$- and $A_{\perp}$-spectra were measured at a nominal stretch ratio of 3.8. The reduction factors $d_{\parallel}$ and $d_{\perp}$ were varied from 0 to 1 at intervals of 0.1.

lem, a plausible assumption is made: the orientation behavior of the neutral form (AO°) is practically the same as that of the monovalent form (AO^+), so that the orientation triangle for AO^+ (Fig. 7 of Ref. 2 or Fig. 4 of Ref. 10) can be utilized to evaluate the orientation factor K_y by using the above K_z. Then, both A_y and A_z may be computed from Eq. 2. The same general techniques apply to other neutral dyes (AY° and PF°). The values of the reduction factors and the orientation factors are given in Table 1.

The Long-axis and Short-axis Polarized Spectra. Figure 6 shows both the long-axis polarized (A_z) and the short-axis polarized (A_y) spectra for three neutral dye species. It is clear that, for each species, the isotropic absorption spectrum in the visible region (Fig. 1) belongs predominantly to the A_z-spectrum, but that the contribution from the A_y-spectrum should not be ignored (dashed lines). The featureless principal band is now concluded to be a composite of two mutually perpendicular transitions (the y- and z-polarizations or the ^1L_a and ^1L_b bands[2-4]). The A_z-spectrum is also predominant in the UV region, but the A_y-spectrum substantially contributes to the observed isotropic band in each case.

The C_{2v} symmetry should be assumed if the reduction procedure is to be applied to the observed $A_{\parallel}$- and $A_{\perp}$-spectra of the divalent dye species on a reliable basis. The C_{2v} symmetry could be preserved for a given divalent species only if an additional proton is attached to the 10-position of the corresponding monovalent acridinium ion. The divalent species probably belong to a class of lower symmetry,[11] since the second protonation is believed to occur at the 3- or 6-position.[4,12] As a consequence, the directions

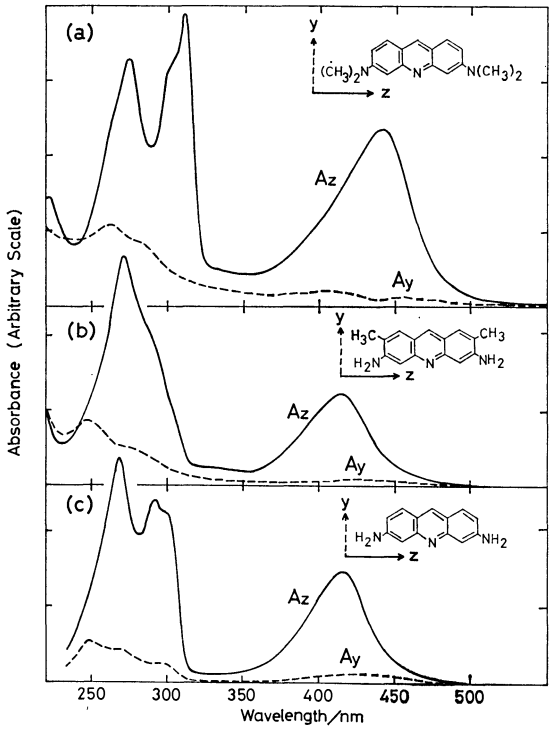

Fig. 6. The short-axis (y) and long-axis (z) polarized component spectra (A_y and A_z) of three 3,6-diaminoacridine dyes in the neutral forms. (a) Acridine Orange, (b) Acridine Yellow, and (c) Proflavine.

of the in-plane transition moments may no longer be mutually perpendicular. We are therefore obliged to postpone the analysis of the dichroic data of the divalent dye species, until an analytical method suitable for the film dichroism of guest molecules of low symmetry is developed.

Closing Remarks. The film dichroism studies on the symmetric 3,6-diaminoacridine dyes in the neutral, monovalent, and divalent forms may be summarized as follows. All dye species in each form clearly show some regular spectral features in the visible absorption spectra. The twin-peaked band appears only in the spectrum of the divalent species. For the neutral and monovalent forms examined so far,[2] the long-axis and the short-axis polarized component spectra overlap each other; the A_z-spectrum is always located on the wavelength side slightly shorter than the A_y-spectrum. We may now conclude that the broad, visible absorption band of the symmetric 3,6-diaminoacridine dyes is a composite of two mutually-polarized, overlapping component spectra regardless of the substituents at the 3,6-nitrogen, at the 2,7-carbon, and at

the 10-nitrogen of the acridine nucleus. These findings should facilitate a new interpretation of the spectral changes of these dyes when bound to various synthetic polyelectrolytes and biopolymers.

We acknowledge with deep gratitude some initial contributions to the present work by Dr. Yukio Matsuoka, who formerly belonged to our research group and was actively engaged in developing film dichroism techniques.

Effect of the Polydispersity of Molecular Length on the Decay Process of Transient Electric Birefringence of Rodlike Macromolecules in Dilute Solution

Kiwamu YAMAOKA* and Kiyohiro FUKUDOME

Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730

(Received July 2, 1982)

The effect of polydispersity on transient electric birefringence (EB) was examined for a dilute solution which contains like macromolecules of varying lengths. The molecules were assumed to be rigid rods of cylindrical symmetry, so that the molecular weight is linearly proportional to length. Polydispersity was expressed by the ratio of the weight-average to the number-average lengths l_w/l_n. A logarithmic-normal type continuous length distribution was generally used. Calculations were performed for the birefringence-average relaxation time $\langle\tau\rangle_{EB}$ and initial slope $\langle S\rangle_{EB}$ as a function of the electric field strength E, which is applied prior to the start of the decay process, with the electric parameter $(\beta_w)^2/2\gamma_w$, which is related to the weight-average permanent dipole moment (the β_w-term) and polarizability anisotropy (the γ_w-term). Both $\langle\tau\rangle_{EB}$ and $\langle S\rangle_{EB}$ are very sensitive to E, l_w/l_n, and $(\beta_w)^2/2\gamma_w$. A convenient method was devised for determining the polydispersity parameters (l_w/l_n and l_w) from the weight-averages of relaxation time and initial slope, which are free from the mechanism of field orientation. Examples are given for a polydisperse, rigid rodlike sonicated DNA sample in aqueous solution.

In the preceding paper on the electric birefringence (EB) and electric dichroism (ED) of sonicated DNA in dilute solutions,[1] we have indicated that the measurement of decay processes is promising for determining the overall molecular shape, even if the sample DNA is polydisperse as regards the molecular length. Although the theoretical basis of the transient EB and ED methods is well advanced for monodisperse systems,[2] analyses of the experimental data of a polydisperse system have often been unsatisfactory because of the lack of an appropriate procedure. For a polydisperse system consisting of particles with a continuous length distribution, Yoshioka and Watanabe[3,4] first introduced the area method, by which the electric birefringence-average relaxation time, $\langle\tau\rangle_{EB}$, can be obtained. They have since developed an elegant method for determining the relaxation spectrum from a single decay curve.[5–11] According to our experience, the application of this method to dilute polymer solutions is often difficult due to low signal-to-noise ratio of observed decay signals. Kobayasi has calculated the variation of relaxation time τ with the polydispersity ratio of a continuous weight distribution for rodlike molecules.[12] Schweitzer and Jennings have shown that the initial slope, S, of a decay curve depends not only on the particle-size distribution and electric field strength, but also on the nature of the electric properties of molecules.[13,14] Coles and Weill have discussed the relation between the initial slopes and various averages of rotary diffusion coefficients.[15]

The objective of this paper is to clarify the effect of the molecular length distribution on the electrooptical and hydrodynamic properties of polydisperse samples and to allow the evaluation of the degree of polydispersity, which is defined as the weight-average to the number-average lengths l_w/l_n, and of the weight-average length l_w from the observed decay data. For this purpose, we first calculate the values of $\langle\tau\rangle_{EB}$ and $\langle S\rangle_{EB}$ numerically for an assembly of nonionized and rodlike dipolar macromolecules, showing the dependence of these values on externally applied electric field strength. We secondly discuss the use of a newly devised "mesh method" for evaluating both l_w/l_n and l_w by applying it to the actually observed relaxation data of a polydisperse, rigid rodlike sonicated DNA sample.[1]

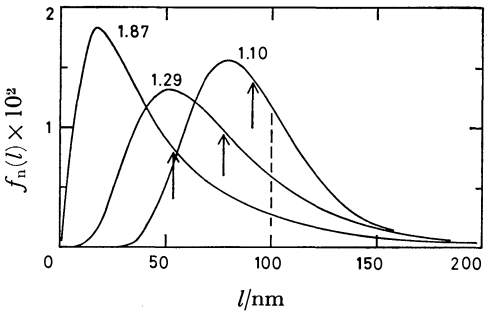

Fig. 1. The logarithmic-normal function $f_n(l)$ for continuous length distribution with various ratios of l_w/l_n. The weight-average length l_w is assumed to be 100 nm in all cases, as indicated by a vertical line. The positions of the number-average length l_n are indicated by arrows. Numerals denote the polydispersity ratio l_w/l_n.

Formalism and Calculations

Continuous Length Distribution. The following assumptions are made. A macromolecular species in a given polydisperse system is a thin, rigid rod of cylindrical symmetry with the longitudinal length l, having the apparent electric permanent dipole moment along the symmetry axis (the 3-axis), μ, and the electric polarizability anisotropy, $\Delta\alpha=(\alpha_{33}-\alpha_{11})$.[16–18] The density and the optical properties of molecules in the system are independent of molecular lengths. Both μ and $\Delta\alpha$ are proportional to l, so that $\mu=\mu_0 l$ and $\Delta\alpha=\Delta\alpha_0 l$, where μ_0 and $\Delta\alpha_0$ are the respective quantities per unit length.[19] The probability density function of l is $f_n(l)$ on the basis of the number of molecules in a solution. For $f_n(l)$, we mostly use a logarithmic-normal distribution, *i.e.*, the Wesslau function (Eq. 1),[20] in order to emphasize the contribution from fewer but longer components. (We have also examined the Schulz-Zimm,[1] the Poisson, and a rectangular distribution function.

The results are qualitatively all the same.)

$$f_n(l) = \frac{l_L}{l^2\omega\sqrt{\pi}\exp\left(\frac{\omega^2}{4}\right)}\exp\left\{-\frac{1}{\omega^2}\left(\ln\frac{l}{l_L}\right)^2\right\}, \quad (1)$$

where l_L is the parameter which determines the absolute position of the distribution and ω is the parameter which determines its breadth. The ratio $l_w/l_n = \exp(\omega^2/2)$, $l_n = l_L\exp(-\omega^2/4)$, and $l_w = l_L\exp(\omega^2/4)$. Figure 1 shows $f_n(l)$ with three different values of l_w/l_n.

Field-strength Dependence of EB Decay Processes. For a polydisperse system, the birefringence-average relaxation time $\langle\tau\rangle_{EB}$ (the same type expressions are also applicable to ED) can be expressed as follows:[3,12,21]

$$\langle\tau\rangle_{EB} = \int_0^\infty \frac{\Delta n(t)}{\Delta n(0)}dt = \frac{\int_a^{a'}\tau(l)\Phi(\beta',\gamma')lf_n(l)dl}{\int_a^{a'}\Phi(\beta',\gamma')lf_n(l)dl}, \quad (2)$$

where $\Delta n(0)$ is the steady-state birefringence at the initial time ($t=0$) when an electric pulse of arbitrary field strength is removed, and $\tau(l)$ is the relaxation time of a component with a length of l. The initial slope is given as[13-15]

$$\langle S\rangle_{EB} = \left[\frac{d\left(\ln\frac{\Delta n(t)}{\Delta n(0)}\right)}{dt}\right]_{t\to 0} = -\left\langle\frac{1}{\tau}\right\rangle_{EB}$$

$$= -\frac{\int_a^{a'}\tau(l)^{-1}\Phi(\beta',\gamma')lf_n(l)dl}{\int_a^{a'}\Phi(\beta',\gamma')lf_n(l)dl}, \quad (3)$$

where $\beta' = \mu_0 lE/kT$ and $\gamma' = \Delta\alpha_0 lE^2/2kT$. Since the orientation function $\Phi(\beta',\gamma')$ approaches unity, as the field strength increases infinitely, both $\langle\tau\rangle_{EB}$ and $\langle S\rangle_{EB}$ at infinitely high field give the weight-average relaxation time $\langle\tau\rangle_w$ and the weight-average initial slope $\langle S\rangle_w$, respectively:

$$\langle\tau\rangle_w = \frac{\int_a^{a'}\tau(l)lf_n(l)dl}{\int_a^{a'}lf_n(l)dl}, \quad (4)$$

and

$$\langle S\rangle_w = -\frac{\int_a^{a'}\tau(l)^{-1}lf_n(l)dl}{\int_a^{a'}lf_n(l)dl}. \quad (5)$$

It should be emphasized that neither $\langle\tau\rangle_w$ nor $\langle S\rangle_w$ depends on the electric properties (β' and γ') and hence, not on the orientation mechanism. The relaxation time $\tau(l)$ for a thin, rodlike molecule of length l may be calculated from several expressions.[2] We employ the Broersma equation[22] (*cf.* Eq. 8 in Ref. 1).

In actual computations for $\Phi(\beta',\gamma')$, $\langle\tau\rangle_{EB}$, and $\langle S\rangle_{EB}$ as a function of electric field strength, the following values were used, unless otherwise specified:

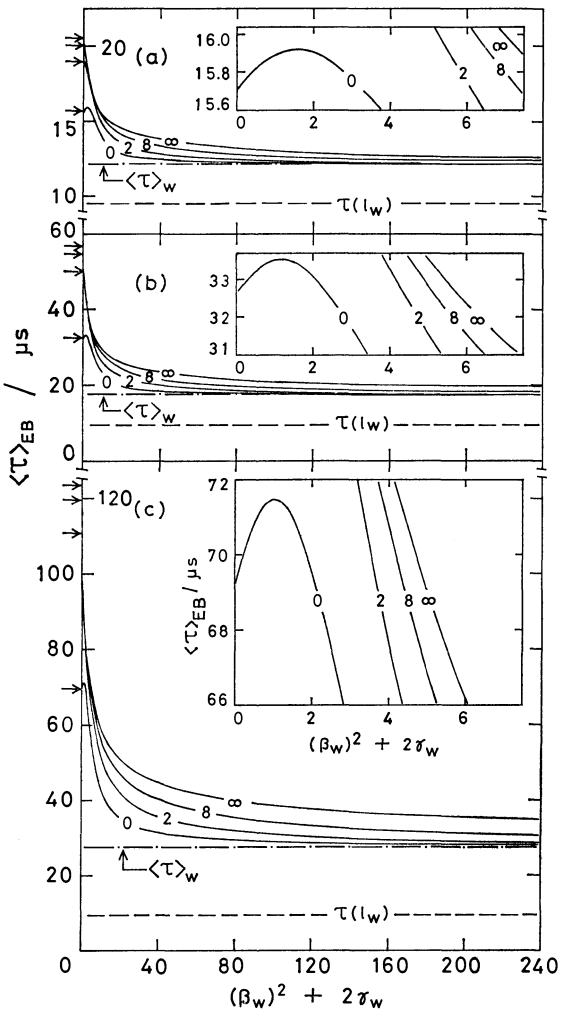

Fig. 2. Electric birefringence-average relaxation time $\langle\tau\rangle_{EB}$ as a function of $[(\beta_w)^2+2\gamma_w]$ for the polydisperse system with the l_w/l_n ratios of (a) 1.10, (b) 1.29, and (c) 1.87. Numerals in each figure correspond to the values of $(\beta_w)^2/2\gamma_w$; polarizability anisotropy only (0), mixed dipole (2 and 8), and permanent dipole only (∞). Lateral arrows on the ordinates indicate values of $\langle\tau\rangle_{EB}$ at limiting low fields. In each figure, the weight-average relaxation time $\langle\tau\rangle_w$ is shown by (—·—), while the field-independent relaxation time $\tau(l_w)$ for a monodisperse system, in which the length $l_w(=l_0)$ is 100 nm, is shown by (----). Inserts are the plots of $\langle\tau\rangle_{EB}$ *vs.* $[(\beta_w)^2+2\gamma_w]$ in the low field region. Note the scale on the ordinate of (a) differs from that of (b) and (c).

$\mu_0 = 3.0\times10^{-19}$ C (or 8.993 D/Å), $\Delta\alpha_0 = 1\times10^{-25}$ F m (or 8.985×10^{-12} cm^2) for the pure anisotropy orientation ($\Delta\alpha$ is variable for the mixed dipole orientation[17,18]), $l_w = 100$ nm, $2b$ (the diameter of a cylinder) $= 1.5$ nm, the viscosity of solvent $\eta_0 = 8.45\times10^{-4}$ Pa s, and $T = 293$ K. The upper and lower integral limits are set as $a = 5$ nm and $a' = 405$ nm, rather than as $a = 0$ and $a' = \infty$, because low molecular-weight-oligomers are often removed from a polymer sample (the upper limit was set for the convenience of completing computations with a sufficient accuracy).

Results and Discussion

Effect of Polydispersity on Relaxation Time. The field-strength dependence of $\langle\tau\rangle_{EB}$, calculated from Eq. 2, is plotted in Fig. 2 against $[(\beta_w)^2+2\gamma_w]$ at several ratios of $(\beta_w)^2/2\gamma_w$, where β_w and γ_w are the weight-averages of β' and γ'. The weight-average relaxation time $\langle\tau\rangle_w$ is drawn in each figure by a dash-dotted line, together with the field-independent single relaxation time $\tau(l_w)$ for the corresponding monodisperse system with the length of $l_o(=l_w)$ (dashed line) for comparison. The results are summarized below. (1) The relaxation time of a given polydisperse system strikingly depends on the electric pulse field applied prior to the start of decay process. This field dependence is quite sensitive to the polydispersity of the sample; hence, it is the best test for a length distribution. (2) The magnitude of $\langle\tau\rangle_{EB}$ is exceedingly large at extremely low electric field, as the ratio l_w/l_n increases. For example, the value of $\langle\tau\rangle_{EB}$ is as high as 123 μs for the most polydisperse sample ($l_w/l_n=1.87$), while it is only 9.62 μs for the corresponding monodisperse system (Fig. 2(c)). This is because $\tau(l)$ is proportional to the cube of l and because the polydisperse sample contains the components whose lengths are much longer than l_w (*cf.* Fig. 1). (3) In each polydisperse system, values of $\langle\tau\rangle_{EB}$ rapidly decrease with increasing field strengths and gradually become level. They should all approach the limiting value, *i.e.*, $\langle\tau\rangle_w$, which depends only on polydispersity and length.[12,17] (4) The field-strength dependence of $\langle\tau\rangle_{EB}$ is characteristic of the orientation mechanism. The pure permanent dipole moment orientation clearly shows a large but monotonous dependence. For pure polarizability orientation, however, the field dependence is not monotonous. In the low field range, there appears a maximum whose magnitude and position depend on polydispersity (see inserts in Figs. 2(a)—(c)). (5) For any polydisperse system, $\langle\tau\rangle_w$ does not coincide with $\tau(l_w)$, unless the length distribution is extremely narrow. This is an important consequence of polydispersity. If an average length of solutes in a polydisperse sample is calculated directly from the Broersma equation by using the experimentally obtained relaxation time $\langle\tau\rangle_w$ or $\langle\tau\rangle_{EB}$, the length would be unreasonably large. (It is $\tau(l_w)$ that is related to the weight-average length l_w.) Hence, an erroneous conclusion may be drawn on the overall solution conformation of the polymer system in which molecular lengths are heterogeneous.

Effect of Polydispersity on Initial Slope. The initial slope $\langle S\rangle_{EB}$ of a decay signal is a measure of polydispersity.[8,9,13,14] The results of the present calculation are illustrated in Fig. 3. Values of $\langle S\rangle_{EB}$ clearly depend on polydispersity ratio and field-orientation mechanism, slowly approaching the weight-average $\langle S\rangle_w$ at limiting high fields, which is, however, independent of the orientation mechanism in a manner similar to the case of relaxation time. It is interesting to note that values of $\langle S\rangle_{EB}$ in the low field range are close to the value of $S(l_w)$ for the monodisperse system (dashed line), if solutes are oriented predominantly by the permanent dipole moment $[(\beta_w)^2/2\gamma_w=\infty—8]$. For pure polarizability orientation, an extremum appears in the low field range, similarly to the case of the corresponding relaxation time.

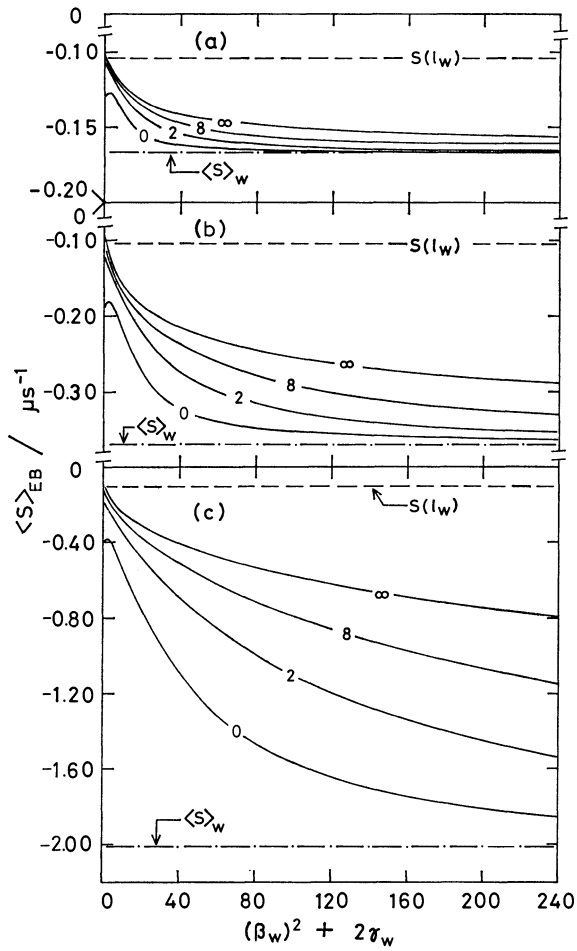

Fig. 3. Electric birefringence-average initial slope $\langle S\rangle_{EB}$ as a function of $[(\beta_w)^2+2\gamma_w]$ for a polydisperse system with three l_w/l_n ratios of (a) 1.10, (b) 1.29, and (c) 1.87. In each figure, the weight-average initial slope $\langle S\rangle_w$ is given by (—·—) and the field-independent initial slope $S(l_w)$ for a monodisperse system by (----), in which the length ($l_w=l_o$) is 100 nm.

Estimation of Weight-average Relaxation Time and Initial Slope. Values of $\langle\tau\rangle_w$ and $\langle S\rangle_w$ can be estimated by extrapolation of those of $\langle\tau\rangle_{EB}$ and $\langle S\rangle_{EB}$ to infinitely high field strength ($E\to\infty$). Figure 4 illustrates this extrapolation procedure with a polydisperse system ($l_w/l_n=1.29$ and $l_w=100$ nm). A problem is associated with the unknown curvature of the plot of $\langle\tau\rangle_{EB}$ or $\langle S\rangle_{EB}$ against the reciprocal of field strength. When $\langle\tau\rangle_{EB}$ is plotted against $[(\beta_w)^2+2\gamma_w]^{-1}$, which is proportional to E^{-2} (Fig. 4(a)), the curvature is convex and quite large for the permanent dipole moment orientation (∞), but it becomes concave with decreasing $(\beta_w)^2/2\gamma_w$ (2 and 0). When $\langle\tau\rangle_{EB}$ is plotted against $[(\beta_w)^2+2\gamma_w]^{-1/2}$, which is proportional to E^{-1} (Fig. 4(b)), the curvature is only slightly concave for all $(\beta_w)^2/2\gamma_w$ (∞—0). The similar results with reversed curvatures are found for $\langle S\rangle_{EB}$ (dashed curves in Figs. 4(a)—(b)). These plots are suggestive of

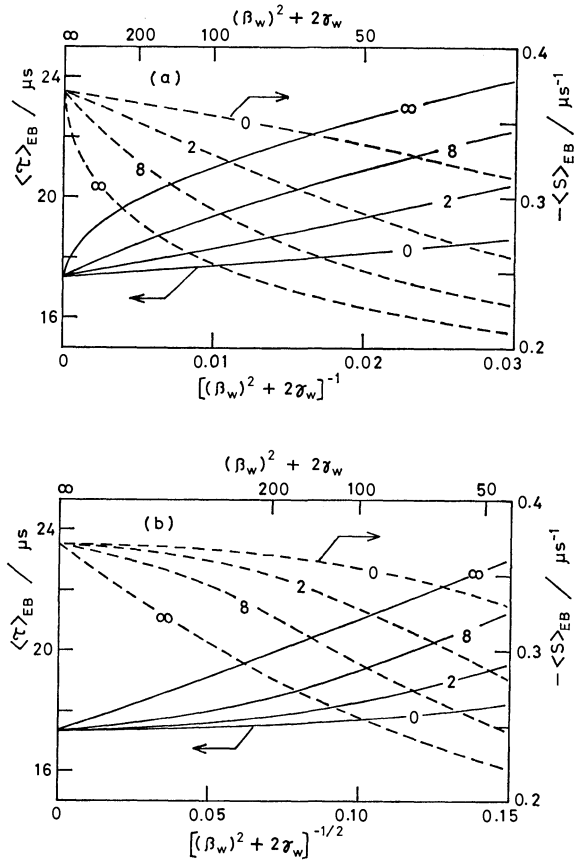

Fig. 4. Extrapolations of the birefringence-average relaxation time $\langle\tau\rangle_{EB}$ and initial slope $\langle S\rangle_{EB}$ to infinitely high electric fields. The birefringence-averages were calculated for a logarithmic-normal distribution with $l_w/l_n=1.29$ and $l_w=100$ nm. Values of $\langle\tau\rangle_{EB}$ (——) and $\langle S\rangle_{EB}$ (----) are plotted against $[(\beta_w)^2+2\gamma_w]^{-1}$ in (a) and against $[(\beta_w)^2+2\gamma_w]^{-1/2}$ in (b). A numeral in each curve is the value of $(\beta_w)^2/2\gamma_w$. Note that all curves intercept the ordinates ($\langle\tau\rangle_w=17.36$ μs and $\langle S\rangle_w=-0.37$ μs^{-1}).

the proper extrapolation procedure for evaluating $\langle\tau\rangle_w$ and $\langle S\rangle_w$. For example, extrapolation of observed values of $\langle\tau\rangle_{EB}$ to the intercept of the ordinate appears to be easier if they are plotted simultaneously against E^{-1} and against E^{-2}.

Application to Measured Decay Signals of sDNA. Figure 5 shows a typical extrapolation to infinitely high field of values of $\langle\tau\rangle_{EB}$ and $\langle S\rangle_{EB}$ which are observed for a sonicated DNA (sDNA) preparation in 0.2 mM NaCl** (the experimental details are found in Ref. 1). In the case of rodlike sDNA in aqueous solutions, the dependence of $\langle\tau\rangle_{EB}$ and $\langle S\rangle_{EB}$ on field strengths has not been fully resolved, since no appropriate counterion-induced orientation function is available as yet. Nevertheless, it has been shown that the "classical" function $\Phi(\beta',\gamma')$ can represent the birefringence and dichroism behavior of sDNA adequately over a wide range of field strength.[1,23,24] The plots in Fig. 4 are based on $\Phi(\beta',\gamma')$; thus, they are instructive as an empirical guide. Observed values of $\langle\tau\rangle_{EB}$ and $\langle S\rangle_{EB}$ for sDNA are plotted both

** 1 M=1 mol dm^{-3}.

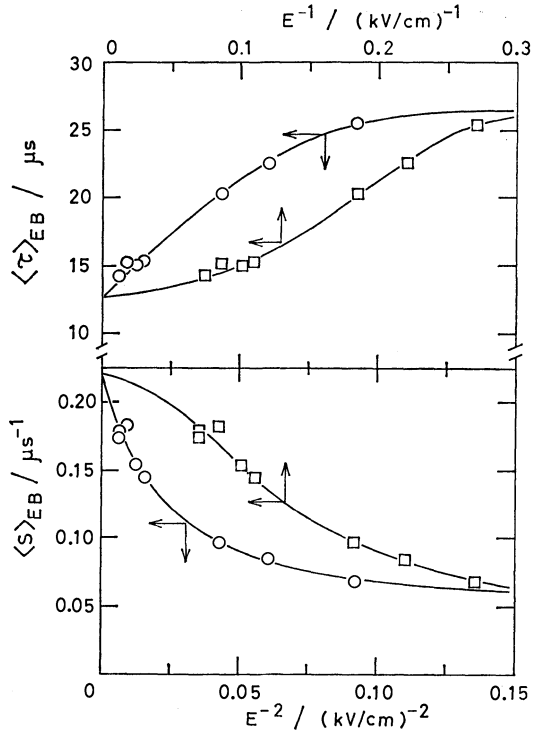

Fig. 5. Extrapolation of values of $\langle\tau\rangle_{EB}$ and $\langle S\rangle_{EB}$ experimentally obtained for a sonicated DNA sample in the 0.2 mM NaCl-containing aqueous solution.

against E^{-2} and against E^{-1} in Fig. 5. Extrapolated values are: $\langle\tau\rangle_w=12.5$ μs and $\langle S\rangle_w=-0.22$ μs^{-1}.

Evaluation of the Degree of Polydispersity and Weight-average Length. With a set of experimental values of $\langle\tau\rangle_w$ and $\langle S\rangle_w$, as obtained in the above section, both the weight-average length l_w and the polydispersity ratio l_w/l_n may be estimated, if the length distribution $f_n(l)$ is known or can be assumed for a given polydisperse system. For this purpose, we devised a new, convenient method, which may be termed the "mesh method," by constructing a theoretical graph of meshes. Examples are shown in Fig. 6, in which theoretical values of $\langle\tau\rangle_w$ (Eq. 4) are plotted against theoretical values of $\langle S\rangle_w$ (Eq. 5) with l_w and l_w/l_n as parameters. The Wesslau function (Fig. 6(a)) and the Schulz-Zimm function (Fig. 6(b))[1] are chosen for the distribution function $f_n(l)$, in order to compare the effect of the distribution curves on the final result. (The latter is said to be an appropriate function for the degradation process of chain length by sonication.[25]) Two values are assigned to 2b to see the effect of the diameter of rodlike molecules on the estimated values of l_w and l_w/l_n. A pair of experimental values ($\langle\tau\rangle_w$ and $\langle S\rangle_w$) defines a point in the $\langle\tau\rangle_w$—$\langle S\rangle_w$ coordinates; hence, the most likely set of l_w and l_w/l_n can be readily evaluated from the network. This mesh method is advantageous in that it can be used for rodlike polymers, whatever the field-orientation mechanism may be, because both $\langle\tau\rangle_w$ and $\langle S\rangle_w$ are independent of the electric parameters β' and γ' or the orientation function $\Phi(\beta',\gamma')$. The optical and electric parameters may be determined separately by the matching method previously mentioned for the steady-state birefringence[23] and dichro-

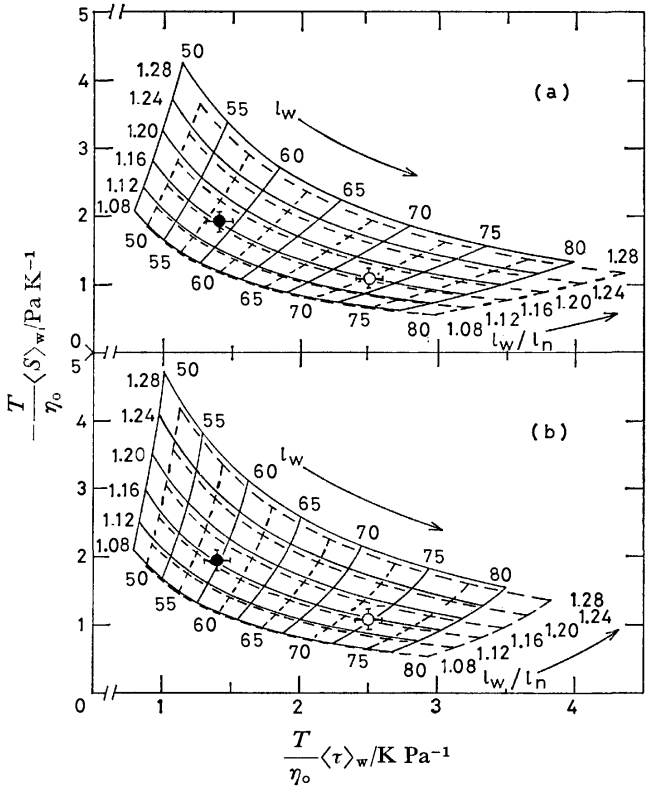

Fig. 6. The relationship between the weight-average relaxation time $\langle\tau\rangle_w$ and initial slope $\langle S\rangle_w$ with the polydispersity ratio l_w/l_n and the weight-average length l_w as the parameters. The distribution functions are the Wesslau type (a) and the Schulz-Zimm type (b). T is the absolute temperature and η_0 is the viscosity of solvent. Two different networks are plotted; one, for which the diameter of cylindrical like molecules, $2b$, is 2 nm (——), and the other with the diameter of 2.6 nm (----). For each set of meshes, values of l_w/l_n are varied between 1.08 and 1.28, while those of l_w between 50 and 80 nm. Experimental values of $\langle\tau\rangle_w$ and $\langle S\rangle_w$ for sDNA are also plotted: (○) in 0.2 mM NaCl and (●) in 0.33 mM $MgCl_2$.

ism,[24] once both l_w and l_w/l_n are available.

Paired-values of $\langle\tau\rangle_w$ and $\langle S\rangle_w$, experimentally obtained for the sDNA sample at different ionic strengths, are also plotted inside the meshes. The most probable values of l_w and l_w/l_n are summarized in Table 1. The effect of the "thickness" of a cylinder on l_w is such that the value of l_w with a diameter of 2.6 nm is smaller than that with 2.0 nm by about 5%. The choice of the distribution function is not too critical, when the range of l_w/l_n is limited to *ca.* 1.2 or less. When values of l_w are divided by the weight-average degree of polymerization or the number of base pairs (=188), the axial translation per base pair can be calculated (*cf.* Table 1 of Ref. 1). The value of l_w/l_n is close to the reported literature values (1.02—1.11),[26-28] which were determined by the sedimentation equilibrium and electron microscopic methods for fractionated sDNA samples. This good agreement, achieved by the utilization of different physical techniques and diverse sonication methods, appears to be a strong support for the present procedure for polydispersity determination.

Table 1. Polydispersity ratio, l_w/l_n, and weight-average length, l_w, of sonicated DNA in aqueous solutions evaluated by use of two distribution functions[a]

		Wesslau function		Schulz-Zimm function[b]	
	$2b$/nm[c]	2.0	2.6	2.0	2.6
A[d]	l_w/l_n	1.16	1.17	1.16	1.17
	l_w/nm	73	70	74	71
B[d]	l_w/l_n	1.16	1.17	1.16	1.17
	l_w/nm	59	56	60	57

a) The number of base pairs of this sDNA is 188.[1] b) The data are cited in Ref. 1. c) The assumed diameter of sDNA. d) sDNA in the 0.2 mM NaCl solution (A) and in the 0.33 mM $MgCl_2$ solution (B).[1]

Conclusion

With numerical calculations we could show how the decay processes of transient EB (and also ED) of a system composed of long, rigid rodlike macromolecules are affected by the polydispersity of continuous length distribution. The dependence of the relaxation time and the initial slope of an EB signal on the electric field strength applied to the system prior to the commencement of the decay is a very sensitive measure of polydispersity and field-orientation mechanism. We could show how incorrect interpretations of experimental data may be avoided. We have also described a new mesh method for determining the degree of polydispersity and the weight-average molecular length. Use of this method in conjunction with well-pursued experimental results will facilitate the EB and ED study of polydisperse, rodlike polymer systems.

(Received July 10, 1982)

The radical ions of (*Z*)-stilbene and its α,β-dialkyl derivatives were produced by γ-ray irradiation of the parent compounds in frozen matrices at 77 K, and their geometries were investigated by electronic absorption spectroscopy. While the relaxed geometries of the radical ions of (*Z*)-stilbene are probably similar to that of the neutral molecule, those of the radical ions of the α,β-dialkyl derivatives are appreciably different from those of the neutral molecules: The torsion angle of the central ethylenic bond is distinctly larger and that of each C–Ph bond is probably smaller in the radical ions than in the neutral molecules. On illumination the radical ions of (*Z*)-stilbene isomerize to the *E* isomers, but those of the α,β-dialkyl derivatives do not. A mechanism of the photoisomerization is proposed, and an interpretation of the difference in the photochemical behavior between the unsubstituted stilbene radical ions and the α,β-dialkyl derivatives is given.

The present paper reports the result of an electronic spectroscopic study of the geometry of the radical ions of (*Z*)-stilbene (abbreviated as ZS), (*Z*)-α,β-dimethylstilbene (ZαβDMS), and (*Z*)-α,β-diethylstilbene (ZαβDES). The radical ions were produced by γ-ray irradiation of frozen solutions of the respective compounds at 77 K, and their electronic absorption spectra measured before and after illumination or limited warming were examined with respect to the geometry of the radical ions.

This work has three purposes as follows.

(1) Previously, we found that the relaxed geometries of radical ions generated from sterically crowded compounds were appreciably different from those of the parent neutral molecules.[1,2] It is one of the purposes of the present work to examine the geometries of the radical ions of the sterically crowded (*Z*)-stilbenes and to compare them with the geometries of the parent molecules.

(2) The π-bond order of the central ethylenic bond (the α–β bond) of stilbene is smaller in the radical ions than in the neutral molecule.[2] Therefore, the thermal $Z \rightarrow E$ isomerization should occur more readily in the radical ions than in the neutral molecule. As expected, the anion radical produced from ZS by reduction with alkali metals in ethereal solutions readily isomerizes to the anion radical of (*E*)-stilbene (ES).[3] When the anion radical of ZS ($ZS^{-\cdot}$) forms an ion pair with the alkali counterion, its isomerization is comparatively slow.[4,5] When $ZS^{-\cdot}$ is not associated with the counterion, its isomerization occurs especially rapidly.[5,6] Wang *et al.* proposed a mechanism involving a dianion for the isomerization of the counterion-free $ZS^{-\cdot}$ to the counterion-free $ES^{-\cdot}$ in hexamethylphosphoric triamide (HMPT).[7] The radical ions produced by γ-ray irradiation in frozen matrices are counterion-free, and the possibility that the radical ions in the frozen matrices disproportionate to a pair of the diion and the neutral molecule should be extremely small. Therefore, it is of interest to examine whether the radical ions of the (*Z*)-stilbenes in frozen matrices isomerize to the *E* isomers on limited warming. This is the second of the purposes of the present work.

(3) Both the cation and the anion radical of ZS in frozen matrices at 77 K undergo the $Z \rightarrow E$ photoisomerization on visible light illumination.[8,9] It is the third of the purposes to examine whether the photoisomerization occurs also in the radical ions of the crowded α,β-dialkyl derivatives.

Experimental

Materials. (Z)-*Stilbene (ZS)*: A commercial product of Aldrich Chemical Co. was used: UV_{max} (heptane) 278.7 nm (ε 1.031×10^4).

(Z)-*α,β-Dimethylstilbene (ZαβDMS)*: This compound was prepared as described previously:[10] UV_{max} (heptane) 252.0 nm (ε 8.88×10^3).

(Z)-*α,β-Diethylstilbene (ZαβDES)*: This compound was newly prepared as follows. Reductive coupling of propiophenone (4.03 g) with titanium(IV) chloride (8.6 g) and zinc (5.9 g) in dioxane (200 cm^3) was carried out according to the procedure of Mukaiyama *et al.*[11] After work-up, the residue was chromatographed twice on silica gel columns by using hexane as the eluent to give 700 mg of a colorless oil. Kugelrohr distillation of the oil gave an analytically pure sample of ZαβDES, which solidified in the receiver: mp 32.5—34.0 °C, uncorrected; UV_{max} (heptane) 248.8 nm (ε 8.87×10^3); ^1H NMR ($CDCl_3$) δ=7.12 (10H, br s, $2C_6H_5$), 2.62 (4H, q, J=8 Hz, $2CH_2$), 1.00 (6H, t, J=8 Hz, $2CH_3$). Found: C, 91.38; H, 8.73%; M^+, 236. Calcd for $C_{18}H_{20}$: C, 91.47; H, 8.53%; M, 236. Earlier reports[12–14] on this compound are now to be corrected, because the sample prepared previously [an oil: UV_{max} (ethanol) 244 nm (ε 7.74×10^3)] has, in the course of the present work, proved not to be pure.

Spectra of Radical Ions. The radical ions of ZS, ZαβDMS, and ZαβDES were prepared by γ-ray irradiation of frozen solutions of the parent compounds in deaerated 2-methyltetrahydrofuran (MTHF) for anion radicals and in *s*-butyl chloride (BC) or a Freon Mixture (FM: an equivolume mixture of trichlorofluoromethane and 1,2-dibromo-1,1,2,2-tetrafluoroethane) for cation radicals both at 77 K. The electronic absorption spectra of the γ-ray irradiated

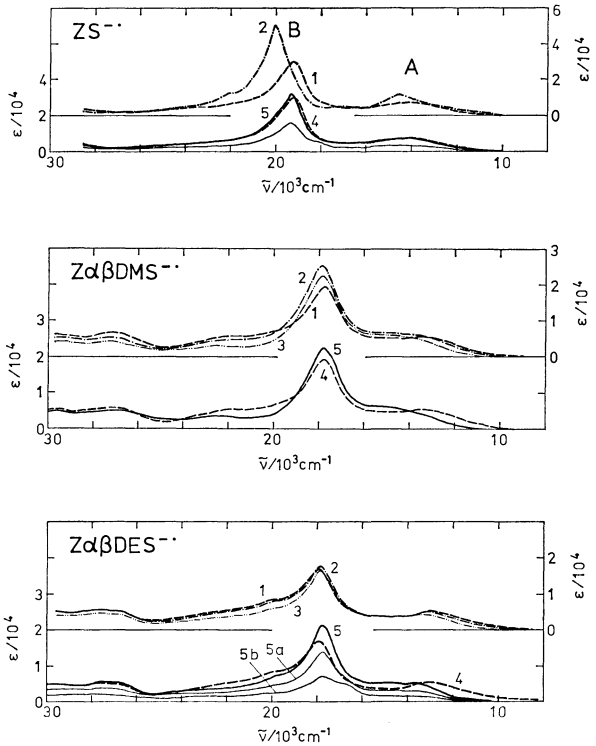

Fig. 2. Electronic absorption spectra of the anion radicals of (Z)-stilbene (ZS), (Z)-α,β-dimethylstilbene (ZαβDMS), and (Z)-α,β-diethylstilbene (ZαβDES). Curves 1 and 4 (----): spectra observed immediately after γ-ray irradiation of frozen solution, designated F in the text. Curve 2 (—·—): spectra observed after illumination of the sample for curve 1 with light of wavelengths corresponding to band A, designated PA in the text. Curve 3 (—··—): spectra observed after illumination of the sample for curve 2 with light of wavelengths corresponding to and longer than band B, designated PB in the text. Curve 5 (——): spectra observed after controlled warming of the sample for curve 4, designated W in the text. Curves 5a and 5b (——): spectra observed after additional controlled warming of the sample for curve 5. The solvent is 2-methyltetrahydrofuran (MTHF) for all the spectra.

samples were measured before and after illumination with visible light or warming for a limited period. The experimental details are the same as described in previous papers.[1,2]

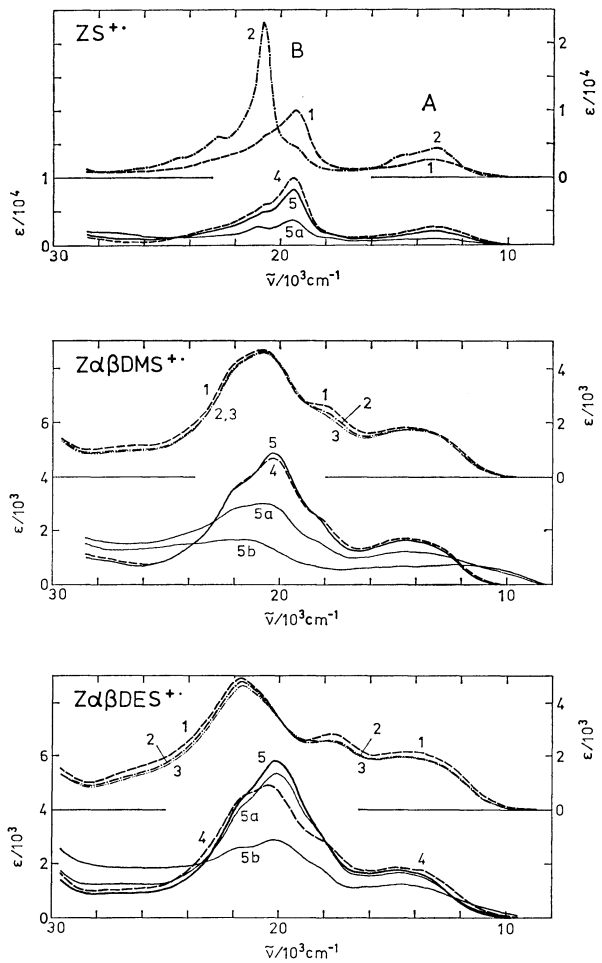

Fig. 3. Electronic absorption spectra of the cation radicals of ZS, ZαβDMS, and ZαβDES. See Caption for Fig. 2. The solvent is s-butyl chloride (BC) for spectra 1, 2, and 3, and is a Freon Mixture (FM) for the other spectra.

Molecular Orbital Calculation

As in the previous work,[1,2] a semiempirical SCF-MO-CI calculation was carried out for the radical ions by the Longuet-Higgins and Pople method.[15]

The numbering of the carbon atoms is illustrated for ZS in Fig. 1. Torsion angles β–α–1–6, α–β–1′–6′, and 1–α–β–1′ are denoted by $\theta_{\alpha 1}$, $\theta_{\beta 1'}$, and $\theta_{\alpha\beta}$, respectively. The value of $\theta_{\alpha\beta}$ is 0° for the planar Z configuration and 180° for the planar E configuration.

Results and Discussion

Designation of Spectra and of Geometries. Representative spectra of the radical ions are shown in Figs. 2 and 3, and relevant data are listed in Tables 1 and 2. As seen in the figures, the radical ions exhibit two major bands in the visible region. The band at the longer wavelength is designated as A, and that at the shorter wavelength as B. For band A, for example, the wavelength (λ) and molar absorption coefficient (ε) at the absorption maximum and the oscillator strength (f) are denoted by λ_A, ε_A, and f_A, re-

a) Transitions are numbered in the order of increasing transition energy. b) Transition energy. c) Oscillator strength of the transition. d) Direction of the transition moment (*cf.* Fig. 1). e) The excited state. f) The symmetry species to which the excited state belongs. The ground state (state D_0) belongs to symmetry species A_2. g) The wave function of the excited state. Only the electron configuration whose coefficient in the wave function is the largest is shown, together with the coefficient. Symbol (i, j) denotes the electron configuration arising from the ground configuration by promotion of an electron from π MO ϕ_i to π MO ϕ_j. The orbital index i runs from +7 for the lowest orbital to −7 for the highest one in the order of increasing energy. Orbitals ϕ_{+1} and ϕ_{-1} correspond, respectively, to HOMO and LUMO in the molecule. The coefficient of the ground configuration in the wave function of state D_0 is 0.989.

spectively.

As in Part II of this series,[2] spectra of radical ions measured after different treatments are designated as follows: The spectrum of a radical ion measured immediately after its production by γ-ray irradiation in a frozen matrix is designated as F (*frozen*), that measured after illumination as P (*photobleached*), that measured after controlled warming as W (*warmed*). Sometimes, spectrum P measured after illumination with light of wavelengths corresponding to band A (illumination A) is referred to as spectrum PA, and that measured after illumination with light of wavelengths corresponding to and longer than band B (illumination B) as spectrum PB. If necessary, the solvent is denoted

a) The values for the nonplanar geometries are relative to the planar geometry.

in parentheses: For example, spectrum F of a cation radical in solution in *s*-butyl chloride is referred to as spectrum F(BC).

The same designations are also used to specify the geometries of radical ions after the respective treatments. That is, for example, the geometry of a cation radical immediately after its production in frozen *s*-butyl chloride is referred to as geometry F(BC). The relaxed geometry of a radical ion, that is, the geometry that the radical ion would take in fluid solutions, is referred to as geometry R (*relaxed*), and that of the parent neutral molecule as geometry N (*neutral*). Geometry W is considered to be nearly equal to geometry R.[1,2)]

We should like to emphasize that the spectral changes caused by illumination or controlled warming, shown in Figs. 2 and 3, are definite and reproducible, which should defy possible skepticism about attaching significance to the apparently small spectral changes discussed in the following text. The instrumental reproducibility is within ±0.1% for both the ordinate and the abscissa of these figures.

Assignment of Absorption Bands. The results of the MO calculation for the stilbene anion radical in the planar *Z* form are shown in Table 3. It is notable that the f values of transitions 3 and 5 are considerably smaller than the corresponding values for the anion radical in the planar *E* form (*cf.* Table 3 in Part II), and that the f value of transition 4 is not zero in contrast to the case of the planar *E* form. The results of the MO calculation for the cation radical are similar to those for the anion radical. The character of each state of the radical ions in the *Z* form is analogous to that of the corresponding state of the radical ions in the *E* form.[2)]

As in the case of the *E* isomers,[2)] bands A and B are ascribed to transitions 3 and 5, respectively. The band appearing between bands A and B in spectra of Z$\alpha\beta$DMS$^{+\cdot}$ and Z$\alpha\beta$DES$^{+\cdot}$ is ascribed to transition 4. In the spectra of the other radical ions, the absorption due to transition 4 is probably masked by the tails of bands A and B. The f values in Tables 1 and 2 may be less accurate than the corresponding values for the radical ions of sterically uncrowded or less crowded (*E*)-stilbenes in Part II,[2)] because of the presence of the superposing absorption due to transition 4 and also because of the comparatively small separation of bands A and B.

Expected Effects of Geometrical Changes on the Electronic Transitions. Table 4 lists the calculated values of the transition energy (ΔE) and oscillator strength (f) of transitions 3, 4, and 5 and of the ratio between the f values of transitions 3 and 5 (f_3/f_5) for the stilbene anion radical in the planar *Z* geometry and also the calculated values of the changes in these quantities associated with the changes from the planar *Z* geometry to nonplanar geometries in which $|\theta_{\alpha 1}|$, $|\theta_{\beta 1'}|$, or $|\theta_{\alpha\beta}|$ is 30°. The corresponding values for the cation radical are very close to the values for the anion radical.

The changes in the properties of the transitions of the anion radical associated with the geometrical changes seen in Table 4 and the corresponding ones of the cation radical should represent the effect of the geometrical changes on the absorption bands: It is expected, for example, that an increase in $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ will cause a large red shift and a very small increase in intensity of band A, a large blue shift and a small decrease in intensity of band B, and an increase in f_A/f_B, and that an increase in $|\theta_{\alpha\beta}|$ will cause a large blue shift and a very small increase in intensity of band A, a large red shift and a small increase in intensity of band B, and a decrease in f_A/f_B.

Geometry of the Neutral Molecules. Before proceeding to the discussion of the geometries of the radical ions, we briefly mention the geometry of the parent neutral molecules, which is relevant to the later discussion.

According to an electron-diffraction study, the molecule of ZS in the gas phase has a propeller-like geometry with C_2 symmetry, in which $\theta_{\alpha 1}$ and $\theta_{\beta 1'}$ are about 43°.[16)] This value is larger than predicted by most theoretical calculations.[17)] The value for the ZS molecule in solution is probably smaller than that for the molecule in the gas phase. The former is estimated at 29° from the λ_{max} value (278.7 nm) of the main absorption band of ZS in heptane solution.[12,14,20)]

By the method described in Refs. 12—14 and 20, the value of $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ is estimated at 52° for Z$\alpha\beta$DMS in solution from its λ_{max} value of 252.0 nm (in heptane) and at 54° for Z$\alpha\beta$DES in solution from its λ_{max} value of 248.8 nm (in heptane). When an allowance for the electronic bathochromic effect of the alkyl substituents is made, these values are revised to 59° and 61°, respectively.[21)]

At any rate, it is evident that the value of $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ in the relaxed geometry of the neutral molecule (*i.e.*, geometry N) increases in the order ZS$\ll$ Z$\alpha\beta$DMS$<$Z$\alpha\beta$DES. The value of $\theta_{\alpha\beta}$ in geometries N of these compounds is probably equal or close to 0°.

Broadness of Absorption Bands. Now, let us return to the spectra of the radical ions. The absorption bands of the radical ions of the (*Z*)-stilbenes are structureless and are much broader than those of the radical

ions of sterically uncrowded (*E*)-stilbenes.[24] This seems to indicate the nonplanarity of the geometry of the radical ions of the (*Z*)-stilbenes.

Effect of Warming and Relaxed Geometries. Cation Radicals: In spectra F(BC) of the cation radicals, λ_B/nm decreases in the order $ZS^{+\cdot} > Z\alpha\beta DMS^{+\cdot} > Z\alpha\beta DES^{+\cdot}$. This indicates that $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ increase in the order $ZS^{+\cdot} < Z\alpha\beta DMS^{+\cdot} < Z\alpha\beta DES^{+\cdot}$ in geometries F(BC) of the cation radicals as in geometries N. If $\theta_{\alpha\beta}$ were nearly 0° or nearly constant in geometries F(BC) of these cation radicals, λ_A/nm and f_A/f_B would increase in the order $ZS^{+\cdot} < Z\alpha\beta DMS^{+\cdot} < Z\alpha\beta DES^{+\cdot}$. In fact, they increase in the order $Z\alpha\beta DMS^{+\cdot} < Z\alpha\beta DES^{+\cdot} < ZS^{+\cdot}$. This fact suggests that in geometries F(BC) $|\theta_{\alpha\beta}|$ is appreciably larger for $Z\alpha\beta DMS^{+\cdot}$ and $Z\alpha\beta DES^{+\cdot}$ than for $ZS^{+\cdot}$.

Spectrum F(FM) of $ZS^{+\cdot}$ is similar to spectrum F(BC), and remains almost unchanged on limited warming. These facts indicate that geometry F(FM) of this cation radical is similar to geometry F(BC), which is probably similar to geometry N, and that any significant geometrical change does not occur on the warming.

On the other hand, spectra F(FM) of $Z\alpha\beta DMS^{+\cdot}$ and $Z\alpha\beta DES^{+\cdot}$ are significantly different from spectra F(BC), and change appreciably on limited warming. In going from spectra F(BC) to spectra W(FM), λ_B/nm increases for both the cation radicals, and λ_A/nm and f_A/f_B decrease for $Z\alpha\beta DES^{+\cdot}$. These changes indicate an increase in $|\theta_{\alpha\beta}|$ and/or a decrease in $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$. The geometrical change from F(BC) to W(FM) appears to be larger for $Z\alpha\beta DES^{+\cdot}$ than for $Z\alpha\beta DMS^{+\cdot}$. Spectra W(FM) of these cation radicals are different from spectra W(FM) of the *E* isomers (*cf.* Part II[2]).

In spectra W(FM), λ_B/nm increases in the order $Z\alpha\beta DMS^{+\cdot} < Z\alpha\beta DES^{+\cdot}$, and λ_A/nm and f_A/f_B decrease in the order $Z\alpha\beta DMS^{+\cdot} > Z\alpha\beta DES^{+\cdot}$. These sequences are opposite to the corresponding ones in spectra F(BC). Since it is unlikely that $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ are larger in $Z\alpha\beta DMS^{+\cdot}$ than in $Z\alpha\beta DES^{+\cdot}$, the above sequences indicate that in geometries W(FM) and therefore in geometries R (*i.e.*, the relaxed geometries) $|\theta_{\alpha\beta}|$ is considerably larger in $Z\alpha\beta DES^{+\cdot}$ than in $Z\alpha\beta DMS^{+\cdot}$.

Thus, it is concluded that, in geometries W and therefore in geometries R of the cation radicals, $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ increase in the order $ZS^{+\cdot} \ll Z\alpha\beta DMS^{+\cdot} \leqq Z\alpha\beta DES^{+\cdot}$ and $|\theta_{\alpha\beta}|$ increases in the order $ZS^{+\cdot} \ll Z\alpha\beta DMS^{+\cdot} \ll Z\alpha\beta DES^{+\cdot}$.

Anion Radicals: In spectra F(MTHF) of the anion radicals, λ_A/nm increases in the order $ZS^{-\cdot} < Z\alpha\beta DMS^{-\cdot} < Z\alpha\beta DES^{-\cdot}$, and λ_B/nm increases and f_A/f_B decreases in the order $ZS^{-\cdot}$, $Z\alpha\beta DES^{-\cdot}$, $Z\alpha\beta DMS^{-\cdot}$. The sequences probably indicate that in geometries F(MTHF) $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ increase in the order $ZS^{-\cdot} < Z\alpha\beta DMS^{-\cdot} < Z\alpha\beta DES^{-\cdot}$ and $|\theta_{\alpha\beta}|$ is noticeably larger in $Z\alpha\beta DMS^{-\cdot}$ and $Z\alpha\beta DES^{-\cdot}$ than in $ZS^{-\cdot}$. This means that geometries F(MTHF) of $Z\alpha\beta DMS^{-\cdot}$ and $Z\alpha\beta DES^{-\cdot}$ have already been relaxed to a considerable extent before being warmed, owing to the softness of the MTHF glass at 77 K.[1,2]

On limited warming, the spectrum of $ZS^{-\cdot}$ changes little, indicating that the geometry remains almost unchanged.

On the other hand, for $Z\alpha\beta DMS^{-\cdot}$ and $Z\alpha\beta DES^{-\cdot}$ the limited warming causes a large blue shift of band A and a small red shift and an increase in intensity of band B. The spectral changes indicate an increase in $|\theta_{\alpha\beta}|$ and/or a decrease in $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$. Spectra W(MTHF) of these anion radicals are different from spectra W(MTHF) of the *E* isomers (*cf.* Part II[2]).

In spectra W(MTHF), the values of λ_A/nm and λ_B/nm of $Z\alpha\beta DMS^{-\cdot}$ are close to those of $Z\alpha\beta DES^{-\cdot}$. This similarity of the band position does not necessarily mean the geometrical similarity of these two anion radicals. Since the value of f_A/f_B is noticeably different between the two anion radicals, and also in view of the above conclusion on geometries W of the corresponding cation radicals, geometries W of these anion radicals seem to be considerably different from each other. Probably both $|\theta_{\alpha\beta}|$ and $|\theta_{\alpha 1}|$ as well as $|\theta_{\beta 1'}|$ increase in the order $Z\alpha\beta DMS^{-\cdot} < Z\alpha\beta DES^{-\cdot}$. The increase in $|\theta_{\alpha\beta}|$ and that in $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ should have opposite effects on the band position. The above-mentioned similarity of the band position is probably a result of balancing of the opposite effects.

Thus, it is concluded that, in geometries W and therefore in geometries R of the anion radicals, $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ increase in the order $ZS^{-\cdot} < Z\alpha\beta DMS^{-\cdot} < Z\alpha\beta DES^{-\cdot}$ and $|\theta_{\alpha\beta}|$ increases in the order $ZS^{-\cdot} \ll Z\alpha\beta DMS^{-\cdot} < Z\alpha\beta DES^{-\cdot}$.

While the position of band B in spectrum W of $ZS^{-\cdot}$ is close to that in spectrum W of $ZS^{+\cdot}$, band B in spectrum W of $Z\alpha\beta DMS^{-\cdot}$ and that of $Z\alpha\beta DES^{-\cdot}$ are located at much longer wavelength than are those of the corresponding cation radicals. In addition, the magnitude of the blue shift of band A in going from spectrum F to spectrum W is much larger for $Z\alpha\beta DMS^{-\cdot}$ and $Z\alpha\beta DES^{-\cdot}$ than for the corresponding cation radicals. These facts probably indicate that $|\theta_{\alpha\beta}|$ is larger in $Z\alpha\beta DMS^{-\cdot}$ and $Z\alpha\beta DES^{-\cdot}$ in geometry R than in the corresponding cation radicals in geometry R.

Comparison with Other Spectral Data: The value of λ_{max} of the sodium salt of $ZS^{-\cdot}$ in fluid solution in THF was reported to be 500 nm (ε 3.3×10^4).[7] This value is considerably smaller than the values of λ_B of $ZS^{-\cdot}$ in the present work. Since the sodium salt in THF probably exists as a contact ion pair, the difference in the λ_{max} value may be mainly ascribed to the effect of the counterion.

The values of λ_{max} of the anion radicals produced by reduction of 1,2-diphenylcyclopentene (DPCP) and 1,2-diphenylcyclohexene (DPCH) with sodium in HMPT were reported to be 530 nm (ε 3.4×10^4) and 560 nm (ε 2.3×10^4), respectively.[25] In this solvent the anion radicals are probably counterion-free. These anion radicals have a $ZS^{-\cdot}$ π system, and obviously the above data refer to band B of the π system. In $DPCP^{-\cdot}$ $|\theta_{\alpha\beta}|$ should be close to 0°, while in $DPCH^{-\cdot}$ it may deviate to some extent from 0°. The fact that the λ_{max} value of $DPCH^{-\cdot}$ is considerably larger than that of $DPCP^{-\cdot}$ indicates that the value of $|\theta_{\alpha\beta}|$ is considerably larger in $DPCH^{-\cdot}$ than in $DPCP^{-\cdot}$.[26]

The values of λ_{max} and ε_{max} of DPCP$^{-\cdot}$ are close to the values of λ_B and ε_B of spectrum W of ZS$^{-\cdot}$. Since the small difference in the λ value may be largely ascribed to the electronic bathochromic effect of the trimethylene chain in DPCP$^{-\cdot}$, if the difference in $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ between these anion radicals is assumed to be small, this spectral similarity is taken as a support to our conclusion that $|\theta_{\alpha\beta}|$ of ZS$^{-\cdot}$ in the relaxed geometry is approximately 0°.

The values of λ_{max} and ε_{max} of DPCH$^{-\cdot}$ are close to the values of λ_B and ε_B of spectra W of Z$\alpha\beta$DMS$^{-\cdot}$ and Z$\alpha\beta$DES$^{-\cdot}$. The electronic effect of the alkyl substituents should be approximately equal in these three anion radicals. Therefore, this spectral similarity indicates the geometrical similarity of the ZS$^{-\cdot}$ π systems in these anion radicals and supports our conclusion that $|\theta_{\alpha\beta}|$ in Z$\alpha\beta$DMS$^{-\cdot}$ and Z$\alpha\beta$DES$^{-\cdot}$ in the relaxed geometry deviates considerably from 0°.

The values of λ_{max} and ε_{max} of spectra F of Z$\alpha\beta$DMS$^{-\cdot}$ and Z$\alpha\beta$DES$^{-\cdot}$ are similar to those of DPCH$^{-\cdot}$, but different from those of DPCP$^{-\cdot}$. This fact seems to support the above inference that geometries F(MTHF) of Z$\alpha\beta$DMS$^{-\cdot}$ and Z$\alpha\beta$DES$^{-\cdot}$ have already been relaxed to a considerable extent.

General Conclusions on the Effect of Warming and on the Relaxed Geometries: From the study of limited warming, the following conclusions are drawn.

(1) Neither the $Z\rightarrow E$ nor the $E\rightarrow Z$ isomerization occurs on limited warming of glassy solutions of the radical ions of ZS, Z$\alpha\beta$DMS, Z$\alpha\beta$DES, or their E isomers (ES, E$\alpha\beta$DMS, E$\alpha\beta$DES).

(2) The relaxed geometries of the radical ions of ZS are almost similar to that of the neutral molecule, in which $|\theta_{\alpha\beta}|$ is approximately 0° and $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ are about 30°. It is possible that $|\theta_{\alpha\beta}|$ in the ZS radical ions in the relaxed geometry is slightly larger than that in the neutral molecule and that $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ in the former are slightly smaller than those in the latter.

(3) In the radical ions of Z$\alpha\beta$DMS and Z$\alpha\beta$DES in the relaxed geometry $|\theta_{\alpha\beta}|$ deviates considerably from 0°.

(4) $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ in the radical ions of Z$\alpha\beta$DMS and Z$\alpha\beta$DES in the relaxed geometry are probably somewhat smaller than those in the corresponding neutral molecules, but they are appreciably larger than those in the radical ions of ZS in the relaxed geometry.

Conclusions 2 and 3 are rationalized as follows. In the radical ions of ZS, the steric interference between the two phenyl groups can be relieved effectively by an increase in $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ as in the neutral molecule. There seems to be no need for the increase in $|\theta_{\alpha\beta}|$. On the other hand, in the radical ions of Z$\alpha\beta$DMS and Z$\alpha\beta$DES, the steric interference between the two alkyl groups is relieved only by an increase in $|\theta_{\alpha\beta}|$.

Conclusion 4 also seems to be quite reasonable, since the steric interference between the phenyl group and the alkyl group connected to the same carbon atom in the radical ions of Z$\alpha\beta$DMS and Z$\alpha\beta$DES remains unrelieved even when $|\theta_{\alpha\beta}|$ increases, and can be relieved only by an increase in $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$.

As mentioned in Part II,[2] the relaxed geometry of a radical ion in its ground state (state D_0) is expected to be intermediate between the geometries of the neutral molecule in its ground state (state S_0) and in its first excited singlet state (state S_1). According to a theoretical calculation by Fischer *et al.*,[19] $\theta_{\alpha\beta}$ is 37° and 49° in ZS and Z$\alpha\beta$DMS, respectively, both in state S_1, while $\theta_{\alpha 1}$ and $\theta_{\beta 1'}$ are 13° in both the molecules in state S_1.[28] The result that $\theta_{\alpha\beta}$ in Z$\alpha\beta$DMS in state S_1 has a considerably large value is consistent with Conclusion 3. However, the other results are inconsistent with Conclusions 2 and 4.

Effect of Illumination. As mentioned above, both the cation and the anion radical of ZS in frozen solutions at 77 K isomerize irreversibly to their E isomers on illumination.

In contrast, the radical ions of Z$\alpha\beta$DMS and Z$\alpha\beta$DES do not isomerize on illumination. The spectra of the cation radicals in frozen BC change only slightly on illumination. In the case of the anion radicals in frozen MTHF, on illumination spectral changes similar to those caused by limited warming occur: Band A shifts to shorter wavelengths, band B increases in intensity, and f_A/f_B decreases. These spectral changes indicate an increase in $|\theta_{\alpha\beta}|$ and a decrease in $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ as in the case of warming, but there is no indication of occurrence of the $Z\rightarrow E$ isomerization.

As seen in Part II,[2] the radical ions of E$\alpha\beta$DMS and E$\alpha\beta$DES do not isomerize on illumination. Spectra PB of the radical ions of Z and E isomers of the α,β-dialkylstilbenes ($\alpha\beta$DAS's) appear distinctly different. Thus, it is concluded that in the radical ions of the $\alpha\beta$DAS's in frozen matrices at 77 K neither the photoisomerization between Z and E isomers nor the photoconversion from both Z and E isomers to a common product occurs.

Mechanism of the Z→E *Photoisomerization of the Unsubstituted Stilbene Radical Ions.* We propose here a mechanism of the photoisomerization of the stilbene radical ions and account for the notable difference in the photochemical behavior between the unsubstituted and the α,β-dialkyl-substituted stilbene radical ions.

The photoisomerization process of the stilbene radical ions is explicable by the diagrams in Fig. 4, which show the state energies as functions of $|\theta_{\alpha\beta}|$. The diagrams were drawn in the light of the results of the MO calculation, spectroscopic data, and the fact that the change in $|\theta_{\alpha\beta}|$ should be accompanied by a change in $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$.

As mentioned above, for both the cation and the anion radical, and for both the Z and the E isomer, state D_5 is approximated as the state arising from state D_0 as a result of promotion of an electron from ψ_{+1} to ψ_{-1}. That is, aside from the closed electron configuration in which the six lowest-energy π orbitals (from ψ_{+7} to ψ_{+2}) are filled, states D_0 and D_5 of the cation radical are approximated by electron configurations $\psi_{+1}{}^1$ and $\psi_{-1}{}^1$, respectively, and states D_0 and D_5 of the anion radical by electron configurations $\psi_{+1}{}^2\psi_{-1}{}^1$ and $\psi_{+1}{}^1\psi_{-1}{}^2$, respectively.

At $|\theta_{\alpha\beta}|=90°$, ψ_{+1} and ψ_{-1} form a degenerate pair of orbitals. When $|\theta_{\alpha\beta}|$ increases from the Z side to the E side across this point, ψ_{+1} and ψ_{-1} are con-

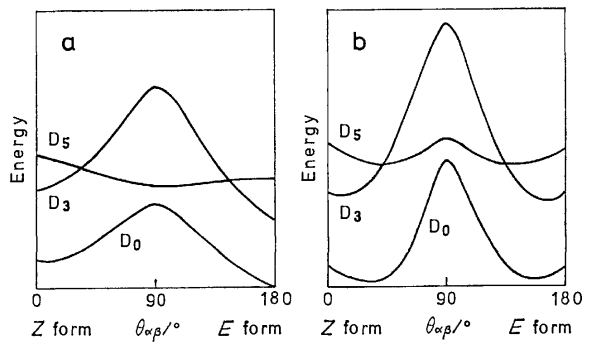

Fig. 4. State energies *vs.* the torsion angle about the central ethylenic bond ($\theta_{\alpha\beta}$).
(a): The unsubstituted stilbene radical ions. (b): The α,β-dialkylstilbene radical ions.

verted into ψ_{-1} and ψ_{+1}, respectively. Therefore, to a first approximation, states D_5 and D_0 are degenerate at $|\theta_{\alpha\beta}|=90°$, and, when $|\theta_{\alpha\beta}|$ increases from the Z side to the E side across this point, states D_5 and D_0 are converted into states D_0 and D_5, respectively. In fact, as a result of configuration interaction, the energy curves for these states must be separated as shown in Fig. 4, but the energy gap between these states at $|\theta_{\alpha\beta}|=90°$ should be small. Therefore, the internal conversion will occur with a high probability from state D_5 to state D_0 near this point.

In the E form of the unsubstituted stilbene radical ions, $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ are approximately 0°. In the Z form also they are small. Therefore, the π-bond order of the α–β bond is low. Accordingly, the energy barrier at $|\theta_{\alpha\beta}|=90°$ in state D_0 should be low, and the energy of state D_5 at this point should also be low. Thus, the energy of state D_5 will decrease as $|\theta_{\alpha\beta}|$ increases from 0° to 90°. The possible small decrease in $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ associated with the increase in $|\theta_{\alpha\beta}|$ will lower the energies of states D_5 and D_0 to some extent.

After all, the $Z\rightarrow E$ photoisomerization is considered to proceed as follows: $D_0(Z) \longrightarrow D_5(Z) \rightsquigarrow D_5(|\theta_{\alpha\beta}|=90°) \rightsquigarrow D_0(|\theta_{\alpha\beta}|=90°) \rightsquigarrow D_0(E)$. In this scheme, a radiative transition is represented by a straight arrow, and radiationless ones by wavy arrows. The basic assumption in this mechanism is that the photoisomerization proceeds via state D_5, the final state of the electronic transition responsible to band B.

Actually, even illumination A (illumination with light of wavelengths corresponding to band A), that is, the excitation to state D_3, induces the $Z\rightarrow E$ isomerization. In this case, the photoisomerization will proceed as follows. The radical ion passes from state D_3 to state D_5 at the crossing point ($0°<|\theta_{\alpha\beta}|<90°$) of the energy curves of the two states (*cf.* Fig. 4 (a)), and then the isomerization occurs: $D_0(Z) \longrightarrow D_3(Z) \rightsquigarrow D_3$(the crossing point) $\rightsquigarrow D_5$(the crossing point) $\rightsquigarrow D_5(|\theta_{\alpha\beta}|=90°) \rightsquigarrow D_0(|\theta_{\alpha\beta}|=90°) \rightsquigarrow D_0(E)$. Passing from state $D_3(Z)$ to the crossing point involves moving along a rising curve, *i.e.*, overriding a small barrier. The energy necessary to override the barrier must be supplied as vibrational energy.

Recently, Sazhnikov *et al.*[29,30] measured the wavelength dependence of the quantum yield of the $Z\rightarrow E$ photoisomerization of the radical ions of the unsubstituted stilbene in glassy solutions at 77 K, and found the following facts. (1) The quantum yield is very high on illumination with light of wavelengths corresponding to the "second absorption band" (*i.e.*, band B in our designation), 400—600 nm. (2) The maximum value of the quantum yield is extremely high. For the anion radical it is as high as 0.60 at 529 nm (nearly the absorption maximum of band B), a value which is much higher than the corresponding value for the $Z\rightarrow E$ photoisomerization of the neutral stilbene molecule (*ca.* 0.05 at −180 °C). (3) The quantum yield drops sharply to zero when the wavelength of the exciting light is varied from *ca.* 650 nm (for the cation radical) or *ca.* 620 nm (for the anion radical) to 800 nm in the region of the "first absorption band" (*i.e.*, band A in our designation). The 0-0 band of band A is probably located at about 800 nm. Fact 3 means that the illumination at this wavelength cannot cause the isomerization, and that, when the radical ions are excited into higher vibrationally excited levels of state D_3, the quantum yield of the isomerization increases sharply.

The facts found by Sazhnikov *et al.* can be satisfactorily rationalized by the above proposed mechanism. States D_1 and D_2 in their papers should be replaced by states D_3 and D_5, respectively.

Interpretation of Nonoccurrence of the E→Z *Photoisomerization in the Unsubstituted Stilbene Radical Ions.* The $Z\rightarrow E$ photoisomerization of the unsubstituted stilbene radical ions is irreversible. That is, the $E\rightarrow Z$ photoisomerization does not occur. In order to interpret this fact, both intramolecular and intermolecular factors should be taken into consideration.

First, we consider the intramolecular factor. In the case of the radical ions of the unsubstituted stilbene the E isomer should be considerably more stable than the Z isomer, as in the case of the neutral molecule[31,32] and the dianion.[27] Considering the difference in the λ_B value between the E and the Z isomer, we infer that the energy of state D_5 of the E isomer should be comparable to or rather lower than that of the Z isomer. Perhaps, the energy of state D_5 may be lower at $|\theta_{\alpha\beta}|=180°$ than at $|\theta_{\alpha\beta}|=90°$. If it is true, it may be possible that the excitation of the E isomer from state D_0 to state D_5 cannot induce the $E\rightarrow Z$ isomerization. However, this interpretation may not be convincing.

With regard to the intermolecular factor, Gegiou *et al.* found that the quantum yield of the $E\rightarrow Z$ photoisomerization of the unsubstituted stilbene molecule in fluid solutions decreased with increasing viscosity of the medium, while that of the $Z\rightarrow E$ photoisomerization was practically unaffected by the viscosity of the medium.[33] Considering the fact that in solution the nonplanar (Z)-stilbene molecule occupies a larger volume than the planar (E)-stilbene molecule by about 2.5%,[34] these authors ascribed the viscosity effect to an increase in molecular volume somewhere along the path of the $E\rightarrow Z$ photoisomerization. Sazhnikov *et al.* stated that the same interpretation appeared to be true for the radical ions of stilbene.[30] A plausible interpretation for the radical ions may be as follows:

The isomerization of the more bulky nonplanar Z isomer to the less bulky planar E isomer is not resisted by the rigid matrix, but the reverse process (the $E \rightarrow Z$ isomerization), which necessitates an increase in the volume of the radical ion, is inhibited.

It is rather surprising that the $Z \rightarrow E$ isomerization, which is obviously accompanied by a large change in the shape of the radical ion, proceeds easily in the rigid matrix such as frozen *s*-butyl chloride. The thermal energy liberated from the optically excited solute radical ion may locally heat and loosen the matrix around the radical ion.

Interpretation of Nonoccurrence of the Z→E *and the* E→Z *Photoisomerization in the α,β-Dialkylstilbene Radical Ions.* The fact that the radical ions of αβDAS's undergo neither the $Z \rightarrow E$ nor the $E \rightarrow Z$ photoisomerization may not be ascribed to the intermolecular effect, but may be intrinsic to the radical ions: Since both Z and E isomers of the αβDAS radical ions are nonplanar to a comparable extent, the isomerization will not be accompanied by an appreciable increase in the volume of the radical ion. In addition, the differences in the shape of the radical ion among the Z form, the 90° twisted form, and the E form are considered to be rather smaller than those in the unsubstituted stilbene radical ions. In this connection, it may be noted that in sterically hindered stilbene derivatives such as 2,2′,4,4′,6,6′-hexamethylstilbene both the quantum yields of the $Z \rightarrow E$ and the $E \rightarrow Z$ photoisomerization of the molecules in fluid solutions are independent of the viscosity of the medium and that this fact is interpreted on the basis of the inference that the volumes occupied by both the isomers are similar.[33]

We must invoke the intramolecular or intrinsic factor. The reason of the nonoccurrence of the photoisomerization is probably as follows. An state energy diagram schematically drawn for the αβDAS radical ions is shown in Fig. 4 (b). The ground states of the Z and the E isomer of α,β-dimethylstilbene have comparable energies.[10,12,13,32] Accordingly, the energy difference between states $D_0(Z)$ and $D_0(E)$ of the αβDAS radical ions is probably also very small. In these radical ions, $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ are always large, and therefore the π-bond order of the α–β bond is high. Therefore, the increase in the energy of state D_0 associated with the deviation of $|\theta_{\alpha\beta}|$ from 0° or 180° should be sharp, and the energy barrier at $|\theta_{\alpha\beta}| = 90°$ in state D_0 should be much higher than in the case of the unsubstituted stilbene radical ions. As a result, the energy of state D_5 should be raised at $|\theta_{\alpha\beta}| = 90°$. Also in this case, the possible small decrease in $|\theta_{\alpha 1}|$ and $|\theta_{\beta 1'}|$ associated with the deviation of $|\theta_{\alpha\beta}|$ from 0° or 180° will lower the energies of states D_5 and D_0 to some extent. Consequently, the energy curve for state D_5 as well as that for state D_0 possibly has a maximum at $|\theta_{\alpha\beta}| = 90°$ and minima between $|\theta_{\alpha\beta}| = 0°$ and 90° and between $|\theta_{\alpha\beta}| = 90°$ and 180°. Therefore, in these radical ions, the excitation to state D_5 does not induce the isomerization in either direction.

21) The allowance for the electronic bathochromic effect of the substituents was simply made by subtracting 5 nm per substituent from the value of λ_{max}, after Woodward's rule[22] and Fieser and Fieser's rule[23] for conjugated diens, which have the main band in nearly the same wavelength region as those of the α,β-dialkylstilbenes. When the allowance is made, the value of 58° estimated for Eαβ DMS and that of 63° estimated for EαβDES[12–14] are revised to 66° and 71°, respectively.

24) The values of $10^4 f_B/\varepsilon_B$ as a measure of broadness of band B for spectra F are as follows: $ZS^{+\cdot}$, 0.15; $Z\alpha\beta DMS^{+\cdot}$, 0.27; $Z\alpha\beta DES^{+\cdot}$, 0.30; $ZS^{-\cdot}$, 0.13; $Z\alpha\beta DMS^{-\cdot}$, 0.17; $Z\alpha\beta DES^{-\cdot}$, 0.18. The values for the radical ions of ZS are larger than those for the radical ions of ES, and the values for the radical ions of ZαβDMS and ZαβDES are much larger and are comparable to those for the radical ions of the E isomers (*cf.* Note 33 in Ref. 2).
25) F. Jachimowicz, G. Levin, and M. Szwarc, *J. Am. Chem. Soc.*, **99**, 5977 (1977).

26) A similar situation is encountered in the corresponding dianions. The values of λ_{max} of the main band of the dianions of the 1,2-diphenylcycloalkenes are as follows: $DPCP^{2-}$, 500 nm (ε 2.9×10^4); $DPCH^{2-}$, 470 nm (ε 2.34×10^4).[25] These bands are attributed to the transition from the ground state (state S_0) to the 3rd excited singlet state (state S_3), a transition which is approximated as a one-electron transition from ϕ_{-1} to ϕ_{-4}.[27] That is, these bands correspond to band A of the anion radicals. According to the result of our MO calculation, the energy of this transition increases as $|\theta_{\alpha\beta}|$ increases from 0°.[27] Therefore, the blue shift of the band of $DPCH^{2-}$ as compared with that of $DPCP^{2-}$ probably reflects the larger value of $|\theta_{\alpha\beta}|$ of $DPCH^{2-}$ as compared with that of $DPCP^{2-}$.

27) H. Suzuki, K. Koyano, and T. L. Kunii, *Bull. Chem. Soc. Jpn.*, **45**, 1979 (1972).

28) According to the study by Fischer *et al.*,[19] on the excitation from state S_0 to state S_1 the calculated value of $\theta_{\alpha\beta}$ increases from 10° to 37° in ZS and from 7° to 49° in Z$\alpha\beta$DMS. That is, the increase ($\Delta\theta_{\alpha\beta}$) is 27° for ZS and 42° for Z$\alpha\beta$DMS. Fischer *et al.* related the observed "Stokes shift" ($\Delta\lambda$) with $\Delta\theta_{\alpha\beta}$. The value of $\Delta\lambda$ is small (26 nm) for ZS and is much larger (76 nm) for Z$\alpha\beta$DMS. The values of $\Delta\lambda_{max}$ and $\Delta\bar{\nu}_{max}$ (*cf.* Note 38 in Ref. 2) are 150 nm and 11.75×10^3 cm^{-1} for ZS, and 200 nm and 16.72×10^3 cm^{-1} for Z$\alpha\beta$DMS.

Kinetic Study of the Oxidation of Formate by Iodine in Micellar Solutions of Alkyltrimethylammonium Chlorides

Katumitu HAYAKAWA,* Mitsuo KANDA, and Iwao SATAKE

Department of Chemistry, Faculty of Science, Kagoshima University, Korimoto, Kagoshima 890

(Received August 23, 1982)

The spectrophotometric study was made of the oxidation of formate by iodine in micellar solutions of decyl- and dodecyltrimethylammonium chlorides. In the presence of the cationic surfactant micelles, the reaction was found to take place only at the micellar surface according to the same mechanism as in water. The experimental second-order rate constant rose steeply to a maximum at the critical micelle concentration and then decreased monotonously with increasing surfactant concentration. A tentative estimation based on a charged-phase separation model led to the true second-order rate constant in micellar phase of 0.03—0.07 mol^{-1} dm^3 s^{-1} at 30 °C, which is comparable with that in water. Thus the observed rate enhancement in cationic surfactant solutions can be interpreted in terms of an increase in surface concentration of the formate ion arising from an electrostatic interaction with the micellar ion. The micellar effects on the formation constant of triiodide ion are also discussed.

In a previous study of the iodine-formate reaction, $I_3^- + HCO_2^- \rightarrow 3I^- + H^+ + CO_2$, in alcohol–water mixed solvents, we confirmed that the reaction proceeds according to the following mechanism.[1]

$$I_2 + I^- \overset{K}{\rightleftharpoons} I_3^-, \quad (1)$$

$$I_2 + HCO_2^- \xrightarrow{k_2} \text{Products}. \quad (2)$$

The second-order rate constant, k_2, was found to depend strongly on the dielectric property of the solvent,[1,2] *e.g.*, it is larger by a factor of about 100 in ethanol than in water at 30 °C.[1] Similar behavior was also observed for the formation constant, K, of triiodide ion.[3]

It is well known that a number of organic reactions involving ionic species such as H^+ or OH^- are catalyzed by oppositely charged micellar ions.[4] One might, therefore, expect that the presence of the cationic surfactant micelle would affect significantly the rate of the iodine-formate reaction through an electrostatic concentration of anionic species to the micellar surface and a possible medium effect of the micellar phase. In this connection, we have determined recently the apparent formation constant, K, of triiodide ion in micellar solution of dodecyltrimethylammonium chloride.[5] It was found that the cationic surfactant micelle solubilizes not only iodine molecule but triiodide ion in its hydrophilic surface region consisting of ionic head groups and results in a remarkable increase in K.

The purpose of the present paper is to study the kinetic aspects of the iodine-formate reaction in micellar solutions of dodecyl- and decyltrimethylammonium chlorides, and to estimate the true rate constant in micellar phase.

Experimental

Materials. Dodecyltrimethylammonium chloride (DTAC) and decyltrimethylammonium chloride (DeTAC), both from Tokyo Kasei Kogyo Co. Ltd., were recrystallized twice from methanol. Other chemicals were of guaranteed grade. Sodium iodide was dried overnight at 100 °C prior to use. Iodine was purified further by sublimation. Sodium formate was purified by recrystallization from water.

Measurements. In the presence of DTAC micelles, the absorption spectrum of the solution of I_2 and NaI is characterized by an absorption band at 360 nm.[5] This is also the case for DeTAC solution. Since in the presence of excess NaI the absorbance at 360 nm is proportional to I_2 concentration, the reaction rate was followed spectrophotometrically as a function of time by measuring the decrease in absorbance at 360 nm. The absorbance was measured with a Hitachi Spectrophotometer model 101 connected to a Valhalla Scientific Digital Multimeter model 4440. The pH and ionic strength of the solution were uncontrolled, because the rate of this reaction in water had been found to be independent of these factors.[1]

The chloride ion activity and the apparent formation constant of triiodide ion in micellar solution of DeTAC were determined by the method described elsewhere.[5]

The measurements were conducted at 21, 30, and 40 °C for DTAC solution and at 21, 30, and 37 °C for DeTAC solution, respectively.

Results and Discussion

Kinetics. In the present system, the micellar effect on the reaction rate is anticipated to arise primarily from an electrostatic interaction between the anionic species and the micellar ion. Therefore, all kinetic measurements were carried out under the conditions of $[\text{Surfactant}] \gg [I^-]$, $[HCO_2^-] \gg [I_2]$, in order to minimize the change in total counterion concentration which is a primary determinant of the electrical potential at the micellar surface. Under these experimental conditions, the reaction rate defined by Eq. 3 was found to be a first-order with respect to triiodide ion.

$$\text{Rate} = -d[I_3^-]_a/dt = k_a[I_3^-]_a \quad (3)$$

Here, the bracket with suffix a refers to the apparent concentration in moles per liter of solution and k_a to the apparent first-order rate constant, respectively. In Fig. 1 is shown the typical change in k_a with surfactant concentration at varying NaI concentrations. Similar results were also obtained at higher temperatures than 21 °C. Unfortunately, we were forced to make the kinetic measurements in the concentration range above the critical micelle concentration (CMC), since at lower surfactant concentrations below CMC the measurements were subject to interference from the precipitate composed presumably of iodine-surfactant complex.[5] However, it is likely that the apparent

first-order rate constant increases abruptly at surfactant concentration around CMC (2.1×10^{-2} mol dm^{-3} for DTAC and 8.7×10^{-2} mol dm^{-3} for DeTAC at 21 °C), though the magnitude of the increase depends regularly on NaI concentration. The k_a *versus* surfactant concentration profile resembles the results observed for micellar catalyzed organic reactions such as alkaline hydrolysis of esters in cationic surfactant solutions[4] in displaying a broad maximum or the leveling-off phenomenon above CMC.

Figure 2 shows the change in k_a with formate concentration at the given concentrations of surfactant and NaI. It can immediately be seen that k_a is directly proportional to the formate concentration, *i.e.*, $k_a=k'[HCO_2^-]_a$. It should be noted here that the value of k' thus determined is still dependent on NaI concentration. In Fig. 3 is plotted the reciprocal of k' against iodide concentration at varying surfactant concentrations. An important feature of Fig. 3 is that the plot of $1/k'$ *vs.* iodide concentration gives a straight line with a small but definite intercept. Based upon these experimental results, the rate equation of the iodine-formate reaction in cationic surfactant solutions can reasonably be written as follows,

$$\text{Rate} = -\frac{d[I_3^-]_a}{dt} = \frac{k''[I_3^-]_a[HCO_2^-]_a}{1+K'[I^-]_a}, \quad (4)$$

$$k_a = \frac{k''[HCO_2^-]_a}{1+K'[I^-]_a}, \quad (5)$$

where k'' denotes the reciprocal of the intercept of the straight line in Fig. 3 and K' the ratio of slope to intercept of the same straight line, respectively. In the determination of these kinetic parameters, however, some inherent errors are unavoidable since the intercepts of the straight lines in Fig. 3 are considerably small. With this reservation in mind, we can estimate the change in k'' and K' with surfactant concentration. The results are summarized in Table 1.

The iodine-formate reaction in methanol–water and ethanol–water mixed solvents proceeds according to Eqs. 1 and 2 as described above.[1] We derived the following rate equation under the assumption that the reaction (1) is in pseudo-equilibrium.

$$\text{Rate} = -\frac{d[I_3^-]_a}{dt} = \frac{k_2[I_3^-]_a[HCO_2^-]_a}{1+K[I^-]_a}. \quad (6)$$

Here, K refers to the formation constant of triiodide ion and k_2 to the rate constant for reaction (2) which is the rate determining step of the overall reaction, respectively. A comparison of Eq. 4 with Eq. 6 leads

The values of K in DTAC solution are from Ref. 5.

immediately to the prediction that the iodine-formate reaction in surfactant solution will also proceed according to the same mechanism as in water. This, in turn, implies that k'' and K' in Eq. 4 have the same meaning as given hereinabove, *i.e.*, $k''=k_2$ and $K'=K$. It is in fact clearly shown in Table 1 that the values of K' estimated kinetically from Fig. 3 are virtually identical with the apparent formation constants, $K(=[I_3^-]_a/[I^-]_a[I_2]_a)$, of triiodide ion determined independently in solution of surfactant without formate ion. This fact enables us to evaluate more reliable values of k_2 from the relation, $k_2=K/$(the slope of the straight line in Fig. 3). The values of k_2 so determined are summarized in the last column of Table 1 and are plotted in Fig. 4 as a function of surfactant concentration. As would be expected, the agreement between k'' and k_2 is satisfactory. In view of the fact that the second-order rate constant, k_2, is much smaller in water than in surfactant solutions, the value of k_2 is considered to rise steeply to a maximum at CMC. At higher concentrations above CMC, k_2 tends to decrease monotonously with increasing surfactant concentration. It should be noted, however, that even in the highest surfactant concentrations studied, the values of k_2 are still large enough as compared with those in water (*cf.*, $k_2=0.068$ mol^{-1} dm^3 s^{-1} at 30 °C).[1] The qualitative feature of k_2 *versus* surfactant concentration plots in Fig. 4 is in accord with that predicted theoretically by Romsted[6] for second-order reactions between organic molecules and hydrophilic ions in micellar solutions.

Rate Constant in Micellar Phase. In the spectrophotometric determination of the formation constant of the triiodide ion in DTAC solution, we pointed out that both iodine molecule and triiodide ion are solubilized almost completely in the hydrophilic surface region of surfactant micelle and are in equilibrium with the surrounding iodide ions immediately adjacent to the micellar surface.[5] It is therefore highly probable that the iodine-formate reaction in cationic surfactant solutions takes place only at the micellar surface. Thus, if we denote the inside and outside regions of the micellar surface by suffix m and s, the reaction mechanism may be described as

$$I_{2,m} + I_s^- \overset{K_m}{\rightleftharpoons} I_{3,m}^-, \tag{7}$$

$$I_{2,m} + HCO_{2,s}^- \xrightarrow{k_m} 2I_s^- + CO_2 + H^+, \tag{8}$$

where, K_m is the true formation constant of triiodide ion and k_m the true rate constant for reaction (8), both in micellar phase, respectively. The corresponding rate equation can immediately be derived from the analogy to Eq. 6.

$$-\frac{d[I_3^-]_m}{dt} = \frac{k_m[I_3^-]_m[HCO_2^-]_s}{1+K_m[I^-]_s}. \tag{9}$$

Here, the bracket with suffix m or s represents the concentration in moles per dm^3 of the respective phase. Since almost all the triiodide ions are solubilized in the surface region of surfactant micelle as noted above, we have

$$\frac{1}{[I_3^-]_a}\frac{d[I_3^-]_a}{dt} = \frac{1}{[I_3^-]_m}\frac{d[I_3^-]_m}{dt}. \quad (10)$$

It follows, therefore, from Eqs. 3 and 9 that

$$k_a = \frac{k_m[HCO_2^-]_s}{1+K_m[I^-]_s}. \quad (11)$$

It is important to note here that both I_s^- and $I_{3,m}^-$ locate at the micellar surface with virtually uniform electrical potential. This means that the activity coefficient ratio of these ions can safely be ignored without loss of accuracy. With this simplification, K_m may be written as follows:

$$K_m = [I_3^-]_m/[I_2]_m[I^-]_s. \quad (12)$$

By taking into account a relationship, $[I_3^-]_m/[I_2]_m = [I_3^-]_a/[I_2]_a$, $K_m[I^-]_s$ in Eq. 11 can be replaced by $K[I^-]_a$. Equation 11 may accordingly be rewritten as

$$k_a = \frac{k_m[HCO_2^-]_s}{1+K[I^-]_a} = \frac{k_m[HCO_2^-]_a}{1+K[I^-]_a}\frac{[HCO_2^-]_s}{[HCO_2^-]_a}. \quad (13)$$

On converting k'' and K' in Eq. 5 to k_2 and K respectively and comparing it with Eq. 13, we have

$$k_2 = k_m[HCO_2^-]_s/[HCO_2^-]_a. \quad (14)$$

According to Eq. 14, the observed second-order rate constant, k_2, should be a decreasing function of surfactant concentration, since an increase in surfactant concentration is necessarily accompanied by a decrease in surface concentration of formate ion by virtue of surface potential depression. Indeed, the foregoing data shown in Fig. 4 are in accord with the prediction based on Eq. 14, reflecting that the coulombic interaction between formate and micellar ions is of primary importance in determining the rate constant, k_2, in surfactant solutions.

Equation 14 allows us to estimate the true rate constant, k_m, in micellar phase provided that an appropriate information is available for $[HCO_2^-]_s/[HCO_2^-]_a$. According to the common practice in theoretical treatment of the micellar catalysis,[4,6,7] it is reasonable to assume that the distribution quilibrium of the formate ion between micellar surface and bulk phase is always established during the course of the reaction. If, therefore, the formate ion has no specific adsorption potential to the micellar surface, the ratio of surface concentration to apparent total concentration of the formate ion may be replaced by that of chloride ion. Thus, noting that $[Cl^-]_a$ is equal to the total surfactant concentration, C, we may write

$$k_2 = k_m C_{1,s}/C, \quad (15)$$

where suffix 1 refers to chloride ion. The usual treatments[6,7] of micellar catalysis suppose that the counterion concentration in surface layer (Stern layer), $C_{1,s}$ is independent of total surfactant concentration

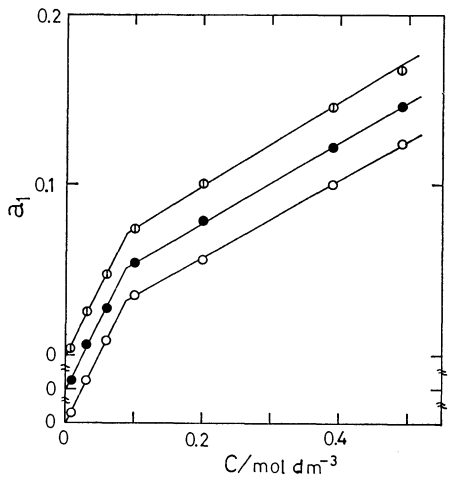

Fig. 5. Change in the chloride ion activity with DeTAC concentration at 37 °C (ⓘ), 30 °C (●), and 21 °C (○).

and is equal to β/LV, where β represents the degree of counterion association to the micelle, V the volume of Stern layer per micelle forming surfactant molecule in dm^3 and L the Avogadro constant, respectively. We can thus estimate the values of k_m by introducing an appropriate value of $C_{1,s}$ into Eq. 15, provided that the product of k_2 and C remains constant throughout whole surfactant concentration range studied. This is in fact the case for the DTAC solution, *i.e.*, the value of k_2C remains virtually constant and lies around 0.12 s^{-1} at 30 °C. However, the situation is somewhat complicated by the fact that in DeTAC solution the value of k_2C increases slightly but regularly with increasing surfactant concentration. In addition, the determination of k_m based on this treatment requires a knowledge of V which is experimentally rather difficult to estimate. For these reasons, we employed the following approach for the estimation of k_m.

Denoting the surfactant ion by suffix 2, the simple thermodynamic consideration leads immediately to the relations

$$kT \ln (C_{1,s}/\text{mol dm}^{-3}) - e\psi = kT \ln a_1, \quad (16)$$

$$\Delta\mu_2^{\circ} + e\psi = kT \ln [a_2/(55.5/\text{mol dm}^{-3})] \quad (17)$$

where, ψ is the surface potential of the micelle, a_i the activity of i-th ion ($C^{\circ}=1$ mol dm^{-3}) and $\Delta\mu_2^{\circ}$ the standard free energy of transfer of surfactant ion from aqueous medium to micellar phase; other symbols have their usual meanings. Combining Eqs. 16 and 17, we have

$$C_{1,s} = (a_1a_2/55.5) \exp(-\Delta\mu_2^{\circ}/kT). \quad (18)$$

Although a_1 and a_2 in Eq. 18 can both be measured potentiometrically as a function of surfactant concentration, the determination of the latter is not necessarily required, because the following relationship based on the phase separation theory[8] has been confirmed to hold in various ionic surfactant solutions.[9]

$$a_2a_1^{\beta} = \text{constant} = K_s \quad (19)$$

It follows, therefore, from Eqs. 15, 18, and 19 that

$$a_1^{1-\beta}/k_2 = (55.5C/k_mK_s) \exp(\Delta\mu_2^{\circ}/kT) \quad (20)$$

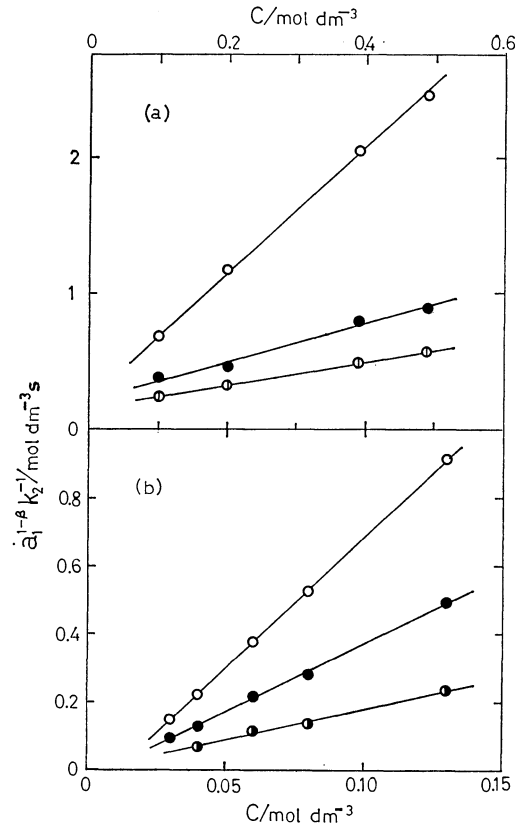

Fig. 6. Plots of the left-hand side of Eq. 20 *vs.* surfactant concentration.
(a) DeTAC solution. ○; 21 °C, ●; 30 °C, ⓘ; 37 °C. (b) DTAC solution. ○; 21 °C, ●; 30 °C, ◑; 40 °C.

This implies that the left-hand side of Eq. 20 should be linearly dependent on total surfactant concentration. Information about β can easily be obtained from the concentration dependence of the chloride ion activity. In Fig. 5 is shown the plots of a_1 *vs.* C for DeTAC solution at varying temperatures. According to Botré *et al.*,[10] the slope of the straight line above CMC divided by the activity coefficient at CMC gives $1-\beta$. Using the values of β so determined for DeTAC and DTAC,[5] the left-hand side of Eq. 20 can now be plotted as a function of surfactant concentration. Figure 6 shows such plots at various temperatures. In accordance with Eq. 20, the plot is found to be linear in all cases studied. Since at CMC the surfactant ion activity is virtually identical with the chloride ion activity, a_1°, the value of K_s can safely be set equal to $(a_1^{\circ})^{1+\beta}$ with reasonable accuracy. In addition, the value of $\Delta\mu_2^{\circ}$ was estimated by Shinoda[11] to be $-1.08\,kT$ per carbon atom in hydrocarbon chain at 25 °C. Introducing these values into Eq. 20 and ignoring the temperature dependence of $\Delta\mu_2^{\circ}$, we can evaluate approximately the true rate constant, k_m, in micellar phase from the slope of the straight line in Fig. 6. The results are summarized in Table 2 together with the rate constants in various solvents.[1] The values of k_m in DTAC solution can also be obtained by estimating an appropriate value of V as described already. On the basis of geometric considerations for various micelle shapes, Tanford[12] has

TABLE 2. A COMPARISON OF THE ESTIMATED VALUES OF THE SECOND-ORDER RATE CONSTANT AND THE FORMATION CONSTANT IN MICELLAR PHASE WITH THOSE IN WATER AND ALCOHOLS

Solvent	Temp °C	β	k_m / mol^{-1} dm^3 s^{-1}	K_m / mol^{-1} dm^3

a) From Ref. 1. b) From Ref. 3.

derived the relationship between the surface area per polar head group of micelle forming surfactant molecules, S, and the micellar aggregation number. According to his calculation for globular micelles, the micellar aggregation number of DTAC of 57[13] corresponds to S of 0.78 nm^2. With an additional assumption that the thickness of the Stern layer is of the order of the diameter of hydrated chloride ion (0.37 nm),[14] the value of $C_{1,s}$ ($=\beta/LV$) is obtained as 4.3 mol dm^{-3} at 30 °C. Thus the use of Eq. 15 leads immediately to k_m of 0.028 mol^{-1} dm^3 s^{-1} at 30 °C. The result is in good agreement with that given in Table 2, indicating the validity of the present approach.

Apart from the detailed calculation of k_m, it is important to note that the estimated values of k_m are similar in magnitude to those in aqueous medium. This fact is consistent with the foregoing view that the iodine-formate reaction in cationic surfactant solutions will take place at the hydrophilic surface region of the micelle. It may thus be concluded that an increase in surface concentration of the formate ion arising from an electrostatic interaction with polyvalent micellar ion is the principal source of the rate enhancement of the iodine-formate reaction in cationic surfactant solutions. The environmental effect of ionic head groups on k_m seems to be, if any, negligibly small. Unfortunately, the values of k_m given in Table 2 are not of sufficient precision to permit the estimation of the activation parameters in micellar environments, since we ignored the temperature dependence of $\Delta\mu_2^{\ddagger}$ in their computation. At the present stage, therefore, it is rather difficult to give any reasonable account of an appreciable dependence of k_m on surfactant chain length at higher temperatures.

Formation Constant in Micellar Phase. Expressions similar to Eqs. 15 and 20 must also hold for the apparent formation constant, K, of triiodide ion. Since $K_m[I^-]_s$ is equal to $K[I^-]_a$ as described already, the substitution of the ratio of surface concentration to apparent total concentration of iodide ion by that of chloride ion leads immediately to

$$K = K_m C_{1,s}/C \qquad (21)$$

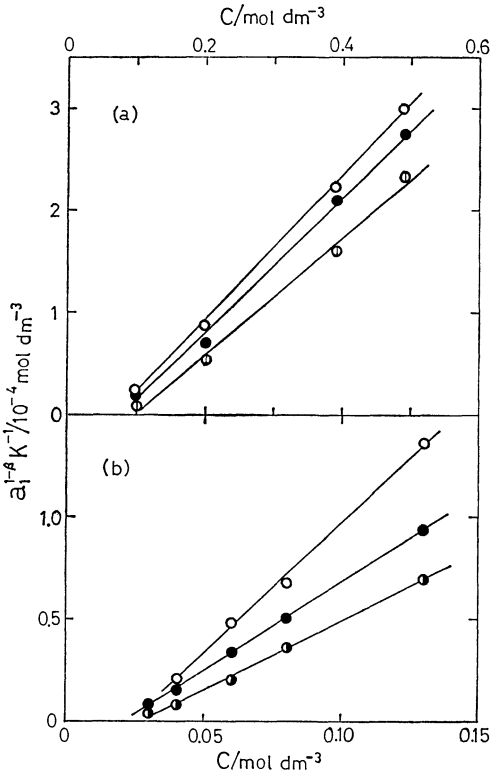

Fig. 7. Plots of the left-hand side of Eq. 22 *vs.* surfactant concentration.
(a) DeTAC solution. ◑; 21 °C, ●; 30 °C, ○; 37 °C. (b) DTAC solution. ◑; 21 °C, ●; 30 °C, ○; 40 °C.

$$a_1^{1-\beta}/K = (55.5C/K_mK_s)\exp(\Delta\mu_2^{\ddagger}/kT). \qquad (22)$$

The resulting expression is noted to be identical with Eq. 20, except that k_2 and k_m are replaced respectively by K and K_m. In Fig. 7 is shown the predicted linear relationship between the left-hand side of Eq. 22 and total surfactant concentration. We can thus estimate the true formation constant, K_m, of triiodide ion in micellar phase from the slope of the straight line in Fig. 7. The results are summarized in the last column of Table 2. For the sake of comparison, the formation constants in various solvents[3] are also included in this table. The fact that the true formation constants are comparable with those in water provides an additional evidence for the occurrence of the iodine-formate reaction at the hydrophilic surface region of the micelle. Thus the marked increase in an apparent formation constant shown in Table 1 is concluded to result predominantly from an increase in surface concentration of the iodide ion due to coulombic interaction with the micellar ion.

In a previous study of K_m in DTAC solution,[5] we applied an expression derived by Shinoda[15] for the surface potential of the lamellar micelle. The only drawback of the treatment was the lack of reliable information about S. For example, a tentative calculation based on S=0.78 nm^2 gave K_m of 650 mol^{-1} dm^3 at 30 °C. On the other hand, the use of S=0.30 nm^2 which corresponds to a lamellar micelle model[12] led to K_m of 190 mol^{-1} dm^3 at 30 °C. It is true that the latter value is in fair agreement with K_m estimated

above from Eq. 22, but we must keep in mind that small errors in the estimation of $\Delta\mu_2^{\ddagger}$ causes an appreciable change in K_m. It is, thus, highly probable that the reliable value of K_m in DTAC solution lies somewhere between 150 and 650 mol^{-1} dm^3 at 30 °C.

(Received June 16, 1982)

Broad structureless charge-transfer (CT) bands of benzyl radical-halide ion (Ḃz---X⁻) complexes have been observed in 3-methylhexane (3MHx) and 2-methyltetrahydrofuran (MTHF) matrices containing BzCl and BzBr irradiated with γ-rays at 4.2 K. 3MHx and ethanol matrices containing BzI also showed the CT band when warmed from the irradiation temperature to 77 K. These observations are in marked contrast with previous ones in which the CT band was found to be present only in alkane matrices when irradiated at 77 K. The CT band has been found to shift to the blue with increasing matrix polarity, as expected from a large contribution of the solvation of the ion to the CT transition energy of the radical–anion complex. The observed nature and behavior of the CT bands indicates that the dissociative electron attachment reaction in the matrices is a stepwise process: The formation of a Ḃz---X⁻ complex and its dissociation. These steps proceed readily in more polar environments and for lighter ions. For the electron attachment to BzI at 4.2 K, an even earlier step, an ionic entity prior to the C–I bond dissociation, was indicated.

The dissociative electron attachment to benzyl halide in glassy matrices of nonpolar alkanes γ-irradiated at 77 K was previously found to give benzyl radical–halide ion complexes.[1,2] These complexes provided us with an interesting example of the charge-transfer (CT) interaction between a neutral open-shell free radical and a closed-shell anion. Their CT band, observed by means of the fluorescence spectrophotometric method, shifted depending on both the ionization energy of the electron donors (halide ions)[2] and the electron affinity of the electron acceptors (ring-substituted mono- and dimethylbenzyl radicals[3]). A similar CT band was also observed for the α-methylbenzyl radical formed from (2-chloroethyl)benzene[4] and the diphenylmethyl radical from diphenylmethyl halides[5] in glassy 3-methylhexane (3MHx) at 77 K. It is likely that a complex of this kind is generally formed as a transient intermediate state during the course of dissociative electron attachment reactions. A detailed study on the nature and behavior of this complex is expected to give a mechanistic insight into the reactions occurring in low temperature glassy matrices.

The CT excitation energy should depend significantly on the energy of solvation of the ions (both in the ground and excited states of the complex) for a neutral radical–anion complex. Actually, this has been proved by changing the ionic radius by using the different halide ions.[2] In this respect, it seems worthwhile studying the effect of the matrix polarity on the CT excitation energy. However, so far only the CT band for the benzyl radical–iodide ion complex in semipolar 2-methyltetrahydrofuran (MTHF) at 77 K,[6] apart from alkane matrices, has been observed. The failure in observing the CT band from polar matrices was attributed to ion solvation effects: polar matrix molecules weakening the interaction between the radical and the ion.

The 4.2 K-γ irradiation technique has proven useful in freezing chemical processes so that the early stages in the processes can be followed. This technique has, for example, enabled the spectrophotometric observations of the precursor of the carbon-halogen bond dissociation which resulted from the electron attachment to benzyl chloride[7] and halobenzenes,[8] and of the toluene anion which is the precursor of the methylcyclohexadienyl radical in a glassy toluene matrix.[9]

The present investigation was planned for observing the benzyl radical–halide ion CT band in organic glassy matrices of different polarity using the 4.2 K-γ irradiation technique. Another aim of the investigation was to elucidate the detailed mechanism of the dissociative electron attachment reaction in these matrices.

Experimental

Benzyl chloride (BzCl) of reagent grade was used without further purification. Benzyl bromide (BzBr) of reagent grade was distilled before use. Benzyl iodide (BzI) was synthesized from BrCl and NaI and purified by repeated recrystallization from methanol. 3MHx, MTHF, and ethanol were purified as described elsewhere.[6]

The solutions of the benzyl halides (10^{-2}—10^{-3} mol/dm³) were deaerated by freeze-pump-thaw cycles to 1.4×10^{-3} Pa, sealed in Suprasil quartz tubes of 2 mm outer diameter, and rapidly frozen into the glassy state by immersion in liquid nitrogen. The samples were transferred into a liquid He dewar of quartz (originally for ESR measurement at 4.2 K), irradiated with ^{60}Co γ-rays to a dose of 5×10^{4}—4×10^{5} rad at 4.2 K, after which excitation and emission spectra were measured with a Hitachi Model MPF-2A fluorescence spectrophotometer. The wavelength resolution of the measurements was 2 nm or less. Thermal annealing was carried out by rapidly transferring the irradiated samples into liquid nitrogen and keeping them there for a predetermined period.

Occasionally, optical absorption measurements were made with a Shimadzu MPS-5000 spectrophotometer and sample solutions sealed in an optical absorption cell of quartz (optical path length: 2 mm), as has been described before.[9]

Results

The fluorescence and excitation spectra recorded from the 3MHx containing BzCl or BzBr irradiated at 4.2 K are essentially the same as the spectra ob-

Table 1. The charge-transfer excitation band (energy) of benzyl radical-halide ion complexes

Halide ion	Matrix	λ_{max}/nm (Transition energy/eV) 4.2 K	77 K
Cl^-	3MHx	364 (3.41)	366[a] (3.39)
	MTHF	340 (3.65)	Unobserved
	EtOH	Unobserved	Unobserved
Br^-	3MHx	413 (3.00)	413[a] (3.00)
	MTHF	370 (3.35)	Unobserved
I^-	3MHx	500[b] (2.48)	500[a] (2.48)
	MTHF	No measurement	420[c] (2.95)
	EtOH	345[b] (3.59)	Unobserved

a) Ref. 2. The previously reported 362 nm of Cl^- has been corrected, based on a careful reexamination in this investigation. b) The band appeared when the samples irradiated at 4.2 K were warmed to 77 K. c) Ref. 6.

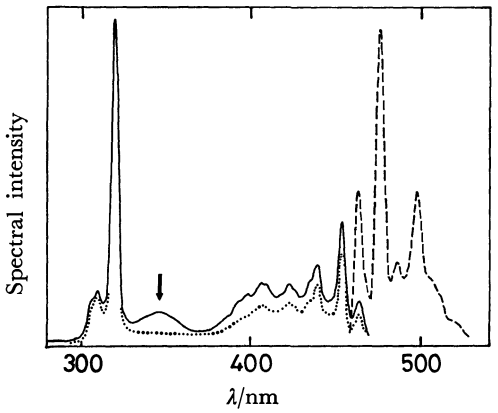

Fig. 1. Fluorescence (dashed curve) and excitation (solid curve) spectra of benzyl radicals generated by irradiating an ethanol matrix containing BzI with γ-rays at 4.2 K and observed immediately after warming to 77 K. Excitation and monitoring were made at 320 nm and 463 nm, respectively. The excitation spectrum changed to that of the dotted curve after 40 min annealing at 77 K. The arrow indicates the CT excitation band of the Ḃz---I^- complex.

served after the irradiation at 77 K.[2] The excitation spectra are comprised of three bands, in the visible (around 460 nm), near-UV (around 320 nm), and far-UV (around 260 nm) regions due respectively to the $1^2A_2 \leftarrow 1^2B_2$, $2^2A_2 \leftarrow 1^2B_2$, and $4^2B_2 \leftarrow 1^2B_2$ electronic transitions in a benzyl radical of C_{2v} symmetry[10] which has been generated by dissociative electron attachment to BzX. In addition, a structureless broad excitation band was observed with a band maximum at 364 nm for BzCl and at 413 nm for BzBr. This band has previously been attributed to the CT band of the Ḃz---X^- complex.[1,2,6] All these excitations induce the fluorescence from the benzyl radical in the wavelength region 460—530 nm.

The main concern of the present investigation was the CT excitation band of the complexes. Upon warming the 3MHx matrices containing BzCl or BzBr to 77 K, no change in the CT band was observed. The CT excitation energy is independent of the irradiation temperature, as can be seen in Table 1. The wavelength difference of 2 nm between 4.2 and 77 K for BzCl/3MHx is within the experimental uncertainty caused by the broad peak of the bands.

The effect of irradiation temperature is significant for the MTHF matrix. CT bands with maximum at 340 nm and 370 nm were observed for BzCl and BzBr after irradiation at 4.2 K. This is in contrast with irradiation at 77 K[2,6] where CT bands were not observed. The CT bands disappeared readily on warming the samples irradiated at 4.2 K to 77 K. The CT band could not be observed for a BzCl/ethanol solution either by irradiation at 77 or at 4.2 K.

The effect of irradiation temperature is more prominent when BzI is the source of benzyl radicals. Immediately after irradiation at 4.2 K, no emission at all was observed from the 3MHx and ethanol matrices. However, the excitation band of the benzyl radical as well as the CT excitation band of the Ḃz---I^- complex could be recorded after warming the samples to 77 K. For BzI/3MHx, the CT band was found to have its maximum at about 500 nm, equal to that observed previously for irradiation at 77 K.[2,6] The CT excited state is lower than the first excited state of the benzyl radical and, therefore, the fluorescent state of the Ḃz---I^- complex, so that a broad structureless CT fluorescence with the maximum at 548 nm was observed. For BzI/ethanol, the CT excitation band was unstable at 77 K: It disappeared within 40 min after its appearance (see Fig. 1).

Table 1 summarizes all the data on the CT excitation band obtained in the present investigation as well as in the previous ones.[2,6]

The absence of a CT band from BzI at 4.2 K raises the question of what the precursor of the Ḃz---I^- complex is. As the precursor does not fluoresce, optical absorption measurements were made for 3MHx, MTHF, and ethanol matrices containing BzI at 4.2 K. Although the shape of the absorption spectra observed varied from sample to sample, typical examples of observed spectra can be seen in Fig. 2. The spectra are generally composed of a sharp line at *ca.* 320 nm (with a satellite line at 310 nm) and a broad component in the longer wavelength region. The latter showed broad peaks whose position is dependent on the matrix. This broad component disappeared upon warming to 77 K. It does not correspond to the CT excitation band. The sharp line has almost the same wavelength position as that of the intense near-UV excitation due to the $2^2A_2 \leftarrow 1^2B_2$ transition of the benzyl radical. The lines seemed to increase in peak intensity and to shift a few nm to the blue side on warming to 77 K. On the whole the observed absorption spectra shows no similarity to the spectrum of the toluene anion generated in the γ-irradiated MTHF matrix.[9] The absorption spectra are very much like the spectrum observed by Higashimura *et al.* from BzCl/ethanol irradiated at 4.2 K.[7] They have attributed the broad component to the precursor of the benzyl radical.

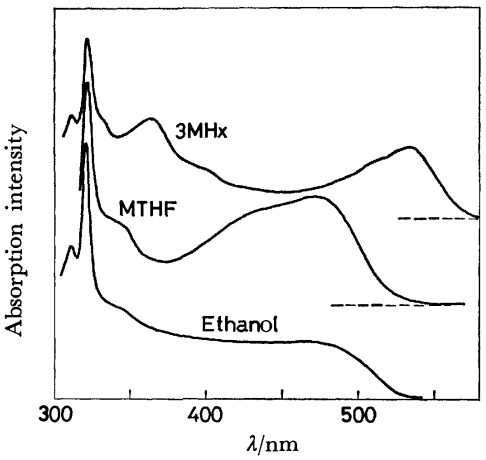

Fig. 2. Optical absorption spectra observed from glassy organic matrices containing BzI irradiated with γ-rays and measured at 4.2 K. Correction has been made for background absorption. The dashed line indicates the zero-absorption level of each spectrum.

Although further studies are evidently needed to attain a definite assignment, the absorption spectra observed here are tentatively assigned to a BzI molecular anion with a partially broken C–I bond (a tightly correlated benzyl radical–iodide ion pair). The absence of fluorescence at 4.2 K seems to indicate that the sharp lines are not due to the (normal) benzyl radicals.

Discussion

The broad structureless excitation band was previously assigned to the CT transition of the transient Ḃz---X$^-$ complexes which are generated by the dissociative electron attachment to BzX in rigid matrices. This assignment was based on the observed dependence of the transition energy on the ionization energy of the electron donors, the halide ions,[2] or on the electron affinity of the electron acceptors, that is benzyl or methyl-substituted benzyl radicals.[2,3]

Following Mulliken's CT resonance model,[11] the CT transition energy, $h\nu_{CT}$, of a weak electron donor-acceptor complex is written as

$$h\nu_{CT} = W_1 - W_0 + \frac{(H_{01}-W_0S_{01})^2+(H_{01}-W_1S_{01})^2}{W_1-W_0}, \quad (1)$$

where W_0 is the eigenvalue of the no-bond wave function ψ_0(A,D) and W_1 the eigenvalue of the dative wave function ψ_1(A$^-$—D$^+$). H_{01} and S_{01} are defined as $\langle\psi_0|H|\psi_1\rangle$ and $\langle\psi_0|\psi_1\rangle$, respectively. The third term on the right hand side cannot be estimated without knowledge of the exact conformation of the complex, but for the Ḃz---X$^-$ case studied here it is small and can be neglected, as will be mentioned below. The main contribution to W_1-W_0 comes from the ionization energy of X$^-$, IP(X$^-$), the electron affinity of Ḃz, EA(Ḃz), and the difference in solvation energy between the excited and ground states of the complex, E_s(Bz$^-$---X)$-E_s$(Ḃz---X$^-$). The solvation energies

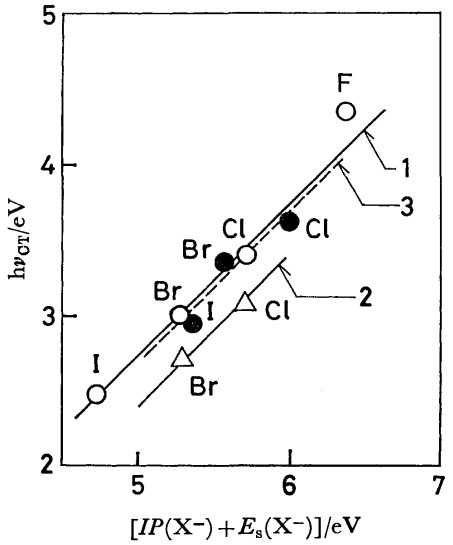

Fig. 3. The dependence of the observed CT transition energy on the calculated sum of the ionization energy and the solvation energy of the halide ion, IP(X$^-$)+E_s(X$^-$). ○: Ḃz---X$^-$ complexes in the 3MHx matrix cited from Ref. 2. Line 1 gives 0.263 nm for the effective radius of Bz$^-$. ●: Ḃz---X$^-$ complexes in the MTHF, for which the dependence expected from an equal effective radius of Bz$^-$ is shown by line 3. △: Dephenylmethyl radical---X$^-$ complex in the 3MHx matrix, cited from Ref. 5, for which a linear dependence with a slope of unity is shown by line 2.

can however be approximated to those of Bz$^-$ and X$^-$ and are then given by Born's formula:

$$E_s = \frac{e^2}{2r}\left(1-\frac{1}{D}\right), \quad (2)$$

where r is the radius of the solvated species. The Franck-Condon principle requires the usage of the static dielectric constant, D_s, and the optical dielectric constant, D_{op}, for the ground and excited states respectively. Thus, Eq. 1 is reduced to

$$h\nu_{CT} = IP(X^-) + E_s(X^-) - \{EA(\dot{B}z)+E_s(Bz^-)\}. \quad (3)$$

A linear relationship between $h\nu_{CT}$ and IP(X$^-$)+E_s(X$^-$) was indeed observed for the Ḃz----X$^-$ complexes in the 3MHx matrix[2] as is shown by the solid line in Fig. 3. From the intercept and the reported EA (Ḃz) value, 0.90 eV,[12] the effective radius of the Bz$^-$ anion can be calculated as 0.263 nm. The linear relationship (3) holds also for diphenylmethyl radical–halide ion complexes.[5]

The present observations of the Ḃz---X$^-$ complex in three different matrices enables us to examine the effect of matrix polarity on the CT excitation energy, as expressed by Eq. 3. Qualitatively speaking, D_{op} is close to 2.0 for all the matrices examined, which means that E_s(Bz$^-$) will be almost constant. The effect of polarity will come mainly from E_s(X$^-$), which is dependent on D_s. For more polar matrices, E_s (X$^-$) will become larger and this will lead to larger $h\nu_{CT}$. Actually, the blue-shift of the CT band was followed by changing the matrix from 3MHx to MTHF,

Table 2. Observed and calculated charge-transfer transition energies of the benzyl radical-halide ion complexes

Matrix	Halide ion	Ionization energy of halide ion[a] $IP(X^-)$	Dielectric const.[b] D_s	Dielectric const.[b] D_{op}	Solvation energy[d] $E_s(X^-)$	Solvation energy[d] $E_s(Bz^-)$	CT excitation energy, $h\nu_{CT}$ Calcd	CT excitation energy, $h\nu_{CT}$ Exptl
MTHF	Cl^-	3.61	2.2[c]	2.0	2.39	1.37	3.73	3.61
	Br^-	3.36	2.2[c]	2.0	2.18	1.37	3.27	3.36
	I^-	3.06	2.88	2.0	2.29	1.37	3.08	2.95
EtOH	I^-	3.06	3.0	1.853	2.34	1.26	3.25	3.59

Energies are given in eV units. a) Ref. 15. b) Ref. 13. c) D_s at 4.2 K is assumed in the present investigation. See text. d) The calculation is based on Born's formula: $E_s=(e^2/2r)(1-1/D)$. $E_s(Bz^-)$ from D_{op} and $r=0.263$ nm, which is assumed to be independent of the solvent. See also Refs. 2 and 6.

for the Cl^- and Br^- series, as shown in Table 1. Combining the new data (the third column) with the previous data (the last column), it can be seen that the CT band for the I^- ion is increasingly blue-shifted in the order 3MHx, MTHF, and ethanol.

The D_s and D_{op} values at 77 and 4.2 K for MTHF and ethanol are needed in order to apply equation (3) for an quantitative examination of the effect of the matrix polarity as observed in the present experiment. From an extrapolation of high temperature data, Kevan has proposed that for MTHF at 77 K, $D_s=2.88$ and $D_{op}=2.0$.[13] Using these values and the reported ionic radii[14] (0.164, 0.180, and 0.205 nm for Cl^-, Br^-, and I^-) and assuming that the Bz^- ion has a constant radius (0.263 nm, irrespective of the matrix), $h\nu_{CT}$ for the $\dot{B}z$---I^- complex in the MTHF matrix has been calculated as 3.08 eV (see Table 2). This is close to the observed value of 2.95 eV at 77 K. The dashed line in Fig. 3 shows the linear relationship between $h\nu_{CT}$ and $IP(X^-)+E_s(X^-)$ calculated for the $\dot{B}z$---X^- complexes in a MTHF matrix with $D_{op}=2.0$. The observed $h\nu_{TC}$ at 4.2 K for the $\dot{B}z$---Cl^- and $\dot{B}z$---Br^- complexes fall on the predicted line, if one assumes that $D_s=2.2$ at 4.2 K. The smaller D_s indicates that the MTHF matrix is similar to nonpolar alkane matrices at 4.2 K. This can be attributed to an inhibition of the rotational relaxation of the polar MTHF molecules surrounding the ions at 4.2 K. Such an inhibition of the rotational relaxation has been verified by observing the evolution of the absorption spectrum of the trapped electrons in a MTHF matrix upon warming from the γ-irradiation temperature 4.2 K to 77 K.[16,17]

By using Kevan's estimates of D_s and D_{op} for ethanol at 77 K,[13] $h\nu_{CT}$ for the $\dot{B}z$---I^- complex can be calculated as 3.24 eV, which is somewhat too small in comparison with the observed value of 3.59 eV (see Table 2). This discrepancy is partly due to the fact that Born's formula, used to calculate the solvation energies, is strictly valid only for the case of continuous matrix media. The main contribution to the solvation, however, will be the rotational relaxation of the polar ethanol molecules in the close vicinity of the I^- ion. In addition, it is possible that the rotational relaxation has not gone to completion after warming the sample to 77 K before the measurement of the CT band. The previous study on the evolution of the spectrum of the trapped electron indicates that the rotational relaxation in the ethanol matrix took about 30 min to be completed at 77 K.[18]

Table 1 shows the general trend in the formation of $\dot{B}z$---X^- complexes. Experimental conditions favor observations of these complexes: (1) When the irradiation temperature is low, (2) when the X^- ion is bulky, and/or (3) when the matrix is nonpolar. Conditions (1) and (2) prevent the ion from escaping from the $\dot{B}z$ radical (cage effect). Condition (3) is somewhat more complex. An increase in matrix polarity will have two effects. The first effect is a solvation effect. The orientational rearrangement of the polar matrix molecules around the X^- ion of the ground state complex increases $E_s(X^-)$ and is the cause of the blue-shift of the CT band. The varying extent of the solvation effect will broaden the band, so that its apparent intensity becomes weaker. The second effect is a separation effect. The molecular reorientation in the immediate vicinity of the X^- ion will push it away from the $\dot{B}z$ radical. A slight increase in the interdistance between X^- and $\dot{B}z$ will significantly reduce the overlap between the electron-donating orbital and the electron-accepting orbital, so that the transition moment of the CT excitation will decrease in magnitude. Neither a blue-shift nor a broadening of the line could be observed during the gradual decay of the $\dot{B}z$---I^- CT band after warming the ethanol matrix to 77 K. This is an indication that the separation effect is more important than the solvation effect in polar matrices.

The absence of both benzyl spectrum or the CT band immediately after 4.2 K irradiation of the matrices containing BzI gives an interesting example of the detailed reaction steps involved in the dissociative electron attachment. A gas phase study has shown that the dissociative attachment of thermal electrons to aromatic halides having low-energy vacant π orbitals occurs according to a mechanism involving an intermediate molecular negative ion as a precursor of the dissociation into a halide ion and a free radical.[19] Although such a precursor is expected to be easily trapped in the solid state, spectroscopic observations of it have been very few.[8,9] In the present case, the precursor was observed at 4.2 K (see Fig. 2). It

unquestionably dissociated into $\dot{B}z$ and I^-, as is evidenced by the excitation spectra after warming BzI/ethanol or 3MHx to 77 K (see, for example, Fig. 1). The cage effect is so prominent at 4.2 K for the most bulky I^- ion that the elongation of the C–I bond distance and/or the change of the $-CH_2$ group from sp^3 to sp^2 conformation is inhibited.

In conclusion, the following reaction steps have been revealed by the present investigation:

$$\mathrm{BzI} \xrightarrow{e^-} \underset{\text{precursor}}{\mathrm{BzI}^-} \longrightarrow \underset{\text{complex}}{(\dot{B}z\text{---}I^-)} \longrightarrow \dot{B}z + I^-.$$

The question whether the precursor observed by the optical absorption measurements is the molecular anion or an intermediate state between the molecular anion and the complex still remains. The precursor dissociates into the complex even at 4.2 K for BzBr and BzCl. The complex is stably trapped at 77 K in the nonpolar 3MHx matrix for all the BzX's examined, but it is unstable in the polar ethanol matrix. The dissociation of the complex could be followed by observing the gradual decay of the CT excitation band for $\dot{B}z\text{---}I^-$ in the ethanol matrix at 77 K. The MTHF matrix is intermediate as concerns the stability of the complex.

(Received March 5, 1982)

Photochemical degradation of a series of tin-manganese bonded complexes was studied. The apparent reactivity of the tin-manganese bond toward UV irradiation is interpreted on the basis of absorption spectra of relevant complexes and available emissions from the light source. Two kinds of orthometalated products were obtained from photolysis of Me_3Sn–$Mn(CO)_3[P(OPh)_3]_2$ in benzene. Various kinds of experiments suggest that their photochemical reactions proceed through homolytic cleavage of the Sn–Mn bond in the initial stage and the resulting 15-electron intermediates abstract hydrogen from the triphenyl phosphite moiety. Molecular structures of the two kinds of orthometalated products, as clarified by X-ray structure analyses, are described.

There is much current research activity on photochemical reactions of metal-metal bonded complexes.[1,2] The impetus behind these studies is to understand the photochemistry of these complexes in connection with excited states and/or to obtain new intriguing derivatives by exploiting photochemically generated unstable intermediates.[1,2] Although the ultimate goal of these studies is to predict theoretically, and to design or control, photochemical reactions for these complexes, only limited understanding of photochemical reaction mechanisms with regard to the photochemical excitation has been obtained up to the present.[1,2] Those metal carbonyl derivatives which possess transition metal-transition metal bonds and transition metal-group IV metal bonds, have so far been explored intensively.[1–3] We have been studying structures, bondings, and syntheses of manganese carbonyl derivatives which have manganese-group IV metal atom bonds.[4] As part of a systematic investigation on structure, bonding, and reactivity of the aforementioned type of manganese carbonyl derivatives, we were led to investigate photochemical behavior of this series of compounds.

According to Wrighton *et al.*,[5] the photochemistry of group IV metal-transition metal bonds for Ph_3M'–$M(CO)_3L$ (M′=Ge and Sn; M=Mn and Re) is dependent on L, M′, and M, and the initial photochemical process is the charge transfer from the M′–M bond (HOMO) to the π^* of L (LUMO) which leads to labilization of the M′–M bond. Reichel and Wrighton,[6] however, have demonstrated that the main result of photoexcitation of R_3Si–$Co(CO)_4$ (R=Ph and Et) is dissociative loss of CO. These studies suggest that the photochemical behavior of the transition metal-group IV metal bond in R_3M'–$M(CO)_xL_y$ type compounds is very much dependent on the substituent of L on the transition metal atom M, the group IV metal atom M′, and the transition metal atom M itself, and that the photochemical behavior can be interpreted in terms of the molecular orbital diagram. When L has no low-lying empty π^* orbital, the lowest energy excitation for M=Mn or Re is the $d\pi\rightarrow\sigma^*$ or $\sigma_b\rightarrow\sigma^*$(M′–M) transition, which may depends on the sp^3 level of atom M′ (Schemes 1(a) and (b)).[5,6] Scheme 1(a) may hold for M′=Si and Scheme 1(b) for M′=Sn. In the combination of M′=Sn and L which has a low-lying empty π^* orbital, the lowest energy excitation is the $\sigma_b\rightarrow\pi^*$(L) transition (Scheme 1(c)).[5,6] It comes out from Scheme 1 that photochemical cleavage of the M′–M bond becomes efficient, which is otherwise reluctant, when the M′–M bond strength is affected by replacing R or L with another substituent and the $\sigma_b\rightarrow\sigma^*$ (M′–M) transition approaches to available excitation energy. In this regard, the manganese-tin bonds in R_3Sn–$Mn(CO)_xL_y$ and $R_{4-x}Sn[Mn(CO)_5]_x$ are enticing candidates to examine this idea; our previous spectro-

Me_3Sn–$Mn(CO)_5$(I)	230 (19000) [a]
$Me_2Sn[Mn(CO)_5]_2$(II)	230 (22200), [a] 320 (17000)
$MeSn[Mn(CO)_5]_3$(III)	230 (38000), [a] 385 (14700)
Me_3Sn–$Mn(CO)_3L_2$(IV)	230 (21900), [a] 270 sh
Me_3Sn–$Mn(CO)_4L$(V)	230 (19600), [a] 270 sh
$Me_2Sn[Mn(CO)_4L]_2$(VI)	230 (18400), [a] 265 sh 320 (14200)
$P(OPh)_3$	265 (1550)

a) Shoulder in hexane solution.

scopic studies have shown that the Sn–Mn bond strength is influenced by replacing the carbonyl in R_3Sn–$Mn(CO)_5$ with triphenylphosphine and its congeners.[4l,4m] The present study was undertaken to demonstrate how the photochemistry of a series of Me_3Sn–$Mn(CO)_{5-x}[P(OPh)_3]_x$ or $Me_{3-x}Sn[Mn(CO)_5]_{x+1}$ (x= 0, 1, and 2) is dependent on change in substituents and to clarify the fate of photochemically generated unstable manganese carbonyl intermediates. A preliminary account appeared elsewhere.[4p]

Experimental

All the syntheses were made under a purified nitrogen atmosphere. Photolyses were performed under a purified argon atmosphere with stirring in a Pyrex reaction vessel in which a Riko 100 W water-cooled high pressure Hg lamp was inserted. No filter was used to isolate particular emission from the Hg lamp. IR spectra were recorded on a JASCO-701G infrared spectrometer with 0.1 mm NaCl windowed liquid cells. Absorption spectra were obtained with a Shimadzu MPS-5000 spectrometer with 1 mm quartz cells. CH_2Cl_2 was employed as a solvent. Absorption data are collated in Table 1.

Materials. Me_3Sn–$Mn(CO)_5$ (I), $Me_2Sn[Mn(CO)_5]_2$ (II), $MeSn[Mn(CO)_5]_3$ (III), and Me_3Sn–$Mn(CO)_3[P(OPh)_3]_2$ (IV) (hereafter L denotes triphenyl phosphite) were prepared as described elsewhere.[4] Me_3Sn–$Mn(CO)_4L$ (V) and $Me_2Sn[Mn(CO)_4L]_2$ (VI) were obtained as follows: 1.4 g (1.5 mmol) of $[Mn(CO)_4L]_2$[7] was dissolved in 30 cm^3 of THF and was reduced to $NaMn(CO)_4L$ by stirring over 1% sodium amalgam. The pale yellow supernatant solution was decanted into a flask and to this was added 0.6 g (3 mmol) of Me_3SnCl or 0.35 g (1.5 mmol) of Me_2SnCl_2 in 25 cm^3 of THF with stirring. The mixture was stirred overnight. The resulting pale yellow solution was filtered by using a fine porosity glass frit and the solvent was vacuum-stripped to leave a pale brown oil. For V, the oil was extracted with hexane and the hexane was almost distilled off at reduced pressure to afford 1.5 g of pale yellow crystals (yield: 78%). For VI, the oil was extracted with hot hexane and the solvent was partially vacuum-stripped to give 1.0 g of pale yellow crystals (Yield: 60%). ν(CO)/cm^{-1} in benzene for V: 2048(w) and 1957(vs); for VI: 2088(vw), 2059(vw), 2036(w), 1990(m,sh), 1970(vs), and 1955(s, sh).

Photolysis of I and V. Each 1.0 g sample was dissolved in 50 cm^3 of dried benzene and was irradiated for more than 15 h, but no appreciable change other than decomposition was detected by IR. More than 95% of I was left intact and about 20% of V was decomposed after 15 h irradiation (based on IR spectra).

Photolysis of II. A 1.0 g sample of II was dissolved in 50 cm^3 of benzene and was photolyzed for 8 h. An IR monitoring showed that II was partially converted into other manganese carbonyl complexes. The solvent was removed under a reduced pressure and the residue was purified by column chromatography over Florisil. An yellow band was eluted with petroleum ether and recrystallization from the same solvent gave a small amount of $Mn_2(CO)_{10}$ (yield: more than 50 mg).

Photolysis of III. A 0.2 g sample of III was dissolved in 40 cm^3 of benzene and the solution was photolyzed for 20 min. An IR monitoring indicated complete digestion of III. Similar work up as in the case of II gave 30 mg of $Mn_2(CO)_{10}$.

Photolysis of IV. A 1.0 g sample of IV was dissolved in 50 cm^3 of benzene and photolysed for 8 h. After the solution was filtered, the solvent was distilled off at reduced pressure to leave a pale brown oil. The oil was dissolved in a minimum amount of benzene and was chromatographed over Florisil (60—100 mesh). Hexane was used as the first eluent. From the first fraction a small amount of V (40 mg) was obtained. Then, a hexane–benzene (1:2) mixture eluted the second, third, and fourth fractions. About 300 mg of the starting material IV was recovered from the second fraction. After the solvents were distilled off from the third and fourth fractions, the pale yellow oil was dissolved in a small amount of benzene and to this was added cyclohexane without agitation. The mixture was stored in a refrigerator for several weeks to yield 30 mg of $(PhO)_2\overline{P(OC_6H_4)}Mn(CO)_2L_2$ (**1**),[4p] 70 mg of *fac-cis*-$(PhO)_2\overline{P(OC_6H_4)}Mn(CO)_3L$ (**2**),[8] and 50 mg of IV. Finally an yellow band was eluted with $CHCl_3$ and recrystallization from benzene gave 15 mg of yellow crystals (**3**). Elemental analyses of **1**. Found: C, 64.24; H, 3.90; P, 8.73%. Calcd for $C_{56}H_{44}MnO_{11}P_3$: C, 64.62; H, 4.26; P, 8.93%.

Photolysis of VI. A 0.6 g sample of VI was dissolved in 50 cm^3 of benzene and the solution was irradiated for 6 h. After similar work up as in the case of IV, the products were separated by column chromatography over Florisil. The first fraction was eluted with hexane to afford a small amount of oil (about 10 mg). The IR spectrum of this oil was consistent with that of authentic $(PhO)_2\overline{P(OC_6H_4)}Mn(CO)_4$ (**4**).[9] An yellow band was then eluted with ethanol. Recrystallization from benzene–petroleum ether gave 15 mg of yellow crystals (**3**).[10]

Yields for photolysis products were averaged for several runs for IV and VI and IR data for photolysis products are given in Table 2.

Photolysis of Orthometalated Products. As a typical example, the photolysis of **2** is described. A 0.27 g sample of **2** was dissolved in 40 cm^3 of benzene and was photolyzed for 3 h. The solvent was removed under a reduced pressure to leave a pale brown oil. The oil was dissolved in a minimum amount of benzene and the solution was loaded on a Florisil column. From the first fraction eluted with petroleum ether, 12 mg of **4** was obtained. The second and third fractions were eluted with hexane–benzene (1:1) and were carefully recrystallized as in the photolysis of IV from benzene–petroleum ether to give 16 mg of **1**, 16 mg of **2** and 38 mg of *mer-trans*-$(PhO)_2\overline{P(OC_6H_4)}Mn(CO)_3L$ (**5**).[11] The fourth fraction was eluted with chloroform and recrystallization from benzene gave a small amount of yellow crystals (**3**).

Photolysis of IV in CCl_4. A 1.0 g sample of IV was dissolved in 50 cm^3 of CCl_4 and the solution was photolyzed for 2 h. After the solvent was vacuum-stripped, the resulting yellow solid was subjected to column chromatography

a) Positional parameters are multiplied by 10^4 and thermal parameters are given by the equivalent temperature factors.

(Florisil). The first fraction was eluted with hexane–benzene (1:1). Recrystallization from hexane–chloroform gave 220 mg of *mer-trans*-$ClMn(CO)_3L_2$.[12] The second fraction was also eluted with hexane–benzene (1:1) and recrystallization from hexane–chloroform yielded 10 mg of *fac-cis*-$ClMn(CO)_3L_2$.[12]

Photolysis of VI in CCl_4. A 0.5 g sample of **VI** was dissolved in 30 cm^3 of CCl_4 and the solution was photolyzed for 2 h. Similar work up as above gave 10 mg of *cis*-$ClMn(CO)_4L$ and 100 mg of *mer-trans*-$ClMn(CO)_3L_2$.[12]

a) Positional parameters are multiplied by 10^4 and thermal parameters are given by the equivalent temperature factors.

X-Ray Molecular Structure Analysis of **1**. Colorless crystals were grown up from hexane–benzene. A crystal of approximate dimensions $0.26\times0.19\times0.07$ mm^3 was mounted on a Rigaku AFC-5 automated four circle diffractometer equipped with graphite monochromated Mo $K\alpha$ radiation (λ=0.71073 Å). The crystal belongs to the triclinic system with unit cell dimensions a=10.820(3), b=25.943(3), c=10.061(2) Å, α=90.61(1), β=115.26(1), γ=82.77(1)°, V=2530.8(10) Å^3, and Z=2. A total of 4199 independent reflections with $|F_o|>3\sigma(|F_o|)$ were obtained at room temperature using the θ-2θ scan technique up to 2θ=50°. No absorption correction was applied. The structure was solved by the standard heavy atom method and refined based on P$\bar{1}$ space group by the use of a UNICS-III program package[13] and computers (HITAC M-180 and M-200H) at Institute for Molecular Science. A series of least-squares refinements for 71 nonhydrogen atoms with anisotropic temperature factors reduced R and R_w to 0.069, where anomalous dispersion correction for Mn and P was applied. The final positional parameters are listed in Table 3. The lists of thermal parameters and F_o and F_c are deposited as Document No. 8304 at the Chemical Society of Japan.

X-Ray Molecular Structure Analysis of **2**. Colorless crystals were obtained from cyclohexane–petroleum ether. Weissenberg photographs using Cu K_α indicated 4/m Laue symmetry. A crystal of approximate dimensions $0.24\times0.24\times0.24$ mm^3 was mounted on a Rigaku AFC-5 automated four circle diffractometer. A preliminary reflection data collection revealed systematic absences h00, 0k0, and 00l for h or k or l=2n+1 and hk0 for $h+k$=2n+1, which define the tetragonal space group P4$_2$/n (C_{4h}^4; No 86). The lattice constants, determined by a least-squares fit to 30 high angle ($20°\leq2\theta\leq30°$) reflections are a=b=25.768(3), c=10.720(3) Å, V=7117.9(24) Å^3, and Z=8. Intensity data were collected at −50 °C by using the same scanning technique as with **1** and a total of 3966 unique reflections with $|F_o|>3\sigma(|F_o|)$ were obtained in the region of h, k, l with $0<h$, k, l up to 2θ=55°. No absorption correction was made. The structure was solved by the standard heavy atom method and refined as mentioned above to give R=0.062 and R_w=0.073 for 51 nonhydrogen atoms with anisotropic temperature factors. Anomalous dispersion correction was applied for Mn and P at the final stage of refinement. Final positional parameters are collected in Table 4 and lists of thermal parameters and F_o and F_c are deposited as Document No. 8304 at the Chemical Society of Japan.

Results and Discussion

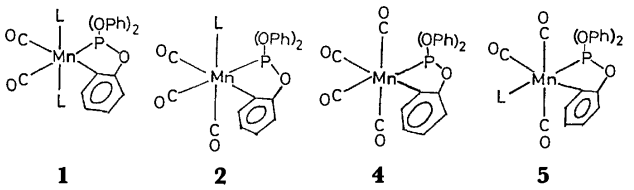
Absorption Spectra and Photoreactivity. The absorption spectra for the series of $(CH_3)_{3-x}Sn[Mn(CO)_5]_{x+1}$ (x=0, 1, and 2) are very much dependent on the number of manganese carbonyl groups; a strong absorption is observed at 385 nm besides a very strong absorption at 230 nm for III which possesses three tin-manganese bonds and a strong absorption is detected at 320 nm besides a very strong absorption at 230 nm for II which contains two tin-manganese bonds, while only a very strong absorption is observed at 230 nm for I which possesses only one tin-manganese bond. The very strong absorptions at 230 nm are as-

singable to the Mn to π^*(CO) charge transfer band and those strong absorptions at 385 and 320 nm are assignable to the σ_b(Sn–Mn)→σ^*(Sn–Mn) transition.[1,14] This transition may be hidden behind the very strong charge transfer band at 230 nm for I. Those compounds which possess triphenyl phosphite ligand(s) exhibit an extra absorption around 270 nm. This band is assignable to the π→π^* transition due to the phenyl groups in triphenyl phosphite, since free triphenyl phosphite itself shows this absorption. From a comparison of the absorption spectra for two groups of compounds, that is, I, IV, and V, and II and VI, we are led to the conclusion that the replacement of CO by triphenyl phosphite ligand(s) does not afford any obvious influence on the σ_b→σ^*(Sn–Mn) transition. Thus, the σ_b→σ^*(Sn–Mn) transition energy is in the order Sn–Mn > $Sn\langle^{Mn}_{Mn}$ > $Sn\langle^{Mn}_{Mn}$.

In order to understand the photochemical reactivity of the tin-manganese bonded compounds in connection with the excited states (Scheme 1), it is interesting to examine the relation between the reactivity of Sn–Mn bond and the excitation energy of this bond; the Sn–Mn bonds in III are degraded smoothly under UV irradiation to give $Mn_2(CO)_{10}$. III decomposes rapidly even under a fluorescent room light in CH_2Cl_2. II is partially digested by UV irradiation to yield $Mn_2(CO)_{10}$, while I does not react seemingly. The formation of $Mn_2(CO)_{10}$ from II and III is accounted for in terms of homolytic cleavage of the Sn–Mn bond[5,6,15] and coupling of the resulting ·$Mn(CO)_5$ radicals. Thus, the apparent order of the photoreactivity of Sn–Mn bond is inversely proportional to the order of the σ_b→σ^*(Sn–Mn) transition energy. This order also seems to be related to the light intensity of the lamp used; II and III can be excited by the intense emissions at 313 and 366 nm, respectively, but the emissions effective to excite I is weak in intensity and moreover, the solvent, C_6H_6, absorbs this range of light.

For I, IV, and V, it is unlikely that an electron in the σ_b(Sn–Mn) orbital is excited directly to σ^*(Sn–Mn) by emissions from the present Hg lamp as mentioned above. The observation that IV is more photosensitive than I and V tempts us to speculate an alternative photochemical reaction pathway; IV has an absorption at 270 nm which is assignable to the π→π^*(P(OPh)$_3$) transition and thus, it is conceivable that the low-lying empty π^* orbital should have some connection with the photoreactivity of IV. In this regard, two possible mechanisms come out, that is, an electron in σ_b(Sn–Mn) orbital is excited to the π^*(P(OPh)$_3$) orbital (Scheme 1(c)) or the Sn–Mn bond in IV, which should be enfeebled by the introduction of two bulky triphenyl phosphite ligands in cis positions toward the Sn–Mn bond, is readily labilized by an energy transfer mechanisms from the π→π^*(P(OPh)$_3$) transition.[16] At present, we have no evidence to differentiate these two mechanisms and this point must wait for future experiment.

Reaction Mechanisms of Orthometalation. As was described in the Experimental section, photodegradation of IV and VI in benzene gave orthometalated products (shown in Fig. 1), which contain no tin moiety. Therefore, the process of orthometalation should entail cleavage of the Sn–Mn bond in a certain process of the photochemical reaction. The Sn–Mn bond cleavage in the primary photoprocess was suggested by several experiments: Photolysis of IV in CCl_4 gave $ClMn(CO)_3L_2$ and photolysis of IV together with benzyl chloride in C_6H_6 gave bibenzyl. When the photolysis of IV is conducted in air-saturated benzene, only trace amounts of **1**, **2**, and V were obtained. The yields of **1**, **2**, and V were considerably decreased when argon was bubbled into the benzene solution during the photolysis to purge out gaseous products such as CO and H_2. These lines of evidence indicate that (i) the initial process of photolysis is homolytic cleavage[17] of the Sn–Mn bond to yield Me_3Sn· and ·$Mn(CO)_3L_2$ radicals according to



1 **2** **4** **5**

Fig. 1. Schematic pictures of orthometalated manganese carbonyl triphenylphosphite derivatives.

$$Me_3Sn\text{–}Mn(CO)_3L_2 \overset{h\nu}{\rightleftharpoons} Me_3Sn\cdot + \cdot Mn(CO)_3L_2, \quad (1)$$

(ii) the resulting 17-electron manganese carbonyl radical undergoes photochemical or thermal dissociation of the ligand, CO and/or L, according to

$$\cdot Mn(CO)_3L_2 \rightleftharpoons \cdot Mn(CO)_3L + L, \quad (2)$$

$$\cdot Mn(CO)_3L_2 \rightleftharpoons \cdot Mn(CO)_2L_2 + CO, \quad (3)$$

to generate 15-electron intermediates, and (iii) various steps which are likely to account for the formation of orthometalated products **1** and **2** and Me_3Sn–Mn(CO)$_4$L V as are described in Scheme 2 and Scheme 3.

In Scheme 2, the 15-electron intermediates play a key role to abstract hydrogen from a benzene ring in the triphenyl phosphite ligand, while in Scheme 3, the 17-electron radicals which are regenerated from the recombination of the 15-electron intermediates with CO or L abstract hydrogen from a benzene ring in the triphenyl phosphite ligand to form an orthometalated five-membered ring. Although the formations of **4** and Me_3Sn–$Mn(CO)_2L_3$ are expected for both Schemes, we could not isolate these products in spite of our repeated experiments. Me_3Sn–$Mn(CO)_2L_3$ may not be formed, since the steric congestion around the cis positions of the manganese atom toward the Sn–Mn bond, is detrimental to the formation of the Sn–Mn bond or this bond is easily cleaved by UV irradiation. On the other hand, no detection of **4** is enigmatic. Presumably, **4** eluded isolation because of its low yield. In order to differentiate the two schemes, we examined photolyses of orthometalated products, **2** and **5**[11] in benzene. The photolysis of **2** gave **1**, **4**, and **5** and the photolysis of **5** gave **1**, **2**, and **4**. These interconversions should proceed *via* dissociation of the ligand CO or L from the original orthometalated

compounds to generate five-coordinate 16-electron intermediates such as those described in Eqs. 4 and 5, and *via* recombination of the intermediates with L or CO to afford six-coordinate products.[18] Thus, it seems reasonable to conclude that five-coordinate orthometalated products can exist with considerable life time. Along the line of this observation together with the reasons described below, we are rather inclined to propose that Scheme 2 represents plausible pathways of the photochemical reaction of Me_3Sn–$Mn(CO)_3L_2$; first, kinetic studies on the photochemical reactions of $Mn_2(CO)_{10}$ with various phosphines and phosphites demonstrated that disubstituted radicals of the type $\cdot Mn(CO)_3L'_2$ are produced during the photolysis, but there is no precedent, to our knowledge,

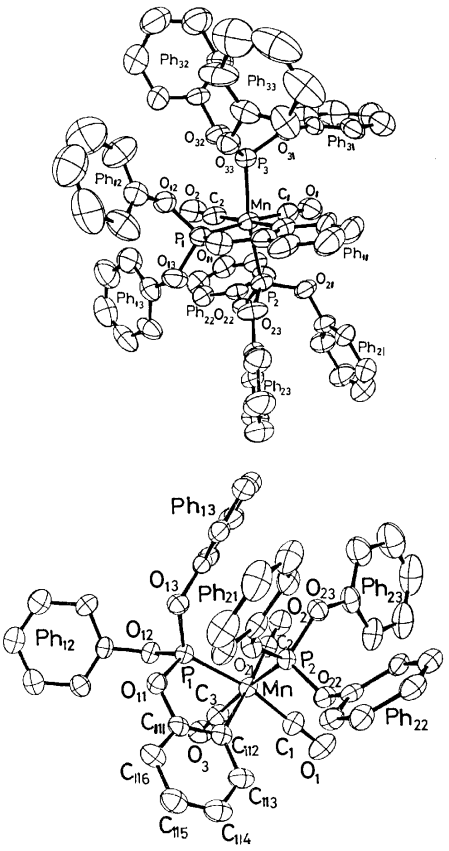

Fig. 2. Molecular structures and atom numbering schemes for **1** (Fig. 2(a)) and for **2** (Fig. 2(b)).

for trisubstituted radicals of the type $\cdot Mn(CO)_2L'_3$, especially for bulky L', the formation of which is mandatory before abstraction of the hydrogen in Scheme 3;[17] second, an ESR study showed that $\cdot Mn(CO)_3L'_2$ radical, which was formed by the photolysis of $Mn_2(CO)_{10}$ with L', possesses a square pyramidal structure where two L' groups occupy basal trans positions. In the present photochemical reaction, it seems certain that the resulting $\cdot Mn(CO)_3L_2$ radical from IV retains its trans geometry as in IV. Therefore, the main product must be **5** even though **5** is partly converted into its isomer **2** if the orthometalated products are formed directly from the 17-electron radical. In spite of this expectation, we could not isolate **5**.

Similar experiments were made for VI as for IV to confirm that the initial photochemical process is homolytic cleavage of the Sn–Mn bond. Photolysis of VI in CCl_4 produced *cis*-$ClMn(CO)_4L$, *mer-trans*-$ClMn(CO)_3L_2$, and a small amount of *fac-cis*-$ClMn(CO)_3L_2$. Photolysis of VI in air-saturated benzene did not afford orthometalated product **4** but gave several unidentified products instead. Photolysis of authentic $ClMn(CO)_4L$ in benzene gave *mer-trans*- and *fac-cis*-$ClMn(CO)_3L_2$. On the basis of these findings, we conclude that the initial photochemical process is homolytic cleavage of one of the Sn–Mn bonds to generate $\cdot Mn(CO)_4L$. Attempts to clarify the fate of the tin moiety have so far been fruitless.

molecular structures and atom numbering schemes for **1** and **2** are shown in Fig. 2. The coordination at the manganese atom approximates to a distorted octahedron for both the molecules. The molecular structure of **2** is similar to that of **1** except that the triphenyl phosphite ligand (P_2) has been replaced by a carbonyl group CO(3). The chelating phosphite is coordinated to the manganese atom through both the phosphorus atom and an ortho carbon atom of one of the phenoxyl groups to form a five-membered ring (Fig. 3). The manganese, phosphorus, oxygen, and six carbon atoms in the orthometalated phenyl group are almost coplanar; the greatest deviation of any of these atoms from the least-squares planes is 0.019 Å for **1** and 0.039 Å for **2**. The carbonyl carbon atoms in CO(1)

and CO(2) are as much as 0.07 Å away for **1** and 0.08 Å away for **2**, respectively, from the least-squares plane (Fig. 3). Although the coplanarity is believed to suggest possible π-electron delocalization over the relevant ring, the bond lengths associated with this ring do not differ significantly from those in the monodentate triphenyl phosphite groups in the same molecule. The selected bond lengths and bond angles are collated in Tables 5 and 6. A comparison of corresponding bond lengths for **1** and **2** indicates that replacement of the triphenyl phosphite on the manganese atom in **1** with a carbonyl leads to significant elongation of the distances from the manganese atom to the phosphorus, carbonyl carbon, and the ortho carbon atoms of the phenyl ring. The Mn–P distances observed for **1** and **2** are considerably shorter than those in analogous triphenylphosphine manganese complexes, 2.279(3)—2.304(4) Å.[19] The Mn–C(phenyl) distances, 2.078(8)—2.099(6) Å, are similar to the generally found Mn–C distances, 2.001—2.097 Å for analogous manganese triphenylphosphine systems.[19] All bond angles relevant to the chelate ring are smaller than normal bond angles of the related atoms, especially the deviation from the ideal angle of 90° is significant in the P_1–Mn–C(phenyl) angles. This angle for **2** is slightly smaller than that of **1**. The two axial triphenyl phosphite groups (we define the plane containing the orthometalated benzene ring as an equatorial plane) are considerably bent toward the orthometalated benzene ring (the angle P_2–Mn–P_3 is 165.7(1)°). The deviation from 180° is supposed to minimize the steric repulsion of the two axial triphenyl phosphite groups with the benzene rings (Ph_{12} and Ph_{13}) in the equatorial triphenyl phosphite group. This deviation is somewhat relaxed in **2** when one of the axial triphenyl phosphite groups is replaced by CO.

8) M. Y. Darensbourg., D. J. Darensbourg, and D. Drew, *J. Organomet. Chem.*, **73**, C25 (1974).

9) R. J. McKinney, R. Hoxmeier, and H. D. Kaesz, *J. Am. Chem. Soc.*, **97**, 3059 (1975).

10) ν(CO) of **3** in $CHCl_3$ is almost identical with that of authentic *mer-trans*-$XMn(CO)_3L_2$ (X=Cl and Br). We suspected at first that a trace amount of the starting material $BrMn(CO)_3L_2$ to synthesize IV is the origin of **3**. However, this possibility is excluded since it was not employed for the synthesis of VI. All the attempts including X-ray molecular structure analysis has so far been fruitless for characterizing this yellow crystal.

11) This product was obtained from the photolysis of $MeMn(CO)_3L_2$. Details of the photochemical reactions of this compound and related compounds will appear in a subsequent paper.

15) D. L. Morse and M. S. Wrighton, *J. Am. Chem. Soc.*, **98**, 3931 (1976).

16) It is a reasonable question that why V is inert to photoexcitation despite that V shows a spectrum similar to that of IV. To this question, we propose a rationale that the Sn–Mn bond in V is stronger than that of IV[41,4m] and that the Sn–Mn bond in V is not readily cleaved.

17) M. S. Wrighton and D. Bredensen, *J. Organomet. Chem.*, **50**, C35 (1973); M. S. Wrighton and D. S. Ginley, *J. Am. Chem. Soc.*, **97**, 2065 (1975); D. R. Kidd, C. P. Cheng, and T. L. Brown, *ibid.*, **100**, 4095, 4103 (1978).

18) For an alternative mechanism, one may think of dissociation of the bidentate triphenyl phosphite ligand, which regenerates free triphenyl phosphite ligand, or simple cleavage of the Mn–C(phenyl) bond, which generates "semi-free" triphenyl phosphite and then produces free triphenyl phosphite ligand. However, this mechanism is less likely, because we could not isolate either **1** or **2** or **5** from the prolonged photolysis of **4**. Presumably the five-membered metalation ring is sterically favorable and resists dissociation.[9]

The Preparation and Some Properties of Cobalt(II) Schiff Base Complexes and Their Molecular Oxygen Adducts

Kuninobu KASUGA,* Takeo NAGAHARA, Akira TSUGE,
Kunihisa SOGABE,† and Yasuo YAMAMOTO

Department of Chemistry, Faculty of Science, Shimane University, Matsue 690
† *Department of Chemistry, Faculty of Education, Shimane University, Matsue 690*

(Received April 10, 1982)

Seven new cobalt(II) complexes with a tetradentate Schiff base and their three oxygen adducts were synthesized. The adducts were stable at room temperature for several weeks. The isolated oxygen adducts showed intense new bands in the 1130—1150 cm^{-1} range characteristic of superoxide-like 1:1 oxygenated metal complexes. The ESR spectra of the adducts showed eight-lined, hyperfine structures with a very small splitting (10—20 G)** at 77 K. The adducts obtained were identified as monomeric 1:1 oxygen species, two complexes of which showed a reversible oxygenation in a 1,2-dichloroethane solution at 6 °C.

Cobalt(II) complexes with Schiff base have received considerable attention as biomimic model compounds for oxygen-carrying and storage proteins, such as hemoglobin and myoglobin.[1] Recently, many investigators have devoted their efforts to elucidate the mechanism of the oxygenation of the cobalt(II) complexes.[2-8] For instance, Basolo *et al.* reported that the electron density on a central cobalt(II) ion of the Schiff base complexes is an important factor in determining the oxygen affinity of the complexes.[3] The crystal structures of oxygen adducts of cobalt(II) Schiff base complexes with some peripheral groups in their ligand have also been determined by means of X-ray-diffraction analysis in order to elucidate the influence of the change in the substituents of the in-plane ligand on the cobalt-oxygen geometry.[9,10]

To date, many studies of the adducts of cobalt(II) Schiff base complexes have been published, but only a few monomeric 1:1 oxygen adducts are known to be stable at room temperature.[5,10-12] Therefore, it is of interest to elucidate the factors which determine the stability of the monomeric 1:1 oxygen adduct in the solid state; it is also important to prepare the adduct in order to improve the biomimic model system.

Seven new cobalt(II) complexes with a Schiff base derived from *N,N'*-bis(1-methyl-3-oxobutylidene)ethylenediamine (A-H) and *N,N'*-bis(1-methyl-3-oxo-3-phenylpropylidene)ethylenediamine (B-H) were synthesized; three of these complexes formed stable monomeric 1:1 oxygen adducts in the solid state. We wish to report here that the isolation of the stable oxygen adducts is affected by the kinds of peripheral groups and that the oxygen affinity of the complexes in solution is also dependent on the groups.

Experimental

Syntheses. Schiff Base Ligands: The ligands of A-Cl, A-succ, A-OPh, B-Cl, and B-succ were obtained by the elimination of metal with hydrogen sulfide from their copper(II) complexes, as has been described previously.[13,14] A-CONHPh and B-CONHPh were synthesized according to the method reported by Howells *et al.*[15]

Co(A-Cl): After A-Cl (1.2 g) had been suspended in 25 cm^3 of an ethanol solution saturated with potassium hydroxide, cobalt(II) acetate tetrahydrate (0.6 g) was added to the solution. Then, the solution was refluxed for 20 min under a nitrogen atmosphere, resulting in orange precipitates. The precipitates thus obtained were washed with ethanol and subsequently recrystallized from chloroform and small amounts of hexane. The other complexes were synthesized by a similar method.

B-CONHPh,	phenylcarbamoyl	phenyl

Fig. 1. Abbreviation of Schiff base ligands.

Oxygen Adducts of Co(A-Cl): By bubbling air through 10 cm^3 of an acetone solution of Co(A-Cl) (0.2 g) in the presence of small amounts of pyridine at 0 °C for several min, a dark-red oxygenated compound was precipitated. The precipitates were subsequently washed with ether and dried in air. The adducts of Co(A-succ) and Co(B-succ) were also obtained by a similar method. In the case of the other complexes, no oxygenated adducts were isolated.

Measurements. The ^{1}H-NMR spectra were recorded with a JEOL-MH 100 spectrophotometer at a frequency of 100 MHz. The chemical shifts were determined in ppm, using TMS as the internal standard. The electronic spectra in solution and the infrared spectra using Nujol-mull methods were measured on a Hitachi 124 spectrophotometer and a Hitachi 215 spectrophotometer respectively. The ESR spectra (X-band) were measured with a JEOL-1X spectrometer. The reversible oxygenation in a 1,2-dichloroethane solution was observed by means of the method reported by Kubokura *et al.*[5]

Results and Discussion

^{1}H-NMR Spectra of Ligands. The ^{1}H-NMR spectra of the ligands obtained are shown in Table 1.

The ^{1}H-NMR signals arising from the methine protons of the parent ligands, A-H and B-H, disappear in their derivatives, indicating the displacement of the methine protons in the derivatives. The ^{1}H-NMR signals of the succinimido groups in A-succ appear at lower magnetic fields than those of its methyl groups. On the other hand, the signals of the succinimido groups in B-succ are shifted to higher magnetic fields compared with those of its methyl groups. This may result from the effect of a ring current of phenyl groups in B-succ. The inductive effects of chloro and phenylcarbamoyl groups in A-Cl, A-CONHPh, B-Cl, and B-CONHPh shift ^{1}H-NMR signals of their methine and methyl protons to lower magnetic fields compared with their parent ligands.

Cobalt(II) Complexes and Their Oxygen Adducts. While Co(A-Cl) and Co(B-Cl) were dark reddish crystals, the other complexes were yellow or yellowish orange. The yellow Co(A-OPh) complex gradually changed to dark brown in polar-solvent moistures. The molecular oxygen adducts of the cobalt(II) complexes with A-Cl, A-succ, and B-succ were isolated and were stable at room temperature for several weeks (the stability was checked by means of the IR spectra). These adducts are sparingly soluble in common organic solvents. On the other hand, the adducts of the other cobalt(II) complexes could not be isolated, not even below 0 °C. When *N*-methylimidazole was employed instead of pyridine, no adducts were isolated. That is, the acetone solution of the complexes containing small amounts of the bases turned dark red when air bubbled in. Subsequently, reddish, tarry substances were formed by the condensation of the solution under reduced pressure or by the addition of hexane to the solution, but no adducts were isolated. The suitable solubility of a complex into a solution containing small amounts of the base seems to be one of the key factors for isolating the oxygen adduct. The results of elemental analyses, the yields, and the electronic spectra of the cobalt(II) complexes and some of their adducts are listed in Table 2.

The infrared spectra of the isolated adducts are shown in Fig. 2. The adducts show intense new bands arising from O–O stretching vibrations in the 1130—1150 cm^{-1} range characteristic of superoxide-like 1:1 oxygenated metal complexes.[1] The oxygenated complexes with succinimide-substituted, Schiff base complexes, Co(A-succ)pyO_2 and Co(B-succ)pyO_2, each show two ν_{O_2} bands. Such an appearance of the doublet of ν_{O_2} was also found in the oxygen adduct of cobalt(II) picket-fence porphirin with 1-tritylimidazole; it was due to two different conformers of molecular oxygen and to the base orientations.[16] In the case of the succinimide derivatives, the carbonyl groups

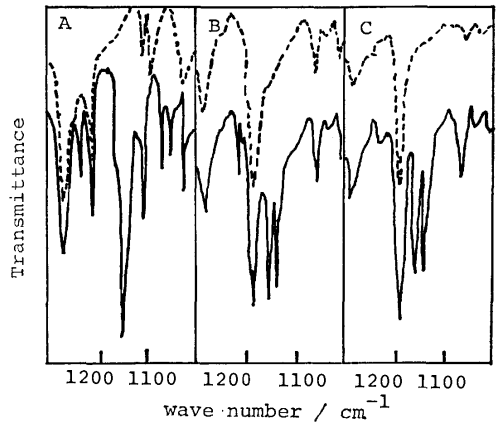

Fig. 2. IR spectra of the complexes and their oxygen adducts.
A: Co(A-Cl), B: Co(A-succ), C: Co(B-succ), ----: complex, ——: oxygen adduct.

vicinal to the imide residues might fix the plane of pyridine with dipole-dipole interactions, resulting in the two conformers.

The ESR data of the adducts were obtained in a 1,2-dichloromethane solution by the use of the X band at 77 K (Table 3). The spectra indicate two signals of $g//$ and $g_\perp$, and each signal consistents of eight lines due to the hyperfine splitting of ^{59}Co nucleus. The eight-lined hyperfine structures with the very small splitting indicate that the 1:1 oxygen adducts are isolated; this is consistent with the results of the IR data.

Reversible Oxygenation. Spectral changes were recorded for a 1,2-dichloroethane solution of Co(A-succ) containing 1% pyridine at different partial pressures of oxygen at 6.0±0.4 °C in order to estimate the oxygen uptake (1):

$$\text{Co(A-succ)py} + \text{O}_2 \overset{K_{\text{O}_2}}{\rightleftharpoons} \text{Co(A-succ)py}\text{O}_2. \quad (1)$$

A new absorption was observed at 525 nm when the complex was oxygenated. The intensity of the band increased with an increase in the partial pressure of oxygen. Subsequently, the original spectrum was recovered by bubbling a nitrogen gas through the solution. The stability constant for oxygenation, K_{O_2} is given by this relation:

$$P_{\text{O}_2} = -1/K_{\text{O}_2} + (\varepsilon_2-\varepsilon_1)[\text{Co(A-succ)}]_t P_{\text{O}_2}/A - A_\text{o}, \quad (2)$$

where A and A_o are the absorbances at 525 nm in the absence of oxygen and at the proper partial pressure of oxygen; ε_1 and ε_2 are the molar absorption coefficients of Co(A-succ)py and Co(A-succ)pyO_2; P_{O_2} is the partial pressure of oxygen; $[\text{Co(A-succ)}]_t$ is the total concentration of the complex. The plot of P_{O_2} against $P_{\text{O}_2}/A-A_\text{o}$ gave a straight line with a slope nearly equal to 1 (Fig. 3). This indicates that the monomeric oxygen adduct is formed in the solution, consistent with the isolation of the monomeric oxygen adduct. The value of $\log K_{\text{O}_2}$ (−2.48±0.01/Torr^{-1}) (1 Torr=133.322 Pa) was also obtained from the intercept of the line. In a similar manner, the value of $\log K_{\text{O}_2}$ (−2.85±0.02/Torr^{-1}) for Co(B-succ) was obtained. In spite of the isolation of the oxygen adduct,

Table 3. The results of IR and ESR spectral data for the oxygen adducts

Adduct	ν_{O_2}/cm^{-1} (Nujol mull)	$g//$	$g_\perp$	$A//$/G	$A_\perp$/G
Co(A-Cl)pyO_2	1141	2.079	1.999	17.5	13.8
Co(A-succ)pyO_2	1136, 1152	2.079	1.999	18.8	13.0
Co(B-succ)pyO_2	1132, 1150	2.079	1.996	17.5	12.5

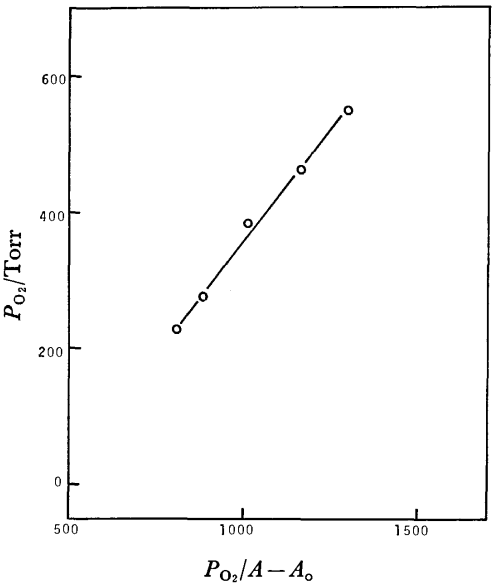

Fig. 3. Plots of P_{O_2} *versus* $P_{\text{O}_2}/A-A_\text{o}$ for the reversible oxygenation of Co(A-succ) (3.4×10^{-4} mol dm^{-3}) in a 1,2-dichloroethane solution containing 1% pyridine at 6.0±0.4 °C.

the reversibility of Co(A-Cl) was not confirmed under the present conditions.

While the phenyl groups in Co(B-succ) withdraw an electron from the chelate ring, resulting in a decrease in the electron density on the cobalt(II) ion, the methyl groups in Co(A-succ) increase the electron density on the cobalt(II) ion and stabilize the binding between the cobalt(II) ion and molecular oxygen. This may stabilize the adduct of Co(A-succ) more strongly than that of Co(B-succ) in solution.

Although the stability of the adduct of Co(A-H) in solution ($\log K_{\text{O}_2}=-2.08\pm0.03$/Torr^{-1} in a toluene solution at 0 °C) is larger than those of Co(A-succ) and Co(B-succ), the adduct of Co(A-H) releases molecular oxygen in the solid state above 0 °C.[17] On the other hand, the adduct of Co(B-H) is relatively stable in the solid state in spite of its low oxygen affinity in solution.[18] This has been explained by means of the coplanarity of the phenyl substituents with the Schiff base cobalt(II) system in the solid state; a π electron donation to the cobalt(II) ion from the π system in the phenyl groups stabilizes the binding between the cobalt(II) ion and molecular oxygen.[19]

However, judging from the fact that the oxygen adducts of Co(A-Cl), Co(A-succ), and Co(B-succ) are stable in the solid state at room temperature, there seem to be predominant factors for stabilizing the adducts in the solid state other than the electronic factor. More detailed studies will be performed in order to

elucidate these factors.

The Dehydrogenation of Nickel(II) Chelates of *rac*- and *meso*-2,2′-[(1,2-Diphenylethylene)bis(iminomethylene)]diphenol and Related Compounds

Hajime KANATOMI

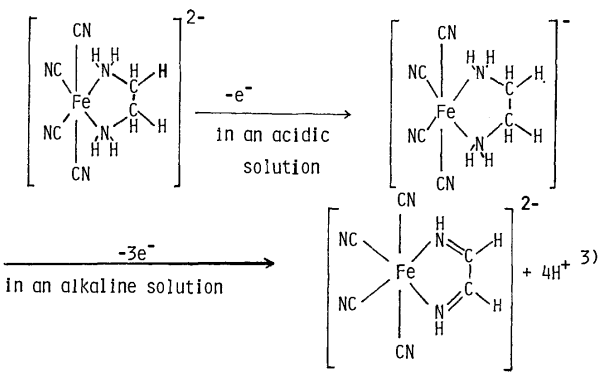
Laboratory of Chemistry, College of General Education, Kyushu University, Ropponmatsu, Chuo-ku, Fukuoka 810

(Received April 24, 1982)

Nickel(II) acetate tetrahydrate and *rac*- and *meso*-2,2′-[(1,2-diphenylethylene)bis(iminomethylene)]diphenol (*rac*- and *meso*-BzPhen-H_2) formed pale green complexes in methanol. A pyridine solution of these complexes deposited deep red diimine complexes after prolonged heating under aerobic conditions. The saturated ligand system of the initial complexes was dehydrogenated to an unsaturated one by molecular oxygen. From the pyridine solution of the *meso*-isomer, [2,2′-{(*cis*-1,2-diphenylethenylene)bis(nitrilomethylidyne)}diphenolato]nickel(II) ([Ni(SalStil)]) was isolated in addition to the diimine complex ([Ni(*meso*-SalPhen)]). In this case, the –HN–CH–CH–NH– bridge was dehydrogenated to =N–C=C–N= conjugated double bonds; that is, a fully conjugated metal chelate was formed by the dehydrogenation of the coordinated ligand.

The dehydrogenation of coordinated ligands has become of interest in recent years, and several reports have been published concerning the dehydrogenation of macrocyclic polyamines to polyimines,[1,2] of aliphatic 1,2-diamines to 1,2-diimines,[3,4] of primary amines to nitriles,[5,6] and of 3,3′,4,4′-tetrahydro-2,2′-bi-2*H*-benzoxazines to fully conjugated metal chelates.[7]

In these oxidations the net reaction is considered to necessarily involve the prior oxidation of a metal ion to unstable, higher oxidation states, followed by the oxidation of the ligands and the reduction of the metal ion. In practice, iron(III) and ruthenium(III) complexes were isolated as intermediates of the dehydrogenation described below:



$$[(bipy)_2Ru(en)]^{2+} \xrightarrow{-e^-} [(bipy)_2Ru(en)]^{3+}$$

$$\xrightarrow{-3e^-} [(bipy)_2Ru(diimine)]^{2+} + 4H^+ \ ^{4)}$$

Macrocyclic tetramine complexes were oxidized to imine complexes of varying degrees of unsaturation, depending upon the reaction conditions. Iron(II) complexes were readily dehydrogenated by molecular oxygen,[1,3] while nickel(II) complexes generally required stronger oxidizing reagents such as Br_2 or HNO_3.[3] In the present case, nickel(II) complexes undergo dehydrogenation under mild conditions.

The structures and abbreviations of nickel(II) chelates are given in Fig. 1.

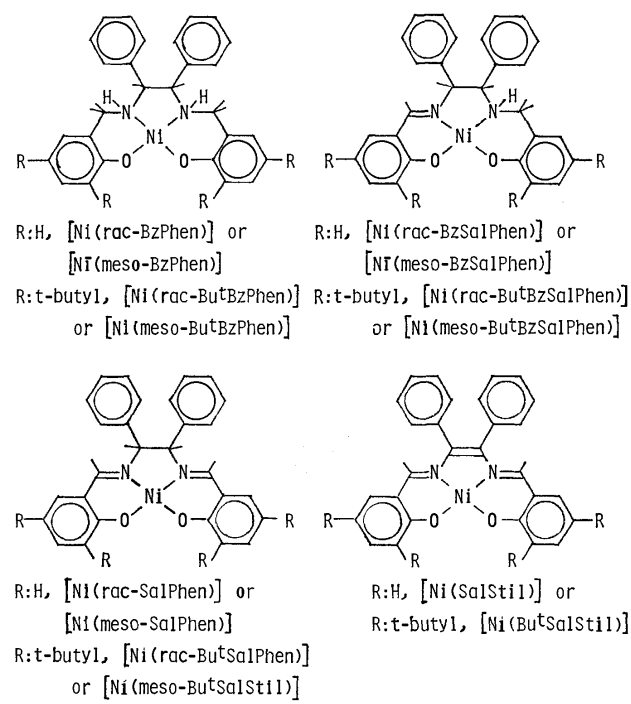


Fig. 1. Structural formulas and abbreviations for starting materials and oxidized products.

Experimental

The analytical data for the free ligands and the nickel(II) chelates are listed in Tables 1 and 2. All the nickel(II) chelates were dried under a vacuum over P_2O_5 at 50 °C.

General Procedure for the Preparation of rac- *and* meso-*BzPhen-H_2, and* rac- *and* meso-*But BzPhen-H_2.* A Schiff base (5 g) was dissolved in pyridine (200 cm³) and to the resulting yellow solution crystals of sodium borohydride were added in small portions on a water bath until the yellow color of the solution disappeared. The reaction mixture was then evaporated to about 50 cm³ under reduced pressure. To the resulting syrup was added dilute acetic acid (300 cm³). The white crystals which separated out were collected by suction and washed with water. The solvents used for recrystallization and the yield of each ligand are listed in Table 1.

*amine (*meso-*BzSalPhen-*H_2*)*. *N*-Benzylidene-*N'*-benzoyl-*meso*-1,2-diphenylethylenediamine[8] (8 g, 0.02 mol) was suspended in concentrated hydrochloric acid (130 cm^3), and the mixture was heated on a water bath for 2 h. After cooling, a colorless precipitate was collected by filtration; from this precipitate *N*-benzoyl-*meso*-1,2-diphenylethylenediamine hydrochloride (1) was extracted by the use of hot methanol (200 cm^3). *N*-Benzoyl-*N'*-salicylidene-*meso*-1,2-diphenylethylenediamine (2) was prepared as colorless crystals from (1) and salicylaldehyde using the ordinary method. (2) was reduced to *N*-benzoyl-*N'*-(2-hydroxybenzyl)-*meso*-1,2-diphenylethylenediamine (3) with sodium borohydride as has been described above. (3) was hydrolyzed by concentrated hydrochloric acid on prolonged heating (24 h) to afford *N*-(2-hydroxybenzyl)-*meso*-1,2-diphenylethylenediamine (4). (4) was then treated with salicylaldehyde to give *N*-(2-hydroxybenzyl)-*N'*-salicylidene-1,2-diphenylethylenediamine (*meso*-BzSalPhen-H_2) as pale yellow crystals, which were subsequently recrystallized from methanol. Yield, 2.5 g.

Preparation of Nickel(II) Complexes. [*Ni(*rac-*BzPhen)*]: *rac*-BzPhen-H_2 (420 mg, 1 mmol) and nickel(II) acetate tetrahydrate (240 mg, 1 mmol) were dissolved in hot methanol (40 cm^3), and the resulting light green solution was allowed to stand overnight at room temperature. The light blue crystals which separated out were collected by filtration and washed with methanol. Yield, 450 mg.

[*Ni(*meso-*BzPhen)*]: *meso*-BzPhen-H_2 (210 mg, 0.5 mmol) and nickel(II) acetate tetrahydrate (120 mg, 0.5 mmol) were dissolved in gently boiling methanol (15 cm^3), after which 4 drops of a 20% sodium hydroxide solution were added to the solution. The pale green crystals which immediately separated out from the pink solution were collected by filtration and washed with methanol. Yield, 200 mg.

[*Ni(*meso-*BzSalPhen)(py)*]: *meso*-BzSalPhen-H_2 (210 mg, 0.5 mmol) and nickel(II) acetate tetrahydrate (120 mg, 0.5 mmol) were dissolved in pyridine (10 cm^3) and water was added to the resulting red solution until it began to become turbid. After the solution had stood several hours, the orange-red crystals which separated out were collected by filtration and washed with pyridine–water. Yield, 180 mg.

[*Ni(*meso-*BzSalPhen)(py)*] *from* [*Ni(*meso-*BzPhen)*]: To a solution of *meso*-BzPhen-H_2 (420 mg, 1 mmol) in acetone (30 cm^3) was added nickel(II) acetate tetrahydrate (240 mg, 1 mmol) in methanol (20 cm^3). To the resulting pale green solution, a 20% sodium hydroxide solution was then added dropwise until the solution turned deep red. After standing overnight at room temperature, the solution was placed in 100-cm^3 flask equipped with a gas inlet tube and a condenser. Air was continuously bubbled through the solution for 5 h at room temperature. After then removing the condenser, the volume of the solution was reduced to 10 cm^3 by air bubbling. The resulting orange-red precipitate was collected by filtration, washed with water, and dissolved in methanol (20 cm^3). The insoluble products were removed by filtration, and the filtrate was evaporated to dryness. The orange-red residue was recrystallized from pyridine–water. Yield, 200 mg (42%).

[*Ni(*meso-*Bu^{t}BzSalPhen)*] *from* [*Ni(*meso-*Bu^{t}BzPhen)*]: *meso*-Bu^{t}BzPhen-H_2 (650 mg, 1 mmol) and nickel(II) acetate tetrahydrate (720 mg, 3 mmol) were dissolved in acetone–methanol (60 cm^3) on a water bath, and 20 drops of a 20% sodium hydroxide solution were added to the solution. The resulting deep red solution was allowed to stand 2 d at room temperature, and the volume of the solution was reduced to about 10 cm^3 by air bubbling. The deep red precipitate was filtered, washed with water, and recrystallized from methanol to give red plates. Yield, 550 mg (75%).

[*Ni(*rac-*BzSalPhen)*] *from* [*Ni(*rac-*BzPhen)*]: *rac*-BzPhen-H_2 (210 mg, 0.5 mmol) and nickel(II) acetate tetrahydrate (120 mg, 0.5 mmol) were dissolved in hot methanol (50 cm^3), after which 12 drops of a 20% sodium hydroxide solution were added to the pale blue solution. The resulting deep red solution was allowed to stand overnight at room temperature, and the orange-red crystals which separated out were collected by filtration and washed with methanol. Yield, 200 mg (84%).

Dehydrogenation in Pyridine Solution. *A)* [*Ni(SalStil)*]

and [*Ni(*meso-*SalPhen)*] *from* [*Ni(*meso-*BzPhen)*]: *meso*-BzPhen-H_2 (420 mg, 1 mmol) and nickel(II) acetate tetrahydrate (240 mg, 1 mmol) were dissolved in pyridine (15 cm^3). The resulting light green solution was heated on a water bath for 30 h. A deep red color formed after heating for 1 h. After cooling, methanol (70 cm^3) was added to the reaction mixture to induce crystallization. The orange-red needles ([Ni(SalStil)]) thus precipitated were filtered and washed with methanol. Yield, 60 mg (13%). After the filtrate had stood overnight at room temperature, [Ni(*meso*-SalPhen)] precipitated from the filtrate as deep red plates. Yield, 200 mg (42%).

B) [*Ni(Bu*^{t}*SalStil)*] *from* [*Ni(*meso-*Bu*^{t}*BzPhen)*]: The procedure was the same as that described for the preparation of [Ni(SalStil)] and [Ni(*meso*-SalPhen)]. *meso*-Bu^{t}BzPhen-H_2 (650 mg, 1 mmol) and nickel(II) acetate tetrahydrate (480 mg, 2 mmol) afforded 430 mg (61%) of [Ni(Bu^{t}SalStil)]. From the filtrate, a trace amount (15 mg) of [Ni(*meso*-Bu^t-SalPhen)] was obtained.

C) [*Ni(*rac-*SalPhen)*] *from* [*Ni(*rac-*BzPhen)*]: *rac*-BzPhen-H_2 (420 mg, 1 mmol) and nickel(II) acetate tetrahydrate (240 mg, 1 mmol) afforded 200 mg (42%) of [Ni(*rac*-SalPhen)].

D) [*Ni(*rac-*Bu*^{t}*SalPhen)*] *from* [*Ni(*rac-*Bu*^{t}*BzPhen)*]: *rac*-Bu^{t}BzPhen-H_2 (650 mg, 1 mmol) and nickel(II) acetate tetrahydrate (240 mg, 1 mmol) afforded 320 mg (46%) of [Ni(*rac*-Bu^{t}SalPhen)].

E) [*Ni(*meso-*SalPhen)*] *from* [*Ni(*meso-*BzSalPhen)*]: *meso*-BzSalPhen-H_2 (210 mg, 0.5 mmol) and nickel(II) acetate tetrahydrate (300 mg, 1.25 mmol) were dissolved in pyridine (10 cm^3), and the resulting red solution was heated on a water bath for 30 h. After cooling, water was added to the reaction mixture until it began to become turbid. The resulting crystals were collected by filtration and washed with methanol. Yield, 150 mg (63%).

F) Formation of [*Ni(*meso-*SalPhen)*] *by* H_2O_2 *oxidation of* [*Ni(*meso-*BzSalPhen)*]: Five drops of a 30% hydrogen peroxide solution were added to a solution of [Ni(*meso*-BzSalPhen)(py)] (110 mg, 0.2 mmol) in pyridine (15 cm^3), after which the mixture was heated on a water bath for 5 h. After cooling, water was added until the mixture began to become turbid. The resulting red crystals were filtered and washed with methanol. Yield, 70 mg (73%).

Measurements. IR spectra and electronic spectra were recorded on a Hitachi EPI S2 spectrometer and a Hitachi EPS 3T spectrometer respectively. NMR spectra were obtained on a Hitachi Model R-24 spectrometer, with Me_4Si as an internal standard.

Results and Discussion

The reaction of *rac*-BzPhen-H_2 or *meso*-BzPhen-H_2 with nickel(II) acetate afforded a pale green nickel(II) chelate, [Ni(*rac*-BzPhen)] or [Ni(*meso*-BzPhen)]. Pyridine solutions of these complexes or a pyridine solution containing an equimolar ligand (*rac*-BzPhen-H_2 or *meso*-BzPhen-H_2) and nickel(II) acetate changed color from light green to deep red on prolonged heating in air. The change was irreversible, and red crystals were deposited from the resulting red-colored solution in each case.

It was found that [Ni(*rac*-BzPhen)] afforded only one deep red product, while [Ni(*meso*-BzPhen)] gave two products, orange-red needles and deep red plates. The deep red products from the *rac*- and *meso*-chelates were identified as [Ni(*rac*-SalPhen)] and [Ni(*meso*-SalPhen)] respectively by a comparison of their IR spectra with those of authentic samples[9] and by elemental analyses.

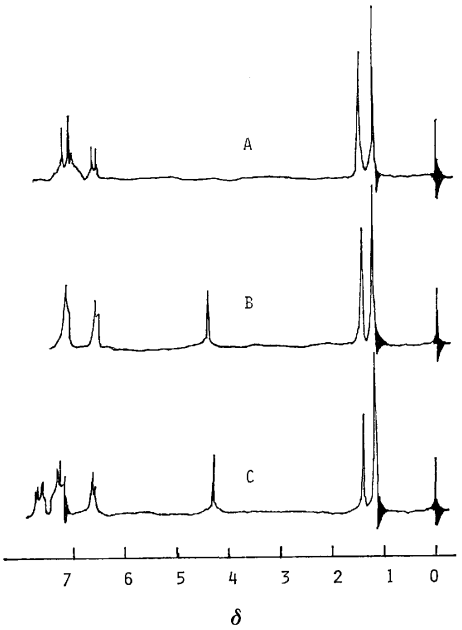

Fig. 2. NMR spectra of [Ni(Bu^{t}SalStil)] (A), [Ni(*meso*-Bu^{t}SalPhen)] (B), and [Ni(*rac*-Bu^{t}SalPhen)] (C).

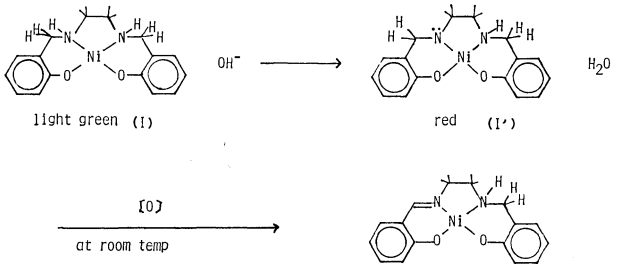
The IR spectrum of the orange-red product from [Ni(*meso*-BzPhen)] was apparently different from that of [Ni(*meso*-SalPhen)]. It exhibits no absorptions in the region of 2900 cm^{-1}, where the C–H stretching vibrations due to the benzylmethylene and methine on the diamine moiety are expected to appear. The latter was observed at 2900 cm^{-1} in the spectrum of [Ni(*meso*-SalPhen)]. This, together with the analytical data, suggested that this chelate contained a fully conjugated ligand system, namely, [Ni(SalStil)], as is illustrated in Fig. 1.

It was difficult to obtain the precise NMR spectrum of this chelate because of its low solubility in organic solvents. For the purpose of increasing the solubility, *meso*-Bu^{t}BzPhen-H_2 was prepared and allowed to react with nickel(II) acetate. Although the corresponding nickel(II) chelate, [Ni(*meso*-Bu^{t}BzPhen)], could not be isolated as crystals from the methanol solution, a red nickel(II) chelate was obtained successfully from the pyridine solution on prolonged heating. The NMR spectrum of this chelate is compared with those of [Ni(*meso*-Bu^{t}SalPhen)] and [Ni(*rac*-Bu^{t}SalPhen)] in Fig. 2. The spectrum apparently lacks a signal attributable to methine protons on the diamine moiety, which is observed in the spectra of [Ni(*rac*-Bu^{t}SalPhen)] and [Ni(*meso*-Bu^{t}SalPhen)] at δ 4.36 and 4.69 respectively. This indicates that the dehydrogenation took place at the bridged carbon atoms to form the *cis*-stilbene moiety. It can deffinitly be concluded that the reaction of *meso*-Bu^{t}BzPhen-H_2 with the nickel(II) ion in the presence of molecular oxygen proceeds with the dehydrogenation of the ligand and affords predominantly the nickel(II) chelate containing a fully conjugated ligand system, namely, [Ni(Bu^{t}SalStil)], while scarcely [Ni(*meso*-Bu^{t}SalPhen)] was formed in

this reaction.

As has been mentioned above, *meso*-BzPhen-H_2 and nickel(II) acetate in methanol formed a pale pink solution upon the addition of a few drops of an aqueous sodium hydroxide solution, and [Ni(*meso*-BzPhen)] separated out as light green crystals from the solution. Dehydrogenation did not proceed under the present reaction conditions. On the other hand, the addition of more aqueous sodium hydroxide to the pink solution before the precipitation of the chelate produced a deep red color and an orange-red precipitate separated out when the mixture stood overnight at room temperature. Recrystallization from pyridine–water gave brilliant red crystals. It was found that a two-electron oxidation took place in this case; the crystals were identified as [Ni(*meso*-BzSalPhen)(py)], the structure of which is shown in Fig. 1. For the purpose of identification, the ligand, *meso*-BzSalPhen-H_2 was prepared by a different route, and the IR spectrum of its nickel(II) chelate was compared with that of the above sample. Under the same reaction conditions, *rac*-BzPhen-H_2 and *meso*-Bu^{t}BzPhen-H_2 also gave the same types of chelates, [Ni(*rac*-BzSalPhen)], and [Ni(*meso*-Bu^{t}BzSalPhen)], in good yields. Thus, it is clear that this type of dehydrogenation reaction readily occurs for these chelates in a basic solution, even at room temperature. The reaction mechanism can be formulated as in Scheme 1. The addition of alkali causes deprotonation, and the deprotonated species I′ is apparently sensitive to molecular oxygen and is readily oxidized to the mono imine nickel(II) chelates.



Scheme 1.

The electronic spectra of [Ni(*meso*-Bu^{t}BzSalPhen)], [Ni(*meso*-Bu^{t}SalPhen)], and [Ni(Bu^{t}SalStil)] in pyridine are compared in Fig. 3. The spectra of [Ni(*meso*-Bu^{t}BzSalPhen)] and [Ni(*meso*-Bu^{t}SalPhen)] show d-d transition bands at 580 and 570 nm respectively. The band for [Ni(Bu^{t}SalStil)] is not observed because of the tailing of an intense charge-transfer band. The spectral changes with the time are shown in Fig. 4 for [Ni(*meso*-Bu^{t}BzSalPhen)] in pyridine and for a pyridine solution containing *meso*-Bu^{t}BzPhen-H_2 and nickel(II) acetate in Fig. 5. As may be seen in Fig. 4, the band at 430 nm increases, and the absorption around 500 nm decreases, in intensity with the time. This indicates that [Ni(*meso*-Bu^{t}BzSalPhen)] is formed exclusively from [Ni(*meso*-Bu^{t}BzSalPhen)] and that the formation of [Ni(Bu^{t}SalStil)] does not occur at all under these conditions. On the other hand, as is shown in Fig. 5, the band around 500 nm which is due to the [Ni(Bu^{t}SalStil)] species increases in intensity with the time from the initial stage. This

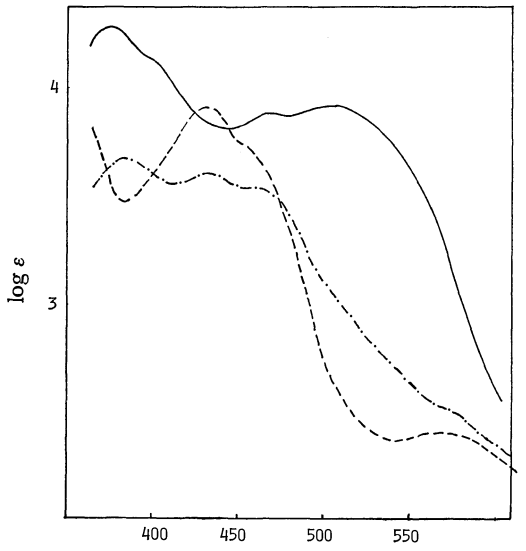


Fig. 3. The electronic spectra of [Ni(Bu^{t}SalStil)] (——), [Ni(*meso*-Bu^{t}SalPhen)] (----), and [Ni(*meso*-Bu^{t}BzSalPhen)] (—·—) in pyridine.

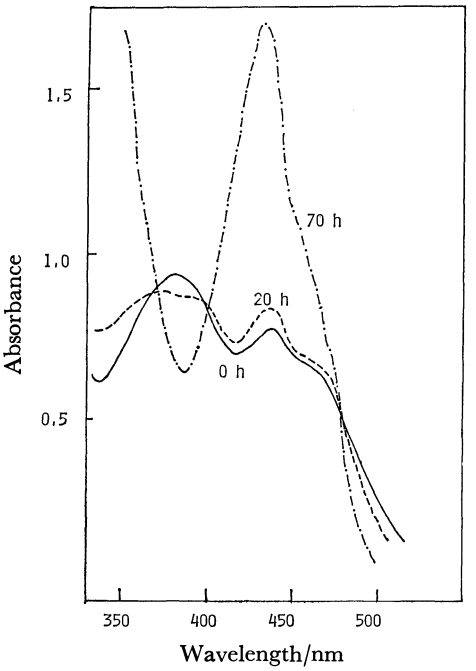

Fig. 4. Spectral changes with the time for the dehydrogenation of [Ni(*meso*-Bu^{t}BzSalPhen)] (1.97×10^{-5} mol) in pyridine (10 cm^3) at 90 °C.

result is consistent with the fact that [Ni(Bu^{t}SalStil)] is exclusively formed in the solution. In other words, the formation of [Ni(Bu^{t}SalStil)] occur even at the initial stage of dehydrogenation. These results give some insight into the formation mechanism of [Ni(Bu^{t}SalStil)] and [Ni(*meso*-Bu^{t}SalPhen)]. The formation of [Ni(*meso*-Bu^{t}SalPhen)] by the dehydrogenation of [Ni(*meso*-Bu^{t}BzPhen)] proceeds in two step by-step processes via the formation of [Ni(*meso*-Bu^{t}BzSalPhen)]. While the formation mechanism of [Ni(Bu^{t}SalStil)] is still unclear, the process via the formation of [Ni(*meso*-

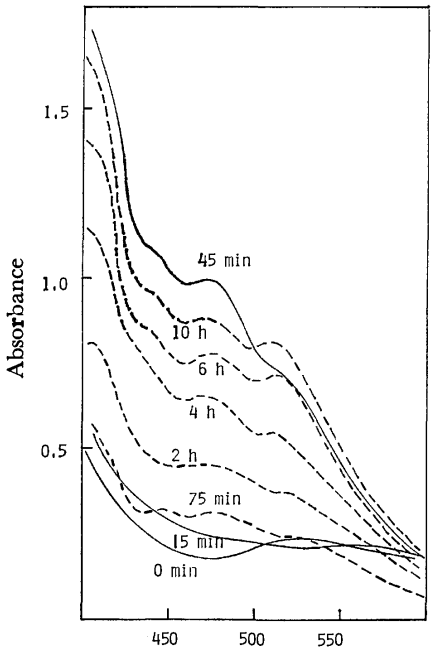

Fig. 5. Spectral changes with the time for the dehydrogenation [Ni(*meso*-Bu^{t}BzPhen)] [*meso*-Bu^{t}BzPhen-H_2 (2.4×10^{-5} mol) and nickel(II) acetate tetrahydrate (3.5×10^{-5} mol) in pyridine (10 cm^3) at 90 °C]; [—— obtained by using 1 cm quartz cell and ---- obtained by using (1 cm quartz cell+9 mm quartz spacer)].

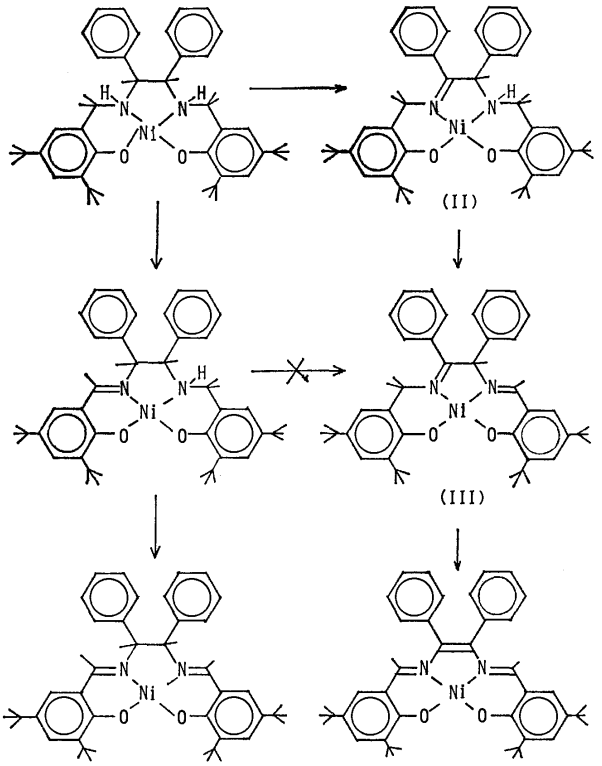
Bu^{t}BzSalPhen)] can be disregarded, as has been described above. Therefore, it is most probable for the formation of [Ni(Bu^{t}SalStil)] to postulate the existence of an intermediate containing an enamine-type ligand system (III). Such intermediates have been isolated in the metal-ion-induced rearrangement of 3,3′,4,4′-tetrahydro-2,2′-bi-2*H*-1,3-benzoxazines and subsequent dehydrogenation reactions,[7] though the isolation of such species was unsuccessful in these cases. The proposed reaction mechanism of the dehydrogenation is summarized in Scheme 2. As has been mentioned before, [Ni(*meso*-BzPhen)] was dehydrogenated to give [Ni(*meso*-SalPhen)], and to give [Ni(SalStil)] as a by-product. This dehydrogenation also proceeds in a manner quite similar to that described in Scheme 2. In practice, the reaction of *meso*-BzSalPhen-H_2 with nickel(II) acetate in pyridine or the dehydrogenation of [Ni(*meso*-BzSalPhen)] with H_2O_2 in pyridine afforded [Ni(*meso*-SalPhen)] as the sole product.

The electron-transfer mechanism in the oxidative dehydrogenation of the nickel(II) chelates is not clear, but probably molecular oxygen combines with the nickel(II) ion at the axial positions and transfers electrons through the nickel(II) ion. If an initial electron loss from the nickel(II) ion is assumed, the transition state of the dehydrogenation may involve the trivalent oxidation state of nickel. The formation of such species has previously been reported in the dehydrogenation of macrocyclic nickel(II) chelates.[10,11] The nickel(III) complexes which were formed by electrochemical or chemical oxidation gave nickel(II) ligand radical species upon treatment with basic solvents such as pyridine according to this scheme;



Scheme 2.

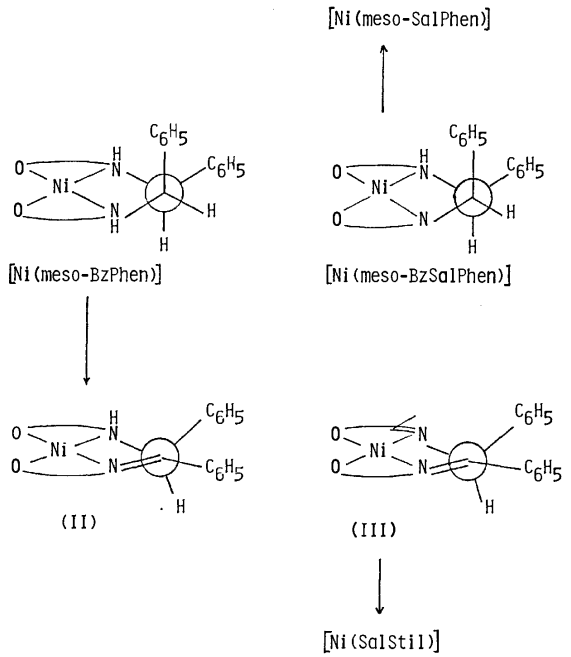
$$\text{Ni(III)N-H} + :\text{B} \longrightarrow \text{Ni(II)N}\cdot + \text{HB}^+$$

Further, the free radical species afforded, via several different processes, monoimine nickel(II) chelates.[11] In the present case, similar nickel(III) chelates and free radical species must be involved prior to the ligand oxidation.

It should be noted that the nickel(II) chelates containing a fully conjugated ligand system were formed only when *meso*-chelates were dehydrogenated. In addition, the *t*-butyl groups on the benzene nucleus promoted the formation of fully conjugated chelates. In the dehydrogenation of [Ni(*meso*-BzPhen)], [Ni(SalStil)] was obtained in a low yield as a by-product, while [Ni(Bu^{t}SalStil)] was exclusively obtained from [Ni(*meso*-Bu^{t}BzPhen)]. It is clear that the *t*-butyl groups situated in the *ortho* position of the phenol oxygen atoms exerted such an effect on the dehydrogenation because in the dehydrogenation of a *meso*-chelate having a *t*-butyl group in the position *para* to the OH group of the hydroxybenzyl moiety the situation was quite similar to that of [Ni(*meso*-BzPhen)].

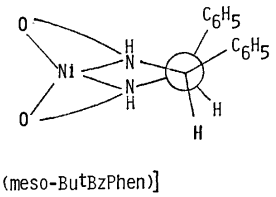
The stereospecific dehydrogenation of *meso*-chelates may be attributable to the conformation of phenyl groups on the diamine moiety; that is, the only possible conformation for the two phenyl groups is axial-equatorial, and they are crowded on one side relative to the metal chelate plane. On the other hand, on the formation of intermediates (II) and (III) from *meso*-chelates, the conformational changes in the two phenyl groups can be assumed to be as is shown in Scheme 3. These conformational changes accompany the partial removal of the unfavourable strain, which

is due to the crowding state of the two phenyl groups in the starting chelate. Thus, this will be the reason why the formation of [Ni(SalStil)] was possible only in the dehydrogenation reaction of the *meso*-chelates.



Scheme 3.

In the [Ni(*meso*-Bu^{t}BzPhen)], the steric repulsion due to the two bulky *t*-butyl groups situated in the *ortho* position of the phenol oxygen atoms may produce a considerable distortion, as is depicted below:



Scheme 4.

In fact, the splitting of the d-d band (540 nm and 630 nm) was observed in the reflectance spectrum of [Cu(*meso*-Bu^{t}SalPhen)], which was considered to be due to a tetrahedral distortion of the chelate ring.[12] Such distortion is common among *meso*-Bu^t-chelates; it may be the reason why the isolation of [Ni(*meso*-Bu^{t}BzPhen)] was difficult. It is apparent that the serious strain in [Ni(*meso*-Bu^{t}BzPhen)] is removed by the formation of the intermediates (II) and (III); this makes it likely to afford [Ni(Bu^{t}SalStil)].

Extractive Spectrophotometric Determination of Antimony(III), Bismuth, Indium, and Gallium with Pyrocatechol Violet and Tridodecylethylammonium Bromide

Yoshio Shijo,* Tokuo Shimizu, and Kaoru Sakai

Department of Environmental Chemistry, Faculty of Engineering, University of Utsunomiya, Ishii-machi, Utsunomiya 321

(Received April 28, 1982)

The spectrophotometric method for the determination of trace amounts of antimony(III), bismuth, indium, and gallium based on the solvent extraction of the ion associate formed between anionic metal–Pyrocatechol Violet complexes and tridodecylethylammonium bromide is proposed. The maximum absorbance of the extracted species occur at 530, 564, 600, and 595 nm for antimony(III), bismuth, indium, and gallium. The molar absorptivities for antimony(III), bismuth, indium, and gallium are 3.32×10^4, 3.31×10^4, 8.20×10^4, and 8.00×10^4 $dm^3\ mol^{-1}\ cm^{-1}$. The optimum pH ranges for the extraction of antimony(III), bismuth, indium, and gallium are from 3.7 to 4.8, from 5.8 to 6.7, from 5.3 to 5.4, and from 5.5 to 6.2 respectively. The composition of the extracted complexes (metal:PV:TDEA) are estimated to be 1:2:3 for antimony(III) and 1:2:2 for the other metals. The interference of foreign ions is described.

The extraction of the anionic metal complexes with lipophilic quaternaryammonium salts has been utilized for various analytical purposes, such as the separation of metal ions,[1] and the extractive spectrophotometric,[2] fluorometric,[3] polarographic,[4] and atomic-absorption spectrophotometric[5,6] determination of metals. Trioctylmethylammonium chloride (Aliquat 336 or Capriquat) has been in common use as an extracting reagent in this field. Iodide of antimony and 17 other elements,[6] anionic complexes with EDTA of bismuth and 14 other elements,[7] iodide of bismuth and six other elements,[8] indium in a hydrochloric–sulfuric system,[9] chloride of indium,[10,11] thiocyanate of indium,[12] and chloride of indium and gallium[13] were extracted with the foregoing reagent.

Tridodecylethylammonium bromide (TDEABr), which is more lipophilic than trioctylmethylammonium chloride, is also useful for the extraction of the anionic metal complexes. The Pyrocatechol Violet (abbreviated to PV hereafter) complexes of aluminium,[14] tungsten,[15] vanadium,[16] *etc.* were extracted with TDEABr in organic solvents. The anionic PV complexes of antimony(III), bismuth, indium, and gallium can also be extracted with TDEABr in several nonpolar solvents. The fundamental conditions for the extractive spectrophotometric determination of antimony(III), bismuth, indium, and gallium with PV and TDEABr are studied in this paper.

Experimental

Reagent. A 2.50×10^{-3} mol dm^{-3} antimony(III) solution was prepared by dissolving 0.4174 g of antimony potassium tartrate in 500 cm^3 of 3 mol dm^{-3} hydrochloric acid. A 2.50×10^{-3} mol dm^{-3} bismuth solution was prepared by dissolving 0.2612 g of bismuth metal in 71.4 cm^3 of 7 mol dm^{-3} nitric acid and then diluting the mixture to 500 cm^3. A 2.50×10^{-3} mol dm^{-3} indium solution was prepared by dissolving 0.1435 g of indium metal in 37.2 cm^3 of nitric acid and then diluting the mixture to 500 cm^3. A 2.50×10^{-2} mol dm^{-3} gallium solution was prepared by dissolving 0.1743 g of gallium metal in 53.6 cm^3 of hydrochloric acid and then diluting the mixture to 100 cm^3. Working solutions of the metals were prepared as needed by the dilution of the stock solutions with the corresponding acid. A 1×10^{-3} mol dm^{-3} PV solution was prepared by dissolving 0.0966 g of the Dotite PV in 250 cm^3 of de-ionized water. TDEABr was prepared by the method described in a previous work.[17] The 2×10^{-3} mol dm^{-3} TDEABr solutions were prepared by dissolving 0.3155 g of TDEABr in 250 cm^3 of carbon tetrachloride for antimony(III) and in xylene for bismuth, indium, and gallium. The acetate buffer solutions were used for these metals. All the other chemicals used were of a guaranteed reagent quality.

Apparatus. A Hitachi 101 spectrophotometer, a Hitachi 200-20 UV-vis. recording spectrophotometer, and a Hitachi Horiba F-7 pH meter were employed.

General Procedure. Mix a working solution of a metal, a definite amount of 2 or 0.2 mol dm^{-3} hydrochloric acid, and 1 cm^3 of a 1×10^{-3} mol dm^{-3} PV solution in a 100-cm^3 polypropylene beaker. Adjust the pH of the solution to 4.5, 5.9, 5.3, or 5.6 for antimony(III), bismuth, indium, or gallium respectively by the addition of a 2 mol dm^{-3} sodium acetate solution, and then dilute to 20 cm^3 with de-ionized water. Transfer the solution into a 35-cm^3 test tube and extract with 5 cm^3 of 2×10^{-3} mol dm^{-3} TDEABr in an organic solvent for 5 min. Separate the phases and centrifuge the organic phase for 2 min at 3000 min^{-1}. Measure the absorbance of the extract against the reagent blank.

Results and Discussion

Absorption Spectra. The absorption spectra of the metal–PV–TDEA complexes extracted into the organic phase, and of the anionic metal–PV complexes in the aqueous solutions and also of the respective blank solutions, are shown in Figs. 1 to 4. There is no or only a little bathochromic shift in the absorption spectrum of the metal–PV–TDEA complexes. The absorbance of the extracted complexes for antimony(III) and indium, however, increase remarkably over that in the aqueous phase.

Effect of pH. The effect of the pH on the extraction of the complexes was studied with solutions containing each metal and PV. For the maximum extraction, the optimum pH values for antimony(III), bismuth, indium, and gallium are in the ranges from 3.7 to 4.8, from 5.8 to 6.7, from 5.3 to 5.4, and from 5.5 to 6.2 respectively. The absorbances of extracts are unchanged for indium and gallium, but decrease about 15%, and 20% for antimony(III) and bismuth respectively for 30 min.

Organic Solvents. Several kinds of solvents were

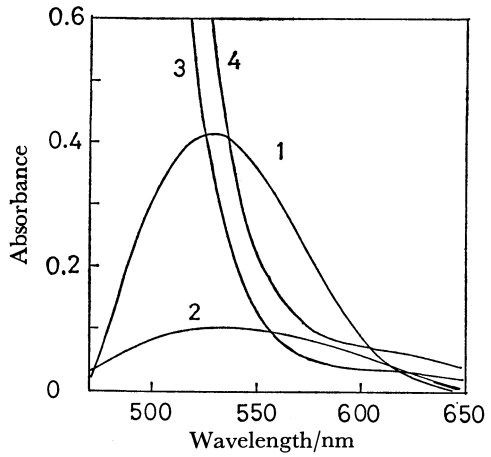

Fig. 1. Absorption spectra of the Sb–PV–TDEA complex in carbon tetrachloride and the Sb–PV complex in aqueous solution.
pH=4.5, V_{aq}=20 cm³, V_o=5 cm³, $[TDEABr]_o=2\times10^{-3}$ mol dm⁻³. 1: Sb–PV–TDEA $[Sb]=3.13\times10^{-6}$ mol dm⁻³, 2: Sb–PV $[Sb]=2.5\times10^{-5}$ mol dm⁻³, 3: PV–TDEA $[PV]=5\times10^{-5}$ mol dm⁻³, 4: PV $[PV]=2\times10^{-4}$ mol dm⁻³.

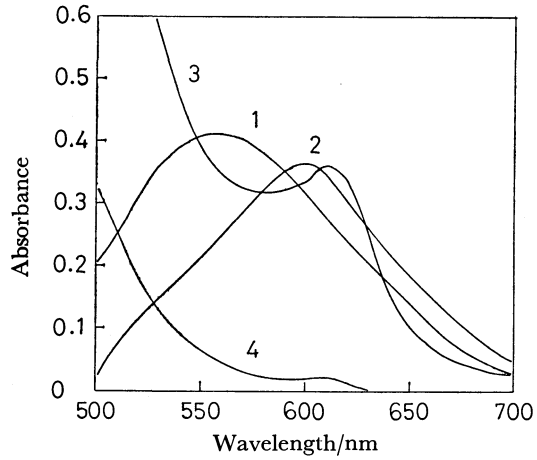

Fig. 2. Absorption spectra of the Bi–PV–TDEA complex in xylene and the Bi–PV complex in aqueous solution.
pH=5.9, V_{aq}=20 cm³, V_o=5 cm³, $[TDEABr]_o=2\times10^{-3}$ mol dm⁻³. 1: Bi–PV–TDEA $[Bi]=3.13\times10^{-6}$ mol dm⁻³, 2: Bi–PV $[Bi]=6.25\times10^{-6}$ mol dm⁻³, 3: PV–TDEA $[PV]=5\times10^{-5}$ mol dm⁻³, 4: PV $[PV]=5\times10^{-5}$ mol dm⁻³.

examined from the standpoints of the absorbance and extractability of the complexes. Spectrophotometric studies indicated carbon tetrachloride to be most efficient for antimony(III), and xylene, for the other metals. The other solvents examined include butyl acetate, chloroform, isobutyl methyl ketone, and 1-butanol. Except for butyl acetate, these vary in performance, causing little or no extraction.

Effect of the Reagent Concentration. The variation in the PV concentration in an aqueous phase containing each metal with the optimum pH gives the constant maximum absorbance of the extracts in the PV concentration ranges from 3×10^{-5} to 1×10^{-4}, from 5×10^{-5} to 2×10^{-4}, 5×10^{-5}, and $>2.5\times10^{-5}$ mol dm⁻³ for antimony(III), bismuth, indium, and

pH=5.3, V_{aq}=20 cm³, V_o=5 cm³, $[TDEABr]_o=2\times10^{-3}$ mol dm⁻³. 1: In–PV–TDEA $[In]=2.5\times10^{-6}$ mol dm⁻³, 2: In–PV $[In]=1\times10^{-5}$ mol dm⁻³, 3: PV–TDEA $[PV]=5\times10^{-5}$ mol dm⁻³, 4: PV $[PV]=8\times10^{-5}$ mol dm⁻³.

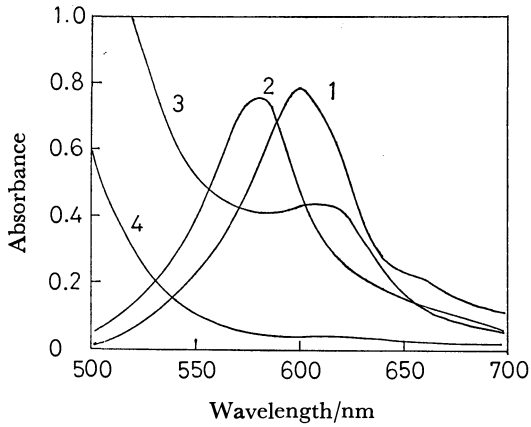

Fig. 4. Absorption spectra of the Ga–PV–TDEA complex in xylene and the Ga–PV complex in aqueous solution.
pH=5.5, V_{aq}=20 cm³, V_o=5 cm³, $[TDEABr]_o=2\times10^{-3}$ mol dm⁻³.
1: Ga–PV–TDEA $[Ga]=2.5\times10^{-6}$ mol dm⁻³, 2: Ga–PV $[Ga]=1\times10^{-5}$ mol dm⁻³, 3: PV–TDEA $[PV]=5\times10^{-5}$ mol dm⁻³, 4: PV $[PV]=8\times10^{-5}$ mol dm⁻³.

gallium respectively. The optimum concentrations of TDEABr in the organic phase are in the ranges from 2×10^{-4} to 5×10^{-3}, $>1\times10^{-3}$, and $>1\times10^{-4}$ mol dm⁻³ for antimony(III), bismuth, and indium or gallium respectively.

Extractability and Molar Absorptivity. An aqueous solution of 20 cm³ containing a definite amount of each metal and PV was shaken with 5 cm³ of 2×10^{-3} mol dm⁻³ TDEABr in organic solvents under the optimum conditions. Extraction was repeated for the remaining aqueous phase after the separation of the extract. The extractability of each metal was calculated from the absorbance of the extracts. It was found that 99.3, 99.0, 97.6, and 98.2% of antimony(III), bismuth, indium, and gallium respectively were extracted by a single extraction. The distribution ratios for antimony(III), bismuth, indium, and gal-

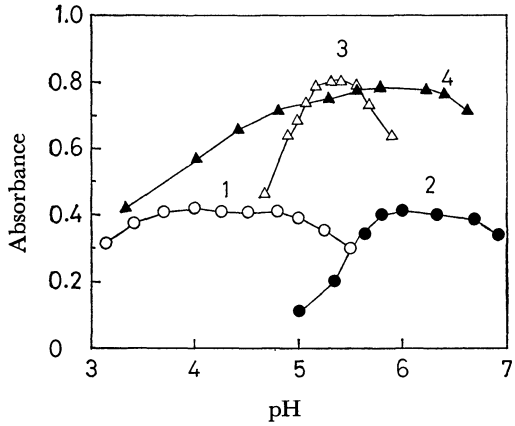

Fig. 5. Effect of pH on the extraction of the metal–PV–TDEA complexes.
[Sb]=[Bi]=3.13×10^{-6} mol dm^{-3}, [In]=[Ga]=2.5×10^{-6} mol dm^{-3}, [TDEABr]$_0$=2×10^{-3} mol dm^{-3}, [PV]=5×10^{-5} mol dm^{-3}. 1: Sb, 2: Bi, 3: In, 4: Ga.

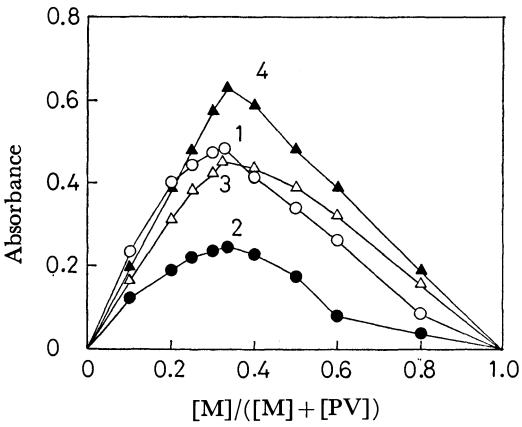

Fig. 6. Continuous variation method applied to the metal–PV–TDEA complexes (metal:PV).
1: Sb–PV–TDEA [Sb]+[PV]=6.25×10^{-5} mol dm^{-3}, 2: Bi–PV–TDEA [Bi]+[PV]=1×10^{-4} mol dm^{-3}, 3: In–PV–TDEA [In]+[PV]=1×10^{-4} mol dm^{-3}, 4:Ga–PV–TDEA [Ga]+[PV]=1×10^{-4} mol dm^{-3}.

lium are 5.59×10^2, 3.96×10^2, 1.63×10^2, and 2.18×10^2 respectively. The molar absorptivity of the complexes are 3.32×10^4, 3.31×10^4, 8.20×10^4, and 8.00×10^4 dm^3 mol^{-1} cm^{-1} for antimony(III), bismuth, indium, and gallium respectively. A calibration curve for the determination of each metal was made under the optimum conditions. A good linear relationship was obtained over the concentration range from 1 to 20, from 2 to 30, from 0.4 to 7.2, and from 0.3 to 4.3 μg of antimony(III), bismuth, indium, and gallium per 5 cm^3 of the organic phase.

The Composition of the Complexes. A continuous-variation method as described in a previous paper[16] was carried out for the metal–PV–TDEA complexes system. The results are shown in Fig. 6 and Fig. 7. The reacting ratios of metal to PV to TDEA balance well at 1:2:3 and 1:2:2 for antimony(III) and for the other metals respectively. Thus, the composition of the complexes are Sb$(PV)_2(R_3R'N)_3$, Bi$(PV)_2(R_3R'N)_2$, In$(PV)_2(R_3R'N)_2$, and Ga$(PV)_2(R_3R'N)_2$ respectively.

Effect of Foreign Ions. The effect of foreign ions

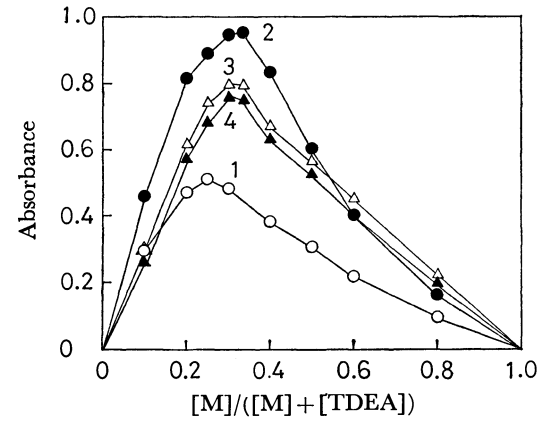

Fig. 7. Continuous variation method applied to the metal–PV–TDEA complexes (metal: TDEA).
1: Sb–PV–TDEA Sb+TDEA=2×10^{-6} mol, 2: Bi–PV–TDEA Bi+TDEA=2×10^{-6} mol, 3: In–PV–TDEA In+TDEA=2×10^{-6} mol, 4: Ga–PV–TDEA Ga+TDEA=1×10^{-6} mol.

on the determination of antimony(III), bismuth, indium, and gallium was examined under optimum conditions. The anionic PV complexes of many metals, such as beryllium, aluminium, titanium(IV), vanadium(V), iron(III), copper, molybdenum(VI), tin(IV), tungsten(VI), thorium, and uranium(VI) can be extracted with TDEABr and interfere with the determination of the foregoing metals. GEDTA for the determination of antimony(III), 1,10-phenanthroline and fluoride for bismuth, and thiourea or hydrogen peroxide for indium and gallium are useful as masking reagents in this system, but the masking power of these reagents is insufficient. Of the anions tested, iodide, thiocyanate, and perchlorate interfere most seriously, giving a negative error.

(Received April 30, 1982)

Sodium [μ-(ethylenediaminetetraacetato)-di-μ-sulfido-bis{oxomolybdate(V)}]·n-hydrates, n=2 and 3, are antiferromagnetic dimers with an exchange interaction within a pair of Mo(V) ions of about $-140\,k$ having an averaged g-value of about 2 for each Mo(V) ion. In these salts, magnetic moments of only about 0.5 Bohr magneton are localized at Mo(V) sites, though Mo(V) has one electron in the 4d orbital. Here a π-bonding looped structure is considered to have a contribution to the diamagnetic susceptibilities of about -5.0×10^{-5} (CGSemu). Sodium [μ-(ethylenediaminetetraacetato)-di-μ-oxo-bis{oxomolybdate(V)}]·n-hydrates, n=3, 4, and 6, are the antiferromagnetic dimers with an exchange interaction within a pair of Mo(V) ions of about $-150\,k$ and an averaged g-value of 1.91. The magnetic moments of only about 0.5 Bohr magneton are localized at Mo(V) sites. In these salts, too, a π-bonding structure in each dimer is considered to make a contribution to the diamagnetic susceptibility of about -4.0×10^{-5} (CGSemu). A broad minimum of the molar magnetic susceptibility of [μ-(ethylenediaminetetraacetato)-di-μ-oxo-bis{oxomolybdate(V)}] salts was considered due to the conformation interconversion.

Polynuclear coordination complex compounds of early transition metals with bridges of sulfur between metal ions sometimes show unstable magnetic behaviours. Some compounds among them, for example, Xanthine Oxidase, are well known to have activities as enzymes.[1]

$Na_2[Mo_2O_2S_2(cysteine)_2]\cdot4H_2O$[2] and $Na_2[Mo_2O_2S_2(histidine)_2]\cdot H_2O$,[2] which are Mo(V) dimers with disulfido bridges, and $[Mo_2O\{O_2(C_2H_5OCS_2)_2\}_2]$,[3] which is a Mo(V) dimer with an oxygen bridge, have been reported to be diamagnetic in solid phase.

$(PyH)_4[Mo_2O_4(NCS)_4]$ has been reported to be paramagnetic with Bohr magneton numbers of 0.59 at 293 K and of 0.39 at 120 K. $Na_2[Mo_2O_4(edta)]\cdot4H_2O$ is also known to be paramagnetic at 293 K. Such paramagnetism with small Bohr magneton numbers was observed by Mitchell and Williams.[4]

In the present paper, the magnetic properties of $Na_2[Mo_2O_2S_2(edta)]\cdot nH_2O$($n$=2 and 3) and $Na_2[Mo_2O_4(edta)]\cdot nH_2O$ (n=3, 4, and 6) are investigated as a first step to elucidate the complex activities of Mo(V) dimer structure in the many enzymes.[2] The sexadentate ethylenediaminetetraacetate salts were chosen as the most strongly constructed dimers. The edta ligand coordinates to each molybdenum atom through two carboxylates and with one nitrogen. Mo(V) was chosen because it is in the simplest $4d^1$ state.

Experimental

Chemicals. $Na_2[Mo_2O_2S_2(edta)]\cdot nH_2O$ (n=2 and 3) and $Na_2[Mo_2O_4(edta)]\cdot nH_2O$ (n=3, 4, and 6) were synthesized following Ott *et al.*,[5] Spivack and Dori,[6] and Pecsok and Sawyer.[7] Numbers of crystalline waters were determined from the results of chemical analysis on C, H, and N, as shown in Table 1.

Measurements. The magnetic susceptibilities were measured by the Faraday method balance (Shimadzu MB-2) under about 6000 G** of applied field using the full scale 2 dyn range. An airtight sample cell was made of Teflon. As the measured amount of susceptibility was very small, the measurements of the empty cell were carefully done to assure the calibrations. As a standard of the magnetic susceptibility, $[Cr(NH_3)_6]Cl_3$ or NaCl was used.

Electron paramagnetic resonances were observed on powder samples by a JEOL PE-3X with a microwave oscillator ES-SCXA. Signals were found with 128 min/2000 G scanning under 10 G modulation at amplitude magnified by 1000. When the resonance was observed at low temperatures, DPPH packed in a thin Teflon tubing was put in the sample as reference.

Measurements of X-ray powder patterns and differential scanning calorimetry were made by usual methods.

Results and Discussion

Molar magnetic susceptibilities of $Na_2[Mo_2O_2S_2(edta)]\cdot nH_2O$, n=2 and 3, which were corrected for atomic diamagnetism using Pascal's law and did not need to be corrected for the temperature independent paramagnetism in view of the absence of absorption in the near infrared region, were less than 1.0×10^{-4} cm^3 (CGSemu) or 1.3×10^{-9} m^3 (SI) and showed a very broad maximum between liquid N_2 temperature and room temperature. The atomic diamagnetic susceptibilities of these salts are about -3×10^{-4} cm^3 (CGSemu) or -4×10^{-9} m^3 (SI) as shown in Table 2; therefore the magnetic susceptibilities characteristic of the magnetic dimers with antiferromagnetic mutual exchange interactions are submerged beneath the sea of the diamagnetism. But at room temperature, namely at higher temperature than that showing the broad maximum of the susceptibilities, electron paramagnetic resonances (X-band) were observed in each salt around 3000 G of the applied field: widths were 600—800 G, showing rapid spin lattice relaxations. Figure 1a shows the experimental molar magnetic susceptibility of $Na_2[Mo_2O_2S_2(edta)]\cdot2H_2O$ as a function of temperature. This curve is already corrected for atomic diamagnetic susceptibility of -2.99×10^{-4} cm^3

** 1 G = 10^{-4} T.

(CGSemu) or -3.76×10^{-9} m³ (SI) following Pascal's law. A π-bonding looped structure may have an anisotropic diamagnetic susceptibility because the π-electrons can move along the looped structure when a magnetic field is applied. Lonsdale[8] showed that the aromatic rings give rise to anisotropic diamagnetic susceptibilities. Namely, a looped π-bonding structure with an effective radius r has an anisotropic diamagnetic susceptibility of $\chi_{ring}=(-Ne^2/4mc^2)\sum_p r^2$, where N is the Avogadro number, p is the number of π-electrons in the π-bonding linkage and other symbols have the usual meanings. The unit of e is CGSesu and r is taken in Å. Following her method, the projections of the area of π-bonding looped structure of the Mo(V) dimers on the planes perpendicular to the external magnetic field directions were calculated in order to estimate the anisotropic diamagnetic susceptibilities. The following linkage was considered to be effective in the dimer:  (*cf.* Fig. 6. In the places of the oxygen double bridges in the figure, $[Mo_2O_2S_2(edta)]$ salts have double bridges of sulfur.) with effective area 4.96 Å² [6] and 22 movable π-electrons, that is, three 4p electrons from each Mo(V)

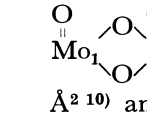
ion whose ligands are a terminal O^{2-} ion, two s^{2-} ions, two O^- ions and a N atom, three 3p electrons from each bridging S^{2-}, and five 2p electrons from terminal O^{2-} ions were accounted for. The diamagnetic susceptibility estimated in this way is about -5.0×10^{-5} cm^3 (CGSemu) or -6.3×10^{-10} m^3 (SI). Setting this value as a new base line, a fit of the experimental magnetic susceptibility to the theoretical susceptibility of the dimer was investigated. If $\vec{S}_1$ and $\vec{S}_2$ denote the spin vectors of the two Mo(V) ions within a dimer and J_{12} the mutual exchange interaction between $\vec{S}_1$ and $\vec{S}_2$, the Hamiltonian $H=-2J_{12}\times(\vec{S}_1\cdot\vec{S}_2)$[9] is taken to calculate the magnetic susceptibility. For the Mo(V) dimer, the molar magnetic susceptibility[1] is

$$\chi_M=\frac{2N\beta^2}{kT}\frac{4}{3+\exp\left(\frac{-2J_{12}}{kT}\right)}, \quad (1)$$

where $g=2$ is used. β is the Bohr magneton, k is Boltzmann's constant and T is absolute temperature. In Fig. 1b an ESR derivative curve of $Na_2[Mo_2O_2S_2$-(edta)]$\cdot2H_2O$ is shown to indicate $g_{av}=2$. The very broad absorption is characteristic of di-μ-sulfido ligands. A tolerable fit of the magnetic susceptibility was obtained if magnetic moments of 0.52 Bohr magneton are assumed to be localized at the Mo sites at 273.15 K, with $J_{12}=-140k$. If one 4d electron of $S=1/2$ is localized at each Mo(V) ion site, the effective Bohr magneton number at 273.15 K is about 0.94.

The molar magnetic susceptibility and ESR of Na_2-$[Mo_2O_2S_2$(edta)]$\cdot3H_2O$ were similar to those of Na_2-$[Mo_2O_2S_2$(edta)]$\cdot2H_2O$ but not completely the same. Therefore X-ray powder patterns were checked for both of $Na_2[Mo_2O_2S_2$(edta)]$\cdot nH_2O$, $n=2$ and 3. These could be assigned to the orthorhombic symmetry, like that of $Cs_2[Mo_2O_2S_2$(edta)]$\cdot2H_2O$ at room temperature. The lattice constants are shown in Table 2, which are near each other but not completely the same, corresponding to the experimental results of the magnetic susceptibilities and ESR.

The experimental molar magnetic susceptibilities of $Na_2[Mo_2O_4$(edta)]$\cdot nH_2O$ ($n=3$, 4, and 6) corrected for the atomic diamagnetism also were smaller than 1.0×10^{-4} cm^3 (CGSemu) or 1.3×10^{-9} m^3 (SI). The atomic diamagnetic susceptibilities are about -3×10^{-4} cm^3 (CGSemu) or -4×10^{-9} m^3 (SI); therefore, Na_2-$[Mo_2O_4$(edta)]$\cdot nH_2O$ salts are seemingly diamagnetic. The molar magnetic susceptibility of $Na_2[Mo_2O_4$-(edta)]$\cdot4H_2O$ is plotted in Fig. 2a. Between liquid N_2 temperature and room temperature, the susceptibility shows two broad maxima accompanied by a very broad minimum centerd about 180 K. As in the case of $Na_2[Mo_2O_2S_2$(edta)]$\cdot nH_2O$ salts, the diamagnetism due to the π-bonding looped structure in the Mo(V) dimer ion was estimated to be about -4.0×10^{-5} cm^3 (CGSemu) or -5.0×10^{-10} m^3 (SI), namely,



($cf.$ Fig. 5) has an effective area of 3.71 Å^2 [10] and the 22 π-electrons consist of three 4p electrons from each Mo^{5+} ion, three 2p electrons from each bridging O^{2-}, and five 2p electrons from each terminal O^{2-} ion. In Fig. 2b, the ESR of $Na_2[Mo_2O_4$-(edta)]$\cdot4H_2O$ is shown. The signal was obtained by 64 min/1000 G scanning with amplitude magnified 1600 times. The best fit of the g-values to the experimental signals was a set of $g_1=1.8780$, $g_2=1.9170$, and $g_3=1.9330$, with a width of 8 G, neglecting the hyperfine structure which is seen in the ESR but is too weak to analyse by a simulation. It is certain that the spin-lattice relaxation times of di-μ-oxo-bis{oxomolybdate}salts are longer than those of di-μ-sulfido-bis-{oxomolybdate}salts. In Fig. 2a, the dashed line shows the curve of the theoretical magnetic susceptibility with $J_{12}=-150k$, $g_{av}=1.91$ and localized spins of about 0.53 Bohr magneton at 273.15 K and the solid line shows the curve with $J_{12}=-150k$, $g_{av}=1.91$ and localized magnetic moments of 0.51 Bohr magneton at 273.15 K. The base line of the theoretical curve is taken at -4.0×10^{-5} cm^3 (CGSemu) or -5.0×10^{-10} m^3 (SI). To see what is the anomalous temperature dependence of the magnetic susceptibility of this Mo(V) dimer, namely the broad minimum of the susceptibility ceterd at about 180 K, the temperature dependence of ESR was observed. As is shown in Fig. 3, no decrease of the ESR signal between 210 K and 150 K was observed. Therefore this anomalous temperature dependence of the magnetic susceptibility

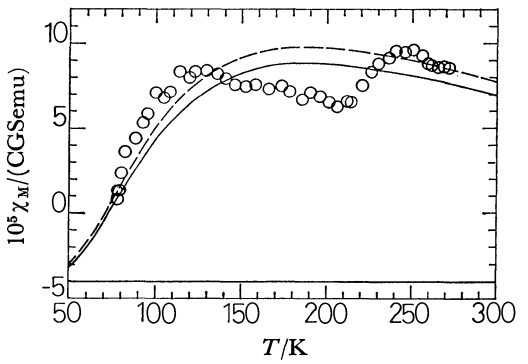


Fig. 2a. The molar magnetic susceptibility of Na_2-$[Mo_2O_4$(edta)]$\cdot4H_2O$. ○: χ'_M, namely, the experimental molar magnetic susceptibility which is corrected for only atomic diamagnetism. ----: The calculated molar magnetic susceptibility of a dimer with $J_{12}=-150k$, $g=1.91$, and $\mu_{eff}=0.53$ at 273.15 K. ——: A dimer with $J_{12}=-150k$, $g=1.91$, and $\mu_{eff}=0.51$ at 273.15 K. The base line of the calculated curves is taken at -4.0×10^{-5} (CGSemu).

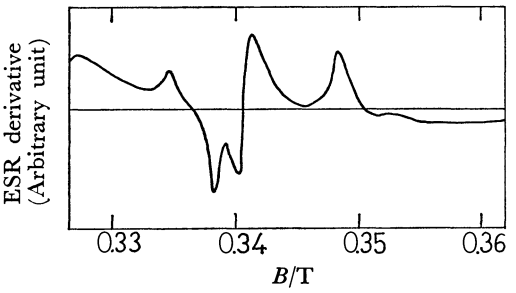

Fig. 2b. The ESR derivative curve of $Na_2[Mo_2O_4$-(edta)]$\cdot4H_2O$ on powder. The ordinate is in an arbitrary unit.

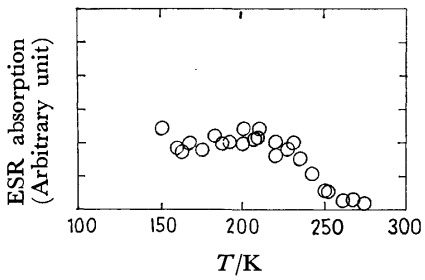

Fig. 3. The temperature dependence of the ESR absorption of $Na_2[Mo_2O_4(edta)]\cdot 4H_2O$ on powder.

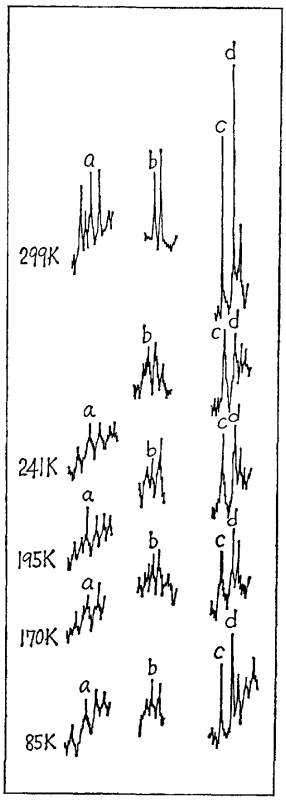

Fig. 4. Temperature dependence of some X-ray diffaction powder patterns. a: Atomic plane distance 3.789 Å, b: 4.822 Å, c: 5.724 Å, and d: 5.946 Å. All the signals were measured by same conditions. In the figure, patterns of each temperature are drawn from the same base line.

is not due to the paramagnetic spins. Then the temperature dependence of the powder X-ray pattern was checked on $Na_2[Mo_2O_4(edta)]\cdot 3H_2O$. When the temperature was changed from 85 K to 299 K, the atomic plane distances did not change but widths and intensities of some lines changed, that is, the widths of the lines of atomic plane distances of 5.946 Å, 5.724 Å, 4.822 Å, and 3.789 Å were broader around 190 K than those of lower and higher temperatures, as shown in Fig. 4. The temperature dependence of the X-ray diffraction intensities was considered due to dynamic vibrations of a conformation, as will be shown below. Differential scanning calorimetries were observed for $Na_2[Mo_2O_4(edta)]\cdot 3H_2O$ and $Na_2[Mo_2O_2S_2(edta)]\cdot 2H_2O$. The former (Fig. 5) showed an exothermic signal at temperatures between 190 K and 230 K in the measurement on cooling from room temperature to 130 K, but the latter showed nothing. It is known from the measurement of ^{13}C NMR[11] that $[Mo_2O_4(edta)]^{2-}$ ion in the aqueous solution has a conformation interconversion. According to Blackmer *et al.*, the ethylene diamine backbone of edta chelate has an interconversion between the two isomeric forms, seen in Fig. 6, which is too rapid at 310 K to split the ^{13}C NMR of about 60 MHz, but at 273 K, the absorption line splits into two, that is, the relaxation time of each conformation becomes long enough to give the line splitting. They assigned a value of 0.5 to the transition coefficient k, since the ethylenediamine backbone of edta complex has an equal probability of returning to its original isomeric conformation or continuing the conversion process to achieve the other isomeric conformational form after reaching a planar intermediate. In the solid state of $[Mo_2O_4(edta)]^{2-}$ complex in a pressed cell, the interconversion has been considered to happen over a broad temperature region from 190 K to 230 K, centerd about 210 K. It is said by X-ray analysis[6] that at room temperature, $[Mo_2O_4(edta)]$ salts have two isomeric conformations with equal probability of the ethylenediamine backbone of edta. The crystal would transform from a higher temperature state to a preferred lower temperature form of the ethylenediamine by the interconversion in the broad temperature region. The interconversion of edta is considered to produce a change of the diamagnetic susceptibility due to the π-bonding

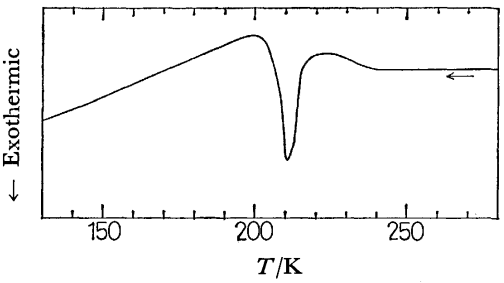

Fig. 5. The differential scanning calorimetry curve of $Na_2[Mo_2O_4(edta)]\cdot 3H_2O$. The graph shows that the sample releases heat in the region between 230 K and 190 K on cooling from room temperature to 130 K.

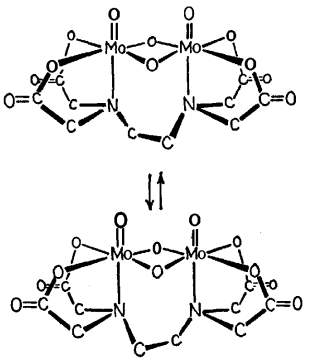

Fig. 6. The interconversion between two isomeric conformations of $[Mo_2O_4(edta)]$ anion.

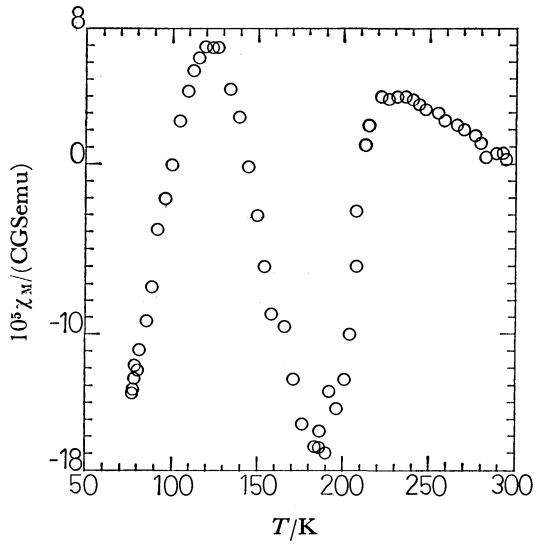

Fig. 7. The molar magnetic susceptibility of $Na_2[Mo_2O_4(edta)]\cdot 3H_2O$ corrected for only atomic diamagnetism as a function of temperature.

looped  structure, though it is not elucidated yet that the change of the diamagnetic susceptibility is caused by the change of the number of the movable electrons or the change of the effective area of the π-bonding looped structure. Now, though we explained the magnetic susceptibility data of $Na_2[Mo_2O_2S_2(edta)]\cdot nH_2O$ by a simple dimer model, the fit with the theoretical curve was never satisfactory. There may be an interconversion between the two forms of the ethylenediamine of edta in di-μ-sulfido-bis{oxomolybdate(V)} ion and it would make the fit poor. But much less energy would be needed for the interconversion because the distances between two Mo(V) ions and two N atoms in the edta in di-μ-sulfido-bis{oxomolybdate} ion are longer than those of di-μ-oxo-bis{oxomolybdate} ion. Thus the difference of the two forms of the ethylenediamine is so small that the DSC signal could not be observed.

We would like to remark on a datum of the molar magnetic susceptibility of $Na_2[Mo_2O_4(edta)]\cdot 3H_2O$, which showed a much smaller magnetic susceptibility, as shown in Fig. 7, than those of $Na_2[Mo_2O_4(edta)]\cdot 4H_2O$ and $Ba[Mo_2O_4(edta)]\cdot 6H_2O$ though its temperature dependence is similar to them. This phenomenon suggests this salt may be trapping some extra even number of electrons in the π-bonding looped structure.

The experimental results show that the complete determination of the diamagnetic susceptibility on a molecule with π-bonding looped structure is necessary. Of course, the molecular orbitals of many polycyclic aromatic hydrocarbon compounds have been calculated and from their energy under an applied magnetic field anisotropic diamagnetic susceptibilities are obtained. But the molecular orbital calculations at present are possible to molecules with 40 atoms and 127 orbitals, therefore the complete calculation of the diamagnetic susceptibilities for molecules containing 4d transition metals with π-bonding looped structure which have more than 200 orbitals may not be possible in the near future. We are going to elucidate the diamagnetic susceptibilities of 4d transition metal coordination compounds with π-bonding looped structures by the observation of the non-magnetic 4d transition metal coordination compound molecules with π-bonding looped structures.

The authors would like to thank Professor Masayasu Mori, Osaka City University, for the measurements of the magnetic susceptibility and for valuable discussions. They wish to thank Dr. Yukio Sugiura, Kyoto University, for the observations of the ESR and for valuable suggestions. One of the authors (H.K.) thanks the faculty and staff of Osaka City University for their kind hospitality during her stay for the measurements.

CD Spectra and Absolute Configurations of *fac*(*a*,*b*,*c*)-[Co(a)(b)(c)(1,4,7-Triazacyclononane)]$^{n+}$ Complexes

Shuhei Fujinami,* Takao Hosokawa, and Muraji Shibata

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received May 12, 1982)

Seventeen kinds of *fac*(*a*,*b*,NH_3)-[Co(a)(b)(NH_3)(tacn)]$^{n+}$ complexes (a, b=CN^-, NO_2^-, SO_3^{2-}, NCS^-, N_3^-, CH_3COO^-, H_2O, OH^-, Cl^-, or Br^-; tacn=1,4,7-triazacyclononane) have been prepared and optically resolved by column chromatography. The absolute configurations of these complexes have been determined by referring to the CD spectra of the related [Co(a)(gly)(tacn)]$^{n+}$ complexes (a=CN^-, NO_2^-, NCS^-, N_3^-, or Cl^-). It has been found that the signs of the Cotton peaks observed in the first absorption band region are closely related to the ligand field strengths of the unidentate ligands, and that the dominant Cotton peak is associated with the electronic transition which arises in the plane containing no ammonia molecule.

There are some reports on optically active cobalt(III) complexes with a chiral arrangement of donor atoms around a central metal ion. These complexes can be classified into two groups. One includes *cis-cis*-[Co(a)$_2$(b)$_2$(CC)]- and *all-cis*-[Co(a)$_2$(b)$_2$(c)$_2$]-type complexes in which the central metal ions are surrounded with three kinds of donor atoms.[1-4] A typical instance is an *all-cis*-[Co(CN)$_2$(NH_3)$_2$(H_2O)$_2$]$^+$ complex, and Mason[5] has attempted to explain the optical activity of the complex in terms of a dynamic coupling model

The other group represents a *fac*(*D*)-[Co(a)(BC)(DDD)]-type complexes where one octahedral face of the complex is coordinated with a symmetrical terdentate ligand such as 1,4,7-triazacyclononane (=tacn) and the opposite face is occupied by three kinds of donor atoms.[6-9] In spite of the existence of two ring-pairs in this type of complex, the optical activity is considered to be mainly derived from a chiral arrangement of donor atoms.[8,9] However, the bidentate ligand (BC) used is limited to an amino acidate ion, and there is little information on the relation between the CD spectrum and the absolute configuration of the complex.

Recently, we reported the preparations and optical resolutions of [Co(CN)(Br)(NH_3)(tacn)]$^+$ [10] and *fac*-(NH_3)-[Co(NO_2)(gly)(NH_3)$_3$]$^+$.[11] No ring-pair is contained in these complexes, and these types of complexes are adequate to allow a study of the optical activity of the complexes with a chiral arrangement of donor atoms.

This paper will deal with further syntheses and optical resolutions of the complexes with a series of [Co(a)(b)(NH_3)(tacn)]$^{n+}$ (a, b=CN^-, NO_2^-, SO_3^{2-}, NCS^-, N_3^-, H_2O, OH^-, CH_3COO^-, Cl^-, or Br^-). The absolute configurations are determined by referring to the CD spectra of [Co(a)(gly)(tacn)]$^{n+}$ (a=CN^-, NO_2^-, NCS^-, N_3^-, or Cl^-)[8] and by chemical derivations from optically active complexes. The signs of the Cotton peaks in the first absorption band region are discussed on the basis of the absolute configurations of the complexes.

Experimental

Ligand. 1,4,7-Triazacyclononane trihydrochloride (tacn·3HCl) was prepared by the literature method.[12]

Preparation of Complexes. *1) [Co(CN)(Br)(NH_3)(tacn)]Cl*: The preparation of this complex has been described in an earlier paper.[10] The description will be given here again with a few modifications. To an aqueous suspension of the complex, [Co(CN)(SO_3)(NH_3)(tacn)][10] (1 g, 3 mmol in 2 cm^3 H_2O), which had been prepared from [Co(CN)(SO_3)(NH_3)$_4$],[13] was added 10 cm^3 of 47% HBr little by little, and the mixed solution was stirred at 50 °C for 6 h, whereupon the color of the solution turned red. After cooling to room temperature, large amounts of ethanol and ether were successively added to the solution. The precipitated material was filtered and dissolved in water (500 cm^3). The solution was chromatographed on a column of Dowex 50W-X8 (3 cm × 10 cm, Na^+ form). By elution with a 0.3 mol/dm^3 NaCl solution, a red band was discharged from the column. The effluent was concentrated by a rotary evaporator below 35 °C, with simultaneous removal of the precipitated salt used as the eluting agent. After addition of a small amount of ethanol to the final filtrate, reddish crystals deposited on standing the mixture in a refrigerator. This crude product was recrystallized from warm water (*ca.* 40 °C). The yield was *ca.* 0.5 g. Found: C, 24.16; H, 5.35; N, 19.96%. Calcd for [Co(CN)(Br)(NH_3)(tacn)]Cl: C, 24.26; H, 5.25; N, 20.21%.

2) [Co(CN)(H_2O)(NH_3)(tacn)](ClO_4)$_2$·H_2O: An aqueous solution (10 cm^3) of the complex, [Co(CN)(Br)(NH_3)(tacn)]Cl (0.7 g, 2 mmol), was adjusted to pH 9 with 5 mol/dm^3 KOH, and stirred until its color changed from red to orange, whereupon the corresponding hydroxo complex, [Co(CN)(OH)(NH_3)(tacn)]$^+$, formed. After the solution had been acidified with 1 mol/dm^3 $HClO_4$ until pH 5, the resulting solution was once filtered and diluted to 500 cm^3 with water. This solution was poured onto a column of SP-Sephadex C-25 (4.5 cm × 20.0 cm, Na^+ form). By elution with 0.1 mol/dm^3 $HClO_4$, a yellow band was discharged from the column. The eluate was treated in a similar way to that in 1). The yield was *ca.* 0.4 g. Found: C, 18.17; H, 4.60; N, 15.11%. Calcd for [Co(CN)(H_2O)(NH_3)(tacn)](ClO_4)$_2$·H_2O: C, 18.03; H, 4.77; N, 15.03%.

3) [Co(CN)(Cl)(NH_3)(tacn)]Cl: For the preparation of the [Co(CN)(H_2O)(NH_3)(tacn)]$^{2+}$ complex, the elution was carried out with 0.1 mol/dm^3 HCl. When the eluate was concentrated to a small volume, the solution turned red. The solution was stirred at 40 °C for 2 h, and poured onto a column of Dowex 50W-X8 (4 cm × 10 cm, H^+ form). The eluate obtained by the elution with 0.3 mol/dm^3 HCl was concentrated to a small volume by a rotary evaporator at 35 °C, and a small amount of ethanol was added to the concentrate. This solution was kept in a refrigerator until red crystals of the desired complex deposited. The crude product was recrystallized from 6 mol/dm^3 HCl. The yield was *ca.* 0.5 g. Found: C, 27.70; H, 6.13; N, 23.21%

Calcd for $[Co(CN)(Cl)(NH_3)(tacn)]Cl$: C, 27.83; H, 6.01; N, 23.18%.

4) *$[Co(CN)(NO_2)(NH_3)(tacn)]Cl\cdot 1.3H_2O$*: To a solution of $[Co(CN)(H_2O)(NH_3)(tacn)](ClO_4)_2\cdot H_2O$ (1 g, in 50 cm³ H_2O), was added $NaNO_2$ (1 g, 14 mmol). The solution was stirred at room temperature until its color changed from orange to lemon yellow. The reacted solution was diluted to 500 cm³ and charged on a column of Dowex 50W-X8 (3 cm × 5.0 cm, Na^+ form). By elution with a 0.3 mol/dm³ NaCl solution, a lemon yellow band was discharged from the column. The effluent was treated in a similar way to that in 1). The yield was *ca.* 0.7 g. Found: C, 25.29; H, 6.14; N, 24.83%. Calcd for $[Co(CN)(NO_2)(NH_3)(tacn)]Cl\cdot 1.3H_2O$: C, 25.02; H, 6.18; N, 25.01%.

5) *$[Co(CN)(NCS)(NH_3)(tacn)]Cl\cdot 2H_2O$*: An aqueous solution (50 cm³) containing $[Co(CN)(H_2O)(NH_3)(tacn)](ClO_4)_2\cdot H_2O$ (0.5 g) and KSCN (1 g, 10 mmol) was adjusted to pH 3 with $HClO_4$, and then stirred at 50 °C for 4—5 h. The resulting orange solution was chromatographed in the same manner as 1). The yield was *ca.* 0.3 g. Found: C, 26.81; H, 6.05; N, 26.62%. Calcd for $[Co(CN)(NCS)(NH_3)(tacn)]Cl\cdot 2H_2O$: C, 26.64; H, 6.15; N, 23.30%.

6) *$[Co(CN)(N_3)(NH_3)(tacn)]Cl$*: This complex was prepared in the same manner as the isothiocyanato complex, except for the use of NaN_3 (1.0 g, 15 mmol) in place of KSCN. The crystals of the desired complex could not be obtained from the orange effluent, because the desired complex decomposed in the concentrated solution. Therefore, the ε value of the desired complex was determined by atomic absorption analysis with the freshly eluted solution.

7) *$[Co(CN)(SO_3)(NH_3)(tacn)]\cdot 0.5H_2O$*: This complex has been prepared from the reaction of $[Co(CN)(SO_3)(NH_3)_4]$ with tacn·3HCl.[10] In this work, the complex was derived from the $[Co(CN)(H_2O)(NH_3)(tacn)]^{2+}$ complex. To a solution of the aqua complex salt (0.3 g, in 20 cm³ H_2O) was added $NaHSO_3$ (0.5 g, 5 mmol), and the solution was adjusted to pH 4 with $HClO_4$. The solution was then stirred at room temperature until its color changed from orange to lemon yellow. The resulting solution was poured onto a column of Dowex 50W-X8 (3 cm × 30 cm, Na^+ form) and the adsorbed species on the column was eluted with water. Two components of noncharged species were collected. The first eluted species was unknown. The fraction of the second component was concentrated by a rotary evaporator at *ca.* 35 °C. This fraction was identified with the desired complex by absorption spectrum. The yield was *ca.* 0.1 g.

8) *$[Co(CN)(CH_3COO)(NH_3)(tacn)]Cl$*: An aqueous solution (20 cm³) containing the aqua complex salt (0.5 g) and potassium acetate (1 g, 10 mmol) was adjusted to pH 4 with acetic acid, and then stirred at 40 °C for 3 h. The resulting solution was concentrated to a small volume by a rotary evaporator at 40 °C, filtered once, and diluted to 1 dm³ with water. This solution was poured onto a column of Dowex 50W-X8 (3.0 cm × 20 cm, Na^+ form). By elution with a 0.3 mol/dm³ NaCl solution, three components corresponding to univalent cationic species were collected. The optical resolution of each species was attempted by means of column chromatography (Dowex 50W-X8, 200—400 mesh, 2.5 cm × 60 cm) by use of a 0.3 mol/dm³ $Na_2[Sb_2(d\text{-tart})_2]$ solution as eluent. The absorption and CD spectra of the second species agreed with those of the $[Co(CN)(Cl)(NH_3)(tacn)]^+$ complex. The optical resolution of the third species was unsuccessful and this fact indicated that the third species was not the desired complex. On the other hand, the first species could be resolved into the optical antipodes, and by comparison with the spectra of $[Co(CN)(H_2O)(NH_3)(tacn)]^{2+}$ and $[Co(CN)(OH)(NH_3)(tacn)]^+$, it was considered that this species had a $[Co(C)(O)(N)_4]$ chromophore. Therefore, the first species was assigned to the desired complex, $[Co(CN)(CH_3COO)(NH_3)(tacn)]^+$. The fact that the first species was converted to the $[Co(CN)(Cl)(NH_3)(tacn)]^+$ complex by treatment with 6 mol/dm³ HCl at 40 °C also supported the assignment. The ε value of the desired complex was evaluated in the same manner as in 6), because the yield was very poor.

9) *$[Co(NO_2)_2(NH_3)(tacn)]Cl\cdot 2H_2O$*: The ligand, tacn·3HCl (1.0 g, 4.2 mmol), was dissolved in a minimum amount of water and neutralized with aqueous KOH. The resulting solution was added dropwise to a solution containing *cis*-$[Co(NO_2)_2(NH_3)_4]NO_3$[14] (1.5 g, 5.3 mmol in 50 cm³ H_2O). The mixed solution was adjusted to pH 9—10 with a 5 mol/dm³ KOH solution and stirred at 55 °C for 12 h. Then, the color of the solution changed from orange to wine-red. After cooling to room temperature, the solution was diluted to 2 dm³ with water, and poured onto a column of Dowex 50W-X8 (4 cm × 25 cm, Na^+ form). The adsorbed species was washed with water and eluted with a 0.3 mol/dm³ NaCl solution. Three components of univalent cationic species were collected in each fraction. The second and third species were identified with *trans*- and *cis*-$[Co(NO_2)_2(NH_3)_4]^+$ respectively.[14] The first lemon-yellow fraction was treated in a similar way to that in 1). The yield was *ca.* 0.5 g. Found: C, 19.70; H, 6.20; N, 23.14%. Calcd for $[Co(NO_2)_2(NH_3)(tacn)]Cl\cdot 2H_2O$: C, 19.55; H, 6.01; N, 22.80%.

10) *$[Co(Cl)(H_2O)(NH_3)(tacn)]Cl_2\cdot NaCl$*: This complex was prepared by an acid-hydrolysis of $[Co(NO_2)_2(NH_3)(tacn)]Cl\cdot 2H_2O$. The dinitro complex salt (1.0 g) was dissolved in 1 mol/dm³ HCl (20 cm³) and the solution was stirred at 60 °C for 2 h. After cooling to room temperature, the solution was neutralized with 5 mol/dm³ NaOH and concentrated to a small volume by a rotary evaporator with simultaneous removal of deposited NaCl. The concentrate was adjusted to pH 10 with 5 mol/dm³ NaOH and stirred at room temperature for a while. Then, the solution was diluted to 2 dm³ with water and adjusted to pH 5 with 5 mol/dm³ $HClO_4$. The solution was poured onto a column of SP-Sephadex C-25 (4.0 cm × 25 cm, Na^+ form). The adsorbed species were eluted with 0.1 mol/dm³ NaCl, and three bands were discharged from the column. The eluate for each band was collected in a fraction and submitted to the measurement of the absorption spectrum. The first eluted species was identified with the dinitro complex. The second species, which contained a bivalent cation, was assumed to be the mixture of the $[Co(NO_2)(H_2O)(NH_3)(tacn)]^{2+}$ and $[Co(Cl)(H_2O)(NH_3)(tacn)]^{2+}$ complex. The last red species, which contained a tervalent cation, was assumed to be $[Co(H_2O)_2(NH_3)(tacn)]^{3+}$ complex. This last fraction was treated in a similar way to that in 1). The fact that the color changed from red to purple by concentrating the effluent indicated the formation of $[Co(Cl)(H_2O)(NH_3)(tacn)]^{2+}$ species. The yield was *ca.* 0.5 g. Found: C, 19.11; H, 5.21; N, 13.46%. Calcd for $[Co(Cl)(H_2O)(NH_3)(tacn)]Cl_2\cdot NaCl$: C, 18.57; H, 5.20; N, 14.44%.

11) *$[Co(NCS)(H_2O)(NH_3)(tacn)](ClO_4)_2\cdot H_2O$*: An aqueous solution (20 cm³) containing $[Co(Cl)(H_2O)(NH_3)(tacn)]Cl_2\cdot NaCl$ (1.0 g, 3 mmol) and an equimolar amount of KSCN (0.4 g) was adjusted to pH 3 with 5 mol/dm³ $HClO_4$ and stirred at *ca.* 40 °C for 1 h. After cooling to room temperature, the solution was adjusted to pH 10 with 5 mol/dm³ KOH, and stirred for a while. After dilution to 2 dm³ with water, the diluted solution was neutralized with 5 mol/dm³ $HClO_4$ and poured onto a column of SP-Sephadex

C-25 (4 cm × 25 cm, Na^+ form). At first, by elution with 0.03 mol/dm^3 NaCl, a red band corresponding to an univalent cation was discharged. This species was assigned to a $[Co(NCS)_2(NH_3)(tacn)]^+$ complex by elemental analysis. Found: C, 25.34; H, 4.33; N, 21.35%. Calcd for $[Co(NCS)_2(NH_3)(tacn)]Cl\cdot 0.5H_2O$: C, 24.89; H, 4.70; N, 21.27%. A red band corresponding to the bivalent cation of the desired complex was eluted with 0.1 mol/dm^3 $HClO_4$. The solution was treated in a similar way to that in 1). The yield was *ca.* 0.5 g. Found: C, 16.52; H, 4.03; N, 14.37%. Calcd for $[Co(NCS)(H_2O)(NH_3)(tacn)](ClO_4)_2\cdot H_2O$: C, 16.87; H, 4.46; N, 14.06%.

12) *[Co(NCS)(NO$_2$)(NH$_3$)(tacn)]Cl·H$_2$O*: To a solution of $[Co(NCS)(H_2O)(NH_3)(tacn)](ClO_4)_2\cdot H_2O$ (0.5 g in 20 cm^3 H_2O), was added $NaNO_2$ (1.0 g, 14 mmol). The solution was adjusted to pH 3 with $HClO_4$, and stirred at room temperature until the color changed from red to orange. The resulting solution was treated in the same manner as in 4). The yield was *ca.* 0.3 g. Found: C, 23.20; H, 5.33; N, 22.85%. Calcd for $[Co(NCS)(NO_2)(NH_3)(tacn)]Cl\cdot H_2O$: C, 23.18; H, 5.56; N, 23.17%.

13) *[Co(NCS)(N$_3$)(NH$_3$)(tacn)]Cl·0.5H$_2$O*: An aqueous solution (20 cm^3) containing $[Co(NCS)(H_2O)(NH_3)(tacn)](ClO_4)_2\cdot H_2O$ (0.5 g) and NaN_3 (1 g, 15 mmol) was adjusted to pH 3 with $HClO_4$, and then stirred at 50 °C for 4—5 h. The resulting red solution was treated in a way similar to that in 4). The yield was *ca.* 0.3 g. Found: C, 23.63; H, 5.28; N, 32.05%. Calcd for $[Co(NCS)(NO_2)(NH_3)(tacn)]Cl\cdot 0.5H_2O$: C, 24.04; H, 5.48; N, 32.04%.

14) *[Co(N$_3$)(H$_2$O)(NH$_3$)(tacn)](ClO$_4$)$_2$*: This complex was prepared in the same manner as the $[Co(NCS)(H_2O)(NH_3)(tacn)]^{2+}$ complex, except for the use of NaN_3 (0.4 g, 6 mmol) in place of KSCN. Since the yield was very poor, the crystals of the desired complex could not be obtained. The ε value of the complex was evaluated in the same manner as in 6). This complex was also prepared from $[Co(NCS)(N_3)(NH_3)(tacn)]^+$ by treatment of H_2O_2 in an acidic solution.

15) *[Co(NO$_2$)(H$_2$O)(NH$_3$)(tacn)](ClO$_4$)$_2$*: This complex was prepared by the reaction of the $[Co(NCS)(NO_2)(NH_3)(tacn)]^+$ complex with H_2O_2, or by acid-hydrolysis of the $[Co(NO_2)_2(NH_3)(tacn)]^+$ complex.

Method 1: A solution containing $[Co(NCS)(NO_2)(NH_3)(tacn)]Cl\cdot 0.5H_2O$ (0.2 g in 50 cm^3 30% H_2O_2) was adjusted to pH 3 with 5 mol/dm^3 $HClO_4$ and stirred for 5—6 h. The resulting solution was diluted to 3 dm^3 and poured onto a column of Dowex 50W-X8 (2.5 cm × 20 cm, Na^+ form). By elution with 0.3 mol/dm^3 NaCl, a lemon-yellow band corresponding to univalent cation was discharged. This species was identified with $[Co(CN)(NO_2)(NH_3)(tacn)]^+$. After this, two yellow bands corresponding to bivalent cations were eluted with 1 mol/dm^3 $HClO_4$. The earlier eluate was assigned to the desired complex by its absorption spectrum and the later eluate was assumed to be $[Co(NO_2)(NH_3)_2(tacn)]^{2+}$ species. After neutralizing the earlier eluate, the solution was treated in a similar way to that in 14).

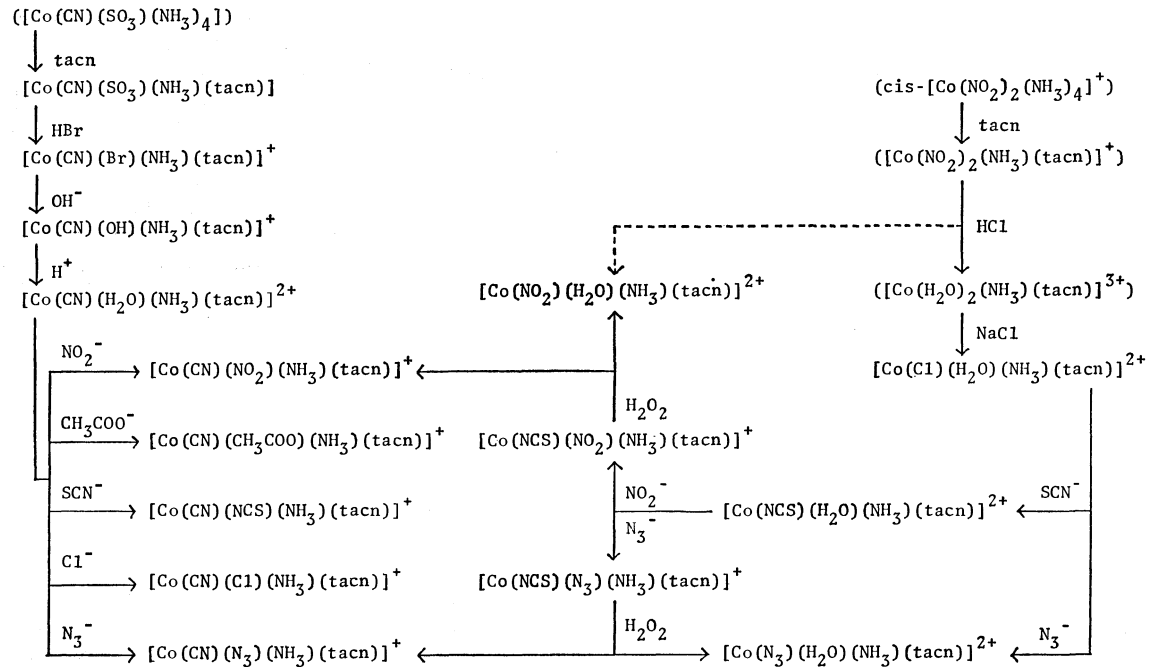
Method 2: On the synthesis of $[Co(Cl)(H_2O)(NH_3)(tacn)]^{2+}$, the orange band corresponding to the bivalent cation was rechromatographed on a column of Dowex 50W-X8 (2.5 cm × 20 cm). The orange and red bands were eluted with 1 mol/dm^3 $HClO_4$. The orange band was assigned to $[Co(NO_2)(H_2O)(NH_3)(tacn)]^{2+}$ and the red band to $[Co(Cl)(H_2O)(NH_3)(tacn)]^{2+}$.

Optical Resolution. Except for the $[Co(NO_2)_2(NH_3)(tacn)]^+$ and $[Co(CN)(SO_3)(NH_3)(tacn)]$ complexes all complexes prepared in this study were partially resolved into the optical antipodes by means of column chromatography. In the cases of bivalent cations, the optical resolutions were carried out on a column of SP-Sephadex C-25 (2.5 cm × 120 cm, Na^+ form) using 0.1 mol/dm^3 $K_2[Sb_2(d\text{-tart})_2]$ solution as eluent. On the other hand, since the $[Co(CN)(NO_2)(NH_3)(tacn)]^+$ and $[Co(CN)(NCS)(NH_3)(tacn)]^+$ complexes were yellowish univalent cations, a column of SP-Sephadex C-25 (2.5 cm × 120 cm, Na^+ form) and 0.03 mol/dm^3 $K_2[Sb_2(d\text{-tart})_2]$ solution as eluent were used. For the remaining complexes, the optical resolutions were performed on a column of Dowex 50W-X8 (200—400 mesh, 2.5 cm × 60 cm, Na^+ form) using 0.3 mol/dm^3 $Na_2[Sb_2(d\text{-tart})_2]$ solution as eluent. When the adsorbed band had descended to one tenth of the column height, the band was washed with water and eluted with 0.1 mol/dm^3 $HClO_4$, 0.03 mol/dm^3 NaCl or 0.3 mol/dm^3 NaCl. The eluates thus concentrated were submitted to the measurements of the CD spectra, while the concentrations of the complex species were evaluated from the absorption spectral data. The isomers are stable enough to measure the spectra in a solution.

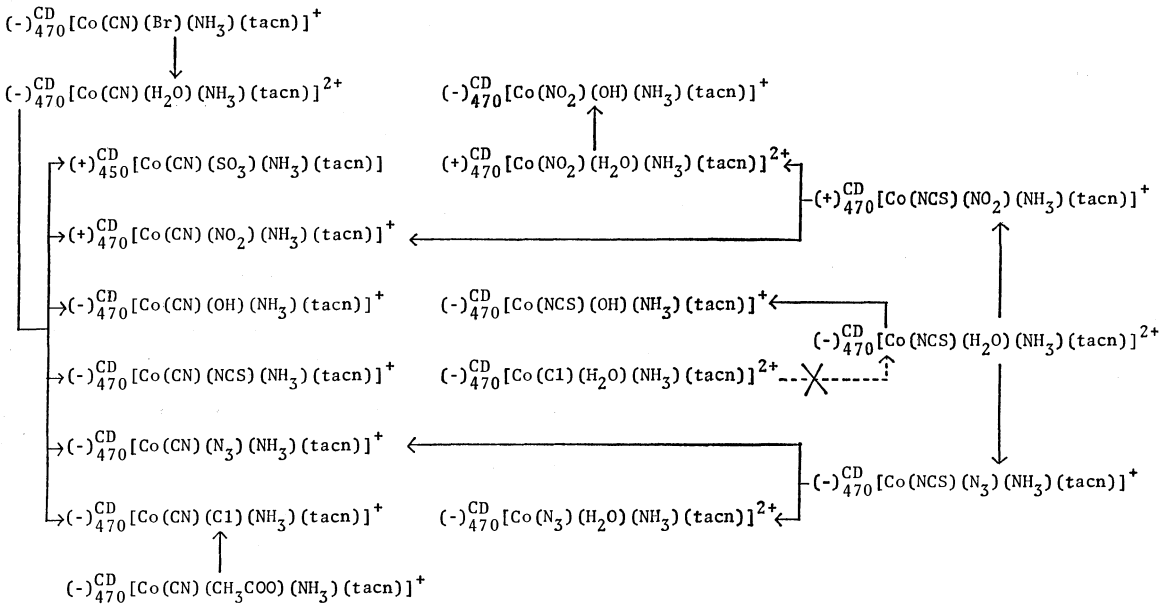
Derivation from Optically Active Complexes. The $(-)^{CD}_{470}[Co(CN)(H_2O)(NH_3)(tacn)]^{2+}$ complex could be derived from the $(-)^{CD}_{470}[Co(CN)(Br)(NH_3)(tacn)]^+$ complex, according to the procedure described in 2). Furthermore, the $(-)^{CD}_{470}[Co(CN)(H_2O)(NH_3)(tacn)]^{2+}$ complex could be converted to the $(-)^{CD}_{470}[Co(CN)(Cl)(NH_3)(tacn)]^+$, $(-)^{CD}_{470}[Co(CN)(OH)(NH_3)(tacn)]^+$, $(-)^{CD}_{470}[Co(CN)(NCS)(NH_3)(tacn)]^+$, $(-)^{CD}_{470}[Co(CN)(N_3)(NH_3)(tacn)]^+$, $(+)^{CD}_{470}[Co(CN)(NO_2)(NH_3)(tacn)]^+$, and $(+)^{CD}_{460}[Co(CN)(SO_3)(NH_3)(tacn)]$ by the methods described in 3)—7), respectively. The $(-)^{CD}_{470}[Co(CN)(CH_3COO)(NH_3)(tacn)]^+$ complex was converted to the $(-)^{CD}_{470}[Co(CN)(Cl)(NH_3)(tacn)]^+$ complex by the treatment with 6 mol/dm^3 HCl at 40 °C.

The $(-)^{CD}_{470}[Co(NCS)(H_2O)(NH_3)(tacn)]^{2+}$ complex could be converted to the $(+)^{CD}_{470}[Co(NCS)(NO_2)(NH_3)(tacn)]^+$ and $(-)^{CD}_{470}[Co(NCS)(N_3)(NH_3)(tacn)]^+$ complexes according to the procedures described in 12) and 13), respectively. On the other hand, the oxidation of the $(+)^{CD}_{470}[Co(NCS)(NO_2)(NH_3)(tacn)]^+$ complex by aqueous H_2O_2 at *ca.* pH 3 produced the $(+)^{CD}_{470}[Co(CN)(NO_2)(NH_3)(tacn)]^+$ and $(+)^{CD}_{470}[Co(NO_2)(H_2O)(NH_3)(tacn)]^{2+}$ complexes, which were separated chromatographically. The similar oxidation of the $(-)^{CD}_{470}[Co(NCS)(N_3)(NH_3)(tacn)]^+$ complex produced the $(-)^{CD}_{470}[Co(CN)(N_3)(NH_3)(tacn)]^+$ and $(-)^{CD}_{470}[Co(N_3)(H_2O)(NH_3)(tacn)]^{2+}$ complexes. The absorption and CD spectra of the optical isomers obtained by the derivations coincided with those of the isomers obtained by the optical resolutions. Through the above derivations from optically active complexes, the absolute configurations of all complexes prepared in this work could be correlated, except for the $[Co(Cl)(H_2O)(NH_3)(tacn)]^{2+}$ complex.

Measurements. The absorption spectra in aqueous solutions were recorded with a Hitachi 323 recording spectrophotometer. The CD spectra were measured with a JASCO J-40C automatic recording spectropolarimeter equipped with a JASCO Model J-DPZ data processor for CD. The absorption and CD spectra of hydroxo complex species were measured with solutions of the corresponding aqua complexes alkalized with 5 mol/dm^3 NaOH (pH 10). The hydroxo complex species were chromatographically pure, and the absorption and CD spectra of the hydroxo complexes were returned to the original spectra of the parent aqua complexes, when the solutions were again acidified with $HClO_4$. This fact suggests that the base-hydrolysis proceeds with retention of the configuration. To determine the ε values of the complexes which could not be crystallized, a Hitachi 170-150 atomic absorption spectrophotometer was used.



Scheme 1. Pathways of syntheses of $[Co(a)(b)(c)(tacn)]^{n+}$ complexes.



Scheme 2. Derivations of optically active complexes.

Results and Discussion

Preparation and Resolution. Various *fac*(*a*,*b*,*c*)-$[Co(a)(b)(c)(tacn)]^{n+}$-type complexes were prepared by derivations starting from the complexes $[Co(CN)(SO_3)(NH_3)_4]$[13] and *cis*-$[Co(NO_2)_2(NH_3)_4](NO_3)$.[14] Scheme 1 represents the pathways of the present syntheses. We failed to crystallize the $[Co(CN)(N_3)(NH_3)(tacn)]^+$, $[Co(CN)(CH_3COO)(NH_3)(tacn)]^+$, $[Co(NO_2)(H_2O)(NH_3)(tacn)]^{2+}$, and $[Co(N_3)(H_2O)(NH_3)(tacn)]^{2+}$ complexes, but the formations of these complexes were ascertained by absorption spectra, chromatographic behavior, optical resolutions, and chemical reactivities with other unidentate ligands.

All complexes except for $[Co(CN)(SO_3)(NH_3)(tacn)]$ were partially resolved into optical antipodes by a column chromatography using $K_2[Sb_2(d\text{-tart})_2]$ or $Na_2[Sb_2(d\text{-tart})_2]$ as eluting agent. When the $[Co(Cl)(H_2O)(NH_3)(tacn)]^{2+}$ complex was optically resolved, the counter ion was changed into a perchlorate at the last stage of the elution, since a chloride brought about racemization of the complex and the effluent exhibited no optical activity.

Absolute Configuration and CD Spectra. In order to investigate the relation between CD spectra and absolute configurations of the *fac*(*a*,*b*,*c*)-$[Co(a)(b)(c)(tacn)]^{n+}$-type complexes, we tried to derive optically active complexes directly from optically active parent complexes. The conversions were successful in giving

the corresponding optically active complexes, except for the [Co(Cl)(H_2O)(NH_3)(tacn)]$^{2+}$ complex. The derivations are shown in Scheme 2. The [Co(CN)-(SO_3)(NH_3)(tacn)] complex could not be resolved by column chromatography, but its active from $(+)^{CD}_{480}$-[Co(CN)(SO_3)(NH_3)(tacn)] was derived from the $(-)^{CD}_{470}$[Co(CN)(H_2O)(NH_3)(tacn)]$^{2+}$ complex.

When the $(+)^{CD}_{470}$[Co(NCS)(NO_2)(NH_3)(tacn)]$^+$ complex was treated with H_2O_2, the $(+)^{CD}_{470}$[Co(CN)-(NO_2)(NH_3)(tacn)]$^+$ and $(-)^{CD}_{470}$[Co(NO_2)(H_2O)(NH_3)-(tacn)]$^+$ complexes were obtained with an optically inactive [Co(CN)(NH_3)$_2$(tacn)]$^{2+}$ complex. The $(-)^{CD}_{470}$[Co(NCS)(N_3)(NH_3)(tacn)]$^+$ complex was also converted to the $(-)^{CD}_{470}$[Co(CN)(N_3)(NH_3)(tacn)]$^+$, $(-)^{CD}_{470}$[Co(N_3)(H_2O)(NH_3)(tacn)]$^{2+}$, and [Co(N_3)-(NH_3)$_2$(tacn)]$^{2+}$ complexes. Similar degradation reaction has been reported for $(-)_{589}$[Co(NCS)-(gly)(tacn)]$^+$; it is considered to proceed with retention of the configuration of the complex.[8] Since optically active isomers are obtained in the substitution or degradation reactions, it is concluded that two complexes which are connected with an arrow in Scheme 2 have the same absolute configuration with respect to the common ligands. Numerical data of absorption and CD spectra of the complexes drawn in Scheme 2 are summarized in Table 1.

For the present chiral complexes, two sources of d-electron optical activity can be considered: 1) A chiral conformation of three chelate rings of tacn and 2) a chiral arrangement of four kinds of donor atoms. However, it is considered that the tacn chelate rings are not fixed to a preferential conformation (λ or δ) and have little effect on the solution CD spectra, since CD spectra of three diastereoisomers of a [Co-(gly)(NH_3)(Metacn)]$^{2+}$ complex are known to be appreciably different from that of an enantiomeric [Co-(gly)(NH_3)(tacn)]$^{2+}$ isomer (Metacn represents (2*R*)-2-methyl-1,4,7-triazacyclononane, the chelate rings of Metacn in the former complex being fixed to λ conformation).[8,9] Therefore, it is considered that the op-

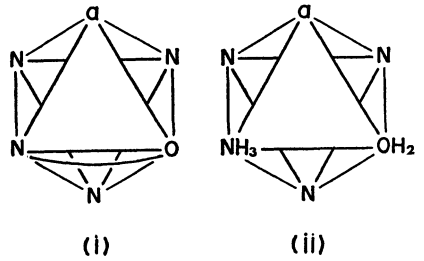

Fig. 1. Absolute configurations of (i) [Co(a)(gly)-(tacn)]$^{n+}$ and (ii) [Co(a)(H_2O)(NH_3)(tacn)]$^{n+}$.

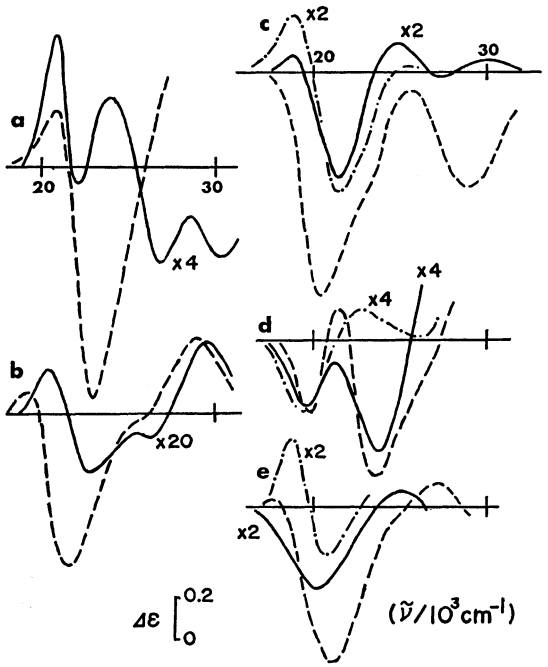

Fig. 2. CD spectra of a) $(+)^{CD}_{470}$[Co(N_3)(H_2O)(NH_3)-(tacn)]$^{2+}$ (——), $(+)_{589}$[Co(N_3)(gly)(tacn)]$^{+}$ (----), b) $(-)^{CD}_{470}$[Co(Cl)(H_2O)(NH_3)(tacn)]$^{2+}$ (——), $(-)_{589}$-[Co(Cl)(gly)(tacn)]$^{+}$ (----), c) $(-)^{CD}_{470}$[Co(CN)(H_2O)-(NH_3)(tacn)]$^{2+}$ (——), $(-)_{589}$[Co(CN)(gly)(tacn)]$^{+}$ (----), $(-)^{CD}_{470}$[Co(CN)(OH)(NH_3)(tacn)]$^{+}$ (—·—), d) $(-)^{CD}_{470}$[Co(NO_2)(H_2O)(NH_3)(tacn)]$^{2+}$ (——), $(-)_{589}$-[Co(NO_2)(gly)(tacn)]$^{+}$ (----), $(+)^{CD}_{470}$[Co(NO_2)(OH)-(NH_3)(tacn)]$^{+}$ (—·—), and e) $(-)^{CD}_{470}$[Co(NCS)(H_2O)-(NH_3)(tacn)]$^{2+}$ (——), $(-)_{589}$[Co(NCS)(gly)(tacn)]$^{+}$ (----), $(-)^{CD}_{470}$[Co(NCS)(OH)(NH_3)(tacn)]$^{+}$ (—·—).

tical source 1) causes little optical activity in the *fac*-(*a*,*b*,*c*)-[Co(a)(b)(c)(tacn)]$^{n+}$ complexes.

A series of [Co(a)(gly)(tacn)]$^{n+}$ complexes (a=CN^-, NO_2^-, NH_3, NCS^-, N_3^-, H_2O, OH^-, or Cl^-) possess the same source of dissymmetry as the present complexes, and the absolute configurations of the glycinato complexes have been determined on the basis of X-ray analysis and chemical derivations.[8,15] The CD spectra of the [Co(a)(gly)(tacn)]$^{n+}$ complexes which have the absolute configuration shown in Fig. 1 (i) are illustrated in Fig. 2 with broken lines. The CD spectra of the [Co(a)(H_2O)(NH_3)(tacn)]$^{2+}$ complexes (a=CN^-, NO_2^-, NCS^-, N_3^-, or Cl^-) are also drawn in Fig. 2 with solid lines. As to the cyano, nitro, isothiocyanato and azido complexes, the enantiomers which exhibit the CD spectra shown in Fig. 2 are

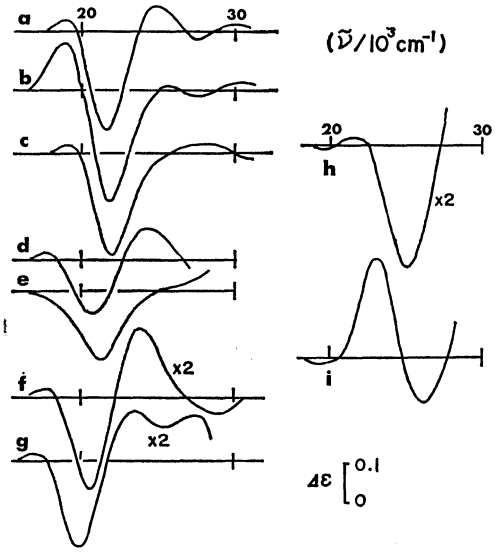

Fig. 3. CD spectra of a) $(-)^{CD}_{470}$[Co(CN)(H_2O)(NH_3)-(tacn)]$^{2+}$, b) $(-)^{CD}_{470}$[Co(CN)(OH)(NH_3)(tacn)]$^{+}$, c) $(-)^{CD}_{470}$[Co(CN)(CH_3COO)(NH_3)(tacn)]$^{+}$, d) $(-)^{CD}_{470}$-[Co(CN)(NCS)(NH_3)(tacn)]$^{+}$, e) $(-)^{CD}_{470}$[Co(CN)(N_3)-(NH_3)(tacn)]$^{+}$, f) $(-)^{CD}_{470}$[Co(CN)(Cl)(NH_3)(tacn)]$^{+}$, g) $(-)^{CD}_{470}$[Co(CN)(Br)(NH_3)(tacn)]$^{+}$, h) $(+)^{CD}_{470}$[Co-(CN)(NO_2)(NH_3)(tacn)]$^{+}$, and i) $(+)^{CD}_{480}$[Co(CN)-(SO_3)(NH_3)(tacn)].

considered to have the same absolute configuration, judging by the chemical derivations drawn in Scheme 2.

When the unidentate, a, is CN^-, NO_2^- or NCS^-, each CD spectrum of the [Co(a)(H_2O)(NH_3)(tacn)]$^{2+}$ complex resembles that of the corresponding [Co(a)-(gly)(tacn)]$^{+}$ complex, although the CD spectra of the azido complexes are somewhat different from each other. Thus, it is concluded that the $(-)^{CD}_{470}$[Co(CN)-(H_2O)(NH_3)(tacn)]$^{2+}$, $(-)^{CD}_{470}$[Co(NO_2)(H_2O)(NH_3)-(tacn)]$^{2+}$, $(-)^{CD}_{470}$[Co(NCS)(H_2O)(NH_3)(tacn)]$^{2+}$, and $(+)^{CD}_{470}$[Co(N_3)(H_2O)(NH_3)(tacn)]$^{2+}$ complexes have the absolute configuration as shown in Fig. 1 (ii).

Though the absolute configuration of $(-)^{CD}_{470}$[Co(Cl)-(H_2O)(NH_3)(tacn)]$^{2+}$ could not be correlated with those of others, it is considered that the $(-)^{CD}_{470}$-isomer has the same absolute configuration as shown in Fig. 1 (ii), since $(-)_{589}$[Co(Cl)(gly)(tacn)]$^{+}$ exhibits a CD spectrum similar to that of the $(-)^{CD}_{470}$-isomer.

The [Co(a)(H_2O)(NH_3)(tacn)]$^{2+}$ complexes are bivalent cations, while the [Co(a)(gly)(tacn)]$^{+}$ complexes are univalent cations. The [Co(CN)(CH_3COO)-(NH_3)(tacn)]$^{+}$ complex is the same univalent cation as [Co(CN)(gly)(tacn)]$^{+}$, and the $(-)^{CD}_{470}$-isomer of the acetato complex exhibits a CD spectrum similar to that of $(-)_{589}$-isomer of the glycinato complex. On this basis, it is predicted that both have the absolute configurations shown in Fig. 1. The absolute configurations of the others can be determined by tracing a pathway in Scheme 2.

a) [Co(a)(CN)(NH_3)(tacn)]$^{n+}$ Complexes. In this series, the unidentate, a, stands for NO_2^-, SO_3^{2-}, NCS^-, H_2O, OH^-, CH_3COO^-, N_3^-, Cl^-, or Br^-. Each of the complexes has a rhombic ligand field, in which there are three electronic transition com-

ponents for the first absorption band. The absorption spectra of the chloro, bromo, and hydroxo complexes exhibit clear splittings of the first absorption bands, while the aqua and acetato complexes show the broad absorption bands.

The CD spectra of [Co(a)(CN)(NH_3)(tacn)]$^{n+}$ with the same absolute configuration are shown in Fig. 3. Our interest is focused on the spectra in the first absorption band region, and the Cotton peaks in the region are described unless otherwise noted. The $(-)^{CD}_{470}$-azido and $(-)^{CD}_{470}$-acetato complexes exhibit one and two Cotton peaks, respectively. The remaining ones exhibit three Cotton peaks with alternating signs; however, the CD spectral pattern on the $(+)^{CD}_{470}$-nitro and $(+)^{CD}_{450}$-sulfito complexes is opposite to that on the $(-)^{CD}_{470}$-aqua, $(-)^{CD}_{470}$-hydroxo, $(-)^{CD}_{470}$-isothiocyanato, $(-)^{CD}_{470}$-chloro, and $(-)^{CD}_{470}$-bromo complexes, the former group exhibits (−), (+), and (−) signs from a lower-frequency side, and the latter group exhibits (+), (−), and (+) signs.

It is predicted by an angular overlap model[16] that three electronic transition components of the first absorption band are well separated with one another in the [Co(a)(CN)(NH_3)(tacn)]$^{n+}$ complexes. The predicted values well coincide with the extrema of the Cotton peaks. When a coordinate system is defined for the [Co(a)(CN)(NH_3)(tacn)]$^{n+}$ complexes as shown in Fig. 4 (i), the transition energy order becomes $E(xy\rightarrow x^2-y^2) < E(yz\rightarrow y^2-z^2) < E(zx\rightarrow z^2-x^2)$ for the aqua, hydroxo, acetato, isothiocyanato, azido, chloro and bromo complexes, and $E(xy\rightarrow x^2-y^2) < E(zx\rightarrow z^2-x^2) < E(yz\rightarrow y^2-z^2)$ for the nitro and sulfito complexes, where the symbols, $E(xy\rightarrow x^2-y^2)$, $E(yz\rightarrow y^2-z^2)$ and $E(zx\rightarrow z^2-x^2)$, designate the transition energies of the electronic transitions in XY, YZ, and ZX plane, respectively. The assignments of the Cotton peaks are listed in Table 2. As to the acetato complex, the two observed Cotton peaks are assigned to the lower-lying two transition components, *i.e.* ($xy\rightarrow x^2-y^2$) and ($yz\rightarrow y^2-z^2$), by comparing with the CD spectra of the aqua and hydroxo complexes. As to the azido complex, the observed Cotton peak is assigned to the ($yz\rightarrow y^2-z^2$) transition, on the basis of the prediction by the angular overlap model.

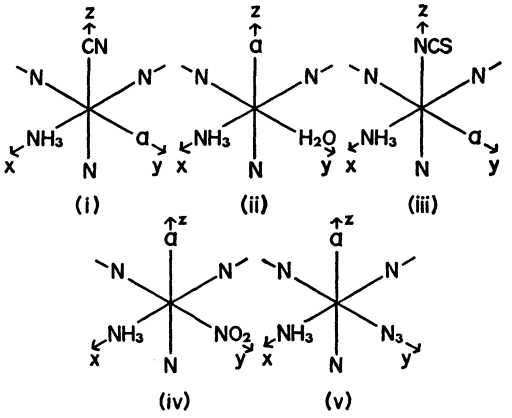

Fig. 4. Absolute configurations and coordinate systems for (i)[Co(a)(CN)(NH_3)(tacn)]$^{n+}$, (ii) [Co(a)(H_2O)(NH_3)(tacn)]$^{n+}$, (iii) [Co(a)(NCS)(NH_3)(tacn)]$^{n+}$, (iv)[Co(a)(NO_2)(NH_3)(tacn)]$^{n+}$, and (v) [Co(a)(N_3)(NH_3)(tacn)]$^{n+}$.

As is seen in Table 2, there are obvious relations between the Cotton signs and the corresponding transition components. The Cotton peaks corresponding to ($zx\rightarrow z^2-x^2$) exhibit positive signs in every complex. As to the peaks corresponding to ($yz\rightarrow y^2-z^2$), negative signs are observed in every complex. On the other hand, the signs of the peaks corresponding to ($xy\rightarrow x^2-y^2$) are variable depending upon the unidentate a. When the unidentate is nitro or sulfito, the sign becomes negative. When the unidentate is aqua, hydroxo, acetato, isothiocyanato, azido, chloro or bromo, the peak has a positive sign. The inversion of the Cotton sign corresponding to the ($xy\rightarrow x^2-y^2$) transition component is considered to relate to the ligand field strengths of the unidentate ligands lying in the XY plane. Nitro and sulfito ligands afford stronger ligand fields than an ammine ligand, and the Cotton peaks corresponding to ($xy\rightarrow x^2-y^2$) exhibit negative signs. On the other hand, the ligand field strengths of H_2O, OH^-, CH_3COO^-, NCS^-, N_3^-, Cl^-, or Br^- are weaker than that of NH_3, and the peaks corresponding to ($xy\rightarrow x^2-y^2$) exhibit positive signs.

As to the YZ plane, the ligand field strength of the unidentate a on the Y axis is weaker than that of the cyano ligand on the Z axis in every complex, and the concerned Cotton peaks exhibit negative signs. The common sign of the peaks corresponding to ($zx \rightarrow z^2-x^2$) associates with the fact that the cyano ligand on the Z axis affords stronger ligand field than the ammine ligand on the X axis. Since the Cotton signs associated with the ($zx \rightarrow z^2-x^2$) transition are independent with the variation of the unidentate a on the Y axis, the sign of the peak corresponding to a given electronic transition is considered to be determined by the ligands ligating in the plane where the electronic transition occurs. It is notable that all negative dominant peaks are assignable to the ($yz \rightarrow y^2-z^2$) transition component, except for the sulfito complex. This electronic transition component is associated with the YZ plane, which contains no ammine ligand.

b) $[Co(a)(H_2O)(NH_3)(tacn)]^{2+}$ Complexes. In these complexes, the unidentate a stands for CN^-, NO_2^-, NCS^-, N_3^-, or Cl^-. The CD spectra of $[Co(a)(H_2O)(NH_3)(tacn)]^{2+}$ are shown in Fig. 2, along with those of the corresponding hydroxo complexes, and the absolute configurations of these enantiomers are illustrated in Fig. 4 (ii). Since the $[Co(CN)(H_2O)(NH_3)(tacn)]^{2+}$ and $[Co(N_3)(H_2O)(NH_3)(tacn)]^{2+}$ complexes exhibit three Cotton peaks, the peaks can be assigned to the electronic transition components in the same manner as in the $[Co(a)(CN)(NH_3)(tacn)]^{n+}$ complexes. In both the complexes, (+), (−), and (+) peaks are observed from a lower frequency side. These peaks are assigned to ($xy \rightarrow x^2-y^2$), ($yz \rightarrow y^2-z^2$), and ($zx \rightarrow z^2-x^2$), respectively, for the cyano complex, and to ($yz \rightarrow y^2-z^2$), ($zx \rightarrow z^2-x^2$), and ($xy \rightarrow x^2-y^2$) for the azido complex. The Cotton peaks corresponding to the ($xy \rightarrow x^2-y^2$) component have (+) signs in these complexes. However, the signs associated with ($yz \rightarrow y^2-x^2$) and ($zx \rightarrow z^2-x^2$) in the cyano complex are opposite to those in the azido complex. These phenomena are also explained in the same manner as in the $[Co(a)(CN)(NH_3)(tacn)]^{n+}$ complexes. The inversions of the Cotton signs are related to the fact that a cyano ligand affords a stronger ligand field than an ammine or aqua ligand, but an azido ligand affords a weaker one than an ammine or aqua ligand. The common Cotton sign associated with ($xy \rightarrow x^2-y^2$) is related to the common ligands in the XY plane. It is also found that the variation of the unidentate on the Z axis does not influence the sign of the peak corresponding to the electronic transition in the XY plane. In both the cyano and azido complexes, the dominant Cotton peaks correspond to the transition component in the plane which contains no ammine ligand (*i.e.*, the YZ plane).

The $[Co(NO_2)(H_2O)(NH_3)(tacn)]^{2+}$ and $[Co(Cl)(H_2O)(NH_3)(tacn)]^{2+}$ complexes exhibit two extrema, and the $[Co(NCS)(H_2O)(NH_3)(tacn)]^{2+}$ complex exhibits one extremum. It is difficult to assign the peaks to the transition components in these complexes. However, if the dominant Cotton peaks can be related to the ($yz \rightarrow y^2-z^2$) component, the negative dominant peaks in the nitro and isothiocyanato complexes support the result in the cyano and azido complexes. A dominant peak with a (−) sign in $[Co(Cl)(H_2O)(NH_3)(tacn)]^{2+}$ may be explained by an overlapping of a peak at 24200 cm^{-1} in the second absorption band region. The chloro complex exhibits a positive Cotton peak at the lowest frequency side like the azido complex.

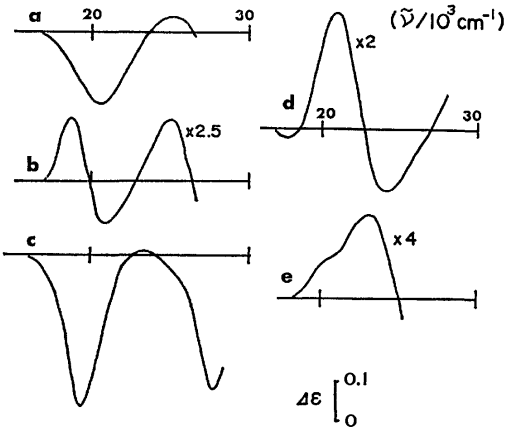

Fig. 5. CD spectra of a) $(-)^{CD}_{470}[Co(NCS)(H_2O)(NH_3)(tacn)]^{2+}$, b) $(-)^{CD}_{470}[Co(NCS)(OH)(NH_3)(tacn)]^{+}$, c) $(-)^{CD}_{470}[Co(NCS)(N_3)(NH_3)(tacn)]^{+}$, d) $(+)^{CD}_{470}[Co(CN)(NCS)(NH_3)(tacn)]^{+}$, and e) $(+)^{CD}_{470}[Co(NO_2)(NCS)(NH_3)(tacn)]^{+}$.

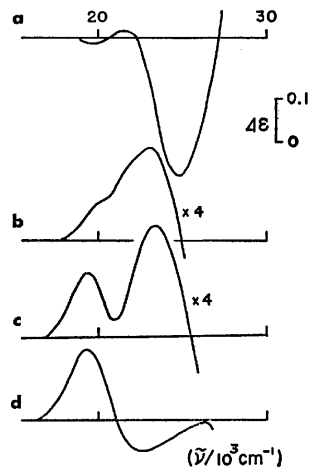

Fig. 6. CD spectra of a) $(+)^{CD}_{470}[Co(CN)(NO_2)(NH_3)(tacn)]^{+}$, b) $(+)^{CD}_{470}[Co(NO_2)(NCS)(NH_3)(tacn)]^{+}$, c) $(+)^{CD}_{470}[Co(NO_2)(H_2O)(NH_3)(tacn)]^{2+}$, and d) $(-)^{CD}_{470}[Co(NO_2)(OH)(NH_3)(tacn)]^{+}$.

The $[Co(CN)(OH)(NH_3)(tacn)]^{+}$ complex exhibits a similar CD spectrum to that of the parent aqua complex, but the spectra of $[Co(NO_2)(OH)(NH_3)(tacn)]^{+}$ and $[Co(NCS)(OH)(NH_3)(tacn)]^{+}$ are different from those of the parent aqua complexes. However, the $[Co(NO_2)(OH)(NH_3)(tacn)]^{+}$ complex also exhibits a (−) dominant peak like the parent aqua complex. It is characteristic that the $[Co(NCS)(OH)(NH_3)(tacn)]^{+}$ complex exhibits an intense peak with positive sign at 25000 cm^{-1} in the second absorption band region.

c) $[Co(a)(NCS)(NH_3)(tacn)]^{n+}$ Complexes. In this series, the unidentate a stands for CN^-, NO_2^-, H_2O, OH^-, or N_3^-. The complexes which have a

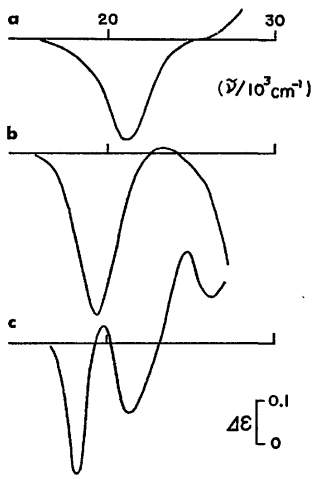

Fig. 7. CD spectra of a) $(-)^{CD}_{470}$[Co(CN)(N_3)(NH_3)-(tacn)]$^+$, b) $(-)^{CD}_{470}$[Co(NCS)(N_3)(NH_3)(tacn)]$^+$, and c) $(-)^{CD}_{470}$[Co(N_3)(H_2O)(NH_3)(tacn)]$^{2+}$.

common absolute configuration drawn in Fig. 4 (iii) exhibit the CD spectra as shown in Fig. 5. Except for the cyano complex, these complexes exhibit one or two Cotton peaks. Positive dominant peaks are observed at the cyano and nitro complexes, and negative ones, at the aqua and azido complexes. This phenomenon is also explained in terms of the ligand field strengths of the unidentates in YZ plane.

d) [Co(a)(NO_2)(NH_3)(tacn)]$^{n+}$ Complexes. In these complexes, the unidentate, a, stands for CN^-, NCS^-, H_2O, or OH^-. The isothiocyanato, aqua and hydroxo complexes exhibit two extrema. As to the complexes with the absolute configuration as shown in Fig. 4 (iv), only the cyano complex exhibits a (−) dominant peak (Fig. 6). This sign is related to the ligand field strength of CN^-, which is stronger than that of NO_2^-.

e) [Co(a)(N_3)(NH_3)(tacn)]$^{n+}$ Complexes. In this series, the unidentate a stands for CN^-, NCS^-, or H_2O. The CD spectra of the enantiomers illustrated in Fig. 4 (v) exhibit (−) dominant peaks (Fig. 7). This observation is also related to the fact that CN^-, NCS^-, and H_2O ligands have stronger ligand field strengths than N_3^-.

As described above, the sign of the Cotton peak of a given electronic transition in the [Co(a)(b)(c)-(tacn)]$^{n+}$ complex is associated with the ligand field strengths of two unidentate ligands contained in the plane where the electronic transition occurs. However, we can not find the obvious participation of two N donors of tacn contained in the same plane. The fact that the Cotton signs are related only with the characters of the unidentates may be concerned with the symmetrical nature of the terdentate ligand. It is notable to point out the followings. The complex, in which the ligand field strengths of three kinds of unidentates decrease clockwise on the octahedral face, exhibits negative, positive, and negative Cotton peaks from the lower frequency side in the first absorption band region, and the complex in which those decrease counterclockwise exhibits positive, negative, and positive Cotton peaks.

Effect of Lattice Anions on the Racemization of Optically Active Metal Chelate Salts in the Solid State. 2.[1] $[Co(phen)_3]X_3$, $[Co(phen)_2(en)]X_3$, and $[Co(phen)(en)_2]X_3$, Where $X^-=Cl^-$, Br^-, or I^-

Terufumi FUJIWARA

(Received May 24, 1982)

The kinetics of racemization of the anhydrous complexes (−)-$[Co(phen)_3]X_3$, (+)-$[Co(phen)_2(en)]X_3$, and (−)-$[Co(phen)(en)_2]X_3$, where phen=1,10-phenanthroline, en=ethylenediamine, and $X^-=Cl^-$, Br^-, or I^-, have been examined in the solid state. A rapid initial loss of optical activity and a subsequent first-order racemization were observed for the complex salts. Enthalpies and entropies of activation, ΔH^* and ΔS^*, were evaluated for the first-order process of $[Co(phen)_3]X_3$ and $[Co(phen)_2(en)]X_3$. It was found that for $[Co(phen)_3]X_3$ the chloride salt racemizes more rapidly than the bromide salt and that ΔH^* and ΔS^* decrease with the lattice anion in the order $X^-=Br^->Cl^-$. On the other hand, the reverse sequence in ΔH^* and ΔS^*, $X^-=Br^-<Cl^-$, was observed for $[Co(phen)_2(en)]X_3$. Moreover, the rate of racemization of $[Co(phen)(en)_2]X_3$ was found to decrease with the lattice anion in the order $X^-=I^->Br^->Cl^-$. These anion effects for the series were successfully interpreted in terms of the chemical interactions due to donicity and hydrogen bonding ability of anions, but not in terms of the physical factor, lattice energy. Thermal decomposition studies of the complexes lend support to the interpretation of the racemization kinetic data.

In our previous study of the solid-state racemization of halide salts of tris-complexes of 1,10-phenanthroline and 2,2′-bipyridine with iron and nickel ions,[1] a difference in racemization mechanism between the iron and nickel complexes was reported as it is in solution.[2,3] The operation of only a twist process without any nucleophilic interaction of lattice anions is postulated for the iron complexes as in solution.[3,4] On the other hand, ΔH^* and ΔS^* values for the nickel complexes were found to decrease with the lattice anion in the order $X^-=ClO_4^->I^->Br^->Cl^-$. Then, we have pointed out that the trend is attributed to the donicity of the anions[5] to stabilize a 7-coordinate transition state which is generated by attack of the lattice anion on the central metal as proposed for solutions.[6,7] Kutal and Bailar found that the rate of racemization of the complex salt, $[Co(en_3)]X_3\cdot nH_2O$, increases in the order of anions $Cl^-<NCS^-<Br^-<I^-$ for the anhydrous compounds, and it was presumed that hydrogen bonding of the type N–H···X was responsible for the rate differences in the series.[8] On the other hand, activation energies or enthalpies for the dehydration of the series of compounds $[M(NH_3)_5(H_2O)]X_3$ in the solid state[9,10] (where M=Cr, Co, or Ru) were found to decrease with the anion in the order $X^-=I^->Br^->Cl^-$ and an S_N2-type mechanism was proposed for the reaction.

However, a different mechanism from them was proposed recently by House[11] for the solid-state reactions in which the generation of a point defect is considered to be the origin of the transition state. The intramolecular racemization of $[Co(en)_3]X_3$ has been shown to be consistent with the substituted ion type of defect, while the dehydration of $[M(NH_3)_5(H_2O)]X_3$ is consistent with the formation of a Frenkel type of defect. Then, energy of the formation of the transition state is discussed in terms of lattice energy and ionic radii. However, we pointed out in previous paper[12] that the anion effects on the racemization of the iron and nickel complexes cannot be accounted for in terms of House's model or the physical factor alone, lattice energy.

In view of these studies, it is of interest to explore the role of the factors which facilitate or retard the solid-state racemization of the series of homo- and heterochelated tris-complexes of 1,10-phenanthroline and ethylenediamine, $[Co(phen)_3]X_3$, $[Co(phen)_2(en)]X_3$, and $[Co(phen)(en)_2]X_3$. An attempt was made to isolate the optically active complex, (−)-$[Co(phen)_3]^{3+}$, as the halide salts by a conventional method, namely, by addition of an excess of sodium halide solutions to aqueous solutions of the active complex. However, we failed to obtain the active halide salts because the complex racemizes very rapidly in halide-containing solutions.[13] Recently by a freeze-drying method, we successfully isolated the optically active chloride and bromide salts of the complex.[14] In addition to the kinetic data, the results of studies on the thermal decomposition of these complexes were incorporated into the analysis of the effect of lattice anions on the transition state for the solid-state racemization.

Experimental

Materials. The bromide and chloride salts of the optical isomer of $[Co(phen)_3]^{3+}$ isolated in our previous study[14] were employed here. The preparation and resolution of $[Co(phen)_2(en)]^{3+}$ were performed according to the method of Gillard *et al.*[15] The complex, $K_3[(+)_{589}$-$Co(L\text{-}cysu)_3]$ [cysu=cysteinesulfinato(2−)-*SN**], prepared by a previously reported method,[16] was used as the resolving agent. The diastereoisomer with $(+)_{589}$-$[Co(L\text{-}cysu)_3]^{3-}$ was converted to its bromide and chloride salts, $(+)_{436}$-$[Co(phen)_2(en)]Br_3\cdot 6H_2O$ and $(+)_{436}$-$[Co(phen)_2(en)]Cl_3\cdot 6H_2O$, by anion exchange (Dowex 21K resin, Br^- or Cl^- form). Found: C, 36.80; H, 3.68; N, 10.39%. Calcd for $C_{26}H_{36}O_6N_6Br_3Co$: C, 37.75; H, 4.39; N, 10.16%. Found: C, 44.56; H, 4.61; N, 13.03%. Calcd for $C_{26}H_{36}O_6N_6Cl_3Co$: C, 45.00; H, 5.23; N, 12.11%. The complex,

* The ligand, cysu, should read β-sulfinato-L-alaninato: $H_2NCH(CO_2^-)CH_2SO_2^-$.

$[Co(phen)(en)_2]^{3+}$, was prepared and resolved using ammonium $(+)_{589}$-3-bromo-8-camphorsulfonate as previously reported.[17] The optical isomer was isolated as the iodide, bromide, and chloride salts, $(-)_{436}$-$[Co(phen)(en)_2]I_3 \cdot H_2O$, $(-)_{436}$-$[Co(phen)(en)_2]Br_3 \cdot 5H_2O$, and $(-)_{436}$-$[Co(phen)(en)_2]Cl_3 \cdot 6H_2O$. Found: C, 25.76; H, 3.20; N, 10.88%. Calcd for $C_{16}H_{26}ON_6I_3Co$: C, 25.35; H, 3.46; N, 11.09%. Found: C, 27.41; H, 4.50; N, 12.88%. Calcd for $C_{16}H_{34}O_5N_6Br_3Co$: C, 27.89; H, 4.97; N, 12.20%. Found: C, 33.39; H, 4.80; N, 15.37%. Calcd for $C_{16}H_{36}O_6N_6Cl_3Co$: C, 33.49; H, 6.32; N, 14.64%. All the complexes were powdered by grinding with a mortar and pestle to pass a 200-mesh sieve. The preparation of anhydrous samples of the complexes was performed by the method given earlier,[1] except that the operation was performed in the dark since exposure to sunlight affects the optical rotations, especially of $[Co(phen)_3]X_3 \cdot nH_2O$.[14]

Measurements. The racemization rates at different temperatures were measured for each complex by using the same heating apparatus as that used in our previous study.[1] Before the measurements were made, all the solid samples(0.005—0.007 g) of the anhydrous complexes were placed in NMR tubes(5 mm in diameter, 5 cm in length) and preserved in a desiccator over P_2O_5 in the dark. The sample tubes were placed in the heating apparatus where it was possible to prevent the samples from exposure to sunlight. The samples were taken out of the apparatus at timed intervals and cooled rapidly. The optical rotations of the samples were measured in triplicate on aqueous solutions in the conventional manner at 365 nm for $[Co(phen)_3]^{3+}$ and at 436 nm for $[Co(phen)_2(en)]^{3+}$ and $[Co(phen)(en)_2]^{3+}$ by using a Perkin-Elmer Model 141 Polarimeter and a Hg lamp, with a cell of 1-dm length. The concentrations of the solutions were determined spectrophotometrically using a Hitachi Perkin Elmer Model 139 UV-vis spectrophotometer. The wavelengths and molar extinction of absorption maximums employed are as follows: 274 nm and 6.95×10^4 mol^{-1} dm^3 cm^{-1} for $[Co(phen)_3]^{3+}$; 305 nm and 1.255×10^4 mol^{-1} dm^3 cm^{-1} for $[Co(phen)_2(en)]^{3+}$; 273 nm and 3.025×10^4 mol^{-1} dm^3 cm^{-1} for $[Co(phen)(en)_2]^{3+}$. Within experimental uncertainties, the specific rotations of aqueous solutions of the complexes were independent of concentration. These results have a precision of better than 5%. Thermogravimetric analysis (TGA) and differential thermal analysis(DTA) were carried out with a Sinku-Riko Model TGD-3000-RH instrument. Samples(0.01—0.02 g) of the hydrates were used. A heating rate of 5°/min and a static air atmosphere were employed in each run.

Results

Typical plots of $\log(10[\alpha_t]/[\alpha_0])$ *vs.* time for the solid-state racemization of anhydrous salts of $(-)$-$[Co(phen)_3]X_3$, $(+)$-$[Co(phen)_2(en)]X_3$, and $(-)$-$[Co(phen)(en)_2]X_3$ (X=I, Br, or Cl) are given in Figs. 1—3, respectively, where $[\alpha_t]$ is the specific rotation at time t and $[\alpha_0]$ is the specific rotation at time zero. Figures 1 and 2 show that all runs with anhydrous materials of the tris- and bis-phenanthroline complexes have the common characteristic of an initial period during which very rapid loss of optical activity occurs, followed by a first-order racemization process. On the other hand, Fig. 3 shows that the chloride and bromide salts of the mono-phenanthroline complex exhibit decreasing rates of racemization after the initial period

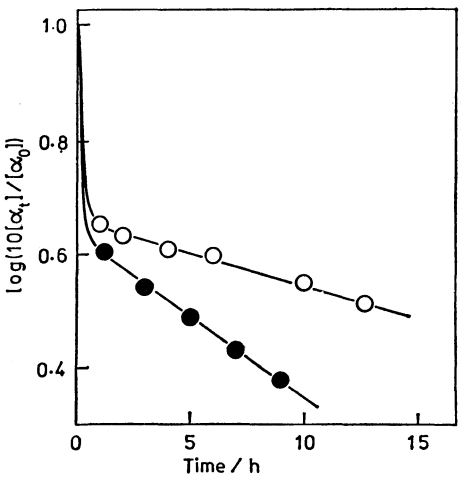

Fig. 1. Racemization of $(-)$-$[Co(phen)_3]Br_3$ at 121 °C (○) and $(-)$-$[Co(phen)_3]Cl_3$ at 119 °C (●).

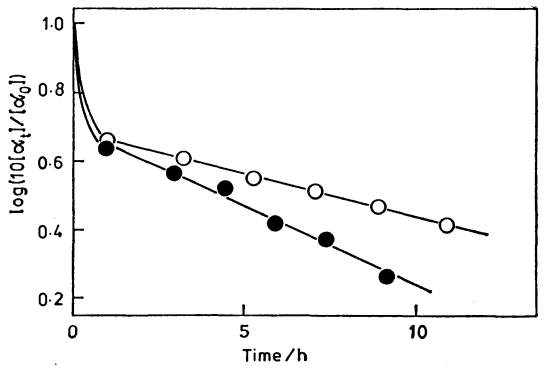

Fig. 2. Racemization of $(+)$-$[Co(phen)_2(en)]Br_3$ (○) and $(+)$-$[Co(phen)_2(en)]Cl_3$ (●) at 148 °C.

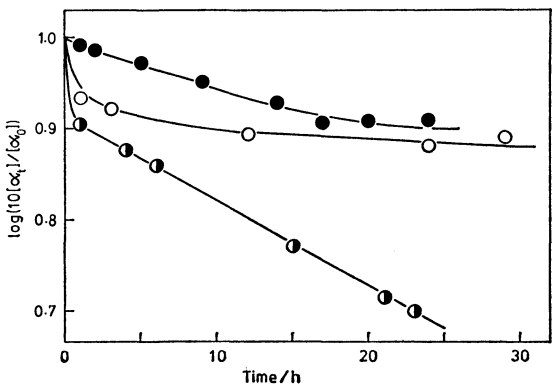

Fig. 3. Racemization of $(-)$-$[Co(phen)(en)_2]Cl_3$ at 145 °C (●), $(-)$-$[Co(phen)(en)_2]Br_3$ at 149 °C (○), and $(-)$-$[Co(phen)(en)_2]I_3$ at 145 °C (◑).

and thus the kinetics depart from simple first-order behavior, although the iodide salt shows a first-order racemization as do the tris- and bis-phenanthroline complexes.

For the first-order racemization, the rate constant, k, is determined by applying the equation used in our previous paper.[1] Table 1 lists the rate constants. The indicated errors are one standard deviation estimated from least-squares fits to the equation. Table 1 shows that the chloride salts racemize faster than

TABLE 2. KINETIC PARAMETERS FOR THE SOLID-STATE RACEMIZATION OF COBALT COMPLEXES WITH THERMAL STABILITY

Complex	ΔH^* / kJ mol^{-1}	ΔS^* / J K^{-1} mol^{-1}	T_d / °C
(−)-$[Co(phen)_3]Br_3$	181±11	108±27	188
(−)-$[Co(phen)_3]Cl_3$	143±7	23±18	170
(+)-$[Co(phen)_2(en)]Br_3$	100±6	−109±14	202
(+)-$[Co(phen)_2(en)]Cl_3$	195±20	124±47	186

the corresponding bromide salts in both series of the complexes. Although attempts were made to fit the racemization data for $[Co(phen)(en)_2]X_3$ to various topochemical rate laws common to solid-state reactions,[18] any fit to such kinetic expressions must be regarded as poor because of the invariably deceleratory plots throughout the course of the racemization.

Activation parameters, ΔH^* and ΔS^*, were determined by least-squares fits to Eyring plots for the first-order racemization as expressed in our previous papers,[1,12] although the first-order process may be the case of random nucleation.[18] These are presented in Table 2. The uncertainties quoted for the activation parameters are the computed standard deviations. Table 2 shows that ΔH^* for $[Co(phen)_3]X_3$ decreases in the order X=Br>Cl, whereas for $[Co(phen)_2(en)]X_3$ the sequence X=Br<Cl lies in the reverse order.

TGA runs on all the hydrated salts of the complexes in static air show that dehydration occurs soon after heating (at 30—35 °C). Then anhydrous weight levels are almost attained at 105—115 °C for $[Co(phen)_3]X_3$ and $[Co(phen)(en)_2]X_3$ and at 115—125 °C for $[Co(phen)_2(en)]X_3$. As the temperature is raised further, thermal decomposition of the complexes occurs in air. The temperatures (T_d) at which weight loss resulting from the decomposition begins are given in Table 2. Under the conditions employed in the racemization rate studies, TGA and DTA confirmed the absence of thermal decomposition, and the lack of color changes offered evidence that there was no change in chemical combination. In addition, when (−)-$[Co(phen)_3]Br_3$ was heated at 114 °C for 38 h in air, no reduction of the complex cation by bromide ion was shown by a conventional potentiometric titration of aqueous solutions of the sample using an Ag/Ag^+ electrode, although the sample lost 70% of its optical activity.

Discussion

A very rapid loss of optical activity in an initial period observed for all the cobalt complexes (Figs. 1—3) is similar to that for $[M(phen)_3]X_2$ and $[M(bpy)_3]X_2$ (M=Fe or Ni and bpy=2,2′-bipyridine).[1] Such an initial phenomenon was also reported for the solid-state racemization of other complexes, $[Co(en)_3]X_3 \cdot nH_2O$[11] and $K_3[Cr(C_2O_4)_3]$[19] and discussed in detail in previous papers.[1,8] Then it was not investigated further in this study and attention is riveted on the racemization process after the initial period as follows.

The cobalt complexes employed here are low-spin d^6 complexes in analogy with the iron complexes[20] and so the operation of the twist mechanism is considered likely. However, $[Co(phen)_3]Cl_3$ was found to racemize more rapidly than $[Co(phen)_3]Br_3$. In addition, the ΔH^* and ΔS^* values for the bromide are larger than those for the chloride. These results indicate that there is interaction of the complex cation with the anions in the transition state. The trend in ΔH^* is the same as observed for $[Ni(phen)_3]X_2$ and $[Ni(bpy)_3]X_2$[1] and then attributed to the donicity of the anions to stabilize the transition state. For the solid-state racemization of tris-chelated metal complexes, an intermolecular mechanism cannot operate owing to the absence of solvents required for dissolution of a released ligand, and for the same reason a mechanism involving one-ended dissociation of a ligand is regarded as improbable.[1,8] Thus it is reasonable to infer that the mechanism of racemization of the cobalt complex would be similar to that of the nickel complexes, that is to say, the mechanism involves expansion of a complex cation to a 7-coordinate transition state with one lattice anion, for example a capped trigonal prism.[21] Moreover, the mechanism is consistent with the decrease in ΔS^* found, as ΔH^* decreases (Table 2) as described for the nickel complexes.[1] Another support for the operation of the mechanism is furnished by thermal decomposition studies of the cobalt complexes. It was pointed out that if the racemization mechanism is operative, the ΔH^* values should be related to T_d values taken as a measure of the strength of metal-anion bonds in thermal decomposition products.[1] This is also corroborated by the present data on ΔH^* and T_d. Table 2 shows that the trend is a decrease in T_d as ΔH^* decreases, indicating that both the mechanisms of racemization and decomposition should be controlled by the donicity of the lattice anion.

It was reported that the rates of thermal decomposition of $[Co(NH_3)_6]X_3$ in the solid state increase with the anion in the order $X^-=Cl^-<Br^-<I^-$, which

agree with that of the electron transfer reaction of the complexes.[22] On the other hand, Kutal and Bailar pointed out in a study of the racemization of $[Co(en)_3]X_3$ that such an electron exchange mechanism is not operative in the solid state.[8] For the racemization of $[Co(phen)_3]X_3$ also, the following results suggest that a process involving reduction of the complex or an electron exchange mechanism is unlikely in the solid state. The order of anion effects on the rate for the complex is opposite to that observed for aqueous solutions ($Cl^- < Br^- < I^-$).[13,23] Moreover, despite the observation that $[Co(phen)_3]Br_3$ lost 70% of its optical activity at 114 °C after 38 h, no reduction of the complex in the solid state was observed.[24] In addition, it was reported that activation energies for the dehydration of the series of compounds $[Co(NH_3)_5(H_2O)]X_3$ in the solid state decrease with the anion in the same order, $X^- = Br^- > Cl^-$, as that observed here for the racemization of $[Co(phen)_3]X_3$.

When one of three phenanthroline ligands in the homochelated tris-complex, $[Co(phen)_3]X_3$, is replaced with an ethylenediamine ligand to yield the heterochelated tris-complex, $[Co(phen)_2(en)]X_3$, it is observed that ΔH^* and ΔS^* values for the bromide of the heterochelated complex are smaller than those for the corresponding chloride. Despite the observation that T_d for $[Co(phen)_2(en)]X_3$ decreases in the order, $X^- = Br^- > Cl^-$, which lies in the order of increasing donor strength of the halide ion as observed for the homochelated complex, the trend in ΔH^* and ΔS^* for the heterochelated complex is opposite to that for the homochelated complex (Table 2). In the racemization studies[1,7] of $[Ni(phen)_3]X_2$ and $[Ni(bpy)_3]X_2$, it was implied that there is no appreciable interaction of the aromatic ligands with the halide ions.[25] Thus, these results reflect some specific effects such as hydrogen bonding, as in $[Co(en)_3]X_3$.[8] If such a twisting motion of all the three chelate rings as in a Bailar twist[26] is performed in the racemization process of the complex, then the hydrogen bonds formed in the ground state are forced to be weakened or broken in the transition state. Thus, the enthalpy of activation for the process should increase with an increase in the strength of hydrogen bonds in the ground state. In conformity with this view, the sequence observed for ΔH^*, $X^- = Br^- < Cl^-$, lies in the order of increasing strength of the hydrogen bonds.[27] The ethylenediamine ligand appears to be frozen more tightly in the lattice owing to the hydrogen bonds for the chloride salt compared with the bromide salt. It is thus reasonable to expect a smaller degree of freedom of the ligand in the ground state for the chloride salt and so a larger increase in the degree of freedom of the ligand on activation. This is reflected in larger ΔS^* for the chloride salt (Table 2).

Table 2 shows that ΔH^* for the bromide of the heterochelated complex is lower than that of the bromide of the homochelated complex in spite of the additional energy required to break the hydrogen bonds on activation, and the entropy of activation is negative. These results may imply that for the racemization of the heterochelated complex such a nucleophilic attack of the halide ions as that for the homochelated complex can occur with the breaking of the hydrogen bonds. Since the ethylenediamine ligand is of lower ligand field strength than the phenanthroline ligand,[28] the replacement of one of three phenanthroline ligands by an ethylenediamine ligand causes a decrease in the enthalpy required to expand Co–N bonds in the transition state. On the other hand, the attack puts restriction on the more flexible ethylenediamine ligands due to removal of any steric hindrance, leading to a decrease in the freedom of movement of the ligand in the transition state. For the chloride salt of the heterochelated complex, however, the effect of the hydrogen bonding interaction in the ground state might be more marked than that of the nucleophilic interaction in the transition state and thus the nucleophilic effect of chloride ion is not appreciable.

Furthermore, for the heterochelated tris-complex, $[Co(phen)(en)_2]X_3$, a more marked retarding effect of the hydrogen bonding was found to be exerted on the racemization as seen in Fig. 3. The rate of racemization of the complex decreases with the lattice anion in the order $X^- = I^- > Br^- > Cl^-$. This sequence lies in the order of increasing strength of the hydrogen bonds of the anions and is the same as that observed for $[Co(en)_3]X_3$,[8] but in the order opposite to that for the homochelated complex, $[Co(phen)_3]X_3$. The iodide salts of the heterochelated complex exhibit a first-order linearity as well as $[Co(phen)_3]X_3$ and $[Co(phen)_2(en)]X_3$. For the chloride and bromide salts, on the other hand, deviations from simple first-order behavior were observed. Similar deviations have been reported for $[Co(en)_3]X_3$.[8]

In the present study, the anion effects for the series cannot be accounted for in terms of House's model as in our previous studies for the nickel complexes.[1,12] House pointed out[11] that the trigonal transition state for the intramolecular racemization process which follows the model is produced only with the expansion of the cation and that the difficulty of the expansion increases with increasing lattice energy according to the Kapustinskii equation;[29] the formation of the transition state would be most difficult in the case of the smallest anion. If the process alone gives rise to anion effects in the racemization of the solid complexes, the rate of racemization is expected to decrease with the lattice anion in the order $X^- = Br^- > Cl^-$ and the expected ΔH^* should increase in the order of anions $Br^- < Cl^-$. However, the opposite orders in the rate and ΔH^*, respectively, were observed for $[Co(phen)_3]X_3$. Moreover, if there is no specific interaction such as hydrogen bonding, the expected order of lattice energy effect for the homochelated complex should be the same as those for the heterochelated complexes and so no change in the order of anion effects on the rate or ΔH^* should be expected for the series. However, the order, in fact, changes as shown above. Therefore, the physical factor alone, lattice energy, is insufficient to explain these anion effects, and thus the chemical factors, donicity and hydrogen bonding ability of lattice anions, as described above, are considered to be responsible for the anion effects or the rate differences. In addition, Kutal and Bailar pointed out that the lattice anions effectively shield the

complex ions from each other.[8)]

The author wishes to thank Prof. Y. Yamamoto for helpful discussions. The author also thanks Mr. S. Sato for his assistance in the experimental work. Grateful acknowledgment is made for the financial support of a Grant-in-Aid for Scientific Research No. 574232 the Ministry of Education, Science and Culture.

(Received June 4, 1982)

Unsymmetrical-facial (*u-fac*) and symmetrical-facial (*s-fac*) isomers of a mixed-ligand type complex, [Co(ida)(Rida)]$^-$ (Rida denotes *N*-methyl- or *N*-ethyliminodiacetate dianion), were prepared and characterized on the basis of their absorption, circular dichroism, ^{1}H NMR, and ^{13}C NMR spectral data. The isomerization and racemization reactions of these isomers were investigated in basic aqueous solution and compared with those of the bis type complexes, [Co(ida)$_2$]$^-$ and [Co(Rida)$_2$]$^-$. The time-course changes in the absorption spectra of [Co(ida)(Rida)]$^-$ and [Co(ida)$_2$]$^-$ indicated that the *mer* isomer exists as a transient labile intermediate in the isomerization reaction of *u-fac* to *s-fac*.

The bis(terdentate) complex of cobalt(III) with *N*-alkyliminodiacetate ion provides three geometrical isomers, as shown in Fig. 1. In a previous paper,[1] we reported the preparation and characterization of the *u-fac* isomers of [Co(mida)$_2$]$^-$ and [Co(eida)$_2$]$^-$, which have large intramolecular steric repulsions. These *u-fac* isomers decomposed in basic aqueous solution; at the same time, the decomposition of the ligands and the reduction of cobalt(III) to cobalt(II) occurred. On the other hand, no such decomposition occurred in the *s-fac* and *mer* isomers of the above two complexes.

In the present paper, the preparation of the mixed-ligand type complexes with both iminodiacetate (ida) and *N*-alkyliminodiacetate (Rida) ions, [Co(ida)(Rida)]$^-$, will be described, and the stereochemistry and the reactivity (isomerization and racemization) in basic aqueous solution will be discussed on the basis of their absorption, circular dichroism (CD), ^{1}H NMR, and ^{13}C NMR spectral data. These results will be compared with those of the bis type complexes, [Co(ida)$_2$]$^-$ and [Co(Rida)$_2$]$^-$.

Experimental

Ligands. Iminodiacetic acid was obtained commercially from Wako Pure Chemical Industries, Ltd. and used without further purification. *N*-Methyl- and *N*-ethyliminodiacetic acids were synthesized by the method in the literature.[2]

Preparation of Complexes. *Potassium Iminodiacetato(N-methyliminodiacetato)cobaltate(III)*, u-fac-*K*[*Co(ida)(mida)*]·2H_2O: This isomer was prepared by a method similar to that used for the *u-fac*-K[Co(mida)$_2$] complex reported in our previous paper.[1]

To a solution containing cobalt(II) chloride hexahydrate (5.95 g, 0.025 mol) in 20 cm^3 of water was added a solution containing a mixture of iminodiacetic acid (3.34 g, 0.025 mol) and *N*-methyliminodiacetic acid (3.68 g, 0.025 mol) in 70 cm^3 of water. Lead dioxide (9.0 g, 0.038 mol) was added gradually to the mixed solution adjusting pH to 4.0—4.5, and then the solution was stirred for 1 h at room temperature. After insoluble materials in the reactant solution were removed by filtration, the filtrate was poured into a QAE-Sephadex column (4.7 cm × 90 cm, Cl$^-$ form). The adsorbed band was separated into a broad red-brown band (containing *s-fac* and *mer* isomers of [Co(mida)$_2$]$^-$, [Co(ida)(mida)]$^-$, and [Co(ida)$_2$]$^-$) and a violet one by elution with an 0.1 mol·dm^{-3} KCl solution. The latter band was separated into three bands of blue (*u-fac*-[Co(mida)$_2$]$^-$), violet (*u-fac*-[Co(ida)(mida)]$^-$), and purple (*u-fac*-[Co(ida)$_2$]$^-$) by repeating developments on the same column. The violet eluate containing *u-fac*-[Co(ida)(mida)]$^-$ was acidified by adding a few drops of acetic acid to it and evaporated by use of a rotary evaporator at 35 °C. The complex obtained from the concentrated solution by addition of methanol and acetone was purified by using a Sephadex G-10 column. Needle crystals of violet color were obtained by recrystallization from water to which a methanol–acetone mixture was added. Found: C, 26.39; H, 3.86; N, 7.06%. Calcd for *u-fac*-K[Co(ida)(mida)]·2H_2O: C, 26.35; H, 3.93; N, 6.83%.

Sodium Iminodiacetato(N-methyliminodiacetato)cobaltate(III), s-fac-*Na*[*Co(ida)(mida)*]·H_2O. This isomer was obtained by the isomerization reaction of *u-fac* to *s-fac*.

An aqueous solution containing *u-fac*-Na[Co(ida)(mida)], which was converted from the corresponding potassium salt using a small SP-Sephadex column of Na$^+$ form, was adjusted to pH 10—10.5 with NaOH aqueous solution and warmed to *ca.* 50 °C. The color of the solution changed immediately from violet to light brown. The solution was evaporated by use of a rotary evaporator. The desired *s-fac* isomer was isolated as flake crystals of light brown by adding methanol to the concentrated solution. Recrystallization was carried out from warm water by addition of methanol. Found: C, 28.60; H, 3.74; N, 7.60%. Calcd for *s-fac*-Na[Co(ida)(mida)]·H_2O: C, 28.74; H, 3.75; N, 7.45%.

An attempt to obtain the *mer* isomer of [Co(ida)(mida)]$^-$ from the red-brown band mentioned above was unsuccessful (*vide post*).

Potassium Iminodiacetato(N-ethyliminodiacetato)cobaltate(III), u-fac-*K*[*Co(ida)(eida)*]·H_2O. This isomer was obtained by the same method as that used for *u-fac*-K[Co(ida)(mida)]·2H_2O. Found: C, 29.25; H, 4.06; N, 6.95%. Calcd for *u-fac*-K[Co(ida)(eida)]·H_2O: C, 29.56; H, 3.97; N, 6.90%.

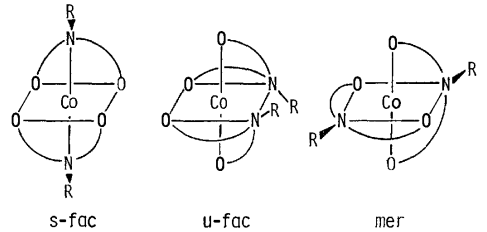

Fig. 1. Three geometrical isomers of [Co(Rida)$_2$]$^-$.

TABLE 1. ABSORPTION DATA OF THE $[Co(ida)_n(Rida)_{2-n}]^-$ TYPE COMPLEXES

Complex	Structure	First band[a]	Second band[a]	Charge-transfer band[a]

		19.88 (1.80)		

a) Wave numbers and $\log \varepsilon$ values (in parentheses) are given in $10^3\,cm^{-1}$ and $mol^{-1}\,dm^3\,cm^{-1}$, respectively. sh) Shoulder bands.

Sodium Iminodiacetato(N-ethyliminodiacetato)cobaltate(III), s-fac-*Na[Co(ida)(eida)]·H₂O*. This isomer was obtained by the same method as that used for *s-fac*-Na[Co(ida)(mida)]·H_2O. Found: C, 30.97; H, 4.17; N, 7.08%. Calcd for *s-fac*-Na[Co(ida)(eida)]·H_2O: C, 30.78; H, 4.13; N, 7.18%.

The preparations of the *u-fac*, *s-fac*, and *mer* isomers of $K[Co(mida)_2]$ and $K[Co(eida)_2]$ are described in our previous paper.[1] The three isomers of $K[Co(ida)_2]$ were prepared by the same method as that used for the isomers of $K[Co(mida)_2]$.[1] The *mer* isomer, which is easily soluble and unstable in water, was obtained as red needle crystals. Recrystallization was carried out from slightly acidic water by adding methanol. Found: C, 25.49; H, 3.02; N, 7.62%. Calcd for *mer*-K[Co(ida)$_2$]·H_2O: C, 25.41; H, 3.20; N, 7.41%.

Optical Resolution. $(+)_{589}$-u-fac-*K[Co(ida)(mida)]*: Resolving agent, $(+)_{589}$-[Co(ox)(en)$_2$]Br·H_2O (1.83 g, 5 mmol) was dissolved in 400 cm^3 of warm water (40 °C) and the bromide ion was converted to the acetate one using a small column containing Dowex 1×8 resin (200—400 mesh, CH_3COO^- form). The solution eluted from the column was concentrated to a volume of *ca.* 30 cm^3. This concentrated solution was mixed with an aqueous solution containing *u-fac*-H[Co(ida)(mida)] (this acidic complex was prepared in solution by loading *u-fac*-K[Co(ida)(mida)]·$2H_2O$ (2.05 g, 5 mmol) on a small column containing Dowex 50W×8 resin of H^+ form). The mixed solution was evaporated to a volume of 20 cm^3 using a rotary evaporator. To the concentrated solution was added 90% methanol until the purple crystals of diastereomer ($(+)_{589}$-[Co(ox)(en)$_2$]-$(+)_{589}$-[Co(ida)(mida)]·$2H_2O$) began to appear. The solution was cooled in a refrigerator for 1—2 h. The crystals which deposited were filtered and washed with water-methanol mixture (1:1), methanol, and then acetone. Yield was 1.40 g. Recrystallization was carried out twice from the concentrated aqueous solution by adding methanol. $[\alpha]_{589}^{15}$ +1274°.

The diastereomer was dissolved in a small amount of water and loaded on a small SP-Sephadex column (K^+ form) to remove $(+)_{589}$-$[Co(ox)(en)_2]^+$. To the solution obtained by elution with water was added a few drops of acetic acid, and the solution was evaporated to a few milliliters. A mixture of methanol–acetone (1:1) was added to the concentrated solution until crystals began to appear, and the solution was allowed to stand in a refrigerator for a few hours. The crystalline powder which deposited was filtered and washed with methanol and then acetone. Recrystallization was carried out from water by adding a methanol-acetone mixture. Found: C, 26.94; H, 3.77; N, 6.98%. Calcd for $(+)_{589}$-*u-fac*-K[Co(ida)(mida)]·$1.5H_2O$: C, 26.75; H, 3.78; N, 7.07%.

The $(-)_{589}$-isomer was obtained from the filtrate of the less soluble diastereomer.

$(+)_{589}$-u-fac-K[Co(ida)(eida)]·2.5H_2O. The diastereomer ($(+)_{589}$-[Co(ox)(en)$_2$]$(+)_{589}$-*u-fac*-[Co(ida)(eida)], $[\alpha]_{589}^{15}$ +1165°) and the $(+)_{589}$-isomer were obtained in the same way as that used for the resolution of *u-fac*-K[Co(ida)-(mida)]·$2H_2O$. Found: C, 27.93; H, 4.17; N, 6.52%. Calcd for $(+)_{589}$-*u-fac*-K[Co(ida)(eida)]·$2.5H_2O$: C, 27.72; H, 4.42; N, 6.47%.

Measurements. The absorption and CD spectra were measured by a Hitachi 557-type spectrometer and a JASCO J-22 spectropolarimeter, respectively. The ^1H NMR spectra were recorded on a JEOL MH-100 NMR spectrometer using DSS as an internal standard. The ^{13}C NMR spectra at 25 MHz were recorded on a JEOL JNM-FX100 spectrometer, in pulsed Fourier transform/proton noise decoupled mode. Peak positions were measured relative to internal dioxane (δ=67.44 ppm).

Results and Discussion

Absorption Spectra. The absorption spectral data of the newly prepared mixed-ligand type complexes are listed in Table 1, together with those of the bis type complexes reported in a previous paper.[1] The comparison of absorption spectra among the three different geometrical isomers of the bis type complexes are shown in Fig. 2. Each isomer exhibits a considerably different spectrum behavior in the d-d transition region. The first ($^1A_1 \rightarrow {}^1T_1$) and second ($^1A_1 \rightarrow {}^1T_2$) bands increase the intensities in the order *s-fac*< *u-fac*<*mer*. This trend is in agreement with that observed in the three geometrical isomers of $[Co(ida)(dien)]^+$.[3] Legg and Cooke have attributed an increment of absorption intensity to the following elements: the removal of the center of the symmetry and the strained structure.[3] If their proposal is applied to the present bis type complexes, the *u-fac* isomer (C_2 symmetry) which lacks the center of symmetry would give a more intense spectrum than the *s-fac* isomer (C_{2h}), which has a plane of symmetry, and the *mer* isomer (C_2), containing both the elements: removal of the center of symmetry and the strained structure would give the most intense spectrum.

In each geometrical isomer, the first and second absorption maxima shift to the lower energy side in the order of $[Co(ida)_2]^-$, $[Co(mida)_2]^-$, and $[Co(eida)_2]^-$ (Fig. 2). This fact indicates that the ligand field strength decreases in the order of ida, mida, and eida, and that the terdentate ligand (ida) containing secondary nitrogen is located at a higher position in the spectrochemical series than the terdentate ligand (mida or eida) containing tertiary nitrogen. This trend agrees with those observed in the *s-fac* and *mer* isomers of $[Co(ida)(dien)]^+$ and $[Co(mida)(dien)]^+$ [3] and in the *s-fac* isomers of the $[Co(dien)_2]^{3+}$ and $[Co(dema)_2]^{3+}$ (dema = 3-methyl-3-azapentane-1,5-diamine) complexes, which contain secondary and tertiary nitrogens, respectively.[4]

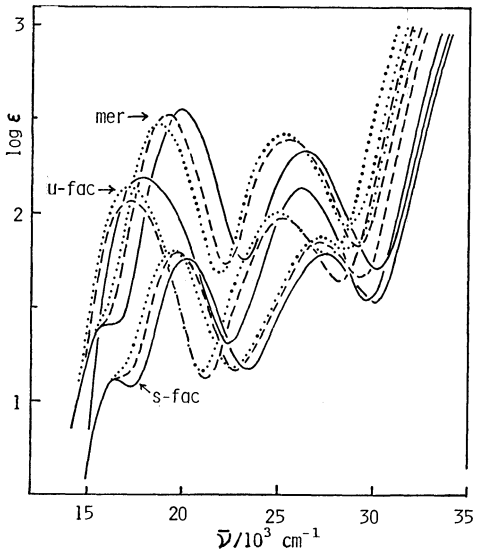

Fig. 2. Absorption spectra of three geometrical isomers of $[Co(ida)_2]^-$ (——), $[Co(mida)_2]^-$ (– – –), and $[Co(eida)_2]^-$ (·····).

As mentioned in the experimental section, for the mixed-ligand type complexes, $[Co(ida)(mida)]^-$ and $[Co(ida)(eida)]^-$, two geometrical isomers with violet and light brown colors were obtained by utilizing the preparative method of acidic conditions. As Fig. 3 shows, the absorption spectra of the violet isomers are identical in band shape and intensity with those of the *u-fac* isomers of the bis type complexes, while the spectra of the light brown isomers are identical with those of the *s-fac* isomers. These facts make it pos-

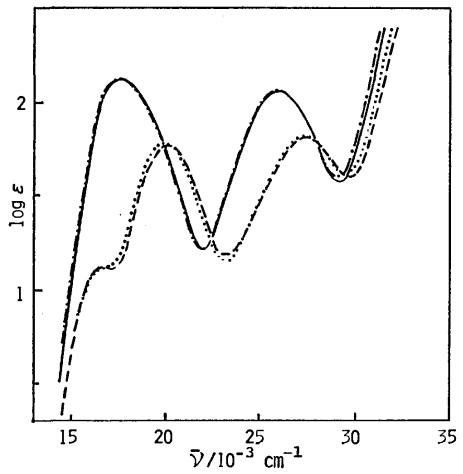

Fig. 3. Absorption spectra of the mixed-ligand complexes: *u-fac* (——) and *s-fac* (----) of [Co(ida)(mida)]⁻; *u-fac* (—·—) and *s-fac* (·····) of [Co(ida)(eida)]⁻.

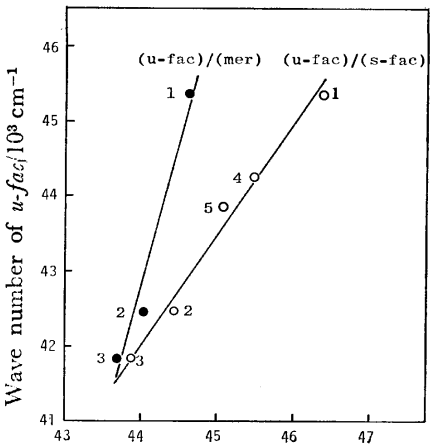

Fig. 4. Correlations of CT band maxima between two geometrical isomers. 1 $[Co(ida)_2]^-$, 2 $[Co(mida)_2]^-$, 3 $[Co(eida)_2]^-$, 4 [Co(ida)(mida)]⁻, and 5 [Co(ida)(eida)]⁻.

sible to assign the structures of the violet and light brown isomers of the mixed complexes to *u-fac* and *s-fac*, respectively.

Both the bis and mixed-ligand complexes exhibit charge transfer (CT) bands with the intensities of log ε=4.26—4.40 in the region 42000—46000 cm^{-1} (Table 1). The maximum positions of these bands vary with the ligands and the geometrical structures. As Fig. 4 shows, all the complexes show linear relationships between the maximum positions of two different isomers. These correlations suggest that the alkyl substituent on the nitrogen atom of coordinated ida brings about a shift of CT band maximum to lower energy in the order *u-fac*>*s-fac*>*mer*.

Circular Dichroism Spectra. The CD data of the *u-fac* isomers of the mixed-ligand type complexes are listed in Table 2, together with those of the bis type complexes. All the $(+)_{589}$-*u-fac* isomers exhibit similar CD patterns in the visible region; that is, these isomers give two component CD bands with (—) and (+) signs at the lower and higher energy sides in

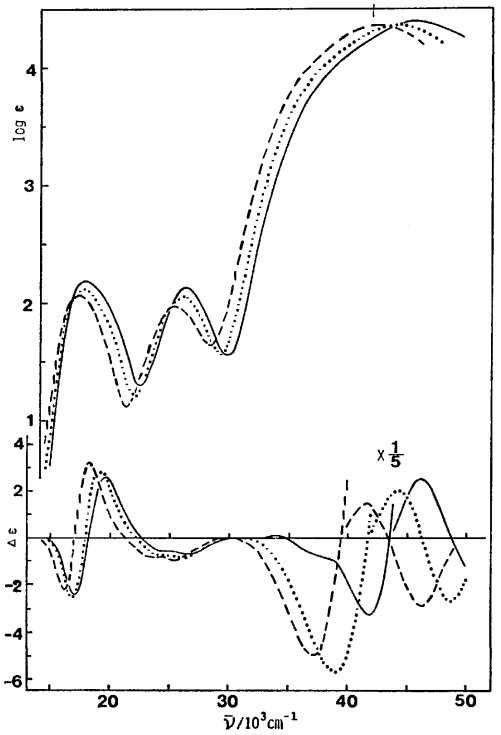

Fig. 5. Absorption and CD spectra of the $(+)_{589}$-*u-fac* isomers: $[Co(ida)_2]^-$ (——), [Co(ida)(mida)]⁻ (·····), and $[Co(mida)_2]^-$ (----).

the first band region, respectively, and with (—) sign in the second band region. Figure 5 shows the comparison of the CD curves among $(+)_{589}$-*u-fac*-[Co(ida)(mida)]⁻, -$[Co(ida)_2]^-$, and -$[Co(mida)_2]^-$. The shift trend of the CD bands is identical with that of the absorption bands.

In a previous study,[1] the absolute configuration of the $(-)_{589}$-isomer in *u-fac*-$[Co(mida)_2]^-$ and -$[Co(eida)_2]^-$ was assigned to $\Lambda\Lambda\Lambda$ (or Λ) from the comparison of CD spectra in the visible region with that of the $(-)_{546}$-isomer of *u-fac*-$[Co(ida)_2]^-$ whose the absolute configuration had been determined as $\Lambda\Lambda\Lambda$.[5,6] Similarly, the absolute configuration of the mixed-ligand complexes can be determined by comparing the CD patterns with those of the bis complexes; that is, the $\Lambda\Lambda\Lambda$ (or Λ) configuration is assigned to the $(+)_{589}$-isomers of *u-fac*-[Co(ida)(mida)]⁻ and -[Co(ida)(eida)]⁻, whose CD spectra give patterns similar to those of $(+)_{589}$-*u-fac*-$[Co(ida)_2]^-$, -$[Co(mida)_2]^-$, and -$[Co(eida)_2]^-$.

Koine *et al.* succeeded in resolving *mer*-$[Co(mida)_2]^-$ into optically active isomers.[7] The optical activity of this isomer arises from a chiral disposition of the two non-coplanar ligands. Therefore, the CD intensity of the *mer* isomer is expected to be lower than that of the *u-fac* isomer, which has the configurational chirality. Actually, the $(+)_{546}$-*mer* isomer give considerably lower CD intensity than those of the $(+)_{589}$-*u-fac* isomers (Table 2). Similar phenomena have been observed for the complexes containing other terdentate ligands, such as dien[7,8] and dema.[4]

^1H NMR Spectra. Cooke measured the ^1H NMR spectra of the *s-fac* and *u-fac* isomers of $[Co(ida)_2]^-$ and the *s-fac* isomer of $[Co(mida)_2]^-$ and as-

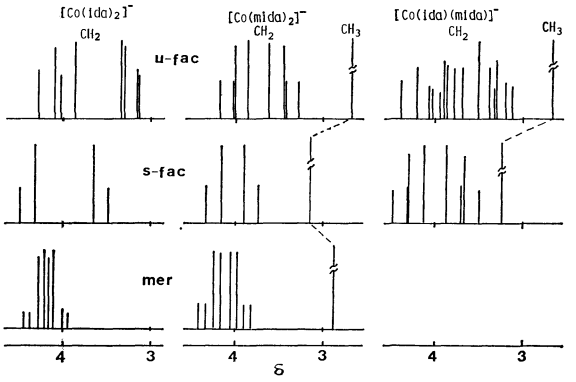

Fig. 6. The ^{1}H NMR spectra of the bis and mixed-ligand complexes in D_2O solution.

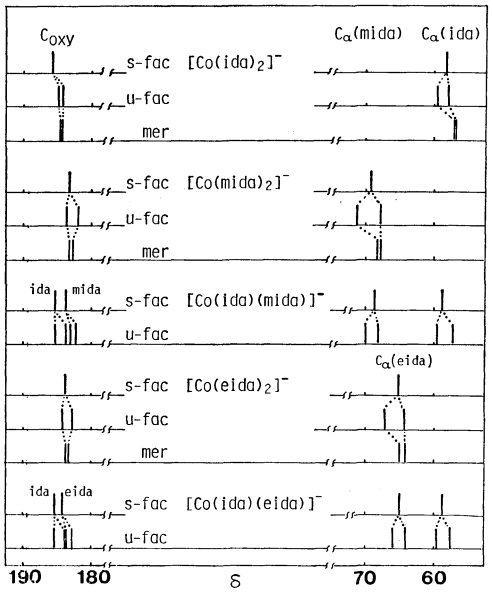

Fig. 7. ^{13}C NMR spectra of bis- and mixed-ligand complexes. The signals of *N*-methyl and -ethyl carbons are omitted.

signed the resonance peaks observed as one or two sets of AB quartets to the acetate-methylene protons.[9] Similar AB patterns (J_{AB}=16.0—18.0 cps) are also observed for the *mer* isomer of $[Co(ida)_2]^-$ and the *u-fac* and *mer* isomers of $[Co(mida)_2]^-$ in the range 3.3—4.3 ppm, as Fig. 6 shows.

The *u-fac* and *s-fac* isomers of $[Co(ida)(mida)]^-$ give the spectra consisting of four and two sets of AB quartets, respectively, in the acetate region (3.1—4.5 ppm), suggesting that the two acetate rings of each ligand are nonequivalent and equivalent in the former and latter isomers, respectively. The spectral patterns of these two isomers are nearly identical with the superimposed spectra of each corresponding isomer in both $[Co(ida)_2]^-$ and $[Co(mida)_2]^-$.

^{13}C NMR Spectra. The ^{13}C NMR chemical shifts of the present complexes are listed in Table 3 and the shift patterns are shown in Fig. 7. In the previous papers,[10,11] we reported that the chelation of α-amino acids to cobalt(III) ion brings about down-field changes (Δ values in Table 3) in the ^{13}C chemical shifts of their carboxyl-carbon (C_{oxy}) and α-carbon (C_α). All the present complexes exhibit down-field shift changes

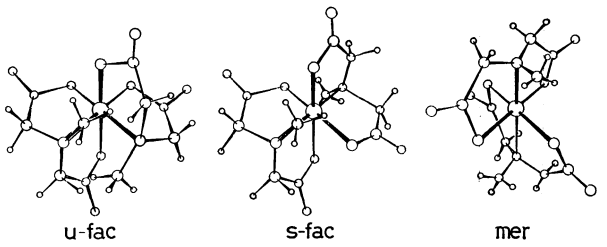

Fig. 8. Molecular models of *u-fac*-, *s-fac*-, and *mer*-$[Co(mida)_2]^-$.

in the range +13.84—+16.50 ppm for carboxyl-carbons, and the values are comparable with those of α-amino acid complexes.[10,11] However, the Δ values (+9.03—+14.38 ppm) of α-carbons for all the present complexes are considerably larger than those (+4.44—+8.29) for the α-amino acid complexes.

It is well-known that ^{13}C resonance patterns reflect the symmetries of the complexes.[12-15] In the cases of $[Co(ida)_2]^-$ and $[Co(Rida)_2]^-$, the ^{13}C signals of the α- and carboxyl-carbons appear as single peaks in the *s-fac* isomer (C_{2h}) and as double peaks in the *u-fac* and *mer* isomers (C_2). The double peaks of the latter isomers indicate that the two acetate rings of each ligand are nonequivalent in chemical environment. As given in Table 3, the shift nonequivalences[13] (resonance separations of the double peaks) are larger in the *u-fac* isomer than in the *mer* one and larger in $[Co(Rida)_2]^-$ than in $[Co(ida)_2]^-$. The difference in shift nonequivalences between these two isomers may be related to the difference in interligand steric repulsions. The molecular model of *u-fac*-$[Co(mida)_2]^-$ (Fig. 8) suggests an existence of large steric repulsions between the *N*-methyl group of one ligand and the methylene and methyl groups of the other ligand. The large steric repulsions can also be related to the fact that the *u-fac*-$[Co(mida)_2]^-$ complex decomposes easily in weakly basic aqueous solution[1] (*vide post*). A similar argument can also be made for the $[Co(eida)_2]^-$ complex.

The assignments of the ^{13}C resonance peaks of $[Co(ida)(Rida)]^-$ were made in comparison with the resonance peaks of $[Co(ida)_2]^-$ and $[Co(Rida)_2]^-$. The α- and carboxyl-carbons of the ida and Rida ligands in *u-fac*-$[Co(ida)(Rida)]^-$ exhibit different behaviors in chemical shift changes from those in *u-fac*-$[Co(ida)_2]^-$ and -$[Co(Rida)_2]^-$ (Fig. 7). For example, the shift nonequivalences of ida (C_α, 2.20 ppm; C_{oxy}, 1.36 ppm) in *u-fac*-$[Co(ida)(mida)]^-$ are larger than those of ida (C_α, 1.61 ppm; C_{oxy}, 0.74 ppm) in *u-fac*-$[Co(ida)_2]^-$. Contrary to this behavior, the shift nonequivalences of mida (C_α, 1.80 ppm; C_{oxy}, 0.72 ppm) in the former complex are smaller than those of mida (C_α, 3.46 ppm; C_{oxy}, 1.60 ppm) in *u-fac*-$[Co(mida)_2]^-$. These observations indicate that the shift nonequivalences of the paired carbons on a ligand are remarkably influenced by the interligand steric repulsions.

Reactions in Basic Aqueous Solution. In a previous paper,[1] we reported that in basic solution the *mer* isomer of $[Co(ida)_2]^-$ isomerizes rapidly to the *u-fac* and/or *s-fac* one and the *u-fac* isomers of $[Co(mida)_2]^-$ and $[Co(eida)_2]^-$ decompose along with

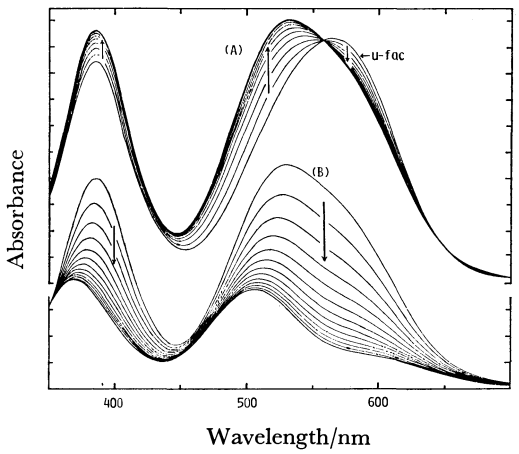

Fig. 9. Time-course changes of absorption spectra of *u-fac*-[Co(ida)(mida)]$^-$ in basic aqueous solutions at 30 °C. Trends of spectral changes with time are shown by arrows. (A): pH, 8.42; record interval, 5 min; time to recording start from pH adjustment, 160 s. (B): pH, 10.10; record interval, 10 min; time to recording start, 40 s.

the decomposition of one ligand per two complex ions and the reduction of cobalt(III) to cobalt(II). Such reactions suggest that the basic conditions are unfavourable to the preparations of the three geometrical isomers of the bis type complexes. Actually, the preparation under basic conditions gave only the *u-fac* and *s-fac* isomers in $[Co(ida)_2]^-$ and only the *s-fac* and *mer* isomers in $[Co(mida)_2]^-$ and $[Co(eida)_2]^-$. The preparation under acidic conditions (pH 4.0—4.5), however, gave all of the three possible isomers in substantial yield; *e.g.* in the case of $[Co(mida)_2]^-$ the formation ratio of the three isomers was *u-fac*:*s-fac*:*mer*=42:34:24. This ratio indicates that the *u-fac* isomer is formed most favourably in an acidic medium, although this isomer is thermodynamically unstable. The preparations of the mixed-ligand complexes have also been performed under the same acidic conditions as used for the bis complexes, but no *mer* isomers were isolated because of the rapid isomerization.

In analogy with the case of *u-fac*-$[Co(ida)_2]^-$ which was described in a previous paper,[1] the *u-fac* isomer of [Co(ida)(mida)]$^-$ also isomerized in basic aqueous solution. Figure 9 shows the spectral changes of *u-fac*-[Co(ida)(mida)]$^-$ in weak and strong basic solutions. In the weak basic solution of pH 8.42, the spectrum changes slowly with the passage of time, giving two isosbestic points at 588 and 647 nm (Fig. 9(A)). A new band peak which is observed near 530 nm is ascribed to the formation of a new complex. However, over about one hour the intensity of the spectrum began to decrease and the prolonged reaction gave a spectrum nearly identical with that of *s-fac*-[Co(ida)(mida)]$^-$. On the other hand, in strong basic solution of pH 10.10, a rapid spectral change is observed (Fig. 9(B)). The pattern of this spectral change is almost identical with that observed in the prolonged reaction of the weak basic solution mentioned above. The spectral changes in these two cases (pH 8.42 and 10.10) suggest that the isomerization of *u-fac* to *s-fac* proceeds in a two-step reaction.

In order to identify the new complex mentioned above, the reactant solution of pH 8.42 was chromatographed by use of a Sephadex G-10 column. The violet band of the unreacted *u-fac* isomer was eluted early and the red band containing the new complex followed as a partially overlapped band. The absorption spectrum of the solution eluted from the red band gave the first and second band maxima at 19490 and 25840 cm^{-1}, respectively. These maximum positions are comparable with those of the *mer* isomers of $[Co(ida)_2]^-$ and $[Co(mida)_2]^-$ (Table 1). This suggests that the new complex takes the *mer* structure. Similar spectral changes were also observed in the basic solutions of *u-fac*-[Co(ida)(eida)]$^-$ and -$[Co(ida)_2]^-$. Therefore, it is expected that the isomerization of these complexes proceeds in a reaction fashion similar to the case of *u-fac*-[Co(ida)(mida)]$^-$.

The preliminary kinetic study of *u-fac*-[Co(ida)(mida)]$^-$ and -$[Co(ida)_2]^-$ in basic aqueous solution give the following results. The rate constants of the racemization and isomerization reactions (*u-fac* to *s-fac*) for [Co(ida)(mida)]$^-$ are 94.8 and 2.03 $M^{-1}\,s^{-1}$ (at 30 °C), respectively; the racemization reaction proceeds more rapid than the isomerization reaction, and these reactions of [Co(ida)(mida)]$^-$ are more rapid than those of $[Co(ida)_2]^-$. These results lead to the following suggestions: the racemization of optically active *u-fac* isomer occurs through the isomerization path of *u-fac* to *mer*; the racemization of *u-fac*-$[Co(ida)_2]^-$ is accelerated by the base catalyzed reaction at the secondary amine nitrogens of coordinated ida,[14] while that of *u-fac*-[Co(ida)(mida)]$^-$ is accelerated by both the base-catalyzed reaction of ida and the steric effect due to *N*-methyl group of mida. A more detailed discussion on the kinetics of the present complexes will be given in the following communication.

Crystal and Molecular Structure of [11,13-Dimethyl-12-(*p*-methylbenzoyl)-1,4,7,10-tetraaza-10,12-cyclotridecadienato]nickel(II) Hexafluorophosphate

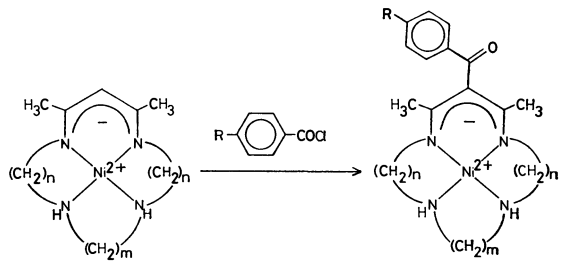
Naohide MATSUMOTO* and Akira OHYOSHI

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kurokami 2-39-1, Kumamoto 860

(Received June 7, 1982)

The title complex prepared through an electrophilic substitution of (11,13-diemthyl-1,4,7,10-tetraaza-10,12-cyclotridecadienato)nickel(II) bromide with *p*-methylbenzoyl chloride was subjected to single-crystal X-ray diffraction analysis. The analysis has revealed completion of the substitution reaction, pseudo C_2 symmetry of the macrocyclic complex minus the substituent, and an essentially square planar coordination environment with slight tetrahedral distortion. The substituted *p*-methylbenzoyl group is tilted with respect to the least-squares plane of the conjugated six-membered chelate ring, where the dihedral angle between them is 69.2°.

In our previous paper[1] we reported synthesis and properties of substituted derivatives $[Ni(Me_2E[Z]dienatoN_4)]PF_6$ (E=benzoyl, *p*-methylbenzoyl, and *p*-nitrobenzoyl; Z=13 and 14) (**2**), which are prepared by electrophilic substitution of $[Ni(Me_2[Z]dienatoN_4)]^+$ (**1**) with *p*-substituted benzoyl chlorides, as shown in Fig. 1. Based on electronic spectral tendencies observed for the series of substituted derivatives (**2**) and considerations on the steric hindrance between the benzoyl and two methyl groups in the acetylacetone residue, we predicted that the conjugated six-membered chelate ring would be perpendicular to the benzoyl group.



1 **2**

Fig. 1. Electrophilic substitution reaction from the parent complex $[Ni(Me_2[Z]dienatoN_4)]^+$ (**1**) to the substituted complex $[Ni(Me_2E[Z]dienatoN_4)]^+$ (**2**), where E denotes *p*-substituted benzoyl group, and Z=13 ($n=2$, $m=2$) and Z=14 ($n=2$, $m=3$).

In this study, the crystal structure of the title complex has been determined by the single-crystal X-ray diffraction method in order to confirm the completion of the substitution reaction and the above prediction.

Experimental

Physical Measurements. Infrared spectra were recorded with KBr disks on a Shimadzu recording spectrophotometer IR-410. Elemental analysis was performed by Mr. S. Miyazaki at the Technical Service Center of Kumamoto University.

Syntheses. (11,13-Dimethyl-1,4,7,10-tetraaza-10,12-cyclotridecadienato)nickel(II) Bromide Hemihydrate (1) (n=m=2): This parent complex, hereafter abbreviated as $[Ni(Me_2[13]dienatoN_4)]Br\cdot 0.5H_2O$, was prepared by the method of Cummings and Sievers.[2]

[11,13-Dimethyl-12-(p-methylbenzoyl)-1,4,7,10-tetraaza-10,12-cyclotridecadienato]nickel(II) Hexafluorophosphate, [Ni(Me$_2$p-MeBzyl[13]dienatoN$_4$)]PF$_6$ (2) (n=m=2): The previously-described method[1] was slightly modified. *p*-Methylbenzoyl chloride of 0.321 g (1.5 mmol) and triethylamine of 0.152 g (1.5 mmol) were added to a solution of 0.357 g (1 mmol) of $[Ni(Me_2[13]dienatoN_4)]Br\cdot 0.5H_2O$ in 100 cm^3 of dichloromethane. The solution was refluxed for 6 h and then evaporated to dryness under reduced pressure. The resultant viscous oil was dissolved in 30 cm^3 of water and filtered. The pH of the solution was adjusted to 10 with 6 M NaOH (1 M=1 mol dm^{-3}). The solution was added dropwise to 20 cm^3 aqueous solution of excess ammonium hexafluorophosphate to give an orange-red precipitate immediately. The product was collected, recrystallized from a mixture of methanol and dichloromethane and dried *in vacuo*. The yield obtained by this procedure was considerably higher than that obtained by the previously-described method.[1] Found: C, 42.96; H, 5.12; N, 10.54%. Calcd for $NiON_4C_{19}H_{27}PF_6$: C, 42.97; H, 5.29; N, 10.48%. IR: 3250 (ν_{NH}) and 1645 cm^{-1} ($\nu_{C=O}$). The perchlorate and tetrafluoroborate salts (**2**) ($n=m=2$) were prepared in the same way except that NH_4PF_6 was replaced by $NaClO_4$ and $NaBF_4$, respectively. $[Ni(Me_2p\text{-}MeBzyl[13]dienatoN_4)]ClO_4$. Found: C, 46.83; H, 5.75; N, 11.60%. Calcd for $NiON_4C_{19}H_{27}ClO_4$: C, 47.00; H, 5.61; N, 11.54%. IR: 3180 (ν_{NH}) and 1635 cm^{-1} ($\nu_{C=O}$). $[Ni(Me_2p\text{-}MeBzyl[13]dienatoN_4)]BF_4\cdot 0.5H_2O$. Found: C, 47.68; H, 5.93; N, 11.73%. Calcd for $NiON_4C_{19}H_{27}BF_4\cdot 0.5H_2O$. Found: C, 47.35; H, 5.80; N, 11.61%. IR: 3200, 3130 (ν_{NH}), and 1635 cm^{-1} ($\nu_{C=O}$).

X-Ray Analysis. Red prismatic crystals of $[Ni(Me_2p\text{-}MeBzyl[13]dienatoN_4)]PF_6$ were obtained from a mixture of methanol and dichloromethane at room temperature. The unit cell parameters and intensities were measured on a Rigaku AFC-5 automated four-circle diffractometer with a graphite-monochromatized Mo Kα radiation (λ=0.71069 Å). A crystal with approximate dimensions of 0.3×0.3×0.5 mm^3 was used for intensity measurement. The unit cell parameters were deterimined by the least-squares refinement based on 20 reflections in the range of $10°<2\theta<36°$. Crystal data: $NiPF_6ON_4C_{19}H_{27}$, F.W.=531.1, triclinic, space group $P\bar{1}$, a=10.629(5), b=13.424(5), c=9.201(4) Å, α=98.95(4), β=108.11(4), γ=109.85(3)°; V=1122.5(11) Å^3, D_m=1.56 (by the flotation method in a mixture of 1,2-dichloroethane and 1,2-dibromoethane), D_x=1.571 g cm^{-3} (Z=2), and μ(Mo Kα)=10.3 cm^{-1}.

Intensity data were collected by the θ-2θ scan technique with a scan rate of 8° min^{-1}. For weak reflections the peak scan was repeated up to three times depending on their intensities. Three standard reflections were monitored every 100 reflections and their intensities showed a good

TABLE 1. THE FINAL ATOMIC PARAMETERS OF [Ni(Me$_2$*p*-MeBzyl[13]dienatoN$_4$)]PF$_6$[a)]
The anisotropic thermal parameters and the atomic parameters of the hydrogen atoms are deposited as supplementary materials.

stability. A total of 3125 reflections with $2.5°<2\theta<45°$ was collected, of which independent 2768 reflections with $|F_o|>3\sigma(|F_o|)$ were considered as "observed" and used for the structure analysis. The intensity data were corrected for the Lorentz and polarization effects, but not for the absorption.

The structure was solved by the conventional heavy-atom method and refined by the block-diagonal least-squares method. In the least-squares calculation, the function minimized was $\sum w(|F_o|-k|F_c|)^2$ where $w=1/\sigma(|F_o|)^2$ was adopted. The neutral atomic scattering factors for H, C_{cov}, N, O, F, P, and Ni were taken from International Tables for X-Ray Crystallography, Vol. IV.[3] Anomalous dispersion corrections, $\Delta f'$ and $\Delta f''$, for all the component atoms were also taken from Ref. 3. All the calculations were carried out on a FACOM M-200 computer at the Computer Center of Kyushu University by use of the UNICS II Crystallographic Computing System.[4-6]

The coordinates of the nickel atom were obtained from a three-dimensional Patterson synthesis. A Fourier synthesis based on the nickel position revealed all the nonhydrogen atoms except for the fluorine atoms of anion PF_6^-. In the course of structure analysis, it became apparent that the fluorine atoms were subjected to disorder. The occupancy factors were assigned to the possible fluorine positions located in the difference Fourier map according to the peak heights. Hydrogen atom positions were located in the difference Fourier map and included in the final least-squares calculation, where isotropic thermal parameters were used for the disordered fluorine atoms and the hydrogen atoms. The final values for $R=\sum||F_o|-|F_c||/\sum|F_o|$ and $R_w=[\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2]^{1/2}$ were 6.65 and 6.59%, respectively. The final difference Fourier synthesis showed no significant features except for two peaks (*ca.* 0.8 e Å^{-3}) appearing in the PF_6^- region.

Final positional parameters with their estimated standard deviations are given in Table 1. Lists of structure factors, anisotropic thermal parameters of nonhydrogen atoms, and atomic parameters of hydrogen atoms have been deposited at the Chemical Society of Japan as Document No. 8306.

Results and Discussion

The perspective drawing of [Ni(Me$_2$*p*-MeBzyl[13]-dienatoN$_4$)]$^+$ cation with the atom numbering scheme is shown in Fig. 2. Interatomic bond distances, angles, and torsion angles are given in Table 2.

As shown in Fig. 2, the present X-ray analysis confirmed the completion of the substitution reaction. The macrocyclic cation, minus the substituent *p*-methylbenzoyl group, exhibits nearly exactly a C_2 symmetry, where the twofold axis passes through C(8) and Ni. The nickel ion is coordinated with two iminate and two secondary amine nitrogen atoms in an essentially square planar fashion. However, there is a slight tetrahedral distortion, because the deviations of the constituent atoms from the least-squares plane NiN_4 are in the range from −0.13 to 0.13 Å and because the dihedral angle between the planes Ni–N(1)–N(2) and Ni–N(3)–N(4) is 11.5°. The four Ni–N bond distances fall into two groups, depending on the difference between iminate and secondary amine nitrogen atoms. The average Ni–N (iminate) bond distance of 1.821(6) Å agree with 1.83(1) Å of the parent complex [Ni(Me$_2$[13]dienatoN$_4$)]ClO$_4$[7] within experimental error but is considerably shorter than 1.862-

(6) Å of the 14-membered complex [Ni(Me$_2$[14]dienatoN$_4$)]Br·H$_2$O.[1] The average Ni–N (amine) distance of 1.901(6) Å is also compatible with that of the parent complex **1** (n=m=2)[7] and shorter than that of the 14-membered complex **2** (n=2, m=3).[1]

For the unsaturated six-memberd chelate ring, the planarity is preserved, where the deviations of the constituent atoms from the least-squares plane defined by the Ni, N(1), N(4), C(7), C(8), and C(9) are within ±0.03 Å. The C–C and C–N bonds of the unsaturated chelate ring are intermediate between the corresponding single and double bond distances.[8] This result indicates that the chelate ring is a π-electron conjugated system.

The conformation of the triethylene tetramine moiety (trien) is similar to that of the trien in [Cu(trien)SCN]NCS[9] and of the parent complex [Ni(Me$_2$[13]dienatoN$_4$)]ClO$_4$.[7] Two of the three saturated five-membered chelate ring (A and B, Fig. 2) are found to have an asymmetrical gauche conformation and their absolute configurations are $\lambda\lambda$ and/or $\delta\delta$, as indicated by the deviations 0.05 and 0.65 Å for C(1) and C(2), respectively, above the N(1)–Ni–N(2) plane and 0.65 and 0.05 Å for C(5) and C(6), respectively, below the N(3)–Ni–N(4) plane. The remaining five-membered chelate ring (C) has a symmetrical gauche conformation with the deviations 0.33 and −0.34 Å for C(3) and C(4), respectively, from the plane N(2)–Ni–N(3). The two hydrogen atoms bonded to the secondary amine nitrogen atoms are positioned at the different side on the NiN$_4$ plane.

The molecular symmetry and dimensions of the macrocyclic cation, minus the substituent *p*-methylbenzoyl group, are similar to those of the parent complex.[7] This result indicates that the blue shift of the d-d transition band of the substituted complex from the parent complex can be achieved without altering the stereochemistry of the coordination sphere, in which the band maxima are 20.2 and 21.4×10^3 cm^{-1} for [Ni(Me$_2$[13]dienatoN$_4$)]PF$_6$ and [Ni(Me$_2$*p*-MeBzyl[13]dienatoN$_4$)]PF$_6$, respectively.[1]

The most striking feature of the present molecular structure is non-coplanarity between the conjugated six-membered chelate ring and the *p*-methylbenzoyl group, where the dihedral angle between them is 69.2°. The overall molecular symmetry is not C_2, although the ^{1}H NMR spectra gave the methyl proton resonance of the acetylacetone residue as a singlet signal.[1] The methyl proton signal of the substituted complex (1.75 ppm) is shifted to a higher magnetic field than that of the parent complex (1.91 ppm). This can be interpreted in terms of the ring current effect of the benzene ring and the shielding effect of the carbonyl group of the *p*-methylbenzoyl group based on the present X-ray analysis.

Figure 3 shows the packing diagram of complex [Ni(Me$_2$*p*-MeBzyl[13]dienatoN$_4$)]PF$_6$. Anion PF$_6^-$ suffers from disorder. Judging from the occupancy factors of the disordered fluorine atoms and the geometry, anion PF$_6^-$ seems to be rotating randomly about the octahedral axes F(1)–P–F(2) and F(3)–P–F(4). There is no intermolecular bond distance which corresponds to any possible hydrogen bonds between the secondary amine nitrogen atoms and anion PF$_6^-$. The infrared frequency due to the NH vibrational mode in the series of complexes [Ni(Me$_2$*p*-MeBzyl[13]dienatoN$_4$)]X with X=ClO$_4^-$, BF$_4^-$, and PF$_6^-$ moves to higher energy side in the order of counter anions ClO$_4^-$<BF$_4^-$<PF$_6^-$. This can be interpreted in terms of the hydrogen bond between the secondary amine nitrogen atoms and the anion or water molecule. In complex [Ni(Me$_2$*p*-MeBzyl[13]dienatoN$_4$)]BF$_4$·0.5H$_2$O, the NH band splits into two bands (3200 and 3130 cm^{-1}). Such a split has also been observed in complex [Ni(Me$_2$[14]dienatoN$_4$)]Br·H$_2$O, in which the Br and the water molecule are hydrogen bonded to

the secondary amine nitrogen atoms.[1)]

The authors wish to express their thanks to Prof. Sigeo Kida at Faculty of Science, Kyushu University, for allowing them to use the diffractometer. Thanks are also due to Mr. Kenichiro Wakizaka for his valuable assistance.

Circular Dichroism Spectra and Racemization of Two Geometrical Isomers of the (2-Aminoethanesulfenato-*S*,*N*)[tris(2-aminoethyl)amine]cobalt(III) Ion

Masaaki Kojima and Junnosuke Fujita*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received June 9, 1982)

Optically active *trans*(*t*-*N*,*S*)(*t*) and *cis*(*t*-*N*,*S*)(*p*) isomers of $[Co\{S(O)CH_2CH_2NH_2\}(tren)]^{2+}$ (tren=tris(2-aminoethyl)amine; *t*-*N*=tertiary amine nitrogen) were prepared, and their circular dichroism spectra were compared with those of *Λ*(*S* or *R*)- and *Λ*(*S* or *R*)-$[Co\{S(O)CH_2CH_2NH_2\}(en)_2]^{2+}$ and two geometrical isomers of $[Co(R\text{-pn})(tren)]^{3+}$ (*R*-pn=(*R*)-1,2-propanediamine) and $[Co(S\text{-dmbn})(tren)]^{3+}$ (*S*-dmbn=(*S*)-3,3-dimethyl-1,2-butanediamine). Racemization or epimerization of these sulfenato complexes was studied in aqueous solutions with ionic strength of 1.0 ($NaClO_4$) in the pH and temperature ranges of 3.65—8.8 and 24.0—40.0 °C, respectively. The rates of *p*- and *t*-isomers of the tren complex are proportional to concentrations of the complex, but independent of pH, the latter isomer accompanying some decomposition during the course of racemization. The first-order rate constants of the *p*- and *t*-isomers are 9.92×10^{-5} and *ca.* 1.2×10^{-6} s^{-1} at 30.0 °C, respectively. No epimerization takes place in the en complexes under the same experimental conditions. The difference in rate of racemization or epimerization of these sulfenato complexes seems to be related closely to the crowding around the S=O group of the complex.

A sulfenate ion becomes chiral upon coordination to a metal ion through the sulfur atom, and a metal–sulfenato complex has a formal analogy with sulfoxides. Sulfoxides are in general optically stable, and typical barriers for the inversion lie in the range of 150 to 180 kJ mol^{-1}.[1] The configurational stability of sulfur atoms in cobalt(III)–sulfenato complexes is also sufficient to support optical activity, and several stable diastereomers involving such chiral sulfur atoms have been obtained.[2–6] However, neither optically active complexes in which a chiral sulfur atom is the sole source of optical activity nor studies on racemization of sulfenato complexes seem to have been reported.

In order to elucidate the optical activity and optical stability of a metal–sulfenato complex, it is desirable to prepare an optically active sulfenato complex whose activity arises only from a chiral sulfur atom. This paper reports resolution, absorption and circular dichroism (CD) spectra, and racemization of two geometrical (*p*- and *t*-)[7] isomers of $[Co\{S(O)CH_2CH_2NH_2\}(tren)]^{2+}$ (Fig. 1; tren=tris(2-aminoethyl)amine) and related complexes, a pair of diastereomers of $[Co\{S(O)CH_2CH_2NH_2\}(en)_2]^{2+}$. Two geometrical isomers of $[Co(R\text{-pn})(tren)]^{3+}$ (*R*-pn=(*R*)-1,2-propanediamine) and $[Co(S\text{-dmbn})(tren)]^{3+}$ (*S*-dmbn=(*S*)-3,3-dimethyl-1,2-butanediamine) were also prepared in order to compare their CD spectra with those of *p*- and *t*-$[Co\{S(O)CH_2CH_2NH_2\}(tren)]^{2+}$.

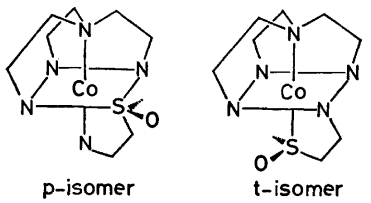

Fig. 1. Two geometrical isomers of $[Co\{S(O)CH_2CH_2NH_2\}(tren)]^{2+}$.

Experimental

The sulfenato complexes in solution were handled in the dark to minimize decomposition.

p- *and* t-[*Co*(*SCH*$_2$*CH*$_2$*NH*$_2$)(*tren*)]*ZnCl*$_4$. These thiolato complexes were prepared by the method of Jackson and Sargeson,[8] and isolated as tetrachlorozincate salts by the same method as that for the corresponding (*R*)-cysteine complex.[8] Found for the *p*-isomer: C, 19.63; H, 4.93; N, 14.34%. Found for the *t*-isomer: C, 19.68; H, 5.08; N, 14.40%. Calcd for $C_8H_{24}N_5Cl_4CoSZn$: C, 19.67; H, 4.95; N, 14.34%.

p-[*Co*{*S*(*O*)*CH*$_2$*CH*$_2$*NH*$_2$}(*tren*)](*ClO*$_4$)$_2$·2*H*$_2$*O and* t-[*Co*{*S*-(*O*)*CH*$_2$*CH*$_2$*NH*$_2$}(*tren*)](*ClO*$_4$)$_2$. These sulfenato complexes were prepared by stoichiometric oxidation of the corresponding thiolato complexes. To a suspension of *p*-$[Co(SCH_2CH_2NH_2)(tren)]ZnCl_4$ (1.95 g, 4 mmol) in a mixture of water (5 cm^3) and 70% $HClO_4$ (1 cm^3) was added an equimolar amount of 35% H_2O_2 (0.39 g, 4 mmol) in 3 cm^3 of water dropwise with stirring. The color of the solution changed immediately from brown to red-orange, and the starting material dissolved completely by reaction with the peroxide. The addition of $NaClO_4$ and cooling led to crystallization of the desired product. It was filtered and recrystallized from water by adding dropwise ethanol saturated with $LiClO_4$. Yield: 1.1 g (52%). Found: C, 18.11; H. 4.94; N, 13.20%. Calcd for $C_8H_{28}N_5Cl_2CoO_{11}S$: C, 18.05; H, 5.30; N, 13.16%.

The *t*-isomer was prepared by a similar procedure, but the complex perchlorate was not precipitated by the addition of $NaClO_4$. The red-orange mixture was diluted with water and passed through a column of SP-Sephadex C-25. After washing the column with water, the product adsorbed was eluted with 1 mol/dm^3 $NaClO_4$, and the effluent was evaporated to a small volume under reduced pressure. The addition of a small amount of ethanol led to crystallization of the desired product. It was filtered and recrystallized by the same method as that for the *p*-isomer. Yield: 30%. Found: C, 19.42; H, 4.94; N, 14.33%. Calcd for $C_8H_{24}N_5Cl_2CoO_9S$: C, 19.36; H, 4.87; N, 14.11%.

Resolution of the p-[*Co*{*S*(*O*)*CH*$_2$*CH*$_2$*NH*$_2$}(*tren*)]$^{2+}$ *Isomer.* To an aqueous solution (15 cm^3) of *p*-$[Co\{S(O)CH_2CH_2NH_2\}(tren)](ClO_4)_2\cdot2H_2O$ (1.16 g, 2 mmol) was added an aqueous solution (10 cm^3) of potassium *d*-tartrate hemihydrate (0.47 g, 2 mmol). The solution was stirred for 30 min and filtered to remove potassium perchlorate precipitated. The filtrate was evaporated to about 5 cm^3 under reduced pressure and filtered again. The filtrate was mixed with 20 cm^3 of methanol and cooled in a refrigerator. After 3 h the orange, crude product was filtered, washed with methanol, and recrystallized twice from water (2 cm^3) by adding 3 cm^3 of

methanol. Yield: 0.35 g. No change in the $\Delta\varepsilon$ value was observed with further recrystallization. Found: C, 29.87; H, 6.86; N, 14.66%. Calcd for $C_{12}H_{32}N_5CoO_9S$=[Co{S-(O)$CH_2CH_2NH_2$}(tren)]($C_4H_4O_6$)·$2H_2O$: C, 29.94; H, 6.70; N, 14.55%.

This diastereomer was converted into perchlorate by use of a DEAE-Sephadex (ClO_4^- form) column. The perchlorate was not isolated and the effluent was used for measurements without delay, because the complex racemizes at a moderate rate (*vide post*). The concentration of the solution was determined by reference to the optical density of the racemate.

Resolution of the t-[*Co*{*S*(*O*)$CH_2CH_2NH_2$}(*tren*)]$^{2+}$ *Isomer.* An aqueous solution of *t*-[Co{S(O)$CH_2CH_2NH_2$}(tren)]-(ClO_4)$_2$ (*ca.* 15 mg) was poured onto a column (ϕ 2.7×50 cm) of SP-Sephadex C-25 and the adsorbed band was eluted with 0.1 mol/dm^3 Na_2[Sb_2(*d*-tartrate)$_2$]. The band was separated into two, the $(+)_{589}$-isomer being eluted faster. Each effluent was diluted with water, passed through an SP-Sephadex column (ϕ 1.5×3 cm), and the complex adsorbed was eluted with 1.0 mol/dm^3 $NaClO_4$. The optically active complex was not isolated because the amount was very small. The $\Delta\varepsilon$ value was determined with the aid of the ε value of the racemate.

Preparation and Resolution of [*Co*{*S*(*O*)$CH_2CH_2NH_2$}(*en*)$_2$]$^{2+}$. The complex was prepared by the method of Adzamli *et al.*[4] The reaction mixture was chromatographed by use of an SP-Sephadex C-25 column. By elution with 0.15 mol/dm^3 Na_2SO_4, the orange band was separated into two, I and II in the order of elution. Bands I and II contain racemates of a pair of diastereomers, $\Lambda(S)$ and $\Lambda(R)$, and $\Delta(R)$ and $\Delta(S)$, respectively. The racemates were isolated as perchlorate by a method similar to that for *t*-[Co{S(O)-$CH_2CH_2NH_2$}(tren)](ClO_4)$_2$. The total yield was about 80%, and the formation ratio, I:II, was *ca.* 2:1. Isomer II is less stable toward decomposition in water. Found for I: C, 15.48; H, 4.84; N, 14.80%. Found for II: C, 15.30; H, 4.71; N, 14.90%. Calcd for $C_6H_{22}N_5Cl_2CoO_9S$: C, 15.33; H, 4.72; N, 14.89%. The racemates were resolved by the same chromatographic method as that for *t*-[Co{S(O)$CH_2CH_2NH_2$}(tren)]$^{2+}$. The faster eluted enantiomers of I and II are $\Lambda(R)$ (I-1) and $\Lambda(S)$ (II-1), respectively. The isomers obtained from the slower eluted bands are thus $\Delta(S)$ (I-2) and $\Delta(R)$ (II-2). The absolute configurations of the isomers were assigned by comparing the CD spectra with that of $\Lambda(S)$-[Co(*R*-cysO)(en)$_2$]$^+$ (*R*-cysO= (*R*)-2-amino-3-sulfenatopropanoate-*N*,*S*),[3] the absolute configuration of which has been determined by the X-ray method.[2] The $\Delta(S)$-isomer (I-2) was isolated as perchlorate by the same method as that for the racemate. Found: C, 15.27; H, 4.59; N, 15.07%. Calcd for $C_6H_{22}N_5Cl_2CoO_9S$: C, 15.33; H, 4.72; N, 14.89%. The enantiomers of isomer II were not isolated because of their instability. Each effluent of the resolved isomer II was loaded on SP-Sephadex C-25, eluted with 1 mol/dm^3 $NaClO_4$, and the effluent was used for measurements.

[*Co*(R-*pn*)(*tren*)](ClO_4)$_3$·*1.5*H_2O *(P-I) and* [*Co*(R-*pn*)-(*tren*]Br_3 *(P-II).* A mixture of (*R*)-1,2-propanediamine dihydrochloride (*R*-pn·2HCl) (0.74 g, 5 mmol) and sodium methoxide (0.54 g, 10 mmol) in methanol (5 cm^3) was stirred for *ca.* 0.5 h. Sodium chloride which deposited was filtered off and washed with a small amount of methanol. The combined filtrate and washings were added to a dimethyl sulfoxide solution (15 cm^3) of [$CoCl_2$(tren)]Cl[9] (1.56 g, 5 mmol), and the mixture was stirred for a day at room temperature. The resulting orange-brown solution was diluted with water and poured onto a column (ϕ2.7×3 cm) of SP-Sephadex C-25. A small portion of the Sephadex charged with the product was placed on the top of a column (ϕ2.7× 120 cm) of SP-Sephadex C-25, and the product was eluted with 0.2 mol/dm^3 Na_2SO_4. The column showed several bands. The effluents of the third (P-I) and fourth (P-II) bands were collected separately. Each effluent was diluted ten times with water and passed again through an SP-Sephadex C-25 column (ϕ1.5×3 cm). Isomer P-II was eluted with 1 mol/dm^3 NaBr, and the effluent was evaporated under reduced pressure to give orange crystals, which were recrystallized from water. Found: C, 20.64; H, 5.68; N, 16.24%. Calcd for $C_9H_{28}N_6Br_3Co$: C, 20.83; H, 5.44; N, 16.19%.

Isomer P-I was isolated as perchlorate, because the bromide was highly soluble. The column charged with isomer P-I was washed with a large amount of 10^{-2} mol/dm^3 HBr, and then the isomer was eluted with 1 mol/dm^3 HBr. The effluent was concentrated to a small volume under reduced pressure. On addition of concd $HClO_4$ the concentrate gave large crystals of the perchlorate, which were filtered and washed with ethanol. Found: C, 17.80; H, 5.08; N, 14.11%. Calcd for $C_9H_{31}N_6Cl_3CoO_{13.5}$: C, 17.88; H, 5.17; N, 13.90%. The formation ratio, P-I:P-II, was *ca.* 1:2, and the total yield was *ca.* 40%.

[*Co*(S-*dmbn*)(*tren*)]Br_3·*2.5*H_2O*(B-I) and* [*Co*(S-*dmbn*)-(*tren*)]Br_3·H_2O *(B-II).* These complexes were prepared by the same method as that for the above *R*-pn complexes, except that (*S*)-3,3-dimethyl-1,2-butanediamine dihydrochloride[10] was used instead of *R*-pn·2HCl. The separation of bands for isomers B-I and B-II was insufficient in chromatography by use of 0.2 mol/dm^3 Na_2SO_4, B-I being eluted faster. The orange effluent containing both isomers B-I and B-II was chromatographed again with 0.15 mol/dm^3 Na_2-[Sb_2(*d*-tartrate)$_2$]. Isomers B-II and B-I were eluted separately in this order, and isolated as bromide by the same method as that for isomer P-II of the *R*-pn complex. The formation ratio, B-I:B-II, was *ca.* 1:1, and the total yield was *ca.* 60%. Found for B-I: C, 23.83; H, 6.42; N, 13.95%. Calcd for $C_{12}H_{39}N_6Br_3CoO_{2.5}$: C, 23.77; H, 6.48; N, 13.86%. Found for B-II: C, 24.88; H, 6.41; N, 14.54%. Calcd for $C_{12}H_{36}N_6Br_3CoO$: C, 24.89; H, 6.27; N, 14.51%.

Measurements. Absorption and CD spectra were recorded on a Hitachi 323 spectrophotometer and a JASCO J-40CS spectropolarimeter, respectively. Optical rotations at 589 nm were measured with a JASCO DIP-4 polarimeter.

Kinetics. All kinetic experiments were carried out in the dark in the pH region of 3.65 (acetate buffer) to 8.8 (phosphate buffer) maintained at constant ionic strength of 1.0 with $NaClO_4$. The complex concentrations were in the range of 1.0×10^{-4} to 2.7×10^{-3} mol/dm^3. The temperatures of the solutions were kept constant in a constant temperature water bath. The racemization or epimerization of the complexes was followed by monitoring CD change as a function of reaction time. Portions of the reacting solution were withdrawn at timed intervals and then their CD spectra were recorded in the range of 400 to 260 nm. CD strengths at two maxima, *ca.* 380 and 280 nm, were used for calculation. Optical densities of bands at *ca.* 370 nm, which are characteristic of the S-bonded sulfenato moiety, were also measured to check the stability of the complexes toward decomposition.

Results and Discussion

Absorption and CD Spectra. Two geometrical isomers of [Co{S(O)$CH_2CH_2NH_2$}(tren)]$^{2+}$ can be prepared easily from the corresponding isomers of [Co-

$(SCH_2CH_2NH_2)$(tren)]$^{2+}$ [8] by stoichiometric oxidation with hydrogen peroxide. The sulfenato complexes thus obtained should have the same geometrical configuration as those of the respective parent thiolato complexes. The *p*- and *t*-[Co{S(O)$CH_2CH_2NH_2$}(tren)]$^{2+}$ isomers show absorption spectra fairly different from each other as seen in Fig. 2 and Table 1. The *p*-isomer gives a more distinct first d-d band (20830 cm^{-1}) and much weaker Co–S charge transfer bands (27030 and 34600 cm^{-1})[4] than the corresponding bands of the *t*-isomer. The first d-d band of the former appears at the higher energy side than that of the latter. In analogous tren complexes of glycinate[11] and (*S*)-alaninate[12] ions, the *p*-isomer also shows the first d-d band at high energy as compared with that of the *t*-isomer. Such a spectral difference in the d-d band region between the *p*- and *t*-isomers may be attributed to the difference in ligand field strength between the tertiary amine and other primary amine nitrogens. Mitsui *et al.*[11] suggested that in [Co(glycinate)(tren)]$^{2+}$ the tertiary amine nitrogen exerts a weaker ligand field than the primary amine nitrogen.

Figure 2 shows CD spectra of $(+)_{589}$-*p*- and $(+)_{589}$-*t*-[Co{S(O)$CH_2CH_2NH_2$}(tren)]$^{2+}$. In the Co–S charge transfer band region (23000—39000 cm^{-1}), both enantiomers give CD patterns very similar to that of *Λ*(*S*)-[Co(*R*-cysO)$(en)_2$]$^{+}$.[3] Another *Λ*(*R*)-diastereomer of the *R*-cysO complex shows an almost enantiomeric CD pattern in this region. Thus the sulfur atoms in both $(+)_{589}$-enantiomers can be assigned to the *S* configuration. The optical activity of both *p*- and *t*-isomers originates from only the chiral sulfur atom of the sulfenate ligand. Thus these CD spectra represent the vicinal effect of a coordinated chiral sulfur atom in a $[CoSN_5]$-type complex. In Fig. 2 are compared the spectra with the calculated vicinal CD curve for the (*S*)-sulfur atom derived from CD spectra of *Δ*(*S*)- and *Λ*(*S*)-[Co{S(O)$CH_2CH_2NH_2$}$(en)_2$]$^{2+}$. The curve and two spectra are very similar in the Co–S charge transfer region. In the first d-d band region, the CD spectrum of the *p*-isomer resembles the calculated curve, but that of the *t*-isomer is fairly different from it, although all of the main CD bands show the positive sign.

Akamatsu *et al.*[12] reported that each pair of the *p*- and *t*-isomers of [Co{(*S*)-alaninate}(tren)]$^{2+}$ and a similar type complex [Co{(*S*)-alaninate}(nitrilotriacetate)]$^{-}$ give CD spectra almost enantiomeric to each other in the d-d band region. They attributed this remarkable feature to the mutually quasi-enantiomeric configuration in the isomers, and called such optical activity the "quasi-enantiomeric" effect. The *p*- and *t*-isomers of these alaninato complexes seem to be quasi-enantiomeric to each other. However, they are mutually geometrical isomers having the tertiary amine nitrogen and oxygen donor atoms in the cis and trans positions, and exhibit absorption spectra fairly different from each other. Consequently, the isomers would inevitably give CD spectra different from each other. The complexes given by Akamatsu *et al.*[12] would not be suitable for estimating how the quasi-enantiomeric effect contributes to CD spectra.

In order to estimate this effect, we have prepared two isomers of [Co(*R*-pn)(tren)]$^{3+}$ and [Co(*S*-dmbn)(tren)]$^{3+}$ and measured their CD spectra. Each of *R*-pn and *S*-dmbn has two different nitrogen donor atoms, but the difference in ligand field strength between these two nitrogen atoms should be negligibly small as compared with that between the oxygen and nitrogen donor atoms of the (*S*)-alaninate ligand. Molecular models indicate that there is no remarkable difference in strain or non-bonded interaction between the isomers of both *R*-pn and *S*-dmbn complexes. Figure 3 shows absorption and CD spectra of the two isomers of these complexes. The differences in ab-

Table 1. Absorption and CD spectral data

Complex	Absorption $\tilde{\nu}_{max}/cm^{-1}$ (log ε)	CD $\tilde{\nu}_{ext}/cm^{-1}(\Delta\varepsilon)$

a) Shoulder.

sorption and CD spectra between the isomers are very small in the *R*-pn complex, while appreciably large in the *S*-dmbn complex. However, the isomers of this *S*-dmbn complex show still the same CD pattern. These observations suggest that the quasi-enantiomeric effect contributes very little to optical activity of metal complexes. The enantiomeric CD spectra reported by Akamatsu *et al.*[12] seem to result from a difference in the order of energies of the d-d transition components between the *p*- and *t*-geometrical isomers. No assignment was made for the geometrical isomers of the *R*-pn and *S*-dmbn complexes.

Racemization at Sulfur Atoms. CD changes of *p*-[Co{S(O)$CH_2CH_2NH_2$}(tren)]$^{2+}$ were recorded over the temperature range of 24.0 to 40.0 °C at $I=1.0$ ($NaClO_4$) in the pH region of 3.65 to 8.8. A representative spectral change is given in Fig. 4. In every kinetic run the plot of $\log(\Delta OD_{376})$ and $\log(\Delta OD_{285})$ against time gave a straight line for at least two half-lives, from which the first-order rate constant k_r/s^{-1} was obtained. No detectable change in the absorption spectrum was observed during the measurements. However, over a longer time period the complex underwent decomposition; the absorbance at 380 nm diminished by 2.3% at 30 °C in 1.0 mol/dm^3 $NaClO_4$ in a day, *i.e.*, 12 half-lives. Eyring treatments of $\log(k_r/T)$ *vs.* T^{-1} yielded an activation enthalpy of 130±3 kJ mol^{-1} and an activation entropy of 109±9 J mol^{-1} K^{-1}. The first-order rate constant is 9.92×10^{-5} s^{-1} at 30.0 °C. The rate was independent of pH. Thus it can be assumed that the racemization takes place intramolecularly. The activation enthalpy of 130 kJ mol^{-1} is smaller by 20—50 kJ mol^{-1} than those reported for sulfoxides.[1] A fairly large difference in activation enthalpy was also observed for the racemization between metal–sulfide complexes (40—60 kJ mol^{-1})[13-19] and sulfonium ions (100—120 kJ mol^{-1}).[1]

The racemization of the *t*-isomer was studied by

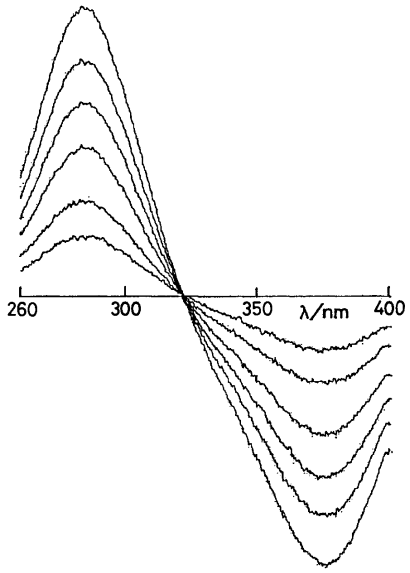

Fig. 4. CD spectral change of *p*-[Co{S(O)CH_2CH_2-NH_2}(tren)]$^{2+}$ in 1.0 mol/dm^3 $NaClO_4$ at 30.0 °C in a period of 264 min.

the same procedure. However, the rate was not determined accurately, because the complex decomposed during the course of racemization. In 1.0 mol/dm^3 $NaClO_4$ at 30.0 °C, the CD strength (382, 286 nm) and absorbance (380 nm) of the complex decreased by 18 and 9.7%, respectively, in a day. When we took the absorbance at 380 nm as a quantitative measure for the concentration of the *t*-isomer, the rate constant of the racemization is approximately 1.2×10^{-6} s^{-1} at 30.0 °C. This value is smaller than that of the *p*-isomer by a factor of *ca.* 80. Thus it is concluded that the *p*-isomer racemizes much faster than the *t*-isomer does, while the former is more stable than the latter toward decomposition. For the analogous [Co($CH_3SeCH_2CH_2NH_2$)(tren)]$^{3+}$ complex, the *t*- and *p*-isomers seem also to have similar relative stability toward racemization; the former was resolved by column chromatography, while the latter was not.[20]

Turley and Haake[21] studied the inversion at sulfur in several platinum(II)–sulfide complexes, and proposed a mechanism involving simultaneous bond making between the metal ion and the other lone-pair on sulfur as the original coordinate bond breaks. This mechanism seems to be a current view on inversion of the sulfur in metal–sulfide complexes. However, Jackson and Sargeson[22] pointed out that the mechanism is the same in principle as the pyramidal inversion mechanism for free sulfoxides and sulfonium ions, which proceeds *via* a trigonal planar intermediate. If we assume that the racemization of [Co{S(O)-$CH_2CH_2NH_2$}(tren)]$^{2+}$ proceeds by the pyramidal inversion at the sulfur atom, the difference in rate of racemization of the *p*- and *t*-isomers seems to stem from a difference in structure around the S=O group between them. According to X-ray analyses on the two [Co(glycinate)(tren)]$^{2+}$ isomers,[11] the cis position to the tertiary amine nitrogen is hindered by atoms H(a) and H(b) as shown in Fig. 5. The trans position is free from such hindrance. Consequently, the

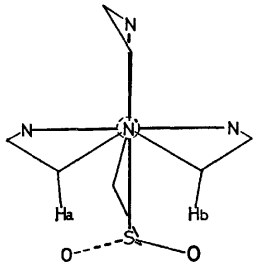

Fig. 5. A schematic structure of *p*-[Co{S(O)CH_2CH_2-NH_2}(tren)]$^{2+}$ viewed from the *t*-N–Co bond axis.

cis ligand is much more labile in substitution reactions than the trans ligand.[23,24] The S=O group in the *p*-isomer of [Co{S(O)$CH_2CH_2NH_2$}(tren)]$^{2+}$ is situated at such a hindered position, and the oxygen atom points close at atom H(a) or H(b). The *t*-isomer seems to have no such hindrance around the S=O group. In the trigonal planar transition state, on the other hand, both *p*- and *t*-isomers seem to have similar structural situation involving no particular steric hindrance around the S=O group. Accordingly, the *p*-isomer will have a lower energy barrier for the inversion than that of the *t*-isomer, and racemizes faster than the *t*-isomer does.

The epimerization at sulfur of a pair of diastereomers, $\Delta(S)$- and $\Lambda(S)$-[Co{S(O)$CH_2CH_2NH_2$}$(en)_2$]$^{2+}$ was examined by the same procedure and the results compared with the racemization of the tren complex. Both en and tren complexes have the same [CoN_5S] type. The structures around the S=O groups of the diastereomers are similar to each other and to that of *t*-[Co{S(O)$CH_2CH_2NH_2$}(tren)]$^{2+}$, and there is no particular steric hindrance among the S=O group and other atoms in these isomers. For the $\Delta(S)$-diastereomer, neither the absorption nor CD spectrum in 1.0 mol/dm^3 $NaClO_4$ showed detectable change in a day at 30.0 °C. On the other hand, the $\Lambda(S)$-diastereomer in 1.0 mol/dm^3 $NaClO_4$ decreased both absorbance (370 nm) and CD strength (375 nm) by the same quantity, 26%, at 30.0 °C in a period of 340 min, being less stable toward decomposition than the $\Delta(S)$-diastereomer. Jackson and Sargeson[22] reported that the Δ-(R) and $\Delta(S)$ diastereomers do not convert into each other over a period of at least 12 h at 25 °C. These results shows that the sulfur atoms in these diastereomers are stable toward racemization like the one in *t*-[Co{S(O)$CH_2CH_2NH_2$}(tren)]$^{2+}$. The *p*-[Co{S(O)-$CH_2CH_2NH_2$}(tren)]$^{2+}$ isomer whose S=O group is hindered by H(a) or H(b) atom racemizes much faster than these isomers do. Thus it is concluded that the rate of racemization of the sulfenate ligand in cobalt(III)–amine complexes is governed by a steric factor, if the racemization proceeds by the pyramidal inversion at the sulfur atom.

The Preparation of $(C_6H_{11})_3Sb(OH)Y$ and Their Infrared Spectra

Yoshikane KAWASAKI,* Yasushi YAMAMOTO, and Masanori WADA

Department of Petroleum Chemistry, Osaka University, Yamadaoka, Suita, Osaka 565

(Received June 14, 1982)

Tris(cyclohexyl)hydroxoantimony(V) compounds, $(C_6H_{11})_3Sb(OH)Y$, Y=Cl, Br, CH_3COO, and NO_3, were prepared by the hydrolysis of μ-oxo-bis[tris(cyclohexyl)haloantimony(V)], $[(C_6H_{11})_3SbX]_2O$, in a mixed solvent of acetone and water(7:3) or by a reaction of silver salts with $[(C_6H_{11})_3SbX]_2O$ in the same solvent. When Y=Cl and Br, the dehydration of the hydroxo compounds, giving the μ-oxo compounds, $[(C_6H_{11})_3SbY]_2O$, occurred readily. However, when Y=CH_3COO and NO_3, the hydroxo form is stable. In the IR spectra of these hydroxo compounds in dichloromethane solution, the ν(O–H) band was observed at *ca.* 3630 cm^{-1} and the ν(Sb–O) band, at 565—513 cm^{-1}. The hydrolysis of several μ-oxo compounds, $[R_3SbY]_2O$, R=CH_3, C_2H_5, *i*-C_3H_7, C_6H_5, and *p*-$CH_3C_6H_4$, Y=Cl, Br, CH_3COO, and NO_3, in a water-saturated dichloromethane solution was studied by using the IR spectra. All the compounds were hydolyzed in this solvent, but only the starting μ-oxo compounds were recovered from this solution.

There has been considerable confusion in the literature regarding the structure of $R_3Sb(OH)Y$ and its dehydrated $[R_3SbY]_2O$ types of compounds. Several workers have reported a number of compounds which were formulated as hydroxo compounds, $R_3Sb(OH)Y$. The hydroxo structure, however, is mainly assigned on the basis of elemental analyses,[1–8] although some workers have obtained the $[R_3SbY]_2O$ type of compounds.[9–12] Therefore, Long and co-workers[13,14] have made a detailed study of these types of compounds. They could not obtain compounds which give elemental analyses corresponding to $R_3Sb(OH)Y$ and which show the hydroxo band in their infrared spectra. The compounds obtained were always $[R_3SbY]_2O$. Accordingly, they concluded that the $R_3Sb(OH)Y$ type of compound probably does not exist in the solid state, although the presence of such species has been assumed in an aqueous solution.[15,16] Recently, however, we have obtained the $R_3Sb(OH)Y$ type of compound when the Y group is a somewhat bulky ligand such as 8-quinolinolate and when R=CH_3, C_6H_5 and *p*-$CH_3C_6H_4$.[8] These compounds show the ν(O–H) band at *ca.* 3610 cm^{-1} and the ν(Sb–O) band at *ca.* 550 cm^{-1}. Therefore, we anticipated that, if the alkyl group is bulky enough, the $R_3Sb(OH)Y$ type of compound may be obtained even if the Y group is halogen. In fact, Hartmann and Kühl have reported the preparation of $(C_6H_{11})_3Sb(OH)Cl$ by the hydrolysis of $(C_6H_{11})_3SbCl_2$.[7] However, they relied only on elemental analysis to elucidate the hydroxo structure of this compound and did not report its infrared spectrum. Actually, there is an error in their calculation, and so their analytical value is much close to that of the μ-oxo compound, $[(C_6H_{11})_3SbCl]_2O$.

In this paper, the preparation of tris(cyclohexyl)-hydroxoantimony(V) compound, $(C_6H_{11})_3Sb(OH)Y$, Y=Cl, Br, CH_3COO, and NO_3, and their infrared spectra in the solid state and in a dichloromethane solution will be reported.

Experimental

*Preparation of μ-Oxo-bis[tris(cyclohexyl)haloantimony(V)], $[(C_6H_{11})_3SbX]_2O$, X=Cl(**1**) and Br(**2**).* To a benzene solution (70 ml) of tris(cyclohexyl)bis(halo)antimony(V) (10 mmol), sodium methoxide (10 mmol) in methanol (10 ml) was added. The mixture was heated at reflux for 1 h, after which the sodium halide thus precipitated was filtered off. The crystalline white compound obtained after distilling off a large portion of the filtrate was purified by recrystallization from dichloromethane.

*Prepartion of Tris(cyclohexyl)halohydroxoantimony(V), $(C_6H_{11})_3Sb(OH)X$, X=Cl(**3**) and Br(**4**).* μ-Oxo-bis[tris(cyclohexyl)haloantimony(V)] (2 mmol) in a mixed solvent of acetone (70 ml) and water (30 ml) was heated at reflux until the solid compound was dissolved (1 h). The crystalline white compound obtained after removing a large portion of the solvent under reduced pressure was recrystallized from a mixed solvent of acetone and water (7:3). The compound was dried in air for a few minutes and then store in a tight-capped bottle. When the compound was stored in a desciccator overnight, air-dried for long time, or recrystallized from acetone, it changed to the dehydrated μ-oxo compound, $[(C_6H_{11})_3SbX]_2O$.

*Preparation of Other Tris(cyclohexyl)hydroxoantimony(V) Compounds, $(C_6H_{11})_3Sb(OH)Y$, Y=CH_3COO (**5**) and NO_3(**6**).* **1** (5 mmol) and the corresponding silver salt (10 mmol) were added to a mixed solvent of acetone (70 ml) and water (10 ml). The mixture was then heated at reflux for 1 h, and the silver chloride thus precipitated was removed by filtration. The crystalline white compounds obtained after removing a large portion of the solvent under reduced pressure was recrystallized from acetone. The compound was then dried in air.

Attempted Preparation of Other $R_3Sb(OH)X$, R=CH_3, C_2H_5, i-C_3H_7, C_6H_5, and p-$CH_3C_6H_4$ and X=Cl and Br. A suspension of μ-oxo-[tris(organo)haloantimony(V)] in a mixed solvent of acetone and water (7:3) was heated at reflux for about 1 h. The hydroxo compound, $R_3Sb(OH)X$, was not obtained by removing the solvent, and only the starting materials were recovered in the case of the phenyl and *p*-tolyl compounds. In the case of the methyl and isopropyl compounds, tris(alkyl)bis(halo)antimony(V) was precipitated from the condensed solution.

*Deuteration of **3**.* **3** (50 mg) was dissolved in a mixture of acetone-d_6 (1 ml) and D_2O (0.3 ml), after which the solution was sealed in a glass ampule. This was heated at about 50 °C for 2 h. After removing the solvent under reduced pressure, the crystalline white compound was obtained. Relevant IR spectral data in Nujol mull; 2520 cm^{-1} (ν(O–D)), 800 cm^{-1} (δ(Sb–O–D)), and 565 cm^{-1} (ν(Sb–O)).

*Reaction of **5** with Picric Acid.* To an acetone solution of **5** (2 mmol), picric acid (2 mmol) was added, after which the mixture was stirred for 30 min at room temperature. A crystalline yellow compound of acetatotris(cyclohexyl)picratoantimony(V) was obtained when the solution had been

TABLE 1. ANALYTICAL DATA OF μ-OXO-BIS[TRIS(CYCLOHEXYL)HALOANTIMONY(V)] AND TRIS(CYCLOHEXYL)HYDROXOANTIMONY(V) COMPOUNDS

	Mp[a] θ_m/°C	Yield %	Found(Calcd) (%) C	H	N
1	198—199	70	51.92 (52.14)	8.19 (8.02)

3	188	61	50.96 (51.03)	8.24 (8.09)	
4	195—196	80	46.29 (46.18)	7.47 (7.32)	
5	135—138	55	53.31 (53.71)	8.40 (8.34)	
6	156—157	25	47.86 (48.02)	7.65 (7.65)	3.10 (3.11)

a) Decomposition occurs gradually before melting.

left to stand at room temperature. This was recrystallized from acetone. Mp 160—171 °C (decomp). Found: C, 47.08; H, 5.93; N, 6.43%. Calcd for $C_{26}H_{38}N_3O_9Sb$: C, 47.43; H, 5.82; N, 6.38%.

Spectral Measurement. The infrared spectra were recorded on a Hitachi 215 spectrometer (4000—650 cm^{-1}) and on a Hitachi EPI-L spectrometer (700—200 cm^{-1}) in Nujol mulls or a dichloromethane solution. The concentration of the solution was 3 wt% or a saturated solution for not very soluble compounds. CaF_2 windows were used for obtaining the solution spectra of the O–H stretching region while KRS-5 plates were used for other region. The cell length used was 0.1 or 0.5 mm.

Conductivity Measurement. The molar conductances of **3**, **5**, and **6** in dichloromethane were measured by using a TOA digital conduct meter, model CM-15A, at 25±0.1 °C. The molar conductances of these compounds at 1×10^{-3} mol dm^{-3} were found to be less than 0.5 Ω^{-1} cm^2 mol^{-1}, indicating that these compounds are non-electrolytes in this solvent.

Solvent. Dichloromethane was dried over P_2O_5 and distilled before use. To dried dichloromethane, water was added and the mixture was shaken vigorously. The amount of water in dichloromethane was determined by referring to the signal strength of the known amount of hexamethylbenzene in the ^1H NMR spectra. The concentration of water was found to be 0.0095 mol dm^{-3}.

Results and Discussion

μ-Oxo-bis[tris(organo)antimony(V)] compound, $[R_3SbY]_2O$, show a characteristic band at around 790—740 cm^{-1} in the IR spectra,[12-14] which is attributed to the presence of the Sb–O–Sb skeleton. Compounds **1** and **2** have given a strong band at 720 cm^{-1}, also indicating the Sb–O–Sb skeleton, this is in accordance with the results of elemental analyses. Such a band, however, was not observed in **3**—**6**, these compounds showed a ν(O–H) band at around 3400—3300 cm^{-1} and ν(Sb–O) band at around 610—560 cm^{-1} in the solid state. Therefore, these compounds were assumed to be hydroxo compounds, $(C_6H_{11})_3Sb(OH)Y$. This is also consistent with the results of elemental analyses.

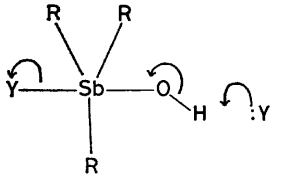
6	3340 br (3625 sh) (3400 br)	609 (565)	—

a) Values in parentheses are observed in a dichloromethane solution.

The frequency of the ν(O–H) band is lower than that of the normal one, indicating the presence of an intermolecular hydrogen bond.[17] The frequency of the ν(Sb–O) band in the solid state is a little higher than those reported for $R_3Sb(OH)$(8-quinol) (570—540 cm^{-1}),[8] $(C_6H_5)_4Sb(OH)$ (528 cm^{-1}),[17] and $[F_5Sb(OH)]^-$ (560 cm^{-1}).[18] Upon the deuteration of the hydroxo group of **3**, the ν(O–D) band appeared at 2520 cm^{-1}, and the ν(Sb–O) band, at 565 cm^{-1}. The latter band does not show any large shift upon deuteration. In the dichloromethane solution, the ν(O–H) band of **3**—**6** shifts to a higher frequency and becomes



I

sharp. The ν(Sb–O) band, on the other hand, shifts to a lower frequency (see Table 2). One of the reasons for the high-frequency shift of the ν(Sb–O) band in the solid state may be an intermolecular hydrogen bond, as is shown in I. As a result of hydrogen bond, the Sb–O bond gains a partial double-bond character and the Sb–Y bond becomes a little ionic (*vide infra*). In a proton-accepting solvent such as *N*,*N*-dimethylformamide, the ν(Sb–O) band appears at a higher frequency (545 and 607 cm^{-1} for **5** and **6** respectively) than that in dichloromethane. In dichloromethane, this type of hydrogen bond is lost and the partial double-bond character of the Sb–O bond is diminished. The high-frequency shift of the ν(O–H) band in the dichloromethane solution is consistent with the above explanation. Chremos and Zingaro estimated, by using Gordy's formula, the frequencies of the ν(Sb–O) and ν(Sb=O) bands to be 550 and 803 cm^{-1} respectively.[19] In trimethyloxoantimony(V), $(CH_3)_3SbO$, the ν(Sb=O) band was observed at 645 cm^{-1}.[20]

The influence of the Y group on the ν(O–H) and ν(Sb–O) bands of $(C_6H_{11})_3Sb(OH)Y$ observed in the dichloromethane solution is not large. The ν(O–H) band, however, has a tendency to decrease frequency

Table 3. Relevant IR data of CH_3COO group of some trisorganoantimony compounds, $R_3Sb(X)O_2CCH_3$ in the solid state[a)]

R	X	ν_{asym}(O-C-O) / cm^{-1}	ν_{sym}(O-C-O) / cm^{-1}	Δ

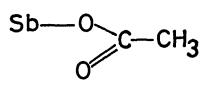
a) Values in parentheses are observed in a dichloromethane solution.

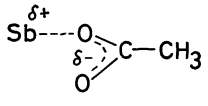
in the following order; NO_3<Cl, Br<CH_3COO. The ν(Sb–O) band, on the other hand, decreases in the reverse order.

The δ(M–O–H) band has been reported to appear in the region of 1200—700 cm^{-1}.[21] In $R_4Sb(OH)$, the band has been reported to be 995 cm^{-1} for R=CH_3[22] and 795 cm^{-1} for R=C_6H_5.[17] Since the IR spectra of **3** and **4** are quite similar to those of **1** and **2** in this region, this band could not be identified, although the deuterated compound of **3** shows the band at 800 cm^{-1}. In **5** and **6**, this band could not be identified unambigously.

In Table 3, some relevant IR data of acetato compounds of tris(cyclohexyl)antimony(V) are shown. In acetato–hydroxo compound, **5**, the frequency of $\nu_{asym}(CO_2)$ is rather low and that of $\nu_{sym}(CO_2)$ is high and the differnce between these frequencies (Δ=$\nu_{asym}(CO_2)-\nu_{sym}(CO_2)$) is the smallest among the compounds shown in Table 3. One of the reasons for small Δ value of **5** in the solid state is the intermolecular hydrogen bond, as is shown in I. The Δ value of **5** in the dichloromethane solution approaches that of $[(CH_3)_3Sb(O_2CCH_3)]_2O$, but it is still smaller than that of diacetate or acetato–picrate. This suggests that, in the acetato–hydroxo compound, **5**, the Sb–$OC(O)CH_3$ bond is more ionic, or the contribution of the Type-III mode to the bond is large, compared with that of diacetate or acetato–picrate, in which the Type-II mode is more predominant.



II



III

The frequencies of the $\nu_{asym}(NO_2)$, $\nu_{sym}(NO_2)$, and ν(N–O) bands of some nitrato compounds of trisorganoantimony(V) are shown in Table 4. The difference (Δ=$\nu_{asym}(NO_2)-\nu_{sym}(NO_2)$) is also shown in this table. These frequencies are characteristic of a nitrato group with essentially a C_{2v} symmetry. Ferraro[23] found that the Δ value is a measure of the covalent character between the metal-nitrato bond of several transition-metal complexes. On the other hand, Gatehouse *et al.*[24] used the frequency of the ν(N–O) band as a criterion of the covalent character of the metal-nitrato bond. As can be seen from Table 4, the Δ value of nitrato–hydroxo compound, **6**, is the smallest, and the frequency of the ν(N–O) band is

p-$CH_3C_6H_4$	Br	3610	545

the highest. If the above criterions could be applied to the antimony compounds, the Sb–ONO_2 bond of **6** may have the largest ionic character. The differences in the Δ values and the frequencies of the ν(N–O) bands of **6** in the solid state and in solution may also be explained by the presence of the intermolecular hydrogen bond in the solid state, as in **5**.

Table 5 summarizes the frequencies of the ν(O–H) and ν(Sb–O) bands observed for several μ-oxo compounds, $[R_3SbY]_2O$, in a water-saturated dichloromethane solution, where R=CH_3, C_2H_5, i-C_3H_7, c-C_6H_{11}, C_6H_5, and p-$CH_3C_6H_4$ and Y=Cl, Br, CH_3COO, and NO_3. In isopropyl and cyclohexyl compounds, the two ν(O–H) bands of water disappeared completely, and only one ν(O–H) band due to the hydroxo group bound to the antimony atom was observed at 3640—3630 cm^{-1}. The ν(Sb–O) band appeared at around 535 cm^{-1}. The frequencies of the ν(O–H) and ν(Sb–O) bands of the cyclohexyl compounds in this solvent are similar to those of the hydroxo compounds, **3** and **4**, shown in Table 2. On the other hand, the solubility of the methyl, ethyl, and aryl compounds to this solvent is poor, and so the saturated solutions were used for the spectral measurements. Therefore, the water molecule in dichloromethane was not completely consumed, and the ν(O–H) bands of the water remained. The ν(O–H) band

of the hydroxo group bound to the antimony atom was found at the position of the ν_{sym}(O–H) band of water; *i.e.*, the intensity ratio of $I[\nu_{sym}(O–H)]/I[\nu_{asym}(O–H)]$ becomes large in the $[R_3SbY]_2O$-saturated solution. From the above results, the hydrolysis of the μ-oxo compounds to the hydroxo compounds was found to occur in the dichloromethane. However, the attempted isolation of the hydroxo compounds from this

$$[R_3SbY]_2O + H_2O \overset{CH_2Cl_2}{\rightleftarrows} 2R_3Sb(OH)Y$$

solution failed, and only the starting materials were recovered.

As has been mentioned in the Experimental part, tris(cyclohexyl)halohydroxoantimony(V) is readily dehydrated, giving the μ-oxo compounds in the solid state, although the latter compounds were hydrolyzed easily by a small amound of water in the solvent. In the acetato and nitrato compounds, however, the hydroxo form is stable in air.

Binuclear Metal Complexes. II.[1] Synthesis, ESR, and Electrochemical Properties of Strati-bis Copper(II)-Nickel(II) Complexes

Hisashi Ōkawa,* Miyuki Kakimoto, Tatuo Izumitani, Masaaki Nakamura, and Sigeo Kida

Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812

(Received June 25, 1982)

Strati-bis copper(II)–nickel(II) complexes, CuNi(R-sata) and CuNi(R-sacta) (R=H, 5-Me, 5-Br), have been prepared, where H_4(R-sata) and H_4(R-sacta) denote 1,2,3,4-tetrakis(R-salicylideneamino)-2,3-dimethylbutane and 1,2-bis(R-salicylideneamino)-1,2-bis(R-salicylideneaminomethyl)cyclohexane, respectively. ESR spectra of the complexes (frozen chloroform solution at liquid nitrogen temperature) showed a tetragonal pattern with a hyperfine coupling constant $A_{//}$ smaller than that of the relevant mononuclear copper(II) complex. Based on cyclic voltammetry and differential pulse polarography, it was shown that the Cu(II)→Cu(I) reduction occurs at a higher potential than that of the mononuclear reference complex. The ESR and electrochemical properties have been interpreted in terms of the stacking of the CuN_2O_2 and NiN_2O_2 planes and hence the electron delocalization over the whole molecule through the ligand π-system.

So far many binucleating ligands have been devised for the studies of magnetic spin-exchange interaction, redox properties and catalytic functions of binuclear metal complexes.[2,3] In almost all of these complexes, metal ions are linked with bridging groups so that two equatorial planes are kept coplanar. On the other hand, there have been obtained few binucleating ligands capable of forming "strati-bis" metal complexes.[4–9]

In the previous paper of this series,[4] we have reported the synthesis and characterization of strati-bis copper(II) complexes of 1,2,3,4-tetrakis(R-salicylideneamino)-2,3-dimethylbutane (H_4(R-sata)) and 1,2-bis(R-salicylideneamino)-1,2-bis(R-salicylideneaminomethyl)cyclohexane (H_4(R-sacta)). By comparing the properties of Cu_2(R-sata) and Cu_2(R-sacta) with Cu(R-salpn) (H_2(R-salpn) = *N*,*N*′-bis(R-salicylideneamino)-1,2-propanediamine) and Cu(R-sacda) (H_2(R-sacda) = 1-(R-salicylideneamino)-1-(R-salicylideneaminomethyl)cyclohexane), respectively, the following characteristics have been recognized for the strati-bis copper(II) complexes: (1) seven-lined hyperfine structure with a small hyperfine coupling constant ($A_{//}\approx 85$ G (1 G=1×10^{-4} T)) in ESR spectrum, (2) red shift of the π-π^* transition band involving azomethine π-character, and (3) one-electron transfer process, Cu(II,II)⇌Cu(II,I), occuring at a high potential compared with the corresponding mononuclear copper(II) complex. These characteristics can be explained in terms of the assumption that the two CuN_2O_2 planes are stacked in a face-to-face manner and interact with each other through the ligand π-system.

As the extension of this study, the strati-bis complexes, CuNi(R-sata) and CuNi(R-sacta), were prepared in the present study and their properties were examined in comparison with those of Cu(R-salpn) and Cu(R-sacda), respectively. Chemical structures of CuNi(R-sata), CuNi(R-sacta), Cu(R-salpn), and Cu(R-sacda) are shown in Fig. 1.

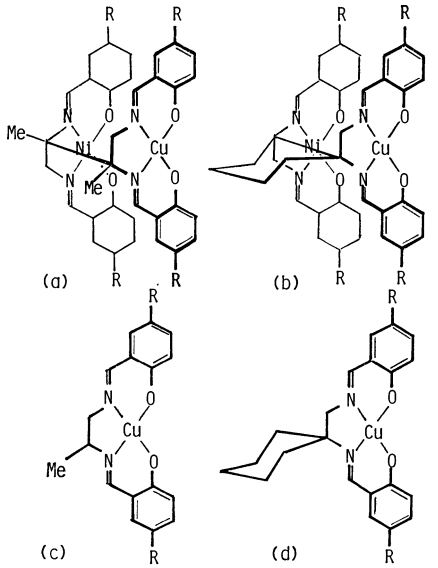

Fig. 1. Chemical structures of (a) CuNi(R-sata), (b) CuNi(R-sacta), (c) Cu(R-salpn), and (d) Cu(R-sacda); R (substituent on the ring)=H, 5-Me, or 5-Br.

Experimental

Syntheses. Synthetic methods for 2,3-dimethyl-1,2,3,4-butanetetramine and 1,2-bis(aminomethyl)-1,2-cyclohexanediamine have been described in the previous paper.[4] Syntheses of Cu(R-salpn)[10] and Cu(R-sacda)[4] were performed by the methods in the literatures.

CuNi(sata). 2,3-Dimethyl-1,2,3,4-butanetetramine (0.30 g) and salicylaldehyde (1.0 g) were dissolved in ethanol (50 cm^3), and the mixture was refluxed with stirring. To this was added an ethanolic solution (30 cm^3) of copper(II) acetate monohydrate (0.41 g) and the mixture was stirred at 60 °C for 10 min. Then, an ethanolic solution (30 cm^3) of nickel(II) acetate tetrahydrate (0.51 g) was added, and the mixture was stirred at 60 °C for 10 min. The reaction mixture was filtered, concentrated to *ca.* 30 cm^3 and allowed to stand in a refrigerator to give brown crystals. They were recrystallized from a chloroform–ethanol mixture.

Found: C, 58.81; H, 4.90; N, 7.91; Cu, 9.37%. Calcd for $C_{34}H_{30}N_4O_4CuNi\cdot H_2O$: C, 58.43; H, 4.62; N, 8.02; Cu, 9.09%.

CuNi(5-Me-sata). This complex was obtained as brown crystals in the same way as that of CuNi(sata), except for using 5-methylsalicylaldehyde instead of salicylaldehyde. It was recrystallized from a chloroform–ethanol mixture.

Found: C, 60.90; H, 5.40; N, 7.34; Cu, 8.26%. Calcd for $C_{38}H_{38}N_4O_4CuNi\cdot 1/2\,H_2O$: C, 61.18; H, 5.27; N, 7.51;

Cu, 8.52%.

CuNi(5-Br-sata). The synthetic method for this complex is the same as that for CuNi(sata), except for using 5-bromosalicylaldehyde instead of salicylaldehyde. It forms brown crystals when crystallized from a chloroform–ethanol mixture.

Found: C, 40.58; H, 3.01; N, 5.33; Cu, 6.52%. Calcd for $C_{34}H_{26}N_4O_4Br_4CuNi \cdot 1/2\,H_2O$: C, 40.61; H, 2.71; N, 5.57; Cu, 6.32%.

CuNi(sacta). An ethanolic solution (50 cm^3) of 1,2-bis(aminomethyl)-1,2-cyclohexanediamine (0.30 g) and salicylaldehyde (0.85 g) was refluxed for 20 min. To this was added copper(II) acetate monohydrate (0.35 g), and the mixture was heated at *ca.* 60 °C for 10 min. To this solution was added nickel(II) acetate tetrahydrate (0.44 g), and the mixture was heated at 60 °C for 10 min. The reaction mixture was filtered and allowed to stand in a refrigerator. A brown precipitate was filtered and recrystallized from a chloroform–ethanol mixture to form brown prisms.

Found: C, 58.44; H, 4.77; N, 7.53; Cu, 8.10%. Calcd for $C_{36}H_{32}N_4O_4CuNi \cdot 2H_2O$: C, 58.20; H, 4.88; N, 7.54; Cu, 8.55%.

CuNi(5-Me-sacta). This complex was obtained as brown prisms in the same way as that of CuNi(sacta), except for using 5-methylsalicylaldehyde in place of salicylaldehyde. It was recrystallized from a chloroform–ethanol mixture.

Found: C, 62.67; H, 5.66; N, 6.80; Cu, 7.74%. Calcd for $C_{40}H_{40}N_4O_4CuNi \cdot C_2H_5OH$: C, 62.35; H, 5.73; N, 6.92; Cu, 7.85%.

CuNi(5-Br-sacta). This complex was obtained as brown prisms in the same way as that of CuNi(sacta), except for using 5-bromosalicylaldehyde instead of salicylaldehyde.

Found: C, 42.73; H, 3.12; N, 5.21; Cu, 6.24%. Calcd for $C_{36}H_{28}N_4O_4Br_4CuNi \cdot C_2H_5OH$: C, 42.71; H, 3.12; N, 5.24; Cu, 5.95%.

Measurements. Electronic spectra were recorded on a Shimadzu MPS-5000 spectrophotometer. Magnetic susceptibilities were measured by the Faraday method at room temperature. Effective magnetic moments were calculated by the equation, $\mu_{eff}=2.828\ (\chi_M \times T)^{1/2}$, where χ_M is the magnetic susceptibility per molecule corrected for diamagnetism by the use of Pascal's constants.[11] ESR spectra were recorded on a JES-FE3X instrument in frozen chloroform solutions near liquid nitrogen temperature. Cyclic voltammograms were recorded on a Yanagimoto P-1000 voltammetric analyzer in dichloromethane containing 0.1 M (1 M = 1 mol dm^{-3}) tetrabutylammonium perchlorate as the supporting electrolyte. The measurements were carried out in a three-electrode cell equipped with a glassy carbon working electrode, a platinum coil auxiliary electrode, and a saturated calomel reference electrode. The potentials were corrected for liquid junction potential by the use of ferrocene as an internal standard.[12,13] Differential pulse polarograms were recorded on the same instrument by the use of dropping mercury electrode instead of glassy carbon electrode.

Results and Discussion

The magnetic moments of CuNi(R-sata) and CuNi(R-sacta) fall in the range 1.80—1.96 BM (Table 1), indicating the presence of one unpaired electron per molecule. Since *N,N'*-disalicylideneethylenediaminatonickel(II) and its congeners are diamagnetic, the magnetic moments in Table 1 clearly indicate that the complexes contain one copper(II) and one nickel(II) ions.

Table 1. Magnetic moments of CuNi(R-sata) and CuNi(R-sacta)

Complex	μ_{eff}/BM
$CuNi(sata) \cdot H_2O$	1.96
$CuNi(5\text{-}Me\text{-}sata) \cdot 1/2\,H_2O$	1.80
$CuNi(5\text{-}Br\text{-}sata) \cdot 1/2\,H_2O$	1.94
$CuNi(sacta) \cdot 2H_2O$	1.80
$CuNi(5\text{-}Me\text{-}sacta) \cdot C_2H_5OH$	1.85
$CuNi(5\text{-}Br\text{-}sacta) \cdot C_2H_5OH$	1.89

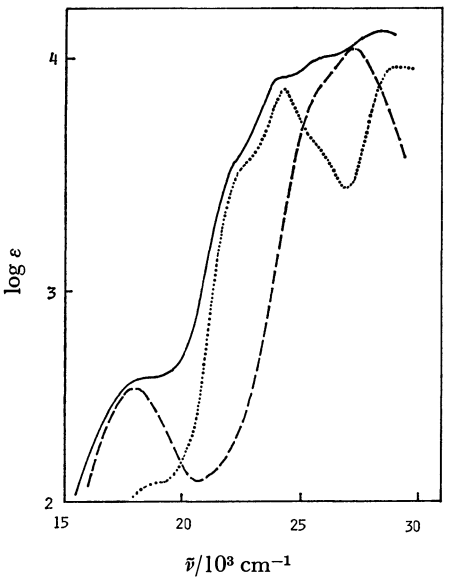

Fig. 2. Electronic spectra of (——) CuNi(sata), (——)-Cu(salpn), and (----)Ni(salpn).

With respect to two asymmetric carbon atoms in the tetramine moieties, two geometrical isomers (*meso-* and *dl-*) are considered for CuNi(R-sata) and CuNi (R-sacta). It has been shown that 1,2-bis(aminomethyl)-1,2-cyclohexanediamine is of the *dl*-form (*trans*-form), since 1,2-dicyano-1,2-cyclohexanediamine (the precursor of 1,2-bis(aminomethyl)-1,2-cyclohexanediamine) forms a *trans*-octahedral nickel(II) complex.[14] The geometrical structure of H_4(R-sacta) has not yet been determined.

Electronic spectra of the CuNi-complexes were well explained by the superposition of the $[CuN_2O_2]$ and $[NiN_2O_2]$ chromophores. The spectrum of CuNi(sata) is shown as an example in Fig. 2, together with the spectra of Cu(salpn) and Ni(salpn) as the references.

ESR spectra of the CuNi-complexes were measured in frozen chloroform solutions (at liquid nitrogen temperature). All the complexes showed a tetragonal pattern. ESR spectrum of CuNi(sata) is shown as an example in Fig. 3. Figure 3 also includes the spectra of Cu_2(sata) and Cu(salpn) for comparison. The spectrum of CuNi(sata) markedly differs from that of Cu_2(sata) and resembles that of Cu(salpn). This clearly indicates that CuNi(sata) is not an equimolar mixture of Cu_2(sata) and Ni_2(sata) but a discrete hetero-metal complex.

The ESR parameters, $A_{//}$ and $g_{//}$, for the CuNi-complexes and their relevant reference complexes are

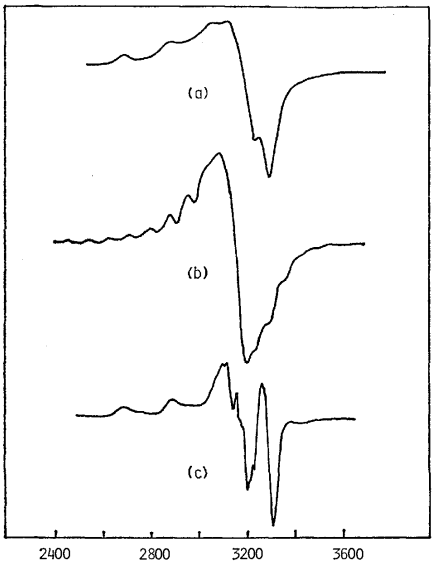

Fig. 3. ESR spectra of (a) CuNi(sata), (b) Cu_2(sata), and (c) Cu(salpn).

TABLE 2. ESR PARAMETERS OF THE CuNi-COMPLEXES AND THEIR REFERENCE COMPLEXES

	$A_{//}$/G	$g_{//}$		$A_{//}$/G	$g_{//}$
CuNi(sata)	183	2.22	Cu(salpn)	193	2.18
CuNi(5-Me-sata)	185	2.22	Cu(5-Me-salpn)	198	2.20
CuNi(sacta)	178	2.24	Cu(sacda)	206	2.18
CuNi(5-Me-sacta)	185	2.25	Cu(5-Me-sacda)	209	2.16

given in Table 2. ESR spectra of CuNi(5-Br-sata) and CuNi(5-Br-sacta) were not well resolved and hence their ESR parameters were not evaluated. Detailed examination of the ESR spectra of the CuNi-complexes revealed that the hyperfine coupling constant $A_{//}$ is smaller than that of the corresponding reference complex. Smaller $A_{//}$ values, compared with the reference complexes, of the CuNi-complexes can be interpreted in terms of the spin-delocalization over the molecule. As was shown for the binuclear copper(II) complexes,[4] it is likely that the CuN_2O_2 and NiN_2O_2 planes are stacked each other and interact through the ligand π-system.

It is to be noted that the $g_{//}$ values for the CuNi-complexes are larger than those of the corresponding reference mononuclear copper(II) complexes. The frequency of the d-d band due to the copper for the CuNi-complexes is practically the same as that of the reference complexes. Therefore, the large $g_{//}$ values of the CuNi-complexes may be attributed to the increase of λ due to the stacked configuration, based on the simple equation $g=2.0-8\lambda/(d_{x^2-y^2}-d_{xy})$.[15]

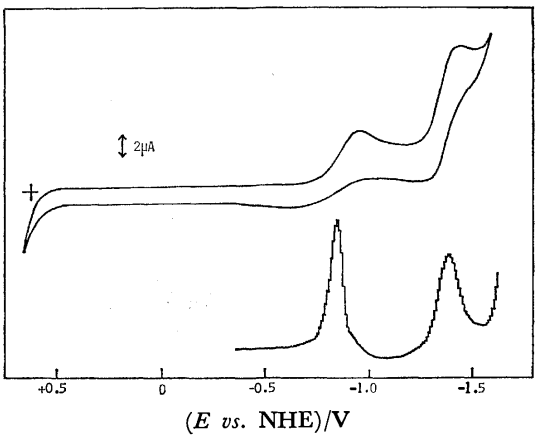

Fig. 4. Cyclic voltammogram and differential pulse polarogram of CuNi(sata).

Both of the cyclic voltammograms and differential pulse polarograms of CuNi(R-sata) and CuNi(R-sacta) showed two reduction waves. Typical examples are given in Fig. 4. The processes are irreversible or quasi-reversible judging from the separation ΔE_p between the cathodic and anodic peaks, E_{pc} and E_{pa}, of the cyclic voltammograms. Electrochemical data for the CuNi-complexes are given in Table 3. Approximate redox potentials $E^f_{1/2}$, which were determined by the arithmetic mean of E_{pa} and E_{pc} of cyclic voltammogram, substantially accord with the half-wave potentials determined from the differential pulse polarogram.

Reduction of Ni(R-salpn) and Ni(R-sacda) did not occur in the accessible range. Thus, all the reduction processes observed for the CuNi-complexes can be attributed to the reduction of copper(II) ion. Appearance of two reduction waves suggests the presence of two species, the stacked and non-stacked species, in solution. Two reduction waves have also been observed for Cu_2(sata), Cu_2(sacta), and Cu_2(5-Me-sacta).[4] For these complexes, the first and second reduction processes can be attributed to the one-electron transfer of the stacked species (Cu(II,II)$\rightleftharpoons$Cu(II,I)) and two electron transfer of the non-stacked species (Cu(II,

$E^f_{1/2}=1/2(E_{pa}+E_{pc})$.

II)⇌Cu(I,I)), respectively, based on the controlled-potential electrolysis.[16] Further, the second reduction potentials of the CuNi-complexes well correspond to the potentials of the reference copper(II) complexes, respectively. Thus, it is natural to assign the first and the second processes to the reductions of copper of the stacked and non-stacked species, respectively.

The redox potential of the stacked species is higher by 0.4—0.5 V than that of the non-stacked species. Therefore, the copper ion of the stacked species must be stabilized by $(3—4)\times10^3$ cm^{-1} (9—12 kcal/mol) compared with that of the non-stacked species or of the reference mononuclear complex. It is likely that such a stabilization is effected by the electron-delocalization over the CuN_2O_2 and NiN_2O_2 coordination units through the ligand π-system. It is also to be noted that the Cu(II)→Cu(I) reduction occurs more easily in the cases of the CuNi-complexes compared with the Cu_2-complexes.[4]

16) Controlled-potential electrolysis of Cu_2(sacta) (which shows two redox waves at −1.09 and −1.40 V *vs.* SCE) at −1.2 V revealed an electron transfer of *ca.* 0.7. ESR spectrum of the reduced solution showed a tetragonal pattern with the parameters $A_{//}=188$ G and $g_{//}=2.25$. These parameters differ from those ($A_{//}=206$ G and $g_{//}=2.18$) of Cu(sacda) but are similar to those ($A_{//}=178$ G and $g_{//}=2.22$) of CuNi(sacta). Thus, this process can be attributed to a one-electron transfer, Cu(II,II)→Cu(II,I), of the stacked species. Electron number transfered by the further electrolysis at −1.6 V could not be determined because of the concomitant reduction of the ligand with the reduction of the non-stacked species. However, the process at −1.40 V should involve a two-electron transfer, since the controlled-potential electrolysis at −1.60 V of Cu_2(5-Me-sata) (which exists only as the non-stacked species and shows one redox wave at −1.42 V) revealed the transfer of two electrons.

The Mode of Stereoselective Association between Complex Cation and Complex Anion[1)]

Ushio Sakaguchi, Ippei Yamamoto, Shinji Izumoto, and Hayami Yoneda*

Department of Chemistry, Faculty of Science, Hiroshima University, Naka-ku, Hiroshima 730

(Received July 7, 1982)

Ion-exchange chromatography on the IEX 220 anion-exchange resin has been used to measure the retention volumes of enantiomers of several complex anions when eluted by an aqueous solution of Δ-$[Co(en)_3]^{3+}$, Δ-$[Co(sep)]^{3+}$, or Δ-$[Co\{(-)\text{-chxn}\}_3]^{3+}$, where en=ethylenediamine, sep=1,3,6,8,10,13,16,19-octaazabicyclo-[6.6.6]eicosane, and chxn=*trans*-1,2-cyclohexanediamine. Comparison of these retention volumes suggests that chiral recognition in solution is effected along the C_2 axis of $[Co(en)_3]^{3+}$, $[Co(mal)_2(en)]^-$, and $[Co(ox)_2(en)]^-$, and along the C_3 (or pseudo C_3) axis of $[Co(chxn)_3]^{3+}$, $[Co(edta)]^-$, $[Co(tdta)]^-$, $[Co(ox)_2(gly)]^{2-}$, $[Cr(mal)_3]^{3-}$, and *fac*-$[Co(\beta\text{-ala})_3]$, where mal=malonate, ox=oxalate, edta=ethylenediaminetetraacetate, tdta=1,4-butanediaminetetraacetate, gly=glycinate, and ala=alaninate. The mode of stereoselective association of these complex ions has been proposed.

Optically active metal complexes have been used more and more frequently as the resolving agent for the optical resolution of complex compounds.[2)] It is now well recognized that an optically active complex cation can discriminate the absolute configuration of an enantiomer of a complex anion in solution. Recently, the mode of stereoselective interaction between optically active complexes in solution has been proposed by several workers.[3–6)] Among these, of particular relevance to the present work is the ion pair $[Co(en)_3]^{3+}\cdots[Co(ox)_2(gly)]^{2-}$,[7)] for which the anion is supposed to face the cation along the C_3 axis of the cation, with its three oxygen atoms of three different chelate rings, thereby forming a triple hydrogen bond with axial N–H hydrogens.[6)] In this work, we have used ion-exchange chromatography to infer the mode of stereoselective ion association between optically active complexes.

Experimental

Materials. The cationic complexes used in this work are the chloride or bromide salts of Δ-$[Co(en)_3]^{3+}$,[8)] Δ-$[Co(sep)]^{3+}$,[9)] and Δ-$[Co\{(-)\text{-chxn}\}_3]^{3+}$,[10)] which were prepared by the literature methods. The preparation and optical resolution of the following anionic complexes were accomplished according to the methods described in the literature; $K_2[Co(ox)_2(gly)]$,[12)] $K[Co(edta)]$,[13)] $Na[Co(ox)_2(en)]$,[14)] and $Na[Co(mal)_2(en)]$.[14)] The complexes $K_3[Cr(mal)_3]$ and *fac*-$[Co(\beta\text{-ala})_3]$ were prepared after Chang[15)] and Celap *et al.*,[16)] respectively.

The preparation of K[Co(tdta)] was reported by Ogino *et al.*[17)] The optical resolution of this complex was effected by Δ-*cis*-$[Co(en)_2(NO_2)_2]^+$ obtained by the method of Dwyer and Garvan.[18)] The Δ enantiomer formed the less-soluble diastereoisomer and the potassium salt of the enantiomer was consistent with the formulation as the monohydrate. Found: C, 33.10; H, 4.25; N, 6.58. Calcd for $KCoC_{12}H_{18}N_2O_9$: C, 33.34; H, 4.20; N, 6.48. The circular dichroism spectrum in water had peaks at 623 ($\Delta\varepsilon=+2.98$), 553 (-4.20), 434 ($+0.752$), and 387 nm ($+1.19$).

The IEX 220 resin was the gift from Dr. S. Yamazaki, Toyo Soda Manufacturing Co., Ltd. (Tokyo).

Chromatographic Experiments. *Type (a) Experiment*: The SP-Sephadex C-25 resin (cation-exchanger) was packed in a column tube with an approximate size of 200 mm × 10 mm (i.d.) and loaded fully with an optically active cationic complex. The column was washed thoroughly with water and a racemic anionic complex was eluted with water. The eluent containing the partially resolved anionic complex was fractionally collected and the circular dichroism spectrum was measured immediately.

Type (b) Experiment: A home-built liquid chromatographic apparatus[19)] was used to measure the retention volume. A column (50 mm × 4 mm) of the IEX 220 resin (anion-exchanger) was equilibrated by an eluent (aqueous solution of an optically active cationic complex). An aqueous solution containing one enantiomer of an anionic complex and bis(glycinato)copper(II), which was used as a marker for void volume measurement, was injected by a syringe on top of the column and eluted by the eluent at an elution rate of 0.3 cm³/min. The adjusted retention volumes were obtained from the elution curves as in the previous studies.[19)] The concentration of the cationic complexes in eluents was varied from 4×10^{-3} to 60×10^{-3} mol dm^{-3}. The retention volumes were found to be reproducible to within 0.002 cm³.

Results and Discussion

In type (a) experiment, an optically active complex cation (Δ cation) was adsorbed on the SP-Sephadex C-25 cation-exchanger and an anionic complex was eluted with water. Thus, the enantiomer that associates more favorably with the Δ cation is eluted later. In some complexes, the degree of optical resolution was very small and unambiguous assertion of later-eluted enantiomers could not be made. Further, it was found that the chirality of the resin matrix itself[20)] contributes to the optical resolution to some extent. Therefore, type (b) experiment was performed to obtain reliable and quantitative data by employing an achiral resin, IEX 220, which is based on the styrene-divinylbenzene-copolymer and carries the tetraalkylammonium functional group. The retention volumes obtained in type (b) experiment are given in Table 1. In type (b) experiment, one enantiomer of an anionic complex was adsorbed on the anion-exchange resin and eluted by an aqueous solution containing a Δ cation. Thus, the enantiomer that associates more favorably with the Δ cation shows a smaller retention volume than its enantiomorph. The results of both types of experiments were consistent with respect to favorable diastereoisomeric combina-

a) From type (a) experiment. b) From type (b) experiment. c) Also reported by A. Tatehata *et al.*; A Tatehara, Y. Ejiri, and K. Kotsuji, Proc. 29th Symposium on Coordination Chemistry, Shizuoka, October 1979, Abstr. No. 1B01, p. 40.

tions. Therefore, both results are incorporated and Table 2 was made to facilitate the following discussion.

Structural Features of Complexes. The cationic complexes chosen for this study were Δ-[Co(en)$_3$]$^{3+}$, Δ-[Co(sep)]$^{3+}$, and Δ-[Co{(−)-chxn}$_3$]$^{3+}$. The chirality of these complexes can be specified by looking at the complexes either along the C_3 axis as P(C_3) or along the C_2 axis as M(C_2). These notations follow those of Mason *et al.*[21] and define the chirality by the handedness of mutual spatial disposition of three or two chelate rings. The chirality of the other complexes used in this work can be specified similarly; a Δ complex has P(C_3) and M(C_2) chiralities. Note here that if an anionic complex approaches a Δ cation from the cation's C_3 axis, the anion will experience the P(C_3) chirality (right-handed propellers), whereas in the case of the C_2 access (the access along the cation's C_2 axis from the side opposite to one ethylenediamine moiety), the anion will experience the reversed chirality, the M(C_2) chirality (left-handed propellers).

The direction of access of anionic complexes that can contribute to chiral discrimination is along either the C_3 or the C_2 axis for Δ-[Co(en)$_3$]$^{3+}$; in other words, Δ-[Co(en)$_3$]$^{3+}$ can "use" its C_3 or C_2 axis in discriminating the chirality of a complex anion. In Δ-[Co(en)$_3$]$^{3+}$, chiral discrimination through the C_3 access has been suggested for the (+)- and (−)-tartrate anions,[22] and that through the C_2 access was proposed for the (+)-tartratoantimonate(III) anion.[23] Therefore, both accesses may potentially contribute to the chiral discrimination by Δ-[Co(en)$_3$]$^{3+}$.

In Δ-[Co(sep)]$^{3+}$, chiral discrimination along its C_3 axis is unlikely owing to the presence of bulky covalent caps along this axis.[9b] This is also supported by the equality of the association constants of Δ-[Co(sep)]$^{3+}$ with (+)- and (−)-tartrate ions (K= 40±2 mol^{-1} dm^3 at 25 °C and μ=0.1 with NaClO$_4$).[24] Thus, the chiral discrimination by this cation along the C_2 axis should be the only possibility, which constitutes the basis for the interpretation of our results.

In Δ-[Co{(−)-chxn}$_3$]$^{3+}$, though it appears that the C_3 access is preferred owing to the presence of bulky cyclohexane rings, the situation is not so clear and we leave both accesses as a possibility.

The reasoning similar to the above can be made for the anionic and electrically neutral complexes. Note here that these complexes contain negatively charged ligands, unlike the cationic complexes which have only electrically neutral ligands. Therefore, significant charge localization is expected for anionic and electrically neutral complexes. Previously, it has been shown[5,25] that in the ion association with complexes with significant charge localization, the site and/or the direction of ion association is dictated by localized electric charges. We here apply this criterion to the direction of ion association of anionic and neutral complexes. Thus, in the case of [Co(ox)$_2$(en)]$^-$ type of complexes, for example, an access of a cation along the C_2 axis and from the side opposite to the ethylenediamine ring is the only likelihood. In [Co(edta)]$^-$ type of complexes, an access of a cation along the anion's pseudo C_3 axis and from the side of three oxygen atoms is conceived. For [Co(ox)$_2$(gly)]$^{2-}$ and [Cr(mal)$_3$]$^{3-}$, we leave the pseudo C_3 and C_3 accesses

as the possibility, respectively. Though other types of accesses can, in principle, lead to chiral discrimination, the above choices for the direction of access will be shown later to be consistent with the experimental results.

Stereoselective Association. The most noteworthy feature in Table 2 is that Δ-$[Co(en)_3]^{3+}$ and Δ-$[Co(sep)]^{3+}$ favor the association with the same enantiomer for all the anionic and electrically neutral complexes investigated here but the opposite enantiomer is preferred by Δ-$[Co\{(-)\text{-chxn}\}_3]^{3+}$. This result indicates clearly that (i) Δ-$[Co(en)_3]^{3+}$ uses its C_2 axis in discriminating the chirality of all the anionic and neutral complexes examined here, because Δ-$[Co(en)_3]^{3+}$ and Δ-$[Co(sep)]^{3+}$ prefer the same enantiomers and the C_2 access is the only effective discriminating interaction in Δ-$[Co(sep)]^{3+}$, (ii) Δ-$[Co\{(-)\text{-chxn}\}_3]^{3+}$ uses its C_3 axis in the chiral discrimination, because this cation has the $P(C_3)$ propellers and prefers the opposite enantiomers to those favored by Δ-$[Co(sep)]^{3+}$ which uses the $M(C_2)$ propellers.

Now that we have identified the directions of the cationic complexes which are used in chiral discrimination and such directions of anionic and neutral complexes are assumed in the above, we can now examine the mode of association between these complexes. Table 2 indicates that Δ-$[Co(en)_3]^{3+}$ favors Δ-$[Co(ox)_2(en)]^-$. Since both ions use their C_2 axes in chiral discrimination, the resulting ion pair should be as illustrated in Fig. 1. Figure 1 depicts schematically the mutual disposition of chelate rings in this Δ-Δ combination, as viewed along the collinear C_2 axes of both ions. The hydrogen atoms are omitted for clarity. As seen from this figure, the handedness of the chelate rings that overlap mutually in association is the same for this pair and this mode of pairing is sterically less hindered. A severe steric hindrance is clearly expected for the Δ-Δ combination, where the first chirality notation refers to the cation and the second one to the anion. The $M(C_2)$–$M(C_2)$ pair depicted in Fig. 1 is also supported by electrostatic considerations; the cation will associate with the anion from the anionic side of the complex anion, namely along the C_2 axis of the anion and from the side opposite to the ethylenediamine chelate ring. Thus, the $M(C_2)$–$M(C_2)$ combination is consistent with both steric and electrostatic considerations. The preference for the pairs Δ-$[Co(en)_3]^{3+}\cdots\Delta$-$[Co(mal)_2(en)]^-$, Δ-$[Co(sep)]^{3+}\cdots\Delta$-$[Co(ox)_2(en)]^-$, and Δ-$[Co(sep)]^{3+}\cdots\Delta$-$[Co(mal)_2(en)]^-$ can be understood similarly.

In the combination of $[Co(ox)_2(en)]^-$ and $[Co(mal)_2(en)]^-$ with Δ-$[Co\{(-)\text{-chxn}\}_3]^{3+}$, the Δ-Δ pair is seen from Table 2 to be preferred. Since the cation uses its C_3 axis and the anions use their C_2 axes in chiral discrimination, this Δ-Δ pair corresponds to the $P(C_3)$–$P(C_2)$ pair. Namely, the propellers of both ions have the same handedness and the preference of this pair can be also understood in terms of a cozy fit of chelate rings of both ions.

Table 2 indicates that Δ-$[Cr(mal)_3]^{3-}$ forms the favorable ion pair with Δ-$[Co(en)_3]^{3+}$ and Δ-$[Co(sep)]^{3+}$. Since this anion uses its C_3 axis and the cations use their C_2 axes in chiral discrimination, these pairs are described as the $M(C_2)$–$M(C_3)$ pairs. Here again we find that the handednesses of chelate rings of cation and anion, as viewed along the direction of the access, coincide. Thus, these Δ-Δ pairs are also explained by the notion that favorable ion pairs are formed between those ions that can fit spatially along the prescribed axes. The fact that the pair Δ-$[Co\{(-)\text{-chxn}\}_3]^{3+}\cdots\Delta$-$[Cr(mal)_3]^{3-}$ is preferred over the Δ-Δ pair is similarly understood by noting that this pair corresponds to the $P(C_3)$-$P(C_3)$ combination. It will be evident from Table 2 that the results for *fac*-$[Co(\beta\text{-ala})_3]$ can be explained in the same way as for $[Cr(mal)_3]^{3-}$.

The Λ-enantiomers of $[Co(edta)]^-$ and $[Co(tdta)]^-$ preferentially associate with Δ-$[Co(en)_3]^{3+}$ and Δ-$[Co(sep)]^{3+}$ (see Table 2). Since these anions use the pseudo C_3 axes and the cations use their C_2 axes in chiral discrimination, the resulting pairs are the $M(C_2)$–M(pseudo C_3) combinations. The mode of ion pairing for the pair Δ-$[Co(edta)]^-\cdots\Delta$-$[Co(en)_3]^{3+}$ is shown schematically in Fig. 2. In Fig. 2, the Δ-$[Co(en)_3]^{3+}$ cation faces the Λ-$[Co(edta)]^-$ anion along the cation's

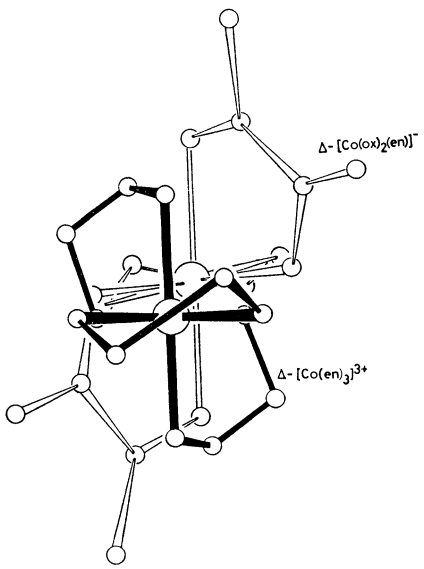

Fig. 1. Proposed structure for the preferred ion pair formed between Δ-$[Co(en)_3]^{3+}$ and Δ-$[Co(ox)_2(en)]^-$.

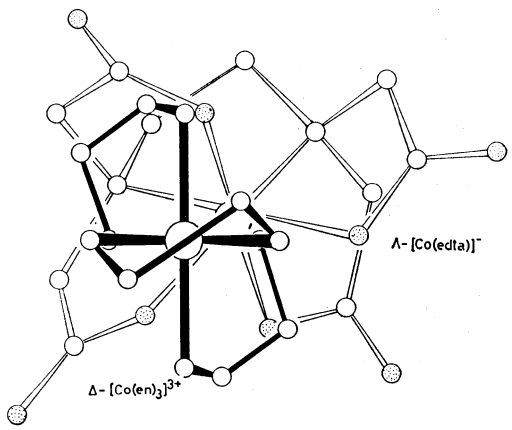

Fig. 2. Proposed structure for the favorable ion pair Δ-$[Co(en)_3]^{3+}\cdots\Lambda$-$[Co(edta)]^-$.

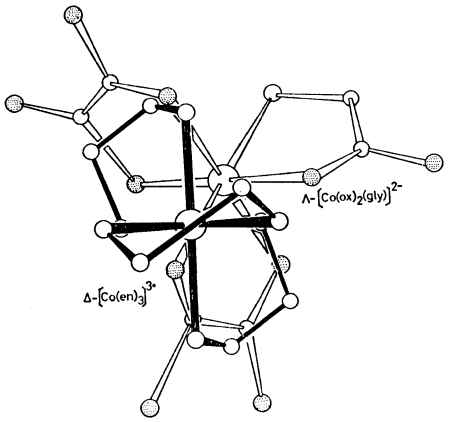

Fig. 3. Proposed mode of ion pairing between *Δ*-[Co(en)$_3$]$^{3+}$ and *Λ*-[Co(ox)$_2$(gly)]$^{2-}$.

C_2 axis and the anion faces the cation along the anion's pseudo C_3 axis with three anionic oxygen atoms. It can be seen from Fig. 2 that the chelate rings of both ions suffer less steric hindrance for the depicted *Δ*-*Λ* combination than for the *Δ*-*Δ* combination. Thus, the *Δ*-*Λ* combinations favored by these ions are again explained by a cozy fit of overlapping chelate rings. The formation of the favorable pair *Δ*-[Co{(−)-chxn}$_3$]$^{3+}$···*Δ*-[Co(edta)]$^-$ or *Δ*-[Co(tdta)]$^-$ can be explained in terms of the P(C_3)-P(pseudo C_3) pair; the propellers of both cation and anion have the same handedness when viewed along the C_3 or the pseudo C_3 axis.

The *Λ*-[Co(ox)$_2$(gly)]$^{2-}$ forms the favorable pairs with *Δ*-[Co(en)$_3$]$^{3+}$ and *Δ*-[Co(sep)]$^{3+}$ (see Table 2). By noting that [Co(ox)$_2$(gly)]$^{2-}$ uses its pseudo C_3 axis and the *Δ*-[Co(en)$_3$]$^{3+}$ cation uses its C_2 axis in chiral discrimination, the structure of the preferred ion pair formed between *Δ*-[Co(en)$_3$]$^{3+}$ and *Λ*-[Co(ox)$_2$(gly)]$^{2-}$ will be as illustrated in Fig. 3. The combination depicted in Fig. 3 is M(C_2)–M(pseudo C_3) and the handednesses of both ions, as viewed along the direction depicted, are the same. The preference of *Δ*-[Co(ox)$_2$(gly)]$^{2-}$ by *Δ*-[Co{(−)-chxn}$_3$]$^{3+}$ is explained in terms of the P(C_3)-P(psedo C_3) combination, namely by the same handedness of overlapping chelate rings.

In conclusion, all the elution orders in Table 2 are consistently explained, if we admit that (i) [Co(en)$_3$]$^{3+}$, [Co(sep)]$^{3+}$, [Co(ox)$_2$(en)]$^-$, and [Co(mal)$_2$(en)]$^-$ use their C_2 axes in chiral discrimination, (ii) [Co(chxn)$_3$]$^{3+}$, [Co(edta)]$^-$, [Co(tdta)]$^-$, [Co(ox)$_2$(gly)]$^{2-}$, and *fac*-[Co(*β*-ala)$_3$] use their C_3 or pseudo C_3 axes in chiral discrimination, and (iii) favorable pairs are formed between those ions that have the same handedness of chelate rings, when viewed along the above axes.

(Received June 29, 1982)

Cobalt(III) complexes containing (2*S*,2′*S*)-1,1′-ethylenedipyrrolidine-2,2′-dicarboxylate (*S,S*-epro) and a bidentate ligand were prepared and characterized. The bidentate ligands were ethylenediamine, trimethylenediamine, oxalate, glycinate, (*R*)- or (*S*)-alaninate, (*R*)- or (*S*)-valinate, (*R*)- or (*S*)-prolinate, (*R*)- or (*S*)-pipecolate, sarcosinate, or *N*-ethylglycinate. The *S,S*-epro ligand coordinates stereoselectively to cobalt(III) ion to take only the *Δ-sym* configuration. The stereochemistry was discussed on the basis of the electronic absorption, CD, and ^{1}H and ^{13}C NMR spectra. The rate constants of isomerization and the Gibbs' free energy difference (*ca.* 0.9 kJ mol^{-1}) between the *R*(*N*) and *S*(*N*) isomers of the sarcosinato or *N*-ethylglycinato complex were investigated in relation to the interligand interaction. The thermodynamics and mechanisms of their isomerization process were little influenced by the *N*-alkyl groups.

For most ethylenediamine-*N,N′*-diacetate (edda) complexes, the symmetric (*sym*) isomer is dominantly formed in comparison with the unsymmetric (*unsym*) one.[1-8] The *unsym* isomer isomerizes to the *sym* one in aqueous solution.[9-11] The formation of the *unsym* isomer for the edda complexes depends mainly on the bidentate ligand coordinated in the remaining two coordination sites,[5,9,12] the geometry of the starting complex,[13] and the reaction temperature.[6] However, the stereospecific formation of the complex with this type of ligand has not been clarified yet.[14]

The optically active quadridentate ligand in this work, (2*S*,2′*S*)-1,1′-ethylenedipyrrolidine-2,2′-dicarboxylate (*S,S*-epro), has two asymmetric carbon atoms and two pyrrolidine rings, although the ligand is an O–N–N–O type similar to the edda. Accordingly, the configurations of the *S,S*-epro ligand are regulated to only two, *Δ*-symmetric and *Λ*-unsymmetric, by coordination to cobalt(III) ion. This selective coordination is suitable for investigation of the stereochemical preference of the amino or cyclic imino carboxylate ligands in the remaining two coordination sites.

In the present paper, some aspects of the stereochemistry of the [Co(*S,S*-epro)(L)] type complexes are dealt with; L denotes ethylenediamine, trimethylenediamine, oxalate, glycinate, (*R*)- or (*S*)-alaninate, (*R*)- or (*S*)-valinate, (*R*)- or (*S*)-prolinate, (*R*)- or (*S*)-pipecolate ((*R*)- or (*S*)-2-piperidinecarboxylate, *R*- or *S*-pipec), sarcosinate (sar), or *N*-ethylglycinate (*N*-et-gly). The *S,S*-epro complexes isolated have been characterized from their electronic absorption, CD, and ^{1}H and ^{13}C NMR spectra. The absolute configurations of the coordinated nitrogen atoms of sar, *N*-et-gly, and *R*- or *S*-pipec were assigned by means of their ^{1}H NMR and CD spectra. The rate constants of isomerizations and the Gibbs' free energy differences are considered for the sar and *N*-et-gly complexes.

Experimental

1) Preparation of Ligands. (2*S*,2′*S*)-1,1′-Ethylenedipyrrolidine-2,2′-dicarboxylic acid was prepared from (*S*)-proline and 1,2-dibromoethane according to the method of Schoenberg *et al.*[15] Found: C, 45.80; H, 7.04; N, 8.82%. Calcd for $C_{12}H_{22}N_2O_4 \cdot 0.75NaCl \cdot H_2O$: C, 45.30; H, 6.97; N, 8.80%.

N-Ethylglycine was prepared by the procedure described previously.[16]

2) Δ-sym-*Ba*[*Co*(S,S-*epro*)(*Cl*)(*OH*)]$_2 \cdot C_2H_5OH$. The complex was prepared and separated by a procedure similar to that used for *Λ-unsym*-[Co(*S,S*-tmpro)(Cl)(OH)]$^-$ (where *S,S*-tmpro denotes (2*S*,2′*S*)-1,1′-trimethylenedipyrrolidine-2,2′-dicarboxylate).[16] The CD spectral pattern in the visible region suggested that the violet complex obtained has the *Δ-sym* configuration. Yield; 0.5 g.

3) Δ-sym-[*Co*(S,S-*epro*)(*en*)]$ClO_4 \cdot 2H_2O$. *Method A*: A solution containing 0.3 g of *trans*-[Co(Cl)$_2$(en)$_2$]Cl[17] and 0.33 g of *S,S*-H$_2$epro·0.75NaCl·H$_2$O in 20 cm^3 of water was adjusted to pH 8.0 by addition of 1 mol dm^{-3} NaOH aqueous solution. After addition of *ca.* 0.1 g of activated charcoal, the mixture was stirred at 50 °C for 30 min. The reaction solution was cooled to room temperature and then filtered. The filtrate was concentrated to a small volume and poured onto a column of SP-Sephadex C-25 (Na^+ form, 3 cm × 35 cm). The adsorbed band was separated into two bands, purple-red and yellow in the order of elution, by eluting with 0.05 mol dm^{-3} $NaClO_4$ aqueous solution. The yellow band remained at the top of the column after the purple-red band had been eluted out, and then the band was eluted with a solution saturated with NaCl. It was found, from the absorption and CD spectra, that the purple-red and yellow bands contained *Δ-sym*-[Co(*S,S*-epro)(en)]$^+$ and [Co(en)$_3$]$^{3+}$, respectively. The first eluate was concentrated to a small volume, and to the solution was added ethanol. The resulting crystals were collected and recrystallized from a water–methanol–ethanol (2:1:1) mixture. The needle crystals were collected, washed with ethanol and then ether, and dried in a vacuum desiccator. Yield: 0.24 g.

Method B: The complex was also prepared by the following procedure. A solution containing 0.27 g of $CoCl_2 \cdot 6H_2O$ in 5 cm^3 of water was added to a solution containing 0.06 g of ethylenediamine and 0.32 g of *S,S*-H$_2$epro·0.75-NaCl·H$_2$O in 6 cm^3 of water. To the solution was added 0.24 g of PbO_2 and the mixture was stirred at 50 °C for 3 h. The solution was cooled in an ice bath and then filtered. The filtrate was poured onto a column of Dowex

†† Present address: Tokuyama Soda Co., Ltd., Endo 2051, Fujisawa, Kanagawa 252.

50W-X8 (200—400 mesh, Na^+ form, 2 cm × 15 cm). The adsorbed band was eluted with 0.2 mol dm^{-3} $NaClO_4$ aqueous solution. It was found that the purple-red band contained only the complex, *Δ-sym*-[Co(*S,S*-epro)(en)]$^+$. The needle crystals were collected by filtration. Yield: 0.09 g.

4) Δ-sym-[*Co*(S,S-*epro*)(*tn*)]$ClO_4 \cdot 0.5C_2H_5OH$. The complex was prepared by the same method as in 3), using trimethylenediamine instead of ethylenediamine.

5) Δ-sym-*K*[*Co*(S,S-*epro*)(*ox*)]$\cdot 4H_2O$. This complex was prepared by a procedure similar to that in Method B of 3), using 1.34 g of $CoCl_2 \cdot 6H_2O$, 0.74 g of oxalic acid, and 1.79 g of *S,S*-H_2epro·0.75NaCl·H_2O. The solution obtained was poured onto a column of QAE-Sephadex A-25 (Cl^- form, 5 cm × 30 cm). The adsorbed band was eluted with 0.07 mol dm^{-3} KCl aqueous solution. The two blue-violet bands were eluted. It was found, from the absorption and CD spectra, that the first eluate contained *Δ-sym*-[Co(*S,S*-epro)(Cl)(OH)]$^-$ and the second one *Δ-sym*-[Co(*S,S*-epro)(ox)]$^-$. The second eluate was concentrated to a small volume with a rotary evaporator. To this solution was added ethanol and it was kept in a refrigerator overnight. The resulted needle crystals were collected and recrystallized from ethanol–water (5:1) mixture. Yield: 0.24 g.

6) Δ-sym-[*Co*(S,S-*epro*)(*gly*)]$\cdot 0.5H_2O$. This complex was prepared and separated by a procedure similar to that used for *Δ-unsym*-[Co(*S,S*-tmpro)(gly)].[16] By the column chromatographic separation, only one band was eluted with water and fractionated into six parts. It was found, from their absorption and CD spectra, that all the fractions contained only *Δ-sym*-[Co(*S,S*-epro)(gly)]. The fractions were combined and concentrated to a small volume. To the solution was added a small amount of ethanol and it was kept in a refrigerator overnight. The needle crystals were collected by filtration, and recrystallized from water by addition of ethanol and then acetone. Yield: 0.43 g.

7) Δ-sym-[*Co*(S,S-*epro*)(S-*ala*)]$\cdot H_2O$, -[*Co*(S,S-*epro*)(R-*ala*)]$\cdot H_2O$, -[*Co*(S,S-*epro*)(S-*val*)]$\cdot 1.5H_2O$, -[*Co*(S,S-*epro*)(R-*val*)], *and* -[*Co*(S,S-*epro*)(S-*pro*)]. These complexes were prepared by the same method as that used for *Δ-sym*-[Co(*S,S*-epro)(gly)].

8) Δ-sym-[*Co*(S,S-*epro*)(R(N)-*sar*)]$\cdot H_2O$ *and* -[*Co*(S,S-*epro*)(S(N)-*sar*)]$\cdot 0.5H_2O$. The solution containing *Δ-sym*-[Co(*S,S*-epro)(Cl)(OH)]$^-$ prepared from 2.4 g of $CoCl_2 \cdot 6H_2O$ was evaporated to dryness in a rotary evaporator below 30 °C, and the complex was extracted with 50 cm^3 of methanol. The methanol solution was added to a solution containing 1.2 g of sarcosine in 150 cm^3 of methanol. After addition of a small amount of activated charcoal, the mixture was stirred at 65 °C for 1 h. The solution was cooled to room temperature and then filtered. The filtrate was concentrated to a pasty cake and *ca.* 20 cm^3 of water was added to it. The solution was passed through columns of Dowex 1-X8 and SP-Sephadex C-25 in order to remove the charged compounds. The concentrated eluate was poured onto a column of QAE-Sephadex A-25 ((*R,R*)-tartrate form, 3.5 cm × 85 cm), and eluted with water. The adsorbed band was separated into three bands: violet, violet, and pink, in this order. It was found, from the absorption and CD spectra, that the first eluate contained *Δ-sym*-[Co(*S,S*-epro)(sar)] (the ratio of the *R*(*N*)-sar and *S*(*N*)-sar isomers was *ca.* 2:3), the second violet one contained *mer*-[Co(sar)$_3$], and the third pink one contained cobalt(II) compound. All the fractions of the first eluate were combined and evaporated to dryness below 30 °C. Yield: 1.1 g. This product was dissolved in methanol. After addition of appropriate volume of ether to it, the solution was kept in a refrigerator overnight. The complex consisted of two kinds of crystalline forms, needle and prism, which could be sorted by hand. It was found, from the absorption and ^{1}H NMR spectra, that the needle and prismatic crystals corresponded to the *R*(*N*)-sar and *S*(*N*)-sar isomers, respectively. Each of them was recrystallized repeatedly from methanol by addition of ether until a constant CD spectrum was obtained.

9) Δ-sym-[*Co*(S,S-*epro*)(R(N)-N-*et-gly*)]$\cdot 0.5H_2O$ *and* -[*Co*(S,S-*epro*)(S(N)-N-*et-gly*)]$\cdot 0.25H_2O$. The complex was prepared and separated into two diastereomers by the same procedure as in 8), using *N*-ethylglycine instead of sarcosine. Yield: 0.59 g. From the CD spectra, the reaction solution also contained the *R*(*N*)-*N*-et-gly and *S*(*N*)-*N*-*et-gly* isomers (the ratio: *ca.* 2:3).

10) Δ-sym-[*Co*(S,S-*epro*)(R-*pro*)]$\cdot 0.5H_2O$. The complex was prepared by the same procedure as in 8), using (*RS*)-proline instead of sarcosine. The complex was chromatographed on a column of QAE-Sephadex A-25 ((*R,R*)-tartrate form, 3.5 cm × 85 cm). The adsorbed band was eluted with water. The two bands, which partially overlapped, were fractionated into eight parts. It was found, from their absorption and CD spectra, that the four earlier fractions contained mainly *Δ-sym*-[Co(*S,S*-epro)(*R*-pro)], and the four later ones contained mainly *Δ-sym*-[Co(*S,S*-epro)(*S*-pro)], which was already prepared in 7). The four eariler fractions were combined and concentrated to a small volume and then chromatographed on the column again. This procedure was repeated several times in order to purify the complex. The eluate was concentrated to a small volume. After addition of ethanol and ether to it, the solution was kept in a refrigerator overnight. The crystals obtained were collected and then recrystallized from an ethanol–acetone (2:1) mixture several times. Yield: 0.09 g. The configuration of the α-carbon atom of the coordinated prolinate was confirmed by the DNP method.[16]

11) Δ-sym-[*Co*(S,S-*epro*)(R-*pipec*)]$\cdot H_2O$ *and* -[*Co*(S,S-*epro*)(S-*pipec*)]. These complexes were prepared and separated by a procedure similar to that in 10). The earlier eluate contained *Δ-sym*-[Co(*S,S*-epro)(*R*-pipec)] and the later one *Δ-sym*-[Co(*S,S*-epro)(*S*-pipec)]. The configuration of the asymmetric carbon atoms of the coordinated pipecolate were also determined by the DNP method.[16] Yields: 0.27 g for the *R*-pipec isomer and 0.015 g for the *S*-pipec one.

Analyses. The analytical results for the complexes obtained are summarized in Table 1.

Measurements. The electronic absorption spectra were recorded with JASCO UVIDEC-1 spectrophotometer and the CD spectra with JASCO J-20 spectropolarimeter in an aqueous solution. These spectra changed very little during the measurements. The ^{1}H NMR spectra were recorded on a JEOL FX-100 NMR spectrometer at probe temperature in three kinds of mixtures: $DClO_4$–CD_3OD, D_2O–$DClO_4$, and $(CD_3)_2SO$–DCl. The ^{13}C NMR spectra were recorded on JEOL FX-90Q NMR spectrometer in the D_2O solution. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) was used as an internal reference for the ^{1}H and ^{13}C NMR measurements.

The isomerization and the equilibrium and kinetic experiments were carried out using both the *R*(*N*) and *S*(*N*) isomers of *Δ-sym*-[Co(*S,S*-epro)(sar)] or -[Co(*S,S*-epro)(*N*-et-gly)]. The rate of CD change with time was measured for a methanol solution of each isomer (*ca.* 1.5×10^{-3} mol dm^{-3}) with JASCO J-500 spectropolarimeter. The runs were carried out in a quartz cell equipped with the water-jacket thermostated at 23.5 °C. The isomerization was followed until equilibrium was reached. The change in the CD intensity was observed at 300—650 nm.

Results and Discussion

Structural Assignments. Only two isomers, *Δ-sym* and *Δ-unsym*, are possible for [Co(*S,S*-epro)(en, tn, or ox)]$^{+\text{ or }-}$, because the *S,S*-epro ligand has two asymmetric carbon atoms, *S*(*C*) and *S*(*C*), and two pyrrolidine rings (Fig. 1). In the ^{13}C NMR spectra of the en and ox complexes, the seven peaks are expected for the *Δ-sym* isomer (C_2 symmetry), whereas fourteen peaks are expected for the *Δ-unsym* one (C_1 symmetry).

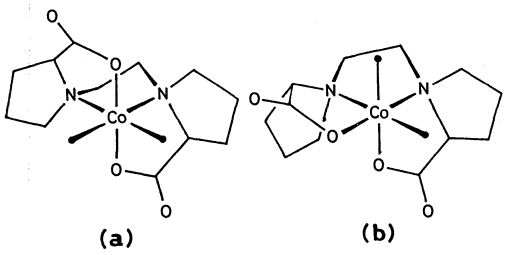

Fig. 1. Two possible configurations of coordinated *S,S*-epro ligand: (a) *Δ-sym* and (b) *Δ-unsym*.

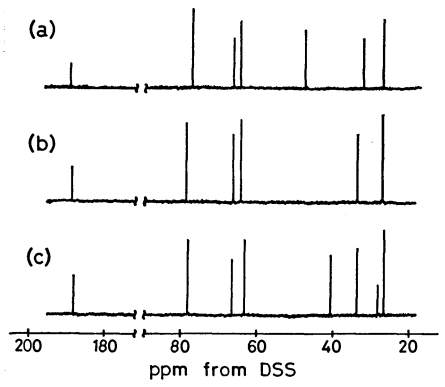

Fig. 2. ^{13}C NMR spectra of *Δ-sym*-[Co(*S,S*-epro)(L)]: L; (a) en, (b) ox, and (c) tn.

As shown in Fig. 2, however, the spectra of the en and ox isomers isolated show seven peaks and indicate that both the isomers are the *Δ-sym*. Similarly, the tn isomer is also the *Δ-sym* type, because it shows eight peaks (C_2 symmetry) (Fig. 2).

The absorption and CD spectra of the en and ox complexes are shown in Fig. 3. The first absorption band of the en and tn complexes have a shoulder at the higher energy side of the major peak (Table 2),

indicating the trans(O) structure.[1,6,7,11,18,19] The CD spectra of the en, tn, and ox complexes show the negative major band in the first absorption band region (Table 3). These absorption and CD spectral behaviors suggest that the en, tn and ox complexes commonly take *Δ* configuration.[4,19-21] From these results, the en, tn, and ox complexes isolated can be assigned to the *Δ-sym* configuration.

Of three possible isomers, *Δ-sym*, *Δ-unsym-mer*, and *Δ-unsym-fac*, for [Co(*S,S*-epro)(amino carboxylato)], only one isomer was selectively isolated for each of

Wave numbers and $\Delta\varepsilon$ values (in parentheses) are given in 10^3 cm^{-1} and mol^{-1} dm^3 cm^{-1}, respectively. sh denotes a shoulder.

the seven amino carboxylato complexes (Table 1). These isomers commonly show the broad first absorption band (Figs. 3—5 and Table 2). This absorption spectral pattern points out that the isomers are mer form, namely, Δ-*sym* and Δ-*unsym-mer*.[11,18] Furthermore, all the isomers exhibit a negative major CD band in the first absorption band region (Figs. 3—5 and Table 3). These facts suggest that the complexes isolated are only the Δ-*sym* configuration.[22]

The selective formation for the Δ-*sym* configuration was also observed for the [Co(*S*,*S*-epro)(L)] complexes (L: $(H_2O)_2$, CO_3, and $(Cl)(H_2O)$).[20] Molecular models reveal that the backbone ethylenediamine ring of the *S*,*S*-epro ligand takes a gauche form for the Δ-symmetric coordination, and an envelope form for the Δ-unsymmetric case. These results mean that the Δ-symmetric preference of the *S*,*S*-epro complexes depends mainly on the more stable conformation of the backbone ethylenediamine ring.[23]

^{1}H NMR and CD Spectra. When the *N*-alkyl substituted amino or cyclic imino carboxylate ligand coordinates to the cobalt(III) ion, the nitrogen atom of the ligand becomes chiral, *R*(*N*) or *S*(*N*). Accordingly, two additional isomers, *R*(*N*) or *S*(*N*), are possible for each of the Δ-*sym*-[Co(*S*,*S*-epro)(am)] complexes (am: sar, *N*-et-gly, *R*- or *S*-pro, and *R*- or *S*-pipec).

In the ^{1}H NMR spectra of the Δ-*sym*-[Co(*S*,*S*-epro)-

(am)] complexes, the resonance lines due to the *N*-bonded protons of the needle crystalline isomers appear at lower field than those of the prismatic crystalline ones (Fig. 6). The asymmetric nitrogen atom of the coordinated (*S*)-prolinate ligand is fixed to the *S*(*N*) configuration and that of the (*R*)-prolinate one is fixed to the *R*(*N*) one.[24] The *N*-bonded protons of the *S*(*N*) isomer for the *Δ-sym*-[Co(*S,S*-epro)(*S*-pro)] complex lies above the carbonyl group of the *S,S*-epro ligand (Fig. 7a-2), while that of the *R*(*N*) one lies in the plane involving the other carbonyl group of the ligand (Fig. 7a-1). In the region of the *N*-bonded protons, the resonance line of the *S*-pro complex (at 6.17 ppm) is observed at higher field than that of the *R*-pro one (at 6.40 ppm).[25] The *N*-bonded protons of the *R*(*N*) isomer of the sar, *N*-et-gly, or pipec complex are similar in environment to that of the (*R*)-prolinate, and those of the *S*(*N*) one to that

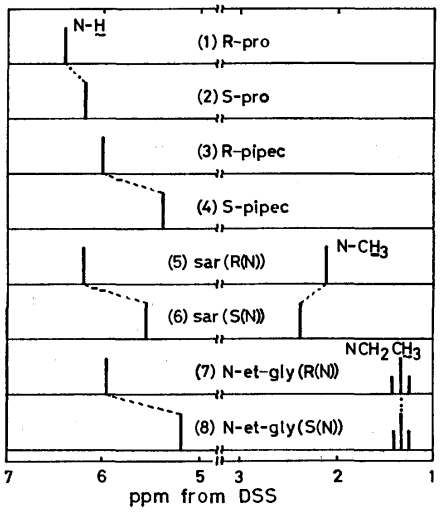

Fig. 6. The distribution of the chemical shifts due to the *N*-bonded and *N*-alkyl protons of *Δ-sym*-[Co(*S,S*-epro)(am)]. (1), (2), (7), and (8) were recorded in $DClO_4$–CD_3OD, (3) and (4) in $(CD_3)_2SO$–DCl, and (5) and (6) in D_2O–$DClO_4$.

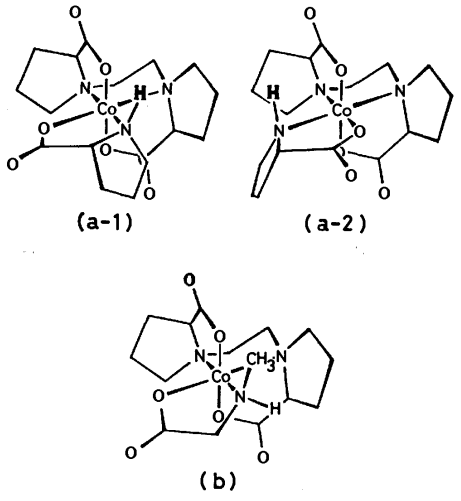

Fig. 7. Probable chiral configurations of the prolinate and sarconsinate ions in *Δ-sym*-[Co(*S,S*-epro)(L)]: L; (a-1) *R*-pro, (a-2) *S*-pro, and (b) *S*(*N*)-sar.

of the (*S*)-prolinate. Accordingly, it is suggested for the *Δ-sym*-[Co(*S,S*-epro)(am)] complexes that the needle crystalline isomers showing the signal at the lower field are the *R*(*N*) configuration and the prismatic crystalline ones at the upper field the *S*(*N*) one. Contrary to the case of the *N*-bonded protons, the resonance lines of the methyl group for the *R*(*N*) isomer of the *Δ-sym*-[Co(*S,S*-epro)(sar)] complex are observed at higher field than that of the *S*(*N*) one. This observation is also explained on the basis of the difference of the magnetic and steric environments of the methyl group.[25] Namely, the methyl group of the *R*(*N*) isomer lies above the carbonyl group of the *S,S*-epro ligand, whereas that of the *S*(*N*) one lies in the plane involving the other carbonyl group of the ligand (Fig. 7b).

In order to estimate the CD contribution of the asymmetric nitrogen atoms in the *Δ-sym*-[Co(*S,S*-epro)-(am)] complexes, the vicinal CD curves are calculated in the same manner as that for the cobalt(III) complexes with the *S,S*-tmpro ligand (Figs. 8 and 9).[16] The vicinal CD curves for the needle crystalline isomers for the sar, *N*-et-gly, and *R*-pipec complexes are similar to that of the *R*-pro complex and the curves of the prismatic ones for the sar, *N*-et-gly, and *S*-pipec complexes are similar to that of the *S*-pro one. Furthermore, the curves for the *R*-pro and *S*-pro complexes show an antipodal relationship in the first absorption band region (Figs. 8 and 9). These results also support the conclusion that the asymmetric nitrogen atoms of the needle and prismatic crystalline isomers take the *R*(*N*) and *S*(*N*) configurations, respectively.

Mutarotation and Equilibrium Distribution. The *R*-(*N*) and *S*(*N*) isomers of the *Δ-sym*-[Co(*S,S*-epro)(sar)] complex show a change of the CD spectra with time in methanol at ambient temperature (23.5 °C), as shown in Fig. 10. When either of the isomers was used as a starting substance, the identical CD curve with two distinct isodichroic points at 512 and 570

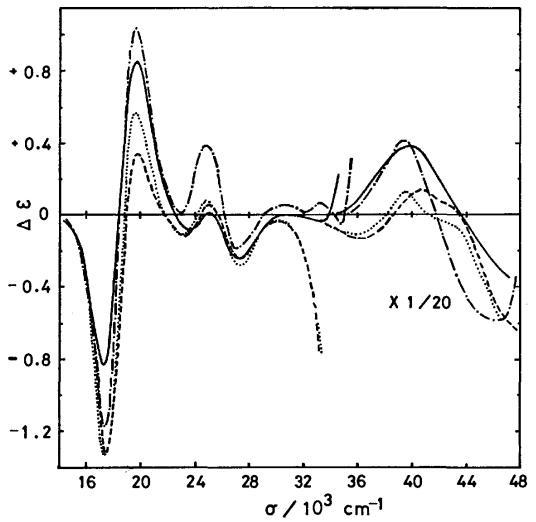

Fig. 8. Calculated vicinal CD curves due to the nitrogen atom of the bidentate ligand in *Δ-sym*-[Co(*S,S*-epro)(am)]: am; *S*(*N*)-sar (----), *S*(*N*)-*N*-et-gly (·····), *S*-pro (——), and *S*-pipec (—·—).

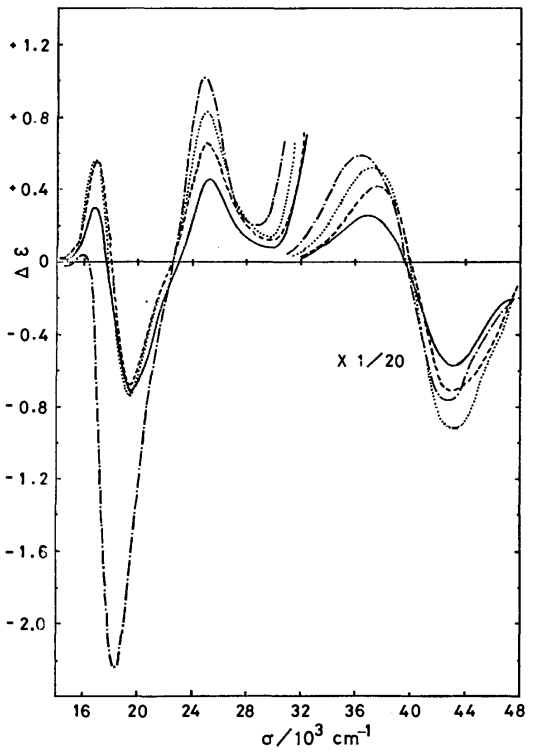

Fig. 9. Calculated vicinal CD curves due to the nitrogen atom of the bidentate ligand in *Δ-sym*-[Co(*S,S*-epro)(am)]: am; *R*(*N*)-sar (----), *R*(*N*)-*N*-et-gly (·····), *R*-pro (——), and *R*-pipec (—·—).

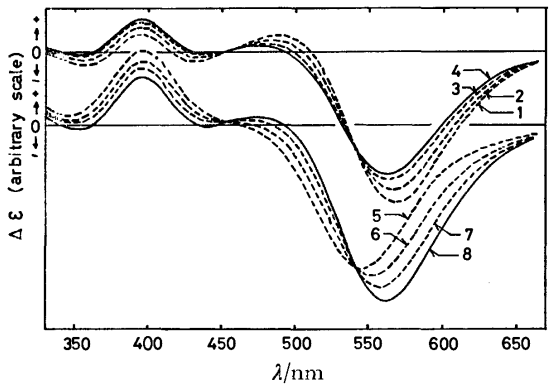

Fig. 10. Change of the CD spectra with time for the *S*(*N*)-sar (upper) and *R*(*N*)-sar (lower) isomers of *Δ-sym*-[Co(*S,S*-epro)(sar)] in methanol at 23.5 °C. The curves 1—4 were measured at 0, 465, 1265, and 3200 min, respectively, and the curves 5—8 at 0, 495, 1295, and 3300 min, respectively.

nm was obtained at equilibrium. No change was noticed with time in the absorption spectra for the two isomers; this fact indicates that mutarotation took place for the two isomers of the sar complex. Similar behavior was also observed for the *R*(*N*) and *S*(*N*) isomers of the *Δ-sym*-[Co(*S,S*-epro)(*N*-et-gly)] complex with two isodichroic points at 516 and 580 nm. These CD spectral characteristics show that epimerization takes place for these isomers at the asymmetric nitrogen atoms as follows:

$$R(N) \underset{k_{SR}}{\overset{k_{RS}}{\rightleftharpoons}} S(N),$$

where k_{RS} and k_{SR} denote the rate constants for the epimerization of the *R*(*N*) isomer to the *S*(*N*) one and of the *S*(*N*) isomer to the *R*(*N*) one, respectively.

The equilibrium constant, K_{eq}, for the epimerization reaction was determined by the CD spectral measurements to be 1.43±0.01 for the sar complex and 1.47±0.01 for the *N*-et-gly one. From these results, the free energy difference, $-\Delta G°$, between the *R*(*N*) and *S*(*N*) isomers could be estimated to be 0.88±0.02 kJ mol^{-1} for the sar complex and 0.95±0.02 kJ mol^{-1} for the *N*-et-gly one, respectively.

The rate constants for the epimerization are calculated from the equilibrium constant and the observed rate constant, k_{obsd}.

$$k_{obsd} = k_{RS} + k_{SR},$$
$$K_{eq} = k_{RS}/k_{SR}.$$

The k_{obsd} was obtained, using each of the two isomers as a starting substance, by the first-order kinetic study:

$$\ln X_e/(X_e - X_t) = k_{obsd} \cdot t,$$

where X_t and X_e stand for concentrations of the isomerized species at any time, *t*, and at equilibrium respectively. The values of k_{RS} and k_{SR}, therefore, were $(1.58\pm0.54)\times10^{-5}$ s^{-1} and $(1.11\pm0.39)\times10^{-5}$ s^{-1} for the sar complex, and $(0.96\pm0.45)\times10^{-5}$ s^{-1} and $(0.65\pm0.31)\times10^{-5}$ s^{-1} for the *N*-et-gly one, respectively.

Both the equilibrium and the kinetic results of the sar complex are in fair agreement with those of the *N*-et-gly one. This fact suggests that the thermodynamics and mechanisms of the isomerization process are little influenced by the size of the *N*-alkyl group on the asymmetric nitrogen atom. The $-\Delta G°$ value of *ca.* 0.9 kJ mol^{-1} for the sar and *N*-et-gly complexes is consistent with that of 1.72 kJ mol^{-1} for the *trans, cis*(*RR*) and *trans,cis*(*SS*) isomers of dichlorobis((*S*)-2-(methylaminomethyl)pyrrolidine)cobalt(III),[26] having two asymmetric nitrogen atoms.

It is interesting to point out from the equilibrium constant value (*ca.* 1.45) that the *N*-alkyl group prefers the *S*(*N*) configuration to the *R*(*N*) one. Inspection of models for the *R*(*N*) and *S*(*N*) isomers of the sar and *N*-et-gly complexes reveal that the *N*-alkyl groups of the *R*(*N*) isomer are in more close proximity to the quadridentate moiety than that of the *S*(*N*) one. It is inferred, therefore, that the preference of the *S*(*N*) configuration over the *R*(*N*) one can be related to an interligand interactions between the *N*-alkyl group and the *S,S*-epro ligand.

Steric Interaction. It was reported that the coordinated *R*- or *S*-pipec have an intrinsic tendency for the stereoselective coordination and take the *S*(*N*), *R*(*C*) and *R*(*N*),*S*(*C*) configurations, respectively.[16,27,28] In the *Δ-sym*-[Co(*S,S*-epro)(pipec)] complex, however, the *R*-pipec takes the *R*(*N*),*R*(*C*) configuration and the, *S*-pipec takes the *S*(*N*),*S*(*C*) one. This selective coordination can be explained in terms of the interligand interaction between the piperidine ring of the pipecolate and the pyrrolidine ring of the *S,S*-epro ligand. Namely, an inspection of the models suggests that the order of the interligand crowd for the possible isomers of the *Δ-sym*-[Co(*S,S*-epro)(*R*- or *S*-pipec)] complex is *S*(*N*),*R*(*C*)>*R*(*N*),*S*(*C*)>*S*(*N*),*S*(*C*)>*R*(*N*),*R*(*C*). This

consideration is supported by X-ray analysis results which show that the *Δ-sym*-[Co(*S*,*S*-epro)(*R*-pipec)], which is the major product, takes the *R*(*N*),*R*(*C*) configuration.[29]

(Received July 15, 1982)

Three kinds of [Co(terdentate-*N,O,S*)$_2$] type complexes were newly prepared; here terdentate-*N,O,S* denotes D-penicillaminate (D-pen), *S*-methyl-D-penicillaminate (D-smp) and *S*-methyl-L-cysteinate (L-smc). Each of the D-smp and L-smc complexes was chromatographically separated into three possible isomers; the D-pen complex was separated into two isomers. These isomers were characterized from their electronic absorption, CD and ^{1}H NMR spectra. Two isomers isolated for [Co(D-pen)$_2$]$^-$ were assigned to *trans(N)* and *trans(O)*, respectively, on the basis of the spectral behavior of the sulfur-to-metal charge transfer band and the reaction with dimethyl sulfate. Three isomers for [Co(D-smp)$_2$]$^+$ were derived from each of two isomers for [Co(D-pen)$_2$]$^-$ by the reaction with dimethyl sulfate. The electronic absorption and CD spectral behaviors are discussed in relation to the comparison of the thioether and thiolato type complexes.

Some cobalt(III) complexes with the thioether type terdentate-*N,O,S* ligands such as L-methionine and *S*-methyl-L-cysteine have been reported,[1-3] and the electronic absorption and CD spectral properties of the thioether type sulfur atom which takes *R* or *S* configuration by coordination have been investigated.[4,5] The contributions of the coordinated thiolato type sulfur atom to the electronic absorption and CD spectra would be interesting in comparison with those of the thioether type sulfur atom; but the electronic absorption and CD spectral behaviors have been little known.[6]

In the present paper, the cobalt(III) complexes with the thioether or thiolato type terdentate-*N,O,S* ligands, [Co(L-smc)$_2$]$^+$, [Co(D-smp)$_2$]$^+$ and [Co(D-pen)$_2$]$^-$, were prepared for the first time and their isomers were chromatographically separated. The three isomers for each of the L-smc and D-smp complexes are characterized from their electronic absorption spectra in comparison with the bis(L-methioninato)cobalt(III) complex, [Co(L-met)$_2$]$^+$.[1] The absolute configurations of the coordinated sulfur atoms for the L-smc and D-smp complexes are suggested on the basis of the ^{1}H NMR spectra. The two isomers for the [Co(D-pen)$_2$]$^-$ complex are assigned on the basis of the spectral behavior of their sulfur-to-metal charge transfer bands and the formation ratios of the D-smp isomers obtained by the reaction with dimethyl sulfate. The electronic absorption and CD spectra are mainly discussed in relation to the comparison of the thioether and thiolato type complexes. A preliminary report has been presented for the [Co(L-smc)$_2$]$^+$ complex.[7]

Experimental

1) Bis(S-methyl-L-cysteinato)cobalt(III) Perchlorate: [*Co(L-smc)$_2$]ClO$_4$*. Three isomers of [Co(L-smc)$_2$]$^+$ were isolated by a procedure similar to that used for those of [Co(L-met)$_2$]$^+$.[1] A solution containing 2.7 g of cobalt(II) chloride hexahydrate in 10 cm^3 of water was added to a hot solution (*ca.* 70 °C) containing *S*-methyl-L-cysteine (3.0 g) in 50 cm^3 of water, and to the mixture 0.5 g of activated charcoal was added. Eight grams of lead dioxide were gradually added to the mixture, which was mechanically stirred at *ca.* 70 °C for 20 min. After cooling to room temperature, the reaction mixture was filtered to remove the activated charcoal and any excess of lead dioxide. A saturated aqueous solution of sodium sulfate (1.5 g) was added to the filtrate and the lead sulfate precipitated was filtered off. The filtrate was poured onto a column of Dowex 50W-X8 (200—400 mesh, H$^+$ form). After the column had been swept with water, two eluates, violet (A-1) and red (A-2), were obtained by eluting with a 0.3 mol dm^{-3} aqueous solution of sodium perchlorate. Another eluate, blue-violet (A-3), was obtained quickly from the remaining adsorbed band by eluting with 0.5 mol dm^{-3} aqueous solution of sodium perchlorate, though the A-3 could be eluted with 0.3 mol dm^{-3} aqueous solution of sodium perchlorate. It was found, from the absorption and CD spectral measurements, that A-1, A-2, and A-3 were *trans(S)*, *trans(O)*, and *trans(N)* isomers, respectively. These eluates were separately concentrated to a small volume with a rotary evaporator at 30 °C and then the deposited sodium perchlorate was filtered off. To each of the filtrates was added a large amount of ethanol. The crude isomers from A-1 and A-3 were recrystallized from as little water as possible by cooling in an ice bath after adding an appropriate amount of ethanol. The isomer from A-2 was less soluble than the other two and was recrystallized from as little warm water (*ca.* 30 °C) as possible by cooling in an ice bath. The pure isomers were washed with ethanol and ether, and then dried in a vacuum desiccator over sulfuric acid. Found for *trans(S)* isomer (A-1): C, 21.70; H, 4.03; N, 6.32%. Found for *trans(O)* isomer (A-2): C, 21.50; H, 4.13; N, 6.08%. Found for *trans(N)* isomer (A-3): C, 21.33; H, 3.99; N, 6.17%. Calcd for [Co(L-smc)$_2$]ClO$_4$·H$_2$O=CoC$_8$H$_{16}$N$_2$O$_8$S$_2$Cl·H$_2$O: C, 21.70; H, 4.09; N, 6.32%.

2) Bis(S-methyl-D-penicillaminato)cobalt(III) Bromide: [*Co(D-smp)$_2$]Br*. This complex was prepared by the reaction of bis(D-penicillaminato)cobalt(III) complex (*vide infra*) with dimethyl sulfate. About 10 cm^3 of dimethyl sulfate was added drop by drop to a solution containing 1 g of the brown isomer of [Co(D-pen)$_2$]$^-$ in 10 cm^3 of water and the mixture was mechanically stirred for a few minutes. When the mixture had been allowed to stand at room temperature for a while, it was separated into two layers, a brown (upper) layer and a cloudy colorless (lower) layer. The former changed gradually to reddish violet. After being allowed

† Present address: TDK Electronic Co., Ltd., 2-14-6, Uchikanda, Chiyoda-ku, Tokyo 101.

††† Present address: Department of Chemistry, Okayama University of Science, 1-1, Ridai-cho, Okayama 700.

to stand at room temperature for about 6 h, the reddish violet solution was separated and poured onto a column (3.5 cm×30 cm) of Dowex 50W-X8 (200—400 mesh, NH_4^+ form). After the column had been swept with water, the adsorbed reddish violet band was eluted with a 0.05 mol dm^{-3} aqueous solution of ammonium bromide. Three bands, dark red (B-1), reddish violet (B-2), and red (B-3), were progressively eluted in this order. Their absorption spectral measurements showed that B-1, B-2, and B-3 were *trans*-(*O*), *trans*(*N*), and *trans*(*S*) isomers, respectively. The eluates were separately concentrated with a rotary evaporator below 20 °C. The ammonium bromide deposited was filtered off and a small amount of acetone was added to the filtrate. The three isomers obtained were recrystallized from as little water as possible by adding acetone. The isomers were washed with ethanol, acetone and ether, and then dried in a vacuum desiccator over calcium chloride. Found for *trans*(*O*) isomer (B-1): C, 31.11; H, 5.25; N, 6.07%. Found for *trans*(*N*) isomer (B-2): C, 30.25; H, 5.29; N, 6.05%. Calcd for $[Co(D\text{-smp})_2]Br=CoC_{12}H_{24}N_2O_4S_2Br$: C, 31.11; H, 5.25; N, 6.05%. Found for *trans*(*S*) isomer (B-3): C, 28.23; H, 5.66; N, 5.59%. Calcd for $[Co(D\text{-smp})_2]Br\cdot 2H_2O$: C, 28.26; H, 5.61; N, 5.65%.

Similarly, the green isomer of $[Co(D\text{-pen})_2]^-$ gave three isomers of $[Co(D\text{-smp})_2]^+$ by the reaction with dimethyl sulfate. However, the formation ratio of the three D-smp isomers derived from the green isomer of $[Co(D\text{-pen})_2]^-$ differs from that of the three isomers from the brown isomer of $[Co(D\text{-pen})_2]^-$; *trans*(*O*):*trans*(*N*):*trans*(*S*)=20:65:15 for the D-smp isomers derived from the brown isomer and 69:18:13 from the green isomer. It seems that the difference in formation ratio reflects the geometrical configuration of $[Co(D\text{-pen})_2]^-$ which is the starting complex.

3) Potassium Bis(D-penicillaminato)cobaltate(III): *K[Co(D-pen)$_2$]*. *Method A*: To a solution containing 1.6 g of cobalt(II) chloride hexahydrate in 10 cm^3 of water was added 2.0 g of D-penicillamine. After the mixture was stirred for a few minutes, the pH was adjusted to *ca.* 7 by the addition of 3.0 mol dm^{-3} aqueous solution of potassium hydroxide. The color of the solution changed from red to brown. After the reaction mixture had been allowed to stand at room temperature for about 6 h, a small amount of acetone was added to it. Then it was kept in a refrigerator overnight. Brown needle crystals (C-1) deposited. These crystals were collected by filtration, washed with ethanol and ether, and then dried in a vacuum desiccator over calcium chloride. Found for brown isomer (C-1): C, 27.18; H, 5.19; N, 6.48%. Calcd for $K[Co(D\text{-pen})_2]\cdot 2H_2O=KCoC_{10}H_{18}N_2O_4S_2\cdot 2H_2O$: C, 27.99; H, 5.19; N, 6.53%.

The filtrate was poured onto a column (3.5 cm×30 cm) of Dowex 1-X8 (100—200 mesh, Cl^- form) in order to see the formation of the other isomers of $[Co(D\text{-pen})_2]^-$. After the column had been swept with water, the adsorbed brown band was eluted with a 0.07 mol dm^{-3} aqueous solution of potassium chloride. The eluate of a broad band was collected in 10 cm^3 portions in a fraction collector. The absorption and CD spectral measurements indicated that the eluate contained two kinds of complexes. The earlier fractions contained a complex which did not have the sulfur-to-metal charge transfer band (*ca.* 33.0×10^3 cm^{-1})[1,2] and the later fractions showed the same spectra as that of the brown crystalline complex isolated before.

Method B: A hot solution (*ca.* 60 °C) containing 1 g of $[Co(NH_3)_6]Cl_3$[8] in 30 cm^3 of water was adjusted to pH 7 with 3.0 mol dm^{-3} aqueous solution of sodium hydroxide. To this solution were added 2 g of D-penicillamine and 0.5 g of activated charcoal. The mixture was mechanically stirred at 60 °C for 15 min. The reaction mixture was filtered in order to remove activated charcoal after cooling to room temperature. The filtrate was poured onto a column (4 cm×60 cm) of QAE-Sephadex A-25 (Cl^- form). After the column had been swept with water, the adsorbed brown band was eluted with 0.1 mol dm^{-3} aqueous solution of potassium chloride. Five colored bands: brown (C-1), yellow, red brown, dark green, and green (C-2), were eluted in this order. Of these five eluates, the brown (C-1) and green (C-2) eluates produced the thioether type complexes by the reaction with dimethyl sulfate, but the remaining ones did not. These results and the absorption spectral measurements suggest that the brown and green eluates contained the desired complex and the remaining three did not. The brown (C-1) eluate showed the same absorption and CD spectra as the isomer isolated in Method A. The green (C-2) eluate was concentrated to a small volume with a rotary evaporator below 20 °C and the deposited potassium chloride was filtered off. A small amount of acetone was added to the filtrate. The green complex obtained was recrystallized from a small amount of water by adding acetone. The complex was washed with ethanol and ether, and then dried in a vacuum desiccator over calcium chloride. Found for the green isomer (C-2): C, 20.19; H, 4.07; N, 4.85%. Calcd for $K[Co(D\text{-pen})_2]\cdot 3H_2O\cdot 2KCl$: C, 20.19; H, 4.06; N, 4.71%.

4) Potassium (L-Penicillaminato)(D-penicillaminato)cobaltate(III): *K[Co(L-pen)(D-pen)]*. This complex was prepared by the method of Hodgson *et al.*[9] Found: C, 29.12; H, 4.92; N, 6.84%. Calcd for $K[Co(L\text{-pen})(D\text{-pen})]\cdot H_2O=KCoC_{10}H_{18}N_2O_4S_2\cdot H_2O$: C, 29.26; H, 4.91; N, 6.82%.

Measurements. The electronic absorption spectra were recorded with a JASCO UVIDEC-1 spectrophotometer, and the CD spectra with a JASCO J-20 spectropolarimeter. All measurements were carried out in an aqueous solution at room temperature.

The ^1H NMR spectra were recorded in deuterium oxide on a JEOL JNM-MH-100 or FX-100 NMR spectrometer at the probe temperature. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) was used as an internal reference.

Results and Discussion

Structural Assignments. Three geometrical isomers are possible for the present [Co(terdentate-*N*,*O*,*S*)$_2$] type complex. The isomers are designated as *trans*(*S*), *trans*(*O*), and *trans*(*N*) with respect to the coordinated atoms, N, O, and S (Fig. 1). The three isomers were chromatographically isolated for each of $[Co(L\text{-smc})_2]^+$ and $[Co(D\text{-smp})_2]^+$, and only two isomers for $[Co(D\text{-pen})_2]^-$. Their absorption and CD spectra are shown in Figs. 2—6 and are summarized in Tables 1 and 2. Of the three isomers for $[Co(L\text{-smc})_2]^+$, the first eluted

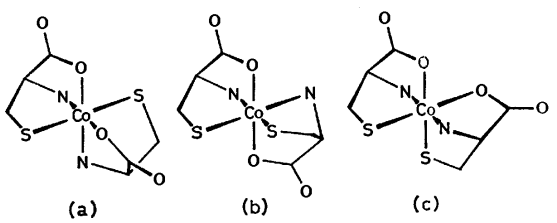

Fig. 1. Three possible isomers of [Co(terdentate-*N*,*O*,*S*)$_2$] type complexes: (a) *trans*(*S*), (b) *trans*(*O*), and (c) *trans*(*N*).

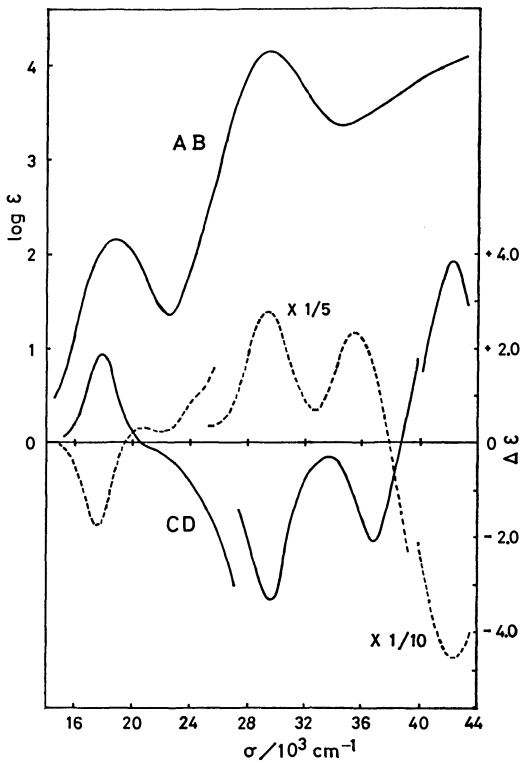

Fig. 2. Absorption and CD spectra of *trans*(*S*)-[Co(L-smc)$_2$]$^+$ (——) and *trans*(*S*)-[Co(D-smp)$_2$]$^+$ (----).

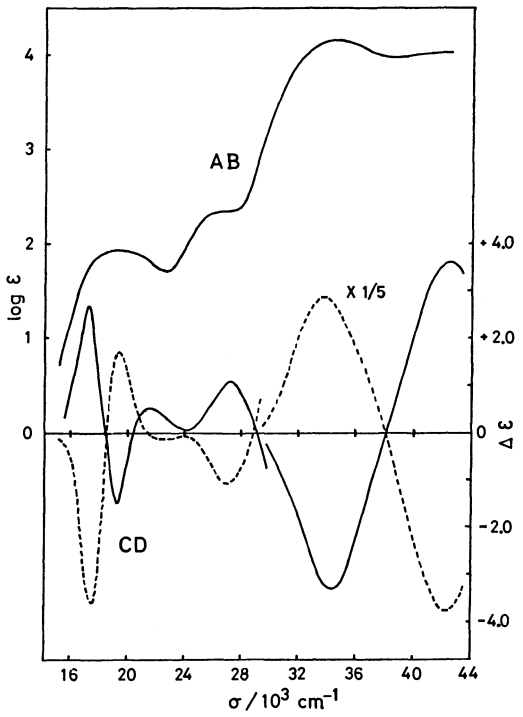

Fig. 3. Absorption and CD spectra of *trans*(*O*)-[Co(L-smc)$_2$]$^+$ (——) and *trans*(*O*)-[Co(D-smp)$_2$]$^+$ (----).

A-1, whose sulfur-to-metal charge transfer band is located at lower energy (29.47×10^3 cm^{-1}) than those of the remaining two isomers (34.47×10^3 cm^{-1} for A-2 and 32.13×10^3 cm^{-1} for A-3),[1,2] was determined to be the *trans*(*S*) isomer by the X-ray crystal structure analysis.[10] The absorption spectra of the isomers for

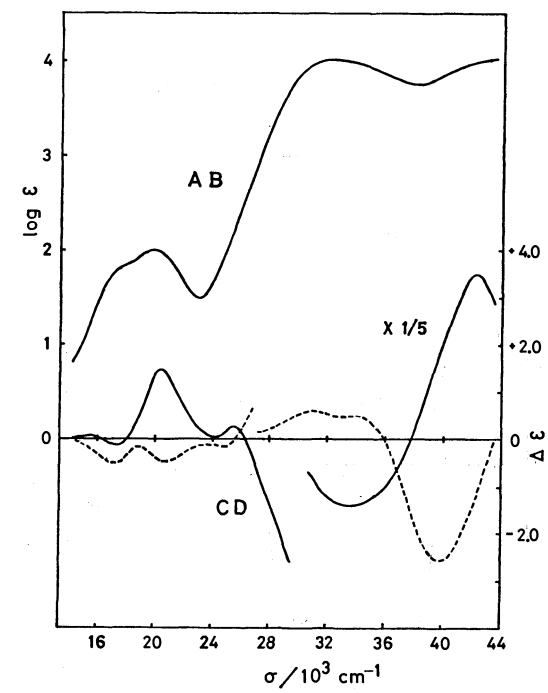

Fig. 4. Absorption and CD spectra of *trans*(*N*)-[Co(L-smc)$_2$]$^+$ (——) and *trans*(*N*)-[Co(D-smp)$_2$]$^+$ (----).

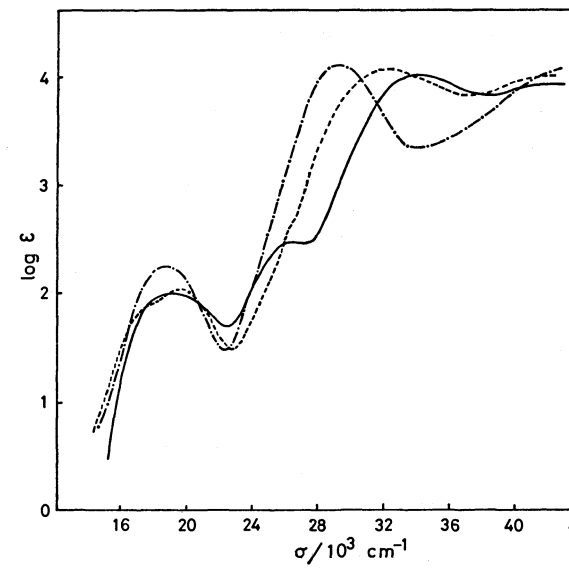

Fig. 5. Absorption spectra for the isomers of [Co(D-smp)$_2$]$^+$: *trans*(*O*) (——), *trans*(*N*) (----), and *trans*(*S*) (—·—).

[Co(L-smc)$_2$]$^+$ correspond quite well with those of the [Co(L-met)$_2$]$^+$ complex,[1] respectively, over the whole region (Figs. 2—4 and Table 1). Accordingly, A-1 can be assigned to *trans*(*S*), A-2 to *trans*(*O*), and A-3 to *trans*(*N*). The same consideration for the absorption spectra of the [Co(L-smc)$_2$]$^+$ isomers is also valid for those of the three isomers, B-1, B-2 and B-3, of [Co(D-smp)$_2$]$^+$ derived from the isomers, C-1 and C-2, of [Co(D-pen)$_2$]$^-$. In the first absorption band region, B-1 shows a broad band with a vague shoulder on the higher energy side, B-2 a band with an explicit shoulder on the lower energy side, and B-3 apparently a sharp band (Fig. 5 and Table 1). These splittings of the first absorp-

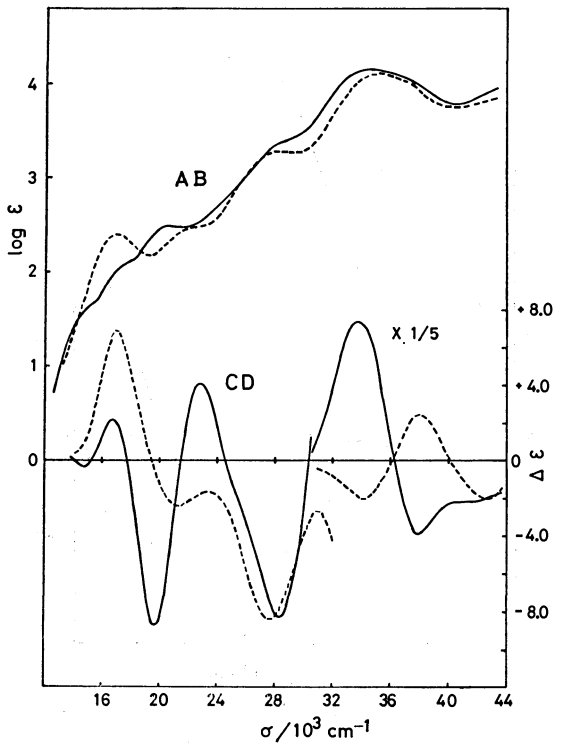

Fig. 6. Absorption and CD spectra of *trans*(*N*)-[Co(D-pen)$_2$]$^-$ (——) and *trans*(*O*)-[Co(D-pen)$_2$]$^-$ (----).

tion bands agree well with those which can be expected from the semiempirical calculation[11] on the basis of the ligand field order $N>S>O$.[2,3] Furthermore, the sulfur-to-metal charge transfer band of B-3 (29.33×10^3 cm^{-1}) locates at lower energy side than those of the remaining two isomers (34.27×10^3 cm^{-1} for B-1 and 32.40×10^3 cm^{-1} for B-2).[1,2] These facts indicate that B-1 is *trans*(*O*), B-2 *trans*(*N*), and B-3 *trans*(*S*).

Of three possible isomers for [Co(D-pen)$_2$]$^-$, only two isomers were obtained, though several preparative methods were attempted. The absorption spectral behavior of [Co(D-pen)$_2$]$^-$, which belongs to [Co(N)$_2$(O)$_2$(S)$_2$] type having two thiolato groups instead of thioether ones, differs from those of [Co(L-smc)$_2$]$^+$ and [Co(D-smp)$_2$]$^+$ (Fig. 6 and Table 1). The notable difference is observed in the region of $(27.0—28.5)\times10^3$ cm^{-1} (*vide infra*).

In the first absorption band region, the splitting for C-1 differs strikingly from that for C-2. Namely, the first absorption band of C-1 is composed of three components (14.1, 17.1 and 20.53×10^3 cm^{-1}) and that of C-2 two components (17.10 and 22.0×10^3 cm^{-1}). However, from the absorption spectral difference in the first absorption band region, it is difficult to distinguish their geometrical structures at present. Recently, it was recognized also for the geometrical isomers having two thiolato donor atoms that the sulfur-to-metal charge transfer band of *trans*(*S*) isomer appears at lower energy than that of *cis*(*S*) one as the case of thioether type complex.[6] The charge transfer bands of the present two isomers are close in maximum position to each other (Fig. 6 and Table 1), specifically, the band of C-1 locates at 33.80×10^3 cm^{-1} and that of C-2 at 34.93×10^3 cm^{-1}. In addition to this fact, *cis*·*cis*·*cis*-[Co(L-pen)(D-pen)]$^-$, which was determined by the X-ray crystal structure analysis,[9] shows the corresponding charge transfer band at 33.77×10^3 cm^{-1}. Taking these facts into consideration, it is probable that the two isomers isolated are *cis*(*S*) rather than *trans*(*S*).

All isomers of the present complexes isomerized in water as was the case of cobalt(III) complexes with terdentate amino carboxylate ligands[12-14] and each isomer generated the mixture of the three isomers after a few days. The isomerization is conspicuous for the isomers of [Co(D-smp)$_2$]$^+$ in comparison with those of [Co(L-smc)$_2$]$^+$ and [Co(L-met)$_2$]$^+$. The three isomers of [Co(D-smp)$_2$]$^+$ were derived from C-1 and from C-2 of [Co(D-pen)$_2$]$^-$. Accordingly, it is probable that the reaction of the coordinated thiolato donor atoms

	22.27(−0.12)		
trans(*N*)-[Co(D-smp)$_2$]$^+$	17.17(−0.53)	24.87(−0.14)	31.07(+3.11)
	20.73(−0.48)		33.93(+2.55)
			39.87(−12.9)
trans(*S*)-[Co(D-smp)$_2$]$^+$	17.60(−1.76)		29.47(+14.1)
	20.73(+0.32)		35.60(+11.6)
			42.40(−46.3)
trans(*N*)-[Co(D-pen)$_2$]$^-$	14.83(−0.34)	22.83(+4.17)	33.73(+36.9)
	16.73(+2.24)	28.40(−8.27)	37.93(−19.5)
	19.73(−8.68)		41.00(−10.7)
trans(*O*)-[Co(D-pen)$_2$]$^-$	17.03(+6.96)	27.67(−8.43)	34.13(−10.2)
	21.27(−2.43)		38.03(+12.5)
			42.60(−10.0)

Wave numbers and $\Delta\varepsilon$ values (in parentheses) are given in 10^3 cm^{-1} and mol^{-1} dm^3 cm^{-1}, respectively.

of [Co(D-pen)$_2$]$^-$ with dimethyl sulfate was accompanied by the isomerization. In the preparations, the *trans*(*N*) isomer formed dominantly for the [Co(D-smp)$_2$]$^+$ complex derived from C-1 and the *trans*(*O*) isomer for the complex from C-2, as described in the experimental section. These results suggest that *trans*-(*N*) is preferable for C-1 and *trans*(*O*) for C-2. In addition, considering the fact that the thiolato type ligand prevents the formation of *trans*(*S*) isomer because of the trans effect,[6] it is tentatively assigned that C-1 is *trans*(*N*) and C-2 *trans*(*O*).

^{1}H NMR and CD Spectra. The ^{1}H NMR spectra of *trans*(*S*)-[Co(L-smc)$_2$]$^+$ and -[Co(D-smp)$_2$]$^+$ show a single peak in the *S*-methyl proton region (2.22 ppm for the L-smc isomer and 2.16 ppm for the D-smp one), like that of *trans*(*S*)-[Co(L-met)$_2$]$^+$.[1] In the column chromatographic separation of the *trans*(*S*) isomers, all the fractions of each isomer showed the same CD spectra. The X-ray crystal structure analysis[10] showed that the two coordinated sulfur atoms of *trans*(*S*)-[Co(L-smc)$_2$]$ClO_4 \cdot H_2O$ take the *S*(*S*),*S*(*S*) configuration which has C_2 symmetry. These results suggest that the two sulfur atoms in *trans*(*S*)-[Co(D-smp)$_2$]$^+$ take selectively the *R*(*S*),*R*(*S*) configuration. In contrast with the *trans*(*S*) isomers, the ^{1}H NMR spectra of the *trans*(*N*) and *trans*(*O*) isomers suggest that each of them is a mixture of some configurations of the coordinated sulfur atoms. The *trans*(*N*) isomer shows three signals due to *S*-methyl protons (2.16, 2.09, and 2.00 ppm) for [Co(L-smc)$_2$]$^+$ and two signals (2.12 and 2.04 ppm) for [Co(D-smp)$_2$]$^+$. Inspection of models concerning the crowd of *S*-methyl groups of the ligand coordinated suggests that *trans*(*N*)-[Co(L-smc)$_2$]$^+$ consists of *S*(*S*),-*S*(*S*), and *R*(*S*),*S*(*S*) configurations, and *trans*(*N*)-[Co(D-smp)$_2$]$^+$ of *R*(*S*),*S*(*S*) and *R*(*S*),*R*(*S*) ones. The *trans*(*O*) isomer shows two signals (2.29 and 2.18 ppm) for [Co(L-smc)$_2$]$^+$ and three signals (2.22, 2.18, and 2.12 ppm) for [Co(D-smp)$_2$]$^+$. Similarly, model inspections suggest that *trans*(*O*)-[Co(L-smc)$_2$]$^+$ and -[Co(D-smp)$_2$]$^+$ are a mixture of *S*(*S*),*S*(*S*), *R*(*S*),*S*(*S*), and *R*(*S*),*R*(*S*) configurations, respectively. These ^{1}H NMR spectral behaviors of the *trans*(*N*) and *trans*(*O*) isomers are also similar to that of the corresponding isomers of [Co(L-met)$_2$]$^+$.[1] In the present [Co(terdentate-*N*,*O*,*S*)$_2$] type complex having two thioether groups, it should be noted that only the *trans*(*S*) isomer shows a distinguishable selectivity concerning the orientation of *S*-methyl groups; the reason for this selectivity is unknown at present.

The CD spectra of the [Co(D-smp)$_2$]$^+$ isomers are almost enantiomeric to those of the [Co(L-smc)$_2$]$^+$ ones, respectively, reflecting the similarity of their rigid frameworks (Figs. 2—4 and Table 2). The CD spectral behavior of the [Co(D-pen)$_2$]$^-$ isomers is in contrast to those of the [Co(D-smp)$_2$]$^+$ and [Co(L-smc)$_2$]$^+$ ones (Fig. 6 and Table 2). In the first absorption band region, the *trans*(*O*)-[Co(D-pen)$_2$]$^-$ isomer shows two CD bands corresponding to two absorption components, and the *trans*(*N*) isomer clearly shows three CD bands corresponding to three absorption components. In the sulfur-to-metal charge transfer band region ((33—35) $\times$ 10^3 cm^{-1}), the *trans*(*N*) and *trans*(*O*) iso-

mers show enantiomeric CD patterns. The absorption and CD spectra in the region of $(27—28)\times10^3$ cm^{-1} are noted as a characteristic difference of the thiolato and thioether type complexes. In this region, each of the D-pen isomers shows an extra band (at 28.30×10^3 cm^{-1} for *trans*(*O*) and 28.0×10^3 cm^{-1} for *trans*(*N*)) which does not appear for the spectra of the thioether type complexes, and the CD bands in this region commonly have a negative sign. Similar absorption and CD spectral behaviors were also observed for the three isomers of $[Co(L\text{-pen})(dien)]^+$.[15] These absorption bands seem to be characteristic for the thiol coordination of the pen ligand, and the sign of the CD band in the corresponding region seems to depend on the absolute configuration (*R*(*C*) or *S*(*C*)) of the optically active penicillaminate coordinated.

The Reaction of Thio-substituted Cyclopropenium Ions with Sulfonium Methylide

Shinichi INOUE* and Takuya HORI

Department of Applied Chemistry, Aichi Institute of Technology, Yagusa-cho, Toyoda, Aichi 470-03

(Received January 21, 1982)

The reaction between thio-substituted cyclopropenium ions and sulfonium methylides gives unanticipated ketene derivatives. This reaction is supposed to proceed through an intermediate sulfonium salt formed from ylide addition to the cyclopropenyl ring.

Recently, interest has focused on the hetero-atom-substituted three-membered rings because of their highly strained character, and a number of interesting reactions have been reported.[1,2] Among them, a variety of reactions of nitrogen-atom-substituted cyclopropenium compounds were studied.[3] We have recently reported the formation of both cyclopropenimines and *N,N'*-dicyclopropenylidenureas.[4] In reactions of nitrogen-atom-substituted cyclopropenium ions with ylides, ring-opened products were not detected and they were supposed to arise exclusively from the nucleophilic substitution reaction. In this paper, we shall describe the reaction[5] between thio-substituted cyclopropenium ions and sulfonium methylide, and an elucidation of the reaction mechanism.

Results and Discussion

When a mixture of **1a** and **2a** (molar ratio of 1 to 4) in THF was treated at room temperature for 8 h under He atmosphere, bis(ethylthio)ketene (**3a**) was obtained. The structure of **3a** was established from its spectroscopic data as well as its elemental analysis. It was found to be identical with a compound prepared by the reaction of bis(ethylthio)acetyl chloride with triethylamine according to the method[6] for the preparation of bis(alkylthio)ketene. Consequently the structure **3a** is assigned to the product.

While the reaction of **1b** with **2a** in THF give predominantly or exclusively the product **3b**, a small amount of compound **4b** is also produced. The ^{1}H-NMR spectrum of **4b** was found to be identical with that of tetrakis(*t*-butylthio)allene.[7] We, therefore, have investigated the reaction of **1** with **2** under various conditions, because it is known that the allene may arise *via* a cyclopropenylidene intermediate. A compound formed by the reaction between **1e** and **2a** was identified as **4b**. The expected **4a** was not found in the reaction mixture of **1d** and **2c** in THF although ketene **3a** was given. No tetrakis(*p-t*-butylphenylthio)-allene, which would be formed along with the corresponding ketenes from reactions of **1c** and **1f** with **2a**, **2b**, and **2c**, was detected. The equation of the reactions between thio-substituted cyclopropenium ions (**1**) and sulfonium methylide (**2**) can be written as in Scheme 1.

The conditions employed for obtaining **3a** in the preliminary work can be applied to the reactions of other thio-substituted cyclopropenium ions. These results are summarized in Table 1. The generation of **3** from the reaction between thio-substituted cyclopropenium ions and sulfonium methylides showed that the original ylide-carbonyl oxygen remains intact in the ketene. This ketene skeleton seems to be composed of the ylide carbon and the ylide-carbonyl group.

All attempts to produce allenes by the reactions of **1a**, **1e**, **1d**, and **1f** and **2a**—**c** have failed. The ketenes were the only products obtained.

When the reaction of **1a** with **2a** (molar ratio of 1 to 1) was carried out in THF at −5 °C for 8 h under He atmosphere, [[tris(ethylthio)cyclopropenyl](ethoxycarbonyl)methyl]dimethylsulfonium perchlorate (**5a**) was isolated in 7.5% yield, along with **3a**. The structure of **5a** was inferred on the basis of the results of

the elemental analysis as well as its ^{1}H-NMR spectrum which has a methyl-singlet at δ 3.15 (6H) and ethyl-signals at δ 1.50 (9H, t), 3.05 (4H, q), and 4.18 (2H, q) in addition to signals for ester group at δ 1.35 (3H, t) and 3.40 (2H, q). Under similar conditions, [[tris(*t*-butylthio)cyclopropenyl]-(**5c**) and [[tris(*p*-*t*-butylphenylthio)cyclopropenyl](ethoxycarbonyl)methyl]dimethylsulfonium perchlorates (**5e**) were isolated in 4.8 and 7.3% yields, respectively.

Likewise, **1d** reacts with **2a** and **2c** in THF at 0 °C for 6 h giving [[tris(ethylthio)cyclopropenyl](ethoxycarbonyl)methyl]dimethylsulfonium tetrafluoroborate (**5g**) and [[tris(ethylthio)cyclopropenyl](ethylthiocarbonyl)methyl]dimethylsulfonium tetrafluoroborate (**5h**), respectively.

Thus, an attempt was made to prepare the sulfonium intermediate **5** by the nucleophilic addition reaction. When the reaction of **1a** with **2a** (molar ratio of 1 to 1) was performed in dry THF at −40 °C for 6 h under He atmosphere, the sulfonium salt **5a** was obtained in good yield. Similarly, reactions of **1b—e** with **2a** and **2c** gave the corresponding sulfonium salts, such as [[tris(ethylthio)cyclopropenyl]-(ethylthiocarbonyl)methyl]dimethylsulfonium perchlorate (**5b**), **5c**, [[tris(*t*-butylthio)cyclopropenyl](ethylthiocarbonyl)methyl]dimethylsulfonium perchlorate (**5d**), **5e**, **5g**, **5h**, [[tris(*t*-butylthio)cyclopropenyl](ethoxycarbonyl)methyl]dimethylsulfonium tetrafluoroborate (**5i**), and [[tris(*t*-butylthio)cyclopropenyl](ethylthiocarbonyl)methyl]dimethylsulfonium tetrafluoroborate (**5j**). However, no sulfonium salt, which would be formed from the reaction of **1f**, was detected. Results are summarized in Table 2. The structures of the sulfonium salts **5** were determined by elemental analyses, ^{1}H-NMR spectroscopic data and IR spectra (showing the three-membered ring and >C=O stretching bands). These results strongly suggest that the reaction of cyclopropenium ions with sulfonium ylides proceeds *via* sulfonium salts, nucleophilic addition products.

The structure of **5** permit us to indicate a possible reaction pathway. The reaction should involve, as the first step, nucleophilic attack of ylide carbanion by ring-carbon. Thus the sulfonium salt formation from thio-substituted cyclopropenium ions can occur with sulfonium methylides. Then the sulfonium salts with an appropriate leaving group SR and $(CH_3)_2S^+$ may be subject to elimination of $(CH_3)_2S^+$, intramolecular rearrangement of SR and ring opening to give the ketene **3**. The allene **4** may arise from a cyclopropenylidene intermediate, generated by elimination of a ketene moiety from **5**. Although we do not believe

Table 3. Physical data of sulfonium salts (**5**)

a) Measured in KBr disk. b) Observed in CH_3CN. * Shoulder.

that the limited data available here can permit us to discuss a further precise mechanism, the present results strongly support the intermediacy of the sulfonium salt such as **5** in reactions between the thio-substituted cyclopropenium ion system and sulfonium methylide.

Experimental

All the melting points are uncorrected. The IR spectra were taken with a Hitachi Model 215 spectrophotometer; the UV spectra with a Hitachi Model EPS-3T spectrometer; and the ^{1}H-NMR spectra with a JEOL Model JNM-C-60H spectrometer. The chemical shifts are expressed in parts per million downfield from internal tetramethylsilane (δ=0). Splitting patterns are indicated as s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet. All the reactions were carried out under He atmosphere unless otherwise noted.

Materials. The sulfonium methylides **2a—c** were synthesized according to reported procedures[8] and identified by elemental analyses and melting points as well as by comparison of IR. The syntheses of thio-substituted cyclopropenium perchlorates (X=ClO_4, **1a—c**) were reported previously.[4,9]

*Tris(ethylthio)cyclopropenium Tetrafluoroborate (**1d**).* To a stirred of tetrachlorocyclopropene (91.6 mmol) in boron trifluoride (abt 49%, 40 g), there was added ethanethiol (36.6 mmol), dropwise, at room temperature. The mixture was stirred under reflux for 3 h. It was then cooled to room temperature, poured into ice–water, and extracted with dichloromethane. The organic layer was dried over $MgSO_4$, stripped of solvent, washed with ether, and dried under reduced pressure to give yellow crystals (**1d**) in 63% yield; mp 107—109 °C; UV_{max} (CH_3OH) 272 nm (ε 3100); IR (KBr) 1250 and 1090 cm^{-1}. Found: C, 35.19; H, 4.82%. Calcd for $C_9H_{15}S_3BF_4$: C, 35.30; H, 4.94%.

*Tris(t-butylthio)- (**1e**) and Tris(p-t-butylphenylthio)cyclopropenium Tetrafluoroborates (**1f**).* In a similar manner to the above, **1e** and **1f** were prepared from the corresponding thiols in 42 and 50% yields, respectively. **1e**: yellow crystals; mp 129—131 °C; UV_{max} (CH_3OH) 272 nm (ε 3570); IR (KBr) 1250 and 1090 cm^{-1}. Found: C, 46.02; H, 7.04%. Calcd for $C_{15}H_{27}S_3BF_4$: C, 46.15; H, 6.97%. **1f**: Colorless needles; mp 149—152 °C; UV max (CH_3OH) 250 (ε 4300) and 275 nm (3600); IR (KBr) 1250 and 1090 cm^{-1}. Found: C, 64.27; H, 6.03%. Calcd for $C_{33}H_{39}S_3BF_4$: C, 64.27; H, 6.35%.

*Reaction of Thio-substituted Cyclopropenium Ions (**1**) with Sulfonium Methylides (**2**). General Procedure*: A mixture of **1** (10 mmol) and **2** (40 mmol) in dry THF (80 or 100 ml) was stirred at room temperature for 6 or 8 h. After which the solvent was removed under reduced pressure. The residue was subjected to column chromatography on silica gel, eluting with carbon tetrachloride to give **3** and **4**. The following ketenes and allene were prepared by this procedure.

Physical Properties: **3a**: Pale yellow oil; UV_{max} (CH_3OH) 288 nm (ε 6000); IR (neat) 2160 (>C=C=O) and 1640 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.25 (6H, t, J=6.8 Hz, CH_3) and 2.75 (4H, q, J=6.8 Hz, CH_2).

3b: Pale yellow oil; UV_{max} (CH_3OH) 251 nm (ε 6700); IR (neat) 2170 (>C=C=O) and 1640 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.45 (18H, s, CH_3).

3c: Pale brown oil; UV_{max} (CH_3OH) 251 nm (ε 11000); IR (neat) 2190 (>C=C=O) and 1660 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.41 (18H, s, CH_3) and 7.15 (8H, m, phenyl).

4b: Colorless needles; mp 140—141 °C; UV_{max} (CH_3OH) 269 nm (ε 6500); IR (KBr) 1910 (>C=C=C<) and 1360 cm^{-1}; ^{1}H-NMR (CCl_4) δ=1.45 (36H, s, CH_3). Found: C, 57.90; H, 9.43%. Calcd for $C_{19}H_{36}S_4$: C, 58.01; H, 9.26%.

*Preparation of Sulfonium Salts (**5**). Preparation of **5e** as a Typical Procedure*: The mixture of **1e** (1.58 mmol) and **2a** (1.58 mmol) in dry THF (80—100 ml) was stirred at −40 °C for 6 h. The reaction mixture was filtered off, and the product was recrystallized from $CHCl_3$–CCl_4 (1:1) to give colorless rod-like crystals, [[tris(*p*-*t*-butylphenylthio)-cyclopropenyl](ethoxycarbonyl)methyl]dimethylsulfonium-perchlorate (**5e**) (57% yield). Other sulfonium salts were prepared by the similar procedure, but **5a**, **5b**, **5c**, **5d**, **5g**, **5h**, **5i**, and **5j** were purified by recrystallization from ethanol. Physical data of **5** are summarized in Tables 2 and 3.

(Received February 22, 1982)

The reaction of 1-ethoxycarbonyl-1*H*-azepine with chlorosilane derivatives in HMPA in the presence of magnesium afforded the silanol derivatives, which upon heating gave the corresponding siloxane derivatives. In the same manner, tropone and 2,5-dimethyl-3,4-diphenylcyclopentadienone afforded the reduced dimers of them. However, tetraphenylcyclopentadienone and 2,5-dimethoxy-3,4-diphenylcyclopentadienone were reduced to the corresponding cyclopentenones under the reaction conditions. These reactions are considered to proceed *via* the corresponding radical anions which are formed by electron transfer from magnesium.

Chlorosilane derivatives are known to add to olefins in the presence of magnesium in hexamethylphosphoric triamide (HMPA).[1] However, the reactions to heterocyclic compounds have not been investigated well, although much attention has been paid to the cycloaddition reactions of heterocyclic compounds.[2] Similarly, much effort has been devoted to the study of the Grignard reactions of troponoid compounds, but no report has been published concerning the reactions of chlorosilanes with these types of compounds.[3] We wish to report the results of reactions of some chlorosilanes to azepine, diazepine, tropone, and cyclopentadienone derivatives.

The reaction of 1-ethoxycarbonyl-1*H*-azepine (**1**) with diphenyldichlorosilane in HMPA in the presence of magnesium at room temperature, followed by quenching with water, afforded **7** and **8** in yields of 40 and 23%, respectively. Similarly, **1** was reacted with dimethyldichlorosilane and trimethylchlorosilane to afford **9** and **11** in yields of 35 and 40%, respectively. Upon standing at room temperature as a chloroform solution, **9** was converted to **10** in nearly quantitative yield. On the other hand, **7** afforded **8** almost quantitatively by heating at 120 °C in toluene.

It is clear from the elemental analyses and mass spectrometry that these products are derived from the 1:2 adducts of **1** and the chlorosilanes. The IR spectra indicate that **7** and **9** are silanol derivatives in which the chlorine atoms bonded to the silicon atoms are replaced with hydroxyl groups. The products **8** and **10** were determined to be siloxane derivatives which are derived from the dehydration of **7** and **9**, respectively, on the basis of the spectral data and of the experiments mentioned above. The fact that there are only three signals of the ring protons in their NMR spectra and that each of these three signals corresponds to two ring protons indicate that these adducts have symmetric structures, suggesting that 2,7-addition, 3,6-addition, or 4,5-addition have occurred. The 3,6-addition is rejected by the facts that the NMR spectra showed no three-membered ring proton resonances and that it is impossible for chlorosilanes to add to the 3 and 6 positions without forming an aziridine ring in the azepine nucleus.

In the low temperature NMR spectra (−30 to −50 °C), the signals of H_a and H_b showed no change, but the doublet signal of H_c was split into two doublets at slightly different chemical shifts. Similar behavior was observed with H_α of the compound **12**.[4] The observed splitting at low temperature is a result of a

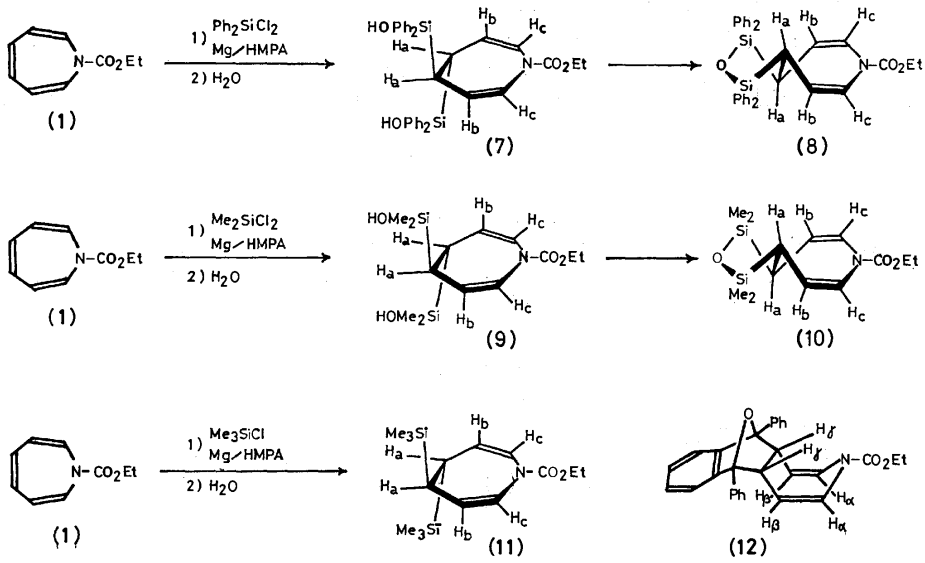

Fig. 1.

different anisotropic effect of the carbonyl group on the two H_e protons, which are revealed to be olefinic protons by the chemical shifts in the NMR spectra. This difference in the anisotropic effect is caused by freezing the free rotation of the ester group.[2b,5] A structure which has olefinic protons adjacent to the nitrogen atom can only be the result of the 4,5-addition. The 4,5-addition is further supported by the similarity of the NMR spectra of the adducts to the spectrum of the structurally analogous compound **12**.

The stereochemistry of the adducts was deduced from the coupling constants between the methine proton H_a and the olefinic proton H_b. The Dreiding models reveal that, for *cis*-addition, the dihedral angle between H_a and H_b is approximately 100°, which corresponds to the coupling constant of about 2 Hz according to the Karplus equation.[6] This value for the coupling constant is in accord with the observed value between H_γ and H_β of the authentic *cis*-adduct **12**. On the other hand, for *trans*-addition, the silyl groups would be expected to be arranged in a diaxial position in order to avoid the steric repulsion between them. In this case, the dihedral angle between the equatorial methine proton H_a and the olefinic proton H_b should be approximately 10°, which corresponds to a coupling constant of approximately 11 Hz. The observed coupling constants of **7**, **9**, and **11** are in accord with the expected value for the *trans*-addition. When the siloxane rings are formed, the silyl groups should be required to approach each other, resulting in the equatorial arrangement of the silyl groups and the axial arrangement of the methine protons. In this conformation, the dihedral angle between the axial methine proton and the olefinic proton is approximately 100°, which corresponds to a coupling constant of about 2 Hz and is in good agreement with the observed values for **8** and **10**. On the basis of these arguments, the structures of these adducts are determined as shown in Fig. 1.

In the same way, tropone (**2**) was reacted with trimethylchlorosilane in HMPA in the presence of magnesium. After quenching with water, **13** was obtained in 27% yield. The similar reactions of **2** with diphenyldichlorosilane or dimethyldichlorosilane resulted in almost the same consequences as above; however, in the absence of chlorosilanes, no reaction occurred.

The elemental analysis and the molecular ion peak in the mass spectrum reveal that **13** is the reduced dimer of **2**. The IR spectrum indicates that the carbonyl group is not conjugated with any double bond.[3b] The NMR spectral data employing the double resonance technique made it clear that **13** contains a 2,4-hexadiene moiety which has geminal protons at one end and a proton at the other end. The coupling constants are reasonably assigned on this carbon arrangement. On the basis of these facts, the structure of **13** is determined as shown in Fig. 2.

The reaction of tetraphenylcyclopentadienone (**3**) with trimethylchlorosilane in HMPA in the presence of magnesium, followed by quenching with water, produced a known cyclopentenone derivative **14**[7] in 74% yield. Similarly, 2,5-bis(methoxycarbonyl)-3,4-

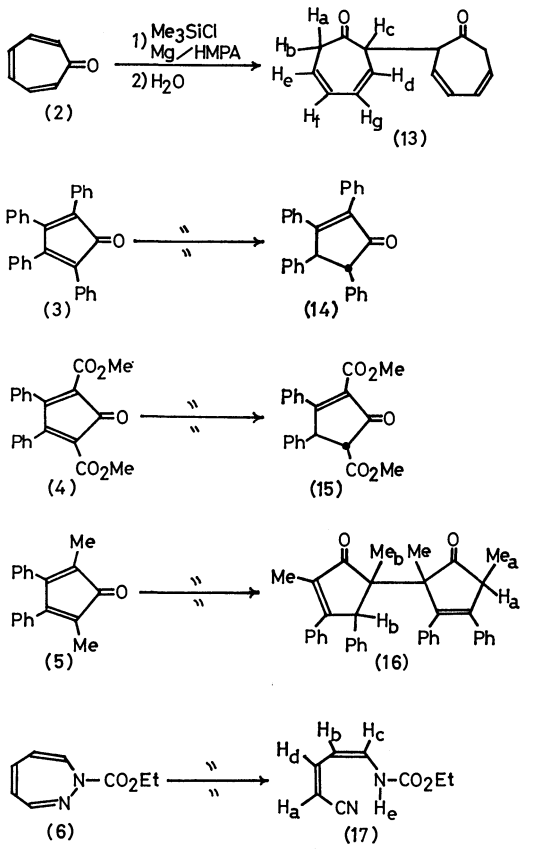

Fig. 2.

diphenylcyclopentadienone (**4**) and 2,5-dimethyl-3,4-diphenylcyclopentadienone (**5**) were reacted with trimethylchlorosilane to yield **15** and **16** in yields of 25 and 18%, respectively. The reactions of **3**, **4**, and **5** with diphenyldichlorosilane or dimethyldichlorosilane gave approximately the same results as above; however, in the absence of chlorosilane derivatives, no reaction proceeded.

The IR spectrum of **15** suggests that this product is a cyclopentenone derivative, which is also supported by the elemental analysis and the molecular ion peak in the mass spectrum. The stereochemistry of **15** was determined on the basis of the coupling constant between the ring protons. The elemental analysis and the molecular ion peak in the mass spectrum reveal that **16** is a reduced dimer of **5**. The IR spectrum indicates the existence of a conjugated and an unconjugated carbonyl group. The NMR spectrum shows that there are two ring protons: one proton (H_a) interacts with a methyl group (Me_a) with a coupling constant of 8 Hz and the other proton (H_b) has a long range coupling of 2 Hz with the other methyl group (Me_b). On the basis of these facts, the structures of **15** and **16** are determined as shown in Fig. 2.

1-Ethoxycarbonyl-1*H*-1,2-diazepine (**6**) was reacted with trimethylchlorosilane in HMPA in the presence of magnesium. After quenching with water, **17** was obtained in 25% yield. However, **17** was also obtained from the reaction of **6** with magnesium in HMPA in the absence of chlorosilanes.

The structure of **17** was determined as shown in

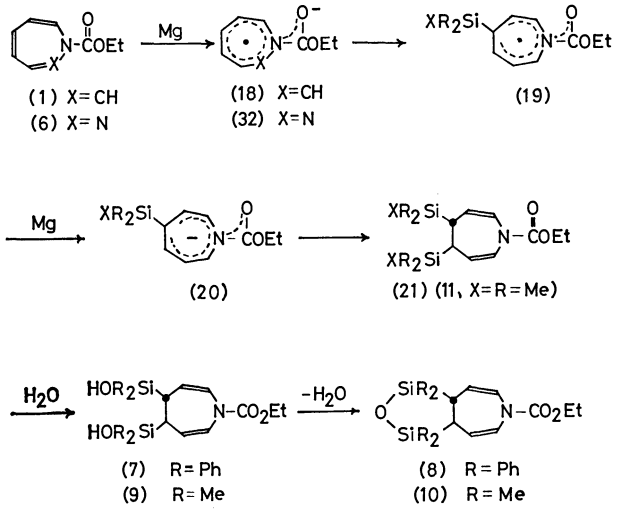

Fig. 3.

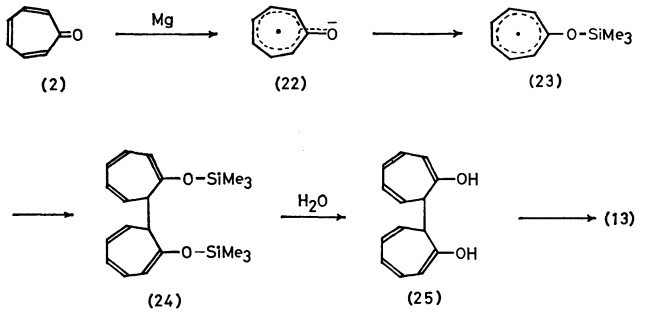

Fig. 4.

Fig. 2 on the basis of its spectral data and the resemblance of its NMR spectrum to that of the analogous compounds.[10]

Discussion

The reaction mechanism of **1** with chlorosilane derivatives can be explained as follows.[1] The first step of the reaction is considered to be one electron transfer from magnesium to **1** in the strongly basic solvent HMPA to form the anion radical **18**, which reacts with chlorosilanes to give the radical **19**, as shown in Fig. 3. One more electron transfer to **19**, followed by the reaction with chlorosilane, gives the disilyl compounds **21** (**11**, X=R=CH_3) *via* the anion **20**. When the reaction mixture is quenched with water, **21** is hydrolyzed to form the silanols. Dehydration of the silanols **7** and **9** to the siloxanes **8** and **10** is a well-documented reaction.[8]

The reaction mechanism of tropone (**2**) is thought to proceed *via* the initial formation of the radical anion **22**, which further reacts with chlorosilanes to yield the silyl ether radical **23**[9] as shown in Fig. 4. Dimerization of **23** affords **24**, which subsequently gives the reduced dimer **13** by the hydrolysis *via* the enol intermediate **25**.

The silyl ether radical **27** is also considered to be formed in the reactions of cyclopentadienones, as shown in Fig. 5. In the case of **5**, which has methyl groups at the 2 and 5 positions, **27** dimerizes to form **28** which

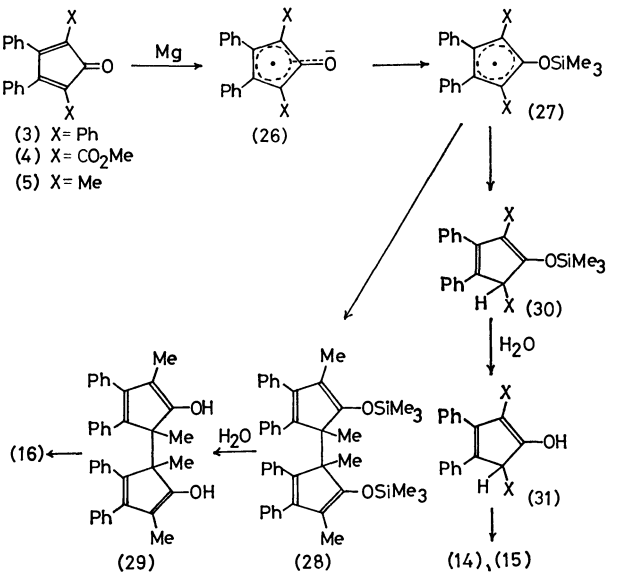

Fig. 5.

affords the reduced dimer **16** by hydrolysis. However, the bulky substituents, phenyl and methoxycarbonyl groups, located at the 2 and 5 positions in **3** and **4**, inhibit the dimerization of **27**. Thus, **27** abstracts a hydrogen from the solvent to yield the silyl ether **30**, which subsequently affords the cyclopentenones **14** and **15** after hydrolysis.

Nitrile compounds similar to **17** are known to be formed in the reaction of diazepine derivatives with strong bases.[10] The reaction products are thought to be formed *via* the N–N bond fission of the radical **32** shown in Fig. 3.

Experimental

All the melting points were uncorrected. IR spectra were measured in carbon tetrachloride solutions or potassium bromide disks and UV spectra in methanol solutions. NMR spectra were measured with Hitachi R-20B or Varian HA-100 spectrometer with deuteriochloroform or carbon tetrachloride as solvent and tetramethylsilane as internal standard. Wakogel C-200 and activated alumina of Wako Pure Chemicals Industries LTD were used for column chromatography.

Reaction of 1 with Diphenyldichlorosilane. A mixture of **1** (1.00 g, 6 mmol), magnesium (0.22 g, 9 mg atom), diphenyldichlorosilane (5.00 g, 20 mmol), and HMPA (30 mL) was stirred at room temperature for 20 h under a nitrogen stream. The reaction mixture was poured into ice water and extracted with ether. The organic layer was washed with water, brine, and dried over anhydrous sodium sulfate. After filtering, the solvent was evaporated on a rotary evaporator to yield a yellow oil (3.7 g). Silica gel chromatography of this oil gave pale yellow crystals **8** (0.85 g) by benzene–ether 50:1, and a pale yellow oil **7** (1.50 g) by benzene–ether 25:1. Recrystallization of **8** from cyclohexane gave colorless crystals (0.73 g, 23%), mp 174—175 °C. The oil **7** was further purified with silica gel chromatography to give a colorless oil (1.30 g, 40%). **7**: Found: C, 70.13; H, 6.11; N, 2.43%. Calcd for $C_{33}H_{33}NO_4Si_2$: C, 70.30; H, 5.90; N, 2.48%. UV_{max} 244 nm (log ε 4.37), 248 (4.39), 254 (4.29), 260 (4.23), 265 (4.01), 272 (3.83). IR (neat) 3420, 1710 cm^{-1}. NMR ($CDCl_3$) δ=1.13 (3H,

t), 2.73 (2H, H_a, d), 3.44 (2H, OH, bs), 4.02 (2H, q), 4.91 (2H, H_b, t), 6.44 (2H, H_c, d), 7.1—7.8 (20H, Ph); coupling constants in Hz $J_{ab}=9.0$, $J_{bc}=11.0$. MS, *m/e* (rel intensity), 545 (M^+-18, 3), 319 (81), 257 (64), 181 (100), 105 (86). **8**: Found: C, 72.88; H, 5.59; N, 2.62%. Calcd for $C_{33}H_{31}NO_3Si_2$: C, 72.62; H, 5.72; N, 2.57%. UV_{max} 244 nm (log ε 4.33), 254 (4.17), 260 (4.11), 265 (4.03), 272 (3.76). IR (KBr) 1720 cm^{-1}. NMR ($CDCl_3$) $\delta=1.22$ (3H, t), 2.73 (2H, H_a, nm), 4.08 (2H, q), 5.20 (2H, H_b, md), 6.62 (2H, H_c, md), 7.1—7.8 (20H, Ph); coupling constants in Hz $J_{ab}=2.0$, $J_{bc}=10.0$. MS, *m/e* (rel intensity) 545 (M^+, 23), 319 (100).

*Reaction of **1** with Dimethyldichlorosilane.* A mixture of **1** (1.65 g, 10 mmol), magnesium (0.36 g, 15 mg atom), dimethyldichlorosilane (4.00 g, 31 mmol), and HMPA (40 mL) was stirred at room temperature for 16 h under a nitrogen stream. The usual workup afforded a pale orange oil (2.55 g), which was chromatographed on silica gel to give pale yellow crystals **9** (1.25 g) by benzene–ether 7:3 and recovered starting material **1** (0.67 g) by benzene–ether 1:1. Recrystallization of **9** from cyclohexane gave colorless crystals (1.10 g, 35%), mp 99—100 °C. Found: C, 49.44; H, 7.96; N, 4.46%. Calcd for $C_{13}H_{25}NO_4Si_2$: C, 49.49; H, 7.99; N, 4.44%. UV_{max} 240 nm (log ε 4.09). IR (KBr) 3400, 1730 cm^{-1}. NMR ($CDCl_3$) $\delta=0.08$ (6H, s), 0.15 (6H, s), 1.41 (3H, t), 2.20 (2H, H_a, d), 3.38 (2H, OH, s), 4.33 (2H, q), 5.24 (2H, H_b, t), 6.68 (2H, H_c, d); coupling constants in Hz $J_{ab}=10.0$, $J_{bc}=10.0$. MS, *m/e* (rel intensity) 315 (M^+, 14), 149 (100).

*Reaction of **1** with Trimethylchlorosilane.* A mixture of **1** (1.00 g, 6 mmol), magnesium (0.22 g, 9 mg atom), trimethylchlorosilane (1.10 g, 10 mmol), and HMPA (20 mL) was stirred under a nitrogen stream for 18 h at room temperature. The usual workup afforded a pale orange oil (1.60 g), which was chromatographed on silica gel to give a colorless oil **11** (0.85 g) by petroleum ether–benzene 3:7 and recovered starting material **1** (0.19 g) by benzene–ether 9:1. The crude oil **11** was purified by chromatography on silica gel to yield a colorless oil (0.76 g, 40%). Found: C, 57.58; H, 9.16; N, 4.52%. Calcd for $C_{15}H_{29}NO_2Si_2$: C, 57.82; H, 9.38; N, 4.50%. UV_{max} 240 nm (log ε 4.16). IR (neat) 1730 cm^{-1}. NMR ($CDCl_3$) $\delta=0.08$ (12H, s), 1.32 (3H, t), 1.79 (2H, H_a, d), 4.11 (2H, q), 4.87 (2H, H_b, t), 6.63 (2H, H_c, d); coupling constants in Hz $J_{ab}=10.0$, $J_{bc}=12.0$. MS, *m/e* (rel intensity) 311 (M^+, 46), 120 (100).

*Reaction of **2** with Trimethylchlorosilane.* A mixture of **2** (2.00 g, 16 mmol), magnesium (0.38 g, 16 mg atom), trimethylchlorosilane (5.43 g, 50 mmol), and HMPA (30 mL) was allowed to react for 2 h at room temperature under a nitrogen stream. The usual workup gave a yellow oil (2.10 g), which was chromatographed on silica gel to give yellow crystals **13** (0.68 g) by benzene. Recrystallization of **13** from methanol gave pale yellow crystals (0.61 g, 27%), mp 91—92 °C. Found: C, 78.25; H, 6.48%. Calcd for $C_{14}H_{14}O_2$: C, 78.48; H, 6.59%. UV_{max} 241 nm (log ε 3.69). IR (KBr) 3010, 2960, 1710 cm^{-1}. NMR ($CDCl_3$) $\delta=3.01$ (2H, H_a, m), 3.53 (2H, H_b, m), 3.90 (2H, H_c, m), 5.65 (2H, H_d, m), 6.04 (2H, H_e, m), 6.35 (4H, H_f, H_g, m); coupling constants $J_{ab}=20.0$, $J_{ac}=1.5$, $J_{ae}=3.5$, $J_{af}=1.5$, $J_{be}=7.0$, $J_{cd}=3.0$, $J_{cg}=0.5$, $J_{dg}=10.5$, $J_{df}=1.5$, $J_{ef}=11.0$, $J_{eg}=1.5$. MS, *m/e* (rel intensity) 214 (M^+, 24), 107 (100).

*Reaction of **3** with Trimethylchlorosilane.* A mixture of **3** (2.50 g, 6.5 mmol), magnesium (0.16 g, 6.6 mg atom), trimethylchlorosilane (2.17 g, 20 mmol), and HMPA (20 mL) was stirred for 20 h at room temperature under a nitrogen stream. The usual workup gave a black mixture of crystalline starting material **3** and a tarry material (3.4 g). After removing the starting material **3** (0.28 g) by filtration, the tarry filtrate was chromatographed on alumina to yield additional starting material **3** (0.22 g) by petroleum ether–benzene 4:6 and colorless crystals **14** (2.03 g) by petroleum ether–benzene 1:9. Recrystallization from cyclohexane gave pure crystals of **14** (1.86 g, 74%), mp 162—163 °C, (lit,[7] 162—163 °C).

*Reaction of **4** with Trimethylchlorosilane.* A mixture of **4** (3.48 g, 10 mmol), magnesium (0.24 g, 10 mg atom), trimethylchlorosilane (4.30 g, 40 mmol), and HMPA (60 mL) was stirred for 2 h under a nitrogen stream at room temperature. The usual workup gave a brown oil (3.33 g) which was chromatographed on silica gel to yield yellow crystals **15** (0.98 g) by benzene–ether 20:1. Recrystallization of **15** from chloroform gave colorless crystals (0.89 g, 25%), mp 113—114 °C. Found: C, 71.92; H, 5.41%. Calcd for $C_{21}H_{18}O_5$: C, 71.99; H, 5.18%. UV_{max} 287 nm (log ε 4.08). IR (KBr) 3030, 2940, 1730 (broad) cm^{-1}. NMR ($CDCl_3$) $\delta=3.58$ (1H, d, $J=3.5$ Hz), 3.80 (6H, s), 5.06 (1H, d, $J=3.5$ Hz), 7.2 (10H, Ph). MS, *m/e* (rel intensity) 350 (M^+, 14), 317 (100).

*Reaction of **5** with Trimethylchlorosilane.* A mixture of **5** (2.03 g, 4 mmol), magnesium (0.19 g, 8 mg atom), trimethylchlorosilane (3.48 g, 32 mmol), and HMPA (20 mL) was stirred at room temperature under a nitrogen stream for 2 h. The usual workup gave a brown oil (2.9 g), which was chromatographed on silica gel to yield yellow crystals **16** (0.41 g) by benzene–ether 20:1. Recrystallization of **16** from ethanol gave colorless crystals (0.36 g, 18%), mp 213—214 °C. Found: C, 87.55; H, 6.39%. Calcd for $C_{38}H_{34}O_2$: C, 87.32; H, 6.56%. UV_{max} 275 nm (log ε 4.26). IR (KBr) 3050, 2970, 1743, 1690 cm^{-1}. NMR ($CDCl_3$) $\delta=$ 0.16 (3H, Me_a, d, $J=8.0$ Hz), 1.30 (3H, Me_b, d, $J=2.0$ Hz), 1.94 (3H, s), 2.08 (3H, s), 3.06 (1H, H_a, q, $J=8.0$ Hz), 4.50 (1H, H_b, q, $J=2.0$ Hz), 7.2 (20H, Ph). MS, *m/e* (rel intensity) 261 ($M^+/2$, 53), 91 (100).

*Reaction of **6** with Trimethylchlorosilane.* A mixture of **6** (0.53 g, 3 mmol), magnesium (0.072 g, 3 mg atom), trimethylchlorosilane (1.08 g, 10 mmol), and HMPA (10 mL) was allowed to react for 2 h at room temperature under a nitrogen stream. The usual workup afforded a red oil (1.5 g), which was chromatographed on silica gel to yield yellow crystals **17** (0.16 g) by benzene–ether 4:1, and recovered starting material **6** (0.086 g) by benzene–ether 3:2. Recrystallization from benzene gave pale yellow crystals **17** (0.13 g, 25%), mp 141—142 °C. Found: C, 57.79; H, 6.23; N, 16.82%. Calcd for $C_8H_{10}N_2O_2$: C, 57.82; H, 6.07; N, 16.86%. UV_{max} 303 nm (log ε 4.43). IR (KBr) 3330, 2210, 1710 cm^{-1}. NMR ($CDCl_3$) $\delta=1.32$ (3H, t), 4.32 (2H, q), 5.09 (1H, H_a, d), 5.73 (1H, H_b, dd), 6.86 (1H, H_c, dd), 7.09 (1H, H_d, dd), 7.75 (1H, H_e, broad); coupling constants in Hz $J_{ad}=10.5$, $J_{bc}=9.0$, $J_{bd}=12.0$, $J_{ce}=12.0$. MS, *m/e* (rel intensity) 166 (M^+, 33), 91 (100).

*Formation of **8** from **7**.* A solution of **7** (1.00 g) in toluene-d_8 (5 mL) was heated at 120 °C under a nitrogen stream for 3 h. The NMR spectrum of this reaction mixture indicated that **7** was converted to **8**. The yield of **8** was found to be nearly quantitative by comparison of the area of the absorption peak of H_c of **8** with the area of the peak of the ethyl group as the standard. The solvent was then evaporated to yield a colorless oil, which was crystallized from cyclohexane to give colorless crystals **8** (0.88 g, 91%).

*Formation of **10** from **9**.* A solution of **9** (0.50 g) in deuteriochloroform (2 mL) was stirred at room temperature under a nitrogen stream for 72 h. The NMR spectrum of this reaction mixture showed that **9** was converted to **10** almost quantitatively, using the absorption signal of H_c of

10 and the signal of the ethyl group as the standard. After evaporation of the solvent, the colorless residue was chromatographed on silica gel to yield a colorless oil **10** (0.14 g, 29%). Compound **10** was unstable and an analytically pure sample could not be obtained. UV_{max} 238 nm (log ε 4.37). IR (neat) 1730 cm^{-1}. NMR ($CDCl_3$) δ=0.16 (6H, s), 0.25 (6H, s), 1.42 (3H, t), 2.06 (2H, H_a, nm), 4.28 (2H, q), 5.13 (2H, H_b, md), 6.68 (2H, H_c, md); coupling constants in Hz J_{ab}=2.0, J_{bc}=10.0. MS, *m/e* (rel intensity) 297 (M^+, 14), 149 (100).

Reaction of Sulfur Dichloride with Nitrile in the Presence of Lewis Acid Forming 1,2,4-Thiadiazole

Mitsuo KOMATSU,* Jun-ichi SHIBATA, Yoshiki OHSHIRO, and Toshio AGAWA

Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Yamada-oka 2-1, Suita, Osaka 565

(Received March 12, 1982)

Formation of 3,5-disubstituted 1,2,4-thiadiazoles by the reaction of sulfur dichloride with nitriles in the presence of a Lewis acid was found. For example, 3,5-diphenyl-1,2,4-thiadiazole was obtained with its chlorinated products, 3-*o*-chlorophenyl-5-phenyl- and 3-*p*-chlorophenyl-5-phenyl-1,2,4-thiadiazoles, from benzonitrile and sulfur dichloride using aluminium chloride as a catalyst (total yield 80%). The extent of chlorination of the aromatic ring was suppressed by use of iron(III) chloride as the catalyst or of sulfur chloride instead of the dichloride. Some substituted benzonitriles and pivalonitrile also gave thiadiazoles in lower yields.

Sulfur dichloride has long been known as a reactive enophile and its additions to olefinic or diolefinic compounds have been widely applied to syntheses of sulfur-containing heterocyclic compounds.[1] However, only a few addition reactions of sulfur dichloride to carbon-nitrogen multiple bonds have been reported in spite of ready availability of sulfur dichloride and its high reactivity to olefins. While no reports on 1,2-addition of sulfur dichloride to carbon-nitrogen double bonds and to carbon-nitrogen triple bonds of aliphatic nitriles, whose aliphatic moiety was chlorinated[2] or chlorosulfenylated,[3] addition reaction was observed for sulfonyl nitriles.[4] The other examples are also limited to some special cyanides and formations of 3,4-dichloro-1,2,5-thiadiazole from cyanogen,[5] 3,5-dichloro-1,2,4-thiadiazole from phosphorus tricyanide,[6] and 3,4,4,5-tetrachloro-4*H*-1,2,6-thiadiazine from dichloromalononitrile[7,8] are reported.

Here we describe the reaction of nitriles activated by a Lewis acid with sulfur dichloride, which leads to formation of 1,2,4-thiadiazoles.[9] Thiadiazoles have been drawing our considerable attention because many of them are known as potential physiologically active substances[10] and, hence, the present reaction would provide us a new application of sulfur dichloride in this field.

Results and Discussion

To a well-stirred mixture of benzonitrile (6 equiv.) and aluminium chloride (1.2 equiv.) under a nitrogen atmosphere was added dropwise sulfur dichloride (1.0 equiv.) and the mixture was stirred at 90 °C for 20 h to give 3,5-diphenyl-1,2,4-thiadiazole (**3a**), 3-*o*-chlorophenyl-5-phenyl-1,2,4-thiadiazole (**4a**), and 3-*p*-chlorophenyl-5-phenyl-1,2,4-thiadiazole (**5a**). The products were separated by silica-gel chromatography and identified with authentic samples. The formation of

180	15	49	46/54

a) PhCN (5 equiv.), SCl_2 (1 equiv.), and $AlCl_3$ (1 equiv.) were used. b) Determined by GLC: 1.2 m×3 mmϕ glass column packed with 5% PS-410 on Chromosorb W 60—80 mesh; oven temp 230 °C; carrier gas, He 1.0 kg/cm^2. c) 0.5 equiv. of $AlCl_3$ was used. d) Hydroquinone (0.15 mol%) was added.

the latter two compounds is attributed to chlorination of the phenyl ring during the reaction.

The results of this reaction under several conditions are listed in Table 1. Any of several solvents we examined was not satisfactory and, hence, excessive amount of the nitrile was employed as the solvent. The total yield of the thiadiazoles was cut in half when 0.5 equiv. of aluminium chloride was used (see Table 1), and the reaction did not proceed at all without the Lewis acid. Therefore, an equimolar amount of the Lewis acid is indispensable for the present reaction.

The lower reaction temperature seemed to suppress the chlorination of the phenyl ring but reduced the total yield of the thiadiazoles at the same time. Addition of hydroquinone (0.15 equiv.) also resulted in a decrease in the yield, but completely controlled the chlorination products as shown in Table 1. Smaller amount (0.10 equiv.) of hydroquinone could afford a better yield (47%) but worse selectivity (**3a**/**4a**+**5a**= 81/19). As is already known, substituted phenols react with sulfur dichloride to form thiobis(phenol) derivatives which are useful as antioxidants.[11] Furthermore, Friedel-Crafts reaction of benzene with sulfur dichloride in the presence of aluminium chloride to form diphenyl sulfide is reported.[12] Hence, the decrease in the yield of the thiadiazoles by the addition of hydroquinone might be caused by the reaction of the quinone with sulfur dichloride. However, the decrease in chlorinated products could not be attributed

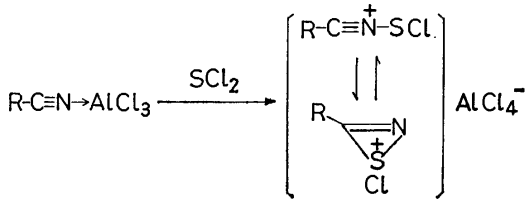
simply to radical trapping ability of the anticipated thiobis(hydroquinone), because other attempts to reduce the extent of chlorination, *e.g.*, the reactions in dark and in the presence of copper(II) chloride or sulfur, were not successful.

As for the catalyst, tin(IV) chloride and antimony (V) chloride were as effective as aluminium chloride. On the other hand, iron(III) chloride depressed the ratio of the chlorinated products. Some effects of Lewis acids as a catalyst are listed in Table 2, and no direct correlation between the yields and acidity was observed.

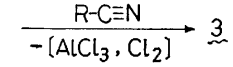
This reaction could be extended to substituted benzonitriles and pivalonitrile (see Table 3). In these reactions, chlorinated products were isolated in very low yields or not detected at all. *o*-Tolunitrile gave no thiadiazole probably because of steric hindrance. *p*-Chlorobenzonitrile did give the corresponding thiadiazole, but sublimation of the nitrile caused a lower yield. On the contrary, benzyl cyanide and acetonitrile gave no thiadiazoles. Consequently protons α to the cyano group seem to be undesirable for the reaction. In fact small amount of a disulfide derivative was isolated from the reaction mixture of sulfur dichloride and isobutyronitrile which gave no thiadiazole.[2)]

$$Me_2CHCN + SCl_2 \xrightarrow{AlCl_3} Me_2\overset{CN}{\overset{|}{C}}-S-S-\overset{CN}{\overset{|}{C}}Me_2$$

We tentatively assume the reaction path as follows. A complex of aluminium chloride and a nitrile was initially formed and successive addition of sulfur dichloride to the complex gave rise to the intermediate **6**. Formation of the thiadiazole **3** can be interpreted by addition of the nitrile to **6** followed by elimination of aluminium chloride and chlorine. It is likely that aluminium chloride was consumed by complexation with the resulted thiadiazole **3**, since equimolar amount of the chloride was necessary for the reaction. It is not clear whether the aromatic ring was chlorinated by sulfur dichloride or by chlorine liberated during the formation of **3** from **6**. In chlorine atmosphere, the reaction did not give the thiadiazoles, but formation of a large amount of chlorinated benzonitrile was observed.



6



As sulfur dichloride is known to form a complex with aluminium chloride,[13)] an alternative path *via* this type of complex leading to **6** was also conceivable. If this path were valid, the reaction of the isolated sulfur dichloride–aluminium chloride complex with benzonitrile under the same conditions should have given better yields of the thiadiazoles. However, the reaction at 120 °C for 12 h afforded **3a**, **4a**, and **5a** in 42% yield (**3a**/**4a**+**5a**=35/65) which is about two thirds of that obtained by addition of sulfur dichloride to a benzonitrile–aluminium chloride mixture. Therefore the path *via* sulfur dichloride–aluminium chloride complex was less likely and, in this case, the complex was probably converted into the benzonitrile–aluminium chloride complex by exchange of the ligands.

Similarly, exchange of one nitrile with another occurred very easily and, hence, scrambling of nitriles was observed when two nitriles were employed in the reaction. In these cases, a mixture of benzonitrile and sulfur dichloride was added to a well-stirred solution of a nitrile and aluminium chloride and was stirred for 12 h at 120 °C. The product was a mixture of four possible types of thiadiazoles, **3a**, **3b**,**e**,**f**, **7**, and **8**. Reverse addition of the two

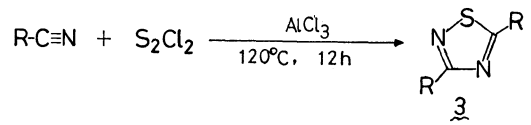
a) Yields were determined by GLC. b) Same to the compound **4a**. c) The thiadiazoles **7** and **8** were not separated.

nitriles also resulted in the formation of the above products but caused slight change in the product distribution.

Another ambiguity we should make clear is that sulfur chloride might be the reactive species in this reaction, because the following equilibrium between sulfur dichloride and sulfur chloride is known. However the possibility was excluded out by the fact that

$$2SCl_2 \rightleftharpoons S_2Cl_2 + Cl_2$$

the use of sulfur chloride instead of sulfur dichloride caused a decrease in the yields of the thiadiazoles. A merit of use of sulfur chloride is that no chlorination products were formed under these conditions. The formation of the thiadiazole **3** is explained by genera-



3

3a (R = Ph) 37%
3d (R = p-tolyl) 32%

tion of sulfur dichloride and sulfur from sulfur chloride according to the following equation. Thus the use of sulfur chloride would decrease the extent of free

$$S_2Cl_2 \rightleftharpoons SCl_2 + S$$

chlorine which derives from sulfur dichloride and/or from the thiadiazole formation and this must be the reason for suppression of chlorination products.

Experimental

Melting points were determined on a Yanagimoto micro melting point apparatus MP-21 and melting and boiling points were uncorrected. Infrared spectra were taken on a JASCO IRA-1 spectrometer in Nujol mull unless otherwise noted. ^1H and ^{13}C NMR spectra were obtained with JEOL JNM PMX-60 and JEOL JNM FX 90Q FT spectrometers, respectively, in $CDCl_3$ solutions using TMS as an internal standard. Mass spectrometry was performed with Hitachi RMU-6E spectrometer at an ionizing voltage of 70 eV. GLC analysis was done with Shimadzu model GC-3BT using a glass column (1.2 m × 3 mmϕ) packed with 5% PS-410 on Chromosorb W 60—80 mesh. All the reactions were carried out under a dry nitrogen atmosphere.

Materials. Commercially available SCl_2, S_2Cl_2, and nitirles were distilled prior to use. $AlCl_3$ and the other Lewis acids were used without further purification.

Reaction of SCl_2 with Benzonitrile. To a well-stirred solution of $AlCl_3$ (16.6 g, 124 mmol) in the nitrile (50.6 g, 491 mmol) was added dropwise a mixture of SCl_2 (10.4 g, 100 mmol) and the nitrile (12.9 g, 125 mmol) and the mixture was stirred for 20 h at 90 °C. The resulting mixture was extracted with ether and dilute sodium hydroxide solution and the ethereal extract was dried (Na_2SO_4), and concentrated. Distillation of the residue gave 19.6 g of a mixture of the three thiadiazoles **3a**, **4a**, and **5a** (bp 150—180 °C/267 Pa). A part (2.22 g) of the mixture was chromatographed on a silica-gel column to give 0.79 g (29%) of 3,5-diphenyl-1,2,4-thiadiazole (**3a**, eluted with 1:1 mixture of benzene and hexane), 0.94 g (31%) of 3-*o*-chlorophenyl-5-phenyl-1,2,4-thiadiazole (**4a**, eluted with benzene), and 0.61 g (20%) of 3-*p*-chlorophenyl-5-phenyl-1,2,4-thiadiazole (**5a**, eluted with 1:3 mixture of benzene and hexane).

The thiadiazole **3a** was recrystallized from benzene–hexane as colorless needles: Mp 95.5—96.5 °C; ^1H NMR δ 7.2—7.6(6H, m), 7.8—8.1(2H, m), 8.2—8.5(2H, m); ^{13}C NMR δ (ppm) 188.1(N–C=N), 173.8(S–C=N), and aromatic carbons at 133.0, 131.9, 130.8, 130.3, 129.3, 128.7, 128.4, 127.5; MS *m/e* (rel intensity) 238(43, M^+), 135(100, M^+—PhCN). The infrared and ^1H NMR spectra of the compound were identical with those of an authentic sample prepared by oxidation of thiobenzamide with iodine.[14] Found: C, 70.54; H, 4.09; N, 11.65; S, 13.67%. Calcd for $C_{14}H_{10}N_2S$: C, 70.59; H, 4.20; N, 11.76; S, 13.45%.

The thiadiazole **4a** was isolated as a colorless oil: Bp 140 °C/133 Pa; ^1H NMR δ 7.2—7.6(6H, m), 7.8—8.2(3H, m); ^{13}C NMR δ (ppm) 187.8(N–C=N), 171.9(S–C=N), and aromatic carbons at 133.3, 132.3, 132.0, 130.9, 130.8, 130.5, 129.3, 127.5, 126.7; MS *m/e* (rel intensity) 272(38, M^+), 169(100, M^+—PhCN), 135(30, M^+—ClC_6H_4CN). The infrared and ^1H NMR spectra of the compound were in good agreement with those of an authentic sample prepared from 5-*o*-chlorophenyl-1,3,4-oxathiazol-2-one and benzonitrile.[15] Found: C, 61.82; H, 3.21; N, 10.34; S, 11.57; Cl, 13.33%. Calcd for $C_{14}H_9N_2SCl$: C, 61.65; H, 3.30; N, 10.28; S, 11.74; Cl, 13.03%.

Recrystallization of the compound **5a** from benzene–hexane gave colorless needles: Mp 121.5—122.5 °C; ^1H NMR δ 7.2—7.6(5H, m), 7.8—8.1(2H, m), 8.25(2H, d); ^{13}C NMR δ (ppm) 188.4(N–C=N), 172.7(S–C=N), and aromatic carbons at 136.5, 132.0, 131.4, 130.6, 129.7, 129.3, 128.9, 127.5; MS *m/e* (rel intensity) 272(41, M^+), 169(100, M^+—PhCN), 135(28, M^+—ClC_6H_4CN). The infrared and ^1H NMR spectra of the compound well agreed with those of an authentic sample.[16] Found: C, 61.40; H, 3.07; N, 10.24; S, 11.63; Cl, 13.32%. Calcd for $C_{14}H_9N_2SCl$: C, 61.65; H, 3.30; N, 10.28; S, 11.74; Cl, 13.03%.

Reactions of SCl_2 with the Other Nitriles. Reactions of SCl_2 with *o*-chlorobenzonitirle, *m*-tolunitrile, *p*-tolunitrile, and pivalonitrile were carried out similarly to the reaction with benzonitrile to afford 3,5-bis(*o*-chlorophenyl)-1,2,4-thiadiazole (**3b**), 3,5-di-*m*-tolyl-1,2,4-thiadiazole (**3d**), 3,5-di-*p*-tolyl-1,2,4-thiadiazole (**3e**), and 3,5-di-*t*-butyl-1,2,4-thiadiazole (**3f**), respectively. Reaction conditions and yields are given in Table 3.

*The Thiadiazole **3b**:* Mp 93—96 °C (colorless needles from benzene); ^1H NMR δ 7.2—7.7(6H, m), 7.8—8.2(1H, m), 8.4—8.8(1H, m); ^{13}C NMR δ (ppm) 183.0(N–C=N), 169.7 (S–C=N), and aromatic carbons at 133.8, 133.3, 132.2, 132.1, 132.0, 130.9, 130.7, 130.6, 130.4, 129.5, 127.4, 126.7; MS *m/e* (rel intensity) 306(14, M^+), 169(100, M^+—ClC_6H_4CN). Found: C, 54.28; H, 2.59; N, 9.05%. Calcd for $C_{14}H_8N_2SCl_2$: C, 54.72; H, 2.61; N, 9.12%.

An analytical sample of the thiadiazole **3d** was obtained by preparative GLC as colorless powder: mp 55—56 °C; ^1H NMR δ 2.43(6H, s), 7.2—7.5(4H, m), 7.7—8.0(2H, m),

8.0—8.3(2H, m); MS *m/e* (rel intensity) 266(37, M^+), 149 (100, $M^+-MeC_6H_4CN$).

The Thiadiazole ***3e***: Mp 135—137 °C (colorless powder from benzene); ^1H NMR δ 2.38(6H, s), 7.22(4H, d), 7.84 (2H, d), 8.23(2H, d); MS *m/e* (rel intensity) 266(39, M^+), 149(100, $M^+-MeC_6H_4CN$). Found: C, 72.06; H, 5.13; N, 10.24; S, 12.32%. Calcd for $C_{16}H_{14}N_2S$: C, 72.18; H, 5.26; N, 10.52; S, 12.03%.

The Thiadiazole ***3f***: Bp 70 °C/133 Pa (colorless oil); ^1H NMR δ 1.44(9H, s), 1.46(9H, s); ^{13}C NMR δ (ppm) 201.0 (N–C=N), 184.6(S–C=N), 37.2 and 37.0(tertiary carbons), 30.4 and 29.5(Me carbons); MS *m/e* (rel intensity) 198 (61, M^+), 183(78, M^+-Me), 115(100, M^+-BuCN). Found: C, 60.26; H, 9.13; N, 13.99; S, 15.94%. Calcd for $C_{10}H_{18}N_2S$: C, 60.61; H, 9.09; N, 14.14; S, 16.16%.

Reaction of SCl_2 with Isobutyronitrile. A mixture of SCl_2 (2.10 g, 20.3 mmol), isobutyronitrile (9.84 g, 142 mmol), and $AlCl_3$ (3.33 g, 25 mmol) was heated at reflux for 40 h and worked up as the other runs. From 600 mg of a benzene fraction of chromatographic treatment of the resultant oil on a silica-gel column, 70 mg of crystalline bis(α-cyanopropyl) disulfide was obtained: mp 51—59 °C; IR 2220 cm^{-1} (C≡N); ^1H NMR δ 1.75(s); MS *m/e* (rel intensity) 200(5, M^+), 136(10, M^+-S_2), 69(100, Me_2CHCN^+), 68(72, Me_2CCN^+).

Formation of 3,5-Unsymmetrically Disubstituted Thiadiazoles ***7*** *and* ***8***. To a well-stirred mixture of a nitrile (RCN, 130—150 mmol) and $AlCl_3$ (30 mmol) was added a mixture of SCl_2 (30 mmol) and benzonitrile (100—120 mmol) and the mixture was heated at 120 °C for 20 h. The reaction mixture was worked up as the other runs to give mixtures of the thiadiazoles **3**, **7**, and **8** whose yields were determined by GLC analysis (see Table 4).

In the reaction using *o*-chlorobenzonitrile, the thiadiazole **4a** and 5-*o*-chlorophenyl-3-phenyl-1,2,4-thiadiazole (**8b**) were identified with authentic samples prepared by the Howe's method.[15]

An analytical sample of a mixture of 5-phenyl-3-*p*-tolyl-1,2,4-thiadiazole (**7e**) and 3-phenyl-5-*p*-tolyl-1,2,4-thiadiazole (**8e**) was obtained by preparative GLC. The retention times of the both compounds were in good agreement with those of authentic samples prepared by the method of Howe:[15] ^1H NMR δ 2.41(3H, s), 7.2—8.5(9H, m); MS *m/e* (rel intensity) 252(58, M^+), 149(100, M^+-PhCN), 135 (53, $M^+-MeC_6H_4CN$). The infrared spectrum of the mixture also showed all the absorptions of the both authentic samples.

Similarly a mixture of 3-*t*-butyl-5-phenyl-1,2,4-thiadiazole (**7f**) and 5-*t*-butyl-3-phenyl-1,2,4-thiadiazole (**8f**) was collected from GLC fraction: MS *m/e* (rel intensity) 218(66, M^+), 203(53, M^+-Me), 135(100, M^+-BuCN), 115(47, M^+-PhCN).

Reactions of S_2Cl_2 with Nitriles. The reactions were carried out similarly to the previous runs at 120 °C for 12 h except that S_2Cl_2 was employed in place of SCl_2. Benzonitrile (15.7 g, 152 mmol) and S_2Cl_2 (4.22 g, 31.2 mmol) reacted in the presence of $AlCl_3$ (4.01 g, 30.1 mmol) to give the thiadiazole **3a** (yield 37% by GLC) without formation of the chlorinated products **4a** and **5a**. The yield of the thiadiazole **3d** was determined to be 32% by GLC when the reaction was started with *p*-tolunitrile (17.6 g, 150 mmol), S_2Cl_2 (4.05 g, 30 mmol), and $AlCl_3$ (3.99 g, 30 mmol).

The authors wish to express their hearty thanks to Dr. Robert K. Howe of Monsanto Agricultural Products Co., St. Louis, Missouri, U. S. A. for his giving us spectral data of some of the thiadiazoles. The present work was partially supported by a Grant-in-Aid for scientific research No. 543025 from the Ministry of Education, Science and Culture to which our thanks are due.

Furan Derivatives. V. The Syntheses of 4,5-Dihydro-3*H*-naphtho[1,8-*bc*]furans Using Strong Bases

Takaaki HORAGUCHI,* Hidetaka NARITA, and Tsuneo SUZUKI†

Department of Chemistry, Faculty of Science, Niigata University, Ikarashi, Niigata 950-21

† *Nippon Dental University, Niigata, 1-8, Hamaura-cho, Niigata 950*

(Received March 15, 1982)

The reaction of ethyl (4-methoxy-8-oxo-5,6,7,8-tetrahydro-1-naphthyloxy)acetate and potassium hydroxide gave a mixture of 6-methoxy-4,5-dihydro-3*H*-naphtho[1,8-*bc*]furan and 6-methoxy-4,5-dihydro-3*H*-naphtho[1,8-*bc*]furan-2-carboxylic acid in total yield above 90%. The mechanisms of formation of two products were examined, and potassium 2a-hydroxy-6-methoxy-2a,3,4,5-tetrahydro-2*H*-naphtho[1,8-*bc*]furan-2-carboxylate was isolated as a precursor of 6-methoxy-4,5-dihydro-3*H*-naphtho[1,8-*bc*]furan. It has become apparent that strong bases such as sodium hydroxide, sodium ethoxide, and sodium hydride were also useful for syntheses of 6-methoxy-4,5-dihydro-3*H*-naphtho[1,8-*bc*]furan derivatives.

4,5-Dihydro-3*H*-naphtho[1,8-*bc*]furans (**4**) are important intermediates to prepare phenanthro[4,5-*bcd*]-furans,[1-4] and unique molecules which have strain[5-8] introduced by condensation of the furan and naphthalene rings at *peri*-positions. Two methods have been employed to synthesize 4,5-dihydro-3*H*-naphtho-[1,8-*bc*]furans (**4**) as shown in Scheme 1. In the first method[9-18] 8-hydroxy-1,2,3,4-tetrahydro-1-naphthalenone (**1**) reacted with ethyl bromoacetate in the presence of potassium carbonate followed by saponification and decarboxylation to give 4,5-dihydro-3*H*-naphtho[1,8-*bc*]furans (**4**).[19] The yields of **2** were below 50% for various kinds of substituents (R^1 and R^2) though decarboxylation reaction of **2** proceeded smoothly in good yields. In the second method[20-28] (8-oxo-5,6,7,8-tetrahydro-1-naphthyloxy)acetic acids (**3**) were treated with acetic anhydride and sodium acetate to give a mixture of 4,5-dihydro-3*H*-naphtho-[1,8-*bc*]furans (**4**) and lactones (**5**).[7,19] The yields of **4** were near 50% because of the formation of lactones (**5**). It seems that these low yields result from the strain[7] in the fused ring system of 4,5-dihydro-3*H*-naphtho[1,8-*bc*]furans. Accordingly, we attempted to improve the yields of 4,5-dihydro-3*H*-naphtho[1,8-*bc*]-furans by using strong bases instead of weak bases. The mechanisms of formation of the furan ring is discussed.

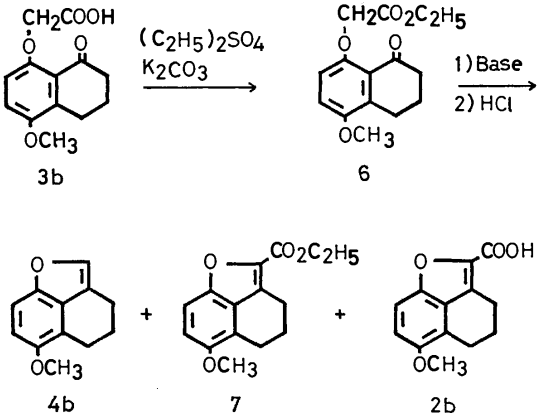
Scheme 1.

Results and Discussion

Ethyl (4-methoxy-8-oxo-5,6,7,8-tetrahydro-1-naphthyloxy)acetate (**6**) was obtained in an 88% yield by esterification of (4-methoxy-8-oxo-5,6,7,8-tetrahydro-1-naphthyloxy)acetic acid (**3b**)[19] with diethyl sulfate[39] and potassium carbonate as shown in Scheme 2.



3b 6 4b 7 2b

Scheme 2.

Compound **6** was treated with four kinds of strong bases (potassium hydroxide, sodium hydroxide, sodium ethoxide, and sodium hydride) in anhydrous dioxane. The results are summarized in Table 1.

When **6** was refluxed with five equivalents of potassium hydroxide in dioxane for 1 h followed by acidification with hydrochloric acid, two products, 6-methoxy-4,5-dihydro-3*H*-naphtho[1,8-*bc*]furan (**4b**) and 6-methoxy-4,5-dihydro-3*H*-naphtho[1,8-*bc*]furan-2-car-

Table 1. The reactions of ethyl (4-methoxy-8-oxo-5,6,7,8-tetrahydro-1-naphthyloxy)acetate (**6**) and strong bases in dioxane

Base[a]	Products yield/%			Total yield/%
	4b	**7**	**2b**	
KOH	71	0	22	93
NaOH	47	0	45	92
C_2H_5ONa	44	0	50	94
NaH	24	49	19	92

a) Compound **6** (0.50 g; 1.80 mmol) was treated with 9.00 mmol of each base.

Table 2. The reactions of ethyl (4-methoxy-8-oxo-5,6,7,8-tetrahydro-1-naphthyloxy)acetate (**6**) and strong bases in benzene

Base[a]	Products yield/%				Total yield/%
	4b	**7**	**2b**	**3b**	
KOH	47	0	0	33	80
NaOH	39	0	0	47	86
C_2H_5ONa	42	0	55	0	97
NaH	42	43	10	0	95

a) Compound **6** (0.50 g; 1.80 mmol) was treated with 9.00 mmol of each base.

boxylic acid (**2b**), were obtained in 71 and 22% yields respectively. The total yield of **4b** and **2b** were 93%, and **2b** was smoothly converted to **4b** by decarboxylation.[19] However, the reaction of **6** with one equivalent of potassium hydroxide afforded **4b**, **2b**, and **3b** in 74, 7, and 12% yields respectively. In the presence of one equivalent of potassium hydroxide the yield of **2b** was reduced. The structures of **4b** and **2b** were confirmed by comparing the IR and ^{1}H NMR spectra and melting point with those of authentic samples.[19] Similarly, the reactions of **6** and other three bases gave 6-methoxy-4,5-dihydro-3*H*-naphtho[1,8-*bc*]furans (**4b**, **7**, and **2b**) in total yield above 90%. The structure of **7** was confirmed by comparing the IR and ^{1}H NMR spectra and the melting point with those of an authentic sample.[19]

Nextly, the reactions of **6** with four strong bases were examined in anhydrous benzene. The results are summarized in Table 2.

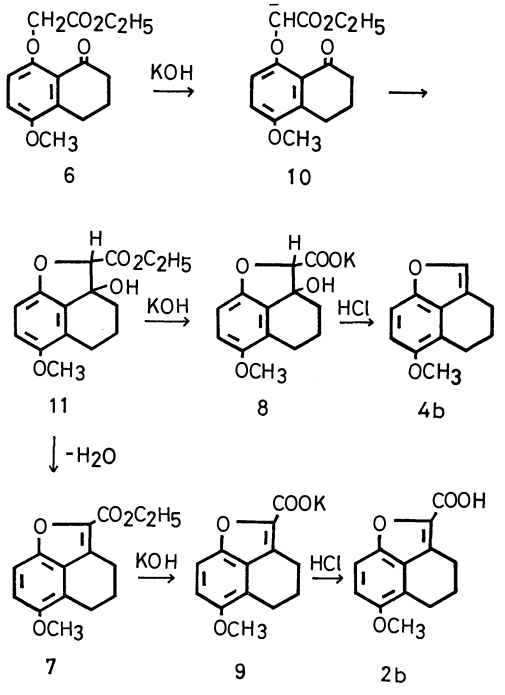
The reactions of **6** and sodium ethoxide or sodium hydride gave 6-methoxy-4,5-dihydro-3*H*-naphtho[1,8-*bc*]furans (**4b**, **7**, and **2b**) in total yield above 90%. However, the reaction of **6** and potassium hydroxide or sodium hydroxide afforded **4b** in poor yields because of the ready saponification of **6** to the acid **3b**. Though ethanol was used as a solvent, favorable results were not obtained.

From the above results, strong bases are seen to be generally useful for synthesizing 4,5-dihydro-3*H*-naphtho[1,8-*bc*]furan derivatives in good yields. The methods seems to be applicable to syntheses of a variety of 4,5-dihydro-3*H*-naphtho[1,8-*bc*]furans.

We have examined the reaction of **6** and potassium hydroxide in detail in order to explain the mechanisms of formation of 6-methoxy-4,5-dihydro-3*H*-naphtho[1,8-*bc*]furans (**4b**, **7**, and **2b**), since the mechanism of formation of the furan ring had not been explored adequately for benzofuran derivatives.[40–46] When **6** was refluxed with one equivalent of potassium hydroxide in dioxane potassium 2a-hydroxy-6-methoxy-2a,3,4,5-tetrahydro-2*H*-naphtho[1,8-*bc*]furan-2-carboxylate (**8**) was obtained as a precipitate in 76% yield. The structure of **8** was confirmed from the spectral properties. The IR spectrum of **8** showed absorption bands due to the carboxylate ion at 1420 and 1610 cm^{-1}. The ^{1}H NMR spectrum of **8** showed a peak due to a methine proton at 4.60 ppm (1H, s), but a hydroxyl group peak was not found because of an exchange reaction between the hydroxyl group and water. The ^{13}C NMR spectrum of **8** exhibited a peak due to a quaternary carbon (2a-position) at 76.8 ppm and a peak due to a tertiary carbon (2-position) at 96.6 ppm. However, the stereochemical relation between the methine proton and the hydroxyl group was not evident from the spectral properties.

In the reaction of **6** with five equivalents of potassium hydroxide in dioxane, compound **4b** was not present in the reaction mixture before acidification with hydrochloric acid judging from TLC analysis. Therefore, **4b** was produced by acidification of the reaction mixture. The ^{1}H and ^{13}C NMR spectra of the precipitates obtained from the reaction of **6** with five equivalents of potassium hydroxide showed that the precipitates consisted of **8** and potassium 6-methoxy-4,5-dihydro-3*H*-naphtho[1,8-*bc*]furan-2-carboxylate (**9**), that is, potassium salt of **2b** was already present in the reaction mixture before acidification. Compound **8**, once produced, was stable and not converted to **4b** or **9** under the reaction conditions of **6** with potassium hydroxide.

When an aqueous solution of **8** was acidified with hydrochloric acid, **4b** was readily obtained in a 90% yield but the yield of **2b** was only 2%. Therefore, it is clear that **4b** was exclusively produced from the intermediate **8**. The reaction of **8** with diethyl sulfate in dioxane gave **4b** and **7** in 65 and 19% yields respectively. In the presence of potassium hydroxide the reaction of **8** with diethyl sulfate afforded **4b** and **2b** in 3 and 26% yields respectively. The results suggest that the ester **11** was unstable and converted easily to **4b** or **7** by elimination of ethyl hydrogen carbonate or water. In the presence of potassium hydroxide elimination of water was accelerated to give **2b**. Compound **8** was converted to **9** by heating at 240 °C for 2 h under reduced pressure in quantitative yield. From the above results the reaction mechanisms of formation of **4b**, **7**, and **2b** were



Scheme 3.

elucidated and are summarized in Scheme 3.

A proton of the active methylene group in **6** is removed by potassium hydroxide to give an anion **10**. The anion **10** cyclize to an ester **11** which reacts in two paths. Saponification of the ester **11** gives **8** which is stable under the reaction conditions and is converted to **4b** only by adding hydrochloric acid. Dehydration of the ester **11** affords **7** which can be saponified easily by excess potassium hydroxide to give **9**. Compound **9** is converted to **2b** by adding hydrochloric acid. Therefore, **11** is a precursor of **4b**, **7**, and **2b**, and **8** is a direct precursor of **4b**. The mechanisms of the reaction of **6** with potassium hydroxide will be applicable to the reactions of **6** and other strong bases. The reactivity and stereochemistry of **8** will be further investigated.

Experimental

All the melting points are uncorrected. The column chromatography was performed on silica gel (Wakogel C-200). Unless otherwise stated anhydrous sodium sulfate was employed as the drying agent. The infrared absorption spectra (IR) were determined on a Hitachi EPI-G grating infrared spectrophotometer. The nuclear magnetic resonance spectra (^{1}H and ^{13}C NMR) were determined at 90 MHz on a JEOL JNM-FX 90Q FT NMR spectrometer. Tetramethylsilane (TMS) was used as the internal standard in organic solvents. Methyl groups of sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) were employed as the internal standard in deuterium oxide: The chemical shift of the methyl groups was taken as 0 ppm.

A General Procedure for the Reactions of Ethyl (4-Methoxy-8-oxo-5,6,7,8-tetrahydro-1-naphthyloxy)acetate (6) with Strong Bases. A mixture of **6** (0.50 g; 1.80 mmol), potassium hydroxide (0.50 g; 9.00 mmol), and anhydrous dioxane (10 ml) was refluxed for 1 h. To the mixture water (20 ml) was added, and the solution was poured into 2 M** hydrochloric acid (100 ml). After 15 min the solution was extracted with ether. The ethereal solution was washed three times with a 1 M potassium carbonate solution (30 ml) and then with water, dried, and evaporated. The resulting oil was chromatographed and eluted with benzene to give 0.24 g (71%) of **4b** as colorless oil. The IR and ^{1}H NMR spectra of the oil are identical with those of an authentic sample.[19] Bp 102 °C at 0.7 Torr.*** ^{13}C NMR ($CDCl_3$): δ (TMS) 19.9, 21.7, 23.5, 56.7, 108.0, 109.4, 116.9, 128.8, 138.5, 148.4, 151.2.

The alkaline solution was acidified with 6M hydrochloric acid and the resulting precipitates were extracted with ether. The ethereal solution was washed with water, dried, and evaporated to give 0.09 g (22%) of **2b** as crystals. Recrystallization from dioxane gave colorless needles; mp 229 °C (decomp). The IR spectrum and melting point of the needles are identical with those of an authentic sample.[19] ^{1}H NMR (CD_3COCD_3): δ (TMS) 1.88—2.16 (2H, m, $-CH_2-$), 2.83 (2H, t, J=6 Hz, $-CH_2-$), 3.07 (2H, t, J=6 Hz, $-CH_2-$), 3.88 (3H, s, Ar–OCH_3), 7.13 (1H, d, J=9 Hz, Ar–H), 7.30 (1H, d, J=9 Hz, Ar–H).

Similarly **6** was treated with sodium hydroxide, sodium ethoxide, or sodium hydride in dioxane. Isolation of **4b** and **7** was performed by chromatography using benzene followed by benzene(9)–ether(1) as developing solvents. The reactions of **6** and four kinds of bases in anhydrous benzene were carried out by a method similar to the reaction of **6** with potassium hydroxide in dioxane.

A Reaction of 6 and One Equivalent of Potassium Hydroxide. A mixture of **6** (0.500 g; 1.80 mmol) and potassium hydroxide (0.100 g; 1.80 mmol) was refluxed for 1 h in dioxane (10 ml). The reaction mixture was treated with 2 M hydrochloric acid by the method mentioned above. Thus, **4b** (0.250 g) was obtained in a 74% yield as a neutral product, and a mixture (0.085 g) of **2b** and **3b** was obtained as acidic products. The yields of **2b** and **3b** were determined to be 7 and 12% respectively by NMR analysis.

Ethyl 6-Methoxy-4,5-dihydro-3H-naphtho[1,8-bc]furan-2-carboxylate (7). Colorless needles from ethanol; mp 95—96 °C (lit,[19] 95—96 °C). The IR and ^{1}H NMR spectra of the needles were identical with those of an authentic sample.[19] ^{13}C NMR ($CDCl_3$): δ (TMS) 14.4, 21.4, 21.8, 23.3, 56.7, 60.8, 108.9, 113.3, 120.9, 126.9, 128.6, 139.3, 148.4, 151.5, 160.2.

Ethyl (4-Methoxy-8-oxo-5,6,7,8-tetrahydro-1-naphthyloxy)acetate (6). A mixture of **3b**[19] (10.0 g), diethyl sulfate (20.0 g), potassium carbonate (40.0 g), and acetone (200 ml) was refluxed for 2 h. After removal of the acetone the mixture was extracted with ether. The ethereal solution was washed with water, dried, and evaporated. The resulting oil was chromatographed and eluted with benzene(7)–ether(3) to give 7.60 g (88%) of **6**. Recrystallization from ethanol gave colorless needles; mp 72—73 °C. IR (KBr): ν_{max} 1680 (C=O), 1760 cm^{-1} ($COOC_2H_5$). ^{1}H NMR ($CDCl_3$): δ (TMS) 1.29 (3H, t, J=7 Hz, CH_3), 2.05 (2H, dt, J=6 and 6 Hz, $-CH_2-$), 2.62 (2H, t, J=6 Hz, $-CH_2-$), 2.87 (2H, t, J=6 Hz, $-CH_2-$), 3.81 (3H, s, OCH_3), 4.24 (2H, q, J=7 Hz, $-OCH_2-$), 4.62 (2H, s, $-OCH_2CO-$), 6.81 (1H, d, J=9 Hz, Ar–H), 6.96 (1H, d, J=9 Hz, Ar–H). ^{13}C NMR ($CDCl_3$): δ (TMS) 14.2, 22.2, 23.6, 40.6, 55.9, 61.0, 68.4, 115.0, 115.2, 124.7, 135.1, 151.8, 152.0, 169.2, 197.2. Found: C, 64.63; H, 6.40%. Calcd for $C_{15}H_{18}O_5$: C, 64.74; H, 6.52%.

Potassium 2a-Hydroxy-6-methoxy-2a,3,4,5-tetrahydro-2H-naphtho[1,8-bc]furan-2-carboxylate (8). A mixture of **6** (1.00 g; 3.60 mmol), potassium hydroxide (0.20 g; 3.60 mmol), and anhydrous dioxane (20 ml) was refluxed for 1 h. After cooling the resulting precipitates were collected by filtration to give 0.84 g (76%) of **8**. Recrystallization from water–dioxane gave colorless needles, mp>250 °C. IR (KBr): ν_{max} 1420, 1610 (COO^-), 3250 cm^{-1} (OH). ^{1}H NMR (D_2O): δ (DSS) 1.38—2.98 (6H, m, $-CH_2-$+$-CH_2-$+$-CH_2-$), 3.77 (3H, s, Ar–OCH_3), 4.60 (1H, s, $-CH=$), 6.70 (1H, d, J=8 Hz, Ar–H), 6.75 (1H, d, J=8 Hz, Ar–H). ^{13}C NMR (D_2O): δ (DSS) 20.1, 22.8, 33.6, 59.0 76.8, 96.6, 109.5, 115.1, 127.3, 131.9, 153.8, 154.1, 176.6. Found: C, 51.20; H, 4.89%. Calcd for $C_{13}H_{13}O_5K\cdot H_2O$: C, 50.97; H, 4.94%.

Potassium 6-Methoxy-4,5-dihydro-3H-naphtho[1,8-bc]furan-2-carboxylate (9). Compound **2b** (0.50 g) was dissolved in an alkaline solution (30 ml) containing potassium hydroxide (0.12 g) and the water was removed under the reduced pressure to give 0.58 g (92%) as crystals. Recrystallization from water–dioxane gave colorless plates; mp 103—105 °C. The melting point of the plates after once melting was above 250 °C. IR (KBr): ν_{max} 1405, 1570 cm^{-1} (COO^-). ^{1}H NMR (D_2O): δ (DSS) 1.82 (2H, dt, J=6 Hz, $-CH_2-$), 2.56 (2H, t, J=6 Hz, $-CH_2-$), 2.83 (2H, t, J=6 Hz, $-CH_2-$), 3.80 (3H, s, Ar–OCH_3), 6.89 (1H, d, J=9 Hz, Ar–H), 7.11 (1H, d, J=9 Hz, Ar–H). ^{13}C NMR (D_2O): δ (DSS) 23.5, 24.0, 25.4, 59.6, 111.1, 115.2, 123.1, 125.2, 131.1, 146.7, 149.8, 152.7, 170.2. Found: C, 51.24; H, 4.98%. Calcd for $C_{13}H_{11}O_4K\cdot 2H_2O$: C, 50.97; H, 4.94%.

The Reaction of Potassium 2a-Hydroxy-6-methoxy-2a,3,4,5-tetra-

** 1 M=1 mol dm^{-3}.

*** 1 Torr≈133.322 Pa.

hydro-2H-naphtho[1,8-bc]furan-2-carboxylate (8) and Hydrochloric Acid. Compound **8** (0.100 g) was dissolved in water (10 ml) and the solution was poured into 2 M hydrochloric acid (100 ml). After 15 min the solution was extracted with ether. The ethereal solution was washed three times with a 1 M potassium carbonate solution and then with water, dried, and evaporated to give 0.55 g (90%) of **4b** as colorless oil. The alkaline solution was acidified with 6 M hydrochloric acid and extracted with ether. The ethereal solution was washed with water, dried, and evaporated to give 0.002 g (2%) of **2b** as colorless crystals.

The Reaction of Potassium 2a-Hydroxy-6-methoxy-2a,3,4,5-tetrahydro-2H-naphtho[1,8-bc]furan-2-carboxylate (8) and Diethyl Sulfate. A mixture of **8** (0.100 g), diethyl sulfate (0.110 g), and dioxane (8 ml) was refluxed for 2 h. The mixture was extracted with ether. The ethereal solution was washed with water, dried, and evaporated. The resulting oil was chromatographed and eluted with benzene. The first fraction gave 0.040 g (65%) of **4b** as colorless oil. The second fraction afforded 0.015 g (19%) of **7** as colorless crystals.

Similarly, **8** (0.100 g) was dealt with diethyl sulfate (0.110 g) in the presence of potassium hydroxide (0.100 g) to give **4b** and **2b** in 3 and 26% yields respectively. The total yield of **4b** and **2b** was low because unreacted **8** remained.

The authors wish to thank Mr. Yoshiaki Takahashi for the elemental analyses.

The Stereoselective Dehydrative α-Glucosylation Using 6-*O*-Acetyl- and 6-*O*-*p*-Nitrobenzoyl-2,3,4-tri-*O*-benzyl-D-glucopyranoses

Shinkiti KOTO,* Naohiko MORISHIMA, Yasuhiro KIHARA, Hideko SUZUKI, Shigeharu KOSUGI, and Shonosuke ZEN

(Received April 5, 1982)

The stereoselective synthesis of α-linked glucobiose derivatives using 6-*O*-acetyl- or 6-*O*-*p*-nitrobenzoyl-2,3,4-tri-*O*-benzyl-D-glucopyranose and a ternary mixture of *p*-nitrobenzenesulfonyl chloride, silver trifluoromethanesulfonate, and triethylamine in dichloromethane is described.

Many methods for systematic oligosaccharide synthesis have been reported.[1] Except for one unique approach,[2] all use the Koenigs-Knorr reaction and relatives[3] to form an interglycosidic linkage. Our objective has been to develop a reagent which will activate the anomeric center of a protected glycose like 2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranose (**1**) in the presence of the alcohol to be glycosylated, in order to simplify the glycosylation procedure as written by Eq. 1[4] (G denotes 2,3,4,6-tetra-*O*-benzyl-D-glucopyranosyl residue and equivalents):[5a,b]

$$\mathrm{GOH} + \mathrm{ROH} \xrightarrow[-\mathrm{H_2O}]{} \mathrm{GOR}. \qquad (1)$$

Until recently, few attempts have been made to simplify the glycosylation procedure.[4,5] This paper will describe the effect of the acyl group of the modified benzylated glucopyranoses, *i.e.*, 6-*O*-acetyl- and 6-*O*-*p*-nitrobenzoyl-2,3,4-tri-*O*-benzyl-D-glucopyranoses (**2** and **3**), on the selectivity of the dehydrative glucosylation using a ternary mixture of *p*-nitrobenzenesulfonyl chloride (NsCl), silver trifluoromethanesulfonate (AgOTf), and triethylamine (Et_3N) (the NST mixture)[4b] in CH_2Cl_2.

Results and Discussion

The NST mixture was found to undergo the stereoselective β-glucosylation of simple alcohols with **1**.[4b] It was later found, however, that such selectivity was retained only for the glucosylation of a primary hydroxyl group and that the glucosylation of a secondary group proceeded with a poor selectivity in the di- and trisaccharide synthesis using **1** and the NST mixture.[6] Therefore, an additional prerequisite is necessary for the dehydrative glucosylation with **1** and the NST mixture to proceed stereoselectively, irrespective of the reactivity of the hydroxyl group of partially benzylated saccharides. This led us to study the dehydrative glucosylation using the NST mixture and such derivatives of D-glucopyranose as **2** and **3**, since the modified benzylated glucopyranosyl bromides with 6-*O*-acetyl- or 6-*O*-*p*-nitrobenzoyl group are good intermediates for the highly stereoselective α-glucosylation.[7,8]

Compound **2** was prepared through the regioselective *O*-deacetylation of 1,6-di-*O*-acetyl-2,3,4-tri-*O*-benzyl-D-glucopyranose (**5**), which is readily available *via* the acetolysis of 1,6-anhydro-2,3,4-tri-*O*-benzyl-β-D-glucopyranose (**6**),[9] by either of three reagents: (i) hot methanolic sodium acetate (NaOAc), (ii) benzylamine ($PhCH_2NH_2$) in $CHCl_3$,[10a] and (iii) N_2H_4 in pyridine.[10b] By the treatment of **6** with acetyl bromide (AcBr),[11] followed by hydrolysis in the presence of Ag_2CO_3, **2** was also prepared. The acylation of 2,3,4-tri-*O*-benzyl-β-D-glucopyranose (**7**)[9] with *N*-acetylimidazole[12] gave **2** with a poor regioselectivity, whereas that with *p*-nitrobenzoyl chloride afforded **3** in a good yield.

As expectedly, **2** was condensed with cyclohexanol by the NST mixture to afford the α-glucoside **8a** predominantly, although a similar glucosylation of the alcohol with **1** showed β-selectivity.[4b] The dehydrative glucosylation of the alcohol with **3** also showed α-selectivity. Judging from the temperature of the precipitation of AgCl, the glucosylation using **2** or **3** appears to proceed at a slightly higher temperature (>−10 °C) than that using **1** (<−20 °C), so that a part of such a simple alcohol as cyclohexanol may be sulfonated concurrently to depress the yield of the glucosides significantly.

The α-glucosylation of the primary hydroxyl group of the protected glucopyranoside **10**[8] with **2** proceeded well: the isomaltose derivative[8] **9a** was synthesized with ease *via* the treatment of a mixture of **2** and **10** with the NST mixture in CH_2Cl_2, followed by *O*-deacetylation, in a 54% yield, while the gentiobiose derivative **9b** was obtained as the by-product in a 21% yield. Compound **3** was similarly condensed with **10** to give the isomaltose derivative,[8] **16a**, and the gentiobiose one, **16b**, in 50 and 29% yields respectively. Thus, it is evident that the α-selectivity was caused by the 6-*O*-acyl group, because a similar glucosylation of benzyl 3-*O*-acetyl-2,4-di-*O*-benzyl-α-D-glucopyranoside with **1** was highly selective to form the gentiobiose derivative.[6] It was found that the glucosylation of the secondary hydroxyl group of the protected glucopyranoside **11**[13] with **2**, followed by *O*-deacetylation, gave the maltose derivative **12** exclusively in a 39% yield; no trace of the cellobiose derivative was found in the reaction mixture.

The present method is more efficient for the α-glucosylation of secondary hydroxyl groups than the method using a mixture of trimethylsilyl bromide (Me_3SiBr), $CoBr_2$, tetrabutylammonium bromide (*n*-Bu_4NBr), and Molecular Sieve (4A) (the TCTM mixture) in CH_2Cl_2,[4d] and may well be balanced with other selective α-glucosylation procedures[14] because of its simplicity and rapidity. For the α-glucosylation of primary hydroxyl groups, the method with the TCTM mixture, which does not need such a modified precursor as **2** or **3**, is more convenient than that with the NST mixture.

The combined use of both methods made it possible to perform the step-by-step synthesis of *O*-α-D-glucopyranosyl-(1→6)-*O*-α-D-glucopyranosyl-(1→4)-D-glucopyranose (panose, **4**),[15] formulated in Fig. 1. The maltose derivative **12**, synthesized through the condensation of **2** and **11** with the NST mixture as has been described above, was glucosylated with **1** using the TCTM mixture to furnish the fully benzylated α-panose (**13a**). The hydrogenolysis of **13a** afforded **4**, which has once been synthesized from maltose.[15c]

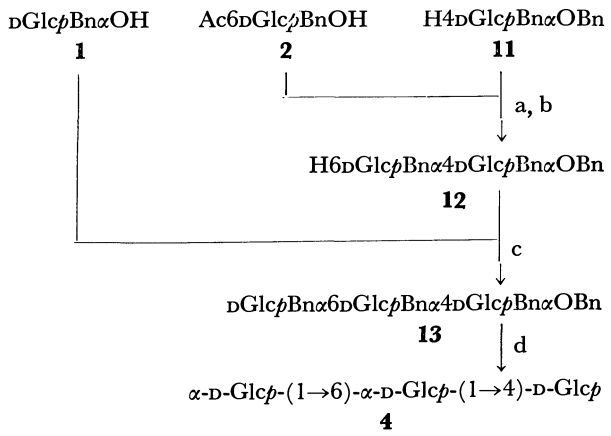
Experimental

General. See Refs. 4b and 6.

6-O-Acetyl-2,3,4-tri-O-benzyl-D-glucopyranose (2). *(1)*: A mixture of **5**[9] (106.4 mg, 0.20 mmol), NaOAc (46 mg), and MeOH (4.6 ml) was refluxed for 5 h. The solution



a (NsCl + TfOAg + Et_3N)/CH_2Cl_2
b NaOMe/(MeOH + 1,4-Diox.)
c (Me_3SiBr + $CoBr_2$ + *n*-Bu_4NBr + Mol. Sieve(4Å))/CH_2Cl_2
d Pd-C(10%)/AcOH(+H_2O)

Fig. 1. The scheme for a stepwise synthesis of panose, **4**.

was evaporated at 20 °C and then chromatographed using a mixture of toluene and 2-butanone (10:1). After the elution of **5** (35.2 mg, 33%) and a trace amount of **17**, there appeared **2** (45.2 mg, 69%). ^1H NMR($CDCl_3$, Me_4Si) δ 2.03 (3H, s, Ac), 5.19 (1H, d, J=4.0 Hz, HI), ^{13}C NMR ($CDCl_3$, Me_4Si) δ 20.9 (Ac), 91.1 (Clα), 97.4 (Clβ).

(2): $PhCH_2NH_2$ (Wako, 60 μl) was added to a cooled solution of **5** (94.5 mg, 0.18 mmol) in $(CH_2Cl)_2$ (0.9 ml). The solution was kept standing for 2 d at room temperature. Evaporation and subsequent chromatography gave **2** (71.1 mg, 80%).

(3): $N_2H_4 \cdot H_2O$ (Wako, ≈90%, 6.6 μl) was added to a cooled solution of **5** (96.6 mg, 0.18 mmol) in pyridine (0.9 ml). The solution was kept standing for 4 d at room temperature. Evaporation and subsequent chromatography gave **2** (63.3 mg, 71%).

(4): A mixture of **6**[9] (5.0 g, 11.6 mmol) and AcBr (5 ml) was stirred for 1.5 h at room temperature. The solution was then evaporated, and the residue was stirred into CH_2Cl_2 (5 ml) containing H_2O (2.05 ml) and Ag_2CO_3 (6.4 g). The mixture was chromatographed to give **2** (4.83 g, 75%).

(5): A mixture of **7**[9] (90 mg, 0.20 mmol), *N*-acetylimidazole (Tokyo Kasei, 30.6 mg), and $(CH_2Cl)_2$ (0.4 ml) was stirred for 16 h at room temperature. The mixture was then chromatographed to give **5** (14.5 mg, 14%, R_f 0.70 (toluene–2-butanone, 10:1)), **17** (27.8 mg, 28%, R_f 0.35), **2** (36.4 mg, 37%, R_f 0.30), and then **7** (8.8 mg, 10%, R_f 0.05); ^1H NMR($CDCl_3$, Me_4Si) δ (**17**) 2.02 (Ac-β), 2.13 (Ac-α), 5.62 (d, J=8.0 Hz, HI-β), 6.17 (d, J=3.5 Hz, HI-α).

2,3,4-Tri-O-benzyl-6-O-p-nitrobenzoyl-D-glucopyranose (3). A mixture of **7** (450 mg, 1.0 mmol), *p*-nitrobenzoyl chloride (Tokyo Kasei, 223 mg), and pyridine (10 ml) was stirred for 3 h at −10 °C and then for 16 h at room temperature. Usual processing and subsequent chromatography with benzene–2-butanone (10:1) gave 2,3,4-tri-*O*-benzyl-1,6-bis-*O*-(*p*-nitrobenzoyl)-β-D-glucopyranose (48 mg, 6%, R_f 0.84 (benzene–2-butanone, 10:1), mp 144.5—145.5 °C (lit,[7b] mp 144.5—145.5 °C), **18** (53 mg, 9%, R_f 0.60), **3** (310 mg, 52%, R_f 0.52), and **7** (129 mg, 29%); ^1H NMR($CDCl_3$, Me_4Si) δ (**3**) 5.24 (d, J=3.8 Hz, HI-α), 7.61—8.31 (4H, m, $-C_6H_4-$), (**18**) 5.71 (1H, d, J=8.0 Hz, HI), 8.05—8.33

(4H, m, $-C_6H_4-$).

*Ethyl 2,3,4-Tri-*O*-benzyl-1-thio-α-*D*-glucopyranoside (**10**)*: A mixture of AcBr (5 ml) and **6** (5.0 g, 11.6 mmol) was stirred for 1.5 h at room temperature and then evaporated. The whole residue was treated with EtSH (Wako, 9.0 ml) in $MeNO_2$ (17 ml) containing 2,6-dimethylpyridine (4.2 ml). After evaporation, the residue was dissolved in MeOH (70 ml) containing methanolic NaOMe (2 M, 10 ml). After 20 h, AcOH (1.5 ml) was added to the mixture, which was evaporated and then chromatographed using benzene–2-butanone (10:1). This gave **10** (4.9 g, 75%), identified with the sample prepared previously through a different route.[8]

*Benzyl 2,3,6-Tri-*O*-benzyl-α-*D*-glucopyranoside (**11**)*: A mixture of benzyl 2,3-di-*O*-benzyl-α-D-glucopyranoside[13a] (0.65 g, 1.44 mmol), $PhCH_2Cl$ (6.5 ml), and NaH (≈50% disp., 70 mg) was vigorously stirred for 40 min at 80 °C. Usual processing and subsequent chromatography with hexane–EtOAc (4:1) gave benzyl 2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranoside (15 mg, 1.7%, R_f 0.75 (hexane–EtOAc, 4:1)), **11** (0.35 g, 45%, R_f 0.52), benzyl 2,3,4-tri-*O*-benzyl-α-D-glucopyranoside[13c] (0.10 g, 13%, R_f 0.30), and the unchanged starting material (0.18 g, 28%, R_f 0.08).

*Cyclohexyl 6-O-Acetyl-2,3,4-tri-*O*-benzyl-α- and -β-*D*-glucopyranoside (**8a** and **8b**)*: Et_3N (31 μl, 0.22 mmol) was added to a mixture of **2** (108 mg, 0.22 mmol), cyclohexanol (21 μl, 0.22 mmol), NsCl (49 mg, 0.22 mmol), and AgOTf (57 mg, 0.22 mmol) in CH_2Cl_2 (1.0 ml) at −35 °C under efficient stirring. The bath temperature was raised to 0 °C at a rate of ≈0.5 °C/min, and then the stirring was continued for 6 h. After the processing described previously,[4b] chromatography with hexane–EtOAc (5:1) gave **8b** (14.6 mg, 12%, R_f 0.66 (hexane–EtOAc, 3:1)), and **8a** (41.4 mg, 33%, R_f 0.60).

*Cyclohexyl 2,3,4-Tri-*O*-benzyl-6-*O*-p-nitrobenzoyl-α- and -β-*D*-glucopyranosides (**15a** and **15b**)*: A similar reaction using **3** (132 mg, 0.22 mmol), cyclohexanol (21 μl), NsCl (49 mg), AgOTf (57 mg), Et_3N (31 μl), and CH_2Cl_2 (1.0 ml) gave **15b** (11.8 mg, 8%, R_f 0.73 (hexane–EtOAc, 3:1)) and **15a** (55.6 mg, 37%, R_f 0.67).

*Ethyl O-(6-O-Acetyl-2,3,4-tri-*O*-benzyl-α- and -β-*D*-glucopyranosyl)-(1→6)-2,3,4-tri-*O*-benzyl-1-thio-α-*D*-glucopyranoside (**14a** and **14b**)*: Et_3N (156 μl, 1.1 mmol) was stirred into a mixture of **2** (492 mg, 1.0 mmol), **10** (494 mg, 1.0 mmol), NsCl (245.5 mg, 1.1 mmol), and AgOTf (283 mg, 1.1 mmol) in CH_2Cl_2 (5.0 ml) at −38 °C, after which the bath temperature was allowed to rise to 0 °C. After having been stirred for 16 h, the mixture was processed[4b] and then chromatographed (benzene–2-butanone, 100:1→3:1, gradient) to give **14a** (543.8 mg, 56%, R_f 0.44, benzene–2-butanone, 20:1)) and **14b** (244.5 mg, 25%, R_f 0.38); ^1H NMR(CCl_4, Me_4Si) δ (**14a**) 1.25 (3H, t, $C\underline{H}_3CH_2S$), 1.94 (3H, s, Ac), 2.57 (2H, m, $CH_3C\underline{H}_2S$), 5.35 (1H, d, J=5.0 Hz, Hl), 7.24 (30H, s, 6Ph); (**14b**) 1.23 (3H, t, $C\underline{H}_3CH_2S$), 1.96 (3H, s, Ac), 2.47 (2H, m, $CH_3C\underline{H}_2S$), 5.30 (1H, d, J=5.0 Hz, Hl), 7.20 (30H, s, 6Ph).

Compound **14a** (530 mg, 0.55 mmol) was treated with methanolic NaOMe (0.05 M, 20 ml) containing 1,4-dioxane (2 ml) to afford **9a** (485 mg, 96%), which was identified with the sample prepared previously.[8]

Compound **14b** (68 mg, 0.07 mmol) was treated with methanolic NaOMe (0.03 M, 3.5 ml) containing Me_2CO (1 ml) to give **9b** (55.2 mg, 85%).

*Ethyl O-(2,3,4-Tri-*O*-benzyl-6-*O*-p-nitrobenzoyl-α- and -β-*D*-glucopyranosyl-(1→6)-2,3,4-tri-*O*-benzyl-1-thio-α-*D*-glucopyranoside (**16a** and **16b**)*: A similar reaction using **3** (100 mg, 0.17 mmol), **10** (84 mg, 0.17 mmol), NsCl (41 mg, 0.19 mmol), AgOTf (48 mg, 0.19 mmol), Et_3N (26 μl, 0.19 mmol), and CH_2Cl_2 (1.0 ml) and subsequent chromatography (benzene–2-butanone, 100:1→5:1, gradient) gave **16a** (90.2 mg, 50%, R_f 0.75 (benzene–2-butanone, 20:1)), identified with the sample synthesized previously[8] and then **16b** (52.0 mg, 29%, R_f 0.65); ^1H NMR(CCl_4, Me_4Si) δ (**16a**) 1.25 (3H, t, $C\underline{H}_3CH_2S$), 2.50 (2H, m, $CH_3C\underline{H}_2S$), 5.28 (1H, d, J= 5.0 Hz, Hl), 7.95—8.17 (4H, m, $-C_6H_4-$); (**16b**) 1.23 (3H, t, $C\underline{H}_3CH_2S$), 2.53 (2H, m, $CH_3C\underline{H}_2S$), 5.27 (1H, d, J=

5.0 Hz, Hl), 8.03—8.12 (4H, m, $-C_6H_4-$).

Benzyl O-(2,3,4-Tri-O-benzyl-α-D-glucopyranosyl)-(1→4)-2,3,6-tri-O-benzyl-α-D-glucopyranoside (12): A similar glucosylation reaction using **2** (180 mg, 0.37 mmol), **11** (197.4 mg, 0.37 mmol), NsCl (97.5 mg, 0.44 mmol), AgOTf (113 mg, 0.44 mmol), Et_3N (61.5 μl, 0.44 mmol), and CH_2Cl_2 (1.8 ml) and subsequent chromatography (benzene–2-butanone) gave a sirup (173.5 mg, R_f 0.60 (benzene–2-butanone, 10:1), this being the sole spot in the region where $R_f > 0.43$). This was then treated with methanolic NaOMe (0.05 M, 11 ml) containing 1,4-dioxane (2 ml) to give a sirup which showed a single spot. ^{13}C NMR of this sirup, composed of **12** (135.6 mg, 39% for **11**), showed no signal of the anomeric carbons corresponding to the β-glucopyranoside; ^{13}C NMR($CDCl_3$, Me_4Si) δ 95.1 (Cl), 96.3 (Cl′).

Benzyl O-(2,3,4,6-Tetra-O-benzyl-α- and -β-D-glucopyranosyl)-(1→6)-O-(2,3,4-tri-O-benzyl-α-D-glucopyranosyl)-(1→4)-2,3,6-tri-O-benzyl-α-D-glucopyranoside (13a and 13b). A mixture of **1** (151 mg, 0.28 mmol), **12** (209 mg, 0.125 mmol), $CoBr_2$ (62 mg, 0.28 mmol), n-Bu_4NBr (90 mg, 0.28 mmol), Molecular Sieve (Linde-4A, 230 mg), and Me_3SiBr (37 μl, 0.28 mmol) in CH_2Cl_2 (0.7 ml) was stirred for 48 h at room temperature. The subsequent chromatography (hexane–2-butanone, 100:1→3:1, gradient) of the reaction mixture gave **13a** (93.2 mg, 29%, R_f 0.58 (hexane–2-butanone, 20:1)) and then **13b** (27.2 mg, 9%, R_f 0.55). ^{13}C NMR ($CDCl_3$, Me_4Si) δ (**13a**) 95.0 (Cl), 96.2 (Cl′), 97.1 (Cl″); (**13b**) 95.1 (Cl), 96.3 (Cl′), 103.7 (Cl″).

O-α-D-Glucopyranosyl-(1→6)-O-α-D-glucopyranosyl-(1→4)-D-glucopyranose (Panose, 4): Two hydrogenations of **13a** (73.8 mg, 0.062 mmol) over Pd–C (10%, 73 mg) in AcOH (7 ml) containing H_2O (0.03 ml) gave a glass, which was then triturated with MeOH to give **4** (19.3 mg, 61%). The ^{13}C NMR (D_2O, Me_4Si (ext.)) of this agreed well with that previously reported;[15d] 61.6 (C6″), 61.8 (C6), 67.0 (C6′), 70.5 (C4″), 70.6 (C4′), 71.1 (C5α), 72.4 (C5′), 72.6 (C2α and C2″), 72.7 (C2′), 72.9 (C5″), 74.2 (C3α, C3′, and C3″). 75.1 (C2β). 75.7 (C3β), 77.2 (C5β), 78.2 (C4β), 78.5 (C4α), 93.0 (C1α), 96.8 (C1β), 99.2 (C1″), 100.8 (C1′).

A sample of **4** (6.8 mg) was treated with aq $NaBH_4$ (0.2%, 4 ml) at room temperature overnight. After the addition of AcOH (1 drop), the mixture was evaporated and coevaporated with MeOH. The residue was stirred in Ac_2O (1 ml)c ontaining NaOAc (14 mg) at 100 °C for 6 h. Subsequent chromatography (benzene–2-butanone) gave a homogeneous glass. This was crystallized with MeOH to give *O*-(2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl)-(1→6)-*O*-(2,3,4-tri-*O*-acetyl-α-D-glucopyranosyl)-(1→4)-1,2,3,5,6-penta-*O*-acetyl-D-glucitol (**19**) (10.0 mg, 74%).

Synthesis of Biphenyloferrocenophanes

Iwao Shimizu, Yoshio Kamei, Takeshi Tezuka, Taeko Izumi, and Akira Kasahara*

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992

(Received April 30, 1982)

Some ferrocenophanes, in which the two cyclopentadienyl rings are linked by biphenyl rings, have been synthesized *via* intramolecular reductive coupling of the corresponding formyl compounds with a low-valent titanium reagent. The structures of these cyclophane compounds were determined by IR, NMR, and UV spectra analyses. Transannular π-electronic interactions between the two biphenyl rings were examined on the basis of electronic spectra.

In contrast to the active interest in cyclophane compounds, the ferrocenophane system having transannular π-electronic interactions has received little attention; the only compounds of this class which have been described are [2.2]ferrocenophane-1,13-diyne,[1] [2.2]-ferrocenophane-1,13-diene,[2] [2]paracyclo[2]paracyclo-[2](1,1′)ferrocenophane,[3] [3.3]- and [5.5](1,1′)ferrocenophane derivatives,[4] and [0]metacyclo[2]metacyclo[0](1,1′)ferrocenophane.[5] We wish to report the synthesis of some ferrocenophanes in which the two cyclopentadienyl rings are linked by biphenyl rings and an ethano or etheno bridge, using the low-valent titanium species.

Results and Discussion

Synthesis. Although a number of synthetic methods have been recently developed for [2.2]cyclophane,[6] a reductive coupling of carbonyl compounds with low-valent titanium reagents[7] is still very convenient and advantageous for the synthesis of cyclophane because of the availability of the intermediary compounds.[2,3,5,8]

In the present work, we applied the same method for the synthesis of [0](4,4′)biphenylo[2](4,4′)biphenylo[0](1,1′)ferrocenophan-13-ene (**1**), [0](4,3′)biphenylo[2](3,4′)biphenylo[0](1,1′)ferrocenophan-13-ene (**3**), and *syn*- and *anti*-[0](4,2′)biphenylo[2](2,4′)biphenylo-[0](1,1′)ferrocenophan-13-ene (**5s** and **5a**). The synthesis of an intermediate, 1,1′-bis(4′-formyl-4-biphenylyl)ferrocene (**13a**), was carried out by the cross coupling reaction[9] of 1,1′-bis(*p*-bromophenyl)ferrocene (**7**) with a Grignard reagent from *p*-bromobenzaldehyde ethylene acetal (**8**) in the presence of phosphino nickel complex. The synthesis of other intermediates, 1,1′-bis(3′-formyl-4-biphenylyl)ferrocene (**13b**) and 1,1′-bis-(2′-formyl-4-biphenylyl)ferrocene (**13c**), were carried out by the Gomberg's arylation of ferrocene with diazonium salt derived from 4′-aminobiphenyl-3-carboxylic acid (**10a**) and 4′-aminobiphenyl-2-carboxylic acid (**10b**), subsequent esterification in methanol, reduction with $LiAlH_4$, and oxidation with active MnO_2 in chloroform.

The reductive coupling reaction of dialdehyde, **13a** and **13b**, with low-valent titanium reagents were carried out according to Mukaiyama's procedure[7a] using a high dilution method. Silica gel column chromatography of the reaction products led to the isolation of **1** and **3**, respectively, accompanied by the formation of the reduction products of **13a** and **13b**. On the other hand, the $TiCl_4$–Zn reductive coupling of **13c** led to the formation of two isomers of **5s** and **5a**.

The catalytic hydrogenation of **1** and **3** with PtO_2 in ethanol–dioxane afforded [0](4,4′)biphenylo[2](4,4′)-biphenylo[0](1,1′)ferrocenophane (**2**) and [0](4,3′)biphenylo[2](3,4′)biphenylo[0](1,1′)ferrocenophane (**4**), respectively. The catalytic hydrogenation of **5s** and **5a** afforded the same product: [0](4,2′)biphenylo[2]-(2,4′)biphenylo[0](1,1′)ferrocenophane (**6**).

Structures. The structures of the cyclophanes, **1**—**6**, were determined on the basis of the IR, NMR, and mass spectra and the elementary analyses. The NMR and IR spectra data of all the cyclophanes and the reference compounds are summarized in Tables 1 and 2, respectively.

In the unsaturated cyclophane **1**, the configuration of –C–C– double bond was confirmed to be *cis*, because the IR spectrum of **1** exhibits a band at 740 cm^{-1} which is characteristic of *cis* vinylene linkage and the characteristic band near 960 cm^{-1} due to *trans* vinylene linkage is absent. In ferrocene, the distance between the two cyclopentadienyl rings is 3.32 Å,[10] while the van der Waals separation between parallel π-system is 3.4 Å.[11] On the other hand, in **1** and **2**, the molecules exist probably in the conformation with the biphenyl rings approximately parallel to one another and approximately coplanar to the plane of the cyclopentadienyl ring. Thus, in **1** and **2**, substantial repulsive interactions must exist between the two biphenyl rings which are bound together by an etheno or ethano bridge at each end. In the NMR spectrum of **1**, as expected, the aromatic protons (δ, 6.85—7.21 ppm) appear at higher fields than the corresponding protons of the reference compounds, 1,1′-bis(4′-methyl-4-biphenylyl)ferrocene (**15a**) (δ, 7.13—7.49 ppm) and (4′-methyl-4-biphenylyl)ferrocene (**16a**) (δ, 7.12—7.56 ppm). In the saturated cyclophane, the protons of biphenyl rings (δ, 6.88—7.21 ppm) are also shifted upfield compared with those of **15a** and **16a**. These phenomena are probably due to diamagnetic shielding effect of the facing biphenyl ring.

In the NMR spectra of **3** and **4**, the aromatic proton signals are observed at nearly the same positions as those of the reference compounds, 1,1′-bis(3′-methyl-4-biphenylyl)ferrocene (**15b**) and (3′-methyl-4-biphenylyl)ferrocene (**16b**). This suggests that the two biphenyl rings in both **3** and **4** are not held a face to face conformation and the *anti*-conformations for **3** and **4** are accommodated.

On the other hand, in two isomers of **5s** and **5a**, the mass spectra show the same pattern, which con-

Table 1. NMR spectra of the cyclophane and reference compounds (δ, in $CDCl_3$)[a)]

Compound	Biphenyl ring protons	Ferrocene ring protons	Other protons
1[a)]	6.85—7.21 (m, 16H)	4.34 (t, 4H, $\underline{H}_\beta$) 4.65 (t, 4H, $\underline{H}_\alpha$)	7.12 (s, 2H, -C$\underline{H}$=C$\underline{H}$-)

a) The spectra of **1** and **2** were observed in pyridine-d_5.

Table 2. IR spectra of the cyclophane and reference compounds (KBr, cm^{-1})

Compound	
1	1600, 1500, 840 (p-disubstituted benzene ring), 1640, 740 (*cis* -CH=CH-, 810 (1,1′-disubstuted ferrocene ring), 720, and 690.
2	1600, 1500, 1450, 830 (p-disubstituted benzene ring), 810 (1,1′-disubstituted ferrocene ring), 725, and 690.
15a	1600, 1500, 840 (p-disubstituted benzene ring), and 805 (1,1′-disubstituted ferrocene ring).
16a	1600, 1500, 840 (p-disubstituted benzene ring), 1100, 1000, and 810 (monosubstituted ferrocene ring).
3	1600, 1500, 780, 750, 695 (aromatic ring), 815 (1,1′-disubstituted ferrocene ring), and 735 (*cis* -CH=CH-).
4	1600, 1500, 1480, 830, 795, 765, 705 (aromatic ring), and 815 (1,1′-disubstituted ferrocene ring).
15b	1605, 1500, 840, 775, 735, 690 (aromatic ring), and 810 (1,1′-disubstituted ferrocene ring).
16b	1600, 1500, 860, 825, 750, 735, 695 (aromatic ring), 1100, 995, and 810 (monosubstituted ferrocene ring).
5s	1600, 1500, 840, 770, 750 (aromatic ring), 800 (1,1′-disubstituted ferrocene ring), and 740 (*cis* -CH=CH-).
5a	1600, 1500, 840, 760, (aromatic ring), 810 (1,1′-disubstituted ferrocene ring), and 975 (*trans* -CH=CH-).
6	1605, 1500, 840, 765, 715 (aromatic ring), and 815 (1,1′-disubstituted ferrocene ring).
15c	1600, 1500, 880, 845, 820, 760, 740, 730 (aromatic ring), and 805 (1,1′-disubstituted ferrocene ring).
16c	1600, 1500, 845, 760, 740 (aromatic ring), 1100, 1000, and 810 (monosubstituted ferrocene ring).

tains the molecular ion peak at *m/e* 514. Thus we call them isomers. The configuration of double bond in **5s** was confirmed to be *cis*, because the IR spectrum of **5s** exhibits a band of 740 cm^{-1} which is characteristic of *cis* vinylene linkage. The configuration of double bond in **5a** exhibits a band of 975 cm^{-1} which is characteristic of *trans* vinylene linkage. The structural difference between **5s** and **5a** is unequivocal in the NMR spectra. In the NMR spectrum of **5s**, it is noteworthy that the vinylene protons of **5s**, which can be easily assigned by relative intensities, appear at lower field than the aromatic protons, in the analogy with the case of [2.2.2](1,3,5)cyclophane-1,9,17-triene.[12] The H_a, H_b, H_e, and H_f protons in **5s** are shifted to higher field than the corresponding protons of the reference compounds, 1,1′-bis(2′-methyl-4-biphenylyl)ferrocene (**15c**) and (2′-methyl-4-biphenylyl)ferrocene (**16c**), showing the strong shielding effect of the proximate aromatic ring. However, the H_c and H_d signals of **5s** were observed at nearly the same positions as those of **15c** and **16c**. These phenomena suggest that the two aromatic A rings in **5s** are approximately parallel and are held face to face with each other; however, the two aromatic B rings are not parallel, and the aromatic A and B rings have a non-planar orientation due to the short length of the side chain which is bridging at the ortho position of B rings. Consequently, the H_a, H_b, H_e, and H_f protons lie closer to the opposed biphenyl ring than do the H_c and H_d protons. The difference of the chemical shifts may be due to the difference in ring current effect of the biphenyl ring on the aromatic protons of **5s**. These data are best accommodated by the *syn*-conformation for **5s**. On the other hand, in **5a**, the shifts of H_a, H_b, H_b', and H_{c-f} protons are negligible, and the upfield shifts (0.24 ppm) of H_a protons are marked and roughly the same as those (0.28 ppm) of H_a protons of **5s**. Small shielding effects on H_a', H_b, H_b', and H_{c-f} protons are also explained by the *anti*-structure for **5a**.

In the NMR spectrum of the saturated cyclophane **6**, the aromatic protons H_a are shifted to higher field by about 0.26 ppm, compared with those of the reference compounds, **15c** and **16c**. However, the signals of H_a' and H_{b-d} were observed at nearly the same positions as those of **15c** and **16c**. These phenomena are also explained by an *anti*-structure for **6**, but not by a *syn*-structure.

The electronic spectra of the cyclophane and the reference compounds are shown in Figs. 1, 2, and 3. Biphenyl itself has no absorption in the long wavelength above 250 nm.[13] The electronic spectra of **1** and **2**, and **5s**, **5a**, and **6** show somewhat bathochromic and hyperchromic shifts and unambiguous broadening in a range 240—310 nm, compared with those of the reference compounds, **15a** and **16a**, and **15c** and **16c**, respectively. This may be due to transannular π-electronic interactions between the two chromopheres in **1**, **2**, **5s**, **5a**, and **6**. The stronger effect in **5s**, relative to that in **5a** or **6**, suggests that the two biphenyl rings in **5s** are closer to being vertically stacked than in the cases of **5a** and **6**. An examination of molecular modela also supports this conclusion.

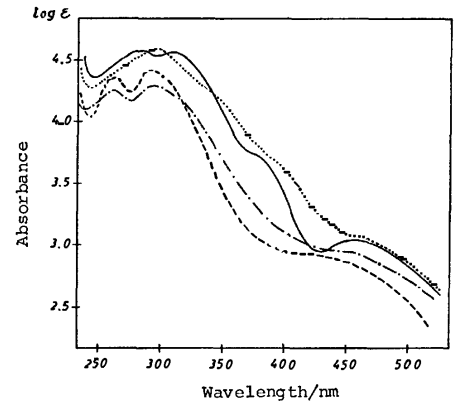

Fig. 1. Electronic spectra of **1**, **2**, **15a**, and **16a** in dioxane.
····· **1**, —— **2**, —·— **15a**, ---- **16a**.

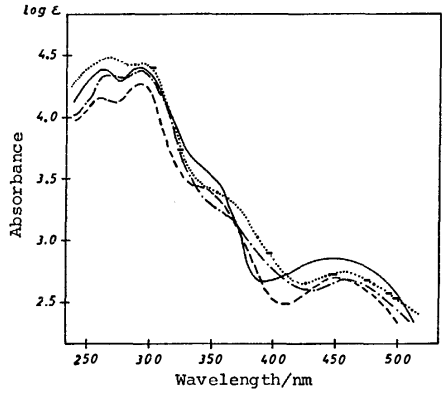

Fig. 2. Electronic spectra of **3**, **4**, **15b**, and **16b** in dioxane.
····· **3**, —— **4**, —·— **15b**, ----**16b**.

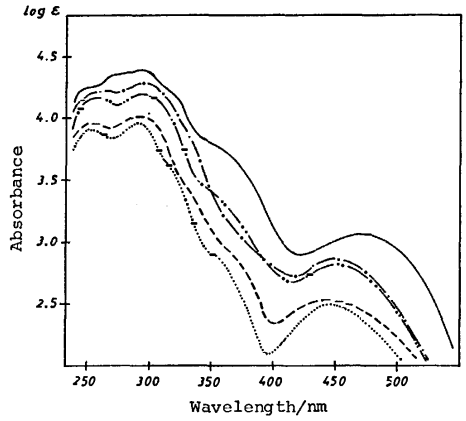

Fig. 3. Electronic spectra of **5s**, **5a**, **6**, **15c**, and **16c** in dioxane.
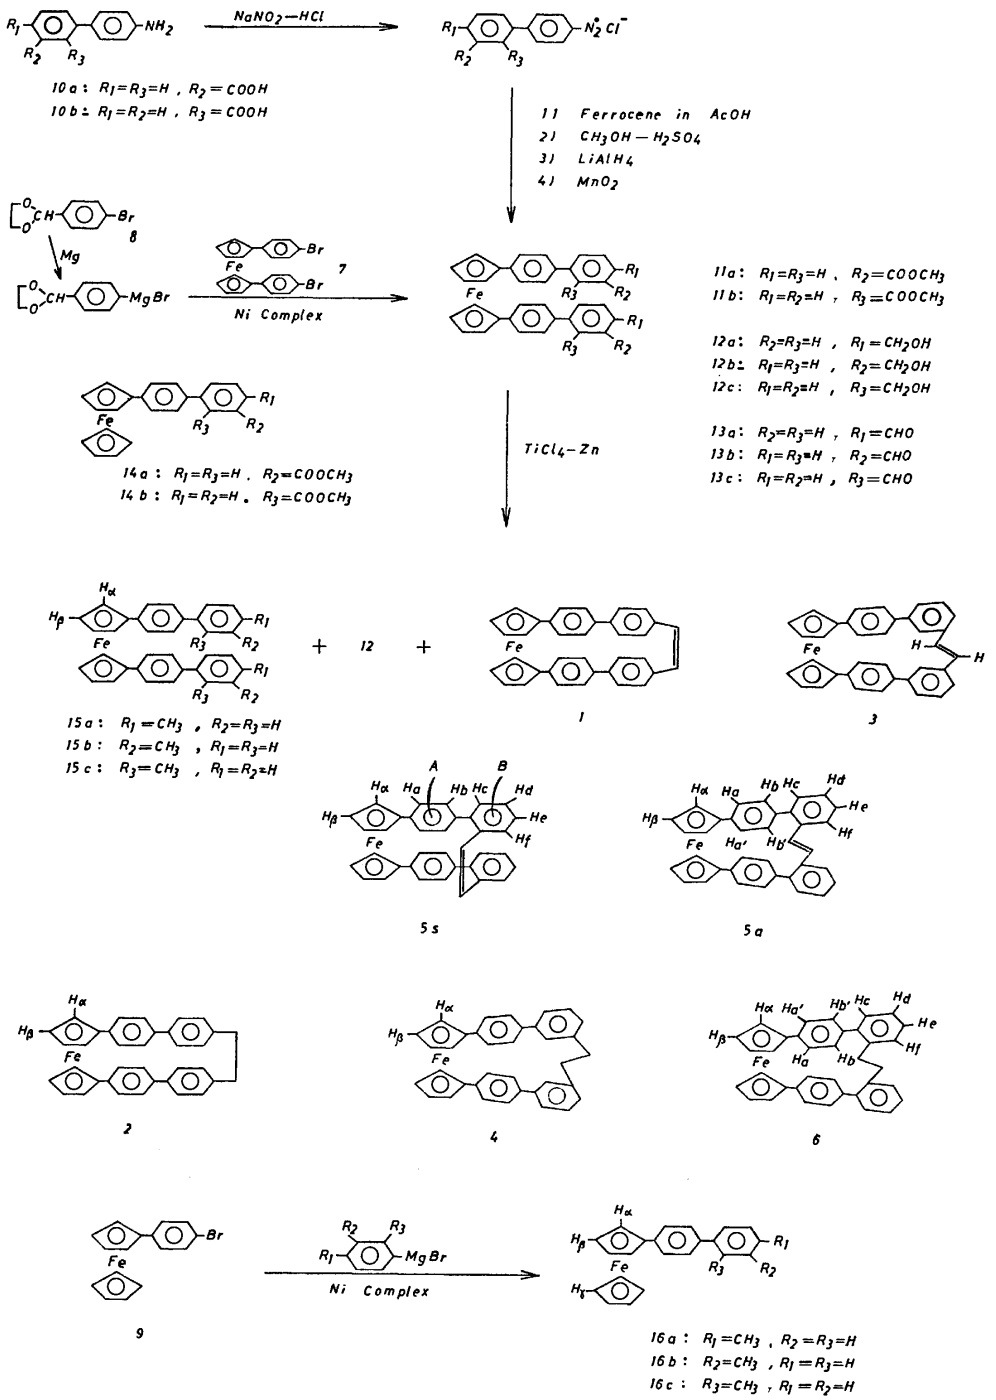
—— **5s**, —·— **5a**, —··— **6**, ---- **15c**, ····· **16c**.

On the other hand, in the 240—300 nm region, the cyclophanes **3** and **4** exhibit two absorption peaks and the intensity of these bands is somewhat increased; however, the spectra are practically identical with those of the reference compounds, **15b** and **16c**. These phenomena indicate that the interaction between the two biphenyl rings in both **3** and **4** is relatively weak and the *anti*-conformations for **3** and **4** can be accommodated.



Scheme 1.

The electronic spectra of ferrocene contain two broad absorptions at 325 and 440 nm.[14] It has been shown that both the position and the intensity of the 440 nm band are particularly sensitive to ferrocene ring-tilt distortion.[15] This is also true for [1]-[16] and [2]-ferrocenophanes;[15] the 440 nm band undergoes a bathochromic shift and increases in intensity. In Fig. 1, both **15a** and **16a**, which bear no tilted ferrocene ring, exhibit two weak absorptions near 335 and 450 nm; however, in the electronic spectra of **1** and **2**, both the 325 and 440 nm bands undergo a bathochromic shift and increase in intensity, compared with those of **15a** and **16a**. These phenomena may be due to ferrocene ring-tilt distortion in **1** and **2**.

The IR spectra of the [2.2]paracyclophane system show some obvious features. One is the increase of the intensity of a band in the 1580—1600 cm^{-1} region, which relates to the increased double bond character due to the distortion of the benzene rings.[17] The other is the appearance of a strong new maximum near the 710 cm^{-1} region. Longone and Warren[18] reported that the strong maximum at 725 cm^{-1} in [2.2]-paracyclophane and at 710 cm^{-1} in 4,7,12,15-tetramethyl[2.2]paracyclophane might be characteristic bands associated with the distorted benzene rings in the [2.2]paracyclophane system. Furthermore, Otsubo

et al.[19] reported the same phenomena in the multilayered [2.2]paracyclophane system. The cyclophanes **1** and **2** also exhibit characteristic bands around 700 cm^{-1}, whereas the reference compounds bearing strain-free benzene rings, **15a** and **16a**, exhibit no bands in this region. This phenomenon may be due to the distortion of the benzene rings in **1** and **2**.

In the cyclophane, **3** and **4**, the electronic spectra in the 330—450 nm region are closely similar to those of the reference compounds bearing a no-tilt ferrocene ring: **15b** and **16b**. This indicates that, in **3** and **4**, the ferrocene ring is not tilted. Moreover, near the 710 cm^{-1} region, the IR spectra of **3** and **4** are closely similar to those of the open-chain models, **15b** and **16b**. This may be due to the non-distortion of benzene rings in **3** and **4**.

On the other hand, in the electronic spectra in the 300—400 nm region, **5s**, **5a**, and **6** show an increased intensity and a bathochromic shift at longer wave length, compared with those of **15c**. These phenomena suggest a ferrocene ring-tilt distortion due to the interaction between the two chromophores in **5s**, **5a**, and **6**. However, in the IR spectra near the 720 cm^{-1} region, the cyclophane, **5s**, **5a**, and **6**, and the open-chain models, **15c** and **16c**, have two absorption bands at approximately the same positions. It indicates that **5s**, **5a**, and **6** bear the no-tilt benzene rings.

Experimental

Materials and Measurement. All melting points are uncorrected. IR spectra were measured using a Hitachi 260-10 spectrophotometer. NMR spectra were obtained at 90 MHz with a Hitachi R-22 spectrometer using TMS as the internal standard. Mass spectra were recorded with a Hitachi RMU-6M spectrometer and electronic spectra with a Hitachi 200-10 spectrophotometer.

1,1′-Bis(*p*-bromophenyl)ferrocene (**7**),[20] *p*-bromobenzaldehyde ethylene acetal (**8**),[21] *p*-bromophenylferrocene (**9**),[22] 4′-aminobiphenyl-3-carboxylic acid (**10a**),[23] and 4′-aminobiphenyl-2-carboxylic acid (**10b**)[23] were prepared by the methods described in the literature.

*1,1′-Bis(4′-formyl-4-biphenylyl)ferrocene (**13a**).* Under a nitrogen atmosphere, the Grignard reagent prepared from **8** (9.16 g, 40 mmol) and magnesium turnings (1.19 g, 49 mmol) in dry THF (60 cm^3) was dropwise added to the mixture of **7** (3.52 g, 8 mmol) and dichloro[1,3-bis(diphenylphosphino)propane]nickel(II) (0.9 g, 1.6 mmol) in dry THF (60 cm^3) at 0 °C with stirring over 2 h. The reaction mixture was stirred for 6 h at 0—5 °C and then was allowed to remain overnight at room temperature. The mixture was hydrolyzed with 10% hydrochloric acid under cooling with an ice bath and extracted with ether. The ether extracts were washed successively with 10% hydrochloric acid, water, aqueous sodium hydrogencarbonate, and brine. After drying over $MgSO_4$, the solution was evaporated *in vacuo*. The reddish residue was chromatographed on silica gel, using benzene as the eluent, to give **13a**, which was recrystallized from ethanol, mp 242—244 °C (decomp). IR (KBr): 1690 (–CHO), 1600, 1580, and 820 cm^{-1} (*p*-disubstituted benzene ring). NMR (pyridine-d_5): δ=4.03 (t, 4H, $\underline{H}_\beta$), 4.38 (t, 4H, $\underline{H}_\alpha$), 7.46—7.88 (m, 16H, Ar–$\underline{H}$), and 10.02 (s, 2H, –C$\underline{H}$O). Found: C, 79.04; H, 4.63%; M^+, 546. Calcd for $C_{36}H_{26}FeO_2$: C, 79.13; H, 4.79%; M, 546.

*1,1′-Bis(3′-methoxycarbonyl-4-biphenylyl)ferrocene (**11a**) and (3′-Methoxycarbonyl-4-biphenylyl)ferrocene (**14a**).* The amine **10a** (10.66 g, 50 mmol) was diazotized in 10% sulfuric acid (300 cm^3) at 0—5 °C with sodium nitrite (3.45 g, 50 mmol). After diazotization was complete, the diazotized salt solution was added rapidly to a solution of ferrocene (3.72 g, 20 mmol) in acetic acid (150 cm^3) under a nitrogen atmosphere. The resulting dark brown solution was stirred overnight at room temperature, and was then poured into water. The precipitates which formed were filtered off, washed with water, dried at room temperature, and then were esterified in refluxing methanol (250 cm^3) containing 3 cm^3 of conc H_2SO_4 under a nitrogen atmosphere. After removal of the solvent *in vacuo*, the residue was extracted with $CHCl_3$ and the $CHCl_3$ extracts were washed with 5% sodium hydrogencarbonate solution and brine, dried over $MgSO_4$, filtered, and concentrated. The residue was purified by column chromatography (silica gel–benzene). First elution with benzene gave the starting materials; ferrocene (0.93 g, 25%), mp 173 °C.

Second elution with benzene afforded 0.82 g (10.3%) of **14a**, orange yellow crystals, mp 78—80 °C. IR (KBr): 1715 (ester), 1100, 1000, and 805 cm^{-1} (monosubstituted ferrocene ring). NMR ($CDCl_3$): δ=3.63 (s, 3H, –COOC$\underline{H}_3$), 4.01 (s, 5H, $\underline{H}_\gamma$), 4.18 (b-s, 8H, $\underline{H}_\alpha$+$\underline{H}_\beta$), and 7.18—8.20 (m, 8H, Ar–$\underline{H}$). Found: C, 72.70; H, 4.97%; M^+, 396. Calcd for $C_{24}H_{20}FeO_2$: C, 72.74; H, 5.08%, M, 396.

Third elution with benzene gave 4.24 g (35%) of **11a**, reddish yellow crystals, mp 153—155 °C. IR (KBr): 1720 (ester), 1600, 1580, 880, 835 (*p*- and *m*-disubstituted benzene rings), and 805 cm^{-1} (1,1′-disubstituted ferrocene ring). NMR ($CDCl_3$): δ=3.87 (s, 6H, –COOC$\underline{H}_3$), 4.08 (m, 8H, $\underline{H}_\alpha$+$\underline{H}_\beta$), and 7.21—8.12 (m, 16H, Ar–$\underline{H}$). Found: C, 75.18; H, 4.92%; M^+, 606. Calcd for $C_{38}H_{30}FeO_4$: C, 75.25; H, 4.98%; M, 606.

*1,1′-Bis(2′-methoxycarbonyl-4-biphenylyl)ferrocene (**11b**) and (2′-Methoxycarbonyl-4-biphenylyl)ferrocene (**14b**).* Gomberg's arylation of ferrocene with diazonium salts derived from **10b**, was carried out in the same way as described for **11a**, **11b** (reddish yellow crystals, mp 62—63 °C) and **14b** (reddish yellow crystals, mp 78—80 °C) were obtained in 18 and 22% yields, respectively.

11b: IR (KBr): 1720 (ester), 810 (1,1′-disubstituted ferrocene ring), 1600, 1500, 845, 820, and 730 cm^{-1} (aromatic ring). NMR ($CDCl_3$): δ=3.91 (s, 6H, –COOC$\underline{H}_3$), 4.22 (t, 4H, $\underline{H}_\beta$), 4.51 (t, 4H, $\underline{H}_\alpha$), and 7.11—7.85 (m, 16H, Ar–$\underline{H}$). Found: C, 75.14; H, 4.87%; M^+, 606. Calcd for $C_{38}H_{30}FeO_4$: C, 75.25; H, 4.98%; M, 606.

14b: IR (KBr): 1720 (ester), 1100, 1000, 805 (monosubstituted ferrocene ring), 1600, 1500, 840, 820, and 740 cm^{-1} (aromatic ring). NMR ($CDCl_3$): δ=3.86 (s, 3H, –COOC$\underline{H}_3$), 4.06 (s, 5H, $\underline{H}_\gamma$), 4.22 (t, 2H, $\underline{H}_\beta$), 4.45 (t, 2H, $\underline{H}_\alpha$), and 7.15—8.12 (m, 8H, Ar–$\underline{H}$). Found: C, 72.66; H, 5.01%; M^+, 396. Calcd for $C_{24}H_{20}FeO_2$: C, 72.74; H, 5.08%; M, 396.

*1,1′-Bis(3′-hydroxymethyl-4-biphenylyl)ferrocene (**12b**).* To a solution of $LiAlH_4$ (1.41 g, 37 mmol) in anhydrous ether (200 cm^3) was added dropwise a solution of **11a** (10.90 g, 18 mmol) in dry benzene (100 cm^3) at room temperature during 1 h, and the reaction mixture was then heated under reflux for additional 5 h. After the reaction mixture was decomposed with a small amount of cold water, the organic layer was washed with 5% hydrochloric acid, 5% aqueous sodium hydrogencarbonate, and brine, and dried over anhydrous $MgSO_4$. After removal of the solvents, the residue was purified by column chromatography on silica gel (benzene) to afford **12b** as reddish yellow crystals, which was recrystallized from ethanol, mp 166—168 °C, in 64% yield.

IR (KBr): 3430 (–OH), 1605, 1500, 880, 840 (aromatic ring), and 810 cm^{-1} (1,1′-disubstituted ferrocene ring). NMR ($CDCl_3$): δ=1.50 (s, 2H, –O<u>H</u>), 4.08 (t, 4H, <u>H</u>$_\beta$), 4.29 (t, 4H, <u>H</u>$_\alpha$), 4.57 (s, 4H, –C<u>H</u>$_2$–), and 7.07—7.76 (m, 16H, Ar–<u>H</u>). Found: C, 78.45; H, 5.35%; M^+, 550. Calcd for $C_{36}H_{30}FeO_2$: C, 78.55; H, 5.49%; M, 550.

*1,1′-Bis(2′-hydroxymethyl-4-biphenylyl)ferrocene (**12c**).* A reduction of **11b** with $LiAlH_4$ was carried out in the same way as described for **12b**, and **12c** (reddish yellow crystals, mp 152—153 °C) was obtained in 73% yield. IR (KBr): 3400 (–OH), 1600, 1500, 850, 820, 735 (aromatic ring), and 805 cm^{-1} (1,1′-disubstituted ferrocene ring). NMR ($CDCl_3$): δ=1.58 (s, 2H, –O<u>H</u>), 4.25 (t, 4H, <u>H</u>$_\beta$), 4.48 (t, 4H, <u>H</u>$_\alpha$), 4.56 (s, 4H, –C<u>H</u>$_2$–), and 7.11—7.56 (m, 16H, Ar–<u>H</u>). Found: C, 78.51; H, 5.40%; M^+, 550. Calcd for $C_{36}H_{30}FeO_2$: C, 78.55; H, 5.49%; M, 550.

*1,1′-Bis(3′-formyl-4-biphenylyl)ferrocene (**13b**).* An active manganese dioxide (100 g) was added to a solution of **12b** (6.47 g, 11.7 mmol) in $CHCl_3$ (200 cm^3) at room temperature, and the mixture was stirred in the dark for 20 h. After filtration to remove manganese dioxide and evaporation to dryness *in vacuo*, the residue was chromatographed in benzene on silica gel to afford reddish crystals **13b** (2.81 g, 44%), which were recrystallized from ethanol, mp 162—163 °C. IR (KBr): 2825, 1690 (–CHO), 1610, 1500, 875, 840 (aromatic ring), and 805 cm^{-1} (1,1′-disubstituted ferrocene ring). NMR ($CDCl_3$): δ=3.92 (t, 4H, <u>H</u>$_\beta$), 4.20 (t, 4H, <u>H</u>$_\alpha$), 7.13—7.80 (m, 16H, Ar–<u>H</u>), and 9.98 (s, 2H, –C<u>H</u>O). Found: C, 79.11; H, 4.68%; M^+, 546. Calcd for $C_{36}H_{26}FeO_2$: C, 79.13; H, 4.79%; M, 546.

*1,1′-Bis(2′-formyl-4-biphenylyl)ferrocene (**13c**).* An oxidation of **12c** with active manganese dioxide was carried out in the same way as described for **13b**, and reddish crystals **13c** (mp 175—176 °C) were obtained in 57% yield. IR (KBr): 2820, 1690 (–CHO), 1600, 1500, 845, 820, 740 (aromatic ring), and 800 cm^{-1} (1,1′-disubstituted ferrocene ring). NMR ($CDCl_3$): δ=4.28 (t, 4H, <u>H</u>$_\beta$), 4.56 (t, 4H, <u>H</u>$_\alpha$), 7.15—7.95 (m, 16H, Ar–<u>H</u>), and 9.96 (s, 2H, –CHO). Found: C, 78.96; H, 4.64%; M^+, 546. Calcd for $C_{36}H_{26}FeO_2$: C, 79.13; H, 4.79%; M, 546.

*The Reductive Coupling of **13a** with $TiCl_4$–Zn.* Under a nitrogen atmosphere, Zn dust (1.56 g, 24 mmol) was added in small portions to a stirred solution of $TiCl_4$ (2.27 g, 12 mmol) in dry THF (60 cm^3) at 0—5 °C. After the resulting mixture was refluxed for 2 h, a solution of **13a** (1.31 g, 2.4 mmol) and dry pyridine (0.20 g) in dry THF (80 cm^3) was added to the refluxing solution over 18 h, followed by a further 10 h period of reflux. The reaction mixture was then cooled to room temperature and quenched by addition of 60 cm^3 of saturated aqueous K_2CO_3 solution. The black mixture was stirred for 0.5 h, diluted with $CHCl_3$, and filtered through celite. The filtrate was washed with brine and dried over $MgSO_4$. After removal of the solvents, the residue was dissolved in benzene and chromatographed on silica gel.

The first fraction, eluted with benzene, gave 0.25 g (20%) of compounds **15a**, reddish yellow crystals, mp 137—138 °C. Found: C, 83.26; H, 5.75%; M^+, 518. Calcd for $C_{36}H_{30}Fe$: C, 83.39; H, 5.83%; M, 518.

The second fraction, eluted with chloroform, gave 1,1′-bis(4′-hydroxymethyl-4-biphenylyl)ferrocene (**12a**), orange yellow crystals, mp 250—252 °C (dec), in 2.5% yield. IR (KBr): 3450 (–OH), 1600, 1500, 820 (*p*-disubstituted benzene ring), and 810 cm^{-1} (1,1′-disubstituted ferrocene ring). NMR (pyridine-d_5): δ=1.58 (s, 2H, –O<u>H</u>), 4.23 (t, 4H, <u>H</u>$_\beta$), 4.48 (t, 4H, <u>H</u>$_\alpha$), 4.59 (s, 4H, –C<u>H</u>$_2$–), and 7.18—7.78 (m, 16H, Ar–<u>H</u>). Found: C, 78.52; H, 5.41%; M^+, 550. Calcd for $C_{36}H_{30}FeO_2$: C, 78.55; H, 5.47%; M, 550.

The third fraction, eluted with a mixture of chloroform and ethanol (10:1), gave **1**, reddish crystals, mp 238—240 °C (decomp), in 32% yield. Found: C, 83.87; H, 4.96%; M^+, 514. Calcd for $C_{36}H_{26}Fe$: C, 84.05; H, 5.09%; M, 514.

*The Catalytic Hydrogenation of **1** to **2**.* In the mixture of dioxane (100 cm^3) and ethanol (100 cm^3), compound **1** (0.50 g) was hydrogenated with PtO_2 (0.1 g) at room temperature under ordinary pressure. The reaction mixture was filtered to remove the catalyst and the filtrate was evaporated to dryness *in vacuo*. The residue was chromatographed on silica gel with chloroform to give 0.35 g (70% yield) of **2**, reddish crystals, mp 240—242 °C (decomp). Found: C, 83.61; H, 5.38%; M^+, 516. Calcd for $C_{36}H_{28}Fe$: C, 83.72; H, 5.46%; M, 516.

*The Reductive Coupling of **13b** with $TiCl_4$–Zn.* The reductive coupling of **13b** with $TiCl_4$–Zn was carried out in the same way as described for the reductive coupling of **13a**, and the products were separated by column chromatography on silica gel.

The first fraction, eluted with benzene, gave compound **15b**, reddish yellow crystals, mp 199—200 °C, in 12.5% yield. Found: C, 83.31; H, 5.73%; M^+, 518. Calcd for $C_{36}H_{30}Fe$: C, 83.39; H, 5.83%; M, 518.

The second fraction, eluted with chloroform, gave **12b**, reddish yellow crystals, mp 166—168 °C, in 8.5% yield.

The third fraction, eluted with chloroform, gave **3**, reddish crystals, mp 215—216 °C, in 28% yield. Found: C, 83.92; H, 4.93%; M^+, 514. Calcd for $C_{36}H_{26}Fe$: C, 84.05; H, 5.09%; M, 514.

*The Catalytic Hydrogenation of **3** to **4**.* The catalytic hydrogenation of **3** was carried out in the same way as described for the catalytic hydrogenation of **1**, and the product was purified by column chromatography on silica gel with chloroform to give **4**, orange yellow crystals, mp 239—240 °C, in 80% yield. Found: C, 83.69; H, 5.40%; M^+, 516. Calcd for $C_{36}H_{28}Fe$: C, 83.72; H, 5.46%; M, 516.

*The Reductive Coupling of **13c** with $TiCl_4$–Zn.* The reductive coupling of **13c** was carried out in the same way as described for the reductive coupling of **13a** with $TiCl_4$–Zn, and the products were separated by column chromatography on silica gel.

The first fraction, eluted with benzene, gave compound **15c**, reddish crystals, mp 137—138 °C, in 11% yield. Found: C, 83.30; H, 5.71%; M^+, 518. Calcd for $C_{36}H_{30}Fe$: C, 83.39; H, 5.83%; M, 518.

The second fraction, eluted with chloroform, gave **12c**, reddish yellow crystals, mp 152—153 °C, in 8.5% yield.

The third fraction, eluted with chloroform, gave **5a**, reddish crystals, mp 287—288 °C, in 34% yield. Found: C, 83.91; H, 4.97%; M^+, 514. Calcd for $C_{36}H_{26}Fe$: C, 84.05; H, 5.09%; M, 514.

The fourth fraction, eluted with chloroform, gave **5s**, reddish crystals, mp >280 °C, in 25% yield. Found: C, 83.88; H, 4.91%; M^+, 514. Calcd for $C_{36}H_{26}Fe$: C, 84.05; H, 5.09%; M, 514.

*The Catalytic Hydrogenation of **5s** and **5a** to **6**.* The catalytic hydrogenation of **5s** was carried out in the same way as described for the catalytic hydrogenation of **1**, and the product was purified by column chromatography on silica gel with chloroform to give **6**, reddish crystals, mp 279—280 °C (decomp), in 54% yield. Found: C, 83.70; H, 4.38%; M^+, 514. Calcd for $C_{36}H_{28}Fe$: C, 83.72; H, 5.46%; M, 516.

The catalytic hydrogenation of **5a** also led to the formation of **6**, mp 279—280 °C (decomp), in 65% yield.

*(4'-Methyl-4-biphenylyl)ferrocene (**16a**).* In the presence of nickel complex, the reaction of **9** with the Grignard reagent prepared from *p*-bromotoluene was carried out in the same way as described for **13a**, and the product was purified by column chromatography on silica gel with benzene to give **16a**, reddish orange crystals, mp 174—176 °C, in 57% yield. Found: C, 78.29; H, 5.65%; M^+, 352. Calcd for $C_{23}H_{20}Fe$: C, 78.42; H, 5.72%; M, 352.

*(3'-Methyl-4-biphenylyl)ferrocene (**16b**).* The reaction of **9** with the Grignard reagent derived from *m*-bromotoluene was carried out in the same way as described for **13a**, and the product was purified by column chromatography on silica gel with benzene to give **16b**, reddish orange crystals, mp 106—108 °C, in 44% yield. Found: C, 78.33; H, 5.59%; M^+, 352. Calcd for $C_{23}H_{20}Fe$: C, 78.42; H, 5.72%; M, 352.

*(2'-Methyl-4-biphenylyl)ferrocene (**16c**).* The reaction of **9** with the Grignard reagent derived from *o*-bromotoluene was carried out in the same way as described for **13a**, and the product was purified by column chromatography on silica gel with benzene to give **16c**, reddish orange crystals, mp 137—138 °C, in 48% yield. Found: C, 78.32; H, 5.61%; M^+, 352. Calcd for $C_{23}H_{20}Fe$: C, 78.42; H, 5.72%; M, 352.

The present work was supported by a Grant-in-Aid for Scientific Research No. 554137 from the Ministry of Education, Science and Culture.

Aryliminodimagnesium Reagents. III. The Deoxygenative Condensation with Nitroso- and Nitroarenes: Electronic Effect of Substituents on Product Distribution

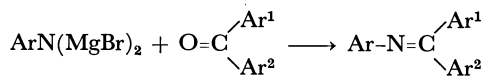
Masao Ōkubo,* Tomoko Takahashi, and Kōji Koga

Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjō-machi, Saga 840

(Received May 12, 1982)

Aryliminodimagnesium reagents ($ArN(MgBr)_2$) condense with nitrosoarenes and nitroarenes giving the corresponding azoarenes and azoxyarenes, respectively. Azoxyarenes were moderately deoxygenated by treatment with excessive amounts of the reagent giving the corresponding azoarenes. The reaction of nitroarenes with differently substituted reagents afforded unsymmetrically substituted azoxy- and azoarenes: Small amounts of symmetrically substituted azoarenes, which originated from the oxidative coupling of the reagent molecules, were also isolated. The distribution of the three types of condensation products are governed by the electronic effect of substituents of both the reagents and the substrates.

It has been reported very recently that aryliminodimagnesium reagents ($ArN(MgBr)_2$, aryl-IDMg), derived from anilines and two molar equivalents of EtMgBr, condense with diaryl ketones giving the corresponding anils[1,2] (Scheme 1). According to the

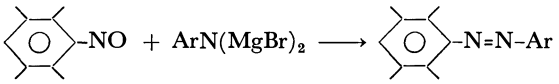


Scheme 1.

manner of deoxygenative condensation, aryl-IDMg are expected to react with a wide variety of substrates. Actually, the treatment of nitroso- and nitroarenes with the reagents afforded the corresponding azo- and azoxyarenes, respectively. In this paper, the electronic effect on the product distribution will be explained in comparison with those reported previously on the reaction of ArMgBr.[3,5,6]

Results and Discussion

The condensation ability of aryl-IDMg towards nitrosoarenes is exemplified by the reaction with highly hindered 2,3,5,6-tetramethylnitrosobenzene(nitrosodurene, Scheme 2 and Table 1). The comparison of the yields of the hindered azoarenes in Expt 1 with that in Expt 2 suggests that the deoxygenative condensation reaction with the nitrosoarene requires two molar equivalents of the reagent: This feature is in contrast with results obtained in the reactions with diaryl ketones which require usually an equimolar amount of the reagent.[1,2] The more strongly electron-donating *p*-methoxyphenyl-IDMg gave an excellent yield of the azo product (Expt 3), though a trace amount of an unidentifiable contaminant was eliminated with difficulty. The less strongly electron-donating *p*-chloro-



Scheme 2.

phenyl-IDMg reduced the yield (Expt 4), which, however, was improved by heating for more than 3 h and/or by use of three or more molar equivalents of the reagent.

The facts that the formation of a radical species in Expt 1 was detected by ESR and that the more strongly electron-donating reagent is more favorable to the reaction (*p*-MeO > *p*-Me > *p*-Cl) suggest that the condensation reaction is governed by the electron-transfer from the reagent to the substrate: The same order was observed for the formation of the nitroxide radical in the Grignard reaction of the same substrate.[3]

The condensation ability of the IDMg reagents with the nitroso functional group is confirmed. This reaction, however, is of no synthetic importance since the facile condensation of nitrosoarenes with arylamines in acetic acid has been well established.[4] The IDMg reaction with nitrosoarenes was not investigated further.

The reaction of nitrobenzene with more than five molar equivalents of phenyl-IDMg was studied first, the results being given in Table 2. High overall yields of azoxy- and azobenzenes were obtained (Expts 5 and 6). An authentic sample of azoxybenzene was

Table 1. Reaction of nitrosodurene with aryl-IDMg reagents

Expt No.	Nitrosodurene (mmol)	*p*-$RC_6H_4N(MgBr)_2$ R	*p*-$RC_6H_4N(MgBr)_2$ (mmol)	*p*-RC_6H_4-N=N-Dur[a] yield/%
1	4.9	H	4.9	15[b]
2	6.1	Me	12.6	84[c]
3	3.0	MeO	6.1	93[c]
4	3.0	Cl	6.1	31[c]

a) Dur = 2,3,5,6-Me_4C_6H. b, c) Yields, based on the amounts of nitrosodurene used, were obtained after heating at 55 °C b) for 2 h, and c) for 3 h.

Table 2. Reaction of aryl-IDMg for converting nitro- and azoxybenzene into azobenzene

Expt No.	Substates	(mmol)	$ArN(MgBr)_2$ Ar	(mmol)	Molar ratio [IDMg]/[Substr.]	Yields[a]/% Overall	PhN=NAr ↓ O	PhN=NAr
5	$PhNO_2$	(4.1)	C_6H_5	(20.5)	5.0	85.1	53.4	31.7
6	$PhNO_2$	(2.6)	C_6H_5	(20.3)	8.0	82.8	21.5	61.3
7	PhN=NPh ↓ O	(5.5)	p-MeC_6H_4	(11.0)	2.0	97.7	75.0[b,c]	22.7[b]

deoxygenated at a moderate rate on treatment with two molar equivalents of p-methylphenyl-IDMg (Expt 7). Thus, the formation of azobenzene *via* the intermediate formation of azoxybenzene followed by its deoxygenation (Scheme 3) is confirmed.

$$Ar^1NO_2 \xrightarrow{ArN(MgBr)_2} Ar^1\overset{\overset{O}{\frown}}{-N=N}-Ar \xrightarrow{ArN(MgBr)_2} Ar^1-N=N-Ar$$

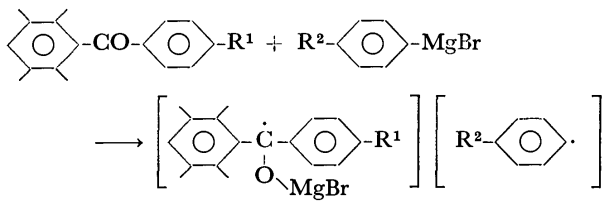
Scheme 3.

Three types of condensation products were obtained in the reaction of a substituted nitroarene with a differently substituted aryl-IDMg (Scheme 4 and

$$Ar^1NO_2 + Ar^2N(MgBr)_2 \longrightarrow Ar^1-N(O)=N-Ar^2 + Ar^1-N=N-Ar^2 + Ar^2-N=N-Ar^2$$

Scheme 4.

Table 3). In the reaction with nitroarenes carried out using a fixed molar ratio of reagent to substrate (Expts 8—11), the distribution of the yields of the unsymmetrically substituted azoxy- and azoarenes varies remarkably with the electronic effect of the substituents of both the substrates and the reagents. The variation can be explained in terms of the electron-accepting and -donating ability of the reactants;[5] the explanation given below is similar to that given previously for the Grignard reaction involving initial electron-transfer process.[6] The process for the Grignard reaction with hindered benzophenones (Scheme 5), as estimat-



Scheme 5.

ed by ESR, is governed by the effect of the substituents R^1 and R^2 as shown in the following:

faster ← electron-transfer → slower

$R^2 = H$: $R^1 = F$, Cl>H>OMe[6]

(← electron-accepting ability of substrates)

$R^1 = H$: $R^2 = OMe > H > F$[7]

(← electron-donating ability of reagents).

The detection of any radical species by ESR at room temperature in Expts 5—11 was unsuccessful, probably due to the unhindered structure[6,7] of the nitroarenes used.

Symmetrical azoarenes (Expts 8—11), which were not observed in the reaction with diaryl ketones,[1,2] should be formed as the result of oxidative coupling of the reagent molecules due to the much higher electron-accepting ability of nitroarenes than that of ketones.[8,9] Yields of the symmetrical azoarenes increase in the reaction of strongly electron-donating reagent (p-MeO>p-Me>p-Cl) with strongly electron-accepting nitroarene (p-Cl>p-Me>p-MeO).

Typical extremes of the product distribution are demonstrated by the results of Expts 10 and 11. The combination of the highly electron-accepting p-chloronitrobenzene with the highly electron-donating p-methoxyphenyl-IDMg gave a high combined yield of the azo products, but no azoxy product. The other combination of p-methoxynitrobenzene with p-chlorophenyl-IDMg gave the highest yield of the azoxy product together with the lowest combined yield of the azo products.

The effect of the molar ratio of reagent to substrate is another factor governing the distribution of the products especially when the highly electron-donating reagent is used. The highest yield of the azoxyarene in Expt 11 is due to the use of the less electron-donating p-chlorophenyl-IDMg: Even the treatment with ten molar equivalents of the reagent for 10 h reduced the yield only slightly (Expts 12 and 13). In contrast, the use of only two molar equivalents of the more electron-donating p-methoxyphenyl-IDMg reduced the yield of the azoxy product (Expts 14 and 15).

It is important to note that the azoxy products obtained in Expts 14 and 15 are isomeric with those obtained in Expts 9 and 11, respectively. Since any isomerization of an azoxy compound was not detected under the reaction conditions, this method provides a new route for preparing isomeric pairs of azoxyarenes, $Ar^1-N(O)=N-Ar^2$ and $Ar^1-N=N(O)-Ar^2$, independently.[10] A more detailed study on the preparation and the deoxygenation of azoxyarenes will be described in the subsequent paper.

All the aryl-IDMg reagents used in this study are

Table 3. Effect of substituents and molar ratio on product distribution in the reaction of p-$R^1C_6H_4NO_2$ with p-$R^2C_6H_4$-IDMg

a) Yields are based on the amount of $ArNO_2$ used. b, c, d) The reaction mixtures were heated at 55 °C for b) 3 h, c) 5 h, and d) 10 h, respectively.

less electron-donating than arylmagnesium bromides since the formers do not affect azoarenes whereas the latters convert azobenzene into hydrazobenzene[11] (Scheme 6). The vigorous reaction of the highly elec-

$$\text{Ph-N=N-Ph} \xrightarrow{\text{ArMgBr}} \text{Ph-N(BrMg)-N(MgBr)-Ph} \xrightarrow{H_2O} \text{Ph-NH-NH-Ph}$$

Scheme 6.

tron-accepting nitrobenzene with the highly electron-donating Grignard reagent (PhMgBr) affords comparable amounts of the products due to the addition-reduction (Ph_2NH), the deoxygenation (PhOH), and the oxidative coupling (Ph–Ph).[12] The reaction has been little studied and attracted no attention until the interesting Grignard reaction of nitrobenzothiazoles was reported.[13] The deoxygenative condensation reaction presented here owes its success to the moderate electron-donating ability of the aryl-IDMg reagents,[1-3] though the detailed structure and the mechanism remain to be investigated.

The overall yield was somewhat lower when the yield of the symmetrical azoarene was higher, and *vice versa* (Table 3): In Expt 10, a recognizable amount of an unidentifiable and poorly soluble black material was formed, probably due to a free radical reaction initiated by the quick electron-transfer from the reagent to the substrate.[14] Some attempts, *i.e.*, the dilution of the reagent and/or the substrate solution, the addition of the reagent solution in the reverse manner, and the addition at −78 °C, were not effective in reducing the formation of the black material as well as the symmetrical azoarene.

The unimportant limitations given are difficult to overcome; nevertheless, the IDMg process provides a general method for preparing unsymmetrical azoxy- and azoarenes.

Experimental

The melting points of azo- and azoxyarenes are uncorrected.

Materials. Nitrosodurene was prepared according to the reported method.[3] All the nitroarenes and the anilines used in this study were commercially available, and were purified by distillation before use.

Procedures. The typical procedure is given as follows. Ethylmagnesium bromide (30.8 mmol) was prepared under N_2 atmosphere as usual in THF (20 ml), and a 2—3% excess amount of the aniline (15.8 mmol) dissolved in THF (15 ml) was added at 0 °C to the Grignard solution. The mixture was stirred gently at 55 °C for 40 min to complete the evolution of ethane.[1] The nitroarene (3.08 mmol) dissolved in THF (15 ml) was added to the IDMg solution at 0 °C; the color of the mixture turned deep reddish brown, The colored mixture was stirred at 55 °C for 3 h, quenched with aqueous NH_4Cl, extracted with diethyl ether followed by washing with dilute HCl (0.5—1.0 mol dm^{-3}) for removing the unreacted aniline. After washing with water, the colored solution was dried on $MgSO_4$ and concentrated under reduced pressure; the product mixture was chromatographed on silica gel (Wako-Gel C-200).

Products. The chromatographic separation of the three types of the products was sometimes incomplete. The yields of the products in individual experiments, however, were estimated easily by ^{1}H-NMR since the signals of the four *ortho*-protons around the –N(O)=N– group appear at lower field than 8.0 ppm while those of the protons around the –N=N– group appear at higher field.

The melting points and ^{1}H-NMR data of azo- and azoxyarenes are given in Tables 4 and 5, respectively. Among the ^{1}H-NMR data, some aromatic proton signals which consist of two AB-quartets are not assigned and the figures are given in parentheses.

The molecular weight of the product was recorded on a Denshi Kagaku EMD-05A Mass Spectrometer. Results of the elemental analyses of the new azo- and azoxyarenes, which are represented by the Expt Nos. as shown in Tables 4 and 5, are given in the following.

Aryliminodimagnesium Reagents. IV. The Independent Preparation of Unsymmetrically Substituted Azoxyarene Isomers and Their Deoxygenation

Masao Ōkubo* and Kōji Koga

Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjō-machi, Saga 840

(Received May 12, 1982)

By use of the condensation reaction of aryliminodimagnesium reagents ($ArN(MgBr)_2$) with nitroarenes, six symmetrical and eight unsymmetrical azoxyarenes including four pairs of isomers were prepared in 40—80% yields. The deoxygenation reaction of the azoxyarenes by treating with five molar equivalents of p-$MeOC_6H_4N(MgBr)_2$ at 55 °C in tetrahydrofuran was also studied, and the reactivity of deoxygenation was correlated to the shift of the electronic absorption maximum of azoxyarene.

So far, unsymmetrical azoxyarenes have been obtained by oxidation of unsymmetrical azoarenes,[1-3] by condensation of nitrosoarenes with *N*-arylhydroxylamines,[4,5] or by selective substitution on azoxybenzenes.[6] The first method often gives a mixture of isomers, their separation not always being easy.[5] The second method is more selective, but is ultimately limited by the instability of the starting materials. A method involving a Grignard reaction of substituted *N*-nitrosohydroxylamine derivatives[7] has also been reported, depending on the uncommon type of the starting material. These limitations have been an obstacle to the development of azoxyarene chemistry: The electronic effect of substituents on the deoxygenation by use of phosphorus(III) reagents, for instance, has not been studied enough.[8]

In the preceding paper,[9] the condensation of nitroarenes with aryliminodimagnesium reagents ($ArN(MgBr)_2$, aryl-IDMg) was reported. The reaction involves rapid deoxygenative condensation affording the azoxyarenes followed by much slower deoxygenation giving the azoarenes (Scheme 1). Since the intermediately formed azoxyarenes do not isomerize under the reaction conditions,[9] the IDMg method provides a novel route for preparing unsymmetrical azoxyarene isomers independently.

$$Ar^1NO_2 + Ar^2N(MgBr)_2 \longrightarrow Ar^1\text{-}N(O)\text{=}N\text{-}Ar^2 + Ar^1\text{-}N\text{=}N\text{-}Ar^2 + Ar^2\text{-}N\text{=}N\text{-}Ar^2$$

Scheme 1.

The authors first endeavored to find the optimum reaction conditions for preparing typical symmetrical and unsymmetrical azoxyarenes, and second to study their substituent effect on the deoxygenation by the treatment with an aryl-IDMg reagent. The results are reported in this paper.

Results and Discussion

Preparation of Azoxyarenes. On the basis of the reaction profiles given in the preceding paper,[9] the reaction conditions suitable for preparing unsymmetrical azoxyarenes (Scheme 1) are i) a less electron-donating reagent, ii) a less electron-accepting substrate, and iii) a lower molar ratio of reagent to substrate. However, the formation of the final products, unsymmetrical azoarenes, as well as that of the oxidative coupling products, symmetrical azoarenes, are unavoidable.

The molar ratio of the IDMg reagents to the nitroarenes used in Expts 1—6 (Table 1) were chosen in order to convert the substrates completely and also to minimize the subsequent deoxygenation of the primarily produced azoxyarenes. No substrate was recovered except in Expt 3 in which *ca.* 5% of the nitroarene was found in the product mixture. The facts that the most electron-donating *p*-methoxyphenyl-IDMg gave the highest combined yield of the azo products and that the least electron-donating *m*-methoxyphenyl-IDMg gave the lowest yield of the symmetrical azo product accord with the previous results.[9]

In the reactions carried out for preparing symmetrically substituted azoxyarenes (Scheme 2), the amount of the symmetrical azoarenes formed comes partly from the deoxygenation of azoxyarenes and partly from the oxidative coupling of the reagent molecules: The results are given in Table 2 (Expts 7—12).

$$RC_6H_4NO_2 + RC_6H_4N(MgBr)_2 \longrightarrow RC_6H_4\text{-}N(O)\text{=}NC_6H_4R + RC_6H_4\text{-}N\text{=}N\text{-}C_6H_4R$$

Scheme 2.

The remarkable recovery of the substrate in Expt 8 is ascribable to the weakest electron-donating ability of *p*-chlorophenyl-IDMg.

Summarizing the results given in Tables 1 and 2, the optimum molar ratio suitable for preparing azoxyarenes seems to depend mainly on the electron-donating ability of the aryl-IDMg reagents. The most, the medium, and the least electron-donating reagents require the lowest, the medium, and the highest molar ratio respectively (Table 3).

An unusual result was obtained when *p*-dimethylaminophenyl-IDMg, which was expected to be more electron-donating than the *p*-methoxyphenyl reagent, was allowed to react with *N*,*N*-dimethyl-*p*-nitroaniline (molar ratio=1.5). A 35% yield of the final product, the symmetrical azoarene, and a 38% of the unreacted substrate were isolated. The result, which is in conflict with all the preceding ones, is probably to be ascribed to the aggregation of the reagent molecules, due to the coordination ability of the nitrogen atom of the substituent.

The effectiveness of the aryl-IDMg method for pre-

paring unsymmetrical azoxyarenes is demonstrated by the successful preparation of a new azoxy isomer derived from 1-phenylazonaphthalene (Scheme 3a).

a. 1-$NaphNO_2$ + $PhN(MgBr)_2$ ⟶ 1-Naph-N(O)=N-Ph (α-isomer)

b. $PhNO_2$ + 1-$NaphN(MgBr)_2$ ⟶ 1-Naph-N=N(O)-Ph (β-isomer)

Scheme 3.

The previous study on the peroxy acid oxidation of 1-phenylazonaphthalene[3] showed the exclusive formation of the sterically less hindered "β"-isomer (*cf.* Scheme 3b). By use of two molar equivalents of the respective reagents and the substrates as shown in the scheme, both the "α"- and "β"-isomers were prepared in yields of 43 and 63% respectively.

Deoxygenation of Azoxyarenes by the Aryl-IDMg Procedure. The deoxygenation of the substituted azoxyarenes by the IDMg method was studied. Since the deoxygenation is quite a mild reaction,[9] the azoxyarenes were treated with five molar equivalents of the most electron-donating *p*-methoxyphenyl-IDMg at 55 °C for 3 h (Scheme 4). The percentage of deoxygenation observed is given in Table 4.

Scheme 4.

Among the results obtained in the deoxygenation of symmetrical azoxyarenes, the strongly retarding effect of the *p*-methoxyl substituent and the accelerating effect of the *m*-chloro substituent of the azoxyarenes should be noted first. The *p*-chloro substituent, which usually shows an electron-attracting character, exhibits a medium retarding effect: Retardation to a comparable extent was also shown by the *p*-methyl substituent which usually acts as a weak electron-donating group. These results suggest a remarkable enhacement of electron-repelling resonance operating in the deoxygenation reaction.

Table 4 also contains the results obtained in the deoxygenation reactions of unsymmetrically substituted azoxyarenes under the same conditions. The effect of the retardation by the *p*-methoxyl substituent as well as the acceleration by the *m*-chloro substituent is evidently enhanced when these groups are attached to the phenyl group opposite to the azoxy nitrogen atom. A qualitative explanation for the retardation by the *p*-methoxyl group opposite to the azoxy nitrogen can be given by the charge-separated resonance structure, A, which reduces the positive charge on the azoxy-nitrogen and prevents the attack of the anionic

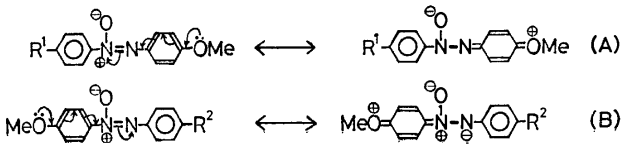
a) The number indicates the Expt No. given in Tables 1 and 2. S3 means the products prepared according to Scheme 3, and P1 means the products obtained in the previous work: N indicates that neither the prepative yield nor the deoxygenation reactivity were determined.

part of the reagent molecule. Since the isomeric resonance structure, B, cannot reduce the positive charge, the dramatic retardation is unexpected in this case.



From the given explanation, the reactivity of deoxygenation should be correlated with the shift of the electronic absorption maximum, λ_{max} for $\pi \rightarrow \pi^*$ transition.[10] Since the deoxygenation is generally slow even on treatment with five molar equivalents of the reagent, the percentage of the deoxygenation given in Table 4 can be substituted, as a rough approximation, for the relative reaction rate constant. The λ_{max}'s of

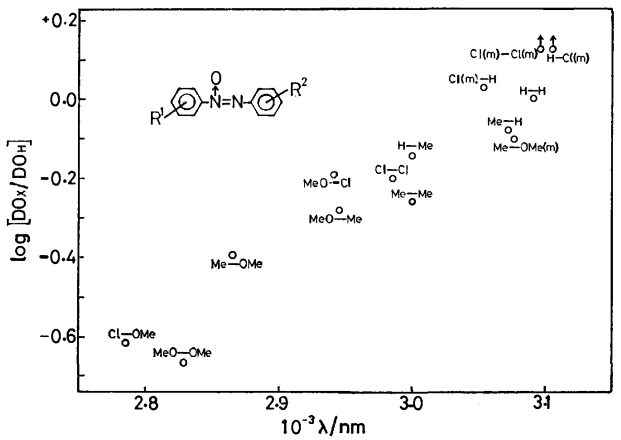


Fig. 1. Correlation between the relative deoxygenation reactivity and $\pi \rightarrow \pi^*$ transition energy.

azoxyarenes are listed in Table 5 together with the other physical constants observed. The expectation is verified as shown in Fig. 1: The logarithm of the relative deoxygenation, $\log[DO_X/DO_H]$ (the value for the unsubstituted substrate was taken as the standard), is less satisfactorily but nevertheless still correlated with the reciprocal of the λ_{max}'s.

Explicit evidence for the attack of the reagent's anionic nitrogen on the substrate's positive nitrogen is provided by the identification of the by-product formed in the reaction. The formation of a trace amount of by-product containing a methoxyl group was detected by NMR in the reaction (Scheme 4) of an azoxyarene which has no methoxyl group; the formation is usually negligible and the structure of the by-product is unidentifiable. The formation, however, becomes notable when a reactive azoxyarene is treated with *p*-methoxyphenyl-IDMg. The most reactive, 3,3'-dichloroazoxybenzene, which was consumed completely under the conditions given in Scheme 4, gave the corresponding azoarene and a 20% yield of 3-chloro-4'-methoxyazobenzene. The same by-product was obtained in a 21% yield in the reaction of 3-chloro-*NNO*-azoxybenzene, m-$ClC_6H_4N(O)=NC_6H_5$. In the reaction of the isomeric 3-chloro-*ONN*-azoxybenzene, m-$ClC_6H_4N=N(O)C_6H_5$, 4-methoxyazobenzene was isolated in a 17% yield. The other possible by-products were not detected. The results show that, in the reaction with $ArN(MgBr)_2$, an unsymmetrical azoxyarene, $Ar^1N(O)=NAr^2$, gives $Ar^1N=NAr$ but not $ArN=NAr^2$ as the by-product.

The mechanism of both the major and minor reaction is still equivocal. Undoubtedly, however, the existence of such an exchange reaction is evidence for the attack of the anionic nitrogen on the positive azoxy nitrogen. In order to reduce the by-product formation in the deoxygenation of the very reactive azoxyarenes, the less electron-donating *p*-methylphenyl-IDMg is recommended.

Experimental

The melting points are uncorrected. All the nitroarenes and the arylamines were commercially available, and were purified by distillation before use.

Procedures. To an aryliminodimagnesium reagent (15.9 mmol) prepared under N_2 atmosphere in THF (35 ml) according to the reported method,[9] a THF solution (15 ml) of nitroarenes was added at once at 0 °C. The deeply colored[9] reaction mixture was stirred gently at 55 °C for 3 h. The mixture was quenched at 0 °C with aqueous ammonium chloride, and worked up as reported previously.[9] The yields of the individual products were obtained by column chromatographic separation as well as estimation by measuring the fractions by NMR.[9]

The experiments for the deoxygenation of azoxyarenes were carried out similarly: The color change of the reaction mixture was slow at 0 °C but a reddish brown color developed on heating.

The electronic spectra of azoxyarenes were recorded on an Hitachi 323 Spectrophotometer using 1.0×10^{-4} mol dm^{-3} solution in 1,4-dioxane (spectrograde).

For convenience, the physical constants of nineteen azoxyarenes prepared in this and the preceding[9] works are summarized in Table 5. The fourteen among the nineteen azoxyarenes are listed in decreasing order of the deoxygenation reactivity (*cf.* Table 4). Among the NMR data, some aromatic proton signals which consist of two AB-quartets are not assigned and the figures are given in parentheses.

Molecular weight of the product was recorded on a Denshi Kagaku EMD-05A Mass Spectrometer. The result of the elemental analyses of the new azoxyarenes, which are represented by the Expt Nos. given in Table 5, are given below.

(Received May 17, 1982)

The absorption spectra of chlorophyll a in isopentane, 3-methylpentane, and methylcyclohexane solutions were studied over the temperature range 300—77 K. In those hydrocarbon solutions which were prepared using methanol treatment, chlorophyll a forms hydrated dimer at low temperatures. The dimer has an absorption peak at 695 nm at 160 K, which gradually shifts to 706 nm with decreasing temperature from 160 K to 77 K. The enthalpy change ($-\Delta H$) for the formation of the dimer was obtained to be 41.0 ± 0.8 kJ mol^{-1}, independent of the solvent used. The entropy changes ($-\Delta S$) were 113 ± 8 J K^{-1} mol^{-1} for isopentane, 118 ± 8 J K^{-1} mol^{-1} for 3-methylpentane and 128 ± 8 J K^{-1} mol^{-1} for methylcyclohexane solutions. Comparative studies carried out of the solutions prepared without the methanol treatment suggest the existence of two kinds of hydrated monomeric chlorophyll a.

Chlorophyll (Chl) a is the best understood of Chl's[1] and has been subject to a variety of studies in connection with the photochemical conversion of solar energy. The optical absorption spectrum of Chl a is known to vary markedly with nature of solvent, temperature, and degree of hydration and aggregation.[2,3]

The absorption spectra of Chl a reported so far are in good agreement with one another as far as polar solvents are used. In nonpolar solvents, on the other hand, the absorption spectrum varies substantially depending on the procedures of preparing the solutions, in particular at low temperatures. Cotton *et al.*[4] reported that the amount of water causes substantial changes in the absorption spectrum of Chl a in hydrocarbon solvents. For instance, the absorption spectrum of Chl a in dry methylcyclohexane+isopentane shows only a slight shift of the peak wavelength from 672 nm at room temperature to 678 nm at 77 K, which is in sharp contrast to the absorption spectral change observed in a toluene solution containing 2 mol H_2O per mol Chl a. For the latter solution, a new absorption band centered at 708 nm was observed to appear with a slight shift of the 667-nm peak to 672 nm at 77 K.

Fong and Koester[5] reported the temperature dependence of the absorption spectrum of Chl a in a 1:1 methylcyclohexane+pentane mixture, in which the absorption peak in the red band region is located at 667 nm at room temperature. The spectrum observed at 121 K indicates that the major Chl a shows the absorption peak at 702.5 nm. This is the first observation that a greater part of Chl a in the hydrocarbon mixture is transformed into a $\approx$700 nm absorbing species at low temperatures.

The formation of 706-nm absorbing species of Chl a (S706) and the optical absorption and ESR studies of its cation radical produced by γ-irradiation, both in glassy 3-methylpentane solutions at 77 K, were reported by Hoshino *et al.*[6] The comparative study on the ESR spectra of the cation radicals of the S706 and monomeric Chl a demonstrates that the S706 is a dimeric Chl a. This result is consistent with the suggestion made by Brody and Broyde[3] that the absorption band centered at around 700 nm appearing at low temperatures is attributed to dimeric Chl a.

The present paper reports the temperature dependence of the absorption spectra of Chl a in isopentane, 3-methylpentane, and methylcyclohexane solutions over the temperature range 300—77 K, and the thermodynamic data for the formation of the dimers.

Experimental

Chl a extracted from spinach leaves with acetone was chromatographed on powdered sugar columns according to standard procedures.[7] Solid Chl a obtained from a Chl a zone of a last column was chromatographed with petroleum ether containing 0.5% 2-propanol as developer. The purified Chl a was dissolved in dry diethyl ether and stored in a freezer at -20 °C. The absorption spectrum of the stock solution had absorption peaks at 428.6 and 660 nm with a ratio of the Soret to red absorption maxima of 1.29 at room temperature.

Isopentane, 3-methylpentane, and methylcyclohexane were distilled and stored on Na–K alloy *in vacuo* in order to remove traces of water.

Absorption spectra were recorded on a Cary 14R spectrophotometer. The temperature was controlled by using an Oxford CF204 cryostat. Optical pathlength of cells were 0.5—1.5 mm.

A suitable volume of the Chl a stock solution was transferred into a cell, and diethyl ether was removed on a vacuum line. After pumped at 10^{-6} Torr (1 Torr=133.322 Pa) at room temperature for 10—20 min, the cell was detached from the vacuum line and freshly distilled methanol was added into the cell. The solid Chl a was completely dissolved in methanol by shaking the cell for a few min. The sample cell was again attached to the vacuum line to remove methanol completely under pumping to 10^{-6} Torr for 10—20 min. This procedure using methanol will be referred to as methanol treatment. The solution was cooled to 77 K and sealed off under pumping.

Comparative studies were also carried out on the Chl a solutions prepared by omission of the methanol treatment described above; unless otherwise specified, the Chl a solutions were prepared using the methanol treatment.

The concentration of Chl a was *ca.* 10^{-4} mol/dm^3 for all the solutions used in the present study.

Results

Figure 1 shows the absorption spectra of Chl a in 3-methylpentane in the temperature range 300—240 K. The absorption spectrum at 300 K has an absorption peak at 662 nm with a shoulder at 680 nm in the red-band region. No isosbestic points were observed for the spectral change of the Chl a solution in this temperature range. The complicated features observed for the temperature-dependent absorption spectra are essentially the same as those reported.[5]

Figure 2 shows the temperature-dependent absorption spectra of Chl a in 3-methylpentane in the temperature range 240—160 K. A series of absorption spectra measured in this temperature range evidently shows several isosbestic points, indicating a simple equilibrium between the species absorbing at 663 and 695 nm. The absorbance at 695 nm increases with decreasing intensity of the peak at 663 nm, which ultimately vanishes at 160 K.

The spectral change below 160 K is shown in Fig. 3. The 695 nm peak at 160 K shows only a slight shift toward long wavelengths without showing isosbestic points with decreasing temperature; no equilibrium seems to exist in this temperature range. The peak wavelength ultimately reached 706 nm at 77 K.[6]

The temperature-dependent absorption spectra were also studied on isopentane and methylcyclohexane solutions. The features of the spectral change are essentially the same as those observed for the 3-methyl-

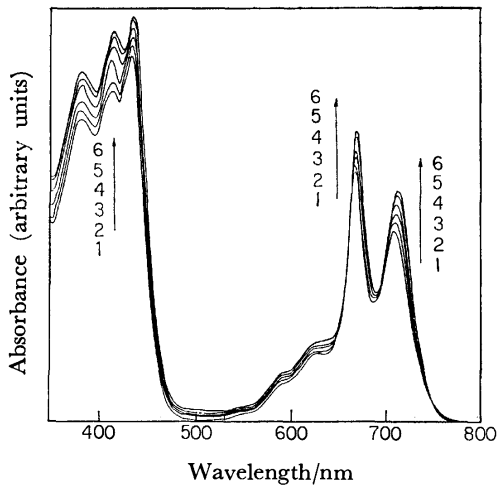

Fig. 5. Temperature-dependent absorption spectra of 3-methylpentane solution of Chl a (the same solution as that in Fig. 4) in the temperature range 180—95 K. 1): 180 K, 2): 160 K, 3): 140 K, 4): 120 K, 5): 100 K, 6): 95 K.

pentane solution; the 663 nm band vanishes at 160 K and a subsequent red shift of the 700 nm band was also observed below 160 K.

Different temperature-dependent absorption spectra were observed for the 3-methylpentane solution of Chl a prepared by omission of the methanol treatment. Typical examples are shown in Figs. 4 and 5. Figure 4 shows the spectral changes in the temperature range 260—180 K. The absorption spectrum at room temperature has an absorption peak at 663 nm with a shoulder at 675 nm. With decreasing temperature, the intensity at 663 nm decreases with a slight shift to 667 nm and a new absorption band appears around 706 nm with an isosbestic point at 678.5 nm. Below 180 K, however, the 667 nm band does not vanish but the intensities of both 667 nm and 706 nm bands increase accompanying slight red shift with decreasing temperature as shown in Fig. 5; their ultimate peak wavelengths reached 668 and 709 nm at 77 K. These results present a striking contrast to those obtained with the Chl a solutions prepared using methanol treatment. These differences will be discussed in the next section.

Discussion

Two Kinds of Hydrated Monomeric Chl a. Fong and Koester[5] reported that Chl a in a hydrocarbon mixture could be transformed into a 702.5 nm absorbing Chl a as a major species at 121 K. Wasielewski *et al.*[8] found that bis(chlorophyllide)ethylene glycol diester in carbon tetrachloride forms a species absorbing at 697 nm at room temperature when the solution was bubbled with wet nitrogen gas. This fact implies that water molecules play an important role in the formation of the ≈700 nm absorbing Chl a. Shipman *et al.*[9] studied the temperature dependence of the absorption spectra of 9.4×10^{-2} mol/dm^3 Chl a solutions in toluene containing 1.5 mol ethanol per mol Chl a and reported the formation of the 702 nm absorbing Chl a as a single species at 175 K. These results indicate that monosolvated Chl a, Chl a·H_2O and Chl a·C_2H_5OH can be converted into the ≈700 nm absorbing species at low temperatures. The structure of the Chl a dimer has been considered to be C_2-symmetrical.[10-12]

The present results show that Chl a in 3-methylpentane has only one absorption peak at 695 nm in the red-band region at 160 K. Since the 695-nm peak grows with decreasing intensity of the absorption at 663 nm from 240 to 160 K, the 663-nm absorbing species is regarded as a precursor of the 695-nm absorbing species. The spectral shift from 695 to 706 nm observed at 160—77 K may be due to some configuration changes of the dimeric Chl a in glassy matrices by cooling. It should be noted that the peak wavelengths reported for the dimeric Chl a are ranged from 695 to 710 nm depending upon the solvent and temperature.

In the present study, we have reasonably concluded that the 695-nm absorbing species at 160 K is a single species from the temperature dependence of the absorption spectra in which clear isosbestic points are observed.

We sometimes observed that Chl a solutions prepared without the methanol treatment show essentially the same temperature dependence as that shown in Figs. 1—3. These observations imply that a trace amount of methanol, which might remain in the samples prepared by using the methanol treatment, is not responsible for the formation of the 695 nm absorbing species at 160 K. The methanol treatment is considered to provide a simple and reproducible procedure for preparing the Chl a solutions which produce 695-nm absorbing species at low temperatures.

The results on the Chl a solutions in 3-methylpentane prepared with and without the methanol treatment seem to indicate that there would be at least two kinds of monomeric Chl a in the hydrocarbon solution: one does form the dimeric Chl a (S706) and other does not. Katz *et al.*[1] examined IR spectra in the OH-stretching region for a nonpolar solution of Chl a containing water, and suggested the presence of two kinds of Chl a species: $Mg\cdots O\langle^{H}_{H}$ and $Mg\cdots O\langle^{H}_{H}\cdots O\langle^{H}_{H}$.

On the basis of their suggested species for the hydrated Chl a, the present results may be interpreted by assuming that the solutions not treated with methanol contain both monohydrated and dihydrated species, the latter of which does not form dimeric Chl a at low temperatures. Supposedly, the methanol treatment used for the preparation of the solutions serves to adjust the water content appropriate for the dimer formation. Since the water content is considered to be not always reproducible for the solutions without the methanol treatment, the complete or nearly complete dimer formation was only sometimes observed for these solutions. In fact, addition of trace amount of water into the methanol treated solutions was found to give similar spectral changes to those shown in Figs. 4 and 5.

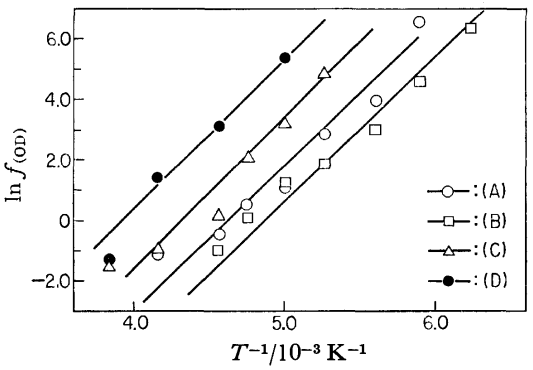

Fig. 6. Plots on $\ln f(A)$ *vs.* T^{-1} for Chl a solutions. (A): 3-Methylpentane, (B): methylcyclohexane, (C): isopentane. A plot (D) was obtained for 3-methylpentane solution of Chl a prepared without methanol treatment.

Enthalpy and Entropy Changes for the Dimer Formation. The spectral changes shown in Figs. 1 and 2 are interpreted in terms of two step equilibria:[5]

$$(\text{Chl a})_2 + 2H_2O \rightleftharpoons 2\text{Chl a}\cdot H_2O \rightleftharpoons (\text{Chl a}\cdot H_2O)_2.$$

The complicated features of the spectral change observed in the temperature range 300—240 K are considered to result from the above two equilibria in the solution. As the temperature decreases below 240 K, the equilibrium shifts toward the right-hand side. The temperature dependence of the spectrum observed between 240 and 160 K is regarded as being due to the equilibrium between Chl a·H_2O (M) and (Chl a·H_2O)$_2$ (D). The equilibrium constant, K, is defined as

$$K = [D]/[M]^2. \quad (1)$$

Below 160 K, M is completely transformed into D, and therefore,

$$2[D] + [M] = 2[D]_0, \quad (2)$$

where $[D]_0$ is the concentration of D at 160 K. From Eqs. 1 and 2,

$$K = [D]/4([D]_0 - [D])^2. \quad (3)$$

Using the molar extinction coefficient of D at 700 nm (ε) and an optical pathlength (l), one obtains

$$K = \varepsilon l A_T/4(A_{160} - A_T) = \varepsilon l \cdot f(A)/4, \quad (4)$$

where A_{160} and A_T are the absorbances at 700 nm at 160 K and T K, respectively.

Equation 4 is transformed into

$$\ln f(A) = [\Delta S/R - \ln(\varepsilon l/4)] - \Delta H/RT. \quad (5)$$

Plots of $\ln f(A)$ *vs.* T^{-1} for the isopentane, 3-methylpentane, and methylcyclohexane solutions are shown in Fig. 6; the data obtained with the 3-methylpentane solutions prepared without the methanol treatment are also plotted for comparison. The enthalpy changes (ΔH) are identical within the experimental errors for these solutions, 41.0 ± 0.8 kJ mol^{-1} (9.8 ± 0.2 kcal mol^{-1}). From the intercept and ε (9.6×10^4 mol^{-1} dm^3 cm^{-1}), the entropy changes (ΔS) are calculated to be 113 ± 8, 118 ± 8, and 128 ± 8 J K^{-1} mol^{-1} for the isopentane, 3-methylpentane, and methylcyclohexane solutions, respectively. The linear plot D in Fig. 6 implies that the monohydrated Chl a existing in the solution forms dimers independently of the coexisting dihydrated species.

The enthalpy change obtained for the dimer formation is double the enthalpy change (4—6 kcal mol^{-1}) estimated for the formation of one hydrogen bond of the type OH···O.[13] This result is in accord with the assumption that a dimeric Chl a has two hydrogen bonds between magnesium atoms and carbonyl groups of two Chl a molecules.

Pheophytins are known to dimerize in hydrocarbon solutions at low temperatures.[14] An estimated enthalpy change of 18 kJ mol^{-1} for the formation of the dimeric pheophytins is about one half that obtained for Chl a. This value also supports the view that two hydrogen bonds serve as principal interaction force between two Chl a molecules in the dimeric Chl a. Slightly different values for the entropy change may be ascribed to somewhat different configurations of the dimer structure in different solvents.

Synthesis of Monoaza Crown Ethers from *N,N*-Di[oligo(oxyalkylene)]amines and Oligoethylene Glycol Di(*p*-toluenesulfonates) or Corresponding Dichlorides

Hirokazu MAEDA, Shigeo FURUYOSHI, Yohji NAKATSUJI, and Mitsuo OKAHARA*

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-oka 2-1, Suita, Osaka 565

(Received May 21, 1982)

Monoaza crown ethers were prepared in satisfactory yields by the one-step reaction between diethanolamine or *N,N*-di[oligo(oxyethylene)]amines and oligoethylene glycol di(*p*-toluenesulfonates) or corresponding dichlorides in *t*-butyl alcohol/dioxane in the presence of sodium or potassium *t*-butoxide. The reaction conditions in the preparation of monoaza 15- and 18-crown ethers were studied. Various monoaza crown ethers having substituents were also prepared and their properties were investigated.

N-Unsubstituted monoaza crown ethers, which are the reactive crown ethers, have complexing ability with metal[1,2] and ammonium cations.[3] Using their reactive amino group, they can be readily transformed to bis-crown compounds,[4-7] lariat ethers,[3,8-10] or *N*-alkyl derivatives useful as surfactants with special properties.[11-13]

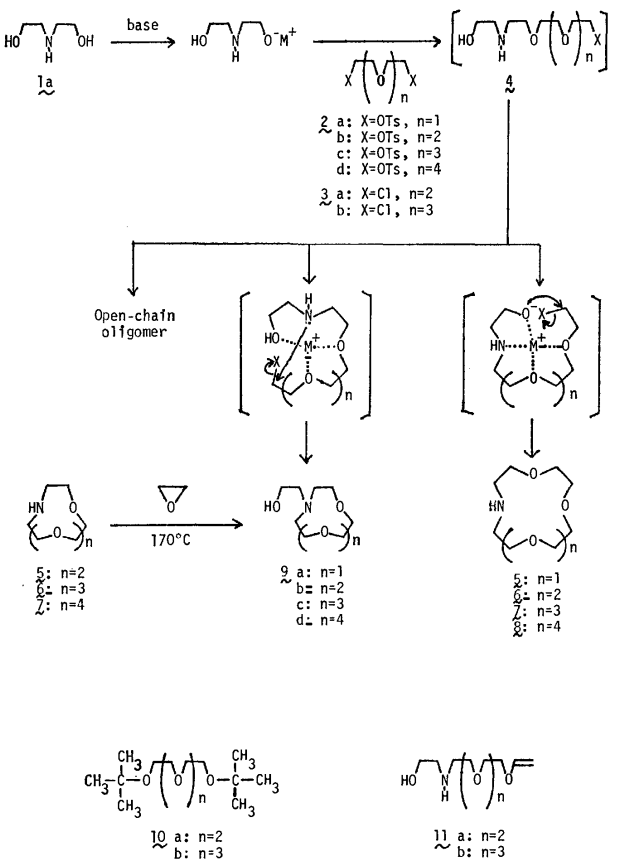
The synthetic methods of monoaza crown ethers can be classified into two categories; with or without employing amino protection. In the former, after the preparation of *N*-substituted monoaza crown ethers (*N*-cyano,[14] *N*-(*p*-tolylsulfonyl),[15] *N*-benzyl,[1,4] or *N*-trityl monoaza crown ether[16]), the deprotection of them by proper means gave *N*-unsubstituted crown ethers. However, these methods are more or less laborious, since the introduction and elimination processes of *N*-substituent are necessary.

On the other hand, 1,4,10,13-tetraoxa-7-azacyclohexadecane possessing oxetane ring was prepared by Krespan[17] by the reaction of 3,3-bis(chloromethyl)-oxetane with bis[2-(2-hydroxyethoxy)ethyl]amine without using amino protection. In accordance with the observation in the synthesis of 18-methylene-1,7,10,16-tetraoxa-4,13-diazacyclononadecane by Tomoi *et al.*,[18] and the synthesis of α,ω-diamino-substituted oligo(oxyethylenes) by Böhmer *et al.*,[19] the results substantiate that *O*-alkylation is far more predominant than *N*-alkylation under the basic conditions which generate an alkoxide.

We have previously reported that *N*-unsubstituted monoaza crown ethers can be obtained in satisfactory yields by the reaction of commercially available dialkanolamines with oligoethylene glycol di(*p*-toluenesulfonates) or corresponding dichlorides without protection of the amino group.[20] In the present paper, the detailed results of the synthesis of monoaza crown ethers from diethanolamine or *N,N*-di[oligo(oxyethylene)]amines are described. Monoaza crown ethers bearing various substituents were also prepared and the scope and the limitations of this method were discussed.

Results and Discussion

Diethanolamine (**1a**) was allowed to react with oligoethylene glycol di(*p*-toluenesulfonates) (**2**) or corresponding dichlorides (**3**) in *t*-butyl alcohol/dioxane in the presence of sodium or potassium *t*-butoxide. After



Scheme 1.

the reaction, the crude products of monoaza crown ethers were separated by extraction and the pure compounds were obtained by Kugelrohr distillation.

As shown in Scheme 1, the *in-situ* generated alkoxide anion of one hydroxyl group may react with di(*p*-toluenesulfonate) or its corresponding dichloride to give an intermediate (**4**), which subsequently cyclizes to monoaza crown ether *via* the intramolecular nucleophilic substitution by the aid of a template ion. However, the alternative attack of amino nitrogen may lead to the formation of *N*-(2-hydroxyethyl) monoaza crown ether (**9**).

The synthesis of monoaza-15-crown-5 (**6**) was carried out under the various reaction conditions by changing solvents, bases, temperature and molar ratio of the reactants. The reaction products were carefully

Table 1. Synthesis of monoaza-15-crown-5 (**6**)[a]

a) **2b** or **3a**, 0.01 mol; solvent, 200 ml; reaction time, 4 h. b) Based on **2b** or **3a** and determined by GLC. c) Values in parentheses are isolated yields obtained on larger scale by extraction and distillation. d) The yield obtained in higher concentration; **2b**, 0.12 mol; solvent, 550 ml. e) Reaction time, 40 h. f) Further purified by thermolyzing the complex of **6** with sodium thiocyante.

examined by GLC and NMR to make a survey of the reaction (Table 1).

Triethylene glycol di(*p*-toluenesulfonate) was dissolved in dioxane or benzene because of its insolubility in *t*-butyl alcohol. The reaction proceeded very little in dioxane whichever base, sodium hydroxide or *t*-butoxide, was used, and **2b** was recovered unchanged. This result may be ascribed to the insolubility of the alkoxide. In the range of 40 to 80 °C, the reactions using sodium or potassium *t*-butoxide as a base gave around 55 and 35% yields of monoaza-15-crown-5, respectively. Thus, the reaction temperature does not seem to affect the reaction, but with respect to the effect of the template ion, the sodium cation is superior to the potassium one, as described in the previous investigations.[21-23] Furthermore, when a two molar quantity of diethanolamine was used, the yield of **6** increased to 77%. On the contrary, use of excess base increased the formation of triethylene glycol di-*t*-butyl ether (**10a**) and caused the reduction of the yield of **6**.

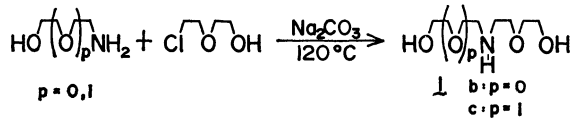
Triethylene glycol di-*t*-butyl ether, which was produced by the attack of *t*-butoxide anion to **2b**, was found in the reactions using **2b**.[24]

When sodium hydroxide was used instead of sodium *t*-butoxide, monoaza-15-crown-5 was obtained in a lower yield.

In the reaction using dichloride (**3a**), the reaction was continued for 40 h, because of its low reactivity. The yields of monoaza-15-crown-5 were found to be low compared with those using di(*p*-toluenesulfonate). In these cases, vinyl ether derivative (**11a**), which was supposed to be generated by the elimination of HCl from the intermediate (**4**), was isolated instead of di-*t*-butyl ether (**10a**). As the by-product (**11a**) could not be separated from crude product by extraction, **6** was isolated by thermolyzing monoaza-15-crown-5 complex with sodium thiocyanate in acetone/hexane. Consequently, the difference between isolated yield and GLC yield was larger than that obtained using **2b**.

The products obtained from all reactions showed a single peak in their gas chromatograms using various columns, and were identified unambiguously as monoaza-15-crown-5 by spectral analyses (^{1}H NMR, IR, and MS). However, to make sure that the possible isomer, *N*-(2-hydroxyethyl)monoaza-12-crown-4 (**9b**), is not formed in the reactions, the authentic **9b** was prepared by the ethoxylation of monoaza-12-crown-4. No indication of the presence of **9b** in the reaction products was obtained, despite a precise check by GLC.

Monoaza-18-crown-6 (**7**) was prepared from the reaction between diethanolamine and tetraethylene glycol di(*p*-toluenesulfonate) (**2c**) or corresponding dichloride (**3b**), and yields were determined by GLC (Table 2). In addition, **7** was also prepared from the reactions of the corresponding oligoethylene glycol di(*p*-toluenesulfonate) with *N*-(2-hydroxyethyl)-2-(2-hydroxyethoxy)ethylamine (**1b**) or bis[2-(2-hydroxyethoxy)ethyl]amine (**1c**), which were obtained by the reactions of oligo(oxyethylene)amines with 2-(2-chloroethoxy)ethanol (Scheme 2).



Scheme 2.

In the reactions using **2c**, no remarkable temperature effect was observed. However, unlike the results of monoaza-15-crown-5, use of both sodium and potassium *t*-butoxides gave almost the same yields. Although a small amount of tetraethylene glycol di-*t*-butyl ether was also formed in these cases, improvement of the yield of **7** to about 80% was attained by using excess diethanolamine or by using the amines

with oligo(oxyethylene) units (**1b** and **1c**). This fact may be interpreted by the increased solubilities of alkoxides of these amines in the solvent.

It was confirmed by the comparison with the authentic sample by GLC that the possible isomer (**9c**) by *N,O*-alkylation was not formed in these reactions.

Furthermore, monoaza-21-crown-7 (**8**) was prepared in a 33% yield by the reaction of diethanolamine with pentaethylene glycol di(*p*-toluenesulfonate) (**2d**). In this case, however, presence of a small amount of the isomer, *N*-(2-hydroxyethyl)monoaza-18-crown-6 (**9d**) was observed by GLC analysis, probably because of the ease of 18-crown ring formation. Similarly, treatment of diethanolamine with diethylene glycol di-(*p*-toluenesulfonate) (**2a**) afforded monoaza-12-crown-4 in very low yield (3%).

TABLE 2. SYNTHESIS OF MONOAZA-18-CROWN-6 (**7**)[a]

Run	**1**	**2** or **3**	Base	Reaction temp/°C	Yield of **7**/%[b]

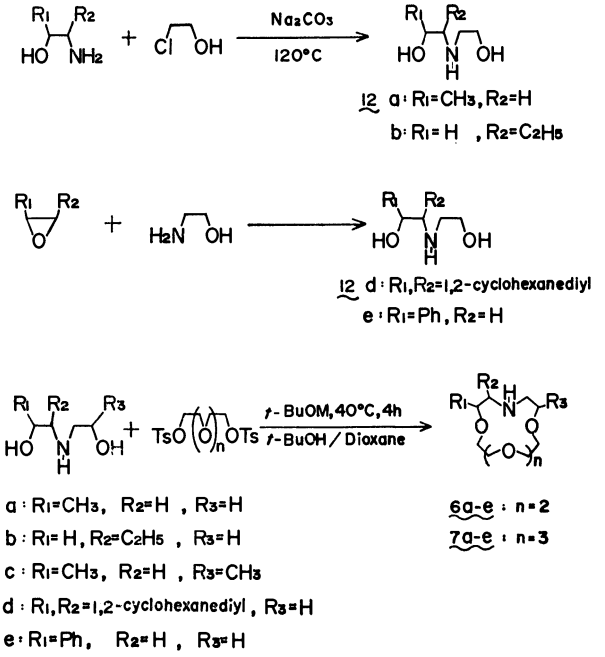
a) **1**, 0.01 mol; **2** or **3**, 0.01 mol; base, 0.024 mol; *t*-BuOH/dioxane, 200 ml; reaction time, 4 h. b) Based on **2** or **3** and determined by GLC. c) Values in parentheses are isolated yields obtained on larger scale by extraction and distillation. d) Excess **1a** was used (0.02 mol). e) The yield in higher concentration; **1a**, 0.24 mol; **2c**, 0.12 mol; base, 0.29 mol; *t*-BuOH/dioxane, 550 ml. f) Solvent, *t*-BuOH; reaction time, 40 h. g) Further purified by recrystallization from hexane.

This method was successfully applied for the preparation of the monoaza crown ethers bearing various substituents. *N*-(2-hydroxyethyl)-2-hydroxyalkylamines (**12**) were prepared by two procedures, as shown in Scheme 3. Equimolar reactions of **12** with oligoethylene glycol di(*p*-toluenesulfonates) were performed in a similar manner to give the substituted monoaza 15- and 18-crown ethers (Table 3).

The yields of crown compounds of which R^1 or R^3 is methyl were observed to be lower than those of crown compounds of which R^2 is ethyl or those of unsubstituted crowns (**6**, **7**). Such results may be attributed to the competitive formation of di-*t*-butyl ethers, because of the lower reactivity of secondary alkoxide than that of normal alkoxide due to a steric effect. The better yields of crown compounds with cyclohexane ring, however, may be explained by the higher solubility of its alkoxide in the solvent. Phenyl monoaza crown ethers (**6e** and **7e**) were also obtained



Scheme 3.

a) **2**, 0.02 mol; **12**, 0.02 mol; base, 0.048 mol; *t*-BuOH/dioxane, 360 ml; 40 °C: 4 h. b) Measured at 40 °C: white waxy solid at 20 °C.

in satisfactory yields.

Most of the reactions in this study were run on a rather small scale in dilute solution (0.01 mol of **2**/200 ml of solvent). However, in the practical preparation on a larger scale in higher concentration (0.12 mol of **2**/550 ml of solvent), monoaza crown ethers were obtained in 50 to 70% yields by using the excess dialkanolamines. Thus, together with the high selectivity and ready accessibility of the starting materials, this method is useful for the practical production of monoaza crown ethers.

Experimental

The infrared spectra were taken on a Hitachi 260-10 spectrometer. The ^{1}H NMR spectra were recorded at 100 MHz on a JEOL JNM-PS 100 spectrometer in $CDCl_3$ solution with tetramethylsilane as the internal standard. The mass spectra were measured with a Hitachi RMU-6E mass spectrometer at an ionization potential of 70 eV. The GLC analyses were performed on a Shimadzu gas chromatograph GC-3BF using 1 m×3 mm column packed with 10% Silicone SE-30 on 60—80 mesh Celite 545 or on a Shimadzu gas chromatograph GC-3BT using 0.7 m×3 mm column packed with 10% Carbowax on 60—80 mesh Celite 545. Amine contents were determined by a conventional titration procedure.[25]

Starting Materials. Starting materials were the commercial products of analytical grade. Their purities were checked by GLC and they were purified by distillation when necessary. Oligoethylene glycol di(*p*-toluenesulfonates) were prepared as reported.[26] α-(2-Chloroethyl)-ω-chlorooligo(oxyethylenes) were prepared from the corresponding glycols and thionyl chloride.

*N-(2-Hydroxyethyl)-2-(2-hydroxyethoxy)ethylamine (**1b**).* 2-(2-Chloroethoxy)ethanol (62.3 g, 0.50 mol) was added to a suspension of powdered sodium carbonate (39.8 g, 0.38 mol) in 2-aminoethanol (91.7 g, 1.50 mol) and the mixture was heated at 120 °C with stirring. After 24 h of reaction, it was cooled to room temperature, filtered and excess 2-aminoethanol was recovered from the filtrate. The residue was purified by fractional distillation at 150—152 °C (0.1 Torr) to give 46.1 g (50%) of **1b** as a pale yellow liquid: ^{1}H NMR δ 2.65—2.97 (m, NCH_2, 4H), 3.46—3.89 (m, OCH_2, 8H), 4.38 (s, OH, NH, 3H); IR (neat) 3350, 3300, 2950, 2860, 1460, 1360, 1120, 1070 cm^{-1}.

Found: C, 48.06; H, 10.29; N, 9.52%. Calcd for $C_6H_{15}NO_3$: C, 48.31; H, 10.13; N, 9.39%.

*Bis[2-(2-hydroxyethoxy)ethyl]amine (**1c**).* The above procedure was followed, using 2-(2-aminoethoxy)ethanol and 2-(2-chloroethoxy)ethanol: bp 154—156 °C (0.05 Torr)**; pale yellow liquid; 55% yield; ^{1}H NMR δ 2.79 (t, 4H), 3.44—3.78 (m, 12H), 3.82 (s, 3H); IR (neat) 3320, 3280, 2950, 2850, 1460, 1350, 1120, 1070 cm^{-1}.

Found: C, 49.93; H, 10.04; N, 7.50%. Calcd for $C_8H_{19}NO_4$: C, 49.72; H, 9.91; N, 7.25%.

*N-(2-Hydroxyethyl)-2-hydroxypropylamine (**12a**).* The above procedure was followed with 1-amino-2-propanol and 2-chloroethanol as reactants: bp 96—98 °C (0.015 Torr, Kugelrohr distillation); colorless liquid; 61% yield; ^{1}H NMR δ 1.17 (d, 3H), 2.37—2.68 (m, 2H), 2.77 (t, 2H), 3.56—4.07 (m, 3H), 3.66 (s, 3H); IR (neat) 3300, 2925, 2850, 1460, 1375, 1040 cm^{-1}.

Found: C, 50.20; H, 11.09; N, 11.69%. Calcd for $C_5H_{13}NO_2$: C, 50.40; H, 11.00; N, 11.75%.

** 1 Torr≈133.322 Pa.

*N-(2-Hydroxyethyl)-1-hydroxymethylpropylamine (**12b**).* The above procedure was used with 2-amino-1-butanol and 2-chloroethanol as reactants: bp 90—95 °C (0.015 Torr, Kugelrohr distillation); pale yellow liquid; ^{1}H NMR δ 0.90 (t, 3H), 1.12—1.76 (m, 2H), 2.32—2.98 (m, 3H), 2.99—3.83 (s+m, 7H); IR (neat) 3300, 2930, 2850, 1460, 1370, 1050 cm^{-1}.

Found: C, 53.97; H, 11.46; N, 10.51%. Calcd for $C_6H_{15}NO_2$: C, 54.11; H, 11.35; N, 10.52%.

*N-(2-Hydroxyethyl)-2-hydroxycyclohexylamine (**12d**).* Cyclohexene oxide (4.91 g, 0.05 mol) was added in drops to 2-aminoethanol (15.27 g, 0.25 mol) during 1 h, at 125 °C. After the addition, the reaction was continued for 3 h and excess 2-aminoethanol was removed. The crude product (8.3 g) was purified by Kugelrohr distillation at 115—120 °C (0.05 Torr) to give 7.6 g (95%) of **12d** as a pale yellow liquid: ^{1}H NMR δ 0.88—2.14 (m, CH_2, 8H), 2.15—2.46 (m, NCH, 1H), 2.47—3.02 (m, NCH_2, 2H), 3.14—3.47 (m, OCH, 1H), 3.69 (t, OCH_2, 2H), 4.01 (s, OH, NH, 3H); IR (neat) 3300, 2940, 2860, 1450, 1375, 1130, 1060 cm^{-1}.

Found: C, 60.12; H, 10.74; N, 9.04%. Calcd for $C_8H_{17}NO_2$: C, 60.35; H, 10.76; N, 8.80%.

*N-(2-Hydroxyethyl)-2-hydroxy-2-phenylethylamine (**12e**).* By a procedure similar to that used for **12d**, the reaction between styrene oxide (6.01 g, 0.05 mol) and 2-aminoethanol (15.27 g, 0.05 mol) was performed. The crude product (9.90 g) was purified by recrystallization from benzene to give 7.07 g (78%) of **12e** as a white solid: mp 98.5—100.5 °C; ^{1}H NMR δ 2.58—2.88 (m, 4H), 3.44 (s, 3H), 3.64 (t, 2H), 4.76 (t, 1H), 7.31 (s, 5H); IR (KBr) 3380, 3250, 3050, 2910, 2850, 1460, 1070, 710 cm^{-1}.

Found: C, 65.96; H, 8.24; N, 7.72%. Calcd for $C_{10}H_{15}NO_2$: C, 66.27; H, 8.34; N, 7.73%.

*2,2,13,13-Tetramethyl-3,6,9,12-tetraoxatetradecane (**10a**).* Potassium metal (5.9 g, 0.15 mol) was dissolved in *t*-butyl alcohol (200 ml), and triethylene glycol di(*p*-toluenesulfonate) (**2b**, 22.9 g, 0.05 mol) was added at 60 °C. After 4 h of reaction, the mixture was filtered and the solvent was evaporated off. Water (30 ml) was added to the residue and the solution was extracted several times with hexane. The hexane extracts were combined, the solvent was removed, and the crude product (11.0 g) was distilled by Kugelrohr apparatus at 78—81 °C (0.05 Torr) to give 4.2 g (32%) of **10a** as a colorless liquid: ^{1}H NMR δ 2.18 (s, 18H), 3.45—3.73 (m, 12H); IR (neat) 2990, 2880, 1460, 1365, 1130, 1100 cm^{-1}.

Found: C, 63.62; H, 11.48%. Calcd for $C_{14}H_{30}O_4$: C, 64.09; H, 11.52%.

*Preparation of 1,4,7,10-Tetraoxa-13-azacyclopentadecane (**6**). (i) Reaction of Triethylene Glycol Di(p-toluenesulfonate) (**2b**) with Diethanolamine (**1a**):* Diethanolamine (**1a**, 3.15 g, 0.03 mol) and sodium metal (1.66 g, 0.072 mol) were dissolved in 420 ml of *t*-butyl alcohol, and triethylene glycol di(*p*-toluenesulfonate) (**2b**, 13.8 g, 0.03 mol) in 180 ml of dioxane was slowly added, drop by drop, into the solution over a period of 2 h under stirring at 40 °C. After the addition, the reaction was continued for two more hours and the reaction product was filtered. The precipitate was washed with dichloromethane, and the solvent was removed from the combined solution of filtrate and washings. Water (20 ml) was added to the residue and the solution was extracted two times with hexane to remove hexane-soluble by-products and then extracted several times with dichloromethane. Hexane was recovered from the hexane extracts, and the main by-product was isolated from the residue by preparative GLC and identified as **10a**. The dichloromethane extracts were combined, the solvent was evaporated off, and the

residue (5.21 g) was distilled by Kugelrohr apparatus at 77—81 °C (0.01 Torr) to give **6** (2.83 g, 43%) as a colorless solid: mp 29—32 °C (lit,[20] 30—32 °C); ^{1}H NMR δ 2.78 (t, 4H), 2.96 (s, 1H), 2.55—3.76 (m, 16H); MS, *m/e* (relative intensity) 219 (M^+, 11), 188 (22), 162 (32), 132 (26), 116 (9), 100 (61), 45 (100); IR (neat) 3320, 2940, 2860, 1460, 1350, 1120 cm^{-1}.

Found: C, 54.81; H, 9.71; N, 6.27%. Calcd for $C_{10}H_{21}NO_4$: C, 54.78; H, 9.65; N, 6.39%.

A larger scale experiment in higher concentration was carried out in a similar manner to that described above. Triethylene glycol di(*p*-toluenesulfonate) (55.0 g, 0.12 mol) in dioxane (200 ml) was added to the solution of diethanolamine (25.2 g, 0.24 mol) and sodium metal (6.6 g, 0.29 mol) dissolved in *t*-butyl alcohol (350 ml). The crude product (23.4 g) was distilled by Kugelrohr apparatus to give **6** (15.5 g, 59%).

GLC analyses for the investigation of the reaction conditions were performed using 0.7 m × 3 mm column packed with 10% Carbowax on 60—80 mesh Celite 545. Triethylene glycol di(*p*-toluenesulfonate) (0.01 mol) in a solvent (60 ml) was slowly added to the solution of diethanolamine and base in a solvent (140 ml) during 2 h. After the reaction was continued for 2 h, the mixture was filtered and the precipitate was washed with dichloromethane. The solvent was removed from the combined solution. The GLC analysis was performed on a diluted sample of the residue, and each yield of **6** and **10a** was determined.

*(ii) Reaction of 1,8-Dichloro-3,6-dioxaoctane (**3a**) with Diethanolamine (**1a**)*: Diethanolamine (3.15 g, 0.03 mol) and sodium metal (1.66 g, 0.072 mol) were dissolved in 420 ml of *t*-butyl alcohol. Into the solution, 1,8-dichloro-3,6-dioxaoctane (5.61 g, 0.03 mol) in 180 ml of *t*-butyl alcohol was slowly added over a period of 2 h under stirring at 60 °C. After the addition, the reaction continued for 38 h, and a work-up was performed similarly to the case of di(*p*-toluenesulfonate). The product (2.60 g) obtained by Kugelrohr distillation showed a single peak in the GLC, using Silicone SE-30 on Celite 545. On the more polar column (10% Carbowax on Celite 545), however, it showed two peaks. Then, the by-product was isolated from the distillation product by preparative GLC: ^{1}H NMR δ 2.39 (s, 2H), 2.68—2.94 (m, 4H), 3.53—3.96 (m, 12H), 4.03 (dd, 1H), 4.20 (dd, 1H), 6.52 (dd, 1H); MS, *m/e* (relative intensity) 219 (M^+, 2), 188 (47), 74 (100); IR (neat) 3320, 2940, 2870, 1620, 1460, 1330, 1110, 990 cm^{-1}. From these data this product was identified as **11a**, but the possible isomer, *N*-(2-hydroxyethyl)monoaza-12-crown-4 (**9b**) was not detected in this reaction. The distillation product was further purified by thermolyzing the monoaza-15-crown-5 complex with sodium thiocyanate in acetone/hexane to give the pure product of **6** (0.79 g, 12%).

*1,4,7,10,13-Pentaoxa-16-azacyclooctadecane (**7**).* This compound was prepared, using a method similar to that used for **6**, from diethanolamine (25.2 g, 0.24 mol), tetraethylene glycol di(*p*-toluenesulfonate) (**2c**, 60.3 g, 0.12 mol), and potassium metal (11.3 g, 0.29 mol). The crude product was distilled by Kugelrohr apparatus at 95—99 °C (0.02 Torr) to give 20.5 g (65%) of **7** as a colorless solid: mp 48—51 °C (lit,[15] 49—51 °C); ^{1}H NMR δ 2.70 (s, 1H), 2.79 (t, 4H), 3.56—3.78 (m, 20H); MS *m/e* (relative intensity) 263 (M^+, 6), 233 (20), 220 (18), 204 (19), 188 (9), 176 (35), 100 (60), 45 (100); IR (neat) 3300, 2940, 2850, 1460, 1350, 1120 cm^{-1}.

Found: C, 54.59; H, 9.88; N, 5.60%. Calcd for $C_{12}H_{25}NO_5$: C, 54.73; H, 9.57; N, 5.32%.

In the same manner as in the preparation of **6** using **3a**, the reaction of 1,11-dichloro-3,6,9-trioxaundecane (**3b**, 6.93 g, 0.03 mol) with diethanolamine (3.15 g, 0.03 mol) was carried out. Since the distillation product (3.12 g) was found as a mixture of **7** and **11b**, it was further purified by recrystallization from hexane to give the pure product of **7** (0.87 g, 11%).

Small-scale experiments for the investigation of the reaction conditions were carried out, using oligoethylene glycol di(*p*-toluenesulfonate) or 1,11-dichloro-3,6,9-trioxaundecane (0.01 mol) and corresponding dihydroxy amines (**1a—c**) in the same manner as that used for **6**.

*1,4,7,10,13,16-Hexaoxa-19-azacycloheneicosane (**8**).* Diethanolamine (10.5 g, 0.1 mol) and potassium metal (9.4 g, 0.24 mol) dissolved in 300 ml of *t*-butyl alcohol and pentaethylene glycol di(*p*-toluenesulfonate) (**2d**, 54.7 g, 0.1 mol) in 250 ml of dioxane were allowed to react, using a method similar to **6**. In the GLC analysis of the crude product (27.6 g), a small peak which was ascribed to **9d** was observed. The product was distilled by Kugelrohr apparatus at 111—114 °C (0.001 Torr) to afford 10.0 g (33%) of **8** as a colorless liquid: n_D^{20} 1.4700; ^{1}H NMR δ 2.64 (s, 1H), 2.79 (t, 4H), 3.56—3.80 (m, 24H); MS, *m/e* (relative intensity) 307 (M^+, 4), 276 (7), 232 (10), 220 (17), 204 (19), 176 (15), 100 (35), 45 (100); IR (neat) 3340, 2940, 2860, 1450, 1350, 1120 cm^{-1}.

Found: C, 54.88; H, 9.79; N, 4.50%. Calcd for $C_{14}H_{29}NO_6$: C, 54.70; H, 9.51; N, 4.56%.

*1,4,7-Trioxa-10-azacyclododecane (**5**).* This compound was prepared using a method similar to that for the macrocycle **6**, from diethanolamine (42.1 g, 0.4 mol), sodium metal (11.0 g, 0.48 mol), and diethylene glycol di(*p*-toluenesulfonate) (82.9 g, 0.2 mol). The crude product was purified by Kugelrohr apparatus giving colorless crystals: bp 58—62 °C (0.005 Torr); mp 57—59 °C (lit,[4] 60 °C); 3% yield; ^{1}H NMR δ 2.52 (s, NH, 1H), 2.72 (t, NCH_2, 4H), 3.48—3.89 (m, OCH_2, 12H); MS, *m/e* (relative intensity) 175 (M^+, 10), 144 (15), 118 (35), 100 (33), 86 (61), 74 (21), 72 (21), 57 (100); IR (neat) 3300, 2940, 2870, 1460, 1360, 1130, 1090 cm^{-1}.

Found: C, 54.89; H, 9.91; N, 7.91%. Calcd for $C_8H_{17}NO_3$: C, 54.84; H, 9.78; N, 7.99%.

*11-Methyl-1,4,7,10-tetraoxa-13-azacyclopentadecane (**6a**).* *N*-(2-Hydroxyethyl)-2-hydroxypropylamine (**12a**, 2.38 g, 0.02 mol) and sodium metal (1.10 g, 0.048 mol) were dissolved in 240 ml of *t*-butyl alcohol and triethylene glycol di(*p*-toluenesulfonate) (9.16 g, 0.02 mol) in 120 ml of dioxane was added in drops to the solution over a period of 2 h under stirring at 40 °C. After the addition, the reaction was continued for two more hours, then the reaction mixture was filtered. The precipitate was washed with dichloromethane, and the solvent was removed from the combined solution of filtrate and washings. Water (15 ml) was added to the residue and the solution was extracted two times with hexane to remove hexane-soluble materials and then extracted several times with dichloromethane. The dichloromethane extracts were combined, the solvent was evaporated off, and the residue was distilled by Kugelrohr apparatus at 80—83 °C (0.01 Torr) to give 1.21 g (26%) of **6a** as a pale yellow liquid: ^{1}H NMR δ 1.10 (d, CH_3, 3H), 2.52—2.80 (m, NCH_2, 4H), 2.83 (s, NH, 1H), 2.42—2.92 (m, OCH, OCH_2, 15H); MS, *m/e* (relative intensity) 233 (M^+, 9), 218 (4), 188 (12), 161 (10), 132 (10), 114 (11), 45 (100); IR (neat) 3330, 2930, 2850, 1460, 1360, 1130 cm^{-1}.

Found: C, 56.35; H, 10.00; N, 6.04%. Calcd for $C_{11}H_{23}NO_4$: C, 56.63; H, 9.94; N, 6.00%.

This procedure is typical for the preparation of other *N*-unsubstituted monoaza crown ethers bearing substituents.

Monoaza 15- and 18-crown ethers were prepared from the reaction of dihydroxy amines (**12a—e**) with triethylene and tetraethylene glycol di(*p*-toluenesulfonates), respectively.

*11,15-Dimethyl-1,4,7,10-tetraoxa-13-azacyclopentadecane (**6c**).* Bp 75—80 °C (0.01 Torr, Kugelrohr distillation); colorless liquid; 26% yield; ^{1}H NMR δ 1.05—1.22 (m, 6H), 2.59 (s, 1H), 2.42—2.80 (m, 4H), 3.40—3.84 (m, 14H); MS, *m/e* (relative intensity) 247 (M^+, 6), 232 (5), 202 (37), 174 (7), 158 (6), 146 (6), 114 (18), 101 (49), 45 (100); IR (neat) 3330, 2970, 2870, 1460, 1340, 1110 cm^{-1}.

Found: C, 58.04; H, 10.38; N, 5.60%. Calcd for $C_{12}H_{25}NO_4$: C, 58.27; H, 10.19; N, 5.66%.

*12-Ethyl-1,4,7,10-tetraoxa-13-azacyclopentadecane (**6b**).* Bp 90—93 °C (0.02 Torr, Kugelrohr distillation); colorless liquid; 46% yield; ^{1}H NMR δ 0.89 (t, 3H), 1.28—1.62 (m, 2H), 2.01 (s, 1H), 2.60—2.92 (m, 3H), 3.18—3.80 (m, 16H); MS, *m/e* (relative intensity) 247 (M^+, 23), 218 (95), 188 (57), 172 (21), 159 (42), 128 (29), 69 (100); IR (neat) 3320, 2930, 2860, 1460, 1350, 1120 cm^{-1}.

Found: C, 58.13; H, 10.05; N, 5.63%. Calcd for $C_{12}H_{25}NO_4$: C, 58.27; H, 10.19; N, 5.66%.

*Perhydro-11,12-benzo-1,4,7,10-tetraoxa-13-azacyclopentadecane (**6d**).* Bp 125—128 °C (0.03 Torr, Kugelrohr distillation); white waxy solid at 20 °C; 52% yield; ^{1}H NMR δ 0.88—2.33 (m, 8H), 2.34—2.51 (m, 1H), 2.72 (t, 2H), 2.98 (s, 1H), 2.88—3.09 (m, 1H), 3.30—4.04 (m, 14H); MS, *m/e* (relative intensity) 273 (M^+, 13), 244 (8), 230 (11), 188 (21), 154 (37), 142 (23), 128 (25), 126 (33), 45 (100); IR (neat) 3320, 2940, 2860, 1460, 1355, 1130 cm^{-1}.

Found: C, 61.11; H, 10.33; N, 4.99%. Calcd for $C_{14}H_{27}NO_4$: C, 61.51; H, 9.95; N, 5.12%.

*11-Phenyl-1,4,7,10-tetraoxa-13-azacyclopentadecane (**6e**).* Bp 139—143 °C (0.02 Torr, Kugelrohr distillation); pale yellow liquid; 33% yield; ^{1}H NMR δ 2.47 (s, 1H), 2.72 (t, 2H), 2.74—3.07 (m, 2H), 3.36—4.04 (m, 14H), 4.40—4.64 (m, 1H), 7.12—7.52 (m, 5H); MS, *m/e* (relative intensity) 295 (M^+, 35), 265 (10), 220 (9), 207 (11), 176 (16), 165 (17), 74 (100); IR (neat) 3325, 3050, 2920, 2880, 1460, 1350, 1110, 760, 700 cm^{-1}.

Found: C, 65.02; H, 8.59; N, 4.98%. Calcd for $C_{16}H_{25}NO_4$: C, 65.06; H, 8.53; N, 4.74%.

*14-Methyl-1,4,7,10,13-pentaoxa-16-azacyclooctadecane (**7a**).* By a similar procedure to that used for **6a**, the reaction between *N*-(2-hydroxyethyl)-2-hydroxypropylamine (**12a**, 2.38 g, 0.02 mol) and tetraethylene glycol di(*p*-toluenesulfonate) (**2c**, 10.04 g, 0.02 mol) was performed in the presence of potassium metal (1.87 g, 0.048 mol) dissolved in *t*-butyl alcohol: bp 102—107 °C (0.01 Torr); colorless liquid; 39% yield; ^{1}H NMR δ 1.12 (d, 3H), 2.52—2.84 (m, 4H), 2.65 (s, 1H), 3.40—3.90 (m, 19H); MS, *m/e* (relative intensity) 277 (M^+, 7), 232 (19), 205 (14), 190 (13), 176 (16), 144 (13), 45 (100); IR (neat) 3350, 2930, 2890, 1460, 1350, 1120 cm^{-1}.

Found: C, 55.89; H, 10.00; N, 4.94%. Calcd for $C_{13}H_{27}NO_5$: C, 56.30; H, 9.81; N, 5.05%.

*14,18-Dimethyl-1,4,7,10,13-pentaoxa-16-azacyclooctadecane (**7c**).* Bp 97—101 °C (0.001 Torr, Kugelrohr distillation); white waxy solid at 20 °C; 28% yield; ^{1}H NMR δ 1.06—1.22 (m, 6H), 2.54 (s, 1H), 2.38—2.83 (m, 4H), 3.37—3.89 (m, 18H); MS, *m/e* (relative intensity) 291 (M^+, 3), 276 (4), 246 (20), 190 (10), 146 (7), 133 (8), 116 (14), 101 (24), 45 (100); IR (neat) 3340, 2970, 2870, 1460, 1350, 1120 cm^{-1}.

Found: C, 57.56; H, 10.24; N, 4.39%. Calcd for $C_{14}H_{29}NO_5$: C, 57.71; H, 10.03; N, 4.81%.

*15-Ethyl-1,4,7,10,13-pentaoxa-16-azacyclooctadecane (**7b**).* Bp 120—124 °C (0.04 Torr, Kugelrohr distillation); pale yellow liquid; 41% yield; ^{1}H NMR δ 0.88 (t, 3H), 1.27—1.64 (m, 2H), 2.23 (s, 1H), 2.63—2.86 (m, 3H), 3.23—3.78 (m, 20H); MS, *m/e* (relative intensity) 291 (M^+, 23), 262 (100), 232 (79), 216 (57), 188 (32), 174 (47), 159 (50); IR (neat) 3370, 2920, 2870, 1460, 1360, 1120 cm^{-1}.

Found: C, 57.38; H, 10.15; N, 4.78%. Calcd for $C_{14}H_{29}NO_5$: C, 57.71; H, 10.03; N, 4.81%.

*Perhydro-14,15-benzo-1,4,7,10,13-pentaoxa-16-azacyclooctadecane (**7d**).* Bp 145—150 °C (0.03 Torr, Kugelrohr distillation); pale yellow liquid; 43% yield; ^{1}H NMR δ 0.92—2.23 (m, 8H), 2.24—2.68 (m, 1H), 2.64 (s, 1H), 2.75 (t, 2H), 2.86—3.28 (m, 1H), 3.32—4.04 (m, 18H); MS, *m/e* (relative intensity) 317 (M^+, 8), 288 (9), 274 (9), 242 (14), 205 (15), 154 (36), 143 (27), 45 (100); IR (neat) 3325, 2930, 2860, 1460, 1350, 1120 cm^{-1}.

Found: C, 60.42; H, 9.87; N, 4.50%. Calcd for $C_{16}H_{31}NO_5$: C, 60.54; H, 9.84; N, 4.41%.

*14-Phenyl-1,4,7,10,13-pentaoxa-16-azacyclooctadecane (**7e**).* Bp 153—157 °C (0.02 Torr, Kugelrohr distillation); yellow liquid; 33% yield; ^{1}H NMR δ 2.38 (s, 1H), 2.74 (t, 2H), 2.72—3.08 (m, 2H), 3.38—3.90 (m, 18H), 4.42—4.68 (m, 1H), 7.12—7.45 (m, 5H); MS, *m/e* (relative intensity) 339 (M^+, 14), 309 (9), 280 (7), 264 (8), 205 (11), 176 (19), 74 (100); IR (neat) 3325, 3050, 2930, 2880, 1450, 1350, 1110, 760, 700 cm^{-1}.

Found: C, 63.35; H, 8.77; N, 4.42%. Calcd for $C_{18}H_{29}NO_5$: C, 63.69; H, 8.61; N, 4.13%.

*10-(2-Hydroxyethyl)-1,4,7-trioxa-10-azacyclododecane (**9b**).* After ethylene oxide was passed through 35% NaOH aqueous solution and dried over NaOH and soda lime, it was introduced to 1,4,7-trioxa-10-azacyclododecane (**5**, 0.88 g, 0.005 mol) at 170 °C for 6 h. By distilling the reaction mixture at 80—85 °C (0.03 Torr) using Kugelrohr apparatus, 0.47 g (43%) of **9b** was obtained as a pale yellow liquid. ^{1}H NMR δ 2.67 (t, NCH_2, 2H), 2.72 (t, NCH_2, 4H), 3.39—3.92 (s+m, OH, OCH_2, 15H); MS, *m/e* (relative intensity) 219 (M^+, 6.2), 188 (100); IR (neat) 3300, 2910, 2840, 1640, 1450, 1360, 1130, 1100 cm^{-1}.

Found: C, 54.21; H, 9.85; N, 6.05%. Calcd for $C_{10}H_{21}NO_4$: C, 54.77; H, 9.65; N, 6.39%.

Using a similar procedure, **9c** and **9d** were also obtained.

*13-(2-Hydroxyethyl)-1,4,7,10-tetraoxa-13-azacyclopentadecane (**9c**).* Bp 80—85 °C (0.005 Torr, Kugelrohr distillation); pale yellow liquid; 41% yield; ^{1}H NMR δ 2.65 (t, 2H), 2.75 (t, 4H), 3.48—3.76 (s+m, 19H); MS, *m/e* (relative intensity) 363 (M^+, 2.7), 232 (100); IR (neat) 3300, 2910, 2840, 1640, 1460, 1360, 1110, 1090 cm^{-1}.

(Received May 31, 1982)

Phosphide anions, prepared by an action of sodium dihydridobis(2-methoxyethanolato)aluminate on derivatives of phosphine, phosphine oxide, or phosphorus esters, react with primary and secondary alkyl halides to produce phosphine derivatives having a newly formed phosphorus-carbon bond. The reactivity increases in the order of chloride<bromide<iodide and of secondary<primary in alkyl halide. Reaction of phosphide anion is also feasible with *p*-toluenesulfonate. Reaction of an anion of diphenylphosphine oxide seems to proceed mainly as an S_N2 type process.

As a chemical modification of sugar derivatives, we[1-3] synthesized compounds having a phosphorus atom instead of oxygen atom in the hemiacetal ring. Paulsen and Greve[4] reported a preparation of sugar derivatives bearing a phosphorus-carbon bond by addition of dialkylphosphonates to glyculoses. The addition of phosphonates to ketoses is a good method to prepare a phosphorus-carbon bond on sugar skeletons,[5] however a fundamental work[6] on the reactivity of α-hydroxyalkylphosphonates with some halogenating reagents failed to afford desired results, *i.e.*, some elimination reactions occurred instead of the substitution reaction.

The addition reaction of phosphorus compounds having a P–H bond to unsaturated double bonds such as C=C, C=N, and C=O always possesses a potential possibility to produce isomeric adducts. Addition of phenylphosphine to 3-*O*-acetyl-5,6-dideoxy-1,2-*O*-isopropylidene-6-*C*-nitro-α-D-*xylo*-hex-5-enofuranose actually gave both compounds of α-D-glucofuranose and β-L-idofuranose derivatives.[7,8]

Preparation and reaction of metal phosphides have widely been investigated.[9] Reactions of alkali phosphides with alkylating reagents are often used for the preparation of tertiary phosphines.[10] Phosphide anions could also be prepared by an action of hydrides on phosphorus compounds in a heterogeneous mixture[9,10] as well as by an action of sodium dihydridobis(2-methoxyethanolato)aluminate (SDMA) in a homogeneous mixture.[11,12] SDMA was sometimes used to prepare a P–H group from P–OR groups of phosphorus esters connected with sugar derivatives such as 5,6-dideoxy-1,2-*O*-isopropylidene-5-*C*-[(methoxy)phenylphosphinyl]-3-*O*-methyl-α-D-*xylo*-hexofuranose;[13] therefore, the reagent seems to be applicable toward sugar derivatives since it does not act on any functional groups other than phosphorus moiety.

To prevent the occurrence of isomeric products at the stage of phosphorus-carbon bond formation, we attempted to adopt a nucleophilic substitution with phosphide anion. This paper deals with a preparation of phosphide anions by an action of SDMA and their reaction with alkyl halides or *p*-toluenesulfonates to produce secondary and tertiary phosphine derivatives.

Results

Reaction with Alkyl Halides. Reaction of diphenylphosphine oxide (**1**) with some alkyl halides was carried out in the presence of SDMA in some solvents under reflux. The reaction proceeded according to

$$\underset{\mathbf{1}}{Ph_2P(O)H} + RX \xrightarrow{NaAlH_2(OCH_2CH_2OMe)_2} \underset{\mathbf{2}}{Ph_2P(O)R}, \quad (1)$$

giving the corresponding alkyldiphenylphosphine oxides in moderate to good yields, results being summarized in Table 1.

The reaction of **1** with SDMA proceeded very fast and predominantly gave the corresponding phosphide anion. The reactivity of the anion with alkyl halides seems to depend largely on the nature of alkyl halides employed. The isolated yield increased in the order of chloride<bromide<iodide in alkyl halides. The reaction with primary alkyl halides proceeded faster than that with secondary alkyl halides which required higher reaction temperature and/or prolonged reaction time. The reaction using SDMA is superior to those using sodium amide or lithium tetrahydridoaluminate, as judged from the product yield. Addition of sodium iodide to the reaction mixture remarkably improved the yield.

Reaction with Alkyl p-*Toluenesulfonates.* Reaction of **1** with alkyl *p*-toluenesulfonates was carried out in the presence of SDMA in tetrahydrofuran under reflux. Yields of products, obtained according to

$$\underset{\mathbf{1}}{Ph_2P(O)H} + R'OTs \xrightarrow{NaAlH_2(OCH_2CH_2OMe)_2} \underset{\mathbf{3}}{Ph_2P(O)R'}, \quad (2)$$

$$R' = i\text{-Pr},\ c\text{-}C_6H_{11},\ C_{10}H_{19}$$

were good and the results were shown in Table 2.

Reaction of Phenylphosphine or Methyl Phosphinates with Alkyl Halides or p-*Toluenesulfonates.* Reaction of methyl phenylphosphinate with isopropyl iodide in tetrahydrofuran in the presence of SDMA under reflux also gave the corresponding phosphine oxide in 46% yield. The reaction of phenylphosphine with alkyl halides or *p*-toluenesulfonates in tetrahydrofuran

proceeded according to

$$\underset{\mathbf{4}}{PhPH_2} + R''X \xrightarrow{NaAlH_2(OCH_2CH_2OMe)_2} \underset{\mathbf{5}}{PhP(H)R''}, \quad (3)$$

R″=Secondary alkyl
X=Halogen or *p*-toluenesulfonyloxy

giving the corresponding secondary phosphines in excellent yields. These results are summarized in Table 2.

Discussion

The improvement of the yield of cyclohexyldiphenylphosphine oxide by addition of sodium iodide to the reaction mixture may be attributed to the first attack of iodine on cyclohexyl chloride followed by its replacement with phosphorus. The additivity effect will make valuable the present phosphorus-carbon bond forming reaction.

Ratios of neomenthyldiphenylphosphine oxide to menthyldiphenylphosphine oxide, as determined by optical rotation or HPLC, are 86:14 for the reaction of diphenylphosphine oxide with menthyl chloride, 63:37 for that with menthyl bromide, and 99:1 for that with menthyl *p*-toluenesulfonate. The ratio of neomenthylphenylphosphine to menthylphenylphosphine is 51:49 for the reaction of phenylphosphine with menthyl chloride in the presence of SDMA. The predominant production of the inverted product in the reaction of diphenylphosphine oxide with menthyl derivatives may indicate that the reaction proceeds mainly *via* an S_N2 process.

A comparison of yields of diphenylphosphine oxide

derivatives such as isopropyldiphenylphosphine oxide (48% yield from diphenylphosphinous chloride with propylene oxide)[14] and cyclohexyldiphenylphosphine oxide (30% yield from diphenylphosphine oxide with cyclohexane)[15] with those obtained in the present reaction may suggest that the reaction using SDMA is a good method to prepare a phosphorus-carbon bond. The homogeneous reaction mixture and simple operation and work-up as well as various types of phosphorus compounds being available as the precursor of phosphorus anion will also make the method useful for preparation of various types of derivatives of phosphines and phosphine oxides. The observed good yield for alkyl *p*-toluenesulfonates will make the present method hopeful in the field of carbohydrates.

Experimental

Instruments and Materials. IR spectra were measured on Hitachi-Perkin-Elmer 337 and JASCO (Japan Spectroscopic Co.) A-3 spectrophotometers. ^{1}H NMR spectra were recorded on Hitachi-Perkin-Elmer R-20 (60 MHz) and Hitachi R-24 (60 MHz) spectrometers using tetramethylsilane as the internal standard. Mass spectra were obtained on a Hitachi RMU DMG GC-MS spectrometer. Optical rotations were determined with JASCO DIP-4 digital and Atago Polax photometers.

Isolation of products was performed by high pressure liquid chromatography using JASCO Uniflow-211 and Uvidec-100-II, by liquid chromatography using a UVICON-540 detector and a SF-100G fraction collector from Toyo Scientific Industry, or by thin layer chromatography. Melting and boiling points were uncorrected.

Phenylphosphine (bp 118 °C), methyl phenylphosphinate (bp 94—95 °C/0.5—1.0 mmHg[16]), and methyl methylphenylphosphinate (bp 100 °C/0.5 mmHg) from phenylphosphonous dichloride,[17-20] and diphenylphosphine oxide (mp 49 °C)[21] were used as the phosphide precursors. Commercially available SDMA (benzene or toluene solution) was used. Cyclohexyl chloride (bp 27.2 °C/8 mmHg) and bromide (bp 54 °C/17.5 mmHg) were prepared from cyclohexanol,[22,23] cyclohexyl iodide from cyclohexene,[24] and 2-chlorooctane from 2-octanol.[25] Menthyl chloride (bp 98 °C/18 mmHg) was prepared from L-menthol; $[\alpha]_D^{15}$ −47.7° (*c* 2.4, EtOH).[26] *p*-Toluenesulfonates of 2-propanol (bp 114 °C/3 mmHg), cyclohexanol, and L-menthol were prepared from corresponding alcohols and *p*-toluenesulfonyl chloride.

Synthesis of Menthyl Bromide. To a mixture of L-menthol (3.0 g) and hydrobromic acid (5.0 g) was added 2.5 ml of concentrated sulfuric acid under ice cooling, and then the solution was heated for 5 h at 105 °C. Filtration of the reaction mixture, extraction of the product by petroleum ether, and successive work-up and distillation gave the bromide in 71% yield: bp 113 °C/22 mmHg; ^{1}H NMR ($CDCl_3$) δ=0.73 (d, J=7.1 Hz, 3H, Me), 0.91 (d, J=7.1 Hz, 6H, $CH(C\underline{H}_3)_2$), 0.58—3.00 (m, 9H, $C\underline{H}(CH_3)_2$ and ring protons other than CHBr), and 3.41—4.38 (m, 1H, CHBr); IR ν_{max}^{neat} 692 cm^{-1} (C-Br); $[\alpha]_D^{27.9}$ −29.0° (*c* 1.22, EtOH).

Found: C, 55.20; H, 8.88%. Calcd for $C_{10}H_{19}Br$; C, 54.79; H, 8.75%.

Product Criteria. The following were identified on the basis of spectra for each product purified by liquid or thin layer chromatography: ethyldiphenylphosphine oxide (^{1}H NMR ($CDCl_3$) δ=1.16 (dt, J_{PCCH}=17.4 Hz, J_{HH}=7.5 Hz, 3H, Me), 2.26 (dq, J_{PCH}=11.7 Hz, J_{HH}=7.5 Hz, 2H, CH_2), and 7.10—8.26 (m, 10H, Ph)], benzyldiphenylphosphine oxide [^{1}H NMR ($CDCl_3$) δ=3.64 (d, J_{PCH}=14.0 Hz, 2H, CH_2) and 7.08—8.06 (m, 15H, Ph)], isopropyldiphenylphosphine oxide [^{1}H NMR ($CDCl_3$) δ=1.16 (dd, J_{PCCH}=16.4 Hz, J_{HH}=7.1 Hz, 6H, Me), 1.63—2.04 (m, 1H, P-CH), and 7.05—8.04 (m, 10H, Ph)], cyclohexyldiphenylphosphine oxide [^{1}H NMR ($CDCl_3$) δ=0.74—2.64 (m, 11H, C_6H_{11}) and 7.14—8.18 (m, 10H, Ph); MS m/e=284 (M^+)], neomenthyldiphenylphosphine oxide [^{1}H NMR ($CDCl_3$) δ= 0.25—3.05 (m, 19H, Me, $C\underline{H}(C\underline{H}_3)_2$, and ring protons) and 7.01—8.02 (m, 10H, Ph); MS m/e=340 (M^+)], (1-methylheptyl)diphenylphosphine oxide,[27] isopropylphenylphosphine [^{1}H NMR (CD_3OD) δ=1.01 (pair of dd, J_{PCCH} =18.3 Hz, J_{HH}=6.8 Hz, 6H, $CH(C\underline{H}_3)_2$), 1.8—2.4 (m, 1H, CH), and 6.7—7.9 (m, 5H, Ph)], (1-methylheptyl)phenylphosphine [^{1}H NMR (CD_3OD) δ=0.41—2.63 (m, 17H, C_8H_{17}), and 7.08—8.02 (m, 5H, Ph)], cyclohexylphenylphosphine [^{1}H NMR (CD_3OD) δ=0.7—2.3 (m, 11H, C_6H_{11}) and 7.2—8.1 (m, 5H, Ph)], menthylphenylphosphine [^{1}H NMR (CD_3OD) δ=0.18—2.63 (m, 19H, $C_{10}H_{19}$) and 6.97—8.14 (m, 5H, Ph)], and isopropylmethylphenylphosphine oxide [^{1}H NMR ($CDCl_3$) δ=1.11 (pair of dd, J_{PCCH}=15.8 Hz, J_{HH}=7.5 Hz, 6H, $CH(C\underline{H}_3)_2$), 1.72 (d, J_{PCH}=12.5 Hz, 3H, P-Me), 1.42—1.93 (m, 1H, CH), and 7.21—8.17 (m, 5H, Ph)].

The structure of the produced secondary phosphines was further confirmed by converting them into methyl esters of the phosphinic acids, *e.g.*, methyl isopropylphenylphosphinate [^{1}H NMR ($CDCl_3$) δ=1.11 (pair of dd, J_{PCCH}=17.3 Hz, J_{HH}=7.2 Hz, 6H, $CH(C\underline{H}_3)_2$), 2.01 (dq, J_{PCH}=14.2 Hz, J_{HH}=7.2 Hz, 1H, CH), 3.63 (d, J_{POCH}=10.8 Hz, POMe), and 7.1—8.0 (m, 5H, Ph); IR ν_{max}^{neat} 1203 (P=O) and 1032 cm^{-1} (P-O-Me); MS m/e=198 (M^+)] and methyl cyclohexylphenylphosphinate [^{1}H NMR ($CDCl_3$) δ=0.72—2.42 (m, 11H, C_6H_{11}), 3.65 (d, J_{POCH}=10.8 Hz, 3H, POMe), and 7.29—8.08 (m, 5H, Ph); IR ν_{max}^{neat} 1215 (P=O) and 1033 cm^{-1} (P-O-Me); MS m/e=238 (M^+)] after oxidation by hydrogen peroxide followed by methylation with diazomethane, and/or by converting them into phosphonium salts with methyl iodide, *e.g.*, isopropylmethylphenylphosphonium iodide [^{1}H NMR (CD_3OD) δ=1.06 (pair of dd, J_{PCCH}=14.4 Hz, J_{HH}=7.2 Hz, 6H, $CH(C\underline{H}_3)_2$), 1.06 (d, J_{PCCH}=16.4 Hz, 3H, P-Me), 1.9—2.7 (m, 1H, CH), and 7.2—7.9 (m, 5H, Ph)].

*Reaction of Diphenylphosphine Oxide (**1**) with Isopropyl Iodide in the Presence of SDMA.* To a stirred tetrahydrofuran solution of diphenylphosphine oxide (2.0 g, 10 mmol) was added SDMA (3.0 g, 15 mmol) dropwise under nitrogen flow and then a solution of isopropyl iodide (3.0 g, 18 mmol) in tetrahydrofuran (8 ml) was added. The reaction mixture was refluxed for 6 h. Addition of 1.5 ml of water to the cooled and stirred reaction mixture at room temperature followed by extraction by chloroform and successive evaporation of the solvent gave crude isopropyldiphenylphosphine oxide in 98% yield. Separation by thin layer chromatography gave the pure product in 91% yield: ^{1}H NMR ($CDCl_3$) δ=1.16 (dd, J_{PCCH}=16.4 Hz, J_{HH}=7.1 Hz, 6H, $CH(C\underline{H}_3)_2$), 1.63—2.04 (m, 1H, $C\underline{H}(CH_3)_2$), and 7.05—8.04 (m, 10H, Ph).

*Reaction of Diphenylphosphine Oxide (**1**) with Menthyl Chloride in the Presence of SDMA.* To a toluene (80 ml) solution of **1** (2.0 g, 9.9 mmol) was added SDMA (2 equivalents) in toluene (10 ml), and then menthyl chloride (1.7 g, 9.9 mmol) was successively added under nitrogen atmosphere. Refluxing the mixture for 16 h at 111 °C followed by work-up, separation of the products from the starting materials by liquid chromatography, and crystallization from petroleum ether gave 0.29 g of a mixture of neomenthyldiphenylphosphine oxide (86%) and menthyldiphenylphosphine oxide

(14%) in 11% yield, $[\alpha]_D^{12.4}$ +34.2° (*c* 0.75, EtOH).[28] The structure was confirmed by ^{1}H NMR and mass spectra.

The following product ratios and optical rotation values were obtained: neomenthyldiphenylphosphine oxide: menthyldiphenylphosphine oxide 63:37 from menthyl bromide, $[\alpha]_D^{24}$ +2.1° (*c* 1.6, MeOH); 99:1 from menthyl *p*-toluenesulfonate with diphenylphosphine oxide; neomenthylphenylphosphine: menthylphenylphosphine 51:49 from menthyl chloride with phenylphosphine, $[\alpha]_D^{27}$ −16° (*c* 1.6, EtOH).[26,28]

Reaction of ***1*** *with Isopropyl* p-*Toluenesulfonate in the Presence of SDMA.* To a stirred tetrahydrofuran (20 ml) solution of **1** (0.43 g, 2.1 mmol) and SDMA (2 equivalents) was added isopropyl *p*-toluenesulfonate (0.46 g, 2.1 mmol), and then the reaction mixture was heated for 10 h under reflux in nitrogen flow. Work-up (addition of 1 ml of water and evaporation of volatile materials) of the reaction mixture and separation of the product by liquid chromatography gave isopropyldiphenylphosphine oxide (0.48 g) in 94% yield, whose structure was confirmed by ^{1}H NMR spectrum.

Reaction of ***1*** *with Isopropyl Iodide in the Presence of Lithium Tetrahydridoaluminate.* To a stirred tetrahydrofuran solution of **1** (0.26 g, 2.1 mmol) was added lithium tetrahydridoaluminate (0.11 g, 2.9 mmol), and then isopropyl iodide (0.45 g, 2.6 mmol) was added. The mixture was heated for 4.5 h under reflux in nitrogen flow. Work-up and purification of the product gave isopropyldiphenylphosphine oxide (0.10 g) in 19% yield: mp 143—144 °C;[29] IR $\nu_{max}^{CHCl_3}$ 1165 cm^{-1} (P=O).

*Reaction of Phenylphosphine (****4****) with Isopropyl Bromide.* To a stirred tetrahydrofuran (50 ml) solution of phenylphosphine (1.02 g, 9.3 mmol) was added SDMA (2 equivalents) in 20 ml of tetrahydrofuran dropwise under nitrogen atmosphere, then isopropyl bromide (1.14 g, 9.3 mmol) was added to the solution, and the mixture was heated for 6 h under reflux. Addition of 2 ml of water followed by filtration and evaporation of the solvent under nitrogen atmosphere and removal of volatile material gave isopropylphenylphosphine (1.73 g) in quantitative yield. The ^{1}H NMR spectrum of the product in CD_3OD confirmed the structure. The structure was further reconfirmed by converting the phosphine to methyl isopropylphenylphosphinate.

The authors wish to express their thanks to Dr. Masao Kidokoro of Sankyo Co., Ltd. for elemental analyses and Professor Morio Suzuki's laboratory of Shizuoka University for giving facility for measurement of optical rotation. This work was partially supported by a Grant-in-Aid for Scientific Research No. 475661 from the Ministry of Education, Science and Culture.

Ozonization of Organic Compounds. VII. Carboxylic Acids, Alcohols, and Carbonyl Compounds

Etsuo NIKI,* Yorihiro YAMAMOTO, Tsuneo SAITO, Keiji NAGANO, Seiichi YOKOI, and Yoshio KAMIYA

Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received June 1, 1982)

The rate and products of the ozonization of carboxylic acids, alcohols, and ketones have been studied in water at 30 °C. The ozonization of alcohols gave corresponding carbonyl compounds as major product. The ozonization of ketones brought about primarily the carbon-carbon bond cleavage and gave carboxylic acids. Saturated carboxylic acids such as acetic acid, propionic acid, and isobutyric acid were ozonized only slowly in neutral water, but they were ozonized faster in alkaline aqueous solution. On the other hand, α-hydroxy carboxylic acids such as glycolic acid and lactic acid were ozonized even in pure water. The mechanism of ozonization of these compounds and the effect of pH are discussed.

The ozonization of organic compounds has been studied extensively for many years[1–4] and it has been applied for the preparation and identification of organic compounds. Water treatment by ozone has received much attention recently because of its advantages over currently employed methods such as chlorine treatment.[5–7] In order to establish the validity and limit of water treatment by ozone, it is of fundamental importance to know the rate and products of the ozonization of various compounds in water. In the course of our study on the ozonization of organic compounds, we have undertaken the study on the ozonization of carboxylic acids, alcohols, and ketones in water. The ozonization of carboxylic acids is especially important since the ozonization of aromatic hydrocarbons,[8–10] phenol,[11–16] and alkylbenzenesulfonic acids[17,18] gives carboxylic acids and they are known as the typical refractory compounds in water.

Experimental

Materials and Procedures. Commercial alcohols, ketones, and carboxylic acids were used as received. Water was purified by passing through an ion exchange resin followed by distillation. Following buffer solutions were used (1 M = 1 mol dm^{-3}).

pH 1.1 : 0.2 M KCl (50 ml) + 0.2 M HCl (97 ml) + H_2O (53 ml)
pH 5.3 : 1/30 M KH_2PO_4 (32 ml) + 1/30 M Na_2HPO_4 (1 ml)
pH 7.1 : 0.2 M KH_2PO_4 (50 ml) + 0.2 M NaOH (29.6 ml) + H_2O (120.4 ml)
pH 9.9 : 0.1 M Na_2CO_3 (5 ml) + 0.1 M $NaHCO_3$ (5 ml)
pH 12.1: 0.1 M Na_2HPO_4 (50 ml) + 0.1 M NaOH (43.2 ml) + H_2O (6.8 ml)

Ozone was produced by a standard ozone generator, Nippon Ozone Co. Ltd., Model O-3-2, by charging pure oxygen dried beforehand by silica gel.

The ozonization was carried out by bubbling ozone-oxygen gas through the reaction mixture at 30 °C. The gas was introduced at a speed of 100—200 ml/min and the rate of ozone supply was 0.12—0.20 mmol/min.

Analytical Methods. The amounts of substrate reacted and products formed were measured by a gas liquid chromatography (GLC, Shimadzu Model GC-4BPTH, with Porapak Q column and FID detector), a high pressure liquid chromatography (HPLC, JASCO, GP-A30, Shodex Ionpak C-811 column and 0.1% H_3PO_4 eluent), and an isotachophoretic analyzer (IP, Shimadzu Model IP-1B).[9,11] Total amount of peroxides was determined by iodometric titration. Hydrogen peroxide was measured separately from the difference between the titers before and after the treatment with catalase as described previously.[11]

Total yield of carbonyl compounds was measured as follows. Product solution was treated with 2,4-dinitrophenylhydrazine saturated in 2 M aqueous hydrochloric acid, allowed to stand overnight at room temperature, and filtered to remove 2,4-dinitrophenylhydrazone. The filtrate was analyzed spectrometrically to measure the consumption of 2,4-dinitrophenylhydrazine, $\lambda_{max} = 322$ nm and $\varepsilon = 1.1 \times 10^4$ M^{-1} cm^{-1}. In some cases, 2,4-dinitrophenylhydrazone was dried and weighed. Carbon dioxide was analyzed as previously.[11]

Results

Ozonization of Alcohols. The results of ozonization of 2-butanol are shown in Table 1. It was found that appreciable amount of 2-butanol was carried away out of the reaction vessel with ozone-oxygen gas; for example, about 2 mmol of 2-butanol was removed in 2 h when only oxygen was introduced under the similar conditions as in Table 1. Therefore, the amount of disappeared 2-butanol shown in Table 1 is larger than that actually reacted. The poor material balance in Table 1 is apparently due to this disappearance of 2-butanol as well as the formation of carbon dioxide.

However, it is clear that ozonization of 2-butanol in water gave 2-butanone as a major product. For example, ozonization for 30 min gave 2-butanone with 83% selectivity. Small amounts of formic, acetic, and propionic acids and hydrogen peroxide were also found. These products are similar to those in the ozonization of 2-butanol in organic solvent.[19]

The ozonization of 1-butanol gave butanal as a major product with smaller amount of butyric acid.

As shown in Table 1, the rate of ozonization was not much affected by the pH of the solution.

Ozonization of 2-Butanone. The results are shown in Table 2. The major product was acetic acid, and smaller amounts of methylglyoxal, pyruvic acid, formic acid, methanol, and acetaldehyde were also observed. Neither ethyl acetate nor methyl propionate was found.

Ozonization of 3-Pentanone. The results are included in Table 2. Formic, acetic, and propionic acids were observed. At high pH, the amount of formic

acid increased appreciably. The formation of acetic acid and propionic acid in the ozonization of 3-pentanone has been reported previously.[1]

Some unknown products were observed by HPLC. Although it was not identified conclusively, one of the unknown products may be 2,3-pentanedione. The formation of 2,3-butanedione in the ozonization of 2-butanone has been reported.[20]

Ozonization of Methylglyoxal. The results included in Table 2 show that the major reaction is the oxidation of formyl group to carboxyl group. Smaller amounts of acetic acid and oxalic acid may have been formed through pyruvic acid.

Ozonization of Glycolic Acid and Lactic Acid. The results of ozonization of glycolic acid gave glyoxylic acid as primary and major product, which was further ozonized to oxalic acid (Table 3). Smaller amount of formic acid was also found. The ozonization of

lactic acid gave pyruvic acid as major product with about 90% selectivity. Small amounts of formic acid and oxalic acid were also observed. The formation of hydrogen peroxide was observed from both glycolic acid and lactic acid, but no organic peroxide was found.

Table 3 also shows the effect of pH in the ozonization of lactic acid. The conversion of lactic acid was higher at higher pH. Pyruvic acid was always formed as a major product.

Ozonization of Pyruvic Acid. Acetic and oxalic acids were formed as major products in the ozonization of pyruvic acid.

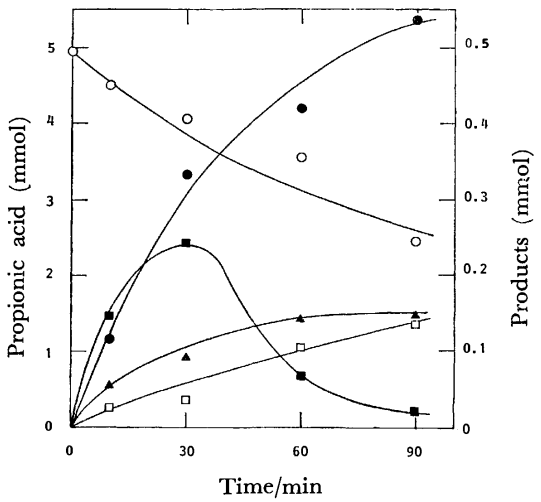

Fig. 1. Ozonization of propionic acid in NaOH-H_2O at 30 °C, initial pH 12.6 (Run 26).

Ozonization of Acetic, Propionic, Isobutyric, and Pivalic Acids. Saturated carboxylic acids such as acetic, propionic, isobutyric, and oxalic acids were stable toward ozone at 30 °C. However, they were ozonized at appreciable rate at higher pH. Table 4 shows the results of ozonization of acetic acid and its sodium salt. Acetic acid has been accepted as an inactive solvent in the ozonization, but it is ozonized in alkaline medium. The products were formic acid, glycolic acid, glyoxylic acid, and oxalic acid. These acids, except oxalic acid, were further ozonized to give eventually oxalic acid and carbon dioxide. Succinic acid was not observed. Sodium acetate was ozonized only slowly at pH 7.

The results of ozonization of propionic acid are shown in Table 5. The change in the product distribution with time is shown in Fig. 1. Again, the rate of ozonization increased with increasing pH of the medium. The products observed were formic acid, acetic acid, lactic acid, pyruvic acid, and oxalic acid. Figure 1 shows that acetic acid and oxalic acid are

stable final products, whereas formic acid is further ozonized to carbon dioxide and water.[11]

The results of ozonization of isobutyric acid are shown in Table 6. Isobutyric acid was virtually resistent toward ozone in water, but the rate of ozonization increased markedly with increasing pH of the solution as observed for propionic acid. The major products were formic acid, acetic acid, pyruvic acid, acetone, and carbon dioxide. Smaller amounts of oxalic acid and α-hydroxyisobutyric acid were also observed. Little peroxide was found.

Pivalic acid was found to be ozonized, although slowly, even in pure water. The rate of ozonization increased similarly at higher pH. Figure 2 shows the results of ozonization of pivalic acid at initial pH 12.97. Acetic acid, acetone, and pyruvic acid were obtained as major products. Acetone and pyruvic acid accounted for 85% of total carbonyls estimated spectrometrically using 2,4-dinitrophenylhydrazine. Formic acid was observed in considerable amount at the initial stage, but it was further ozonized to carbon dioxide and water. Small amount of oxalic acid was also observed.

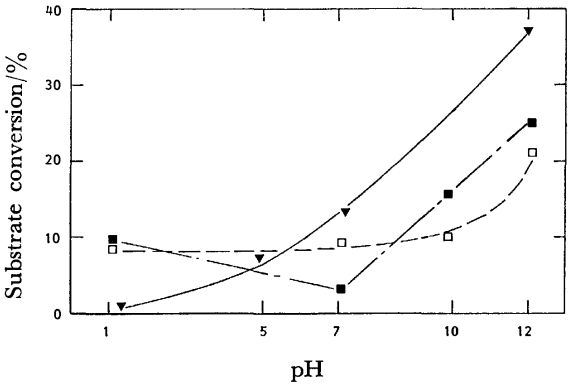

Fig. 3. Effect of pH on the rate of ozonization of isobutyric acid (▼, 5 mmol, 90 min), cyclohexanone (■, 10 mmol, 60 min), and cyclohexanol (□, 10 mmol, 60 min) in 100 ml water at 30 °C.

The effect of pH on the rate of ozonization of isobutyric acid, cyclohexanone, and cyclohexanol is shown in Fig. 3.

Discussion

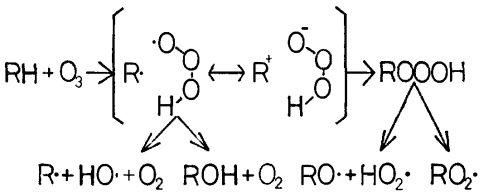
Ozone can behave as a 1,3-dipole, an electrophile or a nucleophile.[4] It reacts quite rapidly with carbon-carbon double bonds, but its electrophilic attack on carbon-hydrogen bonds is usually slow. This accounts for the well known fact that the rate of removal of carboxylic acids from water by ozone is slow.

In alkaline medium, it has been reported that ozone is unstable and gives hydroxyl radical[21-25] and oxygen atom,[26] both of which are more reactive than ozone toward C–H bond. The pK of the hydroxyl radical is 11.85,[26] and hence at pH above 11.85 the oxygen ion O^- must act as the most important attacking species. Furthermore, since the decomposition of ozone is initiated by OH^- ions and accelerated by a free radical chain reaction, the rate of ozone destruction

and that of active hydroxyl radical formation depend on experimental variables such as pH and solutes present in water. Some solutes accelerate the chain reaction, but some inhibit the chain reaction by scavenging hydroxyl radical.[23] It should be noted, therefore, that the relative importance of various active species also varies with experimental variables.

At pH below 9, ozone molecule must be the sole active species.

The detailed mechanisms of the initial attack of ozone toward carbon-hydrogen bonds has not yet been conclusively established. It appears that the ozonization of carbon-hydrogen bonds can proceed both by radical and ionic processes.[27-30] The formation of 1-chloro- and 1-bromoadamantane in the ozonization of adamantane in the presence of bromotrichloromethane[31] suggests the presence of carbon radical. On the other hand, the high ratio of retention of configuration in the ozonization of saturated hydrocarbons[31,32] implies that this radical is not entirely free. The hydrotrioxide,[30,31] whether it is formed by radical or ionic process, should decompose to give eventually alkoxyl and peroxyl radicals under the present reaction conditions. Murray *et al.*[33] have observed a low temperature NMR that indicated the existence of hydrotrioxide.



The mechanism of ozonization of alcohols, ketones, and carboxylic acids will be discussed below taking the above discussion into consideration.

A probable reaction pathway for the ozonization of 2-butanol is shown in Fig. 4. The relative importance of these reactions in Fig. 4 depends, as discussed above, on the experimental variables. The compounds in the boxes were found experimentally. Ozone must attack hydrogen α to hydroxyl group to give hydrotrioxide.[31,33] It decomposes to give 2-butanone, the major product observed experimentally. The radical decomposition can yield alkyl, alkoxyl, and peroxyl radicals. The alkoxyl radical must undergo β-scission or hydrogen atom abstraction to give acetic acid, propionic acid, and 2-butanone. The ethyl and methyl radicals formed simultaneously in the β-scission should react with oxygen and give eventually ethanol, acetaldehyde, acetic acid, methanol, and formic acid. Alkyl and peroxyl radicals should give 2-butanone.

As discussed above, the attack on the α-hydrogen by hydroxyl radical and/or oxygen ion formed from ozone becomes more important at higher pH.

In any event, 2-butanone is formed from 2-butanol as a major product. It has been observed that the ozonization of alcohols gives corresponding carbonyl compounds both in water and in organic solvents.[19,31,34,35]

As shown in Table 2, the ozonization of 2-butanone gave acetic acid as a major product and that of 3-

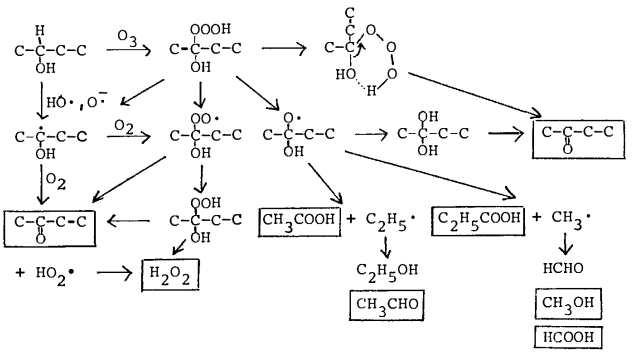


Fig. 4. Major reaction pathway in the ozonization of 2-butanol in water.

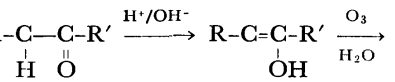
pentanone gave acetic acid and propionic acid. Three processes have been considered for the ozonization of ketone;[1] that is, (1) ozonolysis of double bond of the enol form of ketone, (2) nucleophilic attack of ozone to give ester, followed by oxidation of ester, and (3) ozone-initiated oxidation by molecular oxygen. The absence of ethyl acetate and methyl propionate in the ozonization of 2-butanone (Table 2) and also the absence of ethyl propionate in the ozonization of 3-pentanone (Table 2) indicate that the second process does not play an important role under the present reaction conditions. It was found that these esters were not ozonized at appreciable rate.

Thus, the ozonization of ketones must proceed by the processes both (1) and (3), the relative importance depending on pH and the substrate. The rate of ozonization of ketone is accelerated by both acid and alkaline due to a preferred formation of the enol form; for example,



$$\rightarrow RCHO + H_2O_2 + R'COOH.$$

We have previously reported the ozonolysis of unsaturated carboxylic acids.[11,36] Saturated carboxylic acids are in general stable toward ozone. As described above, acetic acid, propionic acid, isobutyric acid, and oxalic acid were not ozonized easily in pure water. However, α-hydroxy carboxylic acids such as glycolic acid and lactic acid were ozonized even in neutral water. The hydroxy group must have some accelerating effect and the ozonization must proceed as that of 2-butanol, giving corresponding carbonyl compounds as the primary and major product.

The probable major reaction pathway in the ozonization of isobutyric acid is shown as an example in Fig. 5. The ozonization of other saturated carboxylic acids should proceed similary. As shown in Fig. 5, the attack of ozone and/or hydroxyl radical on tertiary C–H bond gives 1-carboxy-1-methylethyl radical and its oxygenated radicals, which eventually yield the observed products, *i.e.*, α-hydroxyisobutyric acid, pyruvic acid, acetic acid, formic acid, acetone, and carbon dioxide.

The products formed from the 2-carboxypropyl radical were not found, although small amounts of un-

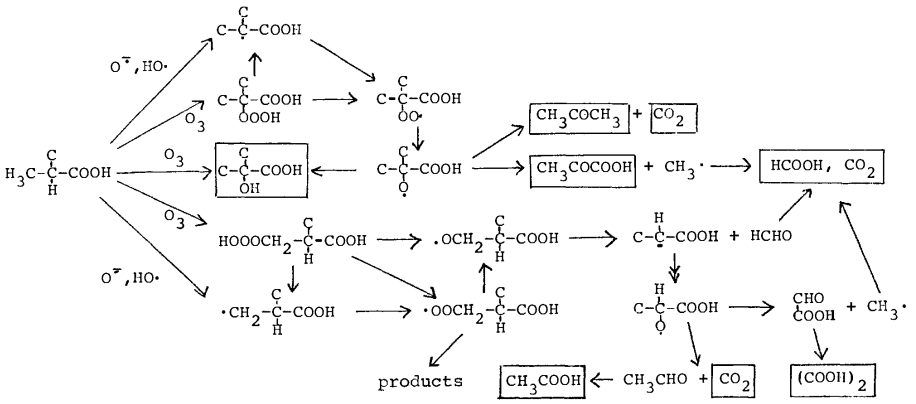


Fig. 5. Probable major reaction pathway in the ozonization of isobutyric acid in water.

identified products were observed.

The increase in the rate of ozonization of carboxylic acids at higher pH must be ascribed to the increase in the reactivities of substrate and to the formation of active attacking species. It has been reported[37] that carboxylate anion has higher reactivity than parent carboxylic acid toward the hydroxyl radical which is also an electron seeking reagent like ozone.

The products observed in the ozonization of carboxylic acids at higher pH are similar with those observed in the oxidation of carboxylic acids induced by hydroxyl radical generated by Fenton reagent and photolysis of hydrogen peroxide.[38]

From the viewpoint of water treatment, it may well be concluded that, as generally accepted, ozone is a powerful oxidizing reagent, especially for aromatic ring, but the complete destruction of saturated carboxylic acids in not practical.

This study was in part supported by The Steel Industry Foundation for the Advancement of Environmental Protection Technology.

Oxidation of Lipids. IV. Formation and Reaction of Chromanoxyl Radicals as Studied by Electron Spin Resonance

Jyunichi Tsuchiya, Etsuo Niki,* and Yoshio Kamiya

Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received June 25, 1982)

In order to study the inhibition of oxidation by vitamin E, the formation and reaction of chromanoxyl radicals and hindered phenoxyl radicals were examined by ESR. *t*-Butoxyl radical abstracted the phenolic hydrogens of α-, β-, γ-, and δ-tocopherols, 2,4,6-tri-*t*-butylphenol (TBP), and 2,6-di-*t*-butyl-4-methylphenol (BMP) to give corresponding phenoxyl radicals which were stable enough to be observed by ESR. 2,2-Diphenyl-1-picrylhydrazyl (DPPH) also induced the formation of chromanoxyl and phenoxyl radicals. The ESR spectra of chromanoxyl radicals were recorded and their hyperfine coupling constants were determined. The phenoxyl radicals from TBP and BMP disappeared quite rapidly when excess *t*-butyl hydroperoxide was added, whereas α-chromanoxyl radical from α-tocopherol remained considerably. α-Chromanoxyl radical and phenoxyl radicals reacted with *p*-*t*-butylbenzenethiol to regenerate α-tocopherol and corresponding phenols respectively. The implications of these results are discussed.

Vitamin E (tocopherols, **1**) is known to contribute in biological systems as a scavenger of peroxyl and alkoxyl radicals, singlet oxygen and superoxide anion radical.[1-3] Among them, the trapping of peroxyl and

δ-Tocopherol : 1*d*. $R_1=H$, $R_2=H$, $R_3=CH_3$.

alkoxyl radicals, the chain carrying species in peroxidation of lipids, must be the most important role of vitamin E. Although the mechanism of inhibition of autoxidation by synthetic hindered phenols is now well understood,[4,5] it is not fully established how vitamin E suppresses the lipid peroxidation. The objective of the present work is to study by ESR technique the formation and reaction of chromanoxyl radicals[6] from tocopherols and compare them with those from the hindered phenols such as 2,4,6-tri-*t*-butylphenol (TBP) and 2,6-di-*t*-butyl-4-methylphenol (BMP). α-Tocopherol, the major component of vitamin E, was studied most extensively.

Experimental

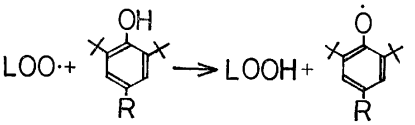
Materials. Natural α-, β-, γ-, and δ-tocopherols were kindly supplied from Eisai Co. Ltd. Commercial TBP and BMP were recrystallized from methanol. *p*-*t*-Butylbenzenethiol was used after distillation. Di-*t*-butyl diperoxyoxalate (DBPO) used as a *t*-butoxyl radical source was prepared by the method described in the literature.[7] Phenylazotriphenylmethane and 2,2-diphenyl-1-picrylhydrazyl (DPPH) were purchased from Eastman Kodak and used as received. *t*-Butyl hydroperoxide was distilled under reduced pressure prior to use, 42 °C/24 Torr (1 Torr=133.322 Pa). The spin traps, 2-nitroso-2-methylpropane, nitrosobenzene, *N*,*N*′-dioxide-2-methyl-*N*-(4-pyridinylmethylene)-2-propanamine (POBN), and 2,4,6-tri-*t*-butylnitrosobenzene was obtained from Aldrich and used without further purification.

Apparatus and Procedure. ESR spectra were recorded on X-band JEOL FE1X spectrometer at room temperature by the following general procedure. Solid DBPO and TBP or BMP were taken directly into the quartz ESR tube, evacuated and benzene was vacuum transferred into the tube and subjected to ESR analysis. DPPH solution was taken into an ESR tube and the solvent was removed by evacuation. Benzene solution of α-tocopherol and spin trap, when necessary, was taken into a side arm of the ESR tube, frozen, evacuated and then mixed with solution of phenol and DBPO or DPPH. The additives such as *t*-butyl hydroperoxide and *p*-*t*-butylbenzenethiol were introduced into ESR tube by vacuum distillation.

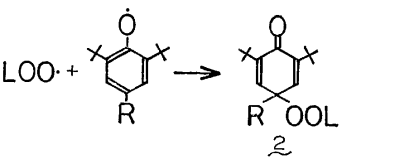
The reaction was carried out at room temperature under vacuum unless otherwise noted. The concentrations of DBPO and DPPH were in the range of 5×10^{-5} to 10^{-2} M (1 M=1 mol dm^{-3}) and excess amount of α-tocopherol, BMP, or TBP was used.

Results and Discussion

It is now understood that hindered phenols such as TBP and BMP inhibit the autoxidation by trapping the chain carrying peroxyl radicals as shown in Eqs. 1 and 2. The rate determining step is Reaction 1, and Reaction 2 proceeds quite rapidly.[4,5] Each TBP or BMP traps two molecules of peroxyl radicals,[4] and peroxyl radical adduct **2** has been isolated and identified.[8]



(1)



(2)

2

+ : $-C(CH_3)_3$

Upon thermal decomposition, DBPO produces two molecules of *t*-butoxyl radicals. When DBPO was decomposed in benzene solution of tocopherols, TBP or

[DBPO] = 1×10^{-4} M, [BMP] = 1×10^{-2} M.

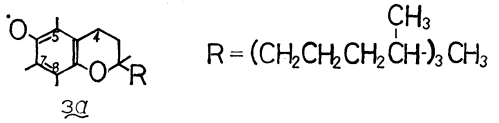
BMP, the corresponding phenoxyl radicals were observed by ESR as shown respectively in Figs. 1, 2, and 3. This shows that *t*-butoxyl radical formed from DBPO abstracts the phenolic hydrogens from tocopherols, TBP, and BMP.

DPPH also gave the same phenoxyl radicals as reported previously,[9-11] that is, when TBP, BMP, or tocopherol was added to the benzene solution of DPPH, the purple color of DPPH, its visible spectrum (λ_{max} = 525 nm), and its ESR spectrum disappeared and new ESR spectra of phenoxyl radicals were observed. On the other hand, when phenylazotriphenylmethane was decomposed instead of DBPO, only triphenylmethyl radical was observed and no phenoxyl radical could be observed.

Table 1. Hyperfine coupling constants of chromanoxyl radicals generated from tocopherols[a]

Radical	5-R_1	7-R_2	8-R_3	4-CH
α-Chromanoxyl	a^{CH_3} 0.602	a^{CH_3} 0.458	a^{CH_3} 0.094	a^{CH_2} 0.148
β-Chromanoxyl	a^{CH_3} 0.625	a^{H} 0.466	a^{CH_3} 0.085	a^{CH_2} 0.168
γ-Chromanoxyl	a^{H} 0.595	a^{CH_3} 0.477	a^{CH_3} 0.116	a^{CH_2} 0.116
δ-Chromanoxyl	a^{H} 0.592	a^{H} 0.460	a^{CH_3} 0.111	a^{CH_2} 0.111

a) In mT, measured in benzene, under vacuum and at room temperature.

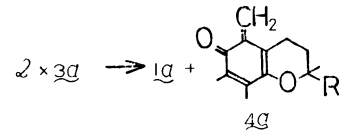


3a

The ESR spectrum of α-chromanoxyl radical **3a** from α-tocopherol shown in Fig. 1 agrees well with those reported previously.[11-13] As assigned previously,[11-13] the ESR spectrum of **3a** shows seven main lines with additional hyperfine structure. The hyperfine splitting constants measured in this work are summarized in Table 1. It is noteworthy that protons at C-5 and C-7 are not equivalent, the spin density being higher at C-5.

The stability of the phenoxyl radicals is dependent on the substituents on the aromatic ring. α-Chromanoxyl radical and 2,4,6-tri-*t*-butylphenoxyl radical were relatively stable at room temperature in the absence of oxygen. On the other hand, 2,6-di-*t*-butyl-4-methylphenoxyl and 2,4,6-trimethylphenoxyl radicals decayed rapidly even in the absence of oxygen. The phenoxyl radicals from α-tocopherol, TBP, and BMP were stable toward spin traps such as 2-methyl-2-nitrosopropane, nitrosobenzene, 2,4,6-tri-*t*-butylnitrosobenzene, and POBN.

Figure 4 shows the rate of disappearance of α-chromanoxyl radical in the absence of oxygen. The second order plot included in Fig. 4 gives the rate constant for the decay of α-chromanoxyl radical as $k = 0.061$ $M^{-1} s^{-1}$. It should be noted that the rate of decay depends on the solvent. The self reaction of α-chromanoxyl radicals is reported to give α-tocopherol and *o*-quinone methide **4a** by disproportionation (Reaction 4).[14-16]



(4)

The effect of addition of hydroperoxide on the sta-

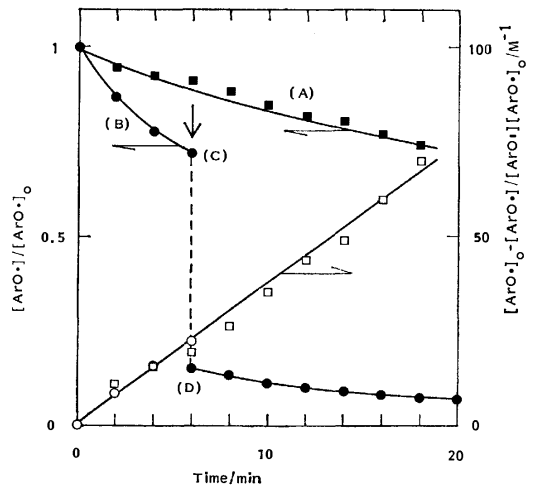


Fig. 4. Decay of α-chromanoxyl radical (ArO·) in benzene at room temperature under vacuum before and after the addition of *t*-butyl hydroperoxide (BOOH).
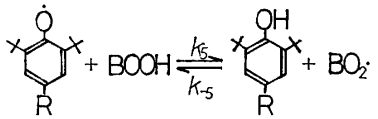
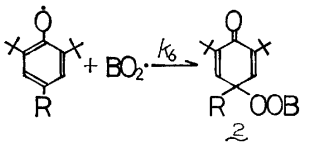
BOOH was added at the point C indicated by an arrow. There is some time lag (a couple of minutes) between the points C and D due to manipulation.

	ArOH(mM)	DPPH(mM)	BOOH(mM)
(A)	14.9	5.02	0
(B)	24.3	17.7	177

bility of phenoxyl radicals was then studied to know the interaction of α-chromanoxyl radical with peroxyl radical. It was found that, when phenoxyl radical was first generated from TBP or BMP in benzene and then *t*-butyl hydroperoxide was transferred from the side arm of the ESR tube into the above solution, the phenoxyl radicals from TBP and BMP disappeared rapidly and completely. These results suggest that the phenoxyl radicals react with hydroperoxide to give peroxyl radicals, which then react with another phenoxyl radical to give adduct **2** (Reactions 5 and 6).



(5)



(6)

2

Interestingly, however, it was found that, as shown in Fig. 4, α-chromanoxyl radical from α-tocopherol did not disappear completely when excess *t*-butyl hydroperoxide was added. It was confirmed that this variation of ESR spectrum was due neither to dilution effect nor to solvent induced variation in cavity Q.[17]

The hydroperoxidic hydrogen of *t*-butyl hydroperoxide is readily abstracted by oxygen radicals to generate *t*-butylperoxyl radical.[18-22] The rate constant for the hydrogen atom abstraction from α,α-dimethylbenzyl hydroperoxide by 2,4,6-tri-*t*-butylphenoxyl radical has been reported as $\log k\ (M^{-1}\,s^{-1}) = 7.1 - 10900/2.303RT$,[23] which gives $k_5 = 0.13\ M^{-1}\,s^{-1}$ at 25 °C. The rate of disappearance of phenoxyl radical (ArO·) is given by

$$-\frac{d[ArO\cdot]}{dt} = \frac{2k_5k_6[ArO\cdot]^2[BOOH]}{k_{-5}[ArOH] + k_6[ArO\cdot]} \quad (7)$$

and since $k_6[ArO\cdot][BO_2\cdot] \gg k_5[ArOH][BO_2\cdot]$,

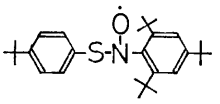
$$-\frac{d[ArO\cdot]}{dt} = 2k_5[ArO\cdot][BOOH]. \quad (8)$$

The amount of *t*-butyl hydroperoxide was 0.1 M and if we assume that *t*-butyl hydroperoxide has the same reactivity as α,α-dimethylbenzyl hydroperoxide toward phenoxyl radical, then, $-d[ArO\cdot]/dt = 0.026\ [ArO\cdot]$, which gives the half life of the phenoxyl radical as about 30 s.

The different behavior of α-chromanoxyl radical from the phenoxyl radicals derived from TBP and BMP observed by the addition of *t*-butyl hydroperoxide may be interpreted by an extraordinary stability of α-chromanoxyl radical; that is, a slower interaction of α-chromanoxyl radical with hydroperoxide and peroxyl radical, higher rate constant for the hydrogen atom abstraction from α-tocopherol by peroxyl radical,[24-26] and/or the instability of the adduct of α-chromanoxyl radical and peroxyl radical. Furthermore, α-tocopherol has much higher equilibrium constant than TBP in the reversible reaction with DPPH and galvinoxyl.

We believe the decrease in α-chromanoxyl radical observed by the addition of *t*-butyl hydroperoxide is not due to oxygen which may possibly be formed from the bimolecular interaction of *t*-butylperoxyl radicals. In one experiment, α-chromanoxyl radical was first generated under vacuum by the reaction with DPPH, analyzed by ESR, and then *t*-butyl hydroperoxide was vacuum transferred into the ESR tube. The amount of α-chromanoxyl radical decreased as observed in Fig. 4. Then the ESR tube was evacuated, but the amount and shape of the ESR spectrum did not change, suggesting that the rapid decrease in α-chromanoxyl radical is not due to oxygen formed from *t*-butylperoxyl radical.[27]

We have previously reported that α-chromanoxyl radical reacted with glutathione and ascorbic acid to regenerate α-tocopherol.[28] Similarly it was found that when *p*-*t*-butylbenzenethiol was added to the mixture of DPPH and phenol in benzene, the phenoxyl radicals from α-tocopherol, TBP, and BMP all disappeared rapidly. When both *p*-*t*-butylbenzenethiol and 2,4,6-tri-*t*-butylnitrosobenzene were added, new ESR spectrum was observed in place of the phenoxyl radical. The observed ESR spectrum shown in Fig. 5 is the same as that observed when DBPO was decomposed in benzene solution of *p*-*t*-butylbenzenethiol and 2,4,6-tri-*t*-butylnitrosobenzene and it is ascribed to spin adduct **5**. The coupling constants obtained, $a_N = 1.630$ mT and $a_H = 0.084$ mT, agree well with those of phenylthiyl radical spin adduct by 2,4,6-tri-*t*-butylnitrosobenzene reported by Terabe and Konaka, $a_N = 1.629$ mT and $a_H = 0.085$ mT.[29]



5

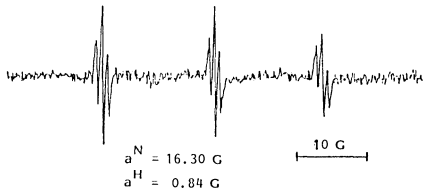


Fig. 5. The ESR spectrum observed when *p*-*t*-butylbenzenethiol was added to the mixture of DPPH, 2,4,6-tri-*t*-butylnitrosobenzene and TBP.

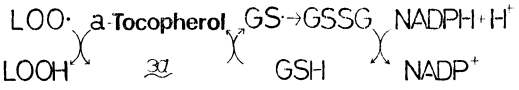
These results suggest that hydrogen atom is quickly transferred from *p*-*t*-butylbenzenethiol to phenoxyl radicals to regenerate the phenols. One of the interesting features of vitamin E in biological systems is the proposed regeneration of vitamin E.[28,30–32] This type of hydrogen transfer from thiol such as glutathione and cysteine to chromanoxyl radicals may contribute in the regeneration and maintenance of vitamin E levels in tissues.



(9)

It must be noted, however, that these observations in vitro in homogeneous solution do not necessarily indicate the contribution of these reactions in heterogeneous systems *in vivo*.

The above results show that *t*-butoxyl radical and DPPH abstract the phenolic hydrogen atom from tocopherols, TBP, and BMP. It has been reported that phenol is more reactive than toluene by a factor of 10^5 to *t*-butylperoxyl radical principally due to a difference in activation energy, even though the heats of these hydrogen atom transfers are comparable.[33] The abstraction of a hydrogen atom by an oxygen radical from oxygen is energetically more favorable than abstraction from carbon. Therefore, the phenolic hydrogen must be abstracted exclusively from α-tocopherol and little benzylic C–H bond should be attacked.

In conclusion, α-tocopherol behaves similarly with TBP and BMP toward alkoxyl radical and DPPH. However, chromanoxyl radical **3** has somewhat different reactivity toward peroxyl radical and/or hydroperoxide.

We wish to express our sincere thanks to Dr. K. U. Ingold for valuable comments and discussion. This work was in part supported by Grant-in-Aid for Developmental Scientific Research of the Ministry of Education, Science and Culture. The financial support by The Toyota Foundation is hereby gratefully acknowledged. A gift of tocopherols from Eisai Co. Ltd. is also acknowledged.

The Effect of Organic Solvents on the Thermal Denaturation of Lysozyme as Measured by Differential Scanning Calorimetry

Yukihisa FUJITA* and Yukinao NODA

Department of Chemistry, Hyogo College of Medicine, Mukogawa, Nishinomiya, Hyogo 663

(Received June 2, 1982)

The thermal denaturation of lysozyme in aqueous solutions of *N,N*-dimethylformamide(DMF), *N,N*-dimethylacetamide(DMA), acetone, and dioxane at pH 3 was investigated by differential scanning calorimetry (DSC). The denaturation temperature, T_d, decreased linearly with an increase in the concentration of organic solvent. The lowering in T_d at identical concentrations of organic solvent increased in the order: acetone< DMF<DMA<dioxane. The calorimetric enthalpy of denaturation, ΔH_d, showed a complex dependence on the solvent composition. For three organic solvents (not dioxane), the ΔH_d first increased slightly with increasing the concentration of organic solvent and then started decreasing at different concentrations of each organic solvent. This behavior is analogous to those observed earlier with monohydric alcohols and with sulfoxides. For dioxane, on the other hand, the ΔH_d decreased gradually with increasing the concentration of dioxane. The effect of these organic solvents on the thermal stability of lysozyme may correlate with their effect on the structure of water, which determines the strength of the hydrophobic interaction of the protein.

Various substances affect the protein–water interactions when added to aqueous protein solution and consequently alter the structural stability of protein. Solvent perturbations have been used extensively as probes of the solution conformation of protein.[1,2] These studies have provided valuable information about the role of the solvent in maintaining the native structure of protein. The conformational changes of lysozyme induced by the addition of organic solvents have been investigated by Hamaguchi and co-workers.[3–5] They have suggested that organic solvents change the conformation of the protein by perturbing the characteristic water structure and by interacting directly with the protein molecule. Izumi and Inoue[6,7] have reported recently the effect of dioxane on the conformation of lysozyme measured by CD, difference spectroscopy, and fluorometry.

Differential scanning calorimetry(DSC) is a useful tool for investigating the thermally induced conformational transition of protein. The thermogram can be used to calculate the van't Hoff enthalpy[8] or an effective enthalpy[9] for comparison to the calorimetric enthalpy to determine the cooperativity of the transition. Application of DSC to the study of protein unfolding has been recently reviewed by Privalov[10] and Biltonen and Freire.[11] A comprehensive thermodynamic investigation of the unfolding of lysozyme has been reported by Pfeil and Privalov.[12]

We have been investigating the effect of various substances on the thermal stability of globular proteins by means of DSC. The thermal denaturation of lysozyme in aqueous solutions of monohydric alcohols and sulfoxides was reported previously.[13,14] These organic solvents lowered the denaturation temperature; this lowering became more pronounced with increasing the concentration and the hydrocarbon content of organic solvent. The calorimetric enthalpy of denaturation passed through a maximum with increasing the concentration of organic solvent. There are many studies of the thermal denaturation of lysozyme in aqueous alcohol solutions by different techniques.[8,15,16] Although various substances may be expected to affect the thermal stability of protein in different ways, the effect of organic solvents other than alcohols on the thermal denaturation of protein has rarely been investigated. So far as we know, Hamaguchi and Sakai[17] have reported the thermal denaturation of lysozyme in aqueous solution of amides and dioxane in a limited concentration of the organic solvent, as determined by spectrophotometry.

In the present paper, the effect of *N,N*-dimethylformamide (DMF), *N,N*-dimethylacetamide (DMA), acetone, and 1,4-dioxane on the thermal denaturation of lysozyme as measured by DSC will be reported.

Experimental

Materials. The hen egg-white lysozyme used was a salt-free, six-times-recrystallized preparation obtained from Seikagaku Kogyo Co. The molecular weight of lysozyme was taken to be 14307. Spectral grade *N,N*-dimethylformamide (DMF), acetone, and 1,4-dioxane were purchased from Wako Pure Chemicals and reagent grade *N,N*-dimethylacetamide (DMA) from Tokyo Kasei Kogyo Co. Solutions were prepared with deionized and distilled water.

Methods. The protein concentration was determined spectrophotometrically on a Hitachi 323 spectrophotometer, using an extinction coefficient of 2.69 dm^3 $(g\ cm)^{-1}$ at 280 nm in glycine buffer at pH 3.0.[17] The organic solvent was added by weight. All the calorimetric experiments were carried out at a protein concentration of 2% in 0.05 mol dm^{-3} glycine buffer adjusted to pH 3.0 as measured by a Horiba model f-7_{ss} pH meter standardized at pH 4.0 in aqueous solution. DSC measurements were performed with a Daini Seikosha SSC-560U differential scanning calorimeter (conduction type). The sample solutions (0.06 cm^3) were hermetically sealed in a silver vessel. An equal amount of solvent was used as reference material. A heating rate of 1 K min^{-1} was typically used, although some measurements were performed at 0.5 to 2.5 K min^{-1} to check the effect of the heating rate. The calorimeter was calibrated with indium, benzophenone, and benzoic acid.

Results and Discussion

Figure 1 presents typical DSC curves for the thermal denaturation of lysozyme in aqueous solutions containing different amounts of DMA at pH 3. In every

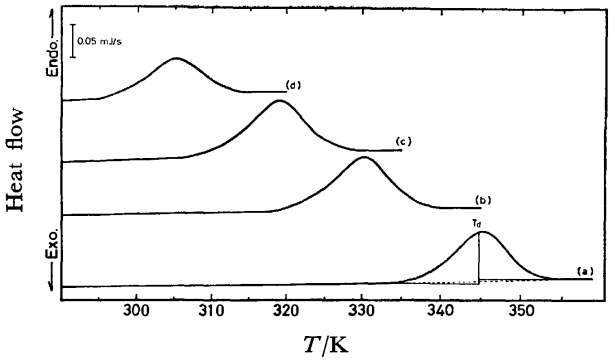

Fig. 1. Typical DSC curves for the thermal denaturation of lysozyme in aqueous DMA solutions at heating rate of 1 K min^{-1}. Protein concentration is 2.0%(w/v).
Curve a is in 0.05 mol dm^{-3} glycine buffer at pH 3.0 with no organic solvent. Curves b, c, and d are with 2, 4, and 6 mol dm^{-3} DMA, respectively.

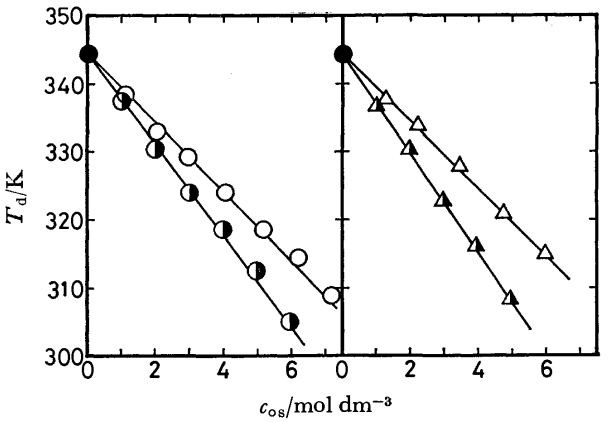

Fig. 2. The denaturation temperature, T_d, of lysozyme as a function of organic solvent concentration.
●: Aqueous, ○: DMF, ◑: DMA, △: acetone, ◭: dioxane.

measurement, a reproducible endothermic peak was observed, occurring over a temperature range of 22—25 K. The endothermic peak shifts to lower temperature with increasing DMA content, while the peak area varies with the solvent composition. The denaturation temperature, T_d, was estimated by assuming that the area under the thermogram was proportional to the amount denatured, and T_d is defined as the temperature at which the protein is half-denatured. According to Velicelebi and Sturtevant,[8] the temperature at which the transition is half complete and the temperature of maximal excess heat flow, T_p, do not coincide, even for a two-state process with no permanent change in heat capacity. They have reported that T_d differs from T_p by 0.75—1.0 K. In the present work, the T_d obtained was lower than the T_p by only 0.3—0.5 K.

There was no significant difference in the T_d obtained at heating rates of 0.5 and 1 K min^{-1}, but the T_d obtained at 2.5 K min^{-1} was higher than those at 0.5 and 1 K min^{-1} by 0.4—0.8 K. This indicates that the denaturation temperature is not much influenced by heating rates lower than 1 K min^{-1}, allowing equilibrium analysis of the data. The denaturation temperature of lysozyme in 0.05 mol dm^{-3} glycine buffer at pH 3.0 was 344.4±0.1 K, which was comparable with previous values obtained from NMR measurements by McDonald *et al.*[18] and from spectrophotometric measurement by Gerlsma and Stuur[15] at similar pH. Parodi *et al.*[16] have reported a slightly lower T_d, 341 K, from ORD measurements, whereas a high T_d value of 347.7 K from calorimetric measurements has been reported by Privalov and Khechinashvili.[19] A number of factors such as protein concentration, ionic strength, and specific buffer effect as well as heating rate could contribute to the difference in T_d values reported from the different laboratories. Variation in the measurement techniques could also contribute to the difference in T_d value.

The calorimetric enthalpy of denaturation, ΔH_d, was estimated by measuring the area between the transition peak and a base line. The ΔH_d obtained was not significantly different from that estimated using the base line based on the heat capacity difference between the native and denatured states. The ΔH_d values have maximum expected errors of ±5%, including errors in calibration constant, sample preparation, and reproducibility. The denaturation enthalpy was almost independent of the heating rate in the range of 0.5 to 2.5 K min^{-1}. The ΔH_d of lysozyme in 0.05 mol dm^{-3} glycine buffer at pH 3.0 was 489 kJ mol^{-1}, the average of nine experiments. Taking into account the difference in measurement conditions, the value of ΔH_d appears to be line with previous values obtained from calorimetric measurements by other investigators, indicating values of 577 kJ mol^{-1} at pH 5[20] and 427[12] and 382 kJ mol^{-1} at pH 2.[8]

There was no significant change in the T_d and ΔH_d on repetitive scans when the sample was rapidly cooled after the preceding scan, indicating that the thermal denaturation of lysozyme in these organic solvent solutions is almost reversible. According to Privalov *et al.*,[9] the effective enthalpy of denaturation, ΔH_{eff}, can be calculated by the half width of the heat absorption peak on the DSC thermogram, if it is assumed that the denaturation is a simple transition between two states without thermodynamically stable intermediate forms. The ratio of the calorimetric to the calculated effective enthalpies of denaturation, $\Delta H_d/\Delta H_{eff}$, showed near-unity value, suggesting that the thermal denaturation of lysozyme in these organic solvent solutions is very nearly a two-state process.

Figure 2 shows the effect of organic solvents on the denaturation temperature. For all the systems investigated, the T_d decreases almost linearly with increasing the concentration of organic solvent. The lowering of T_d at identical concentrations of organic solvent increases in the order: acetone<DMF<DMA<dioxane. The effect of DMF, DMA, and dioxane on the denaturation temperature of lysozyme has been reported earlier from spectrophotometric measurements by Hamaguchi and Sakai.[17] They have observed trends similar to the ones we have observed. The lowering in the T_d of lysozyme by monohydric alcohols and sulfoxides was reported previously.[13,14]

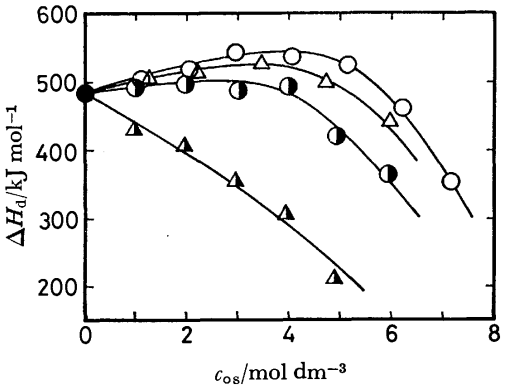

Fig. 3. The denaturation enthalpy, ΔH_d, of lysozyme as a function of organic solvent concentration.
The symbols used are identical with those in Fig. 2.

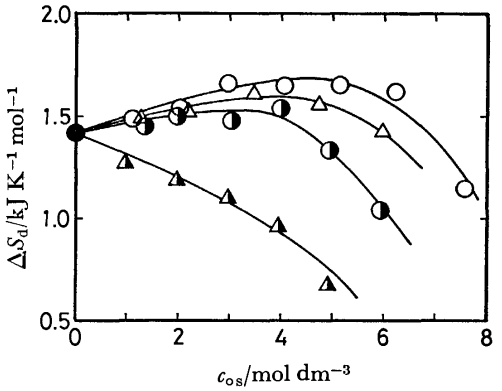

Fig. 4. The denaturation entropy, ΔS_d, calculated at the transition temperature as a function of organic solvent concentration.
The symbols used are identical with those in Fig. 2.

The thermal unstabilization of lysozyme by alcohols has been observed by many investigators through different techniques.[8,15,16] The unstabilizing effect of organic solvents such as alcohols on the thermal stability of protein has been generally interpreted in terms of hydrophobic interactions between the nonpolar groups of protein and the alkyl chain of organic solvent, and thus relatively favoring the denatured state in the mixed solvent. DMA produces a greater decrease in T_d than DMF does, suggesting that the unstabilizing ability of amides is enhanced by an increase in the hydrocarbon content, similarly to those of monohydric alcohols and sulfoxides. This observation also provides the above view with more support.

The dependence of the denaturation enthalpy on the concentration of organic solvent is shown in Fig. 3. For three organic solvents (not dioxane), the ΔH_d shows a maximum, that is, the ΔH_d first increases slightly with increasing the concentration of organic solvent and then starts decreasing at a different concentration of organic solvent. The maximum value of ΔH_d increases in the order: DMA<acetone<DMF. The maximum ΔH_d occurs at approximately 3, 3.5, and 4 mol dm^{-3} for DMA, acetone, and DMF, respectively. The maximum in the ΔH_d of lysozyme has been observed with monohydric alcohols and sulfoxides as well as with the organic solvents used in this experiments.[13,14] A similar trend in ΔH_d with dimethyl sulfoxide has been recently found for ribonuclease A.[21] On the other hand, the ΔH_d with dioxane decreases gradually with an increase in dioxane concentration; this becomes more pronounced at high dioxane contents. It is obvious that the effect of dioxane on the denaturation enthalpy of lysozyme differs from those of other organic solvents.

The entropy of the thermal denaturation, ΔS_d, was calculated for the reversible denaturation by assuming that the free energy change at the midpoint of the transition is zero: $\Delta S_d = \Delta H_d / T_d$. The dependence of ΔS_d on the concentration of organic solvent is shown in Fig. 4. The ΔS_d also shows a behavior similar to ΔH_d. Therefore, the observed decrease in T_d by the addition of organic solvents should result from the complex dependence of ΔH_d and ΔS_d on the solvent composition.

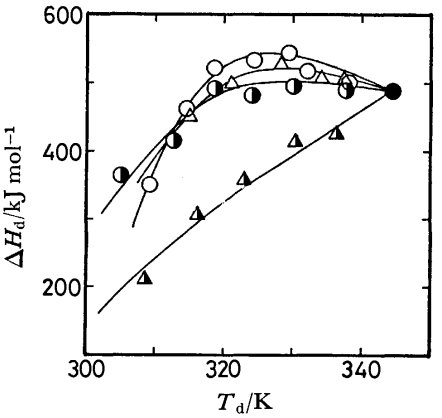

Fig. 5. The variation in the denaturation enthalpy with denaturation temperature.
The symbols used are identical with those in Fig. 2.

Figure 5 represents the dependence of ΔH_d and T_d in the presence of organic solvents. For three organic solvents (not dioxane), the ΔH_d value passes through a maximum with increasing temperature. Such a behavior was also observed with monohydric alcohols and sulfoxides.

For dioxane, on the other hand, the ΔH_d is an increasing function of temperature with slightly downward curvature. There are clear differences in the temperature dependence of ΔH_d for each organic solvent. The dependence of ΔH_d on T_d in the presence of organic solvents thus differs drastically from that reported by Pfeil and Privalov[12] with variations of T_d produced by variation of the pH and addition of guanidine hydrochloride. They found ΔH_d to be a linear function of T_d under all conditions. It is suggested that the nature of the unfolding of lysozyme resulting from the addition of organic solvents is different from that produced by pH changes or by the addition of guanidine hydrochloride.

The conformational changes of lysozyme by the addition of dioxane have been investigated by ORD,[3] CD,[6] and difference spectroscopy.[3,7] These studies show that the tertiary structure of lysozyme is initially disrupted at 20—30% (v/v) dioxane, corresponding to

approximately 3 mol dm^{-3} dioxane, with possible slight disorganization of the ordered secondary structure, and then a pronounced increase in helical structure is induced at very high dioxane concentrations. A similar situation has been observed with DMA and DMF.[3]

These organic solvents have lower dielectric constants than pure water. Thus, electrostatic interaction is stronger in water–organic solvent mixtures than in water, which causes the denaturation enthalpy to increase. However, this contribution appears to be small, as can be seen from decreasing the denaturation enthalpy for the water–dioxane system, because the dielectric constants of aqueous dioxane solutions are relatively lower than those of aqueous solutions of other organic solvents.

The maximum in ΔH_d and ΔS_d for the thermal denaturation of lysozyme has been observed with monohydric alcohols and sulfoxides as well as for the organic solvents examined in the present work. This similarity implies that the effect of organic solvents on the thermal stability of the protein is controlled to a large extent by the common component in the binary mixtures, that is, water. A number of properties of aqueous mixtures of these organic solvents show maxima or minima as a function of composition. This behavior reflects the change in the structure of water by the addition of organic solvents. The complex dependence of ΔH_d and ΔS_d on the solvent composition appears to correlate with the behavior of the water–organic solvent system.

In mixing with water, dioxane[22] shows an exothermic enthalpy of mixing similarly to acetone[23] and both amides,[24] suggesting the strong interactions of dioxane, as well as other organic solvents, with water molecule. The ΔH_d and ΔS_d of lysozyme in water–dioxane mixtures decreased monotonously with increasing concentrations of dioxane, although the maximum in ΔH_d and ΔS_d was predicted. Based on the density data, Oakenfull and Fenwick[25] have suggested that the effect of dioxane on the structure of water differs from those of DMF, ethanol, and dimethyl sulfoxide. The structural contribution to the temperature of maximum density for water–dioxane system shows a negative change, in contrast to a positive change for alcohols and acetone mixing with water.[26,27] Our observation also supports the view that the effect of dioxane on the water structure differs slightly from those of other organic solvents. However, the effects of these organic solvents, including dioxane, on the water structure differ from the so-called structure-making effect of polyhydric alcohols which stabilize the protein strongly against thermal denaturation.[28]

The organic solvents used in the present work, like monohydric alcohols and sulfoxides, unstabilize lysozyme against thermal denaturation. The thermal unstabilization of the protein by organic solvents is enhanced on increasing the concentration and hydrocarbon content of the organic solvent. This observation suggests that organic solvents interact principally with the nonpolar groups of the protein, which causes weakening the hydrophobic interaction of the protein. Bull and Breese[29] have shown from equilibrium dialysis studies that monohydric alcohols are strongly bound to protein. From NMR studies on the solvation of lysozyme in water–dioxane mixtures in the frozen state, Izumi *et al.*[30] have suggested that some water molecules are replaced or expelled by dioxane molecules in the interacting sites due to the more favorable interaction of dioxane with hydrophobic groups lying on the protein surface.

The perturbation of the water structure by the addition of organic solvents also causes the thermal unstabilization of lysozyme. This may contribute more to the thermal unstabilization of the protein than that from the direct interaction of organic solvent with the protein. Since hydrophobic interaction is a result of a rearrangement of the water molecules surrounding hydrophobic groups, the perturbation of the characteristic water structure necessarily causes weakening of the hydrophobic interaction of the protein. Solubility measurements on amino acids in aqueous solutions of ethanol or dioxane have shown favorable free energy of transfer of nonpolar side chains from water to these organic solvent solutions.[31] Thus, the denatured state of protein is stabilized more in the presence of organic solvents than is the native state, since more groups are exposed to solvent in the denatured state than in the native state. It is probable that organic solvents lower the temperature of denaturation as a result of decreased hydrophobic stabilization of the native state.

These results support the hypothesis that the dominant mechanism by which organic solvents unstabilize protein against thermal denaturation is through the perturbation of the characteristic structure of water by organic solvents, which weakens the hydrophobic interaction of the protein.

The Ullmann Condensation Reaction of Haloanthraquinone Derivatives with Amines in Aprotic Solvents. V.[1] The Formation of Active Catalyst by the Partial Oxidation of Copper(I) with Molecular Oxygen

Sadao Arai, Yoshio Hashimoto, Nobuo Takayama, Takamichi Yamagishi, and Mitsuhiko Hida*

Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

(Received June 5, 1982)

Although copper(I) is a more effective catalyst than copper(II) in the Ullmann condensation reaction of haloanthraquinones with ethylenediamine in aprotic solvents under a nitrogen atmosphere, the oxidation products of copper(I) by molecular oxygen enhanced the reaction rate compared to copper(I) catalyst. From the studies on the effect of Cu(II) salt addition to Cu(I) salt, solvent effects, and ESR spectra, it was concluded that alkoxycopper(II) species, formed by the oxidation of Cu(I) with molecular oxygen in alcohol–ethylenediamine solution, acted cooperatively with Cu(I) to increase the catalytic activity. The idea was also supported by the fact that the condensation was remarkably accelerated by the combination of Cu(I) and chloromethoxycopper-(II). Reaction pathways including the alkoxo and halogen bridged Cu(I)···Cu(II) mixed valence complex are proposed and discussed.

The Ullmann condensation reaction, a nucleophilic aromatic substitution with the aid of copper catalyst, is used as an important synthetic tool of various aromatic compounds, especially dyestuffs and drugs.[2] The detailed mechanisms, however, remain ambiguous. From our continuing studies on the Ullmann condensation reaction of haloanthraquinones with amines in aprotic solvents, it was clarified that Cu(II) species, formed by an electron transfer from Cu(I) to haloanthraquinone under a nitrogen atmosphere, plays a very interesting role, though Cu(I) salts are more effective catalysts than Cu(II) salts.[3,4] On the basis of the kinetic studies it was concluded that the resulting Cu(II) species acted cooperatively with Cu(I) to increase the catalytic activity of Cu(I) in the condensation with 2-aminoethanol,[5] while in the condensation with ethylenediamine(EN) only Cu(I) was active and the reaction rate decreased with the formation of the Cu(II) species.[1]

We now have found that in the condensation with EN the partial oxidation of Cu(I) catalyst by molecular oxygen unexpectedly enhanced the reaction rate, while the Cu(I) species will be oxidized into inactive Cu(II) by oxygen.

In this paper we will report the unexpected oxygen effect on the condensation with EN and propose that the alkoxycopper(II) species increase the catalytic activity of Cu(I) species.

Experimental

Materials. 1-Amino-4-bromoanthraquinone (**1**) and 1-bromoanthraquinone (**2**) were prepared as before.[3] 1-Amino-2,4-dibromoanthraquinone (**3**) was prepared from sodium 1-amino-4-bromoanthraquinone-2-sulfonate by bromination and purified by recrystallization from benzene–ethanol: Found: C, 44.00; H, 1.69; N, 3.63%. Mp 229.4—229.7 °C (cor) (lit,[6] 214 °C). Copper(I) bromide and copper(I) chloride were prepared and purified as described in the literature.[7] Commercially available copper(I) iodide was used without further purification. Copper(II) bromide was purified according to the literature.[8] Copper(II) chloride was dried at 100 °C under vacuum. Chloromethoxycopper-(II) was prepared by the reaction of copper(I) chloride with molecular oxygen in methanol[9] (Found: Cu, 49.0%. Calcd for CH_3OClCu: Cu, 48.87%). All solvents were dried and purified by standard procedure, and stored under a nitrogen atmosphere.

Condensation with Ethylenediamine. Catalyst solution was prepared by the reaction of copper(I) bromide with oxygen in ethanol and EN solution. In a typical experiment, copper(I) bromide (71.7 mg, 5×10^{-4} mol) was weighed into a 40 ml Schlenk type flask equipped with a magnetic stirrer and with a gas inlet connected with a gas buret containing air. After evacuation, N_2 was introduced and the same procedure was repeated several times. Ethanol (5 ml) and EN (8 ml, 1.2×10^{-1} mol) were added into the flask with stirring under a nitrogen atmosphere to give a homogeneous Cu(I) solution. Then oxygen was introduced to the solution with stirring and oxygen consumption was measured by a gas buret. On the other hand, **1** (75.5 mg, 2.5×10^{-4} mol) and the solvent (THF 24 ml, C_2H_5OH 23 ml) were mixed in a 50 ml three necked flask equipped with a reflux condenser, thermometer, and a three-way stopcock. After this solution was brought to the reaction temperature, the reaction was initiated by the addition of the catalyst solution (2.7 ml, Cu content 1.04×10^{-4} mol) with the help of a pipette. The condensation was performed under a dry and oxygen-free nitrogen atmosphere. At regular time intervals, 0.5 ml aliquots of the reaction solution were taken out, diluted in 25 ml of ethanol, and subjected to visible spectral measurements. The yields of **4** based on **1** were determined by use of the absorbance of **4** at 615 nm.[1]

Instruments. UV and visible spectra were measured

on a Shimadzu UV-210 spectrophotometer. ESR spectra were measured by the use of a JEOL-PE-3X ESR spectrometer, equipped with a 100 KHz field modulation unit.

Results and Discussion

In the condensation with EN using CuBr catalyst under a N_2 atmosphere, the reaction rate decreased with time. The result is interpreted in terms of the formation of ineffective Cu(II) species by an electron transfer from Cu(I) to haloanthraquinone.[1] Upon the introduction of oxygen to the catalyst solution (CuBr–EN–EtOH), the colorless solution turned immediately to deep blue, which indicated the formation of Cu(II) species. By the use of this blue catalyst, the yield of **4** increased unexpectedly, as shown in

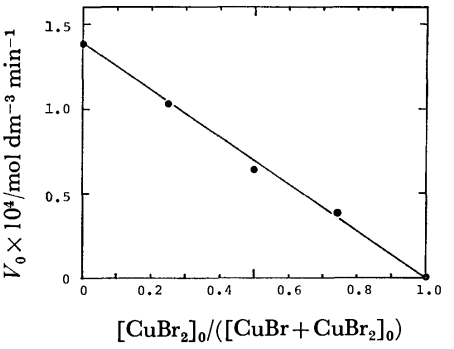

Fig. 3. The effect of the addition of $CuBr_2$ on the initial rates (V_0) in the reaction of **1** with EN by CuBr catalyst.
$[\mathbf{1}]_0=5.0\times10^{-3}$ mol dm^{-3}, $[EN]_0=0.5$ mol dm^{-3}, $[CuBr+CuBr_2]_0=2.1\times10^{-3}$ mol dm^{-3}, temp 50 °C, solvent THF–EtOH 1:1.

Fig. 1. Figure 2 illustrates the plots of the initial rate (V_0) *vs.* the molar ratio(r) of the absorbed oxygen to CuBr. Figures 1 and 2 indicated the following characteristics of the reaction:

i) The initial rate markedly depends on the amount of the oxygen absorbed; the maximum initial rate was observed at the ratio r of about 0.13.

ii) By the catalyst-absorbed small amounts of oxygen, both initial rate and final yield were larger than those obtained by Cu(I) catalyst alone.

iii) In the region of the larger molar ratio(r) the initial rate decreased but the final yield tends to increase. Comparing at 2 h, the catalyst system with a ratio r of 0.56 gave the largest yield, after a clear induction period.

Similar results were observed in other condensation systems such as **1**–EN–CuCl, **2**–EN–CuBr, **2**–EN–CuI, **3**–EN–CuBr, and **3**–EN–CuI. These facts reveal that the oxygen effect is not specific to either haloanthraquinones or copper(I) halides.

Effect of Copper(II) Bromide Addition to Copper(I) Bromide Catalyst System. If copper(II) bromide is used as an alternative to the copper(II) species, formed by the partial oxidation of Cu(I) with molecular oxygen, the reaction rate will increase similarly to the case of the condensation with 2-aminoethanol.[4,5] Figure 3 shows the results of the addition of $CuBr_2$ to CuBr, keeping the total copper amount to be constant, in the condensation with EN under a N_2 atmosphere. Contrary to our expectation, the initial rate decreased linearly with the increase in the molar ratio of $CuBr_2$ to the total copper amount ($CuBr+CuBr_2$). This result shows that $CuBr_2$ does not act as a promoter and only Cu(I) is active in the condensation with EN under N_2. From this result it was concluded that Cu(II) species of the CuBr–EN–EtOH–O_2 catalyst system is different from that of the CuBr–$CuBr_2$–EN–EtOH catalyst system.

Solvent Effects on the Formation of Active Catalyst. The solvent effects on the oxidation of Cu(I) catalyst solution by molecular oxygen were examined as shown in Table 1. These results are compared at the molar ratios(r) ranging from about 0.12 to 0.16: In this region the initial rate revealed a maximum (Fig. 2).

Table 1. Initial rates (V_0) for the reaction of **1** with EN by Cu catalyst[a)]

Entry	Catalyst solution	r[b)]	$V_0\times10^4$/mol dm^{-3} min^{-1}
1	CuBr-EN-EtOH	0.0	1.38
2	CuBr-EN-EtOH-O_2	0.128	1.80
3	CuBr-EN-O_2	0.151	0.91
4	CuBr-EN-O_2+EtOH[c)]	0.130	1.48
5	CuBr-EN-MeOH	0.0	1.32
6	CuBr-EN-MeOH-O_2	0.119	1.74
7	CuBr-EN-py-O_2	0.158	1.53
8	CuBr-EN-*i*-PrOH-O_2	0.135	1.37
9	CuCl-EN-MeOH	0.0	1.45
10	CuCl-EN-MeOH-O_2	0.158	1.58

a) $[\mathbf{1}]_0 = 5.0\times10^{-3}$ mol dm^{-3}, $[EN]_0 = 0.5$ mol dm^{-3}, $[Cu]_0=2.1\times10^{-3}$ mol dm^{-3}, temp 50 °C, solvent THF-EtOH 1:1. b) The molar ratio of the absorbed oxygen to CuX. c) Ethanol was added to CuBr-EN-O_2 system.

The reaction of copper(I) bromide with oxygen in EN-EtOH solution afforded a blue solution containing a blue solid. By this catalyst solution, the yield increased as shown in Fig. 1 (Table 1, Entry 2). The reaction of oxygen with CuBr in EN gave a dark greenish brown solution containing a brown solid. This catalyst solution markedly decreased the initial rate compared with that obtained with CuBr catalyst (Entry 3). However, by the addition of ethanol to the CuBr-EN-O_2 catalyst solution, the color of the solution turned to dark blue and the initial rate increased (Entry 4), though the catalytic activity was smaller than that for the catalyst system CuBr-EN-EtOH-O_2. This result shows that alcohol converted inactive copper(II) species into active ones. The dark greenish brown solution, generated by the reaction of CuBr with O_2 in EN-pyridine solution, also increased the catalytic activity (Entry 7). These results may suggest that ethanol in the condensation solution is related to the formation of active Cu(II) species (see Experimental). The blue catalyst solution formed by the oxidation of CuBr or CuCl with molecular oxygen in EN-MeOH also increased the catalytic activity (Entries 6 and 10). These results indicated that alcohols play a very important role in the formation of active catalyst.

The Role of Alkoxycopper(II) Species. The oxygen uptake by CuBr in methanol was extremely slow without EN, while the reaction of CuCl with oxygen in methanol proceeded moderately and gave a yellowish green solid. The solid is known to be chloromethoxycopper(II) formed by the following stoichiometry:[9)]

$$4CuCl + O_2 \xrightarrow[MeOH]{} 4CuCl(OMe) + 2H_2O. \quad (1)$$

By the addition of CuCl(OMe) the catalytic activity of CuCl increased in spite of the absence of oxygen (Figs. 4 and 5). Further, in the case of CuCl(OMe) alone, an induction period was observed. These results were analogous to the case of oxygen addition.

Figure 6 shows the ESR spectra of the catalyst solution CuCl-EN-MeOH-O_2 (r=0.13), $CuCl_2$-EN-MeOH, and CuCl(OMe)-EN-MeOH at room temperature. The CuCl-EN-MeOH-O_2 system revealed only Cu(II) species as electron paramagnetic species. The coupling constants obtained from the spacing of the third and fourth peaks of the Cu(II) signal are summarized in Table 2. The coupling constant was smaller in the CuX-EN-ROH-O_2 system than in the CuX_2-EN-ROH system. This suggests that the former Cu(II) species has a stronger covalent bond between Cu(II) and the ligand than the latter.[10)] On the other hand, CuCl(OMe) has a more covalent bond character because of strongly electron donating CH_3O ligand than $CuBr_2$ has, and the CuCl(OMe)-EN-MeOH system also indicated a Cu(II) signal with a small coupling constant. These ESR data will also suggest the presence of an alkoxo ligand in the Cu(II)

a) [Cu] $=3.8\times10^{-2}$ mol dm^{-3}, [EN] $=9.2$ mol dm^{-3}. b) 1 G$=10^{-4}$ T. c) $r([O_2]/[CuBr])=0.142$. d) $r=0.205$.

species formed by the oxidation of Cu(I) with molecular oxygen in EN–ROH solution. Consequently, it is concluded that alkoxycopper(II) species is responsible for the activation of Cu(I) catalyst.

In order to clarify the difference between CuX–EN–EtOH–O_2 ($r=0.1$) and CuX–EN–EtOH catalyst system, the apparent activation energy(ΔE^*) was obtained from Arrhenius plots of the initial rate. Partially oxidized catalyst systems have larger activation energies than CuX systems: ΔE^* of **2**–EN–CuI–O_2 and **2**–EN–CuI were 48.5 kJ mol^{-1} and 37.2 kJ mol^{-1} respectively and ΔE^* of **3**–EN–CuI–O_2 and **3**–EN–CuI was 45.2 kJ mol^{-1} and 38.1 kJ mol^{-1}. On the other hand, the preexponential term(A) was increased by the partial oxidation: The ratio of A between **2**–EN–CuI–O_2 and **2**–EN–CuI was 124, and that between **3**–EN–CuI–O_2 and **3**–EN–CuI was 16. These data indicate that the active copper species in the partially oxidized solution differ from the simple Cu(I) species.

In the preparation of the CuBr–$CuBr_2$–EN–EtOH mixture, blue solids were precipitated and these blue precipitates were also observed, though in much smaller amounts, in the CuBr–EN–EtOH–O_2 system. Both of the blue precipitates indicated the same IR spectra and turned to violet (570 nm) when dissolved into THF–MeOH(2:3) solution. It was reported that the colors of $Cu^{II}(EN)$ and $Cu^{II}(EN)_2$ were pale blue and violet respectively, and that the blue $Cu^{II}(EN)_3$ were very unstable and turned to violet $Cu^{II}(EN)_2$ in solution.[11] Consequently, the blue precipitate formed in the presence of large excess EN is considered to be $Cu^{II}(EN)_3$ and it will readily turn to violet $Cu^{II}(EN)_2$ in the reaction mixture(THF–EtOH 1:1).

The blue $Cu^{II}(EN)_3$ or violet $Cu^{II}(EN)_2$ obtained from the CuBr–$CuBr_2$–EN–EtOH system were ineffective to the condensation with EN. Therefore, it was considered that the reaction of CuX and oxygen in EN–ROH generated an inactive copper(II) species and an active alkoxycopper(II) species.

In the CuCl–CuCl(OMe) system, the maximum initial rate appeared when the molar ratio(r') of CuCl(OMe) to total copper was about 0.30 (Fig. 5). On the other hand, in the case of oxygen addition, the maximum rate appeared when the ratio(r) was 0.13 (Fig. 2). If the stoichiometry of the oxidation of Cu(I) by molecular oxygen in EN–ROH solution could be followed by Eq. 2 as done for the oxidation of CuCl in pyridine,[12] these results may be reasonably understood. In Eq. 2, "CuO" and "CuX_2" are active

$$4CuX + O_2 \xrightarrow[EN\text{-}ROH]{} 2\text{“CuO”} + 2\text{“}CuX_2\text{”} \qquad (2)$$

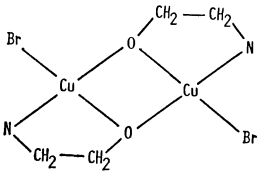
and inactive Cu(II) species, respectively. Thus, in the case of oxygen addition, the maximum initial rate appeared when about a half of the Cu(I) was oxidized. Therefore, the ratio of active Cu(II) to total Cu(II) was 0.25. Thus, the molar ratio of active Cu(II) species to the active copper species was $0.25/(0.5+0.25)=0.33$. This value is in accord with the ratio 0.30 in the CuCl–CuCl(OMe) system under a N_2 atmosphere. The initial rate of CuX–EN–EtOH–O_2 was smaller than that of CuCl–CuCl(OMe). This result can also be understood by the idea that the inactive Cu(II) species was formed along with active Cu(II) species in the CuX–EN–ROH–O_2 system followed by Eq. 2.

Although it has been established that one equivalent of molecular oxygen oxidized 4 molar equivalents of Cu(I),[13–16] Fig. 2 shows that the oxygen consumption in EN–EtOH solution exceeds the molar ratio $r(O_2/CuBr)=0.25$. Davies *et al.* reported that O_2 consumption of more than $r=0.25$ was observed in the reaction of copper(I) chloride with oxygen in pyrrolidine, piperidine, or cyclam, and they described the possibility of the proton removal from N–H groups.[17] In our case, the side reaction such as the oxidation of EN may take place, but the side reaction may occur very slowly and would be negligible at the maximum initial rate, since the oxygen uptake of more than the molar ratio of 0.25 took a very long time.

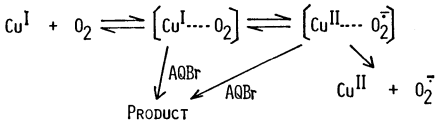
The Presence of an Induction Period. The induction period is observed when CuBr–EN–EtOH–O_2 ($r=0.56$) or CuCl(OMe) only was used (Figs. 1 and 4). The ESR measurement of these condensation systems showed that the Cu(II) signal height gradually decreased. On the contrary, AQBr–EN–$CuBr_2$ system showed no

decrease of Cu(II) signal height under heating. These facts may indicate that a part of the active alkoxycopper(II) species was reduced to active Cu(I), which accelerates the reaction by the combination with the active Cu(II).

These results will shed light on the cooperative behavior between Cu(I) and Cu(II) in the condensation with 2-aminoethanol(AE). As described in the previous papers,[4,5] the induction period in the condensation system of **1** or **2**–AE–CuBr vanished by the addition of $CuBr_2$, which did not activate the condensation with EN. This fact may be reasonably understood by the idea that 2-aminoethanol itself has a OH group and functions as an alkoxide. Hodgson *et al.* reported the molecular structure of Cu(II) complex, prepared by treating $CuBr_2$ with 2-dibutylaminoethanol, to be an oxygen-bridged dimer:[18]

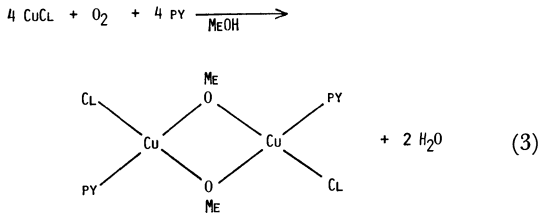


Reaction Pathway. All of the observed results eliminate the possibility of a mechanism as described by Scheme 1,[19] where Cu(I)···O_2 or Cu(II)···superoxide complex functions to activate the condensation reaction:



Scheme 1.

The most plausible reaction pathways are shown in Scheme 2.[19] Under a N_2 atmosphere, only Cu(I) is active; the inactive $Cu^{II}(EN)_2$ is formed by an electron transfer from Cu(I) to AQBr and then the reaction rate decreases with the formation of Cu(II) species. In the presence of oxygen there may be several possible reaction pathways. The reaction of Cu(I) with molecular oxygen in EN–ROH solution affords the active alkoxycopper(II) species and inactive $Cu^{II}(EN)_2$. The CuCl(OMe) and $Cu(OMe)_2$ have been known to exist as a polymer.[20] An oxidation of CuCl in methanol containing pyridine generated di-μ-methoxo-bis[chloropyridinecopper(II)], the structure of which was established by X-ray analysis to be the methoxo bridged dimer (Eq. 3):[14]

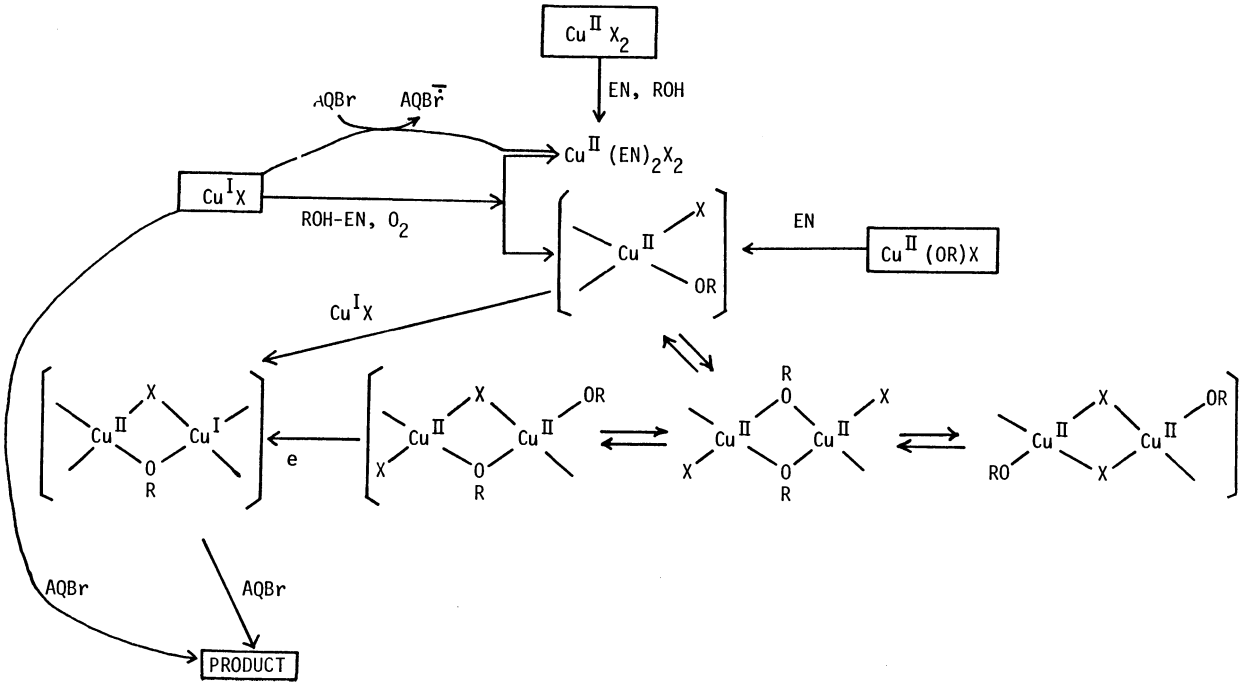


(3)

Therefore, the alkoxycopper(II) species formed by the partial oxidation of Cu(I) in EN–EtOH solution would probably have an ability to form a dimeric structure with Cu(I) or Cu(II) by alkoxo bridge.

One possible pathway is as follows: The Cu^{I}···Cu^{II} mixed valence complex is formed by the reaction between monomeric alkoxycopper(II) species and Cu(I). The cooperative behavior of Cu(I) and Cu(II) may be caused by this dimeric species. The pathway catalyzed by Cu(I) alone also operates independently. On the other hand, in the case of CuCl(OMe) alone the catalytic activity increased gradually with the formation of Cu(I). This result may suggest that alkoxo and/or halogen bridged dimeric species is reduced to give active Cu^{I}···Cu^{II} mixed valence complex.

However, the present data do not exclude another



Scheme 2.

pathway on which Cu(I) and Cu(II) do not form any dimeric species but act cooperatively to enhance the catalytic activity.

These results are helpful in exploration of the more active catalyst of the Ullmann condensation reaction.

Further detailed examinations of the cooperative behavior of Cu(I) and Cu(II) are progress and will be reported in the near future.

Crystal Structure of *N*-Benzyl-α-methoxycarbonylmethanimine *N*-Oxide

Yoshinobu INOUYE

Department of Chemistry, University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 305

(Received June 5, 1982)

The geometry of *N*-benzyl-α-methoxycarbonylmethanimine *N*-oxide in the crystalline state was established to be *Z* by X-ray crystal analysis. The crystal was monoclinic, space group Pc, $a=11.069(1)$, $b=5.2335(7)$, $c=8.620(1)$ Å, $\beta=105.37(1)°$, $Z=2$. The final *R* value was 0.037 for 1760 reflections.

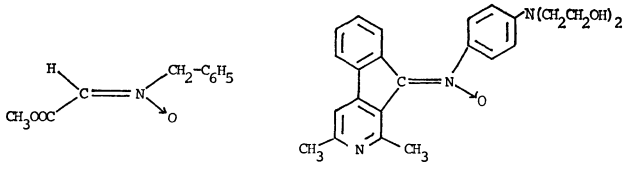
During the last decade, many approaches have been developed by using a nitrone as a constructive unit to provide various kinds of natural products.[1-4] Most of these nitrones have been cyclic, while acyclic ones have been limited to special cases.[4]

Acyclic nitrones, in contrast to cyclic ones, have the possibility of geometrical isomerism around a C=N bond. However, aldonitrones have generally been shown to exist only in a stable *Z*-configuration (**1a**), both in crystals[5] and in solution.[6]

1a **1b**

In 1974, Bjørgo and his co-workers[7] isolated *E*-aldonitrone (**1b**, R:pentamethylphenyl, R′:methyl) by the oxidation of a corresponding imine with *m*-chloroperbenzoic acid and found that the *E*-isomer isomerized to the more stable *Z*-isomer when heated at 35 °C in the presence of benzoic acid. The final *E*/*Z* ratio was found to be 0.20 in $CDCl_3$.

Recently, we found that *N*-benzyl-α-methoxycarbonylmethanimine *N*-oxide (**2**) and its analogues exist in one configuration in the ctystalline state, but in solution exhibit a facile isomerization to give a mixture of *E*- and *Z*-isomers——the *E*/*Z* ratio being 1.6 in $CDCl_3$ (Fig. 1).[8] The assignment of the configuration was deduced from the difference in the chemical shifts of the benzylic protons in the two isomers.



2 **3**

Soon after, a similar time-dependent isomerization of a ketonitrone, **3**, was reported.[9] In both nitrones, **2** and **3**, an *E*-isomer, which is generally thought to be thermodynamically unstable, is predominant in solution.

In this investigation, a single-crystal X-ray analysis of **2** was performed in order to clarify the configuration in the crystalline state.

Experimental

Data Collection. *N*-Benzyl-α-methoxycarbonylmethanimine *N*-oxide (**2**)[4b] was slowly crystallized from benzene. Preliminary oscillation and Weissenberg photographs showed the space group to be either Pc or P2/c. The density was measured by the flotation method in a heptane–carbon tetrachloride mixture. The unit-cell dimensions were refined on a Rigaku automatic four circle diffractometer with graphite-monochromated Mo *Kα* radiation (40 kV, 100 mA). The crystal data are shown in Table 1.

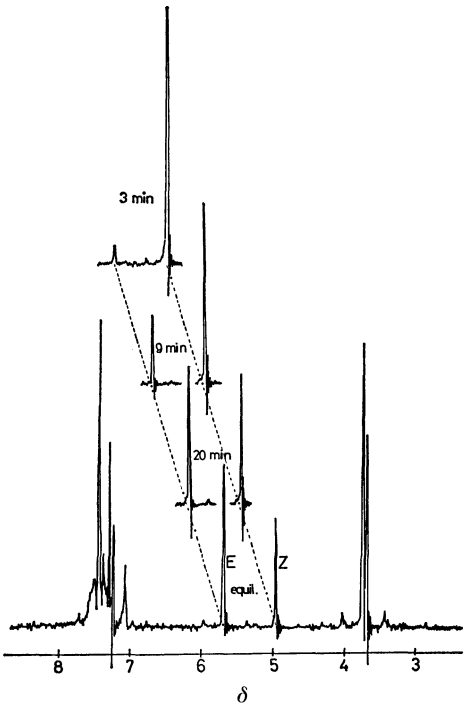


Fig. 1. Time-dependence of the intensities of the benzylic protons in the NMR spectra of **2** in $CDCl_3$.

TABLE 1. CRYSTAL DATA

$C_{10}H_{11}NO_3$	M.W. = 193.2
Monoclinic	Pc
$a=11.069(1)$ Å	
$b=5.2335(7)$ Å	
$c=8.620(1)$ Å	
$\beta=105.37(1)°$	
$D_m=1.32$ g cm^{-3}	
$D_x=1.33$ g cm^{-3}	
$Z=2$	

The intensity data were collected, using a single crystal with dimensions of $0.45\times0.50\times0.53$ mm^3, on a diffractometer by the $\omega/2\theta$ scanning technique within $67°>2\theta$ at room temperature. The intensities of three standard reflections, measured every 50 reflections, were stable within a 2% fluctuation during the course of the data collection.

Of the 1981 unique observed reflections, 1760 reflections with $|F_o|\geq3\sigma(F)$ were used for the structure determinations. The intensities were corrected for Lorentz and polarization effects, but not for absorption. All the computations

were carried out on a FACOM M-200 computer in the Science Information Processing Center of the University of Tsukuba.

Structure Determination. Since the number of molecules in the unit cell was 2, the space goup P2/c was certainly excluded. The structure was solved by using Patterson and Fourier methods and was refined by the full-matrix least-squares method with the *RFINE*-2 program.[10] The atomic scattering factors, given by Cromer and Mann[11] for C, N, or O, and listed on the table[12] for H were used.

From the analysis of a three-dimensional Patterson map, the coordinates of a benzene ring were placed on the plane which includes the Y axis and declines 62° from the X-Y plane. The repeated removal-addition of atoms on difference Fourier syntheses revealed the positions of all the non-hydrogen atoms. A nitrone chromophore, instead of a benzene ring, was finally found to be placed on that plane.

The R value at this stage was 0.258 and was reduced to 0.062 when refined with anisotropic temperature factors. Then, the positions of the hydrogens were obtained from a difference Fourier synthesis and were also refined. The final refinement with anisotropic temperature factors for all non-hydrogen atoms and with an isotropic one for hydrogens reduced the R value to 0.037. The residuals in the difference map were within the range of ±0.17 e/Å^3. The final atomic parameters are listed in Table 2 (for the numbering diagram, see Fig. 2). The F_o-F_c table is kept as

Document No. 8305 at the Chemical Society of Japan.

Results and Discussion

The configuration around the C=N bond was clearly established to be Z as was previously assumed.[8]

The bond distances and bond angles are listed in Table 3. The geometry around the nitrone chromophor is in good agreement with those of *N*-methyl-α-(4-chlorophenyl)methanimine *N*-oxide (**4**),[5a] *N*-methyl-α-(4-chloro-2,6-dimethylphenyl)methanimine *N*-oxide (**5**),[5b] and *N*-methyl-α-(4-nitrophenyl)methanimine *N*-oxide (**6**),[5c] as is shown in Fig. 3, and no unusual bond distances or angles were observed.

The conformation of the molecule projected on the ester plane [O(2)–C(3)–O(4)] is illustrated in Fig. 4. The figures show some short interatomic distances within a molecule. The ester and the nitrone chromophores exist essentially on the same plane (Table 4). This is due to the conjugation effect of both chromophores. Similar effects had also been observed in **4** and **6** as the coplanarity of the benzene ring with the nitrone chromophore. On the other hand, the benzene ring in **2** is twisted toward the direction of minimizing the van der Waals interaction between O(7)–C(9) and N(6)–C(10).

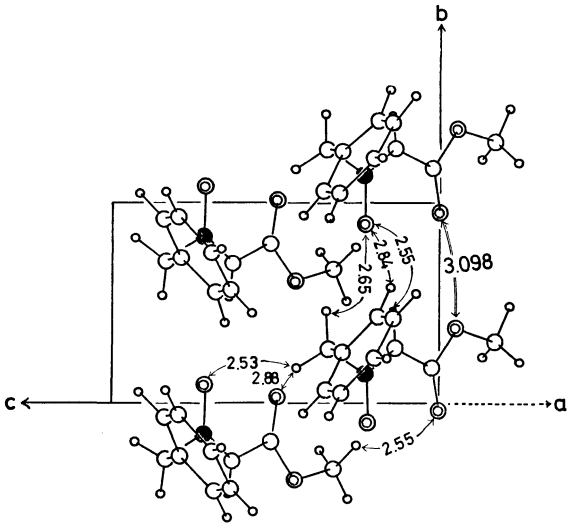
is shown in Fig. 5. All the intermolecular atomic contacts are usual van der Waals distances, the shortest ones are O(2) (x, y, z)—O(4) (x, $y+1$, z) (3.10 Å) between non-hydrogen atoms and H(6) (x, y, z)—O(7) (x, $-y$, $z+0.5$) (2.53 Å) involving hydrogen atoms. The value of 2.53 Å is just the sum of the Kitaigorodskii intermolecular radii, R;[14] the C–H···O attraction, initially found in 2-methyl-3-(4-chloro-2,6-dimethylphenyl)oxazolidine (2.30 Å)[15] and followed in **4** (2.15 Å)[5b] and **5** (2.14 Å),[5b] was not recognized in the present nitrone **2**.

The author wishes to express his deep thanks to Dr. Izumi Nakai, University of Tsukuba, for his varied support in the data collections and computations. The *RFINE*-2 program used in this study is that modified by Dr. Hiroyuki Horiuchi, Osaka University, to whom the author is also deeply obliged.



Eig. 5. The crystal structure of **2** projected on (100) plane.

Nucleophilic Substitution on 4-Methylbenzyl Thiocyanate with Nucleophiles

Shigeru OAE,* Norihiro YAMADA, Ken FUJIMORI, and Osamu KIKUCHI
Department of Chemistry, University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 305
(Received April 21, 1982)

The reactions of 4-methylbenzyl thiocyanate (**1**) with several nucleophiles have been investigated. Compound **1** possesses three electrophilic sites, *i.e.*, benzylic carbon, sulfur and cyano carbon, to receive nucleophilic attack. PhS^- and CN^- which have HOMO's of high energy levels appear to attack preferentially the sulfur atom. MeO^- was found to attack preferably the cyanide carbon, while amines which have HOMO's of low energy levels prefer benzylic carbon to attack. The nucleophilic substitution on the sulfur or the cyanide carbon generates CN^- or *p*-xylene-α-thiolate anion, strong nucleophiles, as the primary products, which then initiate the complex secondary reactions. The selective reactivities of three attacking sites for nucleophiles in **1** have been rationalized in terms of MO theory.

The reactions between organic thiocyanates and nucleophiles are of interest, because organic thiocyanates possess three reacting sites for the nucleophilic attack, *i.e.*, the carbon linked to thiocyanato group (site a), the sulfur atom (site b), and the cyanide carbon atom (site c), (Fig. 1).[1,2] The reactions of organic thiocyanates with a few nucleophiles have been investigated mainly for synthetic interest to prepare thiols from thiocyanates.[3] Giles and Parker carried out mechanistic studies on the reaction between 2,4-dinitrophenyl thiocyanate and various nucleophiles in DMF.[2] They determined the rate constants for the reactions at the sites a, b, and c with various nucleophiles, and concluded that thiolate anion is the only nucleophile which attacked the sulfur atom (site b) among nucleophiles they used, *i.e.*, RS^-, CN^-, ArS^-, RO^-, ArO^-, SCN^-, N_3^-, amines, halide anions, and NO_2^-.

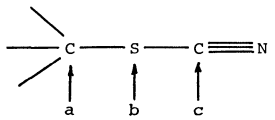

Fig. 1. Three possible sites for the reaction of organic thiocyanate with nucleophiles.

However, no systematic investigation on the reactions between alkyl thiocyanate and various nucleophiles has been reported. Thus, we have initiated the investigation of the reaction between alkyl thiocyanate and various nucleophiles. When the initial attack of nucleophile on 4-methylbenzyl thiocyanate (**1**) took place at the sites b and c, the reactions were found to be very complex because of various secondary reactions initiated by CN^- or $4\text{-}CH_3C_6H_4CH_2S^-$ (**6**) which were generated by the initial nucleophilic displacements at the sites b and c of **1**, respectively. On the other hand, no such secondary reaction was observed, when the initial reaction proceeded at the site a, which produced SCN^-, a relatively weak nucleophile. In order to characterize the leaving ability of thiocyanate upon nucleophilic substitution as a pseudo-halogen, rate constants of the reaction between **1** and 4-methylbenzyl halides and 1,4-diazabicyclo[2.2.2]-octane (DABCO) were measured in an aprotic solvent, *i.e.*, acetonitrile since the nucleophilic attack by DABCO has been found to take place exclusively at the site a.

The nucleophiles used in this work and all possible reaction products with these nucleophiles are listed in Table 1.

Results and Discussion

4-Methylbenzyl thiocyanate (**1**) was chosen as the substrate for this purpose since it has no α-hydrogen atom to initiate the base catalyzed elimination of hydrogen thiocyanate forming olefin and it is convenient to analyze reaction products by the NMR method.

Reaction with Potassium Benzenethiolate in Methanol. The reaction of **1** with potassium benzenethiolate was conducted in methanol at room temperature and followed by GLPC. The starting material **1** was found to disappear immediately, generating 4-methylbenzyl phenyl disulfide (**2**) as the major product along with minor products, *i.e.*, diphenyl disulfide and bis(4-methylbenzyl) disulfide (**4**). Then, three disulfides were gradually converted to 4-methylbenzyl phenyl sulfide (**3**) as shown in Fig. 2. After 2 d at room temperature, **3** was obtained eventually as the sole product (90% isolated yield). This may be rationalized by the mechanism illustrated in Scheme 1. Initial formation of a large amount of the unsymmetrical disulfide **2** as the primary product suggests that the initial

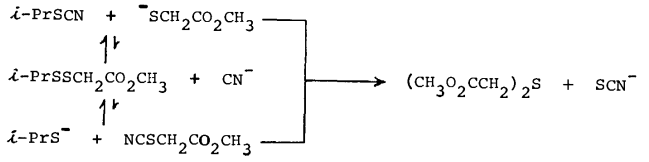
attack of benzenethiolate anion toward **1** takes place mainly on the sulfur atom of **1** (site b) in keeping with the precept that the thiolate anion is an excellent nucleophile toward divalent sulfur,[4] while the reaction at the site a took place very slowly forming **3** irreversibly. However, since cyanide anion, one of the primary product of the reaction at the site b with benzenethiolate anion, has a strong thiophilicity toward divalent sulfur,[4,5] the reaction of the unsymmetrical disulfide **2** with cyanide anion (CN^-) reproduces the staring **1** or generates phenyl thiocyanate depending on the attacking sites of two sulfur atoms of **2**. The unsymmetrical disulfide **2** gives the symmetrical disulfide **4** by the reaction with *p*-xylene-α-thiolate anion (**6**), while the reaction with benzenethiolate anion forms diphenyl disulfide which may react with CN^- to result phenyl thiocyanate. Phenyl thiocyanate reproduces the disulfide **2** and diphenyl disulfide by the reaction with **6** and benzenethiolate anion (PhS^-), respectively.

The control experiment showed, in fact, that the reaction of phenyl thiocyanate with **6** took place immediately to give the same products distribution as the reaction between **1** and PhS^-. The reaction of **1** with **6** (site b) also generates the symmetrical disulfide **4**, which reproduces either **1** upon the reverse reaction with CN^- or **2** by the reaction with PhS^-. In fact, treatment of the symmetrical disulfide **4** with CN^- in a separate experiment gave bis(4-methylbenzyl) sulfide **5** which was produced undoubtedly *via* **1**. Absence of **5** in the final reaction mixture of the reaction of **1** with PhS^- is due to that the steady concentration of the thiolate anion **6** is too small to compare with that of PhS^- during the reaction. Thus, the unsymmetrical sulfide **3** is gradually formed as the final product through the irreversible reaction at the site a of **1** which is regenerated through the reversible reactions, as shown in Scheme 1.

The sequence of the secondary reactions which start from the unsymmetrical disulfide **2** by action of CN^- and thiolate anions have been substantiated by the following control experiment. The reaction between sodium cyanide and the disulfide **2** under the same conditions which have been applied for the reaction of **1** with potassium benzenethiolate, gave the mixture of same products and followed the kinetic course shown in Fig. 3 as the reaction between **1** and potas-

sium benzenethiolate did; *i.e.*, Fig. 3 is roughly identical to Fig. 2.

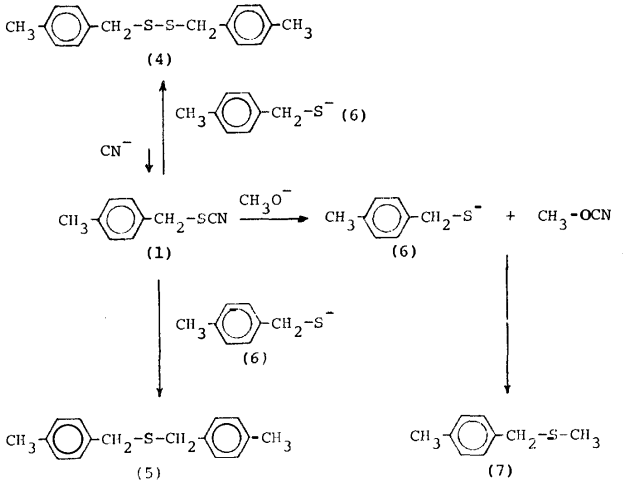
The consequence of this rapid equilibration among two thiocyanates and two disulfides which are promoted by both CN^- and the thiolate anions is well consistent with the result of Harpp *et al.* who observed that CN^- catalyzed S–S bond fission of unsymmetrical disulfide forms the following equilibrium and eventually affords the symmetrical sulfide (Scheme 2).[5]



Scheme 2. Cyanide cleavage of unsymmetrical disulfide.

The rate ratio of the reactions at the site a forming **3** *vs.* that at the site c to afford thiocyanate for the reaction of **1** with PhS^- may be greater than that of the reaction at the site a *vs.* that of the site e for the reaction of 2,4-dinitrophenyl thiocyanate with thiolate anion, because the leaving ability of 2,4-dinitrobenzenethiolate must be much better than that of **6**. Therefore, the fact that the reaction at the site a is 10^3 folds faster than that at the site c in the reaction of 2,4-dinitrophenyl thiocyanate with PhS^- may suggest that the reaction at the site c in the reaction of **1** with PhS^- is less important than that at the site a.

Reaction with Sodium Methoxide in Methanol. The reaction between **1** and sodium methoxide in methanol was completed within a minute at room temperature under argon. The symmetrical disulfide **4** was obtained as the major product (89% isolated yield). Any 4-methylbenzyl methyl ether which is expected to be produced by the reaction at the site a was not detected by GLPC analysis of the reaction mixture, however, a small amount of 4-methylbenzyl methyl sulfide (**7**) was found to be formed (3% isolated yield). The possible mechanism is shown in Scheme 3. The initial reaction may be the nucle-



Scheme 3. Possible reaction paths for the reaction of **1** with sodium methoxide.

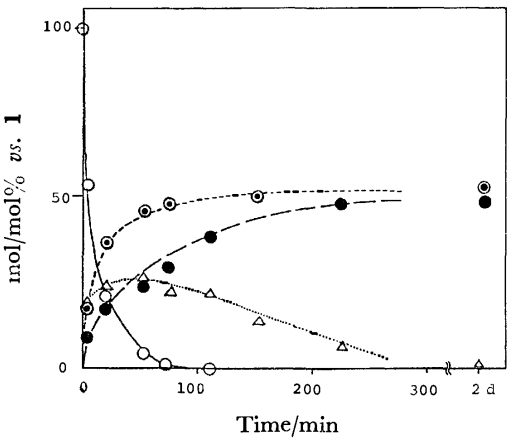


Fig. 4. The reaction of **1** (0.650 mmol) with sodium cyanide (2.5 mmol) in the presence of 18-crown-6 (0.49 mmol) in refluxing acetonitrile (14 ml).

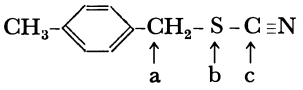
ophilic attack of methoxide anion (MeO^-) on the cyanide carbon (site c) of **1** to give the thiolate anion **6** and methyl cyanate. Failure of detection of methyl cyanate may be due to its instability even at room temperature[6] and its easy consumption by the reaction with the thiolate anion **6**. Since a thiolate anion behaves usually as a much stronger nucleophile than MeO^- in protic solvents, the secondary reaction between **1** and **6** proceeded more rapidly than the primary reaction, after once the thiolate anion **6** was formed by the primary reaction between **1** and MeO^-. There are two possible paths to consume **6**, a very strong nucleophile, thus formed. One is the reaction with **1** to afford **4**. The other is the reaction with methyl cyanate to form the sulfide **7**.[7] Product yields suggest that the former path predominates over the latter path. Since the reaction was conducted under argon, the disulfide **4** was undoubtedly formed by the reaction promoted by the thiolate anion **6** formed as a primary reaction product but not formed by the oxidation of thiolate anion **6** with molecular oxygen as assumed by Parker and Giles in their work on aryl thiocyanates.[2] CN^- is also known to be a rather strong nucleophile especially towards a divalent sulfur, however, much weaker nucleophile than the thiolate anion **6**.[4] Therefore, the reaction of **1** with MeO^- was intercepted by **6** before the complex reactions of the disulfide **4** were promoted by CN^-.

Reaction with Sodium Cyanide in Acetonitrile. The reaction of **1** with sodium cyanide was carried out in the presence of 18-crown-6 ether as the phase transfer catalyst in refluxing acetonitrile under argon. The reaction was monitored by GLPC and the result is illustrated in Fig. 4. Inspection of the figure reveals that a substantial amount of the disulfide **4** is produced at the initial stage and then converted to 4-methylbenzyl cyanide (**8**), and bis(4-methylbenzyl) sulfide (**5**) by subsequent reaction with CN^- as shown in Scheme 4 as Harpp observed in the reaction between CN^- and unsymmetrical disulfide (Scheme 2).[5] As illustrated in Scheme 4, CN^- attacks concurrently the benzyl carbon atom (site a) and the cyanide carbon atom

TABLE 2. REACTION SITES OF **1** TOWARD NUCLEOPHILES



Nucleophile	Solvent	Temp	Time	Attacking site	Initial product	Final product
	MeCN	r. t.	5 h	a			MeCN	r. t.	28 h	a		Et_2NH	MeCN	r. t.	48 h	a	*p*-$TolCH_2$-NEt_2·HSCN	*p*-$TolCH_2NEt_2$·HSCN

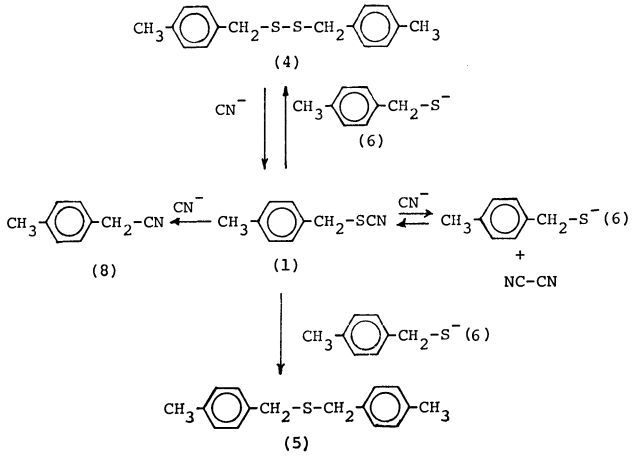


Scheme 4. Possible paths for the reaction of **1** with sodium cyanide.

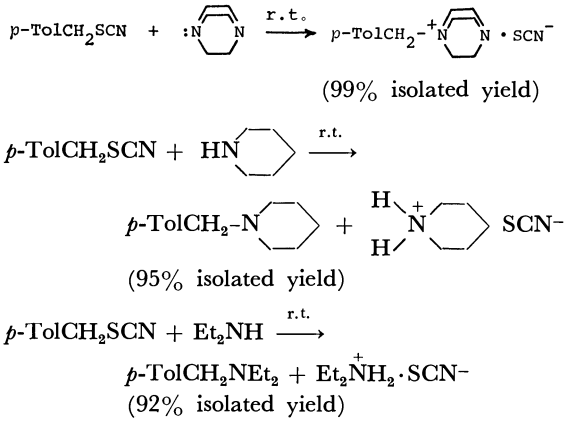
site C of **1** to generate **8**, and **6** and cyanogen, respectively. The thiolate anion **6** thus formed reacts readily with **1** to give **4** and slowly to give the sulfide **5**. The disulfide **4** may be converted to **5** and **8** *via* forming **1**.

Meanwhile, the nucleophilic displacement of cyano group of alkyl thiocyanates with radioactive cyanide anion ($*CN^-$) was known to proceed even at room temperature.[8] Therefore, in the reaction of **1** with CN^-, the reaction at the site b, *i.e.*, cyanide exchange reaction, is concluded to be the fastest,[8] then the reaction at the site c to form **6** and the reaction at the site a affording **8** is the slowest.

$$RSCN + *CN^- \xrightarrow{25\,^\circ C \text{ in MeOH}} RS*CN + CN^-$$

R = Me, Et, *i*-Pr, *t*-Bu, Benzyl, and Phenyl

Reactions with Amine Nucleophiles in Acetonitrile. Both secondary and tertiary aliphatic amines were found to attack exclusively benzyl carbon of **1** (site a) at room temperature (Menschutkin reaction) as follows.[9] The reaction products were identified by IR and NMR spectroscopic analyses, and elemental analysis.



Reaction with Sodium Azide in Acetonitrile. The reaction between **1** and azide anion gave slowly 4-methylbenzyl azide (site a) in 95% isolated yield.

$$p\text{-}TolCH_2SCN + NaN_3 \xrightarrow{\text{reflux}} p\text{-}TolCH_2N_3 + NaSCN$$

*Reaction Site of **1** with Nucleophiles.* As mentioned earlier, the actual reacting site among the three reacting sites of **1** varies with the reacting nucleophile. Table 2 summarizes the preference of the reacting site in the actual reaction of **1** with each nucleophile. Since MeO^- attacks preferentially the site c, the cyanide carbon of **1** is the hardest electrophilic center, while the different reactivities of these nucleophilic reagents toward these three different reacting sites have been explained qualitatively in terms of the HSAB principle.[10] The softest reacting site for the nucleophile is the sulfur atom (site b), while the hardest one is the cyanide carbon atom (site c). In keeping with the HSAB principle, the softest nucleophile, PhS^-, is so thiophilic that it attacks preferentially the site b and even soft CN^- preferentially attacks the site b. Amines and N_3^-, being relatively hard but not very thiophilic, attack the site a. The results of INDO MO calculation are also in a good agreement with those conclusion.

*Theoretical Consideration of Reactivity of **1**.* The

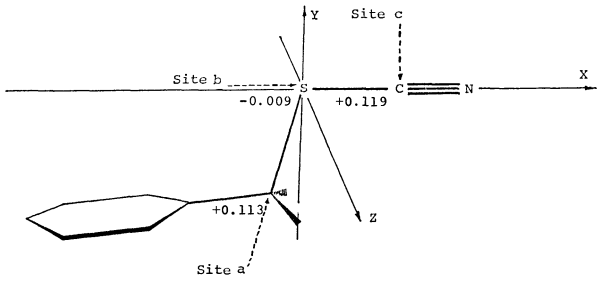


Fig. 5. Geometry of benzyl thiocyanate to be used for the MO calculation, net charge of benzyl thiocyanate and the course of the nucleophilic substitution through the sites a, b, and c.

Table 3. Net-charge on the nucleophilic atom and the HOMO orbital energy of nucleophiles

Nucleophile	Net-charge on the nucleophilic atom	HOMO energy eV

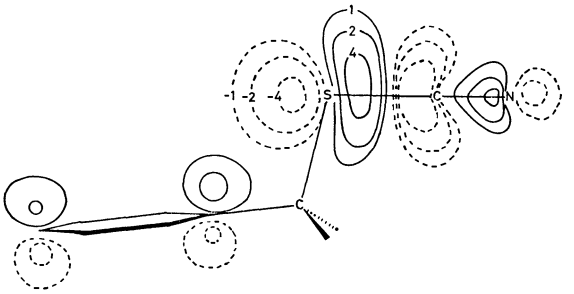

Fig. 6. 28th MO map of benzyl thiocyanate.

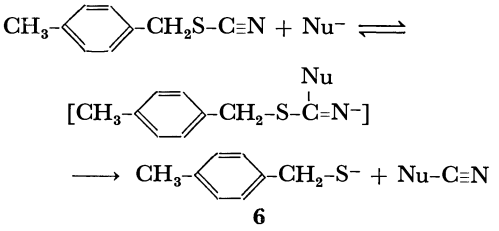
observed preferential sites for nucleophilic attack with different nucleophiles (Table 1) can be compared with the results of the INDO MO calculations.[11] The interaction energy between the nucleophile and the electrophile may be divided in the following two terms, *i.e.*, the electrostatic interaction and orbital interaction.[12] The calculated charge distribution of benzyl thiocyanate is shown in Fig. 5†. The net charges on the nucleophilic atoms of the nucleophiles are listed in Table 3. The calculated orbital interaction energies for the three reaction sites of benzyl thiocyanate toward the various nucleophiles are listed in Table 4. The net-charges on the benzyl carbon atom (site a) and the cyanide carbon atom (site c) are positive. On the other hand, the charge density on the sulfur atom (site b) is very small. The orbital interaction is the largest on the sulfur atom. Thus, the calculation suggests that the charge interaction is important in the reactions at the sites a and c, while the orbital interaction is predominant for the reaction at the site b. This prediction is well consistent with the present experimental results, *i.e.*, the PhS^-, which is a typical soft nucleophile[10] and is expected to undergo the orbital-controlled reaction,[12] attacks indeed the sulfur atom, while the MeO^-, which is a typical hard nucleophile[10] and is expected to undergo the charge-controlled reaction,[12] reacts at the positive carbon atom.

As may be seen from Table 4, the orbital interactrons of PhS^- and CN^- are very large. Their largest orbital interactions at the site b are due to the electron transfer from the nucleophiles to the 28th MO of benzyl thiocyanate. As is shown in Fig. 6, the 28th MO of benzyl thiocyanate has a strong anti-bonding character between the S–CN bond, and the electron transfer from a nucleophile (X^-) to this orbital weakens the S–CN bond and causes eventually the bond breaking to give the reaction products, $PhCH_2X$ and CN^- (X=PhS, *CN). The PhS^- and CN^- are thus expected to react at the site b preferentially through the orbital interaction. Since the calculated orbital interaction energies of MeO^- and amines are quite small, they are expected to attack the positive carbon atom of benzyl thiocyanate by the charge interaction. However, the prediction of the preferential reaction sites, a or c, is difficult, because of the following reasons, namely, the mechanism of the reaction at the sites, a and c, are different from each other and any molecular and electronic structural changes during the reaction process were not taken into account in the present calculation. The reaction at the site c may proceed through the following addition-elimination process[13] in which the second step of the reaction can take place only when the nucleophile is MeO^- among several nucleophiles used in this work, since the thiolate anion **6** is a much better leaving group than MeO^-.



6

Since the reaction at the site a involves the inversion of the sp^3 carbon atom, it requires an appreciable activation energy and hence the reaction of amines at the site a proceeds slowly.

The calculated orbital interaction energies of N_3^-

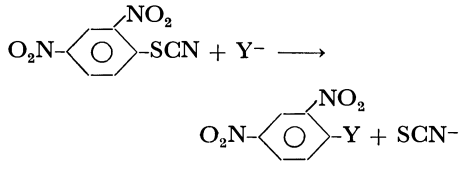
† MO calculation of benzyl thiocyanate has been carried out instead of **1** to simplify the system.

(Table 3) suggests that N_3^- may react on the sulfur atom of **1** to give *p*-TolCH$_2$–S–N=$\overset{+}{N}$=$\overset{-}{N}$, although the formation of *p*-TolCH$_2$SN$_3$ was not detected in the experiment, and only the product which is produced *via* the reaction at the site a was observed experimentally. Since N_3^- is a very good leaving group, *p*-TolCH$_2$SN$_3$ if formed may undergo very fast reverse reaction with CN^-, a strong nucleophile, to regenerate **1** and N_3^-. However, this was unable to be confirmed in the present experiment.

$$p\text{-TolCH}_2\text{–S–C}\equiv\text{N} + N_3^- \rightleftarrows p\text{-TolCH}_2\text{–S–N=}\overset{+}{N}\text{=}\overset{-}{N} + CN^-$$

1

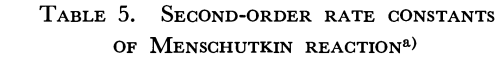
Leaving Ability of Thiocyanate Anion. Thiocyanate anion has been characterized as a pseudo halogen. It is ranked between iodide and chloride in the nucleophilic order of halide anions: $I^- > SCN^- > Br^- > N_3^- > Cl^- > F^-$ in the reaction in protic solvents.[14,15] Nucleophilic order of halides observed in protic solvents is just opposite to that in aprotic solvents and thiocyanate becomes the worst nucleophile toward methyl tosylate in DMF: $F^- > Cl^- > Br^- > SCN^-$, while the following nucleophilic order $F^- > Cl^- > SCN^- > Br^- > I^-$ was reported in the nucleophilic substitution of SCN group of 2,4-dinitrophenyl thiocyanate in DMF.[2] Meanwhile the leaving ability of thiocyanate in the nucleophilic substitution on sp^3 hybridized carbon has not yet been compared with other halides, while the following leaving abilities in the nucleophilic substitution was reported by Giles and Parker.[2]



Leaving ability: $Br^- > I^- > SCN^- > Cl^- > F^-$ in DMF

Thus rate constants for the Menschutkin reactions of 4-methylbenzyl thiocyanate, chloride, and bromide have been measured in acetonitrile at 28±0.05 °C using DABCO as the choice nucleophile, since it has been found to attack the site a of **1** exclusively. The kinetic measurement has been carried out by following the increase of conductivity of the reaction mixture due to the formation of quarternary ammonium salt. The reaction was found to be of first order in both **1** and DABCO. The results are shown in Table 5.

Table 5. Second-order rate constants of Menschutkin reaction[a]



k_{Br}/l mol^{-1} s^{-1}	7.29
k_{Cl}/l mol^{-1} s^{-1}	0.0559
k_{SCN}/l mol^{-1} s^{-1}	0.00328

a) In CH_3CN at 28±0.05 °C.

The rate ratio, $k_{Br}/k_{Cl}=130$, observed in this work is same order as those which have been usually observed in S_N2 reaction on sp^3 carbon (50—180).[16] pK_a Values of the conjugate acid (HX) of the leaving anion (X^-) may be taken as one of criteria for the leaving ability of X. The observed rates, $k_{SCN}:k_{Cl}:k_{Br}=1:17:2200$, is in accordance with pK_a values of HSCN (−1.85), HCl (−6.1), and HBr (−9).[17]

Experimental

All melting points are uncorrected and were taken on Yanaco melting-point apparatus. The IR spectra were obtained on Hitachi 260-50 infrared spectrophotometer and the NMR spectra with Perkin-Elmer Hitachi R-20 (60 MHz) spectrometer. GC-Mass spectra were determined with Hitachi RMU 6MG GC-MS spectrometer equipped with 3 mm×2 m glass column of 15% Silicone OV-1 on Chromosorb W. All the reactions were monitored by the chromatography, namely, TLC (Merck, Kieselgel 60-GF$_{254}$), GLPC (Shimadzu GC-6A or Hitachi 163, using a 7—10% OV-1 on 60—80 mesh Chromosorb W. in 3 mm×2 m glass column), HPLC (Hitachi 638-50).

Materials. Acetonitrile was refluxed over phosphorus pentoxide for 30 h and distilled: bp 82.6 °C/760 mmHg†† Methanol was dehydrated by refluxing with magnesium and distilled: bp 64.0 °C/760 mmHg. Other reagents were obtained from Wako Pure Chemical Industries, Ltd. or Tokyo Kasei Co. Ltd., commercially.

4-Methylbenzyl Thiocyanate (**1**) was prepared by treatment of 4-methylbenzyl chloride with potassium thiocyanate, as follows. A mixture of 5.0 g (0.03 mol) of *p*-methylbenzyl chloride and 5.0 g (0.05 mol) of potassium thiocyanate in 30 ml of 90% ethanol was refluxed for 20 h, diluted with 120 ml of water, extracted three times with 20 ml aliquots of chloroform. The chloroform solution was washed with water, dried over Na_2SO_4 and evaporated to obtain crude 4-methylbenzyl thiocyanate whose GLPC analysis showed the presence of a small amount of 4-methylbenzyl isothiocyanate. 4-Methylbenzyl thiocyanate was separated from the impurities by elution column chlomatography (Merck, Kieselgel 60; eluent: 1:1 benzene–hexane); yield 58%; IR (neat) 2160, 1510, 1250, 820, 720 and 640 cm^{-1}; NMR ($CDCl_3$) δ=2.40 (3H, s, CH_3–), 4.14 (2H, s, –CH_2–) and 7.20 (4H, s, –C_6H_4–).

Found: C, 66.14; H, 5.52; N, 8.79%. Calcd for C_9H_9NS: C, 66.22; H, 5.55; N, 8.58%.

Potassium Benzenethiolate was prepared by dissolving benzenethiol in 2% solution of potassium methoxide in methanol, condensed to dryness under reduced pressure, washed with dry benzene, dried under vacuum and stored in a desiccator.

p-Xylene-α-thiol was prepared by the method reported by Frank and Smith[18] in 63% yield: Colorless oil; bp 110 °C/26.5 mmHg; (lit,[19] 116—118 °C/35 mmHg).

Bis(4-Methylbenzyl) Disulfide (**4**) was prepared by oxidation of *p*-xylene-α-thiol by iodine in 70% yield: Colorless crystals; mp 48.5—50.0 °C (lit,[20] 43 °C); IR (KBr) 1510, 1420, 1205, 820, 720 and 530 cm^{-1}; NMR ($CDCl_3$) δ=2.30 (6H, s, CH_3–), 3.57 (4H, s, –CH_2–) and 7.08 (8H, s, –C_6H_4–).

Bis(4-Methylbenzyl) Sulfide (**5**) was obtained by treating *p*-xylene-α-thiolate with 4-methylbenzyl chloride in ethanol in 90% yield, after recrystallization from ethanol: Colorless crystals; mp 78—79 °C (lit,[21] 76 °C); IR (KBr) 1510, 1420, 1110, 820, 730, and 530 cm^{-1}; NMR ($CDCl_3$) δ=2.36 (6H, s, CH_3–), 3.59 (4H, s, –CH_2–) and 7.12 (8H, s, –C_6H_4–).

4-Methylbenzyl Phenyl Disulfide (**2**). Benzenesulfenyl chloride was prepared by treating diphenyl disulfide with

†† 1 mmHg≈133.3 Pa.

chlorine gas[22] and was purified by vacuum distillation (43.5—44.5 °C/2 mmHg): yield 70%. The disulfide **2** could not be prepared by the method which has been applied for the preparation of other unsymmetrical disulfides by Parker and Kharasch,[4b] but synthesized successfully by the following method. To a solution of benzenesulfenyl chloride 1.05 g (7.25 mmol) dissolved in 10 ml of dry hexane containing dry pyridine was added at −10 °C. Into the mixture, 1.00 g (7.25 mmol) of *p*-xylene-α-thiol was added slowly in dark at −20 °C. The reaction was soon completed and the mixture was washed by water, and then with 5% H_2SO_4 (30 ml). The hexane solution was washed with water again, dried over $MgSO_4$ and evaporated. These must be operated in a dark room to avoid photochemical disproportionation of the unsymmetrical disulfide obtained. The residue was dried with vacuum pump (2 mmHg) for 4 h: Colorless oil; NMR ($CDCl_3$) δ=2.25 (3H, s, CH_3–), 3.82 (2H, s, $-CH_2-$), 6.80—7.60 (9H, m, $-C_6H_4-$ and $-C_6H_5$).

4-Methylbenzyl Phenyl Sulfide (3) was prepared by the same procedure which was applied for the preparation of **5** in 86% yield after recrystallization from ethanol: Colorless crystals; mp 69.0—70.1 °C (lit,[23] 69—70 °C); IR (KBr) 1580, 1510, 1480, 1440, 740, 690, and 480 cm^{-1}; NMR ($CDCl_3$) δ=2.27 (3H, s, CH_3–), 4.00 (2H, s, $-CH_2-$), 7.02 (4H, s, $-C_6H_4-$), and 7.15 (5H, s, C_6H_5–).

1-(4-Methylbenzyl)-4-aza-1-azoniabicyclo[2.2.2]octane Bromide, Chloride and Thiocyanate used for the kinetic study were prepared by the following method. 4-Methylbenzyl halide (0.013 mol) was added into the solution of 0.015 mol of DABCO in 50 ml of dry benzene at room temperature. After 30 min, benzene was evaporated and the residue, a white solid, was recrystallized from acetone–ether.

1-(4-Methylbenzyl)-1,4-Diazoniabicyclo[2.2.2]octane Bromide. 90% yield; Colorless crystals; mp 194.1—196.5 °C; IR (KBr) 2960, 1470, 1060, 820, 600, and 490 cm^{-1}; NMR ($CDCl_3$) δ=2.30 (3H, s, CH_3–), 3.10 (6H, t, J=8 Hz, DABCO), 3.71 (6H, t, J=8 Hz, DABCO), 4.86 (2H, s, $-CH_2-$), 7.01 (2H, d, J=8 Hz, $-C_6H_4-$), and 7.36 (2H, d, J=8 Hz, $-C_6H_4-$).

1-(4-Methylbenzyl)-1,4-Diazoniabicyclo[2.2.2]octane Chloride. 90% yield; Colorless crystals; mp 190.5—193.0 °C; IR (KBr) 2970, 1470, 1060, 820, 600, and 510 cm^{-1}; NMR δ=2.30 (3H, s, CH_3–), 3.07 (6H, t, J=8 Hz, DABCO), 3.69 (6H, t, J=8 Hz, DABCO), 4.86 (2H, s, $-CH_2-$), 6.98 (2H, d, J=8 Hz, $-C_6H_4-$), and 7.35 (2H, d, J=8 Hz, $-C_6H_4-$).

4-Methylbenzyl Cyanide (8) was prepared according to the method reported by Zubrik, Dunbar and Durst[24] in 51% yield after distillation: Colorless oil; bp 84.5 °C/30 mmHg (lit,[25] 220 °C/760 mmHg); IR (neat) 2250, 1515, 1415, 1120, 800, 750, 725, and 480 cm^{-1}; NMR ($CDCl_3$) δ=2.37 (3H, s, CH_3–), 3.67 (2H, s, $-CH_2-$), and 7.18 (4H, s, $-C_6H_4-$).

4-Methylbenzyl Methyl Sulfide (7) was prepared by the alkylation of sodium methoxide with 4-methylbenzyl chloride in 81% yield after distillation: Colorless oil; bp 121 °C/30 mmHg; IR (neat) 1520, 1425, 1240, 1110, 820, 735, 670, 525, and 470 cm^{-1}; NMR ($CDCl_3$) δ=1.94 (3H, s, CH_3–S–), 2.28 (3H, s, CH_3–), 3.56 (2H, s, $-CH_2-$), and 7.02 (4H, s, $-C_6H_4-$).

Reaction of 1 with Potassium Benzenethiolate. 171.0 mg (1.05 mmol) of **1** was added into a 3 ml of dry methanol solution containing 163.4 mg (1.24 mmol) of potassium benzenethiolate. The mixture was allowed to stand in argon atmosphere at room temperature monitoring by GLPC. Products, **2**, **3**, **4**, and diphenyl disulfide were obtained, and were identified by direct comparison with those of authentic samples by GLPC and GC-MS. **2**: (*m/e*) 246 (M^+), 105 ($4\text{-}CH_3C_6H_4CH_2^+$). **3**: (*m/e*) 214 ($M^+$), 105 ($4\text{-}CH_3C_6H_4CH_2^+$). Diphenyl Disulfide: (*m/e*) 218 (M^+), 109 (PhS^+).

Reaction of 4 with Sodium Cyanide. The disulfide **4** (123.1 mg, 0.449 mmol) was added into 5 ml of acetonitrile containing 50.6 mg (1.033 mmol) of sodium cyanide and 297.9 mg (1.128 mmol) of 18-crown-6. The mixture was stirred under reflux in argon atmosphere, the reaction being monitored by GLPC from time to time. The reaction completed in about 20 min. Then **5** and **8** were obtained by GLPC as final products. The same result was obtained when methanol was used as the solvent.

Reaction of Phenyl Thiocyanate with Sodium p-Xylene-α-thiolate. Sodium *p*-xylene-α-thiolate (160 mg, 0.685 mmol) prepared in the same procedure that was applied for the preparation of potassium benzenethiolate, was dissolved in 3 ml of abs. methanol and was added into the solution of phenyl thiocyanate (126.1 mg, 0.933 mmol; prepared by the usual way) at once. The mixture was allowed to stand at room temperature in argon atmosphere, while the reaction was monitored by GLPC at time intervals. Phenyl thiocyanate disappeared within 1 min and the gas liquid chromatogram of the reaction mixture showed the same distribution of products as in the reaction of **1** with potassium benzenethiolate, *i.e.*, initially, **2** was formed, and then disproportionated to **4** and diphenyl disulfide; eventually **3** was obtained as the final product.

Reaction of 2 with Sodium Cyanide. 113.2 mg (0.459 mmol) of **2** was added into a mixture of 24.1 mg (0.492 mmol) of sodium cyanide suspended in 5 ml of acetonitrile containing 30 mg (0.114 mmol) of 18-crown-6 and 56.3 mg (0.366 mmol) of biphenyl which was used as the internal standard on GLPC monitoring. The mixture was stirred in argon atmosphere at room temperature in dark. Figure 3 represents a rough kinetic picture of the reaction.

Reaction of 1 with Sodium Methoxide. Into a solution of sodium methoxide prepared by dissolving 67.8 mg (2.95 mmol) of sodium in 5 ml of absolute methanol, 176.2 mg (1.08 mmol) of **1** was added at once. The mixture was allowed to stand under argon atmosphere at room temperature monitoring by TLC. The reaction completed after 5 min. The remaining sodium methoxide was quenched by adding aqueous acetic acid solution. The mixture was extracted with chloroform twice. The chloroform extracts were combined, washed with water, dried over anhydrous magnesium sulfate and evaporated to afford a mixture of **4** and **7**. The two compounds were separated by silica gel column chlomatography with hexane as eluent. Compound **4** was eluted first (88.9% yield) and then **7** came out (2.2% yield).

Reaction of 1 with Sodium Cyanide. 106.0 mg (0.650 mmol) of **1** was added into a mixture of 121.1 mg (2.50 mmol) of sodium cyanide suspended in 14 ml of acetonitrile which contained 28.9 mg (0.490 mmol) of 18-crown-6. The mixture was refluxed under stirring in argon atmosphere for 300 min while the reaction was monitored by GLPC.

Reaction of 1 with 1,4-Diazabicyclo[2.2.2]octane (DABCO). 461.5 mg (2.80 mmol) of **1** was added into a solution of 272.9 mg (2.40 mmol) of DABCO in 12 ml of acetonitrile in argon atmosphere. The mixture was allowed to stand in argon atmosphere at room temperature, while the reaction was monitored by TLC and GLPC. After 5 h, solvent were distilled off under reduced pressure, the remaining white crystals were washed with hexane and collected, then 1-(4-methylbenzyl)-1,4-diazoniabicyclo[2.2.2]octane thiocyanate was obtained in 99% yield: mp 167.9—169.0 °C; IR (KBr) 2040, 1470, 1380, 1060, 990, 850, 820, and 595 cm^{-1}; NMR ($CDCl_3$) δ=2.41 (3H, s, CH_3–), 3.30 (6H, t, J=6 Hz, $DABCO^+$–), 3.68 (6H, t, J=6 Hz, $DABCO^+$–), 4.77

(2H, s, $-CH_2-$), 7.24 (2H, d, $J=8$ Hz, $-C_6H_4-$), and 7.47 (2H, d, $J=8$ Hz, $-C_6H_4-$).

Found: C, 65.35; H, 7.71; N, 15.04%. Calcd for $C_{15}H_{21}N_3S$: C, 65.42; H, 7.69; N, 15.26%.

Reaction of **1** *with Piperidine.* 338.7 mg (2.08 mmol) of **1** was added into a mixture of 416.2 mg (4.89 mmol) of piperidine and 12 ml of acetonitrile. The reaction mixture was allowed to stand in argon atmosphere at room temperature while the reaction was monitored by TLC and GLPC. After 28 h, the reaction mixture was diluted with 30 ml of water, extracted three times with 10 ml aliquots of ether and the extracts were conbined and washed with 10 ml of water. The solution was dried over anhydrous magnesium sulfate and solvent was evaporated. A colorless oil, obtained, was dissolved in dichloromethane and passed through column of 15 g of Wako activated alumina (200 mesh). The first fraction eluted by dichloromethane gave 30 mg (5%) of **4** which was identified as **4** by comparison with IR and NMR spectra and retention time of GLPC of the authentic sample. Then, the column was washed with ethyl acetate to give 323.2 mg of colorless oil of 1-(4-methylbenzyl)piperidine in 82% yield: IR (neat) 1520, 1440, 1370, 1340, 1300, 1155, 1120, 1100, 1040, 1000, 810, 780, and 490 cm^{-1}; NMR (CCl_4) $\delta=1.25$—1.80 (6H, m, piperidine), 2.04—2.58 (4H, m, piperdine), 2.37 (3H, s, CH_3-), 3.39 (2H, s, $-CH_2-$), 7.01 (2H, d, $J=9$ Hz, $-C_6H_4-$), and 7.12 (2H, d, $J=9$ Hz, $-C_6H_4-$). Colorless crystals of piperidinium thiocyanate 227.9 mg (76%) were obtained from the aqueous layer after evaporation of water and recrystallization of the residue from ethyl acetate: mp 96.5—97.7 °C; IR (KBr) 2960, 2820, 2030, 1435, 1320, 940, and 560 cm^{-1}; NMR (CD_3OD) $\delta=1.50$—2.21 (6H, m, piperidine), 3.06—3.40 (4H, m, piperidine), 4.75 (2H, s, $=N^+H_2$).

Found: C, 49.81; H, 8.39; N, 19.18; S, 21.59%. Calcd for $C_6H_{12}N_2S$; C, 49.96; H, 8.39; N, 19.42; S, 22.23%.

Reaction of **1** *with Diethylamine.* 223.2 mg (1.37 mmol) of **1** was added into a solution of diethylamine 169.1 mg (2.31 mmol) in 7 ml of acetonitrile. The mixture was allowed to stand in argon atmosphere for 15 d at room temperature, while the reaction was monitored by TLC and GLPC. The reaction mixture was diluted with 10 ml of 1% potassium hydroxide aqueous solution, extracted three times each with 10 ml of ether. The combined ether extracts was washed with 10 ml of water, dried over anhydrous magnesium sulfate and upon evaporation of solvent left light yellow oil of *N,N*-diethyl-4-methylbenzylamine (92% yield): IR (neat) 1580, 1515, 1380, 1205, 1170, 820, 800, 755, and 480 cm^{-1}; NMR ($CDCl_3$) $\delta=1.08$ (6H, t, $J=7$ Hz, CH_3CH_2-), 2.37 (3H, s, CH_3-), 2.57 (4H, q, $J=7$ Hz, CH_3CH_2-), 3.56 (2H, s, $-CH_2-$), 7.10 (2H, d, $J=8$ Hz, $-C_6H_4-$), and 7.23 (2H, d, $J=8$ Hz, $-C_6H_4-$).

Reaction of **1** *with Sodium Azide.* 175.7 mg (1.77 mmol) of **1** was added into a mixture of 137.6 mg (2.12 mmol) of sodium azide (containing 10 wt% of methanol and water as stabilizer) suspended in 5 ml of acetonitrile containing 531.3 mg (2.01 mmol) of 18-crown-6 as the phase transfer catalyst. The mixture was refluxed under stirring in argon atmosphere for 20 min, while the reaction was monitored by GLPC. The reaction mixture was diluted with 20 ml of water and extracted three times each with 10 ml of chloroform. Evaporation of the solvent gave a colorless oil of 4-methylbenzyl azide, which was purified through a silica-gel column with 3:1 benzene–hexane: 95% yield; IR (neat) 2080, 1500, 1340, 1250, 800, 750, 530, and 460 cm^{-1}; NMR ($CDCl_3$) $\delta=2.29$ (3H, s, CH_3-), 4.15 (2H, s, $-CH_2-$), and 7.02 (4H, s, $-C_6H_4-$).

Kinetics. A typical run is as follows. To a solution containing the substrate, a solution of DABCO was added at once; the kinetic conditions are shown in Table 5. The temperature was kept at 28 ± 0.05 °C all through the experiment. The conductance of the salt produced in the reaction was measured and recorded automatically, while the concentration of the solution was maintained at constant by comparing with the calibration curve. The rate constants were calculated from the second order rate equation, since the reaction of halides with amine has been known as the Menschutkin reaction which obeyed the second-order rate equation.

Molecular Orbital Calculation. The molecular and electronic structures of benzyl thiocyanate and various nucleophiles were calculated by means of the closed-shell SCF INDO method.[11] All the molecular structures were optimized except the phenyl group in benzyl thiocyanate and benzenethiolate anion. In the calculation of the orbital interaction energies, the resonance integrals were approximated to be proportional to the overlap integrals; $S_{rs}\beta_0$, where S_{rs} is the overal integral between atomic orbitals r and s, and β_0 is a constant. For the donor orbitals, only the HOMO LCAO coefficients on the nucleophilic atom were taken into account. Thus the values listed in Table 3 are:

$$\sum_{m}^{unocc} \frac{(\sum_{r} C_{rm}C_{s,HOMO}S_{rs})^2}{\varepsilon_{HOMO}-\varepsilon_m},$$

where S_{rs} was evaluated between the r AO of benzyl thiocyanate and the s-type AO of the nucleophilic atom in each nucleophile which is placed at 2.0 Å distance along the direction cited in Fig. 5.

Intramolecular Stereospecific Pummerer Reactions of Aryl (Substituted-methyl) Sulfoxides Bearing Electron-withdrawing Groups with Acetic Anhydride

Tatsuo NUMATA, Osamu ITOH, Toshiaki YOSHIMURA, and Shigeru OAE*

Department of Chemistry, University of Tsukuba, Niihari-gun, Sakura-mura, Ibaraki 305

(Received June 7, 1982)

The Pummerer reaction of optically active cyanomethyl aryl sulfoxides with acetic anhydride gave the corresponding α-acetoxy sulfides which were induced with a partial asymmetry nearly 30% at α-carbon, while the ^{18}O-label of the original sulfoxides was retained in more than 85% in the resulting ester, the Pummerer reaction product. Kinetic experiments with cyanomethyl (*p*-substituted phenyl) sulfoxides and α,α-dideuterated cyanomethyl *p*-tolyl sulfoxide in the reaction with acetic anhydride containing a small amount of acetic acid revealed that the rates were correlated with Hammett σ-values and ρ-value of −0.70 was obtained, while the kinetic isotope effect was practically nil, *i.e.*, $k_H/k_D=1.01$. These observations indicate clearly that the rearrangement is intramolecular and proceeds via forming a very intimate ion-pair and the rate-determining step is believed to be the S–O bond cleavage after the initial reversible acylation and deprotonation. Elimination of acetic acid proceeds through the Elcb type process. The uneven distribution of ^{18}O in the two oxygens of the resulted ester, *i.e.*, ether and carbonyl oxygens, suggests the recombination of the α-sulfenyl carbonium ion and acetate ion to be very rapid. The Pummerer reaction of optically active *N,N*-dimethyl-*p*-tolyl-sulfinylacetamide with excess acetic anhydride also gave the corresponding α-acetoxy sulfide in optically active form. In the presence of dicyclohexylcarbodiimide (DCC), the Pummerer reaction was found to be highly stereoselective affording the corresponding α-acetoxy sulfide with 65%e.e. Other optically active α-carbonyl-substituted alkyl sulfoxides, *i.e.*, ethyl *p*-tolylsulfinylacetate and ω-(*p*-tolylsulfinyl)acetophenone also gave the corresponding highly optically active Pummerer rearrangement products in the treatment with acetic anhydride/DCC system. The Pummerer reaction of the ^{18}O-labeled sulfoxides with acetic anhydride/DCC system gave the corresponding α-acetoxy sulfides which retained much of the original ^{18}O-labels of the sulfoxides. These observations reveal clearly that in the Pummerer reaction of these compounds the acetoxyl migration is intramolecular and takes place through intimate ion-pairs.

The reaction of sulfoxides bearing α-methylene protons with acetic anhydride to afford the corresponding α-acetoxy sulfides was named by Horner[2] half a century after the discovery by Pummerer.[1] One earliest investigation of the mechanism of this reaction was our ^{18}O-tracer study using dimethyl sulfoxide and uniformly ^{18}O-labeled acetic anhydride in diethyl ether.[3] On the basis of our finding that all of the oxygen atoms were completely scrambled during the reaction, we suggested the involvement of intermolecular attack of acetate at the α-carbon and also the possible involvement of the acyloxysulfonium ylide. Because of the possible involvement of the Pummerer reaction in the enzymatic demethylation of methionine[4] and the growing potential for versatile organic syntheses,[5] mechanism of this reaction has been investigated quite extensively and well-reviewed.[6,7]

The general scheme of the reaction is believed to be shown in the following four sequential elemental reactions with the rate-determining step varying with changes of both the acylating agent and the sulfoxide. In some cases, the reaction of the steps 2 and 3 became simultaneous, to result in E2 process, as in the Pummerer reaction of *trans*-1- and 2-thiadecalin *S*-oxides with acetic anhydride.[8]

Although there has been no clear-cut example of the Pummerer reaction in which the last recombination step 4 is the rate-determining, we have found all the three examples of the reactions in which each of the three steps is rate-determining.[7c-e]

$$\underset{\underset{O}{\downarrow}}{R\text{-}S\text{-}CH_3} + Ac_2O \overset{\text{step 1}}{\rightleftharpoons} \underset{\underset{OAc}{\downarrow}}{R\text{-}\overset{+}{S}\text{-}CH_3} + AcO^-$$

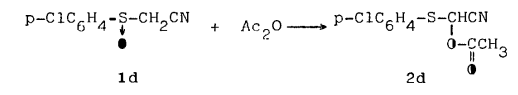
$$\overset{\text{step 2}}{\underset{-H^+}{\rightleftharpoons}} \left[\underset{\underset{OAc}{\downarrow}}{R\text{-}\overset{+}{S}\text{-}\overset{-}{C}H_2} \longleftrightarrow \underset{\underset{OAc}{\downarrow}}{R\text{-}S\text{=}CH_2} \right] + AcOH$$

$$\overset{\text{step 3}}{\longrightarrow} \left[R\text{-}\overset{+}{S}\text{=}CH_2 \longleftrightarrow R\text{-}S\text{-}\overset{+}{C}H_2 \right]$$
$$\qquad\qquad {}^{-}OAc \qquad\qquad {}^{-}OAc$$

$$\overset{\text{step 4}}{\longrightarrow} R\text{-}S\text{-}CH_2OAc$$

While the first example of the Pummerer reaction which results in a substantial asymmetric induction[9] was the novel cyclization of *o*-carboxyphenyl alkyl sulfoxide with acetic anhydride and dicyclohexylcarbodiimide (DCC)[10] to give cyclized 3*H*-4-thiaisocoumarin in 11.2 and 29.9% e.e., respectively, the rate-determining step of this reaction seems to be the initial acylation (step 1). The second example of the Pummerer reaction which leads to the formation of asymmetrically induced α-acetoxy sulfide was the reaction of open-chain optically active cyanomethyl *p*-tolyl sulfoxide (**1b**) with acetic anhydride.[11] The rate-determining step of this reaction appears to be the heterolysis of the S–O linkage of the sulfonium-ylide-ylene intermediate formed by the initial reversible acylation of the sulfoxide and subsequent reversible deprotonation, while the rearrangement seems to proceed predominantly through intramolecular migration of acetoxyl group when the reaction of the ^{18}O-labeled sulfoxide was carried out.

Other examples of the Pummerer reaction which affords the corresponding asymmetrically induced α-acetoxy sulfides are all with optically active open-chain aryl methyl sulfoxides bearing some electron-



withdrawing groups on methyl group,[12-14] while the reaction of aryl 2-propynyl sulfoxide with acetic anhydride gives not only the Pummerer rearrangement product but also the thio-Claisen type rearrangement product, and hence it will be dealt separately.[14] All these optically active aryl (carbonyl-substituted methyl) sulfoxides **3**, **5**, and **7a** were found to react with acetic anhydride affording the corresponding α-acetoxy sulfides **4**, **6**, and **8a** which are substantially induced with optical activities on the α-carbons. In the presence of DCC, scavenger of acetic acid formed, the amounts of asymmetric induction were markedly increased in the resulting Pummerer products. Meanwhile, the usual ^{18}O-tracer experiments with ^{18}O-labeled sulfoxides **3**, **5**, and **7b** revealed that the rearrangements are predominantly intramolecular in view of the high retentions of ^{18}O-label in the resulted corresponding α-acetoxy sulfides **4**, **6**, and **8b**.

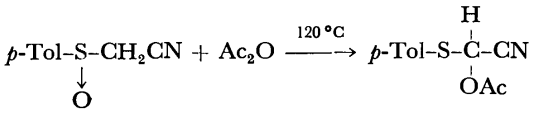
This paper describes detailed accounts of these interesting intramolecular stereoselective Pummerer reactions of aryl (substituted methyl) sulfoxides bearing electron-withdrawing group with acetic anhydride.

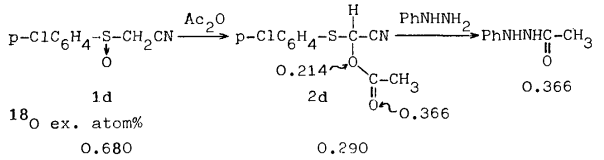
Results and Discussion

Reaction of Aryl Cyanomethyl Sulfoxides with Acetic Anhydride. When optically active cyanomethyl *p*-tolyl sulfoxide (**1b**) $[\alpha]_D$ +252°, was allowed to react with a large excess acetic anhydride at 120 °C for 3.5 h, the resulted acetoxycyanomethyl *p*-tolyl sulfide (**2b**) was found to be optically active, $[\alpha]_D$ +26.8°, which corresponds to 29.0±0.8% of e.e. when determined by NMR using the chiral lanthanoide shift reagent, Eu(hfc), tris(heptafluoropropylhydroxymethyl-d-camphorato)europium.



1b $[\alpha]_D$ +252° **2b** $[\alpha]_D$ +26.8°

In the reaction of ^{18}O-labeled cyanomethyl *p*-chlorophenyl sulfoxide (**1d**) (0.680 ex. atom% of ^{18}O) with a large excess of unlabeled acetic anhydride at 50% conversion (120 °C, 1 h) the unreacted sulfoxide recovered and the Pummerer product **2d** separated by column chromatography were found to be incorporated with 0.655 ex. atom% of ^{18}O (for **1d** recovered) and 0.290 ex. atom% (for **2d**), which correspond to the retention of 96.3%(for **1d** recovered) and 85% (for **2**), respectively. Thus, the rearrangement proceeded through an intramolecular 1,2-acetoxyl migration at least 85%. In order to shed further light on the nature of the acetoxyl migration, the distribution of ^{18}O in the resulted ester **2d** was determined by treating the ester **2d** with 3 molar excess of phenylhydrazine to convert acetyl group to 1-acetyl-2-phenylhydrazine which had 0.366 ex. atom% of ^{18}O. Thus the following ^{18}O distribution in the ester **2d** was ob-



served. This uneven distribution of ^{18}O, rich in favor for carbonyl oxygen, means that the recombination of acetoxyl group to α-carbon after the heterolysis of the S–O linkage is very rapid while the heterolysis of the S–O linkage is partly assisted by the neighboring group effect of carbonyl oxygen at the transition state of the 1,2-acetoxyl migration.

Meanwhile, in the reaction of cyanomethyl-d_2 *p*-tolyl sulfoxide with acetic anhydride containing a small amount of acetic acid, the recovered sulfoxide was found to have lost the D-label completely within a few minutes of the reaction at 120 °C, suggesting strongly that the initial acetylation (step 1) and the deprotonation to form the ylide **9** (step 2) are both fast and reversible, and the rate-determining step is the subsequent S–O bond heterolysis followed by very fast recombination of the resulting α-sulfenyl carbenium ion with acetate within the ion-pair **10a** and **10b**.

Kinetic experiments of the Pummerer reactions of cyanomethyl *p*-substituted phenyl sulfoxides in a large excess acetic anhydride containing a small amount of acetic acid (0—13.8 mmol) were carried out by following the UV absorption spectra of the starting sulfoxides. The rate of the Pummerer reaction was found to increase as the amount of acetic acid increased as shown in Fig. 1 which illustrates the rate change *vs.* the concentration of acetic acid used. When an equimolar amount of DCC was added into the reaction mixture, the Pummerer reaction was extremely slowed down and could have hardly been seen after heating the reaction mixture for a few hours. Acetic acid is undoubtedly acting as a catalyst in the initial acetylation step (step 1). A strong acid such as *p*-toluenesulfonic acid was found to accelerate the Pummerer reaction of these sulfoxides markedly. Meanwhile, the reduction of aryl cyanomethyl sulfoxide with trimethylsilyl chloride in the presence of pyridine is known to be extremely sluggish as compared to other sulfoxides[15] due mainly to the difficulty of the initial trimethylsilylation of the sulfinyl function of which the basicity is very low.

The kinetic data of the Pummerer reactions of a few cyanomethyl (*p*-substituted phenyl) sulfoxides **1a—e** are summarized in Table 1. The rate was found to decrease with the increase of electron-withdrawing effect of substituent and the Hammett plot of the logarithms of rates against σ-values gave ρ-value of

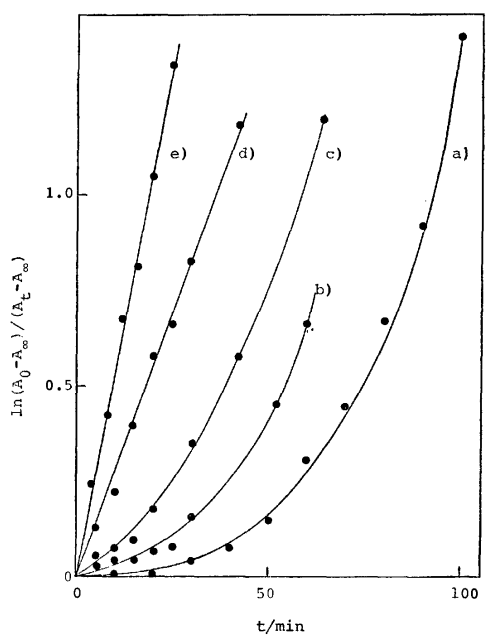

Fig. 1. Time course of the Pummerer reaction of cyanomethyl phenyl sulfoxide (**1c**) with acetic anhydride containing acetic acid.
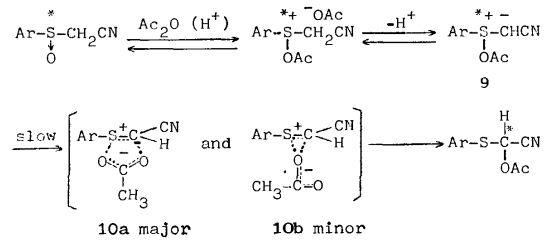
a): [AcOH]=0 M, b): 0.83 M, c): 1.75 M, d): 3.50 M, e): 6.92 M. A: UV Absorption intensity.

-0.7 ± 0.1 ($\gamma=0.9803$). The negative ρ-value also supports the rate-determining heterolysis of the S–O bond of the ylide intermediate **9**. The values of activation parameters at 120 °C $E_a=(70.3\pm1.7)$ kJ mol^{-1}, $\Delta H^*=(66.9\pm1.7)$ kJ mol^{-1}, $\Delta S^*=(-141\pm4)$ J K^{-1} mol^{-1}, are quite different from those of the intermolecular Pummerer reaction of methyl phenyl sulfoxide at 120 °C ($E_a=88.7$ kJ mol^{-1}, $\Delta S^*=-86.6$ J K^{-1} mol^{-1})[16] and also those of the Pummerer reaction of arylmethylsulfonium bis(methoxycarbonyl)methylide with acetic anhydride ($\Delta H^*=89.5$ kJ mol^{-1}, $\Delta S^*=-92.9$ J K^{-1} mol^{-1}) in which the rate-determining step is believed to be the S–C linkage cleavage.[17] The large negative value of entropy of activation ($\Delta S^*=-141$ J K^{-1} mol^{-1}) seems to suggest the transition state to be very tight, as in a similar intramolecular tosyloxyl migration in the reaction of isoquinoline *N*-oxide with *p*-toluenesulfonyl chloride, *i.e.*, $\Delta H^*=40.2$ kJ mol^{-1}, $\Delta S^*=-168$ J K^{-1} mol^{-1}.[18] Based on all these observations and related data, the scheme of the Pummerer reaction of cyanomethyl aryl sulfoxides leading to the asymmetric induction may be illustrated as shown below. The initial acetylation is an acid-catalyzed equilibrium reaction and the second step of proton-removal is also fast and reversible in view of the lack of kinetic isotope effect, $k_H/k_D=1.01$, and the loss of α-deuterium during the reaction. The rate-determining S–O bond heterolysis is considered to be followed by



very rapid recombination of acetate with α-carbon atom intramolecularly. The asymmetric induction cannot be caused by the stereoselective proton removal from the acetoxysulfonium salt, as was suggested by Allenmark in their stereoselective Pummerer reaction,[9] since the resulting α-cyano carbanion, the ylide **9**, is known to be a coplaner resonance-stabilized carbanion. The dual pathways for the acetoxyl migration in which the five-membered cyclic path predominates over the three-membered sliding path is not particularly strange. Similar dual paths for acyloxyl migration have been known in several rearrangements of tertiary amine oxides with acylating agents.[18] Then what factor is important in inducing the chirality from the chiral sulfur atom to prochiral α-carbon in this Pummerer reaction? The preferential structural difference between

Table 2. Reaction of optically active sulfoxides with acetic anhydride in the presence of DCC

a) Equivalent to the sulfoxide. b) e.e. values were determined on the basis of NMR spectra using the chiral shift reagent, $Eu(hfc)_3$. c) e.e. value was calculated on the basis of the other e.e. value determined with the shift reagent.

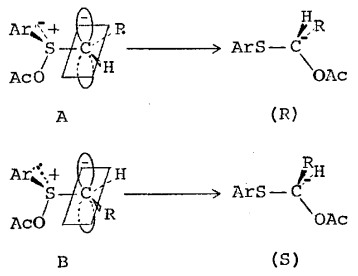

Fig. 2.

the two sulfonium ylides (A) and (B) would reflect on the preferential formation of one enanthiomeric ester to the other. Then which one of the conformers (A) and (B) would be the more favored would be solved when the absolute configuration of the resulted ester is determined. From the X-ray crystallographic analysis of (−)-**4**,[25] which is also product we obtained as optically active form and was recrystallized to optically pure crystals as described in the next section, (−)-**4** was found to have *R*-configuration, suggesting that the sterically more favored structure (A) is predominant among the acetoxysulfonium intermediates (A) and (B).

Reaction of Optically Active Carbonyl-substituted Methyl p-*Tolyl Sulfoxides* ***3***, ***5***, *and* ***7a*** *with Acetic Anhydride.* In the intramolecular Pummerer reactions of optically active sulfoxides to afford the corresponding optically active α-acetoxy sulfides **4**, **6**, and **8a** under the usual conditions, the extent of asymmetric induction has never exceeded 30% e.e. The low percents of e.e. are considered to be due to the formation of acetic acid which assists the dissociation of the intimate ion-pair during the migration of acetoxyl group. Since the Pummerer reaction of optically active carbonyl-substituted methyl *p*-tolyl sulfoxides with acetic anhydride were found to proceed slowly but quite well in the presence of DCC, unlike the cyanomethyl anolog, we have carried out the Pummerer reactions of a few optically active carbonyl-substituted methyl *p*-tolyl sulfoxides **3**, **5**, and **7a** in a large excess of acetic anhydride with two equivalent amounts of DCC in the temperature range of 110—130 °C for a few hours and found a remarkable increase of up to 70% e.e. of asymmetric induction at the α-carbon of the resulted esters.

When optically active *N*,*N*-dimethyl-*p*-tolylsulfinylacetamide (**3**) with $[\alpha]_D$ +188° was heated with a large excess of acetic anhydride in the presence of two equivalent amounts of DCC at 100 °C for 6 h, the recovered sulfoxide and the corresponding α-acetoxy sulfide **4** formed were obtained in 63% and 35% yields, respectively and the Pummerer product **4** was found to be optically active, $[\alpha]_D$ −44.0°, to the extent of 66% e.e. A similar reaction of ethyl *p*-tolylsulfinylacetate (**5**) with $[\alpha]_D$ +188° and ω-(*p*-tolylsulfinyl)-acetophenone (**7a**) with $[\alpha]_D$ +272° under the same conditions gave the corresponding highly optically active α-acetoxy sulfides **6** and **8a** in the early stage of the reaction (before a half completion). The asymmetric induction was found to be rather low, *i.e.*, below 30% e.e., when the Pummerer reaction of these optically active sulfoxides **3**, **5** and **7a** were carried out without DCC, the scavenger of acetic acid. All the stereochemical results of the reactions are tabulated in Table 2. The usual ^{18}O-tracer experiments were carried out using ^{18}O-labeled sulfoxides **3** and **7b** and the esters formed were also allowed to react with 2 equivalent amounts of phenylhydrazine to convert acetyl group to 1-acetyl-2-phenylhydrazine in order to determine the distribution of ^{18}O in the two oxygens of the ester function of the migrated esters **4** and **8b**. The results are summarized in Table 3 and illustrated in the equations shown below. When the Pummerer reaction was carried out with the sulfoxide **3** labeled with 0.607 ex. atom% of ^{18}O in 60 equiv. amounts of acetic acid at 130 °C for 10.5 h without DCC, the corresponding Pummerer reaction product **4**, obtained in 50% yield was found to have 0.198 ex. atom% of ^{18}O while the sulfoxide recovered in 50% yield retained 92% (0.558 ex. atom%) of ^{18}O of the original

^{18}O-label of the sulfoxide **3**. The uneven distribution of ^{18}O rich in favor for the carbonyl oxygen in the resulting Pummerer product **4** is also in keeping with the result observed in the Pummerer product **2d**. All these observations together with other pertinent data clearly indicate that these stereoselective intramolecular acetoxyl migrations proceed *via* intimate ion-pairs formed by concurrent electron-transfer within the acetoxysulfonium ylide and S–O bond heterolysis, and the subsequent recombination of the sulfenyl carbenium ion and acetate is so rapid that there is not enough time to achieve complete racemization and complete ^{18}O-scrambling in the resulted esters.

Experimental

General. All melting points were uncorrected. IR spectra were taken on a Hitachi 260-50 spectrometer. NMR spectra were recorded with a Hitachi Perkin-Elmer R-20 spectrometer in $CDCl_3$ using TMS as an internal standard. Mass spectra were determined with a Hitachi RMU-6MG mass spectrometer. UV absorptions were measured using a JASCO UNIDEC-1 spectrophotometer. Acetic anhydride was purified by stirring with sodium metal for 7 d followed by a refluxing under reduced pressure below 50 °C for 5 h and then distilled under reduced pressure, bp 47—48 °C/20 mmHg.**

^{18}O-Analysis. ^{18}O-Analysis was carried out by the method developed by Rittenberg and Ponticorvo,[19] with a modification which involves the use of $Pb(OAc)_2$ to remove H_2S gas from the gas produced by the thermolysis of sample: About 20 mg of sample was pyrolyzed with 250 mg each of purified $HgCl_2$ and $Hg(CN)_2$, respectively, in an evacuated sealed pyrex tube at ca 500 °C for 12 h. Then the tube was broken in a vacuum line and CO_2 gas formed was purified by distillation and the mass peaks of *m/e* 44 and 46 which correspond to $C^{16}O_2$ and $C^{16}O^{18}O$, respectively, were recorded on a mass spectrometer.

Materials. *Aryl Cyanomethyl Sulfides*: Chloroacetonitrile was treated with respective sodium arenethiolates in ethanol at room temperature. The sulfides thus obtained in 70—80% yields have the following physical properties. R-S-CH_2CN: R, bp (or mp), NMR ($CDCl_3$) δ; Ph, 107—109 °C/3 mmHg, 3.52 (2H, s), 7.6 (5H, s broad); *p*-tolyl, 114—116 °C/3 mmHg, 2.38 (3H, s), 3.52 (2H, s), 7.1—7.6 (4H, m); *p*-ClC_6H_4, mp 85—87 °C, 3.52 (2H, s), 7.3—7.6 (4H, m); *p*-$MeOC_6H_4$, liquid (bp not determined), 3.46 (2H, s), 3.83 (3H, s), 6.8—7.6 (4H, m).

Cyanomethyl p-Nitrophenyl Sulfide: Chloroacetonitrile was treated with *p*-nitrobenzenethiol in the presence of triethylamine in chloroform at room temperature to give cyanomethyl *p*-nitrophenyl sulfide in 75% yield, mp 84—85 °C, 3.78 (2H, s), 7.5—8.3 (4H, m).

*Aryl Cyanomethyl Sulfoxides (**1a**—**e**)*: The corresponding sulfides were allowed to react with *m*-chloroperbenzoic acid in chloroform at room temperature. The sulfoxides obtained in nearly quantitative yields were recrystallized from either benzene or acetonitrile. Physical properties are the followings. R-S(O)-CH_2CN: R, mp, NMR ($CDCl_3$) δ, anal; *p*-$MeOC_6H_4$, **1a**, 65—66 °C, 3.70 (2H, s), 3.87 (3H, s), 7.0—7.8 (4H, m), Found: C, 55.35; H, 4.72; N, 7.41%. Calcd for $C_9H_9NO_2S$: C, 55.38; H, 4.65; N, 7.18%. *p*-tolyl, **1b**, 72—3 °C, 2.47 (3H, s), 3.70 (2H, s), 7.3—7.8 (4H, m), Found: C, 60.33; H, 5.10; N, 7.66%. Calcd for C_9H_9NOS: C, 60.33; H, 5.06; N, 7.82%. Ph, **1c**, 65—66 °C, 3.70 (2H, s), 7.4—7.8 (5H, m), Found: C, 58.04; H, 4.29; N, 8.68%. Calcd for C_8H_7NOS: C, 58.18; H, 4.27; N, 8.48%. *p*-ClC_6H_4, **1d**, 87—88 °C, 3.73 (2H, s), 7.5—7.8 (4H, m), Found: C, 48.00; H, 3.03; N, 6.86%. Calcd for C_8H_6ClNOS: C, 48.09; H, 3.01; N, 7.01%. *p*-$NO_2C_6H_4$, **1e**, 153—154 °C, (DMSO-d_6) 4.50 (2H, AB quartet), 7.9—8.5 (4H, m), Found: C, 45.73; H, 2.96; N, 13.18%. Calcd for $C_8H_6N_2O_3S$: C, 45.72; H, 2.88; N, 13.33%.

*Optically Active Cyanomethyl p-Tolyl Sulfoxide (**1b**)*: The optically active **1b** was synthesized by either one of the following two procedures.

1): HMPT solution (50 ml) of (+)-bromomethyl *p*-tolyl sulfoxide (2.0 g), synthesized according to the reported procedure,[20] was mixed with aqueous solution (2 ml) of potassium cyanide (1 g), and heated at 50 °C for 1 d. The HMPT sulution was diluted with 100 ml of chloroform, and the whole solution was washed three times with 1000 ml portion of water. Then the resultant chloroform solution was dried and concentrated to afford a dark red oily product which was separated through silica-gel chromatography with chloroform as an eluent, giving crystalline optically active cyanomethyl *p*-tolyl sulfoxide which was recrystallized from benzene-hexane. Thus, (+)-cyanomethyl *p*-tolyl sulfoxide (**1b**) obtained (300 mg, 15% yield) has $[\alpha]_D$ +252° (*c* 1,

** 1 mmHg ≈ 133.3 Pa.

EtOH), mp 72 °C. Upon measurement of NMR contact shift using chiral lanthanoid shift reagent, Eu(hfc)$_3$, the sulfoxide was found to be more than 90% optically pure. (*vide infra*)

2): Optically active bromomethyl *p*-tolyl sulfoxide (220 mg), prepared by usual α-bromination of optically active methyl *p*-tolyl sulfoxide,[20] was treated with 1.2 equiv. amount of KCN (68 mg) in the presence of 18-crown-6 (23 mg) in $CHCl_3$ (10 ml) under reflux for 4 h. The crude optically active cyanomethyl *p*-tolyl sulfoxide (**1b**) (125 mg) obtained in 72% yield was recrystallized from benzene–hexane giving 100 mg of the partially optically active title compound with $[\alpha]_D$ +145° (*c* 1.5, acetone).

Optically Active N,N-*Dimethyl*-p-*tolylsulfinylacetamide (3)*: A solution of 6.4 ml of butyllithium (15 wt% in hexane) was added to a solution containing optically active (+)-(*R*)-methyl *p*-tolyl sulfoxide (1.54 g, 10 mmol) in 20 ml of a freshly distilled THF at −70 °C in an acetone–Dry Ice bath and then the mixture was stirred for 30 min. After dimethylcarbamoyl chloride (537.5 mg, 5 mmol) was added to the THF solution with a syringe at −70 °C, the reaction mixture was allowed to stir at room temperature for 1 h. Into this mixture 20 ml of cold water was added, then the solution was acidified with aqueous solution of ammonium chloride (*ca.* pH 3) and extracted with chloroform. The combined orange layer was washed twice, and then dried over Na_2SO_4. Evaporation of the solvent gave an oily residue which was separated through silica-gel column chromatography with benzene–acetone (4:1) as an eluent. Then the product was distilled to give a colorless oil (584 mg, 40% yield): bp 130 °C/1 mmHg (Kugelrohr), $[\alpha]_D$ +188° (acetone).

Optically Active Ethyl p-*Tolylsulfinylacetate (5)*: Diethyl carbonate (590 mg, 5 mmol) was treated with 2 equivalent molar amount of a *p*-tolylsulfinylmethylide ion dried from the corresponding (+)-methyl *p*-tolyl sulfoxide (1.54 g, 10 mmol) with $[\alpha]_D$ +154° (in acetone) and lithium diethylamide prepared from 6.4 ml of butyllithium solution (0.1 g/ml) in hexane and diethylamine (730 mg, 10 ml) at −70 °C. The reaction mixture was then stirred at 0 °C for 1 h. After addition of 20 ml of water, the solution was acidified with aqueous ammonium chloride solution (*ca.* pH 3) and extracted with 50 ml of chloroform three times, dried over $MgSO_4$, and the solvent was evaporated to give an oily residue which was separated through silica-gel column chromatography with benzene–ethyl acetate (4:1) as an eluent. Then the product was distilled to give a colorless oil (531 mg, 47% yield) with bp 130 °C/1.5 mmHg (Kugelrohr) and $[\alpha]_D$ +188° (*c* 1.0, acetone). IR (KBr) 1730 and 1045 cm^{-1}; NMR ($CDCl_3$) δ=7.36 (4H, ABq), 4.12 (2H, q), 3.67 (2H, ABq), 2.40 (3H, s), 1.21 (3H, s); Found: C, 57.92; H, 6.28%. Calcd for $C_{11}H_{14}O_3S$: C, 58.38; H, 6.28%.

*Optically Active ω-(*p-*Tolylsulfinyl)acetophenone (7a)*: Reaction of ethyl benzoate with *p*-tolylsulfinylmethylide ion prepared by treating (+)-(*R*)-methyl *p*-tolyl sulfoxide ($[\alpha]_D$ +154°, acetone) with butyllithium in diethylamine gave the optically active **7a**: $[\alpha]_D$ +272° (*c* 1, acetone), mp 87—88 °C; lit,[21] $[\alpha]_D$ +264.5° (acetone), mp 74 °C.

^{18}O-*Labeled Cyanomethyl* p-*Chlorophenyl Sulfoxide (1d)*: Cyanomethyl *p*-chlorophenyl sulfide (4.5 g, 24 mmol) was dissolved in a mixture of acetic acid (20 ml), pyridine (6 ml) and ^{18}O-enriched water (1.8 ml) (1.6 atom%). To the cooled sulution was added bromine (3.9 g, 24 mmol) at 0 °C.[22] After keeping the solution for 2 h at 0 °C, the reaction mixture was quenched with 200 ml of water and extracted with chloroform (200 ml). The chloroform solution was washed with aqueous $Na_2S_2O_3$ solution, diluted aqueous HCl solution and water, and then dried ($MgSO_4$). After evaporation of chloroform with a rotary evaporator, an oily substance obtained was separated through silica-gel column chromatography, giving ^{18}O-labeled cyanomethyl *p*-chlorophenyl sulfoxide (**1d**) which was recrystallized from benzene. Thus the ^{18}O-labeled **1d** obtained (600 mg, 12% yield) was found to contain 0.680 ex. ^{18}O atom%.

^{18}O-*Labeled* N,N-*Dimethyl*-p-*tolylsulfinylacetamide (3)*: The ^{18}O-labeled sulfoxide **3** was obtained by the reaction of dimethylcarbamoyl chloride (613 mg, 5.7 mmol) with *p*-tolylsulfinylmethylide ion prepared by treating ^{18}O-labeled methyl *p*-tolyl sulfoxide (1.747 g, 11.3 mmol) with lithium diethylamide (prepared from 0.1 g/ml solution of butyllithium in hexane and diethylamine in THF). Then the usual work-up as mentioned above gave the ^{18}O-labeled **3**: mp 59—60 °C, 0.607 ex. atom% of ^{18}O, IR (KBr) 1640, 1265, and 1045 cm^{-1}, NMR ($CDCl_3$) δ=7.41 (4H, ABq), 3.33 (2H, ABq), 2.93 (3H, s), 2.90 (3H, s) and 2.39 (3H, s); Found: C, 58.77; H, 6.72; N, 6.20%. Calcd for $C_{11}H_{15}NO_2S$: C, 58.64, H. 6.71; N, 6.21%.

^{18}O-*Labeled ω-Phenylsulfinylacetophenone (7b)*: The reaction of ethyl benzoate with the phenylsulfinylmethylide ion prepared by treating ^{18}O-labeled methyl phenyl sulfoxide (1.621 ex. atom%) with butyllithium in diethylamine gave the ^{18}O-labeled **7b**: mp 70—71 °C, (lit,[23] mp 70—71 °C), ^{18}O-content: 0.840 ex. atom%.

Cyanomethyl-d$_2$ *Phenyl and Cyanomethyl*-d$_2$ p-*Tolyl Sulfoxides*: The nonlabeled sulfoxide (370 mg) was dissolved in anhydrous chloroform (10 ml) containing two drops of anhydrous pyridine. The chloroform solution was vigrously shaken with D_2O (1 ml) at room temperature in a separatory unnel, and the aqueous layer was separated out. After the chloroform solution was dried over anhydrous Na_2SO_4 and concentrated under reduced pressure, the solid dideuterated sulfoxide was obtained. Then the partially labeled sulfoxide thus obtained was treated additionally with D_2O for H–D exchange as the same procedure mentioned above. Thus the sulfoxide obtained by the two consecutive H–D exchange was found to be completely labeled by D upon NMR measurement and recrystallized from anhydrous benzene.

Reaction of Aryl Cyanomethyl Sulfoxides (1b—e) with Acetic Anhydride. The sulfoxides **1b—e** (*ca.* 400 mg) were heated with 20 ml of acetic anhydride at 110—115 °C for 4—6 h untill the sulfoxides were found to have disappeared upon monitoring with TLC method. After evaporation of excess acetic anhydride and any volatile product *in vacuo*, the remaining residue was separated by column chromatography through silica gel with benzene as an eluent. The corresponding α-acetoxy sulfides, the Pummerer products, were obtained in 85—90% yields. Physical properties of R–S–CH(OAc)CN (**2b—e**) were the followings: R, mp (or bp), NMR ($CDCl_3$) δ, Anal; *p*-tolyl **2b**: 100 °C/4 mmHg (Kugelrohr), 2.15 (3H, s), 2.39 (3H, s), 6.48 (1H, s), 7.1—7.6 (4H, m). Ph **2c**: 100 °C/4 mmHg (Kugelrohr oven), 2.17 (3H, s), 6.52 (1H, s), 7.4—7.7 (5H, m), Found: C, 57.86; H, 4.50; N, 6.76%. Calcd for $C_{10}H_9NO_2S$: C, 57.97; H, 4.38; N, 6.76%. *p*-ClC_6H_4 **2d**: 53—55 °C, 2.18 (3H, s), 6.49 (1H, s), 7.3—7.7 (4H, m), Found: C, 49.63; H, 3.36; N, 5.80%. Calcd for $C_{10}H_8ClNO_2S$: C, 49.59; H, 3.31; N, 5.79%. *p*-$NO_2C_6H_4$ **2e**: 92—3 °C, 2.21 (3H, s), 6.63 (1H, s), 7.7—8.3 (4H, m).

Reaction of Optically Active Cyanomethyl p-*Tolyl Sulfoxide (1b) with Acetic Anhydride.* *1)*: After heating of the optically active sulfoxide **1b** ($[\alpha]_D$ +252° 50 mg) with 1 ml of acetic anhydride at 120 °C for 3.5 h and then evaporation of an excess acetic anhydride and any volatile product *in vacuo*,

an oily product was purified through column chromatography (silica gel, benzene as an eluent) to afford a colorless oily Pummerer product, acetoxycyanomethyl *p*-tolyl sulfide (**2b**) (50 mg, 81% yield). The oily **2b** was further purified by distillation with micro-distillation apparatus (100 °C/1 mmHg bath temp) giving the pure **2b** with $[\alpha]_D$ +26.8° (*c* 5, EtOH). This optically active α-acetoxy sulfide **2b** was found to be of 29.0±0.8% of enantiomer excess (e.e.) by treatment with the chiral lanthanoids shift reagent, Eu(hfc)$_3$. (*vide infra*). Prolonged heating (120 °C, 7 h) of the sulfoxide **1b** with acetic anhydride also gave the partially optically active Pummerer product **2b** with $[\alpha]_D$ +25.7° (*c* 4.35, EtOH).

2): When the optically active **1b** (50 mg) was heated with 1 ml of acetic anhydride containing 0.2 ml of acetic acid (120 °C, 3 h), the Pummerer product **2b** obtained (52 mg) after the same work-up has only $[\alpha]_D$ +1.2° (*c* 5.2, EtOH).

3): When the optically active **1b** (51 mg) was heated with acetic anhydride (1 ml) at 120 °C for 6 min, the Pummerer reaction was found to have proceeded only to 22% conversion by monitoring with NMR measurement of the reaction mixture of the sulfoxide and the α-acetoxy sulfide **2b** after evaporation of excess of acetic anhydride. The only mixture was separated through column chromatography (silica gel, benzene, and then chloroform as eluents), giving the recovered sulfoxide **1b** (42 mg) with $[\alpha]_D$ +234° (*c* 4.2, EtOH, and with $[\alpha]_D$ +251° (*c* 0.63, EtOH) after recrystallization from benzene-hexane.

Reaction of ^{18}O*-Labeled Cyanomethyl* p*-Chlorophenyl Sulfoxide (**1d**) with Acetic Anhydride. 1)*: When the ^{18}O-labeled title sulfoxide **1d** (600 mg) (0.680 ex. atom%) was heated with 5 ml of acetic anhydride at 120 °C for 1 h, the oily residue obtained after evaporation of excess of acetic anhydride and any volatile product in vacuo was separated by column chromatography through silica gel with benzene and then chloroform as eluents. The sulfoxide recovered and the Pummerer product **2d** were recrystallized from benzene and hexane, respectively, to afford the sulfoxide (332 mg, 55% yield) and the Pummerer product (252 mg, 35% yield). The starting sulfoxide, the recovered sulfoxide and the Pummerer product were subjected to measurement of ^{18}O-content by the routine ^{18}O-analysis technique and the ^{18}O-contents were found to be 0.680, 0.655, and 0.290 ex. atom%, respectively.

2): When the ^{18}O-labeled **1d** (100 mg, 0.680 ex. atom%) was heated with 4 ml of acetic anhydride containing 830 mg of acetic acid at 100 °C for 16 min, the Pummerer reaction proceeded to 10% conversion, and the unreacted starting sulfoxide recovered was found to retain original ^{18}O-label completely (0.680 ex. atom%). While the sulfoxide **1d** (102 mg, 0.680 ex. atom%) was heated with acetic anhydride (2 ml) containing acetic acid (0.4 ml) at 120 °C for 2 h, the Pummerer product **2d** recrystallized from hexane was found to contain 0.154 ex. atom% of ^{18}O.

^{18}O*-Distribution in Ester Function of the Pummerer Product (**2d**).* When the Pummerer product (400 mg, 0.290 ex atom%) was treated with three molar excess of phenylhydrazine (540 mg) in 5 ml of benzene at 60 °C for 0.5 h, 1-acetyl-2-phenylhydrazine precipitated was collected (130 mg) and recrystallized twice from benzene. The pure 1-acetyl-2-phenylhydrazine (80 mg, mp 125—128 °C) was found to contain 0.366 ex atom% of ^{18}O by the routine ^{18}O-analysis.

*Kinetic Procedure for the Pummerer Reaction of Aryl Cyanomethyl Sulfoxide (**1a—e**).* The Pummerer reaction was carried out at 120.0±0.07 °C in sealed tubes, in which each sulfoxide **1a—e** (0.22—0.38 mmol) was dissolved in 2 ml of acetic anhydride solution containing acetic acid (0—13.8 mmol). In this solution, the concentration of acetic anhydride was maintained above 50 molar excess as compared with that of the sulfoxide. A sealed tube containing 200 μl solution of the above mixture was recovered at several time intervals and was cooled in an ice-bath to stop the reaction. The aliquot portion (50—70 μl) was pipetted out and then diluted with ethanol resulting in making of 50 ml of ethanol solution, which was measured by UV spectrometer around 246—282 nm. Thus the rate of the Pummerer reaction was readily obtained by following the decrease of the band of the starting sulfoxide at 246—282 nm, since the starting sulfoxides absorb light at 246—282 nm (ε=7000—7500) and the Pummerer products absorb light at the same range with substantially small absorption coefficient (ε=4000—6000).

Reaction of Aryl Cyanomethyl-d_2 *Sulfoxides with Acetic Anhydride. 1)*: After heating of cyanomethyl-d_2 phenyl sulfoxide (45 mg) with 0.4 ml of acetic anhydride at 120 °C for 40 min, and separation of product mixture through column chromatography, the starting sulfoxide recovered (29 mg, 35% conversion) was found to have lost deuterium substantially (66% H-incorporation) upon determination by NMR measurement.

2): Cyanomethyl-d_2 *p*-tolyl sulfoxide (55 mg) was heated with 2 ml of acetic anhydride solution containing acetic acid (0.416 g, 6.93 mmol) at 120 °C for 16 min, where the Pummerer reaction was found to have proceeded 51% conversion upon determination by monitoring with UV. Then after evaporation of solvent of the reaction solution and measurement of the residue redissolved in $CDCl_3$ with NMR instrument, both the sulfoxide and the Pummerer product were found to retain no deuterium.

Reaction of the Optically Active N,N*-Dimethyl-*p*-tolylsulfinylacetamide with Acetic Anhydride. 1)*: The optically active sulfoxide **3** (74.4 mg, $[\alpha]_D$ +188°) was heated with 2 ml of acetic anhydride at 120 °C for 4 h. Then, after evaporation of excess acetic anhydride and any volatile product *in vacuo*, the remaining residue was separated by column chromatography through silica gel with benzene–ethyl acetate (4:1) as an eluent. The Pummerer product (**4**, 44.7 mg, 51% yield) with $[\alpha]_D$ −18.8° (*c* 2.0, acetone) was obtained.

2): The sulfoxide **3** (55 mg) was heated with 2 ml of acetic anhydride in the presence of 2 equiv. molar amount of DCC to the sulfoxide at 110 °C for 6 h, the Pummerer product **4** (22.7 mg, 35% yield) with $[\alpha]_D$ −44° (acetone) and the recovered sulfoxide (34 mg, 63% yield, $[\alpha]_D$ +146°) were obtained. The product **4** was recrystallized repeatedly from hexane to give optically pure crystals with maximum rotation $[\alpha]_D$ −59.2° (*c* 0.4, acetone). Mp 65—65.5 °C.

3): When the sulfoxide **3** (50 mg) was heated with 2 ml of acetic anhydride in the presence of 4 equiv. of DCC (163 mg) to the sulfoxide at 120 °C for 8 h, the Pummerer product **4** (59.3 mg) with $[\alpha]_D$ −36.4° was obtained.

Reaction of the Optically Active Ethyl p*-Tolylsulfinylacetate (**5**) with Acetic Anhydride. 1)*: The sulfoxide **5** (101 mg, $[\alpha]_D$ +188°) was heated with 2 ml of acetic anhydride at 110 °C for 4 h. Then after evaporation of excess acetic anhydride and any volatile product *in vacuo*, the remaining residue was separated through silica-gel column chromatography with benzene–ethyl acetate (4:1) as the eluent to give the Pummerer product **6** (26 mg, 22% yield) with $[\alpha]_D$ −18.8° (*c* 2.6, acetone) and the sulfoxide recovered retaining nearly the same initial optical purity ($[\alpha]_D$ +180°). The e.e. value of the chiral Pummerer product was found

to be 29% by measurement of the peak splitted on NMR recorder using the chiral lanthanoid shift reagent, Eu(hfc)$_3$. Mp 39.5—41.0 °C; IR (KBr) 1750, 1742, and 1203 cm^{-1}; NMR ($CDCl_3$) δ=7.45 (2H, d, J=8.4 Hz), 7.18 (2H, d, J=8.4 Hz), 6.16 (1H, s), 4.15 (2H, q), 2.35 (3H, s), 2.20 (3H, s), 1.20 (3H, t); Found: C, 58.43; H, 6.02%. Calcd for $C_{13}H_{16}O_4S$: C, 58.19; H, 6.01%.

2): The sulfoxide **5** (100 mg) was heated with 2 ml of acetic anhydride in the presence of 2 equiv. of DCC (182 mg) to the sulfoxide at 110 °C for 6 h. After the work-up as mentioned above, the Pummerer product **6** (11.8 mg, 10%) with $[\alpha]_D$ −52.5° (*c* 1.18, acetone) was obtained. The e.e. value of this Pummerer product induced with optical activity was 69.5% by treatment as mentioned above.

3): The sulfoxide **5** (45.0 mg) was heated with 1 ml of acetic anhydride in the presence of 4 equiv. DCC (165 mg) to the sulfoxide at 120 °C for 8 h. The Pummerer product **6** (22.9 mg, 43% yield with $[\alpha]_D$ +163° was obtained.

*Reaction of the Optically Active ω-(p-Tolylsulfinyl)acetophenone (**7a**) with Acetic Anhydride.* The optically active sulfoxide **7a** (200 mg) was heated with acetic anhydride (5 ml) at 110 °C for 1 h, and after evaporation of excess acetic anhydride and any volatile product an yellow oily residue was separated by column chromatography on silica gel with benzene as an eluent. The Pummerer product **8a** (204 mg, 88% yield) with $[\alpha]_D$ −0.5° (*c* 11, acetone) and a small amount of deoxygenated product (*p*-TolSCH$_2$COPh, 18 mg, 10% yield) were obtained. Both products gave the same IR and NMR spectra of the authentic samples reported.[24]

*Reaction of ^{18}O-Labeled N,N-Dimethyl-p-tolylsulfinylacetamide (**3**) with Acetic Anhydride. 1)*: The ^{18}O-labeled sulfoxide **3** (400 mg, 0.607 ex. atom%) was heated with 60 equiv. acetic anhydride at 130 °C for 10.5 min. Then after work-up as mentioned above the reaction of optically active **3** and chromatography on silica gel gave the Pummerer product **4** (237 mg, 50% yield) and the sulfoxide recovered (200 mg, 50% yield) which were recrystallized from ether–hexane and ethyl acetate–hexane, respectively, were found to have 0.198 and 0.558 ex. atom% of ^{18}O, respectively. **4**: mp 59—60 °C; IR (KBr) 1750, 1653 and 1230 cm^{-1}; NMR ($CDCl_3$) δ=7.5—7.1 (9H, m), 6.20 (1H, s), 2.29 (3H, s), 2.06 (3H, s); Found: C, 58.43; H, 6.42; N, 5.90%. Calcd for $C_{13}H_{17}NO_3S$: C, 58.40; H, 6.40; N, 5.23%.

2) After the sulfoxide **3** (400 mg) was allowed to react with 60 equiv. acetic anhydride at 120 °C for 8 h in the presence of 4 equivalent DCC, the usual work-up and chromatography on silica gel gave the Pummerer product **4** (361 mg, 76% yield). The Pummerer product **4** was found to contain 0.267 ex. atom% of ^{18}O.

*^{18}O-Distribution in Ester Function of the Pummerer Product (**4**).* After the Pummerer products **4** (134 mg, 0.198 ex. atom% of ^{18}O and 143 mg, 0.267 ex. atom% of ^{18}O) in 2 ml of benzene with 2 molar excess of phenylhydrazine were heated at 80 °C for 12 h, the reaction mixture was cooled to precipitate 1-acetyl-2-phenylhydrazine which was filtered off and washed with benzene. Then the product was recrystallized twice from benzene to give pure crystals (48 mg and 50 mg, respectively, mp 130—131 °C) which were found to contain 0.386 and 0.480 ex. atom% of ^{18}O, respectively.

*Reaction of ^{18}O-Labeled ω-Phenylsulfinylacetophenone (**7b**) with Acetic Anhydride.* ^{18}O-Labeled sulfoxide **7b** (310 mg, 0.840 ex. atom%) was heated with acetic anhydride (5 ml) at 110 °C for 1 h. After the usual work-up process, the Pummerer product **8b** obtained was recrystallized from benzene–hexane giving colorless needles (270 mg, 74% yield). The product **8b**: mp 65—67 °C; 0.243 ex. atom% of ^{18}O; IR (KBr) 1730, 1690, and 1220 cm^{-1}; NMR ($CDCl_3$) δ= 2.13 (3H, s), 6.87 (1H, s), 7.2—7.9 (10H, m); MS (20 eV), *m/e* (rel intensity), 286 (M^+, 10), 181 (M−PhCO$^+$, 38), 105 (PhCO$^+$, 72), 43 (Ac$^+$, 100).

*^{18}O-Distribution in the Ester Function of the Pummerer Product (**8b**).* The Pummerer product **8b** (220 mg) with 0.243 ex. atom% of ^{18}O was heated with three equivalent amounts of phenylhydrazine (250 mg) at 120 °C for 1 h. Into this red solution, benzene was added to precipitate 1-acetyl-2-phenylhydrazine which was filtered off and washed with benzene. Then the product was recrystallized from benzene giving colorless crystals (59 mg, 51% yield) with mp 129—131 °C, and 0.411 ex. atom% of ^{18}O.

Authors are grateful to Dr. Fujiko Iwasaki, The University of Electro-Communications, for X-ray crystallographic analysis of **4**, and for Torey Science and Technology Prize and Grants for 1980 and Grant-in-Aid for Scientific Reseach B No. 00547018 of the Ministry of Education, Science and Culture for 1980, which enabled us to continue the research works along this line.

Predominant Intramolecular Pummerer Reactions of Substituted Benzyl *p*-Tolyl Sulfoxides with Acetic Anhydride

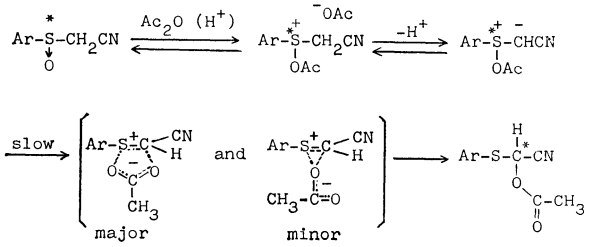
Osamu Itoh, Tatsuo Numata, Toshiaki Yoshimura, and Shigeru Oae*

Department of Chemistry, University of Tsukuba, Niihari-gun, Sakura-mura, Ibaraki 305

(Received June 7, 1982)

In the Pummerer reactions of ^{18}O-labeled benzyl, and 3,5-dichlorobenzyl *p*-tolyl sulfoxides with a large excess of unlabeled acetic anhydride in the presence of DCC as acid scavenger, the resulted Pummerer reaction products, the α-acetoxy sulfides, were found to have retained substantial amounts of ^{18}O-label of the original sulfoxides, *i.e.*, nearly a half or more. Meanwhile, when optically active benzyl, 3-chlorobenzyl, and 3,5-dichlorobenzyl *p*-tolyl sulfoxides were allowed to react with excess acetic anhydride in the presence of DCC, the α-acetoxy sulfides, the Pummerer reaction products obtained, were found to have no optical activity. These observations suggest that the acetoxyl migration from sulfur atom to α-carbon is predominantly intramolecular, however, the α-(*p*-tolylthio) carbenium acetate ion-pair formed during the reaction prior to racemization is less intimate than those which are formed in the reactions of cyanomethyl and (α-carbonyl-substituted methyl) *p*-tolyl sulfoxides which give the corresponding highly optically active α-acetoxy sulfides.

Most early examples of the Pummerer reaction in the mechanistic studies were found to be intermolecular rearrangements, based mainly on ^{18}O-tracer experiments.[1,2] Sulfoxides are usually dialkyl or aryl alkyl derivatives and the rate-determining setp is generally the α-proton-removal from the acyloxysulfonium salts after the initial acylation of the sulfoxides. Years later, we found a clear-cut case of intramolecular 1,2-rearrangement of acetoxyl group by the aid of ^{18}O-tracer experiments and stereochemistry; namely the Pummerer reaction of optically acetive aryl cyanomethyl sulfoxide with acetic anhydride was stereospecific, inducing a partial asymmetry at α-carbon and most of the ^{18}O-label in the original sulfoxide was retained in the resulted α-acetoxy sulfide.[3] Many more examples of intramolecular Pummerer reaction have been found ever since.[2,4] In these intramolecular rearrangements, the rate-determining step is generally the S–O bond cleavage after the reversible proton removal from the acetoxysulfonium intermediate, and the asymmetric induction from the chiral sulfur atom to the prochiral α-carbon is believed to be due to both the very tight nature of the α-thio carbenium acetate ion-pair, and the very rapid recombination, *i.e.*, ion-pair return.

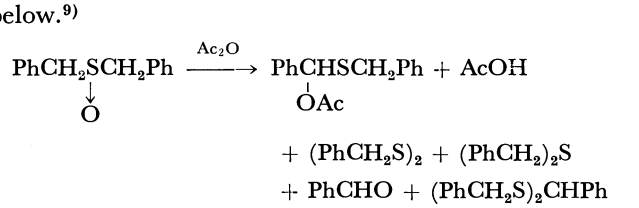


In the solvolytic S_N1 type reactions of optically active alkyl arenesulfonate-^{18}O, stereochemistry and the extent of oxygen scrambling are known to vary with the change of the alkyl derivatives and the reaction medium, and closely related to the tightness of the ion-pair formed by the initial cleavage of C–O bond of the sulfonate.[5] There are cases that the internal return is nearly quantitative with partial oxygen scrambling, however, with nearly complete racemization.[6]

We now have found the Pummerer reaction which proceeds predominantly intramolecularly, however, the original chirality of the sulfoxide is completely lost in the resulted α-acetoxy sulfide, namely, in the Pummerer reactions of benzyl, 3-chlorobenzyl, and 3,5-dichlorobenzyl *p*-tolyl sulfoxides (**1**, **3**, and **5**) with acetic anhydride in the presence of dicyclohexylcarbodiimide (DCC), scavenger of acetic acid. This paper deals with the mechanistic investigation with our usual ^{18}O-tracer and stereochemical experiments and their implication on the understanding of the mechanism.

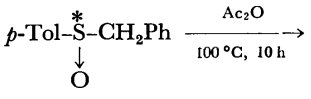
Results and Discussion

Earlier, when ^{18}O-labeled and optically active aryl benzyl sulfoxides were treated with acetic anhydride at about 100 °C for 1—2 h in polar media, the main reaction was found to be the oxygen exchange which causes racemization and the Pummerer reaction was of rather minor.[7] However, dibenzyl sulfoxide has been known to undergo the Pummerer reaction with acetic anhydride,[8] and when the reaction was carried out at 76 °C, Wilson *et al.* actually obtained the Pummerer rearrangement product, the α-acetoxy sulfide which upon heating further with acetic acid decomposed to afford benzyl disulfide, benzyl sulfide, benzaldehyde and α,α-bis(benzylthio)toluene, as shown below.[9]



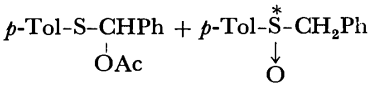
When the reaction of ^{18}O-labeled benzyl *p*-tolyl sulfoxide (**1**) [1.246 ex. atm% of ^{18}O] was allowed to react again, however, this time with a large excess of acetic anhydride in the presence of an equimolar amount of DCC which scavenges acetic acid formed, at 100 °C for 10 h, the corresponding Pummerer reaction product, *i.e.*, α-acetoxy sulfide **2**, was obtained in *ca.* 10% yield while recovering much of the original sulfoxide. The recovered sulfoxide was found to retain 99.6% of original ^{18}O; namely, 1.241 ex. atom% of ^{18}O and the α-acetoxy sulfide was found to be incorporated with 46% of the original ^{18}O-label of the sulfoxide, namely 0.286 ex. atom% of ^{18}O, respectively.

This means, that the oxygen exchange of the sulfoxide with acetic anhydride is catalyzed markedly by acetic acid or any acid formed or present in the reaction mixture, while the overall rearrangement is predominantly intramolecular. However, when optically active benzyl *p*-tolyl sulfoxide (**1**) was allowed to react with excess acetic anhydride in the presence of DCC under the same conditions, the corresponding α-acetoxy sulfide (**2**) was found to have no optical activity while the sulfoxide recovered was found to have retained 90% of the original optical activity. Since α-acetoxybenzyl *p*-tolyl sulfide (**2**) formed in the reaction would be rather unstable, the chirality, once induced in the α-acetoxy sulfide **2** might have lost upon prolonged heating. However, in view of the high retention of



1

$[\alpha]_D$ +251°



2 recovered

$[\alpha]_D$ 0° $[\alpha]_D$ +243°

^{18}O in the resulting product **2**, the racemization of the α-acetoxy sulfide after its formation is rather inconceivable. Probably the ion-pair between the α-sulfur stabilized carbenium ion and acetate ion-pair is less intimate than those which are formed in the reactions of cyanomethyl aryl sulfoxide and (α-carbonyl-substituted methyl) aryl sulfoxides with acetic anhydride, though the ion-pair would be intimate enough to hold the original ^{18}O. Substitution of an electron-withdrawing group would increase the tightness of the ion-pair so that the corresponding resulting α-acetoxy sulfides can keep more of the original ^{18}O-label of the sulfoxide in the resulted α-acetoxy sulfide **2**, which might also be asymmetrically induced as in the Pummerer reaction of aryl cyanomethyl sulfoxide with acetic anhydride. Thus, the Pummerer reactions of optically active 3-chlorobenzyl *p*-tolyl and 3,5-dichlorobenzyl *p*-tolyl sulfoxides (**3** and **5**) were carried out. When these two optically active sulfoxides were allowed to react with excess acetic anhydride in the presence of 5 equivalent amounts of DCC for 4 h at 120 °C and 130 °C, respectively, the resulting both α-acetoxy sulfides **4** and **6** had no optical activity, while the recovered sulfoxides ($[\alpha]_D$ 290.3° for **3** and $[\alpha]_D$ 164° for **5**) retained the optical activities substantially.

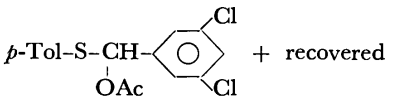
5 $[\alpha]_D$ +288°



6 $[\alpha]_D$ 0° $[\alpha]_D$ +164°

When ^{18}O-labeled 3,5-dichlorobenzyl *p*-tolyl sulfoxide (**5**) [0.790 ex. atom% of ^{18}O] was heated with a large excess acetic anhydride (60 equiv. amount) in the presence of 5 equiv. amount of DCC under the same conditions for the optically active sulfoxide **5**, the corresponding α-acetoxy sulfide **6** obtained in 9% yield, was found to retain 65% of ^{18}O [0.255 ex. atom% of ^{18}O] of the original ^{18}O-label in the starting sulfoxide **5**. The retention of 65% of ^{18}O in the ester **6** is substantially higher than that, *i.e.*, 46%, found in the ester **2** formed in the reaction of benzyl *p*-tolyl sulfoxide. This means that due to the destabilization of the carbenium ion formed from the acetoxysulfonium ylide derived from benzyl *p*-tolyl sulfoxide bearing two electron-withdrawing chlorines on the aromatic ring of the benzyl group, the ion-pair formed between 3,5-dichlorophenyl(*p*-tolylthio)methylium ion and acetate is considered to be more intimate than that derived from the reaction of unsubstituted benzyl *p*-tolyl sulfoxide and hence the intramolecularity of the migration of acetoxyl group increased. However, this intimate ion-pair is not enough to transfer the chirality on the sulfur atom to α-carbon. The lack of asymmetric induction into the benzylic α-carbon may be partly due to the highly resonance-stabilized nature of benzylic cation.

The Pummerer reaction of aryl benzyl sulfoxides would be at the threshold between a typical intramolecular and an intermolecular rearrangements in the mechanistic stectrum of the 1,2-acetoxyl migration which would reflect on the extent of tightness of the intimate ion-pair formed from the intermediary acetoxysulfonium ylide.

Experimental

General. All melting points were uncorrected. IR spectra were taken on a Hitachi 260-50 spectrometer. NMR spectra were recorded with a Hitachi Perkin-Elmer R-20 spectrometer in $CDCl_3$ using TMS as an internal standard. Mass spectra were determined with a Hitachi RMU-6MG mass spectrometer. Acetic anhydride was purified by stirring with sodium metal for 7 d followed by refluxing under reduced pressure below 50 °C for 5 h under vacuum and then distillation under reduced pressure, bp 47—48 °C/20 mmHg.**

^{18}O-*Analysis.* ^{18}O-Analysis was carried out by the method developed by Rittenberg and Ponticorvo,[10] with a modification which involves the use of $Pb(OAc)_2$ to remove H_2S gas from the gas produced by the thermolysis of sample: About 20 mg of sample was pyrolyzed with

** 1 mmHg≈133.3 Pa.

250 mg each of purified $HgCl_2$ and $Hg(CN)_2$, respectively, in an evacuated sealed Pyrex tube at *ca.* 500 °C for 12 h. Then the tube was broken in a vacuum line and CO_2 gas formed was purified by distillation and the mass peaks of *m/e* 44 and 46 which correspond to $C^{16}O_2$ and $C^{16}O^{18}O$, respectively, were recorded on a mass spectrometer.

Materials. Optically Active Benzyl p-*Tolyl Sulfoxide (1)*:[11] The optically active **1** was prepared by known method[11] from menthyl *p*-toluenesulfinate and benzyl Grignard reagent. $[\alpha]_D$ +251° (acetone).

^{18}O-*Labeled Benzyl* p-*Tolyl Sulfoxide (1)*: The corresponding sulfide (2.16 g, 10 mmol) prepared from benzyl chloride and *p*-toluenethiol was dissolved in a mixture of acetic acid (40 ml), pyridine (2.4 g) and ^{18}O-enriched water (4 ml, 1.5 atom%). To the cooled solution was added bromine (1.60 g, 10 mmol) at 0 °C.[12] When reaction was complete, 100 ml of water was added and extracted with 100 ml portions of chloroform. The chloroform solution was washed with aqueous $Na_2S_2O_3$ solution, diluted aqueous HCl solution and water, and then dried ($MgSO_4$). The solvent was removed and the residue was recrystallized from ethyl acetate–hexane to give the ^{18}O-labeled **1** in 70% yield (1.629 g). The title sulfoxide was found to contain 1.246 ex. atom% of ^{18}O.

Optically Active 3-Chlorobenzyl p-*Tolyl Sulfoxide (3)*: To a stirred solution of 3-chlorobenzylmagnesium chloride prepared from 3-chlorobenzyl chloride (1.23 g, 8 mmol) and magnesium (194 mg, 8 mmol) in 100 ml of dry ether at −15 °C under argon was added diastereomerically pure (−)-menthyl *p*-toluenesulfinate (1.176 g, 4 mmol) at −78 °C. The work-up mentioned above gave the title sulfoxide **3** (972 mg, 92% yield) with $[\alpha]_D$ +295° (acetone). Mp 88—88.5 °C; IR (KBr) 1045 and 820 cm^{-1}; NMR ($CDCl_3$) δ= 7.18—6.73 (8H, m), 3.83 (2H, s), 2.37 (3H, s); Found: C, 63.52; H, 4.90%. Calcd for $C_{14}H_{13}ClOS$: C, 63.50; H, 4.94%.

^{18}O-*Labeled Optically Active 3,5-Dichlorobenzyl* p-*Tolyl Sulfoxide (5)*: To a stirred solution of 3,5-dichlorobenzylmagnesium chloride prepared from 3.128 g (16 mmol) of 3,5-dichlorobenzyl chloride in dry ether at −15 °C under argon was added at −78 °C ^{18}O-labeled diastereomerically pure (−)-menthyl *p*-toluenesulfinate (2.35 g, 8 mmol, $[\alpha]_D$ −199° in acetone) synthesized from the reaction between ^{18}O-labeled *p*-toluenesulfinyl chloride and *l*-methol. The usual work-up gave the title sulfoxide **5** (1.568 g) which have an optical activity $[\alpha]_D$ +288° and ^{18}O-content was found to be 0.790 ex. atom%. Mp 106.5—107 °C; IR (KBr) 1560, 1040, and 800 cm^{-1}; NMR ($CDCl_3$) δ=7.17—6.73 (7H, m), 3.87 (2H, s), and 2.35 (3H, s); Found: C, 56.40; H, 4.04%. Calcd for $C_{14}H_{12}OSCl_2$: C, 56.19; H, 4.40%. Racemic **5** was also prepared by oxidation of the corresponding sulfide with H_2O_2 in acetic acid. Mp 130—130.5 °C.

Reaction of ^{18}O-*Labeled Benzyl* p-*Tolyl Sulfoxide (1) with Acetic Anhydride.* After the ^{18}O-labeled sulfoxide **1** (1.2 g) was heated with 60 equiv. molar amount of acetic anhydride to the sulfoxide in the presence of 5 equiv. DCC at 100 °C for 10 h, a large excess acetic anhydride and any volatile substance were removed under vacuum to afford the residue which was separated through silica gel column chromatography with hexane–ethyl acetate (4:1) and then with chloroform as eluents. The Pummerer product **2** (92 mg) and the sulfoxide (840 mg) which were found to contain 0.288 and 1.241 ex. atom% of ^{18}O, respectively. **2**: mp 66—67 °C; IR (KBr) 1740 and 1220 cm^{-1}; NMR ($CDCl_3$) δ=7.25 (1H, broad s), 7.08 (1H, s) and 1.99 (3H, s). Since **2** is unstable, it was converted to the corresponding sulfone: mp 153—154 °C; IR (KBr) 1755, 1320, 1220, and 1160 cm^{-1}; Found: C, 63.22; H, 5.30%. Calcd for $C_{16}H_{16}O_4S$: C, 63.14; H, 5.29%.

Reaction of Optically Active Benzyl p-*Tolyl Sulfoxide (1) with Acetic Anhydride in the Presence of DCC.* When the optically active sulfoxide **1** (220 mg, $[\alpha]_D$ +251° was heated with 5 ml of acetic anhydride at 100 °C for 10 h in the presence of 5 equiv. DCC to the sulfoxide, the resulting semi-oily residue obtained, after evaporation of excess acetic anhydride and any volatile product *in vacuo*, was separated through silica gel column chromatography with hexane–ethyl acetate (4:1) and then with benzene–ethyl acetate (4:1) as eluents at 0—4 °C in a low-temperature room. The Pummerer product (**2**, $[\alpha]_D$ 0°) was obtained in 10% yield and the sulfoxide recovered was purified through alumina column chromatography with hexane–ethyl acetate (3:1) and then silica-gel column chromatography with chloroform to afford the sulfoxide (158 mg, $[\alpha]_D$ +243°) which retained 97% of optical activity based on the starting sulfoxide.

Reaction of Optically Active 3-Chlorobenzyl p-*Tolyl Sulfoxide (3) with Acetic Anhydride in the Presence of DCC.* After the optically active sulfoxide **3** (397 mg, $[\alpha]_D$ +295°) was heated at 120 °C for 4 h with 7 ml of acetic anhydride in the presence of 5 equiv. DCC, the usual work-up and silica-gel column chromatography with hexane–ethyl acetate (4:1) in a low-temperature room gave the Pummerer product **4** (43.3 mg, 9.4% yield, $[\alpha]_D$ 0°) while the chromatography with benzene–ethyl acetate (4:1) as eluents at room temperature afforded the sulfoxide recovered which was further purified through alumina and then silica-gel column chromatography using hexane–ethyl acetate (3:1) and chloroform, respectively, giving the pure sulfoxide **3** (359 mg, $[\alpha]_D$ +290.3°). **4**: Oil; IR (neat) 1745 and 1217 cm^{-1}; NMR ($CDCl_3$) δ=6.80—7.23 (9H, m), 2.27 (3H, s), 2.00 (3H, s). Sulfone derivative of **4**: mp 113—114 °C; IR (KBr) 1760, 1320, 1205, and 1155 cm^{-1}; NMR ($CDCl_3$ δ=7.08—7.55) (8H, m), 6.55 (1H, s), 2.38 (3H, s); Found: C, 56.81; H, 4.46%. Calcd for $C_{16}H_{15}ClO_4S$: C, 56.72; H, 4.46%.

Reaction of ^{18}O-*Labeled Optically Active 3,5-Dichlorobenzyl* p-*Tolyl Sulfoxide (5) with Acetic Anhydride in the Presence of DCC.* When the title sulfoxide **5** (800 mg) was heated with 60 equiv. acetic anhydride in the presence of 5 equiv. DCC at 130 °C for 4 h, after the usual work-up and chromatography through silica gel with benzene and chloroform as eluents the Pummerer product **6** (64 mg, 7% yield) and the sulfoxide recovered which was purified through alumina column chromatography with hexane–ethyl acetate (4:1) as an eluent giving the pure sulfoxide in 93% yield (716 mg). The Pummerer product had practically no optical rotation but the ^{18}O-content was found to be 0.255 ex. atom% of ^{18}O. No enathiomeric excess of the Pummerer product was observed from a measurement of NMR contact shift using chiral lanthanoids shift reagent, $Eu(hfc)_3$. **6**: Mp 63.5—64 °C; IR (KBr) 1740, 1230, and 800 cm^{-1}; NMR ($CDCl_3$) δ=7.20—6.85 (7H, m), 6.78 (1H, s), 2.30 (3H, s), 2.10 (3H, s); Found: C, 56.43; H, 4.12%. Calcd for $C_{16}H_{14}Cl_2O_2S$: C, 56.31; H, 4.13%.

Intermolecular Stereoselective Pummerer Reactions of 4-(*p*-Chlorophenyl)thiane 1-Oxides and *trans*-1-Thiadecalin 1-Oxides and 2-Thiadecalin 2-Oxides with Acetic Anhydride

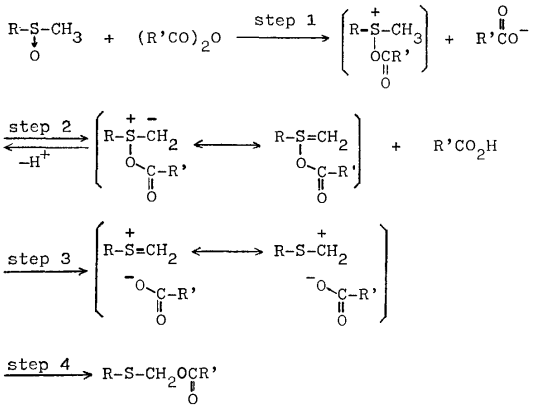
Shigeru Oae,* Osamu Itoh, Tatsuo Numata, and Toshiaki Yoshimura
Department of Chemistry, University of Tsukuba, Niihari-gun, Sakura-mura, Ibaraki 305

(Received June 7, 1982)

The Pummerer reactions of conformationally fixed 4-(*p*-chlorophenyl)thiane 1-oxides and *trans*-1-thiadecalin 1-oxides and *trans*-2-thiadecalin 2-oxides with acetic anhydride are either stereoselective or stereospecific, both in the absence and in the presence of a scavenger of acetic acid formed, such as dicyclohexylcarbodiimide (DCC) or 2,6-lutidine. However, the ^{18}O-tracer experiments with the ^{18}O-labeled sulfoxide revealed the reaction to be an intermolecular rearrangement, while the kinetic experiment with α-deuterated 4-(*p*-chlorophenyl)thiane 1-oxides gave sizable values of kinetic isotope effect, *i.e.*, 2.8 for the *cis* isomer and 3.4 for the *trans* isomer. In the reaction of 4-arylthiane 1-oxides with acetic anhydride, the thermodynamically controlled product is axial 2-acetoxy-4-(*p*-chlorophenyl)thiane while the kinetically controlled product is the equatorial isomer which is formed in the presence of the acid scavenger, DCC. In the Pummerer reaction of the thiadecalins *S*-oxides the equatorial α-acetoxy sulfides are the preferential products, however, the isomer preference is more pronounced in the reaction with DCC. These observations, along with other pertinent data seem to suggest that the rate-determining step in the Pummerer reaction of these simple heterocyclic sulfoxides is E2 elimination of acetic acid from the acetoxysulfonium intermediates.

Since Horner proposed[1] to call the reaction between alkyl sulfoxides with acetic anhydride leading to the formation of corresponding α-acetoxy sulfides as the Pummerer reaction fifty years after the original works of Pummerer,[2] numerous investigations have been carried out to clarify the mechanism of this interesting rearrangement and the mechanistic studies on the Pummerer reaction have been well-documented in many reviews in recent years.[3-10]

The general scheme of the Pummerer reaction is believed to be shown in the following four sequential steps of elemental reactions and the rate-determining step is known to vary with changes of both the acylating agent and the sulfoxide.[8,9] Many of the early examples of the Pummerer reactions of open chain alkyl sulfoxides with acetylating reagents were shown by ^{18}O-tracer studies to be intermolecular rearrangements which have the rate-determining step at step 2 and no stereoselectivity or specificity was observed.[11,12]



Recently, however, several examples of the Pummerer reactions which proceed through intramolecular migration to afford stereoselective (or stereospecific) products have been reported.[13-17] In most of these intramolecular rearrangements, the slowest step has been shown to be the S–O bond cleavage at step 3 with a few exceptions in which the step 1 is the rate-determining.[18,19] Among several examples of the Pummerer reaction of *S*-oxides of sulfur-heterocycles with acetic anhydride, stereoselectivity was observed in only two cases of five-membered sulfur-heterocycles, *i.e.*, *S*-oxides of thiosugar derivatives[20] and *S*-oxides of 1,3-oxathiolane derivatives.[21] However, no legitimate observation was made as to the nature of acetoxyl migration. Thus, the only example of intermolecular stereoselective Pummerer reaction of the *S*-oxide of a simple sulfur-heterocycle has been that of 4-(*p*-chlorophenyl)thiane 1-oxide (**1**) with acetic anhydride.[22] We now have found that another example of intermolecular stereoselective Pummerer reaction, *i.e.*, the reaction of conformationally rigid *trans*-1-thia- and 2-thiadecalin *S*-oxides (**3** and **5**) with acetic anhydride. This paper gives a full account of our mechanistic investigation on the Pummerer reactions of *cis*- and *trans*-4-(*p*-chlorophenyl)thiane 1-oxides (**1c** and **1t**) and *trans*-1-thiadecalin 1-oxides (axial **3a** and equatorial **3e**) and 2-thiadecalin 2-oxides (axial **5a** and equatorial **5e**) with acetic anhydride.

Results and Discussion

*Reaction of 4-(*p*-Chlorophenyl)thiane 1-Oxides with Acetic Anhydride.* Configurationally fixed *cis*- and *trans*-4-(*p*-chlorophenyl)thiane 1-oxides (**1c** and **1t**) were allowed to react with excess acetic anhydride with or without DCC or 2,6-lutidine, the acetic acid scavenger, both the axial 2-acetoxy-4-(*p*-chlorophenyl)thiane (**2a**), and the equatorial isomer (**2e**), were obtained along with the elimination product, *i.e.*, 4-(*p*-chlorophenyl)-3,4-dihydro-2*H*-thiopyran (**2o**) in the ratios as summarized in Table 1.

When the sulfoxides, **1c** and **1t** were heated with a large excess of acetic anhydride at 100 °C, only the corresponding axial α-acetoxy sulfide **2a** and the olefinic product **2o** were obtained in 72—73% and 20% yields, respectively (runs 1 and 2). The axial α-acetoxy sulfide **2a** was found to be formed stereoselectively (**2e**:**2a**=1:15) from both the *trans*-sulfoxide **1t** and the *cis* isomer **1c**. Whereas, when the sulfoxides (**1t** and **1c**) were allowed to react with excess acetic anhydride in the presence of dicyclohexylcarbodiimide (DCC) or 2,6-lutidine at 100 °C for 4—6 h, the pre-

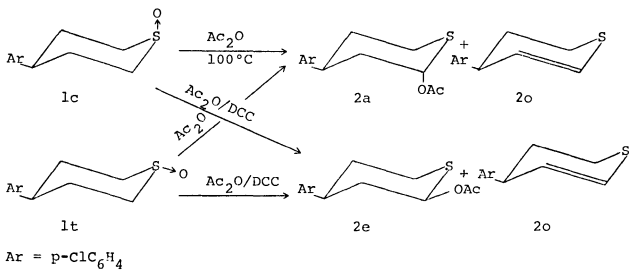

Fig. 1.

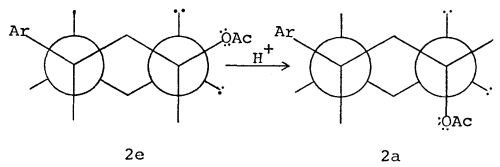

Fig. 2.

ferential product, obtained in 77—80% yield, was the equatorial α-acetoxy sulfide **2e**. Thus, the stereoselectivity of the reaction was found to be changed drastically by addition of DCC or 2,6-lutidine into the reaction mixture (runs 5—11). For example, treatment of the two isomeric sulfoxides with acetic anhydride in the presence of 5 equiv. amounts of DCC gave the corresponding crystalline equatorial α-acetoxy sulfide **2e** as the main product (runs 8 and 9) as shown in Fig. 1.

These interesting stereoselectivities in the Pummerer reaction suggest that the equatorial α-acetoxy sulfide **2e** is the kinetically controlled product and the equatorial α-acetoxy sulfide **2e** is isomerized in the presence of acetic acid formed to the axial isomer **2a** when there is no acid scavenger such as DCC or 2,6-lutidine. Indeed, in the presence of acetic acid, the equatorial α-acetoxy sulfide was found to isomerize readily to the axial isomer **2a** which is considered to be more stable than the equatorial isomer **2e** due mainly to the less electron repulsion between the lone electron pairs of sulfur atom and those of terminal oxygen in **2a** than that in **2e**, as illustrated in Fig. 2.

When one compares runs 1 and 2 with 3 and 4,

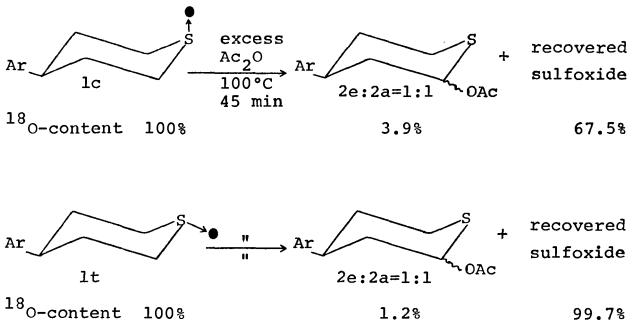

Fig. 3.

the isomerization is found to be multiplied by acetic acid formed in the reaction mixture. Upon treatment of the equatorial isomer **2e** with hot acetic anhydride in the presence of acetic acid at 100 °C for 3 h, the axial isomer **2a** and the olefinic product **2o** were obtained in 70 and 20% yields, respectively. The olefinic sulfide **2o** would obviously be formed by 1,2-elimination of acetic acid from the axial isomer **2a**.

In order to scrutinize the nature of acetoxyl migration, our usual ^{18}O-tracer experiments were carried out using the ^{18}O-labeled sulfoxides and the acetoxyl migration was found to proceed intermolecularly based on the following observations. Namely, when the ^{18}O-labeled *trans*-sulfoxide **1t** [1.092 ex. atom%] was treated with 60 mol equivalents of acetic anhydride at 100 °C for 45 min, during when the reaction was at about half completion, the recovered sulfoxide, [1.089 ex. atom% of ^{18}O], was contaminated with no *cis* sulfoxide **1c**, while the sulfoxide recovered was found to have retained the original ^{18}O-content nearly completely. Whereas, the Pummerer rearrangement product, the α-acetoxy sulfide **2**, was found to retain only 0.013 ex. atom% of ^{18}O which corresponds to 1.2% incorporation of ^{18}O from the starting sulfoxide **1t**-^{18}O. The ^{18}O-labeled *cis* sulfoxide **1c**-^{18}O, [0.495 ex. atom% of ^{18}O] under the same conditions gave the recovered sulfoxide and the Pummerer rearrangement product of which ^{18}O-contents were found to be 0.334 and 0.019 ex. atom% of ^{18}O, which corresponds to 3.9% incorporation of ^{18}O from the starting sulfoxide **1c**-

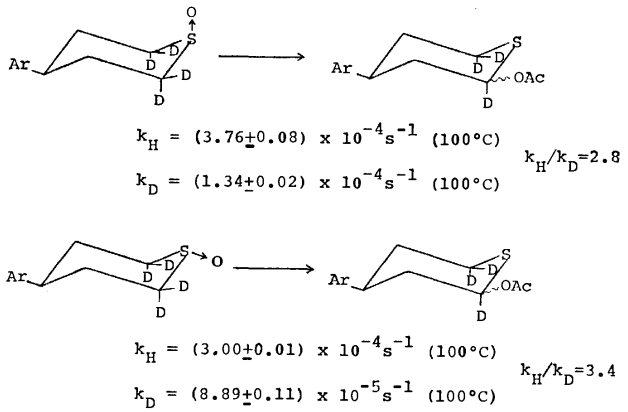

Fig. 5.

^{18}O respectively. The *cis*-sulfoxide **1c**-^{18}O was shown to undergo concurrent oxygen exchange in acetic anhydride[23] to the extent of 35% as illustrated in Fig. 3. All these ^{18}O-tracer data reveal clearly the acetoxyl migration is intermolecular, and the rearrangement is considered to proceed through the formation of the α-sulfenyl carbenium ion intermediate **7** which is then attacked by external acetoxyl group preferentially from the direction (path a) to give the equatorial α-acetoxy sulfide **2e**. The acid-catalyzed isomerization of the α-acetoxy sulfide **2e** to the other isomer **2a** is also considered to proceed via the formation of the carbenium ion intermediate **7** as shown in Fig. 4.

In the Pummerer reaction of most alkyl sulfoxides with acetic anhydride, the rate-determining step seems to be the proton-removal, *i.e.*, step 2, or E2 type elimination of acetic acid in the general scheme of the reaction, as revealed in a few sizable values of kinetic isotope effect, k_H/k_D, found in the rearrangements.[12,24] In order to find out the rate-determining step of the Pummerer reaction of 4-(*p*-chlorophenyl)thiane 1-oxides with acetic anhydride, kinetic experiments with 4-(*p*-chlorophenyl)thiane-2,2,6,6-d_4 1-oxides were carried out, and the values of the kinetic isotope effect (k_H/k_D) were found to be 2.8 for the *cis* isomer and 3.4 for the *trans* isomer. The sizes of the kinetic isotope effects are similar to that in the Pummerer reaction of methyl phenyl sulfoxide with acetic anhydride as illustrated in Fig. 5. Thus the rate-determining step of this reaction is clearly the step 2. If the subsequent S–O bond cleavage is very fast, as was found to be the case, the proton-removal could actually be a part of the E2 reaction, which was found to be the most likely in view of the stereochemistry of the Pummerer reaction of more rigid *trans*-1-thia- and 2-thiadecalin *S*-oxides (**3** and **5**) with acetic anhydride, (*vide infra*).

Reaction of trans-*1-Thiadecalin 1-Oxides (**3**) and* trans-*2-Thiadecalin 2-Oxides (**5**) with Acetic Anhydride.* In the Pummerer reaction of conformationally rigid 4-(*p*-chlorophenyl)-thiane 1-oxides (**1c** and **1t**) with acetic anhydride, the kinetically controlled initial product was the equatorial α-acetoxy thiane **2e**, although the rearrangement was shown to be intermolecular. The stereoselectivity is expected to be more pronounced in the Pummerer reaction of more rigid heterocyclic sulfoxides. Our choice sulfoxides are *trans*-1-thiadecalin 1-oxides (axial **3a** and equatorial **3e**) and *trans*-2-thiadecalin 2-oxides (axial **5a** and equatorial **5e**) which are conformationally more rigid six-membered cyclic sulfoxides than 4-(*p*-chlorophenyl)thiane 1-oxides (**1c** and **1t**). When *trans*-1-thiadecalin 1-oxides (**3a** and **3e**) were allowed to react with excess acetic anhydride at 100 °C for 3—4 h, both in the absence and in the presence of DCC, both the corresponding axial α-acetoxy sulfide **4a** and the equatorial isomer **4e** were obtained, respectively. Similarly, in the reactions between *trans*-2-thiadecalin 2-oxides (**5a** and **5e**) and acetic anhydride at 100 °C for 3 h, both the corresponding axial and equatorial α-acetoxy sulfides [(**6a1**:**6a3**=1:1) and (**6e1**:**6e3**=1:1)] were obtained, respectively both in the absence and in the presence of DCC, as illustrated in Fig. 6.

These data reveal clearly that there is a preferential direction for acetate ion to attack the α-sulfenyl stabilized carbenium ion, *i.e.*, the attack of acetate takes place at the opposite side of γ-axial hydrogen to avoid the steric repulsion of the γ-axial hydrogen. The preferential formation of the equatorial acetoxy sulfides is more pronounced in the Pummerer reactions of these

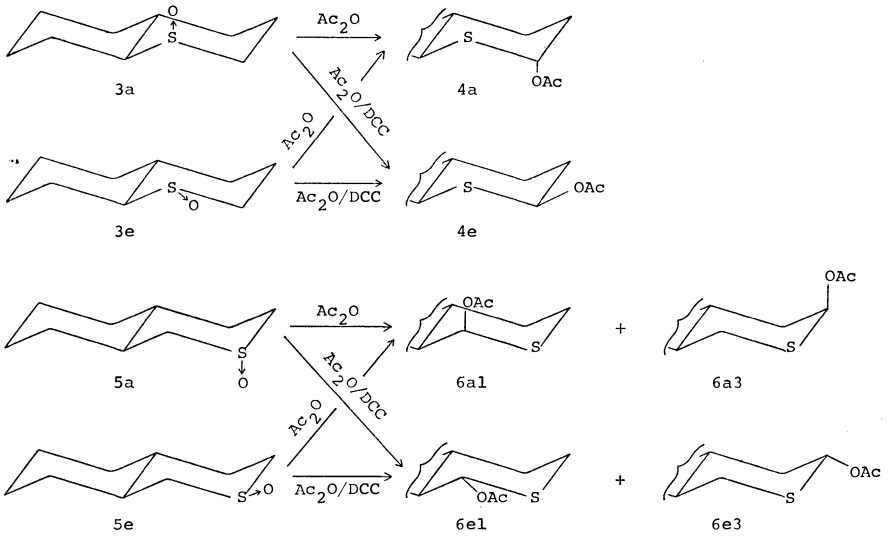

Fig. 6.

Table 2. ^{18}O-Experiments in the reaction of *trans*-1-thiadecalin-1-oxides with acetic anhydride

Sulfoxide (ex. atom% of ^{18}O)	Reaction conditions		Pummerer products			Recovered sulfoxide		
	t/°C	t/min	Yield %	(ex. atom%)	Incorporation %	Yield %	(ex. atom%)	Retention %
3a (0.856)	Ac_2O		28	**4e** (0.057)[a]	13	25	(0.710)	83
	100	45	(**4e**:**4a**=6:1)	**4a** (0.043)[a]	10

	100	75	(**4e**:**4a**=19:1)					
3e (0.955)	Ac_2O		37	(0)[b]	0	53	(0.774)	81
	100	45	(**4e**:**4a**=8:1)					
3e (0.955)	Ac_2O/DCC		34	(0)[b]	0	59	(0.812)	85
	100	75	(**4e**:**4a**=19:1)					

a) Axial and equatorial acetoxy sulfides were separated through silica-gel column chromatography, and their ^{18}O-contents were analyzed. b) A mixture of axial and equatorial acetoxy sulfides was subjected to ^{18}O-analysis.

highly rigidly fixed *trans*-1- and 2-thiadecalin *S*-oxides. Addition of DCC, the scavenger of acetic acid, was also found to slow down the reaction but the isomeric preference is more remarkable in favor for the equatorial acetoxy sulfides.

The usual ^{18}O-tracer experiments were carried out with ^{18}O-labeled *trans*-1-thiadecalin 1-oxides (**3a**-^{18}O and **3e**-^{18}O) with acetic anhydride both in the absence and in the presence of DCC and the results are shown in Table 2.

The results are quite interesting. The Pummerer reaction of the equatorial sulfoxide **3e** is obviously an intermolecular rearrangement since the acetoxyl group of the resulted ester was found to be completely diluted with oxygen of excess acetic anhydride, while the sulfoxide recovered retained more than 80% of original ^{18}O-label both in the absence and in the presence of DCC. The Pummerer reaction of the axial sulfoxide **3a** is also an intermolecular rearrangement, though the incorporation of 13% or 16% of ^{18}O of the original sulfoxide in the 2-acetoxy-1-thiadecalin (**4**) and the sulfoxide recovered have 83% or 67% of original ^{18}O-label mean that the rearrangement is partially intramolecular. When one looks at the preferential conformations and conformational changes required for the rate-determining elimination of acetic acid and the subsequent rapid recombination for the Pummerer reactions of both isomeric sulfoxides, it is quite evident that both E2 type elimination of acetic acid and recombination with acetate in the reaction of the axial sulfoxide requires less conformational change, and hence the reaction of the axial sulfoxide would be more facile than that of the equatorial sulfoxide which would have to undergo conformational change for E2 elimination and also in the product formation. Perhaps, the facile E2 reaction of acetic acid and recombination would have increased the chance of intramolecular rearrangement for the axial sulfoxide **3a**.

One interesting observation we made was the stereochemistry of proton-removal and cleavage of acetate in this rearrangement. Thus, *trans*-1-thiadecalin-2e-*d* 1a-oxide (D:59%) (**9**), *trans*-1-thiadecalin-2a-*d* 1a-oxide (D:57%) (**10**), and *trans*-1-thiadecalin-2a-*d* 1e-oxide (D:57%) (**11**) were subjected to the Pummerer reaction with excess acetic anhydride in the presence of 5 equivalent amounts of DCC. The deuterium contents of the corresponding 2e-acetoxy sulfides were found to be 59, 13, and 50%, respectively, upon measurement of the NMR spectra using 14% of Eu(dpm)$_3$ shift reagent, to the α-acetoxy sulfides. As

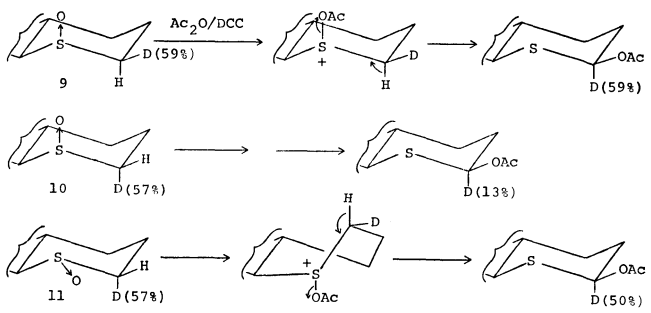

Fig. 7.

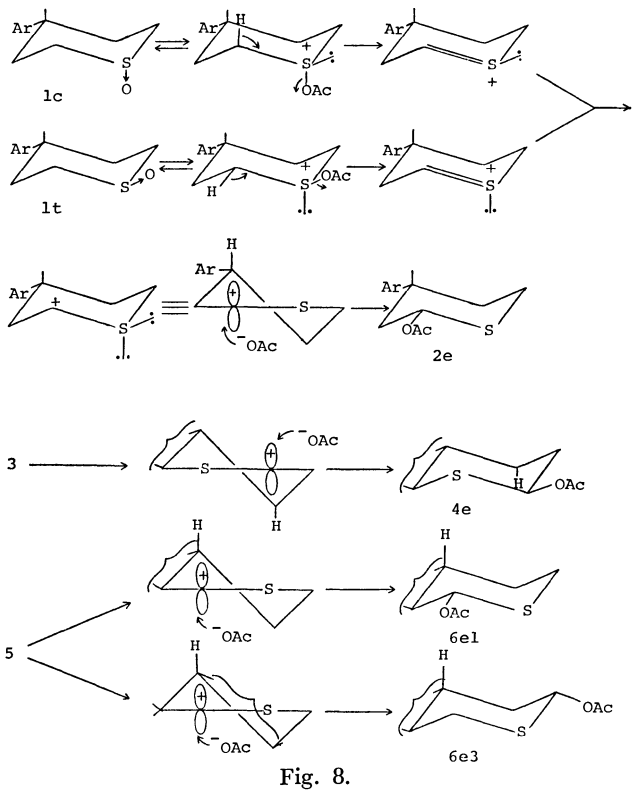

Fig. 8.

the mechanistic scheme indicates, the reaction of each isomer of 2-monodeuterated *trans*-1-thiadecalin 1-oxides gave only the corresponding each one product formed by the E2 elimination of acetic acid from the corresponding acetoxysulfonium intermediate as illustrated in Fig. 7. This is the first clean-cut example of *trans* E2 type elimination of acetic acid from the acetoxysulfonium intermediate in the Pummerer reaction, although E2 elimination was suggested early by us[6,9] and also Wolfe and Kazmeier.[25]

Conclusion

The Pummerer reaction of conformationally rigid six-membered thiane 1-oxides with acetic anhydride is stereoselective and the rearrangement is mainly intermolecular, while the rate-determining step appears to be the E2 1,2-elimination of acetic acid from the acetoxysulfonium intermediates formed in the initial acetylation of the sulfoxides. Meanwhile, the preferential formation of the equatorial α-acetoxy sulfides in the initial rearrangement is considered to be due to the facile sterically access of the acetate to the equatorial position, whereas the isomerization to the more stable axial α-acetoxy sulfide in the case of 4-arylthiane derivatives is catalyzed by acetic acid present in the system. Thus, the overall mechanism of the Pummerer reaction of these conformationally rigid thiane 1-oxides may be illustrated as shown in Fig. 8.

Experimental

General. All melting points were uncorrected. IR spectra were taken on a Hitachi 260-50 spectrometer. NMR spectra were recorded with a Hitachi Perkin-Elmer R-20 spectrometer in $CDCl_3$ using TMS as an internal standard. Mass spectra were determined with a Hitachi RMU-6MG mass spectrometer. Acetic anhydride was purified by stirring with sodium metal for 7 d, followed by a refluxing under reduced pressure below 50 °C for 5 h and then distillation under reduced pressure, bp 47—48 °C/20 mmHg.**

^{18}O-Analysis. ^{18}O-Analysis was carried out by the method developed by Rittenberg and Ponticorvo,[26] with a modification which involves the use of $Pb(OAc)_2$ to remove H_2S gas from the gas produced by the thermolysis of sample: about 20 mg of sample was pyrolyzed with 250 mg each of purified $HgCl_2$ and $Hg(CN)_2$, respectively in an evacuated sealed Pyrex tube at *ca.* 500 °C for 12 h. Then the tube was broken in a vacuum line and CO_2 gas formed was purified by distillation and the mass peaks of *m/e* 44 and 46 which correspond to $C^{16}O_2$ and $C^{16}O^{18}O$, respectively, were recorded on a mass spectrometer.

Materials. The NMR shift reagent $Eu(dpm)_3$ (tris-(dipivaloylmetanato)europium) is Dotite Reagents purchased from Wako Pure Chemical Co.

cis-*4*-(p-*Chlorophenyl)thiane 1-Oxide (**1c**)*: To a stirred solution of 4-(*p*-chlorophenyl)thiane[27] (1.06 g, 5 mmol) in 50 ml of dry methanol cooled to −70 °C in an acetone–Dry Ice bath was added an equimolar amount of *t*-butyl hypochlorite. When the temperature of the bath reached −40 °C, anhydrous sodium carbonate was added. The mixture was allowed to warm up to room temperature and methanol was removed under vacuum. The residue was washed three times with 50 ml portion of chloroform and the chloroform solution was dried. The solvent was evaporated to give a solid product **1c** containing a very small amount of *trans*-4-(*p*-chlorophenyl)thiane 1-oxide (**1t**). The product was recrystallized from ethyl acetate to afford a pure **1c**: mp 171—172 °C (lit,[27] 172.5—173 °C).

trans-*4*-(p-*Chlorophenyl)thiane 1-Oxide (**1t**)*: To a stirred solution of 4-(*p*-chlorophenyl)thiane[27] (1.06 g, 5 mmol) in 50 ml of dichloromethane cooled in an ice bath was added 1.05 equiv. of *m*-chloroperbenzoic acid. The solution was washed with saturated sodium hydrogencarbonate, and the aqueous layer was extracted with 50 ml of chloroform three times. The whole solution was washed with water, dried ($MgSO_4$) and evaporated to afford solid products which were separated through alumina column chromatography with ethyl acetate–chloroform (2:1) as the eluent giving *cis*-4-(*p*-chlorophenyl)thiane 1-oxide from the former solution, *trans*-4-(*p*-chlorophenyl)thiane 1-oxide from the latter solution. Then the solvent was removed to give the *cis* derivative (634 mg, 60%) and the *trans* derivative (372 mg, 35%). The *trans* derivative was recrystallized from ethyl acetate–hexane to afford a colorless crystals: mp 120—120.5 °C (lit,[27] 120—120.5 °C).

** 1 mmHg=133.3 Pa.

trans-*1-Thiadecalin*:[28] *trans*-1-Thiadecalin was prepared by the reported procedure.[28,29] After 4.86 g (30 mmol) of *trans*-2-allylcyclohexanethiol in 200 ml of dry benzene was refluxed in the presence of 1% benzoyl peroxide to the thiol for 10 h, the solvent was removed under reduced pressure. The resultant residue was separated through silica-gel column chromatography with hexane as an eluent to give an oily product (4.05 g, 86%).

trans-*1-Thiadecalin 1-Oxides (**3a** and **3e**)*: The sulfoxides **3a** and **3e** were prepared by the following three methods.

1) To a stirred solution of the corresponding sulfide (156 mg, 1 mmol) in 10 ml of dry methanol cooled to −70 °C with an acetone–Dry Ice bath was added 1 equiv. of *t*-butyl hypochlorite. When the temperature of the bath reached −40 °C, anhydrous sodium carbonate was added. The mixture was allowed to come up to room temperature and then methanol was removed under vacuum. The residue was washed four times with 20 ml portion of chloroform and the chloroform solution was dried and concentrated to afford an oily product which was purified through alumina column chromatography with ethyl acetate as an eluent, giving crystalline *trans*-1-thiadecalin 1-oxide (**3a**) (123 mg, 71% yield).

2) To a stirred solution of the sulfide (2.34 g, 15 mmol) in 150 ml of acetone cooled with an ice bath was added dropwise 1.05 equiv. of sodium periodate dissolved in the least amount of water in which the metaperiodate is soluble. Then the solution was stirred at room temperature for 2 h and poured into 100 ml of water. The solution was extracted with 100 ml of chloroform seven times. The combined solution was dried and concentrated to afford oily substances which were separated through alumina column chromatography with ethyl acetate–benzene as an eluent giving *trans*-1-thiadecalin 1a-oxide (**3a**, 947 mg) from the former solution, *trans*-1-thiadecalin 1e-oxide (**3e**, 374 mg) from the latter solution.

3) To a stirred solution of the sulfide (2.50 g, 6 mmol) and methanesulfonic acid (1.54 g, 8 mmol) in a 30 ml of methanol cooled with ice bath was added 1.1 equiv. of hydrogen peroxide in 30 wt%. The mixture was stirred at room temperature until the sulfide disappeared. The resulting mixture was extracted, dried over K_2CO_3 and then concentrated to give oily products which were separated as in the above-mentioned case. Sulfoxides **3a** and **3e** were obtained in 35% (985 mg) and 38% (1080 mg) yields, respectively. **3a**: mp 87—88 °C (lit,[30,31] 82.5—86.0 °C); IR (KBr) 2930 and 1027 cm^{-1}; Found: C, 62.67; H, 9.45%. **3e**: mp 71—72 °C (lit,[30,31] 72.0—74.0 °C); IR (KBr) 2930 and 1035 cm^{-1}; Found: C, 62.80; H, 9.39%.

trans-*2-Thiadecalin*: *trans*-2-Thiadecalin was synthesized by a similar method as reported by Birch *et al.*[32] from *trans*-1-bromomethyl-2-(2-bromoethyl)cyclohexane prepared by the following procedure which is different from that of Brich *et al.*

1-Ethoxycarbonyl-trans-*hexahydro-2-indanone*. A solution of 32.0 g (0.125 mol) of diethyl *trans*-1,2-cyclohexanediacetate in 840 ml of dry toluene and 3.73 g of sodium ethoxide was heated at 110 °C for 8 h, ethanol formed was removed and then the residue was poured into 200 ml of water. The solution was neutralized with ammonium chloride. The toluene layer was separated and the aqueous layer was extracted with 200 ml of benzene twice. The combined organic solution was dried and the solvent was evaporated to give an oily product which was distilled (14.7 g, 56% yield). Bp 102 °C/12 mmHg; IR (neat) 1753 and 1720 cm^{-1}; NMR (CCl_4) δ=4.14 (2H, q), 2.88—1.00 (13H, m), 1.28 (3H, t).

trans-*2-Oxadecalin-3-one*. A solution of 14.7 g (70.6 mmol) of 1-ethoxycarbonyl-*trans*-hexahydro-2-indanone in 50 ml of 25% sulfuric acid was refluxed for 1.5 h and poured into 50 ml of water. The solution was extracted with 100 ml of ether three times and the ether solution was neutralized with diluted sodium hydroxide, then washed with water and dried. The solvent was evaporated to afford an oily *trans*-hexahydro-2-indanone[33] which was added into 500 ml of dichloromethane. To the dichloromethane solution, 22.5 g of *m*-chloroperbenzoic acid was added gradually under stirring over night. The solution was filtered and the filtrate was neutralized with diluted sodium hydroxide, washed with water and dried. The solvent was evaporated and the residue was distilled to give an oily *trans*-2-oxadecalin-3-one (5.6 g, 52% yield): bp 114—116 °C/4 mmHg (lit,[34] 102—104 °C/0.1 mmHg).

trans-*1-Bromomethyl-2-(2-bromoethyl)cyclohexane*: To a slurry of 1.5 g (40 mmol) of lithium aluminum hydride in 100 ml of dry ether was added dropwise while stirring the solution of 5.6 g (36 mmol) of *trans*-2-oxadecalin-3-one in 50 ml of ether. When the addition was complete, the mixture was refluxed for an additional 1 h and then treated successively with 1.5 ml of water, 1.5 ml of 15% aqueous sodium hydroxide, and 4.1 ml of water under stirring while cooling in an ice bath. The mixture was filtered and the filtrate was dried and concentrated. The residue was dried thoroughly under vacuum to give oily *trans*-2-(hydroxymethyl)-cyclohexaneethanol.[35] A portion of 10.7 g (39 mmol) of phosphorus tribromide was slowly dropped into 30 ml of dichloromethane solution of the oil under cooling in an ice bath. After dichloromethane was removed at 60 °C, the solution was heated at 100 °C for 6 h, cooled in an ice bath, and water was carefully added. Then the solution was extracted with dichloromethane, washed, dried, and concentrated. The residue was distilled with Kugelrohr (6.5 g, 63% yield); bp 115 °C/2 mmHg (lit,[32] 104—106 °C/0.8 mmHg).

trans-*2-Thiadecalin*: To a refluxing solution of sodium sulfide nonahydrate (4.15 g, 17.5 mmol) in 50 ml of 50% aqueous ethanol was added dropwise 6.5 g of the dibromide and an additional 50 ml of the sodium sulfide (4.15 g) solution at such a rate that the addition of both was complete in 1 h. After refluxing for 8 h, the mixture was extracted with ether. The combined organic extract was dried over anhydrous magnesium sulfate, the solvent was removed by evaporation and the residue was purified through silica-gel chromatography with hexane as an eluent (2.135 g, 38% yield).

trans-*2-Thiadecalin 2-Oxides (**5a** and **5e**)*: 1) To a stirred solution of *trans*-2-thiadecalin (156 mg, 1 mmol) in 10 ml of dry methanol cooled to −70 °C with an acetone–Dry Ice bath was added 1 equiv. of *t*-butyl hypochlorite. When the temperature of the bath reached −40 °C, anhydrous sodium carbonate was added. The mixture was allowed to come up to room temperature and then methanol was removed under reduced pressure. The residue was washed three times with 20 ml portion of chloroform and the chloroform solution was dried and concentrated to give an oily product which was separated through alumina column chromatography with ethyl acetate as an eluent, giving crystalline *trans*-2-thiadecalin 2a-oxide (**5a**) (97 mg) in 56% yield.

2) To a stirred solution of the sulfide (80 mg, 5 mmol) in 50 ml of acetone cooled with an ice bath was added dropwise 1.05 equiv. of sodium periodate dissolved in the least amount of water. When the addition was complete, the solution was stirred at room temperature for 2 h and poured into 50 ml of water. The solution was extracted with 100

ml of chloroform four times. The organic solution was dried and concentrated to give oily substance which was separated through alumina column chromatography with ethyl acetate–benzene (1:1) as an eluent giving *trans*-2-thiadecalin 2a-oxide (**5a**, 611 mg) from the former solution and *trans*-2-thiadecalin 2e-oxide (**5e**, 162 mg) from the latter solution.

3) To a stirred solution of the sulfide (5 mmol) in 50 ml of dichloromethane cooled with an ice bath was added 1.05 equiv. of *m*-chloroperbenzoic acid. The solution was washed with saturated sodium hydrogencarbonate, and the aqueous layer was extracted with chloroform three times. The combined organic layer was washed with water, dried and concentrated to afford oily product which was separated as in the above-mentioned case. The sulfoxide **5a** and **5e** were given in 31% (265 mg) and 57% (492 mg) yields, respectively. **5a**: mp 98—99 °C; IR (KBr) 1029 and 2930 cm^{-1}; Found: C, 62.61; H, 9.23%. Calcd for $C_9H_{16}OS$: C, 62.74; H, 9.36%. **5e**: mp 53—54.5 °C; IR (KBr) 1036 cm^{-1}; Found: C, 62.39; H, 9.20%. Calcd for $C_9H_{16}OS$: C, 62.74; H, 9.36%.

^{18}O-*Labeled* trans-*4-(*p-*Chlorophenyl)thiane 1-Oxide (**1t**-^{18}O)*: The title sulfoxide **1t**-^{18}O was prepared by the usual oxidation of the corresponding sulfide with bromine.[36] The sulfide (1 g, 4.7 mmol) was dissolved in a mixture of acetic acid (30 ml), pyridine (5 ml) and ^{18}O-enriched water (3 ml) (1.6 ex. atm%). To the cooled solution was added bromine (753 mg) in 5 ml of acetic acid at 0 °C. After the mixture was kept standing for 2 h at 0 °C, the reaction mixture was quenched with 50 ml of water and extracted with 50 ml of chloroform four times. The chloroform solution was washed with aqueous $Na_2S_2O_3$ solution, diluted aqueous hydrochloric acid, water and then dried ($MgSO_4$). After evaporation of chloroform with a rotary evaporator, a resulting substance was separated through alumina column chromatography with ethyl acetate–chloroform (2:1) as the eluent, giving ^{18}O-labeled corresponding equatorial sulfoxide **1t**-^{18}O (750 mg) and ^{18}O-labeled *cis*-sulfoxide **1c**-^{18}O (108 mg). The ^{18}O-labeled *trans*-4-(*p*-chlorophenyl)thiane 1-oxide was recrystallized from ethyl acetate–hexane and found to contain 1.092 ex. atom% of ^{18}O.

^{18}O-*Labeled* cis-*4-(*p-*Chlorophenyl)thiane 1-Oxide (**1c**-^{18}O)*: To a stirred solution of the *trans*-sulfoxide **1t** (600 mg, 2.63 mmol) in dichloromethane (3 ml) *ca.* 0.9 g (4.73 mmol) of triethyloxonium tetrafluoroborate (Et_3OBF_4) was added. After the mixture was stirred at room temperature for 1 h, 40 ml of anhydrous ether was added at 0 °C to give the oily ethoxysulfonium salt as a precipitate. After the mixture was kept standing for 2 h, the solvent was removed by decantation, and to the residue was added 5 ml of a 2 mol dm^{-3} $Na^{18}OH$ solution which was prepared by treating sodium metal with $H_2{}^{18}O$ (1.5 ex. atm%) under nitrogen atmosphere. The mixture was then extracted with dichloromethane. The solution was dried over $MgSO_4$ and the solvent was evaporated. The residue was then chromatographed on alumina with ethyl acetate–chloroform (2:1) as the eluent. The solvent of the former elution was removed to afford colorless crystals which were recrystallized from ethyl acetate (294 mg, 49%). The title sulfoxide (**1c**-^{18}O) was found to contain 0.4295 ex. atom% of ^{18}O.

^{18}O-*Labeled* trans-*1-Thiadecalin 1e-Oxide (**3e**-^{18}O)*: The *trans*-1-thiadecalin was similarly oxidized with bromine and ^{18}O-enriched water to give an oily substance which was separated through alumina column chromatography with ethyl acetate as the eluent to give the corresponding ^{18}O-labeled equatorial sulfoxide from the latter elution and the corresponding axial sulfoxide from the former one. The ^{18}O-labeled *trans*-1-thiadecalin 1e-oxide (**3e**-^{18}O) (654 mg, 69% yield) was recrystallized from hexane and found to contain 0.955 ex. atom% of ^{18}O.

^{18}O-*Labeled* trans-*1-Thiadecalin 1a-Oxide (**3a**-^{18}O)*: After a solution of 1e-sulfoxide **3e** (900 mg, 5.2 mmol) and Et_3OBF_4 (1.89 g, 9.4 mmol) in dichloromethane (**3** ml) was stirred at room temperature for 1 h, 30 ml of anhydrous ether was added at 0 °C. Then the mixture was kept standing for 2 h, the solvent was removed by decantation, and to the residue was added 3 ml of a 2 mol dm^{-3} $Na^{18}OH$ solution. The usual work-up and alumina chromatography gave the ^{18}O-labeled title sulfoxide **3a** which was recrystallized from hexane, and found to contain 0.856 ex. atom% of ^{18}O.

trans-*1-Thiadecalin-2e*-d *1a-Oxide (**9**)*:[37] After a solution of 1.1 ml of lithium (0.1 g/ml in hexane) was added to a stirred solution of a *trans*-1-thiadecalin 1a-oxide (**3a**) (253 mg, 1.47 mmol) in 5 ml of a freshly distilled THF cooled at −78 °C in an acetone–Dry Ice bath for 1 h, 2 ml of MeOD was added to the cooled solution at −78 °C under stirring for 0.5 h. The reaction mixture was quenched with 20 ml of water and neutralized with 10 ml of aqueous ammonium chloride and extracted with 30 ml of chloroform seven times. The whole solution was dried with $MgSO_4$ and the solvent was evaporated to afford the D-labeled product **9** which was recrystallized from hexane. Thus the title sulfoxide **9** obtained (250 mg, 99% yield) was found to contain 59% of D-atom at α-equatorial position upon treatment with 1 equiv. molar mixture of the lanthanoids shift reagent, Eu(dpm)$_3$ and the sulfoxide.

trans-*1-Thiadecalin-2a*-d *1e-Oxide (**11**)*: The title sulfoxide **11** was synthesized from the equatorial sulfoxide (344 mg) by the work-up as mentioned above (337 mg, 97%). The title sulfoxide **11** was found to contain 57% of D-atom at α-axial position upon treatment with 1 equiv. molar of Eu(dpm)$_3$.

trans-*1-Thiadecalin-2a*-d *1a-Oxide (**10**)*: The title sulfoxide **10** was prepared by the same chemical transformation of *trans*-1-thiadecalin-2a-*d* 1e-oxide (**11**). A solution of **11** (104 mg, 0.6 mmol) and (342 mg, 1.8 mmol) of triethyloxonium tetrafluoroborate in dichloromethane (2 ml) was stirred at room temperature for 1 h and 30 ml of anhydrous ether was added at 0 °C to give the oily ethoxysulfonium salt. After the mixture was kept standing for 2 h, the solvent was removed by decantation twice. Then to the residue was added 10 ml of a 0.5 M NaOH solution. The solution was neutralized with 10 ml of aqueous ammonium chloride solution and extracted with chloroform seven times. The solvent was dried with $MgSO_4$ and evaporated to afford a residue, which was then chromatographed through alumina with ethyl acetate–chloroform (2:1) to give the sulfoxide **10** (12.8 mg, 80%) which was found to contain 57% of D-atom at α-axial position upon treatment with an equimolar amount of Eu(dpm)$_3$.

*Reaction of 4-(*p-*Chlorophenyl)thiane 1-Oxides (**1c** and **1t**) with Acetic Anhydride.* The *trans* **1t** or *cis*-sulfoxide **1c** (45.7 mg, 0.2 mmol) was heated with 1 ml of acetic anhydride at 100 °C for 3 h until the sulfoxide disappeared upon monitoring with TLC. Then after evaporation of excess acetic anhydride and any volatile product *in vacuo*, the remaining residue was separated through silica-gel column chromatography with hexane–ether (4:1) as the eluent, in a low-temperature room at 0—4 °C. The corresponding axial α-acetoxy sulfide **2a** and olefinic product **2o** were obtained in 72—73% and 20% yields, respectively. **2a**: IR (neat) 1740 and 1223 cm^{-1}; NMR ($CDCl_3$) δ=7.15 (4H, aromatic), 5.98 (1H, t-like J=3.0 Hz), 2.12 (3H, s). Oxidation of **2a** gave the corresponding sulfone: mp 204—204.5 °C; IR (KBr) 1755, 1330, 1210, and 1140 cm^{-1}; Found: C, 51.44; H,

4.94%. Calcd for $C_{13}H_{15}ClO_4S$: C, 51.57; H, 4.99%. **2o**: bp 110 °C/5 mmHg (Kugerohr); Found: C, 62.98; H, 5.24%. Calcd for $C_{11}H_{11}ClS$: C, 62.69; H, 5.26%.

*Reaction of 4-(p-Chlorophenyl)thiane 1-Oxides (**1c** and **1t**) with Acetic Anhydride in the Presence of DCC or 2,6-Lutidine. 1)*: The *trans*- or *cis*-sulfoxide **1t** or **1c** (45.7 mg, 0.2 mmol) was heated with 1 ml of acetic anhydride in the presence of 1 equiv. of DCC to the sulfoxide at 100 °C for 4 h. When the reaction mixture was treated according to the above-mentioned procedure, the Pummerer products (the corresponding equatorial α-acetoxy sulfide **2e** and axial α-acetoxy sulfide **2a** in the ratio of 2:1 respectively) and olefinic product **2o** were obtained in 77% and 21% yields, respectively.

2): The *trans*-sulfoxide **1t** was heated with 1 ml of acetic anhydride in the presence of 3 equiv. of DCC at 100 °C for 4 h. The Pummerer products **2e** and **2a** (ratio of 9:1, respectively) and the olefinic product were obtained in 85% and 11% yields, respectively.

3): The *trans*-sulfoxide **1t** was heated with 1 ml of acetic anhydride in the presence of 5 equiv. of DCC at 100 °C for 4 h. The Pummerer products **2e** and **2a** (ratio of 13:1, respectively) and the olefinic product were obtained in 83% and 9% yields, respectively. **2e**: mp 78.5—80 °C; IR (KBr) 1745 and 1225 cm^{-1}; NMR ($CDCl_3$) 7.15 (4H, aromatic) 5.88 (1H, dd, J=9.9 and 3.3 Hz) 2.04 (3H, s); Found: C, 57.75; H, 5.57%. Calcd for $C_{13}H_{15}ClO_2S$: C, 57.66; H, 5.58%.

4): The *cis*-sulfoxide **1c** was heated with 1 ml of acetic anhydride in the presence of 5 equiv. of DCC at 100 °C for 6 h. The Pummerer products (**2e** and **2a** ratio of 14:1, respectively) and the olefinic product were obtained in 83% and 12% yields, respectively.

5): The *cis*-sulfoxide **1c** was heated with acetic anhydride in the presence of 5 or 10 equiv. of 2,6-lutidine at 100 °C for 4.5 h. The Pummerer products (**2e** and **2a** ratio of 5:2 or 5:1, respectively) and the olefinic product were obtained in 81 or 86% and 15 or 12% yields, respectively.

*Isomerization Reaction of 2e-Acetoxy-4-(p-Chlorophenyl)thiane (**2e**) with Acetic Anhydride in the Presence of Acetic Acid.* After the sulfide **2e** (60 mg) was heated with 1 ml of acetic anhydride in the presence of 1 equiv. of acetic acid to the acetoxy sulfide at 100 °C for 3 h and then evaporation of excess acetic anhydride and any volatile substance *in vacuo*, an oily product was purified through silica-gel column chromatography with hexane–ether 4:1 as an eluent at 0—4 °C to afford the corresponding 2a-acetoxy sulfide (**2a** 42 mg, 70% yield) and the olefinic compound **2o** (13 mg, 28%).

Reaction of trans-*1-Thiadecalin 1-Oxides (**3e** and **3a**) with Acetic Anhydride.* The sulfoxide **3e** or **3a** (71.2 mg, 0.4 mmol) was heated with 2 ml of acetic anhydride at 100 °C for 3 or 4 h until the sulfoxide completely disappeared upon monitoring with TLC of alumina. Then after evaporation of excess acetic anhydride and any volatile product *in vacuo*, the remaining residue was separated through silica-gel column chromatography with hexane–ether (5:1) as an eluent in a low temperature room at 0—4 °C. The corresponding equatorial and axial α-acetoxy sulfides **4e** and **4a** (ratio of 1:19, respectively) were obtained in 40—50% yield. To the trapped volatile products in an acetone–Dry Ice bath was added a saturated sodium hydrogencarbonate solution until the solution became alkaline and then the solution were extracted with dichloromethane. The dichloromethane solution was washed with water, dried, and concentrated to afford the olefinic product. **4a**: oil; IR (neat) 2930, 1700, and 1220 cm^{-1}; NMR 5.81 (1H, t, J=3.3 Hz), 2.01 (3H, s). Oxidation of **4a** with *m*-CPBA gave the corresponding sulfone: mp 86—86.5 °C; IR (KBr) 2930, 1760, 1750, and 1215 cm^{-1}; NMR ($CDCl_3$) δ=5.70 (1H, t, J=3 Hz), 2.15 (3H, s); Found: C, 53.63; H, 7.30%. Calcd for $C_{11}H_{18}O_4S$: C, 53.63; H, 7.36%.

Reaction of trans-*1-Thiadecalin 1-Oxides (**3e** and **3a**) with Acetic Anhydride in the Presence of DCC.* The sulfoxide **3a** or **3e** (71.2 mg, 0.4 mmol) was heated with 2 ml of acetic anhydride in the presence of 5 equiv. of DCC to the sulfoxide at 100 °C for 4 h. When the reaction mixture was treated according to the above-mentioned procedure, the corresponding equatorial and axial α-acetoxy sulfides **4e** and **4a** (ratio of 19:1, respectively) were obtained in 45—52% yield. To the trapped volatile products cooled in an acetone–Dry Ice bath was added a saturated sodium hydrogencarbonate solution until the solution became alkaline and then the solution was extracted with dichloromethane. The dichloromethane solution was washed with water, dried $Mg(SO_4)$, and concentrated to give an olefinic product. **4e**: mp 41—42 °C; IR (KBr) 1740 and 1240 cm^{-1}; NMR ($CDCl_3$) δ=5.69 (1H, dd J=9.9 and 3.3 Hz), 2.04 (3H, s); Found: C, 61.75; H, 8.49%. Calcd for $C_{11}H_{18}O_2S$: C, 61.64; H, 8.46%. The olefinic product was converted to the corresponding sulfone: mp 106—7.5 °C; IR (KBr) 2930, 1620, 1300, and 1110 cm^{-1}; Found: C, 57.86; H, 7.53%. Calcd for $C_9H_{14}O_2S$: C, 58.03; H, 7.57%.

Reaction of trans-*2-Thiadecalin 2-Oxides (**5e** and **5a**) with Acetic Anhydride.* The sulfoxide **5e** or **5a** (71.2 mg, 0.4 mmol) was heated with 2 ml of acetic anhydride at 100 °C for 3 h. The usual work-up and silica gel column chromatography with hexane–ether (5:1) as an eluent at 0—4 °C gave 42 mg (48% yield) of a 1:1 mixture of the corresponding 1a- and 3a-acetoxy sulfide **6a1** and **6a3** as main products: oil; IR (neat) 1740, 1230, and 1219 cm^{-1}; NMR ($CDCl_3$) δ=5.67 (t, J=3 Hz, methine proton of **6a1**), 5.88 (d, J=3 Hz, methine protone of **6a3**), 2.13(s). Sulfone: mp 79—80 °C; IR (KBr) 2930, 1760, 1750, and 1215 cm^{-1}; Found: C, 53.75; H, 7.37%. Calcd for $C_{11}H_{18}O_4S$: C, 53.63; H, 7.36%.

Reaction of trans-*2-Thiadecalin 2-Oxides (**5e** and **5a**) with Acetic Anhydride in the Presence of DCC.* The sulfoxide **5e** or **5a** (71.2 mg, 0.4 mmol) was heated with 2 ml of acetic anhydride in the presence of 5 equiv. of DCC to the sulfoxide at 100 °C for 4 h. An about 1:1 mixture of the Pummerer products, the corresponding 1e- and 3e-acetoxy sulfides were obtained as main products (45 mg, 51%): oil; NMR ($CDCl_3$) δ=5.49 (d, J=9.5 Hz, methine proton of **6e1**), 5.82 (dd, J=10.5 and 3.0 Hz, methine proton of **6e3**), and 2.08(s). Sulfone: mp 121—122 °C; IR (KBr) 2970, 1760, 1220, and 1207 cm^{-1}; Found: C, 53.72; H, 7.35%. Calcd for $C_{11}H_{18}O_4S$: C, 53.63; H, 7.36%.

Reaction of ^{18}O-*Labeled* trans-*4-(p-Chlorophenyl)thiane 1-Oxide (**1t**) with Acetic Anhydride.* When the ^{18}O-labeled title sulfoxide **1t** (685.5 mg) was heated with 60 equiv. of acetic anhydride at 100 °C for 0.75 h, the oily residue obtained after evaporation of excess acetic anhydride and any volatile product under vacuum was separated through silica-gel column chromatography with hexane–ether (4:1) as an eluent in a low-temperature room at 0—4 °C and then acetone as eluent to give the Pummerer products **2e** and **2a** (325 mg, 40% yield (e:a/1:1) and the recovered sulfoxide (341 mg, 50% yield), respectively, which was recrystallized from ethyl acetate–hexane. The starting sulfoxide, the Pummerer products and the recovered sulfoxide were subjected to measurement of ^{18}O-content by the routine ^{18}O-analysis technique and the ^{18}O-contents were found to be 1.092, 0.013, and 1.088 ex. atom%, respectively.

Reaction of ^{18}O-*Labeled* cis-*4-(p-Chlorophenyl)thiane 1-Oxide (**1c**-^{18}O) with Acetic Anhydride.* After the ^{18}O-labeled

title sulfoxide (**1c**-^{18}O) (330 mg) was heated with 60 equiv. of acetic anhydride at 100 °C for 0.75 h, the reaction mixture was treated according to the above-mentioned procedure to afford the mixture of Pummerer products **2e** and **2a** (156 mg) in 40% yield (e:a/1:1) and the recovered sulfoxide (155 mg) in 47% yield, which were recrystallized from ethyl acetate. The ^{18}O-contents of the starting sulfoxide, Pummerer products and the recovered sulfoxide were found to be 0.495, 0.019, and 0.334 ex. atom%, respectively.

Reaction of ^{18}O-*Labeled* trans-*1-Thiadecalin 1e-Oxide (**3e**) with Acetic Anhydride.* When the ^{18}O-labeled title sulfoxide **3e** (152.3 mg) thoroughly dried under vacuum was heated with 60 equiv. of acetic anhydride at 100 °C for 0.75 h, the oily residue, obtained after evaporation of excess of acetic anhydride and any volatile product under vacuum, was separated through silica-gel column chromatography with hexane–ether (5:1) as the eluent to give the Pummerer products **4e** and **4a** (52.7 mg, 28% yield, e:a/6:1) and the recovered sulfoxide (81.4 mg, 53% yield) which was recrystallized from hexane. The ^{18}O-contents of starting sulfoxide, the Pummerer products and recovered sulfoxide were found to be 0.955, 0 and 0.812 ex. atom% of ^{18}O, respectively.

Reaction of ^{18}O-*Labeled* trans-*1-Thiadecalin 1a-Oxide (**3a**-*^{18}O*) with Acetic Anhydride.* The ^{18}O-labeled title sulfoxide (**3a**-^{18}O) (152.3 mg) was heated with acetic anhydride (60 equiv.) at 100 °C for 0.75 h. After the work-up procedure as mentioned above, the Pummerer products **4e** and **4a** (80.6 mg, 43% yield, e:a/8:1) and the recovered sulfoxide (43.3 mg, 28% yield) were obtained and the recovered sulfoxide was recrystallized from hexane. The ^{18}O-contents of the starting sulfoxide, the Pummerer products and the sulfoxide recovered were found to be 0.856, 0.057, and 0.710 ex. atom% of ^{18}O, respectively. The Pummerer products (**4e**:**4a**=6:1) incorporated with 13% of ^{18}O, based on the starting sulfoxide, was recrystallized from hexane to give the pure **4e** (mp 43 °C). Then the filtrate was condensed and separated through silica-gel column chromatography with hexane–ether–ethyl acetate (77:2:1) as an eluent. The ^{18}O-contents of the pure **4e** and **4a** were found to be 0.057 and 0.043 ex. atom%.

Reaction of ^{18}O-*Labeled* trans-*1-Thiadecalin 1e-Oxide (**3e**) with Acetic Anhydride in the Presence of DCC.* When the ^{18}O-labeled sulfoxide (**3e**-^{18}O) (152.3 mg) thoroughly dried was heated with 60 equiv. of acetic anhydride in the presence of 5 equiv. DCC to the sulfoxide at 100 °C for 1.25 h, the residue was obtained after evaporation of excess acetic anhydride and any volatile product under vacuum. To the resultant residue was added 5 ml of ether–hexane and the mixture was filtered. The solvent of the filtrate was removed and the oily residue was separated through silica-gel column chromatography with hexane–ether (5:1) as the eluent at 0—4 °C and then with benzene–acetone (1:1) to give the Pummerer products **4e** and **4a** (97.0 mg, 51% yield, e:a/19:1), and the recovered sulfoxide (45.8 mg, 30% yield) which was recrystallized from hexane. The filtered product was recrystallized from ethyl acetate–hexane giving 650 mg of the *N*-acetyl-*N,N'*-dicyclohexylurea (IR 1600 and 1680 cm^{-1}, NMR δ=2.1, 5.0, 1—2). The ^{18}O-contents of the recovered sulfoxide, the Pummerer products and *N*-acetyl-*N,N'*-dicyclohexylurea were found to be 0.812, 0, and 0 ex. atom%, respectively.

Reaction of ^{18}O-*Labeled* trans-*1-Thiadecalin 1a-Oxide (**1a**-*^{18}O*) with Acetic Anhydride in the Presence of DCC.* The ^{18}O-labeled sulfoxide (**3a**-^{18}O) (152.3 mg) was heated with 60 equiv. of acetic anhydride at 100 °C for 1.25 h. After the work-up procedure as mentioned above, the Pummerer products **4e** and **4a** (65.2 mg, 34% e:a/19:1), recovered sulfoxide (89.9 mg, 59% yield) and the *N*-acetyl-*N,N'*-dicyclohexylurea were obtained. The ^{18}O-contents of the recovered sulfoxide, the Pummerer products and the *N*-acetylurea were found to be 0.574, 0.068, and 0 ex. atom%.

*Hydrogen-Deuterium Kinetic Isotope Effect in the Reaction Between 4-(*p*-Chlorophenyl)thiane-2,2,6,6-*d_4 *1-Oxides with Acetic Anhydride.* 4-(*p*-Chlorophenyl)thiane-2,2,6,6-d_4 1-oxides (*cis* and *trans*) were prepared by the treatment with diethyl 3-(*p*-chlorophenyl)glutarate and lithium aluminum deuteride in the ether and the successive procedures mentioned-above.[27]

Each 4-(*p*-chlorophenyl)thiane 1-oxide (*cis* or *trans*) (0.1 mmol) was dissolved in 10 ml of acetic anhydride. The solution was heated at 100 °C. The solution 10 μl picked up with syringe at time intervals was cooled at 0 °C to stop the reaction. The rate of the reaction was followed by measurement of the GLPC peaks of the Pummerer products (OV1 2% on chromosorb 2 m). The rate constants were obtained from the pseudo-first-order kinetic equation.

Reaction of trans-*1-Thiadecalin-2e-*d *1a-Oxide (**9**) with Acetic Anhydride in the Presence of DCC.* The stereoselectively D-labeled sulfoxide **9** (D, 59%, 103 mg at equatorial position) was heated with 2 ml of acetic anhydride in the presence of DCC (617 mg, 5 equiv. molar to the sulfoxide) at 100 °C for 4 h. After the work-up procedure as mentioned, the 2e-acetoxy sulfide, the Pummerer product, obtained in 39% yield (50 mg) was found to retain 59% of D-content upon measurement of NMR using 14% of $Eu(dpm)_3$.

Reaction of trans-*1-Thiadecalin-2a-*d *1a-Oxide (**10**) with Acetic Anhydride in the Presence of DCC.* When the stereoselectively D-labeled axial sulfoxide **10** (49.4 mg, D, 57% at axial position) was heated with 1 ml of acetic anhydride in the presence of DCC (250 mg) at 100 °C for 4 h, the corresponding 2e-acetoxy sulfide given in 45% yield (27.9 mg) was found to contain only 13% of D-content according to the usual procedure.

Reaction of trans-*1-Thiadecalin-2e-*d *1e-Oxide (**11**) with Acetic anhydride in the Presence of DCC.* After the D-labeled title sulfoxide **11** (108 mg, D, 57% at axial position) was heated with 2 ml of acetic anhydride in the presence of DCC (648 mg) at 100 °C for 6 h, the usual work-up was carried out. The corresponding 2e-acetoxy sulfide obtained in 41% yield (55 mg) had 50% of D-content.

N-Alkylation of Pyrrole, Indole, and Several Other Nitrogen Heterocycles Using Potassium Hydroxide as a Base in the Presence of Polyethylene Glycols or Their Dialkyl Ethers

Kazuaki SUKATA

Nihon Tokushu Chemical Ind. Co., Ltd. 3-36, Tohda-cho, Moriguchi, Osaka 570

(Received June 7, 1982)

The alkylation of pyrrole and indole in aqueous potassium hydroxide-organic two-phase systems in the presence of polyethylene glycols (PEG) or their dialkyl ethers (PEG-ether) as phase transfer catalysts (PTC) gave substantial quantities of the *C*-alkylated and *C,N*-polyalkylated products as well as the *N*-alkylated products. This fact is similar to that obtained in the presence of quaternary ammonium salts as PTC. In powdered potassium hydroxide-organic two-phase systems, the yields of the *N*-alkylated products were generally high. Especially, when PEG-ether were employed as solvents, the *N*-alkylated products were obtained in excellent yields under mild conditions. Imidazole, benzimidazole, carbazole, 2-methylindole, and benzotriazole were similarly *N*-alkylated in high yields by this method.

It has been reported that the *N*-alkylation of nitrogen heterocycles such as pyrrole and indole can be achieved by use of various bases such as potassium,[1] sodium amide,[2] sodium hydroxide in hexamethylphosphoric triamide,[3] potassium hydroxide in dimethyl sulfoxide,[4] and thallium(I) ethoxide.[5] Moreover, phase transfer procedures have been recently developed.[6] In many cases, concentrated aqueous sodium hydroxide was employed as a base in the presence of quaternary ammonium salts as phase transfer catalysts (PTC), and substantial quantities of the *C*-alkylated and *C,N*-polyalkylated (*C*- and *C,N*-alkylated) derivatives were obtained as by-products.

On the other hand, Santaniello *et al.*[7] have reported that *N*-alkylpyrrole and indole are obtained in good yields by use of potassium hydroxide as a base in the presence of crown ethers as PTC. Also Guida and Mathre[8] found that the *N*-alkylation of nitrogen heterocycles can be achieved in good yields by use of potassium *t*-butoxide as a base in the presence of crown ethers as PTC.

In this paper, the author reports the *N*-alkylation of nitrogen heterocycles using aqueous or powdered potassium hydroxide as a base in the presence of polyethylene glycols (PEG) or their dialkyl ethers (PEG-ether).

Results and Discussion

N-Alkylation of Pyrrole and Indole in Aqueous Potassium Hydroxide-organic Two-phase Systems in the Presence of PEG or PEG-ether as PTC. Table 1 shows that the results of *N*-alkylation of pyrrole and indole in aqueous potassium hydroxide-organic two-phase systems in the presence of PEG-1000, PEG-1000-diethyl ether (PEG-1000-Et_2) or PEG-600-dibutyl ether (PEG-600-Bu_2) as PTC. The yields of the *N*-alkylation were similar to those of the reported method[6] using quaternary ammonium salts as PTC.

It is well known[9] that the pyrrolyl and indolyl anion exhibit ambident behavior, and thus substantial quantities of the *C*- and *C,N*-alkylated products as well as the *N*-alkylated products are obtained. Under the present experimental conditions, the alkylation of pyrrole also gave many *C*- and *C,N*-alkylated products, which were detected by GLC. In the case of indole, GLC showed the presence of a few components except the *N*-alkylated products. In the cases of both pyrrole and indole, the alkylation with isopropyl bromide gave the *N*-alkylated products in extremely low yields because of the elimination of hydrogen bromide from isopropyl bromide, induced by the pyrrolyl or indolyl anion. This result contrasts with the result in which α-isopropylphenylacetonitrile is obtained in high yields under the same conditions,[10] indicating that the pyrrolyl and indolyl anions are much harder[11] than $PhC\bar{H}CN^{\ominus}$.

N-Alkylation of Pyrrole and Indole in Powdered Potassium Hydroxide-organic Two-phase Systems in the Presence of PEG or PEG-ether as PTC. Table 2 shows the results of the *N*-alkylation of pyrrole and indole using PEG-1000 or PEG-1000-Et_2. On the basis of the results reported by Santaniello *et al.*,[7] equimolar amounts of potassium hydroxide and pyrrole or indole (molar ratio: KOH/heterocycle=1/1) were used. However, the yields of the *N*-alkylation were lower than those reported by them.

Table 3 shows the effects of the relative amount of potassium hydroxide to pyrrole on the *N*-ethylation. For the molar ratio: KOH/pyrrole=1/1, an incomplete conversion of pyrrole to the product was observed. Furthermore, substantial quantities of the *C*- and *C,N*-ethylated products were obtained. For the molar ratio: KOH/pyrrole=2/1—3/1, the yields of the *N*-ethylation came to the constant value (88% by GLC).

On the basis of the data given in Table 3, the *N*-alkylations were carried out under the molar ratio: KOH/heterocycle=3/1, giving *N*-alkylated products in high yields (Table 2). These facts suggest that the water formed is absorbed by the excess potassium hydroxide and fixed in the solid phase, completing the conversion to the product.

N-Alkylation of Pyrrole and Indole Using Powdered Potassium Hydroxide as a Base and PEG-ether as Solvents. Table 4 shows the *N*-alkylation of pyrrole and indole using PEG-400-Et_2 as a solvent (molar ratio: PEG-400-Et_2/heterocycle=1/1 or 2/1). When the alkylating agents except isopropyl bromide and *t*-butyl bromide were employed, the *N*-alkylated products were obtained in extremely high yields. Moreover, the

a) All reactions were carried out with 0.1 mol of heterocycle and 0.15 mol of alkyl halide in 30 ml of benzene. b) A: PEG-1000-Et_2, B: PEG-1000. c),d) see footnotes c), d) in Table 1, respectively. e),f),g),h),i),j) Purities were 92, 97, 92, 91, 97, and 98% by GLC, respectively.

yields of the *C*- and *C*,*N*-alkylated products were generally extremely low. The alkylation of indole with primary alkyl bromide or benzyl chloride gave *N*-alkylated products in almost quantitative yields. Even *N*-allylindole was obtained in 89—91% yields, which were comparable to that of the reported method using sodium hydride as a base in hexamethylphosphoric triamide.[3]

When isopropyl bromide was used as an alkylating agent, the considerable evolution of gas was observed during the reaction, and pyrrole or indole was recovered in 25-8 or 76—80%, respectively. As shown

in Table 1, the reaction of pyrrole or indole with isopropyl bromide using PEG or PEG-ether as PTC also gave pyrrole or indole in 26 or 75% yields, respectively. These facts indicate that the indolyl anion tends to induce the elimination reaction with isopropyl bromide in comparison with the pyrrolyl anion and is much harder[11] than the latter.

When PEG-400 was employed as a solvent in place of PEG-400-Et_2, the yields of *N*-alkylated products were extremely low because of the accompanied alkylation of PEG. For example, the alkylation of pyrrole with ethyl bromide gave pyrrole (49%), *N*-ethylpyrrole (43%), and *C*- and *C,N*-ethylated products (8% by GLC). The alkylation with *n*-butyl bromide gave pyrrole (39%), *N*-butylpyrrole (53%), and *C*- and *C,N*-butylated products (8% by GLC).

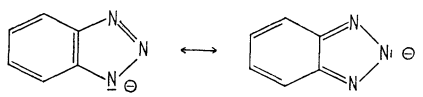
Table 3. Influence of the amounts of potassium hydroxide on the ethylation of pyrrole[a]

KOH (mol)	Yield[b]/%		
	1a	c)	Starting material
0.1	67	13	20
0.15	78	14	8
0.2	86	13	1
0.3	88	12	—
0.4	88	12	—
0.5	89	11	—

a) All reactions were carried out with 0.1 mol of pyrrole, 0.15 mol of ethyl bromide, and 30 ml of benzene at 65 °C for 4 h in the presence of 2.5 mmol of PEG-1000-Et_2 as PTC. b) Determined by GLC. c) See footnote d) in Table 1.

Since hydrogen bond is a hard-hard interaction,[11] under the condition containing large amount of water such as the aqueous-organic phase transfer system or in protic solvents such as PEG, water or PEG is capable of forming hydrogen bonding with the harder nitrogen atom of the heterocycle anion, suppressing the *N*-alkylation.[12] Therefore, the *C*-alkylation will increase. However, in PEG-ether, which is aprotic and would greatly increase the degree of dissociation[13] of the heterocycle anion, the exclusive *N*-alkylation could be achieved.

The method using potassium hydroxide as a base and PEG-ether as a solvent was applied to the alkylation of several nitrogen heterocycles. Table 5 shows the results. The alkylation of carbazole, imidazole, and benzimidazole gave 1-alkylated products in extremely high yields. However, in the case of benzotriazole, substantial quantities of 2-alkylbenzotriazole were obtained, in contrast to the alkylation of benzimidazole. This fact indicates that canonical structure of **13** would significantly contribute to the reactivity of the benzotriazolyl anion.



12 13

In contrast to the alkylation of indole, the alkylation of 2-methylindole with ethyl bromide or benzyl chloride gave 1,3-dialkylated products as well as 1-alkylated products in 2 or 16% yields, respectively.

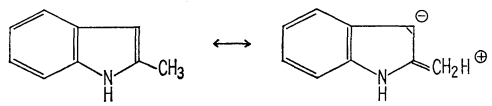
	CH_2=$CHCH_2Br$	**e**	2	(**7e**) 66[g]	(69)	2-Allylbenzotriazole (**10**)	16[h]	(24)
	$PhCH_2Cl$	**f**	3	(**7f**) 70	(78)	2-Benzylbenzotriazole (**11**)		(19)

a) All reactions were carried out with 0.05 mol of heterocycle and 0.15 mol of potassium hydroxide in 0.05 mol of PEG-400-Et_2 at 30 °C. b) In the cases of **3** and **4**, 0.075 mol of alkyl halide was used. In the cases of **5**, **6**, and **7**, 0.0525 mol of alkyl halide was used. c) Isolated yields by distillation or recrystallization. *N*-Ethyl- and *N*-allylimidazole were directly distilled from the reaction mixture. The values in parentheses were the yields determined by GLC. Unless otherwise noted, the purities of the products were >99% by GLC. d) Probably 1,3-diethyl-2-methylindole. e), f), g), and h) Purities were 94, 95, 90, and 91% by GLC, respectively.

This fact suggests that canonical structure of **14** should not be ignored.



3 14

Experimental

Materials. Pyrrole, indole, carbazole, benzimidazole, imidazole, 2-methylindole, benzotriazole, and alkyl halides (reagent grade, Tokyo Kasei Kogyo Co., Ltd.) were used without further purification. PEG, benzene, and 85% potassium hydroxide (reagent grade, Kishida Kagaku Co., Ltd.) were used also without further purification. PEG-ether were prepared by the method previously reported.[14]

The physical properties of **1a,b,f**,[7] **1c**,[15] **1e**,[16] **1g**,[17] **2a, b,f**,[7] **2e**,[3] **3a**,[7] **3f**,[18] **4a,b,e,f**,[19] **5a**,[20] **5e**,[21] **5f**,[22] **6a**,[23] **6e**,[24] **6f**,[25] **7a**,[26] **7e**,[27] **7f**,[21] **9**,[26] and **10**[27] were in good agreement with those reported in the literatures. *N*-Isopropylindole (**2c**)[12] and 2-benzylbenzotriazole (**11**)[28] were not isolated and were identified by comparing GLC retention times with those of authentic samples prepared by the literature procedures. *N*-Octylindole (**2g**) had bp 131—132 °C/0.3 mmHg (1 mmHg=133.322 Pa). Found: C, 83.60; H, 10.19; N, 6.00%. Calcd for $C_{16}H_{23}N$: C, 83.79; H, 10.11; N, 6.11%. 1,3-Dibenzyl-2-methylindole (**8**) had mp 95 °C (from ethanol). Found: C, 88.98; H, 6.94; N, 4.44%. Calcd for $C_{23}H_{21}N$: C, 88.70; H, 6.80; N, 4.50%.

General Procedure of N-*Alkylation in Aqueous Potassium Hydroxide-organic Two-phase Systems in the Presence of PEG or PEG-ether as PTC.* N-*Butylpyrrole (**1b**)*: *n*-Butyl bromide (20.6 g, 0.15 mol) was added dropwise over a period of 30 min at 45 °C with vigorous stirring to a mixture of 6.7 g (0.1 mol) of pyrrole, 2.7 g (2.5 mmol) of PEG-1000-Et_2, 33.0 g (0.5 mol) of 85% potassium hydroxide, 14 g of water, and 30 ml of benzene. After the mixture had been stirred at 45 °C for further 2 h, it was cooled to room temperature. To the mixture was added 50 ml of water and then the two layers were separated. The aqueous layer was extracted with 10 ml of benzene. The benzene layer was combined with the organic layer, extracted with 3.5% hydrochloric acid (50 ml×2), washed with water (50 ml×3), and then dried. After removal of the benzene, the residue was distilled under reduced pressure, giving *N*-butylpyrrole (**1b**), 8.0 g (65%), bp 75—77 °C/28 mmHg (lit,[7] 171 °C/760 mmHg). The hydrochloric acid extract was treated according to the method previously reported,[10] giving 2.6 g (98%) of PEG-1000-Et_2.

General Procedure of N-*Alkylation in Powdered Potassium Hydroxide-organic Two-phase Systems in the Presence of PEG or PEG-ether as PTC.* N-*Benzylindole (**2f**)*: A mixture of 11.7 g (0.1 mol) of indole, 2.7 g (2.5 mmol) of PEG-1000-Et_2, 19.8 g (0.3 mol) of powdered 85% potassium hydroxide, and 30 ml of benzene was heated under reflux with vigorous stirring for 1 h. Benzyl bromide (19.0 g, 0.15 mol) was added dropwise to the mixture over a period of 30 min at 80—85 °C with vigorous stirring. After the mixture had been heated at 85 °C with vigorous stirring for 2 h, it was cooled to room temperature. To the mixture was added 50 ml of water. The mixture was worked up as described above, giving 17.2 g (83%) of *N*-benzylindole (**2f**), bp 142—144 °C/0.5 mmHg, mp 43 °C (lit,[4] 133—138 °C/0.3 mmHg, mp 42—43 °C).

General Procedure of N-*Alkylation Using Powdered Potassium Hydroxide as a Base and PEG-ether as Solvents.* N-*Allylindole (**2e**)*: A mixture of 11.7 g (0.1 mol) of indole, 46 g (0.1

mol) of PEG-400-Et_2, and 19.8 g (0.3 mol) of powdered 85% potassium hydroxide was vigorously stirred at room temperature for 30 min. Allyl bromide (18.2 g, 0.15 mol) was added dropwise over a period of 30 min at 30 °C with vigorous stirring to the mixture. After the mixture had been vigorously stirred for further 1 h, 50 ml of water was added. The two layers were separated. To the organic layer was added 100 ml of 3.5% hydrochloric acid and extracted with benzene (30 ml × 3). The benzene extract was extracted with 3.5% hydrochloric acid (50 ml × 2), washed with water and then dried. After removal of the benzene, the residue was distilled under reduced pressure, giving 14.0 g (89%) of *N*-allylindole (**2e**), bp 96—98 °C/2 mmHg (lit,[3] bp 114—116 °C/6 mmHg, 72—73 °C/0.12 mmHg). The hydrochloric acid solutions were combined, washed with 10 ml of benzene, added 40 g of sodium hydroxide, and then extracted with benzene (50 ml × 2). The benzene extract was dried and the benzene was removed to recover 45.5 g (99%) of PEG-400-Et_2.

*1-Benzylbenzimidazole (**6f**)*: A mixture of 5.9 g (0.05 mol) of benzimidazole, 23 g (0.05 mol) of PEG-400-Et_2 and 9.9 g (0.15 mol) of powdered 85% potassium hydroxide was vigorously stirred at room temperature for 30 min. Benzyl chloride (6.6 g, 0.0525 mol) was added dropwise over a period of 30 min at 30 °C with vigorous stirring to the mixture. The mixture was vigorously stirred for further 3 h at 30 °C. The reaction mixture was poured into 200 ml of 1.9% hydrochloric acid (0.104 mol). The precipitated solid was collected, washed with water, dried, and recrystallized from ethanol, giving 10.1 g (97%) of 1-benzylbenzimidazole (**6f**), mp 116—117 °C (lit,[25] mp 116—117 °C). The filtrate was washed with 10 ml of benzene and treated according to the manner used for *N*-allylindole (**2e**) to recover 22 g (96%) of PEG-400-Et_2.

The author wishes to thank Nihon Tokushu Chemical Ind. Co., Ltd. for permission to publish this article, and also Dr. Nobuaki Wada for useful suggestions during this work.

Metal-catalyzed Organic Photoreactions. The Photooxidation of Vinylsilanes and Vinyl Sulfides in the Presence of Iron(III) Chloride, and the Regioselective Synthesis of α-Chloro Ketones

Tadashi SATO,* Tamotsu TONEGAWA, Kunio NAOI, and Eigoro MURAYAMA

Department of Applied Chemistry, Waseda University, Ookubo 3, Shinjuku-ku, Tokyo 160

(Received June 26, 1982)

The irradiation of a pyridine solution of vinylsilanes or vinyl sulfides in the presence of iron(III) chloride under oxygen produced α-chloro ketones, with a carbonyl group at the olefinic carbon originally bearing a silicon or sulfur atom.

We have previously reported that the iron(III) chloride-catalyzed photooxidation of mono- or disubstituted olefin gives an α-chloro ketone (Type A), while that of tri- or tetrasubstituted olefin gives a *gem*-dichloro ketone (Type B) or an α,ω-dichloro ketone (Type C), depending upon the substitution pattern of the starting olefins.[1] The selectivity of the reaction type is generally excellent, and no products from the alternative reaction type are observed. In the Type-A reaction of unsymmetrical olefin, however, the regioselectivity is poor, and a 1:1 mixture of 2-chloro-3-octanone (**2**) and 3-chloro-2-octanone (**3**) has been obtained from 2-octene (**1**) in a total yield of 58%. In the present study, we investigated the photooxidation of vinylsilane and vinyl sulfide in order to find a way to control the regioselectivity.

Results and Discussion

Pyridine solutions of vinylsilanes or vinyl sulfides **4**—**12** containing an equivalent amount of iron(III) chloride were irradiated with Pyrex-filtered light for 1 h while oxygen was being bubbled through. The subsequent evaporation of the solvent, followed by extraction, gave α-chloro ketones or aldehyde **13**—**21** as almost exclusive products. The results are summarized in the table. The structures of the products were determined by comparison with authentic samples prepared by known methods. It is evident from the table that the carbonyl group is introduced regioselectively at the olefinic carbon originally bearing a silicon or sulfur atom in every case except the reaction from **4**, which has the trimethylsilyl group at the terminal position. The steric effect caused by the presence of the alkyl group on the ring system is not sufficient to induce the regioselectivity, as exemplified by the reaction of 3-methylcyclohexene. The product was assumed from NMR analysis to be a mixture of *cis*- and *trans*-2-chloro-3-methylcyclohexanone (**18**) and 2-chloro-6-methylcyclohexanone (**21**). The assumption was confirmed by the dehydrochlorination of the mixture with lithium chloride in *N,N*-dimethylformamide to afford a 1:1 mixture of 2- and 3-methyl-2-cyclohexenone. It was confirmed that **21** produced 2-methyl-2-cyclohexenone under dehydrochlorination conditions, presumably because of the isomerization of the primary product, 6-methyl-2-cyclohexenone.

The usefulness of these reactions as a synthetic method is demonstrated by the regioselective preparation of alkyl-substituted 2-chlorocyclohexanones from appropriate vinylsilanes or vinyl sulfides. The requisite vinyl compounds have been conveniently prepared from the appropriate ketones either by an acid-actalyzed reaction with thiols[2] or by a modified Shapiro reaction.[3] These alkyl-substituted 2-chlorocyclohexanones have also been prepared by other methods,[4,5] but the regioselectivity is not as high as that observed in the present study. The diastereoselectivity concerning the alkyl group and chlorine atom was not attained because the α-chloro ketones underwent a *cis-trans* isomerization under the present reaction conditions.

As for the reaction mechanism of the iron(III) chloride-catalyzed photooxidation of olefin, we have proposed a reaction scheme involving a photoinduced interligand electron transfer (long-range electron transfer), followed by a chlorine and oxygen attack on the double bond.[1a] We assumed that the same type of reaction proceeds in the present case and that the chlorine atom produced by the long-range electron transfer attacks the double bond in such a way as to produce a radical stabilized by a silicon or sulfur atom. The succeeding attack by the oxygen-radical anion, followed by protonation, produces a hydroperoxide **23**, which then affords the observed product. The isolated by-product was either *S*-methyl methanethiosulfonate, *S*-ethyl ethanethiosulfonate, or diphenyl disulfide, depending on the substituent (methyl, ethyl, or phenyl respectively) on the sulfur atom of the starting vinyl sulfide. The poor regioselectivity in the case of vinylsilane **4** suggests that the stabilizing effect of the trimethylsilyl group for the α-radical is comparable to that of the alkyl group. However, it seems that the sulfur atom stabilizes the α-radical more effectively than the methyl group, as is indicated by the formation of a single product **17** from vinyl sulfide **8**.

Experimental

Starting Materials. 1-Trimethylsilyl-(*Z*)-1-octene (**4**) was prepared from 1-trimethylsilyl-1-octyne by hydroboration, followed by protonolysis.[6] Vinylsilanes **5**, **6**, **7a**, and **12a** were prepared from the corresponding tosylhydrazones and chlorotrimethylsilane according to the reported method.[7] In a similar way, vinyl sulfide **12b** was prepared from 2-methylcyclohexanone tosylhydrazone and dimethyl disulfide in a 51% yield. **12b**: IR, 3040, 2920, 1620, 1435, 1335, 995, and 790 cm^{-1}; NMR, δ 1.22 (3H, d, J=8 Hz), 1.5—2.0 (4H, m), 2.31 (3H, s), 2.0—2.6 (3H, m), and 5.60 (1H, t, J=4 Hz). Vinyl sulfides **7b**, **7c**, **8**, and **10b** were prepared from the corresponding cyclohexanones and thiols, using *p*-toluenesulfonic acid or titanium(IV) chloride–triethylamine as a catalyst, according to the previously reported method.[2] Vinyl sulfides **9** and **11** were prepared from the

tosylhydrazone of 2-methylcyclohexanone or of 4-methylcyclohexanone respectively by utilizing a modified Shapiro reaction, according to the previously reported method.[3]

X=SR or SiR_3

Photooxidation. The irradiation was carried out on a solution of vinylsilane or vinyl sulfide (10 ml, 0.025 M)† containing an equivalent molar amount of iron(III) chloride; it was done in Pyrex tubes for 30 min or 60 min while oxygen gas was being bubbled through. A high-pressure mercury lamp [Ushio UM 452 (450 W)] was used as the light source. The irradiated solution was worked up by either of the following two ways. Work-up I: The solvent was removed *in vacuo*, and the reaction product was extracted with carbon tetrachloride or dichloromethane from the residue. The extract was passed through a short column of Florisil, and the eluate was concentrated *in vacuo*. The material thus obtained was analyzed directly by GLC or NMR techniques. 1,1,2,2-Tetrachloroethane was used as an internal reference for the NMR analysis. Work-up II: The pyridine solution after the irradiation was neutralized with 4 M hydrochloric acid and shaken with chloroform or dichloromethane. The extract was dried over sodium sulfate, and the solvent was removed *in vacuo*. The residue was analyzed as above.

In all cases except the reaction of **10**, each product was isolated in a pure form on preparative GLC or TLC; the spectroscopic data and retention time on a GLC were compared with those of authentic samples prepared by known methods: **13**,[8] **14**,[1b] **15**,[9] **16**,[1b] **17**,[5b] **18**,[5a] **19**,[4] **20**,[5a] and **21**.[5b] The spectroscopic data of **13** and **15** are as follows: **13**: IR, 2950, 2925, 2855, 2710, 1733, 1470, 1380, and 785 cm^{-1}; NMR δ 0.88 (3H, dist. t), 1.1—1.6 (8H, m), 1.7—2.0 (2H, m), 4.03 (1H, dt, J=6 and 2 Hz), and 9.48 (1H, d, J=2 Hz); **15**: IR, 2960, 2875, 1715, 1460, and 785 cm^{-1}; NMR δ 0.95 (3H, t, J=8 Hz), 1.03 (3H, t, J=8 Hz), 1.4—2.1 (4H, m), 2.62 (2H, t, J=7 Hz), and 3.93 (1H, t, J=7 Hz).

The spectroscopic and GLC analyses of **19** were carried out and the results compared with those of an authentic sample as a mixture of *cis*- and *trans*-isomers.[4]

Alcoholysis Equilibria of Dialkoxydimethylsilanes Catalyzed by Iodine or Iodine Monobromide

Katsuko Ito and Takeshi Ibaraki*

Department of Natural Science, Osaka Women's University, Daisen-cho, Sakai, Osaka 590

(Received July 29, 1982)

Iodine or iodine monobromide was found to be an especially favorable catalyst for the study of the alcoholysis equilibria of dialkoxydimethylsilanes by gas chromatography. Iodine monobromide was employed to promote the reactions associated with tertiary alcohols, and iodine was used for the other reactions. Eight alcohols were allowed to react with diethoxydimethylsilane, and successive equilibrium constants, K_1 and K_2, were determined at 20 °C. K_1=2.36—2.75 and K_2=0.66—0.69 (by the use of primary alcohols), K_1=1.34—1.38 and K_2=0.28—0.30 (secondary alcohols), and K_1=0.15—0.16 (tertiary alcohols) were observed. These values express precisely the difference of reactivities of the three groups of alcohols with diethoxydimethylsilane. Out of the dialkoxydimethylsilanes used in this study, eight unreported compounds were isolated and characterized.

For alcoholysis or disproportionation of alkoxysilanes, iodine and interhalogen compounds such as iodine monobromide exhibit excellent catalytic action.[1,2] These catalysts lead such reaction systems readily to equilibrium even at ordinary temperature; the reaction mixtures with the catalyst can be satisfactorily analyzed by gas chromatography.

Alcoholysis of diethoxydimethylsilane[3-6] and the other alkoxysilanes has been well studied. However, the equilibrium constants of these reactions can not be found in the literature, although a few quantitative studies of disproportionation equilibria of alkoxysilanes have been reported.[7-9]

Thus, the alcoholysis equilibria of alkylalkoxysilanes catalyzed by iodine or iodine monobromide were investigated, and the equilibrium constants of these reactions were determined. This paper presents the alcoholysis equilibrium data of dialkoxydimethylsilanes at 20 °C, following the previous report on the alcoholyses of alkoxytriethylsilanes.[2]

The reactivities of alcohols to alkoxysilanes are considered in the order of primary>secondary>tertiary,[10,11] and the alcoholysis equilibrium constants of alkoxytriethylsilanes have been found to follow this order.[2] The difference in alcohol reactivities may be revealed more distinctly by the data of dialkoxydimethylsilanes, as the two alkoxyl groups should be exchanged in these cases.

Experimental

General Procedure. Given amounts of dialkoxydimethylsilane and alcohol were placed in a 5-cm^3 reaction vessel. Molar ratios of alcohols to alkoxysilanes in the reaction mixtures were in the range of about 0.7 to 5.1. Iodine or iodine monobromide was added to the reaction mixtures as the solution in each alcohol.

Each reaction associated with primary and secondary alkoxyl groups was promoted by iodine. Three directions were investigated:

A-series: $Me_2Si(OEt)_2$ + ROH ⟶

B-series: $Me_2Si(OEt)(OR)$ + ROH or EtOH ⟶

C-series: $Me_2Si(OR)_2$ + EtOH ⟶

Equilibrium compositions were ascertained by GLPC, from which data K_1 and K_2 values were estimated.

As the pure di-*t*-butoxydimethylsilane and dimethyldi-*t*-pentyloxysilane could not be isolated, the reactions associated with *t*-alkoxyl groups were examined for A- and B-series, and only K_1 values were determined. In this case, iodine monobromide was employed to accelerate the reactions. Each reaction mixture was divided into two or three parts and maintained in a thermostat setting at (20.0± 0.1) °C. One of them was used to monitor the time course of the reaction until the composition became constant, and then the others were used to determine the equilibrium compositions.

Analysis. Analyses were performed by GLPC using a Shimadzu model GC-4B gas chromatograph with a thermal conductivity detector. The packings with the following stationary phases were used. PEG 4000+PEG 6000 (ROH: Bu^nOH), PEG 1000+SPAN 80 (Bu^iOH, Bu^sOH), SPAN 80 (Bu^tOH), PEG 1000 ($C_5H_{11}{}^nOH$, $C_5H_{11}{}^tOH$), PEG 4000 ($MePr^nCHOH$, Et_2CHOH).

Reagents. Diethoxydimethylsilane was prepared by the reaction of octamethylcyclotetrasiloxane with tetraethoxysilane in the presence of potassium hydroxide.[14] The other alkoxysilanes were prepared by iodine or iodine monobromide-catalyzed alcoholysis of diethoxydimethylsilane. After the resulting ethanol and excess alcohol were removed by distillation, each alkoxysilane was obtained by fractional distillation.

Ethoxydimethyl-*t*-pentyloxysilane was purified by means of GLPC fractional elution, employing a Shimadzu model GC-5A gas chromatograph, equipped with a model APP-5 autofraction collector. A stainless column (6 mm ϕ × 4.5 m) containing 25% PEG 1000 on Chromosorb P was used. The other dialkoxydimethylsilanes were purified by repeated fractional distillation.

The fifteen dialkoxydimethylsilanes mentioned below were prepared and characterized by ^{13}C NMR, MS, and elemental analyses. As eight of these were unreported compounds, their boiling points, refractive indices, and analytical data are added. Di-*t*-alkoxydimethylsilanes were detected by GC-MS in the reaction mixtures, but the contents were too small to isolate.

Results and Discussion

The following successive equilibrium constants were determined at 20 °C.

$Me_2Si(OEt)_2 + ROH \rightleftharpoons Me_2Si(OEt)(OR) + EtOH$

$K_1 = \{[Me_2Si(OEt)(OR)][EtOH]\}/\{[Me_2Si(OEt)_2][ROH]\}$

$Me_2Si(OEt)(OR) + ROH \rightleftharpoons Me_2Si(OR)_2 + EtOH$

$K_2 = \{[Me_2Si(OR)_2][EtOH]\}/\{[Me_2Si(OEt)(OR)][ROH]\}$

The following alcohols were examined in this study:

ROH: Bu^nOH, Bu^iOH, Bu^sOH, Bu^tOH, $C_5H_{11}{}^nOH$, $MePr^nCHOH$, Et_2CHOH, $C_5H_{11}{}^tOH$.

The reactions were well-promoted in the presence of about 0.1 mol% catalyst (iodine or iodine monobromide), and in most cases the reactions attained equilibrium within several hours.

To make sure that the equilibrium compositions can be determined by means of GLPC even in the presence of the catalyst, a test similar to the previous study[1] was attempted. A reaction mixture, $Me_2Si(OEt)_2$–Bu^nOH (I_2), was divided into two parts, one of which was treated with silver powder to remove the catalyst from the reaction system,[15] while the other was left untreated; the compositions of both samples were determined by GLPC at about one hour intervals. In the latter case, the reaction proceeded to equilibrium, and $K_1=2.45$, $K_2=0.69$ were observed. In the former case, $\{[Me_2Si(OEt)(OBu^n)][EtOH]\}/\{[Me_2Si(OEt)_2]-[Bu^nOH]\}=1.27$, 1.33, 1.31, and $\{[Me_2Si(OBu^n)_2]-[EtOH]\}/\{[Me_2Si(OEt)(OBu^n)][Bu^nOH]\}=0.31$, 0.33, 0.30, proving that the reaction practically stopped due to silver-treatment. Moreover, a similar test was undertaken for the equilibrium mixture, and it was confirmed that the equilibrium did not shift during GLPC analysis even in the presence of the catalyst.

Each reaction was carried out from two or three directions as mentioned above, but the resulting equilibrium constants agreed very well with each other; the data are summarized in Table 1.

The K_1 and K_2 values are close to 2 and 0.5, when both alkoxyl groups have about the same binding ability to silicon and both alcohols have similar reactivity.

In case ROH are primary alcohols, *i.e.* Bu^nOH, Bu^iOH, $C_5H_{11}{}^nOH$, $K_1=2.36$—2.75 and $K_2=0.66$—0.69; these values are somewhat larger than those described above.

However, in the case of the reaction systems associated with secondary alkoxyl groups, K_1 and K_2

are smaller than the above values. $K_1=1.34$, $K_2=0.28$ (ROH:Bu^{s}OH); $K_1=1.43$, $K_2=0.30$ (MePr^{n}CHOH); $K_1=1.38$, $K_2=0.29$ (Et_2CHOH). Therefore, secondary alcohols seem to be less reactive to diethoxydimethylsilane than primary alcohols.

Tertiary alcohols are still more inactive than secondary alcohols,[10-13] and so the observed K_1 values of the reactions involving tertiary alcohols are fairly small, *i.e.* 0.148 (ROH:Bu^{t}OH) and 0.156 ($C_5H_{11}{}^tOH$).

As it was impossible to obtain the GLPC calibration curves of the di-*t*-alkoxydimethylsilanes, because of the inaccessibility of the pure sample, the accurate K_2 values could not be evaluated. But these values are estimated to be about 0.005 or below, when the slope of the calibration curves are inferred from analogy with the other alkoxysilanes. Such small values suggest that the di-*t*-alkoxysilanes are especially unstable, based on the steric repulsion between the two *t*-alkoxyl groups.

As described above, the K_1 and K_2 values of the reaction systems associated with primary, secondary, and tertiary alkoxyl groups decrease in this order, and these values reflect clearly the extent of the binding abilities of alkoxyl groups to silicon.

The catalytic function of iodine or iodine monobromide may also be illustrated by a mechanism *via* a four-centered transition state analogous to that previouly proposed.[1,2] Iodine or iodine monobromide forms charge transfer complexes with alcohols, and also with alkoxysilanes, and the dative forms of these complexes, *e.g.* $[ROH\cdots I]^+I^-$ or $[Me_2Si(OR)_2\cdots I]^+I^-$, seem to make up the above transition state.

The authors wish to thank professor Toshiyuki Shono of Osaka University and his co-workers for the elemental analyses and for the NMR and mass spectral data.

Asymmetric Reduction of Chiral Pyruvamide with Sodium Borohydride

Toratane MUNEGUMI and Kaoru HARADA*

Department of Chemistry, University of Tsukuba, Sakura-Mura, Niihari, Ibaraki 305

(Received August 2, 1982)

Several amides of pyruvic acid with (*S*)-amines were reduced with sodium borohydride (NBH) in several alcohols and *N*-[(*R*)-lactoyl]-(*S*)-amines were obtained in excess. When the reductions were carried out in methanol or ethanol in the presence of metallic salt, *N*-[(*S*)-lactoyl]-(*S*)-amines were obtained in asymmetric yields up to 22%.

Many studies[1-4] on the homogeneous reduction of chiral esters of α-keto acids have been performed, while few studies[4] on that of chiral α-keto acid amides have been reported. In the former case, an empirical rule was found between the absolute configuration of the chiral source and that of the product. This rule is called the Prelog's rule[2] and has been applied to the determination of the absolute configuration of chiral alcohols. In the latter, enough data have not been obtained to establish such a rule. The reduction of *N*-[(*S*)-α-methylbenzyl]benzoylformamide with sodium borohydride (NBH) was carried out by Mitsui and Kanai,[4] and (*R*)-mandelic acid was obtained in optical purity of 5.1%. According to the stereochemical consideration using a molecular model of the substrate, it seems unlikely that the benzoyl and the carbamoyl group coexist on the same plane, because of the steric repulsion between the phenyl and the carbamoyl group. In such a case the discussion on the steric course of the NBH reduction is more difficult compared with that of the esters.

In this paper, the NBH reduction of chiral amides of pyruvic acid, in which the above-stated steric repulsion is smaller than that of benzoylformamide, is described. The chiral amines used are (*S*)-α-methylbenzylamine, (*S*)- and (*R*)-α-ethylbenzylamine, and (*S*)- and (*R*)-1-(1-naphthyl)ethylamine. The substrates **2a**—**c** and **2b′**—**c′** were prepared by the condensation of the chiral amines and pyruvic acid with dicyclohexylcarbodiimide and *N*-hydroxysuccinimide (Fig. 1). The solvent used in the NBH reduction were methanol, ethanol, 2-propanol, *t*-butanol. The chemical and asymmetric yields of the products were determined by gas chromatographic analysis. The reduction of the substrate was also carried out in methanol and ethanol in the presence of a metallic salt.

Experimental

All the melting points were uncorrected. Optical rotations were measured with a JASCO DIP-181 Digital Polarimeter. All the GC analyses were carried out with a Hitachi 163 gas chromatograph, and the peaks on the chromatogram were integrated with a Hitachi 834-30 chromatoprocessor.

N-[(S)-α-Methylbenzyl]pyruvamide(2a) and Other Substrates 2b—c and 2b′—c′. To a cooled ethyl acetate solution (200 ml), in which pyruvic acid(5.00 g, 0.0567 mol), (*S*)-α-methylbenzylamine(6.87 g, 0.0567 mol), and *N*-hydroxylsuccinimide(7.84 g, 0.0681 mol) were dissolved, dicyclohexylcarbodiimide(12.9 g, 0.0624 mol) was added. The reaction mixture was stirred for 2 h at 0 °C and for 12 h at room temperature and filtered. The filtrate was extracted with three 100 ml portions of 1 mol dm^{-3} HCl, three 100 ml portions of an aquous $NaHCO_3$ solution(10%), and three 100 ml portions of a saturated aquous NaCl solution. The ethyl acetate layer was dried with anhydrous magnesium sulfate. The solvent was removed *in vacuo*, and a crude oily product was obtained. This product was purified by means of silica gel flash chromatography[5] (column: 15 cm×4 cm i.d., eluting solvent: ethyl acetate-hexane(1:5)).

The other four pyruvamide were prepared in a similar method. The optical rotations, elementary analyses, yields and melting points of the products are summarized in Table 1.

NBH Reduction of the Substrates 2a—c and 2b′—c′ without Metallic Salt. Substrates **2a—c** and **2b′—c′** (20 mg, 1×10^{-4} mol) were dissolved in a solvent(methanol, ethanol, isopropanol, and *t*-butanol), and were reduced by NBH (10 mg, 2.6×10^{-4} mol) at 30 °C for 90 min. After the reduction was over, the boron complex was decomposed by addition of 1 mol dm^{-3} HCl (2 ml). An aquous solution (20 ml) of saturated sodium chloride was added in the reaction mixture, and the resulted solution was extracted by three 20 ml portions of ethyl acetate. After drying the ethyl acetate layer, the solvent was removed and an oily product was obtained. Both the reaction yield and the ratio of each diastereomer were determined by gas chromatography.

NBH Reduction of Substrate 2a—c and 2b′ with Metallic Salt. The NBH reduction with a metallic salt(magnesium chloride or zinc chloride) was carried out by addition of NBH (10 mg, 2.6×10^{-4} mol) to 3 ml of a methanol or an ethanol solution of the substrate(20 mg, 1×10^{-4} mol) and the metallic salt(1×10^{-4} mol). The amount of the metallic salt in the reaction mixture of the substrate **2b′** was changed from 10 mg (1×10^{-4} mol) to 100 mg(1×10^{-3} mol). The reaction conditions, the work-up of the reaction mixture, and the analysis of the product was carried out in a similar manner as in the reduction without metallic salt.

Determination of the Reaction Yield. The oily product obtained by reduction was redissolved in chloroform(0.5 ml), and a part of the solution was injected into a gas chromatograph with a stainless column(4 m×3 mm i.d.), which was filled with Chromosorb W AW DMCS coated with 5% SE-52. Column temperature was raised from 100 °C to 250 °C at a rate of 5 °C per minute. The flow rate of carrier gas(nitrogen) was 39 ml/min and the temperature of injection port was 300 °C. The detector was flame-ionization detector.

Determination of the Diastereoisomeric Purity. TMS-Im Method:[6] Ten seconds after the injection of the pyridine solution of *N*-trimethylsilylimidazole, a 3 μl portion of the chloroform solution of the product was applied into the gas chromatograph equipped with the same column(SE-52) as described in the previous section. The column temperature was raised from 100 °C to 250 °C at a rate of 2 °C per minute. The other analytical conditions were same as those of the determination of the chemical yield. The diastereomeric lactamides were separated, and the diastereoisomeric purity was determined from the ratio of the integrated values of the diastereomeric peaks. This TMS-Im method was applied to the analyses of the entries 1—4, 6—9, 12—20, and 26—28.

TFA Method: To the NBH reduction product, trifluoroacetic acid (3 ml) saturated with HCl was added, and the resulting solution was refluxed for 15 min. The residue obtained by the evaporation of trifluoroacetic acid was redissolved in chloroform. The chloroform solution was injected into the gas chromatograph equipped with a glass capillary column(25 m×0.3 mm i.d.) coated with a chiral stationary phase, Chirasil-Val.[7] The O-TFA derivatives of the two diastereomers of each lactamide were separated on the chromatogram. The column temperature was raised from 90 °C to 180 °C at 4 °C per minute. The temperature of the injection port was 250 °C. This method was applied to the analyses of the reactions of entries 5, 10, 11, and 21—25 in Table 3 or 4. The retention times of O-TFA derivatives of the diastereomeric lactamides(**3a**, **3b′**, and **3c′**) are summarized in Table 2, and typical chromatographic peaks of O-TFA derivatives of lactamide **3b′** are shown in Fig. 2. The analyzed asymmetric yields were found to be similar by both TMS-Im and TFA methods.

Results and Discussion

The results of the NBH reduction without and with a metallic salt are shown in Tables 3 and 4, respectively.

In the NBH reduction without metallic salt, *N*-[(*R*)-lactoyl]-(*S*)-amine ((*R,S*)-lactamide) was obtained in excess over *N*-[(*S*)-lactoyl]-(*S*)-amine ((*S,S*)-lactamide) from the pyruvamide in which the chiral source was (*S*)-amine. The asymmetric yields were equal to or less than 11%, and substrate **2a** gave the lowest values. In the NBH reduction with metallic salts, the substrate in which the chiral source was (*S*)-amine gave (*S,S*)-lactamide in excess. Thus, the configuration of the lactoyl moiety of the resulting lactamide was reversed to the opposite structure in the reduction with metallic salts. When magnesium chloride was added to the reaction mixture, the asymmetric yield of (*R,R*)-lactamide increased with the increase of the concen-

tration of magnesium chloride in the reaction mixture (entries 21—24 in Table 4).

From these results, the conformation of the substrate in the solution and the steric course of the NBH reduction could be discussed as follows. Because of the electrostatic repulsion between the two carbonyl groups in the molecule, these carbonyl groups and the N–H bond should be on the same plane. Therefore, the asymmetric induction in the reduction without metallic salts could be discussed only by the consideration of the conformation of the chiral amine moiety.

The conformation of the pyruvamide in solution could be a mixture of the two conformers A and B shown in Fig. 3. The (*R,S*)-lactamide is formed in excess from conformer A, and the (*S,S*)-lactamide from conformer B in excess. Therefore, the observed asymmetric yield would be interpreted as the combined asymmetric induction of the reduction of each conformer. Since conformer A is more stable than conformer B, the (*R,S*)-lactamide could be formed in excess over the (*S,S*)-lactamide through the reduction. The X-ray crystallographic study[8,9] and the NMR measurement[10] of similar amides indicate that conformer A is more stable than conformer B. On the other hand, the asymmetric yield of the reduction of substrate **2b** was larger than that of **2a**. This could be explained by the steric repulsion between the ethyl group in the chiral source and the carbonyl group of the amide. Thus, the population of conformer B

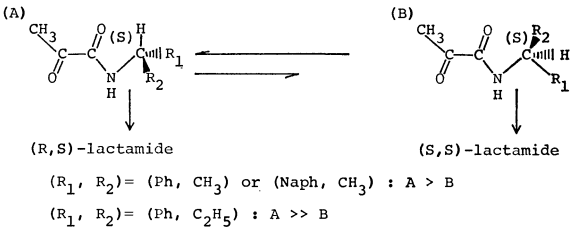

Fig. 3. Steric courses of the reduction without metallic salt.

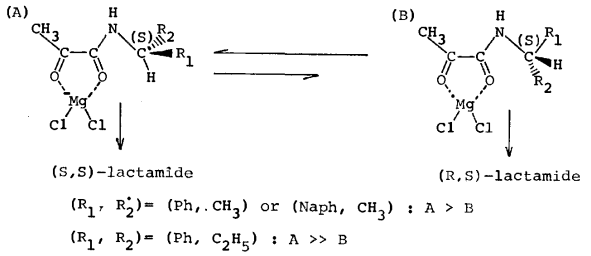

Fig. 4. Steric courses of the reductions with metallic salt.

is much smaller than that of conformer A as shown in Fig. 3, and the reduction of conformer A governs the asymmetric yield of the whole reaction. In the reduction of substrate **2c**, the asymmetric yield would be larger than the reduction of substrate **2a**, because of the difference in the bulkiness between the naphthyl and phenyl groups in substrates **2a** and **2c**.

The reduction with metallic salts may be explained in terms of the formation of a chelated substrate. The two carbonyl groups in the substrate could coordinate to the metallic salt and be fixed weakly in a *s*-cis conformation as shown in Fig. 4. And the asymmetric induction could be determined by the conformation of the asymmetric moiety of the substrate. The most preferred conformation could be that where the C–H bond of the asymmetric moiety is on the same plane with the chelated part of the substrate (Fig. 4). The hydrogenation of the substrate resulted in the formation of the (*S*,*S*)-lactamide. Thus, the configuration of the lactoyl moiety of the product ((*S*,*S*)-lactamide) reversed to the opposite structure from that obtained in the NBH reduction without metallic salt. The asymmetric yields of the NBH reduction with metallic salt were larger than those without metallic salt, possibly because of the fixation of the conformation by the chelation of the two carbonyl groups with the metallic salt.

Restricted Rotation Involving the Tetrahedral Carbon. XLIV. Atropisomers of 2,3-Dichloro-9-(1-hydroxy-1-methylethyl)-triptycene and Related Compounds[1]

Michinori Ōki,* Yoshiyuki Tanaka, Gaku Yamamoto, and Nobuo Nakamura
Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113
(Received August 10, 1982)

Atropisomers of 2,3-dichloro-9-(1-hydroxy-1-methylethyl)triptycene were obtained as stable compounds at room temperature. The barrier to rotation (±*sc*→*ap*) was 34.0 kcal/mol at 153 °C. Other 9-(1-hydroxy-1-methylethyl)triptycenes carrying a substituent in the 1-position of the skeleton gave ±*sc* isomers only. Attempted isomerization of the ±*sc* forms failed because the free energy difference between the ±*sc* and *ap* forms is great due to the steric effect. ±*sc*-9-(1-Methoxy-1-methylethyl)-1,4-dimethyltriptycene was prepared in a hope that increasing the steric size of the hydroxyl group would help to produce an *ap*-isomer on heating. The *ap* isomer was detected but the population ratio *ap*/±*sc* was too small to isolate the *ap*.

Various triptycene derivatives were found to give stable rotational isomers at room temperature provided that the 9-substituent is tertiary and the triptycene skeleton carries a substituent which provides necessary breaking of the symmetry.[2] However, the 9-substituent was confined to those carrying three carbons in the 1-position of the substituent so far. It may be of interest to see how the barriers to rotation and populations of rotamers are affected if one of the substituents in the 1-position of the 9-substituent is changed to a hetero atom. As the first of such investigations, we have undertaken the investigation on the case of a 9-(1-hydroxy-1-methylethyl) substituent. This paper is to report the results and to discuss implications therefrom.

The syntheses of the compounds were rather interesting. Although benzynes are known to react with hydroxylic compounds to give aromatic oxygen derivatives,[3] 9-(1-hydroxy-1-methylethyl)anthracene (**1**) gave the desired triptycenes (**2**) when it was treated

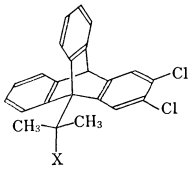
with benzynes. We believe that the result is caused because the anthracene moiety is strongly nucleophilic and the hydroxyl group is protected from the attack by the steric effect. The only exception to the normal cases was the reaction of tetrafluorobenzyne, which gave 9-isopropenylanthracene only as a product of the benzyne reaction. Since tetrafluorobenzyne is very strongly electrophilic, it seems to react with the oxygen of the alcohol (**1**) preferentially. In accordance with this explanation, other benzynes which are strongly electrophilic gave also 9-isopropenylanthracene to some extent.

The reaction, if proceeded as expected, gave ±*sc* conformational isomers of a desired compound as a sole product. This is reasonable in the sense that a methyl group is much larger than an oxygen group: the benzyne addition to 9-substituted anthracene is known to proceed from the less crowded side with great preference.[4] The assignment of the stereostructure of the product is straightforward. The ±*sc* conformation should show two methyl signals in ^{1}H NMR spectra because the environments of the two methyls are different in this conformation, whereas the environments of the methyls in the *ap* conformation are identical.

Table 1. Rates of isomerization (±*sc*→*ap*) and equilibrium constants in 2,3-dichloro-9-(1-hydroxy-1-methylethyl)triptycene (**2b**) in 1-chloronaphthalene

Temperature/°C	k/s^{-1}	K (*ap*/±*sc*)
212	—	0.30
165.6	8.63×10^{-5}	0.27
153.0	3.34×10^{-5}	0.29
144.6	1.69×10^{-5}	0.29
132.5	5.21×10^{-6}	0.31

The rate constants for isomerization of ±*sc*-**2b** are summarized in Table 1. The Eyring plot yielded ΔH^* 29.1±2.5 kcal/mol (1 cal=4.18 J) and ΔS^* −11.5± 6.0 e. u. (1 e. u.=4.18 J K^{-1} mol^{-1}). If these activation parameters are compared with those of 2,3-dichloro-9-(1-methoxycarbonyl-1-methylethyl)triptycene (**3**) (ΔH^* 33.8 kcal/mol and ΔS^* −1.8 e. u.),[5] 2,3-dichloro-9-(1-cyano-1-methylethyl)triptycene (**4**) (ΔH^* 39.4 kcal/mol and ΔS^* 6.5 e. u.),[5] and 2,3-dichloro-9-(1,1-dimethyl-2-phenylethyl)triptycene (**5**) (ΔH^* 35.7



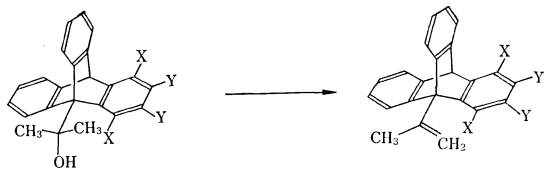
3: X=$COOCH_3$
4: X=CN
5: X=$CH_2C_6H_5$

kcal/mol and ΔS^* −9.3 e. u.),[4] one notices that the enthalpy of activation of **2b** is definitely small. The results may be attributed to the small bulkiness of the oxygen group in **2b** relative to a methoxycarbonyl, cyano, or benzyl group. Namely, the lowering of the transition state energy is more effective than lowering of the ground state energy in determining the barrier

to rotation in **2b**.

The equilibrium constants ($ap/\pm sc$) of **2b** are smaller than the statistical value and are even smaller than those compounds cited above (**3**—**5**). Two possibilities emerge for the explanation. One is that the *ap* conformation of **2b** is destabilized relative to *ap* conformations of other compounds and the other is the special stabilization of the $\pm sc$ conformation of **2b**. The 1-H undoubtedly suffers from the buttressing effect of the 2-Cl group, thus it should be larger in effective size than other *peri*-hydrogens. Then probably the repulsive interaction between the 1-H and the flanking groups (two methyls) in the *ap* conformation is more severe than that between the 8(or 13) -H and two methyl groups in $\pm sc$ conformations. We believe this kind of steric effect is an important factor among others that favor the $\pm sc$ conformation of **2b** in the ground state, since no effect of stabilization of the $\pm sc$ form is apparent. Indeed, 2,3-dichloro-9-(1,1-dimethyl-2-phenylethyl)triptycene (**5**) gives $ap/\pm sc$ of 0.50,[4] which is the statistical value, because the effective sizes of the benzyl and the methyl groups are almost the same.

Other triptycenes (**2**) carrying (a) substituent in 1-position failed to give any sign of the presence of *ap* isomers, although their solutions were heated at 212 °C for a long time. Instead, they afforded compounds of which ^{1}H NMR spectra are compatible with 9-isopropenyltriptycenes (**6**): indeed, 1,4-dimethyl derivative of **6** was characterized. Since this dehydration did not occur at 164 °C after 40 h, the dehydration is caused by heating at >200 °C. The results indicate that the *ap* conformation in these compounds are extremety unstable relative to the $\pm sc$, since the barriers to rotation in other analogous compounds[4,5] suggest that the internal rotation about the C_9–C_{subst} bond must be occurring under the conditions of the heating. It is not clear at the moment at what conformation the dehydration takes place.



1 6

The ^{1}H NMR spectra of isopropenyltriptycenes (**6**) indicate that the internal rotation about the C_9–C_{ipr} bond in these compounds is fast on the NMR time scale. This is interesting, if one considers a very high barrier to rotation in 9-*t*-alkyltriptycenes. But there is a precedent of this instance: 9-*o*-tolyltriptycenes show rather low barriers to rotation.[6] If a 9-substituent has an sp^2-hybridized carbon in its 1-position, the ground state seems to be raised owing to the interaction of the triptycene skeleton with the trigonal group.

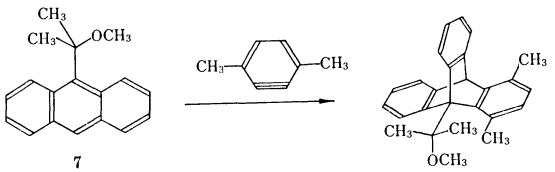
The great stability of the $\pm sc$ forms of **2c**—**e** relative to the *ap* must be attributed to the steric effect. If a 9-substituent in triptycenes contain a small group in its 1-position and the triptycene skeleton carries a *peri*-substituent, there is seen a strong preference of a conformation in which the small group gives the gauche interaction with the *peri*-substituent. If the 9-substituent is a secondary alkyl group, a conformation in which two bulky groups flank the *peri*-substituent is not usually detected.[7] Even in the tertiary alkyl cases, it is true: if a 1-substituent in the 9-substituent of triptycene is either trigonal or linear, the conformation in which the trigonal or linear group is $\pm sc$ to the *peri*-substituent is strongly favored.[5] The case of compound **2** is considered to be in the same line, since the OH group is much smaller than a methyl. The OH-*sc* conformation must be favored relative to the OH-*ap* conformation.

Hydrogen bonding between the OH group and the *peri*-substituent may be playing some role in stabilizing the $\pm sc$ conformation. Indeed, ^{1}H NMR spectra show that the OH proton gives a sharp peak if there is a *peri*-substituent with lone pair electrons, whereas the OH proton signal either was broad or could not be detected in others. However, the effect of the hydrogen bond must be of minor importance, because even the 1,4-dimethyl compound (**2e**) gives only $\pm sc$ conformations.

This consideration suggests that, if the hydroxyl group is modified to make a larger group, there is a possibility that *ap* conformation exists. Thus ester formations and ether formations of both the anthracene–alcohol (**1**) and the triptycene–alcohol (**2**) were tried under various conditions. However, all the attempts failed because of the steric effect except for one case, that is the methylation of **1**.

Treatment of the methyl ether (**7**) with tetrachlorobenzyne did not afford a triptycene derivative but 9-isopropenylanthracene. It is not clear why the methyl ether (**7**) gives 9-isopropenylanthracene, whereas the hydroxy compound (**1**) gives a triptycene to some extent, since the oxygen in the methyl ether seems to be more protected than the hydroxylic oxygen on the steric ground. Probably the electronic effect and/or the steric deceleration of the attack of benzyne toward the anthracene ring, due to introduction of the methyl group to the hydroxyl, is important.

Tetrachlorobenzyne has been known to give an olefin if it reacts with an ether[8] because of its electrophilic nature. If we could lower the electrophilicity of a benzyne, there is a chance of obtaining a triptycene derivative. Thus we treated **7** with 3,6-dimethylbenzyne and indeed obtained *sc*-9-(1-methoxy-1-methylethyl)-1,4-dimethyltriptycene (**8**). Isomerization of **8**, however, gave only a minute amount of the *ap* isomer, of which isolation was not practical. The steric effect of a methoxyl group is indeed greater than a hydroxyl group, because we could detect the presence of the *ap* form of **8**, but is not great enough to give sizable amount of the *ap*.



7 8

Experimental

3,6-Dimethoxyanthranilic Acid. To 90 mL of chilled nitric acid (d=1.38) was added portionwise 9.1 g (0.05 mol) of 2,5-dimethoxybenzoic acid[9] during the course of 30 min and the solution was stirred at 0—5 °C for 3 h. The mixture was poured into 300 mL of ice–water and the precipitate was collected by filtration. The product was shown to be a mixture (*ca.* 5:1) of 2,5-dimethoxy-6-nitrobenzoic acid and 2,5-dimethoxy-4(or 3)-nitrobenzoic acid by ^{1}H NMR spectra. The mixture (10.4 g) was hydrogenated over Pd–C in ethyl acetate under normal pressure. Removal of the catalyst, evaporation of the solvent, and recrystallization of the residue from aqueous ethanol gave 3.4 g (38%) of the desired acid as white needles, mp 92—94 °C (lit,[10] mp 97 °C).

*9-(1-Hydroxy-1-methylethyl)anthracene (**1**).* A Grignard reagent was prepared from 1.42 g (60 mmol) of magnesium, 5.0 g (20 mmol) of 9-bromoanthracene[11] and 90 mL of ether. To the solution, 5 mL (68 mmol) of acetone in 20 mL of ether was added and the whole was stirred overnight. The mixture was decomposed with ice and aqueous ammonium chloride and the ether layer was separated. The ether layer was washed thoroughly and dried over magnesium sulfate. After evaporation of the solvent, the residue was recrystallized from benzene. For further purification, the product was submitted to silica gel chromatography (hexane–dichloromethane eluent) to give 1.6 g of the desired product, mp 139.0—140.5 °C (lit,[12] mp 136 °C). ^{1}H NMR ($CDCl_3$, δ): 2.15 (6H, s), 7.1—7.6 (4H, m), 7.7—8.1 (2H, m), 8.28 (1H, s), 8.6—8.9 (2H, m).

*±sc-2,3-Dichloro-9-(1-hydroxy-1-methylethyl)triptycene (**2b**).* To a solution of 473 mg (2.0 mmol) of the alcohol (**1**) and 0.5 mL (3.8 mmol) of isopentyl nitrite in 40 mL of chlorobenzene, was added 828 mg (4.0 mmol) of 4,5-dichloroanthranilic acid[4] in 50 mL of chlorobenzene in *ca.* 2 h with stirring and heating. More isopentyl nitrite was added after *ca.* 1 h during the addition of the anthranilic acid. After heating for another hour, the solvents were evaporated *in vacuo* and the residue was taken up in dichloromethane. The solution was submitted to chromatography on silica gel with hexane–dichloromethane eluents (5:1—2:1) to give *±sc*-**2b**, mp 193.5—195 °C, in 13% yield. Found: C, 72.22; H, 4.62; Cl, 18.47%. Calcd for $C_{23}H_{18}Cl_2O$: C, 72.45; H, 4.76; Cl, 18.60%. ^{1}H NMR ($CDCl_3$, δ): 2.20 (3H, s), 2.24 (3H, s), 5.16 (1H, s), 6.85—7.1 (4H, m), 7.2—7.45 (2H, m), 7.41 (1H, s), 7.55 (1H, m), 8.0 (1H, m), 8.15 (1H, s).

Attempted Synthesis of 1,2,3,4-Tetrafluoro-9-(1-hydroxy-1-methylethyl)triptycene. A similar treatment of the alcohol (**1**) and isopentyl nitrite in dichloromethane with tetrafluoroanthranilic acid[13] in tetrahydrofuran afforded anthraquinone and 9-isopropenylanthracene, mp 84.5—86.0 °C (lit,[14] mp 84.5—86 °C). ^{1}H NMR ($CDCl_3$, δ) of isopropenylanthracene exhibited the following signals: 2.15 (3H, d, J=1 Hz), 5.05 (1H, m), 5.63 (1H, m), 7.2—7.5 (4H, m), 7.7—7.9 (2H, m), 7.9—8.2 (2H, m), 8.18 (1H, s). No tetrafluorotriptycene derivative was detected.

*9-(1-Hydroxy-1-methylethyl)triptycene (**2a**)*, mp 200—202 °C, was prepared similarly from **1** and isopentyl nitrite in dichloromethane and anthranilic acid in acetone in 75% yield. The original product was contaminated with a small amount of 9-isopropenylanthracene. The product was purified by recrystallization from tetrahydrofuran–hexane. Found: C, 88.64; H, 6.39%. Calcd for $C_{23}H_{20}O$: C, 88.43; H, 6.45%. ^{1}H NMR ($CDCl_3$, δ): 2.31 (6H, s), 2.58 (1H, br s), 5.25 (1H, s), 6.8—7.5 (9H, m), 7.5—7.7 (1H, m), 7.9—8.1 (2H, m).

*±sc-1,2,3,4-Tetrachloro-9-(1-hydroxy-1-methylethyl)triptycene (**2d**)*, mp 299—300.5 °C, was similarly prepared from the alcohol (**1**) and isopentyl nitrite in dichloromethane and tetrachloroanthranilic acid[15] in acetone in 11.2% yield. A fair amount of isopropenylanthracene was detected. Found: C, 61.06; H, 3.38; Cl, 31.31%. Calcd for $C_{23}H_{16}Cl_4O$: C, 61.36; H, 3.58; Cl, 31.50%. ^{1}H NMR ($CDCl_3$, δ): 2.12 (3H, s), 2.42 (3H, s), 4.33 (1H, s), 6.03 (1H, s), 6.9—7.25 (4H, m), 7.3—7.6 (2H, m), 7.6—7.8 (1H, m), 8.5—8.7 (1H, m).

*±sc-9-(1-Hydroxy-1-methylethyl)-1,4-dimethoxytriptycene (**2c**)*, mp 272—273 °C, was prepared similarly from the alcohol and isopentyl nitrite in dichloromethane and 3,6-dimethoxyanthranilic acid in tetrahydrofuran in 14% yield. Found: C, 80.72; H, 6.46%. Calcd for $C_{25}H_{24}O_3$: C, 80.62; H, 6.49%. ^{1}H NMR ($CDCl_3$, δ): 2.16 (6H, s), 3.77 (3H, s), 3.82 (3H, s), 5.86 (1H, s), 5.90 (1H, s), 6.55 (2H, s), 6.85—7.1 (4H, m), 7.25—7.55 (2H, m), 7.65 (1H, m), 8.4 (1H, m). On addition of benzene-d_6 to the chloroform-d solution, the methyl proton signal at δ 2.16 was split into two.

*±sc-9-(1-Hydroxy-1-methylethyl)-1,4-dimethyltriptycene (**2e**)*, mp 255—257 °C, was similarly prepared from the alcohol (**1**) and 3,6-dimethylanthranilic acid[16] in 50% yield. Found: C, 88.06; H, 7.01%. Calcd for $C_{25}H_{24}O$: C, 88.20; H, 7.10%. ^{1}H NMR ($CDCl_3$, δ): 2.22 (3H, s), 2.32 (3H, s), 2.46 (3H, s), 2.82 (3H, s), 5.57 (1H, s), 6.71 (2H, s), 6.85—7.1 (4H, m), 7.2—7.45 (2H, m), 7.6 (1H, m), 8.2 (1H, m).

*9-(1-Methoxy-1-methylethyl)anthracene (**7**).* To a solution of 718 mg (3.0 mmol) of the alcohol (**1**) in 100 mL of tetrahydrofuran was added 2 mL of 1.5 M butyllithium in hexane and the whole was stirred for 3 h. Methyl iodide (5 mL) was added and the mixture was stirred for 3 h. The solvent and the excess of methyl iodide were evaporated in vacuo and the residue was taken up in ether. The ethereal solution was washed and dried. Evaporation of the solvent followed by recrystallization of the residue from dichloromethane–hexane afforded 526 mg of the desired product, mp 107—108.5 °C. Found: C, 86.29; H, 7.06%. Calcd for $C_{18}H_{18}O$: C, 86.36; H, 7.25%. ^{1}H NMR ($CDCl_3$, δ): 2.15 (6H, s), 2.80 (3H, s), 7.2—7.45 (4H, m), 7.85—8.05 (2H, m), 8.33 (1H, s), 8.6—8.95 (2H, m).

*±sc-9-(1-Methoxy-1-methylethyl)-1,4-dimethyltriptycene (**8**)*, mp 251—252 °C, was prepared by treating **7** with 3,6-dimethylbenzyne as above. Found: C, 87.95; H, 7.15%. Calcd for $C_{26}H_{26}O$: C, 88.09; H, 7.39%. ^{1}H NMR ($CDCl_3$, δ): 2.09 (3H, s), 2.13 (3H, s), 2.46 (3H, s), 2.64 (3H, s), 3.55 (3H, s), 5.57 (1H, s), 6.69 (2H, s), 6.7—7.2 (4H, m), 7.2—7.4 (2H, m), 7.56 (1H, m), 8.00 (1H, m).

A 1-chloronaphthalene solution of *±sc*-**8** showed the following ^{1}H NMR signals (ppm from internal cyclododecane): 0.52 (6H, s), 1.16 (3H, s), 1.38 (3H, s), 1.87 (3H, s). When the solution was heated in a boiling-nitrobenzene bath, the following ^{1}H NMR signals were observed: 0.72 (6H, s), 0.97 (3H, s), 1.91 (3H, s). Another signal for 1(or 4)-methyl protons is missing: it probably overlaps with one of the signals due to 1- and 4-methyls of the *±sc* form. The equilibrium was reached within 5 h at this temperature and the equilibrium constant (*ap*/*±sc*) was *ca.* 1/30. Prolonged heating of the solution caused decomposition of the solute.

Determination of Barriers to Rotation. A sample (55 mg) of *±sc*-**2b** was dissolved in 1.4 mL of 1-chloronaphthalene and placed in NMR sample tubes, the solution being divided into 4 portions. The NMR sample tube was placed in an appropriate boiling-solvent bath and the isomerization rate was determined by ^{1}H NMR spectroscopy. The temperature was directly read by a thermometer. The integration of the peak area was carried out 5 times and the

average of the middle three was taken for calculation of the rate constant. The conversion rate was treated assuming a reversible first-order reaction. The solvents used for the bath are nitrobenzene (212 °C), mesitylene (165.5 °C), anisole (153.0 °C), *o*-xylene (144.6 °C), and chlorobenzene (132.5 °C). The rate constants were put into the Eyring equation and the activation parameters were obtained.

*ap-2,3-Dichloro-9-(1-hydroxy-1-methylethyl)triptycene (**2b**).* The equilibrium mixture of ±*sc*- and *ap*-**2b**, obtained as a result of the isomerization experiments, was concentrated *in vacuo* and submitted to chromatography on alumina. After the solvent was eluted with hexane, a ±*sc*-*ap* mixture was obtained by elution with dichloromethane. The mixture was separated by TLC on silica gel (2:1 dichloromethane–hexane solvent). The *ap* form, mp 207—209 °C, had a smaller R_f value than the ±*sc* form. High resolution mass spectrum showed molecular ion peaks at *m/e* 380.0775, 382.0759, and 384.0707, whereas $C_{23}H_{18}Cl_2O$ requires those at 380.0735, 382.0706, and 384.0676. The intensities of these peaks agreed well with those calculated from the natural abundance of ^{35}Cl and ^{37}Cl. ^1H NMR ($CDCl_3$, δ): 2.26 (6H, s), 5.17 (1H, s), 6.85—7.1 (4H, m), 7.2—7.45 (2H, m), 7.46 (1H, s), 7.59 (1H, s), 8.0 (2H, m).

*9-Isopropenyl-1,4-dimethyltriptycene (**6**: X=CH_3, Y=H).* A solution of ±*sc*-**2e** (20 mg) in 0.4 mL of 1-chloronaphthalene was heated in a boiling-nitrobenzene bath for 40 h. The solution was submitted to chromatography on alumina (hexane eluent) and the product was recrystallized from pentane to give 14 mg of the product, mp 149—150 °C. Found: C, 92.99; H, 6.84%. Calcd for $C_{25}H_{22}$: C, 93.12; H, 6.88%. ^1H NMR ($CDCl_3$, δ): 2.27 (3H, s), 2.44 (6H, s), 5.48 (1H, s), 5.79 (1H, br s), 5.93 (1H, br s), 6.63 (2H, s), 6.85—7.1 (4H, m), 7.2—7.6 (2H, m), 7.6—7.9 (2H, m).

Determination of Spectra. ^1H NMR spectra were obtained on a Varian EM 390 spectrometer.

Restricted Rotation Involving the Tetrahedral Carbon. XLV. Appearance of a Maximum in the Rotational Barriers of 9-(1,1-Dimethyl-2-phenylethyl)triptycenes at a Medium-sized *peri*-Substituent[1]

Gaku YAMAMOTO, Masahiko SUZUKI, and Michinori ŌKI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received August 10, 1982)

Rotational isomers of seven *peri*-substituted 9-(1,1-dimethyl-2-phenylethyl)triptycene derivatives were stereoselectively synthesized and classical kinetics on rotational isomerization were studied. While compounds with relatively small *peri*-substituents (F and OCH_3) showed higher barriers than the *peri*-unsubstituted one, the *peri*-chloro compound had almost the same barrier with and those carrying bulkier *peri*-substituents (Br, CH_3, and CF_3) showed lower barriers than the *peri*-unsubstituted one. These apparently anomalous phenomena may be explained in terms of large molecular deformation of these highly congested compounds.

We have shown by NMR spectroscopy that 9-substituted triptycene derivatives constitute an excellent model system in the investigation of rotational isomerism about a single bond.[2] The compounds have high barriers to rotation about the bridgehead-to-substituent bond because of the rigidity of the triptycene skeleton. Thus, even a methyl group shows restricted rotation on the NMR time scale in some 9-methyltriptycene derivatives.[3]

Bulkiness of the 9-substituent is the largest factor governing the height of the barrier. Thus, 9-*t*-alkyltriptycenes have high rotational barriers enough to give rise to rotational isomers isolable at room temperature (atropisomers).[4]

Substitution at *peri*-positions (1-, 8-, and 13-positions) also has a large influence on the barrier. While 9-benzyltriptycenes carrying one *peri*-substituent showed the rotational barrier of *ca.* 12 kcal mol^{-1} (1 cal=4.184 J),[5] a triply *peri*-substituted 9-benzyltriptycene could give rise to stable atropisomers with the barrier of 25.3 kcal mol^{-1}.[6] Influence of the nature (mainly steric) of *peri*-substituents on the rotational barrier has been studied in some of singly *peri*-substituted 9-alkyl(or aralkyl)triptycenes. When the 9-substituent is a primary or a secondary alkyl group, the barrier increases with the bulkiness of the *peri*-substituent.[3,7,8] This tendency can be easily understood if one accepts that the effect of steric crowding due to the *peri*-substitution should be larger in the transition state than in the ground state.

In the case of 9-(1-cyano or 1-methoxycarbonyl-1-methylethyl)triptycene, however, introduction of a chloro or a methyl group into a *peri*-position was found to decrease the rotational barrier, the clear explanation remaining to be solved.[9]

In order to see if this phenomenon is generally observed in 9-*t*-alkyltriptycene derivatives, and also to get a deeper insight into the origin of the phenomena by investigating the effects of some other *peri*-substituents, we studied the rotational barriers of a variety of *peri*-substituted 9-(1,1-dimethyl-2-phenylethyl)triptycene derivatives **2**—**8**.[10] The results are presented in this paper. The choice of this particular system is based on the following reasons. Firstly, the 9-substituent has no polar bond which might have special interaction with *peri*-substituents. Secondly, similarity in bulkiness between methyl and benzyl groups might not cause a large shift of the rotational equilibrium from the statistical value, which would make kinetic measurements easy. Thirdly, we previously reported on the synthesis of and the rotational barrier in the *peri*-unsubstituted derivative **1**.[4]

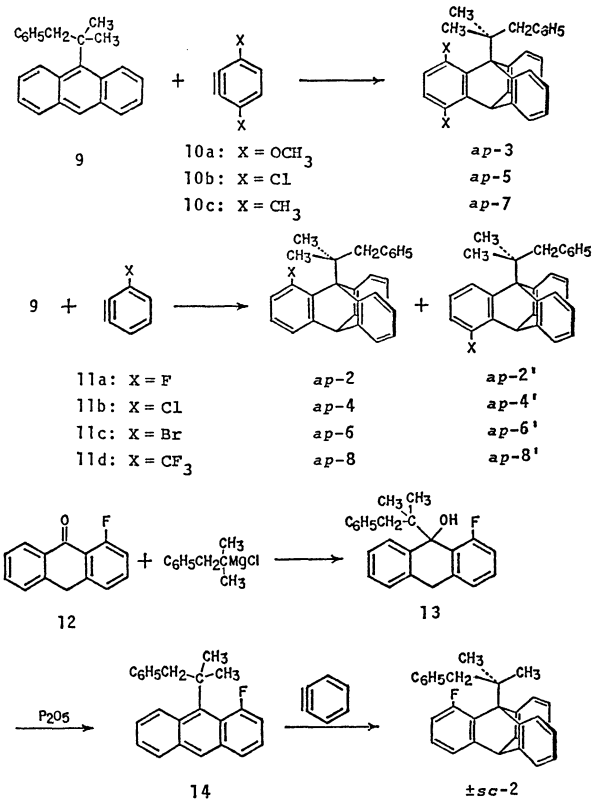
Results

Syntheses. Triptycenes investigated were synthesized by the reactions of 9-(1,1-dimethyl-2-phenylethyl)-anthracene (**9**) with benzynes **10** and **11**. The benzyne (**11a**) was generated by decomposition of 2,6-difluorophenyllithium prepared from *m*-difluorobenzene and butyllithium.[11] The other benzynes were generated by decomposition of 3- or 3,6-substituted 2-diazoniobenzoates prepared from the corresponding anthranilic acids and isopentyl nitrite. The triptycenes formed existed exclusively in the *ap* atropisomer in accordance with the stereoselectivity previously found in the case of **1**. Thus, the atropisomer is selectively formed in which the bulkier group in the 9-substituent assumes the antiperiplanar position to the benzeno bridge derived from the benzyne.[4] In the reactions of **9** with benzynes **11**, the regioisomeric 4-substituted triptycenes were formed in addition to the desired 1-substituted ones. Identification of the regioisomers was made by the chemical shifts of the bridgehead protons: those of 1-substituted derivatives appeared at δ 5.20—5.27, while those of 4-substituted ones appeared at a lower field because of the anisotropic and/or steric compression effects of the 4-substituent. The ratio of formation of 1- *vs.* 4-substituted compounds were as follows: 5.0 for **2**/**2**′, 1.3 for **4**/**4**′, 1.0 for **6**/**6**′ and **8**/**8**′. Preferred formation of the more crowded regioisomers may be apparently anomalous, but is not unprecedented.[12] Separation of the two regioisomers was successfully made by chromatography for **4**/**4**′, **6**/**6**′, and **8**/**8**′pairs. In the case of the fluoro derivatives (**2**/**2**′), the separation was extremely difficult, and the pure sample of

2 was obtained only in a minute amount. Therefore, synthesis of **2** by another route was explored. 9-(1,1-Dimethyl-2-phenylethyl)-1-fluoroanthracene (**14**) was prepared by the reaction of 1,1-dimethyl-2-phenylethylmagnesium chloride with 1-fluoroanthrone (**12**) followed by dehydration, and was treated with benzyne. In this reaction, the ±*sc* rotamer of **2** was stereoselectively obtained.

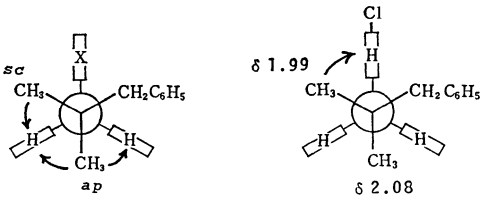


First choice for the isolation of the ±*sc* rotamers of compounds **3**—**8** was chromatography of the equilibrated rotamer mixture on alumina or silica-gel columns. In all cases the *ap* rotamers eluted slightly faster than the ±*sc*. The intrinsically small differences of the chromatographic properties between the rotamers as well as the unavolidable tailing of the bands of *ap* rotamers made isolation of the pure ±*sc* rotamers highly difficult, and the isolation in pure state was successful only for **3**. Secondly, separation by fractional recrystallization was tried but here again the situation was similar because the *ap* rotamers generally had better crystallizability than the ±*sc* rotamer and complete purification of the ±*sc* rotamer was made only for **7**. For compounds **4**, **5**, and **6**, the ±*sc*-enriched mixtures with the content of the *ap* rotamers of 20, 15, and 8%, respectively, were finally obtained. As for **8**, the ±*sc* rotamer was enriched only to 25%.

NMR Spectra. ^{1}H NMR spectral data for both rotamers of the triptycenes (**1**—**8**) are given in Table 1. As for the ±*sc* rotamers of **4**, **5**, **6**, and **8**, the data were obtained from the most enriched samples mentioned above by subtracting the signals due to the *ap* rotamers. Rotameric assignment was explicitly made from the NMR data. The *gem*-dimethyl groups of the *ap* rotamers are enantiotopic and appear as a singlet except for those of **2** and **8**, in which they appear as a doublet and a quartet, respectively, because of the long-range couplings with ^{19}F.[13] The methylene protons are singlets in all of the *ap* rotamers.

In the ±*sc* rotamers, the *gem*-dimethyl groups are *a priori* diastereotopic and actually are anisochronous. Positional assignment of the methyl signals was made as follows. In fluorine-containing compounds **2** and **8**, the signal exhibiting a large coupling with ^{19}F was assigned to the ±*sc*-methyl group, because the coupling should operate through-space under these circumstances and thus the protons located proximate to the ^{19}F nuclei show the coupling.[13]

Nuclear Overhauser effect (NOE) experiments allowed the definite assignment of the methyl signals for **3**—**6**. In any of the compounds, irradiation of the higher-field methyl signal enhanced the intensity of both of the *peri*-proton (8-H and 13-H) signals which appeared as two isolated multiplets at the lowest field region (δ 7.7—8.1). On the other hand, only the



lower-field *peri*-proton signal showed enhancement of the intensity upon irradiation of the lower-field methyl signal. Therefore, the higher-field methyl signal is assigned to the *ap*-methyl group as shown in Table 1. In the ±*sc* rotamer of **1**, the 1-H signal appeared as a singlet at the lowest field (δ 8.03) together with two multiplets for 8-H and 13-H, and its intensity increased only when the higher-field methyl signal at δ 1.99 was irradiated, indicating that the signal should be assigned to the ±*sc*-methyl group. In ±*sc*-**7**, NOE experiments did not afford any information on the assignment because of the small chemical shift difference between the *gem*-dimethyl signals, and tentative assignment is given in Table 1.

It is noticed that the *ap*-methyl signal appears at a lower field than that for the ±*sc*-methyl in **1** and **2**, but the reverse is observed in the other compounds. Roughly speaking, the ±*sc*-methyl signal shifts downfield and the *ap*-methyl upfield as the bulkiness of the *peri*-substituent increases. Large downfield shifts of the ±*sc*-methyl signals in **4**, **5**, **6**, and **8** must be due to the anisotropy and/or steric compression effects exerted by the *peri*-substituents. Upfield shift of the *ap*-methyl signals in these compounds may partly be ascribed to the molecular deformation, which is discussed in the later section.

The methylene protons of the ±*sc* rotamers are diastereotopic and appear as an AB-quartet except for those of ±*sc*-**8**, which give an apparent singlet in $CDCl_3$ because of the small chemical shift difference but show an AB-quartet signal (δ 4.11 and 4.24, J= 15.3 Hz) in a benzene solution.

Kinetics of Isomerization. A solution of a pure rotamer (±*sc* for **2**, *ap* for the others) in 1-chloronaphthalene was heated at a given temperature using

a boiling solvent bath. At appropriate intervals the sample was taken out of the bath and cooled to room temperature. NMR spectrum was taken to obtain the rotamer population. The ^{19}F signals were used for compounds **2** and **8**, and the *gem*-dimethyl proton signals for the others. Change in the rotamer population upon time obeyed the rate law for a first-order reversible reaction and the rate constant for the isomerization was obtained. The measurements were made at three to four temperatures over the range of 32—50 °C, and the Eyring kinetic parameters were calculated using least square analysis. In Table 4 are given the rate constants for the $ap \rightarrow \pm sc$ conversion by taking into account the degeneracy of the $\pm sc$ rotamers and the free energies of activation therefrom. Eyring parameters as well as free energies of activation and rate constants at 500 K are given in Table 3. The thermodynamic parameters were calculated from the equilibrium constants using the van't Hoff equation and are given in Table 2. Here also the degeneracy of the $\pm sc$ rotamers was taken into account.

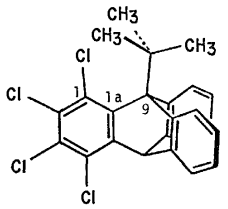
Discussion

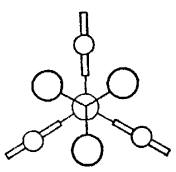
General Consideration. Inspection of molecular models reveals that even in the simplest 9-*t*-alkyltriptycene, 9-*t*-butyltriptycene, the distance between a *peri*-hydrogen and the nearest methyl-hydrogen in the staggered conformation is only 1.5 Å, far shorter than the sum of the van der Waals radii, indicating that the compound itself is a highly crowded molecule. This suggests that introduction of a substituent into one of the *peri*-positions of the triptycyl skeleton should heavily affect the geometry and energy of the molecule.

As an energy barrier to internal rotation is the difference between the ground and the transition states, the influence of the *peri*-substitution on the energy barrier should be understood in terms of perturbation to the both states by the *peri*-substitution. Although the geometry and energy of the transition state can not be directly obtained experimentally, information about those of the ground state may be obtained from several sources.

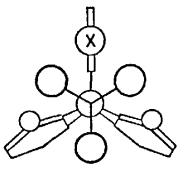
X-Ray structural analysis of 9-*t*-butyl-1,2,3,4-tetrachlorotriptycene (**15**) revealed the presence of considerable molecular deformation.[14] The most prominent features are the tiltings of the *t*-butyl and the *peri*-chloro groups away from each other (*t*-Bu–C_9–C_{1a}: 118.9°, C_{1a}–C_1–Cl: 125.4°) and the elongation of the C_9–C_{arom} bonds (especially C_9–C_{1a}: 1.603 Å) owing to steric compression.



15



16



17

We now concentrate our attention to the tilting of the *t*-butyl–C_9 bond from the axis of the triptycene skeleton. The Newman projection of a *peri*-unsubsti-

tuted 9-*t*-butyltriptycene along the *t*-butyl–C_9 bond is shown by **16**. If a substituent is introduced into one of the *peri*-positions, the steric repulsion between the *peri*-substituent and the *t*-butyl group should cause the tilting of the axis bond away from the *peri*-substituent. This feature can be represented by the Newman projection **17**. The degree of the tilting of the axis bond should become larger as the bulkiness of the *peri*-substituent increases. Similar molecular deformation should occur in 9-(1,1-dimethyl-2-phenylethyl)triptycenes.

^{1}H NMR spectral data in Table 1 indicate the tendency that the *ap*-methyl signal of the $\pm sc$ rotamer shifts upfield as the *peri*-substituent becomes bulkier. It is especially remarkable in the *peri*-trifluoromethyl derivative **8**, which shows the *ap*-methyl signal at δ 1.85. This trend seems compatible with the hypothesis that the molecular deformation becomes larger as the *peri*-substituent becomes bulkier. Thus, the larger tilting of the axis bond is rendering the *ap*-methyl group more susceptible to the shielding effect of the flanking benzene rings. Although less remarkable, similar trend is also observed in the methylene signals of the *ap* rotamers.

These features suggest that the ground state of a 9-(1,1-dimethyl-2-phenylethyl)triptycene becomes less and less stable as the *peri*-substituent becomes bulkier.

Rotational Equilibrium. Table 2 shows that the equilibrium is mainly governed by the enthalpy term ($\Delta H°$), the entropy term ($\Delta S°$) being very small. The equilibrium constant K for the *peri*-unsubstituted derivative **1** is a statistical value of 2.0, and this is thought reasonable if one admits that the 2,3-dichloro groups exert no appreciable effects as the first approximation. The $\Delta H°$ value gradually increases and the equilibrium constant at 500 K, K_{500}, monotonously decreases as the *peri*-substituent becomes bulkier. The bulkiness of the substituents is evaluated from the van der Waals radii of the groups. As for a methoxyl group, the radius of an oxygen atom may be used because the steric interaction of the *peri*-methoxyl group with the 9-substituent occurs primarily at the oxygen atom.

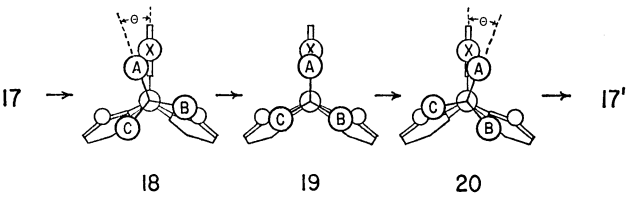
If one admits that a benzyl group is bulkier than a methyl, and that the degree of the tilting of the axis bond is similar between the rotamers, it is understood that the $\pm sc$ rotamer is more destabilized than the *ap* rotamer with the increasing bulkiness of the *peri*-substituent, in accordance with the observed tendency.

Rotational Barriers. Table 3 reveals a very interesting dependence of the rotational barrier on the *peri*-substituent. Introduction of a relatively small substituent, such as fluoro and methoxyl, raises the rotational barrier relative to the *peri*-unsubstituted compound **1**, which seems natural according to the normal chemical intuition. However, further increase in the bulkiness of the *peri*-substituent decreases the barrier. Thus, the *peri*-chloro derivatives **4** and **5** have almost the same barrier as **1**, and the *peri*-bromo (**6**) and the *peri*-methyl (**7**) compounds show lower barriers than **1**. Compound **8**, with the bulkiest *peri*-substituent examined, has a barrier 6.6 kcal mol^{-1} lower than that of **1**. Difference in free energies of activation between **2** and **8** amounts to 9.4 kcal mol^{-1}, which corresponds to the rate ratio of 16000 at 500 K. Drop in the barrier height upon introduction of a chloro or a methyl group into a *peri*-position is in accordance with our earlier observation in 9-(1-cyano or methoxycarbonyl-1-methylethyl)triptycenes,[9] and these phenomena seem to be general in 9-*t*-alkyltriptycenes.

As discussed above, the ground state should become less and less stable with the increasing bulkiness of the *peri*-substituent. The trend of the observed barrier heights implies that in the compounds with a bulky *peri*-substituent such as bromo, methyl, and trifluoromethyl, the transition state for rotation is destabilized to a lesser extent than the ground state and that this tendency becomes more remarkable as the *peri*-substituent becomes bulkier. In compounds **2** and **3** with a small *peri*-substituent the destabilization of the transition state exceeds that of the ground state.

It is noteworthy that in the compounds carrying a bulky *peri*-substituent the transition state is not destabilized to such an extent that is expected from the bulkiness of the *peri*-substituent. Consideration on the deformed model with the tilted axis bond mentioned above affords a transition state model which may partly explain the lesser stabilization of the transition state relative to the ground state, as described in the following sections.

For the sake of simplicity, we will discuss on the 9-*t*-butyl compounds, but the similar argument should apply to the 9-(1,1-dimethyl-2-phenylethyl) system. We now consider to rotate the *t*-butyl group around the tilted axis. Here we assume that both the triptycyl skeleton and the *t*-butyl group can be regarded as rigid rotors. The rotational itinerary can be shown by the Newman projections in Scheme 1. We notice



Scheme 1.

that the eclipsing of a methyl in the *t*-butyl group with the *peri*-substituent or a *peri*-hydrogen does not occur simultaneously but sequentially at the three sites. Thus, while eclipsing of methyl A with the *peri*-substituent X occurs in the conformation **19**, that of methyls B and C with nearby *peri*-hydrogens is attained before and after **19**, in conformations **18** and **20** with the torsion angle of $\pm\theta$. Intervals of the maximal eclipsing at the three sites as expressed by the torsion angle θ should become larger as the bulkiness of the *peri*-substituent increases.

Figure 1 schematically illustrates how these situations affect the energy barrier to rotation. We assume that the potential energy profile for rotation (solid lines) can be divided into three mutually independent potential curves (broken lines), each of

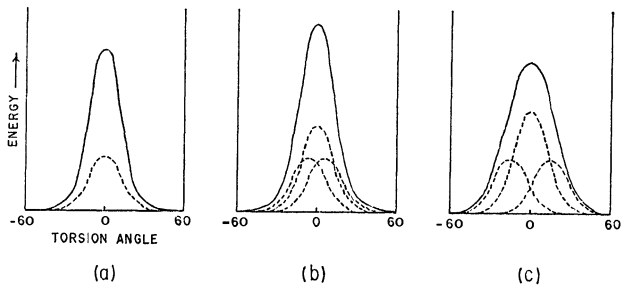


Fig. 1. Schematical illustration of the dependence of the rotational barrier on the molecular deformation. Increase of the tilting of the axis bond causes the increase of separation of the maximal points of the component curves (broken lines) on the abscissa. (a) *peri*-Unsubstituted derivative. (b) Derivatives with a small *peri*-substituent. (c) Derivatives with a bulky *peri*-substituent.

which represents the steric interaction between a methyl of the *t*-butyl group and a nearby *peri*-substituent or a *peri*-hydrogen. Figure 1a shows the energy profile for a *peri*-unsubstituted compound; steric interaction between a methyl and a *peri*-hydrogen has the same potential curve at the three sites and reaches the maximum simultaneously, and thus the solid curve is just three times of the broken line. Figure 1b represents the energy profile for the derivatives with a small *peri*-substituent such as fluoro and methoxyl. Intervals between the maximal interactions at the three sites is small because the tilting of the axis bond is not large, and the rotational barrier (solid line) is higher than that for the *peri*-unsubstituted compound, reflecting that the eclipsing interaction of a methyl with a *peri*-substituent is larger than that with a *peri*-hydrogen. Figure 1c represents the energy profile for the derivatives with a bulky *peri*-substituent. Steric repulsion due to the bulky *peri*-substituent causes a large tilting of the axis bond and thus large separation of the maximal points of the component curves. This results in an energy barrier as high as or even lower than that for the *peri*-unsubstituted compound, in spite of the large increase of the eclipsing interaction between a methyl and the *peri*-substituent.

It has thus been shown that the rough model of two connected rigid rotors with a tilted axis bond can partly explain the observed dependence of the rotational barriers on the bulkiness of the *peri*-substituents. We have assumed that the factors other than the degree of tilting of the axis bond are common among all the derivatives. Quite naturally in actual molecules, each derivative has its own relaxed structure and the triptycene skeleton itself should have different geometry depending on the substitution pattern. Therefore, a substituent remote from the axis bond could affect the rotational equilbrium and the energy barrier. An example is shown by comparison of the data for compounds **4** and **5** which differ only in the presence of the 4-chloro substituent. Although no meaningful difference is observed in the thermodynamic data, the rate data show a small but significant differnce between the two. Compound **5** isomerizes 1.7 times faster than **4** at 500 K with the $\Delta\Delta G^*$ of 0.5 kcal mol^{-1}. This should come from the subtle difference in the structural deformation which is neglected in our rough model.

Experimental

Melting points are not corrected. ^{1}H NMR spectra were recorded on a Hitachi R-20B (60 MHz) or a Varian EM-390 (90 MHz) spectrometer at *ca.* 35 °C with tetramethylsilane as an internal standard. ^{19}F NMR spectra were obtained on a Varian EM-390 spectrometer at 84.67 MHz and the chemical shifts are given in ppm downfield from internal hexafluorobenzene.

1-Fluoroanthraquinone. A mixture of 36.4 g (0.15 mol) of well-dried 1-chloroanthraquinone and 31 g (0.20 mol) of completely anhydrous caesium fluoride in 100 mL of anhydrous dimethyl sulfoxide was heated at 140 °C for 6 h with magnetic stirring. After being cooled to room temperature, the mixture was poured into water. The solid formed was collected by filtration, washed with water and dried in air. The solid was taken up in dichloromethane and then was chromatographed through an alumina column with dichloromethane–hexane (1:4) as eluent, affording 25.1 g (74%) of 1-fluoroanthraquinone as yellow crystals, mp 228—230 °C (lit,[15] 220 °C). ^{19}F NMR ($CDCl_3$): 51.1 ppm (dd, J=4.8 and 10.5 Hz).

*9-(1,1-Dimethyl-2-phenylethyl)-1-fluoro-9,10-dihydro-9-anthrol (**13**).* A mixture of 4.52 g (20 mmol) of 1-fluoroanthraquinone and 1.8 g of aluminium powder in 50 mL of concentrated sulfuric acid was stirred at room temperature for 6 h and poured onto ice–water. The solid formed was collected by filtration, washed with water and dried in air. The crude product was shown to be a 10:1 mixture of 1-fluoroanthrone (^{19}F NMR in $CDCl_3$: 50.0 ppm) and 4-fluoroanthrone (43.9 ppm). Recrystallization from benzene–hexane gave 2.86 g (67%) of a crystalline solid, which was still a 10:1 mixture of the two anthrones. The mixture was used in the subsequent reaction without further purification.

To an ethereal Grignard solution prepared from 16.9 g (100 mmol) of 1,1-dimethyl-2-phenylethyl chloride,[16] was added portionwise 11.0 g (51.3 mmol) of 1-fluoroanthrone and the mixture was decomposed with aqueous ammonium chloride after stirring at room temperature for 1 h. Column chromatography on alumina gave 2.67 g (15%) of **13** as colorless crystals, mp 128—130 °C. Found: C, 83.14; H, 6.60%. Calcd for $C_{24}H_{23}FO$: C, 83.21; H, 6.69%. ^{1}H NMR ($CDCl_3$, δ): 0.75 (3H, d, J_{HF}=1.5 Hz), 0.80 (3H, d, J_{HF}=2.1 Hz), 2.59 and 2.74 (2H, AB-q, J=12.3 Hz), 3.71 (1H, d, J_{HF}=16.3 Hz), 3.90 and 4.18 (2H, AB-q, J=20.0 Hz), 6.6—7.5 (11H, m), 7.92 (1H, m). ^{19}F NMR ($CDCl_3$): 52.21 ppm (br t; br d upon addition of D_2O, J=13 Hz).

*±sc-9-(1,1-Dimethyl-2-phenylethyl)-1-fluorotriptycene (±sc-**2**).* To a solution of 1.445 g (4.17 mmol) of the alcohol (**13**) in 60 mL of carbon tetrachloride was added *ca.* 10 g of phosphorus pentaoxide. The mixture was heated under reflux for 2 min with continuous shaking, and filtered while hot. The solid was washed with hot carbon tetrachloride. The combined solutions were found to contain almost equal amount of 9-(1,1-dimethyl-2-phenylethyl)-1-fluoroanthracene (**14**) and 1-fluoroanthracene, indicating that the dealkylation of **14** under the reaction conditions was considerably fast. The anthracene mixture was immediately treated with 2.0 g of anthranilic acid and 1 mL of isopentyl nitrite in boiling dichloromethane. Column chromatography of the reaction mixture on alumina with hexane as eluent afforded 546 mg (32% based on **13**) of ±*sc*-**2**, mp 193—195 °C. Found: C, 89.20; H, 6.20%. Calcd for $C_{30}H_{25}F$: C, 89.07;

6.23%. ^{19}F NMR ($CDCl_3$): 67.64 ppm (br s).

ap-*9-(1,1-Dimethyl-2-phenylethyl)-1-fluorotriptycene* (ap-**2**). To a solution of 621 mg (2.0 mmol) of 9-(1,1-dimethyl-2-phenylethyl)anthracene (**9**)[17] and 0.4 mL (*ca.* 4 mmol) of *m*-difluorobenzene in 50 mL of anhydrous diethyl ether was added 3.0 mmol of butyllithium in hexane at −78 °C. The mixture was stirred at −78 °C for 1 h, allowed to gradually warm up to room temperature with stirring overnight, and then heated under reflux for 1 h. The ethereal solution was washed with water, dried over magnesium sulfate and evaporated to afford 544 mg (67%) of a 5:1 mixture of *ap*-**2** (^{19}F NMR in $CDCl_3$: 65.07 ppm) and *ap*-**2′** (37.19 ppm). Repeated fractional recrystallizations from hexane gave a pure sample of *ap*-**2**, mp 189—190 °C. Found: C, 88.96; H, 6.25%. Calcd for $C_{30}H_{25}F$: C, 89.07; H, 6.23%. ^{19}F NMR ($CDCl_3$): 65.07 ppm (br s).

General Procedure for the Synthesis of Triptycenes Using Anthranilic Acids. A solution of 2—3 fold excess of an appropriate anthranilic acid in tetrahydrofuran or acetone was added dropwise to a boiling solution of 9-(1,1-dimethyl-2-phenylethyl)anthracene (**9**)[17] and 3-fold excess of isopentyl nitrite in dichloromethane (1,2-dimethoxyethane in the case of **8**) during the course of 1 h and the mixture was heated under reflux for 1 h. After evaporation of the solvent, the residual mixture was chromatographed through an alumina column unless otherwise stated. The desired fractions were evaporated and recrystallized from tetrahydrofuran–hexane.

ap-*9-(1,1-Dimethyl-2-phenylethyl)-1,4-dimethoxytriptycene* (ap-**3**), mp 285—288 °C, was obtained from **9** and 3,6-dimethoxyanthranilic acid[1] in 27% yield. Found: C, 86.04; H, 6.71%. Calcd for $C_{32}H_{30}O_2$: C, 86.06; H, 6.77%.

ap-*1-Chloro-9-(1,1-dimethyl-2-phenylethyl)triptycene* (ap-**4**). Reaction of **9** with 3-chloroanthranilic acid[18] and isopentyl nitrite gave a mixture of *ap*-**4** and *ap*-**4′** in 4:3 ratio. The mixture was chromatographed on a Lobar LiChroprep Si 60 column with hexane as eluent. *ap*-**4′** eluted faster: mp 264—266 °C. Found: C, 85.72; H, 5.72; Cl, 8.40%. Calcd for $C_{30}H_{25}Cl$: C, 85.59; H, 5.99; Cl, 8.42%. ^{1}H NMR ($CDCl_3$, δ): 2.06 (6H, s), 3.92 (2H, s), 5.91 (1H, s), 6.7—8.1 (16H, m). *ap*-**4** followed *ap*-**4′** and was obtained in 16% yield: mp 214—216 °C. Found: C, 85.88; H, 5.75; Cl, 8.50%. Calcd for $C_{30}H_{25}Cl$: C, 85.59; H, 5.99; Cl, 8.42%.

ap-*1,4-Dichloro-9-(1,1-dimethyl-2-phenylethyl)triptycene* (ap-**5**), mp 297—299 °C, was obtained from **9** and 3,6-dichloroanthranilic acid[19] in 48% yield. Found: C, 79.03; H, 5.03; Cl, 15.37%. Calcd for $C_{30}H_{24}Cl_2$: C, 79.12; H, 5.31; Cl, 15.57%.

ap-*1-Bromo-9-(1,1-dimethyl-2-phenylethyl)triptycene* (ap-**6**). Reaction of **9** with 3-bromoanthranilic acid[18] and isopentyl nitrite gave a mixture of *ap*-**6** and *ap*-**6′** in 1:1 ratio. The mixture was chromatographed on a silica-gel column with hexane as eluent. *ap*-**6′** eluted faster: mp 282—284 °C. Found: C, 77.60; H, 5.61; Br, 17.51%. Calcd for $C_{30}H_{25}Br$: C, 77.42; H, 5.41; Br, 17.17%. ^{1}H NMR ($CDCl_3$, δ): 2.07 (6H, s), 3.92 (2H, s), 5.91 (1H, s), 6.6—8.1 (16H, m). Following *ap*-**6′**, *ap*-**6** was obtained in *ca.* 15% yield: mp 226—227 °C. Found: C, 77.63; H, 5.20; Br, 17.46%. Calcd for $C_{30}H_{25}Br$: C, 77.42; H, 5.41; Br, 17.17%.

ap-*9-(1,1-Dimethyl-2-phenylethyl)-1,4-dimethyltriptycene* (ap-**7**), mp 306—308 °C, was obtained from **9** and 3,6-dimethylanthranilic acid[20] in 26% yield. Found: C, 92.99; H, 7.48%. Calcd for $C_{32}H_{30}$: C, 92.71; H, 7.29%.

ap-*9-(1,1-Dimethyl-2-phenylethyl)-1-(trifluoromethyl)triptycene* (ap-**8**). Reaction of **9** with 3-(trifluoromethyl)anthranilic acid[18] and isopentyl nitrite in boiling 1,2-dimethoxyethane gave a 1:1 mixture of *ap*-**8** and *ap*-**8′** in 12% yield. The mixture was separated by chromatography on a Lobar LiChroprep Si 60 column with hexane as eluent. *ap*-**8′** eluted faster mp 249—250 °C. Found: C, 81.74; H, 5.54%. Calcd for $C_{31}H_{25}F_3$: C, 81.92; H, 5.54%. ^{1}H NMR ($CDCl_3$, δ): 2.07 (6H, s), 3.95 (2H, s), 5.83 (1H, s), 6.8—8.2 (16H, m). ^{19}F NMR ($CDCl_3$): 102.90 ppm (s). *ap*-**8** eluted following *ap*-**8′**: mp 210—211 °C. Found: C, 81.67; H, 5.54%. Calcd for $C_{31}H_{25}F_3$: C, 81.92; H, 5.54%. ^{19}F NMR ($CDCl_3$): 115.05 ppm (septet, J=4 Hz).

±sc-*9-(1,1-Dimethyl-2-phenylethyl)-1,4-dimethoxytriptycene* (±sc-**3**) was eluted following the *ap* rotamer in the column chromatography on alumina of the equilibrated mixture of rotamers: mp 218—219 °C. Found: C, 85.78; H, 6.81%. Calcd for $C_{32}H_{30}O_2$: C, 86.06; H, 6.77%.

±sc-*9-(1,1-Dimethyl-2-phenylethyl)-1,4-dimethyltriptycene* (±sc-**7**). The equilibrated mixture of rotamers (±*sc*/*ap*= 0.4) was recrystallized from dichloromethane. Almost pure *ap*-**7** crystallized, leaving a ±*sc*-enriched mixture (±*sc*/*ap*= 5) in the mother liquor, which was evaporated and recrystallized from tetrahydrofuran–hexane affording pure ±*sc*-**7**: mp 209—211 °C. Found: C, 92.48; H, 7.18%. Calcd for $C_{32}H_{30}$: C, 92.71: H, 7.29%.

Kinetic Measurements. Pure rotamers of the compounds examined (±*sc* for **2** and *ap* for the others) were dissolved in 1-chloronaphthalene to make up *ca.* 5—7 wt% solutions. To solutions of **2** and **8** were added *ca.* 3% of 1,4-dibromo-2,3,5,6-tetrafluorobenzene and *p*-chlorobenzylidyne trifluoride, respectively, as lock substances for ^{19}F NMR measurements. An aliquot of *ca.* 0.4 mL of the solutions was put in an NMR sample tube and was heated at a given temperature using a bath of an appropriate boiling liquid. The liquids used are as follows: diphenyl ether (258 °C), diethylene glycol (246 °C), quinoline (238—239 °C), hexylbenzene (226.5 °C), *o*-nitrotoluene (224—225 °C), naphthalene (219—220 °C), nitrobenzene (212—212.5 °C), *trans*-decalin (187—189 °C), decane (175 °C), *p*-xylene (139.5 °C), 2-methoxyethanol (125.5 °C), toluene (111.5 °C), and heptane (99.5 °C). Boiling points were constant within ±0.5 °C. The sample was taken out of the bath at appropriate intervals and the rotamer ratio was obtained by integration of the NMR signals (^{19}F for **2** and **8**, the *gem*-dimethylprotons for the others). Time dependence of the rotamer ratio was analyzed in terms of a first-order reversible reaction and the rate constant was calculated. This procedure was performed at three to four temperatures over 32—50 °C range for each compound, and the Eyring parameters were obtained.

Kinetics and Mechanism of the Addition of Iodine Monochloride to Alkenes in Acetic Acid

Nagarajan AMIRTHA, Seshaiyer VISWANATHAN,* and Ramachandran GANESAN

Department of Physical Chemistry, University of Madras, Madras 600025, India

(Received April 16, 1982)

A kinetic investigation of the addition of iodine monochloride (ICl) to some allyl and vinyl compounds in dry acetic acid medium has been carried out at 20,30,40, and 50 °C. In all the cases, the reaction obeys a total third order kinetics, second order in ICl and first order in the substrate. The product formed has been analysed by ^{1}H NMR technique. The reaction stoichiometry was found to be 1:1. The formation of a 1:1 complex between an alkene and ICl has been established for the first time spectrophotometrically and the equilibrium constant evaluated. The effect of the addition of the chloride ion on the reaction rate has been studied. The kinetic and thermodynamic parameters evaluated strongly suggest a mechanism involving dipole-dipole interaction with a bridged iodonium ion intermediate.

This paper deals with the kinetics and mechanism of iodine monochloride addition to some alkenes in acetic acid solvent. Investigations carried out so far on the addition of ICl to unsaturated compounds show that ICl has been mainly used as a reagent to estimate unsaturation. The kinetic aspect of the problem has not received sufficient attention. Only the relative rates of Cl_2–, ICl–, and BrCl– addition to alkenes[1] and the kinetics and mechanism of ICl addition to allyl alcohol,[2] stilbene,[3] and α-eleostearic acid[4] have been reported. This paper reports the first systematic study of the kinetics of ICl addition to allyl and vinyl compounds in dry acetic acid. In this article we report and discuss the kinetic and thermodynamic parameters obtained in the present investigation.

Experimental

Materials. Iodine monochloride,[5] 1-hexene,[6] and methyl crotonate[7] were prepared by the procedures given in the literature. Allyl chloride from BDH (LR) and allyl acetate from Fluka AG (Pract.) were purified by distillation. Methyl acrylate and methyl methacrylate both from Koch Light Co., England,[8] acrylamide from American Cyanamide Co., New York,[9] methacrylamide from Rohm and Haas, Philadelphia,[10] allyl bromide from Riedel,[11] and acetic acid from BDH (LR, 99.5% assay)[12] were all purified according to the methods given in the literature. Potassium iodide, sodium thiosulfate and potassium dichromate used were all BDH analytical grade samples.

Kinetic Measurements. Required volumes of the ICl and the substrate solutions in dry acetic acid of required concentration were thermostated and then mixed in a 500 cm^3 iodine flask with a B-19 standard ground-glass stopper. Known volumes of aliquots were withdrawn after various intervals of time and estimated iodometrically. From the observations made in several experiments, it has been concluded that, unlike in any other halogenation reaction, the loss of ICl from its solution due to volatility is practically nil. It is worth noting that the reproducibility of kinetic runs throughout this study was therefore excellent. Moreover, the reaction was found to be unaffected by light.

Stoichiometry. The stoichiometry of the reaction was investigated by employing the well-known method[13] using a mixture of $KBrO_3$ and KBr.

Product Analysis. The solutions of the substrate and ICl in dry acetic acid of required concentration were mixed and the reaction was allowed to go to completion at 30 °C (24 h). Then the solvent acetic ac l was completely neutralized by the addition of a required quantity of sodium hydrogencarbonate solution. The organic material was then ether extracted, dried with sodium sulfate, the ether was distilled off, and it was subjected to TLC and ^{1}H NMR analyses. TLC analysis showed a single spot indicating the formation of one product only. Further analyses of the products of iodochlorination of allylic and vinylic compounds were carried out in Varian T60 NMR spectrometer using carbon tetrachloride as the solvent and TMS as the internal standard.

UV Absorption Studies. During the course of this work, the existence of an alkene–ICl complex has been proved for the first time spectrophotometrically.[14] The measurements were made on a Specord UV-VIS recording spectrophotometer. The nature of the complex and its formation constant were also determined experimentally.

Results and Discussion

The overall order of the reaction and the individual orders in the reactants were determined by the integration and the differential methods, respectively.[15] The total order was found to be three for allyl and vinyl substrates (Fig. 1). The orders in ICl and in substrate were found to be two and one, respectively (Fig. 2).

With equal initial molar concentrations (in the range 1.0×10^{-3}—4.0×10^{-2} mol dm^{-3}) of the reactants, the reactions were carried out at 20, 30, 40, and 50 °C. The experimental data fitted well into the integrated third order equation which was used in the form $1/(a-x)^2=2k_3t+1/a^2$. The values of $1/(a-x)^2$ were plotted against the time (t) and the rate constant (k_3) values were calculated from the slope of the straight line obtained. Figure 3 shows the integration plots for the methyl acrylate–ICl reaction at different temperatures. Plots were made with $\log k_3$ *versus* $1/T$ (Figs. 4 and 5) for the determination of Arrhenius activation energies (E_a) for the ICl addition to various alkenes studied. The data were analyzed by a least-squares procedure (computer programmed) to get the E_a values together with their standard deviations. The activation entropies (ΔS^*) and the free energies of activation (ΔG^*) were evaluated at 30 °C.

The stoichiometry of the reaction was established

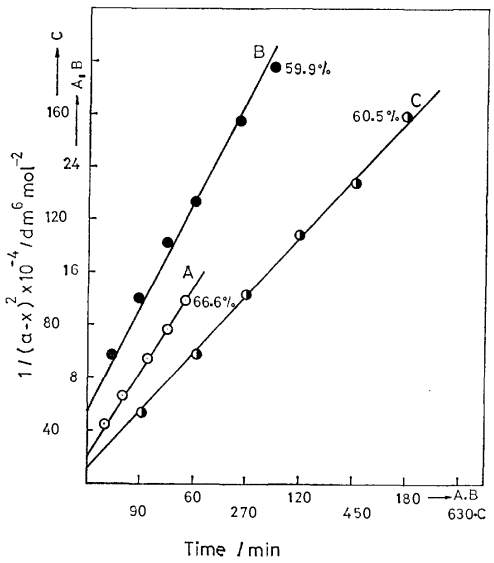

Fig. 1. Plots of $1/(a-x)^2$ against time for allyl chloride-ICl reaction with various equal initial molar concentrations at 50 °C.
A: 8.00×10^{-3} mol dm^{-3}, B: 4.45×10^{-3} mol dm^{-3}, C: 2.00×10^{-3} mol dm^{-3}.

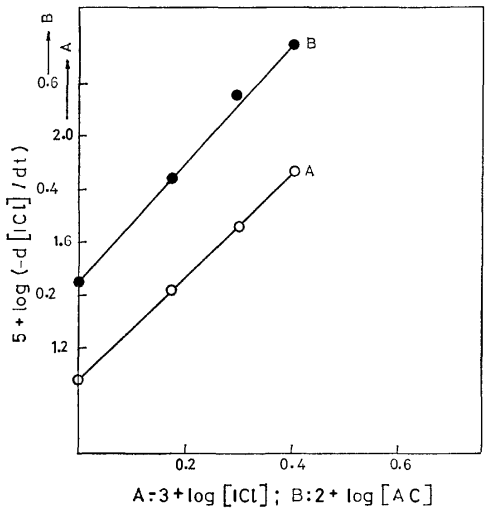

Fig. 2. Plots of log (initial rate) against
A: log [ICl], B: log [AC] for allyl chloride-ICl reaction at 30 °C.

as 1:1. ^{1}H NMR analysis showed $CH_2ICHClCH_2X$ (X=Cl, Br, $COOCH_3$, and $CH_2CH_2CH_3$) to be the product of the allyl substrate–ICl reactions. For the methyl acrylate–ICl reaction, the product was found to be $CH_2ClCHICOOCH_3$. The mode of addition of I and Cl is very similar to this in the case of the other vinyl compounds also. The complex between an alkene and ICl had a characteristic absorption in the region 290—310 nm. Applying Benesi-Hildebrand equation[16] to the methyl methacrylate–ICl reaction, as an example, the formation of a 1:1 complex was proved (ε_c=769.3 dm^3 mol^{-1} cm^{-1}; $K=2.42\times10^{-1}$ dm^3 mol^{-1}).[14]

Based on the above results, the following mechanism, involving a dipole-dipole interaction, may be proposed: Therefore, based on the above mechanism, the rate

(1)

(2)

(3)

equation can be written as

$$\frac{-d[ICl]}{dt} = k[\pi\text{-complex}][ICl]. \quad (4)$$

The formation of the π-complex is a fast equilibrium process and substituting the expression for [π-complex]

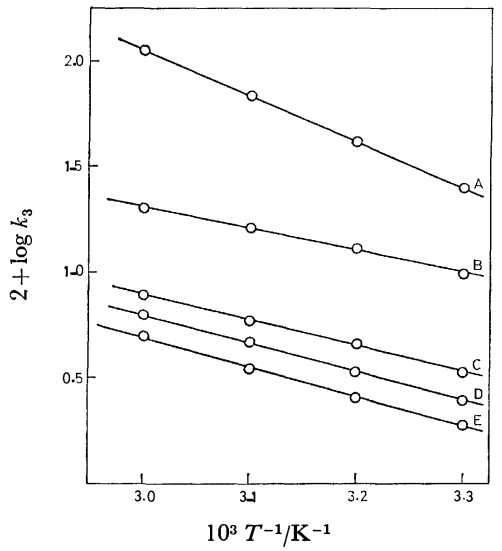

Fig. 5. Plots of log k_3 against $1/T$ for vinyl compounds. A: Acrylamide, B: methacrylamide, C: methyl methacrylate, D: methyl acrylate, E: methyl crotonate.

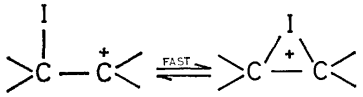
from Eq. 1 in Eq. 4, the rate equation becomes

$$\frac{-\mathrm{d[ICl]}}{\mathrm{d}t} = kK[\text{alkene}][\text{ICl}]^2, \qquad (5)$$

where $kK=k_3$, (unit $\mathrm{dm^6\,mol^{-2}\,s^{-1}}$). This mechanism, in which a dipolar ICl molecule is the attacking species, is thus consistent with the observed overall third order kinetics with first order in alkene and second order in ICl.

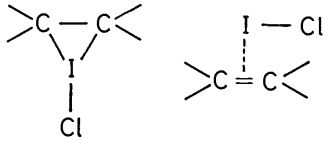
The formation of the π-complex was identified experimentally as mentioned earlier. The second molecule of ICl which attacks the π-complex seems to facilitate the heterolysis of the I–Cl bond in the π-complex by forming ICl_2^- and the carbonium ion. The open carbonium ion formed in Eq. 2 can rearrange itself, in a very fast step, into a more stable cyclic iodonium ion by the interaction of the unshared electrons of iodine with the carbonium ionic centre, as shown below.



(6)

The existence of the bridged iodonium ion intermediate has been well established by Olah and Bollinger[17] by NMR studies. The activated complex and the measured activation energy correspond to the step (2).

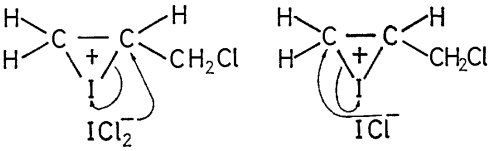
Contrary to the structure **1** proposed in the literature[1] for the π-complex, structure **2** is proposed by



1 **2**

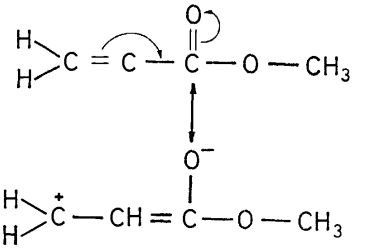
us. As structure **1** is somewhat rigid, free rotation of the I–Cl bond can be only about the I–Cl axis, thus preventing other types of rotations. Moreover, the structure **1** being rigid, the chances of attack by the second molecule of ICl with it will be very remote. If we assume that the C=C bond be in one plane, the I–Cl bond almost parallel to and above or below this plane and the dotted line to be only a loose molecular binding, then the ICl molecule, as depicted in structure **2**, can freely rotate about the dotted line. The second molecule of ICl can, of course, attack the loosely-bound and freely-rotating ICl molecule from any direction. A carbonium ion intermediate is thus formed from the interaction of neutral but slightly dipolar reactant molecules. The activated complex for such a reaction may therefore be expected to be more polar than the reactants and it should closely resemble the ionic intermediate.

The products formed need some explanation. The allyl chloride–ICl and the methyl acrylate–ICl reactions may be considered as representative examples. In the case of allyl chloride, the iodonium ion formed can be opened in two ways (structures **3** and **4**) by



3 **4**

the attack of the nucleophile, ICl_2^-. The opening as in III leads to a secondary carbonium ion and that in IV, a primary carbonium ion. Since the former is more stable than the latter, the iodine atom should attach to the primary carbon and the chlorine atom to the secondary carbon and hence the product, $CH_2ICHClCH_2Cl$. The reverse was, however, found to be the case with methyl acrylate, that is, iodine goes to the secondary carbon and chlorine to the primary carbon. Due to the electron-withdrawing ability of '$COOCH_3$' group and the extensive conjugation, the primary carbon becomes more positive



than the secondary. Therefore, in the case of methyl acrylate, iodine atom attaches itself to the secondary carbon and chlorine atom to the primary carbon. Ingold and Smith[18] also obtained a similar product for the reaction between CH_2=CH–SO_3H and ICl. By analogy with the reactions involving the addition of iodine azide[19] and iodine isocyanate,[20] it may be suggested that the ring opening of the iodonium ion intermediate would be expected to occur in a trans manner leading to trans addition products. The iodonium ion proposed in this investigation is strongly supported by these evidences.

Table 1 shows that as the concentration of added chloride ion increases, the rate of the reaction between

Table 1. Effect of added chloride ion on allyl chloride-ICl reaction at 30 °C
[Allyl chloride] = [ICl] = 4.0×10^{-3} mol dm^{-3}.

[Chloride ion] $\times 10^4$/mol dm^{-3}	$(-d[ICl]/dt) \times 10^3$/mol dm^{-3} s^{-1}
5.6	22.05
6.7	19.45
8.7	15.09
10.5	13.03
12.3	9.56

allyl chloride and ICl decreases. This may be due to the equilibrium process

$$ICl + Cl^- \rightleftharpoons ICl_2^-, \quad (7)$$

which results in a decrease of [ICl] available for the reaction. Since ICl is the attacking species, the reaction rate decreases as more and more chloride ion is added to the system. The formation of ICl_2^- is well established and its existence has been reported.[21]

Another possible mechanism to explain the third order kinetics is to postulate the existence of the dimeric species $(ICl)_2$, which can simply react with the alkene to give the products. No evidence could be obtained for the existence of such a dimer, however. From spectrophotometric measurements, it was found that the solutions of ICl in acetic acid obeyed Beer's law over a range in which the concentration of ICl was increased twenty times.

From Table 2, it is seen that the ΔS^* values are negative showing loss in entropy during the formation of the activated complex. The large negative values for ΔS^* are consistent with the fact that the overall reaction is of the third order. The E_a values for the compounds allyl chloride, allyl bromide and allyl acetate are more or less constant. It may be said that the substituents, which are far away from the double bond, do not have any significant effect on the electron density at the reaction site. This is true because the unsubstituted simple alkene, 1-hexene, also has the same E_a value. The subtle changes in the rate constants are due to variations in ΔS^*. In the case of methyl acrylate, methyl methacrylate, methyl crotonate, acrylamide and methacrylamide, the E_a value for a methyl substituted alkene is always lower than that of the corresponding unsubstituted one. It is evident that the electron density at the double bond of the former is greater due to both inductive (+I) and hyperconjugative effects of a methyl group. The same reason can be attributed to the difference in the E_a and k_3 values observed between methyl methacrylate and methyl crotonate.

The rate constants are reversed in the case of the pair, acrylamide and methacrylamide because of the very high and negative ΔS^* value for methacrylamide compared to that for acrylamide. That is, the gain in energy is lost in entropy, in the case of methacrylamide.

The ΔG^* values remain more or less the same for the allyl substrates studied, showing that E_a and ΔS^* compensate each other. The same is found to be the case with the vinyl substrates too.

(Received February 16, 1982)

Metal ion catalyzed aquation of tris(malonato)chromate(III) ion has been followed spectrophotometrically in perchloric acid solution ($[H^+]=0.05$ M) over a temperature range at an ionic strength of 2.0 M. Under these conditions $k_{obsd}=k_H[H^+]+k_M[M^{2+}]$ where k_{obsd} is the observed first order rate constants for the protons and the metal ion catalyzed pathways. Metal ions exert appreciable catalytic effect on the aquation of the complex with k_M following the sequence Cu(II)>Ni(II)>Co(II)>Zn(II)>Mn(II), which runs parallel to the metal monomalonato complex formation constants. A plausible mechanism for the metal promoted reactions is proposed.

Electrophillic catalysis by metal ions on the coordinated ligands receives much attention in recent years because of the vital role played by Lewis acids in biological processes. It is well known that the phosphate, carboxylate, amino and imidazolyl groups are important metal ion binding sites in biological systems.[1] Metal ions promoted hydrolysis of such coordinated ligands in metal complexes serves as a model for a better understanding of the mechanistic aspects of the biological processes. Bivalent metal ions are required by most enzymes which catalyze phosphate transfer reactions.[2] However the role of Zn(II) and Cu(II) in promoting the biologically important decarboxylation reactions of various acids,[3-5] amino acids and their esters[6] have recently been reviewed and in all cases promotions of hydrolytic reactions requires at least in aqueous solvents the involvement of the catalyzing metal ions and the potentially coordinating sites of the respective acids or esters.

The results of many investigations[7] have already been reported on various reactions of oxalato complexes of Cr(III), but much less informations is available on the analogous Cr(III)–malonato complex because of the inherent instability (kinetic and thermodynamic) of the six membered ring of the malonato system in comparison to the more stable (kinetic and thermodynamic) five membered ring of the oxalato complexes.

Some aquation;[8,9] anation,[10] and isomerization[7,11-13] reactions have been studied and the behavior of the malonato complex appears to be somewhat intriguing from that of the corresponding oxalato complex. In the acid assisted aquation of several carboxylato complexes of Cr(III) it was reported[8,14a-d] that aquation proceeds by a rapid preequilibrium protonation followed by cleavage of the Cr(III)–O bond. In continuation to our earlier studies[15,16] on the metal ion catalyzed aquation of Cr(III) complexes[15-18] it appears worthy of investigation to study the aquation of the title complex into cisdiaquabis(malonato)chromate(III) ion by bivalent metal ions of first transition series.

Here we are reporting the results of investigations on Mn(II), Co(II), Ni(II), Cu(II), and Zn(II) ion catalyzed aquation of $Cr(mal)_3^{3-}$ and the probable mechanism of the Lewis acid catalyzed aquations have been discussed.

The present investigation was undertaken with a view to examine the i) complexing ability of the chelated ligand towards the incoming metal ions and ii) effectiveness of various metal ions in promoting the hydrolysis of the coordinated malonato ligand to chromium(III).

Experimental

Materials and Method. Pure samples of potassium salt of tris and bis complex anions, $K_3[Cr(C_3H_2O_4)_3]\cdot 3H_2O$[19] and *cis*-$K[Cr(C_3H_2O_4)_2(OH_2)_2]$[10] were prepared by methods described in the literature. The purity of the compounds was checked by elemental analysis. Metal(II) perchlorate solutions were prepared by dissolving the corresponding carbonates with A.R. grade perchloric acid and after complete ceasession of the effervesence a slight excess of perchloric acid was added to check any possibility of hydrolysis. The metal ions and the free acid concentrations were determined by standard methods.[20] Other chemicals used were of reagent quality.

Complex		Cr(%)	C(%)	H(%)
$K_3[Cr(C_3H_2O_4)_3]\cdot 3H_2O$	Calcd	9.82	20.42	2.27
	Found	9.90	20.31	2.40
cis-$K[Cr(C_3H_2O_4)_2(OH_2)_2]$	Calcd	15.71	21.76	2.42
	Found	15.66	21.60	2.51

Experimental procedures are the same as described elsewhere.[16] Plots of $\log\{(A_0-A_t)/(A_t-A_\infty)\}$ *versus* time (t) were linear for at least three to four half lives and passing through the origin, where A_∞ is the absorbance of diaqua species and A_t are that at different time interval. The preliminary spectral observations of the reacting solutions after digesting for at least ten half lives agrees well with spectra of the corresponding cis-diaqua product which further indicates that the reaction is free of any undue complication, which may arise from the subsequent aquation of diaqua to tetraaqua products.

Results and Discussion

At a constant hydrogen ion concentration the pseudo first order rate constant, k_{obsd}, is found to increase

† Presented at the XXIst ICCC at Toulouse, France 1980.

††† Present address: Chemistry Department, University College, London, England.

with increasing metal ion concentration and at a fixed metal ion concentration, k_{obsd}, also increases with increase in the acidity of the medium.

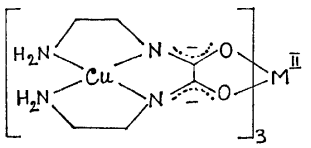
Detailed analysis of the results indicates that the dissociation of the title complex follows a two term rate law:

$$k_{obsd} = k_1[H^+] + k_2[M^{2+}], \quad (1)$$

where k_1 represents the specific rate constants for the acid catalyzed pathway and k_2 is the catalytic rate constant for the metal-ion-catalyzed process. Using the least squares method, values of $k_1[H^+]$ and k_2 have been evaluated from the linear plot of k_{obsd} *versus* $[M^{2+}]$ (*cf.* Fig. 1). The present k_1 values agree well with that reported earlier.[14b] Values of k_{obsd} at 40 °C for all the metal ions are given in Table 1. Values of k_1 and k_2 corresponding to H^+ ion and different metal ions catalyzed path and the corresponding activation parameters are given in Table 2.

The metal ions exert a substantial catalytic effect and a possible mechanism for the metal ion catalyzed pathway is summarized in Fig. 2.

The mechanistic feature of the above mentioned process is thought to involve a rapid pre-equilibrium step to form an ion pair or a binuclear bridged complex followed by the cleavage of the first Cr(III)–O malonate bond in a slow rate determining step. Very



1

recently Kida *et al.*[21] isolated and characterised some tetranuclear bridged complexes of **1** where M^{II}=Co(II),Ni(II). From this it appears that the electron rich carbonyl oxygen can form bonds with catalyzing aquo metal ion centre in the transition state which enhances the ring opening of the malonate ligand as shown in Fig. 2. In view of the above findings the

a) $\sigma(k_{cat})=\pm5\%$. b) $\sigma(\Delta H^*)=\pm2.5$ kJ mol^{-1}. c) $\sigma(\Delta S^*)=\pm5.5$ J K mol^{-1}. N.B. For H^+, k_{cat} stands for k_1 and for other metal ions it represents k_2.

formation of a bridged complex is quite probable in the transition state of the metal catalyzed pathway for the present system.

The kinetic scheme for the aquation of the title complex are as follows.

a) Acid catalyzed pathway was discussed earlier.[14b]

b) Metal ion assisted pathway:

$$Cr(mal)_3^{3-} + M^{2+} \overset{K_2}{\rightleftharpoons} [Cr(mal)_3^{3-} \cdot M^{2+}]$$

$$mal = CH_2(COO^-)_2 \qquad k_2' \downarrow \text{slow}$$

$$(k_2 = k_2' \cdot K_2) \qquad \text{Products.}$$

The catalytic rate constants k_2 is related to K_2 and k'_2 by the relation

$$k_2 = \frac{k_2' \cdot K_2}{1 + K_2[M^{2+}]}. \qquad (2)$$

Under the present experimental conditions $K_2[M^{2+}] \ll 1$ as evident from the linearity of the plot of k_{obsd} *vs.* $[M^{2+}]$ even at highest metal ion concentrations. Hence Eq. 2 reduces to

$$k_2 = k_2' \cdot K_2.$$

The activation parameters corresponding to k_2 values involve both rate constants and equilibrium constants. The overall rate constants for the metal catalyzed process follows the sequence $Cu^{2+} > Ni^{2+} > Co^{2+} > Zn^{2+} > Mn^{2+}$, which follows the Irving-Williams natural order of stability,[22] of the catalyzing metal monomalonato complex. The activation parameters clearly reveal that the metal ion catalyzed aquations with lowest activation enthalpies have more negative entropies of activation whereas for reactions of high enthalpy of activation have positive entropy of activation. The parrallel increase of both ΔH^* and ΔS^* clearly suggests the applicability of kinetic compensation law.[23] Further a linear correlation between $\log k_2$ and $\log K_M$ (K_M=the formation constants of the monomalonato complexes) clearly reflects the dominating effect of K_2 on the metal catalyzed pathway.

We thankfully acknowledge the assistance offered by Professor D. Banerjea, Calcutta University, India regarding laboratory facilities and other critical suggestions in writting the paper.

Spectrofluorimetric Determination of Zirconium in Hafnium Metal with Salicylic Acid and Rhodamine B after Its Separation Using Chloroacetic Acid and Salicylic Acid

T. V. RAMAKRISHNA* and M. S. SUBRAMANIAN

Department of Chemistry, Indian Institute of Technology, Madras-600 036, India

(Received April 12, 1982)

A spectrofluorimetric method is described for the determination of 2 to 16 μg of zirconium based on the formation of an ion-association complex with salicylic acid and Rhodamine B. Hafnium behaved similarly to zirconium, but the interference can be overcome by selective extraction of zirconium at pH 1.4—1.6 from 1 mol dm^{-3} chloroacetic acid medium into 0.3 mol dm^{-3} solution of salicylic acid in 2:3 mixture of isobutyl methyl ketone (IBMK) and chloroform. The spectrofluorimetric method in conjunction with the separation procedure has been used for the determination of 4.4 to 14.5% of zirconium in hafnium metal.

Methods have been described for the spectrophotometric determination of zirconium based on the ion-association between its anionic chelates with cationic dyes.[1,2] These complexes were not fluorescent and were extracted into organic solvents prior to determination. In the present work it was found that the ion-association complex involving zirconium(IV), salicylic acid and Rhodamine B can form the basis of an extractive spectrofluorimetric procedure as the presence of traces of zirconium with salicylic acid caused the nonfluorescent Rhodamine B in benzene to intensely fluoresce. However, hafnium behaved very similarly to zirconium and therefore necessitated their separation to be realised beforehand.

Methods have been described for the extractive separation of zirconium from various carboxylic acid solutions. Zirconium was shown to be preferentially extracted in the presence of H_2O_2 at pH 3.2 to 3.6 into organic phase containing 0.5 mol dm^{-3} solution of mixed C_7 to C_9 fatty acids.[3] Cole and Brown[4] achieved a separation factor of 22 for zirconium by using a saturated solution of salicylic acid (1.115 mol dm^{-3}) in furfural. Quantitative extraction of zirconium from 33% trichloroacetic acid solution into 1-butanol[5] and from 0.01 mol dm^{-3} malonic acid at pH 3.0 into a 4% solution of Amberlite LA-1 or LA-2 in xylene[6] have been reported, but the use of these methods for the separation of zirconium from hafnium has not been demonstrated. The preferential extraction of zirconium to the extent of 80% from solutions at pH 1.4± 0.1 into a chloroform solution containing 0.05 mol dm^{-3} salicylic acid and 0.37 mol dm^{-3} collidine has also been described.[7] In the course of our study, it was found that zirconium can be selectively extracted from hafnium, rapidly and quantitatively, from 1 mol dm^{-3} chloroacetic acid at pH 1.4—1.6 into IBMK and chloroform mixture containing salicylic acid. The organic phase upon equilibration with dilute hydrochloric acid returned the zirconium quantitatively into the aqueous phase thus making it available for fluorimetric determination. In conjunction with the extractionprocedure the fluorimetric method developed was found useful for application to samples containing high concentration of hafnium.

Experimental

Reagents. *Standard Zirconium Solution*: Dissolve 0.3532 g of $ZrOCl_2 \cdot 8H_2O$ in 20 cm^3 of 1:1 perchloric acid and dilute to 100 cm^3 with distilled water to provide a 1000 ppm Zr stock solution. Dilute appropriate volume of the stock solution with water, just before use, to obtain 100 ppm and 4 ppm solution.

Salicylic Acid Extraction Solution (0.3 mol dm^{-3}): Dissolve 4.14 g of salicylic acid in 1000 cm^3 of 2:3 mixture of IBMK and chloroform.

Chloroacetic Acid (3 mol dm^{-3}):

Hydrochloric Acid (2.5 mol dm^{-3}):

Salicylic Acid Solution (2%): Dissolve 2 g of salicylic acid in 100 cm^3 methanol and store in a stoppered bottle.

Rhodamine B Solution (0.03%):

Acetate Buffer (pH 4.0):

Apparatus. A Carl Zeiss PMQ II spectrophotometer with a ZFM fluorescent attachment provided with a 250 VA mercury vapour lamp was used. Slit widths of 5 mm for excitation filter and 0.03 mm for emission monochromator were employed for the fluorescence measurements with 10 mm × 10 mm × 45 mm quartz cells with polished bottoms. The instrument was standardised using standard glass fluorescer F53 supplied by the manufacturer.

Procedure. To an aliquot of the sample containing not more than 1000 μg of zirconium, add 5 cm^3 of 3 mol dm^{-3} chloroacetic acid and adjust the pH of the solution to 1.4 to 1.6 using dilute sodium hydroxide and hydrochloric acid. Transfer the solution to 60 cm^3 separatory funnel and dilute to 15 cm^3 with water. Equilibrate the solution for 1 min with 10 cm^3 of salicylic acid extraction solution. Drain the organic phase into another separatory funnel and strip twice with 5 cm^3 portions of 2.5 mol dm^{-3} hydrochloric acid. Boil the solution over a hot plate for 5 min, cool and make up to a suitable volume with water.

Determination of Zirconium: Transfer an aliquot of the stripped phase containing not more than 16 μg of zirconium into a 25 cm^3 beaker. Add 1 cm^3 each of salicylic acid and Rhodamine B solution followed by 5 cm^3 of 0.5 mol dm^{-3} solution of sodium acetate. Adjust the pH to 4.0 and transfer to a 60 cm^3 separatory funnel. Dilute the solution to about 15 cm^3 with water and shake for 1 min with 5 cm^3 benzene. After separating the benzene phase and centrifuging off the water droplets measure the fluorescence intensity of the extracts at 575 nm using 546 nm excitation filter. Subtract the blank reading and establish the concentration of zirconium by reference to a calibration graph prepared by applying the procedure to 0.5 cm^3 to 4 cm^3 of 4 ppm zirconium solution in place of sample solution.

Results and Discussion

The fluorimetric method resulted from an investiga-

TABLE 1. EFFECT OF DIFFERENT PARAMETERS ON THE EXTRACTION OF THE COMPLEX
(Salicylic acid (2.0%) and Rhodamine B (0.03%) solutions 1 cm^3 each at pH 4.0 except when varied as shown) (Zr : 10 μg).

pH	3.4	3.6	3.7	3.9	4.1	4.3	4.4

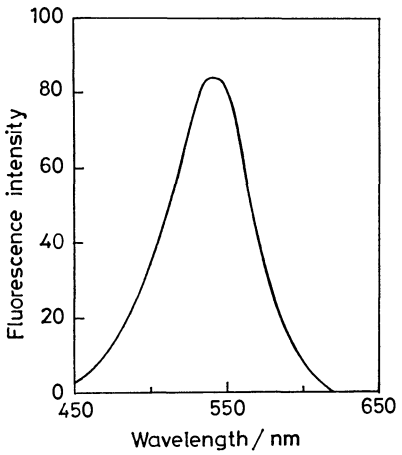

Fig. 1. Excitation spectra (uncorrected) 10 μg of zirconium treated as in determination.

tion of the interaction of Rhodamine B with zirconium after the addition of various carboxylic acids over the pH range 1 to 5. The carboxylic acids examined included mandelic acid, cinnamic acid, anthranilic acid, salicylic acid, and *N*-phenylanthranilic acid. Amongst these, salicylic acid was found to be the best as in its presence the benzene extract was found to be strongly fluorescent with excitation and emission maximum at 546 nm and 575 nm respectively (Figs. 1 and 2). The blank was found to fluoresce only feebly under similar conditions. Using 5 cm^3 benzene for extraction purposes and maintaining an equeous phase volume of 15 cm^3, optimum analytical conditions were established and the results are summarised in Table 1.

The fluorescent intensity of the benzene extract remained stable for at least 4 h and the calibration graph was linear in the range 2 to 16 μg of zirconium.

Ten replicate standard solution containing 10 μg of zirconium gave an average recovery of 101% with a relative standard deviation of 3.9%.

Composition of the Complex. The ratio of zirconium to Rhodamine B in the complex was found to be 1:1 by both mole ratio and continuous variation methods. However the ratio of zirconium to salicylic acid in the complex could not be found out since the extraction of the ion-association complex into benzene was found to be negligible when the salicylic acid

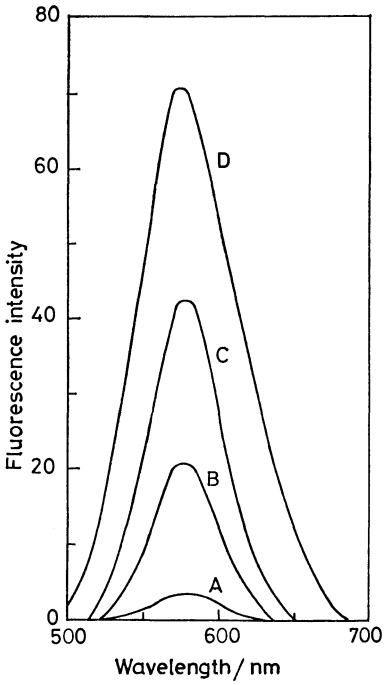

Fig. 2. Emission spectra. (A) 0 μg, (B) 5 μg, (C) 10 μg, and (D) 15 μg of zirconium treated as in determination.

concentration was present in molar proportions.

Interference Studies. Besides hafnium many ions were found to interfere in the determination of 10 μg of zirconium when present in excess of the amounts shown in parantheses. The ions that caused enhancement of fluorescent intensity included UO_2^{2+} (10 μg), Th^{4+} (50 μg) and Sb^{5+} (50 μg), while the presence of Al^{3+} (200 μg), Fe^{3+} or Fe^{2+} (50 μg), Cr^{3+} (50 μg), Ce^{4+} (50 μg), VO_3^- (500 μg), Ti^{4+} (100 μg), MoO_4^{2-} (500 μg), WO_4^{2-} (500 μg), Pd^{2-} (500 μg), Pt^{4+} (500 μg), Bi^{3+} (200 μg), and Sn^{2+} (100 μg) caused a decrease in fluorescent intensity. No interference was encountered from one milligram amounts of Ag^+, Mg^{2+}, Sr^{2+}, Ba^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Mn^{2+}, Zn^{2+}, Hg^{2+}, Cd^{2+}, rare earths, CrO_4^{2-}, AsO_4^{3-}, $S_2O_3^{2-}$, SO_4^{2-}, and SCN^-.

Extractive Separation of Zirconium. Initial studies were made using 1 mol dm^{-3} solution of chloroacetic acid and trichloroacetic acid and 100 μg of zirconium or hafnium. Extractions were made from 15 cm^3 aque-

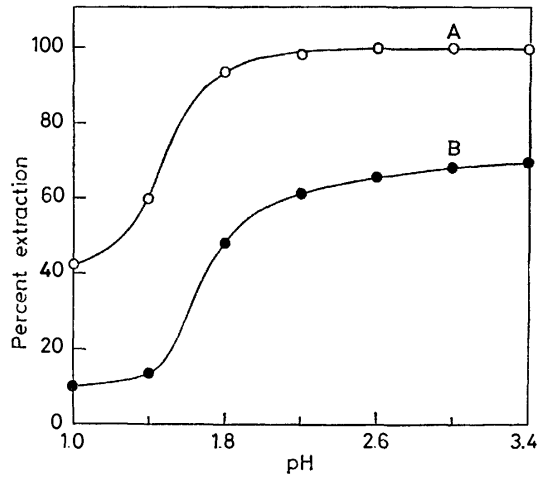

Fig. 3. Percentage extraction of (A) 100 μg of zirconium (B) 100 μg of hafnium as a function of pH. Chloroacetic acid: 1 mol dm^{-3}, IBMK solvent.

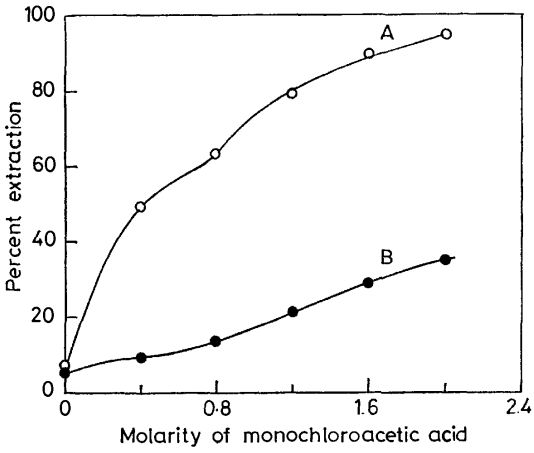

Fig. 4. Percentage extraction of (A) 100 μg of zirconium and (B) 100 μg of hafnium as a function of chloroacetic acid concentration. pH: 1.5, IBMK solvent.

ous phase maintained at pH 0.5, 1.5, and 2.5 into 10 cm^3 IBMK for 5 min. The percentage of zirconium or hafnium extracted was established after stripping the organic phase twice with 5 cm^3 of 2.5 mol dm^{-3} of hydrochloric acid and applying the quercetin procedure.[8] The results showed that zirconium and hafnium extract to varying extent from each of these aqueous systems. Chloroacetic acid at pH 2.5 was found to quantitatively extract zirconium and 60% of hafnium while under similar conditions trichloroacetic acid extracted 82% of zirconium and 40% of hafnium. At other pH conditions, zirconium and hafnium were found to extract to a lesser extent from both systems. Extraction from chloroacetic acid was therefore chosen for further study.

The extraction of zirconium or hafnium as a function of pH is shown in Fig. 3. It is evident that the extraction of zirconium (curve A) is quantitative at pH's greater than 2.5. Hafnium (curve B), though did not extract quantitatively, showed a trend which was very similar to zirconium. The separation factor

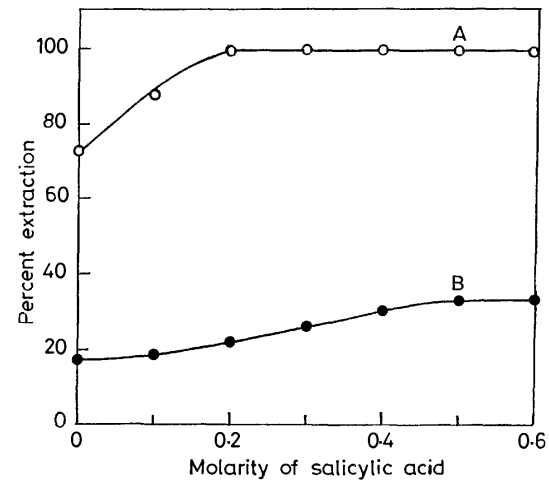

Fig. 5. Effect of salicylic acid concentration on the extraction of (A) 100 μg of zirconium and (B) 100 μg of hafnium into IBMK from 1 mol dm^{-3} chloroacetic acid at pH 1.5.

for zirconium was maximum (13.8) at pH 1.5, where zirconium extraction was incomplete (75%) and hafnium coextracted to a significant extent (18%).

Figure 4 shows the effect of chloroacetic acid concentration maintained at pH 1.5 on the extraction of zirconium (curve A) and hafnium (curve B) into IBMK. It is clear that zirconium extraction does not reach a quantitative value even upon raising the concentration of chloroacetic acid to 2 mol dm^{-3}. In addition, as evident from curve B, the presence of higher concentration of chloroacetic acid also increased the coextraction of hafnium and therefore it was decided to confine the investigation using 1 mol dm^{-3} solution.

Other solvents examined included chloroform butyl acetate, cyclohexanone, benzene, cyclohexane, 1-butanol, and carbon tetrachloride to ascertain the most suitable solvent for the quantitative extraction of zirconium from hafnium. Amongst these chloroform and carbon tetrachloride did not extract either zirconium or hafnium. Cyclohexanone, 1-butanol, cyclohexane, and benzene gave very low separation factor for zirconium. Butyl acetate behaved almost similar to IBMK, but the extraction of hafnium into this solvent was slightly more (22%) than into IBMK (18%).

Studies to improve the extraction of zirconium revealed that the addition of salicylic acid to be effective, as its presence in IBMK was found to quantitatively extract zirconium from 1 mol dm^{-3} chloroacetic acid at pH 1.5. Figure 5 shows the effect of variation of salicylic acid concentration on the extraction of these elements. It is evident that the salicyclic acid concentration should be at least 0.2 mol dm^{-3} for the quantitative extraction of zirconium and that its presence in excess of this amount also increases the extraction of hafnium. To ensure quantitative extraction of zirconium, it was decided to use a 0.3 mol dm^{-3} solution of salicyclic acid in IBMK, though this resulted in the coextraction of hafnium to an extent of 25%.

Attempts to render the organic extract free from hafnium revealed that retrograde extraction with a

fresh aqueous phase of 1 mol dm^{-3} chloroacetic acid at pH 1.5 is ineffective as it caused 5% decrease in the recovery of zirconium. As chloroform did not extract zirconium or hafnium the use of 0.3 mol dm^{-3} salicyclic acid in IBMK–chloroform mixture for extraction was considered. Detailed examination showed that the presence of 5.5 to 6.5 cm^3 of chloroform in 10 cm^3 of the solvent mixture was sufficient for the quantitative extraction of zirconium without the coextraction of hafnium. The presence of chloroform in excess of the volume indicated, resulted in the lower recovery of zirconium.

A shaking time of 1 min was found to be sufficient for the quantitative extraction of zirconium and the extraction remained unaffected up to an aqueous to organic phase volume ratio of 3:2. After extraction, equilibration for 1 min with 10 cm^3 of hydrochloric acid of acidity 1.25 mol dm^{-3} was found to be sufficient for stripping the zirconium quantitatively from the organic phase. However, the use of 2.5 mol dm^{-3} hydrochloric acid was preferred for back-extraction as polymerization of zirconium in this medium has been shown to be minimum.[9]

The results of extraction and back-extraction of 5 to 1000 μg of zirconium showed quantitative recovery over the concentration range examined. In the presence of hafnium there was no evidence of its extraction up to 500 μg. However, when hafnium was present at 1 mg level a slight enhancement in the recovery of zirconium (to the extent of 4%) was noticed.

Nature of the Extracted Species. The plots of log *D* *vs.* log[chloroacetic acid] when extractions were carried out using IBMK containing 0.3 mol dm^{-3} salicyclic acid at pH 1.5 gave straight lines for both zirconium and hafnium with slopes of 0.80 and 0.98 respectively indicating that chloroacetic acid forms 1:1 species with both zirconium and hafnium. Similarly plot of log *D* *vs.* log[salicylic acid] when extractions were carried in the presence of 1 mol dm^{-3} chloroacetic acid, gave slopes of 1.2 and 0.84 for zirconium and hafnium, thus showing that both zirconium and hafnium form 1:1 complexes with both chloroacetic acid and salicylic acid.

Attempts to establish the molar ratio of solvent to metal using benzene as diluent were unsuccessful probably due to the existence of many species with varying number of solvent molecules occupying the coordination positions.

Under the optimal conditions for zirconium, the behaviour of aluminium, titanium, iron(III), thorium, uranium(VI), and vanadium(V) were ascertained using 1 mg amounts of the respective metal ions. After the organic phase was stripped twice with 5 cm^3 portions of 2.5 mol dm^{-3} hydrochloric acid, the concentration of the metal ion in the strippings and in the aqueous phase first subjected to extraction were spectrophotometrically determined using arsenazo III for thorium and uranium,[10] hydrogen peroxide for titanium,[11] 1,10-phenanthroline for iron,[12] Eriochrome cyanine R for aluminium[13] and tungstophosphoric acid for vanadium.[14] The results showed that uranium was not detected in the strippings but 5% of titanium, aluminium, and vanadium, 2.5% of iron and 2% of thorium were found to accompany zirconium.

TABLE 2. RECOVERY OF ZIRCONIUM IN SYNTHETIC MIXTURE

Mixture compositions (μg)	Amount of Zr found (μg)
Zr(100)+Hf(100)+Ti(1000)+SO_4^{2-}(1000)	101
Zr(500)+Hf(5)+La(1000)+Fe(III)(1000)	495
Zr(5)+Hf(500)+U(VI)(1000)+Al(1000)	5.0
Zr(10)+Hf(10)+Th(1000)+U(VI)(1000)	10.2
Zr(20)+Hf(200)+La(1000)+Ti(1000)	19.8

TABLE 3. DETERMINATION OF ZIRCONIUM IN HAFNIUM METAL[a]

Weight of the sample taken (mg/100 cm^3)	Zr added (wt%)	Zr found (wt%)	Average concentration %
50	—	4.40	
50	—	4.60	
50	2.5	7.20	4.60
50	5.0	9.75	
50	10.0	14.50	

a) The sample containing 4.55% zirconium was supplied by Bhabha Atomic Research Centre, Bombay.

The results of the study of the anions revealed that the presence of one milligram amounts of fluoride and phosphate caused a low recovery and sulfate up to 2 mg does not affect the extraction of zirconium.

The method developed was applied in conjunction with the fluorimetric procedure for the determination of 2 to 16 μg of zirconium. After back-extraction into two 5 cm^3 portions of 2.5 mol dm^{-3} hydrochloric acid, the combined strippings in each instance was heated on a hot plate to reduce the volume to 5 cm^3. The solutions were then subjected to determination as described under experimental. A linear relationship was obtained over the whole range and the slope was identical to that obtained for aliquots of standard zirconium solutions that were not subjected to extraction and back-extraction step.

Recovery Studies. The method developed was applied in conjunction with spectrofluorimetry for the determination of zirconium in synthetic mixtures. After back-extraction, the strippings were subjected to the determination as described under determination. The results shown in Table 2 indicate satisfactory recovery in all instances.

Analysis of Hafnium Metal. The zirconium content of a hafnium metal sample was determined by the method developed. 50 mg of the impure hafnium metal was initially brought into solution by dissolving in 3 to 4 drops of hydrofluoric acid in a platinum crucible. Then 10 cm^3 of perchloric acid was added and the solution was evaporated to fumes of perchloric acid. The solution was cooled and made up to 100 cm^3 with water. A suitable aliquot of the solution was pipetted out and the zirconium content was determined by the method described under procedure. Samples to which known amounts of zirconium were added prior to dissolution were also analysed. The

results are shown in Table 3. The close agreement of the results obtained with the reported value suggests that the method developed is useful for the determination of zirconium in hafnium-containing samples.

Chemistry Department, Faculty of Science, Assiut University, Assiut, Egypt

(Received February 3, 1982)

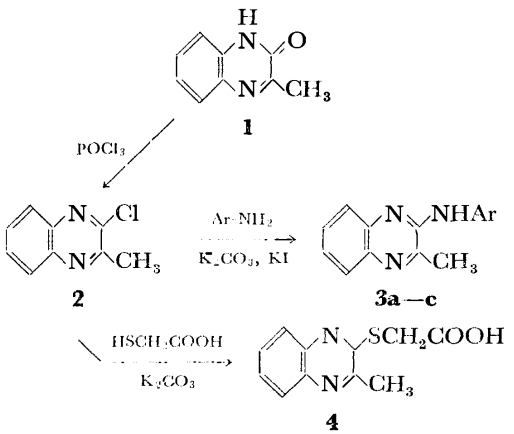
2-Chloro-3-methylquinoxaline reacts with aromatic amines in basic medium forming 2-arylamino-3-methylquinoxalines, also it reacts with mercaptoacetic acid. The 3-methyl-2(1*H*)-quinoxalinone condenses with aromatic aldehydes forming the corresponding 3-(substituted styryl)-2(1*H*)-quinoxalinones which add bromine in acetic acid to yield the corresponding dibromo derivatives which react with morpholine, sodium methoxide, and piperidine to give the corresponding compounds. 3-Methyl-2(1*H*)-quinoxalinone undergoes side-chain bromination to yield 3-bromomethyl-2(1*H*)-quinoxalinone, which reacts with aromatic amines, sodium salt of saccharine, potassium phthalimide··· 3-Methyl-2(1*H*)-quinoxalinone with P_2S_5 gave 3-methyl-2(1*H*)-quinoxalinethione which reacts with 2-aminoethanol, dimethyl sulfate, and halo acids.

2- and 3-Substituted quinoxalines were prepared by direct condensation of *o*-phenylenediamines with the proper reagents.[1] However many of such substituents could be prepared by direct substitution on the nucleus[2] or on the side chain.[3]

The present study deals with the synthesis and study of the reactivity of different 2- and 3-substituted quinoxalines and quinoxalinones towards nucleophilic substitution and condensation reactions.

3-Methyl-2(1*H*)-quinoxalinone (**1**) was prepared by condensation of *o*-phenylenediamine and sodium pyruvate.[4] The 3-methyl-2(1*H*)-quinoxalinone reacts with phosphoryl chloride[5] to yield 2-chloro-3-methylquinoxaline (**2**), whose NMR spectra showed a singlet at δ 2.85 (3H, $-CH_3$) and a multiplet centered at δ 7.85 (4H, aromatic ring).

2-Chloro-3-methylquinoxaline reacts with aromatic amines as nucleophilic reagents in dry benzene in presence of anhydrous potassium carbonate and potassium iodide forming the corresponding 2-arylamino-3-methylquinoxalines (**3a—c**).



The NMR of the compounds (**3a—c**) were in agreement with the given structures as shown in Table 1. Their IR spectra showed NH band at 3350—3200 cm^{-1}.

Similarly, 2-chloro-3-methylquinoxaline reacts with mercaptoacetic acid in presence of potassium carbonate in dry benzene to yield 2-(carboxymethylthio)-3-methylquinoxaline (**4**) whose IR spectrum showed absorption band at 1710 cm^{-1} (C=O of COOH) and a broad band between 3000—2500 cm^{-1} (associated –OH of COOH). The NMR spectrum shows a singlet at δ 2.75 (3H, $-CH_3$), a singlet at δ 4.1 (2H, $-CH_2-$), a multiplet at δ 7.85 (4H, aromatic ring) and a singlet at δ 11 (1H, –COOH).

3-Methyl-2(1*H*)-quinoxalinone undergoes condensation on fusion with aromatic aldehydes in presence of piperidine forming the corresponding 3-(substituted styryl)-2(1*H*)-quinoxalinones (**5a—k**). The IR spectra showed absorption band at 1620 cm^{-1} of the conjugated C=C. In UV spectra (Table 2) a bathochromic shift (red shift) of the K-band observed in 3-styryl-2(1*H*)-quinoxalinones (**5a—k**) as compared with the parent compound (**1**) (λ_{max} 340 nm) which was attributed to the difference in auxochromic character of the quinoxalinone ring in conjugation with –C=N– group.

o-Hydroxystyryl derivative (λ_{max} 400 nm) showed less bathochromic shift than its *p*-isomer (λ_{max} 406 nm) and this may be attributed to the steric hindrance of the bulky group at the ortho-position, thus distorting the coplanarity of the conjugated system.

The coupling constant of the styryl protons is 15—16 Hz indicating its trans configuration (Table 3).

3-(Substituted styryl)-2(1*H*)-quinoxalinones (**5a—k**) undergo reactions characteristic for α,β-unsaturated compounds. Bromine adds on such compounds in acetic acid to yield the corresponding dibromo derivatives **6a—d**. In the UV spectra of these dibromo compounds, peak near 390—396 nm corresponding to the parent styryl group **5** disappears and only absorbs in the region 346—350 nm which is closely similar to the absorption of the parent quinoxalone nucleus, confirming the absence of the sidechain conjugation at position-2. The NMR spectrum of the dibromide **6b** showed the following characteristic signals: two doublets at δ 2.42 (1H, –CH–C=N) and δ 3.23 (1H, –CH–ph); singlet at δ 6.1 (1H, NH) and symmetrical multiplet centered at 7.52 (8H, aromatic).

The effect of *p*-substituents of the phenethyl moiety of **6a**, **6b** on the halogen susceptibility towards some nucleophilic displacement reactions have been examined. The presence of an electron-donating group such as the *p*-methoxyl group in compound **6a** facilitates the removal of the bromine atoms when refluxed with ethanol to give the corresponding styryl compound. However when refluxed with morpholine in dry benzene it gave a product which contains no bromine

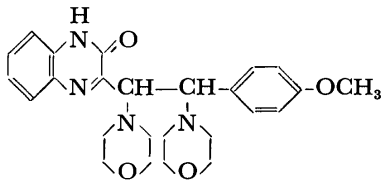
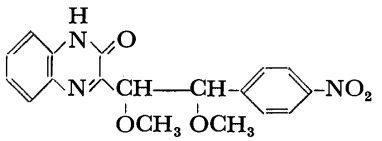
5d	3.15(s) (6H, $-N(CH_3)_2$	6.8	7.4	8.25	7.7

and is identified as 3-[1,2-dimorpholino-2-(p-methoxyphenyl)ethyl]-2(1*H*)-quinoxalinone (**7**).



7

On the other hand, the presence of an electron-withdrawing group such as the p-nitro group **6d** gives an additional stability to the halogen atoms to such an extent that they are displaced by sodium methoxide in methanol to give 3-[1,2-dimethoxy-2-(p-nitrophenyl)ethyl]-2(1*H*)-quinoxalinone (**8**).



8

When the dibromide **6d** was refluxed with piperidine in dry dioxane, dehydrobromination of the β-bromine occurs followed by substitution of the α-bromine to give the corresponding (α-piperidinostyryl)quinoxalinone (**9**) where the IR spectrum showed absorption band at 1610 cm^{-1} of conjugated C=C. The UV spectra showed λ_{max} at 380 nm confirming the presence of conjugating styryl residue at position-3 with the quinoxalinone ring system.

3-Methyl-2(1*H*)-quinoxalinone dissolved in acetic acid undergoes side-chain bromination in the presence of sodium acetate[6] yielding 3-bromomethyl-2(1*H*)-quinoxalinone (**10**). The latter compound reacts with p-bromoaniline and 1-naphthylamine forming the corresponding 3-arylaminomethyl-2(1*H*)-quinoxalinones (**11a, 11b**). Also it reacts with phenylhydrazine to give 3-(2-phenylhydrazinomethyl)-2(1*H*)-quinoxalinone (**12**) whose IR spectrum showed side-chain -NH- absorption band at 3380 cm^{-1}. The NMR spectrum of compound **12** showed a singlet at δ 2.4 (1H, $-CH_2-NH-$), a singlet at δ 3.3 (2H, $-CH_2-$), a singlet at δ 6.8 (1H, -NH- of quinoxalinone nucleus), a multiplet centered at δ 7.3 (9H, aromatic rings) and a singlet at δ 8.2 (1H, -NH-ph).

3-Bromomethyl-2(1*H*)-quinoxalinone reacts with the sodium salt of saccharin, potassium phthalimide, sodium p-nitrophenolate, thiophenol, silver acetate and thiourea in ethanol as a solvent to give the corresponding substituted compounds **13**, **14**, **15**, **16**, **17**, and **18** respectively.

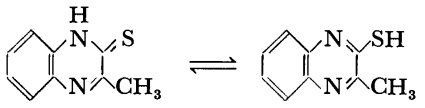
14			

3-Methyl-2(1*H*)-quinoxalinone (**1**) when refluxed with phosphorus pentasulfide in dry pyridine gave 3-methyl-2(1*H*)-quinoxalinethione (**19**), where IR spectrum showed bands at 3350 cm^{-1} (NH) and 1550 cm^{-1} (C=S).



19

The NMR spectrum is in agreement with the thione form and showed a singlet at δ 2.8 (3H, $-CH_3$), a singlet at δ 7.25 (1H, NH) and a multiplet at δ 7.35—7.95 (4H, aromatic).

3-Methyl-2(1*H*)-quinoxalinethione (**19**) reacts with 2-aminoethanol to yield 2-(2-hydroxyethylamino)-3-methylquinoxaline (**20**).

20

The NMR spectrum showed a singlet at δ 2.55 (3H, CH_3), triplet at δ 3.85 (4H, $-CH_2-CH_2-$), singlet at 4.85 (1H, –OH), singlet at δ 5.42 (1H, NH) and multiplet at δ 7.65 (4H, aromatic).

The thione derivative **19** undergo *S*-alkylation, where it reacts with dimethyl sulfate in alkaline medium to give 2-methyl-3-(methylthio)quinoxaline (**21**), with chloroacetic acid to give 3-(carboxymethylthio)-2-methylquinoxaline (**4**) and with 3-bromopropionic acid to give 3-(2-carboxyethylthio)-2-methylquinoxaline (**22**). The NMR spectra of **21** showed a singlet at δ 2.65 (6H, $-CH_3$, S–CH_3) and a symmetrical multiplet centered at δ 7.75 (4H, aromatic).

2-Methyl-3-(methylthio)quinoxaline (**21**) dissolved in acetic acid undergoes side-chain bromination in presence of anhydrous sodium acetate to yield 2-bromomethyl-3-(methylthio)quinoxaline (**23**), whose NMR spectrum showed a singlet at δ 2.75 (3H, S–CH_3), a singlet at δ 4.75 (2H, $-CH_2Br$) and symmetrical multiplet centered at δ 7.85 (4H, aromatic ring).

Experimental

Melting points reported are uncorrected. Elemental analysis was carried out at the microanalytical unit of the National Research Center, El-Doky, Cairo. IR spectra were recorded on a Beckman 20 infrared spectrophotometer using KBr Wafer technique. UV spectra in ethanol were recorded on a Pye-Unicam SP 8000 spectrophotometer and NMR spectra on 90 MHz Bruker spectrospin and Varian EM-390 90 MHz.

*2-Chloro-3-methylquinoxaline (**2**).*[5] Colourless needles from light petroleum, mp 86 °C.

Reaction of 2-Chloro-3-methylquinoxaline with Aromatic Amines. A mixture of 2-chloro-3-methylquinoxaline (0.01 mol) and an aromatic amine (0.012 mol) was refluxed for 10 h in dry benzene (20 ml) in presence of anhydrous potassium carbonate and potassium iodide. The reaction mixture was filtered while hot, concentrated and cooled. The separated product was recrystallized from the proper solvent.

*2-(Anilino)-3-methylquinoxaline (**3a**),* colourless needles from ethanol, mp 126—27 °C. Found: N, 17.83%. Calcd for $C_{15}H_{13}N_3$: N, 17.87%. The IR spectrum showed (NH) band at 3350 cm^{-1}.

*2-(p-Toluidino)-3-methylquinoxaline (**3b**),* gray crystals from benzene, mp 172—73 °C. Found: C, 77.08; H, 6.03%. Calcd for $C_{16}H_{15}N_3$: C, 77.11; H, 6.02%. The IR spectrum showed bands, (NH) at 3200 cm^{-1}, (C=N) at 1620 cm^{-1}.

*2-(p-Chloroanilino)-3-methylquinoxaline (**3c**),* yellow crystals from benzene, mp 124 °C. Found: N, 15.53%. Calcd for $C_{15}H_{12}ClN_3$: N, 15.58%. The IR spectrum showed bands, at 3270 cm^{-1} (NH), 1620 cm^{-1} (C=N).

*2-(Carboxymethylthio)-3-methylquinoxaline (**4**).* A mixture of 2-chloro-3-methylquinoxaline (0.01 mol) and mercaptoacetic acid (0.012 mol) was refluxed for 4 h in dry benzene (20 ml) in presence of anhydrous potassium carbonate. Solvent was evaporated and the residue was treated with dil hydrochloric acid and extracted with ether. The ethereal layer was dried and evaporated. The solid product was recrystallized from benzene as yellow crystals, mp 150 °C. Found: C, 56.46; H, 4.26; N, 11.9%. Calcd for $C_{11}H_{10}N_2O_2S$: C, 56.41; H, 4.27; N, 11.97%.

Reaction of 3-Methyl-2(1H)-quinoxalinone with Aromatic Aldehydes. 3-Methyl-2(1*H*)-quinoxalinone (**1**) (0.1 mol) and the aldehyde (0.12 mol) were fused together in presence of few drops of piperidine. The reaction product washed with petroleum ether (60—80 °C) and recrystallized from the proper solvent (Table 4).

Addition of Bromine on 3-(Substituted styryl)-2(1H)-quinoxalinone. To a cold solution of the styryl compound (0.01 mol) in glacial acetic acid (30 ml), bromine (0.01 mol) in glacial acetic acid was added gradually while stirring and the reaction mixture stirred for 1 h. The product was precipitated, filtered off, washed with glacial acetic acid and recrystallized from xylene, yield 65—75%.

*3-[1,2-Dibromo-2-(p-methoxyphenyl)ethyl]-2(1H)-quinoxalinone (**6a**),* white crystals, mp 180 °C. Found: N, 6.45; Br, 36.4%. Calcd for $C_{17}H_{11}Br_2N_2O_2$: N, 6.39; Br, 36.2%.

*3-[1,2-Dibromo-2-(p-chlorophenyl)ethyl]-2(1H)-quinoxalinone (**6b**),* white crystals, mp 255—56 °C. Found: C, 43.36; H, 2.50; N, 6.39%. Calcd for $C_{16}H_{11}Br_2ClN_2O$: C, 43.29; H, 2.48; N, 6.31%.

*3-[1,2-Dibromo-2-(m-nitrophenyl)ethyl]-2(1H)-quinoxalinone (**6c**),* white crystals, mp 275 °C. Found: C, 42.30; H, 2.58; N, 9.23%. Calcd for $C_{16}H_{11}Br_2N_3O_3$: C, 42.38; H, 2.42; N, 9.27%.

*Reaction of Nucleophiles with the Dibromides **6** to Produce the α,β-Disubstituted Products. General Procedure:* A mixture of **6** (0.01 mol) and nucleophile (0.024 mol) in solvent (40 ml) was refluxed together. The hot solution filtered, evap-

orated and the solid separated crystallized from the proper solvent.

3-[1,2-Dimorpholino-2-(p-methoxyphenyl)ethyl]-2(1H)-quinoxalinone (7). From morpholine in dry benzene; 4 h reflux, recrystallized from dioxane as yellow crystals, mp 245 °C, yield 23%. Found: N, 12.37%. Calcd for $C_{25}H_{30}N_4O_4$: N, 12.44%.

3-[1,2-Dimethoxy-2-(p-nitrophenyl)ethyl]-2(1H)-quinoxalinone (8). From sodium methoxide in methanol, 3 h reflux, recrystallized from aqueous methanol as yellow crystals, mp 265 °C, yield 29%. Found: N, 11.90%. Calcd for $C_{18}H_{17}N_3O_5$: N, 11.83%.

3-(α-Piperidino-p-nitrostyryl)-2(1H)-quinoxalinone (9). A mixture of **6d** (0.01 mol) and piperidine (0.024 mol) in dry dioxane (50 ml) was refluxed for 1 h. The hot solution was filtered and concentrated and diluted with drops of water. The separated solid was recrystallized from petroleum ether (60—80) as orange crystals, mp 232—33 °C, yield 49%. Found: N, 14.86%. Calcd for $C_{21}H_{20}N_4O_3$: N, 14.89%.

3-Bromomethyl-2(1H)-quinoxalinone (10),[6] white crystals by sublimation, mp 225 °C (decomp).

Reaction of 3-Bromomethyl-2(1H)-quinoxalinone with Aromatic Amines. A mixture of 3-bromomethyl-2(1*H*)-quinoxalinone (**10**) (0.01 mol), the aromatic amine (0.012 mol) and sodium carbonate was refluxed in ethanol (40 ml) for 3 h. The hot solution was filtered and concentrated, then diluted with few drops of water and the separated solid was recrystallized from the proper solvent.

3-(p-Bromoanilinomethyl)-2(1H)-quinoxalinone (11a), crystallized from ethanol, mp 250 °C (decomp), yield 61%. Found: C, 54.63; H, 3.62; N, 12.75%. Calcd for $C_{15}H_{12}BrN_3O$: C, 54.54; H, 3.63; N, 12.72%.

3-(1-Naphthylaminomethyl)-2(1H)-quinoxalinone (11b), crystallized from ethanol, mp 335 °C, yield 50%. Found: N, 14.04%. Calcd for $C_{19}H_{15}N_3O$: N, 14.00%.

3-(2-Phenylhydrazinomethyl)-2(1H)-quinoxalinone (12), red needles from dioxane, mp 305 °C, yield 83%. Found: C, 67.6; H, 5.22%. Calcd for $C_{15}H_{14}N_4O$: C, 67.66; H, 5.26%.

Reaction of 3-Bromomethyl-2(1H)-quinoxalinone with Organic Acid and Base Compounds. A mixture of 3-bromomethyl-2(1*H*)-quinoxalinone (**10**) (0.01 mol) and (0.012 mol) of each one of the following compounds; sodium salt of saccharin, potassium phthalimide, sodium *p*-nitrophenolate, thiophenol, silver acetate, thiourea, was refluxed for 4 h in ethanol (30 ml). The hot solution was filtered and concentrated, then diluted with few drops of water, the separated solid was recrystallized from aqueous ethanol.

N-(3-Oxo-3,4-Dihydro-2-Quinoxalinylmethyl)saccharin (13), pale brownish crystals, mp 265 °C, yield 59%. Found: N, 12.33%. Calcd for $C_{16}H_{11}N_3O_4S$: N, 12.30%. The IR spectrum showed bands at 3450 cm^{-1} (NH), 1740 cm^{-1} (C=O of saccharin), 1670 cm^{-1} (C=O of quinoxalinone).

3-(Phthalimidomethyl)-2(1H)-quinoxalinone (14), reddish crystals, mp 188 °C, yield 50%. Found: N, 13.74%. Calcd for $C_{17}H_{11}N_3O_3$: N, 13.77%. The IR spectrum showed bands at 3120 cm^{-1} (NH), 1780, 1730 cm^{-1} (2 C=O of phthalimide), 1675 cm^{-1} (C=O of quinoxalinone nucleus).

3-(p-Nitrophenoxymethyl)-2(1H)-quinoxalinone (15), yellowish crystals, mp 190 °C, yield 51%. Found: C, 60.53; H, 3.74%. Calcd for $C_{15}H_{11}N_3O_4$: C, 60.60; H, 3.70%. The IR spectrum showed bands at 3450 cm^{-1} (NH), 1670 cm^{-1} (C=O), 1610 cm^{-1} (C=N), 1520 and 1350 cm^{-1} (NO_2).

3-(Phenylthiomethyl)-2(1H)-quinoxalinone (16), pale brownish needles, mp 178 °C, yield 75%. Found: C, 67.09; H, 4.55%. Calcd for $C_{15}H_{12}N_2OS$: C, 67.16; H, 4.47%. The IR spectrum showed bands at 3150 cm^{-1} (NH), 1675 cm^{-1} (C=O), 1610 cm^{-1} (C=N).

3-(Acetyloxymethyl)-2(1H)-quinoxalinone (17), red crystals, mp 180 °C (decomp), yield 46%. Found: N, 12.82%. Calcd for $C_{11}H_{10}N_2O_3$: N, 12.84%. The IR spectrum showed bands at 3450 cm^{-1} (NH), 1740 cm^{-1} (C=O of ester), 1670 cm^{-1} (C=O of quinoxalinone).

S-(3-Oxo-3,4-dihydro-2-quinoxalinylmethyl)thiouronium Bromide (18), pale brownish needles, mp 232 °C (decomp), yield 64%. Found: C, 38.12; H, 3.54; N, 17.69; Br, 25.42%. Calcd for $C_{10}H_{11}BrN_4OS$: C, 38.09; H, 3.49; N, 17.78; Br, 25.39%. The IR spectrum showed bands at 3300 cm^{-1} (C=NH), 3200 cm^{-1} (NH of quinoxalinone nucleus), 3100—3080 cm^{-1} ($-\overset{+}{N}H_3$), 1655 cm^{-1} (C=O), 1620 cm^{-1} (C=N) and 1280 cm^{-1} (S–R).

3-Methyl-2(1H)-quinoxalinethione (19), 3-Methyl-2(1*H*)-quinoxalinone (**1**) (0.1 mol) and phosphorus pentasulfide (0.1 mol) were refluxed for 4 h in dry pyridine (100 ml). The solvent was evaporated, the residue washed with dil acetic acid, then with water and crystallized from ethanol as yellowish needles, mp 250 °C (sublm.), yield 86%. Found: C, 61.39; H, 4.71; N, 15.79%. Calcd for $C_9H_8N_2S$: C, 61.36; H, 4.54; N, 15.90%. The IR spectrum showed bands at 3350 cm^{-1} (NH), 1620 cm^{-1} (C=N), and 1500 cm^{-1} (C=S).

2-(2-Hydroxyethylamino)-3-methylquinoxaline (20), A mixture of 3-methyl-2(1*H*)-quinoxalinethione (0.01 mol) and 2-aminoethanol (0.012 mol) was refluxed in absolute ethanol (20 ml) for 2 h. The hot solution was filtered and evaporated. The product was recrystallized from ethanol as reddish crystals, mp 105—107 °C, yield 15%. Found: N, 20.76%. Calcd for $C_{11}H_{13}N_3O$: N, 20.69%. The IR spectrum showed bands at 3400 cm^{-1} (OH), 3300 cm^{-1} (NH).

2-Methyl-3-(methylthio)quinoxaline (21), Dimethyl sulfate (0.01 mol) was stirred with 3-methyl-2(1*H*)-quinoxalinethione (0.01 mol) in sodium hydroxide solution (0.01 mol in 10 ml H_2O). The reaction mixture was kept overnight. Ammonium hydroxide was added and the solid product was filtered, washed with water, recrystallized from petroleum ether (60—80) as pale brown crystals, mp 53—54 °C, yield 79%. Found: C, 63.06; H, 5.32; N, 14.47%. Calcd for $C_{10}H_{10}N_2S$: C, 63.15; H, 5.26; N, 14.74%. The IR spectrum showed bands at 1620 cm^{-1} (C=N) and 1250 cm^{-1} (S–CH_3).

Reaction of 3-Methyl-2(1H)-quinoxalonethione with Chloroacetic Acid and 3-Bromopropionic Acid. A mixture of 3-methyl-2(1*H*)-quinoxalinethione (0.01 mol), chloroacetic acid or 3-bromopropionic acid (0.01 mol) and potassium carbonate in ethanol (20 ml) was heated for 15 min. The hot solution filtered and acidified with drops of acetic acid. The product was separated after cooling and recrystallized from the proper solvent.

2-(Carboxymethylthio)-3-methylquinoxaline (4), yellowish crystals from benzene, mp 150 °C, yield 55%. Found: S, 13.62 %. Calcd for $C_{11}H_{10}N_2O_2S$: S, 13.68%. The IR spectrum was coincident with that of reference sample.

2-(2-Carboxyethylthio)-3-methylquinoxaline (22), brownish needles from methanol, mp 194—95 °C, yield 80%. Found: S, 12.82%. Calcd for $C_{12}H_{12}N_2O_2S$: S, 12.90%. The IR spectrum showed bands at 3000—2500 cm^{-1} (associated OH of –COOH), 1730 cm^{-1} (C=O of acid).

3-Bromomethyl-2-(methylthio)quinoxaline (23), a solution of bromine (0.01 mol in 5 ml acetic acid) was added gradually while stirring to a mixture of 2-methyl-3-(methylthio)quinoxaline (0.01 mol) and anhydrous sodium acetate (0.01 mol) in acetic acid (30 ml). The reaction mixture was heated for 15 min. The reaction product was collected by filtration and recrystallized from ethanol as white needles,

mp 136 °C, yield 19%. Found: C, 44.74; H, 3.42; N, 10.12; Br, 29.45%. Calcd for $C_{10}H_9BrN_2S$: C, 44.60; H, 3.35; N, 10.40; Br, 29.74%. The IR spectrum showed bands at 1620 cm^{-1} (C=N) and 1220 cm^{-1} (S–CH_3).

Zeta Potentials of Metal Oxide Surfaces Modified with Silane Coupling Agents

Kunio Esumi* and Kenjiro Meguro

Department of Applied Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received June 22, 1982)

Synopsis. The zeta potentials of metal oxide surfaces modified with silane coupling agents were measured as a function of pH in the suspensions. The methylations of the samples by methyltrimethoxysilane showed lower zeta potential values than those of the samples untreated. On the other hand, the treatment of the samples by two different amino silanes rendered the surfaces more cationic. The stability of the deposited silane layers was low; such a layer was easily removed from alumina and anatase-type titanium dioxide.

Coupling agents for modifying many oxide surfaces have been used to improve the bonding between reinforcements and polymer matrix. To elucidate the modified metal oxide surfaces, Fourier transform infrared spectroscopy and Auger electron spectroscopy have been employed. Chiang and Koenig[1] used Fourier transform infrared spectroscopy to study the orientation of silane coupling agents on glass surfaces. However, when surface treatments are applied to a dispersion system containing porous material in solution, the above techniques become inapplicable. In this case, electrokinetic measurements such as zeta potential could be a useful method to detect changes in surface properties. Indeed, Koh[2] reported the change in surface charge density of alumina coated with (3-aminopropyl)triethoxysilane from streaming potential measurements. However, no systematic study has been made on the electrokinetic effects of metal oxides modified with silane coupling agents.

In this work surface properties of several metal oxides modified with silane coupling agents were investigated by measuring the zeta potentials as a function of pH in aqueous solution.

Three silane coupling agents, (3-aminopropyl)tri-

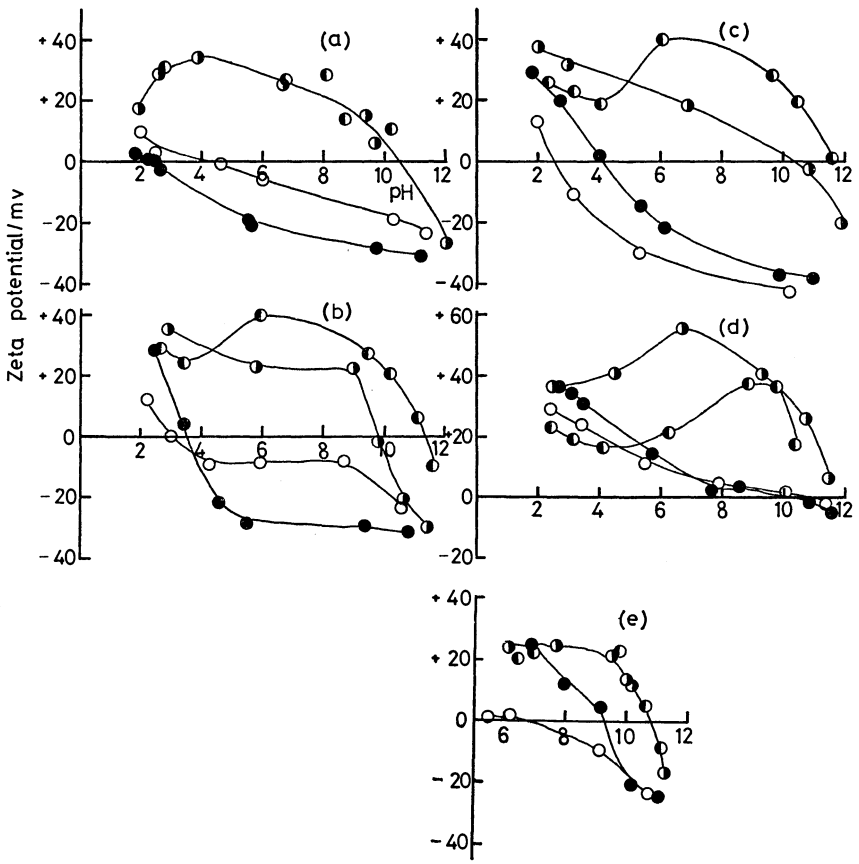

Fig. 1. Zeta potentials of untreated and silane coupling agents treated metal oxides as a function of pH in suspensions: (a) silica, (b) iron oxide, (c) rutile-type titanium dioxide, (d) anatase-type titanium dioxide, (e) alumina; (●) untreated, (○) methyltrimethoxysilane, (◑) (3-aminopropyl)triethoxysilane, (◐) [3-(2-aminoethylamino)propyl]trimethoxysilane.

ethoxysilane, [3-(2-aminoethylamino) propyl] trimethoxysilane, and methyltrimethoxysilane were kindly supplied by Tisso Chemicals, and were used without further purification. Metal oxides employed were titanium dioxide(anatase-type, rutile-type), alumina, iron oxide, and silica supplied by Teikoku Chemicals, Kokusan Chemicals, Titan Chemicals, and Nippon Aerosil Co., respectively.

Coating of silane coupling agents on metal oxide surfaces was carried out with about 3 wt% solution of silane coupling agents in methanol–water mixture (4:1 by volume). Two drops of glacial acetic acid were added to catalyze the hydrolysis. The metal oxide was added and stirred into the silane coupling agent solution for 20 min at room temperature. Then the metal oxide coated with the silane coupling agent was collected and dried in an oven at 80 °C for 10 min.

Measurements of zeta potential for the metal oxides before and after their silane coupling treatments were made using a Pen Kem Laser 500 Zeta Potential. The pH of the suspension containing the metal oxide treated with a silane coupling agent was adjusted with HCl or NaOH.

The stability of untreated and silane coupling agent treated metal oxide suspensions was compared visually in small beakers. The untreated metal oxides were readily dispersible by gentle shaking, whereas the treated metal oxides were initially aggregated. However, they dispersed when the suspensions were treated in an ultrasonic cleaning bath.

Figure 1 depicts zeta potentials of untreated and silane coupling agents treated metal oxides as a function of pH in the suspensions. As can be seen from Fig. 1, the magnitude of zeta potentials for most of the samples treated with methyltrimethoxysilane was smaller over the entire pH range(pH 2—12) than that of untreated samples. This suggests that methylation for the metal oxides affects the electrical double layers to some extent. Further, it was found that the zero point of charge(zpc) for all the samples was not changed significantly after the methyltrimethoxysilane treatment. On the other hand, the zeta potentials of all the samples treated with (3-aminopropyl)-triethoxysilane and [3-(2-aminoethylamino)propyl]trimethoxysilane were positively over a wide pH range. In the case of silica and alumina, no differences of the zeta potentials treated with two kinds of amino silane coupling agents were observed. It is noteworthy

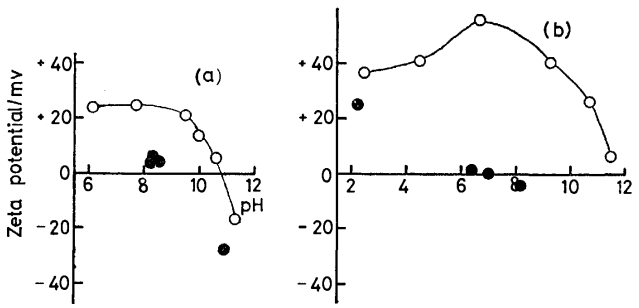

Fig. 2. Change in zeta potential of metal oxide treated with (3-aminopropyl)triethoxysilane: (a) alumina, (b) anatase-type titanium dioxide; (○) immediately, (●) after 1 d.

that the zpc of all the samples treated with two kinds of amino silane coupling agents is shifted to pH 10—12, in spite of the different acid-base character for the metal oxides. These results support the assertion that the polyaminosiloxanes films formed from the hydrolysis of the amino silane coupling agents are coated completely on the metal oxides.

It is also important to study the stability of deposited silane layers on the metal oxides. For this purpose, the samples treated with two kinds of amino silane coupling agents were allowed to stand for one day in aqueous solution a some pH value and then the zeta potential was measured. The results are shown in Fig. 2. The zeta potential after one day became near the original value due to detachment of the silane layers from the metal oxide surface. Especially, as shown in Fig. 2, the changes in the zeta potential after one day were remarkably significant for alumina and anatase-type titanium dioxide coated with the amino silane. Chiang and Koenig[1] studied the hydrothermal stability of silica treated with diamino silane coupling agent; they found that the coupling agent was rapidly removed from the silica surface after it was immersed in boiling water.

Accordingly, zeta potential measurement is a useful method to analyze surface properties of metal oxides treated with silane coupling agents.

Fluorescence as a Means for Kinetic Studies. II. Preparation and Reactions of Bifunctional Fluorescent Reagents as Kinetic Probes

Akio Okamoto,* Kumiko Toyoshima, and Itaru Mita

Institute of Interdisciplinary Research, Faculty of Engineering, The University of Tokyo, 4-6-1, Komaba, Meguro-ku, Tokyo 153

(Received August 12, 1982)

Synopsis. 1,5-Naphthalenedisulfonyl dichloride was found to be useful as a bifunctional fluorescent probe for kinetic studies. Its reaction with butylamine in chloroform proceeds stepwise. The first reaction produces a nonfluorescent monosulfonamide and the second slow process forms a fluorescent disulfamide. Their rate constants were obtained. Another bifonunctional fluorescent probe was also examined briefly.

Bifunctional reagents have been used extensively in coupling reactions for the network formation of polymers *etc.* The coupling reactions of a bifunctional reagent, X-X, with functional groups in polymers, Y-Ⓟ, consist of two elementary steps, *viz.*, X-X+Y-Ⓟ→X-Ⓟ (k_2^1) and Ⓟ-X+Y-Ⓟ→Ⓟ-Ⓟ (k_2^2). The latter step is a polymer-polymer reaction and may differ from a corresponding polymer-small molecule reaction. However, kinetic studies on the latter step, separately from the former, have been rarely reported because of its experimental difficulties.[1,2] When appropriate bifunctional fluorescent reagents are prepared, they will become useful "kinetic probes" to analyse the coupling reactions for following reasons: (i) The coupling reaction can be traced by fluorometry in very dilute concentration region (10^{-5} to 10^{-7} M) and (ii) if only the final reaction product is fluorescent, the reaction of the second functional group could be traced independently. Fluorescent reagents used widely in biochemistry are usually effective only in aqueous media.[3] But in our previous paper,[4] some monofunctional fluorescent reagents for amine were shown to react with substrates quantitatively by simple bimolecular reaction in organic solvents.

In this note, the reaction of some bifunctional fluorescent reagents with butylamine are investigated in chloroform as a simple model reaction and it will be shown that the reagents meet the requirments stated above and they are useful as bifunctional reagents for the coupling reaction of amino groups.

Experimental

Materials. 1,5-Naphthalenedisulfonyl dichloride (NDSCl) was prepared by the reaction of disodium 1,5-naphthalenedisulfonate with phosphorus pentachloride (72% yield).[5] 7-Dimethylamino-2,4-naphthalenedisulfonyl dichloride (DNDSCl) was prepared from 7-amino-2,4-naphthalenedisulfonic acid *via* trimethylammonium formation (the method of Cope *et al.*:[6] 76% yield), and dimethylamination (a similar method to that of Hünig *et al.*:[7] 83% yield), followed by chlorination (60% yield). The orange extract by chloroform was recrystallized from diethyl ether to give red needles which melted at 124—125 °C (68% yield). The structure was ascertained by NMR and IR. NMR ($CDCl_3$): δ 3.2 (N-C<u>H</u>$_3$), δ 7.6—9.2 (Ar<u>H</u>). IR: 1170 and 1370 cm^{-1} (<u>S</u>O$_2$Cl), 2900 cm^{-1} (N-<u>C</u>H$_3$). Butylamine (*n*-BuNH_2) and 5-dimethylamino-1-naphthalenesulfonyl chloride (DNSCl), both from Tokyo Kasei, and chloroform of "Dotite Spectrosol" grade were used as received.

Apparatus. NMR and infrared spectra were obtained with a 100-MHz JEOL MH-100 and a JASCO IR-G spectrometer, respectively. A Toyo Soda GPC chromatograph (HCL-802UR; G2000H8×2) was used with THF at 40 °C. The fluorometry for kinetic studies was performed without degassing with a JASCO FP-550 spectrofluorometer. Fluorescence was excited at 290 nm (350 nm) and observed in the range of 320—350 nm (475—500 mn) for NDSCl(DNSCl and DNDSCl).

Results and Discussion

As we have reported already,[4] DNSCl is unstable and converted to fluorescent products at room temperature in polar solvents such as methanol, pyridine, and DMF, while it is stable in less polar solvents such as THF, ethyl acetate, and chloroform. In organic solvents, hydrogen chloride formed reacts imediately with amine. The total reaction of NDSCl with amines is expressed as

$$ClO_2S\text{-}R\text{-}SO_2Cl + 2H_2NR' \xrightarrow{k_2^1} ClO_2S\text{-}R\text{-}SO_2NHR' + H_3N^+R'Cl^- \quad (1)$$

and

$$ClO_2S\text{-}R\text{-}SO_2NHR' + 2H_2NR' \xrightarrow{k_2^2} R'NHO_2S\text{-}R\text{-}SO_2NHR' + H_3N^+R'Cl^-. \quad (2)$$

As a bifunctional fluorescent kinetic probe, NDSCl has to satisfy the following requirements: (i) Only the disulfonamide is fluorescent and (ii) the reaction of the second sulfonyl chloride with amine is the rate determining step.

Fluorescence of each of the GPC fraction of the mixture of NDSCl, the monosulfonamide, and the disulfonamide was checked and it was confirmed that only the disulfonamide is fluorescent. Its fluorescence spectrum is shown in Fig. 1 together with its absorption spectrum.

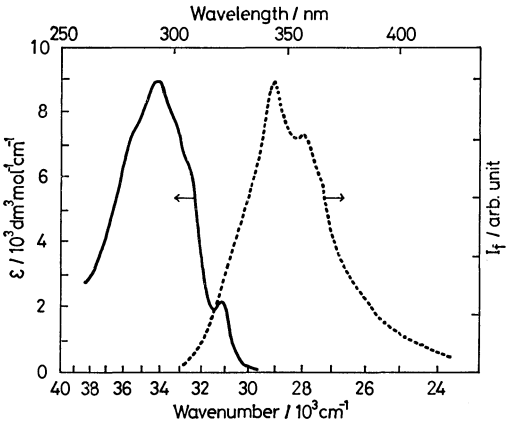

Fig. 1. Absorption and fluorescence spectra of the final reaction product of NDSCl with *n*-BuNH_2 in chloroform.

Table 1. Reaction conditions and k_2^1 for competitive reactions of NDSCl and DNSCl with n-$BuNH_2$

$[n\text{-BuNH}_2]_0$ / 10^{-5} M	$[\text{DNSCl}]_0$ / 10^{-5} M	$[\text{NDSCl}]_0$ / 10^{-5} M	t_1		t_2	
			$\frac{[\text{DNSCl}]}{[\text{DNSCl}]_0}\times 100$	k_2^1 / $M^{-1}\,s^{-1}$	$\frac{[\text{DNSCl}]}{[\text{DNSCl}]_0}\times 100$	k_2^1 / $M^{-1}\,s^{-1}$
1.01	0.99	1.00	9.32	0.56	9.83	0.53
0.99	0.98	—	28.2		30.3	
0.20	0.99	0.20	3.78	0.59	3.90	0.59
0.20	0.99	—	5.66		5.90	

While the chloroform solution of NDSCl (*ca.* 10^{-5} M) and n-$BuNH_2$ in equimolar amount or excess to the sulfonyl group becomes highly fluorescent in a few hours at room temperature, the reaction mixture with n-$BuNH_2$ in half equimolar amount to the sulfonyl chloride group or less is almost nonfluorescent even after a few days. This preliminary test clearly shows that the reaction of the first sulfonyl chloride group is much faster than that of the second one.

The second-order rate constants, k_2^1 and k_2^2, were estimated from the pseudo first-order rate constants for the reaction of NDSCl with large excess of n-$BuNH_2$ $k_1=k_2^1[n\text{-BuNH}_2]$ and $k_2=k_2^2[n\text{-BuNH}_2]$. The concentration of the final product, [$BuNHO_2S$-R-SO_2NHBu], at a certain time t can be obtained as,

$$\frac{[\text{BuNHO}_2\text{S-R-SO}_2\text{NHBu}]}{[\text{ClO}_2\text{S-R-SO}_2\text{Cl}]_0} = 1 - \frac{k_2}{k_2-k_1}\cdot\exp(-k_1t) - \frac{k_1}{k_1-k_2}\cdot\exp(-k_2t). \quad (3)$$

For $k_1>k_2$ and large t, the last term can be disregarded and Eq. 3 is converted to

$$\ln\left(1-\frac{[\text{BuNHO}_2\text{S-R-SO}_2\text{NHBu}]}{[\text{ClO}_2\text{S-R-SO}_2\text{Cl}]_0}\right) = \ln\left(\frac{k_1}{k_1-k_2}\right) - k_2t. \quad (4)$$

Figure 2 shows the pseudo first-order plot of the reaction of NDSCl with large excess of n-$BuNH_2$ in chloroform at 40 °C. The slope and the intercept of the extraporation of the linear line at the later stage of the reaction give k_2 (hence k_2^2) and the ratio k_1/k_2 (hence k_2^1). They are: $k_2^1=5.0\times10^{-1}\,M^{-1}\,s^{-1}$ and $k_2^2=4.8\times10^{-2}\,M^{-1}\,s^{-1}$.

The values of k_2^2 of the reaction was obtained also by the analysis of the three competitive reactions, *i.e.*, the reactions (1), (2), and the reaction of DNSCl with n-$BuNH_2$,

$$\text{DN-SO}_2\text{Cl} + 2\text{H}_2\text{N-Bu} \xrightarrow{k_2^3} \text{DN-SO}_2\text{NHBu} + \text{H}_3\text{N}^+\text{BuCl}^-. \quad (5)$$

For the reactions between DNSCl and n-$BuNH_2$ with and without NDSCl in chloroform at 40 °C, the concentration of the reaction product from DNSCl at a certain time was obtained by fluorometry. With the values of k_2^2 and k_2^3 (4.8×10^{-2} and 3.3×10^{-2}[5] $M^{-1}\,s^{-1}$ respectively), computer simulations of the competitive and non competitive reactions were performed to obtain the optimum value of k_2^1 which satisfies a couple of values of $[\text{DNSCl}]/[\text{DNSCl}]_0$ at a certain time. Table 1 shows that four values of k_2^1, obtained independently for two different concentrations of NDSCl and two different moments, are in fair agreement with each other. The mean value of k_2^1, 0.57 $M^{-1}\,s^{-1}$, is in accord with the value from the pseudo first-order reaction described above. These results confirm that the reactivity of the first sulfonyl chloride group in NDSCl is about 10 times higher than that of the second one and the rate determining step is the reaction of the second sulfonyl chloride group.

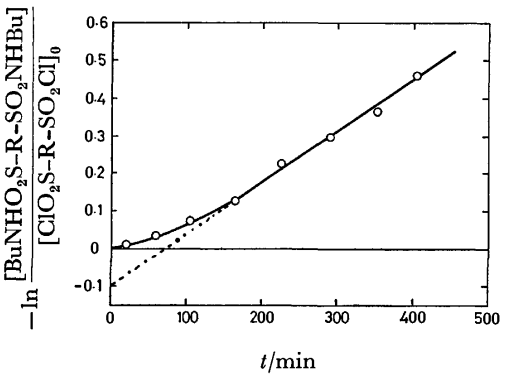

Fig. 2. Pseudo first-order plot of the reaction of NDSCl with n-$BuNH_2$ in chloroform at 40 °C: $[\text{NDSCl}]_0=1.13\times10^{-5}$ M and $[n\text{-BuNH}_2]_0/[\text{NDSCl}]_0=42$.

As another bifunctional fluorescent amine reagent, DNDSCl was synthesized and its reaction with n-$BuNH_2$ was studied briefly. The preliminary test similar to NDSCl indicates that the second reaction of DNDSCl with amine can be detected by the fluorometry which is characterized by an excitation wavelength reached at visible region (absorption maxima: 280 and 390 nm). DNDSCl may, therefore, be more useful than NDSCl as a general fluorescent probe for studies in many fields, because even the presence of most chromophores (benzene derivatives, indole rings, *etc.*) does not interfere the fluorescence measurements with the excitation wavelength.

In conclusion, NDSCl and probably DNDSCl as well are proved to be useful as bifunctional fluorescent probes to analyse the coupling reaction of amino groups kinetically. Its application will be published in near future.[8]

Relative Stabilities of 2*n* Framework Electron Clusters. Perhalogenated Neutral *closo*-Boranes

Jun-ichi AIHARA

Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422

(Received January 8, 1982)

Synopsis. As in the case of the *closo*-borane dianions, relative stabilities of the title compounds can be elucidated by means of the graph theory of aromaticity.

The perhalogenated neutral *closo*-boranes are of special interest because so little is known about their bonding character.[1,2] In many cluster compounds the geometric shape of the framework is determined by the number of electrons delocalized within the framework molecular orbitals.[3,4] Polyhedral species with $(2n+2)$ framework electrons usually have deltahedral geometries while those with only 2n framework electrons are often found to be capped deltahedra.[3,4] The perhalogenated *closo*-boranes of the general formula B_nX_n (X=Cl, Br), however, appear to be quite a different class of molecules which do not adopt the structures predicted by the framework electron counting rules.[1,2] Each of these boranes has only $2n$ framework electrons, but the structures observed for them are mostly the ones associated with the frameworks containing two additional electrons.[1,2,4,5]

We have been developing the graph theory of aromaticity.[6] I previously applied it to the *closo*-borane dianions,[7] and correctly predicted high stabilities of $B_{12}H_{12}^{2-}$ and $B_{10}H_{10}^{2-}$. Therefore, we can fully expect that the same theory might be useful for estimating stabilities of the neutral *closo*-boranes, and that the results might give an important clue to predicting stabilities of the perhalogenated derivatives. In order for this to be seen, the theory was applied to nine neutral *closo*-boranes. All the frameworks were assumed to be deltahedral in shape.[5] The Kettle-Tomlinson bonding model[8] was adopted to describe the framework molecular orbitals. This model uses three-center BBB bonding orbitals, localized at the individual faces of deltahedral borane, as basis functions for the molecular orbital calculation. Resonance energies thus calculated for the neutral *closo*-boranes, *i.e.*, the stabilization energies due to aromaticity, are listed in Table 1. Reference polynomials needed to evaluate the resonance energies can easily be obtained by the use of the computer program reported by Mohar and Trinajstić.[11] The quntity 'resonance energy per face (REPF)' was defined as the resonance energy divided by the number of faces of the deltahedral framework.[7] This can be regarded as a resonance energy normalized with respect to the size of the framework. The REPF values are also listed in Table 1. All the energies are given in units of β or the absolute value of the resonance integral between three-center BBB bonding orbitals which correspond to polyhedron faces with an edge in common.

First, the resonance energies of all B_nH_n species are found to be much smaller than the resonance energy of any *closo*-borane dianion. This implies that the neutral *closo*-boranes are not highly aromatic, and tend to undergo reductions to the dianions. These species should be much less stable. Incidentally none has been observed to date.

TABLE 1. RESONANCE ENERGIES OF NEUTRAL *closo*-BORANES

Species	$RE^{a)}/\beta$	$REPF^{b)}/\beta$
B_4H_4	0.0000	0.0000
B_5H_5	−0.9806	−0.1634
B_6H_6	−1.0196	−0.1274
B_7H_7	−0.9125	−0.0913
B_8H_8	0.1523	0.0127
B_9H_9	0.4596	0.0328
$B_{10}H_{10}$	0.0723	0.0045
$B_{11}H_{11}$	0.2517	0.0140
$B_{12}H_{12}$	0.1829	0.0091

a) Resonance energy. b) Resonance energy per face.

In sharp contrast, perhalogenated derivatives of these neutral boranes, B_4Cl_4, B_8Cl_8, B_9Cl_9, and B_9Br_9, have been prepared and isolated.[12,13] Massey's group confirmed the formation of the compounds B_nCl_n (n=8—12) in the mass spectra.[13,14] Kutz and Morrison recently prepared B_7Br_7, B_8Br_8, and $B_{10}Br_{10}$ by the thermal decomposition of B_2Br_4.[1] Although these compounds lack the number $(2n+2)$ of framework electrons, they are considered to be deltahedral in shape.[1,2,5] They are not air stable, but thermally stable. The most stable of the compounds, B_9Br_9, survives temperatures of 300 °C for days and 200 °C for weeks.[1] One of the most distinct features of the perhalogenated borane series is that the nine-atom cluster is much more stable than the ten-atom cluster,[1,2,13,14] which is the opposite of the results reported for carboranes and *closo*-borane dianions.[15] The existence and isolation of the neutral B_nX_n species have been postulated as owing to extensive halogen back-donation into the polyhedra.[1,2,4] This explanation may be supported by the limited structural data of some compounds,[2] but it cannot justify the highest stability of B_9X_9. The details of the back-bonding are as yet unknown.

The present REPF values may be only approximations for the perhalogenated species since they do not take the substituents into account. It is, however, noteworthy that these values are quite consistent with the chemistry of perhalogenated *closo*-boranes. The most familiar species B_nCl_n (n=8—12)[13,14] are all derivatives of weakly aromatic neutral *closo*-boranes. The REPF value of B_9H_9 is larger than that of any other *closo*-borane. This compound alone may be classified as aromatic in comparison with the dianions.[7] In harmony with this, B_9X_9 is the most stable perhalogenated species and naturally much more stable than $B_{10}X_{10}$. B_5H_5 and B_6H_6 are predicted to be

the most antiaromatic *closo*-boranes with the largest negative REPF values. Their halogenated derivatives have been neither prepared nor observed in the mass spectra. As mentioned above, B_4Cl_4 and B_7Br_7 have also been isolated.[1,12] B_7Br_7 is the only antiaromatic species so far prepared and identified.[1] $B_{11}H_{11}$ and $B_{12}H_{12}$ are predicted to be as stable as B_8H_8 and $B_{10}H_{10}$. Although $B_{11}X_{11}$ and $B_{12}X_{12}$ have not been isolated yet, the formation of these species has often been observed in the mass spectra.[13,14] These will be isolated in the near future.

The present comparative study showed that although the effect on cluster stabilities of the back bonding between the boron cluster and the halogen substituents may not be negligible, the relative stabilities of perhalogenated *closo*-boranes are primarily determined by the aromatic character of the clusters. This implies that the halogen substituents uniformly modify the Coulomb and resonance integrals in the cluster. Furthermore, bulky halogen substituents and large B–X bond energies possibly enhance the kinetic stability of the B_nX_n series. These all are quite likely to constitute the reason why the B_nX_n species are more stable than the B_nH_n species. Finally, it should be stressed that by means of our graph theory of aromaticity[6,7] stabilities of the neutral *closo*-boranes and their dianions can be explained consistently.

8) The electronic structure of boranes has in general been rationalized in terms of central three-center BBB bonds,[9] in each of which all three boron atoms are pairwise neighbors and topologically equivalent. Kettle and Tomlinson demonstrated that the localized three-center BBB bonds may be used as basis functions for molecular orbital calculations on *closo*-boranes.[10] They located a localized three-center BBB bonding orbital at every face of a deltahedral borane, and took the individual such orbitals to be non-orthogonal to each other. The framework electrons can then be treated in a Hückel manner, each localized three-center orbital being assigned a Coulomb integral α and all resonance integrals being set equal to zero, except those between orbitals which correspond to polyhedron faces with an edge in common, which are given the value β. This bonding model leads to a delocalized molecular orbital energy level scheme similar to those obtained from more elaborate molecular orbital calculations.[10]

Determination of Fe-O Bond Energy in Water-gas Shift Catalyst

G. SENGUPTA,* Keshav PRASAD, and S. P. SEN
Projects and Development India Limited, Sindri, Bihar, India
(Received November 27, 1981)

Synopsis. Oxygen catalyst bond energy may play an important role in determining the catalytic activity in water-gas shift reaction. In the present investigation a method for determining this parameter from electrical conductivity has been suggested.

In view of the fact that water-gas shift reaction in iron(III) oxide catalysts is a typical oxidation-reduction reaction, it is quite obvious that there should exist some correlation between the oxygen catalyst bond energy and shift reaction activity. In case of redox reaction in presence of oxygen this bond energy has been measured by various techniques.[1,2] But in case of reactions taking place under reducing conditions *e.g.*, water-gas shift reactions, the only reported method is that of Rachkovsky and Yurjeva[3] who studied the isotope exchange between hydrogen and deuterium oxide on spinels to estimate the oxygen-catalyst bond energy under reducing conditions. In the present investigation a simple method has been suggested to measure this bond energy from electrical conductivity of iron oxide catalyst.

Experimental

The samples A to E were all shift catalysts of commercial variety containing different type of iron(III) oxides promoted with 7—10% chromium(III) oxide. Sample F is pure iron oxide prepared by precipitation from iron(II) sulfate solution with ammonium carbonate followed by curing in air at 500 °C.

The conductivity cell and the circuit used for measurement have been described in detail in an earlier communication.[4] Prior to measurement the catalyst was heated to 200 °C in a flow of N_2+steam in the ratio of 1:5. At 200 °C nitrogen was replaced by hydrogen and the temperature was slowly raised to 350±10 °C. The catalyst was finally stabilized at 460±10 °C. The stabilization was indicated by a constant value of the potential drop. The temperature was slowly brought down to 250 °C and the potential drop was measured at different temperatures after stabilization. Both heating and cooling cycles gave good reproducibility of conductivity values.

Results and Discussion

On reduction with H_2+H_2O mixture the iron oxide catalysts are all reduced to Fe_3O_4. In the present investigation it has been observed that all catalysts show good conductivity which means conduction takes place through Fe_3O_4 phase only irrespective of the presence of chromium(III) oxide. Following Suenaga[5] and Parravano[6] the Fe_3O_4 phase can be assumed to be in oxygen excess nonstoichiometric form which can be represented as:

$$Fe^{3+}[\square_{\delta}Fe^{2+}_{1-3\delta}\ Fe^{3+}_{1+2\delta}]O_4, \qquad (1)$$

where $\square$ is the cation vacancy and δ is the mole fraction of cation vacancies and is a measure of the degree of nonstoichiometry. The conductivity (σ) at any temperature T (in K) can then be written as[7]

$$\sigma = C[1-3\delta][1+2\delta]\exp(-E/RT), \qquad (2)$$

where C is constant and E is activation energy of conduction. Since δ is very small,

$$\sigma = C[1-\delta]\exp(-E/RT). \qquad (3)$$

Therefore,

$$\log\sigma = \log C + \log(1-\delta) - \frac{E}{2.303RT}. \qquad (4)$$

Let δ_i, δ, and σ_i, σ are the degree of nonstoichiometry and conductivities at temperature T_i and T respectively,
Then

$$\log\frac{\sigma_i}{\sigma} = \log\frac{(1-\delta_i)}{(1-\delta)} + \frac{E}{2.303R}\left(\frac{1}{T}-\frac{1}{T_i}\right). \qquad (5)$$

If the catalyst is stoichiometric ($\delta=0$) at the temperature T,

$$\log\frac{\sigma_i}{\sigma} = \log(1-\delta_i) + \frac{E}{2.303R}\left(\frac{1}{T}-\frac{1}{T_i}\right). \qquad (6)$$

From Fig. 1 it can be seen that the plot of $\log(\sigma_i/\sigma)$ *vs.* $(1/T-1/T_i)$ where T_i is the maximum temperature of measurement *i.e.*, 460±10 °C consists of two parts-linear at lower temperature and nonlinear at higher temperature for all catalysts. The general nature of the conductivity temperature plot obtained for different catalysts is presented in Fig. 2. This shows that the catalyst exhibits variable nonstoichiometry only when $T>T_s$. Thus Eq. 5 is obeyed for $T>T_s$ and Eq. 6 for $T\leqslant T_s$. If the catalyst does not show any variation in stoichiometry throughout the temperature range studied the conductivity temperature relationship can be represented by extrapolating the linear portion corresponding to lower temperature part

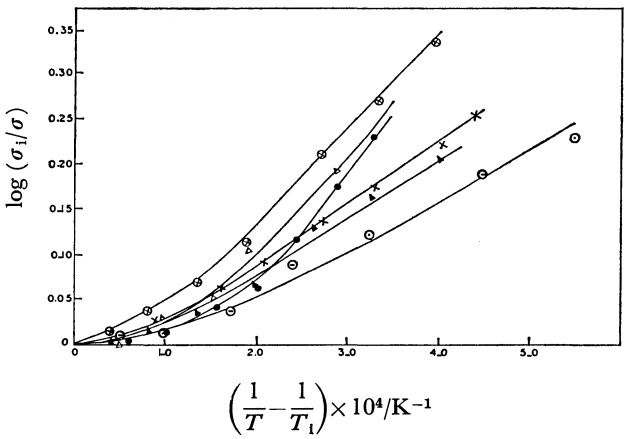

Fig. 1. Variation of resistance of the catalyst with temperature.
Sample A: —△—△—, Sample B: —⊗—⊗—, Sample C: —×—×—, Sample D: —●—●—, Sample E: —▲—▲—, Sample F: —⊙—⊙—.

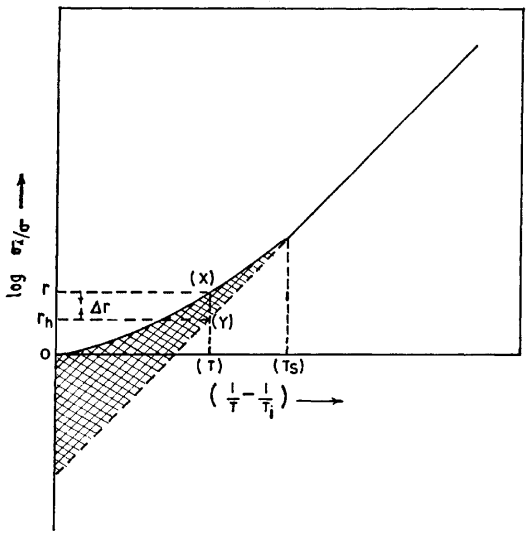

Fig. 2. Change in log (conductivity) *vs.* (temperature)$^{-1}$ plot due to variation in degree of nonstoichiometry.

to higher temperature as shown by the dotted line in Fig. 2. Let σ and σ_h be the conductivities at temperature T corresponding to points X and Y on the actual curve and on the hypothetical extrapolated line respectively. Since Eq. 5 holds for point X and Eq. 6 for point Y respectively then combining both Eqs. 5 and 6,

$$\log\frac{\sigma_h}{\sigma} = \log\frac{\sigma_i}{\sigma} - \log\frac{\sigma_i}{\sigma_h} = r - r_h = \Delta r$$
$$= -\log(1-\delta), \qquad (7)$$

if E is assumed to be independent of the degree of nonstoichiometry. Such an assumption can be justified on the basis of the reported value of E for Fe_3O_4 and γ-Fe_2O_3.[8,9]

The degree of nonstoichiometry (δ) of an oxide catalyst can be expressed by the following empirical equation.

$$1-\delta = \left[\exp\left\{-\frac{\Delta H}{R}\left(\frac{1}{T_s}-\frac{1}{T}\right)\right\}\right]\left(\frac{p^s_{O_2}}{p_{O_2}}\right)^{1/2}, \qquad (8)$$

where ΔH is enthalpy of vacancy formation/mol, $p^s_{O_2}$, p_{O_2} are the equilibrium partial pressure of oxygen at temperatures T_s and T respectively. When $T=T_s$, $p_{O_2}=p^s_{O_2}$, and $\delta=0$. Since in the present case the partial pressure of oxygen at different temperatures is determined by the dissociation of steam ($H_2O \rightleftharpoons H_2+\frac{1}{2}O_2$) we can write

$$\frac{1}{2}\log\left(\frac{p^s_{O_2}}{p_{O_2}}\right) = -\frac{\Delta H_w}{2.303R}\left(\frac{1}{T_s}-\frac{1}{T}\right), \qquad (9)$$

where ΔH_w is the enthalpy of dissociation of steam. Combining Eqs. 7, 8, and 9 and putting $T=T_r$

$$\Delta r = \frac{1}{2.303R}\left(\frac{1}{T_s}-\frac{1}{T_i}\right)(\Delta H+\Delta H_w). \qquad (10)$$

ΔH for different catalysts has been calculated from Eq .10 utilizing the values of Δr and $(1/T_s-1/T_i)$ from Fig. 1 and are presented in Table 1. The average value of oxygen catalyst bond energy is 61.6±2.4 kcal/mol. Since the adsorption/desorption of each oxygen atom results in formation/rupture of two Fe–O bond, average energy per bond is 30.8±1.2 kcal which is good agreement with that calculated by Vijh.[10]

Table 1. Calculation of oxygen catalyst bond energy(ΔH)

ΔH_w=59.3 kcal/mol, T_i=460±10 °C.

	Sample					
	A	B	C	D	E	F
Δr	0.157	0.077	0.053	0.205	0.050	0.100
$\frac{(1/T_s-1/T_i)}{10^{-4}\,K}$	2.9	1.675	1.675	2.475	1.75	4.25
ΔH/kcal mol^{-1}	61.7	61.0	60.7	63.0	60.5	60.3

Synthesis and Properties of Novel Type Binuclear Copper(II) Complexes Whose Coordination Units Are Linked by a Flexible Polyatomic Chain

Kazuhiro TAKAHASHI, Yuzo NISHIDA,* and Sigeo KIDA

Department of Chemistry, Faculty of Science Kyushu University 33, Higashi-ku, Fukuoka 812

(Received May 4, 1982)

Synopsis. Binuclear copper(II) complexes with two bis(2-benzimidazolylmethyl)amine moieties linked by a flexible polyatomic chain were prepared. Their ESR spectral properties were highly dependent on the bridging chains linking two coordination units.

In the preceding paper,[1] we reported that the reactivities of binuclear copper(I) complexes with (L-px), (L-mx), and (L-cy) (for the abbreviations of the ligands, see Fig. 1) towards molecular oxygen are highly dependent on the bridging chains (R in Fig. 1) linking two coordination units. The above facts are suggesting that the steric arrangements of the two copper ions in these binuclear complexes are controlled by the bridging chain, making the reactivity of the copper(I) complexes towards O_2 molecule different from each other. In order to obtain additional support for the above view, in this study, we have investigated the ESR spectra of the copper(II) complexes with the binucleating ligands shown in Fig. 1.

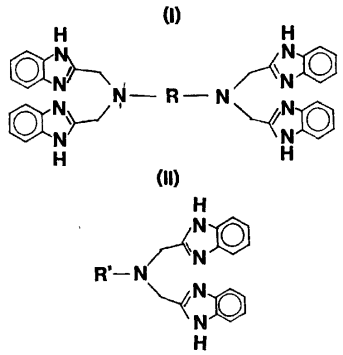

Fig. 1. Chemical structures of the ligands cited in this study and their abbreviations.
(I) Binucleating ligands, R=$-CH_2CH_2-$, (L-2); R=$-(CH_2)_3-$, (L-3); R=$-(CH_2)_4-$, (L-4); R=$-(CH_2)_6-$, (L-6); R=$-CH_2-C_6H_4-CH_2-$, (L-px); R=$C_6H_4(CH_2-)_2$ (L-mx); R=$C_6H_{10}(CH_2-)_2$, (L-cy) (II) mononucleating ligand, R'=H, (ibz); R'=$-CH_2-C_6H_5$, (babz).

Experimental

The ligands cited in Fig. 1 were prepared according to the method described in the literature.[1] The analytical data of the new compounds are summarized in the Table 1. The copper(II) complexes were obtained as blue or bluish-green crystals by mixing the methanol solution of the ligand and the stoichiometric amount of $Cu(NO_3)_2 \cdot 3H_2O$, and recrystallized from a *N,N*-dimethylformamide–methanol solution. The analytical data of the copper(II) complexes are listed in the Table 1.

ESR spectra of the complexes ($[Cu^{2+}]=1\times10^{-3}$ mol dm^{-3}) were obtained with a JEOL ESR apparatus model JES FE3X by the use of an X-band at 77 and 291 K.

Results and Discussion

ESR spectra of Cu_2(L-2)$(NO_3)_4$[2] and Cu_2(L-3)$(NO_3)_4$ in *N,N*-dimethylforamide, obtained at 291 K are shown in Fig. 2. The spectrum of mononuclear complex, Cu(babz)$(NO_3)_2$ is similar to that of Cu_2(L-2)$(NO_3)_4$, showing four hyperfine splittings due to the nuclear spin($I=3/2$) of copper atom. In the spectrum of other binuclear copper(II) complexes, only a broad peak was observed, as exemplified by Cu_2(L-3)$(NO_3)_4$ in Fig. 2.

ESR spectra of the binuclear copper(II) complexes obtained at 77 K are shown in Fig. 3. Mononuclear complex, Cu(babz)$(NO_3)_2$ exhibits the spectrum characteristic of the tetragonal copper(II) complexes[3] ($g_{//}=2.27$, $g_\perp=2.05$, $|A_{//}|=145$ G, 1 G$=1\times10^{-4}$ T). In the spectrum of Cu_2(L-4)$(NO_3)_4$, six hyperfine peaks (the seventh peak may be overlapped with the $g_\perp$

Table 1. Analytical data of the new compounds

Compound	C (%) Found(Calcd)	H (%) Found(Calcd)	N (%) Found(Calcd)	Cu(%) Found(Calcd)
(L-3)	70.17(70.69)	5.75(5.76)	23.36(23.55)	
(L-4)·H_2O	69.24(68.99)	6.08(6.11)	22.23(22.35)	
(L-6)·H_2O	70.20(69.70)	6.42(6.47)	21.56(21.39)	
(L-mx)·H_2O	70.89(71.19)	5.75(5.68)	20.43(20.76)	
(L-px)·1/2 H_2O	72.43(72.16)	5.63(5.60)	20.99(21.04)	
Cu_2(L-3)$(NO_3)_4\cdot3H_2O$	40.97(41.06)	3.87(3.94)	18.98(19.15)	12.4(11.9)
Cu_2(L-4)$(NO_3)_4\cdot2H_2O$	42.12(42.40)	3.84(3.95)	18.97(19.23)	12.7(12.5)
Cu_2(L-6)$(NO_3)_4\cdot H_2O$	44.35(44.32)	4.02(4.11)	18.94(19.04)	12.5(12.3)
Cu_2(L-mx)$(NO_3)_4\cdot H_2O$	45.72(45.70)	3.58(3.64)	18.36(18.65)	12.4(12.1)
Cu_2(L-px)$(NO_3)_4\cdot H_2O\cdot CH_3OH$	45.51(45.70)	3.94(3.64)	18.65(18.12)	11.7(11.7)
Cu_2(L-cy)$(NO_3)_4\cdot4H_2O$	43.37(43.28)	4.37(4.54)	17.67(17.67)	11.5(11.4)

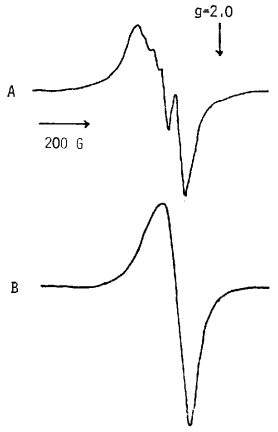

Fig. 2. ESR spectra of A: $Cu_2(L\text{-}2)(NO_3)_4$ and B: $Cu_2(L\text{-}3)(NO_3)_4$ (dmf, 291 K).

peak) are observed; hyperfine splitting ($|A|=71$ G) is as half as that of $Cu(babz)(NO_3)_2$. The spectra of $Cu_2(L\text{-}px)(NO_3)_4$ and $Cu_2(L\text{-}cy)(NO_3)_4$ were similar to that of $Cu_2(L\text{-}4)(NO_3)_4$.

The spectrum of $Cu_2(L\text{-}6)(NO_3)_4$ (and also $Cu_2(L\text{-}mx)(NO_3)_4$) is different from that of $Cu_2(L\text{-}4)(NO_3)_4$, and similar to those of $Cu_2(L\text{-}2)(NO_3)_4$ and $Cu(babz)(NO_3)_2$. The spectrum of $Cu_2(L\text{-}3)(NO_3)_4$ is rather complicated, different from either of $Cu_2(L\text{-}4)(NO_3)_4$ and also $Cu_2(L\text{-}6)(NO_3)_4$. In the case of $Cu_2(L\text{-}2)(NO_3)_4$, the ESR spectra at 291 and 77 K closely resemble those of mononuclear complex, $Cu(babz)(NO_3)_2$. Thus, it has became apparant that the ESR spectral properties of the binuclear copper(II) complexes obtained in this study are dependent on

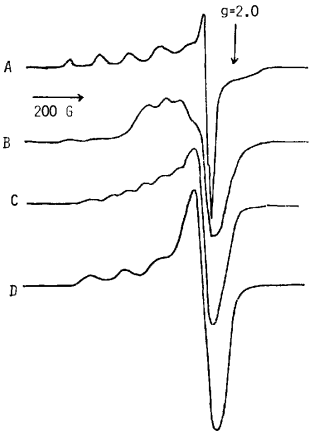

Fig. 3. ESR spectra of binuclear copper(II) complexes (dmf, 77 K).
A: $Cu_2(L\text{-}2)(NO_3)_4$, B: $Cu_2(L\text{-}3)(NO_3)_4$, C: $Cu_2(L\text{-}4)(NO_3)_4$, D: $Cu_2(L\text{-}6)(NO_3)_4$.

the bridging chains linking two coordination units. These facts may be due to the difference in the weak interaction between two copper(II) ions, controlled by the flexible polyatomic chain used.

Alizarin Red-S, an Amperometric Reagent for Ultramicro and Microgram Estimation of Sm^{3+} and Gd^{3+}

S. C. LAVALE* and K. S. PITRE

Department of Chemistry, University of Saugar, Sagar (M. P.) 470003, India

(Received January 5, 1982)

Synopsis. Alizarin Red-S has been employed successfully as an amperometric reagent for the precise determination of Sm^{3+} and Gd^{3+} in aqueous and partially non aqueous media. Amperometric titrations have been performed at −0.7 V *vs.* Hg-pool, pH=4.5 and μ=0.1. The current-volume titration curves obtained were well defined, indicating 1:2 stoichiometric ratio of metal:ARS complexation in each case. The absorptiometric studies made on the equilibrium of above complexation also confirm the said ratio. Many ions do not interfere the titration procedure.

Alizarin Red-S (Abbr. as ARS) has been employed in analytical chemistry since Atack[1] discovered that Al^{3+} could be detected with this reagent. The use of ARS as an complexometric, spectrophotometric and pH-metric reagent is described in the literature.[2-5] Larson and Hirozawa[6] have studied the complexation of Zr^{2+} and Hf^{2+} with ARS in aqueous and alcoholic media using amperometric titrations. In continuation of our work[7-10] on trace estimation of rare earths, the present paper deals with the results of amperometric estimation of Sm^{3+} and Gd^{3+} with ARS using a d.m.e. -Hg pool electrode system. The amperometric estimations have been supplemented by absorption studies to establish the metal-ligand equilibria.

Experimental

The chemicals used were of AnalaR or Extra pure quality. Sm^{3+} and Gd^{3+} solutions were prepared and standardized.[10] The solution of ARS was prepared by dissolving requisite quantity of this reagent in conductivity water and standardized by the analytical procedure developed by Larson and Hirozawa.[6]

Amperometric titrations were done on mannually operated polarograph with multiflex galvanometer (sens. 8.10×10^{-9} A/div.) using d.m.e. as indicator and Hg-pool as reference electrode. An Elico digital pH meter (model LI.120) was used for measuring pH of the test solutions. A Beckman DU-2 spectrophotometer was used to study the equilibrium of metal-ligand complexation.

For titrations a number of solutions, containing calculated amounts of Sm^{3+} or Gd^{3+} in 0.1 mol/dm^3 KCl as supporting electrolyte were prepared and pH of these test solutions was fixed at 4.5 using acetate buffer.

Results and Discussion

The current voltage behaviour of ARS has been studied in 0.1 M (1 M=1 mol dm^{-3}) KCl and acetate buffer at pH 4.5. ARS gives a well defined cathodic wave[11] (Fig. 1-A). The height of diffusion current is proportional to the concentration of ARS. The test solution of Sm^{3+} or Gd^{3+} was taken in a titration cell. The plateau potential of the polarogram for ARS *i.e.* −0.7 V *vs.* Hg pool (at which Sm^{3+} or Gd^{3+} do not give any diffusion current Fig. 1-M) was applied.

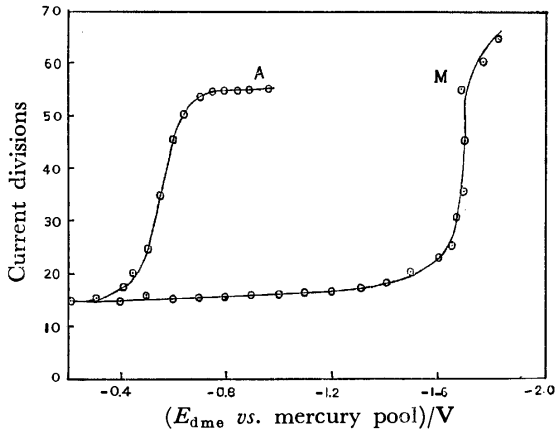

Fig. 1. A: Polarogram of 1 mM Alizarin Red-S in 0.1 M KCl at pH=4.5. M: Polarogram of 2 mM metal(Sm^{3+} or Gd^{3+}) in 0.1 M KCl at pH=4.5.

The standard solution of ARS (pH=4.5) was added drop by drop from 1 cm^3 semi-micro burette, a pinkish red coloration was observed. The current was noted with multiflex galvanometer. On plotting galvanometer reading after necessary volume correction[12] against titrant volume a reversed L shaped curve was obtained. The end point indicated a metal: ARS ratio of 1:2, which is in good agreement with the results reported in the literature[13,14] and that observed by the authors with absorbtiometric studies discussed in this paper. Moreover, it is also observed that each of these titrations can be performed in 25% ethanol medium which may be fruitful for the estimation of Sm^{3+} and Gd^{3+} in a compound or ore soluble in partially ethanol medium.

Study of the Effect of Diverse Ions. For interference studies, known amout of foreign ions were added to a definite amount of metal ion (Sm^{3+} or Gd^{3+}) and the metal was titrated following the procedure described above. The maximum amount of diverse ions reported in Table 1. do not hamper the titrations. It is also observed that 100 folds of concentrations of the ions NH_4^+, Cl^-, ClO_4^-, SO_4^{2-}, NO_3^-, and CH_3COO^- do not interfere in this titrimetric procedure. However, small amounts of Ag^+, Pb^{2+}, Bi^{3+}, Ca^{2+}, Al^{3+}, Fe^{3+}, VO_3^{2-}, $Cr_2O_7^{2-}$, MoO_4^{2-}, and CO_3^{2-} ions interfere the titration procedure appreciably.

Absorbtion Studies on Complexation. Vosburgh and Cooper's[15] method was used to study the nature of complex formed. The visible absorbtion spectra of 1×10^{-4} M ARS at pH 4.5 consists a single maximum at 420 nm and ARS complexes with Sm^{3+} or Gd^{3+} at 530 nm. The shift in λ_{max} is attributed to the formation of complex. Under varying ratio of mixing and varying pHs only one absorption maximum was obtained, supports to the formation of complex. To determine the stoichiometry of the complexes job's

Table 1. An amperometric determination of Sm^{3+} and Gd^{3+} with ARS in presence of diverse ions

Metal taken: Sm^{3+}=1.504 mg (0.01 mM), Gd^{3+}=1.592 mg (0.01 mM).

Diverse ion added	Sm^{+3} found (mg)	% error	Gd^{3+} found (mg)	% error
K^+ (195 mg)	1.49	−0.97	1.599	+0.43
Na (115 mg)	1.499	−0.32	1.587	−0.31
Mg^{2+} (48.6 mg)	1.51	+0.39	1.584	−0.50
Zn^{2+} (24.3 mg)	1.518	+0.93	1.60	+0.50
Tl^{+1} (15.3 mg)	1.501	−0.19	1.601	+0.56
Sn^{2+} (11.86 mg)	1.51	+0.39	1.588	−0.25
Cd^{2+} (11.24 mg)	1.495	−0.59	1.583	−0.56

Se^{4+} (3.94 mg)	1.507	+0.19	1.59	−0.12
Te^{4+} (3.19 mg)	1.498	+0.39	1.583	−0.56

a) The figure within parenthesis shows the amount of foregn ion added under the prescribed experimental conditions.

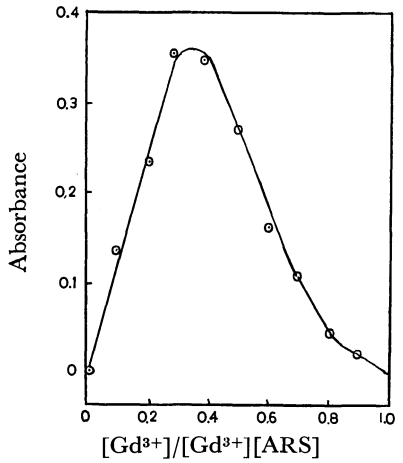

Fig. 2. Job's plot for composition at 530 nm.

method of continuous variations[16] (Fig. 2) has been successfully applied. The measurements were carried out at pH 4.5 and wavelength 530 nm. The fresh solution of ARS was prepared before use and the experimental sets were made. The color development of complex is instanteneous. Absorbtion studies were made within 1 h, as it is found that a gelatineous precipitation takes place on standing for nearly three hours. Stoichiometric ratio of Sm^{3+} and Gd^{3+} complexes with ARS were found to be 1:2 in both the cases, which confirms the ratio observed by authors in amperometric titration technique. The equilibrium constants were evaluated by mole ratio method and nonlinear method of job. The log conditional formation constants are found to be 10.94 and 11.51 for Sm^{3+}–ARS and Gd^{3+}–ARS complexes in solution. The molar ratio and numerical values of stability constants obtained using absorption studies supplemented the authors view on amperometric estimations of Sm^{3+} and Gd^{3+} with ARS.

Accuracy and Precision. The ultramicro and microgram quantities of Sm^{3+} and Gd^{3+} have been estimated amperometrically with an error of less than ±0.8%. For each set replicate titrations were done and statistical methods have been applied to interpret the data obtained. A more accurate measure of precision known as coefficient of variation never exceeded 0.55.

One of the authors (SCL) is grateful to the UGC, New Delhi, for awarding him Teacher Fellowship.

Intermolecular Pummerer Rearrangement Reactions of Alkyl Phenyl and Dialkyl Sulfoxides with Acetic Anhydride

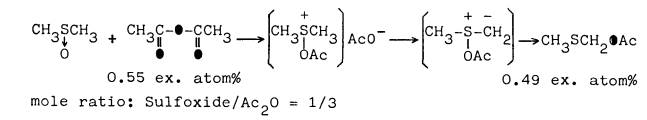
Osamu Itoh, Tatsuo Numata, Toshiaki Yoshimura, and Shigeru Oae*

Department of Chemistry, The University of Tsukuba, Niihari-gun Sakura-mura, Ibaraki 305

(Received June 7, 1982)

Synopsis. The Pummerer reactions of alkyl phenyl sulfoxides, PhS(O)R (R: methyl and isobutyl), and benzyl methyl sulfoxide with acetic anhydride were found to proceed through the intermolecular acetoxyl migration, based on the ^{18}O-tracer experiments with ^{18}O-labeled sulfoxides and unlabeled acetic anhydride.

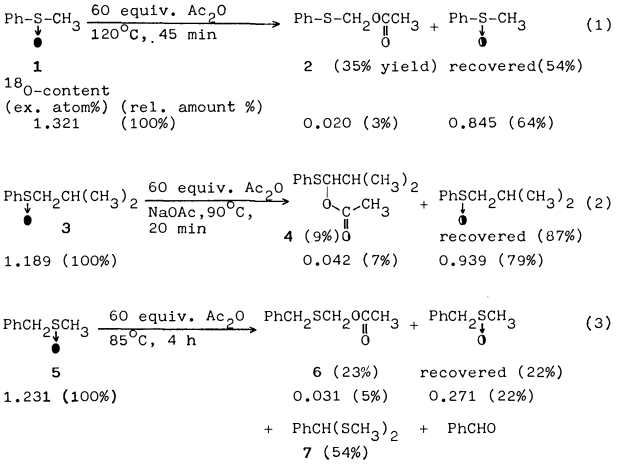
In our earliest ^{18}O-tracer experiment on the Pummerer reaction of dimethyl sulfoxide with 3 equiv. molar amount of uniformly ^{18}O-labeled acetic anhydride in ether solution, the amount of ^{18}O-label in the resulting ester was 9/10 of that of the acetic anhydride used.[1] Namely, all the oxygen atoms of the starting materials were found to be completely scrambled in the resulting ester as shown below. Thus,



the intermolecular migration of acetate from the acetoxysulfonium ion to the α-carbon was postulated for this Pummerer reaction. Years later, we found that sulfoxides undergo oxygen exchange with acetic anhydride[2] and various other acids.[3,4] However, the rate of oxygen exchange of methyl *p*-tolyl sulfoxide with acetic anhydride at 120 °C was found by us to be only 1/6 of that of the Pummerer reaction, revealing clearly that the earlier postulate of the predominant intermolecular nucleophilic attack of acetoxyl group at the α-carbon terminal is still valid.[5,6] However, our recent findings of several intramolecular Pummerer reactions with the aid of ^{18}O-tracer experiments[7–9] and others[7d,8d] have led us to reinvestigate the Pummerer reactions of a few other alkyl aryl sulfoxides and dialkyl sulfoxides, using this time ^{18}O-labeled sulfoxides so that the ^{18}O-distribution in the resulting ester can be determined in order to estimate the extent of the intermolecular acetoxyl migration and also the extent of ^{18}O-exchange in the recovered sulfoxides. As the results of this new investigation, our earlier observation and conclusion have been found to be quite acceptable.

Results and Discussion

The Pummerer reactions of two alkyl aryl sulfoxides with a large excess of unlabeled acetic anhydride have been carried out using ^{18}O-labeled methyl phenyl sulfoxide (**1**) and isobutyl phenyl sulfoxide (**3**) to examine the fate of ^{18}O-label in the resulting ester, **2** and **4**, along with the sulfoxide recovered at partial completion of the reaction. ^{18}O-Labeled benzyl methyl sulfoxide **5** was treated similarly. These ^{18}O-tracer experimental results are illustrated in the following equations.



When the Pummerer reaction product (**2**-^{18}O) [0.760 ex. atom% of ^{18}O] was allowed to react with 60 equiv. amount of acetic anhydride in the presence of ether 0.4 or 2 equiv. amount of acetic acid at 120 °C for 45 min, the ^{18}O-content of the α-acetoxy sulfide, the Pummerer reaction product (**2**-^{18}O) recovered were found to retain 0.755 or 0.708 ex. atom% of ^{18}O, respectively. This implies explicitly that acetoxymethyl phenyl sulfide (**2**) once formed does not seem to exchange acetoxyl group readily with acetic acid present under the Pummerer reaction conditions. The sulfoxides recovered, **1** and **3** after 40 and 10% conversions respectively were found to have retained the ^{18}O-label of the original sulfoxides in 64 and 79%, respectively. Thus the large loss of ^{18}O-label in the Pummerer reaction products is not due to the concurrent oxygen exchange of the ^{18}O-labeled sulfoxides with acetic anhydride.[5] All these observations suggest clearly that the Pummerer reaction of these sulfoxides proceeds through the intermolecular acetoxyl migration, after the rate-determining α-proton-removal.[3] Earlier, acetoxyl group was reported to migrate preferentially to the benzylic carbon in the reaction of sulfoxide **5** with acetic anhydride.[10] However, we found that the migration of acetoxyl group occurs to both benzylic and methyl carbon in the ratio of 2:1. α,α-Bis(methylthio)toluene (**7**) is the secondary product formed by the migration of acetoxyl group to the benzylic carbon. The Pummerer reactions of dibenzyl and benzyl phenyl sulfoxides are not facile and require relatively higher temperatures than would be expected from the acidity of benzylic protons.[11–14] The relatively low basicity of the sulfinyl oxygen in **5** and steric shielding by phenyl group may be partly responsible for the somewhat low reactivity of the Pummerer reaction, however, the oxygen exchange reaction of this sulfoxide **5** with acetic anhydride is as facile as that of benzyl phenyl sulfoxide with acetic anhydride.[13]

The large kinetic isotope effect k_H/k_D=5—9 in the

Pummerer reaction of dibenzyl sulfoxide with acetic anhydride,[11,12] seems to indicate that the rate-determining step of this intermolecular rearrangement of benzyl methyl sulfoxide is the α-proton removal.

Experimental

^{18}O-Analysis. ^{18}O-Analysis was carried out by the method developed by Rittenberg and Ponticorvo.[15]

^{18}O-Labeled Sulfoxides. ^{18}O-Labeled methyl phenyl sulfoxide (**1**), isobutyl phenyl sulfoxide (**3**), and benzyl methyl sulfoxide (**5**) were synthesized according to our usual method by oxidation of the corresponding sulfides with bromine in the presence of ^{18}O-enriched water.[16] Thus methyl phenyl sulfoxide, isobutyl phenyl sulfoxide, and benzyl methyl sulfoxide containing 1.321, 1.189, and 1.231 ex. atom% of ^{18}O, respectively, were obtained in 65, 61, and 57% yields.

Reaction of ^{18}O-Labeled Methyl Phenyl Sulfoxide (1), Isobutyl Phenyl Sulfoxide (3), and Benzyl Methyl Sulfoxide (5) with Acetic Anhydride. When the ^{18}O-labeled title sulfoxides **1**, **3**, and **5** (a few hundred mg) were heated separately with a large excess (*ca.* 60 fold) of acetic anhydride at a set temperature for some length of time, the oily residue, obtained after evaporation of excess acetic anhydride and any volatile product in vacuo, was separated through column chromatography with benzene and then $CHCl_3$ as eluents or Kugelrohr distillation. The Pummerer product **2** (120 °C/20 mmHg** (Kugelrohr)), **4** (130 °C/20 mmHg (Kugelrohr)), and **6** (126 °C/20 mmHg (Kugelrohr)) and the recovered sulfoxides were obtained along with some minor by-products as shown in Eqs. 1, 2, and 3.

Preparation of ^{18}O-Labeled Acetoxymethyl Phenyl Sulfide (2-^{18}O). When methyl phenyl sulfoxide (**1**) (500 mg) was allowed to react with 2 equiv. molar amount of ^{18}O-labeled acetic anhydride at 120 °C for 3 h. The ^{18}O-labeled Pummerer product **2** (0.760 ex. atm% of ^{18}O) was obtained in 90% yield (585 mg), upon distillation with Kugelrohr (120 °C/20 mmHg).

Acetate Exchange Reaction of ^{18}O-Labeled Acetoxymethyl Phenyl Sulfide (2-^{18}O) with Acetic Anhydride in the Presence of Acetic Acid. After the ^{18}O-labeled title compound **2**-^{18}O [0.760 ex. atom% of ^{18}O] was heated with 60 equiv. acetic anhydride in the presence of ether 0.4 or 2 equiv. amount of acetic acid to the ester (**2**-^{18}O) at 120 °C for 45 min. Upon removal of the solvent *in vacuo*, chromatography and final distillation, the pure acetoxymethyl phenyl sulfide recovered was found to remain either 0.755 or 0 708 ex. atom% of ^{18}O, respectively.

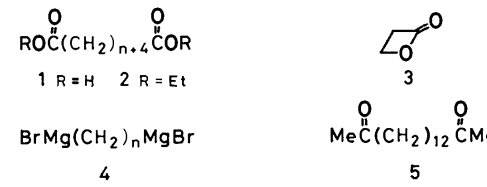
(Received June 28, 1982)

Synopsis. Copper-catalyzed reaction of β-propiolactone with α,ω-di-Grignard reagents, followed by esterification gave six-carbon homologated α,ω-dicarboxylic acid esters in good yields.

Long-chain aliphatic α,ω-dicarboxylic acids or esters are useful synthetic intermediates for many-membered carbon rings. Especially, α,ω-dicarboxylic acids of C_{14}—C_{18} have been used for the syntheses of alicyclic ketones which possess a musk or civet odor.[1] Although a number of synthetic methods for these acids have been reported,[2-4] the most direct ones are the Kolbe electrolytic synthesis from half esters of α,ω-dicarboxylic acids[3] or α-alkylation of carboxylic acids or esters with α,ω-dibromoalkanes.[4] However, such methods are generally not satisfactory with respect to yield or to availability of starting materials.

Recently the regioselective ring-opening reaction of β-propiolactones with Grignard reagents in the presence of a copper(I) catalyst has been found to give three-carbon homologated carboxylic acids in high yields.[5] We wish to describe here a novel one-step synthesis of six-carbon homologated α,ω-dicarboxylic acids (**1**) by the reaction of two equivalents of β-propiolactone (**3**) with α,ω-di-Grignard reagents (**4**) in the presence of a copper catalyst.[6]



Scheme 1.

Grignard reagent **4**, easily prepared from α,ω-dibromoalkane,[7] was added to a solution of two equivalents of **3** and a copper catalvst (2—3 mol%) at −10 °C. After the reaction mixture was allowed to warm to 0 °C and stirred for 3 h, **1** was obtained. As a catalyst, lithium tetrachlorocuprate was slightly superior to copper(I) iodide. Esterification of **1** with ethanol gave diester **2**, which was isolated by distillation. The yields of **2** of C_{14}—C_{18} are listed in Table 1.

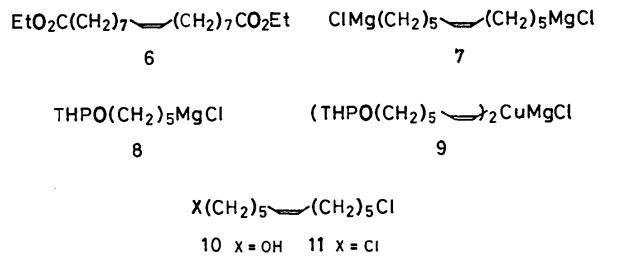
Tetradecanedioic acid (**2**, n=8), prepared by the reaction of **3** with 1,8-octanediyldimagnesium dibromide, was easily converted into hexadecane-2,15-dione (**5**), which is a useful precursor for 3-methylcyclopentadecanone (muscone).[8] The acid was treated with thionyl chloride and then bromomagnesium dimethylcuprate to give **5** in an overall yield of 57% from the Grignard reagent.

Diethyl (*Z*)-9-octadecene-1,18-dioate (**6**), an important precursor for (*Z*)-9-cycloheptadecenone (civetone)[9] was easily obtained in 53% yield by the reaction

Table 1. Yields of α,ω-dicarboxylic acid diesters **2**

Grignard reagent	**2**	Yield/%
$BrMg(CH_2)_8MgBr$	$EtO_2C(CH_2)_{12}CO_2Et$	68
$BrMg(CH_2)_9MgBr$	$EtO_2C(CH_2)_{13}CO_2Et$	63
$BrMg(CH_2)_{10}MgBr$	$EtO_2C(CH_2)_{14}CO_2Et$	60
$BrMg(CH_2)_{11}MgBr$	$EtO_2C(CH_2)_{15}CO_2Et$	68
$BrMg(CH_2)_{12}MgBr$	$EtO_2C(CH_2)_{16}CO_2Et$	62

of **3** with di-Grignard reagents **7**. According to the modified procedure of Normant *et al.*,[10] alkylation of dialkenylcuprate **9**, prepared from Grignard reagent **8**,[11] copper(I) iodide and acetylene, with 1-chloro-5-iodopentane and deprotection gave chloro alcohol **10** which was converted to **7** *via* α,ω-dichloride **11**.



Scheme 1.

Experimental

The IR spectra were recorded on a Hitachi EPI-G2 spectrometer. The NMR spectra were taken with a Varian A-60 spectrometer in CCl_4 using TMS as an internal standard. Di-Grignard reagent was prepared from α,ω-dibromoalkane in THF.[7]

General Procedure for the Reaction of β-Propiolactone (3) with α,ω-Di-Grignard Reagents 4. To a solution of Li_2CuCl_4 (3 mmol) and **3** (5.62 g, 78 mmol) in THF (250 ml) was slowly added **4** (30 mmol) at −10 °C and stirred at 0 °C for 3 h. After addition of 3 M† HCl (100 ml), the mixture was extracted with ether and concentrated. The residue was solved in methanol (20 ml) and 3 M KOH (100 ml) was added. After removal of methanol, the solution was washed with ether and acidified with 6 M HCl (100 ml). Extraction with ether and concentration gave crude **1**. Esterification of **1** with ethanol by an azeotropic method and distillation gave pure **2**. Yields and physical data of **2** are as follows: Diethyl tetradecanedioate (yield 68%); bp 144—151 °C/0.4 Torr (lit,[12] 135—136 °C/0.15 Torr); mp 28.0—29.0 °C (lit,[12] 27 °C). Diethyl pentadecanedioate (yield 63%); bp 160—161 °C/0.35 Torr (lit,[3b] 152 °C/0.23 Torr); mp 29.5—30.0 °C (lit,[1a] 30 °C). Diethyl hexadecanedioate (yield 60%); bp 146—148 °C/0.1 Torr (lit,[3a] 165 °C/1 Torr); mp 38.0—39.0 °C (lit,[3c] 39.0 °C). Diethyl heptadecanedioate (yield 68%); bp 153—155 °C/0.15 Torr (lit,[3b] 162 °C/0.02 Torr); mp 40.0—40.5 °C (lit,[1a] 40—41 °C). Diethyl octadecanedioate (yield 62%); bp 165—170 °C/0.45

† 1 M=1 mol dm^{-3}.

Torr (lit,[3a] 180—190 °C/0.35 Torr; mp 46.0—47.0 °C (lit,[3c] 47.8—48.4 °C).

Hexadecane-2,15-dione (5). The crude tetradecanedioic acid (11.43 g), obtained by the reaction of **3** (2.39 g, 33 mmol) with 1,8-octanediyldimagnesium dibromide (10.7 mmol), was added into thionyl chloride (9.84 g, 82 mmol) and stirred at room temp overnight and at 40 °C for 2 h. Excess thionyl chloride was evaporated and the residue was dissolved in 10 ml of THF. To a suspension of bromomagnesium dimethylcuprate, prepared from copper(I) iodide (8.55 g, 45 mmol) and methylmagnesium bromide (90 mmol) in THF (150 ml) and Me_2S (15 ml) at −30 °C for 1.5 h, was added the solution of the acid chloride at −78 °C. After stirring at −78 °C for 30 min, cold sat. NH_4Cl solution was added. Extraction with ether and distillation gave **5** (1.55 g, 57%); bp 152—154 °C/0.25 Torr; mp 82—83 °C (lit,[13] 83.5—84.5 °C).

(Z)-12-Chloro-6-dodecen-1-ol (10). To a solution of copper(I) iodide (1.90 g, 10 mmol) in THF (30 ml) and Me_2S (3 ml) was added Grignard reagent **8**[11] (20 mmol) at −30 °C and stirred for 1 h. After allowing the mixture to warm to −25 °C, acetylene (560 ml) was introduced over a period of 30 min, and stirring was continued at −25—−20 °C for 30 min. Hexamethylphosphoric triamide (4 ml), 1-chloro-5-iodopentane (4.66 g, 20 mmol), and trimethyl phosphite (3.5 ml) were added successively and stirred at room temp overnight. After cooling to 0 °C, 3 M HCl (20 ml) was added. The mixture was extracted with hexane and concentrated. After the residue was heated in methanol (100 ml) in the presence of *p*-toluenesulfonic acid monohydrate (0.2 g) at 50 °C for 3 h, sat. $NaHCO_3$ solution (50 ml) was added. Extraction with hexane and distillation gave **10** (2.7 g, 63%); bp 116—120 °C/0.35 Torr; NMR δ 1.1—2.3 (16H), 3.13 (1H, s), 3.48 (2H, t, J=7 Hz), 3.52 (2H, t, J=7 Hz), 5.29 (2H, t, J=5 Hz); IR (neat) 3400 (OH) and 720 cm^{-1} (*cis*-CH=CH). Found: C, 65.90; H, 10.45; Cl, 16.06%. Calcd for $C_{12}H_{23}ClO$: C, 65.88; H, 10.60; Cl, 16.21%.

(Z)-1,12-Dichloro-6-dodecene (11). Chloro alcohol **10** (2.99 g, 13.7 mmol) and triphenylphosphine (9.40 g, 40 mmol) were refluxed in CCl_4 (28 ml) for 1 h. After addition of dry hexane (14 ml), the white precipitate was filtered off. Concentration and distillation gave **11** (2.13 g, 66%); bp 106—108 °C/0.3 Torr; NMR δ 1.5—2.2 (16H), 3.51 (4H, t, J=6 Hz), 5.30 (2H, t, J=4 Hz); IR (neat) 720 cm^{-1} (*cis*-CH=CH). Found: C, 60.56; H, 9.54; Cl, 29.61%. Calcd for $C_{12}H_{22}Cl_2$: C, 60.76; H, 9.35; Cl, 29.89%.

Diethyl (Z)-9-Octadecene-1,18-dioate (6). Grignard reagent **7** was prepared in 79% yield from **11** (2.11 g, 8.91 mmol) and magnesium in THF (23 ml) under reflux for 2 h. Diester **6** was prepared from **3** and **7**. Purification by TLC on silica gel (R_f 0.4, hexane:ether=5:1) gave **6** (1.19 g, 50%); bp 156—160 °C/0.3 Torr; NMR δ 1.23 (6H, t, J=7 Hz), 1.30—2.1 (24H), 2.20 (4H, t, J=7 Hz), 4.05 (4H, q, J=7 Hz), 5.33 (2H, t, J=4 Hz); IR (neat) 1725 (C=O) and 720 cm^{-1} (*cis*-CH=CH). Found: C, 71.80; H, 10.76%. Calcd for $C_{22}H_{40}O_4$: C, 71.69; H, 10.94%.

Sweetness of Hesperetin Dihydrochalcone Derivatives Linked to ω-Amino Acid or Its Oligomer

Masao KAWAI,* Kyoko KUWABARA, Ritsuko KIMURA, and Sachiko SEKIDO
Mitsubishi-Kasei Institute of Life Sciences, Minamiooya 11, Machida, Tokyo 194
(Received May 15, 1982)

Synopsis. Derivatives of hesperetin dihydrochalcone having ω-amino acid, oligoglycine, or oligo-(γ-aminobutyric acid) were synthesized and tasted. The hydrophobicity of the introduced group is important for understanding the structure-sweet taste relationship of these compounds, though other factors than hydrophobicity also must be taken into account.

Neohesperedin dihydrochalcone (**1**) is an intensely sweet substance derived from a rind-constituent of citrus fruits.[1] The aglycone of **1**, namely hesperetin dihydrochalcone (**2**) (DHC–OH), and its ω-carboxyalkyl derivatives DHC–O$(CH_2)_mCO_2H$ (**3**) (m=1, 3) and ω-sulfoalkyl derivatives DHC–O$(CH_2)_mSO_3H$ (**4**) (m=1—4) are also known to elicit sweet sensation.[2] We have attempted to prepare derivatives of **2** having an amino acid or peptide in group R in Fig. 1 for the purpose of investigating the structure-sweet taste relationship of these compounds.

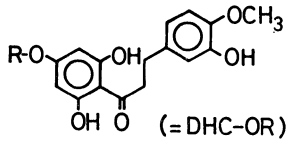

Fig. 1. Structure of hesperetin dihydrochalcone derivatives (DHC–OR).
1: R=$C_{12}H_{21}O_9$ (β-neohespesperidosyl), **2**: R=H, **3**—**8**: see text and Tables 1 and 2.

Results and Discussion

Oligomers of glycine were introduced to **3** (m=3)[3] affording DHC–O$(CH_2)_3CO(NHCH_2CO)_nOH$ (**5**). Results of semiquantitative taste evaluation are given in Table 1. The compound having one glycyl residue, **5** (n=1), is sweeter than the parent compound **3** (m=3), but further addition of glycyl residue results in decrease in sweetness. Another series of derivatives prepared includes those having ω-amino acid residue in the side chain, namely DHC–O$(CH_2)_3CONH(CH_2)_nCO_2H$ (**6**), the sweetness of which is summarized in Table 2. Successive addition of a methylene group causes marked decrease in sweet potency, finally giving tasteless derivative **6** (n=5).

Since the sweetness of aglycone **2** is of the same order of magnitude as that of the parent glycoside **1**,[2a] group R in Fig. 1 is considered not to be directly involved in the interaction of these sweetener molecules with the taste receptors. DuBois *et al.*[4] recently reported zwitterionic amino acid derivatives of **2**, relating their relative sweetness to a chromatographic parameter which quantitates the hydrophobic-hydrophilic balance of molecule. We assumed that the change in hydrophobicity caused by the introduction of group R would mainly affect the sweet potency. Thus the structure-sweet taste relationship found here for the **5** and **6** series can be explained in terms of increase and decrease in hydrophobicity of molecule,

Table 1. Relative sweetness, melting points, and analytical data of DHC–O$(CH_2)_3CO(NHCH_2CO)_nOH$ (**5**)

n	Relative sweetness[5]	Mp θ_m/°C (crystallized from)	Found(%)			Calcd(%)		
			C	H	N	C	H	N

a) Compound **3** (m=3). b) Ref. 3, 193—195 decomp. c) $\frac{1}{2}H_2O$. d) $\frac{1}{4}H_2O$. e) $\frac{3}{2}H_2O$.

Table 2. Relative sweetness, melting points, and analytical data of DHC–O$(CH_2)_3CONH(CH_2)_nCO_2H$ (**6**)

n	Relative sweetness[5]	Mp θ_m/°C (crystallized from)	Found(%)			Calcd(%)		
			C	H	N	C	H	N
1[a]	500	see Table 1						
2	200	66—68 (lyophilized)	60.13	5.66	3.07	59.86	5.90	3.04
3	200	178—183 (MeOH)	60.20	6.14	3.03	60.62	6.15	2.95
4	100	166—167 (MeOH)	60.03	6.33	2.74	59.87	6.76	2.69[b]
5	0	204—208 decomp (MeOH–AcOEt)	61.63	6.51	2.60	62.01	6.61	2.78

a) Compound **5** (n=1). b) $C_{25}H_{31}O_9N\cdot CH_3OH$.

respectively, suggesting that group R be required to possess optimal hydrophobicity for showing sweet taste. Indeed, maximal sweetness is developed for the compounds of the **4** series when the number of methylenes is 2.[2b] In the case of DHC–$OCH_2CONH(CH_2)_n$-CO_2H (**7**), relative sweetness[5] is as follows: 200 (n=1), 200—300 (n=2), 200 (n=3), and 100—200 (n=5), *i.e.*, the compound (n=2) is the sweetest in this series, though its sweetness is less than that of **5** (n=1). In view of substituent constants of hydrophobic parameters[6] it is expected that the hydrophobicity of a molecule will not be much affected by the introduction of a γ-aminobutyric acid residue $NH(CH_2)_3CO$. The sweetness of DHC–$O(CH_2)_3CO[NH(CH_2)_3CO]_nOH$ (**8**) (100, n=2; 0, n=4)[5] is, however, less than those of the corresponding oligoglycine derivatives **5**, indicating that not only the hydrophobicity but also other factors must be considered for better understanding of the structure-sweet taste relationship of these compounds.

Experimental

Melting points were uncorrected. Compounds **3** (m=1 and 3) were prepared from hesperetin as described in Ref. 3.

N-Hydroxysuccinimide Ester of **3** *(m=3).* To an ice-cooled solution of 4 mmol of **3** (m=3) and 6 mmol of *N*-hydroxysuccinimide in tetrahydrofuran (10 cm^3) was added 4.4 mmol of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride and the mixture was stirred at room temperature. After 42 h the solution was evaporated and the residue dissolved in AcOEt was washed successively with aqueous solutions of 10% citric acid, 4% $NaHCO_3$, and saturated NaCl. The *N*-hydroxysuccinimide ester was crystallized from AcOEt–hexane, mp 137—142 °C (Found: C, 58.55; H, 5.29; N, 2.93%. $C_{24}H_{25}O_{10}\cdot\frac{1}{4}H_2O$).

General Procedures. *Method A*: Amino acid or peptide (0.6—0.7 mmol) was dissolved in H_2O containing Et_3N (0.6—0.7 mmol) and added to a solution of 0.5 mmole of *N*-hydroxysuccinimide ester of **3** (m=3) in tetrahydrofuran. After stirring at room temperature the reaction mixture was acidified and evaporated and the residue was subjected to Sephadex LH-20 column chromatography using MeOH as eluent. Crystallization from MeOH or MeOH–AcOEt afforded the desired product **5** or **6**.

Method B: To a solution of hydrochloride of methyl or ethyl ester of amino acid or peptide (1.5 mmol) in $CHCl_3$ or H_2O were added Et_3N (1.5 mmol) and a solution of 1 mmol of *N*-hydroxysuccinimide ester of **3** (m=3) in tetrahydrofuran and stirred at room temperature. Usual workup and SiO_2 column chromatography (if necessary) gave the methyl or ethyl ester of the dihydrochalcone derivative. Without further purification the ester was dissolved in 0.5 M NaOH (1 M=1 mol dm^{-3}) and stirred for 20 min at room temperature. The solution was acidified by addition of HCl aq and the precipitate was purified by Sephadex LH-20 column chromatography.

Method C: To an ice-cooled solution of 1 mmol of **3** (m=1), amino acid methyl or ethyl ester hydrochloride (1.5 mmol), Et_3N (1.5 mmol), and 1-hydroxybenzotriazole (0.5 mmol) in a mixture of tetrahydrofuran and *N,N*-dimethylformamide was added 1.5 mmol of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride. After stirring for 24—48 h at room temperature the reaction mixture was worked up as usual and the product was subjected to alkaline hydrolysis as described in Method B.

Mp's and results of elemental analyses of **5** and **6** are given in Tables 1 and 2. Compounds **5** (n=2 and 3) and **6** (n=2—4) were synthesized with Method A. The following derivatives were prepared by using method B *via* ethyl ester: **5** (n=1 and 4); **8** (n=2), mp 166—167 °C (Found: C, 59.44; H, 6.32; N, 4.92%. $C_{28}H_{36}O_{10}N_2\cdot\frac{1}{4}H_2O$); **8** ($n$=4), mp 131—134 °C. Compound **6** (n=5) was prepared with method B *via* methyl ester. Method C afforded the following compounds: **7** (n=1) *via* ethyl ester, mp 198—210 °C decomp (Found: C, 55.92; H, 5.21; N, 2.97%. $C_{20}H_{21}O_9N\cdot\frac{1}{2}H_2O$); **7** ($n$=2) *via* methyl ester, mp 173—180 °C (Found: C, 57.10; H, 5.34; N, 2.91%. $C_{21}H_{23}O_9N\cdot\frac{1}{2}H_2O$); **7** ($n$=3) *via* ethyl ester, mp 240—256 °C decomp (Found: C, 58.08; H, 5.63; N, 3.08%. $C_{22}H_{25}O_9N\cdot\frac{1}{2}H_2O$); **7** ($n$=5) *via* methyl ester, mp 211—212 °C (Found: C, 50.65; H, 6.39; N, 3.01%).

The authors are grateful to Dr. Ukon Nagai of our Institute for helpful discussions and to the members of the Analytical Department of System Engineering Laboratory, Mitsubishi-Kasei Industries, Ltd. for elemental analyses.

(Received May 19, 1982)

Synopsis. Direct *C*-sulfinylation of Grignard reagents with sulfinic acid (**4**) in the presence of activating reagents, such as phenyl phosphorodichloridate (**1**), diphenyl phosphorochloridate (**2**), and 3-phthalimidooxy-1,2-benzisothiazole 1,1-dioxide, were investigated. β-Keto sulfoxides were also formed by the reaction of enamines with **4** using **1** and **2** under similar conditions.

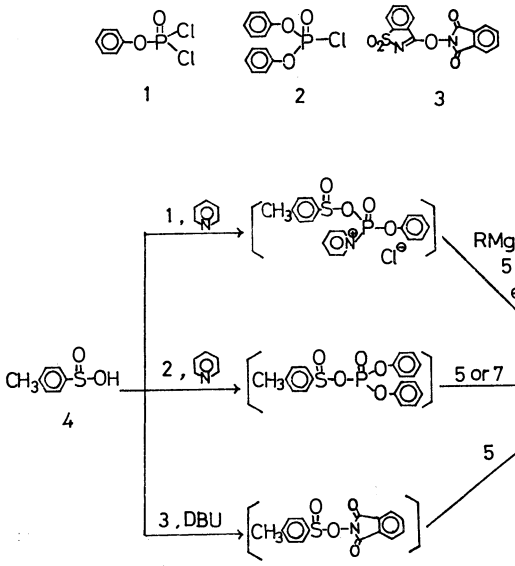
We have recently developed a series of new one-pot *O*- and *N*-sulfinylations with sulfinic acid in the presence of an activating reagent,[1] and more recently found that some reagents were sufficiently effective for *S*-sulfinylation of thiols, giving thiosulfinates in comparatively good yields.[2]

We newly tried to extend these methods to *C*-sulfinylations of Grignard reagents and enamines. The employed activating reagents are as follows: Phenyl phosphorodichloridate (**1**), diphenyl phosphorochloridate (**2**), and 3-phthalimidooxy-1,2-benzisothiazole 1,1-dioxide (**3**). The methods differ from each other only in the reagents employed for activation of sulfinic acid. In one case, **1** or **2** and pyridine (or triethylamine) are used, and in the other, **3** and 1,8-diazabicyclo-[5,4,0]undec-7-ene (DBU).

The reagent **1** has been reported to be sufficiently effective as an activating reagent for transformation of carboxylic acids to the esters[3] under virtually neutral and mild conditions. In the present study, p-toluenesulfinic acid (**4**) was treated with an equivalent of **1** and an excess pyridine in THF at −15—0 °C; when this mixture was then allowed to react with Grignard reagents (**5**) at room temperature, the corresponding sulfoxides (**6**) were obtained in low yields.

A comparable activating effect was observed by using **2**, which possesses a similar structural moiety; this gave somewhat lower yields of **6**. The reaction probably proceeds *via* a mixed anhydride intermediate, as well as by *O*-sulfinylation.[2]

Better results for sulfinylation of **5** were obtained by using **3** and DBU in some cases. The reaction was achieved by adding a solution of two equivalents of **5** in ether to a mixture of equivalents of **4**, **3**, and DBU in THF below −5 °C under a nitrogen stream and by stirring the reaction mixture at room temperature. Purification was carried out by silica gel column chromatography. The yields of sulfoxides obtained by these methods are shown in Table 1.



Scheme 1.

We also tried to extend these methods to sulfinylation of enamines (**7**). An example of β-sulfinylation of **7** has not been reported in the literature. The reaction was carried out by treating **7** with an equivalent of **4** in dichloromethane in the presence of equivalent of **1** and an excess of triethylamine to afford the corresponding β-keto sulfoxides (**6**, R=α-keto alkyl) in 10—43% yields, along with small amounts of several

Table 1. Yields of sulfoxides and β-keto sulfoxides $CH_3C_6H_4S(O)R$

	43	50		99—101	1042	1710	66.10(66.05)	6.78(6.84)

by-products such as disulfide and thiosulfonate.

Better results were obtained by using **2** instead of **1** to give **6** (R=α-keto alkyl) in 34—50% yields. In this case, a small amount of diphenyl *N,N*-pentamethylenephosphoramidate was isolated as the by-product, no formation of disulfide and thiosulfonate being observed. In both cases, purification was carried out by column chromatography on silica gel. The results are summarized in Table 1. Unfortunately, **3** was inaffective as the activating reagent.

β-Keto sulfoxides are known to be useful starting materials and versatile synthetic intermediates in organic synthesis.[4] These vicinally difunctionalized compounds have previously been prepared by oxidation of α-substituted thioketone,[5] acylation of sulfinyl stabilized carbanions with esters,[6] or sulfinylation of ketone enolate anions with sulfinates.[7] An especially notable feature of our methods is the application of mild and nearly neutral conditions throughout the reactions; therefore the acid or base sensitive functional groups will be expected to remain unaffected.

Experimental

All the melting points are uncorrected. IR and NMR spectra were measured on a JASCO IRA-1 grating infrared spectrometer and JEOL high resolution NMR instrument C-60 at 60 MHz, respectively. Mass spectra were determined at 75 eV on a JEOL-01SG mass spectrometer.

Preparation of Sulfoxides (6). *Method A*: A solution of **1** (2.11 g, 10 mmol) in anhyd THF (5 ml) was added dropwise with stirring into a solution of **4** (1.56 g, 10 mmol) and pyridine (2.37 g, 30 mmol) in anhyd THF (30 ml) at −15 °C under a nitrogen atmosphere; then the mixture was stirred for 1 h. A Grignard reagent (**5**) (20 mmol) prepared in the usual way in ether was added slowly to the mixture below −5 °C under a nitrogen atmosphere. The mixture was stirred for 3 h from 0 °C up to room temperature. After the solvents were evaporated under reduced pressure, the residue was dissolved in $CHCl_3$ (60 ml), and the solution was washed with 1 M HCl (1 M = 1 mol dm^{-3}), 5% aq $NaHCO_3$, and finally with H_2O, dried over anhyd Na_2SO_4 and evaporated. The residue was chromatographed on silica gel by using benzene–ethyl acetate (4:1) as an eluent to give **6** and by-products, di-*p*-tolyl disulfide and *S*-*p*-tolyl *p*-toluenethiosulfonate.

Method B: A solution of pyridine (0.9 g, 12 mmol) in anhyd THF (5 ml) was added dropwise with stirring into a solution of **4** (1.56 g, 10 mmol) and **2** (2.7 g, 10 mmol) in anhyd THF (30 ml) at −10 °C under a nitrogen atmosphere, and the mixture was stirred for 1 h. A solution of **5** (20 mmol) prepared in the usual way in ether was added slowly to the mixture below −5 °C. After stirring for 3 h, the mixture was quenched with H_2O and extracted with ether (50 ml × 3), and the extracts were worked up and chromatographed as in Method A to give **6**, along with di-*p*-tolyl disulfide and *S*-*p*-tolyl *p*-toluenethiosulfonate.

Method C: To a solution of **4** (0.78 g, 5 mmol) and **3** (1.64 g, 5 mmol) in anhyd THF (30 ml) was added dropwise with stirring a solution of DBU (0.76 g, 5 mmol) in anhyd THF (5 ml) at room temperature under a nitrogen atmosphere. Grignard reagent **5** (15 mmol) prepared in the usual way in ether was added slowly to the mixture below −5 °C under a nitrogen stream. After stirring at −15 °C for 30 min, the mixture was stirred at room temperature for 1.5 h and evaporated. The residue was dissolved in $CHCl_3$ (60 ml), and the solution was treated and chromatographed as in Method A to give **6** along with di-*p*-tolyl disulfide and *S*-*p*-tolyl *p*-toluenethiosulfonate as by-products.

Preparation of β-Keto Sulfoxides (6, R=α-Keto Alkyl). *Method A*: A solution of triethylamine (1.1 g, 11 mmol) in anhyd CH_2Cl_2 (10 ml) was added dropwise with stirring into a solution of **4** (1.56 g, 10 mmol) and **1** (2.3 g, 11 mmol) in anhyd CH_2Cl_2 (30 ml) at −10 °C under a nitrogen atmosphere, and the mixture was stirred for 1 h below −10 °C. A solution of **7** (12 mmol) and triethylamine (2.2 g, 22 mmol) in anhyd CH_2Cl_2 (10 ml) was added gradually to the mixture. After stirring for 3 h, the mixture was washed with 0.1 M HCl, 1% aq $NaHCO_3$, and H_2O, dried over anhyd Na_2SO_4, and evaporated. The residue was purified by silica gel column chromatography using benzene–ethyl acetate (4:1 100 ml, 2:1 50 ml, 1:1 150 ml) to give β-keto sulfoxide along with di-*p*-tolyl disulfide and *S*-*p*-tolyl *p*-toluenethiosulfonate as by-products.

Method B: A solution of triethylamine (1.2 g, 12 mmol) in anhyd CH_2Cl_2 (10 ml) was added dropwise with stirring into a solution of **4** (1.56 g, 10 mmol) and **2** (2.7 g, 10 mmol) in anhyd CH_2Cl_2 (40 ml) at −10 °C under a nitrogen atmosphere. After the mixture was stirred for 1 h, a solution of **7** (12 mmol) and triethylamine (1.2 g, 12 mmol) in anhyd CH_2Cl_2 (15 ml) was gradually added. The mixture was stirred for 2 h at room temperature, and washed with 0.1 M HCl, 1% aq $NaHCO_3$, and with H_2O, dried over anhyd Na_2SO_4, and evaporated. The residue was purified by silica-gel column chromatography using benzene–ethyl acetate (4:1 100 ml, 2:1 50 ml, 1:1 100 ml) to give β-keto sulfoxide along with diphenyl *N,N*-pentamethylenephosphoramidate.

Preparation of 3-Phthalimidooxy-1,2-benzisothiazole 1,1-Dioxide (3). A solution of triethylamine (3.8 g, 28 mmol) in acetonitrile (10 ml) was added dropwise into a suspension of 3-chloro-1,2-benzisothiazole 1,1-dioxide (5.6 g, 28 mmol) and *N*-hydroxyphthalimide (4.8 g, 30 mmol) in acetonitrile (60 ml) with stirring at 0—5 °C, and the mixture was stirred overnight. After removal of the precipitates, the filtrate was concentrated. The residue was recrystallized from $CHCl_3$–CH_2Cl_2. Yield 66%. Mp 238—241 °C. Found: C, 54.85; H, 2.25; N, 8.53%. Calcd for $C_{15}H_8N_2O_5S$: C, 54.87; H, 2.45; N, 8.53%. IR (KBr): 1760, 1625, 1570, 1470, 1350, 1190, and 800 cm^{-1}. MS *m/e*: 328 (M^+), 166, 162, 104, 76.

The Reactivity of Radical Anions Generated by Electron-transfer Reaction of Allyl Acetates

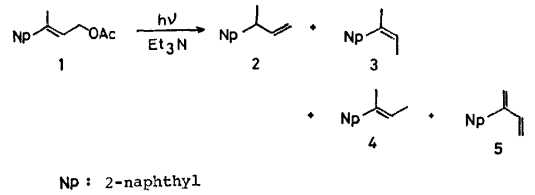
Kazuo TSUJIMOTO,* Yojiro KAMIYAMA, Yuji FURUKAWA, and Mamoru OHASHI
Department of Materials Science, The University of Electro-Communications, Chofu, Tokyo 182
(Received May 21, 1982)

Synopsis. Photoinduced electron-transfer reactions of 3-(2-naphthyl)-2-butenyl acetate gave the reduced products, while the electrochemical and Birch reduction of the acetate furnished (*E*)-2-(2-naphthyl)-2-butene as the sole product. One-electron reduction was suggested by mechanistic studies of the photoreaction on the basis of deuterium incorporation into the products. A similar mechanism can operate in the photoreduction of cinnamyl acetate.

For ten years many photochemists have focused[1] their interest on photoinduced electron-transfer reactions. The reactions involving a system which consists of a pair of donor and acceptor molecules are triggered by irradiation. Now we report the reactivity of the anion radical produced by electron-transfer in the photoinduced reaction of an allyl acetate.[2]

Results and Discussion

Irradiation upon acetonitrile solution of 3-(2-naphthyl)-2-butenyl acetate (**1**) in the presence of triethylamine[3] gave 3-(2-naphthyl)-1-butene (**2**), (*Z*)- and (*E*)-2-(2-naphthyl)-2-butene (**3** and **4** respectively), and 2-(2-naphthyl)-1,3-butadiene (**5**) as hydrocarbon fractions in 14, 2.6, 7.0, and 3.0% yields respectively. When diethylamine and butylamine, which have higher ionization potentials than that of triethylamine, were used as an electron donor, the yields of **2**, **3**, and **4** decreased. The formation of **5**, however, is independent of the ionization potential of the donor, as shown in Table 1. Results which suggest that the photoreaction is proceeding *via* charge transfer in the excited state were also observed in fluorescence quenching of **1** with aliphatic amines, as shown in Table 2.



Scheme 1.

When a mixture of methanol–acetonitrile (1:1) was used instead of acetonitrile as a solvent, a photosolvolytic reaction took place to give 3-methoxy-3-(2-naphthyl)-1-butene (**6**) in 44% yield as a major product.[4] The hydrocarbon products were also isolated. Deuterium incorporation by use of methanol-*d* in place of methanol was observed in the formation of **3** and **4**, while the use of methan-d_3-ol contributed little to the incorporation, as shown in Table 3.

The Birch reduction of **1** in liquid ammonia gave **4** in 49% yield, together with a small amount of dihydro- and tetrahydronaphthalenes. In a reduction similar to the Birch reaction, **1** was reduced on the anode. When an acetonitrile solution of **1** with tetrabutylammonium iodide was electrolyzed in 2.1 F/mol, the product **4** was isolated in 73% yield.

Among three kinds of reactions, the photochemical, the Birch, and the electrochemical reduction,[5] the products for the anion radical generated photochemically are different from that of the others. In the photoinduced electron-transfer reaction, the radical which results from the ionic dissociation of the anion radical can hydrogen-abstract from triethylamine to furnish reduction products. On the other hand, the radical generated from the ionic dissociation of the anion radical can be reduced further in the Birch or the electrochemical reaction, resulting in the formation of an anion intermediate which subsequently reacts with the proton added.

In conclusion, the following schematic mechanism is proposed to elucidate the reactivity of the intermediate, as shown in Scheme 2.

According to the reactivity of the radical generated from a photochemical electron-transfer reaction, it is understandable that the photoreaction of cinnamyl acetate with aliphatic amines gave not only 1-phenylpropene (16%) but also allylbenzene (22%).

Experimental

Melting points were obtained with a hot-stage apparatus and are uncorrected. IR spectra were determined on a JASCO IRA-1 spectrometer. NMR spectra were detected by using a Hitachi R-20B 60-MHz instrument. GC-MS analyses were carried out on a Hitachi RMU-6MG instrument. A Pyrex column (0.3 cm i.d.×1.2 m) packed with Diasolid ZF 80—100 mesh (Nippon Chromato Kogyo Co.) was used for separation. Quantitative and preparative GC were performed on a Shimadzu GC-3BF and on a Varian 90 P-3 instrument, respectively. Fluorescence spectra were recorded on a Hitachi 204 spectrometer.

*Preparation of 3-(2-Naphthyl)-2-butenyl Acetate (**1**).* To a suspension of NaH (5.5 g, 50% oil dispersion) in dry 1,2-dimethoxyethane (70 cm³, DME) was added a solution of triethyl phosphonoacetate (17.8 g) in dry DME (50 cm³) at 0 °C under N_2 gas. Then a solution of 2-acetylnaphthlene (10.3 g) in anhydrous DME (70 cm³) was added dropwise at 0 °C under stirring and the mixture was stirred continuously at room temp for 8 h. After extraction with diethyl ether, the obtained material was chromatographed on a short-column (PF_{254} Merck/10% ether in hexane), and the pure *E*-isomer (7.0 g) was obtained in 48% yield. Mp 45.3—45.7 °C. MS *m/z* 240(M^+), ^{1}H-NMR (CCl_4) δ=1.26 (3H, t, J=8 Hz), 2.63(3H, d, J=1.5 Hz), 4.17(2H, q, J=8 Hz), 6.17(1H, q, J=1.5 Hz), and 7.2—7.8(7H, m). The *Z*-isomer was also isolated by the chromatography, of which NMR spectrum showed peaks at δ=0.93(3H, t, J=8 Hz), 2.16(3H, d, J=1.5 Hz), 3.88(2H, q, J=8 Hz), 5.86 (1H, q, J=1.5 Hz), and 7.1—7.8(7H, m).

To a suspension of $LiAlH_4$ (3.1 g) in anhydrous ether (70 cm³) was added an etheral solution of the *E*-isomer (7.0 g in 90 cm³) at room temp under N_2 atmosphere. After stirring for 5 h, the ether extraction afforded crude crystals which were recrystallized from benzene–hexane (1:1). The recrystallized alcohol weighed 4.3 g (74%), mp 85.8—86.5 °C. MS *m/z* 198(100, M^+), 180(66, $M-H_2O$), 179(48), 178(21), 165(62). ^{1}H-NMR δ=1.74(1H, s, OH), 2.13(3H, d, J=1.5 Hz), 4.40(2H, d, J=7 Hz), 6.11(1H, tq, J=7 and 1.5 Hz), and 7.3—7.9(7H, m).

To a solution of the alcohol (2.0 g) in anhydrous ether (60 cm³) was added acetyl chloride (3.0 cm³) and then triethylamine (6.0 cm³) at 0 °C. After 90 min, the ether extracted fraction was chromatographed on silica gel (PF_{254}/20% ether in hexane). The obtained crystals weighed 2.3 g(95%); their mp was in the range of 47.8—48.5 °C. MS 241(18), 240(100, M^+), 198(38), 197(41), 183(45), 180(55), 179(34), 169(25), and 165(53). Found: *m/z* 240.1152. Calcd for $C_{16}H_{16}O_2$: M, 240.1150. ^{1}H-NMR δ=2.0(3H, s), 2.18 (3H, s), 4.75(2H, d, J=8 Hz), 5.96(1H, t, J=8 Hz), and 7.2—7.8(7H, m). IR(KBr) 1740 cm^{-1}. UV(CH_3CN) 243 (44000), 274(10000), 284(12000), 295(8900) nm.

*Preparative Photoreaction of **1** with Triethylamine.* A 0.02 M acetonitrile solution (200 cm³) of **1** with triethylamine (6.0 cm³) was irradiated with a high-pressure mercury arc for 1.5 h at room temp under N_2 bubbling. After removal of low-boiling point materials, the residue was chromatographed on a precolumn of silica gel (Wako gel Q-50/10% ether in hexane) and rechromatographed on silica gel PF_{254}/hexane). The developed fraction was collected and injected in a GC. Four products showed the following chromatograms: retention time: **2**, 14′; **3**, 12′; **4**, 25′ and **5**, 18′. **2**: MS *m/z* 183(12), 182(69, M^+), 181(15), 168(14), 167(100), 166(13), 165(15), and 152(11). Found: *m/z* 182.1071. Calcd for $C_{14}H_{14}$: M, 182.1094. IR 1640 cm^{-1}. ^{1}H-NMR δ=1.40(3H, d, J=7 Hz, CH_3), 3.57(1H, qdt, J=7, 6, and 2 Hz), 5.05(2H, dd, J=17 and 2 Hz and dd, J=10 and 2 Hz), 6.05(1H, ddd, J=17, 10 and 6 Hz), and 7.4(7H, m). **3**: MS *m/z* 183(22), 182(100, M^+), 181(26), 168(17) 167(70), 166(13), and 165(17). ^{1}H-NMR δ=1.65(3H, d, J=7 Hz), 2.09(3H, s), 5.75(1H, q, J=7 Hz), and 7.5(7H, m). **4**: MS *m/z* 183(20), 182(100, M^+), 181(26), 168(16), 167(84), 166(16) and 165(20). Found: *m/z* 182.1079. Calcd for $C_{14}H_{14}$: M, 182.1094. ^{1}H-NMR 1.82(3H, d, J=7 Hz), 2.09(3H, s), 5.92(1H, q, J=7 Hz), and 7.5(7H, m). **5**: MS *m/z* 181(18) 180(100, M^+), 179(77), 178(32), and 165 (41). Found: *m/z* 180.0943. Calcd for $C_{14}H_{12}$: M, 180.0939. ^{1}H-NMR δ=5.2(2H, dd, J=17 and 9 Hz), 5.3 (2H, s), 6.7(1H, dd, J=17 and 9 Hz), and 7.5(7H, m).

*Photoreaction of **1** with Methanol.* A mixture of methanol–acetonitrile (1:1) was used (80 cm³) as a solvent for irradiation of **1** (400 mg) in the presence of triethylamine (2.4 cm³) with a 6 W-low pressure mercury arc for 1.5 h. TLC separation (PF_{254}/10% ether in hexane) gave **2**, **3**, **4**, **5**, and **6** in 20, 1.6, 14, 10, and 44% yields respectively. **6**: MS *m/z* 212(52), 197(43), 182(7), 181(45), 180(100), 179(73), 178(16), 166(18), and 165(59). Found: *m/z* 212.1212. Calcd for $C_{15}H_{16}O$: 212.1200. ^{1}H-NMR δ= 1.60(3H, s), 3.12(3H, s), 5.15(1H, dd, J=10 and 2 Hz), 5.20(1H, dd, J=18 and 2 Hz), 6.00(1H, dd, J=18 and 10 Hz), and 7.5(7H, m).

*Electrolytic Reduction of **1**.* An acetonitrile solution (40 cm³) of **1** (114 mg) with tetrabutylammonium iodide (1.48 g) as a supporting electrolyte was electrolyzed (3.3 V, Pt) under N_2 gas for 1 h. The etheral extraction and TLC separation gave **4** (63 mg).

*Birch Reduction of **1** in Liquid Ammonia.* At −78 °C, an acetonitrile solution (2.0 cm³) of **1** (105 mg) was dropwise added to a liquid ammonia solution (100 cm³) of sodium (762 mg). After adding methanol (0.5 cm³) the mixture was allowed to warm up. The etheral extraction and then TLC separation gave **4** in 49% yield.

Photochemical Reaction of Cinnamyl Acetate with Triethylamine. An acetonitrile solution (350 cm³) of cinnamyl acetate (1.89 g) with triethylamine (10.9 g) was irradiated with a 12-W low pressure mercury arc under N_2 gas for 2.5 h. The reaction mixture was short-path chromatographed on silica gel with ether. The obtained mixture (190 mg) showed two peaks in GC (10% DEGS on Diasolid 80—100 mesh). Each fraction was preparatively isolated. The first fraction was identified with allylbenzene and the last was 1-phenylpropene by comparison with the spectral data (^{1}H-NMR, IR, and UV). Quantum yields for the formation of the products were 0.22 (allylbenzene) and 0.17 (1-phenylpropene).

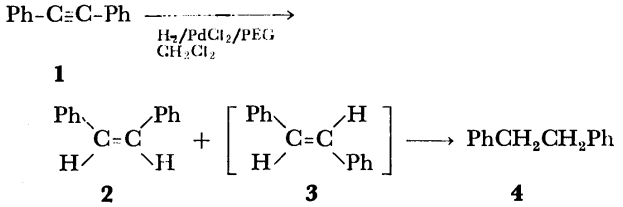
Synopsis. A practically homogeneous system of $PdCl_2$ in CH_2Cl_2 in the presence of polyethylene glycol catalyzed hydrogenation reactions of diphenylethyne (**1**) and *cis*-1,2-diphenylethene (**2**) to **2** and/or 1,2-diphenylethane (**4**). Under the conditions, the selectivity of the hydrogenation of **1** to **2** against that of **1** to **4** was excellent, compared to that using the Pd/C system.

Polyethylene glycol (PEG) is an excellent substitute of crown ether because of its low-price, low-toxicity, non-volatility, and solubility in both organic solvents and water (easily removable). It has been used as a co-solvent as described in our previous reports[1] and in others.[2]

Much data have been accumulated for the heterogeneous[3] and homogeneous[4] catalysts of hydrogenation. However, there has been no report on the hydrogenation catalyzed by $PdCl_2$ which is made soluble in organic solvents by means of some co-solvent(s). Although a few nucleophilic additions to alkenes and alkynes proceeding by initial formation of a double or triple bond-$PdCl_2$ complex were known,[5] there have been no reports on the hydrogenation of them catalyzed by $PdCl_2$. We describe here a novel homogeneous catalyst for the hydrogenation of diphenylethyne (**1**) and 1,2-diphenylethene (**2**) to the corresponding *cis*-olefin (**2**) and the saturated hydrocarbon (**4**), respectively. Good selectivity for the partial reduction of **1** to **2** was achieved. The reactions can be interrupted simply by washing with water. This makes it easy to maximize the selectivity. This is the first example of a homogeneous catalyst using a host-guest complex between PEG and palladium for the hydrogenation of alkynes and olefins.



Palladium chloride[6] placed in a round-bottomed flask was covered with H_2 gas. Into the flask was added a solution of diphenylethyne[6] (**1**) in CH_2Cl_2 or some other solvent(s) with or without PEG[7] through an injection needle. The resulting clear solution was stirred at 10 °C. The hydrogenation reactions were monitored by GLC by comparing with the authentic *cis*- and *trans*-1,2-diphenylethenes[6] (**2** and **3**) and 1,2-diphenylethane[7] (**4**). Palladium/C (10%) was employed for comparisons. The results are shown in Table 1. In the case of using PEG, the aliquots were washed with water to remove the PEG and the other water soluble components before the application on GLC. Conversion yields for **2** and **4** were calculated on the basis of the conversion of **1**, ignoring a trace of **3** (less than few %). Selectivity is represented by the ratio of [**2**]/[**4**]. Palladium black seemed not to be formed during the reaction.

Table 1 shows that $PdCl_2$ worked in EtOH similarly to the Pd/C, but the selectivity is lower than for the latter (runs No. 1 and 2 in Table 1). In CH_2Cl_2, Pd/C did not catalyze the reaction well and the conversion of **1** was low, while $PdCl_2$ worked well (runs No. 4—5).

Employment of PEG as a co-solvent in CH_2Cl_2 accelerated the reaction and gave higher selectivity (runs No. 3 and 7). A higher concentration of PEG #200, however, seems to lower the reaction rate and the selectivity (runs No. 3 and 6). The viscosity of the medium may affect these values.

Molecular weight of PEG affected both the rates and the selectivity: PEG #400 gave the highest selectivity (runs No. 6—9). This may be explained by the ease of the formation of complex between the PEG molecule and Pd^{2+} cation.[8] If the cation forms a complex bound with PEG too tightly, the complex formation might also cause the difficulty of contact between the catalyst and the substrate: Consequently, the reaction rates decreased when PEG of higher molecular weight was used.

The other solvents used gave less effective results (runs No. 10—13). PEG #200 did not give higher selectivity in $CHCl_3$.

Ethylene oxide-condensed pentaerythritols (PEO-8.3EO and PEO-15.8EO)[9] worked well as co-solvents as PEG (runs No. 14—15).

Similar catalytic hydrogenation occurred when *cis*-1,2-diphenylethene (**2**) was used as a substrate (see Table 2) under similar conditions to those used above. The conversion yields were quantitative, but the reaction rates were not satisfactory for the preparation of **4**.

Experimental

Diphenylethyne[6] (**1**), *cis*- and *trans*-1,2-diphenylethenes[6] (**2** and **3**), 1,2-diphenylethane[6] (**4**), $PdCl_2$,[6] and 10% Pd/C were purchased. Polyethylene glycols #200, #400, #600, and #1000 were purchased[7] and dried azeotropically (benzene) before use. EtOH (Mg) and CH_2Cl_2 (CaH_2) were dried over and distilled from the desiccant shown in the parentheses. GLC tests were performed on a Yanagimoto Yanaco G-80F (FID): 5% PEG-20 M on Gasport (60—80 mesh) in a stainless steel column (ϕ 2 mm×2.0 m); col. temp 160 °C, inj. temp 180 °C, carrier gas (N_2), 20.9 ml/min.

Catalytic Hydrogenation of Diphenylethyne (1) or cis*-1,2-Diphenylethene (2).* Palladium chloride or 10% Pd/C (final concentration: 0.94 mM) (1 M=1 mol dm^{-3}) was placed in a 50 ml-round-bottomed flask which was kept in a thermostated bath (10±0.5 °C) with a serum cap. The flask

was evacuated with an aspirator through an injection needle which pierced the serum cap. A balloon containing H_2 gas was attached through another injection needle. The evacuation and the filling with H_2 gas were repeated three times. Finally, the needle with the aspirator was disconnected, while the needle with the balloon of H_2 gas was kept in place. A solution (25 ml) of diphenylethyne (**1**: 10 mM) or *cis*-1,2-diphenylethene (**2**: 40 mM) in CH_2Cl_2 or the other solvent(s) with/without PEG (1 M) was added into the flask through an injection needle. The resulting clear solution was stirred at 10 °C. The hydrogenation reactions were monitored by GLC, comparing with the authentic samples, *cis*- and *trans*-1,2-diphenylethenes (**2** and **3**) and/or 1,2-diphenylethane (**4**). Recovery of **1** and generation of **2**, **3**, and **4** were observed. Conversion yields for **2** and **4** were calculated on the basis of the conversion of **1**, ignoring the trace amounts of **3** (less than a few %). Selectivity of the hydrogenation is represented by the ratio of [**2**]/[**4**]. The results are summarized in Tables 1 and 2.

Steroids. III.[1] New Synthesis of Ring-D Seco Steroids

Tomoyoshi TAKAHASHI* and Yasuo SATOH†

Department of Chemistry, The Jikei University School of Medicine, Kokuryo Chofu, Tokyo 182

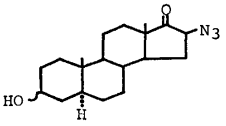
† *Department of Chemistry, Faculty of Science, Rikkyo University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171*

(Received June 3, 1982)

Synopsis. 16β-Azido-5α-androstan-17-one derivatives were cleaved with bromine in acetic acid at room temperature, to furnish 16-cyano and 16-carbamoyl-16,17-seco-5α-androstan-17-oic acids. 17-Aza-D-homo-5α-androstan-16,17a-dione derivatives were also synthesized.

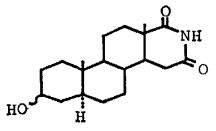
Recently, we described a novel single step C–C bond cleavage of various α-azido steroidal ketones.[1,2] Our preliminary studies concerning the cleavage of a cyclopentane ring having an α-azido ketone group and the fact that certain ring D seco derivatives show hypocholesterolemic activity[3]prompted us to investigate the cleavage reaction in ring D of a steroid.

Treatment of α-azido steroidal ketones **1a** and **1b** with bromine (1 equiv.) in acetic acid for 10 h gave seco-carboxylic acids **2a** and **2b**, respectively. The IR spectra of **2a** and **2b** confirmed the presence of the cyano and carboxyl groups. The ^{1}H NMR spectra displayed a three-proton singlet at δ 2.00 (**2a**), 1.95 (**2b**) assigned to the 3-CH_3CO, and a broad one-proton peak at δ 10.19 (**2a**), 9.23 (**2b**) assigned to the carboxylic proton. 18-Angular methyl group appeared as a singlet at lower field, δ 1.25, suggesting that ring D was no longer intact but had undergone a cleavage with formation of a carboxyl group.



1a: 3α-OH
1b: 3β-OH

	R^1	R^2	R^3
2a:	α-OAc	CN	COOH
2b:	β-OAc	CN	COOH
3a:	α-OAc	$CONH_2$	COOH
3b:	β-OAc	$CONH_2$	COOH
4a:	α-OAc	$CONH_2$	$COOCH_3$
4b:	β-OAc	$CONH_2$	$COOCH_3$



5a: 3α-OH
5b: 3β-OH

When **1a** and **1b** were allowed to react under the above conditions for a long period of time, the seco-amides **3a**[1] and **3b** were formed by hydrolysis. The IR spectra showed absorption bands at 2600—2700 cm^{-1} and 1706 cm^{-1} indicative of a carboxyl group. The ^{1}H NMR spectra of **3b** showed two peaks for the amide protons at δ 6.54 and δ 6.98, which disappeared on addition of deuterium oxide.

The cleavage reaction was also useful for introduction of a nitrogen atom into the steroid D ring. Treatment of the seco-amides **3a** and **3b** with diazomethane in ether gave the methyl esters **4a** and **4b**. The ^{1}H NMR spectra showed a characteristic three-proton singlet for the methyl ester at δ 3.66, and the broad peaks centered at δ 6.63 and 7.18 (**4a**), and 6.30 (**4b**), assigned to the amide protons.

The esters were cyclized with sodium methoxide in methanol to give the imides **5a** and **5b**. The imides were characterized by their IR spectra which showed the signals for the carbonyl groups at 1690, 1726 (**5a**) and at 1690, 1721 cm^{-1} (**5b**).

Experimental

General. All the melting points are uncorrected. The IR spectra were measured with a Hitachi model 215 infrared spectrophotometer. The ^{1}H NMR spectra were obtained in a CCl_4 solution, with TMS as the internal standard, using a Hitachi-Perkin Elmer R-20A. The MS spectra were measured by means of a Hitachi M-80 instrument with direct inlet at 70 eV.

*16β-Azido-3β-hydroxy-5α-androstan-17-one (**1b**).* This compound was synthesized from 3β-hydroxy-16α-bromo-5α-androstan-17-one[4] by Ponsold's method[5] as prisms, mp 113—116 °C; Found: C, 68.85; H, 8.6; N, 12.8%. Calcd for $C_{19}H_{29}N_3O_2$: C, 68.85; H, 8.82; N, 12.68%; IR (KBr): 3300, 2100 (N_3), and 1749 cm^{-1}; ^{1}H NMR (CCl_4) δ=3.67 (2H, m, 3α-H and 16-H).

*3α-Acetoxy-16-cyano-16,17-seco-5α-androstan-17-oic Acid (**2a**) and 3β-Acetoxy-16-cyano-16,17-seco-5α-androstan-17-oic Acid (**2b**).* To a solution of **1a**[1] (200 mg) in acetic acid (10 ml) was added bromine (97 mg) in acetic acid (5 ml) with stirring for 10 h at room temperature. After the usual work-up, the resulting oil was chromatographed on a silica-gel column. Elution with 20% ether in benzene afforded an oil (**2a**) (152 mg, 70%), which resisted crystallization from various solvents. IR (NaCl): 3150, 2700—2600 (bonded COOH), 2250 (CN), 1730, and 1698 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.25 (3H, s, 18-CH_3), 2.00 (3H, s, MeCO), 2.27 (2H, m, 15-CH_2), 4.92 (1H, m, 3β-H), and 10.19 (1H, br, COOH).

A similar cleavage reaction of **1b** (200 mg) gave **2b** (144 mg, 66%) as a colorless oil. IR (NaCl): 3100, 2700—2600 (bonded COOH), 2250 (CN), 1730, and 1697 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.25 (3H, s, 18-CH_3), 1.95 (3H, s, MeCO), 2.25 (2H, m, 15-CH_2), 4.56 (1H, m, 3α-H), and 9.23 (1H, br, COOH).

*3β-Acetoxy-16-carbamoyl-16,17-seco-5α-androstan-17-oic Acid (**3b**).* To a solution of the α-azido ketone (**1b**) (2 g) in acetic acid (100 ml) saturated with hydrogen chloride gas was added bromine (1 g) in acetic acid (50 ml), and the reaction mixture was stirred for one week at room temperature. After work-up, crystallization of the resulting oil from hexane–ether gave compound **3b** (1.261 g, 55%), mp 185—192 °C; Found: *m/e* 379.2372. Calcd for $C_{21}H_{33}NO_5$: M, 379.2359; IR (KBr): 3450, 3350, 3200, 2700—2600 (bonded COOH), 1728, 1706, 1694, 1655 (sh), 1592, and 1241 cm^{-1}; ^{1}H NMR (DMSO) δ=1.97 (3H, s, MeCO), 4.53 (1H, br, 3α-H), 6.54 (1H, br, NH), and 6.98 (1H, br, NH); MS (70 eV), *m/e* (rel intensity), 379 (100%, M^+), 301 (66), 216 (75), and 201 (93).

Methyl 3α-Acetoxy-16-carbamoyl-16,17-seco-5α-androstan-17-oate

(4a) and Methyl 3β-Acetoxy-16-carbamoyl-16,17-seco-5α-androstan-17-oate (4b). An excess of diazomethane in ether was added dropwise to a stirred solution of the amido-acid (**3a**) (500 mg) in ether (50 ml) at room temperature until the yellow color persisted. Evaporation and crystallization of the residue from carbon tetrachloride gave compound **4a** (320 mg, 62%), mp 149—151 °C; Found: *m/e* 393.2521. Calcd for $C_{22}H_{35}NO_5$: M, 393.2515; IR (KBr): 3425, 3350, 3200, 1724, 1713, 1660, 1608, and 1247 cm^{-1}; ^1H NMR (CCl_4) $\delta=1.98$ (3H, s, MeCO), 3.66 (3H, s, MeO), 4.93 (1H, br, 3β-H), 6.63 (1H, br, NH), and 7.18 (1H, br, NH); MS (70 eV), *m/e* (rel intensity), 393 (100%, M^+), 376 (10), 361 (20), 348 (16), 333 (25), and 274 (40).

The compound **4b** was obtained in a similar way. After the usual work-up, the resulting oil was chromatographed on silica-gel column. Elution with 40% benzene in ethyl acetate afforded compound **4b** (40%), mp 75—82 °C; Found: *m/e* 393.2572. Calcd for $C_{22}H_{35}NO_5$: M, 393.2515; IR (KBr): 3430, 3350, 3200, 1723, 1608, and 1239 cm^{-1}; ^1H NMR (CCl_4) $\delta=1.93$ (3H, s, MeCO), 3.66 (3H, s, MeO), and 6.30 (2H, br, NH_2); MS (70 eV), *m/e* (rel intensity), 393 (100%, M^+), 376 (9), 361 (15), 348 (22), 333 (17), and 274 (25).

3α-Hydroxy-17-aza-D-homo-5α-androstan-16,17a-dione (5a) and 3β-Hydroxy-17-aza-D-homo-5α-androstan-16,17a-dione (5b). The synthesis was carried out following the procedure of Meakins.[6] The amic-ester (**4a**) (500 mg) was dissolved in a solution of sodium (35 mg) in methanol (7 ml), and the solution was refluxed for 10 min. After the usual work-up, crystallization of the resulting oil from ether–methanol gave **5a** (170 mg, 42%), mp 223—226 °C; Found: *m/e* 319.2149. Calcd for $C_{19}H_{29}NO_3$: M, 319.2147; IR (KBr): 3420, 3260, 3100, 1726, 1690, 1675, and 1275 cm^{-1}; ^1H NMR ($CDCl_3$) $\delta=4.03$ (1H, br, 3β-H) and 8.16 (1H, br, NH); MS (70 eV), *m/e* (rel intensity), 319 (27%, M^+), 304 (51), 301 (100), 286 (100), and (12).

Compound **5b** was obtained in a similar way. The reaction mixture was refluxed for 20 min. After the usual work-up, crystallization of the resulting oil from ethyl acetate gave **5b** (46%), mp 216—219 °C; Found: *m/e* 319.2152. Calcd for $C_{19}H_{29}NO_3$: M, 319.2147; IR (KBr): 3370, 3200, 3070, 1721 (sh), 1705 (sh), 1690, and 1270 cm^{-1}; ^1H NMR ($CDCl_3$) $\delta=3.60$ (1H, br, 3α-H), and 8.50 (1H, br, NH); MS (70 eV), *m/e* (rel intensity), 319 (54%, M^+), 304 (35), 301 (100), 286 (52), and 261 (24).

Photochromic Behavior of Schiff Base-Metal Complexes. I. Photoinduced Hydrolysis of Pyridoxal 5′-Phosphate- and Salicylaldehyde-α-amino Acid-Zinc(II) Complexes

Yoshiaki KURAUCHI, Kazuya OHGA,* Akihiko YOKOYAMA, and Shigeru MORITA
Department of Environmental Chemistry and Engineering, Oita University, Dannoharu, Oita 870-11

(Received June 16, 1982)

Synopsis. Pyridoxal 5′-phosphate-α-amino acid-Zn(II) complexes and their salicylaldehyde analogues showed photochromic behavior in borate buffer at pH 9.5. A detailed comparison of UV spectral changes during the thermal back reaction with those for the complex formation indicates that the photoexcitation of the complexes induces the hydrolysis of the Schiff base ligands and that the back reaction corresponds to regeneration of the complexes.

Pyridoxal 5′-phosphate (PLP) is an essential cofactor for many amino acid transformations in biological systems. PLP or pyridoxal (PL) itself also non-enzymically catalyzes some of these reactions, which proceed *via* the Schiff bases with amino acids.[1] We have found that the photoexcitation of the PLP Schiff bases causes a half-reaction of decarboxylation-dependent transamination.[2] This type of decarboxylation has not been observed in thermal model systems for α-amino acids having an α-hydrogen. This difference between the photochemical and thermal reactions led us to investigate the photochemical behavior of the Schiff base-metal ion complexes which have been used much more frequently in the non-enzymic model systems.

The Zn(II) complex of PL–Val (Val=valine) Schiff base has been reported by Metzler *et al.*[3] to be exceedingly photolabile in aqueous solutions. We here report that the Zn(II) complexes of PLP–α-amino acid Schiff bases and their salicylaldehyde (SAL) analogues are photochemically hydrolyzed in an aqueous solution.

Experimental

PLP (Sigma), α-amino acids (Wako),[4] and zinc perchlorates (Kishida) were of reagent grade or better and were used without further purification. SAL (Wako) was distilled under reduced pressure and stored in the dark at about −20 °C. UV absorption spectra were taken with a Shimadzu UV 202 spectrophotometer. All kinetic runs were carried out spectrophotometrically in 0.05 mol dm^{-3} borate buffer (pH 9.5) at an ionic strength of 0.5 (KCl) with a Shimadzu MPS-5000 spectrophotometer. The cell compartments were thermostated (±0.1 °C) at desired temperatures.

Complex Formation and Rate Determination. α-Amino acid, zinc perchlorate, and PLP or SAL were simultaneously mixed. The Zn(II) complex solutions equilibrated within 30 min or less showed absorption maxima at 378 nm (0 in Fig. 1, ε 5620) for PLP-Ala (Ala=alanine), 375 nm (ε 5820) for PLP-AIB (AIB=α-aminoisobutyric acid), 351 nm (ε 5880) for SAL-Ala, and 350 nm (ε 5920) for SAL-AIB complexes. The molar absorption coefficients in parentheses were based on the initial concentration (1.00×10^{-4} mol dm^{-3}) of PLP or SAL, and were obtained under the conditions of the relative concentrations of three components given in the footnote of Table 1. These concentration conditions gave the greatest absorbances at the absorption maxima of the complexes. The molar absorption coefficient for the SAL-Ala-Zn(II) complex is in good agreement with that reported by Leussing and Bai.[5] The first-order rate constants (k_c) of the complex formations were determined by recording the increases in absorbances (A) at the wavelengths of the absorption maxima with respect to time, and by plotting $-\ln(A_\infty-A)$ *vs.* time. A_∞ is the absorbance at $t=\infty$. The activation energies ($E_{a,c}$) were calculated from the Arrhenius plot of the rate constants obtained.

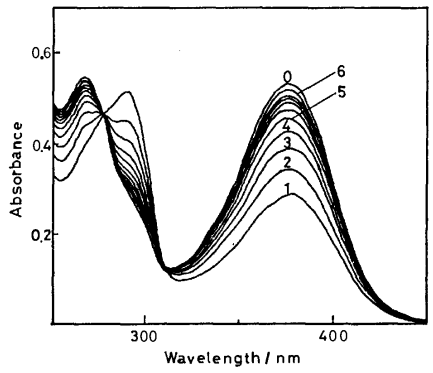

Fig. 1. Spectral changes of the PLP-Ala-Zn(II) complex in 0.05 mol dm^{-3} borate buffer at 25 °C after UV irradiation.
0: Before irradiation, 1: immediately after irradiation of 3 min, 2—5: thermal UV spectral changes at intervals of 1.5 min, 6: 30 min after irradiation. Other conditions: see the footnote in Table 1.

UV Irradiation and Thermal Back Reaction. The equilibrated solutions of the Zn(II) complexes were deaerated by repeated evacuation and flushing with argon gas seven or more times. The solutions were then placed in a 1-cm quartz spectrophotometric cell, thermostated at desired temperatures, and irradiated with a 500-W super high-pressure Hg lamp (Ushio USH-500D) through glass filters (Toshiba UV-39 transmitting less than 10% light below 380 nm, for PLP complexes; UV-D36A transmitting less than 10% light below 330 nm, for SAL complexes). The progress of a thermal back reaction was followed by determining the absorption spectra. The kinetic data (k_b and $E_{a,b}$) of this process were obtained by the method described above.

Results and Discussion

The irradiation of a buffered solution of the PLP–Ala–Zn(II) complex in an argon atmosphere caused the immediate decrease of the complex absorption band at 378 nm (Fig. 1, 0→1). When the photolysate was kept in the dark, a thermal reaction occurred; the UV spectrum of the photolysate returned more than 98% to its initial figure within 30 min at 25 °C (Fig. 1, 1→6), and showed two isosbestic points at 278 and 311 nm. The spectral changes during the thermal reaction were the same in shape as those during the complex formation. In addition, more than 95% of the original absorbance at 378 nm was restored even after the photochemical and thermal processes were repeated three times. These results suggest that the

a) All the experiments were carried out in 0.05 mol dm^{-3} borate buffer, pH 9.5 (0.5 mol dm^{-3} KCl). The initial concentration of PLP or SAL was 1.00×10^{-4} mol dm^{-3}. The initial concentrations of amino acid and Zn^{2+} were 1.0×10^{-2} and 7.0×10^{-4} for PLP-Ala, 5.0×10^{-2} and 5.0×10^{-3} for PLP-AIB, 1.0×10^{-2} and 1.5×10^{-3} for SAL-Ala, and 5.0×10^{-2} and 5.0×10^{-3} mol dm^{-3} for SAL-AIB systems, respectively. b) Errors given are standard deviations. c) Not determined.

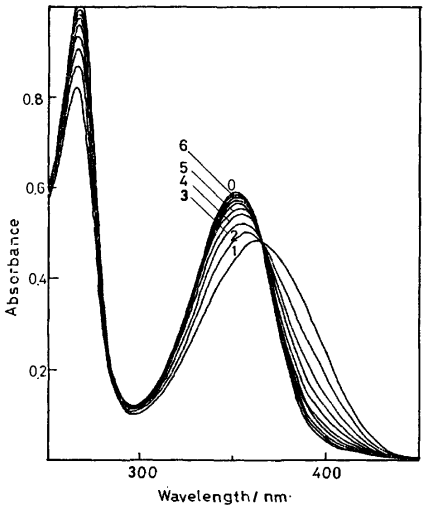

Fig. 2. Spectral changes of the SAL–Ala–Zn(II) complex in 0.05 mol dm^{-3} borate buffer at 25 °C after UV irradiation.
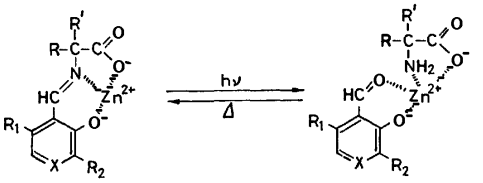
The numbers represent the order of the spectral changes at the same intervals as those in Fig. 1. Other conditions: see the footnote in Table 1.

photoexcitation of the complex caused the hydrolysis of the Schiff base ligand followed by the thermal regeneration of the complex (Scheme 1), and that a very minor side reaction took place only during irradiation. When other amino acids, Val and AIB were used, almost the same spectral changes were observed. The Zn(II) complex of SAL–Ala or SAL–AIB Schiff base also showed the same photochromic behavior (Fig. 2 for SAL–Ala–Zn(II) complex). The photochemical hydrolysis of these Zn(II)–Schiff base complexes was confirmed by the excellent agreement between the observed kinetic data (k_b and $E_{a,b}$) of the thermal back reaction and those of the complex formation (k_c and $E_{a,c}$), as shown in Table 1.

It has been proposed on the basis of kinetics of SAL–amino acid–divalent metal systems by Leussing *et al.*[6)] that rapid preequilibrium just after mixing the three components gives a mixed complex such as **2**, which is slowly transformed into the Schiff base

Scheme 1



1 **2**

PLP systems: X=N, $R_1=CH_2OPO_3^{2-}$, $R_2=CH_3$
SAL systems: X=CH, $R_1=R_2=H$

complex (**1**) *via* an α-hydroxy amine complex. Under the conditions of excess Zn^{2+} and amino acid concentrations and at pH 9.5 employed in this work, the *o*-hydroxy aromatic aldehydes of UV-absorbing species are considered to exist in the mixed complex form after the photochemical hydrolysis. The first-order rate constants observed are probably those for the proton-independent formation path of the Schiff base complexes from the mixed complexes.

Metal-free PLP–α-amino acid Schiff bases underwent photochemically decarboxylation.[2)] Evidently the coordination of the carboxylato group to Zn(II) depresses this photo-decarboxylation.

An irreversible absorption band due to a by-product appeared around 330 nm on irradiation of the PLP–Ala–Zn(II) complex in air. It seems to us that the by-product, probably an oxidation product, corresponds to a photoproduct from PL–Val–Zn(II) complex[3)] having a similar absorption at 330 nm.

The Preparation of Tri-*t*-butoxysiloxy-substituted 1,3,5-Triazines

Yoshimoto ABE,* Yukinori NAGAO, Kenji SATO, and Takahisa MISONO

Department of Industrial Chemistry, Faculty of Science and Technology, Science University of Tokyo, Noda, Chiba 278

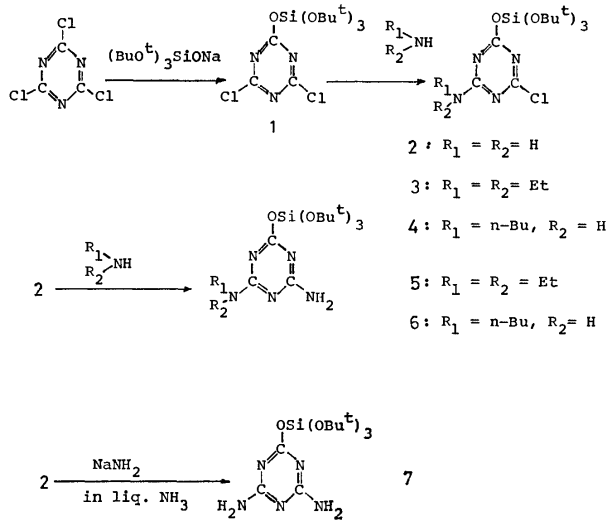
(Received June 17, 1982)

Synopsis. The title derivatives were prepared to obtain 1,3,5-triazines with a better solubility than chloro- and amino-1,3,5-triazine, which are not very soluble in common organic solvents.

Several reports have been published on the preparation and reaction of 1,3,5-triazines substituted with trimethylsilyl groups.[1-6] These silicon-containing derivatives are prepared by the reaction of cyanurate, ammeline, and melamine with hexamethyldisilazane, which are purified by distillation *in vacuo*. This implies that the substitution with trimethylsilyl group affords a high volatility and/or a good solubility to the starting materials by prevention of interactions among molecules. However, these derivatives are sensitive to hydrolysis.

In this work, therefore, the chloro- and amino-substituted 1,3,5-triazines with tri-*t*-butoxysiloxy group were prepared. Our hope was that derivatives with a good solubility in organic solvents together with hydrolytic stability may be obtained by the prevention of interactions among molecules through introducing this group into the 1,3,5-triazine ring. Earlier results showed that condensations of functional groups such as amino and hydroxyl group are effectively protected.[7]

The experimental results showed that the reaction of cyanuric chloride with sodium tri-*t*-butoxysilanolate gave the compound **1**, but further replacement of the chlorine atom of **1** by this group did not take place. Compound **1** was allowed to react with ammonia, diethylamine and butylamine to give the derivatives **2,3**, and **4**, respectively. The reaction of **2** with ammonia did not occur under the conditions. Amines such as diethylamine and butylamine, however, were reacted with **2** to form the products **5** and **6**, which indicates that a low reactivity of the last chlorine atom is not due to the steric factor of tri-*t*-butoxysiloxy group but to the low electrophilicity of the carbon of carbon–chlorine bond. An attempt to isolate **7** from the reaction product of **2** with sodium amide in liquid ammonia was not successful, but it was obtained as the hydrochloride.



All these compounds were very soluble in organic solvents such as methanol, ethanol, acetone, ether, tetrahydrofuran, chloroform, and benzene and were stable to hydrolysis; most of **2** was recovered without hydrolysis after it was heated at 50 °C for about thirty minutes in a mixed solvent of water and dioxane. The hydrochloride of **7** was also soluble in methanol, ethanol, and acetone. These results indicate that introduction of tri-*t*-butoxysiloxy group affords an appreciable solubility and hydrolytic stability to the derivatives.

Experimental

Materials. All the melting points and boiling points were uncorrected. The solvents and reagents were dehydrated and purified by distillation or recrystallization. Tri-*t*-butoxysilanol was prepared by the method already mentioned.[7] Sodium tri-*t*-butoxysilanolate was prepared by the reaction of tri-*t*-butoxysilanol and sodium in benzene and was used without isolation.

2,4-Dichloro-6-(tri-t-butoxysiloxy)-1,3,5-triazine (1). Sodium silanolate prepared by the reaction of tri-*t*-butoxysilanol (14.0 g) with sodium (1.1 g) in benzene (80 ml) was reacted with cyanuric chloride (9.2 g) in benzene (100 ml) under reflux for 3 h to give **1**, 12.9 g (62.8%); bp 139 °C—/2 Torr†; IR 1533, 1501, 1475, 1393, 1377, 1085, 1038, 855, 818 cm^{-1}. Found: C, 43.59; H, 10.07; N, 6.81; Si, 6.52%. Calcd for $C_{15}H_{17}N_3Cl_2O_4Si$: C, 43.69; H, 10.19; N, 6.60; Si, 6.81 %.

2-Amino-4-chloro-6-(tri-t-butoxysiloxy)-1,3,5-triazine (2). The reaction of **1** (30.0 g) in benzene (300 ml) with dry ammonia gas at 5—10 °C for 2 h gave **2**; 23.3 g (recrystallized from hexane 73.3%); mp 105 °C; IR: 3350, 3225, 1608, 1557, 1517, 1393, 1370, 1082, 1030, 820 cm^{-1}. Found: C, 45.42; H, 7.35; N, 13.79; Si, 7.13%. Calcd for $C_{15}H_{19}N_4ClO_4Si$: C, 45.85; H, 7.44; N, 14.26; Si, 7.15%.

Compound **2** was also obtained by introducing ammonia into the reaction mixture of sodium tri-*t*-butoxysilanolate with cyanuric chloride without isolation of **1** (44% yield).

2-Chloro-4-diethylamino-6-(tri-t-butoxysiloxy)-1,3,5-triazine (3) and 2-Chloro-4-butylamino-6-(tri-t-butoxysiloxy)-1,3,5-triazine (4). To the reaction mixture of tri-*t*-butoxysilanol (28.0 g) with sodium (2.3 g) in benzene (150 ml), followed by addition of cyanuric chloride (18.4 g) in benzene (200 ml), diethylamine or butylamine (15.0 g) in benzene (100 ml) was added. Recrystallization of a residue from the reaction mixtures with hexane gave the compounds: **3**, 21.5 g (47.8%); mp 58.0—58.5 °C; IR 1595, 1514, 1430, 1405, 1378, 1080, 1060, 810 cm^{-1}; NMR (CCl_4): δ 1.2 (t, 6H), 1.35 (s, 27H), 3.62 (q, 4H); MS: *m/e* 448 (M^+). Compound **4**, 28.3 g (63%); mp 94.3—94.5 °C; IR 1585, 1550, 1405, 1380, 1080, 1055, 1030, 813 cm^{-1}; NMR (CCl_4): δ 0.95 (m, 7H),

† 1 Torr ≈ 133.322 Pa.

1.35 (s, 27H), 3.50 (q, 2H), 8.08 (t, 1H); MS: *m/e* 448 (M^+). Found for **3**: C, 51.36; H, 8.64; N, 12.16%. Found for **4**: C, 50.30; H, 8.45; N, 12.57%. Calcd for $C_{19}H_{27}N_4ClO_4Si$; C, 50.82; H, 8.30; N, 12.48%.

*2-Amino-4-diethylamino-6-(tri-t-butoxysiloxy)-1,3,5-triazine (**5**) and 2-amino-4-butylamino-6-(tri-t-butoxysiloxy)-1,3,5-triazine (**6**).* Compound **2** (5.0 g) in benzene (100 ml) was reacted with diethyamine or butylamine (2.0 g) in benzene (50 ml) under reflux for 2 h. Removal of the solvent and subsequent recrystallization of a residue with ether (**5**) or petroleum ether (**6**) gave the compounds: **5**, 5.9 g (56.8%); mp 89.0—90.0 °C; IR: 3390, 3220, 3070, 1640, 1540, 1520, 1404, 1380, 1045, 1028, 830 cm^{-1}; NMR (CCl_4): δ 1.14 (t, 6H), 1.34 (s, 27H), 3.53 (q, 4H); MS: *m/e* 429 (M^+). Compound **6**, 2.3 g (44.5%); mp 110.0 °C (decomp); IR: 3510, 3050, 3000, 1646, 1547, 1503, 1403, 1378, 1050, 1025, 830 cm^{-1}; MS: *m/e* 429 (M^+). Found for **5**: C, 53.17, H, 9.39; N, 16.30%. Found for **6**: C, 53.28; H, 9.42; N, 16.18%. Calcd for $C_{19}H_{38}N_4O_4Si$: C, 53.12; H, 9.15; N, 16.30%.

*2,4-Diamino-6-(tri-t-butoxysiloxy)-1,3,5-triazine (**7**).* Into a flask containing dry liquid ammonia (about 100 ml) trapped under cooling with Dry Ice–acetone was added with stirring first a catalytic amount of iron (III) nitrate hydrate (0.05 g) and then 0.55 g of sodium divided into several pieces over several times. After the completion of disappearance of a blue color, 10.1 g of **2** was added, and the mixture was stirred for 2 h. The ammonia was evaporated while the reaction mixture was allowed to rise to room temperature after addition of hexane. The mixture was refluxed, and the solid was filtered by hot filtration. After drying in vacuo and dissolving into methanol, it was reacted with a dilute hydrochloric acid solution. The precipitate was filtered, washed with water, and dried. It was recrystallized with methanol to give crystals (2.7 g, 30% yield) of the hydrochloride of **7**. Mp 178 °C (decomp); IR: 3160, 3080, 2985, 1710, 1590, 1430, 1396, 1379, 1080, 843 cm^{-1}; NMR ($(CD_3)_2SO$): δ 1.25 (s, 28H), 8.70 (s, 4H). Found for hydrochloride of **7**: C, 44.38; H, 7.41; N, 17.07; Si, 6.87%. Calcd for $C_{15}H_{32}N_5O_4ClSi$: C, 43.93; H, 7.86; N, 17.08; Si, 6.85%.

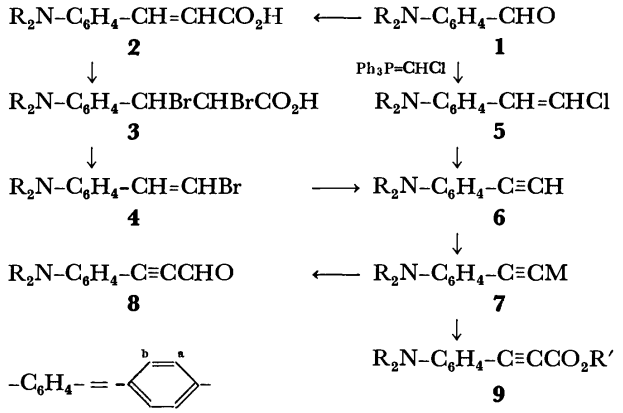
(Received June 24, 1982)

Synopsis. Two convenient methods for the preparation of *p*-dialkylaminophenylacetylenes are reported: a) Dehydrobromination of the brominated compounds obtained easily from the dialkylamino substituted cinnamic acids in acetic acid instead of chloroform; b) dehydrochlorination of the 2-chlorostyrene derivative obtained from the reaction of *p*-dimethylaminobenzaldehyde with chloromethylenetriphenylphosphorane.

In our study on ethynologs of triphenylmethane dyes,[1] *p*-dialkylaminophenylacetylenes (**6**) are important starting materials. However, no convenient method is known for easy and large-scale production. The synthesis of *p*-dimethylaminophenylacetylene (**6**, R=CH_3) has been reported by Barbieri[2] and by Oliver and Walton.[3] Barbieri's method is depicted by the path (**2**→**3**→**4**→**6**) in Scheme 1. The yield of **6** based on **2** was only 18%. On the other hand, Oliver and Walton's method is made up by the reaction of *p*-dimethylaminophenylcopper with (iodoethynyl)trimethylsilane, from which **6** as trimethylsilyl derivative is obtained in 52% yield.

p-Diethylaminophenylacetylene (**6**, R=C_2H_5) has been prepared as a mixture of *p*- and *m*-isomers by the reaction of *p*-bromophenylacetylene with diethylamine in the presence of sodium amide.[4]

Now, we wish to report here the convenient synthesis of *p*-dialkylaminophenylacetylenes and their derives, as outlined in Scheme 1.



Scheme 1.

The bromination of **2** to obtain **3** according to the literature[2] has been reinvestigated unsatisfactorily in chloroform. The reaction seemed to proceed very little because **2** is almost insoluble in chloroform. However, we have found that the reaction proceeds dramatically under homogeneous conditions to give the brominated acid **3** if we use acetic acid instead of chloroform as a solvent. The bromide **4** obtained by the treatment of **3** with aq Na_2CO_3 was dehydrobrominated with several bases (*e.g.*, *n*-BuLi, $NaNH_2$, and *t*-BuOK) yielding the acetylene **6** in moderate yields. The above method seems to be easy and suitable for larger scale production. Contrary to this, Oliver and Walton's method appears to be fairly troublesome because of tedious reagents' preparation. Furthermore, we have developed an alternative route (**1**→**5**→**6**). The reaction of *p*-dimethylaminobenzaldehyde (**1**) with easily accessible chloromethylenetriphenylphosphorane[5] generated from the corresponding phosphonium salt by the treatment with the base (*t*-BuOK or *n*-BuLi) at low temperature gave 2-chlorovinyl compound (**5**, R=CH_3), which could be easily isolated and interestingly was composed mostly of *cis*-isomers.[6] The action of one mol of *n*-BuLi, *t*-BuOK, or $NaNH_2$ against **5** (R=CH_3) provided **6** (R=CH_3) in a high yield. Two mol of *n*-BuLi or *t*-BuOK gave the metalated compound (**7**, R=CH_3, M=Li or K), which reacted succeedingly with ethyl chloroformate to yield the ester (**9**, R=CH_3, R'=C_2H_5) and with *N*,*N*-dimethylformamide to give the aldehyde (**8**, R=CH_3).

It was clear that the general procedure for preparing ethylnyl compounds from acetyl derivatives was not applied here, since the attempted chlorination of *p*-dimethylaminoacetophenone (**10**)[7] with PCl_5 in benzene under reflux to obtain the corresponding chloride was unsuccessful due to decomposition under several reaction conditions.[8]

In conclusion, the preparation of **6** became easy along the route (**2**→**3**→**4**→**6**) including the modified bromination method. The alternative route (**1**→**5**→**6**) had also an advantage of being able to isolate **5** easily.

Experimental

The melting points were uncorrected. The IR spectra were obtained on a JASCO IRA-2 spectrophotometer. The ^1H NMR spectra were measured on a JEOL FX 90Q and the parameters were given in δ-values with respect to TMS used as an internal standard. The UV spectra were obtained in EtOH on a Shimadzu UV 300.

p-*Dimethylaminophenylacetylene* (**6**, *R*=CH_3). *From* p-*Dimethylaminocinnamic Acid* (**2**, *R*=CH_3): *Bromination of* **2**: To a solution of **2** (R=CH_3, 9.50 g, 0.05 mol) in acetic acid (300 ml) was added over 10 min bromine (8.0 g, 0.05 mol) in the same solvent (10 ml) at 16—20 °C. After the mixture had been stirred for 30 min, the solvent was evaporated. The residue was stirred with Na_2CO_3 (40 g, 0.38 mol) in water (200 ml) at room temperature for 30 min and extracted with hexane (400 ml). The extract, after being washed with brine and dried ($MgSO_4$), was concentrated to give a light brown oily substance (10.20 g); this was **4** and was used without purification in the next reaction.

Dehydrobromination. a) By Potassium t-*Butoxide*: To the above bromide (10.20 g) in THF (60 ml) was added *t*-BuOK (12.0 g, 0.11 mol) in THF (100 ml) over 1 h at room temperature. After stirring overnight the mixture was evaporated, worked up in the usual way, and then extracted with hexane (250 ml). The extract was washed with brine and dried ($MgSO_4$). Orange yellow crystals obtained on evaporating the solvent were dissolved in cyclohexane–benzene and passed through a short column of alumina (10

g). The filtrate was concentrated to give light yellow crystals (**6**, 2.01 g, 28% from **2**), mp 52—53 °C, lit,[2] 52—53 °C, ^{1}H NMR ($CDCl_3$) δ=2.73 (1H, s, ≡CH), 2.93 (6H, s, NMe_2), 6.49 (2H, d, J=8 Hz, H^b), and 7.25 (2H, d, J=8 Hz, H^a). (Found: C, 82.56; H, 7.68; N, 9.39%; M^+, 145).

b) By Sodium Amide: To a suspension of $NaNH_2$ (prepared from Na, 3.0 g, 0.13 mol in NH_3 (l) (150 ml)) was added **4** (10.45 g) which was prepared from **2** (R=CH_3, 9.50 g, 0.05 mol) in THF (50 ml) over 15 min at −60 °C. After being stirred overnight at −50——30 °C, the mixture was worked up in the usual way. The residue was extracted with benzene (250 ml). The extract was washed with water and dried ($MgSO_4$). The orange-brown material obtained on evaporating the solvent was dissolved in hexane–benzene and passed through a short column of alumina (20 g). The eluate was concentrated to afford **6** (2.67 g, 37%), mp 52—53 °C.

c) By Butyllithium: To a solution of **4** (8.54 g, derived from **2**, 7.60 g, 0.04 mol) in THF (50 ml) was added *n*-BuLi in hexane (1.5 M 40.0 ml, 60 mmol) with stirring under nitrogen atmosphere at −60 °C for 1 h. From the reaction mixture worked up in the usual way, **6** (2.23 g, 38%, mp 52—53 °C) was obtained.

*From p-Dimethylaminobenzaldehyde: p-Dimethylamino-β-chlorostyrene (**5**, R=CH_3)*: To a suspension of chloromethyltriphenylphosphonium chloride[5] (3.57 g, 0.01 mol) in THF (20 ml) was added a hexane solution of *n*-BuLi (1.5 M 6.7 ml, 0.01 mol) in an ice–salt bath. After the mixture being stirred for 30 min, powdered *p*-dimethylaminobenzaldehyde (1.04 g, 7 mmol) was added to the resulting orange red solution of chloromethylenetriphenylphosphorane. The mixture was stirred overnight at room temperature. The residue obtained by evaporating the solvent was extracted with heptane (300 ml). The extract was percolated through a short column of silica gel (5 g) and concentrated to give light yellow crystals (**5**, 0.96 g, 76% based on **1**), which were recrystallized from ether and exclusively composed of *cis*-isomer of **5**, as shown by ^{1}H NMR; mp 42—44 °C, IR (KBr) 1610 cm^{-1} (C=C), ^{1}H NMR ($CDCl_3$) δ=2.95 (6H, s, NMe_2), 6.00 (1H, d, J=8 Hz, olefinic H), 6.48 (1H, d, J=8 Hz, olefinic H), 6.66 (2H, d, J=9 Hz, H^b), and 7.61 (2H, d, J=9 Hz, H^a).

Found: C, 66.13; H, 6.70; N, 7.78%; M^+, 183. Calcd for $C_{10}H_{12}NCl$: C, 66.11; H, 6.66; N, 7.71%; M, 183.

*Dehydrochlorination of **5** (R=CH_3)*: To a solution of **5** (0.20 g, 1.1 mmol) in THF was added *n*-BuLi in hexane (1.5 M 2.0 ml, 3 mmol) for 30 min in an ice–salt bath under nitrogen atmosphere. After being stirred for 1 h, the mixture was quenched by adding water (50 ml). The aq layer was extracted with benzene (50 ml). The combined organic layer was dried ($MgSO_4$) and evaporated to give **6** (R=CH_3) as light yellow crystals (0.15 g, 94%, mp 52—53 °C). The use of *t*-BuOK instead of *n*-BuLi gave nearly the same result. The yield by $NaNH_2$ in NH_3(l) was 61%.

*p-Diethylaminophenylacetylene (**6**, R=C_2H_5)*: According to the same procedure as used for the dimethyl derivative, the bromination of **2** (R=C_2H_5)[9] was done. The successive dehydrobromination of **4** by *n*-BuLi, $NaNH_2$, and *t*-BuOK gave **6** in 42,[10] 28,[11] and 27%[12] based on **2**, respectively: bp 116 °C (4 mmHg); IR (Neat) 3290 (≡CH) and 2090 cm^{-1} (C≡C); MS M^+, 173, M, 173; ^{1}H NMR ($CDCl_3$) δ=1.16 (6H, t, J=7 Hz, $CH_2C\underline{H}_3$), 3.34 (4H, q, J=7 Hz, $C\underline{H}_2CH_3$), 2.94 (1H, s, ≡CH), 6.56 (2H, d, J=9 Hz, H^b), and 7.32 (2H, d, J=9 Hz, H^a).

*Ethyl p-Dimethylaminophenylpropiolate (**9**, R=CH_3, R'=C_2H_5)*: To a solution of **5** (R=CH_3, 2.00 g, 11 mmol) in THF (20 ml) was added *n*-BuLi in hexane (1.5 M 8.00 ml, 12 mmol) with stirring under nitrogen atmosphere in an ice–salt bath. After the mixture was stirred for 1 h, an excess of ethyl chloroformate (3.3 g, 30 mmol) was added; the resulting mixture was stirred overnight, and extracted with benzene (200 ml). The extract was passed through a short column of alumina (10 g) and concentrated to give yellow crystals (0.96 g, 40%), mp 36—38 °C. UV: 335 (ε 36000); IR (KBr) 2200 (C≡C) and 1700 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=1.65 (3H, t, J=7 Hz, $CH_2C\underline{H}_3$), 3.35 (6H, s, NMe_2) 4.50 (2H, q, J=7 Hz, $C\underline{H}_2CH_3$), 6.49 (2H, J=9 Hz, H^b), and 7.15 (2H, J=9 Hz, H^a). Found: C, 71.70; H, 6.99; N, 6.52%; M^+, 217. Calcd for $C_{13}H_{15}NO_2$: C, 71.86; H, 6.96; N, 6.45%; M, 217.

*p-Dimethylaminophenylpropynal (**8**, R=CH_3)*: To a solution of **5** (R=CH_3, 1.02 g, 5.6 mmol) in THF (40 ml) was added *n*-BuLi in hexane (1.5 M 5.0 ml, 7.5 mmol) with stirring under nitrogen atmosphere in an ice–salt bath. After 1 h, an excess of DMF (1 ml) was added and stirred for 1 h. The reaction mixture was worked up with 1% H_2SO_4 and extracted with benzene (200 ml). Crude crystals obtained here by concentrating the extract were dissolved in benzene (3 ml). The solution was passed through a short column of alumina (10 g) and concentrated to give **8** as light yellow crystals (0.39 g, 40%), mp 86—88 °C, IR (KBr) 2200 (C≡C) and 1660 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=3.18 (6H, s, NMe_2), 6.60 (2H, d, J=8 Hz, H^b), 7.41 (2H, d, J=8 Hz, H^a), and 9.32 (1H, s, CHO); UV: 365 (ε 15200). Found: C, 76.05; H, 6.39; N, 7.66%; M^+, 174. Calcd for $C_{10}H_{11}NO$: C, 76.27; H, 6.40; N, 8.09%; M, 174.

We thank Misses Rika Doi, Sanae Nishiyama, and Mie Kawano for their assistance in the experimental work. The present work was partly supported by a Grant-in-Aid for Scientific Research (No. 56470022). The authors (S. A., S. N., and K. N.) are grateful to the Ministry of Education, Science and Culture.

Asymmetric Cross-coupling of Organozinc Reagents with Alkenyl Bromides Catalyzed by a Chiral Ferrocenylphosphine–Palladium Complex

Tamio HAYASHI, Toshiya HAGIHARA, Yoshio KATSURO, and Makoto KUMADA*

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received July 12, 1982)

Synopsis. Organozinc reagents, prepared from secondary alkyl Grignard reagents (ArRCHMgCl: Ar=Ph, *p*-Tol; R=Me, Et) and excess zinc halides, were allowed to react with vinyl bromide and (*E*)-*β*-bromostyrene in the presence of dichloro[(*R*)-*N*,*N*-dimethyl-1-[(*S*)-2-(diphenylphosphino)ferrocenyl]ethylamine]palladium(II) as a catalyst to give the corresponding coupling products of up to 86% enantiomeric excess.

It has been well recognized that asymmetric synthesis catalyzed by chiral phosphine-transition metal complexes is one of the most useful methods for preparation of optically active compounds, and intense interest is now aroused by asymmetric carbon-carbon bond forming reactions with chiral transition metal catalysts.[1] Nickel- or palladium-catalyzed asymmetric Grignard cross-coupling has been reported by us and other research groups to afford optically active olefins of moderate to high enantiomeric excess: 3-Phenyl-1-butene obtained from reaction of 1-phenylethylmagnesium chloride has 68, 81, 67, and 15% ee with nickel catalysts for phosphine ligands, PPFA, Valphos, Norphos, and DIOP, respectively.[2-5] We report here that coupling products of higher enantiomeric purities can be obtained by use of organozinc reagents instead of Grignard reagents.

Results and Discussion

The secondary alkyl zinc reagents **1** were prepared *in situ* by mixing corresponding Grignard reagents with excess zinc halides. Preparation from alkyl halides and zinc metal was less convenient due to low yield and poor reproducibility. For the reaction of 1-phenylethylzinc halide (**1a**) with vinyl bromide, several nickel and palladium complexes with chiral phosphine ligands have been examined. Dichloro[(*R*)-*N*,*N*-dimethyl-1-[(*S*)-2-(diphenylphosphino)ferrocenyl]ethylamine]palladium(II) ($PdCl_2$[(*R*)-(*S*)-PPFA])[2,6] was found to be the most effective catalyst giving rise to high yield of optically active 3-phenyl-1-butene (**2a**) in THF at 0 °C for 20—40 h. It is noteworthy that the coupling reaction of the zinc reagents proceeded successfully only in THF,[7] although ether is usually the best solvent for the reaction of Grignard reagents.[2] Palladium complexes with other phosphine ligands were less catalytically active. Nickel complexes were almost inactive under the reaction conditions.

Results obtained for the asymmetric cross-coupling of **1** in the presence of $PdCl_2$[(*R*)-(*S*)-PPFA] catalyst are summarized in Table 1, which also contains data obtained for the reaction of organomagnesium and -aluminium reagents for comparison. The organozinc reagent **1a** prepared from 1-phenylethylmagnesium chloride and zinc chloride or iodide gave the olefin **2a** of 85—86% ee (*S*) in quantitative yield (entries 1 and

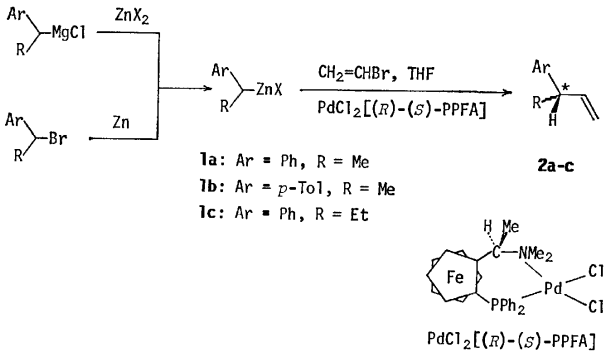

TABLE 1. ASYMMETRIC CROSS-COUPLING OF ORGANOZINC REAGENTS WITH VINYL BROMIDE CATALYZED BY $PdCl_2$[(*R*)-(*S*)-PPFA]

Entry		Organometallics	Solvent	Reaction condition		Yield[a]	$[\alpha]_D^{22}$/° (neat)	% ee (Confign.)
				Temp/°C	Time/h	%		
1	**1a**	PhMeCHMgCl/$ZnCl_2$ (1/2)	THF/Et_2O	0	40	>95	+5.05	85[b] (*S*)
2	**1a**	PhMeCHMgCl/ZnI_2 (1/2)	THF/Et_2O	0	21	>95	+5.08	86[b] (*S*)
3	**1a**	PhMeCHZnBr	THF	10	70	51	+5.10	86[b] (*S*)
4		PhMeCHMgCl	Et_2O	0	21	>95	+3.86	65[b] (*S*)
5		PhMeCHMgCl/$AlCl_3$ (1/2)	Et_2O	5	22	>95	+2.52	43[b] (*S*)
6	**1b**	*p*-TolMeCHMgCl/ZnI_2 (1/2)	THF/Et_2O	0	44	>95	+6.97	86[c] (*S*)
7	**1c**	PhEtCHMgCl/ZnI_2 (1/2)	THF/Et_2O	0	22	57	+35.0[d]	61[e] (*S*)
8[f]	**1a**	PhMeCHMgCl/$ZnCl_2$ (1/2)	THF/Et_2O	0	22	88	−31.7[g]	60[h] (*S*)

a) Yields based on vinyl bromide were determined by GLC analysis using an internal standard. Isolated yields were usually over 70%. b) (*R*)-3-Phenyl-1-butene (**2a**) has $[\alpha]_D^{22}$ −5.91±0.04° (neat), d_4^{22} 0.8809 (Ref. 2). c) (*R*)-3-*p*-Tolyl-1-butene (**2b**) has $[\alpha]_D^{23}$ −8.15° (neat), d_4^{23} 0.885 (Ref. 8). d) $[\alpha]_D^{20}$ (*c* 6, benzene). e) The olefin **2c** was oxidized into the known (*R*)-(−)-2-phenylbutyric acid; $[\alpha]_D^{21}$ −60.0° (*c* 3, benzene) (Ref. 9). f) Reaction with (*E*)-*β*-bromostyrene. g) $[\alpha]_D^{20}$ (*c* 3, benzene). h) (*R*)-(*E*)-1,3-Diphenyl-1-butene has $[\alpha]_D^{20}$ +52.9° (*c* 3, benzene) (Ref. 2).

2). The reagent **1a** from 1-phenylethyl bromide and zinc metal also gave (*S*)-**2a** of 86% ee, though the reaction was slower (entry 3). The stereoselectivity attained here is the highest for the asymmetric cross-coupling. The olefin **2a** of lower enantiomeric purity was obtained in a similar reaction of 1-phenylethylmagnesium chloride or organoaluminium reagent prepared *in situ* from the Grignard reagent and aluminium chloride (entries 4 and 5). The palladium complex $PdCl_2$[(*R*)-(*S*)-PPFA] also catalyzed effectively the reaction of other zinc reagents, (*S*)-3-*p*-tolyl-1-butene (**2b**) (86% ee) and (*S*)-3-phenyl-1-pentene (**2c**) (61% ee) being produced from the corresponding *in situ* organozinc reagents **1b** and **1c** (entries 6 and 7).

Experimental

Asymmetric Cross-coupling. The results are summarized in Table 1. The following experimental procedure for entry 2 is typical. To a mixture of 31 mg (0.05 mmol) of $PdCl_2$-[(*R*)-(*S*)-PPFA] and 19.2 g (60 mmol) of ZnI_2 were added successively 70 ml of THF, 42 ml (30 mmol) of 0.7 M 1-phenylethylmagnesium chloride in ether (1 M=1 mol dm^{-3}), and 1.07 g (10 mmol) of vinyl bromide under argon at −78 °C. The mixture was stirred at 0 °C for 21 h and hydrolyzed with 10% hydrochloric acid. GLC analysis of the organic layer indicated the formation of quantitative yield of 3-phenyl-1-butene (**2a**). The organic layer and ether extracts from the aqueous layer were combined, washed with saturated $NaHCO_3$ and then 10% $Na_2S_2O_3$, and dried over anhydrous Na_2SO_4. Distillation under reduced pressure (65 °C/20 mmHg) (1 mmHg=133.322 Pa) and purification by preparative GLC (Silicone DC550) gave 1.05 g (80%) of pure **2a**: $[\alpha]_D^{22}$ +5.08° (neat).

Oxidation of **2c** into 2-phenylbutyric acid was effected with sodium periodate and potassium permanganate in *t*-butyl alcohol according to a reported procedure.[10]

We thank the Ministry of Education, Science and Culture Japan for the Grant-in-Aid for Scientific Research No. 00547080 serving as a partial financial support for this work.

One-step Synthesis of (2-Amino-2-carboxyethylthio)dopas (Cys-dopas) from Dopa and Cysteine by Hydrogen Peroxide in the Presence of Iron-EDTA Complex

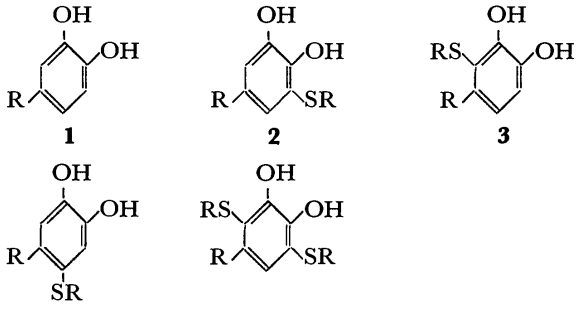
Shosuke Ito

Institute for Comprehensive Medical Science, School of Medicine, Fujita-Gakuen University, Toyoake, Aichi 470-11

(Received July 22, 1982)

Synopsis. 5-(2-Amino-2-carboxyethylthio)dopa, 2-(2-amino-2-carboxyethylthio)dopa, and 2,5-bis(2-amino-2-carboxyethylthio)dopa were synthesized from dopa and cysteine by oxidation in a neutral buffer with H_2O_2 in the presence of iron-EDTA complex. H_2O_2, iron salt, and EDTA were essential for the reaction. Ultimate oxidizing species seem to be hydroxyl and superoxide radicals.

(2-Amino-2-carboxyethylthio)dopas (represented as Cys-dopas in the following; **2**—**5**) arise in melanocytes by the addition of cysteine to dopaquinone formed by tyrosinase oxidation of dopa (3,4-dihydroxyphenylalanine; **1**).[1] They are precursors of pheomelanin, yellow to reddish-brown pigment of feathers and hair. Increased amounts of these catechols, especially **2**, have been found in the urine of melanoma patients.[2] We have recently shown that **2** is selectively toxic to a variety of human tumor cells *in vitro* and possesses antitumor activity against murine L1210 leukemia and B16 melanoma.[3]



R=$CH_2CH(NH_2)COOH$

Three methods have been reported for the preparation of Cys-dopas (**2**—**5**). 1) Tyrosinase-catalyzed oxidation of dopa in the presence of cysteine gives Cys-dopas (**2**—**5**) in a high total yield;[4] however, this method is not suitable for a large-scale preparation. 2) Multi-step chemical synthesis of **2** and **3** involving nucleophilic addition of cysteine to *N*-acetyldopaquinone ethyl ester requires expensive silver oxide as oxidant.[5,6] 3) Reaction of dopa with cystine in boiling aqueous HBr yields Cys-dopas (**2**—**4**) with the 6-isomer (**4**) being the major product (6—7% yield).[6] This paper presents a more convenient method for a large-scale preparation of **2**, **3**, and **5** by oxidation of a mixture of dopa and cysteine with H_2O_2 and Fe^{2+}–EDTA complex.

The oxidation, performed on an analytical scale, was followed by TLC on cellulose (in 1-propanol–1 M HCl,† 3:2) and the increase of absorbance at 300 nm where Cys-dopas (**2**—**5**) show strong absorption[6] while **1** does not. In some instances the products were also analyzed by column chromatography. Under the standard conditions (Expt 1 in Table 1), **2**, **3**, and **5** were obtained in 13.9, 3.1, and 4.2%, respectively, while **4** was found only in a trace amount (much less than 1%). The relative yields of the Cys-dopa isomers (**2**—**4**) paralleled those obtained with the tyrosinase oxidation,[4] suggesting that the present reaction also proceeds *via* dopaquinone. Most of the cysteine was consumed as cystine in addition to Cys-dopas. Sum of the yields of **1**—**5** approached nearly 100%, indicating that the reaction did not give pigments or ill-defined products.

Effects of pH, concentrations of H_2O_2, iron salts, and EDTA, and addition of radical scavengers were summarized in Table 1. The optimum pH of the reaction was around pH 7 (Expts 2—4). Omitting any one of H_2O_2, iron salts, and EDTA resulted in no formation Cys-dopas (Expts 5, 8, 15). Almost identical yields of Cys-dopas were obtained when $FeCl_3$ was used in place of $FeSO_4$ (Expt 13), while $CuSO_4$ had no catalytic activity (Expt 14). Doubling the amount of H_2O_2 (and cysteine) did not improve the yield of **2**, but it led to a great increase in the yield of **5** (Expts 21, 22).

Reaction of H_2O_2 with Fe^{2+}–EDTA complex produces hydroxyl radical (·OH) (Reaction 1) which is a powerful oxidizing agent.[7] The resulting Fe^{3+}–EDTA complex may be reduced back by H_2O_2 with the formation of superoxide radical ($O_2^{\cdot-}$) (Reaction 2).[7]

$$Fe^{2+}\text{-EDTA} + H_2O_2 \longrightarrow Fe^{3+}\text{-EDTA} + \cdot OH + OH^- \quad (1)$$

$$Fe^{3+}\text{-EDTA} + H_2O_2 \longrightarrow Fe^{3+}\text{-EDTA} + O_2^{\cdot-} + 2H^+ \quad (2)$$

Scavengers of hydroxyl radical, D-mannitol and formate,[8] inhibited the formation of Cys-dopas by 20 and 17%, respectively (Expts 18, 19). Addition of superoxide dismutase also caused a 21% inhibition of the reaction (Expt 20). These results suggest that not only ·OH (Reaction 1) but also $O_2^{\cdot-}$ (Reaction 2) participated in the iron–EDTA-catalyzed oxidation of dopa with H_2O_2. We have recently shown that superoxide radical generated in hypoxanthine–xanthine oxidase system can mediate the formation of Cys-dopas from dopa and cysteine.[9]

When **2** was used in place of **1**, a 6.3% yield of **5** was obtained with a 93.6% recovery of **2**.

Based on these results, the following conditions were established for the preparation of **2**, **3**, and **5** on a preparative scale. The reaction mixture consisted of dopa, cysteine (added in 5 portions), $FeSO_4$, EDTA·2Na, and H_2O_2 (added in 5 portions) at a molar ratio

† 1 M=1 mol dm^{-3}.

a) L-Dopa (1 mmol), L-cysteine (2 mmol), and $FeSO_4$ (0.1 mmol) were dissolved in water (100 ml), pH being adjusted to 7.0 with Na_2HPO_4. Then, H_2O_2 (1 mmol) was added in 5 portions every 10 min and the mixture was vigorously stirred at room temperature (23—26 °C). The reaction was terminated 10 min after the final addition of H_2O_2 by adding 1 ml of 6 M HCl. The mixture was applied on a column (1.0 cm×7 cm) of Dowex 50W-X2 and the products eluted with 3 M HCl after washing with 0.5 M HCl (100 ml). The products were separated by rechromatography on Dowex 50W-X2 (2.0 cm×24 cm; equilibrated with 2 M HCl) as described in Ref. 4. b) Difference in absorbances at 300 and 340 nm. Cys-dopas (2—5) show strong absorptions at 300 nm where 1 shows no absorption. Aliquots of the reaction mixture were diluted 50-fold with 1 M HCl and the UV spectra recorded. c) Some formation of purple pigment was noted. d) The formation of cystine was greatly accelerated. e) Not determined. f) L-Cysteine (2 mmol) was added in 5 portions 1 min prior to the additions of H_2O_2. g) L-Cysteine (4 mmol) and H_2O_2 (2 mmol) were added in 10 portions every 10 min.

of 1:2:0.1:0.2:1. Starting from 9.9 g of dopa and 12.1 g of cysteine, the reaction gave, in addition to 7.5 g (76%) of dopa recovered, 2.4 g (14%) of **2**, 0.5 g (3%) of **3**, and 0.9 g (4%) of **5** after chromatographic separation and crystallization. Thus, the present method appears to be the most convenient one for the large-scale preparation of **2**, **3**, and **5**.

Udenfriend and co-workers[10)] have described a system, consisting of L-ascorbic acid, iron-EDTA complex, and either O_2 or H_2O_2, and a buffer around neutral pH, which can hydroxylate various aromatic compounds. Our present system offered another example of chemical oxidation using H_2O_2 and iron–EDTA complex which mimics enzymic oxidation.

Experimental

Synthesis of Cys-dopas on a Preparative Scale. A solution of 9.86 g (50 mmol) of L-dopa, 3.72 g (10 mmol) of EDTA·2Na, and 1.39 g (5 mmol) of $FeSO_4 \cdot 7H_2O$ in 5 l of water was adjusted to pH 7.0 with crystals of $Na_2HPO_4 \cdot 12H_2O$. To the vigorously stirred solution were added at 23 °C 2.42 g (20 mmol) of L-cysteine and 1 min later 860 μl (10 mmol) of 11.6 M H_2O_2. The additions of the same amounts of L-cysteine and H_2O_2 were repeated 5 times at 10-min intervals. The reaction was terminated 10 min after the final addition of H_2O_2 by adding 50 ml of 6 M HCl and 5 ml of mercaptoacetic acid. The mixture was evaporated *in vacuo* at 60 °C to *ca.* 300 ml and stored overnight in a refrigerator. The resulting precipitate of cystine and EDTA was filtered off and the filtrate was applied on a column (3.6 cm×25 cm) of Dowex 50W-X2 (H^+ form, 200—400 mesh; equilibrated with water). Elution with 0.5 M HCl gave dopa (frs. 48—144; 20 ml per fraction) which was recovered as 7.48 g (75.9%) of crystals after evaporation and neutralization. Further elution with 3 M HCl afforded a mixture of **2**—**5** (frs. 20—140; 20 ml per fraction). The mixture was rechromatographed on a column (3.6 cm×25 cm) of Dowex 50W-X2 (equilibrated and eluted with 3 M HCl) and fractions of 20 ml were collected and analyzed by UV. Fractions 104—128, 132—220, and 229—325 contained **3**, **2**, and **5**, respectively, which were evaporated to give HCl salts of the amino acids. They were crystallized from aqueous 1% $Na_2S_2O_5$ adjusted to pH 6 with CH_3COONa to afford 2420 mg (14.4%) of **2**, 520 mg (2.8%) of **3**, and 932 mg (4.0%) of **5**. These catechols were identified with the authentic samples[6)] by comparison of chromatographic behaviors and UV spectra.

The author wishes to thank Prof. Keisuke Fujita for his continuous support and encouragement for this study.

Synthesis of Lactone-opened Derivatives of *anti* and *syn* Head-to-Head Coumarin Dimers

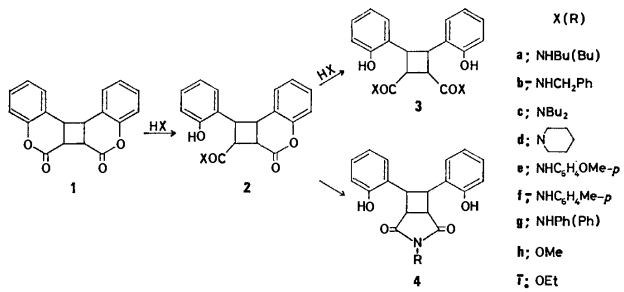
Noriyuki YONEZAWA and Masaki HASEGAWA*

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received July 29, 1982)

Synopsis. *anti* and *syn* Head-to-head coumarin dimers reacted readily with amines and alcohols to give the corresponding diamides, diesters, imides, or the monoactone derivatives.

Little work has been reported on the lactone-opening reaction of coumarin dimers except for the synthesis of 3,4-bis(2-hydroxyphenyl)-1,2-cyclobutanedicarboxylic acids.[1-3] It prompted us to study the lactone-opening reactions of coumarin dimers with amines or alcohols, as reported briefly in the preceding communications.[4-6] The configuration of two strained lactone rings is sterically so tight that these rings are readily opened by nucleophiles. In this paper we wish to report a preparative study on several lactone-opened derivatives of *anti* and *syn* head-to-head coumarin dimers.



anti Head-to-head coumarin dimer (*anti* **1**) reacted smoothly with aliphatic amines such as butylamine, benzylamine, dibutylamine, and piperidine in dioxane at 60 °C within 2 h to give *N,N'*-dibutyl-, *N,N'*-dibenzyl-, and *N,N,N',N'*-tetrabutyl-*t*-3,*c*-4-bis(2-hydroxyphenyl)-*r*-1,*t*-2-cyclobutanedicarboxamides, and *N,N'*-[*t*-3,*c*-4-bis(2-hydroxyphenyl)-*r*-1,*t*-2-cyclobutanedicarbonyl]dipiperidine (*anti* **3a**—**d**) in high yields. When weaker amines such as *p*-anisidine, *p*-toluidine, and aniline were employed as nucleophiles, a longer reaction time (4 h) was required for high conversions to the corresponding diamides (*anti* **3e**—**g**).

By treatment with methanol or ethanol at refluxing temperature, *anti* **1** was also converted to the corresponding dimethyl or diethyl dicarboxylate (*anti* **3h,i**) in a quantitative yield. In the early stage of the esterification with ethanol, the heterogeneous mixture became clear. At this stage, the monolactone/monoester, 2-ethoxy-1-(2-hydroxyphenyl)-1α,2α,2aβ,8bβ-tetrahydro-3*H*-cyclobuta[*c*]chromen-3-one (*anti* **2i**), was isolated as the sole product in a high yield. The structure of *anti* **2i** was confirmed by comparing its ^{1}H-NMR, ^{13}C-NMR, and IR spectra with those of *anti* **1** and *anti* **3i**. Similarly, the monolactone/monoamide derivatives (*anti* **2a,g**) were obtained in moderate yields by the reaction of *anti* **1** with an equimolar amount of amines in dioxane. The reaction produced the diamide as a minor product, and the amount of the diamide decreased with decreasing the nucleophilicity of the amine used. The attainable isolation of the monolactone derivatives implies that the lactone ring in the monolactone derivatives is less reactive than that in *anti* **1**. The higher stability of the monolactone derivatives would be attributed to the release of strain by the first lactone-opening in *anti* **1**.

Contrarily, *N*-butyl- and *N*-phenyl-*c*-3,*c*-4-bis(2-hydroxyphenyl)-*r*-1,*c*-2-cyclobutanedicarboximide (*syn* **4a, g**) were produced exclusively by the reaction of *syn* **1** with butylamine and aniline, respectively. The diamide, *syn* **3a**, was obtained in a high yield only when the reaction was carried out under specified conditions, whereas the dianilide, *syn* **3g**, was undetectable under any reaction conditions examined. In all cases, *syn* monolactone derivatives could not be isolated. These results show that in *syn* **1**, contrary to *anti* **1**, the second lactone-opening reaction is faster than the first one, since in the monolactone derivatives of *syn* **1** the newly introduced steric repulsion between *o*-hydroxyphenyl group, carbonyl group, and 2-chromanone moiety is considered to overcome the released strain through the first lactone-opening reaction. Further, in the second lactone-opening there are two types of reactions, namely, inter- and intramolecular nucleophilic attacks. At low temperature the intermolecular attack of an amine occurred preferentially to the intramolecular attack of the carbamoyl group in *syn* monolactone/monoamide. With raising the reaction temperature and with decreasing the amount of the amine, intramolecular attack becomes advantageous and gives the imide preferentially. A relatively weak primary amine such as aniline requires rather drastic conditions for the first lactone-opening; this in turn results in the formation of the imide by the successive intramolecular second lactone-opening. The imide was also obtained by the intramolecular substitution of *syn* **3a** at higher temperature (>144 °C)[6] with the release of the repulsion.

Similar intramolecular substitution was observed in the attempts to isolate *syn* diester. The quantitative formation of *syn* **3i** *in situ* was confirmed by spectroscopy, but, *syn* **3i** was always contaminated with *syn* **1** by re-lactonization on recrystallization.

The lactone-opening reaction of *syn* **1** with dibutylamine did not proceed at temperatures below 130 °C, whereas the reaction took place at 150 °C to give *N,N,N',N'*-tetrabutyl-*c*-3,*c*-4-bis(2-hydroxyphenyl)-*r*-1,*t*-2-cyclobutanedicarboxamide (*syn'* **3c**) in a high yield with quantitative epimerization, which is similar to Anet's observation in the synthesis of dimethyl *c*-3,*c*-4-bis(2-methoxyphenyl)-*r*-1,*t*-2-cyclobutanedicarboxylate.[1] In the case of secondary amine, the epimerization would occur instead of the imide formation to dissolve the large repulsion between the four substituents situated on the same side of the cyclobutane ring.

Table 1. Yields, elemental analyses, and physical data for lactone-opened derivatives of *anti* **1** and *syn* **1**

a) Yields are listed for the crude substances which are spectrometrically identical with recrystallized ones. Yields in parentheses are those of substances purified by recrystallization. b) The cyclobutane ring protons appeared as two pseudo doublets of A,A',B,B' systems. The peaks of aromatic protons and hydroxy protons of *o*-hydroxyphenyl groups appeared at δ=6.0—7.6(m) and at δ=8.83—9.44(s), respectively. All other peaks appeared at reasonable positions. c) 4H(m) of ABCD system. d) Two methylene protons of ethyl group were overlapped. e) Six methylene protons of butyl groups were overlapped.

Experimental

^{1}H-NMR spectra were recorded on a HITACHI R-40 spectrometer (90 MHz). IR spectra were measured on JASCO IRA-1 spectrophotometer. Both *anti* and *syn* **1** were synthesized by the method of Krauch *et al.*[2]

Synthesis of the anti *Diamides (*anti ***3a—g***).* A solution of *anti* **1** (1.00 g, 3.42 mmol) and 4 equimolar amounts of aliphatic amine in dioxane (10 ml) was heated at 60 °C for 2 h, followed by cooling to room temperature. The white precipitates were collected by filtration, washed with dioxane, and dried *in vacuo* (recrystallized from acetone). When aromatic amine was employed, the reaction time was prolonged to 4 h.

Synthesis of the anti *Esters (*anti ***3h, i***; ***2i***).* A suspension of *anti* **1** (5.0 g, 17.1 mmol) in an alcohol (160 ml) was heated at refluxing temperature for 12 h. The solution was concentrated and dried *in vacuo* (recrystallized from corresponding alcohol). In the reaction of *anti* **1** with ethanol, evaporation of the solvent just after the solution became clear (about 10 min) resulted in the isolation of *anti* **2i** (recrystallized from benzene).

Synthesis of the anti *Monolactone/Monoamides (*anti ***2a,g***).* A solution of *anti* **1** (1.00 g, 3.42 mmol) and an equimolar amount of an amine in dioxane (150 ml) was heated at 60 °C for 2—4 h. After filtration of powdery white precipitates, the filtrate was evaporated and dried *in vacuo*. The crude product of monolactone/monoamide, containing a small amount of *anti* **1**, was recrystallized from acetone.

Synthesis of syn ***3a***. To butylamine (16.4 g, 0.22 mol), cooled at −25 °C, was added *syn* **1** (2.20 g, 7.53 mmol) with vigorous stirring. Then the reaction temperature was gradually raised to room temperature over a period of 2 h and the solution was stirred for additional 40 min. The solution was poured into petroleum ether (1000 ml) to yield white precipitates. The precipitates were collected by filtration, washed with petroleum ether, and dried *in vacuo* (recrystallized from acetone).

Synthesis of syn ***4a***. A suspension of *syn* **1** (5.9 g, 20 mmol) in methanol (200 ml) containing butylamine (10.0 g, 0.14 mol) was heated at refluxing temperature for 2 h. After evaporation of the solution, the residue was dissolved into 1 M aqueous KOH (50 ml), then the solution was acidified with 2 M HCl (30 ml) to yield white precipitates, which were collected by filtration, washed thoroughly with water, and dried *in vacuo* (recrystallized from acetone).

Synthesis of syn ***4g***. A mixture of *syn* **1** (2.0 g, 6.8 mmol) and aniline (20.4 g, 0.22 mol) was stirred at room temperature for 24 h. The solution was poured into ice-cooled 1 M HCl (200 ml). The resulting precipitates were collected by filtration, washed thoroughly with water, and dried *in vacuo* (recrystallized from acetone).

Synthesis of syn' ***3c***. A mixture of *syn* **1** (1.00 g, 3.42 mmol) and dibutylamine (77.0 g, 0.60 mol) was heated at 150 °C for 3.5 h. The solution was evaporated and dried *in vacuo* (recrystallized from acetone).

Vibrational Spectra of Organic Conductors. Charge Transfer Salts of TTF with Substituted *p*-Benzoquinones

Susumu MATSUZAKI, Toshiharu MORIYAMA, Mitsukazu ONOMICHI,† and Koichi TOYODA*
Department of Chemistry, Faculty of Science, Kumamoto University, Kumamoto 860
†*College of Medical Technology, Kumamoto University, Kumamoto 860*
(Received May 17, 1982)

Charge transfer salts of tetrathiafulvalen (TTF) with five substituted *p*-benzoquinones (fluoranil, chloranil, bromanil, iodanil, and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone) were prepared by diffusion and cooling methods. IR, Raman, and electronic spectra of these salts measured at room temperature showed that all except fluoranil salt formed two crystal phases, *i.e.*, the diffusion and the cooling methods gave a mixed-valent and a monovalent ionic phases respectively. The degrees of charge transfer (ρ) of the mixed-valent salts were estimated from the Raman frequencies of a_g ν_3 of TTF, and nearly equal values (*ca.* 0.7) were obtained for all of them.

Since the discovery of the unusual electrical properties of TTF-TCNQ,[1] a vast amount of research has been carried out to understand the properties of the organic conductors. The research has shown that the organic charge transfer salts must satisfy two essential requirements in order to exhibit high electrical conductivity:[2] (1) The component molecules form segregated stacks of donors and acceptors; (2) charge transfer from the donor to the acceptor is incomplete, *i.e.*, $\rho<1$. At present, it is difficult to control the first requirement, whereas conditions for the satisfaction of the second requirement have been discussed considerably;[3] *i.e.*, incomplete charge transfer occurs when the difference between the ionization potential of the donor and the electron affinity of the acceptor is comparable to the crystal Madelung energy.

Determination of ρ is important to understand the conduction mechanism in organic conductors and various methods have been used to estimate the value.[4] Recently we found that the plot of Raman frequencies *vs.* ρ is linear in the case of TCNQ salts[5] and TTF salts,[6] and demonstrated that Raman spectroscopy is a useful and reliable means to estimate ρ of organic conductors.

In this work, many charge transfer salts of TTF with substituted *p*-benzoquinones are prepared by use of two different methods. The vibrational and electronic spectra of the salts are compared with each other, and the degrees of charge transfer of the mixed-valent salts are estimated from the Raman frequencies.

Experimental

TTF was synthesized by the method of Wudl *et al.*,[7] and recrystallized from hexane–cyclohexane, and sublimed twice *in vacuo*. The product was identified by spectral methods (IR and Raman) and elemental analysis. Fluoranil (tetrafluoro-*p*-benzoquinone), chloranil (tetrachloro-*p*-benzoquinone), bromanil (tetrabromo-*p*-benzoquinone), and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone were all obtained commercially, and recrystallized twice from benzene and sublimed *in vacuo*: These acceptors are abbreviated to FA, CA, BA, and DDQ respectively. Iodanil (tetraiodo-*p*-benzoquinone) was synthesized by the method of Torrey and Hunter,[8] and recrystallized several times from ethyl acetate: This acceptor is abbreviated to IA.

Charge transfer salts of TTF with the substituted *p*-benzoquinones were prepared by the following two methods: (1) Diffusion method in acetonitrile (same as reported in the literature)[9] and (2) cooling method (mixing of the stoichiometric amounts of the components in hot acetonitrile and cooling of the solution). Preparation by the diffusion method was performed at 34 ± 1 °C in evacuated H-tubes which were placed in a thermostated air bath of our own making and the periods of preparation were typically *ca.* 3 months. The composition of the salts was determined by elemental analysis.

Raman spectra of the powder samples were recorded (in the back scattering geometry) on a JASCO R-800 spectrometer equipped with NEC GLG-3200 Ar^+ and GLG-108 He–Ne lasers as exciting light sources. In order to avoid thermal decomposition of the sample, exciting laser light was focused by a cylindrical lens and sample-rotating technique was used. IR and electronic absorption spectra of the powder samples dispersed in KBr were recorded on a JASCO DS-403G IR spectrometer and a Hitachi 200-20 or a(EPS-3T) spectrophotometer, respectively. Electrical conductivity was measured bythe two probe method in an evacuated bell jar by use of a Takeda Riken TR-8561 electrometer.

Results and Discussion

TTF–FA, TTF–CA, and TTF–BA. Recently, Torrance *et al.*[10] reported that TTF formed mixed-valent crystals of good conductivity with fluoranil, whereas it formed monovalent poor conductors with chloranil and bromanil. In this work, we also have obtained a mixed-valent salt for TTF–FA by both methods, and the IR and Raman spectra are shown in Fig. 1. This salt was fairly unstable and the reproducibility of the spectra was not so good; nevertheless, the

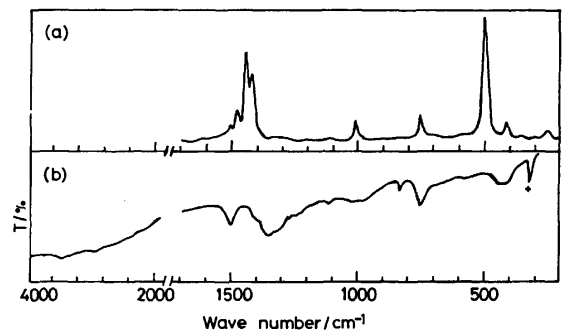

Fig. 1. Vibrational spectra of TTF-FA. (a) Raman and (b) IR; +, fault signal which is due to the exchange of gratings of the instrument.

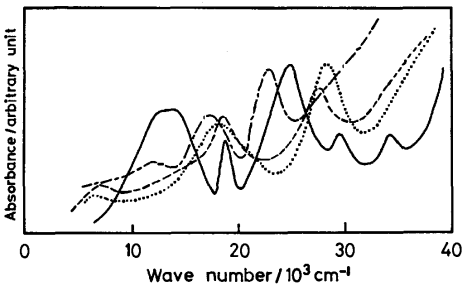

Fig. 2. Electronic spectra of TTF–CA and TTF–BA. TTF-CA(I), ------; TTF-CA(II), ——; TTF-BA(I), ·····; TTF-BA(II), —·—.

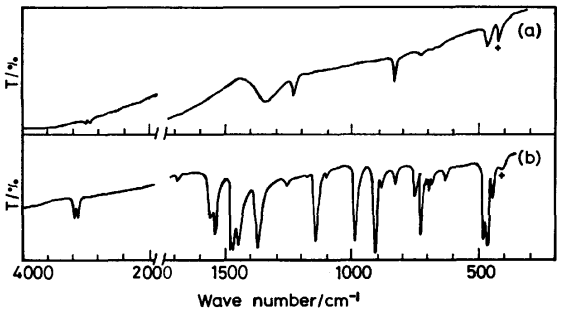

Fig. 3. IR spectra of TTF–CA. (a) TTF-CA(I) and (b) TTF-CA(II); +, fault signal which is due to the exchange of gratings of the instrument.

IR spectrum clearly shows the mixed-valency (see the discussion for TTF–CA). The Raman lines at 1443 cm^{-1} and 1418 cm^{-1} will be assigned to a_g ν_3 modes of mixed-valent and monovalent TTF cations respectively.[11] The result shows that the sample is a mixture of two salts.[12]

On the other hand, for TTF-CA and TTF-BA, we have found that the salts give a monovalent or a mixed-valent phase depending on the method of preparation.[13] The salts prepared by the diffusion method and the cooling method are represented by the symbols (I) and (II), respectively, throughout this section. Both TTF–CA(I) and TTF-CA(II) were obtained as black needles. Electronic spectra of the two salts are shown in Fig. 2. Absorption bands in the higher frequency region are assigned to LE transitions of TTF^+, which are 18500 and 27500 cm^{-1} for the salt (I), and 18700, 24700, and 29000 cm^{-1} for the salt (II).[14] Thus the result shows that both the salts contain TTF^+. In the spectrum of the salt (I), an absorption band appears at *ca.* 6700 cm^{-1} tailing to the middle infrared region (Fig. 3). It is known that mixed-valent TTF salts exhibit a low frequency band around 5000 cm^{-1} which is assigned to the mixed-valent CT transition between the neutral molecule (TTF^0) and the cation radical (TTF^+).[14,15] The band at 6700 cm^{-1} will be assigned to this CT transition, and appearance of the band strongly suggests that TTF–CA(I) is a mixed-valent salt. On the other hand, the salt (II) shows no such a low frequency band but a broad absorption band of an unusual profile at 13500 cm^{-1}. This feature will be attributed to an overlap of the two dimer-type CT bands of $(TTF^+)_2$ and $(CA^-)_2$.[15,16] The result suggests that TTF–CA(II) is a monovalent salt of dimeric structure. The salt probably corresponds to the monovalent salt reported in the literature.[10]

In the IR spectrum of TTF–CA(I), a characteristic broad band appears at 1347 cm^{-1}, whereas the corresponding band is fairly sharp in the salt (II) (Fig. 3). The component molecules have no IR-active modes in this region, and the band will be attributed to the IR-activation of a_g modes by the electron-vibration mechanism. Bozio *et al.*[11] reported that $(TTF^+)_2$ exhibits a strong IR band at 1360 cm^{-1} in DMSO solution, and assigned it to a_g ν_3 of TTF^+. Normal vibrations of the component molecules couple to each other in the dimer unit, and new normal vibrations of the dimer are produced. In the case of a_g modes, in-phase coupling modes are totally symmetric and Raman-active, whereas out-of-phase coupling modes are ungerade and IR-active. The latter promotes electron oscillation between the component radicals of the dimer, and has strong IR intensity and a lowered frequency; on the other hand the former causes no vibronic effect and the frequency is almost equal to that of the component radical.[17] Therefore, IR frequency of the out-of-phase coupling mode is usually several tens of wave numbers lower than the corresponding Raman frequency of the in-phase coupling mode. Vibronically allowed a_g modes of CA^- are also expected to be observed in the spectrum of the salt (II) because the dimerization of CA^- is suggested from the electronic spectrum as mentioned above. A strong band at 987 cm^{-1} probably arises from such an activation mechanism and will be assigned to the out-of-phase coupling mode of a_g ν_3 of CA^- because the component molecules have no IR-active fundamentals in this region and $(CA^-)_2$ was reported to show a strong IR band at 1008 cm^{-1} in potassium salt of chloranil which was assigned to this mode.[18,19]

Electronic spectra (Fig. 2) and IR spectra of TTF–BA showed characteristic features similar to those of TTF–CA. Thus it is concluded also in this case that TTF–BA(I) and TTF–BA(II) are a mixed-valent and a monovalent salts respectively. Observed IR frequencies and the tentative assignment of TTF–BA are given in Table 1 together with those of TTF–CA.

Raman spectra of TTF–CA are shown in Fig. 4. Almost all the Raman lines observed are attributable to a_g modes of TTF^+ (Table 2). This result probably arises from stronger resonance enhancement of the

a) 514.5 nm excitation. b) The assignment follows Bozio *et al.* (Ref. 11) and Girlando *et al.* (Ref. 19).

Raman lines of TTF^+ than those of CA^- with 514.5 nm excitation. We have already reported[6] that the frequency of TTF a_g ν_3 is very sensitive to the formal charge and can be a suitable measure of ρ.. This mode is observed at 1448 cm^{-1} in TTF-CA(I). The frequency is located between TTF^0 (1518 cm^{-1}) and the monovalent salt (1421 cm^{-1}), and clearly shows the mixed-valency of the salt. The salt (I) was unstable under strong laser-irradiation even by use of the cylindrical lens and the sample-rotating technique, and showed a time-dependence of the spectrum similar to that of mixed-valent TTF halides reported previously.[6] The spectrum shown in Fig. 4 was, therefore, measured under the minimized laser power (<20 mW). Kinetic study on the dependence will be reported elsewhere.[20] TTF-BA(I) and TTF-BA(II) gave the Raman spectra

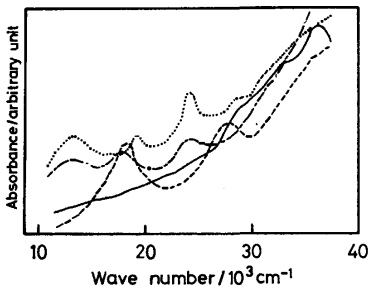

Fig. 5. Electronic spectra of TTF–IA and TTF–DDQ. TTF-IA(I), ------; TTF-IA(II), ——; TTF-DDQ(I), ·····; TTF-DDQ(II), —·—.

similar to those of TTF–CA(I) and TTF-CA(II) respectively. The frequencies and tentative assignment of the salts are given in Table 2 together with those of TTF–CA.

Electrical conductivity of TTF–CA(I) was measured to be $1\times10^{-2}\ \Omega^{-1}\ cm^{-1}$. The shape of the crystals was not so good and the maximum values were taken for the dimensions, so that the conductivity corresponds to the minimum value. This value is two to three orders of magnitude lower than those of the mixed-valent TMTTF–CA and TMTTF–BA reported by Torrance, *et al.*,[10] probably due to imperfections of the crystals in this work. Nevertheless, the value is large enough to demonstrate the mixed-valency of TTF–CA(I).

Stoichiometries of TTF-CA(II) and TTF–BA(II) were found to be 1 : 1 by the elemental analyses, but the values of the salts (I) varied from 2 : 1 to 1 : 2. This variation probably arises from mixing of the component molecules with the crystals of the salts, because it was observed by an optical microscope that yellow areas scattered on the black surface of the crystals. Thus the compositions of the salt (I) are unknown at present. It has been reported that TMTTF forms the mixed-valent salts of 1 : 1 stoichiometry with chloranil and bromanil,[10] and it seems natural to consider the 1 : 1 stoichiometry also in the present case.

TTF–IA. TTF–IA(I) and TTF–IA(II) were obtained as black powder and black needles respectively. Electronic spectra of the two salts are much different from one another (Fig. 5). TTF-IA(II) shows no absorption bands around 18000 cm^{-1}, so that it contains no TTF^+ species; furthermore, IR and Raman spectra (Figs. 6 and 7) of the salt are reasonably explained as an overlapp of those of TTF^0 and IA^0 (Tables 3 and 4). The result shows that the salt (II) is a non-ionic CT complex and will be an analog of the neutral mixed-stack crystals of TTF–CA and TTF–BA reported by Mayerle *et al.*[21] On the other hand, the absorption bands of TTF^+ appear in the electronic spectrum of TTF-IA(I) (Fig. 5); furthermore, the IR spectrum shows apparent similarity to that of the mixed-valent TTF–CA(I) (Figs. 6 and 3). The Raman spectrum also shows the mixed-valent TTF $a_g\ \nu_3$ line at 1448 cm^{-1} (Fig. 7). It is, therefore, evident that TTF–IA(I) is a mixed-valent salt.[22]

No vibrational assignment has been reported for the Raman-active fundamentals, and we have assigned them by referring to the assignment for chloranil and bromanil by Girlando *et al.*[19] As given in Table 4, main Raman lines are reasonably assigned on the basis of the rule that the frequency must be lowered because of the larger atomic weight of iodine than chlorine and bromine. Assignment of the IR-active vibrations has been reported by Iida,[23] and we use the result in this study.

Several vibrational features show fairly large frequency shifts (20—40 cm^{-1}) by the complex formation, *e.g.*, ν_1 and ν_{10} of iodanil, and ν_3 of TTF (the frequency of TTF^0 is 1518 cm^{-1}). The result shows the fairly strong CT interaction operating between TTF and iodanil in this non-ionic CT complex. The degree of charge transfer is estimated to be 0.3 from the ν_3 frequency of TTF assuming that the linear relation between the frequency and ρ is valid for mixed-stack complexes.

IR spectrum of this non-ionic CT complex is influenced by the vibronic effect as in the radical salts. A

strong IR band at 1487 cm^{-1} has the same frequency as the Raman line of TTF a_g ν_3 (Tables 3 and 4) and will be assigned to this mode. In the case of mixed-stack CT complexes, the normal vibration of totally symmetric modes itself promotes the electron oscillation between the donor and the acceptor. Therefore, the IR frequency is equal to the Raman frequency, in contrast to the case of the segregated-stack radical salts of dimeric structure where the Raman and IR intensities are induced by the in-phase and out-of-phase coupling modes respectively. It may also be possible to assign the band at 1487 cm^{-1} to b_{2u} ν_{18} of iodanil. However, it is hard to accept from the standpoint of the frequency shift. Ion radical of iodanil has not yet been prepared and the frequency shift by full charge transfer ($\rho=1$) is unknown, but the shifts in chloranil and bromanil were reported to be 27 and 20 cm^{-1} respectively.[19] Therefore, it is not reasonable to expect that the shift of 33 cm^{-1} occurs in the present case of the partial charge transfer ($\rho=0.3$).

TTF–DDQ. Electron affinities of all the tetrahalo-*p*-benzoquinones are practically equal to each other; on the other hand, DDQ has the fairly larger value than the others.[24] Therefore, formation of the mixed-valent phase was considered to be difficult. The cooling method gave the monovalent salt, TTF–DDQ(II), as evident from the spectra (Figs. 5, 8, and 9). Mayerle and Torrance[25] reported the formation of single crystals of the monovalent salt by the diffusion method. The samples obtained by this method were mostly the monovalent salt also in this work; nevertheless, a few samples, TTF–DDQ(I),[26] showed the characteristic IR

a) 514.5 nm excitation. b) This line is probably attributable to a monovalent TTF^+ contained as an impurity.

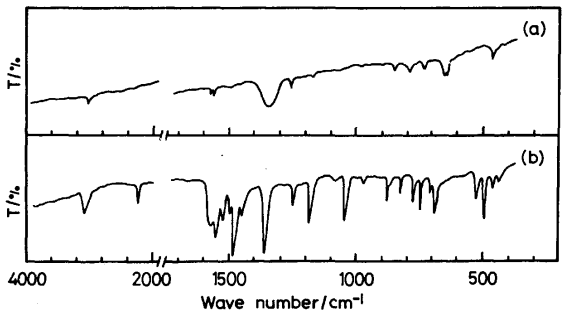

Fig. 8. IR spectra of TTF–DDQ. (a) TTF–DDQ(I) and (b) TTF–DDQ(II).

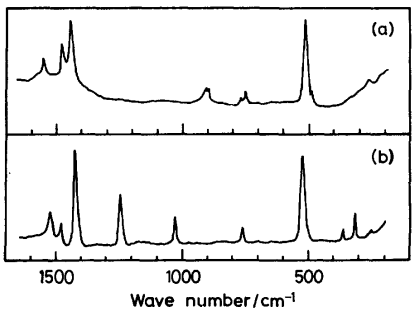

Fig. 9. Raman spectra of TTF–DDQ. (a) TTF–DDQ(I) and (b) TTF–DDQ(II); 514.5 nm excitation.

and Raman spectra of the mixed-valent salt (Figs. 8 and 9). Raman lines at 1423 and 1453 cm^{-1} are assigned to a_g ν_3 modes of the monovalent and the mixed-valent TTF cations respectively. Relative intensity of the two lines shows that the fraction of the mixed-valent salt is small, *i.e.*, the salt is not so easy to be formed. The result is consistent with the large electron affinity of DDQ.

Estimation of ρ. In the case of TTF salts, it has been shown that the ν_3 mode gives the best result for the estimation of the degree of charge transfer (ρ).[6] In this investigation, therefore, the values of ρ of the mixed-valent salts were estimated from the ν_3 frequencies by use of the calibration curve obtained previously. The

values of ρ thus obtained are: 0.75 (TTF–FA); 0.71 (TTF–CA); 0.72 (TTF–BA); 0.71 (TTF–IA); and 0.66 (TTF–DDQ). These values inherently contain uncertainty because of the crystal field effect on the frequency.[5] The uncertainty is estimated to be 0.1 for TTF ν_3 from the frequency variation of many monovalent salts of TTF. Therefore, it should be considered that the mixed-valent salts in this work have the values of ρ which are practically equal to each other.[27] The degree of charge transfer is determined by the two quantities, $(I-A)$ and E_M, in the mixed-valent salt of the segregated structure,[2,3] where $(I-A)$ is the difference between the ionization potential (I) of the donor and the electron affinity (A) of the acceptor, and E_M is the crystal Madelung energy. If $(I-A)>E_M$, neutral ground state is more stable in energy and, on the contrary, ionic ground state is favorable if $(I-A)<E_M$. The mixed-valent state will be realized when $(I-A)\simeq E_M$. The tetrahalo-*p*-benzoquinones have the electron affinities which are almost equal to each other, and $(I-A)$ is practically constant in all the mixed-valent salts except the DDQ salt. The result of the practically equal values of ρ, therefore, suggests that E_M is almost constant in all the salts, *i.e.*, the crystal structures are similar to each other. On the other hand, the electron affinity of DDQ is fairly large;[24] therefore, it may be difficult to explain the value of ρ from this standpoint. X-ray structural analyses of these salts are necessary for further discussion.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 56470009 from the Ministry of Education, Science and Culture.

NMR Lanthanoid-probe Analyses of Conformational Properties of 8,2′-*S*-Cycloadenosine 3′-Monophosphate in Aqueous Solution

Shigeyuki Yokoyama, Tetsuya Oida, Seiichi Uesugi,† Morio Ikehara,† and Tatsuo Miyazawa*

Department of Biophysics and Biochemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received May 21, 1982)

The advanced method of NMR lanthanoid-probe analyses was used for studying the molecular conformations of 8,2′-anhydro-8-thio-9-β-D-arabinofuranosyladenine (8,2′-*S*-cycloadenosine) 3′-monophosphate in aqueous solution. From the observed ratios of Pr(III)-induced shifts, Gd(III)-enhanced relaxation rates as well as vicinal spin-coupling constants, the most probable values (and standard deviations) of the fractional populations of the local conformations for the C5′–C4′ bond, sugar ring, C3′–O3′ bond, and O3′–P bond and the internal rotation angles of the two forms about the C3′–O3′ bond were determined by the program COFLEM. The internal rotation equilibrium about the C3′–O3′ bond was found to be interrelated with the puckering of the sugar ring. The advanced lanthanoid probe method is thus useful for the analyses of the conformational characteristics of cyclonucleotides as well as of unmodified nucleotides in aqueous solution.

The conformational properties of modified nucleotide units have been found to be related with the biological functions of transfer ribonucleic acids. For example, 2-thiouridine derivatives contribute to the correct codon recognition,[1] and to the thermostability[2] through the conformational characteristics that the C3′-endo form is much more stable than the C2′-endo form. Previously, NMR chemical shifts, spin-coupling constants, nuclear relaxation rates, and nuclear Overhauser effect have been used for elucidating local conformations.[3] However, these NMR data are not sufficient for studying overall conformations of nucleotide molecules. For such studies on flexible molecules, the lanthanoid probe analyses have been successfully utilized.[4] Recently, we have developed an advanced computer program (COFLEM) for the lanthanoid probe analysis;[5] the overall conformer mixture of flexible molecule is now treated as a combination of local conformational equilibria.

8,2′-Anhydro-8-thio-9-β-D-arabinofuranosyladenine (8,2′-*S*-cycloadenosine, to be abbreviated as A^s) (Fig. 1) is a cyclic nucleoside with the fixed internal rotation angle ($\chi \approx 120°$) about the glycosidic bond.[6] This χ value of A^s is in the high-anti region, as compared with the anti χ value ($\approx 0°$) of adenosine (A). By the analyses of the UV and CD spectra, the molecules of dinucleoside monophosphate (A^spA^s) and oligonucleotides $(pA^s)_n$ [$n=2$—10] have been found to take left-handed helical conformations with stacked bases.[6] For A^spA^s in aqueous solution, the proton NMR spectra have been analyzed.[7] However, as an aid for studying the conformation of A^spA^s in solution, it is important to analyze the conformational feature of the modified nucleoside A^s, which will be different from that of A. Accordingly, in the present study, the advanced lanthanoid probe analysis has been made for elucidating the conformational characteristics of the sugar-phosphate moiety of 8,2′-*S*-cycloadenosine 3′-monophosphate (A^sp) in aqueous solution.

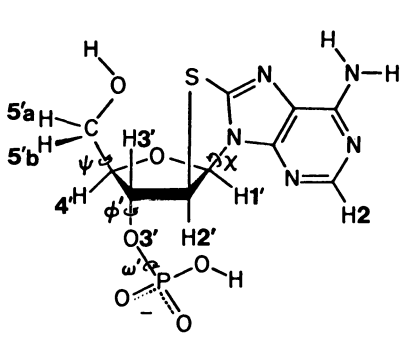

Fig. 1. Structure of A^sp.

Experimental

Materials. The sample of A^sp was synthesized as reported previously.[8] The nitrates of Pr(III) and Gd(III) of higher than 99.9% purity were obtained from Nakarai Chemical Co. Lanthanum oxide of higher than 99.99% purity was purchased from Nakarai Chemical Co. and was dissolved in nitric acid to obtain lanthanum nitrate.

Sample Solutions. For the measurements of lanthanoid-induced proton shift-ratios of A^sp, the successive dilution method[9,10] was used. The initial concentrations of A^sp and Pr(III) ion were 50 mM and 45 mM, respectively, in ^2H_2O solution at pH 1.7 (direct pH meter reading). Diamagnetic La(III) ion was used for the correction for the complex formation shifts. The initial solution was diluted stepwise with ^2H_2O, so that the sample solution was lowered from 50 mM to 5 mM without changing the molar ratio of A^sp/Pr(III) or A^sp/La(III). For the measurements of Gd(III)-enhanced proton relaxation rates of A^sp in ^2H_2O solution (A^sp 60 mM, pH 1.7), the concentration of Gd(III) ion was raised stepwise, by 5 μM, from 0 to 20 μM. The ^{13}C NMR spectrum of A^sp was measured in ^2H_2O solution (85 mM) at pH 2.0.

NMR Measurements. NMR spectra were measured with a Bruker WH270 spectrometer operating at 270 MHz for ^1H and 67.9 MHz for ^{13}C. The probe temperature was kept at 23 °C. Spin-lattice relaxation rates were obtained by a standard 180°-τ-90° pulse sequence.

Data Analyses. The computer program COFLEM developed previously[5] was used on the M-200H system at the Computer Center of the University of Tokyo.

Conformational Analysis

Observed NMR Data. The observed ratios of Pr(III)-induced shifts and Gd(III)-enhanced relaxation

TABLE 1. RATIOS OF Pr(III)-INDUCED SHIFTS AND Gd(III)-ENHANCED RELAXATION RATES, AND VICINAL COUPLING CONSTANTS OF A^sp

	Shift ratio		Relax. ratio	
	Obsd	Calcd	Obsd	Calcd
H1′	0.39	0.44	0.30	0.21
H2′	1.20	1.29	1.58	1.60
H3′	2.17	1.82	2.50	2.56
H4′	1.00	1.00	1.00	1.00
H5′a	0.28	0.38	0.60	0.59
H5′b	0.35	0.42	0.70	0.70

C4′–P	6.7	6.6

rates of A^sp are listed in Table 1. The ^1H resonances of A^sp in ^2H_2O solution (pH 2) are broadened on addition of a large excess of $LaCl_3$ but the ^1H–^1H and ^1H–^{31}P vicinal coupling constants are unaffected within the experimental uncertainty of 0.3 Hz. Therefore, the ^1H–^1H, ^1H–^{31}P, and ^{13}C–^{31}P coupling constants of free A^sp (Table 1) may be used for conformation analyses.

Local Conformations. The ribose ring and deoxyribose ring of unmodified nucleosides have been known to take two puckering forms, namely the N (C3′-endo) form or the S (C2′-endo) form. However, for 8,2′-*S*-cyclonucleosides, the N and S forms of the sugar ring are probably distorted from those of unmodified nucleosides, because the C2′ atom of 8,2′-*S*-cyclonucleosides is covalently linked, through a sulfur atom, to the C8 atom of the purine base. In fact, in the crystal of 8,2′-*S*-cycloinosinyl-(3′,5′)-8,2′-*S*-cycloadenosine (I^spA^s) hexahydrate,[11] the sugar ring of I^s nucleoside is slightly distorted from the C2′-endo form to the C4′-endo form. On the other hand, the sugar-ring conformation of A^s nucleoside in I^spA^s is nearly the same as the C3′-endo form. Accordingly, in the present conformation analysis of A^sp in aqueous solution, the C3′-endo (N) form and C4′-endo (S) form were used as the two types of sugar-ring conformations of A^sp. For this sugar ring, there is only one population parameter since the sum of the fractional populations of N and S forms is equal to unity. As for the internal rotation about the C3′–O3′ bond of A^sp, the two rotamers (G^+ and G^-)[5] were used (Fig. 2), and accordingly there is only one population parameter for this flexible site. The ϕ' [C4′–C3′–O3′–P] angles of these two rotamers of A^sp were taken as adjustable structure parameters in the present study. The three-rotamer equilibria were adopted for the internal rotation about the C5′–C4′ bond (gg, gt, and tg) and the O3′–P bond (g^+, t, and g^-) (see Fig. 2 of Ref. 5).

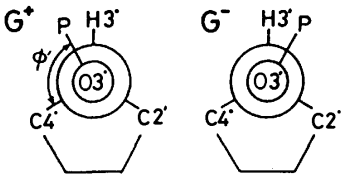

Fig. 2. Two rotamers about the C3′–O3′ bond of A^sp.

For each of these bonds, there are two population parameters since the sum of the fractional populations of three rotamers is equal to unity. The lanthanoid ion was set on the bisector of monoanionic OPO angle, 0.3 nm away from the phosphorus atom as in the case of uridine 3′-monophosphate.[5]

Interrelations among Local Conformational Equilibria. As a prominent feature of the advanced lanthanoid probe method of conformation analyses,[5] the interrelations among local conformational equilibria of flexible sites may be elucidated quantitatively. For the example of uridine 3′-monophosphate, the fractional populations of the G^+ and G^- forms have been determined for each of the C3′-endo form and C2′-endo form.[5]

In the present conformation analysis on A^sp in aqueous solution, four schemes of interdependency were examined among local conformational equilibria of three flexible sites, namely C5′–C4′ bond, sugar ring, and C3′–O3′ bond. The rotamer equilibrium about the O3′–P bond was set to be independent of the conformational equilibria of the other three flexible sites, as found previously for uridine 3′-monophosphate.[5]

Conformation of A^sp in Solution. By the use of the program COFLEM,[5] the most probable values (and standard deviations) of population parameters and structure parameters were obtained, so that the calculated values of the ratios of lanthanoid-induced shifts and relaxation rates as well as spin-coupling constants agreed best with the observed data (Table 1). There are six shift ratios, six relaxation-rate ratios and eight coupling constants and thus are a total of twenty observed data for the conformation analysis of A^sp in aqueous solution. The quality of the fit between the calculated values and observed data was judged by the agreement factor (R), as described previously.[5]

In Scheme 1, the local conformation equilibria are all independent of one another, and there are eight adjustable parameters, including six population parameters and two structure parameters. Even with this small number of parameters, the total of twenty observed data were reproduced with the agreement factor of R= 9.2%. On the introduction of the interdependency between the puckering of sugar ring and the internal rotation about the C5′–C4′ bond (Scheme 2), the number of adjustable parameters was increased from eight to ten and the agreement factor was slightly improved to 8.6%. On the other hand, the introduction of the interdependency between the ring-puckering and the internal rotation about the C3′–O3′ bond (Scheme 3) increased the number of parameters only by one but significantly improved the agreement factor to 8.3%. With this scheme, the calculated values of shifts ratios, relaxation-rate ratios and coupling con-

stants agreed quite well with the observed data (Table 1). However, when the internal-rotation equilibria about the C5′–C4′ bond and the C3′–O3′ bond were both assumed to depend upon the ring puckering (Scheme 4 with eleven parameters), the agreement factor (R=8.2%) was nearly the same as that of Scheme 3 and the standard deviations of adjustable parameters were much larger than those for Scheme 2. This indicates that, in Scheme 4, there are actually too many parameters as compared with the available set of observed data even though the number of parameters is much smaller than the nominal number of observed data. Thus, in the present study, Scheme 3 was adopted as the most reliable model and the most probable values (and standard deviations) of the population parameters and structure parameters are shown in Fig. 3.

It may be remarked here that the structure of the C1′–C2′–C3′ moiety of A^{s}p is different from that of ribonucleotides. Because of 8,2′-*S*-cyclization, the N–C1′–C2′ bond angle of A^{s}p is decreased by about 10° and the spin-coupling constants of the C1′–C2′–C3′ moiety are possibly affected. In fact, for the H1′–H2′ and H2′–H3′ coupling constants, the deviations of the calculated values from the experimental ones are larger than those for other coupling constants (Table 1). Nevertheless, the conformational analysis of the A^{s}p has been successfully carried out by the use of lanthanoid-induced shifts and relaxations as well as various spin coupling constants.

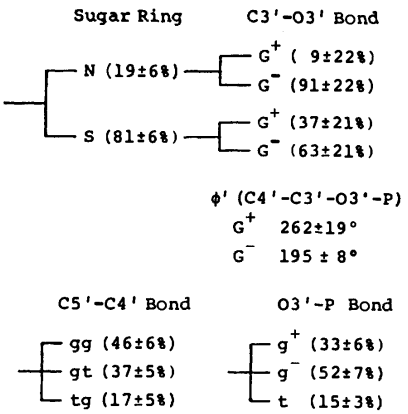

Fig. 3. Molecular conformation and conformational equilibrium of A^{s}p in aqueous solution (Scheme 3).

Discussion

Recently, the crystal structure of A^{s}p was analyzed, and crystallographically independent two molecules of A^{s}p were both found to take the S (C4′-endo) form of the sugar ring.[12] However, in the present study, the conformational equilibria of A^{s}p in aqueous solution were quantitatively analyzed by the advanced lanthanoid probe method.[5] Thus, the fractional populations of the S (C4′-endo) form and N (C3′-endo) form of the sugar ring were determined to be 81±6% and 19±6%, respectively, in solution (Fig. 3). This is consistent with the observation that the molecules of 8,2′-cyclonucleotides mostly take the S form in crystal.[12]

The interdependency of the sugar-ring puckering and the internal rotation about the C3′–O3′ bond of A^{s}p was experimentally established, in the present study, by the lanthanoid probe method. For the sugar ring in the N (C3′-endo) form, the fractional populations of the G$^+$ and G$^-$ forms are found to be 9±22% and 91±22%, respectively (Fig. 3); in other words, the sugar ring of the N form exclusively takes the G$^-$ form. This is probably because of strong steric repulsion between the 5′-CH_2OH group and the 3′-phosphate group in the N-G$^+$ form of the sugar-phosphate moiety. The molecular conformation of the gg-N-G$^-$-g$^-$ form is shown in Fig. 4.

For the sugar ring in the S (C4′-endo) form, the fractional populations of the G$^+$ and G$^-$ forms are found to be 37±21% and 63±21%, respectively (Fig. 3). In this case, the 5′-CH_2OH group is nearly oriented to the axial direction and there is no serious steric repulsion between the 5′-CH_2OH group and the 3′-phosphate group even in the S-G$^+$ form. By the combination of local conformational equilibria of the sugar ring and C3′–O3′ bond, the fractional populations of the S-G$^+$ form and S-G$^-$ form of A^{s}p are obtained to be about 30% and 50%, respectively, in aqueous solution. This again is consistent with the result of the X-ray

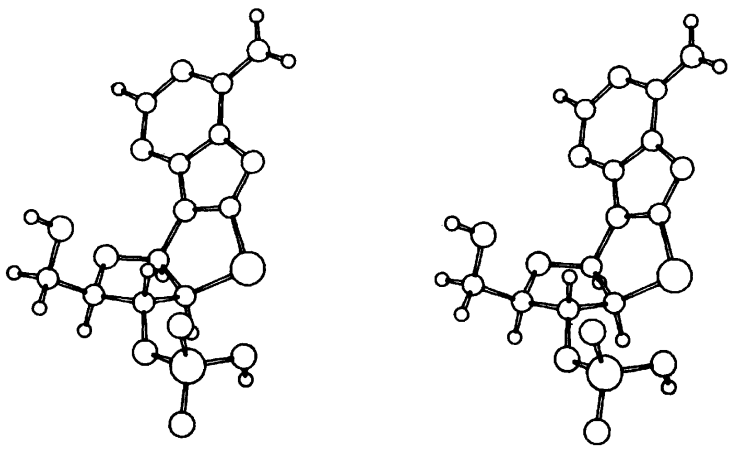

Fig. 4. The stereoscopic view of the gg-N-G$^-$-g$^-$ form drawn by the ORTEP program (Ref. 13).

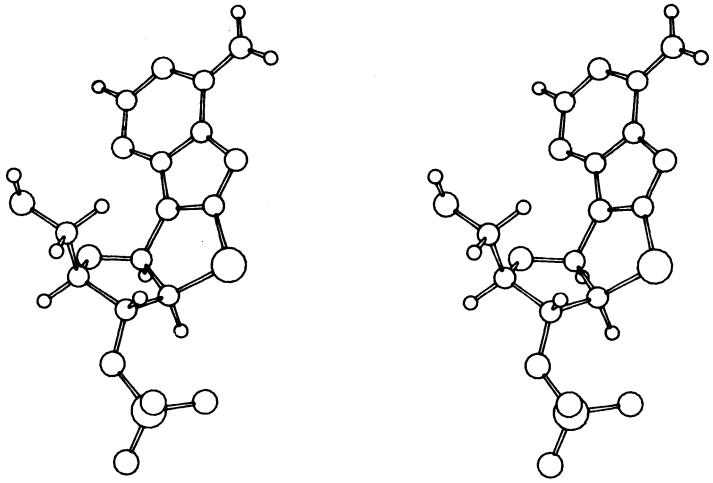

Fig. 5. The stereoscopic view of the gt-S-G$^-$-g$^-$ form drawn by the ORTEP program (Ref. 13).

analysis[12] that, in the crystal of A^{s}p, one molecule takes the S-G$^+$ form and the other takes the S-G$^-$ form. Furthermore, in the present study, the internal rotation angles (ϕ') about the C3′–O3′ bond were determined to be $262\pm19°$ and $195\pm8°$ for the G$^+$ and G$^-$ forms, respectively, in aqueous solution. Surprisingly, these values for A^{s}p in solution closely agree with the ϕ' values found in the crystal (G$^+$: 255° and G$^-$: 192°),[12] indicating the potentiality of the advanced lanthanoid probe method of conformation analyses.[5]

As for the local conformations about the C5′–C4′ bond, both of the two A^{s}p molecules in the crystal were found to take the gt form. However, in aqueous solution, the gt and gg forms are both the major conformations about the C5′–C4′ bond (Fig. 3). Previously, for the molecule of uridine 3′-monophosphate, the local conformational equilibrium about the C5′–C4′ bond was found to be interrelated with the ribose ring puckering.[5] However, in the present study on the 8,2′-cycloadenosine moiety, the conformational equilibrium about the C5′–C4′ bond was not found to depend significantly on the puckering of sugar ring. The molecular conformation of a major form (gt-S-G$^-$-g$^-$) of A^{s}p in solution is shown in Fig. 5.

Thus, the advanced lanthanoid-probe method[5] is further found to be useful for the quantitative elucidation of the molecular conformations and conformational equilibria of modified cyclonucleotides as well as of unmodified nucleotides (such as uridine 3′-monophosphate[5]). The conformational characteristics of the A^{s}p molecule in aqueous solution, as elucidated in the present study, may be utilized in the model-building analyses on the left-handed helical conformations of A^{s}p containing polynucleotides.

The authors are grateful to Professor K. Tomita of Osaka University for the atomic coordinates of I^{s}pA^s and for helpful discussions.

A Study of Local Structure Formation in Binary Solutions of 2-Butoxyethanol and Water by Rayleigh Scatterring and Raman Spectra

Nobuyuki Ito,† (the late)Tsunetake Fujiyama, and Yasuo Udagawa*

Institute for Molecular Science, Myodaiji, Okazaki 444

†*Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158*

(Received June 22, 1982)

The concentration dependence of concentration fluctuations at 21, 32, and 42 °C and of Raman spectra at 21 °C were measured for binary solutions of 2-butoxyethanol (BE) and water. The existence of the two kinds of local structures is inferred; clathrate hydrate-like structure $g[(H_2O)_{50}BE]$ and aggregate $h[(H_2O)_4BE]$. The compositions of these two structures are the same as those of the two phases into which the solution separates above the critical solution temperature. The phase separation is understood to be the end of the growth of the local structures, which already exist well below the critical solution temperature.

Molecules such as acetone and *t*-butyl alcohol (TBA) are known to form solid clathrate hydrates at low temperature.[1] The existence of clathrate hydrate-like structure of these molecules has been reported in aqueous solutions also.[2-5] In the binary solution of TBA and water, an increase in the mean-square concentration fluctuations with temperature has been observed and interpreted to be due to the growth of clathrate hydrate-like structure. This has lead us to conjecture that the growth of the aggregates with temperature eventually causes phase separation.[2] Since the TBA–water mixture does not show phase separation at atmospheric pressure, however, the relationship between the local structure formation and the phase separation has not been proved.

The binary solution of 2-butoxyethanol (BE) and water is known to show phase separation and has a lower critical solution temperature (LCST) at atmospheric pressure. In the previous work the concentration fluctuation and mutual diffusion coefficients at 21 °C were reported and the formation of clathrate hydrate-like structure was concluded.[4] In the present work, concentration fluctuations are measured at various temperatures below the LCST in order to make clear the relationship between the local structure formation and the phase separation.

The formation of local structures in BE–water mixture has been postulated because of thermodynamic studies[9] and light scattering measurements,[4] but it seems that no one has studied it in terms of molecular structure. In the formation of clathrate hydrate-like structure, flexible molecules such as BE with many internal rotational axes are expected to show conformational changes. In other words, observation of conformational changes would be evidence for such a structure. Vibrational spectroscopy is known to be sensitive to such changes. In this paper Raman spectra of BE at various concentration are investigated in relation to the conformational changes by local structure formation.

Experimental

Measurements of Concentration Fluctuations. The light scattering spectra were observed with a spectrometer designed and constructed in our laboratory.[5] The refractive indices of the sample solution were measured by means of an Abbe refractometer (Atago). All the measurements were performed at 21, 32, and 42 °C (±0.5 °C).

Measurements of Raman Spectra. The Raman spectra were obtained at 21 °C by the use of a Spex 1403 spectrometer with a Spectra Physics 165-09 argon ion laser.

Measurement of Miscibility Curve. The miscibility curve was measured by the following procedures. The samples in sealed tubes were set in a water bath and irradiated with a He–Ne laser light. By the visual observation of scattered light with raising the temperature, the phase-separation temperatures were determined. Each point recorded is the average of at least two readings. The temperature was measured by the use of a Hewlett Packard quartz thermometer (model 2804A).

Materials. 2-Butoxyethanol (BE) purchased from Tokyo Kasei Co. Ltd. was used without further purification for the measurements of light scattering and Raman spectra. BE used for the measurement of the miscibility curve was, distilled with a spinning band distiller. The purity was ascertained to be better than 99.99% by gas chromatography. Water was passed through the Mili-Q Purification System (Millipore) after distillation. The relative electric resistance of water was more than 15 MΩ cm^{-1}. Deuterium oxide purchased from E. Merck AG. was used for the measurement of Raman Spectra without further purification.

Normal Coordinate Calculations. For the assignments of Raman bands, a normal coordinate treatment was carried out with a computer program NCTB (IMS program library) and HITAC M 200Hcomputer system at the Computer Center of Institute for Molecular Science (IMS).

Results

Concentration Fluctuations and the Miscibility Curve. Figure 1 shows the miscibility curve obtained in this work along with those reported in the literatures.[6,7] It was noticed that the miscibility curve is strongly affected by the existence of impurities. This is the reason for the wide discrepancies in the literature. Accordingly special care was taken to purify the material and the curve reported here is believed to be better than those previously reported. BE and water mix at all temperatures in the concentration range of $x_{BE}<0.02$ and $x_{BE}>0.2$, but the solution separates into two phases upon raising the temperature when $0.02<x_{BE}<0.2$. The steep edges of the miscibility curve at both ends suggest that the concentrations of the two phases have tendencies to be close to 0.2 or 0.02. This implies that the solution have particularly stable structures when $x_{BE}=0.02$ an 0.2. It is found that the LCST is 49.4 °C

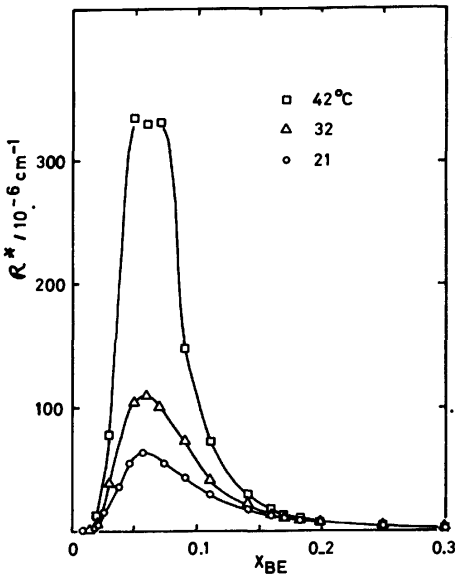

Fig. 2. Concentration dependence of Rayleigh intensities for BE–water mixtures.

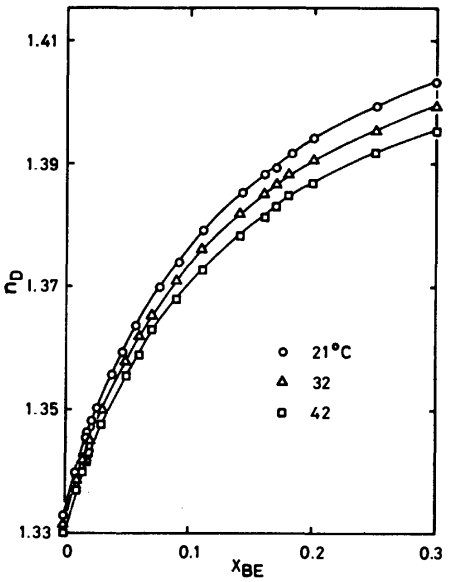

Fig. 3. Concentration dependence of the refractive index of BE–water mixtures.

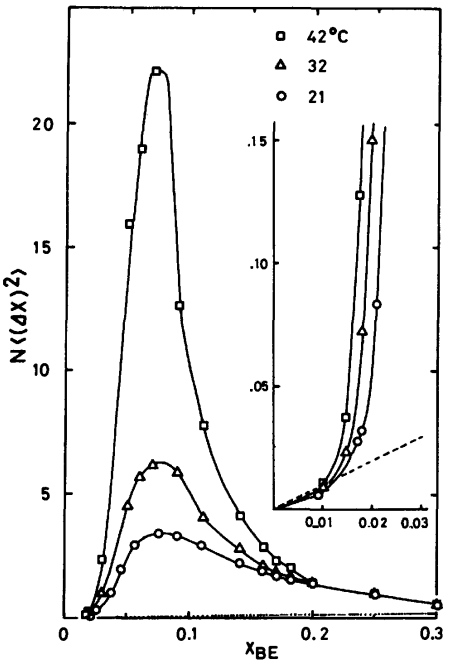

Fig. 4. Concentration dependence of the concentration fluctuation observed for BE–water mixtures. The dashed line corresponds to the concentration fluctuation expected for a n ideal binary solution.

at $x_{BE}=0.07$. As will be shown below the concentration fluctuations $N\langle(\Delta x)^2\rangle$ take its maximum value at the same concentration as the LCST. This indicates that local structure formation is closely related to the phase separation.

The concentration fluctuations can be derived from the light scattering intensity and the refractive indices which are shown in Figs. 2 and 3, respectively. The procedure is the same as described in the previous paper.[8] The isobaric heat capacity and the density necessary for the calculation were obtained from the literature.[9] In Fig. 4 the mean-square concentration fluctuations, $N\langle(\Delta x)^2\rangle$, at various temperatures are plotted against the mole fraction of BE, x_{BE}, where N is the total number of molecules in the observation volume. The dashed line in the figure corresponds to the $N\langle(\Delta x)^2\rangle$ expected for an ideal binary solution. It is seen from the figure that the observed concentration fluctuations are close to those of an ideal binary solution in the concentration range $0<x_{BE}<0.02$. However, it increases abruptly near $x_{BE}=0.02$, attains a maximum

at about $x_{BE}=0.07$, the value of which is about two orders of magnitude larger than that of the ideal solution, and decreases gradually with the increase of concentration of BE, and especially above 0.2 it varies little in magnitude. Also it is noticed from the figure that the $N\langle(\Delta x)^2\rangle$ increases rapidly with temperature in the concentration range $0.02<x_{BE}<0.2$. On the other hand, it is almost independent of the temperature if x_{BE} is above 0.2 and below 0.02.

Analysis of $N\langle(\Delta x)^2\rangle$. In the previous papers we have reported that the local structures existing in the solution can be determined from the analysis of the concentration dependence of $N\langle(\Delta x)^2\rangle$.[8] In the case of the ideal solution the concentration fluctuation is expressed as $x_B(1-x_B)$ for the binary solution of A and B, where x_B is the mole fraction of B. In the case where the same species gather together, the concentration fluctuation is greater than that of the ideal solution. In the case in which the different species gather together, the concentration fluctuation is smaller than that of the ideal solution. The observed concentration fluctuation indicates that BE-water mixture belongs to the former case.

From a comparison of the concentration dependence of $N\langle(\Delta x)^2\rangle$ with the miscibility curve, we can make a picture of the local structure formed in the solution. It is seen from Fig. 1 and Fig. 4 that the concentration where the concentration fluctuations increase/decrease corresponds to that where the miscibillity curve rises/falls. As mentioned above, this suggests the fact that stable local structures are formed at these concentrations. Their compositions must be $A_{50}B$ and A_4B, where A means water and B means BE, because the concentrations at issue are 0.02 and 0.2.

In order to understand the mixing state of BE–water mixture in all the concentration range, the following model is assumed; (1) local structures of types A_l and $A_lB(l=50)$ in the concentration range $0<x_B<0.02$, (2) simultaneous existence of A_lB and $A_mB(l=50, m=4)$ in the concentration range $0.02<x_B<0.2$, and (3) a local structure of type $A_mB(m=4)$ and molecules B in the concentration range $0.2<x_B$. The distribution of the two types of local structure calculated from the model above is shown in Fig. 5a. The concentration fluctuation for this model can be calculated for the following concentration range as:

$[0<x_B<0\ 02]$

$$N\langle(\Delta x_B)^2\rangle = x_B(1-x_B)[1-(l+1)x_B] \tag{2a}$$

$[0\ 02<x_B<0\ 2]$

$$N\langle(\Delta x_B)^2\rangle = x_B[(l+1)x_B-1][1-(m+1)x_B] \tag{2b}$$

$[0\ 2<x_B<0\ 3]$

$$N\langle(\Delta x_B)^2\rangle = x_B(1-x_B)[1-(m+1)x_B] \tag{2c}$$

Figure 5b demonstrates the concentration dependence of concentration fluctuations calculated from Eq. 2 for $l=50$ and $m=4$. The calculated concentration fluctuations coincide well with the observed ones in the following ways: (1) The calculated concentration fluctuation is small and close to that expected for the ideal solution for $0<x_B<0.02$, and (2) it has a minimum at near $x_{BE}=0.02$ and 0.2 where the slope of observed ones change abruptly, and (3) it reaches a maximum in the concentration rage of $0.02<x_B<0.2$.

However, the observed concentration fluctuation is much greater than the calculated one by an order of magnitude, as is noticed from the ordinate of Fig. 4 and Fig. 5b. In order to overcome this, we have to modify the model in the following manner. In the concentration range of $0.02<x_B<0.2$, the local structures of types A_lB and A_mB gather together and form $g(A_lB)$ and $h(A_mB)$, respectively. In this case the concentration fluctuation is given by the following equation:

$$N\langle(\Delta x_B)^2\rangle=(l-m)^{-1}[(l+1)x_B-1][1-(m+1)x_B] \times\{g[(l+1)x_B-1]+h[1-(m+1)x_B]\} \tag{2b'}$$

The concentration fluctuations increase with both g and h, but these two can not be determined independently.

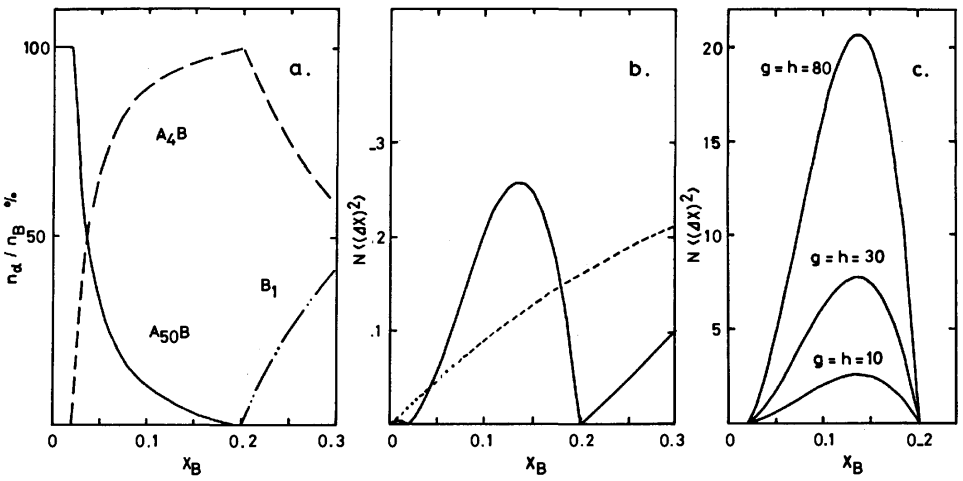

Fig. 5. (a) Distribution of B molecules among several local structures α; $A_{50}B$, A_4B, and B_1. In the figure n_B means the total number of B molecule and n_α means the number of α species. All the B molecules are in $A_{50}B$ for $0<x_{BE}<0.02$, in $A_{50}B$ and A_4B for $0.02<x_{BE}<0.2$, and in A_4B and B_1 for $0.2<x_{BE}<0.3$. (b) The theoretical value of concentration fluctuation calculated from Eq. 2. (c) The theoretical value calculated from Eq. 2b′ in the concentration range $0.02<x_{BE}<0.2$ for $g=h=10$, 30, and 80.

By arbitrarily assuming $g=h$, the calculated concentration fluctuations are shown in Fig. 5c. The maximum values of observed ones at 21 and 42 °C are close to calculated ones when $g=h$ are about ten and one hundred, respectively. Also it takes maximum at about $x_B=0.1$ in both the observed and calculated ones.

While the calculated concentration fluctuation become zero at $x_B=0.02$ and 0.2, the observed one does not. In the above model, all the local structure is assumed to be $A_{50}B$ and A_4B at 0.02 and 0.2, respectively. This is improved by taking the following association equilibrium Eq. 3 into consideration. Although the association of A_{50} may proceed stepwise in real solution, Eq. 3 is assumed since this is the simplest form in order to examine the contribution of the equilibrium. If more equilibrium were taken into account, the calculation should be tedious and meaningless for the understanding of the mixing state of binary solution.

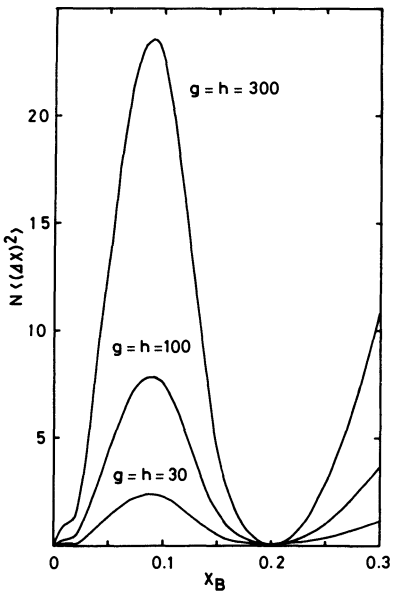

Fig. 6. Theoretical value of concentration fluctuation calculated by equillibrium of Eq. 3 for $g=h=30$, 100, 300, $K_1=10^3$, $K_2=10$, and $K_3=1$.

$$A_{50} + B \rightleftharpoons K_1 \rightleftharpoons A_{50}B \longrightarrow g(A_{50}B) \quad (3a)$$

$$A_4 + B \rightleftharpoons K_2 \rightleftharpoons A_4B \longrightarrow h(A_4B) \quad (3b)$$

$$4A_{50} \rightleftharpoons K_3 \rightleftharpoons 50A_4 \quad (3c)$$

Figure 6 shows the concentration dependence of concentration fluctuation numerically calculated assuming the above equilibrium for $K_1=10^3$, $K_2=10$, $K_3=1$, and various $g=h$. The calculated concentration fluctuations correspond more closely with the observed ones. Figure 7 shows the aggregation schematically. In principle it is possible to search for the best set of parameters (K_1, K_2, K_3, l, m, g, h) that gives the best fit to the observed concentration fluctuation. This was not attempted because none of them can be determined uniquely.

From the analysis of concentration fluctuation given above the following conclusions are obtained. (1) For $0<x_{BE}<0.02$ local structures of types $A_{50}B$ and A_{50} are formed. (2) For $0.02<x_{BE}<0.2$ local structures of types $g(A_{50}B)$ and $h(A_4B)$ exist simultaneously. The values of g and h depend on temperature, and vary between ten and several hundreds. (3) For $0.2<x_{BE}$ the local structures of types $h'(A_4B)$ and B_1 are formed, where the value of h' is independent of temperature. The conclusions are consistent with the Raman Spectra described in the following section.

Raman Spectra. Raman spectra of aqueous BE solution at various concentrations were obtained in order to ascertain whether a conformational change of BE occurs through the formation of clathrate hydrate-like structure. Shimanouchi *et al.* studied the Raman and IR spectra of many long chain ethers and have reached the following conclusions.[10] (1) Various rotational isomers due to many internal rotation axes exist in the liquid state. (2) The spectra of the various isomers are different, especially in the 200—600 cm^{-1} region of the skeletal deformation and torsional vibration modes and in the 800—1200 cm^{-1} region of the skeletal stretching and methyl and methylene rocking vibrations. Since the conformation of BE molecule is supposed to alter when it is within a clathrate hydrate structure, the change of the Raman spectra in these two regions are expected. Since water has a strong and broad Raman signal in the low frequency region, however, only the high frequency region gave positive results.

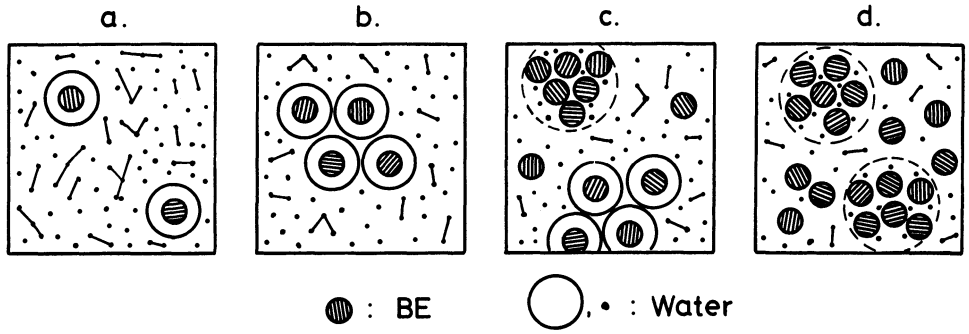

Fig. 7. Mixing state of BE–water mixtures drawn schematically. (a); for $0.02>x_{BE}$, (b); for $0.02<x_{BE}<0.05$, (c); for $0.05<x_{BE}0.2$, and (d); for $0.2<x_{BE}$. (○, ●) and ◍ correspond to the water molecule and the BE molecule, respectively. ◎ and ❁ mean clathrate hydrate-like structure $g(A_{50}B)$ and aggregate $h(A_4B)$, respectively.

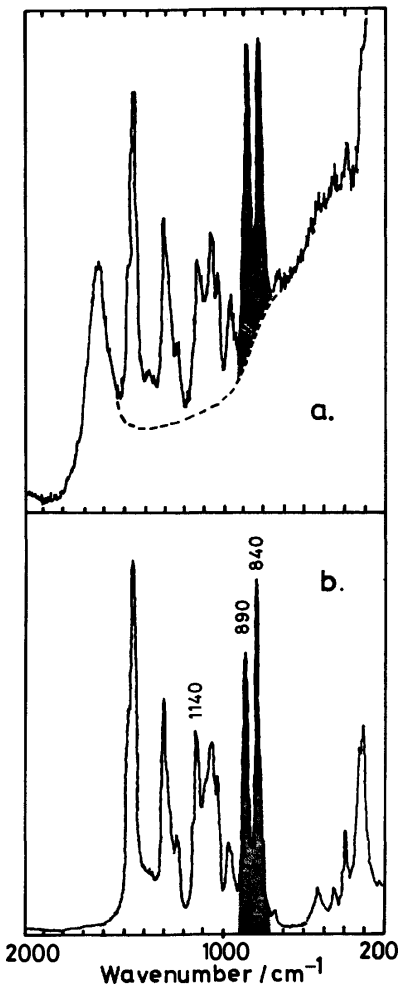

Fig. 8. Observed Raman spectra of aqueous BE solution of x_{BE}=0.009 (a) and neat liquid of BE (b) in the 200—2000 cm^{-1} region. Dashed line in (a) is the scattering from solvent water.

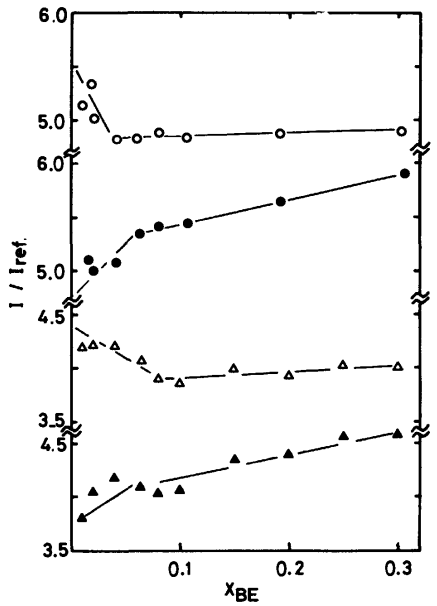

Fig. 9. Intensities of 840 and 890 cm^{-1} peaks relative to the intensity of 970 cm^{-1} peak in the Raman spectra of BE as functions of the concentration in aqueous solution at 21 °C. ●; $I(\approx840)/I(\approx970)$, ○;$(\approx890)/I(\approx970)$. For BE–deuterium oxide mixture, ▲; $I(840)/I(\approx970)$, △; $I(\approx890)/I(\approx970)$.

In Fig. 8 the Raman spectra of neat liquid and aqueous (x_{BE}=0.009) solution of BE are shown. From the comparison of Fig. 8a and b, it is evident that the peak intensities of bands at 840, 890, and 1140 cm^{-1} change with the concentration of BE. Out of the above three bands the one at 1140 cm^{-1} shifts in the BE–deuterium oxide solution, and is due to alcoholic OH groups. By comparison with Shimanouchi *et al.*'s results, the other two can be assigned to C–O stretching vibrations of ether bond. Since the bandwidths scarcely alter with concentration, peak heights can be taken as intensities if background from the solvent is properly subtracted. Figure 9 shows the intensity ratios of the 840 and 890 cm^{-1} bands to the 970 cm^{-1} band as a function of concentration.[11] As is seen from the dotted line in Fig. 8, a broad Raman signal from the solvent water overlaps the BE Raman signal and may lead to error. Since the use of deuterium oxide reduces the overlap, the data with deuterium oxide are also obtained and shown in Fig. 9. Both water and deuterium oxide give similar results. It can be seen from Fig. 9 that the intensity of 840 cm^{-1} band decreases and that of 890 cm^{-1} band increases with concentration. However, the changes are not monotonic but rather there are bends around x_{BE}=0.05, where the change in concentration fluctuation is the largest.

These observations as well as the results of Shimanouchi *et al.* lead to the following conclusions; a clathrate hydrate-like structure is formed at low concentration and the BE molecule changes its conformation when freed from clathrate above x_{BE}=0.05. At higher concentration where x_{BE}>0.05, the conformation of BE molecules is the same as that in neat liquid. The BE molecule in clathrate must prefer a compact form to an elongated one, and must assume the gauche form around some internal rotation axes. In order to make this conclusion clearer, a normal coordinate calculation was carried out with general force constants given by Shimanouchi *et al.*[12] Unfortunately the force constants for the alcohol were not available, so the calculation was done for butyl ethyl ether. The Raman spectrum of this molecule is similar to that of BE, reflecting that the skeleton of these two are the same.

Since butyl ether has four internal rotation axes, there are thirty four rotational isomers. Shimanouchi *et al.* have reported that ethyl propyl ether (CH_3CH_2–CH_2–O–CH_2CH_3) assumes the forms of GTT and TTT, and butyl methyl ether (CH_3CH_2–CH_2–CH_2–OCH_3) takes the forms of TTT and TGT in the liquid state.[13] That is, the trans conformation about CO–CC axis is much more stable than the gauche, but gauche conformation is also as stable as the trans about C–C axis. From these results the forms of TTTT, TGTT, GGTT, and GTTT are most likely for butyl ethyl ether (CH_3CH_2–CH_2–CH_2–O–CH_2CH_3) in the liquid state. As mentioned above, the COC symmetric vibration dominates in the 800—1000 cm^{-1} region of the Raman

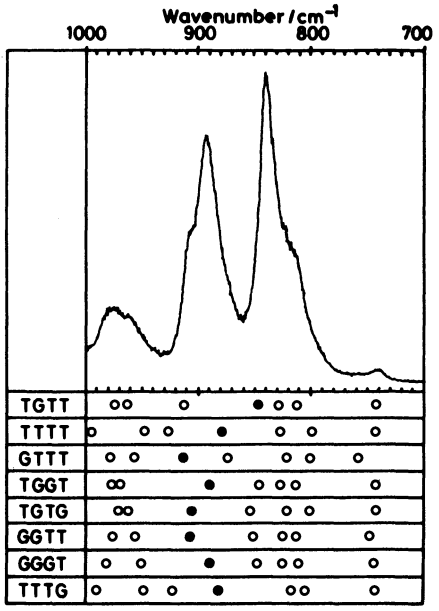

Fig. 10. Observed Raman spectra of BE and the calculated frequencies of butyl ethyl ether in the 700—1000 cm^{-1} region. Solid circles indicate C–O stretching vibrations, which are expected to dominate in this region.

spectrum of ethers,[14] and the bands at 840 and 890 cm^{-1} in Fig. 9 are assigned to this vibration of several rotational isomers. Calculations show that only TGTT has COC stretching frequency smaller than 850 cm^{-1}, and frequencies of other conformers all fall between 880 and 910 cm^{-1}, as is shown in Fig. 10. Since the intensity of 840 cm^{-1} vibration is higher than that of 890 cm^{-1}, the major form of BE is TGTT in the neat liquid. In higher concentrations of water, the intensity of 890 cm^{-1} band increases and that of the 840 cm^{-1} band decreases. This means that proportion of TGTT gets smaller with dilution and conformers such as GTTT and GGTT increase in number. By the formation of clathrate hydrate-like structure, BE is surrounded by water. Since the gauche conformation about CO–CC axis is more advantageous for the ether –O– in contact with water molecule, the conformers such as TGGT and TGTG must also increase. Nevertheless the frequency differences are too small to distinguish those rotational isomers.

Discussion

In the previous papers,[2] it was shown that in a binary solution of TBA and water the local structures of types $g[(H_2O)_{20}TBA]$ and $(H_2O)_{20}$ are formed for $0<x_{TBA}<0.04$ and local structures of types $g[(H_2O)_{20}TBA]$ and $(TBA)_s$ are formed for $0.04<x_{TBA}$. The local structure of $g[(H_2O)_{20}TBA]$ has been postulated to be a clathrate hydrate-like structure. From the analysis of mutual diffusion coefficients the clathrate hydrate-like structure has been considered to be an "aggregated polyhedron" (that is, one in which the polyhedra gather together to form an aggregate without sharing faces with each other), not an "associated polyhedron" (that is, one in which water molecules form polyhedra, each of which encages a guest molecule and that the several polyhedra share one of their faces).

In the binary solution of BE and water, the local structure of type $g[(H_2O)_{50}BE]$ is also considered to be "aggregated polyhedron." Below the concentration $x_{BE}=0.05$ more BE molecules whose conformation is close to spherical one are expected to exist from the analysis of Raman spectra. The conformation change of BE must be due to the formation of polyhedra of water molecules. The difference in size between the polyhedra formed in TBA–water and those in the BE–water mixture arises from the difference in bulk of the hydrophobic group of the two molecules. Above the concentration $x_{BE}=0.05$, the local structure of type $g[(H_2O)_{50}BE]$ is destroyed and the amount of local structures of type $h[(H_2O)_4BE]$ increases due to the increase of BE molecules, as shown in Fig. 8a, where the distribution of two types of local structures is expressed as $A_{50}B$ and A_4B, respectively. Formation of the local structure of type $h[(H_2O)_4BE]$ is reminiscent of micelles in an aqueous solution of surfactants. BE molecule is a member of polyethylene glycol monoalkyl ether $C_nH_{2n+1}O(CH_2CH_2O)_mH$ family where $n=4$ and $m=1$. Micelle formation is known in this class of molecules where $n\geqq 8$ in the case of $m=1$. The critical micelle concentration (CMC) for $n=8$ and $m=1$ is 4.9 mmol/l (that is, about 1×10^{-4} in the mole fraction of solute) which is about five hundred times lower than the concentration at which BE takes the form $h[(H_2O)_4BE]$. Since BE has a relatively strong affinity for water, the hydrophobic interaction between BE molecules is weaker than that between its longer chain homologs. It does not have distinct CMC.

The phase transition is understood from the idea of the local structure in the following manner. The increase of concentration fluctuation with temperature is caused by the increase of either g and h of local structures of types $g[(H_2O)_{50}BE]$ and $h[(H_2O)_4BE]$. That is, by raising the temperature the "aggregated polyhedron" and the aggregates of BE molecules gather together and become larger, and finally the solution separates into two phases at critical solution temperature. Therefore the phase separation is the result of the growth of local structures which already exist about thirty degrees below the LCST. In TBA–water mixture the aggregate of TBA does not seem to become large enough with the increase of temperature. This can be attributed to the small size of hydrophobic part of TBA.

The existence of local structure has been postulated by a thermodynamic study of G. Roux, G. Perron, and J. E. Desnoyers. They have reported the apparent molal heat capacity ϕ_c and volume ϕ_v.[9] They indicate that the change in mixing states occurs near the concentration $x_{BE}=0.02$ where ϕ_c has maximum, and the microphase which is constructed from aggregate of BE is made beyond the concentration. They have also pointed out that the clathrate hydrate-like structures may be formed in the concentration region where ϕ_c has a maximum. The present results support their explanation from another viewpoint.

Concluding Remark. The phase separation phe-

nomenon has been treated as one of the critical phenomena which occur at near critical solution temperature. The present results indicate that the phase separation occurs in microscopic regions even thirty degrees below the critical solution temperature. It is well-known that there is an LCST in many nonelectrolyte aqueous solutions. The formation of local structures with clathrate hydrate-like structure and the aggregates of solutes will be common in those systems and essential factors for phase separation.

The authors wish to express their thanks to Dr. Yoko Sugawara of the Institute for Physical and Chemical Research for her help in the normal coordinate calculation with a computer program LCTB. We also would like to thank Prof. J. E. Desnoyers of Univ. de Sherbrooke for suggesting to us this interesting system, Prof. Hidemasa Takaya of IMS for his helpful advices for preparing high quality BE, and Prof. P. G. Wolynes of Univ. of Illinois for a critical reading of manuscript.

13) The generic symbols T and G which represent the conformation of rotational isomers is described in Ref. 10.

14) F. R. Dollish, W. G. Fateley, and F. F. Bentley, "Characteristic Raman Frequencies of Organic Compounds," John Wiley and Sons, Inc., New York (1974), Chap. 3. It has been known that the CCO symmetric vibration of alcohol is also strong in the 800—1000 cm^{-1} region. The intensity of the Raman band of ethanol at 890 cm^{-1}, however, dose not show concentration dependence. Therefore the concentration dependence of 890 cm^{-1} in BE–water mixture is due to the conformational change of butoxy group.

Study of the Behavior of "Uptake and Release" of Oxygen into Perfluorocarbon-Water Emulsions

Kenjiro MEGURO,* Hiroshi WATANABE, Hiromu KATO, Kimihiko OGIHARA, and Kunio ESUMI
Department of Applied Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received June 30, 1982)

Stable O/W type emulsions of perfluorocarbon such as perfluorodecalin (FDC) and perfluorotributylamine (FTBA) were prepared by using poly(oxyethylene)-poly(oxypropylene) block copolymer (Pluronic F-68) and sorbitan monolaurate (SL-10) as emulsifiers. The relationships between the behavior of "uptake and release" of oxygen into the emulsions and the factors responsible for a stable emulsion were studied. The initial rates of "uptake and release" of oxygen into the emulsions decreased with increasing the mean particle size, the concentration of emulsifiers, and the viscosities of the emulsions. On the other hand, the saturated amount of oxygen in the emulsions was independent on the mean particle size, but depended on the total amount of the perfluorocarbons in the emulsion.

Perfluorocarbon compounds have a characteristic property of dissolving a relatively large amounts of gases such as oxygen and carbon dioxide.[1,2] This property can be applied to the preparation of an artificial blood. Indeed, many researches on the use of perfluorochemical emulsions in artificial blood have been proceeding.[3-12] To use perfluorochemicals effectively for this purpose, it is necessary to prepare them as stable O/W type emulsion. Such emulsions should exhibit suitable behavior of "uptake and release" of oxygen, but there have been few reports about fundamental studies of these emulsions from the view point of colloid science.

In this work, the relationship between "uptake and release" of oxygen into perfluorocarbon emulsions and the factors associated with stable emulsions will be discussed.

Experimental

Materials. Perfluorocarbon compounds used for preparing an artificial blood substitute must be nontoxic and have the ability to dissolve oxygen. From this standpoint, perfluorodecalin (FDC) and perfluorobutylamine (FTBA) were employed. They were supplied by Dainippon Ink Chemical Co., Ltd.

For the preparation of O/W type emulsion of these compounds, poly(oxyethylene)-poly(oxypropylene) block copolymer (Pluronic F-68) and sorbitan monolaurate (SL-10) were used as emulsifiers. They were supplied by Nikko Chemical Co.

Emulsification. For the preparation of the emulsion in a small scale, a homogenizer was used. While in a large scale, FDC and FTBA were preemulsified by use of the homogenizer for several minutes, followed by passing through a Manton Gaulin Homogenizer under about 500 kg/cm^2.

Measurements. The particle size distribution of the emulsion was determined by using a centrifugal particle size analyzer (Shimadzu Seisakusho Ltd.). The viscosity of the emulsion was measured by using a corn plate type rotation viscometer (Tokyo Keiki Co., Ltd.). The amount of oxygen dissolved in the emulsion was measured by an oxygen meter (Central Kagaku Co., Ltd.) at 25±0.1 °C. The procedure was as follows; after setting 100 ml of the emulsion into a beaker, nitrogen gas was blown into it to displace the oxygen initially dissolved in the emulsion. Oxygen was then blown into this emulsion until saturation was achieved. This process is named "uptake" of oxygen. Next, the oxygen was replaced with nitrogen, which process is called "release" of oxygen. These processes are shown in Fig. 1. Here, the concentration of oxygen in the emulsion is estimated by subtracting the concentration of oxygen in water phase from that in the total system.

Results and Discussion

For the application of a perfluorochemical emulsion to an artificial blood, the emulsion must have fine particles and exhibit a high stability for a long period. Thus, it is necessary to prepare a stable emulsion of perfluorocarbon compound. Since it is important to select suitable emulsifiers for the preparation of stable emulsions of FDC and FTBA, the emulsification tests were carried out by using several different emulsifiers. As a result, it was found that the combination of Pluronic F-68 and SL-10 provided relatively stable emulsions for both FDC and FTBA. Accordingly, these two emulsifiers were used for preparing the emulsions in this experiment.

In order to estimate optimum conditions for emulsifying FDC and FTBA, the emulsification stability tests were conducted using various ratios of Pluronic F-68 and SL-10. Figure 2 shows the photographs of emulsions of FDC with different HLB values. From Fig. 2, it can be seen that the required HLB value of FDC is located at 9.5. Also, Figure 3 illustrates the photographs of emulsions prepared with different concentra-

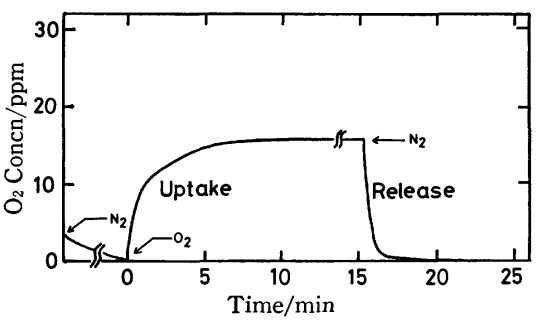

Fig. 1. The processes of "uptake and release" of oxygen into emulsion.

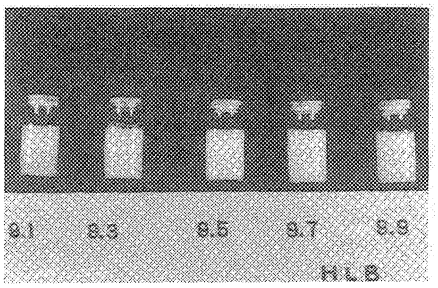

Fig. 2. Photographs of FDC emulsions with different HLB values.

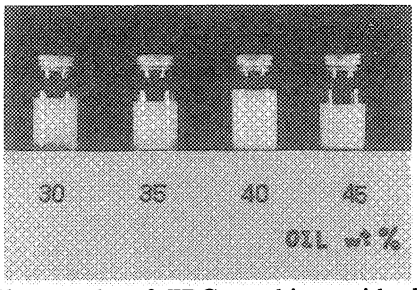

Fig. 3. Photographs of FDC emulsions with different concentration of FDC.

tion of FDC. The emulsion became stable when the concentration of FDC was above 40 wt%. Further, it was found that the stable emulsion was obtained when the concentration of the emulsifiers was above 30 wt% of FDC concentration. In the case of FTBA, similar results were obtained. That is, the required HLB value of FTBA was found to be 10.3 and the stable FTBA emulsion was prepared at the conditions which the concentration of FTBA was above 40 wt% and the concentration of the emulsifiers was above 30 wt% of FTBA concentration. The mean particle size of FDC and FTBA emulsions prepared in the above conditions was below 0.2 μm and further the separation of FDC and FTBA from the continuous phase was not observed for period exceeding 60 d, respectively.

The relationships between the rates of "uptake and release" of oxygen into the emulsion and the factors which affect the emulsion stability of FDC and FTBA were examined. At first, in order to study the effect of particle size distributions of the emulsions, three kinds of FDC and FTBA emulsions with different particle size distributions were prepared. The rates of "uptake and release" of oxygen into these emulsions were measured. The proportions in weight of the emulsion particles below 0.2 μm were 96.5% in A, 58.7% in B, and 17.5% in C, respectively. The results are shown in Table 1. In the process of "uptake and release" of oxygen, the concentration of oxygen in the emulsion was changed most rapidly in A, but most slowly in C for FDC and ETBA. These results can be correlated with the interfacial area between the emulsion particles and the continuous phase. That is, the initial rates of "uptake and release" of oxygen decreased with decreasing interfacial area. Furthermore, it is noteworty

Table 1. The initial rates of "uptake and release" of oxygen into the fluorocarbon emulsions

Sample	Initial rate of uptake/ppm min^{-1}	Initial rate of release/ppm min^{-1}
FDC-A	12.4	6.8
FDC-B	4.4	1.8
FDC-C	2.4	0.9
FTBA-A	8.0	6.9
FTBA-B	4.4	4.9
FTBA-C	—	—
FDC-10%	10.8	8.9
FDC-20%	3.0	4.9
FDC-30%	0.4	1.7
FDC-0 d	18.4	8.9
FDC-30 d	1.0	4.9

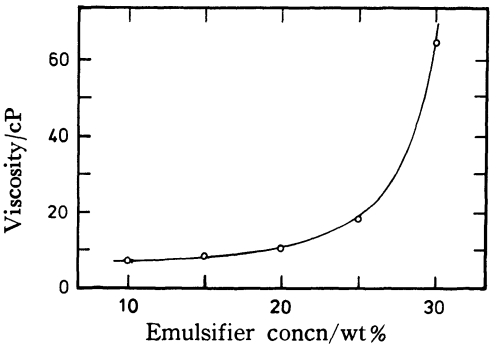

Fig. 4. The changes of the viscosity of FDC emulsion against the concentration of emulsifier.

that the saturated amounts of oxygen in the emulsions were constant for three samples in spite of different mean particle sizes. This indicates that the amount of oxygen dissolved in the emulsion is dependent on the total amount of perfluorocarbon, but is independent on the interfacial properties between perfluorocarbon and the continuous phase.

Figure 4 depicts how the concentrations of the emulsifiers affect the viscosity of FDC emulsions. The viscosity of the emulsion increased with increasing concentration of the emulsifiers, rapidly at above 30 wt% of them. As a next step, the effect of the viscosity of the emulsions on the rates of "uptake and release" of oxygen into them was studied. This result is given in Table 1. The concentrations of the emulsifier against FDC were 10, 20, and 30 wt%, respectively. In this case, from the measurement of particle size distribution, it was confirmed that the mean particle sizes of the three emulsions were almost the same. When the concentration of the emulsifier was 10 wt%, the concentration of oxygen dissolved in the emulsion was changed most rapidly, while at 30 wt%, it was changed most slowly. Thus, the initial rates of "uptake and release" of oxygen decreased with increasing the concentration of the emulsifier from 10 to 30 wt%. This suggests that the interfacial film of the emulsion particles would become thicker on increasing the concentration of the emulsifier.

Further, the relationship between the aging of the emulsions and the rates of "uptake and release" of

oxygen into them was studied. In this study, two FDC emulsions were used. One was the emulsion freshly prepared, and the other was that aged for 30 d. The initial rates of the two emulsion are given in Table 1. The increases of the mean particle size and the viscosity were observed for the emulsion aged for 30 d compared with that freshly prepared. In addition, the initial rate of "uptake and release" of oxygen for the emulsion aged for 30 d was slower than that freshly prepared.

The results obtained in this study are summarized as follows:

(1) The initial rate of "uptake and release" of oxygen into the emulsion decreased with increasing the mean particle size of the emulsion.

(2) The saturated amount of oxygen in the emusion was independent of the mean particle size of the emulsion, but was dependent on the total amount of fluorocarbon in the emulsion.

(3) The initial rate of "uptake and release" of oxygen into the emulsion decreased with increasing the concentration of the emulsifiers and the viscosity of the emulsion.

We thank Dr. S. Yoshikawa and Mr. N. Yanagi for their suggestion and assistance in this work.

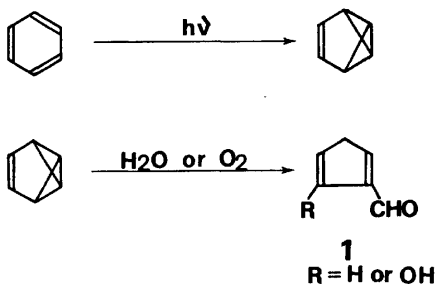
Laser Flash Photolysis of Benzene. VI.[1] Photolysis in Aqueous Solution

Nobuo SHIMO,† Nobuaki NAKASHIMA, and Keitaro YOSHIHARA*
Institute for Molecular Science, Myodaiji, Okazaki 444
(Received July 21, 1982)

Three transient absorption spectra in aqueous solution were observed by irradiation of benzene with an excimer laser (KrF, 248 nm or ArF, 193 nm). A short-lived absorption with a peak at 275 nm is assigned to the $S_n \leftarrow S_1$ absorption. A long-lived absorption, which appears as a clear shoulder at 230 nm, stays longer than 500 ns and is not shortened by oxygen. This species is tentatively assigned to benzvalene, and the quantum yield is determined to be *ca.* 0.1. Solvated electron with a peak at 720 nm was formed *via* multiphoton processes at a power level of 60 mJ/cm² of an ArF laser. The $T_n \leftarrow T_1$ absorption was lower than our detection limit ($\Phi_T < 0.1$).

Nanosecond laser photolysis has been successfully applied to benzene in cyclohexane and in the gas phase, and $S_n \leftarrow S_1$ absorptions, a $T_n \leftarrow T_1$ absorption, a vibrationally highly excited state, and mist formation were observed.[2-5] The first three observations brought detailed information on the properties of excited states and the last observations gave an interesting phenomenon of multiphoton photochemistry in the gas phase. Phenol was observed at quantum yield of 0.01 in the presence of O_2. Most recently we observed with gaseous benzene that the major deactivation process at 248 nm excitation was formation of highly excited vibrational states in the ground electronic manifold.[1] In order to investigate photochemistry of benzene in solution, we chose aqueous solution in this report because of the following reasons.

(1) The photochemistry of benzene in aqueous solution was investigated by Kaplan[6] and Stein[7,8] with steady-state irradiation and the conventional flash photolysis technique in the microsecond timescale. They reported that excitation of benzene to the $^1B_{2u}$ or $^1B_{1u}$ state in aerated aqueous solution gave the final photoproduct **1**. Benzvalene has been postulated as an intermediate, which reacts with H_2O or O_2 to produce **1**. The quantum yield of total process is 0.07[6] or 0.18.[7] (Eqs. 1 and 2)



(1)

(2)

(2) Since the quantum yields of fluorescence and triplet formation are only 0.006[7] and 0.07,[9] respectively, the major process (0.75) is unknown in aqueous solution. Thus photochemical reaction leading to benzvalene as an unstable photoproduct is expected to occur. Internal conversion to the ground state must also be an important process. (3) Because of the low yield of triplet formation, some transient species other than the triplet benzene could be observed in aqueous solution. It is essential to confirm Eq. 1 and to know the nature of the unknown processes.[10]

† On leave from Idemitsu Kosan Co., Ltd., Central Research Laboratory, Kamiizumi, Sodegaura, Kimitsu, Chiba 292-01.

Experimental

Benzene in aerated aqueous solution (10^{-3} M, 1 M = 1 mol dm^{-3}) in a $1 \times 1 \times 2.5$ cm³ quartz cell was excited by an excimer laser (KrF, 248 nm or ArF, 193 nm). The laser beam was not focused and had a cross section of 2.5×0.2 cm². The details of the flash photolysis apparatus have been described elsewhere.[2,3] Sample was renewed at every laser excitation because of an efficient formation of photoproducts. The absorbance of each wavelength at each laser shot was normalized at 230 nm by dual beam observation, one at 230 nm and the other at different wavelengths. Benzene (Merck, 99.9%), acetonitrile (Merck, Uvasol), methyl alcohol (Katayama Chemical, absorption spectrum grade), and oxygen (Nippon Sanso) were used without further purification. Water was distilled and passed through ion exchange resin (Toyo Aquarius GS-100T).

Results and Discussion

Figures 1 and 2 show three transient absorption spectra (A,B,C) of benzene in aqueous solution. The spectra of components A and C are taken immediately after excitation and the spectrum of component B is taken

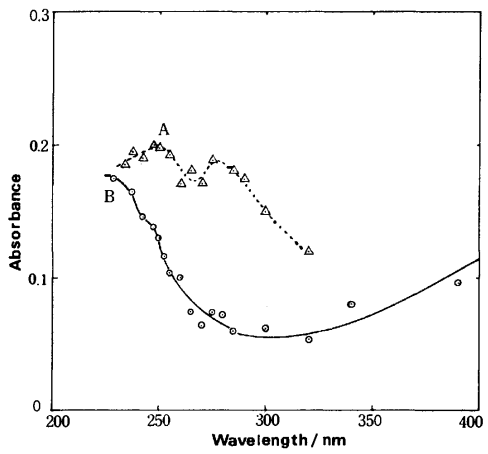


Fig. 1. Transient absorption spectra of benzene in aqueous solution by excitation at 193 nm (ArF). The spectrum A is taken immediately after excitation and the spectrum B is taken at 100 ns after excitation. Absorbance is normalized at 230 nm.

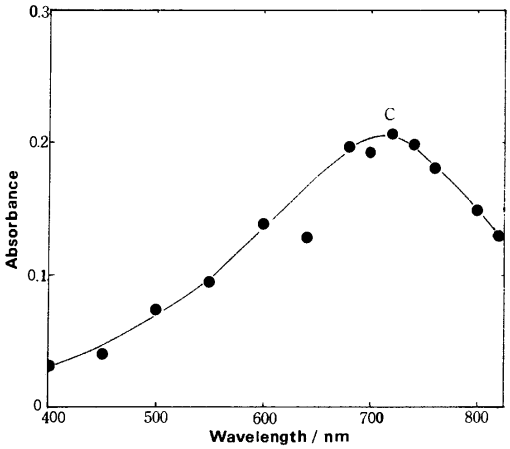

Fig. 2. Transient absorption spectrum of benzene in aqueous solution by excitation at 248 nm (KrF). The spectrum is taken immediately after excitation. Absorbance is normalized at 230 nm.

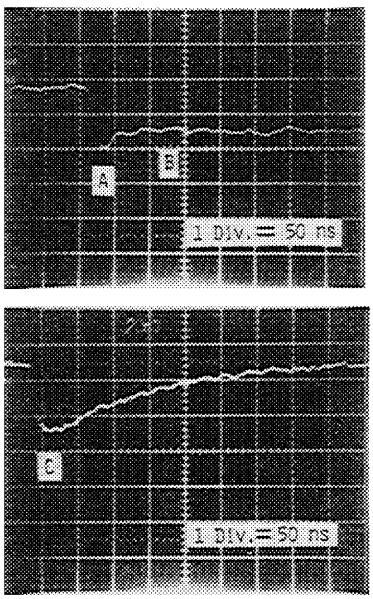

Fig. 3. Photolysis of benzene in water by excimer laser. (1) Excitation by ArF laser (193 nm), monitoring at 260 nm. (2) Excitation by KrF laser (248 nm), monitoring at 800 nm. The spectra of A (Fig. 1) and C (Fig. 2) are taken immediately after excitation, and the spectrum of B (Fig 1) is taken at 100 ns after laser excitation.

at 100 ns after laser excitation (Fig. 3). The spectra obtained by excitation at 248 nm (KrF) and at 193 nm (ArF) are similar to each other.

The broad absorption spectrum (C), between 400 nm and 850 nm, has a maximum absorbance at 720 nm. Both absorption peak position and the long-tailing character of the spectrum are in good agreement with that of solvated electron in water (hydrated electron).[11] The lifetime ($\approx$150 ns) of this transient absorption is reasonably explained by quenching of solvated electron by oxygen (Eq. 3).[12]

$$e^-_{aq} + O_2 \longrightarrow O_2^- \qquad (3)$$

In acetonitrile, methyl alcohol, or cyclohexane solutions, no absorption corresponding to the spectrum C is observed in the present power level. Because the laser power dependence of the formation of C is not linear even with 193 nm (6.4 eV) excitation, solvated electron is formed *via* ionization of benzene by multiphoton process. Integrated concentration of excited species is 4.2×10^{-4} M at a laser power of 60 mJ, while the concentration of solvated electron is estimated to be 1.5×10^{-5} M. About 7% of absorbed laser energy was utilized for formation of solvated electron. It should be noted that solvated electron is rather efficiently formed only in aqueous solution among the solvents we used.

The other transient absorptions, A and B, are obtained between 220 nm and 350 nm. The spectrum of component A, with a peak at 275 nm, is quite similar to that of the $S_n \leftarrow S_1$ absorption observed previously.[4] This component decays just after excitation and is not quenched by oxygen, because the fluorescence lifetime in water is too short (2 ns) to interact with oxygen.[13] These observations indicate that this spectrum is due to the $S_n \leftarrow S_1$ absorption. The absorbance at the 248 nm excitation is stronger than at the 193 nm excitation to some extent. This is reasonable because the fluorescence quantum yield decreases by excitation to the S_2 and/or S_3 electronic states.[8]

The component B, with a clear shoulder at 230 nm has a slightly weaker absorbance than the $S_n \leftarrow S_1$ absorption. This component does not decay during the period of observation ($\approx$500 ns) and is not quenched by oxygen saturated in water. These observations indicate that the absorption is not due to the $T_n \leftarrow T_1$ absorption. The latter should have an absorption peak at 235 nm and should be quenched by oxygen with a bimolecular rate constant of $\approx 6 \times 10^9$ M^{-1} s^{-1}.[2] The saturated concentration of oxygen in water is 0.3×10^{-3} M.[12] Thus, if the absorption were due to the triplet state, it should have decayed with a lifetime of $\approx$600 ns. It is reasonable that no $T_n \leftarrow T_1$ absorption is observed in our experiment, because the quantum yield of triplet formation is known to be only 0.07.[10]

The component B has a linear dependence on laser power at the 248 nm excitation, while the solvated electron is produced with a hyper-linear dependence. The situation is almost the same at the 193 nm excitation. The component B is suggested to be formed by one photon process. The absorption spectrum of benzvalene shows a shoulder at 230 nm in isohexane.[14] The component B has a similar absorption spectrum to benzvalene. Thus, we tentatively assign this transient to benzvalene.

If the component B is benzvalene, the quantum yield is estimated to be about 0.1 by calculating the concentration of excited species and the extinction coefficient of benzvalene. This value is close to the previous data.[6,7] The spectral shape, dynamic behavior, and other discussions on component B suggest that benzvalene is formed as an intermediate of product **1** in Eq. 2. We irradiated aqueous benzene solution with a KrF excimer laser and actually confirmed the final product **1** by UV absorption spectroscopy.

Judging from production of solvated electron, benzene

cation or dimer cation must also be formed. However we were unable to observe these species, which should appear at ≈550 nm or ≈900 nm. Benzene cation is known to react efficiently with water,[8,15] thus the transient concentration must be very low. The absorption of the product from benzene cation also seems to be too weak to be observed. It is less than our detection limit. Very recently Irion *et al.* photolized an aqueous benzene solution by excimer lasers. Phenol was observed with low quantum yield of 10^{-3} *via* multiphoton absorption.[16]

Photolysis of benzene in cyclohexane solution gave ring opening products, trienes.[2] As these compounds are postulated to be formed *via* triplet state,[2] it is reasonable that the absorption spectra of the ring opening products are not observed in aqueous solution because of low triplet yield.

In aqueous solution, high yield of solvated electron is observed, but in cyclohexane the yield of electron transfer process seems to be very small. We were not able to observe the dimer cation.

The quantum yield of processes other than fluorescence and triplet formation in aqueous solution is known to be about 0.92. In our present investigation with laser photolysis, we observed formation of a photoproduct, which is most likely to be benzvalene, with a quantum yield of *ca.* 0.1. We do not observe the high yield of other photoproducts or transients. The major process is suggested to be a nonradiative transition to the ground state.[1]

Molecular Force Fields of *s-trans*-1,3-Butadiene and the Second Stable Conformer

Yukio FURUKAWA,† Hideo TAKEUCHI,† Issei HARADA,† and Mitsuo TASUMI*
Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113
(Received July 23, 1982)

Normal-coordinate analyses of *s-trans*-1,3-butadiene and its various deuterated and ^{13}C-substituted analogs were performed using the group-coordinate force field, and a set of force constants was determined. The infrared spectra of the second stable conformer of 1,3-butadiene-d_0, -1,1,4,4-d_4, and -d_6 were analyzed on the basis of normal-coordinate calculations of the planar *s-cis* form and a nonplanar *gauche* form. Such an analysis suggests that the second stable conformer takes a *gauche* form rather than the *s-cis*. To increase the number of reliable data to be used in this study, the infrared and Raman spectra of the d_0, 1,1,4,4-d_4, and d_6 species were observed in low-temperature Ar matrices. The infrared spectra of the second stable conformer were also observed using a combination of the high-temperature nozzle and low-temperature matrix techniques.

1,3-Butadiene has been a target molecule of numerous structural, spectroscopic, and theoretical studies. Part of these studies has treated the structure of the most stable *s-trans* form of this molecule[1-5] and the assignments of the vibrational spectra arising from this form.[6-15] On the other hand, various efforts have been made toward the elucidation of the internal-rotation potential and the second stable conformer around the central C–C bond.[16-23] This subject has been studied also by various methods of quantum-chemical calculations.[24-33] Interest in this direction of study has been renewed by the recent observation of the infrared bands associated with the second stable conformer trapped in low-temperature Ar matrices.[34-36] The in-plane vibrational frequencies as well as the in-plane force constants of the *s-trans* and *s-cis* forms were calculated by an *ab initio* method[37] and the normal-coordinate analyses based on the observed data for deuterated and ^{13}C-substituted species were also performed.[36]

The purpose of the present study is twofold. (1) One is to obtain reliable force constants which can be conveniently used (at least as initial values) in the normal-coordinate analyses of longer molecules with conjugated double bonds, for example, isomers of 1,3,5-hexatriene, poly(acetylene), various isomers of retinal and β-carotene, *etc.* Although many authors have already reported various sets of force constants of *s-trans*- and *s-cis*-1,3-butadiene,[13-15,36,37] those force constants do not seem satisfactory for such a purpose. (2) The other is to examine if it is possible to obtain information on the internal-rotation angle of the second stable conformer through the normal-coordinate analyses. Whether the second stable conformer is in the planar *s-cis* form or in the nonplanar (*gauche*) form is a long-standing problem which still remains to be solved.

Reliable experimental data are absolutely necessary for this kind of study. Therefore, we have observed the infrared and Raman spectra of 1,3-butadiene and its 1,1,4,4-d_4 and d_6 analogs in low-temperature Ar matrices. Also, we have observed the infrared spectra of these compounds using a combination of the high-temperature nozzle and the low-temperature Ar matrix techniques, in order to obtain the bands due to the second stable conformer. In this way we have confirmed the results of other authors for the d_0 and d_6-samples[34-36] and have obtained the data for the 1,1,4,4-d_4 analog for the first time.

Method

Infrared and Raman Measurements. Infrared and Raman spectra were observed for 1,3-butadiene-d_0 and two deuterated analogs (1,1,4,4-d_4 and d_6) in low-temperature Ar matrices. The d_0 sample was obtained from Takachiho Kagaku Kogyo Co., Ltd. (purity 99%) and the d_4 and d_6 samples from Merck Sharp and Dohme Canada Ltd. (98 atom% D). No further purification was undertaken.

Infrared spectra were recorded on a Hitachi 260-50 infrared spectrophotometer. Raman spectra were observed on a Raman spectrometer consisting of a Spex 1401 double monochromator, an NEC GLG 3300 Ar-ion laser, an HTV 649 photomultiplier and a home-made photon counter.

The low-temperature apparatus for the low-temperature matrix infrared measurements consisted of a CTI Model 21 Cryocooler and a sample chamber equipped with a CsI plate, KBr windows, and a fine Pyrex nozzle through which the Ar/sample mixture was passed. The temperature of the nozzle could be raised to about 770 K with a surrounding tungsten heater. The temperature of the Ar/sample mixture was monitored with an alumel-chromel thermocouple placed inside the nozzle. For low-temperature Raman measurements an Osaka Oxygen Co. Cryo Mini D equipped with a cold head of silver-coated copper and a sample chamber with quartz windows was used.

TABLE 1. INTERNAL COORDINATES

Symbol	Description
Δr_{ij}	Stretching of the bond linking the atoms i and j
$\Delta\phi_{ijk}$	Bending of the angle between the two bonds r_{ij} and r_{jk}
$\Delta\theta_{i-jkl}$	Out-of-plane bending of the plane formed by the atoms i(apex), j, k, and l.
Δt_{ij}	Torsion around the bond r_{ij}

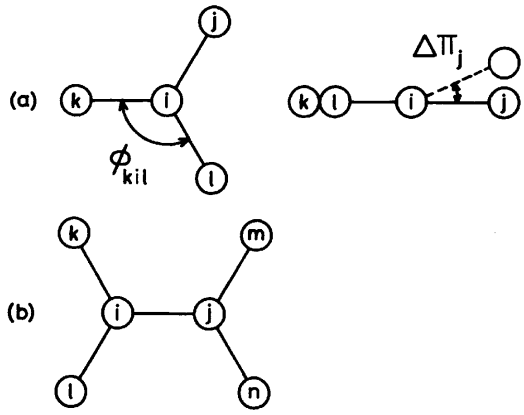

Fig. 2. Numbering of the atoms and the angles relating to the definitions of (a) out-of-plane bending and (b) torsion.

Normal Coordinate Analysis. The normal coordinate analyses of 1,3-butadiene-d_0 and its deuterated and ^{13}C-substituted analogs were performed using the program NCTB[38] on a FACOM M190 computer system at the Laboratory of International Collaboration on Elementary Particle Physics, Faculty of Science, the University of Tokyo.

The structure and numbering of atoms of *s-trans-* and *s-cis*-1,3-butadiene are shown in Fig. 1. The notations for the internal coordinates are given in Table 1. The out-of-plane bending coordinate ($\Delta\theta_{i-jkl}$) and the torsional coordinate (Δt_{ij}) are defined according to the IUPAC recommendations.[39] Therefore, $\Delta\theta_{i-jkl}$ is defined as

$$\Delta\theta_{i-jkl} = \Delta\pi_j \sin\phi_{kil}$$

where $\Delta\pi_j$ and ϕ_{kil} are given in Fig. 2(a). The sign of $\Delta\theta_{i-jkl}$ is defined in such a way that $\Delta\pi_j$ is plus when the atom j moves above the plane defined by the atoms k, i, and l. The torsional coordinate Δt_{ij} is defined as

$$\Delta t_{ij} = (\Delta\tau_{kijm} + \Delta\tau_{kijn} + \Delta\tau_{lijm} + \Delta\tau_{lijn})/4,$$

where $\Delta\tau_{xijy}$ denotes the change in the individual torsional angle between the bonds xi and yj [see Fig. 2(b)].

Group coordinates were defined on the basis of the internal coordinates as given in Table 2. (Previously the group coordinates were called the local-symmetry coordinates.[40])

In the first step of the normal coordinate analysis the

Table 2. Group coordinates[a]

Group coordinate	Mode [Abbreviation]
$S_a^1=(\Delta r_{12}+\Delta r_{23})/\sqrt{2}$	CH_2^1 symmetric stretching [$\nu_s(CH_2^1)$]
$S_a^2=(\Delta r_{67}+\Delta r_{78})/\sqrt{2}$	CH_2^2 symmetric stretching [$\nu_s(CH_2^2)$]
$S_b^1=(\Delta r_{12}-\Delta r_{23})/\sqrt{2}$	CH_2^1 antisymmetric stretching [$\nu_a(CH_2^1)$]
$S_b^2=(\Delta r_{67}-\Delta r_{78})/\sqrt{2}$	CH_2^2 antisymmetric stretching [$\nu_a(CH_2^2)$]
$S_c^1=\Delta r_{45}$	CH^1 stretching [$\nu(CH^1)$]
$S_c^2=\Delta r_{90}$	CH^2 stretching [$\nu(CH^2)$]
$S_d^1=\Delta r_{25}$	$C{=}C^1$ stretching [$\nu(C{-}C^1)$]
$S_d^2=\Delta r_{70}$	$C{=}C^2$ stretching [$\nu(C{=}C^2)$]
$S_e^1=(2\Delta\phi_{123}-\Delta\phi_{325}-\Delta\phi_{521})/\sqrt{6}$	CH_2^1 scissors [$\delta(CH_2^1)$]
$S_e^2=(2\Delta\phi_{678}-\Delta\phi_{870}-\Delta\phi_{076})/\sqrt{6}$	CH_2^2 scissors [$\delta(CH_2^2)$]
$S_f^1=(\Delta\phi_{325}-\Delta\phi_{521})/\sqrt{2}$	CH_2^1 rocking [$\gamma_r(CH_2^1)$]
$S_f^2=(\Delta\phi_{870}-\Delta\phi_{076})/\sqrt{2}$	CH_2^2 rocking [$\gamma_r(CH_2^2)$]
$S_g^1=(2\Delta\phi_{250}-\Delta\phi_{054}-\Delta\phi_{452})/\sqrt{6}$	$C{=}C{-}C^1$ deformation [$\delta(CCC^1)$]
$S_g^2=(2\Delta\phi_{705}-\Delta\phi_{509}-\Delta\phi_{907})/\sqrt{6}$	$C{=}C{-}C^2$ deformation [$\delta(CCC^2)$]
$S_h^1=(\Delta\phi_{452}-\Delta\phi_{054})/\sqrt{2}$	CH^1 in-plane bending [$\delta(CH^1)$]
$S_h^2=(\Delta\phi_{907}-\Delta\phi_{509})/\sqrt{2}$	CH^2 in-plane bending [$\delta(CH^2)$]
$S_i=\Delta r_{50}$	C–C stretching [ν(C–C)]
$S_j^1=\Delta\theta_{2-135}$	CH_2^1 wagging [$\gamma_w(CH_2^1)$]
$S_j^2=\Delta\theta_{7-680}$	CH_2^2 wagging [$\gamma_w(CH_2^2)$]
$S_k^1=\Delta\theta_{5-420}$	CH^1 out-of-plane bending [$\gamma_w(CH^1)$]
$S_k^2=\Delta\theta_{0-975}$	CH^2 out-of-plane bending [$\gamma_w(CH^2)$]
$S_l^1=\Delta t_{25}$	CH_2^1 twisting [$\gamma_t(CH_2^1)$]
$S_l^2=\Delta t_{70}$	CH_2^2 twisting [$\gamma_t(CH_2^2)$]
$S_m=\Delta t_{50}$	C–C torsion [τ(C–C)]

a) The index zero in the subscripts corresponds to the atom 10.

F_{ll}	CH_2 twisting/CH_2 twisting

modified Urey-Bradley-Shimanouchi force field[40] based on the work of Abe[13] was assumed. However, it became clear that some force constants were strongly correlated and accordingly had large uncertainties. Then, we employed the group-coordinate force field (GCFF),[41] which was previously called the local-symmetry force field (LSFF).[40] The definition of the GC force constants used are given in Table 3.

s-trans-*1,3-Butadiene*: The planar C_{2h} structure[4] with $r_{C=C}$=1.342 Å, r_{C-C}=1.463 Å, r_{C-H}=1.093 Å, $\phi_{C=C-C}$=123.6°, and $\phi_{C=C-H}$ (three kinds)=120.9° was used in the present calculation. The least-squares adjustments of the in-plane GC force constants were made against 96 observed frequencies in total (11 for d_0, 11 for 1,1,4,4-d_4, 11 for d_6, 9 for 1,1,2-d_3, 9 for *trans,trans*-1,4-d_2, 8 for *cis,cis*-1,4-d_2, 7 for 2,3-d_2, 10 for *trans*-1-d_1, 4 for *cis*-1-d_1, 7 for 1,4-$^{13}C_2$, and 9 for 1-$^{13}C_1$). The observed frequencies of the d_0, 1,1,4,4-d_4, and d_6 samples were obtained from the present low-temperature matrix infrared and Raman measurements. The observed frequencies of the other deuterated and ^{13}C-substituted analogs were selected from Refs. 13—15 and 36. The following assumptions were made to obtain a good fit between the calculated and observed frequencies using a relatively small number of force constants (9 diagonal and 11 off-diagonal). (a) The CH_2 and CH stretching frequencies (CD_2, CD, and CHD stretching as well) were not included in the least-squares adjustments because of their uncertainties due to possible Fermi resonances. The diagonal force constants (F_a and F_b for CH_2 and F_c for CH) were fixed to the values given in Table 4 and no off-diagonal constants were taken into account. Slightly different values were used for the diagonal force constants of CD_2 (F'_a and F'_b), CD (F'_c), and CHD (F''_a and F''_b). (b) The off-diagonal force constants F_{di}(C=C/C–C) and F_{dd}(C=C/C=C) had large uncertainties when they were included in the least-squares adjustments. Therefore, these force constants were fixed to the values which were obtained from an *ab initio* calculation.[37]

For the out-of-plane vibrations nine force constants listed in Tables 3 and 4 were determined by the least-squares method against 74 observed frequencies in total (7 for d_0, 7 for 1,1,4,4-d_4, 7 for d_6, 6 for 1,1,2-d_3, 5 for *trans,trans*-1,4-d_2, 5 for *cis,cis*-1,4-d_2, 5 for *cis,trans*-1,4-d_2, 4 for 2,3-d_2, 6 for *trans*-1-d_1, 5 for *cis*-1-d_1, 6 for 2-d_1, 6 for 1,4-$^{13}C_2$, and 5 for 1-$^{13}C_1$). Here again, the observed data of the d_0, 1,1,4,4-d_4, and d_6 samples were from the present measurements, while those of the other deuterated and ^{13}C-substituted analogs were taken from Refs. 13—15 and 36. Choice of the kinds of force constants used was somewhat arbitrary, but the agreement between the calculated and observed frequencies was quite satisfactory.

Second Stable Conformer of 1,3-Butadiene: Since the structure of the second stable conformer of 1,3-butadiene has not been experimentally determined, two model structures, *s-cis* and *gauche*, were chosen for normal coordinate analysis. For the *s-cis* form all the bond lengths and bond angles were set equal to those of the *s-trans* form and the internal-rotation angle around the central C_5–C_{10} bond was rotated by 180° from *s-trans* as shown in Fig. 1(b). The same kinds of force constants as used for *s-trans* were taken into account. Normal-coordinate calculations were carried out in two steps. At first the force constants of *s-trans* were transferred to *s-cis* and the observed infrared bands of the latter were assigned with reference to the results of this calculation. The force constants of *s-cis* were then adjusted in order to obtain the best fit between the calculated and observed frequencies. In this procedure the force constants associated with the in-plane vibrations of the terminal CH_2 group were fixed to the values of *s-trans*. The off-diagonal force constants, F_{dd} and F_{di}, were again fixed to the values obtained from an *ab initio* calculation.[37] The other six force constants, F_d, F_g, F_h, F_i, F_{gg}, and

F_{kk}	−0.005 (0.004)	0.024 (0.005)	0.013 (0.015)
F'_{kl}	0.023 (0.002)	−0.026 (0.003)	−0.014 (0.009)
F_{ll}	−0.017 (0.005)	0.011 (0.008)	−0.003 (0.017)

F_{hh}, were adjusted freely by the least-squares method using 30 observed frequencies in total (6 for d_0, 7 for 1,1,4,4-d_4, 7 for d_6, 5 for 1,4-$^{13}C_2$, 5 for 1-$^{13}C_1$). The observed data for the 1,4-$^{13}C_2$ and 1-$^{13}C_1$ analogs were taken from Ref. 36. As for the out-of-plane vibrations, the eight force constants, F_k, F_l, F_m, F_{jk}, F_{kl}, F_{kk}, F'_{kl}, and F_{ll} were adjusted freely by the least-squares method using 28 observed frequencies (7 for d_0, 6 for 1,1,4,4-d_4, 4 for d_6, 5 for 1,4-$^{13}C_2$, 6 for 1-$^{13}C_1$). Only the CH_2 wagging force constant, F_j, was fixed to the value of *s-trans*.

As the structural parameters of the *gauche* form the values calculated by Skaarup *et al.*[30] were slightly modified with reference to the deviations between the *ab initio* and experimental results for the *s-trans* form. The parameters used were as follows: $r_{C=C}=1.341$ Å, $r_{C-C}=1.474$ Å, $r_{C-H}=1.092$ Å, $\phi_{C=C-C}=119.3°$, $\phi_{C=C-H}(2\text{-}5\text{-}4)=119.3°$, $\phi_{C=C-H}(5\text{-}2\text{-}3)=121.5°$, $\phi_{C=C-H}(5\text{-}2\text{-}1)=121.8°$, and t(internal-rotation angle around C_5–C_{10})=40° from *s-cis*. In the normal-coordinate analysis of the *gauche* form no interaction force constants between the "in-plane" and "out-of-plane" coordinates were taken into account. Under the same assumptions as made for the *s-cis* case the 14 force constants were determined from 58 observed frequencies by the least-squares method.

Results

The infrared and Raman spectra of 1,3-butadiene and its 1,1,4,4-d_4 and d_6 analogs observed in low-temperature Ar matrices are shown in Figs. 3 and 4. Since the Ar/sample ratio was not high, the sample molecules might not be completely isolated in the Ar matrix. However, the sharpness of individual bands inherent to the low-temperature matrix measurements made it possible to detect many weak bands. The Raman spectra of these compounds in low-temperature

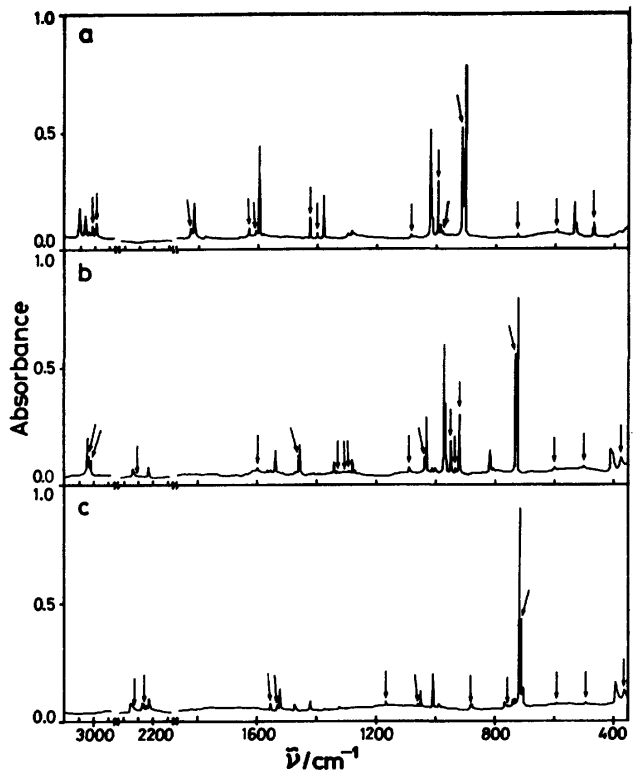

Fig. 3. Infrared spectra of (a) 1,3-butadiene-d_0, (b) -1,1,4,4-d_4, and (c) -d_6 observed in Ar matrices at 20 K. Mixtures of Ar and the samples (Ar/sample ratio 250) were heated to about 770 K in the nozzle and then deposited onto the cold CsI plate. The arrows indicate the bands due to the second stable conformer.

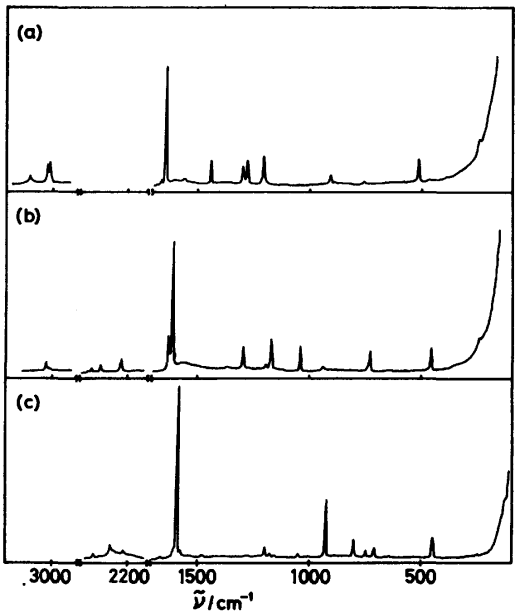

Fig. 4. Raman spectra of (a) 1,3-butadiene-d_0, (b) -1,1,4,4-d_4, and (c) -d_6 observed in Ar matrices (Ar/sample ratio 50) at 15 K. Excitation wavelength, 514.5 nm.

Ar matrices were observed in this study for the first time. The infrared spectra in Fig. 3 were observed from the low-temperature Ar matrices obtained by depositing a mixture of Ar and the sample which had been heated to about 770 K. Therefore, the intensities of the bands due to the second stable conformer are enhanced in Fig. 3 and they are indicated with arrows. The bands without arrows are associated with the most stable *s-trans* form. The bands with arrows were found to decrease in intensity on irradiation of light from a Xe-lamp, indicating that these bands were due to the second stable conformer.[35] Our present results for the d_0 and d_6 samples (Figs. 3a and 3c) agreed with the findings of previous authors,[34-36] except for some minor features. Huber-Wälchli and Günthard[36] observed more bands than we did; for example, we could not observe the medium-intensity band at 1740 cm^{-1} of the d_0 species which they assigned to a combination tone of the second stable conformer. The infrared spectrum of the second stable conformer of the 1,1,4,4-d_4 species (Fig. 3b) was obtained for the first time.

The results of normal-coordinate analyses will be described below.

Discussion

Band Assignments and Force Constants of the s-trans *Form.* As described earlier, we started the normal-coordinate analyses of 1,3-butadiene and its deuterated and ^{13}C-

substituted analogs using the modified Urey-Bradley-Shimanouchi force constants obtained by Abe.[13] Since the band assignments by Abe and other authors[36] mostly seemed reasonable, we refined the GC* force constants on the basis of their assignments. By fixing the force constants relating to the carbon-hydrogen stretching (F_a, F_b, and F_c) and the interaction force constants between the skeletal stretchings (F_{dd} and F_{di}) to reasonable values (see the section of Method), a convergent set of force constants was obtained with satisfactorily small uncertainties as given in Table 4. The results of calculation for the d_0, 1,1,4,4-d_4, and d_6 species in the *s-trans* form are shown in Tables 5—7, together with the observed frequencies. The results of calculation for the other deuterated and ^{13}C-substituted analogs are available on request.

Internal-rotation Angle of the Second Stable Conformer. The normal frequencies of the planar *s-cis* and nonplanar *gauche* forms were calculated in the same manner as is described in the section on Method. The results of calculations for the d_0 species are given in Tables 8 and 9. Similar tables for the 1,1,4,4-d_4 and d_6 species are available from the authors on request. The force constants obtained for the *s-cis* and *gauche* forms are also listed in Table 4. Although most of the observed frequencies can be interpreted on the basis of either the *s-cis* or *gauche* form, the presence of a very weak band at

a) See the footnote a) of Table 5. b) Estimated from $\nu_9+\nu_{22}=1829$ cm^{-1}. c) Ref. 21.

983 cm^{-1} and a weak band at 727 cm^{-1} is better acounted for by assuming the *gauche* form. When the *s-cis* form is assumed, both of these bands must be assigned to the infrared-inactive a_2 modes, ν_{10} and ν_{12}, in which the CH_2 twisting and CH out-of-plane bending are almost equally coupled. The corresponding bands are found at 927 cm^{-1} (ν_{10}) and 594 cm^{-1} (ν_{12}) for the 1,1,4,4-d_4 species and at 587 cm^{-1} (ν_{12}) for the d_6 species. It is likely that the a_2 modes of the *s-cis* form (C_{2v}) are made infrared-active due to the lowering of molecular symmetry from C_{2v} (*s-cis*) to C_2 (*gauche*).

As described above, the second stable conformer probably exists in the *gauche* form rather than in the *s-cis* form. However, it is interesting to note that most of the infrared bands due to the second stable conformer can be reasonably assigned on assuming the planar *s-cis* form. Therefore, as far as the vibrational assignment for a less stable conformer of a compound with conjugated double bonds is concerned, it seems justifiable to use the *s-cis* form as a practical model instead of paying too much attention to the problem of internal-rotation angle which is inherently difficult to determine.

Assignments of Infrared and Raman Bands. Most of the infrared and Raman bands shown in Figs. 3 and 4 could be assigned. The tables which list the observed infrared and Raman frequencies together with their assignments are available from the authors on request.

A Model of Nematic Liquid Crystals for Viscosity and Self-diffusion

Seiichi MIYAJIMA,*,† Nobuo NAKAMURA, and Hideaki CHIHARA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka 560
(Received August 2, 1982)

A Geometrical model is presented which rationalizes the viscosity and self-diffusion coefficients and their anisotrcpies in nematic liquid crystals. The model is an extension of Eyring's theory of the liquid state to the anisotropic fluid, based on the geometry of the constituent molecule. A novel concept, effective anisotropy factor of a molecule, is introduced which is determined from the viscosity coefficients. An empirical law on the principal viscosity coefficients by Kneppe *et al.* is given its molecular basis by this model. Self-diffusion coefficient tensor calculated from the available viscosity data of PAA, MBBA, and HBAB agree well with experiment.

General understanding of cohesion of organic molecules shows that the nature of mesophases which appear between the rigid molecular crystal and the isotropic liquid is essentially determined by the geometrical characteristics of the constituent molecules: The liquid crystalline mesophase is formed by a rodlike molecule having a certain degree of internal rigidity,[1] whereas the special kinds of mesophases such as discotic or columnar ones are formed by a disk-like molecule[2] and the plastic crystal consists of a globular molecule.[3] One is thus tempted to develop a model theory of such mesophases, which will help to understand their features at least qualitatively like the one presented here for viscosity and self-diffusion in the nematic liquid crystal, the most typical mesophase formed by rodlike molecules.

Since Miesowicz[4] pointed out that external magnetic field has an effect on the viscosity of 4,4′-dimethoxyazoxybenzene (PAA) in 1935, the flow properties of nematic liquid crystals have been one of the interesting problems in rheology[5] and molecular dynamics.[6] Continuum theory of the viscoelastic properties of nematic liquid crystal was developed by Ericksen and Leslie.[7] On the basis of their theory, Lubensky[8] proposed relations between Franck's elastic constants and the nematic order parameter, $\langle p_2 \rangle$, and later, Imura and Okano[9] derived phenomenological relations between $\langle p_2 \rangle$ and viscosity coefficients. These theories could, however, interpret the experimental data with only partial success.[10] Recently, a comparative experimental study of the viscosity coefficients of some nematic liquid crystals were carried out by Kneppe *et al.*[11] and some rules concerning relationship among the principal viscosity coefficients were found in a purely empirical manner.

Our standpoint is very different from the models of the former authors; it is not an elastic continuum theory but a very simple model theory based on the geometrical characteristic of the constituent molecule. Our treatment has its origin in Eyring's theory of the rate processes[12] and of significant liquid structure,[13] and is an extension of Eyring's theory of the liquid state to the system of uniaxial symmetry. We will describe in this paper how the anisotropic shape of the molecule is reflected on anisotropies of the diffusion coefficient tensor and of the viscosity coefficients and will derive phenomenological relations between diffusion and viscosity coefficients. Finally, comparisons with the experiments will be given. An empirical law recently found by Kneppe *et al.*[11] will find its molecular basis in our simple model.

Theory

The essential points of Eyring's idea are: (1) the liquid state consists of solid-like molecules and gas-like mobile molecules adjacent to the holes, (2) viscous flow and diffusion can be treated on a common physical basis by supposing that the two phenomena are the results of molecular friction when a molecule jumps into a hole. Eyring *et al.* developed their theory for isotropic liquids, and we will now treat the case of anisotropic fluid.

Diffusion coefficient tensor in a three-dimensional system is defined by the Fick's first law,

$$\boldsymbol{J} + \boldsymbol{D}\nabla c = 0. \tag{1}$$

Here, c and $\boldsymbol{J}$ denote the concentration of the diffusing solute and the flow density, respectively. If we take a coordinate system in which the z-axis is parallel to $\boldsymbol{n}$, the nematic director, the tensor $\boldsymbol{D}$ can be diagonalized according to the axial symmetry of the system,

$$\boldsymbol{D} = \begin{bmatrix} D_\perp & 0 & 0 \\ 0 & D_\perp & 0 \\ 0 & 0 & D_{//} \end{bmatrix}, \tag{2}$$

and Eq. 1 consists of two independent differential equations. If the velocity of flow is represented by $\boldsymbol{u}$, the following set of equations hold by virtue of the relation, $\boldsymbol{J}=c\boldsymbol{u}$ for the flow along the axis q_j (q denotes the generalized coordinate and j indicates a specific direction, x, y, or z):

$$c\,u_j + D_{jj}\frac{\partial c}{\partial q_j} = 0. \tag{3}$$

On the other hand, the viscosity of the nematic liquid crystal can be defined by the Newton's law.†† When the shear stress is applied along j on the plane perpendicular to i, the viscosity coefficient η_{ji} is represented by

$$\eta_{ji} = \frac{(F_{ji}/A_i)}{\left[\dfrac{\partial u_j(q_i)}{\partial q_i}\right]}, \tag{4}$$

† Present address: Department of Chemistry, College of Humanities and Sciences, Nihon University, Sakurajosui, Setagaya-ku, Tokyo 156.

†† In fact, Newtonian property of nematic liquid crystals was confirmed experimentally (in Ref. 18) under ordinary rate of shear.

where F_{ji} denotes the shear force, and A_i is the area on which the shear force acts. If we consider a gas–like mobile molecule jumping into the nearby hole by overcoming the friction arising from interactions with solid-like molecules, the denominator in Eq. 4 is replaced by u_j/σ_i (σ_i is the nearest neighbor distance along i), and Eq. 4 is replaced by

$$\eta_{ji} = \frac{\sigma_i}{A_i} \cdot \frac{F_{ji}}{u_j}. \tag{5}$$

Let us now relate the viscosity coefficient to the diffusion coefficient by thermodynamic considerations. Generalized force $\boldsymbol{f}$ which is brought about by the spatial gradient of chemical potential is represented by

$$f_j = -kT \frac{\partial \ln \lambda}{\partial q_j}, \tag{6}$$

where λ is the absolute activity. Suppose that some fraction, κ_j, of this phenomenological force acts as the shear force along j on the plane perpendicular to i, *i.e.*,

$$F_{ji} = \kappa_j f_j. \tag{7}$$

The information about the local structure of the fluid system is included in the phenomenological parameter κ_j. Combinig Eqs. 3 and 5—7, one gets

$$\eta_{ji} = kT \frac{\sigma_i}{A_i} \cdot \frac{\kappa_j}{D_{jj}} \cdot \frac{\partial \ln \lambda}{\partial \ln c}, \tag{8}$$

which is an extended equation of Eyring and Ree[13] and can be applied to an anisotropic system. We will treat in this paper the high concentration limit, $\lambda = c$, which corresponds to the case of self-diffusion.

We now derive specific expressions of viscosity in nematic liquid crystals. In such an anisotropic fluid, viscosity depends on the direction of flow (j) and of the velocity gradient (i) with respect to the orientation of the director, $\boldsymbol{n}$. Miesowicz[14] first gave definitions of the three principal viscosity coefficients corresponding to the cases in which $\boldsymbol{n}$ is (1) parallel to the velocity gradient, (2) parallel to the flow, and (3) perpendicular to both the flow and the velocity gradient. The orientations are drawn in Fig. 1, in which η_1, η_2, and η_3 are defined by

$$\eta_1 \equiv \eta_{yx},\ \eta_2 \equiv \eta_{zy},\ \text{and}\ \eta_3 \equiv \eta_{yz},$$

corresponding to the definition by Helfrich,[15] Gähwiller,[16] and Kneppe and Schneider.[17] Note, however, the difference (η_1 and η_2 have been interchanged) from the definition by Miesowicz,[14] and Porter and Johnson.[18] An appropriate set of the geometrical factors, A_i and σ_i, are necessary to describe

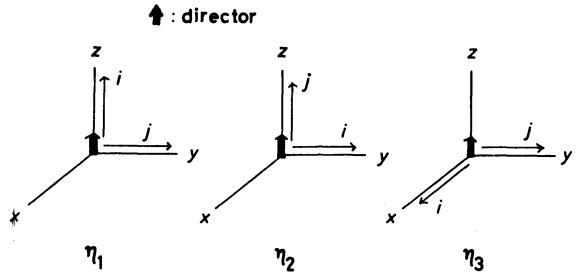

Fig. 1. Geometries for the three principal viscosity coefficients in a wall-aligned nematic liquid crystal system.

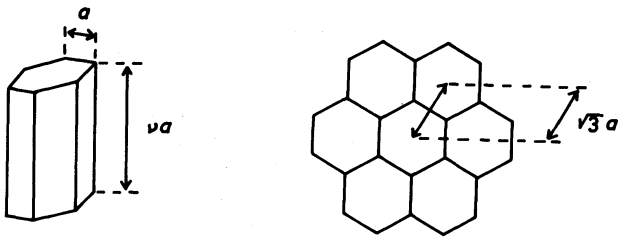

Fig. 2. Model of packing of molecules in the nematic liquid crystal.

these viscosity coefficients through Eq. 8. We will thus introduce a very simple model treatment for these factors. The nematic liquid crystal system is regarded as an assembly of closely packed molecules having a shape of elongated regular hexagonal prism as shown in Fig. 2. We assume according to Eyring's significant structure theory that some of the molecular sites are vacant, the concentration of the holes being dependent on temperature. The symbols, a and νa, represent the dimensions of individual molecules, with ν the effective anisotropy factor of the molecular shape. This model may be called the "pencil model," by use of which A_i and σ_i can be determined from purely geometrical considerations for each of the three principal viscosity coefficients, *i.e.*, in the case of η_2, all of the six side-planes undergo a shear stress, whereas in the case of η_1, the two base hexagons, and in the case of η_3 two side-planes do, respectively. The quantity σ_i is equal to νa for η_1 whereas $\sqrt{3}\ a$ for η_2 and η_3. It will be noticed that steric hindrance is rather strong when a molecule jumps perpendicularly to $\boldsymbol{n}$ but when it jumps parallel to $\boldsymbol{n}$, the steric hindrance will be weaker and the effective forces between molecules are mainly shear forces. Therefore, we put $\kappa_z = 1$ and $\kappa_y = \kappa$, where κ remains to be determined empirically.

The following set of equations are thus obtained from Eq. 8:

$$\eta_1 = \frac{\sqrt{3}\nu}{9a} \cdot \frac{\kappa kT}{D_\perp}, \tag{9}$$

$$\eta_2 = \frac{\sqrt{3}}{6\nu a} \cdot \frac{kT}{D_{//}}, \tag{10}$$

and

$$\eta_3 = \frac{\sqrt{3}}{2\nu a} \cdot \frac{\kappa kT}{D_\perp}, \tag{11}$$

which provide phenomenological relations between the viscosity and the diffusion coefficients.

A simple relation

$$\nu = 3\left(\frac{\eta_1}{2\eta_3}\right)^{1/2} \tag{12}$$

is obtained from Eqs. 9 and 11, which enables us to determine ν when the experimental data of the viscosity coefficients are available. Anisotropy of the diffusion coefficient tensor may be predicted from Eqs. 9—11 to be

$$\frac{D_{//}}{D_\perp} = \frac{\eta_3}{3\kappa\eta_2} = \frac{3\eta_1}{2\kappa\nu^2\eta_2}. \tag{13}$$

Comparison with Experiment

Now, comparisons of our model with experiments will be made on three typical nematic liquid crystals, 4,4'-dimethoxyazoxybenzene, *N*-(4-methoxybenzylidene)-4-butylaniline, and 4-(4-hexyloxybenzylideneamino)benzonitrile, which will be called in this paper PAA, MBBA, and HBAB according to their usual acronyms.

Table 1 lists the principal viscosity coefficients of PAA measured by Miesowicz,[14] those of MBBA by Kneppe and Schneider,[17] and those of HBAB by Gähwiller.[16] Anisotropic self-diffusion coefficients of nematic liquid crystals were first measured by Yun and Frederickson[19] for PAA by means of ^{14}C radioactive tracer technique, and later by Zupančič *et al.*[20] for MBBA by means of NMR pulsed field gradient technique coupled with multiple-pulse line-narrowing technique. The diffusion coefficients of HBAB were estimated from NMR relaxation measurements by the present authors.[21] These data are tabulated in Table 2.

Effective Anisotropy Factor of a Molecule in the Nematic State. This factor, ν, can be calculated from the data of η_1 and η_3 (Table 1) by using Eq. 12, and is shown in Table 2 for each of the three compounds. Temperature-dependences of ν in MBBA and in HBAB are also calculated††† and shown in Figs. 3 and 4, where temperatures are reduced by T_c, the clearing temperature. In these figures the temperature-dependences of the nematic orientational order parameter, $\langle p_2 \rangle$, are also shown.

Table 1. Experimental data of principal viscosity coefficients[a]

	Temperature	Principal viscosity coefficients		
	T/K	η_1	η_2	η_3/Pa s
PAA[a]	395.15	0.0092	0.0024	0.0034
MBBA[b]	298.15	0.1361	0.0240	0.0413
HBAB[c]	333.15	0.0960	0.0175	0.0290

a) Ref. 14. b) Ref. 17. c) Ref. 16.

Table 2. Comparison of theoretical prediction with experiment[a]

	T/K	ν_{theory}	$D_{//theory}$ / $D_{//expt}$	$D_{\perp theory}$ / $D_{\perp expt}$	$(D_{//}/D_{\perp})_{theory}$ / $(D_{//}/D_{\perp})_{expt}$
PAA	395.15	3.49	6.5×10^{-10}	5.5×10^{-10}	1.2
			4.1×10^{-10}	3.2×10^{-10}	1.3
MBBA	298.15	3.85	4.4×10^{-11}	3.1×10^{-11}	1.4
			1.2×10^{-10}	9.0×10^{-11}	1.3
HBAB	333.15	3.86	3.9×10^{-11}	2.9×10^{-11}	1.4
			(2.7×10^{-10})	1.7×10^{-10}	(1.6)

a) Diffusion coefficients are given in units of $m^2\ s^{-1}$. Experimental data of the diffusion coefficients are quoted from Ref. 19 (^{14}C-tracer) for PAA, from Ref. 20 (NMR pulsed field gradient) for MBBA, and from Ref. 21 (NMR relaxation) for HBAB. The data $D_{//}$ and $D_{//}/D_{\perp}$ of HBAB are less reliable because $D_{//}/D_{\perp} \to 2.0$ in the low temperature limit was assumed to derive them.

††† The data on the temperature-dependences of η_1 and η_3 of PAA are not available to the authors.

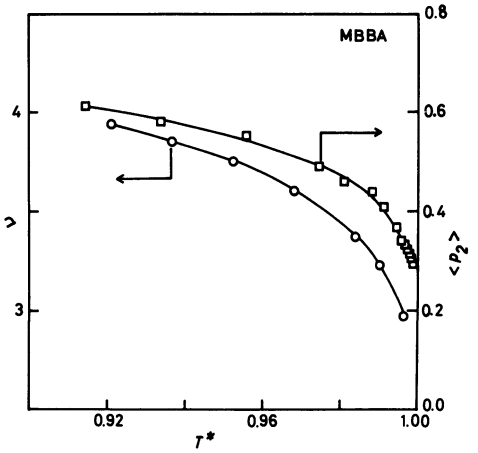

Fig. 3. Effective anisotropy factor ν of a molecule (○), and orientational order parameter $\langle p_2 \rangle$ (□) in MBBA as a function of reduced temperature, $T^* = T/T_c$. The ν was calculated from the data of Ref. 17 by using Eq. 12; the $\langle p_2 \rangle$ was taken from Ref. 22.

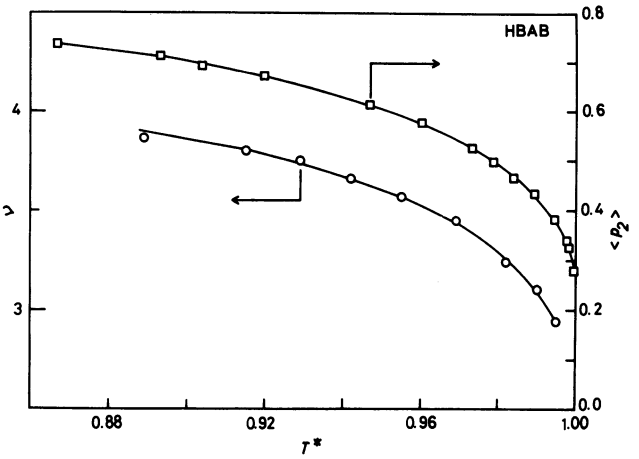

Fig. 4. Effective anisotropy factor ν of a molecule (○), and orientational order parameter $\langle p_2 \rangle$ (□) in HBAB as a function of reduced temperature, $T^* = T/T_c$. The ν was calculated from the data of Ref. 16 by using Eq. 12; the $\langle p_2 \rangle$ was taken from Ref. 21.

According to our model, ν calculated from η_1 and η_3 is a measure of the effective geometrical anisotropy of a molecule at each temperature, and should exhibit the temperature-dependence that resembles that of $\langle p_2 \rangle$ because $\langle p_2 \rangle$ is defined as the ensemble average of the second rank Legendre polynomial

$$\langle p_2 \rangle = \langle p_2(\cos\Theta) \rangle = \frac{1}{2}\langle 3\cos^2\Theta - 1 \rangle,$$

where Θ is the angle between $\boldsymbol{n}$ and the instantaneous molecular axis. In other words, both ν and $\langle p_2 \rangle$ are some motional average of the shape of molecular volume. The asymptotic value of ν in the low temperature limit, *i.e.*, on the condition $\langle p_2 \rangle = 1$ will be identical with ν derived on the basis of static molecular structure. The results of calculation given in Figs. 3 and 4 and Table 2 show that these are in fact the case: The ν_0, asymptotic value of ν in the low temperature limit, are

$$\nu_0 = 4.2 \pm 0.1 \text{ for MBBA,}$$

and

$$\nu_0 = 4\ 1 \pm 0\ 1 \text{ for HBAB.}$$

The ν of PAA is smaller than the ν of the other two compounds, corresponding to the fact that only PAA does not have an end chain. Thus, the calculated value of ν for the three compounds reflect their static molecular structure well in their relative as well as the absolute magnitude. The temperature dependence of ν in the two compounds has good parallelism to that of $\langle p_2 \rangle$.

We can thus conclude that the quantity ν derived from the "pencil model" has a clear physical significance as an effective anisotropy factor of a molecule in the nematic liquid crystalline state.

Self-diffusion Coefficient Tensor. Experimental data on self-diffusion coefficient tensor known until now[19,20] has revealed that its anisotropy, $D_{//}/D_{\perp}$, is not strongly dependent on material, and that $D_{//}/D_{\perp} \approx 1.4 \pm 0.2$ holds except in the close vicinity of T_c. The value κ, the only adjustable parameter in our theory is estimated to be $\kappa \approx 0.4$ by utilizing Eq. 13 and the viscosity data.

The principal values of the tensor $\boldsymbol{D}$ can now be calculated by using Eqs. 9—11 and the viscosity data (Table 1), and by assuming $\kappa = 0.4$. The value of a was taken from the X-ray work[23] ($\sqrt{3}\,a = 0.50$ nm, for all materials). The results of the calculation are tabulated and compared with the experimental data in Table 2. The agreements are satisfactory.

Kneppe-Schneider-Sharma's Empirical Law on η_3/η_2. Kneppe, *et al.*[11] pointed out recently that the quantity η_3/η_2 is almost independent of temperature, and has a relatively constant value irrespective of the material. The η_3/η_2 for MBBA and HBAB are shown in Fig. 5, which confirms that empirical law. The law is interesting as the quantity η_3/η_1, on the contrary, exhibits strong dependence on temperature as discussed above.

This law can be rationalized by our model. By rewriting Eqs. 12 and 13, the relations

$$\frac{\eta_3}{\eta_1} = \frac{9}{2\nu^2} \tag{14}$$

and

$$\frac{\eta_3}{\eta_2} = 3\kappa \frac{D_{//}}{D_{\perp}} \tag{15}$$

follow. Strongly temperature-dependent factor ν does not appear in Eq. 15. One can see that the empirical law by Kneppe *et al.* is consistent with the well-accepted knowledge[6] that the diffusion anisotropy $D_{//}/D_{\perp}$ is not strongly dependent on either material or temperature. If we take a rough approximation that diffusion anisotropy is independent of temperature, *i.e.*, $D_{//}/D_{\perp} = 1.40$ and taking $\kappa = 0.40$, Eq. 15 gives

$$\frac{\eta_3}{\eta_2} = 1.68, \tag{16}$$

which is in fair agreement with experiment as is seen in Fig. 5. The residual small dependence of η_3/η_2 on temperature will be attributed to the temperature-dependence of $D_{//}/D_{\perp}$.

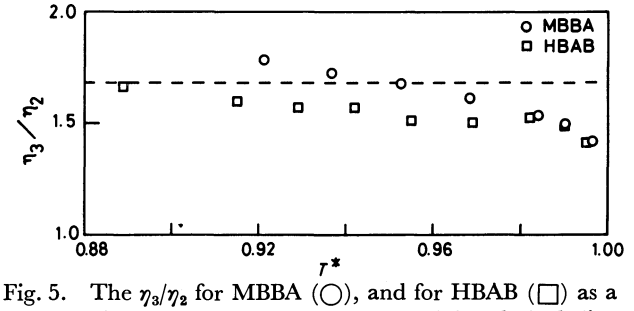

Fig. 5. The η_3/η_2 for MBBA (○), and for HBAB (□) as a function of reduced temperature. The dashed line represents Eq. 16.

In conclusion, it has been demonstrated that the properties of viscosity and self-diffusion in the nematic liquid crystals can be explained fairly well by using the "pencil model," a simple model which is based on the geometrical characteristic of the constituent molecule and which involves only one adjustable parameter κ ($\kappa = 0.4$ is universally adopted in this paper).

We thank Dr. Ch. Gähwiller for kindly providing us with the numerical data of the viscosity coefficients of HBAB. One of the authors (S. M.) is grateful to the fellowship of Yukawa Memorial Fund.

Electronic Spectra and Crystal Structure of Organic Radical Salt: Dimethyldibenzotetrathiafulvalenium Tetrafluoroborate

Chizuko TANAKA,* Jiro TANAKA, Karlheinz DIETZ,†† Chuji KATAYAMA, and Masashi TANAKA†

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

†*College of General Education, Nagoya University, Chikusa-ku, Nagoya 464*

(Received August 16, 1982)

The single crystal of dimethyldibenzotetrathiafulvalenium tetrafluoroborate (1 : 1) has been prepared by electrocrystallization. The crystal structure has been determined by X-ray crystal analysis. The salt crystallizes in Ibam with $a=14.637(3)$, $b=17.625(6)$, $c=13.614(3)$ Å. The radical cations align along the c axis at nearly equal spacing forming eclipsed dimers and the dimeric units are stacked with a staggered mode. The electronic spectra of the radical cation and the dimer have been measured in solution and the assignment has been presented with an aid of the MO calculation by Pariser-Parr-Pople method. A charge transfer (CT) band observed in the dimer has been correlated with the charge resonance of unpaired electron between the HOMOs of the radical cations. Polarized reflection spectra of single crystal have been measured with three different crystal planes and the assignment of both the CT and molecular type bands have been confirmed with polarization measurement. The energy and the intensity of the CT band indicate that the unpaired electron is localized on each radical, but the CT configuration is involved significantly. The crystal is an insulator as is expected from the electronic structure; the large U, which is evidenced by the energy of the CT band, and the staggered packing hinders electronic conduction. It implies that a monovalent radical salt is difficult to be metallic unless a mixed valence state is involved.

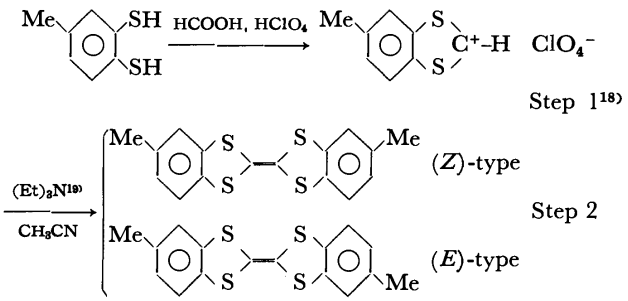
Tetrathiafulvalene (TTF) and its family are good electron donors[1] which form donor-acceptor complex[2,3] and mixed valence salts as well as monovalence salts depending on the oxidation conditions. The oxidation is carried out either by the chemical method with suitable oxidants[4] or electron acceptor, or by electrochemical method.[5,6] A structural characteristic of organic metal is that the crystal has segregated columns of mixed valence donor or/acceptor stacks.[7] Torrance[8] discussed the relation between the redox-potentials of the donor and acceptor and the degree of charge transfer. The examination of the crystal structures and properties of ion-radical salts and charge transfer compounds is of theoretical and experimental importance to develop new organic metal.

The title compound is a 1 : 1 salt of cation radical of 5,5′-dimethyl-2,2′-bi-1,3-benzodithiol-2-ylidene, which is a dimethyl derivative of dibenzotetrathiafulvalene (DBTTF) and is abbreviated as DMDBTTF in the present paper. Hünig *et al.*[9] reported the oxidation potentials and the electronic spectra of TTF, DBTTF, DMDBTTF, and their cation radicals. The oxidation potential of DMDBTTF is slightly lower than that of DBTTF and the comparison of the structures of these complexes will be interesting. Both DMDBTTF–TCNQ[10] and DBTTF–TCNQ are insulators with alternating donor acceptor stacking.[11–13] DBTTF–$TCNQCl_2$ shows high electrical conductivity because it crystallizes in the segregated stacks of the donor and acceptor.[14,15] DBTTF–DDQ also shows high electrical conductivity and is considered as a mixed valence crystal with a segregated stack of acceptor.[16] DBTTF–$(BF_4)_{0.8}$ has been reported to be a mixed valence and conducting material,[17] but its crystal structure has not been reported yet.

In this paper we report the preparation, the crystal structure and the electronic spectra of DMDBTTF·BF_4 (1 : 1) crystal. We also discuss the electronic structure of the radical monomer and dimer as well as the crystal. The crystal structure found is an unique dimeric type and it is an insulator because the dimer is so stable that the delocalization of unpaired electron is limited within the dimer, and the CT state has fairly large energy characterized by U.

Preparation

DMDBTTF was prepared by the following reaction route using commercial GR. grade toluene-3,4-dithiol.



5-Methyl-1,3-benzodithiol-2-ylium perchlorate (4.2 g) obtained in Step 1 was dissolved in 180 ml of acetonitrile. Stirring the solution at 0 °C, acetonitrile solution of triethylamine (2.8 g/10 ml) was added dropwise. Yellow precipitate of DMDBTTF formed immediately. The stirring was continued for 15 min after the addition was completed. The precipitate was collected, washed with acetonitrile and dried. The yields of Steps 1 and 2 were 82 and 93% respectively. The product was purified by column chromatography and recrystallized with benzene and acetonitrile. As shown in above scheme two isomers, (*Z*) and (*E*), are considered for 5,5′-dimethyl-2,2′-bi-1,3-benzodithiol-2-ylidene. But it is not certain whether our product consists of only one isomer or a mixture of isomers.[10]

The electrocrystallization was carried out in the H shaped glass tube with Pt wire electrodes (same results were obtained with Ni electrodes) using dry CH_2Cl_2 solution of DMDBTTF and $(n\text{-Bu})_4N\cdot BF_4$ in inert atmosphere. The yellow color of

neutral DMDBTTF changed to dark green by electrolysis. Within a few days dark violet prisms covered the (+) electrode, and these crystals were used for X-ray and spectral investigations.

Structural Determination

The crystal shape is shown in Fig. 1. The reflection color of the crystal is dark violet on the (010), silvery purple on the (110) and (1$\bar{1}$0), and brilliant pink on the (001) plane. The Weissenberg photographs showed the space group either Ibam or Iba2 from systematic absences. The reflection data for X-ray structural determination were collected with a Rigaku four-circle diffractometer AFC-5 using graphite-monochromatized Cu $K\alpha$ radiation. Intensities of 1617 reflections were measured up to $\theta=63°$ with the crystal of the size $0.2\times0.08\times0.08$ mm^3. The intensity statistics indicated the structure to be centrosymmetric, therefore the space group was determined as Ibam. The lattice parameters determined using 13 selected reflections are given in Table 1. The structure was solved by Patterson function method. The refinement of the structure was performed by the block-diagonal least-squares method with 1058 independent reflections of $|F_o|\geqq3\sigma$ with anisotropic thermal parameters. The final R index converged to 0.082.** The atomic parameters are shown in Table 2,

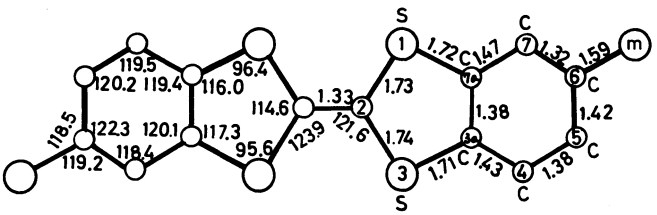

Fig. 2. Bond length (Å) and angles (°) of DMDBTTF$^+$.

and the molecular structure is illustrated in Fig. 2.

The DMDBTTF radical cation is approximately planar, but it is slightly bent towards both ends. The crystallographic two-fold axis coincides with the two-fold axis of the molecule. The least-squares plane for the half of the molecule, the 1,3-benzodithiole ring, is represented as $-0.0348x-0.0371y+0.9987z=1.6100$ (x, y, and z are coordinates in Å referred to the a, b, and c crystal axses, respectively). The deviation of the atoms from the plane is less than 0.04 Å. The dihedral angle between this and the other corresponding plane is 5.8°. The boron atom and two of the four fluorine atoms, F(1) and F(2), of the tetrafluoroborate ion are on the mirror plane and the remaining two fluorine atoms, F(3), are above and below the plane keeping the mirror symmetry. Three residual peaks, which could not be explained by hydrogen atoms, were found in the difference Fourier map. Two of them were around the anion site indicating disordered arrangement of anions. The other one was found in the region to which the methyl group attached to C(5) could be assigned. This suggests the stack includes some molecules whose methyl groups occupy the site on C(5) instead of C(6). However the distance between the methyl group on C(5) and the fluorine atom, F(2), is considerably shorter than normal contact. This may be related to the unusually short bond length of B–F(2), 1.27 Å, and the large anisotropy of thermal ellipsoid of boron atom. Hence, it is considered that the disordered arrangement of the anion is closely connected with that of the cation radical.

The projection of the cations onto three different planes are illustrated in Figs. 3, 4, and 5. Two adjacent cations form an eclipsed dimer whose interplanar spacing at the central bond region is 3.36 Å. The S···S contacts in the dimer are 3.31 and 3.37 Å. These values are comparable with the values found in the eclipsed dimer in TTF·I_3[20] and other integral oxidation state salts.[21,22] The dimers align along the c axis in a staggered mode.

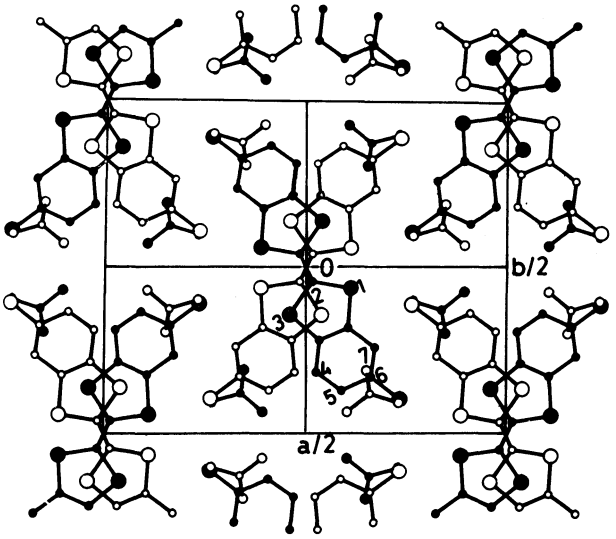

Fig. 3. Projection of the structure onto the (001) plane. The molecules shown with black circles locate above and below the mirror plane at $z=0$. The molecules shown with white circles locate above and below the mirror plane at $z=1/2$. Boron atoms are on the mirror planes.

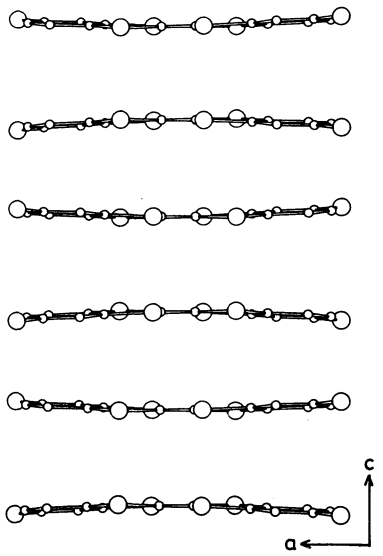

Fig. 4. Projection of the structure onto the (010) plane.

The interplanar spacing between the centers of molecules in the staggered overlapping is 3.45 Å which is almost equal to the interplanar spacing in the dimer. Such a pattern of cation stacking is rather unique as a monocation salt. The structural characteristic will be reflected on the optical and other electronic properties of the crystal.

Electrical Conductivity

The powder conductivity of the crystal is measured with a compressed pellet (diameter=5 mm) under the pressure of 20 kg/cm^2 at room temperature. The conductivity was $\sigma=5\times10^{-8}\ \Omega^{-1}\,cm^{-1}$. It indicates that the crystal is an insulator. This is reasonable since the crystal is not a mixed valence having an odd electron

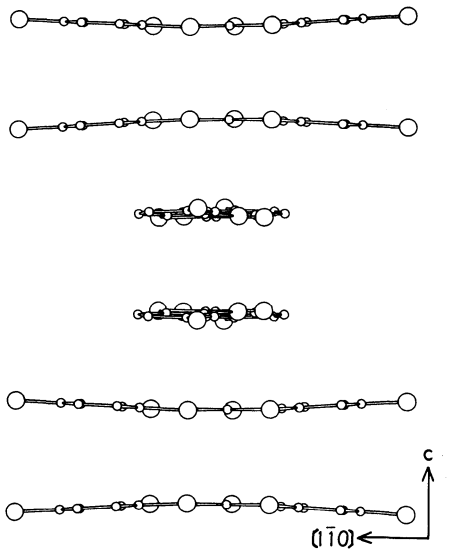

Fig. 5. Projection of the structure onto the (110) plane.

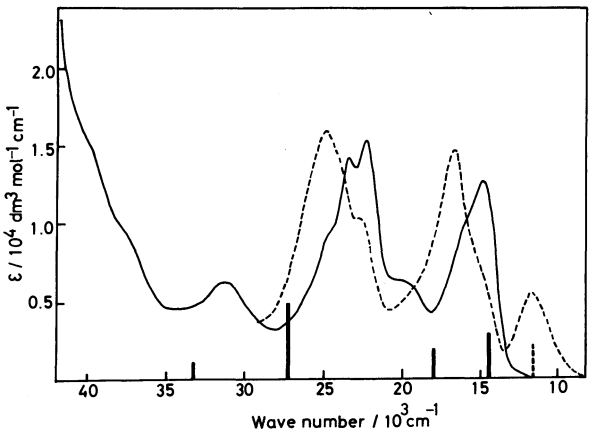

Fig. 6. Absorption spectra of DMDTTF$^+$ in solution (——, 0.26×10^{-5} mol dm^{-3} in CH_2Cl_2 at room temp; ------, 0.67×10^{-3} mol dm^{-3} in CH_3CN at *ca.* −40 °C) and calculated values (——, L1, M1, L2, and M2 for the monomer, from right to left; ------, CT for the dimer).

on each site as is shown by structural analysis and stoichiometry. The electrostatic repulsive energy is big enough to prevent electrons moving freely in the crystal. This point will be discussed below from optical evidence and its theoretical analysis.

Electronic Spectra of the Cation Radical in Solution

Electronic absorption spectra of the cation radical salt in monomeric and dimeric states measured in dichloromethane and in acetonitrile solutions, respectively, are shown in Fig. 6. As reported by Hünig *et al.*,[9] the neutral molecule has only a weak absorption band in the region below 25000 cm^{-1}, therefore the strong bands observed at 14600 and 22000—24000 cm^{-1} region are attributed to the radical monomer. The monomer has no absorption band in the region between 5000—11000 cm^{-1}. The electronic spectra of the dimer

was already reported by Hünig *et al.*,[9] and we confirmed their result more clearly by measuring the spectra at lower temperature as is shown in Fig. 6. In the dimeric state, the CT band between the radicals is observed at 11600 cm^{-1}. The bands at 14600 and 22000—24000 cm^{-1} in the monomeric state are shifted by 2000—2600 cm^{-1} to higher energy upon dimerization. Similar spectral change was reported in TTF^+ dimer.[23]

Calculation of the Excited States of the Monomer

In order to give an assignment of radical monomer spectra, Pariser-Parr-Pople type calculation for the open shell system was performed. The computer program developed in our laboratory based on the scheme of Lowitz[24] was used for the calculation. The value of the valence state orbital energies and the one-center Coulomb integrals used in our calculation were as follows; $U_{cc}=-11.22$ eV, $(CC|CC)=10.60$ eV, $U_{ss}=-9.16$ eV, $(SS|SS)=10.01$ eV. The values for U_{cc} and $(CC|CC)$ are the standard values. The value of $(SS|SS)$ has been evaluated from the data of Hinze and Jaffe[25] by the use of Pariser-Parr approximation. The value of U_{ss} was selected in order that the result of the calculation might be in reasonable agreement with the observed data. The core resonance integral β was calculated by the use of Wolfsberg and Helmholz formula,[26] where the proportional constant was set as $K=0.39$. All calculations were carried out using the single exponent Slater AO. The results of the calculation on energies, intensities and polarizations are shown in Table 3 and illustrated in Fig. 6. The bands at 14600 and 22000—24000 cm^{-1} are found to be polarized in the direction of the molecular long axis (L1 and L2), while the 19500 and 31500 cm^{-1} bands are polarized in the direction of the molecular short axis (M1 and M2). The agreement of the calculated and observed values was satisfactory particularly on sequence of transition energies and intensities, and on polarizations. The polarization characteristics were all confirmed by the polarized spectral measurement of the single crystal as is discussed below.

Theoretical Treatment of the Dimer Spectra

Before going to the discussion of the crystalline spectra, we will consider the electronic structure of the dimer, since molecules are paired tightly in the crystal forming the eclipsed dimer. The molecular overlap integral between the molecules in the eclipsed pair is 0.0260, while that between the molecules in the staggered pair is 0.0015, therefore the molecular interaction is much larger in the eclipsed pair than in the staggered pair. Under this condition the crystalline electronic states can be described as an assembly of the eclipsed dimer.

The electronic structure of the cation radical dimer can be described by Hubbard Hamiltonian as was shown in our earlier paper on TCNQ complexes.[7] The electronic states are factored into a symmetric and an antisymmetric states under the inversion symmetry of the dimer. Matrix elements of the secular equations are given as follows.

$$\begin{vmatrix} 0 & 2t_{mm} & 0 \\ & U & \sqrt{2}\,t_{mm-1} \\ & & \Delta-\delta \end{vmatrix} \begin{matrix} \text{G} \\ \text{CT}^{(+)} \\ \text{LE}^{(+)} \end{matrix} \qquad \begin{vmatrix} U & \sqrt{2}\,(t_{mm-1}+2\text{D}) \\ & \Delta+\delta \end{vmatrix} \begin{matrix} \text{CT}^{(-)} \\ \text{LE}^{(-)} \end{matrix}$$

Symmetric state Antisymmetric state

The dipole transition from the G to the $CT^{(-)}$ and $LE^{(-)}$ states are allowed by the selection rule. The diagonal energy of the CT state is given as $U=\eta(U^{pp}_{mm}-U^{pq}_{mm})$, where U^{pp}_{mm} is the Coulomb repulsion energy between two electrons on the (mth) MO (HOMO) of the same molecule (p), and U^{pq}_{mm} is the one between two electrons on the HOMOs of the adjacent molecule (p and q). The numerical values of U^{pp}_{mm} and U^{pq}_{mm} were calculated as 4.12 and 2.44 eV respectively, by the use of Nishimoto-Mataga potential. The difference between these two terms was 1.68 eV. Δ is the energy of the LE state in the monomer (1.81 eV for the L1 state and 2.74 eV for the L2 state). η is the screening constant due to the electronic polarization. t_{mm} in the off-diagonal matrix element is a transfer integral, the numerical value of which is estimated by the relation $t_{mm}=-kS_{mm}$ where S_{mm} is the overlap integral between the HOMOs m, and k is an empirical parameter. t_{mm-1} and D (the dipole interaction energy between the $CT^{(-)}$ and $LE^{(-)}$ states) can be ignored because the symmetries of the states are different and the transition moments are orthogonal to each other. The diagonal energy for the $LE^{(-)}$ states, Δ, are lifted by the amount δ, the exiton type dipole-dipole interaction, which was not explicitly described in the earlier paper.[7] The numerical value of δ was evaluated as 0.07 eV, by a dipole calculation based on a weak coupling model scaled by the transition density method[27] for the L1 and the L2 bands. When the set of parameters $\eta=0.74$ and $k=10.0$ eV were chosen to estimate U and t, the calculated transition energies from the G state to the $CT^{(-)}$, $L1^{(-)}$, and $L2^{(-)}$ states are in good agreement

with the observed energies of the dimer in solution (Table 3). The assignment of the dimer spectra is confirmed by this calculation.

Electronic Spectra of Crystals

The crystalline reflection spectra were measured with the crystals of the size about $0.3\times0.3\times0.6$ mm^3 for the (010) and (110) faces and $0.5\times0.3\times0.2$ mm^3 for the (001) face by the use of a polarized microspectrophotometer. The results are shown in Figs. 7—9. The calculation of the excited states were carried out for these planes by summing up the dipole-dipole interaction over molecules within 200 Å radius and 30 Å depth in order to consider the directional dispersion of the exciton states.[28,29] The transition energies of the dimer

in solution were used for the diagonal energies of the CT, L1, M1, and L2 bands. However, we made the correction for the standard of the state energies by $-1000\ cm^{-1}$ for the CT level and $-2000\ cm^{-1}$ for other levels by taking into account the crystalline polarization effect. For the calculation of the off-diagonal energies of the dipole-dipole interaction, the length of transition moment estimated from the solution spectra of the dimer for each bands were used. All calculations were based on the dimer unit and the transition moments are placed in the center of the dimer. By this procedure the second order mixing and the exaggeration of the band shift were avoided. The results of calculation are tabulated in Table 4 and the calculated transition energies are compared with the observed crystalline spectra in the following.

In Figs. 4 and 5 the projection of molecules onto the (010) and (110) planes are illustrated. On these planes, the CT band is expected along the c axis. In Figs. 7 and 8 the reflectivities, Kramers-Kronig transformed spectra are illustrated. Although the absolute magnitude of reflectance is different between the planes, the CT band is found with a great intensity only along the c axis. The intensity is enhanced in the crystal by a factor of 2—4 as compared with that of the dimer in solution. This gives an evidence of an increase of the intermolecular CT interaction in the crystal. The observed CT energies were at 9000—9400 cm^{-1}, while the calculated values were 9000—9100 cm^{-1}, hence the agreement between the calculated and observed values was quite satisfactory. The result shows that the electron electron repulsion U is predominant in determining the energy level of the CT band in the monovalence radical salt. A similar spectral characteristic was reported by Kuroda *et al.*[30] and by Torrance *et al.*[23] on several TTF salts.

For the (001) plane the projection of molecules is shown in Fig. 3 and the reflection spectra and Kramers-Kronig transformation to molar absorption coefficent are shown in Fig. 9. The long-axis of the molecule is at the angle of 24.5° with the a axis, therefore the L type bands should be stronger along the a axis than the b axis, while that of the M type bands are stronger along the b axis. The Kramers-Kronig transformed spectra are in perfect agreement with this expectation that the L1 band appearing at 15000 cm^{-1} region and the L2 band at 22000 cm^{-1} range are stronger along the a axis than the b axis, while the M1 and M2 bands found at 17000 and 31000 cm^{-1}, which are correlated with the solution bands at 19500 cm^{-1} and 31500 cm^{-1}, are stronger along the b axis than along the a axis. The observed band position for the (001) plane are well explained by the calculation of the exciton splitting, however, the Davydov splitting for the L1 band is reversed in order. The calculated intensities shown in Table 4 are larger by a factor of 2, but the order of its size is in agreement with the observed ones. Although the intermolecular CT transition is not expected with the (001) plane since it is polarized along the c axis, but the absorption tail is found around at 10000 cm^{-1} region, and it may be due to the admixture of the c axis transition in this measurement because the incident beam has a glazing angle of 4—11°, hence it may have a slight component along the c axis.

Table 4. Polarized crystalline spectra

Plane	State	Pol. axis	Energy/$10^3\ cm^{-1}$		f	
			Obsd	Calcd	Obsd	Calcd
(001)	L1	a	14.2	14.8	0.50	0.91
		b	14.7	13.3	0.09	0.22
	M1	a		17.4		0.07
		b	17.0	17.6	0.05	0.24
	L2	a	22.5	23.2	0.33	1.81
		b	22.0	22.0	0.17	0.28
	M2	a	31.0		0.14	
		b	29.5		0.48	
	CT	c	—	10.3	—	0.35
(110)	CT	c	9.0	9.0	0.50	0.31
	L1	[1$\bar{1}$0]	13.5	16.2	0.36	0.23
				14.2		0.11
(010)	CT	c	9.4	9.1	0.23	0.32
	L1	a	13.0	14.8	0.43	0.91

Thus the assignment of electronic transitions is confirmed by the polarized spectral measurement and the calculation of exciton band shift for each planes.

Conclusion

$(DMDBTTF)^+$ radical obtained by electrochemical oxidation of neutral molecule crystallizes with BF_4^- forming a pseudo-one-dimensional crystal with unpaired electrons on each site. The radicals form eclipsed dimers in the crystal, and the dimers are aligned along the crystalline c axis with a staggered mode. This type of molecular packing may be occurred through a steric hindrance of the methyl groups at both ends. In this structure the transfer integral for the eclipsed pair (t_1) is much larger than that of the staggered pair (t_2), therefore the electronic structure of the dimer is conserved in the crystal. Namely the electronic spectra of the crystal is almost same with that of the dimer in solution, except that the molecular bands are red shifted and the CT band is enhanced. It reflects that the molecular character of the dimer is reserved in the crystal in spite of the CT interaction is conceivable between the dimer. It is reasonable since t_2 is negligibly small as compared to t_1.

The energy of the CT band gives an estimate of U for the dimer interaction, where the value of U is the change of repulsive energy of electrons accompanied with the charge transfer. It is significantly large as $U=1.24$ eV ($\simeq 5t_1$). The CT configuration in the ground state is estimated as 12% from the normalized wavefunction. A fairly large oscillator strength of the CT band is accounted for by this contribution. The crystal is an insulator in spite of apparent one-dimensional stacking of radicals, because U is large as usually found in monovalence salts. Moreover, the one-dimensional equality of the electronic structure is not realized since $t_1 \gg t_2$. Anyway the mixed valence state is most important to find organic metal.

All computations were carried out at the Nagoya University Computation Center; NUNICS program was used for crystal structure analysis.

The authors thank to JSPS for the fellowship to K. Dietz.

A Simple Pressurized High-temperature Proton NMR Apparatus for the Thermal Degradation of Polymers†

Shigezo SHIMOKAWA,* Eiji YAMADA, and Kazuo MAKINO††
NMR Laboratory, Faculty of Engineering, Hokkaido University, Sapporo 060
††*Department of Applied Chemistry, Faculty of Engineering, Hokkaido University, Sapporo 060*
(Received August 17, 1982)

A simple pressurized, externally heated, high-temperature proton NMR apparatus for the temperature range from 293 to 823 K and pressure range from 0.1 to 40 MPa is reported. The sample cell has a capillary opening and the vessel is pressurized by inert gas. An application of this apparatus to the thermal degradation of poly(vinyl chloride) is presented.

Some of polymers in the molten state at high temperature are in an equilibrium where competitive reactions such as the decomposition, polymerization and polycondensation are balanced. And there are some ordered states such as liquid crystalline phases (mesophase) in the molten state under growing temperature.[1] Previously we showed[2] that the thermal decomposition of poly(vinyl chloride) (TD-PVC) is a good model to study such a molten state at high temperatures. It was found[3] that high-temperature high resolution proton NMR provided a useful tool to detect the dynamic structure of molten polymers at high temperature.

However, such an atmospheric pressure experiment gives sometimes insufficient information, because the escape of gaseous products causes much loss of the liquid residue product. It is well known that a pressure vessel for thermal reaction is almost black box which is used only for the detection of thermal change.[4]

There is dangerous and difficult procedure for us to increase the pressure, keeping high temperature in the static magnetic field. Several studies[5-11] of high-temperature and high-pressure NMR only focused on pure liquid materials, for example, water or molten metals. As far as we know, there is no example of application of NMR under pressure to the process of thermal reaction at high temperature. Recently we developed an internally heated high-temperature and high-pressure C-13 NMR apparatus for direct measurements of pyrolysis of polymers.[12] In this report, the design of an externally heated high-temperature and high-pressure proton NMR apparatus and its application to thermal degradation process of TD-PVC have been presented.

Design of Apparatus

We constructed a heat and pressure resisting vessel for NMR study at high temperature of 823 K under high pressure of 40 MPa. Figure 1 shows the block-diagram of the homemade apparatus used in this study. The apparatus consists of a high resolution magnet, an externally heated high pressure vessel, a pressurizing system with inert gas, and an external field frequency lock system. A wide gap (6 cm) electromagnet of modified JEOL 3H type was used. The electromagnet was equipped with homogeneity current shim coils, a flux stabilizer and an external ^1H field frequency lock system in order to keep the good homogeneity and stability of the magnetic field. The basic spectrometer

used was a Bruker SXP 4-100 high power pulse spectrometer with Nicolet BNC-12 computer system.

Figure 2 shows the high pressure vessel made of titanium alloy (KS-130A, supplied by Kobe Steel Co. Ltd.). The vessel was externally heated. The tensile strength of the titanium alloy was 11600 kg cm^{-2} over extended periods (10000 h) at 673 K. The maximum working pressure of the vessel was reached over 40 MPa, but in this study the working pressure was restricted to 30 MPa, because of the limiting pressure of the Bourdon gauge and valves. Figure 3 shows a simple sample cell. The cell was made of heat resisting glass and it consists of three parts, *i.e.*, the bottom of the cell, the body of coil and the capillary. The bottom of the cell, which was needed for homogeneity of H_1 field for relaxation measurement. The sample cell was simply inserted into the vessel. 0.2 g of powder sample can be put into the cell. After introduction of the sample, the top of the cell was made in the form of capillary. Resonance coil for each sample cell was wound and fixed on the cell by heat resisting cement (Sauereisen cement No. 8). Rf lead wire was insulated by 1 mm ceramic tube. The sample cell was always renewed after each experimental run and tuning for probe balance was readjusted easily. The top of the vessel which contained the closure plug and nuts with rf terminals was cooled by a water jacket: The sealing was made by copper washer and an rf lead wire was insulated by ceramic tubes. The outlet of the rf lead wire was sealed and insulated by Teflon cone, which was located away from the vessel. One of the terminals of the lead wire was grounded to the vessel. The escape of the sample from the sample cell as gaseous products at high temperature was much reduced by use of capillary. Very small amount of eluted gas caused slight contamination of the inner wall of the vessel as well as outer surface of the sample cell. This did not, however, give any trouble to get a good signal from the sample.

A high temperature probe assembly was made of aluminum block. A pure Nichrome wire noninductively wound on a quartz tube (25 mm o.d.). The temperature on the surface of the bottom of the titanium vessel was monitored by a YEW 2575 digital thermometer using an Alumel/Chromel thermocouple. Cooling water of controlled temperature was flown through the aluminum jacket. There was no dissipation of heat to the magnet and to external lock probe even at temperature above 823 K. 150 W of the electric power was used to elevate temperature up to 823 K. Readjustment of the field homogeneity control was necessary for each setting of the power supply. The resolution of signal for water proton of 5 mm sample cell in this vessel was about 10 Hz at 293 K, 1 MPa without sample spinning. Line width of 10 Hz is considered to be good enough for measurements of the thermal decomposition process of polymers in the molten state, because at high temperature proton spectra of molten polymer are usually complicated by superposition of various signals and line widths become much broader due to thermally produced radicals.

Results and Discussion

Figure 4 shows the proton spectra of TD-PVC at various temperatures and pressures. Assignment of the two peaks was made by comparing them with the peaks of pure ethylbenzene. The chemical shift difference of the two peaks was 5.5 ppm (200 Hz). Because TD-PVC was thermally pretreated to liberate HCl at 623 K under atmospheric pressure, only hydrocarbons were considered in the residue of the thermal degradation PVC. It is known[2] that the TD-PVC melts at about 673 K. Then, liquid crystalline phases were formed in the TD-PVC under growing temperature.[3] This formation of liquid crystalline phases depended on heating rate. The heating rate was 2 K min^{-1} in further experiments. From the temperature and pressure dependence of the spectra given in Fig. 4, it is

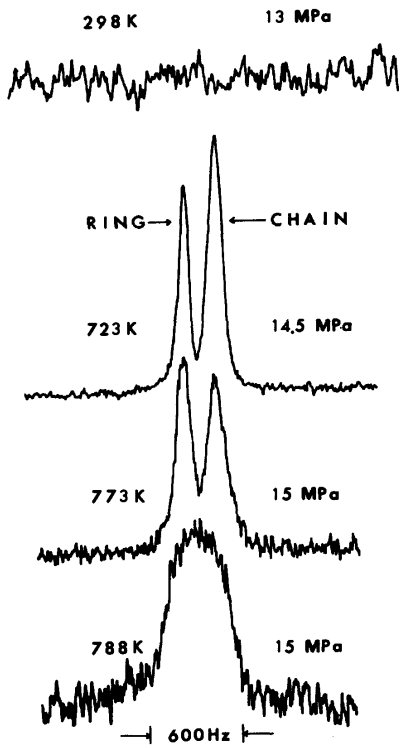

Fig. 4. Temperature and pressure dependence of proton spectra for TD-PVC.

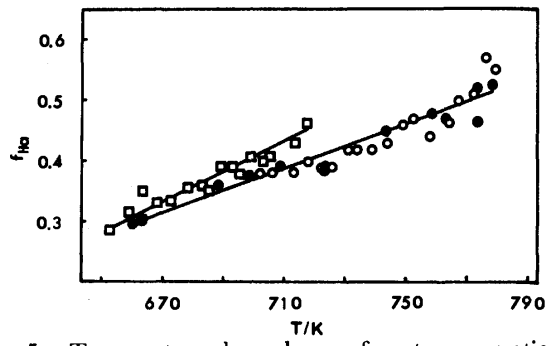

Fig. 5. Temperature dependence of proton aromaticity of TD-PVC.
□: Atmospheric pressure; pressurized condition. ●: (13 to 15 MPa), ○: (23 to 31 MPa).

found that the ring formation already occurs in the residue of TD-PVC at 723 K. At this temperature, aromatic protons are 30% of total protons. On further heating, the line width of the two peaks is broadened. At 815 K and 15 MPa, the spectrum shows an early stage of growing of liquid crystalline phases. The formation of the liquid crystalline structure was confirmed by the observation of polarized light-microscopy of quenched samples from this temperature.

It is very important to compare the present results with the data on the same material under atmospheric pressure. We define the hydrogen aromaticity as

$$f_{Ha} = H_{aroma}/(H_{alipha}+H_{aroma}), \quad (1)$$

where H_{aroma} and H_{alipha} are the integral intensities of signals for aromatic and aliphatic protons, respectively. At atmospheric pressure the hydrogen aromaticity (f_{Ha}) became 0.5 at 723 K but the same aromaticity was attained at 773 K under the pressurized condition, as shown in Fig. 5. The difference in the observed aromaticity for the atmospheric and pressurized conditions can be explained by the fact that the data at atmospheric pressure did not give a correct aromaticity, because the experiment at atmospheric pressure was made allowing an elusion of hydrocarbon gases from degradated TD-PVC residue. It was found that the pressure dependence of the aromaticity was not detected in the pressure range from 15 to 30 MPa.

It is known that free radicals are generated in the dehydrochlorinated PVC at high temperature.[2] The concentration of the unpaired electrons in the TD-PVC residue quenched from 673 K was found to $\approx 10^{18}$ spins·g^{-1} from ESR measurements. The TD-PVC melt at 683 K takes a polyene-like structure and the unpaired electrons are delocalized in the aromatic ring and polyene chains. Although there are two possible mechanisms for proton spin-lattice relaxation, *i.e.*, proton-proton dipolar interaction and proton-electron interaction, the latter is reasonably assumed to be predominant. We examined the spin-lattice relaxation time, T_1, of two kinds of protons. The values of T_1 measured by partially relaxed Fourier transform method at 733 K and 17 MPa were 151 and 153 ms for the ring and chain protons, respectively. These values of T_1 are larger by a factor of about 1.5 than those obtained at atmospheric pressure and 693 K.[3] We suppose that the existence of free radicals is suppressed in the pressurized condition by the remaining lower molecular weight fraction. This corresponds to the observed longer relaxation times in the pressurized condition at 733 K.

Conclusion

A simple pressurized high-temperature proton NMR apparatus was constructed and applied to the study of thermal degradation process of TD-PVC up to 823 K and 30 MPa. From the temperature and pressure dependence of the observed proton spectra, correct values of hydrogen aromaticity were obtained as a function of temperature. This result was also supported by spin-lattice relaxation measurements. This apparatus can also be used for investigation of thermal reaction processes of various organic compounds at high pressures, which are ordinarily carried out in autoclaves.

We greatly appreciate the encouragement of the work by Mr. Yuichi Kanda, Dr. Toshio Sato, and Professor J. Sohma and the financial support of Nishin Soft Science Foundation.

Infrared Intensities in Methyl Chloride. I. The Fundamental Bands

Shigeo KONDO,* Yoshinori KOGA, Taisuke NAKANAGA, and Shinnosuke SAËKI
National Chemical Laboratory for Industry, Tsukuba Research Center, Yatabe, Ibaraki 305
(Received August 20, 1982)

The integrated intensities of the fundamental bands of CH_3Cl and CD_3Cl molecules have been measured by the pressure broadening technique. The Coriolis intensity perturbation between ν_3 and ν_6 bands of CD_3Cl has been analysed to determine the sign to be negative. The intensity analysis has been carried out to determine the correct signs of $(\partial p/\partial Q_i)$. The resulting signs are $(-++)$ for A_1 and $(-+-)$ for E species. The $(\partial p/\partial S_J^R)$ values as well as the atomic polar tensors have been obtained.

Recently, several investigations have been carried out on the infrared intensities of a series of methyl halide molecules.[1-4] This is not only because these molecules are fundamental ones from a spectroscopic viewpoint, but because there has been a well known sign ambiguity problem which was described in a very clearcut manner by Abbate and Gussoni.[3]

A first study on the subject made by Barrow and McKean[5] did not give any definite answer to this question, for they only measured intensities of the parent molecules, and had nothing but chemical intuition to determine the correct sign combination for $(\partial p/\partial Q_i)$, which can not be enough to solve this tough problem in the infrared intensity studies. On the other hand, Dickson *et al.*[6] have measured the fundamental band intensities for both CH_3X and CD_3X molecules, where X=Cl, Br, and I. Their measurements were carried out very carefully, and reasonably accurate intensity values have been obtained except those which are badly overlapped with each other. In fact, they have almost succeeded in determining the signs of $(\partial p/\partial Q_i)$ simply by comparing the values of the intensity parameters obtained for the two isotopic molecules for various sign combinations. Their best sign choice was $(-++)$ for A_1 and $(-+-)$ for E species.[6] However, Russell *et al.*[1] have pointed out that a number of other sign combinations become possible when the intensity errors due to overlappings and also the force field errors are taken into account.

On the other hand, Newton and Person[2] have selected a sign combination of $(\partial p/\partial Q_i)$ of methyl fluoride on the basis of the CNDO/2 method, and extended that particular choice to the methyl chloride molecule. Their signs are $(-++)$ both for A_1 and E species.[2] Later, however, Abbate and Gussoni[3] have pointed out that the choice for methyl fluoride made by Newton and Person[2] is definitely against the isotopic invariance rule.

In a previous paper,[4] we have shown that this confusion on the sign problem of methyl fluoride was completely due to an erroneous intensity value of ν_6 band of CD_3F molecule. The final answer was found to be $(-++)$ both for A_1 and E species of this molecule. Then, a question arises whether we can still extend the same sign combination to the methyl chloride molecule.

Considering the experimental results reported thus far, there seems little doubt that the signs for A_1 species are $(-++)$. However, the signs for E species are still debatable. Therefore, the current question is whether the recently improved technique for the infrared intensity measurement and analysis can give a definite answer for the E species signs. For that purpose, we have carefully remeasured all the fundamental band intensities of CH_3Cl and CD_3Cl molecules. We have also determined the sign of the Coriolis interaction between ν_3 and ν_6 of CD_3Cl molecule. Then, a least squares calculation has been carried out to determine definitely the correct signs of $(\partial p/\partial Q_i)$.

Experimental

The CH_3Cl gas was purchased from Takachiho Chemical Co. and CD_3Cl gas from Merck Sharp and Dohme Co. Canada. The purity of CH_3Cl was stated as 99.5% and that of CD_3Cl was 99 atom%. Inspection of full region of the infrared spectra of these gases well guaranteed the stated sample purities.[7]

Spectra were all observed with a resolution of 0.25 cm^{-1} (optical path length of 4 cm, with Happ-Genzel apodization). A Nicolet model 7199 FT-IR spectrophotometer was used with a mercury-cadmium telluride detector. For intensity measurements, a 6 cm high pressure cell accommodated with KBr windows was used under a total pressure of 1.11×10^6 Pa. In order to investigate rotational fine structure of the bands, a conventional 10 cm glass body cell was also used. The sample pressure was measured with an MKS baratron type 220, which covers a pressure range of 1.333×10^5 to 1.333×10^2 Pa with a stated accuracy of 0.25%. Integration of the "isolated" band area were carried out in a manner similar to the one described in Ref. 8. Separation of the overlapping bands was done by the simulation technique as usual.[4,9]

Results

Fundamental Band Intensities. In the CH stretching region of CH_3Cl molecule, ν_1 and ν_4 overlap with each other. Also $2\nu_5$ band appears with a fairly high intensity presumably due to the Fermi resonance with the ν_1 band. Separation of the ν_1 and ν_4 bands was made by a simulation calculation taking account of the Fermi resonance between ν_4 and $3\nu_6$ bands, by using the molecular parameters in Refs. 10 and 11. The result is shown in Fig. 1. The $2\nu_5$ intensity was obtained simply by integrating the absorption area from 2920 through 2820 cm^{-1}. The integrated band intensity is defined by

$$B_i = (1/nl)\int_{\text{band}} \ln(T_0/T)\mathrm{d}\nu, \qquad (1)$$

where n is the sample concentration (mol/m^3), l is the optical path length (m), T and T_0 are the transmittance

values of the cell with and without the sample gas, respectively. The band intensity is given by units of km/mol. In the CH deformation region, ν_2 and ν_5 bands overlap with each other. Band separation was made by using the molecular parameters reported in the literature,[12–14] taking into account the Coriolis

a) Frequencies for ^{35}Cl molecules. b) Numbers in parentheses are the uncertainties to be used in the intensity calculation, which are the largest of 0.10 km/mol, 2 % of the band intensity and the estimated error for the band. The estimated error is twice the standard error from the Beer's law plot plus something due to the overlappings, where necessary. c) Ref. 10. d) Ref. 11. e) Ref. 12. f) Ref. 14.

interaction between ν_2 and ν_5. The result is shown in Fig. 2. On the other hand, the ν_3 and ν_6 bands are well isolated from other bands, and their intensities were obtained by simply integrating the respective band area. The result is summarized in Table 1.

In the CD stretching region of CD_3Cl, ν_4 band is well isolated from other bands. As for the ν_1 band, which is the symmetric CD_3 stretching mode, there are two neighboring overtone bands, $2\nu_5$ and $2\nu_2$. However, since their band contours are all similar (parallel bands), and overlappings are not so serious, separation of these bands is by no means difficult.

On the other hand, in the CD deformation region ν_2 and ν_5 bands are mutually heavily overlapped, and furthermore, they are in strong Coriolis resonance as well. Their separation was carried out by simulation method by using the parameters reported in Ref. 14, and is shown in Fig. 3.

ν_3 band is the strongest fundamental band of the CD_3Cl molecule, near which a weak perpendicular band of ν_6 is observed. Since the ν_6 band is very much weaker than the ν_3 band, it is quite possible that the former suffers a considerable intensity perturbation from the latter. By using the molecular parameters in Refs. 12 and 14, together with the calculated value for the zeta constant $\zeta_{3,6a}^{y}$ (+0.276), simulation calculations have been carried out for different signs of the perturbation. If the sign is negative, the higher frequency region of ν_6 band is such that partly obscured Q branch peaks are distributed over a rather thick back ground which is composed of the degraded R and P branches, and in the lower frequency region rather sharp Q branches are located against a relatively thin back ground. On the other hand, if the sign is positive,

	$S_{6a}=(2\Delta\beta_1-\Delta\beta_2-\Delta\beta_3)/\sqrt{6}$
	$S_{4b}=(\Delta r_2-\Delta r_3)/\sqrt{2}$
	$S_{5b}=(\Delta\alpha_2-\Delta\alpha_3)/\sqrt{2}$
	$S_{6b}=(\Delta\beta_2-\Delta\beta_3)/\sqrt{2}$

a) $K=-3\sin\beta\cos\beta/\sin\alpha$.

completely the reverse is true. These features are exactly what are expected from the theory by DiLauro and Mills.[15] The observed spectrum definitely agrees better with the one calculated for a negative sign, as shown in Fig. 4. Thus, the sign of the ν_3-ν_6 interaction in CD_3Cl molecule has been determined as negative. The ν_6 band intensity was obtained through simulation calculation for a pressurized spectrum of this region.

Intensity Calculation. If the pressure broadening effect is sufficiently large compared with the employed spectral resolving power,[16] the integrated band intensity B_i can be taken as the absolute intensity A_i which is expressed by,[17]

$$A_i = (N\pi/3c^2)(\partial p/\partial Q_i)^2, \quad (2)$$

where N is Avogadro's number, c is the light velocity, p is the molecular dipole moment, and Q_i is the ith normal coordinate. Further, $(\partial p/\partial Q_i)$ is expressed by a linear combination of $(\partial p/\partial S_j)$, where S_j is the jth symmetry

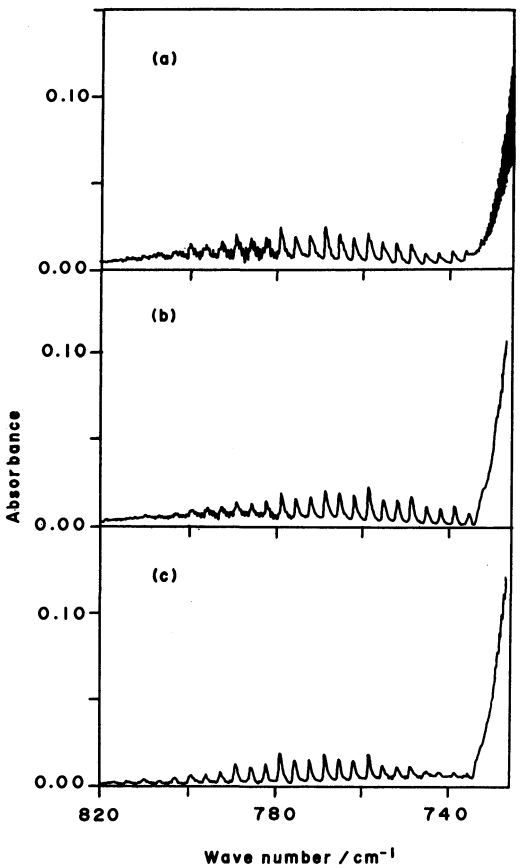

Fig. 4. Observed and calculated spectra of ν_6 region of CD_3Cl. (a) Observed spectrum with sample pressure of 4.95×10^3 Pa in a 10 cm cell.Resolution of 0.25 cm^{-1} was used, and calculated spectra (b) with a negative Coriolis perturbation between ν_6 and ν_3, and (c) with a positive interaction. The molecular constants reported in Ref. 14 were used.

coordinate, namely,

$$(\partial p/\partial Q_i) = \Sigma(\partial p/\partial S_j)L_{ji}, \quad (3)$$

where L_{ji} is the L matrix element.

As usual, the intensity parameter is defined by the following equation,[18]

$$p_j = (\partial p/\partial S_j^R) = (\partial p/\partial S_j) + p^0K_j, \quad (4)$$

where p^0 is the permanent dipole moment and K_j is the rotational correction coefficient. The symmetry coordinates were defined the same as in Ref. 4, and are shown in Table 2. The molecular coordinate system and the internal coordinates are shown in Fig. 5. As usual, we have preferred to set up the whole molecular system so that we may have a positive permanent dipole moment. (The positive dipole moment is defined to be directed from the negative to the positive end of the molecule. There may be little doubt that the chlorine atom is the negative end of the methyl chloride molecule.) The absolute value of p^0 has been determined as 1.869(10) D by Shulman *et al.*[19]

Table 3 shows the L matrices for CH_3Cl and CD_3Cl molecules, which are obtained by using the harmonic force field reported by Duncan *et al.*[20] Definition of the symmetry coordinates in reference molecule S_j^R

Table 3. L matrices of methyl chloride[a)]

a) Units are Å^{-1} for S_{4a} and rad^{-1} for S_{5a} and S_{6a}.

and the values of the rotational correction coefficients are listed in Table 4.

Intensity calculations were carried out by a least squares method varying the signs of $(\partial p/\partial Q_i)$ for A_1 and E species separately. For the calculation, the residual value was defined as,

$$\text{Res.} = \Sigma(X_i^{obsd} - X_i^{calcd})^2/(\Delta X_i^{obsd})^2, \quad (5)$$

where X_i denotes the dipole moment derivatives $(\partial p/\partial Q_i)$ for the parent molecule and the band intensity A_i for the isotopic species. The signs of $(\partial p/\partial Q_i)$ for the parent molecule are actually examined in that calculation. The residual value was used to examine the propriety of the sign combination postulated in the calculation.[18)] Since there are three normal vibrations both for A_1 and E species, eight sign combinations are possible for each of them. In Table 5, residual values have been obtained from the least squares calculations for eight sign combinations of both symmetry species.

In A_1 species, considering that the number of the intensity data is six, possibility is limited either to $(-++)$ or to $(+--)$ set, for these are only sets whose residuals are less than the data number of six, while those of other sets are by far larger than that. Similarly, in E species, the residual values for $(++-)$ and $(-+-)$ sets are much smaller than the others. Therefore, we may pick up these two sets as possible ones. But for the sake of security, we also included $(+--)$ and $(---)$ sets together to go to further checking.

Table 5. Residual values from the least squares calculations for the intensities varying the signs of $(\partial p/\partial Q_i)$[a)]

A_1 species $(123)^H(123)^D$	Res.	E species $(456)^H(456)^D$	Res.

p_5/D rad^{-1}	0.353(9)	0.348	0.34
p_6/D rad^{-1}	−0.293(12)	−0.299	−0.38

a) The preferred combination is $(-++)(-+-)^H$. b) Calculated with the 6-31G* basis set; Ref. 20. c) Numbers in parentheses are the standard errors from least squares calculations.

Now, we can further restrict possibility by the Coriolis sign information. According to DiLauro and Mills,[15)] the sign of ν_2-ν_5 Coriolis interaction in CD_3Cl molecule is negative. Since the zeta constant $\zeta_{2,5a}^y$ is calculated as negative (−0.596) from the present L matrices, which are shown in Table 3, the sign of the product $(\partial p/\partial Q_2)(\partial p/\partial Q_5)$ must be positive, *i.e.* $(\partial p/\partial Q_2)^D$ and $(\partial p/\partial Q_5)^D$ are of the same sign. Further, as described in a previous section, the sign of the ν_3-ν_6 Coriolis perturbation of CD_3Cl has been found to be negative. Since the zeta constant $\zeta_{3,6a}^y$ is calculated to be +0.276 from the L matrix, the sign of $(\partial p/\partial Q_3)(\partial p/\partial Q_6)^D$ must be negative. Therefore, inspection of the $(-++)$ and $(+--)$ sets of A_1 species together with the $(++-)$, $(-+-)$, $(+--)$, and $(---)$ sets of E species reveals that only possible combinations are $(-++)$ set from A_1 together with either $(++-)$ or $(-+-)$ set

from E species.

Finally, of the two sets preferred in E species, there is at present no experimental preference of one to the other. We need additional information to determine the final choice. For that purpose, the CNDO/2 method[2] or ab initio calculation[21] may be helpful. Table 6 shows a comparison of the resulting parameter values for the $(-++)(-+-)^{H}$ and $(-++)(++-)^{H}$ sets with the *ab initio* values. As is seen in the table, the obtained values of the parameters other than p_4 agree well with the *ab initio* result. As for the parameter p_4, the sign is different in the two sets while the magnitude is obtained almost the same. The *ab initio* calculation predicts it to be negative. Therefore, the $(-++)(-+-)$ set may be the correct signs of $(\partial p/\partial Q_i)$ for methyl chloride. Table 7 shows a comparison of the observed band intensities with the calculated. The polar tensor[22] calculated from these parameter values is shown in Table 8.

TABLE 7. OBSERVED AND CALCULATED INTENSITIES OF THE FUNDAMENTAL BANDS OF METHYL CHLORIDE(km/mol)

Band		Obsd[a]	Calcd[b]
CH_3Cl	ν_1	23.31(148)[c]	22.40

	ν_4	5.42(12)	5.44
	ν_5	5.76(46)	5.76
	ν_6	0.57(10)	0.60

a) Numbers in parentheses are the uncertainty indicators, reciprocal squares of which were utilized as the weighting factors in the least squares calculation. See Table 1. b) Calculated with the parameter values obtained for the $(-++)(-+-)^{H}$ signs. c) Sum of the intensities for ν_1 and $2\nu_5$ in Table 1. d) Sum of the intensities for ν_1, $2\nu_5$, and $2\nu_2$ in Table 1.

Discussion

As was discussed by Russell *et al.*,[1] major contributions to the errors in the resulting intensity parameters are from the uncertainties in the intensity data and force constants. For the experimental data utilized in Ref. 1, the latter was shown to be much smaller than the former. Furthermore, the errors in the force field utilized in the present study have been reduced much (on the average, a factor of ten for A_1 and of about three for E species[20]). Therefore, in the present case, contribution from the force error should be negligible and the intensity factor only remains effective, which has also been reduced much, indeed. Besides that, we have been able to use two pieces of definite information on the relative signs of $(\partial p/\partial Q_i)$. These were obtained from the Coriolis intensity analyses in Ref. 15 (for ν_2-ν_5) and in the present study (for ν_3-ν_6) for the CD_3Cl molecule. Considering these conditions, it is a natural consequence that the correct sign combination has definitely been determined in this study.

It has become widely known that *ab initio* calculations can be critically checked by use of the experimentally determined values and signs of the molecular dipole moment and its derivatives. Wiberg[21] has carried out *ab initio* calculations to predict that the correct signs of $(\partial p/\partial Q_i)$ for methyl fluoride is $(-++)(-++)$, which perfectly agreed with the result in Ref. 4. He has also calculated the dipole derivatives of methyl chloride, and expected that the signs may be $(-++)$ for A_1 and $(-+-)$ for E species. In the present study this prediction has certainly been confirmed to be correct. Moreover, the sign of $(\partial p/\partial Q_4)$ was so determined that the resulting sign of p_4 agrees with the *ab initio* result.

We are planning in a subsequent paper[7] to analyze the intensities of the overtones and combinations of this molecule, utilizing the result obtained here for the fundamentals.

16) In the present study, the measurement was carried out under the pressure of 1.11×10^6 Pa, which means that the true width of individual vibration-rotation lines is expected to be about 2 cm^{-1}. On the other hand, the resolution used was 0.25 cm^{-1}. Considering the fact that the absorption bands are composed of many overlapping vibration-rotation lines, the present combination of line width and resolution should indeed be sufficient to obtain the absolute band intensities.

†*Faculty of Pharmaceutical Sciences, The University of Tokyo, Bunkyo-ku, Tokyo 113*
(Received September 28, 1981)

Bis(methanol)-α,β,γ,δ-tetraphenylporphinatomanganese(III) perchlorate crystallizes as the methanol solvate in the triclinic system, space group $P\bar{1}$, $a=16.225(8)$, $b=13.167(7)$, $c=10.793(5)$ Å, $\alpha=106.51(5)°$, $\beta=100.36(5)°$, $\gamma=101.60(5)°$, and $Z=2$. The structure was determined by the heavy-atom method and the block-diagonal least-squares refinement using a total of 9992 reflections. The final R and R_w values are 6.3 and 7.1%, respectively. Two slightly different but substantially identical coordination spheres of high-spin Mn(III) porphyrin were revealed. The long axial Mn–O(methanol) bond distance and medium-sized porphyrin core were emphasized as structural characteristics in relation to the intermediate-spin iron(III) porphyrin.

Althoug there is no support for the idea that manganese chlorophyll or porphyrin is involved in photosynthesis, the photochemistry of manganese[1,2] and other metal porphyrins[3–5] is interesting to explore the possibility of the solar energy conversion imitating biological systems. In a previous paper,[3] we reported the photochemical reduction of the central metal ions of some metal-TPPS[6] by alcohols ligating the axial positions. The coordination of weakly ligating substances, *e.g.*, water, alcohol, and DMSO, to metalloporphyrins has only recently been established by the definitive X-ray studies.[7–9,22] Thus, this work aims, at first, to establish the explicit occupation of methanols on the axial positions of $MnTPP^+$ as a basis of our interpretation of the photochemical reaction mechanism of Mn-porphyrins in alcoholic solution.

On the other hand, the extensive studies of the spin state/stereochemistry relationship in metalloporphyrins conducted by Scheidt and co-workers have proposed two structural types of intermediate-spin iron(III) porphyrins,[10–12] namely five coordination[10,11,13] and six-coordination.[12] The high-spin state of Mn(III) porphyrins has an electron configuration analogous to the intermediate-spin iron(III) porphyrins, *i.e.*, unoccupied $d_{x^2-y^2}$ and singly occupied d_{z^2}. The crystal structure of the high-spin six-coordinate $MnTPP^+$ is a proper example for supporting the assignment of structural characteristics of the six-coordinate intermediate-spin iron(III) porphyrin.

Experimental

Preparation. The starting manganese porphyrin, MnTPP(OH), which has not yet been characterized definitively, was prepared as described previously.[14] All other chemicals and solvents were reagent grade and used without further purification.

A chloroform solution of MnTPP(OH) (200 mg/100 ml) was shaken with an aqueous $HClO_4$ solution (*ca.* 10%) in a separatory funnel. The chloroform layer was separated and evaporated to dryness under reduced pressure. The resulting solid was extracted with methanol. Single crystals of $MnTPP(CH_3OH)_2ClO_4\cdot CH_3OH$ were obtained by slow evaporation of solvent from the solution (yield: 100 mg as crystals). The crystals appear to lose easily the methanol molecule of solvation; hence freshly prepared crystals were sealed into thin-walled glass capillaries.

The infrared spectrum of the crystalline material was obtained as a KBr pellet on a JASCO IRA-2 spectrometer. The intence and broad absorption centered at 1090 cm^{-1} and the strong, sharp band at 620 cm^{-1} were consistent with the assignment of free perchlorate ion.[15]

Found: C, 65.69; H, 3.88; N, 6.72%. Calcd for $MnC_{47}H_{40}N_4ClO_7$: C, 65.40; H, 4.68; N, 6.50%. The low value found for hydrogen may be due to loss of methanol. UV (CH_3OH) λ_{max} (log ε): 597 (3.66), 564 (3.80), 514 (3.54), 467 (4.74), 439 (4.14), 399 (4.50), and 378 nm (4.50).

Magnetic Measurement in Solution. The Evans NMR method[16] was applied to measure the magnetic susceptibility of this Mn(III) porphyrin, using a coaxial NMR double tube (4 mm o.d.) purchased from Nippon Seimitsukagaku Co., Ltd. TMS in $CDCl_3$ (*ca.* 2 vol%) was used as the tracer signals in the reference and sample in the tube, since TMS would not coordinate to the metalloporphyrin. A 0.166 ppm splitting of the TMS ptotons in 7.8 mmol dm^{-3} $MnTPP^+$ solution from the reference was observed in the spectrum recorded on a JEOL FX-100 spectrometer operating at 99.5 MHz radiowave frequency and at 20 °C. The magnetic moment was calculated with diamagnetic corrections according to the reported equation.[16] The μ_{eff} was 5.3 μ_B.

Crystal Structure Determination. A crystal of $MnTPP(CH_3OH)_2ClO_4\cdot CH_3OH$ with approximate dimensions of $0.5\times0.7\times0.9$ mm was mounted in a thin-walled capillary. Lattice constants were determined by the angular settings for 18 carefully centered reflections on a Philips PW-1100 four-circle X-ray diffractometer. Crystallographic data at 20 ± 1 °C ($\lambda=0.71069$ Å): triclinic, $a=16.225(8)$, $b=13.167(7)$, $c=10.793(5)$ Å, $\alpha=106.51(5)°$, $\beta=100.36(5)°$, $\gamma=101.60(5)°$, the unit cell volume (U)=2095.6 Å^3, $Z=2$, the calculated density (D_x)=1.368 g/cm^3, and the experimentally determined density (D_m)=1.373 g/cm^3.

Intensity data were collected using graphite-monochromated Mo $K\alpha$ radiation and θ-2θ scanning. All independent reflections for which $(\sin\theta)/\lambda<0.704$ Å^{-1} were measured. A total of 9992 reflections (81% of the theoretical number possible) having F_o greater than $2\sigma(F_o)$ were used in the solution and refinement of structure. No absorption or extinction correction was made. Data collection and reduction were carried out at the Unversity of Tokyo.

A Patterson map revealed that the manganese atoms are

a) Primed (') atoms are related to unprimed atoms by the symmetric transformation. The estimated standard deviations of the least significant digits are given in parentheses.

located at 0,0,0 and 1/2, 1/2, 0. A series of difference Fourier calculations phased with two Mn and several atoms of the porphyrin skeleton revealed the positions of all non-hydrogen atoms. Atomic scattering factors were taken from Table 2.2B of Ref. 17. After several cycles of block-diagonal least-squares refinement with anisotropic temperature factors for all non-hydrogen atoms, difference Fourier maps revealed all hydrogen atom positions except those of the solvated methanol. These invisible hydrogens were ignored in this work. The 36 hydrogen atoms refined two cycles, then, placed on the positions as the fixed contributors with their isotropic thermal parameters.

The refinement was carried to convergence using anisotropic temperature factors for all non-hydrogen atoms. The final values of the discrepancy indexes were $R=\sum||F_o|-|F_c||/\sum|F_o|=0.063$ and $R_w=[\sum(w(|F_o|-|F_c|)^2)/\sum w(F_o)^2]^{1/2}=0.071$, $w=1/\sigma^2(F_o)$. The highest residual in the difference map, 1.1 e/Å^3, was found near one oxygen atom (O_4) of the perchlorate ion and others (less than 0.6 e/Å^3) were featureless. All calculations were carried out at the Computing Center of Nagoya City University using locally modified versions of the X-ray programs.[18)]

Tables of the anisotropic thermal factors of 61 non-hydrogen atoms, the coordinates and isotropic thermal factors of hydrogen atoms, the observed and calculated structure factors (29 pages), and Fig. 4[30)] are available as supplementary materials on request (kept at the Editorial Office of the Chemical Society of Japan as a Document No. 8301).

Results and Discussion

Atomic coordinates and the associated isotropic equivalent temperature factors of the final non-hydrogen atoms are listed in Table 1. Figures 1 and 4[30)] are computer-drawn models of the two unique $MnTPP(CH_3OH)_2^+$ ions. The two Mn ions, the hydrogen bonds formed by the coordinated methanols with perchlorate ion and solvated methanol, and the nearest contacts to them are collectively illustrated in Fig. 2. Individual bond lengths and angles are summarized in Tables 2 and 3.

The requirement of the inversion symmetry with respect to both manganese positions leads to square bipyramidal coordination spheres made of the porphinato core and axial methanols with rigorous centering of the Mn(III) ions. The symbols and displacements of the atoms from the least-squares mean plane of the porphyrin core for both ions are given by means of the usual diagram expression[19)] in Fig. 3. This shows planar porphyrin core normally seen in the six-coordinate Mn(III)[20)] and iron(III) porphyrins.[19)]

The conformation of two independent $MnTPP(CH_3OH)_2^+$ ions is apparently identical. The dihedral angles between the least-squares mean planes of porphyrin core (24 atoms) and peripheral phenyl rings are 84.4° and 75.2° for the molecule shown in Fig. 1 and 70.8° and 72.7° for the second molecule.[30)] These are normal dihedral angles observed in ordinary TPP conformation.[21)] The most crucial structural difference distinguishing the complexes is the geometry of ions, ligands, and solvated molecules linked by the hydrogen bonds. As seen in Fig. 2, one oxygen atom (O_4) of the

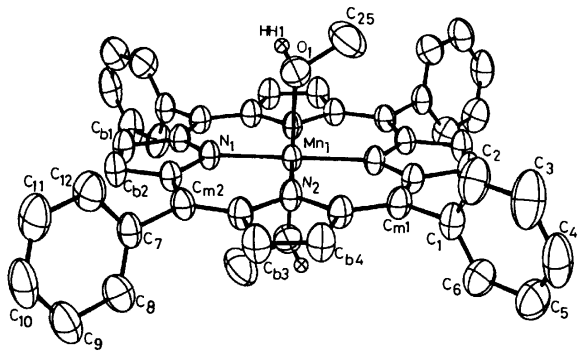

Fig. 1. Computer-drawn model of the first MnTPP$(CH_3OH)_2^+$ species. The thermal ellipsoids are contoured at the 50% probability level except for the hydrogen atom HH1.

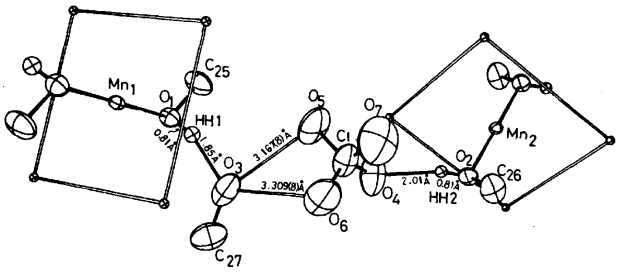

Fig. 2. An ORTEP plot of a pair of Mn(III)porphyrin ions and a perchlorate ion. The porphyrin planes are shown by simple squares linking the *meso*-carbons of the skeleton. Interatomic distances between perchlorate and solvated methanol oxygens and tentative distances between hydrogen and oxygen atoms forming hydrogen bonds are entered on the diagram.

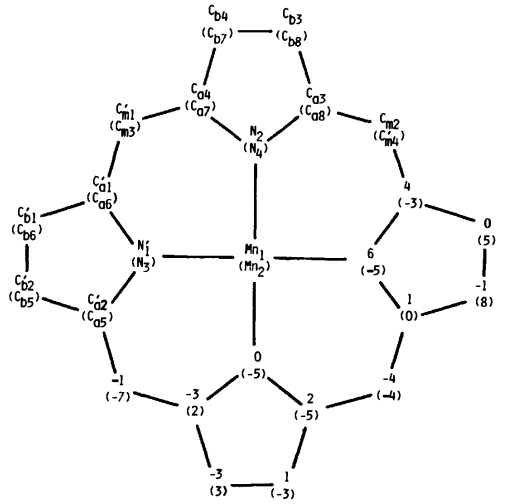

Fig. 3. A formal diagram of the porphinato core of the two unique Mn(III)porphyrins correspondings to Figs. 1 and 4[30] (in parentheses), respectively. On the upper left, the numbering scheme used for the atoms is displayed. The number on the atom positions in the centrosymmetric diagram, on the lower right, is the perpendicular displacement from the mean plane of the porphyrin core in units of 0.01 Å.

perchlorate ion interacts directly with the oxygen (O_2) of methanol coordinated to Mn_2 through a hydrogen bond (O_4–O_2 distance 2.798(5) Å). On the other side, the perchlorate ion has a close contact only with the solvated methanol at 3.16 Å that is too far for significant hydrogen bonding. The solvated methanol makes a dimeric interaction with the methanol coordinated to Mn_1 through an apparent hydrogen bond (O_1–O_3 distance 2.618(7) Å). Therefore, the crystal structure suggests a better description of the molecules in the solid state as $[MnTPP((CH_3OH)_2)_2]^+$ and $[MnTPP(CH_3OH\cdot ClO_4)_2]^-$ forming an ion pair. However, the description is not necessarily or strictly adapted to the present system because of the possible disorder suggested by the large thermal parameters and the high residual electron densities around the perchlorate and solvated methanol.

The ion pair makes a quasi-linear arrangement parallel to the (a—b) vector on the (0,0,1) plane; hence two manganese atoms sitting at 0,1,0 and 1/2,1/2,0 can be linked as shown in Fig. 2. The closest distance between two manganese atoms sitting on the quasi-chain is 9.3 Å. The dihedral angle between the two independent porphyrin planes is 51.8°.

The axial bond length of Mn_1–O_1 and Mn_2–O_2 are 2.252(2) Å (in the cationic species) and 2.270(2) Å (in the anionic species), respectively. These distances are considerably longer than the 2.11—2.16 Å values found in $[FeOEP(C_2H_5OH)_2]^+$ [8] and $[FeTPP(C_2H_5OH)_2]^+$[22] in which both Fe(III) ions are assigned to be high-spin, but fairly shorter than 2.329(7) Å in $MnTPP(N_3)(CH_3OH)$.[20] The distances are comparable rather to the longer pair of Mn–N (imidazolate) bond lengths (2.280(4) Å) in $(MnTPP(Im))_n$[23] or the value 2.308(3) Å found in the high-spin $MnTPP(1\text{-}MeIm)_2ClO_4$[24] in spite of the weak ligating nature of alcohol to metals. Axial bond lengths of high-spin Mn(III) porphyrin complexes are unexceptionally long (>2.2 Å) compared with normal equatorial Mn–N (porphyrin) bond lengths (*vide infra*). The difference between the axial bond lengths in the two independent species is statistically significant but substantially not distinct, since the 0.018 Å difference is small and considered to be due to the subtle electrostatic or crystal packing effect.

The average equatorial bond length (Mn–N(porphyrin)) in these ions is 2.006(2) Å, which is at the short limit of those found in four six-coordinate Mn(III) porphyrins; 2.009(9) Å in MnTPP(Cl)(Py),[25] 2.015(4) Å in $MnTPP(1\text{-}MeIm)_2ClO_4$,[24] 2.019(4) Å in $(MnTPP(Im))_n$,[23] and 2.031(12) Å in $MnTPP(N_3)(CH_3OH)$.[20] The present average length of Mn–N is located at the middle of the extent of the equatorial bond lengths (1.93—2.09 Å) observed for a series of the first row transition metal-porphyrins.[29] Thus, the long axial bonds to methanol and medium size porphyrin core surround the high-spin Mn(III) ions. These structural characteristics in the six-coordinate high-spin Mn(III) porphyrins have already been pointed out as the tetragonal distortion found in those complexes.[20,23,25]

We are interested in the spin state/structure relationship of metalloporphyrins, especially biologically important iron porphyrins. Spin states of the central metal

TABLE 4. THE STRUCTURE-ELECTRONIC CONFIGURATION IN SELECTED SIX-COORDINATE METALLOPORPHYRINS HAVING ONE ELECTRON IN THE e_g ORBITAL

Number of electrons in 3d-orbital	Electronic configuration and spin state	Metalloporphyrins	Bond length of metal to axial ligand l/Å	Average bond length of metal to porphyrin l/Å	Ref.
4	$(t_{2g})^3(e_g)^1$	$MnTPP(CH_3OH)_2^+$	2.250(2) 2.272(2)	2.006(2)	This work
	$S=4/2$	$MnTPP(1\text{-}MeIm)_2^+$	2.308(3)	2.009(9)	24
		$(MnTPP(Im))_n$[a]	2.280(4)	2.019(4)	23
5	$(t_{2g})^4(e_g)^1$ $S=3/2$	$(FeTPP(C(CN)_3))_n$	2.317(3)	1.995(3)	12
6	$(t_{2g})^5(e_g)^1$ $S=2/2$	Unknown			
7	$(t_{2g})^6(e_g)^1$	CoTPP(Pip)$_2$[b]	2.436(2)	1.987(2)	27
	$S=1/2$	CoOEP(β-Pic)$_2$[b]	2.386(2)	1.992(1)	28

a) The high-spin form. b) Abbreviations: Pip=piperidine, OEP=octaethylporphinato, and β-Pic=3-methylpyridine.

ions define the distribution of electrons in the 3d-orbitals. The high-spin manganese(III) has an electron population in the 3d-orbitals of $(d_{xy},d_{yz},d_{zx})^3(d_{z^2})^1(d_{x^2-y^2})^0$ or $(t_{2g})^3(e_g)^1$ in the expression of cubic symmetry. The structures of the metalloporphyrins with similar electron configuration and six-coordinate geometry are compared and summarized in Table 4. The presence of a single electron in the e_g orbitals leads to a structural similarity, *i.e.*, tetragonal distortion. The addition of electrons into half-occupied t_{2g} orbitals -spin-pairing- appears to give only minor changes in the structural prameters of the porphyrin core, *i.e.*, metal to porphyrin bond lengths.

For the six-coordinate intermediate-spin iron(III) porphyrin, a true 3/2 spin-state has been suggested[12] as distinguished from a quantum mechanically admixed $S=3/2$, 5/2 state postulated for the five-coordinate iron(III) complexes.[11,13] The comparison of the structural parameters in Table 4 including the present Mn(III) porphyrins gives a stereochemical support for the assignment of the $S=3/2$ ground state electron configuration of the six-coordinate $FeTPP(C(CN)_3)$ in the solid state, despite of the higher than expected value of the observed magnetic moment. The magnetic properties may be elucidated by various experimental and theoretical ascriptions such as the thermal "spin-equilibrium" or the admixture of the excited state with the ground state configuration as has been adapted to the low-spin hemes.[26] We wish to remark conclusively that the present structure will contribute not only to the coordination chemistry of methanol to Mn(III) porphyrins but also to the electronic state consideration of related metalloporphyrins.

We are grateful to Prof. W. R. Scheidt of the University of Notre Dame for helpful discussions and editorial assistance. The aid of Ayako Ohta, Kuniko Uchiyama, and Kyoko Kawasaki in computing work is also acknowledged. K. H. thanks Prof. Noritake Yasuoka for the access to the source programs for the X-ray analysis filed at the Computing Center of the Osaka University.

(Received September 28, 1981)

The reaction of sodium nitrite with silica has been investigated over the relatively wide composition range (Na/Si=0 to 10.0) below 800 °C. In an argon atmosphere, sodium nitrite reacts with oxygen to form sodium nitrate above 400 °C and decomposes to sodium oxide *via* other oxide species above 500 °C, irrespective of the coexistence of silica. The reaction of sodium nitrite with silica in an argon atmosphere consists of two stages. In the early stage (<600 °C), the main gaseous product is NO, while in the later stage nearly equimolar amounts of NO and O_2 are formed. The early stage is further divided into two reaction processes: Process I, in which peroxide is considered to be formed in the melt by generating NO, and Process II, in which nitrate and silicates are formed by generating NO and a trace amount of O_2. Peroxide is supposed to be stabilized at the solid-liquid interface, even if no silicates have been formed at relatively low temperatures. In the later stage, the reaction process or mechanism can be regarded as similar to that of sodium nitrate with silica, as the concentration of nitrite in the melt is very low.
